The assignment of a labile, dimeric structure to compound **4A**, which is spontaneously formed from **4**, is supported by its chemical behaviour and by its mass spectrum, the latter being very similar to the spectrum of **4** as a consequence of a reversion of the equilibrium between the monomer and the dimer upon volatilization; however, its detailed structure is not definitely established. On the basis of the presence in its ^{1}Hmr spectrum of signals attributable to a tetrahydropyran ring (in particular, $\delta = 1.53$, td, in acetone-d_6), it would appear that the dimer **4A** is formed by the addition of the 1-OH function of one molecule of **4** to the keto group of a second molecule of **4** (see Scheme 2). This dimerization is important because it probably is the initial, reversible step for the formation of the dianhydrides of **4** in a protic medium. As shown by the behaviour of the two isomers under these conditions, **5** is the *thermodynamic* dianhydride, and the subsequent steps for its formation involve a series of reversible, internal acetalizations of a tautomer of **4A**. Thus, treatment of pure isomer **6** in 4:1 (v/v) 1,4-dioxane – water containing trifluoroacetic acid (10%) led rapidly to the disappearance of **6** and the formation of **4** and **5** (~1:1 ratio, equilibrium composition); the formation, although more slowly, of the monomer **4** from **5** was observed also under the same conditions. Furthermore, the dianhydride **6** was converted immediately into **4** and some **5** in 80% acetic acid at reflux temperature, a result which is in agreement with the exclusive formation of the thermodynamic isomer **5** during the detritylation of **3** under these conditions.

In contrast, the kinetically controlled formation of the two dianhydrides from **4** was achieved under anhydrous conditions

[2]A complete list of atomic parameters (Table 1) and a list of the structure factors (Table 3) are available from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

(trifluoroacetic acid in 1,4-dioxane); this interpretation was confirmed by the observation of the extremely slow conversion of **6** into **5** under a similar set of conditions (trifluoroacetic acid in tetrahydrofuran, less than 25% of **5** from **6** after 10 days at 20°C). A different dimerization mechanism might be involved in this case such as, for example, an initial "glycosylation" of 2-hydroxy-2-(hydroxymethyl)tetrahydropyran by a second molecule of **4** through its 1-OH group.

Because of the presence of a large proportion of the open-chain form at equilibrium in water, sweetness tests of **4**, to assess the taste of 2-hydroxy-2-(hydroxymethyl)tetrahydropyran, would be of doubtful value and have thus not been undertaken.

Experimental

Melting points were determined on a Fisher–Johns apparatus or on a Thomas Hoover capillary melting point apparatus and are uncorrected. Infrared spectra were recorded with a Perkin–Elmer 598 spectrophotometer. The nmr spectra were recorded with a Bruker CXP-200 spectrometer (^{1}H: 200 MHz, ^{13}C: 50.307 MHz) in chloroform-*d* with tetramethylsilane (TMS) as internal standard, unless otherwise stated; TMS was used as external standard for the spectra in deuterium oxide. Chemical shifts are given in parts per million downfield from TMS. Mass spectra were recorded on a Hewlett–Packard HP 5985 B gc–ms spectrometer. Thin-layer chromatography (tlc) was performed using silica gel G as the adsorbent in the following solvent systems (v/v): (A) toluene; (B) ethyl acetate; (C) toluene – ethyl acetate 2:1; (D) hexane – ethyl acetate 3:1; (E) hexane – ethyl acetate 4:1; (F) petroleum ether – acetone 2:1. The developed plates were dried and compounds located by spraying with 10% aqueous sulfuric acid containing 1% cerium sulfate and 1.5% molybdic acid, and heating at 150°C. Column chromatography was performed on silica gel 60 (70–230 mesh, Merck). 1,2,6-Hexanetriol was purchased from Aldrich and used without further purification. The term "petroleum ether" refers to the fraction of bp 30–60°C.

1,2,6-Hexanetriol 1,6-ditrityl ether (2)

To a solution of 1,2,6-hexanetriol (**1**, 0.8 g, 5.96 mmol) in dry pyridine (30 mL) was added triphenylmethyl chloride (3.65 g, 13.1 mmol, 2.2 equiv.). The mixture was stirred for 64 h at room temperature, and then poured into ice-water (100 g) and chloroform (60 mL). The organic phase was separated and the aqueous layer washed with chloroform (30 mL). The combined organic phases were washed at 0°C with 1 *N* hydrochloric acid to remove pyridine, then washed with a saturated aqueous sodium hydrogen carbonate solution (2 × 20 mL) and with water (2 × 20 mL), dried ($MgSO_4$), and concentrated. Column chromatography (solvent A; then A–B, 10:1 (v/v)) of the crude product afforded **2** (3.45 g, 94%) contaminated by a small amount of triphenylcarbinol. An analytical sample was obtained by column chromatography (solvent A–B, 50:1 (v/v)) and crystallization from ether; mp 129.5–130.5°C; R_f 0.26 (solvent A); ν_{max} (KBr): 3570, 3430 (OH), 1595, 1488, 1445, 1215, 1070, 760, 705 cm^{-1}; ^{1}Hmr δ: 1.2–1.47 (m, 4H) and 1.47–1.70 (m, 2H) (2H(3), 2H(4), 2H(5)), 2.34 (d, 1H, $J_{2,OH}$ = 3.3 Hz, exchanged in D_2O, 2-OH), 3.05 (dd, 1H, $J_{1A,1B}$ = 9.8 Hz, $J_{1A,2}$ = 7.5 Hz, H(1A)), 3.06 (t, 2H, $J_{5,6}$ = 6.1 Hz, 2H(6)), 3.21 (dd, 1H, $J_{1B,2}$ = 3.0 Hz, H(1B)), 3.73 (br m, 1H, H(2)), 7.22–7.55 (m, 30 H, $2(C_6H_5)_3C$). *Anal.* calcd. for $C_{44}H_{42}O_3$ (618.81): C 85.40, H 6.84; found: C 85.19, H 6.69.

1,6-Dihydroxy-2-hexanone ditrityl ether (3)

To a solution of dry pyridine (7.67 g, 97.0 mmol, 12 equiv.) in dry methylene chloride (125 mL) was added chromium trioxide (4.85 g, 48.5 mmol, 6 equiv.) and the mixture stirred for 30 min at room temperature. A solution of compound **2** (5.0 g, 8.08 mmol) in methylene chloride (45 mL) was then added in one portion. The reaction mixture was stirred for 17 min at room temperature, the solution decanted, and the black residue washed with ether (3 × 60 mL). The combined organic phases were washed successively with a 5% (v/v) aqueous sodium hydroxide solution (4 × 85 mL), cold 1 *N* hydrochloric acid (85 mL), a saturated aqueous sodium hydrogen carbonate solution (3 × 85 mL) and a saturated aqueous sodium chloride solution (3 × 85 mL), dried ($MgSO_4$), and concentrated. Crystallization of crude **3** from ether gave pure **3** (3.69 g, 73.9%); mp 145–147°C; R_f 0.44 (solvent A); ν_{max} (KBr): 1715 (C═O), 1595, 1490, 1450, 1220, 1070, 765, 748, 732, 713, 698 cm^{-1}; ^{1}Hmr δ: 1.64 (m, 4H, 2H(4), 2H(5)), 2.51 (br t, 2H, 2H(3)), 3.06 (br t, 2H, 2H(6)), 3.74 (s, 2H, 2H(1)), 7.16–7.50 (m, 30 H, $2(C_6H_5)_3C$). *Anal.* calcd. for $C_{44}H_{40}O_3$ (616.80): C 85.68, H 6.54; found: C 85.67, H 6.45.

1,6-Dihydroxy-2-hexanone, 2-hydroxy-2-(hydroxymethyl)tetrahydropyran (4)

Procedure A

Ketone **3** (10.5 g, 17.02 mmol) was gently heated at reflux temperature in 80% acetic acid (300 mL) for 1.5 h. The clear solution was cooled and concentrated under reduced pressure. The residue was triturated with water (150 mL) and the insoluble triphenylcarbinol derivatives removed by filtration. The aqueous solution of crude **4** was treated then with 20% sodium hydroxide (15 mL) for 0.5 h, neutralized with Dowex 50W-X8 (H^+) resin and concentrated. Column chromatography (solvent B) of the residue afforded compound **5** (205 mg, 10.5%) and pure, syrupy **4** (1.01 g, 45%).

Procedure B

To a solution of ketone **3** (1.1 g, 1.78 mmol) in 1,4-dioxane (70 mL) was added water (20 mL) and trifluoroacetic acid (5.4 mL). The mixture was stirred for 2 h at 55°C, cooled, and then neutralized with Amberlite IRA-400 (OH^-) resin; the resin and the precipitated triphenylcarbinol were removed by filtration and the filtrate concentrated. The residue was triturated with water, the resulting suspension filtered through Celite, and the filtrate concentrated to afford homogeneous and colorless **4** (146 mg, 62%); R_f 0.26 (solvent B); ν_{max} (film): 3380 (very broad, OH), 1720 (C═O), 1405, 1080, 1045 cm^{-1}; ^{1}Hmr (a = acyclic, c = cyclic form), (D_2O, 60% acyclic form) δ: 0.83–1.13 (br m, 4.8H, 2H(3c), 2H(4), 2H(5)), 1.88 (t, 1.2H, *J* = 6 Hz, 2H(3a)), 2.81 (s, 0.8H, 2H(1c)), 2.97 (t, 1.2H, *J* = 6 Hz, 2H(6a)), 3.0–3.38 (m, 0.8H, 2H(6c)), 3.74 (s, 1.2H, 2H(1a)); (DMSO-d_6, 55% acyclic form) δ: 1.31–1.61, 1.61–1.88 (m, 4.9H, 2H(3c), 2H(4), 2H(5)), 2.41 (t, 1.1H, *J* = 7 Hz, 2H(3a)), 3.19 (br t, 0.9H, 2H(1c)), 3.10–3.90 (s, DOH; several m, 2H(6)), 4.05 (d, 1.1H, $J_{1,OH}$ = 5.5 Hz, 2H(1a)), 4.41 (t, 0.55H, $J_{6,OH}$ = 5 Hz, 6a-OH), 4.59 (t, 0.45H, $J_{1,OH}$ = 6 Hz, 1c-OH), 5.06 (t, 0.55H, 1a-OH), 5.13 (s, 0.45H, 2c-OH); ^{13}Cmr (D_2O) acyclic form δ: 19.46 (C(4)), 30.77 (C(5)), 37.51 (C(3)), 61.29 (C(6)), 67.12 (C(1)), 214.45 (C(2)); cyclic form δ: 17.68 (C(4)), 24.41 (C(5)), 29.75 (C(3)), 61.44 (C(6)), 67.60 (C(1)), 95.85 (C(2)); *m/z* (%): 115 (100) ($M^{+\cdot} - HO^{\cdot}$), 101 (53) ($M^{+\cdot} - HOCH_2^{\cdot}$), 97 (51), 83 (30), 55 (29), 98 (25), 57 (13), 69 (11), 41 (10), 43 (10).

Dimer 4A

Upon standing, compound **4** was slowly converted into several new products including the dianhydride **5**. The main new compound, **4A**, was separated from **4** by column chromatography (solvent F, R_f of **4**: 0.17), syrup, R_f 0.22 (solvent F); ν_{max} (film): 3430 (OH), 1705 (C═O); *m/z* (%): 43 (100) (from residual Me_2CO), 115 (53), 101 (37), 55 (30), 58 (27) ($Me_2CO^{+\cdot}$), 97 (25), 83 (24), 41 (19), 98 (19), 100 (16), 114 (13), 57 (10).

(6R,9S and 6S,9R)-1,7,10,15-tetraoxadispiro[5,2,5,2]hexadecane (5) (trans-isomer)

The sample of compound **5** obtained during detritylation of ketone **3** (Procedure A above) was recrystallized from ether – petroleum ether; mp 163–164°C (lit. (7) mp 161°C); R_f 0.58 (solvent C), 0.29 (solvent E); ν_{max} (KBr): 1430, 1282, 1222, 1180, 1030, 935, 870 cm^{-1}; ^{1}Hmr δ: 1.34 (td, 2H) and 1.47–2.03 (several m, 10H) (2H(3), 2H(4), 2H(5), 2H(12), 2H(13), 2H(14)), 3.39 (d, 2H, J_{AB} = 11 Hz, H(8A), H(16A)), 3.70 (d and m, 6H, H(8B), H(16B), 2H(2), 2H(11)); *m/z* (%): 98 (100), 100 (18), 99 (7), 101 (7), 83 (7), 55 (7), 115 (5), 228 (4) ($M^{+\cdot}$), 70 (4), 129 (3.3). *Anal.* calcd. for $C_{12}H_{20}O_4$ (228.29): C 63.14, H 8.83; found: C 63.04, H 8.96.

(6R,9R and 6S,9S)-1,7,10,15-tetraoxadispiro[5,2,5,2]hexadecane (6) (cis-isomer)

To a solution of compound **4** (52 mg, 0.39 mmol) in 1,4-dioxane (1.1 mL) was added trifluoroacetic acid (0.11 mL) and, after 6 h at room temperature, 4 Å molecular sieves. The mixture was stirred further for 15 h, diluted with ether (10 mL), filtered, and the filtrate washed with a saturated aqueous sodium hydrogen carbonate solution (5 mL). The separated aqueous phase was washed with ether (5 mL), the combined organic phases washed with water (5 mL), dried ($MgSO_4$), and concentrated. Column chromtography (solvent D) of the residue containing **5** and **6** in an ~1:1 ratio afforded 12 mg (27%) of the faster-moving isomer **6** and 12 mg (27%) of **5**. A crystalline sample of **6** was obtained by crystallization from pentane at −15°C; mp 44.5−45°C; R_f 0.39 (solvent E); ν_{max} (KBr): 1440, 1360, 1290, 1220, 1185, 1110, 1080, 1055, 1040, 960, 895, 875 cm^{-1}; ^{1}Hmr (a = axial, e = equatorial) δ: 1.41 (td, 2H, $J_{5a,5e} = J_{14a,14e} = 13$ Hz, $J_{4a,5a} = J_{13a,14a} = 13$ Hz, $J_{4e,5a} = J_{13e,14a} = 4.3$ Hz, H(5a), H(14a)), 1.51−1.92 (m, 8H, 2H(3), 2H(4), 2H(12), 2H(13)), 2.00 (dm, 2H, H(5e), H(14e)), 3.44 (d, 2H, $J_{AB} = 12$ Hz, H(8A), H(16A)), 3.68 (d, 2H, H(8B), H(16B)), 3.70 (dm, 2H, $J_{2a,2e} = J_{11a,11e} \simeq 11$ Hz, H(2e), H(11e)), 3.92 (td, 2H, $J_{2a,3a} = J_{11a,12a} \simeq 11$ Hz, $J_{2a,3e} = J_{11a,12e} \simeq 3.5$ Hz, H(2a), H(11a)); *m/z* (%): 98 (100), 41 (18), 55 (16), 228 (15) ($M^{+\cdot}$), 114 (14), 83 (13), 43 (11), 101 (11), 115 (10), 198 (9). *Anal.* calcd. for $C_{12}H_{20}O_4$ (228.29): C 63.14, H 8.83; found: C 63.18, H 8.74.

Protonation of purines and related compounds in dimethylsulfoxide and water

ROBERT L. BENOIT, DANIELLE BOULET, LUC SÉGUIN, AND MONIQUE FRÉCHETTE
Département de Chimie, Université de Montréal, Montréal (Que.), Canada H3C 3V1

Received September 24, 1984

ROBERT L. BENOIT, DANIELLE BOULET, LUC SÉGUIN, and MONIQUE FRÉCHETTE. Can. J. Chem. **63**, 1228 (1985).

The ionization constants of the conjugated acids BH^+ of purine, adenine, 9-methyladenine, adenosine, guanine, and hypoxanthine, and of the related compounds imidazole, *N*-methylimidazole, benzimidazole, and 4-amino-2,6-dimethylpyrimidine have been determined potentiometrically in Me_2SO. The heats of solution and the heats of protonation of most of these bases have been obtained by calorimetry. Some additional determinations were carried out in water so that thermodynamic data in Me_2SO and in water could be compared. Our discussion of the solvent effect on these data is largely based on a consideration of the enthalpies of transfer of B and BH^+ and emphasizes the contrasting H-bonding properties of the solvents and of the functional groups on the solutes B and BH^+.

ROBERT L. BENOIT, DANIELLE BOULET, LUC SÉGUIN et MONIQUE FRÉCHETTE. Can. J. Chem. **63**, 1228 (1985).

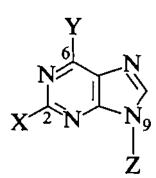
On a déterminé par potentiométrie dans le Me_2SO les constantes d'ionisation des acides conjugués BH^+ de la purine, de l'adénine, de la méthyl-9 adénine, de l'adénosine, de la guanine et de l'hypoxanthine, et des composés voisins, imidazole, *N*-méthylimidazole, benzimidazole et amino-4 diméthyl-2,6 pyrimidine. Les chaleurs de solution et les chaleurs de protonation de la plupart de ces bases ont été obtenues par calorimétrie. Des déterminations supplémentaires ont été effectuées dans l'eau afin de pouvoir comparer les données thermodynamiques dans le Me_2SO et l'eau. Notre discussion de l'effet du solvant sur ces données est, en grande partie, basée sur une considération des enthalpies de transfert de B et BH^+ et met l'accent sur les différences au niveau des propriétés "donneur–accepteur" de liaisons-H tant avec les solvants qu'avec les groupements fonctionnels des solutés B et BH^+.

Purines are important constituents of nucleic acids, and their reactions with the proton and metal ions form the subject of many studies. While the thermodynamics of the first protonation steps of purines in aqueous media is well documented (1), there are few data on these reactions in dimethylsulfoxide even though this solvent, because of its high solubilizing power, is widely used as a reaction medium for related studies, particularly for nmr work. Since we have already compared the thermodynamics of protonation of some nitrogen bases in Me_2SO and in water (2), we have extended our study to include some important purine bases: purine, adenine, 9-methyladenine, adenosine, guanine, and hypoxanthine, as well as some parent and related compounds: imidazole, *N*-methylimidazole, benzimidazole, and 4-amino-2,6-dimethylpyrimidine. We present here the results of our research. The compounds used are listed below.

Experimental

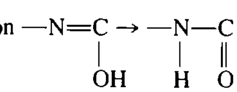
Materials

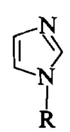
Purine, pyrimidine (Sigma), adenine, adenosine, *N*-methylimidazole (Aldrich), and hypoxanthine and guanine (L. Light) were used without further purification. Imidazole (Aldrich) was doubly recrystallized in benzene and dried under vacuum at 50°C for 30 min. Benzimidazole (Sigma) was doubly recrystallized in distilled water and dried under vacuum at 60°C for 2 h. 4-Amino-2,6-dimethylpyrimidine (Aldrich) was recrystallized in a 2:1 mixture of ethyl acetate and absolute ethanol and dried under vacuum at room temperature for 2 h. 9-Methyladenine was synthesized as follows. An



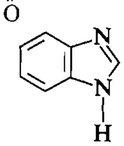
X-2	Y-6	Z-9	Purine
H	H	H	Purine (Pur)
H	NH_2	H	Adenine (Ade)
H	NH_2	D-Ribose	Adenosine (Ado)
H	NH_2	CH_3	9-Methyladenine (MeAde)
NH_2	OH*	H	Guanine (Gua)
H	OH*	H	Hypoxanthine (Hyp)

* Tautomerization

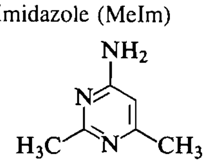




R = H, imidazole (Im)
R = CH_3, *N*-methylimidazole (MeIm)



Benzimidazole
(BzIm)



4-Amino-2,6-dimethylpyrimidine
(Dap)

ethanolic solution of adenine and methyl iodide was heated under reflux at about 80°C for 1 h. The solid obtained was washed with a dilute sodium hydroxide solution, recrystallized in water, and dried under reduced pressure at 40°C for 2 h. The compound was identified by its ^1H and ^{13}C nmr spectra. All samples were checked for purity by means of acid–base titrations in acetic acid or in dimethylsulfoxide (Me_2SO), or by comparing their uv spectra with those published (3).

Trifluoromethanesulfonic acid (Aldrich) and HCl (McArthur) were used as supplied. Picric acid (BDH) (HPic) was dried under reduced pressure over P_2O_5 for 48 h. The HCF_3SO_3 and HPic solutions were prepared by weight or dilution and standardized with NaOH. Potassium chloride (McArthur) was used as received. Tetraethylammonium perchlorate (Eastman Kodak) was recrystallized in a 4:1 mixture of water and ethanol and dried under vacuum at room temperature for 1 h. Finally, Me_2SO (BDH, analytical reagent) was used without further purification.

Potentiometry

Potentiometric titrations of Me_2SO solutions of the bases (10^{-4} to 10^{-2} *M*) with standardized 0.1 *M* HCF_3SO_3 or HPic in Me_2SO were carried out at 25.0 ± 0.1°C in a thermostated cell. The electrodes used were a Radiometer G202B glass electrode and an I^-/I_3^- reference electrode consisting of a platinum wire in a Me_2SO solution 10^{-2} *M* in I_2 and 2×10^{-2} *M* in I^- (2). The junction connecting the reference electrode to the cell was a 10^{-1} *M* Et_4NClO_4 solution in Me_2SO. The solution was made initially 0.100 *M* in Et_4NClO_4 to keep the ionic strength constant. The potentials were measured either with a laboratory-constructed or with a Radiometer PHM 84 potentiometer. The glass electrode was calibrated before each series of experiments with standardized 0.1 *M* HCF_3SO_3 or HPic to give a 62 ± 2 mV slope (intercept 75 ± 5 mV, $r = 0.9996$) in a ΔE vs. pH plot. Potentiometric titrations of 0.1 *M* KCl aqueous solutions of the bases with standardized HCl were similarly obtained using a Radiometer K401 reference calomel electrode.

Calorimetry

The heat of solution and neutralization of solid and liquid bases were determined at 25.00 ± 0.01°C. The LKB Model 8721-1 Isoperibol Calorimeter and procedure have been described (4). The amount of base dissolved or reacted was known from the weights of the glass ampoules. An excess of 0.1 *M* HCF_3SO_3 or HPic in Me_2SO and 0.1 *M* HCl in water was used in the protonation experiments. For each base, 3–10 separate determinations were made at different concentrations.

Results

Ionization constants

The values of the ionization constants K of the protonated bases BH^+ in Me_2SO and water were obtained from the potentiometric neutralization data using the slightly modified program described previously (5). Our pK values, which are strictly valid for 0.10 ionic strength, are given in Table 1 with literature data. No corrections were made for the effect of ionic strength, which would be small for such a type of protonation reaction.

Solution enthalpies

The values of the heats of solution of the liquid (l) or solid (c) bases B in 100 mL Me_2SO or water were plotted against the number of moles of base dissolved (1 to 14×10^{-4} mol for Im, BzIm, Dap, Ade, Me Ade, Ado, and Pur, and 1 to 9×10^{-3} mol for MeIm). The slopes of the least-squares lines gave the enthalpy of solution of B, $\Delta H_s(B)$ (kJ mol^{-1}) which refers to eq. [1].

$$[1] \quad B(l \text{ or } c) = B(s)$$

No concentration dependence was observed in the range of base concentrations used, so that the $\Delta H_s(B)$ values were taken as being equal to $\Delta H_s^0(B)$. These ΔH_s^0 values are given in Table 2 together with published data. The corresponding enthalpies of transfer from water to Me_2SO, on the molar scale

$$[2] \quad \Delta H_t^0 = \Delta H_s^0 - \Delta H_w^0$$

are also given in Table 2.

Protonation enthalpies

The heats of solution of the bases in Me_2SO solutions of 0.1 *M* HCF_3SO_3 or HPic (both strong acids in Me_2SO (6)) and in aqueous 0.1 *M* HCl were plotted against the number of moles of bases dissolved (2 to 12×10^{-4} mol). The plots were linear and the least-squares slopes gave $\Delta H_n^0(B)$ (kJ mol^{-1}), the heat of neutralization of the base, according to

$$[3] \quad B(l \text{ or } c) + H^+(s) = BH^+(s)$$

For Pur, the weakest base in the series, a correction, based on the value of K, was made to account for its incomplete protonation. By combining the $\Delta H_n^0(B)$ values with those of $\Delta H_s^0(B)$, we calculated the heat of protonation of B, $\Delta H_p^0(B)$, in Me_2SO or water, for

$$[4] \quad B(s) + H^+(s) = BH^+(s)$$

with

$$[5] \quad \Delta H_p^0(B) = \Delta H_n^0(B) - \Delta H_s^0(B)$$

The existence of a second step in the protonation of the purines introduces a small error in our values for ΔH_n^0 and hence for ΔH_p^0. Using the values of the ionization constants K_{BH^+} and $K_{BH_2^{2+}}$ (4), the error calculated for ΔH_p^0 is estimated to be 3.0% or less for Ade, assuming that the heat of protonation for the second step is equal to or less than that for the first step. Similarly, the error calculated would be 1.2% or less for MeAde and negligible for Pur and Ado.

Some of the bases (marked with a double asterisk in Tables 2 and 3) were either too insoluble or dissolved too slowly to give meaningful heat changes. Therefore, for MeAde, ΔH_p^0 was determined directly in both solvents, by adding acid to a solution of B. Our value for ΔH_p^0 in water was combined with ΔH_n^0 to yield ΔH_s^0 according to eq. [5]. For BzIm, the value for

ΔH^0_p was taken from the literature and then combined with our ΔH^0_n to give ΔH^0_s. The ΔH^0_p values presented in Table 3 correspond to a 0.1 (usually 0.1 *M* acid) ionic strength. Judging from data of Hepler and co-workers (8) for Im in water, the values of ΔH^0_p at zero ionic strength are not likely to be very different: their ΔH^0_p values are −36.4 kJ mol^{-1} (μ = 0.02), −36.9 (μ = 0.2), while we found −36.8 (μ = 0.1) and 2 other values near −38.0 (μ = 0.5) have been reported (15, 20). However, as pointed out by a referee, for Ade μ may have a large effect on ΔH^0_p (14): ΔH^0_p passes from −21.4 kJ mol^{-1} (μ = 0.025) to −17.6 (μ = 0.10). This large effect is surprising and needs to be confirmed, particularly when one considers that for related Ado, ΔH^0_p varies only from −16.4 kJ mol^{-1} ($\mu \approx$ 0) to −15.9 (μ = 0.1). Our ΔH^0_p(B) values were combined with the ΔG^0_p(B) values calculated from the p*K* in Table 1 to give the protonation entropies ΔS^0_p listed in Table 3.

Discussion

First, if we look at the solvent effect on the ionization constants *K* of the conjugate acids BH^+ of the purines and related bases, the data in Table 1 show only minor changes of the p*K* when passing from water to Me_2SO, and this is particularly noticeable for the purines. Just as we observed with pyridine and anilines (2), the p*K* values are slightly lower in Me_2SO (except, interestingly enough, for the two hydroxypurines) but by less than 1.4 units. On the basis of eq. [1] it is clear that the lower pK's of BH^+ in Me_2SO, which means that they are stronger acids in Me_2SO, are qualitatively in line with the known higher basicity of this solvent compared with that of water. However, if we attempt to give figures for this, given that the free energy of solvation of H^+ is 18.8 kJ mol^{-1} more exothermic in Me_2SO than in water (2), the pK values should have been 3.3 units lower in Me_2SO than in water. Clearly, there are some compensating solvation effects on B and BH^+ which must be considered with those on H^+ to account fully for the small solvent effect on eq. [1] and the resulting pK changes.

Since the free energy data on B (and BH^+) are not easily attainable, we will pursue our discussion of the solvent effect on eq. [1] by comparing, in turn, the enthalpy data for B (Table 2), and then for BH^+ (Table 3), both in Me_2SO and in water. We first note in Table 3 that, contrary to what we would have expected, the protonation enthalpies $\Delta H^0_p(B)$ are more exothermic in Me_2SO than in water even though the enthalpy of solvation of H^+ is 25.5 kJ mol^{-1} more exothermic in Me_2SO than in water (2), which again emphasizes large solvation effects on B and BH^+. If we begin by examining the solution enthalpies and enthalpies of transfer of B, the data in Table 2 show some very interesting differences which we will attempt to relate to the contrasting H-bond properties of Me_2SO and water and to the nature of B functional groups. First, we see that for MeIm, ΔH^0_s is some 10 kJ mol^{-1} more exothermic in water than in Me_2SO ($\Delta H^0_t \approx +10$ kJ mol^{-1}), just as it is for Py and for Pym, while for benzene, which could approximate Py (and MeIm) for cavity and non-specific effects, $\Delta H^0_t = -0.3$ kJ mol^{-1} (7). Since MeIm and Py are both related H-bond acceptors but have no donor properties, we can advance that their more exothermic ΔH^0_s in water is due in part to the formation of H-bonds, H_2O acting as a donor. For Im, the smallness of ΔH^0_t (-1.8 kJ mol^{-1}) when compared with that of ΔH^0_t for Py or Pym and MeIm, can be viewed as resulting from a positive ΔH^0_t contribution due to the "pyridine" nitrogens counterbalanced by a negative contribution of the "pyrrole" —NH group, which gives stronger H-bonds with Me_2SO than with water. Then for Dap, ignoring the contribution of the Me groups on the basis of data for toluene (7), the negative contribution of the —NH_2 group, deduced from $\Delta H^0_t = -11$ kJ mol^{-1} for ϕNH_2, is more than offset by the positive contribution of the "pyridine" nitrogens. Now, it is not possible to relate the ΔH^0_t of the fused ring compounds to those of their imidazole and benzene or pyrimidine moieties. This is shown, for example, by comparing $\Delta H^0_t \sim -8$ kJ mol^{-1} for BzIm with the values for Bz, -0.3 kJ mol^{-1}, and for Im, -1.8 kJ mol^{-1}. A similar situation has recently been observed for such transfers from water to methanol (18). However, if we take BzIm as the reference base, we can also discuss the ΔH^0_t of the purines on the basis of group contributions. Thus, proceeding from BzIm to Pur, we note a positive ΔH^0_t increment, admittedly small, due to the "pyridine" nitrogens. Form Pur to Ade, there is the expected negative ΔH^0_t contribution from the —NH_2 group, although it is larger than that observed with ϕNH_2. From MeAde to Ade, we find the predictably negative increment due to the NH group, though smaller than when passing from MeIm to Im. Finally, for Ado, the replacement of the Me substituent of MeAde by the D-ribose group gives rise to a -8 kJ mol^{-1} contribution to ΔH^0_t, which we can attribute to stronger —OH interactions with Me_2SO.

Let us now consider the solvent effect on BH^+ ions. The paucity of data on proton affinities and heats of sublimation of the bases studied (unlike Py and ϕNH_2(2)) made it impossible to calculate and compare the solvation enthalpies of the gaseous ions BH^+. We have therefore based our discussion on the enthalpies of transfer ΔH^0_t of BH^+ ions from water to Me_2SO, calculated according to:

$$[6] \quad \Delta H^0_t(BH^+) = \Delta H^0_t(B) + \Delta H^0_t(H^+) + \Delta H^0_{p,s} - \Delta H^0_{p,w}$$

where $\Delta H^0_{p,s}$ and $\Delta H^0_{p,w}$ are the enthalpies of protonation of B in Me_2SO and water respectively, and $\Delta H^0_t(H^+)$ is taken as being equal to -25.5 kJ mol^{-1} (2). The values of $\Delta H^0_t(B)$ come from Table 2, those of ΔH^0_p from Table 3, and the results for $\Delta H^0_t(BH^+)$ are given in Table 3. The uniformly large negative values of ΔH^0_t, going from -20 to -60 kJ mol^{-1}, indicate a strong stabilization of BH^+ ions when passing from water to Me_2SO. This increased stabilization must come in part from stronger H-bonding of BH^+ with the more basic solvent Me_2SO. We have attempted to determine whether $\Delta H^0_t(BH^+)$ could not be decomposed into a non-electrostatic term approximated by $\Delta H^0_t(B)$ as well as an electrostatic term (2). This latter electrostatic contribution to the transfer of BH^+ is found to be near 32 kJ mol^{-1} for most of the bases considered. Such a constant contribution would mean, by considering eq. [6], that $\Delta H^0_{p,s} - \Delta H^0_{p,w}$ should be constant at about 7 kJ mol^{-1}. The values in Table 3 generally indicate differences of that magnitude. When we plot $\Delta H^0_t(BH^+)$ against $\Delta H^0_t(B)$, we also obtain $\Delta H^0_t(BH^+) = 0.92\,\Delta H^0_t(B) - 32.0$ ($r = 0.981$) excluding values for ϕNH_2, which is the only base that does not protonate on a pyridine nitrogen.

The entropy data for the protonation of the bases in Table 3 show wide differences for Me_2SO and water, i.e. negative entropy values in Me_2SO contrasting with the positive values in water. We have already observed similar results for the protonation of other nitrogen bases (2). This decrease in the protonation entropy when passing from water to Me_2SO reflects an increased amount of solvent immobilized in the protonation process, with likely contributions from all three particles involved, H^+, B, and BH^+. Finally, we have reported (2) a linear relation between the enthalpy of ionization ($\Delta H^0_{i,s} = -\Delta H^0_{p,s}$) and the p$K$ of the conjugate acids BH^+ of alkylamines, anilines, and pyridine in Me_2SO: $\Delta H^0_{i,s} = 6.855$ p$K + 4.907$ ($r = 0.997$). When we add our present data for the 8 nitrogen bases, we still obtain a fair correlation, $\Delta H^0_{i,s} = 7.02$ p$K + 1.86$ ($r = 0.990$) now for 18 bases with $1.8 <$ p$K < 11.0$, this is evidence of a clear enthalpy–entropy type relationship.

A study of the self-association of the anthracycline antibiotics adriamycin and daunomycin was undertaken in D_2O and methanol using nmr at 400 MHz. From the concentration dependence of the ^2H linewidths obtained on selectively deuterated daunomycin it was determined that daunomycin forms a dimer in aqueous solution. The concentration dependence of the chemical shift of the 4 methoxy group of adriamycin was fit to a dimer model in which only the non-protonated neutral species of adriamycin participated in the self-association process. The data were in agreement with the dimer model if a pK of 7.4 was used. The pH dependence of the self-association was fit to two ionizations, one with a pK of 8.2 and the other with a pK of 8.8. The latter pK was attributed to the ionization of the phenol based on the work of Eksborg. It was concluded that only the deprotonated amine of adriamycin took part in the dimerization process. The dimerization of adriamycin is characterized by a ΔS of approximately 3 cal deg^{-1} M^{-1} and a ΔH of -3.45 kcal M^{-1}. At room temperature the association constant for the dimerization process was found to be 4.0×10^5 M^{-1}. These results were discussed in terms of earlier studies by Barthelemy-Clavey *et al.*, Martin, and Chaires *et al.*

I. J. McLennan, R. E. Lenkinski et Y. Yanuka. Can. J. Chem. **63**, 1233 (1985).

Faisant appel à la rmn à 400 MHz, on a entrepris une étude sur l'auto-association des antibiotiques anthracyclines, adriamycine et daunomycine, en solutions dans le D_2O et le méthanol. En se basant sur la corrélation qui existe entre la concentration et les largeurs des bandes ^2H, obtenue à l'aide d'une daunomycine deutérée sélectivement, on a déterminé que la daunomycine forme un dimère en solution aqueuse. La corrélation qui existe entre la concentration et la déplacement chimique du groupement méthoxyle en position 4 suggère l'existence d'un modèle dans lequel seules les espèces neutres non-protonées de l'adriamycine participeraient dans le processus d'auto-association. Si on utilise un pK de 7,4, les données sont en accord avec le modèle dimère. La corrélation qui existe entre le pH et l'auto-association correspond à deux ionisations, une avec un pK de 8,2 et une autre avec un pK de 8,8. En se basant sur le travail de Eksborg, on attribue ce dernier pK à l'ionisation du phénol. On en conclut que seule l'amine déprotonée de l'adriamycine prend part au processus de dimérisation. La dimérisation de l'adriamycine est caractérisée par un ΔS d'environ 3 cal deg^{-1} M^{-1} et un ΔH de $-3{,}45$ kcal M^{-1}. À la température ambiante, on a trouvé que la constante d'association du processus de dimérisation est égale à $4{,}0 \times 10^5$ M^{-1}. On discute de ces résultats en fonction d'études antérieures de Barthelemy-Clavey et ses collaborateurs, Martin et Chaires et ses collaborateurs.

[Traduit par le journal]

Introduction

Adriamycin (doxorubicin, Adm) (**I**) and daunomycin (daunorubicin) are aminoglycoside anthracycline antibiotics that have been found to be effective antineoplastic agents in the treatment of promyelocytic leukemia and other lymphomas (1). Adm differs from daunomycin in that it has a hydroxyl group on the C14 of the keto-alkyl side chain on the A ring. Since the discovery of Adm in the early 1950's a large amount of information has been accumulated on its mechanism of action both at the molecular and cellular level (2, 3). These anthracyclines are known to bind strongly to DNA in vitro although different modes of binding have been observed (4, 5). In addition, alternate modes of activity have been proposed (6).

There have been several reports of metal ion complexes of Adm (7). We have recently shown that Adm can form complexes of relatively high stability with the trivalent lanthanide ions (8). These complexes were characterized by a variety of spectroscopic techniques including ^1H nmr. In the course of these latter studies we found that in aqueous solution the chemical shifts of several of the resonances of the antibiotic were dependent on the concentration of the drug present. This phenomenon is usually indicative of self-association (9, 10). Similar observations have been reported by Barthelemy-Clavey *et al.* (11), Martin (12), and Chaires *et al.* (13), all of whom have interpreted the concentration dependence of nmr chemical shifts in terms of the self-association of Adm. The self-association process has also been investigated by Eksborg (14) using partitioning experiments based on an extraction procedure. Eksborg (14) determined an effective association constant for the dimerization process of 3.09×10^4 M^{-1}, whereas the dimerization constant determined by Barthelemy-Clavey *et al.* was 570 M^{-1} and that of Martin ranged from 5000 to 9000 M^{-1}. Both of these latter studies utilized visible absorption and circular dichroism spectroscopy. This has been a more traditional approach in examining the aggregation of planar aromatic systems in solution. Recently, Chaires *et al.* (13) have examined the self-association process by visible absorption spectroscopy and ^1H nmr. Using a dimer model they obtained a dimerization constant for Adm of 3300 M^{-1}. These authors have also employed a second more complicated model called the indefinite association model, which takes into account higher aggregates. Using this model, Chaires *et al.* (13) obtained an intrinsic association constant of 1500 M^{-1} from an analysis of sedimentation equilibrium measurements. With the exception of the treatment by Eksborg (14) all of the above analyses neglected the various possible ionization equilibria for Adm in aqueous solution. This implies that all of the species

[1]Supported by the Natural Sciences and Engineering Research Council of Canada (R.E.L.).

(i.e. protonated, nonprotonated) of Adm present in solution can participate equally in the self-association process. Since we have found the self-association process to be pH dependent, *vide infra*, we believe that the neglect of the various ionization processes is a serious flaw in these analyses. In view of the apparent discrepancies in the reported self-association constants for Adm in solution, we undertook a systematic nmr investigation of the self-association process. Our main motivation for this study stems from our view that a knowledge of the solution properties of the antibiotic is important in understanding the metal binding properties and perhaps even the biological effects at the molecular level.

In this study we monitored the effects of variations in Adm concentration, pH, ionic strength, and temperature on the chemical shifts of Adm. The data were fit to an association process that took into account the ionization of the amino group on the glycosidic moiety of Adm. We have also employed ^2H relaxation time measurements as a means of monitoring the extent of self-association. We have analyzed the ^2H linewidths of daunomycin, specifically deuterated at position 14, in aqueous solutions to obtain estimates of the volume of the aggregate(s) formed. We report the results of these studies in the present communication.

Materials and methods

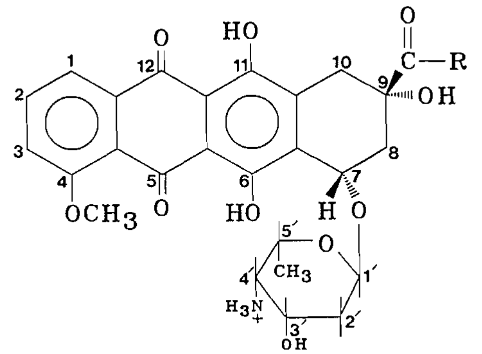
Materials

Adriamycin hydrochloride and daunomycin hydrochloride were kindly supplied by Dr. F. Arcamone of Adria Farmitalia Carlo Erba (Milan, Italy) and were used without further purification. D_2O (99.8%), deuterated methanol, and sodium dimethyl-2-silapentanesulfonate (DDS) were obtained from Merck, Sharp and Dohme. DCl (37% in D_2O) and NaOD (40% in D_2O) were obtained from Sigma. The KCl and EDTA (analytical grade) were from Baker.

Daunomycin specifically deuterated at position 14 was prepared by treating a solution of daunomycin (~6 mM) in methanol-d_4 with metallic sodium. After the reaction was complete (i.e. ca. 10 min) the solution was treated with D_2O and dilute DCl. The resulting solution was evaporated. The remaining solid was extracted with D_2O. A significant amount of nonwater-soluble red-coloured material was observed, suggesting that the aglycone may have formed. The 400-MHz ^1H nmr spectrum of the product was identical to that of daunomycin with the resonance at 2.48 (assigned to the C-14 methyl) missing in the product. The ^2H nmr spectrum obtained at 61.4 MHz showed only one resonance at 2.48, indicating that the methyl group at C-14 of daunomycin had been deuterated.

Nuclear magnetic resonance experiments

The ^1H nmr experiments were performed on a Bruker WH-400 spectrometer operating at 400.13 MHz in the Fourier transform mode using quadrature phase detection. Field/frequency lock was achieved by locking on D_2O in the samples. The temperature was controlled and was calibrated to ±1°C with neat ethylene glycol. For variable temperature experiments the samples were equilibrated for 10 min prior to acquisition of spectra. All spectra were referenced to the internal standard (DSS), whose chemical shift did not change significantly with the temperature and pH ranges used in this study. The shifts of DSS have been reported to change with varying concentrations of purine and uridine (32). However, the concentrations of Adm used in our studies were below 10 mM and hence any perturbations in the shift of DSS due to interactions between DSS and Adm were negligible. This was verified experimentally by examining the chemical shifts of a number of non-aromatic resonances of Adm. At all concentrations employed, all of the chemical shifts of these resonances were indentical. The chemical shift of DSS has been reported to be invariant with temperature over the range of 19° to 90°C (32). We have verified this observation with our own studies down to the temperature of 0°C where we found that the chemical shifts of certain nonaromatic protons



I

(H1′, H2′, H3′, 5′ Me) are invariant within experimental error (<5 Hz) (c.f. I). Typical acquisition parameters were: pulse width 4.5 μs (90°) at 400 MHz, relaxation delay 1 s, sweep width 7000 Hz, and 16 K data points. Approximately 60 to 200 FID's were accumulated depending on the concentration of the sample.

The adriamycin concentration was determined by monitoring the absorbance at 477 nm (ϵ = 11 500 M^{-1} cm^{-1}) (15). The solutions of Adm were made up in D_2O within 24 h prior to use and the pH was adjusted with 0.01 M NaOD or 0.01 M DCl using a Fisher model 620 pH meter with an Ingold model 6060-02 electrode directly in the nmr tube. The pH values reported are uncorrected for any isotope effects. For all of the experiments the ionic strength was adjusted with KCl. The calculation of K_D and curve fitting routines were performed on an OHIO 8000 16K Computer.

Results and discussion

The analysis of ^2H relaxation times of deuterated daunomycin

The applications of ^2H relaxation time measurements to monitor molecular dynamics have been reviewed by Mantsch *et al.* (16). In the extreme narrowing limit, the relaxation rates of a deuterium nucleus are given by (17)

$$[1] \quad \frac{1}{T_1} = \frac{1}{T_2} = \frac{3}{8}\left(\frac{e^2qQ}{\hbar}\right)^2\left(1 + \frac{n}{3}\right)\tau_c$$

where $(e^2qQ/\hbar)$ is the quadrupolar coupling constant along the deuteron–carbon bond, n is the asymmetry parameter (usually assumed to be close to zero), and τ_c is the correlation time for overall molecular reorientation. In the case of a freely-rotating CD_3 group with a correlation time of τ_i attached to a rigid molecule undergoing molecular reorientation with a correlation time of τ_c, eq. [1] can be modified as follows (18).

$$[2] \quad \frac{1}{T_1} = \frac{1}{T_2} = \frac{3}{8}\left(\frac{e^2qQ}{\hbar}\right)^2(0.11\tau_c)$$

if $\tau_c \geq \tau_i$.

For a spherical molecule the correlation time for molecular reorientation is given by

$$[3] \quad \tau_c = \frac{4\pi\eta a^3}{3kT}$$

where η is the viscosity of the solution, a is the radius of the molecule, k is Boltzmann's constant, and T is the temperature in degrees Kelvin. Glasel *et al.* (19) analyzed the ^2H spin lattice relaxation times of 7-methylguanine deuterated at the 7-methyl position to provide information concerning the rotational motion of 7-methylguanine and poly-7-methylguanylic acid. Ellis and co-workers (20) have shown that the linewidth of specifically deuterated molecules can be used as a measure of the real transverse relaxation rate of the deuterium nucleus in

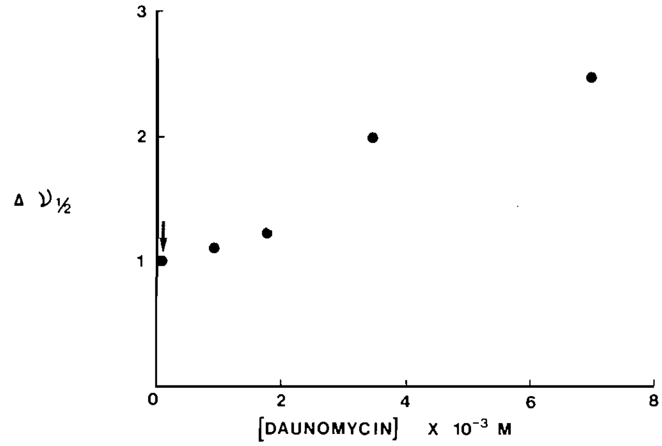


FIG. 1. The variation in the ^2H linewidth of daunomycin deuterated at position 14, with daunomycin concentration. The pH was 6.92, ionic strength 0.052, and the temperature was 22°C. These linewidths were corrected for inhomogeneity by monitoring the linewidth of ^2H from natural abundance deuterium in H_2O (0.5 Hz). The point indicated by an arrow is the linewidth obtained in methanol.

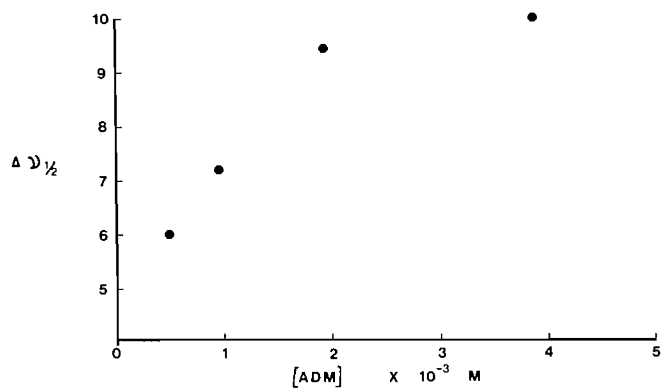

FIG. 2. The variation in the linewidth of the 4-O-methyl resonances of Adm with Adm concentration. The pH was 6.92, ionic strength 0.052, and temperature 21°C.

the molecule. In carrying out our analysis we employed an approach similar to the one described by Egan (21) in his analysis of the association of AMP in aqueous solution using ^2H nmr.

The variation in the linewidth of the deuterium resonance of 14-CD_3-daunomycin with the concentration of drug present is shown in Fig. 1. These linewidths have been corrected for any inhomogeneity of the magnetic field. Note that in Fig. 1 the linewidth at infinite dilution is around 1.0 Hz.

We can obtain an estimate for the correlation time of daunomycin as a monomer in H_2O at 22°C from [3]. From molecular models we find that daunomycin has molecular dimensions approximated by a sphere of ca. 3 Å radius. This corresponds to a correlation time of 8×10^{-11} s in eq. [3]. By using a value for the quadrupolar coupling constant of 170 kHz, a value for the linewidth of the ^2H resonance of 1.2 Hz can be obtained from eq. [2]. The good agreement between the linewidth observed at low daunomycin concentrations and estimated values for the ^2H linewidth indicates that daunomycin exists as a monomer at low concentrations in aqueous solution.

From Fig. 1 it is clear that the ^2H linewidth at higher daunomycin concentrations reaches a limit of around 2.5 Hz. This indicates that there is self-association occurring in solution. This is confirmed by the change in the chemical shifts observed

TABLE 1. ^1H Chemical shift data for adriamycin in methanol

Position	δ (ppm from DSS)	Position	δ (ppm from DSS)
H1	7.97	H4′	3.66
H2	7.85	H3′	3.56
H3	7.59	H10	3.05
H1′	5.45	H8	2.36
H7	5.11	H8	2.18
H14 OH	4.71	H2′	2.04
H5′	4.28	H2′	1.88
4 OMe	4.04	5′CH_3	1.29

in the molecule as well (*vide infra*). Moreover it is clear that the rotational correlation time of the associated species is twice that observed for the monomer. This strongly suggests that the associated species is a dimer in aqueous solution. This conclusion is also qualitatively supported by the variation observed in the linewidth of the ^1H resonance of the 4-O-methyl resonance of Adm with Adm concentration shown in Fig. 2.

Analysis of the chemical shift data

Figure 3 shows a ^1H 2D COSY spectrum (22) of Adm in methanol at 250 MHz. Analysis of the spectrum confirms some of the assignments based on homonuclear decoupling experiments performed at 400 MHz with Adm in methanol. In addition, selective nOe experiments performed at 400 MHz established the assignments of the three aromatic protons.[2] The assignments of the ^1H spectrum in methanol are summarized in Table 1. In methanol, the chemical shift positions of all of the peaks in the proton spectrum of Adm did not vary with the concentration of the drug present. On the other hand, in D_2O there were substantial changes in the chemical shifts of many of the resonances at higher concentrations. As outlined in the Introduction, several workers have analyzed the shifts of resonances of nuclei in Adm and other planar aromatic systems in examining the self-association process in aqueous solutions.

The analysis of chemical shifts in this study was based on a dimer model for Adm first proposed by Barthelemy-Clavey *et al.* (11) and is similar to the method of analysis used by Stein and Tomkiewicz (23). The equilibrium for the dimerization of Adm in aqueous solution can be written as

$$[4] \quad A + A \rightleftharpoons A_2$$

and, K_D, the dimerization constant can be defined as

$$[5] \quad K_D = \frac{[A_2]}{[A][A]}$$

where A is the free monomer, A_2 is the dimer, and the square brackets denote equilibrium concentrations. Similarly for the ionization of the glycosidic amine

$$[6] \quad K_a = \frac{[A][H^+]}{[AH]}$$

where K_a is the ionization constant for the 3′-amino group of Adm. Since we observed only one set of ^1H resonances throughout our study, and the self-association process of planar aromatic systems has been found to be fast on the ^1H nmr chemical shift time scale (24), we may write

$$[7] \quad \delta_{obs} = \frac{\delta_M([AH] + [A] + \delta_D[A_2]}{A_T}$$

[2]McLennan and Lenkinski, unpublished results.

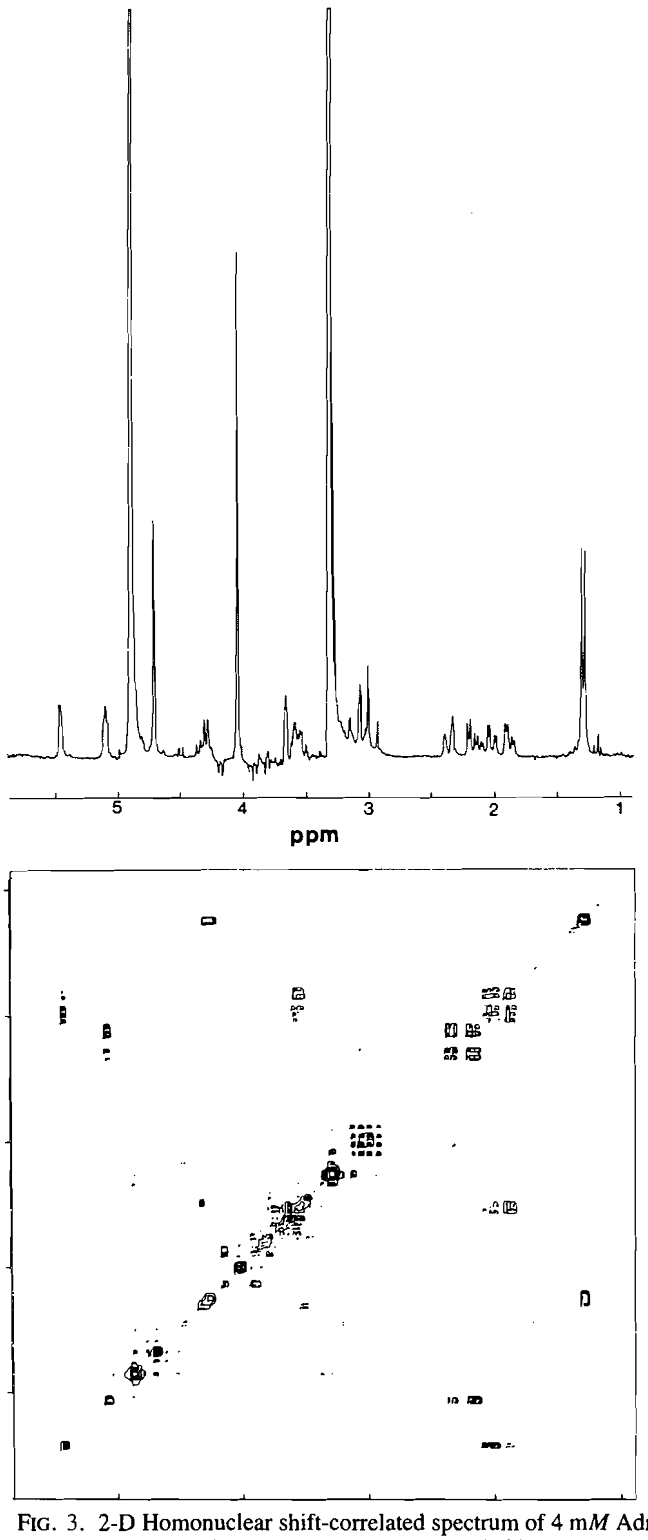

FIG. 3. 2-D Homonuclear shift-correlated spectrum of 4 mM Adm in deuterated methanol at 250 MHz. For chemical shift assignments see Table 1.

(assuming the phenolate anion does not participate in the association process) where AH refers to the protonated amine, A_T is the total Adm concentration, δ_{obs} is the observed chemical shift, δ_M is the chemical shift of the monomer, and δ_D is the chemical shift of the dimer. Substituting eqs. [5] and [6] into eq. [7] and rearranging gives eq. [8].

$$[8] \quad \delta_{obs} = \frac{[AH] + [A]}{A_T}(\delta_D - \delta_M) + \delta_M$$

A mass balance equation can be written in terms of A_T as

$$[9] \quad A_T = [A] + [AH] + 2[A_2]$$

and by substituting eqs. [5] and [6] into eq. [9] we can obtain a quadratic equation in [A],

$$[10] \quad [A]^2 K_A K_D + [A](K_A + [H^+]) - K_A A_T = 0$$

which can be solved by standard mathematical methods. The chemical shift data used to determine K_D was fit to eq. [10] using an interative method based on a sum of squares routine which utilized eq. [8]. A plot of δ_{obs} versus $([AH] + [A])/A_T$ yields both δ_M and δ_D. A similar procedure was used for determining the pK's from the pH titration data. The 4-methoxy peak was chosen as a monitor of the self-association since it is particularly sensitive ($\Delta\delta_{obs} \simeq 70$ Hz) to the Adm concentration. Also, this resonance occurs in a region of the ^{1}H nmr spectrum where there is minimal overlap with any other peaks and thus its chemical shift can be measured relatively precisely even at higher concentrations of Adm where linebroadening occurs (>2.1 mM). It should be noted that in eq. [7] we have made the assumption that δ_M is the same for all of the monomeric forms of Adm, i.e. both protonated and nonprotonated (AH and A respectively). This assumption was verified in experiments in methanol where the chemical shifts of both the protonated and nonprotonated forms of Adm have been measured. The chemical shift of the protonated form of Adm in methanol was found to be 3.98 ppm and the shift for the phenolate anion was found to be 3.96, which is well within the experimental error of the experiment. In addition, as was pointed out earlier, it is reasonable to assume that there is no self-association of Adm in methanol based on the chemical shift of the 4-methoxy resonance (Table 1).

The variation in the chemical shift of the 4-methoxy peak with the temperature and concentration of Adm is presented in Fig. 4. The solid lines represent the calculated shifts based on eq. [10]. Note the good agreement between the calculated and experimental data with a slight deviation seen at $T = 0$°C. This deviation may represent partial freezing of the sample, although this could not be observed visually.

The overall temperature dependence of the association process is shown in Fig. 5. The enthalpy for the process (derived from the slope of the plot in Fig. 5) was found to be -3.45 kcal M^{-1} with an estimate for ΔS (obtained from the intercept) of ca. 3 cal deg^{-1} M^{-1}. Due to the limitations of performing a variable temperature study in aqueous systems only an estimate of ΔS can be obtained, but this is a reasonable value, characteristic of stacking interactions in solutions of high dielectric constant (25).

The results obtained in this study are in agreement with a number of studies of other planar aromatic ring systems (11, 12, 26). In solutions of high dielectric constant the degree of self-association should be greater and this is seen in Fig. 6, which shows the effect of ionic strength on the self-association process. This has been attributed to non-specific interactions between the aromatic rings (27).

A value of K_D of $4.0 \times 10^5\ M^{-1}$ at 22°C contrasts with values of K_D of $5.0 \times 10^3\ M^{-1}$ determined by Martin (12) and $5.7 \times 10^2\ M^{-1}$ determined by Barthelemy-Clavey (11). Although in their studies they used daunomycin, the presence of the hydroxyl group at C14 is not expected to account for the large difference in K_D. Chaires *et al.* (13) have reported a value of 1500 M^{-1} for the association constant based on an analysis employing an indefinite association model. As was pointed out

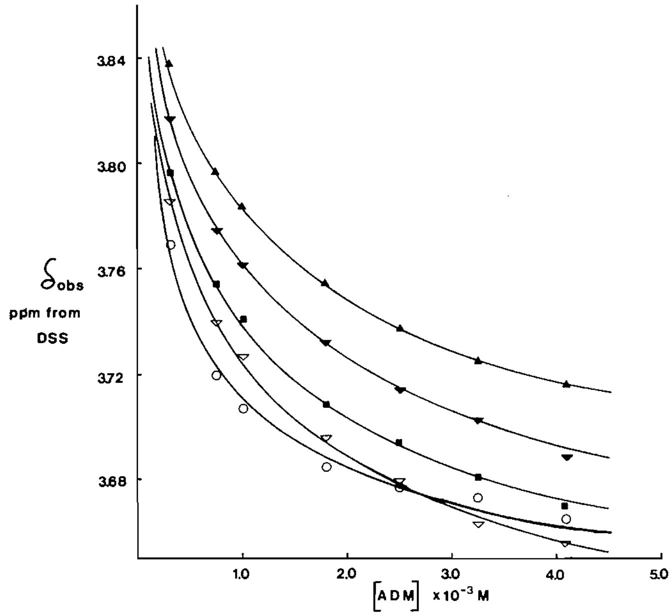

FIG. 4. Plots of δ_{obs}, the chemical shift of the 4-OMe resonance, versus Adm concentration referenced to internal DSS. $\mu = 0.052\ M$, pH 6.91 in D_2O. ○—○ 0°C, ▽—▽ 10°C, ■—■ 22°C, ▼—▼ 35°C, ▲—▲ 50°C. The solid line is calculated from the dimer model.

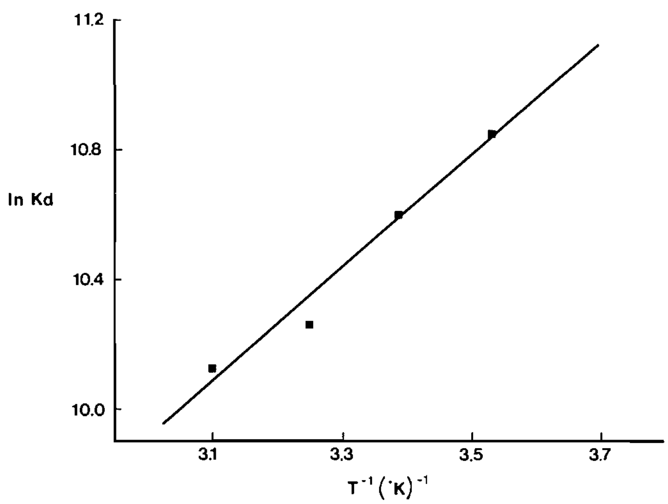

FIG. 5. A van't Hoff plot for the temperature dependence of the dimerization process from the data presented in Fig. 4.

earlier, the same authors also analyzed their data in terms of a dimerization model ($K = 3300\ M^{-1}$). A direct comparison between their results and the dimerization constant determined in the present study may not be relevant because none of the models proposed by Chaires *et al.* (13) take into account the pH dependence of the association process. A plausible reason for these differences is that by taking into account the ionization of the amino group (and assuming the phenolate anion does not participate in the dimerization process) the effective K_D is raised in our model. The pH dependence studies on the dimerization of Adm, shown in Fig. 7, appear to support this.

Eksborg (14) concluded that the free amine was the only species taking part in the dimerization process. In our studies the best fit was obtained using a dimer model in which only the free amine participates in dimerization. Using this model (based on eqs. [8] and [10]) we found a value for the pK of

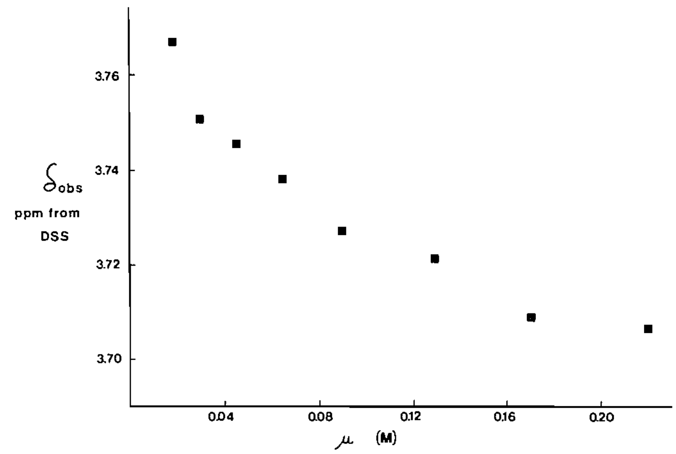

FIG. 6. The variation in δ_{obs} with the ionic strength of the solution. $1.71 \times 10^{-3}\ M$ Adm, pH 6.76, $T = 22°C$.

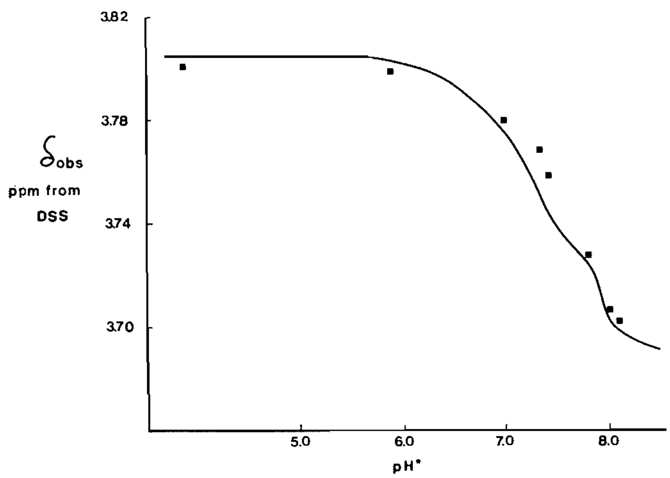

FIG. 7. The pH dependence on the self-association process of Adm in which the ionic strength was initially adjusted to $0.052\ M$. The solid line is calculated from the dimer model. 2 mM Adm, $T = 22°C$.

7.4 ± 0.2 for the protonation of the amine. Eksborg (14) has determined the pK_a of the glycosidic amine to be 8.2, whereas Righetti *et al.* (28) have determined it to be 7.8. The difference between our pK and the values reported by these authors (determined in H_2O) falls within the isotope effect of D_2O on the pK of primary amines, which is approximately -0.60 at this particular pH range (29). Taking into account our assumption about the phenolate anion, the isotope effect would make 7.4 a reasonable value. Figure 7 shows the results of a pH titration of 2 mM Adm in D_2O. Using the dimer model in the analysis of the chemical shift data, the data were fit to two ionizations characterized by pK's of 8.2 ± 0.2 and 8.8 ± 0.2, corresponding to the glycosidic amine and one of the phenols, respectively. Note that the value for the K_D obtained from this titration is $4.0 \times 10^4\ M^{-1}$, which is in good agreement with the value obtained from our previous analysis of the data for the concentration dependence of the chemical shift shown in Fig. 4. We believe that the discrepancy between the value obtained for the pK of the amino group (8.2 ± 0.2 in this case, 7.4 ± 0.2 for the data in Fig. 4) can be ascribed to differences in the ionic strength at which the two experiments were performed.

Lam and Neville (30) determined binding constants for acridine orange using visible absorption spectroscopy. Two models were proposed for its self-association, one involving anion participation and another involving only the neutral species of acridine orange. It was found that both models gave good agreement with the experimental data. Acridine orange has served as a prototype for many studies of stacking interactions of planar aromatic systems, although in the case of Adm direct anion participation in the self-association process has been ruled out based on the arguments stated earlier in the results and discussion.

A serious drawback to using visible absorption spectroscopy or nmr to monitor the extent of dimerization is that there are no clear criteria for ascertaining whether the absorbance peak or resonance signal arises from only monomer–dimer interactions or higher order association into *n*-mers. In the case of Adm, where the crystal structure of the dimer is not accurately known, Pople's treatment (9) cannot be used with confidence to determine whether the shifted resonance signal is strictly due to shielding interactions that arise from the dimerization between two monomers.

We have provided evidence (based on our ^2H relaxation measurements) that the two anthracyclines probably form only dimers in aqueous solution. There is no evidence that, at the higher concentrations employed in this study, the self-association process includes higher order association into tetramers or *n*-mers. This is contrary to the model proposed by Chaires *et al.* (13).

There has been some controversy regarding the validity of calculating binding constants by various graphical methods. To this end we have avoided the use of double reciprocal plots in evaluating K_D. The data were fit directly to the model equation (eq. [10]) as explained in the materials and methods. Deranleau (31) has pointed out (based on information theory) that meaningful conclusions regarding the validity of the equilibrium model and the value of the binding constant can be obtained when the observed data cover 75% of the binding curve. Using the value of $\Delta\delta_{obs}/(\delta_D - \delta_M)$ as a measure of the degree of observable data, relative to the complete binding curve, we have obtained data covering approximately 50% of the total binding curve for the various temperatures (Fig. 4). Unfortunately, due to solubility problems with Adm in water (>6 m*M*) and the sensitivity problems associated with the nmr experiment, it was difficult to obtain data covering a larger portion of the binding curve.

Conclusion

The self-association of Adm was studied using ^1H nmr. The results of the ^2H relaxation data provide strong evidence in support of a dimer model for Adm in aqueous solutions. The chemical shift data fit closely to a dimer model which took into account the ionization of the glycosidic amine. From the temperature dependence of the dimerization process it was determined that the process was characterized by an enthalpy of -3.45 kcal M^{-1} and an approximate value for ΔS of 3 cal $\deg^{-1} M^{-1}$. The relative value of K_D determined in our studies should aid in the understanding of metal ion binding and the interaction of Adm with DNA.

Acknowledgements

We thank Dr. Charles Rodger of Bruker Spectrospin (Canada) for help in obtaining the 2-D spectrum of Adm. The ^1H nmr and ^2H experiments, at 400 MHz in this study, were performed at the Southwestern Ontario High Field NMR Centre at the University of Guelph, which was established by a Major Installation grant from the Natural Sciences and Engineering Research Council of Canada. We would like to thank Dr. R. Wasylishen for helpful discussions.

CHRISTOPHER I. RATCLIFFE. Can. J. Chem. **63**, 1239 (1985).

Guanidinium $[C(NH_2)_3^+]$ chloride, bromide, and iodide salts have been studied by ^1H and ^2H nmr as a function of temperature. The ^2H powder lineshapes show conclusively that reorientation of the guanidinium ion occurs about the principal three-fold axis in the chloride, bromide, and high temperature phase of the iodide. Activation energies for this process have been obtained from ^1H spin-lattice relaxation results. The question of whether or not there are concurrent two-fold flips of the —NH_2 units is discussed, but must presently remain unresolved. It was found that the high temperature phase of the iodide can be supercooled.

CHRISTOPHER I. RATCLIFFE. Can. J. Chem. **63**, 1239 (1985).

Faisant appel à la rmn du ^1H ou du ^2H à des températures variables, on a étudié les chlorure, bromure et iodure de guanidinium $[C(NH_2)_3^+]$. Sur la base de la forme des raies des spectres ^2H de poudres, on démontre sans ambiguité que la réorientation de l'ion guanidinium se produit autour d'un axe principal ternaire dans le chlorure et le bromure ainsi que dans la phase à haute température de l'iodure. On a déduit les énergies d'activation de ces processus en se basant sur les résultats obtenus pour la relaxation spin-réseau du ^1H. On discute de la possibilité de l'existence de deux inversions concurrentes des unités —NH_2; toutefois, cette question n'est pas résolue. On a trouvé que la phase à haute température de l'iodure peut donner lieu à de la surfusion.

[Traduit par le journal]

Introduction

The guanidinium ion $[C(NH_2)_3]^+$ is one of a number of molecules in which the —NH_2 groups, and in this case the whole molecule, are planar because of π overlap of the P_z orbitals of nitrogen and carbon. This has been substantiated by *ab initio* calculations (1–4). Further examples include urea and other amide groups. Barriers to rotation about the C—N bond are expected to be much higher than in materials such as amines where the π-bonding is not present. The barriers obtained in the *ab initio* calculations (1–4) differ among themselves, but from one nmr study of the guanidinium ion in liquid crystal solution a barrier of 13 kcal/mol was reported (1). This value seems rather low, however, when compared to the barriers reported from nmr studies of formamide and acetamide in solution, which are upwards of 16 kcal/mol (e.g. refs. 5–7) and solvent dependent. In solids the barriers would, if anything, be expected to increase due to external hindrances, but no values have as yet been reported.

The work done on simple salts of guanidinium has not been extensive. Infrared and Raman studies (8–13) and early ^1H nmr lineshape studies (14–16) helped to establish the planar structure of the ion. An NQR study has reported ^{14}N quadrupole coupling parameters for a number of salts (17).

Concerning motions of the ion, Kotera *et al.* (14) reported rigid lattice ^1H nmr second moments for the iodide at liquid nitrogen (20.94 G^2) and Dry Ice temperatures (20.02 G^2) and a value of 13.81 G^2 at room temperature. Lundin *et al.* (16) interpreted second moments for $[C(NH_2)_3]Al(SO_4)_2 \cdot 6H_20$ in terms of C_3 reorientation of the guanidinium above ~130 K with an estimated activation energy of 6 kcal/mol. Pająk *et al.* (18) recently reported ^1H second moment (M_2) and spin-lattice relaxation (T_1) results for $[C(NH_2)_3]ClO_4$ and suggested that C_3 reorientation of the whole ion occurs concurrently with two-fold flips of the —NH_2 groups.

This paper presents the results of ^1H T_1 studies of guanidinium chloride, bromide, and iodide performed at an earlier date (1977), together with some recent ^2H nmr lineshapes which have helped to clarify what motions occur. X-ray structural information is available on all three salts (19, 20). At room temperature the chloride and bromide are orthorhombic. The iodide is hexagonal, but a higher temperature modification previously thought to be orthorhombic has been reported (21). The hexagonal structure is interesting in that it has two inequivalent guanidinium ions; however, its space group is piezoelectric (22), a property which sometimes makes nmr measurements difficult if not impossible.

At the time of writing of this manuscript, Grottel and Pająk (23) published results which included ^1H M_2 and T_1 results of the Cl^-, Br^-, I^-, and BF_4^- salts. They also mention that X-ray powder results on the high temperature phase of the iodide suggest that it is cubic. While their T_1 results qualitatively resemble those presented here, a number of quantitative differences have been found which will be discussed in context. The results presented here also extend the T_1 measurements for the high temperature phase of the iodide into the metastable region below 350 K.

Experimental

The three halide salts were prepared by addition of the appropriate dilute acid to a solution of guanidinium carbonate until neutral. The resulting solutions were then evaporated until crystallization set in on cooling and the filtered products were then recrystallized from water.

Proton spin lattice relaxation times (T_1) were measured at 30.2 MHz over a range of temperatures using an inversion–recovery, $\pi - t - \pi/2$ pulse sequence on a Bruker B-KR322S spectrometer described before (24) (Chemistry Department, University of British Columbia). The free induction decay was apparently exponential within experimental error for the chloride, bromide, and higher temperature phase of the iodide. Further measurements on the bromide were obtained at 16 MHz.

The hexagonal phase of the iodide proved to be more unusual. In

[1]Issued as NRCC No. 24143.

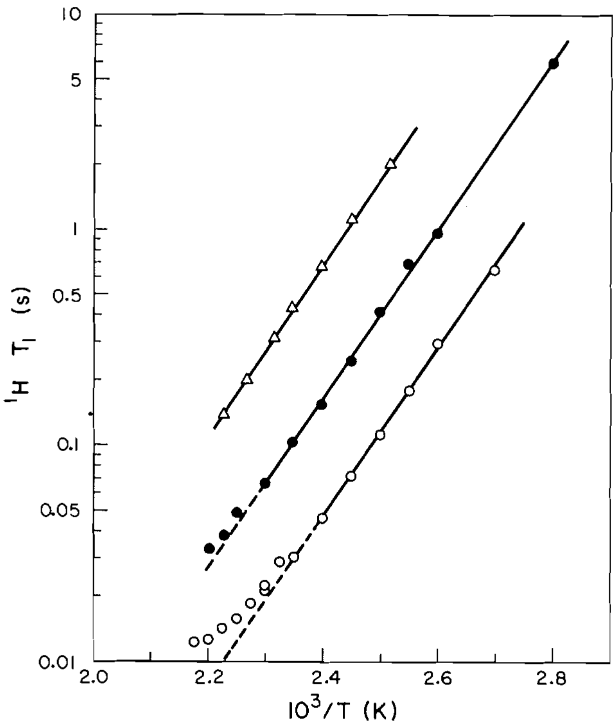

FIG. 1. The temperature dependence of the proton spin-lattice relaxation times observed for guanidinium chloride (△) at 30.2 MHz, bromide (●) at 30.2 MHz, and bromide (○) at 16.0 MHz. The solid lines indicate the linear least-squares fits.

the first place its piezoelectric nature was confirmed by the presence of a "noise" superimposed on the free induction decay. The noise was also present if the sample was removed from the magnetic field. Such signals often make measurement of T_1 impossible without special screening of the sample from the r.f. coil (25). However, in this case the piezoelectric signal was not excessive, appearing as a weaker signal superimposed on the free induction decay, and its pattern remained constant with each pulse. Consequently measurements of the magnetization recovery were still attempted. However, the relaxation proved to be quite non-exponential. An approximate relaxation parameter T_1' was therefore obtained from the time at which the magnetization recovery crossed zero assuming $T_1' \approx (t_0)/\ln 2$ (the so-called "null" method). The reasons for this non-exponential behaviour are obscure, but one is inclined to believe, in the absence of other obvious factors, that it may be due to an error introduced by the superimposed piezoelectric noise. Neither the piezoelectric behaviour nor the non-exponential decay were mentioned by Grottel and Pająk (23).

Deuterated samples of the salts were prepared from the fully protonated materials by repeated dissolution in and evaporation from D_2O (3 times). The ^2H nmr powder lineshapes were obtained at 27.63 MHz using a Bruker CXP 180 spectrometer, a Bruker/Oxford Instruments cryomagnet, and a variable temperature N_2 gas-flow probe with a Bruker B-VT-1000 temperature controller (Chemistry Division, NRCC). A quadrupole echo pulse sequence (26) was used with a delay time of 35 μs between X and Y pulses of 2.5 μs, and phase alternation. The cycle repetition rates varied from 0.4 to 20 s depending on T_1.

Results and analysis

Plots of log T_1 vs. $1000/T$ are shown in Figs. 1 and 2. The chloride and bromide have very long T_1's up to temperatures of about 370 K. Above this temperature the results show the linear low temperature slope of some relaxation mechanism, up to the highest temperatures before the samples melt. The results at

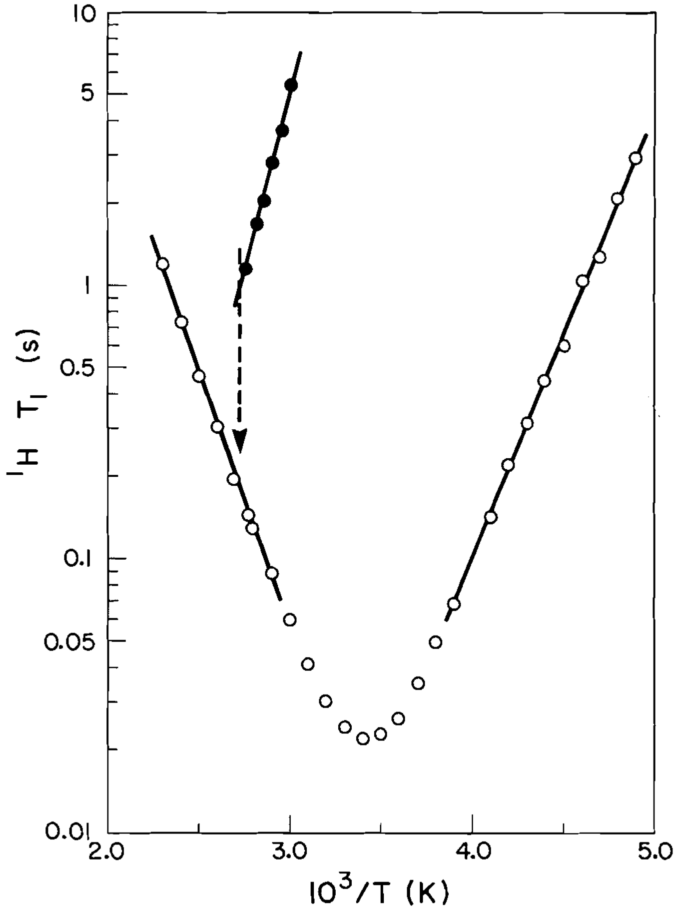

FIG. 2. The temperature dependence of the proton spin-lattice relaxation times observed for guanidinium iodide at 30.2 MHz; hexagonal phase (●), high temperature (and metastable) phase (○). The solid lines indicate the linear least-squares fits.

16 MHz for the bromide were obtained specifically to try to reach a T_1 minimum and, as can be seen, this was practically achieved. A value for $(T_1)_{min}$ = 12.0 ms at 460 K and 16 MHz is indicated. (An equivalent minimum at 30.2 MHz should therefore be 22.7 ms.) Also note that the T_1 results at the two frequencies fit the expected ω_0^2 dependence.

For the iodide the behaviour at the phase change varied somewhat, dependent upon the history of the sample. On warming, as the phase change was reached T_1 decreased dramatically and the piezoelectric effect disappeared over a period of several minutes. For a sample which had been previously melted to achieve greater packing in the sample tube this change took place at about 350 K, but for a powdered sample it occurred at about 365 K. This high temperature phase of both samples could then be supercooled. When left in this state at room temperature the powdered sample reverted to the hexagonal phase within an hour whereas the melted sample took much longer. Both gave similar values of T_1 in the supercooled state. (Note that Grottel and Pająk's (23) results do not extend into the supercooled region.) The complete T_1 curve in Fig. 2 thus represents the higher temperature phase. The higher temperature slope is greater than the lower temperature slope. The curve reaches a $(T_1)_{min}$ of 22 ms consistent with the bromide result (converted to 30.2 MHz), which suggests that the two minima are representative of similar relaxation mechanisms. Since the chloride appears to behave in a manner similar to the bromide it seems reasonable to assume that it too is relaxing by the same mechanism.

The few T_1−null results for the hexagonal phase of the iodide fall on a straight line, forming the low temperature slope of a T_1 curve. There is insufficient information in this to determine the relaxation mechanism, though one might again anticipate C_3' reorientation. It should be remembered, however, that for this phase (hexagonal) there are two inequivalent guanidinium ions in the cell, which might reorient at different rates.

Theoretical calculations of ^1H $(T_1)_{min}$ values for different motions

The T_1 results may be interpreted using the framework of the modified B.P.P. theory (27, 28). Modulation of the internuclear dipole−dipole interactions by molecular motions leads to spin-lattice relaxation. For an interproton vector:

$$\left(\frac{1}{T_1}\right)_{H-H} = \frac{3}{2}\gamma_H^4\hbar^2 I(I+1)[J^{(1)}(\omega_H) + J^{(2)}(2\omega_H)]$$

γ_H = magnetogyric ratio for ^{1}H, $\hbar = h/2\pi$, $I = 1/2$ for ^{1}H, ω_H = ^{1}H Larmor frequency. The $J^{(n)}(\omega)$ represent the spectral density functions for the particular motion concerned.

For a proton−nitrogen vector the situation is more complex (29), but it was shown in a previous paper concerning —NH_3^+ group ^{1}H relaxation (30) that the cross-relaxation terms had little effect on the observed ^{1}H T_1. Assuming a similar situation in the present case, the ^{14}N contribution to the proton relaxation is then well approximated by

$$\left(\frac{1}{T_1}\right)_{N-H} = \gamma_H^2\gamma_N^2\hbar^2 S(S+1) \times \left[\frac{1}{12}J^{(0)}(\omega_H - \omega_N) + \frac{3}{2}J^{(1)}(\omega_H) + \frac{3}{4}J^{(2)}(\omega_H + \omega_N)\right]$$

where $S = 1$ for ^{14}N. (Note this also neglects any ^{14}N quadrupolar interactions.)

The spectral density functions $J^{(n)}(\omega)$ must then be evaluated for each motion. The methods of Woessner (31) are probably the most frequently used to do this. However, in cases where the internuclear distance is changed by the motion, it is more convenient to use an apparently less well-known method (29, 32, 33). To obtain the overall relaxation rate for a particular motion one must (1) calculate, for each proton, the sum of the effects of motion on all the dipole−dipole vectors connecting that target proton to other nuclei, and (2) assuming rapid spin diffusion, average over all protons.

Calculated theoretical $(T_1)_{minimum}$ values for a number of possible motions are outlined below (values are given in Table 1). The molecular parameters used were N—H = 1.00 Å, C—N = 1.33 Å, and all bond angles 120° in the plane.

The final expressions for motions of the ion when *no internal rotation* occurs are relatively simple. For reorientation about the 3-fold axis (C_3' motion)

$$\left(\frac{1}{T_1}\right)_{C_3'} = \frac{9}{40}\frac{\gamma_H^4\hbar^2}{\omega_H}f(\omega_H\tau_c)\sum_i\frac{1}{r_{Hi}^6} + 2\frac{\gamma_H^2\gamma_N^2\hbar^2}{\omega_H}f'(\omega_H\tau_c)\sum_j\frac{1}{r_{Nj}^6}$$

where

$$f(\omega_H\tau_c) = \left[\frac{\omega_H\tau_c}{1+\omega_H^2\tau_c^2} + \frac{4\omega_H\tau_c}{1+4\omega_H^2\tau_c^2}\right]$$

and

TABLE 1. Calculated T_1 minimum values (ms) for motions of the guanidinium ion

Motion	T_1 (ms) 16 MHz	30.2 MHz
C_3' threefold axis	9.2	17.3
C_2' twofold axis	18.3	34.6
Isotropic	6.9	13.0
C_2 internal twofold reorientation of —NH_2	91.0	171.7
All 3 —NH_2 groups performing C_2	60.6	114.5

$$f'(\omega_H\tau_c) = \left[\frac{\omega_H\tau_c}{1+\omega_H^2\tau_c^2}\right]$$

and the r_{Hi}, r_{Nj} are the H---H and N---H distances. Implicit in the expression $f'(\omega_H\tau_c)$ for the N---H contribution is the approximation that $(\omega_H - \omega_N) \approx \omega_H \approx (\omega_H + \omega_N)$. τ_c is the correlation time for the motion and is assumed to have an Arrhenius dependence on temperature T and the activation energy E_a:

$$\tau_c = \tau_c^0 \exp(E_a/RT)$$

For isotropic motion one finds

$$\left(\frac{1}{T_1}\right)_{iso} = \frac{4}{3}\left(\frac{1}{T_1}\right)_{C_3'}$$

For reorientation about a two-fold axis (C_2' motion)

$$\left(\frac{1}{T_1}\right)_{C_2'} = \frac{9}{40}\frac{\gamma_H^4\hbar^2}{\omega_H}f(\omega_H\tau_c)\sum_i\left[\frac{\sin^2(2\Delta i)}{r_{Hi}^6}\right] + \frac{2\gamma_H^2\gamma_N^2\hbar^2}{\omega_H}f'(\omega_H\tau_c)\sum_j\left[\frac{\sin^2(2\Delta j)}{r_{Nj}^6}\right]$$

where Δi, Δj refer to the angle between an internuclear vector and the rotation axis. Coincidentally it is found that for this specific case where all bond angles in the plane are 120°

$$\left(\frac{1}{T_1}\right)_{C_2'} = \frac{1}{2}\left(\frac{1}{T_1}\right)_{C_3'}$$

For C_2 rotation of one NH_2 group with the rest of the molecule rigid (i.e. internal reorientation), the final expression is more complex:

$$\left(\frac{1}{T_1}\right)_{C_2} = \frac{1}{20}\frac{\gamma_H^4\hbar^2}{\omega_H}f(\omega_H\tau_c)\sum_i \times\left[\frac{1}{r_{Hi}^6} + \frac{1}{s_{Hi}^6} - (3\cos^2\Omega_i - 1)\cdot\frac{1}{r_{Hi}^3}\cdot\frac{1}{s_{Hi}^3}\right] + \frac{2}{9}\frac{\gamma_H^2\gamma_N^2\hbar^2}{\omega_H}f'(\omega_H\tau_c)\sum_j \times\left[\frac{1}{r_{Nj}^6} + \frac{1}{s_{Nj}^6} - (3\cos^2\Omega_j - 1)\cdot\frac{1}{r_{Nj}^3}\cdot\frac{1}{s_{Nj}^3}\right]$$

where the summations over i, j cover the interaction between *one of the mobile protons* and the other protons or nitrogens. r and s refer to the internuclear distances in the two sites and Ω refers to the angle between the two orientations. If all three —NH_2 groups are able to rotate with similar correlation times then the above expression for C_2 motion must be multiplied by

TABLE 2. Activation energies (kcal/mol)*

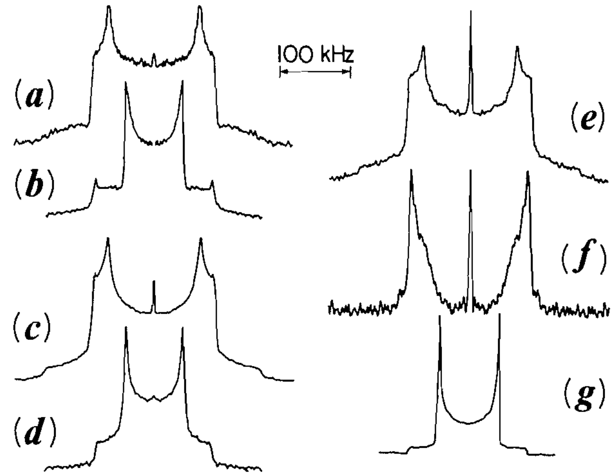

FIG. 3. The ^2H nmr powder lineshapes of guanidinium chloride (a) 307 K; (b) 425 K; bromide (c) 303 K, (d) 420 K; hexagonal iodide (e) 302 K, (f) 345 K; and metastable iodide (g) 311 K.

3/2. (Note these are independent flips, not a concerted reorientation of all three NH_2 groups at once.)

When the molecular parameters have been introduced, all the expressions above reduce to the form

$$\frac{1}{T_1} = (A + B)\left(\frac{\omega_H\tau_c}{1 + \omega_H^2\tau_c^2}\right) + 4A\left(\frac{\omega_H\tau_c}{1 + 4\omega_H^2\tau_c^2}\right)$$

which can then be solved for a minimum in T_1. Results are given in Table 1. It should be pointed out that the contribution to T_1 (at the minimum) of N—H interactions in the cases where the molecule is internally rigid is ~26%, whereas for internal rotation of $—NH_2$ groups this contribution jumps to ~67%. In the latter case it is then quite possible that cross-relaxation terms, which were neglected earlier, could affect the ^1H relaxation behaviour to some degree. However, further calculations to take this effect into account are not really warranted at this point, since it is quite clear that internal rotations of $—NH_2$ groups are far less efficient at producing ^1H relaxation than any of the rigid ion motions.

The observed T_1 minima for the bromide and iodide clearly correspond most closely to the calculated value for C_3' motion. (Calculated T_1 values are almost invariably found to be slightly less than those observed and in any case depend on the structural parameters chosen.) However, one more type of motion which should be considered is the composite motion of NH_2 flips concurrent with whole ion C_3' motion. Without going into a complex and very involved calculation for this particular case, one can assert that if the two processes have similar correlation times then the resultant T_1 minimum should not be less than that given by

$$\left(\frac{1}{T_1}\right)_{\text{composite min}} = \left(\frac{1}{T_1}\right)_{C_3' \text{ min}} + \left(\frac{1}{T_1}\right)_{C_2 \text{ min}}$$

For all three NH_2 groups flipping, this means that the T_1 minimum value should be no lower than 15 ms (30.2 MHz). This is not much different from the value for C_3' alone. Considering experimental errors and the usual discrepancies between observed and calculated T_1 minima, it does not seem realistic to distinguish between these two types of motion. In either case C_3' motion occurs and is the principal cause of relaxation, so that one can be reasonably certain from the T_1 results that such a motion is occurring. The question of whether or not there are concurrent NH_2 flips, however, should remain open. At this point the author diverges from the view of Grottel and Pająk (23) who interpreted their T_1 and M_2 results in terms of the $(C_3' + C_2)$ model. There is no reason to believe that their M_2 results provide any firmer grounds than the T_1 results for preferring $(C_3' + C_2)$ over C_3' alone.

Activation energies obtained from the linear slopes of the ln T_1 vs. $1000/T$ plots by least-squares fits are given in Table 2. It is in these activation energies that one first notices discrepancies between Grottel and Pająk's (23) and the present results. Also, when the difference in frequencies is taken into account it is found that the T_1 values for the chloride and bromide salts in the current work are lower than Grottel and Pająk's, but the situation is reversed for the high temperature phase of the iodide. The reasons for these differences are obscure at the present. Attempts were also made to fit the complete T_1 curve for the metastable iodide, using the model for C_3' motion including $^1H{-}{-}{-}^{14}N$ terms. However, the appreciable difference in slope on either side of the minimum would not permit a satisfactory fit, though the attempted fit gave an indication of the order of magnitude of the correlation time constant τ_c^0 as roughly 6×10^{-15} s.

^2H Lineshapes

Conclusive confirmation of motion around the C_3' axis comes from the ^2H lineshapes shown in Fig. 3. Close to room temperature the chloride, bromide, and hexagonal iodide have essentially rigid lattice lineshapes (Fig. 3 a, c, e, respectively) characteristic of planar $—ND_2$ groups involved in a π-bonding system. Note that this shows that both crystallographic types of guanidinium in the hexagonal iodide are rigid. The quadrupole coupling constants and asymmetry parameters are very similar to those observed in urea and thiourea (34, 35), Table 3.

The chloride and bromide at temperatures above 410 K and the high temperature phase of the iodide (even when supercooled to room temperature) show narrowed lineshapes (Fig. 3 b, d, g, respectively) corresponding to an axially symmetric coupling tensor, Table 3. At 345 K the hexagonal phase of the iodide is clearly undergoing a line narrowing transition but unfortunately does not reach the rapid motion limit before the phase change sets in (Fig. 3f). Figure 4 shows the calcu-

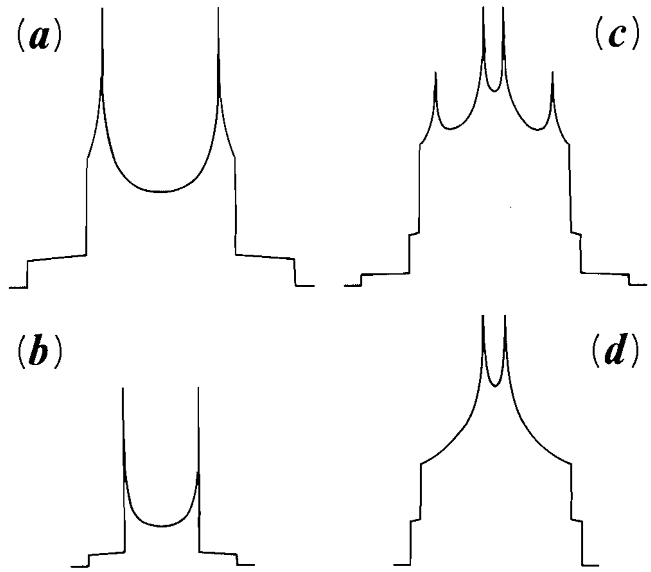

FIG. 4. Calculated ^{2}H powder nmr lineshapes for different motional processes (a) rigid, (b) C_3' reorientation, (c) C_2' reorientation, and (d) C_2 (NH_2) reorientation.

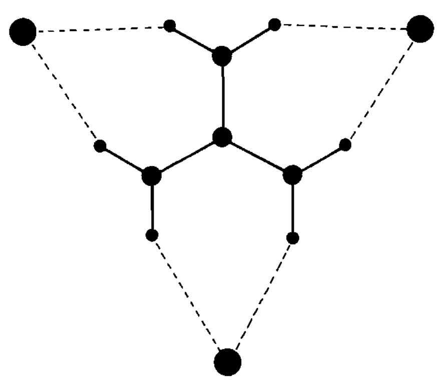

FIG. 5. A view down the C_3 axis of the chloride showing the arrangement of the three chloride ions with which there are hydrogen bonding contacts.

lated lineshapes for various cases of rapid motional averaging, assuming a rigid lattice value of $\eta = 0.12$ and bond angles all 120°. If the rigid q_{zz} is assumed to be along the ND bond axis then q_{yy} turns out to be perpendicular to the molecular plane (q_{xx} in the plane). (Lineshapes, other than rigid, are calculated by averaging the tensor components at all the equilibrium positions sampled by the motion, see ref. 36.) It is quite clear from a comparison of observed and calculated lineshapes that C_3' motion occurs; however, one again cannot distinguish between C_3' alone and C_3' concurrent with C_2 flips (the averaged lineshapes would be the same).

Structural considerations

It is informative to consider the immediate environment of the guanidinium ions, using the structural information available (19, 20). Since accurate H atom positions are not available, the lattices were regenerated in Cartesian space and the original (X-ray) CN_3 units were replaced by the symmetrical guanidinium ion, including the six H atoms, which was used earlier in the paper. Closest contacts of the protons in the rigid lattice case and their closest approaches to the surrounding atoms for C_2, C_2', and C_3' motions were then calculated. Contacts less than the sum of the van der Waals radii were taken as significant. The following important features emerged.

TABLE 3. ^{2}H Quadrupole coupling constants and asymmetry parameters

		Rigid lattice		Rapid C_3' motion	
Salt	T (K)	e^2qQ/h (Hz)	η	e^2qQ/h	η
Chloride	307	200 500	0.1445		
	425			107 400	0
Bromide	303	205 100	0.1416		
	420			109 900	0

TABLE 4. Closest contacts with halide ions at equilibrium and during C_3' rotation (Å) (idealized guanidinium geometry as used in text)

	Cl	Br	I1*	I2*
C_3' rotation	1.73	1.86	2.14	2.38
Equilibrium	2.33	2.42	2.75	2.94

*The hexagonal iodide has two inequivalent guanidinium ions.

(1) In all cases, at the equilibrium position (rigid case) each H atom has only *one* significant overlap and that occurs with a halide ion. This is indicative of a hydrogen-bonding interaction.

(2) In all cases, three halide ions which are close to the plane of the guanidinium ion form a 3-fold or near 3-fold arrangement around the C_3 axis of the guanidinium. (In the cases of the bromide and iodide these three ions fall in a plane parallel to the plane of the guanidinium.) Figure 5 shows a view down the C_3 axis of the chloride, indicating these contacts. The view is essentially the same for the bromide and for the two types of guanidinium ion in the hexagonal iodide, except that the halide ions are further removed from the central axis.

(3) These three halide ions are also the only atoms which overlap the H atoms of the guanidinium during a C_3' reorientation.

(4) In all cases it was found that a C_2 flip of NH_2 would cause overlaps with halide ions to about the same extent as in the equilibrium position, and in most cases *slight* overlaps with one H atom (other than those within the guanidinium ion).

(5) In all cases C_2' rotation would cause a large number of overlaps with all types of atoms, suggesting that this motion should be sterically very unfavourable.

It is difficult to judge at what point a close approach to a halide ion becomes a repulsive rather than attractive (hydrogen-bonding) interaction, but these two forces presumably come into play in the C_3' motion (which has now been shown to occur in these materials). Table 4 lists the closest contacts with the three neighbouring halide ions. At the equilibrium position the geometry is most favourable for hydrogen bonding to all the protons and appreciable overlaps are already present. During the C_3' rotation the overlaps become much greater, first for one set of three protons and then the other three, but since these positions are not at the equilibrium position the interaction has presumably become more repulsive than attractive. The 3-fold arrangement of halide ions around the C_3' axis also means that the contributions to the total barrier from each individual halide ion add up constructively. The large barriers (particularly in the chloride and bromide) are then quite understandable.

In concluding, it is worth returning to the question of whether or not C_2 flips occur concurrently with the C_3' motion. One can advance some arguments against C_2 flips, based on observed and anticipated barriers. Note that the C_3' barrier depends *entirely* on interactions with atoms external to the guanidinium ion, and hence the large variations from one salt to another are easily rationalized. On the other hand, the barrier to C_2 flipping depends both on an internal and an external barrier. It was pointed out in the introduction that the internal barrier to C_2 flips should be at the very least 13 kcal/mol and probably significantly higher. This internal barrier should be similar in all salts and any difference from one salt to another would then be due to the additional external barrier. Clearly the activation energies observed in the I^-, ClO_4^-, and BF_4^- salts (this work and refs. 18, 23) are well below the minimum level anticipated for the internal barrier alone, for C_2 flips. This is perhaps the strongest argument against concurrent ($C_3' + C_2$) motions, at least for these salts. Further, one would not expect C_3' and C_2 motions to occur simultaneously in *all* the salts, especially when the observed range of barriers is so great and particularly when it would appear that the internal barrier dominates the C_2 flipping motion. A complete resolution of this question, however, must await further experimental evidence from a technique which is able to sufficiently distinguish the two motions.[2]

Kinetics of the reduction of nicotinonitrile cations by 1,4-dihydronicotinamides

JOHN W. BUNTING AND JOHN C. BREWER[1]
Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received September 20, 1984

JOHN W. BUNTING and JOHN C. BREWER. Can. J. Chem. **63**, 1245 (1985).

The rates of reduction of a series of 1-(Z-benzyl)nicotinonitrile cations by a series of 1-(X-benzyl)-1,4-dihydronicotinamides have been studied at 25°C in 20% CH_3CN – 80% H_2O (pH 7.0 (5 m*M* phosphate), ionic strength 1.0 (KCl)). Spectral studies indicate the formation of 1,4-dihydronicotinonitrile products, without the formation of the isomeric 1,2-dihydro- or 1,6-dihydro-nicotinamide intermediates. Second-order rate constants (k_2) for these reductions are closely correlated with the Hammett σ constants for X and Z. Thus, for X = H, $\log k_2 = 0.63\sigma_z - 1.05$, while for Z = 4-CN, $\log k_2 = -0.64\sigma_x - 0.65$. The close correspondence between these ρ_x and ρ_z values indicates that charge neutralization on the nicotinonitrile cation exactly balances charge generation on the nicotinamide cation product in the rate-determining transition state. Thus the migrating hydrogen species is electrically neutral in the rate-determining transition state, which contrasts with the hydridic transition states previously reported in the reduction of isoquinolinium cations by 1,4-dihydronicotinamides. When 1-benzyl-4,4-dideuterio-1,4-dihydronicotinamide is used as the reductant, primary kinetic isotope effects of 3.0 and 2.7 are observed for the reduction of the 1-methylnicotinonitrile and 1-(4-cyanobenzyl)-nicotinonitrile cations, respectively. These data are evaluated in terms of the various mechanistic possibilities for hydride transfer.

JOHN W. BUNTING et JOHN C. BREWER. Can. J. Chem. **63**, 1245 (1985).

Opérant à 25°C, dans des solutions à 20% CH_3CN – 80% H_2O, à un pH de 7,0 (5 m*M* de phosphate) et à une force ionique de 1,0 (KCl), on a déterminé les vitesses de réduction d'une série de cations (Z-benzyl)-1 nicotinonitrile par une série de (X-benzyl)-1 dihydro-1,4 nicotinamides. Des études spectrales indiquent qu'il y a formation de produits dihydro-1,4 nicotinonitrile, sans formation des intermédiaires isomères dihydro-1,2 ou dihydro-1,6 nicotinamides. Il existe une corrélation entre les constantes de vitesse du deuxième ordre (k_2) de ces réductions et les constantes σ de Hammett des substituants X et Z. Ainsi, pour X = H, $\log k_2 = 0,63\sigma_z - 1,05$, alors que pour Z = CN-4, $\log k_2 = -0,64\sigma_x - 0,65$. La bonne correspondance entre ces valeurs de ρ_x et de ρ_z indique que, dans l'état de transition déterminant la vitesse de la réaction, la neutralisation de la charge du cation nicotinonitrile contrebalance exactement la génération de la charge sur le produit cationique nicotinamide. Dans l'état de transition qui détermine la vitesse de la réaction, l'hydrogène qui migre est électriquement neutre et ceci est en opposition avec les états de transition impliqués dans les réductions par les hydrures dont il était fait mention dans les rapports antérieurs sur la réduction de cations isoquinolinium par les dihydro-1,4 nicotinamides. Lorsqu'on utilise la benzyl-1 dideutéro-4,4 dihydro-1,4 nicotinamide comme réducteur, on observe des effets isotopiques primaires de 3,0 et 2,7 respectivement pour les réductions des cations méthyl-1 nicotinonitrile et (cyano-4 benzyl)-1 nicotinonitrile. On évalue ces données en fonction des diverses possibilités mécanistiques pour le transfert d'hydrure.

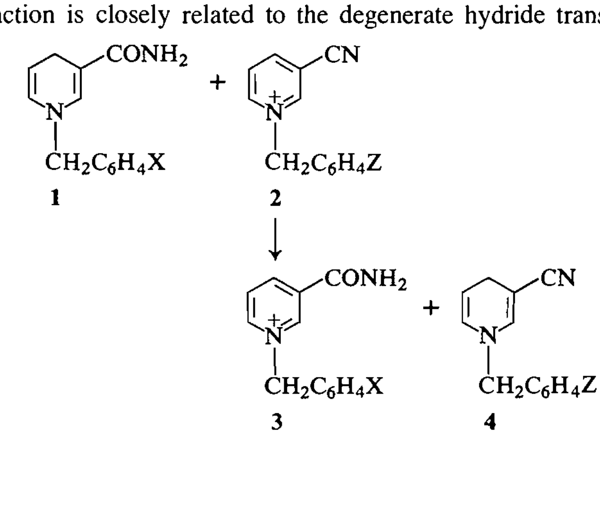
[Traduit par le journal]

We have recently reported kinetic studies of the reduction of a variety of quinolinium (1), isoquinolinium (2, 3), 3,4-dihydroisoquinolinium (4), and acridinium cations (5) by 1,4-dihydronicotinamides as part of our continuing investigation of the kinetics and mechanisms of hydride transfer in such reactions. For isoquinolinium and 3,4-dihydroisoquinolinium cations, the combination of substituent effects in the hydride donor and acceptor and deuterium primary kinetic isotope effects are only consistent with a direct one-step hydride transfer in which the migrating hydrogen bears a significant fractional negative charge and is thus clearly hydridic in character. Kinetic data for the reduction of quinolinium and acridinium cations (1, 5) are not easily rationalized in terms of one-step hydride transfer, and the possibility of one of the often considered one-electron reduction mechanisms ($e^- + H\cdot$ or $e^- + H^+ + e^-$) is thus indicated in these cases. This interpretation is supported by the enhanced rates of 1,4-dihydronicotinamide reduction that are found for quinolinium (at C-4) and acridinium cations relative to the analogous reaction for isoquinolinium cations. This rate enhancement is particularly dramatic in comparison with the rates of other nucleophilic attacks on these heteroaromatic cations (1, 5).

Van Eikeren *et al.* (6, 7) have studied the degenerate reaction between 1-benzyl-1,4-dihydronicotinamide and the 1-benzylnicotinamide cation and have concluded that this reaction is best rationalized in terms of an $e^- + H^+ + e^-$ mechanism for the formal hydride transfer. The reductions of quinolinium and acridinium cations by 1,4-dihydronicotinamides also differ from isoquinolinium cation reductions in generating 1,4-dihydropyridine derivatives rather than 1,2-dihydropyridines as reaction products. It therefore seems possible that one-electron mechanisms for hydride transfer predominate over direct hydride transfer for the formation of 1,4-dihydropyridines.

As a further test of this hypothesis we have now studied substituent effects in both the hydride donor and acceptor for the reduction of a series of 1-(Z-benzyl)nicotinonitrile cations by 1-(X-benzyl)-1,4-dihydronicotinamides (eq. [1]). This reaction is closely related to the degenerate hydride transfer

[1]



[1]Recipient of a 1983 NSERC Summer Bursary for undergraduate research.

studied by van Eikeren and Grier (6), but has the advantage of being somewhat faster because of the electronic effect of the cyano group, and also of easily allowing independent evaluation of substituent effects in the hydride donor and acceptor.

Experimental

1-(X-benzyl)-1,4-dihydronicotinamides and 1-benzyl-4,4-dideuterio-1,4-dihydronicotinamide were prepared and characterized as previously described (2).

1-(Z-benzyl)nicotinonitrile bromides

Nicotinonitrile (2 g) and the appropriately substituted benzyl bromide (in 20% stoichiometric excess) were refluxed in acetone (35 mL) for 10–16 h. The bromide salts precipitated from this solvent as fine white powders that were recrystallized from either ethanol or aqueous ethanol in the presence of a few drops of concentrated hydrobromic acid. These salts were characterized by ^{1}Hmr spectroscopy, and their purities determined to be 100 ± 2% by titration of the bromide ion by the Volhard method (8).

1-Methylnicotinonitrile bromide was prepared by stirring nicotinonitrile with methyl bromide in a pressure bottle at room temperature, and was similarly characterized.

Kinetic studies

All kinetic data were obtained spectrophotometrically on either Varian Cary 219 or Unicam SP-1800 instruments at 25°C. All reactions were studied in 20% acetonitrile – 80% water solutions buffered at pH 7.0 (5 m*M* phosphate) in the presence of 1 *M* potassium chloride. The decrease in absorbance due to the consumption of the dihydronicotinamide derivative (0.05–0.1 m*M*) was monitored at 380 nm in the presence of at least six different concentrations of each nicotinonitrile cation in the range 1.0–50 m*M*. Individual concentration ranges were determined by the solubility of the bromide salt and the reactivity of each cation. All reactions displayed absorbance changes that were strictly pseudo first order in the dihydronicotinamide over at least the first three reaction half-times. Rates of decomposition of the dihydronicotinamide derivatives were found to be insignificant under the current reaction conditions.

The equilibrium constant for the addition of cyanide ion to the 1-benzylnicotinonitrile cation was measured in aqueous solution at pH 11.0 (1 m*M* KOH) at 25°C in the presence of 1 *M* KCl, as previously described (9) for cyanide ion addition to nicotinamide cations. Potassium cyanide concentrations in the range 1.0–40 m*M* were employed.

Results

Reaction products

The time dependence of the electronic absorption spectrum of an equimolar mixture of 1-benzyl-1,4-dihydronicotinamide and the 1-benzylnicotinonitrile cation in 20% CH_3CN – 80% H_2O, ionic strength 1.0 at 25°C, is shown in Fig. 1. The shift to shorter wavelength of the long wavelength maximum during the course of this reaction is consistent with the formation of 1-benzyl-1,4-dihydronicotinonitrile, since 1,4-dihydronicotinonitriles are known to have absorption maxima at shorter wavelength than their 1,4-dihydronicotinamide analogs (10). The reaction product in Fig. 1 displays $\lambda_{max}(\epsilon)$ = 344 nm (6200 M^{-1} cm^{-1}) which is in agreement with 341 nm (5750 M^{-1} cm^{-1}) observed for a genuine sample of **4**:Z = H in neat acetonitrile solution (3).

The course of these reductions was also monitored by ^{1}Hmr spectroscopy. The overlapping of reactant and product signals is minimized in the reaction of 1-benzyl-1,4-dihydronicotinamide with the 1-methylnicotinonitrile cation. Changes in the ^{1}Hmr spectrum of an equimolar (0.1 *M*) solution of each of these species in 50% CD_3CN – 50% D_2O were monitored over a period of 4 h. All signals appearing in the spectra of this

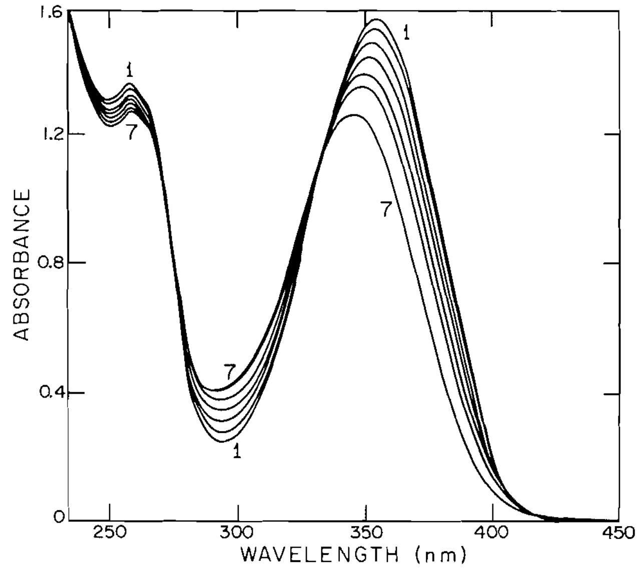


FIG. 1. Time dependence of the electronic absorption spectrum (1-mm path length) of a solution containing 1-benzyl-1,4-dihydronicotinamide (2.0 m*M*) and 1-benzylnicotinonitrile bromide (2.1 m*M*) in 20% CH_3CN – 80% H_2O at 25°C (pH 7.0, ionic strength 1.0). Curves 1–7 are recorded at reaction times of 0, 6, 16, 31, 56, 86, 240 min.

reaction in progress were readily attributable to signals from either these reactants or the products, 1-benzylnicotinamide cation and 1,4-dihydro-1-methylnicotinonitrile, by comparison with the spectra of genuine samples of each of these four species in this solvent system. There were no extraneous signals which might have been attributable to reaction intermediates. Signal integrations indicated no exchange with solvent deuterium during the course of this reaction. In particular, the multiplet centered at δ 3.00 ppm and attributable to the C-4 methylene group of the 1,4-dihydro-1-methylnicotinonitrile product integrates for two hydrogen atoms, and the signal for H-5 also has the appropriate multiplicity for coupling with two protons at C-4. It is thus clear that this formal hydride transfer reaction occurs without exchange of the migrating hydrogen atom with solvent deuterium.

Kinetic studies

Rates of all reactions were studied spectrophotometrically in the presence of limiting concentrations of the 1,4-dihydronicotinamide reductant and 10- to 400-fold excesses of the nicotinonitrile cations in 20% CH_3CN – 80% H_2O, ionic strength 1.0 at 25°C. Under these conditions, all reactions proved to be kinetically first order in reductant over greater than 90% reaction. Pseudo-first-order rate constants were evaluated, and found to be strictly proportional to nicotinonitrile cation concentration in each case. This allowed the evaluation of the second-order rate constants (k_2) reported in Table 1.

Rates of reduction of the 1-methylnicotinonitrile and 1-(4-cyanobenzyl)-nicotinonitrile cations by 1-benzyl-4,4-dideuterio-1,4-dihydronicotinamide were also measured (Table 1). These data allow the evaluation of the (predominantly) primary kinetic isotope effects of $k_2^H/k_2^D = 3.0 \pm 0.3$ and 2.7 ± 0.1 respectively.

The substituent effects on k_2 reported in Table 1 are closely correlated with the Hammett σ constants for the X and Z substituents. Thus, for the reaction of 1-benzyl-1,4-dihydronicotinamide with a series of 1-(Z-benzyl)nico-

[c]Data for 3-cyano-1-methylpyridinium cation.

tinonitrile cations, eq. [2] is obtained.

[2] $\log k_2 = 0.63(\pm 0.03)\sigma_z - 1.05(\pm 0.01)$ (corr. coeff. = 0.996)

For the reduction of the 1-(4-cyanobenzyl)nicotinonitrile cation by a series of 1-(X-benzyl)-1,4-dihydronicotinamides the correlation eq. [3] is obtained.

[3] $\log k_2 = -0.64(\pm 0.05)\sigma_x - 0.65(\pm 0.02)$ (corr. coeff. = 0.982)

We have also investigated the equilibrium between the 1-benzylnicotinonitrile cation and 1-benzyl-4-cyano-1,4-dihydronicotinonitrile in the presence of cyanide ion. We find a dissociation constant of $9.2(\pm 0.5) \times 10^{-4}$ M for this equilibrium in aqueous solution under the same conditions as previously used for evaluation of the analogous equilibrium for 1-benzylnicotinamide cations (9). The dissociation constant for 1-benzyl-4-cyano-1,4-dihydronicotinamide under these conditions is 0.41 M (9).

Discussion

The electronic and ^{1}Hmr spectral data reported above are both consistent with the 1,4-dihydronicotinonitriles being the predominant products of the reaction of these nicotinonitrile cations with 1-benzyl-1,4-dihydronicotinamides. We cannot of course rule out the presence of minor amounts (<5%) of the corresponding 1,2-dihydro- and 1,6-dihydro-nicotinonitriles in the products. This observation is consistent with previous studies which have indicated that 1,4-dihydronicotinamides cleanly transfer hydride to C-4 of other nicotinamide cations and 3-acetylpyridinium cations (6, 11–17). There seems to be just one report of the formation of a 1,6-dihydropyridine in a 1,4-dihydronicotinamide reduction of a C-3 substituted pyridinium cation; Minato *et al.* (18) have reported the establishment of a 4:1 equilibrium mixture of 1,4-dihydro-1-methylnicotinamide and its 1,6-dihydro isomer when the former isomer is treated with the 1-methylnicotinamide cation in D_2O at 34°C.

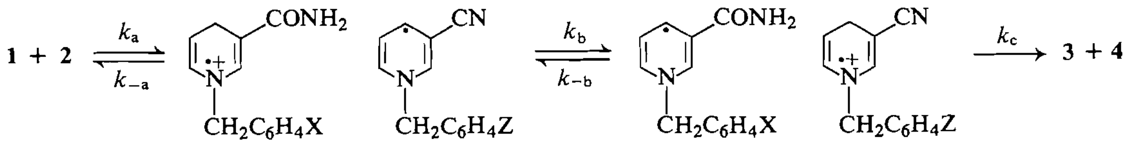
The clean isosbestic points observed in Fig. 1, and the lack of any extraneous signals in the ^{1}Hmr spectra indicate the absence of any significant concentration of intermediate species in these reactions. While this observation does not unconditionally rule out 1,2- or 1,6-dihydronicotinonitriles as intermediates in these reactions, it does put very stringent requirements on rates of reactions leading to, and from, such potential intermediates. Thus both their formation and also their subsequent reaction with a further nicotinonitrile cation would have to be much faster than the rate of the overall reaction to prevent the accumulation of significant concentrations of these species. These conditions are inconsistent with the observations of Minato *et al.* (18) mentioned above; the second-order rate constant for the equilibration of the 1,4-dihydro- and 1,6-dihydro-1-methylnicotinamides via reaction with the 1-methylnicotinamide cation is several orders of magnitude smaller than observed for the current reactions in Table 1. Furthermore, van Eikeren and Grier (6) report that the transfer of deuterium from 1-benzyl-4,4-dideuterio-1,4-dihydronicotinamide to C-4 of the 1-benzylnicotinamide cation occurs without any exchange at C-2 or C-6. We therefore feel that we can safely rule out the 1,2-dihydro and 1,6-dihydro isomers as intermediates in the formation of the 1,4-dihydronicotinonitriles in the current reaction.

The second-order rate constant for reaction of 1-benzyl-1,4-dihydronicotinamide with the 1-benzylnicotinonitrile cation (0.092 M^{-1} s^{-1} at 25°C (Table 1)) is at least 50-fold greater than the rate constant reported by van Eikeren and Grier (6) for the degenerate hydride transfer between 1-benzyl-1,4-dihydronicotinamide and the 1-benzylnicotinamide cation (0.002 M^{-1} s^{-1} in 25% CH_3CN – 75% H_2O at 40°C). This is consistent with the greater electrophilicity of the former cation than that of the latter; for instance the equilibrium constant for cyanide ion addition at C-4 is 450-fold larger for the 1-benzylnicotinonitrile cation than for the 1-benzylnicotinamide cation. The 5-fold greater rate of attack on the 1-benzylnicotinonitrile cation than on the corresponding 1-methyl cation (Table 1) is also consistent with the relative susceptibilities of N-methyl and N-benzyl heteroaromatic cations to nucleophilic attack.

Reduction of the 1-methylnicotinonitrile cation (k_2 = 0.018 M^{-1} s^{-1} (Table 1)) by 1-benzyl-1,4-dihydronicotinamide occurs much more slowly than for the 1-methyl-3-cyanoquinolinium cation (121 M^{-1} s^{-1} (1) under the current experimental conditions). We have also shown (1) that the second-order rate constants for reduction of 1-methylquinolinium cations at C-4 are correlated with the pK_{R^+} values for these cations by eq. [4].

[4] $\log k_2 = -0.54\ pK_{R^+} + 7.3$

The direct estimation of pK_{R^+} for pseudobase formation by nicotinonitrile cations is difficult since these cations readily undergo a variety of decomposition reactions in aqueous base (19–21). However, we can estimate pK_{R^+} for pseudobase formation at C-4 of the 1-methylnicotinonitrile cation to be approximately 12.8 from the known pK_{R^+} of 13.3 for the 3-acetyl-1-methylpyridinium cation (22) and the relative affinities of these two cations for cyanide ion addition at C-4. Use of pK_{R^+} = 12.8 in eq. [4] then allows a prediction of k_2 = 2 M^{-1} s^{-1}, which is 100-fold larger than the value actually observed. Thus the linear free energy relationship established for quinolinium cations does not seem to be applicable to the



SCHEME 1

dihydronicotinamide reduction of pyridinium cations. It is not clear at present whether this result is due to inherent differences in the reactivities of pyridinium and quinolinium cations or, alternatively, to differences in the mechanisms of reduction for these two series of heterocyclic cations.

A further difference between the 1,4-dihydronicotinamide reductions of pyridinium and quinolinium cations can be found in the primary deuterium kinetic isotope effects for these reactions. The relationship in eq. [5] has been established (1) for the C-4 reduction of quinolinium cations by 1-benzyl-1,4-dihydronicotinamide and its 4,4-dideuterio derivative.

$$[5] \quad \ln (k_2^{H}/k_2^{D}) = 1.66\,(1 - ((pK_{R^+} - 14.6)/8.4)^2)$$

Application of this relationship to the reduction of the 1-methylnicotinonitrile cation ($pK_{R^+} = 12.8$ estimated above) and the 1-(4-cyanobenzyl)nicotinonitrile cation (estimated $pK_{R^+} = 11.2$) gives $k_2^{H}/k_2^{D} = 4.9$ and 4.0, respectively. These estimates are somewhat larger than the experimental values of 3.0 and 2.7. These experimental isotope effects are also much smaller than found for the 1-benzyl-1,4-dihydronicotinamide reduction of the 2-benzyl-5-nitroisoquinolinium cation ($k_2^{H}/k_2^{D} = 6.6$ (2)) which has $pK_{R^+} = 11.3$ (23) and is reduced at a similar rate ($k_2 = 0.4\ M^{-1}\ s^{-1}$ (2)) to the 1-(4-cyanobenzyl)nicotinonitrile cation ($k_2 = 0.246\ M^{-1}\ s^{-1}$ (Table 1)).

Comparison of the Hammett ρ values in eqs. [2] and [3] with the equilibrium ρ = 0.95 for unit positive charge neutralization in nicotinamide cations (9) indicates that positive charge development is about 65% complete on the nicotinamide moiety in the rate-determining transition state, and that charge neutralization is also about 65% complete on the nicotinonitrile moiety in this transition state.[2] This exact balance between charge creation and neutralization on the hydride donor and acceptor respectively is quite different from the situation found in analogous studies of the 1,4-dihydronicotinamide reductions of 5-nitroisoquinolinium (2) and 3,4-dihydroisoquinolinium cations (4). In these cases, positive charge development on the hydride donor "gets ahead" of charge neutralization on the hydride acceptor, and results in a fractional negative charge (0.3–0.4 unit charge) being borne by the migrating hydrogen atom in the transition state. The similarity of the two ρ values in eqs. [2] and [3] indicates that the migrating hydrogen atom must be essentially electrically neutral in the transition state for the reaction in the current study.

The mechanism of the degenerate transhydrogenation between 1-benzyl-1,4-dihydronicotinamide and the 1-benzylnicotinamide cation has been interpreted by van Eikeren *et al.* (6, 7) as involving successive electron, proton, and electron transfer steps, with the proton transfer being rate determining as indicated by the primary deuterium kinetic isotope effect of 6.2. The current data for the reduction of nicotinonitrile cations can be accommodated by such a mechanism provided that neither the initial electron transfer, nor the proton transfer, are clearly rate determining, and provided the migrating proton is not assigned any electron deficiency (i.e. no fractional positive charge). Such a mechanism is outlined in Scheme 1, and in simplified form in eq. [6], where A and B represent the appropriate radical – radical cation caged species and it is assumed that the k_c step is essentially irreversible.

$$[6] \quad \mathbf{1} + \mathbf{2} \underset{k_{-a}}{\overset{k_a}{\rightleftharpoons}} A \underset{k_{-b}}{\overset{k_b}{\rightleftharpoons}} B \xrightarrow{k_c} \mathbf{3} + \mathbf{4}$$

Assuming steady-state concentrations of A and B in eq. [6], one derives an overall second-order rate constant:

$$[7] \quad k_2 = \frac{k_a k_b k_c}{k_{-a}(k_{-b} + k_c) + k_b k_c}$$

Clearly, neither k_a nor k_c can be cleanly rate determining, since either of these conditions would require k_2^{H}/k_2^{D} close to unity. On the other hand, if k_b were cleanly rate determining the initial electron transfer would be a rapid pre-equilibrium, and the Hammett ρ values would be expected to reflect complete unit charge generation and neutralization in the hydride donor and acceptor respectively, and also k_2^{H}/k_2^{D} would be expected to be larger than is observed.

The small isotope effects upon k_a, k_{-a}, and k_c may be neglected, and the general expression for k_2^{H}/k_2^{D} then becomes

$$[8] \quad k_2^{H}/k_2^{D} = \frac{k_{-a}k_b^{H}(k_{-b}^{D} + k_c) + k_b^{H}k_b^{D}k_c}{k_{-a}k_b^{D}(k_{-b}^{H} + k_c) + k_b^{H}k_b^{D}k_c}$$

and for the condition $k_c \gg k_{-b}$, this further simplifies to

$$[9] \quad k_2^{H}/k_2^{D} = \frac{k_b^{H}(k_{-a} + k_b^{D})}{k_b^{D}(k_{-a} + k_b^{H})}$$

Equations [8] and [9] both predict experimentally observed isotope effects less than the true isotope effect (k_b^{H}/k_b^{D}) for the proton transfer step.

The alternative mechanism of electron followed by hydrogen atom transfer (eq. [10]) leads to eq. [11] for k_2, and also predicts eq. [9] for k_2^{H}/k_2^{D}.

$$[10] \quad \mathbf{1} + \mathbf{2} \underset{k_{-a}}{\overset{k_a}{\rightleftharpoons}} A \xrightarrow{k_b} \mathbf{3} + \mathbf{4}$$

$$[11] \quad k_2 = \frac{k_a k_b}{k_{-a} + k_b}$$

For this case, also, k_2^{H}/k_2^{D} is too large to allow k_a to be cleanly rate determining. Again, a cleanly rate-determining k_b would be inconsistent with the observed magnitude of the ρ values.

We have a situation then in which the mechanisms of eqs. [6] and [10] cannot be readily distinguished via substituent effects and isotope effects if more than one rate constant contributes significantly to the observed k_2. The $e^- + H^+ + e^-$ process of eq. [6] has the precedent of the related transhydrogenation between nicotinamide species studied by van Eikeren and Grier (6). On the other hand, the $e^- + H^{\bullet}$ process of eq. [10] is particularly attractive in the light of the requirement for an

[2]The assumptions inherent in the conversion of Hammett ρ values to fractional charges have been detailed previously (2).

electrically neutral migrating hydrogen species in the rate-determining transition state. This latter mechanism has also been proposed as a rationalization of the substituent effects and isotope effects found in the reduction of acridinium cations by 1,4-dihydronicotinamides in aqueous solutions (5).

Additionally, we cannot unambiguously rule out a direct one-step hydride transfer mechanism for these nicotinonitrile cation reductions at the present time, although the measured primary isotope effects in these reactions are somewhat less than the range found for analogous reactions which are believed to be genuine one-step hydride transfer processes (15, 24, 25). We note that k_2 for C-4 reduction of nicotinonitrile cations is of the order predicted from the linear free energy relationship (eq. [12]) established (3) for reduction of isoquinolinium cations by 1-benzyl-1,4-dihydronicotinamide. Such isoquinolinium cation reductions have been established to occur via direct one-step hydride transfers.

$$[12] \quad \log k_2 = -0.5\ \mathrm{p}K_{\mathrm{R}^+} + 4.9$$

However, the current linear free energy relationships (eqs. [2] and [3]) indicate that, unlike isoquinolinium cation reductions, the migrating hydrogen species in nicotinonitrile cation reductions does not bear any significant excess negative charge in the transition state.

^{13}C nuclear magnetic resonance studies. 114.[1] An examination of the [3.3.1.0] → [4.3.0.0] rearrangement via β-enolization and H/D exchange in tricyclic ketones

ARTHUR J. RAGAUSKAS AND J. B. STOTHERS
Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received October 15, 1984

ARTHUR J. RAGAUSKAS and J. B. STOTHERS. Can. J. Chem. **63**, 1250 (1985).

The behavior of the *exo* and *endo* isomers of 7,7-dimethyltricyclo[3.3.1.0^{2,4}]nonan-6-one (**5**, **6**) under strongly basic conditions (t-BuO$^-$/t-BuOH/185°C) has been examined. In sharp contrast to their [3.2.1.0^{2,4}] analogs, the *endo* isomer is stable while the *exo* readily rearranges to 8,8-dimethyltricyclo-[4.3.0.0^{2,4}]nonan-7-one (**16**). Experiments were carried out in *tert*-butyl alcohol-O-d_1 to establish the sites of deuterium incorporation in the initial ketones as well as the relative rates and stereoselectivities of the exchange processes. Ketones **5** and **6** were prepared through ring expansion by ketonization of cyclopropoxides generated from the [3.2.1.0] homologs; the stereochemistry of these ketonizations was established by ^{2}H labelling.

ARTHUR J. RAGAUSKAS et J. B. STOTHERS. Can. J. Chem. **63**, 1250 (1985).

On a étudié le comportement des isomères *exo* et *endo* (**5** et **6**) de la diméthyl-7,7 tricyclo[3.3.1.0^{2,4}]nonanone-6 dans des conditions fortement basiques (t-BuO$^-$/t-BuOH/185°C). Par opposition au comportement de leurs analogues [3.2.1.0^{2,4}], l'isomère *endo* est stable alors que le produit *exo* se transpose facilement en diméthyl-8,8 tricyclo[4.3.0.0^{2,4}]nonanone-7 (**16**). On a réalisé des expériences dans le *tert*-butanol-O-d_1 afin de déterminer les sites d'incorporation du deutérium dans les cétones initiales ainsi que les vitesses relatives et les stéréosélectivités des processus d'échanges. On a préparé les cétones **5** et **6** grâce à une extension de cycle par le biais d'une cétonisation de cyclopropoxydes générés à partir des analogues [3.2.1.0]; on a déterminé la stéréochimie de ces cétonisations grâce à des marquages au ^{2}H.

[Traduit par le journal]

Introduction

Since the discovery of homoenolization (1), several examples for both acyclic and polycyclic monoketones have been found in which proton abstraction occurs from centres other than the α-carbons in ketones under strongly basic conditions (2). For most of these systems, proton abstraction from β-carbons, or β-enolization, has been observed, but there are a few examples of γ-enolization. The removal of a remote proton can lead to skeletal rearrangement and (or) deuterium exchange, if the reaction is carried out in a deuterated medium. The factors governing the regioselectivity and relative reactivity of such proton abstractions are of considerable interest since, in principle, the rearrangements (isomerizations) can provide a means of generating carbon skeletons which are not readily accessible through other routes. Some examples of the use of β-enolization in the syntheses of some naturally occurring carbon skeletons from more readily available systems have been described (3–5). With a better understanding of both the regioselectivity and stereoselectivity of β- and γ-enolization the scope of their synthetic applications could be enhanced.

Earlier, we reported the unidirectional conversion of 3,3-dimethylbicyclo[3.2.1]octan-2-one (**1**) to the isomeric [3.3.0] system **2** (6) and of 7,7-dimethyl-*endo*-tricyclo[3.2.1.0^{2,4}]-octan-6-one (**3**) to 4,4-dimethyltricyclo[3.3.0.0^{2,8}]octan-3-one (**4**) (7) as examples of β- and γ-enolization, respectively. To examine the question of relative reactivity in a closely related system, we elected to study the behavior of the 7,7-dimethyltricyclo[3.3.1.0^{2,4}]nonan-6-ones, under typical homoenolization conditions, t-BuO$^-$/t-BuOH at 185°C. By analogy with **1** and **3**, one could envisage proton abstraction to occur from C-3 and C-9 in the *endo* isomer **5**, constituting an intramolecular competition between γ- and β-enolization, respectively, while a comparison of the behavior of the *exo* isomer **6** with that of the *exo* counterpart of **3** was of interest because of the some-

6

what surprising H/D exchange results found for the latter (7). For this reason, the sites and stereoselectivity of proton abstraction in **5** and **6** were established by the requisite H/D exchange experiments. The results of these experiments with **5** and **6** are described in this paper.

Results and discussion

Syntheses

The preparation of **5** and **6** was accomplished by ring expansion of the lower homologs in the [3.2.1.0^{2,4}] series through cyclopropanation of the enol ethers followed by base-catalyzed ketonization of the corresponding cyclopropoxides, as illustrated by **7a** → **10** for the *exo* series, and α,α-dimethylation of the resulting ketones. The ^{13}Cmr data for each of the intermediates in this sequence for the *exo* and *endo* series are listed in Table 1. Some stereochemical features of the conversion of **8** → **10** merit comment.

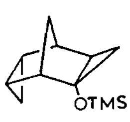
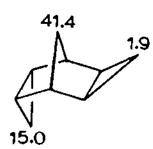
c R = R' = Me

Since finding that this sequence provides an efficient means of ring expansion for a variety of polycyclic ketones (8), we have accumulated more than two dozen examples (3, 5, 9) and in each case a single cyclopropanation product was obtained. The stereochemical assignment for **9** followed from its ^{13}Cmr spectrum, which contained three methylene signals at δ_C 6.3, 15.4, and 18.1 which were assigned to C-3, -7, and -9, respectively.[2] The high field positions of these absorptions is only consistent with cyclopropanation at the *exo* face of **8** since an *endo* cyclopropyl ring in these systems tends to deshield C-9 substantially (10) such that its absorption would be expected to be near δ_C 40. For the corresponding cyclopropanation product **11** in the *endo* series leading to **5**, the three methylene carbons



11



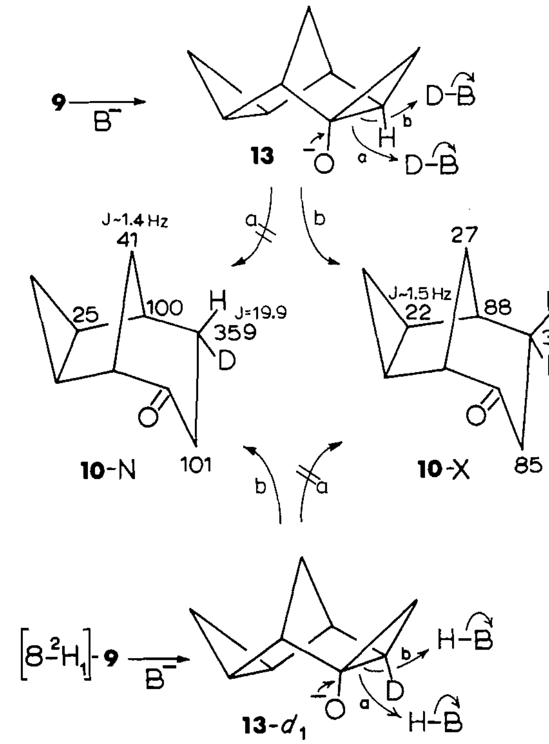
12

absorb at 10.0, 19.0, and 45.5 (C-3, -7, and -9, respectively[2]); these shieldings agree reasonably with the methylene data for **12** (10) after allowance for the presence of the *endo* oxygen in **11**. Hence we conclude that *exo* cyclopropanation also occurs in the *endo* series.

Upon cleavage of the trimethylsilyl ethers with base, the resulting cyclopropoxides can ketonize in two ways, either to produce the α-methyl derivative of the initial ketone or to undergo ring expansion to the homologous ketone. We could anticipate that the cleavage of **9** would favor ring expansion to **10** rather than generation of **7***b*, on the basis of earlier results in related systems (8). In the event, treatment of both **9** and **11** with NaOH–MeOH at 0°C furnished single ketones having no methyl absorption in their ^{1}H and ^{13}Cmr spectra. Although cleavage of the corresponding cyclopropyl TMS ether from norcamphor leads predominantly to ring expansion, the product contains 12% of 3-methylnorcamphor. Presumably the fact that **10** and its *endo* counterpart are less strained than **7***b* and its *endo* isomer governs the course of the ketonization of **9** and **11**, since it has been demonstrated that the process is subject to thermodynamic control (2, 11).

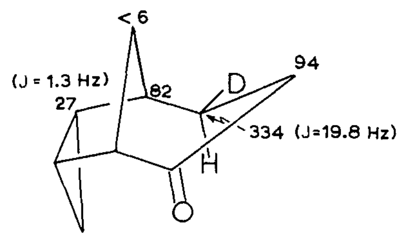
The opening of the cyclopropoxide anion **13**, generated by base-catalysed cleavage of TMS ether **9**, can proceed in either of two ways, i.e. with retention or inversion of configuration. These are shown as a and b in Scheme 1, to illustrate that the stereochemistry of the process can be determined by cleavage in a deuterated medium. While, in general, ketonizations of cyclopropoxides in polycyclic systems have been found to undergo inversion of configuration, there are some strained systems which exhibit retention (2). Thus it was of interest to establish the point in the present cases. To distinguish between paths a and b, **9** was cleaved in KOD/*t*-BuOD and the product treated with KOH/MeOH to back-exchange the α-deuterium picked up by exchange after the cleavage. The ^{13}Cmr spectrum of a 1:1 mixture of the **10**-d_1 obtained in this manner and **10** was recorded to determine the stereochemistry of the deuterium atom at C-8 in the latter material, since the magnitude of vicinal $^2H-^{13}C$ coupling interactions and the ^{2}H-induced isotope shifts depends on the relative orientation of the two nuclei (12). From this spectrum *exo*-deuterium incorporation was revealed; the observed isotope effects on the ^{13}C shieldings in ppb and the resolved couplings are shown in **10**-X. A key feature is the fact that vicinal $^{13}C-^2H$ coupling was readily apparent for the cyclopropyl methine carbon (C-2) with J = 1.5 Hz, while the C-9 signal was only slightly broadened; this is consistent with

[2]For ease of comparison of the shielding data listed in Table 1, the unconventional numbering scheme shown in **9** has been employed for **9** and **11**.



SCHEME 1

deuterium antiperiplanar to C-2 and, therefore, in the *exo*-orientation. To confirm this assignment, a sample of [7,7-$^2H_2$]-**7**a was converted to [8-$^2H_1$]-**9** which was subsequently opened with NaOH/MeOH to form **10**-d_1. The ^{13}Cmr spectrum of a 1:1 mixture of this material and **10** revealed the ^{2}H effects shown for **10**-N (Scheme 1). In this case, C-9 exhibited vicinal coupling of 1.4 Hz while the C-2 signal was only broadened by the deuterium, indicating that C-9 and the deuterium atom are antiperiplanar. These results establish that the cleavage of **13** proceeds with inversion. Treatment of **11** with KOD/t-BuOD followed by back-exchange with KOH/MeOH gave **14**-d_1 for which the ^{2}H effects in its ^{13}Cmr spectrum are shown. These constitute good evidence for the presence of *exo*-deuterium at C-8 and, hence, for inversion of configuration upon homoketonization of the cyclopropoxide generated from **11**.



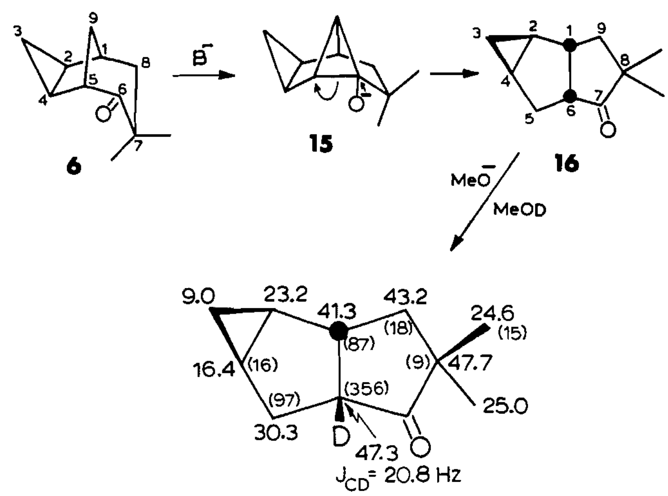
14-d_1

For **10**-X and **14**-d_1 it may be noted that the ^{2}H-induced shifts as well as the $^2H-^{13}C$ vicinal coupling with C-2 differ, presumably reflecting conformational differences in the two ring systems. In **14**, the *endo* disposition of C-3 will preclude a chair conformation for the six-membered ring which is probably the favored arrangement for **10** and in which the dihedral angle relating an *exo*-8-deuterium and C-2 is ~180°. In contrast, for a boat-like conformation of the six-membered ring, as is likely for **14**-d_1, this dihedral angle will be reduced to ~120°.

Homoenolization experiments

The behavior of **5** under homoenolization conditions was examined initially following our usual procedures (13); **5** was dissolved in anhydrous t-BuO$^-$/t-BuOH and aliquots were transferred to predried glass tubes under nitrogen, which were sealed and heated at ≥180°C for varying periods of time. The neutral product (~80% yields) was isolated and analyzed by gas–liquid chromatography (glc). In each case, the starting material was recovered unchanged and there was no indication of the formation of isomeric material in the neutral fraction even after >200 h at 185°C.

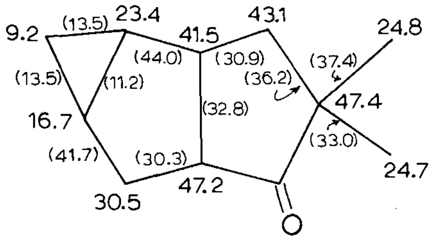
In contrast, under the same conditions and with the same batch of t-BuO$^-$/t-BuOH employed for some of the experiments with **5**, the *exo*-tricyclic ketone **6** was smoothly transformed to a new isomeric ketone which contained a cyclopentanone moiety on the basis of its carbonyl absorption data (1730 cm^{-1}, δ_C 223.9). The half-life for the disappearance of **6** and the appearance of the new ketone was found to be ca. 75 h at 180°C. The ^{13}C spectrum of the product contained ten



16-d_1

signals in addition to the carbonyl peak, δ_C ($CDCl_3$): 24.6, 25.0 (2 × CH_3), 9.0, 30.3, 43.2 (3 × CH_2), 16.4, 23.2, 41.3, 47.3 (4 × CH), and 47.7 (quat. C). From these data the ketone could be tentatively assigned structure **16** which could arise by proton abstraction from C-9 of **6** to generate β-enolate **15**, or its equivalent, subsequently opening with protonation at the original C-5 site. This rearrangement is constrained to give the *cis*, *anti*, *cis*-tricyclo[4.3.0.0^{2,4}]nonane skeleton.

To confirm this structure and the initial ^{13}Cmr signal assignments, a sample of the ketone was treated with MeONa/MeOD under mild conditions. Mass spectrometry indicated that exchange occurred at a single site (99.5% d_1) and in the ^{13}C spectrum of the recovered material the δ 47.3 α-methine signal was transformed to a 1:1:1 triplet, J_{CD} = 20.8 Hz, shifted upfield by 356 ppb. Precise isotope shifts for the signals of the neighboring carbons were obtained from the spectrum of a 1:1 mixture of **16** and **16**-d_1; these data are shown in the formula with the isotope shifts (in ppb) given in parentheses; these are entirely consistent with expectations for the assigned structure. As a final confirmation of structure **16**, the individual coupling constants for the sp^3 carbons in the skeleton were determined from its INADEQUATE spectrum (14); these results are sum-

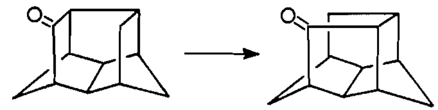


16A

marized in **16A** with the J values in parentheses. Since these spectra were run in C_6D_6 the shieldings differ slightly from those given with **16**-d_1 in $CDCl_3$.

The ^1H spectrum of **16** contained eight one-proton multiplets, one two-proton pattern, and two methyl singlets, δ 1.097 and 1.013. The cyclopropyl methylene protons appeared at highest field, δ 0.015 (*syn*-3-H, d(t), J = 5.1, 3.9 Hz) and 0.460 (*anti*-3-H, d(t), J = 5.1, 7.9 Hz), while the cyclopropyl methine protons gave rise to a complex multiplet, δ 1.24–1.38. The lowest field multiplet, δ 2.73 (d(t), J = 7.4, 11.2 Hz), was assigned to H-1 with a somewhat broadened pattern, δ 2.404 (ddd, J = 7.4, 9.2, 10.0 Hz), arising from H-6. A clear doublet of doublets, δ 2.156 (J = 10.0, 13.0 Hz), and an ill-defined 8-line pattern, δ 1.720, were assigned to the 5-protons while a clean multiplet, δ 1.995 (ddd, J = 1.6, 7.4, 12.8 Hz), and a somewhat broadened doublet of doublets, δ 1.492 (J = 11.2, 12.8 Hz), could be ascribed to the 9-protons. These ^1H assignments were confirmed by a $^{13}C(^1H)$ two-dimensional heteronuclear correlation experiment.

The stability of **5** under these strongly basic conditions stands in direct contrast to the behavior of **1** and **3**, which are smoothly transformed to **2** and **4**, respectively, upon treatment with t-BuO$^-$/t-BuOH at elevated temperatures (6, 7). Our original notion that **5** could conceivably provide an intramolecular competition for β- and γ-enolization was clearly incorrect and more subtle factors must play a role in governing isomerization via homoenolization. By analogy with **1**, in which proton abstraction from C-8 leads to rearrangement to form **2**, we anticipated that abstraction from C-9 in **5** would give the corresponding rearrangement product, while proton abstraction from C-3 could provide the [4.3.0.0] homolog of **4**, but there is no evidence of formation of isomeric material. On the other hand, **6** is smoothly converted to **16**, a rearrangement which is strictly analogous to the **1** → **2** conversion and which must involve proton abstraction from C-9 in **6**, as noted above, to form **15** with subsequent opening to **16**. The difference in behavior of **5** and **6** suggests that the relative orientation of the carbonyl group and C-9 must be highly important. While the six-membered ring in **6** can adopt a chair conformation, this arrangement is precluded for **5** because the *endo*-orientation of C-3 and its six-membered ring presumably assumes a boat-like conformation. An inspection of molecular models indicates that the dihedral angle between C-9 and the carbonyl oxygen increases from ca. 120° to ca. 170° with the chair-to-boat change for the six-membered ring in **6** and **5**, respectively. This change tips the π-system of the carbonyl group away from C-9, thereby rendering potential overlap with a developing carbanionic centre at C-9 less likely. It seems reasonable to suggest that this difference in the relative orientation of the carbonyl group and the methano bridge carbon in **5** and **6** may account for the marked change in reactivity. Some experiments to test this suggestion are in progress. The reluctance of **5** to rearrange via γ-enolization at C-3, in a manner analogous to that found for **3**, is more difficult to interpret. A comparison of the orientation of the carbonyl group with respect to C-3 in **3** and **5** indicates little difference except that the separation between the carbonyl carbon and C-3 is ca. 10% greater in **5**. It may be noted that, from Dreiding models, the distance between C-9 and the carbonyl carbon in **6** is comparable to that between C-3 and the carbonyl carbon in **3**, both of which isomerize under the reaction conditions. It may be relevant that there is a similar separation between the carbonyl carbon and the methylene carbon involved in the γ-enolate rearrangement of half-cage ketone **17** to **18**, which was the first example of this



17 **18**

phenomenon (15). At the present time, we lack an alternative rationalization for the failure of **5** to undergo γ-enolate rearrangement and can only suggest that the separation between the carbonyl group and C-3 exceeds some critical value required for effective interaction of the carbonyl group with an incipient carbanionic centre. To gain further insight into the behavior of **5** and **6** under our reaction conditions, the results of H/D exchange experiments were also examined.

H/D exchange experiments

Although ketone **5** was found to be stable under strongly basic conditions, this does not preclude the occurrence of H/D exchange and, thus, it was of interest to examine samples after treatment with t-BuO$^-$/t-BuOD at 185°C for various times. After 88 h, recovered **5**-d_x was found to contain 3.96 atoms ^2H/molecule by mass spectrometry and ^{2}Hmr revealed five sites of incorporation; the relative amounts for each were determined by integration. The ^{2}Hmr signals and ^2H content were found to be δ 0.42 (0.64), 0.60 (0.16), 0.93 (1.66), 1.52 (0.75), 2.77 (0.75). The ^{1}Hmr spectrum of **5** contained methyl singlets at δ 0.930 and 1.060 which correlate with the ^{13}C methyl signals at δ_C 19.2 and 11.2, respectively, and can be assigned to the *exo*- and *endo*-methyl groups, respectively. Thus, **5** undergoes exchange at the *exo*-methyl site preferentially, as expected by analogy with several related systems. In addition, the bridgehead protons H-1 and -5 gave rise to multiplets at δ 2.405 and 2.765, respectively, while the methano bridge protons at C-9 appeared at δ 1.767 and 1.858, J_{AB} = 11.5 Hz. The 3-methylene protons absorb at δ 0.416 and 0.603, J_{AB} = 6.3 Hz, with the higher field component exhibiting additional couplings of 8.1 Hz to two protons and 1.8 Hz to one other proton; the lower field component contained a coupling of 3.6 Hz to two other protons. The higher field absorption, δ 0.416, therefore, was assigned to the *exo*-3-proton since it is well-established that $J_{cis} > J_{trans}$ for vicinal coupling in cyclopropyl rings (16); the small 1.8-Hz coupling was subsequently shown to involve the H-9 absorption at δ 1.858, by spin decoupling, thus identifying the latter as the *syn* proton. A somewhat broadened doublet, δ 1.102, J = 14.5 Hz, and a doublet of doublets, δ 1.418, J = 7.5 and 14.5 Hz, could be readily ascribed to the *endo*- and *exo*-protons on C-8, while the remaining absorptions, a pair of multiplets at δ 1.403 and 1.518, arise from H-2 and -4, respectively. From these data, it was concluded that deuterium exchange occurred at C-3, -4, -5, and the *exo*-methyl sites in **5**.

Confirmation for these sites of exchange was obtained by examination of the ^{13}C spectra of the **5**-d_x samples. Characteristic triplets, centred upfield from the normal **5** signals, arising by one-bond $^{13}C-^{2}H$ coupling were apparent for the bridgehead C-5 (J_{CD} = 19.6 Hz, isotope shift (Δ) = 398 ppb), the cyclopropyl methine C-4 (J_{CD} = 26.5 Hz, Δ = 404 ppb), the C-3 methylene (J_{CD} = 24.2 Hz, Δ = 292 ppb), and the *exo*-methyl carbon (J_{CD} = 19.5 Hz, Δ = 287 ppb), while the remaining absorptions exhibited the effects typical of deuterium substitution at neighboring carbons. Precise measurements of the ^{2}H-induced shifts for each of the patterns were accomplished by examination of the spectra of 1 : 1 mixtures of **5** and **5**-d_x. The *exo*-methyl absorption consisted of the original singlet at δ_C 34.0 and a pair of triplets, the signals of which were separated by 17 ppb. This small shift is attributable to the long range effect of deuterium at C-5. The *endo*-methyl absorption contained singlets for species containing deuterium at C-5 and at the *exo*-methyl carbon, with isotope shifts of 24 and 30 ppb, respectively. The quaternary C-7 pattern also consisted of three singlets because of isotope shifts in the corresponding deuterated species; these effects are 29 (C-5) and 64 (*exo*-Me) ppb. Similarly, the 8-methylene carbon pattern contained components exhibiting isotope shifts of 24 and 30 ppb while the C-1 pattern appeared to contain similar components but was too ill-resolved to permit precise measurements, presumably because of small isotope shifts and weak $^{13}C-^{2}H$ coupling in the various deuterated species. The absorption for C-2 contained three isotope-shifted components ascribable to species having deuterium at C-3 (114 ppb), at C-4 (84 ppb), and at both C-3 and -4. A similar pattern was found for C-9 because of deuterium at C-5 (68 ppb) and at C-4 (21 ppb). The isotope shifts in ppb for the remaining centres were found to be: C-3, 121 (C-4), 23 (C-5); C-4, 76 (C-3), 82 (C-5); C-5, 86 (C-4), 23 (C-3). These ^{13}C data establish the presence of deuterium at C-3, -4, -5, and the *exo*-methyl carbon, while the ^{2}Hmr spectrum showed that both methylene protons on C-3 undergo exchange, albeit at distinctly different rates. From results for a series of samples of **5**-d_x, recovered after treatment with *t*-BuO$^-$/*t*-BuOD at 195°C for 3, 6, 12, and 19 h, the relative proportions of deuterium at the various sites of exchange were determined; these data aided the determination of the specific isotope shifts noted above and permitted the extraction of approximate first-order rate constants for the exchange processes which are considered later.

To determine the regio- and stereoselectivity of proton abstraction in **6** under these homoenolization conditions, a series of experiments in deuterated base was carried out. Samples of **6**-d_x were isolated from the resulting mixtures with **16** by preparative glc after reaction times of 10, 20, and 40 h at 185°C in *t*-BuO$^-$/*t*-BuOD. The 40-h sample contained 1.84 atoms ^{2}H/molecule by mass spectrometry and its ^{2}Hmr spectrum revealed six sites of deuterium incorporation for which the relative amounts were measured by integration. These absorptions and the ^{2}H content were found at δ 0.13 (0.38), 0.28 (0.055), 0.87 (0.18), 0.93 (0.22), 1.14 (0.11), and 2.66 (0.89). The ^{1}Hmr spectrum of **6** exhibited methyl singlets at δ 1.142 and 1.111, which were found to correlate with the ^{13}C methyl signals at δ 31.7 and 30.4 and could be assigned to the *exo*- and *endo*-methyl groups, respectively, since deuterium exchange occurred exclusively at the former site. The bridgehead protons in **6** absorbed at δ 2.665 (d, J = 4.4 Hz, H-5) and 1.925 (m, H-1) while an AB pattern, each component of which contained

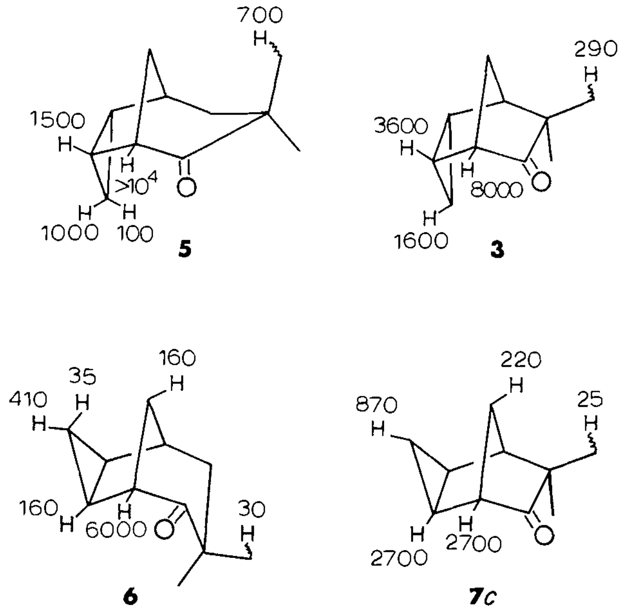


FIG. 1. Deuterium exchange rates ($k \times 10^8$ s^{-1}) at the various sites in **3**, **5**, **6** and **7***c* by β- and γ-enolization at 185°C in *t*-BuO$^-$/*t*-BuOD.

additional couplings, was readily ascribed to the 8-methylene protons: δ 1.341 (J = 4.1, 14.0 Hz) and 1.480 (J = 2.0, 2.8, 14.0 Hz); the latter pattern correlated with the methylene carbon signal at δ_C 45.2. A second AB pattern, each component of which appeared as a triplet, could be assigned to the 3-methylene protons: δ 0.133 (J = 5.4, 7.7 Hz) and 0.278 (J = 3.6, 5.4 Hz), and was found to correlate with the methylene carbon signal at δ_C 6.6. The larger vicinal couplings for the higher field pattern show it to be due to the proton *cis* to the cyclopropyl methine protons, H-2 and -4. A third AB pattern, which correlated with the methylene carbon at δ_C 26.0, was discernible for the 9-methylene protons; the higher field portion, δ 0.873, was a doublet, J = 12.5 Hz, broadened by small, unresolved couplings, while the lower field portion, δ 0.995, was partially masked by one of the two remaining multiplets, δ 0.79 and 0.93. The latter were assigned to H-2 and -4, and were found to correlate with the methine carbon signals at δ_C 18.8 and 17.0, respectively. An inspection of molecular models indicated that the dihedral angles between the *syn*-9-proton and the 1- and 5-bridgehead protons are ~90°. Hence the slightly broadened doublet at δ 0.873 could be assigned to *syn*-H-9. From these data we deduce that deuterium exchange occurred at C-3, -4, -5, -9, and the *exo*-methyl carbon. For further confirmation of deuterium incorporation at C-4, the C-3 absorption in the ^{13}Cmr spectrum of **6**-d_x recovered after 10 h was examined carefully. This pattern contained, in addition to a small singlet at δ_C 6.6 arising from non-deuterated material, a prominent singlet shifted upfield by 16 ppb owing to [5-$^{2}H_1$]-**6**, a 1 : 1 : 1 triplet, J_{CD} = 24.2 Hz, Δ = 298 ppb from [3,5-$^{2}H_2$]-**6**, and a weak singlet, Δ = 109 ppb, attributable to [4,5-$^{2}H_2$]-**6**. While both methylene hydrogens at C-3 undergo exchange, although at distinctly different rates, only the *syn*-hydrogen at C-9 was involved.

Approximate first-order rate constants for exchange at the various sites in **5** and **6** were extracted from the deuterium incorporation data and are given in Fig. 1, together with the earlier results (7) for their [3.2.1.0] analogs, **3** and **7***c*. In each case, exchange at the 3-methylene sites is highly stereoselective, indicative of steric hindrance, and the rates for the more reactive proton are comparable, although this centre is only involved in enolate rearrangement in the case of **3**. This seems to indicate that the carbonyl group has little influence on proton abstraction from C-3 and the reactivity of these protons can be attributed to the fact that cyclopropyl methylene hydrogens are more acidic than their alicyclic counterparts. On the other hand, their less acidic vicinal neighbors, the cyclopropyl methine hydrogens, are distinctly activated by the carbonyl group, since exchange occurred only at C-4 in each compound with no evidence of exchange at C-2. It is curious, however, that the rate of exchange at C-4 in **6** is slower than that at C-3 while the reverse was found for **3**, **5**, and **7***c*. The detection of exchange at the methano bridge in the related systems, fenchone and 3,3,6,6-tetramethylnorcamphor, is relatively recent (17). Hence it is interesting that the *syn*-proton at this position undergoes exchange selectively, but only in the *exo* series, **6** and **7***c*, and at comparable rates. In the bicyclic systems, *syn* exchange is strongly favored but proceeds at only ca. 1/100 of the rate found for **6** and **7***c*; this increased reactivity is difficult to explain.[3] The incorporation of a *syn*-deuterium at C-9 in **6** would suggest that the cleavage of β-enolate **15** to regenerate **6** proceeds with retention of configuration if this is indeed the mode of exchange. However, the absence of deuterium at the corresponding position in **1** (C-8) indicated that the conversion of **1** → **2** is unidirectional. For **6** it is conceivable that exchange at C-9 involves a different intermediate species than **15**. As already noted, methyl exchange occurred preferentially at the *exo*-groups, with the puzzling difference that this process is distinctly faster in the *endo* examples **3** and **5** than their *exo* counterparts, **6** and **7***c*.[3] Clearly, rather subtle factors govern the reactivity of exchange in these compounds and additional data are required before definitive interpretations can be devised.

Experimental

Boiling points are uncorrected. Gas–liquid chromatography was carried out on Varian 920 and 3700 instruments using columns of 10% Carbowax 20 M, 6% FFAP, or 10% SE-30 on Chromosorb W, as indicated. Tetrahydrofuran (THF) and ether were dried over sodium and freshly distilled before use. Diisopropyl amine, triethyl amine, and pyridine were distilled from CaH_2 and stored over 4A molecular sieves; methyl iodide was dried over 4A sieves. The ketones, *exo*-tricyclo[3.2.1.0^{2,4}]octan-6-one (**7**) and its *endo* isomer, were the starting materials for the preparation of **5** and **6** and had been described previously (10).

Infrared spectra were recorded with a Beckman 4250 instrument and mass spectra were obtained on a Varian MAT-311A system at 70 eV (direct inlet). Routine ^{1}Hmr spectra were obtained with either Varian T-60 or EM-360 instruments while data for pure samples were collected with a Varian XL-200 instrument. The latter spectrometer and a Varian XL-300 were employed to record the ^{2}H and ^{13}Cmr spectra, and comparison of the fully decoupled ^{13}C spectra with those obtained with either the APT (18) or DEPT (19) sequences identified the methyl, methylene, methine, and fully-substituted carbon signals. Correlation of the ^{1}H and ^{13}C spectra for **5** and **6** was accomplished using the HETCOR sequence of the XL software with a 2048 × 128 data matrix, 3600 (**5**) and 2600 Hz (**6**) spectral widths for ^{13}C and 1000 Hz for ^{1}H, transforming 2048 and 512 points, respectively. INADEQUATE (14) spectra of **16** were recorded with the C13SAT sequence of the XL software using a 3200-Hz sweep width (sp^3 carbons only), 12 and 16-s repetition rates, 60 000 points, and 64K transforms.

*6-Trimethylsilyloxy-*exo*-tricyclo[3.2.1.0^{2,4}]oct-6-ene (8)*

To a stirred solution of LDA (prepared from diisopropyl amine (3.31 mL, 23.6 mmol), THF (23 mL), *n*-BuLi (2.50 *M*, 8.26 mL) at −78°C, 30 min) under nitrogen was added **7** (1.80 g, 14.8 mmol) in THF (4.0 mL) and stirring was continued for 45 min at −78°C. A quenching solution (prepared by centrifugation of a mixture of trimethylsilyl chloride (3.37 mL, 26.6 mmol) and Et_3N (1.23 mL) in THF (3 mL) in a N_2-purged tube) was added and stirring was continued for 2 h after removal of the Dry Ice cooling bath. The reaction was then cooled to 0°C and cold saturated aqueous Na_2CO_3 solution (30 mL) was added by syringe with vigorous stirring. The organic layer was decanted, the aqueous layer extracted with pentane (3 × 25 mL), and the combined extracts washed with Na_2CO_3 solution (25 mL) and H_2O (2 × 25 mL) before drying over $MgSO_4$. Removal of the solvent under reduced pressure gave crude **8** which was purified by bulb-to-bulb distillation, bp 90–95°C/4 Torr (1 Torr = 133.3 Pa), 2.57 g, 90% yield; glc analysis (FFAP) indicated >90% purity. An analytical sample was collected by preparative glc, for characterization; ir ($CHCl_3$): 1598 cm^{-1} (C=C); ^{1}Hmr (C_6D_6) δ: 0.20 (s, 9H, Me_3Si), 0.5–1.5 (complex absorption, 6H), 2.53 (m, 2H, H-1, H-4), 5.05 (bd, 1H, H-7); ^{13}Cmr, see Table 1. *Exact Mass* calcd. for $C_{11}H_{18}OSi$: 194.1127; found: 194.1125.

2-Trimethylsilyloxytetracyclo[3.3.1.0^{2,4}0^{6,8}]nonane (9)

A zinc–silver couple (2.22 g, 34 mmol) was placed in a N_2-purged flask fitted with a reflux condenser and magnetic stirring bar and the apparatus was flame dried before cooling to room temperature. Methylene iodide (1.50 mL, 18.6 mmol) and Et_2O (4 mL) were added and the flask warmed to initiate reaction. On completion of the exothermic reaction, enol ether **8** (2.00 g, 10.3 mmol) in Et_2O (46 mL) was added with stirring and the resulting mixture was refluxed for 8 h. After cooling to 0°C, a 50:50 mixture of pyridine–ether (10 mL) was added. The precipitate was removed by filtration through Celite and the filtrate was concentrated under reduced pressure. The residue was taken up in pentane and the last traces of precipitate removed by filtration. Evaporation of the solvent gave oily liquid **9** (1.98 g, 92%); glc analysis (FFAP) indicated the product to be ca. 80% pure. An analytical sample (prep. glc) was collected for characterization; ^{1}Hmr ($CDCl_3$) δ: 0.18 (s, 9H, Me_3Si), 0.35 (m, 2H), 0.72 (m, 3H), 1.06 (m, 3H), 1.76 (m, 1H), 2.18 (m, 1H), 2.32 (m, 1H); ^{13}Cmr, see Table 1. *Exact Mass* calcd. for $C_{12}H_{20}OSi$: 208.1283; found: 208.1279.

exo-*Tricyclo[3.3.1.0^{2,4}]nonan-6-one (10)*

The tetracyclic TMS ether **9** (1.88 g) was added to methanolic NaOH solution (3 *M*, 90 mL) and allowed to stir for 24 h at 0°C before the addition of H_2O (70 mL). The product was extracted with pentane (4 × 50 mL) and the combined extracts washed with H_2O (3 × 40 mL); the combined aqueous washings were back-extracted with pentane (50 mL). The pentane extracts were dried over $MgSO_4$ before removal of the solvent by distillation to give **10** (1.09 g, 82%). Preparative glc was used to obtain pure samples for further work. The absence of **7***b* in the ketonization product was confirmed by glc since samples of the latter were available from earlier studies (10); ir ($CHCl_3$): 1710 cm^{-1} (C=O); ^{13}Cmr, see Table 1. *Exact Mass* calcd. for $C_9H_{12}O$: 136.0888; found: 136.0886.

Preparation of exo-*deuterio-**10**-d$_1$ (**10**-X)*

A solution of KOD in *t*-BuOD (2 *M*, 2 mL) was added to **9** (90 mg) and allowed to stand with stirring under a nitrogen atmosphere overnight. After the addition of D_2O (3 mL), the product was isolated as described for **10** to furnish **10**-d_3 (60 mg); ms: 0.9% d_0, 2.9% d_1, 19.7% d_2, 76.5% d_3 (total 2.715 D/molecule). This material was added to methanolic NaOH solution (3.6 *M*, 1.5 mL) and allowed to stand with stirring overnight before the addition of 10% NaCl solution (3 mL) and extraction with pentane (4 × 10 mL). The combined extracts were washed with 10% NaCl solution (3 × 10 mL) and the aqueous washings extracted once with pentane (30 mL). The pentane extracts were dried over $MgSO_4$ before removal of the solvent by

[3]A reviewer has suggested that a homoconjugative interaction between the *exo*-cyclopropyl ring and the carbonyl group may facilitate exchange at the methano bridges of **6** and **7***c*. This interaction could reduce the "electrophilicity" of the carbonyl group and thereby reduce its activation of the α-methyl carbons.

distillation to furnish *exo*-8-deuterio-**10**-d_1 (57 mg); ms: 7.7% d_0, 83.1% d_1, 5.1% d_2 (total 0.93 D/molecule); ^{13}Cmr, see text.

Preparation of endo-*8-deuterio-**10**-*d$_1$ *(**10-N**)*

The sequence **7** → **10** described above was repeated using 7,7-dideuterio-**7**-d_2 as the starting material prepared as follows. To a solution of NaOD/D_2O (0.5 *M*, 9.5 mL) was added **7** (1.40 g) under a nitrogen atmosphere and the solution was refluxed for 22 h. The product was extracted with pentane (3 × 10 mL) and the combined extracts washed with 10% NaCl solution (3 × 10 mL). The aqueous portion was reextracted with pentane (30 mL) and the pentane extracts dried over $MgSO_4$ before removal of the solvent by distillation to afford **7**-d_2 (1.34 g). The ^{13}Cmr spectrum of this product indicated almost complete exchange of the α-methylene hydrogens and this material was employed directly for the generation of **10**-d_1 via 7-deuterio-**8**-d_1 followed by cyclopropanation and ketonization as described above for **9** and **10**. The resulting product, *endo*-8-deuterio-**10**-d_1, was characterized by ^{13}Cmr (see text) and ms: 9.3% d_0, 70.7% d_1 (total 0.707 D/molecule).

*7,7-Dimethyl-*exo-*tricyclo[3.3.1.0^{2,4}]nonan-6-one (**6**)*

A solution of **10** (0.12 g, 0.9 mmol) in anhydrous Et_2O (6 mL) was added to $NaNH_2$ (0.19 g, 4.9 mmol) in Et_2O (5 mL) under a N_2 atmosphere and the mixture refluxed for 4 h. After cooling, methyl iodide (0.33 mL, 5.3 mmol) was added and the mixture refluxed overnight. Methyl iodide (0.11 mL, 1.8 mmol) was added and the mixture stirred for 3 h before cooling to 0°C. Water (5 mL) was slowly added and the organic phase decanted. The aqueous phase was extracted with pentane (3 × 8 mL) and the organic extracts washed with H_2O (3 × 6 mL). The combined washings were reextracted with pentane (10 mL). The combined extracts were dried over $MgSO_4$ before removal of the solvent which furnished crude **6**. Pure **6** (0.11 g, 76%) was obtained by column chromatography on alumina using pentane–ether, 90:10, as eluent; ir ($CHCl_3$): 1712 cm^{-1} (C=O); ^{1}Hmr, see text; ^{13}Cmr, see Table 1. *Exact Mass* calcd. for $C_{11}H_{16}O$: 164.1201; found: 164.1198.

*7,7-Dimethyl-*endo-*tricyclo[3.3.1.0^{2,4}]nonan-6-one (**5**)*

The analogous sequence described for **6** was employed for the preparation of **5**.

(*i*) 6-Trimethylsilyloxy-*endo*-tricyclo[3.2.1.0^{2,4}]oct-6-ene was obtained from the corresponding ketone (0.719 g, 5.8 mmol) using LDA (diisopropyl amine (1.30 mL, 9.3 mmol), THF (13 mL), *n*-BuLi (2.26 *M*, 3.60 mL) at −78°C) and trimethylsilyl chloride (1.20 mL, 9.5 mmol), Et_3N (0.45 mL, 3.2 mmol), and THF as described in detail above for **8**. The desired enol ether was purified by bulb-to-bulb distillation (bp 114–122°C/17 Torr) to yield 0.79 g (70% yield) for which glc (FFAP) indicated a purity of >98%; ir ($CHCl_3$); 1610 cm^{-1} (C=C); ^{1}Hmr ($CDCl_3$) δ: 0.30 (s, 9H, Me_3Si), 0.5–2.0 (complex absorption, 6H), 2.62, 2.72 (overlapping m, 1H each), 4.62 (bd, 1H, H-7); ^{13}Cmr, see Table 1. *Exact Mass* calcd. for $C_{11}H_{18}OSi$: 194.1127; found: 194.1123.

(*ii*) Cyclopropanation of this enol ether was accomplished using a Zn/Ag couple (0.87 g, 13 mmol), methylene iodide (0.59 mL, 7.3 mmol) in Et_2O (2 mL), and the work-up described for **9**. This procedure furnished **11** (0.70 g) which glc indicated to be >90% pure. Preparative glc (SE-30) furnished pure samples for characterization and for the following step in the sequence; ^{1}Hmr ($CDCl_3$) δ: 0.18 (s, 9H, Me_3Si) with one-proton multiplets at 0.36, 0.88, 2.11, 2.18, and 2.33 and two-proton multiplets at 0.71, 1.25, and 1.29; ^{13}Cmr, see Table 1. *Exact Mass* calcd. for $C_{12}H_{20}OSi$: 208.1283; found: 208.1277.

(*iii*) Tetracyclic ether **11** was ketonized in 90% yield with methanolic NaOH solution in a manner analogous to that described above for **9** and, as is the case for **9**, a single ketonic product was obtained; ir ($CHCl_3$): 1715 cm^{-1} (C=O); ^{13}Cmr, see Table 1. *Exact Mass* calcd. for $C_9H_{12}O$: 136.0888; found: 136.0889.

In a separate experiment **11** (95 mg) was treated with KOD in *t*-BuOD (2 *M*, 2 mL) using the procedure described above for the preparation of the trideuterated **10**-X. The trideuterated ketone produced contained (ms) 2.6% d_0, 7.9% d_1, 35.5% d_2, 54.0% d_3 (total 2.41 D/molecule). Subsequent treatment with methanolic NaOH solution (3.6 *M*, 2 mL) at room temperature overnight, followed by the usual work-up, furnished **14**-d_1, the ^{13}Cmr spectrum of which indicated the presence of ca. 0.8 atoms D/molecule at C-8 (see text).

(*iv*) The protio analog of **14** (0.20 g, 1.5 mmol) was dimethylated as described above for **10**, using $NaNH_2$ (0.33 g) in Et_2O (11 mL) and methyl iodide (0.58 mL for the first addition, and 0.19 mL for the second addition). The usual work-up furnished **5** (0.20 g, 83%); ir ($CHCl_3$): 1703 cm^{-1} (C=O); ^{1}Hmr, see text; ^{13}Cmr, see Table 1. *Exact Mass* calcd. for $C_{11}H_{16}O$: 164.1201; found: 164.1201.

Homoenolization experiments

The general procedures for the rearrangement and exchange experiments, reported previously (13), were followed as illustrated for **6**. To a solution of *t*-BuO$^-$/*t*-BuOH (1.27 *M*, H_2O content = 250 μg/mL) was added **6** to give a solution which was 0.26 *M* in ketone. To a series of 5-mL predried, thick-walled glass tubes were transferred 0.5-mL aliquots of the reaction solution; the tubes were degassed and sealed before immersion in an oil bath at 180°C. Tubes were removed at various times, cooled before opening, and the contents removed by washing with H_2O (10 mL). The organic product was isolated by pentane extraction (3 × 15 mL) and the combined extracts backwashed with H_2O (3 × 10 mL). The aqueous washings were reextracted with pentane (2 × 15 mL) and the pentane extracts dried over $MgSO_4$. Removal of the solvent by distillation afforded a neutral organic product, representing 75–80% yields from the various tubes, which was analyzed by glc to reveal the presence of two components, one of which was the starting ketone. The new component was ketonic (1730 cm^{-1}) and isomeric with the initial ketone; *Exact Mass* calcd. for $C_{11}H_{16}O$: 164.1201; found: 164.1198. This new ketone was identified as **16** by ^{13}Cmr as described in the text. Two other series of tubes were examined in a similar fashion using an oven at 185 ± 5°C. With reaction times >300 h, the starting material could not be detected in the product. A series of samples using *tert*-butyl alcohol-O-d_1 (99% deuterated, H_2O content = 264 μg/mL) was also run to examine the exchange processes occurring under these reaction conditions; the results are described in the text. An exactly analogous series of experiments was carried out using **5** as the starting material. In all cases, the neutral product, ~80% recovery, contained only the initial ketone; even after >300 h at 180°C there was no evidence (glc, ^{13}Cmr) of the presence of a new component.

*Preparation of **16**-*d$_1$

Ketone **16** (60 mg) was added to a stirred solution of MeONa/MeOD (1 *M*, 2.6 mL) under a N_2 atmosphere and stirring was continued for 12 h at room temperature. After the addition of D_2O (3 mL), the product was extracted with pentane (4 × 10 mL) and the combined extracts washed with 10% NaCl solution (2 × 15 mL) and H_2O (15 mL) before drying over $MgSO_4$. Removal of the solvent by distillation furnished **16**-d_1 (60 mg), the ^{13}Cmr spectrum of which indicated essentially complete deuteration at C-6; ms: 1.2% d_0, 98.8% d_1 (total 0.988 D/molecule).

Minor anthraquinonoid metabolites of *Cercospora arachidicola*[1]

ALBERT STOESSL AND J. B. STOTHERS

London Research Centre, Agriculture Canada and the Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received October 22, 1984

ALBERT STOESSL and J. B. STOTHERS. Can. J. Chem. **63**, 1258 (1985).

Minor metabolites of the fungus *Cercospora arachidicola* have been identified as the known pigments versicolorin B (**3**), averantin (**4**), and nidurufin (**2*b***) and the new, but closely related compounds 4′-deoxydothistromin (**1*b***), 3′,4′-dehydro-4′-deoxydothistromin (**5*a***), and 4′,5-bisdeoxydothistromin (**1*d***). The ^{1}H and ^{13}Cmr spectra of **1*d***, **2*b***, and the tetracetates **1*c*** and **5*b*** are presented in detail. Biosynthetic and chemotaxonomic aspects are discussed.

ALBERT STOESSL et J. B. STOTHERS. Can. J. Chem. **63**, 1258 (1985).

On a identifié les métabolites mineurs du champignon *Cercospora arachidicola* comme étant les pigments connus versicolorine B (**3**), averantine (**4**) et nidurufine (**2*b***) ainsi que les nouveau composés déoxy-4′ dothistromine (**1*b***), déhydro-3′,4′ déoxy-4′ dothistromine (**5*a***) et bisdéoxy-4′,5 dothistromine (**1*d***) qui leurs sont très apparentés. On rapporte en détail les spectres rmn du ^{1}H et du ^{13}C des composés **1*d*** et **2*b*** ainsi que ceux des tétraacétates **1*c*** et **5*b***. On discute des aspects biosynthétiques et chémotaxonomiques.

[Traduit par le journal]

The peanut pathogen *Cercospora arachidicola* was found recently to produce dothistromin (**1*a***) and averufin (**2*a***) in a liquid medium (1). Subsequent work, employing a solid agar medium, resulted in greatly increased yields of **1*a*** and **2*a*** and in the isolation of brassicasterol and substantial amounts of long-chain fatty aldehydes as other metabolites of the fungus (2). Several other anthraquinones were also isolated, in small amounts, and their identities are reported here. Three of these compounds, versicolorin B (**3**), averantin (**4**), and nidurufin (**2*b***) are well-known fungal metabolites that are implicated in or close to the biosynthetic routes to sterigmatocystin and the aflatoxins (3–5). Three other compounds, **1*b***, **1*d***, and **5*a***, closely related to dothistromin (**1*a***), are reported here for the first time.

The identification of **3** followed unambiguously from its physical and spectroscopic data together with its negative optical rotation at 589 mμ. The identification of averantin (**4**) is tentative, based on its ^{1}Hmr and mass spectra and the melting point (227–235°C) compared to literature data but the sample decomposed before it could be fully characterized. Nidurufin

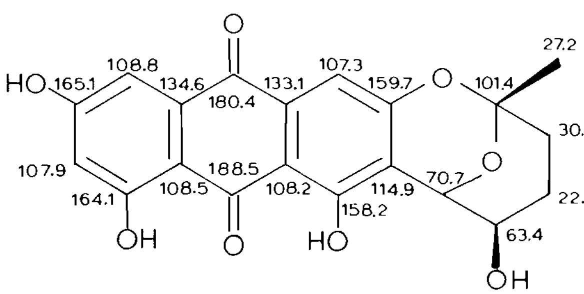
(**2***b*) melted at 267–268°C, with prior darkening, partial melting and resetting at ca. 200°C, in contrast to the mp (188°C) reported previously (6). A plausible explanation for this divergence may be dehydration of our samples on the Kofler stage to the anhydro compound. A comparison sample of authentic nidurufin, originally described as a metabolite of *Aspergillus nidulans* (6), could not be obtained. For this reason we present full ^{1}H and ^{13}Cmr data, which have not been specified in the other reports (4, 7) on the compound, but our ^{1}Hmr data (DMSO-d_6 solutions) are in reasonable accord with the few details given in the original publication (6) for acetone-d_6 solutions. The ^{1}Hmr spectrum contained three aryl proton absorptions at δ 6.89 (s), 7.00 (d, J = 2.5 Hz), and 6.50 (d, J = 2.5 Hz) assignable to H-4, -5, and -7, respectively, together with methine patterns at δ 5.00 (H-1′) and 5.38 (H-2′), methylene absorptions at δ 1.55, 1.78, 2.12, and 2.45 (H-3′, -4′) and a methyl singlet at δ 1.50. Phenolic hydroxyl signals were found at δ 12.00 (6-OH) and 12.40 (1- and 8-OH). The ^{13}Cmr spectrum bears a strong resemblance to that reported (8) for averufin (**2***a*), as expected, since the two compounds differ only by the additional hydroxyl group at C-2′ in **2***b*. The observed shieldings for **2***b* are shown in **6**. The dif-



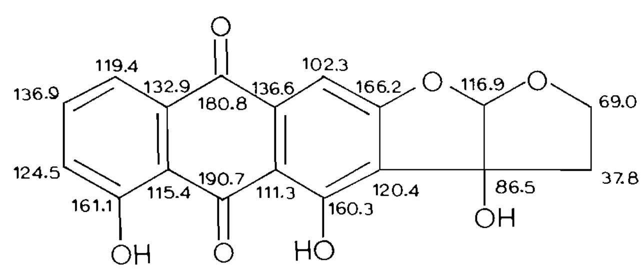
6

ferences, $\Delta\delta_C(\mathbf{2}b - \mathbf{2}a)$, found for C-1′ (+4.4 ppm), −2′ (+36.3 ppm), and −3′ (+7.1 ppm) are reasonable for hydroxyl substitution at C-2′, while the upfield −5.3 ppm shift for C-4′ indicates that the hydroxyl group is axial, i.e., *exo* with respect to the ring system, in complete agreement with the stereochemical assignment reported on the basis of synthesis (4) and contrasting with the original proposal of **2***c* (6). From our evidence we conclude that the metabolite isolated from *C. arachidicola* is identical with the synthetic *exo*-alcohol of Townsend and Christensen (4) and, hence, also with authentic nidurufin.

The two 2-deoxydothistromins **1***b* and **5***a*, separable only with considerable difficulty, were obtained as amorphous red solids. These were characterized as the tetraacetates **1***c* and **5***b*, which were easily purified by chromatography and crystallization. Their ^{1}Hmr, ^{13}Cmr, and mass spectra led to the structural assignments. Additional support was provided by the remarkable similarities of the ^{1}Hmr data (see Experimental) with those for the corresponding protons in **5***c*, which was used to characterize **5***d* reported as a cometabolite of **1***a* in *Dothistroma pini* (7). The ^{13}C spectrum of **1***c* contained methyl absorptions at δ_C 20.7, 20.9, 21.1, and 21.2, methylene signals at δ_C 37.5 (C-3′) and 67.2 (C-4′), methine peaks at 106.4 (C-4), 113.4 (C-1′), 130.3, and 131.2 (C-6, -7), and sixteen signals arising from nonprotonated carbons: δ 179.6, 180.5 (C-9, -10), 168.7, 169.2, 169.4, 169.7 (MeCO—), 165.6 (C-3), 147.3, 147.8, 147.9 (C-1, -5, -8), 138.8 (C-14), 125.5, 125.6, 126.8 (C-11, -12, -13), 119.5 (C-2), and 91.1 (C-2′). Apart from the replacement of the methylene signals with methine absorption at δ_C 101.7 and 151.1 (C-3′ and -4′), the ^{13}C spectrum of **5***b* was very similar, having methyl signals at δ_C 20.9, 21.0, 21.2, 21.3, methine peaks at 107.0 (C-4), 113.6 (C-1′), 130.3, 131.2 (C-6, -7), and sixteen nonprotonated carbon signals: 179.4 (C-9), 180.2 (C-10), 168.5, 169.1, 169.2, 169.4 (MeCO—), 164.6 (C-3), 146.3 147.7, 147.8 (C-1, -5, -8), 137.9 (C-14), 125.4, 126.6, 126.7 (C-11, -12, -13), 113.6 (C-1′), and 93.6 (C-2′). The signals arising from the anthraquinone moiety in each of the derivatives were readily assigned upon comparison with the data reported for an array of acetoxyanthraquinones (9).

Metabolite **1***d*, although obtained only in very small amount, crystallized readily. Its uv spectrum, differing markedly from those of its cometabolites, was typical of a 1,3,8-trioxyanthraquinone, as exemplified by 6-deoxy-8-*O*-methyl versicolorin A (**5***e*) from *Aspergillus ustus* (10). The mass spectrum indicated a composition of $C_{18}H_{12}O_7$ and that the sample was contaminated with an O-homolog $C_{18}H_{12}O_8$. This impurity, possibly **1***b* or other deoxydothistromin, must, however, be present in very small amounts since there was no evidence of its presence in the nmr spectra.

The ^{13}Cmr spectrum, 1.2 mg in DMSO-d_6, contained eighteen signals, seven of which were shown to arise from protonated carbons by a DEPT spectrum (11). Methylene signals appeared at δ 37.8 and 69.0 with CH absorptions at δ 102.3, 116.9, 119.4, 124.5, and 136.9. Signals for fully substituted carbons were found at δ 86.5, 111.3, 115.4, 120.4, 132.9, 136.6, 160.3, 161.1, 166.2, 180.8, and 190.7. From these data it was apparent that the two signals at lowest field must represent the carbonyl centres of the anthraquinone moiety with the more deshielded of the pair (C-9) flanked by two *peri*-hydroxyl groups. Comparison with the shieldings for 1,8-dihydroxy anthraquinone (9) led readily to assignments for C-5, -6, -7, -8, -11, and -12 which differ, on average, by 0.2 ppm from those of the model. Earlier detailed study of several anthraquinones has established that substitution on one of the aryl rings has relatively little effect on the ^{13}C shieldings of the other ring (9). Assignments for each of the remaining signals were made by comparison with the data observed for **3** and reported for versicolorin C (12), which require allowances for the additional hydroxyl substituent at C-2′. The differences of +4.0, +43.3, and +7.8 ppm for C-1′, -2′, and -3′, respectively, are quite consistent with this substitution. For C-1, -2, -3, -4, -13, and -14, the differences average 1.4 ppm, which also seem reasonable. The specific assignments are set out in **7**. The ^{1}Hmr



7

spectrum in $CDCl_3$ exhibited three signals readily ascribed to hydroxyl protons through their facile exchange with D_2O. Two of these, δ 12.05 and 12.56, must arise from strongly hydrogen-bonded phenolic groups while the third, appearing as a broad singlet at 2.88, could be attributed to an aliphatic hydroxyl. There were four aryl proton absorptions: a singlet, δ 7.343, and three doublets of doublets characteristic of three contiguous protonated centres, δ 7.826 (J = 1.3, 7.6 Hz), 7.676 (J = 7.6, 8.3 Hz), 7.308 (J = 1.3, 8.3 Hz). A one-proton singlet, δ 6.155, was clearly evident while the four remaining protons appeared as multiplets at 2.520, 2.786, 3.811, and 4.324, from which it was apparent that each was coupled to each of the others. The multiplet at δ 2.786 contained an "extra" coupling of 0.9 Hz which collapsed upon exchange of the hydroxyl protons, showing it to be coupled to the aliphatic hydroxyl proton. The coupling constants for the 2.786 absorption were 12.4, 4.7, and 0.9 Hz while the multiplet at δ 2.520 exhibited couplings of 12.4, 12.4, and 7.9 Hz; these data lead to the assignment of these as the methylene protons at C-3′. The pattern at δ 3.811 showed couplings of 12.4, 9.4, and 4.7 Hz while J values of 9.4, 7.9, and 0.9 Hz were apparent for the 4.324 pattern; thus these absorptions arise from the 4′-methylene protons. The observed J values are consistent with the relative orientations indicated in **8**.

a R = H

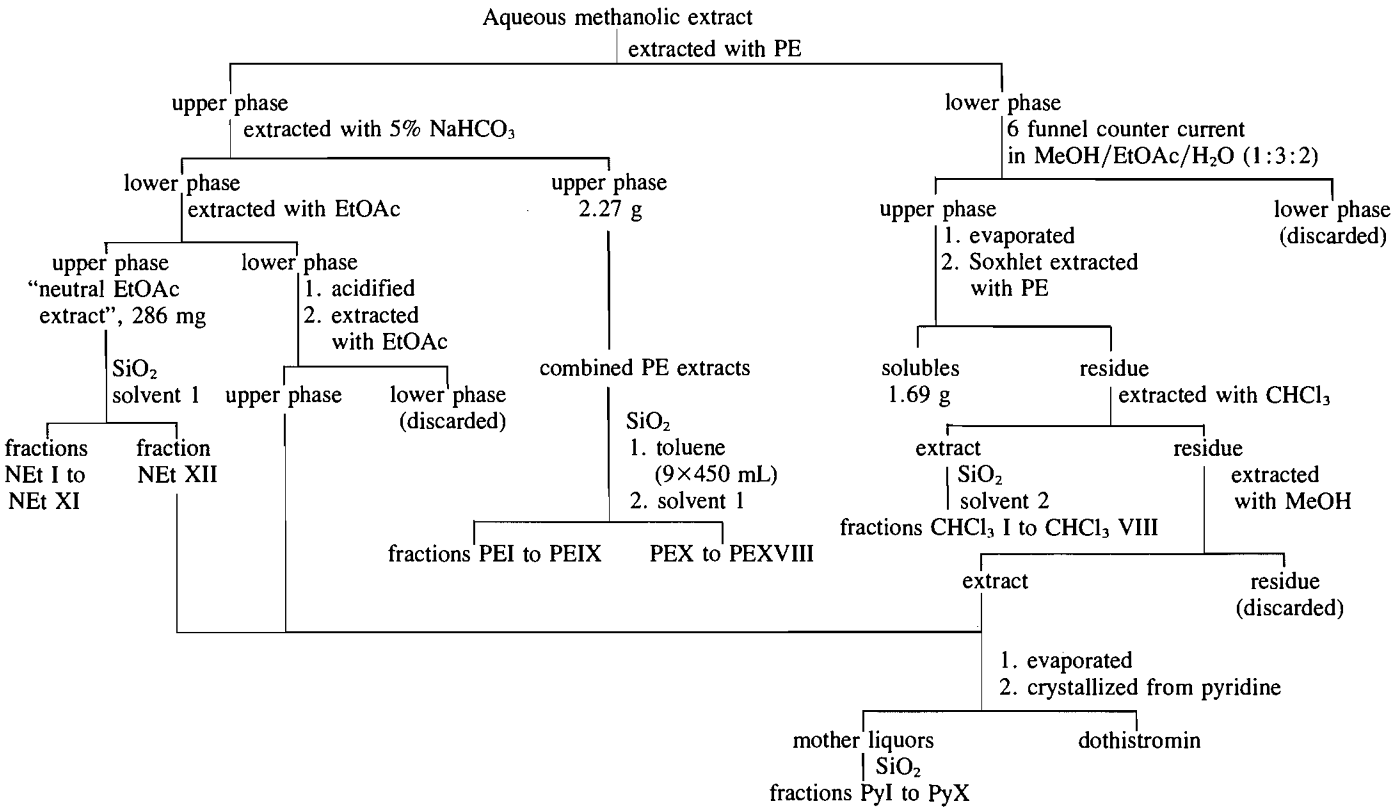
b R = Ac

The isolation from *C. arachidicola* of small amounts of **1***b*,*d*, **2***a*,*b*, **3**, **4**, **5***a* as congeners of the major metabolite dothistromin (**1***a*) illustrates the remarkable similarity in the metabolism of certain *Cercospora* spp. and *Dothistroma pini*. The latter fungus has been found to produce **1***a* as a major metabolite, together with small amounts of **2***a*,*b*, averythrin (**9**), deoxyversicolorin C (**1***e*, identified tentatively), **1***f*, and **5***d* (7). The last three compounds are formally related to the *C. arachidicola* metabolites **1***d*,*b*, and **5***a*, respectively, merely by hydroxyl substitution at C-2′. Numerous *Cercospora* species, but exclusive of *C. arachidicola*, have been the subject of a chemotaxonomic study by Assante *et al.* (13, 14). Among other, not directly pertinent metabolites, they found **1***a* in *C. smilacis* and seven other spp., and **2***a* and **9** in *C. smilacis*. A deoxydothistromin, apparently not identical with **1***b* from *C. arachidicola*, was identified as a *D. pini* metabolite by mass spectral and preliminary unpublished evidence (15) but no evidence for this compound was obtained for *C. smilacis* (13).

While dothistromin and derivatives thus far appear to have been found only in *D. pini* and *Cercospora* spp., averufin (**2***a*) is known from *Aspergillus* spp. (16), *Bipolaris sorokiniana* (6, 17), and *Monocillium nordinii* (18). Versicolorin B similarly is known from *Aspergilli* (16*a*, *b*) while averantin occurs in *A. versicolor* (16*a*), *A. parasiticus*, and *Solorina crocea* (16*b*). Averantin (**4**), derived from polyacetate via norsolorinic acid, is well established as a precursor of averufin (**2***a*) which, in turn, is converted via versiconal acetate and subsequent steps to sterigmatocystin and hence, the aflatoxins (3–5, 16*b*, *c*). It has recently been suggested that the biotransformation of **2***a* into versiconal acetate may proceed with nidurufin (**2***b*) as a crucial intermediate (4, 19); the isolation of **2***b* as a congener of **2***a* in *A. nidulans* (6), *D. pini* (7), and now also *C. arachidicola* is therefore of some moment. Further, the mechanism of conversion of versiconal acetate into sterigmatocystin has been postulated to involve versicolorin A (**10**), which is indeed known to be incorporated into sterigmatocystin and the aflatoxins (3, 16*b*). Recently, however, it was found that versicolorin A hemiacetal (**11***a*) and its acetate **11***b*, but not **5***e*, were efficiently incorporated into aflatoxin B. It was suggested that **11***a* and **11***b* may be the true intermediates while versicolorin A (**10**) and versicolorin C (racemic-**3**) may be shunts which, however, can reenter the pathway (20). The compounds **11***a* and **11***b* were prepared from **10** by chemical methods and do not appear to be known as fungal products; it is therefore of considerable interest that the salient tetrahydro-2-hydroxybisfuran grouping occurs in dothistromin (**1***a*) (as well as in some aflatoxins).

Averufin and the versicolorins have long been regarded as mycotoxins (3, 12) while dothistromin (**1***a*) has considerable importance as a phytotoxin directly implicated in Dothistroma blight of pine (21); preliminary evidence from our laboratory (1) and elsewhere[2] suggests that it is also a mycotoxin. It is

[2]R. A. Franich, personal communication.



SCHEME 1. Fractionation of *C. arachidicola* extract

probable that similar biological activities are attached to some of the other anthraquinones from *C. arachidicola*; the compounds should therefore be handled with caution.

Experimental

The compounds described here were obtained in the same experiment as the aldehydes reported previously (2). In summary, *C. arachidicola* ATCC 18667 was cultured on potato-dextrose agar (320 Petri dishes, 20 mL each), the cultures being extracted with EtOAc/MeOH (1:1) after 3 weeks. After concentration till aqueous, the extracts were fractionated (Scheme 1) to provide light petrol extracts (PE I, PE II, . . .), neutral ethyl acetate extracts (NEt I, NEt II, . . .), chloroform extracts ($CHCl_3$ I, $CHCl_3$ II, . . .), dothistromin (from pyridine), and dothistromin mother liquors (Py I, Py II, . . .), where the Roman numerals denote consecutive fractions obtained by column chromatography over silica (Camag DF O), with EtOAc/toluene/HOAc (30:60:1; solvent 1) and $EtOAc/CH_2Cl_2/HOAc$ (20:80:1; solvent 2) as irrigants.

General procedures, materials, and instrumentation were as previously specified (2). The ^{13}Cmr spectra were obtained with Varian XL-200 and -300 instruments at 50.3 and 75.4 MHz, respectively (30° pulses, 4-s rep rates with 200-ppm sweep widths, and 32 K points/32 K transforms (XL-200) or 60 000 points/64 K transforms (XL-300) at ambient temperatures). Optical rotations were determined with a Perkin–Elmer 141 polarimeter; we thank Prof. W. A. Ayer for these measurements.

Dothistromin (**1***a*) was obtained substantially pure (824 mg) by one crystallization of the appropriate fraction (Scheme 1) from pyridine. Its identity (1) was further confirmed by acetylation (1, 15) of a recrystallized sample (24 mg) which on chromatography (solvent 1) gave as the only pure product the tetraacetate (14 mg), mp 125–128°C (from EtOH); ^{1}Hmr, $\delta(CDCl_3)$: 7.47 (s, H-6 and H-7), 7.28 (s, H-4), 6.56 (d, $J \sim$ 3Hz, H-4′), 6.54 (s, H-1′), 2.95 (m, H_2-3′), 2.51 and 2.49 (2s, 5-, 8-OAc), 2.14 (s, 2′-OAc), and 1.75 (s, 4′-OAc).

Averufin (**2***a*) was isolated by rechromatography and (or) recrystallization from fractions PE XIII, PE XIV, and NEt VI. It had the requisite uv and ^{1}Hmr spectra and was also identical with an authentic specimen (14) by tlc (several systems), mp, mp in admixture, and ms.

Versicolorin B (**3**) (10 mg) was obtained by repeated rechromatography and (or) crystallization (H_2O/isopropanol or MeOH/EtOAc) from fractions PE XV, NEt VII and VIII, and $CHCl_3$ III, and identified by comparison of its mp (303–306°C), uv, ^{1}Hmr, ^{13}Cmr, and ms parameters with literature data (12). The compound had $[\alpha]_D$ −155.2° (*c* 0.32, dioxane).

Averantin (**4**) (6 mg) was isolated by repeated rechromatography ($MeOH/CHCl_3/HOAc$ 5:95:0.1) of fractions NEt VII and VIII, and $CHCl_3$ IV; mp 213–219°C (from toluene/EtOAc), 227–235°C (from $CHCl_3$); λ_{max} (ϵ): 221 (42 800), 255 (sh) (20 900), 264 (23 400), 293 (38 600), 324 (19 500), 452 (11 300), and 462 (sh) (11 200); ^{1}Hmr, δ(DMSO-d_6): 7.16 (d, J = 2.5 Hz, H-5), 7.14 (s, H-4), 6.62 (d, J = 2.5 Hz, H-7), 5.17 (t, J = 6 Hz, H-1′), 1.80 (m, H_2-2′), 1.5–1.1 (m, H_2-3′, H_2-4′, H_2-5′), and 0.84 (t, J = 6 Hz, Me). The mass spectrum was indistinguishable from that published (5).

Nidurufin (**2***b*) (8 mg) was obtained from fractions NEt X and $CHCl_3$ XI, VII, and VIII, mostly by extensive refractionations (solvents 1, 2, $MeOH/CHCl_3/HOAc$ 10:90:1, and EtOAc/HOAc 99:1) and was recrystallized from MeOH/EtOAc; λ_{max} (ϵ): 221 (35 800), 256 (sh) (16 100), 264 (17 600), 293 (29 600), 315 (13 600), and 459 (8 000); *m/e*: 384, 366 (100%), 326, 323, 314, 299, 297, 286; $[\alpha]_D$ −12.6° (*c* 0.37, dioxane). *Exact mass* calcd. for $C_{20}H_{16}O_3$: 384.08452; found: 384.08464.

4′-Deoxydothistromin (**1***b*) and 3′,4′-dehydro-4′-deoxydothistromin (**5***a*) were separable from each other only by extensive rechromatography, substantial proportions of the compounds being invariably eluted as a mixture. Final yields were substantially pure **1***b*, 18 mg; **5***a*, 21 mg; unresolved mixture, 33 mg.

Acetylation (pyridine/Ac_2O 3:2, room temperature, overnight) of crude **1***b* (11 mg) gave the tetraacetate **1***c* (7.9 mg after chromatography in solvent 1); crystals from $MeOH/CHCl_3$, dec. >220°C without melting; λ_{max} (ϵ): 209 (15 600), 238 (10 200), 272 (23 900), 348 (3 500); ^{1}Hmr, $\delta(CDCl_3)$: 7.54 (s, 1H, H-4), 7.40 (s, 2H, H-6 and H-7), 6.47 (s, 1H, H-1′), 4.25 (m, 1H, H-4′ eq), 3.70 (m, 1H, H-4′ ax), ca. 2.6 (m, 2H, H-3′), 2.47 (s, 6H, 2 ArOAc), 2.42 (s, 3H, ArOAc), and 2.04 (s, 3H, 2′-OAc); *m/e*: 524, 482, 440 (100%), 398, 338 (100%), 310 (100%); $[\alpha]_D$ −72.4° (*c* 0.32, $CHCl_3$). *Exact Mass* calcd for $C_{26}H_{20}O_{12}$: 524.05941; found: 524.09587.

3′,4′-Dehydro-4′-deoxydothistromin (**5***a*) had [1]Hmr, δ(DMSO-d_6): 7.41 (br s, 2H, H-6, -7), 7.27 (br s, 1H, H-4), 6.48 (s, 1H, H-1′), and 5.66 (d, J = 3 Hz, 1H, H-3′). The tetraacetate **5***b*, prepared as **1***c*, was recrystallized from MeOH/$CHCl_3$; mp 211–213°C; λ_{max} (ε): 209 (29 700), 239 (16 400), 272 (30 500), 344 (6 200); [1]Hmr, δ($CDCl_3$): 7.58 (s, 1H, H-4), 7.37 (s, 2H, H-6 and H-7), 6.86 (s, 1H, H-1′), 6.69 (d, J = 2.8 Hz, 1H, H-4′), 5.43 (d, J = 2.8 Hz, 1H, H-3′), 2.46 (s, 6H, 2 ArOAc), 2.42 (s, 3H, ArOAc), and 2.06 (s, 3H, 2′-OAc); *m/e*: 522, 480, 462, 438, 420, 396, 378, 354, 336 (100%); $[\alpha]_D$ −49.5° (*c* 0.67, $CHCl_3$). *Exact Mass* calcd. for $C_{26}H_{18}O_{12}$: 522.07956; found: 522.07941.

4′-5-Bisdeoxydothistromin (**1***d*), 1.8 mg on repeated rechromatography of fractions NEt IX and X, and $CHCl_3$ IV, 1.0 mg after recrystallization ($CHCl_3$), had mp 254–258°C; λ_{max} (ε) 248 (16 300), 268 (22 200), 279 (21 400), 432 (4 500), and 455 (sh) (4 100). *m/e*: 356, 340 (M^+, 100%), 322, 312, 311, 294, 283, 281, 267, 256, 240, and 228. *Exact Mass* calcd. for $C_{18}H_{12}O_7$: 340.05827; found: 340.05935.

NOTE ADDED IN PROOF: The role of nidurufin as an aflatoxin precursor has become doubtful on the basis of a very recent study (ref. 24).

Acknowledgements

Thanks are due to G. L. Rock for general experimental assistance, D. Hairsine and S. Wilson for measuring mass and 200-MHz [1]Hmr spectra, and to the Natural Sciences and Engineering Research Council of Canada for financial support. We are very grateful to Dr. R. A. Franich for communicating results on the mutagenicity of dothistromin prior to their publication.

Received November 25, 1983[2]

J. STUART GROSSERT, PRAMOD K. DUBEY, and TOM ELWOOD. Can. J. Chem. **63**, 1263 (1985).

The α-halo-β-ketosulfonyl functionality was attacked by ethanethiolate at the halogen which, in the presence of a proton source, usually resulted in reduction to the β-ketosulfone. A range of other soft nucleophiles did not react, whereas hard nucleophiles invariably attacked at the carbonyl, with subsequent cleavage to α-halosulfones. Ambident arylsulfinate anions usually attacked at halogen to form the sulfonyl halide, which reacted with excess sulfinate to give an intermediate that is readily attacked by alcohols. This reaction resulted in the formation of alkyl arylsulfinate esters in reasonable yields. The same reaction occurred when sulfonyl chlorides were reacted with sulfinate salts and it was rationalized by using HSAB principles. Spectral properties of some sulfinate esters are presented.

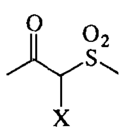
J. STUART GROSSERT, PRAMOD K. DUBEY et TOM ELWOOD. Can. J. Chem. **63**, 1263 (1985).

On a fait réagir l'éthanethiolate sur l'halogène de composés α-halo β-cétosulfonyle qui, en présence d'une source de protons, conduisent habituellement à une réduction en β-cétosulfone. Un certain nombre d'autres nucléophiles nous ne réagissent pas tandis que les nucléophiles durs attaquent invariablement le carbonyle avec un clivage subséquent conduisant aux α-halosulfones. Les anions arylsulfinates possèdent deux positions réactives et réagissent habituellement au niveau de l'halogène pour conduire à l'halogénure de sulfonyle qui réagit alors avec un excès de sulfinate pour donner un intermédiaire que les alcools attaquent facilement. Cette réaction conduit à la formation d'esters arylsulfinates alkyles avec des rendements raisonnables. La même réaction se produit lorsqu'on fait réagir des chlorures de sulfonyles avec des sels de sulfinates et on rationalise cette réaction en faisant appel aux principes ABDM. On présente les propriétés spectrales de quelques esters sulfinates.

[Traduit par le journal]

Introduction

The α-halo-β-ketosulfone functionality (**A**) has not been extensively studied (1–4), yet has considerable potential as a complex functionality in which interactions between proximate groups can be studied. For instance, it combines an α-halosulfone, a functionality that is known to undergo substitution reactions at carbon with difficulty, with an α-haloketone, a functionality that is usually susceptible to such substitutions (5). There are several ways in which **A** could react with a



A

nucleophile, namely (*1*) attack at the α-carbon with displacement of the best leaving group, that is, the halogen X; (*2*) attack at the halogen X (6), with displacement of the enolate anion; (*3*) removal of the acidic α-proton (pK_a ~10)[3] if the attacking nucleophile is sufficiently basic; or, (*4*) attack at the β-carbonyl carbon, either to give a carbonyl addition product, or to displace an α-halosulfonyl carbanion as a leaving group (cleavage of C—C bond).

We have reported on reactions of the 4th type (4) in which cleavage could be induced by hydroxide or alkoxide anions, anions that are classified as hard in the HSAB terminology. Owing to our interest in the preparation of sulfenylated β-ketosulfones (7), we were attracted by the possible reaction of thiolate anions (soft nucleophiles) with **A**. This could, in principle, provide a route to α-sulfenylated-β-ketosulfones (and thus be of synthetic utility), and it could provide evidence as to whether a sulfonyl or a carbonyl group would control the course of a substitution reaction (and thus be of mechanistic interest). Our results (*vide infra*) have shown that the reaction is of little synthetic utility, but did provide some interesting evidence regarding mechanism. Also reported on are the reactions of **A** with a series of nucleophiles that can be classified as having varying degrees of hardness or softness.

Results and discussion

Reactions with thiolate anions

The α-halo-β-ketosulfones $PhCOCHBrSO_2Me$ (**1**) and $PhCOCHClSO_2Me$ (**2**) were used to study the reaction with thiolate since they were readily available (4). The results (Table 1) can be divided into three groups, namely entries 1, 2, entries 3–5, and entries 6–10. In the first group, the solvent was polar and protic, the product was that due to a reduction reaction, and attack by thiolate was therefore apparently exclusively at the halogen. Previous work on the reaction of α-halosulfones with nucleophiles has shown that reduction is significantly favoured over substitution as the degree of substitution at the halogen-bearing carbon is increased (6, 8, 9), especially in a protic solvent. In the case of **1** and **2**, attack at the halogen could be expected since the carbonyl group would stabilize the resulting anion. The other product of this reaction (eq. [1]) will be the sulfenyl halide, which is decomposed by the ethanol solvent. Reduction must be a rapid reaction since no cleavage products (4) from attack on **1** or **2** by ethoxide, formed by the reaction depicted in eq. [2], were detected.

$$[1]\quad RCO\cdot CHX\cdot SO_2Me + EtS^- \rightarrow [RCO\cdot CH\cdot SO_2Me]^- + EtSX$$

$$[2]\quad [RCO\cdot CH\cdot SO_2Me]^- + EtOH \rightarrow PhCOCH_2SO_2Me\ (\mathbf{3}) + EtO^-$$

The use of a polar, aprotic solvent (DMF, entries 3–5) permitted isolation of both the reduction product (**3**) and the

10	**2**	PhMe	24	**3** + **4** + **5**‖

*All reactions were carried out on a 2-mmol scale with 4 mmol of thiolate, except for entries 1 and 2 when 10 mmol was used.
†Yields are estimated from integration of an ^1H nmr spectrum of weighed material that was also examined by tlc against reference compounds, unless otherwise stated.
‡Yield of pure, isolated material.
§The reaction was carried out in the dark in the presence of nitrobenzene (4 mmol, entries 4 and 8) or *m*-dinitrobenzene (2 mmol, entries 5 and 9), more than 80% of which was present in a product mixture.
‖The yields were not determined.

disulfide, **4**, formed by attack of excess thiolate on the intermediate sulfenyl chloride (eq. [3]).

$$[3]\quad EtSX + EtS^- \rightarrow EtSSEt\ (\mathbf{4}) + X^-$$

Repetition of the experiments in the presence of the radical-chain inhibitors nitrobenzene and *m*-dinitrobenzene (10) had no obvious effects, thus suggesting that the reaction most likely involves a two-electron attack of thiolate on halogen. No sign of any substitution product $PhCO\cdot CHSEt\cdot SO_2Me$ (**5**) was observed in the proton nmr spectra of crude reaction mixtures.

In aprotic solvents of lower polarity (THF, dimethoxyethane (DME), or toluene), both **1** and **2** yielded mixtures of the reduction product **3**, the substitution product **5**, plus the disulfide, **4**. The production of **5** must involve a process described in eq. [4] in competition with that in eq. [3], since it is unlikely

$$[4]\quad [RCO\cdot CH\cdot SO_2Me]^- + EtSX \rightarrow RCO\cdot CHSEt\cdot SO_2Me\ (\mathbf{5}) + X^-$$

that the mechanism of the reaction would change on switching solvents from DMF to THF. The results for DME as solvent were quite similar to entry 6 (Table 1) and are thus not reported. The complex product mixtures obtained from the experiments for checking whether a radical-chain reaction was involved (entries 8, 9) could not be analyzed with sufficient confidence to merit publication and thus bear further investigation.

It does seem reasonable to conclude from the above experiments that the reaction leading to the substitution product **5** does not involve a nucleophilic attack by thiolate at carbon (an S_N2 reaction), but rather an attack at the halogen, followed by subsequent reaction of the intermediate carbanion with the resulting sulfenyl halide. This type of reaction (eq. [1] followed by eq. [4]) has been suggested previously, but has not been definitively proven (8). We propose that the differences between the three classes of solvent reflect differences in solvation around the intermediate carbanion and the degree of reactivity of the solvent with the sulfenyl halide, and that attack both on carbon and on halogen, operating in competition during a given reaction (9), does not occur. The determination of the actual relative energy barriers for the various processes remains to be made.

‖These yields were estimated from the ^1H nmr spectra. No other products were observed.

Reactions with various hard and soft nucleophiles

Since we have observed attack on **1** and **2** at the carbonyl by hard oxygen nucleophiles and at the halogen by soft sulfur nucleophiles, we extended the range of nucleophiles to encompass others of varying degrees of hardness. The results for reactions with **2** are reported in Table 2.

Thioamides and thioureas are known (11, 12) to be excellent nucleophiles for attack at electrophilic sp^3-hybridized carbons. Apparently they are not efficient nucleophiles for attack at chlorine, as they did not effect reduction of **2**. Likewise, thiocyanates can be good nucleophiles for attack at carbon (13), yet no reaction was observed. These experiments reinforce the belief, implied by the results in the previous section, that nucleophilic attack at carbon in α-halo-β-ketosulfones has a relatively high energy of activation.

The results with iodide (entries 4, 5) are not readily explicable; the reaction with potassium iodide in ethanol was re-

TABLE 3. The reactions of 2-bromo-2-methylsulfonyl-1-phenylethanone (**1**) and 2-chloro-2-methylsulfonyl-1-phenylethanone (**2**) with sodium benzenesulfinate dihydrate at room temperature

*All reactions were done on a 2-mmol scale with 4 mmol of reagent.
[†]Yields are estimated from integration of a ^{1}H nmr spectrum of weighed product that was checked against reference compounds, except for entry 5 in which a single compound was isolated.
[‡]The yield of **3** ($PhCOCH_2SO_2Me$) is based on 59% of **1** being recovered.
[§]Entry 2, solvent was DMF–EtOH = 4:1 v/v; entries 6,7 = 2:1; entry 9 = 1:1 dichloromethane–ethanol.
[‖]The yield of **3** is based on 78% of **2** being recovered.
[¶]The reagent was triethylammonium benzene sulfinate, see Experimental.
**DCM = dichloromethane.
[††]The yield of **3** is based on 85% of **2** being recovered.
[‡‡]The yields of **3** and **8** are based on 29% of **2** being recovered.

producible, yet yielded a complex mixture of products that was not readily amenable to analysis. Further work in this area is required.

The reactions of **2** with hard nucleophiles paralleled those with alkoxides (4). In each case, only cleavage products were observed, corresponding to preferred attack at the carbonyl carbon.

Reactions with sulfinate salts

The sulfinate anion is especially interesting since it is an ambident nucleophile, with a soft center on sulfur and a hard center on oxygen (14–16). It has a significant affinity for electrophilic carbon (17), although it has been used to reduce α-halosulfones (18). Our results, obtained from carrying out the reaction under a wide range of conditions, are presented in Table 3. Two facts stand out: (*a*) the predominant reaction is reduction, as found previously for α-halosulfones (18); (*b*) in ethanol (entry 3), attack at the carbonyl is competitive since the cleavage product, ethyl benzoate (**7**), was present in the product mixture.

The reduction of bromo compound **1** (entry 1) was more facile than that of chloro compound **2** (entry 4), as would be expected if reaction is occurring by attack at the halogen. Reaction was only really effective in more polar solvents, even when a solubilizing counterion (entry 8) was used. Similar reductions of active halogen compounds by sulfinate anions have in fact been known for many years (19).

If a sulfinate anion attacked an active halogen atom at sulfur the product would be a sulfonyl halide (eq. [5]). It was thus rather surprising to find that the sulfur-containing products in

$$[5] \quad R{-}SO_2^- + Cl{-}Z \rightarrow R{-}SO_2{-}Cl + :Z^-$$

Table 3, entries 2, 6, 7, and 9, were sulfinate rather than sulfonate esters. The origin of these sulfinate esters was determined when we investigated the reaction of sodium arylsulfinates with arylsulfonyl chlorides in mixed DMF–alcohol solvents, the major product being the alkyl arylsulfinate esters. The relatively unstable oils were characterized by independent syntheses using the classical route through the sulfinyl chlo-

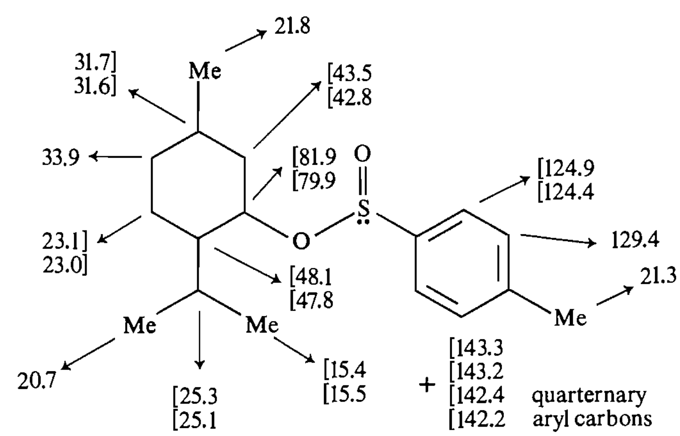

FIG. 1. (−)-Menthyl *p*-toluenesulfinate, **12**, with ^{13}C chemical shifts expressed as δ values.

rides. Spectral properties of the sulfinate esters synthesized by the two routes were identical; especially interesting were the ^{1}H nmr spectra of the ethyl sulfinate esters, which showed their methylene absorptions as classic 16-line patterns of an ABX_3 system (20). At 80 MHz these showed as two pairs of separated double quartets, but all the lines were not separated at 60 MHz. The ^{13}C nmr spectrum of the (−)-menthyl sulfinate (see Fig. 1) provided clear evidence that the sample was a diastereomeric mixture. The assignments of the resonances in this spectrum were made by comparison with the literature assignment for the spectrum of (−)-menthol (21), which agreed very closely with our own spectrum of (−)-menthol. The infrared spectrum of our sample of ethyl *p*-toluenesulfinate was identical to that previously published (22). The fragmentation pattern of the sulfinate esters under electron impact was straightforward, with the expected $ArSO_2]^+$, $ArSO]^+$, $ArS]^+$, and $Ar]^+$ ions predominating. In the case of the ethyl esters, the McLafferty rearrangement ions, $ArSO_2H]^{+\bullet}$, were important also.

We propose therefore that the sulfinate esters observed in entries 2, 6, 7, and 9 are formed by the reaction depicted in eq. [5], followed by two subsequent reactions (eqs. [6], [7]).

[6] $Ar \cdot SO_2 \cdot Cl + Ar \cdot SO \cdot O^- \rightarrow Ar \cdot SO_2 \cdot O \cdot SO \cdot Ar$ (**10**)

[7] **10** + $ROH \rightarrow ArSO_3H + RO \cdot SO \cdot Ar$

The attack by $ArSO_2^-$ at oxygen on the sulfur of the sulfonyl chloride would lead to an intermediate mixed anhydride **10**.[4] This species would be susceptible to nucleophilic attack at the sulfinyl sulfur (25), thus leading to sulfinate esters as depicted in eq. [7]. These reactions provide an elegant example of the ambidence of the sulfinate anion, with two nucleophilic centers having differing degrees of hardness. The reactions may, under certain circumstances, have some preparative merit and they appear to be of comparable convenience to a recently reported synthesis of sulfinate esters (26).

Two further points merit comment. Kohler and MacDonald (27) found that sodium *p*-toluenesulfinate and an arylsulfonyl chloride reacted in water–ether to give an α-disulfone, albeit in an unspecified yield.[5] We believe that this reaction also proceeds through **10**, which could undergo thermal rearrangement to an α-disulfone. Indeed, α-disulfones were a persistent minor contaminant in all our reactions leading to the sulfinate esters, but the formation of these disulfones was not efficient even if the sulfinate salt was warmed with the sulfonyl chloride in a solution of DMF.

The second point concerns the stability of aryl sulfinate esters. We have found these to be quite unstable at room temperature and were intrigued to find that the mass spectrum of a decomposed sample of ethyl *p*-toluenesulfinate, **11**, could readily be interpreted as resulting almost entirely from the disulfide **13** and the ethyl sulfonate ester **14**. The spectrum was very clean and the intensities of the isotope peaks for both molecular ions and for two fragment ions from **14** fitted their correct empirical formulae. There was apparently some *p*-toluenesulfonic acid present in the mixture also, although the evidence for this is less certain.

Thermal disproportionation reactions of sulfinate esters have been described by Müller and Schank (28), who found thiolsulfonates and disulfides as major products, these presumably being formed by the intermediacy of sulfenic acids. Apparently, the formation of sulfonate esters has not been described previously. The sulfonate likely derives from a nucleophilic attack of the sulfinate ester oxygen on the sulfur of a second ester molecule, leading to a sulfonate and sulfenate ester pair

[8] $2ArSO \cdot OR \rightarrow ArSO_2 \cdot OR + ArS \cdot OR$

(eq. [8]). Disproportionation reactions of sulfinate esters therefore merit further work.

Conclusions

The reactions of α-halo-β-ketosulfones described in this and in the previous (4) paper can be explained either by preferred attack of hard nucleophiles at the carbonyl group or by attack of soft nucleophiles at the halogen. With a suitable ambident nucleophile and solvent (cf. Table 3, entry 3) both processes can be observed, suggesting that the relative energy barriers are quite comparable. There does not seem to be any evidence for S_N2 attack at carbon. The results obtained, however, do not permit any assessment to be made whether the barrier for S_N2 attack has been raised vis-à-vis an alkyl halide, or whether the observed reactions occur because their activation energies are lowered as a result of structural features in α-halo-β-ketosulfones. Qualitative assessments of the reactions were assisted by the application of HSAB principles.

Experimental

General

Solvents were dried (usually 4 Å molecular sieves) or distilled as appropriate; THF was stored over P_2O_5, distilled from fresh P_2O_5, and then stored under nitrogen over $NaAlH_4$, from which it was freshly distilled before use. Sodium hydride (Alfa or Aldrich, 50% in oil dispersion) was washed several times with dry ligroin (bp 40–60°C) and dried *in vacuo*. The preparation of the halosulfones **1** and **2** has been described previously (4). For some experiments, sodium benzenesulfinate dihydrate was dried at 100°C/0.1 Torr (1 Torr = 133.3 Pa). Most reactions were carried out under a nitrogen atmosphere and volatile solvents were rotary evaporated before work-up; work-up was by pouring into water, appropriate adjustment of the pH, and extraction with dichloromethane; this extract was then washed with water, dried ($MgSO_4$), and evaporated. However, reactions performed in *N,N*-dimethylformamide (DMF) solvent were always extracted with diethyl ether, and then thoroughly washed with water to remove residual DMF. Since **3** is not very ether-soluble, recoveries by this procedure were not outstanding. Diethyl disulfide, **4** (Table 1, entries 6–9), was isolated by extracting the crude reaction products (after rotary evaporation) with ligroin (bp 40–60°C), which did not dissolve **1**–**3**.

Reduction of 2-chloro-2-methylsulfonyl-1-phenylethanone (**2**) *with sodium ethanethiolate in ethanol – typical procedure*

Freshly cut and washed sodium metal (263 mg) was dissolved in absolute EtOH (10 mL) to which was added EtSH (~1 mL, 12 mmol), followed by **2** (471 mg, 2 mmol). The resulting clear solution was stirred for 5 h (with protection from moisture) and rotary evaporated to an oil which was partitioned between dilute HCl and dichloromethane to give a colourless crystalline solid (290 mg, 72%), ^{1}H nmr identical to authentic **3**. Recrystallization (toluene) gave mp 105–107°C (lit. (4) mp 106–107°C).

Reaction of **2** *with sodium ethanethiolate in THF – typical procedure*

A solution of **2** (2 mmol) in dry THF (30 mL) was added under nitrogen to a solution of sodium ethanethiolate (4 mmol) in dry THF (20 mL), generated from NaH and EtSH. After stirring for 24 h, the solvent was rotary evaporated and the resulting oil triturated with ligroin (3 × 25 mL) to give diethyl disulfide (**4**) as a colourless oil (166 mg, 66% based on **2**). The residue was partitioned between dilute HCl and dichloromethane in the usual way to give an oil which solidified on standing (397 mg). Examination by tlc and ^{1}H nmr showed only $PhCOCH_2SO_2Me$ (**3**) and $PhCO \cdot CHSEt \cdot SO_2Me$ (**5**) to be present, in a molar ratio of 5:3. The identity of **5** was established by its preparation in an alternative manner (7).

The reaction of **2** *with sodium ethanethiolate in DMF – typical procedure*

The reaction was carried out as above, when THF was used as a solvent. After stirring for 24 h, the mixture was rotary evaporated at room temperature for 30 min before being partitioned between dilute HCl and ether in the usual way. The product was an oily solid (330 mg) that on careful examination by tlc and ^{1}H nmr was found to be a mixture of sulfone **3** and EtSSEt (**4**) in a molar ratio of 8:10. The identity of **4** was confirmed by comparison with an authentic sample using glc, and **3** could be washed free of **4** with ligroin for crystallization and comparison with an authentic sample; mp 105–106°C, (lit. (4) mp 106–107°C).

The reaction of **2** *with sodium phenylsulfinate – typical procedure*

A combination of **2** (465 mg, 2 mmol) and $PhSO_2Na \cdot 2H_2O$ (864

[4] Although sulfinic acid anhydrides $RSO \cdot O \cdot SOR$ (23) have been shown actually to be sulfinylsulfones $RSO \cdot SO_2R$ (22), the existence of species with structures very similar to **10** has to be invoked to explain the results of Kobayashi and Terao (24).

[5] A referee has pointed out that, for a number of years, this reported formation of α-disulfones has been known informally among some sulfur chemists to be incorrect; that these disulfones are formed in very poor yields was confirmed by the present work.

mg, 4.3 mmol) in a mixture of DMF (40 mL) and MeOH (20 mL) was stirred at room temperature under nitrogen for 72 h. Most of the methanol was removed by rotary evaporation; the solution was then poured into dilute HCl (200 mL, pH ~2) and extracted with diethyl ether (3 × 100 mL). Usual work-up gave a colourless oil (505 mg) that by tlc and ^{1}H nmr consisted of **3** (60%) and Ph·SO·OMe (**9**, 80% based on **2**). The sulfinate ester **9** was identified by its ^{1}H nmr (δ 3.50), coincident with the resonance of an authentic sample prepared by reacting PhSOCl (from $PhSO_2Na$ + $SOCl_2$) and MeOH in the presence of Et_3N. This was different from authentic Ph·SO_2·OMe (δ 3.77).

The preparation of triethylammonium phenylsulfinate

A solution of $PhSO_2Na\cdot 2H_2O$ (675 mg, 4 mmol) and triethylammonium chloride (585 mg, 4 mmol) in methanol was stirred at room temperature for 3 h. The solvent was removed by rotary evaporation and the syrupy residue was lixiviated with chloroform which was dried, filtered, and evaporated to a clear syrup; the ^{1}H nmr spectrum corresponded to a formulation of $PhSO_2\cdot HNEt_3$.

The reaction of sodium benzenesulfinate with benzenesulfonyl chloride in the presence of ethanol – the preparation of ethyl benzenesulfinate

Dried sodium benzenesulfinate (360 mg, 2.2 mmol) in dry DMF (10 mL) was added portionwise over a 20-min period to a stirred solution (N_2 atmosphere) of benzenesulfonyl chloride (0.29 mL, 2 mmol) in dry DMF (20 mL) and EtOH (5 mL). The reaction mixture was heated to 50°C for 15 min, poured into dilute NaCl solution, and worked up with ether in the usual way to give an oil that was lixiviated with ligroin (bp 40–60°C). The ligroin-soluble fraction gave ethyl benzenesulfinate (**8**) as a colourless oil (210 mg, 62%); ir (film) ν_{max}: 1135 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ (TMS): 1.27 (3H, t, J = 7.1 Hz), 3.73, 4.11 (2H of ABX_3, J_{AX} = 7.1 Hz, J_{AB} = 10.1 Hz), 7.4–7.9 (5H, m); ^{13}C nmr ($CDCl_3$) δ (TMS): 15.3 (—CH_2CH_3), 60.8 (—CH_2CH_3), 124.9 (*ortho* C), 128.7 (*meta* C), 131.8 (*para* C), 144.6 (quart. Ph *C*); ms m/z: 172 (4.1), 171 (8.0), 170 (77.1), 142 (50), 141 (38), 126 (14), 125 (100), 110 (31), 109 (27), 97 (14), 94 (24), 78 (62), 77 (92).

This oil was identical (^{1}H nmr and tlc) to the oil obtained by reacting PhSOCl (from $PhSO_2Na$ + $SOCl_2$) and EtOH in the presence of Et_3N.

The preparation of ethyl p-*toluenesulfinate (11)*

This was prepared from sodium *p*-toluenesulfinate and TsCl on a 2-mmol scale to give a 63% yield of a colourless oil; ir (film) ν_{max}: 1130 cm^{-1}, identical to the published spectrum (23); ^{1}H nmr ($CDCl_3$) δ (TMS): 1.25 (3H, t, J = 7 Hz), 2.41 (3H, s), 3.69, 4.06 (2H of ABX_3, J_{AX} = 7, J_{AB} = 10 Hz), 7.20–7.62 (4H AA′BB′, J_{AB} = 8 Hz); ^{13}C nmr ($CDCl_3$) δ (TMS): 15.2 (—CH_2—CH_3), 21.1 (CH_3—Ar), 60.4 (—O—CH_2—), 124.8 (—SO—C—*C*(Ar)), 129.3 (Me—C—*C*(Ar)), 141.6 (—SO—*C*(Ar)), 142.2 (Me—*C*(Ar)).

The preparation of (−)-menthyl p-*toluenesulfinate (12)*

This was prepared in DMF solvent as above, on a 2-mmol scale, except that the reaction was stirred for 24 h at room temperature. The product (**12**), after chromatography over silica gel with dichloromethane as the eluant, crystallized in fine colourless needles as a mixture of diastereomers, 300 mg, 51%; mp 104–106°C (lit. (27) mp 102–106°C);[6] for ^{13}C nmr, see Fig. 1.

The decomposition of ethyl p-*toluenesulfinate (11)*

A sample of **11** was left on the laboratory bench for 1 week, at which point it was a colourless semisolid that was devoid of **11**. The material gave a mass spectrum that could readily be assigned as m/z: 248 (10.0), 247 (17.1), 246 (100), 214 (2), 123 (57), and 91 (205) with m^* = 186 ($214^2/246$ = 186.2) arising from *p*-tolyl disulfide (**13**), and m/z: 202 (2.4), 201 (4.8), 200 (43.2), 174 (4.4), 173 (7.3), 172 (83.1), 157 (3.5), 156 (6.8), 155 (63.1), 108 (26), 107 (36), and 91 (205) with m^* = 67.2 ($108^2/172$ = 67.8 or $91^2/123$ = 67.3, see above) arising from ethyl *p*-toluenesulfonate (**14**); ions at m/z 244 (6) and 211 (2) could not be assigned. The ion at m/z 172 varied in intensity over several scans and could probably be assigned to some free *p*-toluenesulfonic acid in the mixture. No other ions above m/z 155 were detected.

[6] We thank Dr. J. Hoyle for assistance with this experiment.

No morphinan analog carrying a heteroatom other than nitrogen at position 17 has yet been synthesized. The synthesis of the position 17 sulfur analog of the perchlorate salt of (±)-isolevorphanol is described. The strategy adopted is based on the classical Grewe synthesis of morphinans and, under narrowly defined conditions, the title compound isosulforphanol (**3***a*) and an intermediate by-product **13** resulting from an unusual non-bridged head ring closure of **11***a* were obtained. The X-ray structures of both **3***a* and **13** were determined. Crystals of **13** ($C_{17}H_{22}OS$) are monoclinic, space group $P2_1/a$, $a = 17.080(2)$, $b = 9.372(1)$, $c = 9.327(1)$ Å, $\beta = 108.67(1)$, $V = 1414.4$ Å^3, $Z = 4$. Final $R = 0.034$ for 2545 reflections. The crystals of **3***a* ($C_{17}H_{23}OS^+ \cdot ClO_4^-$) are orthorhombic, space group $Pna2_1$, $a = 10.934(1)$, $b = 9.219(1)$, $c = 17.131(2)$ Å, $V = 1726.8$ Å^3, $Z = 4$. Final $R = 0.053$ for 1018 reflections. The $C_{17}H_{23}OS^+$ molecule has been identified by this X-ray analysis as *S*-methyl isosulforphanol (Fig. 2). The structure of **13** is shown in Fig. 1. The stereochemical outcome of the Grewe-like synthesis is thus established as proceeding in a reversed manner when sulfur replaces the nitrogen in the final cyclization step. Preliminary pharmacological studies showed that **3***a* is a potent agonist in the central nervous system but a potent antagonist on the guinea-pig ileum.

BERNARD BELLEAU, UGO GULINI, BARBARA GOUR-SALIN et F. R. AHMED. Can. J. Chem. **63**, 1268 (1985).

Jusqu'à maintenant, aucun analogue de la morphinane portant un hétéroatome autre que l'azote en position 17 n'a été synthétisé. On décrit la synthèse d'un analogue portant un atome de soufre en position 17; il s'agit du perchlorate du (±)-isolévorphanol. La stratégie adoptée se base sur la synthèse classique des morphinanes développée par Grewe et, utilisant des conditions étroitement définies, on a obtenu le composé isosulforphanol (**3***a*) mentionné dans le titre ainsi qu'un sous-produit intermédiaire (**13**) provenant d'une cyclisation inhabituelle du composé **11***a* à une position différente de la tête de pont. Faisant appel à la diffraction des rayons-X. On a déterminé les structures des deux composés **3***a* et **13**. Les cristaux du composé **13** ($C_{17}H_{22}OS$) sont monocliniques et appartiennent au groupe d'espace $P2_1/a$ avec $a = 17{,}080(2)$, $b = 9{,}372(1)$, $c = 9{,}327(1)$ Å, $\beta = 108{,}67(1)$, $V = 1414{,}4$ Å^3, $Z = 4$. On a obtenu une valeur de R de 0,034 pour 2545 réflexions. Les cristaux du composé **3***a* ($C_{17}H_{23}OS^+ \cdot ClO_4^-$) sont orthorhombiques et appartiennent au groupe d'espace $Pna2_1$ avec $a = 10{,}934(1)$, $b = 9{,}219(1)$, $c = 17{,}131(2)$ Å, $V = 1726{,}8$ Å^3 et $Z = 4$. On a obtenu une valeur finale de R de 0,053 pour 1018 réflexions. L'analyse par rayons-X de la molécule de $C_{17}H_{23}OS^+$ a permis de l'identifier comme étant le *S*-methyl isosulforphanol (fig. 2). La figure 1 illustre la structure du composé **13**. On a ainsi établi que le résultat stéréochimique de la synthèse de Grewe est inversé lorsqu'on remplace l'azote par le soufre dans l'étape finale de cyclisation. Des études pharmacologiques préliminaires indiquent que le composé **3***a* est un agoniste potentiel dans le système nerveux central mais un antagoniste potentiel dans l'iléum du cochon d'inde.

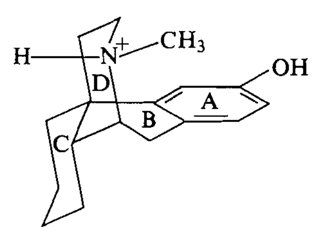
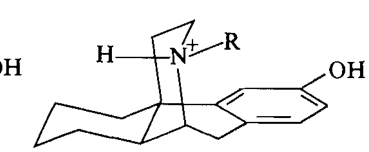
Introduction

A decade ago we reported the surprising observation that structurally induced pyramidal inversion about the basic nitrogen of the potent narcotic analgesic levorphanol (**1**) suppressed its in vivo activity (1). The idea that the nitrogen lone-pair directionality in levorphanol (**1**) and analogous narcotic analgesics is a stereoselective determinant of productive interaction with the morphine receptor was put forward, and the most obvious implication of this stereoelectronic parameter centers on the ability of the N lone pair to act as a proton acceptor and (or) donor at physiological pH (1), the rest of the molecule serving as a selective carrier of this pivotal atom (2). Although the quality of the receptor response can sometimes be modulated by geometrical inversion to the isomeric planar stereochemistry as in **2**, the available evidence based on studies with several analogs (3) allows the firm conclusion that affinity for the receptor can be favoured equally well by the flattened main skeleton of the isomorphinans (**2**).



1



2

In recent years, a number of publications have appeared which purport to demonstrate that the N lone-pair directionality as we perceived it (1) would be unimportant in the receptor recognition process (4–6). However, in all these cases the morphinan analogs studied either exhibited very weak activity (5, 6) or were "so toxic that the observed activity was equivocal" (4).

In an effort to clarify further the stereoelectronic role on activity of the N lone pair of morphinan related compounds, we undertook the synthesis of the sulfonium analogs **3***a* and **3***b* which, for convenience, shall be referred to as *S*-methyl isosulforphanol and *S*-methyl sulforphanol respectively. In the

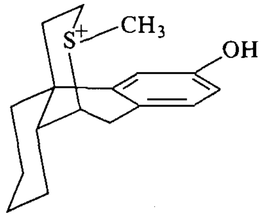
3*a*



3*b*

stereoelectronic and physico-chemical sense, sulfonium ions are, for the purpose of electrostatic pairing, close relatives of protonated tertiary amines and not of quaternary nitrogen compounds. Therefore, we hoped that pharmacological studies with the sulfonium analogs 3*a* and 3*b* would help in the clarification of the separate roles of ion pairing and of hydrogen bond complex formation at the counter-acceptor site level of the morphine receptor.

The purpose of this report is to describe a synthetic route leading exclusively to stereochemistry 3*a*. A non-morphinan-like side product of structure **13** was also obtained. A following paper will describe an alternate methodology allowing the generation of both 3*a* and 3*b*.

The commercial Grewe synthesis (7) of levorphanol (8–10) (**1**) provides a conceptual basis for the construction of the ring system of **3**. However, the scheme as applied to levorphanol (**1**) has not been previously tested with a relevant sulphur analog and special experimental methodologies had to be introduced for the successful production of the sulphur-containing ring system.

Results and discussion

The synthesis of *S*-methyl isosulforphanol (3*a*) was carried out as summarized in Scheme 1.

The nitrile group of 1-cyclohexen-1-yl acetonitrile (**4**) (11) was hydrolyzed with aqueous sodium hydroxide to yield the known acid (**5**) in 85% yield. Lithium aluminum hydride reduction of the acid functionality led cleanly to the alcohol (**6**) which was treated with *p*-toluenesulfonyl chloride to yield **7** in 72% yield. The latter tosylate was reacted with potassium thioacetate in dry THF to give 2-(cyclohexen-1-yl)ethanethiol acetate (**8**) in 85% yield after purification by distillation. The thiol acetate functionality of **8** was cleaved with sodium methoxide in methanol at room temperature to yield the free thiol **9**, which was reacted with *p*-methoxyacetaldehyde (**10**) (12) in a mixture of trifluoroacetic acid and acetic acid at room temperature to yield a mixture of double bond isomers of intermediate **11** in 37% yield. These experimental conditions appeared critical and are unlike those employed in the nitrogen series. Reaction of the latter with anhydrous hydrogen fluoride at −78°C, followed by chromatographic purification of the crude product, afforded a 34% yield of 3-methoxy-17-deaza-17-thiaisomorphinan (**12**) and a 5% yield of the isomeric ring structure (**13**). It is worth noting that, in our hands, the success of this reaction was critically dependent on the use of hydrogen fluoride as solvent and catalyst. Boron tribromide treatment of **12** at −78°C led to 3-hydroxy-17-deaza-17-thiaisomorphinan (**14**), which was converted to the methyl iodide salt (**15**) in 88% yield by reaction with methyl iodide in acetonitrile at room temperature. Anion exchange processing yielded (±)*S*-methyl isosulforphanol perchlorate (3*a*) whose nmr spectrum in chloroform indicated that only one geometrical isomer was present. The assigned structure 3*a* and that of the by-product **13** were elucidated by X-ray diffraction analysis.

Crystal structure analysis

(a) *Data measurement (Tables 1–4)*

Crystal data for $C_{17}H_{22}OS$ (**13**) and the *S*-methyl isosulforphanol perchlorate, $C_{17}H_{23}OS^+ \cdot ClO_4^-$ (3*a*), are presented in Table 1. The X-ray measurements were carried out on a Nonius

CAD-4 diffractometer using Ni-filtered Cu radiation. While crystals of **13** were well formed and of good size, those of **3*a*** were minute and poorly formed; hence, data collection for **13** was taken to 2θ = 150° while that for **3*a*** was limited to 2θ = 130°. The cell parameters were derived by a least-squares fit to the angular settings of 22 reflections with 84 < 2θ < 148° for **13**, and 20 reflections with 52 < 2θ < 88° for **3*a***. The intensities were measured in the ω–2θ scan mode for the ranges stated in Table 1, and extended by 25% at each side for the background measurements. Three standard reflections measured after every hour of exposure time varied within ±1.3% of their mean values. The net intensities were corrected for scale variations, Lorentz and polarization effects, and for absorption by Gaussian integration. The absorption corrections were in the range 1.206–2.597 for **13** and 1.109–2.467 for **3*a***.

(b) *Structure determination*

Structure **13** was determined by the direct method of symbolic addition (13). All the non-hydrogen atoms were observed in the *E* map and, after partial refinement of their parameters, the H atoms were located from a difference Fourier map. Refinement of the atomic coordinates and anisotropic thermal parameters (isotropic for H) and a scale factor, constituting a total of 260 parameters, was by block-diagonal least squares, minimizing $\Sigma w(F_o - F_c)^2$ with $w = \{1 + [(|F_o| - 3)/25]^2\}^{-1}$ and excluding the unobserved reflections as well as four strong ones (020, 320, 400, and 20$\bar{1}$) showing extinction effect.

Structure **3*a*** was determined by the heavy atom method, using a Patterson and three Fourier syntheses for location of the non-hydrogen atoms. The H atoms were located from a difference map at a later stage. Refinement was as described for **13**, except that the weights were calculated according to the expression $w = \{1 + [(|F_o| - 10/30]^2\}^{-1}$; the *z* coordinate for Cl was fixed to define the origin along the *z* axis, and the H parameters were not refined, so that the number of refined parameters was 216. The (020) reflection which showed an extinction effect was excluded.

The scattering factor curves were from refs. 14 and 15, and all calculations were performed with the aid of the NRC program system (16) and ORTEP (17). The final atomic coordinates and equivalent isotropic thermal parameters are listed in Tables 2 and 3.[2]

[2] The structure factor tables, parameters for the H atoms, and anisotropic thermal parameters for the non-hydrogen atoms are available, at a nominal charge, from the depository of unpublished data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

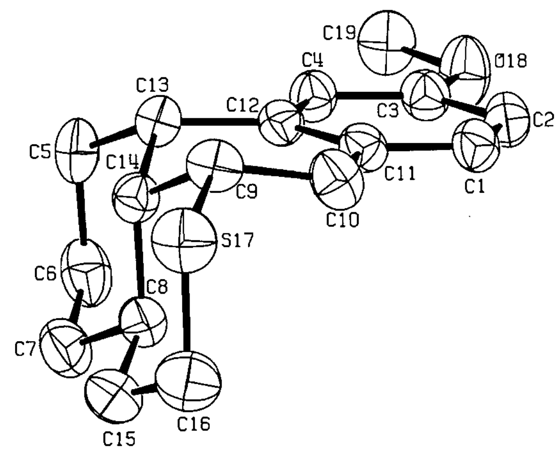

FIG. 1. A view of the molecular structure of $C_{17}H_{22}OS$ (**13**) showing the conformation and atom numbering. The thermal ellipsoids are drawn at 50% probability and the H atoms have been omitted.

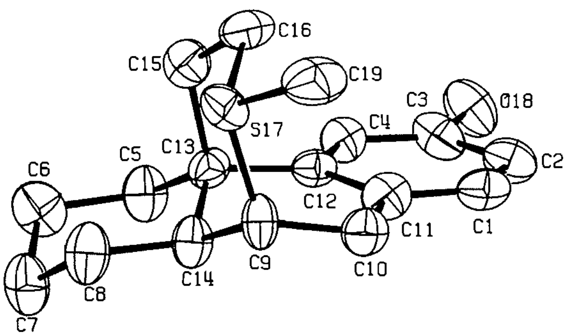

FIG. 2. A view of the molecular structure of $C_{17}H_{23}OS^+$ (*3a*) showing the conformation and atom numbering. The thermal ellipsoids are drawn at 50% probability and the H atoms have been omitted. This view is for the opposite enantiomorph of the coordinates listed in Table 3.

Structural analyses

The molecular conformations and atom numbering for compounds **13** and **3***a* are presented in Figs. 1 and 2, respectively. Whereas the piperidine ring in levorphanol is fused along the C(9)—C(14) and C(13)—C(14) bonds, the $C_{17}H_{22}OS$ product shown in Fig. 1 has the corresponding ring fused at C(9)—C(14) and C(8)—C(14). Also, the methyl group which is substituted at N(17) in levorphanol is found to be substituted instead at O(18). These anomalies, however, are not present in molecule **3***a* (Fig. 2), which is shown to possess the correct *S*-methyl isosulforphanol structure.

The bond lengths and valence angles for compounds **13** and **3***a* are listed in Table 4. Equivalent bond lengths in the two molecules are comparable, with the largest difference of 0.032(11) Å in the C(3)—O(18) bond being insignificant at the 0.1% probability level. However, six pairs of equivalent valence angles show significant differences of 3.3(8)–5.2(6)° with the largest difference occurring at C(10)—C(9)—S(17) and C(14)—C(9)—S(17), probably as a result of the differences in molecular conformations. In both molecules the endocyclic angle C(9)—S(17)—C(16) is 99.0 ± 0.4°, which is considerably smaller than the normal tetrahedral angle of 109.7°.

The aromatic ring is planar; χ^2 (= $\Sigma\Delta^2/\sigma^2$) is 7.7 for molecule **13** and 11.1 for **3***a*. The adjacent ring has nearly the same conformation in both molecules with insignificant differences (within ±1.3°) in the corresponding torsion angles. The absolute values of the torsion angles in the sulfonium ring and the remaining ring are 52.5(2)–61.1(2)° and 53.4(2)–57.1(s)° for molecule **13**, compared to 58.7(7)–67.0(8)° and 50.6(10)–58.2(11)° for molecule **3***a*, respectively.

While there are no short intermolecular interactions in the crystals of compound **13**, there is a short contact in **3***a* of 2.789(12) Å between the hydroxyl O(18) and O(3) of the perchlorate group, indicative of a possible hydrogen bond between them.

These structural analyses establish that the substitution of a basic nitrogen by a sulfur in a Grewe-like process for morphinan synthesis unexpectedly leads to a complete reversal of the B/C ring junction stereochemistry of the product. The *trans*-geometry of the resulting sulforphan **12** can hardly be attributed to the different nature of the Friedel–Crafts catalyst (hydrogen fluoride); rather, it is likely that the longer C—S bonds (>1.8 Å) relative to the C—N bonds of morphinans serve to relieve 1,3-axial compressions between the ring D sulfur atom and the ring C hydrogens, thus reversing the thermodynamic stability of the transition states leading respectively to morphinans and sulforphans.

The unexpected formation of the polyhydro-thiabenzanthracene by-product **13** is best explained by the involvement of a double bond isomerization of **11***a* followed by direct electrophilic attack of the phenyl ring. This implies the intermediacy of a secondary carbonium ion intermediate which probably accounts for the very low yield (~5%) of product.

The sulfonium analog **3***a* (isosulforphanol) was tested as the perchlorate salt for its effect on the opiate receptors of the guinea-pig ileum (GPI) longitudinal muscle, the mouse *vas deferens*, and the central nervous system (CNS) of hooded rats by the intracerebroventricular route of administration. The results, which have been recently reported in preliminary form (18), showed that analog **3***a* displays marked affinity for the opiate receptor while inducing divergent effects in the GPI and the CNS respectively. The mechanistic significance of these observations is under active investigation.

Experimental

General

Melting points and distillation temperatures are uncorrected. Infrared spectra were recorded on a Perkin–Elmer model 297 spectrophotometer. Proton nuclear magnetic resonance (^1H nmr) spectra were measured using a Varian XL-200 spectrometer. Tetramethylsilane was employed as the internal standard for all compounds. Mass spectrometric measurements were recorded on Dupont 21-492B or LKB 9000 mass spectrometers.

2-(1-Cyclohexen-1-yl) acetic acid (5)

1-Cyclohexen-1-yl acetonitrile (**4**) (50 g, 0.415 mol) and sodium hydroxide (30 g, 0.075 mol) were dissolved in H_2O (300 mL) and heated at reflux for 20 h. The reaction mixture was extracted with chloroform (3 × 75 mL) to remove any unwanted side products. The remaining aqueous layer was acidified and again extracted with chloroform (3 × 75 mL). The combined extracts were dried and solvent removed *in vacuo* to yield a green oil which was distilled (bp 155–157°C/20 Torr; 1 Torr = 133.3 Pa) to give 49 g (0.35 mol, 85% yield) of a white waxy solid, mp ≈ 26°C; ir ($CHCl_3$): 2920, 1700 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.56–1.92 (m, 4H), 2.00–2.18 (m, 4H, allylic), 3.00 (s, 2H, CH_2COO), 5.71 (s, 1H, C=CH), 8.00 (br s, 1H, COOH); *m/e*: 111 (M^+ − COOH, base peak).

in dry ether (30 mL) was added dropwise to a suspension of $LiAlH_4$ (2.8 g, 0.074 mol) in dry ether (20 mL) under N_2. After the addition had been completed the reaction mixture was allowed to stir under N_2 for an additional 1.5 h. The remaining unreacted $LiAlH_4$ was decomposed by the dropwise addition of water. The reaction mixture was slowly added to a 1 *N* aqueous solution of HCl (100 mL). The ether layer was removed and the remaining aqueous layer extracted with ether (3 × 75 mL). The combined organic extracts were dried and the ether removed *in vacuo*. The residue was distilled (bp 101–102°C/20 Torr) to yield 7.16 g (0.57 mol, 80% yield) of a colorless oil; ir ($CHCl_3$): 3610 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.58–1.80 (m, 4H), 1.96–2.15 (m, 4H, allylic), 2.26 (m, 2H, = —CH_2), 3.54 (s, 1H, OH), 3.68 (t, 2H, *J* = 4 Hz, CH_2O), 5.56 (s, 1H, C=CH); *m/e*: 126 (M^+), 108, 79 (base peak).

2-(1-Cyclohexen-1-yl)ethanol tosylate (7)

2-(1-Cyclohexen-1-yl)ethanol (**6**) (9.0 g, 0.071 mol) was dissolved in dry pyridine (50 mL) and cooled to 0°C. A solution of *p*-toluenesulfonyl chloride (15 g, 0.079 mol) in dry pyridine (75 mL) was added at 0°C and the reaction mixture was sitrred at 0°C for 2 h. After a further 24 h at 0°C the solution was poured into a solution of ice-water (300 g) and extracted with methylene chloride (3 × 75 mL). The combined organic extracts were washed with cold 10% aqueous HCl (6 × 50 mL) to remove any pyridine. The organic layer was dried and the solvent removed *in vacuo*. Low temperature recrystallization yielded 14.2 g (0.051 mol, 72.3% yield) of a white solid; mp ≈ 23°C; ir ($CHCl_3$): 2940, 1600, 1360, 1170, 970, 930 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.4–1.5 (m, 4H), 1.53–1.9 (m, 4H, allylic), 2.2–2.3 (m, 2H, = —CH_2), 2.41 (s, 3H, $ArCH_3$), 4.05 (t, 2H, *J* = 2 Hz, CH_2O), 5.37 (br s, 1H, =CH), 7.33, 7.75 (ABq, 4H, *J* = 4 Hz, ArH); *m/e*: 280 (M^+), 200, 155, 109 (base peak).

2-(1-Cyclohexen-1-yl)ethanethiol acetate (8)

2-(1-Cyclohexen-1-yl)ethanol tosylate (**7**) (16 g, 0.057 mol) was dissolved in dry THF (150 mL) and a solution of potassium thioacetate (25 g, 0.23 mol) in dry THF (200 mL) was added. The reaction mixture was heated at reflux for 2 h and the THF was removed *in vacuo*. The residue was dissolved in H_2O (100 mL) and extracted with methylene chloride (3 × 75 mL). The combined organic extracts were dried and the solvent removed *in vacuo*. The yellow oil was purified by distillation (bp 113°C/5 Torr) to yield 8.97 g (0.049 mol, 85.5% yield) of a pale yellow oil; ir (neat): 1690, 1435, 1350, 1120, 950, 620 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.4–1.64 (m, 4H), 1.94–1.98 (m, 4H, allylic), 2.12–2.20 (m, 2H, = —CH_2), 2.28 (s, 3H, $C(O)CH_3$), 2.91 (t, 2H, *J* = 4 Hz, CH_2S), 5.44 (s, 1H, =CH); *m/e*: 184 (M^+), 108 (base peak). *Anal.* calcd. for $C_{10}H_{16}OS$: C 65.17, H 8.75; found: C 65.39, H 8.75.

2-(1-Cyclohexen-1-yl)ethanethiol (9)

Methanol (50 mL) was degassed by passing N_2 through the solution. Sodium (1.44 g, 0.063 mol) was added and the solution stirred until all the sodium had dissolved. A solution of 2-(1-cyclohexen-1-yl)-ethanethiol acetate (4.4 g, 0.024 mol) in dry THF (10 mL) was added and the reaction mixture was stirred under N_2 for 4 h. The solution was diluted with saturated aqueous NaCl (100 mL) and the pH adjusted to 4 with 10% aqueous citric acid. The aqueous layer was extracted with ether (4 × 75 mL). The combined organic extracts were dried and the solvent removed *in vacuo*. The residue was distilled (bp 116°C/45 Torr) to give 0.065 g (0.0455 mol, 72.3% yield) of a colorless oil; ir (neat): 2900, 1440, 720 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.34–1.39 (m, 1H, SH), 1.51–1.65 (m, 4H, CH_2CH_2), 2.53–2.59 (m, 2H, CH_2S), 5.46 (br s, 1H, C=CH); *m/e*: 142 (M^+, base peak), 126, 108. *Anal.* calcd. for $C_8H_{14}S$: C 67.54, H 9.91; found: C 67.32, H 9.80.

p-*Methoxyacetaldehyde (10) (ref. 12)*[3]

4-Allylanisole (5 mL) was added to a vigorously stirred solution of aqueous H_2O_2 (30%, 37 mL, 1.2 mol) and aqueous formic acid (90%, 160 mL, 4.2 mol) and the reaction mixture was heated to 40°C. The temperature was maintained between 40 and 45°C by heating or cooling as necessary while a further 35 mL of 4-allylanisole (0.26 mol) was added dropwise. The reaction mixture was stirred overnight at room temperature and evaporated to dryness *in vacuo*. To the remaining red residue was added aqueous NaOH (37%, 45 mL), at 45°C, and H_2O (65 mL). The solution was heated to 50°C for 1 h. After cooling, concentrated HCl (33 mL) was added and the aqueous layer extracted with $CHCl_3$ (3 × 75 mL). The combined organic extracts were dried, filtered, and the solvent removed *in vacuo*. The residue was purified by distillation (bp 150–152°C/25 Torr) through an air-cooled condenser to afford 29.8 g (0.16 mol, 63% yield) of 1,2-dihydroxy-3-(4-methoxyphenyl)propane; ir ($CHCl_3$): 3400, 2930, 1610, 1505 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 2.6 (d, 2H, J = 4 Hz, CH_2Ar), 3.4 (m, 1H, CHO), 3.5–3.8 (m, 2H, CH_2O), 3.7 (s, 3H, OCH_3), 4.1 (br s, 1H, OH), 6.78 (d, 2H, J = 4 Hz, ArH), 7.1 (d, 2H, J = 4 Hz, ArH); *m/e*: 182 (M^+), 148, 121 (base peak).

1,2-Dihydroxy-3-(4-methoxyphenyl)propane (22.3 g, 0.12 mol) was dissolved in dry benzene (1250 mL). One-tenth of the solvent (125 mL) was distilled off under N_2 and, after cooling, one equivalent of lead tetraacetate (55.4 g, 0.12 mol) was added and the mixture stirred at room temperature overnight. The suspension was poured onto H_2O (1000 mL) and the lead oxides removed by filtration through Celite. The aqueous layer was separated, the organic layer washed with H_2O (2 × 500 mL), saturated $NaHCO_3$ (1 × 500 mL), and then dried, filtered, and concentrated *in vacuo*. The residue was distilled (bp 76–77°C/0.25 Torr) to yield 8.3 g (0.06 mol, 45% yield) of *p*-methoxyacetaldehyde as a yellow liquid; ir (neat): 1720, 1670, 1580, 1510 cm^{-1}; ^1H nmr (CD_2Cl_2) δ: 3.48 (br s, 2H, CH_2O), 3.7 (s, 3H, OCH_3), 6.8–7.1 (m, 4H, ArH), 9.6 (br s, HCO); *m/e*: 150 (M^+), 121 (base peak).

*1-(*p*-Methoxybenzyl)-3,4,5,6,7,8-hexahydro-1*H*-isobenzothiapyran (11*a*)*

2-(Cyclohexen-1-yl)ethanethiol (**9**) (3.5 g, 0.025 mol) was dissolved in acetic acid (6 mL) and the solution added dropwise to a stirred solution of the preceding *p*-methoxyphenylacetaldehyde (9.2 g, 0.061 mol) in trifluoroacetic acid (12 mL) and acetic acid (6 mL) under argon at room temperature. The reaction mixture was stirred for 20 h and then poured onto ice-water (50 mL) and the mixture neutralized with saturated sodium bicarbonate solution. The aqueous layer was extracted with ether (3 × 75 mL), the combined extracts dried, and the solvent removed *in vacuo* to yield a yellow oil which was purified by flash chromatography (8 in. × 1 in. silica gel 60 (230–400 mesh)) using petroleum ether/ethyl acetate 50:1 (v/v) as the eluent to give 1.2 g (4.69 mmol) of **11***a* and 0.6 g (2.34 mmol) of **11***b* (28.1% yield overall); ir (**11***a*) (neat): 2920, 1610, 1510, 1240, 750 cm^{-1}; ^1H nmr (**11***a*) ($CDCl_3$) δ: 1.0–3.0 (complex m, 15H), 3.75 (s, 3H, OCH_3), 6.8 (d, 2H, J = 4 Hz, ArH), 7.1 (d, 2H, J = 4 Hz, ArH); *m/e* (**11***a*): 274 (M^+), 153, 83 (base peak). *Anal.* calcd. for $C_{17}H_{22}OS$: C 74.40, H 8.08; found: C 74.36, H 8.01. Infrared (**11***b*) (neat): 2920, 1610, 1510, 1240, 750 cm^{-1}; ^1H nmr (**11***b*) ($CDCl_3$) δ: 1.0–3.0 (complex m, 14H), 3.75 (s, 3H, OCH_3), 5.6 (br s, 1H, =CH), 6.8 (d, 2H, J = 8.6 Hz, ArH), 7.1 (d, 2H, J = 8.55 Hz, ArH); *m/e* (**11***b*): 274 (M^+), 83 (base peak).

3-Methoxy-17-deaza-17-isothioamorphinan (12)

The isomers of **11** (1.8 g, 7.03 mmol) were dissolved in anhydrous HF at −78°C. The reaction mixture was allowed to warm to room temperature and stirred for an additional 24 h. The HF was evaporated and the remaining residue dissolved in ether. The ethereal solution was washed several times with water, dried, and the solvent removed *in vacuo*. The red-colored residue was purified by flash chromatography (8 in. × 1 in. silica gel 60 (230–400 mesh)) using petroleum ether/ethyl acetate 50:1 (v/v) to give 0.61 g (2.2 mmol), 34% yield of **12** (mp 73–74°C) and 0.1 g (0.36 mmol), 5.1% yield of **13**; mp 134–135°C; ir (**12**) (KBr disc): 1610, 1570, 1490, 1420, 1280, 1040, 800, 590 cm^{-1}; ^1H nmr (**12**) ($CDCl_3$) δ: 1.2–2.8 (complex m, 14H), 3.24 (d, 1H, J = 8 Hz, CHAr), 3.8 (s, 3H, OCH_3), 6.7–7.0 (m, 4H, ArH); *m/e* (**12**): 274 (M^+), 213 (base peak). *Anal.* calcd. for $C_{17}H_{22}OS$: C 74.40, H 8.08; found: C 74.61, H 8.17. Infrared (**13**) (KBr disc): 2930, 1610, 1500, 1260, 1230, 1040, 800 cm^{-1}; ^1H nmr (**13**) ($CDCl_3$) δ: 0.8–3.2 (complex m, 16H), 3.7 (s, 3H, OCH_3), 6.8–7.2 (m, 3H, ArH); *m/e* (**13**): 274 (M^+, base peak). The X-ray of this compound is shown in Fig. 1.

3-Hydroxy-17-deaza-17-isothiamorphinan (14)

3-Methoxy-17-deaza-17-isothiamorphinan (**12**) (0.59 g, 2.14 mmol) was dissolved in dry methylene chloride (20 mL) at −78°C under argon. A solution of BBr_3 (0.342 mL in 3 mL CH_2Cl_2) was added at −78°C and the reaction allowed to warm to room temperature. After 17 h the solution was poured onto H_2O (50 mL) and the organic layer collected. The aqueous layer was extracted with methylene chloride (3 × 50 mL) and the combined organic extracts were dried and the solvent removed *in vacuo*. The residue was purified by flash chromatography (1 in. × 4 in. silica gel 60 (230–400 mesh)) using chloroform as the eluent to yield 0.47 g (1.82 mmol, 85.6% yield) of white crystals; mp 177–178°C; ir (KBr disc): 3290, 2910, 1620, 1580, 1500, 1285 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.1–2.8 (m, 14H), 3.25 (d, 1H, J = 8 Hz, J = 3 Hz, CHAr), 4.6 (s, 1H, OH), 6.6–7.1 (m, 3H, ArH); *m/e*: 260 (M^+), 57 (base peak). *Anal.* calcd. for $C_{16}H_{20}OS$: C 73.80, H 7.74; found: C 73.98, H 7.70.

3-Hydroxy-17-deaza-17-isothiamorphinan-17-methyl onium iodide (15)

3-Hydroxy-17-deaza-17-isothiamorphinan (0.155 g, 0.596 mmol) was dissolved in CH_3CN (1.5 mL) containing methyl iodide (4 mL). The reaction mixture was allowed to stand for 20 h and dry ether was added to maximum precipitation of white crystals of the iodide salt. These were collected, washed with dry ether, and dried *in vacuo* to yield 0.210 g (5.22 × 10^{-1} mmol, 88% yield) of white crystals; ir (KBr disc): 3260, 2930, 1615, 1490, 1290 cm^{-1}; ^1H nmr ($CDCl_3/CF_3COOH$) δ: 1.0–4.0 (m, 16H), 2.95 (s, 3H, SCH_3), 6.7–7.2 (m, 3H, ArH); *m/e*: 260 ($M^+ - CH_3I$), 142 (CH_3I, base peak). *Anal.* calcd. for $C_{17}H_{23}IOS$: C 50.75, H 5.76; found: C 50.61, H 5.57.

S-*Methyl isosulforphanol perchlorate (3a)*

A methanol solution of the preceding salt (**15**) (0.210 g, 0.52 mmol) was passed through an anion exchange column in the perchlorate form (prepared as described below) to yield a methanol solution of *S*-methyl isosulforphanol perchlorate. Removal of the solvent yielded 0.154 g (0.412 mmol, 79% yield) of white crystals. The product was recrystallized from CH_3CN/hexane to give 0.132 g (0.352 mmol, 67.5% yield) of long white needles. Nuclear magnetic resonance analysis indicated only one type of methyl group was present; ir (KBr disc): 3350, 1610, 1100 (ClO_4^-), 620 (ClO_4^-) cm^{-1}; ^1H nmr (CD_3CN)

[3] Experimental details previously unreported in this reference.

δ: 1.1–4.0 (m, 16H), 2.9 (s, 3H, SCH_3), 6.7–7.1 (m, 3H, ArH); *m*/*e*: 260 ($M^+ - MeClO_4$), 28 (base peak). The X-ray structure of the compound is shown in Fig. 2.

The anion exchange column was prepared using analytical grade resin AG1-X8 from B10-RAD (100–200 mesh) in the chloride form. The resin was washed with aqueous NaOH (1 *N*) and then to neutrality with distilled water, followed by washing with dilute aqueous perchloric acid (5%). The resin was again washed to neutrality with distilled water and then methanol. It was packed into a small column (1/2 in. × 2 in.), a methanol solution of **15** applied to the top of the column, and the product eluted under a low pressure of nitrogen.

Received August 27, 1984

DONALD G. LEE and JOAQUIN F. PEREZ-BENITO. Can. J. Chem. **63**, 1275 (1985).

Autocatalysis has been detected during the reaction of methyltributylammonium permanganate with 1-tetradecene in methylene chloride solutions. Activation of permanganate by adsorption on colloidal particles of the product, manganese dioxide, appears to be responsible for the observed autocatalysis. Permanganate so activated can then be reduced either by reaction with the alkene or by thermal decomposition.

DONALD G. LEE et JOAQUIN F. PEREZ-BENITO. Can. J. Chem. **63**, 1275 (1985).

On a pu détecter de l'autocatalyse au cours de la réaction, en solution dans le chlorure de méthylène, du permanganate de méthyltributylammonium avec le tétradécène-1. Il semble qu'une activation du permanganate par adsorbtion sur des particules colloïdales du produit de la réaction (le bioxyde de manganèse) serait responsable de l'autocatalyse observée. Le permanganate qui est ainsi activé peut alors provoquer une réduction soit par réaction avec l'alcène soit par décomposition thermique.

[Traduit par le journal]

Introduction

It is well known that certain permanganate reactions are autocatalytic. For example, the oxidation of amines (1, 2), hydrogen peroxide (3), and oxalic acid (4), as well as the thermal decomposition of aqueous potassium permanganate (5), have been observed to be autocatalytic.

Despite its extensive occurrence in other reactions, evidence for autocatalysis during the reduction of permanganate by alkenes has not previously been reported. However, we have now obtained results which establish the importance of this phenomenon during the oxidation of 1-tetradecene by methyltributylammonium permanganate. In this paper we wish to describe these results and attempt to identify the mechanism of the autocatalytic reactions.

Experimental

Reaction rates were determined by periodic scanning of the uv–vis absorption spectrum using an HP 8450A spectrophotometer equipped with a temperaure controlled cuvette holder. The good isosbestic point observed when sequential spectra are plotted as in Fig. 1 indicates that no long-lived intermediates are formed during the course of the reaction. The concentration of permanganate corresponding to any spectrum can therefore be determined by noting the absorbance at 526 nm (A^{526}), and subtracting from it that portion due to absorption by the product. The latter can be obtained from the absorbance at 418 nm (A^{418}), where permanganate is transparent. As indicated by eqs. [1]–[3], where the product is denoted by the symbol "P", the superscripts indicate wavelengths, and the subscripts i, f, and t stand for initial, final, and variable times respectively, it is possible to calculate the permanganate concentration from absorbance measurements at 526 nm and 418 nm.

[1] $$[QMnO_4]_t = (A_t^{526} - \epsilon_P^{526}[P]_t)/\epsilon_{QMnO_4}^{526}$$

[2] $$[QMnO_4]_t = (A_t^{526} - \epsilon_P^{526}A_t^{418}/\epsilon_P^{418})([QMnO_4]_i/A_i^{526})$$

[3] $$[QMnO_4]_t = (A_t^{526} - A_f^{526}A_t^{418}/A_f^{418})([QMnO_4]_i/A_i^{526})$$

Permanganate solutions were prepared by dissolving weighed amounts of methyltributylammonium permanganate in anhydrous methylene chloride that had been carefully distilled from molecular sieves. Since permanganate reacts slowly with the solvent under these conditions, the solutions were freshly prepared prior to each experiment and the calculated rate constants were all appropriately corrected

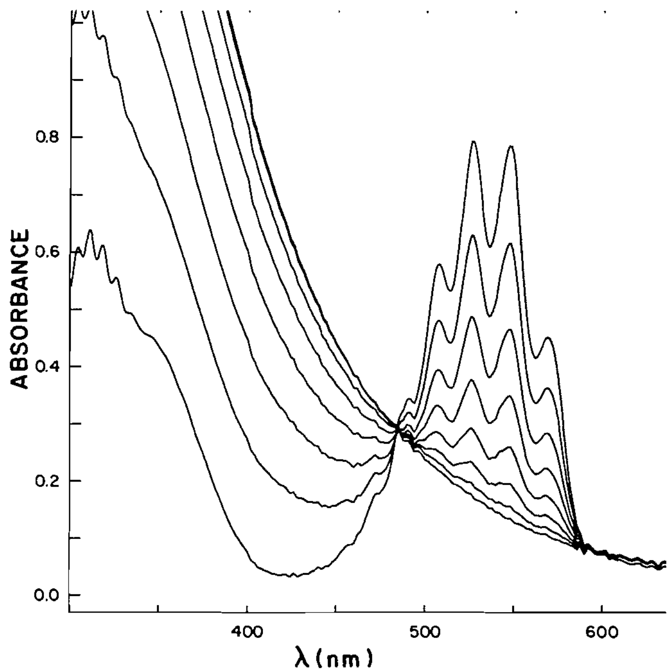

FIG. 1. Successive scans obtained during the oxidation of 1-tetradecene (7.89 × 10^{-3} M) by methyltributylammonium permanganate (3.02 × 10^{-4} M) in methylene chloride at 25.0°C. Isosbestic point at 484 nm.

by subtracting the rate of reduction of the oxidant by the solvent.

In a typical experiment, a 50-mL volumetric flask containing a solution of the desired concentration of 1-tetradecene in methylene chloride was thermostated in an ethylene glycol/water bath for about 20 min. Then, solid methyltributylammonium permanganate (0.0049 g) was added and the solution stirred until homogeneous. A portion of this solution (~2 mL) was then transferred to a cuvette in the thermostated cell compartment of the spectrophotometer, absorbances were measured at intervals, and the concentration of permanganate calculated using eq. [3].

At the conclusion of the reaction the oxidation state of the product was determined iodometrically using the following procedure. A solution of methyltributylammonium permanganate (2.98 × 10^{-4} M) in methylene chloride was allowed to react until no trace of permanganate could be seen in the absorption spectrum. An aliquot (2.0 mL) of the resulting brown-yellow solution was titrated by adding

2.0 mL of tetrabutylammonium iodide (3.00×10^{-2} M) in methylene chloride and 5.0 mL of glacial acetic acid, followed by dilution with CH_2Cl_2 to 50.0 mL. The amount of iodine liberated was then determined spectrophotometrically by measuring absorbances at 365 nm ($\epsilon = 2.62 \times 10^4$). These were found to be 0.318 and 0.316 in duplicate determinations.

Results

The oxidation state of the final product was determined by iodometric titration to be 4.01 ± 0.04.

The order of the reaction with respect to oxidant was determined by measuring the initial reaction rate at several different permanganate concentrations while the concentration of 1-tetradecene was held in a constant, large excess. As the data in Table 1 indicate, the order of the reaction with respect to permanganate is unity. The observation that the pseudo-first-order rate constants so obtained are directly proportional to the concentration of 1-tetradecene (Table 2) indicates that the rate of reaction is also first order in alkene.

Therefore, in the absence of complications, it would be expected that plots of ln $[QMnO_4]$ vs. time should be linear. However, all of the plots obtained were found to exhibit a definite concave upward curvature. Typical examples (which have been reproduced in Fig. 2) indicate that the reaction is obviously more complicated than suggested from the initial reaction rate studies.

The activation energies obtained from plots of ln k vs. $1/T$ (Fig. 3) have been summarized in Table 3.

Discussion

Evidence available in the literature indicates that alkenes react with permanganate to form cyclic manganate(V) diesters as in eq. [4] (6).

[4] 
The results of isotopic labelling experiments (7) as well as several product studies (8) are consistent with this conclusion. For example, Wagner (9) converted 3-methyl-1-butene into 1,2-dihydroxy-3-methylbutane by use of alkaline permanganate, and Ogino and Mochizuki (10) found that 1,2-dihydroxyoctane was formed by basic hydrolysis of the product obtained when 1-octene was oxidized under conditions similar to those used in these experiments.

Since the oxidation state of the product appears to be +4 and since no long-lived intermediate could be detected, this initial reaction must be followed by a very fast reaction in which the manganate(V) diester is reduced to manganate(IV), possibly by abstraction of a hydrogen atom from the solvent as in eq. [5].

[5] 
Two properties of the product suggest that it must be colloidal in nature. Firstly, the intensity of its absorption spectrum increases with time, presumably because flocculation is slowly occurring. If traces of moisture are added, the rate of flocculation increases and a brown solid eventually precipitates. Secondly, the logarithm of the absorption of the product is linearly related to the logarithm of the wavelength, a property

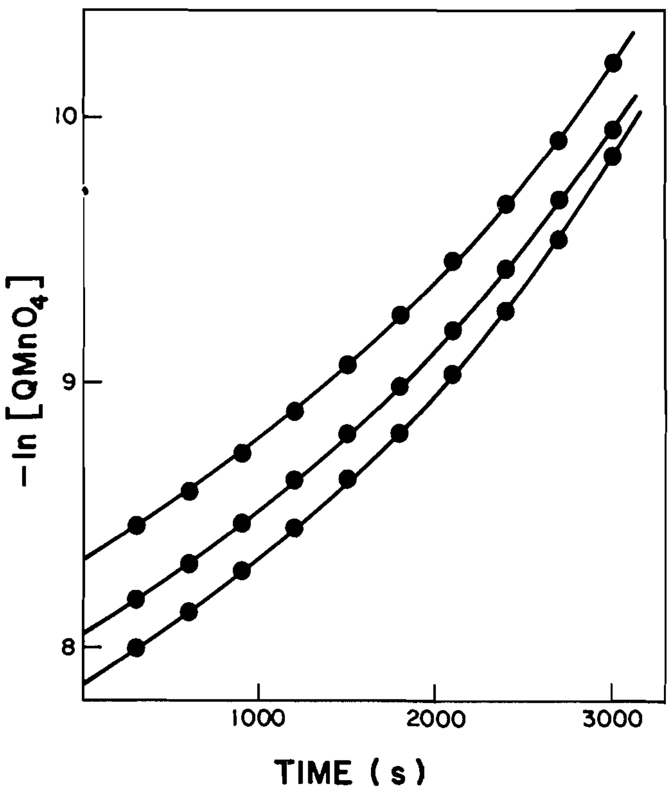

FIG. 2. Attempted pseudo-first-order plots.

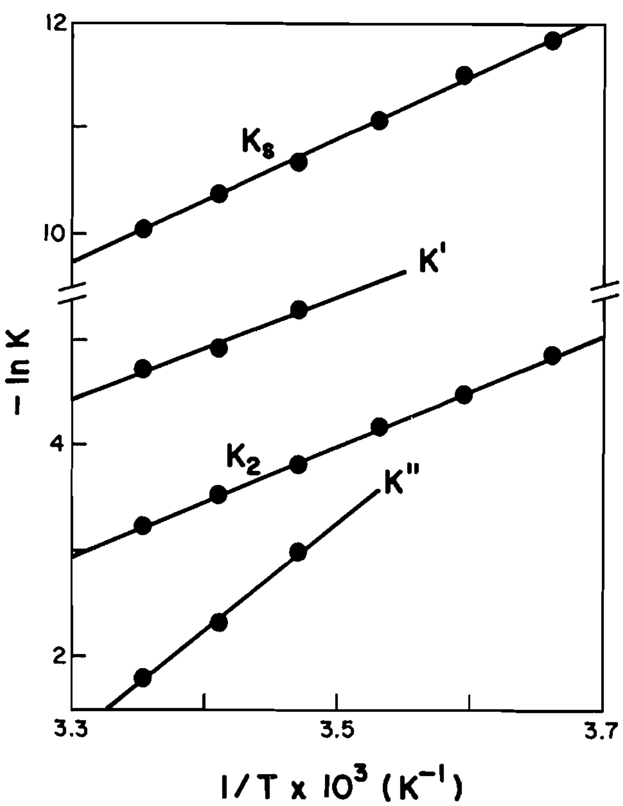

FIG. 3. Arrhenius plots. Symbols defined in text. For k_s plot, $[QMnO_4]_i = 3.00 \times 10^{-4}\ M$. For k_2 plot, $[QMnO_4]_i = 3.00 \times 10^{-4}\ M$, [1-tetradecene] = 7.9×10^{-3} to $7.9 \times 10^{-2}\ M$. For k' and k'' plots, $[QMnO_4]_i = 3.00 \times 10^{-4}\ M$, $[MnO_2]_i = 2.96 \times 10^{-4}\ M$, [1-tetradecene] = 6.3×10^{-3} to $8.5 \times 10^{-2}\ M$.

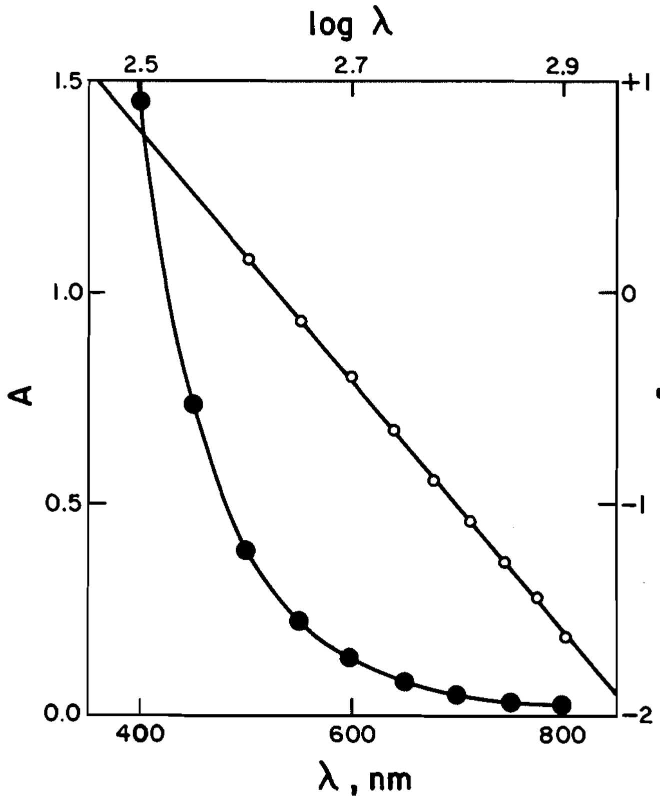

FIG. 4. Closed circles: spectrum of the product formed from the reaction of 1-tetradecene ($4.74 \times 10^{-2}\ M$) with methyltributylammonium permanganate ($5.56 \times 10^{-4}\ M$) in methylene chloride at 25.0°C. Open circles: log (absorbance) vs. log (λ) calculated from this spectrum. Slope = −5.90, r = 1.000.

TABLE 3. Activation energies

Rate constant[a]	E_a(kJ/mol)
k_s	49.0
k_2	43.8
k'	40.7
k''	85.1

[a]The rate constants are defined in eqs. [8]–[10].

exhibited by most colloids (11*a*). See Fig. 4.

The observance of concave rate plots, as in Fig. 2, suggests that the reaction may be autocatalytic. This was confirmed by determining initial rates in solutions that contained varying concentrations of product obtained from a previous experiment. When fresh methyltributylammonium permanganate was added to solutions in which the permanganate had been completely reduced, the rate of reaction was found to increase with the concentration of manganese(IV) in the solutions (Fig. 5). Consequently, it appears as if the autocatalysis may be associated with the formation of a manganese(IV) colloid, most likely MnO_2, that would provide a surface on which the catalyzed reaction could take place.

On the basis of these results it can be seen that the total rate law for the disappearance of permanganate should take the form of eq. [6],

$$[6] \quad \text{Rate}_{obs} = \text{rate}_{solvent} + \text{rate}_{alkene} + \text{rate}_{cat}$$

where

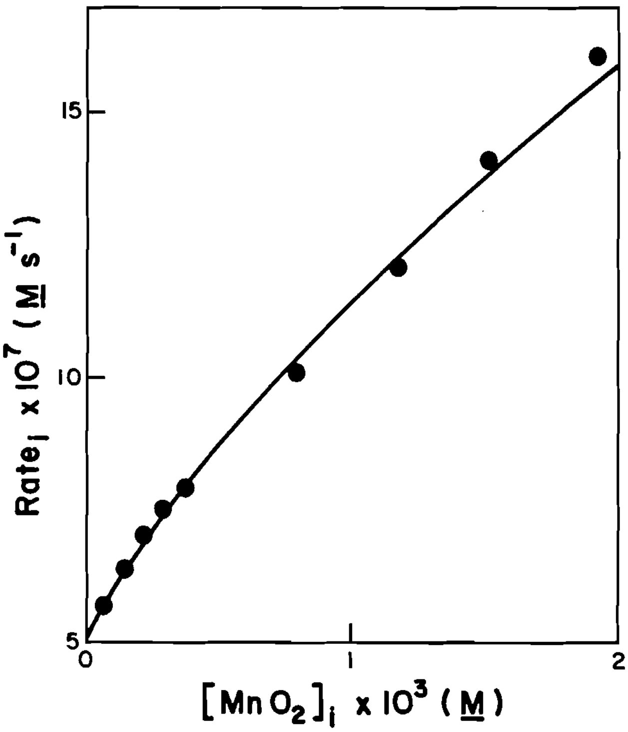

FIG. 5. Dependence of initial rates on manganese dioxide concentrations.

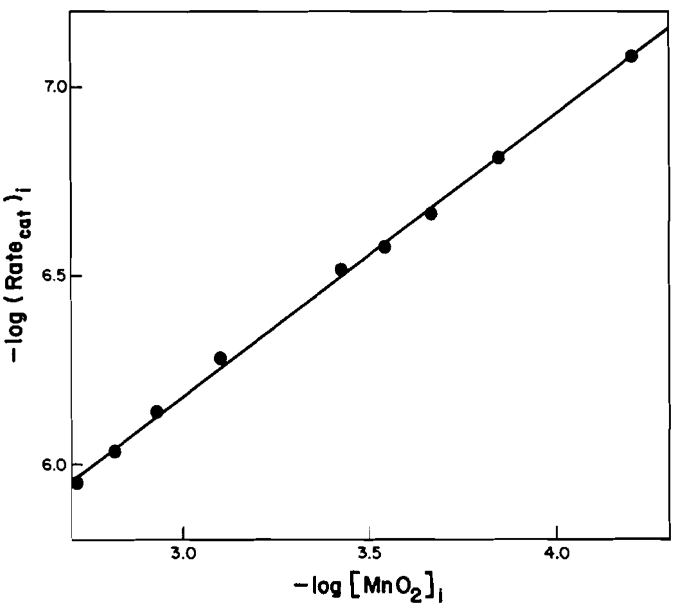

FIG. 6. Dependence of the rate of the catalytic reaction on the apparent concentration of MnO_2 present in the solution. $[QMnO_4]_i$ = 3.00×10^{-4} *M*, [1-tetradecene] = 3.95×10^{-2} *M*, 25°C, slope = 0.75, r = 0.999.

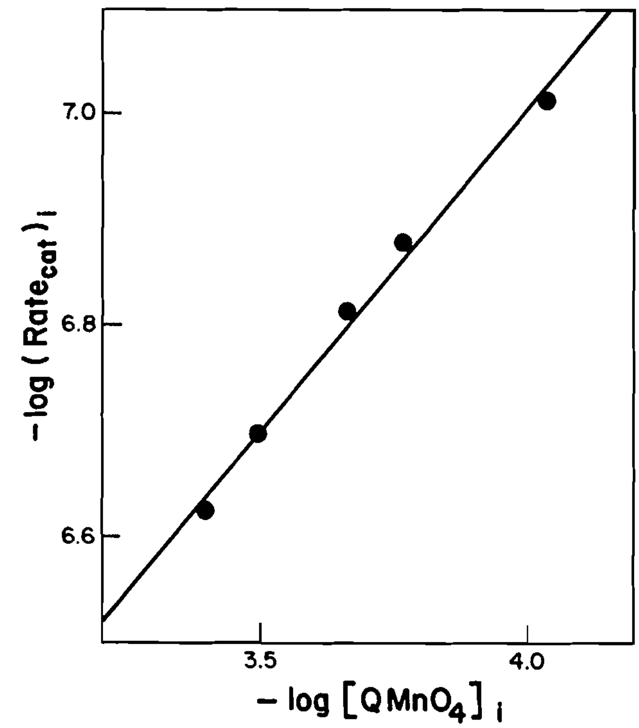

FIG. 7. Dependence of the rate of the catalytic reaction on the permanganate concentration. $[MnO_2]_i$ = 3.01×10^{-4} *M*, [1-tetradecene] = 7.89×10^{-3} *M*, 25°C, slope = 0.61, r = 0.996.

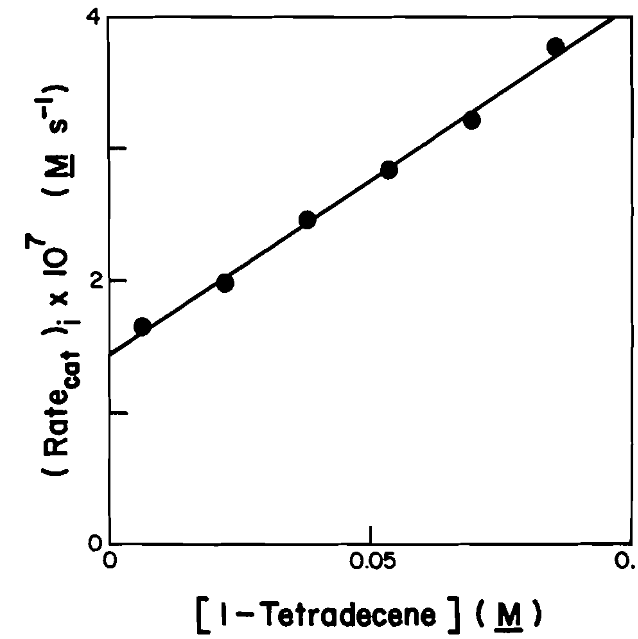

FIG. 8. Dependence of the rate of the catalytic reaction on the concentration of 1-tetradecene. $[QMnO_4]_i$ = 3.00×10^{-4} *M*, $[MnO_2]_i$ = 2.96×10^{-4} *M*, 25°C, slope = 2.68×10^{-6} s^{-1}, intercept = 1.43×10^{-7} *M* s^{-1}, r = 0.997.

$$[7] \quad \text{Rate}_{\text{obs}} = -\frac{d[MnO_4^-]_t}{dt}$$

$$[8] \quad \text{Rate}_{\text{solvent}} = k_s[MnO_4^-]$$

$$[9] \quad \text{Rate}_{\text{alkene}} = k_2[MnO_4^-][\text{1-tetradecene}]$$

Since k_s and k_2 can be independently determined, as described above, it is possible to investigate the catalytic portion of the rate law by subtracting the rate due to solvent oxidation plus the rate due to alkene oxidation from the observed reaction rates (eq. [6]). When this is done it is found empirically that the catalytic rate conforms to eq. [10] (Figs. 6, 7, and 8).

$$[10] \quad \text{Rate}_{\text{cat}} = (k' + k''[\text{1-tetradecene}])[MnO_2]^{0.75}[QMnO_4]^{0.61}$$

The nonintegral order of the reaction with respect to MnO_2 is not surprising since the rate of reaction would be dependent on the number of colloidal particles in solution rather than on the number of moles of MnO_2 present. Consequently, if the extent of flocculation is greater at higher MnO_2 concentrations, the apparent order, based on absorbance measurements, will appear to be less than unity.

Similarly, the apparent nonintegral order with respect to permanganate must arise because the rate of reaction is proportional to the amount of permanganate adsorbed rather than the amount in solution. According to the empirical isotherm of Freundlich the amount of permanganate adsorbed (y) is related to the amount in solution (c) by eq. [11], where a and b are constants (11*b*). Since b is always less than unity the observed

$$[11] \quad y = ac^b$$

order with respect to the concentration of permanganate in solution would also be fractional.

The part of eq. [10] that is independent of alkene concentration probably arises from the thermal decomposition of permanganate, which is known to take place readily in the presence of manganese dioxide (5). The total catalytic contribution to the rate of reaction can therefore be visualized as resulting from an activation of permanganate by adsorption on the surface of colloidal MnO_2 particles. These "activated" MnO_4^- ions can then be reduced by reaction with alkene or by the thermal explusion of oxygen (12). In fact, at low alkene concentrations, thermal decomposition of the activated permanganate appears to be the primary autocatalytic mechanism (see Fig. 8). As expected, the activation energy for this process (40.7 kJ/mol) is substantially less than for the decomposition of unactivated $KMnO_4$, which is known to have an activation energy of approximately 150 kJ/mol (12).

ZDZISŁAW PARYZEK and ROMAN WYDRA. 1985. Can. J. Chem. **63**, 1280 (1985).

The boron trifluoride etherate catalyzed rearrangement of 3β-acetoxy-9α, 11α-epoxy-5α-lanostan-7-one (**1**) in acetic anhydride resulted in formation of 19(10 → 9β)*abeo* compounds **2** and **4** along with 18(13 → 12β)*abeo* compound **5**, as the major product. These structures are supported by spectral data and chemical transformations. The possible mechanism of the rearrangement is discussed.

ZDZISŁAW PARYZEK et ROMAN WYDRA. 1985. Can. J. Chem. **63**, 1280 (1985).

La transposition, catalysée l'éthérate du fluorure de bore, de l'acétoxy-3β époxy-9α, 11α 5α-lanostanone-7 (**1**) en solutiion dans l'anhydride acétique conduit à la formation des composés 19(10 → 9β)*abeo* (**2** et **4**) en plus du composé 18(13 → 12β)*abeo* (**5**) qui se forme comme produit principal. Les structures proposées sont en accord avec les données spectrales et les transformations chimiques. On discute du mécanisme possible de cette transposition.

[Traduit par le journal]

The rearrangement of lanostane derivatives which possess the oxirane fragment in ring C has been a subject of several studies in recent years (1). These investigations were undertaken in connection with the possible transformation of the lanostane skeleton into the related, biologically important, skeletons of cycloartane, cucurbitane, and protostane. Indeed, by this approach effective transformations into the last two types have been achieved (1*b*, 2–4).

Our interest in the rearrangement of 3β-acetoxy-9,11-epoxy-5α-lanostan-7-ones was based on the assumption that the carbonyl group, due to its electronic effect, might suppress the rearrangement to a protostane skeleton. Consequently, formation of compounds with cucurbitane and (or) cycloartane skeletons was expected. This was the case when 9β,11β-epoxy-7-ketone was treated with boron trifluoride in acetic anhydride at room temperature (3) or at 0°C (4). However, the 9α,11α-epimer has been reported to react under similar conditions (0°C) with exclusive migration of the 13-methyl group to position 12 (4). This result was rather unexpected if one takes into account the 1,2-*trans* relationship of the oxirane oxygen and the 10-methyl group. Indeed, we found this rearrangement to be a more complex reaction than had been reported. Reinvestigation of the rearrangement of 3β-acetoxy-9α,11α-epoxy-5α-lanostan-7-one (5) is now presented in full.

The rearrangement of epoxide **1** catalyzed by boron trifluoride etherate in acetic anhydride at room temperature gave a complex mixture. By combining repeated column chromatography and tlc separations, four compounds **2**, **4**, **5**, and **6** were isolated in yields of 13, 10, 44, and 12%, respectively.

The structure assignment of compound **2** was based on spectral data. Its uv (λ_{max}: 244 nm, ϵ 11 600) and ir (ν_{max}: 1658 cm^{-1}) spectra agreed with an α,β-unsaturated ketone moiety with the double bond in position 5,6. This was supported by its ^{1}H nmr spectrum, in which all characteristic signals were present: singlet from the 6-H (δ 6.06), triplet from the 11β-H (δ 5.18, J = 8 Hz), and singlet from the 3α-H (δ 4.85). The comparison of its ^{13}C nmr spectrum with those of compounds with a different substitution pattern, **7**, **8**, and **9** (see Table 1), has also been valuable. The carbon resonances in these compounds were assigned on the basis of the residual splittings in

off-resonance decoupled spectra, chemical shift rules (6), chemical shift comparison from compound to compound, correlation with values for related compounds from our collection, and low power selective enhancement of signals from quaternary carbon atoms (7). Besides the readily assigned signals (C-3, C-5, C-6, C-7, C-11, and the side chain carbons (8)) the most characteristic resonances in this series are those of carbon atoms 8, 9, and 10.

Confirmation of the structure of compound **2** came from its mild basic hydrolysis to the amorphous 3,11-dihydroxy compound **3** followed by oxidation with Jones reagent to the crystalline triketone **10**, identical with the product obtained from the 3β,11β-diacetoxy compound **8** (3*a*) by similar transformations.

The second product isolated as an oil was assigned structure **4** on the basis of the following spectral properties. The ^{1}H nmr spectrum revealed three separate singlets for the acetate methyl groups at δ 2.09, 2.06, 2.02, and a sharp singlet arising from one olefinic proton at δ 5.86. The presence of a sharp singlet at δ 2.27 ascribed to the 8β-proton confirms the absence of protons in the 7 and 9 positions and is characteristic of all cucurbitane derivatives which lack hydrogen atoms in position 7 (3). Its uv spectrum had the maximum expected for the 5(10),6-diene system at 275 nm. Compound **4** was most

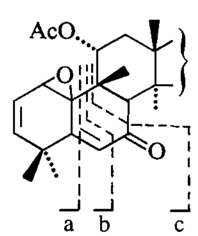
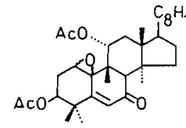
[a]CH_3COO signals appear at 21.02 to 21.70 and CH_3COO signals at ca. 170 ppm.
[b]Chemical shifts marked with asterisks may be interchanged.

probably formed via 3β-aceotxy-19(10 → 9β*abeo*-lanost-5(10)-en-7-one, since compound **2** did not give the dienol acetate **4** under the rearrangement conditions.

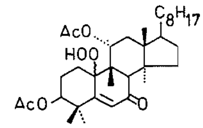
Pure compound **4**, when left for several weeks, gave after tlc purification an oily substance, whose uv spectrum showed λ_{max} at 249 nm suggesting the presence of a Δ^5-7-ketone chromophore. This was confirmed by ν_{max}: 1660 cm^{-1} in the ir spectrum. In the ^{1}H nmr spectrum the following signals were important: sharp singlet from one proton at δ 6.33, multiplet from one proton at δ 5.08, triplet at δ 4.86, doublet at δ 4.25, and two acetate methyl group singlets at δ 2.10 and 2.00. The high resolution mass spectrum showed molecular ion corresponding to the formula $C_{34}H_{52}O_6$. All these data were in accordance with formula **11**. In the mass spectrum, fragments m/z 121, 135, and 162 confirmed the presence of the oxirane oxygen atom in position 1,10 assuming that fragmentation *a*, *b*, and *c* occurs, respectively:



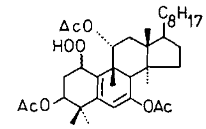
The accurate mass measurement was in agreement with the constitution of these fragments. The mechanism of the trans-



11



12

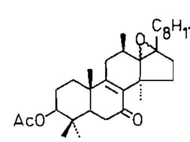


13

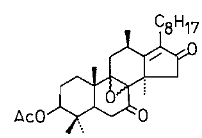
formation **4** → **11** is unknown; however, the intermediacy of hydroperoxides **12** or **13** is considered (9). Allylic hydroperoxides are known to give the respective α,β-unsaturated ketones (10), but we are not aware of the formation of an epoxide which, in this case, would involve abstraction of a hydrogen atom from C-1 in **12**. More probably, compound **11** arose by the sequence shown in eq. [1].

[1] 
Compound **5** has been reported previously (4); however, the 18(13 → 12β)*abeo* structure was proposed solely on the basis of spectral data. Since rearrangement which involved the 13-methyl group migration to position 12 was rather unusual, we sought further evidence in favour of structure **5**.

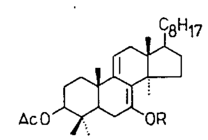
Epoxidation of **5** with *m*-chloroperbenzoic acid gave epoxide **14**, whose uv spectrum showed λ_{max} at 251 nm and whose ir spectrum showed ν_{max} at 1658 cm^{-1}, equally characteristic of a Δ^8-7-ketone chromophore. Reaction of compound **5** with chromium trioxide in acetic acid gave a complex mixture from



14 R=H_2



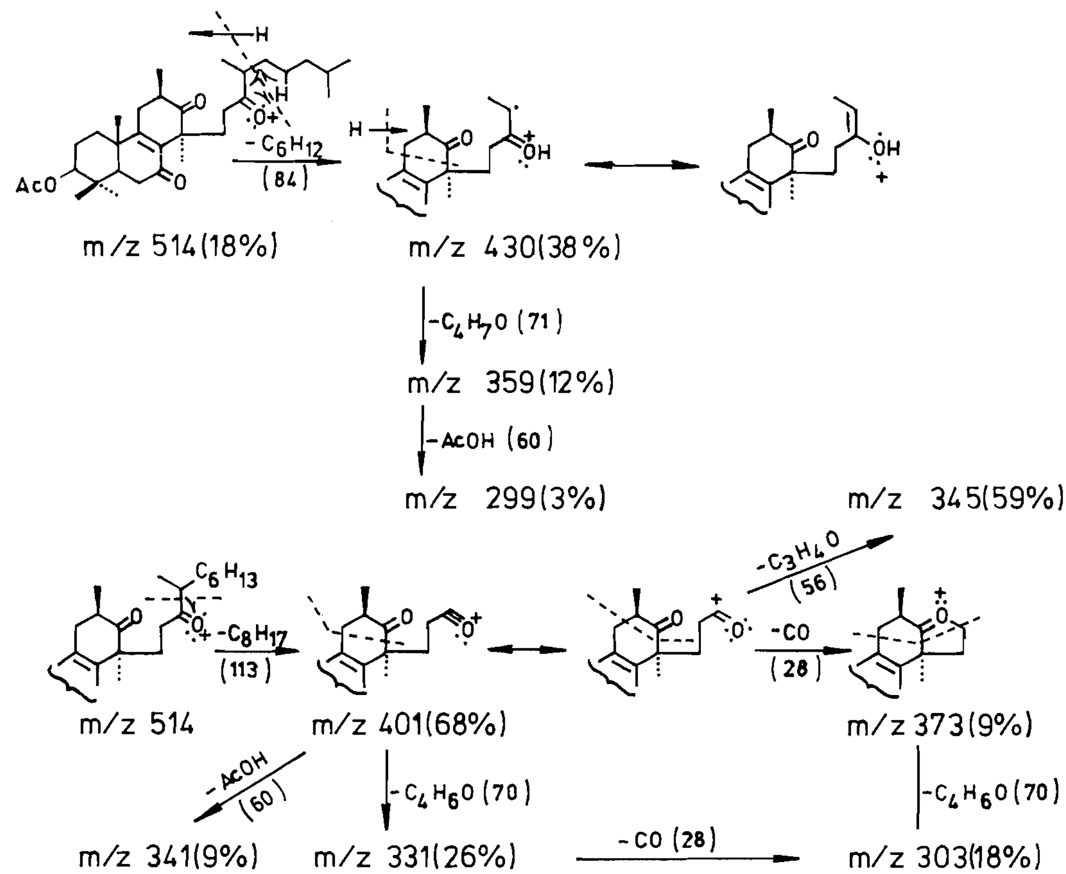
15



16 R=$COCH_3$
17 R=$COCF_3$

which a major compound could be isolated in pure form. Its elemental analysis and molecular ion at m/z 512 suggested incorporation of two oxygen atoms into **5**. Its ir spectrum did not contain absorption associated with the Δ^8-7-ketone moeity. However, a strong band indicating two carbonyl groups was present at 1710 cm^{-1} with a shoulder at 1728 cm^{-1}. The uv maximum at 253 nm was in agreement with the presence of a 16-carbonyl group conjugated with a 13,17-double bond. A weak absorption around 290 nm suggested the presence of the saturated carbonyl group in position 7. These data were in agreement with structure **15** resulting from allylic oxidation of position 16 and an unusual epoxidation of the conjugated 8,9-double bond in compound **5**. Substantial oxidation of the allylic 11-carbon atom in compound **5** was not observed, in contrast to the easy oxidation of 3β-acetoxy-5α-lanost-8-en-7-one (11) to 3β-acetoxy-5α-lanost-8-ene-7,11-dione (12) under similar conditions.

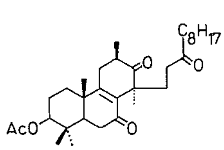
Compound **5** was found to behave abnormally in enol acetylation reactions. It formed 3β,7-diacetoxy-18(13→ 12β)*abeo*-lanosta-6,8,13(17)-triene on action of sulfuric acid and isopropenyl acetate (4) and did not give enol trifluoroacetate with trifluoroacetic acid anhydride. Contrary to the behaviour of compound **5**, 3β-acetoxy-5α-lanost-8-en-7-one gave heteroannular dienol acetate **16** on the action of *p*-toluenesulfonic



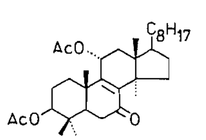
SCHEME 1

acid in acetic anhydride (13) and was very easily transformed to the dienol trifluoroacetate **17** upon dissolving in trifluoroacetic acid anhydride. The last reaction seems to be specific for the 8-ene-7-one functionality in lanostane since, for example, cholest-4-en-3-one does not react under similar conditions.

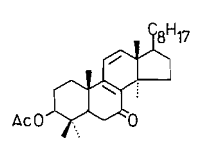
Finally, ruthenium tetraoxide – sodium metaperiodate oxidation of compound **5** afforded the seco compound **18** as an oil. Its ^{1}H nmr spectrum had two broadened signals ascribed to the 11β- and 11α-protons at δ 3.12 and 3.02, which were well



18



19

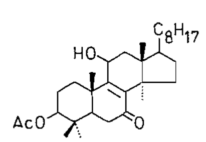


20

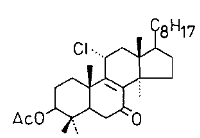
separated from signals of protons α to carbonyl groups in the region 2.75 and 2.45. The ir spectrum showed the presence of both conjugated (1663 cm^{-1}) and unconjugated (1715 cm^{-1}) carbonyl groups. Its uv spectrum had λ_{max}: 248 nm (ε 8200). Very important information came from mass spectral fragmentation of the seco compound **18** shown in Scheme 1. The fragmentation pattern confirms the presence of a methyl group in position 12.

The formation of compounds **2** and **4** having the cucurbitane skeleton results from the opening of the oxirane ring in **1**, probably in a concerted process involving migration of the 10-methyl group to position 9. However, this is not a predominant pathway despite the favourable *trans* relationship between the migrating group and the breaking carbon–oxygen bond. The carbonyl group in position 7 clearly prevents formation of a transient carbocation at C-8. For example, in the rearrangement of 9,11-epoxylanostanes without a 7-carbonyl group, compounds with the protostane skeleton are formed (1*b*, 2).

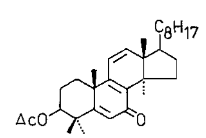
To find an explanation for the formation of the 18(13 → 12β)*abeo* compound **5** from **1** it was of interest to test the possible intermediacy of compounds **19** or **20** in the rearrangement. It was hoped to obtain dienone **20** from 3β-acetoxy-11β-hydroxy-5α-lanost-8-en-7-one (**21**) according



21

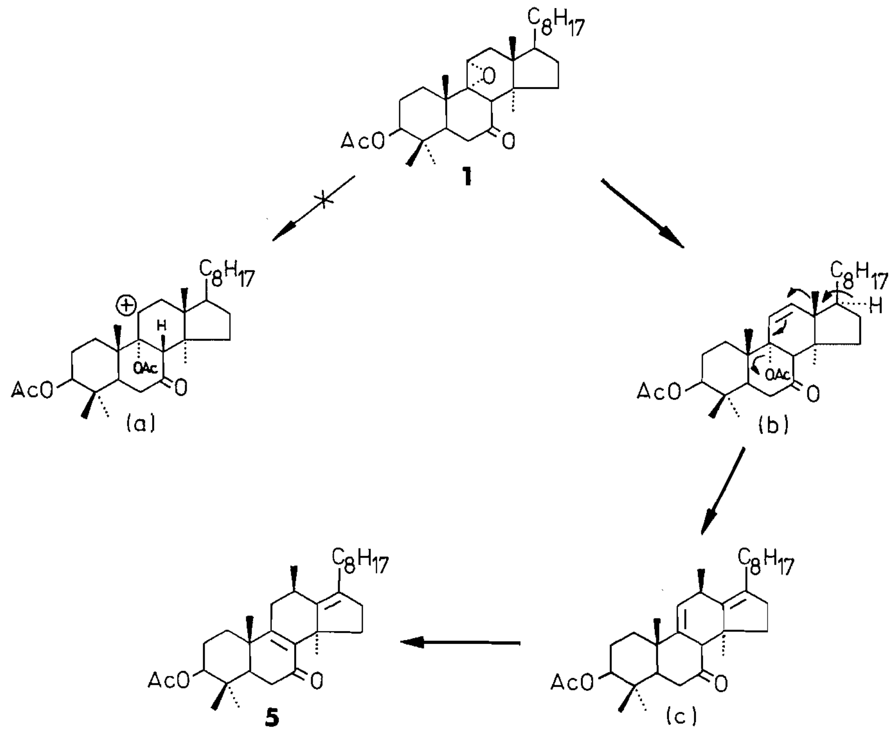


22



23

to the procedure described by Dias (14). Thus, sodium borohydride reduction of 3β-acetoxy-5α-lanost-8-ene-7,11-dione was carried out. The reaction was reported to give either 3β-acetoxy-7β-hydroxy-5α-lanost-8-en-11-one (15) or a mixture of the same compound and 3β-acetoxy-11β-hydroxy-5α-lanost-8-en-7-one in the ratio 3:1 (14, 16). We have identified three products of the reduction carried out under similar conditions. 3β-Acetoxy-11β-hydroxy-5α-lanost-8-en-7-one (**21**) (14, 16), 3β-acetoxy-7α-hydroxy-5α-lanost-8-en-11-one, and 3β-acetoxy-7β-hydroxy-5α-lanost-8-en-11-one (15) were formed in the yield 3, 10, and 76%, respectively. Hence, the desired 11β-alcohol **21** was obtained in only minute amounts. However, it was formed with 3β-acetoxy-9β,11β-epoxy-5α-lanostan-7-one (**5*a***) was treated with a solution of potassium



SCHEME 2

carbonate in methanol to give 3β,11β-dihydroxy-5α-lanost-8-en-7-one, which upon acetylation gave compound **21**.

The attempts to prepare dienone **20** from **21**, according to the described procedure (14, 16), failed. Reaction of **21** with *p*-toluenesulfonyl chloride in benzene gave 3β-acetoxy-5α-lanostane-7,11-dione (17). When a mixture of benzene–pyridine was used as the solvent the above reaction gave 3β-acetoxy-5α-lanost-8-ene-7,11-dione (17) and 3β-acetoxy-5α-lanostane-7,11-dione in the ratio 1:2. In pyridine itself, the ratio was close to 2:1. Compound **21** could not be dehydrated by action of thionyl chloride in pyridine. Instead, 3β-acetoxy-11α-chloro-5α-lanost-8-en-7-one (**22**) was formed in 55% yield. It had ν_{max}: 1668 cm^{-1} and λ_{max}: 256 nm (ε 9200). Its ^{1}H nmr spectrum had signals due to an 11-proton at δ 4.66 and a 3α-proton at δ 4.49. The ^{13}C nmr spectrum showed all expected low field signals and, in the off-resonance spectrum, a doublet centered at δ 53.4 of the 11-carbon atom. The proof of the configuration of the chlorine atom was based on the comparison of the shape of the 11-proton signal in compounds **19**, **21**, and **22**. Also, the region of methyl group signals (δ 1.3–0.5) had a similar pattern for compounds **19** and **22** in contrast to compound **21** and its 3-hydroxy derivative. Similar replacement of a hydroxy group has been reported (18). Bromination of 3β-acetoxy-5α-lanost-8-en-7-one followed by dehydrobromination of the crude reaction product with calcium carbonate in dimethylacetamide gave 3β-acetoxy-5α-lanosta-8,11-diene-7-one (**20**) (19) and 3β-acetoxylanosta-5,8,11,trien-7-one (**23**) (20).

When the dienone **20** was treated with boron trifluoride – ether complex in acetic anhydride (conditions used in the rearrangement of the title epoxide) a complex mixture was formed. Careful tlc examination showed the absence of compound **5**, therefore excluding the intermediacy of the dienone **20** in the rearrangement. Similarly, 3β,11α-diacetoxy-5α-lanost-8-en-7-one (**19**) (5*a*) was excluded as an intermediate since it remained unchanged when it was treated with boron trifluoride – ether complex in acetic anhydride for 10 min.

On the basis of the above results two alternatives seem to remain for the mechanism of formation of **5**. One is the opening of the epoxide to give the secondary cation (Scheme 2, (a)) followed by elimination to the 9α-acetoxy-11-ene (b). The formation of the allylic cation from (b) could then initiate the migration of C-18 and loss of the 17-hydrogen to give (c). Final conjugation of the 9(11) double bond with the carbonyl would give **5**. However, the secondary cation (a) is undoubtedly around 10 kcal/mol less stable[3] than the tertiary cation on C-9. It thus seems probable that the acetylium ion opens the epoxide with elimination of the 12β-hydrogen, giving (b) directly, the subsequent steps being as indicated above.

The present and previous results clearly indicate that in these rigid triterpenoid epoxides a delicate balance between electronic and steric factors determines the main pathway of a particular rearrangement leading to various structurally important products. These reactions are also sensitive to small variations in reaction conditions.

Experimental

Melting points were determined on a Kofler hot-stage apparatus and are uncorrected. The ir spectra were determined with a Perkin Elmer 580 spectrophotometer for solutions in chloroform. The uv spectra were recorded with a Zeiss Specord uv–vis spectrophotometer for solutions in ethanol. The ^{1}H nmr spectra were recorded with Varian EM-360 or Tesla BS 467 60-MHz spectrometers for solutions in deuteriochloroform with tetramethylsilane as an internal standard. The ^{13}C nmr spectra were recorded on a Varian XL-100-15 spectrometer operating at 25.2 MHz and (or) on a JEOL FX 900 spectrometer operating at 22.5 MHz, in the Fourier transform mode, using approximately 0.5 *M* solutions in deuteriochloroform. Solvent signal (δ 77.0) was used as an internal standard. The chemical shifts (δ) are expressed

[3]We thank the referees for critical comment on the mechanism.

in ppm relative to tetramethylsilane. Mass spectra were recorded with a JEOL JMS-D 100 spectrometer using electron impact.

Rearrangement of epoxide 1

To a solution of epoxide **1** (864 mg) in acetic anhydride (30 mL), boron trifluoride – diethyl ether complex (0.86 mL) was added at room temperature. After 1 min the solution was poured on ice and the product was extracted with a benzene–ether (1:1) mixture. The organic layer was washed with a pyridine–water mixture, hydrochloric acid (5%), water, sodium hydroxide solution (2%), and finally with water. After drying with magnesium sulfate and evaporation, the residue was chromatographed on a silica column eluted with benzene – methylene chloride mixtures. The appropriate fractions were combined and were rechromatographed on preparative silica gel tlc plates with methylene chloride as eluent. Four substances were isolated in order of increasing polarity, as follows.

*3β-Acetoxy-18(13→12β)*abeo*-5α-lanosta-8,13(17)-dien-7-one* (**5**) (366 mg, 44% yield); mp 136–138.5°C (lit.(4) mp 135–136°C); ^{1}H nmr, ir, and uv spectra were in accord with the reported data.

3β,7,11α-Triacetoxy-cucurbita-5(10),6-diene (**4**) (oil, 101 mg, 10% yield); λ_{max}: 275 nm; δ: 5.86 (s, 6-H), 5.15 (m, 11β-H), 4.71 (t, J = 6.5 Hz, 3α-H), 2.09, 2.06, and 2.02 (3 s, acetate methyl groups), 1.19, 1.02, 0.97, 0.89, and 0.81 (methyl groups); m/z: 584 (M^+). *Anal.* calcd. for $C_{36}H_{56}O_6$: C 73.93, H 9.65; found: C 74.16, H 9.80.

3β-Acetoxy-5α-lanostan-7,11-dion (**6**) (104 mg, 12% yield); mp 208–210°C; ir, ^{1}H nmr, and mass spectra were in agreement with those of an authentic sample (5*a*).

3β,11α-Diacetoxy-10α-cucurbit-5-en-7-one (**2**) (122 mg, 13% yield); mp 151–153°C; ν_{max}: 1730 and 1658 cm^{-1}; λ_{max}: 244 nm (ε 11 600); δ: 6.06 (br s, 6-H), 5.18 (t, J = 8 Hz, 11β-H), 4.85 (br s, $w_{1/2}$ = 6 Hz, 3α-H), 2.47 (s, 8β-H), 2.06 and 2.00 (2 s, acetate methyl groups), 1.24, 1.14, 1.07, 1.00, 0.84, and 0.79 (methyl groups; m/z: 542 (M^+), 482, 422, 407, 343, 261, and 189. *Anal.* calcd. for $C_{34}H_{54}O_5$: C 75.23, H 10.03; found: C 75.01, H 10.20.

Hydrolysis of 2

Compound **2** (60 mg) was treated with a methanolic solution of potassium carbonate (5 mL) at room temperature for 5 days. Dilution with water and extraction with benzene gave dihydroxy derivative **3** as an oil; λ_{max}: 248 nm; δ: 6.06 (s, 6-H), 3.90 (t, J = 8 Hz, 11β-H), 3.58 (br s, 3α-H); m/z: 458 (M^+). *Anal.* calcd. for $C_{30}H_{50}O_3$: C 78.55, H 10.99; found: C 78.28, H 10.72.

Oxidation of 3 to triketone 10

Compound **3** (40 mg) was dissolved in acetone (1 mL) and oxidized with Jones reagent. The reaction mixture was poured onto ice, the precipitate filtered off, washed with water, and dried. The crude product was crystallized from heptane–benzene mixture to give 10α-cucurbit-5-ene-3,7,11-trione (**10**) (26 mg); mp 175–178°C; ν_{max}: 1718, 1698, 1658, and 1620 cm^{-1}; λ_{max}: 248 nm (ε 8800); m/z: 454 (M^+), 439, 411, 291, and 205. *Anal.* calcd. for $C_{30}H_{46}O_3$: C 79.25, H 10.20; found: C 79.50, H 10.32. Compound **10** was identical in all respects with the product obtained from 3β,11β-diacetoxy-10α-cucurbit-5-en-7-one (**8**) (3*b*) by hydrolysis and oxidation procedures similar to those described above.

Air oxidation of dienol acetate 4

Compound **4** (58 mg) was stored for several weeks at room temperature. Then it was chromatographed on a silica tlc plate developed twice with methylene chloride. Compound **11** (24 mg) was separated as an oil, which had ν_{max}: 1735, 1660, and 1623 cm^{-1}; λ_{max}: 249 nm (ε 8200); δ: 6.33 (s, 6-H), 5.08 (dd, J = 12 Hz, J = 4 Hz, 11β-H), 4.86 (*t*, J = 4 Hz, 3α-H), 4.25 (br d, J = 3.5 Hz, 1-H), 2.52 (s, 8β-H), 2.10 and 2.00 (2 s, acetate methyl groups), 1.22, 1.15, 1.04, 0.88, and 0.81 (methyl groups); m/z: 556 (M^+), 514, 496, 481, 454, 436, 348, 335, 322, 275, 162, 135, and 121; HR mass measurements: calcd. for C_8H_9O: 121.0653; found: 121.0655; calcd. for $C_9H_{11}O$: 135.0809; found; 135.0809; calcd. for $C_{10}H_{10}O_2$: 162.0680; found: 162.0671; calcd. for $C_{34}H_{52}O_6$: 556.3761; found: 556.3771 (M^+). *Anal.* calcd. for $C_{34}H_{52}O_6$: C 73.35, H 9.41; found: C 73.06, H 9.35.

Epoxidation of compound 5

Compound **5** (50 mg) was oxidized with *m*-chloroperbenzoic acid in methylene chloride (3 mL) at room temperature for 45 min. After work-up, a crude product was crystallized from heptane to give epoxide **14** (41 mg), mp 162–164°C; ν_{max}: 1728 and 1658 cm^{-1}; λ_{max}: 251 nm (ε 10 000); δ: 4.49 (br s, 3α-H), 2.49 (m, protons α to carbonyl and in allylic position), 2.05 (s, acetate methyl group), 1.26, 1.08, 1.00, 0.95, 0.92, and 0.82 (methyl groups); m/z: 498 (M^+), 385, 372, 330, 164, and 149. *Anal.* calcd. for $C_{32}H_{50}O_4$: C 77.06, H 10.10; found: C 76.92, H 10.40.

Oxidation of compound 5 with chromium trioxide

To a stirred solution of **5** (43 mg) in acetic acid (4.3 mL) a solution of chromium trioxide (43 mg) in 90% acetic acid (0.43 mL) was added and the reaction mixture was stirred at room temperature for 15 min. Then it was poured into water, and extracted with a 1:1 mixture of benzene–ether. The organic layer was washed with water and dried over magnesium sulfate. The crude product was purified on a silica gel tlc plate developed four times with benzene – ethyl acetate 10:1 mixture to give 3β-acetoxy-8α,9α-epoxy-18(13→12β)*abeo*-5α-lanost-13(17)-ene-7,16-dione (**15**) (12.4 mg, 27% yield) which had mp 203–205°C (from ethanol); ν_{max} 1728 sh, 1710 (very intense absorption); λ_{max}: 253 nm (ε 11 200); m/z: 512 (M^+), 496, 481, 301. *Anal.* calcd. for $C_{32}H_{48}O_5$: C 74.96, H 9.44; found: C 75.12, H 9.52.

Oxidation of 3β-acetoxy-5α-lanost-8-en-7-one with chromium trioxide

To a solution of the substrate (40 mg) in acetic acid (4 mL) a solution of chromium trioxide (40 mg) in acetic acid (90%, 0.4 mL) was added at room temperature. After 20 min, the reaction mixture was poured into water and the product extracted with benzene. The organic layer was washed with water, then with sodium carbonate solution, dried over magnesium sulfate, and the solvent evaporated to give 38 mg of the residue, which on two crystallizations from methanol–chloroform gave 3β-acetoxy-5α-lanost-8-ene-7,11-dione, mp 155–158°C (lit. (12) mp 155–157°C), whose spectra (ir, uv, and ^{1}H nmr) were identical with those of an authentic sample (12).

Action of trifluoracetic acid anhydride on conjugated enones

(a) *Reaction with 3β-acetoxy-5α-lanost-8-en-7-one(11)*

The substrate (133 mg) was dissolved in trifluoracetic acid anhydride (0.8 mL) at room temperature. After 40 min the solvent was evaporated and the residue was crystallized from methanol to give 3β-acetoxy-7-trifluoroacetoxy-5α-lanosta-7,9(11)-dien (**17**) (135 mg, 85% yield), which had mp 97–99°C; λ_{max}: 238 nm (ε 13 400); δ: 5.44 (t, J = 4 Hz, 11-H), 4.49 (m, $W_{1/2}$ = 14 Hz, 3α-H), 2.03 (s, acetate methyl group), 1.06, 0.93, 0.91, 0.86, 0.83, 0.80, and 0.63 (methyl groups); m/z: 580 (M^+), 565 365, 352. *Anal.* calcd. for $C_{34}H_{51}F_3O_4$: C 70.31, H 8.85; found: C 70.68, H 8.96.

(b) *Reaction with compound 5*

Compound **5** when treated as above for 1 h gave only the substrate. Reaction in the presence of a catalytic amount of *p*-toluenesulfonic acid gave the same negative result.

(c) *Reaction with cholest-4-en-3-one (21)*

Cholest-4-en-3-one was treated as in (a) and only the substrate was recovered.

Oxidation of compound 5 to seco-compound 18

To a stirred solution of compound **5** (50.5 mg) in chloroform (5 mL), ruthenium dioxide (5.5 mg) and a 5% aqueous solution of sodium metaperiodate (3 mL) were added at room temperature. The reaction mixture was stirred for 11 h. Ethanol (2 mL) was added and the mixture diluted with ether. The organic layer was washed with water, dried with magnesium sulfate, and evaporated. The crude product was chromatographed on a silica gel tlc plate developed three times with benzene – ethyl acetate (3:1) mixture. This gave 3β-acetoxy-13,17-seco-18(13→12β)*abeo*-5α-lanost-8-ene-7,13,20-trione (**18**) as an oil (31 mg, 57% yield) which had ν_{max}:

1728 sh, 1715, 1663, and 1620 cm^{-1}; λ_{max}: 248 nm (ϵ 8200); δ: 4.53(m, $W_{1/2}$ = 20 Hz, 3α-H), 3.12 (br s, $W_{1/2}$ = 4 Hz, 11β-H), 3.02 (br s, $W_{1/2}$ = 4 Hz, 11α-H), 2.75–2.45 (protons α to carbonyls), 2.07 (s, acetate methyl group), 1.31, 1.12, 1.01, 0.91, and 0.70(methyl groups); m/z: 514(M$^+$), 430, 401, 373, 359, 345, 341, 331, 303, and 164. *Anal.* calcd. for $C_{32}H_{50}O_5$: C 74.67, H 9.79; found: C 74.42, H 9.93.

Sodium borohydride reduction of 3β-acetoxy-5α-lanost-8-ene-7,11-dione

3β-Acetoxy-5α-lanost-8-ene-7,11-dione (12) (1 g) was dissolved in a mixture of tetrahydrofuran (2 mL), methanol (2.65 mL), and ethyl acetate (0.65 mL). To this stirred solution sodium borohydride (0.065 g) was added gradually at 0°C. After being stirred at room temperature for a further 2 h the reaction mixture was poured into water and the precipitate filtered and dried. The solid, consisting of three components, was crystallized thrice form chloroform–methanol to give 503 mg (50% yield) of 3β-acetoxy-7β-hydroxy-5α-lanost-8-en-11-one, which had mp 210–212°C (lit.(16) mp 213–215°C); λ_{max}: 256 nm (ϵ 9600). The ^{1}H nmr and mass spectra of this compound were in agreement with those reported (16). The combined mother liquors were evaporated and chromatographed on a silica gel column eluted with benzene or a benzene – ethyl acetate 50:1 mixture. Three compounds were separated: 3β-acetoxy-11β-hydroxy-5α-lanost-8-ene-7-one (**21**) (33 mg, 3% yield), which had physical and spectral properties identical with compound **21** obtained from 3β-acetoxy-9β,11β-epoxy-5α-lanostan-7-one; 3β-acetoxy-7α-hydroxy-5α-lanost-8-en-11-one (101 mg, 10% yield), which had mp 214–215°C; δ: 4.63–4.23 (m, 3α-H and 7β-H), 2.60 (d, 12 -H$_2$), 2.00 (s, acetate methyl group), 1.21, 1.11, 0.84, and 0.77 (methyl groups); m/z: 500 (M$^+$), 485, 319, and 293. *Anal.* calcd. for $C_{32}H_{52}O_4$: C 76.75, H 10.47; found: C 76.80, H 10.57; and an additional crop of 3β-acetoxy-7β-hydroxy-5α-lanost-8-en-11-one (259 mg, 26% yield).

3β-Acetoxy-11β-hydroxy-5α-lanost-8-en-7-one (21)

3β-Acetoxy-9β,11β-epoxy-5α-lanostan-7-one (702 mg) was dissolved in a methanol (28 mL) and benzene (14 mL) mixture. Saturated potassium carbonate solution in methanol (3 mL) was added and the reaction mixture was left at room temperature for 70 h. Work-up gave crude 3β,11β-dihydroxy-5α-lanost-8-en-7-one (640 mg) which was acetylated in a pyridine (5 mL) and acetic anhydride (2.5 mL) mixture at room temperature for 5 h. The reaction mixture was poured into water and the precipitate was filtered off and dried. Two crystallizations from chloroform–methanol gave 3β-acetoxy-11β-hydroxy-5α-lanost-8-en-7-one (**21**) (366 mg), which had mp 211–214°C (lit.(14, 16) mp 217–218°C); λ_{max}: 256 nm (ϵ 9900). The ^{1}H nmr and ir spectra of this sample were in agreement with those reported (16).

3β-Acetoxy-11α-chloro-5α-lanost-8-en-7-one (22)

To a solution of compound **21** (243 mg) in pyridine (5 mL), thionyl chloride (0.2 mL) was added and the reaction mixture was stirred at room temperature for 20 min. Then it was poured into water and the product extracted with a benzene–ether 1:1 mixture. The organic layer was washed with water and dried with magnesium sulfate. The crude product was crystallized from chloroform–methanol to give 3β-acetoxy-11α-chloro-5α-lanost-8-en-7-one (**22**) (139 mg, 55% yield), which had mp 173–175°C; ν_{max}: 1728 and 1668 cm^{-1}; λ_{max}: 256 nm (ϵ 9200); δ: 4.66 (t, J = 5.5 Hz, 11β-H), 4.49 (t, J = 6 Hz, 3α-H), 2.00 (s, acetate methyl group), 1.18, 0.91, 0.86, 0.77, and 0.59; ^{13}C nmr δ 198.8 (C-7), 170.5 (CH_3COO), 157.9(C-9), 143.4(C-8), 79.5(C-3), and 53.4(C-11); m/z: 482 (M$^+$ − HCl), 467, and 407. *Anal.* calcd. for $C_{32}H_{51}O_3Cl$: C 74.03, H 9.90; found: C 73.94, H 10.04.

Action of p*-toluenesulfonic acid chloride on 3β-acetoxy-11β-hydroxy-5α-lanost-8-en-7-one (21)*

(a) *In pyridine*

To a solution of compound **21** (53 mg) in pyridine (5 mL), *p*-toluenesulfonic acid chloride (320 mg) was added and the mixture refluxed under argon for 3 h. Then it was poured into water, the precipitate filtered off, washed with water, and dried. The resulting mixture of two components was separated on a preparative silica gel plate developed with benzene – ethyl acetate 50:1. Two compounds were isolated: 3β-acetoxy-5α-lanost-8-ene-7,11-dione (35 mg, 67% yield), which had mp 155–158°C (from methanol) and λ_{max} 272 nm (ϵ 9000) (lit. (12*b*) mp 155–157°C, λ_{max}: 272 nm (log ϵ 3.96), and 3β-acetoxy-5α-lanostane-7,11-dione (16 mg, 30% yield), which had mp 223–225°C (from methanol–chloroform) (lit. (17*b*) mp 222–224°C) and all spectral properties of the authentic specimen.

(b) *In benzene*

Refluxing a benzene solution of compound **21** and *p*-toluenesulfonyl chloride (6.5 molar excess) in an argon atmosphere for 2.5 h gave only one product, 3β-acetoxy-5α-lanost-8-ene-7,11-dione.

(c) *In benzene–pyridine (10:1) mixture*

Refluxing of compound **21** and *p*-toluenesulfonyl chloride dissolved in the above mixture of solvents in an argon atmosphere for 8 h gave a mixture of 3β-acetoxy-5α-lanost-8-ene-7,11-dione and 3β-acetoxy-5α-lanostane-7,11-dione in the ratio 1:2.

Bromination–dehydrobromination of 3β-acetoxy-5α-lanost-8-en-7-one

To a solution of 3β-acetoxy-5α-lanost-8-en-7-one (150 mg) in acetic acid (5.6 mL), a solution of bromine (50 mg) in acetic acid (0.75 mL) was added dropwise. When the reaction mixture became colorless a few milliliters of water were added and the resulting precipitate was filtered off and dried. The crude product (189 mg) was dissolved in dimethylacetamide (3.25 mL) and this solution was added dropwise to a boiling solution of calcium carbonate (161 mg) in dimethylacetamide (1.6 mL). Refluxing was continued for 15 min. The reaction mixture was cooled down, water was added, and the product was extracted with ether. The organic layer was washed with water, dried with magnesium sulfate, and evaporated. The crude product was chromatographed on a preparative silica gel plate developed with benzene – ethyl acetate (20:1) mixture to give two compounds. The one with higher R_f was 3β-acetoxy-5α-lanosta-8,11-dien-7-one (**20**) (89 mg, 60% yield), which had mp 134–136°C, (from methanol) λ_{max}: 318 nm (ϵ 7400) (lit.(18) mp 150°C, λ_{max}: 315 nm (log ϵ 3.52); lit.(14) mp 120–123°C). Its ^{1}H nmr spectrum contained all important signals reported in refs. 14 and 18 and its mass spectrum was in agreement with data reported by Dias (14). The product with lower R_f was 3β-acetoxy-lanosta-5,8,11-trien-7-one (**23**) (49 mg, 33% yield), which had mp 192–194°C (from methanol); λ_{max}: 256 nm (ϵ 7800) and 327 nm (ϵ 7000); δ: 6.67(d, J = 10 Hz, 11-H), 6.26(br s, 6-H), 6.06(d, J = 10 Hz, 12-H), 4.56(m, 3α-H), 2.11(s, acetate methyl group), 1.38, 1.28, 1.17, 0.97, 0.90, and 0.82(methyl groups); m/z: 480(M$^+$), 465, 405, and 240 (lit.(19) mp 195–196°C, λ_{max}: 256 and 327 nm (log ϵ 3.9)).

*Treatment of 3β,11α-diacetoxy-5α-lanost-8-en-7-one (**19**) with boron trifluoride – ether complex in acetic anhydride*

Compound **19** (50 mg) was dissolved in acetic anhydride (2.5 mL) and boron trifluoride – ether complex (0.05 mL) was added. The solution was kept for 10 min at room temperature. After work-up the residue was carefully examined by tlc which showed no spot of other substance than that of the substrate. This was confirmed by the ^{1}H nmr spectrum.

*Treatment of 3β-acetoxy-5α-lanosta-8,11-dien-7-one (**20**) with boron trifluoride – ether complex in acetic anhydride*

Dienone **20** (38 mg) dissolved in acetic anhydride (2 mL) was treated with boron trifluoride – ether complex (0.038 mL) at room temperature for 5 min. After work-up, 34 mg of the complicated mixture was isolated. It showed at least seven spots on the tlc plate, most of them having lower R_f than the substrate. Careful tlc examination of the reaction product using various solvent systems showed no presence of compound **5**. The mixture was not further examined.

Enantioselective hydrolysis of racemic acetates of *cis*- and *trans*-1-hydroxy-4-methyl-1,2,3,4-tetrahydronaphthalene using *Rhizopus nigricans* yields chiral alcohols. The *absolute stereochemistry* of these compounds, and that of a key intermediate in their stereoselective synthesis, r-1-hydroxy-2,*t*-bromo-4,*c*-methyl-1,2,3,4-tetrahydronaphthalene, were determined by chemical transformations to 1-oxo-4-methyl-1,2,3,4-tetrahydronaphthalene of known absolute stereochemistry. The *relative stereochemistry* of the acetate of the key intermediate was established by X-ray crystallography.

MASAJI KASAI, HERMAN ZIFFER et J. V. SILVERTON. Can. J. Chem. **63**, 1287 (1985).

L'hydrolyse énantiosélective des acétates racémiques des hydroxy-1 méthyl-4 tétrahydro-1,2,3,4 naphtalènes-*cis* et *trans*, effectuée en présence de *Rhizopus nigricans*, conduit à des alcools chiraux. On a déterminé la *stéréochimie absolue* de ces composés ainsi que celle d'un intermédiaire clé dans leur synthèse stéréosélective, le hydroxy-1-r bromo-2,*t* méthyl-4,*c* tétrahydro-1,2,3,4 naphtalène, en leur faisant subir des transformations chimiques conduisant à l'oxo-1 méthyl-4 tétrahydro-1,2,3,4 naphtalène de stéréochimie absolue connue. On a déterminé la *stéréochimie relative* de l'acétate de l'intermédiaire clé en faisant appel à la diffraction des rayons-X.

[Traduit par le journal]

We recently reported (1) on a method for preparing chiral alcohols of a predictable absolute stereochemistry using the mold, *Rhizopus nigricans*, by enantioselective hydrolysis of the corresponding racemic acetates. The absolute stereochemistry of the alcohols formed was accounted for by a suggested rule (1*a*) which states that the enantiomer shown in Fig. 1 is the one more rapidly hydrolyzed. The relative sizes of R_1 and R_2 required to account for our results in these hydrolyses are identical to those employed in Horeau's method (2). For example, an aromatic group (R_1) is always larger than an alkyl group (R_2) and, in cyclic carbinols, a substituted methylene group is larger than an unsubstituted one, etc. This simple concept and the associated empirical observations (1) account for the configurations of some fifty acyclic and cyclic carbinols, several of which required special explanations in order to reconcile their known absolute stereochemistry with data from Horeau's method. Since knowledge of the relative sizes of substituents is critical in predicting the absolute stereochemistry of carbinols formed in these hydrolyses, we needed to establish the influence of distant groups on the relative sizes of substituents on the carbinol carbon. Many data (1*c*) have been collected on 2-substituted 1-acetoxy-1,2,3,4-tetrahydronaphthalenes, and it has been established that a fused benzene ring is effectively larger than a saturated carbon bearing two hydrogens, but smaller than one in which one or both of the hydrogens has been replaced by a chlorine or bromine atom or a methyl or hydroxyl group. In order to examine the influence of distant groups, we have therefore investigated the effects associated with replacing a hydrogen on C-4 by a *cis*- or *trans*-methyl group. Since the presence of the methyl on C-4 could

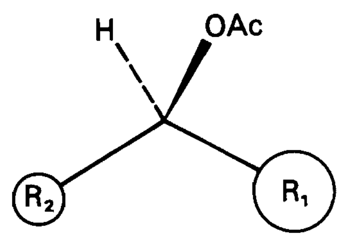

FIG. 1. Enantiomer more rapidly hydrolyzed (where R_1 is effectively larger than R_2).

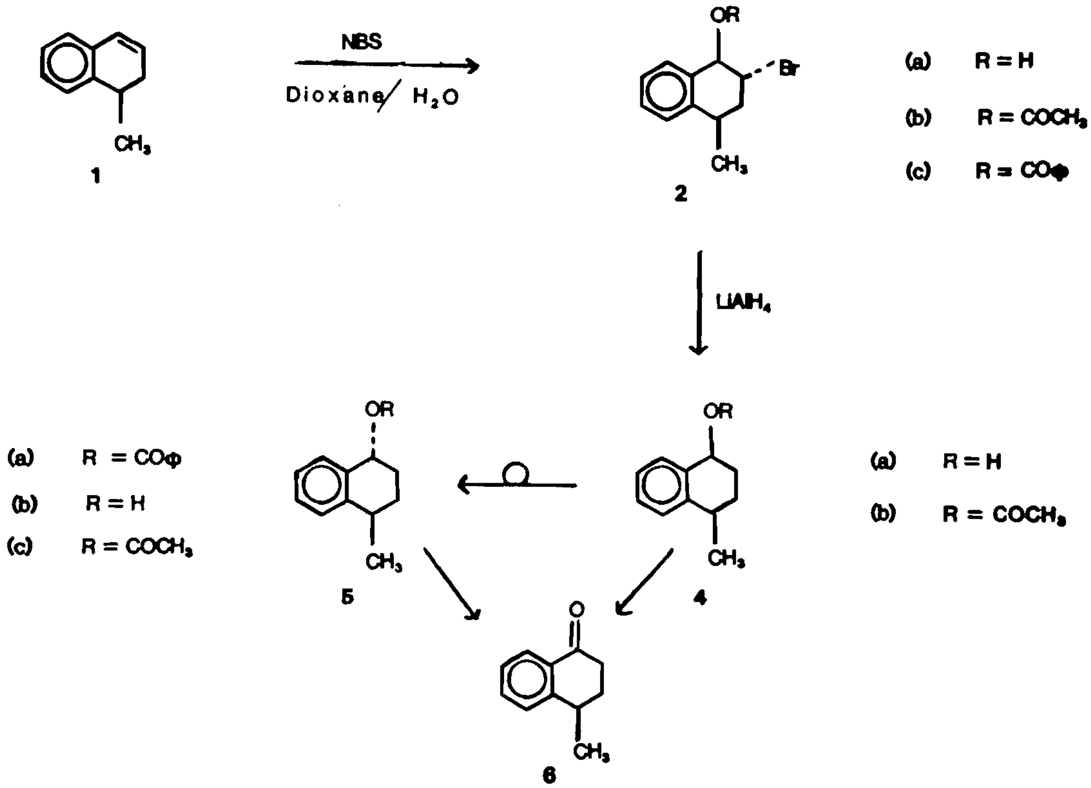
increase the relative size of the fused aromatic ring in both compounds, the hydrolysis of **2***b* was also examined, where the fused aromatic ring was the smaller substituent and an increase in its size might alter the effective sizes of a fused aromatic ring and a saturated carbon with an additional substituent.

Finally, we also tested the ability of a chiral Pirkle hplc (high performance liquid chromatography) column ((*R*)-*N*-(3,5-dinitrobenzoyl)phenylglycine ionically bonded to γ-aminopropyl-silanized silica) to resolve **4***a* and **5***b*. Earlier studies (3) focused on the relation between the absolute stereochemistry of an enantiomer and the order, relative to its antipode, in which it is eluted from the chiral column. However, many 2-substituted 1-hydroxy-1,2,3,4-tetrahydronaphthalenes were not resolved by this column and, in an attempt to understand the relation between the structure of these cyclic carbinols and the ability of a Pirkle column to separate enantiomers, the chromatographic behavior of **4***a* and **5***b* was examined.

Synthesis

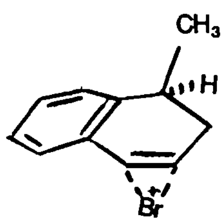
There are literature reports (4) describing the preparation of mixtures of *cis*- and *trans*-1-hydroxy-4-methyl-1,2,3,4-tetrahydronaphthalene (**4***a* and **5***b*). However, we were unable to

[1]On leave from Kyowa Hakko Kogyo Co., Ltd., Tokyo Research Laboratory, 3-6-6 Asahi-machi Machida-shi, Tokyo 194, Japan.

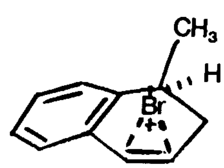


SCHEME 1

locate a description of a stereoselective synthesis of either isomer. Furthermore, an examination of the ^{1}H nmr spectrum of a mixture of isomers prepared by lithium aluminum hydride reduction of 1-oxo-4-methyl-1,2,3,4-tetrahydronaphthalene, **6**, indicated that it would be extremely difficult to assign relative stereochemistry with confidence from data on coupling constants and chemical shifts. A stereoselective synthesis was therefore designed in which the methyl group was used to affect the stabilities of two possible bromonium intermediates **3***a* and **3***b*. Thus the relative concentration of these species and the relative rates of attack by water on C-1 controlled the amount

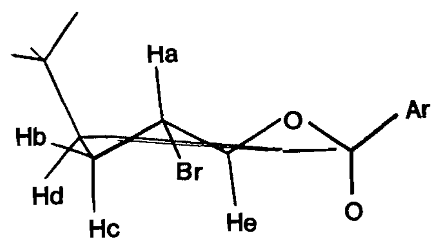


3a



3b

of each bromohydrin formed. Reaction of **1** with *N*-bromosuccinimide in dioxane–water yielded a mixture of bromohydrins in which one isomer predominated (16:1). The major isomer was readily purified by crystallization of the acetyl derivative. Neither its ^{1}H nmr spectrum nor that of the free alcohol could be used to assign relative stereochemistry. However, a series of decoupling experiments on a benzoate derivative suggested the stereochemistry shown in **2***c*. Since **2***b* was to be used for preparation of **4***a* and **5***b*, the relative stereochemistry was verified by an X-ray crystallographic structure determination.



2c

The crystal structure of **2***b* was determined as described in the experimental section. The final bond lengths and angles are given in Fig. 2 and appear unexceptional.

The reactions employed for converting **2***b* to the *cis*-isomer, **4***a*, and the *trans*-isomer, **5***b*, are outlined in Scheme 1. Our expectation that the use of the Misunobu reaction would cleanly invert the configuration at C-1 was based, in part, on results of an earlier study (5) in which we had shown that this reaction on (1*R*)-phenylethanol yielded the *S*-enantiomer with an optical purity of better than 95%.

Preparation of chiral alcohols and a determination of their absolute stereochemistry

Microbial hydrolysis of **4***b* yielded (−)-**4***a* whose specific rotation was surprisingly small (see summary of results in Table 1). In order to estimate the enantiomeric excess (e.e.) and to establish its absolute stereochemistry, (−)-**4***a* was oxidized with Jones' reagent to 4*S*-methyl-1-tetralone, (−)-**6**, of known absolute stereochemistry (6). The sign and magnitude of the specific rotation of the (−)-**6** obtained and its cd (circular dichroism) spectrum was used to assign the absolute stereochemistry of (−)-**4***a* (e.e. 33%) as 1*R*,4*S*. Thus, the presence

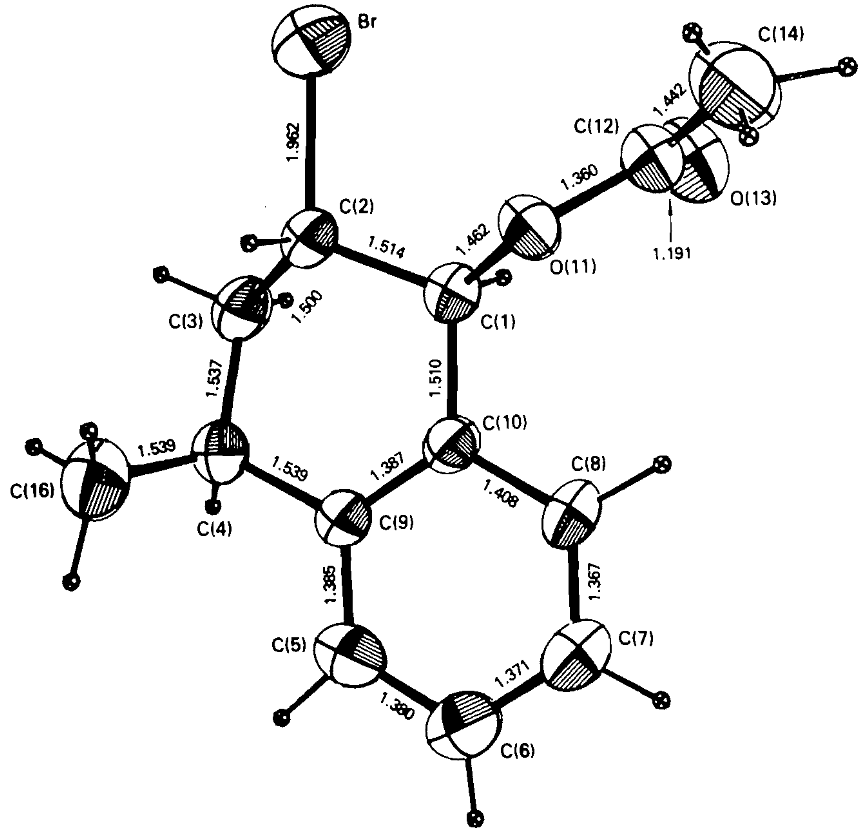


FIG. 2. Crystal conformation of **2***b* showing bond lengths.

TABLE 1. A summary of data on the enantioselective hydrolyses of acetates

Compound	Absolute stereochemistry of alcohol formed (enantiomeric excess)	Percent hydrolysis	Specific rotation: Acetate	Specific rotation: Alcohol
4*b*	1*R*,4*S* (33%)	37%	−18.0° (c 5.1, $CHCl_3$)	−1.9° (c 4.8, $CHCl_3$)
5*c*	1*R*,4*R* (15%)	81%	−14.0° (c 1.6, $CHCl_3$)	−10.9° (c 3.9, $CHCl_3$)
2*b*	1*R*,2*R*,4*R* (53%)	8%	+4.9° (c 5.9, $CHCl_3$)	+12.2° (c 1.3, $CHCl_3$)

of a *cis*-methyl group on C-4 did not alter the absolute stereochemistry at the carbinol carbon; however, the e.e. of the alcohol was smaller (33%) than that obtained for 1-tetralol (71%).

Data on the hydrolysis of the *trans*-isomer, **5***c*, is summarized in Table 1. The absolute stereochemistry of (−)-**5***b* formed in the hydrolysis was established as 1*R*,4*R* by oxidation to the 4*R*-ketone (6). Thus the presence of a *trans*-methyl group again did not alter the stereochemical course of the hydrolysis.

Hydrolysis of **2***b* by *R. nigricans* yielded (+)-**2***a* and its absolute stereochemistry was established by chemical transformation to (+)-**4***a*. A sample of (+)-**2***b* recovered from the microbially mediated hydrolysis (the *antipode* of the alcohol formed) was reduced with lithium aluminum hydride to (−)-**4***a*. Since the specific rotation of the alcohol obtained was small, the stereochemical assignment was confirmed by acetylation to yield a sample of (+)-**4***b* with a larger specific rotation. These transformations established the absolute stereochemistry at the carbinol carbon as *S*, i.e. the presence of the 4-methyl group *did not alter* the relative sizes of the fused aromatic ring and C-2. The e.e. of the alcohol was essentially identical (53 vs. 56) with that reported for the des-methyl compound. While it may be tempting to try to relate the observed e.e. with steric and electronic factors, it is important to remember that these are kinetic resolutions and the e.e. depends upon the quantity of substrate hydrolysed. Furthermore, the culture of *R. nigricans* contains a variety of other enzymes that oxidize varying amounts of substrate and product. Thus, although a considerable effort was made to standardize the cultures employed, there were significant variations in the rates of hydrolysis of different substrates.

The major advantages of using *R. nigricans* to assign the absolute stereochemistry of a secondary alcohol are: (*1*) The enzyme system responsible for the hydrolyses does not appear to be sensitive to the presence of groups some distance from the carbinol carbon, i.e. the stereochemistry of the alcohol formed is primarily dependent on the relative size of substituents on the carbinol carbon. (*2*) This method provides chiral material that can be used to verify assigned configurations. This latter point is important, since absolute stereochemistries assigned by this method, that of Horeau, and other proposed methods (3) are not completely certain. However, since each general method depends on a different property or reaction of the alcohol, one can be more confident of assignments based on data from several methods.

Experimental

General procedure

Melting points were determined by using a hot-stage apparatus; they are uncorrected. Proton magnetic resonance spectra were recorded on a Varian HR-220 MHz instrument; chemical shifts are reported in parts per million (δ) downfield from tetramethylsilane as an internal standard, with coupling constants (J) in hertz. Optical rotations were recorded on a Perkin–Elmer 241MC polarimeter, mass spectra on an LKB instrument. Microbial hydrolyses were carried out as described earlier (ref. 1), using *Rhizopus nigricans* (ATCC 6227b).

Synthesis

*1-Methyl-1,2-dihydronaphthalene (**1**)*

A solution of 4-methyl-1-tetralone (5.0 g) in anhydrous ether (5 mL) was added dropwise to a slurry of $LiAlH_4$ (0.408 g) in anhydrous ether (50 mL) with stirring at room temperature. When the addition was complete, the solution was refluxed for 1 h and worked up in the usual manner. The crude mixture of alcohols was dissolved in benzene (100 mL), *p*-toluene sulfonic acid (50 mg) was added, and the solution was refluxed for 4 h. The reaction mixture was cooled, washed with aqueous sodium bicarbonate, then with water, and dried. The solvent was removed *in vacuo* and the residue distilled under reduced pressure to give **1** as a colorless liquid (3.44 g), bp 59–61°C/1.4 Torr (1 Torr = 133.3 Pa), in 77% yield (lit. (7) bp 70–85°C/0.07 Torr).

*2-Bromo-4-methyl-1,2,3,4-tetrahydronaphth-1-yl acetate (**2**b)*

N-Bromosuccinimide (7.95 g) was added to a solution of **1** (6.3 g) in 51 mL of dioxane–water (44:7.3) and the solution was stirred overnight at room temperature. It was poured into water (330 mL) and the mixture was extracted with methylene chloride (3 × 100 mL). The combined organic layers were washed with water, brine, and dried. The solvent was removed under reduced pressure and the reaction products were acetylated with acetic anhydride (8.3 mL) and pyridine (35 mL) at room temperature. An estimate of the stereoselectivity of the reaction (~16:1) of the *cis* and *trans*-4-methyl bromohydrins was made from an nmr spectrum of the crude acetylation mixture, which was worked up in the usual manner and chromatographed on silica gel to give crude **2***b*, which was crystallized from hexane to yield pure **2***b* (8.64 g) in 70% yield, mp 85–86°C; ^1H nmr ($CDCl_3$) δ: 1.36 (d, 3H), 2.08 (s, 3H), 2.23 (m, 2H), 3.16 (q, 1H), 4.50 (m, 1H), 6.11 (d, 1H), 7.15–7.27 (m, 4H). *Anal.* calcd. for $C_{13}H_{15}O_2Br$: C 55.14, H 5.34; found: C 55.29, H 5.51.

A sample of **2***a* was treated with benzoyl chloride and pyridine in the usual manner to yield **2***c*; ^1H nmr ($CDCl_3$) showed peaks at δ (ppm): 1.42 (d, 3H), 2.26–2.47 (m, 2H), 3.22 (m, 1H), 4.66 (m, 1H), 6.38 (d, 1H), 7.23–8.28 (m, 9H).

The coupling constants H_A-H_E (**2***c*) were determined by decoupling experiments on the 300 MHz Bruker spectrometer.

J_{AB} = 3.2 Hz	J_{BD} = 6.0 Hz
J_{AC} = 6.9 Hz	J_{BC} = 14.5 Hz
J_{AE} = 5.0 Hz	J_{CD} = 7.9 Hz

*cis-1-Hydroxy-4-methyl-1,2,3,4-tetrahydronaphthalene (**4**a)*

A solution of **2***b* (2.83 g) in THF (10 mL) was added dropwise over 10 min to a stirred slurry of $LiAlH_4$ (0.570 g) in anhydrous THF (10 mL). The reaction mixture was then refluxed for 4 h and worked up in the standard manner. The product was chromatographed on silica gel (hexane/ethyl acetate 9:1) to afford **4***a* (1.35 g, 83% yield) as a colorless solid, mp 66–68°C; ^1H nmr ($CDCl_3$) showed peaks at δ (ppm): 1.31 (d, 3H), 1.66–1.95 (m, 4H), 2.22 (s, 1H), 2.81 (q, 1H), 4.67 (bs, 1H), 7.19–7.39 (m, 4H).

*cis-4-Methyl-1,2,3,4-tetrahydronaphth-1-yl acetate (**4**b)*

A sample of **4***a* was acetylated with acetic anhydride/pyridine in the usual manner to yield **4***b* as a colorless oil; ^1H nmr ($CDCl_3$) showed peaks at δ (ppm): 1.33 (d, 3H), 1.60–1.99 (m, 4H), 2.04 (s, 3H), 2.80 (q, 1H), 5.94 (t, 1H), 7.12–7.28 (m, 4H).

*trans-1-Hydroxy-4-methyl-1,2,3,4-tetrahydronaphthalene (**5**b)*

A mixture of diisopropyl azodicarboxylate (1.62 g) and triphenylphosphine (2.10 g) in freshly distilled THF (20 mL) was stirred at 0°C for 30 min. To this solution was added a solution of **4***a* (0.648 g) and benzoic acid (0.976 g) in THF (7.5 mL) dropwise over 5 min. The reaction mixture was stirred at 0°C for 1 h and left in the refrigerator overnight. The solvent was removed *in vacuo* and the residue chromatographed on silica gel to give **5***a* (1.02 g) as a colorless oil in 96% yield; ^1H nmr ($CDCl_3$) showed peaks at δ (ppm): 1.27 (d, 3H), 1.57 (m, 2H), 1.98 (m, 1H), 2.23 (m, 1H), 2.99 (m, 1H), 6.06 (d, 1H), 6.95–7.41 (m, 3H), 7.89 (d, 1H). The benzoate was hydrolyzed by refluxing for 1 h in methanol–water (25 mL) containing sodium hydroxide (1.3 g). The reaction mixture was diluted with water (100 mL) and extracted with ethyl acetate (3 × 100 mL). The combined extracts were washed with brine, and dried and concentrated *in vacuo*. The residue was chromatographed on silica gel to give **5***b* as a colorless solid (0.611 g) in 98% yield, mp 35–37°C; ^1H nmr ($CDCl_3$) showed peaks at δ (ppm): 1.22 (d, 3H), 1.45 (m, 1H), 1.73 (m, 1H), 2.08 (m, 2H), 2.36 (s, 1H), 2.91 (q, 1H), 4.66 (bs, 1H), 7.15–7.38 (m, 4H).

Microbial hydrolyses

The potato-dextrose medium for growing *R. nigricans* was prepared as previously described (1). A 1-L Erlenmeyer flask containing 250 mL of this medium was inoculated with *Rhizopus nigricans* (ATTC 6227b) grown in liquid culture, and shaken for 6–7 days at 25°C. The substrate (~450 mg) in 1 mL of THF was added and the flask was shaken for 26 h. The mycelium and medium were extracted with ethyl acetate (3 × 100 mL) and the combined extracts were dried and concentrated. An nmr spectrum of the crude product was used to determine percent hydrolysis. The recovered acetate and the alcohol formed were separated by column chromatography on silica gel with *n*-hexane and ethyl acetate as eluants. Results for the hydrolysis of **2***b*, **4***b*, and **5***c* are given in Table 1.

*Absolute stereochemistry of (−)-**4**a*

Jones' reagent was added dropwise with stirring to a solution of (−)-**4***a* (22.7 mg, $[\alpha]_D^{25}$ −1.9° (c 4.75, $CHCl_3$)) in acetone (4 mL) at 0°C. After 30 min the reaction mixture was diluted with water (50 mL) and the solution was extracted with ethyl acetate (3 × 30 mL). The ethyl acetate extract was washed with aqueous sodium bicarbonate and brine. The solvent was removed *in vacuo* and the residue was purified by column chromatography on silica gel to yield (−)-4-methyl-1-tetralone, (−)-**6** (22.4 mg, $[\alpha]_D^{25}$ −6.4° (c 1.5, $CHCl_3$)). The optical purity of (−)-4-methyl-1-tetralone was determined as 33% by averaging a comparison of the measured values with those reported in the literature (6): 376 nm (−72.2, reported −214.5), 367 nm (+51.0, reported 161.7), 359 nm (−118.8, reported −363), 351 nm (+137.2, reported 429), 344 nm (−88.4, reported −277), 337 nm (+189.4, reported 594), 330 nm (−20.3, reported −52.8), 323 nm (+196.9, reported 528), 312 nm (+133.6, reported +429).

*Conversion of (−)-**4**a to (+)-**4**b*

A sample of (−)-**4***a* (24.3 mg, $[\alpha]_D^{25}$ −1.9° (c 4.75, $CHCl_3$)) was acetylated in the usual manner to yield (+)-**4***b* (27.3 mg, 89% yield); $[\alpha]_D^{25}$ +37.6° (c 1.8, $CHCl_3$). The ^1H nmr spectrum of (+)-**4***b* was identical with that of racemic material described above.

*Absolute stereochemistry of (−)-**5**b*

A sample of (−)-**5***b* (38.8 mg, $[\alpha]_D^{25}$ −10.9° (c 3.9, $CHCl_3$)) was oxidized as described for (−)-**4***a* to give an oil, (+)-4-methyl-1-tetralone (37.1 mg, $[\alpha]_D^{25}$ +2.9° (c 3.1, $CHCl_3$)), e.e. 15%.

*Absolute stereochemistry of (+)-**2**a*

A sample of (−)-**2***a* (19.0 mg, $[\alpha]_D^{25}$ + 12.2° (c 1.3, $CHCl_3$)) was acetylated in the usual manner to yield (−)-**2***b* (20.0 mg, $[\alpha]_D^{25}$ −90.0°

(c 1.3, $CHCl_3$)), e.e. 53%.

The absolute stereochemistry of (−)-**2***a* was established by reduction of a sample of (+)-**2***b* (85.1 mg, $[\alpha]_D^{25}$ +10.2° (c 5.14, $CHCl_3$)) with excess $LiAlH_4$ in THF to yield (−)-**4***a* (27.5 mg, $[\alpha]_D^{25}$ −0.16° (c 1.83, $CHCl_3$). The observed rotation was very small so the compound was acetylated in the usual manner to yield (+)-**4***b*, 32.0 mg $[\alpha]_D^{25}$ +6.90° (c 2.13, $CHCl_3$). The absolute stereochemistry of this material is therefore 1*R*,4*S* and that of (+)-**2***a* formed in the hydrolysis 1*R*,2*R*,4*R*.

High performance liquid chromatography studies with Pirkle column

The hplc measurements were made using a column purchased from the Regis Chemical Co., Martin Grove, IL 60053. The column consists of (*R*)-*N*-(3,5-dinitrobenzoyl)phenylglycine ionically bonded to a γ-aminopropyl-silanized silica column. The solvent system was 0.5% isopropanol in hexane. No separation was observed for **4***a* or **5***b* under these conditions.

X-ray crystal structure determination of **2b**

Crystal data for compound **2***b* are:
Molecular formula: $C_{13}H_{15}O_2Br$ Mol. wt. 283.16
Habit: elongated plates; radiation: Cu Kα (graphite monochromator); wavelength: 1.5418 Å; space group: $P2_12_12_1$ (No. 19); cell dimensions (from LS reft. of ±θ data), a = 8.810(1) Å, b = 9.661(1) Å, c = 14.852(1) Å, V = 1264.10 Å^3, Z = 4, D_x = 1.488 g cm^{-3}. Crystal size: ca. 0.3 × 0.1 × 0.05 mm; reflections: 1468 (193 < 1σ); maximum sin θ/λ: 0.6229 Å^{-1}. Diffractometer: Nonius CAD-4; function minimized: $\Sigma w\Delta^2$; anisotropic temperature factor: exp $(-2\pi^2(\Sigma_i\Sigma_j U_{ij}a_i^* a_j^* h_ih_j))$. Final R-factor (observed reflections only): 4.9%.

The crystals were very thin elongated plates but by careful selection it was possible to obtain adequate samples for crystallographic work. Interestingly, the crystal habit was not centrosymmetric and the plates had a triangular cross section when viewed perpendicular to the smallest face. It is possible that spontaneous resolution has taken place in view of the chiral space group but hand sorting would not be practical in view of the small size of the crystals. The compound is sensitive to X-radiation and a preliminary experiment indicated a fall-off of 33% in the intensities of standard reflections after only 10 h of exposure. Five crystals were used to collect the X-ray intensity data; each crystal was replaced when the periodically measured standard intensities had fallen to 90% of their initial values. The dimensions of all crystals used were as indicated in the crystal data section except for the last one which was somewhat thicker. Two scale factors were used for each group of data except for the last group whose standards had only dropped 5% at the end of the data collection. Since several crystals were used to collect the X-ray data, no attempt was made to determine absolute configuration nor was anomalous dispersion taken into account in the refinement.

The structure was solved using a Patterson map to find the Br atom and then by use of the programs of MULTAN 78 (8). The structure was refined using XRAY 72 (9). After anisotropic refinement of the heavier atoms, a difference map gave evidence for all H atoms. The positional parameters of the H atoms were refined but not the temperature factors, which were estimated from the isotropic thermal parameters of the heavier atoms.

The diagram showing the X-ray results was drawn by ORTEP (10).

A proposal that the physiological activity of a chlorinated biphenyl is related to its degree of molecular planarity is explored through experimental measurements of inter-ring dihedral angles in the gas phase. A known correlation between the difference between fourth and first ionization energies of substituted biphenyls (via photoelectron spectroscopy), and the thermally averaged inter-ring dihedral angle as established by electron diffraction techniques, is confirmed and exploited for the present purpose. The expectation, based on both qualitative and quantitative theoretical considerations, that increased *ortho* substitution causes an increase in inter-ring angle, is confirmed. However, the observation that, for 2,2′-substituted halobiphenyls the only observed conformation is the near-*syn* form, is not easy to explain, and is discussed in terms of a non-bonding attractive force between halogen atoms.

J. J. DYNES, F. L. BAUDAIS et R. K. BOYD. Can. J. Chem. **63**, 1292 (1985).

Faisant appel aux mesures expérimentales effectuées en phase gazeuse des angles dièdres entre les cycles, on a étudié l'hypothèse suggérant que l'activité physiologique des biphényles chlorés est reliée à son degré de planéarité moléculaire. Dans cette étude, on a confirmé et exploité la corrélation connue qui existe entre les quatrième et première énergies d'ionisation des biphényles susbtitués telles que mesurées (via la spectroscopie photoélectronique) et l'angle dièdre inter-cycle pondéré thermiquement tel qu'établi par les techniques de diffraction électronique. En se basant sur des considérations théoriques tant qualitatives que quantitatives, on peut prévoir qu'une augmentation de la substitution en position *ortho* provoquera une augmentation de l'angle inter-cycle; nos résultats confirment cette hypothèse. Cependant, on ne peut pas expliquer facilement le fait que, dans le cas des biphényles halogénés substituées en positions 2,2′, la forme quasi-*syn* est la seule conformation observée. On en discute en fonction d'une force attractive non liée entre les atomes d'halogènes.

[Traduit par le journal]

Introduction

Maier and Turner (1) showed how the dihedral angle between the two rings of a series of gaseous biphenyls is related to the difference in ionization energies for electrons in the π_3 and π_6 molecular orbitals. This difference between fourth and first ionization energies was shown (1) empirically to vary linearly with cos θ, where θ is the inter-ring dihedral angle determined by electron diffraction. The qualitative trends observed were satisfactorily accounted for (1) by simple analogies drawn with the molecular orbitals (MO's) of substituted benzenes, as determined (2) by photoelectron spectroscopy (PES). The linear correlation between $\Delta E(\pi_3 - \pi_6)$ and cos θ was satisfactorily accounted for (1) by an ingenious analysis of the π-MO's described by a Huckel approach using as basis set the semi-localized π-MO's of the phenyl moieties, in place of the more usual atomic orbitals. Together with a frozen-orbital (Koopmans' theorem) assumption to permit identification of an orbital energy with the negative of the corresponding experimental ionization energy (I.E.), this approach was shown by Maier and Turner (1) to lead to the following prediction:

$$[1] \quad \Delta E(\pi_3 - \pi_6) = B \cos \theta$$

where B is related to the standard Huckel resonance integral. Not surprisingly, this Huckel formalism predicts the correct qualitative relationship, but fails to predict quantitatively the values of the parameters, e.g. the experimental intercept at $\theta = 90°$ is non-zero (1).

Apart from these and other considerations of the more fundamental aspects of the PES results, the empirically determined linear relationship between $\Delta E(\pi_3 - \pi_6)$ and cos θ was used (1) to determine the inter-ring dihedral angles θ for several substituted biphenyls which had not been subjected to electron diffraction analysis.

Recently a theoretical investigation of the conformations of some polychlorinated biphenyls (PCB's) was published (3). Rotation potentials (potential energy as a function of θ) were determined for biphenyl itself and for three dichloro isomers as well as one tetrachloro and one hexachloro isomer (3). The experimentally determined inter-ring angles θ presumably correspond to the minima in these potential profiles (3). The motivation behind this theoretical study (3) lies in the strong isomer dependence of physiological activity of different PCB congeners. For example, it was shown (4) that the induction by PCB's of aryl hydrocarbon hydroxylase (AHH) and ethoxyresorufin (OR) O-deethylase activity in rat hepatoma H-4-II-E cells was strongly dependent on substitution pattern in the PCB's. Chlorine substitution at both *para* and at least two *meta* positions was shown (4) to result in maximum activity, whereas *ortho* chlorines resulted in appreciably decreased activities. *Ortho*-substituted PCB's are more soluble in water, and thus have lower octanol–water partition coefficients (5) than do their non-*ortho*-substituted isomers. This and similar evidence has led to the suggestion (6) that the degree of planarity of the PCB molecule is a major determinant of its lipid solubility and thus its physiological activity. *Ortho*-substituted PCB's are expected to exhibit the largest values of θ, thus accounting for the lower activities.

The motivation for the present work was similar to that for the theoretical study cited (3), viz. to investigate the relationship between molecular planarity and physiological activity. The dihedral angles for a series of PCB congeners have been determined from PES, using the correlation described previously (1). In this work we concentrated upon the more volatile lower congeners (mono, di, and trichlorobiphenyls), although examples of compounds of more immediate toxicological interest are also included. In addition, some other

[1] Present address: Bomem Inc., 625 Rue Marier, Vanier, Ont., Canada G1M 2Y2.

biphenyls were investigated, both to test our experimental technique against the original work (1) and to investigate the effect of methyl groups as replacement substituents for chlorine atoms.

Experimental

The electron energy spectrometer is of the differential retarding field type first described by Lindau *et al.* (7), and more recently by Hotop and Hubler (8). In its present configuration, resolution has been sacrificed for sensitivity since many of the compounds to be studied are of low volatility.

The light source (He I line) is a sealed helium discharge lamp, based on the design of Kinsinger *et al.* (9). The aluminum filter window was constructed from metal film purchased from Luxel Corporation, Santa Barbara, CA. The discharge was maintained by a Raytheon Model PGM 10 × 1 microwave generator. Titanium getter wires (Vacuum Instrument Co., New York) were used in a manner similar to that described previously (9).

The electron multiplier used was a SEM Model 4219 spiraltron (Galileo Inc., Sturbridge, MA). Signal detection and amplification was achieved via a pulse amplifier/discriminator and counter, based on the design of Borders *et al.* (10). A Rockwell AIM 65 microprocessor (Rockwell International, Aneheim, CA) with Dram Plus Expansion Board (Computerist Inc., Chelmsford, MA), was programmed to control spectrometer scan functions and to acquire and store data on conventional magnetic tape cassetes. Multiple-scan accumulation permitted a considerable increase in attainable signal/noise ratios.

The high vacuum was maintained by an Edwards EO 6 diffusion pump (1350 L/s for air). Ultimate vacuum better than 2×10^{-7} Torr (1 Torr = 133.3 Pa) could be achieved.

Most of the polychlorinated biphenyl samples were obtained from Ultra Scientific Inc. (Hope, RI). The samples of the 2,2′,5,5′ and 2,2′,4,4′,5,5′ congeners were gifts from Dr. S. Safe, Texas A and M University. All other samples used were purchased from Aldrich or Chemicals Procurement Labs, Inc. and were used as received. The helium used in the discharge lamp was Matheson 99.9999% purity.

Results

A photoelectron spectrum of nitrogen was always taken just prior to each biphenyl compound, in order to check on instrument performance, energy-scale calibration, etc. The inherent instrumental energy resolution is of the order of 0.1 eV. This is less than that ultimately obtainable on an instrument of this type (7, 8) by a factor of about 5, but is adequate for the present purpose.

The spectra of the compounds studied in the present work are shown in Figs. 1–3. The signal-to-noise ratio is somewhat variable due partly to differences in sample volatility, and also to deterioration of the aluminum foil window on the helium discharge source. In those cases where comparisons are pertinent, the present results are in good agreement with those of Maier and Turner (1).

Table 1 summarizes the data obtained for:

$$[2] \quad \Delta E \equiv (\mathrm{IE}_4 - \mathrm{IE}_1) = E(\pi_6) - E(\pi_3)$$

for those compounds for which gas-phase electron-diffraction data on inter-ring angles θ are available. This list contains one compound (4,4′-difluorobiphenyl) which was not included in the corresponding table of Maier and Turner (1), even though this compound was indeed studied in the original work (1). In fact, the value of ΔE for this compound is extremely close to that for 2-fluorobiphenyl and to that for biphenyl itself, so that its omission from the calibration table makes little difference to the final correlation. In addition, 2,2′-dichlorobiphenyl was studied here, but not previously (1). Figure 4 shows the data of Table 1 plotted as ΔE vs. cos θ, as proposed previously (1). Least-squares linear regression analysis of the combined data of Table 1 yields:

$$[3] \quad \Delta E = 1.60 \cos \theta + 0.31$$

The status of the electron-diffraction measurements in the gas phase has been reviewed (16). A general review of principles and applications of conformational analysis by PES has been published (17).

Table 2 lists the experimental data for those compounds, studied in the present work, for which no electron-diffraction data are available. The values of inter-ring angle θ quoted for these compounds are those calculated from the experimental value for ΔE together with eq. [3]. The main uncertainty in the measurement of θ, in most cases, arose from difficulties in identifying ΔE from the spectra. The uncertainties in the present values of θ (Tables 1 and 2) are standard deviations calculated for four independent estimates of ΔE for each spectrum, made by two different observers. In Table 3 are listed more complete data for all ionization energies which could be determined reasonably unambiguously from the spectra.

In the spectra of a few of the compounds which were of low volatility, a rather sharp peak appears at an ionization energy of around 13.8 eV. No such feature is apparent in any other of the spectra, and it is believed that this corresponds to an impurity resulting from thermal decomposition of the sample at the high temperatures used.

Discussion

The general trends observed in the photoelectron spectra appear to agree well with those observed in the original work of Maier and Turner (1), and thus require little additional comment here. Some of the inter-ring angles listed in Table 2 are of the order of 80°, which corresponds to the angle at which the energies of the π_4 and π_6 MO's (and also of the π_3 and π_5 MO's) cross over (1). Thus, these estimates are subject to uncertainties of interpretation, quite apart from those arising from difficulties in estimating ΔE. A similar comment applies to a recent PES measurement of the conformation of 2,2′-diethynylbiphenyl (18), which indicated an inter-ring dihedral angle in the range 80–90°.

The present discussion will concentrate upon the values found for the inter-ring angles. In general, these follow the expected pattern, with increased *ortho* substitution causing an increase in θ. Of course, such angles represent some appropriate thermal average over the inter-ring twisting motion, as has been emphasized (16) in the review of the electron diffraction work upon which the present measurements are ultimately based. The existence of a potential well which is broad with respect to twist angle θ, deduced from the electron diffraction data for biphenyls (16), is confirmed by theoretical calculations (3, 14, 19, 20). However, none of these calculations which considered halobiphenyls (3, 14) was able to account for the observation (16) that the prevailing conformer in all the 2,2′-dihalobiphenyls is that with the two halogen atoms on the same side, i.e. close to the *syn* rather than the *anti* conformation. In terms of the definition of inter-ring angle used in the most recent theoretical work (3), (θ = 0 for 2,2′-dichlorobiphenyl defined as the planar molecule with the chlorine atoms in the *transoid* configuration), experiment (13, 15) finds that the preferred value of θ lies between $\pi/2$ and π rather than

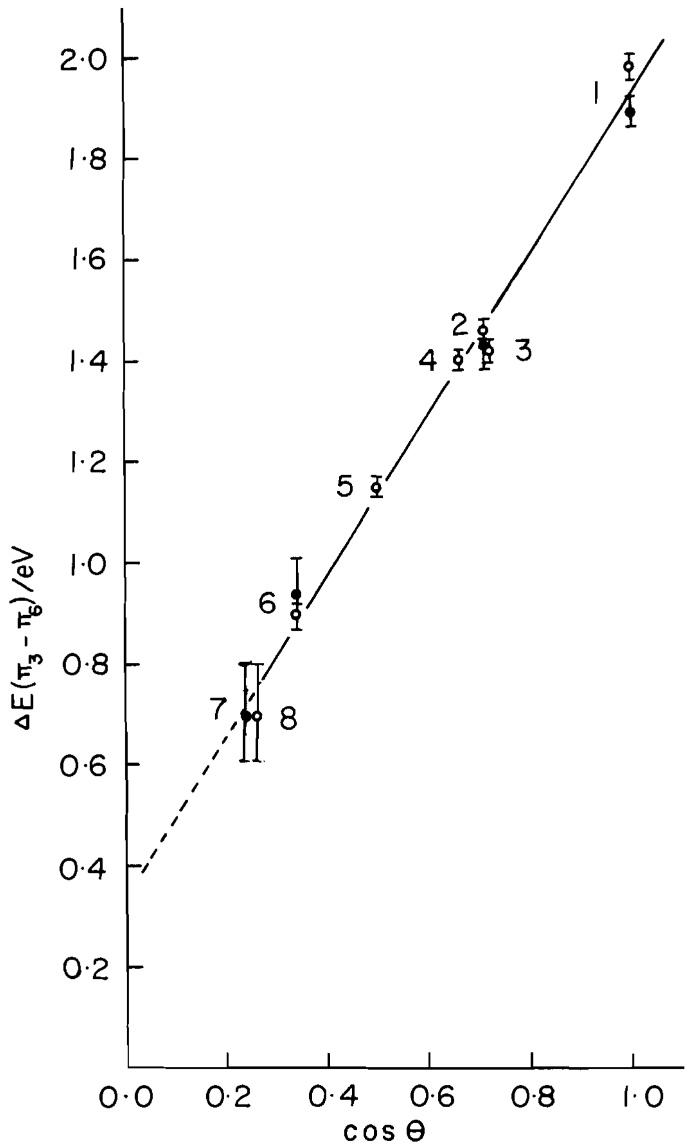

FIG. 4. Plot of ΔE (I.E.$_4$ − I.E.$_1$) vs. cos θ (from electron diffraction); data of Table 1. Full symbols, ref. 1; open symbols, present work.

between 0 and $\pi/2$. On the other hand, theory predicts the opposite to be the case; e.g. in the more recent work (3), the potential minimum occurs at approximately 75° from the zero defined as above, i.e. the near-*anti* configuration. It was a similar discrepancy between early experimental (13) and theoretical (14) results which led to a careful re-examination of the electron diffraction experiment on 2,2′-dichlorobiphenyl (15). This study (15), which essentially confirmed the earlier experimental work on this compound (13), used a rather high temperature of 300°C in a (fruitless) search for the other conformer. As was clearly shown (15) by X-ray diffraction, this compound in the crystalline state also exists exclusively as the near-*syn* form.

As was shown previously (16), the electron-diffraction results for 2,2′-dihalobiphenyls fall into a general pattern in which the dihedral angle increases with increasing size of the halogen substituents. More interestingly, however, the near-*syn* configuration is always that observed. Further, the experimental X—X distances (X ≡ halogen, except for F) are shorter than those predicted on the basis of Pauling's van der Waals radii (21), the discrepancy increasing with increasing atomic number of X. In the case of X = F the X—X distance is actually slightly larger than that predicted on the basis of van der Waals radii (21), but values are shorter by 14, 28, and 48 pm for X = Cl, Br, and I respectively (16).

These observations (16) strongly suggest the existence of some halogen–halogen non-bonded attraction force, which was not taken into account in the theoretical work (3, 14). A similar conclusion can be reached from the results of the present work, through comparison of inter-ring angles for corresponding methyl and chloro-substituted biphenyls. The relevant data are drawn together in Table 4. The point of comparing X = CH_3 with X = Cl is that the steric requirements of these two substituents are essentially identical (22) provided that the CH_3 groups are freely rotating. While the differences in Table 4 are not large, barely statistically significant, it is interesting that the 3,3′- and 4,4′-disubstituted compounds show $\theta(CH_3) < \theta(Cl)$, while the reverse is true for the 2,2′-disubstituted biphenyls. This trend is thus also consistent with the existence of an attractive force between two nonbonded Cl atoms, which is absent if X = CH_3.

Table 2 also shows that further substitution at sites well removed from the *ortho* positions induces small but significant decreases in θ from the value for 2,2′-dichlorobiphenyl itself.

With the exception of 2,2′-difluorobiphenyl, for which electrostatic repulsion between highly electronegative fluorine atoms could be expected to dominate, the existence of an intramolecular attractive force between nonbonded halogen atoms seems to be established for 2,2′-dihalobiphenyls. A corresponding intermolecular attractive force underlies the so-called "chlorine atom effect" of Schmidt and Green (23–25). This effect manifests itself via the production of close-packed, highly overlapped parallel molecules in the crystal structures of

aromatic molecules, induced by halogen (and particularly dichloro) substitution on phenyl rings. This is a dramatic change from the highly characteristic herring-bond structure of alternate layers of phenyl rings in the crystalline state, and has been exploited (23–25) in the engineering of crystal structures for stereospecific photodimerization reactions in the solid state.

The intramolecular effect observed (16) for 2,2′-dihalobiphenyls may also be related to the relative stabilities of *cis* and *trans* isomers of 1,2-dihaloethylenes. In the gas-phase, the *cis* forms are generally more stable than the *trans*, again in opposition to predictions based only on van der Waals effects. This observation has been investigated theoretically by Epiotis *et al.* (26, 27), and characterized as due to a through-space interaction of lone pair orbitals, akin to a charge-transfer inter-

TABLE 4. Inter-ring dihedral angles (degrees) for corresponding methyl and chloro-substituted biphenyls (values in parentheses for ref. 1)

action. Such an interaction could also be responsible for difficulties in accounting for the observed crystal structure of Cl_2 (28).

The broad implications of the present work, for the relative toxicities of different PCB congeners, is based upon the proposal (6) that it is the planar conformations which are the most active in this respect. Certainly the experimental evidence (4) bears out the implication that *ortho* chlorine substitution should decrease physiological activity. The present work, which in this one respect is best viewed as an extension of the electron diffraction work (16), confirms that increasing *ortho* substitution drives the preferred conformation further from planarity. The failure to observe both conformers in gaseous 2,2′-dichlorobiphenyl (15) suggests that the barrier to rotation from the near-*syn* to the near-*anti* conformation must be much higher than the value of RT ($\approx$5 kJ mol^{-1}) at the experimental temperature (15). This observation (15) is difficult to understand in terms of either qualitative intuition or of quantitative theoretical estimates (3, 14) of the potential energy profile for inter-ring rotation. It is clear that understanding of the problem of conformation of substituted biphenyls still leaves much to be desired.

Acknowledgements

We are indebted to Dr. Stephen Safe for the gift of the tetrachloro and hexachloro biphenyls, and to Dr. Giacinto Scoles for the loan of the microwave generator. The criticisms of Dr. N. Westwood greatly improved the final manuscript. Financial support by NSERC is acknowledged.

MITCHELL A. WINNIK, ANDREW M. SINCLAIR, and GÉRARD BEINERT. Can. J. Chem. **63**, 1300 (1985).

An asymmetrically end-labelled polystyrene of low polydispersity has been synthesized. The labels are pyrene and dimethylaniline, which can form an emissive exciplex from excited pyrene. End-to-end cyclization rate constants $\langle k_1 \rangle$ have been calculated from fluorescence decay data in a variety of solvents. Steady-state measurements are also presented. Correction of the $\langle k_1 \rangle$'s for differences in solvent viscosity yields cyclization rate constants of $0.7 \times 10^6\ s^{-1}$ in good solvents and about twice this in poor (sub-θ) solvents. Cyclization rate constants $\langle k_1 \rangle$ in toluene and cyclohexane at 22°C obtained using this pyrene/dimethylaniline exciplex probe are compared with those obtained previously using a pyrene/pyrene excimer probe.

MITCHELL A. WINNIK, ANDREW M. SINCLAIR et GÉRARD BEINERT. Can. J. Chem. **63**, 1300 (1985).

On a synthétisé un polystyrène de faible polydispersité et marqué de façon asymétrique aux extrémités. Les marqueurs sont le pyrène et la diméthylaniline qui peuvent former un exciplex émissif à partir du pyrène excité. On a calculé les constantes de vitesse $\langle k_1 \rangle$ de la cyclisation bout à bout, à partir des données de décroissance de la fluorescence dans divers solvants. On présente également des mesures effectuées dans l'état stationnaire. Les corrections apportées aux valeurs de $\langle k_1 \rangle$, pour tenir compte des différences de viscosités des solvants, donnent des constantes de vitesse de cyclisation de $0{,}7 \times 10^6\ s^{-1}$ dans les bons solvants et environ le double dans les solvants (sub-θ) pauvres. On compare les constantes de vitesse de cyclisation $\langle k_1 \rangle$ dans le toluène et le cyclohexane, obtenues à 22°C en utilisant cette sonde d'exciplex pyrène/diméthylaniline, avec celles obtenues antérieurement en utilisant comme sonde d'excimère le couple pyrène/pyrène.

[Traduit par le journal]

Introduction

Since the seminal papers by Wilemski and Fixman (1) (WF) on the theory of cyclization dynamics of polymers, various experimental methods have been used to try to measure these rates. Cuniberti and Perico (2) used steady-state measurements of pyrene excimer formation to study poly(ethylene oxide). Mita, Horie *et al.* (3) examined triplet–triplet (TT) annihilation between anthracene groups to study polystyrene. Redpath, Winnik, and co-workers used a combination of fluorescence decay and steady state of pyrene excimer formation to study polystyrene (4, 5) poly(ethylene oxide) (6), and polydimethylsiloxane (7). Each of these experiments required the synthesis of polymers of narrow molecular weight distribution, specifically substituted on both chain ends with spectroscopically appropriate (anthracene or pyrene) luminescent groups.

The important questions addressed, for polymer cyclization in dilute solution, have been the chain length (N) dependence of the cyclization rate constant k_{cy}, and the effect of solvent on these rates. Chain length enters the problem because the mean-squared separation of the chain ends R_F^2 increases with chain length, as do the low frequency relaxation times of the chain. Solvent viscosity retards dynamic motion of the chain, whereas solvent quality (good solvent, poor solvent, θ-solvent for the polymer) affects the degree of chain swelling, and hence R_F (8).

WF theory addresses these features in terms of the bead-and-spring model, Fig. 1 (9). In this model one views the chain as

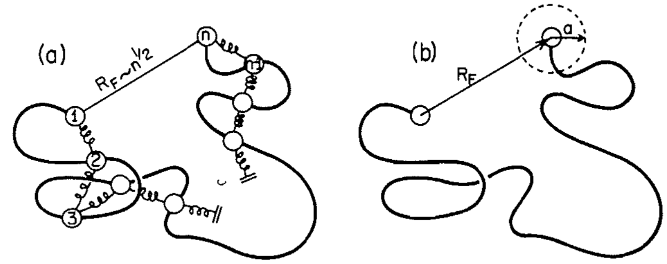

FIG. 1. (a) Depiction of the bead-and-spring (Rouse–Zimm) model for a polymer chain. (b) Depiction of the root-mean-squared end-to-end distance R_F and the quenching radius a for a polymer chain.

a sequence of beads (mass and friction centers) connected by harmonic springs. In the Rouse model, the beads act as independent friction centers, whereas in the Zimm model the solvent is viewed as being trapped (non-draining) inside the coil. Finite chains are partially draining: one must take account of the extent of hydrodynamic coupling between beads which, separated along the chain contour, happen to be in proximity (8).

The original WF papers raised a number of important theoretical issues which were subsequently examined in detail by Doi (10), by Perico and co-workers (11*a*–*c*; see also 11*d*), and by Perico and Cuniberti (12). This subject was recently reviewed in some detail (8).

One of the central predictions of the theory is that $k_{cy} \propto N^{\alpha}$, with α taking he value of $-3/2$ for very long chains in a θ-solvent. For long chains in a good solvent α should approach the value $-9/5$ because of excluded volume effects (4*a*, 8). Furthermore, k_{cy}^{-1} for these long chains should be almost equal

[1] This and the following papers are dedicated to the memory of Li Xiao-Bai of Nankai University, Peoples Republic of China, who died of a sudden illness after returning home from two fruitful years of research in the laboratories of M.A. Winnik and J.E. Guillet at the University of Toronto.

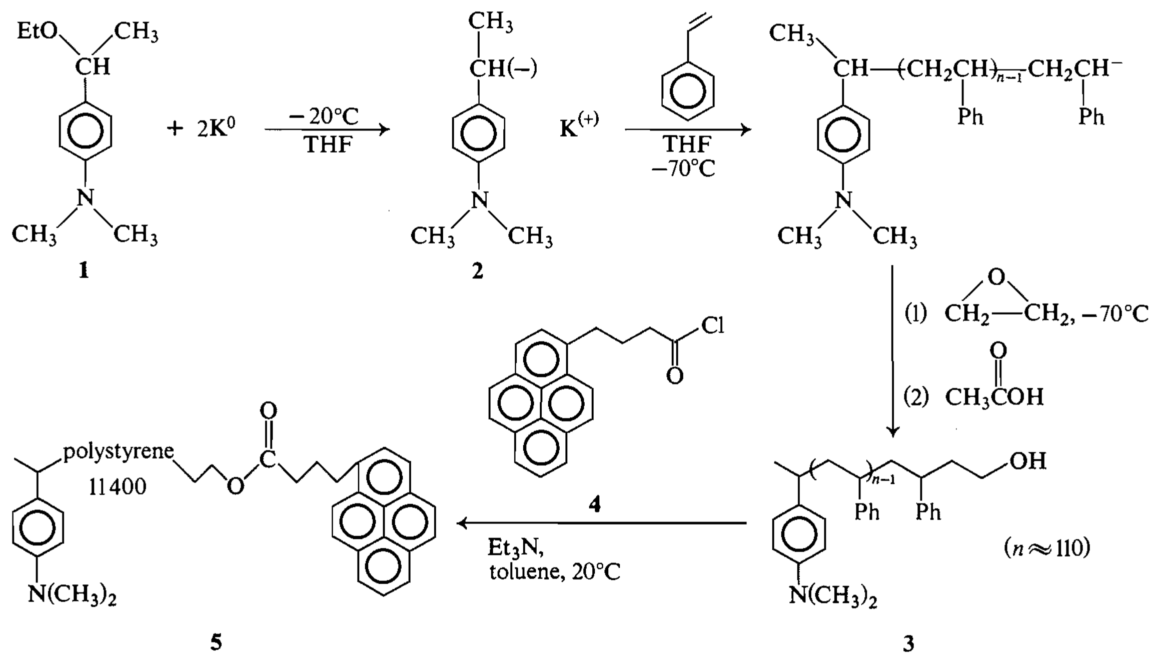

SCHEME 1

to τ_1, the slowest internal relaxation time of the chain, as determined, for example, by viscoelastic relaxation experiments (13).

For shorter chains, other features appear. Cyclization is no longer dominated exclusively by τ_1; all the higher order relaxation modes contribute to k_{cy}. In addition, and of particular importance here, the size of the capture (or quenching) radius a enters into the magnitude of k_{cy} as the ratio of a/R_G, where R_G is the radius of gyration of the chain. Since R_G changes with chain length, but a does not, the value of α is affected. This effect is quite subtle. It has been examined in some detail by Perico and Cuniberti (8, 12) who showed that as $N \rightarrow \infty$, $a/R_G \rightarrow 0$, and k_{cy} becomes independent of a.

One of the curious features of the experimental determinations of the cyclization rate constants has been the discrepancies that exist between results reported by different laboratories. Gross features of the theory have been confirmed in all experiments (2–8). Thus where sufficient data exist, one can quite reasonably draw straight lines through plots of log k_{cy} vs. log N. The slopes frequently differ (although they fall in the range -1 to -1.8) and the magnitudes of k_{cy} sometimes differ for the same polymer–solvent – chain length combination by more than one might anticipate from the precision of the individual experiments.

A notable case concerns the cyclization of polystyrene chains of M = 30 000 to 100 000 in cyclohexane at 34.5°C, the θ-temperature. Rates determined by the study of intramolecular excimer formation of pyrene-end-capped polymers (4, 5) are more than an order of magnitude faster than rates determined by TT annihilation of chains terminated by anthracene groups (3).

In order to test the idea that *measured cyclization rates* might depend upon the spectroscopic technique used to detect cyclization, we decided to examine exciplex formation in a polystyrene polymer containing an aromatic amine at one end and a pyrene group at the other. We chose a chain length ($\bar{M}_n$ = 11 400) sufficiently small that a/R_G was significant, with a value of ca. 0.2. Since a for exciplex formation is larger than for excimer formation (see below), at least in polar solvents, we felt that we would have the means to examine the probe dependence of the cyclization process. We also recognized that exciplexes themselves are sensitive to solvent polarity, whereas pyrene excimers are not (14). We therefore were curious to see whether changes in solvent polarity had significant effects on the rates of polystyrene cyclization as measured by exciplex formation.

Results and discussion

Design and synthesis

Both spectroscopic and synthetic considerations enter into the choice of end groups to be incorporated into the polymer. Our philisophy was to choose a derivative of one of these groups (D) as an initiator for anionic polymerization of styrene, and to terminate the polymerization with ethylene oxide. In this way we could produce a polymer of the form D∿∿OH, and a variety of chromophores could be attached to the other end via the hydroxy group. If D had several spectroscopic properties of interest, quite a broad range of experiments could be carried out on one polymeric starting material. For example, if D could form an exciplex with pyrene and also serve as an effective triplet quencher, two quite different experiments could be performed on polymers to which pyrene groups or aromatic ketone groups could be attached.

From a spectroscopic point of view, the *N,N*-dimethylaminophenyl (DMAP) group serves all of these functions. Dimethylaniline and dimethyltoluidine form exciplexes with pyrene and with a variety of other polycyclic aromatic groups. These amines quench ketone triplet states by an electron-transfer process, and they are compatible chemically with the conditions of anionic polymerization. Worsfold, for example, has initiated anionic polymerization using lithiated aliphatic species containing the Me_2N— group (15).

Our initial attempt to add *sec*-butyllithium to 4-isopropenyl-*N,N*-dimethylaniline did not provide useful polymers. Instead we generated the initiator **2** by treatment of 1-[4′-(*N,N*-dimethylaminophenyl)phenyl]ethyl ethyl ether (**1**) with potassium metal in tetrahydrofuran, Scheme 1. The reaction was terminated with ethylene oxide in keeping with our philosophy that

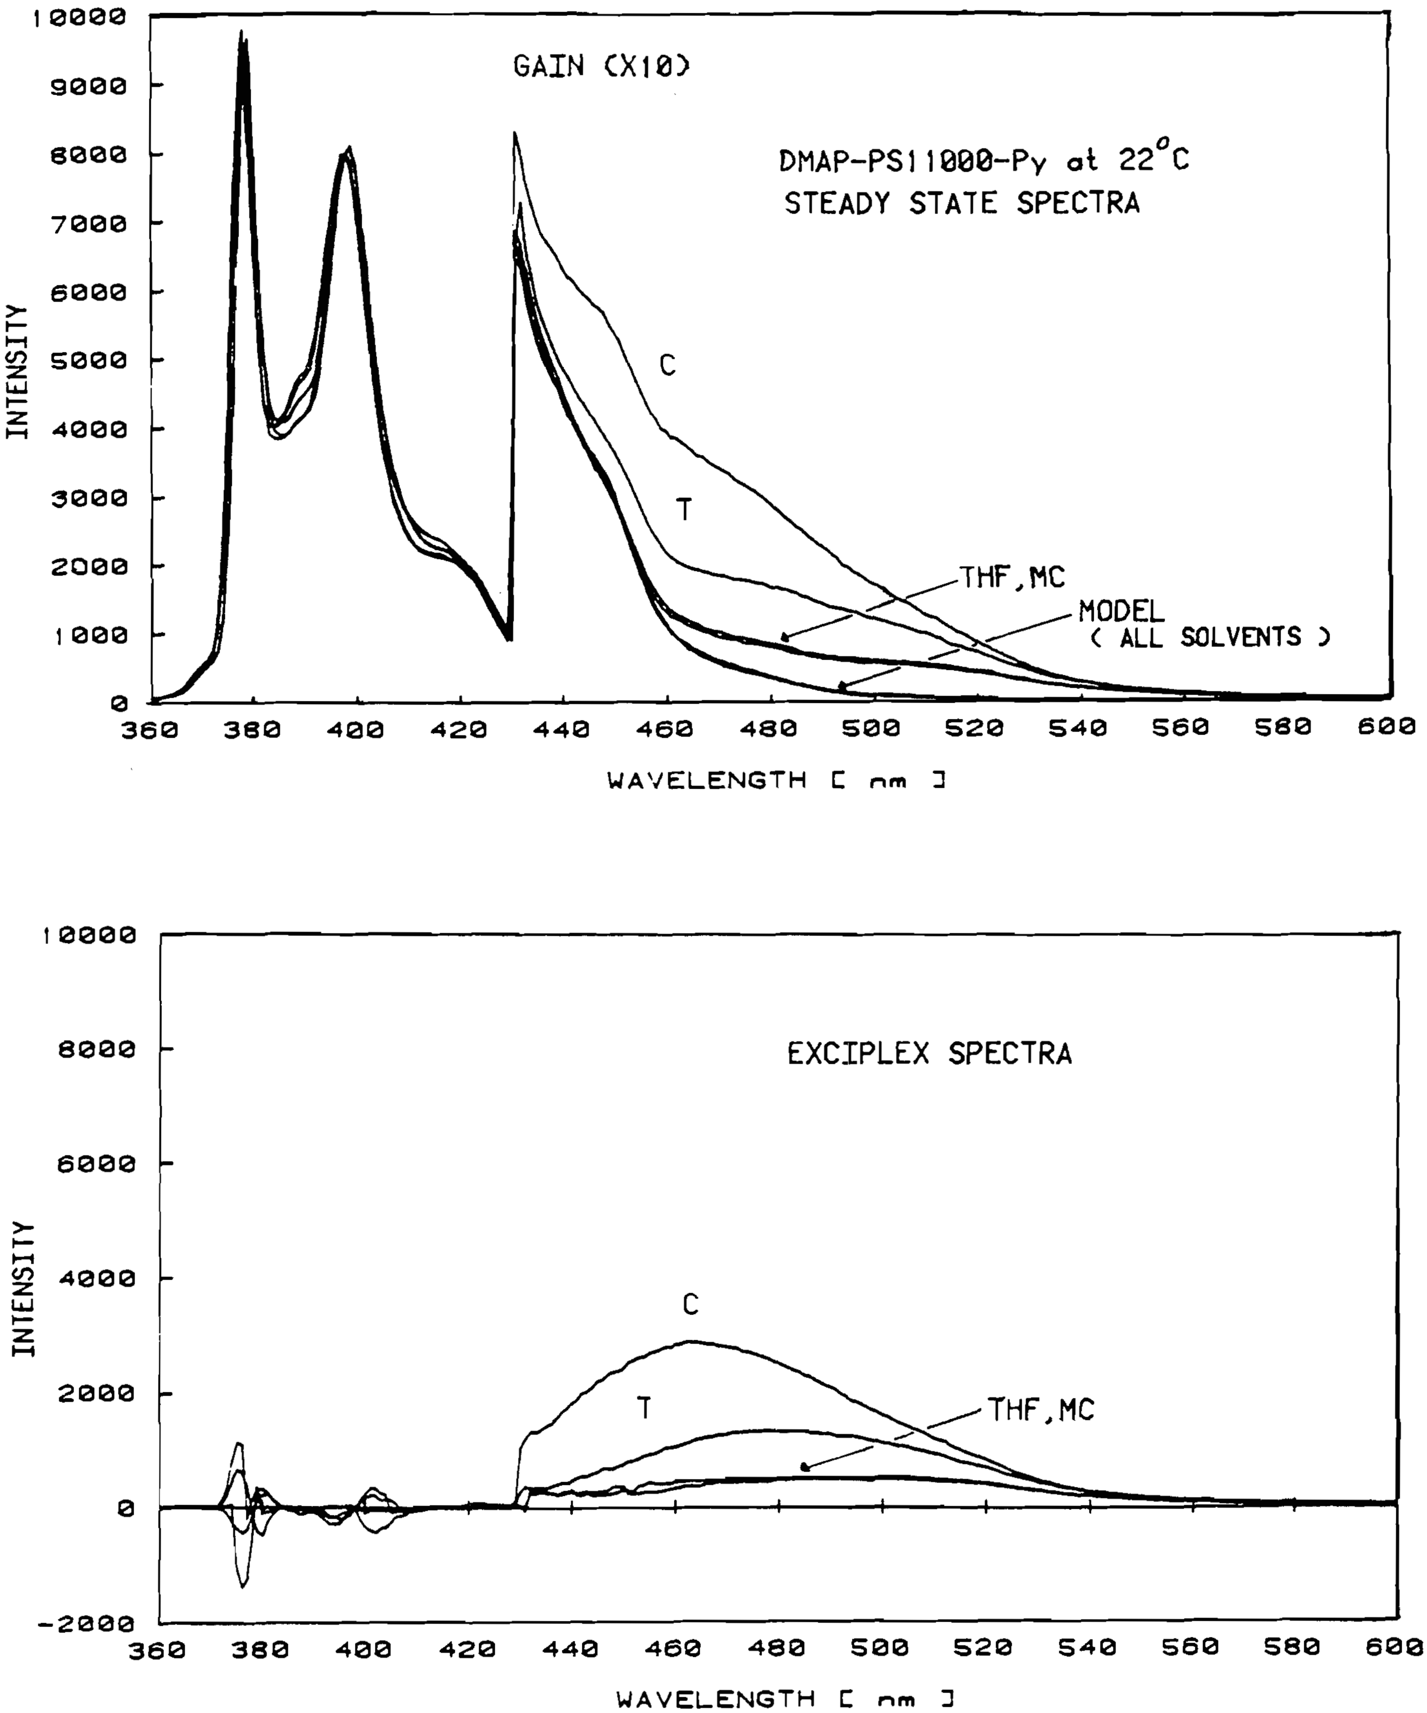

FIG. 2. Fluorescence spectra of DMAP-PS11000-Py **5** and PS5900-Py (Model, *b*) at 22°C in several solvents. Intensities are arbitrarily normalized at 398 nm. The model polymer **6** had nearly identical spectra in all solvents. For **5**, spectra are shown in cyclohexane (C), toluene (T), tetrahydrofuran (THF), and methylene chloride (MC). The lower curves are exciplex spectra obtained by subtracting the normalized spectrum of **6** from that of **5**.

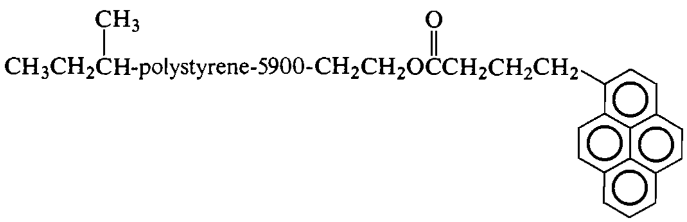
functional group manipulation on polymer termini is much less onerous than synthesis of the polymers themselves. Small amounts of the polymer $Me_2N—C_6H_4—CH(CH_3)$-polystyrene-CH_2CH_2OH (DMAP-PS-OH, **3**) were treated at a later stage with $PyCH_2CH_2CH_2C(O)Cl$ (**4**) in order to obtain the final polymer DMAP-PS-Py (**5**).

Ultraviolet analysis of the polymer **3** indicated 1.0 ± 0.1 $Me_2N—C_6H_4—$ groups per chain based upon M_n = 11 400 for the polymer. Corresponding analysis of **5** showed only 0.8 ± 0.1 pyrenes per chain. The reason for incorporation of less than one pyrene per chain is not yet clear. One possibility may be incomplete esterification. Since the fluorescence experiments at high dilution examine only those chains with excited pyrene groups, our results do not require that every chain carry a pyrene.

Spectroscopy

In order to interpret fluorescence studies of exciplex formation in **5**, one must compare the data to the fluorescence of a model polymer in which no intramolecular exciplex can be formed. For example, in Fig. 2 we show the fluorescence spectra of **5** in four solvents: cyclohexane, toluene, tetrahydrofuran (THF), and methylene chloride. In the same figure we also show the fluorescence of **6** in these same four solvents. These spectra have been normalized in intensity at the



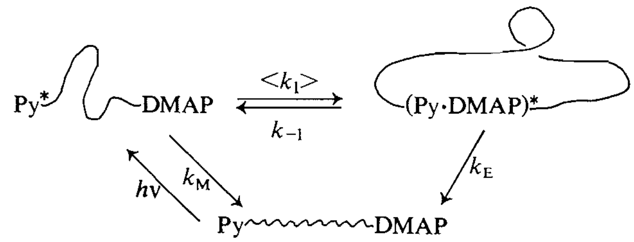
PS5900-Py, **6**

(0,2) band at 398 nm. One sees that the change in solvent or the presence of the terminal DMAP group has little effect on the emission spectrum of the locally excited pyrene.

At longer wavelengths, exciplex emission can be seen in samples of **5** at a Py group concentration of ca. 6 × 10^{-6} *M*. The exciplex emission from **5** was quite weak; therefore the gain was increased by a factor of 10 above 430 nm to increase sensitivity. Exciplex spectra, Fig. 2b, were obtained by subtracting spectra of the model polymer **6** from those of **5** in the same solvent. There are two important features to note in Fig. 2b. First, exciplex intensity I_E decreases, relative to that of the locally excited pyrene intensity I_M, with increasing solvent polarity. In addition, the exciplex emission maximum shifts to the red, as the solvent polarity increases.

The red shift is consistent with the charge-transfer nature of the exciplex, which is stabilized relative to the ground state in polar solvents (14). It is also known that radiationless decay rates of exciplexes increase in polar solvents. Their emission quantum yields decrease and therefore I_E/I_M values should decrease with increasing solvent polarity. Since the rate and extent of cyclization will also affect I_E/I_M values, a simple interpretation of these relative intensities is not possible at this time.

Fluorescence decay profiles were measured using the time-correlated single photon counting technique. An example is shown in Fig. 3 where we present both pyrene ($I_M(t)$) and excimer ($I_E(t)$) fluorescence profiles for the DMAP-PS11000-Py sample in cyclohexane. Lifetimes are obtained by iterative reconvolution of a trial function with the lamp profile. The $I_M(t)$ decays gave good fits to a single exponential decay func-



SCHEME 2

tion, whereas the growing-in and decay of the exciplex had to be fit to a difference of two exponential terms.

In the experiments reported here, the $I_M(t)$ decay times were always 3% to 5% longer than the corresponding long component of the $I_E(t)$ decays. We note that our polymer samples with $\bar{M}_w/\bar{M}_n$ = 1.08 have a finite polydispersity. The decay constants obtained from the measurements and the calculated rate constants are therefore averages over that distribution. On the other hand, the longer value of the $I_M(t)$ decay times could arise from a small fraction of polymer containing Py but no DMAP groups. In this case, using the $I_E(t)$ values to calculate rate constants should avoid any complications due to incomplete chain functionalization.

Data and data analysis

Exciplex formation is normally diffusion controlled. In Scheme 2, the rate constant $\langle k_1 \rangle$ describes cyclization leading to intramolecular exciplex formation. The angle brackets $\langle\rangle$ emphasize that k_1 should vary sensitively with chain length, and that values obtained from the study of polymers with a finite polydispersity represent averages over the molecular weight distribution in the sample. We denote exciplex dissociation (ring opening) by k_{-1}; k_M and k_E describe the reciprocal lifetimes of the locally excited pyrene ("monomer") and exciplex lifetimes, respectively.

Scheme 2 predicts the fluorescence decay laws

$$[1] \quad I_M(t) = a_1 \exp(-\lambda_1 t) + a_2 \exp(-\lambda_2 t)$$

$$[2] \quad I_E(t) = a_3 [\exp(-\lambda_1 t) - \exp(-\lambda_2 t)]$$

where the decay constants λ_1, λ_2 are related to the rate constants by the expression

$$[3] \quad 2\lambda_1, \lambda_2 = (k_M + \langle k_1 \rangle + k_E + k_{-1}) \mp \{[(k_E + k_{-1}) - (k_M + \langle k_1 \rangle)]^2 + 4\langle k_1 \rangle k_{-1}\}^{1/2}$$

Note that when $4\langle k_1 \rangle k_{-1}$ is small compared to the squared term in brackets, eq. [3] simplifies to

$$[4] \quad \lambda_1 = \langle k_1 \rangle + k_M$$

$$[5] \quad \lambda_2 = k_{-1} + k_E$$

Values of $\langle k_1 \rangle$ were calculated from eq. [4], using λ_1 values from the pyrene decay, with k_M taken to be the exponential decay rate of the model polymer **6**. One should note that all the rate constants in Scheme 2 might be expected to vary with solvent. This is emphasized by the variation of λ_M^{-1} values from solvent to solvent, Table 1, where, for example, one sees that λ_M^{-1} (cyclopentane) = 243 ns and λ_M^{-1} (benzene) = 156 ns. Cyclization rate constants obtained in this way are collected in Table 1.

Cyclization rates

Values of $\langle k_1 \rangle$ for DMAP-PS11000-Py at 22°C vary from

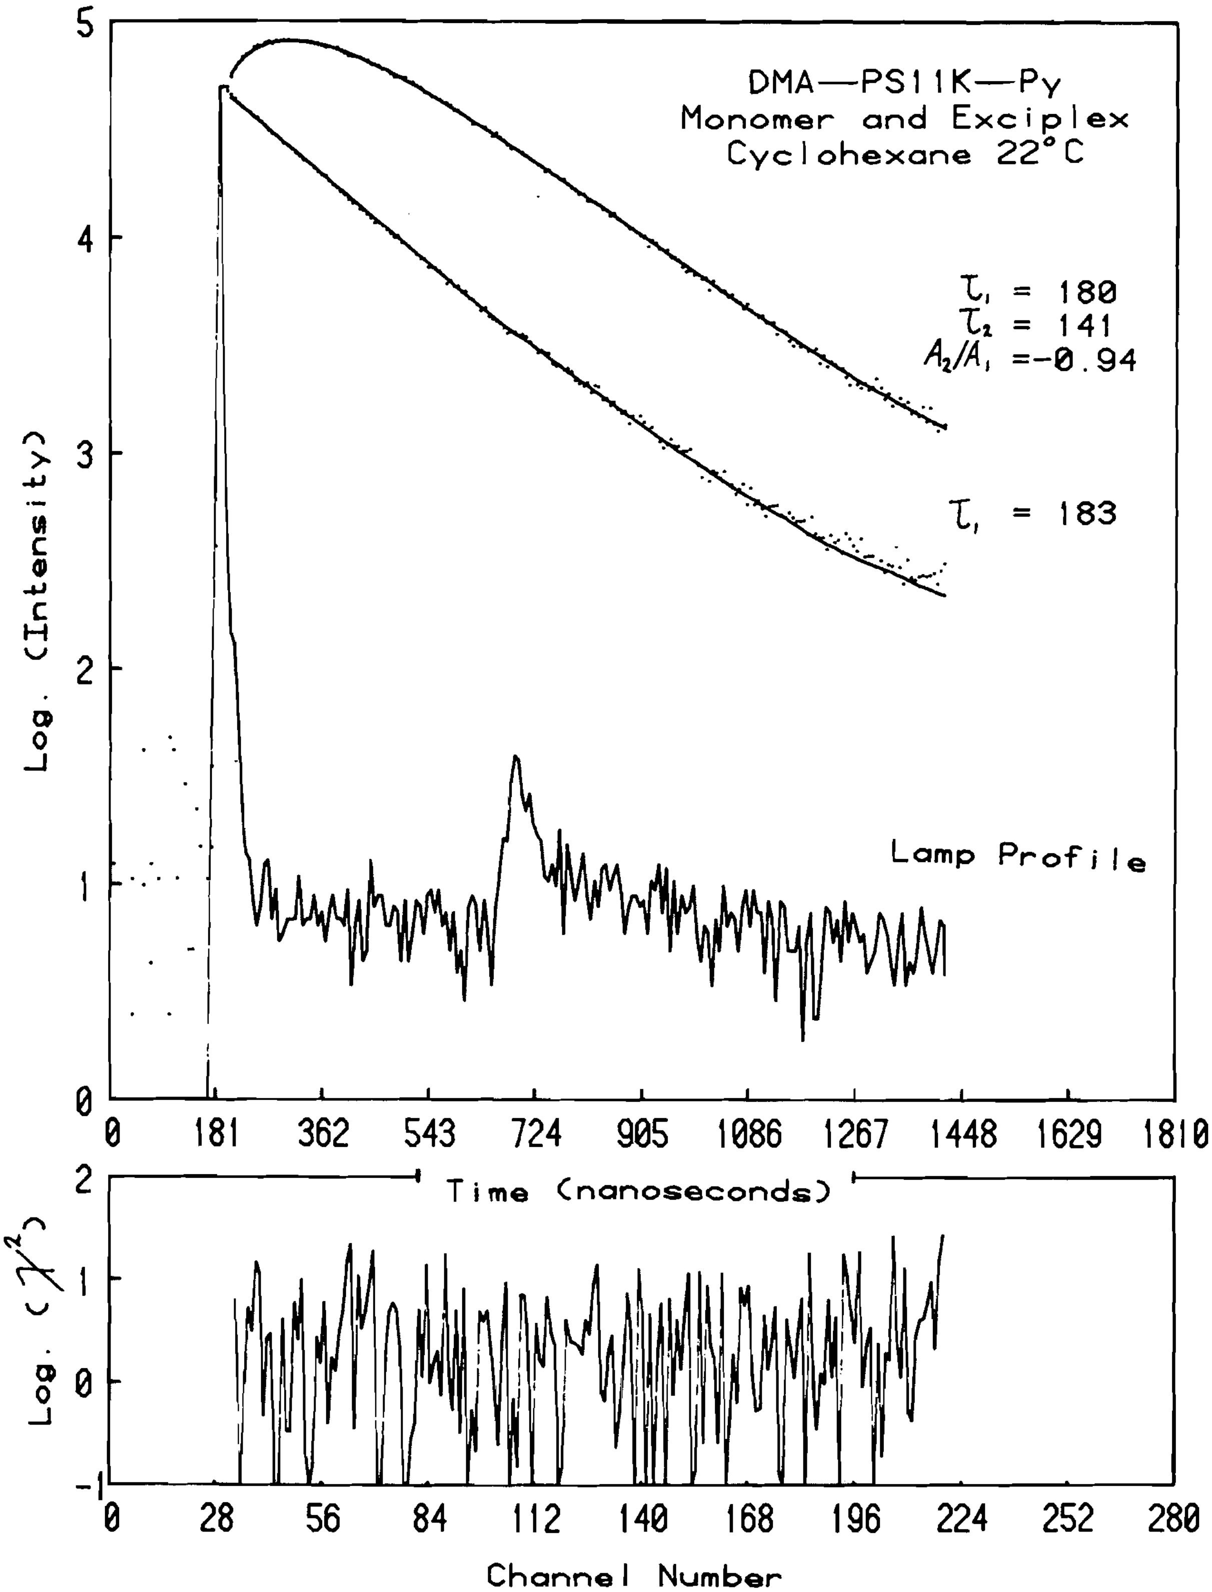


FIG. 3. Fluorescent decay profiles of DMAP-PS11000-Py in cyclohexane at 22°C. The upper curve is the exciplex emission ($\lambda_{EM} > 500$ nm). The middle curve is the monomer emission (370 nm $> \lambda_{EM} >$ 400 nm) and the lower curve is the excitation lamp profile ($\lambda_{EM} = \lambda_{EX} = 345$ nm). Both spectra are normalized to the lamp maximum of 50 000 counts for presentation. The lower graph is a representative plot of the log of the point by point χ^2 versus channel number.

1.01×10^6 s^{-1} in benzene to 2.67×10^6 s^{-1} in cyclopentane. Two factors affect the magnitude of the cyclization rates; the polymer dimensions in the solvent, and the solvent viscosity. Since diffusion rates vary as T/η, where η is the solvent viscosity, we define $\eta_{rel} = \eta/\eta_{cyclohexane}$ and calculate values of $\langle k_1\rangle_{corr} = \eta_{rel}\,\langle k_1\rangle$. These are plotted in Fig. 4 as a function of solvent viscosity. Figure 4 emphasizes that for benzene, toluene, and THF, the viscosity corrected cyclization rates are

[a] $I_M(t)$ decay measured at 380–400 nm. Uncertainties are typically ±1 ns.
[b] Exciplex data measured above 500 nm. Fits are somwhat soft, especially in THF where the intensity is very low.
[c] Calculated from $I_M(t)$ data. Uncertainties are ca. $\pm 0.1 \times 10^6$ s^{-1}.
[d] Viscosity at 22°C (1 cP = 10^{-3} Pa s).
[e] Hildebrand solubility parameter (22*a*, *b*). Note that δ_H for polystyrene is ca. 9.1 (see footnote 3).
[f] Dielectric constant at the temperature indicated (21).

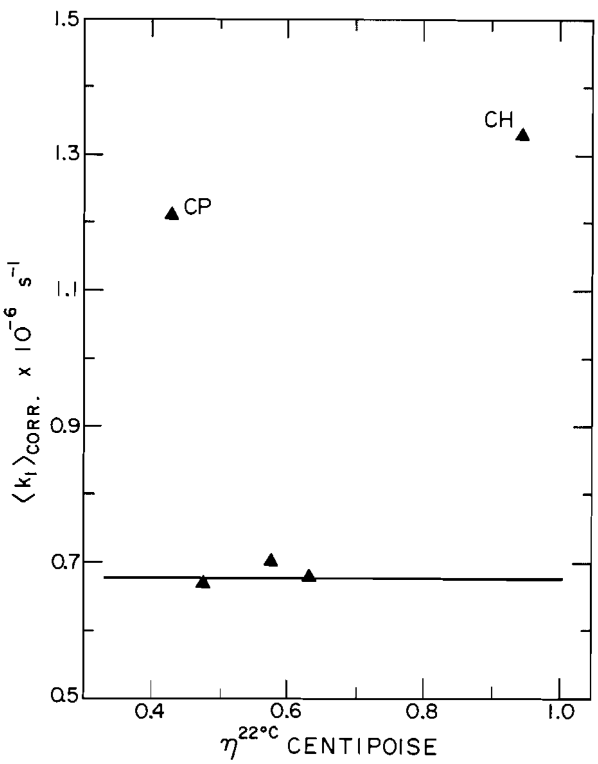

FIG. 4. Viscosity corrected cyclization rate constant versus solvent viscosity at 22°C for DMAP-PS11000-Py in four solvents. $\eta_{rel} = \eta_{solvent}/\eta_{cyclohexane}$.

indistinguishable. Cyclization in cyclohexane and cyclopentane are significantly faster.

Benzene, toluene, and THF are good solvents for PS. For a polymer as short as M = 11 000 one anticipates similar values of the root-mean-square radius of gyration R_G or end-to-end distance R_F for the polymer in each of these solvents. Cyclopentane at 23°C is a θ-solvent for polystyrene. The θ-temperature for PS in cyclohexane is 34.5°C; thus in our experiments at 22°C, cyclopentane represents θ-conditions, and cyclohexane, sub-θ-conditions. R_F and R_G values here are smaller than for the polymer in the good solvents. In addition, attractive interactions between chain elements distort the end vector distribution function to enhance the probability of the two chain ends being in proximity.

Comparison with excimer probes of cyclization

The extensive studies of Redpath and co-workers (4, 5) on excimer formation in Py-PS-Py provide cyclization rate constants with which our values can be compared. In the discussion which follows, we denote these values obtained from excimer studies as $\langle k_1\rangle_{exm}$. The Redpath experiments in toluene were carried out at 22°C for polymers of M = 3000 to 10^5. Experiments in cyclohexane for this span of molecular weights were carried out at the θ-temperature. Three samples with M = 3000 to 9200 were examined as a function of temperature, from 34 to 84°C. Activation energies were obtained; with these data a value for cyclization at 22°C of a Py-PS-Py sample of M = 11 400 can be estimated. We also remeasured the decay parameters at 22°C and 34.5°C for Redpath's samples in cyclohexane and toluene for Py-PS-Py of $\bar{M}_n$ = 9200 and $\bar{M}_n$ = 15 500.[3] These data provide an alternative estimate of $\langle k_1\rangle_{exm}$ for a sample of M = 11 400.

The interpolated value of the cyclization rate constant using $I_M(t)$ data in toluene at 22°C for Py-PS11400-Py (excimer formation) is 0.79×10^6 s^{-1}. This compares, Table 2, with a value of 1.15×10^6 s^{-1} for DMAP-PS11400-Py (exciplex formation). In toluene at 22°C, exciplex formation occurs 1.5 times faster than excimer formation, suggesting that the end group or the spectroscopic technique may affect the measured rate of diffusion controlled cyclization. If the $I_E(t)$ data are used to calculate $\langle k_1\rangle$, we obtain values 0.2×10^6 s^{-1} larger.

In cyclohexane, the interpolated best-fit value at 34.5°C for $\bar{M}_n$ is 11 400 (2.2×10^6 s^{-1}) and, correcting it to 22°C using the value of 3.1 kcal/mol determined from $\langle k_1\rangle_{exm}$ for several chain lengths of Py-PS-Py,[4] we obtain a value of 1.78×10^6 s^{-1}. On the other hand, reexamining two of Redpath's original samples at 22°C led to an interpolated $\langle k_1\rangle_{exm}$ value of 1.56×10^6 s^{-1}.

Our value $\langle k_1\rangle$ for DMAP-PS11400-Py is 1.33×10^6 s^{-1} in cyclohexane at 22°C. This value increases to 1.70×10^6 s^{-1} if

[3] It is worth noting that, three years after sample preparation, virtually identical lifetimes are obtained for the samples prepared by Redpath.

TABLE 2. Comparison of cyclization rates for PS11400 obtained by pyrene excimer $\langle k_1\rangle_{exm}$ and DMAP/Py exciplex $\langle k_1\rangle_{exp}$ measurements

Cyclization: Probe		Cyclization: Data	$10^{-6}\langle k_1\rangle^a$ Toluene 22°C	$10^{-6}\langle k_1\rangle^a$ Cyclohexane 22°C	
DMAP	Py	Monomer	1.15	1.33	
		Exciplex	1.35	1.70	
Py	Py[b]	Monomer	0.79	1.56	
		Excimer	0.99	1.79	1.78[c]

[a] From $\langle k_1\rangle = \lambda_1 - k_M$ for the monomer λ_1 from single exponential fits and for the excimer/exciplex λ_1 from double exponential fits.

[b] Estimated by log–log interpolation between the $\langle k_1\rangle$ values of Py-PS9600-Py and Py-PS15600-Py.

[c] By correcting the least-squares best fit data of Redpath and co-workers (4*c*), reported at 34.5°C, to 22°C using $E_a(k_1) = 3$ kcal/mol.

the $I_E(t)$ data are used to calculate $\langle k_1\rangle$.

Figure 3 shows typical monomer and exciplex decay profiles for DMAP-PS11400-Py in cyclohexane at 22°C. In all the cases examined, for this molecular weight, the monomer decays fit well to single exponential decay laws to yield λ_1. The excimer and exciplex fit to a difference of two exponentials with a λ_2 growing-in component and a λ_1 decaying component. It is found in all cases that the monomer λ_1 is always 2 to 5% larger than the excimer or exciplex λ_1. This may be due, in the case of excimers (Py-PS-Py), to a small percentage of monofunctionalized polymer, or, in the case of exciplexes (DMAP-PS-Py), to polymers with no dimethylamino end group. In either case the small impurity would give rise to the model compound **6** decay lifetime which would increase the apparent monomer lifetime. The excimer or exciplex would not form from the impurity and thus would give rise to the better data.

The difference is magnified when calculating $\langle k_1\rangle$, obtained as the difference of two large numbers. Thus we find that $\langle k_1\rangle$ values calculated from $I_E(t)$ data are 10% to 20% larger than those calculated from $I_M(t)$ data. These data are summarized in Table 2. The conclusions we draw are independent of which set of data are compared.

From the data in Table 2 it appears that in toluene the exciplex probe (DMAP-PS-Py) gives a $\langle k_1\rangle$ value 1.5 times larger than that obtained from the excimer probe (Py-PS-Py). In cyclohexane, the $\langle k_1\rangle$ values agree to within 10%. If anything, exciplex formation is a bit slower.

Mechanism of exciplex formation

Long range interactions are not thought to be important in *excimer* formation. Py/Py separation in the excimer is ca. 3.5 Å (14), and the reactive radius for excimer formation is probably not much larger than 5 Å. *Exciplexes* are formed by a different mechanism. There is compelling evidence that electron transfer occurs between the donor (here DMAP-) and the acceptor (here Py-) to form a solvent-separated ion pair (16, 17). Under the force of the coulombic attraction, the ions come together to form the exciplex. This is sometimes referred to as a "harpooning" mechanism. While there are no rigorous measurements, the reactive distance for electron transfer is commonly taken to be 7 Å. In very polar solvents, the ion pair dissociates into free ions; no exciplex emission is seen (14).

The free energy of ion pair formation can be estimated from the oxidation potential of the donor ($E_{1/2}$(ox)), the reduction potential of the acceptor ($E_{1/2}$(red)), and the excitation energy of the excited state species (here E_{00}(py)) (18). For DMAP- and Py- one calculates from

$$[6]\quad \Delta G = E_{1/2}(\mathrm{ox}) - E_{1/2}(\mathrm{red}) - E_{00}(\mathrm{py})$$

that $\Delta G = -10$ kcal/mol. For electron transfer reactions of such exergonicity, solvent effects on the electron transfer rate are expected to be small (18*a*). Thus we see no important differences in $\eta_{rel}\langle k_1\rangle$ values determined in benzene, THF, or toluene. It may well be that ΔG is not sufficiently exergonic to allow a harpooning mechanism in cyclohexane or cyclopentane.

Reactive radius effects on the cyclization process

Calculations carried out by Perico and Cuniberti (12) on the cyclization of partially draining finite chains within the framework of the bead-band-spring model indicate that the magnitude of the reactive radius a can affect the rate of cyclization. The ratio a/R_G enters into the calculation of k_{cy} in a complicated way. For example, the dependence of k_{cy} upon a/R_G disappears for chains of sufficient length (large R_G) and appears to be relatively unimportant for $a/R_G < 0.1$. One can estimate from literature data (19) that R_G for PS11400 in toluene is ca. 32 Å. Taking $a = 5$ Å for excimer formation and $a = 7$ Å for exciplex formation, one obtains values of 0.16 and 0.22 respectively for a/R_G. Thus we can rationalize the faster cyclization rate for exciplex formation vs. excimer formation in toluene in terms of the larger reactive radius of the former process.

In cyclohexane the results are less clear and hence more difficult to intepret. One knows from studies of molecules substituted with bulky groups that exciplex formation in aliphatic hydrocarbon solvents is less sensitive to steric effects than is excimer formation (20). Thus there is no evidence to suggest that reactive distances for the two processes become comparable in nonpolar solvents. In the absence of further results, further speculation seems unwarranted.

Experimental

Synthesis

The unsymmetrical difunctional polymer DMAP-PS11000-OH **3** was prepared by anionic polymerization in THF at −70°C under argon. The polymerization was initiated by the anion **2**, formed from the treatment of 1-[4′-(*N*,*N*-dimethylamino)phenyl]ethyl ethyl ether **1** with potassium metal in THF at −20°C. The solution was cooled to −70°C and styrene was added. After completion of the reaction the living polymer was reacted with a large excess of ethylene oxide. Decoloration of the solution due to quenching of the living anion occurs at ca. −50°C. After addition, first, of aqueous hydrochloric acid and then ammonium hydroxide, the potassium chloride produced is filtered off. The hydroxy-terminated polymer **3** is precipitated by addition of the solution to a large excess of methanol. Polymer **3** was further purified by reprecipitation of a concentrated THF solution in methanol containing a small amount of ammonium hydroxide that facilitated decantation. Further details of the polymerization will be reported elsewhere.

4-(1′-Pyrene)butyryl chloride **4** was prepared from the corresponding acid by treatment with excess oxalyl chloride in benzene. It was recrystallized from a toluene–hexane mixture to give pale yellow crystals, mp 80–81°C.

Functionalization of the polymer **3** with **4** to yield DMAP-PS11000-Py **5** was effected by mixing 1.0 g (0.09 mmol) of **3** with 0.1 g (0.36 mmol) of **4** in 20 mL of toluene that was freshly distilled under nitrogen from sodium metal. Triethylamine (1.0 mL, 7.2 mmol; distilled under nitrogen from CaH_2) was then added. The reaction mixture was then outgassed with nitrogen and stirred under N_2 in the dark for 12 days. To terminate the reaction, 0.2 g of dry silica gel was added. After stirring for an hour, the solution was filtered through a glass wool plug into 200 mL of vigorously stirred methanol. The precipitated polymer was collected, redissolved in toluene, and then reprecipitated twice in methanol. The yield of polymer **5** was effectively quantitative.

The synthesis of the model polymer PS5900-Py **6** has been described previously (4*c*).

Characterization

The molecular weight of the polymer **3** was obtained using a Waters associates high pressure liquid chromatograph (hplc) with a pair of Shodex A 80M gpc columns in THF solution using a Waters R401 refractive index detector. The 2-(4′-*N*,*N*-dimethylaminophenyl)-propane end group could be detected by its absorbance at 304 nm ($\epsilon = 2050$). The M_n and M_w were found to be 11 400 and 12 300 respectively.

Polymer **5** was also analyzed by hplc. By examining the uv absorbance at 345 nm it was found that all of the pyrene in the sample was attached to the polymer. End group analysis showed that about 80% of the polymers had a pyrene end group. It should be pointed out that, as these measurements involve only intrapolymer exciplex formation, polymers with no pyrene end group will not enter into the results.

Sample preparation

Polymer samples were weighed on a microbalance, dissolved in the appropriate solvent, and diluted to 10 mL in a volumetric flask. Toluene, benzene, and cyclohexane were distilled from sodium, cyclopentane and tetrahydrofuran from $LiAlH_4$ and dichloromethane from P_2O_5. The solutions (2×10^{-6} *M*) were then degassed by five freeze–pump–thaw cycles to lower than 10^{-5} Torr (1 Torr = 133.3 Pa) and then sealed under vacuum. Two sets of samples were prepared, one in cylindrical Pyrex cells for lifetime measurements and another in 10 mm × 10 mm rectangular cells for steady-state measurements.

Steady-state spectra

Emission spectra (see Fig. 1) were measured on a SLM model 4800 fluorescence spectrometer. The excitation wavelength was 345 nm and the emission was scanned from 360–600 nm in 1-nm steps. The output was digitally recorded on a Tektronix 4051 computer and stored on disc. All manipulations of the spectra, integrations, normalizations, and subtractions were performed by the computer.

Lifetime measurements

Fluorescent lifetimes were measured by the time correlated single photon counting technique (4). Decays were fit from two channels after the lamp maximum to the end of the measured decay and in all cases the χ^2 values were less than 2.0. The excitation wavelength for all samples was 345 nm. Pyrene monomer decays were measured from emission between 370 nm and 400 nm collected through filters. The pyrene monomer decays were fit to single exponential decay laws by a process of iterative reconvolution with the excitation lamp profile. Pyrene–dimethylaniline exciplex decays were measured above 500 nm using a cutoff filter, and were fit to the difference of two exponential terms.

Acknowledgments

The authors thank NSERC Canada and the Petroleum Research Fund administered by the American Chemical Society for their contribution to the support of this work. We would also like to thank Dr. François Isel for his assistance in synthesizing the polymers. We acknowledge the contribution of Mr. Li Xiao Bai to the early stages of this research, noting that his efforts led to the previous three papers in this series (5*b*, 22).

The luminescent properties of several aromatic ketones included in the hydrophobic zeolite Silicalite have been examined. Acetophenone, benzophenone, and β-phenylpropiophenone show readily detectable phosphorescence; by contrast, valerophenone does not luminesce, but undergoes the Norrish Type II reaction. Thus, irradiated samples of valerophenone in Silicalite show phosphorescence due to the accumulation of acetophenone. In the case of β-phenylpropiophenone the triplet lifetime is ca. 100 000 times longer than the solution value, suggesting severe conformational restrictions. Co-inclusion of acetophenone with various substrates and oxygen quenching studies indicate that Silicalite has at least two distinct classes of inclusion sites. In one of them energy transfer processes are rapid and efficient, suggesting a cooperative effect in the inclusion of ketones in these regions of the Silicalite framework.

H. L. CASAL et J. C. SCAIANO. Can. J. Chem. **63**, 1308 (1985).

On étudie les propriétés luminescentes de plusieurs cétones aromatiques contenues dans la zéolite hydrophobe Silicalite. L'acétophénone, la benzophénone et la β-phénylpropiophénone présentent une phosphorescence que l'on peut déceler facilement; par ailleurs, la valérophénone n'est pas luminescente, mais elle subit une réaction de type Norrish II. Ainsi, les échantillons irradiés de valérophénone dans la Silicalite ont une phosphorescence qui provient d'une accumulation d'acétophénone. Dans le cas de la β-phénylpropiophénone, le temps de vie du triplet est environ 100 000 fois plus long que la valeur en solution et ceci suggère la présence d'importantes contraintes conformationnelles. La co-inclusion de l'acétophénone avec différents substrats et des études de piégage d'oxygène indiquent que la Silicalite a au moins deux classes distinctes de sites d'inclusion. Dans l'un d'eux, le processus de transfert d'énergie est rapide et efficace; ceci suggère un effet d'ensemble lors de l'inclusion des cétones dans ces régions du squelette de la Silicalite.

[Traduit par le journal]

Introduction

Photoprocesses in solid systems, including surfaces, crystals, and inclusion compounds, have been the subject of several recent reports (1–3). In spite of the extensive and varied use that zeolites receive in industry, organic photoprocesses have received very limited attention in these media (4–6).

In a preliminary report (7), we showed that the triplet lifetime of β-phenylpropiophenone in Silicalite is enhanced by five orders of magnitude, by comparison with the value in solution under otherwise comparable conditions. This enhancement was attributed to restrictions to mobility that prevent the intramolecular quenching process.

Silicalite forms part of a recently developed class of zeolites with a new topologic type of tetrahedral framework (8). The channel system of this zeolite consists of near-circular zig-zag channels defined by 10 oxygen centres, which are cross-linked by elliptical straight channels. The diameter of the circular channels is 5.4 ± 0.2 Å, and the free cross-section of the elliptical ones is 5.75×5.15 Å^2. One of the remarkable properties of this zeolite is its high hydrophobicity which ensures no deactivation effect due to water, and allows the selective extraction of organic materials from their aqueous solutions (9).

We have examined the possibility of using the luminescence of aromatic ketones in zeolites to probe their dynamics and concurrently to examine the properties of the various sites available to the guest molecules. This report deals with the phosphorescence properties of several aromatic ketones included in the channel structure of Silicalite. We conclude that there are several classes of sites accessible to the guest molecules. The geometry of the Silicalite channels has preferential adsorption of the different aromatic ketones. While it seems that all sites are probably accessible to acetophenone, β-phenylpropiophenone, and valerophenone, benzophenone cannot reach at least one class of sites. This particular class is not readily accessible to oxygen.

Experimental

Silicalite S-115 was purchased from Union Carbide Canada and calcined at 500°C for 24 h and kept under vacuum for 12 h prior to use. Acetophenone and valerophenone (Aldrich) were distilled prior to use, while benzophenone (Eastman Kodak) had been recrystallized from ethanol. β-Phenylpropiophenone was prepared and purified according to literature procedures (10). 1-Phenylhexane (Aldrich) was distilled under reduced pressure, and 1,4-cyclohexadiene (Aldrich) and 2,2,4-trimethylpentane (isooctane, Aldrich Gold Label) were used as received. 1-Phenyl-3-pentanone (Wiley) was used as received. Silica gel was from Merck (70–230 mesh) and Mordenite was obtained from Norton.

The phosphorescence emission spectra (uncorrected, front face) were recorded using a computer controlled Perkin–Elmer LS-5 fluorescence spectrometer. Sample excitation was at 254 or 313 nm, using the appropriate monochromator setting plus suitable interference filters, while a microscope slide was used as a ~300-nm emission cut-off. Excitation and emission bandpasses were <10 nm. The samples were contained in cells made of 3×7 mm^2 Suprasil tubing, and were continuously flushed with N_2, O_2, or appropriate mixtures delivered through a Matheson model 610 gas mixing system. The LS-5 is a gated instrument, its excitation source providing 10-μs pulses at 60 Hz. The design of this instrument is such that Stern–Volmer phosphorescence plots require a more elaborate interpretation than in conventional steady-state spectrometers (*vide infra*).

Inclusion in Silicalite was achieved using the following procedure, illustrated here for the case of β-phenylpropiophenone: 3 g of Silicalite were mixed with a solution of 80 mg of β-phenylpropiophenone in 5 mL of 2,2,4-trimethylpentane (isooctane) in air at room temperature. The molecules of this solvent are sufficiently large that

reportedly (11) they cannot enter the channels of Silicalite. The resulting slurry was stirred for 3 h. The excess solvent was then removed by filtration and the solid washed with a further 4 mL of isooctane and allowed to dry for 10–16 h in a current of dry air at room temperature.

The actual yield of inclusion was also determined by elemental analysis (C, H, and inorganic residue) of the zeolite substrate samples (see Table 1).

The sample of Silicalite used (empty) was also examined using X-ray fluorescence, which, in addition to silicon, only showed a small amount of aluminum (<0.5%) and traces of potassium and calcium or indium (probably the former). Potassium and calcium could be impurities introduced through sample handling and preparation in our laboratory or at the manufacturer's. The presence of aluminum (presumably as AlO_2^-) as impurity is consistent with the results of nmr studies (12).

Results

Phosphorescence of aromatic ketones under nitrogen

The phosphorescence emission spectra of acetophenone, β-phenylpropiophenone, and benzophenone in Silicalite are shown in Fig. 1. The spectrum in Fig. 1D shows the luminescence from Silicalite with no guests. The ordinate scales have been expanded for presentation and no direct comparison of the relative intensities can be made from this figure. The emission from Silicalite is much weaker than that from any of the others (λ_{max} ~405 nm) and a correction for this background signal is not essential. No phosphorescence could be observed in the case of fresh samples (*vide infra*) of valerophenone in Silicalite.

The spectra obtained in Silicalite are in good agreement with those obtained in glasses, or with solution spectra in the case of acetophenone and benzophenone (β-phenylpropiophenone does not phosphoresce in solution (13)). The vibrational structure is evident in the cases of acetophenone and β-phenylpropiophenone, while no structure is apparent in the case of benzophenone (Fig. 1). It should be noted that in the case of benzophenone the elemental analysis showed very poor inclusion (see Table 1).

The phosphorescence decay of ketones in Silicalite was typically nonexponential. This is common to the decay law of other luminescent probes in heterogeneous media (ref. 14 and refs. therein). Table 2 includes several phosphorescence lifetimes obtained at room temperature; these refer to the first

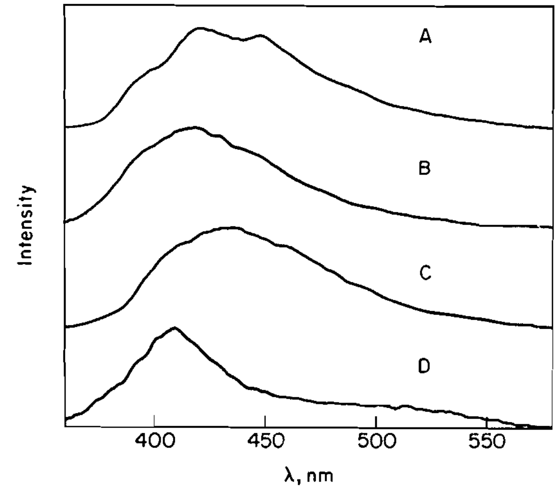

FIG. 1. Phosphorescence emission spectra (λ_{ex} = 254 nm) of acetophenone (A), β-phenylpropiophenone (B), and benzophenone (C) included in Silicalite at room temperature, and (D) luminescence of Silicalite (no guests) recorded under the same conditions. The intensity scales have been arbitrarily expanded, and no intensity comparisons can be made.

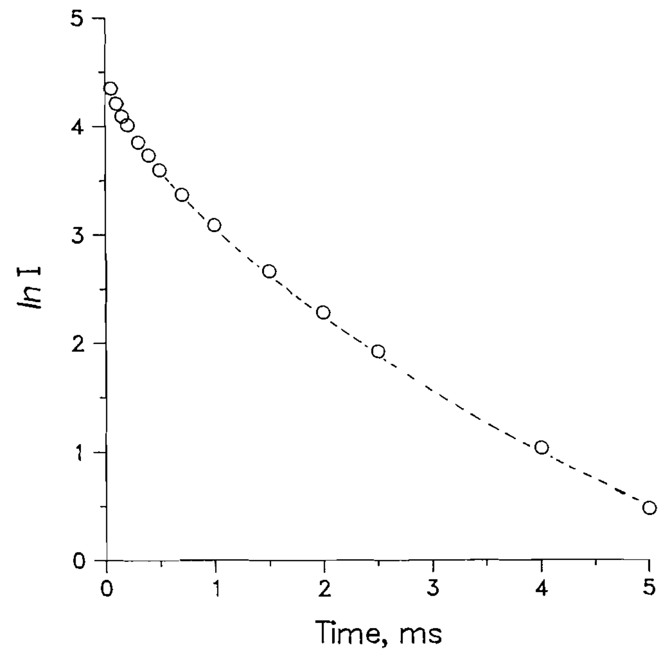

FIG. 2. Luminescence (ln I) intensity of acetophenone in Silicalite as a function of time.

lifetime monitored following a 20-μs delay after a 10-μs excitation pulse. Substantially longer lifetimes can be obtained by monitoring the emission after a longer delay between the excitation pulse and the beginning of the monitoring period. Figure 2 shows a logarithmic plot of the luminescence intensity from acetophenone as a function of time; similar plots were obtained for the other substrates.

Plots similar to that of Fig. 2 show a much better linear correlation when plotted against $t^{\frac{1}{2}}$ rather than t. This is frequently indicative of reaction (emission in this case) from multiple sites of an inhomogeneous matrix (15). Further work in this area is continuing, in an attempt to monitor the phosphorescence over several decades in emission intensity.

Effect of co-inclusion on phosphorescence

In a reference to valerophenone above, we have emphasized that no phosphorescence is observed in *fresh* samples; i.e., samples prepared and kept in the dark. If valerophenone is exposed to uv radiation, analysis of the organic fraction following extraction reveals the presence of products of the Norrish Type II reaction (16), i.e.

[1] 
After even very short irradiation periods (2–3 min) the emission from the acetophenone formed becomes readily observable, and the intensity of the resulting phosphorescence increases with irradiation time. Alternatively, it is possible to prepare acetophenone–valerophenone samples by direct co-inclusion of a mixture of the two ketones, rather than *in situ* generation of acetophenone. The spectrum obtained following co-inclusion is similar, but not identical to that obtained by *in situ* generation; Fig. 3 shows the various spectra in the valerophenone-containing samples. The vibrational structure in co-included acetophenone samples also appears to be somewhat different from that obtained from acetophenone itself (compare Fig. 3 with Fig. 1A). It should also be noted that the samples used have different levels of occupancy (see Table 1).

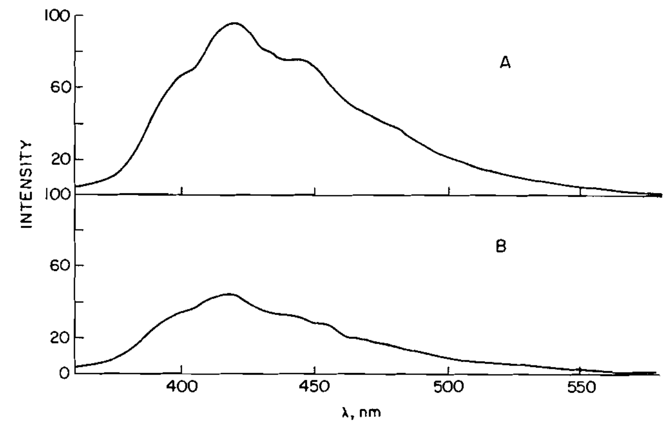

FIG. 4. Phosphorescence emission spectrum (λ_{ex} = 254 nm) of acetophenone and 1-phenylhexane (co-included in the ratio 5:95 mol/mol); (A) under 1 atm of N_2; (B) under 1 atm of O_2.

Studies involving co-inclusion of two ketones raise questions relating to energy transfer and (or) questions of preferential adsorption (*vide infra*). In order to be able to address these questions we carried out control experiments by co-inclusion of acetophenone and 1-phenylhexane as well as acetophenone and 1-phenyl-3-pentanone (5:95 molar ratio) in Silicalite. These cosubstrates were selected because their kinetic diameter and volume are comparable to those of valerophenone. The phosphorescence spectrum from acetophenone in the mixture with 1-phenylhexane is shown in Fig. 4; the spectrum under these conditions is quite strong and well resolved.

Phosphorescence quenching by oxygen

Oxygen was found to quench the phosphorescence of aromatic ketones to a different degree, depending on the ketone and its inclusion partners. All quenching experiments were performed by flowing oxygen through the samples while these remained in the spectrofluorimeter. Figure 5 shows the time dependence of the phosphorescence emission from included acetophenone (Fig. 5A) and benzophenone (Fig. 5B) with changing conditions. In both cases we observe luminescence quenching upon addition of oxygen. Quenching occurs over a few seconds, and is apparently controlled by the rate at which the composition of the gas in contact with the sample can be changed. When nitrogen is flowed again through the sample, the phosphorescence recovers; however, this process takes place over a longer period (~100 s) than that required for oxygen quenching. In these experiments the delay between excitation and monitoring was kept constant at 60 μs and the detection gate was 10 μs.

In the case of the sample of acetophenone co-included with 1-phenylhexane, 1 atm of pure oxygen quenched only 45% of the emission observed under nitrogen (see Figs. 4A and 4B). The vibrational structure of the acetophenone emission remains well resolved even in the spectrum recorded under an oxygen atmosphere. The quenching process for this sample was slow compared with all other samples examined; i.e. it was not controlled by the rate at which the gas was replaced. This is

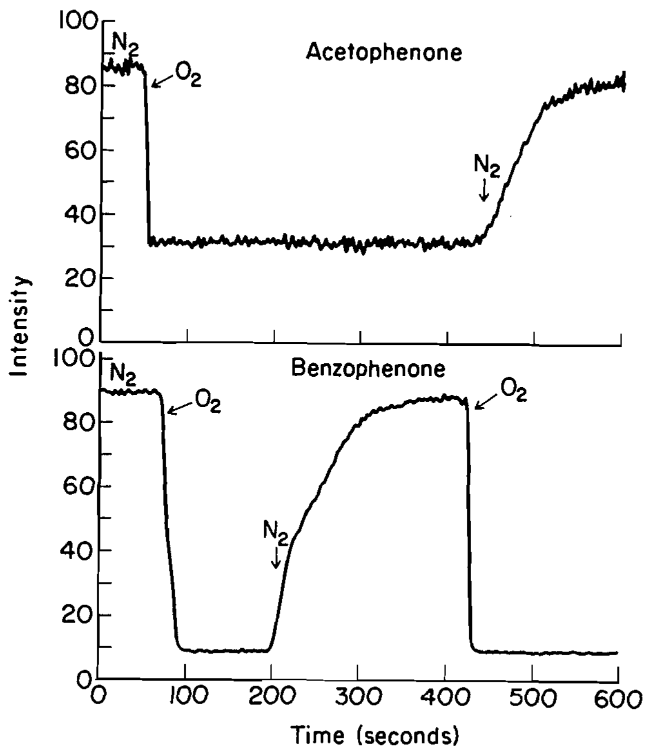

FIG. 5. Effect of changing the atmosphere of the sample cell on the phosphorescence emission (measured at 430 nm) of (A) acetophenone and (B) benzophenone in Silicalite.

illustrated in Fig. 6; oxygen takes ~50 s to quench the initial emission, and nitrogen takes ~150 s to restore it.

We have also monitored the dependence of the phosphorescence intensity with the composition of oxygen–nitrogen mixtures. It should be noted that the equivalent of Stern–Volmer plots takes a different form in the case of gated spectrometers. If the luminescence intensity is monitored at a constant preselected time (t_d) following pulsed excitation, the ratio I_t^0/I_t of the luminescence intensities in the absence and presence of quencher, respectively, is given by:

$$[2] \quad (I_t^0/I_t) = \exp\,(k_q t_d[Q])$$

Thus, eq. [2] contains the delay, t_d, rather than the triplet lifetime (which cancels out), and assumes an exponential form. Analysis of the luminescence yield according to the log form of eq. [2] as a function of the mole fraction of oxygen (total pressure = 1 atm) leads to nonlinear plots (for representative examples see Figs. 7–9). This behaviour can be approximated on the basis of (at least) two sites of different accessibility. This analysis, for t_d = 60 μs, has been included in Table 3 for several samples, in terms of a fast and a slow rate constant and the percent contribution from each process. Note that the rate constants (already divided by t_d) have units of s^{-1}, since they are based on mole fractions, not actual concentrations.

β-Phenylpropiophenone on other materials

This ketone does not phosphoresce in solution at ambient temperatures as a result of its efficient intramolecular deactivation which leads to a triplet lifetime in the neighborhood of 1 ns (13). This lifetime increases by about five orders of magnitude when β-phenylpropiophenone is included in Silicalite, and results in readily observable phosphorescence. In order to explore further the nature of this remarkable phosphorescence

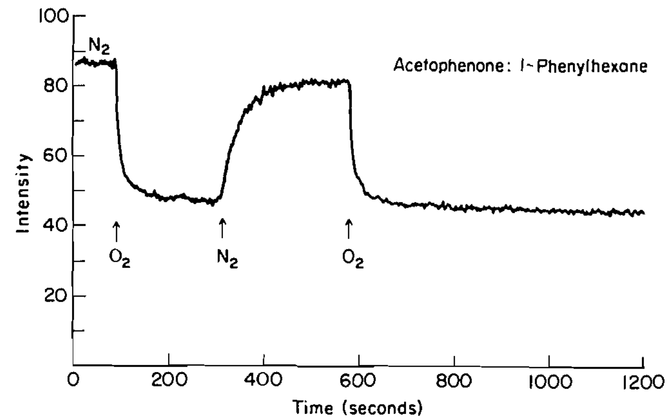

FIG. 6. Effect of changing the atmosphere of the sample cell on the phosphorescence emission (measured at 430 nm) of a mixture of acetophenone and 1-phenylhexane (5:95 mol/mol) co-included in Silicalite.

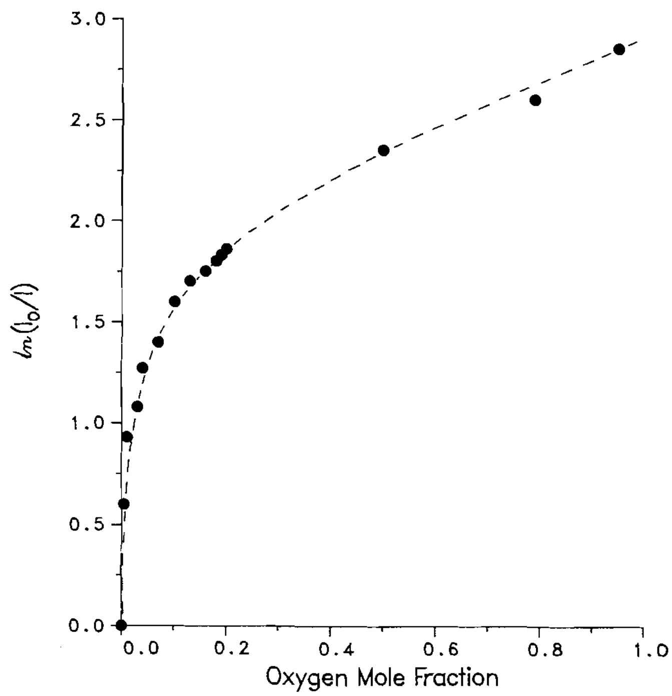

FIG. 7. Quenching of benzophenone phosphorescence by O_2 according to eq. [2]. Excitation: 254 nm; emission: 450 nm.

enhancement, we examined the luminescence of β-phenylpropiophenone in other two materials. A sample of silica gel (70–230 mesh) was subjected to the same protocol as Silicalite and no phosphorescence could be detected. Similarly, a sample of Mordenite, which has a much larger pore diameter (~9 Å) (17) gave no phosphorescence after treatment to include β-phenylpropiophenone.

Discussion

It seems clear from the results presented in the previous sections that the behaviour of aromatic ketones cannot be fully interpreted from the assumption of a single class of sites. The channel structure of Silicalite imposes a considerable restriction on some types of molecular motion. For example, in the case of β-phenylpropiophenone in solution, its lifetime at room temperature is around 1 ns (13); this short lifetime reflects intramolecular quenching by the aromatic ring, in a process that

TABLE 3. Stern–Volmer slopes for the quenching of phosphorescence by oxygen

No.	Substrate	λ_{ex}(nm)	k_q (slow)[a]	k_q (fast)[a]	% Fast[b] quenching

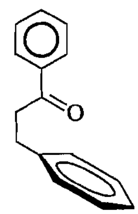
8	Acetophenone/1-phenyl-3-pentanone	254	2×10^4	$(1-3\times10^5)$	19
		313	2×10^4	3×10^5	45

[a]In units of s^{-1} (see text).
[b]Contribution of fast quenching to the total of quenching events.
[c]Continuous variation does not allow a proper separation of the two components. Quenching is essentially complete for 1 atm of oxygen.

with less efficiency also takes place in the case of other carbonyl triplets in aromatic solvents (see, for example, ref. 18). We have shown (13) that quenching occurs from the following conformation:



Not only does quenching require this conformation, but in fact triplet lifetimes are largely determined by the rate at which this conformation can be achieved (13). The strong phosphorescence from β-phenylpropiophenone and the fact that its triplet lifetime is comparable to that for acetophenone in Silicalite indicates that this molecule phosphoresces from regions where the conformation required for deactivation cannot be achieved. This should not be taken to mean that other sites where deactivation would be permitted are not populated as well, since those sites would not be observable using phosphorescence techniques. We suggest that β-phenylpropiophenone is mainly included within the channel structure of Silicalite (as opposed to the surface), where folding cannot occur. This conclusion is further supported by the absence of phosphorescence on silica gel, where only surface-adsorbed species are found, as well as in the case of Mordenite, where the cavities are much larger than in Silicalite (17). It should, however, be noted that these comparisons do leave room to some reservations, since the surface of silica gel is quite hydrophilic (19), in contrast with the hydrophobicity of the Silicalite channels. A critical dependence of the phosphorescence emission intensity of β-phenylpropiophenone and its derivatives on cavity size has also been observed in recent experiments in which this ketone was complexed with cyclodextrins.[2]

Deactivation in the case of valerophenone (see reaction [1]) requires a conformation similar to that required in the case of β-phenylpropiophenone; however, the absence of an aromatic ring on the hydrocarbon chain permits larger mobility, thus making the process possible, even if kinetically it may be slower than in solution, where triplet valerophenone lives less than 10 ns (20). Quite clearly, spatial requirements in the case of valerophenone are less stringent than for β-phenylpropiophenone. The occurrence of the Norrish Type II reaction in the case of valerophenone was also confirmed by product studies, and in fact is not unexpected in view of results from this laboratory showing that the reaction also occurs in other phenyl alkyl ketones when they are included in urea clathrates, where the diameter of the channel is ~5.5 Å (ref. 21).

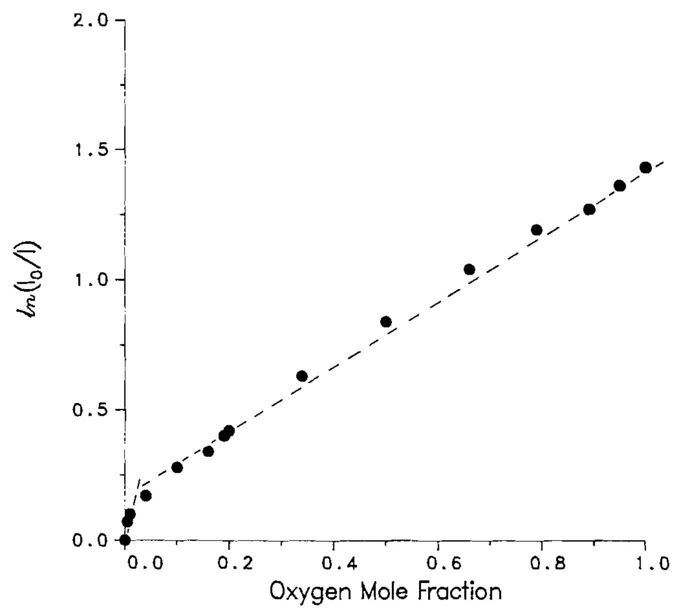


FIG. 8. Quenching of acetophenone phosphorescence by O_2 according to eq. [2]. Excitation: 254 nm; emission: 450 nm; nominal occupancy: 80%.

Phosphorescence from other ketones, such as acetophenone and benzophenone, is not surprising, since emission from these is readily observable in solution at room temperature in inert solvents (22).

Oxygen quenching experiments are quite useful in trying to understand the accessibility of different types of sites available in Silicalite. Thus, acetophenone an β-phenylpropiophenone are only partially quenched by 1 atm of oxygen. In the case of acetophenone, co-inclusion with 1-phenylhexane changes the rate and fraction of quenching, but not the qualitative observation that only partial quenching can be achieved under these conditions. By contrast, when acetophenone is generated *in situ* by photodecomposition of valerophenone, over 95% of its

[2]J. C. Netto-Ferreira, H. L. Casal, and J. C. Scaiano. Unpublished results.

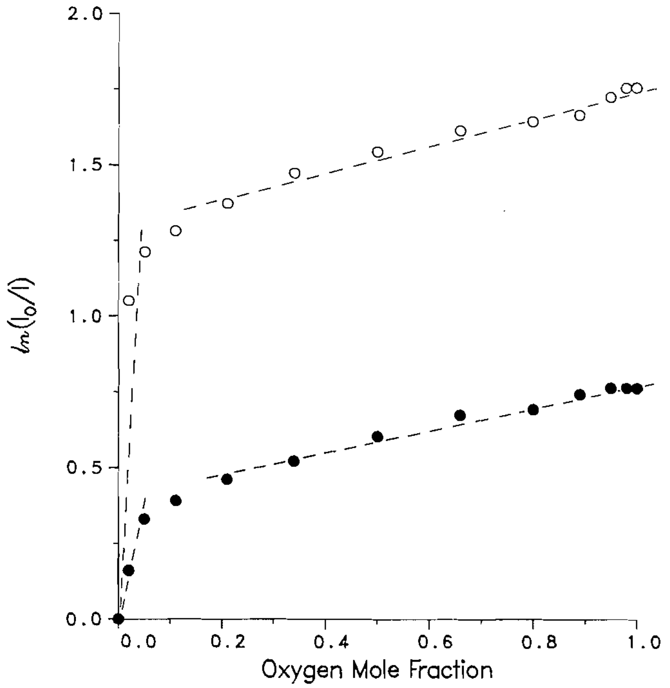

FIG. 9. Plots for the quenching of acetophenone phosphorescence by O_2 in a sample consisting of a mixture (5:95 mol/mol) of acetophenone and 1-phenylhexane in Silicalite (occupancy: 40%). Excitation: 254 nm (●); 313 nm (○). In both cases the emission was measured at 450 nm.

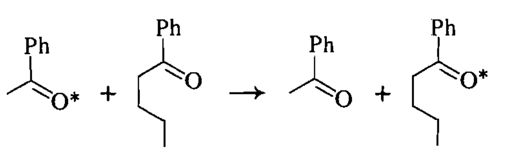
phosphorescence is quenched by 1 atm of oxygen. In principle, this observation could be the result of the occurrence of the Norrish Type II reaction in only one type of site (i.e. that which is readily accessible to oxygen). However, the phosphorescence of acetophenone is also suppressed by oxygen when acetophenone and valerophenone are co-included from a mixture of the two substrates. Here it is reasonable to assume that acetophenone is included in all types of sites, even if not necessarily with equal probability, and is supported by the result using acetophenone – 1-phenylhexane and acetophenone – 1-phenyl-3-pentanone mixtures, where their sizes are comparable to that of valerophenone; in these cases only partial quenching is observed.

From the analysis above, we conclude that the Norrish Type II reaction of valerophenone must occur in sites of all types. Why is acetophenone phosphorescence, observable only from the same sites that are accessible to oxygen? We believe that, in the more protected sites, the triplet state of acetophenone is quenched by valerophenone (reaction [3]), thus leading to a sensitized Norrish Type II reaction. Quasi-isoenergetic energy transfer between phenyl alkyl ketones has been shown to occur in solution with rate constants in the neighborhood of $10^9\ M^{-1}\ s^{-1}$ (23), while in polymer systems typical frequencies for energy hopping between nearby chromophores are in the $10^{10}-10^{12}\ s^{-1}$ range (24).

[3]



Thus, the evidence presented above indicates the presence of *at least* two different types of sites, which for convenience we will call A and B. Class A represents the more protected type of sites, which are not readily accessible to oxygen as shown by the only partial quenching observed in several of the examples examined. The guest molecules in sites of type A must be in close proximity, since no luminescence from these sites is observed when acetophenone is co-included with valerophenone, the result being the same regardless of the mode of co-inclusion (*in situ* generation of acetophenone or using substrate mixtures). Since quenching of acetophenone by valerophenone takes place even when the guest molecules occupy only 20% of the void volume of Silicalite, it is interesting to speculate that inclusion in these sites may involve a considerable degree of cooperative effect.

In the second class of sites (B), quenching by oxygen occurs efficiently and rapidly, implying fast diffusion in these regions. Further, the molecules must be well separated, since valerophenone is unable to quench acetophenone in these regions. In spite of the apparent separation between molecules and the rapid quenching by oxygen, molecular motion is sufficiently limited as to prevent intramolecular quenching in the case of β-phenylpropiophenone.

The phosphorescence of β-phenylpropiophenone must arise from sites located within the channel structure of Silicalite and not on its surface. Some β-phenylpropiophenone may be adsorbed on the surface, but (assuming that surface-adsorbed species are not immobilized) this fraction is not expected to show phosphorescence.

An analysis of the luminescence quenching data (Table 3) provides further information on the nature and characteristics of the various sites in Silicalite. Benzophenone shows a continuous variation of the slope, suggesting many sites. It is important to note (see Table 1) that this is the only substrate for which the experimental carbon content of the sample is much lower than the value calculated on the basis of the amount of material used during sample preparation. This suggests that most of the benzophenone is adsorbed in areas readily accessible to isooctane, which does not enter the Silicalite channel framework (11) and washes surface-absorbed species during preparation. Thus, most of the benzophenone may actually be on the surface of Silicalite or, perhaps, in structural defects. The kinetic diameter and shape of benzophenone probably make it a borderline case for inclusion in Silicalite.

The samples of acetophenone co-included with various substrates are particularly interesting. The marked differences in k_q (particularly for 1-phenylhexane) probably reflect differences in accessibility, since the triplet lifetimes do not enter in eq. [2], and in any event do not seem to change much (see Table 2). Thus, in the samples with valerophenone (No. 5 and No. 6) the luminescence is readily quenched by oxygen (Tables 2 and 3). The situation contrasts with that for samples No. 7 and No. 8 where a large fraction of the luminescence arises from the better protected triplet. We believe that this is due to the quenching of acetophenone triplets by valerophenone, which occcurs efficiently in the "slow" A sites. It would thus seem that in this class of sites the two ketones are in close proximity, further suggesting a cooperative binding effect.

These ideas are further supported by the data for the sample containing acetophenone and 1-phenylhexane (No. 7). Note that the same two triplets are produced in different ratio (Table 3) depending on the excitation wavelength. A simple explanation of this effect is that, while at 313 nm the light is almost exclusively absorbed by the ketone, at 254 nm about 90% of the radiation will be absorbed by 1-phenylhexane. In sites "A", where the substrates are in close proximity, sensitization via energy transfer takes place efficiently; by contrast, in sites "B", a larger separation minimizes energy transfer. As a result, luminescence from sites of type "A" is favoured at 254 nm. The same ideas apply to sample No. 8. A related example has been published in a recent report showing very efficient sensitization of the fluorescence from anthracene on filter paper, coadsorbed with naphthalene, used as a sensitizer (25).

In the case of acetophenone most of the luminescence seems to arise from well-protected sites. This probably reflects the easy access of acetophenone to the channel framework of Silicalite. Further, it is also possible that energy migration and self-quenching processes that are well established in micellar solution (26) may play an important role.

We would like to note that we have referred to sites A, B, and the surface as "classes or types" of sites in an attempt to emphasize that each group may include several locations within the framework of Silicalite; these locations have common properties in the case of phosphorescent aromatic ketones and their quenching by oxygen; the latter probably reflects differences in accessibility. Recent work by Fyfe *et al.* (12) suggests the presence of numerous sites in the case of Silicalite, an observation that seems consistent with our preliminary observation of a $t^{\frac{1}{2}}$ dependence of the phosphorescence intensity.

Finally, while the data in Table 3 have been obtained taking into account the values of t_d (see eq. [2]), we have not varied this parameter systematically. Current work is concentrating on this particular aspect, i.e. the time dependence of the luminescence quenching data, in the hope that this will help to understand better the nature of the different classes of sites.

This paper focuses on a study of unimolecular and bimolecular photoreactions occurring with reactants which can be incorporated into the linear polysugars amylose and carboxymethylamylose. Hydrophobic and surfactant *trans* (E) stilbene derivatives form complexes in which the stilbene chromophore shows enhanced fluorescence and reduced *trans* → *cis* isomerization efficiencies. The reactivity of the excited surfactant–stilbene singlet towards the quencher iodide ion has been compared in water/dimethylsulfoxide in the presence and absence of amylose under conditions where complex formation is nearly complete. Some relatively hydrophobic viologen dications have also been found to form complexes with the water soluble carboxymethylamylose. Although the dications complex relatively weakly, the partially reduced monocations complex more strongly. This results in selective retardation of back electron transfer rates when the viologens are used as electron transfer quencher-oxidants for certain luminescent ruthenium polypyridine complexes.

BRIAN R. SUDDABY, RAYMOND N. DOMINEY, Y. HUI et DAVID G. WHITTEN. Can. J. Chem. **63**, 1315 (1985).

On étudie les photoréactions uni- et bi-moléculaires qui se manifestent dans le cas de réactifs que l'on peut incorporer dans les polysucres linéaires de l'amylose et du carboxyméthylamylose. Les dérivés hydrophobes et tensioactifs du *trans* (E) stilbène forment des complexes dans lesquels le chromophore stilbène présente des efficacités accrue de fluorescence et réduite d'isomérisation *trans* → *cis*. Opérant dans un mélange eau/diméthylsulfoxyde, en présence ou en l'absence d'amylose et dans des conditions où la formation du complexe est pratiquement totale, on a comparé la réactivité du singulet du stilbène tensioactif excité vis-à-vis d'un ion iodure, agissant comme piège. On a aussi trouvé que quelques dications viologènes relativement hydrophobes forment des complexes avec le carboxyméthylamylose soluble dans l'eau. Bien que les dications forment des complexes relativement faibles, les monocations partiellement réduits se complexent plus fortement. Ceci conduit à des retards sélectifs dans les vitesses de transfert en retour d'électrons lorsqu'on utilise les viologènes comme oxydants pièges de transfert d'électrons pour certains complexes luminescents de ruthénium polypyridine.

Introduction

The interaction of small molecules dissolved as solutes in solution with various sorts of interfaces, the binding of small molecules to reactive sites in soluble and insoluble polymers, and the formation of inclusion complexes between small molecules or ions and various types of "hosts" such as zeolites, cyclodextrins, cryptates, and crown ethers represent seemingly disparate but often closely related studies of what might best be grouped under the broad title of interfacial chemistry (1–9). When small molecules are bound or sequestered at the various interfacial sites described above, their behavior and reactivity is often modified compared to that in fluid solution. The modified reactivity encountered in such situations is of wide interest both due to its possible utility and to its frequent apparent relationship to biochemical and biophysical phenomena.

Among the various kinds of inclusion complexes studied, those with cyclodextrins as hosts and relatively small, nonpolar molecules as guests have been widely and thoroughly investigated (10–16). The cyclodextrin host is generally water soluble and presents a "cavity" into which small molecules can be imbedded. Molecular models indicate that this cavity is relatively hydrophobic and it has been found indeed that association is often very strong between nonpolar "guests" and the cyclodextrin host (14, 15). When the cyclodextrin incorporates specific molecules it is frequently observed that the reactivity of the incorporated molecule is substantially modified both with respect to unimolecular and biomolecular reactivity (10–16). In some cases conformationally flexible molecules give evidence that incorporation into a cyclodextrin complex leads to preferential "locking" into specific configuration. In other cases it has been found that bimolecular reactions of the guest are either retarded or, in some examples, completely inhibited (17). While rigid cyclodextrins can specifically incorporate molecules depending upon their size and hydrophobicity, it has also been found that the much more flexible glucose polymer amylose can also incorporate a variety of small molecules in what appear to be relatively similar inclusion complexes (18–23). Studies of binding constants for various molecules indicate that the amylose host provides a "cavity" with at least some characteristics similar to those of the cyclodextrins. However, in the case of the amylose it appears clear that there is considerably more flexibility in the size and length of the guest binding sites. Studies of the behavior of incorporated molecules have suggested that at least in some cases the binding sites are, like the cyclodextrins, relatively hydrophobic; for example, investigation with the fluorescent probe 2-(p-toluidinyl)-naphthalene-6-sulfonate, which shows unusual sensitivity to environment polarity, indicates that in low molecular weight amylose–water the fluorescence of the complex probe is similar to that observed in organic solvents or relatively hydrophobic sites of proteins (19). A number of investigations have suggested that amylose can exist in a variety of conformations in the absence of guests; it has been proposed that these conformations can easily rearrange to helical segments which are the site for inclusion complex formation (20). For both amylose and the somewhat more polar carboxymethylamylose it appears that the conformation of the macromolecule and its binding properties are strongly influenced by the solvent composition (22).

As par of our investigations of the properties in reactivity of

[1] Paper 39 is ref. 36.

[2] Permanent address: Shanghai Institute of Organic Chemistry, Academia Sinica, People's Republic of China.

organized assemblies and small molecules incorporated therein, we have recently examined the photochemical and photophysical behavior of functionalized surfactant molecules containing reactive chromophores in a number of different media; recently we found that a series of surfactant ketones and stilbenes form inclusion complexes with amylose and carboxymethylamylose (24, 25). In both studies we found evidence that the chromophore experiences a moderately hydrophobic environment in which there is reduced conformational flexibility. In the present paper we report an extension of these studies to include both a more detailed study of the various kinds of complexes formed from substituted stilbenes, as well as new investigations of bimolecular photoreactions in which one of the partners can be complexed or at least partially associated with carboxymethylamylose.

Experimental

Materials

Amylose (Aldrich, mol. wt. over 150 000) was used as received. Carboxymethylamylose was prepared as described below. The surfactant *trans*-stilbene probes were prepared by procedures described elsewhere (26). Distilled water was used in all studies and dimethylsulfoxide (Mallinckrodt) was spectrophotometric grade. The viologen derivatives were commercial (Aldrich) samples while the tris(2,2′-bipyridine) ruthenium hexafluorophosphate was prepared from a commercial (Aldrich) sample of the dichloride hexahydrate.

Carboxymethylamylose

Ten grams of amylose (Aldrich mol. wt. $\sim 1.5 \times 10^5$) is dissolved in 200 mL of 20% aqueous NaOH (40 g NaOH/200 mL H_2O). Dissolution is accomplished by *small* batch additions of the amylose to the continuously stirred NaOH solution while holding the temperature of solution at ~60°C (*T* must be <80°C to prevent decomposition which produces a yellow coloration). This may take 1–2 h. After complete dissolution, 7.5 g of $ClCH_2COOH$ is added and the mixture stirred for 15–24 h at room temperature. While stirring, the solution is diluted with ~600 mL 95% EtOH to produce a white precipitate. After decanting the liquid phase the Na-CMA can be purified by redissolving in 150–250 mL H_2O. Reprecipitation is then effected by *slow* addition to a *vigorously* stirred volume (~1 L) of EtOH (95%). After filter collection, the Na-CMA is vacuum dried and ground to a powder. The measurement of the degree of substitution (DS) is based on a conductometric procedure. Dried CMA (200 mg) is dissolved in 175 mL of distilled H_2O and 1.5 mL of 0.4 *N* NaOH solution is added. The solution is titrated with 0.14 *N* aqueous HCl, followed by conductivity measurements. Calculation of DS is made according to the following equation:

$$\mathrm{DS} = \frac{A \times 0.162}{1 - 0.080 \times A}$$

where $A = (V_2 - V_1)N/(\text{g sample})$, V_2 and V_1 are obtained from the titration curve, and N is the normality of the HCl solution (27).

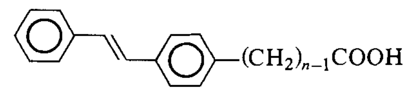
Spectroscopic measurements

Luminescence spectra were recorded on an SLM 800 or a SPEX Fluorolog2 digital, photon-counting spectrofluorimeter. Absorption spectra were obtained using a Perkin–Elmer 576ST spectrophotometer.

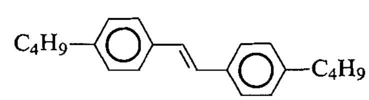
Results and discussion

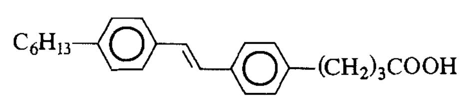
Complexes between functionalized trans-*stilbene derivatives and amylose*

As reported previously (24), we have found that while *trans*-stilbene itself gives no evidence for association with low or moderate molecular weight amylose in 1:1 dimethylsulfoxide (DMSO)/water, the substituted *trans*-stilbene derivatives S_nA, where n = 4, 6, and 12, form complexes in which there is a



modest increase in fluorescence with a concomitant decrease in the quantum yield for *trans–cis* isomerization. For all three of these stilbenes the quantum yield within the inclusion complex shows an approximate four-fold increase to a value of ϕ_f = 0.23. The increase in fluorescence upon addition of amylose to the DMSO/water solution can be used to evaluate the association constants for the different stilbenes with amylose. It is found, in accord with other studies (17–22), that the association constants increase with effective increases in the chain length or hydrophobicity of the surfactant stilbene. In recent investigations we have prepared additional substitute stilbenes including both surfactant and hydrophobic derivatives which contain the *trans*-stilbene chromophore in the middle of a long alkyl chain (26). Compounds we have studied with amylose include ${}_4S_4$ and ${}_6S_4A$. These structures are shown below.





These stilbenes exhibit modest solubility in DMSO/water but at even relatively low or moderate concentrations they show evidence of aggregation to form what are apparently H-aggregates (26). Our investigations have revealed that addition of amylose to solutions of the stilbenes in DMSO/water results in a sharp decrease in the fluorescence spectrum of the H-aggregated species in both cases, concurrent with an appearance of a sharp fluorescence attributable to the monomeric species (Fig. 1). The effect is especially striking with ${}_6S_4A$ where the two species have quite different fluorescence spectra. Although both ${}_4S_4$ and ${}_6S_4A$ show aggregates at low concentrations, dilution of DMSO/water solutions of the latter leads to monomeric absorption and fluorescence spectra at low concentrations. Under these conditions the ratio of fluorescence quantum yields in the presence and absence of amylose (1%) is 5.06 (Fig. 2). Since the quantum yield of fluorescence of ${}_6S_4A$ in the absence of amylose is 0.20 ± 0.01, this indicates that the presence of amylose raises ϕ_f to ~1.0 and further indicates that virtually all of the ${}_6S_4A$ is complexed. The effect with the intrachain stilbene is thus considerably greater than with the previously studied hydrophobic compounds in which the chromophore is at the end of the chain. For example, $S_{12}A$, which has an effectively "longer" hydrophobic chain, gives a fraction complexed at the same concentration of amylose of 0.70 and a limiting quantum yield of ϕ_f = 0.23; for this compound, as well as with S_4A and S_6A, an appreciable fraction of included stilbene molecules activated by light undergo *trans* → *cis* isomerization. In contrast, for complexes ${}_6S_4A$ there is effectively no photoisomerization. Iodide ion, which has been previously shown to quench *trans*-stilbene in 2:3 acetonitrile/water with a rate constant $k_q = 2.2 \times 10^{10}\ M^{-1}\ s^{-1}$ (28), has been examined as a quencher of the luminescence of ${}_6S_4A$ in the presence and absence of amylose. Preliminary studies indicate that amylose incorporation substantially reduces, but does not eliminate, quenching of the stilbene chro-

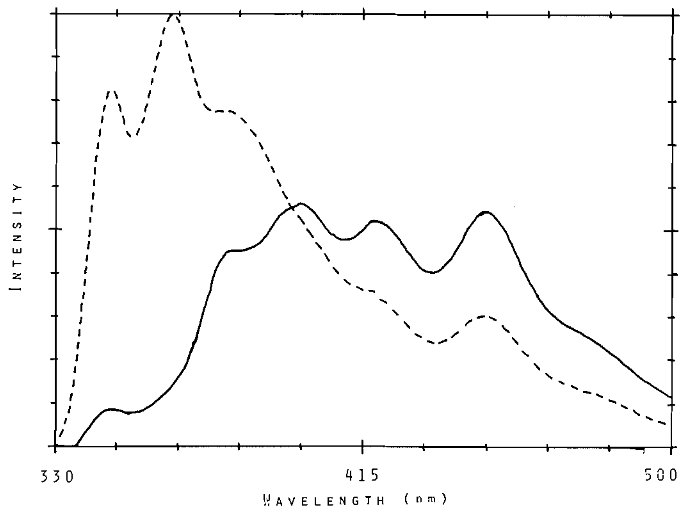


FIG. 1. Fluorescence spectra of $_6S_4A$ 5.0 × 10^{-5} M in 1:1 DMSO/H_2O (—) and 1% amylose in 1:1 DMSO/H_2O (- - -). λ_{ex} = 300 nm.

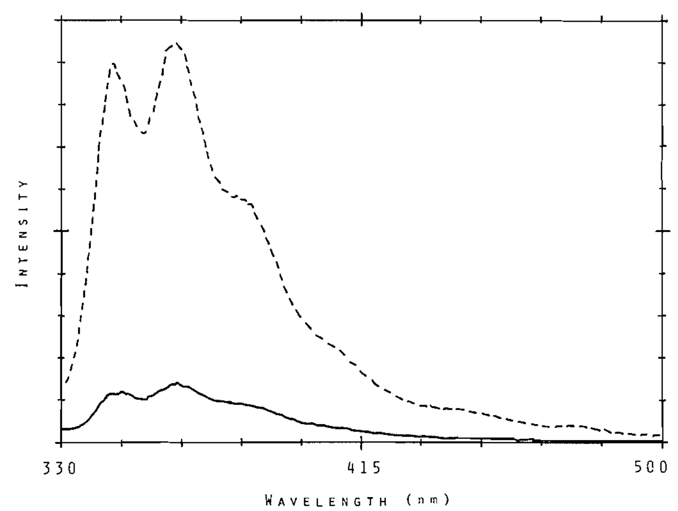

FIG. 2. Fluorescence spectra of $_6S_4A$ 5 × 10^{-7} M in 1:1 DMSO/H_2O (—) and 1% amylose in 1:1 DMSO/H_2O (- - -). λ_{ex} = 300 nm.

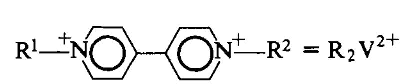
mophore singlet. Thus we find the Stern–Volmer quenching constants are 2.5 and 0.5 for $_6S_4A$ in the absence and presence of amylose respectively. Using lifetimes estimated from fluorescence efficiencies, we obtain k_q values of 4.4 × 10^8 M^{-1} s^{-1} and 1.3 × 10^{10} M^{-1} s^{-1} in DMSO/water in the presence and absence of amylose. Thus quenching is reduced about thirty-fold for iodide by amylose incorporation of the stilbene chromophore. It has been suggested that quenching of stilbene by iodide is a "charge-transfer" interaction since the quenching constants for several inorganic ions correlated with oxidation potentials (28); however, since fluorescence quenching is accompanied by an increase in *trans* → *cis* isomerization, heavy atom effects may also be important (28). The latter should require relatively close approach between the iodine nucleus and the stilbene chromophore and thus would explain in part the reduction in quenching rate. This seems not unreasonable in view of the presumed structure of the complex, in which any kind of major rotation of the stilbene chromophore around the ethylenic bond should be difficult, if not entirely forbidden, during the lifetime of excited singlet or triplet states. Studies on the photoreactivity of bound and free $_6S_4A$ also reveal sharp differences between the H-aggregated and amylose-incorporated species. Thus we find that the H-aggregate undergoes rapid photobleaching while the $_6S_4A$ shows relatively low photoreactivity. At the present time we have not established whether the photobleaching of the H-aggregated species is due to *trans* → *cis* isomerization or, perhaps, dimerization.

We are currently examining reactivity of amylose-incorporated $_6S_4A$ with a variety of potential quenchers of its excited singlet state. These studies should provide further insights into how reactions such as photoaddition, light induced electron transfer, or other processes can be modified by formation of the inclusion complexes.

Modification of rates of light induced electron transfer reactions by carboxymethylamylose host–guest interactions

As described above, we and others have found that organic chromophores, especially relatively linear or rod-like molecules that are more or less compatible with polymethylene chains, frequently form complexes with amylose and carboxymethylamylose. A very well-studied class of redox active molecules which might appear to belong in this category are the dialkyl viologens, R_2V^{2+},



whose basic 4,4′-bipyridinium structure can be easily modified by varying structure of the N and N′ alkyl groups. Thus it would seem that dialkyl viologens having one or two long alkyl chains should form reasonably good complexes with amylose derivatives in either their oxidized (dication) or mono reduced (cation-radical) forms. Towards this end we have investigated both complex formation with various viologen derivatives as well as their participation in light induced electron transfer reactions.

Unlike the previously described stilbene derivatives, which show pronounced absorption and fluorescent spectral changes upon incorporation into amylose, the viologen cations undergo no discernible spectral changes and are not easy to detect if they are complexed. To assay the binding of various viologen derivatives to carboxymethylamylose in water, we have taken advantage of the fact that the amylose and carboxymethylamylose form intensely blue colored complexes with polyiodide ions (29–31). This complex evidently consists of linear I_x^- (x = 3 or 5) incorporated into helical cavities formed by the amylose chain (29). The complex has a reasonably sharp absorption with λ_{max} = 600 nm, an absorbance which is relatively stable over time. The 600-nm band is discharged by the addition of long chain alcohols such as decanol or surfactants such as dodecyltrimethylammonium ion but not by small ions such as tetramethylammonium or shorter chain alcohols such as 1-hexanol. Examination of the viologen derivatives shows that dimethyl viologen (R^1, R^2 = CH_3) has no effect on the iodide absorption at 600 nm while, in contrast, addition of heptyl viologen (R^1, R^2 = C_7H_{15}) causes rapid bleaching of the band at 600 nm. In fact, there is a linear decrease in the absorbance at 600 nm as the concentration of heptyl viologen increases. From the degree of bleaching it can be ascertained that there are approximately 35 binding sites for heptyl viologen molecules per unit of carboxymethylamylose used. Thus, with the viologens as with the stilbenes, we find evidence that formation of the inclusion complexes can be correlated quite well with apparent chain length or overall hydrophobicity.

Since the monoreduced viologen derivatives should be substantially more hydrophobic than the dications, it might be expected that reduction would result in increased facility to form host–guest inclusion complexes. This is not easy to ascertain with dimethyl viologen; however, some evidence that this is the case can be obtained by studying reduced heptyl viologen. For the latter compound it has been established that the monocation reversibly dimerizes in aqueous solutions for $[H_2V^+] = 1 \times 10^{-5}$ *M*. This is accompanied by a decrease in the absorbance at 605 nm, the λ_{max} for the heptyl viologen cation radical monomer, and a corresponding increase at 565 nm, where the dimer absorbs. Thus we find that independent preparation of the radical cation in the absence of CMA leads to dimerization at these concentrations, and the addition of 1% CMA results in detection of only monomer until concentrations of the radical cation greater than 10^{-4} *M* are reached. This affirms once again that the radical cation readily forms an inclusion complex with CMA.

A reaction of various viologen derivatives which has been particularly well studied involves light induced oxidation of the tris(2,2′-bipyridine) ruthenium(II) dication (32–35). In this reaction (eq. [1]) the excited state of the ruthenium complex is quenched by single electron transfer to viologens such as dimethyl viologen.

[1] $Ru(bpy)_3^{2+*} + RV^{2+} \rightarrow Ru(bpy)_3^{3+} + RV^{\dot{+}}$

[2] $Ru(bpy)_3^{3+} + RV^{\dot{+}} \rightarrow Ru(bpy)_3^{2+} + RV^{2+}$

This reaction, which occurs at rates very close to diffusion controlled, involves efficient oxidation of the metal complex excited state; however, it is followed almost immediately by a back electron transfer process (eq. [2]) which regenerates the starting materials in their ground states. Rates of reaction [1] and analogous quenching processes are easily measured by examining either quenching of the phosphorescence of the luminescent ruthenium complex or reduction of the phosphorescent lifetime, while rates of the second reaction (eq. [2]) are easily studied by flash photolysis techniques. Interestingly, we find with $Ru(bpy)_3^{2+}$ there is *no effect* upon addition of CMA of quenching by either methyl viologen or heptyl viologen (Table 1). Replacement of $Ru(bpy)_3^{2+}$ with the anionic complex RuL_3^{4-} (where L = 4,4′-dicarboxy-2,2′-bipyridine) results once again in no effect upon addition of CMA on the quenching process by methyl viologen. Here, however, a Stern–Volmer quenching plot with heptyl viologen shows a curvature consistent with at least some intial sequestering of the viologen at very low concentrations. Nonetheless the overall effect observed on bimolecular quenching by both viologens upon addition of CMA is essentially negligible. This is surprising for several reasons. First of all, one might expect that a sequestered viologen would have considerably lowered reactivity as a quencher for an excited state and a process such as eq. [1]. Secondly, addition of CMA to aqueous solutions would surely be expected to increase the bulk viscosity of the solution. In fact, viscosity measurements indicate that at the levels of CMA used (1%) there is an apparent increase in viscosity of a factor of 1.5. This indicates that a diffusion controlled reaction should experience a change in rate constant of about 0.67; such a change is clearly not observed even under conditions where a significant fraction of the heptyl viologen should be complexed. With regard to the present results, the most reasonable explanation seems to be that with methyl viologen (which does not complex with CMA), although the bulk viscosity is increased, the microviscosity of the solution where the quenching process (eq. [1]) occurs is effectively unaffected. It is more difficult to come up with an explanation for the lack of effect noted with heptyl viologen; however, one possible explanation is that the equilibrium between complexed and uncomplexed viologen is rapid and favors the uncomplexed form at the concentration used in the quenching experiments; thus the effect is minimal and difficult to detect. An alternative explanation, that complexed and uncomplexed heptyl viologen react at similar rates, appears relatively unattractive.

In contrast to the lack of effect of CMA on the quenching processes, examination of the rates of back electron transfer (eq. [2]), as measured by the disappearance of the viologen radical cation absorption at 605 nm, shows that substantial effects are observed for both methyl and heptyl viologens (Table 2). The back reaction rates are retarded by factors of 3 to 5 for heptyl viologens (depending upon pH) and by factors of 2 to 3 for methyl viologens. These retardations are clearly greater than would be predicted simply on the basis of the change in bulk viscosity mentioned above. The reactions follow clean second-order equal concentration kinetics and suggest that the reaction involves almost exclusively viologen cation contained within the inclusion complex.

Results obtained in the study are interesting in that they point out the degree of control or selectivity which may be possible in modification of bimolecular reactions. Thus in the electron transfer overall sequence the difference in hydrophobicity of the viologen monocations compared to the dications allows selective, although modest, retardation of the back electron transfer process. However, the relatively modest extent of the retardation on the exothermic back electron transfer reaction raises questions as to just how "sequestered" an amylose-incorporated molecule is for different kinds of reactions. There is increasing evidence that exothermic electron transfer reactions can occur over distances of several angstroms; one possibility is that the net retardation observed is due to a combination of the viscosity effect noted above and reasonably close

contact permitted between the complexed viologen and oxidized metal complex. Subsequent studies will be performed to indicate whether greater sequestering can be obtained in related electron transfer reactions. Of additional interest, of course, is a comparison of electron transfer reactions with other bimolecular processes involving these apparently sequestered molecules. It is clearly reasonable that processes which involve specific bond formation – bond breaking interactions should be much more sensitive to molecular separation than simple electron transfer reactions. The relatively larger retardation observed for stilbene quenching may either be an example of this effect or it may reflect differences in the type of interaction among different host–guest combinations. We are currently extending these studies to better define the range of interactions that can occur with these complexes.

This paper is dedicated to the memory of Li Xiao-Bai

J. S. HARGREAVES and S. E. WEBBER. Can. J. Chem. **63**, 1320 (1985).

Polystyrene containing small mole fractions of pendent 9,10-diphenylanthracene (DPA) and fluorescein (F) was prepared. Absorption of light by DPA results in very efficient intracoil sensitization of the ^{1}F* state. The quantum efficiency (χ) of this process has been estimated as 0.75 in dimethylformamide (DMF) and 0.95 in 5:1 DMF/H_2O. The increase in χ in this latter solvent mixture is ascribed to the diminished polymer coil size in this poorer solvent. Analysis of the time dependence of fuorescence suggests a combined static and dynamic quenching of ^{1}(DPA)* by energy transfer. Studies of ^{1}(DPA)* and ^{1}(F)* fluorescence quenching by DABCO corroborate this model.

J. S. HARGREAVES et S. E. WEBBER. Can. J. Chem. **63**, 1320 (1985).

On a préparé du polystyrène contenant de faibles fractions molaires de diphényl-9,10 anthracène (DPA) et de fluoresceine (F). L'absorption de la lumière par le DPA est dûe à une sensibilisation très efficace et intraréseau de l'état ^{1}F*. On a évalué que l'efficacité quantique (χ) de ce processus est égale à 0,75 dans le diméthylformamide (DMF) et à 0,95 dans un mélange 5:1 de DMF/H_2O. On attribue l'augmentation de χ dans ce dernier mélange de solvants, à une diminution de la taille de l'enroulement du polymère dans ce solvant plus pauvre. Une analyse de l'influence du temps sur la fluorescence suggère l'existence de piégeages combinés statique et dynamique du ^{1}(DPA)* par transfert d'énergie. Des études de piégeage de fluorescence ^{1}(DPA)* et ^{1}(F)* par le DABCO corroborent ce modèle.

Introduction

Energy migration within isolated polymer coils has been studied extensively by a number of groups in the last few years (for reviews see ref. 1). Energy transfer phenomena can be expected to play an important role in polymer photodegradation and in the utilization of polymers as photon collection moieties. In all previous cases it has been difficult to distinguish between "excitonic" (down-chain) energy transfer and cross-chain energy transfer since both mechanisms may be reasonably expected to occur.

The present study is motivated by the following: (1) elucidation of a polymeric energy transfer system in which the extent of the excitonic mechanism can be varied, (2) characterization of some of the photophysical properties of polymer-bound dyes, and (3) demonstration that effective energy transfer can extend the response function of a polymer-bound dye.

The system discussed herein is composed of three components: (1) a polystyrene chain, spectroscopically inert in the present context, (2) polymer-bound 9,10-diphenylanthracene (DPA), which is a very efficient fluorophore, and (3) polymer-bound fluorescein, one of the most studied of the xanthene dyes, itself an efficient fluorophore and also efficiently sensitized by DPA via the Forster mechanism. Soluble polymers containing fluorescein have been prepared but very little spectroscopic work has been carried out on them (2, 3). Insoluble polymers of rose bengal covalently bound to an inert polymer support have been used by Neckers to produce singlet oxygen, which in turn acts as a photooxidizer (4). The polymer-bound photosensitizer has several advantages over the unbound dye. As will be shown, the quantum efficiency of sensitization of the fluorescein by DPA is ca. 75% in "good" polymer solvent (pure dimethylformamide, DMF) and ca. 95% in a "poor" polymer solution (5:1 DMF/H_2O). This solvent effect is interpreted in terms of the change in the coil size of a polymer containing at least one DPA–fluorescein pair. Fluorescence decay measurements demonstrate that most of the sensitization in pure DMF is static in nature, i.e. with little effect on the decay of the residual DPA fluorescence. In DMF/H_2O the DPA fluorescence lifetime is shortened, indicative of dynamic quenching. This implies that in DMF/H_2O essentially all DPA moieties are within the Forster radius (R_0) of a fluorescein.

Experimental

(a) *Chemical*

9-(*p*-Ethenylphenyl)-10-phenylanthracene was synthesized and purified as previously described (5). Styrene (Aldrich) and chloromethylstyrene (Polysciences) were purified by column chromatography using activated alumina immediately before use.

Dibenzylfluorescein (DPF) (IUPAC name: benzoic acid, 2-(6-benzyloxy-3-oxo-3*H*-xanthen-9-yl)-benzyl ester) was prepared by refluxing 0.05 mol of the disodium salt of fluorescein in 100 mL of dimethylformamide (DMF) with excess of α-chlorotoluene (MCB) for 3 h. After cooling, the solution was poured into water and the precipitate filtered. As much of this solid as possible was dissolved in methylene dichloride (CH_2Cl_2), the solution filtered, and the solvent removed under vacuum to give a brown material. The solid was repeatedly washed with NaOH solution until thin layer chromatographic analysis using activated silica and 4:1 Skelly B – ethyl acetate as eluent showed only one spot (R_f = 0.26). Finally, the solid was precipitated from a DMF solution by addition of acidified water, washed thoroughly with distilled water, and dried to give an orange powder: mp 185–187°C; ir (KBr): 1740 cm^{-1} (ester[3]); λ_{max} (C_6H_6): 460 nm, $\epsilon = 2 \times 10^4$ L M^{-1} cm^{-1}; nmr ($CDCl_3$) δ: 4.9 (s, 2H), 5.1 (s, 2H), 6.2–8.3 (m, 20H); m/e = 512.

Terpolymers of 9-(*p*-ethenylphenyl)-10-phenylanthracene, styrene, and chloromethylstyrene were prepared by dissolving selected mole ratios of the monomers (see Table 1), along with 1% by weight of 2,2′-azobis(isobutyronitrile) (AIBN), in 10 mL of benzene in a polymerization tube. After thoroughly degassing the solution by three

[1]Present address: Hewlett–Packard, Palo Alto, California.
[2]Author to whom correspondence may be addressed.

[3]This band is not present in normal fluorescein (see ref. 6). The detection of the ether linkage by ir was difficult because of the complexity of the spectrum.

freeze–pump–thaw cycles, the tubes were sealed under vacuum and maintained at 70°C for 60 h.

The polymers were then purified by repeated precipitation of toluene solutions by methanol. After drying under vacuum the diphenylanthracene content in the polymer were determined by visible absorption spectroscopy (5).

Fluorescein was attached to the methyl chloride group on the polymer support by the method described by Neckers and co-workers (7) using the chemistry of Merrifield (8). To a solution of 1 g of the above polymer in about 50 mL DMF, disodium fluorescein was added in excess. The solution was refluxed for 3 h, after which it was cooled, filtered, and poured into water. The solid was filtered off and the above purification repeated three times. After drying, the polymer was dissolved in CH_2Cl_2, filtered, precipitated out with methanol, and refiltered. As a final precaution, and to remove traces of sodium, a DMF solution of the polymer was precipitated out with acidified water. After thoroughly washing with distilled water the polymer was dried under vacuum to give a yellow powder.

Polymers were prepared that contained, apart from the inert polystyrene backbone, diphenylanthracene only, fluorescein only, or both diphenylanthracene and fluorescein. For convenience these polymers will be designated as PA, PF, or PAF respectively.

Molecular weights of the polymers were determined using a Waters hplc chromatograph (with Waters μ-Styragel columns, 500, 10^3, 10^4, and 10^5 Å pore size and CH_2Cl_2 or THF as the mobile phase) calibrated with polystrene standards. This also provided a final means of purification and, in fact, all emission spectra were taken only on polymers that had been purified by this method. The molecular weights determined from gpc traces agreed with those determined from viscosity measurements (using the Mark–Houwink parameters for polystyrene) (9).

The fluorescein content in the polymers was determined by visible absorption spectroscopy using solutions in DMF made basic by the addition of 0.1 *M* triethylamine. Extinction coefficients for fluorescein in this solvent were taken from this work and that of Martin (10).

1,4-Diazabicyclo[2.2.2]octane (DABCO, Aldrich) was purified by sublimination before use. Dimethylformamide (DMF) was purified by fractional distillation. Water was similarly purified. The ratio of DMF/H_2O used as a polymer solvent was 5:1 (by volume) in all cases, and the concentration of polymer in this solvent mixture was always less than 0.01% by weight. Increasing the water content by a small amount above the 5:1 ratio did not further alter the absorption and fluorescence spectra. Addition of a larger amount of water (~5:2) resulted in precipitation of the polymer. Increasing the concentration of polymer above 0.01% resulted in the precipitation of the polymer at lower H_2O content. As will be pointed out in the next section, the fluorescein photophysics is very sensitive to a polar solvent like H_2O. For that reason we did not study these polymers extensively in solvents like THF or CH_2Cl_2 because significant variations might be observed according to the adventitious H_2O content (which will be low in any case).

(b) *Optical*

All steady state fluorescence spectra were taken on a SPEX 1905 Fluorolog as previously described. All solutions for fluorescence work were thoroughly degassed and had an optical density of <0.1 at the absorption maximum. Absorption spectra were taken on a Cary 17 spectrophotometer.

Fluorescence decay curves were measured several different ways. At the Center for Fast Kinetics Research a 30-ps tripled Nd:YAG pulse (355 nm) was used for excitation and the fluorescence signal was digitized by either a Tektronix R7912 digitizer or a Hammamatsu streak camera. In our own labs a home-built correlated single-photon apparatus was used. In this system a Photochemical Research Associates nanosecond lamp is the excitation source, which when air filled at ~400 Torr (1 Torr = 133.3 Pa) has a half-width on the order of 4.8 ns. In this case excitation was at 358 nm. Standard ORTEC pulse shaping modules and an ORTEC model 457 time-to-amplitude (TAC) was used. The photomultiplier was a RCA 8850, wired for photon counting. A LeCroy model 3501 24 bit analog-to-digital converter was used to digitize the TAC output into the histogram memory of a LeCroy 3500M multichannel analyzer. These data were transferred to the University of Texas Cyber system and fit to exponential decay functions using reconvolution techniques (see, for example, ref. 11) in this technique the value of Δ is minimized for the quantity

$$[1] \qquad \Delta(k) = \int_0^{t_{max}} \left| I_{obs}(t) - \int_0^t F(t-\tau;\, k) R_{obs}(\tau)\mathrm{d}\tau \right|^2 \omega(t)\mathrm{d}t$$

where $I_{obs}(t)$ is the experimentally observed fluorescence at time t, $R_{obs}(t-\tau)$ is the experimentally observed response function of the excitation lamp and detector combination, and $F(t-\tau;\, k)$ is a proposed fluorescence decay function with parameter(s) k. We have taken the weighting function, $\omega(t)$, to be $I_{obs}(t)^{-1}$. The integral in eq. [1] is actually a summation over all the data channels (corresponding to 0–50 ns for these experiments). In addition to minimizing the quantity $\Delta(k)$ with respect to variations in k, the residuals

$$[2] \qquad D(t) = \left(I_{obs}(t) - \int_0^t F(t-\tau;\, k') R_{obs}(\tau)\mathrm{d}\tau \right) \omega(t)$$

were inspected for randomness. Based on the appearance of $D(t)$ it would seem that there is a systematic time shift between photons detected at the excitation wavelength (358 nm) and the two observation wavelengths (at 440 nm, ~ +0.4 ns and at 540 nm, ~ +0.6 ns) that has nothing to do with the normal shift between excitation and fluorescence maxima. If the fluorescence decay data were shifted by ca. −0.4 and −0.6 ns at 440 and 540 nm respectively, the best fits by the Δ criterion and the appearance of $D(t)$ are frequently obtained. This time shift always shortens the single exponential lifetimes obtained by 0.3–0.5 ns and slightly worsens the fit at longer times. Thus our estimated error for fluorescence lifetimes is ca. 0.3–0.5 ns based on this analysis.

Fluorescence quantum yields of polymeric fluorescein were taken as previously described (12), using an alkaline aqueous solution of fluorescein (purified by the method similar to that of Cramer and Spears, ref. 13) as the standard. Fluorescence quantum yield, lifetimes, and λ_{max} for fluorescence for compounds relevant to this paper are compiled in Table 2. For the sake of comparison, quantum yield, lifetime, and λ_{max} data for several fluorescein derivatives have also been collected in this table.

PAF-3	1	3.4×10^{-2}	57×10^{-3}

Results

(a) *Absorption, steady-state fluorescence*

The absorption and fluorescence properties of fluorescein depend strongly on the degree of ionization and the polarity of the solvent (14). An example of this effect can be found in the recent study by Lamberts and Neckers (15) on substituted rose bengal, which is also a dye in the xanthene group. The method of fluorescein attachment to our copolymers can lead to either of the species, dye I or dye II. Ionization of the phenol group in dye I is expected to lead to the usual dianion fluorescein absorption and fluorescence. Ionization of the carboxylic group in dye II is expected to have relatively little effect on the dye absorption and fluorescence since the phenyl group is only weakly conjugated with the main xanthene ring. This is illustrated by the work of Martin and Lindquist on 6-hydroxy-9-phenyl fluoran (HPF) in which the absorption properties of HPF are virtually identical to the fluorescein dianion (14*d*). In Fig. 1 the absorption spectra of HPF, DBF, and PF in DMF are compared. The polymer, PF, is a clear superposition of "HPF" and "DBF" which we take to indicate the presence of dye I and dye II respectively. Also presented in Fig. 1 is the fluorescence excitation spectrum (λ_{obs} = 560 nm) for the range 420–550 nm. Clearly it is primarily the "HPF" (dye I) component of the polymer-bound fluorescein that is contributing to the fluorescein fluorescence. We will return to this point in the Discussion. We do not believe that there is any significant amount of intracoil doubly substituted fluorescein in PF because (1) the mole fraction of chloromethylstyrene in the polymer is very low, (2) there is no evidence for cross-linking upon reacting the fluorescein with the polymer, and (3) the hplc traces before and after fluorescein attachment are virtually identical. In addition,

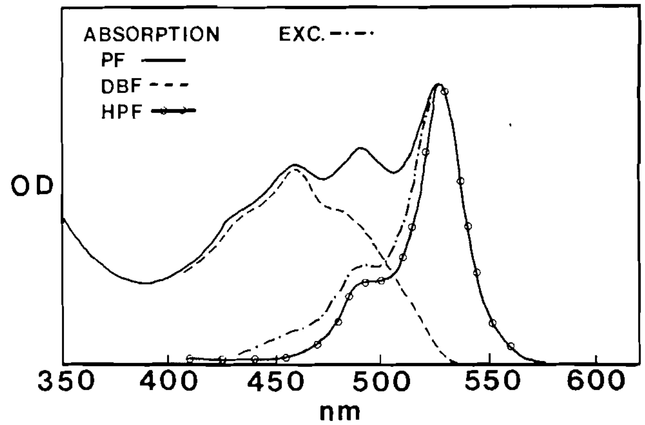

FIG. 1. Absorption spectra of PF (—), DBF (––), and HPF (ref. 14*d*) (⊖), (–·–) excitation spectra of PF or PAF (λ_{obs} = 560 nm) (all in DMF) scaled to match at long wavelength peak).

the fluorescence spectrum of doubly substituted fluorescein (DBF) is distinctly different from that of the PS-bound fluorescein (see Fig. 2 and cf. fluorescence lifetimes for PF and DBF in Table 2). In the present set of experiments the same ratio of styrene/chloromethylstyrene was used for all polymers and the degree of polymerization was very similar in all cases such that the average number of fluorescein moieties per chain was nearly identical (see Table 3). The relative fraction of dye I and II could be estimated from the long wavelength part of the absorption spectrum (see Fig. 1), i.e. the optical density at 460 nm is primarily due to dye II while that at 526 nm is primarily from dye I. Dye II was favored for PAF-2 and PAF-3 whilst dye I was favored for PAF-1 (Table 3). We defer to the Discussson our analysis of the effect of having two types of fluorescein moieties.

The effect of solvent polarity on fluorescein photophysics cannot be overemphasized (14). In Fig. 3 the absorption spectra of PF in DMF and CH_2Cl_2 are compared. In the latter solvent the spectrum looks like that of DBF, i.e. unionized fluorescein. Similarly we expect the fluorescein emission intensity to depend on solvent polarity (see below). The Forster R_0 value for DPA–fluorescein energy transfer might also be expected to depend on solvent because of this spectral change. In Fig. 3

[a]Determined using fluorescein in DMF as a standard and exciting at 520 nm. This quantum yield is independent of the presence of DPA and is the same for PF or PAF samples.

[b]The quantum yield of DPA fluorescence does not depend significantly on solvent. Equation [12] is derived considering only one kind of energy transfer mechanism per fluorescein. We have argued that the bulk of the energy transfer can be thought of as a static mechanism (i.e. no lifetime shortening). Stricttly speaking, each χ_i in eq. [12] should be replaced by $(\chi_i^{static} + \chi_i^{dynamic})$.

[c]Estimated from quantum yield data in ref. 10.

[d]This work, using single photon method.

[e]Phosphate buffered saline solution, pH = 7.2.

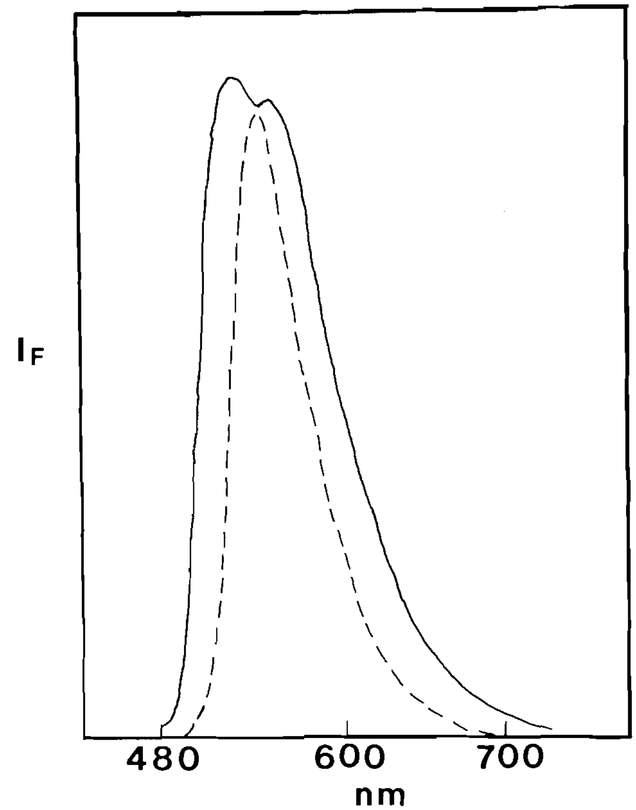

FIG. 2. Fluorescence spectra of PF (--) and DBF (—) in 5:1 DMF/H_2O, λ_{ex} = 475 nm (in arbitrary units, scaled for ease of comparison; uncorrected for PM response).

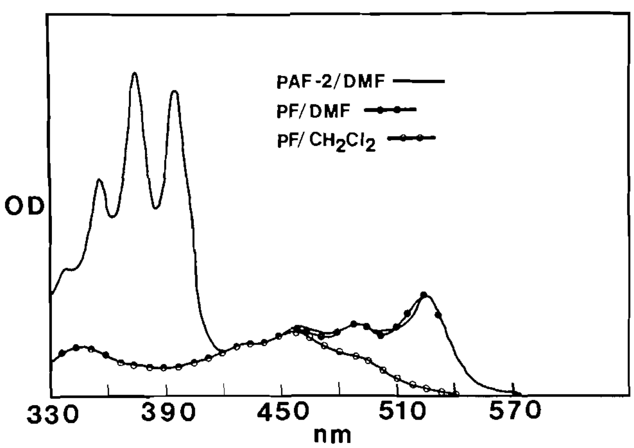

FIG. 3. Absorption spectra of PAF-2 in DMF (—), PF in DMF (●), and PF in CH_2Cl_2 (○) (equal concentrations of fluorescein).

we have also presented the absorption spectrum of PAF-2 in DMF at a concentration such that the fluorescein absorption is equal to that of PF. The DPA component at wavelengths below 420 nm is obvious.

The primary observation that we wish to discuss in this section is presented in Fig. 4 for PAF-2 and PF solutions optically matched in the fluorescein absorption region. Excitation light at 375 nm is absorbed primarily by DPA moieties in the case of PAF-2, yet the fluorescein component in the total steady-state fluorescence spectrum for PAF-2 is much larger than PF directly excited at 375 nm. Clearly very efficient energy transfer from DPA to fluorescein is occurring. This effect is

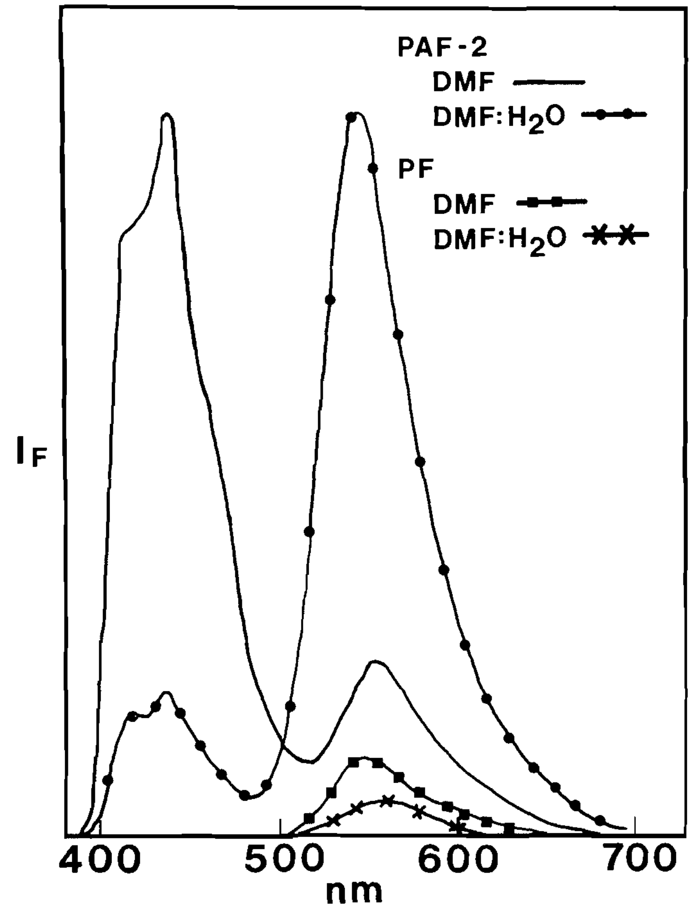

FIG. 4. Fluorescence spectra excited at 375 nm: (1) PAF-2 in DMF (—); (2) PAF-2 in 5:1 DMF/H_2O (●); (3) PF in DMF (×); (4) PF in 5:1 DMF/H_2O (■). The OD of the PF and PAF-2 solutions are matched at 430 nm (uncorrected for PM response).

especially pronounced in 5:1 DMF/H_2O, where the fluorescein component dominates the total fluorescence spectrum. This solvent effect is much larger than can be rationalized by the effect of solvent on the fluorescence quantum yield of PF or on the solvent shift of the fluorescein absorption spectrum. We interpret this very large enhancement to be the result of the diminution of the coil size of PAF by the more polar solvent, which decreases the average DPA–fluorescein separation (see Discussion) (16).

The efficiency of energy transfer can be quantified by means of the following equation (12, 17):

$$[3] \qquad \chi/(1-\chi) = (\phi_{DPA}/\phi_F)(I_F/I_{DPA})$$

In eq. [3] ϕ and I are respectively the quantum yield of fluorescence and the relative fluorescence intensity (as measured by relative areas in the total corrected fluorescence spectrum) for a given species. The subscripts DPA and F correspond to diphenylanthracene and fluorescein. One may interpret χ as the fraction of photons absorbed by the sensitizer (DPA) that are transferred to the fluorescein acceptor. Using ϕ_F for PS-bound fluorescein in Table 2, the χ values were identical within experimental error for all PAF samples and go from ca. 0.75 for DMF to ca. 0.95 for 5:1 DMF/H_2O. We will argue in the next subsection that most of this energy transfer is equivalent to static (i.e. contact) quenching of the DPA fluorescence.

It should be emphasized that, within experimental error, the

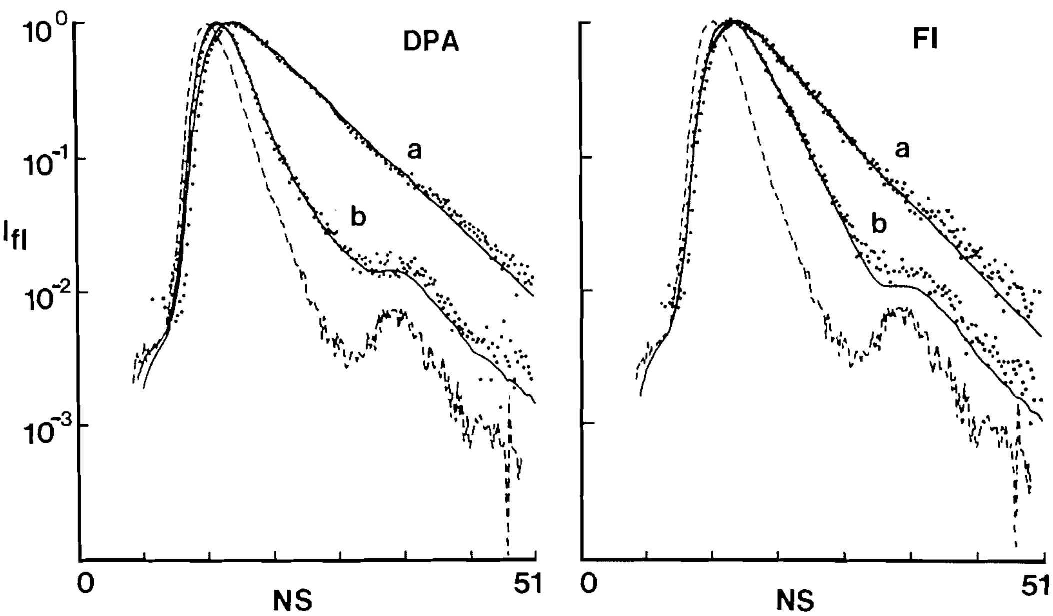

FIG. 5. Fluorescence decay curves for DPA and fluorescein (Fl); (––) instrumental resonse function; (···) raw data; (—) best fit curve. Curve a, DMF; curve b; 5:1 DMF/H_2O. Except for curve b, DPA, all best fits are a single exponential (see text).

value of χ does not depend on the average number of anthracenes per coil. This implies that the fluorescein sensitization occurs primarily by a single-step transfer with minimal contribution from DPA–DPA self-transfer. Furthermore, the average DPA–fluorescein separation must be on the order of R_0. R_0 for DPA–fluorescein in ethanol has been calculated as 41 Å (18), which is the same order of magnitude as the polymer coil dimension (estimated as 52 Å for polystyrene of comparable molecular weight in toluene).

We should also mention the striking effect of pendent fluorescein moieties on the solubility properties of PAF. PA is soluble in pure DMF but only very sightly soluble in 5:1 DMF/H_2O. Reaction of a PA polymer (these polymers always contain chloromethylstyrene groups) with fluorescein renders the resultant PAF soluble in DMF/H_2O to reasonable concentrations (0.01 wt.%), despite the fact that there is on the average approximately one fluorescein per polymer chain (Table 3). It was not possible to dissolve 0.01 wt.% PAF in DMF with higher mole fractions of added H_2O.

(b) *Fluorescence decay measurements*

The values of the fluorescence lifetime measured in DMF or DMF/H_2O at 440 nm (DPA) or 543 nm and 553 nm (fluorescein) are tabulated in Table 4. The fluorescence lifetime (τ_{fl}) of PA in DMF was typical of DPA (as noted in the previous section, it is not possible to dissolve PA in DMF/H_2O). The fluorescence lifetimes for the anthracene emission in all the PAF samples in DMF were slightly shortened (~1 ns) but were fit adequately by a single exponential (see Fig. 5 for PAF-2 data). Likewise, the fluorescence decay of the fluorescein was adequately fit by a single expontential for either DMF or DMF/H_2O, but the τ_{fl} value is slightly *longer* in the PAF samples than PF. We attempted to detect differences in the fluorescence build-up rate constant using 30-ps excitation at 353 nm, a 500-nm cut-off filter, and a streak camera. Within experimental error, there was no difference in these rate constants between PF and PAF-3 in DMF (4.4×10^{10} s^{-1} and 4.9×10^{10} s^{-1} respectively). This is consistent with the existence of significant static quenching of $^1(DPA)^*$ by the fluorescein.

TABLE 3. Mole ratios of components of polymers[a]

Polymer	DPA/S	DPA/(I+II)	I/II	(I+II)/S
PA	0.0038 (1.1)	—	—	—
PF	—		0.31	0.0032 (0.96)
PAF-1	0.0038 (1.1)	1.3	1.26	0.0029 (0.87)
PAF-2	0.026 (7.8)	8	0.37	0.0032 (0.96)
PAF-3	0.077 (23.1)	25	0.42	0.0030 (0.90)

[a]DPA = 9,10-diphenylanthracene; S = styrene; I and II = dye I and dye II. Degree of polymerization for all polymers ca. 300 ($M_N/M_n \cong 1.8$). Values in parentheses are the average number of DPA and fluorescein moieties per chain (columns 2 and 5 respectively).

The most important effect illustrated by the data presented in Table 4 or Fig. 5 is the drastic shortening of the anthracene fluorescence lifetime in going to DMF/H_2O. The shortening is especially noticeable for PAF-3, which contains the highest mole fraction of anthracene. We interpret this as the result of dynamic (i.e. diffusive) quenching of $^1(DPA)^*$ via energy transfer to the fluorescein. Furthermore, we take the fact that PAF-3 has the most shortened lifetime to imply the presence of energy migration between DPA groups which further enhances dynamic quenching of $^1(DPA)^*$. For PAF-1 and PAF-2 the anthracene fluorescence decay could not fit satisfactorily to a single exponential. The fit to a biexponential decay function of the following form was satisfactory, even if the slow component lifetime (τ_2) was constrained to be that of unquenched anthracene (τ_2 = 6.8 ns).

$$[4] \qquad I(t) = a_1 e^{-t/\tau_1} + a_2 e^{-t/\tau_2}$$

For these constrained biexponential fits $a_1/(a_1 + a_2) \geqq 0.98$ (see Table 4). This implies that in DMF/H_2O $\leqq$2% of the DPA moieties are outside the range of dynamic energy transfer (these could be the DPA groups that reside on a polymer coil without a pendent fluorescein). The remaining DPA's must be located either much less than R_0 from the fluorescein (equivalent to static quenching) or on the order of R_0 from the fluorescein, leading to lifetime shortening. The fluorescence decay

TABLE 4. Fluorescence lifetime data (ns)[a]

Sample	DMF/H_2O (5:1)		DMF	
	DPA	F	DPA	F
PA	—	—	6.8 [6.5]	—
PF	—	2.2 [1.6] (2.7)[b]	—	4.8 [4.3] (4.0)[b]
PAF-1	1.0 (0.98)[c]	2.2 [1.7]	5.5 [5.2]	5.5 [5.0][d]
PAF-2	1.1 (0.98)[c]	3.0 [2.6]	6.0 [5.7]	5.5 [5.0][d]
PAF-3	0.8 (~1.0)[c]	3.3 [2.9]	5.9 [5.5]	6.0 [5.5][d]

[a]Solutions outgassed. Values in brackets result from fit to time-shifted decay curve (see experimental section). We estimate our error in best fit lifetimes to be approximately 0.5 ns. For DPA λ_{obs} is 440 nm, and for F λ_{obs} is 543 nm for DMF/H_2O and 553 nm for DMF.

[b]Determined for very dilute solutions to minimize apparent lifetime lengthening by self-absorption. Because of poor S/N the quality of the raw data and subsequent fit is diminished.

[c]A single exponential fit for PAF-1, PAF-2 is unsatisfactory. The data were fit to a constrained biexponential with one lifetime at 6.8 ns (unquenched DPA). Value in parentheses is the fraction of the short lifetime component in the best fit.

[d]These lifetimes are observed from sensitized fluorescence. The lifetimes obtained by direct excitation are like PF.

of PAF-3 was fit in the same way but was almost a pure exponential.

A rough calculation shows that these results are consistent with our χ values. For this calculation we assume that the DPA's can be divided into two independent groups, those statically quenched and those uniformly dynamically quenched. We assume that 0.75 of all DPA's are quenched statically (from the DMF data), and the remaining DPA's are quenched dynamically in DMF/H_2O. For this latter group

$$[5] \qquad \chi_{\text{dynamic}} = k_T/(k_0 + k_T)$$

where k_0 is the rate constant for all excited state relaxation processes other than energy transfer and k_T is the energy transfer rate. We take k_0 to be equivalent to the rate constant for PA in DMF and k_T may be calculated by

$$[6] \qquad k_T = k_{PAF} - k_0$$

From the observed lifetimes in Table 4 χ_{dynamic} is estimated as 0.86. Thus summing 0.75 (static transfer) plus (0.86)(0.25) = 0.22 (dynamic transfer) the net transfer efficiency is calculated as 0.97, within the experimental error of 0.95 determined by steady-state methods. In this calculation we are neglecting enhanced static quenching that results from coil contraction. Despite the crudeness of this calculation we feel it illustrates the overall consistency of our steady-state and time-dependent data.

(c) *Fluorescence quenching of PAF-3 by DABCO*

These experiments were designed to further elucidate the effect of rapid energy transfer from ^{1}(DPA)* to fluorescein. In order to minimize direct absorption by fluorescein only PAF-3 was studied. The quencher chosen was DABCO (1,4-diazabicyclo[2.2.2]octane) which is known to be an efficient singlet-state quencher, presumably by an electron transfer mechanism (19). The quenching of the steady-state fluorescence of the anthracene or the fluorescein could be fit satisfactorily to a Stern–Volmer plot.

$$[7] \qquad I_0/I_Q = I + K_{SV}[Q] = 1 + k_q\tau_0[Q]$$

In the case of fluorescein the fit was satisfactory for either direct excitation at 500 nm or sensitized by DPA absorption at 375 nm. The data are collected in Table 5.

TABLE 5. DABCO quenching data[a]

Polymer	λ_{obs} (nm)	λ_{exc} (nm)	K_{sv} (M^{-1})	τ_0 (ns)	$k_q \times 10^{-9}$ (M^{-1} s^{-1})
PA	440	375	18[b]	6.8[b]	2.6
PAF-3	440	375	1.6	0.8	2.0
	545	375	1.1	3.3	0.33
PAF-3	545	500	0.48	2.2	0.22

[a]All data for 5:1 DMF/H_2O except where noted.

[b]From PA in DMF. There are no data for PA in DMF/H_2O because of poor solubility. However, in separate experiments, DPA bound to water-soluble polymers exhibits a normal fluorscence lifetime of ~6.8 ns.

For the ^{1}(DPA)* fluorescence quenching the k_q value was very similar in DMF and DMF/H_2O (note that there is a very large effect of τ_0 in the calculation of k_q). Alternatively, the change in K_{SV} could be used to estimate τ_0 for the quenched ^{1}(DPA)* in DMF/H_2O. The estimated value of τ_0 is 0.53 ns, in reasonable agreement with the experimentally measured 0.8 ns. The conclusion from these results is that the DPA moieties that do fluoresce are equally well quenched by DABCO in DMF and DMF/H_2O, which implies that they remain accessible to the DABCO (i.e. the DPA are not protected by a partially collapsed coil).

Perhaps of more importance is the fact that the quenching rate of fluorescein emission is essentially the same for direct or sensitized excitation and this quenching is fit satisfactorily by a Stern–Volmer plot. One can easily show that the quenching of sensitized fluorescein fluorescence also reflects the quenching of the precursor state, i.e. ^{1}(DPA)*, leading to the following equation:

$$[8] \qquad I_0^F/I_Q^F = (1 + K_{SV}^{DPA}[Q])(1 + K_{SV}^F[Q]) = 1 + (K_{SV}^{DPA} + K_{SV}^F)[Q] + K_{SV}^{DPA}K_{SV}^F[Q]^2$$

where K_{SV}^{DPA}, K_{SV}^F are the products $k_q\tau_0$ for DPA and fluorescein respectively. While it is not surprising that the quadratic dependence on $[Q]$ has not shown up in our data (i.e. the product $K_{SV}^{DPA}K_{SV}^F$ is not large), clearly the experimental K_{SV}^F value is much smaller than predicted in eq. [8]. We conclude that the DPA's monitored by fluorescence are not the primary precursors of the fluorescein singlet state, ^{1}F*. This is consistent with our model of this system in which a large fraction of the ^{1}(DPA)* species are quenched statically. The remaining ^{1}(DPA)* are quenched dynamically, i.e. fluorescence lifetime and yield nearly equally decreased.

Discussion

In this work we have demonstrated that very efficient energy transfer can occur between ^{1}(DPA)* and fluorescein moieties, thereby enhancing the action spectrum of fluorescein into the uv. Based on our mole fraction data, we find that high quantum efficiencies (χ) can exist even if there is on the average only one DPA–fluorescein pair per polymer coil (e.g. PAF-1, Table 3).

In a good solvent (DMF) the energy transfer mechanism is largely equivalent to static quenching since the lifetime shortening of ^{1}(DPA)* in the PAF samples is much less than expected for a χ value of 0.75 (see the discussion below concerning the χ value calculation for this system). Furthermore, the ^{1}(DPA)* fluorescence decay can be fit by a single exponential within experimental error. This implies that there is not a significant population of ^{1}(DPA)* species that resides on polymers without a pendent fluorescein[4] (but see the next paragraph). We note that the fluorescence lifetime of *sensitized* ^{1}(F)* is longer than directly excited ^{1}(F)*, which is what is to be expected if there exists a relatively long-lived precursor state (^{1}(DPA)*). We conclude that in DMF all energy transfer processes are intracoil and that all ^{1}(DPA)* species are affected by energy transfer to some extent. There is no systematic effect of DPA mole fraction, such that DPA–DPA energy transfer does not seem to play a major role in the value of χ.

Reducing the solvent quality by the addition of H_2O drastically alters the ^{1}(DPA)* fluorescence properties. The χ value increases to ca. 0.95 and the ^{1}(DPA)* fluorescence lifetime is greatly shortened. In this case a biexponential fit is possible and the two lifetimes obtained are quite different. The mole fraction of ^{1}(DPA)*'s with an unchanged fluorescence lifetime (i.e. fluorescein-free polymers) is estimated to be $\leqq 0.02$ (see Table 4). Our interpretation is as follows: the addition of the H_2O nonsolvent reduces the coil dimensions to the point that essentially all DPA's are within the Forster R_0 distances of a fluorescein moiety (R_0 is estimated as 41 Å for ^{1}(DPA)*–fluorescein in ethanol). Addition of a nonsolvent can encourage polymer aggregation, which also would serve to reduce the average DPA–fluorescein separation. There is no evidence for aggregation for our 0.01 wt.% polymer in DMF/H_2O solutions since: (1) there is no measurable turbidity, either immediately after addition of H_2O or after standing for days, and (2) the spectral properties of these solutions do not change upon standing. However, the presence of some degree of aggregation cannot be completely eliminated based on direct experimental evidence.

We must now consider the complications in the present system because of the existence of two different fluorescein derivatives on the polymer chain (dye I and II). Equation [3] is obtained from a classical kinetic scheme in which ^{1}(DPA)* is the sole precursur of ^{1}(F)*, the fluorescein singlet state. Under steady-state conditions

$$[9a]\quad [^1(\mathrm{DPA})^*] = I_{\mathrm{ex}}(k_{\mathrm{DPA}} + k_{\mathrm{T}})^{-1}$$

$$[9b]\quad [^1(\mathrm{F})^*] = [^1(\mathrm{DPA})^*](k_{\mathrm{T}}/k_{\mathrm{F}}) = (I_{\mathrm{ex}}/k_{\mathrm{F}})\chi$$

where

$$[10]\quad \chi = k_{\mathrm{T}}(k_{\mathrm{DPA}} + k_{\mathrm{T}})^{-1}$$

In eqs. [9] and [10] I_{ex} is the rate of DPA excitation, k_{DPA} and k_F are the normal first-order decay rates, and k_T is the energy transfer rate for ^{1}(DPA)* $\rightarrow$ ^{1}(F)*. The intensity of fluorescence for each species is given by

$$[11]\quad \begin{aligned} I_{\mathrm{DPA}} &= \phi_{\mathrm{DPA}}(1-\chi)I_{\mathrm{ex}} \\ I_{\mathrm{F}} &= \phi_{\mathrm{F}}\chi I_{\mathrm{ex}} \end{aligned}$$

where ϕ_{DPA} and ϕ_F are the fluorescence quantum yields for each species for direct excitation and in the absence of energy transfer. If we have two types of fluorescein moieties, but only one per polymer chain, then eq. [11] can be extended as follows (19):

$$[12]\quad (I_{\mathrm{F}}/I_{\mathrm{DPA}})(\bar{\phi}_{\mathrm{F}}/\phi_{\mathrm{D}}) = [X_1\chi_1(\phi_{\mathrm{F}_1}/\bar{\phi}_{\mathrm{F}}) + X_2\chi_2(\phi_{\mathrm{F}_2}/\bar{\phi}_{\mathrm{F}})]/[X_1(1-\chi_1) + X_2(1-\chi_2)]$$

where

$$[13]\quad \bar{\phi}_{\mathrm{F}} = X_1\phi_{\mathrm{F}_1} + X_2\phi_{\mathrm{F}_2}$$

In eqs. [12] and [13] X_1 and X_2 are the mole fraction of each type of fluorescein, ϕ_{F_1} and ϕ_{F_2} the appropriate fluorescence quantum yields, and χ_1 and χ_2 the quantum efficiency of sensitization for each species (the subscripts 1, 2 refer to dye I and II respectively). In deriving eq. [12] it is assumed that the DPA's are spectroscopically equivalent for both types of coils. I_F is taken to be the total "fluorescein" fluorescence. This is strictly appropriate only if the fluorescence of F_1 and F_2 overlap extensively. In eq. [12] we experimentally determine $\bar{\phi}_F$ (Table 2) and X_1 and X_2 (Table 3).

Obviously eq. [12] is more complex to analyze than eq. [3]. The only simple cases are

$$[14a]\quad 1.\ \phi_{\mathrm{F}_2} = 0 \text{ and } \chi_2 = 1;\ \chi = X_1$$

$$[14b]\quad 2.\ \phi_{\mathrm{F}_2} = 0 \text{ and } \chi_2 = 0;\ \chi = X_1\chi_1$$

$$[14c]\quad 3.\ \phi_{\mathrm{F}_1} = \phi_{\mathrm{F}_2};\ \chi = X_1\chi_1 + X_2\chi_2 = \bar{\chi}$$

In general the spectroscopic properties of fluorescein derivatives are sensitive to solvent and substitution (see Table 2). While we were able to prepare a doubly substituted fluorescein derivative (DBF), we were not able to prepare separate analogs of dye I and II using methods analogous to our polymer modification scheme. However, other experimental evidence exists that suggests $\phi_{F_2} = 0$, as follows.

(1) The "fluorescein" fluorescence spectrum does not change with excitation wavelength, despite the very striking difference in dye I and II absorption spectra (Fig. 1). (Note, for example, that the fluorescence of DBF is significantly broader than PF (Fig. 2).)

(2) There is no evidence for biexponentiality in the fluorescein fluorescence decay, nor was any significant effect of observation wavelength found in the fluorescence lifetime.

(3) The excitation spectrum for PF or PAF fluorescence is very different from the absorption spectrum and is essentially identical to the HPF absorption spectrum (see Fig. 1).

4) The spectral overlap of ^{1}(DPA)* fluorescence with DBF or dye II moieties is much more favorable for Forster energy transfer than ^{1}(DPA)* – dye I. The absorption strength of these two moieties is similar, hence it is reasonable to suppose $\chi_2 > \chi_1$.

Taking all these facts into account we believe that our system is an example of case (1) (eq. [14*a*]), i.e. $\phi_{F_2} \approx 0$, $\chi_2 \approx 1$, such that our χ value actually is χ_1 and all our photophysical observations are for the part of our polymer ensemble for which there is one dye I fluorescein per chain in addition to some number of DPA's. The copolymers with dye II fluorescein make no contribution to our observations because the net fluorescence yield from either DPA or dye II is essentially zero.

In addition to enhancing the spectral response of a pendent dye, polymers of the type discussed herein provide a very nice model for theories of energy transfer in disordered media. In particular there is the possibility of simultaneous down-chain transfer and single-step transfer to the dye trapping site. The use of DPA is advantageous because excimer formation is avoided. However, a detailed theoretical analysis of the present results may not be justified because of the complication that two types of fluorescein moieties exist. Future studies will be directed toward alternative dye systems and (or) attachment methods that avoid this complication.

[4]A biexponential fit is not very accurate if the two lifetimes are very close (see ref. 11). This biexponential analysis is much more accurate in the case of DMF/H_2O.

Acknowledgements

This work has been sponsored by the national Science Foundation (DMR8013709) and a grant from the 3M Corporation. The single-photon lifetime apparatus was purchased with NSF equipment grant DMR8211353. We gratefully acknowledge this financial support. We also acknowledge the help of the staff and the use of the facilities of the Center for Fast Kinetics Research, which is supported jointly by the Biotechnology Branch of the Division of Research Resources of the NIH (grant RR00886) and The University of Texas at Austin. We would like to thank Edward Gaffney for his help with the fluorescence lifetime measurements.

Energy migration in the aromatic vinyl polymers. 5. Poly(2-vinyl naphthalene) and polystyrene

STEVEN N. SEMERAK AND CURTIS W. FRANK

Department of Chemical Engineering, Stanford University, Stanford, CA 94305, U.S.A.

Received August 1, 1984

This paper is dedicated to the memory of Li Xiao-Bai

STEVEN N. SEMERAK and CURTIS W. FRANK. Can. J. Chem. **63**, 1328 (1985).

Electronic energy migration in pure poly(2-vinyl naphthalene) (P2VN) is analyzed in terms of a theory for three-dimensional transport and trapping in a homogeneous system of randomly distributed chromophores. A simpler theory for 3-D transport on a spatially periodic lattice, which was applied previously to polystyrene (PS) gave self-contradictory results for P2VN because of higher transport rates in P2VN. The fraction of rings in excimer-forming sites (EFS) in pure P2VN, analyzed by the former theory, is found to be 0.072 – moderately larger than the single-chain fraction of 0.026. In contrast, the EFS ring fraction in pure PS was 0.33, much larger than the single-chain fraction of 0.051. This reflects the reduced probability, relative to a phenyl ring pair, of packing a naphthyl ring pair into the necessary sandwich arrangement in the pure polymers. Energy migration in very dilute, miscible blends containing P2VN is analyzed by a one-dimensional transport model, which was applied previously to similar blends containing PS. The nearest-neighbor migration rates obtained from the data for both P2VN and PS are about one hundred times higher than the expected dipole–dipole rates. This suggests that (1) migration is not limited to nearest-neighbor rings, (2) the morphology of the dilute blends does not consist of isolated chains of the aromatic vinyl polymers, or (3) short-range electronic interactions other than dipole–dipole are involved in energy migration.

STEVEN N. SEMERAK et CURTIS W. FRANK. Can. J. Chem. **63**, 1328 (1985).

Faisant appel à une théorie de transport tridimensionnel et de piégage dans un système homogène de chromophores distribués au hasard, on analyse la migration de l'énergie électronique dans le poly(vinyl-2 naphtalène) (PV2N) à l'état pur. Une théorie plus simple pour le transport 3-D sur un réseau périodique dans l'espace, qui a été utilisée antérieurement pour le polystyrène (PS), donne des résultats auto-contradictoires avec le PV2N; ceci est du à des vitesses de transport plus grandes dans le PV2N. Si l'on se base sur la première théorie, on trouve que la fraction des cycles dans les sites de formation des excimères (SFE) du PV2N à l'état pur est égale à 0,072 et cette valeur est modérément plus élevée que la valeur de 0,026 obtenue pour la fraction de chaîne unique. Par ailleurs, la fraction de cycle dans les SFE d'une fraction de cycle dans le PS à l'état pur est égale à 0,33 et cette valeur est beaucoup plus grande que la valeur de 0,051 obtenue pour la fraction de chaîne unique. Ces résultats reflètent une probabilité réduite, par rapport à une paire de cycles phényles, d'entassement d'une paire de cycles naphtyles dans l'arrangement nécessaire en sandwich dans le polymère à l'état pur. Utilisant un modèle de transport unidimensionnel, utilisé antérieurement dans le cas de mélanges analogues contenant du PS, on a analysé la migration d'énergie dans des mélanges très dilués et miscibles contenant du PV2N. Les vitesses de migration du voisin le plus proche, obtenues à partir de données relatives au PV2N ainsi qu'au PS, sont environ 100 fois plus élevées que les vitesses de dipôle–dipôle attendues. Ceci suggère que: (1) la migration n'est pas limitée aux cycles les plus voisins, (2) la morphologie des mélanges dilués n'est pas constituée de chaînes isolées de polymères vinyl-aromatiques ou (3) des interactions électroniques à courte distance, autres que les interaction dipôle–dipôle, sont impliqués dans la migration d'énergie.

[Traduit par le journal]

Introduction

Photophysical phenomena exhibited by the aryl vinyl polymers in the solid state include, among others, "monomer" fluorescence from an individual pendant aromatic ring in its excited singlet state, "excimer" fluorescence resulting from trapping of incident excitation energy at the conformational structure formed between two coplanar, opposed pendant rings on the same or different chains (termed an "excimer-forming-site" or EFS), and energy migration among the individual chromophores. A recent review (1) has discussed the photophysics of excimer formation in some detail. The purpose of the present paper is to investigate the rate of singlet energy migration and the number of excimeric traps occurring in poly(2-vinyl naphthalene) (P2VN) and polystyrene (PS), in dilute and concentrated blends with nonfluorescent host polymers and in the pure state.

Previous work on energy migration in dilute solution or solid miscible blends in which the fluorescent polymer may be considered to be isolated has involved application of a strictly one-dimensional random walk analysis to toluene solutions of P2VN (2), miscible blends of PS with poly(vinyl methyl ether) (PVME) (3), and miscible blends of P2VN with poly(cyclohexyl methacrylate) (4). At sufficiently high concentrations of the aryl vinyl polymer, energy migration in miscible PS/PVME blends has been treated approximately as a three-dimensional random walk on a spatially periodic lattice (5).

These studies are extended in two ways in this paper. First, the three-dimensional migration process in pure P2VN and PS is treated successfully under a recent theory of exciton transport in homogeneous systems containing donors and traps (6). We show, after making a slight correction to the 3-D lattice model (5), that it cannot be accurately applied to P2VN because of the higher migration rates in P2VN relative to PS. Second, the 1-D migration model (2–4) is presented graphically, and the nearest-neighbor migration rates in dilute, miscible blends containing P2VN or PS are extracted from published data. Implications for the 1-D model and for the morphology of the dilute blends are briefly discussed.

Experimental

All P2VN/PS blends and pure films were cast from toluene solution and dried at room temperature. The spectrofluorimeter and solvent casting procedure have been described previously, as have the sources of the P2VN(70 000) and P2VN(265 000) samples and the PS(2200) sample with which they were blended (7). Pure P2VN and the 35% blend were examined by front face excitation, and the 0.3% blend by back face excitation. The excitation wavelength was 290 nm. Spectral data for the 0.3% and 35% P2VN blends have been published in refs. 7 and 8, respectively. The pure P2VN(70 000) and P2VN(265 000) samples examined in this work had spectra which were identical at room temperature, and were similar to published P2VN spectra, e.g. ref. 21.

The 60% PS(100 000)/poly(vinyl methyl ether) blend and the pure PS(100 000) film were described previously (5), as was the 5% PS(100 000)/PVME blend (3). Spectra were taken under front face excitation.

Results and discussion

A. *Three-dimensional energy migration and photophysics of undiluted P2VN and PS*

1. *Spatially periodic lattice model*

Gelles and Frank (5) (GF) have proposed a three-dimensional migration model for pure PS and miscible PS/PVME blends containing more than 60% PS. Only nearest-neighbor migration or transfer is allowed at a uniform rate W per neighbor in a lattice with N nearest neighbors. Each lattice point represents a phenyl ring. In the blends, the value of N is reduced to $N\nu_{PS}$, where ν_{PS} is the volume fraction of PS; $1 - \nu_{PS} \ll 1$. The EFS ring fraction, q, is expressed as the sum of an intramolecular part arising from *tt meso* rotational dyads, q_{intra}, and an intermolecular portion due to segmental association between different chains, q_{inter}. The latter part was taken to be proportional to ν_{PS}. In the analysis, the migrating singlet was assumed not to resample chromophores. That is, the number of steps from the point of absorption to the excimer trap should be small, so that there is no backtracking.

There is a slight error in the GF analysis which concerns the fact that an EFS contains two rings. Because of this, the migrating singlet excitation samples the state of the neighboring *dyad* at each step. However, the EFS are not randomly distributed over the ring pairs in the system due to the strict requirements for coplanar overlap of the aromatic rings (1). For example, one ring in a lattice site oriented with the normal to the ring plane along the, e.g., *x*-axis, could form an EFS only with a second ring placed in a lattice site along that same axis. The mutually perpendicular axes would not provide the necessary overlap.

This problem can be handled by considering that any migrating singlet excitation samples a one-dimensional string of chromophores within the three-dimensional system. We will assume that the EFS are randomly distributed among the dyads of the sampling string with the quasi-dyad fraction

$$[1] \quad q_D = 1 - (1 - q)^{1/2}$$

where q is the ring fraction of EFS. Rearrangement gives the relation

$$[2] \quad q = q_D(2 - q_D)$$

Following the lines of the GF model with this correction, M, the probability of ultimate decay of the excitation through a monomer radiative or nonradiative process, is given by

$$[3] \quad M = \frac{(\alpha - q\alpha)}{\left[\alpha + q\left[\dfrac{1-\alpha}{2-q_D}\right]\right]}$$

in which

$$[4] \quad q_D = q_{D,\text{intra}} + (N-2)\Omega_D\nu$$

and

$$[5] \quad \alpha = (1 + N\nu W\tau)^{-1}$$

TABLE 1. Excimer-to-monomer fluorescence ratio, R, of pure P2VN, PS, and concentrated blends

Guest/host polymers	Fluorescent polymer concentration (wt.%)	R	Φ_D/Φ_M[b]	$1/M - 1$
P2VN	100	45 ± 2[a]	47	85 ± 5[c]
P2VN/PS	35	7.6[a,d]	7.9	14.4[c]
PS	100	12.6[e]	—	30
PS/PVME	60	4.3[e]	—	10.2

[a] Ratio of fluorescence envelope intensities, I_{398}/I_{337}, measured under front face illumination and corrected for spectral overlap.
[b] Obtained from R after multiplying by the front face spectrometer instrumental calibration constant of 1.04.
[c] Given by $(\Phi_D/\Phi_M)/(Q_D/Q_M)$, where Q_D/Q_M is taken to be 0.55 ± 0.15 (1).
[d] Reference 8.
[e] Ratio of fluorescence envelope intensities, I_{332}/I_{280}, measured under front face illumination (5). No overlap correction was necessary.

TABLE 2. Parameters of the modified Gelles–Frank three-dimensional migration model for undiluted P2VN and PS

Polymer	$NW\tau$	$(N-2)\Omega_D$	q[a]	E[b,c]	Ω_D[c]
P2VN	1440 ± 100	0.04 ± 0.005	0.10	144	0.005
PS	105	0.16	0.34	10.5	0.02

[a] For undiluted polymer.
[b] $E = W\tau$.
[c] Computed assuming $N = 10$.

The quantity α is the probability of monomer decay during each energy migration step, τ is the measured lifetime of the excitation in the absence of transfer, ν is the volume fraction of the fluorescent polymer, and Ω_D is the probability that two adjacent chromophores are in an intermolecular EFS. The excimer-to-monomer quantum yield ratio for the system is then given by

$$[6] \quad \frac{\Phi_D}{\Phi_M} = \frac{Q_D}{Q_M}\left[\frac{1-M}{M}\right]$$

Q_D and Q_M are the intrinsic quantum yields for excimer and monomer fluorescence, respectively.

By combining eqs. [1]–[6], the fluorescence ratio of undiluted aryl vinyl polymers or concentrated blends may be predicted from the parameters of the modified GF model. Experimental values of the fluorescence ratio of P2VN and PS are given in Table 1; the fitted parameters $NW\tau$ and $(N-2)\Omega_D$ appear in Table 2. If $N = 10$ is arbitrarily assumed, the three-dimensional migration parameter $E = W\tau$ is found to be 144 and 10.5 for P2VN and PS, respectively.

To evaluate whether the assumption of no resampling in the P2VN systems is valid, the expected number of steps $\langle S\rangle$ made by the migrating singlet exciton must be computed. After making the same corrections as before, $\langle S\rangle$ becomes

$$[7] \quad \langle S\rangle = \frac{1-q}{\left[\alpha + q\left[\dfrac{1-\alpha}{2-q_D}\right]\right]}$$

where q_D is again defined by eq. [1]. The corrected values of $\langle S\rangle$ for pure PS and 60% PS/PVME are 3.4 and 5.7, respectively. Values of $\langle S\rangle$ for pure P2VN and 35% P2VN/PS are 17 and 33, respectively. The approximation of no resampling in P2VN systems is, thus, poor, since $\langle S \rangle$ is larger than the number of nearest neighbors N.

2. *Self-consistent two-body model for random systems*

Because the assumption of no resampling in the three-dimensional nearest-neighbor lattice model (5) does not seem valid for P2VN, we will consider a second model that does not restrict either resampling or migration to more distant chromophores. Loring, Andersen, and Fayer (6) have recently solved the Förster problem in which energy migration among the donors is allowed. The solution was given in terms of the Laplace transform of the donor response function, $G_d(s)$. Moreover, $G_d(s)$ has been shown to be directly related to M, the probability that an excited chromophore decays through a donor, or monomer, pathway (9). M is thus related to the chromophore density, the donor–donor and donor–acceptor Förster radii, and the fraction of excimer forming sites acting as exciton traps (10). This model is best applied to undiluted polymers, however, since the assumption of a random isotropic distribution of chromophores is less accurate in dilute polymer blends.

The probability of ultimate monomer decay M according to the LAF model is[1]

$$[8] \quad M = \frac{(1-q)X^2}{(1-YX)}$$

where

$$[9] \quad X = (Z^2+1)^{1/2} - Z$$

$$[10] \quad Y = \frac{\pi}{2\sqrt{2}} C_d$$

$$[11] \quad Z = \frac{\pi}{4\sqrt{2}} (C_d + \sqrt{2}\, C_a)$$

$$[12] \quad C_d = \frac{4\pi}{3} n_d R^3_{0,d-d}$$

$$[13] \quad C_a = \frac{4\pi}{3} n_a R^3_{0,d-a}$$

The quantities n_d and n_a are the number densities of donor and acceptor, respectively, and have units of Å^{-3}. The subscripts d–d and d–a on R_0 indicate the donor–donor and donor–acceptor Förster radii, in Å. The above relations were obtained by a combination of eq. 33 in ref. 9 and eqs. 40, 48, and 54 in ref. 6. The latter three equations (6) were based on the two-body approximation, which has been shown to be a physically realistic approximation. The more exact solutions of the problem (6) were not considered here, in the interest of simplicity.

In applying eqs. [8]–[13] to determine the fluorescence ratio of undiluted aryl vinyl polymers, both n_a and n_d may be related to the chromophore density of the polymer n. Utilizing the same quasi-dyad approximation discussed earlier, we have (d = monomer, a = excimer forming site)

$$[14] \quad n_a = \frac{nq}{(2-q_D)}$$

and

$$[15] \quad n_d = n(1-q)$$

where q_D is given by eq. [1]. By the same token, the migration and transfer Förster radii are related by the expression

[1] G. H. Fredrickson, personal communication.

TABLE 3. Parameters of the Loring–Andersen–Fayer three-dimensional migration model for undiluted P2VN and PS

Polymer	q_{intra} (Å)	$R_{0,max}$	E_{max}[a]	$R_{0,Förster}$	$E_{Förster}$[b]	q_{max}
P2VN	0.026	14.0	147	11.75[c]	51	0.072
PS	0.051	9.45	26	6.47[d]	2.7	0.33

[a] $E_{max} = W_T = (R_{0,max}/r)^6$; r = 6.11 Å for P2VN and 5.48 Å for PS (1).
[b] As in note a, except $R_{0,Förster}$ replaces $R_{0,max}$.
[c] Value for 2-methyl naphthalene/2-methyl naphthalene (20).
[d] Value for isopropyl benzene/isopropyl benzene (20).

$$[16] \quad R^6_{0,d-a} = (2-q_D)R^6_{0,d-d}$$

Combination of eqs. [1]–[16] and elimination of the d–d subscript yields the following expressions for Y and Z

$$[17] \quad Y = \frac{\sqrt{2}\,\pi^2}{3} nR_0^3(1-q)$$

$$[18] \quad Z = \frac{\sqrt{2}\,\pi^2}{6} nR_0^3[(1-q) + q(1-0.5q_D)^{-1/2}]$$

Analysis of the experimental results requires that the Förster radius R_0 and the EFS trap concentration q be known. Although R_0 values are available for the low molecular weight aromatic chromophores, it is not clear whether the same values should apply when the chromophores are bound to the polymer backbone. In addition, whereas the intramolecular contribution to the trap concentration arising from the *tt meso* dyads may be calculated, there is some evidence that the intermolecular EFS concentration may depend upon the degree to which residual casting solvent is removed from the sample.[2] Nevertheless, it is possible to use the LAF model to set limits on R_0 and q.

Two limits will be examined. First, the apparent maximum value of the donor–donor Förster radius, $R_{0,d-d}$, will be obtained by assuming that there are only intramolecular contributions to the EFS ring fraction, q. Second, q for pure P2VN will be determined by taking $R_{0,d-d}$ equal to the Förster value for 2-methylnaphthalene/2-methylnaphthalene. The fluorescence ratio of pure PS (5) will also be examined under the LAF model to complete the earlier work in which the GF model was applied to PS and PS/PVME blends (5).

The limiting parameters, which were calculated for the fluorescence ratios of pure P2VN and PS taken from Table 1, are collected in Table 3. For q = 0.33 in PS, E takes its Förster value of 2.7 in the LAF model, whereas E = 10.5 (and N = 10 neighbors) in the GF model. To achieve E = 2.7 with the GF model requires that N = 40 neighbors in PS, which is unreasonable. The inclusion of migration steps other than to nearest neighbors, as in the LAF model, yields an energy migration parameter which is lower and thus more realistic. The same trend holds for P2VN, although the GF parameters are less meaningful because of the breakdown of that model.

The ring fraction of EFS in pure P2VN, given by the LAF model, is 0.072 for the Förster value of E = 51. This is rather small, considering that q = 0.33 for PS, but seems plausible, given the lower symmetry of the naphthyl pair. The difference in the EFS fraction between PS and P2VN is lower for isolated polymer chains, as shown in Table 3. The values of q_{intra} have been determined for PS (3) and P2VN (1) assuming an atactic (45% *meso*) polymer. It would be useful to examine the photophysics of isotactic samples of PS and P2VN in the pure state,

[2] J. W. Thomas and C. W. Frank, unpublished results.

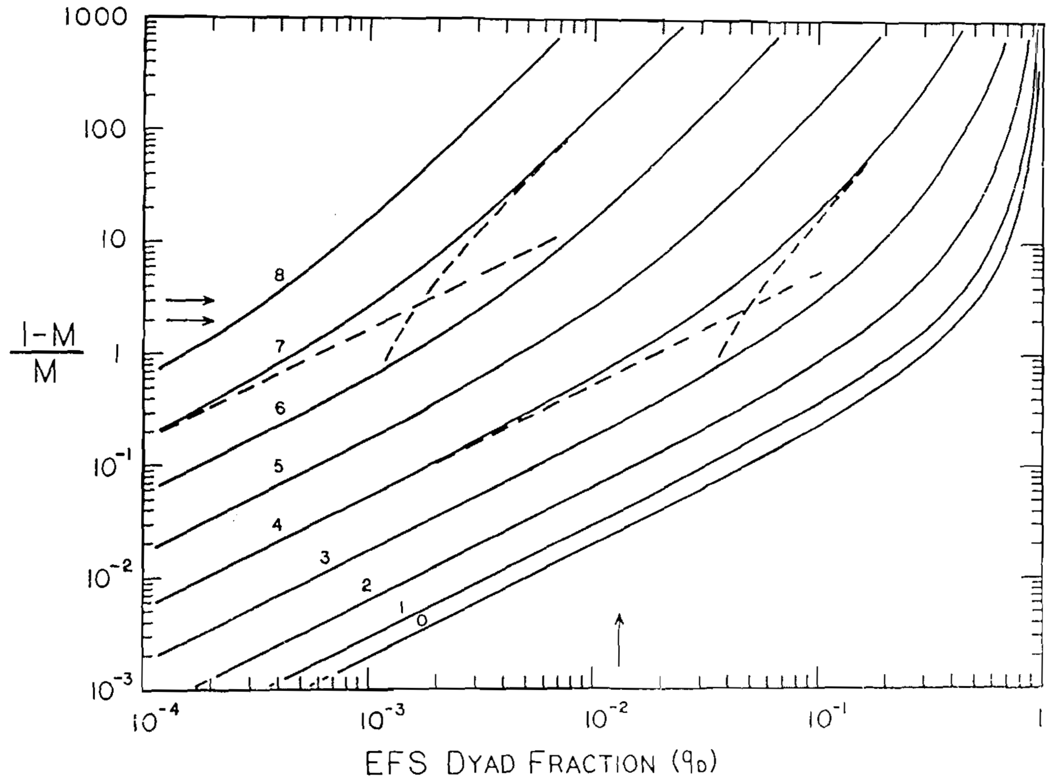

FIG. 1. Relationship between the dyad fraction of traps, q_d, and the probability ratio $(1 - M)/M$ for photons absorbed on an infinite one-dimensional lattice. The relative energy migration rates $E = W\tau$ for the solid curves numbered 0 to 8 are E = 0, 0.7, 7, 70, 700, 7 000, 70 000, 700 000, and 7 000 000, respectively. The dashed curves are the asymptotes given by eqs. [21] and [22] for curves 4 and 7. The vertical arrow indicates the value $q_D = 0.013$, while the horizontal arrows indicate values of the ratio $(1 - M)/M$ = 2 and 3.

to see whether the number of EFS traps would change. Also, the effect of low molecular weights on the fluorescence of pure films would provide an interesting study, if the foreign end groups which can cause spurious fluorescence could be removed.

B. *One-dimensional energy migration in dilute miscible blends*

The statistical model for strictly one-dimensional migration on an isolated polymer chain employed in this and previous (2, 3) studies is based on the original analysis for an infinite lattice by Levinson (11). If the EFS traps are completely effective in removing the captured photons, each sequence of nontrap sites can be analyzed without regard to the neighboring sequences. The probability M that an absorbed photon ultimately decays from the nontrap sites was computed (2) by averaging the value of M for each sequence length over the distribution of nontrap sequence lengths. As a result, Levinson's analysis was extended to the one-dimensional lattice of finite extent, and the fact that excimer-forming sites acting as traps consist of two adjacent trapping chromophores was taken into account.

The probability of ultimate monomer decay, M, of an infinite molecular weight aryl vinyl polymer is given by (2, 11).

$$[19] \quad M = 1 - q_D - \frac{q_D^2}{\tanh(\Gamma)} \sum_{x=1}^{\infty} (1 - q_D)^x \tanh(\Gamma x)$$

where

$$[20] \quad \Gamma = 0.5 \ln \left[\frac{1 + 2E + (1 + 4E)^{1/2}}{2E}\right]$$

In eq. [20], $E = W\tau$ and q_D is the dyad fraction of EFS. While eq. [19] must generally be evaluated numerically, there are two analytical expressions (11) in the limit when $E \gg 1$ and, hence $\Gamma \approx 0.5\, E^{-1/2}$. The first case, $q_D \ll \Gamma$, yields

$$[21] \quad M \approx 1 - 2q_D(E^{1/2} + 1)$$

while the second case, $q_D \gg \Gamma$, yields

$$[22] \quad M \approx \frac{[1 + q_D]^2}{2q_D^2 E}$$

Equation [21] has also been obtained by Fredrickson and Frank (10).

Because the asymptotes fail for $(1/M - 1) = 0.3$ to 30, the quantity $(1/M - 1)$ has been numerically evaluated from eq. [19] and plotted as a function of q_D for various discrete values of E. The results are presented in log–log form in Fig. 1. The dashed lines illustrate the asymptotic expressions, eqs. [21] and [22], for $E = 700$ and 7×10^5.

In this work, we wish to evaluate W for P2VN in 0.3% P2VN/PS(2200) blends, which were earlier determined to be miscible (7, 8). While Q_D/Q_M and the instrument factor relating I_D/I_M to the quantum yield ratio Φ_D/Φ_M are known (1), only an upper bound of $q_D = 0.013$ has been estimated for the dyad fraction of EFS in P2VN (1). Moreover, only three P2VN samples having broad and poorly characterized molecular weight distributions were studied. Thus, we will deduce W by comparing the fluorescence ratio of the miscible P2VN(70 000) and P2VN(265 000) guests (7) with the infinite molecular weight limit given by eq. [19].

In order to obtain a value of E from Fig. 1, both q_D and $(1/M - 1)$ must be known for the infinite molecular weight polymer. The fluorescence intensity ratios of dilute miscible blends con-

TABLE 4. Energy migration parameter, E, calculated from the excimer-to-monomer fluorescence ratio, R, of 0.3% P2VN/PS (2200) blends and of a 5% PS/PVME(44 600) blend

P2VN Mol.Wt.	R^a	$\Phi_D/\Phi_M{}^b$	$1/M - 1$	E
70 000	0.895	1.07	2 ± 0.5^c	2400^d
265 000	1.42	1.70	3 ± 0.8^c	4500^d
PS(100 000)^e	0.9^e	0.85^e	2.1^e	660^e

[a] Ratio of fluorescence envelope intensities, I_{398}/I_{337}, measured under back face illumination and corrected for spectral overlap (7).

[b] Obtained from the overlap-corrected value of R after multiplying by the back face spectrometer instrumental calibration constant of 1.2.

[c] Given by $(\Phi_D/\Phi_M)/(Q_D/Q_M)$, where Q_D/Q_M is taken to be 0.55 $\pm$ 0.15 (1).

[d] Obtained from Fig. 1, given that $q_D = 0.013$.

[e] Data from ref. 3. See Note e in Table 1. Take $Q_D/Q_M = 0.4$ and $q_D = 0.026$.

taining P2VN of molecular weights 70 000 and 265 000 and the calculations that transform this ratio into $(1/M - 1)$ are collected in Table 4. If the excimer dyad fraction, q_D, is taken to be 0.013, the values of $E = 2400$ and 4500 may be interpolated from Fig. 1 for P2VN(70 000) and P2VN(265 000), respectively. Thus, W for P2VN is about 4×10^{10} to 8×10^{10} s^{-1}, if we choose a rate constant of $\tau^{-1} = 1.8 \pm 0.2 \times 10^7$ s^{-1} for the 2-naphthyl group (1). By comparison, the energy migration parameter for PS, evaluated as described in Table 4 from the fluorescence ratio of dilute PS/PVME blends (3), was $E = 660$ at 298 K. If τ^{-1} for PS is taken (12) to be 4.5×10^7 s^{-1}, then $W = 3 \times 10^{10}$ s^{-1} for PS.

The Förster dipole–dipole expression (13) was used earlier (1) to estimate E for PS and P2VN, based on average distances between chromophores of 6.11 Å for P2VN and 5.48 Å for PS. The results were $E = 51$ for P2VN and 2.7 for PS. Comparison of the Förster prediction with the one-dimensional random walk model leads to two observations. The most significant is the dramatic disagreement between the values for W for each polymer. For P2VN, the 1-D random walk model predicts migration rates from 47 (for P2VN(70 000)) to 88 (for P2VN(265 000)) times faster than the Förster expression. For PS, the predictions differ by a factor of 244. Secondly, we note that both the Förster model and the 1-D random walk model indicate that excitation migration in P2VN is much faster than in PS.

There are three problems which could explain why the Förster migration rates are lower than those derived by the 1-D random walk analysis. First, we note that the 1-D migration rate for P2VN is only 1/15th the rate of migration observed experimentally in crystalline naphthalene (14). In fact, the Förster mechanism is strictly dipole–dipole, whereas the dipole–dipole term is only one of a variety of short-range interactions (such as octupole–octupole (15)) that may come into play when the 2-naphthyl chromophores are only 5 or 6 Å apart. Second, the occurrence of "cross-loop" migration steps would increase the efficiency of sampling the EFS traps. The apparent migration rate derived from the 1-D model would thus be too high. Finally, the PS or P2VN chains in the dilute blends may not be isolated, despite the fact that these blends have been determined to be miscible.

An improved model of energy migration in "quasi-one-dimensional" systems has not yet appeared. There are analytical techniques for treating excitation transport and trapping on polymer chains that contain a small concentration or randomly distributed chromophores along the chain contour (16–19). It is hoped that such techniques can eventually be extended to cover the dilute aryl vinyl polymer blends in this study.

Studies of the photocyclization of α-(*o*-tolyl)acetophenone dissolved in crosslinked ethylene – vinyl acetate beads show that quantum yields close to unity can be achieved, even in the solid polymer matrix. In preliminary experiments using solar radiation it was demonstrated that the rates of photochemical transformations are close to those calculated from the photon energy distribution of the solar spectrum.

J. E. GUILLET, W. K. MACINNIS et A. E. REDPATH. Can. J. Chem. **63**, 1333 (1985).

Des études sur la photocyclisation de l'α-(*o*-tolyl)acétophénone dissoute dans des billes d'un polymère réticulé d'éthylène et d'acétate de vinyle ont permis de montrer que l'on peut obtenir des rendements quantiques qui s'approchent de l'unité, même dans la matrice solide d'un polymère. Dans des expériences préliminaires faisant appel à la radiation solaire, on a pu démontrer que les vitesses des transformations photochimiques se rapprochent de celles que l'on peut calculer en utilisant la distribution des énergies des photons du spectre solaire.

Introduction

The study of organic photochemistry has been an active field of research for many years. As a result of this work there is a wide variety of synthetic photochemical routes to the synthesis of novel organic compounds and intermediates. Surprisingly, very few applications of these synthetic routes have reached commercial practice, probably because of the high cost of using electrically driven lamps to provide the necessary photon energy. For a number of years, we have been interested in exploring the possible use of polymeric devices which could utilize natural sunlight to carry out photochemical processes in a manner which could be easily expanded to large-scale commercial production. In this paper we report a method of carrying out photochemical reactions in small crosslinked polymer beads. The beads can be supported on water which provides both a self-levelling support and a means of transporting the beads from the exposure area to a collection device.

The sun as a photochemical light source

In principle, the sun is an excellent source of photon energy for initiating the synthesis of organic compounds. An obvious example of this is the relatively high efficiency of plant photosynthesis and the myriad of biochemical reactions which flow from it. However, sunlight is much less intense, in certain photon ranges, than electrically driven lamps and so exposure must usually be carried out over much larger areas. Figure 1 shows the distribution of solar photon energy at the earth's surface for air mass 1, i.e., with the sun directly overhead at sea level. This distribution is slightly affected by both air mass and latitude, but can be considered to be relatively independent of geographic location to a first approximation. However, seasonal variations in intensity do occur because of latitude and cloud cover. The total daily energy ranges from about 110 W/m^2 in southern Sweden to about 300 W/m^2 in arid equatorial zones. Thus the energy input on a 1-hectare area (10^4 m^2) ranges from 26 400 to 72 000 kW h/day. As shown in Fig. 1 the photon flux remains relatively constant from about 450-nm to 850-nm wavelengths, but even below 450 nm a substantial number of photons is available (1). Using the data in Fig. 1, one can calculate the solar power available over different wavelength ranges. These are summarized in Table 1 along with the theoretical production of a 1-hectare solar chemical reactor. The latter data are calculated assuming that the product has a molecular weight of 400 and a quantum yield of unity. Even for short-wavelength uv, $\lambda < 300$ nm, theoretical yields of several metric tonnes a day are calculated. If visible light can be used (i.e., λ = 400–700), the yield might be as much as several hundred tonnes per day. Of course these calculations represent an upper maximum because of inefficiencies due to absorption and reflection losses as well as side reactions and other chemical causes of reduced efficiency. Nonetheless, the potential of

solar synthesis for producing large quantities of organic compounds is obvious, provided a suitable means of exposure and collection is possible.

Principles of reactor design

The most successful reactor design so far achieved is that of the leaf of a green plant. The photons are strongly absorbed by thin layers of organic pigments in a relatively thin flat membrane containing mechanical devices to assure access to the reagents, and removal or storage of the products. Leaves also contain photon-harvesting devices (antenna chlorophyll) which absorb photons and transfer the photon energy to active sites where the photochemical energy conversion process takes place. In recent studies in our laboratories we have shown how to construct polymeric macromolecules which can mimic this essential feature of plant photosynthesis (2–4). These antenna polymers have the property of being able to collect photon energy by absorption in chromophores attached to a polymer chain. This energy is transferred by one or more energy-transfer steps to a trap at the middle or end of the chain where photochemical reactions can be induced to take place. The "antenna effect" is believed to be required for processes involving multiphoton reactions but may not contribute to the efficiency of simple one-step single-photon photochemistry.

In a previous paper (5) we have described the initiation of photochemical reactions in crosslinked plastic beads or platelets which are floated on water for exposure to sunlight. The design was to imitate the highly efficient photochemical collection system of the aquatic plant *Lemna minor* (duckweed). In the early work we showed that a variety of photochemical reactions, including the Norrish type I and type II processes in aliphatic ketones, and the addition of singlet oxygen to olefins could be carried out in these polymeric devices. In this paper we wish to report studies on a model photochemical reaction which can be used to illustrate the potential for commercial synthesis.

Recently, Meador and Wagner (6) have reported that α-(*o*-tolyl)acetophenone undergoes a photocyclization reaction via the intramolecular abstraction of the γ-hydrogen, eq. [1],

[1] 
with a quantum yield close to unity. The ketone absorbs available solar energy in the 280–360 nm region but the product 2-phenyl-2-indanol is transparent above 280 nm, as shown in Fig. 2. This is of particular value because the reaction can be run to a high degree of conversion with no interference by light absorption by the product. This then represents an ideal actinometer system to study potential yields of solar photochemical processes in this wavelength region.

Experimental

α-(*o*-Tolyl)acetophenone was synthesized by the procedure described in a previous publication (5). Analytical determinations were made in early runs by gas chromatography using a flame ionization detector and a 5% Carbowax 1540 on a Chromosorb WHP 80–110 column at 212°C. Later analytical data were obtained by hplc using a μ Porosil column with chloroform/hexane/ethyl acetate 70:30:2 solvent system and a 254-nm uv detector. The system was calibrated in both cases with known amounts of the pure components, using 9-fluorene methanol as an internal standard for the gc work and benzyl alcohol as the internal standard for hplc. The bead reactors were prepared by crosslinking a commercially available ethylene – vinyl acetate copolymer (Elvax 150N) which contains about 20% vinyl acetate. The beads were sealed in a glass jar under nitrogen and exposed in an AECL Gammacel 220 to 60 Mrad of γ-radiation from ^{60}Co. Before use the beads were extracted for 16 h with diethyl ether, thus removing all uncrosslinked polymer. They were then dried in the air at 35°C.

For calibration purposes the exposure of the beads was compared with exposures in solution in the absence of air. The bead samples were prepared as follows. The starting material (100 mg) was dissolved in ether and loaded onto 2 g of crosslinked EVA beads. The beads swell in a few minutes with the ether solution, after which they are dried in air to remove the ether. They were then placed in a single layer in quartz tubes which were flushed with nitrogen. In a control experiment, a solution of 150 mg of α-(*o*-tolyl)acetophenone was dissolved in 15 mL of ethyl acetate. The samples were exposed in similar quartz tubes under nitrogen.

During exposure to solar uv radiation the intensity was monitored as hourly integrated totals using a detector (Optical Associates Inc., Santa Clara, Calif.) with a peak sensitivity at 313 nm. The band-pass of the filter was ca. 40 nm. Bead samples and solution aliquots were removed periodically for work-up. The ethyl acetate solution was analyzed as received; the beads were extracted three times with ether (3 × 20 mL) to remove the product. (In an earlier experiment, gc analysis indicated that a mass balance of 90% was achieved by one extraction of the beads with solvent.) Each sample was analyzed by hplc to determine product yields and by uv to monitor changes in the absorbance spectrum.

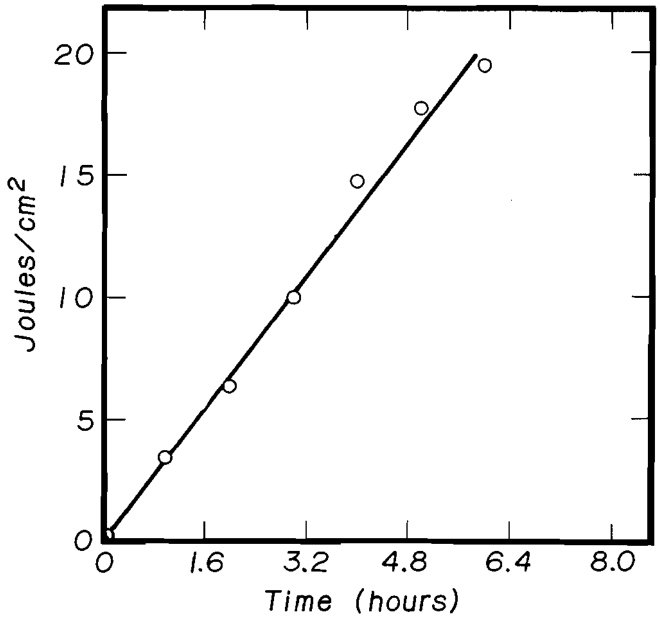

FIG. 3. Integrated exposure (OAI actinometer) vs. time.

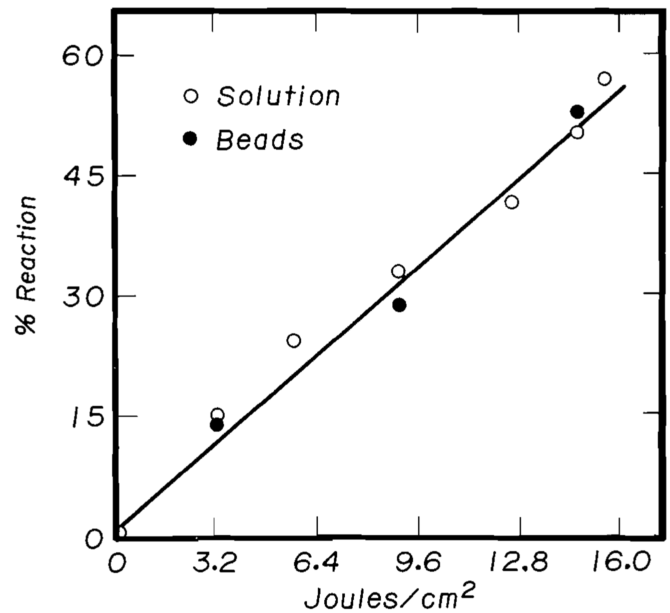

FIG. 5. Percent reaction vs. exposure (corrected).

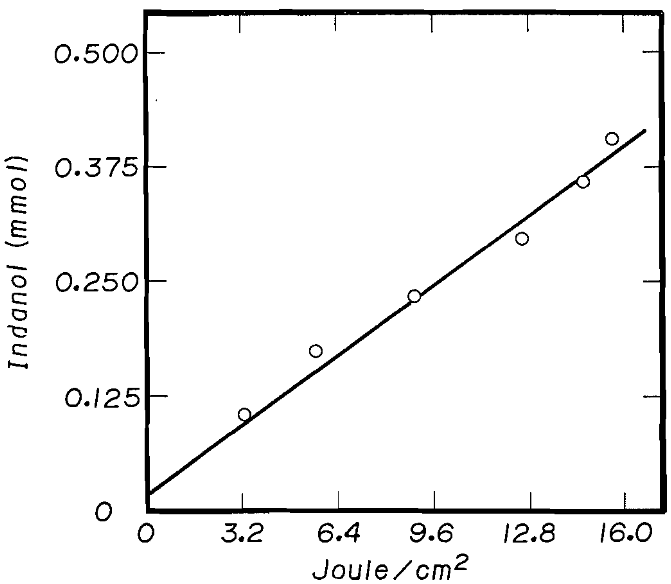

FIG. 4. Millimoles of product vs. corrected exposure (reaction in solution).

Results

Figure 3 shows the solar intensity as a function of time for exposure for daylight hours in the middle of May 1984 in Toronto. Exposures were initiated at 10:00 and terminated at 17:00 hours. An approximately linear relationship exists between intensity at 313 nm and exposure time in hours over most of the time period. These data form the basis of our calculation of the rate of conversion of the α-(*o*-tolyl)acetophenone as a function of photon exposure, as shown in Fig. 4 for reactions in ethyl acetate solution. However, the uv spectra of the product solutions showed evidence not only for the disappearance of the α-(*o*-tolyl)acetophenone starting material, but also for the appearance of a uv absorbing by-product. In our earlier work this problem was considered and attributed to 2-phenylindene formation. Although gc and hplc analyses show this by-product to be present in very small quantities, its uv absorbance in the 280–360 nm region is not negligible. This has the effect of reducing the photon flux available to the ketone. Since the hplc analysis permits us to calculate the amount of ketone present in any solution, and thus the uv absorbance due to the ketone, the absorbance due to the by-product could be estimated. The ratio of these absorbance values was used to correct the incident photon flux over each successive sample interval. This correction factor increased over time to a maximum of 25–30% at the longest times of the experiment. Figure 5 shows the percent conversion in solution and in the beads as a function of photon energy absorbed, corrected as described above for both bead and solution experiments. the results are essentially identical.

From these data, the apparent quantum yield can be estimated if the actual exposure areas are known. This is most readily done for the solution experiments from which we calculate a quantum yield of close to unity (and, as shown in Fig. 5, similarly so in the beads), in good agreement with the literature value (6).

The data in Fig. 5 also lead to the conclusion that the production rates estimated in Table 1 can indeed be approached in a practical photochemical reaction. In these exposures 0.05 mmol of product were made in one day with beads covering 2 cm^2. Thus for a 1-hectare reactor area, 10^8 cm^2, we should obtain 2.5×10^3 mol or 525 kg of product. This amounts to about 0.5 metric tonnes per day, which is lower than, but of the same order of magnitude as, the values listed in Table 1 for reactions sensitized by uv light, $\lambda < 350$ nm, once correction is made for our lower light intensity and the lower molecular weight of our product.

Conclusions

From these experiments we conclude that the higher internal viscosity of the crosslinked plastic beads does not interfere with the photochemical efficiency of intramolecular photocyclization reactions of the type described here, and that the bead reactors may well be useful for carrying out a variety of photochemical reactions by means of solar radiation.

Cet article est dédié à la mémoire de Monsieur Li Xiao-Bai

SYLVIANE BOIVIN, PATRICK HEMERY et SYLVIE BOILEAU. Can. J. Chem. **63**, 1337 (1985).

La polymérisation radicalaire du chloroformiate de vinyle a été étudiée dans le chlorure de méthylène à 35°C, avec le peroxydicarbonate de dicyclohexyle comme amorceur. Des mesures cinétiques ont été effectuées par dilatométrie dans des appareils entièrement scellés sous vide poussé. L'ordre de la réaction de polymérisation par rapport à la concentration en monomère est égal à 1 et celui relatif à la concentration en amorceur est égal à 0,5.

Par ailleurs, des polymères nouveaux ont été préparés soit par polymérisation radicalaire de monomères dérivés du chloroformiate de vinyle, soit par modification chimique du polychloroformiate de vinyle par des amines, des alcools, des thiols, des acides carboxyliques, KCN . . . , par catalyse par transfert de phase. La structure de ces polymères ainsi que leur comportement thermique ont été examinés.

SYLVIANE BOIVIN, PATRICK HEMERY, and SYLVIE BOILEAU. Can. J. Chem. **63**, 1337 (1985).

The free-radical polymerization of vinyl chloroformate has been studied in methylene chloride at 35°C using dicyclohexyl peroxydicarbonate as initiator. Kinetic measurements performed by dilatometry under high vacuum have shown that the reaction order in monomer is equal to one whereas that in catalyst is equal to 0.5.

New polymers have been prepared either by free-radical polymerization of monomers derived from vinyl chloroformate or by chemical modification of poly(vinyl chloroformate) with amines, alcohols, thiols, carboxylic acids, KCN . . . using phase transfer catalysis. The structure of these polymers as well as their thermal behaviour have been studied.

Introduction

L'intérêt croissant suscité par le chloroformiate de vinyle (CH_2=CHOCOCl : VOCCl) provient du fait qu'il sert de matière première pour la préparation de nombreux médicaments ainsi que pour la synthèse de monomères vinyliques variés. Toutefois, la polymérisation du chloroformiate de vinyle (1) et de certains de ses dérivés – carbamates vinyliques (1–3), carbonates vinyliques (1, 4) et cyanoformiate de vinyle (1) – a été très peu étudiée jusqu'à ces dernières années, en raison des difficultés de préparation et de purification de ce monomère.

Un nouveau procédé de synthèse de chloroformiate de vinyle quasiment exempt d'impuretés, avec un rendement de 80% a été mis au point récemment (5). Ceci nous a incités à examiner en détail la polymérisation de ce monomère (6–8) et de quelques dérivés (6, 8, 9) ainsi que la modification chimique du polychloroformiate de vinyle (6, 10–12).

L'emploi de peroxydicarbonates comme amorceurs de la polymérisation radicalaire du chloroformiate de vinyle, en masse et en solution, conduit à des polymères de masses molaires élevées (7, 8). Les résultats de l'étude cinétique effectuée dans le chlorure de méthylène à 35°C, en présence de peroxydicarbonate de dicyclohexyle, sont exposés dans le présent article.

Par ailleurs, de nouveaux polymères ont été préparés soit par polymérisation radicalaire de monomères dérivés du chloroformiate de vinyle, soit par modification chimique du PVOCCl par des amines, des alcools, des phénols, des thiols, des acides carboxyliques et leurs sels alcalins, KCN ... en utilisant la catalyse par transfert de phase. Les résultats récents obtenus dans ce domaine sont mentionnés dans cet article.

Partie expérimentale

La pureté du VOCCl (Société Nationale des Poudres et Explosifs) est généralement supérieure à 99%. Ce monomère est introduit dans un ballon scellé sous vide poussé; il est conservé dans des tubes gradués munis de joints fragiles, à −35°C, à l'obscurité. Il est débarrassé de son stabilisant juste avant emploi.

Les carbamates vinyliques tels que le carbamate de vinyle et de *N*-diéthyle ($VOCNEt_2$ où VOC: CH_2=CH—O—C(O)—) et le carbamate de vinyle et de *N*-pipéridine ($VOCNC_5H_{10}$) sont obtenus par réaction du VOCCl avec la triéthylamine et la *N*-éthylpipéridine respectivement, selon le procédé général de déalkylation des amines tertiaires développé par Schnur et Olofson *et al.* (13–15). Les autres carbamates vinyliques comme le carbamate de vinyle et de n-butyle (VOCNHBu) et le carbamate de vinyle et de *N*-méthyl cyclohexyle ($VOCN(CH_3)C_6H_{11}$) sont préparés par réaction du VOCCl avec les amines correspondantes en présence d'un capteur d'acide chlorhydrique (8, 13).

La réaction du VOCCl avec le phénol et le menthol en présence de soude ou de pyridine conduit aux carbonates vinyliques correspondants (VOCOPh, VOCOMenthyle) (8, 13). Le thiocarbonate de vinyle et de phényle (VOCSPh) est préparé selon une méthode déjà décrite (16).

Le chlorure de méthylène est purifié sur P_2O_5 puis sur des miroirs de sodium successifs, selon la méthode mise au point au laboratoire (17). L'azobisisobutyronitrile (AIBN) et le peroxydicarbonate de dicyclohexyle (DCPD) sont séchés sous vide avant emploi.

La plupart des polymérisations sont effectuées dans des appareils en verre entièrement scellés sous vide poussé, selon la technique utilisée pour les polymérisations anioniques (18). Le monomère (VOCCl) est condensé dans un tube annexe afin d'éliminer l'inhibiteur, avant d'être introduit par distillation sur paroi froide, ainsi que le solvant, dans un ballon contenant l'amorceur. Les polymérisations des dérivés du VOCCl sont effectuées sous azote, dans des appareils reliés à une ligne à vide. Le monomère est introduit avec une seringue à travers un bouchon de caoutchouc à jupe rabattable, dans un ballon contenant le catalyseur qui est séché sous vide au préalable. Dans tous les cas, l'agitation du milieu est assurée par un barreau aimanté enrobé de verre, à une température donnée. Les polymères sont récupérés après dissolution dans le chlorure de méthylène et précipitation dans l'éther de pétrole. Ils sont ensuite séchés sous vide poussé.

Nous avons utilisé une méthode dilatométrique comme moyen d'étude cinétique selon la technique expérimentale mise au point au laboratoire (19). Les masses spécifiques du monomère (VOCCl) et du

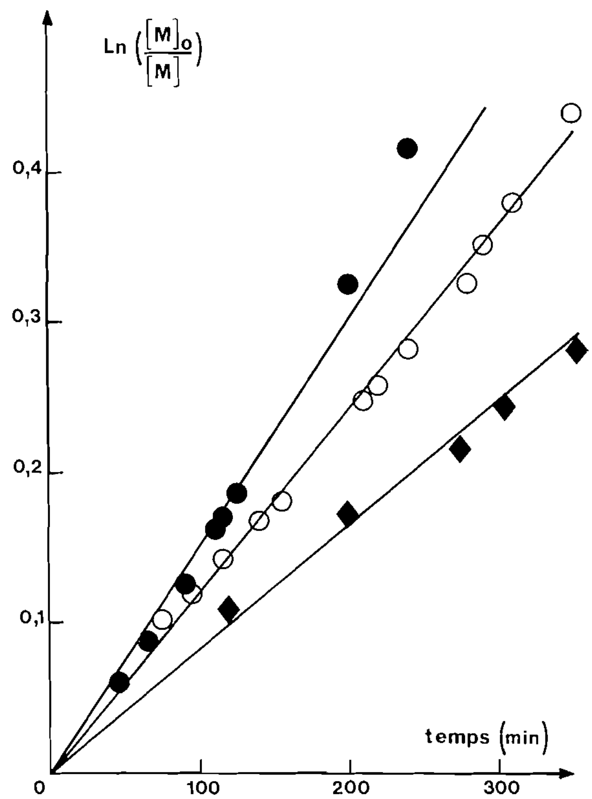

FIG. 1. Variations de ln $[M]_0/[M]$ en fonction du temps lors de la polymérisation radicalaire du VOCCl amorcée par le DCPD dans CH_2Cl_2 à 35°C: ● $[M]_0 = 1{,}98$ mol L^{-1}, $[A] = 9{,}98 \times 10^{-3}$ mol L^{-1}; ○ $[M]_0 = 1{,}98$ mol L^{-1}, $[A] = 7{,}15 \times 10^{-3}$ mol L^{-1}; ◆ $[M]_0 = 1{,}98$ mol L^{-1}, $[A] = 3{,}99 \times 10^{-3}$ mol L^{-1}.

polymère en solution dans CH_2Cl_2 à 35°C ont été mesurées avec un densimètre électronique à tube vibrant (PAAR DMA 45).

La technique de modification chimique du PVOCCl a été décrite précédemment (10). Les substituants sont des produits commerciaux utilisés sans purification spéciale à l'exception des amines qui sont redistillées avant emploi. Les catalyseurs: dicyclohexyl-18 couronne-6 (DCHE); sulfate acide de tétrabutylammonium (TBAH); Kryptofix [222] sont des produits commerciaux séchés sous vide poussé. Le degré de substitution est déterminé d'après l'analyse élémentaire des polymères modifiés. Ceux-ci sont conservés à −30°C dans des tubes scellés sous vide poussé.

Les polymères sont examinés par spectrophotométrie ir et par rmn du carbone 13. Dans ce dernier cas, les spectres de solutions de polymères dans un mélange 90:10 de trichloro-1,2,4 benzène et de nitrobenzène deutérié sont enregistrés à 100°C sur un appareil Brucker WP 250 à 62,5 MHz. Les masses molaires moyennes en nombre des polymères sont mesurées par osmométrie dans le toluène à 37°C. Les températures de transition vitreuse sont déterminées grâce à un analyseur thermique du Pont 1090 et la stabilité thermique des polymères est examinée par thermogravimétrie en chauffant les échantillons de 20 à 700°C à 5°C/min à l'air (9).

Résultats et discussion

1. *Polymérisation du chloroformiate de vinyle*

Nous avons montré que la polymérisation radicalaire du chloroformiate de vinyle donne des polymères de masses molaires élevées, avec des rendements quantitatifs (7, 8). Les meilleurs systèmes catalytiques sont les peroxydicarbonates, en solution dans le chlorure de méthylène, car ils permettent d'opérer à des températures n'excédant pas 40°C. Dans ces conditions, on n'observe pas de dégradation des polymères.

Nous avons donc effectué une étude cinétique de la polymérisation du VOCCl amorcée par le peroxydicarbonate de dicyclohexyle, dans CH_2Cl_2 à 35°C. Nous avons utilisé une technique dilatométrique et nous avons effectué toutes les mesures à partir d'un même lot de monomère afin d'avoir des résultats reproductibles.

Le facteur de contraction α correspondant à la variation de volume spécifique lorsqu'on passe du monomère au polymère a été déterminé par deux méthodes. La première consiste à conduire une réaction de polymérisation, dans un dilatomètre, jusqu'à conversion totale. La mesure des différences de niveau dans le capillaire, entre le début et la fin de la réaction, permet de calculer α. La deuxième technique consiste à mesurer les masses spécifiques du monomère, m_{35} (VOCCl), et du polymère, m_{35}(PVOCCl), dans CH_2Cl_2 à 35°C. Le facteur de contraction, α_{35}, est calculé d'après la relation:

$$[1] \quad \alpha_{35} = \frac{1}{m_{35}(\text{VOCCl})} - \frac{1}{m_{35}(\text{PVOCCl})}$$

On obtient ainsi $\alpha_{35} = 0{,}229$ mL g^{-1} pour des concentrations en monomère et en polymère ($\overline{M}_n = 18\,500$) égales à 1,96 mol L^{-1}. Cette valeur est en excellent accord avec celles déterminées lors de deux expériences dilatométriques (essais 3 et 7 du tableau 1): $\alpha = 0{,}23$ mL g^{-1}.

Les résultats cinétiques sont indiqués dans le tableau 1. Sur la fig. 1, nous avons porté les variations de ln$[M]_0/[M]$ en fonction du temps, où $[M]_0$ et $[M]$ sont les concentrations en monomère respectivement au temps zéro et à l'instant *t*, pour les essais 1, 3 et 7. On obtient des droites passant par l'origine jusqu'à des taux de conversion de 30 à 50%, ce qui montre que l'ordre interne de la réaction de polymérisation par rapport à la concentration en monomère est égal à 1. Les pentes de ces droites sont égales à $V_p/[M]$.

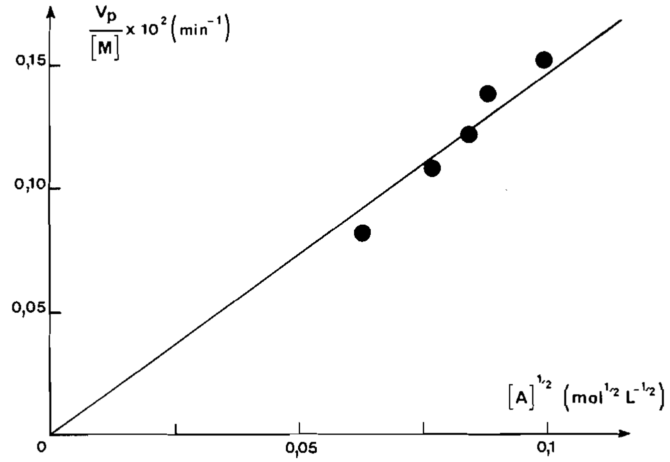

FIG. 2. Variations de $V_p/[M]$ en fonction de $[A]^{1/2}$ lors de la polymérisation radicalaire du VOCCl amorcée par le DCPD dans CH_2Cl_2 à 35°C.

Si l'on admet que l'hypothèse de l'état stationnaire est vérifiée pour ce système, la vitesse de polymérisation V_p est donnée par la relation suivante:

$$[2] \quad V_p = -\frac{d[M]}{dt} = k_p\left(f\frac{k_d}{k_t}[A]\right)^{1/2}[M]$$

où [M] et [A] sont les concentrations en monomère et en amorceur; k_p, k_d et k_t sont respectivement les constantes de propagation, de dissociation de l'amorceur et de terminaison et où f représente l'efficacité de l'amorceur.

Nous avons vérifié que la vitesse de polymérisation est proportionnelle à [M] et à $[A]^{1/2}$ car on observe bien des relations linéaires entre $V_p/[M]$ et $[A]^{1/2}$ d'une part et entre $V_p/[A]^{1/2}$ et [M] d'autre part, ainsi qu'en témoignent les figures 2 et 3. La valeur de la constante apparente de vitesse

$$k_{app} = \frac{V_p}{[M][A]^{1/2}}$$

est égale à $1{,}4 \times 10^{-2} \pm 0{,}1 \times 10^{-2}\ L^{1/2}\ mol^{-1/2}\ min^{-1}$.

2. *Polymères dérivés du polychloroformiate de vinyle*

Deux voies d'accès aux polymères dérivés du PVOCCl ont été examinées: d'une part, la polymérisation radicalaire de composés provenant du VOCCl et d'autre part, la modification chimique du PVOCCl par des substituants appropriés.

Le tableau 2 rassemble les résultats les plus significatifs de la polymérisation radicalaire, en masse, de quelques dérivés du chloroformiate de vinyle tels que des carbonates, thiocarbonates et carbamates vinyliques. On obtient des polymères de masses molaires élevées avec de bons rendements. Les résultats sont améliorés lorsqu'on opère dans des conditions rigoureuses de pureté (essais 15 et 16).

La modification chimique du PVOCCl par des amines et des alcools a été décrite par Schaefgen (1). Cependant, cet auteur a généralement observé des réactions secondaires d'hydrolyse conduisant à des polymères réticulés dont le degré de substitution ne dépasse pas 30%. Nous avons mis au point des conditions opératoires qui permettent d'éviter les réactions de dégradation (6, 10–12). Les polymères ainsi modifiés sont solubles et les degrés de substitution sont excellents. Les rendements en polymères solubles sont de l'ordre de 80%. Les résultats concernant la modification chimique du PVOCCl par les amines, les alcools, thiols et phénols, les acides carboxyliques et les sels alcalins (carboxylates et cyanures) sont rassemblés dans les tableaux 3 à 7.

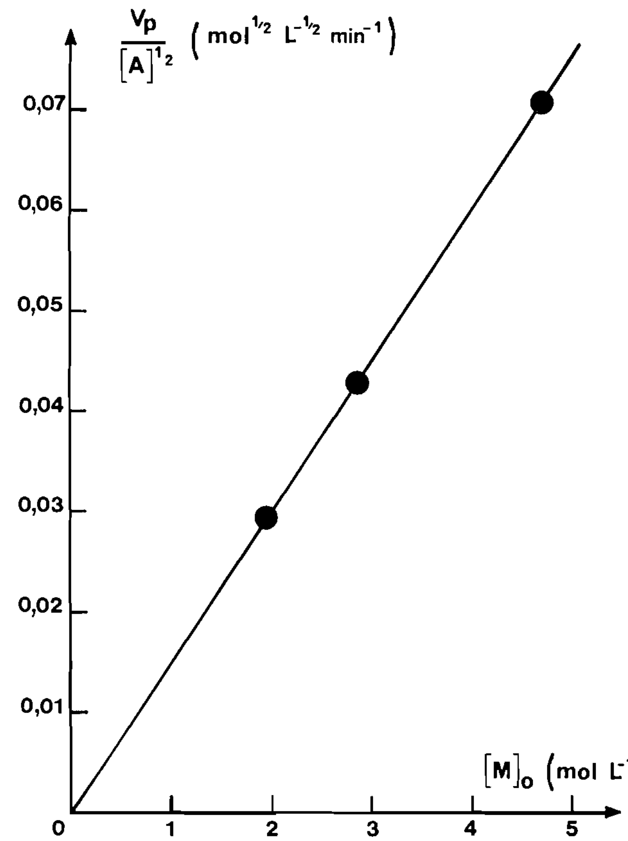

FIG. 3. Variations de $V_p/[A]^{1/2}$ en fonction de $[M]_0$ lors de la polymérisation radicalaire du VOCCl amorcée par le DCPD dans CH_2Cl_2 à 35°C.

Les amines aliphatiques conduisent à des degrés de substitution voisins de 100% (essais 17 à 24, tableau 3) selon un mécanisme faisant intervenir une attaque nucléophile du carbonyle par ces amines. Parmi les différents capteurs d'acide chlorhydrique utilisés, c'est la soude à 50% qui est le plus efficace comme le montrent les essais 18 et 19 effectués avec la *N*-méthylbenzylamine. Les amines primaires réagissent aussi bien que les amines secondaires. De plus, dans le cas de l'éthyléthanolamine (essai 23), la réaction s'effectue de façon sélective par l'intermédiaire de la fonction amine ainsi qu'en témoigne le spectre ir du polymère modifié. Le faible caractère nucléophile présenté par les amines aromatiques telles que le carbazole ou le diméthyl-2,3 indole nécessite l'emploi de la catalyse par transfert de phase. Les essais 25 et 26 montrent qu'en absence d'un sel d'ammonium quaternaire, la réaction des groupements chloroformiate avec le carbazole n'a pas lieu alors qu'elle s'effectue avec 100% de rendement après 3 h à 20°C, en présence de SO_4HNBu_4.

Il n'est pas possible de mesurer directement les masses molaires des échantillons de PVOCCl, par osmométrie ou par gpc, en raison de la grande réactivité des fonctions chloroformiate. Elles ont donc été déterminées indirectement à partir des masses molaires des polymères modifiés, en tenant compte du degré de substitution. Quelques résultats significatifs obtenus avec trois lots différents de PVOCCl sont rassemblés dans le tableau 4. On observe un excellent accord entre les valeurs de $\overline{M}_n$ pour un même échantillon de PVOCCl quelle que soit la nature du substituant (essais 29 et 20; essais 31, 22 et 32) et

quelles que soient les conditions opératoires pour un substituant donné (essais 30 et 19). En particulier, on peut conclure que la modification chimique du PVOCCl en solution dans CH_2Cl_2, en présence de NaOH 50% et d'un catalyseur de transfert de phase (essai 32) ne provoque pas de dégradation du polymère avec un substituant comme le phénol.

Les résultats de la modification chimique du PVOCCl par des alcools, des phénols et un thiol sont rassemblés dans le tableau 5. Les phénols et les alcools sont moins réactifs que les amines aliphatiques vis-à-vis des chloroformiates (20). La catalyse par transfert de phase donne d'excellents résultats en ce qui concerne le phénol et la mercapto-2 pyrimidine (essais 32 et 38). D'une façon générale, il faut noter que, contrairement à certains résultats publiés récemment (21), les conditions opé-

ratoires que nous avons utilisées conduisent à l'obtention de polymères solubles possédant des degrés de substitution élevés.

La catalyse par transfert de phase constitue une excellente méthode pour modifier le PVOCCl par les acides carboxyliques ainsi qu'en témoignent les résultats du tableau 6 (essais 41, 42, 44 et 45). On obtient des polymères solubles porteurs de fonctions anhydride mixte —OCOOCOR latérales (12). Ces polymères sont également préparés par réaction de carboxylates alcalins avec le PVOCCl au moyen de la catalyse par transfert de phase solide–liquide. Les résultats sont indiqués dans le tableau 7. En l'absence de catalyseur, on n'observe aucune réaction entre le benzoate de sodium et le PVOCCl dans le chlorure de méthylène même après 17 h à 20°C (essai 46). Par contre, on obtient des degrés de substitution voisins de 100% en présence d'un catalyseur de transfert de phase comme le sulfate acide de tétrabutylammonium (essai 48 et 49), un éther-couronne (essai 47) ou un cryptand (essai 50). La réaction avec le benzoate de tétraéthylammonium est extrêmement rapide (essai 51); ceci montre que l'intermédiaire réactionnel dans le cas des benzoates de sodium et de potassium, en présence de TBAH, est un carboxylate de tétraalkylammonium. Une étude cinétique détaillée de ce type de réaction est actuellement en cours.

Nous avons également fait figurer, dans le tableau 7, quelques résultats relatifs à la réaction de KCN avec le PVOCCl (8). Un sel d'ammonium quaternaire comme le TBAH est un catalyseur plus efficace qu'un éther-couronne, dans CH_2Cl_2 à 20°C (essais 52 et 53).

En conclusion, nous avons montré les avantages de la catalyse par transfert de phase lors de la modification chimique du

PVOCCl par des substituants variés. Cette méthode permet d'obtenir des polymères solubles possédant des degrés de substitution élevés, à la température ordinaire.

3. *Propriétés des dérivés du polychloroformiate de vinyle*

Les polymères obtenus soit à partir de dérivés du VOCCl, soit par modification chimique du PVOCCl ont été caractérisés par spectrophotométrie ir et par rmn du carbone 13. La bande d'absorption du groupe carbonyle est située à 1770 cm^{-1} pour le PVOCCl. Elle apparaît à 1690 cm^{-1} pour les polycarbamates vinyliques, à 1735 cm^{-1} pour le polycyanoformiate de vinyle,

TABLEAU 8. Déplacements chimiques des atomes de carbone de la chaîne principale et du groupe carbonyle de quelques dérivés du PVOCCl: $-[-CH_2-CH-(O-\overset{\displaystyle O}{\underset{\|}{C}}-R)-]_n-$ (ppm; réf.: HMDS; 100°C; $C_6H_3Cl_3/C_6D_5NO_2$ = 90: 10; 62,5 MHz; m: multiplet)

à 1730 cm^{-1} pour le polythiocarbonate de vinyle et de phényle et à 1750 cm^{-1} pour le polycarbonate de vinyle et de phényle. Les polymères porteurs de fonctions anhydride mixte présentent deux bandes d'absorption des groupements carbonyle situées vers 1810 et 1745 cm^{-1}. Ces bandes sont suffisamment distinctes de celle correspondant au PVOCCl si bien que l'on peut suivre la cinétique de la réaction de ce polymère avec les acides carboxyliques par spectrophotométrie ir.

Les déplacements chimiques des atomes de carbone de la chaîne principale et du groupement carbonyle sont indiqués dans le tableau 8, pour quelques polymères dérivés du PVOCCl. Dans tous les cas, on observe une stéréosensibilité des carbones de la chaîne principale. Les carbones méthyléniques sont sensibles à des effets de diades, de tétrades et parfois même d'hexades. On observe des effets de triades pour les carbones tertiaires. Les surfaces des trois pics correspondent approximativement au rapport 1:2:1. On peut en déduire que tous les polymères sont atactiques et qu'ils obéissent probablement à une statistique de Bernouilli comme attendu pour des échantillons préparés par polymérisation radicalaire. Pour quelques polymères, on observe une stéréosensibilité du carbone du groupement carbonyle. Il faut remarquer que ces polymères possèdent des valeurs de T_g plus élevées que les autres ce qui correspond à une moins grande mobilité des groupements latéraux (tableau 9).

Les températures de transition vitreuse et la stabilité

[b]Calculée à partir de la valeur de $\bar{M}_n$ du PVOCCl (34 000) car le polymère est insoluble dans le toluène.

thermique de quelques polymères ont été déterminées. Les résultats sont rassemblés dans le tableau 9. La stabilité thermique des polymères semble décroître légèrement selon l'ordre suivant: polycarbamates > polycarbonates > polythiocarbonates. Par ailleurs, les valeurs de T_g des polymères $-[-CH_2-CH-(O-\overset{\displaystyle O}{\underset{\|}{C}}-R-)-]_n-$ décroissent selon l'ordre suivant pour R: —O—Ph > —S—Ph > —$N(CH_3)$—Ph. Les légères différences observées parmi les valeurs de T_g des polycarbamates vinyliques peuvent être expliquées par la structure des groupements latéraux qui influence la mobilité de la chaîne principale (23).

En conclusion, nous avons déterminé les paramètres cinétiques de la polymérisation radicalaire du chloroformiate de vinyle amorcée par le peroxydicarbonate de dicyclohexyle, à 35°C dans CH_2Cl_2. Ceci nous a permis de préparer des échantillons de polychloroformiate de vinyle bien définis dont nous avons examiné la modification chimique. La catalyse par transfert de phase est une méthode de choix pour obtenir des polymères solubles possédant des degrés de substitution très élevés. Par ailleurs de nouveaux polymères ont été préparés par polymérisation radicalaire de monomères dérivés du chloroformiate de vinyle. Les capacités réactionnelles remarquables du chloroformiate vinylique ainsi que du polymère correspondant ou de ses copolymères ouvrent un champ d'investigations très vaste et permettent d'envisager des applications très variées.

Remerciements

Nous remercions la Société Nationale des Poudres et Explosifs pour son aide matérielle. Nous remercions également le Professeur R. Olofson et le Docteur G. Wooden pour la préparation de certains monomères, le Professeur H. Chéradame et Madame E. Rousset pour leur contribution à l'analyse des polymères par rmn du carbone 13 ainsi que Madame C. Noël pour son aide dans l'interprétation des thermogrammes.

Charge transfer electron–exciton complexes in single crystals[1]

CONSTANTINE MAVROYANNIS
Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6

Received March 8, 1984

This paper is dedicated to Professor Camille Sandorfy on the occasion of his 65th birthday

CONSTANTINE MAVROYANNIS. Can. J. Chem. **63**, 1345 (1985).

We have considered the excitation spectrum arising from the coherent electron–exciton pairing in crystals at low temperatures. For the pairing processes, three different types of excitons have been considered: Frenkel excitons (tightly bound), Wannier–Mott excitons (loosely bound), and excitons of the intermediate binding. Expressions for the gap functions and transition temperatures at which metal-to-nonmetal phase transitions occur have been derived and discussed for each type of pairing. In the electron pairing with the intermediate exciton, the dispersion relations which determine the exciton and the electron–exciton modes are solved numerically and the derived results are graphically presented. The physical picture for the electron–exciton coupled modes is analogous to that for polaritons and magnon–phonon modes in crystals.

CONSTANTINE MAVROYANNIS. Can. J. Chem. **63**, 1345 (1985).

Nous avons étudié les spectres d'excitation provenant de l'appariement cohérent électron–exciton dans des cristaux à basse température. Pour le processus d'appariement, nous avons considéré les trois types d'exciton suivants: les excitons de Frenkel (fortement liés), les excitons de Wannier–Mott (faiblement liés) et des excitons ayant des forces de liaisons intermédiaires. On a déduit des expressions pouvant représenter les fonctions d'intervalle et les températures de transition auxquelles les transitions de la phase métal à la phase non-métal se produisent et on en discute pour chaque type d'appariement. Dans le cas de l'appariement de l'électron avec l'exciton intermédiaire, on a résolu les relations de dispersion qui déterminent les modes de l'exciton et du couple électron–exciton d'une façon mathématique et on présente les résultats obtenus d'une façon graphique. La représentation physique des modes pour l'électron–exciton couplés est analogue à celle des modes des polaritons et du couple magnon–phonon dans les cristaux.

[Traduit par le journal]

I. Introduction

Considerable interest has been recently given to the existence of charged excitons in insulating and semiconducting crystals. A charged exciton is a quasiparticle consisting of a bound state of an exciton and either an electron in the conduction band or a hole in the valence band, which moves with definite energy and wave vector through the crystal (1–3). At the present time, experimental evidence for the existence of such conducting states is limited (4, 5) but these types of excitations may play an important role in the metal–insulator transitions at high excitation intensities (6). Theoretical calculations have been done so far when conduction electrons interact with Frenkel excitons (1, 2, 7, 8) and Wannier–Mott excitons (3), which are the appropriate collective excitations for molecular crystals and semiconductors, respectively. However, excitons with intermediate binding have also been found to exist in rare-gas solids (9, 10). We shall describe here our recent work (11) concerning the formation of a bound state consisting of an exciton of the intermediate binding and an electron which is excited into the conduction band. The derived results will be compared with those obtained when the pairing process takes place with a Frenkel exciton (1, 7, 8) and a Wannier–Mott exciton (3), respectively.

II. Intermediate exciton–electron pairing

We consider a simple model for the crystal consisting of N identical atoms on a rigid cubic lattice with one atom per unit cell and lattice spacing a_0. Each atom is assumed to have two nondegenerate levels corresponding to the valence and conduction bands and all effects due to electron spin are discarded. At $T = 0$ K, the valence band is full of electrons while the conduction band is empty. The exciton (electron–hole pair) under consideration is formed when an electron from the valence band is excited into the conduction band, leaving behind a hole in the valence band at the same lattice site. In addition, the usual band motions of electrons and holes from one lattice site to another without creating excitons are included. The Hamiltonian of such a system may be taken as (11–13)

$$[1] \quad H = \sum_{\langle ll'\rangle} T_\alpha(ll')\alpha_{l'}^{+}\alpha_l - \sum_{\langle ll'\rangle} T_\beta(ll')\beta_{l'}^{+}\beta_l + E_\alpha \sum_l \alpha_l^{+}\alpha_l - E_\beta \sum_l \beta_l^{+}\beta_l + u_0 \sum_l \beta_l^{+}\beta_l\alpha_l^{+}\alpha_l - \sum_{\langle ll'\rangle} u(ll')\beta_l^{+}\alpha_l\alpha_{l'}^{+}\beta_{l'} + \sum_{\langle ll'\rangle} v(ll')\alpha_l^{+}\alpha_l\beta_{l'}^{+}\beta_{l'}$$

where α_l^{+}, α_l are the creation and destruction operators for electrons at the lattice site $\boldsymbol{R}_l^0$ in the conduction band, and β_l^{+}, β_l are the corresponding operators for electrons in the valence band. E_α, E_β denote the on-site energy of the electron in the conduction and valence bands, respectively, and $\langle ll'\rangle$ denotes that the sum is to be done over nearest-neighbor pairs $\boldsymbol{R}_l^0$ and $\boldsymbol{R}_{l'}^0$. T_α and T_β are the hopping energies for electrons in the respective bands, u_0 is the on-site Coulomb interaction, and $u(ll')$, $v(ll')$ are the exchange and direct Coulomb interactions between electrons on neighboring lattices sites.

Let us introduce the exciton operator $b_l \equiv \beta_l^{+}\alpha_l$. For the two level system, we have $\beta_l^{+}\beta_l + \alpha_l^{+}\alpha_l = 1$. Using this and the usual anticommutation relations for the electron operators, we have $\beta_l^{+}\beta_l = b_l b_l^{+}$ and $\alpha_l^{+}\alpha_l = b_l^{+}b_l$. Making use of these results in eq. [1], we find that the exchange Coulomb term is quadratic in the exciton operators. We also find that the direct Coulomb term is quartic in (a) the exciton operators and (b) the exciton and electron operators. When written in the form (a), we find that the direct Coulomb term describes an exciton density interacting with an exciton density at a neighbouring lattice site. The form (b) describes an electron density interacting with an exciton density on a neighbouring lattice site.

[1]NRCC No. 23963.

The excitation energy of the conduction electron–exciton complex is obtained by making use of the Green function method. The two Green functions which we are going to evaluate are defined as $G(ll';t) = \langle\langle b_l(t);b_{l'}^+(0)\rangle\rangle$ and $F(ll';t) = \langle\langle \alpha_l(t);b_{l'}^+(0)\rangle\rangle$, where the operators are in the Heisenberg representation and use has been made of the notation, $\langle\langle A(t);B(0)\rangle\rangle = -i\theta(t)\,\langle[A(t),B(0)]_+\rangle$ for the operators A and B. The diamond brackets stand for an ensemble average. The properties of the Green functions can be found elsewhere (14).

Commuting the operators b_l and α_l in turn with the Hamiltonian in eq. [1] and then decoupling the resulting equations of motion, we find that the Green functions $G(ll';t)$ and $F(ll';t)$ are solutions of the two sets of coupled equations, whose Fourier transforms with respect to $(l - l')$ and the time, are given by ($\hbar = 1$)

$$[2] \quad G(k,\omega) = G^{\mathrm{HF}}(k,\omega) - G^{\mathrm{HF}}(k,\omega)\Delta(k)F(k,\omega)$$

$$[3] \quad [\omega - E_\alpha(k) - u_0 - v(k=0)]F(k,\omega) = -\Delta^*(k)G(k,\omega)$$

where

$$[4] \quad \Delta(k) = \frac{1}{N}\sum_{k'} v(k-k')\,\langle b_{k'}\alpha_k^+\rangle$$

$$[5] \quad G^{\mathrm{HF}}(k,\omega) = \frac{G_0(k,\omega)}{\epsilon_+(k,\omega)}$$

with the single-particle Green function given by

$$[6] \quad G_0(k,\omega) = \frac{1}{N}\sum_q \frac{1}{\omega - E_\beta^0 - E_\alpha(q-k) - E_\beta(q)}$$

and $\epsilon_+(k,\omega)$ is defined by

$$[7] \quad \epsilon_+(k,\omega) = 1 + [u(k)G_0(k,\omega) - v(k=0)G_0(k=0,\omega)]$$

$E_\alpha(k)$ and $E_\beta(k)$ are the energy bands (13) and we have chosen $E_\beta = E_\beta^0 + 6T_\beta$ and $E_\alpha = 6T_\alpha$ where $T_{\alpha,\beta}(ll') = -T_{\alpha,\beta}$ for nearest-neighbour lattice sites. $u(k)$ and $v(k)$ are the Fourier transforms for the nearest neighbour exchange and direct Coulomb interactions of strength u and v, respectively. In eqs. [2]–[7], $G^{\mathrm{HF}}(k,\omega)$ is the exciton–exciton Green function which is correct in the Hartree–Fock (HF) approximation, $G_0(k,\omega)$ is the noninteracting Green function (13) while $\Delta(k)$ is the coupling parameter describing the pairing of an exciton at the lattice site $\boldsymbol{R}_l$ with an electron, which is excited into the conduction band, at the nearest-neighbour lattice site $\boldsymbol{R}_{l'}$.

Solving eqs. [2] and [6], we obtain

$$[8] \quad G(k,\omega) = [\omega - E_\alpha(k) - u_0 - v(k=0)]\frac{G_0(k,\omega)}{D^{\mathrm{B}}(k,\omega)}$$

$$[9] \quad F(k,\omega) = -\Delta^*(k)\frac{G_0(k,\omega)}{D^{\mathrm{B}}(k,\omega)}$$

where

$$[10] \quad D^{\mathrm{B}}(k,\omega) = [\omega - E_\alpha(k) - u - v(k=0)]\epsilon_+(k,\omega) - |\Delta(k)|^2G_0(k,\omega)$$

Singularities of $G(k,\omega)$ and $F(k,\omega)$ are located at the solutions of $D^{\mathrm{B}}(k,\omega) = 0$. These correspond to the bound states of the electron–exciton complex, provided the roots of $D^{\mathrm{B}}(k,\omega) = 0$ are separated from the solution of the equation $\epsilon_+(k,\omega) = 0$ which determine the frequencies of the exciton band. They must also be different from $\omega = E_\alpha(k) + u_0 + v(k=0)$ which corresponds to the band energies of the conduction electron renormalized by the screened Coulomb interactions. Referring to eq. [10], we see that a finite value of $\Delta(k)$ may produce a bound state for the electron–exciton complex.

In the denominator of eq. [6], E_β^0 is the separation between the valence and conduction bands for zero wave vector and it also corresponds to the value of the lower bound of the electron-hold excitations for $k = 0$. For a stable electron–exciton complex, we therefore require that E_β^0 should satisfy the relation $E_\beta^0 > u_0 + 6v$. For a simple cubic lattice, since we have $\Delta(k) = [v(k)/6v]\Delta_0$, where $\Delta_0 = \Delta\ (k=0)$, it is straightforward to calculate the frequency of the (electron–exciton) mode in the long wavelength limit. In particular, the frequency of the mode for $k = 0$ is

$$[11] \quad \omega_0 = E_\beta^0 - 2x_0(T_\alpha + T_\beta)$$

where x_0 is the solution of the nonlinear equation

$$[12] \quad [E_\beta^0 - u_0 - 6v - 2x_0(T_\alpha + T_\beta)][3(u-v)J(x_0) - (T_\alpha + T_\beta)] = \tfrac{1}{2}\Delta_0^2 J(x_0)$$

Here, $J(x_0)$ is a one-dimensional integral:

$$[13] \quad J(x_0) = \int_0^\infty \mathrm{d}s\,[\exp(-s(3+x_0))]I_0^3(S)$$

where $I_0(S)$ is the modified Bessel function of the first kind, of order zero.

We have evaluated $D^{\mathrm{D}}(k,\omega)$ numerically, assuming for simplicity that the coupling parameter $\Delta(k)$ is a constant Δ. We have chosen the bandwidth of the conduction band ($12T_\alpha$) and that of the valence band ($12T_\beta$) to be 0.6 eV. The nearest-neighbour exchange interaction (u) and the nearest-neighbour direct interaction (v) are set equal to 0.3 and 0.01 eV, respectively. The energy gap between the valence and conduction bands at zero wave vector is $\epsilon_\beta^0 = 1.5$ eV and the coupling parameter Δ is chosen as 0.1 eV. A schematic plot of $D^{\mathrm{B}}(k,\omega)$ is shown in Fig. 1. There we see that, for a given value of k, there are two coupled mode frequencies below the electron-hold continuum so that there are two branches to the dispersion relation. In Fig. 2, we have plotted the dispersion relation for the electron–exciton complex in the (100) direction. The dispersion relation for the coupled mode has a form similar to that for polaritons and magnon–phonon modes in ferromagnets. Referring to Fig. 2, we find that as $k \rightarrow \pi/a_0$, the upper branch approaches the exciton band and the lower branch approaches the conduction band. However, as k decreases the separation between these modes becomes larger.

III. Frenkel exciton–electron pairing

For the process of coherent pairing of a Frenkel exciton with an excited electron, the fifth term in the Hamiltonian [1], which describes the Coulomb interaction u_0 between the electron and hole densities located on the same lattice site in the crystal, does not make any contribution and, therefore, is discarded. Such a model is appropriate for excitations occurring in molecular crystals where van der Waals interactions between the atoms are prevailing. Then using the Hamiltonian [1] and the Green function formalism, which is analogous to that used in the theory of superconductivity (15), the gap functions $\Delta(k)$ describing the Frenkel exciton–electron pairing (1, 8) is found to be

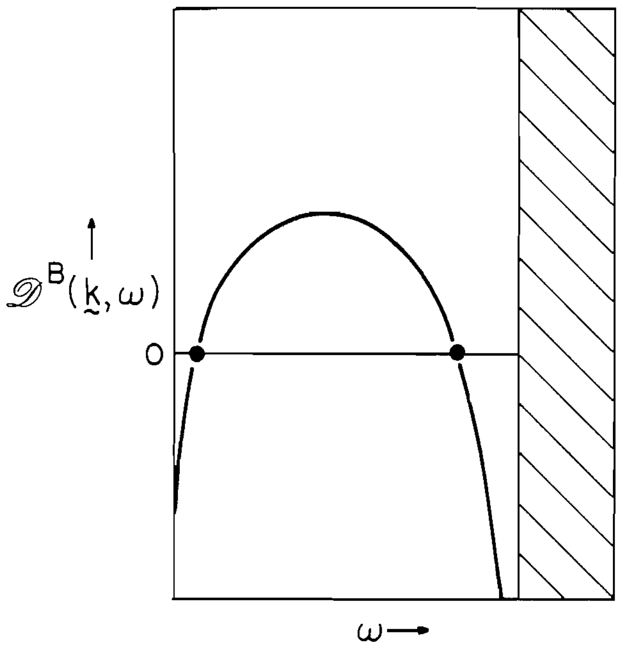

FIG. 1. Schematic of $D^B(k,\omega)$ as a function of frequency, for a fixed wave vector. The two solutions of $D^B(k,\omega) = 0$ correspond to the coupled conduction electron–exciton modes. The hatched area corresponds to the single-particle excitons of electrons and holes.

$$[14]\quad \Delta(k) = \frac{\bar{\omega}}{\sinh(1/\rho)} \approx 2\bar{\omega}e^{-1/\rho}$$

where

$$[15]\quad \bar{\omega} = \xi^2\sigma/4m, \qquad \xi = (6\pi^2 n)^{1/3}$$

$$[16]\quad \rho = N(0)v(k) = 3v(k)/2\bar{\omega}, \qquad \sigma = m\left|\frac{1}{m_e} - \frac{1}{m_{exc}}\right|$$

with $n = N/V$ is the exciton (electron) density, $N(0)$ is the density of states, m_e and m_{ex} are the effective masses for the electron and exciton, respectively; m is the mass of the free electron and $v(k)$ is the Fourier transform of the interaction energy $v(ll')$. In deriving eq. [14], use has been made of the effective mass approximation for the Frenkel exciton and excited electron spectra, respectively. The transition temperature T_c may be found by the relation

$$[17]\quad T_c = 0.57\Delta(k)/k_B$$

where k_B is Boltzmann's constant. The coherent energy W_0, which describes the binding energy corresponding to the electron–exciton pairing, has been calculated by averaging the Hamiltonian (1) to obtain the ground-state energy of the system (1, 7, 8) and it is found to be

$$[18]\quad W_0 = -\frac{N(0)\bar{\omega}^2}{\tanh(1/\rho)} = -\frac{3\bar{\omega}}{2\tanh(1/\rho)}$$

Estimates for the gap function $\Delta(k)$, transition temperature T_c, binding energy W_0 divided by σ are given in Table 1 as a function of the exciton (electron) density n. The data in Table 1 indicate that for exciton concentrations $n \geq 2 \times 10^{18}$ cm^{-3}, the energy-gap function is a measurable quantity provided that we are dealing with the strong coupling limit which occurs when the average interaction energy is equal or greater than the average kinetic energy, $v(k) \geq \bar{\omega}$. The last column in Table 1 gives the values $\bar{\omega}/\sigma$ for different exciton densities which indicate the condition of strong coupling limit $v(k) \geq \bar{\omega}$ can be easily fulfilled with a reasonable strength of the required interaction $v(k)$. The results of the present study imply that at exciton densities $n \geq 2 \times 10^{18}$ cm^{-3}, the obser-

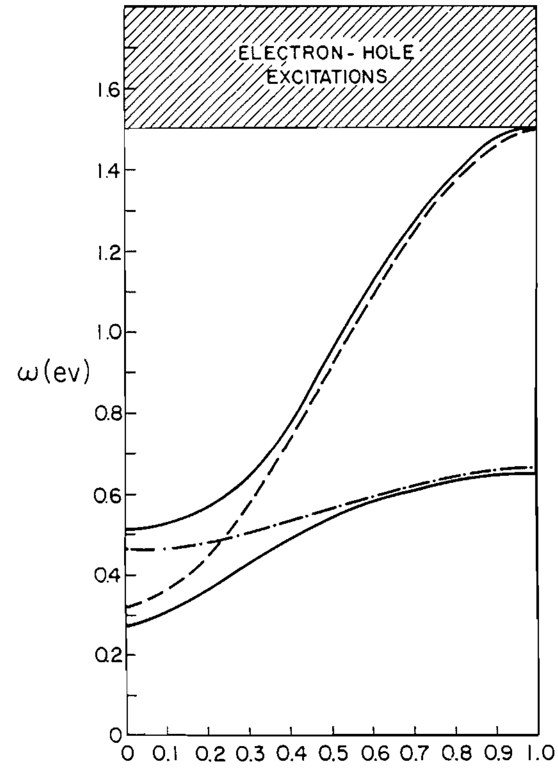

FIG. 2. Dispersion relation for coupled electron–exciton modes (—) in an insulator, with intermediate binding for the excitons. Also shown are the exciton band (- - -) and the conduction electron band (-·-·-) from which the coupled mode is formed. The parameters used in the calculation are given in the text.

vation of the charge carrying electron–exciton states is feasible in molecular organic solids.

IV. Wannier–Mott exciton–electron pairing

For the process under consideration, the sixth term in the Hamiltonian [1], which describes the interaction between two Frenkel excitons, does not contribute and, hence, it is neglected. Then the Hamiltonian [1] is appropriate to describe excitations occurring in semiconducting crystals which are characterized by small energy gaps between the valence and conduction bands and large dielectric constants. In this case, a similar calculation (3) to that used before gives the following expression for the gap function

$$[19]\quad \Delta(k) = \frac{\bar{\omega}}{\sinh(1/\rho)}\left[1 - \frac{2d}{\bar{\omega}}\left(1 + \frac{d}{\bar{\omega}}\right)\left(\cosh\frac{1}{\rho} - 1\right)\right]^{1/2}$$

$$[20]\quad \simeq \frac{\bar{\omega}}{\sinh(1/\rho)} \quad \text{for either } \frac{d}{\bar{\omega}} \ll 1 \text{ or } \frac{d}{\bar{\omega}} \approx 1$$

where $d = \mu e^4/4$ is one-half of the energy of the exciton Rydberg and μ is the reduced mass of the electron–hole pair. The binding energy W_0 is found to be

$$[21]\quad W_0 = \frac{N(0)\bar{\omega}^2}{\tanh(1/\rho)}\left[\left(1 + \frac{d}{\bar{\omega}}\right)^2 + \left(\frac{d}{\bar{\omega}}\right)^2 - \frac{2d}{\bar{\omega}}\left(1 + \frac{d}{\bar{\omega}}\right)\Big/\cosh(1/\rho)\right]$$

$$[22]\quad \simeq \frac{-N(0)\bar{\omega}^2}{\tanh(1/\rho)} = \frac{-3\bar{\omega}}{2\tanh(1/\rho)} \quad \text{for either } \frac{d}{\bar{\omega}} \ll 1 \text{ or } \frac{d}{\bar{\omega}} \approx 1$$

For most semiconducting solids $\nu(k)$ is expected to be of the order of the energy of the exciton Rydberg. Then considering eq. [16] for ρ, the limit $d \ll \bar{\omega}$ also implies that $\rho \ll 1$ provided that $\nu(k) \approx 2d$, which is the weak coupling limit. In the limiting case when $d \approx \bar{\omega}$ then $\rho \geq 1$ which may be considered as the intermediate or strong coupling limit. In both cases, $\Delta(k)$ and W_0 are determined by eqs. [20] and [22], respectively. Finally, when $d \gg \bar{\omega}$, $\Delta(k)$ is given by eq. [19] provided that the relation

$$\frac{2d}{\bar{\omega}}\left(1 + \frac{d}{\bar{\omega}}\right)\left(\cosh\frac{1}{\rho} - 1\right) < 1$$

is satisfied. This corresponds to the extreme strong coupling limit where $\rho \gg 1$ provided that $\nu(k) \approx d$. In this case an enhancement of the binding energy of the complex is anticipated to occur.

V. Summary

In conclusion, we have discussed the excitation spectra arising from the interaction of Frenkel, Wannier–Mott, and intermediate type excitons with conduction electrons to form bound states at low temperatures; such conducting states are appropriate to occur in molecular crystals, semiconductors and rare-gas solids, respectively. We hope that the present discussions will stimulate experimental interest on the spectroscopic properties of electron–exciton complexes and their transport properties as well.

MARCO ANTONIO CHAER NASCIMENTO. Can. J. Chem. **63**, 1349 (1985).

The multiphoton spectra of all-*trans* 1,3,5-hexatriene, in the region of 6.0 eV, is investigated using highly correlated wavefunctions. On the basis of the computed transition energies, intensities, and polarization ratios, an attempt is made to explain the experimentally observed spectra.

MARCO ANTONIO CHAER NASCIMENTO. Can. J. Chem. **63**, 1349 (1985).

Opérant dans la région de 6,0 eV et faisant appel à des fonctions d'ondes très coordonnées, on a étudié le spectre multiphoton de l'hexatriène-1,3,5 qui est complètement trans. En se basant sur les énergies de transition, les intensités et les rapports de polarisation calculés, on essaye d'expliquer le spectre obtenu expérimentalement.

[Traduit par le journal]

1. Introduction

The electronic spectra of linear polyenes has been the subject of intensive experimental and theoretical studies since they were first prepared in the early 1930's. Recently there has been a revival of interest in the subject (1). By forming the basic chromophore of important photobiological systems, such as visual pigments (2) and bacteriorhodopsin (3), the longer polyenes (for which hexatriene serves as a model) have become the subject of numerous photochemical, spectroscopic, and theoretical studies (1).

Several experimental techniques (4–6) have been applied to all-*trans* 1,3,5-hexatriene (hereafter hexatriene). Despite the numerous studies, there are still uncertainties concerning the character, location, and assignment of the excited states. Most important is the characterization of the low-lying excited states which could be involved in the photochemistry of the visual process.

There have been suggestions that the first excited state of all polyenes is a symmetry-forbidden ^1A_g state (7). For both butadiene and hexatriene, extensive *ab initio* calculations (8) have placed the $2\,^1A_g$ state above the experimentally observed strong dipole-allowed ^1B_u state. For butadiene the $2\,^1A_g$ state is calculated at 7.06 eV and 5.87 eV for hexatriene. The experimentally observed ^1B_u states are at 5.92 eV for butadiene and at 4.95 eV for hexatriene. Since the ^1A_g states are dipole-forbidden, they would appear in the one-photon spectra as weak vibronic transitions. Therefore, they should be more easily observed in the two-photon spectra of the polyene compounds. Electron impact spectroscopy can also be used to reveal optically-forbidden states.

Johnson (9) has looked at the two-photon spectra of butadiene and did not detect any ^1A_g state below 5.92 eV as has been suggested (7). Unfortunately, he was not able to record the spectra for energies above 6.79 eV and, therefore, was unable to verify the state at 7.06 eV. Doering and McDiarmid (5*b*) examined the electron impact spectra of butadiene and concluded that the $2\,^1A_g$ state should correspond to the band observed at 7.3 eV in the spectra. There are, therefore, no experimental evidences for the occurrence of a $2\,^1A_g$ valence state below the ^1B_u, in butadiene.

For the hexatriene molecule the work of Flicker *et al.* (5*a*) does not show the presence of any ^1A_g state below 4.95 eV. More recently, El-Sayed (10) investigated the two-photon spectra of hexatriene in the region of 6.0 eV (6.0–6.7 eV). In this region, he observed a single transition at 6.23 eV (and its vibronic structure). From polarization studies (11, 12) he concluded that the excited state should have A_g symmetry.

From our previous calculations (8), the $2\,^1A_g$ valence state should be at 5.87 eV. The fact that the 3*s* Rydberg state is two-photon forbidden leaves the 3*p* Rydbergs as possible candidates for the observed state. From the present calculations both the ^1A_g (π-$3p_x$) and the two ^1B_g ($\pi \rightarrow 3p_y, 3p_z$) Rydberg states occur in this region of the spectra (6.0–6.3 eV).

Comparing the experimental and theoretical results, one sees that some questions remain to be answered. First of all, what is the nature of the observed ^1A_g state? Would it be the theoretically predicted $3p_x$ Rydberg state or the $2\,^1A_g$ valence state, placed at 5.87 eV by the *ab initio* calculation (8)? If the theoretical predictions are correct, why the ^1B_g states were not observed in the two-photon experiment of El-Sayed (10)?

To answer these questions, we calculated the intensities for the transitions from the $X\,^1A_g$ state of the hexatriene molecule to all of the above mentioned states, for both linearly and circularly polarized light. We also computed Ω (the polarization ratio (12)) as an internal check to our calculations.

2. Computational details

All the calculations were carried out using the Dunning (13) valence double-ζ (DZ) contraction of Huzinaga (14) double-ζ ($9s/5p$, $4s$) gaussian basis set, augmented with diffuse basis functions of $3p_\sigma$ and $3p_\pi$ character ($\zeta = 0.021$), in order to provide adequate description of the Rydberg excited states.

With the molecule in the *yz* plane, we used the experimentally-determined ground-state geometry (15) in all the calculations.

The ground state, $X\,^1A_g$, was solved self-consistently at the GVB(3/PP) level (correlating the three π bonds) and the orbitals of this calculation used for the CI calculations of the valence ^1A_g states. These calculations have been extensively discussed in a previous publication (8). The natural orbitals of the GVB calculation were recombined into symmetry orbitals, to be used as starting guesses in the SCF calculations of the Rydberg states.

For the σ Rydberg states we used the IVO's (for Improved Virtual Orbitals, see ref. 16) obtained from the ground state orbitals, and with the basis set augmented with one $3p_\sigma$ basis on each carbon atom, as starting guesses for the excited orbital. Using the first IVO of b_u ($3p_\sigma$) symmetry, we solved self-

TABLE 1. Transition energies (ΔE), two-photon transition rates (τ) and polarization ratios (Ω) for some electronic transitions of the hexatriene molecule

State	ΔE (eV)[a]	τ_c[b]	τ_l[b]	Ω[c] (τ_c/τ_l)
2^1A_g ($\pi \rightarrow \pi^*$)	5.87	3.40(−50)	4.90(−50)	0.69
3^1A_g ($3p_x$)	6.26	0.90(−52)	1.90(−52)	0.47[d]
1^1B_g ($3p_y$)	6.00	4.82(−54)	3.83(−54)	1.26
2^1B_g ($3p_z$)	6.20	7.46(−54)	6.06(−54)	1.23

[a]Transition energies relative to the ground state (X^1A_g) energy of −231.81913 hartrees.

[c]$\Omega < 1$ for $A_g \leftrightarrow A_g$ transitions and equal 3/2 for $A_g \leftrightarrow B_g$ transitions. See ref. 12.

[d]Ω observed = 0.25−0.40. See ref. 10.

consistently for the ^1B_g ($3p_\sigma$) Rydberg state. At this level of calculation we obtained a transition energy (referred to a ground-state energy of −271.72322 hartree) of 5.29 eV. The CI calculation was performed in the following way. The π space was formed by the orbitals generated by SCF calculation. The σ space was formed by the $3p_\sigma$ self-consistently optimized orbital plus five σ IVO's (three a_g + two b_u), properly reorthogonalized to the HF orbitals. Using this space, we allowed up to triple excitations among the twelve π MO's simultaneously allowing the σ electrons the readjust among the six σ orbitals. The first two roots of this calculation correspond to the $3p_y$ and $3p_z$ Rydberg states.

For the π Rydberg state, the IVO's were obtained with DZ basis augment with one $3p_\pi$ basis on each carbon atom. The first IVO of a_u ($3p_\pi$) symmetry was used in the HF calculation of the ^1A_g ($3p_\pi$) Rydberg state. At this level of calculation the transition energy to the X^1A_g state is meaningless since the Rydberg state is not yet a pure state. For the CI calculations the π space was composed of the HF π orbitals plus six π IVO's (three a_u + three b_g), properly reorthogonalized. Using this space we allowed up to quadruple excitations in the CI calculation. The first root corresponds to the X^1A_g ground state. The second root is also a valence state and exhibits the doubly-excited dominant configuration characteristic of the $2^1A_g(\pi \rightarrow \pi^*)$ state (8). Finally, the third root corresponds to a diffuse state and it is assigned to the ^1A_g ($3p_x$) Rydberg state.

With these wavefunctions we computed the two-photon transition rates, and polarization ratios (12). The virtual intermediate states (12) were generated at the same level of excitation.

3. Results and discussion

Table 1 shows the results of these calculations. From the results, we assign the transition at 6.23 eV to the $\pi \rightarrow 3p_x$ (π^*) ^1A_g state, because of the excellent agreement between the theoretical and experimental result for the transition energy and for Ω.

One also sees from Table 1 that the two-photon intensities of the transition to the ^1A_g ($3p_{\pi_x}$) state relative the ^1B_g states ($\pi \rightarrow \sigma^*$) ($W_{A_g \rightarrow A_g}/W_{A_g \rightarrow B_g}$) are 18.65 ($3p_y$) and 12.05 ($3p_z$), respectively, for circularly polarized light and 49.60 ($3p_y$) and 31.35 ($3p_z$), respectively, for linearly polarized light. Thus, the ^1B_g states should be much more difficult to detect in the El-Sayed experiment (10).

Finally, with respect to the 2^1A_g valence state, one sees from Table 1 that its transition rate is much larger than the one for Rydberg states, implying that it should be easily detected by El-Sayed, would it occur in the 6.0−6.7 eV region of the spectra. Our calculations suggest that an experiment conducted at lower energies should reveal the presence of the 2^1A_g valence state.

Raman spectral studies of solutions of alkali metal perchlorates in dimethyl sulfoxide and water

M. I. S. SASTRY AND SURJIT SINGH
Structural Chemistry Group, Department of Chemistry, Indian Institute of Technology, Madras 600036, India

Received April 19, 1984

This paper is dedicated to Professor Camille Sandorfy on the occasion of his 65th birthday

M. I. S. SASTRY and SURJIT SINGH. Can. J. Chem. **63**, 1351 (1985).

Raman spectra of solutions of alkali metal perchlorates in dimethyl sulfoxide (DMSO) in the Cl—O, C—S, and S=O stretching regions, as well as of perchlorates in aqueous solutions in the Cl—O stretching region are reported. The results are discussed in terms of half-bandwidths, relative intensities, and depolarization ratios. For H_2O the half-bandwidth of the Cl—O stretching band at ~935 cm^{-1} is almost double the value in DMSO solutions. Solutions of perchlorates in DMSO show two symmetric bands in the Cl—O stretching region, whereas in aqueous solutions only one band is observed. The half-bandwidths in perchlorate solutions in DMSO for the C—S stretching band increase with increase in concentration of perchlorate compared to that of liquid DMSO. The band contours in the S=O stretching region in DMSO solutions also show significant changes. These observations are explained on the basis of formation of ion pairs of metal perchlorates in solutions of DMSO and ion hydrates in the case of aqueous solutions.

M. I. S. SASTRY et SURJIT SINGH. Can. J. Chem. **63**, 1351 (1985).

On rapporte les spectres Raman de perchlorates de métaux alcalins en solution dans le diméthylsulfoxyde (DMSO) dans les régions d'élongation du Cl—O, du C—S et du S=O ainsi que ceux de solutions aqueuses de perchlorates dans la région d'élongation du Cl—O. On discute des résultats en fonction de la largeur à mi-hauteur des bandes, des intensités relatives et des rapports de dépolarisation. Dans l'eau, la largeur à mi-hauteur de la bande d'élongation du Cl—O à 935 cm^{-1} est à peu près le double de la valeur dans le DMSO. Les solutions de perchlorate dans le DMSO montrent deux bandes symétriques dans la région d'élongation du Cl—O alors qu'on n'en observe qu'une seule en solution aqueuse. La largeur à mi-hauteur de la bande d'élongation du C—S des solutions de perchlorate dans le DMSO augmente avec une augmentation de la concentration de perchlorate par rapport à celle du DMSO liquide. Les contours des bandes dans la région d'élongation du S=O dans les solutions de DMSO changent d'une façon importante. On explique ces observations par la formation de paires d'ions dans les perchlorates métalliques en solution dans le DMSO et par la formation d'hydrate d'ions dans le cas de solutions aqueuses.
[Traduit par le journal]

Introduction

In the past two decades vibrational spectral studies of electrolytes have attracted considerable attention. Several reports (1–13) on this subject have appeared, dealing with various aspects of aqueous and nonaqueous solutions of electrolytes, molten salts, effect on solvent vibrational bands in aqueous and non-aqueous solutions of electrolytes, etc. While studying the vibrational spectra of solutions of electrolytes several effects, such as ion solvation, ion association, as well as the effect of dissolved electrolytes on the vibrational spectra of the solvent bands, are considered. Ionic and molecular associates found in solutions are often short-lived and may have a well-defined identity on the vibrational time scale only. Since Raman spectra can be recorded for the solute and solvent bands simultaneously for the same concentration of the solution with varying photon count and other such parameters, this branch of vibrational spectroscopy has been widely used for the study of electrolyte solutions. Several papers have appeared on the studies of ion association by vibrational spectroscopy. Alkali metal perchlorates have not been found to show any detectable ion pairs in aqueous solutions (14). The perchlorate band is often used in Raman spectra as an internal standard because of an apparent inability of ClO_4 ions to form inner-sphere ion pairs with most cations. No definite evidence has been reported to indicate the splitting of the $\nu_3(f_2)$ band of ClO_4^- in dilute aqueous solutions. Metal perchlorates in matrix isolation spectra show pronounced splitting of the ν_3 band (14), indicating the formation of ion pairs. Raman spectral studies of aqueous metal chlorates show $\nu_3(e)$ doublets even in the spectra of dilute solutions, similar to the doublets in aqueous metal nitrate solutions (15–17). A possible explanation for the difference between the ν_3 region of ClO_4^- (aq) and ClO_3^- (aq) is that the ClO_4^- (aq) is less strongly hydrogen bonded to the water (1). Symons and Waddington (18) studied the ir spectra of aqueous perchlorate solutions and assigned a new band at a frequency higher than that of the stretching modes of pure water to the $ClO_4^- \ldots H_2O$ complex and computed a hydration number of 4 from intensity measurements. Sodium perchlorate in acetonitrile, tetrahydrofuran, and pyridine was found to show ion association by ^{23}Na nmr chemical shift and vibrational spectral studies (19). Similarly lithium, sodium, and magnesium perchlorates in acetone (20, 21), and lithium and sodium perchlorates in pyridine (22) show splittings. Definite support for the presence of ion pairs in solutions comes from analogous splittings observed in matrices (14) and crystalline perchlorate complexes (23).

All the above studies on vibrational spectra of solutions of ClO_4^- are confined to the splitting of the $\nu_3(f_2)$ Cl—O stretching vibrational band. A survey of the perchlorate vibrations under T_d, C_{3v}, and C_{2v} symmetries shows that for an equilibrium between free perchlorates (T_d) and singly (C_{3v}) or doubly (C_{2v}) associated perchlorates, additional bands should also be observed in the totally symmetric Cl—O stretching (A_1) region. In addition to these effects, the solvent bands may also show certain changes in the band profiles, in case the solvent structure changes during the equilibrium. We have recently reported results on the Raman spectral studies of the structure of DMSO and the effect of dilution when its solutions in water and CCl_4 (24, 25) are considered. We report here Raman spectra of solutions of alkali metal perchlorates in DMSO with a view to understanding the ion association and ion–solvent interactions. For comparison, spectra of aqueous solutions of perchlorates in the Cl—O stretching region are also included.

Experimental

Analar DMSO (Merck) was purified by vacuum distillation and kept on 4A Linde sieves. Sodium perchlorate monohydrate (Fluka), lithium perchlorate monohydrate (BDH), and potassium perchlorate (Reidel) were used as such without further purification. They were kept in a desiccator over calcium chloride. Vacuum distilled DMSO, and triple distilled water were used for preparation of solutions. The solutions were separately prepared in 25-mL standard flasks.

Raman spectral measurements were made at room temperature, on a Cary 82 laser Raman spectrometer equipped with a Spectra Physics argon ion laser (Model 165), with the sample contained in a glass cell. All the spectra were recorded employing a 514.5-nm exciting line, varying in the range 300–500 mW power. A 90° scattering geometry was employed. Slit widths of 1.2–2 cm^{-1} were used for different concentrations, with 2–5 s time constant. Spectra were recorded with 0.10 cm^{-1}/s monochromator speed. Both parallel and perpendicularly polarized spectra were recorded at the same instrumental settings. The spectra are reproducible to within ±1 cm^{-1}.

Results and discussion

Raman spectra of solutions of lithium, sodium, and potassium perchlorates were recorded in solutions of varying concentrations in DMSO and water. The results are presented below.

Cl—O stretching region

In Figs. 1 to 4 are given Raman spectra of DMSO and solutions of metal perchlorates in the 900–1100 cm^{-1} region. Pure DMSO shows band due to CH_3 rocking at ~953 cm^{-1}. The ClO_4^- ion in its T_d symmetry is known (2) to show a totally symmetric Raman band at ~935 cm^{-1}. In Figs. 2 to 4 perchlorates are found to show a sharp band in this region. In addition to this strong and sharp band, a low frequency band is observed in all the solutions of perchlorates in DMSO at ~910 cm^{-1}. Raman spectra of aqueous solutions of lithium and sodium perchlorates given in Figs. 5 and 6 do not show flow frequency bands as observed in the respective solutions in DMSO. Matrix isolation studies on metal perchlorates were carried out by Smyrl and Devlin (14). Perchlorates when deposited in argon matrices only have ion pairs with definite dipole moments. Such ion pairs are assumed to have the perchlorate ions in C_{3v} symmetry, in contrast to free perchlorate ions which have T_d symmetry. In a system where both free perchlorate ions as well as their ion pairs are present, it is expected to observe separate bands because of totally symmetric Cl—O stretchings for the free ClO_4 ion under the T_d symmetry, as well as for the ion-paired ClO_4 ion under the C_{3v} symmetry. The low frequency band at ~910 cm^{-1} may be assigned to the totally symmetric stretching vibration of the ion-paired ClO_4^-. Weak bands in the ir spectra of matrix-isolated perchlorates have been reported in this region by Smyrl and Devlin (14). Neither of the two bands at ~910 cm^{-1} and ~935 cm^{-1} are shown in the Raman spectra in the perpendicular polarized mode. This shows that both the bands are totally symmetric. The lower frequency Cl—O stretching band was reported in the Raman spectra of perchlorates in acetonitrile, THF, and pyridine by Greenberg and Popov (19), and in acetone by James and Mayes (21), in the figures included in these reports, without giving any proper assignments for such bands. However, appearance of a weak band in this region in the matrix-isolated ir spectra of perchlorates may justify the assignment of this band to the ion-paired perchlorates. In the early reports (19, 21), components of the main Cl—O stretching band contour at frequencies higher than the 935 cm^{-1} band are assigned to ion pairs. Since the Cl—(OH) stretching band in

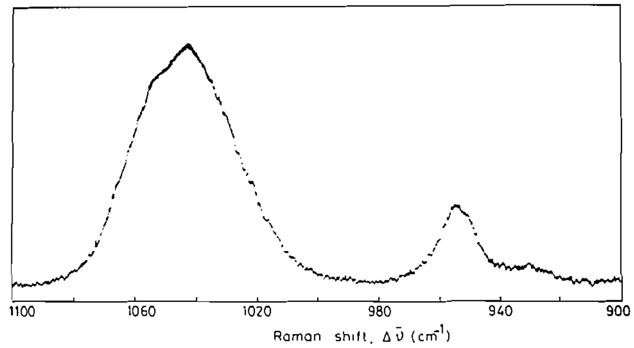

FIG. 1. S=O stretching band in Raman spectra of pure DMSO ($I_{\parallel}$).

$HClO_4$ is assigned to the 734 cm^{-1} band (26, 27), which is lower than the 935 cm^{-1} band, as an analogy we believe the Cl—(OM^+) stretching should be assigned to the lower frequency band at ~910 cm^{-1} as reported in the present work. As mentioned above, in aqueous solutions of perchlorates no band is seen in this region. This is not surprising as ion pairs cannot be formed in aqueous solutions of perchlorates because of the greater possibility of hydration of M^+ and ClO_4^- ions (1, 18). In Tables 1 and 2, spectral parameters of the Cl—O stretching bands in terms of band positions, half-bandwidths, and band heights are given for the various systems considered. The ratios of the intensities of the high frequency band to the low frequency band are shown in the last columns of Table 1. It is noticed that positions of the two bands do not change from system to system and from one concentration to another. The intensity ratio is found to decrease with higher concentrations of perchlorate, indicating greater possibility of association at higher perchlorate concentrations. It is noticed (Tables 1 and 2) that the half-bandwidth of the Cl—O stretching band at ~935 cm^{-1} is about twice as great when ClO_4^- is in aqueous solution compared to when in DMSO solutions. For example, for a 1.0 *M* solution of sodium perchlorate in DMSO the $\Delta\nu_{1/2}$ is 4.0 cm^{-1}, whereas for the same concentration of sodium perchlorate in aqueous solution the value is found to be 8.5 cm^{-1}. It is further noticed that the half-bandwidth increases considerably with increasing concentration of perchlorate in aqueous solutions (varying from 8.5 cm^{-1} for a 1.0 *M* solution to 14.5 cm^{-1} for a 5.0 *M* solution). These observations support the possibility of hydration of ClO_4^- as suggested by Symons and Waddington (18), though the broadening of the Cl—O stretching bands can also be explained in part by the dynamics of the spherical perchlorate ions in aqueous solutions. Dean and Wilkinson have recently reported (28) that the A_1 stretching bands for SO_4^{2-}, WO_4^{2-}, and MoO_4^{2-} ions in aqueous solutions shift to higher frequencies with increasing concentrations of the solutions. We have obtained similar results in sodium perchlorate solutions: the Cl—O stretching band is found to shift from 933.5 cm^{-1} for a 1 *M* solution to 936 cm^{-1} for a 5 *M* solution. In the case of $LiClO_4$, however, no significant shift is observed. The ν_0 value extrapolated to infinite dilution is approximately 933.5 cm^{-1} in both cases.

S=O Stretching region

Figure 1 shows the band contour for the S=O stretching mode of pure liquid DMSO. In earlier publications from this group (24, 25) it was shown that this band is made up of at least four bands at ~1070 cm^{-1}, ~1058 cm^{-1}, ~1040 cm^{-1}, and ~1025 cm^{-1}. It was suggested (25) that the high frequency

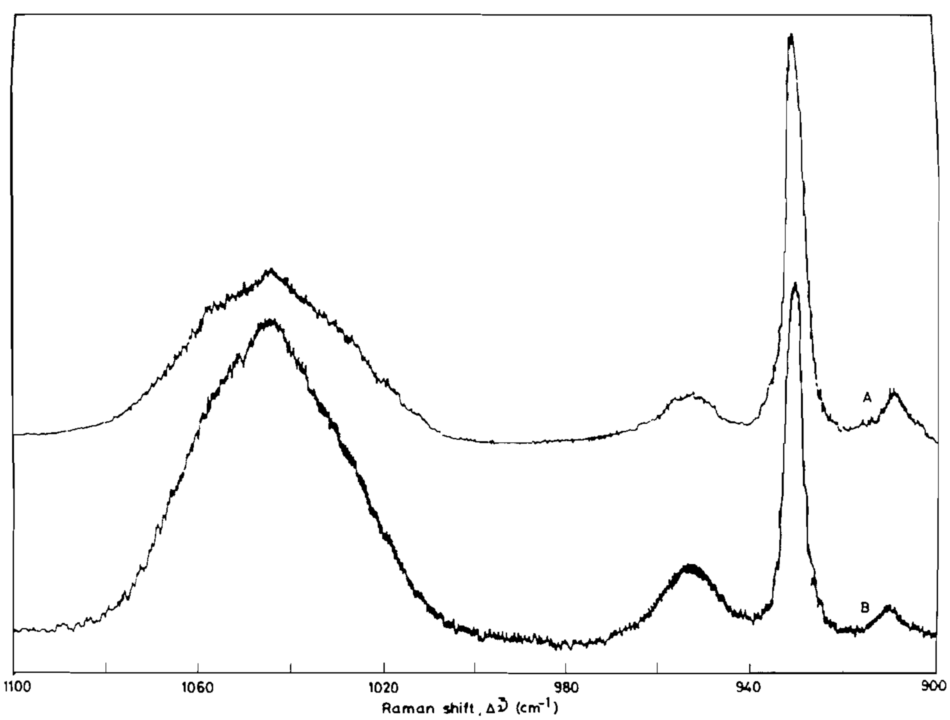

FIG. 3. S=O and Cl—O stretching bands in Raman spectra of solutions of sodium perchlorate in DMSO ($I_{\parallel}$) with concentrations: A, 1.0; B, 0.5 *M*.

band belongs to free S=O stretching, whereas the low frequency bands at ~1058 cm^{-1} and ~1040 cm^{-1} belong to a cyclic dimer and at ~1025 cm^{-1} to a linear dimer and other open-chain polymers. Addition of perchlorates clearly shows perturbation in the structure of the S=O stretching band (Figs. 2–4). The half-bandwith is found to increase with the addition of perchlorates. The increase is of the order of 10–20% for 1.5 molar solutions of perchlorates. It is also noticed that the relative intensity of the low frequency band at ~1025 cm^{-1}, with respect to higher frequency bands, increases considerably with increasing concentration of perchlorates. This may well indicate the presence of ion pairs and the structure making character of perchlorates for liquid DMSO. If the ions were to be solvated by DMSO one would expect structure breaking of

liquid DMSO leading to decrease of intensity of the low frequency band (~1025 cm^{-1}) which is assigned to various associated species of DMSO. In all the perchlorate solutions, concentrations more than 1.5 mol L^{-1} could not be considered because of the solubility limitation, except for $KClO_4$, where the spectra were also recorded for a 2 M solution. In the case of a 2 M solution of potassium perchlorate in DMSO it is further observed that the relative intensities of the 1040 cm^{-1} and ~1050 cm^{-1} components are nearly similar, unlike the case in dilute solutions, as well as in pure DMSO, where the relative intensity of the ~1040 cm^{-1} band is slightly higher than that of the ~1050 cm^{-1} band. This effect may be brought about by the lowering of the concentration of cyclic dimers and

free DMSO molecules with increasing concentration of perchlorates, which is in conformity with the above observations on corresponding increase in intensity of the low frequency component of the S=O stretching band.

C—S Stretching region

The spectral parameters of the C—S symmetric and asymmetric stretching bands are given in Table 3. The depolarization ratios for the low frequency band are in the range of 0.08 to 0.10; whereas for the high frequency band they range between 0.50 and 0.65. It is noticed that the half-bandwidth of the high frequency band increases wih increasing concentration of perchlorates, being 15 cm^{-1} for pure DMSO and nearly 20 cm^{-1} for a 1 *M* solution of $LiClO_4$. Similar increases are observed in the half-bandwidths for other solutions as well. The low frequency symmetric stretching band for solutions of $LiClO_4$ shows a considerable increase in the bandwidth, whereas those for the solutions of potassium and sodium perchlorates have similar bandwidths for the concentration range of 0.5–2 *M*, which is about 2 cm^{-1} higher than the pure DMSO band. Since the spectral parameters were different for different concentrations for recording the Raman spectra, the intensities of the bands cannot be accurately compared for the same system over a range of concentrations. However, the variation in half-bandwidths as well as depolarization ratios with varying concentrations of perchlorates definitely shows reordering of the DMSO molecules in the perchlorate solutions, when compared with pure liquid DMSO. Fourier transform of these bands may be helpful in determining the vibrational relaxation times, which may give extra support to the proposed structure-making properties of perchlorates for liquid DMSO. Work in this direction is under progress and will be published elsewhere.

Conclusions

Raman spectra of perchlorate solutions in DMSO suggest the presence of ion pairs in the solutions of DMSO on the basis of the Cl—O stretching bands. The band contours in the S=O stretching region also show significant changes. The bands in the C—S stretching region show increase in the half-bandwidths, and decrease in the depolarization ratio of the higher frequency asymmetric stretching bands. Raman spectra of aqueous perchlorate solutions do not show the low frequency Cl—O stretching band due to ion-paired ClO_4^- species with the C_{3v} point group observed in the case of solutions in DMSO, which is in accordance with earlier conclusions that ClO_4^- ions do not show evidence of ion association in aqueous solutions.

Reactions of lumiflavin with amine radicals

PARMINDER S. SURDHAR, DOUGLAS E. BADER, AND DAVID A. ARMSTRONG
Department of Chemistry, University of Calgary, Calgary, Alta., Canada T2N 1N4

Received April 26, 1984

This paper is dedicated to Professor Camille Sandorfy on the occasion of his 65th birthday

PARMINDER S. SURDHAR, DOUGLAS E. BADER, and DAVID A. ARMSTRONG. Can. J. Chem. **63**, 1357 (1985).

The amino radicals ($\cdot$AH) formed by the ^{60}Co radiolysis of N_2O-saturated 0.05 *M* solutions of ethylene diamine tetraacetate (EDTA) at pH 7 and 11.2 and of glycine at pH 11.2 brought about an efficient two-electron reduction of lumiflavin (Fl). The spectra of the products were identical to those formed by photolysis of the same solutions and by reduction of the lumiflavin with $\cdot CO_2^-$ radicals. The products were reoxidised to flavin by oxygen. The quantum yield for flavin disappearance was 0.52 $\pm$ 0.07 and 0.17 $\pm$ 0.01 in the presence of EDTA at pH 7 and 11.2 and 0.065 $\pm$ 0.008 and 0.17 $\pm$ 0.01 for glycine at the same pHs, respectively.

The overall two-electron reduction can be explained by the mechanism:

[4] $\cdot AH + Fl \rightarrow \cdot FlH + A$

[5] $\cdot FlH + \cdot FlH \rightarrow Fl + FlH^- + H^+$

[6] $\cdot FlH + \cdot AH \rightarrow FlH^- + A + H^+$

The rate constants of reaction [4] were found by pulse radiolysis to be $1.8 \pm 0.3 \times 10^9$ and $1.5 \pm 0.3 \times 10^9$ M^{-1} s^{-1} for the radicals of glycine and EDTA at pH 7 and $3.6 \pm 0.3 \times 10^8$ M s^{-1} for glycine radicals at pH 11.2. The spectrum of $\cdot$FlH formed by glycine radicals at pH 7 is similar to that produced by $\cdot CO_2^-$, but there was some perturbation, which is apparently due to interaction with the amine.

The radicals formed from the secondary amines piperazine and diethylamine at pH 11.8 also effected reversible two-electron reduction. However, the radicals from glycine anhydride and the primary amine ethylamine yielded significant amounts of non-oxidisable products. The reaction mechanisms are discussed and effects of pH are considered.

PARMINDER S. SURDHAR, DOUGLAS E. BADER et DAVID A. ARMSTRONG. Can. J. Chem. **63**, 1357 (1985).

Les radicaux aminés ($\cdot$AH) issus de la radiolyse au ^{60}Co de solutions saturées en N_2O, contenant 0,05 *M* de tétraacétate d'éthylène diamine (TAED) at maintenues à des pH de 7 ou 11,2 ou contenant de la glycine à un pH 11,2, provoquent une réduction à deux électrons efficace de la lumiflavine (Fl). Les spectres des produits sont identiques à ceux des produits obtenus par la photolyse des mêmes solutions et par la réduction de la lumiflavine par les radicaux $\cdot CO_2^-$. L'oxygène provoque une réoxydation des produits en flavine. A des pH de 7 et 11,2 et en présence du TAED, les rendements quantiques pour la disparition de la flavine sont respectivement égaux à 0,52 $\pm$ 0,07 et de 0,17 $\pm$ 0,01 alors qu'en présence de glycine et aux mêmes pH ces rendements sont égaux à 0,065 $\pm$ 0,008 et 0,17 $\pm$ 0,01.

On peut ilustrer la réduction globale à deux électrons, par le mécanisme suivant:

[4] $\cdot AH + Fl \rightarrow \cdot FlH + A$

[5] $\cdot FlH + \cdot FlH \rightarrow Fl + FlH^- + H^+$

[6] $\cdot FlH + \cdot AH \rightarrow FlH^- + A + H^+$

Faisant appel à la radiolyse à pulsation, on a pu établir que les constantes de vitesse de la réaction [4] sont égales à $1,8 \pm 0,3 \times 10^9$ et à $1,5 \pm 0,3 \times 10^9$ M^{-1} s^{-1} respectivement pour les radicaux glycine et TAED à un pH de 7 et à $3,6 \pm 0,3 \times 10^8$ M^{-1} s^{-1} pour les radicaux glycine à un pH de 11,2. Le spectre du $\cdot$FlH formé par les radicaux glycine à pH de 7 est semblable à celui produit par le $\cdot CO_2^-$, mais il y a une certaine perturbation qui provient apparemment d'une interaction avec l'amine.

Les radicaux formés à un pH de 11,8, à partir des amines secondaires comme la pipérazine et la diéthylamine, provoquent également une réduction réversible impliquant deux électrons. Cependant, les radicaux provenant de l'anhydre de la glycine ainsi que de l'amine primaire l'éthylamine donnent des quantité importantes de produits qui ne sont pas oxydables. On discute du mécanisme de la réaction et on considère l'influence du pH.

[Traduit par le journal]

Introduction

Apart from their intrinsic interest in the chemistry of organic free radicals, the reactions of amine radicals with flavins are of potential relevance to the mechanism of action of monoamine oxidase enzymes (1, 2), and to the important area of pharmacology which is based on monoamine oxidase inhibition (1–4). This study is concerned with the one and two electron reduction of lumiflavin (Fl) by amino radicals ($\cdot$AH) formed from glycine and ethylene diamine tetraacetate (EDTA), and with certain other types of reaction which occur for radicals formed from ethylamine, diethylamine, piperazine, and glycine anhydride.

The radicals were produced by radiolysis or by photolysis. In the former technique the following well-established sequence of reactions occurs in nitrous oxide-saturated solutions (5, 6):

[1] $$4.2\ H_2O \rightsquigarrow 2.7\ e_{aq}^- + 0.6\ \cdot H + 2.8\ \cdot OH + 2.7\ H^+ + 0.5\ H_2 + 0.7\ H_2O_2$$

[2] $$e_{aq}^- + N_2O + H_2O \rightarrow OH^- + \cdot OH + N_2$$

[3] $$\cdot OH\ (\text{or}\ \cdot H) + AH_2 \rightarrow H_2O\ (\text{or}\ H_2) + \cdot AH$$

Concentrations of AH_2 and Fl were chosen so that the time scale of reactions [1] to [3] was much shorter ($\lesssim 10^{-7}$ s) than that for the reaction of Fl with any of the primary radicals. Depending on its rate constant, reaction [4]

[4] $$\cdot AH + Fl \rightarrow A + \cdot FlH$$

would then occur on a 1 μs or longer time scale. Its kinetics can be followed directly in pulse radiolysis experiments (6). Alternatively, in continuous γ radiolysis experiments at low intensity, the product[1] FlH^- produced by the disproportionation of ·FlH (reaction [5] (7, 8)) can be detected by spectro-

[5]/[−5] $2\ \cdot FlH \rightleftarrows Fl + FlH^- + H^+$

photometry (9). Analogy with reaction of *reducing* radicals formed from alcohols (9) would suggest that the sequence [4]–[5], and possibly also reaction [6], would continue until all

[6] $\cdot FlH + \cdot AH \rightarrow FlH^- + A + H^+$

Fl have been converted to FlH^-, at which point the disproportionation *cum* combination of ·AH would become the dominant

[7] $2\ \cdot AH \rightarrow A + AH_2$ or $(AH)_2$

mode of radical loss. This of course assumes that FlH^- is inert to ·AH.

The photochemical technique produces equal yields of ·FlH and ·AH through the sequence of reactions shown in Scheme 1.

The values of many of the rate constants for the photophysical steps are known for representative flavins (2, 10–14), and the overall quantum yield for ·FlH formation has been reported for several amines (11, 12). Reactions [b] and [e] are favoured by the cage effect for the geminate radical pair. However, one study has shown that the radicals may diffuse appart before reacting (14). In flash experiments radical–radical reactions are rapid, and ·FlH + ·AH reactions may occur preferentially (12) with diffusing radicals. Thus reactions [5], [6], and [7] cannot be excluded. However, for the low intensity continuous photolysis procedure used here ·AH should disappear mainly via reaction [4], which should be followed by [5]. The yield of FlH^- would therefore be equal to the yield of ·FlH and ·AH, assuming [b] is negligible.

The structures of the radicals, which should be produced in reaction [3] at pH 7 are shown below for each of the amines. Where there is evidence for pKs of AH_2 and ·AH in the pH 7 to 12 range these are also given, along with references (in parentheses) to both the structures and the pKs. Spin resonance and other studies show that when the amine is deprotonated, hydrogen atom abstraction is primarily from the α-carbon. Thus far the ethylamines α-type radicals dominate at pH ≥ 11

[1] The pK of FlH_2 is ~6.7 and that of ·FlH is ~8.3 (7). Our equations have been written for pH just above 7.

[2] Abstraction of ·H by ·OH is mainly from β carbon for protonated amine and from α carbon for unprotonated amine (20). Thus (β) should be the main radical species below pK_b and (α) the main one above pK_b.

although some β-radicals must be anticipated (15–18, 20). Two types of radicals are also possible for EDTA, and the p*K*s are not known. For glycine and probably for piperazine one radical type should be dominant at pH 7 or 11.8. For glycine anhydride at pH 11.8, the radical structure will differ from that shown by the loss of the proton from the N atom adjacent to the radical sight.

Experimental

Materials

Chemicals obtained were EDTA and lumiflavin (Sigma Chemical Co.), analar grade diethylamine and glycine (British Drug Houses), ethylamine and piperazine (Eastman Kodak Co.). All other chemicals were the purest available grade and used as supplied.

Apparatus

The pulse radiolysis experiments were performed by utilizing 2 μs pulses of electrons with a dose of 2 to 4 gray per pulse from the 1.5 MeV Van de Graaff generator described earlier (21). A 1.0 cm path length optical cell was used with a fresh solution for each pulse. Dosimetry was based on absorbance changes in N_2O-saturated 1×10^{-2} *M* potassium ferrocyanide solutions with ($G \times \epsilon_{420}$) taken as 6.4×10^3 molecules $(100 \text{ eV})^{-1}$ M^{-1} cm^{-1} (22). Here *G* is the yield of the product (ferricyanide) in molecules per 100 eV of radiation energy and ϵ_{420} the difference in molar absorbance co-efficients of ferri- and ferrocyanide at 420 nm.

Values of ΔA, the change in absorption per unit dose observed at any given time after the radiation pulse, were converted to [ε(Fl radical) − ε(Fl)] at each wavelength by dividing ΔA by the concentration of radicals produced per kilogray. Values of ε(Fl radical) were then obtained by adding values of ε(Fl), which were measured on a Cary-219 spectrophotometer. Radical yields per kGy were 5.6×10^{-4} *M* for 0.05–0.1 *M* glycine at pH 7, 7.0×10^{-4} *M* for 0.05 *M* glycine at pH 11.2, and for 0.05 *M* EDTA 6.4×10^{-4} *M* and 7.0×10^{-4} *M* at pH 7 and 11.2, respectively. The differences reflect the different reactivities towards ·OH (5, 23).

Steady state radiolyses were performed in an AECL ^{60}Co γ cell with a steady dose rate of 10.0 Gy min^{-1}. The dose rate was determined by ferrous sulphate dosimetry, assuming $G(Fe^{3+}) = 15.6$ molecules per 100 eV (5), and checked periodically.

All solutions were prepared from triply distilled water and purged with N_2O or argon as indicated. The gases were first passed through a column of ridox (Fisher Scientific Co.) to remove traces of oxygen. All solutions were buffered with 10 m*M* phosphate and protected from light as much as possible. Experiments were performed at 23 ± 2°C. The net number of moles of radicals produced per litre of solution for a given radiation dose, e_{red}, was calculated by means of eq. [12] of ref. 9.

The photolysing lamp consisted of a 250W Halogen Bellophot fitted with a water filter. The light was collimated through filters with maximum and minimum transmissions of λ445 and λ420 nm, respectively. Light intensities at various distances were determined chemically using ferrioxalate actinometry (24). The actinometer solution was 0.15 *M* potassium ferrioxalate in 0.1 *N* sulphuric acid. A molar extinction coefficient of 1.05×10^4 M^{-1} cm^{-1} at 510 nm for the 1,10-phenanthroline complex was determined experimentally by procedures of Hatchard and Parker (24). The spectrum incident on the 1 cm square quartz photolysis cell was calculated from the emission spectrum of the lamp and the percentage transmissions of the filters. The fraction of light absorbed over the band of wavelengths was calculated from the absorption spectrum for each irradiated solution.

Results

Pulse radiolysis

The solid line, the mean of four determinations, in Fig. 1 shows the spectrum at pH 7 produced by the reaction of the glycine radical with 40 μm Fl at 60 μs after the pulse in N_2O-saturated solutions, while the dashed line is the spectrum

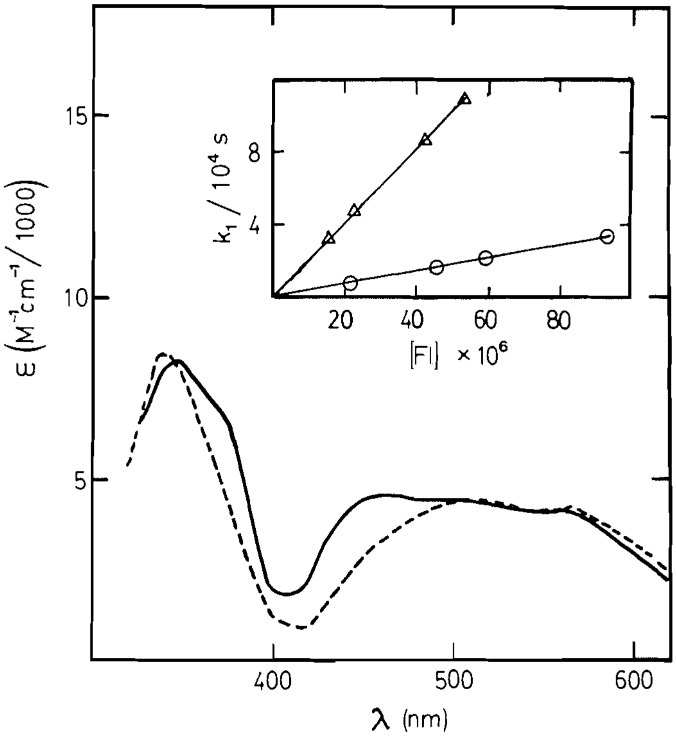

FIG. 1. Absorption spectra 60 μs after pulse radiolysis of 40 μ*M* Fl at pH 7, in phosphate buffer. Reacting radicals: (- - -) $\cdot CO_2^-$ in formate solutions (20×10^{-3} *M*) and N_2O-saturated; $\dot{C}H(NH_2)CO_2^-$ in 0.05 *M* – 0.1 *M* glycine solution, argon, and N_2O-saturated. Inset: plots of pseudo first order rate constants vs. concentration of Fl for pH 11.2 (○) and 7 (△).

of ·FlH produced by the reaction of $\cdot CO_2^-$ with Fl. The main features of the spectrum produced by $\cdot CO_2^-$ were a minimum at 415 nm, maxima at 340 and 510 nm, and a broad shoulder at 570 nm. The spectrum produced by the glycine radical is somewhat different. In addition to the maximum at 345 nm it has a shoulder around 380 nm and there is an increase in absorption in the 400–500 nm region. A similar spectrum was obtained in argon-saturated solutions indicating that the radical species produced by glycine in argon or N_2O-saturated solutions are the same. The spectrum was independent of glycine concentration in the range 0.05 to 0.1 *M*. The growth in absorbance above 500 nm and the change in absorbance at other selected wavelengths exhibited a pseudo-first order behaviour when plotted as a function of time.

The slope of the plot of the pseudo-first order rate constant versus [Fl] for four concentrations in the range 10–100 μ*M* gave a k_4 value of $1.8 \pm 0.3 \times 10^9$ M^{-1} s^{-1}. The rate constant for reaction of the glycine radical with Fl was similarly determined at pH 11.2 and found to be $3.6 \pm 0.3 \times 10^8$ M^{-1} s^{-1}. The plots are shown in the inset of Fig. 1. Likewise the observed value of k_4 for EDTA radicals at pH 7 was $1.5 \pm 0.3 \times 10^9$ M^{-1} s^{-1}. Absorption spectra for the flavin species formed by the radicals of EDTA and of glycine at pH 11.2 will be discussed separately in a future publication.

^{60}Co γ radiolysis and photolysis of glycine and EDTA solutions of Fl

Spectral changes resulting from the reduction of 20 μ*M* Fl with radicals from 0.1 *M* glycine in N_2O-saturated solutions at pH 7 and 11.2 are shown in Figs. 2 and 3, respectively. The initial spectrum of Fl was suppressed by each successive dose

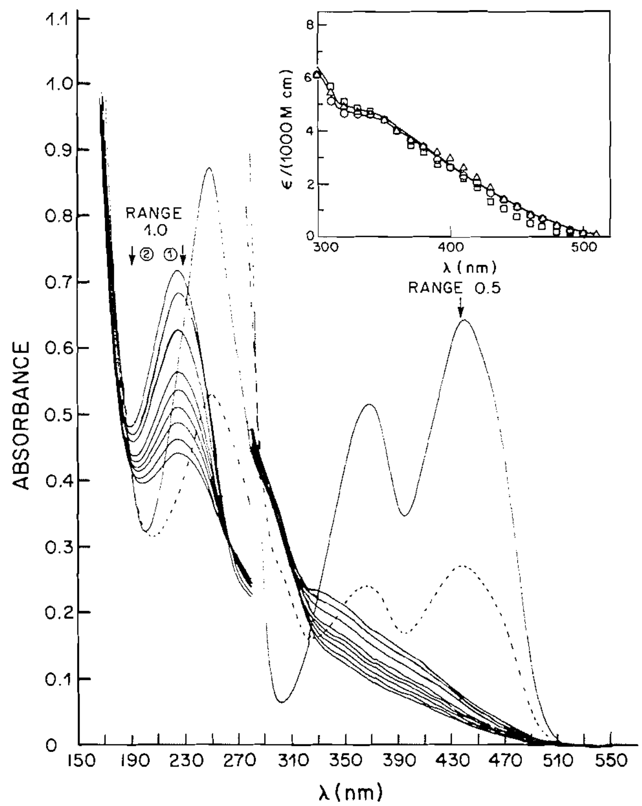

FIG. 2. Spectra obtained from N_2O-saturated solutions of 20 μM LF in 0.1 M glycine and 10 mM phosphate buffer at pH 7 before irradiation, and after 16, 20, 28, 36, 40, 44, 48, 52, and 56 min of γ irradiation at 10 gray min^{-1}. Dashed line: spectrum after reaeration of the irradiated solution. Inset shows spectrum of the reduced species formed by the reacting radicals produced from: photolysis in 0.05 M EDTA (△), 0.05 M Glycine (○); and γ radiolysis of 0.1 M EDTA (□) in buffered solutions containing 20–40 μM Fl. Lines: error limits for species produced by the $\cdot CO_2^-$ radicals in irradiated formate solutions.

of radiation at pH 11.2 and there was no further change in the spectrum after 20 min of radiation. The original spectrum of Fl was regenerated on aeration as shown by the dotted lines in Fig. 3. At pH 7.0, however, the spectrum did not reach a steady state. On addition of air the original spectrum of Fl was not regenerated as shown by the dotted lines in Fig. 2, indicating the formation of a new product. The identification of this new product was not pursued.

In the case of reduction of 20 μm Fl irradiated in 0.1 M EDTA the spectra reached a steady state and the original spectrum of Fl was regenerated at both pH 7 and 11.2 on addition of air.

The insets of Figs. 2 and 3 show that the spectra of the species produced from Fl by γ-radiolysis and photolysis of 0.05–0.1 M glycine and EDTA and by $\cdot CO_2^-$ are identical. There are small differences between pH 7 and 11.2, due to the more complete ionisation of FlH_2 at the higher pH.

Figure 4 shows a plot of $\Delta[Fl] \times 10^6$ M versus $e_{red} \times 10^5$ M. From the initial slopes values of η, the number of moles of reducing equivalents taken up per mole of flavin were calculated. They were 2.28 and 2.34 for EDTA, and 2.25 and 2.42 for glycine at pH 7.0 and 11.2, respectively. These values were consistent with the overall two-electron reduction, viz.

[8] $2AH\cdot + Fl \rightarrow FlH_2 + 2A$

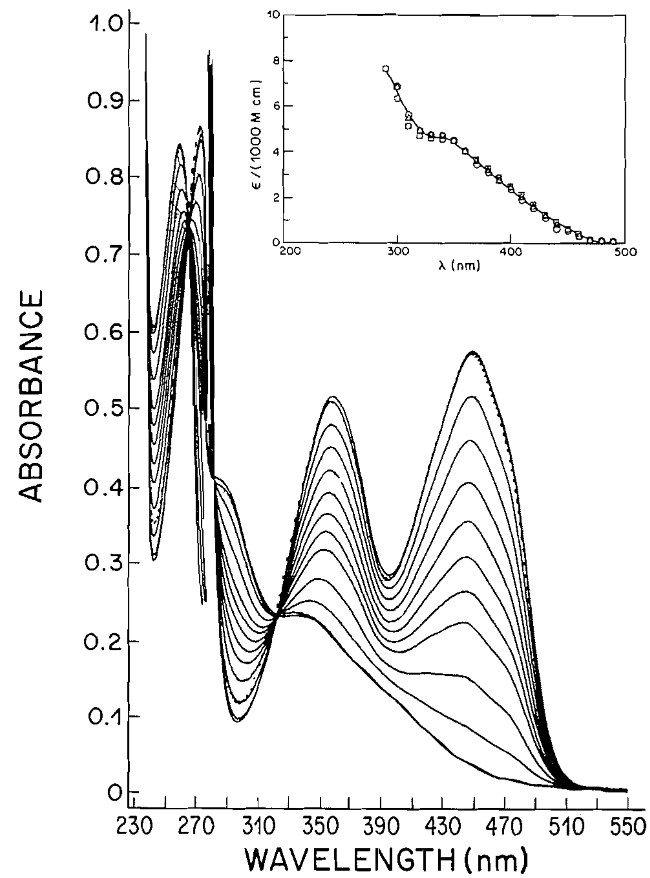

FIG. 3. Spectra obtained from N_2O-saturated solutions of 20 μM Fl in 0.1 M glycine and 10 mM phosphate buffer at pH 11.2 before irradiation and after 2, 3, 4, 5, 6, 7, 8, 10, 12, 16, and 20 min of γ irradiation at 10 gray min^{-1}. Dotted line: spectrum after reaeration of the irradiated solution. Inset shows spectrum of the reduced species formed by the reacting radicals produced from photolysis in 0.05 M glycine (□); and γ radiolysis of 0.1 M EDTA (○) and 0.1 M Glycine (△) at pH 11.2 in buffered solutions containing 20–40 μM Fl. The line shows the species produced by $\cdot CO_2^-$ in formate solutions.

Quantum yields for the photoreduction of 20–40 μM Fl in 0.05 M EDTA and glycine at pH 7 and 11.2 were 0.52 ± 0.07, 0.17 ± 0.01, and 0.065 ± 0.008 and 0.17 ± 0.01, respectively. These are average values determined at several light intensities from the initial slopes of Δ[Fl] versus time over a small period of time or by using the integrated rate law $\ln[10^{A_0} - 1)/(10^{A_t} - 1)] = \Phi\bar{\epsilon}I_0t$ (11). Here I_0 is the incident light intensity, A is the absorbance at time t, Φ the quantum yield of photoreduction, and $\bar{\epsilon}$ the molar extinction coefficient of Fl weighted for the overall spectrum transmitted by the filters. This was determined to be 8459 M^{-1} cm^{-1}. Both methods gave the same values of Φ. The integrated plots for three different light intensities are shown in Fig. 5. The average quantum yield for EDTA at pH 7 was made for six different intensities with I_0 covering the range 1 to 226 × 10^{-7} einsteins cm^{-2} s^{-1}.

^{60}Co γ radiolysis and photolysis of Fl solutions containing other amines

Spectral changes resulting from the gamma radiolysis or photolysis of 20–40 μM Fl in the presence of the amines listed in Table 1, other than EDTA and glycine, were followed in the same way as those described above for glycine and EDTA. In most cases γ radiolysis experiments were carried out in argon-

TABLE 1. Quantum yields for Fl disappearance

Amine*	pH 7			pH 11.2–11.8		
	$2/\eta_{N_2O}$	$2/\eta_{Ar}$	Φ/Φ EDTA	$2/\eta_{N_2O}$	$2/\eta_{Ar}$	Φ/Φ EDTA
EDTA	0.89(99+)	—	1.00(99+)	0.83(99+)	—	1.00(99+)
Diethylamine	0.74(17)	0.64(23)	0.21(80)	0.64(87)	0.80(93)	0.035(100)
Piperazine	—	0.38(91)	0.03(85)	0.18(96)	0.56(98)	0.0057(95)

Glycine	0.88(99+)	—	0.13(99+)	0.85(99+)	—	1.00(99+)
Glycine anhydride	0.37(42)	—	0.008(6)	0.98(21)	—	0.18(90)

*[Amine] = 0.1 *M* and 0.05 *M*, respectively, for γ-radiolysis and photolysis, except for glycine anhydride where the concentration in radiolysis was 20 m*M*. [Fl] is 20 μ*M* and 40 μ*M* for γ-radiolysis and photolysis, respectively. Photolysis was carried out in N_2O purged solutions. The subscript only indicates purging gas for radiolysis method. Standard deviations are typically ±5%.

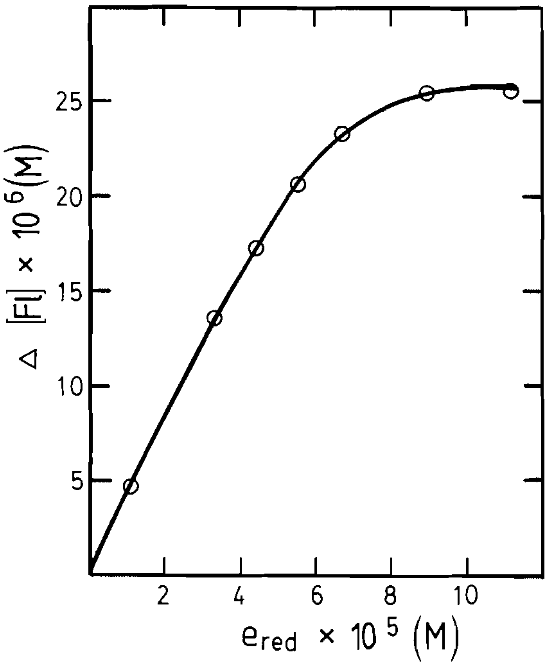

FIG. 4. Change in Δ[Fl] versus e_{red}, number of equivalents of reducing species reacted, for Fl + $H\dot{C}(NH_2)CO_2^-$ at pH 11.2.

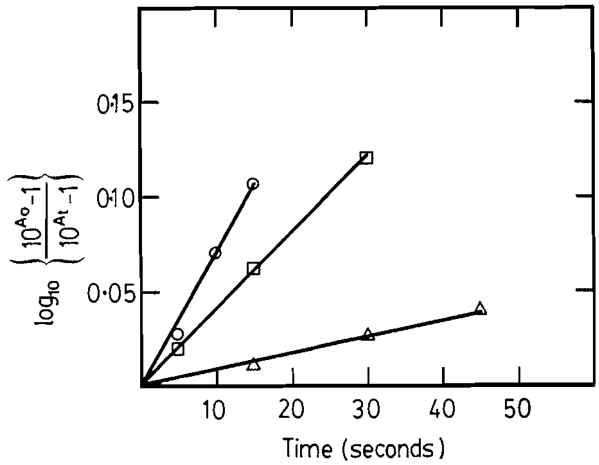

FIG. 5. Plot of $\log_{10}\{(10^{A_0} - 1)/(10^{A_t} - 1)\}$ versus time for three different light intensities. The I_0 values are 1.08×10^{-7} (△), 4.82×10^{-7} (□), and 8.12×10^{-7} (○) einsteins cm^2 s^{-1}.

purged, as well as N_2O-saturated solutions.

The purpose of these experiments was to examine the efficiency of two electron reduction of Fl by different kinds of amine radicals and to determine whether any products, which were not oxidisable by oxygen, were formed. Values of η for the radiolysis were determined from initial slopes of plots of Δ[Fl] versus e_{red}, as in Fig. 4. The efficiencies, given as 2/η have been presented in Table 1. Quantum yields for the photolysis, determined as for EDTA and glycine, were for diethylamine, piperazine, ethylamine, and glycine anhydride 0.01_1, 0.016, 0.055, and 0.043 at pH 7 and 0.0059, 0.0010, 0.0096, and 0.03_1 at pH 11.8, respectively. These have been expressed in Table 1 relative to those of EDTA at the same pH. The reversible reduction was determined by expressing the increase in absorbance at 440–447 nm on addition of air as a percentage of the total loss of absorbance. In cases like that of glycine at pH 7, where the spectrum did not reach a steady state, reoxidation was carried out well before the stoichiometric equivalence point. Those cases were glycine, ethylamine, and diethylamine. The percentages of reoxidation by air have been given in italics in Table 1.

It should be noted that for ethylamine and diethylamine at pH 7, if radiolytic reduction was taken beyond the stoichiometric equivalence point, there was less than 5% reoxidation. The products of the radical plus flavin reactions exhibited maxima at 310 nm and lower absorbance in the region from 330 to 470 nm than the reduced flavins formed by $\cdot CO_2^-$ or EDTA radicals. This was true for both N_2O- and argon-saturated solutions.

Discussion

Formation of ·FlH by glycine and EDTA radicals

As shown in eq. [2], in nitrous oxide-saturated solutions e_{aq}^- is converted to ·OH. Glycine radicals produced via reaction [3] are then the only significant species reacting with Fl. On the other hand, in argon-purged solutions e_{aq}^- reacts directly with Fl (reaction [9] (8)) in a yield comparable to that of the glycine

$$[9] \quad e_{aq}^- + Fl + H^+ \rightarrow \cdot FlH$$

radical ($G_{e_{aq}^-} = 2.7$ and $G_{\cdot OH} = 2.8$ from eq. [1]). Since the spectra were the same in N_2O- and argon-purged solutions, one must conclude that the species produced by glycine radicals and e_{aq}^- were the same. Also, since in the absence of glycine the spectrum of ·FlH produced in reaction [9] is the same as that formed by $\cdot CO_2^-$ and other reducing radicals (8, 25), it would appear that the difference between the two ·FlH spectra in Fig. 1 was caused by the presence of glycine and not by the different reducing radicals $\cdot CO_2^-$ and $H_2N\dot{C}HCO_2^-$. Similar experiments performed at pH 10 showed that addition of glycine to formate solutions, in which Fl^- was formed by reaction of Fl with $\cdot CO_2^-$ and e_{aq}^-, again caused perturbation of the $\cdot Fl^-$ spectrum. Furthermore at pH 7 several of the other amines used here created an even stronger enhancement of the ·FlH absorbance in the region near 450 nm than that seen in Fig. 1. A systematic study of these effects will be reported in detail elsewhere. However, it is evident that several amines interact relatively strongly with ·FlH and $\cdot Fl^-$, causing significant alterations in their absorption spectra. Some evidence for interactions between flavin radicals and certain amino acids has been reported previously (26).

The rate constants for reaction of glycine and EDTA radicals with Fl at pH 7 were $1.8 \pm 0.3 \times 10^9$ and $1.5 \pm 0.3 \times 10^9\ M^{-1}\ s^{-1}$, respectively. These may be compared with 3.6 ± 0.3, 2.6 ± 0.3, and $2.0 \pm 0.3 \times 10^9\ M^{-1}\ s^{-1}$ for $\cdot CO_2^-$, $CH_3\dot{C}(OH)H$, and $(CH_3)_2\dot{C}OH$, respectively. All of these radical reduction processes appear to be close to the diffusion-controlled limit. The smaller rate constant for glycine radicals and Fl at pH 11.2, $3.6 \times 10^8\ M^{-1}\ s^{-1}$, is probably due to the development of a negative charge on the lumiflavin, which has a pK of about 10 (7), and the consequent interaction with the negatively charged glycine radical. The present value of $k_4 = 1.5 \times 10^9\ M^{-1}\ s^{-1}$ for EDTA radicals plus lumiflavin at pH 7 may be compared with published rate constants of 2×10^8 and $5 \times 10^8\ M^{-1}\ s^{-1}$, respectively, for the corresponding reaction of EDTA radicals with flavin mononucleotide (27) and 3-methyllumiflavin (14), which are slightly smaller.

The formation of FlH^- by glycine and EDTA radicals

The spectra of the products formed in γ radiolysis from EDTA radical at pH 7 and 11.2 and from glycine radicals at pH 11.2 were identical to those produced by photolysis of the same solutions and by $\cdot CO_2^-$ (9) (see Figs. 2 and 3). This feature and the fact that all of these products can be reoxidised to Fl by air are consistent with FlH^- as the only significant compound formed by these radicals.

The case of the glycine radical at pH 7 is interesting, since the spectrum did not reach a steady state. The spectral changes in the 310 to 510 nm region of Fig. 2 for the addition of the first 5 mol of $H_2N\dot{C}HCO_2^-$ radical per mole of flavin demonstrates that reduction to FlH^- did occur (cf. the data in the inset). The stepwise spectral changes for added radical concentration up to this point were quite similar to those in Fig. 3 and have been omitted for clarity. However, beyond that point there was a reduction in the absorbance at the 220 nm peak and in the 310 to 510 nm region. Also, after prolonged irradiation such as the one shown in the Fig. 2, the initial concentration of Fl was not recovered on addition of air. These observations demonstrate that at pH 7 glycine radicals react with FlH^-, causing an irreversible change and producing a product, which cannot be oxidised to Fl by oxygen. The effect of this process will obviously be less apparent when glycine radicals are produced by photolysis, since the rate of formation of glycine radicals becomes zero when all Fl has been converted to FlH^-. In contrast, in γ radiolysis the rate of radical production is independent of [Fl] and [FlH^-]. The only other radical for which similar behaviour has been observed thus far is e_{aq}^- (9).

As stated in the Results section, the initial slopes of plots of Δ[Fl] versus e_{red} as in Fig. 4 yield values of $\eta = 2.2$ to 2.4 for both glycine and EDTA radicals at pH 7 and 11.2. This feature indicates a relatively efficient two radical per flavin reduction process as in eq. [8]. Thus reaction [7] cannot be of very great significance, certainly not in the initial phases of the reduction. The reactions contributing to reduction may be taken to be [4] and [5] with some possible contribution from [6]. The present study is a necessary prelude to a determination of the rate of this reaction by the technique of long pulses (28).

Interpretation of the quantum yields for flavin disappearance is not as easy as for the values of η. However, the values of Φ_{ISC} (= $k_{ISC}(k_{ISC} + k_f)^{-1}$, if other singlet loss processes are neglected) lie between 0.5 and 0.7 at pH 7 and fall off at high pH to about 0.17 at pH 10.3 (10–13). Thus the quantum yields for EDTA reduction at both pHs and for glycine at pH 11.2 are equal or close to the maximum values, which can be obtained from reactions [t], [h], [e] and [6] or [4] + [5]. Actually the present quantum yields at pH 7 are in gratifyingly good agreement with those reported for the photoreduction of riboflavin (11) and of FMN (13) by EDTA at pH 7. One may note that the data of ref. 13, indicate a quantum yield of 0.67 ± 0.09 for ·FlH from a flash experiment, while $\Phi(FlH_2)$ was 0.54 ± 0.05 in steady-state photolysis and 0.61 ± 0.12 in the flash experiment. These results suggest that slightly fewer radicals produce FlH^- at low intensity, but in both cases the conversion of ·FlH + ·AH radicals pairs to FlH^- was ≥70%. For comparison the efficiencies for the two-radical reductions, which can be calculated from the η values for the γ radiolysis (= $2\ \eta^{-1} \times 100\%$) reported above are ≥80%. These figures are presented in Table 1 as fractions.

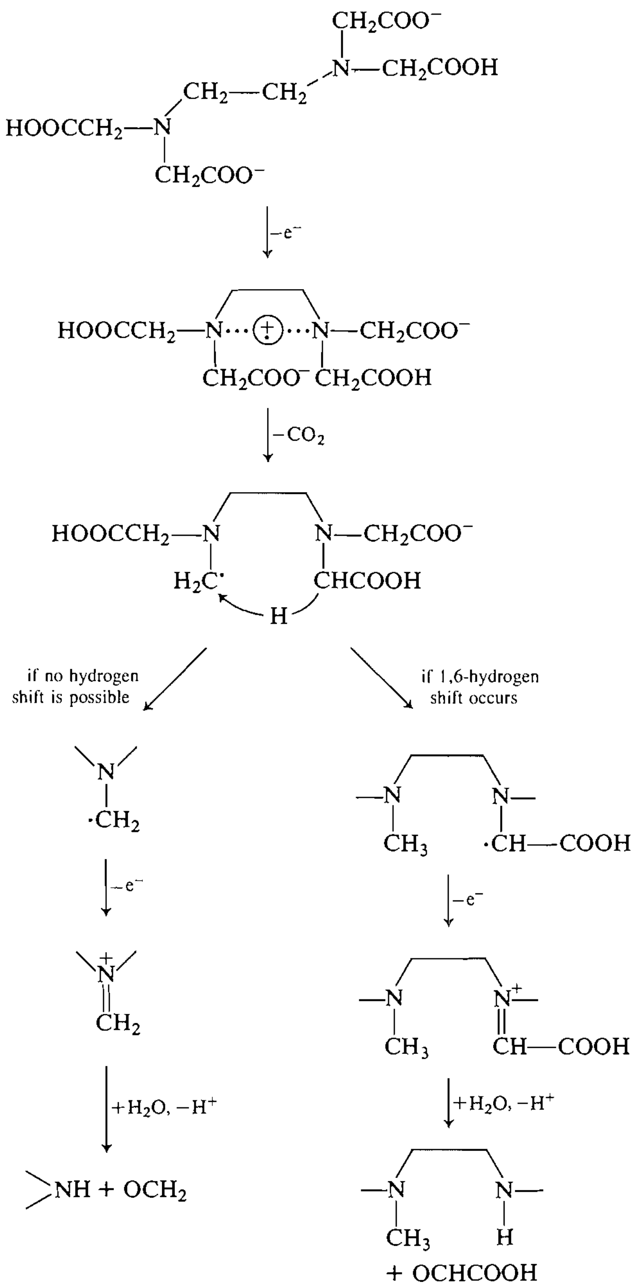
The much smaller quantum yield for photosensitised reduction in the presence of glycine at pH 7 ($\Phi(FlH_2) = 0.065$) may be attributed to the small value of k_t (<$10^5\ M^{-1}\ s^{-1}$ for FMN[3] at pH 7 (12)), which has been reported for the amino acid. For EDTA k_t is apparently much larger (6.2×10^8 for 3-methyllumiflavin (14)).

The products derived from EDTA for radical reductions of Fl to FlH^- have been discussed by Armstrong, Hemmerich, and Traber (29). In the absence of metal ions 1 mol of glyoxalate and of CO_2 were formed per mol of flavin reduced. The reactions which they propose are shown in Scheme 2. The major ·AH radical is seen to be $-\overset{|}{N}-\dot{C}HCOOH$, which is the type b radical expected from ·OH abstraction. This radical probably dominates over the (*a*) radical in γ radiolysis, since there are twice as many C—H bonds from which it may be produced. Support for that comes from the observation that glyoxalic acid is also the main product of the radiolysis of EDTA in air-free solutions (18). This product plus the amine formed with it correspond to A in reaction [4]. In the case of glycine, electron transfer from $H_2N\dot{C}HCO_2^-$ produces $H_2\overset{+}{N}{=}CHCO_2^-$, which hydrolyses to ammonia plus glyoxylic acid and a smaller amount of formaldehyde (30, 31).

Reactions of other amine radicals

The experiments reported here were carried out to determine whether the reversible two electron reductions observed with glycine and EDTA radicals occurred with other amine radicals. The quantum yields for Fl disappearance are seen (Table 1) to be much smaller than those for EDTA, which probably represent the values of the yields for Fl^{*1} intersystem crossing in the two pH regimes. Evidently with the other amines there is more singlet quenching (without product formation) and/or the values of k_t are significantly lower. In addition, the γ radiolysis results imply that the reactions of ·AH may now be slightly less effective in forming FlH^- (see below).

The results in Table 1 at pH 11.8, where the amines are



SCHEME 2. Reaction pathways of Fl_{ox} sensitised photooxidation of EDTA (29).

deprotonated, will be considered in detail first. In the case of piperazine both photolysis and radiolysis led to products, which could be reoxidised to flavin to the extent of 95+%. In this regard it was probably significant that only one type of radical could be formed by ·OH abstractions of H from CH_2 groups, which is expected to be the main site of ·OH attack (32). From published mechanisms for flavin-catalysed amine oxidations, one may reasonably expect this to be the same as the radical arising from photolysis (Scheme 1). For the other secondary amine, diethylamine, one sees on the other hand the percentage of reoxidisable product fall to 87 in going from the photolysis to the radiolysis in N_2O-saturated solutions. Here some ·OH abstraction of H from β-carbon atoms may occur, and from studies with alcohols it has been found that such radicals form non-oxidisable products via reaction [10] (9). Thus it seems probable that the α-amine radicals of diethylamine reacted similarly to those of piperazine and the non-

[10] ·FlH + ·AH → HFl—AH

oxidisable product was due primarily to the presence of some 10% or so of β radicals. Evidently these species are not found in the photolysis at all. The above results with secondary amines are in contrast to the behaviour for the primary amine ethylamine. Here, both photolysis and radiolysis yielded large percentages of non-oxidisable product. These results could be explained if reaction [h] and [t] in Scheme 1 were in competition with a β-hydrogen abstraction by Fl^3 and this and the ·OH in the N_2O-saturated irradiated solutions produced roughly 40% of β-amine radicals. However, based on conclusions from pulse radiolysis (20) this seems to be a rather high proportion of β-radicals, and the alternative hypothesis, that α-amine radicals of ethylamine form oxygen-stable products, must be considered. Rather interestingly, substitution of the —CO_2^- group of glycine for the β-CH_3 of ethylamine completely altered the situation and only reoxidisable product was seen (Table 1).

At pH 7 the proportion of ·OH abstraction of H from the β-carbon rises, due to protonation of the amine (20). Reference to Table 1 shows that the percentages of flavin product reoxidised by air after irradiation of N_2O-saturated solutions of diethylamine and ethylamine fell dramatically, which is in accord with the formation of β-radical adducts in reaction [10]. Based on earlier studies these were probably C-4*a*-alkylated 4*a*,5-dihydroflavins (9), but we did not attempt to identify them here.

It is interesting that the percentage of reversible reduction also fell off for the photolysed solutions, although by a much smaller amount. Evidently for these primary and secondary amines either pH influences the photochemical reactions or the mechanism of reaction between ·FlH and ·AH is different from that between $Fl^{\cdot -}$ and ·AH. This is in contrast to the pH independent yield of reduction for the tertiary amine EDTA. One may note that other tertiary amines, Et_3N and Me_2NCH_2Ph, have been reported to produce 100% oxygen reversible reduction on photolysis (2) at pH 7.

The percentages of reoxidation for glycine anhydride are different from those for the other two secondary amines. Clearly the reactions which occur are altered quite drastically by the replacement of CH_2 by CO (cf. piperazine).

The values of $2/\eta$ for the other amines are also different from those of EDTA. As stated earlier ·AH and ·FlH are produced from ·OH and e^-_{aq} in approximately equal yields in argon-purged solutions. The values of $2/\eta_{Ar}$ in Table 1 are therefore a measure of the efficiency of conversion of the ·AH plus ·FlH mixtures to products. The fact that these were significantly less than unity for diethylamine, piperazine and ethylamine implies that reaction [7] and/or the back donation [b] are important. The even lower efficiencies in N_2O-saturated solutions, where there was no source of ·FlH apart from reaction [4], is an indication that some ·AH radicals *were lost* via reaction [7].

Finally it is interesting that the percentage of reversible oxidation fell off when the number of radicals reacted per flavin at pH 7 was taken beyond the stoichiometric equivalence point. This implies that oxidisable product formed in the initial stages may be converted to an oxygen stable form. In this connection one may recall that there is an equilibrium between Fl, FlH^-, and ·FlH (reactions [5] and [−5]). This provides an avenue for the conversion of FlH^- to HFl—AH through reactions [−5]–[10]. Further work on this aspect is desirable. Also needed is a more quantitative assessment of the proportion of

>N· radicals produced by ·OH and Fl^3 reactions both above and below the amine pK. It is not possible at present to say whether that type of radical undergoes addition or electron transfer.

Raman intensity calculations with the CNDO method. Part III: *N*,*N*-dimethylamide – water complexes

EDUARD D. SCHMID AND ELEONORE BRODBEK

Institut für Physikalische Chemie der Universität Freiburg, Albertstrasse 23a, 7800 Freiburg, Federal Republic of Germany

Received June 1, 1984

This paper is dedicated to Professor Camille Sandorfy on the occasion of his 65th birthday

EDWARD D. SCHMID and ELEONORE BRODBEK. Can. J. Chem. **63**, 1365 (1985).

Absolute differential Raman scattering coefficients of hydrogen bonded *N*,*N*-dimethylformamide (DMF) – water complexes and a *N*,*N*-dimethylacetamide (DMA) – water complex are calculated with a variational method within the CNDO approximation using an extended basis set. Changes of Raman intensities caused by intermolecular interactions are modeled in our Raman intensity calculations and the calculated intensities of the amide I (C=O stretching), OCN bending, and N—(Me)$_2$ stretching vibration of the DMF (and DMA) – water complexes are compared with the experimental absolute Raman intensities of DMF and DMA dissolved in water. The calculated Raman intensities of characteristic normal modes of DMF and DMA and their 1:2 amide–water model are in good agreement with the experimental data. The results show that it is possible to obtain qualitative information on solute–solvent interactions from Raman intensity calculations of complex molecular systems like hydrated DMF and DMA.

EDWARD D. SCHMID et ELEONORE BRODBEK. Can. J. Chem. **63**, 1365 (1985).

Faisant appel à une méthode variationnelle, dans les limites de l'approximation DNDO et à l'aide d'un ensemble de base étendu, on a calculé les coefficients absolus de dispersion Raman différentielle des complexes de *N*,*N*-diméthylformamide (DMF) – eau et d'un complexe de *N*,*N*-diméthylacétamide (DMA) – eau comportant des liaisons hydrogènes. Les changements dans les intensités Raman qui sont causés par des interactions intermoléculaires sont insérés dans notre modèle de calculs des intensités Raman; on compare les intensités calculées pour l'amide I (élongation C=O), la déformation OCN et vibration d'élongation N—(CH$_3$)$_2$ des complexes DMF (et DMA) – eau avec les intensitiés expérimentales Raman absolues de la DMF et de la DMA dissoutes dans l'eau. Les intensités Raman calculées pour les modes normaux caractéristiques de la DMF, de la DMA et de leur modèle 1:2 amide–eau sont en bon accord avec les données expérimentales. Les résultats montrent qu'il est possible d'obtenir des informations qualitatives sur les interactions soluté–solvant à partir de calculs d'intensité Raman sur des systèmes comme la DMF et la DMA hydratées.

[Traduit par le journal]

I. Introduction

Recently it has been shown that it is possible to predict with considerable accuracy absolute Raman intensities of diatomic molecules like H_2, N_2, CO, Cl_2, HCl, and HF (1, 2). These predictions are made by using normal coordinate analysis based on empirical or *ab initio* calculated force constants and intensity parameters calculated by *ab initio* methods. Absolute Raman intensities for molecules larger than diatomic molecules are also calculated with *ab initio* methods for H_2O, NH_3, CH_4, C_2H_4 (2–5). Since the experimental data are often incompletely determined, only a part of the predicted spectra can be compared with the experiment. It is important to realize that the predicted Raman intensities of these small molecules are in agreement with the experimental intensities of the isolated molecule within a factor of two.

The aim of our Raman studies is to comprehend molecular interactions via a comparison of predicted and experimental absolute Raman intensities. Our experimental investigations of substituent effects on benzene derivatives (6, 7) and solvent effects on the Raman intensities of numerous substrate molecules (8) have shown that the Raman intensity is very sensitive to molecular interactions. These studies represent a challenge with respect to extension of Raman intensity calculations to larger molecules (>6 atoms) and with respect to elucidation of effects of intermolecular interactions with these computations. In order to understand the effect of intermolecular interactions on the spectrum of a molecule it is important first to understand the spectrum of the isolated molecule. Calculations of absolute Raman intensities of larger molecules were performed for benzene (9), but only within the semiempirical CNDO approximation (10) with an extended basis set. *Ab initio* calculations of Raman intensities for this type of molecule are at present too extensive. The experimental intensities of benzene in the gas phase and the calculated non-resonant absolute Raman intensities of the 3032 cm^{-1} and 992 cm^{-1} vibrations are in good agreement. This might be an indication that Raman intensities of larger molecules (>6 atoms) can be calculated with the CNDO method with an extended basis set. We adopted this CNDO program developed by E. N. Svendsen *et al.* (11, 12) without changing any parameter of the CNDO method, and calculated the absolute intensities of the in-plane vibrations of formamide (13), and of DMF, and DMA (14). The predicted Raman intensities were compared with experimental intensities of these amides dissolved in an "inert" solvent (carbon tetrachloride) and the agreement is within a factor of two. Raman intensities of the gas phase or of matrix isolated molecules are not available.

Encouraged by this success, we extend our Raman intensity calculations to study intermolecular interactions. We have two reasons to calculate Raman intensities of amide–water complexes. First, we know from our experimental Raman studies that water as a solvent shows the most pronounced intensity change relative to an inert solvent. Second, the amide–water interaction is predominantly determined by hydrogen bonding and this specific interaction can be more easily taken into account in the calculation than the numerous solvent polarity–polarizability effects. The Raman intensity calculations of the DMF (DMA) – water complexes are compared with experimental data for the characteristic modes of DMF (DMA) dissolved in water: the amide I (C=O stretching), δOCN bending, and νN—(Me)$_2$ stretching vibrations. The results of these investigations are reviewed in this paper.

II. CNDO calculations

The polarizabilities and absolute differential Raman scattering coefficients are computed with a variational method which has been applied in previous calculations (9, 11, 13, 14). The valence basis set of the CNDO approximation is extended with polarization functions. The hydrogen atoms are defined with *s*- and *p*-functions. Similarly, *d*-functions are added to the first row elements. A description of this Raman intensity calculation method has been given in previous papers (9, 11, 13).

The absolute differential scattering coefficient for observation at right angles to the laser beam using linear polarized light is defined (17) as:

$$[1] \quad \frac{d\sigma}{d\Omega} = \frac{(2\pi)^4}{45} \cdot \frac{(\nu_0 - \nu_j)^4 g_j}{1 - \exp(-hc\nu_j/kT)} \cdot \frac{h}{8\pi^2 c\nu_j} \times (45\bar{\alpha}_j'^2 + 7\gamma_j'^2)$$

$\bar{\alpha}_j'$ and γ_j' are the derivatives of the mean polarizability and the anisotropy with respect to the *j*'th normal coordinate. Here, g_j denotes the degree of degeneracy of the normal mode ν_j, h Planck's constant, c the velocity of light in a vacuum, k Boltzmann's constant, and T the absolute temperature.

The experimental Raman intensities are determined relative to the ν_1 band of CCl_4 at 469 cm^{-1}. The conversion of the relative Raman intensities S_j into absolute differential Raman scattering coefficients $d\sigma/d\Omega$ is performed with the absolute value of $\frac{d\sigma}{d\Omega}(\nu_0 - \nu_1)^{-4} = 137 \times 10^{-48}$ cm^6 for the ν_1 band of CCl_4 measured by Kato and Takuma (27):

$$[2] \quad \left(\frac{d\sigma}{d\Omega}\right)_j = S_j \cdot 137 \cdot 10^{-48}\ \text{cm}^6\ (\nu_0 - \nu_j)^4 \cdot \frac{\nu_1}{\nu_j} \cdot \frac{g_j}{g_1} \cdot \frac{1 - \exp(-hc\nu_1)/kT}{1 - \exp(-hc\nu_j/kT}$$

The electron densities and the dipole moments for the equilibrium geometries are calculated with the CNDO method (9) with only a valence basis set, since this method already gives reliable results for first-order quantities. We have not fitted any parameter in the CNDO method to our problems. The empirical parameters defined by Pople and Beveridge (10) are used.

III. *N,N*-Dimethylformamide – water complexes

(a) *Equilibrium geometry*

Structural studies of amide–water complexes predict that the oxygen atom in amides can accommodate two water molecules (16, 19–22). *Ab initio* calculations of hydrogen bond energies (20, 21) show that the hydrogen bond is formed between the directed lone pairs of electrons on the oxygen atom in amides and two water molecules. This model of a 1:2 amide–water complex seems to reflect an important part of the amide–water interaction. Pullman *et al.* (20, 23) made explicit computations with a third H_2O molecule and found that it is bound to one of the two water molecules of such a 1:2 amide–water complex. The interaction of water with amide molecules through the intermediacy of a second water molecule reflects effects from the second hydration shell.

There is also a possibility of water hydrogen bonding to the π-system of amides. Calculations of Kollmann and co-workers (21) and Schreiner and Kern (22) indicate that the interaction with the π-system would occur when the water molecule is located perpendicular to the OCN plane at the oxygen atom of the amide molecule. But inclusion of further water molecules at the oxygen atom of the amide molecule weakens the interaction between the π-system and H_2O.

A 1:1 amide–water complex can also be considered as an interaction model complex (18).[1] But this complex seems not to exist actually in nature, since the binding energy between one water molecule and the amide molecule is much smaller than in the 1:2 amide–water complex. The O—H bond of a H_2O molecule would be directed along the C═O bond of the amide molecule bisecting the angle of the lone pairs of the C═O bond. This 1:1 amide–water complex can be considered as a test of the sensitivity of the Raman intensity calculation to distinguish between different interaction models.

All these studies on amide–water complexes were performed with formamide, *N*-methylformamide (NMF), and *N*-methylacetamide (NMA). No explicit models for DMF–water complexes or DMA–water complexes are available. Therefore we constructed three DMF–water complexes which are based on the results of the discussed amide–water models.

(1) A 1:2 DMF–water complex (Fig. 1*c*) where two water molecules take part in the formation of linear hydrogen bonds with the oxygen atom of DMF. The hydrogen bond lengths and the orientation of the two water molecules are taken from an *ab initio* study of *N*-methylformamide (NMF) – water complexes (19).

(2) A 1:3 DMF–water complex (Fig. 1*d*) which is based on a study of Pullman *et al.* (20) of formamide–water complexes. The third H_2O molecule is located at one of the water molecules of the 1:2 DMF–water complex.

(3) A 1:1 DMF–water complex (Fig. 1*b*) with a linear hydrogen bond between the O—H bond of H_2O and the C═O bond of DMF. The hydrogen bond length has been taken from *ab initio* calculations of a formamide–water comlex.[1]

Experimental geometries determined by electron diffraction were used for DMF (24) and H_2O (25). The methyl group "*cis*" to the C═O bond must be rotated in a staggered conformation with respect to the H_2O molecule at the oxygen atom of DMF to avoid steric interaction with water (22). The structural parameters of these complexes are listed in Table 1.

(b) *Normal coordinate analysis*

The normal coordinates are calculated with Wilson's GF-matrix method (15). The methyl groups and water molecules are considered as point masses. The approximation to consider H_2O as a point mass is justified, since the intramolecular vibrations of H_2O are not the subject of this study. We are interested in the effect of the hydrogen bond between DMF and the water molecules on the vibrations of DMF.

As a first step in our normal coordinate analysis of the 1:2 DMF–water complex we use the valence force field of the isolated DMF, which is reported in a previous paper (14), and an assumed hydrogen bond stretching force constant of 0.1 mdyne/Å. This force field is refined with experimental frequencies of DMF dissolved in water.[2] The fitted hydrogen bond stretching force constant of 0.23 mdyne/Å is in agreement with an *ab initio* calculated value of 0.27 mdyne/Å of a formamide–water hydrogen bond stretching force constant (16). This might be an indication that our force field is not far from the actual force field, which could be calculated by quantum mechanical procedures. The internal coordinate definitions

[a]Force constants in internal coordinates. Units: stretch in mdyne/Å, bend in mdyne Å/rad^2, stretch−bend interaction in mdyne/rad, torsion in mdyne Å/rad^2.

(Table 2), the fitted force field (Table 3), and the assignments of the normal vibrations of the DMF−water complex which are considered in the Raman intensity calculations are listed in Table 4.

(c) *Results and discussion of the normal coordinate analysis and the Raman intensity calculation*

The valence force field (Table 3) of DMF changes in some force constants when an intermolecular stretching force constant between DMF and water is assumed. The C=O stretching and the HCN bending force constants decrease due to hydrogen bonding and the calculated frequency of the amide I (C=O stretching) vibration shifts from 1712 cm^{-1} in DMF to 1658 cm^{-1} in the DMF−water complexes. This corresponds to the experimental frequency shift of the amide I mode of DMF from 1684 cm^{-1} to 1655 cm^{-1} when the solvent varies from carbon tetrachloride to water. The experimental frequencies of the δ OCN bending and νN—(Me)$_2$ symmetrical stretching vibrations remain almost unchanged in these two solvents. This is also confirmed by the normal coordinate analysis where considerable changes are calculated only for the frequency and potential energy distribution (PED) of the amide I vibration (Table 4).

Based on our normal coordinate analysis and the intensity calculation with the variational method, we predict Raman intensities of DMF−water complexes for three amide vibrations. The predicted and experimental values are listed in Table 5. The predicted intensities of the isolated DMF molecule and measured intensities of DMF dissolved in CCl_4 are in agreement within a factor of two (Table 5). Calculated and experimental Raman intensities can be directly compared, since both of them are independent of the resonance denominator of the polarizability tensor.

The same agreement as for the isolated molecules has been obtained between predicted intensities of the 1:2 DMF−water complex and the experimental Raman intensities of DMF dissolved in H_2O (Table 5). Considerable changes in the Raman intensities of DMF due to the DMF−water interaction are observed for the amide I band. If we compare the intensity of the amide I vibration of the isolated DMF, or rather DMF dissolved in CCl_4, with the 1:2 DMF−water complex, or rather DMF dissolved in water, there exists a pronounced decrease of the Raman intensity by a factor larger than 4. The predicted intensities of the amide I mode of the 1:2 DMF−water and 1:3 DMF−water complexes are equal within the accuracy of the calculation.

To check the sensitivity of the Raman intensity calculation with respect to the intermolecular interaction models we predicted the force field and the Raman intensity of the amide I vibration of the 1:1 DMF−water complex. The result of the normal coordinate analysis shows that the calculated force field and PED for the 1:1 complex are the same as for the 1:2 complex. As shown in Table 5, the calculated Raman intensity of the amide I vibration of the 1:1 DMF−water complex is smaller by 1/10 than that of the 1:2 DMF−water complex, and a factor 1/6 smaller than the experimental value. Though the accuracy of such a small value is not assessible, it could be concluded at least qualitatively that the 1:1 complex is not favoured to describe the intermolecular interaction between amide and water.

The experimental and calculated Raman intensity of the νN—(Me)$_2$ stretching vibration increases slightly. Because the normal coordinate and frequency are nearly identical for DMF and the DMF−water complex, a possible explanation of this intensity shift is the decrease of negative charge in the N—Me bond of the complex, caused by an electron loss at the nitrogen atom (Fig. 1).

The calculated δ OCN band intensity remains unchanged when intermolecular interaction between DMF and water is assumed. The normal coordinate of this mode, as well as the derivatives of the polarizabilities with respect to the normal coordinate, show no evident changes compared to the DMF monomer.

Because of the approximations of the CNDO method and the arbitrariness of the experimental force constants used in the Raman intensity calculation, the absolute values of our calculated Raman scattering coefficients have predominantly qualitative significance. But the results suggest that the simplest interaction model has to consider two H_2O molecules at the oxygen of DMF. The following discussion will show that our findings are consistent with other physical properties of

amide−water complexes.

In the models of the 1:2 and 1:3 DMF−water complexes, hydrogen bonds arise between the lone pairs of electrons on the oxygen atom of DMF and the water molecules (Fig. 1*c*, 1*d*). Our electron density calculation shows that negative charge is moved through the DMF molecule to the oxygen atom in DMF. The nitrogen and carbon atoms of DMF and the hydrogen bonded H-atoms of water lose electrons and this negative charge is moved to all oxygens of the complex and the non-bonded H atoms of water. This is in agreement with the "pileup effect" of negative charge to the donor atom and the "spillover effect" of negative charge from the acceptor atom (26).

The additional water molecule in the 1:3 DMF−water complex acts as proton donor to a H_2O molecule, which in turn acts as proton donor to the C═O bond of DMF (Fig. 1*d*). The charge transfer from the DMF molecule to the water dimer increases, compared to the charge transfer induced by one water molecule.

The polarizabilities of the 1:2 and 1:3 DMF−water complexes increase, compared to the DMF monomer (Table 6). The calculated dipole moments of the 1:2 and 1:3 DMF−water complexes are smaller than the dipole moment of DMF (Table 6). The partial C═O bond order decreases with growing number of H_2O molecules in the complex. The smaller overlap of $2p\pi$ atomic orbitals of the C═O bond of the complexes, compared with the $2p\pi$ atomic orbital overlap of the C═O bond of DMF, is responsible for the decreasing bond order. These results are consistent with other calculations of electron density distributions of amide−water complexes (16, 19−22).

The decrease of C═O bond order indicates that the polarizability in the carbonyl group is reduced. Moreover, the normal coordinate of the amide I vibration which is located in the OCN group is influenced by hydrogen bonding. Both effects are responsible for the smaller Raman intensity of the amide I (C═O stretching) band of the DMF−water complex. This is consistent with the empirical rule that bond order and Raman intensity of a vibration which is located in this bond behave in the same way (28).

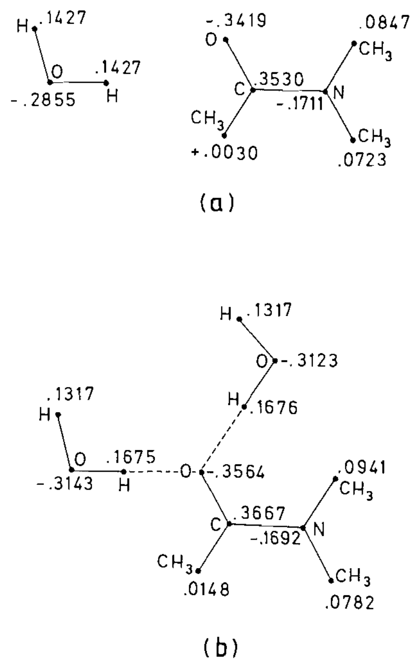

FIG. 2. Equilibrium geometries and electron densities of DMA and the DMA−water complex. (a) Non-interacting DMA and H_2O molecules; (b) 1:2 DMA−water complex.

IV. *N,N*-Dimethylacetamide − water complexes

(a) *Equilibrium geometry*

In the 1:2 DMA−water model considered (Fig. 2), two H_2O molecules form hydrogen bonds with the oxygen of the DMA analog to the 1:2 DMF−water complex. The hydrogen bond length and the orientation of the two water molecules are taken from *ab initio* calculations (19). These structural parameters are different from those of the 1:2 DMF−water complex. The experimental geometries of DMA (29) and H_2O (25), determined by electron diffraction, are chosen and have not been modified through the calculation. The methyl groups of the DMA−water complex are staggered to the C=O bond to avoid steric interaction with the two water molecules (22). All structural parameters are listed in Table 1.

(b) *Normal vibrations and Raman intensities*

The force constants of the isolated DMA (14) and the hydrogen bond stretching force constant predicted for the DMF−water complex are taken as the force field for the normal coordinate analysis of the 1:2 DMA−water complex. Only the force constants of the DMA part of the force field are fitted with experimental frequencies of DMA dissolved in water.[2]

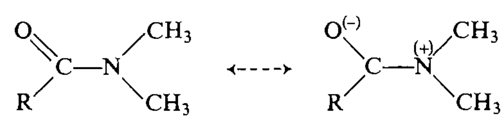
Essential wavenumber shifts of 55 cm^{-1} are observed for the amide I mode of DMA if the solvent changes from carbon tetrachloride to water (Table 7). The normal coordinate analysis also shows a decrease of the amide I wavenumber of 57 cm^{-1} and no important changes for the other vibrations of the DMA−water complex. Since the potential energy distribution (PED) remains nearly unchanged for all considered modes of the DMA−water complex, compared to the DMA monomer (Table 7), the reason for the wavenumber shift of the amide I vibration is the decrease of the C=O stretching force constant by about 10% (Table 3). The C=O stretching force constant does not contribute to the PED of the δOCN bending and νN—Me stretching vibration.

The measured Raman intensity of the amide I mode of the DMA decreases from 4.069×10^{-30} cm^2 in carbon tetrachloride to 0.324×10^{-30} cm^2 in water (Table 5). Hydrogen bonding at the oxygen of DMA contributes to a decrease of C=O bond order and C=O stretching force constant. This indicates a loss of double bond character of the C=O bond and is also reflected in the smaller wavenumber and Raman intensity of the amide I vibration of the DMA−water complex, compared to the DMA molecule (Table 5).

The absolute differential scattering cross sections of the δOCN bending and νN—(Me)$_2$ stretching vibrations are not changed if DMA is dissolved in water (Table 5). This is in agreement with the normal coordinate analysis and the Raman intensity calculation of these two vibrations of DMA and the 1:2 DMA−water complex.

V. Conclusions

Hydrogen bonding between *N,N*-disubstituted amides (DMF, DMA) and water causes a charge transfer in the amide molecule which can be described with the resonance structures:



If one compares the gross electronic charges of the atoms of DMF and DMA in the 1:2 amide−water complex (Figs. 1 and 2) it is found that the carbon methyl group of DMA supplies electrons to the complex, and therefore the average binding energy per H_2O molecule is larger than in the DMF−water complex (Table 6). The stronger interaction between DMA and water causes a larger decrease of the C=O bond order and the absolute differential Raman scattering coefficient of the amide I (C=O stretching) mode in the DMA−water complex, compared to the DMF−water complex (Table 5).

The results of the Raman intensity calculation of amide−water complexes show that the variational method and the

CNDO approximation supply reliable absolute Raman intensities of complex molecular systems. The agreement between measured and calculated Raman intensities makes it possible to correlate the changes in Raman intensities with intermolecular interactions which are considered in a 1:2 amide–water model complex. But the limitations of the CNDO method and the arbitrariness inherent in any force field not supported by accurate quantum mechanical force constant calculations permit only a qualitative, rather than a quantitative, description of the solute–solvent interactions. An improvement of the Raman intensity calculation can surely be achieved by quantum mechanical force field methods.

This is a first investigation of intermolecular interactions by means of Raman intensity calculations. Such studies of intermolecular interaction via Raman intensity calculations have not been published up to now.

A blind chemist's approach to automated scientific information

JEAN-PIERRE CARTIER[1,2] AND FRANCINE PAQUIN
Département de chimie, Université du Québec à Montréal, Montréal (Qué.), Canada H3C 3P8

Received June 12, 1984

This paper is dedicated to Professor Camille Sandorfy on the occasion of his 65th birthday

JEAN-PIERRE CARTIER and FRANCINE PAQUIN. Can. J. Chem. **63**, 1372 (1985).

Computer access to chemical information by a blind chemist is made possible with a VersaBraille system (Braille Information Processor). The CAS database of the DIALOG system is used in this updating assay. Preliminary trials showed the need to establish a rigorous procedure to avoid loss of data. In this study, a functional method is suggested as a substratum to circumvent costly problems.

JEAN-PIERRE CARTIER et FRANCINE PAQUIN. Can. J. Chem. **63**, 1372 (1985).

Grâce au VersaBraille (Processeur d'Information en Braille), l'accès aux bases de données est maintenant devenu possible pour le chimiste handicapé de la vue. Les séances de mise à jour, sont ici faites en utilisant le fichier CAS du réseau DIALOG. Des tentatives préliminaires ont démontré la nécessité d'utiliser une procédure rigoureusement définie, afin d'éviter la perte de données. La présente étude veut proposer une méthode fonctionnelle, dont le substratum tend à circonvenir des problèmes coûteux.

[Traduit par le journal]

Introduction

The time-consuming task of updating bibliography has long been an accepted fact of a chemist's life. In a certain way, the printed form of the Chemical Abstracts facilitates access to scientific information. In 1970, more than 3×10^7 printed pages (1) of scientific papers were published. The chemist, who wishes then to be informed of the latest scientific results, faces an almost impossible task. Today, certain computer networks (2) offer a personal and instantaneous access to chemical data.

Now, consider what would happen if the researcher is blind. Years ago, for many, blindness would have been treated as a catastrophe. However, technological developments (3, 4) may favor a "detour" (5) and allow for successful achievement (6). The advent of braille information processors places this chemist in a "quasi-normal" state of endeavor.

The objectives of this paper are twofold: to illustrate the facility of communication between the VersaBraille system (7) and the DATAPAC/DIALOG network; to emphasize the necessity of a procedure to avoid loss of data.

Experimental

The apparatus used in this updating experiment consists of a braille information processor, a teleprinter with a keyboard, and an acoustic coupler or MODEM. The braille information processor is a model P2 VersaBraille, version C2. The procedure described below worked equally well with earlier versions, which are presented elsewhere (3, 8). Both the VersaBraille and the teleprinter are connected to the MODEM by a "Y" cable (9). This provides a means to verify the "loss of data" and allows each unit to be enabled separately or simultaneously. Once the configuration control parameters are fixed for compatibility with the DIALOG system, the VersaBraille is then set in remote mode. It is understood that the operator, being blind, is at ease with the remote mode and computer braille (10). On some occasions, a knowledge of the teleprinter's keyboard did appear helpful. In this case, the important keys were marked with transparent braille-embossed DYMO tape.

Results

The experimental assays on bibliographic updating with a database gave rise to the following procedure. In this procedure, the commands and search expressions are exactly the same as specified in the GUIDE TO DIALOG SEARCHING (2). The difference resides only in their written form, which the blind operator enters in computer braille on the VersaBraille. Each element of the sequence (SIGNON, SEARCH, TYPE LOGOFF) has its own chapter on the braillecassette.

GETTING ONLINE or SIGNON needs no special action, except for the detection of the carrier light on the acoustic coupler or on the MODEM. This is accomplished with a light sensor (11) or with the Optacon (12). Once the network is chosen and the password entered, the operator may read rapidly the news and status messages. Normally, this information adds up to less than 1000 characters (a full page buffer in the VersaBraille). By pressing occasionally the "LOCATE" key, the operator can verify the fullness of the page buffer. When about 800 characters have been transmitted, he then saves the output on a new page of the braillecassette. The appearance of the prompt character indicates the end of this first chapter.

SEARCH is the title of the newly opened second chapter. It includes the request for connection to a specific file. In this case, chemical information is sought by the command BEGIN 311 (b 311). After the unit cost and the latest update, the prompt character reappears. Moving to the next blank page in this SEARCH chapter, the operator enters a maximum of five words chosen from his keyword strategy. These keywords were previously written on a paperbraille list. It is on this list that the set number and the number of records are assigned to each keyword as they are given. Here again, the operator verifies the character count. Using the "word" key, he scans the page and constructs a search expression. Returning to the current cursor position, the search expression is then entered. At this point, the user verifies the first records of this retrieval by writing the command: T Si/6/X (where T = TYPE; i = set number; 6 = format option; X = first records). If these records are not relevant, he then forms a different keyword combination. If the results of the search are pertinent, they are stored in a chapter called TYPE.

A new chapter, TYPE, is opened on the VersaBraille unit. The command, T Si/5/1 $- x$ (where x = number of the last record), lists the selected records. As the first lines are displayed, the received data are stored on the VersaBraille tape.

[1]Author to whom correspondence may be addressed.
[2]Operator of the VersaBraille unit.

During the automatic transfer, no scrolling occurs. The "LOCATE" key is then used to see if the data characters are still coming in. When the output is completed, the VersaBraille system is switched to operative function. If the search is continued, new chapters would be opened and executed: SEARCH2, TYPE2 as describd above.

LOGOFF is the name of the fourth and last chapter of the CA retrieval. It is also the command used to terminate the search session. Furthermore, if desired, the END/SAVE command is utilised to store the search strategy.

Discussion and conclusion

Two facts should be kept in mind as one reads through these lines. First, the operator types the entries in braille code, e.g., computer braille, which is translated to the ASCII data communication code. Thus, the VersaBraille system produces the same electronic signals as those from a standard terminal. Secondly, the display appears on a tactile array which is a 20-character window that can be moved through the page buffer.

The sequence described in the procedure is based on the methods for simulation (13). Obviously, online communication with a database requires careful planning. Therefore, it is necessary to inscribe the keywords and their priority in the SEARCH on a paperbraille list. This list is organized in such a way as to permit the subsequent inscription of the set numbers and their corresponding number of records.

The critical point, at which scrolling occurs most frequently, is the SEARCH section. The use of more than five keywords will also result in scrolling of information. And the operator is confronted with a large amount of data that causes confusion. Consequently, the utilization of the paperbraille list demands less concentration on his part, therefore, reducing the online cost of the search. However, the operator must be cautious to write and form the final search expression on his paperbraille list. This step eliminates the need to back scan the set combinations on the braillecassette.

If a pause is needed, the database offers certain options, such as a ten-minute hold or a temporary save. During this break, the paperbraille list can be reviewed with ease.

It was found in the TYPE section that an average of 75 lines at 30 cps were lost when the operator does a manual page advance. The change to automatic transfer mode prevents any loss of data.

Personal online searching of literature is an indispensable and powerful tool (14) to retrieve and update scientific information. During the past year, the CA SEARCH was done entirely with a VersaBraille unit and the DIALOG Information Retrieval Services. This automated method proved to be more efficient and more rapid than the search in the printed form of the CA. Nonetheless, the updating procedure is but one of the many applications of the VersaBraille system in the field of chemical research and education (15).

In the last ten years, many technological tools have enhanced the capabilities of the physically handicapped to fulfill the duties of a normal work load. Braille information processors, in this case the VersaBraille, offer a means for the blind worker to succeed on the same basis as his sighted colleagues. Recent developments in computer technology have broadened the horizon for many visually impaired individuals. Technology may resolve the numerous problems inherent in a physical handicap. However, a huge problem still remains unsolved; it concerns the discrimatory attitude as pointed out in the manual (16) of the ACS Committee on the Handicapped.

This paper is dedicated to Professor Camille Sandorfy on the occasion of his 65th birthday

KAIDEE LEE and SANFORD LIPSKY. Can. J. Chem. **63**, 1374 (1985).

The photocurrent of *N,N,N',N'*-tetramethyl-*p*-phenylenediamine (TMPD) in 2,2,4-trimethylpentane (isooctane) excited at 5.90 eV has been studied as a function of temperature from 195 to 298 K both in the absence and presence of the electron scavengers *n*-perfluoroheptane and perfluoromethylcyclohexane. Using an exponential radial distribution function for geminate pair separation distances with range parameter corrected to accommodate its change with temperature, it is found that the photoejection quantum yield of TMPD is essentially independent of temperature from 298 K to ≃250 K and then increases slightly (by ≃20%) on further cooling to 195 K. In the presence of electron scavengers there is a contribution to the magnitude of the range parameter from the action of the scavenger to pre-thermalize the epithermal electron. The temperature dependence of this contribution is analyzed and found to increase with decreasing temperature.

KAIDEE LEE et SANFORD LIPSKY. Can. J. Chem. **63**, 1374 (1985).

Opérant à des températures allant de 195 à 298 K, tant en présence qu'en l'absence de pièges à électrons comme le *n*-perfluoroheptane et la perfluorométhylcyclohexane, on a étudié le photocourant de la *N,N,N',N'*-tétraméthyl *p*-phénylènediamine (TMPD) dans le triméthyl-2,2,4 pentane (isooctane) excité à 5,90 eV. On a utilisé une fonction de distribution radiale exponentielle pour les distances qui séparent les paires géminées et, à l'aide de cette fonction qui inclut un paramètre de correction des intervalles permettant d'accomoder sa variation avec la température, on a pu établir que le rendement quantique pour la photoéjection de la TMPD est pratiquement indépendant de la température de 298 K jusqu'à environ 250 K et que, si la température est abaissée jusqu'à 195 K, ce rendement n'augmente que légèrement (environ 20%). En présence de pièges à électrons, il existe une contribution à l'amplitude du paramètre d'intervalle qui provient de l'action des pièges à électrons qui pré-thermalisent les électrons épithermaux. On a analysé la variation de cette contribution avec la température et on a trouvé qu'elle augmente avec une diminution de la température.

[Traduit par le journal]

Introduction

Tetramethyl-*p*-phenylenediamine (TMPD) photoionizes in 2,2,4-trimethylpentane (isooctane) at 25°C at a threshold energy of 4.66 eV (1). Above this energy a photocurrent is observed, the quantum yield of which, ψ_J can be expressed as

$$[1]\quad \psi_J = \phi_{\pm}\int_0^{\infty} P_{esc}(r)f(r)r^2\mathrm{d}r$$

where $\phi_{\pm}$ is the primary quantum yield for electron ejection, $P_{esc}(r)$ is the Coulomb escape probability of the thermalized geminate ion-pair at a separation distance, r, and $f(r)$ is the radial probability density of ion-pair separation distances.

From measurement of the temperature dependence of ψ_J, Holroyd and Russell (1) in their early work on TMPD photoionization, estimated that $\phi_{\pm}$ increased with increasing temperature (over the range $T \simeq 196-298$ K) with an activation energy of ≃870 cal/mol. This estimate was based on the assumption that $r^2f(r)$ could be represented by a Dirac delta function, $\delta(r-b)$ with range b, independent of temperature. Our purpose in this Note is to attempt to improve on this estimate.

We utilize a radial distribution function

$$[2]\quad f(r) = \frac{\alpha^3}{2}\mathrm{e}^{-\alpha r}$$

which has been demonstrated to predict well the observed dependence of ψ_J on electric field strength (2, 3). The range parameter, α, in eq. [2] is also corrected to accommodate its change with temperature due to an implicit dependence on the liquid density. This latter dependence derives, in part, from the effect of density on the "stopping power" of the liquid and, in part, from the effect of density on the vertical polarization energy of the ion-pair. By changing this polarization energy, there is effected a change in the threshold energy for photoejection and, therefore, a change in the kinetic energy with which the electron is ejected.

As will be documented in what follows, we find that the temperature dependence of $\phi_{\pm}$ is much weaker than estimated by Holroyd and Russell (1) and, in fact, $\phi_{\pm}$ increases slightly at low temperatures. Also we have utilized this temperature dependence of $\phi_{\pm}$ to extract the temperature dependence of α when electron scavengers are present that act to pre-thermalize the epithermal geminate electron. In the presence of such scavengers, eq. [2] has been shown to continue to predict the field dependence of ψ_J and also the dependence of ψ_J on scavenger concentration, c, when α is given the empirical form:

$$[3]\quad \alpha = (\gamma_0 + \gamma_1 c)^{1/3}$$

where $\gamma_0^{1/3}$ is the range parameter at $c = 0$ and γ_1 is a measure of the epithermal electron-scavenger thermalization cross-section (3, 4).

Experimental

A D_2 lamp (Bausch & Lomb, DE50A) was used as a light source. The light was dispersed through a 0.3 m f/5.3 monochromator (McPherson, Model 218) operating at bandpasses ranging from 1.86 nm to 4.77 nm. The light from the monochromator was focused by an f/1.8 LiF lens into a temperature-controlled cell consisting of three concentric cylinders to each of which was fused a 0.16 cm thick Supersil quartz window. Two 1 × 2 cm stainless steel electrodes, parallel to and separated from each other by 0.533 cm were situated in the innermost cylinder with their edges in close contact with the

[1]Present address: Physics Division, Argonne National Laboratory, 9700 South Cass Avenue, Argonne, IL 60439, U.S.A.

quartz window (clearance ca. 0.01 cm). The electrodes were welded under He-arc, each to a Kovar rod, to which was spot-welded, under He, a braided molybdenum wire extending through the feedthrough tube to external electrical connections. Temperature control of the cell solution was achieved by varying the flow rate of precooled nitrogen, directed through a capillary to the space between the middle and the innermost cylinders. The temperature was monitored by thermocouples. The solution temperature was calibrated by the difference in temperatures recorded in the solution and in the nitrogen jacket when the electric field was absent. The solution temperature, thus determined, is accurate to within ±1 K. Thermal insulation of the cell was provided by a vacuum jacket formed by the outermost and middle cylinders.

TMPD (Aldrich) was purified by vacuum sublimation followed by zone refining. Isooctane (Aldrich), perfluoroheptane (kindly donated by the 3M Company), and perfluoromethylcyclohexane (PCR Research Chemicals) were purified by passing through silica gel which had been activated at 150°C for 24 h.

The TMPD concentrations were $2-3 \times 10^{-4}$ *M*. The quencher concentrations were within the range of 0.0090–0.07 *M*, the upper limit being set by the quencher solubility at the lowest temperature employed in each case. All the solutions were carefully purged with N_2. The excitation energy was 5.90 eV (210 nm) and the applied electric field strength, 3.75 kV/cm in all experiments reported here.

Results and discussion

According to the Onsager theory (5), at low field strenghts, E, the geminate pair escape probability, $P_{esc}(r)$, approaches

$$[4] \quad P_{esc}(r) = [\exp(-r_0/r)]\left(1 + \frac{\epsilon r_0^2}{2|e|}E\right)$$

where $r_0 = e^2/\epsilon kT$, e is the electron charge, ϵ is the dielectric constant, and k the Boltzmann constant. The next highest term in the expansion of P_{esc} in powers of E (6) contributes less than 1% at the applied field strength of E = 3.75 kV/cm and at all temperatures studied and can be safely ignored. Substitution of eqs. [2] and [4] into eq. [1] gives

$$[5] \quad \psi_J = \phi_{\pm}\left(1 + \frac{\epsilon r_0^2}{2|e|}E\right)(\alpha r_0)^{3/2}\, K_3(2\sqrt{\alpha r_0})$$

where K_3 is the modified Bessel function of order 3 (4, 7).

The dashed curve in Fig. 1 represents a least-square fit of the right hand side of eq. [5] to the experimental dependence of ψ_J on T (shown as open circles and normalized to unity at T = 298 K), using α as a least-square parameter and assuming that $\phi_{\pm}$ and α are temperature independent (i.e., that the entire temperature dependence of ψ_J resides in ϵ and r_0). The failure of this assumption is clearly indicated by the poorness of the fit and the large discrepancy between the least-square estimate of α (0.0563 Å^{-1}) and the more reliable value obtained from the field dependence of ψ_J (0.0361 Å^{-1}) (3).[2]

To correct for the temperature dependence of α at a fixed initial kinetic energy, K, of the ejected electron, we presume α to be proportional to the isooctane density, ρ. This approximation, which assumes a temperature invariant thermalization cross-section, has been successfully applied in predicting the temperature dependence of the free-ion yield in high-energy radiation experiments (8–10). Next, in order to accommodate the dependence of K on temperature (at a fixed excitation energy) we utilize the connection between the TMPD ioniz-

[2]In ref. 3, α is reported as 0.0370 Å^{-1} at an excitation energy of 5.80 eV. The value 0.0361 Å^{-1} at 5.90 eV is obtained by interpolation and normalization of the data of Choi *et al.* (2).

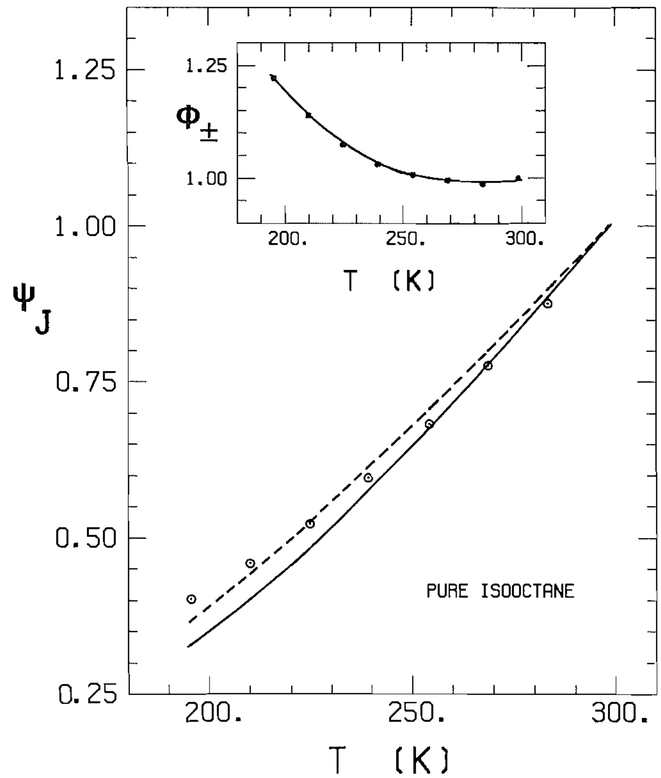

FIG. 1. The dependence of the yield of photocurrent, ψ_J, on temperature T, for TMPD in pure isooctane excited at 5.90 eV. The yield is normalized to unity at T = 298 K. Open circles: experimental data; dashed curve: least-square fit of eq. [5] with α as least-square parameter and assuming α and $\phi_{\pm}$ to be independent of T; solid curve: eq. [5] with α corrected for temperature variation but assuming $\phi_{\pm}$ independent of T. Insert: variation of $\phi_{\pm}$ with T (normalized to unity at 298 K).

ation potentials in liquid (I_l) and gas (I_g) phases and the "vertical" polarization energies of TMPD$^+$ (P_+) and e$^-$ (V_0), i.e.,

$$[6] \quad I_l = I_g + P_+ + V_0$$

The temperature dependence of P_+ was obtained from the Born equation:

$$[7] \quad P_+ = \frac{-e^2}{2r_i}\left(1 - \frac{1}{\epsilon}\right)$$

using Holroyd's value of $e^2/2r_i$ = 2.89 eV (1) and the temperature dependence of the isooctane dielectric constant, ϵ. To evaluate the temperature dependence of V_0, we have adopted the model of Springett, Jortner, and Cohen (11) which has previously been successfully applied by Fueki, Feng, and Kevan (12) and by Holroyd and Russell (1). Our results for both P_+ and V_0 are given in Table 1 and show that from 298 K to 195 K the ionization potential of TMPD increases by 0.083 eV. The effect of this on α was then deduced from the experimental dependence of α on excitation energy, ϵ_{exc}, as determined at 25°C by Choi, Sethi, and Braun (2). Normalizing their results to a value of α = 0.0361 Å^{-1} at ϵ_{exc} = 5.90 eV (3), the change in α with a small change in temperature, ΔT, is obtained by simply incrementing α by $(d\alpha/d\epsilon_{exc})\Delta K$ where $\Delta K = -\Delta I_l$.

The total change in α with temperature was therefore constructed from

TABLE 1. Temperature dependence of the range parameter, α, of photoejected electrons from TMPD in isooctane at ϵ_{exc} = 5.90 eV and of some parameters that determine this dependence in the absence of scavengers

T (K)	ρ (g cm^{-3})	P_+ (eV)	V_0 (eV)	α ($Å^{-1}$)
298	0.689	−1.395	−0.17	0.0361
283	0.700	−1.411	−0.15	0.0368
269	0.712	−1.427	−0.12	0.0375
254	0.724	−1.442	−0.099	0.0382
239	0.736	−1.457	−0.071	0.0390
225	0.748	−1.471	−0.043	0.0397
210	0.760	−1.486	−0.013	0.0405
195	0.772	−1.500	+0.018	0.0413

$$[8] \quad \alpha(T + \Delta T) = \left[\alpha(T) + \left(\frac{d\alpha}{d\epsilon_{exc}}\right)_T \Delta K\right] \frac{\rho(T + \Delta T)}{\rho(T)}$$

where α (T = 298 K) is the range parameter at ϵ_{exc} = 5.90 eV. The results of this calculation are displayed in Table 1. Using these values of α, the right hand side of eq. [5] was reevaluated and is shown plotted as the solid line in Fig. 1 (again normalized to unity at T = 298 K). The discrepancy between this solid line and the experimental points (open circles) we presume now to derive mainly from the variation of $\phi_\pm$ with temperature. The insert in Fig. 1 shows this variation to be less than 1% from 298 K to 250 K and to increase by about 20% from 250 K to 195 K. Since the photoejection process appears to be an autoionization (13), this relatively small increase in $\phi_\pm$ may be attributed to the competition between electron ejection and neutral decay channels of the autoionizing state that are temperature activated.

The temperature dependence of ψ_J has also been measured in the presence of various concentrations of n-perfluoroheptane and perfluoromethylcyclohexane. Figure 2 shows some of this data (normalized to unity at T = 298 K) for six concentrations, c, of n-perfluoroheptane. It will be noted that as c increases, ψ_J becomes increasingly sensitive to T. This has also been observed for perfluoromethylcyclohexane (4). Since most of the temperature dependence of ψ_J resides in r_0, this increased sensitivity can be simply explained as due to the effect of the scavenger to make the distribution function, $f(r)$, more spatially compact. This consequence of epithermal "scavenging" has already been established, and more definitively, from the effect of scavengers to alter the field dependence of ψ_J (3).

Using the variation of $\phi_\pm$ with temperature, we can now, via eq. [5], extract from the data of Fig. 2, the range parameter α as a function of both temperature and scavenger concentration. According to eq. [3], α^3 should be linear on c with intercept of γ_0 and slope of γ_1. Such plots are shown at various temperatures in the insert of Fig. 2. The solid lines are linear least-square fits. The cube roots of the intercepts at the four temperatures of 298 K, 268 K, 240 K, and 207 K are, respectively, 0.037 $Å^{-1}$, 0.039 $Å^{-1}$, 0.040 $Å^{-1}$, and 0.042 $Å^{-1}$, all of which agree reasonably well with the range parameters obtained at c = 0 (see Table 1). The slopes, γ_1, increase monotonically with decrease in temperature, i.e., 1.0 × 10^{-3} at 298 K, 1.1 × 10^{-3} at 268 K, 1.2 × 10^{-3} at 240 K, and 1.5 × 10^{-3} at 207 K. Similar results are obtained for perfluoromethylcyclohexane, but γ_1 increases about half as fast over the same temperature range. Some of the temperature dependence of γ_1 may be attributed to the dependence on density of the electron mean free path (which is implicitly contained in γ_1 as is suggested by dimensional arguments (4)). The remaining change is associated with the effect of temperature on the cross-section, σ, of the epithermal scavenging process via its dependence on both the kinetic energy, K, of the ejected electron and on the electron affinity, $-V_0$, of the fluid. The kinetic energy effect, as has been previously discussed (4), should increase σ as T (and, therefore, K), declines whereas increase in V_0 with decreasing T (see Table 1) will, through Franck–Condon factors, increase or decrease σ depending on the nature of the scavenger (14–16). It is this latter effect which we presume to be responsible for the relatively small difference between n-perfluoroheptane and perfluoromethylcyclohexane.

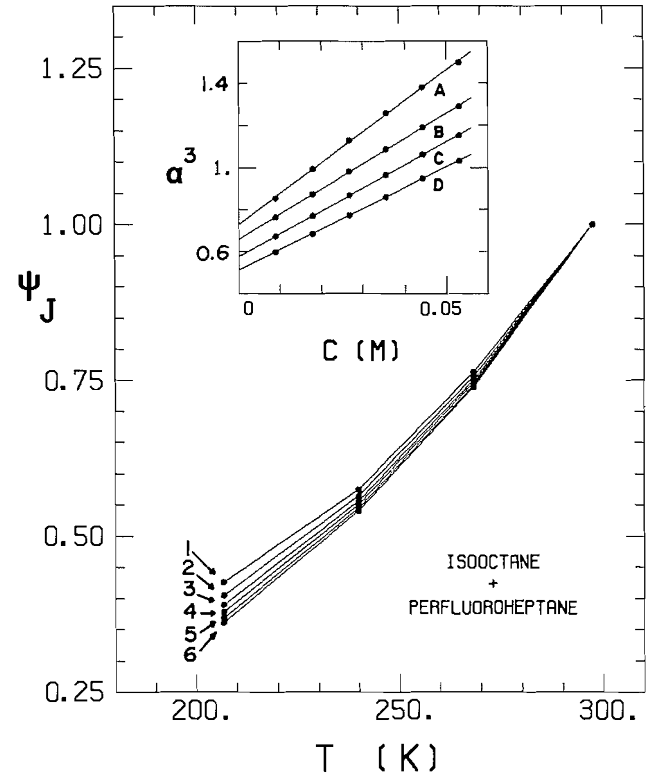

FIG. 2. The dependence of the yield of photocurrent, ψ_J, on temperature, T, for TMPD in isooctane at various concentrations, c, of n-perfluoroheptane and excited at 5.90 eV. The yields are all normalized to unity at T = 298 K. Closed circles: experimental data at 0.00892 M (*1*), 0.0178 M (*2*), 0.0266 M (*3*), 0.0355 M (*4*), 0.0442 M (*5*), and 0.0530 M (*6*). The solid lines merely connect the data points. Insert: plot of α^3 (units of 10^{-4} $Å^{-3}$) vs. c at various temperatures 207 K (*A*), 240 K (*B*), 268 K (*C*), 298 K (*D*). The solid lines are linear least-square fits to eq. [3].

Received July 4, 1984

This paper is dedicated to Professor Camille Sandorfy on the occasion of his 65th birthday

D. C. MOULE and K. H. K. NG. Can. J. Chem. **63**, 1378 (1985).

The first electronic absorption system of acetaldehyde was recorded in the vapour phase at room temperature. The many-banded spectrum proved to be very complex and it was only at the extreme red edge of the absorption that the pattern became simple enough to analyze. The major experimental requirement was a high pressure × path length (500 Torr × 168 m). Spectra were interpreted in terms of the torsional mode ν'_{15} and ν''_{15} attached to the ν'_{14} out-of-plane bending mode. Both modes were highly Franck–Condon active and the 0^0_0 band at 27240.4 cm^{-1} was not directly observed. The barrier to rotation of the methyl group was 618.5 cm^{-1}. More surprising was the observation that the methyl group undergoes a rotation from a $\tilde{X}$ eclipsed configuration to a staggered configuration. The intensity of the ν'_{14} quantum addition and its position in the spectrum suggest that the aldehydic hydrogen is nonplanar in the $\tilde{a}$ state.

D. C. MOULE and K. H. K. NG. Can. J. Chem. **63**, 1378 (1985).

Opérant en phase gazeuse et à la température ambiante, on a enregistré le spectre de la première absorption électronique de l'acétaldéhyde. Le spectre comporte plusieurs bandes, il est très complexe et ce n'est que l'extrémité du spectre qui absorbe dans le rouge que l'on a pu analyser. L'exigence expérimentale principale est une valeur élevée pour la pression × la longueur de parcours (500 Torr × 168 m). On a interprété les spectres en fonction des modes de torsion ν'_{15} et ν''_{15} attachés au mode de vibration angulaire hors-plan ν'_{14}. Les deux modes sont très actifs dans la région de Franck–Condon et on n'a pas pu observer la bande 0^0_0 à 27240,4 cm^{-1}. La barrière à la rotation du groupe méthyle est égale à 618,5 cm^{-1}. Le résultat le plus surprenant est l'observation que le groupe méthyle subit une rotation qui le fait passer de la configuration éclipsée $\tilde{X}$ vers une configuration décalée. L'intensité de l'addition du quantum ν'_{14} ainsi que sa position dans le spectre suggèrent que, dans l'état $\tilde{a}$, l'hydrogène aldéhydique n'est pas dans le plan.

[Traduit par le journal]

Introduction

The banded absorption system of acetaldehyde at 330 nm has been the subject of a number of studies. The assignment of the vibrational fine structure has been hampered by a spectral congestion which extends throughout this system and progress has been slow. Rao and Rao (1), the first investigators to attempt a complete vibrational assignment, placed the singlet–singlet system origin at 320.4 nm. Somewhat later, Giddings and Innes (2) revised this value upwards to 348.4 nm. More recently, Hubbard, Bocian, and Birge (3) combined a medium resolution absorption study with resolved laser fluorescence to place the origin at 346.4 nm. This problem has been solved by the powerful technique of supersonic jet spectroscopy. Noble, Apel, and Lee (4) observed the excitation spectrum of a sample of jet cooled CH_3CHO which was free from the complications of thermally induced vibration–rotation fine structure. They were able to unequivocally fix the origin at 29771 cm^{-1} (335.9 nm), the V'_3 three-fold barrier to 653 cm^{-1} and the O^-—O^+ inversion splitting to 33 cm^{-1}.

Ng (5) has made a study of this system in absorption at path lengths up to 168 m and temperatures down to −90°C. He established that a large number of bands in the 363–351 nm region were temperature insensitive. It follows from the jet studies that these bands must result from the spin forbidden triplet–singlet $\tilde{a}^3A'' \leftarrow \tilde{X}^1A'$ electronic transition. The other information which is available for the $\tilde{a}$ state comes from emission spectroscopy. CH_3CHO is known to fluoresce as well as phosphoresce, and a difficulty has been to resolve contributions of each from the total emission spectrum. Schuh *et al.* (6) optically excited the $\tilde{A}$ singlet system at 320 nm with a YAG laser-pumped dye laser system. They observed that the resulting emission could be resolved into a very short-lived 5 ns component and a much longer 25 μs emission. These they attributed to the separate $\tilde{A} \rightarrow \tilde{X}$, S–S and $\tilde{a} \rightarrow \tilde{X}$, T–S fluorescence and phosphorescence emissions. From the onset of the phosphorescence, the origin of the T–S system may be estimated to lie in the region of 369 nm.

Recently (7), we have made a vibronic assignment of the $\tilde{a} \leftarrow \tilde{X}$ and $\tilde{A} \leftarrow \tilde{X}$ transitions in CH_3CHS. We felt that we might be able to combine the $E(\tilde{A}) - E(\tilde{a})$ intervals from this work with the corresponding values for CH_2S and CH_2O and arrive at an estimate for CH_3CHO. Also, the vibronic fine structure of the T–S system is expected to be simplified as a result of the more stringent vibronic–spin–orbit selection rules. That is, the inversion doublets which greatly complicate the S–S system are expected to be absent in the T–S spectrum.

Experimental

Acetaldehyde, CH_3CHO, was obtained from B.D.H. Chemicals, Ltd., and was purified by trap-to-trap distillation. The spectra at room temperature were recorded at a path length of 168 m which was obtained from 28 traversals of a 6 m multiple reflection cell. The pressures of the vapour in these experiments varied from 25 to 500 Torr. A total of 250 mL of acetaldehyde was required to fill the cell at its highest pressure which made it impractical to record the spectrum of the D compounds in the region of the origin. The temperature effect was observed with a 2 m multiple reflection cell (8) which could be thermostated at temperatures down to −90°C. Spectra were recorded under conditions of modest resolution with a Bausch and Lomb 1.5 m grating spectrograph. The plate holder on this instrument is fixed so that wavelengths shorter than 375 nm are recorded in the second order and those greater than 375 nm in the first order. A 450 W Xe arc was used as a source of continuous radiation and a Fe–Ne hollow cathode lamp for the iron standard lines. Spectra were calibrated from 10-fold enlargements of the photographic film.

Results and discussion

The starting point for the assignment of the bands in the T–S came from the jet-laser studies of the S–S system which place the origin of the $\tilde{A} \leftarrow \tilde{X}$ system at 29771 cm^{-1}. The separation between the $\tilde{A}$ singlet and $\tilde{a}$ triplet states $\Delta E = E(\tilde{A}) - E(\tilde{a})$ was estimated from CH_2O (9), CH_2S (9), and CH_3CHS (10). The data were combined as follows: $\Delta E(CH_3CHO) = \Delta E(CH_2O)$. $\Delta E(CH_3CHS)/\Delta E(CH_2S) = (2996)(1522)/(1853) = 2461$ cm^{-1}. The origin band for the $\tilde{a} \leftarrow \tilde{X}$ transition therefore should lie at $29771 - 2461 = 27310$ cm^{-1}. A second estimate comes from the phosphorescence of Schuh *et al.* (6) who placed the origin at 27100 cm^{-1}.

The temperature effect showed that the bands in the 26900–28200 cm^{-1} region do not bear ground state excitation energies of 1571 cm^{-1} or greater and they are assigned to the T–S system. The key to the analysis was the recognition that the ν_{15} torsional mode was highly active and formed long progressions in the spectrum. As a consequence of the large Boltzmann populations, the hot bands bearing ground state excitation of ν''_{15} should be present in the spectrum. Sequences and progressions in ν''_{15} should be among the first bands encountered at the red edge of the spectrum.

The bands at 27098.5 and 26985.3 are free from congestion and are among the few simple bands that were observed. It was felt that these were hot bands and that their assignments could be obtained by comparing their frequency difference of 113.2 cm^{-1} against ground state energy levels derived from microwave data (11). From a combination of all pairs of levels in ν''_{15} the difference $15_{2A} - 15_{1E} = 111.5$ cm^{-1}. This would give the lower frequency band the assignment 15^{0A}_{2A} and the higher band 15^{0E}_{1E}. These bands would fix the 0^{0A}_{0A} origin at $27098.5 + 140.1 = 27238.6$ or alternatively $26985.3 + 251.6 = 27236.9$ cm^{-1}. The assignment of the S–S bands at higher frequencies by Noble *et al.* (4) was used as an aid in establishing the quantum numbering for the $\tilde{a}$ state. For the S–S system the ν'_{15} torsional frequency is $15^{1E} - 15^{0A} = 185.5$. With this interval as a guide, we assigned the bands at 27278.3 and 27148.1 cm^{-1} to the transitions 15^{1A}_{1A} and 15^{1E}_{2E}. The other assignments locked into the vibrational pattern. A strong band at 27474.4 cm^{-1} is +334.0 cm^{-1} above the 0^{0A}_{0A} origin. It is assigned to the transition 15^{2A}_{0A}. The identification of the band at 26967.3 as 15^{0E}_{2E} completed the assignment of the pure torsional transitions.

Many bands are found in this region which could not be fitted into the above assignments. These bands were too close to the origin to be classified as fundamentals and they were attributed to hot bands derived from higher vibrational states. The pattern of the vibrational fine structure at energies in excess of +300 cm^{-1} from the T–S origin can be inferred from the jet spectra of Noble *et al.* (4). These authors observed the low frequency quanta of the out-of-plane bending mode 14^1_0 and 14^2_0 as well as the single quantum addition 10^1_0. As the quanta were attached to each other and to quanta of the torsional mode they found that the spectrum became complex very quickly. Even though the vibronic–spin–orbit selection rules (12) do not allow for 14^1_0 here we felt that a detailed analysis of our room temperature spectrum would not be realistic. Instead we made a search for the two strongest members of the progression $14^2_0\ 15^{2A}_{0A}$ and $10^1_0\ 15^{2A}_{0A}$. Bands were found at 27934.6 and 28074.6 cm^{-1} which lead to $2\nu'_{14} = 500.2$ and $\nu'_{10} = 360.2$ cm^{-1}. These values are to be compared to the 487 and 373 cm^{-1} set obtained for the $\tilde{A}$ state. While in principle it should be possible to verify these assignments by identifying other members of the ν'_{15} progression, the complexity of the absorption allows for too many alternatives. Rather, a detailed analysis of this region will have to await methods more powerful than absorption spectroscopy.

TABLE 1. Assignment of the main vibrational features in the 362–371 region of acetaldehyde

Assignment	Observed	Calculated[a]
15^{2A}_{0A}	27574.4	27576.21

Discussion

When interaction with others vibrational modes is neglected, the torsional motion in acetaldehyde is governed by the Hamiltonian

$$[1]\quad H = -\frac{Fd^2}{d\phi^2} + \frac{V_3}{2}(1 - \cos 3\phi)$$

where F is the reduced rotational constant, V_3 is the height of the barrier to internal rotation, and ϕ the torsional angle. Following the method of Lewis *et al.* (13), the Hamiltonian matrix corresponding to eq. [1] was set up in terms of sine and cosine basis functions and diagonalized to yield the eigenvalues and wavefunctions. The energies of the transitions allowed by the selection rules $A_1 \leftrightarrow A_1$, $A_2 \leftrightarrow A_2$, $E \leftrightarrow E$ were calculated by combining levels of the upper $\tilde{a}$ state with the lower $\tilde{X}$ ground state. The V''_3 and F'' parameters of the lower state were recalculated from the levels derived from the microwave spectrum (11) using the model function of eq. [1]. The calculated transition energies were fitted to the torsional data by a least squares procedure in which the electronic origin V'_3 and F' were refined. The fit to the data is illustrated in Table 1 and the resulting spectroscopic parameters are given in Table 2. An inspection of the spectrum at 27240.4 cm^{-1} indicates that this region does not contain bands which can be assigned to the 0^{0A}_{0A} origin. The two estimates for the position of the origin do bracket the value observed here in that the correlation between CH_3CHS, CH_2S, and CH_2O gave 27310 cm^{-1} while the phosphorescence measurements gave 27100 cm^{-1}.

Torsional dynamics for CH_3CHO have been determined for the 4 states $\tilde{X}$, $\tilde{a}$, $\tilde{A}$, and $\tilde{B}$. The parameters are tabulated in Table 2. It is not too surprising that the V_3 and F constants of

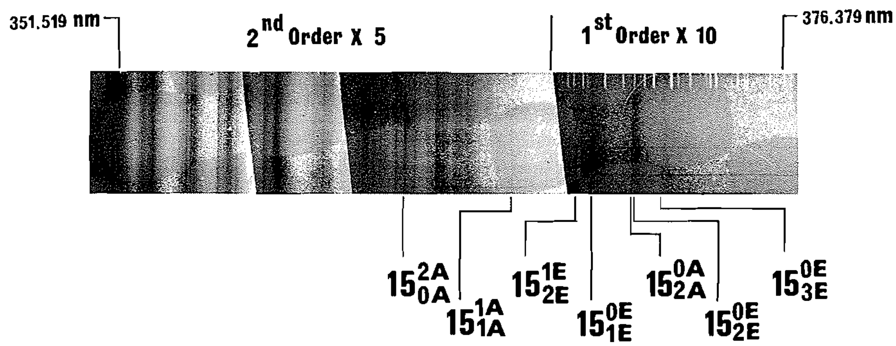

FIG. 1. Low resolution absorption spectrum of acetaldehyde CH_3CHO recorded at a pressure × path length of 500 Torr × 168 m.

the $\tilde{a}$ and $\tilde{A}$ states resemble each other since the states are derived from the same nπ^* electron configurations. What is unusual is that the gross features of the torsional structure in the $\tilde{B} \leftarrow \tilde{X}$ Rydberg transition are very different from those of the two lower $\tilde{a}$, $\tilde{A} \leftarrow \tilde{X}$ valence transitions. That is, the n $\rightarrow$ 3s transition is characterized by a 0^0_0 band which is very strong and dominates the spectrum whereas in the n $\rightarrow \pi^*$ transitions this band is too weak to be observed. A simple explanation for these results is to assume that on excitation to the $\tilde{B}$ state the methyl group does not change its conformation. The three-fold barriers would be in phase (eclipsed conformations in both states). The strongest transitions are found in Δv sequences in which successive members decrease rapidly because of their increasing Boltzmann factors. Indeed, Gordon (16) has been able to replicate the intensity patterns in the $\tilde{B} \leftarrow \tilde{X}$ spectrum from a Franck–Condon calculation based on this model. On the other hand, the intensity profiles of the torsional transitions in the near uv systems would be rationalized by a change in conformation. On electronic excitation, the methyl hydrogens would undergo a rotation from their eclipsed ground state configuration to a staggered configuration in the upper state. In this case the strongest transitions in absorption would come from the $v'' = 0$ level and terminate on levels just below the top of the upper barrier. Noble and Lee (15) used this model to explain the observed intensities in the torsional progressions in the $\tilde{A} \leftarrow \tilde{X}$ spectrum. The problem here is compounded by the inversion motion of the aldehyde wagging mode.

A major question which emerges from this analysis is why the methyl group undergoes a torsional distortion on excitation to the nπ^* state yet retains its conformation on excitation to the n3s state. A somewhat simplistic viewpoint is to break the structural changes into two parts: those arising from the removal of the electron from the n orbital and those resulting from the addition of the electron to either the 3s or π^* orbitals. Information about the first process comes from a comparison of the Rydberg spectrum (14) with the first transition in the photoelectron spectrum (17). Both of these transitions have in common the loss of the n electron. Also, they have torsional transitions which are Franck–Condon allowed. It follows that the removal of the n electron in the n $\rightarrow \pi^*$ process is not responsible for the observed torsional distortion. Rather, the source for this effect comes from the addition of the electron to the π^* orbital. The effects of the methyl group on the out-of-plane electronic structure of a molecule can be treated by simple Hückel MO theory. If the methyl group is assumed to have a three-fold symmetry, the σ MO's can be decomposed into the representations $2a' + a''$ of the C_s point group. This means that one of the σ orbitals transforms as a''. It is constructed from a set of 1s orbitals at the non-planar methyl hydrogens and has a node at the molecular plane. It has the resemblance of a p orbital. Three other p orbitals are required to complete the description of the π network. Two of these are located in the CHO frame, at the carbonyl carbon and oxygen atoms while the fourth is at the methyl carbon. Figure 2 shows the arrangement. This model is not unlike that of the butadiene system in which 4π MO's are derived from 4p type AO's. The order of these orbitals in decreasing stability would be (a) + + + +, (b) + + − −, (c) + − − +, and (d) + − + −. In the $\tilde{X}$ state of the molecule, the lowest orbitals (a) and (b) would be fully occupied. The $\tilde{a}$ or $\tilde{A}$ states which are arrived at by n $\rightarrow \pi^*$ excitation have the configuration $(a)^2(b)^2(c)^1$. If weak interactions were postulated between the terminal orbitals it is clear that (a) and (c) would give bonding end-to-end contribution whereas (b) and (d) would be antibonding. Simple MO theory predicts that the *trans* isomer would be the preferred conformer for the $\tilde{X}$ and $\tilde{B}$ states and that the $\tilde{a}$ and $\tilde{A}$ states should adopt a *cis* conformation.

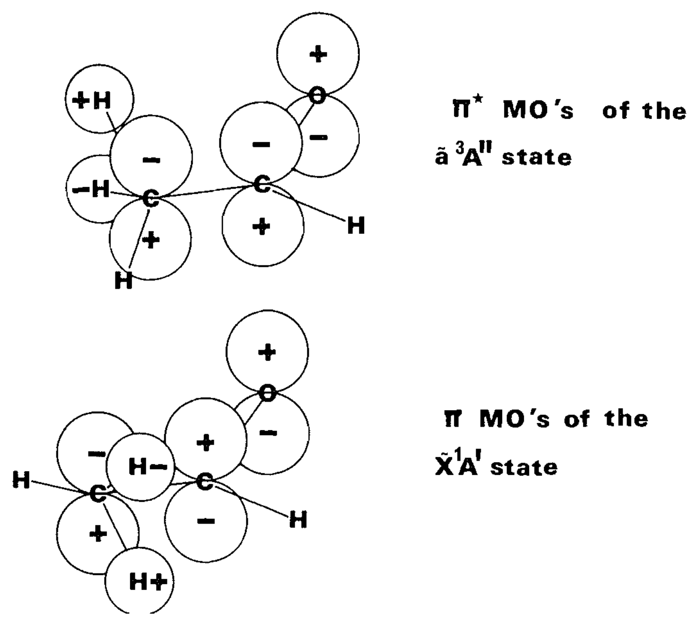

FIG. 2. Conjugative Hückel MO model for the second and third MO's of acetaldehyde. The AO's on the C_1, C_2, and O centers are p-type while the AO on the hydrogens are s-type.

The microwave spectrum (11) clearly shows that the methyl group eclipses the carbonyl double bond. That is, acetaldehyde adopts a configuration in the $\tilde{X}$ state which minimizes the antibonding repulsions between the p-type terminal orbitals. As n $\rightarrow$ 3s Rydberg excitation does not directly involve the π network, the model predicts that the methyl group would retain its conformation in the $\tilde{B}$ state, and that the torsional transitions would be Franck–Condon allowed in the spectrum. This is precisely what is observed in the multiphoton ionization spectrum of Heath *et al.* (14). The results obtained here for the T–S transition and those of Noble *et al.* (4) for the S–S transition can best be explained by a gross displacement of the torsional angle on excitation. The MO model predicts that the angle would be 60°. A complication here is that on $n \rightarrow \pi^*$ excitation the molecule undergoes a second out-of-plane distortion. This is the well-known tendency for the aldehyde hydrogen to assume a pyramidal geometry. In the $\tilde{A}$ state this leads to the inversion manifold of 0, 33, 487 cm^{-1}. While selection rules do not allow for the observation of the first quantum, we do see the 14^2 interval of 500.2 cm^{-1}. In the carbonyl series of molecules the $\tilde{a}$ states in general are known to have higher inversion barriers than the $\tilde{A}$ states. Certainly, the planarity of the CHO frame would be lost in the $\tilde{a}$ state of acetaldehyde and it is doubtful if the displacement of the torsional angle is a full 60°. In any case, a complete description of the dynamics of either the $\tilde{A}$ or the $\tilde{a}$ states would have to involve a set of coupled large amplitude oscillators, one of which would be described as an inversion doubling of the aldehyde hydrogen and the other would be methyl group internal rotation.

A survey of the molecules which have methyl groups next to chromophores which undergo $n \rightarrow \pi^*$ excitation shows that the phenomena observed here for acetaldehyde may be quite widespread. Ernsting *et al.* (18) and Gordon (19) have conclusively demonstrated that the torsional fine structure in the 675 nm band system of CH_3NO can only be explained by a *trans–cis* displacement on electronic excitation. Under supersonic jet conditions (20), the methyl-substituted glyoxals $CHOCCH_3O$ and $(CH_3CO)_2$ give rise to an excitation spectrum which displays progressions in the torsional mode. The spectra would be interpreted in terms of the model used here. Finally, we have recently observed the S–S and T–S transitions resulting from $n \rightarrow \pi^*$ excitations in thioacetone (7) and thioacetaldehyde (10). Again, the spectra are assigned on the basis of a *trans–cis* change in conformation. In all of the examples cited here the molecular frame is either rigidly planar or it is slightly flexible at the aldehydic carbon. None of these molecules undergo the pyramidal distortion which is observed for acetaldehyde yet they all display the same conformational displacements. The above analysis does suggest a generalization, namely, that the conformation of a methyl group attached to a frame undergoing $n \rightarrow \pi^*$ excitation adopts a 60° staggered configuration in the upper state.

Conclusions

The majority of bands in the room temperature absorption spectrum of acetaldehyde are too complex and too congested for a vibronic analysis. It was found that the extreme red edge of the spectrum, under conditions of a very long path of 168 m and a high pressure of 500 Torr, was sufficiently simple that an assignment could be made. The bands observed here were assigned to the spin-forbidden $\tilde{a}^3A'' \leftarrow \tilde{X}^1A'$, $n \rightarrow \pi^*$ transition. A correlation with the recent (4) jet spectrum fixed the 0_0^0 origin at 27240.4 cm^{-1} and the barrier in the triple-minimum torsional potential function to 618.5 cm^{-1}. The strength of the progression in the torsional mode was attributed to a change in the conformation of the methyl group on electronic excitation. The displacement was accounted for by a simple Hückel model in which the 1*s* AO's of the methyl group were conjugated into the 2*p* AO's which formed the π and π^* MO's. The equilibrium conformation was determined by the antibonding repulsions between the end orbitals with the $\tilde{X}$ and $\tilde{B}$ states favouring the *trans* form and the $\tilde{a}$ and $\tilde{A}$ states the *cis* form.

Intermolecular perturbation approach to specific solvent effects

Ottó B. Nagy

Laboratoire de Chimie Organique Physique, Université Catholique de Louvain, Bâtiment Lavoisier, 1, Pl. L. Pasteur, 1348-Louvain-la-Neuve, Belgium

Received July 13, 1984

This paper is dedicated to Professor Camille Sandorfy on the occasion of his 65th birthday

Ottó B. Nagy. Can. J. Chem. **63**, 1382 (1985).

One possible specific solvent effect, namely, the π-donor ability is considered in the light of simple intermolecular second order perturbation theory. By using the Polányi–Evans–Bell principle this theory predicts that increasing π-donor ability of solvent should decrease the reaction rate. This prediction is fully borne out by experimental data observed for the solvent effect on 4 + 2 cycloaddition of tetracyanoethylene to anthracene.

Ottó B. Nagy. Can. J. Chem. **63**, 1382 (1985).

Un effet de solvant spécifique possible, à savoir la capacité π-donneur, est considéré à la lumière d'une simple théorie perturbationnelle intermoléculaire de deuxième ordre. En utilisant le principe de Polányi–Evans–Bell, cette théorie prédit que l'augmentation de la capacité π-donneur du solvant doit diminuer la vitesse réactionnelle. Cette prédiction est complètement corroborée par les données expérimentales observées pour l'effet de solvant sur la cycloaddition 4 + 2 du tétracyanoethylène à l'anthracène.

Solute–solvent interactions are ubiquitous in most fields of chemistry and their importance in influencing the physico-chemical properties of molecules needs no further comments.

The complexity of the phenomena involved is quite appropriately reflected by the overwhelming literature on the subject. The approaches to the solution of this problem used by various authors range from purely empirical to highly sophisticated theoretical considerations (1, 2).

In this paper an intermolecular perturbational approach will be presented to account for specific solvent effects observed in reactions between neutral molecules. The astonishing success achieved by simple perturbation theory (3) especially in the frontier molecular orbital (FMO, which should mean, more appropriately, Fukui molecular orbitals) approximation (4) suggests that some aspects of solute–solvent interactions might be handled along the same line (6).

Solvent effects may be general or specific. General solvent effects are based on polarity and polarizability of solvent molecules while specific solvent effects stem from their n-donor, π-donor, and hydrogen bond forming abilities.

The hydrogen bond problem has been dealt with recently by Sandorfy and co-workers (7) who ably demonstrate the subtleties responsible for the therapeutic action of some anesthetic agents.

In the present paper only aprotic solvents will be examined. These must be divided into various classes (8) in which the specific and general effects intervene to different extents. Both spectroscopic and kinetic studies show, as a general rule, that wherever specific solvent effects are present they dominate the overall effects (8–13). This is clearly demonstrated also by the solvent effects observed for cycloaddition reactions. It is well known that 2 + 2 cycloaddition reactions usually involve a zwitterionic intermediate (14). This highly charged species is very sensitive to solvent polarity (general effect) and it is not surprising that one single straight line is observed when the logarithm of the second order rate constant (log k) is plotted against a general solvent effect parameter (E_T (2) or S_M (9)).

On the other hand, 4 + 2 cycloadditions are concerted reactions involving only uncharged species (15). The latter are especially sensitive to the n-donor or π-donor ability of the solvent (specific effects). Therefore a log k vs. S_M plot reveals the same solvent classes that have been observed previously (16), namely, halogenated, n-donor, and π-donor solvents.

Table 1. Reaction of tetracyanoethylene (A) with anthracene (D) in π-donor solvents (S) at T = 20 ± 0.1°C

[a]The data for solvents **1**, **2**, **3**, and **7** are taken from ref. 17.
[b]Solvent ionization potential (18).
[c]Highest occupied Hückel molecular orbital energy of solvent relative to the α = 0 level. These values have been calculated by perturbation theory (25, 26) using the following perturbation parameters: $\delta\alpha_r$ = −0.5β, + 0.5β, and +0.2β for —CH_3, —Cl, and —Br respectively (r designates the substituent bearing atom).

The results for the reaction of tetracyanoethylene with anthracene in π-donor solvents are given in Table 1.

They suggest that the monotonic decrease of reactivity when going from *o*-dichlorobenzene to mesitylene might be due to the increasing electron donor character of the solvent as reflected roughly by their ionization potentials (I_S). This seems reasonable in light of the detailed mechanism of this reaction. The very first step is the formation of a charge-transfer molecular complex (C) between the electron acceptor tetracyanoethylene (A) and the electron donor anthracene molecules (D). It has been suggested (10) that such complexes are true reaction intermediates sitting on the reaction path and their presence in any reaction must be quite general. It turned out that this is really so (19) and evidence was put forward demonstrating the intermediacy of these complexes (20, 21). We have therefore the following reaction scheme:

$$\mathrm{A} + \mathrm{D} \overset{K}{\rightleftharpoons} \mathrm{C} \overset{k}{\rightarrow} \text{product}$$

where C is a binary complex AD. If the solvent can also form

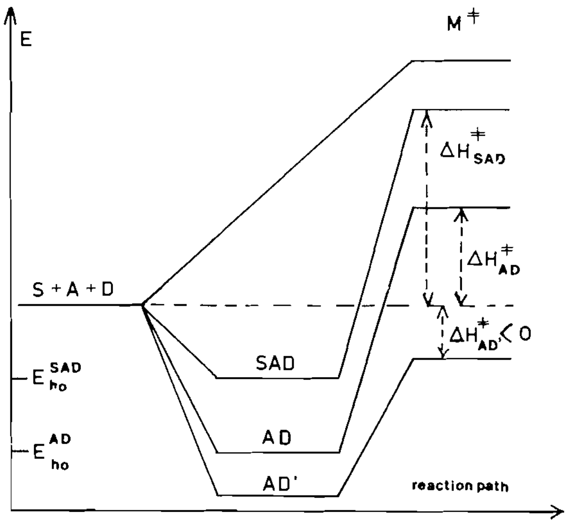

FIG. 1. Energetics of activation processes in bimolecular reaction. The energy of transition state ($M^{\ddagger}$) is strongly depending on the stability of the intermediate complex (AD, AD', or SAD).

molecular complexes with A, the solvent molecules (S) will compete with D and the formation of C will be more difficult:

$$A + D + S \rightleftharpoons AS + D \rightleftharpoons C' \rightarrow \text{product}$$

where C' is a ternary complex SAD. This reduces the reaction rate since the stability of C favours the reaction leading even to negative activation energies in favorable cases (20, 21) (Fig. 1).

Let us now see how this qualitative conclusion can be supported quantitatively by simple intermolecular perturbation theory.

Since the perturbation is an intermolecular one it is necessary to use second or higher order perturbation theory. The following treatment will be limited to second order.

According to standard perturbation theory (24, 25) the interaction of two energy levels E_i and E_j brings about a second order energy variation which is directly proportional to the perturbation matrix element and inversely proportional to the energy separation of the two interacting levels. In the present case the π-donor solvent molecules (S) interact with the π-acceptor substrate (A) leading to a new species AS. In the FMO approximation (Fig. 2) the energy of its lowest unoccupied orbital (E^{AS}_{lu}) is

$$[1] \quad E^{AS}_{lu} = E^{A}_{lu} + \frac{\langle l_A|H^S|h_S\rangle^2}{E^{A}_{lu} - E^{S}_{ho}}$$

It is directly related to the corresponding energy (E^{A}_{lu}) of the isolated acceptor molecule. The corresponding wave function (to first order, unnormalized) is

$$[2] \quad |l_{AS}\rangle = |l_A\rangle + \frac{\langle l_A|H^S|h_S\rangle}{E^{A}_{lu} - E^{S}_{ho}}|h_S\rangle$$

H^S is the solute–solvent interaction Hamiltonian; $|l_A\rangle$ and $|h_S\rangle$ are the zeroth order lowest unoccupied orbital of the acceptor and the highest occupied orbital of the solvent (donor), respectively; E^{A}_{lu} and E^{S}_{ho} are the corresponding energies. The interaction between the levels E_{ho} of the acceptor and E_{lu} of the donor will be neglected. On the other hand, the donor reagent (D) attacks the species AS to form a new intermediate SAD. The lowest unoccupied level of the AS complex of energy E^{AS}_{lu} and wave function $|l_{AS}\rangle$, interacts with the highest occupied

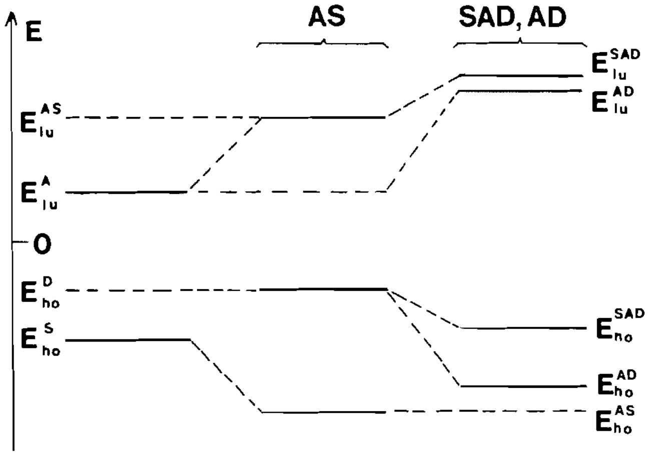

FIG. 2. Variation of energies of the highest occupied (E^{i}_{ho}) and lowest unoccupied (E^{i}_{lu}) orbitals of the interacting partners according to second order perturbation theory.

molecular orbital (E^{D}_{ho}, $|h_D\rangle$) of the donor reagent (D). The energy of the highest occupied level of the actual intermediate (E^{SAD}_{ho}) is given by

$$[3] \quad E^{SAD}_{ho} = E^{D}_{ho} + \frac{\langle l_{AS}|H^D|h_D\rangle^2}{E^{D}_{ho} - E^{AS}_{lu}}$$

where H^D is the perturbing Hamiltonian. Substituting eqs. [1] and [2] (normalized) into eq. [3] and remembering that $\langle h_S|H^D|h_D\rangle = 0$ in the zero differential overlap approximation (i.e., the donor reagent is not influenced by donor solvents) one obtains:

$$[4] \quad E^{SAD}_{ho} = E^{D}_{ho} + \langle l_A|H^D|h_D\rangle^2 \left[(E^{D}_{ho} - E^{A}_{lu}) - \frac{\langle l_A|H^S|h_S\rangle^2}{E^{A}_{lu} - E^{S}_{ho}} + \left(\frac{\langle l_A|H^S|h_S\rangle}{E^{A}_{lu} - E^{S}_{ho}}\right)^2 (E^{D}_{ho} - E^{A}_{lu}) - \left(\frac{\langle l_A|H^S|h_S\rangle}{E^{A}_{lu} - E^{S}_{ho}}\right)^4 (E^{A}_{lu} - E^{S}_{ho})\right]^{-1}$$

The last two higher order terms in the denominator may be safely neglected except when $(E^{A}_{lu} - E^{S}_{ho}) = (E^{A}_{lu} - E^{D}_{ho})$ in which case the third term becomes identical to the second one and it will be no longer negligible. The matrix element $\langle l_A|H^D|h_D\rangle \equiv K_1$ is constant throughout since it involves the same interacting partners, i.e., the two reagents. For the same reason $(E^{D}_{ho} - E^{A}_{lu}) \equiv K_2$. Since the solvents used are quite similar it is supposed that the matrix element $\langle l_A|H^S|h_S\rangle \equiv K_3$ does not vary much in the class of π-donor solvents and it may safely be considered as constant. Hence

$$[5] \quad E^{SAD}_{ho} = E^{D}_{ho} + \frac{K_1^2}{K_2 - K_3^2(E^{A}_{lu} - E^{S}_{ho})^{-1}}$$

This equation shows that when $(E^{A}_{lu} - E^{S}_{ho})$ decreases the acceptor–solvent interaction increases leading to a reduced absolute value of $(E^{SAD}_{ho} - E^{D}_{ho})$ (Fig. 2). This means that the intermediate charge transfer complex C' involving the solvent is less stabilized than the complex C which contains only the reagents.

The change in reagent (i.e., intermediate complex C') stability is directly related to the activation enthalpy $\Delta H^{\ddagger}$ through the Polányi–Evans–Bell principle (22, 23):

$$[6] \quad \Delta H^{\ddagger} = a + bE^{SAD}_{ho}$$

where a and b are constants (see also Fig. 1). This relation is valid in a homologous series if the various potential hyper-

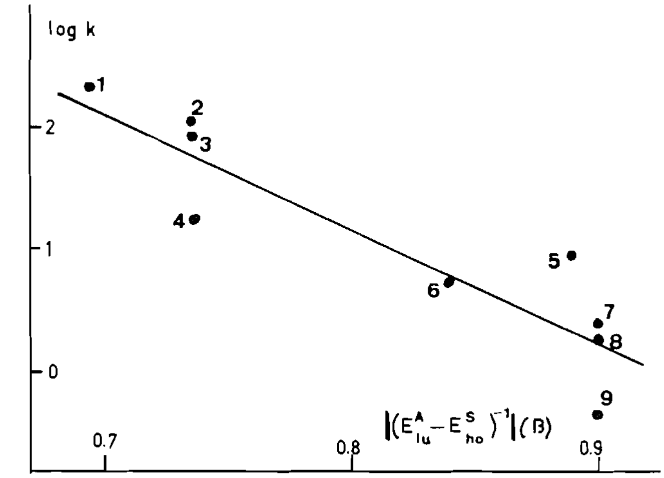

FIG. 3. Dependence of rate constants on the energy separation of interacting orbitals (eq. [7]).

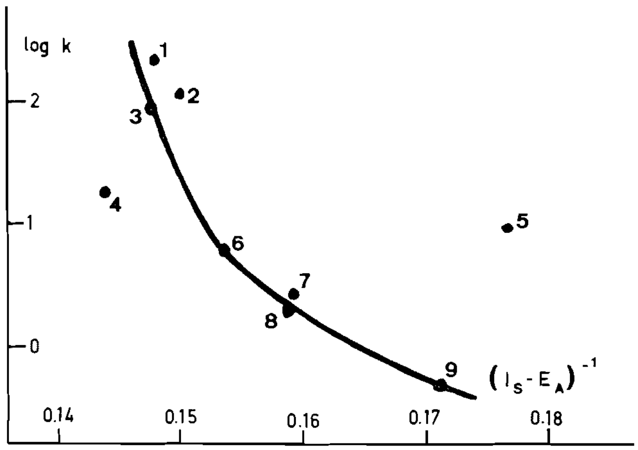

FIG. 4. Influence of solvent ionization potential on the reaction rate (eq. [8]).

surfaces do not cross and if the activation entropy remains reasonably constant. Therefore we have $\log k \sim -\Delta H^{\ddagger}$. Using eqs. [5] and [6] a new relationship is obtained which relates the experimental rate constants to the stabilization energy of the intermediate complex:

$$[7] \quad \log k = P + Q[1 - K(E^{A}_{lu} - E^{S}_{ho})^{-1}]^{-1}$$

where P, Q, and K are composite constants. By substituting the data of Table 1 into eq. [7] together with the value (Hückel approximation) $E^{A}_{lu} = -0.36\beta$ (27) of tetracyanoethylene one obtains Fig. 3 when $\log k$ is plotted as a function of $|(E^{A}_{lu} - E^{S}_{ho})^{-1}|$: $\log k = 8.63(\pm 1.32) - 9.29(\pm 1.62)|(E^{A}_{lu} - E^{S}_{ho})^{-1}|$, $r = 0.91$, $\sigma = 0.40$. It can be seen that the prediction of our model is corroborated by experiment: the reaction rate diminishes when the solvent–tetracyanoethylene interaction increases. It seems that the dispersion of certain points might be due to the simple first order approach used to calculate the E^{S}_{ho} values. As a consequence some solvents cannot be differentiated from each other (see Table 1). However, going to second order intramolecular perturbation does not much improve the situation (26).

A much better correlation is obtained when the theoretical energies are replaced by experimental values. According to Koopmans' theorem the energy of the highest occupied molecular orbital is directly related to the ionisation potential and by extension that of the lowest unoccupied orbital is given by the electron affinity. Therefore we have

$$E^{S}_{ho} = -I_S \text{ and } E^{A}_{lu} = -E_A$$

Using this substitution together with $E_A = 2.3$ eV (5), one obtains eq. [8] and Fig. 4:

$$[8] \quad \log k = P + Q[1 - K(I_S - E_A)^{-1}]^{-1}$$

It can be seen that both the monotonic decrease of reactivity with increasing $(I_S - E_A)^{-1}$ and the curved behaviour are correctly represented as required by eq. [7]. It should be noted that α-methylnaphthalene deviates considerably from the observed correlation. However, this behaviour disappears when empirical solvent effect parameters are used to account for specific effects (12).

In conclusion, it appears that simple intermolecular perturbation theory can successfully account for the specific solvent effect stemming from the π-donor ability of solvent molecules shedding new light on the behaviour of intermediate molecular complexes.

Experimental

Tetracyanoethylene (UCB) was purified by several sublimations while anthracene (UCB) was recrystallized from ethanol. All the solvents (Aldrich) used have been refluxed over P_2O_5 for 24 h and freshly distilled before use. The kinetic measurements have been carried out using a CARY 16 spectrophotometer according to standard procedure described in the literature (17, 21). The temperature was kept constant at 20 ± 0.1°C.

The search for fluorescence and the study of radiationless transitions of electronic excited states of NH_3^+

GÉRALD DUJARDIN AND SYDNEY LEACH

Laboratoire de Photophysique Moléculaire du C.N.R.S., Bâtiment 213, Université Paris-Sud, 91405 Orsay Cédex, France

Received July 16, 1984

This paper is dedicated to Professor Camille Sandorfy on the occasion of his 65th birthday

GÉRALD DUJARDIN and SYDNEY LEACH. Can. J. Chem. **63**, 1386 (1985).

Photoion – fluorescence photon coincidence experiments were carried out in order to detect the fluorescence of NH_3^+ which is expected to occur from that part of its $\tilde{A}$ electronic state that lies below the lowest dissociation limit. HeI and NeI sources were used to produce the ions. No NH_3^+ fluorescence was detected and upper limits for its quantum yield under our experimental conditions are given. We show that the lifetime of the $\tilde{A}$ state is probably very long, making it difficult to observe fluorescence. Furthermore, we argue that the molecular parameters and potential energy surfaces of the $\tilde{A}$ and $\tilde{X}$ states are such that resonance limit nonradiative coupling to high rovibrational levels of the $\tilde{X}$ state could be an efficient process for apparent intramolecular quenching of NH_3^+ $\tilde{A}$ state fluorescence.

GÉRALD DUJARDIN et SYDNEY LEACH. Can. J. Chem. **63**, 1386 (1985).

Une partie de l'état électronique $\tilde{A}$ de NH_3^+ se trouve en dessous de la limite de dissociation de cet ion. On a essayé de détecter la fluorescence de l'état $\tilde{A}$ par la technique de coincidences entre photoion et photon de fluorescence, en utilisant des sources HeI et NeI pour former les ions. Aucune fluorescence de NH_3^+ n'a été détectée; on donne des valeurs limites supérieures pour le rendement quantique dans nos conditions expérimentales. On montre que la durée de vie de l'état $\tilde{A}$ est probablement très longue, ce qui rend difficile l'observation de la fluorescence. De plus, on montre que les paramètres moléculaires et les surfaces d'énergie potentielle des états $\tilde{A}$ et $\tilde{X}$ devraient permettre un couplage non radiatif, de type limite de résonnance, aux niveaux rovibrationnels élevés de l'état $\tilde{X}$. Ceci correspond à un processus efficace pour l'extinction intramoléculaire apparente de la fluorescence de l'état $\tilde{A}$ de NH_3^+.

1. Introduction

Previous studies of the relaxation of excited electronic states of the gas phase ammonia cation have essentially been concerned with the dissociative mode (1).

The threshold of the lowest dissociative channel, $NH_3 + h\nu \rightarrow NH_2^+ + H + e^-$, is at 15.768 ± 0.008 eV as determined by photoionization mass spectrometry (2). This corresponds to an energy within the second photoelectron band (3, 4), forming the $\tilde{A}^2E'$ state of NH_3^+, which extends approximately from 14.98 to approximately 18 eV. Predissociation appears to be 100% above the threshold (5). However, since the origin of the first excited electronic state of NH_3^+, at 14.98 eV, lies below the first dissociation limit, radiative relaxation to the ground state of the ion at 10.15 eV is conceivable. Indeed Herzberg and Lew (6, 7) have observed an emission spectrum in the 2200–2400 Å region by electron beam excitation of a low pressure jet of ammonia gas. A band near 2338 Å was provisionally assigned to NH_3^+, whereas other features in this spectral region are possibly due to NH_2 or NH_2^+ (7). Electronic spectra of these species are of astrophysical interest, especially for cometary science.

In the present work we investigate whether NH_3^+ emits photons, by measurement of the fluorescence quantum yield of this ion using a photoion – fluorescence photon coincidence (PIFCO) (8, 9) technique. In an earlier attempt to measure this quantum yield, Devoret failed to find NH_3^+ fluorescence (10), but his experiment was carried out with a PIFCO apparatus of much lesser sensitivity (8) than the one used here (9).

The photoions are produced by excitation of NH_3 with HeI (21.22 eV) or NeI (16.85, 16.67 eV) radiation. In this excitation range, only two electronic states of the ammonia ion can be formed, the $\tilde{X}^2A_2''$ ground state and $\tilde{A}^2E'$ excited state, whose electron configurations and adiabatic ionization potentials (IP) (3, 4) are as follows:

$$(1a_1')^2\,(2a_1')^2\,(1e')^4\,(1a_2'')^1\ \tilde{X}^2A_2''\ \text{IP (adiab.)} = 10.15\ \text{eV}$$

$$(1a_1')^2\,(2a_1')^2\,(1e')^3\,(1a_2'')^2\ \tilde{A}^2E'\ \text{IP (adiab.)} = 14.98\ \text{eV}$$

The ion is assumed to have a D_{3h} planar geometry, at least in its ground state (see later), in conformity with the quasi-planar structure of the isoelectronic species CH_3 (11, 12).

2. Experimental and results

The photoion – fluorescence photon coincidence (PIFCO) technique has been described in detail elsewhere (8, 9) and only a short outline will be given here. NH_3 molecules are photoionized in a gas jet issuing from a hypodermic needle, using dc rare gas lamp sources (HeI, 21.22 eV; NeI, 16.85, 16.67 eV) mounted on a VUV monochromator. In our experiments the pressure of NH_3 was in the range 10^{-3} – 10^{-4} Torr (1 Torr = 133.3 Pa). Photoions and photoelectrons are accelerated away from the region of formation by an electric field ($\cong$100 V cm^{-1}) towards microchannel plates and a channeltron respectively. Fluorescence photons emitted from excited ions or molecules are detected at right angles by an EMI 9635QB photomultiplier (NeI excitation) or via a glass lens system and a cooled Hamamatsu R943 photomultiplier (HeI excitation). The fluorescence wavelength detection range was 175–360 nm and 380–910 nm with the respective photomultipliers.

Photoion–photoelectron coincidences are first recorded and give a time-of-flight mass analysis of parent and fragment photoions. After this analysis, which enabled us to identify the NH_3^+ time-of-flight, coincidences between fluorescnce photons and NH_3^+ photoions were counted as a function of delay time, together with the total number of photoions.

The fluorescence efficiency $\eta_F(NH_3^+)$ of the NH_3^+ ion can be deduced from the ratio N_c/N_i where N_c is the number of NH_3^+ photoion – fluorescence photon coincidences and N_i the number of photoions detected in the same time interval. Instrumental factors are determined and calibration carried out by experiments with N_2^+ $B^2\Sigma_u^+ - X^2\Sigma_g^+$ emission, which has unit fluorescence quantum yield (8, 9).

Coincidence counts between NH_3^+ ions and fluorescence photons were made under the following experimental conditions for HeI excitation: photon count rate, 10 photons/s; ion count rate, 6500 ions/s; cumulative count time, 120 h; photon detection region 380–910 nm with a Hamamatsu R943 photomultiplier. Experiments were also carried out with NeI excitation, using an EMI 9635QB photomultiplier (175–630 nm), which is several times more sensitive than the Hamamatsu photomultiplier over the common spectral detection range; cumulative count time was 13 h.

The PIFCO signal showed no evidence for NH_3^+ fluorescence. From the noise level in the false coincidence spectrum, using a coincidence gate open time of 500 ns, we determine the following upper limiting values of the fluorescence efficiency $\eta_F(NH_3^+)$:

HeI excitation, 380–910 nm detection range:

$$\eta_F(NH_3^+) < 4 \times 10^{-5}$$

NeI excitation, 175–630 nm detection range:

$$\eta_F(NH_3^+) < 2.5 \times 10^{-4}$$

The fluorescence quantum yield of an ion M^+ in the jth electronic state, averaged over accessible vibrational levels of this state, is given by the relation:

$$\bar{\Phi}_F(M^+, j) = \eta_F(M^+, j)/f(j)$$

where $f(j)$ is the branching ratio for forming the jth state with the particular excitation source used.

In the case of the $\tilde{A}(^2E')$ state of NH_3^+, a value of $f(\tilde{A}) \approx 0.75$ is obtained for HeI excitation (13, 14); electron impact dipole (e, 2e) coincidence measurements give $f(\tilde{A}) \approx 0.8$ for an excitation energy of 21.22 eV (15). NeI photons (16.85, 16.67 eV) are in the same energy range as the $\tilde{A}^2E'$ state of NH_3^+, which is moreover a region of incomplete ionization (1, 15). Thus it is difficult to obtain reliable $f(\tilde{A})$ values for NeI excitation. A calculated value $f(\tilde{A}) = 0.52$ has been given for 16.85 eV excitation energy (13).

The upper limiting value for the fluorescence quantum yield under our experimental conditions is:

$$\text{HeI excitation: } \bar{\Phi}_F(NH_3^+\ \tilde{A}^2E') < 5 \times 10^{-5}$$

Using the theoretical value of $f(\tilde{A}) = 0.52$ for NeI excitation, one obtains in this case:

$$\bar{\Phi}_F(NH_3^+\ \tilde{A}^2E') < 5 \times 10^{-4}$$

We recall that the fluorescence efficiency, and thus the $\bar{\Phi}_F$ values, were determined using a coincidence gate open time of 500 ns.

3. Discussion

The very low upper limiting value for NH_3^+ $\tilde{A}^2E'$ fluorescence indicates that it would be extremely difficult to observe a dispersed emission spectrum of NH_3^+. It is therefore highly unlikely that any of the observed features in the emission spectrum in the 2200–2400 Å region reported by Herzberg (6, 7) is due to NH_3^+.

The absence of $\tilde{A}^2E'$ state fluorescence from NH_3^+ vibronic levels between 14.98 and 15.77 eV could result from one, or the conjunction of a number of causes. Before presenting the relevant arguments, it is necessary to discuss the geometry of the $\tilde{A}$ and $\tilde{X}$ electronic states of NH_3^+.

From calculations and analysis of the first band in the photoelectron spectrum of NH_3, the ground state of the ion has been shown to be planar (13, 16, 17), as is the corresponding state of the isoelectronic species CH_3 whose optical spectrum has been analyzed (11, 12). However, although the $\tilde{A}^2E'$ state is usually expected to be pyrimidal (13), there is no direct evidence for this structure. On the basis of SCF calculations, Köppel *et al.* (18) do derive a C_{3v} structure for this state. However, it should be stated that for the analogous state of the isoelectronic species CH_3, calculations also predict a C_{3v} structure (19), but that a search for the $\tilde{A}^2E' - \tilde{X}^2A_1$ (C_{3v} notation) transition, which is optically allowed for a C_{3v} upper state, has been fruitless (11); we remark that this transition is forbidden in strict D_{3h} symmetry (see later).

Whether an XH_3 species will be pyrimidal or planar depends on a critical balance of opposing forces (20–22). Furthermore, existing calculations on the electronic states of NH_3^+ were made in order to interpret photoelectron spectra. In these calculations, a planar structure was imposed on the $\tilde{X}$ state (17), a pyrimidal structure on the $\tilde{A}$ state (18). The existence of a Jahn–Teller effect in the $\tilde{A}$ state adds to the complications of interpretation (13). Thus although one can advance reasonable theoretical arguments in favour of a pyrimidal structure for the $\tilde{A}$ state, we consider it best to retain an open mind on this question. The discussion which follows will therefore consider both possible structures, D_{3h} and C_{3v}, for the $\tilde{A}$ state of NH_3^+.

A. *The strength of the* $\tilde{A} \rightarrow \tilde{X}$ *radiative transition*

The $\tilde{A}^2E' - \tilde{X}^2A_2''$ transition is electric dipole forbidden if both electronic states are planar. In principle, the excitation of an a_2'' or an e' vibration in either upper or lower state could create a vibronically (Herzberg–Teller) (24) induced transition. The strength of the vibronic interaction depends on the proximity of a third electronic state having an allowed dipole transition to either the $\tilde{A}^2E'$ or $\tilde{X}^2A_2''$ states. The closest known state of this type is the $(2a_1'^{-1})\ ^2A_1'$ level which is at about 12 eV above $\tilde{A}^2E'$ and 17 eV above $\tilde{X}^2A_2''$ (3, 15, 23). For the large energy intervals, ΔE, involved, we predict that any Herzberg–Teller induced transition strength, which is a function of $(\Delta E)^{-2}$ (24), will be small. Thus we expect $\tau(\tilde{A})$, the lifetime of the $\tilde{A}^2E'$ state, to be long. If $\tau(\tilde{A})$ is greater than $\approx 50\ \mu s$, a true coincidence PIFCO signal would not be detectable unless the cumulative count time was impracticably long, i.e. one or more orders of magnitude greater than in the present experiments. If this is indeed the case, the true fluorescence quantum yield could be of the order of unity, our low value of $\bar{\Phi}_F$ being an effective value under our experimental conditions. Indeed, we estimate that under our experimental conditions $\tau(\tilde{A}) > 400\ \mu s$ if $\bar{\Phi}_F = 1$.

We remark, however, that this discussion posits a D_{3h} symmetry for both the $\tilde{A}$ and $\tilde{X}$ states. In the event that one of these states has a lesser symmetry, one must consider the common symmetry elements of the two states. If the $\tilde{A}$ state belongs to the C_{3v} point group, the $\tilde{A}$–$\tilde{X}$ transition would then become formally allowed and one would expect both ν_1 and ν_2 to be active vibrations since they become totally symmetric in the reduced point group. Thus, the $\tilde{A}$–$\tilde{X}$ transition may be considerably stronger, and the lifetime of the $\tilde{A}$ state considerably shorter, than would occur if a rigorous D_{3h} group symmetry applied.

B. *Intramolecular radiationless coupling*

B.1. *Coupling with the* $\tilde{X}$ *state*

Since no emission is observed, relaxation of the $\tilde{A}$ state below the dissociation limit must occur via an intramolecular process and implies, in the first instance, coupling of $\tilde{A}$ with isoenergetic levels of the $\tilde{X}$ state. In this case, not only the electronic matrix element coupling the two states must be nonzero but also the Franck–Condon vibrational overlap integrals $\langle\psi_v(\tilde{A})|\psi_v(\tilde{X})\rangle$. For the latter condition to be met requires that the potential energy surfaces of the $\tilde{A}$ and $\tilde{X}$ states approach each other or even intersect at energies in the 15-eV region.

Before examining the situation of the potential energy surfaces we will first consider another parameter, the density of vibrational levels ρ_v of the $\tilde{X}$ state in the $\tilde{A}$ state region. The order of magnitude of ρ_v provides an indication as to the particular case of the radiationless transition to be expected, each case having its own physical characteristics: resonance limit ($\rho_v \lesssim 10^2$ states/cm^{-1}), intermediate case ($\rho_v \approx 10^4 - 10^5$ states/cm^{-1}), or statistical limit ($\rho_v \gg 10^5$ states/cm^{-1}) (25). The density of states ρ_v was calculated by Haarhoff's approximation (26) to the harmonic density of states, using the following vibrational frequencies (in cm^{-1}), $\nu_1(a_1') = 3340$, $\nu_2(a_2'') = 950$, $\nu_3(e') = 3445$, $\nu_4(e') = 1630$, which were assumed to be the same in NH_3 (27) and NH_3^+. This calculation gave the following values: $\rho_v = 18$ states/cm^{-1} at the $\tilde{A}$ state origin level energy, and $\rho_v = 33$ states/cm^{-1} at the dissociation threshold. In spite of the approximations involved, these results should provide reliable order of magnitude values for ρ_v. The values obtained indicate that intramolecular coupling, if it exists, between the $\tilde{A}$ and $\tilde{X}$ states would correspond to the resonance limit of radiationless transitions. In this case one would expect lifetime lengthening of the $\tilde{A}$ state with respect to what might be expected on the basis of the integrated absorption intensity (apparent oscillator strength), i.e. manifestations of the Douglas effect (28). This would enhance the possibility of the existence and consequences of a long radiative lifetime, discussed in a previous section.

In discussing now the vibrational parameters involved in an $\tilde{A}$, $\tilde{X}$ intramolecular coupling process we first pay attention to the promoter modes. The D_{3h} symmetry selection rule for intramolecular radiationless coupling between the $\tilde{A}^2E'$ and $\tilde{X}^2A_2''$ states induced by vibrations (we neglect Coriolis coupling) is that the product $A_2'' \times E' \times \Gamma_v = A_1'$, where Γ_v is the representation of the vibrational mode(s) excited. This is satisfied by the condition $\Gamma_v = e''$; however, NH_3^+ is a "symmetry deficient" molecule in the Kasha sense (29), in that there is no vibrational mode of e'' symmetry. Therefore single one-quantum vibrations cannot correspond to promoting modes. Two quantum combinations $\nu_2(a_2'') + \nu_3(e')$ or $\nu_2(a_2'') + \nu_4(e')$ could give $\Gamma_v = e''$; however, these would be of second-order strength in inducing the $\tilde{A} \rightsquigarrow \tilde{X}$ radiationless transition. If the $\tilde{A}$ state has a C_{3v} structure, then each and any of the four vibrational modes could be single quantum promoting modes.

We now consider the relevant potential energy functions of the $\tilde{A}$ and $\tilde{X}$ states in order to investigate other parameters involved in both radiative and nonradiative transitions. Excitation of NH_3 with HeI or NeI radiation will form a progression of ν_2 vibrational levels in the $\tilde{A}$ state, and will also excite one or both of the e' vibrations (ν_3, ν_4) which induce Jahn–Teller coupling in this state (3, 4). Furthermore, because of the bonding nature of the $1e'$ orbital, there will be an important change of the r(NH) distance in forming the $\tilde{A}$ state, thus the a_1' vibration is also expected to be excited (18). We consider first the bending potential.

In Fig. 1 are shown potential energy functions of the ν_2 bending mode for NH_3^+ in the $\tilde{X}$ and $\tilde{A}$ states; the curves are adapted from published figures (17, 18) resulting from theoretical calculations made in order to interpret the vibrational

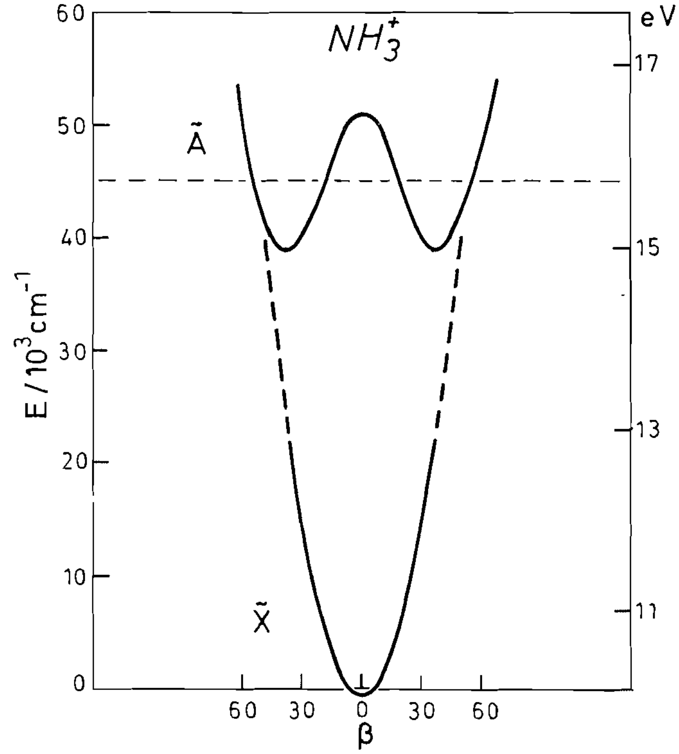

FIG. 1. Potential energy functions of the ν_2 bending mode of NH_3^+ in its $\tilde{X}$ ground state and $\tilde{A}$ first excited electronic state. β is the angle (in degrees) between an N—H bond and the plane vertical to the C_3 rotation axis. The horizontal dashed line at 15.77 eV coresponds to the threshold energy of the lowest dissociation channel $NH_3 + h\nu \rightarrow NH_2^+ + H + e^-$.

structure in the photoelectron spectrum of ammonia. The abscissa represents the angle β between the N—H bonds and the plane vertical to the C_3 rotation axis. The $v = 0$ energies of the states have been adjusted to their experimental values. We use this figure to make some qualitative statements, as follows.

(*i*) *Radiative transitions*: the equilibrium structure of the $\tilde{A}$ state is apparently pyrimidal, that of the $\tilde{X}$ state is planar. However, no geometry optimization was carried out for different bond angles (17, 18). On the basis of the equilibrium structures in Fig. 1, the D_{3h} symmetry selection rules for both radiative and nonradiative transitions between the $\tilde{A}^2E'$ and $\tilde{X}^2A_2''$ states will be somewhat relaxed. However, we note that radiative transitions from occupied vibrational levels in the $\tilde{A}$ state below the dissociation limit will have very high vibrational levels of the $\tilde{X}$ state as their final states. Thus the individual Franck–Condon factors for the vibrational components of an $\tilde{A} \rightarrow \tilde{X}$ transition will tend to be small, so that any emission from the $\tilde{A}$ state will be spread out over a very wide spectral region, rendering more difficult its detection.

(*ii*) *Nonradiative transitions*: extrapolation (thick dashed line) of the $\tilde{X}$ potential energy curve to higher energies indicates that it approaches close to the $\tilde{A}$ surface. This is conducive to intramolecular radiationless coupling between $\tilde{A}$ and $\tilde{X}$. The possibility of $\tilde{A}$, $\tilde{X}$ interaction might be amplified by concomitant Jahn–Teller effects involving e' vibration excitation. Furthermore, Köppel[1] has recently taken into account simultaneous shortening of the N—H bond in going from $\tilde{A}$ to $\tilde{X}$. He finds that the energy of the crossing between $\tilde{A}$ and $\tilde{X}$ is strong-

[1] H. Köppel, private communication (1983).

ly lowered and concludes that consideration only of the pure bending potential energy curves underestimates the importance of the $\tilde{A}-\tilde{X}$ conical intersection. The latter will, of course, give rise to strong non-adiabatic effects which would reinforce the Franck–Condon factors in $\tilde{A}-\tilde{X}$ coupling.

B.2. *Coupling with other states*

We now consider the possibility of states other than the $\tilde{X}$ state as final (or intermediate) states in intramolecular coupling with the $\tilde{A}$ state.

Low-lying $^2A_1'$ *Rydberg state*

Based on Walsh-rules arguments one can predict that the lowest Rydberg state of NH_3^+ should be planar and have the electron configuration $(1a_1')^2\,(2a_1')^2\,(1e')^4\,(3a_1')^1$ and electronic symmetry $^2A_1'$. The analogous state has been observed in optical absorption of the isoelectronic species CH_3 (11). According to Walsh-type diagrams (22), for a planar configuration, the vertical transition energy $(1e')^3\,(2a_2'')^2\,{}^2E' \leftarrow (1e')^4\,(2a_2'')^1\,{}^2A_2''$ would be expected to be greater than $(1e')^4\,(3a_1')^1\,{}^2A_1' \leftarrow (1e')^4\,(2a_2'')^1\,{}^2A_2$. Calculations of the Rydberg state have not been made, but for CH_3, *ab initio* SCF calculations (19) of vertical energies have been carried out for both the $^2E'$ and $^2A_1'$ states. For the $^2A_1'$ state the calculated energy agrees well with that observed; it is predicted to have an energy 71% of that of the $^2E'$ state. The $(3a_1')^1\,{}^2A_1'$ state of NH_3^+ is not accessible by photoelectron spectroscopy of NH_3 since its formation would involve a two-electron transition. If we assume that this state lies lower than $^2E'$ by the same proportion as that calculated for CH_3, then we would expect the vertical energy of the $3a_1'\,{}^2A_1'$ state of NH_3^+ to lie at $\approx$14.3 eV. Let us call this Rydberg state $\tilde{R}(^2A_1')$.

If the $\tilde{R}(^2A_1')$ state does indeed lie in this energy region, one would expect Herzberg–Teller interaction to occur since $^2A_1' - {}^2A_2''$ corresponds to an allowed dipole transition. If $\tilde{R}(^2A_1')$ and $\tilde{A}(^2E')$ are close in energy, mixed $\tilde{R}$, $\tilde{A}$ states resulting from vibronic close coupling (via e' promoter modes) could have a non-negligible dipole transition moment for radiative coupling with the $\tilde{X}$ state. The absence of observed emission for NH_3^+ implies that the $\tilde{R}(^2A_1')$ state lies well above A^2E', or that it lies considerably below the estimated 14.3 eV energy.[2]

Low-lying quartet state

The lowest quartet state of NH_3^+ would have the (single) electron configuration $(1e')^3\,(1a_2'')^1\,(2a_1')^1$ and thus be doubly excited with respect to the ground state of the ion. Its vertical energy would therefore be greater than either the $(1e')^4\,(2a_1')^1\,\tilde{R}(^2A_1')$ or the $(1e')^3\,(1a_2'')^2\,\tilde{A}(^2E')$ state. Thus we can discount coupling of the optically excited $\tilde{A}^2E'$ state with a low-lying quartet state as a source of intramolecular quenching of NH_3^+ fluorescence.

Conclusion

Although a significant proportion of the $\tilde{A}$ state of NH_3^+ lies below the dissociation limit, our PIFCO measurements have demonstrated that the fluorescence quantum yield of this state is effectively zero under our experimental conditions. We have examined various possible reasons for apparent intramolecular fluorescence quenching. From our discussion we conclude that the lifetime of the $\tilde{A}$ state could be very long, making it difficult to observe fluorescence. Furthermore, the molecular parameters and potential energy surfaces of the $\tilde{A}$ and $\tilde{X}$ states are such that resonance limit nonradiative coupling of the $\tilde{A}$ state to high rovibrational levels of the $\tilde{X}$ state of NH_3^+ is likely to be an efficient intramolecular quenching process. On the other hand we argue that neither the $(1e')^4\,(2a_1')^1\,{}^2A_1'$ Rydberg state, nor a low-lying quartet state of NH_3^+ is involved in the $\tilde{A}$ state relaxation process. Our results show that the emission band near 2338 Å observed in an electron impact experiment in ammonia is unlikely to be due to NH_3^+, as tentatively assigned by Herzberg (6, 7). Detailed information on this potentially important astrophysical species must be sought by experiments other than optical emission spectroscopy.

[2] NOTE ADDED IN PROOF: A recent calculation by A. R. Rossi and P. Avouris (ref. 30) predicts that the $\tilde{R}$ state lies 5–6 eV above the $\tilde{A}$ state.

Received July 17, 1984

This paper is dedicated to Professor Camille Sandorfy on the occasion of his 65th birthday

A. BERTOLUZZA, S. BONORA, G. FINI, and M. A. MORELLI. Can. J. Chem. **63**, 1390 (1985).

Dimyristoylphosphatidylcholine (DMPC) – polylysine and DMPC–histones systems have been studied by Raman spectroscopy and differential scanning calorimetry. The results of both techniques indicate that the interactions are mainly confined to the lipid–water interface. The protein fraction of histones giving rise to a partial penetration into the bilayer is not the lysine-rich fraction but rather the non-polar component of the proteins. On the basis of the results obtained, the formation of lipoprotein complexes between histones and DMPC appears to be ruled out.

A. BERTOLUZZA, S. BONORA, G. FINI et M. A. MORELLI. Can. J. Chem. **63**, 1390 (1985).

Faisant appel à la spectroscopie Raman ainsi qu'à la calorimétrie à balayage différenciel, on a étudié les systèmes dimyristoylphosphatidylcholines (DMPC) – polylysine et DMPC–histones. Les résultats obtenus par chacune des techniques indiquent que les interactions sont principalement confinées à l'interface lipide–eau. La fraction de la protéine des histones qui donne lieu à une pénétration partielle de la double couche n'est pas la fraction qui est riche en lysine; il s'agit plutôt de la portion des protéines qui n'est pas polaire. Sur la base des résultats obtenus, il semble que l'on doive exclure la possibilité de formation de complexes entre les histones et le DMPC.

[Traduit par le journal]

Introduction

Molecular interactions between proteins and phospholipids in biomembranes have been shown to play an important role in the regulation of both the structural and dynamical properties of biomembranes and of the biological function of membrane proteins. Intrinsic proteins show non-specific hydrophobic interactions with the hydrocarbon moiety of lipid molecules and the changes in the lipid environment are reflected in the protein activity. On the contrary, extrinsic proteins are bound by means of specific H-bond interactions with the polar head of lipid molecules on the surface of the bilayer. A previous paper (1) was devoted to a characterization of different types of surface binding of polypeptides on the lipid bilayer by means of differential scanning calorimetry and Raman spectroscopy. These interactions on the one hand can display a well-defined topography (which is important in determining the specific local interactions between lipid and extrinsic protein molecules), on the other hand can bring about a change in the core of the lipid membrane.

In an attempt to characterize the interactions between dimyristoylphosphatidylcholine (DMPC) and extrinsic proteins, the binding of polylysine and some basic proteins to DMPC liposomes has been investigated. Histones, which enter in the composition of chromatin, have been chosen as representatives of basic protein; it is known that the nucleohistone component of eukaryotic chromatin is organized as a string of closely packed subunits, called nucleosomes. Histones H4, H3, H2A, and H2B ("inner histones") are present in the core of nucleosomes. Lysine-rich histones H1 and H5 are located outside of the core particle, on the internucleosomal linker region, and are bound to DNA; they modulate the interactions between chromatin and phospholipids (2, 3). The importance of these interactions in the control of the genome activities has been frequently pointed out (4). This work was undertaken as a contribution to the study of the specific interactions between histones with different content of lysine and arginine, and lipidic multilayers.

This work is part of a research programme involving Raman and ir spectroscopic studies of the physico-chemical characterization and biological function of the phospholipids, as the more significant component of biological membranes. It follows previous papers devoted to the nature and strength of the hydrogen bond between phospholipids and proton donors (5), to the interactions between polyglycine and phospholipids (1), and to the interactions between water and cholesterol–phospholipid mixed liposomes and between water and phospholipid in an inert solvent (6).

Experimental

L-α-Dimyristoylphosphatidylcholine (DMPC), polylysine hydrobromide type II (average molecular weight 4000) (PL), histone type III-S from calf thymus (lysine rich, H1), and histone type VI-S from calf thymus (slightly lysine rich and H2A–H4 mixture) were obtained from Sigma Chemical Company; they were used without further purification. The average compositions of histones in lysine and arginine are: lysine 11.8 wt.% and arginine 17.6 wt.% for histone VI-S, lysine 25.6 wt.% and arginine 1.6 wt.% for histone III-S.

DMPC liposomes were prepared by adding the appropriate amount of aqueous solutions of PL or histones and twice-distilled water to a final lipid concentration of about 25 wt.%. The suspensions were incubated overnight at 10°C above the main phase transition temperature and then transferred into glass capillaries (1.5 mm) for Raman measurements.

Vibrational Raman spectra were recorded with a Jasco R-500 spectrometer equipped with a Lexel Ar^+ laser; typical laser power at sample was 300 mW at 488 nm. The spectral resolution was 3–5 cm^{-1}. All samples were contained in a cell holder regulated thermostatically to ±1°C. Eight repeated scans of the C—H and of the C—C

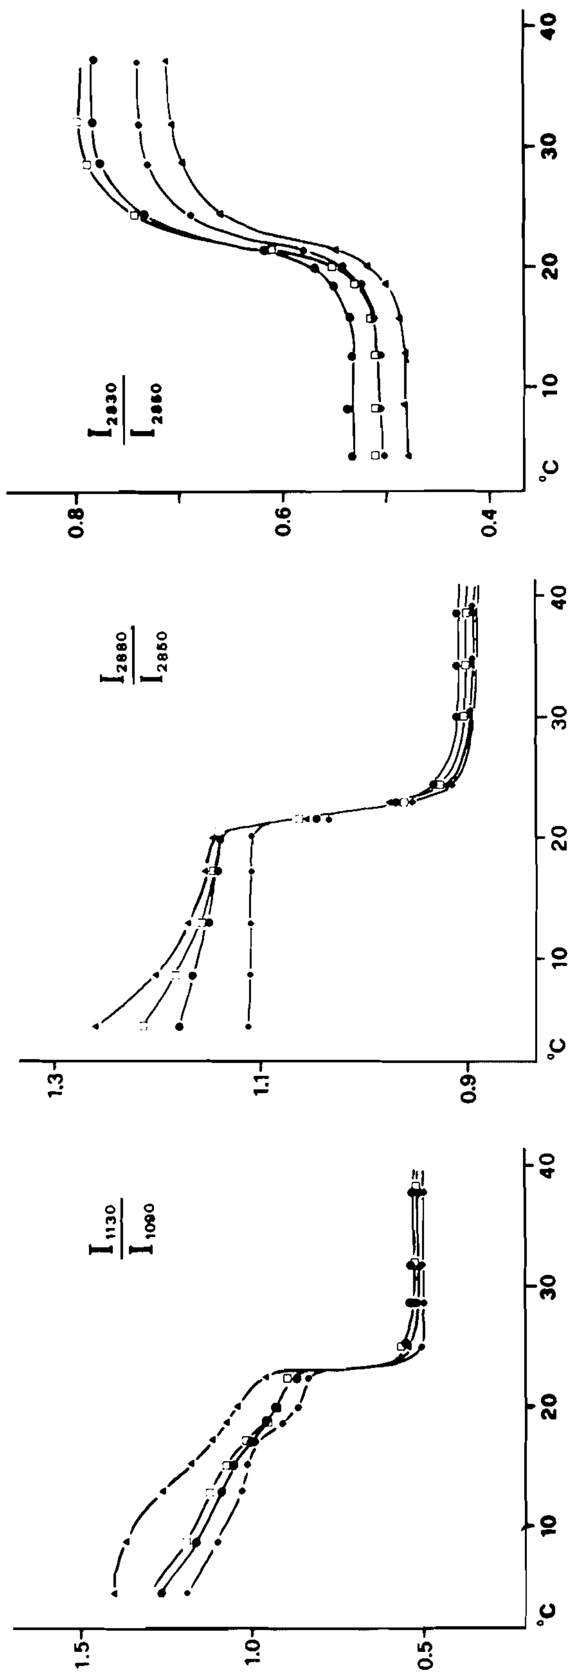

FIG. 1. Melting curves for dispersions of dimyristoylphosphatidylcholine: (▲) DMPC; (●) DMPC + 15% polylysine; (*) DMPC + 15% histone III-S; (□) DMPC + 15% histone VI-S.

stretching mode regions were computer averaged for each temperature to provide high quality spectra. Raman intensities were measured from peak heights (7).

Differential scanning calorimetry (DSC) measurements were obtained on a Mettler DSC 20 calorimeter. The heating rate was 2°C per min. To calibrate the temperature and enthalphy scales, indium samples were used; the temperature scale in the range studied was also calibrated with caprylic acid.

Results and discussion

The structure of the lipid bilayer and the modification induced by the interaction with polypeptides can be described in terms of various kinds of parameters. S_T and S_L order parameters are derived empirically from the $I_{1130\ \mathrm{cm}^{-1}}/I_{1090\ \mathrm{cm}^{-1}}$ and $I_{2880\ \mathrm{cm}^{-1}}/I_{2850\ \mathrm{cm}^{-1}}$ peak height intensity ratios of Raman spectra in the C—C and in the C—H stretching mode regions respectively (8). These parameters are widely used in the analysis of membrane structure by means of Raman spectroscopy, although they are of value only in qualitative analysis (9, 10). More recently Vogel and Stockburger (11) introduced a new order parameter

$$\frac{I_{1130\ \mathrm{cm}^{-1}}}{I_{1090\ \mathrm{cm}^{-1}}} = \frac{c_t P_t}{c_g(1 - P_t) + 0.45}$$

whereby the conformational order is expressed in terms of the probability of finding a C—C bond in a *trans* conformation (P_t) and is related to the $I_{1130\ \mathrm{cm}^{-1}}/I_{1090\ \mathrm{cm}^{-1}}$ intensity ratio. For the systems considered by us, the constant values which appear in the P_t expression have been calculated by assuming $P_t = 1$ in the solid phase at a low temperature (−30°C), and $P_t = 0.62$ for the fluid membrane, according to Vogel and Jänig (12). The assumption that $P_t = 1$ at −30°C is arbitrary because a gel–gel phase transition was observed at −60°C (13); however, P_t does not vary very much in the gel phase when the measured peak intensity ratios are higher than 1 and, consequently, we suppose that our assumption does not introduce a significant error.

Figure 1 shows the $I_{1130\ \mathrm{cm}^{-1}}/I_{1090\ \mathrm{cm}^{-1}}$, $I_{2880\ \mathrm{cm}^{-1}}/I_{2850\ \mathrm{cm}^{-1}}$, and $I_{2930\ \mathrm{cm}^{-1}}/I_{2850\ \mathrm{cm}^{-1}}$ intensity ratios as a function of temperature. The shape of the plot does not change noticeably when PL and proteins are added. In the gel phase some levelling of the curves is noted; this indicates a lowering of the number of C—C bonds in a *trans* conformation and a decrease of the lateral packing in the gel phase. This structure buffering effect has been noted also in the gel phase of DMPC liposomes when polyglycine is added (1).

S_T and S_L order parameters behave similarly to the intensity ratios shown in Fig. 1. The presence of PL and histones decreases both parameters below T_m. The greatest decrease is observed in the presence of histone III-S: S_T decreases by about 5% and S_L by about 30%.

The same conclusions can be drawn on the basis of the previously defined P_t order parameter. In this case the changes are smaller, actually about 2%. According to the order parameter of Vogel (11), the effect of PL and histones is so small that it cannot decrease appreciably the number of C—C bonds in a *trans* configuration in the acylic chains of lipid molecules below T_m ($P_t = 0.90 \pm 0.02$). Likewise, at a temperature above T_m, the behaviour of the P_t order parameter suggests that the number of C—C bonds remaining in a *trans* configuration after the melting does not change by addition of PL and histones ($P_t = 0.63 \pm 0.02$).

Figure 1 shows that the decrease of the lateral packing in the gel phase is maximum for the systems DMPC – histone III-S;

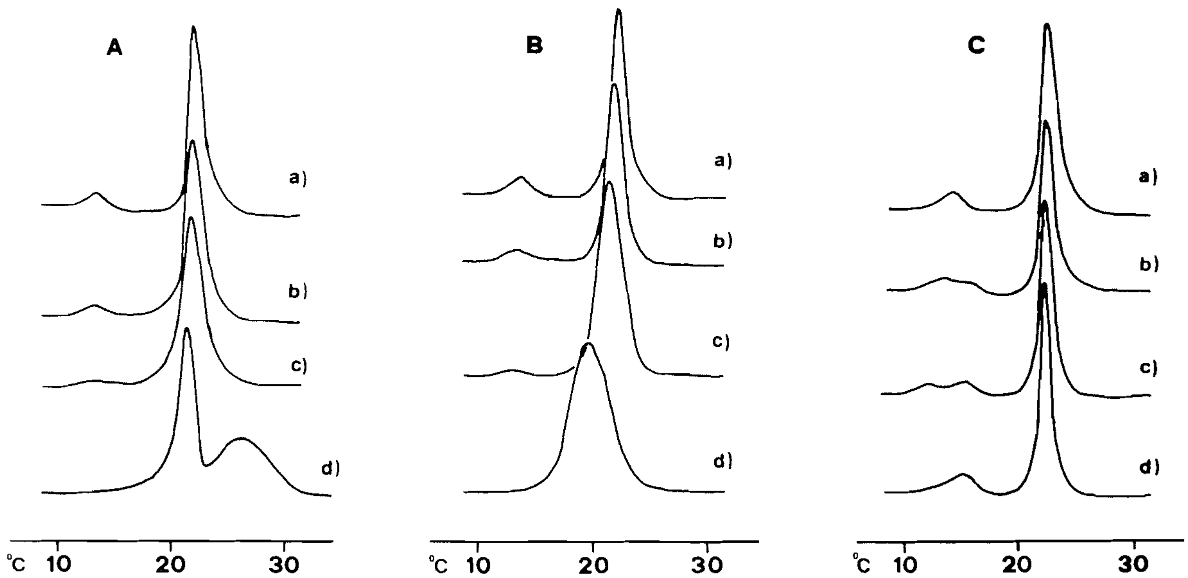

FIG. 2. Differential scanning calorimetry of dimyristoylphosphatidylcholine dispersions with increasing amount of (A) polylysine, (B) histone III-S, and (C) histone VI-S: (a) O wt.%; (b) 10 wt.%; (c) 25 wt.%; (d) 50 wt.%.

TABLE 1. Effects of polylysine and histones on the thermal data for dispersions of dimyristoylphosphatidylcholine

Dispersion	T_m(°C)	ΔH (kcal mol^{-1})
DMPC	22.5	5.4
+ 10% PL	22.3	4.9
+ 25% PL	22.1	4.7
+ 50% PL	21.9	5.4
+ 10% Hist. VI-S	22.8	5.6
+ 25% Hist. VI-S	22.6	5.9
+ 50% Hist. VI-S	22.5	6.3
+ 10% Hist. III-S	21.8	5.6
+ 25% Hist. III-S	21.3	5.9
+ 50% Hist. III-S	19.3	6.1

on the contrary, the effects of PL and histone VI-S are similar. This leads us to conclude that the observed structural modifications induced by histone III-S on the lipid bilayers are not due to the lysine fraction, but rather to the domains containing hydrophobic residues (14).

The $I_{2930\ cm^{-1}}/I_{2850\ cm^{-1}}$ intensity ratios increase both in the gel and in the liquid-crystalline phase when PL or histones are added to the lipid bilayers. PL and histone VI-S show similar effects above T_m; on the contrary, histone III-S induces only a slight enhancement of the measured intensity ratios in the liquid-crystalline phase. Similar effects were observed in DMPC–polyglycine systems and attributed to an increase of the mobility of —CH_3 terminal groups or to a lowering of the symmetry arising from the increased mobility of the acyl chains (1). Nevertheless, the increase observed in the systems actually considered might be far from meaningful because of the overlapping effect due to the strong bands of PL and histones over the 2900–3000 cm^{-1} spectral range (15, 16).

The systems DMPC–PL and DMPC–histones were studied up to a 0.5 w/w polypeptide/lipid weight ratio by means of differential scanning calorimetry. Raman investigations of the systems with the amount of PL and histones greater than 15% were not possible because of the overlapping of the spectra.

Figure 2 shows DSC heating curves of lipid bilayers with increasing amounts of added PL and histones. The presence of PL does not noticeably change T_m, whereas the associated ΔH decreases (Table 1). When a greater amount of PL is present (0.5 w/w) a doubling of the transition is observed, and a broad heat absorption appears at about 27°C. A similar behaviour observed in lipid–cholesterol mixed liposomes has been attributed to a lateral phase separation followed by melting, first of free lipid and then of a lipid–cholesterol complex (14). The presence of this broad absorption and the existence of a phase separation could explain the observed increase of ΔH. DSC heating curves of lipid bilayers with an increasing amount of histone III-S show a decrease of T_m with a broadening of the transition. On the contrary, in the system DMPC – histone VI-S, T_m and the width of the transition do not change, and a weak broad transition appears at about 16°C, its intensity increasing with the amount of histone present. Both histones increase ΔH of the main transition by about 15% for the systems with a 0.5 w/w ratio.

Conclusions

Polylysine exhibits mainly superficial interactions with dimyristoylphosphatidylcholine bilayers, as our Raman and DSC results suggest, both through the persistence of the pretransition, at least in the systems with a low amount of PL, and through the unaltered cooperativity of the melting processes as deduced from the width of the main transition. The presence of a broad transition at 27°C could be attributed to a phase separation induced by the great quantity of PL. The double melting process should indicate the setting up of regions with different amounts of bound PL on the bilayer surface.

PL–lipid molecular interactions are mainly due to the electrostatic binding between the polar groups of phospholipid and PL molecules, according to the literature data (17, 18). As a consequence of these superficial interactions, interchain interactions decrease, the rotational freedom of acyl chains increases in the gel phase, and the polarity of the hydrocarbon chain environment also increases, probably because of the penetration of water into the bilayers. A proof of the increased polarity can be deduced by the increase of the $I_{2930\ cm^{-1}}/I_{2850\ cm^{-1}}$ intensity ratio (9), provided we disregard overlapping effects, at least in the presence of small amounts of PL and histones.

Alternatively, a partial penetration of PL into the DMPC bilayers could be supposed, but this hypothesis seems to be less probable, because PL has been used as a model for an extrinsic protein (17, 18).

Histone VI-S (slightly lysine rich) behaves similarly to PL; indeed it does not affect the T_m of the main transition nor the cooperativity of the melting.

On the contrary, the addition of histone III-S (lysine rich) to DMPC bilayers decreases both T_m and the cooperativity of the melting process, as DSC data show. Moreover, in the gel phase, the protein exhibits a noticeable structure buffering effect, analogous to that observed with certain intrinsic proteins. The results suggest that partial penetration together with surface adsorption takes place and the behaviour is different from that of PL and similar to that of a few other basic proteins (18, 19). The different behaviour of PL and histone III-S, and the analogies between PL and histone VI-S, lead to the conclusion that the protein fraction giving rise to the partial penetration into the DMPC bilayers may not be the lysine-rich fraction present in the protein. Therefore, to explain the different behaviour of the two histones considered, the different content of non-polar aminoacids and the domain distribution into the protein molecule should be taken into account. In determining the bilayer properties, hydrophobic interactions between lipid and protein fraction may be, in this case, more important than the electrostatic interactions. According to this hypothesis, the partial penetration of a few basic proteins, such as for example myelin (18, 20), could be due to the non-polar component of the proteins, since no specific interactions between DMPC and basic aminoacids have been found.

For the systems examined we can conclude that the hydrophobic interactions of the non-polar domains of histone molecules have a more important role than the electrostatic binding between the polar groups in determining the structural and dynamical properties of biomembranes. Moreover, the formation of lipoprotein complexes between histones and DMPC can be ruled out.

Laboratoire de Spectrochimie Infrarouge et Raman, C.N.R.S., 2, rue Henry Dunant, 94320-Thiais, France

Reçu le 17 juillet 1984

Cet article est dédié au Professeur Camille Sandorfy à l'occasion de son 65^e anniversaire

ALAIN LAUTIÉ, MARIE-FRANCE LAUTIÉ et ALEXANDRE NOVAK. Can. J. Chem. **63**, 1394 (1985).

Les spectres infrarouges et Raman de l'acide deltique et de son dérivé deutérié cristallisés ont été étudiés entre 4000 et 20

cm^{-1}. Les 18 vibrations intramoléculaires ont été attribuées sur la base d'une symétrie moléculaire C_{2v}. Le groupe d'espace cristallin doit être $P\bar{1}$ ou $P2/m$ avec Z = 2. Les molécules sont associées entre elles par deux liaisons hydrogène OH...O différentes, très fortes et asymétriques, en formant probablement des chaînes infinies; les distances O...O sont estimées à 2,49 et 2,56 Å.

ALAIN LAUTIÉ, MARIE-FRANCE LAUTIÉ, and ALEXANDRE NOVAK. Can. J. Chem. **63**, 1394 (1985).

The infrared and Raman spectra of crystalline deltic acid and its deuterated derivative have been investigated in the 4000–20

cm^{-1} range. An assignment of all the intramolecular fundamentals has been proposed assuming a C_{2v} molecular symmetry. The crystal symmetry is likely to be described by the $P\bar{1}$ or $P2/m$ space group with Z = 2. Deltic acid molecules probably form infinite chains linked with two very strong, asymmetric, and different OH...O hydrogen bonds, with O...O distances estimated at 2.49 and 2.56 Å.

Introduction

A la suite d'une étude de l'acide carré $C_4O_4H_2$ (1), dont le cristal subit une transition de phase para-ferroélectrique, nous nous sommes intéressés à l'acide deltique $C_3O_3H_2$ (dihydroxy-2,3 cyclopropènone). Ce composé a été synthétisé récemment (2,3) et contient le cycle cyclopropènone dont le spectre de vibration présente de nombreuses particularités (4–7). Le but principal de notre travail était de préciser la structure cristalline de cet acide en déterminant notamment son mode d'association ainsi que le type et la force des liaisons hydrogène OH...O.

A notre connaissance, aucune étude spectroscopique antérieure n'a encore été publiée. Par contre, son anion $C_3O_3^{2-}$ a fait l'object de travaux tant à l'état solide qu'en solution aqueuse (8). Nous avons donc enregistrée, à température ambiante et à celle de l'azote liquide, les spectres infrarouges et Raman de l'acide deltique et de son dérivé deutérié entre 4000 et 20 cm^{-1}.

Conditions expérimentales

L'acide deltique a été synthétisé par l'intermédiaire du diester de tertiobutyle (3). Bien que cette méthode donne des rendements en acide aléatoires, elle est plus fiable que celle précédemment décrite (2). Le produit cristallisé dans CF_3COOH (CF_3COOD pour le dérivé deutérié) a été utilisé sans purifications ultérieures.

Les spectres infrarouges de suspensions dans le Nujol et le Fluorolube ont été enregistrés sur les spectromètres Perkin–Elmer 180 et Bruker IFS113V. Des faces de CaF_2, CsI ou TPX ont été utilisées. Les spectres Raman ont été obtenus avec la microsonde Raman MOLE (Jobin–Yvon) sur des microcristaux d'une dizaine de µm. La puissance de la raie excitatrice à 514,5 nm d'un laser à Ar^+ Spectraphysics 164 était de 10 mW au niveau de l'échantillon. Le spectre du dérivé deutérié est difficilement exploitable à cause d'une fluorescence importante. Seules les raies les plus intenses ont pu être identifiées et aucune n'a été mise en évidence au-dessus de 1000 cm^{-1}. Les spectromètres ont été étalonnés à partir des spectres des composés gazeux habituels (infrarouge) et des raies parasites du plasma (Raman). La précision sur les fréquences est de ±1 cm^{-1} pour les raies fines; par contre, les vibrations ν OH, apparaissant sous forme de massifs complexes, ne sont déterminées qu'à 50 cm^{-1} près.

Interprétation des spectres

En l'absence de données structurales, nous supposerons que la molécule est plane et possède, en première approximation, la symétrie C_{2v}. Dans ce cas, ses 18 vibrations fondamentales se répartissent en 13 vibrations planes (7 A_1 et 6 B_1) et cinq vibrations hors du plan (2 A_2 et 3 B_2). Toutes sont actives en diffusion Raman et seules celles de type A_2 sont interdites en absorption. D'un autre côté, il est commode d'utiliser la représentation en terme de vibrations de groupe reportée dans le tableau 1.

Les spectres infrarouges et Raman des acides deltiques $C_3O_3H_2$ et $C_3O_3D_2$ à 35°C sont représentés sur la fig. 1. Les fréquences, les intensités relatives et l'attribution proposée sont réunies dans le tableau 2. Cette dernière est basée sur la substitution isotopique, les intensités relatives en infrarouge et en Raman et les analogies avec les spectres des composés contenant le cycle cyclopropènone.

Vibrations des groupements OH

Les deux vibrations ν OH de l'acide deltique apparaissent en absorption sous la forme de bandes larges et intenses centrées vers 2360 et 1450 cm^{-1} sur lesquelles d'autres bandes sont superposées; elles sont peu sensibles à la température entre 300 et 90 K. La contrepartie Raman n'est observée clairement que pour celle de haute fréquence vers 2500 cm^{-1} (fig. 1). La

substitution isotopique de l'hydrogène par le deutérium déplace la bande vers 2360 cm^{-1} à 1920 cm^{-1} alors que la fréquence de l'autre ne varie pratiquement pas. Les rapports isotopiques ν OH/ν OD sont donc très différents: 1,23 et 1,00 respectivement. Ce comportement indique l'existence de deux groupements OH engagés dans deux liaisons hydrogène fortes différentes. En aucun cas, l'existence de ces deux bandes ν OH ne peut correspondre à un couplage intra ou intermoléculaire de groupements OH similaires.

Leurs déplacements isotopiques permettent d'identifier les déformations planes δ OH et hors du plan γ OH (tableau 2). Comme dans le cas des vibrations de valence, l'écart important des fréquences de déformation montre que chacun de ces modes correspond plutôt à un groupement OH donné qu'à un effet de couplage. Nous faisons donc correspondre les fréquences élevées δ OH à 1660 cm^{-1} et γ OH à 1169 cm^{-1} à la liaison hydrogène la plus forte (notée $O_{(2)}H_{(2)}$ sur le tableau 2 et la fig. 2) responsable de la bande ν OH à 1450 cm^{-1} et les plus

†ν/ν' est le rapport des fréquences des molécules $C_3O_3H_2$ et $C_3O_3D_2$.
‡Les souscrits (1) et (2) correspondent aux deux liaisons hydrogène différentes.

basses à 1465 et 906 cm^{-1} à la liaison hydrogène la plus faible ($O_{(1)}H_{(1)}$) caractérisée par la vibration ν OH à 2360 cm^{-1}. Contrairement aux vibrations de valence, celles de déformation sont sensibles à la température; leurs fréquences s'élèvent d'une dizaine de cm^{-1} à 90 K. Les vibrations δ $O_{(2)}H_{(2)}$ et δ $O_{(2)}D_{(2)}$ présentent une élévation encore plus importante en même temps qu'une exaltation d'intensité.

Les rapports isotopiques ν/ν' des modes de déformation varient entre 1,31 et 1,36 indiquant que leur energie potentielle est concentrée principalement dans les mouvements correspondant aux vibrations δ OH ou γ OH. Cependant, certains couplages avec des vibrations du squelette peuvent être mis en évidence. C'est ainsi que la vibration δ $O_{(2)}H_{(2)}$ à 1660 cm^{-1} apparaît couplée avec la vibration ν C—OH de type B_1 dont la fréquence monte de 1406 à 1447 cm^{-1} après la deutériation. Il en est de même des vibrations δ $O_{(1)}H_{(1)}$ à 1465 cm^{-1} et du cycle vers 1025 cm^{-1} de symétrie A_1. Il faut souligner ici le caractère approximatif des types de symétrie de l'acide deltique. En effet, la mise en évidence de deux liaisons hydrogène différentes implique que la symétrie C_{2v} moléculaire ne peut exister en toute rigueur dans le cristal et que la symétrie maximale est C_s. C'est ainsi que la vibration γ OH de type A_2 apparaît en absorption, mais son intensité est cependant beaucoup plus faible que celle de type B_2.

Les deux composantes qui apparaissent sur le spectre infrarouge de $C_3O_3D_2$ (fig. 1) vers 640 cm^{-1} sont attribuées à deux vibrations différentes car l'intensité de celle de plus haute fréquence augmente quand la température s'abaisse alors que l'autre subit l'effet inverse. La première est donc attribuée à γ $O_{(1)}D_{(1)}$, alors que la seconde correspond à la vibration γ C=O, non détectée en infrarouge pour $C_3O_3H_2$, dont l'intensité se trouve renforcée par un mécanisme de résonance.

Vibrations du squelette

Les vibrations du squelette sont attribuées par comparaison avec l'ion deltate (8) et les cyclopropènones substituées (6, 7); dans les spectres de ces dernières, on attend en particulier deux vibrations vers 1900 et 1600 cm^{-1} (6). La première, correspondant principalement à ν C=O, apparaît pour l'acide deltique à 1940 cm^{-1} en Raman et comme un doublet à 1976–1931 cm^{-1} en infrarouge. Ce doublet est interprété en terme de résonance de Fermi entre ν C=O et une combinai-

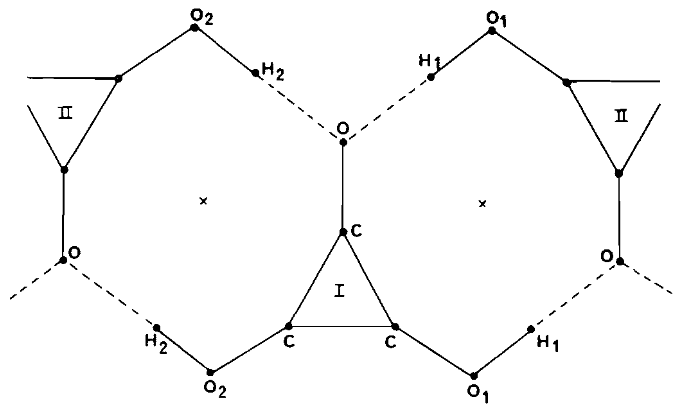

FIG. 2. Structure cristalline de l'acide deltique compatible avec les données spectroscopiques.

son, probablement l'harmonique de la vibration de déformation δ C═O à 965 cm^{-1} ou de la vibration du cycle à 1025 cm^{-1}. La vibration ν C═O du dérivé deutérié est plus difficile à localiser car elle est masquée par la forte absorption d'une des vibrations ν OD; nous lui faisons correspondre le doublet, encore attribué à une résonance de Fermi, avec 2 δ C═O, à 1925–1809 cm^{-1}. Quant à la vibration du cycle de plus haute fréquence, elle absorbe fortement vers 1610 cm^{-1} (fig. 1). Signalons que nous avons observé ces deux vibrations respectivement à 1877 et 1640 cm^{-1} sur le spectre infrarouge du deltate de tertiobutyle.

Les autres vibrations de fréquences supérieures à 600 cm^{-1} sont attribuées sans difficulté. Ainsi, la raie Raman très intense à 799 cm^{-1} correspond vraisemblablement à la respiration du cycle. Les fréquences de déformation δ C═O et γ C═O sont légèrement supérieures à celles de l'acide carré (9); ceci peut s'intepréter par le fait que le groupement C═O de l'acide deltique est engagé dans deux liaisons hydrogène au lieu d'une.

Entre 600 et 300 cm^{-1}, les seules vibrations intramoléculaires attendues sont celles de déformation des liaisons C—OH que nous attribuons donc aux quatre bandes observées dans cette région. Comme pour l'ion $C_3O_3^{2-}$ (8), les fréquences des déformations hors du plan γ OH sont supérieures à celles des déformations planes.

En résumé, toutes les vibrations fondamentales de l'acide deltique ont été identifiées sur la base d'une symétrie moléculaire C_{2v}. Bien que ses distances interatomiques n'aient pas encore été déterminées, nous avons tenté d'appliquer la règle du produit des rapports (10) en considérant une structure moyenne: C—C = 1,40 Å; C═O = 1,24 Å; C—O = 1,27 Å et O—H = 1,00 Å. En ne faisant pas intervenir les vibrations ν OH dont l'anharmonicité importante conduit à des rapports isotopiques faibles, les valeurs expérimentales sont proches de celles calculées: 1,37 pour 1,40 (A_1); 1,36 pour 1,39 (B_1); 1,34 pour 1,35 (A_2) et 1,36 pour 1,36 (B_2).

Discussion

Structure cristalline

Aucune vibration intramoléculaire n'étant attendue endessous de 300 cm^{-1}, nous attribuons les trois bandes infrarouges, et les cinq raies Raman observées dans cette région aux vibrations de réseau. En l'absence de données sur la structure cristalline, une analyse rigoureuse paraît difficile. Cependant, le nombre réduit de vibrations externes est en faveur d'une maille primitive ne contenant que deux molécules. Celleci doit être centrée car aucune fréquence Raman ne coïncide avec une fréquence infrarouge. Le groupe ponctuel isomorphe du groupe spatial est donc C_i ou C_{2h} avec $Z = 2$. Ceci est compatible avec le comportement des vibrations intramoléculaires qui montrent généralement deux composantes, une en infrarouge et une en Raman, dont les écarts de fréquence, compris entre 10 et 37 cm^{-1}, sont bien supérieurs aux erreurs expérimentales. Seules les trois vibrations du groupement C═O présentent des doublets en absorption ou en diffusion. Celui de la vibration de valence a été attribué à une résonance de Fermi et un phénomène analogue doit probablement être invoqué pour les vibrations de déformation.

D'un autre côté, nous avons vu que les deux groupements OH de l'acide deltique sont engagés dans des liaisons hydrogène fortes; celles-ci doivent donc être pratiquement linéaires. Les trois seules structures cristallines compatibles avec une molécule plane sont alors $P\bar{1}$, $P2/m$ (groupe de site C_s) ou $P2/b$ (groupe de site C_2). La non équivalence des liaisons hydrogène est en faveur des deux premières et l'arrangement des molécules serait alors celui représenté sur la figure 2. Signalons que nous n'avons observé aucune transition de phase entre 90 et 300 K; à une température supérieure, le produit se décompose assez rapidement.

Vibrations externes

A partir de ces résultats, nous pouvons préciser l'attribution des vibrations externes. Les trois librations R' actives en absorption ont été observées à 247, 91 et 36 cm^{-1}. Celle de plus haute fréquence, qui est aussi la plus intense, correspond probablement à un mouvement de valence des liaisons hydrogène OH...O; sa fréquence est voisine de celle relevée pour l'acide carré: 230 cm^{-1} (1). Elle est attribuée à un mouvement de rotation autour de l'axe perpendiculaire au plan de la molécule R'_y, car son rapport isotopique est égal à la racine carrée du rapport des moments d'inertie autour de cet axe: $(I_D/I_H)_y^{1/2} = 1{,}03$. Pour les deux autres axes, les valeurs sont nettement différentes: 1,01 et 1,05.

En diffusion Raman, cinq (tableau 2) des six vibrations attendues ($3R' + 3T'$) sont mises en évidence, mais la distinction entre les mouvements T' et R' est difficile. Cependant, les premières impliquent nécessairement une modification des distances O...O et mettent donc en jeu, contrairement à ce qui se passait pour l'acide carré (1), les liaisons hydrogène. D'autre part, la libration R'_y correspondant ici à une rotation des molécules dans le même sens ne joue pratiquement pas sur la distance O...O et doit donc se trouver à plus basse fréquence que celle qui lui correspond en infrarouge. Nous attribuons alors la faible raie Raman à 269 cm^{-1} à une antitranslation T'; son rapport isotopique, voisin du rapport de la racine carrée des masses $(M_D/M_H)^{1/2} = 1{,}01$, est compatible avec cette interpretation.

Liaisons hydrogène

Comme en témoignent leurs vibrations de valence et de déformation, les groupements OH de l'acide deltique sont engagés dans deux liaisons hydrogène fortes OH...O différentes, ($O_{(1)}H_{(1)}$...O et $O_{(2)}H_{(2)}$...O sur la figure 2). La longueur de la plus faible, déterminée à partir de la fréquence ν OH (11) à 2360 cm^{-1}, est $R_{O...O} = 2{,}56$ Å; la distance R_{O-H} peut être estimée de la même façon (11) à 1,10 Å. Ces caractéristiques montrent que la force de cette liaison hydrogène est sensiblement équivalente à celle existant dans le cristal de $RbHCO_3$ (11). La fréquence ν OH de l'autre vibrateur, 1450 cm^{-1}, conduit à des distances $R_{O...O} = 2{,}49$ Å et $R_{O-H} = 1{,}16$ Å; il est donc engagé dans une liaison hydrogène comparable à celle observée pour $KH(CH_3COO)_2$ (11). Bien que fortes, ces deux liaisons hydrogène sont donc asymétriques. Ceci est confirmé par les faibles rapports isotopiques ν OH/ν OD égaux respectivement à 1,23 et 1,00. Ces valeurs sont très proches de celles obtenues à l'aide de la relation $\nu \text{ OH}/\nu \text{ OD} = 2/[(\sqrt{2} - 1)\nu^0 \text{ OH}/\nu \text{ OH} + 1]$ (12): 1,22 et 0,98 pour une fréquence ν^0 du vibrateur non perturbé estimée voisine de 3600 cm^{-1}.

Deux modes externes ont été interprétés comme des vibrations de valence des liaisons hydrogène. Dans l'approximation du modèle diatomique, leur constante de force F_h peut être évaluée à partir de l'antitranslation T' à 269 cm^{-1} en utilisant la géométrie de la figure 2. Elle est comprise entre 60 et 70 N m^{-1} suivant l'orientation de T'. Ce résultat est compatible avec les valeurs obtenues pour d'autres liaisons hydrogène de force voisine (11).

Remerciements

Nous tenons à remercier le professeur F. Serratosa (Université de Barcelone) pour les précisions qu'il nous a données sur la synthèse de l'acide deltique et pour l'échantillon du diester de tertiobutyle qu'il nous a aimablement fourni.

The hydrogen bond energies of the bihalide ions XHX^- and YHX^-

G. CALDWELL AND P. KEBARLE
Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received July 17, 1984

This paper is dedicated to Professor Camille Sandorfy on the occasion of his 65th birthday

G. CALDWELL and P. KEBARLE. Can. J. Chem. **63**, 1399 (1985).

Experimental measurements of the gas phase ion equilibria $X^- + HX = XHX^-$, $X^-(HX)_{n-1} + HX = X^-(HX)_n$, and $X^- + HY = XHY$ where X, Y = Cl, Br, I, with a high pressure mass spectrometer, combined with the recent determination of $F^- + HF = FHF^-$ by Larson and McMahon, provide a very complete set of hydrogen bond dissociation enthalpies and free energies for the hydrogen bihalide ions. The bond energy trends in the different XHX^- and XHY^- are discussed. The data can be used also for the evaluation of lattice energies of salts containing the bihalide ions and for determinations of the solvation energies of these ions.

G. CALDWELL et P. KEBARLE. Can. J. Chem. **63**, 1399 (1985).

Utilisant un spectromètre de masse à haute pression, on a obtenu des mesures expérimentales pour les équilibres ioniques en phase gazeuse $X^- + HX = XHX^-$; $X^-(HX)_{n-1} + HX = X^-(HX)_n$ et $X^- + HY = XHY$ où X, Y = Cl, Br, I. On a combiné ces résultats avec ceux obtenus récemment par Larson et McMahon, pour l'équilibre $F^- + HF = FHF^-$, pour développer un ensemble complet des enthalpies et des énergies libres de dissociation des liaisons hydrogènes des ions hydrogènes bihalogénés étudiés. On discute des tendances observées dans les énergies de liaisons des différents ions XHX^- et XHY^-. On peut également utiliser les données pour évaluer les énergies du réseau des sels contenant des ions bihalogénés et pour déterminer les énergies de solvatation de ces ions.

[Traduit par le journal]

Introduction

The bihalide ions XHX^- and YHX^- where (X, Y) = F, Cl, Br, and I, are of particular interest since they contain only the three atoms normally considered to constitute the hydrogen bond. The strong ion–neutral hydrogen bonds are distinctly different from the weaker neutral–neutral interactions and usually merit a classification of their own (for a review, see ref. 1). Consequently, the hydrogen bihalide ions have been made the subject of numerous theoretical investigations (2) and spectroscopic studies (3) including ir spectroscopy (3*a*), X-ray (3*b*), and neutron (3*c*) diffraction and nmr spectroscopy (3*d*).

Although the homobihalides (XHX^-) and heterobihalides (XHY^-) ions have been studied for many years, no reliable data for the hydrogen bond energies X^-HX and X^-HY were available until the advent of gas phase ion equilibria measurements (4). The hydrogen bond energies were originally estimated from Born cycles which relied on calculations of alkali metal bihalide $M^+(HX_2^-)$ crystal lattice energies (5) or assumptions (6) that the lattice energies of tetrabutylammonium halides and tetrabutylammonium hydrogen bihalides were similar. Martin and co-workers (7), using a simple electrostatic model, estimated the binding energies of several bihalide ions.

Over a decade ago, Yamdagni and Kebarle (8) measured the gas phase ion–molecule equilibria [1] and [2] for X = Cl, with a high pressure mass spectrometer (HPMS).

$$[1] \quad X^- + HX = XHX^- \qquad (0, 1)$$

$$[2] \quad X^-(HX)_{n-1} + HX = X^-(HX)_n \qquad (n-1, n)$$

The bond energy, $D(Cl^-—HCl)$ = 23.7 kcal/mol, determined in that work was 10 kcal/mol greater than that obtained with McDaniel's assumption (6). Recently, Larson and McMahon (9, 10), using ion cyclotron resonance (ICR) to measure the gas phase exchange equilibria [3], were able to determine the very important bond

$$[3] \quad X^-HR + HB = X^-HB + HR$$

energy $D(F^-—HF)$ = 38.6 kcal/mol (9). These authors also obtained $D(Cl^-—HF)$ = 21.8 kcal/mol and $D(Cl^-—HCl)$ = 23 kcal/mol, the latter value being very close to the HPMS value from this laboratory (8).

Larson and McMahon (10) were also able to predict some bond energies, which are not yet experimentally available, from a correlation of the hydrogen bond energy in the bihalide ions with spectroscopically measured frequency shifts ($\Delta\nu$) of the hydrogen bond frequencies relative to the frequencies of the free halogen acids. From such $\Delta\nu$ vs. ΔH plots, the following binding energies were estimated: $Br^-—HCl$ (19 kcal/mol), $I^-—HCl$ (13 kcal/mol), $Br^-—HF$ (17 kcal/mol), and $I^-—HF$ (15 kcal/mol) (10).

In view of the importance of the bihalide ions and past uncertainty concerning their bond energies we have experimentally determined, using HPMS, the temperature dependence for several gas-phase equilibria [1] and [2] where X = Cl, Br, and I. These measurements permit the evaluation of $D(X^-—HX) = \Delta H^0_{1,0}$ and also binding energies for the higher order clusters, $X^-(HX)_n$. Similar measurements involving the heterobihalides $X^-(HY)_n$ were also performed.

It will be shown that the thermodynamic quantities obtained in the present work support the bihalide binding energies predictions made by McMahon (10). The new data also permit evaluation of the lattice energy of alkali bihalides and other thermochemical data of interest.

Experimental

The high-pressure ion source mass spectrometer with which the measurements were made has been described previously (8, 12). Briefly, a 2000 eV electron beam was pulsed "on" for 10–50 μs and "off" for 2–4 ms through the high pressure ion source. The ion source contains a suitable reaction mixture. The resulting ions react with the gas molecules and under suitable conditions the desired ion–molecule equilibria establish themselves. Some of the ions escape, through a very small sampling slit, into an evacuated region where they are mass analyzed, counted, and by means of a multiscaler recorded as a function of their arrival time after the electron pulse. The arrival times are equal to the residence times in the ion source, since the time required for mass analysis is very short. The gas mixture supplied to the ion source consisted of methane as major gas (2–3 Torr) containing mix-

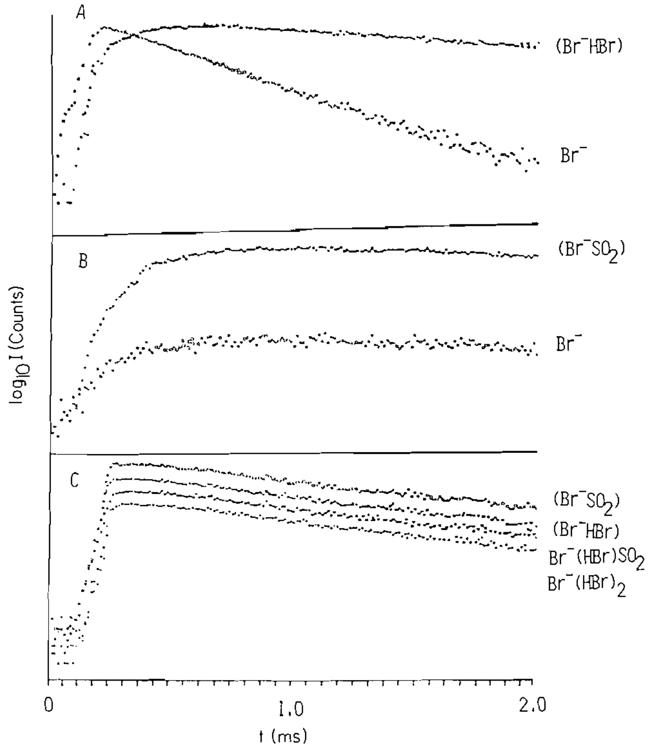

FIG. 1. (*a*) Plot of log (ion counts) vs. time. Concentration used: HBr 270 mTorr, CH_2Br_2 2 mTorr, third gas CH_4 at 4.3 Torr. Temperature 424 K. Br^- is produced by rapid dissociative capture of near thermal electrons by CH_2Br_2. The observed first order disappearance of Br^- is due to the termolecular association: $Br^- + HBr + CH_4 \rightarrow BrHBr^- + CH_4$ (1). Rate constant $k_1 = 7 \times 10^{-30}$ molecule^{-2} cm^6 s^{-1} obtained from slope $\nu_1 = k_1[CH_4][HBr]$ is very low. This must be due to termolecular complex being only triatomic. (*b*) Same conditions as in (*a*) but HBr has been replaced with SO_2 at the same pressure. Termolecular association with SO_2 is much faster and system is in equilibrium: $Br^- + SO_2 = BrSO_2^-$. (*c*) Rapid association with SO_2 used as catalyst for attainment of clustering equilibrium Br^- + HBr = $(BrHBr)^-$. The $BrSO_2^-$ produced rapidly as in (*b*) undergoes the rapid switching reaction $BrSO_2^- + HBr = BrHBr^- + SO_2$. Higher clusters $Br(HBr)_2^-$ and $Br^-(HBr)SO_2$ are also present. Constant difference between log (ion counts) plots observed after about 0.3 ms indicates equilibrium. SO_2 1.1 Torr, HBr 0.17 Torr, CH_4 3 Torr, T = 328 K.

tures of HX in the 0.03 to 0.2 Torr range. Electron capture agents (CCl_4, CH_2Br_2, and CH_3I) were also added at some 0.001 Torr in order to produce the desired ions Cl^-, Br^-, and I^-. Some of the equilibria measurements were performed in the presence of SO_2, which was found to speed up the attainment of the equilibria (see next section). All chemicals used were commercially available and were used without further purification.

Reaction mechanisms in equilibria measurements and thermodynamic results

The reactions occurring in a typical experiment are summarized below:

[4] $AX + e \rightarrow X^- + A$

[1] $X^- + HX = X^-HX$

[2] $X^-(HX)_{n-1} + HX = X^-(HX)_n$

Secondary near thermal electrons produced by the primary electron pulse are captured by traces of AX (= CCl_4 for Cl^-, CH_2Br_2 for Br^-, and CH_3I for I^-) introduced in the ion source

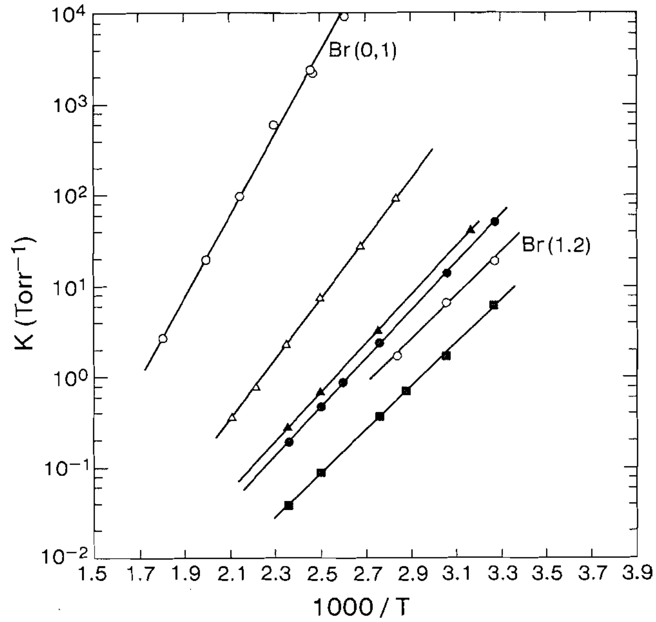

FIG. 2. van't Hoff plots of equilibrium constants $K_{n-1,n}$ for the clustering reaction: ○, $Br^-(HBr)_{n-1} + HBr = Br^-(HBr)_n$; △, I^- + HCl = I^-HCl; ●, $Br^-HCl + SO_2 = Br^-(HCl)SO_2$; ▲, $Cl^-HCl + SO_2 = Cl^-(HCl)SO_2$; ■, $Br^-HBr + SO_2 = Br^-(HBr)SO_2$.

with the reaction mixture. The desired ion X^- is created by the dissociative electron capture reaction [4]. In the presence of the clustering gas HX clustering reactions [1] and [2] occur. For HBr and HI, the first step [1] in the clustering sequence proved to be very slow, particularly at the high temperatures at which the equilibrium [1] was to be measured. The results from such an experiment involving the (0, 1) clusters of Br^- + HBr are shown in Fig. 1*a*. The disappearance of Br^- is clearly too slow under these conditions to lead to the equilibrium [1].

The rate constant k_1 for the forward clustering reaction is third order for the conditions of the experiments and decreases with temperature increase (13). The magnitude of the rate constant in an ion molecule association reaction $A^{\pm} + B \rightarrow (AB^{\pm})^* \rightarrow AB^{\pm}$ increases with the number of internal degrees of freedom of the complex $AB^{\pm}$ and the binding energy ($A^{\pm}$—B) (13). For the triatomic complexes XHX^-, the available degrees of freedom are very few and this leads to a very small k_1.

The k_1 determined from the observed concentration changes in Fig. 1*a* is 7×10^{-30} cm^2 molecule^{-1} s^{-1}. This value is two to three orders of magnitude smaller than the rate constant for an association reaction involving polyatomic reactants $A^{\pm}$ and B and an $A^{\pm}$—B binding energy similar to the Br^-—HBr bond energy (for other references for third order and temperature dependence kinetics see ref. 13*b*). Increase of the HX concentration speeds up the rate of [1]. The equilibria results in Fig. 2 and 3 were obtained from experiments where the HX pressure was increased to the 1 Torr range. However, the high HX pressure led, for reasons that we do not fully understand, to a more rapid decrease of the total X^- and X^-HX signal with time. Better conditions for the equilibria measurements were created with the introduction of SO_2 gas in the reaction mixture. The presence of SO_2 led to the clustering reactions [5] and [6].

[5] $X^- + SO_2 = X^-(SO_2)$

[6] $X^-(SO_2)_{n-1} + SO_2 = X^-(SO_2)_n$

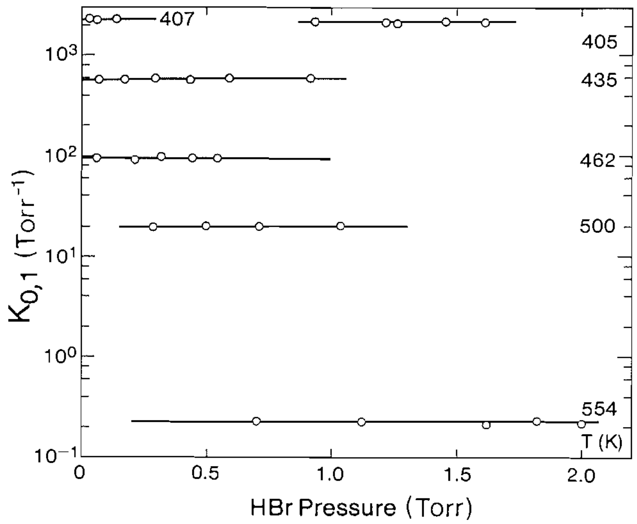

FIG. 3. Equilibrium constants $K_{0,1}$ for reaction: $Br^- + HBr = Br^-HBr$ as a function of temperature and HBr pressure. Measurements in the presence of 3–4 Torr CH_4. Standard state 1 Torr.

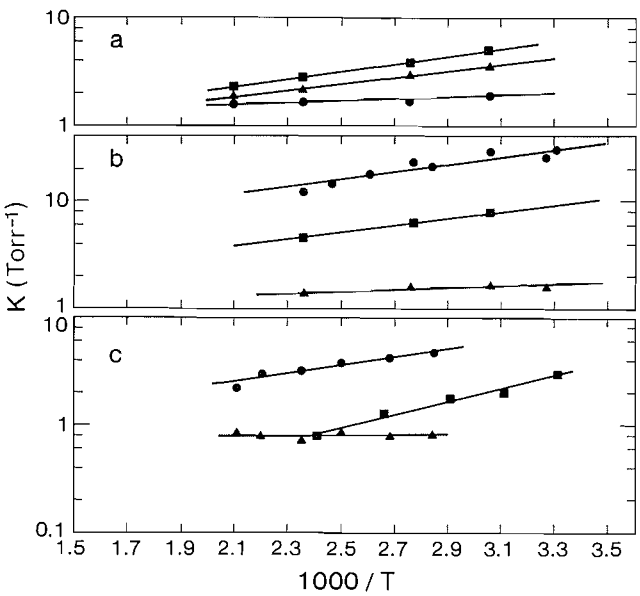

FIG. 4. van't Hoff plots of equilibrium constants $K_{n-1,n}$ for the exchange reactions: Plot *a*: ■, $Cl^-(HCl)SO_2 + HCl = Cl^-(HCl)_2 + SO_2$; ▲, $Br^-(HBr)SO_2 + HBr = Br^-(HBr)_2 + SO$; ●, $Br^-(HCl)SO_2 + HCl = Br^-(HCl)_2 + SO_2$. Plot *b*: ●, $Br^-SO_2 + HBr = Br^-HBr + SO_2$; ■, $Cl^-SO_2 + HCl = Cl^-HCl + SO_2$; ▲, $Br^-SO_2 + HCl = Br^-HCl + SO_2$. Plot *c*: ●, $I^-SO_2 + HBr = I^-HBr + SO_2$; ■, $I^-SO_2 + HI = I^-HI + SO_2$; ▲, $I^-SO_2 + HCl = I^-HCl + SO_2$.

[7] $X^-(SO_2)_n + HX = X^-(SO_2)_{n-1}HX + SO_2$

[8] $X^-(HX)_{n-1}SO_2 + HX = X^-(HX)_n + SO_2$

The clustering reaction [5] involving Br^- and SO_2 was much faster than the corresponding reaction of Br^- and HBr. This fact is demonstrated by the results shown in Fig. 1*b*. Evidently the additional vibrations in the triatomic SO_2 molecule lead to a much higher termolecular rate constant. When both SO_2 and HX are present, as in Fig. 1*c*, the rapid X^-SO_2 clustering is followed by the switching reactions [7] and [8] in which the stronger bonding HX displaces the SO_2 molecules from the ion X^-. Measurement of the exchange equilibria [7] and [8] from

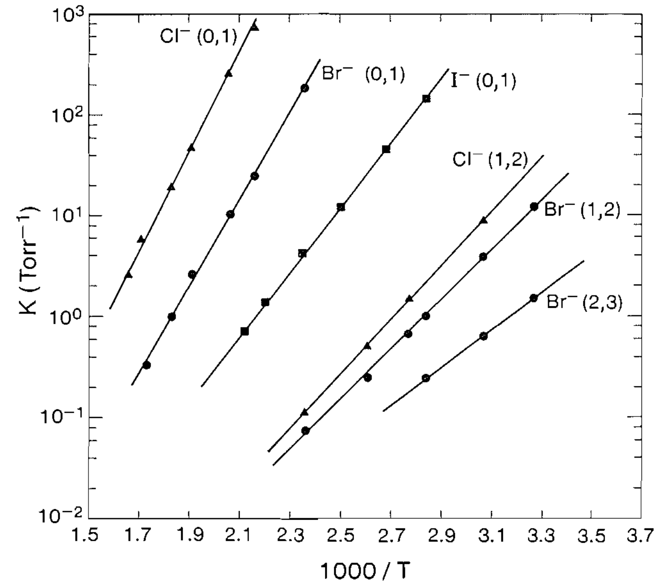

FIG. 5. van't Hoff plots of equilibrium constants $K_{n-1,n}$ for reactions ▲, $Cl^-(SO_2)_{n-1} + SO_2 = Cl^-(SO_2)_n$; ●, $Br^-(SO_2)_{n-1} + SO_2 = Br^-(SO_2)_n$; ■, $I^-(SO_2)_{n-1} + SO_2 = I^-(SO_2)_n$.

runs like that shown in Fig. 1*c* led to the exchange equilibria van't Hoff plots shown in Fig. 4. In addition to these exchange reactions, the X^-, SO_2 clustering equilibria [5] and [6] were measured in the absence of HX. The van't Hoff plots for these results are shown in Fig. 5. Combining the SO_2 clustering equilibria [5] and [6] with the HX exchange equilibria [7] and [8] in a thermodynamic cycle leads to the $X^-(HX)_n$ or $X^-(HY)_n$ equilibria and associated thermochemical quantities.

The thermochemical data from measurements involving SO_2, association and exchange are given in Table 2. Table 1 contains data from the direct X^-HX association equilibria measurements and also association equilibria data derived from the SO_2 cycles described above.

Data from the literature are also included in Table 1. All determinations involving F^- are due to McMahon and co-workers (9, 10). Included are also the results of Castleman and co-workers (14) for X^-SO_2 association reactions. There is generally good agreement between determinations from different laboratories. Thus, the Cl^-—SO_2 and Cl^-—HCl bond enthalpies from three different determinations are within 1 kcal/mol (Table 1).

Discussion of results

(*a*) *The dissociation energies in* $(XHX)^-$ *and* $(XHY)^-$

The hydrogen bond energies corresponding to dissociations $(XHX)^- \rightarrow X^- + HX$ and $(XHY)^- \rightarrow X^- + HY$ are summarized in Table 3. First we consider the XHX^-, which lie on the diagonal in Table 3. The bond enthalpy values are 38.6, 23.5, 20.9, and 17.0 kcal/mol for X = F, Cl, Br, I. Prior to the experimental determination of $D(F^-$—$HF)$ = 38.6 kcal/mol due to Larson and McMahon (9), theoretical MO calculations (2) had not provided a reliable or consistent result for this bond energy. In retrospect only the calculation of Noble and Kortzeborn (2*h*) with 40 kcal/mol has turned out to be a result close to the experimental value. Emsley and co-workers (2*d*) have discussed the reasons for the theoretical difficulties and the special need for a large flexible Gaussian basis set when dealing with the F^-HF system. Theoretical calculations for

[12]	$I^- + SO_2 = I^-SO_2$	14.3	17.6	9.0
[13]	$I^-SO_2 + HCl = I^-HCl + SO_2$	0.0	0.4	−0.1
[14]	$I^-SO_2 + HBr = I^-HBr + SO_2$	1.8	2.0	1.2
[15]	$I^-SO_2 + HI = I^-HI + SO_2$	2.7	6.8	0.7

[a] All values are in kcal/mol, ΔG^0 values for 300 K, ΔS^0 in eu, standard state 1 atm.

$D(Cl^-—HCl) = 20$ kcal/mol were obtained by Almlöf (2*g*) in fairly good agreement with the experimental result of 23.5 kcal/mol from this laboratory (8). MO calculations for Br^-HBr and I^-HI have not been performed.

Martin and Fujiwara (3) have published results from some very simple electrostatic calculations for the bond energies X^-HX and X^-HY. These authors obtained the binding energy U by considering the ion dipole and the ion-induced dipole interaction as shown in eq. [9].

[9*a*] $$U = U_{dip} + U_{pol}$$

[9*b*] $$U_{dip} = -\frac{69.1}{r^2}\mu \text{ (kcal/mol)}$$

[9*c*] $$U_{pol} = -\frac{165.6}{r^4}\alpha \text{ (kcal/mol)}$$

[9*d*] $$r = r_{X^-} + (1/2)r_{HX}$$

μ and α are the dipole moment and the polarizability (along the bond axis) of HX and the numerical factors in [9*b*] and [9*c*] are adjusted for use with μ in Debye and α in Å^3 units. A rigid sphere approach was used where the distance r between the ion and the point dipole and polarizability was taken as the sum of the Pauling ion radius and half of the HX bond distance r_{HX}. The values for α, μ, and r_{HX} and the resulting bonding energy $-U$ are shown in Table 4. Apart from the too high value for $-U(F^-HF) = 51$ kcal/mol, there is good agreement with the

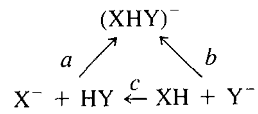
[c]Estimated from $\Delta\nu$ vs. ΔH plot, see text and refs. 10 and 11.
[d]Value based on an average from Table 1.
[e]Values obtained for reaction $(XHY) \rightarrow Y^- + HX$ by addition of halide binding energy to the difference in gas phase acidities of HX and HY, see text.

experimental values. Electrostatic calculations like [9] depend critically on the choice of the radius r. The choice of r in Martin's calculation is arbitrary since the radius of the H atom was not taken into consideration. Increasing the value of r by adding r_H would lead to much too low binding energies for all X^-HX, particularly the higher members. While the evaluation of quantitative data via [9] is not truly meaningful, the qualitative features are of interest. Thus, the binding energy in the series F $\rightarrow$ I decreases because of the increasing radius of X which leads to an increase of r_{X^-} and r_{HX}. An additional decrease of bonding is due to the large (factor of 5) decrease of the HX dipole from HF to HI (see Table 4). The combined effects of the r and μ changes lead to a tenfold decrease of U_{dip} from F^-HF to I^-HI. On the other hand, the rapidly increasing polarizability of X leads to an almost constant U_{pol} term for the whole series.

The results in Table 3 also provide information on the bond energy changes in X^-HY where X^- is kept constant and HY is changed. The general trend observed is that the bond energy increases as HY is changed from HF to HI. For example, in Br^-—HF, Br^-—HCl, and Br^-—HBr the energies are 17, 19.6, and 20.9 kcal/mol. The bond energies obtained with the electrostatic calculations (9) using the parameters from Table 5 are 25, 23, and 22 kcal/mol (see also Table IV in ref. 7*c*). Thus, numerically the electrostatic results are not too far off, but the predicted trend, i.e. a decrease of bonding from HF to HBr, is incorrect. It should be noted that the gas phase acidity of HY increases from HF to HI, which means that the observed hydrogen bond energy in X^-HY increases with the acidity of HY. This type of dependence has been observed for many systems B^-HA. Yamdagni and Kebarle (4, 15) were the first to document that the hydrogen bond energy in B^-HA increases with the gas phase acidity of AH and the gas phase basicity of B^-. For systems where AH are series of related compounds, a linear relationship between the bond energy and the acidity of AH is found. Examples of such behavior were obtained for $B^- = Cl^-$ and AH = substituted phenols (16) and Cl^- and a variety of acids (17). More recently Larson and McMahon (9) in a comprehensive examination of the hydrogen bonding in F^-HA have demonstrated the existence of such a linear relationship for HA corresponding to a variety of alcohols. The observed increase of binding energy of B^-HA with acidity of AH suggests the reason for the failure of the electrostatic approach (eq. [9]) to predict the correct trend of binding energies in $Br^-.HY$ and generally $X^-.HY$. In a series like



SCHEME 1

Br^-HF, Br^-HCl, Br^-HBr on formation of the hydrogen bond from Br^- and HY there is increasing proton donation from HY to Br^-. Thus, while in Br^-HF the proton is associated largely with HF in Br^-HBr the proton is already shared equally. The electrostatic calculation which treats HY as rigid fails to take this progressive proton shift into account. The largest exothermicity for the series $Br^- + HY = (BrHY)^-$ is observed for HI. (See Table 3). Of the two association reaction exothermicities shown in Scheme 1, by convention, only one is considered as a hydrogen bond energy. This would be ΔH_a assuming that X^- is a weaker base than Y^-. ΔH_b is not considered as representing the energy for the formation of a hydrogen bond since a large part of the exothermicity of [*b*] is due to proton transfer [*c*] from XH to Y^-, the product $(XHY)^-$ being (largely) $X^-.HY$. While the convention may be meaningful for a classification of hydrogen bonds, there is some degree of proton transfer on formation of all XHY^- hydrogen bonds as was shown above for the series Br^- + HF, HCl, HBr. Therefore, the inclusion of HI into the series is natural and extends the illustration of the progressively increasing proton transfer. All horizontal rows in Table 3 represent series with proton transfer and exothermicities increasing from left to right. A theoretical analysis of the role of proton transfer (proton drift) in hydrogen bonds has been given by Desmeules and Allen (18).

It is interesting to note that the proton transfer discussed above can be reversed by the presence of the cationic counter ion. In the matrix isolation studies of Ault (3), the alkali halides MX and the halogen acids HY were codeposited from the gas phase in an argon matrix to produce the unsymmetrical ions XHY^- together with M^+ as counterion. Evidence from the vibrational spectra obtained showed the presence of two isomers $X^-.HY$ and $XH.Y^-$ whose abundance depended on the nature of the counterion M^+. If X^- is the larger halide ion (i.e. the weaker base) then $X^-.HY$ will be more stable than $XH.Y^-$ in the absence of M^+. The interactions being largely electrostatic, the cations M^+ will bond preferentially to the smaller anion, i.e. the presence of M^+ will promote a proton transfer in $X^-.HY$ leading to $XH.Y^-M^+$. This tendency will increase if the size of M^+ is decreased. This corresponds exactly to the findings in the matrix isolation studies of Ault (3) where the abundance of the $XH.Y^-M^+$ species was observed to increase as the radius of M^+ was decreased.

A discussion of the potential energy changes in the (gaseous) XHY^- with proton transfer from X to Y has been given by Larson and McMahon (10).

The enthalpies for the reaction [10] have been measured (19, 20) in solution of the aprotic solvents, sulfolane (SF) (19), and propylene carbonate (PC) (20).

[10] $X^- + HCl = X^-HCl$

The gas phase and solution data are shown in Table 5. The exothermicities for [10] in solution are seen to be much lower. One factor decreasing the exothermicity is the solvation energy of HCl. The solvation energy of gaseous HCl in SF has been quoted by Benoit *et al.* (19) as ΔH_S (HCl) = −5.8 kcal/mol. The other factor decreasing the exothermicities of reaction [1]

TABLE 5. Comparison of enthalpies for the reaction [10] $X^- + HCl = X^-HCl$ in gas phase and solution[a]

Parameter	Value when X^- = Cl$^-$	Br$^-$	I$^-$
$-\Delta H_{10(g)}$	23.5	19.6	14.4
$-\Delta H_{10}(SF)^b$	8.1	4.9	2.2
$-\Delta H_{10}(PC)^c$	2.5	1.2	0.9
$\delta\Delta H_S(X^-HCl)(SF)^d$	9.6	8.9	6.4
$\delta\Delta H_S(X^-HCl)(PC)^e$	~14.0	~11.4	~6.5

[a]All values in kcal/mol.
[b]In sulfolane, Benoit *et al.* (19).
[c]In propylene carbonate, Bates and co-workers (20).
[d]$\Delta H_S(X^-HCl) - \Delta H_S(X^-)$ from cycle (11) and $\Delta H_S(HCl) = -5.8$ kcal/mol (19).
[e]Same as *d* but solvation of HCl in PC, for which an experimental value is not available, assumed $\Delta H_S(HCl) = -7$ kcal/mol.

in solution is the solvation energy difference $\Delta H_S(X^-) - \Delta H_S(X^-HCl)$. This difference can be evaluated from cycle

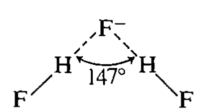
$$[11] \qquad \begin{array}{ccc} X^-_{(g)} + HCl_{(g)} & \xrightarrow{\Delta H_{10(g)}} & X^-HCl_{(g)} \\ \uparrow {\scriptstyle -\Delta H_S(X^-) \atop -\Delta H_S(HCl)} & & \downarrow {\scriptstyle \Delta H_S(X^-HCl)} \\ X^-_{(s)} + HCl_{(s)} & \xrightarrow{\Delta H_{10(s)}} & X^-HCl_{(s)} \end{array}$$

$$\Delta H_S(X^-HCl) - \Delta H_S(X^-) = \Delta H_{10(s)} - \Delta H_{10(g)} + \Delta H_S(HCl)$$

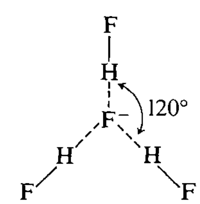
[11]. The results obtained are given in Table 5. Dipolar aprotic solvents like SF and PC are known to solvate negative ions inefficiently. What is more significant for reaction [10] is that in these liquids the solvation of negative ions decreases less with increasing size of the negative ion than is the case for protic solvents (21). Examining the data in Table 5 we conclude that in sulfolane, solvation decreases less with increasing size of the negative ion than is the case for PC. Thus, propylene carbonate is, in this respect, closer to protic solvents. In protic solvents reaction (10) does not occur at all, exactly because negative ion solvation in these solvents decreases so much more with increasing size of the ion, i.e., the large, unfavorable energy difference for the solvation X^- and X^-HY leads to an unfavorable free energy change for [10] in protic solvents.

(*b*) *Binding energies and structure of the polyhalide ions* $X^-(HX)_n$

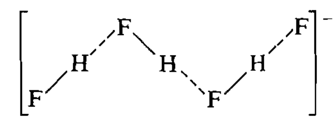
The changes of $\Delta H_{n-1,n}$ with n are shown in Fig. 6. The data used are from Table 1 except the $F^-(HF)_n$ data which represent results from MO calculations by Emsley *et al.* (2*c*, 2*d*). No experimental data for $F^-(HF)_n$ are available. Emsley's results are of interest because they provide structural information on the clusters. Thus while FHF^- is linear (as are the other XHX^-), $F^-(HF)_2$ is bent (C_{2v} symmetry, see structure **I**). This appears to result from a compromise between the covalent bonding angle of 109° and the 180° angle expected on electrostatic grounds due to the repulsion between the two HF dipoles. $F^-(HF)_3$ is found to be planar with the three HF molecules pointing towards F^-, D_{3h} symmetry (see structure **II**). This structure was found to be more stable than the chain structure $H_3F_7^-$ (**III**), expected, on the basis of covalent bonding.



I



II



III

The stable structure for $F^-(HF)_4$ was tetrahedral with F^- in the centre and four HF pointing towards it (T_d symmetry). Evidently, as n in $F^-(HF)_n$ increases, the structures become increasingly determined by electrostatic type forces. For $Cl^-(HCl)_n$ and other $X^-(HX)_n$ we expect that electrostatic demands will dominate even more. Therefore we expect that the tendency for $X^-(HX)_2$ to become linear will increase from X = F to X = I.

The $-\Delta H_{n-1,n}$ in Fig. 5 are seen to decrease with n for all $X^-(HX)_n$. However, the pattern for $F^-(HF)_n$ is somewhat different. The largest drop off occurs for the addition of the third HF in $F^-(HF)_n$. For the other $X^-(HX)_n$ the largest drop off occurs between $\Delta H_{0,1}$ and $\Delta H_{1,2}$, i.e., already for the addition of the second HX. Assuming that the theoretical HF and experimental HX results are reliable, the above difference may be rationalized by the stronger covalent contribution to the bonding in $F^-(HF)_2$. Thus, covalent bonding stabilizes

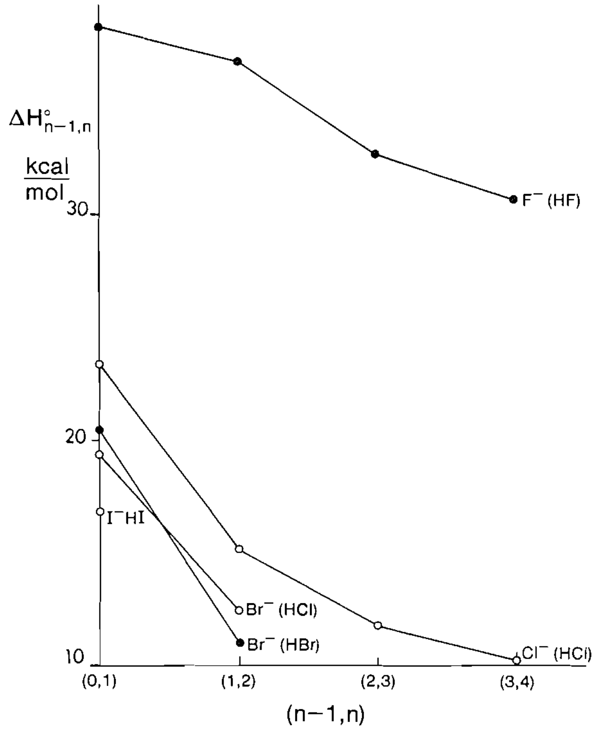


FIG. 6. Plot of $\Delta H^0_{n-1,n}$ for solvation reaction in the gas-phase: $X^-(HX)_{n-1} + HX = X^-(HX)_n$. $F(HF)_n$ data from refs. 2*c* and *d*.

$F^-(HF)_2$ (structure **II**) but probably plays no role in the other $X^-(HX)_2$ and $X^-(HX)_n$ whose fall off of binding energy with n is characteristic of electrostatic type bonding (see for example $Br^-(H_2O)_n$ and other similar systems (4).

(*c*) *Lattice energies of* $M^+.X_2H^-$

As mentioned in the Introduction, lattice energies of $M^+X_2H^-$ and the binding energies X^-—HX can be related by means of a Born type cycle (see [12])

[12]
$$\begin{tikzcd} M^+_{(g)} + X^-_{(g)} + HX_{(g)} \arrow[r, "\Delta H_{0,1}"] \arrow[d, "-\Delta H_L(MX)"] & M^+_{(g)} + HX_2{}^-_{(g)} \\ MX_{(s)} + HX_{(g)} \arrow[r, "\Delta H_r"] & MHX_{2(s)} \arrow[u, "\Delta H_L(MHX_2)"'] \end{tikzcd}$$

[12*a*] $\Delta H_{0,1} = \Delta H_L(MHX_2) - \Delta H_L(MX) + \Delta H_r$

[12*b*] $\delta\Delta H_L = \Delta H_L(MX) - \Delta H_L(MHX_2)$

where ΔH_L stands for lattice energy. $\Delta H_L(MX)$ can be evaluated from experimental data and ΔH_r can be obtained from the experimentally available heats of formation of the reactants. $\Delta H_{0,1}$ can be obtained if $\Delta H_L(MHX_2)$ is available or vice versa. In the early work (2*e*) classical lattice energy calculations for MHX_2 were used in [12*a*] to estimate $\Delta H_{0,1}$ for X = F. These led to $-\Delta H_{0,1}$ which were much higher than the experimental value given in Table 3. Now, using the experimental $\Delta H_{0,1}$ from Table 3 we can reverse the procedure and provide experimental lattice energies $\Delta H_L(MHX_2)$. The data for MHF_2 are summarized in Table 6. Lattice energies for the other MHX_2 can be also evaluated provided that the ΔH_r are available. Comparing the $\Delta H_L(MHF_2)$ in Table 6 with recent lattice energy calculations of Jenkins and Pratt (23) one finds that the classically calculated values are, on the average, too small by some 13 kcal/mol.

TABLE 6. Lattice energies of MHF_2 salts[a]

	Value				
Parameter	$LiHF_2$	$NaHF_2$	KHF_2	$RbHF_2$	$CsHF_2$
ΔH_r[a]	13.2	18.0	21.3	22.4	23.7
$\Delta H_L(MF)$[b]	250.0	221.7	197.5	189.3	180.7
$\Delta H_L(MHF_2)$[c]	224.6	201.1	180.2	173.1	165.8

[a]All values in kcal/mol at ~300 K. For symbols used and evaluation see eq. [12].
[b]Lattice energy of MHF_2 from Wagman *et al.* (22).
[c]From eq. [12*a*], $\Delta H_{0,1} = -38.6$ kcal/mol (for X = F), Larson and McMahon (9, 10). Estimated error of $\Delta H_L(MHF_2)$, +4 kcal/mol.

Previous estimates of hydrogen bond energies for $HF_2{}^-$, $HCl_2{}^-$, $HBr_2{}^-$, and $HI_2{}^-$ based on lattice energies considerations were made by McDaniel and co-workers (6). These authors determined experimentally the enthalpy changes (ΔH_r) for reaction [13].

[13] $R_4NX(s) + HX(g) = R_4NHX_2(s)$

They argued that as the size of R_4N^+ is increased the lattice energy of R_4NHX_2 should gradually approach that of R_4NX. When the quantities become equal, it follows from eq. [12*a*] that $\Delta H_{0,1}$ will become equal to $\Delta H_r = \Delta H_{13}$, i.e., ΔH_{13} should give the desired hydrogen bond energy. McDaniel and co-workers (6) were able to measure ΔH_{13} for (Cl, Br, I) and gradually increasing R (Me, Et, *n*-Bu). They found, as expected, that $-\Delta H_{13}$ increases with increasing size of the alkyl group and that it seems to reach a limiting value. The approach to the limiting value was fastest for Cl and slowest for I (see Fig. 7 in ref. 6*b*). The limiting values for $-\Delta H_{13}$ were: ~14 (Cl), 12.8 (Br), 12.4 (I) while the corresponding $-\Delta H_{0,1}$ from Table 3 are 23, 21, and 17 kcal/mol. Only a single $-\Delta H_{13}$ (R = Me) experimental value could be obtained for F. This value was 37 kcal/mol while $-\Delta H_{0,1}$ is 38.6 kcal/mol. Evidently, McDaniel *et al.* provide legitimate lower limits for the hydrogen bond energies of all the XHX^-. However, the results are somewhat confusing. For $ClHCl^-$ where a limiting value seemed to have been reached, the $-\Delta H_{13}$ shows the largest deviation from the $\Delta H_{0,1}$, while for FHF^- where attainment of the limiting value already for R = Me could be in doubt, closest agreement with the $\Delta H_{0,1}$ is observed. It is not clear whether these complexities result from experimental error or are due to intricate changes of the lattice energies of the compounds involved.

Relativistic MS-Xα calculations are reported for a $PtCl_4^{2-}$ cluster. Good agreement with experiment is obtained for the optical spectrum. A ligand field approach has been used to evaluate the $d-d$ transitions through the use of a strong field matrix, where the crystal field parameters have been replaced by values derived from the Xα calculation. The high intensity spectrum is clearly interpreted in terms of Rydberg Pt $5d \rightarrow 6p$ transitions.

A GOURSOT et H. CHERMETTE. Can. J. Chem. **63**, 1407 (1985).

On rapporte des calculs relativistes MS-Xα pour le cluster $PtCl_4^{2-}$. Pour le spectre optique, on obtient une bonne corrélation avec l'expérience. Dans le but d'évaluer les transitions $d-d$, on a utilisé une approche par la théorie du champ de ligand pour laquelle on fait appel à une matrice champ fort, dans laquelle on a remplacé les paramètres de champ cristallin par des valeurs obtenues par les calculs Xα. On interprète facilement le spectre de forte intensité sur la base de transitions de Rydberg Pt $5d \rightarrow 6p$.

[Traduit par le journal]

Introduction

The electronic absorption spectra of transition metal complexes are generally interpreted as displaying a low-intensity part attributed to the ligand field transitions, and intense absorption bands referred to as charge transfer (CT) transitions.

The $d-d$ spectra have been extensively studied by application of the ligand field theory. On the other hand, CT bands are generally assigned with the aid of energy levels diagrams. Quantitative analyses of the CT spectra through molecular orbital (MO) methods require a realistic description of the relative energies of the metal and ligand orbitals, together with a satisfactory representation of the metal–ligand interactions. Moreover, a quantitative description of CT transitions requires ΔSCF Hartree–Fock calculations in order to account for orbital relaxation. These requirements explain that such transitions are not extensively studied, although they represent an interesting characteristic part of the absorption spectra of transition metal complexes, often involved in their photochemical properties.

Moreover, the high-intensity absorptions could also be due to transitions from the metal nd orbitals to mainly metal $(n+1)s$ or $(n+1)p$ orbitals. This possibility of encountering Rydberg transitions, in a wavelength region generally assigned to CT bands, has already been mentioned, particularly in the case of square planar complexes (1). In this paper, we want to put some emphasis upon the assignment of the high-intensity bands of $PtCl_4^{2-}$, and more specifically upon the Rydberg alternative to the CT assignment.

Considerable experimental work has been devoted to the elucidation of the absorption spectrum of $PtCl_4^{2-}$. However, most of the experimental studies as well as the previous theoretical works are principally interested in the ligand field transitions. Even though some of them mention Rydberg $5d \rightarrow 6p$ transitions as possible assignments for the high-intensity bands, no quantitative analysis has been presented to support these proposals. This is why we have chosen to perform relativistic MS-Xα calculations in order to assign the main features of the $PtCl_4^{2-}$ absorption spectrum and to assess their ligand field, CT, or Rydberg origin. The relativistic Xα method (2) is based on the Cowan and Griffin (3) approximation of the Dirac–Hartree–Fock equations. The effects of the mass–velocity and Darwin corrections are included self-consistently, while those of the spin–orbit operator are thus neglected. The spin–orbit effects may then be taken into account after self-consistency, by first order perturbation theory.

Calculation parameters

The Pt—Cl bond length is taken as 2.30 Å (4). The atomic α value for Pt (0.69306) and Cl (0.72325) are taken from the compilation of Schwarz (5, 6). A weighted average of these atomic values is chosen for the interatomic and extramolecular regions (0.71721). As for previous calculations on halide complexes (7–9), the Pt and Cl spheres are allowed to overlap by an amount of 20% (r(Pt) = 2.58951; r(Cl) = 2.62613). An external tangent outer sphere is used ($r_{OUT} = 6.97250$), which also serves as a "Watson Sphere" (10) on which a positive charge +2.5 is distributed. This +2.5 value has been used to push down the valence levels and thus to find the upper virtual levels with negative energies. It has been shown extensively that such a small increase of the Watson Sphere charge (usually 0.5) involves only a uniform stabilization of the eigenvalues, thus providing the ability of finding more virtual levels.

Partial waves up to $l = 4$ are included in the multiple scattering expansion in the platinum sphere and extramolecular region, and up to $l = 1$ in the chlorine spheres.

All calculations of transition energies have been performed with the use of Slater's transition-state method (11).

The use of the Slater's transition state (TS) procedure in MS Xα calculations has been criticized by Oliveira and Maffeo (12), who concluded that the best estimate of the excitation energy is indeed given by the TS procedure, only when both occupied and virtual orbitals involved in the transition are con-

TABLE 1. Ground state energy levels[a] (Ry) and charge distribution of $PtCl_4^{2-}$

		Pt								Cl

$1a_{1g}$	−1.545				1					90	1		3	1

[a]The highest occupied level is $2b_{2g}$.

centrated in the same atomic sphere. In the case of different atomic spheres (CT transitions), they concluded that a TS calculation may not necessarily provide an improvement over the "Koopmans" difference of the ground state (GS) eigenvalues. In our opinion, even though it does not provide the exact ΔSCF energies,[1] the TS procedure allows one to take into account the major portion of the relaxation effect, leading to good estimates of the CT spectra and particularly of the differences between metal−metal and ligand−metal transition energies. This point has been verified by the authors in various studies (7−9, 13−15). In those cases, and in the present one, the relaxation of the orbitals involved in the TS procedure imply some redistribution of the electronic density inside the atomic spheres, but without altering the intersphere contribution by more than 1%, with respect to the GS structure. Moreover, when the virtual orbital is located in the outersphere region, previous work (16, 17) has shown that the calculated relaxation energies are substantial, requiring the use of the TS procedure rather than the Koopmans one.

Ground state electronic structure

The GS valence levels of $PtCl_4^{2-}$ and the corresponding charge distribution are reported in Table 1 (spin-restricted calculation).

Previous SCF-Xα calculations (18−21) have already been performed on this complex, but without introducing relativistic corrections. As described previously for Ir or Pt halides (7−9), the main effect of the relativistic contraction of the metal s and p orbitals, which increases the nuclear shielding, is to allow the expansion of the d and f orbitals. The valence molecular orbitals (MOs), which display a preponderant metal $5d$ character are thus all shifted upwards. Moreover, with respect to non-relativistic results, the upper occupied antibonding MOs, namely, $3a_{1g}$, $2e_{2g}$, $2b_{2g}$, have substantially increased contributions, while their bonding counterparts ($2a_{1g}$, $1e_g$, $1b_{2g}$) have a decreased Pt $5d$ participation. This upwards energy shift of the Pt $5d$ levels moves them away from the pure ligand π levels ($1a_{2g}$, $3e_u$, $1b_{2u}$, $1a_{2u}$) which remain nearly unchanged, while the energy separations between the Pt $5d$ levels themselves are not so much perturbed. The same tendency is obtained from a relativistic extended Hückel (REX) calculation (22), while the Dirac−Slater (DS) method (22) leads to a somewhat different situation, where the upward energy shift concerns only the $3a_{1g}$ level and the $2e_g$ (3/2) component (calculation performed in the double group D^*_{4h}).

In our case, the metal levels ordering is maintained, with respect to the non-relativistic case. This will lead to roughly comparable ligand field transitions. On the contrary, the ligand-to-metal or metal-to-ligand CT transitions will undergo substantial modifications. The calculated ordering of the "$5d$-like" MOs is

$$3b_{1g}(d_{x^2-y^2}) > 2b_{2g}(d_{xy}) > 2e_g(d_{xz}, d_{yz}) > 3a_{1g}(d_{z^2})$$

This ordering is consistent with the experimental observations on the basis of MCD data (23), of spectra recorded with polarized light (24). It was also obtained from EH calculations (25, 26). However, a comparison with these earlier theoretical results shows some important differences in the values of the energy separations: Δ1 ($3b_{1g} - 2b_{2g}$), Δ2 ($2b_{2g} - 2e_g$), and Δ3 ($2e_g - 3a_{1g}$) which are calculated as 26 550, 2 950, and 5 950 cm^{-1} in the present work. The virtual MOs, except $3b_{1g}$, are essentially localized outside of the atomic spheres and may be considered as Rydberg orbitals, which are considered as one-center expansions about the molecular center. Their charge analysis shows that $2a_{2u}$, $3a_{2u}$, $4e_u$, and $5e_u$ have predominant contributions of the outersphere (sphere surrounding the whole

[1]For example, the ΔSCF energy of the LMCT transition $3e_u \rightarrow 3b_{1g}$ of $PtCl_4^{2-}$ is 51 300 cm^{-1}, which compares very well with the TS value of 51 000 cm^{-1} (cf. Table 3).

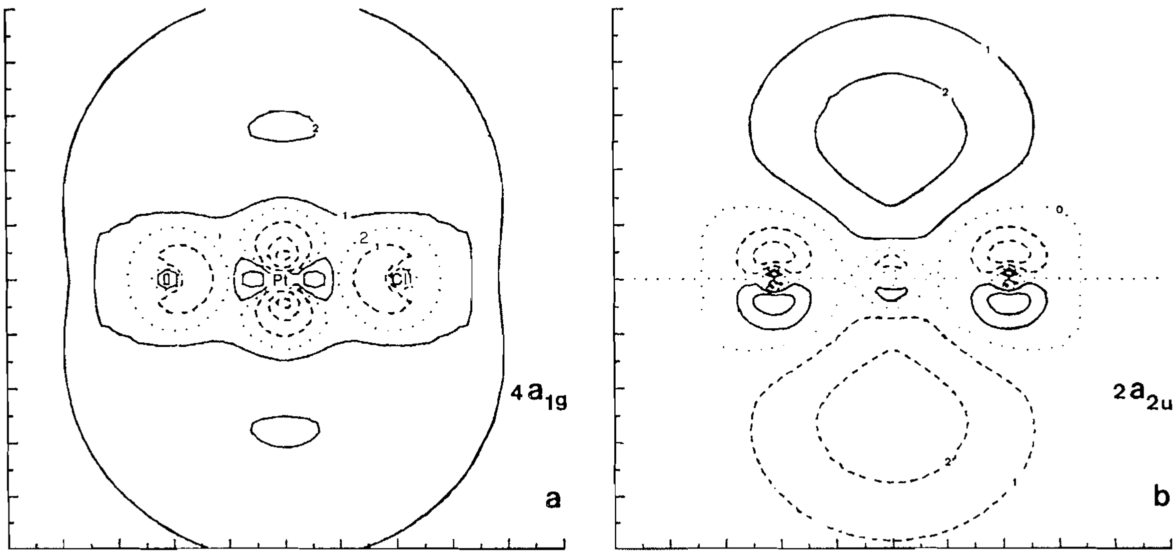

FIG. 1. Contours labelled 0, 1, 2 are equal to 0, 0.019, and 0.038 (electrons/bohr^3)$^{1/2}$ for case *a* and 0, 0.066, and 0.132 (electrons/bohr^3)$^{1/2}$ for case *b*. Positive wavefunction contours are represented by a solid line, negative contours by a dashed line, and dotted lines are related to the contour 0.

molecule), which corresponds essentially to a *p* partial wave (for 95% p_z, 98% p_z, 95% p_{xy}, and 98% p_{xy}, respectively). For the $4a_{1g}$ and $5a_{1g}$ MOs, the principal component in the outer sphere region is an *s* partial wave for the former (93%) and a *d* partial wave for the latter (63% *d*, 37% *s*). The low-lying $4a_{1g}$ and $2a_{2u}$ MOs have a substantial intersphere contribution. This is certainly due to the use of the Xα division of space in the case of a square planar structure, providing a strong intersphere participation to the diffuse *s* and p_z metal orbitals. The diffuseness of these MOs is illustrated in Fig. 1, which gives a clear indication of their 4*s* ($4a_{1g}$) and $4p_z$ ($2a_{2u}$) Rydberg character.

Ligand field spectrum

As reported previously (7, 8, 18), Xα spin polarized calculations in D_{4h} symmetry would lead to the complete determination of the multiplet states corresponding to the excited configurations ($3a_{1g}^2 2e_g^2 2b_{2g}^1 3b_{1g}^1$), ($3a_{1g}^2 2e_g^1 2b_{2g}^2 3b_{1g}^1$), and ($3a_{1g}^1 2e_g^2 2b_{2g}^2 3b_{1g}^1$). The spin–orbit parameters ζ_{nl} may be calculated for every radial function $R_{nl}(r)$ through the use of the spin–orbit operator

$$\zeta(r) = 2(\alpha^2/4)[1 + \alpha^2/4(\epsilon - V)]^{-1} \frac{1}{r} \frac{dV}{dr}$$

(for details see refs. 2, 8). The ζ_{5d}(Pt) parameters, related to the MOs involved in the *d–d* transitions, have large calculated values (around 6500 cm^{-1}). Thus it seems desirable to take into account the spin–orbit interaction which mixes the ligand field excited states and the ground state $^1A_{1g}$ with the triplet $^1A_{2g}$ and ^3E_g. As in previous works (7, 8), we are thus led to use a ligand field approach on the basis of parameters derived from the Xα calculation for the ground-state. The energies of the ground and excited states have been evaluated through the strong field matrix elements for square planar d^8 systems (27, 28) where the crystal field parameters have been replaced by the Δ1, Δ2, Δ3 values obtained from our Xα calculation, so as the spin–orbit coupling parameter $\alpha = (1/2)\ \zeta_{5d}(\text{eff}) = 1850$ cm^{-1}. ζ_{5d}(eff) is calculated as the average value over $3a_{1g}$, $2e_g$, $2b_{2g}$, and $3b_{1g}$ of the products $\rho_M \times \zeta_{5d}$(Pt), specific to each MO, where ρ_M is the fraction of the 5*d* Pt charge involved in this MO. The two Slater–Condon parameters F_2 and F_4 can then be treated as arbitrary parameters, kept within reasonable limits. The better agreement with the observed spectra is obtained for F_4 = 65 cm^{-1} and F_2 = 775 cm^{-1}.

Table 2 presents a comparison between the calculated ligand field transition energies and the experimental peak positions. These g–g transitions are forbidden according to the symmetry selection rules. They correspond to the low-intensity part of the spectrum (up to 34 000 cm^{-1}).

The spin–orbit interaction allows transitions from the ground state to excited states derived from triplet states, which may appear as very low intensity absorptions. The assignment presented in Table 2 is consistent with the experimental intensities and peak positions, as well as with the indications provided by the spectra in polarized light and MCD data. In agreement with the results of Martin *et al.* (24) and McCaffery *et al.* (23), the bands around 27 000 and 30 000 cm^{-1} are assigned to the $A_{1g}(^1A_g) \rightarrow A_{2g}(^1A_{2g})$ and $A_{1g}(^1A_{1g}) \rightarrow E_g(^1E_g)$, respectively. In fact, the two corresponding excited states keep a preponderant singlet character (cf. Table 2). The $A_{1g}(^1A_{1g}) \rightarrow B_{1g}(^1B_{1g})$ transition is calculated to occur at 34 200 cm^{-1}, that is on the low-energy side of the first high-intensity band. These assignments are at variance with CI + spin–orbit results obtained with the use of relativistic effective core potentials (29). This technique (RECP) yields a different singlet state ordering ($^1A_{2g} > {}^1E_g > {}^1B_{1g}$) from ours, which implies that, after diagonalizing the spin–orbit matrix, the $A_{1g}(^1A_{1g}) \rightarrow A_{2g}(^1A_{2g})$ and $A_{1g}(^1A_{1g}) \rightarrow E_g(^1E_g)$ transitions are correlated respectively with the 30 000 cm^{-1} and 27 000 cm^{-1} absorptions. This result is in full disagreement with the MCD (23) and polarized crystal data (24, 30). Our results are in agreement with previous assignments based on MO calculations (19, 26) or on ligand field calculations using substantial Δ3 values (24, 25, 28) particularly as alternative A proposed by Martin *et al.* (28). Elding and Olsson (31), following the proposal of alternative B by Martin *et al.* (28), suggested that the a_{1g} (d_{z^2}) and e_g ($d_{xz,yz}$) MOs might have very similar energies, leading to quasi degenerate $A_{1g}(^1A_{1g}) \rightarrow E_g(^1E_g)$ and $A_{1g}(^1A_{1g}) \rightarrow B_{1g}(^1B_{1g})$ transitions near 30 000 cm^{-1}. This assignment would imply Δ3 <

TABLE 2. Calculated ligand field excitation energies (cm^{-1}) and experimental peak positions (K_2PtCl_4 crystal spectrum)

Ligand field excited state	Calculated energies and singlet or triplet major participations	Observed peak positions (from ref. 20)
B_{1g}	34 300 ($^1B_{1g}$ 86)	
E_g	30 400 (^1E_g 54; $^3B_{1g}$ 33)	30 000
B_{2g}	28 500 ($^3B_{1g}$ 62; ^3E_g 36)	27 100
A_{2g}	27 250 ($^1A_{2g}$ 86)	
E_g	24 800 ($^3A_{2g}$ 34; $^3B_{1g}$ 23; ^3E_g 20; ^1E_g 21)	24 500
A_{1g}	23 750 ($^3A_{2g}$ 66; ^3E_g 25)	
E_g	21 100 ($^3A_{2g}$ 41; $^3B_{1g}$ 32; ^1E_g 18)	21 300
B_{1g}	20 700 (^3E_g 83)	
B_{2g}	18 800 (^3E_g 62; $^3B_{1g}$ 36)	18 000–19 000
E_g	17 450 (^3E_g 64; $^3A_{2g}$ 22)	
A_{2g}	17 100 ($^3A_{2g}$ 90)	
A_{1g}	16 400 (^3E_g 72)	

TABLE 3. Calculated Rydberg-type and CT-type transitions (cm^{-1}) compared with the available experimental peak positions

Transition[a]	Type[b]	Calculated value	Experimental value[c]
$2b_{2g} \rightarrow 2a_{2u}$ (F)	R $5d_{xy} \rightarrow 6p_z$	37 300	37 600
$2e_g \rightarrow 2a_{2u}$ (A)	R $5d_{xz,yz} \rightarrow 6p_z$	39 150	42 600 – 43 700
$2b_{2g} \rightarrow 4e_u$ (A)	R $5d_{xy} \rightarrow 6p_{x,y}$	44 300	
$3a_{1g} \rightarrow 2a_{2u}$ (A)	R $5d_{z^2} \rightarrow 6p_z$	45 200	45 050 – 46 300
$2e_g \rightarrow 4e_u$ (A)	R $5d_{xz,yz} \rightarrow 6p_{x,y}$	46 400

1000 cm^{-1}. This assumption disagrees with MO calculations and, particularly, with the present one, which yields a separation of 5950 cm^{-1} between the $3a_{1g}$ and $2e_g$ MOs. The low-intensity band around 17 000 – 18 000 cm^{-1} is assigned to the $A_{1g}(^1A_{1g}) \rightarrow A_{1g}(^3E_g)$, $A_{1g}(^1A_{1g}) \rightarrow A_{2g}(^3A_{2g})$, and $A_{1g}(^1A_{1g}) \rightarrow E_g(^3A_{2g})$ transitions. The broad absorption near 20 000 – 21 000 cm^{-1} and the shoulder at 24 000 cm^{-1} are assigned to the superposition of several transitions to states derived from triplet states.

High intensity spectrum

It consists of a moderately intense absorption band with a maximum peak at 46 200 cm^{-1} and a pronounced shoulder at 43 400 cm^{-1} (ϵ = 8 500) (23, 32). A weak shoulder ($\epsilon \simeq 400$) appears on its low-energy edge, near 37 500 cm^{-1}.

Most MO calculations have considered these intense bands as ligand-to-metal CT transitions (19, 25, 33–35), with the exception of Cotton and Harris (26), who proposed a metal $5d \rightarrow 6p$ assignment, in agreement with an earlier suggestion by Chatt *et al.* (36).

Later, the analysis of the polarized single-crystal spectra of K_2PtCl_4 (32) supported the suggestion that the 46 000 cm^{-1} band contains a low-lying Pt $5d_{z^2} \rightarrow 6p_z$ component. In their comparative study of the solution spectra of $PtX_n(H_2O)_{4-n}^{2-n}$ (X = Cl, Br), Elding and Olsson (31) have described the high intensity bands as the superposition of the metal-to-ligand CT transitions $3a_{1g} \rightarrow 2a_{2u}$ and $2e_g \rightarrow 2a_{2u}$. This assignment retains the $5d \rightarrow a_{2u}$ proposal (26, 32) but considers now a_{2u} as a predominantly ligand level instead of a Pt $6p$ one, on the basis of arguments drawn from the comparison of $PtCl_4^{2-}$ and $PdCl_4^{2-}$ spectra. Very recently, Larsson *et al.* (22) concluded to a $5d \rightarrow 6p$ assignment for the $2e_g \rightarrow 2a_{2u}$ transition, on the basis of their REX calculation, while their DS results show a strongly underestimated value for this transition energy.

As underlined previously, the relativistic corrections used in the present calculation have induced an increased separation between the upper occupied ligand $p\pi$ levels ($1b_{2u}$, $3e_u$) and the Pt $5d$ levels ($3a_{1g}$, $2e_g$, $2b_{2g}$) with respect to non relativistic MO results. Consequently, the ligand-to-metal CT transitions from ($1b_{2u}$, $3e_u$) to $3b_{1g}$ are calculated at higher energies than the $5d \rightarrow 6p$ transitions of Rydberg type, from ($3a_{1g}$, $2e_g$, $2b_{2g}$) to ($2a_{2u}$, $4e_u$).

As Table 3 shows, the orbitally forbidden $^1A_{1g} \rightarrow {}^1B_u$ ($2b_{2g} \rightarrow 2a_{2u}$) Rydberg transition is the lowest one and its calculated value compares very well with the shoulder of weak intensity located near 37 600 cm^{-1}.

In the same way, the structured band that peaks at 46 300 cm^{-1} is assigned to the superposition of absorption bands related to the transitions from the $^1A_{1g}$ ground state to the Rydberg-type excited states of configuration $5d^76p$, with the exception of the ^1E_u state which is calculated at a higher energy (52 600 cm^{-1}).

The results presented in Table 3 correspond to non spin-polarized calculations. They have been obtained without including configuration interaction, via the spin–orbit coupling, between the singlet and triplet $5d^7\,6p$ excited states. The intense absorption bands are related to singlet–singlet transitions and in this case, the spin–orbit coupling vanishes in a first-order approximation.

Relativistic MS-Xα calculations, performed in the double group D_{4h}^* symmetry would certainly lead to a more precise description of the fine structure of the 43 000 – 46 000 cm^{-1} band. Further work in this direction is in progress. Nevertheless, the present work does support unambiguously the assignment of the high intensity bands of the $PtCl_4^{2-}$ spectrum as Rydberg Pt $5d \rightarrow 6p$ transitions.

This paper is dedicated to Professor Camille Sandorfy on the occasion of his 65th birthday

ALFREDO M. SIMAS, VEDENE H. SMITH, JR., and AJIT J. THAKKAR. Can. J. Chem. **63**, 1412 (1985).

A priori quantum mechanical calculations are made for the alkynes XCCH (X = H, Li, F, Cl, and NC), and the cyanides XCN (X = H, F, Cl, O^-, S^-, and NC) in order to examine how substituent effects in these homologous series are reflected by changes in the three-dimensional one-electron momentum density. Our qualitative analysis is based on a partial wave decomposition of the momentum density, and is in harmony with analogous studies of the position space charge density. Our quantitative analysis is based on various properties of the isotropic momentum density and on the kinetic energy anisotropy. Values of the latter quantity relative to the parent unsubstituted molecule of the pertinent homologous series are found to correlate with the Taft resonance and Dewar–Grisdale mesomeric substituent constants.

ALFREDO M. SIMAS, VEDENE H. SMITH, JR. et AJIT J. THAKKAR. Can. J. Chem. **63**, 1412 (1985).

Dans le but d'évaluer si les effets de substituants dans ces séries se réflètent par des changements dans la densité tri-dimentionnelle du moment d'un électron, on a effectué des calculs a priori de mécanique quantique sur les alcynes XCCH (X = H, Li, F, Cl et NC) et sur les cyanures XCN (X = H, F, Cl, O^-, S^- et NC). Notre analyse qualitative est basée sur une décomposition par ondes partielle de la densité du moment et elle est en harmonie avec des études analogues sur la densité de charge dans l'espace de la position. Notre analyse quantitative est basée sur diverses propriétés de la densité du moment isotrope et sur l'anisotropie de l'énergie cinétique. On a trouvé que l'on peut établir une corrélation entre la valeur de cette dernière quantité, relative à celle de la molécule de base non substituée des séries homologues pertinentes, et les constantes de résonance de Taft et mésomérique de Dewar et Grisdale relatives aux substituants.

[Traduit par le journal]

Introduction

Compton scattering provides a powerful experimental probe of electronic momentum distributions in atoms, molecules, and solids. Hence, much effort has been expended (1) to correlate chemical properties with the usual gas-phase isotropic Compton profiles $\bar{J}(q)$ and their parent spherically averaged one electron momentum densities $\bar{\Pi}(p)$. Unfortunately detailed correlations have not been easy to find because the numerous integrations necessary to obtain $\bar{J}(q)$ from a wave function seem to wash the chemical information away. Nevertheless, some progress has been made with the help of bond difference profiles (2). However, the most promising avenue for obtaining chemistry from Compton scattering seems to be via directional Compton profiles $J(\mathbf{q})$ and their parent three-dimensional one-electron momentum densities $\Pi(\mathbf{p})$.

A few studies of the anisotropic $\Pi(\mathbf{p})$ and $J(\mathbf{q})$ have already been made (for extensive bibliographies, see refs. 3 and 4) and attempts to gain insight into their structure have been based on contour maps, difference contours with respect to prepared atoms, and partitioning into orbital contributions. Since the isotropic momentum density $\bar{\Pi}(p)$ has already been studied extensively, it seems that a useful partitioning scheme should first separate $\bar{\Pi}(p)$ from $\Pi(\mathbf{p})$, and then separate the anisotropic remainder into appropriately chosen components. We have shown recently (3, 4) that a partial wave decomposition of $\Pi(\mathbf{p})$ provides such a partitioning. This analysis takes a particularly simple form for linear molecules, and our studies (3–5) on 21 linear molecules, with occupied σ and π MO's only, show that if attention is restricted to the valence region then all qualitative features of the momentum density are described by merely four partial waves. The purpose of this paper is to examine how substituent effects in alkynes and cyanides are reflected by changes in these four chemically dominant partial waves of the momentum density.

Review of theory

In the case of linear molecules with the molecular axis aligned along the polar axis, which will be the sole concern of this paper, $\Pi(\mathbf{p})$ has $D_{\infty h}$ symmetry irrespective of whether the molecular skeleton has $C_{\infty v}$ or $D_{\infty h}$ symmetry (3). Thus the momentum density of a linear molecule may be expanded as follows:

$$\Pi(\mathbf{p}) = \Pi_0(p) + \Pi_2(p)P_2(\cos\theta_p) + \Pi_4(p)P_4(\cos\theta_p) + \ldots$$

where the $P_L(\cos\theta_p)$ are Legendre polynomials, $\Pi_0(p)$ is precisely equal to the spherically averaged momentum density $\bar{\Pi}(p)$, and the higher partial waves $\Pi_2, \Pi_4, \ldots$, represent the anisotropy. We call this partitioning process a *partial wave analysis of the momentum density* (3, 4). Such an analysis is well suited to the momentum density because it is essentially a monocentric function. Clearly all expectation values of the form $\langle\Sigma_i f(p_i)\rangle$ are determined by $\Pi_0(p)$ alone:

$$\langle\Sigma_i f(p_i)\rangle = \int\Pi(\mathbf{p})f(p)\,d\mathbf{p} = 4\pi\int_0^\infty\Pi_0(p)\,f(p)\,p^2\,dp \equiv \langle f(p)\rangle$$

An example of the above is the total kinetic energy T which corresponds to $f(p) = p^2/2$. Hartree atomic units (6) are used throughout this section. An illustration of the power of partial wave analysis is provided by the fact that the anisotropy of the kinetic energy tensor is determined by Π_2 alone. Thus

$$T_\parallel - T_\perp = (2\pi/5)\int_0^\infty\Pi_2(p)p^4\,dp$$

[1] Based in part on the Ph.D. dissertation of A.M.S.
[2] NSERCC University Research Fellow.

where $T_{\|}$ and $T_{\perp}$, respectively, are the components of the kinetic energy parallel and perpendicular to the molecular axis. Of course $T = T_{\|} + 2T_{\perp}$. These components of the kinetic energy are important because they are experimentally accessible (7) through directional Compton profiles, and because they play a pivotal role in certain types of analyses of chemical bonding (8).

Convergence studies (3, 4) on 21 linear molecules (including all those considered in this paper) have indicated that such an expansion converges particularly rapidly for small momentum, p, and less rapidly for large momentum. However, we have shown (3) for these 21 molecules, that the region $0 \le p \le 3\hbar a_0^{-1}$ is essentially the valence region and that the anisotropic momentum density $\Pi(\boldsymbol{p})$ in this region can be studied satisfactorily from a chemical point of view by considering merely four partial waves: $\Pi_0(p)$, $\Pi_2(p)$, $\Pi_4(p)$, and $\Pi_6(p)$.

Evaluation of the partial waves of the momentum density from a wave function constructed from an orbital basis set is not difficult. Analytic formulae for these purposes are implicit in eqs. (129)–(133) and eqs. (145)–(147) of ref. 9 for spherical harmonic and cartesian Gaussian-type basis functions, respectively. All the wavefunctions that are employed in this paper are built from Slater type orbital (STO) basis sets which are a special case of spherical harmonic basis sets. Hence all partial waves displayed in this paper were obtained via analytic formulae. It is worth noting that STO basis sets provide a reasonable balance between accuracy in position space and accuracy in momentum space (10).

It has been pointed out (3) that the partial wave $\Pi_L(p)$ behaves as p^L for small p, and that $\Pi_L(p)$ decays to zero as $p^{\delta(L,0)-9}$ where $\delta(L,0)$ is the Kronecker delta, for all STO basis sets that include at least one $1s$ STO — a condition fulfilled in an overwhelming majority of STO basis sets including all those considered in this paper. Moreover, empirical rules outlined earlier (3–5) enable one to predict the qualitative valence region (small p) behaviour of the contributions of various types of canonical molecular orbitals (MO's) to the chemically dominant partial waves. These rules are summarized in Table 1 for the reader's convenience.

Qualitative substituent effects

Momentum densities and pertinent partial wave expansions were calculated for two homologous series: the cyanides XCN with X = H, F, Cl, O^-, S^-, and NC, and the alkynes XCCH with X = H, Li, F, Cl, and NC. These two series have been considered together because the ethynil and cyano groups are isoelectronic, have very similar electronic structures, and both contain a nominal triple bond. The self consistent field (SCF) wavefunctions used were those of McLean and Yoshimine (11) at the geometries corresponding to the lowest computed energies and are built from atom optimized STO basis sets of double-ζ plus polarization quality or better.

Politzer and co-workers (12) used exactly the same wavefunctions for their position space studies of these molecules. Their studies indicate that the ethynil and cyano groups maintain their properties across their respective homologous series. Thus the lengths and force constants of the CC and CN bonds are virtually independent of the substituent in the alkynes and cyanides, respectively. Moreover, Politzer and Kasten (12*d*) have demonstrated that the charge densities of the ethynil and cyano fragments are relatively little affected by the nature of the substituent.

Figures 1 and 2 show partial waves of the momentum density for the cyanides and alkynes, respectively. Note that all quantities are per electron (i.e. divided by the number of electrons) to facilitate comparisons between molecules. Moreover, all the spherically averaged momentum densities $\Pi_0(p)$ are shown to the same scale, and all the higher order partial waves, except those for HCCH and LiCCH, are shown to another uniform scale. In view of some recent interest (13) in the monotonicity or otherwise of $\bar{\Pi}(p)$, note that the vast majority of the alkynes and cyanides shown in Figs. 1 and 2 have *nonmonotonic* isotropic momentum densities.

TABLE 1. Empirical rules (3) governing the valence region (small p) behaviour of the contributions from various types of canonical MO's to the partial waves of the momentum density

L/MO	σ bonding	σ antibonding	π bonding	π antibonding
2	−	+	−	~0
4	~0	~0	+	−
6	~0	~0	−	+

First consider only those substituents (X = H, F, Cl, and CN) for which partial waves are shown for both the cyanide and alkyne. The figures show that, for fixed X, the partial waves of the isoelectronic XCCH and XCN molecules are rather similar. This is the momentum density analog of Politzer and Kasten's observation (12*d*) that the charge densities of the XC fragments in the XCCH and XCN molecules are very similar for fixed X. Proceeding further, the interpretation of the curves is straightforward. The extrema of the non-zero L $\Pi_L(p)$'s for XCCH occur at a smaller p value than the corresponding extrema for XCN for the same X. This is a result of the fact that XCCH is longer than XCN. Furthermore, the amplitudes of the non-zero L $\Pi_L(p)$'s for X = H, F, and Cl are larger for XCCH as compared to the corresponding XCN indicating that the position space representation of the highest occupied molecular orbital (HOMO), which in all cases is a π orbital, is more delocalized in XCCH. This is consistent with the finding of Politzer and Harris (12*a*) that a very significant portion of the π electronic charge density is not in the bonding region but spread in regions adjacent to it resulting in a very significant degree of π bonding with the neighbouring atoms even if one of them is a hydrogen. On the other hand, the non-zero L $\Pi_L(p)$'s of NCCN have a larger amplitude than their NCCCH counterparts indicating, as expected, that the higher symmetry in the former enhances the position space delocalization of the π orbitals. On the other hand the partial waves are very different for different X implying that a substituent can indeed substantially modify the momentum density (per electron) of a compound. The partial waves of HCCH and HCN, especially the negative Π_6's, clearly indicate (see Table 1) that the HOMO for these molecules is a π bonding orbital as opposed to the other molecules, with X = F, Cl, and CN, where the HOMO is an antibonding π orbital which leads to a positive $\Pi_6(p)$.

Thus substituent effects in these small series are seen to be strongly correlated with the electronic structure of the substituent and its interaction with the electronic structure of the functional group. On the basis of the partial waves it is possible to separate the molecules into three clusters. One defined by X = H and characterized by a negative $\Pi_6(p)$, another defined by X = F, Cl and characterized by a negative small amplitude $\Pi_4(p)$ and a positive $\Pi_6(p)$, and the last one defined by X = CN and characterized by a positive Π_6 and a clearly oscillating $\Pi_4(p)$ starting from negative values at low p. These last two clusters

have in common the fact that antibonding π orbitals are occupied.

Consider now the partial waves of LiCCH in Fig. 2. Clearly the negative $\Pi_6(p)$, evidence of only bonding π orbitals, places it into the X = H cluster. The large amplitudes of the non-zero $L\,\Pi_L(p)$'s indicate a large degree of π electronic interaction in HCCH and LiCCH. On the other hand, Fig. 1 clearly shows that $[OCN]^-$ and $[SCN]^-$ belong to the X = F, Cl cluster. In

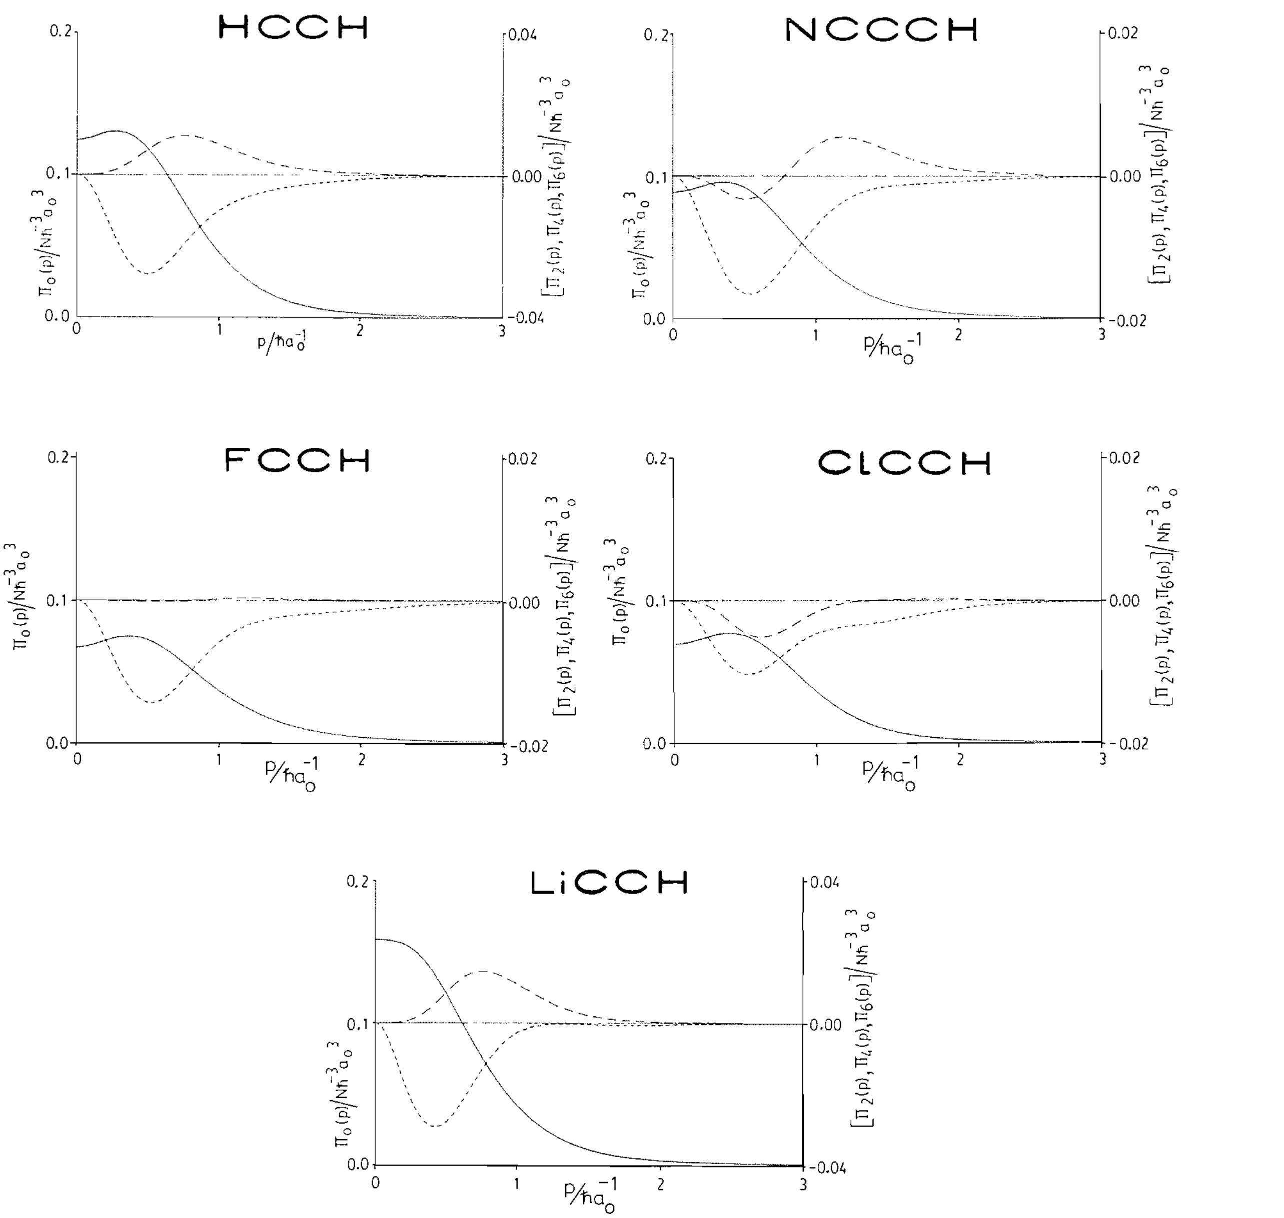

FIG. 2. Partial waves of the momentum density (per electron) for the alkynes XCCH with X = H, NC, F, Cl, and Li. See the caption to Fig. 1. Also note that the higher order partial waves for HCCH and LiCCH are shown on a scale that is one-half of that to which the $\Pi_L(p)$ ($L \neq 0$) for the remaining alkynes are shown.

fact, there is such a strong similarity between the partial waves of the isoelectronic pairs $[OCN]^-$ and FCN, and $[SCN]^-$ and ClCN that the only means of deciding which one is which is comparison of $\Pi_0(0)$; the latter is larger in the negative molecular ions than in their isoelectronic neutral counterparts.

Quantitative substituent effects

Quantitative results are considered next. Table 2 lists values of $\bar{\Pi}(0)$ and the well-defined moments $\langle p^k \rangle$ ($-2 \leq k \leq 4$) for each of the 11 molecules considered in this study while Table 3 lists their characteristic momenta defined (7*c*) by

$$p^* = [\bar{J}(0)/2\pi\bar{\Pi}(0)]^{1/2}$$

where $\bar{J}(0) = \langle p^{-1} \rangle/2$. The characteristic momentum is related to the valence momentum density. Like the characteristic momenta of the atoms which correlate, within a period, with the electronic saturation of the valence shell (7*c*, 13*c*), the characteristic momenta of the molecules increase with increasing electron sharing and number of valence electrons. Thus, of the molecules considered, FCN possesses the largest and LiCCH the smallest p^*.

TABLE 3. Characteristic momenta

	$p^*/\hbar a_0^{-1}$

Since substituent effects are of interest in this paper, Table 4 lists differences between the molecular properties and those of isolated ground state atoms and fragments. The higher moments $\langle p^3\rangle$ and $\langle p^4\rangle$ are not considered since they are primarily large momentum, and hence core electron, properties. The atomic properties used in Table 4 were computed from atomic SCF wavefunctions built from STO basis sets of a quality comparable to the pertinent molecular basis sets. These atomic properties have been listed elsewhere (4). Table 4 shows a high correlation between the various difference properties of XCCH and XCN when X is the same implying that substituent effects in momentum space can, within reasonable limits, be transferred across different homologous series. The largest differences in Table 4 occur for LiCCH due not to the molecule itself, but to the momentum space properties of the lithium atom which has a huge value for $\Pi(0)$ that is highly dependent on the quality of the basis set employed. Unfortunately, each of the difference properties orders the various substituents in different ways.

Substituent effects are often described in terms of substituent constants (14, 15). Of these σ_P is the relative effect of a substituent in the *para* position on benzoic acid dissociation in water at 25°C. It is interpreted as the ability of the substituent to withdraw electronic charge from the rest of the molecule. It can be divided into an inductive part, σ_I, and a resonance part, σ_R, such that $\sigma_P = \sigma_I + \sigma_R$. The constant σ_I is interpreted as the ability to withdraw charge through "inductive" interactions which occur in the electronic σ system while the Taft resonance constant σ_R is interpreted as a measure of the tendency of a substituent to withdraw electronic charge through some sort of conjugative or resonance effect which should occur mainly in the electronic π system. These constants, despite being obtained from substituent effects on acid dissociation, have proven to be useful in a wide range of other equilibria and rate processes. We tried to find correlations between the various difference properties in Table 4 and the substituent constants. None could be found for σ_I. On the other hand the difference $\bar{J}(0) = \langle p^{-1}\rangle/2$ could correlate with σ_P for the XCN series because for O^- it is equal to $-0.3211/\hbar^{-1}a_0$ and σ_P is −0.5 (14) while for CN it is $0.201/\hbar^{-1}a_0$ and σ_P is 0.69 (14). Such correlation, however, predicts F and Cl to be overall weak electron-releasing substituents which is clearly wrong.

So far we have only considered difference properties of the isotropic momentum density Π_0. Let us now turn to the anisotropy of the kinetic energy tensor – a property of Π_2 alone (see theory section). Table 5 lists values of $T_\| - T_\perp$ relative to HCCH and HCN for the alkynes and cyanides, respectively. Table 5 shows that the substituent constant σ_R correlates in a consistent way with the *relative* $T_\| - T_\perp$. The correlation is better for the XCCH series which is not surprising given the definition of σ_R. The implication is that if the relative $T_\| - T_\perp > 0$ then X is a conjugative electron-withdrawing substituent, while if the relative $T_\| - T_\perp < 0$ then X is a conjugative electron-releasing substituent. The Dewar–Grisdale mesomeric constant M (14), which is supposed to include the π-inductive as well as the resonance polar effect, also correlates well with the relative $T_\| - T_\perp$ as indicated by Table 5. At the moment it is not safe to try an interpretation of this correlation because of the small number of substituents involved.

TABLE 5. Comparison between the relative kinetic energy anisotropy, $(T_\| - T_\perp)$, and the Taft resonance, σ_R, and Dewar–Grisdale mesomeric, M, substituent constants[a] for the XCCH and XCN series[b]

	$(T_\| - T_\perp)/E_h$

[b] $(T_\| - T_\perp)/E_h = -0.547$ and −0.22 for HCCH and HCN, respectively.

Concluding remarks

In this paper we have examined how substituent effects in alkynes and cyanides are reflected in the three-dimensional one-electron momentum density $\Pi(\mathbf{p})$. Qualitative studies, based on the four chemically dominant partial waves (3, 4) of the momentum density, were in harmony with previous studies (12) of the position space charge densities. Quantitative correlations between properties of the isotropic momentum density and chemical indices could not be found as in many other studies (1). However, a correlation *was* found between the usual substituent constants of physical organic chemistry (14,

15) and the values of the kinetic energy anisotropy $T_\parallel - T_\perp$ relative to the hydrogen-containing (or non-substituted) parent of the pertinent homologous series. This correlation, meagre as it may seem to the reader unfamiliar with momentum density studies (1), is, in our opinion, a significant step towards locating the elusive chemical information content of momentum densities.

Vibronic analysis of the $\tilde{A}(^1A_2) \leftarrow \tilde{X}(^1A_1)$ spectrum of Br_2CS

B. SIMARD AND R. P. STEER[1]

Department of Chemistry, University of Saskatchewan, Saskatoon, Sask., Canada S7N 0W0

Received July 20, 1984

This paper is dedicated to Professor Camille Sandorfy on the occasion of his 65th birthday

B. SIMARD and R. P. STEER. Can. J. Chem. **63**, 1418 (1985).

$\tilde{A}(^1A_2)-\tilde{X}(^1A_1)$ fluorescence excitation and emission spectra of Br_2CS have been recorded. A vibronic analysis shows that the molecule is non-planar in the $\tilde{A}$ state with an equilibrium out-of-plane angle of 13° and a barrier to inversion of 164 cm^{-1}. Upper state vibrational frequencies of modes 1, 2, 3, 4, and 6 have been obtained. Comparisons with other tetraatomic thiocarbonyls support the assignments. A ground state C—Br dissociation energy of 52.3 kcal mol^{-1} has been obtained from the onset of diffuseness in the $\tilde{A}-\tilde{X}$ spectra. A search for phosphorescence proved unsuccessful.

B. SIMARD et R. P. STEER. Can. J. Chem. **63**, 1418 (1985).

Les spectres d'excitation et d'émission de la transition $\tilde{A}(^1A_2)-\tilde{X}(^1A_1)$ du Br_2CS ont été enregistrés. L'analyse vibrationnelle indique que la molecule est non-planaire avec une barrière d'inversion de 164 cm^{-1} et d'un angle d'équilibre hors du plan de 13°. Les fréquences vibrationnelles des modes 1, 2, 3, 4 et 6 dans l'état excité ont aussi été evaluées. Des comparaisons avec d'autre thiocarbonyles tétra-atomiques appuient les attributions vibrationnelles apportées. Une energie de dissociation de 52.3 kcal/mol a été calculée pour la liaison C—Br à partir du seuil de diffusion du spectre. La recherche de la phosphorescence s'est avérée négative.

[Traduit par le journal]

Introduction

The spectroscopy of tetraatomic molecules containing the thiocarbonyl group has been extensively studied for the last two decades. Two electronic transitions involving $n \rightarrow \pi^*$ electron promotions are found in the visible whereas at least four transitions, three Rydberg and one $\pi \rightarrow \pi^*$ intravalence, have been observed in the near uv. Unlike most of their carbonyl counterparts, these compounds are photostable when excited to low-lying vibrational levels of their $\tilde{a}$, $\tilde{A}$, and in some cases $\tilde{B}$ states (1). As a result linewidths are narrow so that vibronically resolved absorption and emission spectra can be recorded and the structures of the excited states elucidated. The spectra of H_2CS (2), D_2CS (2), F_2CS (1), ClFCS (1), and Cl_2CS (3) have been examined to date, but little is known about the heavier, Br and I substituted compounds, including Br_2CS.

The structure of the ground state of Br_2CS has been determined by electron diffraction (4) and ir—Raman force field (5) methods. The microwave spectrum has not been reported and the ground state rotational constants therefore remain unknown. No electronic spectra have been measured so that no information at all about any of its upper states is presently available. We report here a partial vibrational analysis of the $\tilde{A}(^1A_2)-\tilde{X}(^1A_1)$ band system and extract from it several parameters which characterize the structure of its $\tilde{A}$ state.

Experimental

Br_2CS was prepared by the reaction of thiophosgene (Aldrich) with boron tribromide (Aldrich) at 60°C according to the method of Diderrich and Hass (6). Purification was achieved by trap-to-trap vacuum distillation. Mass spectral analysis showed that traces of BBr_3 and BCl_3 (both non-emissive) were the main contaminants; there was no evidence of residual Cl_2CS. When not in use the product was kept in the dark at about −10°C to prevent dimerization. Before recording a spectrum, the sample was thoroughly degassed by freeze—pump—thaw cycles to remove traces of oxygen.

The experimental arrangement used for recording emission and excitation spectra is shown schematically in Fig. 1. Sample fluorescence was excited in a double pass cell by a Spectra-Physics argon-ion pumped dye laser equipped with a three-plate birefringent filter. The output linewidth was about 40 GHz (1.3 cm^{-1}). Disodium fluorescein, rhodamine-6G, and DCM dyes were used to cover the 535—700 nm spectral region.

Emission was collected at right angles to the excitation axis by a telescope lens and reflecting mirror system and was focussed onto the entrance slit of a Jarrell-Ash 0.75 m f/6.5 monochromator fitted with an 1800 line/mm holographic grating. Emission was detected by single photon counting with a red-sensitive RCA 31034A photomultiplier tube coupled to a Tracor Northern Model 7200 multichannel analyzer operating in the multichannel scaling mode. Data were transferred from the MCA to a time-shared DEC 2060 computer for background subtraction, correction for spectral sensitivity of the detection system and correction for the variation in laser power with wavelength. First order diffraction was observed when emission spectra were measured. When excitation spectra were recorded the birefringent filter of the dye laser was coupled to a stepping motor drive system and zero order diffraction was viewed through a single cut-off filter (Corning 26-4424 or 26-4416 or CS-1-69) to eliminate scattered exciting light. Wavelength calibration was effected by interpolation between lines in the Ne arc spectrum; spectral bands could be determined to an accuracy of ± 15 cm^{-1}.

Low resolution absorption spectra were recorded with a Cary 118 double beam spectrophotometer. Gas phase spectra were obtained by filling a 10 cm long fused quartz absorption cell with Br_2CS at its room temperature vapor pressure, ca. 6 Torr, using a grease and mercury-free vacuum line equipped with a Wallace and Tiernan metallic membrane manometer. Background pressures, measured with an ionization gauge, were $<10^{-3}$ Torr. All experiments were carried out at a room temperature of 22 ± 2°C.

Results and discussion

A low resolution absorption spectrum of Br_2CS taken in the gas phase at a pressure—path of ca. 60 Torr—cm is shown in Fig. 2. Under these conditions measurable absorption in the visible occurs between approximately 620 and 380 nm and exhibits a maximum at 480 nm, at which the molar extinction coefficient is 5.6 M^{-1} cm^{-1}. Similar spectra taken in $CHCl_3$ or CCl_4 solution reveal that the absorption in the visible has an onset which lies near 630 nm and increases monotonically to the maximum with very little evidence of gross vibronic structure. On the other hand a spectrum of pure Br_2CS (l) in a

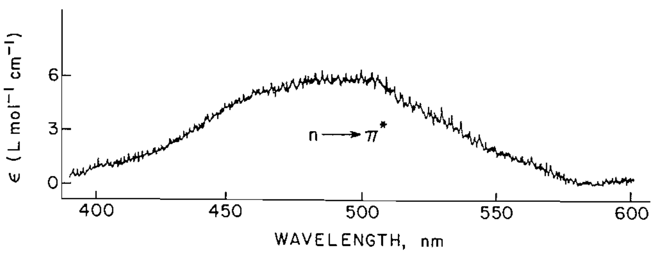

FIG. 2. Low resolution gas phase absorption spectrum of Br_2CS at a pressure–path of 60 Torr–cm and room temperature.

1 cm cell exhibits an absorption onset at ca. 660 nm. By analogy with the previous analyses of similar molecules (1), the absorption in this region is attributed to forbidden transitions of largely n → π* character.

A major problem concerns the separation of absorptions due to the $\tilde{A}(^1A_2) \leftarrow \tilde{X}(^1A_1)$ system from those due to the $\tilde{a}(^3A_2) \leftarrow \tilde{X}(^1A_1)$ system in this region. In Cl_2CS both the $\tilde{A} \leftarrow \tilde{X}$ (3) and $\tilde{a} \leftarrow \tilde{X}$ (7, 8) systems have been identified; their origins are separated by only 1224 cm^{-1}, and their oscillator strengths probably differ by no more than a factor of ten. The difference in the frequencies of the $\tilde{A} \leftarrow \tilde{X}$ and $\tilde{a} \leftarrow \tilde{X}$ origins in Br_2CS should be similar to that of Cl_2CS, so that extensive overlap of the two absorption systems is inevitable. Compounding the problem, the oscillator strength of the triplet system is expected to be greater (relative to the singlet system) in Br_2CS than in Cl_2CS due to the more effective induction of spin–orbit coupling resulting from the presence of heavy Br atoms in the former. Such expectations are realized in the tetraatomic carbonyls in which the $\tilde{a} \leftarrow \tilde{X}$ oscillator strength of Br_2CO is calculated to be ca. 100 times greater than that of Cl_2CO (9). On these grounds the visible absorption spectrum of Br_2CS is expected to be complex and the unequivocal assignment of bands difficult, especially in the region of overlap of the two systems.

Fortunately, the identification of bands which are part of the singlet system in the presence of those which belong to the triplet may be achieved using laser-induced emission excitation spectroscopy if the photophysical behaviors of the $\tilde{a}$ and $\tilde{A}$ states are significantly different. Differences in the radiative lifetimes of the two states are not expected to be large, for the same reasons that the oscillator strengths of the two absorption systems are expected to be comparable. On the other hand, both intramolecular nonradiative decay and collisional quenching processes could occur at greatly different rates in the two states. Thus, under appropriate conditions, the quantum yield of emission from the $\tilde{A}$ state could differ from that of the $\tilde{a}$ state by a large factor, so that the emission excitation spectrum of one system would be much more intense than the emission excitation spectrum of the other. This is certainly the case in Cl_2CS in which fluorescence from the $\tilde{A}(^1A_2)$ state (with quantum yield approaching unity in the collision-free limit (10)) can be observed very easily using laser excitation methods (11), whereas phosphorescence from the $\tilde{a}(^3A_2)$ state has never been observed despite repeated attempts to find it (12). Although the excited state dynamics of Br_2CS will be the subject of a separate investigation, we assume here that Br_2CS and Cl_2CS will exhibit similar photophysical properties; namely, the $\tilde{A}$ states will emit with relatively large quantum yields whereas the $\tilde{a}$ states will be "dark" (or nearly so) under the experimental conditions ($P \sim 0.1-6$ Torr) which we have employed. We therefore assume that emission from Br_2CS excited in the 630–535 nm region originates largely in the $\tilde{A}(^1A_2)$ state. The ability to analyze both the excitation and emission spectra and to assign all of the strong and most of the weak bands on this basis would appear to justify the assumption.

Laser excitation spectra have been recorded from 630 to 535 nm. Figure 3 shows that portion from 630 to 570 nm (taken with R6G dye). This spectrum is uncorrected for the variation in laser output power with wavelength so that quantitative comparisons of the relative intensities of bands which are not adjacent is inappropriate. A search for additional emission to the red (610–700 nm) using DCM as a laser dye proved unsuccessful. The observed band system is highly structured from 628 to 547 nm. The spectrum becomes much more congested near 547 nm and to the blue consists of a series of crowded sharp features superimposed on what appears to be a diffuse continuum at the resolution employed. To the red of 547 nm, bands are well-resolved (although their frequencies could not be measured with an absolute accuracy of better than ±15 cm^{-1} with the experimental arrangement employed).

The emission excitation spectrum was analyzed within the following theoretical framework. First, using vibrational frequencies determined by Willner and Hauswirth (5) from infrared and Raman spectra (Table 1), room temperature Boltzmann populations of the ground state levels were calculated. Accordingly, only cold bands ($v_i'' = 0$) and hot bands originating from $v_i'' = 1$ were considered to contribute significantly to the spectrum on relative intensity grounds. It is important to note that $v_4'' = 1$ has a population which is 13% of that of $v_4'' = 0$ at room temperature, so that hot bands originating in mode 4, an important promoting mode (vide infra), should be observable. Second, Herzberg–Teller vibronic coupling (13) was assumed to be the mechanism whereby intensity is acquired by the symmetry forbidden $^1A_2 \leftarrow {}^1A_1$ transition, similar to the cases of the analogous molecules, Cl_2CS (3) and H_2CO (14). According to the Herzberg–Teller mechanism the orbitally forbidden transition "borrows" intensity from nearby electric-dipole allowed transitions to valence or Rydberg states of B_1 or B_2 symmetry via non-totally symmetric vibrations. In the case of tetraatomic molecules exhibiting C_{2v} ground state symmetry but having non-planar excited state geometries, the most active symmetry-breaking vibration is $\nu_4(b_1)$, the out-of-plane ben-

ding mode. Vibronic bands characterized by odd quantum number changes in v_4 are expected to be intense; cold and hot band progressions converge on the false origins 4^1_0 and 4^0_1, respectively. Bands involving unrestricted quantum number changes in the totally symmetric modes (ν_1, ν_2, and ν_3; cf. Table 1) in combination with odd quantum number changes in mode 4 are also expected to be prominent.

Experimentally, measurement of the emission spectrum excited in the strong band at 576.6 nm proved very useful in the analysis. This spectrum, shown in Fig. 4, exhibits three resonance fluorescence progressions in which members are separated by $2\nu_4''$ and one resonance fluorescence progression in which members are separated by ν_1''. From the band spacing in these progressions one obtains vibrational frequencies of $\nu_4'' = 412$ cm^{-1} and $\nu_1'' = 1110$ cm^{-1}, which compare very favorably with values of 415 cm^{-1} and 1116 cm^{-1} obtained by ir and Raman measurements (cf. Table 1). One prominent progression of four members in the emission spectrum, identified by asterisks in Fig. 4, could not be assigned to resonance emission. These bands are wider than any other bands in the spectrum, and the distribution of their intensities is different. Their peak-to-peak spacing, ca. 320 cm^{-1}, does not fit any ground state vibrational frequency. The only reasonable course was to assign these bands to non-resonant emission resulting from collisional vibrational relaxation in the excited state. Since upper state frequencies are almost certain to be more or less smaller than those of the corresponding modes in the ground state, and since only modes 1–4 are likely to be prominent, reasonable deduction led to a tentative assignment of the 576.6 nm band as $2^4_0 4^1_0$. Using this band as a starting point, the 4^1_0 false origin in the excitation spectrum could easily be identified and most of the bands assigned.

Reasonable assignments of all bands in the $\tilde{A}-\tilde{X}$ system having intensities $\geq 10\%$ of those of the strongest nearby bands are listed in Table 2. Figure 5 shows graphically the convergence of members of prominent progressions to the 4^1_0 false origin. The convergences of other progressions are shown in Fig. 6. Assignments of many of the weaker bands should be

[b]Extrapolated value.

regarded as highly tentative since the errors in measuring band frequencies are relatively large and there was no reasonable way, using the present data, to distinguish between weak cold bands and sequence bands which might be observable due to favorable Boltzmann factors for ν_3'' and ν_6''. With the exception of bands originating in the ν_4'' stack (which are expected to be prominent on Franck–Condon grounds), weak bands were arbitrarily assigned as cold in cases where hot sequence bands were reasonable alternatives.

As will be discussed later, it was quite reasonable to locate the origin of the $\tilde{A}-\tilde{X}$ system 75 cm^{-1} to the red of the 4^1_0 band, i.e. at 15930 cm^{-1}. If vibronic intensity borrowing were the only mechanism whereby bands in the $\tilde{A}-\tilde{X}$ spectra acquired intensity, the 0^0_0 band would be completely absent. In fact a very weak band is observed at the calculated origin frequency (vide infra). The origin band has been observed in the $\tilde{A}-\tilde{X}$ transitions of H_2CS and D_2CS (15, 16) in which cases the observed intensity was attributed to magnetic dipole transitions similar to that seen in H_2CO (17). However, the origin band has never been observed in the $\tilde{A}-\tilde{X}$ system of Cl_2CS (3, 11). If the band at 15930 cm^{-1} is the origin, the magnetic-dipole allowed 4^2_0 band ca. 280 cm^{-1} to the blue should also be observable on Franck–Condon grounds. A broad, weak feature is found in the required spectral region, but lack of sufficient intensity and resolution precluded its assignment. The nature of this and the origin band of the $\tilde{A}-\tilde{X}$ system in Br_2CS remains uncertain.

The experimental and calculated energy levels of ν_4' are shown schematically in Fig. 7. The calculations were performed by modelling the excited state double minimum potential-energy along the inversion vibration coordinate by a harmonic function perturbed by a Gaussian barrier, following the method of Coon *et al.* (18). This model has previously been used successfully to calculate the inversion vibrational energies and the equilibrium out-of-plane angles of the lowest triplet and excited singlet states of a number of tetraatomic carbonyls (19) and thiocarbonyls (3, 20). The function has the form

$$[1] \quad V(Q) = (1/2)\lambda Q^2 + \delta e^{\rho} \exp\{-\lambda Q_2/2\delta\}$$

where $\lambda = (2\pi c \nu_0)^2$ is the harmonic force constant and $\delta = Bhc\nu_0/(e^{\rho} - \rho - 1)$. $B\nu_0$ is the inversion barrier height in

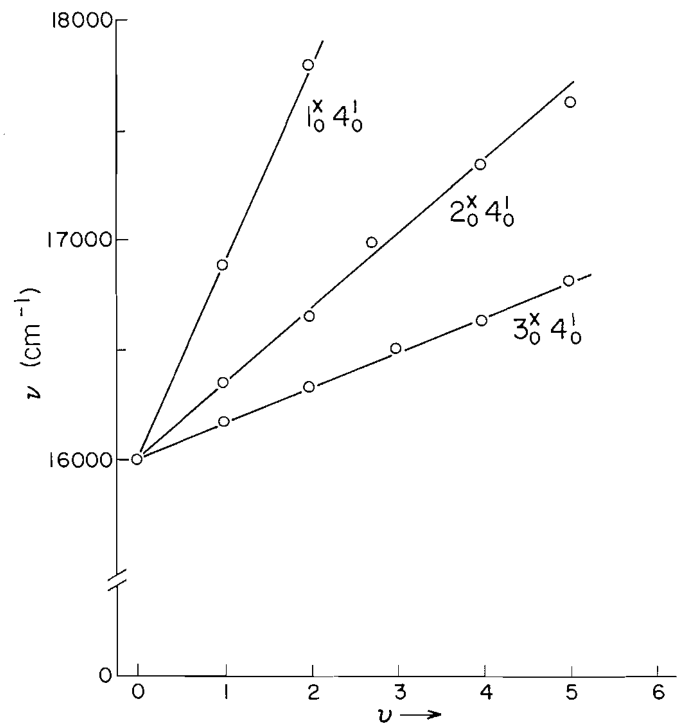

FIG. 5. Convergence of strong progressions in the excitation spectrum to the false origin at 16005 cm^{-1} (4^1_0).

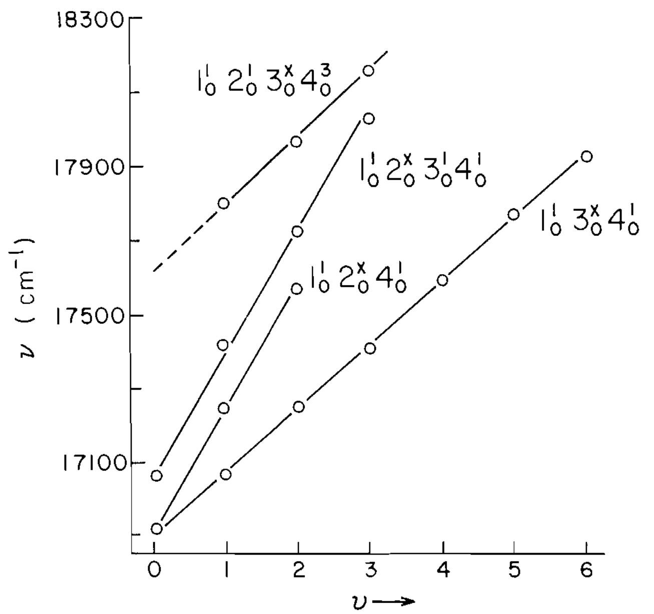

FIG. 6. Progressions in modes 2 and 3 in the excitation spectrum.

wavenumbers, and ρ is a shape factor related to the relative steepness of the inner and outer sides of the double minimum surface. Using the linear variation method the final vibrational eigenvalues are given in the form

$$[2]\quad \frac{G}{\nu_0} = \frac{E}{hc\nu_0} - \frac{B(\rho + 1)}{e^{\rho} - \rho - 1}$$

These eigenvalues have been tabulated by Coon *et al.* (18) for values of ρ from 0.6 yo 2.4 and values of B from 0 to 5. Values of B and ν_0 were calculated for each fixed value of ρ and the iteration continued until the best fit between the calculated and

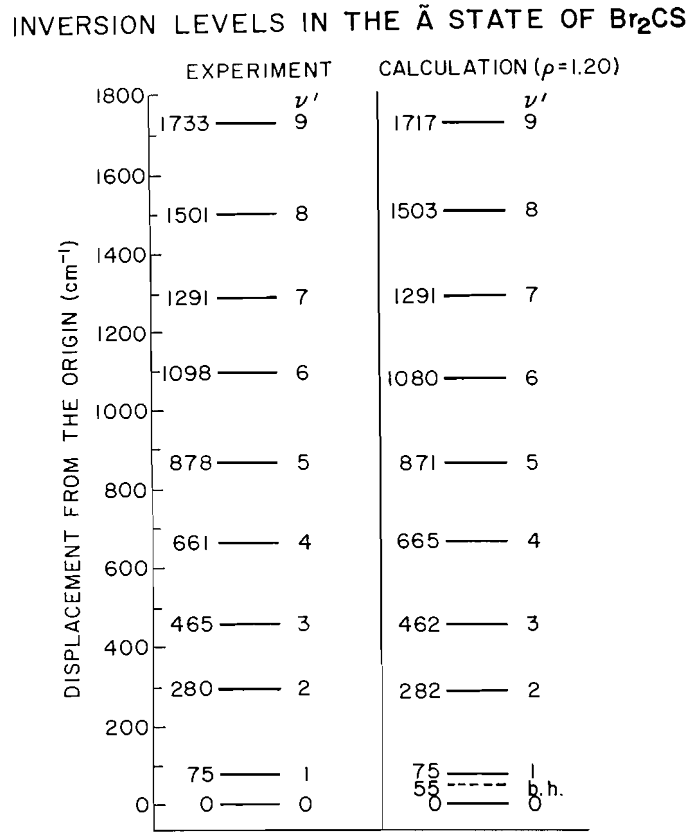

FIG. 7. Experimental and calculated energies of ν_4' in the $\tilde{A}$ state of Br_2CS. The dashed line indicates the position of the top of the barrier to inversion.

observed values of ν_4' was found. In the case of Br_2CS in its $\tilde{A}$ state the best fit was obtained with $\rho = 1.20$, $\nu_0 = 218$ cm^{-1} and a barrier height of 164 cm^{-1}. The agreement between calculated and experimental values of ν_4' is reasonably good, taking into account the fact that the experimental frequencies could be determined to no better than ± 15 cm^{-1}.

A barrier height of the order of 164 cm^{-1} is reasonable on qualitative, comparative grounds. It has been established empirically that the inversion barrier heights in the $\tilde{a}$ states of tetraatomic thiocarbonyl halides increase with increasing electronegativities of the substituent atoms (20). (This observation is rationalized by the fact that, in accord with Walsh's postulate (21), the p electron density on the central carbon atom in the excited state governs the barrier height (22).) Since the electronegativities of the halogens decrease in the order F > Cl > Br, the inversion barrier heights in the $\tilde{A}$ states should be in the order F_2CS > ClFCS > Cl_2CS > Br_2CS, as observed (1).

The equilibrium out-of-plane angle for Br_2CS in the $\tilde{A}$ state was calculated using the relation

$$[3]\quad \theta_{min} = Q_{min}/(\mu^{1/2}r)$$

where Q_{min} is the mass weighted coordinate at θ_{min}, r is the C—S bond distance, and μ is the reduced mass (18). The equilibrium geometry of Br_2CS in its $\tilde{A}$ (or any other excited) state has not been determined so that μ and r are not known. Fortunately both parameters can be estimated reasonably closely by extrapolation from the ground state geometry using the changes in vibrational frequencies and the behavior of other thiocarbonyl halides on $\tilde{A} \leftarrow \tilde{X}$ excitation as guides. The C—S bond lengths of H_2CS, F_2CS, and Cl_2CS all increase by ca.

[b]Reference 1.

0.1 Å on $n \rightarrow \pi^*$ excitation whereas the C—X (X ≡ F, Cl, H, D) bond lengths remain approximately constant (1). Using estimated equilibrium bond lengths and angles for Br_2CS $\tilde{A}(^1A_2)$ given in Table 3, an equilibrium out-of-plane angle of 13° was obtained. This angle is substantially smaller than those of F_2CS, ClFCS, and Cl_2CS (1), possibly due to repulsive electronic interactions between the large substituent bromine atoms in Br_2CS.

Modes 1, 2, and 3 are totally symmetric and appear with no restrictions in quantum number change when combined with odd quantum number changes in mode 4. The frequencies of these modes can be extracted from the slopes of the lines in Figs. 5 and 6 (or from averaging combination differences). Frequencies of 902 cm^{-1}, 332 cm^{-1}, and 168 cm^{-1} are obtained for ν_1', ν_2', and ν_3' respectively. As shown in Table 4, the ratio of the frequencies of the C—S stretching mode in the $\tilde{X}:\tilde{A}$ states is almost constant for all the tetraatomic thiocarbonyls examined to date. We take this as an indication that the change in electron distribution in the C—S bond resulting from $n \rightarrow \pi^*$ excitation is approximately the same for all of these molecules, a notion which is reasonable, given that the excitation is primarily localized in the C—S moiety. An approximately constant ratio is also obtained for the frequencies of the C—X_2 symmetric stretching mode. However substantial differences occur in the X—C—X symmetric bending mode frequency changes.

A single weak band located 158 cm^{-1} to the blue of the origin could not be assigned reasonably as either a hot band or as part of a progression involving modes 1−4 in the upper state. It might reasonably be assigned as 6_0^1. This mode is weakly active in Cl_2CS (3, 11) and a frequency for ν_6' of 158 cm^{-1} is not unreasonable for Br_2CS. However, such an assignment should be considered as highly tentative.

The fluorescence excitation spectrum also exhibits diffuseness with an onset near 547 nm. By analogy with Cl_2CS (10, 23), it is reasonable to assume that predissociation of the $\tilde{A}$ state by unbound levels of the ground state is responsible. Using a frequency of ca. 18300 cm^{-1} for the onset of predissociation, a value of 52.3 kcal mol^{-1} is calculated for the ground state C—Br dissociation energy of Br_2CS. The ground state C—Cl dissociation energy is a factor of 1.258 larger in CH_2Cl_2 than in $CSCl_2$ (24). A similar factor should apply when comparing CH_2Br_2 and $CSBr_2$. Given that D_0(Br—CH_2Br_2) = 66.9 kcal mol^{-1} (24), a value of D_0(Br—CSBr) = 53.2 kcal mol^{-1} is obtained which compares very well with that calculated from the onset of spectral diffuseness.

The high pressure photochemistry of alkenes. III. The 184.9 nm photoisomerization processes in acyclic alkenes

Guy J. Collin[1] and Hélène Deslauriers

Département des sciences fondamentales, Université du Québec à Chicoutimi, Chicoutimi (Qué.), Canada G7H 2B1

Received July 19, 1984

This paper is dedicated to Professor Camille Sandorfy on the occasion of his 65th birthday

Guy J. Collin and Hélène Deslauriers. Can. J. Chem. **63**, 1424 (1985).

We have made a systematic study of the 184.9 nm photoisomerization of the gaseous acyclic alkenes. Apart from the *cis–trans* isomerization (geometric isomerization), we have also observed the formation of products arising from the 1,3-hydrogen and methylene shifts (structural isomerization). 1-Alkenes do not show evidence of structural isomerization. This kind of isomerization increases with an increase in the number of alkyl substituents around the double bond. These observations, combined with those from the literature, may be explained on the basis of the following: (*a*) the $^1\pi,\pi^*$ state is involved in the *cis–trans* isomerization process; (*b*) the $^1\pi$,R(3*s*) state is responsible for the methylene shifts; (*c*) another singlet state is required for the 1,3-hydrogen shift; (*d*) this last state is either at an energy level higher than that of the Rydberg state or the hot ground state. Finally, the photoexcited molecules, through internal conversion, may convert from one state to another, and their lifetime is long enough to be stabilized by collision.

Guy J. Collin et Hélène Deslauriers. Can. J. Chem. **63**, 1424 (1985).

Nous avons entrepris une étude systématique de la photoisomérisation des alcènes non-cycliques à 184,9 nm en phase gazeuse. Outre l'isomérisation *cis–trans* (isomérisation géométrique) nous avons pu observer la formation d'isomères résultant d'un transfert interne soit d'un atome d'hydrogène, soit d'un groupe méthylène (isomérisation structurale). Alors que les oléfines terminales ne montrent pas d'isomérisation structurale évidente, celle-ci semble de plus en plus importante, au fur et à mesure que s'accroît le nombre de substituants autour de la double liaison. L'ensemble de ces observations, combinées à celles relevées dans la littérature, peuvent être expliquées par l'intervention: (*a*) de l'état $^1\pi,\pi^*$ dans l'isomérisation *cis–trans*; (*b*) de l'état $^1\pi$,R(3*s*) dans le transfert d'un groupe méthylène; (*c*) d'un autre état singulet excité dans le transfert d'un atome d'hydrogène. Ce dernier état excité est soit situé à un niveau d'énergie plus haut que celui de l'état Rydberg ou est l'état fondamental vibrationnellement excité. En outre il semble que la molécule puisse passer d'un état à l'autre par conversion interne et que le temps de vie de ces états électroniques est suffisamment long pour que ceux-ci soient stabilisés par collision.

Introduction

The isomerization of alkenes was observed under various conditions. Of course, in ethylene (for a review and a theoretical approach, see ref. 1) the isomerization process involves isotopic scrambling of hydrogen atoms in the direct photolysis of various dideuterioethylenes in condensed phases (2, 3). Similar behavior was reported in triplet-sensitized gas-phase chemistry (1, 4–6). Direct or sensitized higher alkene photoisomerization was also observed in various systems. For example, the *cis–trans* isomerization of partially deuterated propene was observed in sensitized systems (7). Of course, 2-butene is a "test case": the geometric *cis–trans* isomerization process was observed by several authors and is described in textbooks (see, for example, ref. 8*a*). Direct photoisomerization results are relatively scarce. However, the *cis–trans* isomerization of 2-butene was observed at 202.6–206.2 nm (9) as well as at 184.9 nm (10). Moreover, structural isomerization was also observed either in the gas (11) or liquid phases (12–14). Some of these reports tried to link the nature of the excited state(s) with the product formation (1, 10, 12*b*, 14*b*). Although it is well known that the *cis–trans* isomerization process involves the formation of the $^1\pi,\pi^*$ electronic singlet state (the V state), the formation of other isomers is not unambiguously linked to other excited state(s) (14*b*).

In this report we shall describe a systematic study of the 184.9 nm photochemistry of gaseous acyclic alkenes, and, with results taken from the literature, we shall try to throw more light on the relationship linking the available excited states to the formation of isomers.

Experimental

Experimental details were the same as those reported in previous studies from this laboratory (11, 15, 16).

Materials

All the alkenes are API products (Table 1): they are used after being degassed under high vacuum and at low temperature in a mercury-free Pyrex line (Teflon stopcocks, Wallace and Tiernan membrane manometers). Propane (99.99%) and oxygen (99.98%) — Research purity materials — are from Matheson and are used as received.

Photolysis

All the photolyses are performed in two different cells. The first one (a 90.3 cm^3 Pyrex one) is used at pressures lower than 1 atm, the second one (a 4.2 cm^3 brass one) is used at higher pressures (16). They have quartz windows. All the experiments are made with a mixture of alkene : oxygen (100 : 10) in order to prevent the formation of isomers through radical recombination reactions. The standard pressures of the alkene are as follows: (*1*) in the Pyrex cell the alkene pressure is 5 Torr (665 N m^{-2}); (*2*) in the brass cell the alkene pressure is 50 Torr (6650 N m^{-2}). In each case propane is added in order to obtain the desired total pressure. The incident photon beam is completely absorbed by the starting alkene material due to its very high absorption coefficient. The actinometry has also been described elsewhere (11, 15, 16). Ethylene ($\Phi(C_2H_2) = 0.50$) is used to determine the quantum yields. The conversion percentage of the starting alkene is kept below 1% in order to avoid back reactions.

Analysis

All analyses are done chromatographically. A squalane column (25% on firebrick) is used at room temperature. The gas-chromatograph is equipped with a dual flame ionisation detector.

Results

The quantum yields of isomers formed in the photolytic

TABLE 1. Starting materials

Alkenes	Abbreviation[a]	Stated impurity (mol%)	Main C_5 or C_6 analyzed impurities[b] (ppm)
2-Methyl-2-butene	2M2B	0.06±0.04	2M1B: 14–16; 3M1B: 11
4-Methyl-*trans*-2-pentene	4M*t*2P	0.14±0.07	4M*c*2P: 50; 2,3dM2B: 210; 3M*t*2P: 2–5
4-Methyl-*cis*-2-pentene	4M*c*2P	0.08±0.07	4M1P: 130–160; 3,3DM1B: 2–4
cis-3-Hexene	*c*3H	0.086±0.013	1H: 11–13; 4M*t*2P: 2–4
3-Methyl-*trans*-2-pentene	3M*t*2P	0.15±0.08	3M*c*2P: 1000–1700; 3H: 31
3-Methyl-*cis*-2-pentene	3M*c*2P	0.03±0.01	2E1B: 35–70; 4M*c*2P: 200; 3,3DM1B: 20
2,3-Dimethyl-2-butene	2,3dM2B	0.03±0.02	None

[a] Symbols are as follows: M ≡ methyl, E ≡ ethyl, B ≡ butene, P ≡ pentene. H ≡ hexene, cyPr ≡ cyclopropane; for example, 4M*t*2P stands for 4-methyl-*trans*-2-pentene.
[b] Analysis of the starting material may vary from one sample to another.

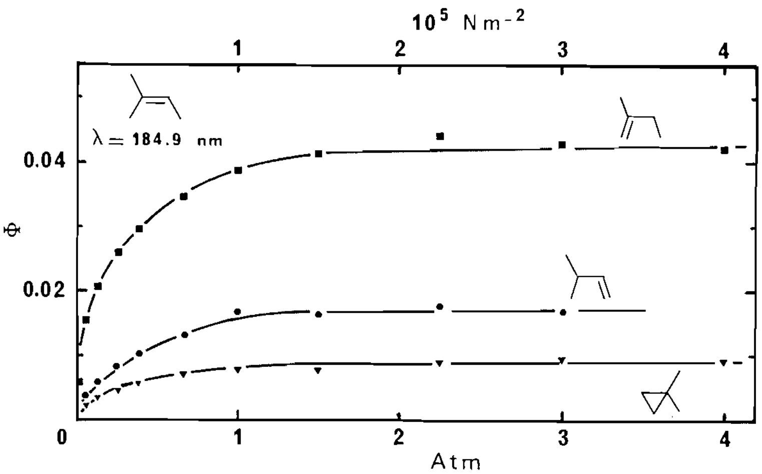

FIG. 1. Plot of product quantum yields vs. pressure in the photolysis of 2-methyl-2-butene at 184.9 nm. *cis*-1,2-Dimethylcyclopropane (c1,2,dMcyPr) is also formed and its quantum yield is similar to that of the 1,1-dimethylcyclopropane (1,1dMcyPr) — see Table 2.

experiments are reported in Figs. 1–5. For example, Fig. 1 shows the quantum yields of 2-methyl-1-butene, 3-methyl-1-butene, and dimethyl-1,1-cyclopropane measured in the 184.9 nm photolysis of 2-methyl-2-butene (trimethylethylene). In all cases, the quantum yields increase from the lower pressure regimes to plateau values obtained at pressures higher than 1 atm. Table 2 shows the quantum yields measured at higher pressures. In fact, they are measured in the plateau regions that can be identified from the previous figures. Other results from this laboratory also appear in Table 2. Table 3 gives other results taken from the literature.

Discussion

(A) The isomerization processes

(a) The cis–trans *isomerization process*

Table 2 lists the photochemical quantum yields of isomer formation from various acyclic alkenes. In the case of 1-alkenes, the *cis–trans* isomerization process could not be oserved in this work. In fact, it is known from the literature that it is an efficient one, and was observed in the direct photolysis of ethylene at 184.9 nm in nitrogen solution at 77 K (3); it probably involves the relaxation of either an excited ethylene molecule to an ethylidene structure or an excited $^1\pi,\pi^*$ state (see later) or both (1, 3).

Of course, the *cis–trans* isomerization process in the direct photolysis of 2-alkenes has been observed in several laboratories. For example, Borrell *et al.* measured the following quantum yields (Table 3): $\Phi(cis \rightarrow trans) \simeq \Phi(trans \rightarrow cis) \simeq 0.1$ at a pressure lower than 80 Torr. Moreover, *trans*-2-butene also appears to be the major product at 202.6–206.2 nm provided that the pressure is high enough to stabilize the excited intermediate (9). The 2-pentene case has been published recently (16). At 184.9 nm the *cis–trans* interconversion has a high quantum yield ($\Phi \simeq 0.40$) in the pressure region higher than 3 atm. Similar results were obtained for the case of 4-methyl-*trans*-2-pentene (Fig. 5). Finally, 3-methyl-2-pentene undergoes *cis–trans* isomerization with peculiar quantum yields: it appears that the formation of the *cis*-structure is preferentially formed. Some steric effect may be responsible for such behavior (17).

(b) The [1,3]-sigmatropic hydrogen shift

In addition to the *cis–trans* isomerization process, 1,3-hydrogen internal atom transfer (a 1,2-double bond migration) was recognized very early. However, in several studies from this laboratory, it was impossible to observe this internal shift in 1-alkenes (18, 19), i.e. the quantum yield of 2-alkene formation is smaller than 0.005. Conversely, this transfer was observed in various liquid 2-alkene systems (9, 12). In the gas phase, this transfer is a general occurrence (Table 2). Although not all the pertinent products have been analyzed due to chromatographic difficulties, the quantum yields for such a process are between 0.02 and 0.10 in disubstituted alkenes. It must also be realized that in 2-pentene, for example, 1,3-hydrogen shift gives rise to the formation of either 1-pentene or 2-pentene. Thus, the Φ(1-pentene) value is a lower limit of the total Φ(1,3-hydrogen shift) value.

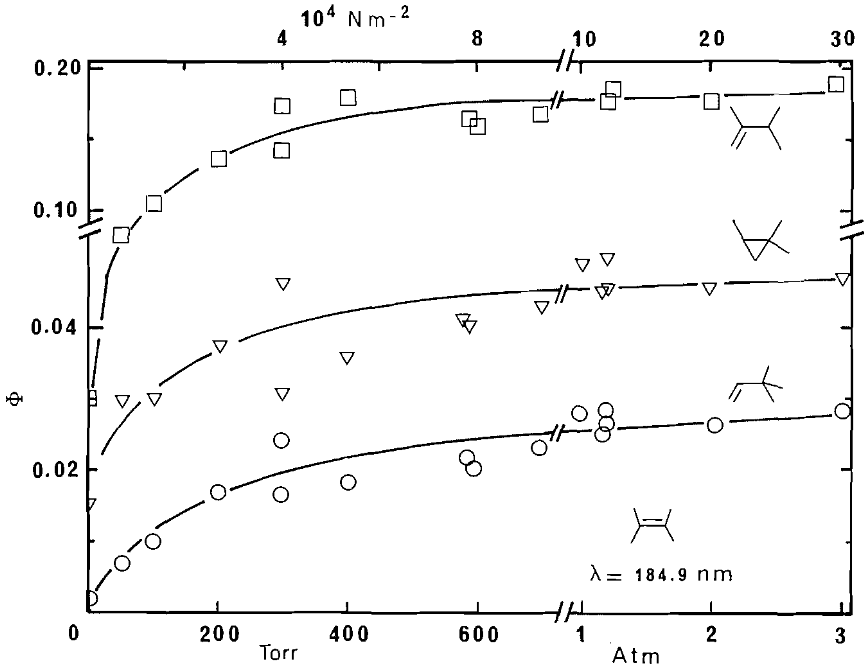

FIG. 2. Plot of product quantum yields vs. pressure in the photolysis of 2,3-dimethyl-2-butene at 184.9 nm.

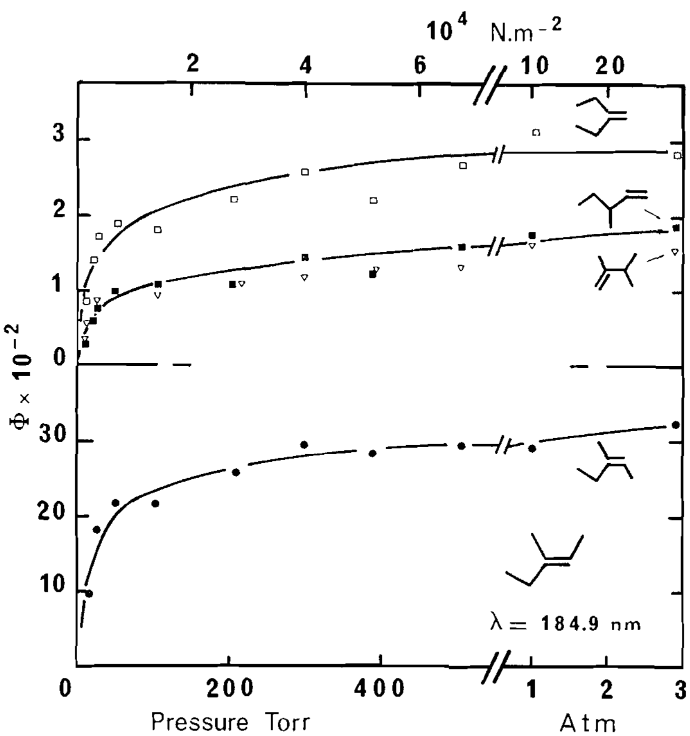

FIG. 3. Plot of product quantum yields vs. pressure in the photolysis of 3-methyl-*cis*-2-pentene at 184.9 nm.

Again in the 3-methyl-2-pentene case, the starting material is among the products for such a process, and part of the hydrogen transfer is embedded in the *cis–trans* isomerization process. Thus, the Φ(3-methyl-1-pentene + 2-ethyl-1-butene) value is smaller than the true Φ(1,3-Hydrogen shift) value. Finally, for the tetramethylethylene case, the extent of this process undergoes a drastic increase.

(c) The methylene shift

Again, there is no indication of an additional structural isomerization process for the case of 1-alkenes. Conversely, small quantities of isomers, requiring extensive rearrangement, are formed in the case of 2-alkenes. For example, 2-methyl-1-butene is a product of the *cis*-2-pentene photolysis: Φ(2-methyl-1-butene) $\simeq$ 0.01_5. Alkyl-substituted cyclopropanes are found in this category of reactions (12, 13). Again, it must be recalled that the chromatographic separations of the pertinent products from the starting materials are often very bad. Thus, the given quantum yields represent lower values for these methylene shift reactions. However, one can say that the quantum yields of such a process increase with an increase in the number of alkyl substituents on the double bond.

(B) The nature of the excited states

(a) The absorption spectra

The obvious question arising at this point is pertinent to the nature of the excited states leading to each of the previously reported processes. The absorption spectra of this class of molecules are well known and a full description of the transitions involved has been given (20) although a large number of details are evidently lacking (21, 22). However, definite trends may be observed from these spectra. At 184.9 nm, all these C_4, C_5, and C_6 alkenes have a very strong absorption band corresponding to the formation of a $^1\pi,\pi^*$ electronic excited state (the V State). The stable configuration of this excited state has a skew structure as shown for the example of ethylene in Fig. 6. On its way back to the electronic ground state the molecule has an equal probability of finding either its original structure or its geometric isomer. On the red side of this strong $^1\pi,\pi^*$ absorption band, a much smaller, not resolved one, appears in the 2M2B spectrum. This band is also badly resolved in the 2,3dM2B case (2) and was attributed to the formation of the Rydberg — $^1\pi$,R(3*s*) — excited state (20). This electronic state is thought to be responsible for the formation of a carbene intermediate (23) leading to the observed methylene shifts (8*b*). The increase in the quantum yields for methylene shifts with increasing alkyl substitution on the double bond has been linked to the probably greater stability of the Rydberg state of tetramethylethylene as compared to that of the V State (23). The correlation between the electronic states and the [1,3]-sigmatropic hydrogen shift, however, is not so evident. Kropp has proposed that the $^1\pi,\sigma^*$ state is the one involved in such a transfer (23) although some controversy exists (14*b*).

(b) The photofragmentation

From the Stern–Volmer plots of the methyl radical formation (a product of the primary β(C—C) bond rupture) we have been able to measure the rate constant for β(C—C) bond rupture. These experimentally derived rate constants are in the 0.5–5 $\times$ 10^9 s^{-1} range for the C_6 1-alkene (19) and 2-alkene groups (25). Moreover, the rate constants of these processes have also been estimated using the RRKM method, assuming that all the photon energy is redistributed in the vibrational framework of the molecule. The rate constants of the fragmentation process calculated in this way are again in the 10^9 s^{-1} range. Thus it is quite reasonable to assume that the fragmentation products arise from the vibrationally excited ground state. In the case of 4-methyl-*cis*-2-pentene, the lifetime of this excited precursor has been determined from the Stern–Volmer plot and is around 3 ns (24). From Fig. 7, the lifetime of the precursor of the *trans–cis* process may be estimated to be around 0.3 ns. Except for some unlikely difference between the *cis*- and the *trans*-compounds, it appears that the precursors of the isomerization and of the fragmentation processes are not the same.

(c) The dynamics of the excited states

Thus, at 184.9 nm it is relatively safe to assume that the absorption of a photon by monoalkenes leads to the population of the V state. This $^1\pi,\pi^*$ excited state is the one involved in the *cis–trans* process. On its way to its skew structure, the

SCHEMATIC POTENTIAL ENERGY DIAGRAM

FIG. 6. Schematic potential energy diagram of ethylene, see refs. 22 and 29.

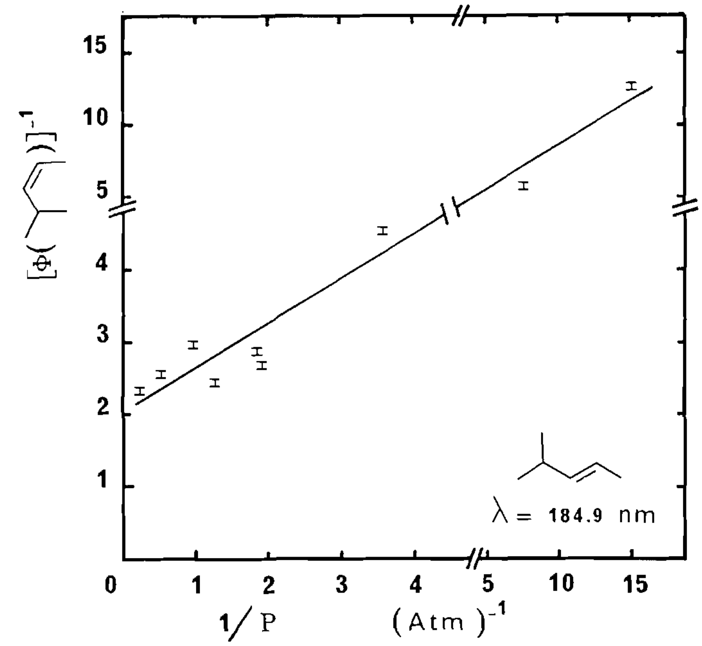

FIG. 7. Stern–Volmer plot for the formation of the *cis* isomer in the photolysis of 4-methyl-*trans*-2-pentene at 184.9 nm.

molecule, on the V surface, crosses the Rydberg energy surface, and it may remain on the V surface or, by internal conversion, cross to the ^{1}R state. (Fig. 8).[2] The relative energy levels of the two states determine the equilibrium (?) ratio of the two exit channels. Since the relative position of the two states is dependent on the number of alkyl substituents, this ratio is also affected (12). Again, it may be assumed that the excited ^{1}R state of the starting alkene is in equilibrium with the ^{1}R state of the isomers (25) (Fig. 8). The situation is even more complex since some of the isomers are alkenic in nature and their ^{1}R state is also, by the same token, in equilibrium with their ^{1}V state. Of course, one may assume that the excited states of 2,3dM2B have lower energy levels, so that their concentrations are higher than those of the other isomers. The lifetimes of the excited isomers are long enough to be stabilized by collisions. Obviously, the resulting products depend on the structure of the excited intermediate.

The same argument may be used to explain the formation of 2,3-dM1B from 2,3-dM2B. However, the nature of the excited state of the intermediate involved in the formation of this product is different from the one involved in the methylene shift processes. With regard to the latter, it is known that the 3,3-dimethyl-1-butene/1,1,2-trimethylcyclopropane ratio is independent of temperature (11*b*) and incident wavelength (11*b*, 14*b*). On the other hand, the 2,3-dimethyl-1-butene/3,3-dimethyl-1-butene ratio is not constant. Moreover, since the latter ratio decreases with an increase in the wavelength from 184.9 to 228.8 nm, it is reasonable to assume that the energy level of the state involved in the 1,3-hydrogen shift is higher than that involved in the methylene shifts. This observation does not favor the involvement of the $^1\pi,\sigma^*$ state, since it is accepted that this state is the lowest in energy (ref. 14*b* and references therein). Another argument in favor of internal conversion between these excited singlet states may be seen in

[2] In this kind of study, no reference is made to triplet states. For different reasons it is thought that triplet states are not involved in the direct photolysis. However, definite proof would be helpful.

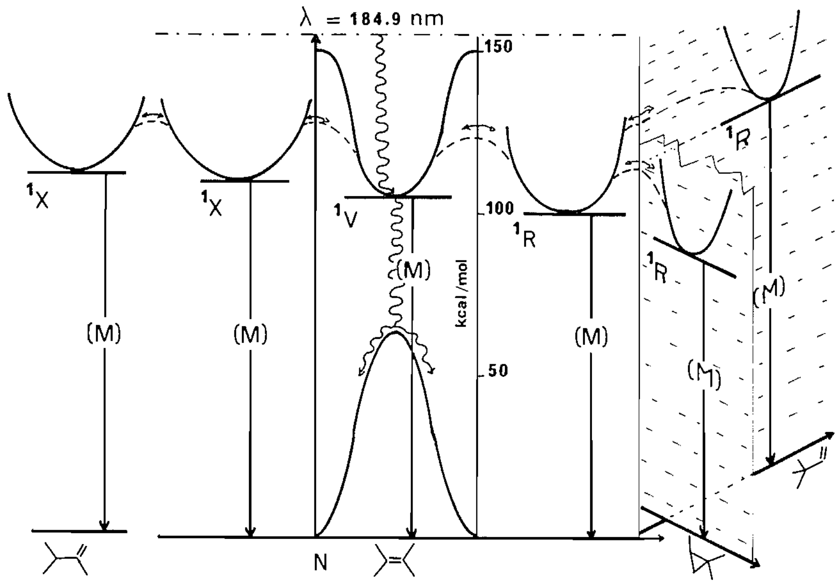

FIG. 8. Schematic representation of the tetramethylethylene excited singlet-state surface.

Figs. 1–5 where it appears that, in each case, the magnitudes of the pressure dependence of the various isomer quantum yields are similar. Although this similarity may be fortuitous, we would expect different pressure behavior in the absence of internal conversion.

Of course, the hot or vibrationally excited ground state cannot be ruled out. We have recently shown that the thermal isomerization of 2,3dM2B to 3,3dM1B and 2,3dM1B is efficient (26). However, 1,1,2tMcyPr is not formed and the ratio 3,3dM1B/2,3dM1B is close to 15, contrary to what is observed in photochemical experiments (Table 3). Thus, it can be said that the lower vibrationally excited levels of the ground state are not involved in the photoisomerization processes, although part of 3,3dM1B may be formed from the hot ground state.

(d) Fluorescence

Fluorescence of monoalkenes was observed either in the gas or in the liquid phases by Hirayama and Lipsky (27). They measured very low quantum yields: $\Phi(\text{fluor}) \simeq 10^{-6}$; and indicated that this could be due to the presence of a very efficient channel for non-radiative decay (27). The other main characteristics are the following: the quantum yield increases with an increase in (*a*) the number of substituents on the double bond; (*b*) the concentration of the alkene, i.e. on going from 1 atm (gas) to the neat liquid. The authors conclude that their "...entire...discussion has been able to argue only for the reasonableness of the Rydberg assignment" to fluorescence (14*b*).

Since we know that the molecule photoexcited in this region of the spectrum may isomerize, an alternative to the assignment of the fluorescence may be found for the case of 2,3dM2B in one or several excited isomers. It is known that the fluorescence quantum yields of saturated hydrocarbons are around two orders of magnitude greater than those of the monoalkenes (28). Thus, it is not unlikely that some of the initially formed excited cyclopropane derivatives are responsible for the observed fluorescence. Unfortunately, the authors have no indication whether the cyclopropanes fluoresce.

NOTE ADDED IN PROOF: After this study was submitted, the 193 nm laser photolysis of two C_7 alkenes appeared in literature. The results show an important β(C—C) split and, using absorption spectroscopy, the authors were able to follow the increase in the trimethally radical concentration with time. The lifetime of the photoexcited molecules were found in the 50–70 ns range (32). The longer lifetimes observed in this study are in line with the ones mentioned above of the C_6 photoexcited alkene molecules. The RRKM calculations show that the addition of one CH_2 group decreases the probability to find the needed energy in the right β(C—C) bond (33).

Acknowledgments

We would like to express our gratitude to the University of Quebec at Chicoutimi for the supporting salary given to one of us (H.D.) and the Natural Sciences and Engineering Research Council of Canada for financial assistance throughout this work.

Synthesis of 8-, 9-, 12-, and 13-mono-^{13}C-retinal

J. A. PARDOEN, P. P. J. MULDER, E. M. M. VAN DEN BERG, AND J. LUGTENBURG
Gorlaeus Laboratory, Department of Chemistry, Leiden University, 2300 RA Leiden, The Netherlands

Received July 24, 1984

This paper is dedicated to Professor Camille Sandorfy on the occasion of his 65th birthday

J. A. PARDOEN, P. P. J. MULDER, E. M. M. VAN DEN BERG, and J. LUGTENBURG. Can. J. Chem. **63**, 1431 (1985).

The 8-, 9-, 12-, and 13-mono-^{13}C-retinals were synthesized with >98% chemical purity and 93% ^{13}C incorporation from ^{13}C-labelled acetonitrile. Their ^{13}C$-$^{13}C and ^{13}C$-$^{1}H nmr coupling constants were determined.

J. A. PARDOEN, P. P. J. MULDER, E. M. M. VAN DEN BERG et J. LUGTENBURG. Can. J. Chem. **63**, 1431 (1985).

Les 8-, 9-, 12- et 13-mono-^{13}C rétinènes ont été synthétisés avec plus de 98% de pureté chimique et 93% d'incorporation de ^{13}C à partir d'acetonitrile marqué au ^{13}C. Leurs constants ^{13}C$-$^{13}C et ^{13}C$-$^{1}H de couplage de rmn ont été déterminées.

[Traduit par le journal]

Introduction

The retinylidene group occurs as the chromophoric part of the membrane proteins bacteriorhodopsin and rhodopsin, and is formed by reaction of all-*trans* or 11-*cis* retinal with a lysine ε-amino group of the peptide chain under formation of a protonated Schiff base bond as shown in Fig. 1 (1, 2). We have synthesized a number of ^{13}C-labelled retinals (3, 4) and prepared ^{13}C-labelled bacteriorhodopsins from these materials. Recently we obtained solid state cross polarization magic angle spinning ^{13}C nmr (CP$-$MAS ^{13}C nmr) spectra of bacteriorhodopsins with the ^{13}C-enriched chromophore (5, 6). These spectra gave the first *in situ* ^{13}C nmr information of the chromophore within a protein, establishing that in dark-adapted bacteriorhodopsin the chromophore occurs in a 40% all-*trans* protonated Schiff base and 60% 13-*cis*, 15-*cis* protonated Schiff base structure which are not interconverting on the ^{13}C nmr time scale. These results were strongly supported by resonance Raman (RR) (7, 8) and Fourier transform infrared difference (FTIR diff.) (9) vibrational studies of the ^{13}C-labelled bacteriorhodopsins and further detailed information concerning the chromophore structure was obtained. In order to extend these studies we needed bacteriorhodopsins with a ^{13}C-label at positions 9 and 13. These are quaternary positions with a substantial positive charge in a protonated Schiff base structure (10). ^{13}C nuclear magnetic resonance spectroscopy may give insight into how these positions of the chromophore interact with the protein part. Position 8 can give us information on how the 7,8 double bond interacts with the peptide, since this interaction is essential for the colour of light- and dark-adapted bacteriorhodopsin (11). In the rhodopsin bleaching sequence, isomerization takes place around the 11,12 double bond, and to investigate this isomerization process by CP$-$MAS ^{13}C nmr, RR and FTIR diff. studies we needed retinal with a ^{13}C-label at position 12.

In this paper we describe the synthetic schemes by which we prepared retinal ^{13}C-labelled at positions 8 and 9 and at positions 12 and 13 with a level of ^{13}C-enrichment of more than 90%.

Synthesis and spectroscopic characterization

For the preparation of 8-^{13}C and 9-^{13}C retinal, we used the reaction sequence as presented in Scheme 1. The starting aldehyde β-cyclocitral **3** necessary for this synthesis is obtained by cyclization of the *N*-phenylimine of citral **2** with 95% sulfuric acid at -20°C by the method of Gedye *et al.* (12). Addition at -60°C of ^{13}C lithioacetonitrile, obtained by the

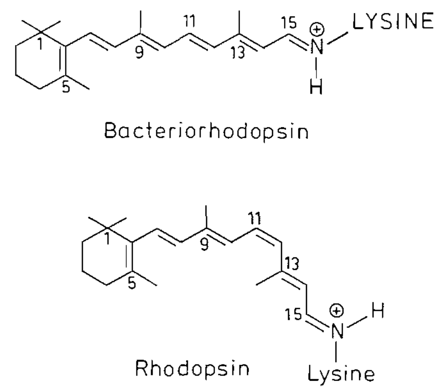

FIG. 1. Chromophoric groups of bacteriorhodopsin and rhodopsin.

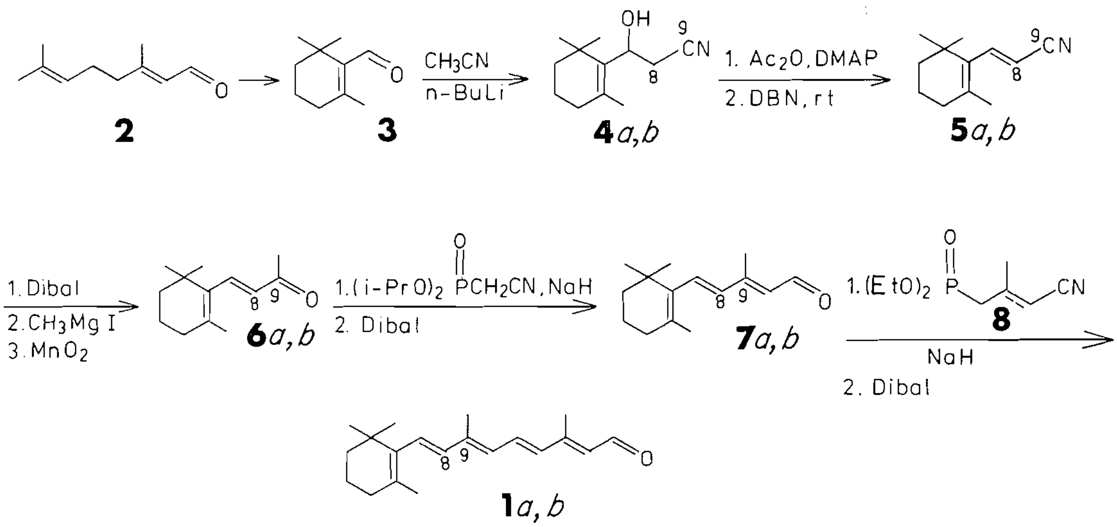
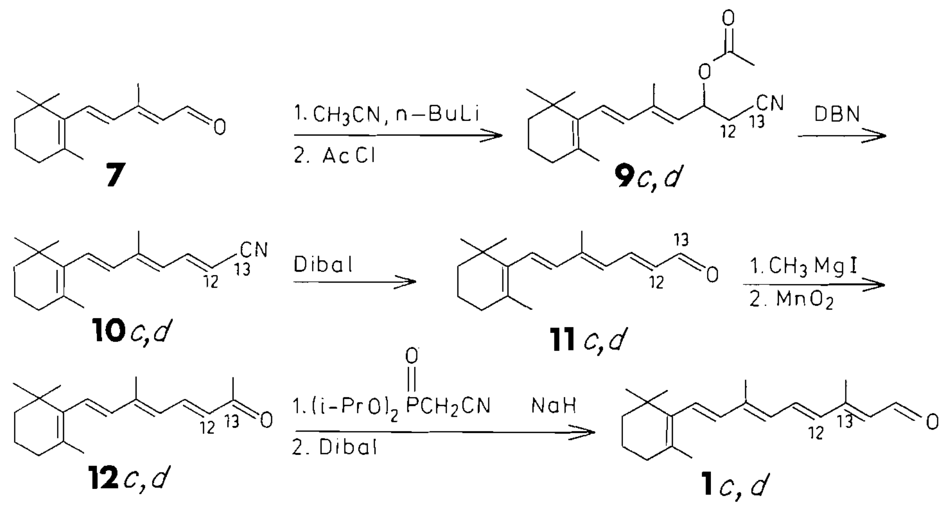
reaction of 1 equiv. of n-butyllithium with ^{13}C acetonitrile, to β-cyclocitral **3** gives the alcohol-nitrile **4***a*,*b* in 95% yield. Starting with 2-^{13}C-acetonitrile introduces the label at position 8 (**4***a*) and with 1-^{13}C-acetonitrile at position 9 (**4***b*). For the dehydration we used a two-step method under basic conditions. Quantitative conversion of the alcohol **4***a*,*b* into its acetate with acetic anhydride (Ac_2O) and 4-dimethylaminopyridine (DMAP) is followed by deacetylation using diazabicyclononene (DBN) in toluene. Performing the deacetylation at room temperature $-$ which is completed in 3 days $-$ the nitrile **5***a*,*b* is obtained in 80% yield as a 7-*E*/*Z* (3:1) mixture (determination by ^{1}H nmr spectroscopy), which is converted to ^{13}C-labelled β-ionone **6***a*,*b* in three steps. The nitrile is reduced with diisobutylaluminium hydride (Dibal) to the aldehyde, after which conversion the complete double bond isomerization has taken place, leading to the 7-*E* aldehyde only. Reaction with excess methyl magnesium iodide (CH_3MgI) and oxidation of the α,β-unsaturated alcohol with active manganese dioxide (MnO_2) yields the ^{13}C-labelled β-ionone **6***a*,*b* in 60% overall yield from **5***a*,*b*. The β-ionone ^{13}C-labelled at position 8 or 9 is transformed to the C15-aldehyde **7***a*,*b* with high 9-*E* content, in 80% yield, in two steps by reaction with the anion of diisopropylphosphonoacetonitrile (13) followed by Dibal reduction of the nitrile. The C15-aldehyde **7***a*,*b* is converted into retinal **1***a*,*b* by Horner$-$Emmons coupling with the C5-synthon **8** (14), leading to retinonitrile, followed by Dibal reduction, providing 8-^{13}C-retinal **1***a* and 9-^{13}C-retinal **1***b* in 80% yield from the C15-aldehyde **7***a*,*b*.

For the synthesis of 12-^{13}C (**1***c*) and 13-^{13}C-retinal (**1***d*) an analogous reaction scheme is used, with the C15-aldehyde **7** as the starting aldehyde (Scheme 2). Addition of 9-*E* C15-



SCHEME. 1. Synthesis of (8-^{13}C) **1***a* and (9-^{13}C) retinal **1***b*; *a*, $^{13}CH_3CN$; *b*, $CH_3{}^{13}CN$.



SCHEME 2. Synthesis of (12-^{13}C) **1***c* and (13-^{13}C) retinal **1***d*; *c*, $^{13}CH_3CN$; *d*, $CH_3{}^{13}CN$.

aldehyde **7** to lithioacetonitrile is followed by quenching the reaction mixture with acetyl chloride, leading to the secondary acetate **9***c*,*d* in a one-pot reaction. The addition of the C15-aldehyde **7** to lithioacetonitrile has to be performed at −90°C to prevent base-catalyzed side reactions of the aldehyde (15). The quenching is then performed at −60°C to give **9***c*,*d* in 85% yield after column chromatography. Base-induced acetic acid elimination with DBN in refluxing toluene gives the tetraenenitrile **10***c*,*d* in 88% yield. Dibal reduction leads to the C17-aldehyde **11***c*,*d* (95%) and reaction with excess methyl magnesium iodide (CH_3MgI) and subsequent MnO_2 oxidation gives the desired C18-ketone **12***c*,*d* in 60% yield. Horner–Emmons coupling of **12***c*,*d* with diisopropylphosphonoacetonitrile followed by Dibal reduction of the resulting retinonitrile affords the ^{13}C-labelled retinal in 90% yield, with 85% 13-*E* configuration. Starting with 2-^{13}C-acetonitrile leads to 12-^{13}C-retinal **1***c* and with 1-^{13}C-acetonitrile leads to 13-^{13}C-retinal **1***d* in 38% overall yield from the ^{13}C-labelled acetonitriles. From 0.25 g labelled acetonitrile, 0.64 g ^{13}C-labelled retinal is obtained in eight steps.

The all-*trans* isomers of the labelled retinals **1***a*–*d* can be separated by column chromatography. Irradiation of the all-*trans* isomer with visible light in acetonitrile gives an isomeric mixture which is separated by preparative hplc to yield pure 9-*cis*, 11-*cis*, 13-*cis*, and all-*trans* isomers. The uv–vis spectra of these retinals are identical with those of the unmodified retinal isomers. The mass spectra of the ^{13}C-labelled retinals **1***a*–*d* show the expected 92–93% ^{13}C-incorporation, based on the incorporation of the starting materials.

From the multiplet splittings in the 300-MHz ^{1}H nmr spectra of **1***a*–*d* the location of the ^{13}C is immediately evident. For 8-^{13}C (**1***a*) and 12-^{13}C-retinal (**1***c*) the signals of the H-atoms directly bonded to the labelled position show large splittings with the ^1J(C–H) values of 155.7 Hz for position 8 and 154.6 Hz for position 12. The intensity ratio is 93% ^{13}C-enriched to 7% non-enriched retinal, as has been found by mass spectrometery. For 9-^{13}C (**1***b*) and 13-^{13}C-retinal (**1***d*), containing a quaternary ^{13}C-atom, no one-bond C—H couplings occur. For all four ^{13}C-retinals two- and three-bond C—H couplings are determined from the spectra and these values are presented in Table 1.

The ^{1}H noise-decoupled ^{13}C nmr spectra of the ^{13}C-labelled retinals clearly show the position of ^{13}C-enrichment. They display one strong single line due to the labelled carbon atom at the chemical shift value known from the natural abundance ^{13}C nmr spectrum of unmodified retinal (16). The enriched

materials also contain the natural abundance (1.1%) of ^{13}C at each of the non-enriched positions. The singly labelled materials therefore contain two ^{13}C isotopes at the 1.0% level (0.93 × 1.1%), in which one position is enriched and the other is at the natural abundance level. From the ^{1}H noise-decoupled ^{13}C nmr spectra the $^{13}C-^{13}C$ coupling constants are obtained, as shown in Table 2.

Discussion

The four ^{13}C-labelled retinals with the required purity were prepared in high yield by the methods shown in Schemes 1 and 2. In both reaction schemes, by choosing the appropriately ^{13}C-labelled acetonitrile, we can label two different polyene carbon positions. This, together with the fact that in our syntheses we get a high percentage of the all-*trans* isomer, is an advantage over the published synthesis of 9-^{13}C-retinal (17). A further advantage of our methods is that in the first step a simple synthon is added to a higher molecular weight compound in high yield. As after coupling the product has in general only to undergo a number of high yield conversions, the ^{13}C-labelled material is put to an efficient use.

For the introduction of a sp^2-^{13}C label at all retinal chain positions 8 to 15, we used ^{13}C-labelled acetonitrile, whose anion, obtained with n-butyllithium, is coupled in an aldol-type reaction with ketones (3, 4) as well as aldehydes in good yield. To obtain good yields low temperatures have to be used for this addition reaction, especially in the case of the C15-aldehyde **7** (−90°C, Scheme 2). After introduction of the labelled synthon by the aldol-type reaction, dehydration is the first step to be performed. To prevent dehydration taking place in the direction of the trimethylcyclohexyl ring, with formation of retro compounds (18), we needed to use the basic reaction conditions described.

From these labelled retinals, nmr parameters such as $J(^{13}C$-$^{1}H)$ and $J(^{13}C-^{13}C)$ are easily obtained from the high-field nmr spectra. The $J(^{13}C-^{1}H)$ values found are in agreement with values known for sp^2 bonded hydrogens in a hydrocarbon chain (19) and those we found before for the other retinal chain positions (3, 4). The $^{1}J(^{13}C-^{13}C)$ values in particular show a good relation to the double or single bond character of the bond between two carbon atoms. The values found for the various types of bonds in this large polyene chain are around 70 Hz for carbons bonded via a double bond, around 55 Hz for a single bond in the chain, and 40 Hz for the sp^2-sp^3 single bonds to the 9- and 13-methyl group (Table 2). These values are in good agreement with values known for small systems like butadiene and 1-methyl-cyclohexene (20) and are a measure of the hybridization and bond lengths of the C—C bond in question.

From the ^{13}C-labelled retinals, specifically ^{13}C-labelled visual pigments and bacteriorhodopsin can be obtained. The isotopic substitution does not introduce ambiguities due to changes in the electronic structure of the chromophore or protein–chromophore interaction, nor are changes in quantum yields and photostationary state compositions to be expected. These highly ^{13}C-labelled retinals serve as the basic materials both for the solid state CP–MAS ^{13}C nmr studies of the chromophore of the retinylidene pigments as well as for the unambiguous assignments of the resonance Raman and FTIR difference vibrational spectra. Some of the spectroscopic results obtained from the isotopically labelled rhodopsins and bacteriorhodopsins have been published (8, 21, 22).

Experimental

All experiments were carried out in a dry nitrogen atmosphere, and the purified polyenes were handled in dim red light. Distilled dry solvents were used; pet. ether refers to low boiling petroleum ether 40–60°C. Unless otherwise stated, purification was performed by flash chromatography (23) (Merck silica gel 60, 230–400 mesh) using ether/pet. ether mixtures. The tlc analyses were performed on Schleicher & Schüll F 1500/LS 254 silica gel plates using ether/pet. ether mixtures. Evaporation of the solvents was carried out *in vacuo* (10 Torr; 1 Torr = 133.3 Pa).

The ^{1}H nmr spectra were recorded on a Brucker WM-300 or on a JEOL PS-100 spectrometer using tetramethylsilane (TMS; δ 0 ppm) as internal standard. The ^{13}C nmr spectra were recorded on a Brucker WM-300 spectrometer at 75.5 MHz or on a JEOL PFT system at 25 MHz using tetramethylsilane (TMS; δ 0 ppm) as internal standard. The mass spectra were recorded using an AEI MS 902 instrument. The ir spectra were obtained using a Pye–Unicam SP3-200 and the uv–vis spectra using a Cary 219 spectrophotometer. The hplc separations were performed using a Dupont 830 equipped with a Dupont spectrophotometer (360 nm) and a 25 cm × 22.5 mm Zorbax Sil column. Elution was effected using 10% ether in pentane at a flow rate of 20 mL/min. The glc analyses were performed using a Hewlett–Packard 5700 with a 50-m OV101 capillary column at 160°C. The experimental conditions and spectral assignments are given for the unlabelled compounds. For the labelled compounds only the changes relative to the unlabelled compounds are given. Spectra signal designations were based on the retinoid numbering system (24). (1-^{13}C) Acetonitrile and (2-^{13}C) acetonitrile (90% ^{13}C enrichment) were purchased from Merck Sharp and Dohme Isotopes.

*C12-Alcohol-nitrile **4**: 3-hydroxy-3(2,6,6-trimethyl-1-cyclohexenyl)-propanenitrile*

To a stirred solution of 6 mmol of acetonitrile (0.25 g) in 20 mL dry THF, 6 mmol of n-butyllithium (4.3 mL of a 1.4 *M* solution in hexane) were added dropwise at −60°C and warmed to −20°C. After 15 min, 6 mmol of β-cyclocitral **3** (12) (0.9 g) in 5 mL dry THF were added dropwise at −60°C. The mixture was warmed to 0°C in 1 h, poured into half-saturated NH_4Cl, and extracted with ether. The organic layer was washed with water followed by brine, and then dried ($MgSO_4$). Evaporation of the solvent afforded 1.1 g (95%) of pure C12-alcohol-nitrile **4**; ir (KBr): 3470 cm^{-1} (OH stretch), 2250 cm^{-1} (C≡N stretch); ^{1}H nmr (100 MHz, $CDCl_3/CCl_4$ 1:1), δ: 0.98−1.09 (2s, $(CH_3)_2C$), 1.79 (s, 5-CH_3), 2.44 (dd, *J* 17 Hz, *J* 4.5 Hz, H8), 2.87 (dd, *J* 17 Hz, *J* 10 Hz, H8), 3.04 (s, OH), 4.60 (dd, *J* 10 Hz, *J* 4.5 Hz, H7).

C12-Acetate-nitrile: 3-acetoxy-3-(2,6,6-trimethyl-1-cyclohexenyl)-propanenitrile

To a solution of 5.7 mmol of the C12-alcohol-nitrile (1.1 g) in 30 mL dry toluene and 10 mL pyridine were added 11.4 mmol of acetic anhydride (2 equiv., 1.2 g) and a catalytic amount of 4-(dimethylamino)pyridine and the mixture stirred at room temperature. After 20 h, when the reaction was complete according to glc, the solids were filtered and washed with ether. The organic filtrates were washed with water, followed by brine, and then dried ($MgSO_4$). Evaporation of the solvents afforded the acetate in quantitative yield; ir (KBr): 2250 cm^{-1} (C≡N stretch), 1745 cm^{-1} (C=O stretch); ^{1}H nmr (100 MHz, $CDCl_3/CCl_4$ 1:1), δ: 1.03−1.08 (2s, $(CH_3)_2C$), 1.79 (s, 5-CH_3), 2.04 (s, CO—CH_3), 2.61 (dd, *J* 17.3 Hz, *J* 5.2 Hz, H8), 2.94 (dd, *J* 17.3 Hz, *J* 10.0 Hz, H8), 5.75 (dd, *J* 10.0 Hz, *J* 5.2 Hz, H7).

β-Cyclocitrylideneacetonitrile 5: 3-(2,6,6-trimethyl-1-cyclohexenyl)-2-propenenitrile

Two equivalents of diazabicyclononene (DBN) (11 mmol, 1.4 g) were added to a solution of 5.5 mmol C12-acetate-nitrile (1.3 g) in toluene and the mixture stirred at room temperature for 72 h, when the reaction according to glc was complete, and then poured into water. The aqueous layer was washed with ether and the organic layers were washed with water until neutral, followed by brine, and then dried ($MgSO_4$) and concentrated. The residue was purified by chromatography using 5% ether/pet. ether to yield 0.8 g (80%) of a 3:1 *E*/*Z* mixture of **5**; ir (KBr): 2210 cm^{-1} (C≡N stretch); ^{1}H nmr (100 MHz, $CDCl_3/CCl_4$ 1:1), 7-*E*, δ: 1.08 (s, $(CH_3)_2C$), 1.75 (s, 5-CH_3), 5.27 (d, *J* 17.5 Hz, H8), 7.08 (d, *J* 17.5 Hz, H7); 7-*Z*, δ: 5.48 (d, *J* 12.0 Hz, H8), 6.72 (d, *J* 12.0 Hz, H7).

5*a*: ^{1}H nmr, 7-*E*, δ: 5.27 (dd, ^1J(C8−H8) 172 Hz, *J* 17.5 Hz, H8), 7.08 (dd, *J* 17.5 Hz, ^2J(C8−H7) 1.9 Hz, H7); 7-*Z*, δ: 5.48 (dd, ^1J(C8−H8) 172 Hz, *J* 12.0 Hz, H8), 6.72 (dd, *J* 12.0 Hz, ^2J(C8−H7) 1.6 Hz, H7).

5*b*: ^{1}H nmr, 7-*E*, δ: 5.27 (dd, *J* 17.5 Hz, ^2J(C9-H8) 3.0 Hz, H8), 7.08 (dd, *J* 17.5 Hz, ^3J(C9−H7) 8.0 Hz); 7-*Z*, δ: 5.48 (dd, *J* 12.0 Hz, ^2J(C9−H8) 3.0 Hz, H8), 6.72 (dd, *J* 12.0 Hz, ^3J(C9−H7) 12.0 Hz, H7).

β-Ionone 6

A 1 *M* solution (1.5 equiv.) of diisobutylaluminium hydride (Dibal) in hexane (6.9 mL) was added dropwise by syringe to a solution of 4.6 mmol **5** (0.8 g) in dry pet. ether at −60°C and the mixture warmed to −20°C in 1 h. A suspension of 1:5 water/silicagel in ether/pet. ether 1:1 was added and the mixture stirred at room temperature for 1 h. After drying with $MgSO_4$, the solids were filtered off and washed with dry ether. Evaporation of the solvents yielded the C12-aldehyde in 95% yield; ^{1}H nmr (100 MHz, $CDCl_3/CCl_4$ 1:1), δ: 6.14 (dd, *J* 16.0 Hz, *J* 8.0 Hz, H8), 7.27 (d, *J* 16.0 Hz, H7), 9.52 (d, *J* 8.0 Hz, H9). The C12-aldehyde (4.2 mmol, 0.75 g) in dry ether was added dropwise to a solution of 2 equiv. of methyl magnesium iodide in dry ether, freshly prepared from methyl iodide (1.2 g) and magnesium (0.2 g). The solution was refluxed for 1 h, poured into half-saturated NH_4Cl, and extracted with ether. The organic layer was washed with water followed by brine, and then dried ($MgSO_4$). Evaporation of the solvent afforded the β-ionol in 90% yield. The β-ionol dissolved in hexane was added to an 8-fold excess of active manganese dioxide in hexane and stirred at room temperature until no further β-ionol could be detected by tlc. The solids were filtered off through Celite, washed with ether, and the filtrates concentrated to afford an oil which was purified by preparative hplc to give the β-ionone in 70% yield; ^{1}H nmr (100 MHz, $CDCl_3/CCl_4$ 1:1), δ: 1.09 (s, $(CH_3)_2C$), 1.76 (s, 5-CH_3), 2.26 (s, 9-CH_3), 6.09 (d, *J* 17.0 Hz, H8), 7.28 (d, *J* 17.0 Hz, H7).

6*a*: ^{1}H nmr, δ: 6.09 (dd, ^1J(C8−H8) 156 Hz, *J* 17.0 Hz, H8).

6*b*: ^{1}H nmr, δ: 2.26 (d, ^2J(C9−(9-CH_3)) 6 Hz, 9-CH_3), 6.09 (dd, *J* 17.0 Hz, ^2J(C9−H8) 3.3 Hz, H8), 7.28 (dd, *J* 17.0 Hz, ^3J(C9−H7) 6.5 Hz, H7).

*β-Ionylidene acetaldehyde 7: (4*E*)-3-methyl-5-(2,6,6-trimethyl-1-cyclohexenyl)-2,4-pentadienal*

Sodium hydride (NaH, 120 mg, 2.7 mmol, 55% in mineral oil) was washed three times with dry pet. ether to remove the mineral oil, and suspended in 10 mL dry THF. A solution of 3.1 mmol of diisopropylphosphonoacetonitrile (0.65 g) in dry THF was added dropwise and stirred for 30 min at room temperature. After cooling to 0°C a solution of 2.1 mmol β-ionone (0.4 g) in dry THF was added dropwise and the mixture stirred and warmed to room temperature. After 2 h the solution was poured into half-saturated NH_4Cl and extracted with ether. The organic layers were washed with water followed by brine, and dried ($MgSO_4$). After filtration through a layer of silica gel the solvents were evaporated to afford β-ionylidene acetonitrile which was reduced with Dibal as described for the reduction of **5** to yield 0.36 g (80%) of β-ionylidene acetonitrile **7** as a 9-*E*/*Z* 85:15 mixture; ^{1}H nmr (100 MHz, $CDCl_3/CCl_4$ 1:1), 9-*E*, δ: 1.01 (s, $(CH_3)_2C$), 1.70 (s, 5-CH_3), 2.28 (s, 9-CH_3), 5.87 (d, *J* 8.0 Hz, H10), 6.15 (d, *J* 16.0 Hz, H8), 6.68 (d, *J* 6.0 Hz, H7), 10.19 (d, *J* 8.0 Hz, H11); 9-*Z*, δ: 1.03 (s, $(CH_3)_2$), 1.75 (s, 5-CH_3), 2.09 (s, 9-CH_3), 5.80 (d, *J* 8.0 Hz, H10), 6.56 (d, *J* 16.0 Hz, H7), 7.11 (d, *J* 16.0 Hz, H8), 10.23 (d, *J* 8.0 Hz, H11).

7*a*: ^{1}H nmr, 9-*E*, δ: 5.87 (dd, *J* 8.0 Hz, ^3J(C8−H10) 6.0 Hz, H10), 6.15 (dd, ^1J(C8−H8) 162 Hz, *J* 16.0 Hz, H8).

7*b*: ^{1}H nmr, 9-*E*, δ: 2.28 (d, ^2J(C9−(9-CH_3)) 6.0 Hz, 9-CH_3), 5.87 (dd, *J* 8.0 Hz, ^2J(C9−H10) 1.0 Hz, H10), 6.15 (dd, *J* 16.0 Hz, ^2J(C9−H8) 3.2 Hz, H8), 6.68 (dd, *J* 16.0 Hz, ^3J(C9−H7) 6.4 Hz, H7).

*Retinal 1*a,b

Sodium hydride (NaH, 80 mg, 1.8 mmol, 55% in mineral oil) was washed three times with dry pet. ether to remove the mineral oil, and suspended in 10 mL dry THF. A solution of 2.1 mmol diethyl-3-cyano-2-methylprop-2-enylphosphonate **8** (14) (0.45 g) in dry THF was added dropwise and stirred for 30 min at room temperature. After cooling to 0°C a solution of 1.4 mmol β-ionylidene acetaldehyde **7** (0.3 g) in dry THF was added dropwise and the mixture stirred and warmed to room temperature. After 2 h the solution was poured into half-saturated NH_4Cl and extracted with ether. The organic layers were washed with water followed by brine, dried ($MgSO_4/K_2CO_3$), and then concentrated. The residue was purified by chromatography using 5% ether/pet. ether to yield the pure retinonitrile, which was reduced with Dibal as described for the reduction of **5** to provide the crude retinal in 80% yield (0.3 g). The all-*trans* isomer **1** was separated by column chromatography (silica gel >230 mesh, 4% ether/pet. ether) and further purified by prep. hplc. The 300-MHz ^{1}H nmr spectra of **1***a*,*b* are identical to those described by Patel (25) except for the additional ^{13}C-^{1}H coupling constants as shown in Table 1. The 75.5-MHz ^{13}C nmr spectra of **1***a*,*b* display the enriched signals and are further identical to those described by Englert (16) except for the additional ^{13}C−^{13}C coupling constants as shown in Table 2; ms: **1***a* and **1***b* *m*/*z* 285 (M^+); level of ^{13}C enrichment calculated from the mass spectra: 93%.

*C17-Acetate-nitrile 9: (4*E*,6*E*)-3-acetoxy-5-methyl-7-(2,6,6-trimethyl-1-cyclohexenyl)-4,6-heptadienenitrile*

To a stirred solution of 6 mmol of acetonitrile (0.25 g) in 20 mL dry THF, 6 mmol of n-butyllithium (4.3 mL of a 1.4 *M* solution in hexane) were added dropwise at −60°C and stirred at −20°C for 15 min. The reaction mixture was cooled to −90°C and 6 mmol of 7*E*,9*E*-β-ionylidene acetaldehyde (1.3 g) in 10 mL dry THF were slowly added dropwise. The mixture was warmed to −60°C in 30 min and 12 mmol acetyl chloride (0.9 g) was added dropwise. After warming to 10°C, 20 mL of half-saturated $NaHCO_3$ solution was added and the mixture extracted with ether. The organic layer was washed with water followed by brine, and then dried ($MgSO_4$). Evaporation of the solvent afforded an oil which was purified by chromatography using 15% ether/pet. ether to yield 1.5 g (85%) of C17-acetate-nitrile **9**; ir (KBr): 2250 cm^{-1} (C≡N stretch), 1745 cm^{-1} (C=O stretch); ^1H nmr (100 MHz, $CDCl_3/CCl_4$ 1:1), δ: 0.99 (s, $(CH_3)_2C$), 1.65 (s, 5-CH_3), 1.90 (s, 9-CH_3), 2.06 (s, CO—CH_3), 2.64 (d, *J* 6.0 Hz, H12), 5.35 (d, *J* 10.0 Hz, H10), 5.80 (dt, *J* 10.0 Hz, *J* 6.0 Hz, H11), 5.94 (d, *J* 16.5 Hz, H8), 6.22 (d, *J* 16.5 Hz, H7); ^{13}C nmr (25 MHz, $CDCl_3$), δ: 13.1, 19.2, 21.0, 21.6, 24.0, 28.8, 32.9, 34.2, 39.5, 66.0, 116.2, 123.7, 129.5, 129.7, 135.6, 137.1, 140.1, 169.8.

9*c*: ^1H nmr, δ: 2.64 (dd, ^1J(C12−H12) 137.0, *J* 6.0 Hz, H12), 5.80 (dtd, *J* 10.0 Hz, *J* 6.0 Hz, ^2J(C12−H11) 1.9 Hz, H11); ^{13}C nmr, 92% enriched signal, δ: 24.0.

9*d*: ^1H nmr, δ: 2.64 (dd, ^2J(C13−H12) 9.0 Hz, *J* 6.0 Hz, H12); ^{13}C nmr, 92% enriched signal, δ: 116.2.

*C17-Nitrile **10**: 5-methyl-7-(2,6,6-trimethyl-1-cyclohexenyl)-2,4,6-heptatrienenitrile*

Two equivalents of diazabicyclononene (DBN) were added to a solution of the C17-acetate-nitrile **9** in toluene and the mixture was brought to a gentle reflux. After 90 min (no acetate left by tlc) the mixture was cooled, poured into water, and extracted with ether. The organic layers were washed with water until neutral, followed by brine, and then dried ($MgSO_4$) and concentrated. The residue was purified by chromatography using 5% ether/pet. ether. Yield: 88% of a 11-*E*/*Z* mixture which was used in the next step.

*β-C18-ketone **12**: 6-methyl-8-(2,6,6-trimethyl-1-cyclohexenyl)-3,5,7-octatriene2-one*

The β-C18-ketone **12** was prepared in two steps from the C17-nitrile **10** in 60% yield as described for the preparation of **6** from **5**; ^1H nmr (300 MHz, $CDCl_3$), δ: 1.04 (s, $(CH_3)_2C$), 1.72 (s, 5-CH_3), 2.07 (s, 3H, 9-CH_3), 2.30 (s, 13-CH_3), 6.16 (d, *J* 11.7 Hz, H10), 6.17 (d, *J* 15.4 Hz, H12), 6.17 (d, *J* 16.1 Hz, H8), 6.42 (d, *J* 16.1 Hz, H7), 7.55 (dd, *J* 15.4 Hz, *J* 11.7 Hz, H11).

*Retinal **1**c,d*

The retinal **1***c,d* was prepared in two steps from the β-C18-ketone **12***c,d* in 85% yield as described for the synthesis of **7** from **6**. The all-*trans* isomer **1** was separated by column chromatography (silicagel >230 mesh, 4% ether/pet. ether) and further purified by preparative hplc; ms: **1***c* and **1***b* *m*/*z* 285 (M^+); level of ^{13}C enrichment calculated from the mass spectra: 93%. For ^1H nmr, compare **1***a,b*.

Received July 27, 1984

This paper is dedicated to Professor Camille Sandorfy on the occasion of his 65th birthday

C. GARRIGOU-LAGRANGE, M. OUCHETTO, and B. ELOUADI. Can. J. Chem. **63**, 1436 (1985).

Infrared reflection spectra of vitreous phosphates $(1 - x - \chi)Li_2O - xCdO-\chi P_2O_5$ are analysed in relation to the conformation when it is known. The evolution of the spectra with the different constituents is studied and the oxide forming-character of CdO is discussed.

C. GARRIGOU-LAGRANGE, M. OUCHETTO et B. ELOUADI. Can. J. Chem. **63**, 1436 (1985).

Les spectres de réflexion infrarouges de verres de phosphate de composition $(1 - x - \chi)Li_2O - xCdO-\chi\ P_2O_5$ ont été analysés et reliés à leur conformation lorsque celle-ci était connue. L'évolution des spectres avec les différents constituants a été étudiée et le caractère "oxyde formateur" du CdO discuté.

Introduction

The glass region of the binary systems $A_2O-P_2O_5$ and $BO-P_2O_5$ (A = monovalent cation; B = bivalent cation) has been widely studied, but no complete vibrational survey is actually available for the ternary diagram $Li_2O-CdO-P_2O_5$ (1, 2).

The purpose of this paper is to complete our earlier Raman studies, by giving the interpretation of the evolution of the infrared spectra inside the vitreous domain of this ternary system (3, 4).

Experimental

The glass samples were prepared by the same procedure as described in ref. 3. Figure 1 and Table 1 give the chemical compositions of the specimens studied. Any point of the glass-forming region in the ternary system can be characterized by the general formula:

$$(1 - x - \chi)Li_2O.xCdO.xP_2O_5 \qquad (0 < x < 1; 0 < \chi < 1)$$

where x = CdO molar fraction ratio; χ = P_2O_5 molar fraction ratio.

Infrared reflection spectra were recorded with the P.E.599 spectrometer, and Nicolet MX1 and 7000 and Polytec IR30 interferometers. The Kramers–Kronig method was used for spectra analysis using a Vax computer.

The results of the infrared spectroscopic measurements are presented in Figs. 2–10. The absorption band frequencies are given in Tables 2–10.

Results and discussion

The structural modifications are widely dependent upon the forming oxide (P_2O_5) molar ratio which is decreasing as the glass region extends (from P_2O_5) inside the ternary system $Li_2O-CdO-P_2O_5$ (3). Furthermore, the modifier character of the alkaline oxides is well established, but, for CdO, this is not definitely clear.

With a rough approximation, the spectrum of a compound can usually be considered as the sum of the absorption peaks arising from individual group vibrations. In order to clear up the role of each component in the phosphate glasses studied, the present infrared study has been carried out in the following order (Fig. 1).

1. Pure P_2O_5.
2. Metaphosphates region (χ = 0.5) situated along the line $Li_2O.P_2O_5$ N $CdO.P_2O_5$.

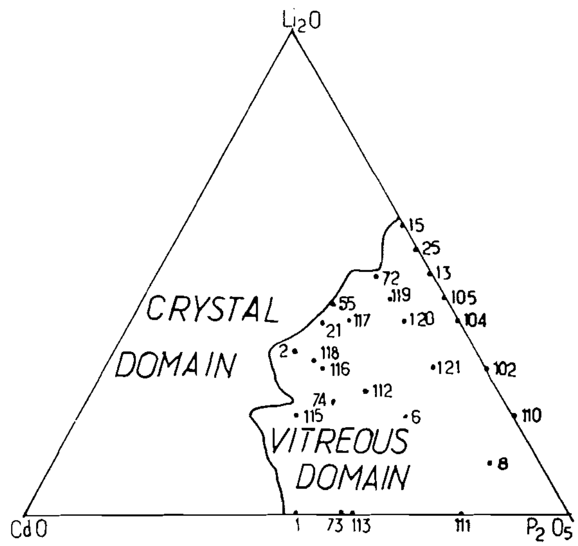

FIG. 1. Vitreous domain inside the system $Li_2O.CdO.P_2O_5$ at 1000°C (cf. Table 1 for the correspondence between the numbers of samples and their composition).

3. Ultraphosphates (lines χ = 0.6 and 0.8) extending on the surface of the triangle $P_2O_5-Li_2O.P_2O_5-CdO.P_2O_5$.
4. Oligophosphates (lines χ = 0.4 and 0.33) included inside the trapezium $Li_2O.P_2O_5-CdO.P_2O_5-2Li_2O.P_2O_5-CdO.P_2O_5$.
5. Lines with a constant ratio Li_2O/CdO and variable χ (lines $P_2O_5-Li_2O$; $CdO-P_2O_5$; $(1 - x)/2\ Li_2O.(1 - x)/2\ CdO-\chi P_2O_5$; $xLi_2O.xCdO.(1 - 2x)P_2O_5$.

This order of investigation has been adopted so that some simple and well-established structural types can be used to approach the more complicated ones. For example: (*i*) infrared spectra of pure P_2O_5 (built up as a tridimensional disordered network of PO_4 tetrahedra sharing three of their oxygens) and those of the metaphosphates (built up as infinite PO_4 tetrahedral chains) will allow the interpretation of the structural evolution inside the ultraphosphate domain. (*ii*) Infrared spectra of metaphosphates (infinite chain structure) and pyrophosphate (two linked tetrahedra) will permit the interpretation of the

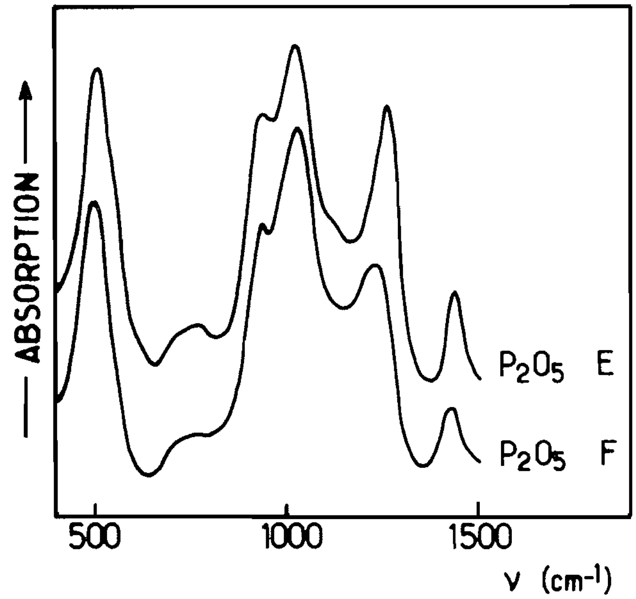

FIG. 2. Infrared spectra of vitreous P_2O_5 (sample F is more hydrated than sample E).

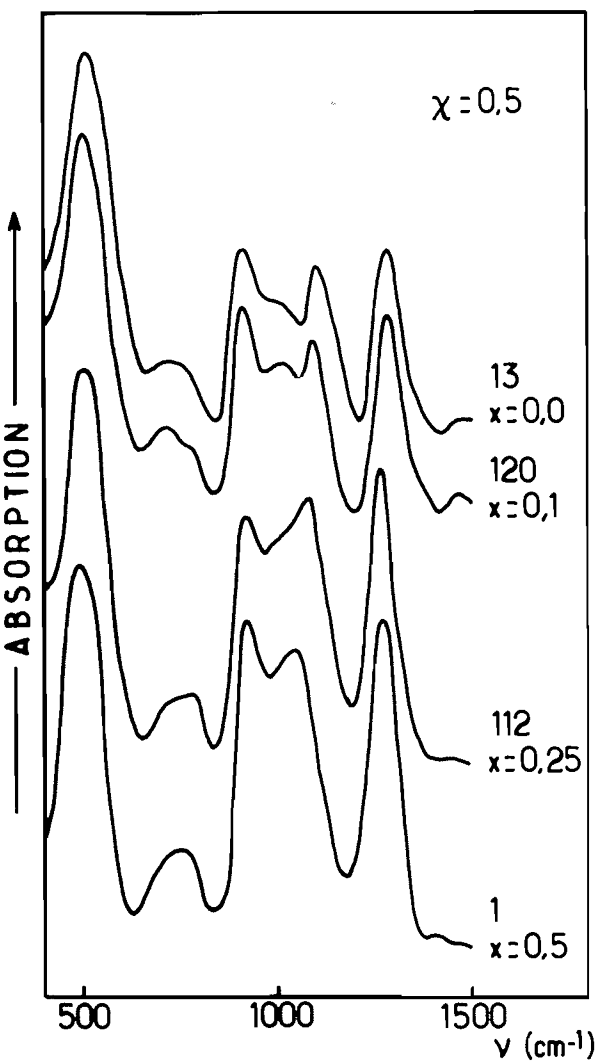

FIG. 3. Infrared spectra of metaphosphates $(0.5 - x)Li_2O - xCdO - 0.5P_2O_5$.

near 1270 cm^{-1} attributed to ν P=O is lower than the one observed by Raman spectroscopy (1) because of the association with water. Two absorptions near 946 and 780 cm^{-1} are due to the ν_a POP and ν_s' POP vibrations. The comparison between the spectra of the two samples noted E and F in Fig. 2, each having a different quantity of water, shows that the absorption at 1030 cm^{-1} is due to hydration.

2. *Metaphosphate glasses*

2.1. *Previous results*

Infrared spectra of metaphosphate glasses have been studied by several authors (1−13). It is also well established that metaphosphate glasses are composed of linear chains of polyphosphate anions with the cations situated between the chains. Shih and Su have discussed two models of the chain arrange-

ment, viz. the straight chain and the zigzag chain models (2).

(a) *Straight chain model* (Fig. 11a)

According to this model, the PO_4 tetrahedra are disposed in such a way that all phosphorus should stand in a straight line (chain axis). The straight-chain symmetry is C_{2v}. Eight vibrational modes can thus be predicted, if a translation unit —$OP(O_2)O$— is admitted:

$$[1] \quad \Gamma_s = 3A_1 + A_2 + 2B_1 + 2B_2 = 8$$

According to the selection rules, the A_2 mode should be

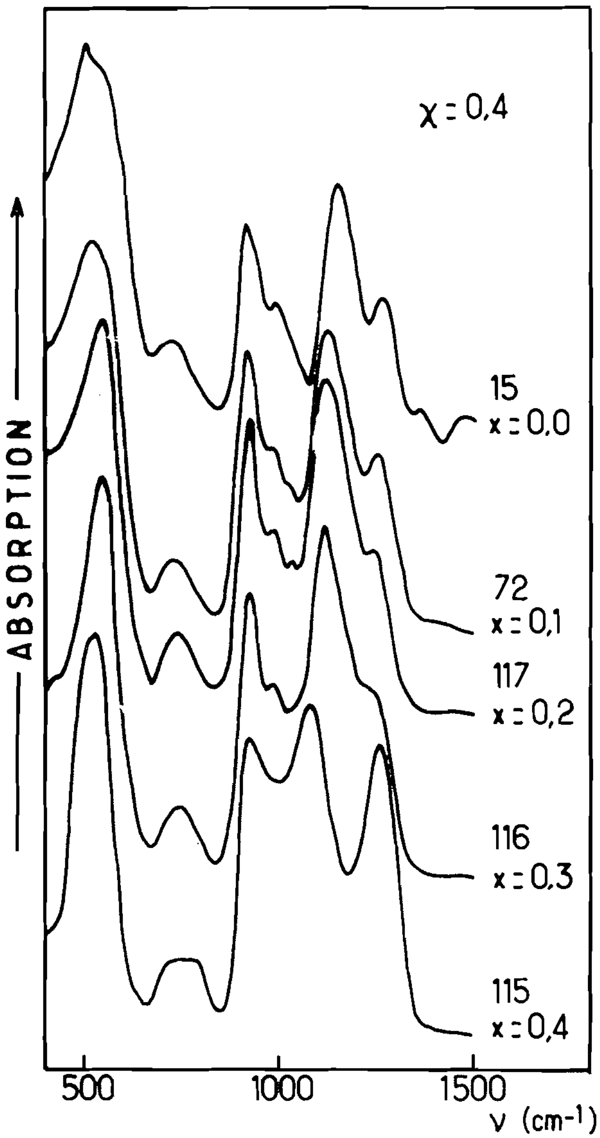

FIG. 7. Infrared spectra of oligophosphates $(0.6-x)\text{Li}_2\text{O}-x\text{CdO}-0.4\text{P}_2\text{O}_5$.

active in Raman and forbidden in infrared. The other modes are active in both spectroscopies.

Since more than seven absorption bands were observed in the recorded spectra, this model was rejected by Shih and Su.

(b) *Zigzag chain model* (Fig. 11b)

In this case, all the phosphorus and bridging oxygen atoms are localized in a plane passing through the chain axis; the identical PO_4 tetrahedra are aligned in a zigzag manner. The resulting point group symmetry is C_s. Twenty vibrational modes can be predicted; they all are active in both spectroscopies:

$$[2] \quad \Gamma_s = 12A' + 8A'' = 20$$

According to SHIH and SU (2), the calculated results (on the basis of the Wilson F−G matrix) seem to agree with the observed infrared spectra.

2.2. *Analysis of our results*

In the frequency domain explored (200−1600 cm^{-1}), we expect to observe the following vibrational modes: ν_s POP, ν_a POP, ν_s PO_2, ν_a PO_2, ν(OPOP), and the skeleton

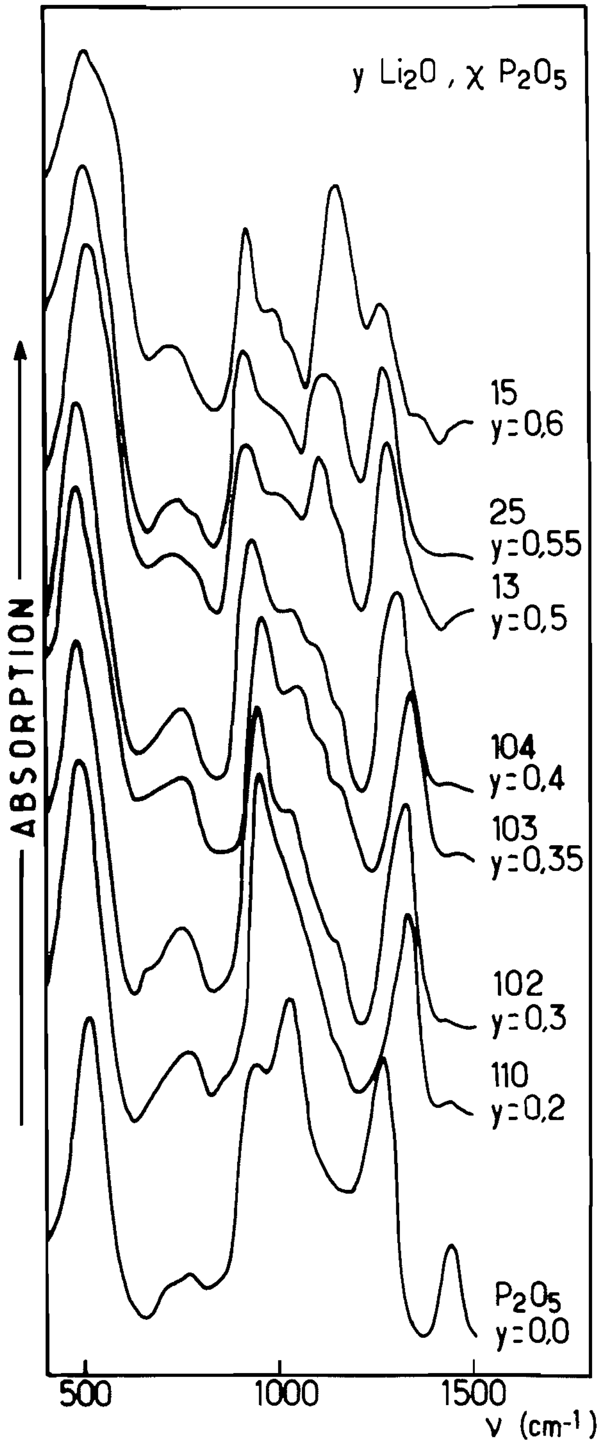

FIG. 8. Infrared spectra of binary phosphates $y\mathrm{Li_2O}-\chi\mathrm{P_2O_5}$.

deformations.

Let us remember that the recorded Raman spectra are relatively simple: two intense and polarized bands are observed at 700 and 1170 cm^{-1}; they were respectively attributed to ν_s POP and ν_s PO_2 (3) (Table 3). Furthermore, four strong absorption bands have been observed in the infrared spectra; the corresponding frequencies are 520, 920, 1100, and 1270 cm^{-1} (Fig. 3).

The bands at 500, 920, and 1270 cm^{-1} were respectively attributed to the skeleton deformation and the ν_a POP and ν_a PO_2 vibrations.

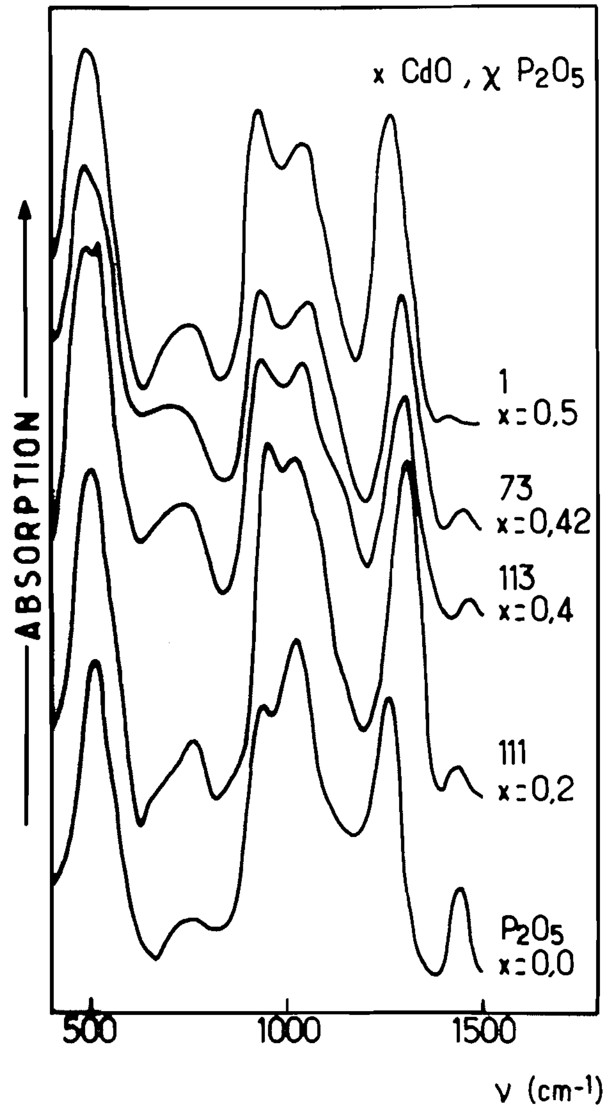

FIG. 9. Infrared spectra of binary phosphates $x\mathrm{CdO}-\chi\mathrm{P_2O_5}$.

The band near 1100 cm^{-1} is more difficult to explain. In Fig. 12, we compare the Raman spectra of some crystalline and vitreous compounds. It can be seen that the spectra of vitreous compounds can be described as the envelope of the crystalline ones. Thus we consider that, in the glasses containing lithium, this infrared absorption corresponds to a component of the ν_s PO_2, the displacement viz. the Raman frequency being due to a correlation effect.

This band is not seen in the pure cadmium metaphosphate, but a new strong band appears at 1046 cm^{-1}. We note that, in the Raman spectrum of the crystallized $CdPO_3$ (Fig. 12), the Davydov splitting is less pronounced than in $LiPO_3$. We think that the 1046 cm^{-1} absorption in the glass is due to the ν_a POP vibration, split because the Cd^{2+} ion introduces a dissymmetry in the skeleton.

The weak bands observed at about 750–800 cm^{-1} are probably due to a third normal mode called ν(OPOP).

All the observed infrared and Raman bands of metaposphate glasses inside the ternary system $Li_2O-CdO-P_2O_5$ have been assigned according to the hypothesis that metaphosphates adopt infinite zigzag chain models: $(PO_3)_\infty$. No vibration mode corresponding to ν P=O has been observed in this case.

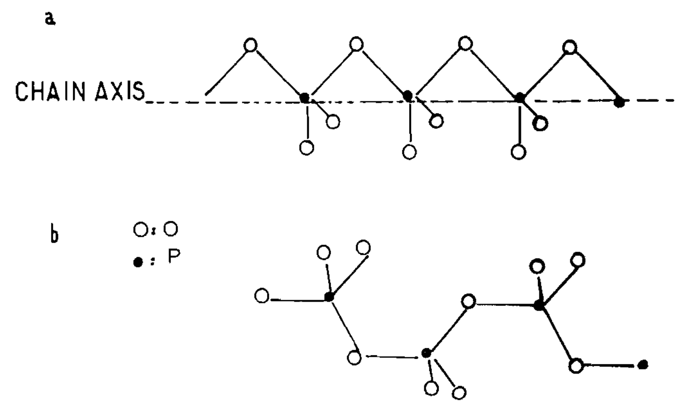

FIG. 11. Model of linear chains (a) and zigzag chains (b).

3. *Ultraphosphate domain*

In order to approach the glass structure in this domain, two lines have been studied: the one corresponds to $0.6P_2O_5(2Li_2O.3P_2O_5 - 2CdO.3P_2O_5)$ and the other one to $0.8P_2O_5(Li_2O.4P_2O_5 - CdO.4P_2O_5)$.

The bands observed in Raman and infrared are given in Tables 4 and 5. In all infrared spectra of these compounds (Figs. 4 and 5), a weak shoulder and a band have been respectively observed at 1100 and 1040 cm^{-1}. The latter becomes stronger as the amount of CdO increases. We adopt here the interpretation given formerly for metaphosphate glasses. The band at 1300 cm^{-1} was attributed to ν_a PO_2 superposed with ν P=O.

4. *Oligophosphate region*

The compounds studied are those situated on the line ($\chi = 0.4P_2O_5$) and the point corresponding to the composition $Li_2O.CdO.P_2O_5$ ($Li_2CdP_2O_7$).

The infrared spectrum of $Li_2CdP_2O_7$ is given in Fig. 6 (N2; $\chi = 0.33$). Twenty-one vibrations are expected for this compound: 3 vibrations due to POP bonds: ν_s POP, ν_a POP, POP;

and 18 vibrations due to the PO_3 groups.

The interpretations of the Raman and infrared spectra are given in Table 6, according to this assignment.

Fig. 7 shows infrared spectra of some glasses situated on the line $\chi = 0.4P_2O_5$. Their attributions (Table 7) are based on a comparison with metaphosphate and pyrophosphate spectra.

The ν PO_3 bands are observed in both infrared and Raman spectra. Raman ν_s PO_3 intensity decreases when xCdO increases, while ν_a PO_3 intensity (ir) remains strong for all the values of x, the corresponding frequency decreasing from 1144 to 1080 cm^{-1}. This can be explained if we admit that an oxygen atom of the PO_3 group is partially linked to the Cd^{2+} ion, due to the electronegativity of this ion (1.69), very close to that of the phosphorus (2.19) (ref. 14). Other techniques like nmr, epr, etc. should be useful in verifying this assumption.

5. *Vibrational spectra of glass regions existing along lines with a variable amount of P_2O_5*

5.1. *Binary systems $Li_2O-P_2O_5$ and $CdO-P_2O_5$*

Infrared spectra recorded along the lines $(1 - \chi)Li_2O - \chi P_2O_5$ and $(1 - \chi)CdO - \chi P_2O_5$ are shown in Figs. 8 and 9. Tables 8 and 9 give the interpretation of the infrared and Raman spectra.

The Raman spectra are very similar to those recorded by other authors for various binary systems $Na_2O-P_2O_5$, $CaO-P_2O_5$, etc. (15, 16). The infrared spectra of the Cd glasses contain a doublet (920−1050 cm^{-1}) which does not exist in Li glasses. It can be explained by a doubling of the vibration ν_a POP due to the dissymmetry of the bands introduced locally by Cd^{2+}.

5.2. *The medium line of the triangle $Li_2O-CdO-P_2O_5$ crossing the point P_2O_5*

The composition along this line can be written:

[3] $(1 - \chi)/2Li_2O.(1 - \chi)/2CdO.\chi P_2O_5$

or

[4] $xLi_2O.xCdO.(1 - 2x)P_2O_5$

Both Raman (3, 4) and infrared spectra (Fig. 6) recorded are similar to those of the previously discussed binary systems $Li_2O-P_2O_5$ and $CdO-P_2O_5$.

The frequency of ν_s POP decreases substantially when χ increases:

ν_s POP = 752 cm^{-1} for $\chi = 0.33$ (pyrophosphate P_2O_7) containing only one POP bond.

ν_s POP = 700 cm^{-1} for $\chi = 0.50$ (metaphosphates containing infinite chains and two POP bonds by P atom).

ν_s POP = 648 cm^{-1} for $\chi = 1$ (pure P_2O_5 containing a 3-dimensionally bounded PO_4 and three POP bonds on each P atom).

The value of this frequency may give an indication of the nature of the bonds between phosphorus and oxygen in the glass region.

Conclusion

Vibrational spectroscopy has allowed us to follow the evolution of the glass structure inside the ternary system $Li_2O-CdO-P_2O_5$. In glasses containing a high Li_2O ratio CdO, the oxide LiO_2 acts as a modifier, like all the alkali oxides. When the proportion of CdO increases in the vitreous domain, the dissymmetry introduced by this oxide in the PO_4 network could be consistent with an oxide-forming character. The ν_s POP frequency can given an indication of the dimensionality of the phosphate skeleton.

Acknowledgments

The authors are grateful to Drs. Davidovics and Pourcin, University of Provence, and to Professor Lascombe and Dr. Marchand, University of Bordeaux I, for having allowed them to record some spectra on their ir spectrometers and interferometers.

Étude théorique des réactions d'abstraction d'hydrogène RH + X $\rightleftharpoons$ R + HX, avec R, X$\equiv$H, CH_3, NH_2, OH et F

GEORGES LEROY,[1] MICHEL SANA[2] ET ANNE TINANT

Reçu le 27 juillet 1984

Cet article est dédié au Professeur Camille Sandorfy à l'occasion de son 65ᵉ anniversaire

GEORGES LEROY, MICHEL SANA et ANNE TINANT. Can. J. Chem. **63**, 1447 (1985).

Nous avons étudié théoriquement les réactions d'abstraction d'hydrogène RH + X $\rightleftharpoons$ R + HX avec R, X$\equiv$H, CH_3, NH_2, OH et F. Tous les calculs *ab initio* ont été effectués par la méthode UHF avec la base 6-31G. Cependant, les grandeurs énergétiques ont été recalculées au niveau CI. Les constantes de vitesse et les paramètres d'Arrhénius ont été obtenus par la théorie de l'état de transition avec une correction d'effet tunnel basée sur le potentiel d'Eckart. L'accord peu satisfaisant entre résultats théoriques et expérimentaux nous a conduit à élaborer un procédé semi-empirique de calcul des barrières d'activation dans lequel les liaisons en évolution sont représentées par des courbes de Morse. Les résultats obtenus dans cette optique sont en bon accord avec l'expérience. Ils mettent en évidence le comportement "non-Arrhénius" de toutes les réactions étudiées et permettent de rationaliser un ensemble important de faits expérimentaux

GEORGES LEROY, MICHEL SANA, and ANNE TINANT. Can. J. Chem. **63**, 1447 (1985).

Hydrogen abstraction reactions RH + X $\rightleftharpoons$ R + HX with R, X$\equiv$H, CH_3, NH_2, OH, and F have been studied at the *ab initio* 6-31G − UHF level. However, energetic properties were computed at the CI level. Rate constants and Arrhenius parameters have been obtained using the transition state theory formalism with Eckart's tunneling correction. The discrepancy between theoretical and experimental results led us to elaborate a semi-empirical procedure to calculate activation barriers, in which the bonds R—H and X—H are represented by Morse curves. Thus, the agreement between theory and experiment is much better. Moreover, the results obtained by this procedure demonstrate the non-Arrhenius behavior of all the reactions under consideration and allow us to rationalize a large number of experimental facts.

Introduction

Dans le cadre de nos travaux théoriques sur les radicaux libres (1−13), nous avons étudié un ensemble de réactions d'abstraction d'hydrogène décrites par l'équation générale:

$$RH + X \rightleftharpoons R + HX$$

dans laquelle R et X désignent l'un des atomes ou groupes suivants: H, CH_3, NH_2, OH et F.

Tous les calculs théoriques ont été effectués suivant une démarche décrite par ailleurs (12) et dont nous rappelons schématiquement les points essentiels:

Utilisation de la méthode UHF de Pople−Nesbet (14) avec la base 6-31G de Hehre *et al.* (15) grâce au programme GAUSSIAN-70 (16) complété par le programme FORCE de Schlegel (17).

Recherche des points stationnaires (réactifs, points de transition et produits) grâce à la construction de formes analytiques locales de la surface de potentiel, dans l'espace des paramètres de structure comportant $3N - 6$ degrés de liberté (N: nombre d'atomes de la supermolécule).

Détermination des modes normaux de vibration et des fréquences correspondantes, dans l'approximation quadratique.

Calcul des corrections thermiques, des capacités calorifiques et des entropies grâce au formalisme de la thermodynamique statistique.

Calcul des énergies totales des points stationnaires en méthode d'interaction de configurations avec: (*i*) sélection itérative, par perturbation, des configurations importantes; (*ii*) traitement en orbitales naturelles; (*iii*) extrapolation pour un nombre infini de déterminants.

Calcul des constantes de vitesse selon le formalisme de la théorie de l'état de transition, avec correction d'effet tunnel:

$$[1] \quad k(T) = x(T)\cdot k^{\mathrm{TST}}(T)$$

$$[2] \quad k(T) = x(T)\cdot\frac{N(\chi T)^2}{h}\exp\left(-\frac{\Delta G_0^{\ddagger}}{RT}\right)$$

Résultats théoriques

I. *Structures géométriques*

Les paramètres géométriques de la supermolécule sont définis sur la fig. 1. Leurs valeurs à l'état de transition sont réunies dans le tableau 1. Les résultats relatifs aux réactifs et produits sont donnés par ailleurs (12).

On notera que, dans la plupart des structures de transition, les atomes A_1, H_2 et B_6 sont pratiquement sur une droite. Pour analyser les paramètres de structure r_1 et r_2, à l'état de transition, nous définissons les rapports suivants:

$$[3] \quad r_1(\text{rel.}) = \frac{r_1^{\ddagger}}{r_1(AH_{n+1})}$$

et

$$[4] \quad r_2(\text{rel.}) = \frac{r_2^{\ddagger}}{r_2(BH_{m+1})}$$

On constate aisément qu'ils varient relativement peu d'une réaction à l'autre comme l'illustrent également les résultats ci-dessous:

$$[5] \quad \left\langle\frac{r_1(\text{rel.}) + r_2(\text{rel.})}{2}\right\rangle = 1{,}25 \text{ (écart type: 0,03)}$$

et

$$[6] \quad \langle r_1(\text{rel.})/r_2(\text{rel.})\rangle = 0{,}99 \text{ (écart type: 0,04)}$$

Au total, dans les réactions d'abstraction d'hydrogène, la liai-

son qui se rompt subit un allongement d'environ 25%, à l'état de transition, par rapport à sa valeur initiale. De même, la liaison en formation est plus longue d'environ 25% dans le complexe activé que dans la molécule-produit. Il est intéressant de noter que, dans les réactions en couches fermées que nous avons étudiées précédemment (18−34), l'allongement des liaisons à l'état de transition est généralement de l'ordre de 50%.

II. *Surfaces de potentiel locales*

Au voisinage de chaque point stationnaire, nous avons construit une forme analytique locale de la surface de potentiel. Il s'agit d'un développement polynomial d'ordre deux, paramétrisé par régression linéaire sur les gradients de potentiel calculés pour $2k + 1$ ($k = 3N - 6$) structures moléculaires judicieusement choisies (35). Ceci nous a permis d'effectuer l'analyse vibrationnelle de Wilson et de calculer les modes normaux de vibration dans l'approximation harmonique en négligeant le couplage de Coriolis. Comme nous l'avons montré par ailleurs (12), l'approximation quadratique est tout à fait satisfaisante dans le cas des composés polyatomiques. Les fréquences obtenues pour les points de transition sont réunies dans le tableau 2. Ces résultats permettront le calcul des corrections thermiques et des entropies grâce aux équations de la thermodynamique statistique.

III. *Grandeurs énergétiques*

Les énergies totales des points stationnaires ont été calculées en méthode d'interaction de configurations en utilisant les géométries optimisées au niveau SCF.

Dans le tableau 3, différentes énergies théoriques des structures d'équilibre sont comparées aux valeurs expérimentales correspondantes. Nous y donnons également les énergies UHF et CI des structures de transition. Ces données permettent d'évaluer les effets thermiques à 0 K et les barrières d'activation des différentes réactions considérées. Nous les donnons dans le tableau 4 avec quelques résultats théoriques plus précis obtenus par d'autres auteurs.

Les valeurs de ΔE_0^0 (CI extr.) sont souvent très sous-estimées. Ceci révèle l'existence d'erreurs plus ou moins importantes au niveau des barrières d'activation des réactions correspondantes. La comparaison de celles-ci à des données expérimentales nécessite l'introduction d'un modèle tel que celui de l'état de transition, avec ou sans effet tunnel. Cependant, en comparant certaines d'entre elles à des résultats théoriques plus précis, on s'aperçoit qu'elles peuvent être assez fortement surestimées.

IV. *Constantes de vitesse et énergies d'activation*

En vue de tester la fiabilité de nos résultats théoriques, nous avons calculé les constantes de vitesse et les énergies d'activation des réactions considérées en utilisant la théorie de l'état de transition avec correction d'effet tunnel. Rappelons qu'en l'absence de celle-ci, la constante de vitesse d'un processus bimoléculaire s'écrit, dans le cadre de la théorie de l'état de transition:

$$[7] \qquad k(T) = \frac{N(\chi T)^2}{h} \exp\left(-\frac{\Delta G_0^{\ddagger}}{RT}\right)$$

où:

$$[8] \qquad \Delta G_0^{\ddagger} = \Delta H_0^{\ddagger} - T\Delta S_0^{\ddagger}$$

$\Delta H_0^{\ddagger}$ est l'enthalpie d'activation à la température T.

La dépendance thermique de la constante de vitesse s'exprime par la relation:

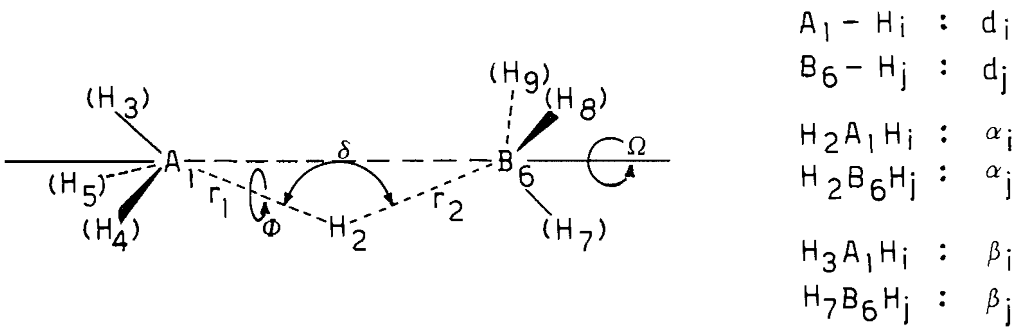

FIG. 1. Paramètres géométriques de la supermolécule.

[a] Rotateur libre.

$$[9] \quad RT^2 \left(\frac{d\ln k}{dT}\right)_P = \Delta H_0^{\ddagger} + 2\,RT$$

Cette expression s'identifie à l'énergie d'activation classique d'Arrhénius:

$$[10] \quad E_a = \Delta H_0^{\ddagger} + 2\,RT$$

Pour tenir compte de l'effet tunnel, on multiplie la constante de vitesse [7] par un terme correctif supérieur à un, $x(T)$, qui mesure la perméabilité de la surface aux trajectoires réactives. On écrit donc:

$$[11] \quad k^*(T) = x(T)\,k(T)$$

où:

$$[12] \quad x(T) = \int_a^{\infty} W(t)\,\exp(-t)\mathrm{d}t$$

avec:

$$[13] \quad a = \frac{Q - P}{\chi T}$$

Les termes Q et P désignent respectivement l'effet thermique (à 0 K) et la barrière d'activation de la réaction considérée dans le sens endothermique ($Q \geq 0$; $P > 0$). La fonction $W(t)$ dépend de la température et de la forme de la surface de potentiel au voisinage du point selle. On adopte, en général, un potentiel à une dimension pour exprimer $W(t)$. Dans ce travail, nous avons choisi le potentiel d'Eckart (43) plus réaliste que le potentiel parabolique de Christov (44). Cependant, sa forme

[a]Calculés avec les fréquences théoriques de la réf. 36.
[b]On a utilisé la fréquence de "stretching" asymétrique R—H pour obtenir ce résultat.

particulière ne permet pas la résolution analytique de l'intégrale [12]. Celle-ci a donc dû être calculée par intégration numérique.

A basse température, les corrections d'effet tunnel deviennent très importantes et cessent d'être valables. On peut admettre qu'en dessous de la température caractéristique de Christov (44) définie par la relation:

$$[14] \quad T_c = \frac{h\nu^{\neq}}{\pi\chi}$$

où $\nu^{\neq}$ désigne la fréquence imaginaire associée à la courbure négative du point de transition, un calcul quantique complet devrait être effectué.

Connaissant numériquement la fonction k^* (T) [11] il est aisé de calculer les paramètres d'Arrhénius A^* et E_a^* à toute température supérieure à $T_c/2$ (dans la suite, l'astérisque sera systématiquement omis).

La comparaison théorie–expérience peut s'effectuer au niveau de log k, log A et E_a. Elle n'est possible que dans un nombre relativement restreint de cas. En effet, les calculs théoriques ne sont valables qu'à des températures supérieures à $T_c/2$ auxquelles il est assez rare que des données expérimentales existent. Par ailleurs, celles-ci sont très disparates ce qui rend difficile un choix cohérent de valeurs. Le tableau 5 permet de comparer nos énergies d'activation théoriques à des données expérimentales de la littérature.

L'accord théorie–expérience est loin d'être excellent. De plus, la surestimation de certaines barrières d'activation signalée plus haut (voir tableau 4) est confirmée au niveau des énergies d'activation proprement dites.

La qualité médiocre de nos résultats théoriques trouve essentiellement son origine dans la limitation des calculs d'interaction de configurations qui découle elle-même de la troncature de la base atomique utilisée. L'introduction d'orbitales de polarisation aurait sans conteste un effet bénéfique sur les résultats CI mais nous ne pouvions pas l'envisager systématiquement dans ce travail vu la taille des systèmes étudiés. D'autre part, nous n'avons pas effectué la correction dite de contrepoids sur les énergies des réactifs et des produits car nous lui trouvons un caractère très arbitraire non seulement au niveau SCF où plusieurs méthodes ont été proposées pour l'évaluer mais encore, a fortiori, au niveau CI où elle n'est généralement pas effectuée. Notons d'ailleurs que les énergies de réaction calculées à la limite Hartree–Fock, où tous les effets de base ont disparu, restent très sous-estimées.

V. *Calcul simplifié des barrières d'activation*

En vue d'obtenir des résultats théoriques plus précis que ceux du tableau 5, nous avons élaboré un modèle original permettant de calculer très simplement les barrières d'activation des réactions d'abstraction d'hydrogène et, par là, de vérifier et de rationaliser un ensemble important de faits expérimentaux. Soit le processus réversible:

$$AH + B \underset{2}{\overset{1}{\rightleftharpoons}} A + HB$$

Le diagramme énergétique repris sur la fig. 2 permet d'exprimer la barrière d'activation de la réaction directe (notée 1) par la relation:

TABLEAU 7. Barrières d'activation modifiées (kcal/mol)

Réaction	$r_1^\ddagger$	$u_1(r_1^\ddagger)$	$r_2^\ddagger$	$u_2(r_2^\ddagger)$	$\Delta E^\ddagger$

F − H + OH	1,199	30,49	1,109	14,07	29,81
F − H + F	1,126	19,41	1,126	19,41	19,41

[15] $\Delta E_1^\ddagger = D_1 - [E(A\cdots H) + E(B\cdots H)]$

Représentons par des courbes de Morse les énergies potentielles des liaisons A—H et B—H:

[16] $u_1 = D_1[1 - e^{-a_1(r_1 - r_{1e})}]^2$

[17] $u_2 = D_2[1 - e^{-a_2(r_2 - r_{2e})}]^2$

Les paramètres des différentes courbes de Morse sont données dans le tableau 6.

Nous admettons que la somme des énergies de liaison $E(\mathrm{A}\cdots\mathrm{H}) + E(\mathrm{B}\cdots\mathrm{H})$ peut se mettre sous la forme:

[18] $E(\mathrm{A}\cdots\mathrm{H}) + E(\mathrm{B}\cdots\mathrm{H}) = \frac{1}{2}[D_1 - u_1(r_1^\ddagger) + D_2 - u_2(r_2^\ddagger)]$

Les barrières d'activation des réactions 1 et 2 s'écrivent alors simplement:

[19] $\Delta E_1^\ddagger = D_1 - \frac{1}{2}[D_1 - u_1(r_1^\ddagger) + D_2 - u_2(r_2^\ddagger)]$

[20] $\Delta E_2^\ddagger = D_2 - \frac{1}{2}[D_1 - u_1(r_1^\ddagger) + D_2 - u_2(r_2^\ddagger)]$

et les chaleurs de réaction à 0 K:

[21] $\Delta E_0^1 = \Delta E_2^\ddagger - \Delta E_1^\ddagger = D_2 - D_1 = -\Delta E_0^2$

Dans le cas de réactions thermoneutres, les barrières d'activation s'obtiennent par l'équation:

[22] $\Delta E_1^\ddagger = u_1(r_1^\ddagger) = u_2(r_2^\ddagger) = \Delta E_2^\ddagger$

Dès lors, il est aisé de recalculer tous les $\Delta E_i^\ddagger$ en utilisant les géométries optimisées des structures de transition données dans le tableau 1. On obtient ainsi les résultats repris au tableau 7. On constate qu'ils se rapprochent des valeurs correspondantes obtenues par des calculs théoriques plus élaborés (voir tableau 4). Ils nous ont permis de repréciser les paramètres cinétiques et thermodynamiques de toutes les réactions étudiées, à différentes températures.

Dans le tableau 8, nous les comparons à des données expérimentales disponibles. Dans l'ensemble, l'accord théorie–expérience peut être considéré comme très satisfaisant. Ceci constitue une justification du modèle simple qui nous a permis de déterminer les barrières d'activation. Nous pouvons donc aussi l'utiliser pour interpréter la cinétique des réactions d'abstraction d'hydrogène.

VI. *Utilisation des barrières d'activation*

Passons brièvement en revue quelques applications concrètes de nos résultats théoriques.

Tout d'abord, les énergies d'activation calculées à partir des barrières correspondantes permettent d'analyser la cohérence des résultats expérimentaux concernant les processus d'abstraction d'hydrogène. Sans insister sur ce point, relevons cependant que, dans cette optique, certaines énergies d'activation mesurées pour les réactions $CH_4 + H \rightleftharpoons CH_3 + H_2$ semblent contestables.

Ensuite, nos barrières d'activation permettent de préciser les limites d'applicabilité de la relation d'Evans–Polanyi (à 0 K). Nous avons constaté que, pour toute série de réactions faisant intervenir le même radical abstracteur, la barrière d'activation est une fonction linéaire de l'énergie de réaction. C'est ce que montrent les résultats repris dans le tableau 9.

On peut trouver la signification des paramètres α et β en identifiant la relation d'Evans–Polanyi à l'équation [19] écrite sous la forme:

[23] $\Delta E^\ddagger = \left(\frac{1 + a}{2}\right) \Delta E_0^0 + \left(\frac{a + b}{2}\right) D_2$

où a et b sont respectivement définis par les formules:

[24] $a = \frac{u_1(r_1^\ddagger)}{D_1}$

[25] $b = \frac{u_2(r_2^\ddagger)}{D_2}$

TABLEAU 8. Comparaison des paramètres cinétiques théoriques et expérimentaux (cm^3/mol s et kcal/mol)

TABLEAU 9. Relations d'Evans–Polanyi

Réaction	$\Delta E^{\neq} = \alpha \Delta E_0^0 + \beta$(kcal/mol)	r
AH + H	$\Delta E^{\neq} = 0{,}596\ \Delta E_0^0 + 12{,}512$	0,990
AH + CH_3	$\Delta E^{\neq} = 0{,}609\ \Delta E_0^0 + 15{,}301$	0,994
AH + NH_2	$\Delta E^{\neq} = 0{,}632\ \Delta E_0^0 + 15{,}605$	0,967
AH + OH	$\Delta E^{\neq} = 0{,}705\ \Delta E_0^0 + 18{,}618$	0,990
AH + F	$\Delta E^{\neq} = 0{,}616\ \Delta E_0^0 + 21{,}017$	0,968

Les barrières d'activation peuvent encore s'exprimer en fonction de D_1 et D_2, selon la relation:

$$[26] \quad \Delta E^{\neq} = \left(\frac{1+a}{2}\right) D_1 - \left(\frac{1-b}{2}\right) D_2$$

Les formes explicites des équations [23] et [26] sont données dans le tableau 10 pour les différentes classes de réactions considérées.

Comme le montrent les relations [24] et [25], les constantes a et b et, dès lors, α et β dépendent de la structure des complexes activés ($r_1^{\neq}$, $r_2^{\neq}$) et des paramètres des courbes de Morse. En principe, seul un calcul théorique permet de déterminer $r_1^{\neq}$ et $r_2^{\neq}$. Cependant, nous avons constaté qu'en adoptant pour $r_1^{\neq}$ ($r_2^{\neq}$) les valeurs trouvées dans les complexes activés symétriques, on pouvait obtenir des barrières d'activation très correctes grâce à la formule [19]. Il est, par ailleurs, intéressant de noter que ces valeurs "standards" de $r_1^{\neq}$ ($r_2^{\neq}$) sont systématiquement égales à 80% du "rayon" de l'atome lié à l'hydrogène transféré.

Les données nécessaires pour effectuer ces calculs ainsi que les résultats obtenus sont respectivement rassemblés dans les tableaux 11 et 12.

On peut dès lors imaginer une démarche très simple pour estimer la barrière d'activation d'une réaction d'abstraction d'hydrogène. Nous l'illustrons par un exemple. Soit à calculer $\Delta E^{\neq}$ pour le processus:

$$H - H + Cl \rightarrow H + HCl$$

Posant:

$$[27] \quad r^{\neq}(H \cdots H) = 0{,}936\ Å$$

et

$$[28] \quad r^{\neq}(H \cdots Cl) = 0{,}80\ r(Cl) = 1{,}416\ Å$$

et utilisant la courbe de Morse (49):

$$[29] \quad u(HCl) = 106{,}515\ [1 - e^{-1{,}868(r_2 - 1{,}275)}]^2$$

on trouve aisément, en utilisant la relation [19]

$$[30] \quad \Delta E_1^{\neq} = 109{,}405 - \frac{1}{2}[109{,}405 - 10{,}83 + 106{,}515 - 5{,}711]$$

TABLEAU 11. Valeurs standards de $r_i^{\neq}$ et $u_i(r_i^{\neq})$

Atome (A)	r(Å) (52)	$r^{\neq}$(A···H) (Å)	$u(r^{\neq})$ (kcal/mol)
H	1,17	0,936	10,83
C	1,70	1,357	15,84
N	1,40	1,253	17,05
O	1,47	1,175	17,24
F	1,41	1,126	19,41

soit encore:

$$[31] \quad \Delta E_1^{\neq} = 9{,}72\ \text{kcal/mol}$$

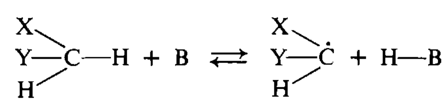
Un calcul semblable fournit la barrière d'activation du processus inverse:

$$[32] \quad \Delta E_2^{\neq} = 6{,}83\ \text{kcal/mol}$$

Les énergies d'activation expérimentales à 300 K, soit respectivement $E_a^1 = 4{,}5$ à 5,3 et $E_a^2 = 3{,}2$ kcal/mol (45), ne sont pas directement comparables à nos résultats mais elles se classent dans le même ordre.

Au total, les barrières d'activation des réactions d'abstraction d'hydrogène se rationalisent bien à partir des propriétés des espèces isolées et des atomes directement impliqués dans le processus.

Enfin, la relation [26] permet d'étudier l'influence des substituants sur ces barrières d'activation. Considérons, par exemple, les réactions d'arrachement d'hydrogène de méthanes disubstitués:



Comme l'un de nous l'a montré par ailleurs (53), D_1 dépend de la nature des substituants X et Y comme indiqué ci-dessous (c≡capteur; d≡donneur):

X	Y	BDE(C—H) = D_1
d	d	Très élevé
c	c	Très petit
c	d	Relativement petit

Dès lors, pour un radical abstracteur donné, la barrière d'activation de la réaction précédente sera plus importante pour les composés ddCH_2 que pour les espèces cdCH_2 et, a fortiori, ccCH_2.

Conclusion

Les résultats énergétiques obtenus dans ce travail au niveau 6-31G – SCF-CI fournissent des paramètres thermodyna-

TABLEAU 10. Expressions des barrières d'activation (kcal/mol)

Réaction	Equation [23]	Equation [26]
AH + H	$\Delta E^{\neq} = 0{,}596\ \Delta E_0^0 + 0{,}114\ D_2$	$\Delta E^{\neq} = 0{,}596\ D_1 - 0{,}482\ D_2$
AH + CH_3	$\Delta E^{\neq} = 0{,}609\ \Delta E_0^0 + 0{,}136\ D_2$	$\Delta E^{\neq} = 0{,}609\ D_1 - 0{,}473\ D_2$
AH + NH_2	$\Delta E^{\neq} = 0{,}632\ \Delta E_0^0 + 0{,}140\ D_2$	$\Delta E^{\neq} = 0{,}632\ D_1 - 0{,}492\ D_2$
AH + OH	$\Delta E^{\neq} = 0{,}705\ \Delta E_0^0 + 0{,}148\ D_2$	$\Delta E^{\neq} = 0{,}705\ D_1 - 0{,}557\ D_2$
AH + F	$\Delta E^{\neq} = 0{,}616\ \Delta E_0^0 + 0{,}150\ D_2$	$\Delta E^{\neq} = 0{,}616\ D_1 - 0{,}466\ D_2$

miques et cinétiques peu réalistes pour les réactions d'abstraction d'hydrogène, dans le cadre de la théorie de l'état de transition avec correction d'effet tunnel. On peut pallier cette difficulté en utilisant des barrières d'activation semiempiriques dont la forme découle d'une expression intuitive de la somme des énergies de liaison $E(A \cdots H) + E(B \cdots H)$, à l'état de transition.

Les résultats obtenus avec ces nouvelles barrières sont en bon accord avec les données expérimentales correspondantes. Ils mettent en évidence le comportement "non-Arrhénius" des réactions d'abstraction d'hydrogène considérées. En outre, ils permettent de tester la cohérence des résultats expérimentaux, d'analyser de façon critique la relation d'Evans−Polanyi et de préciser la signification des paramètres qu'elle renferme.

Des barrières d'activation très satisfaisantes peuvent aussi s'obtenir à partir de valeurs standards de longueurs de liaison à l'état de transition. Celles-ci se rencontrent dans les complexes activés symétriques. Elles peuvent également se déduire de rayons des sphères atomiques. Des barrières d'activation sont ainsi accessibles sans effectuer de calculs *ab initio*.

Enfin, l'influence de substituants sur la cinétique des réactions d'échange d'hydrogène peut être, en principe, rationalisée grâce aux expressions de barrières d'activation que nous avons déduites.

Au total, ce travail montre que l'utilisation conjointe de résultats théoriques et expérimentaux, dans le cadre d'un modèle approprié, permet non seulement d'interpréter de nombreux faits connus mais aussi d'effectuer certaines prévisions originales.

Received July 27, 1984

This paper is dedicated to Professor Camille Sandorfy on the occasion of his 65th birthday

RODRIGUE SAVOIE, ANDRÉ RODRIGUE, MARIE PIGEON-GOSSELIN, and ROBERT CHÊNEVERT. Can. J. Chem. **63**, 1457 (1985).

The neutral-component complexes $(HCOOH)_3 \cdot (18\text{-crown-}6)_2$, $(CH_3COOH)_2 \cdot 18$-crown-6, and various halogenated CH_3COOH/18-crown-6 adducts have been isolated and studied by infrared and Raman spectroscopy. The halogenated (F, Cl, and Br) derivatives, which occur as $(\text{acid} \cdot \text{water})_x \cdot 18$-crown-6($x = 1$ or 2) adducts, probably have a structure which is similar to that of the known $CH_2(CN)COOH \cdot H_2O \cdot 18$-crown-6 complex.

RODRIGUE SAVOIE, ANDRÉ RODRIGUE, MARIE PIGEON-GOSSELIN et ROBERT CHÊNEVERT. Can. J. Chem. **63**, 1457 (1985).

Les complexes à composantes neutres $(HCOOH)_3 \cdot (18\text{-couronne-}6)_2$, $(CH_3COOH)_2 \cdot 18$-couronne-6, de même que plusieurs autres obtenus à partir de dérivés halogénés de l'acide acétique, ont été isolés et étudiés par spectroscopie infrarouge et Raman. Les complexes halogénés (F, Cl et Br), qui ont une stoechiométrie acide/eau/18-couronne-6 égale à 2:2:1 ou 1:1:1, semblent avoir une structure similaire à celle du composé d'addition connu $CH_2(CN)COOH \cdot H_2O \cdot 18$-couronne-6.

Introduction

The macrocyclic polyether 18-crown-6 (hereafter referred to as 18C6) readily forms complexes with hydrates of very strong acids, which exist as hydronium salts (1–3). In these complexes, the hydronium ion is retained within the ether cavity by electrostatic interactions as well as by hydrogen bonds of the $OH_3^+ \cdots$ ether type, with a resulting noticeable lowering of the crown D_{3d} symmetry. Neutral-component complexes have been reported with hydrates of weaker acids. With nitric acid, the $(HNO_3 \cdot H_2O)_2 \cdot 18C6$ complex was obtained (2), whereas a 1:1:1 stoichiometry was determined in the case of the adduct $CH_2(CN)COOH \cdot H_2O \cdot 18C6$ (4, 5).

In this paper we report the synthesis of a number of new complexes of 18C6, with formic, acetic, and halogenated acetic acids. The infrared and Raman spectra of these adducts have been recorded in an attempt to characterize their structure.

Experimental

The complexes were prepared by the following methods.

Method A

The 18C6 (1.057 g, 4 mmol) and the carboxylic acid (13.3 mmol) are dissolved in a specified volume of diethyl ether. Petroleum ether (30–60°C) is added and the complex crystallizes after lowering the temperature.

Method B

The concentrated acid (0.5 mL) is slowly added to a solution of the crown (528 mg, 2 mmol) in diethyl ether (40 mL). If needed, the temperature of the resulting solution is lowered to allow for the crystallization of the complex.

The complexes were filtered under reduced pressure, washed with petroleum ether (30–60°C), and dried. Their stoichiometry was determined from the integrated intensity of the ^{1}H nmr peaks (in $CDCl_3$, using a Bruker HX-90 instrument), from elemental analysis, or from titration by 0.1 *N* NaOH (complexes with CF_3COOH and CCl_3COOH). The ^{13}C nmr spectra were recorded in $CDCl_3$, on a Bruker WP-80 spectrometer working at 20 MHz. Details pertaining to the individual complexes are given below.

$(HCOOH)_3 \cdot (18C6)_2$

Prepared by method A, using 20 mL diethyl ether and 40 mL petroleum ether. Precipitation starts at room temperature and is further favored by lowering the temperature to 0°C. The solid is dried 30 min under vacuum. This complex can also be prepared by method B. Yield: 96%; mp: 79–80°C; ^{1}H nmr δ: 10.24 (s, 3H, COOH), 8.30 (s, 3H, H—C), 3.69 (s, 48H, 18C6); ^{13}C nmr δ: 164.121 (3C, COOH), 70.463 (24C, 18C6). *Anal.* calcd.: C 48.64, H 8.16; found: C 48.34, H 7.43%.

$(CH_3COOH)_2 \cdot 18C6$

Prepared by method A, using 20 mL diethyl ether and 40 mL petroleum ether. This complex can also be prepared by method B. It decomposes slowly at room temperature. It is dried in air during approximately 1 h and kept in a closed container at low temperature. Yield: 92%; mp: 45–50°C; ^{1}H nmr δ: 10.86 (multiplet, 2H, COOH), 3.70 (s, 24H, 18C6), 2.10 (s, 6H, CH_3); ^{13}C nmr δ: 175.755 (2C, COOH), 70.755 (12C, 18C6), 20.634 (2C, CH_3).

$CF_3COOH \cdot H_2O \cdot 18C6$

Prepared by method A, using 20 and 50 mL, respectively, of diethyl ether and petroleum ether. (The complex can also be obtained by dissolving the acid and 18C6 in 5 mL diethyl ether.) The complex precipitates at −20°C. It is dried under vacuum for a few minutes. This adduct is not stable under vacuum, and it decomposes slowly at atmospheric pressure and room temperature. Yield: 69%; mp: 53–54°C; ^{1}H nmr δ: 8.00 (s, 3H, H_2O and COOH), 3.69 (s, 24H, 18C6); ^{13}C nmr δ: 162.517, 160.513, 158.509, and 156.565 (q, 1C, COOH), 137.192, 122.859, 108.648, 94.376 (q, 1C, CF_3), 70.266 (12C, 18C6). *Anal.* calcd.: C 42.42, H 6.86; found: C 41.85, H 6.13%. Titration of the complex dissolved in H_2O by 0.1 *N* NaOH confirmed the 1:1:1 stoichiometry (within 1.5%). We have had indications that under certain conditions a complex of 2:2:1 stoichiometry can be formed. The crystals then have a globular shape instead of the fine needles characteristic of the 1:1:1 complex.

$(CCl_3COOH \cdot H_2O)_2 \cdot 18C6$

Prepared by method A, using 20 and 40 mL of diethyl ether and petroleum ether, respectively. The crystallization temperature is −20°C (a stoichiometry intermediate between 1:1:1 and 2:2:1 is obtained at lower temperatures). The solid is dried under vacuum for 30 min. Yield: 73%; mp: 72–73°C; ^{1}H nmr δ: 8.10 (s, 6H, H_2O and COOH), 3.71 (s, 24H, 18C6); ^{13}C nmr δ: 163.087 (2C, COOH), 91.316 (2C, CCl_3), 70.097 (12C, 18C6). *Anal.* calcd.: C 30.64, H 4.82; found: C 30.14, H 4.40%. Titration of the complex dissolved in water by 0.1 *N* NaOH indicated 6% acid missing for a 2:2:1 stoichiometry.

$(CHCl_2COOH \cdot H_2O)_2 \cdot 18C6$

Prepared as the complex above. This complex slowly decomposes

[1]Authors to whom correspondence should be addressed.

under vacuum. It is dried in air at room temperature. Yield: 81%; mp: 41.0–41.5°C; ^{1}H nmr δ: 7.37 (s, 6H, H_2O and COOH), 6.00 (s, 2H, $CHCl_2$), 3.70 (s, 24H, 18C6); ^{13}C nmr δ: 166.023 (2C, COOH), 70.097 (12C, 18C6), 65.121 (2C, $CHCl_2$).

$CH_2ClCOOH \cdot H_2O \cdot 18C6$

Prepared by method A, using 20 mL of diethyl ether and 40 mL of petroleum ether. The complex is crystallized at 0°C. (An intermediate stoichiometry, 1:1:1 – 2:2:1, is obtained with this complex, as well as with the one with monobromoacetic acid, when the temperature of crystallization is higher than 0°C.) The solid is dried under vacuum for 30 min. Yield: 57%; mp: 51.5–52°C; ^{1}H nmr δ: 6.70 (s, 3H, H_2O and COOH), 4.10 (s, 2H, CH_2Cl), 3.70 (s, 24H, 18C6); ^{13}C nmr δ: 169.023 (1C, COOH), 70.536 (12C, 18C6), 41.194 (1C, CH_2Cl). *Anal.* calcd.: C 44.62, H 7.76; found: C 44.33, H 7.21%.

$CH_2BrCOOH \cdot H_2O \cdot 18C6$

Prepared as the complex above, using 30 and 10 mL, respectively, of diethyl ether and petroleum ether. Yield: 75%; mp: 65–66°C; ^{1}H nmr δ: 6.70 (s, 3H, H_2O and COOH), 3.87 (s, 2H, CH_2Br), 3.69 (s, 24H, 18C6); ^{13}C nmr δ: 168.877 (1C, COOH), 70.390 (12C, 18C6), 26.707 (1C, CH_2Br). *Anal.* calcd.: C 39.91, H 6.93; found: C 40.37, H 6.40%.

$CH_2(CN)COOH \cdot H_2O \cdot 18C6$

This complex was prepared as described by Elbasyouny *et al.* (4).

Vibrational spectra

The infrared spectra, obtained from Nujol and hexachlorobutadiene mulls pressed between Irtran-4 (ZnSe) or silver chloride windows, were recorded on a Beckman IR 4250 spectrophotometer. The Raman spectra were obtained from the solids contained in sealed glass capillary cells. For the low temperature measurements, the glass cell was placed inside a cavity in the copper tail section of a liquid nitrogen cryostat. The spectra were recorded on a microcomputer-controlled Spex Model 1400 spectrometer (6), using the 514.5-nm exciting line from a Spectra Physics Model 165 argon ion laser. The spectra were usually obtained at 300 mW laser power at the sample, 2 cm^{-1} spectral slit width, an integration time of 2 s, and a frequency increment of 2 cm^{-1} at room temperature (1 cm^{-1} at liquid nitrogen temperature).

Results and discussion

Except for the ν(C=O) and ν(CH_2) regions, at 1750 and 2900 cm^{-1} respectively, the high-frequency region of the infrared spectra of the complexes described here mostly contains bands due to O—H vibrations. As can be seen in Fig. 1, a number of weaker peaks, attributable to overtones and combination modes, are also present in the spectra. The O—H vibrations are also seen in the Raman spectra, but they are comparatively very weak. At frequencies lower than 1500 cm^{-1} (see, for example, Fig. 2), both the infrared and Raman spectra mostly reveal the vibrational bands of the crown ether, although some of the bands of the acid can also be indentified in both types of spectra.

Both the frequencies and spectral activity of the crown ether bands in the infrared and Raman spectra of the complexes are comparable to those found in various complexes (7) in which the 18C6 crown is known to have a highly regular D_{3d} symmetry. It is therefore concluded that the crown essentially retains this high symmetry in the complexes involving carboxylic acids. This contrasts with the situation found in complexes involving the hydronium ion, such as with very strong acids, where distortion of the crown occurs, causing a splitting of many of the vibrational bands of the ether (1–3). This type of splitting, which is particularly evident in the 850 and 950 cm^{-1} regions of the infrared spectrum, does not occur in the spectra of the complexes reported here. The structures of the acid·18C6 and acid·water·18C6 basic units found in those complexes are discussed separately below.

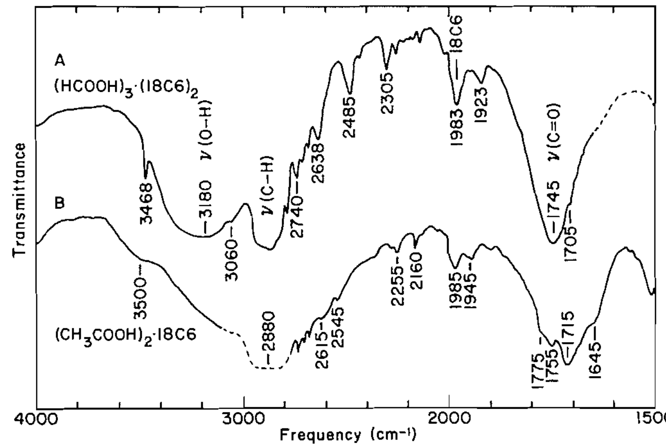

FIG. 1. Infrared spectra of (A) $(HCOOH)_3 \cdot (18C6)_2$ and (B) $(CH_3COOH)_2 \cdot 18C6$ in Nujol or hexachlorobutadiene mulls. The dotted sections refer to the spectrum in the complementary mulling agent.

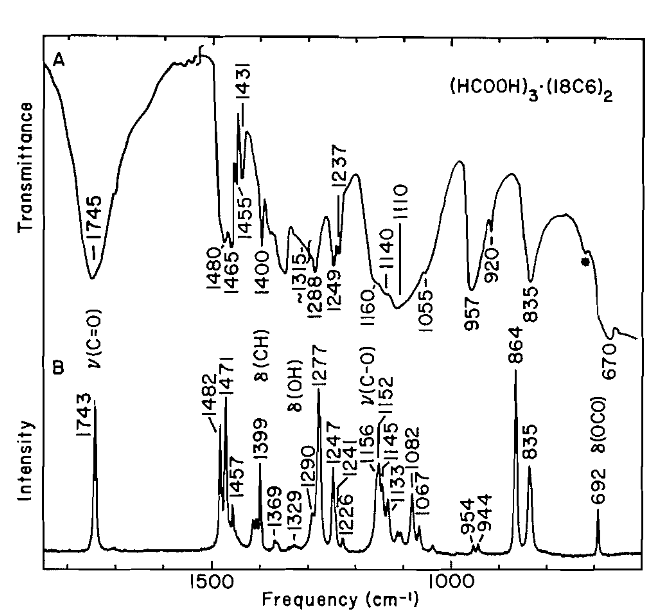

FIG. 2. (A) Infrared and (B) Raman spectra of the $(HCOOH)_3 \cdot (18C6)_2$ in the 600–1850 cm^{-1} region. The infrared spectrum was obtained in Nujol, except for the 1300–1520 cm^{-1} region (C_4Cl_6).

$(HCOOH)_3 \cdot (18C6)_2$

This complex is particularly stable as compared to the other adducts involving carboxylic acids, and it is much more resistant to decomposition under vacuum. This stability is reflected in its melting point (79–80°C), which is higher than those of the other adducts in the same series.

The high-frequency region of the infrared spectrum of the complex (Fig. 1) clearly indicates that the acidic proton of HCOOH is rather weakly hydrogen bonded (ν(O—H) = 3180 cm^{-1}). The spectrum is very similar to that of the acid associated with acetonitrile in CCl_4 solution (ν(O—H) = 3200 cm^{-1}) (8), and it also contains many of the weaker bands due to overtones and combination modes present in the latter. The fundamentals are identified in the Raman and infrared spectra (700–1800 cm^{-1} region) reproduced in Fig. 2.

Among the various structures which can be considered for the complex, many can be eliminated from characteristic features in the vibrational spectra. For example, the possibility of having hydrogen-bonded molecular chains of HCOOH, similar to those in the pure solid (9), intercalated between 18C6 molecules in the complex is not borne out by experiment, as in such a case one should get a ν(O—H) absorption band in the 2500–2800 cm^{-1} region (10, 11). Similarly, the presence of cyclic dimers is not consistent with the spectroscopic results. Normal coordinate analyses (12, 13) have shown that intermolecular vibrational coupling in such dimers causes an appreciable splitting of the vibrational energy levels, the infrared and Raman active modes having sometimes widely different frequencies. The ν(C═O) mode is particularly characteristic on that account, as it shows a splitting of more than 60 cm^{-1}. In the present case, both the infrared and Raman components have essentially identical frequencies (1745 cm^{-1}).

One of the most striking features in the Raman spectrum of the $(HCOOH)_3\cdot(18C6)_2$ complex in the crystalline state is the sharpness of the bands of the acid and the lack of noticeable splitting of these bands. With the exception of the weak doublet at 1329/1335 cm^{-1} (1335/1341 cm^{-1} at −189°C), which is tentatively assigned to the δ (C—O—H) mode, all the other HCOOH peaks occur as singlets, whose width at half-intensity is less than 4 cm^{-1} at −189°C (for a 2 cm^{-1} spectral slit width). This suggests that (*i*) the HCOOH molecules interact only weakly with each other in the complex, and (*ii*) that the three acid molecules in each basic unit are symmetrically equivalent.

The model proposed in Fig. 3 is consistent with the above interpretation and the 3:2 stoichiometry of the complex. In this model, three HCOOH molecules related by a threefold symmetry axis are linked to alternate oxygen atoms of the crown by hydrogen bonds, with an O···O distance estimated at 2.73 Å from the observed ν(O—H) frequency (14). The CH tail section of each acid molecule is assumed to interact weakly with the oxygen atoms of a second 18C6 molecule. The HCOOH molecules in this structure are equivalent in the sense that each is linked to two different 18C6 molecules in the same manner. They are not strongly bonded to each other, so that they are not expected to give rise to any appreciable intermolecular vibrational coupling. Obviously, variants of this simple model could also be considered, and disorder could be introduced by interchanging the relative orientation of some of the acid molecules. However, the sharpness of the Raman lines is not indicative of such disorder, even though the ν(O—H) band in the infrared spectrum appears to be abnormally broad, given its relatively high frequency.

$(CH_3COOH)_2\cdot 18C6$

This complex (mp: 45–50°C) is not nearly as stable as the 3:2 adduct obtained with formic acid. It decomposes rapidly under normal conditions and it has to be kept in an inert atmosphere and at low temperature. Some of the secondary features in the infrared spectrum (Fig. 1) suggest the presence in the sample of a small amount of H_2O (~3500 and 1645 cm^{-1}) and possibly of unbound acid (1775 cm^{-1}). Otherwise, the spectrum is characterized by a broad ν(O—H) band centered at ~2880 cm^{-1}, a frequency which is comparable to that in crystalline CH_3COOH (14, 15) but significantly lower than the average calculated for the $(CH_3COOH)_2$ dimer (~3100 cm^{-1}) (12). On the other hand, the strong ν(C═O) band with maximum at 1715 cm^{-1} has a frequency which is much higher than in the crystalline acid (1657 cm^{-1}) (15). These observations indicate that the C═O group of each acid molecule in the complex is not an acceptor of a strong hydrogen bond and, consequently, that the OH groups are bonded to the oxygen

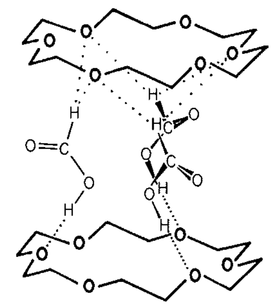

FIG. 3. Structural model for the $(HCOOH)_3\cdot(18C6)_2$ complex.

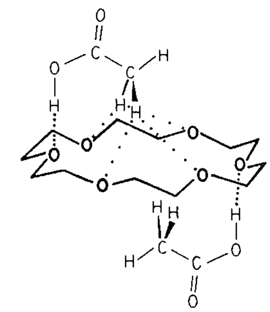

FIG. 4. Structural model for the $(CH_3COOH)_2\cdot 18C6$ complex.

atoms of the crown ether.

Two different types of structure are consistent with the above deductions. One can first consider a structure somewhat similar to that proposed for the HCOOH complex, in which stacked 18C6 molecules are linked to each other by two molecules of CH_3COOH. These acid molecules (disposed in a parallel or antiparallel manner) would be linked to one of the 18C6 units through an O—H···O bond, with O···O distance of ~2.65 Å (14), and to the other unit by weak CH_3···O interactions. In the second model, the two ends of each CH_3COOH molecule are linked to the same crown molecule, as illustrated in Fig. 4. This second model is perhaps to be favored, as this complex differs from that with formic acid in that it contains stronger XOH···O bonds, which suggests that the two compounds have different basic structures. Furthermore, it is generally observed that in 1:2 host/guests complexes of this type the guest molecules approach the crown ring from both sides of the plane (16). Whatever the model chosen, it is not surprising that this complex is much less stable than the corresponding 3:2 adduct with HCOOH: it contains proportionally fewer acid linkers in the 18C6 supporting matrix, and the CH···O interactions are certainly weaker with CH_3COOH than with HCOOH, due to the lower relative acidity of the methyl substituent.

Substituted $CH_3COOH/H_2O/18C6$

Spectroscopic data are available in the literature for the substituted acetic acids involved in the complexes reported here: CF_3COOH (17–19), CCl_3COOH (20, 21), $CHCl_2COOH$ (21, 22), $CH_2ClCOOH$ (20, 23), $CH_2BrCOOH$ (24), and $CH_2(CN)COOH$ (25). Two different types of complexes are formed with these acids and 18C6. In general, they have an acid/water/18C6 stoichiometry of 1:1:1, such as with CF_3COOH, $CH_2ClCOOH$, $CH_2BrCOOH$, and $CH_2(CN)COOH$, but the complexes with the trichloro and dichloroacetic acids were obtained as 2:2:1 adducts. The high-frequency regions of the infrared spectra of these complexes are

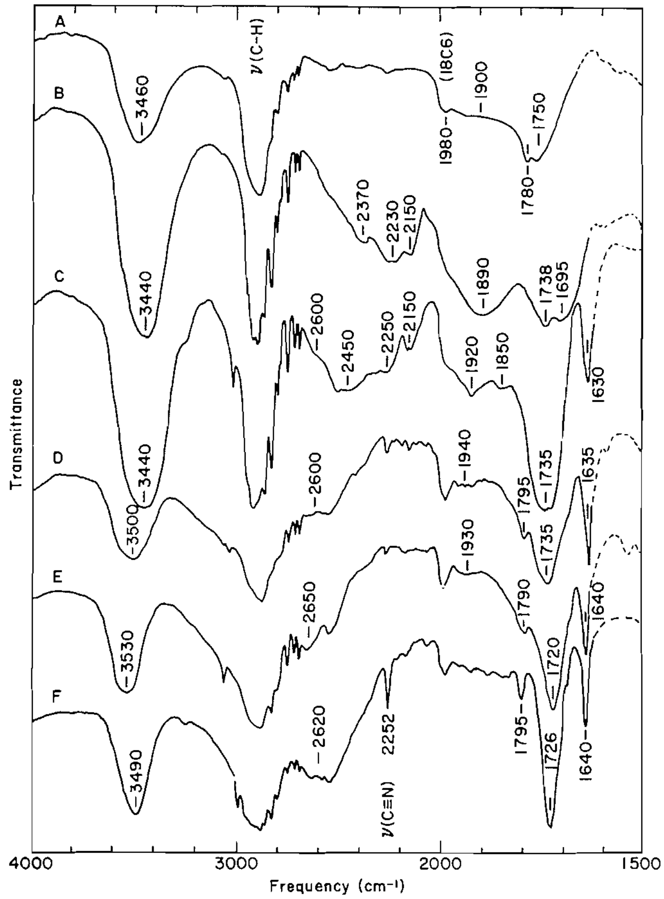

FIG. 5. Infrared spectra of (A) $CF_3COOH \cdot H_2O \cdot 18C6$, (B) $(CCl_3COOH \cdot H_2O)_2 \cdot 18C6$, (C) $(CHCl_2COOH \cdot H_2O)_2 \cdot 18C6$, (D) $CH_2ClCOOH \cdot H_2O \cdot 18C6$, (E) $CH_2BrCOOH \cdot H_2O \cdot 18C6$, and (F) $CH_2(CN)COOH \cdot H_2O \cdot 18C6$ in hexachlorobutadiene (—) or Nujol (- - -).

reproduced in Fig. 5. The synthesis of the complex with $CH_2(CN)COOH$, whose spectrum is also included in the figure, has been reported earlier (4) and its crystal structure has been determined by X-ray crystallography (5). As shown schematically in Fig. 6, the H_2O molecule in this adduct acts as a linker between the acid and 18C6 molecules. Each H_2O molecule interacts weakly with two oxygen atoms of a crown (O···O distance ≃ 2.92 Å), and it acts as a strong hydrogen bond acceptor from the acid (O···O distance of 2.6 Å). The CH_2 group of the acid also interacts weakly with oxygen atoms from the next 18C6 unit.

The likeness of the spectra in Fig. 5 strongly suggests that all of the complexes in this series have similar structures. It can be assumed that the 2:2:1 adducts differ from the 1:1:1 complexes only in that they contain one water·acid unit on both sides of a crown, instead of only on one side as in the latter. Therefore, the structures of the 2:2:1 complexes obtained here are probably similar to those of diaquo complexes of 18C6, such as those with 3-nitrophenol and *p*-nitrobenzaldehyde oxime (16). The similarity of structure between the 1:1:1 and 2:2:1 complexes obtained with the halogenated acetic acids probably explains why adducts of intermediate composition are commonly obtained with these compounds when they are recrystallized at an improper temperature (e.g. below −20°C or above 0°C).

The spectra in Fig. 5 are best interpreted by comparison with

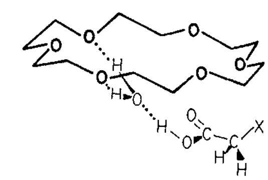

FIG. 6. Basic structure of the $CH_2(CN)COOH \cdot H_2O \cdot 18C6$ complex.

that of the $CH_2(CN)COOH$ complex, whose molecular and crystal structures are known (5). In this complex, the very weak bonding of the water molecules to the crown leads to a relatively high frequency of the stretching fundamentals of water, which occur in the 3440–3530 cm^{-1} range for all the complexes. These values are consistent with the 2.9 Å O···O distances of the OH_2···crown hydrogen bonds determined by X-ray diffraction (5). Note that this frequency in the 2:2:1 complexes is slightly lower than in the 1:1:1 adducts, but this could be fortuitous as the difference is quite small. The ν(OH) band of H_2O is also present in the Raman spectra. In the $CH_2(CN)COOH$ complex, the maximum is found at 3460 cm^{-1}, with shoulder at ~3500 cm^{-1} where the maximum of the infrared band occurs. At liquid nitrogen temperature, the two Raman peaks (width at half-intensity ≃ 12 cm^{-1}) are well separated at 3438 and 3475 cm^{-1}. These two peaks most likely belong to the ν_1 and ν_3 vibrations of H_2O, as their separation (37 cm^{-1}) is close to that expected from the established relation between ($\nu_1 - \nu_3$) and the average ν_{OH} frequency (47 cm^{-1}) (26). This interpretation is also supported from the fact that the corresponding ν_{OH} vibration from HOD species gives a single peak at an intermediate frequency in the spectra of partly deuterated samples.

In most spectra, the bending mode of water $\delta(OH_2)$ gives a very sharp peak at 1635 cm^{-1}, on the low-frequency side of the strong ν(C=O) band. The absence of such a peak from the spectra of the complexes with CF_3COOH and CCl_3COOH will be discussed below. In the case of the complex with $CHCl_2COOH$, the frequency of this band is comparable to that of the $\nu_{as}(CO_2^-)$ mode of the corresponding carboxylate ion ($CHCl_2COO^-$) (27), which could be taken as an indication of the presence of this anion in the sample. However, such an hypothesis does not hold, as the $\nu_{as}(CO_2^-)$ frequency differs appreciably from 1635 cm^{-1} for the other acids (e.g. 1596 cm^{-1} for CH_2BrCOO^-) (27). It should be noted that the occurrence of a very sharp peak for the ν_2 vibration of water is not uncommon. For example, it has been observed in various crystalline hydrates, such as $NaClO_4 \cdot H_2O$ (28), in which the O···O distance between the weakly bound water molecules and ClO_4^- ions is ~2.96 Å long. In this case the ν_2 mode of water gives a sharp singlet at 1628 cm^{-1} in the infrared spectrum.

The 2620 cm^{-1} ν(OH) frequency of the acid in $CH_2(CN)COOH \cdot H_2O \cdot 18C6$ (Fig. 5-F) reflects the short XOH···OH_2 hydrogen bond linking this molecule to water (O···O = 2.6 Å) in the complex. Approximately the same frequency is observed in the adducts with the monochloro and monobromoacetic acids. These three complexes probably have isomorphous crystal structures, with very similar lattice parameters. The strength of the XOH···OH_2 bond increases with acid strength, and the ν(OH) frequency of the acid decreases appreciably, to 2450 and 2230 cm^{-1}, in the complexes with dichloro and trichloroacetic acid, respectively. The infrared spectra of these adducts are characteristic of strongly hydrogen-bonded systems, and they are very similar to those of complexes of these same acids with strong hydrogen bond acceptors, such as trioctylphosphine oxide (20, 22). The subbands associated with the main transition appear to be similar to those observed in the spectra of HCl–ether systems, where they were interpreted as sum and difference bands arising from combinations of the acid stretching vibration with the hydrogen bond stretching motion (29, 30).

Another characteristic feature linked to the increase in hydrogen bond strength in the complexes studied is the increased intensity of the band in the 1900 cm^{-1} region, which is normally attributed to the overtone of the (out-of-plane) γ(OH) mode. Part of the intensity increase is probably caused by electrical anharmonicity (31), but Fermi resonance with ν(OH) is also involved (20, 22). This latter effect is evident in Fig. 5, where it is seen that the 1900 cm^{-1} band decreases in frequency with increased hydrogen bond strength, whereas the frequency of the γ(OH) mode itself is expected to increase slightly under the same conditions (14). Note that the ν(OH) band, at ~2230 cm^{-1} in the CCl_3COOH complex, is displaced to higher frequency on account of this resonance interaction. Were it not for this effect, it would probably occur near 2150 cm^{-1}, a value which normally reflects an O···O distance of ~2.55 Å and a very strong hydrogen bond of energy ~11 kcal/mol (14, 32).

The spectrum of the CF_3COOH complex (Fig. 5-A) is unique among the series shown, as it apparently contains no band attributable to the ν(OH) mode of the acid. However, if one correlates the strength of the acids contained in the complexes (pK_a = 2.85 ($CH_2ClCOOH$), 1.00 (CCl_3COOH), and −0.25 (CF_3COOH)) (21) with the observed ν(OH) frequency in the spectra, extrapolation to the CF_3COOH complex suggests a ν(OH) frequency of less than 2000 cm^{-1}. Therefore, it is likely that both the ν(OH) frequency an the 2 γ(OH) overtone overlap at ~1900 cm^{-1} in the spectrum of this complex.

The low frequency of the ν(OH) mode in the CF_3COOH and CCl_3COOH complexes is probably responsible for the disappearance of the ν_2 band of water near 1640 cm^{-1} in the infrared spectra of these compounds. As the ν(OH) frequency gets close to that of the $\delta(OH_2)$ vibration of water, coupling is likely to occur between these two vibrations. An in-phase induced stretching of the acid O—H group by the $\delta(OH_2)$ motion of water could give rise to a dipole change opposed to that caused by the latter vibration, with very small resulting value of the dipole derivative associated with the overall motion, and consequent reduction of the intensity of the $\delta(OH_2)$ infrared band. It is also possible that the coupling of the acid ν(OH) mode with the $\delta(OH_2)$ vibration of water could give rise to a splitting of the $\delta(OH_2)$ mode, the two components having appreciably different frequencies and infrared intensities, as they involve inphase and out-of-phase motions, with corresponding addition and subtraction of the dipole changes associated with each individual mode. In the CCl_3COOH complex, the two modes could occur at 1695 cm^{-1} (strong) and 1605 cm^{-1} (very weak). The 1738 cm^{-1} band in the spectrum is attributed to the ν(C=O) mode in view of the 1742 cm^{-1} frequency of this vibration of the free acid in the liquid state (21). In the CF_3COOH complex, the two $\delta(OH_2)$ modes would be further apart, and the high-frequency component could overlap the ν(C=O) mode in the 1750 cm^{-1} region, whereas its low-frequency counterpart could be responsible for the weak and broad band centered at 1613 cm^{-1} in the Raman spectrum. Whatever the exact mechanism responsible for the disappearance of the $\delta(OH_2)$ band of water in the infrared spectra of the CF_3COOH and CCl_3COOH complexes, the very low frequency of the acid ν(OH) vibration suggests that the XOH···OH_2 bond is very short, with the acidic proton located near the center of the O···O bond, in an asymmetric potential well.

Although the various adducts involving substituted acetic acids were not systematically studied at low temperature, the $CH_2(CN)COOH$ complex was investigated by Raman spectroscopy at temperatures down to −185°C. Splitting of the vibrational bands of the acid by ~5 cm^{-1} was found to occur at low temperature, an effect which is not observed at room temperature. It is unlikely that this splitting results from intermolecular vibrational coupling, as the molecules of the acid are well isolated from each other in the solid. More likely, the observed splitting is caused by the presence of two crystallographically nonequivalent acid molecules in the primitive cell of the crystal. This interpretation is also suggested from the fact that the two components of the observed doublets have nearly equal intensities in all cases.

Other complexes

The stoichiometric complexes isolated as solids using the substituted acetic acids all contained water, with a ratio of one water per acid molecule. Attempts to isolate water-free complexes with these acids failed. However, we have had indications that adducts with approximate 2:1 and 6:1 acid/18C6 stoichiometry are formed by direct mixing of the acid and crown ether in rigorously anhydrous solvents such as dichloromethane and diethyl ether, although it was not possible to crystallize the oily material resulting from such mixtures. Of particular interest was the 6:1 complex with CF_3COOH, obtained using an excess of acid in the preparation procedure. After evaporation of the solvent and excess acid, this complex proved to be very stable, showing a loss of acid of ~5% only after 3 h at 1 Torr pressure (1 Torr = 133.3 Pa). Presumably, in such a 6:1 adduct there is one acid molecule hydrogen bonded to each of the oxygen atoms of the cyclic ether, giving a complex with three acid molecules on each face of the crown. The 2:1 corresponding binary adduct would have a structure similar to that of the $(CH_3COOH)_2$·18C6 complex, with one acid molecule bonded on each side of the crown. The infrared and Raman spectra of these ill-defined complexes are consistent with this type of bonding, as the acid ν(OH) region is quite similar for the 2:1 and 6:1 adducts, showing generally two main peaks at ~2700 and 2550 cm^{-1}, irrespective of the acid involved.

The way in which the complexes studied are formed, be it by direct hydrogen bonding of the acid COOH group to an oxygen of the crown or by the use of a water molecule as a linker between the acid and the ether, is quite straightforward. Although our study has been limited to a few small carboxylic acids, it is likely that larger acids of this type could also form stoichiometric adducts with 18C6. As is generally observed in neutral-component complexes containing one hydrogen bond donor only, these adducts are expected to be of the aquo type, similar to those obtained with the halogenated acetic acids.

The absorbance and fluorescence spectra of Hematoporphyrin IX, Photofrin, and Photofrin II are measured as a function of pH, concentration, and temperature, in order to isolate the ionic equilibria from the monomer/dimer/aggregate equilibria. Based on photometric and volumetric titrations, the distribution diagram for four ionic species is presented, with pK_a values of 2.7, 5.2, and 9.1. Protonation sites for these pK_a's are assigned.

Les spectres d'absorption et de fluorescence de l'Hématoporphyrine IX, du Photofrin et Photofrin II ont été mesurés en fonction du pH, de la concentration et de la température, dans le but d'isoler les équilibres ioniques des équilibres monomères/dimères/aggrégats. A partir des titrages photométriques et volumiques, les courbes de distribution contenant quatre espèces ioniques sont présentées, avec des pK_a de 2,7, 5,2 et 9,1. Les sites de protonation pour ces pK_a sont discutés.

Introduction

Hematoporphyrin derivatives (Hpd) are a complex mixture of porphyrins that are used for photochemotherapy of cancer. This technique is based on two properties that are at present only partially understood. The first is that of selective biodistribution, whereby most types of malignant tissue preferentially retain one or more of the components of Hpd. The second is that of photosensitization, sometimes referred to by photobiologists as photodynamic action, which is believed to occur via the type II mechanism involving singlet oxygen. The photophysics, photochemistry, and phototherapy of Hematoporphyrin and Hpd have recently been reviewed by Kessel (1). More comprehensive background can be obtained in refs. 2, 3, and 4.

A fuller understanding of the selective biodistribution mechanism has been hampered mainly by two complications. First, most investigations have been carried out on solutions of Hpd in which the true composition of these solutions was unknown. The information obtained could only be termed semiquantitative at best. Second, two basic sets of equilibria are simultaneously involved in porphyrin derivatives: the ionic equilibria, dependent on pH, and the monomer/dimer/aggregate equilibria for each ionic species present. Because each set of equilibria is interlinked, a variation in pH will not only affect the ionic species present, but will also affect the proportion of monomers, dimers, and aggregates of each ionic species present. Results obtained at different pH's thus become very difficult to compare. Buffering the solutions to fix the pH has its drawbacks also, since the buffer tends to modify the results, as has been observed in the singlet oxygen production in thiazine photosensitization studies (5). If one adds to this the fact that tumor cells have a lower pH than normal cells, it clearly becomes apparent that knowledge of the ionic distribution diagrams, along with quantitative information on any dimerization/aggregation process, becomes a prerequisite to any detailed understanding of the operative mechanism of selective biodistribution of Hpd in cells.

In an attempt to shed some light on this problem, we have undertaken a spectroscopic study of commercially available preparations of Hpd, known as Photofrins.

Experimental

Chemicals and solutions

Photofrin (PF) and Photofrin II (PFII) were obtained from Photofrin Medical Inc., Cheektowaga, N.Y. Hematoporphyrin IX dihydrochloride (HP) was obtained from Porphyrin Products, Logan, UT. All materials were prepared in 0.9% aqueous NaCl solutions. Solutions at different pH's were prepared by two different methods:

(*a*) A measured amount (volume for the Photofrins, mass for Hematoporphyrin IX) was dissolved in a dark volumetric flask, and sufficient saline solvent was added to obtain the required porphyrin concentration. Just prior to making the spectral measurements, the pH was measured and adjusted to the required pH value by adding the required amount of concentrated HCl (for low pH values) or by dipping a wetted sodium hydroxide pellet (for high pH values). This technique introduced a slight error due to dilution by the HCl solution or the NaOH pellet, but this effect was quite small. On the other hand, this method has the advantage that one can adjust the pH just prior to the actual measurement. This is especially important if the composition of the strongly acidic or strongly basic solutions changes with time.

(*b*) A series of solutions, all containing the same Photofrin concentrations, were prepared at different pH's. Any pH could thus be obtained by mixing appropriate solutions of lower and higher pH's. This method has the advantage that the concentration of the Photofrin is held constant, but suffers from the disadvantage that the Photofrin remains in the presence of the hydronium or hydroxide ions longer than in method (*a*). Method (*a*) was preferred for the strongly acidic or strongly basic solutions, in order to reduce the time that the solution was in contact with the acid or base, whereas method (*b*) was preferred for intermediate pH values, since these solutions were relatively stable. All solutions were kept in dark bottles and fresh solutions were prepared daily.

Spectrophotometry

The effect of concentration on absorbance was studied with the use of a Varian DMS-100 double beam ratio recording spectrophotometer. The scanning rate was 100 nm min^{-1} and the time to record one

[1] To whom all correspondence should be addressed.
[2] Cancer Scientist of the Ontario Treatment and Research Foundation.

spectrum was approximately 1.5 min. The path length of matched quartz cells was varied from 0.01 to 100 mm with the concentration of the Porphyrin being varied inversely. Temperature and pH effects were done on a Tracor-Northern 1710 spectrophotometer. This instrument is a single beam system, with a photodiode array containing 1024 photodiodes that allows the full spectrum to be recorded simultaneously. The exposure time of the analyzing light on the solution was typically of the order of 3 s, during which 200 spectra were accumulated. The average (for absorbance) or sum (for fluorescence) was stored in digitalized form on diskettes for future analysis. The grating used for absorbance studied is blazed at 300 nm, and the spectral range studied was from 225 to 525 nm. For emission studied, the spectral range studied was between 500 and 800 nm.

For the temperature measurements, a series of solutions at fixed pH were brought to a fixed temperature in an ice bath or warm water bath, then placed in the instrument sample holder and the spectrum was recorded. The actual temperature of the solution was recorded at the time of spectral measurement. Temperature changes during measurement time (3 s) were negligible.

Quartz cells were used in all measurements, and were cleaned in 3 *M* nitric acid overnight prior to any series of measurements. Before any specific measurement was done, the cells were further washed with methanol, distilled water, and rinsed with the analytical solution.

Titrations

The commercial solutions of PF and PFII had been pre-adjusted to pH 7 (unbuffered). Titrations of these solutions had to be done in two parts; above pH 7 using freshly prepared NaOH solutions, and below pH 7 using standardized HCl. The titrated solutions were then back-titrated, and this procedure was repeated several times using a variety of relative concentrations of the Photofrin solutions and the acid/base solutions. HP was prepared by a standard weighing procedure. A Fisher Accumet digitalized pH meter, Model 810, was used with a combination Ag/AgCl reference electrode (Canadawide Scientific No. 6471-06).

Results and discussion

Absorbance and fluorescence spectra

A parallel study was carried out on HP, PF, and PFII at various conditions of concentration, temperature and pH. Sample data are presented in Fig. 1, showing the absorbance and fluorescence feature of all three solutions at low, neutral, and high pH. By using HP as a reference, with a sharp soret peak at 399.5 nm in acidic solutions and 392.9 nm in both neutral and basic solutions, several salient features of the Photofrins can be pointed out. First and foremost is the presence of a broad band in both PF and PFII, having a λ_{max} near 370 nm in acidic solutions, 365 nm in neutral solutions, and 375 nm in basic solutions. This new band clearly reflects a different type of Hpd. PFII is specified to contain mainly Dihematoporphyrin IX ether. Dougherty has proposed that the structure of this compound consists of isomers of bis-1-[8-(1-hydroxyethyl)deuteroporphyrin-3-yl] ester ether, which he calls DHE, containing two HP rings attached by an ether link (6). In fact, an ether-linked polymer had previously been proposed by Bonnett (7), on the basis of HPLC data. Grossweiner has recently proposed that the 570 nm band is due to a "folded over" dihematoporphyrin, which he refers to as Hpd-A (8). Ward has also recently proposed a small polymeric structure for the main component of the Photofrins (9). On the basis of separation data, he extends the structure proposed by Dougherty to include approximately 20 Porphyrin rings.

The fluorescence spectra of PF and PFII are identical to that of HP, except for an intensity factor. At low pH, two maxima, with near equal intensity, are observed at 595 nm and 654 nm. When the pH is greater than 3.5, the maxima are red shifted to 614 nm and 675 nm, with relative intensities of 2.5 and 1, respectively. The change in relative intensities upon change of pH is probably related to a change in symmetry of the different ionic species responsible for the emission (10).

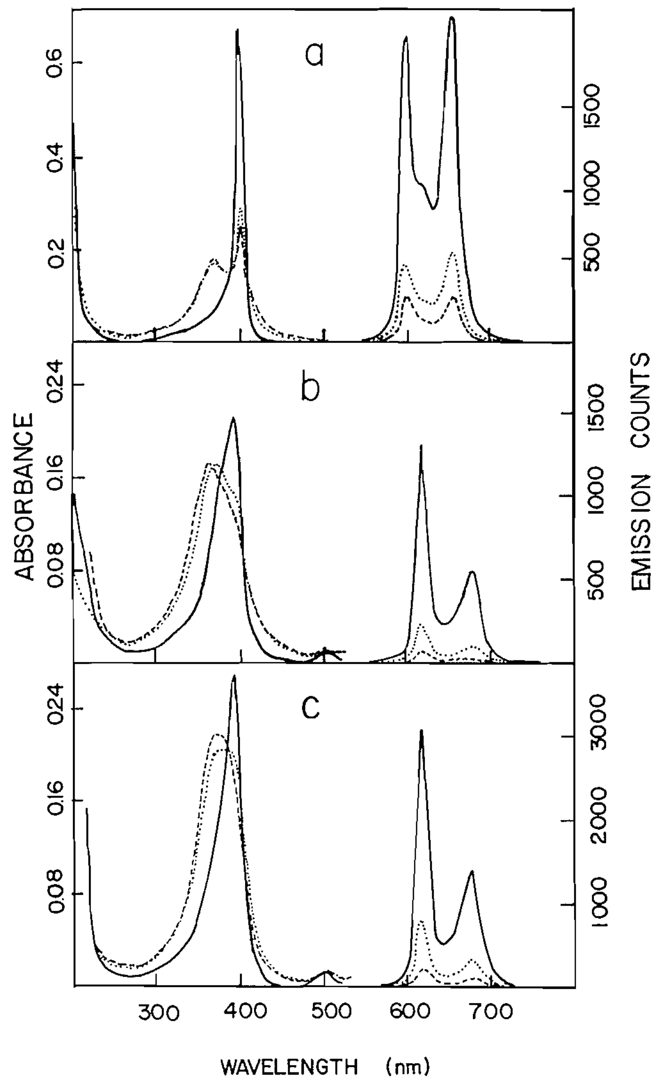

FIG. 1. Absorbance and fluorescence of Hematoporphyrin IX (—), Photofrin (······), and Photofrin II (---). (*a*) pH = 1.1, (*b*) pH = 7.0, (*c*) pH = 11.6. Concentration is 1 μM and path length is 1.00 cm. Temperature is 22°C.

The relative intensity of the entire spectrum of HP:PF:PFII emission is roughly 10:3:1. This ratio observed is for all pH values between 0 and 14. It is important to note that no other fluorescence was observed in PF and PFII. We are thus led to the conclusion that attempts to study the main component of the Photofrins by fluorescence lead to an observation of its HP or similar impurities. This being the case, one can easily estimate the percentage of HP or similar impurities present in PF and PFII as being approximately 30% and 10%, respectively.

The concentration and temperature effects are much more pronounced on HP than on PF or PFII. Sample data comparing the concentration effects on HP and PFII are shown in Fig. 2. Concentration studies on HP have been reported by Karns (11) and Brown (12). Both authors observed a rapid λ_{max} shift as a function of concentration, this drop occurring in the vicinity of 4 μM. They have attributed this effect as being due to aggregation of HP. Our data show that at high pH (11.6) two such

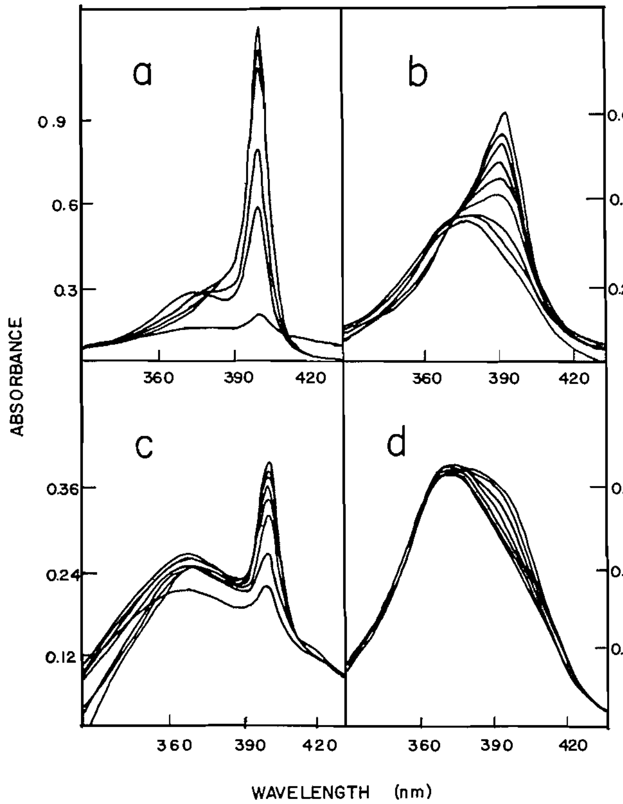

FIG. 2. Concentration effect on Hematoporphyrin IX and Photofrin II. (*a*) HP, pH = 1.9, concentration from 0.04 to 2000 μM; (*b*) HP, pH = 11.6, concentration from 0.04 to 2000 μM; (*c*) PFII, pH = 1.9, concentration from 0.4 to 400 μM; (*d*) PFII, pH = 11.7, concentration from 0.4 to 400 μM.

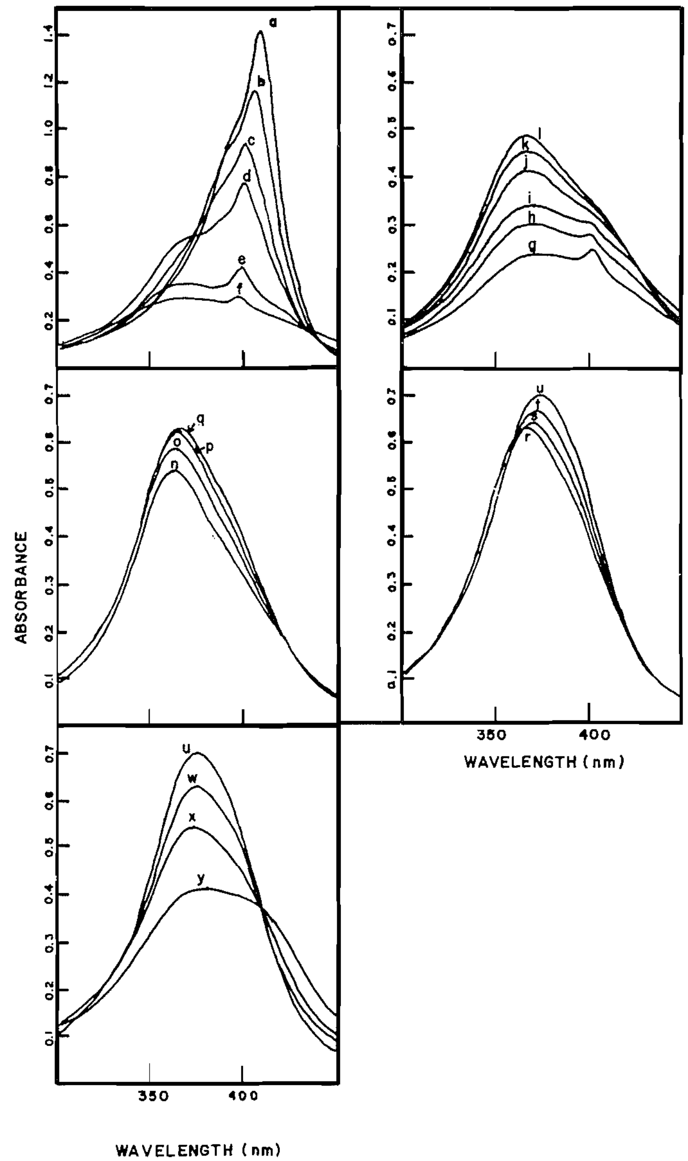

FIG. 3. Absorbance spectra of Photofrin II as a function of pH. Values of pH are *a* to *y* (with the omission of *m* and *v*) respectively: −1, −0.7, 0.2, 0.65, 1.8, 2.38, 2.68, 2.82, 3.17, 3.61, 4.20, 4.80, 5.75, 6.25, 7.25, 8.10, 8.65, 9.31, 10.20, 11.70, 14.0, 14.7, 15.0. Concentration is 4 μM and pathlength is 1.00 cm.

change in spectra occur, one λ_{max} change in the range 2–4 μM, and another in the 15–25 μM concentration range, possibly reflecting the dimerization and aggregation processes, respectively. This would place the λ_{max} values for the monomer, dimer and, aggregates at 392.7 nm, 390.7 nm, and 370.0 nm, respectively, for alkali solutions. PF and PFII, on the other hand, showed much less sensitivity to changes in concentration. The effects observed can be attributed to the HP type impurities. In fact, if one subtracts the contribution of HP from the spectra of PF and PFII, one finds that the remaining spectrum is not effected by a 500-fold increase in concentration (range, 0.4 to 200 μM). This is in agreement with the recent published results of Grossweiner (8), who reported that Beer's law is observed over a 100-fold increase in concentration for purified Hpd-A.

Results obtained by an increase in concentration were also obtained by a decrease in temperature. Spectra observed at 4°C compared well with those at high concentration, and those obtained at 35°C are similar to the ones obtained at low concentrations.

Titrations

Absorbance photometric titrations (pH 0 to 15) were carried out at low concentration (4 μM) in order to keep the interference from dimers or aggregates as low as possible while still retaining sufficient sensitivity on the absorbance measurements. The spectra at the various pH studied are shown in Fig. 3, and have been separated in five subsections to show more clearly the various changes that occur in the spectra as the pH is varied. A plot of the 400 nm absorbance versus pH shows minima at pH 2.5 and 5.5 (see Fig. 4(*a*)). In an attempt to remove the interference from spectral overlap at a fixed wavelength, we used the entire spectrum from 300 to 600 nm (1024 data points) and mixed coefficients of observed spectra at different pH values in order to generate a composite spectrum at another intermediate pH. The distribution diagram thus obtained is presented in Fig. 5(*a*), and represents our best fit. This gives three pK_a values at 2.7, 5.2, and 9.1.

Fluorescence, photometric titrations between pH 1 and 13 were carried out at low concentration (1 μM), and, except for an intensity factor, both HP and PFII gave the same results. See Fig. 4(*b*).

Volumetric titrations on HP, PF, and PFII were carried out and typical results obtained are shown in Fig. 6. All the titration curves have two inflection points. These titrations were repeated several times, using concentrations 5 to 20 μM of Porphyrins, and different concentrations of acid and base ti-

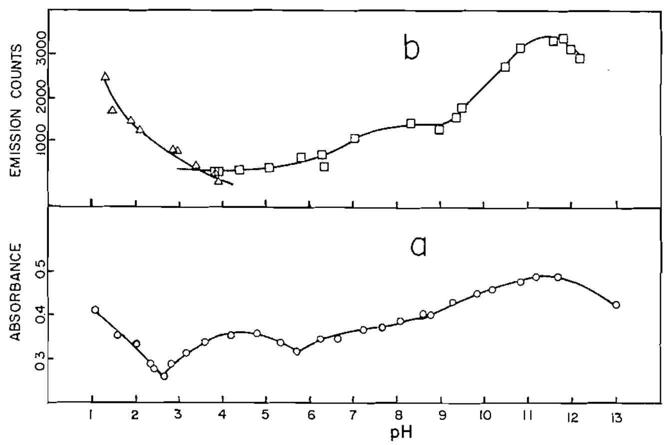

FIG. 4. Effect of pH on Photofrin II. (*a*) Absorbance, λ = 399.0 nm concentration, 4 μM; (*b*) Emission, λ_{ex} = 400 nm, λ_{anal} = 595 nm ($\triangle$) and 616 nm ($\square$). Concentration, 1 μM.

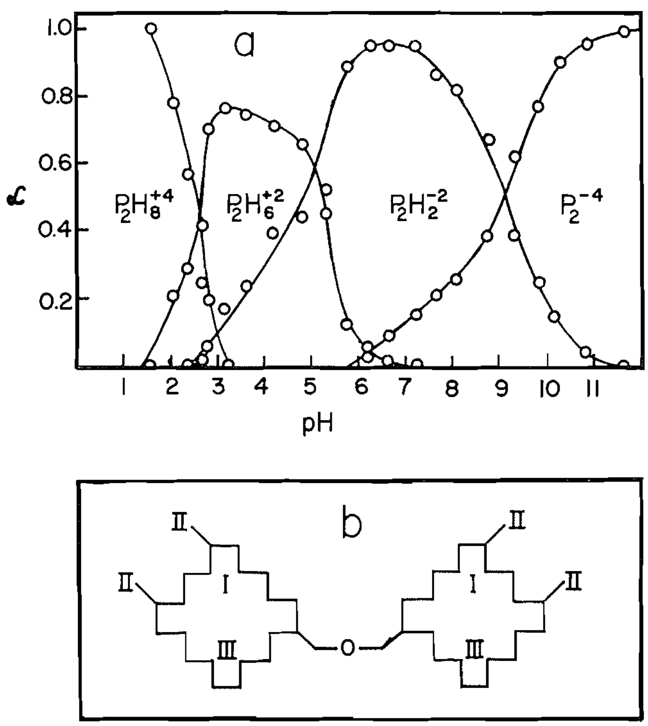

FIG. 5. (*a*) Distribution diagram of Photofrin II, as calculated from the absorbance data. (*b*) Protonation sites on Dihematoporphyrin ether.

trant. As mentioned above, one would expect more aggregate formation at higher concentrations and the first inflection point in the vicinity of pH 5 could possibly be interpreted as being an artifact due to aggregate formations. If this were the case, one would expect a diminution of this inflection point at lower Porphyrin concentrations, but this was not observed. For HP, the analytical mass and the original pH could be measured, and one can calculate the two pK_a's as 3.7 and 6.0. However, the original pH of PF and PFII (prior to being adjusted to pH 7 by manufacturer) is unknown, and one cannot calculate a reliable value for the first pK_a from the volumetric titrations. The second pK_a, located halfway between the two inflection points, gives a pK_a of ~6.

If one adopts the Dihematoporphyrin ether (DHE) as the

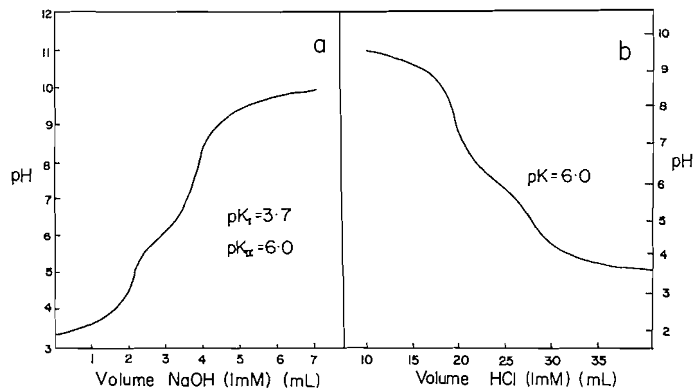

FIG. 6. Volumetric titration curves for Hematoporphyrin IX (*a*) and Photofrin II (*b*).

structure of the main component of the Photofrins (6), then tentative assignments of the protonation sites for PFII at 4 μM concentration can be made. The monomeric ionic equilibria can be represented as:

$$P_2H_8^{4+} \rightleftarrows P_2H_6^{2+} + 2H^+ \qquad pK_a(I) = 2.7$$

$$P_2H_6^{2+} \rightleftarrows P_2H_2^{2-} + 4H^+ \qquad pK_a(II) = 5.2$$

$$P_2H_2^{2-} \rightleftarrows P_2^{4-} + 2H^+ \qquad pK_a(III) = 9.1$$

where $P_2H_8^{4+}$ represents the DHE with four protons on the ring nitrogens and four protons on the carboxylic acid groups. pK_a(I) is believed to involve the protons on the double bonded nitrogen atoms, one proton on each Porphyrin ring. pK_a(II) is assigned to the carboxylic group protons, whereas pK_a(III) is assigned to the removal of the last two protons on the Porphyrin rings. These protonation sites are illustrated in Fig. 5(*b*).

It is interesting to note that the polymeric model proposed by Ward (9), including ~20 Porphyrin rings, can also be fitted to this scheme. Each ring would contain the same number of protons, and all the carboxylic acid groups would also be in the same ratio. One need only rewrite the ionic equilibria, starting with nPH_4^{2+} instead of $P_2H_8^{4+}$, n being the number of Porphyrin rings.

It must be emphasized that, although solutions at 4 μM looked clear, they undoubtedly contain some dimers and possibly aggregates in the pH range 2–5. The asymmetric nature of the distribution diagram (Fig. 5(*a*)) is possibly the result of interference from dimers or aggregates. Thus, Fig. 5(*a*) should be considered with caution, until independent measurements can be made that will distinguish unambiguously between the various monomeric ionic species and their corresponding dimers or aggregates. Moan has recently reported that although both aggregated and non aggregated components of PFII bind to human cells, only the non-aggregated porphyrins contribute significantly to the photosensitivity of the cells (15). Our results lead us to infer that what is sometimes referred to as properties of dimers could be due to a different ionic species in its monomeric form. Keeping in mind the lower pH of cancer cells, such a finding could possibly play a role in the selective biodistribution of Porphyrins in tumors.

Summary and conclusions

The absorbance data can be fitted to three ionic equilibria, involving four monomeric species. The interfering effects of dimers or aggregates, especially in the pH range 2–5, cannot be totally ignored.

Fluorescence emission from the Photofrin solutions is believed to be solely from impurities, and spectral changes in these impurities reflect their various monomeric species. This is to be contrasted with the assignment of two fluorescence decay lifetimes as being due to the monomeric and dimeric species in HP and PFII (13, 14). We present an alternative view whereby the different fluorescence lifetimes could be assigned to different monomeric species, the relative concentration of each species being dependent on the pH.

We have recently initiated a series of laser light scattering on the Photofrins. Until more experiments of this nature are carried out, the question of the ionic species present at various pH's, along with their different states of aggregation, remains a topic of open controversy.

A theoretical investigation of energetics and structures of $CH_5^+(CH_4)_n$ clusters for $n = 1-4$

ETTORE FOIS, ALDO GAMBA, AND MASSIMO SIMONETTA[1]
Dipartimento di Chimica Fisica ed Elettrochimica, Università di Milano, V. Golgi 19-I-20133 Milano, Italy

Received July 27, 1984

This paper is dedicated to Professor Camille Sandorfy on the occasion of his 65th birthday

ETTORE FOIS, ALDO GAMBA, and MASSIMO SIMONETTA. Can. J. Chem. **63**, 1468 (1985).

The structures of $CH_5^+(CH_4)_n$ ($n = 1-4$) are determined by semiempirical and *ab initio* MO calculations. The results of the present calculations are in fair agreement with the values of $-\Delta H$ obtained in mass spectrometric experiments. It appears that a three-center–two-electron bond has the most efficient attractive power for the incoming methane molecules.

ETTORE FOIS, ALDO GAMBA et MASSIMO SIMONETTA. Can. J. Chem. **63**, 1468 (1985).

On a déterminé les structures des ions $CH_5^+(CH_4)_n$ ($n = 1-4$) en faisant appel à des calculs d'OM *ab initio* ainsi que semi-empiriques. Les résultats obtenus à l'aide de ces calculs sont en bon accord avec les valeurs de $-\Delta H$ qui ont été obtenues à l'aide d'expériences de spectroscopie de masse. Il semble qu'une liaison à trois centres et à deux électrons présente le pouvoir d'attraction le plus efficace pour les molécules incidentes de méthane.

[Traduit par le journal]

Introduction

Strong interest on alkane protonation was provoked by the work of Olah (1, 2), who investigated the reaction in superacid solutions. A three-center bond structure with C_s symmetry (**1** in Fig. 1) was proposed for the methonium ion (CH_5^+) on the basis of these studies, and several theoretical calculations performed at different levels of approximation have provided independent evidence that the lowest energy structure of CH_5^+ in the gas phase has C_s symmetry, corresponding to a three-center–two-electron (3c–2e) bond complex between CH_3^+ and H_2 (3–10). However, when energy correlation corrections are included in the calculations, the energies of C_s, C_{2v}, C_{4v}, and D_{3h} structures are compressed in a small range (10).

On the other hand, there is a continuing refinement in the study of energies and structures of carbocations by gas phase experimental methods, and measurements of clustering ion equilibria of the methonium ion were performed for the reaction with methane itself (11, 12):

[1] $CH_5^+(CH_4)_{n-1} + CH_4 \rightarrow CH_5^+(CH_4)_n$ ($n = 1-4$)

Binding energies obtained by these investigations are of general thermochemical interest and can also provide information on the structure of CH_5^+. The measured enthalpy changes for the (n, $n-1$) reactions ($n = 1-4$) showed a decrease with n, expected in the case of ion clusters because of the gradual charge dispersion with the addition of new methane units. The observed decrease is not regular: the fall-off between the first two interactions ($\Delta H_{1,0}$, $\Delta H_{2,1}$) is relatively small; a comparable but slightly higher decrease occurs between $\Delta H_{2,1}$ and $\Delta H_{3,2}$, followed by a very low decrease to $\Delta H_{4,3}$. This trend is interpreted as due to the relatively strong interaction with CH_5^+ of the first two incoming CH_4 molecules, while the next units experience weaker and quite different interactions (12).

The fact that experimental information on these compounds is available makes it tempting to investigate theoretically their structures and stabilities. It is also of interest to examine the accuracy of theoretical methods applied at different levels of approximation to reproduce experimental data. In the present study *ab initio* HF SCF MO and semi-empirical CNDO/2 methods are employed to calculate optimized geometries and energies of the clusters $CH_5^+(CH_4)_n$ formed by one methonium ion and a number ($n = 1-4$) of methane molecules.

Methods of calculation

Total energies and stabilization energies $\Delta E_{n,n-1}$ were computed by the *ab initio* spin-restricted Hartree–Fock method, using the GAUSSIAN 80 series of programs (13, 14). The geometry of the smallest cluster $CH_5^+CH_4$ was fully optimized using the standard 3-21G basis set. For the larger clusters ($n > 1$), complete optimization was performed on C_s symmetry constrained structures. Single point calculations with 6-31G** basis set were carried out on the 3-21G optimized geometries ($n = 1, 2$), and they are designated as HF/6-31G**//3-21G.

The analysis of the force constant matrix was performed for $CH_5^+CH_4$ to ensure a complete characterization of the potential energy surface (15, 16). In CNDO/2 calculations (17) the parametrization of Wiberg (18) was adopted, which was the first to predict a C_s structure (3) for CH_5^+. The geometry of the smallest cluster ($n = 1$) was fully optimized. For larger clusters the geometry of the methane units was kept rigid. The Powell technique (19) was employed in the optimization process.

Results and discussion

The total energy calculated by the different methods for methonium ion/methane clusters are collected in Table 1, where enthalpy changes $\Delta H_{n,n-1}$ are also reported.

$CH_5^+CH_4$

The most interesting geometrical parameters of the fully optimized ground-state structure are reported in Table 2, referring for atom numbering to Fig. 1.

It appears that CH_5^+ retains in the 1:1 complex the C_s structure of the isolated ion, and in particular the geometry of the characteristic 3c–2e bond is slightly affected by the interaction with methane: H1—H2 = 0.86 Å (0.85); ∠H1—C1—H2 = 41° (40°); C1—H1 = 1.24 Å (1.24); C1—H2 = 1.22 Å (1.24), values in parentheses referring to isolated CH_5^+. The lengthening of C1—H2 bond is negligible and H1 lies very near to the line connecting C1 and C2 atoms (∠C2—C1—H1 = 4.2°).

The presence of a 3c–2e stabilizing interaction in all the clusters is not surprising as one or more 3e–2c bonds have

been predicted by refined HF calculations performed on different carbo and dicarbo cations, such as CH_6^{2+}, $C_2H_6^{2+}$, and $C_2H_8^{2+}$ (20, 21). The presence of a two 3c−2e bond structure, suggested by Hiraoka and Kebarle (12) by analogy with the H_5^+ structure, was accurately checked. The potential energy surface was fully investigated using the 3-21G basis set. Numerical second derivatives with respect to all nuclear coordinates were evaluated. Only two stationary points were found; one was characterized by no imaginary frequency corresponds to the minimum energy structure **2** with one 3c−2e bond while the other (one imaginary frequency) is associated with structure **3** (saddle point), showing no 3c−2e bond. The latter probably represents the transition state for proton transfer between methonium ion and methane. It appears that one proton is symmetrically coordinated by two methane molecules (C—H1 = 1.46 Å, Q(H) = 0.475 e in HF/6-31G**//3-21G calculations) and C1—C2 distance (2.92 Å) is significantly shorter than in the ground state (3.60 Å). The energy barrier predicted by HF/3-21G calculations is 14.6 kcal mol^{-1}, which raises to 24.04 kcal mol^{-1} in HF/6-31G**//3-21G calculations.

Also the CNDO/2 method predicts correctly two structures only, whose geometries are very similar to the *ab initio* ones; however, the energy barrier is lower and corresponds to 1.55 kcal mol^{-1}, and the C1—C2 distances are 3.2 and 2.7 Å in the ground and transition states, respectively.

$CH_5^+(CH_4)_n$, n = 2−4

A complete *ab initio* geometry optimization was allowed using the 3-21G basis set, with the only constraint of C_s symmetry conservation. The optimized structures are shown in Figs. 1 and 2, and the values of the most relevant geometrical parameters are reported in Table 2. The typical structure of isolated CH_5^+ is retained in the clusters, and the CH_4 units coordinate progressively to the different hydrogens of the ion, the first two methanes interacting with the two protons of the 3c−2e bond, as shown in Fig. 1. The structure of this bond is also slightly modified by clustering methanes. CNDO/2 calculations predict similar structures, but C—C distances are shorter by about 0.5 ~ 0.6 Å with respect to the *ab initio* optimized values. This finding is expected if one considers that

[a]The geometries of methane molecules remains practically unchanged; their geometrical parameters are available from the author upon request.
[b]"$i-j$" represents a distance and "ijk" represents an angle.

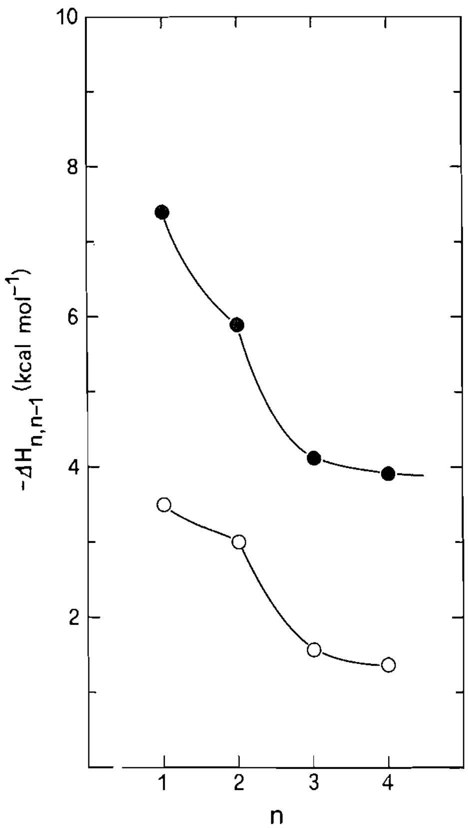

FIG. 3. Plots of experimental $\Delta H_{n,n-1}$ (full circles) and calculated (empty circles) $\Delta E_{n,n-1}$ by HF/3-21G basis set.

the semiempirical method systematically overestimates the bonding properties.

The plot of the experimental $\Delta H_{n,n-1}$ value for reaction [1] is shown in Fig. 3, where the corresponding plot of *ab initio* computed $\Delta E_{n,n-1}$ are also reported. The qualitative agreement is excellent, and the anomaly observed at $n = 2$ is correctly reproduced. The corresponding values calculated for the smallest clusters at the HF/6-31G**//3-21G level are slightly lower and confirm the decrease of $\Delta E_{n,n-1}$ as n increases. It appears that each added CH_4 (at least till $n = 4$) interacts with each free hydrogen of CH_5^+ to form a regular cluster around the methonium ion, so that polymer structures appear less favoured. The finding is expected because of the relatively small interaction energy involved. In contrast, the interaction is stronger for ammonia cluster ions ($NH_4^+(NH_3)_n$) where hydrogen bonds are formed. The larger enthalpies measured by molecular-beams mass spectrometry (22) and confirmed by HF calculations (23), put in evidence the different extent of the interaction for the two types of ion clusters. The analysis of the ordering and the relative stabilities of the most relevant MO's can explain the anomaly present at $n = 2$ in the experimental $\Delta H_{n,n-1}$ plot, well reproduced by HF/3-21G calculations. The occupied MO energy levels for the different clusters are collected in Fig. 4 where those of CH_4 and CH_5^+ are also reported for reference. It is noteworthy that the ordering is independent of the basis set (3-21G and 6-31G**) at least in the case where comparison was possible. It emerges that all MO's of CH_5^+ are slightly destabilized in each of the clusters considered, while CH_4 MO's are always stabilized by the interaction. Moreover the MO stabilization of the first two methanes, localized in the region of the 3c−2e bond, is stronger than that of the subsequently added CH_4 units which interact with the remaining less acidic hydrogen of CH_5^+.

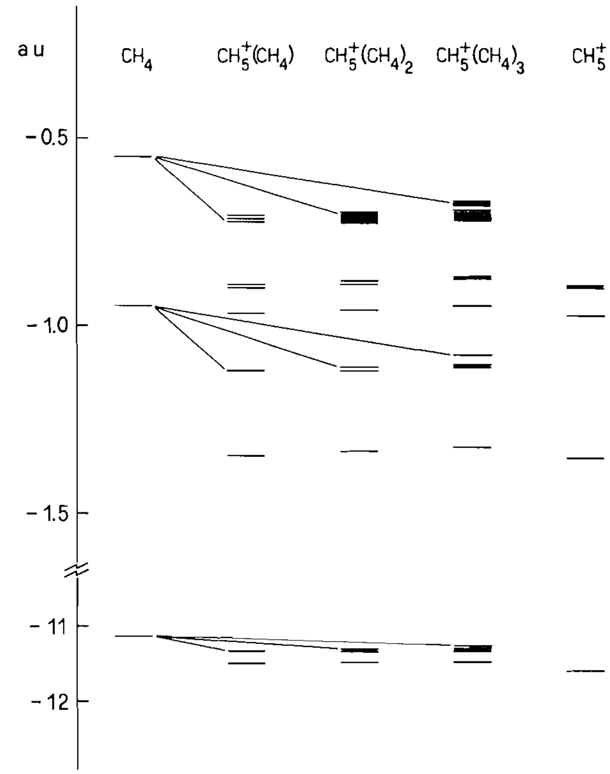

FIG. 4. Occupied MO's energy levels (HF/3-21G) for structures **1**, **2**, **4**, **5**, and free methane.

The irregular decrease of the enthalpy vs. n in the gas phase clustering of methonium ions by methane can therefore be unequivocally explained by the different extent of the interaction of methane molecules with the two kinds of protons of the methonium ion.

Vibrational spectra and structure of *N*-methylacetamide in some solid complexes with neutral salts

M. H. BARON AND F. FILLAUX

Laboratoire de Spectrochimie Infrarouge et Raman, Centre National de la Recherche Scientifique, 2 rue Henri-Dunant, 94320 Thiais, France

Received July 27, 1984

This paper is dedicated to Professor Camille Sandorfy on the occasion of his 65th birthday

M. H. BARON and F. FILLAUX. Can. J. Chem. **63**, 1473 (1985).

Infrared spectra of crystalline complexes of *N*-methylacetamide ($CH_3CONHCH_3$) and of its ND analog with alcaline perchlorates, tetrabutylammonium halogenides, and alcaline halogenides have been investigated in NH stretching (3500–3050 cm^{-1}), CO stretching (amide **I**, 1750–1500 cm^{-1}), and NH bending (800–400 cm^{-1}) regions. Possible structures for the complexes are proposed and the non-planarity of the amide group is discussed.

M. H. BARON et F. FILLAUX. Can. J. Chem. **63**, 1473 (1985).

Les spectres infrarouge de complexes cristallins formés à partir de *N*-méthylacétamide (NH ou ND) et des perchlorates alcalins, ou des halogénures de tétrabutylammonium, ou des halogénures alcalins, sont étudiés dans les régions spectrales 3500–3050 cm^{-1}(νNH), 1750–1500 cm^{-1} (amide **I**) et 800–400 cm^{-1} (γNH). Les différentes structures possible et la non planéarité du groupement peptidique sont discutés.

I. Introduction

N-Methylacetamide (NMA) has been shown to be non-planar in the crystalline state as well as in solution (1–4) and new assignments have been proposed for infrared and Raman bands corresponding to the torsion (τ_{CN}) around the CN central bond, to the $\gamma_{NH(ND)}$ bending and to the $\nu_{NH(ND)}$ stretching modes.

We were interested in complexes formed between NMA and neutral salts (5–7) and wanted to find out the influence of various interactions between the amide group and ions on the structure of the CONH entity.

II. Experimental

Two different methods have been used to obtain the complexes.

In the first one the salts were dissolved in NMA heated at 60–70°C in order to obtain the desired amide/salt ratio. Complexes were crystallized at room temperature for the following compositions: amide/$Ba(ClO_4)_2$ = 6 or 5, amide/$LiClO_4$ = 4, 3, or 2, amide/Bu_4NBr = 4 or 2, (Bu_4N^+ is the tetrabutylammonium anion), amide/LiBr = 4.

In the second route the salts were added to a solution of amide in methanol or pyridine with the desired amide/salt ratio. The solvent was then slowly pumped out under vacuum.

Infrared spectra were recorded with a Perkin-Elmer 225 spectrometer with a slit width of 2 cm^{-1}. The uncertainty on frequency was about ±2 cm^{-1}. Thin films of Nujol or Fluorolube mulls were examined between KBr or CsI windows.

For each complex the infrared spectrum of the NH and ND derivatives were recorded in order to settle the NH bending assignment.

II. Results and discussion

II.1. Spectral ranges and band assignment

Interactions of the CONH group manifest themselves in infrared as frequency shifts of the normal modes involving mainly the CO and NH bonds. Due to tunnel effect, the mean structure of NMA has the C_s symmetry and the denomination for the normal modes proposed by Miyazawa (8) can be kept. Three spectral regions are selected where the most localized modes appear (8–15): 400–800 cm^{-1} ($\gamma_{NH(ND)}$), 1500–1700 cm^{-1} (amide **I** and **II**) and 3050–3600 cm^{-1} (ν_{NH}). The spectra of pure NMA at room and liquid nitrogen temperature are given in Fig. 1*a* and 1*b*, respectively.

[a]Observed only at low temperature.
[b]Bu_4N^+ represents the tetrabutylammonium entity.
[c]Complex obtained from a mixture of amide and salt.
[d]Complex obtained from a mixture of amide and salt in methanol. In this case, some of the interactions cannot be localized definitively.

II.2. Interactions with neutral salts

Depending on the amide/salt ratio four different types of local structures have been identified (5) (Table 1): self-associated chains (**I**), complexes of a single molecule with ions (**II** and **III**), and self-associated chains interacting with ions (**IV**). These representations are quite schematic since they do not account for the real coordination of the ions.

II.2.1. Interactions with perchlorate salts

Infrared spectra corresponding to NMA interacting with barium perchlorate ($Ba(ClO_4)_2$, amide/salt = 5 or 6) are typical of a complex of type **II** (5) with an amide A band at 3405 cm^{-1} and amide **V** and **VI** bands at 666, 582 cm^{-1} due to weak NH···ClO_4^- interaction. The amide **I** at 1652 cm^{-1} corre-

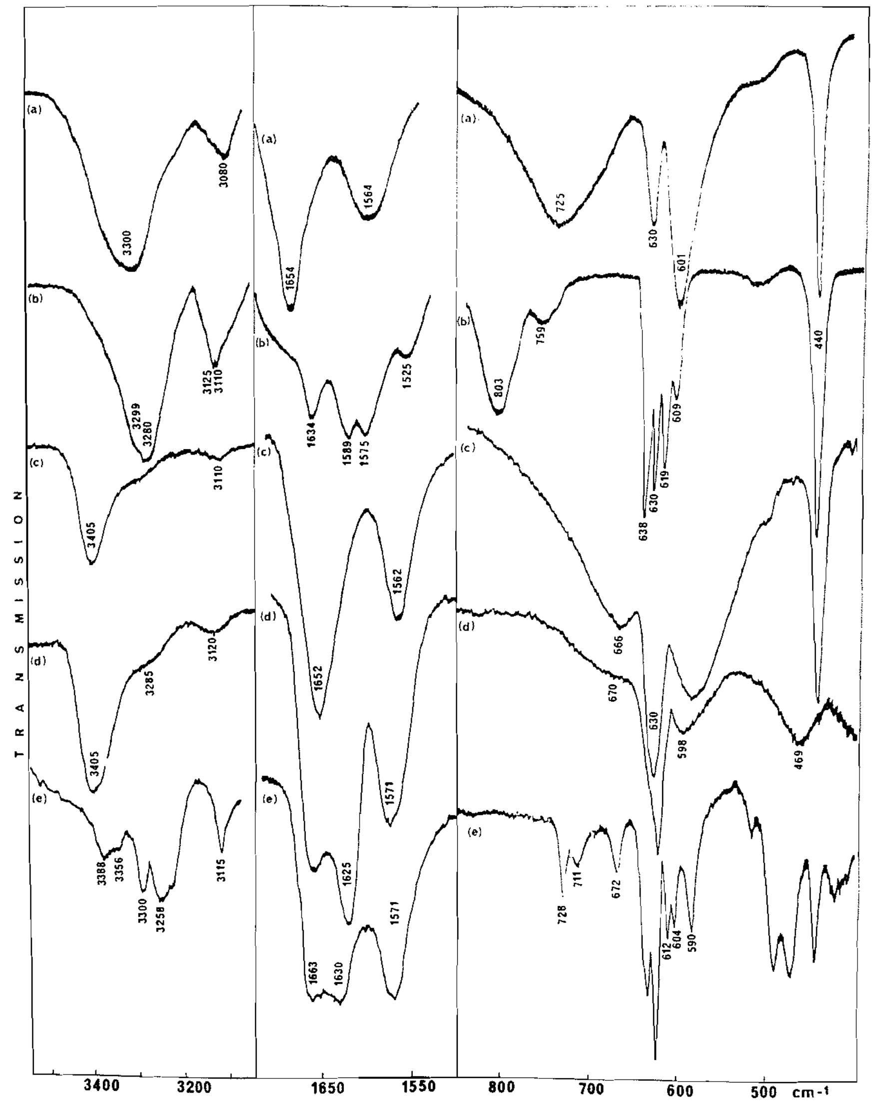

FIG. 1. Infrared spectra in the γ_{NH}, ν_{CO}, and ν_{NH} regions of NMA and its complexes in Nujol or Fluorolube mulls: (*a*) pure liquid NMA at room temperature; (*b*) pure NMA crystallized at liquid nitrogen temperature; (*c*) NMA with barium perchlorate (amide/salt = 5) at room temperature; (*d*) NMA with lithium perchlorate (amide/salt = 2) at room temperature; (*e*) NMA with lithium perchlorate (amide/salt = 2) at liquid nitrogen temperature.

sponds to $CO\cdots Ba^{2+}$ contacts (Fig. 1*c* and Table 1). It must be noticed that the strong band at 630 cm^{-1} is due to the overlapping of the ClO_4^- stretching with the bending of the carbonyl group.

The situation is quite similar for $LiClO_4$ salt at room temperature but depending on the amide/salt ratio the amide **I** band shows one or two components corresponding to one or two Li^+ interacting with the carbonyl group (1663 and 1625 cm^{-1}, respectively) indicating the existence of complexes **II** and **III** (Table 1). Figure 1*d* shows an example of a mixture of the two complexes. In this case the Li^+ vibration is observed at 469 cm^{-1}. At low temperature (Fig 1*e*), the amide A band splits in several components (3258, 3300, 3356, 3388 cm^{-1}) and three amide **V–VI** doublets (728–612, 711–604, and 672–590 cm^{-1}) are well resolved in the NH bending region, which suggest that there may be several different interactions acting simultaneously. A tentative interpretation is given (Table 1) on the ground of the relationship between frequencies and the strength of the interactions previously discussed (3–7, 14, 15).

II.2.2 Interactions with tetrabutylammonium bromide

Infrared spectrum of a mixture of NMA with tetrabutylammonium bromide (Fig. 2) shows that self-association is destroyed while rather strong $NH\cdots Br^-$ (amide A at 3258 cm^{-1}) interactions appear. The observed frequencies are all consistent with type **II** complex (Table 1) (5). Amide **V** and **VI** bands appear at 593 and 720 cm^{-1}, respectively, the latter overlapping with a band at 738 cm^{-1} due to the tetrabutylammonium ion.

II.2.3. Interactions with lithium bromide

In this case the spectrum depends on the sample preparation method.

When the salt is dissolved in pure NMA the spectra in the NH stretching and bending regions are similar to those observed for the complex with tetrabutylammonium bromide, while the amide **I** frequency corresponds to that observed for $CO\cdots Li^+$ interactions (Fig. 3*a*). These results support the existence of type **II** and **III** complexes in which one or two Li^+ ions interact with the carbonyl group. Crystallographic data (16) indicate that the carbonyl group interacts with only one lithium but there are two different $CO\cdots Li^+$ distances in the

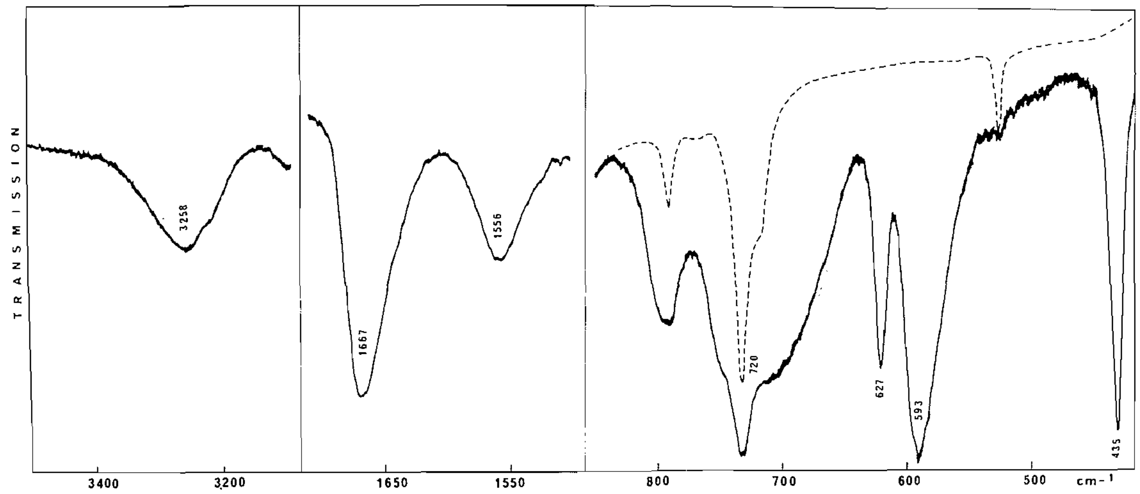

FIG. 2. Infrared spectra in the γ_{NH}, ν_{CO}, and ν_{NH} regions of (——) NMA with tetrabutylammonium bromide (amide/salt = 4); (----) tetrabutylammonium bromide; in Nujol or Fluorolube mulls at room temperature.

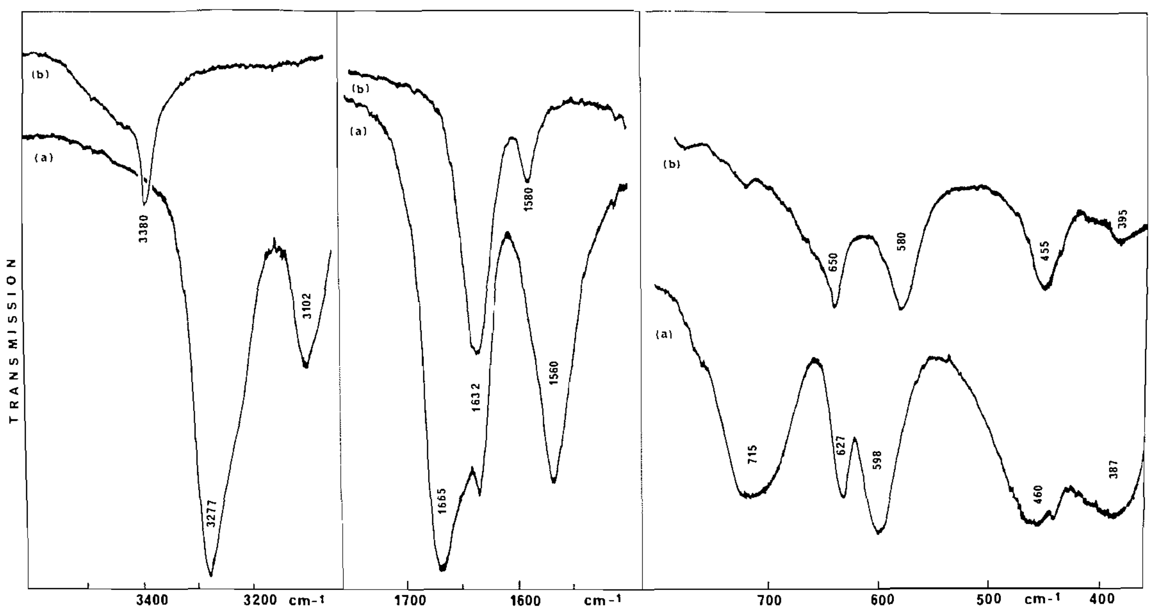

FIG. 3. Infrared spectra in the γ_{NH}, ν_{CO}, and ν_{NH} regions of NMA with LiBr in Nujol or Fluorolube mulls: (*a*) complex obtained from a simple mixture of amide and salt; (*b*) complex obtained from a mixture of amide and salt in methanol.

unit cell which may account for the two observed amide **I** bands. Amide **V** and **VI** are at 598 and 715 cm^{-1}, respectively. The strong bands near 400 and 460 cm^{-1} are ascribed to Li^+ vibrations.

If NMA and LiBr are dissolved with the same amide/salt ratio in methanol which is then removed slowly, a completely different spectrum is observed (Fig. 3*b*): the amide A band appears at 3380 cm^{-1} indicating a very weak interaction of the NH group, while the frequency of the amide **I** band (1633 cm^{-1}) is rather low. The amide B band is very weak. There is only one NH bending mode at 580 cm^{-1} which can be clearly identified upon deuteration but there may be a weak component about 650 cm^{-1} overlapping with the amide **IV** band at 630 cm^{-1}.

Frequencies of the amide A and of the NH bending appear too high and too low, respectively, to be ascribed to $NH\cdots Br^-$ or self associated species alone (5). A possible interpretation could be to consider some additional interactions between the nitrogen atom or π electrons and the Li^+ ion.

II.3 Discussion

In pure NMA (Fig. 1*a*) amide **V** and **VI** bands observed between 600–620 and 700–800 cm^{-1}, respetively (Fig. 1*a* and *b*) have been ascribed to a tunnel effect due to the inversion of the NH bond (3). These bands are hydrogen bond sensitive: the frequencies and the splitting decrease when the $NH\cdots X$ bond strength decreases (3). Amide **V** and **VI** bands are clearly identified in complexes with neutral salts which suggests a non-planar structure of the nitrogen atom. The complex with LiBr (Fig. 3*b*) is the only case where there is no clear-cut evidence for tunnel effect and it is difficult to decide whether the structure is planar or not.

Amide A and B bands for pure NMA appear in the 3050–3150 and 3250–3300 cm^{-1} ranges (Fig. 1*a* and *b*).

They have been ascribed to the fundamental ν_{NH} transition (amide B) and to the combination $\nu_{NH} + \gamma^{*}_{NH}$ (amide A, γ^{*}_{NH} representing the frequency of the bending mode in the excited state of the NH stretching (4)). According to this interpretation, the amide A and B bands depend on the strength of the interaction in which the NH group is engaged and their relative intensities are related to the non-planarity of the nitrogen atom in the fundamental state (4). In complexes with neutral salts the amide B band remains always weak relatively to the amide A band which is consistent with a pyramidal structure of the nitrogen atom.

III. Conclusion

Infrared spectra of complexes of NMA with neutral salts give evidence for various interactions of the CO and NH groups with the ions and schematic structures are proposed in agreement with previous results (5). In every case, much in the same way as for NMA in solutions (3), the NH bending mode gives one or several doublets which may be ascribed to tunnel effect indicating a non-planar structure of the nitrogen atom and a fast inversion of the NH bond. This interpretation is consistent with the fact that the amide B band remains weak relatively to the amide A band in every case (4) and confirms that the pyramidal structure is but not too sensitive to the strength and to the nature (hydrogen bond or ionic) of the interactions of the CONH entity with the surrounding medium.

Determination of stretching force constants of weakly bound dimers from centrifugal distortion constants

D. J. MILLEN

Christopher Ingold Laboratories, Department of Chemistry, University College London, 20 Gordon Street, London WC1H 0AJ, England

Received July 27, 1984

This paper is dedicated to Professor Camille Sandorfy on the occasion of his 65th birthday

D. J. MILLEN. Can. J. Chem. **63**, 1477 (1985).

Expressions are derived from which stretching force constants for the weak bond in weakly bound dimers may be evaluated directly from observed rotational constants and centrifugal stretching distortion constants.

D. J. MILLEN. Can. J. Chem. **63**, 1477 (1985).

On a dérivé des expressions à partir desquelles on peut évaluer les constantes de force d'élongation pour la faible liaison dans des dimères faiblement liés; cette évaluation peut se faire directement à partir des constantes rotationnelles observées et des constantes de distortion lors de l'élongation des liaisons par force centrifuge.

[Traduit par le journal]

Introduction

In recent years stretching force constants have been obtained for many weakly bound dimers. In some cases such force constants have been determined in the well-established way from vibrational wavenumbers associated with the stretching modes of the weakly bound dimer (1). In the majority of cases, however, they have been determined from the centrifugal distortion constant D_J since the information available is limited, by the experimental technique employed, to properties of the vibrational ground state (2, 3). Often a pseudo-diatomic model, which is equivalent to regarding each monomer as a point mass, has been used although it has been pointed out that this model is found to be satisfactory only when moments of inertia of the constituent monomers are small (4). Expressions have been obtained when this restriction is relaxed and allowance made for the inertial properties of the monomers for the specific case of a linear triatomic dimer (5) and for other particular cases (4), although these latter expressions contain a geometrical parameter which refers to the distance between the monomer units in the dimer. The present paper derives expressions in a general manner, for various classes of dimer, in a form which can be used for the evaluation of force constants directly from centrifugal distortion constants and rotational constants without introducing any structural parameters or indeed any assumption about internuclear distances in the dimer. It is clearly advantageous for such purposes as the comparison of force constants for series of hydrogen bonded dimers if force constants are evaluated from expressions not limited by the pseudo-diatomic approximation. Indeed, in some cases force constants free of this limitation have already been reported (4, 6).

Results and discussion

Dimers of the general type to be examined are conveniently denoted as B···H—A. The proton donor H—A may be a diatomic molecule, e.g. HF, HCl, or a polyatomic linear molecule, e.g., HCN, H—C≡C—H. The acceptor B is taken in turn to be a linear molecule, a symmetric top, and then cases are examined where B is a planar asymmetric top, first with HA in the plane of the asymmetric top and then with HA perpendicular to the plane of the asymmetric top. The model employed throughout regards force constants for distortions which contribute to D_J, other than the force constant for the stretching of the weak bond, to be so large by comparison with the stretching force constant of the weak bond that all distortions other than stretching of the weak bond can be neglected. Thus for a linear dimer where D_J, measured as a frequency, is given by

$$[1] \quad D_J h = \frac{\hbar^4}{8I^4} \sum_{ij} J_{xx}^{(i)} (f^{-1})_{ij} J_{xx}^{(i)}$$

in which I is the principal moment of inertia, $J_{xx}^{(i)} = \partial I_{xx}/\partial R_i$, where R_i is the ith internal co-ordinate and $(f^{-1})_{ij}$ is the ijth compliance constant, all the $(f^{-1})_{ij}$ which contribute to D_J are put to zero except for the compliance constant which refers to the stretching of the weak bond.

The derivations use relationships between moments of inertia of dimer and monomers as for rigid bodies and so the expressions obtained will be strictly applicable to equilibrium rotational constants. The use of ground state rotational constants may lead to significant deviation where vibration–rotation constants α arise which are significant by comparison with rotational constants, as for example for large amplitude bending or stretching modes of very weakly bonded dimers.

Triatomic linear dimers B···H—A

A number of dimers of this class have been studied, including for example Ar···HF (7) and also Kr···ClF (8). Geometrical parameters and masses for such a dimer are defined in Fig. 1. B is represented by the mass m_B while D and d refer to the distances of B from centres of masses of dimer and H—A monomer, respectively. The principal moment of inertia of the dimer is given by

$$[2] \quad I_D = m_B D^2 + I_{HA} + m_{HA}(d - D)^2$$

where m_{HA} and I_{HA} refer to the mass and principal moment of inertia of HA. Substituting for D from the centre of mass condition we obtain

$$[3] \quad I_D = I_{HA} + \mu_D d^2$$

where

$$[4] \quad \frac{1}{\mu_D} = \frac{1}{m_B} + \frac{1}{m_{HA}}$$

Now if we use eq. [3] to insert into eq. [1] the single term that arises in the model, namely, that for stretching the weak intermolecular bond for which the force constant is k, the result is

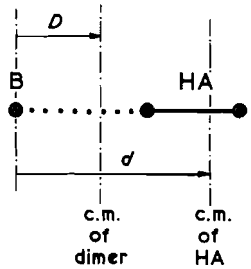

FIG. 1. Geometrical parameters and masses for triatomic linear dimers.

$$[5] \quad D_J h = \frac{\hbar^4}{2I_D^4}\frac{\mu_D^2 d^2}{k}$$

Finally eliminating d from this equation by using eq. [3] leads to

$$[6] \quad k = \frac{16\pi^2 \mu_D B_D^3}{D_J}\left(1 - \frac{B_D}{B_{HA}}\right)$$

where B_D and B_{HA} are the rotational constants for the dimer B···HA and for the monomer HA, respectively. If the stretching frequency ω of the dimer is assumed to be given as for a diatomic molecule, that is, if coupling with the H—A stretching motion through the stretching force constant for this bond and the cross term in the potential function are ignored, then eq. [6] leads to

$$[7] \quad D_J = \frac{4B_D^3}{\omega^2}\left(1 - \frac{B_D}{B_{HA}}\right)$$

an equation which has been obtained by Novick (5) using an alternative derivation for the particular case of the triatomic dimer. The equation reduces to the well known expression for the pseudo-diatomic case

$$[8] \quad D_J = \frac{4B_D^3}{\omega^2}$$

when $B_{HA} >> B_D$.

Polyatomic linear dimer

The geometrical parameters required for discussion of the general case are defined in an analogous way to those for the triatomic dimer and are shown in Fig. 2. In this case the principal moment of inertia of the dimer is given by

$$[9] \quad I_D = I_B + m_B D^2 + I_{HA} + m_{HA}(d - D)^2$$

where m_B and I_B are the mass and principal moment of inertia of B. Proceeding as before we obtain

$$[10] \quad D_J h = \frac{\hbar^4}{2I_D^4}\frac{\mu_D^2 d^2}{k}$$

In this case $\mu_D d^2$ is given by

$$[11] \quad \mu_D d^2 = I_D\left(1 - \frac{I_{HA} + I_B}{I_D}\right)$$

and hence the force constant k is given by

$$[12] \quad k = \frac{16\pi^2 \mu_D B_D^3}{D_J}\left(1 - \frac{B_D}{B_{HA}} - \frac{B_D}{B_B}\right)$$

When B is a point mass eq. [12] reduces to eq. [6]. The conditions under which this expression reduces to that for the pseudo-diatomic model are seen to be $B_{HA} >> B_D$ and $B_B >> B_D$.

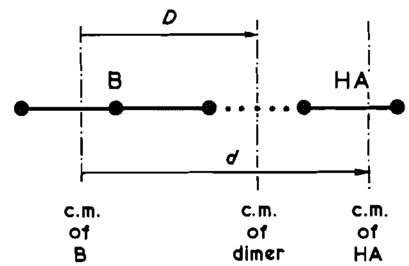

FIG. 2. Geometrical parameters and masses for polyatomic linear dimers.

Symmetric top dimers

Numerous examples of symmetric top dimers such as CH_3CN···HF (9), PH_3···HCl (10), and H_3N···H—C≡C—H (11) have been examined. The parameters D and d are defined again as in Fig. 2. D and d are related through the centre of mass condition.

$$[13] \quad \sum_{B} m_i(z_i - D) + \sum_{HA} m_j(z_j + d - D) = 0$$

where z refers to the symmetry axis of the top. These lead to

$$[14] \quad D = \frac{m_{HA} d}{m_B + m_{HA}}$$

and making use of the expression for a symmetric rotor (16)

$$[15] \quad D_J h = -\frac{\hbar^4}{4}\tau_{xxxx}$$

we obtain

$$[16] \quad k = \frac{16\pi^2 \mu_D B_D^3}{D_J}\left(1 - \frac{B_D}{B_{HA}} - \frac{B_D}{B_B}\right)$$

An alternative expression (4) has been obtained by a similar derivation for symmetric tops, but the present expression has the advantage of allowing calculation of k directly from the centrifugal distortion constants and rotational constants without requiring the evaluation of any structural parameter of the dimer.

Asymmetric top dimers

Planar asymmetric top dimers with C_{2v} symmetry

Examples of this group of dimer are formed by H—C≡C—H with HF (12) and HCl (13), and the group may be extended to include H_2O···HF (14) and H_2O···HCl (15), which are effectively planar. The parameters D and d are defined in an analogous way to that in Fig. 2. If we take the case where the symmetry axis z is the a-axis, we have for the principal moments of inertia about the b- and c-axes

$$[17] \quad I_D^b = I_B^b + I_{HA} + \mu_D d^2$$

and

$$[18] \quad I_D^c = I_B^c + I_{HA} + \mu_D d^2$$

In this case it has been shown (16)

$$[19] \quad D_J h = -\frac{\hbar^4}{32}(3\tau_{bbbb} + 3\tau_{cccc} + 2\tau_{ccbb})$$

Following the procedure as before we obtain

$$[20] \quad D_J h = 16\pi^4 \mu_D^2 d^2 k^{-1}[4B_D^4 + 4C_D^4 - (B_D - C_D)^2(B_D + C_D)^2]$$

which, when combined with eqs. [17] and [18], leads to

$$[21] \quad k = \frac{8\pi^2\mu_D}{D_J}[B_D^3(1-b) + C_D^3(1-c) - \tfrac{1}{4}(B_D - C_D)^2(B_D + C_D)(2-b-c)]$$

where

$$[22] \quad b = \frac{B_D}{B_B} + \frac{B_D}{B_{HA}}$$

and c is given by an analogous expression. In the case when $B_D = C_D$ eq. [21] reduces to eq. [12].

Asymmetric top dimers with hydrogen bond perpendicular to planar momomer

Dimers of this kind include hydrogen bonded complexes formed by $H_2C{=}CH_2$ with HF (17) and HCl (18). The parameters D and d now refer to the distance along the z-direction of the molecular plane of B from the centres of mass of dimer and HA respectively. I_D^b and I_D^c are again given by eqs. [17] and [18]. The centrifugal distortion constant Δ_J is given by (19).

$$[23] \quad \Delta_J h = -\frac{\hbar^4}{8}(\tau_{xxxx} + \tau_{yyyy})$$

and following the procedures used previously we obtain

$$[24] \quad \Delta_J h = 64\pi^4\mu_D^2 d^2 k^{-1}[B_D^4 + C_D^4]$$

Substituting for $\mu_D d^2$ from eqs. [17] and [18] leads to

$$[25] \quad k = \frac{8\pi^2\mu_D}{\Delta_J}[B_D^3(1-b) + C_D^3(1-c)]$$

where b and c are defined as before. This expression is generally applicable to asymmetric rotor dimers with HA along a principal axis of inertia and thus also applies to planar dimers. It is seen from eq. [25] that significant deviations from the pseudo-diatomic model will arise when rotational constants for the dimer, B_D and C_D, are not small by comparison with B and C values for either of the constituent monomers of the dimer.

Discussion

Expressions have been obtained which relate stretching force constants for the weak bond in weakly bound dimers to centrifugal stretching distortion constants. The expressions, which are free of limitations of the pseudo-diatomic model, are in a convenient form for direct application to dimers B···HA of linear and symmetric rotor types and also to certain asymmetric rotor types. Calculations have already been made (4) which show that use of the pseudo-diatomic model can lead to significant error in the force constant k as a consequence of neglecting the inertial properties of the components which constitute the dimer. Other calculations have been made which show that the expressions obtained lead to consistent results when applied to a series of molecules (6), to series of several isotopic species of a linear dimer, $N_2\cdots HCN$ (20), and to a series of several isotopic species of an asymmetric rotor dimer, $H_2O\cdots HCN$ (21). Recent applications have also been made to the linear dimer $HC{\equiv}C{-}C{\equiv}N\cdots HF$ (22) and to the symmetric rotor $(CH_3)_3P\cdots HCN$ (23).

Étude d'un modèle simplifié de la rhodopsine: la toute *trans*-rétinylidène *tert*-butylamine en présence de divers acides carboxyliques

MARTINE BISSONNETTE, HOA LE THANH ET DANIEL VOCELLE[1]

Département de chimie, Université du Québec à Montréal, C.P. 8888 succ. A, Montréal (Qué.), Canada H3C 3P8

Reçu le 29 juillet 1984

Cet article est dédié au Professeur Camille Sandorfy à l'occasion de son 65e anniversaire

MARTINE BISSONNETTE, HOA LE THANH et DANIEL VOCELLE. Can. J. Chem. **63**, 1480 (1985).

Un système modèle du chromophore de la rhodopsine consistant en une base de Schiff (la toute *trans*-rétinylidène *tert*-butylamine) et divers acides carboxyliques a été étudié par les spectroscopies ultraviolette–visible (uv–vis) et par résonance magnétique nucléaire du proton. Dans le méthanol, un solvant polaire, les résultats montrent que les acides faibles sont capables de protoner complètement la fonction imine, que les doubles liaisons sont perturbées par la protonation, qu'un effet de nivellement est présent et que finalement, il existe un échange de protons entre l'imine protonée et le solvant. Dans le chloroforme, les résultats indiquent que les acides faibles ne peuvent pas protoner complètement la base de Schiff et qu'un équilibre existe entre une paire d'ions ($—\overset{+}{N}H$----$\overset{-}{O}_2C—$) et sa contre-partie neutre ($—N$:----$HO_2C—$). De plus, une interaction similaire à celle proposée par Nakanishi (théorie de l'effet de charges externes) semble se produire entre la chaîne polyénique de la base de Schiff et une fonction polaire localisée sur l'acide. Finalement, deux comparaisons sont faites: l'une utilise une base de Schiff similaire (la *trans,trans*-heptadiénylidène-2,4 *tert*-butylamine), l'autre se réfère à la rhodopsine.

MARTINE BISSONNETTE, HOA LE THANH, and DANIEL VOCELLE. Can. J. Chem. **63**, 1480 (1985).

A model system of the chromophore of rhodopsin consisting of a Schiff base (all-*trans*-retinylidene *tert*-butylamine) and several carboxylic acids has been studied by uv–vis and ^1H nmr spectroscopy. In methanol, a polar solvent, results indicate that weak acids are able to protonate fully the imine function, that all the double bonds are perturbed by protonation, that a leveling effect is present, and, finally, that a proton exchange between the protonated Schiff base and the solvent is also present. In chloroform, results indicate that weak acids cannot fully protonate the Schiff base and that an equilibrium exists between an ion pair ($—\overset{+}{N}H$----$\overset{-}{O}_2C—$) and a neutral species ($—\dot{N}$----$HO_2C—$). Furthermore, an interaction similar to Nakanishi's external point charge seems to exist between the polyenic chain of the Schiff base and a polar function on the acid. Finally, two comparisons are established: one with a similar Schiff base – the *trans,trans*-2,4-heptadienylidene *tert*-butylamine – the other with rhodopsine.

Introduction

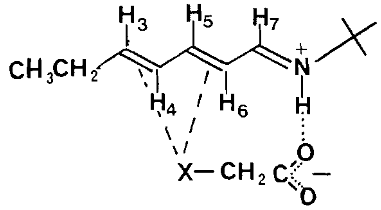
Le mécanisme moléculaire de la vision est encore mal connu même si de multiples travaux ont été faits au cours des vingt dernières années. Plusiers excellentes revues et monographies ont été publiées récemment (1). La structure exacte de la rhodopsine, le pigment visuel, fait encore l'objet de controverse, surtout au niveau de la protonation de la fonction imine et de la nature des interactions protéine–chromophore. Suite aux travaux de Kropf et Hubbard (2*a*), de Wiesenfeld et Abrahamson (2*b*) et de Kakitani et Kakitani (2*c*) sur la régulation de l'absorption maximale (λ_{max}) de la rhodopsine, Nakanishi et coll. (2*d*, *e*, *f*) ont présenté, sur la base de modèles expérimentaux, une proposition qui fait appel à deux interactions principales: la première résulte de la protonation de la fonction imine tandis que la seconde provient de charges situées près des doubles liaisons $C_{11}—C_{12}$ et $C_{13}—C_{14}$. Tout récemment, Mateescu et Igbal (2*g*) ont décrite des modèles qui, eux aussi, font appel à des interactions dues à un azote chargé positivement et à un ion carboxylate. Toutefois, des études en résonance magnétique nucléaire du ^{13}C et ^{15}N tendent à démontrer que la protonation est très variable et que celle-ci semble dépendre pour beaucoup de la préparation de l'échantillon (3) (voir aussi la réf. 3*e* au sujet de la bactériorhodopsine).

Afin d'approfondir ces deux questions, il est impérieux de connaître quel acide de l'opsine peut servir d'agent de protonation de la base de Schiff et quelle est la nature du milieu environnant le chromophore. Maintenant que la structure primaire de l'opsine est mieux connue (4), il est vraisemblable de penser que le chromophore puisse être protoné par les fonctions carboxyles terminales des acides glutamique ou aspartique tandis que les charges responsables du déplacement dû à l'opsine puissent provenir également d'une fonction carboxylate. Le milieu entourant le chromophore se doit d'être aussi évalué car il influe beaucoup sur ces interactions électrostatiques. Ainsi Honig *et al.* (5), afin d'expliquer le grande différence d'énergie entre la rhodopsine et la bathorhodopsine (tout près de 35 kcal/mol, réf. 6), ont proposé une séparation de charge entre l'imine protonée et son contre-ion carboxylate. Pour ce faire, ils ont suggéré un environnement hydrophobe (de faible constante diélectrique) afin d'avoir une paire d'ions de type $—\overset{+}{N}H$----$\overset{-}{O}_2C—$. Toutefois, Rafferty et Shichi (7) ont montré la présence d'eau autour du chromophore tandis que Warshel et Barboy (8) doutent de la présence d'un environnement non polaire car les paires d'ions n'y seraient pas stables. Les problèmes concernant les interactions du chromophore de la rhodopsine avec son milieu protéinique ne sont donc pas résolus ce qui retarde d'autant plus la solution du mécanisme moléculaire de la vision, du moins dans son étape initiale.

Afin de jeter quelques lumières sur la nature de ces interactions, nous avions imaginé, dans un premier temps, un modèle très simplifié de la rhodopsine. Ce modèle consistait en une base de Schiff trois fois conjuguées, la *trans,trans*-heptadiénylidène-2,4 *tert*-butylamine (HBA), et divers acides carboxyliques servant à la fois d'agent de protonation et d'agent de perturbation des doubles liaisons. La figure 1(a) montre ce modèle et la nature des interactions espérées. Pour explorer le rôle du milieu environnant le chromophore dans la rhodopsine, deux solvants – le chloroforme et le méthanol – ont été utilisés dans notre modèle. Puisque Honig *et al.* (5) préconisent l'existence d'un environnement peu polaire, de faible constante diélectrique, nous avons pensé utiliser le chloroforme afin d'imiter ce milieu. Quoique ce solvant ressemble peu au milieu biologique, notre choix s'explique par les faits suivants: le

[1] Auteur à qui adresser la correspondance.

(a)



(b)

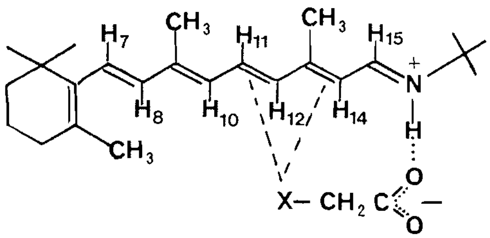


FIG. 1. Modèle simplifié de la rhodopsine; (a) la *trans,trans*-heptadiénylidène-2,4 *tert*-butylamine en présence d'un acide carboxylique; (b) la toute *trans*-rétinylidène *tert*-butylamine.

solvant doit être hydrophobe, les acides carboxyliques de même que leurs sels choisis pour notre étude doivent y avoir une solubilité assez grande pour que des spectres de ^{1}H rmn puissent être pris (il faut aussi que l'analogue deutérié existe) et finalement, le solvant utilisé doit permettre des recoupements avec d'autres études faites sur ce sujet. Le chloroforme remplit ces trois conditions et a donc été retenu. Le choix du méthanol repose sur les mêmes conditions que précédemment sauf que nous voulions un milieu plus hydrophile, l'eau étant exclue puisque l'imine protonée y réagit instantanément pour donner l'heptadiénal et la *tert*-butylamine. L'étude spectroscopique (uv – ^{1}H rmn) de ce modèle (9) a permis de mettre en évidence les points suivants. 1. Les acides carboxyliques modérément acides (pK_a (H_2O) entre 2 et 4) ne parviennent à protoner que partiellement la base de Schiff dans le chloroforme. 2. Également dans le chloroforme, un équilibre est établi entre une paire d'ions et la paire non-ionisée tel que montré ci-dessous (éq. [1]):

$$[1] \quad \mathrm{RCH{=}\overset{\displaystyle R'}{\underset{+}{N}}{-}H{-}{-}{-}{-}\underset{-}{O_2}C{-}R''} \rightleftharpoons \mathrm{RCH{=}\overset{\displaystyle R'}{N}{-}{-}{-}{-}H{-}O_2CR''}$$

3. Dans le méthanol, la protonation est cette fois-ci complète et aucune paire d'ions ne semble exister. Un effet de nivellement (tous les résultats sont les mêmes) est créé par le solvant.

Comme ces données sont fort importantes en regard de leur implication dans le mécanisme moléculaire de la vision, nous avons voulu les vérifier à l'aide d'un modèle s'apparentant encore mieux avec la rhodopsine où le chromophore est une rétinylidène amine de configuration 11 *cis*. Le modèle retenu consiste en la toute-*trans*-rétinylidène *tert*-butylamine (RBA) et en les mêmes acides et solvants qu'auparavant. La figure 1(b) montre notre modèle. La similitude de ce modèle avec celui de la fig. 1(a) est très grande de telle sorte que d'utiles comparaisons pourront être établies.

Méthode et procédure

La toute-*trans*-rétinylidène *tert*-butylamine a été synthétisée de la manière usuelle en suivant les indications fournies par Blatz *et al.* (10). Pour ce faire, le tout *trans*-rétinal (Aldrich Chemical Co.) est ajouté à la *tert*-butylamine fraîchement distillée, sous atmosphère d'azote et à l'obscurité. Du méthanol anhydre est utilisé comme solvant et quelques billes de tamis moléculaire (4A) sont ajoutées au mélange afin d'enlever l'eau produite par la réaction. Le tout est gardé à 0°C et un solide jaunâtre est obtenu. Plusieurs lavages à l'éther éthylique puis une évaporation poussée ont conduit à la *trans*-rétinylidène *tert*-butylamine. La pureté du produit a été évaluée par rmn et par uv–vis. Les acides utilisés étaient des produits commerciaux qui ont été séchés soit par distillation sur tamis moléculaire soit sous vide en présence de P_2O_5. Le chloroforme a été chromatographié sur une colonne d'alumine basique puis distillé sur du tamis moléculaire tandis que le méthanol a été rendu anhydre par la méthode de Perrin *et al.* (11).

Les spectres électroniques ont été obtenus en utilisant un spectrophotomètre Cary 17 et des solutions de RBA et d'acides à des concentrations de 10^{-5} *M*. Les spectres de rmn du proton ont été obtenus à l'aide d'un instrument Brucker WH/DS (400 MHz). Les concentrations dans ces cas étaient de l'ordre de 10^{-2} *M*. L'attribution des pics aux différents hydrogènes va de soi pour H_{15} et H_{11} qui sont les deux hydrogènes les plus déblindés mais est plus complexe pour les autres hydrogènes éthyléniques. L'attribution des pics à H_{14} et aux couples H_7, H_8 et H_{10}, H_{12} a été faite en utilisant la technique de la double résonance. Cette technique a été utilisée pour tous les spectres de mélange de RBA et d'acides. L'identification des pics pour H_7 et H_8 de même que pour H_{10} et H_{12} a été possible en se référant au spectre du tout *trans*-retinal et des attributions faites par Patel (12). Sur la base de ces travaux, H_7 est plus déblindé que H_8 et H_{12} est plus déblindé que H_{10} (voir plus loin dans le texte pour une discussion plus approfondie). Les solvants deutérés: $CDCl_3$, CD_3OD et CD_3OH ont été utilisés sans autre purification (MSD-Isotopes).

Résultats et discussion

Étude des spectres électroniques

La toute *trans*-rétinylidène *tert*-butylamine a été mélangée dans un rapport 1:1 avec différents acides carboxyliques en utilisant le chloroforme et le méthanol comme solvants. L'étude des spectres électroniques de ces systèmes est présentée au tableau 1. Dans le méthanol, les résultats sont simples: les spectres ne montrent qu'une seule bande à 440 nm. La figure 2 montre le spectre électronique de RBA avec l'acide chloroacétique dans le méthanol. Comme la RBA seule absorbe à 365 nm, les acides carboxyliques ont par conséquent exercé un effet bathochrome d'environ 75 nm. En se servant des travaux de Blatz *et al.* (10, 13) comme référence, l'interprétation des résultats est aisée: la bande à 440 nm représente la transition $\pi^* \leftarrow \pi$ de RBA protonée. La protonation est complète et puisque tous les spectres obtenus sont à toutes fins pratiques superposables, le méthanol a aussi créé un effet de nivellement (leveling effect). Ce nivellement des données implique que l'ion immonium est solvaté par le méthanol ce qui sépare ainsi le cation de son anion. Dans le méthanol, il n'existe donc pas de paire d'ions formée de l'ion rétinylidène immonium et de son contre-ion carboxylate. De plus, dans ce solvant, l'interaction du groupe polaire (l'atome d'halogène dans les acides acétiques halogénés) avec les doubles liaisons éthyléniques n'est pas présente car alors les résultats divergeraient selon l'acide utilisé.

Dans le chloroforme, les spectres électroniques varient selon l'acide utilisé. Sauf pour l'acide trichloroacétique qui n'induit qu'une seule bande (λ_{max} 453 nm), les autres systèmes présentent deux bandes: l'une à 366 nm, l'autre bande varie de 445 à 453 nm. Le spectre électronique de RBA en présence d'acide chloroacétique dans le chloroforme est représenté à la fig. 3. Lorsque la proportion d'acide est augmentée de telle sorte que le rapport imine–acide passe de 1:1 à 1:100, les

spectres électroniques n'indiquent plus qu'une seule bande et cela pour tous les acides utilisés. Ainsi, par exemple, l'acide chloroacétique dans des concentrations équimolaires avec RBA réussit à perturber la base de Schiff de telle sorte que deux bandes sont obtenues: l'une n'ayant pas bougé (λ_{max} 366 nm), l'autre ayant un λ_{max} de 445 nm. La première bande disparaît au profit de la deuxième dès qu'un large excès d'acide est utilisé et celle-ci a une absorption maximale à 450 nm et une absorptivité de 32 600. Cette dernière a servi à quantifier la proportion de la bande à 445 nm pour un rapport imine–acide de 1:1. Cette façon de faire a été suivie pour tous les autres acides. Dès qu'une seule bande apparaît, celle-ci a un λ_{max} qui ne varie que légèrement (maximum de variation: 9 nm pour l'acide dichloroacétique) par rapport à la première indiquant ainsi qu'un large excès d'acide a peu d'influence sur le λ_{max} de RBA. Considérant que la bande à 445 nm est due à la transition $\pi^* \leftarrow \pi$ de RBA protonée tandis que la bande à 366 nm est due à l'imine non protonée, on doit donc conclure que la plupart des

TABLEAU 2. Comparaison des pourcentages de protonation dans le $CHCl_3$, entre HBA et RBA en présence des mêmes acides

acides du tableau 1 ne réussissent à protoner que partiellement la base de Schiff et un équilibre tel que préconisé auparavant (éq. [1]) pour le système HBA, est aussi valable pour le système rétinylidène. D'ailleurs, les résultats obtenus à partir du système rétinylidène offrent une assez grande similitude avec le système heptadiénylidène. Le tableau 2 établit cette comparaison. Deux acides montrent des résultats divergents (les acides dichloroacétique et nitro-3 propanoïque) mais généralement les données de l'un ou de l'autre système concordent assez bien. Cette similitude dans les résultats implique que dans le système du rétinal, la partie de la molécule comprenant le cycle hexénique ainsi que les doubles liaisons situées sur les carbones C_7—C_8 et C_9—C_{10} n'interagissent pas avec les acides. Ces derniers exercent leur action surtout au niveau des atomes C_{11} jusqu'à N_{16}. Tout comme pour HBA, le pourcentage de protonation de RBA n'est pas linéairement relié avec le pK_a, mesuré dans l'eau, des acides carboxyliques. Toutefois, plus l'acide est fort plus grande est la protonation de RBA.

En conclusion, l'étude des spectres uv–vis de RBA en présence de divers acides confirme ce qui avait été trouvé précédemment pour HBA (9), à savoir que dans un solvant peu polaire comme le chloroforme, les acides carboxyliques ressemblant à ceux du tableau 1 ne peuvent pas protoner complètement l'imine conjuguée et un équilibre existe entre l'imine non protonée et protonée (voir éq. [1]). Extrapolée à la rhodopsine, cette conclusion porte à croire que si le milieu a une constante diélectrique faible (milieu hydrophobe), les acides glutamique ou aspartique ne pourront pas protoner le chromo-

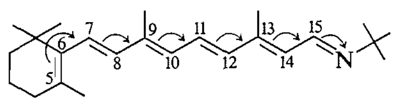
phore. Si le milieu est plus polaire la protonation pourra être complète mais le cation immonium devrait être alors solvaté par le milieu.

Étude en résonance magnétique nucléaire

Les mêmes systèmes que précédemment ont été étudiés par résonance magnétique nucléaire du proton (^1H rmn). Les données paraissent au tableau 3. Elle montre dans un premier temps les déplacements chimiques de tous les hydrogènes éthyléniques de RBA en plus de ceux des deux groupes méthyles (C_{13}—CH_3 et C_9—CH_3). Dans un second temps, le tableau 3 montre les valeurs de déblindage de ces hydrogènes lorsque RBA est mis en présence d'acides carboxyliques dans des concentrations équimolaires. La partie éthylénique du spectre de rmn de RBA est présentée à la fig. 4. L'attribution des différents pics aux hydrogènes éthyléniques s'est faite à l'aide de découplage spin–spin et par correlation avec les données fournies par Patel (12) pour le tout *trans*-retinal. L'attribution paraît logique car H_7 étant situé sur un carbone porteur d'une charge positive résiduelle par résonance, devrait être plus déblindé que H_8 qui lui, n'en porte pas. H_{10} et H_{12} sont situés sur des carbones qui ne portent pas de charge positive résiduelle mais comme H_{12} est plus près de la fonction imine que H_{10}, il devrait être plus déblindé. La délocalisation des électrons dans le système RBA se fait comme suit:



Les carbones 5, 7, 9, 11, 13 et 15 ont une charge positive résiduelle tandis que les atomes de carbone 6, 8, 10, 12 et 14 n'en ont pas. En présence d'acide, la délocalisation des électrons du système rétinylidène s'accroît et ainsi, la présence d'acide conduit à un déblindage de tous les hydrogènes, ce déblindage étant plus important là où réside une charge positive partielle. Ce n'est toutefois pas le cas de H_{15} car cet hydrogène varie que peu lorsque RBA est protoné. Ceci est montré au tableau 3 et est en tous points similaires aux résultats obtenus précédemment par nous (9) et par d'autres (13, 14). Sharma et Roels (14) ont expliqué le peu de changement subi par H_{15} lors de la protonation de l'azométhine par le fait que le déblindage normalement attendu, à cause de la présence d'une charge positive résiduelle sur ce carbone, est contrebalancé par la diminution du caractère de double liaison de la fonction imine ce qui diminue d'autant l'anisotropie du lien C—N. Le tableau 3 indique que H_{15} est blindé plutôt que déblindé; l'effet inverse est donc obtenu.

Dans le méthanol

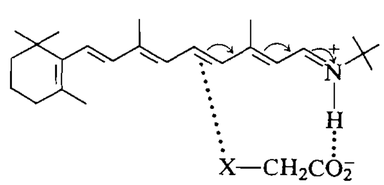
L'examen des colonnes de droite du tableau 3 indique qu'à l'exception des acides cyanoacétique et propiolique (et de façon moindre, de l'acide propionique), les sept autres acides ont des déblindages très semblables. Cela implique un effet de nivellement tel que préconisé déjà par Blatz (13) pour le méthanol. Ce nivellement des valeurs de déblindage est encore perçu par le fait que H_{14} est peu déblindé (dans le chloroforme H_{14} l'est beaucoup plus) ce qui implique que le contre-ion carboxylate est remplacé par des molécules de solvant. De plus, le tableau 3 révèle que l'action des acides sur RBA se répercute tout le long de la chaîne polyénique. Pour le moment, les résultats obtenus à partir des acides cyanoacétique et propiolique paraissent incohérents. Dans le système heptadiénylidène, leur comportement était aligné aux autres acides.

En conclusion, les données obtenues par rmn confirment les résultats obtenus en uv–vis: le méthanol a un efffet de nivellement.

Dans le chloroforme

Le spectre de RBA et de l'acide chloroacétique dans le $CDCl_3$ est représenté à la fig. 5 et il montre bien le déblindage subi par les hydrogènes par la présence de l'acide. Les résultats paraissent au tableau 3, colonne de gauche. On notera que dans ce solvant, les données diffèrent sensiblement selon l'acide utilisé. C'est l'acide dichloroacétique qui perturbe le plus le système rétinylidène et pourtant, les résultats en uv–vis indiquent que cet acide ne réussit à protoner RBA qu'à 82%. L'acide nitro-3 propanoïque vient en second suivi par l'acide trichloroacétique. Il est visible qu'il n'existe pas de relation linéaire entre ces valeurs de déblindage et le pK_a des acides mesuré dans l'eau.

On peut expliquer les résultats obtenus en recourant à la théorie de Nakanishi sur l'intéraction causée par la présence de charges externes ("external point charge theory" – réf. 2*a*). La présence d'un groupe polaire en bout de chaîne de l'acide peut stabiliser la charge positive partielle générée par la protonation. Cet effet de pince est illustré ci-dessous:



Cette explication semble être vérifiée par le fait que l'acide propionique qui n'a pas de groupe polaire terminal ne réussit pas à déblinder de façon sensible les hydrogènes de RBA (le tableau 1 montre par contre, que cet acide est incapable de protoner RBA). Plus important est le fait que les valeurs des déblindages des hydrogènes H_7, H_{11}, H_{12}, H_{14} varient selon le caractère nucléophile des atomes d'hydrogènes: l'iode causant un déblindage plus important que le brome, que le chlore et que le fluor. À noter que le déblindage est à l'inverse de la force des acides. Lorsque l'acide porte deux chlores (acide dichloroacétique), le maximum de déblindage est obtenu. Même si l'acide trichloroacétique est un acide plus fort que l'acide di-

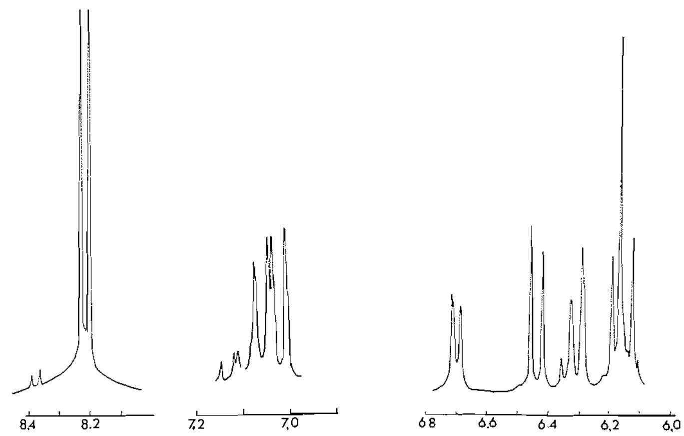


FIG. 5. Spectre de rmn du proton (400 MHz) de la toute *trans*-rétinylidène *tert*-butylamine en présence d'acide chloroacétique dans des concentrations équimolaires dans le $CDCl_3$.

chloroacétique, il cause un déblindage moindre. Tout ceci semble donc aller dans le sens indiqué: à savoir, que le groupe polaire de l'acide interagit avec la chaîne polyénique du système rétinylidène. Dans le chloroforme, les acides cyanoacétique et propiolique continuent à avoir un comportement différent des autres acides.

La présence d'une interaction entre les groupes polaires et la RBA présuppose l'existence d'une paire d'ions car il faut nécessairement que l'acide soit très près des doubles liaisons pour que l'interaction soit présente. L'existence ou non de paires d'ions dans ce système est un point fort important car, il faut le rappeler, Nakanishi et Honig (2, 5) préconisent l'existence de paires d'ions semblables dans la rhodopsine où elles jouent un rôle fondamental lors de la transformation photochimique du pigment visuel en bathorhodopsine. Les résultats du tableau 3, dans le chloroforme, montrent que cette paire d'ions existent car l'important déblindage de H_{14} résulte fort probablement de la présence du contre-ion carboxylate près de cet hydrogène. Si une paire d'ions existe, la fig. 1(b) montre que l'anion carboxylate devrait être près près de H_{14}; l'anisotropie causée par cette fonction devrait donc être responsable de l'important déblindage subi par H_{14}.

Le couplage de H_{15} est aussi très important car il indique ce qui se passe au niveau de l'azote de l'imine. En effet, H_{15} est un doublet lorsque la base de Schiff n'est pas protonée et devient un doublet de doublets si celle-ci est protonée (14). Or, tous les spectres indiquent un doublet pour H_{15}, même dans le cas où l'agent de protonation est l'acide trichloroacétique. Ceci ne signifie pas que RBA ne soit pas protonée (tous les hydrogènes, sauf H_{15}, sont largement déblindés) mais plutôt vérifie le fait, déjà trouvé par l'étude en uv–vis, qu'un équilibre semblable à celui montré à l'éq. [1] existe dans le chloroforme. Ce comportement de H_{15} est tout à fait conforme à celui trouvé pour le proton aldimine dans le système heptadiénylidène (9). Dans ce dernier cas, en utilisant un large excès d'acide, l'équilibre était déplacé en faveur de la paire d'ions et un doublet de doublets en résultait dès lors.

En conclusion, dans un solvant peu polaire comme le chloroforme, les données obtenus par rmn du proton indiquent que l'effet de charges externes tel que préconisé par Nakanishi peut expliquer les déblindages des hydrogènes éthyléniques mais que la question de la protonation de la fonction imine est plus complexe que prévue car les résultats montrent fort bien l'exis-

tence d'un équilibre entre une paire d'ions ($R_2{-}\overset{+}{N}H{-}{-}{-}{-}\bar{O}_2R$) et une association de molécules neutres ($R_2N{-}{-}{-}{-}HO_2C{-}R$).

Comparaison entre les systèmes rétinylidène et heptadiénylidène

Tout au long de ce travail, d'utiles recoupements avec la *trans,trans*-heptadiénylidène-2,4 *tert*-butylamine (HBA) ont été invoqués. Une comparaison entre les données de rmn obtenues dans le chloroforme pour ces deux bases de Schiff pouvait être fort intéressante. À partir des données fournies par la réf. 9, le tableau 4 a pu être établie. On notera la correspondance des hydrogènes H_{15} pour RBA et H_7 pour HBA et ainsi de suite (voir figures 1(a) et 1(b)) qui existe entre les deux systèmes. Le tableau 4 montre que quatre des dix acides perturbent les bases de Schiff de façon fort semblable. Les acides nitro-3 propanoïque, iodoacétique, bromoacétique et dichloroacétique exercent donc leurs effets surtout au niveau des trois premières doubles liaisons dans le système RBA. Par contre, les six autres acides causent des déblindages dont la valeur varie selon l'un ou l'autre système. Le tableau 4 indique, pour ces acides, une valeur de déblindage toujours plus basse pour les hydrogènes de RBA. Pour ces six acides, leur action est moins localisée et comme RBA est beaucoup plus conjuguée que HBA, la perturbation causée par ces acides peut dès lors s'étendre sur un plus grand nombre de liaisons.

Dans le méthanol, les résultats offrent des similitudes plus frappantes. Les deux systèmes montrent l'effet de nivellement du méthanol; H_{14} pour RBA et H_6 pour HBA ont un déblindage très voisin (0,3 ppm) mais comme RBA est une imine plus conjuguée que HBA, les autres hydrogènes ont des valeurs de déblindage moindres. L'emploi comme solvant de CD_3OD ne permet pas de noter la présence d'un échange de proton entre la base Schiff et le solvant; aussi, pour obvier à ce problème et puisque cette question est fort importante, les systèmes RBA – acide chloroacétique et RBA – acide trichloroacétique ont été aussi étudiés dans le CD_3OH. Les valeurs de déblindage sont bien sûr les mêmes que précédemment mais H_{15} est toujours un doublet. HBA a donné aussi ce résultat et les deux imines indiquent bien qu'un échange de proton s'établit entre la base de Schiff protonée et le solvant.

De cette étude comparative il ressort que le système heptadiénylidène est un modèle fort approprié de celui du rétinal et a comme avantage d'être facilement disponible, d'être économique, et surtout de présenter en rmn des données facilement interprétables.

Comparaison du système RBA avec la rhodopsine

Des résultats obtenus en uv–vis et rmn, il est possible de faire plusieurs hypothèses concernant la rhodopsine. En premier lieu, si le milieu environnant le chromophore est polaire, on peut prévoir une protonation complète du chromophore par les acides glutamique ou aspartique. Par contre, une paire d'ions de type $-\overset{+}{N}H{-}{-}{-}{-}\bar{O}_2C-$ apparaît comme peu probable à cause de l'effet de nivellement. De même, l'interaction directe entre une charge et les doubles liaisons selon la théorie de Nakanishi paraît aussi improbable. Il demeure possible, toutefois, qu'un système d'interactions par l'intermédiaire de l'eau puisse exister mais cela ne peut être montré par nos résultats. Dans un second temps, si le milieu protéinique entourant le chromophore a une constante diélectrique basse s'approchant de celle du chloroforme (dont la valeur est de 4,8), alors il est à prévoir que les acides glutamique ou aspartique ne pourront protoner que partiellement (voir même, pas du tout) le chromophore. De plus, une paire d'ions ($-\overset{+}{N}H{-}{-}{-}{-}\bar{O}_2C-$) sera en équilibre avec l'espèce neutre ($-N{:}{-}{-}{-}{-}HO_2C$) et l'interaction directe de charges avec les doubles liaisons pourra se faire.

Quelle que soit la polarité du milieu, un échange de proton existera entre la base de Schiff protonée et le contre-ion (milieu hydrophobe) ou l'eau (milieu polaire).

Remerciements

Cette étude a bénéficié des conseils judicieux du professeur C. Sandorfy que nous désirons remercier vivement. Les spectres de rmn ont été obtenus grâce aux bons offices du Centre régional de rmn à haut champ de l'Université de Montréal. Nous désirons remercier également Madame Sylvie Pepin pour la dactylographie de ce texte. Finalement, ce travail a reçu le secours financier du CRSNG (A0943) et de l'Université du Québec à Montréal.

Net charges and valence AO's for ammonia, methylamine, dimethylamine, and trimethylamine were calculated using extended basis sets. Superposition effects, evaluated by replacing Pople's standard 6-31G* basis by an extended form in which the basis of the ammonia H atoms and of the methyl groups of trimethylamine are retained in the treatment of each molecule, indicate that the quality of the treatment of amine nitrogen atoms is strongly dependent on the number of methyl groups. A new, augmented basis is proposed for the hydrogens, which appears to be reasonably well balanced: comparison with familiar (e.g., 6-31G*) calculations illustrates in what manner the treatment of nitrogen is worsened when even just one methyl group is replaced by hydrogen unless the impoverishment of the basis is suitably taken care of.

GIUSEPPE DEL RE, SÁNDOR FLISZÁR, MICHEL COMEAU et CLAUDE MIJOULE. Can. J. Chem. **63**, 1487 (1985).

Faisant appel à des ensembles de base élargis, on a effectué des calculs sur l'ammoniac, la méthylamine, la diméthylamine et la triméthylamine. Si on remplace la base normale 6-31G* de Pople par une forme élargie dans laquelle on conserve la base des atomes d'hydrogène de l'ammoniac et des groupes méthyles de la triméthylamine dans le traitement de chaque molecule, on peut évaluer les effets de superposition; ces effets indiquent que la qualité du traitement des atomes d'hydrogène de l'amine dépend fortement du nombre de groupes méthyles. Pour l'hydrogène, on propose une nouvelle base encore plus élargie qui semble être bien balancée; une comparaison avec des calculs familiers comme 6-31G* permet d'illustrer les complications qui interviennent dans l'étude de l'azote même lorsqu'on ne substitue qu'un seul groupe méthyle par un hydrogène si on ne fait pas les corrections qu'impose l'appauvrissement de la base.

[Traduit par le journal]

Introduction

It has been known for a long time, but seldom duly emphasized, that the properties of atoms carrying one or more hydrogens may differ significantly from those of the same atoms when linked only to atoms other than hydrogen. The debate on the electric dipole moment of the CH bond (1) and the pioneering discussion by Parks and Parr (2) do not seem to have been followed by much *ad hoc* theoretical work. Yet, even the special parametrization required by hydrogen in the empirical method proposed by one of us (3) pointed to the need for further theoretical investigations.

Quite recently, the treatment of hydrogen in *ab initio* computations has been investigated in connection with small molecules (4*a*) and with hydrogen-bonded dimers (4*b*). These papers point to the conclusion that *ad hoc* scaling of hydrogen may be equivalent to an important basis extension with counterpoise correction (4*c*). These exhaustive studies, however, have left open the case of larger molecules, where the interplay of hydrogen polarization and superposition effects may affect the results for ordinary chemical bonds.

We have come across this question in connection with an attempt to extend previous work on the relationships between Mulliken net charges and nuclear magnetic resonance shifts (5) to the alkylamines (6): the behavior of trialkylamines appeared to follow a trend differing from that of mono- and dialkylamines.

As is well known, not only are Mulliken net charges just one of the possible definitions of atomic net charges (7), but widely different values are produced with comparatively small changes in a basis set even in *ab initio* SCF calculations (5*a*, 8). Since trends within similar series are generally little affected by the computational scheme (5*a*, 8), this has not received great attention so far in applications to chemical problems. But our present problem is one where the choice of the basis could play a very important role.

Indeed, the superposition effect in a standard treatment of a series of amines certainly depends on the number and geometrical arrangement of the alkyl groups. Consideration of the local symmetry about the nitrogen atom suggests that two or three hydrogens (or two alkyl groups) should have roughly the same effect on nitrogen as one, whereas tertiary amines, where there is no N-bonded hydrogen at all, could differ significantly in the importance of superposition. Most important is also that the replacement of alkyl groups by hydrogens greatly impoverishes the basis, so that nitrogen is treated in a very special way when the presence of alkyl groups makes superposition effects likely to be very marked.

With these considerations in mind, we have first of all carried out a calculation of ammonia and its methyl-substituted derivatives using one and the same extended basis, 6-31G*, including the hydrogen basis set used for ammonia as well as the carbon and hydrogen orbitals used for trimethylamine. Then we have studied the possibility, usefulness, and physical significance of an improved basis set for hydrogen, following

TABLE 1. Superposition effect (SE) on calculated energies, electric dipole moments, and Mulliken N net charges in the 6-31G* basis[a]

Molecule	Energy (au)		μ (debyes)		q_N (me)	
	No SE	With SE	No SE	With SE	No SE	With SE
NH_3	−56.1844	−56.1961	1.92	1.58	−996	−940
NH_2CH_3	−95.2087	−95.2167	1.65	1.47	−832	−812
$NH(CH_3)_2$	−134.2360	−134.2404	1.34	1.26	−680	−701
$N(CH_3)_3$	−173.2654	−173.2664	1.02	1.00	−546	−590

[a] NH_3, $N(CH_3)_3$, (C_{3v}) and NH_2CH_3, $NH(CH_3)_2$ (C_s symmetry) were calculated in all cases using "standard" geometries closely copying optimized STO-3G results, namely (Å, viz. decimal degrees), r(NH) = 1.0032, r(CN) = 1.4900, $r(CH_t)$ = 1.0938, r(CH) = 1.0880, ∠HNH = 107.15, ∠CNH = 108.60, ∠H_tCN = 112.34, ∠HCN = 109.84, ∠HCH = 109.10, ∠H_tCH = 107.82, and ∠CNC = 109.94, where H_t is the hydrogen *trans* with respect to the nitrogen lone pair.

the line of reasoning explained below, and analyzing the MO's in terms of localized orbitals and of the procedure proposed by Del Re and Barbier (9).

Superposition effect

Table 1 indicates the results obtained when the standard 6-31G* basis set is replaced by the extended form 6-31G*-super, in which the basis set of the H atoms of ammonia and of the methyl groups of $N(CH_3)_3$ are all retained in the treatment of any of the four molecules listed.[3]

As expected, it is ammonia which benefits most from the presence of the "dummy" centers: the energy improvement is of the order of 30 kJ mol^{-1}, which is quite significant. On the other hand, the influence of the dummy ammonia hydrogen on the predicted SCF energy of trimethylamine only produces a ~3 kJ mol^{-1} decrease in total energy. This confirms that the quality of the treatment of nitrogen obtained by the standard basis is strongly dependent on the number of methyl groups.

In contrast with the trend suggested in the introduction, the energy corrections appear to decrease practically linearly with the number of methyl groups. However, this is not the case for dipole moments. The dipole moment of ammonia is reduced by 0.34 D, those of NH_2CH_3 and $NH(CH_3)_2$ by 0.18 and 0.08 D, respectively, and that of $N(CH_3)_3$ by 0.02 D. This suggests that, in addition to the slight improvement of the energy, the superposition effect leads to a reduction in polarization which corresponds to restoring electrons on the hydrogens – the greatest change being associated with axial symmetry.

The results for the net charge of nitrogen, q_N, suggest that inclusion of dummy centers produces two effects. In ammonia, nitrogen as well as the hydrogens lose electrons which move to the dummy centers beyond the hydrogens: there is a buildup of electronic charge in the outer sphere of the molecule. In trimethylamine, nitrogen gains electrons, as well as the three carbons and the dummy hydrogens: the electrons all come from the methyl hydrogens. The other two amines appear to be intermediate cases.

Since in trimethylamine the energy and dipole moment changes in going from 6-31G* to 6-31G*-super are minor, indeed, we infer tentatively that the internal charge redistribution is not physically very significant. The case of ammonia is quite different: not only are the energy and the electric dipole moment changes very important, but the reduction in electron population of nitrogen takes place with a basis set which certainly describes the correct situation about nitrogen in a more detailed way.

TABLE 2. Summary of results obtained for NH_3 from different basis sets

Basis set	Energy (au)	μ (debyes)	q_N (me)
1 6-31G*	−56.1844	1.92	−996
2 6-31G*+SE	−56.1961	1.58	−940
3 6-31G**	−56.1955	1.86	−790
4 6-31G*; 6-31 H	−56.2031	1.66	−533
5 6-311G**	−56.2104	1.74	−563
6 6-311 H	−56.2177	1.62	−556
7 6-311G** Opt.	−56.2104	1.73	−564
8 6-311 H Opt.	−56.2178	1.61	−556
9 6-311++G(3*df*, 3*pd*)	−56.2184		

Note: basis **9**, studied by Frisch, Pople, and Binkley (11) is the best result obtained by those authors in an instructive comparison of a variety of basis sets. Our result **8** is marginally better than that deduced from the 6-311++G(2*df*, 2*p*) set described in ref. 11 (E = −56.2176 au).

Of course, results obtained by means of a somewhat artificial and clumsy basis such as 6-31G*-super are subject to doubts, particularly as regards net charges. For instance, one may wonder if the reduced nitrogen charge in ammonia is not a purely artificial result: additional contributions to the electron density near that atom could be associated with basis functions protruding from the dummy centers. It is difficult to construct a logically consistent argument in this direction, but the awkwardness of a basis involving dummy centers is sufficient reason for not insisting on its use. We have tried to proceed in our study by constructing a basis that would take into account the lessons taught by Table 1 without introducing dummy centers. Indeed, our purpose will be to use the new basis in an attempt to recover a chemical description of valence effects in the molecules under consideration.

Optimized bases 6-31 H and 6-311 H

The fact that the presence of a NH bond seems to make a lot of difference as concerns superposition effects suggests that the treatment of hydrogen should be improved. Also the need for improvement in the treatment of nitrogen should be explored lest the extension of the hydrogen basis should be used to the benefit of the nitrogen electron density. Therefore, we have started from the two well-known 6-31G* and 6-311G* basis sets (10) and optimized an extended basis on hydrogen (Tables 2 and 3). The relevant results are indicated in Table 4.

[3] We use here the term superposition only because the basis is that typically used to estimate superposition errors. Actually, within the scope of this study, the floating part of the basis can be interpreted to some extent as a set of off-center polarization functions; its role should be compared with results obtained from a standard basis saturated on all centers.

TABLE 3. Optimized extensions of the 6-31G* and 6-311G* basis sets for H of NH_3

Basis	Type	α_K[a]	$d_{K,2s}$	$d_{K,2p}$

TABLE 4. Effect of augmented bases for H attached to N

	Energy (au)		μ (debyes)		q_N (me)	
Molecule	6-31 H	6-311 H	6-31 H	6-311 H	6-31 H	6-311 H
NH_3	−56.2031	−56.2177	1.66	1.62	−533	−556
NH_2CH_3	−95.2209	−95.2234	1.59	1.56	−532	−670
$NH(CH_3)_2$	−134.2422	−134.2320	1.38	1.38	−528	−667
$N(CH_3)_3$	−173.2654	−173.2422	1.02	1.05	−546	−619

Table 2 presents a familiar picture: small improvements in energy are associated with large oscillations in the values of expected electric dipole moments. The nitrogen net charge seems to follow a more regular trend. However, optimization of an enlarged hydrogen basis at the 6-31G* level (basis 6-31 H) leads to a sharp decrease of the nitrogen charge; this is slightly compensated by further extension of the nitrogen basis and it would seem that, as far as charges on ammonia are concerned, the saturation limit is reasonably well approached already with 6-311G*. However, the importance of an extended treatment of hydrogen (basis 6-31 H) is clear from the sudden jump between case **3** and case **4** (Table 2). Moreover, as can be seen in Table 4, the 6-311 H basis is really not very good for dimethyl- and trimethylamine. Thus, it appears that the 6-31 H basis actually represents the basis of choice for treating alkylamines, both because of the quality of the energy and dipole moments and because, in contrast with more extended bases (11), we can use it for the whole $NH_m(CH_3)_{3-m}$ series.

A few comments are in order. The hydrogen basis has been extended here to include not only polarization but radial distortion as well. This approach has been followed only for hydrogens linked to nitrogen because here we are only interested in improving the description of that atom.[4] The importance of the radial distortion of the hydrogen 1*s* orbital in bond formation will be discussed below. At this stage, we only point out that the analysis of Boys' localized orbitals indicates that the long-range components seem especially important in order to reproduce correctly the hydrogen–hydrogen interactions, but also carry a non-negligible weight in the bonding orbitals. In fact, due to the large overlap values, the additional 2*sp* component goes to improve the quality of the standard 6-31G* 1*s* component: its weight is roughly 30%, 20%, and 10% of the latter in NH_3, NH_2CH_3, and $NH(CH_3)_2$, respectively. These results confirm that, as expected, the higher flexibility in the hydrogen basis set is largely used to improve the description of the electron density about the nitrogen. This conclusion is certainly relevant in any assessment of calculated net charges which reveal, indeed, surprising features (Table 4).

Discussion

(a) *Energies and dipole moments*

The energy values shown in Tables 1 and 4 have already been discussed. Let us only emphasize here that the poor quality of the 6-311G* set for trimethylamine indicates that a mere increase in the flexibility of the basis is not sufficient to improve the results. On the other hand, the great improvement obtained for ammonia is sufficient proof that the poor quality of the 6-31G* set depends on an insufficient allowance for polarization and radial distortion in the hydrogen basis. The predicted electric dipole moments are also in line with the suggestion that the 6-31 H basis is well balanced: note that once again the 6-31G* result is better than that given by the 6-311G* basis.

(b) *Charges*

The most striking feature of the nitrogen net charges, q_N, obtained from the 6-31 H basis is that the presence of at least one hydrogen atom is sufficient to lower q_N to a "standard" value of ~ -0.53 e; in turn, this value is very close to that given for trimethylamine by the 6-31G* set. The trend is thus entirely different from that obtained with the 6-31G* and 6-311 H sets. It is in line with the thesis that the treatment of nitrogen is greatly worsened when even just one methyl group is replaced by hydrogen unless the impoverishment of the basis is suitably taken care of.

[4] The fact that we have combinations of three Gaussians for the additional *sp* basis functions is a purely technical detail, which is probably a superfluous feature. In fact, the exponents (whose original choice was the standard one for carbon atoms) include one value practically unaffected by optimizations. This is indirectly confirmed by the triple-ζ optimized basis of 6-311 H, where the additional (*s*,*p*) gaussian turns out to have a width close to the leading gaussian of the 3G group, so as to give something quite close to the (2*sp*) group of 6-31 H.

TABLE 5. The orbitals of the nitrogen and hydrogen atoms, from Boys localized MO's

(a) Overall coefficients of N									
	N—H bond			N—C bond			Lone pair		
Molecule	6-31G*	6-31 H	6-311 H	6-31G*	6-31 H	6-311 H	6-31G*	6-31 H	6-311 H
NH_3	0.687	0.644	0.660				1.031	0.960	0.940
NH_2CH_3	0.690	0.655	0.651	0.674	0.660	0.837	1.028	0.977	0.943
$NH(CH_3)_2$	0.694	0.666	0.648	0.680	0.674	0.746	1.024	0.993	0.978
$N(CH_3)_3$				0.687	0.687	0.712	1.021	1.021	1.012
(b) *p*-characters of N									
NH_3	2.92	2.96	1.92				1.73	1.61	1.78
NH_2CH_3	2.78	2.80	2.56	2.67	2.47	0.85	1.82	1.66	2.64
$NH(CH_3)_2$	2.56	2.64	3.05	2.56	2.40	1.53	1.84	1.73	2.32
$N(CH_3)_3$				2.38	2.38	2.22	1.77	1.77	2.09
(c) Overall coefficients of H in NH bonds				(d) c_s	c_p	d_H (NH bonds)			
NH_3	0.425	0.415	0.479	−0.92037	0.39104	−0.12170			
NH_2CH_3	0.427	0.432	0.463	−0.86182	0.50722	−0.08007			
$NH(CH_3)_2$	0.428	0.455	0.474	0.44392	0.89607	0.03822			

One question still remains open: are the 6-31 H charges really representative of the electron density around nitrogen? The fact that they are quite independent of the molecule suggests at first sight that all the difference in bond polarization due to substitution of H with C is taken up by the atomic orbital assigned to other atoms. This is not the case, at least in a first approximation: the Mulliken net charges of the hydrogen atoms linked to N are 178, 185, and 175 me from ammonia on, those of the methyl groups are 162, 175, and 181 me from methylamine on. Note also that the methyl groups are slightly less charged than the hydrogen atoms, when both are present. Thus, there are reasons to believe (*cum grano salis*) that the major features revealed by Mulliken net charges computed by the 6-31 H basis set are physically significant, in particular as concerns nitrogen. One last argument concerns the point charge approximation based on the experimental dipole (1.48 D), which gives $|q_N| \simeq 0.3$ e for ammonia and even smaller values for the amines (3).

(c) *Orbital energies*

Assuming now that the new basis is reasonably reliable, additional information can be obtained by analyzing suitable molecular orbitals in terms of the simple valence theory (9). This requires assigning to each atom A a single contribution to a given MO, $|j\rangle$, so that

$$|j\rangle = \Sigma\, c_A |h_{Aj}\rangle$$

where $|h_{Aj}\rangle$ is a fully contracted *in situ* atomic orbital (CAO), i.e., a normalized hybrid AO characterized by: (*i*) a *p* character *n* (defined as $(c_p/c_s)^2$, c_s, c_p being the coefficients of the *s* and *p* components in the expansion of the hybrid) and (*ii*) radially distorted *s*, *p*, and *d* parts, where by radial distortion we mean a change in the radial part of the AO with respect to the free-atom (or some similar) standard. The radial distortion is difficult to represent by a single number but can be measured to some extent by overlap values.

The choice of the molecular orbitals for use in this analysis is difficult whenever equivalent bonds appear. In this paper we shall refer to Boys' localized MO's such as they are produced by the library MONSTERGAUSS program (12). These orbitals have serious shortcomings: for one thing, they yield, in general, overlapping hydrids of the same atom – a mathematically unobjectionable but a chemically unpleasant result. The adoption of a localization criterion more in line with the tenets of the elementary theory of valency is the subject of work in progress.

The coefficients c_N of the CAO's of nitrogen are listed in the first part of Table 5 for the three relevant bases. In all cases, the c_N values for a given Boys bond orbital are fairly close to one another. This is satisfactory because it confirms first-order transferability of at least the atomic orbital coefficients. That the 6-311 H basis should give the least transferable values is in line with the claim that it is not well balanced.

Of course, complete transferability would be in contrast with the well-known existence of inductive effects: thus, the modest and quite regular changes in the c_N's along the series are acceptable. It is also interesting that the weights of nitrogen in the NH and NC bonds are very close to one another, except in the unbalanced basis 6-311 H. This supports to some extent the naïve idea that the coefficients with which atoms enter bonds are related to electronegativities. The electronegativities of carbon and hydrogen being close to each other, the c_N's must also be close.

The lone pair AO's should carry weight 1. That this is not the case depends, of course, on "non-bonding" couplings. We can, in a way, see in the deviation a measure of the transferability to be expected in the coefficients of AO's: in the best basis it is of the order of 4%, which corresponds to the dispersion of the values for the NH and NC bonds.

The third part of Table 5 shows the overall coefficients of H. The greater flexibility of the hydrogen subset in 6-31 H and 6-311 H is evident from the variation of the coefficients along the series but, once again, 6-31 H is physically much more satisfactory. Note also that with 6-31 H the coefficients of H (as well as those of N) increase as the *p*-characters, *n*, of the nitrogen hydrids (discussed below) decrease. This should correspond to a slight decrease in the "bond charge" due to the inductive effect of the methyl group.

We come now to hybridization. The *p*-characters indicated in Table 5 are particularly instructive. On the one hand, the 6-31 H basis yields the most regular set of values, thus indicating that the extension of the hydrogen basis has cured 6-31G* of its main shortcomings. It is also evident that the values deduced from 6-311 H are ill-behaved. On the other hand, the hybrids obtained are obviously not orthogonal. Indeed, the property that the sum of $1/(1 + n)$ for the four hybrids should give unity is certainly not satisfied with any basis. Now, even though a theoretical justification of the orthogonality requirement on hybrids is not immediate, the importance of that requirement in determining the direction of, say, equivalent hybrids is well known. The difficulty, of course, lies with Boys' localization criterion, which should be replaced by another one if the scheme of the elementary theory of valence is to be followed. At any rate, the 6-31 H basis does give the expected results for the binding orbitals of nitrogen (almost tetrahedral hybrids) and consistently with the other bases indicates that nitrogen polarization is slightly higher in the NH bond than in the NC bond. Also the lower *p*-character of the lone-pair hybrids is in line with results from hybridization theory (13).

In addition to the orthogonality problem, the difference in the radial parts of the *s* and *p* components also makes somewhat delicate the application of the standard concept of hybridization (9). In any case, all the considerations given here hold for distances where the radial parts of the components are approximately equal – which is well within the physically significant range.

Finally, the last part of Table 5 (d) contains information concerning the role of the basis set added to hydrogen in passing from 6-31G* to 6-31 H (on NH bonds only). They are the coefficients c_s, c_p of the normalized additional *sp* hybrids contracted to a single *s* orbital and a single *p* orbital, and the overall coefficient d_H of the distortion–polarization subset in question. Whereas d_H decreases regularly in the series, the interplay of polarization and distortion is less regular. This is obviously due to the combination of the inductive and through-space effects of the methyl groups.

Conclusion

The above discussion shows first of all that an adequate treatment of hydrogen is much more important than brute force basis extension in the description of organic molecules. This is a comforting conclusion because it confirms other indications that a physically satisfactory basis need not necessarily be too large.

Secondly, the comparatively small 6-31 H basis optimized with respect to hydrogen yields a description of the valence orbitals of nitrogen that is clearly in line with customary chemical intuition.

Of course, additional work is necessary. In particular, the hydrogen basis set can probably be further simplified while retaining its flexibility and the localized orbitals used to obtain the valence orbitals should satisfy criteria other than that of Boys. A detailed analysis of the radial distortion could also yield information about the optimal way of improving the basis sets.

It seems to us, at any rate, that the results and the type of analysis described in this paper should be kept in mind by all those trying to use *ab initio* SCF calculations for interpreting the chemical properties of relatively large molecules.

As concerns the methylamines, in particular, we emphasize, among other things, the result that the net charges of nitrogen appear to be almost invariant under substitution of hydrogen with a methyl group – a situation somewhat reminiscent of similar findings for alkane carbon atoms (5*a*).

Acknowledgements

This article is dedicated to Professor Camille Sándorfy for his 65th birthday. It is a welcome opportunity for Sándor Fliszár and Giuseppe Del Re to express to him their gratitude for the constant encouragement and invaluable advice received from him for many years. We are also greatly indebted to Dr. J. Andzelm for extremely useful advice on Gaussian basis sets and thank Dr. J. Bridet for assistance in the computations. G. DR. acknowledges the hospitality of the Departments of Chemistry, Université de Montréal and of Applied Mathematics, University of Waterloo. Support received from the National Research Council of Canada, the France-Québec exchange program, and from the Italian Research Council, CNR, (G. DR) is also gratefully acknowledged, as well as the cooperation offered by Le Centre de Calcul de l'Université de Montréal.

Reçu le 30 juillet 1984

Cet article est dédié au Professeur Camille Sandorfy à l'occasion de son 65^e anniversaire

MARIE-HÉLÈNE HERZOG-CANCE, ANTOINE POTIER et JACQUELINE POTIER. Can. J. Chem. **63**, 1492 (1985).

L'étude spectroscopique ir et Raman de HNO_3 dans les états cristallisé et liquide a été entreprise afin de régler le problème de l'autodissociation de cet acide. On a ainsi identifié l'oligomère en chaîne $(HNO_3)_x$, des ions NO_2^+ et $(NO_3 \cdot 3HNO_3)^-$, du monohydrate sous deux formes: la paire ionique $H_2OH^+ \ldots ONO_2^-$ et l'association moléculaire $H_2O \ldots HONO_2$ et enfin très peu d'ions H_3O^+.

MARIE-HÉLÈNE HERZOG-CANCE, ANTOINE POTIER, and JACQUELINE POTIER. Can. J. Chem. **63**, 1492 (1985).

The ir and Raman spectra of solid and liquid anhydrous HNO_3 have been investigated for the purpose of solving the self-dissociation problem. Identified species are: the oligomer $(HNO_3)_x$ (chains), NO_2^+ and $(NO_3 \cdot 3HNO_3)^-$ ions, two monohydrate forms: the ionic pair $H_2OH^+ \ldots ONO_2^-$ and the molecular association $H_2O \ldots HONO_2$, and, finally, some free H_3O^+ ions.

Introduction

Le problème de l'autoprotolyse de l'acide nitrique absolu liquide a fait, il y a bien longtemps, l'objet de nombreux travaux et en particulier, ceux de Gillespie *et al.* (1) et de Lee et Millen (2). Il a été établi que l'autodissociation thermodynamique pouvait s'écrire:

[1] $2HNO_3 \rightleftharpoons NO_2^+ + NO_3^- + H_2O$

De plus la cryoscopie autour de l'acide nitrique (2) a conduit à considérer que les ions nitrate et nitryle (nitronium) étaient solvatés par un total de 4 molécules d'acide nitrique et que l'eau l'était par 2 autres. Des considérations basées sur les connaissances du moment ont permis de proposer une solvatation de 2 pour NO_3^- et donc de 2 pour NO_2^+.

En 1956, Wyatt (3) a préféré proposer un équilibre d'autodissociation faisant apparaître $HNO_3 \cdot H_2O$, NO_2^+ et $NO_3^-(HNO_3)_2$.

Cependant à l'époque le manque normal de données spectroscopiques n'avait pas permis d'aller plus loin et il est bien clair que la cryoscopie, si elle permet de dénombrer le degré de solvatation des espèces d'une solution, est d'un intérêt limité pour l'identification des espèces réellement présentes. D'ailleurs l'équilibre [1] lui-même n'avait été écrit qu'après reconnaissance spectroscopique des espèces par Ingold et Millen (4).

Belin et Potier (5) ont étudié l'autoassociation de HNO_3 en solvant inerte par spectroscopie de vibration ir et abaissement cryoscopique, ils ont montré ainsi la formation unique de polymères $(HNO_3)_x$ ouverts.

Les études spectroscopiques faites récemment sur les composés $HNO_3 \cdot H_2O$[2] (6) et $4HNO_3 \cdot H_2O$[2] (7) dans le verre et le liquide ont permis de trouver les espèces existantes dans ces deux états désordonnés, les interprétations n'ont été possibles pour le 4:1 qu'après avoir montré que le cristal est le trihydrogénotétranitrate d'oxonium: $H_3O^+(NO_3 \cdot 3HNO_3)^-$. On peut donc penser que les mêmes techniques permettraient de faire avancer le problème des espèces réellement présentes dans l'acide nitrique absolu. Dans cette optique, il est clair que les recherches précédentes (6, 7), devraient être d'un précieux secours ne serait-ce que parce que l'ion $(NO_3 \cdot 3HNO_3)^-$ présent dans des solutions très concentrées en acide nitrique peut être soupçonné d'exister encore dans l'acide absolu.

Par ailleurs, depuis les travaux de l'école d'Ingold, peu de progrès ont été faits sur le spectre de l'espèce HNO_3 dans l'acide absolu puisqu'on ne peut citer que le travail de MacGraw *et al.* (8) sur la vapeur, leur exploration très partielle du liquide et du solide, et le travail de Guillory et Bernstein (9) sur HNO_3 isolé en matrice. Il est donc apparu nécessaire de commencer la présente étude par l'acide nitrique cristallisé dont une image plus ou moins déformée pouvait apparaître dans le liquide. Pour cette raison nous avons malgré l'ancienneté de la structure établie par Luzzati (10) tenté de la concilier avec les spectres que nous avons obtenus.

Il faut souligner que, comme les précédentes (6, 7), cette recherche est en grande partie une étude du comportement de la liaison hydrogène en relation avec les propriétés de donneur ou d'accepteur des molécules constituant les supermolécules recontrées.

Ceci doit permettre d'avoir une idée plus nette de la nature de l'autoprotolyse de la molécule amphiprotique HNO_3.

L'acide nitrique cristallisé

La seule détermination structurale est celle de Luzzati (10) en 1951. Ce travail ancien a été, avec les possibilités de l'époque, réalisé sur un monocristal mâclé, cependant son auteur a pu proposer le groupe d'espace $P2_1/c(C_{2h}^5)$ avec les paramètres suivants: a = 16,23; b = 8,57; c = 6,31 Å et β = 90°. Ceci impose 16 molécules dans la maille tandis que l'unité asymétrique n'en comporte que quatre.

Les différentes distances NO obtenues dans ces conditions sont $d_{N-OH} = 1{,}30 \pm 0{,}045$ Å et $d_{N-O} = 1{,}24 \pm 0{,}025$ Å. Les molécules d'acide nitrique s'organisent en chaîne qui se correspondent par un centre d'inversion. Cette structure est à rapprocher de celle trouvée pour CH_3COOH (11) ou $NaHCO_3$ (12, 13) par exemple.

Les travaux de spectroscopie de vibration ont été plus nombreux (8, 9, 14, 15) mais aucun n'a été fait en s'appuyant sur la structure proposée par Luzzati.

Sur les figures 1 et 2 sont représentés les spectres ir des acides hydrogéné et deutérié et les tracés de certains domaines

[1] Auteur à qui toute correspondance doit être adressée.
[2] Appelés respectivement 1:1 et 4:1 dans ce travail.

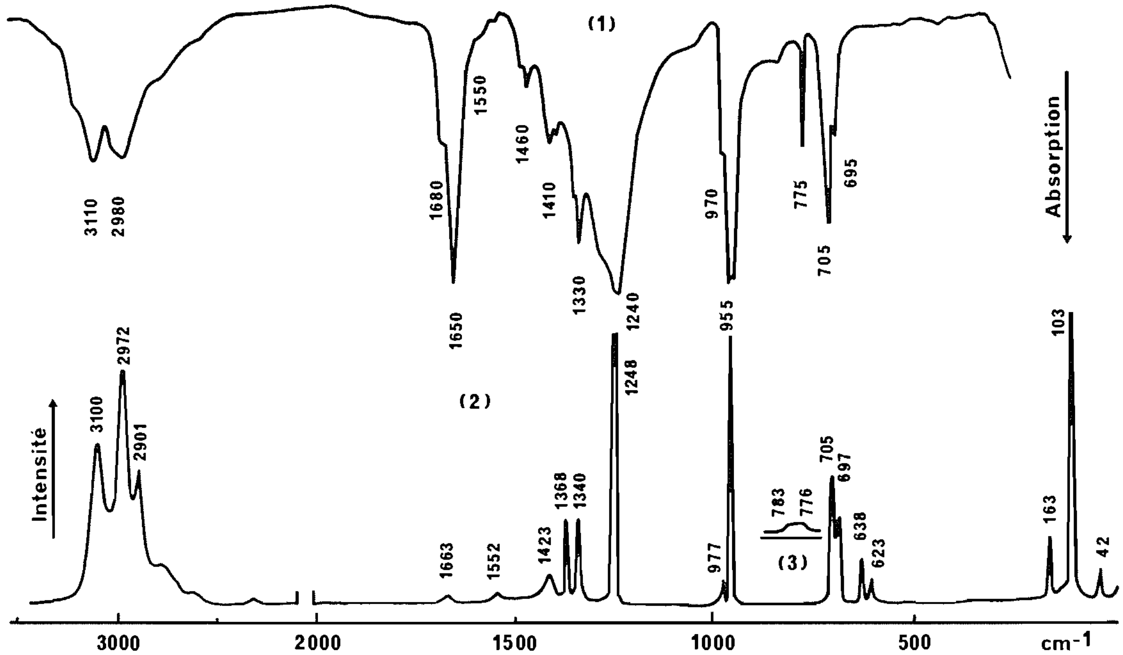

FIG. 1. HNO_3 cristal: spectres ir (1) et Raman (2).

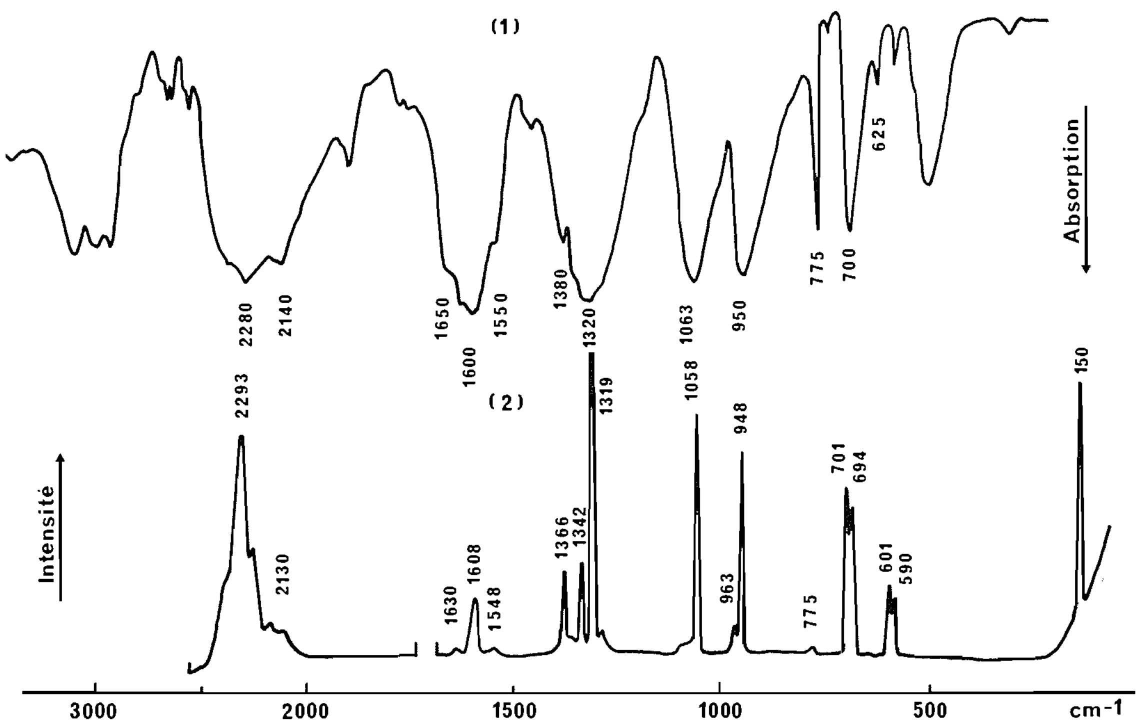

FIG. 2. DNO_3 cristal: spectres ir (1) et Raman (2).

les plus caractéristiques observés en Raman. On remarque leur complexité.

Pour la molécule HNO_3 de symétrie C_s on attend 9 vibrations (7 A' et 2 A''). Si on tient compte des 16 molécules par maille on attend 237 modes de vibration soit:

pour les vibrations internes: 32 Ag + 39 Au + 40 Bg + 30 Bu

pour les rotations: 16 Ag + 8 Au + 8 Bg + 16 Bu

pour les translations: 16 Ag + 8 Au + 8 Bg + 16 Bu

La complexité du spectre ne permet pas de prévoir l'ensemble, ce qui paraît d'ailleurs peu raisonnable.

Si on essaie de raisonner avec l'unité asymétrique proposée par Luzzati, et de symétrie C_{2h}, on arrive à 57 vibrations:

pour les vibrations internes: 12 Ag + 6 Au + 6 Bg + 12 Bu

pour les rotations: 4 Ag + 2 Au + 2 Bg + 4 Bu

pour les translations: 4 Ag + 1 Au + 2 Bg + 2 Bu

ce qui paraît être plus abordable.

Avec ce mode de raisonnement, on voit que chaque vibration de HNO_3 donnera deux composantes actives en ir et deux en Raman.

On peut cependant proposer une autre analyse basée sur l'analogie avec $(HCO_3^-)_x$ dans le sel de sodium (12).

Cette dernière repose sur l'hypothèse que les couplages interchaînes seront faibles voire non existants. Dans ces conditions on analyse les spectres en ne prenant en compte qu'une chaîne $(HNO_3)_x$ de symétrie C_{2v}. Par ailleurs si on prend en compte les éléments de symétrie du cristal on peut décrire les mouvements de ce polymère (16) en analysant ceux du dimère $(HNO_3)_2$ comme cela a été fait pour $(HCO_3)_x$ dans $NaHCO_3$ par la réf. 12.

On attend alors, en ir et en Raman, deux composantes pour chaque vibration interne sauf pour les vibrations d'espèce A'' qui ne donnent qu'une composante en ir.

Le choix entre ces deux modes de raisonnement n'est pas que subjectif puisque, dans la première analyse, on doit noter une activité sélective ir et Raman et que de ce fait les fréquences observées doivent être, au moins dans la majorité des cas, différentes.

Dans une première étape, on peut retenir que, quelle que soit l'hypothèse choisie, on attend deux composantes pour les vibrations d'espèce A'.

On peut donc essayer d'interpréter le spectre.

Domaine des vibrations de valence: ν OH (2000–4000 cm⁻¹)

On relève sur le spectre ir du composé hydrogéné deux bandes importantes à 3110 et 2980 cm^{-1} tandis qu'en Raman on observe essentiellement deux raies à 3100 et 2972 cm^{-1}. Les composantes de DNO_3 sont relevées en ir à 2280 et 2140 cm^{-1} (avec des rapports isotopiques de 1,36 et 1,39) et en Raman à 2293 et 2130 cm^{-1} (avec ρ = 1,36 et 1,39).

On note au passage la différence d'intensité pour la seconde composante en Raman.

Par ailleurs, il ne faut pas négliger les différents épaulements observés tant en ir qu'en Raman et attribuables tout au moins partiellement à des harmoniques ou des combinaisons.

Sur le spectre partiellement deutérié, on remarque la présence de trois bandes de même intensité sur lesquelles nous reviendrons un peu plus loin. La fréquence moyenne de ν OH (≃3050 cm^{-1}) conduit, en référence à la courbe de Novak (17), à une distance $d_{O\ldots O}$ comprise entre 2,64 et 2,66 Å alors que Luzzati indique $d_{O\ldots O}$ = 2,87 Å en moyenne.

Domaine des vibrations de valence asymétriques: ν_{as} NO_2 (1500–1700 cm⁻¹)

On observe dans ce domaine sur le spectre ir de HNO_3 cristallisé une composante à 1650, un épaulement à 1680 cm^{-1} et une autre composante très faible à 1550 cm^{-1} tandis qu'en Raman apparaissent une raie à 1663 cm^{-1} avec un épaulement à plus haute fréquence et une raie d'intensité plus faible (mais toutefois plus intense qu'en ir) à 1542 cm^{-1}.

Pour l'homologue deutérié, on observe les mêmes composantes avec un déplacement vers les basses fréquences dû à un effet secondaire de la deutériation.

Si on ne tient compte que des raies et bandes les plus importantes, les deux modes d'analyses envisagés sont corrects.

Domaine des vibrations de valence symétriques: ν_s NO_2 (1200–1500 cm⁻¹)

Ce domaine est très sensible à la deutération puisque la bande (ou raie) la plus intense (1240 cm^{-1}) se déplace alors de +70 cm^{-1} (tableau 1). Cette évolution est la preuve d'un couplage entre la vibration ν_s NO_2 et la vibration du mode de déformation δ OH dû à la formation de la chaîne. On observe effectivement dans le spectre de DNO_3 la disparition de la bande (ou raie) à 1410 cm^{-1} (1423 cm^{-1}) tandis qu'apparaissent à 1058 cm^{-1} (Raman) et 1063 cm^{-1} (ir) une raie et une bande relativement intenses. Au passage signalons que ce mode de vibration est observé par Guillory et Bernstein (9) à 1343 cm^{-1} dans le monomère et à 1398 cm^{-1} dans le dimère. Ce glissement de +67 cm^{-1} semble logique et correspond au glissement de −440 cm^{-1} observé pour ν OH.

Pour éviter l'interférence δ OH − ν_s NO_2, on peut analyser le spectre de DNO_3; on y relève, en Raman, quatre raies d'inégales intensités à 1297; 1319; 1342 et 1366 cm^{-1} (en ir à 1320; 1350 et 1380 cm^{-1}). Les composantes supplémentaires sont dues soit à des harmoniques soit à des combinaisons avec les modes de vibration par effet de corrélation; dans ce dernier cas il convient d'espérer une autre détermination structurale.

Domaine 800–1200 cm⁻¹

Dans ce domaine, on attend pour $(HNO_3)_x$ essentiellement ν N(OH) (= ν NO').

Nous ne reviendrons pas ici sur le choix d'attribution proposé par Diop et Potier (18) et confirmé par Guillory et Bernstein (9).

Cette bande apparaît à 955 cm^{-1} (953 en Raman) mais cependant elle n'est pas unique comme on le voit sur la figure 1. La deutériation simplifie la bande ir; on n'observe qu'une composante principale à 950 cm^{-1} mais simultanément apparaît une bande à 740 cm^{-1}. Ceci conduit à attribuer une des deux bandes autour de 950 cm^{-1} à γ OH $(HNO_3)_x$. (On note un glissement de fréquence de −5 cm^{-1} dû à l'effet de la deutériation (Fig. 2).)

Pour ν NOH la présence d'une raie intense et d'une plus faible à 977 cm^{-1} (Raman) est toujours compatible avec le mode de raisonnement adopté.

Domaine 800–700 cm⁻¹

On doit trouver essentiellement, dans ce domaine, les vibrations de déformations de NO_2 et de l'angle ON(OH). Les éclatements y sont plus faibles, ils apparaissent cependant en Raman où la résolution est meilleure. Pour ρ NO_2 (783–776 cm^{-1} en Raman; 775 en ir), il semble qu'on ait la preuve que dans le cristal HNO_3 tout se passe comme si, seul intervenait dans le dénombrement des modes de vibration, le motif $(HNO_3)_2$.

Il n'est pas utile de discuter de façon détaillée les attributions; elles sont reportées dans le tableau 1 et ne s'écartent pas des attributions classiquement proposées.

Domaine des vibrations de réseau

On observe en Raman trois vibrations de réseau à 42,103 et 163 cm^{-1}. On peut penser comme Hadzi *et al.* (19) que la vibration à 163 cm^{-1} correspond à un mode de liaison hydrogène.

En conclusion, il semble que l'analyse des données spectroscopiques ne prenant en compte que l'unité asymétrique soit correcte. Cependant il reste le problème des trois composantes ν OH d'égale intensité observées en ir dans le composé partiellement deutérié et la présence en Raman de trois composantes dans $(HNO_3)_x$ ou $(DNO_3)_x$. Il n'est guère possible d'attribuer une de ces trois bandes à une combinaison. L'égalité de leur intensité conduirait à les attribuer à 3 vibrations O—H—O d'inégale longueur ainsi que le propose Luzzati. Ce dernier a trouvé des liaisons hydrogène de 2,84 à 2,98 Å, ce qui correspondrait selon la courbe de Novak (17) à des fréquences ν OH de 3400 à 3500 cm^{-1}. Les différentes fréquences observées ici conduisent à des distances de 2,66 à 2,64 Å, soit des différences de distances O...O comparables. Signalons que Rozière *et al.* (20, 21) ont réinterprété pour $[NO_3 . HNO_3]^-$ les

analyses structurales et, en introduisant un désordre ont amené la distance O...O de 2,85 (22) à 2,44 Å.

L'acide nitrique liquide

Comme nous l'avons vu en introduction, l'équilibre d'auto-dissociation de l'acide proposé par Ingold et coll. (1) fait apparaître des ions NO_2^+ (solvatés par deux molécules d'acide nitrique), l'ion dihydrogénotrinitrate et de l'eau elle aussi solvatée par deux molécules d'acide.

Depuis ce travail, Leuchs et Zundel pour HNO_3-H_2O (23) et nous mêmes pour $HNO_3 \cdot H_2O$ et $4HNO_3 \cdot H_2O$ (6, 7) avons montré que l'interaction H_2O – acide nitrique correspondait à la réaction acide–base sans transfert de proton: $H_2O \cdots HONO_2$ avec l'oxygène de la molécule d'eau comme centre basique plutôt qu'à la création de l'entité $H_2O(HNO_3)_2$.

Il faut aussi rappeler que HNO_3 dans un solvant neutre (5) est dissocié à grande dilution en donnant le monomère caractérisé par une bande à 3484 cm^{-1} avec une constante d'anharmonicité selon Sandorfy (24) $X_{12} = 64$; $X_{23} = 80$; $X_{13} = 72$ tandis que pour HNO_3 anhydre on observe $X_{12} = 43$; $X_{23} = 93$ et $X_{13} = 68$ ce qui permet d'éliminer l'hypothèse de la présence unique de monomère. Et ce d'autant plus que la vibration OH du polymère ouvert est observée à la même fréquence que le monomère (25).

Par ailleurs, une étude des abaissements cryoscopiques en solvant inerte avait conduit Belin et Potier (5) à n'admettre que la présence de polymères ouverts. Notons également que ces auteurs n'ont pas envisagé pour HNO_3 liquide la présence possible de plusieurs espèces liées à la formation de l'équilibre d'auto déshydratation.

Présence de l'ion NO_2^+

Ce travail confirme sans ambiguïté la présence de l'ion NO_2^+ (avec ν_s = 1399 cm^{-1} en Raman et ν_{as} = 2330–2360 cm^{-1}; δ_{deg} = 550 cm^{-1} et $\nu_s + \nu_{as}$ = 3740 cm^{-1} en ir).

Sur la figure 3 on voit que les fréquences relevées pour cet ion s'intègrent parmi les fréquences relevées pour des ions NO_2^+ libres comme l'ont montré des études structurales. L'absence de tout abaissement de fréquence notamment pour ν_s

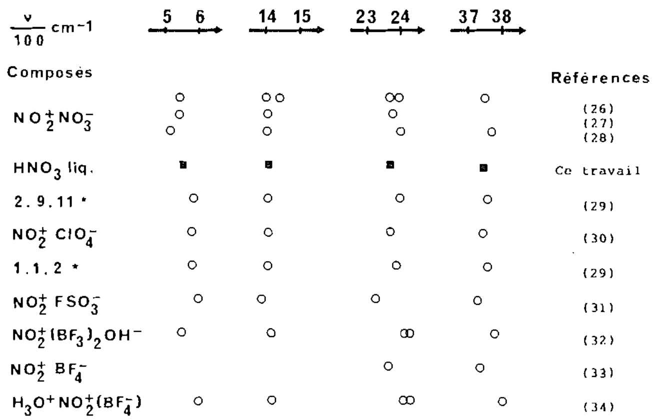

FIG. 3. Evolution des fréquences caractéristiques de l'ion NO_2^+ dans différents sels de nitryle (× 2.9. 11 = $(H_3O^+)_2(NO_2^+)_9(ClO_4^-)_{11}$ et 1.1.2 = $H_3O^+ NO_2^+(ClO_4^-)_2$).

(NO_2^+) **permet de ne pas retenir l'hypothèse d'une solvatation de ce cation par deux molécules d'acide nitrique.**

Recherche de l'ion $(NO_3 \cdot 2HNO_3)^-$

Il apparaît normal de rechercher la présence potentielle de cet anion qui a été caractérisé tant par diffraction de rayons X (35) que par spectroscopie de vibration (18) dans la série des dihydrogénotrinitrates, $MNO_3 \cdot 2HNO_3$ (M = K^+, NH_4^+, Cs^+, Rb^+...).

Sur les spectres de Potier et Diop (18) on peut noter quelques bandes ou raies caractéristiques de l'anion $(NO_3 \cdot 2HNO_3)^-$ en particulier, la présence de la liaison hydrogène de 2,60 Å entraîne celle d'une bande large à 2500 cm^{-1}. Un autre fait spécifique de cet anion est l'existence à côté de la raie à 1312 cm^{-1} d'une raie d'égale importance à 1367 cm^{-1} liée à la solvatation de l'ion nitrate par deux molécules HNO_3 et à la présence d'un vibrateur NO libre.

L'absence de la bande à 2500 cm^{-1} et de la raie à 1367 cm^{-1} dans les spectres de HNO_3 dans l'état liquide permet sans ambiguïté de réfuter la formation de cet anion dans l'acide nitrique anhydre. Une conclusion semblable avait été proposée lors de l'analyse des spectres du 4:1 et de 1:1 dans les états désordonnés (6, 7).

Domaine des vibrations de valence ν NOH (ν NO′)

Ayant montré la présence d'un ion NO_2^+ non solvaté et l'absence de $(NO_3 \cdot 2HNO_3)^-$, il reste à rechercher les espèces responsables de la complexité des spectres. Comme cela a été fait pour le 4:1 et le 1:1 (6, 7), on étudie en premier lieu le domaine des vibrations ν NO′ où peuvent apparaître différents types de vibrateurs.

Une première analyse du spectre Raman (Fig. 4) montre que HNO_3 liquide a un comportement comparable à celui de 4:1 liquide et que la raie centrée autour de 940 cm^{-1} est complexe. Il semble logique de lier ici l'apparition des différentes composantes, à l'existence de divers vibrateurs ν NO′. On remarque toutefois des variations d'intensité quand on passe de HNO_3 au 4:1.

On peut penser que dans les deux cas, les mêmes modes de vibrations sont responsables des raies ou bandes observées à des fréquences proches. Dans le tableau 2, on a rassemblé les attributions proposées en fonction de cette hypothèse de travail; ceci permet d'envisager la présence:

de l'ion trihydrogénotétranitrate $(NO_3 \cdot 3HNO_3)^-$

de l'association moléculaire $H_2O \cdots HONO_2$

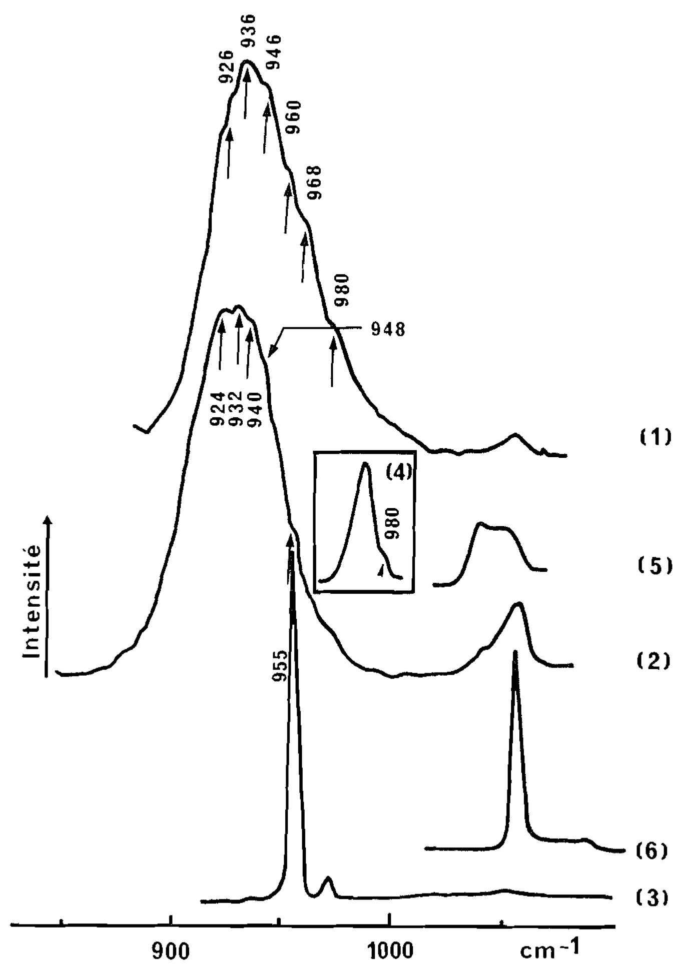

FIG. 4. Spectres Raman entre 850 et 1050 cm^{-1}: (1) $4HNO_3 \cdot H_2O$ liquide, (2) HNO_3 liquide, (3) HNO_3 cristal, (4) HNO_3 liquide: épaulement à 980 cm^{-1}, (5) DNO_3 liquide autour de 1050 cm^{-1}, (6) HNO_3 cristal autour de 1050 cm^{-1}.

d'acide nitrique "libre"

(Bien entendu il faut que l'analyse des autres domaines de fréquence corrobore ces attributions.)

Plus précisément on relève sur la spectre Raman enregistré à −35°C (liquide froid) un épaulement à 980 cm^{-1} noyé dans la plupart des autres spectres, dans le pied de la raie autour de 940 cm^{-1} (fig. 4(4)). Cette composante est à rapprocher de celle attribuée à ν NO′ de la liaison hydrogène centrale de $(NO_3 \cdot 3HNO_3)^-$. Ceci est une des premières indications de la présence de cette espèce dans HNO_3 liquide et justifie la recherche des autres espèces susceptibles d'exister (tableau 2).

En plus de ces composantes, on trouve pour HNO_3 liquide, une vibration ν NO′ à 950 cm^{-1} absente dans le 4:1 et le 1:1. Cette fréquence est à rapprocher de celle observée dans le cristal où les molécules d'acide nitrique forment le polymère ouvert $(HNO_3)_x$. Le déplacement de fréquence traduit un affaiblissement de la liaison hydrogène qui peut être lié à un effet de température.

Domaine des vibrations de valence ν OH (4000–2000 cm^{-1})

Sur la figure 5 on a regroupé les tracés ir du 4:1, de HNO_3 et DNO_3 liquide. On note, mis à part des différences au niveau des fréquences des ν OH, une allure similaire avec apparition des bandes A, B et C caractéristiques des liaisons hydrogène. Il semble logique d'attribuer ce comportement, comme dans le

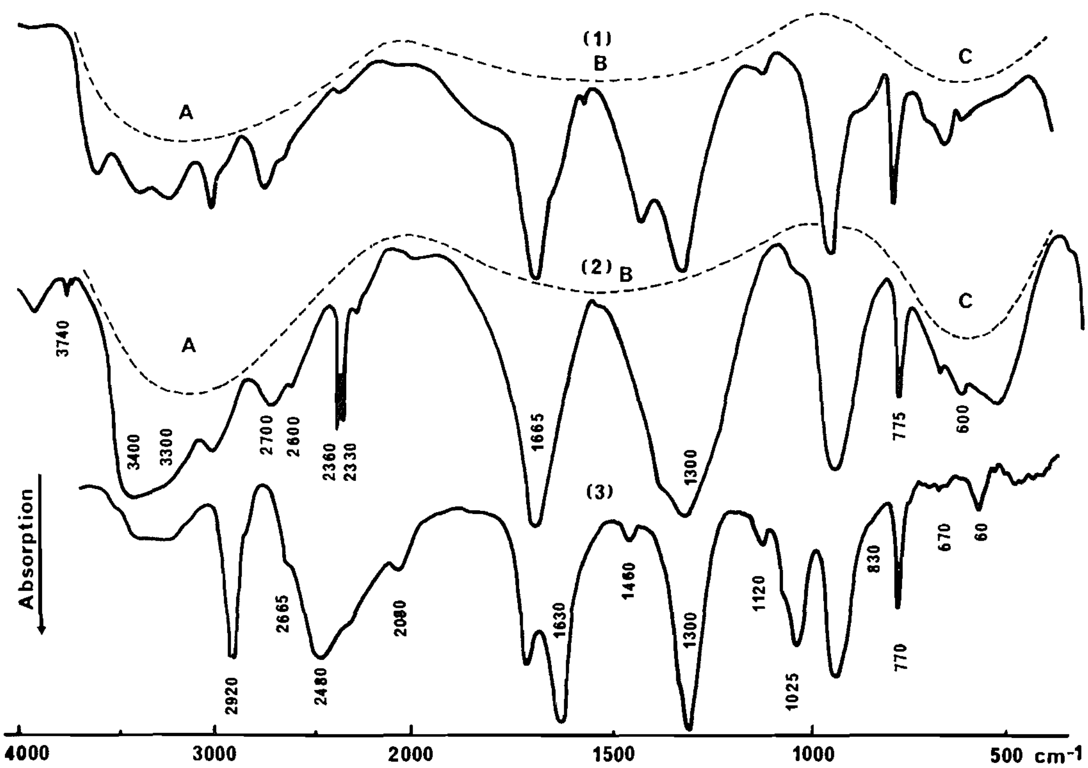

FIG. 5. Spectres ir de $4HNO_3 \cdot H_2O$ liquide (1), HNO_3 liquide (2) et DNO_3 liquide (3).

4:1, à la présence d'une liaison hydrogène moyennement forte centrée autour de 1500 cm^{-1} due à la même espèce: l'ion $(NO_3 \cdot 3HNO_3)^-$ dont la vibration ν NO′ est observée à 980 cm^{-1}.

Cependant, traditionnellement la recherche des autres espèces est effectuée sur les spectres Raman souvent mieux résolus. Sur la figure 6 sont reportés les spectres Raman de HNO_3 et du 4:1 dans l'état liquide. On y relève trois domaines principaux de vibration autour de 3350, 3050 et 2650 cm^{-1}, les intensités des deux derniers sont plus faibles que dans le 4:1.

Comme pour le 4:1, le massif large centré autour de 2650 cm^{-1} correspond aux vibrations ν OH (H_3O^+) de la paire ionique. De même on retrouve ν OH (HNO_3) de l'association moléculaire $H_2O\ldots HONO_2$ autour de 3020 cm^{-1} tandis que ν_s et ν_{as} (H_2O) de cette association apparaissent à 3545 cm^{-1} en épaulement au massif large entre 3100 et 3500 cm^{-1} (il convient de noter que dans le 1:1 (6) l'intensité de cette raie est particulièrement importante).

En ir (fig. 5) sur le spectre de HNO_3 deutérié, on observe comme pour le 4:1, la présence d'une bande fine à 2920 cm^{-1} qui glisse par deutériation à 2080 cm^{-1}. Cette bande n'existe pas sur le spectre ir de HNO_3; à sa place on observe une fenêtre de transmission d'Evans (due à 2 δ OH) comme nous l'avions déjà noté et discuté pour le 4:1.

Bien qu'une analyse quantitative des variations d'intensité ne soit pas possible, on peut remarquer cependant, comme sur les spectres Raman, une diminution des intensités des bandes caractéristiques des espèces $H_2O\ldots HONO_2$ et $H_2OH^+\ldots ONO_2^-$ quand on passe de 4:1 à HNO_3; en particulier le rapport ν OH $(H_2OHONO_2)/\nu_{as}NO_2$ est de 0,45 dans le 4:1 et n'est que de 0,33 pour HNO_3.

Dans le 4:1 on a attribué à HNO_3 "libre", une raie à 3280 cm^{-1}, ici on retrouve une raie à 3330 cm^{-1}; on peut penser qu'elle provient de la présence d'acide nitrique "libre", sa

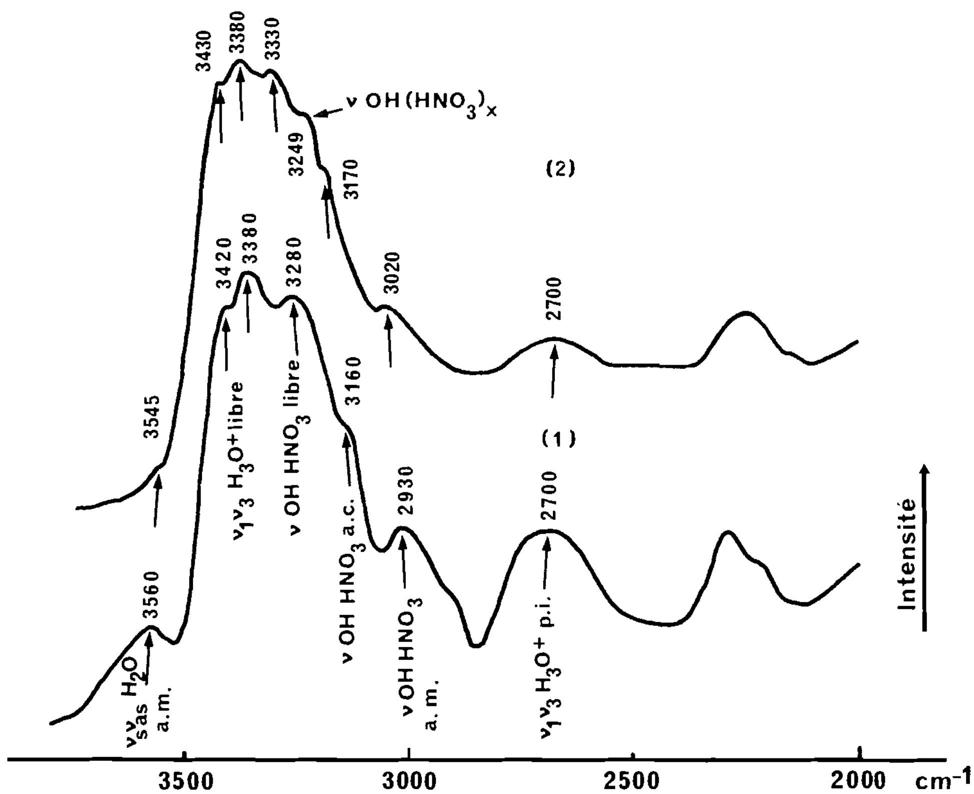

FIG. 6. Spectres Raman de $4HNO_3 \cdot H_2O$ liquide (1) et HNO_3 liquide (2) entre 2000 et 4000 cm^{-1} (a.c. = anion complexe; a.m. = association moléculaire; p.i. = paire ionique).

fréquence est plus élevée à cause de l'affaiblissement des liaisons hydrogène par rapport à celles du cristal. On remarque que dans le spectre HNO_3 liquide, la raie relative à ν OH (HNO_3) libre est plus intense que dans le 4:1 ce qui est tout à fait logique et que sa fréquence y est plus élevée (+50 cm^{-1}). Ce glissement de fréquence de 50 cm^{-1}, général quand on passe de 4:1 à HNO_3 amène quelques commentaires. Dans le gaz en matrice Bernstein a observé ν OH à 3490 cm^{-1} tandis qu'il a noté pour le dimère 3280 cm^{-1} (9). Il semble que ce que nous appelons acide nitrique "libre" est en réalité **un acide déjà engagé dans une liaison hydrogène très faible**; comme Belin et Potier l'on déjà indiqué (5) pour la suite de ce mémoire, nous garderons le terme "HNO_3 libre".

La raie à 3170 cm^{-1} qui se déplace à 2336 cm^{-1} par deutération est comparable à celle qui est observée à 3160 cm^{-1} dans le 4:1 et est attribuée à ν OH (HNO_3) terminal de l'anion complexe.

Ayant confirmé la présence de l'anion complexe $(NO_3 \cdot 3HNO_3)^-$ il importe de rechercher l'existence d'ions H_3O^+ libres. Il semble que l'on puisse attribuer à ν_1 et ν_3 H_3O^+ les vibrations observées à 3380 et 3430 cm^{-1} en Raman (3380 et 3420 cm^{-1} en ir) qui se déplacent par deutération (ρ = 1,37). Dans ce domaine de fréquences sont également attendus les vibrateurs ν OH de HNO_3 monomère et ν OH terminaux du polymère ouvert.

Reste à examiner le cas du vibrateur ν OH à 3250 cm^{-1}, ce vibrateur est absent dans le 4:1; il semble justifié de l'attribuer au vibrateur OH engagé du polymère $(HNO_3)_x$ observé dans HNO_3 cristal. Sa fréquence supérieure à celle relevée dans ce dernier (3110 cm^{-1}) indique un affaiblissement des liaisons hydrogène de ce polymère ou une dépolymérisation partielle mais est aussi lié à un effet de température.

La variation des fréquences des diverses vibrations ν NO′ et ν OH quand on passe de HNO_3 à $4HNO_3 \cdot H_2O$ et $HNO_3 \cdot H_2O$ est reportée sur la figure 7.

Domaine des vibrations de valence ν_s et ν_{as} NO_2

L'ensemble des attributions proposées dans le domaine des vibrations de valence ν_s et ν_{as} NO_2 est reporté dans le tableau 3. On doit souligner qu'en ir on observe deux composantes à 1300 et 1350 cm^{-1}. De plus on remarque la disparition du déplacement de ν_s NO_2 sous l'effet de la deutération.

La présence de la raie à 1380 cm^{-1} dans DNO_3, absente sur le spectre du 4:1 semble difficilement attribuable à une harmonique mais paraît plutôt due à une des composantes du polymère $(HNO_3)_x$.

Domaine entre 1000 et 700 cm^{-1}

Si les espèces apparemment détectées jusqu'à maintenant sont réellement présentes, on attend dans HNO_3 autour de 1000 cm^{-1} ν_2 (H_3O^+) et en plus en Raman ν_1 NO_3^- de la paire ionique, tandis que pour DNO_3 on doit retrouver les déformations δ OD de HNO_3 "libre", δ OD du (ou des) polymères et enfin ν_1 NO_3^-.

En ir, si on compare au spectre de HNO_3 cristal, on observe ici une bande de très faible intensité (1050 cm^{-1}). Tandis que, si dans DNO_3 cristal on note une bande à 1065 cm^{-1}, pour DNO_3 liquide on n'observe qu'une bande large à 1025 cm^{-1} avec un épaulement à 1055 cm^{-1} et par ailleurs un épaulement à 830 cm^{-1}, épaulement absent sur le spectre de HNO_3 liquide ce qui conduit à y voir ν_2 H_3O^+ et ν_2 D_3O^+ (ρ = 1,27).

En Raman (fig. 4), les modifications rencontrées quand on passe de HNO_3 à DNO_3 sont plus importantes (on rappelle que dans HNO_3 cristal il n'y a qu'une raie dans ce domaine, fig. 4 (6)). On voit pour HNO_3 une raie fine à 1055 cm^{-1} avec un

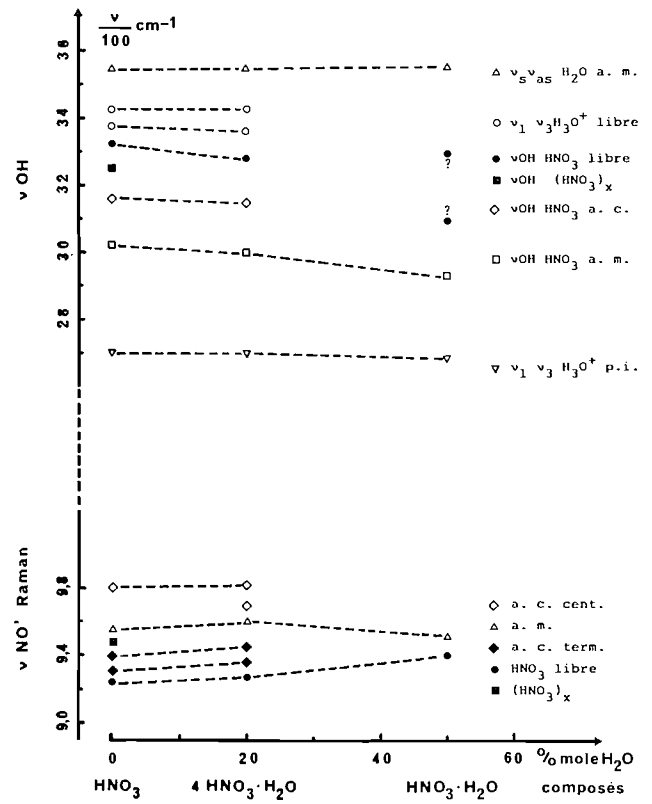

FIG. 7. Variation des fréquences des vibrateurs ν NO' et ν OH entre HNO_3, $4HNO_3 \cdot H_2O$ et $HNO_3 \cdot H_2O$.

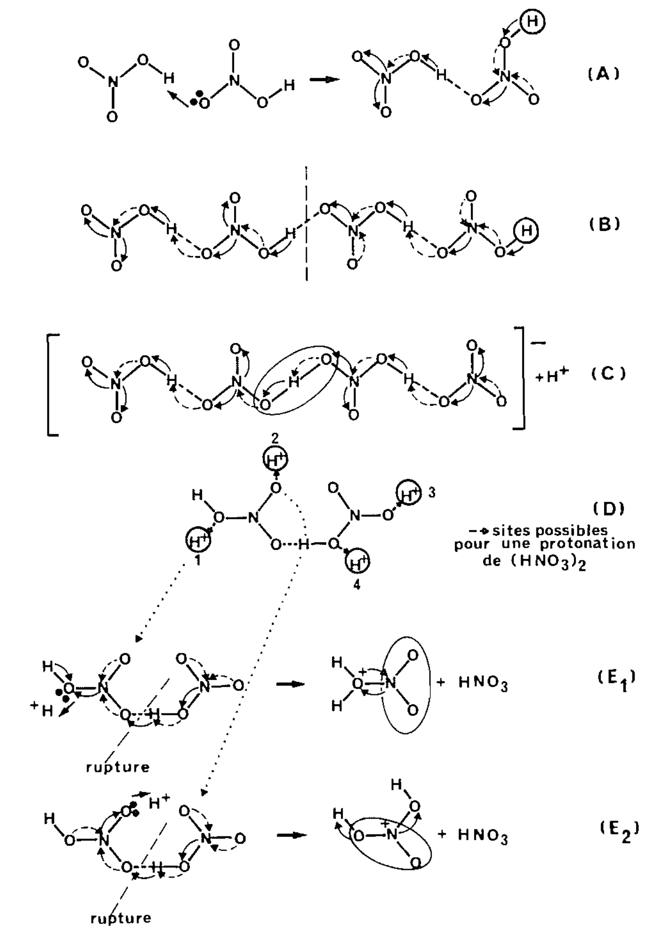

FIG. 8. (A) Formation du dimère; (B) formation du tétramère; (C) l'ion trihydrogénotétranitrate; (D) possibilités d'attaque du dimère; (E) réaction résultante (la direction des flèches indique le sens du transport des électrons – flèche en trait plein = allongement de la liaison, en tireté = raccourcissement).

épaulement à 1040 cm^{-1} (fig. 4 (2)) tandis que pour DNO_3, la raie à 1055 cm^{-1} diminue d'intensité et qu'apparaît une raie plus intense à 1034 cm^{-1} (fig. 4 (5)).

Ces faits semblent rendre compte de la présence de ν_2 H_3O^+ (diminution de la raie à 1055 cm^{-1} et apparition de l'épaulement à 830 cm^{-1} sur le spectre de DNO_3) tandis que les deux raies de DNO_3 seraient attribuables aux vibrateurs δ OD des polymères et de HNO_3 "libre" attendus.

L'épaulement à 1040 cm^{-1} dans HNO_3 liquide indique la présence de ν_1 NO_3^- de la paire ionique. Il semble que les liaisons hydrogène sont affaiblies (la fréquence de ν_1 NO_3^- est supérieure à celle observée dans le 4:1).

La fréquence relevée à 1034 cm^{-1} sur le spectre Raman de DNO_3 peut être attribuée à δ OD de HNO_3 "libre"; rappelons que pour HNO_3 gaz en matrice Bernstein (9) avec ν OH = 3490 cm^{-1} observe δ OD à 1031 cm^{-1}, il est donc logique avec ν OH = 3300 cm^{-1} de retrouver δ OD à 1034 cm^{-1} compte tenu des effets de température (−180°C pour la réf. 9 et 0°C dans ce travail). La raie à 1055 cm^{-1} serait due à δ OD du polymère.

En dessous de 800 cm^{-1} apparaissent classiquement, les déformations des groupes NO_2 et des angles ON(OH) comme on le voit sur le tableau 3. On doit rappeler le comportement similaire noté en ir au niveau de la bande large autour de 600 cm^{-1} pour le 4:1.

Le tableau 3 rassemble l'ensemble des fréquences et attributions proposées pour les espèces présentes dans HNO_3 et DNO_3 liquide.

Conclusion. Proposition pour une autoprotolyse de l'acide nitrique absolu

Les résultats précédents conduisent à préciser l'équation thermodynamique de Ingold et coll. (1) en:

$$[a] \quad \frac{6}{x}(HNO_3)_x \rightleftharpoons NO_2^+ + (NO_3 \cdot 3HNO_3)^- + H_2O \ldots HONO_2$$

qui est l'équilibre principal auquel on doit ajouter:

$$H_2O \ldots HONO_2 \rightleftharpoons H_2OH^+ \ldots ONO_2^-$$

déjà écrit pour le quart et le monohydrate (6, 7) et:

$$\frac{4}{y}(HNO_3)_y + H_2O \rightleftharpoons (NO_3 \cdot 3HNO_3)^- + H_3O^+$$

avec $y \leq 4$.

Ceci rend compte de l'identification spectroscopique: (*i*) de l'oligomère en chaîne $(HNO_3)_x$ peu condensé; (*ii*) des espèces NO_2^+ et $(NO_3 \cdot 3HNO_3)^-$, (*iii*) des deux formes du monohydrate (association moléculaire et paire ionique), et (*iv*) de la présence de très peu d'ions oxonium.

On doit alors noter que l'acidité protonique est celle du polymère nitrique, a priori plus acide que la molécule isolée. Mais cette acidité est réduite par ionisation du tétramère qui créée l'ion $(NO_3 \cdot 3HNO_3)^-$ en libérant un proton qui, cherchant un accepteur protonique ne peut le trouver que sur une espèce existante c'est-à-dire un autre oligomère nitrique ($x < 4$ peut être 3 ou 2) plus basique que le tétramère. Cette attaque conduit à $H_2NO_3^+$ qui se déshydrate facilement donnant alors l'ion NO_2^+ et la base H_2O qui se recombine avec $(HNO_3)_x$ en donnant le monohydrate. Ceci peut être présenté dans le contexte des lois

de Gutmann (36).

La figure 8(A) montre les effets dus à la formation du dimère. Les faits notables sont le raccourcissement des liaisons N—(OH), l'allongement de (NO)—H dans la formation de la liaison hydrogène et surtout l'allongement du OH terminal (affaiblissement et transport simultané d'électrons de H à O) c'est à dire **l'augmentation d'acidité de l'hydrogène terminal** par rapport à l'acide monomère.

La figure 8(B) présente la formation du tétramère conduisant à celle du trihydrogénotétranitrate. A l'allongement d'une liaison O—H et au raccourcissement d'une liaison H...O correspond (lois de Gutmann) un raccourcissement de la liaison hydrogène O—H...O. Mais on note surtout l'augmentation de l'acidité de l'hydrogène terminal (entouré).

Plus la chaîne d'oligomère s'allonge, plus elle est acide et a tendance à "relarguer" H^+. Ici, ceci conduit à l'ion trihydrogénotétranitrate représenté sur la figure 8(C).

On comprend que les liaisons hydrogène doivent se raccourcir et surtout que la liaison hydrogène centrale peut devenir symétrique.

La figure 8(D) correspond à la suite de la réaction [a]. On considère que le tétramère (fig. 8(B)) "relargue" son proton en donnant $(NO_3 \cdot 3HNO_3)^-$ (fig. 8(C)). Le proton disponible attaque, par exemple, un dimère.

A priori, il est difficile de localiser l'oxygène de protonation puisque lors de la formation du dimère (fig. 8(A)), tous les oxygènes se sont chargés. Parmi les quatre positions, la troisième et la quatrième apparaissent les moins favorables (fig. 8(E)).

Dans les deux premiers cas, les liaisons NO pouvant conduire à NO_2^+ sont effectivement raccourcies et les liaisons NO dont il faut envisager la rupture sont allongées.

En tout état de cause la réaction résultante est:

$$NO_3H_2^+ \rightarrow NO_2^+ + H_2O$$

L'eau libérée vient attaquer une molécule HNO_3 et donne l'association moléculaire $H_2O \cdots HONO_2$.

Remarque 1:

Le processus d'oligomérisation de l'acide nitrique conduit à une raccourcissement des liaisons hydrogène de chaînes à condensation croissante. Ceci confirme l'inteprétation de nos données spectroscopiques et conduit à une révision probable des distances données par Luzzati dans le cristal HNO_3.

Remarque 2:

En plus des règles de Gutmann on est conduit à ajouter **la**

règle sur la liaison hydrogène: tout allongement de la liaison O—H, la plus courte de O—H...O, conduit à un raccourcissement de la liaison O...O, tout allongement de H...O provoque un allongement de O...O.

Partie expérimentale

Echantillons

L'acide nitrique est obtenu selon la méthode mise au point par Potier (37).

L'acide deutéronitrique est obtenu à partir de l'anhydride nitrique N_2O_5 dont la méthode de préparation mise au point au laboratoire (30) est une adaptation de celle de Hackspill et Besson (38).

Pour les études Raman, les échantillons sont introduits, en boîte à gants, dans des tubes de verre Pyrex de 5 mm de diamètre qui sont ensuite scellés sous vide. La cristallisation des échantillons nécessite des traitements thermiques. Le cycle est le suivant: on fait une trempe à 90 K suivie d'un réchauffement lent jusqu'à l'apparition des premiers cristaux puis de nouveau trempe et réchauffement et ce jusqu'à cristallisation totale.

Appareillage

Les spectres ir ont été enregistrés sur un spectromètre Perkin Elmer 180. La cellule à température variable est de type conventionnel (VLT2). Les échantillons sont placés en boîte à gants entre des faces en AgCl.

Les spectres Raman sont enregistrés sur un spectromètre Raman Dilor couplé à un analyseur modulaire multicanaux Tracor (Northern Instrument). Le laser à argon ionisé Spectra Physics a une puissance maximale de 1 W sur la raie à 5145 Å. Le refroidissement des échantillons est assuré par un ensemble cryostat et régulation de température Coderg.

Received July 31, 1984

This paper is dedicated to Professor Camille Sandorfy on the occasion of his 65th birthday

JAMES HAGER and STEPHEN C. WALLACE. Can. J. Chem. **63**, 1502 (1985).

We report the findings of a supersonic beam investigation of the 1:1 gas phase complexes of indole with various halomethanes. The unique environment of the supersonic jet provides a method by which the pairwise intermolecular interactions of these complexes can be studied without the complications of condensed media effects. The behavior of argon and methane van der Waals molecules is described first in order to provide examples of simple dispersive interactions. These are then contrasted with complexing species such as CF_4 and CCl_4 where repulsive interactions offset the stabilization due to dispersive and dipole – induced dipole forces. Finally, we show that the interaction between the probe molecule and $CHCl_3$ and CH_2Cl_2 is apparently hydrogen bonding with the indole π electronic system. The implications of these intermolecular interactions on the area of general anesthesia are discussed in terms of a picture in which both the hydrophobic and polar portions of cell membrane may be reversibly affected.

JAMES HAGER et STEPHEN C. WALLACE. Can. J. Chem. **63**, 1502 (1985).

On rapporte les résultats obtenus au cours d'une étude, effectuée en phase gazeuse et à l'aide d'un faisceau supersonique, de complexes 1:1 d'indole avec divers halométhanes. L'environnement unique du jet supersonique fournit une méthode par laquelle les interactions intermoléculaires pairées de ces complexes peuvent être étudiées sans les complications inhérentes aux effets des milieux condensés. Dans le but d'avoir des exemples d'interactions dispersives simples, on décrit en premier le comportement des molécules de van der Waals entre l'argon et le méthane. On met ensuite ces molécules en opposition avec des espèces complexantes comme le CF_4 et le CCl_4 dans lesquelles les interactions répulsives compensent la stabilisation qui provient des forces dispersives et des forces dipolaires induites par des dipôles. Enfin, on démontre que l'interaction entre la molécule qui sert de sonde et le $CHCl_3$ ou le CH_2Cl_2 est apparemment due à une liaison hydrogène avec le système électronique π de l'indole. On discute des implications de ces interactions intermoléculaires sur le domaine de l'anesthésie générale en fonction d'une hypothèse par laquelle les portions tant hydrophobes que polaires de la membrane cellulaire peuvent être affectées d'une façon réversible.

Introduction

Supersonic beams technology has enabled the synthesis of a wide variety of van der Waals molecules in which a "probe" molecule is embedded in a well-characterized "solvent" of finite extent (1–4). This has opened the way for the comparison of isolated molecule behavior with that of the same molecule associated with a chemical interesting ligand. The versatility of this technique can be seen by examining the enormous range of atoms and molecules that have been investigated in this way. These systems include rare gas dimers and clusters (2), hydrogen bonding species (3), and even bio-molecules such as tetraporphyrins and their associated van der Waals molecules (4). In this paper we examine the excited state behavior of indole van der Waals complexes with a series of halocarbons that are of interest in the area of general anesthesia. Supersonic expansions provides a unique medium in which to study the *pairwise* intermolecular interactions that are of great interest with respect to these weak forces.

General anesthetics encompass a group of atoms and molecules of widely differing chemical behavior. Substances such as molecular hydrogen and nitrogen as well as CF_4 and SF_6 exhibit limited anesthetic activity (5). Other more potent anesthetics include ether, chloroform, halothane ($CF_3CHClBr$), and methoxyflurane ($CH_3OCF_2CHCl_2$). The molecular view of the way in which this diverse group of chemical substances can reversibly affect the nerve cell membrane indicates that weak molecular associations are the physical interactions responsible for their anesthetic action (5). It has been suggested (6) that the study of weak molecular interactions can shed light on the perturbations of the optimum conditions for ion transport in and out of the nerve cells. Due to the good relationship between anesthetic potency and lipid solubility it has been routinely assumed that anesthetics are involved almost exclusively with interactions at the hydrophobic parts of the membrane lipids. The universality of this point has recently been questioned by Sandorfy and co-workers (6, 7) based on their infrared spectroscopic investigations of intermolecular associations between various functionalities and a wide variety of anesthetic molecules.

Briefly, the results of these investigations indicate that polar interactions may be very important in determining the anesthetic potency of a given molecule. A classification scheme based on the types of intermolecular interactions through which a given anesthetic molecule can affect molecular associations has been proposed by Sandorfy (6, 7). First there are those anesthetics that are non-polar and can associate only through dispersion forces, ion – induced dipole interactions, and dipole – induced dipole interactions. These anesthetics would be expected to interact primarily with the membrane lipids or proteins. Examples of these include Xe, SF_6, C_2F_6, and C_2H_4. Highly polarizable anesthetics in this class may also associate with the ionic and polar sites. Secondly, there are anesthetics that interact through charge transfer complex formation, though there are no confirmed examples of this as of yet. Thirdly, there are the anesthetics with an appreciable dipole moment, and consequently, can enter into electrostatic ion–dipole and dipole–dipole interactions. This group also contains those anesthetics that participate in hydrogen bonding as either a proton donor or proton acceptor.

The studies of the Sandorfy group have clearly shown, both

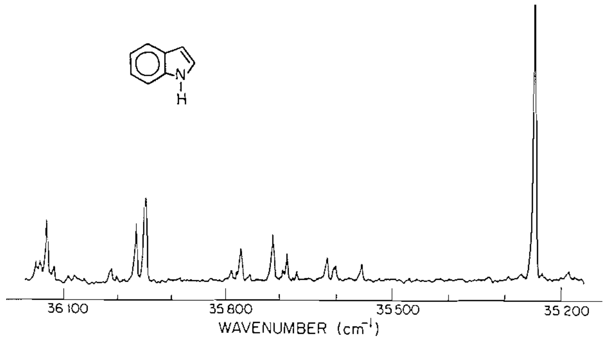

FIG. 1. Fluorescence excitation spectrum of bare indole.

experimentally and theoretically, that certain halogenated anesthetics perturb hydrogen bonds, shifting the equilibrium away from associated molecules toward the free species. In addition it appears that the degree to which a given fluorocarbon molecule perturbs this equilibrium is directly proportional to its anesthetic potency. Especially interesting is that the presence of a hydrogen atom in the halocarbon anesthetic greatly increases the hydrogen-bond perturbing potency and anesthetic activity.

We have undertaken a supersonic beam investigation of van der Waals complexes of indole with a variety of molecules of anesthetic interest in order to try to identify the relevant intermolecular interactions under isolated cluster conditions. The technique involves the *in situ* synthesis of a given indole – van der Waals complex and then probing the complex via laser-induced fluorescence excitation spectroscopy. Due to the very low vibrational and rotational temperatures in the jet, the complicated ultraviolet spectrum of the indole probe molecule is greatly simplified (1). Most vibronic hot bands are completely eliminated and the rotational envelope of the S_1 0–0 transition is reduced to ≤ 1.8 cm^{-1} as shown in Fig. 1. That this technique is useful for investigating weak molecular interactions has been demonstrated by many workers (1, 8, 9). Upon electronic excitation of a mixture of bare probe molecule and associated van der Waals complexes, one observes a spectral feature displaced from the bare molecular origin by a frequency interval that is a direct measure of the difference in the ground state binding energies of the complex. This energy difference is referred to as the spectral shift. From the direction and magnitude of this frequency shift for a given probe molecule and a series of complexing partners, one can often identify the relevant intermolecular forces of a van der Waals molecule. Based on the above discussion, this would yield particularly important results for the anesthetic halocarbons.

First, we present excited state results of isolated, uncomplexed indole spectral positions and fluorescence lifetimes. With this characterization of the probe molecule, we then proceed to the results of van der Waals molecule formation with a series of halogen-substituted methanes.

Experimental

Details of the molecular beam apparatus have been provided in previous publications (9). The Quanta Ray Nd:YAG (DCR-1) pumped dye (PDL-1) pulsed laser system was operated with rhodamine 590 and frequency doubled in a KD*P crystal for the entire spectral region of this study. Typical uv pulse energies were ≥ 5 mJ with a resulting linewidth in the uv of 0.2 cm^{-1}. For all fluorescence lifetime measurements this linewidth was further reduced to 0.01 cm^{-1}, as measured by a 0.25 cm^{-1} spectral free energy Fabry-Perot, by introducing an intracavity etalon in the dye laser.

Fluorescence was detected with a high-quality collection lens (f/1, quartz doublet), a spectral mask to exclude hot background signal and an RCA 4840 photomultiplier. Lifetime measurements were made with a Tektronix 7912AD transient digitizer with a dedicated 4052 microcomputer. All fluorescence decays were averaged a minimum of 400 times and are corrected for small (<1%) baseline wrinkles intrinsic to the oscilloscope. The dynamic linearity was verified over a range of two decades.

Indole was obtained from Aldrich (99+%) and was used without further purification. The liquid complexing partners were of spectrograde quality. The complexing gases Ar, CH_4, CF_4, and CF_2Cl_2 were all obtained from Matheson. The principle carrier gas was He, and van der Waals complexes were then prepared by introducing a few percent of the complexing species in a flow system. The liquid complexing partners were placed in a stainless steel vessel attached to a separate helium flow line monitored by one of two Hastings linear mass flow meters. The other mass flow meter monitored the total flow of the expansion mixture. A similar procedure was used for the gaseous complexing species as described in a previous publication (8).

Results

A. *Indole spectroscopy*

Indole is an aromatic molecule of C_s symmetry that has been investigated by several groups (8, 10, 13). Despite these investigations there is still no normal mode analysis available in either the ground or excited states. In 1964 Hollas investigated the ultraviolet absorption spectrum of indole vapor (10). His studies show that electronic excitation to the first excited electronic state is an allowed $\pi^* \leftarrow \pi$ transition ($A' \leftarrow A'$) with only totally symmetric (a') vibrations active. This work also shows complex vibrational structure to approximately 2500 cm^{-1} above the origin with no strong progressions and with more than two members, indicating little change in shape or size upon electronic excitation. Mani and Lombardi (13) have interpreted the high resolution spectrum of the rotational fine structure at the indole origin in terms of a general loosening of the electronic structure upon excitation. The magnitude of this ring expansion is approximately one quarter of that of benzene. The electronic transition moment of indole is oriented at $\pm 26 \pm 7°$ relative to the long axis of the molecule.

The jet-cooled fluorescence excitation spectrum of the isolated indole molecule is shown in Fig. 1. As one can readily see that the 0–0 transition is by far the most intense feature in this spectrum. This confirms the suggestion by Hollas (10) and Mani and Lombardi (13) that there is only a small change in geometry upon electronic excitation with $\Delta v = 0$ transitions being favored. The excited state vibrational line positions are listed in Table 1. These values are in good agreement with Hollas' spectrum, though we have observed many more weak cold vibronic bands as expected. Since our earlier published work on the indole spectrum (8) two other supersonic jet studies have appeared (11, 12). Nibu *et al.* (11) have investigated the dispersed fluorescence of major vibronic bands below 1300 cm^{-1} and have clearly shown that in all cases the excited state vibrational bands exhibit relatively small decrease in frequency over their ground state counterparts. This, again, is indicative of the small expansion of the molecular dimensions in the excited state.

Bersohn *et al.* (12) have examined the indole fluorescence excitation spectrum and a few selected fluorescence decay times. Our line position data agree quite well with theirs, however, a comparison of the fluorescence lifetimes between the two studies shows a systematic difference between the two sets of results, even including the error bars of ±10% in the work

TABLE 1. Band positions and fluorescence lifetimes for the indole S_1 transition

Band position (cm^{-1})	Lifetime (ns)
0–0 (35 239 cm^{-1})	17.5 ± 0.5
0 + 316	14.7
0 + 365	13.2
0 + 380	15.8
0 + 456	14.6
0 + 480	15.2
0 + 540	13.8
0 + 718	13.1
0 + 720	13.9
0 + 738	11.0
0 + 909	12.7
0 + 920	11.3
0 + 969	12.3
0 + 990	10.2

of Bersohn *et al.* (12). Our value of 17.5 ± 0.5 ns for the bare indole origin is substantially different from the 30 ns ± 10% reported by Bersohn *et al.* (12). We have reexamined the fluorescence decay behavior of bare indole in light of this difference and have found the 17.5 ns lifetime to be independent of carrier gas and interrogation distance downstream from the expansion orifice.

Table 1 also lists the remaining fluorescence decay times of the vibronic transitions below 1000 cm^{-1}. The monotonic decrease in fluorescence lifetime is indicative of an increase in nonradiative rate due to coupling with a dense manifold of triplet electronic states isoenergetic with the S_1 state. Glasser and Lami (14) have shown that the fluorescence quantum yield of indole and substituted indoles decreases in a similar fashion as a function of excess energy above the S_1 origin. Calculations (15) have put T_1 at 1.3 eV below S_1, T_2 and T_3 at lower energies than S_1, and T_4 and T_5 approximately isoenergetic with S_1. Thus, the high density of triplet electronic levels in the S_1 spectral region provide the necessary acceptor states to explain the monotonic decrease in fluorescence quantum yield as being due to intersystem crossing.

B. Molecular interactions of indole with selected halomethanes

Since dispersion forces will always be present in the van der Waals molecules we are investigating, it is useful to consider the behavior of a system in which this is the major interaction present. To this end the indole–Ar van der Waals molecule spectrum and its interpretation will be presented first. In the simplest form the expression for dispersion interactions between two species is given by (16)

$$u(r) = -\frac{3}{2}\frac{h}{r^6}\left(\frac{\nu_1\nu_2}{\nu_1+\nu_2}\right)\alpha_1\alpha_2$$

where r is the separation distance of the two species of the complex, α_1 and α_2 are the polarizabilities of the two molecules in the complex, and ν_1 and ν_2 are the transition frequencies to the respective ionization potentials. Argon is a fairly polarizable complexing partner, and thus based on theoretical treatments of intermolecular forces, should give rise to an attractive excited state interaction and a shift to lower energies of the associated electronic transition. This is indeed what is observed experimentally as shown in Fig. 2 where the indole–argon 0–0 electronic transition is shifted 25 cm^{-1} to lower energy than that of complexed indole. Since the polarizability of argon (17) is

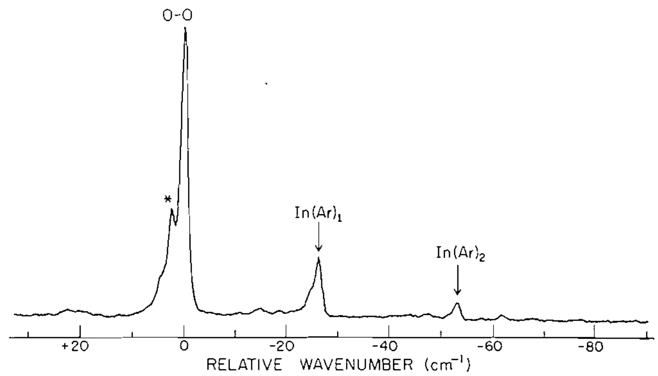

FIG. 2. Fluorescence excitation spectrum of the indole–argon van der Waals molecule in the region of the bare indole origin. The starred feature is due to the indole–helium van der Waals complex.

0.18×10^{-23} cm^3, one would expect any complexing partner with a polarizability of this value or greater to lead to a stabilization of the excited state well over that of the ground state of 26 cm^{-1} or more if dispersion interactions are dominant.

This turns out to be a useful relationship since the difference between the excited state binding energy over that in the ground state of the van der Waals molecules with a nonpolar complexing partner can be approximately written as the sum of three terms (18).

$$\Delta\nu_{TOT} = \Delta\nu_{REP} + \Delta\nu_{DISP} + \Delta\nu_{DIDI}$$

Here $\Delta\nu_{REP}$ is due to short range repulsive interactions, $\Delta\nu_{DISP}$ is the dispersion contributions, and $\Delta\nu_{DIDI}$ is due to dipole-induced interactions. Of these three terms, only that arising from short range repulsive interactions will be reflected in a destabilization of the excited state complex and is most often observed with helium van der Waals molecules. The other two terms are due to attractive forces, and without the presence of any repulsive interactions, will lead to a spectral shift to lower energies (i.e. to the red of the associated bare molecule transition). Amirav *et al.* (19) have shown that for the aniline–Ar van der Waals system, the contribution of dipole – induced dipole interactions to the total excited spectral shift is approximately 5%. The simplest expression for this dipole – induced dipole stabilization energy using a point dipole approximation is given by (16),

$$u(r) = -4\alpha\mu^2/r^6$$

where μ is the dipole moment of the polarizer (in this case indole) and α is the polarizability of the complexing partner in the van der Waals molecule. Thus, one can see that the total interaction energy (neglecting repulsive terms) in this case can also be directly related to the polarizability of the complexing partner. A more rigorous treatment is given in the appendix of ref. 19.

Turning to the spherically symmetric molecule methane, one would expect similar behavior to that of argon in an indole – van der Waals molecule with a dominating excited state dispersive stabilization. Experimentally, we have observed a red spectral shift of 36 cm^{-1} from the indole origin. Figure 3 shows the associated fluorescence excitation spectrum in the lowest energy spectral region. The polarizability (19) of CH_4 is 0.29 $\times 10^{-23}$ cm^3 which is greater than that of Ar and thus, based on the above discussion, dispersion interactions again appear to be the major source of the excited state stabilization. This is illus-

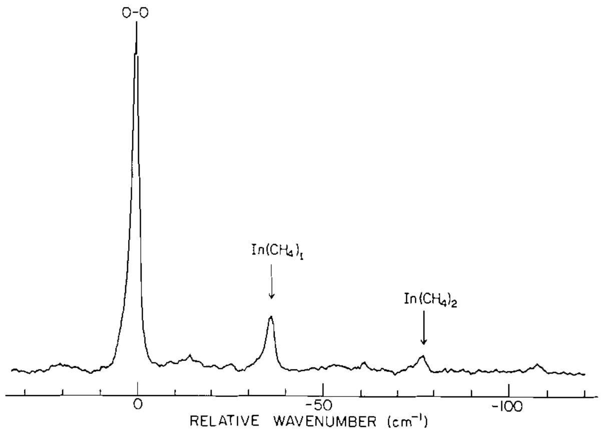

FIG. 3. Fluorescence excitation spectrum of the indole–methane van der Waals molecule in the region of the bare indole origin.

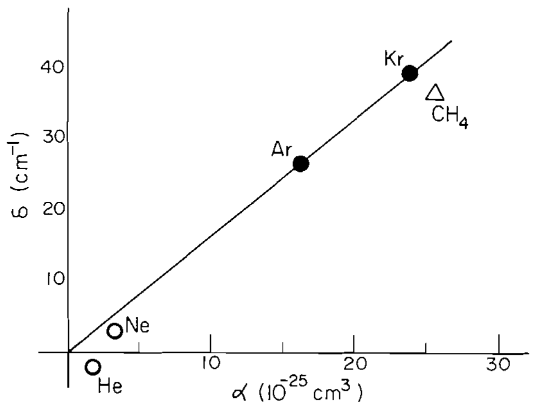

FIG. 4. The relationship between the observed spectral shift and the static polarizability of the complexing partner for indole van der Waals molecules.

trated in Fig. 4 where a linear relationship between the rare gas polarizability and the observed spectral shift is observed for the rare gases where dispersion interactions are dominant (1). There is only a slight deviation for indole–methane. Two additional features of this figure should be noted. First, for rare gas atoms such as He and Ne with small polarizabilities, repulsive interactions largely off-set the attractive contributions. Secondly, the reasonably good agreement of indole–methane within this picture indicates that the behavior of argon and methane as complexing partners is quite similar, reflecting the importance of dispersion interactions for these systems.

From this examination of these relatively simple interactions with fairly polarizable nonpolar molecules, we expanded our investigations to the halomethanes CF_4 and CCl_4. These two systems should help provide a starting point for the studies of the halomethanes of anesthetic interest.

Both CF_4 and CCl_4 are fully substituted methanes and have isotropic polarizabilities substantially greater than those of argon and methane ($\alpha(CF_4) = 0.43 \times 10^{-23}$ cm^3 and $\alpha(CCl_4) = 1.25 \times 10^{-23}$ cm^3). Consequently, one might expect that the experimental spectral shift to be at least as large as that observed for indole–methane. In fact, assuming that the spectral shifts and polarizabilities do follow the linear relationship put forward, a rough estimate would lead to the prediction of a ~ -55 cm^{-1} spectral shift for indole–CF_4 and ~ -180 cm^{-1} for indole–CCl_4. These estimates will only be approximately correct ($\sim \pm 20\%$) if the major interactions terms are due to dispersive forces and dipole – induced dipole forces under the assumptions mentioned above. The actual experimentally observed spectral shifts are $+10$ cm^{-1} for indole–CF_4 (see Fig. 5*a*) and 0 cm^{-1} for indole–CCl_4.

We are confident that the indole–CCl_4 van der Waals molecule does indeed have a 0 cm^{-1} spectral shift at the bare molecule origin for two reasons. First, we can indirectly observe the formation of van der Waals complexes by monitoring the intensity of the bare molecule features as a function of CCl_4 concentration. As this concentration is increased there is an associated decrease in the intensity of the bare molecule band. Second, at several higher energy spectral features, where we have observed a general trend of spectral shifts slightly to the blue of their position at the origin regardless of complexing partner, we were able to locate two indole–CCl_4 features. These two features are blue shifted from the associated bare molecule bands (see Fig. 5*b*) confirming our assignment of a 0 cm^{-1} spectral shift at the origin.

These results indicate that in some fashion the normally dominant polarizability-induced dispersive and dipole – induced dipole interactions are offset by excited state destabilizing interactions. A possible source of this destabilization, short-range repulsive interactions, has already been mentioned. This has almost exclusively been seen in the cases of helium and neon van der Waals molecules. Electrostatic potential interaction calculations by Ruelle and Sandorfy (20) demonstrate that for CF_4, there is a considerable repulsive effect for the short range interaction with a complexing partner due to the fluorine lone pair electrons. This appears to be a satisfactory explanation for the excited state energetics of indole–CF_4.

It seems surprising, however, that the indole–CCl_4 van der Waals complex spectral shift can be due to these short range interactions. Previous workers investigating aromatic – CCl_4 van der Waals molecules have reported quite large spectral shifts; tetracene – CCl_4 = -176 cm^{-1} (21), fluorobenzene – CCl_4 = -89 cm^{-1} (22), and 2-aminopyridine – CCl_4 = -195 cm^{-1} (23). In these systems, dispersive interactions have been found to give the major contribution to the electronic spectral shifts resulting in the most likely structures involve a CCl_4 molecule above the molecular plane. In the case of indole–CCl_4, we find that the binding energies in the ground and excited state are approximately the same (within 2 cm^{-1}), and thus, some excited state interaction has offset the normally attractive dispersive forces. As mentioned above, it seems surprising that short-range repulsive interactions can be responsible for the entire effect. A possible explanation is that, upon electronic excitation, the more bulky CCl_4 molecule is no longer in the optimum geometry for maximum complex stabilization, but rather in a local minimum on the potential energy surface. In this case the full effect of the dispersion stabilization interaction is not experienced by the van der Waals molecule. Further investigations of this system are currently underway in our laboratory.

The next system to be studied is the indole–CF_2Cl_2 van der Waals molecule. In this case the polarizability of the complexing partner is anisotropic and there is a small dipole moment present. The interaction of a polar indole molecule with a polar van der Waals partner complicates the simple picture presented for nonpolar ligands. Previous studies (21) indicate that these polar forces can result in either an attractive or repulsive interaction. Also, it is not clear whether even the approximately

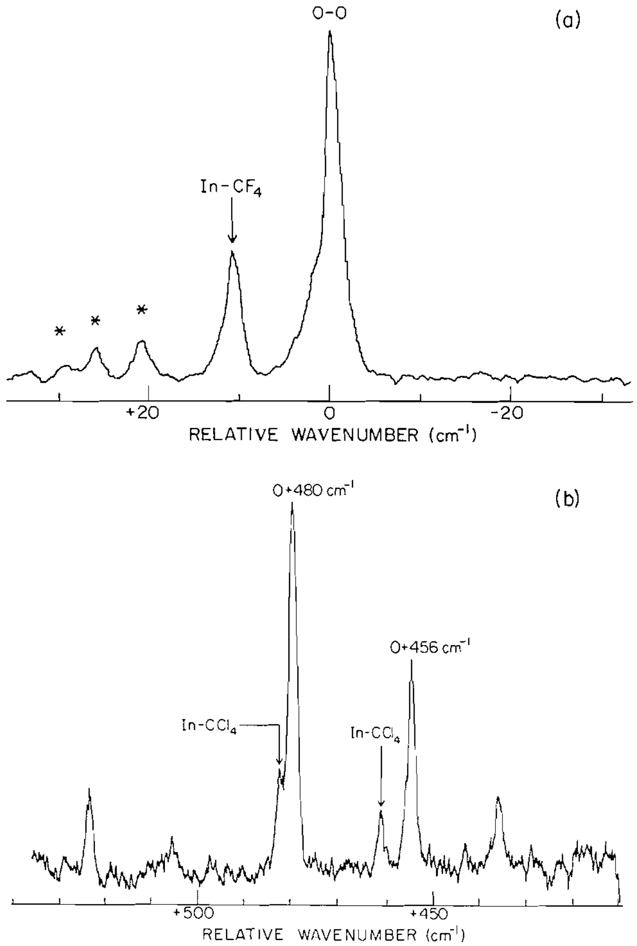

FIG. 5. (*a*) The fluorescence excitation spectrum of the indole–CF_4 van der Waals molecule in the region of the bare indole origin. The starred features are due to vibrational excitation of the van der Waals molecule in the first excited state. FIG. 6. The fluorescence excitation spectrum of the indole–CF_2Cl_2 van der Waals molecule in the region of the bare indole origin. The starred features are due to vibrational excitation of the van der Waals molecule in the first excited state.

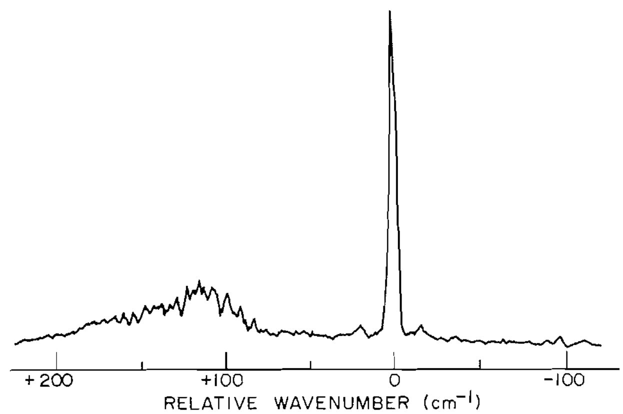

FIG. 7. The fluorescence excitation spectrum of the indole–$HCCl_3$ complex near the bare indole origin.

additive relationship between the various interaction contributions remains valid. However, though indole is a polar molecule, the change of dipole moment upon excitation is small (24) ($|\Delta\mu| = 0.14 \pm 0.05$ D), and thus we do not expect much deviation from the simple picture presented.

The experiment fluorescence excitation spectrum of indole–CF_2Cl_2 in the region of the bare molecule origin is shown in Fig. 6. There are two points to note regarding this spectrum, first, the spectral shift is to the red (-36 cm^{-1}) showing that the excited state is stabilized to a greater degree than the ground state. This suggests that a treatment based on dispersive and polar interactions is appropriate. Secondly, there is a prominant 4 cm^{-1} vibrational progression in the van der Waals molecule spectrum. This vibrational activity does not arise from hot band excitation because of the low rotational and vibrational temperatures in the jet. From the very low frequency of this motion it may be due to a van der Waals bending-type motion or movement of the CF_2Cl_2 parallel to the indole molecular plane. The possibility of several of these features arising from different chemical isomers also exists.

The remaining two halocarbon van der Waals molecules in this family that we have investigated are dichloromethane and chloroform. The chloroform–indole results will be discussed first. Chloroform is commonly known as a general anesthetic. A major reason for its anesthetic potency has been suggested to be due to the presence of the lone acidic hydrogen (7). When methane hydrogens are successively replaced by chlorine atoms there is an associated increase in the acidity of the remaining hydrogens. Consequently, one intuitively expects that chloroform is a better proton donor than dichloromethane. Electrostatic potential calculations (20) show that the region of positive potential for the remaining hydrogens reaches farther for chloroform and dichloromethane than for methylchloride. In addition this larger positive region helps to offset the chlorine lone pair repulsive interactions. These considerations suggest that the interaction between indole and chloroform and dichloromethane will be highly directional in nature and that the possibility of hydrogen bond formation exists.

The experimental fluorescence excitation spectrum of indole–$HCCl_3$ near the indole origin is shown in Fig. 7. Here the maximum of the complex features is located at approximately 120 cm^{-1} to the blue of the bare molecule band. The structure associated with this relatively broad feature is initially quite regular with a spacing of approximately 8 cm^{-1}. Beyond this point, however, the spectrum becomes quite complex. The nature of the spectral shift and considerations of the most likely directionality of the interaction has led us to the interpretation that the chloroform molecule is the proton donating moiety in

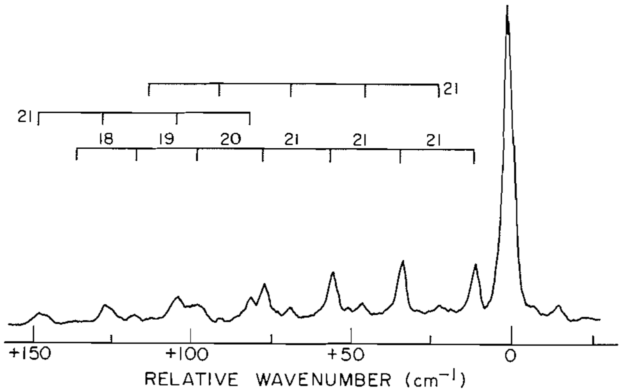

FIG. 8. The fluorescence excitation spectrum of the indole–H_2CCl_2 complex near the bare indole origin.

a π-hydrogen bond (3). Gonohe *et al.* (22) have proposed a similar explanation for the behaviour of the fluorobenzene–$HCCl_3$ complex which shows a blue shift of 117 cm^{-1} from the fluorobenzene origin. This type of π-hydrogen bonding interaction has also been proposed as the mechanism for indole auto-association (25). The fact that, from the direction and magnitude of the electronic spectral shift, one can identify hydrogen bonded species in a supersonic molecular beam makes this technique very useful.

The lowest energy portion of the indole–CH_2Cl_2 fluorescence excitation spectrum is shown in Fig. 8. The most striking feature of this spectrum is the great amount of excited state vibrational activity. There is a well developed progression that begins at +12 cm^{-1} from the bare indole origin and finally dies out at approximately +160 cm^{-1}. In all we have identified three progressions with spacings of ~21 cm^{-1} one of which is comprised of seven members. The prominence of these low frequency excited state vibrations in both this spectrum and that of indole–$HCCl_3$ indicates a substantial change in equilibrium geometry of these binary clusters upon electronic excitation.

Our spectral results show that the net effect of the indole–CH_2Cl_2 interactions lead to a destabilization of the first excited electronic state with respect to the ground state. This suggests that the relevant intermolecular interactions for the indole–CH_2Cl_2 arise from either (*a*) van der Waals interactions or (*b*) π-hydrogen bonding. As discussed above, recent investigations of van der Waals molecules containing a highly polarizable complexing partner such as dichloromethane demonstrate a substantial stabilization of the excited state relative to the ground state of the complex in the absence of a large dipole moment change of the probe molecule (21). In addition, we have found that when indole forms a one-to-one complex with the fluorine-substituted analogue of dichloromethane, CF_2Cl_2, there is a red electronic spectral shift as expected from simple van der Waals interaction arguments. Thus, the replacement of the hydrogen atoms by inert fluorine atoms in this halomethane complexing partner leads to dramatic spectroscopic changes reflecting the differences in interaction potentials between these two indole complexes. This spectroscopic evidence indicates that the highly directional nature of the electrostatic potential around dichloromethane molecule plays a crucial role in the pairwise interaction of the complex. We therefore favor the view of the π-hydrogen bonding is the appropriate explanation for the indole–dichloromethane intermolecular interaction.

We have also investigated the fluorescence decay behavior of all of these binary indole complexes near the bare molecule origin and have observed a wide range of behavior. One expects that for a sufficiently inert complexing partner there will be no change in the fluorescence lifetime of the van der Waals molecule relative to the bare probe molecule (1). In this case there is minimal modification of the energy levels due to the weak nature of the intermolecular interactions. For stronger interactions such as hydrogen bonding other investigators have shown that one can expect rather large changes in the measured fluorescence lifetimes upon complexation (3, 27).

TABLE 2. Fluorescence decay times for indole complexes

Species	Lifetime (ns)
Indole, $S_1(0-0)$	17.5 ± 0.5
In–He_1	18.1 ± 0.5
In–Ne_1	18.2 ± 0.5
In–Ar_1	16.7 ± 0.5
In–Kr_1	≤ 1
In–$(CH_4)_1$	21.9 ± 0.5
In–$(CF_4)_1$	18.0 ± 0.5
In–$(CF_2Cl_2)_1$	17.1 ± 0
In–$(CCl_4)_1$[a]	≤ 1
In–$(CHCl_3)_1$	5 – 8
In–$(CH_2Cl_2)_1$	7 ± 1

[a]The fluorescence decay times for this complex was measured at the van der Waals features associated with the 0 + 456 cm^{-1} and 0 + 480 cm^{-1} bare indole features (see Fig. 5*b*).

For van der Waals complexes of indole and species such as the rare gases He, Ne, and Ar, methane, CF_4, and CF_2Cl_2 we do indeed observe fluorescence decay times very close to that of the bare indole origin (Table 2). This is indicative of the weak nature of interaction potential between the indole probe molecule and the van der Waals partner. Thus, these inert partners do not modify either the radiative rate or the nonradiative rate characteristic of bare indole.

This simple picture of the absence of one-solvent molecule perturbations of the indole fluorescence lifetime is no longer valid when one looks at the behavior of the indole–krypton van der Waals molecule. Here the measured fluorescence decay time is much shorter than that of the bare probe molecule owing to a substantial modification of the spin–orbit coupling between S_1 and the triplet manifold (1, 8). Thus, the external heavy atom effect leads to a large change in the nonradiative rate from the vibrationless level of the first excited singlet state of the van der Waals complex relative to that for bare indole. We have also measured the fluorescence lifetimes of the indole–CCl_4 van der Waals molecule at the spectral region indicated in Fig. 5*b*. These features also show a dramatic lifetime shortening similar to that observed for indole–krypton.

Measurements of the fluorescence decay times for the π-hydrogen bonded systems indole–CH_2Cl_2 and indole–$CHCl_3$ also indicate a substantial perturbation of bare molecules radiative and/or nonradiative rates (see Table 2). Felker and Zewail (26) have shown for hydrogen bonded isoquinoline that the fluorescence lifetimes of these complexes approach those found for liquid phase behavior in hydrogen bonding solvents. We have also demonstrated similar behavior for indole hydrogen bonded to a series of alcohols and amines investigated in a supersonic jet (3). Thus the radiative behaviour of indole is quite susceptible to changes in energy levels induced by hydrogen bond formation. We are unaware of any solution phase lifetime measurements of unsubstituted indole in dichloromethane or chloroform and therefore cannot make any direct comparisons with our jet data. However, the values for these supersonic jet complexes are similar to those found (27) for indole in various other hydrogen bonding solvents (3–6 ns).

Discussion

Since our investigation is specifically based on the study of individual indole van der Waals complexes in the more general context of anesthesia, this discussion will relate the observed excited state spectral features with anesthetic potency. The excited state spectral shifts reflects the sensitivity of the weak intermolecular forces to the electronic transition moment making *changes* in these interactions experimentally observable. As discussed earlier both a stabilized and a destabilized excited state of the complex (with respect to the ground state) have been observed. It is the direction and magnitude of this change in binding energies that is of interest in the following discussion. In addition fluorescence lifetime measurements provide an indication of the absolute strength of the intermolecular interactions. Relatively weak interactions results in little modification of the observed decay time relative to that of the incomplexed molecule while stronger interactions are reflected by greater changes in the time-resolved behavior.

The investigations of the indole–Ar and indole–CH_4 van der Waals complexes were undertaken to exemplify the effects of complexing species that can only interact through dispersion forces and provide a measure of the effects of the presence of other types of intermolecular interactions. Deviations from the spectral shifts expected based on dispersion interactions alone can be attributed to repulsive interactions and/or dipole–induced dipole interactions. The fluorescence lifetimes of these van der Waals molecules indicate a negligible modification of the indole radiative behavior due to complex formation, putting them in the weakly interacting category.

The results for indole–CF_4 and indole–CCl_4 illustrate the usefulness of this comparative technique. In both cases the stabilizing dispersion and dipole – induced dipole forces were found to be offset by some excited state repulsive interaction. This is not unexpected in the case of CF_4 based on the electrostatic potential calculations of Ruelle and Sandorfy (20) where the fluorine lone pairs tend to hinder interaction with a negative site such as benzene ring of an aromatic molecule. However, based on other studies of carbon tetrachloride van der Waals complexes (21–23), one would not expect this behavior for indole–CCl_4. This might indicate that the indole probe molecule is much more sensitive to repulsive interactions with complexing partners of the form CX_4, where X is a halogen atom, than previously studied systems.

The lifetime studies of these two van der Waals molecules show that CF_4 behaves similarly to argon and methane in that it does not alter the radiative rates of the indole probe molecule. Carbon tetrachloride, on the other hand, must be more strongly interacting as can be seen from the fluorescence lifetime measurements reflecting the propensity of this complexing molecule to lead to more efficient spin–orbit coupling.

The van der Waals molecules mentioned above deal with complexing species that have negligible anesthetic potency. These halocarbons can only interact through dispersive and dipole – induced dipole forces. On the other hand, the molecule CF_2Cl_2 (weakly anesthetic) can associate through the additional interaction of polar forces. The lack of a large repulsive contribution to the observed spectral shift, unlike that observed for indole–CF_4 and indole–CCl_4 may indicate that anesthetic action in fully halogenated methanes is related to this additional mechanism of association. Time-resolved measurements of the indole–CF_2Cl_2 van der Waals molecule illustrate behavior indicative of weak intermolecular interactions. This observation may be related to the fact that CF_2Cl_2 is only weakly anesthetic in nature.

The anesthetic potency of halocarbons is greatly increased with the presence of a lone "acidic" hydrogen (7). Electrostatic potential calculations (20) on these anesthetic species reveal that the region of positive potential is quite extensive extending to greater range of $CHCl_3$ than CHF_3. In addition, this positive region helps to shield the halogen lone pairs reducing repulsive interactions with an approaching nucleophile. Thus, one would not be surprised at the formation of hydrogen bonds with these complexing partners and a proton acceptor such as a π system of an aromatic molecule. This is indeed what we have observed in the case of indole–$HCCl_3$ and to a lesser extent for indole–H_2CCl_2. The implications of this finding can be seen by considering some proposed mechanisms of anesthetic action. Recently, the suggestion (6, 9) that, for more potent anesthetics, polar interactions can be quite important in determining activity has been put forward. In this picture these potent anesthetics act in the polar, rather than hydrophobic, portions of the membrane lipids. Thus, anesthetics containing an acidic hydrogen can be expected to perturb the existing intermolecular associations or actually break hydrogen bands (6). This is in contrast to those anesthetic molecules that are either nonpolar or weakly polar that mainly effect the hydrophobic network in lipids. Our studies on indole–$HCCl_3$ and indole–H_2CCl_2 show that π-hydrogen bonding is an important mechanism for the association of these halocarbons with aromatic molecules. The mechanism of π-hydrogen bonding is also responsible for indole autoassociation in solution, and consequently, indole–$HCCl_3$ formation would be expected to directly compete with indole dimerization reducing the concentration of the dimer. This stronger type of intermolecular interaction would have profound consequences if it took place in the cell membrane of ionic channels due to a disruption of optimum conditions for ion transport in and out of the nerve cells.

Conclusions

Supersonic beam technology has been proven useful in directly measuring the type of intermolecular associations operative for indole–halomethane excited state complexes. Though this is a gas phase technique, it is of great interest to investigate these associations in an environment in which only pairwise interactions are present and extend the results to the solution phase studies in the area of general anesthesia. Species such as CF_4 and CCl_4 exhibit an unusually strong repulsive interaction under these experimental conditions which may be attributable to the repulsion between the halogen lone pair electrons and the aromatic π-electrons. Indole–CF_2Cl_2 illustrates a system in which dispersive and induction forces are the main contributions to the intermolecular association. Based on this one would expect this weakly anesthetic molecule to interact with the hydrophobic parts of the membrane lipids. On the other hand, species such as chloroform and dichloromethane choose to interact with the indole probe molecule by means of hydrogen bonding rather than through van der Waals complex formation. This supports the proposal of Sandorfy and co-workers (6, 7) that the hydrophobic portions of the cell membrane may not be the major interaction sites for polar anesthetics of this type.

The Raman spectrum of microcrystalline dodecacarbonyldirhenium(0), $Re_2(CO)_{10}$, has been reinvestigated at 67 K using one of the latest fully-computerized spectrometers available. Previously unobserved peaks have been detected mainly in the ^{13}CO-satellite (2150–1900 cm^{-1}), and overtone and combination regions (1300–700 and 4300–3800 cm^{-1}). This is the first time that Raman-active first CO overtones and combinations of a metal carbonyl complex have been reported. They were earlier thought to be too weak to be detected. Assignments are proposed for the majority of these new peaks together with those from a similar low-temperature (~70 K) FT-ir study. In general, the D_{4d} selection rules are obeyed, but the activity of some forbidden bands reveals that the molecule is slightly distorted in the solid state in agreement with its X-ray structure. The similarity of the low-temperature spectra to those obtained at room temperature indicates that no phase change occurs throughout the temperature range investigated.

PIERRE D. HARVEY et IAN S. BUTLER. Can. J. Chem. **63**, 1510 (1985).

Opérant à 67 K et utilisant un des plus récents spectromètres complètement informatisé, on a réétudié le spectre Raman du dodécacarbonyldirhenium(0), $Re_2(CO)_{10}$, microcristallin. On a pu détecter des bandes qui n'avaient pas été observées antérieurement, principalement dans les régions du satellite du ^{13}CO (2150–1900 cm^{-1}) et des harmoniques et des combinaisons (1300–700 et 4300–3800 cm^{-1}). Aucune publication antérieure n'avait fait rapport de l'observation, dans le spectre Raman, des premières bandes harmoniques et de combinaisons du CO d'un complexe de métal carbonyle. Il était antérieurement supposé que ces bandes étaient trop faibles pour être détectées. On propose des attributions pour la plupart de ces nouvelles bandes anisi que pour celles observées au cours d'une étude semblable effectuée à basse température et à l'aide d'un appareil de FT-ir. En général, les règles de sélection D_{4d} sont suivies; toutefois, l'activité de quelques bandes interdites révèle que, à l'état solide, la molécule est légèrement déformée comme le laissait supposer sa structure déterminée par diffraction des rayons-X. La similarité qui existe entre les spectres obtenus à basse température et ceux obtenus à la température ambiante suggère qu'il ne se produit pas de changement de phase sur la plage des températures étudiées.

Introduction

The ir and Raman spectra of dodecacarbonyldirhenium(0), $Re_2(CO)_{10}$ have been investigated extensively since its discovery in 1941 (1). The molecule has a single Re—Re bond joining together two staggered square-pyramidal $Re(CO)_5$ fragments (2, 3) and is regarded as one of the important prototypes for metal–metal bonded cluster compounds. Despite the innumerable vibrational studies on $Re_2(CO)_{10}$ (4–18) from which the assignments of all the fundamentals are now well established, there are relatively few data for low intensity features such as naturally-occurring ^{13}CO-satellite peaks and overtone and combination modes. A few $\nu(^{13}CO)$ modes have been identified in the ir (4, 6, 9, 13, 14, 16) and Raman (13, 16) and some overtones and combinations in the ir (4, 8, 9, 13, 16) and near-ir (5, 9, 11, 14), but the analysis is still far from complete. In view of this and because the assignments for the fundamentals were so well known, we decided to reinvestigate the Raman spectra of $Re_2(CO)_{10}$ at 67 K and in CCl_4 solution using one of the latest computerized, high-resolution Raman spectrometers available. We are particularly interested in seeing whether or not we could observe any bands in the ν(CO) first overtone and combination region with this new type of instrumentation. All earlier attempts for metal carbonyls had failed in this regard. This region is especially important for determining the anharmonicities of the CO stretching vibrations. In this paper, we report the results of our new Raman study together with some FT-ir data for the solid (at ~70 K) and in CCl_4 solution at room temperature.

Experimental

Pure $Re_2(CO)_{10}$ from Strem Chemicals was used without further purification. The Raman spectra were recorded on an Instruments S.A. spectrometer equipped with a U-1000 Jobin-Yvon 1.0-m double monochromator coupled to a Columbia Data Products minicomputer using Instruments S.A. in-house software. The excitation source was the 514.5-nm green line of Spectra Physics model 164 argon-ion laser (~300 mW at the sample). The spectra were calibrated against the emission lines of a standard neon lamp and the peak positions are accurate to ±0.2 cm^{-1}. A Pyrex tube containing the white, microcrystalline solid was mounted on a Cryodyne Cyrocooler (Cryogenics Technology, Inc., model 21) for the variable-temperature measurements (±1 K). All FT-ir spectra were recorded on a Nicolet model 6000 spectrometer (accuracy ±0.2 cm^{-1}), the same cryostat described above being used for low-temperature (~70 K) measurements.

Results and discussion

The main investigations of the solid-state vibrational spectra of $Re_2(CO)_{10}$ have been by Adams *et al.* (17, 18) who have succeeded in assigning all the ir-active ($6b_2 + 8e_1$) and Raman-active ($7a_1 + 6e_2 + 8e_3$) fundamentals expected for D_{4d} molecular symmetry by very thorough ir reflectance and Raman measurements on single crystals. These assignments will be used extensively in our own work. The symmetry descriptions of the normal modes and their spectral activities for D_{4d} symmetry are given in Table 1, together with the selection rules for the first overtones and combinations.

The 200–10 cm^{-1} region

A typical Raman spectrum of solid $Re_2(CO)_{10}$ at 67 K is

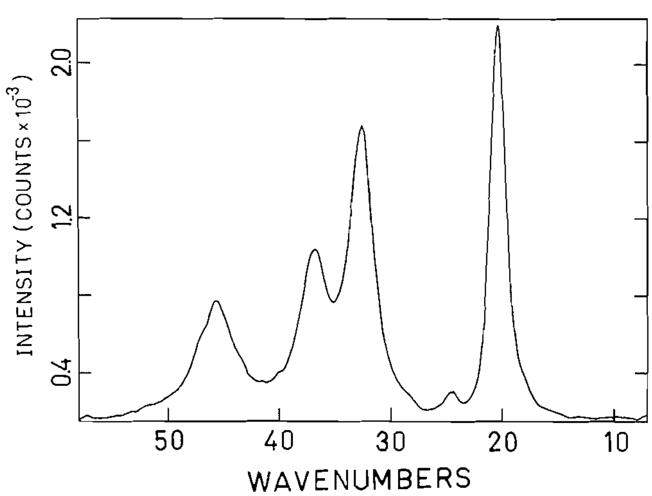

FIG. 1. Low-frequency Raman spectrum (60–7 cm^{-1}) of solid $Re_2(CO)_{10}$ at 67 K (excitation 514.5 nm, 300 mW, slit widths 30 μm, 1 scan, 1 s/data point, data point spacing 0.2 cm^{-1}, no smoothing).

shown in Fig. 1. We were able to approach to within 4 cm^{-1} of the Rayleigh line and in doing so we could resolve completely a feature at 24.5 cm^{-1}, unobserved in the low-temperature study of Adams *et al.* (11) and barely discernible in the spectrum published by Prasad (15). In their latest single crystal work, however, Adams and Hooper did manage to detect this lattice mode at room temperature (17). This peak has been assigned to a lattice translatory mode. While the overall quality of our data is clearly superior to those in the literature, we did not resolve the bands reported by Adams *et al.* (11) at 143 and 138 cm^{-1}, even using other laser excitation lines (e.g., 488.0 nm). The observed peaks are given in Table 2.

The 700–300 cm^{-1} region

The bands found in this region are given also in Table 2. In general, they correspond well with the literature values. A re-examination of the ir spectrum at ~70 K using superior quality FT-ir instrumentation did reveal some differences. The a_1, ν(Re—CO) mode was detected at 461.2 cm^{-1} (compared to 462.8 cm^{-1} in the Raman). Several of degenerate *e* modes are also split in the solid-state spectra.

[a]The accuracy of Raman frequencies varies with the resolution, 4250–3850 cm^{-1}; ± 2 cm^{-1}, 2150–1900 cm^{-1}; ± 0.5 cm^{-1}, 1250–700 cm^{-1}; ± 0.5 cm^{-1}, 600–10 cm^{-1}; ± 0.2 cm^{-1}. The values in parentheses for selected frequencies represent relative intensities to 120 cm^{-1} peak taken to 100.

[b]The accuracy of ir frequencies is ± 0.1 cm^{-1}. In the 4250–3850 cm^{-1} and 2150–1900 cm^{-1} regions, the last significant figure is not considered. The values in parentheses for selected frequencies represent the relative intensity (in absorbance scale) to 2004 cm^{-1} peak taken to 100.

[c]$\Delta\nu$ = observed frequency − calculated frequency.

[d]According to ref. 11; sh, shoulder; v, very.

Overtone and combination region (1300–700 cm^{-1})

Typical FT-ir and Raman spectra for this region are shown in Fig. 2. At the outset, it is apparent that there are not many coincidences between the two spectra, as would be expected for overtones and combinations of a D_{4d} symmetry molecule. The proposed assignments are given in Table 2. The calculated frequencies were generated by a computer program that matched all the allowed overtones and combinations from the accepted assignments of the fundamentals with the observed peaks assuming a variation of 0 to −3 cm^{-1}. Over 200 possibilities were initially generated and eventually 144 of these were selected to account for the 55 observed frequencies in accord with the D_{4d} molecular and C_{2h} crystal symmetry selection rules and bearing in mind the intensities of the original fundamentals. Many of the observed peaks could be assigned unambiguously, especially those appearing in the less complicated regions of the spectra.

CO stretching region (2150–1900 cm^{-1})

An example of the high-quality Raman spectrum obtained at 67 K is shown in Fig. 3 (the peak positions are given in Table 2). Two new peaks were detected for the first time: 2043.5 and 1965.0 cm^{-1}. These correspond to ir features, one of which was attributed to ν_{12} (b_2) by Adams and Taylor (18). There is most

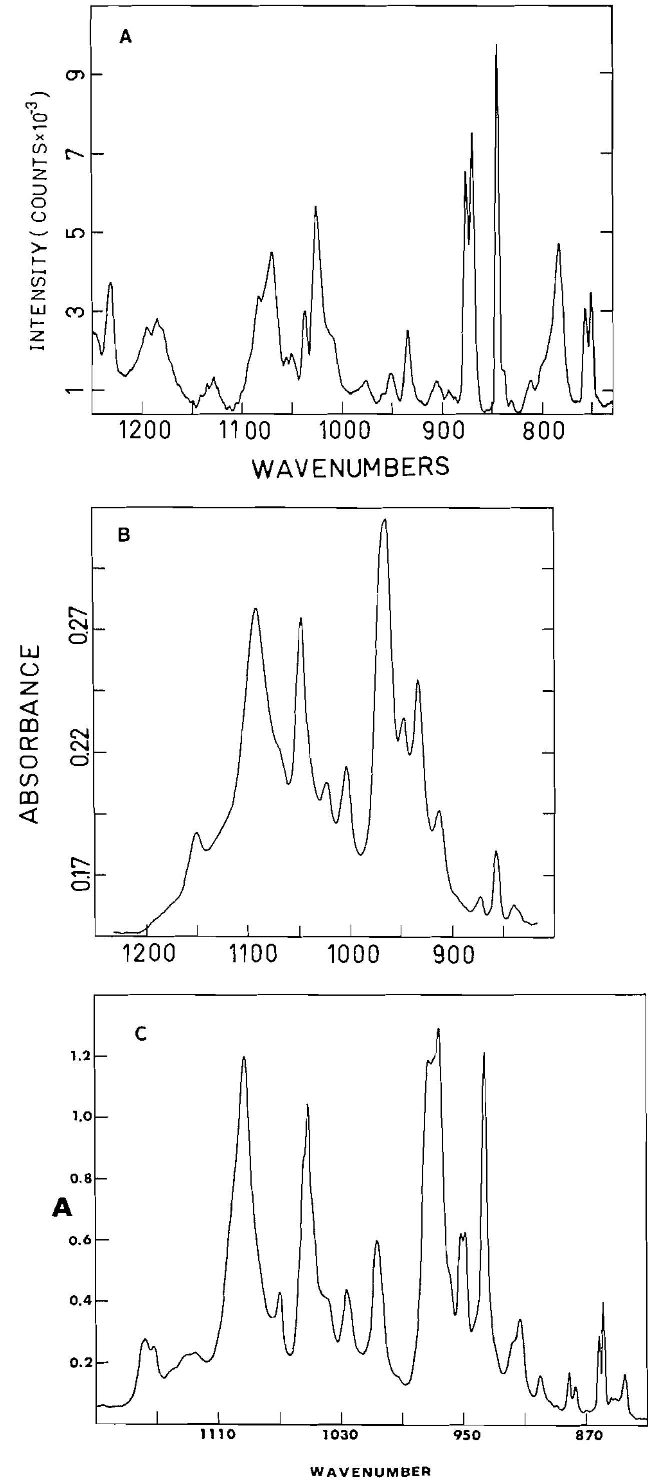

FIG. 2. (*A*) Raman spectrum (1250–700 cm^{-1}) of solid $Re_2(CO)_{10}$ at 67 K (excitation 514.5 nm, 350 mW, slit widths 150 μm, 5 scans, 1s/data point, data point spacing 0.5 cm^{-1}, 9-point smoothing). (*B*) FT-ir spectrum (same region) of $Re_2(CO)_{10}$ in CsI disk at 296 K (300 scans, 2 cm^{-1} resolution). (*C*) FT-ir spectrum (same region) of $Re_2(CO)_{10}$ in CsI disk at ~70 K (300 scans, 1 cm^{-1} resolution).

probably a combination mode in Fermi resonance with the 1980 cm^{-1} (ν_{31}, e_3) mode. Some additional data are available for the ^{13}CO-satellite peaks and the assignments for these are also listed in Table 2. These assignments are in part based on the calculated values from the work of Wozniak and Sheline (13).

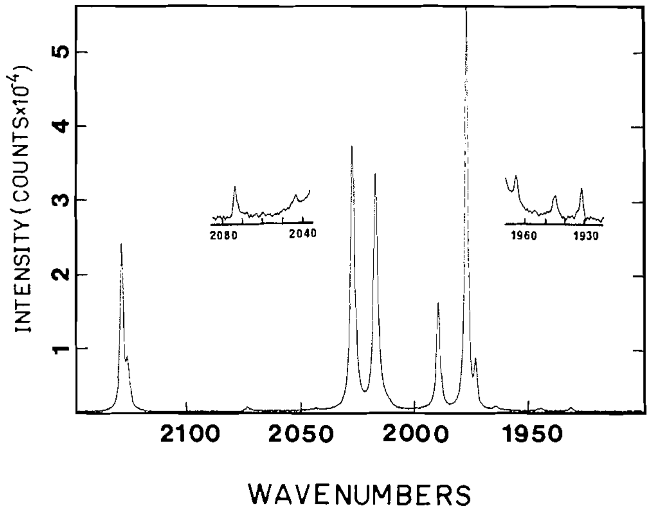

FIG. 3. Raman spectrum (2150–1900 cm^{-1}) of solid $Re_2(CO)_{10}$ at 67 K (excitation 514.5 nm, 300 mW, slit widths 50 μm, 1 scan, 1 s/data point, data point spacing, 0.2 cm^{-1}, no smoothing).

First CO stretching overtone and combination region (4300–3800 cm^{-1})

The FT-ir and Raman spectra of solid $Re_2(CO)_{10}$ in this region are presented in Fig. 4. Although there have been several detailed ir reports for various metal carbonyl complexes(19), Raman data have never been investigated previously in this region owing to the very low peak intensities anticipated and the lack of multiscanning and spectral enhancement capabilities in the earlier instrumentation. The poor response of the phototube removed from the exciting line was also a factor. However, it is now clear that with modern equipment, these problems are no longer insurmountable, at least for the solid. The proposed assignments are given in Table 2. Some CCl_4 solution ir data are also given (Table 3), but solution Raman data for this region still remain elusive. In general, the proposed assignments satisfy the D_{4d} selection rules, especially remembering that ν(CO) modes are highly anharmonic (19). The CCl_4 solution and solid-state ir spectra do exhibit some striking differences but it is possible to see that in the main there are some close similarities especially in terms of clusters of bands for the solid being associated with one or two bands for the solution. Two peaks do stand out in the comparison: the peaks at 4178 and 3920 cm^{-1} in the solid-state ir. The latter feature is by far the strongest band observed in the complete region. The assignment given for the peak necessitates a breakdown in the D_{4d} selection rules indicating a distortion of the $Re_2(CO)_{10}$ molecule in the solid state, as has been found in the two X-ray studies reported for the complex (2, 3).

In conclusion, it is clearly possible to use modern Raman spectrometers to obtain excellent spectra and to detect previously unobtainable features in the spectra of metal carbonyl complexes, especially in the ν(CO) first overtone and combination region. In addition, this particular region is strikingly sensitive to small distortions in the solid-state structures. Finally, although no room-temperature Raman spectra of solid $Re_2(CO)_{10}$ are presented here, the spectra are closely similar to the low-temperature data except for the poorer resolution indicating that there is no phase transition in the temperature range investigated. Adams and co-workers have reported a pressure-induced phase transition for this material, however (20, 21).

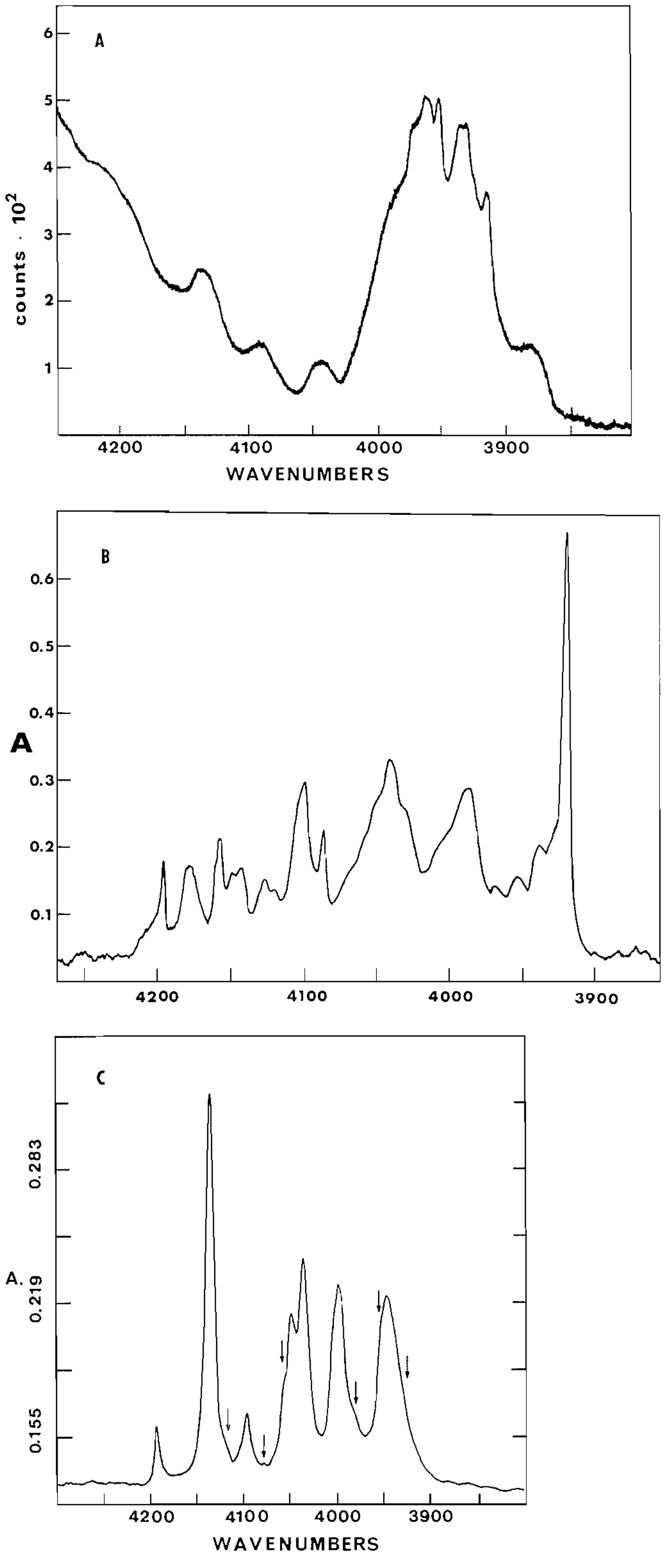

FIG. 4. (*A*) Raman spectrum (4250–3800 cm^{-1}) of solid $Re_2(CO)_{10}$ at 67 K (excitation 514.5 nm, 300 mW, slit widths 400 μm, 4 scans, 5 s/data point, data point spacing 1.0 cm^{-1}, baseline subtracted, 9-point smoothing). (*B*) FT-ir spectrum (same region) of $Re_2(CO)_{10}$ in CsI disk at ~70 K (300 scans, 2 cm^{-1} resolution). (*C*) FT-ir spectrum (same region) of $Re_2(CO)_{10}$ in CCl_4 solution at 296 K (300 scans, 1 cm^{-1} resolution).

Acknowledgments

This work was generously supported by operating grants from N.S.E.R.C. (Canada) and F.C.A.C. (Quebec). P.D.H. acknowledges McGill University Graduate Research Faculty and N.S.E.R.C. (Canada) for graduate assistantships. We would like to thank Professor Denis F. R. Gilson (McGill University) for having written and processed the computer program calculating the harmonics and combinations frequencies. One of us (I.S.B.) wishes to thank the C.N.R.S. Laboratoire de Chimie de Coordination, Toulouse, and the Laboratoire de Cristallochimie, Université de Rennes I, for their warm hospitality while on sabbatical leave in France during which period this manuscript was written.

Une étude a été réalisée en MS Xα sur de nouvelles entités à courte durée de vie: la diméthyl germathione et la diméthyl silathione. La détection par spectroscopie photoélectronique de la diméthyl germathione a été confirmée sur la base de calculs effectués sur ce dérivé, le dimère et le trimère correspondants: potentiels d'ionisation et sections efficaces de photoionisation. L'examen comparatif des résultats obtenus pour la diméthyl germathione, la diméthyl silathione et leur homologue le thioformaldéhyde a permis de préciser certaines caractéristiques de leur structure électronique: forte polarité de la liaison, états de Rydberg de faible énergie.

JEAN-LUC GARCIA, DANIELLE GONBEAU, GENEVIÈVE PFISTER-GUILLOUZO, MICHEL ROCH, and JACQUES WEBER. Can. J. Chem. **63**, 1518 (1985).

A study was undertaken in MS Xα on new short-life species: dimethylgermathione and dimethylsilathione. The spectroscopic detection of dimethylgermathione was confirmed by calculations performed on this compound and the corresponding dimer and trimer: ionization potentials and photoionization cross sections. The analysis of results obtained for the dimethylgermathione, the dimethylsilathione and the parent compound, thioformaldehyde, has shown certain characteristics of their electronic structure: strong polarity of the bond, low-energy Rydberg states.

Introduction

Ces dernières années un intérêt croissant s'est manifesté pour les liaisons à caractère multiple mettant en jeu deux atomes de période différente et qualifiées habituellement de liaisons à caractère $p_\pi p_\pi$. C'est dans ce cadre que se situent les études entreprises pour générer des espèces organométalliques présentant une liaison double entre un atome de métal (Si, Ge) et un hétéroatome (2).

La difficulté d'accéder à de telles entités est liée à l'instabilité intrinsèque de ce type de liaison, leur très grande réactivité conduisant fréquemment à l'existence des seuls *n*-mères. Certaines de ces espèces à courte durée de vie ont toutefois pu être mises en évidence par voie spectroscopique. Ainsi, récemment la diméthyl germathione et la diméthyl silathione ont été détectées par dégradation thermique des trimères en spectroscopie photoélectronique (3).

Dans ce travail nous avons entrepris l'examen des caractéristiques électroniques de ces entités, en comparaison avec celles de leur homologue mieux connu le thioformaldéhyde. Cette étude a été effectuée sur la base d'une analyse précise de spectres photoélectroniques et de résultats de calculs réalisés dans le cadre de la méthode MS Xα (4).

Cette méthode qui a déjà conduit à des résultats satisfaisants pour les systèmes comportant des atomes de silicium ou de germanium (5), présente de plus des avantages certains de par son formalisme pour l'analyse des différentes grandeurs liées à l'ionisation (potentiels d'ionisation, sections efficaces de photoionisation).

Conditions de calcul

Nous avons travaillé à partir d'une version standard de la méthode MS Xα en utilisant le formalisme développé initialement par Dill et Dehmer (6) pour son extension à l'étude d'états du continu.

Suivant ce procédé, l'évaluation des sections efficaces de photoionisation nécessite la connaissance de deux fonctions monoélectroniques, l'une décrivant l'électron avant ionisation et l'autre après ionisation. La fonction d'état initial est une fonction normée obtenue par un calcul autocohérent MS Xα; la fonction d'état final est une fonction du continu parfaitement déterminée dès que l'on définit la valeur propre qui lui est associée. Compte tenu de l'utilisation de la méthode des perturbations dépendant du temps ces deux fonctions doivent être évaluées avec le même potentiel. Ceci nous a amené, contrairement à certains auteurs (7), mais en accord avec Dill et Dehmer et très récemment Grimm et coll. (8), à introduire la correction de Latter (9) pour le calcul de tous les états initiaux (états liés) en la prenant en compte à chaque itération de calcul MS Xα. Cette correction, qui nous a permis d'obtenir un potentiel strictement identique pour l'évaluation des fonctions d'états initial et final, s'est révélée indispensable pour obtenir une stabilisation des résultats de calculs de sections efficaces vis à vis d'une variation des différents paramètres de la méthode MS Xα (α, rayons des sphères, *l*).

Au niveau des atomes, les valeurs du paramètre α optimisées par Schwarz (10) ont été choisies, une moyenne pondérée des α atomiques ayant été utilisée pour les régions intersphère et outersphère. Les rayons des sphères atomiques ont été obtenus de façon non empirique (11), en réduisant de 12% les rayons obtenus à l'itération 0 pour des sphères englobant un nombre d'électrons égal au numéro atomique.

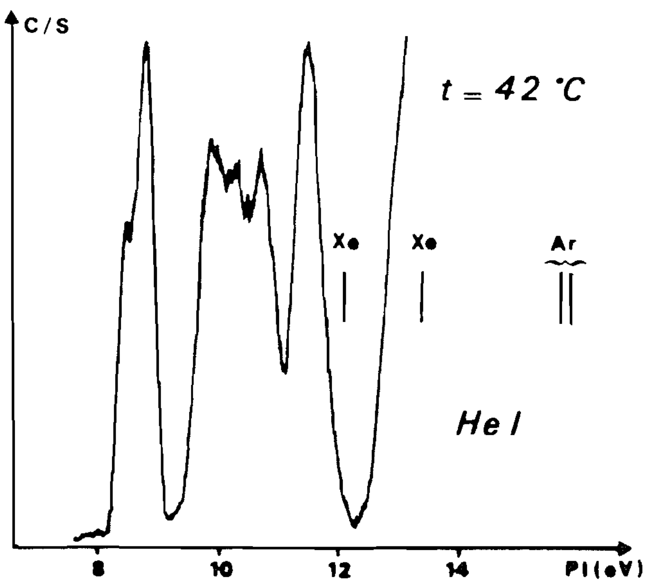

FIG. 1. Spectre photoélectronique (HeI) de $(Me_2GeS)_3$ à 42°C.

le cas de l'atome d'hydrogène nous a conduit à toujours faire choix, compte tenu de l'expérience acquise pour d'autres systèmes (12), de la valeur de 0,85 ua dans tous les cas.

Le calcul de la fonction d'état initial étant couplé à celui de la fonction d'état final pour l'évaluation des sections efficaces de photoionisation, nous avons adopté, pour chaque atome et pour le calcul de tous les états initiaux, en accord avec d'autres auteurs (13), une valeur de $l_{max} = l + 1$.

Pour les fonctions d'état final, les valeurs de l_{max} étant imposées par les règles de sélection au niveau des régions atomiques $l_{initial} = l_{final} + 1$, nous avons choisi $l_{max\,f} = l_{max\,i} + 1$, la valeur de l_{max} dans le cas de l'outersphère a été déterminée par l'examen de la convergence des résultats. ($l_{max\,f} = 7$ pour $Me_2Ge{=}S$, $l_{max\,f} = 10$ pour $(Me_2GeS)_2$.)

Spectres photoélectroniques de la diméthyl germathione, du tétraméthyl cyclodigermathione et de l'hexaméthyl cyclotrigermathione

Nous nous sommes attachés en un premier temps à préciser les potentiels d'ionisation caractéristiques de la diméthyl germathione, système pour lequel nous disposions d'un support expérimental important.

En effet, par pyrolyse à 273°C et 0,05 mbar, le spectre du trimère obtenu vers 42°C a été profondément modifié (figures 1 et 2), le nombre de bandes observées laissant présumer de la présence de deux entités. Si une conversion partielle trimère → monomère n'était pas envisageable étant donné les profondes modifications du spectre, une réaction de dimérisation ne pouvait être exclue. L'analyse du spectre du dimère stable de la n-butyl germathione a été réalisée et a permis de lever l'ambiguïté (fig. 3).

Afin de conforter les attributions antérieurement réalisées à l'aide de ces données expérimentales et d'un calcul pseudo-potentiel sur le monomère (3), nous avons abordé conjointement l'étude du trimère, du dimère et du monomère par la méthode MS Xα.

$(Me_2GeS)_3$

Sur la base des paramètres géométriques déterminés expérimentalement pour l'hexaméthyl cyclotrisilathione (14) nous avons réalisé un calcul MS Xα sur le trimère de la diméthyl germathione en symétrie C_{3v} (tableau 1), avec évaluation des potentiels d'ionisation selon le principe de l'état de transition.

Les valeurs ainsi calculées pour chaque potentiel d'ionisation ont été trouvées très voisines de celles des énergies monoélectroniques obtenues lors du calcul du potentiel d'ionisation associé au dernier niveau occupé. Ainsi, ce sont ces énergies monoélectroniques que nous avons retenues comme valeurs pour tous les potentiels d'ionisation dans le cas du trimère, ainsi que pour les systèmes examinés ultérieurement.

Le spectre obtenu pour le trimère à 42°C est caractérisé par une première bande aux environs de 9 eV avec un épaulement du côté des faibles énergies (fig. 1), attribué à des ionisations mettant en jeu les orbitales $17e$ et $12a_1$ caractéristiques des combinaisons de symétrie π des paires des atomes de soufre (tableau 1).

D'après l'allure du spectre on aurait attendu un ordre inverse $12a_1$, $17e$, il faut toutefois remarquer que les deux premiers potentiels d'ionisation sont obtenus voisins (9,95 et 10,22 eV).

Entre 10 et 11 eV, un massif intense apparaît avec trois potentiels d'ionisation distincts (9,88, 10,3 et 10,70 eV) correspondant à des ionisations faisant intervenir les paires libres de symétrie σ des atomes de soufre (orbitale $16e$) et les combinaisons des liaisons σ_{Ge-S} et σ_{Ge-C} (orbitales $15e$, $11a_1$). Les interactions notables observées entre ces liaisons sont imposées par la structure géométrique du cycle.

Enfin, à 11,45 eV on observe une bande intense liée à l'ioni-

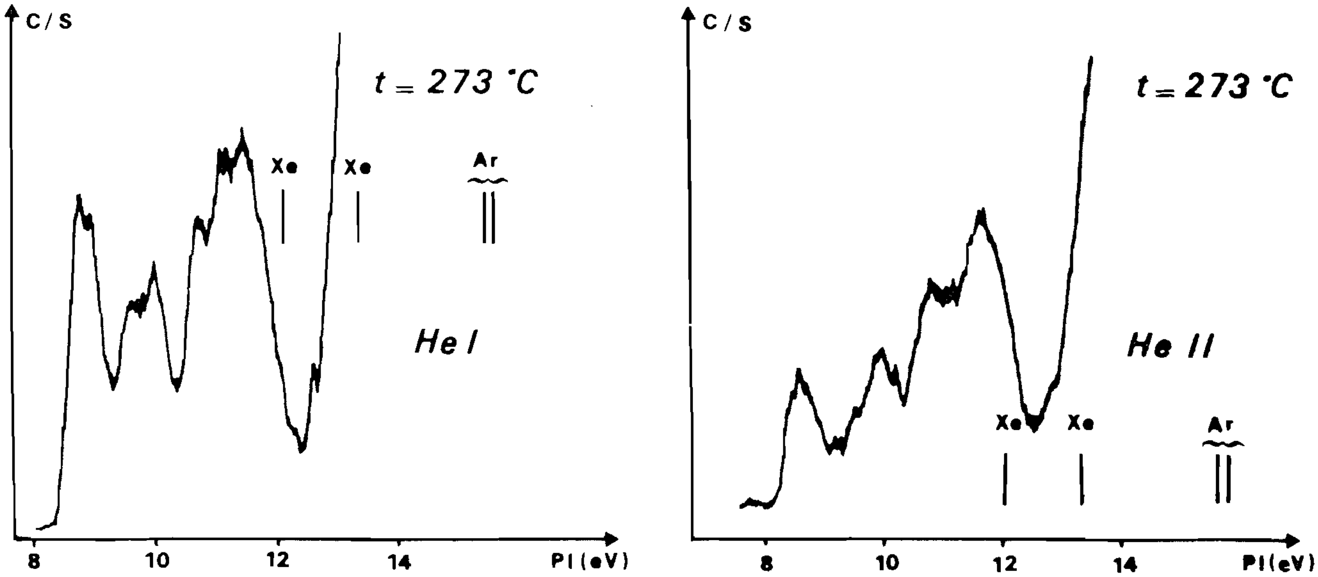

FIG. 2. Spectre photoélectronique (HeI, HeII) de $(Me_2GeS)_3$ à 273°C.

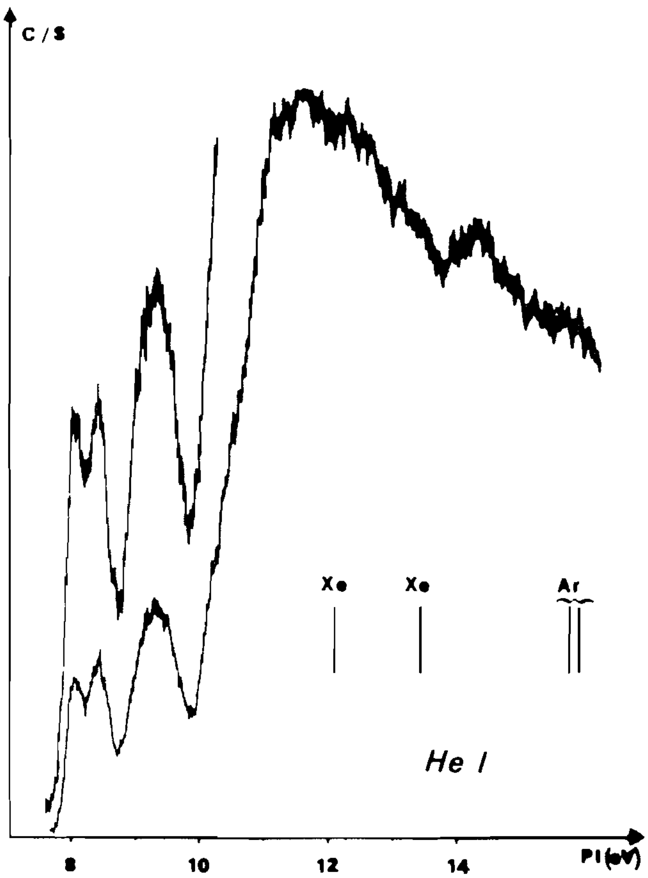

FIG. 3. Spectre photoélectronique (HeI) de $(nBu_2GeS)_2$.

sation des orbitales $10a_1$, $14e$ et $5a_2$ caractéristiques des liaisons σ_{Ge-C} et d'une combinaison des paires d'électrons libres de symétrie σ des atomes de soufre.

Me₂Ge=S, (Me₂GeS)₂

La complexité du spectre obtenu par pyrolyse du trimère à 272°C et certaines observations particulières concernant les variations d'intensité des bandes selon le rayonnement incident nous ont amenés à réaliser une étude complète des grandeurs liées à l'ionisation (potentiels d'ionisation, sections efficaces) pour le monomère et le dimère.

Potentiels d'ionisation

Les résultats présentés dans les tableaux 2 et 3 nous ont permis de proposer une attribution cohérente du spectre expérimental (tableau 4) qui s'interprète bien comme nous l'avions proposé par la présence du monomère et du dimère.

Le premier massif composé de deux bandes très proches à 8,6 eV et 8,85 eV (fig. 2) recouvre trois ionisations, celles mettant en jeu respectivement la paire non liante de l'atome de soufre de $Me_2Ge{=}S$ (orbitale $4b_1$) et les combinaisons liante et antiliante des paires π des atomes de soufre du dimère (orbitales $4b_{1u}$ et $2b_{3g}$).

Au niveau du deuxième massif, nous associons la bande à 9,55 eV à une ionisation faisant intervenir l'orbitale $2b_2$ ($\pi_{Ge=S}$) du monomère. La bande à 9,9 eV correspond au deuxième massif observé expérimentalement dans le cas de $(nBu_2GeS)_2$ (fig. 3); elle provient des états ioniques générés par éjection d'un électron des orbitales caractéristiques de la liaison σ_{Ge-S} et de la combinaison liante des paires σ des atomes de soufre (orbitales $4b_{3u}$ et $3b_{2u}$).

Pour le troisième massif, nous faisons correspondre à la bande à 10,75 eV une ionisation du monomère mettant en jeu l'orbitale $5a_1$ (σ_{Ge-S}). La bande observée à 11,15 eV est due à la présence du dimère et correspond à l'ionisation relative à l'orbitale $3b_{2g}$ associée aux liaisons σ_{Ge-C}. L'ionisation mettant en jeu l'orbitale $2b_{1g}$ du dimère intervient également vraisemblablement dans cette région. Pour les attributions respectives de ces bandes, il faut prendre en compte le fait qu'expérimentalement, sur une plage de température de 20°C autour de la température de décomposition du trimère, une diminution d'intensité du premier massif a été observée et conjointement, une légère augmentation des bandes à 9,9 eV et 11,15 eV.

Enfin, nous attribuons la bande à 11,47 eV à des ionisations du monomère et du dimère mettant en jeu les orbitales fortement localisées sur les σ_{Ge-C} dans le cas du monomère (orbitale $3b_1$) et sur les σ_{Ge-C} et σ_{Ge-S} dans le cas du dimère (orbitales $5a_g$ et $3b_{1u}$).

Sections efficaces de photoionisation

Comme le fait apparaître un examen de la fig. 2, le passage d'un rayonnement HeI à HeII a conduit à de très notables diminutions d'intensité au niveau des trois massifs. Si a priori de telles diminutions pouvaient être prévues pour les deux premiers massifs mettant en jeu essentiellement les atomes de soufre, celles concernant le troisième massif, et en particulier la diminution très nette observée pour la bande à 11,15 eV associée à une ionisation faisant intervenir les liaisons $\sigma_{Ge—C}$ du dimère, était difficilement explicable. Afin de compléter notre analyse et conforter les attributions précédentes nous avons donc réalisé pour les premiers états initiaux du monomère et du dimère le calcul des sections efficaces différentielles de photoionisation, grandeurs comparables aux intensité des bandes expérimentales.

Les résultats obtenus ont été visualisés sous forme de courbes (figures 4 et 5), un balayage en énergie cinétique par pas de 5 eV ayant été effectué dans un domaine compris entre 5 eV et 50 eV. Nous avons dans tous les cas matérialisé par des traits verticaux les énergies de photons correspondant aux deux sources de rayonnement utilisées HeI (21,22 eV) et HeII (40,81 eV).

Les données des figures 4 et 5 traduisent dans l'ensemble de façon satisfaisante les observations expérimentales: (*i*) pour une énergie de photons correspondant à un rayonnement HeI, nous observons aussi bien pour le monomère que pour le dimère des valeurs voisines et assez faibles de sections efficaces pour tous les états faisant intervenir les paires des atomes de soufre (aussi bien σ que π), les liaisons de type π comme σ du motif Ge═S. Par contre, des valeurs nettement plus élevées apparaissent lors d'ionisations mettant en jeu des orbitales caractéristiques des liaisons $\sigma_{Ge—C}$ (Me_2Ge═S: $3b_1$, $(Me_2GeS)_2$: $3b_{2g}$). De fait le spectre expérimental (fig. 2) présente bien deux premiers massifs d'intensité peu différenciée et au contraire un troisième massif nettement plus intense. (*ii*) En ce qui concerne les variations d'intensité en fonction du rayonnement incident, les sections efficaces calculées pour toutes les orbitales traduisent bien les diminutions observées expérimentalement pour l'ensemble du spectre lors du passage d'une énergie de photons de 21,22 eV à 40,81 eV (figures 4 et 5).

Compte tenu du recouvrement des différentes bandes il est difficile de discuter des importances respectives de ces diminutions; toutefois un certain nombre de remarques peuvent être faites.

Pour les deux bandes à 9,55 eV et 10,75 eV associées au monomère, le calcul conduit à des diminutions sensiblement du même ordre, légèrement plus importante pour l'état initial $2b_2$ que pour l'état $5a_1$, ce que l'on observe bien expérimentalement.

Un accord moins satisfaisant apparaît lorsque l'on compare les intensités respectives des bandes du monomère et du dimère, notamment de celles à 9,55 eV et 9,9 eV; d'après les résultats des calculs, les diminutions d'intensité sont attendues à peu près du même ordre pour ces deux bandes, ce qui n'est pas observé expérimentalement (diminution plus importante dans le cas du monomère). Notons toutefois que, lors de l'enregistrement des spectres HeI et HeII, la composition du mélange a pu être modifiée dans le sens d'un accroissement du dimère.

Le point le plus intéressant de cette analyse concerne la bande à 11,15 eV pour laquelle une diminution nette a été observée au niveau des spectres et que nous attribuons à une ionisation mettant en jeu l'orbitale $3b_{2g}$ du dimère caractéristique des liaisons Ge—C. Or précisément nous observons

11,47	11,36	$^2B_1$	11,27	^2A_g
			11,33	$^2B_{1u}$

(fig. 5) une allure de résonance aux environs de 22 eV et donc pour cet état initial une forte diminution de section efficace en passant de $h\nu$ = 21,22 eV à $h\nu$ = 40,81 eV. Les observations expérimentales et les résultats déduits des calculs de sections efficaces forment donc un ensemble tout à fait cohérent.

Ainsi, l'utilisation conjointe de calculs de potentiels d'ionisation et de sections efficaces en MS Xα nous a permis de réaliser une attribution précise des différentes bandes du spectre observé par dégradation thermique du trimère de la diméthyl germathione et donc d'interpréter sans ambiguïté les ionisations caractéristiques du monomère.

Caractéristiques électroniques de la diméthyl germathione et de la diméthyl silathione

La méthode MS Xα se révélant bien adaptée à l'étude de ces molécules thioorganométalliques, nous avons étendu notre approche à la silathione (3) et réalisé parallèlement un calcul sur le thioformaldéhyde (15).

État fondamental

Pour les trois dérivés $H_2C═S$, $Me_2Si═S$ et $Me_2Ge═S$ (tableau 2) nous notons une séquence analogue des dernières orbitales occupées:

X = C : $2b_1$ (−7,02 eV), $1b_2$ (−9,09 eV), $3a_1$ (−11,19 eV)
X = Si : $4b_1$ (−6,52 eV), $2b_2$ (−7,13 eV), $5a_1$ (−8,91 eV)
X = Ge: $4b_1$ (−6,18 eV), $2b_2$ (−6,77 eV), $5a_1$ (−8,42 eV).

La dernière orbitale occupée est associée à la paire libre non liante de l'atome de soufre. Les orbitales moléculaires suivantes correspondent respectivement aux liaisons $\pi_{X═S}$ et $\sigma_{X—S}$ (X = C, Si, Ge). La quatrième orbitale moléculaire met en jeu les liaisons $\sigma_{C—H}$ et les liaisons $\sigma_{X—C}$ (X = Si, Ge).

Les distributions de charge font apparaître des localisations voisines pour ces trois dérivés en ce qui concerne les orbitales caractéristiques de la paire libre de l'atome de soufre ($4b_1$ et $2b_1$) et celles associées aux liaisons $\sigma_{X—S}$ ($5a_1$ et $3a_1$); ces dernières presentent dans les trois cas une localisation importante sur l'atome de soufre.

Par contre, les orbitales $2b_2$ et $1b_2$ se différencient plus nettement. Dans le cas du thioformaldéhyde, nous observons une liaison π assez bien répartie sur les deux atomes (fig. 6). Pour la diméthyl silathione et la diméthyl germathione, les contours présentent une nette dissymétrie avec une forte densité autour de l'atome de soufre (fig. 6); cette dissymétrie a déjà été observée lors d'une étude réalisée sur $H_2Ge═S$ en PSHONDO (16).

Des conclusions similaires peuvent être déduites de l'analyse des distributions électroniques π pour les trois systèmes.

Un caractère polaire nettement plus marqué pour >Si═S et >Ge═S que pour >C═S apparaît, réflétant les électronégativités respectives des atomes, Si, Ge, C et S (en charges nettes q_{Si} = +0,69, q_S = −0,65; q_{Ge} = +0,71, q_S = −0,69; q_C = +0,23, q_S = −0,21).[3]

Cette très forte polarisation du système π dans la diméthyl silathione et la diméthyl germathione permet de prévoir a priori une grande réactivité de ces systèmes.

De fait, expérimentalement, il n'a pas été possible d'isoler ces entités; par contre différents *n*-mères ont pu être caractérisés. Dans le cas du thioformaldéhyde, seuls des polymères insolubles ont été obtenus alors que pour la diméthyl silathione et la diméthyl germathione, des dimères ont pu être isolés (2), la structure du tétraméthylcyclodisilathiane ayant d'ailleurs été déterminée par diffraction électronique (14).

L'analyse simultanée des contours tracés pour les $\pi_{X═S}$ et $\pi^*_{X═S}$ (X = C, Si, Ge) (fig. 6) nous a permis de mieux appré-

[3]La charge de l'intersphère a été répartie sur les atomes proportionnellement à leur participation à l'orbitale moléculaire.

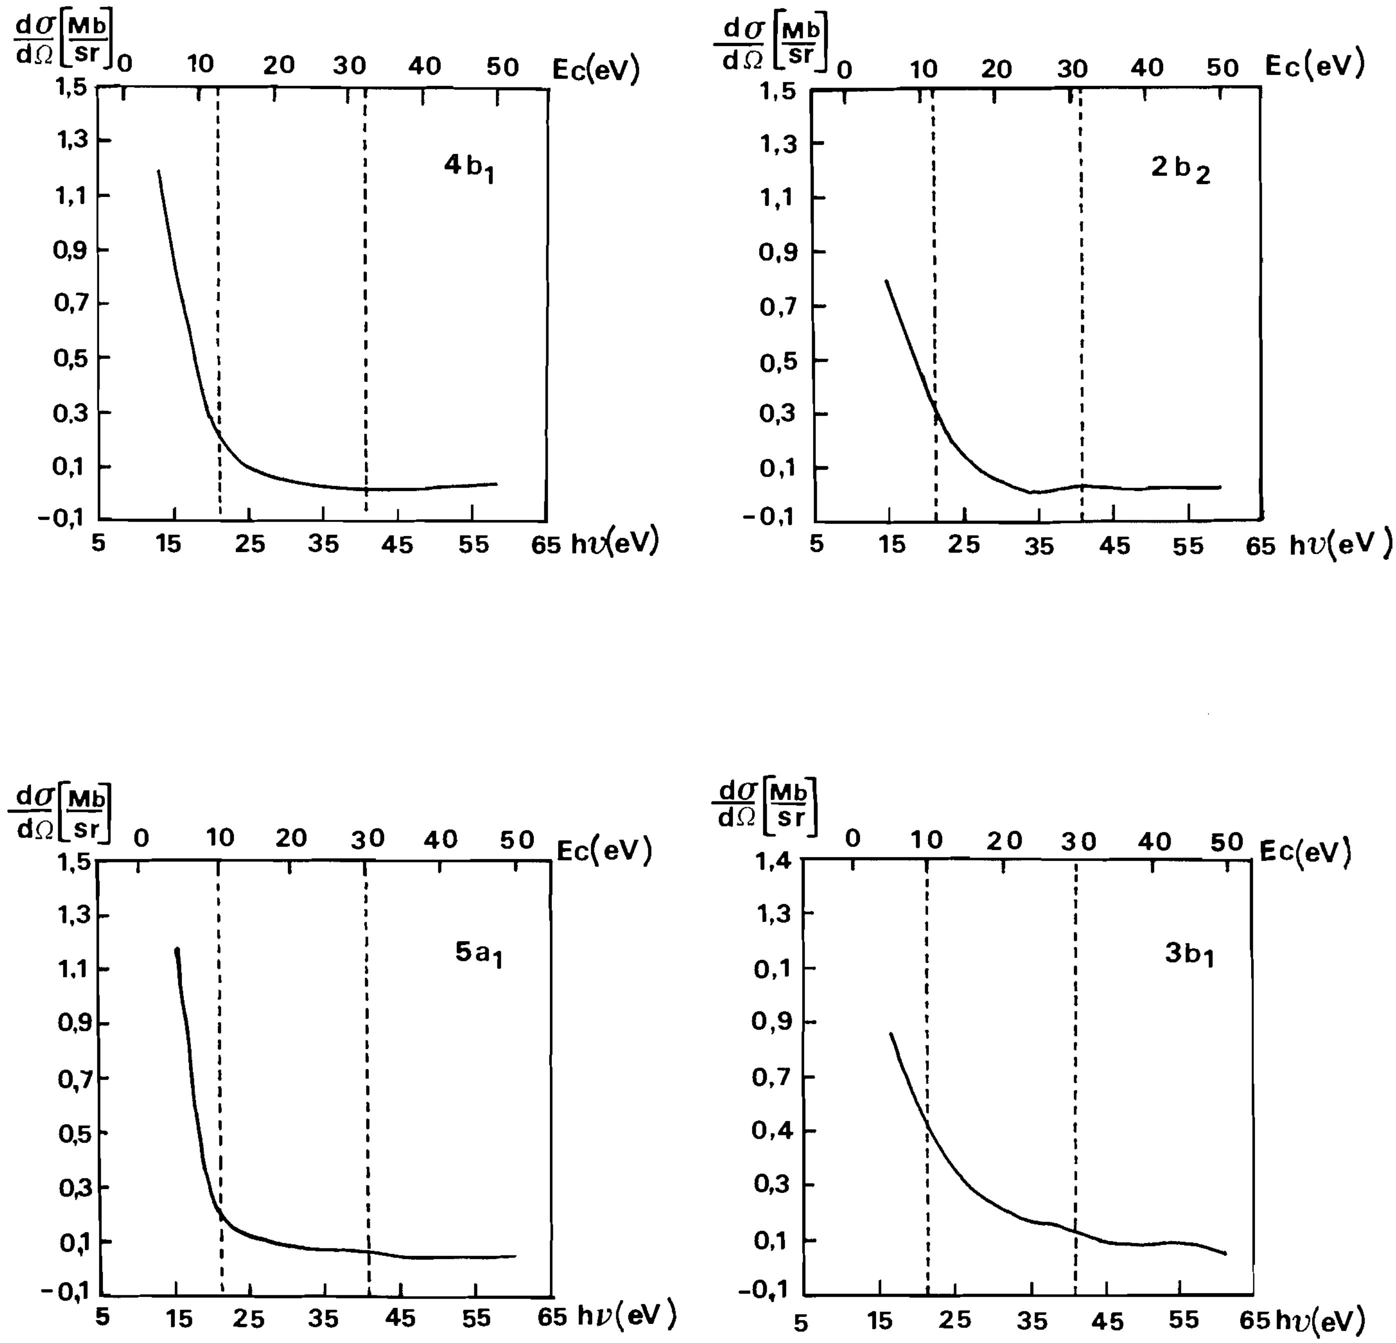

FIG. 4. dσ/dΩ pour les orbitales $4b_1$, $2b_2$, $5a_1$ et $3b_1$ de $Me_2Ge{=}S$.

hender ces différences de comportement.

Pour la diméthyl silathione et la diméthyl germathione, la dissymétrie des contours permet de lever la restriction bien connue de symétrie pour de telles dimérisations (17) (fig. 6). On conçoit alors que l'étape déterminante correspondra à la formation d'une liaison X—S puisqu'elle conduit à un recouvrement maximal entre les contours obtenus pour les orbitales occupées (autour de S) et les orbitales virtuelles (autour de Ge ou Si).

Ces caractéristiques déjà observées pour de nombreux dérivés $Me_2Si{=}CH_2$ (18), HP=NH (19) permettent d'expliquer la formation aisée de dimères tête-bêche.

Il n'en est pas de même en ce qui concerne le thioformaldéhyde où des contours symétriques sont observés pour les orbitales $\pi_{C=S}$ et $\pi^*_{C=S}$ (fig. 6). Ceci est en accord avec le fait qu'expérimentalement aucune formation de dimère n'a été observée dans ce cas.

États de Rydberg

Sans entreprendre une étude théorique complète des états excités des trois systèmes examinés, nous avons procédé à la caractérisation de leurs premières orbitales virtuelles, le formalisme de la méthode MS Xα étant particulièrement bien adaptée pour la description de ces orbitales vis à vis d'approches plus traditionnelles.

Compte tenu des valeurs relatives des charges partielles sur les sphères atomiques et sur l'outersphère, les différentes orbitales sont distinguées comme étant à caractère multicentrique (orbitale de valence) ou monocentrique (orbitale de Rydberg).

Dans le cas de $H_2C{=}S$, nous observons une première or-

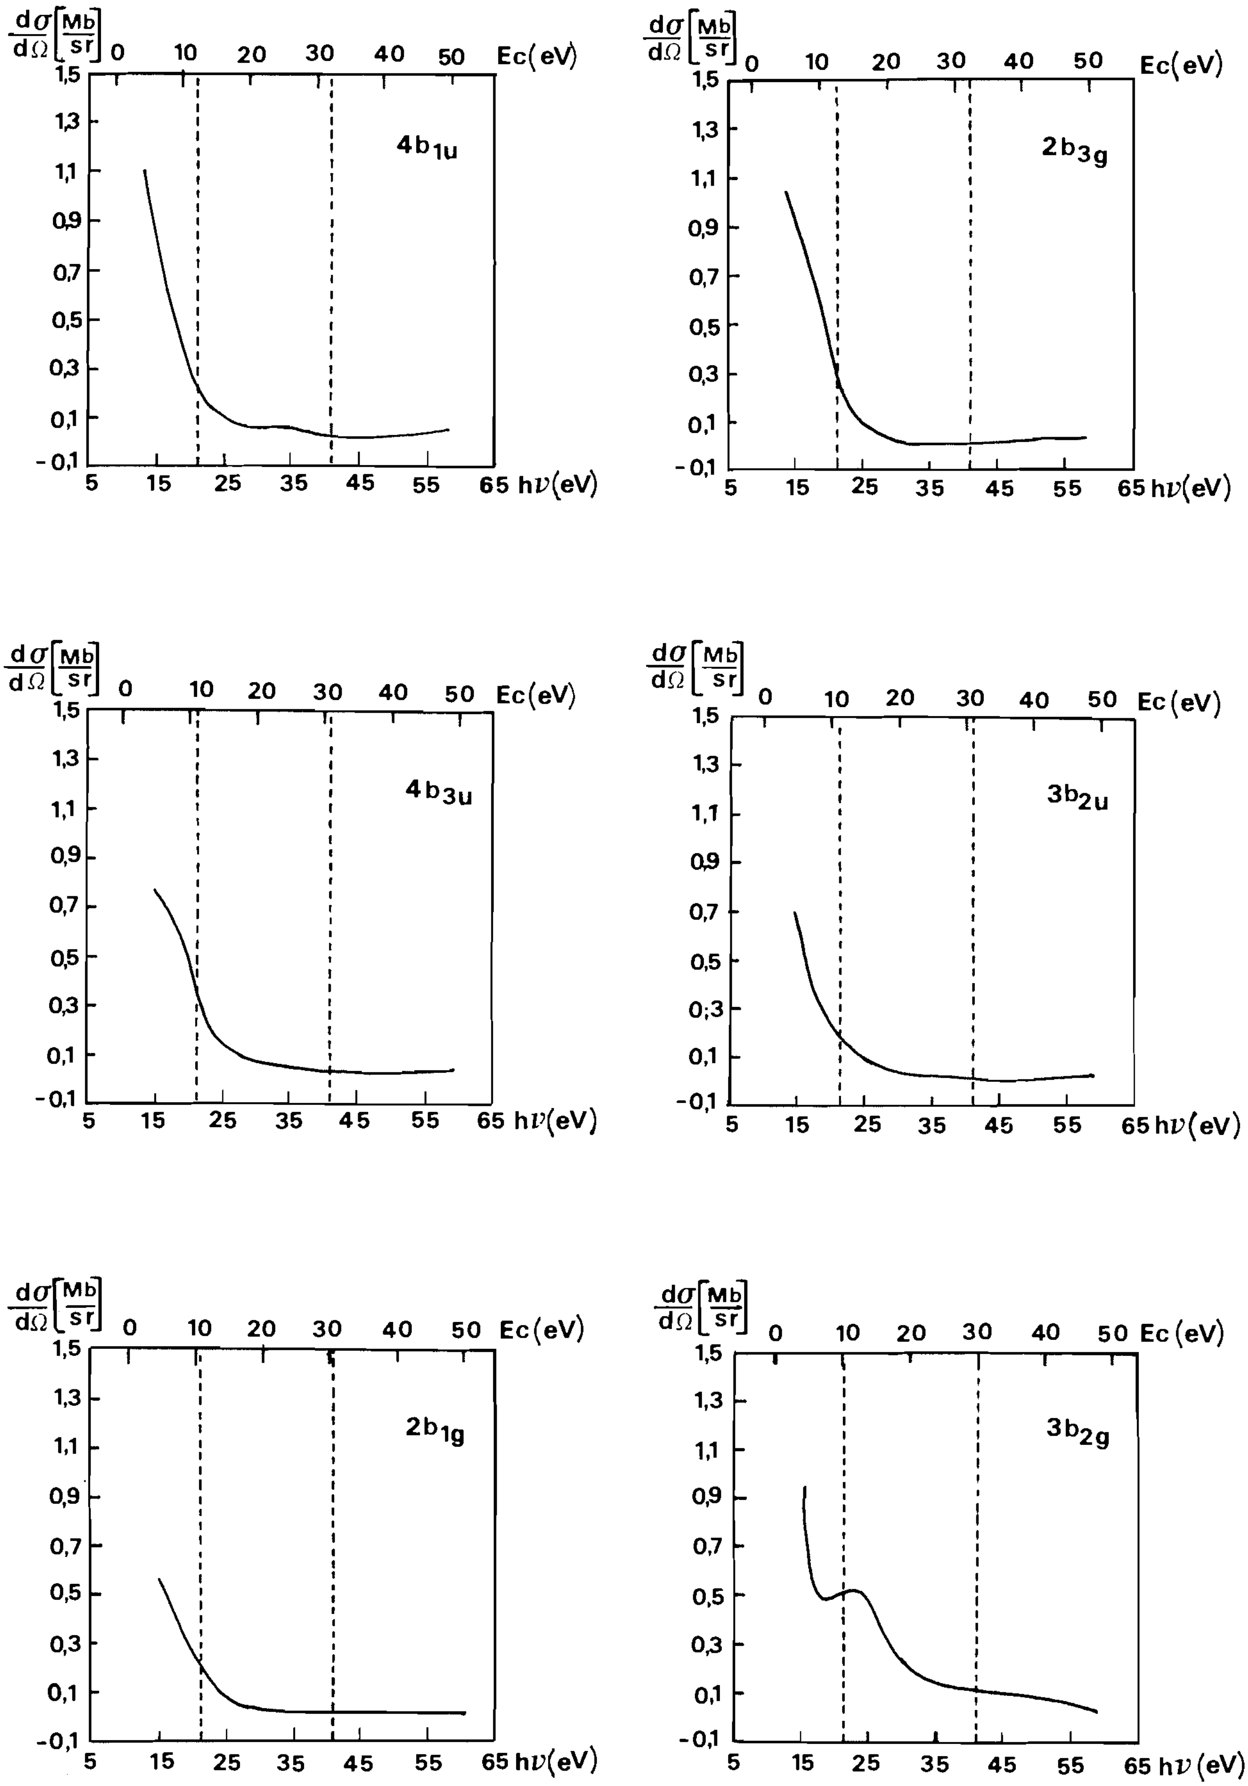

FIG. 5. $d\sigma/d\Omega$ pour les orbitales $4b_{1u}$, $2b_{3g}$, $4b_{3u}$, $3b_{2u}$, $2b_{1g}$ et $3b_{2g}$.

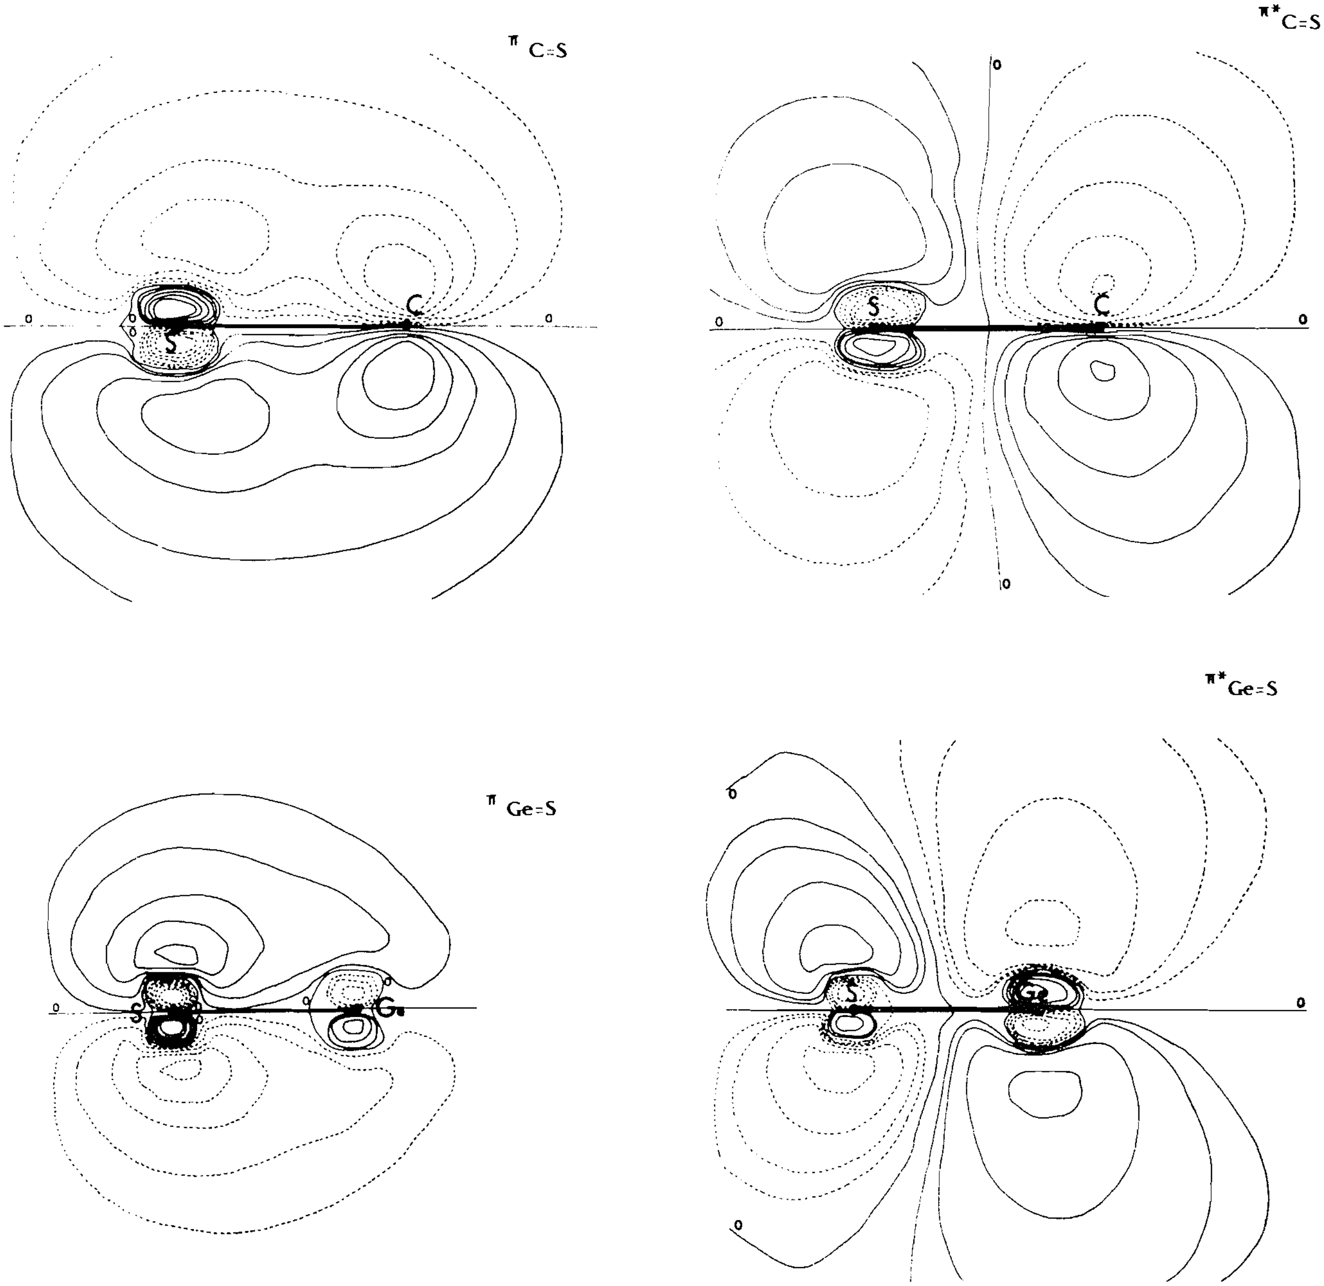

FIG. 6. Courbes de niveau pour les orbitales $\pi_{C=S}, \pi^*_{C=S}$ de $H_2C{=}S$ et $\pi_{Ge=S}, \pi^*_{Ge=S}$ de $Me_2Ge{=}S$ pour les valeurs suivantes de ψ:
$1b_2(\pi_{C=S})$: 0, ± 0,025, ± 0,05, ± 0,1, ± 0,15, ± 0,2 $(e/ua^3)^{1/2}$
$3b_2(\pi^*_{C=S})$: 0, ± 0,025, ± 0,05, ± 0,1, ± 0,2, ± 0,3 $(e/ua^3)^{1/2}$
$2b_2(\pi_{Ge=S})$: 0, ± 0,025, ± 0,05, ± 0,1, ± 0,15, ± 0,2 $(e/ua^3)^{1/2}$
$3b_2(\pi^*_{Ge=S})$: 0, ± 0,015, ± 0,025, ± 0,05, ± 0,1, ±0,2 $(e/ua^3)^{1/2}$.

bitale virtuelle de valence $2b_2$ (−4,80 eV) avec un relativement faible pourcentage d'outersphère (de l'ordre de 17%) et correspondant à la $\pi^*_{C=S}$.

Les orbitales suivantes $4a_1$ (−3,12 eV), $3b_1$ (−2,24 eV), $3b_2$ (−2,22 eV) et $5a_1$ (−2,16 eV) présentent des pourcentages de charge dans la région extramoléculaire de plus de 85% et sont donc à prédominance Rydberg, de type *s* pour l'orbitale $4a_1$ et de type *p* pour les orbitales $3b_1$, $3b_2$ et $5a_1$.

Les tracés reportés dans la fig. 7 font apparaître le caractère diffus de ces orbitales dans des régions loin des noyaux, de symétrie sphérique pour l'orbitale $4a_1$ et de type *p* pour l'orbitale $3b_1$.

Des tracés réalisés à une autre échelle ont permis de constater une intervention non négligeable des atomes dans les régions proches des noyaux. Ceci met bien en évidence, comme l'avaient déjà noté Roberge et Salahub (20) lors de calculs sur H_2S, les difficultés à établir une distinction nette entre orbitale de valence et orbitale de Rydberg.

Nos résultats, caractérisés par la présence d'orbitales Rydberg assez basses à caractère *s* et *p*, rejoignent ceux obtenus antérieurement par Bruna *et al.* (21) pour $H_2C{=}S$ lors d'un calcul Hartree Fock *ab initio* avec interaction de configuration.

Par ailleurs, étant donné les récents travaux spectroscopiques réalisés sur le thioformaldéhyde (22), nous avons procédé au

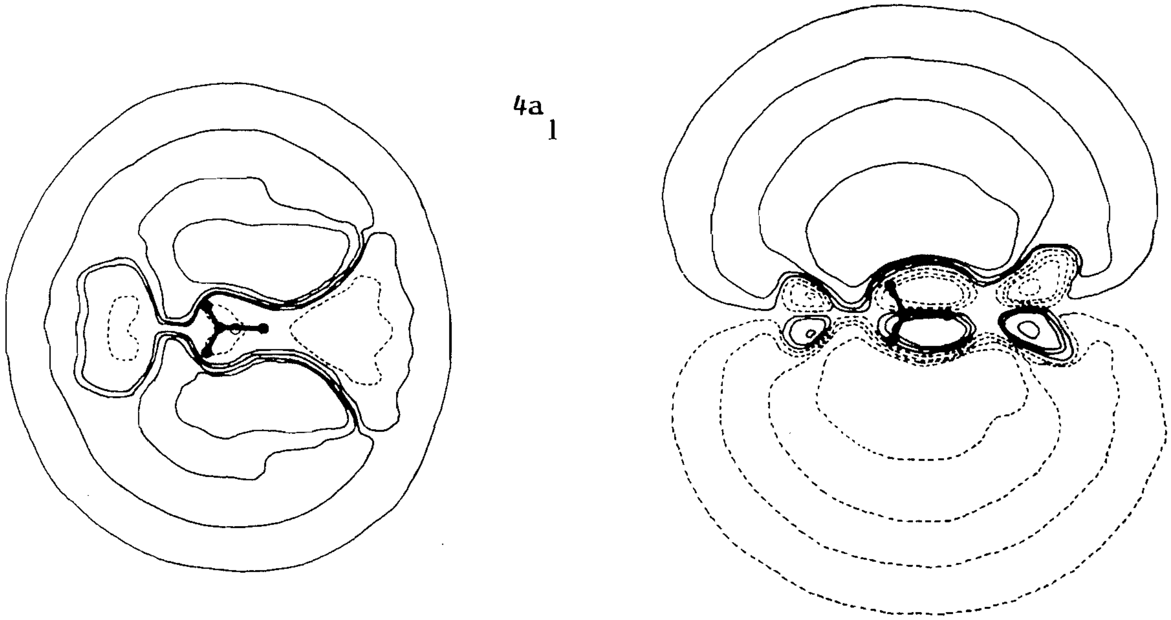

FIG. 7. Courbes de niveau pour les orbitales $4a_1$, $3b_1$ de $H_2C{=}S$ pour les valeurs suivantes de ψ:
$4a_1$: + 0,0003, + 0,001, + 0,003, ± 0,01 $(e/ua^3)^{1/2}$
$3b_1$: ± 0,0003, ± 0,001, ± 0,003, ± 0,01 $(e/ua^3)^{1/2}$.

calcul des premières transitions électroniques, en utilisant en version sans polarisation des spins la méthode de l'état de transition. Il faut cependant remarquer que les calculs ainsi réalisés ne permettent d'atteindre qu'une moyenne des énergies associées aux états singulet et triplet (23).

Expérimentalement, les états excités les plus hauts en énergie ont pu être caractérisés par analyse des structures fines rotationnelles; les bandes à 5,8, 6,6 et 6,82 eV ont été attribuées à des transitions 0—0 respectivement de type $n \rightarrow 3sa_1$ $(^1B_1)$, $n \rightarrow 3pb_1$ $(^1A_1)$, $n \rightarrow 3pa_1$ $(^1B_1)$, la faible bande à 5,6 eV correspondant à une transition $\pi \rightarrow \pi^*$ $(^1A_1)$.

Les résultats des calculs effectués confortent ces attributions expérimentales puisque nous obtenons par ordre d'énergie croissante pour les transitions permises $\pi \rightarrow \pi^*$ ($1b_2 \rightarrow 2b_2$: 4,33 eV), $n \rightarrow 3sa_1$ ($2b_1 \rightarrow 4a_1$: 4,91 eV), $n \rightarrow 3pb_1$ ($2b_1 \rightarrow 3b_1$: 6,30 eV), $n \rightarrow 3pa_1$ ($2b_1 \rightarrow 5a_1$: 6,45 eV).

Dans le cas de $Me_2Ge{=}S$ (tableau 2), nous observons une première orbitale virtuelle $3b_2$ essentiellement de valence (17% dans l'outersphère) caractéristique de la $\pi^*_{Ge=S}$.

L'orbitale suivante $6a_1$ apparaît à la fois à caractère Rydberg et de valence avec un pourcentage de 57% dans la région extramoléculaire (tableau 2). Les tracés réalisés mettent en évidence dans des régions éloignées des noyaux son caractère diffus d'orbitale *s* de Rydberg mais également près des noyaux les caractères antiliants Ge—S et Ge—C de cette orbitale.

Les deux autres orbitales $7a_1$ et $4b_2$ sont comme dans $H_2C{=}S$ à caractère Rydberg de symétrie *p*.

Les résultats obtenus pour $Me_2Si{=}S$ sont très voisins de ceux de $Me_2Ge{=}S$ quant aux distributions de charge, tant sur les atomes que sur l'outersphère. On remarque seulement une inversion des deux premières virtuelles $6a_1$ et $3b_2$ ainsi que de $4b_2$ et $7a_1$ vis à vis de $Me_2Ge{=}S$.

Nous n'avons pas entrepris de calculs de transitions électroniques pour la diméthyl germathione et la diméthyl silathione puisque nous ne disposions d'aucun support expérimental.

Il semblerait toutefois, compte tenu des résultats obtenus, que l'on puisse attendre pour ces deux systèmes des transitions de Rydberg dans la même région ou précédant les transitions de valence.

Conclusion

Cette étude menée par MS Xα nous a conduit à préciser certaines caractéristiques de nouvelles entités à courte durée de vie récemment mises en évidence la diméthyl silathione et la diméthyl germathione.

Nous avons en premier lieu confirmé la détection en spectroscopie photoélectronique de la diméthyl germathione par la détermination des diverses grandeurs liées à l'ionisation de ce système.

Par ailleurs, l'analyse comparative des résultats obtenus pour la diméthyl silathione, la diméthyl germathione et leur homologue le thioformaldéhyde nous a permis de mieux percevoir les modifications induites au niveau de la structure électronique (caractéristiques de l'état fondamental et des états Rydberg) lors du remplacement d'un atome de carbone par un atome de silicium ou de germanium.

Remerciements

Deux des auteurs (G.P. et D.G.) remercient le Professeur Salahub pour leur avoir communiqué le programme de calcul des sections efficaces et le Dr M. Roche pour de fructueuses discussions.

Une partie de ce travail a été accomplie dans le cadre d'une recherche subventionnée par le Fonds National Suisse de la Recherche Scientifique (projet 2.615-0.82). Les calculs ont été partiellement effectués sur un ordinateur aimablement mis à notre disposition par le Centre de Calcul de l'Université de Genève.

Ab-initio calculations on the retinal Schiff base – formic acid and allylimine – formic acid hydrogen bonds

MILAN HODOŠČEK AND DUŠAN HADŽI
Boris Kidrič Institute of Chemistry and Lek-Pharmaceutical and Chemical Works, Ljubljana, Yugoslavia

Received August 1, 1984

This paper is dedicated to Professor Camille Sandorfy on the occasion of his 65th birthday

MILAN HODOŠČEK and DUŠAN HADŽI. Can. J. Chem. **63**, 1528 (1985).

The proton potential functions of Schiff base – formic acid complexes were calculated in the *ab-initio* scheme with STO-3G and 4-31G basis sets without and with the inclusion of a perturbing charge. The comparison of the curves with the retinal Schiff base and allylimine obtained by using the short base encouraged further calculations with the longer base on the truncated system only. The curve obtained with the 4-31G set on the allylimine – formic acid complex is of a double minimum type with the deeper well still at the formyl oxygen. Inclusion of a perturbing negative charge near the hydrogen bond reverses the depth of the wells making the N-protonated form more stable.

MILAN HODOŠČEK et DUŠAN HADŽI. Can. J. Chem. **63**, 1528 (1985).

Faisant appel à des schémas *ab-initio* et utilisant des bases STO-3G et 4-31G avec ou sans l'inclusion d'une charge perturbante, on a calculé les fonctions de potentiel des protons de complexes entre l'acide formique et des bases de Schiff. Une comparaison des courbes relatives à la base de Schiff du rétinal et de l'allylamine, obtenues à l'aide de la base la plus courte, nous a encouragé à procéder à des calculs plus approfondis que nous avons effectués uniquement sur le système tronqué en utilisant un base de calcul élargie. La courbe que nous avons obtenue pour le complexe de l'acide formique et de l'allylimine, en utilisant une base de calcul 4-31G, comporte un double minimum et le puit le plus profond est encore fixé à l'oxygène. L'inclusion, près de la liaison hydrogène, d'une charge perturbante négative renverse la profondeur des puits et rend ainsi la forme N-protonée plus stable.

[Traduit par le journal]

Introduction

In the series of hydrogen bonds involved in the light transduction mechanisms of both rhodopsin and bacteriorhodopsin (1, 2), the bond between the retinal Schiff base nitrogen (N_{16}) and a proton offering group in the opsin deserves particular attention. In explaining the bathochochromic shift that occurs upon bonding of retinal to the apoprotein it was necessary to invoke both a positive charge on N_{16} of the retinal Schiff base and a negative charge in the vicinity of C_{14} of retinal (refs. 3, 4 and references therein). Although the electronic absorption of the retinylic chromophore in the ground state could be explained equally well by assuming covalent N^+—H bonding or by a strong hydrogen bond between N_{16} and a proton donor belonging to the apoprotein (5), it was the interpretation of the resonance Raman spectra of rhodopsin that led to the prevalent opinion in favour of protonated N_{16} (6, 7). However, the ^{13}C nmr spectra of rhodopsin appeared to oppose this view (8) and also the results of differential kinetic infrared spectroscopy were interpreted in terms of the initially unprotonated N_{16} (9). Sandorfy and co-workers have elaborated a scheme (10–15) reconciling both extreme views, i.e. the protonated and unprotonated Schiff base. The essence of this scheme is a strong hydrogen bond with a double minimum type of the proton potential function with the deeper well away from N_{16} in the ground state and a reversal occurring upon excitation. A single minimum type, nearly symmetric hydrogen bond was also considered. By this assumption, substantiated with semi-empirical calculations of the electronic energies as well as by infrared spectroscopic investigations of model Schiff bases interacting with various proton donors, it was possible to explain the resonance Raman spectroscopic results. The latest infrared work (16, 17) is indicative of the ground state protonation the main argument being deuterium mass effect on the C=N stretching mode that was observed previously in the resonance Raman spectra.

Until now, there is no experimental evidence of the nature of the group donating a proton to N_{16} either in full protonation or by hydrogen bonding. In the theoretical calculations of the electronic spectra both a carboxylate and an ammonium group were considered to be potential proton donors to N_{16} (5, 18, 19). Recent *ab-initio* calculations of the proton potential function of the retinal chromophore modelling systems: (*i*) allylimine – formic acid and (*ii*) allylimine – ammonium ion have shown that in model (*i*) the proton is located nearer to the formyl oxygen whereas in (*ii*) a nearly symmetrical double minimum type curve resulted (18). The curve shapes were not essentially altered by the inclusion of an extraneous charge and of the reaction field. Thus this work appears to exclude the possibility of the protonation of N_{16} by a carboxylic group. From the point of view of the reprotonation of the Schiff base after the completion of the photochemical cycle a negative counterion appears to be more likely. Thus the theoretical work (18) just mentioned requires some qualification since the calculation was done using a short basis (STO-3G). The deficiencies of such basis sets in calculating the relative energies of neutral and charged species are well known (20, 21). Thus the use of a more flexible basis set is indicated for the treatment of systems such as are the present ones. The application of larger basis sets requires for reasons of economy a truncation of the retinal moiety which poses, however, the question of the effect of truncation on the resulting proton potential function. This question is certainly important for a conjugated system. Therefore, we performed the calculations first on the retinal (without methyl groups) Schiff base – formic acid system using the STO-3G basis and then, using the same base, on the allylimine – formic acid complex. Since there was no dramatic difference between the shapes of both curves, we have carried out subsequent calculations on the truncated system, but using the 4-31G basis. This resulted in a qualitatively different curve which can be considered to be more realistic.

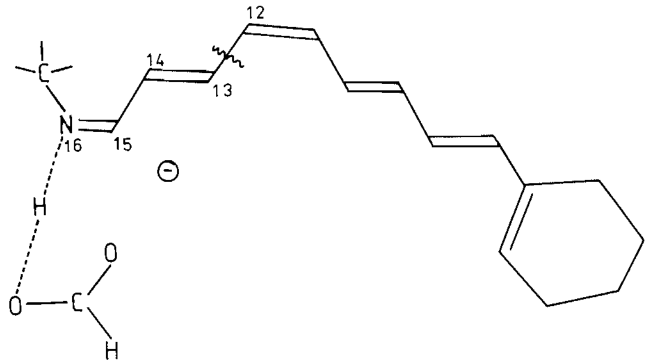

FIG. 1. Schematic representation of the (desmethyl) retinal Schiff base — formic acid system. ∿ indicates truncation and ⊖ the position of the negative charge.

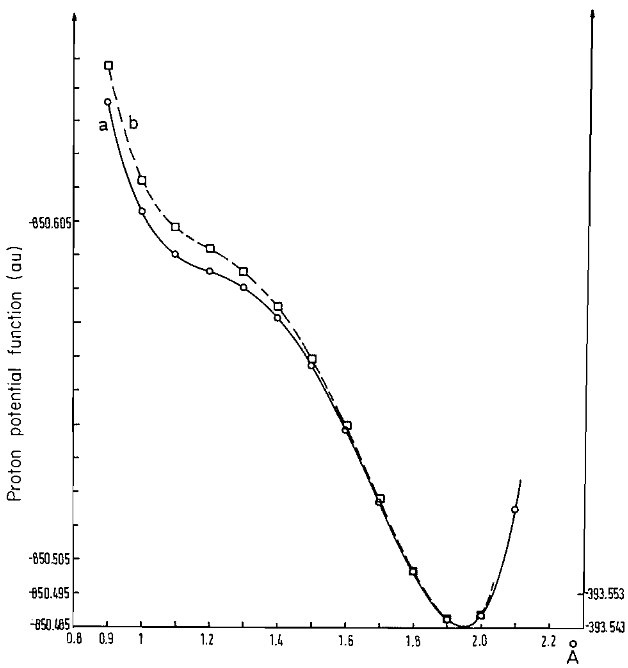

FIG. 2. Proton potential function (STO-3G basis) of (*a*) desmethyl retinal Schiff base — formic acid, and (*b*) allylimine — formic acid systems. Note the different energy scales. The horizontal scale in this and the following figures refers to the distance of the proton from the nitrogen.

Computational

Geometrical parameters

The parameters for the polyene Schiff base were taken from ref. 22 and those for the cyclohexene ring from available molecular mechanics calculations (D. Kocjan, private communication). The average plane of the ring and of the polyene chain were taken to be parallel. The geometric parameters for the amine — formic acid part (Fig. 1) were taken from ref. 22. The perturbing negative charge was placed (4) either in the N, O, C, O plane (distance from C_{13} = 3.0 Å and from N_{16} = 3.776 Å) or above the plane (distance from C_{14} = 3.030 Å, from C_{15} = 2.834 Å, and from N_{16} = 3.444 Å). The perturbing charge was introduced in the Fock Hamiltonian as an electrostatic perturbation of the form:

$$[1] \quad V' = q\int \frac{\rho^0}{|r - r'|} d^3r' + \sum_i \frac{Z_i q}{|r - r_i|}$$

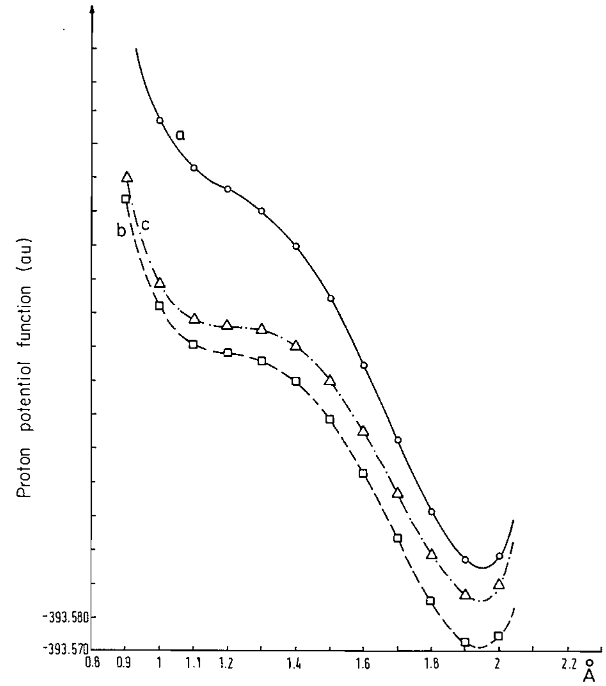

FIG. 3. Proton potential functions (STO-3G basis) of (*a*) allylimine — formic acid (no extra charge), (*b*) with unit negative charge in the plane, and (*c*) with charge above the plane (see Computational section).

where q is the value of the perturbing charge (equal to -1 au), ρ^0 is the unperturbed electron density of the respective molecule, r' is the position of the charge, and Z_i are the nuclear charges. The integral in [1] was solved using the *ab-initio* method described in ref. 23. The electrostatic potential V' was included in the Hamiltonian and the SCF procedure was switched on. The new energy was then obtained. For calculations the GAUSSIAN 80 program package (24) was used. The programs were implemented on a VAX 11/780 computer.

Results and discussion

Figures 2 and 3 show the proton potential curves for the retinylidene Schiff base — formic acid and allylimine — formic acid complexes computed using the STO-3G basis. The characteristic data are given in Table 1. The truncation of the conjugated chain has obviously a minor effect only on the depth of the inflection. This is considered to justify further calculations on the truncated system. The inclusion of a unit negative charge causes a flattening of the inflection which is more pronounced if the charge is placed above the plane. The results of the calculation with the 4-31G basis (Fig. 4) are more significant. The curve has now two minima separated by a low barrier. Without charge, the deeper well is still closer to the formyl oxygen whereas the inclusion of a charge in the plane makes the potential lower at the nitrogen site. For the charge placed above the plane we have calculated the energy in three points only (Table 1). The minimum nearer to the nitrogen is now deeper relatively to the one nearer to the oxygen, but the overall energy is less negative than with the charge in the plane. The results are qualitatively similar to those obtained previously on the methylamine — formic acid complex (21) except that in the latter the difference in energies of the two minima is larger. This corresponds well to the experimental estimate of the proton accepting propensities of alkylamines and aliphatic Schiff

TABLE 1. Calculated energies (in au) of the retinal Schiff base − formic acid (R) and allylimine − formic acid (A) systems at relevant distances v of the proton from nitrogen

	Energy					
	STO-3G			4-31G		
System	v = 1.9 Å	v = 1.5 Å	v = 1.1 Å	v = 2.0 Å	v = 1.5 Å	v = 1.1 Å
R	−850.4822	−850.4073	−850.3748	—	—	—
A	−393.5413	−393.4643	−393.4258	−398.1066	−398.0711	−398.0889
A	−393.5661	−393.500	−393.4780	−398.1426	−398.1193	−398.1473
A	−393.5517	−393.4886	−393.4708	−398.1168	−398.0968	−398.1279

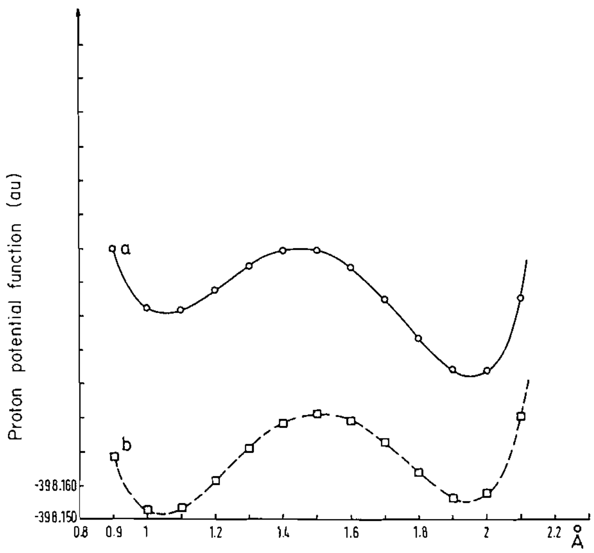

FIG. 4. Proton potential functions (4-31G basis) of allylimine − formic acid (a) without charge and (b) with a unit charge in the plane.

bases on the ground of infrared spectra of acid−base complexes carried out by Sandorfy and co-workers (5) by which it was shown that the Schiff bases are weaker proton acceptors than the amines. The results of our calculation indicate the tautomeric form $N^+H\ldots{}^-OCO$ to be the dominant one provided that a negative charge is present near the hydrogen bond. The analogous calculation on the full retinylidene system is expected to make the minimum nearer to N_{16} even deeper because the positive charge would be more dispersed. Higher levels of calculation should not radically change the picture. More extended basis sets including polarization functions are expected to lower somewhat the energy of the ionic form (20) whereas the electron correlation would lower the energy of the transition state that is anyway rather low (25, 26). Probably more important would be a full geometry optimization. Thus the results of the *ab-initio* calculation of the retinal Schiff base − formic acid are on the line considered by Sandorfy and co-workers (11−15), but give some more weight to the protonated form. We are continuing our *ab-initio* calculations in the direction of modelling possible groups that may subtend protons to the Schiff base − anion switch, and accept it from, after the photocycle had been completed.

NOTE ADDED IN PROOF: Recent uv and nmr investigations of hydrogen bonding between a dienylidene Schiff base and different halogeno acids indicate a rapid, dynamic equilibrium between the protomeric forms (27). Resonance Raman studies of hydrated and dried purple membrane of Halobacterium halobium lead to the conclusion that the protonated retinylidine Schiff base reverts to the unprotonated state in the absence of water (28). These results are in a good agreement with the theoretically predicted type of proton potential function.

The dehydrogenation reaction paths of methanethiol CH_3SH were analyzed by *ab initio* MO calculations. The geometries and energies of the reactants, transition states, and products have been determined on the singlet potential energy surface of the ground state. We also analyze the similar dehydrogenation reactions of methanol (CH_3OH) and ethanol (CH_3CH_2OH) for the purpose of comparison. The activation energy and the heat of reaction calculated by incorporating the effect of electronic correlation shows that the product $H_2C{=}S$ is chemically more unstable than the product $H_2C{=}O$. "Reaction ergodography" along the intrinsic reaction coordinate (IRC) for these dehydrogenation paths clarifies the distinct differences in atomic movement. The path of methanethiol has two characteristic steps before the transition state, while neither paths of the two carbinols have such multisteps. The electronic intramolecular interaction between subsystems of the reactant molecule is investigated in terms of Interaction Hybrid Molecular Orbital (IHMO).

Utilisant des calculs d'OM *ab initio*, on a analysé les voies réactionnelles associées à la déshydrogénation du méthanethiol (CH_3SH). On a déterminé les géométries et les énergies des réactifs, des états de transition et des produits sur la surface d'énergie potentielle singulet de l'état fondamental. Pour fins de comparaisons, on a aussi analysé les réactions de déshydrogénation semblables du méthanol (CH_3OH) et de l'éthanol (CH_3CH_2OH). Les énergies d'activation et les chaleurs des réactions, calculées en incorporant l'effet de la corrélation électronique, montrent que le produit $H_2C{=}S$ est chimiquement plus instable que le produit $H_2C{=}O$. L'application de l'"ergodographie réactionnelle" aux coordonnées réactionnelles intrinsèques (CRI) de ces voies de déshydrogénation permet de clarifier les différences qui les distinguent au niveau du mouvement atomique. La voie du méthanethiol possède deux étapes caractéristiques avant son état de transition; par ailleurs, ni l'un ni l'autre des voies des carbinols ne possède de telles étapes multiples. Utilisant la notion d'interaction entre orbitales moléculaires hybrides, on a étudié l'interaction intramoléculaire électronique entre les sous-systèmes des molécules qui réagissent.

1. Introduction

The dynamic analysis of elementary reaction is developed as part of a recent big stream of the theoretical study of chemical reactions. The selection of the reaction coordinate which shows the nature of structural change of reactant molecules during the reaction process is an important key, particularly for reactions in which polyatomic molecules participate. The reaction coordinate is hence considered to be an essential concept for constructing the theory of chemical reaction based on the chemical reaction pathway. There are many theories of chemical reaction in which the concept of the reaction coordinate plays an important role (1). The absolute rate theory of Eyring which first clarified the usefulness of the concept of the reaction coordinate is particularly well-known (2*a*). This is a representative theory of the so-called transition state theory and predicts the reaction rate based on the statistical treatment of molecules assuming the equilibrium between the reactants and the transition state (TS). As one focusses on the dynamical aspects, the unimolecular reaction rate theory of RRKM and its basic concept are developed to predict the reaction energy distribution of products and the effect of vibrational excitation (2*b*). The natural collision coordinate was introduced by Marcus to describe the statistical or dynamical aspects of chemical reaction using reaction coordinate and to treat the reactive scattering between an atom and a diatomic molecule (2*c*).

We have analyzed the dynamical aspects of various elementary reaction processes of polyatomic molecules in terms of the Intrinsic Reaction Coordinate (IRC) proposed by Fukui in 1970 (3), and investigated the topological structure of potential energy surface. The analysis of the dynamic aspects of some physical properties along IRC is called "reaction ergodography" (4). IRC is a solution of simultaneous first-order differential equations including the effect of mass of the nuclei which constitute the reactant molecules, and is useful to analyze the promoting mode of structural transformation, the quantum-mechanical tunneling effect, or the isotope effect of the reaction dynamics.

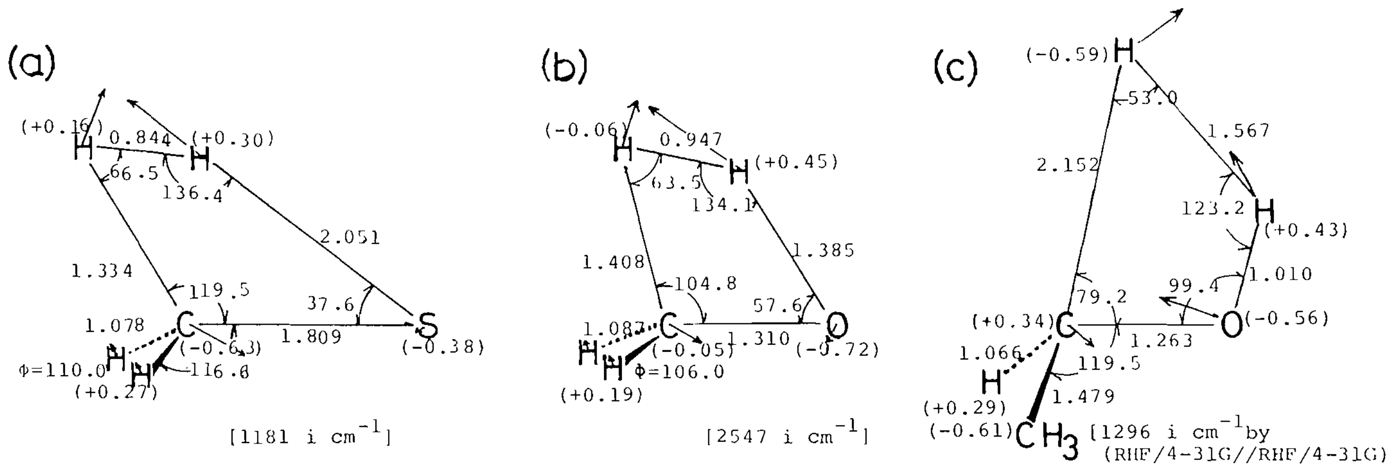

FIG. 1. RHF/6-31G fully-optimized geometries and displacement vectors of normal mode with imaginary frequency of transition states (TS's) for (*a*) methanethiol, (*b*) methanol, and (*c*) ethanol.

Thus reaction ergodography gives a clear definition of the concept of reaction coordinate which was previously used qualitatively and can present a dynamic picture of chemical reaction. Owing to the recent progress of large computers and software, it is now much easier to calculate the potential surface precisely by non-empirical method. The extent of reaction ergodography based on IRC is therefore more broadly applicable (5). The theoretical development to a special-functional molecule or to a dynamical analysis of reaction of the biochemically important molecules can be anticipated. Sulfur-containing organic compounds are of biochemical interest and little attention has been paid to their dynamical process, and their physical property and reactivity (6).

This article reports the reaction ergodography for the unimolecular reaction process of methanethiol which is a basic sulfur-containing compound. We analyzed the dehydrogenation path as the simplest example: $CH_3SH \rightarrow H_2C{=}S + H_2$. In order to investigate the electronic process of this reaction, we analyze the electronic interaction between intramolecular subsystems along the IRC using the Interaction Hybrid Molecular Orbital (IHMO) method (7). We also compare this reaction path with the similar dehydrogenation reaction paths of analogous compounds, methanol and ethanol:

$$CH_3OH \rightarrow H_2C{=}O + H_2$$

$$CH_3CH_2OH \rightarrow CH_3CH{=}O + H_2$$

2. Method of calculation

We used GAUSSIAN 80 (8) program package for the following *ab initio* MO calculations. The optimization of geometries of equilibrium points and the calculation of IRC were performed by the energy gradient method (9), with the 6-31G* basis set (10).

We performed the Møller-Plesset calculations (11) and configuration interaction (CI) calculations (12) with the 6-31G** basis set (10) in order to obtain more reliable energy estimates considering the effect of the electronic correlation at the 6-31G* optimized geometry. All the doubly excitations from the HF reference configuration were included in the CI wave functions with the 1*s* orbitals of carbon and oxygen and the 1*s*, 2*s* orbitals of sulfur kept fully occupied. In addition, the contribution of unlinked quadruple excitations (QC) was estimated (13).

The vibrational analysis and the tracing of IRC were carried out using the HONDO (14) program with the 6-31G* basis set. For ethanol, the vibrational and IRC analyses were carried out with the 4-31G basis set (15). The second derivatives of the potential energy surface required for the vibrational analysis at some optimized geometries were obtained by numerical differentiation of the analytically calculated energy gradient (9). The contribution of zero-point energy (ZC) was also used for more accurate total energy estimate.

The statistical *A* factors were estimated by the simplified transition state (TS) theory (2) expression

$$A_\infty = \frac{\nu_1 \nu_2 \ldots \nu_n}{\nu_1^\ddagger \nu_2^\ddagger \ldots \nu_{n-1}^\ddagger}$$

$$(n = 3N - 6; \quad N = \text{the number of atoms})$$

where ν_i and $\nu_i^\ddagger$ are the reactant and the TS vibrational frequencies, respectively.

3. Results and discussion

(1) Structures and vibrational modes of the transition states

The fully-optimized geometries of the TS's and the displacement vectors of normal modes with imaginary frequency are shown in Fig. 1. These vectors provide the initial direction of IRC leading to the products. The net charges on each atom are in parentheses. The TS of methanol (*b*) is optimized in Pople's early work (16). For TS of ethanol, we used the 4-31G geometry in our previous work (17). The first two TS (*a*), (*b*) have C_s symmetry of which symmetry planes are square C—X—H—H (X = S or O) plane, while the TS of ethanol (*c*) does not have C_s symmetry.

Let us compare the TS of methanethiol with that of methanol. The S—H bond length at the TS of CH_3SH (2.051 Å) is longer than the O—H bond length at the TS of CH_3OH (1.385 Å). This reflects the weakness of the S—H bond as compared with the strength of the O—H bond. Moreover, ∠CSH (37.6°) is lesser than ∠COH (57.6°). On the contrary, the breaking C—H bond of CH_3SH (1.334 Å) is shorter than that in CH_3OH (1.408 Å). These features show that the hydrogen atom separating from the heavy atoms are bound more strongly to the O atom than to the C atom in the CH_3OH molecule, to the C atom than to the S atom in the CH_3SH molecule.

Interestingly, in the TS of methanethiol, the H—H bond

length (0.844 Å) is rather close to the H—H bond length (0.730 Å) in the product, while the H—H bond length in the TS of methanol (a) (0.932 Å) is much longer (about 28%). It should also be noted that the C—S bond length in the TS of methanethiol (1.809 Å) does not change very much from the C—S bond length (1.817 Å) in the reactant, compared with the C—O bond length in the TS of methanol (1.310 Å) which is shorter (about 7%) than that in the reactant.

The C—O bond length (1.263 Å) in the TS of ethanol is also closer to that in the reactant ethanol than to the carbonyl bond length of the product acetaldehyde. The decomposing C—H bondlength is twice as long as that in the reactant and the Mulliken overlap population (0.041) between these two atoms shows that this bond is almost cleaved. In contrast, the decomposing O—H bond length (1.010 Å) stretches by only 5%. It should be noted that the H atom leaving the C atom is anionic while the other H atom leaving the O atom is cationic. The net charges of these atoms are −0.56 on the O atom, −0.59 on the H atom leaving the C atom, and +0.43 on the H atom leaving the O atom, respectively. This localization may be attributed to the long C—H bond length at TS, which is allowed by the electron-donating character of the substituted CH_3— group on the C atom of ethanol.

(2) Activation energies and frequency factors

Table 1 shows the various levels of calculated values for the activation energy and the heats of reaction and Table 2 lists the complete set of calculated harmonic frequencies (RHF/

[b]RHF/6-31G* results.
[c]RHF/4-31G results from ref. 17.

6-31G*). It shows the activation energy of CH_3SH to be 95.6 kcal/mol and the heat of reaction to be 30.8 kcal/mol, based on the CID + QC + ZC/6-31G**//RHF/6-31G* calculation. The activation energy and the heat of reaction for similar dehydrogenation of CH_3OH are 98.8 and 18.2 kcal/mol, respectively (16). These results indicate that the reactivity of CH_3SH is higher and the product $H_2C{=}S$ is more unstable chemically. These results agree with the experimental results (6).

The effect of electron correlation is estimated to be greater for CH_3OH than for CH_3SH with respect to all reactants, TS's, and products.

The second factor to be considered is the frequency factor (the *A* factor) for each process. The values calculated are given in Table 3 and show that the *A* factor of the methanol dehydrogenation is two times larger than that of the methanethiol. The former reaction is therefore considered more favorable than the latter in terms of the entropy factor. However, in this temperature region under moderate experimental conditions, this entropy factor may not be so important.

(3) Analysis of Intrinsic Reaction Coordinate (IRC)

Here we show the analysis for the reaction path of the dehydrogenation process of methanethiol. In Fig. 2(*a*), (*b*), (*c*), and (*d*) we show the change of potential energy, norm of energy gradient, bond length, and bond angles along the IRC of the reaction of methanethiol, respectively. For the reaction coordinate, s is the length measured along IRC on the potential energy surface and the unit of s is (atomic mass unit)$^{1/2}$ (bohr). The TS is located at $s = 0.0$ and the positive s values indicate the product region of the reaction. The reaction is thus considered to proceed as s value increases and by passing through the TS at $s = 0.0$.

Since the TS of this process has C_s symmetry, we assume that the IRC conserves this symmetry. It is interesting to note that the norm of the energy gradient has two local maxima before reaching the TS. This reaction thus proceeds through two characteristic stages. We can see from Fig. 2 (*c*) that the main process at the vicinity of the first local maximum $s = -3.0$ is the stretching of C—S bond length. On the other hand, we can read from Fig. 2 (*c*) and (*d*) that the main process at the vicinity of the second local maximum $s = -1.5$ is a decrease in the bond angle ∠CSHb, and an increase in the bond angles ∠SCHa accompanied by an increase in the S—Hb bond length.

Moreover, at the TS $s = 0.0$, both the C—Ha and the S—Hb bonds are weakened and the formation of the H_2 molecule has been accomplished.

Figure 3 shows the results from the analysis along the IRC of the similar dehydrogenation reaction of methanol.

In contrast to the case of CH_3SH, the potential barrier has a very sharp peak, corresponding to the large imaginary frequency of normal mode at TS, and the norm of the potential energy is bigger and has only a single local maximum before the TS.

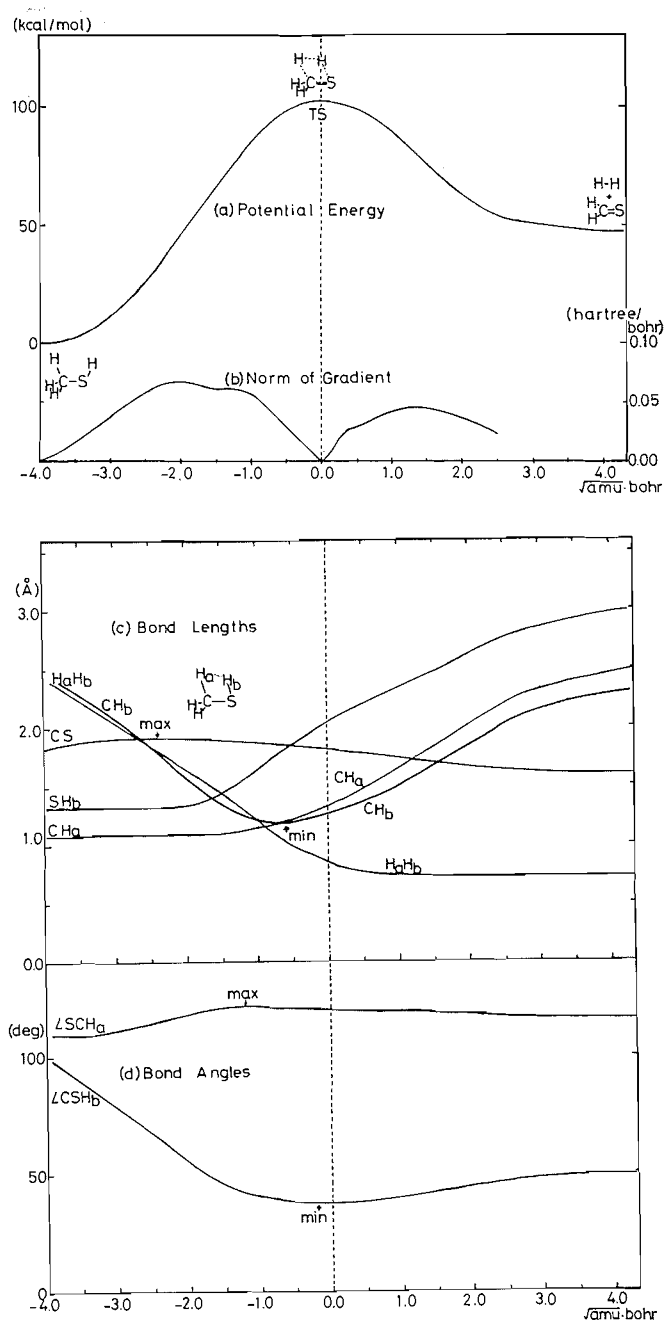

FIG. 2. Analysis for the reaction path of the dehydrogenation process of methanethiol. Change of (*a*) potential energy, (*b*) norm of gradient, (*c*) bond lengths, and (*d*) bond angles.

Parallelling the above statements, the geometry change along the IRC in Fig. 3 (*c*) and (*d*) does not have a two-step movement before reaching the TS as opposed to CH_3SH. For example, the bond length of CO is decreasing monotonically and does not have a local maximum as the CS bond length.

These observations can be explained by the different feature of MO's of each reactant. In the case of CH_3SH, the LUMO+1 of the reactant is antibonding CS—σ*. This will facilitate the electronic process of the C—S bond elongation. In contrast to this, the LUMO of CH_3OH does not have such character, but the LUMO+2 has the character of an antibonding CO—σ*.

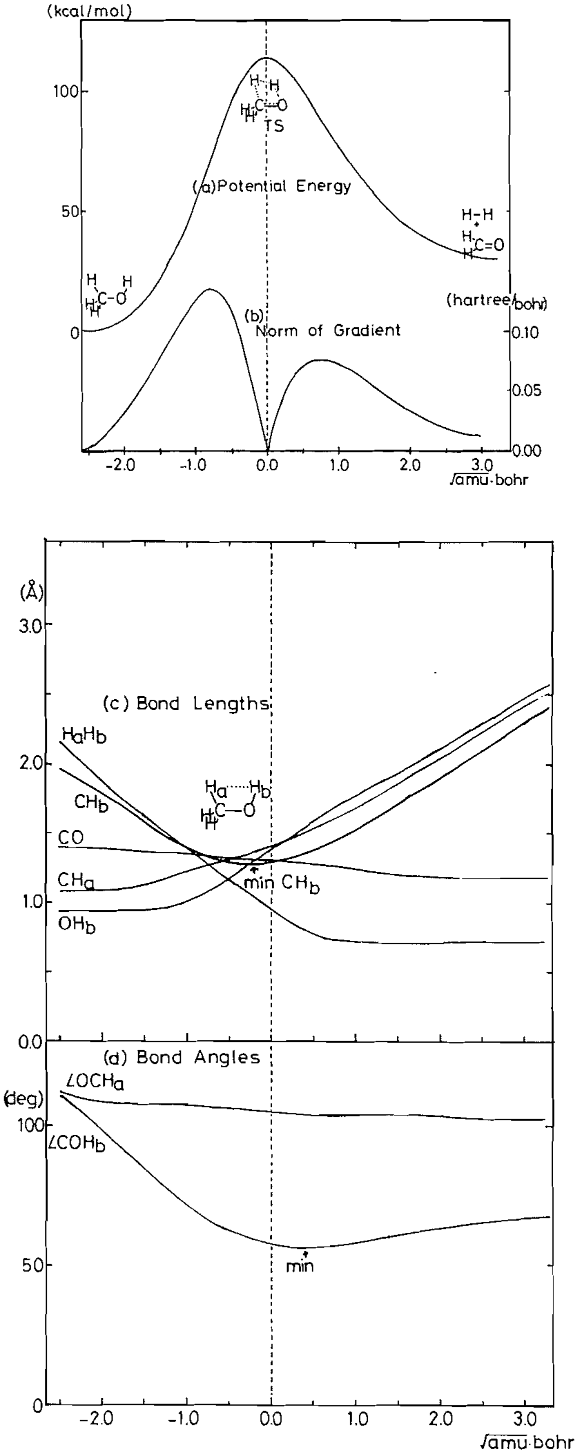

FIG. 3. Analysis for the reaction path of the dehydrogenation process of methanol. (*a*), (*b*), (*c*), and (*d*) are similar to Fig. 2.

The CS bond takes better advantage of the feasible electronic process for molecular deformation than does the CO bond, when the reaction proceeds. This contribution of antibonding CX bond (X = S or C) can be seen in the large difference of frequencies for each CX stretching mode (see Table 2) (9).

The atomic movement in similar dehydrogenation reaction of ethanol has appeared in our early study (17). Figure 4 shows the analysis of the IRC for this reaction. The substituted CH_3— group for one of the H's of CH_3OH brings about the large difference of the atomic movements. In the CH_3CH_2OH reac-

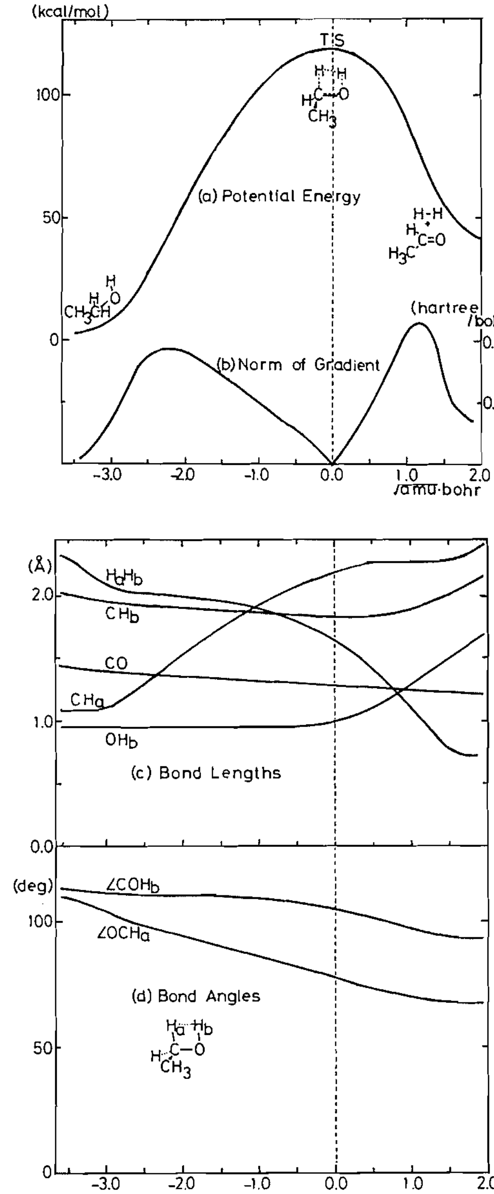

FIG. 4. Analysis for the reaction path of the dehydrogenation process of ethanol. (*a*), (*b*), (*c*), and (*d*) are similar to Fig. 2.

tion, the C—Ha bond stretches vigorously and almost breaks in the vicinity of the TS, the change of ∠OCHa is also very large. The H—H bond length is yet far from that of the product H_2 molecule in the vicinity of TS. Corresponding to these atomic movements, Ha becomes anionic and the reaction center C becomes cationic. This localized nature of charges is stabilized by the electron donation of the substituted CH_3— group, as mentioned before (17).

We try to explain the role of the vibrational modes of the reactant in the reaction selectivity of the experiment by using laser (18, 19). What kind of vibrational mode of a reactant molecule is excited initially and how does the reaction pathway interact with the excited vibrational mode?

Our previous work (5(*a*), 17) and others (20) have clarified the relationship between the vibrational modes and IRC in the asymptotic region of the reactant and the role of the vibrational modes are summarized below.

The dynamic aspects of a reacting system are well described by the coupling between IRC and the vibrational modes perpen-

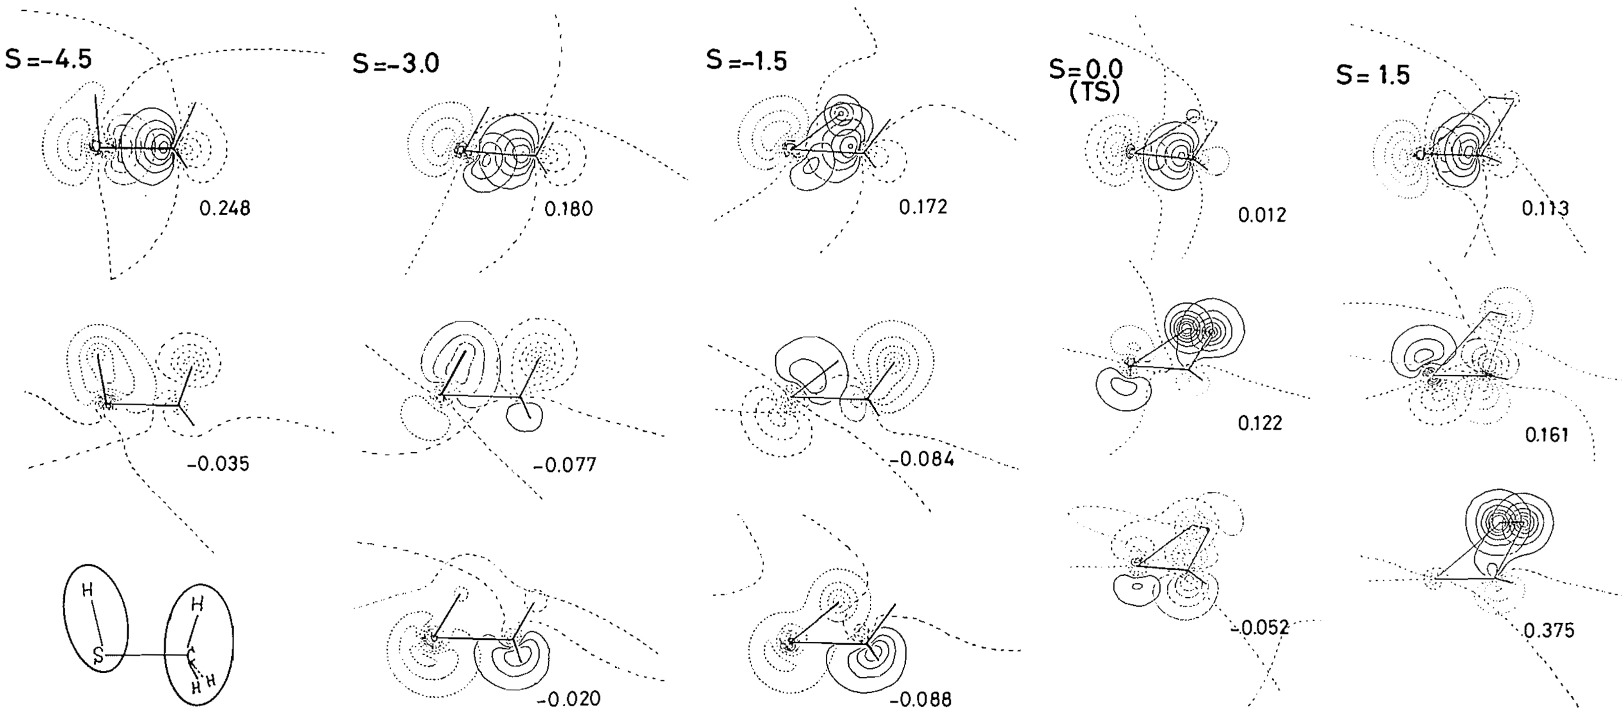

FIG. 5. Change of IHMO along the IRC for $s = -4.5$ to 1.5. Subsystems are CH_3 and SH.

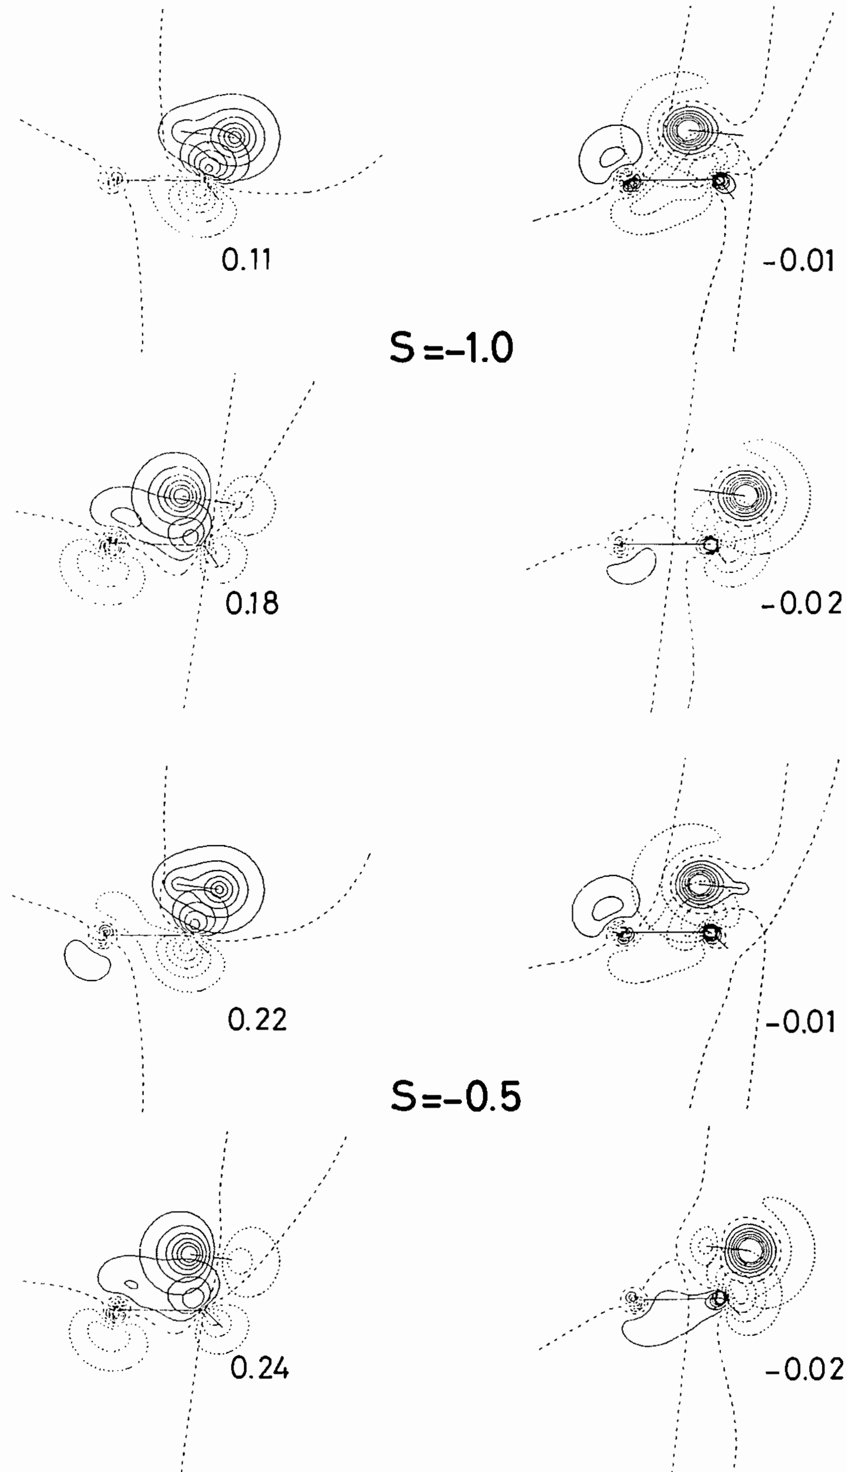

FIG. 6. Change of IHMO along the IRC for s = −1.0 to 1.5. Subsystems are $H_2C{=}S$ and H_2.

dicular to IRC. Some vibrational modes are strongly coupled with IRC and these strongly coupled modes twist IRC in the configuration space. Between the twisting of IRC and the location of the barrier, (*1*) the excitation of the vibrational mode to which IRC converged at the reactant is most effective for a channel where IRC twists after the TS (the late twisting IRC), (*2*) the excitation of a strongly coupled mode is most effective for a channel where IRC twists before the TS (the early twisting IRC). Another type of vibrational mode plays a part of energy supply mode. The vibrational energy pumped in this mode by laser is transferred to the particular mode mentioned above. A mechanism of this intramolecular vibrational energy transfer is determined by the mode coupling between the vibrational modes along IRC.

Table 2 shows the main normal vibrational modes of the methanethiol (reactant). It is well accepted that the ordering of vibrational frequencies are well reproduced in our level of calculations and that the experimental frequencies would be

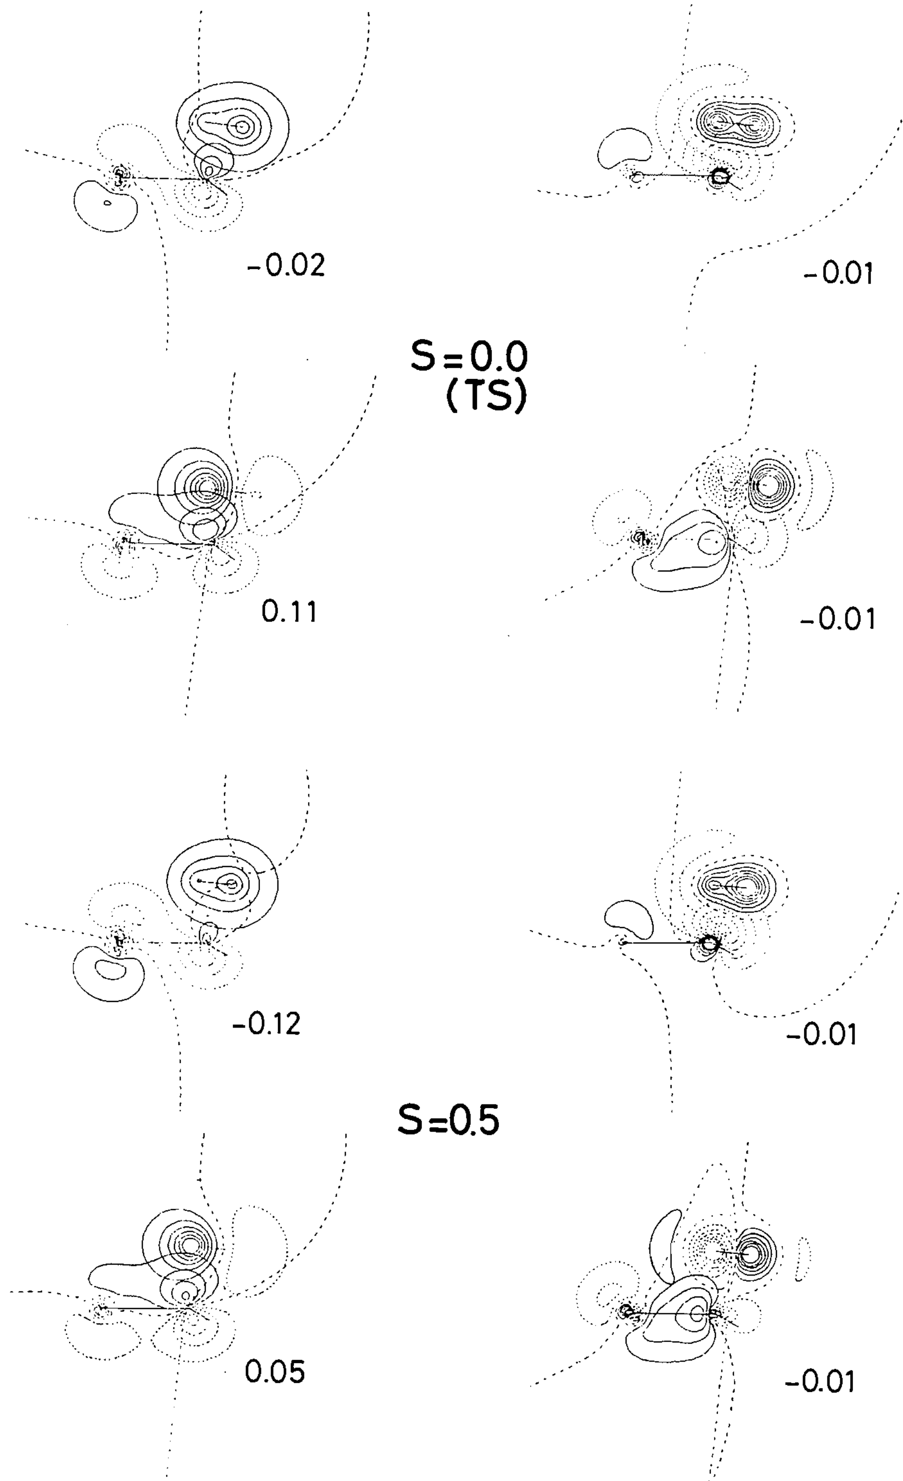

FIG. 6. (*Continued*)

obtained by a reduction of 10–15% from the calculated ones (9). Among these modes, the mode with an imaginary frequency 1181i cm^{-1} (RHF/6-31G*) corresponds to the displacement vector of IRC and this represents well the elimination of H_2 from the thiocarbonyl part $H_2C{=}S$. Reactant CH_3SH has a C—S stretching mode of 776 cm^{-1} and an asymmetric (A'') CSH bending mode of 874 cm^{-1}. These vibrational modes are considered to interact easily with the motion of nuclei along IRC at the early stage of the reaction process. Therefore, it can be predicted that the dehydrogenation of CH_3SH is directly promoted if either of the two modes is excited by a laser with an appropriate wave length.

(4) The electronic process on the reaction

Figure 5 shows the result obtained from the analysis of the electronic process following the reaction of CH_3SH along IRC from the viewpoint of IHMO.

Here the reactant molecule is separated into two subsystems CH_3 and SH based on the aspect of the weakened C—S bond and the newly forming H—H bond in the reactant region. Also

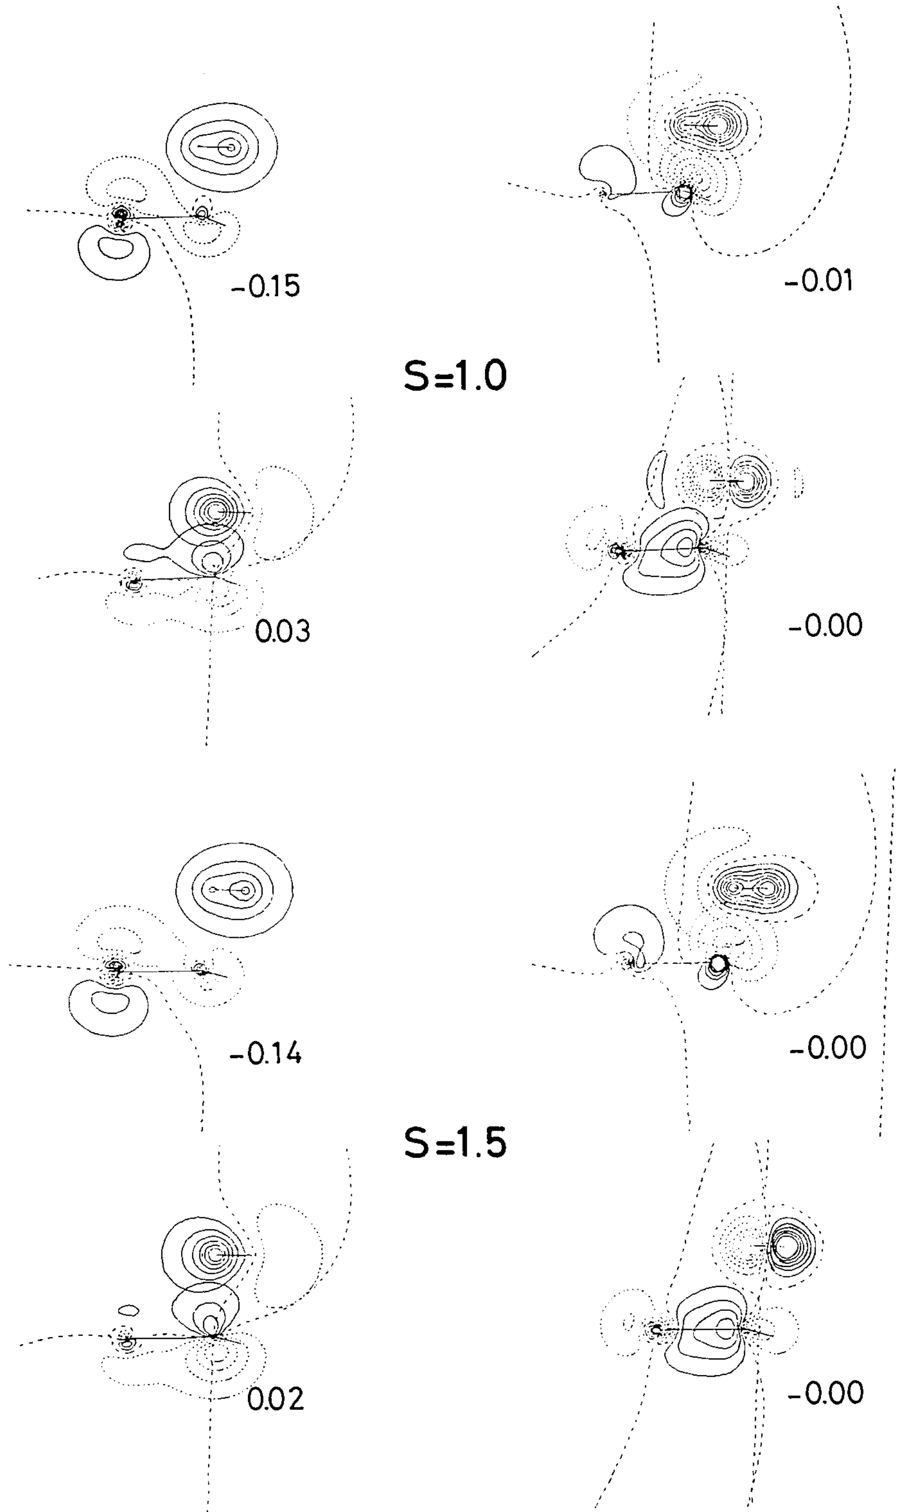

FIG. 6. (*Concluded*)

drawn are the IHMO's which diagonalize the overlap population matrix between these subsystems. Each number in this figure is the diagonalized value of the overlap population, so a larger positive value means a stronger interaction between these subsystems. At the early stage of the reaction $s = -3.0$, a σ-type IHMO is localized in the weakened C—S bond. Secondly, an IHMO representing the weakened S—H bond appears at $s = -1.5$. At the TS, the H—H σ bond which is near the value in the product H_2 molecule appears and it well represents the interaction between these two subsystems. At the product region $s = 1.5$ a new IHMO of C=S π bond appears clearly.

Now these subsystems are allocated to the product molecules H_2 and $H_2C{=}S$. The IHMO corresponding to these subsystems are shown in Fig. 6. If we obtain the IHMO whose interaction is that between H_2 and $H_2C{=}S$, we can easily describe the electronic process of the formation of H—H σ bond and C=S π bond and the elimination of S—H σ bond and C—H σ bond.

Among the four IHMO's at each s value, the first one is the charge transfer (CT) interaction from H—H σ bond to C═S π^* bond, and the second one is that from the C═S π bond to the H—H σ^* bond. These two HOMO–LUMO interactions are very important in the vicinity of the TS. Both of them have maximum values of overlap population at $s = -0.5$, and these values are decreasing, as the reaction proceeds through TS. The value of $\sigma \rightarrow \pi^*$ CT has already changed the sign at TS. It then decreased significantly, resulting in this interaction becoming unimportant. Compared with this, only the value of $\pi \rightarrow \sigma^*$ CT maintains a positive sign through $s = -1.0 \sim 1.5$, and this interaction is the most important of the four. It contributes to the formation of C—Hb bond, which corresponds to the fact that the C—Ha bond length is larger than the C—Hb bond length and the Hb atom is bound more strongly to the C atom than the Ha atom is bound to the C atom at the TS. The electronic processes along IRC are therefore remarkably described by the IHMO method as shown above.

4. Conclusion

In this study we investigated the reaction paths of the unimolecular decomposition of methanethiol.

The dehydrogenation path is analyzed by *ab initio* MO calculations. The geometries and energies of the reactants, TS's, reaction intermediates, and products have been determined on the singlet potential energy surface. We find that even similar dehydrogenation reactions of CH_3SH, CH_3OH, and CH_3CH_2OH have large differences in atomic movement. The dehydrogenation mechanism of CH_3SH is divided into two stages including the earlier stretching of the C—S bond and the reducing of the ∠CSHb angle as the first and the subsequent formation of the two stable molecules H_2 + H_2C═S as the second. The earlier activation energy of the reaction is attributed to the stretching of the C—S bond and the reducing of ∠CSHb, so if energy transfer to these modes can be possible, for example by laser, it is predicted that the reaction can proceed. The IRC analysis for the chemical reaction path is useful in laser chemistry. This theory is expected to apply to broader areas of chemistry in future.

For a detailed theoretical *ab initio* study of the X^2A_1/A^2B_2 system of the NO_2 molecule, three-dimensional potential energy surfaces have been calculated with the MRD-CI method for both symmetric and asymmetric NO bond distances. The calculated data are given here together with the technical parameters of the respective treatment, and the main features of the surfaces are discussed. The geometrical locations and depths of the computed energy minima as well as the $A-X$ vertical transition energy are found to be in good agreement with all known experimental data and allow for a good qualitative understanding of the overall appearance of the observed spectrum. The wavefunctions and potential energy surfaces will be used in subsequent investigations for the study of various molecular properties and coupling elements involved in the X^2A_1/A^2B_2 system of NO_2.

GERHARD HIRSCH et ROBERT J. BUENKER. Can. J. Chem. **63**, 1542 (1985).

Dans le but d'effectuer une étude théorique *ab initio* très détaillée du système X^2A_1/A^2B_2 de la molécule de NO_2, on a calculé les surfaces d'énergie potentielle tri-dimensionnelles par la méthode de MRD-CI tant pour les longueurs des liaisons symétriques et non symétriques. On présente les données calculées ainsi que les paramètres techniques de chacune des études respectives et on discute des caractéristiques principales de ces surfaces. On a trouvé que les positions géométriques et les profondeurs calculées des puits d'énergie ainsi que l'énergie de transition verticale $A-X$ s'accordent très bien avec toutes les données expérimentales connues et permettent de bien comprendre qualitativement l'allure générale du spectre observé. Au cours de recherches subséquentes, on se servira des fonctions d'onde et des surfaces d'énergie potentielle dans le but d'étudier les diverses propriétés moléculaires et les éléments de couplage impliqués dans le système X^2A_1/A^2B_2 du NO_2.

[Traduit par le journal]

1. Introduction

The NO_2 molecule continues to attract a great deal of interest because it is not only an important element in the discussion of environmental pollution, but also a system possessing a very complex spectrum in the visible and near-infrared regions. In the last decade there has been progress in unravelling the details of the NO_2 spectrum, both by means of a variety of experimental methods (1) and also by various *ab initio* calculations (2–5). Jackels and Davidson (3) pointed out that a curve crossing between the $^2A_1$ ground and the $^2B_2$ excited states, with its associated Herzberg–Teller interaction, is mainly responsible for the almost chaotic appearence of the NO_2 spectrum in the visible and near-infrared regions. In more recent times more detailed experimental studies (6, 7) have concentrated on the $A^2B_2-X^2A_1$ transition, which is known to be responsible for the brown color of gaseous NO_2.

In surveying the latest experimental data on this problem it has become apparent that a quantitative theoretical treatment of the vibronic motion of the NO_2 molecule in its X and A electronic states would be extremely useful in helping to understand the complex nature of this spectrum. For this purpose it is first necessary that (three-dimensional) NO_2 potential surfaces be generated by employing large-scale CI calculations and a high-quality AO basis, along with the associated electronic wavefunctions. Beyond this task it is required that non-adiabatic effects associated with the Herzberg–Teller $X-A$ interaction be computed explicitly and that the vibronic functions associated with either the adiabatic (CI) or diabatic electronic states be allowed to mix to form the best possible approximations to the true solutions of the global Schrödinger equation for this system. The goal of the present study is to significantly improve upon the quality and scope of NO_2 potential surfaces available in the literature, which have thus far been limited in the main to a 2×2 non-orthogonal CI employing only a double-ζ AO basis (3) in addition to a small number of points obtained with order-100 orthogonal CI's in a basis containing some polarization functions (2). Problems arising during the course of the present calculations will be considered in some detail, and comparison with known details of the experimental spectral data will be given. Explicit treatment of the vibronic wavefunctions based on these potential surfaces, including computation of the key non-adiabatic coupling matrix elements, will then be the subject of a succeeding paper (8).

2. Technical details of the theoretical treatment

In the present work an AO basis proposed by Huzinaga (9) and Dunning (10) is employed. It consists of nine s and five p functions (9) in a $[5s\,3p]$ contraction (10) for both nitrogen and oxygen. In addition, a set of cartesian d polarization functions has been placed at each atom with exponents $\alpha(d) = 0.80$ for the nitrogen and $\alpha(d) = 0.85$ for the oxygen atoms having been chosen. This choice leads to a total number of 60 atomic orbitals, with 20 functions located at each atom.

The earlier study of Jackels and Davidson (3) employed a lobe-function variant of the double-ζ (DZ) contraction of Huzinaga's ($9s\,5p$) but did not add any polarization functions. A similar (DZ) basis augmented by Rydberg-type s and p functions (39 AO's in all) was used in the computation of the NO_2 vertical spectrum by Shih *et al.* (5). Finally the basis set of Gillispie *et al.* (2) did include d polarization functions, but employed a $[4s\,3p]$ contraction, i.e., one less s function per atom than in the present basis.

All calculations for the various conformations of the NO_2 system have been carried out in C_s symmetry. It is known (3, 11, 12) that imposition of symmetry constraints on SCF wavefunctions can result in an energy increase and cause potential surfaces to be discontinuous at conformations of higher symmetry if the highest-order pointgroup is always employed. Hence even in the case of equal bond lengths no C_{2v} symmetry constraints have been imposed on the wavefunction, since the results should describe the characteristics of the potential surfaces of the two lowest doublet states consistently over the whole range of geometrical conformations. All nuclear arrangements of the NO_2 molecule are expressed in terms of the three coordinates $r_1 = R_{NO1}$, $r_2 = R_{NO2}$ and the ONO bond angle θ. Such a procedure nevertheless gives rise to additional problems connected with the symmetry breaking which appear as instabilities in the electronic wavefunctions and energies (13, 14). Details concerning this point will be discussed in the following section.

The SCF calculations for this study have been carried out for the lowest $^2A'$ state corresponding to the configuration $9a'^2 2a''^2$ $10a'^1$. This occupation corresponds to a $^2A_1$ state in symmetric (C_{2v}) conformations for larger bond angles, but to the $^2B_2$ state for smaller bond angles. The configuration interaction treatment is of the standard MRD-CI type with configuration selection and energy extrapolation (15, 16) using Table CI algorithms (17–19). A core of six molecular orbitals of the a' irreducible representation corresponding to the $1s$ and $2s$ shells of nitrogen and the two oxygen atoms has been kept doubly occupied in all calculations, while the corresponding six complementary MO's with highest orbital energies in the a' representation have been excluded from consideration entirely; the eleven remaining valence electrons of NO_2 are then distributed among the remaining 48 MO's through single and double excitations relative to a given set of reference configurations. These have been chosen so as to give a final contribution of more than 90% to the CI wavefunctions for both the first and the second roots of $^2A'$ symmetry. The total number of symmetry-adapted functions (SAFT) generated by single and double excitations from this set of reference configurations varies from about 350 000 to 550 000. This dimension is reduced by employing an energy selection criterion (20) with a threshold of 10 μh with respect to the two lowest roots of the matrix for all calculations presented here. The number of reference configurations (reference), of generated SAF's (SAFT) and of selected SAF's (SAF) for each nuclear conformation treated can be found in the various tables to be discussed in the next section.

The lowest two eigenvalues have been calculated in each case by diagonalizing the matrix corresponding to the 10 μh threshold (dimension generally on the order of 10 000) as well as a smaller matrix (of order 7 000) corresponding to a 15 μh threshold throughout. The eigenvalues together with the summed perturbative energy lowerings of the non-selected configurations in the total MRD-CI space have then been employed in the usual way (21) to determine an extrapolated zero-threshold value designated as E_{CI} in the tables. Finally energy contributions of higher than double-excitation configurations are estimated in analogy to the formula $\Delta E = (1 - c_0^2)(E_{SCF} - E_{CI})$ of Langhoff and Davidson (22), i.e., by replacing E_{SCF} with the eigenvalues of a small-matrix corresponding only to the reference set, and substituting Σc_i^2 for c_0^2, where the latter sum runs over all contributions from the reference configurations which appear in the final (T = 10 μh) wavefunction. The resulting total energy is referred to as the full CI limit (E_{FCI}) in the ensuing discussion.

The level of CI undertaken thus goes far beyond that employed in the only previous comprehensive calculation of the lowest two $^2A'$ potential surfaces of NO_2 (3). In the latter study Jackels and Davidson employed a 2 × 2 non-orthogonal CI based on separately optimized SCF functions, leading to total energies which are on the average some 0.45 hartree (12.2 eV) higher than in the present study. The same authors reported larger (orthogonal) CI computations for several key geometries, but even in these cases the dimensions of the secular equations did not exceed on order of 3600 SAF's. Otherwise the work of Gillispie *et al.* (2), also dealing with these $^2A'$ states at a small series of geometries employs MC-SCF wavefunctions corresponding to only about 100 configurations. Finally, the earlier study of Shih *et al.* (5) does report large CI wavefunctions, of roughly half the order described in this work, but no geometries were considered other than that of the ground state at equilibrium in this instance.

3. Results of the calculations

SCF and CI calculations have been performed for a variety of nuclear conformations of NO_2 with both equal and unequal bond lengths r_1 and r_2. The results given here are restricted to the first two states of $^2A'$ symmetry. Table 1 contains the data calculated for a symmetric arrangement of NO_2 with r_1 and r_2 fixed at 2.32 bohr. This value has been chosen on the basis of the results by Jackels and Davidson (4) giving 2.32 bohr for the equilibrium bond distance and 132.7° for the equilibrium bond angle of the X^2A_1 ground state based on their *ab initio* study. The range of bond angles covered in the present calculation is from 90° up to the linear arrangement of 180°. It can be seen from Table 1 that a much closer grid of calculated points has been chosen from 95° to 120°, the interval containing the (non-) crossing of the two $^2A'$ states. Figure 1 gives the resulting potential curves for the X^2A_1 and A^2B_2 states, and also indicates the angular region near the crossing point which will be analyzed in greater detail in what follows (Fig. 2).

Three different bond lengths have been considered in this study, namely the value of 2.32 bohr already mentioned, along with 2.20 bohr and 2.50 bohr. Combination of these bond lengths yields six different cuts through the multidimensional potential surfaces.

Tables 2 and 3 contain information about the other symmetric combinations of bond distances: 2.20/2.20 and 2.50/2.50, respectively, with their respective graphical display shown in the Figs. 3 and 4. Problems arise in connecting the various calculated points in the crossing region (105°–110°) and interpolating them to give smooth $^2A_1$ and $^2B_2$ potential curves, as must be expected for such symmetric conformations. This situation can be seen clearly in the figures: the dots represent the actual calculated values for the extrapolated energy E_{CI} and the estimated full CI limit E_{FCI} with dashed lines for the E_{CI} and solid lines for the E_{FCI}. The lack of smoothness in the computed curves in this region is a consequence of the fact that all calculations are carried out in formal C_s symmetry, even when the bond lengths are equal; as a result symmetry-breaking artifacts in the SCF calculations still lead to instabilities at the large-scale CI level. The general features of symmetry breaking have been recently summarized by Davidson and Borden, including a discussion of the NO_2 example (13). Specifically the near degeneracy of the $9a'$ and $10a'$ MO's ($6a_1$ and $4b_2$ in C_{2v} notation) leads to apparent discontinuities in the Born–Oppenheimer SCF wavefunctions. These circumstances lead to special problems in the computation of non-adiabatic coupling matrix elements between the two $^2A'$ electronic states as well as other properties, as will be discussed in a subsequent paper (8) dealing explicitly with vibronic effects associated with the Herzberg–Teller interaction associated with the A and X states of NO_2. In principle the problem can be overcome by resorting to a full CI treatment, in which case the results are

independent of the choice of one-electron transformation, but the MRD-CI results E_{CI}, in which only single and double excitations with respect to a limited series of reference configurations are treated, do not fulfill the same conditions. Instead the resulting potential curves tend to exhibit an avoided crossing similar to those which occur in true C_s geometries for which the NO bond lengths are unequal.

The higher-excitation corrections contained in the corresponding E_{FCI} data can only approximate the full CI limit and hence do not succeed completely in removing the above discontinuities, but the corresponding plots (E_{FCI}) in Figs. 2–4 show that at all three bond lengths a smaller energy gap separates the $^2A_1$ and $^2B_2$ states than is the case for the E_{CI} data. Since the dimensions of secular equations solved are already in the order of 10 000 it seems unlikely that the situation would be greatly improved by carrying out larger diagonalizations of still man-

ageable proportions. Furthermore the choice of another MO basis (e.g. $^4B_2$ or $^4A'$) does not remove the asymmetries in the molecular orbitals and there remain the consequences that individual configurations do not transform according to C_{2v} representations (4). On the other hand, a calculation in which C_{2v} symmetry is imposed for $r_1 = r_2$ gives rise to discontinuity problems, as already mentioned in the previous section and also as encountered by Gillispie *et al.* in their NO_2 study (2). The problem of the variation of CI results on the choice of the one-electron basis for close-lying electronic states has been previously discussed in a CI study of the sudden polarization effect (23, 24).

Figures 2–4 show that the crossing seam in the $^2A'$ surfaces is located near 107° for all chosen distances, but that the energy of the crossing goes up considerably when going to smaller bond distances. Essentially the same result is obtained for both the E_{CI} and the E_{FCI} curves. The data for the three pairs of unequal NO bond lengths are given in Tables 4–6 and the corresponding angular potential curves are plotted in Figs. 5–7. In these cases there is no reason to avoid the highest-order point group (C_s) in the SCF calculations and the calculated energy results do not show any discontinuities of the type noted for the more symmetric geometries.

The energy gaps between the two $^2A'$ states are found to be slightly increased in going from the MRD-CI to the estimated full-CI level of treatment, even though for the symmetric conformations discussed earlier it was noted that the full CI correction tends to reduce the magnitude of the artificial splitting which occurs in the region where the $^2A_1$ and $^2B_2$ potential curves should cross. The lowest-lying $^2A'$ state exhibits a double minimum for $r_1 = 2.32$ and $r_2 = 2.50$ bohr (Fig. 6), but at the (2.20, 2.50) bond-distance pair it is found that a very shallow E_{CI} minimum at small bond angles is not present in the E_{FCI} data. Finally it should be pointed out that all of the calculations in the 95°–120° range of bond angle have been carried out with the same set of 15 reference configurations, giving rise

to an MRD-CI space of dimension 514978 (SAFT), from which from 8 000 to 10 000 functions are actually employed to construct the secular equations explicitly solved in the theoretical treatment. The high quality of the resulting calculations is indicated by the fact that these reference states comprise from 90 to 92% of the final CI wavefunctions on a Σc_i^2 basis for the entire geometrical region considered.

4. Comparison with experiment

There are four key geometrical conformations to be considered in the foregoing results for equal NO bond lengths and the corresponding internuclear distances, bond angles, and relative energies are given in Table 7. The X^2A_1 ground state equilibrium geometry is seen to be in good agreement with that deduced from experiment (θ = 134.07° and $r = r_1 = r_2 =$

2.2552 bohr) (25). Since the latter state becomes degenerate with the $^2B_1$ at the linear nuclear arrangement, which in turn is known to be most stable in this geometry, it is also possible to extract the T_e value for the corresponding transition between $^2B_1$ and X^2A_1. This result is found to be 1.905 eV, which also compares favorably with that inferred experimentally of 1.83 eV (26). The calculated bond distance of both states are found to be equal, however, although the experimental data suggest that the $^2B_1$ value is 0.04 bohr larger. A Renner–Teller effect is expected and observed near the onset of this transition.

The A^2B_2 state is found to have a smaller bond angle than the ground state (102.4°), as is expected from Walsh's rules and the fact that the two states differ by a replacement of the $4b_2$ linear MO of $^2A_1$ by the strongly bent $6a_1$ species in $^2B_2$. The $^2B_2$ bond length is calculated to be 0.12 bohr greater than of X^2A_1. As the NO distances are reduced below 2.40 bohr the angular potential minimum of the X^2A_1 state is lowered relative to that of $^2B_2$ and the expected double minimum character of the lowest $^2A'$ adiabatic surface is gradually negated (see Fig. 1). The reverse is true for larger bond lengths but at the minimal energy of the C_{2v} $^2B_2$ state, there is only a slight well separating it from the X^2A_1 crossing point; this energy is only 0.917 eV above the ground state minimum. By comparison the lowest crossing energy (cusp) for the two states occurs at 0.955 eV, only 0.038 eV higher, and this for nearly the identical NO bond length of 2.395 bohr (Table 7).

These results mesh very well with the known facts about the key A–X transition in the NO_2 spectrum. The above T_e value does not take into account the influence of the antisymmetric stretch vibration but it at least suggests that the assumption of Douglas and Huber (27) that this spectrum extends beyond the last observed feature at 1.20 eV (10 300 Å) is correct. On the other hand, allowing the NO bond lengths to be unequal does not produce any significant energy lowering relative to the $^2B_2$

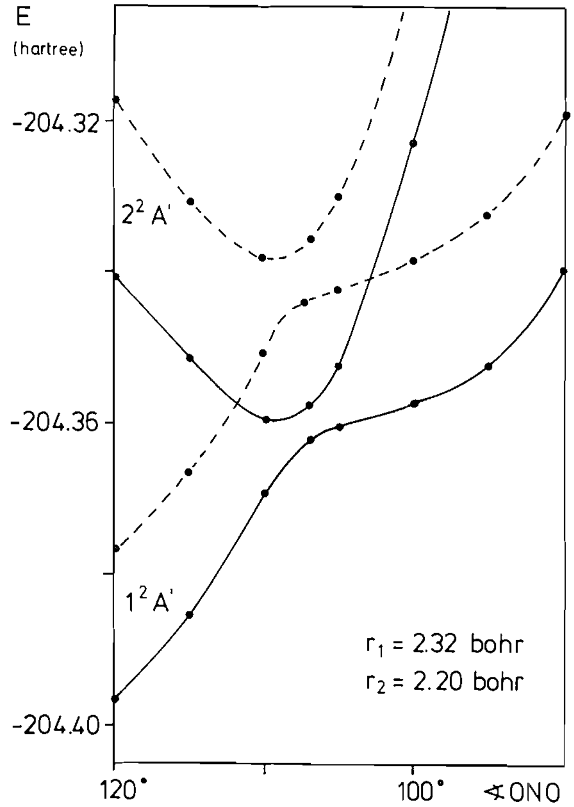

FIG. 5. Potential energy curves of the $1^2A'$ and $2^2A'$ states of NO_2 as a function of bond angle (r_1 = 2.32 bohr, r_2 = 2.20 bohr). Solid lines correspond to the E_{FCI}, dashed lines to the E_{CI} values given in Table 4.

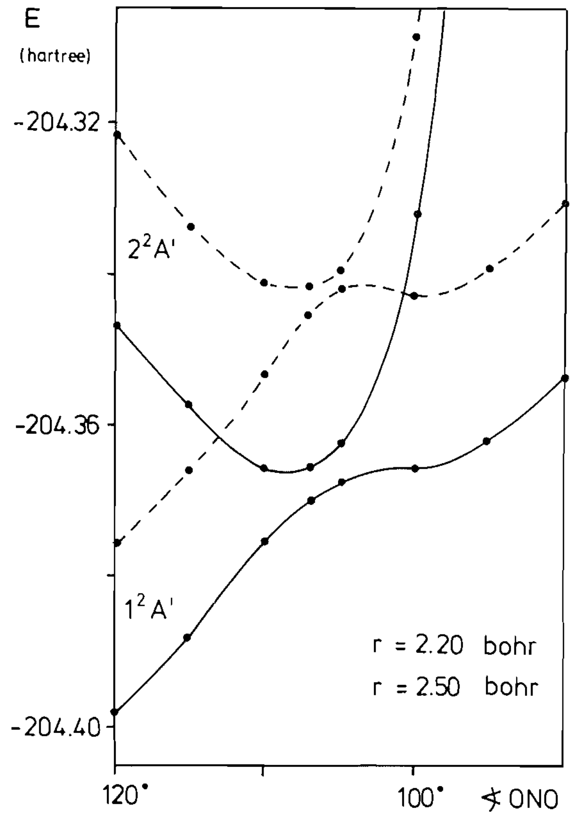

FIG. 7. Potential energy curves of the $1^2A'$ and $2^2A'$ states of NO_2 as a function of bond angle (r_1 = 2.20 bohr, r_2 = 2.50 bohr). Solid lines correspond to the E_{FCI}, dashed lines to the E_{CI} values given in Table 6.

TABLE 7. Calculated key geometrical conformations and corresponding energies

	r (bohr)	θ	E_{FCI} (hartree)	E_{rel} (eV)
X^2A_1 minimum	2.28	133.4°	−204.4118	0.0
A^2B_2 minimum	2.40	102.4°	−204.3781	0.917
$^2B_1$ minimum ($^2\Pi_u$)	2.28	180.0°	−204.3418	1.905
cusp $^2A_1/^2B_2$	2.395	107.8°	−204.3767	0.955

C_{2v} minimum shown in Table 7, as can be judged by the results of Tables 4–6, especially for r_1 = 2.32 and r_2 = 2.50 bohr. If the $^2B_2$ had a protracted potential well it could be expected that several progressions could be perceived in the experimental data, corresponding to transitions involving the NO symmetric stretching and bending vibrations for two well-defined adiabatic states. The lack of such a minimum in the calculations, however, indicates that even the lowest Born–Oppenheimer vibrational states of the A^2B_2 electronic state are strongly mixed with relatively high-lying X^2A_1 levels, making a conventional vibrational analysis very difficult. Furthermore, since the optimum bond angle and NO bond distance for the A^2B_2 state and those describing the cusp location for the $^2A_1$–$^2B_2$ surface crossing are so close to one another (differing by only about 5° and less than 0.01 bohr, Table 7), it follows that for higher vibrational quantum numbers similar mixing between Born–Oppenheimer vibronic levels should occur giving the spectrum a uniformally chaotic appearance up to the energy of the absorption maximum and beyond. The vertical transition energy relative to the X^2A_1 equilibrium geometry is computed to be 2.92 eV, which is also in good agreement with the finding that maximum absorption occurs in the 2.9–3.0 eV region of the NO_2 spectrum (28). The indication is therefore that the $^2B_2$ state can lower its energy by 2.0 eV through increasing its NO bond distance and decreasing its bond angle relative to the equilibrium values of the ground state, a circumstance which also contributes to the very broad appearance of the NO_2 spectrum in the 3 000 – 10 000 Å region.

Relativistic Hartree–Fock–Roothaan wavefunctions for atoms

TAKASHI KAGAWA[1] AND GULZARI MALLI

Department of Chemistry, Simon Fraser University, Burnaby, B.C., Canada V5A 1S6

Received July 29, 1984

This paper is dedicated to Professor Camille Sandorfy on the occasion of his 65th birthday

TAKASHI KAGAWA and GULZARI MALLI. Can. J. Chem. **63**, 1550 (1985).

Relativistic Hartree–Fock–Roothaan (RHFR) wavefunctions have been calculated for a large number of atoms up to radon ($Z = 86$) under the point nucleus approximation using STO's as basis functions. The calculated total as well as orbital energies are in very good agreement with the corresponding results obtained by the numerical integration method.

TAKASHI KAGAWA et GULZARI MALLI. Can. J. Chem. **63**, 1550 (1985).

Utilisant des orbitales du type de Slater (STO) comme fonctions de base et travaillant dans l'approximation ponctuelle, on a calculé les fonctions d'onde relativistes de Hartree–Fock–Roothaan (RHFR) pour un grand nombre d'atomes allant jusqu'au radon ($Z = 86$). Les énergies totales ainsi qu'orbitales obtenues par ces calculs sont en très bon accord avec les résultats correspondants obtenus par la méthode d'intégration numérique.

Introduction

The relativistic self-consistent-field (RSCF) Scheme (1) has been used to calculate the wavefunctions and energy levels of the ground states of atoms (2–5) using the numerical integration method.

Alternatively, Kim (6) developed a relativistic Hartree–Fock–Roothaan (RHFR) formalism for closed-shell atoms and reported the results for He, Be, and Ne atoms.

Kagawa (7) extended the RHFR (also called Dirac–Hartree–Fock–Roothaan (DHFR)) formalism of Kim (6) to a large class of open shells and he reported results for the ground as well as excited states for Sc through Cu atoms.

Theory and computations

We refer the reader to Kim (6) and Kagawa (7) for the details of the formalism for closed- and open-shell atoms, respectively. Kagawa's computer program, however, was severely limited because it was unable to calculate heavy atoms involving f-orbitals and because it could not handle a large enough number of basis sets necessary to represent the large number of occupied orbitals.

A computer program based upon his formalism has been developed in double-precision which at present can handle seven symmetries (s, $p_\pm$, $d_\pm$, and $f_\pm$) and for each symmetry up to a maximum of twenty Slater-type orbital (STO) basic functions can be used. The same set of non-integer STO (NISTO) basis set was used for the large and small components of the relativistic radial function where the STO (with non-integer principal quantum number) $f_{\kappa p}$ have the following form:

$$[1] \quad f_{\kappa p} = (2\zeta_{\kappa p})^{n'_{\kappa p}+1/2}\,[\Gamma(2n'_{\kappa p}+1)]^{-1/2}\, r^{n'_{\kappa p}} \times e^{-\zeta_{\kappa p} r}$$

where $\zeta_{\kappa p}$ is the orbital exponent, $\Gamma(X)$ is a gamma function, and

$$[2] \quad n'_{\kappa p} = n_{\kappa p} + (\kappa^2 - Z^2\alpha^2)^{1/2},\; n_{\kappa p} = 0, 1, 2, \ldots$$

In eq. [2], α is the fine-structure constant and κ, the relativistic quantum number, is given by the relation:

$$[3] \quad \kappa = \pm\,(j + 1/2) \text{ for } l = j \pm 1/2 \text{ and } \bar{l} = j \mp 1/2$$

where l and $\bar{l}$ denote the orbital angular momentum quantum numbers of the large $P(r)$ and small $Q(r)$ components of the radial wavefunction.

The pseudo-eigenvalue relativistic Hartree–Fock–Roothaan (RHFR) equations were solved for closed- and open-shell vectors of the expansion coefficients of the large and small components by an iterative procedure unti the self-consistency is obtained.

It should be pointed out that, in the relativistic Hartree–Fock calculations, the ground state energy is obtained as the lowest stationary value amongst the positive energy states because there are negative energy states below the state under consideration. The relativistic virial theorem for a system with a Coulomb force is given by

$$[4] \quad \langle T\rangle = -\langle V\rangle$$

which is different from the non-relativistic virial theorem. In all cases, the ratio of $\langle T\rangle/\langle V\rangle$ was found to be in excellent agreement with eq. [4], and so its tabulation is omitted. The maximum deviation was found to be ± 1 in the fifth figure. One should, however, be reminded that satisfying the relativistic virial theorem is not a sufficient condition for the energy obtained to be the lowest stationary value.

The number of STO basis functions used for radon were 12 for s_+, 11 for p_-, 10 for p_+, 7 for d_-, 6 for d_+, 5 for f_-, and 4 for f_+ symmetries, respectively; i.e., a total of 55 basis functions for a system of 86 electrons with 24 occupied orbitals. It should be mentioned that, although there is only one occupied orbital for f_- and f_+ symmetries, five f_- and four f_+ STO's were used, while for other symmetries it turns out that on the average about two STO's are needed for each occupied orbital.

The CPU time of 189.2 s was required for the radon calculation (the heaviest atom reported here), using the abovementioned set of 55 basis functions, while the numerical multiconfiguration Dirac–Fock (MCDF) programs of Grant (8) and Desclaux (9), for the identical calculation, took 179.5 and 153.8 s, respectively, on the IBM 3033 computer at SFU, operating under MTS. Furthermore, in all other cases, the CPU time was roughly the same for all the three computer programs. Unfortunately, the computer program used by Maly and Houssonnois (4) is not available to us and, thus, no statements about the CPU can be made regarding their calculation on radon.

Results and discussion

In order to check the correctness of the computer program and the results reported here, we repeated the calculations reported by Kagawa (7) in double-precision and in *all* cases an excellent agreement was found. A large number of closed- as well as open-shell atoms have been calculated and a few representative results are presented in Tables 1 and 2.

The limitations of the RHFR wavefunction calculations and the details of the method of calculation, choice of basis set, etc., have been delineated in detail elsewhere (6, 7). However, we would like to make the following remarks. These calculations were performed under a point nucleus approximation which is not strictly valid for very heavy atoms (e.g., Hg and Rn); however, the effect of finite nucleus can be treated via a perturbation theory along with the Breit interaction, which we have also neglected in these calculations. One should bear in mind, however, that the effect of finite nucleus is especially important for the orbital energies of the inner shells $1s$ and $2p_-$, although its contribution to the total energy of the heavy systems is quite small.

Furthermore, the use of point-nucleus necessitates the use of non-integer "n quantum number" STO basis functions (6) in order to satisfy the relativistic wave equation at the origin. In addition, it is necessary to include in the basis set for the lower components of p_-, d_-, and f_- shells at least one basis function with (integer) $n = l$; i.e., $1p_-$, $2d_-$, and $3f_-$, respectively.

The orbital exponent (ζ) optimization at present was limited by *trial and error* which is quite time-consuming. The desirability of ζ optimization cannot be overstressed. We also use the relativistic virial (6) for ascertaining the "goodness" of the wavefunctions.

In Table 1, we present the total relativistic energies ($-E$) in atomic units (au) for the ground states of the various atoms with closed shell configurations (using the relativistic shell notation (1)). The corresponding results, calculated using the MCDF programs (8, 9) based on the numerical integration method, are given for comparison in Table 1 under the heading "Numerical DF", i.e. numerical Dirac–Fock, where the results reported by Maly and Houssonnois (4) are also included.

It can be seen that there is an excellent agreement between the results reported by the two methods, however, in some cases, our results differ by about 1.5 au from the more accurate results (4, 8, 9).

The orbital energies for radon (the heaviest atom reported by us) are collected in Table 2, which also contains the orbital energies calculated by the numerical integration method for radon (8). It is admitted that for some orbitals there are discrepancies of the order of 0.1 au; however, it is gratifying that the orbital energies of the inner shells as well as the outer shells can be calculated by the RHFR method with a fairly good accuracy so as to be comparable with the numerical Dirac–Fock (DF) method.

In conclusion, a lot of effort and time has been spent in developing this basis set and, although we can by no means claim the results as "final", we hope that further efforts will be directed to reveal the "deficiencies" so as to goad us and others to improve upon the present results.

Acknowledgements

This work was supported through grant No. A3598 by the Natural Sciences and Engineering Research Council of Canada (NSERC), which is gratefully acknowledged. We appreciate very much the continuous help, co-operation, and patience of the staff of our Computing Centre, without which these calculations could not be performed. Finally, we thank an anonymous referee for very constructive remarks which have helped to improve the manuscript.

Self-consistent-field calculations of the vibrational spectrum of undoped and doped transpolyacetylene

ANDREA PELUSO, MAX SEEL, and JANOS LADIK
Lehrstuhl für Theoretische Chemie, Friedrich-Alexander-Universität Erlangen-Nürnberg, Egerlandstrasse 3, D-8520 Erlangen, West Germany

Received August 7, 1984

This paper is dedicated to Professor Camille Sandorfy on the occasion of his 65th birthday

ANDREA PELUSO, MAX SEEL, and JANOS LADIK. Can. J. Chem. **63**, 1553 (1985).

Semiempirical self-consistent-field calculations are carried out to compute the force constants for various cluster models of periodic transpolyacetylene and of neutral and charged soliton and polaron defects. The phonon spectrum of undoped polyacetylene is analyzed and compared with the vibrational spectrum of various polyene chains in which soliton or polaron defects have been introduced in a random way. The results support the interpretation that the 1100 cm^{-1} Raman band of undoped polyacetylene should be ascribed to a C—C single bond stretching motion weakly coupled to a C—H in-plane bending vibration. The 1292 cm^{-1} infrared peak of pure transpolyacetylene is ascribed to the C—H in-plane deformation, the strong adsorption at 1015 cm^{-1} has to be assigned to an infrared-active out-of-plane C—H deformation. The new narrow band around 1300 cm^{-1} seen in the infrared spectrum of doped polyacetylene is ascribed to C—C bond stretching, the additional very broad band between 800 and 900 cm^{-1} results from in-plane C—C—H bending and C—H out-of-plane bending motions involving relaxed bond lengths of the defect sites. The interpretation is not uniquely in favor of the soliton picture, polaron defects can serve as alternative explanation.

ANDREA PELUSO, MAX SEEL et JANOS LADIK. Can. J. Chem. **63**, 1553 (1985).

On a effectué des calculs semi-empiriques en champ autocohérent dans le but d'évaluer les constantes de force pour divers modèles d'aggrégats de polyacétylène-*trans* périodique avec des défauts de polaron et de soliton neutres ou chargés. On a analysé le spectre phononique du polyacétylène qui n'a pas été dopé et on l'a comparé avec le spectre vibrationnel de diverses chaînes de polyènes dans lesquels on a introduit au hasard des défauts de soliton ou de polaron. Les résultats sont en accord avec l'interprétation selon laquelle la bande observée à 1100 cm^{-1} du spectre Raman du polyacétylène non dopé doit être attribuée à un mouvement d'élongation de la liaison simple C—C qui serait couplé à une vibration de déformation dans le plan d'une liaison C—H. La bande observée à 1292 cm^{-1} du spectre infrarouge du polyacétylène-*trans* pur est attribuée à une déformation dans le plan d'une liaison C—H alors que la forte absorption observée à 1015 cm^{-1} serait attribuable à une déformation hors du plan d'une liaison C—H qui serait active dans l'infrarouge. La nouvelle bande étroite observée vers 1300 cm^{-1} dans le spectre infrarouge du polyacétylène dopé est attribué à une élongation de la liaison C—C alors que la bande très large supplémentaire qui est observée entre 800 et 900 cm^{-1} proviendrait d'une déformation dans le plan des atomes C—C—H et de mouvements hors-plan de la liaison C—H qui impliqueraient des longueurs de liaisons relaxées des sites des défauts. L'interprétation ne favorise pas uniquement la théorie du soliton; les défauts de polaron peuvent aussi servir d'explication.

I. Introduction

Long conjugated polyene chains have attracted the attention of chemists for a long time (1). Polyacetylene (PA), the prototype of this class of organic compounds, has recently stimulated much interest also among solid-state researchers due to its large increase in electrical conductivity upon doping (2). Although many techniques have been used which could provide information on the electronic and structural properties of *trans*-PA, a complete understanding has not yet been achieved; the main difficulty in the interpretation of the experimental results lies in the uncertainty of the real chemical structure of both doped and undoped PA.

The question whether undoped PA exhibits an equidistant or alternant structure (Peierls distorted ground state) seems to have settled, at least from the theoretical point of view, in favor of the alternant ground state solution (3–10). The latest calculation by Suhai (10) shows that the inclusion of correlation effects reduces the bond length alternation compared to the restricted Hartree–Fock (RHF) solution. The lowest energy equidistant unrestricted Hartree–Fock (UHF) ground state solution for PA (11, 12) shows a gap due to a spin density wave which is much too large.

X-ray diffraction (13, 14) gives only limited information about the structure due to the fibric nature of PA. The small number of reflection data excludes a full refinement of the structure. Infrared and Raman spectra have been highly useful in the investigation of the chemical properties and structure of undoped and doped PA (15–18). However, they cannot provide a complete and conclusive answer to the question whether the ground-state structure is equidistant or alternant. The presence of two different absorption peaks, by the majority assigned to C—C double and single bond stretching, does not ensure the presence of two different bond lengths. Symmetry considerations cannot distinguish because group theory predicts for the equidistant chain, belonging to the D_{2h} point group, and for the alternant chain, belonging to the C_{2h} point group, the same number of absorption peaks in the Raman and infrared spectrum (19).

The vibrational spectrum of doped PA was first interpreted in terms of soliton formation (20, 21), i.e., a defect which switches the phase of bond alternation. Recently, Zannoni and Zerbi have suggested (22, 23) that the interpretation is not uniquely in favor of solitons, but a polaron-like structure, i.e., a local relaxation of the bond alternation without changing the phase, may be an alternative explanation. This was thought to be consistent with the bipolaron or soliton–antisoliton pair picture (24) since a (singly charged) polaron seemed to be incompatible with esr experiments (25). However, it could be shown (26) that it is not necessary to invoke bipolarons since a polaron defect leads to localized states which are spin paired and therefore not in contradiction to the esr experiments when electron–electron interactions is included self-consistently.

The previous work on the interpretation of the vibrational spectrum of doped PA (20, 22, 23) has been based on a simple adaption of Hückel theory. Since there is no explicit treatment of electron–electron interaction, it is not possible to distinguish between neutral and charged defects. This paper is the first to calculate more seriously the vibrational spectrum of PA with soliton and polaron defects by taking into account electron–electron interaction in a self-consistent way. This allows for changes in the force constants for bond stretching, bending, and out-of-plane motions if an extra electron is added. The calculations are carried out using the semiempirical MNDO (modified neglect of differential overlap) scheme of Dewar and Thiel (27) which includes all valence σ and π electron interactions self-consistently. While it is an approximate scheme with limitations it will show the trends in the changes in the vibrational spectrum when PA is doped.

We report the phonon dispersion curves and the corresponding density of states of undoped PA and compare with previous interpretations of the vibrational spectrum. Then we focus on the explanation of the two new bands around 800 cm^{-1} and 1300 cm^{-1} seen in the infrared spectrum of PA doped both with donor and acceptor species. Our calculations show that they can be related best either to neutral solitons (but not to charged solitons) or to singly charged polarons leaving the latter defects as the more likely structural changes which occur upon charge transfer doping.

The organization of the paper is as follows: in Section II the method of calculation of the force constants and of the density of states of undoped PA as well as of doped PA with a random distribution of defects is described. Section III gives a discussion of the resulting force constants for cluster models of undoped PA and of neutral and charged soliton and polaron defects. The phonon dispersion curves and density of states of undoped PA are analyzed in Section IV. In Section V, the vibrational spectrum of PA with soliton and polaron defects is compared with the experimental spectrum of doped PA.

II. Method of calculation

II. A. Force constant calculation

Today the calculation of force constants by theoretical methods is carried out routinely. It is found that *ab initio* and appropriate semiempirical calculations reproduce the vibrational spectrum of a molecule with errors generally not larger than 20% (28). The theoretical force constants calculated in the harmonic approximation, the second derivative of self-consistent field Hartree–Fock (SCF HF) total energies, are usually overestimated. The errors for the diagonal stretching and bending force constants are about 10–20% both for *ab initio* and semiempirical methods, while the off-diagonal semiempirical coupling constants are much more overestimated, sometimes by up to 50% as compared to experimental and *ab initio* ones. However, a constructive comparison especially between theoretical and experimental off-diagonal force constants is quite difficult: the experimental ones are often obtained by using assumptions which have no counterpart in the theoretical calculation. These assumptions become necessary to overcome the problem that the number of experimental frequencies is smaller than the number of force constants.

The calculations were carried out in the MNDO approximation (27) using the QCPE-program package by Dewar *et al.* (29). MNDO is parametrized to optimize molecular geometries and heats of formation. Since the parameters are fitted to experimental data an (unknown) part of the electron correlation is included (30). In open shell cases (soliton, singly charged polaron model) an UHF treatment was used instead of the modified "half-electron" RHF treatment (31) (placing 1/2 electron of each spin in the open shell) which was employed by Boudreaux *et al.* (24). It should be emphasized that MNDO has been tested less rigorously for radical and ion geometries and it is an open question whether the use of the modified RHF half-electron scheme is superior to the UHF treatment. For the calculation of force constants difficulties arise in the case of the half-electron procedure because the resulting wave function is not variationally optimized (with respect to the total electronic energy); consequently it is not invariant under small changes in the geometry and therefore not suitable for calculating the derivative of the energy analytically (32). The use of the UHF treatment leads to some overallowance for electron correlation which can be corrected with a scale factor (32).

Gradients have been calculated analytically, force constants have been obtained by a numerical differentiation procedure. For details of the analytical derivation we refer to the fundamental work of Pulay (33). The force constant matrix has been calculated in a cartesian coordinate system. This choice avoids the occurrence of redundant coordinates. Moreover, the first derivative is easily calculated analytically. To improve agreement with the experimental vibrational spectrum we have introduced scale factors as suggested by Blom *et al.* (34). These factors have been obtained by comparing the MNDO with the experimental results for 1,3-butadiene (51) and they have then been used in the calculation of the spectrum of doped and undoped polyacetylene. To compare with experimental force constants one has to transform the calculated values from the cartesian to the internal coordinate system. The internal coordinate system has to be chosen in such a way as to avoid the presence of redundant coordinates (force constants for a redundant coordinate system cannot be determined (35)) and to allow for maximum transferability between related molecules. We have used local symmetric coordinates, first introduced by Shimanouchi (36) and defined in such a way that angle redundancies are avoided but transferability is still conserved (37). Then the transformation matrix $\mathbf{B}$ between internal coordinates R and cartesian coordinates X

$$[1] \quad R = \mathbf{B}X$$

is not singular, and the internal force constant matrix $\mathbf{F}_R$ can be obtained by the relation

$$[2] \quad \mathbf{F}_R = (\mathbf{B}^{\mathrm{T}})^{-1}\,\mathbf{F}_X\,\mathbf{B}^{-1}$$

$\mathbf{B}$ is a rectangular matrix $(3N - 6) \times 3N$, therefore it is necessary to calculate a generalized inverse defined in the following way (38)

$$[3] \quad \mathbf{B}^{-1} = (\mathbf{B}^{\mathrm{T}}\mathbf{B})^{-1}\,\mathbf{B}^{\mathrm{T}}$$

We have used this procedure instead of introducing six additional translational and rotational coordinates (39) in order to generate a square matrix $\mathbf{B}$.

II. B. Calculation of dispersion curves and density of states of a periodic chain

The dispersion curves for transpolyacetylene have been calculated by Wilson's well known **GF**-method (40) generalized to crystal vibrations by Piseri and Zerbi (41). The dispersion curve of the polymer are obtained from the eigenvalue equation

$$[4] \quad [\mathbf{D}(k) - \omega^2\,\mathbf{1}]\,L(k) = 0$$

with

$$[5]\quad \mathbf{D}(k) = \mathbf{M}^{-1/2}\,\mathbf{F}_x(k)\,\mathbf{M}^{-1/2}$$

M is a diagonal matrix whose elements are the masses of the atoms contained in the unit cell and $\mathbf{F}_x(k)$ is the force constant matrix in cartesian coordinates which is obtained from the force constant matrix in internal coordinates $\mathbf{F}_R(k)$

$$[6]\quad \mathbf{F}_R(k) = \mathbf{F}^0 + \sum_s (\mathbf{F}^{sT}\mathrm{e}^{-iks} + \mathbf{F}^s\mathrm{e}^{iks})$$

by an appropriate transformation

$$[7]\quad \mathbf{F}_x(k) = \mathbf{B}(k)^+\,\mathbf{F}_R(k)\,\mathbf{B}(k)$$

The density of states $N(\omega)$ has been calculated by replacing the δ-function with a Lorentzian of half-width ϵ

$$[8]\quad \delta[\omega - \omega(k)] = \frac{1}{\pi}\frac{\epsilon}{\epsilon^2 + [\omega - \omega(k)]^2}$$

and numerical integration

$$[9]\quad N(\omega) = \sum_i \int \mathrm{d}k\,\frac{1}{\pi}\frac{\epsilon}{\epsilon^2 + [\omega - \omega_i(k)]^2}$$

A trigonometric interpolation of the calculated frequencies for different wave vector values was used to obtain at least 50 points for each dispersion curve $\omega_i(k)$.

II. C. Calculation of density of states and eigenvectors of chains with defects

The density of states and normal modes for polyacetylene chains containing various soliton and polaron defects have been calculated using Dean's negative factor counting technique (42) in which the distribution of eigenvalues of a finite (random) chain is calculated numerically by a fast recursion algorithm. This method has been successfully applied to study the electronic (23, 43) and vibrational (22, 42, 44) spectrum of disordered polymers. The calculations are performed for four different polyacetylene chains, each consisting of 25 C_2H_2 units, which contain neutral or charged soliton or polaron defects distributed randomly. The force constant matrix of such a finite chain is built up from small matrix blocks corresponding to different subunits with or without defects. A subunit containing the polaron defect, for example, contains six CH units. For such a cluster, a self-consistent MNDO calculation is performed and yields the force constant matrix elements for the defect site and its surrounding. Selected eigenvectors of the finite chain have been calculated by the inverse iteration method (45).

III. Results and discussion of force constants

In order to obtain a reasonable force field for *trans*-PA we have calculated the force constants for the *trans*-1,3,5-hexatriene molecule in a geometry shown in Fig. 1. The geometrical parameters used are slightly different from the experimental geometry but more appropriate to simulate a *trans*-PA chain. The C—C double bond and single bond lengths have been assumed to be 1.36 and 1.44 Å, respectively, with the alternation parameter $r = 0.08$ Å, as suggested by recent calculations (46). Our molecular model is therefore also slightly different from the one used by Zannoni and Zerbi (15) and Inagaki (16). The scale factors have been transferred from the *trans*-butadiene molecule which was calculated previously. Table 1 shows the most important force constant of butadiene and hexatriene. As mentioned before the errors with respect to the experimental values are between 10 and 20%, only the carbon–carbon double bond force constant is somewhat more overestimated. The changes in the force constants in going from butadiene to hexatriene show the expected trend: the double bond force constant decreases, while the single bond one increases. Both C—C and C=C stretching force constants are larger than the ones obtained by Gavin and Rice (47) using the relationships deduced by Coulson (1) and Longuet–Higgins (3) for the dependence of stretching force constants on π-electron bond order and self-polarizability.

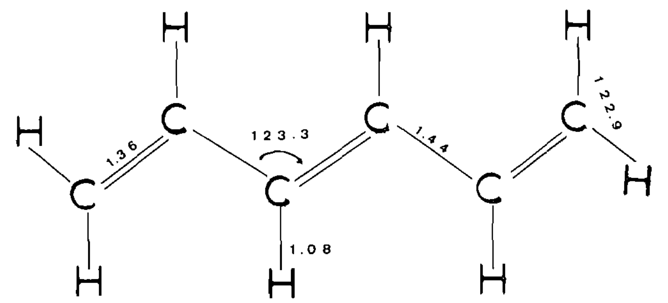

FIG. 1. Bond lengths and angles used for *trans*-1,3,5-hexatriene. The bond lengths are given in Å.

However, a direct comparison is not easy because quite different bond lengths have been used. For the same reason we find sensitive changes in C—C and C=C stretching force constants in going from butadiene to hexatriene that have no counterpart in the calculation of Gavin and Rice. On the other hand, the bending force constants and the C—H stretching force constants show only small changes. For the off-diagonal C=C/C—C stretching coupling the value of 0.84 mdyn/Å is in good agreement with 0.7 obtained by Gavin and Rice. The Kakitani sign rule (48) according to which the sign of the off-diagonal coupling force constant alternates (C=C/C—C is positive, C=C/C=C is negative etc.) is reflected in the MNDO results. Their absolute value is consistently smaller than the values of Gavin and Rice. This is very probably due to the short length of our cluster and therefore due to the unsufficient delocalization of the π-electrons.

On the basis of the considerations given above about theoretical and experimental force constants we introduce empirical scale factors. According to Török and Pulay (49), they can be obtained as the geometrical mean value of the corresponding diagonal force constants. The resulting force constants which are used for the calculation of the spectrum of PA and PA with defects are also given in Table 1.

The clusters used to calculate the force constants for solitonic and polaronic defects are shown in Fig. 2. The calculations have been carried out for neutral and singly charged clusters, assuming complete charge transfer of one electron from the donor dopant to the polymer backbone. For the open shell cases, the UHF treatment was used. As it was pointed out by Dewar (32) the overestimation of electron correlation can be reduced with a correction factor. In our case this was done by using a scale factor for the UHF–MNDO force constants which was the geometric mean of RHF scale factors for C=C and C—C stretching, or for the deformation and rocking-bending force constants, respectively.

The most important force constants are given in Table 2. As expected, important variations can be observed, especially when the defect creates an unpaired electron. The stretching force constant for the C=C double bond in the *neighborhood*

TABLE 1. The most important force constants for butadiene and hexatriene. For butadiene the MNDO and the experimental values are given, for the hexatriene the MNDO and the scaled MNDO force constants are shown. The force constants for stretching and stretching–stretching coupling are given in mdyn/Å, for bending in mdyn Å/rad² and for stretching–bending coupling in mdyn/rad; α denotes the deformation, β the rocking force constant

[a] From ref. 51.
[b] As suggested in ref. 47.

of the defect site decreases for the neutral soliton and charged polaron defects, while in the other cases the change is less pronounced. In all cases the force constants are lower with respect to the normal C=C bond. This leads to the conclusion that both the soliton and polaron defect are not localized in only two or three bonds. *On the defect site*, where the C—C bond length has been taken in our simple model as the average of the short and long bond, we found different behavior for the soliton and polaron cases. For the neutral soliton model the MNDO method predicts a very low force constant, comparable to the single bond case, while in the charged soliton as well as in both polaron models these force constants are close to the arithmetic mean of the single and double bond force constants.

In the neutral polaron defect the C—C stretching force constants decrease monotonously from the center of the defect on, while in the charged polaron case a small alternation is predicted. The general trend in the change of the bending force constant is the decrease of the deformation bending constant and the increase in the rocking force constant. It is also interesting to observe the increase of the coupling force constants between C—C bonds, especially in the neutral soliton cluster. A very large coupling is predicted for the double and intermediate bond and between the two intermediate C—C bonds. Long range coupling constants are increased.

Finally, we discuss briefly the out-of-plane force constants. Until now only one recent study (50) included also the out-of-plane motions of the hydrogen and the carbon atoms. We have included these motions because we believe they may be useful in the interpretation of the additional new bands in the infrared spectrum of doped PA. The scale factor for the out-of-plane C—H bending force constant has been obtained by comparing the MNDO results and experimental frequencies; the symmetry

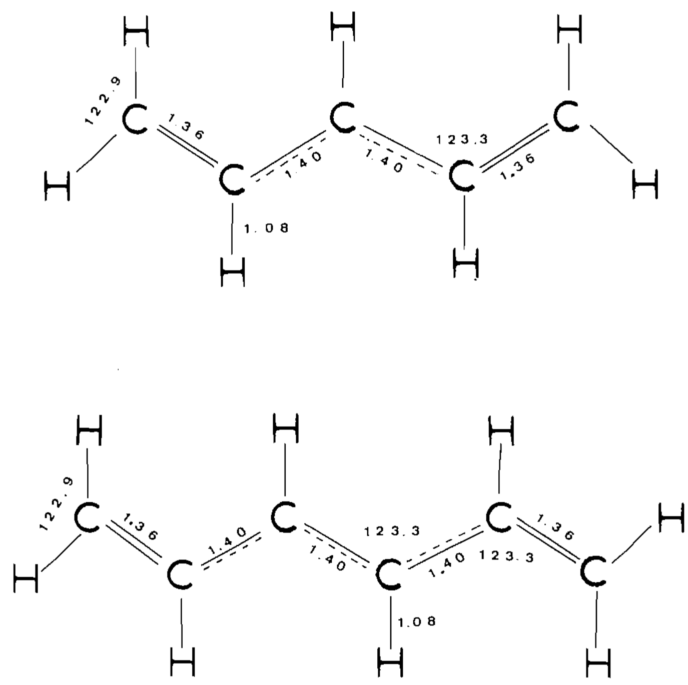

FIG. 2. Cluster model for a soliton (*a*) and a polaron (*b*) defect. The bond lengths are given in Å.

decoupling of these modes from the in-plane modes makes this procedure possible. The calculations confirmed our conjecture: a large lowering of out-of-plane force constants has been found for both soliton models and for the charged polaron cluster.

IV. Phonon dispersion curves for undoped polyacetylene

The force constant matrix $\mathbf{F}_R(k)$ for an infinite PA chain in internal coordinates has been constructed from the force constants from hexatriene discussed in the previous section. No changes of the long-range coupling force constants have been introduced in order to take into account electron–phonon coupling, as suggested by Mele and Rice (20) and Zannoni and Zerbi (15). We followed the suggestion of Gavin and Rice (47) according to which these interaction force constants do not decrease as the bond separation increases but retain a value between 30% and 50% of the nearest neighbor ones. The calculation has been carried out in the second neighbor interactions' approximation.

The phonon dispersion curves and the corresponding density of states are shown in Fig. 3, the atomic displacements of normal modes for $q = 0$ are sketched in Fig. 4. The Raman spectrum of all-*trans*-PA, measured by Shirakawa *et al.* (18), shows two strong bands at 1474 and 1080 cm^{-1} and a weak band at 1010 cm^{-1} (see Table 3). The last one has been ascribed to the C—H out-of-plane motion. The bands at 1474 and 1080 cm^{-1} were tentatively assigned to the C—C double and single bond stretching motions, respectively. However, this interpretation is still subject of discussions. Our results are in agreement with the ones of Zannoni and Zerbi (15) and Inagaki (16). The mode at 1100 cm^{-1} — our calculation gives 1142 cm^{-1} (all values are given, as usual, for $q = 0$) — should be ascribed mainly to the C—C stretching motion, coupled to C—H in-plane bending whereas Mele and Rice (20) and Schügerl and Kuzmany (52) find the single bond stretching mode at 1200 cm^{-1} and ascribe the 1100 cm^{-1} mode to C—H in-plane bending with some amount of C=C and C—C stretching mo-

tions. We find a Raman-active C—H in-plane bending motion at a frequency of 1028 cm^{-1}, in very good agreement with the value of 1021 cm^{-1} calculated by Inagaki (16) while other authors (52) have found a value between 1200 and 1290 cm^{-1}. The band at 1474 cm^{-1} can be ascribed without doubt to the C=C stretching vibration weakly coupled with the C—H bending motion.

The infrared spectrum of polyacetylene shows three peaks at 3013, 1292, and 1015 cm^{-1} (18) (see Table 3). The peak at 3013 cm^{-1} is assigned to the C—H stretching vibration. Shirakawa and Ikeda assigned the mode at 1292 cm^{-1} to the *trans*-

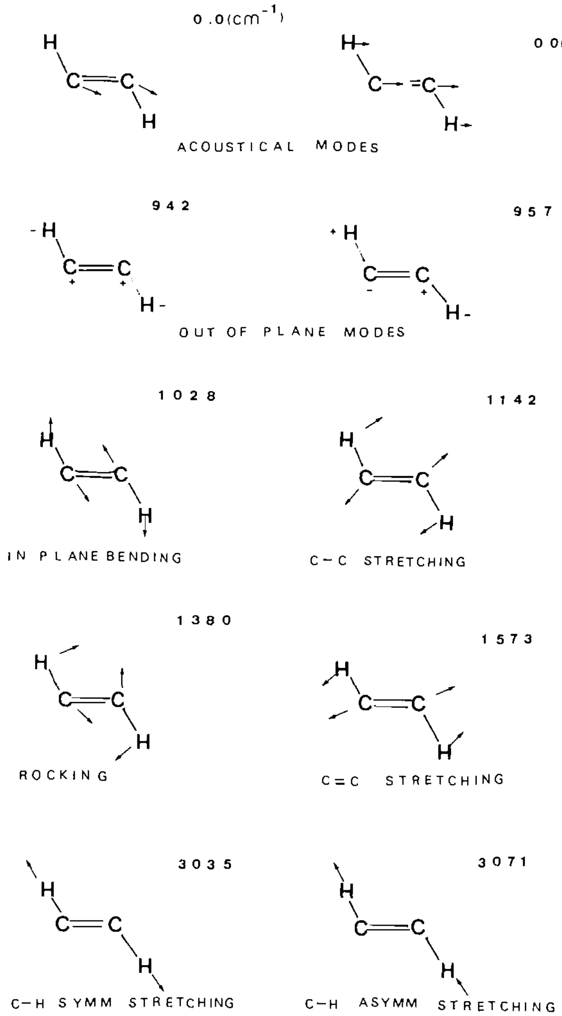

FIG. 4. Atomic displacements of normal modes for selected frequencies in periodic *trans*-polyacetylene. The numbers indicate the frequency and are given in cm^{-1}.

C—H in-plane deformation using previous results of Bellamy (53) and the band at 1015 cm^{-1} to the out-of-plane C—H deformation. Our results for these two bands are in good agreement with this interpretation.

For the out-of-plane motion we have found two bands between 950 cm^{-1} (infrared) and 1000 cm^{-1} (Raman), in good agreement with the experimental results obtained by Lunde and Zechmeister (54) for several conjugated systems.

V. Density of states of doped polyacetylene

The experimental spectra of PA doped both by donor and acceptor species show the following main features (see Table 3):

The Raman spectrum does not exhibit additional peaks compared with undoped PA. In the infrared spectrum, on the other hand, at least two additional bands have been detected. The first, very broad band falls between 800 and 900 cm^{-1}, the second, much narrower band lies around 1300 cm^{-1} (55). While there is agreement on the nature of the 1300 cm^{-1} band, the origin of the broad band starting at 800 cm^{-1} has been a matter of discussion for quite some time (20, 55, 56). Before introducing the soliton concept Heeger and co-workers (55) have suggested that this band is due to ionization of the dopant state in the semiconductor gap. Later on the isotopic shift of this band to lower frequencies found by Harada *et al.* (18*c*) demonstrated beyond doubt the vibrational origin of this band. These authors assigned the band to the in-plane C—C—H bending motion which is, in undoped PA, at 1010 cm^{-1}, but the reason of its large width could still not be explained.

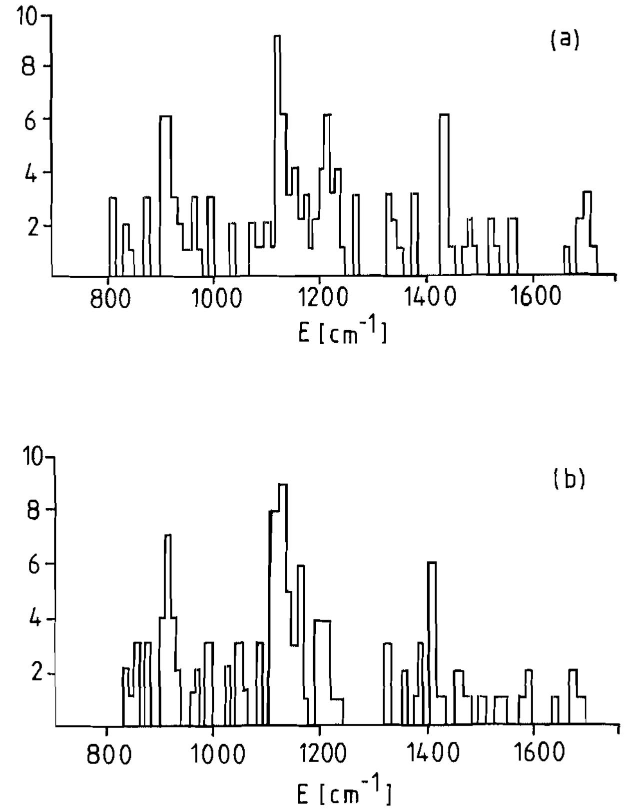

FIG. 5. Phonon density of state histogram of a $C_{50}H_{52}$ chain containing three neutral (*a*) or three negatively charged solitons (*b*).

The theoretical investigation of doped PA by Zannoni and Zerbi (44) has given a few peaks in this region. They ascribed the large band width to the overlap of several molecular-like absorptions caused by the large dimension of the defect or by the presence of a distribution of defects of the same type but with slightly different electronic and geometrical characteristics. In our opinion, however, it is difficult to understand the formation of defects with different characteristics in very lightly doped samples of PA which still show this very broad band.

In the band around 1300 cm^{-1} Harada *et al.* have found two peaks at 1288 cm^{-1} and 1397 cm^{-1}. The widths of these peaks is comparable to those of undoped PA. The band at 1397 cm^{-1} has been ascribed to the C—C stretching in the defect site. This assignment is in agreement both with the soliton and polaron model which predict bond relaxation in the middle of the defect and therefore a shift of the C=C double bond stretching vibration at 1474 cm^{-1} to lower frequencies. The other band near 1288 cm^{-1} has been ascribed to the C—H in-plane deformation which, in undoped PA, lies at 1290 cm^{-1}.

We have calculated the eigenvalue spectrum of four different finite PA chains. Each consists of 25 C_2H_2 units and contains three defects, either neutral (charged) solitons or neutral (charged) polarons, respectively, on positions 8, 18, and 23. These position numbers were generated by a random number generator. In Fig. 5, the densities of states for the chains containing neutral or charged solitons are shown, in Fig. 6 the

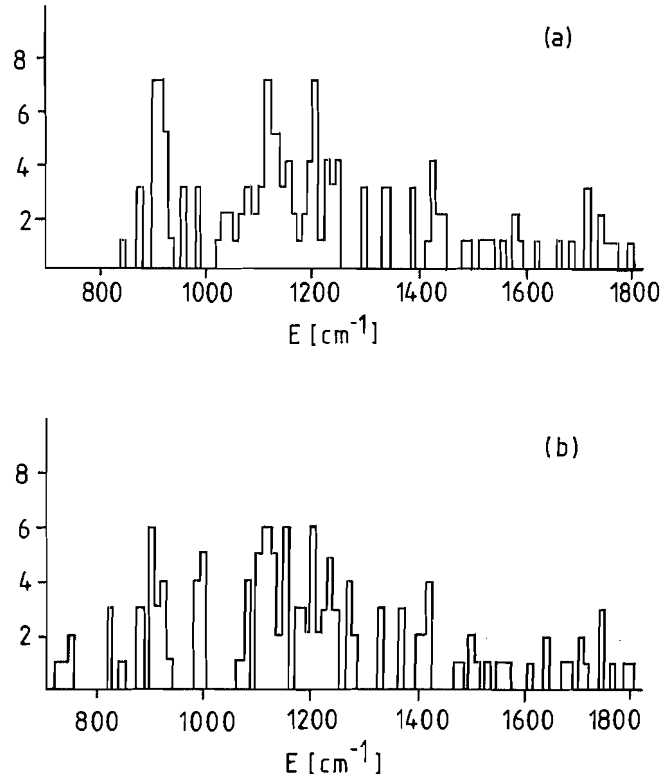

FIG. 6. Phonon density of state histogram of a $C_{50}H_{52}$ chain containing three neutral (a) or three negatively charged (b) polarons.

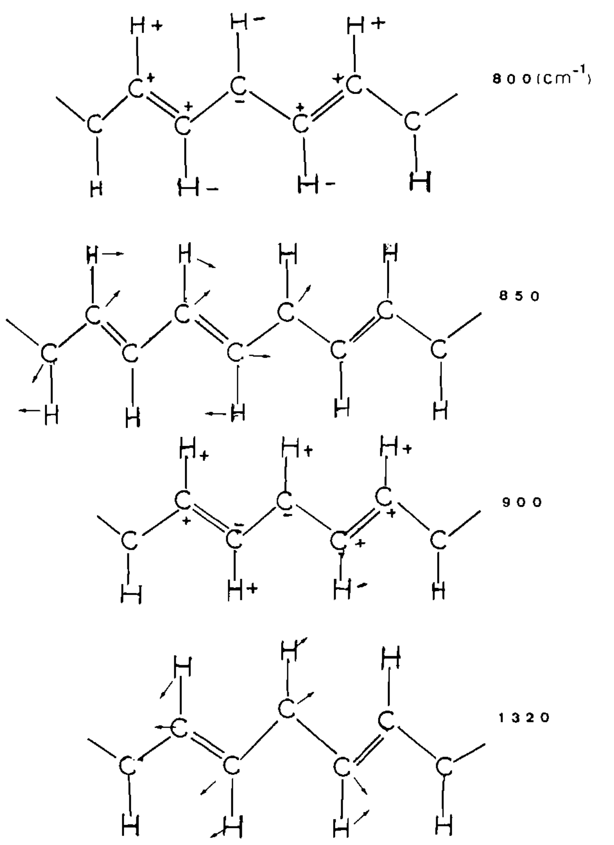

FIG. 7. Selected normal modes for the $C_{50}H_{52}$ chain with three neutral solitons. The numbers indicate the frequency and are given in cm^{-1}; +, indicates above-the-plane bending; −, below-the-plane bending.

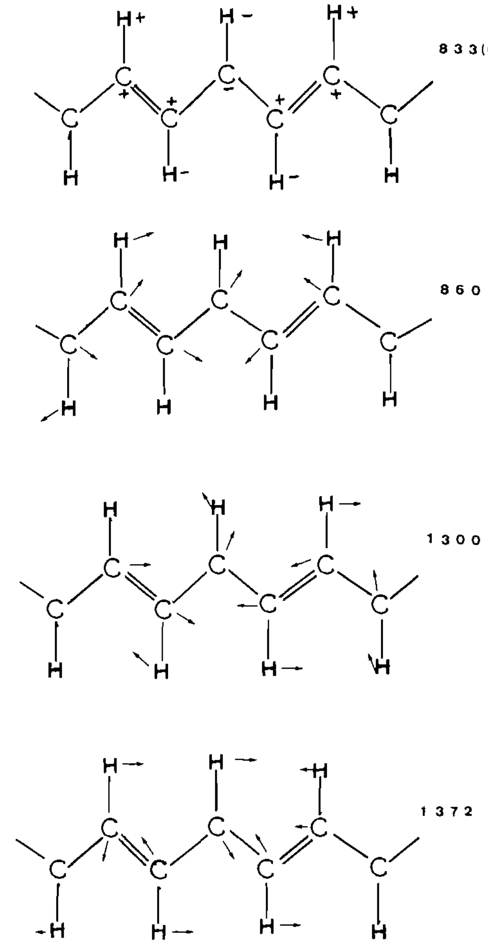

FIG. 8. Selected normal modes for the $C_{50}H_{52}$ chain with three negatively charged solitons.

densities of states for the corresponding polaron cases are plotted. Selected normal modes for the neutral and charged soliton cases are depicted in Fig. 7 and Fig. 8, respectively, and in Fig. 9 and 10 normal modes for the chains containing either three neutral or three charged polaron defects are shown.

First of all it has to be pointed out that no large differences between the four cases are found. The calculated spectra for the charged and neutral soliton as well as for the corresponding polaron defects are generally in agreement with the experimental trends and could at first sight explain the infrared spectrum of doped PA.

For the band approximately located around 1300 cm^{-1} our calculations yield the same assignment as the one given by Harada *et al.* Different behavior, however, has been found for the band at 800 cm^{-1}. In all four cases we have found in this range the presence of peaks which have to be assigned to out-of-plane C—H motions and to in-plane C—C—H bending motions. Harada *et al.* have discussed the possibility of assigning this band to C—H out-of-plane motions on the basis of deuteration and polarization experiments. In fact, the band at 888 cm^{-1} shifts to 790 cm^{-1} in the case of deuteration, while the C—D out-of-plane bending peak is located at 747 cm^{-1} in undoped PA. On the other hand, studies on the polarization dependence of these absorption bands have shown that the 800–900 cm^{-1} absorption are much more strongly polarized along the chain although a perpendicular polarization has also been observed. Therefore the possibility that the out-of-plane

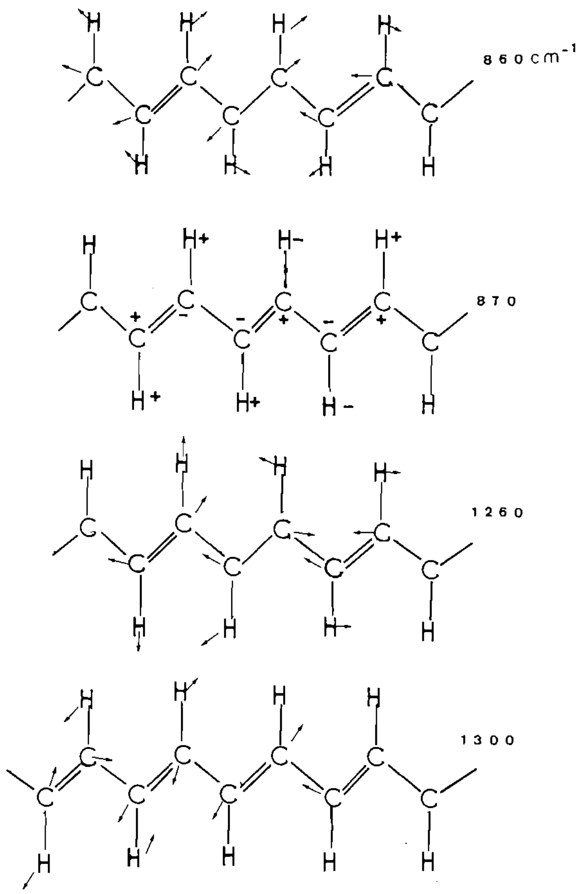

FIG. 9. Selected normal modes for the $C_{50}H_{52}$ chain with three neutral polarons.

C—H bending deformation lies in the same region as the in-plane C—C—H bending motions is, in our opinion, not ruled out by the experimental results. Our theoretical results strongly suggest that the broad band between 800 and 900 cm^{-1} is due to the presence of these two motions. This interpretation was also put forward by Zannoni and Zerbi (44) on the basis of preliminary calculations for the out-of-plane vibrations.

Finally, we discuss the differences in the spectra and normal modes of the four chains investigated in this study. In the case of the neutral polaron model we have found two peaks at 1290 and 1380 cm^{-1} which are in excellent agreement with experiment. In the range of 800–900 cm^{-1}, however, only a narrow band near 870 cm^{-1} (ascribed to the C—H out-of-plane bending) and one peak at 840 cm^{-1} (in-plane bending) are obtained. Therefore, the large width of the band is difficult to explain. In the case of charged soliton defects more peaks are found, but the majority of them has to be assigned to out-of-plane bending whereas the experiments show the dominant role of the in-plane motions. The spectrum most consistent with the experimental results is obtained for chains with either neutral solitons or charged polarons.

Our calculation of the vibrational spectrum of doped PA in which the electron–electron interaction is included for the first time in a self-consistent way shows that the infrared spectrum can be explained in terms of defects which invoke a local relaxation of the bond alternation. The interpretation is not uniquely in favor of the soliton picture. The polaron defect can serve as alternative explanation. The broad band between 800 and 900 cm^{-1} results from in-plane C—C—H bending and

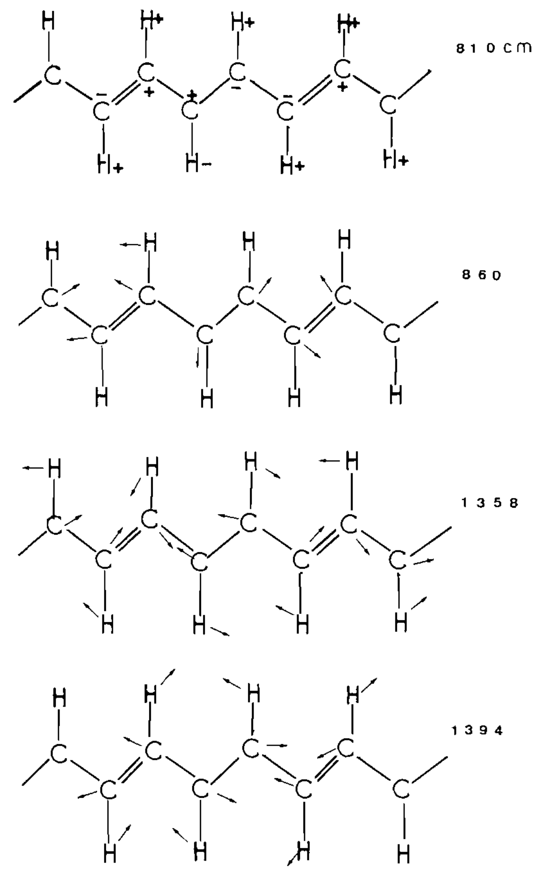

FIG. 10. Selected normal modes for the $C_{50}H_{52}$ chain with three negatively charged polarons.

C—H out-of-plane bending motions involving relaxed bond lengths of the defect site.

HENRYK T. FLAKUS and RUSSELL J. BOYD. Can. J. Chem. **63**, 1562 (1985).

Extensive *ab initio* molecular orbital calculations are reported for the hydrogen bonded complexes of the formula $(CH_3)_mNH^+_{4-m}$---F—H and $(CH_3)_mNH_{3-m}$---H—F, where m = 0, 1, 2, and 3. The one-proton ("linear") hydrogen bonded complexes of the ammonium ions and hydrogen fluoride are predicted to be more stable by about 1 or 2 kcal/mol than the two- and three-proton ("bent") complexes. Several systematic trends and a number of differences between the neutral and protonated series of complexes are observed. The basis set dependence of the results, basis set superposition errors and electron correlation effects are discussed.

HENRYK T. FLAKUS et RUSSELL J. BOYD. Can. J. Chem. **63**, 1562 (1985).

On rapporte les résultats de calculs d'orbitales moléculaires *ab initio* étendus effectués sur des complexes de formules $(CH_3)_mNH^+_{4-m}$---F—H et $(CH_3)_mNH_{3-m}$---H—F, où m = 0, 1, 2 ou 3. Sur la base de ces calculs, on prédit que les complexes des ions ammonium et du fluorure d'hydrogène qui sont liés par des liaisons hydrogènes impliquant un seul proton ("linéaires") sont plus stables que ceux impliquant deux ou trois protons ("repliés") et que la différence d'énergie entre ces deux types de complexes est égale à environ 1 à 2 kcal/mol. On discute de la variation des résultats avec la nature des ensembles utilisés, de la superposition des erreurs avec la nature des ensembles utilisés et des effets de corrélation des électrons.

[Traduit par le journal]

Introduction

Very few studies of hydrogen bonds between positive ions and neutral molecules have been reported in comparison to the extensive literature on the theory of the normal (neutral) H-bond (1−25). The only major report with which we are familiar is the *ab initio* molecular orbital study of Desmeules and Allen (26) for the twenty-one binary complexes formed from the hydrides of N, O, F, P, S, and Cl. Their systematic investigation has shown that the 4-31G basis set is adequate for predicting the geometries of the strong hydrogen bonds formed between protonated complexes and that a linear relationship exists between the heavy atom separation and length of the hydrogen bond. The latter conclusion also applies to the corresponding negative ions and to the normal hydrogen bonds of second- and third-row hydrides (27). In four of the twenty-one complexes there is an unusual net gain of charge on the proton relative to the monomers at infinite separation.

In this paper we report a 4-31G study of the hydrogen bonded complexes of the general formula $(CH_3)_mNH^+_{4-m}$---F—H, where m = 0, 1, 2, and 3. Particular attention is paid to the strengths of the conventional one-proton hydrogen bonds relative to two- and three-proton hydrogen-bonded complexes,[3] as illustrated in Fig. 1 for the methylammonium complex, and to the effect of multiple substituents within the series of protonated complexes. For completeness we present a complementary study of the neutral H-bonds in the related $(CH_3)_mNH_{3-m}$---H—F complexes.

Method

The majority of the computations were performed on a Perkin-Elmer 3230 computer using the GAUSSIAN 80 series of programs (28). The structures of the monomers and complexes with m = 0 and 1 were optimized completely at the 4-31G level. For the monomers and complexes with m = 2 and 3, the following constraints were imposed on the optimizations: a model methyl group (r(C—H) = 1.080 Å and ∠(HCH) = 109.471°) was assumed, the CNC angles were fixed at 109.471°, and the C—N bond length was taken to be 1.472 Å. In every case the monomers and complex were treated at a uniform level of theory, i.e. the same geometrical parameters were optimized for both the monomers and complex. The N—F distance was optimized in all complexes.

Estimates of the basis set superposition errors were obtained by means of GAUSSIAN 76 calculations (29) on the Dalhousie University CYBER 170−730 computer.

Choice of the basis set

The neutral NH_3---H—F complex has been studied at a variety of theoretical levels (7, 11−20), while the corresponding protonated complex has only been treated at the 4-31G level (26). In order to provide some indication of the basis set error associated with our 4-31G calculations on the protonated complexes, we show in Table 1 the computed properties of the H-bond between NH_4^+ and HF at the STO-3G, 3-21G, 4-31G, and 6-31G* levels.

Our results for the one-proton H-bond indicate a strong basis set dependence with the length increasing and the strength decreasing as the flexibility of the basis set is improved. Adding another set of basis functions to the valence shell of each atom and polarization functions to the hydrogens (i.e. the 6-311G** basis set) lowers the H-bond energy to 13.3 kcal/mol at the 6-31G* geometry. Including the effects of electron correlation by means of Møller−Plesset perturbation theory (30−32) terminated at second (MP2) and third order (MP3) with the same triple-split valence, polarized basis set and 6-31G* geometry raises the H-bond energy to 14.2 and 13.9 kcal/mol, respectively.

Calculations on the two- and three-proton complexes be-

[1]On leave from Department of Chemistry, Silesian University, Katowice, Poland.

[2]To whom all correspondence should be addressed.

[3]This is a matter of continuing experimental interest both in the solid state (see, for example ref. 42) and in the gas phase (see, for example ref. 43). The problem has not been addressed previously by the methods of quantum chemistry.

[b]The symbol "m" denotes the number of methyl groups.

tween NH_4^+ and HF show the same pattern: the H-bond energy decreases and the length of the H-bond increases as the flexibility of the basis set increases. The only exception occurs for the H-bond energy at the minimal basis set level. With basis sets of split-valence or better quality the trends are the same as those illustrated in Table 1.

On the basis of our calculations with extended basis sets and previous studies of the hydrogen bond (3−22, 24−27), we conclude that the 4-31G basis set represents a satisfactory compromise between computational convenience and reliability. We do not recommend the use of minimal basis sets for hydrogen bond studies and we do not think it is necessary to allow for electron correlation where the objective is to study chemical trends rather than to calculate accurate values of the H-bond energy.

Results and discussion

The 4-31G optimized N—H bond lengths of the free amines and ammonium ions are listed in Table 2. The 4-31G equilibrium geometries of the two series of complexes are listed in Table 3 and the corresponding total energies and hydrogen-bond energies are compiled in Table 4. For convenience we discuss first the neutral complexes and then the protonated complexes.

The 4-31G equilibrium geometries of the $(CH_3)_mNH_{3-m}$---H—F complexes show some very regular trends: the N—F and N—H distances of the hydrogen bond decrease with m, while the other bonds lengthen. The rate of change tends to diminish as m increases. Unfortunately there is insufficient experimental structural data for these complexes. As the length of the hydrogen bond decreases, the H-bond energy tends to increase. The one exception being the lower H-bond energy with m = 3. The somewhat lower H-bond energy for m = 3 may be a result of two opposing trends: the tendency of the H-bond to become shorter and stronger as a function of m and the increase in steric repulsion between the methyl groups and the H—F fragment of the complexes.[4] Although the H-bond energies of the complexes have not been measured, we note that the observed proton affinities of the methylamines also increase as a function of the number of methyl groups (33, 34). The difference between the 4-31G relative proton affinities (33) and the experimental values is remarkably constant: 14.5 ± 1.0 kcal/mol.

In accordance with the familiar correlation between the geometries of hydrogen-bonded complexes and their spectroscopic properties (1, 2) the H—F stretching frequencies of the

[4]A referee has suggested that a Morokuma energy component analysis (ref. 44), as reported by Kollman and Rothenberg (ref. 45), may provide an alternate explanation. We intend to investigate this suggestion in the future.

[a]In au.
[b]In kcal/mol.
[c]The symbol "m" denotes the number of methyl groups and "p" the number of protons involved in the hydrogen bond.

complexes are predicted to decrease relative to the isolated HF molecule, with the effect increasing with m. Furthermore the integral H—F stretching band intensities should increase as the number of methyl groups increases. On the other hand, the N—H bonds of the complexes are predicted to show very small differences (less than 0.007 Å versus up to 0.034 Å for the H—F bond) relative to the free amines and, therefore, hydrogen bonding is expected to have very little effect on the N—H stretching frequencies. The latter effects are likely to be more complex and of minor importance.

Ionic hydrogen-bonds in $(CH_3)_mNH^+_{4-m}$---F—H dimers

The 4-31G equilibrium structures suggest that the length of the one-proton hydrogen bond of the protonated complexes, as measured by the N—F distance, increases as a function of m, in contrast to the trend observed for the neutral complexes. Moreover, the length decreases in a regular fashion as the number of protons (denoted by the symbol "p") involved in hydrogen bonding increases: 0.103 ± 0.001 and 0.075 ± 0.001 Å for the first and second differences, respectively. As the N—F distance increases, a concomitant but smaller decrease of the N—H distance of the hydrogen bond is observed, in agreement with one of the observations of Desmeules and Allen (26). The other N—H bonds are relatively insensitive to the values of m and p, while the H—F bond remains almost constant (0.927 ± 0.001 Å) and close to the 4-31G value (0.925 Å) for the isolated molecule.

For a given type of hydrogen bond (that is fixed p), Table 4 reveals a strong correlation between the length and energy of the hydrogen bond: as the length increases the H-bond energy decreases monotonically. This observation may be contrasted with the situation in the complexes where the H-bond energy increases as a function of the number of methyl groups. Because the N—F distance of the ionic complexes increases as a function of m, repulsive interactions between methyl groups are expected to have less influence on the trends than in the neutral complexes where the H-bond energy of the m = 3 complex is an anomaly.

Hydrogen bonding is expected to decrease the N—H stretching frequencies relative to the isolated ammonium ion with the effect decreasing as m and p increase. The formation of a complex is predicted to have very little effect on the F—H frequencies and the N—H stretching frequencies of the N—H bonds not directly involved in hydrogen bonding.

The differences between the hydrogen bonds of the neutral and ionic complexes may be emphasized by considering the ratio between the N—F distance in the neutral and ionic complexes. The ratio decreases steadily from 0.98 for m = 0 to 0.93 for m = 3. Earlier work has shown that for a variety of complexes the ratio is close to 1.2 (26). The protonated complex between NH_4^+ and HF is an exception: our calculations and previous calculations (20, 26) yield 0.98, whereas the ratio has been incorrectly reported as 1.19 (26).

Linear (referred to herein as one-centre) hydrogen bonding lengthens the N—H bonds involved in hydrogen bonding more than bent (referred to herein as two- and three-centre) hydrogen bonding. The maximum lengthening is only 0.01 Å (compare Tables 2 and 3), while the shortening of the non-active N—H bonds is 0.003 Å or less. Within the two- and three-proton hydrogen bonded complexes, the N—H bond lengths remain within 0.004 Å of the free ion values.The small differences between the two- and three-proton complexes and the free ammonium ion suggest that the two forms would be indistinguishable by infrared spectroscopy, whereas the linear complex would show a larger shift of the N—H stretch to low frequency. The F—H bond length and, therefore, the F—H stretching frequency by inference is insensitive to the geometry of the complex, whereas the length of the C—N bond for m = 1 complexes diminishes from 1.517 to 1.511 Å as the number of protons in the hydrogen bond increases (see Table 3). For the m = 1 complexes the HNF angles of the multiproton hydrogen bonds vary by less than 0.5° as a function of the three basis sets listed in Table 5.

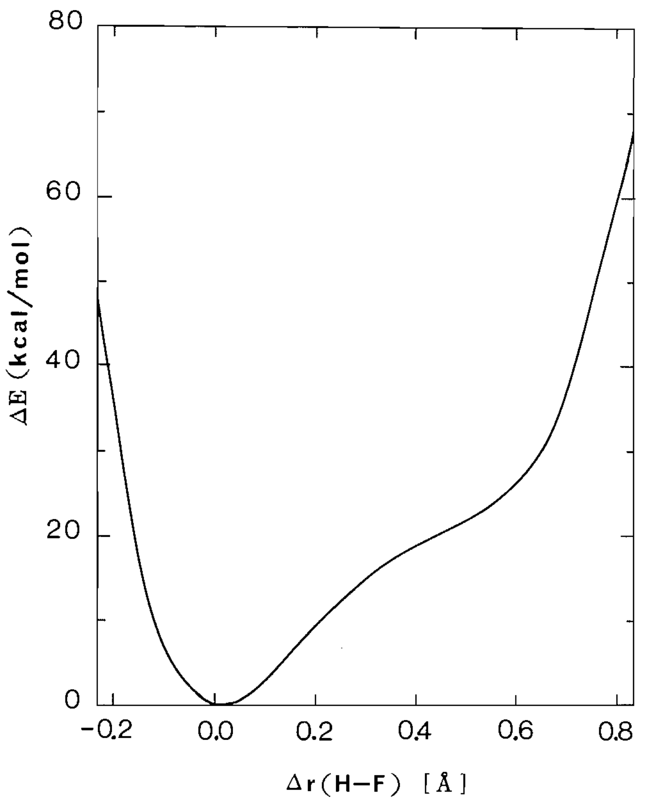

FIG. 2. 4-31G potential curve for stretching the H—F bond in the $(CH_3)_3N$---H—F complex.

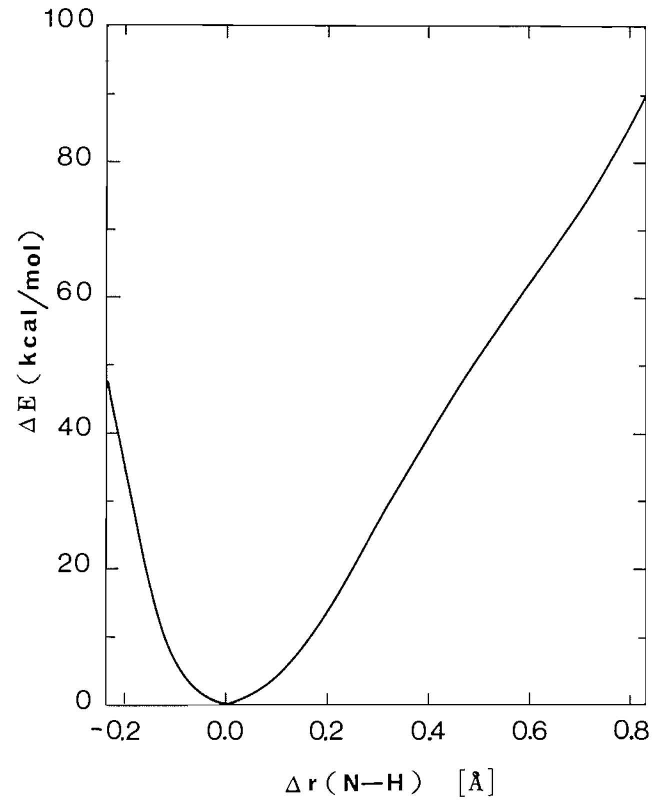

FIG. 3. 4-31G potential for N—H stretching motion in the $(CH_3)_3N^+$—H---F—H complex.

Proton motion in hydrogen-bonded complexes

Figure 2 illustrates the potential for the motion of the proton in the hydrogen bond of the trimethylamine – hydrogen fluoride complex, where the other nuclei are clamped in their equilibrium positions. Similar potentials have been calculated for the other complexes. Positive displacements of the proton correspond to stretching the H—F bond. The minimum represents the normal one-proton bond between $(CH_3)_3N$ and HF, while the shoulder associated with displacements of about 0.5 Å corresponds to a complex in which the proton has been totally transferred to the amine. The proton transfer may be represented schematically by

$$(CH_3)_3N\text{---}H\text{—}F \rightarrow (CH_3)_3N^+\text{—}H\text{---}F^-$$

With a stronger donor, i.e., weaker H—X bond we might expect a double minimum for the potential. In fact gas-phase studies of the trimethylamine – hydrogen bromide complex (3) indicate that the structure of the complex is $(CH_3)_3N^+$—H---Br^-, whereas the NH_3---HF and NH_3---HCl complexes do not exhibit proton transfer in the gas phase (7, 11, 22). Proton transfer also occurs in the gas phase complex of NH_3 and HI (22). Figure 2 implies that for a suitable choice of a donor and an acceptor the two minima would have equal stabilities and therefore a gas-phase complex would consist of a 1 : 1 ratio of the two types.

Figure 3 illustrates the analogous potential for the protonated complex in which the minimum is represented by $(CH_3)_3N^+$—H---F—H. The shoulder corresponding to transfer of the proton to HF is only slightly discernible. With a stronger donor and a stronger acceptor, proton transfer should occur. Where the protonated complex is formed by using the same compound for the donor and acceptor, e.g. HF or NH_3 (26), a double minimum will result:

$$H\text{—}F^+\text{—}H\text{---}F\text{—}H \leftrightarrow H\text{—}F\text{---}H\text{—}F^+\text{—}H$$

By suitable choice of the constituents, an unsymmetrical complex in which a double minimum exists for the motion of the proton could be formed.

Perturbations of the H-bonded complex by the environment, as for example in solution or in a crystal, can also change the donor and the acceptor properties of the dimer fragments. Previous theoretical work (35) has shown that the potential for H—F stretching in the NH_3---H—F complex exhibits a second minimum, corresponding to proton transfer, when the quantum chemical model is refined to allow for interactions between the dimer and a number of water molecules. Environmental effects are beyond the scope of the present study and are not considered further in this paper.

TABLE 5. Comparison of the H-bond energies of protonated complexes for different basis sets

	H-bond energy		
Complex	STO-3G	4-31G	6-31G*
$m = 0, p = 1$ (C_{3v})	20.8	18.1	13.5
$p = 2$ (C_{2v})	9.6	16.2	12.6
$p = 3$ (C_{3v})	8.2	15.9	12.8
$m = 1, p = 1$ (C_s)	18.0	16.5	12.3
$p = 2$ (C_s)	9.1	14.9	11.7
$p = 3$ (C_{3v})	8.0	14.6	11.7
$m = 2, p = 1$ (C_s)	16.4	15.5	—
$p = 2$ (C_{3v})	8.4	14.3	—

One-, two-, and three-proton ionic hydrogen bonds

Experimental data show that the majority of H-bonds involve the interaction of one proton with a single acceptor. There are, however, numerous examples of multicenter H-bonds in which one proton interacts with two or three proton acceptors (36). In this paper we consider yet another situation in which up to three protons interact with a single acceptor. A few *ab initio* studies of multiproton hydrogen bonds in neutral systems (7, 16, 19) have shown the one-proton ("linear") hydrogen bonds to be energetically favoured over the two- or three-proton ("bent") hydrogen bonds. For the protonated complexes we have reached the same conclusion. Table 5 lists the hydrogen-bond energies of the protonated complexes at three different theoretical levels. All calculations favour the one-proton hydrogen bonded complexes with the differences being greatest at the STO-3G level. With the larger basis sets the differences between the one-proton and multiproton hydrogen-bond energies are small.

The large differences at the STO-3G level require further comment. Our study of hydrogen bonding has been carried out within the supermolecule approximation and, therefore, the magnitude of the basis set superposition error (BSSE) should be assessed. By application of the counterpoise method (37–40) we have estimated the BSSE to be -9.2 kcal/mol for the one-proton complex and -1.4 kcal/mol for the three-proton complex of NH_4^+---F—H at the STO-3G level. The corresponding 4-31G values are -1.3 and -1.4 kcal/mol, respectively, which is comparable to the 4-31G BSSE in the neutral complexes of NH_3, H_2O, and HF (21). These results imply that the BSSE is fairly constant at the 4-31G level and not a serious source of error. At the STO-3G level the BSSE is a major source of error and in fact forms a large part of the hydrogen-bond energy of the one-proton hydrogen bonded ionic complexes.

Conclusions

On the basis of the calculations reported in this paper, the following conclusions regarding the hydrogen bonded complexes of ammonium ions and amines with hydrogen fluoride may be drawn.

(*1*) At the 4-31G level the one-proton hydrogen bonded complexes of the ammonium ions and hydrogen fluoride are predicted to be more stable by about 1 or 2 kcal/mol than the two- and three-proton complexes.

(*2*) The length (N—F distance) of the one-proton hydrogen bond of the protonated complexes increases systematically as a function of the number of methyl groups, whereas the same property decreases in neutral complexes.

(*3*) In agreement with earlier studies of hydrogen bonds between positive ions and neutral molecules (26), the N—H distance of the hydrogen bond of the protonated complexes decreases as the N—F distance increases.

(*4*) The ratio of the N—F distance in the neutral and ionic complexes decreases steadily from 0.98 to 0.93 as a function of the number of methyl groups. This may be contrasted with previous work (26) which has shown the ratio of heavy atom distances to be about 1.2 in a variety of complexes.

(*5*) The potentials for the motion of the proton in the hydrogen bond of the linear complexes of trimethylamine and the trimethylammonium ion with hydrogen fluoride have different shapes. For the neutral complex, a shoulder corresponding to transfer of the proton to the amine is clearly visible.

(*6*) Extensive calculations for the one-proton hydrogen bonded complex of NH_4^+ and HF exhibit a strong basis set dependence with the length increasing and the strength decreasing as the flexibility of the basis set improves. With a triple-split valence, polarized basis set (6-311G**) the MP2 and MP3 correlation corrections are only 0.9 and 0.6 kcal/mol, respectively.

(*7*) The basis set superposition error (BSSE) has been estimated by the counterpoise method to be -9.2 and -1.4 kcal/mol for the one-proton and three-proton complexes of NH_4^+---F—H at the STO-3G level. The corresponding 4-31G values are -1.3 and -1.4 kcal/mol.

(*8*) In every case the charge on the proton of the hydrogen bond decreases relative to the corresponding monomers at infinite separation. Earlier work (26) has shown that there are a few special cases where the charge increases.

(*9*) The 4-31G basis set represents a satisfactory compromise between computational convenience and reliability. Due to large variations in the BSSE the STO-3G basis set is not recommended for hydrogen bond studies. Electron correlation effects are of minor importance.

Des mesures de capacité calorifique de polyélectrolytes en solution dans l'eau ont été réalisées à 25°C à l'aide d'un microcalorimètre dynamique du type Picker. Cet appareil est d'une précision telle que le calcul de capacité calorifique molaire apparente ($C_{p,\phi}$) du soluté devient possible même à haute dilution. Les polymères étudiés furent l'acide polyméthacrylique (HPMA) et l'acide polyacrylique (HPA) ainsi que son sel de sodium, de même que le polystyrènesulfonate de sodium. Les résultats montrent que pour les sels, la valeur de $C_{p,\phi}$ décroit rapidement avec la dilution à faible concentration en parfait accord avec une relation obtenue à partir de la théorie de Lifson et Katchalsky. Une étude de la variation de $C_{p,\phi}$, à concentration fixe, en fonction du degré de neutralisation de l'HPA et de l'HPMA a aussi été réalisée. Comme il a déjà été démontré par d'autres travaux, la chaîne de l'HPMA subit une transformation conformationnelle lorsque le degré de neutralisation atteint environ 25%. Cette transformation se réflète par une augmentation de $C_{p,\phi}$.

HUBERT DAOUST, HOA LE THANH, PIERRE FERLAND, and DANIEL ST-CYR. Can. J. Chem. **63**, 1568 (1985).

Heat capacities of polyelectrolytes in aqueous solutions have been measured at 25°C using a Picker-type dynamic microcalorimeter. The precision of the apparatus is such that it is possible to calculate the apparent molar heat capacity ($C_{p,\phi}$) of the solute, even at high dilution. The polymers that were studied include polymethacrylic acid (PMAH) and polyacrylic acid (PAH), as well as its sodium salt and the sodium salt of the polystyrenesulfonate. For the salts, the results show that the value of $C_{p,\phi}$ decreases rapidly with dilution to low concentrations; this result is in perfect concordance with a relation derived from the theory of Lifson and Katchalsky. A study of the variation of $C_{p,\phi}$, at a constant concentration, with the extent of the neutralization of the acids PMAH and PAH has also been conducted. As has been shown previously, the chain of the PMAH undergoes a conformational transformation when the level of neutralization gets close to 25%. This transformation implies an increase of the value of $C_{p,\phi}$.

Introduction

Les solutions de polyélectrolytes sans addition d'électrolyte neutre présentent un défi à tout traitement théorique global (1). Le comportement d'une chaîne polyélectrolytique change considérablement avec la dilution. En effet, cinq domaines de concentrations ont été décrits par Wolff (2) lors d'une étude sur la viscosité de solutions de polyélectrolytes et par Odijk (3) qui a appliqué la loi d'échelle aux solutions semi-diluées de polyélectrolytes. Trois concentrations critiques ont alors été définies: C_G^*, concentration à laquelle les chaînes de polyions fortement alongées ne peuvent plus s'orienter librement commencent à former un réseau tridimensionnel; C^*, concentration à laquelle les polyions interagissent assez fortement pour faire plier les chaînes; C^{**}, concentration à laquelle le réseau tridimensionnel est détruit. Contrairement à C_G^* et à C^*, C^{**} ne dépend pas de la longueur de la chaîne étalée. Les cinq domaines de concentrations sont alors (2, 3): (I) $C < C_G^*$, domaine très dilué où les chaînes sont étirées à leur longueur maximum et où les interactions entre polyions sont négligeables; (II) $C_G^* < C < C^*$, domaine dilué où les chaînes demeurent rigides mais interagissent fortement de façon à former un réseau tridimensionnel; (III) $C^* < C < C^{**}$, domaine semi-dilué où le réseau est toujours existant mais les dimensions de chaînes décroissent; (IV) $C > C^{**}$, domaine où le réseau tridimensionnel disparaît pour faire place à un système plus ou moins ordonnée de polyions de conformation sphérique en contact les uns avec les autres; (V), $C \gg C^{**}$, domaine où les polyions sont enchevêtrés et leur conformation est gaussienne tel un polymère neutre. Il serait très intéressant de pouvoir faire des études expérimentales couvrant tous les cinq domaines de concentrations. Cependant, les valeurs calculées pour C_G^* pour des chaînes vinyliques ayant des degrés de polymérisation de 10^4 et 10^5 sont $1,1 \times 10^{-6}$ et $1,1 \times 10^{-8}$ monomol L^{-1} respectivement (1). Les valeurs correspondantes pour C^* sont $7,6 \times 10^{-5}$ et $7,6 \times 10^{-6}$ monomol L^{-1}. Les domaines I et II ne sont donc pas accessibles à l'expérience, du moins pour des macromolécules ayant une masse molaire suffisamment élevée pour être considérées comme telles. D'autre part, le domaine III est accessible car la valeur de C^{**} est estimée à $4,3 \times 10^{-2}$ monomol L^{-1} (1). La loi d'échelle telle qu'appliquée par Odijk sous-évalue peut-être C^* et C^{**}. En effet, des résultats obtenus en diffusion quasi-élastique de la lumière par des solutions de polystyrènesulfonate de sodium indiquent que la dimension de la chaîne se rapproche de celle d'une chaîne complètement étendue (4). Les mêmes résultats indiquent aussi un comportement non-uniforme pour les chaînes dans le domaine de concentrations III; ceci est confirmé par des expériences en relaxation magnétique nucléaire dans le même domaine (5).

Les propriétés thermodynamiques de solutions de polyélectrolytes dépendent de plusieurs facteurs. Entre autres, les interactions électrostatiques sont très importantes. De fait, elles sont considérées comme étant l'unique facteur responsable de la valeur de la chaleur de dilution de solutions de polyélectrolytes dans le domaine de concentrations III (6). Parmi les fonctions thermodynamiques intéressantes, il y a la capacité calorifique.

Dans un article précédent (7), la capacité calorifique molaire apparente à pression constante, $C_{p,\phi}$, pour un polyélectrolyte a été définie par la somme de deux termes. Le premier, $C_{p,\phi n}$, est la contribution venant des effets non-électrostatiques et le second, $C_{p,\phi c}$, la contribution venant des interactions électros-

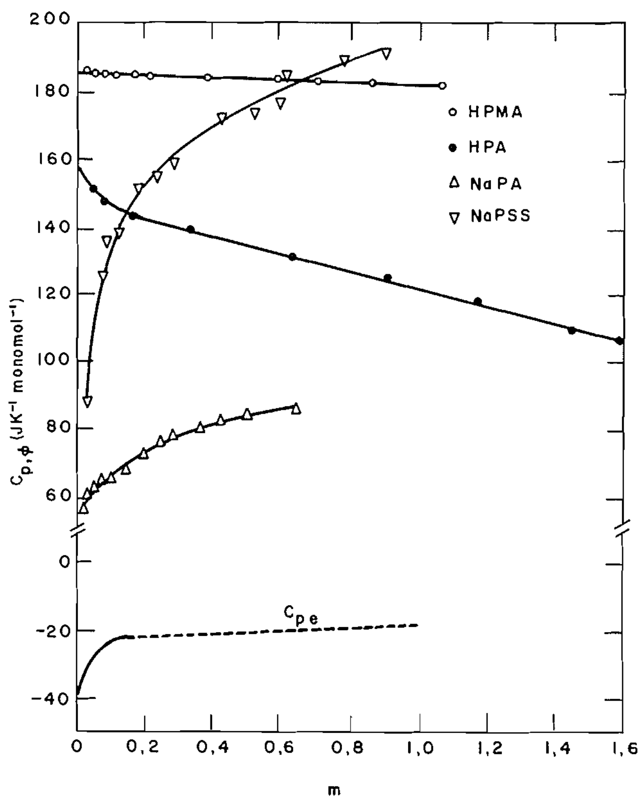

FIG. 1. Variation de la capacité calorifique molaire apparente en fonction de la molalité dans l'eau à 25°C.

tatiques. En posant $C_{p,\phi c} = C_{pc}$, il a été possible d'obtenir une relation pour C_{pc} à partir du modèle cellulaire de Lifson et Katchalsky (LK) pour un polyion en solution diluée (8):

$$[1] \quad C_{pc} = \frac{\alpha z_1 R}{z_2 \lambda}\left\{\mu\left(2 + 4\frac{\mathrm{d}\ln D}{\mathrm{d}\ln T} + \frac{T^2\mathrm{d}^2 D}{D\,\mathrm{d}T^2}\right) + \left(1 + \frac{\mathrm{d}\ln V}{\mathrm{d}\ln T}\right) \times \left[\frac{1+\beta^2}{2}\frac{\mathrm{d}\ln V}{\mathrm{d}\ln T} + \lambda\left(1 + \frac{\mathrm{d}\ln D}{\mathrm{d}\ln T}\right)\frac{1-\lambda^2+\beta^2}{(1-\lambda)^2-\beta^2}\right]\right\}$$

avec

$$[2] \quad \mu = (1+\beta^2)\gamma + \ln\{[(1-\lambda)^2 - \beta^2]/(1-\beta^2)\} + \lambda$$

où α est le degré d'ionisation du polyélectrolyte; z_1, le nombre de charges des groupements ionisés sur le polyion; z_2, le nombre de charges des contreions; λ, le paramètre de densité de charges; D, la constante diélectrique du solvant; V, le volume de la solution; β, une constante d'intégration et γ, un paramètre de la concentration. Il a été démontré que dans l'eau, C_{pc} est une quantité négative (7) et varie d'une façon logarithmique avec la concentration dans le domaine de concentrations où le modèle cellulaire le LK est applicable, soit dans les domaines I et II, et au début du domaine III. Des résultats expérimentaux obtenus autour de la concentration C^{**} semblent confirmer les prédictions théoriques (7). Tant qu'à $C_{p,\phi n}$, sa valeur est sûrement affectée par les forces électrostatiques qui ont une très grande influence sur les changements de conformation des chaînes et sur la mobilité des segments à l'intérieur des chaînes en fonction de la concentration. D'autres effets secondaires mais de très grande importance tels l'hydratation coulombique et les effets structuraux au niveau du solvant affectent la valeur de $C_{p,\phi n}$ (9). De plus, la solvatation hydrophobe affecte aussi cette quantité (9).

Dans le présent travail, une étude plus approfondie de la capacité calorifique des polyélectrolytes en solution sans addition d'électrolyte neutre est présentée. Les effets du degré d'ionisation sont discutés.

Partie expérimentale

Produits utilisés

Les différents polymères utilisés dans ce travail sont: un échantillon d'acide polyméthacrylique (HPMA) déjà décrit ailleurs (10) ayant un degré de polymérisation viscosimétrique moyen ($\overline{\mathrm{DP}}_v$) de 1920; un échantillon d'acide polyacrylique (HPA) provenant de chez Polysciences, Inc. et ayant un $\overline{\mathrm{DP}}_v$ de 2080; finalement, un échantillon de polystyrènesulfonate de sodium (NaPSS) provenant de chez Dow Chemical International (Sarnia, Ontario) et ayant un $\overline{\mathrm{DP}}_v$ de 2750. Le sel de sodium de HPA a été préparé selon une méthode décrite ailleurs (11). Tous les autres produits utilisés étaient des réactifs analytiques. Les solutions ont été préparées par voie gravimétrique, l'eau utilisée était distillée et déionisée.

Méthode expérimentale

Les capacités calorifiques volumiques (J mL^{-1}) des solutions ont été déterminées à l'aide d'un microcalorimètre différentiel dynamique Picker; elles ont été converties en capacités calorifiques massiques (J g^{-1}) en les divisant par les densités des solutions déterminées à l'aide d'un densimètre dynamique Picker. La technique expérimentale a déjà été décrite précédemment (12). L'erreur estimée sur le calcul de $C_{p,\phi}$ diminue sensiblement lorsque la concentration augmente. Par exemple, elle est moins de $\pm 10\%$ pour une molalité de 0,02 et moins de $\pm 2\%$ pour une molalité de 0,1. Tous les résultats sont exprimés pour une mole de motif de base.

Résultats et discussion

La variation de $C_{p,\phi}$ en fonction de la molalité est représentée sur la fig. 1 pour les différents polymères en solution dans l'eau à 25°C. Les données expérimentales sont disponibles sur demande.[4] Les résultats indiquent une diminution de $C_{p,\phi}$ lorsque la concentration augmente dans le cas des deux polyacides faibles. Des résultats similaires ont été obtenus pour le polyoxyéthylène dans l'eau (12). L'augmentation de la concentration intensifie l'enchevêtrement des chaînes, ce qui réduit leur mobilité ou leur mouvement de reptation et cela se reflète dans la valeur de $C_{p,\phi}$. Cependant, l'application de l'éq. [8] de la réf. 12 prévoit une augmentation de $C_{p,\phi}$ avec la concentration car le paramètre enthalpique d'interaction est positif et constant (0,48) à 25°C (13) et est positif mais plus petit et variable à 35°C.[5] Il semble bien que l'application seule de la thermodynamique des solutions de macromolécules ne suffit pas pour expliquer l'allure de la variation de $C_{p,\phi}$ avec la concentration.

Les résultats obtenus pour les deux polyélectrolytes forts sont aussi représentés sur la même figure. Pour NaPSS, la chute de $C_{p,\phi}$ lorsque la concentration diminue vers le domaine III est remarquable. Même lorsque la valeur de C_{pc}, indiquée au bas du graphique, est retranchée de celle de $C_{p,\phi}$, l'allure de $C_{p,\phi n}$ demeure très fortement affectée par la dilution. La dilution d'une solution aqueuse semi-diluée d'un polyélectrolyte fort est accompagnée par la rupture ou le relâchement de liaisons électrostatiques fortes entre les sites chargés sur les polyions et les contreions, ce qui donne lieu à l'augmentation du degré d'hydratation coulombique des espèces ioniques ainsi libérées. D'après la loi de Born, la

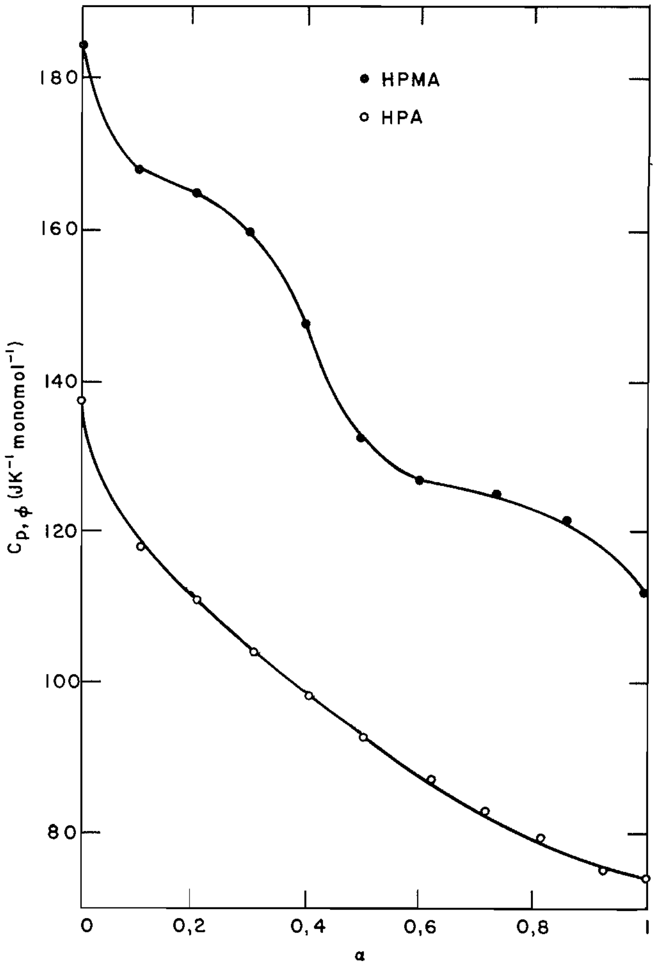

FIG. 2. Variation de la capacité calorifique molaire apparente moyenne en fonction du degré de neutralisation à 25°C (molalités: 0,32 pour HPA et 0,20 pour HPMA).

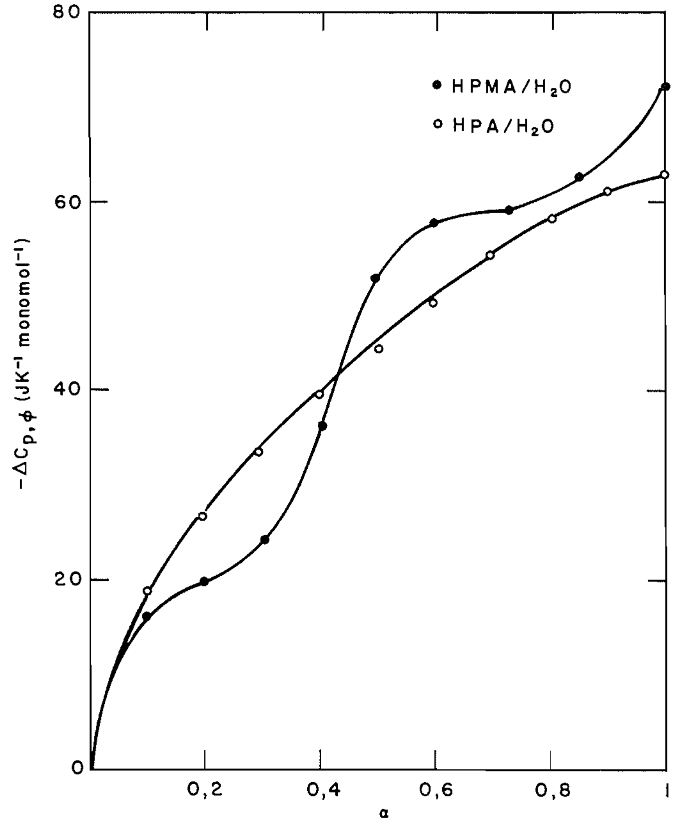

FIG. 3. Variation de l'incrément de la capacité calorifique molaire apparente moyenne en fonction du degré de neutralisation à 25°C (molalités: 0,32 pour HPA et 0,20 pour HPMA).

solvatation coulombique doit apporter une contribution négative à $C_{p,\phi}$ mais des résultats expérimentaux obtenus dans le cas de petits ions en solvants non-aqueux ont contredit cette prédiction théorique (9). La loi de Born serait peut-être applicable dans le cas de solutions aqueuses de polyélectrolytes. Par ailleurs, si la dilution doit conduire à un système tridimensionnel de polyions rigides (domaine II), en passant par un système plus ou moins ordonné de sphères rigides (domaine III), $C_{p,\phi}$ doit nécessairement chuter vers une valeur plus faible et ce passage devrait se faire graduellement. Dans le cas de NaPA, l'allure des résultats est semblable quoique moins prononcée. Cette différence pourrait être due au pourcentage élevé ($\approx$60%) d'ions sodium qui demeurent liés aux chaînes même à faible concentration de polymère (14).

La figure 2 représente la variation de la valeur moyenne de $C_{p,\phi}$ en fonction du degré de neutralisation, à concentration de polymère fixe, pour HPMA et pour HPA dans l'eau. Dans le cas présent, la masse molaire moyenne d'un motif de base est définie par $M_A + (1 - \alpha)M_H + \alpha\, M_{Na}$ où M_A est la masse molaire du motif acrylate ou méthacrylate selon le cas, M_H, celle de l'hydrogène et M_{Na}, celle du sodium. L'allure générale des résultats indique bien la diminution de $C_{p,\phi}$ avec l'augmentation de α en accord avec l'éq. [1], compte tenu du fait que la contribution de l'ion sodium à $C_{p,\phi}$ à dilution infinie est de 23 J K^{-1} mol^{-1} plus élevée que celle de l'ion hydrogène (15). (Cette contribution par rapport au proton hydrogène n'est pas connue.) Cette diminution de $C_{p,\phi}$ lorsque α augmente, se retrouve également lors de l'étude de la neutralisation de l'acide acétique (16, 17). Cependant, le grand écart entre la valeur de $C_{p,\phi}$ à $\alpha = 0$ et sa valeur à $\alpha = 1$ ne peut être expliqué seulement que par des interactions électrostatiques. Lors de l'ionisation, un effet destructeur de la structure de l'eau est produit par les ions formés et cet effet amène une contribution négative à $C_{p,\phi}$ (9, 17). La figure 3 permet une meilleure comparaison entre les résultats obtenus pour HPMA et HPA dans l'eau. La valeur de $\Delta C_{p,\phi}$ représente la différence entre celle de $C_{p,\phi}$ pour l'acide ($\alpha = 0$) et la valeur moyenne de $C_{p,\phi}$ pour la valeur de α correspondante. La valeur de $\Delta C_{p,\phi}$ diminue d'une façon monotone depuis l'acide jusqu'au sel dans le cas de HPA et cette courbe a la même allure que celle du pourcentage d'ions sodium fixés sur les polyions en fonction de α (14); ceci revient à dire que $\Delta C_{p,\phi}$ varie linéairement avec ce pourcentage d'ions liés. Dans le cas de HPMA, deux anomalies ressortent des résultats. La première anomalie apparaît autour d'une valeur d'environ 0,3 pour α. Cette anomalie doit correspondre à la transition bien connue pour la chaîne de HPMA qui passe d'une structure compacte globulaire où les groupements méthyles sont dirigés vers l'intérieur de la chaîne à une structure plus étendue où ces mêmes groupements deviennent accessibles aux molécules d'eau (18, 19). L'hydratation hydrophobe accompagnant cette transition expliquerait l'augmentation de $C_{p,\phi}$ (9) de HPMA partiellement neutralisé par rapport à HPA. Une augmentation de $C_{p,\phi}$ a aussi été observée lors de la dénaturation de plusieurs protéines gobulaires en solution dans l'eau par addition d'urée (16, 17). Cette dénaturation amène la protéine à se déplier en pelote statistique et l'aug-

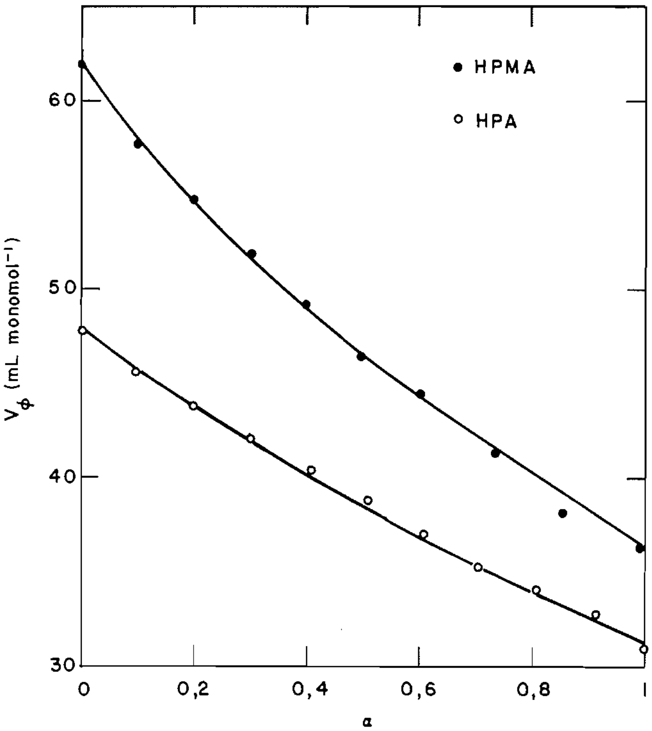

FIG. 4. Variation du volume molaire apparent moyen en fonction du degré de neutralisation à 25°C (molalités: 0,32 pour HPA et 0,20 pour HPMA).

mentation de $C_{p,\phi}$ est attribuée à l'hydratation hydrophobe qui accompagne la dénaturation. La courbe pour HPMA devrait demeurer sous celle de HPA au-delà de $\alpha = 0{,}3$ car seulement l'ionisation et l'hydratation coulombique devraient se poursuivre. Mais une deuxième anomalie se présente lorsque α augmente et cette fois $C_{p,\phi}$ diminue. La littérature ne rapporte pas de seconde transition lors de la neutralisation de HPMA. L'explication de cette deuxième anomalie pourrait se trouver dans une déshydratation partielle des groupements méthyles. Ce phénomène se passerait aussi dans le cas de solutions diluées d'espèces ioniques possédant des groupements hydrophobes (10, 20). Lors de l'ouverture de la chaîne polyméthacrylique, il est permis de présumer que presque tous les groupements méthyles s'hydratent. Mais à ce moment, la charge nette portée par la chaîne est faible. Au fur et à mesure que α augmente, cette charge nette augmente également et le champ électrostatique ainsi créé peut briser la structure pentagonale des molécules d'eau (21) autour de quelques groupements méthyles.

La figure 4 représente la variation du volume molaire apparent (V_ϕ) en fonction du degré de neutralisation pour les deux polyacides. L'allure des deux courbes est monotone et aucune anomalie ne ressort de la courbe relative à HPMA autour de $\alpha = 0{,}3$ et $\alpha = 0{,}6$. Cette absence de variation subite dans la valeur de V_ϕ lors de l'ouverture de la chaîne polyméthacrylique n'est pas unique au cas présent. Alors que la valeur de $C_{p,\phi}$ augmente appréciablement lors de la dénaturation des protéines globulaires, la valeur de V_ϕ varie peu ou ne varie pas lors de la transformation conformationnelle (16). Cependant, la chute de V_ϕ en fonction de α est initialement plus rapide lors de la neutralisation de HPMA comparativement à HPA. La présence du groupement méthyle sur le carbone porteur du groupement carboxylate et le changement conformationnel de HPMA ne sont sûrement pas étrangers à ce phénomène. En effet, l'hydratation hydrophobe, tout comme les interactions électrostatiques et l'effet destructeur de la structure de l'eau, apporte une contribution négative à V_ϕ (9).

Conclusions

Le modèle cellulaire de LK pour un polyion en solution très diluée et la structure d'une solution de polyélectrolyte évoluant avec la concentration tel que proposé par Wolff et Odijk semblent expliquer qualitativement l'allure des résultats obtenus à partir de mesures de capacités calorifiques. Par ailleurs, l'hydratation coulombique et l'hydratation hydrophobe jouent un rôle très important dans la valeur de cette quantité pour les polyélectrolytes.

Remerciements

Violation of Hund's multiplicity rule in the electronically excited states of conjugated hydrocarbons is studied by using the Pariser–Parr–Pople type SCF MO method and the *ab initio* MO method with STO-3G basis set, both methods being augmented by CI-type treatments. It is shown that for symmetrical structures (D_{2h}) of the nonalternant hydrocarbons, propalene, pentalene, and heptalene, the lowest excited singlet state is energetically lower than the corresponding triplet state. This is mainly due to the spin polarization (SP) effects. For D_{2h} structures of pentalene and heptalene the open-shell excited singlet state is predicted to be lower in energy than the closed-shell state, with the result that the former is really the ground state. Further, calculations made by including electron correlation effects reveal that in linear polyenes and polyacenes, the lowest excited singlet "minus" state (using Pariser's classification of the alternancy symmetry species) is lower in energy than the corresponding triplet state. The energy lowering of the singlet "minus" state in linear polyenes is due mostly to the mixing with the doubly excited configurations ($mm \rightarrow nn$), while the considerable part of it in polyacenes is due to the SP effects.

SHIRO KOSEKI, TAKESHI NAKAJIMA et AZUMAO TOYOTA. Can. J. Chem. **63**, 1572 (1985).

Utilisant la méthode des OM CAC du type de Pariser–Parr–Pople ainsi que la méthode des OM *ab initio* à l'aide d'un ensemble de base STO-3G alors que les deux méthodes ont été renforcées par des traitements de type IC, on a étudié la violation de la règle de multiplicité de Hund dans les états électroniques excités des hydrocarbures conjugués. On montre qu'au niveau des structures symétriques (D_{2h}) des hydrocarbures non alternants, comme le propalène, le pentalène et l'heptalène, le plus bas état singulet excité est énergiquement plus faible que l'état triplet correspondant. Ceci est dû principalement à des effets de polarisation de spin (PS). Dans les structures D_{2h} du pentalène et de l'heptalène, on prédit que l'état singulet excité à couche électronique incomplète est énergiquement plus faible que l'état à couche électronique complète; il en découle que le premier est réellement l'état fondamental. Des calculs plus poussés, incluant les effets de corrélation de l'électron, révèlent que dans les polyènes linéaires et les polyacènes, l'état singulet moins le moins excité (en utilisant la classification de Pariser des espèces de symétrie alternée) a une énergie inférieure à celle de l'état triplet correspondant. La baisse d'énergie de l'état singulet moins des polyènes linéaires est principalement due à un mélange avec des configurations doublement excitées ($mm \rightarrow nn$) tandis qu'une partie considérable de cette baisse d'énergie dans les polyacènes est due aux effets de PS.

Introduction

The energetic order of the singlet–triplet pair arising from a given electronic configuration in atoms and molecules is determined by using Hund's multiplicity rule (1), and the utility of this rule has well been known. In certain cases (2–8), however, Hund's multiplicity rule breaks down. In molecular systems, of particular notice is the ground-state multiplicity of cyclobutadiene. Buenker and Peyerimhoff (3) have shown that in the square geometry (D_{4h}) of this molecule the B_{1g} singlet state is more stable than the A_{2g} triplet state by about 3.6 kcal mol^{-1}, both states arising from the same electronic configuration. The theoretical explanation of this unusual fact has firstly been given by Borden (4), followed by other authors (5–7). In connection with cyclobutadiene, the ground-state multiplicities in conjugated hydrocarbon diradicals have been examined by Borden and Davidson (6), and they have shown that the ground states of some diradicals are singlet. In these unusual molecules, the two Hueckel nonbonding molecular orbitals (NBMO's) are confined to disjoint sets of carbon atoms. In such a case, the exchange integral responsible for the energy separation of the singlet–triplet pair arising from the occupation of the NBMO's by a total of two electrons is negligibly small, and the spin polarization (SP) effects (5) can reverse the energy ordering such that the singlet state lies below the corresponding triplet state. On the other hand, if the NBMO's are not localized to disjoint sets of atoms, the triplet state lies well below the corresponding singlet state at the Hartree–Fock level, and it is less probable that the energy ordering is reversed by the SP effects.

Ruling out atomic systems, theoretical studies so far reported (3–7) have been limited to the ground-state multiplicities. In this paper, we are concerned with the possible violation of Hund's multiplicity rule for the singlet–triplet pair arising from the same singly excited electronic configuration in molecules, particularly conjugated hydrocarbons. In Section I, we give a brief account of the SP effect. In the first half of Section II, we study the energetic orders of the singlet–triplet pairs of the lowest excited states at the most symmetrical structures (D_{2h}) of the nonalternant hydrocarbons, propalene, pentalene and heptalene, which can be regarded as the weakly perturbed [4*n*]annulenes. In these antiaromatic annulenes, if they are assumed to have the most symmetrical structures, the doubly-degenerate NBMO's are confined to different sets of atoms. It follows then from the previous treatments of antiaromatic annulenes like cyclobutadiene that in the D_{2h} structures of propalene and its higher homologues Hund's multiplicity rule is most likely violated in the lowest excited states. It is shown by

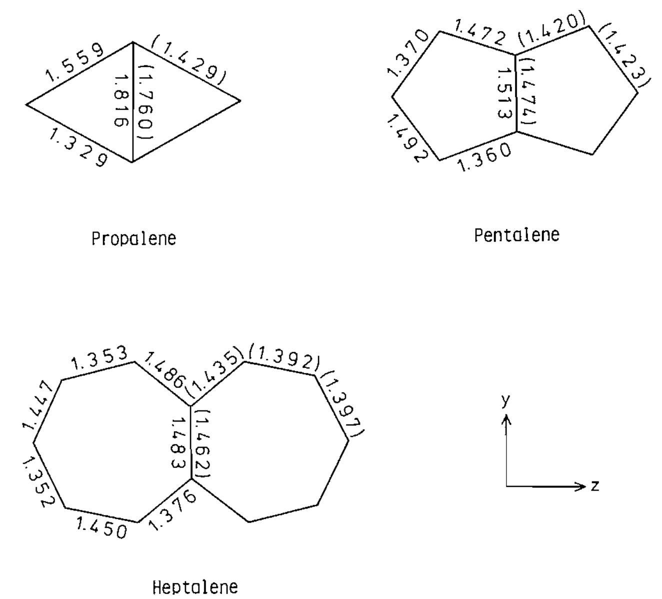

FIG. 1. Bond lengths (in Å) of the D_{2h} and C_{2h} structures of propalene, pentalene, and heptalene optimized by using the MNDO method and the choice of axes in the D_{2h} structures. The figures in parentheses are the bond lengths of the D_{2h} structures.

using the Pariser–Parr–Pople (PPP) type and *ab initio* MO methods, both the methods being augmented by the CI-type treatments, that in the D_{2h} structures of propalene, pentalene, and heptalene the lowest excited singlet state lies below the corresponding triplet state. Furthermore, in the D_{2h} structures of pentalene and heptalene, the lowest excited state ($^1B_{3g}$) is predicted to lie even below the closed-shell state (^1A_g), with the result that the open-shell singlet state is the true ground state. In the second half of Section II, we study the energetic orders of the singlet–triplet pairs of the low-lying excited "minus" and "plus" states (using Pariser's classification of the alternancy symmetry species) in linear polyenes and polyacenes.

I. Spin polarization (SP) effects

Here we give only a brief account of the SP effects on the lowest excited singlet–triplet pair, taking propalene (Fig. 1), the simplest molecule among those treated in this paper, as an example. Since propalene is formed by the introduction of a cross link to cyclobutadiene, we follow the treatment of the SP effects on the ground-state multiplicity of the square cyclobutadiene (3).

In propalene, there are four π orbitals, ϕ_1, ϕ_2, ϕ_3, and ϕ_4 in increasing order of energy. The lowest excited singlet state and the corresponding triplet state are represented by the two-determinantal wavefunctions:

$$[1a] \quad \Phi_{S,T} = \frac{1}{\sqrt{2}}(\Phi_A, \mp \Phi_B)$$

$$[1b] \quad \Phi_A = |\phi_1\, \bar{\phi}_1\, \phi_2\, \bar{\phi}_3|, \qquad \Phi_B = |\phi_1\, \bar{\phi}_1\, \bar{\phi}_2\, \phi_3|$$

where for the sake of simplicity only π orbitals were denoted. The SP effects for the singlet–triplet pair can be taken into account by including in a CI-type treatment the doubly excited configurations describing the further excitation of one electron from the doubly occupied orbital (ϕ_1) into the virtual orbital (ϕ_4), which have nonvanishing matrix elements with Φ_S and Φ_T, because ϕ_1 and ϕ_4 belong to the same irreducible representation (*vide infra*). The relevant doubly excited configurations are

$$[2a] \quad \Phi_S^1 = \frac{1}{2\sqrt{3}}\{2|\bar{\phi}_1\, \bar{\phi}_4\, \phi_2\, \phi_3| + 2|\phi_1\, \phi_4\, \bar{\phi}_2\, \bar{\phi}_3| - |\bar{\phi}_1\, \phi_4\, \bar{\phi}_2\, \phi_3| - |\phi_1\, \bar{\phi}_4\, \phi_2\, \bar{\phi}_3| - |\bar{\phi}_1\, \phi_4\, \phi_2\, \bar{\phi}_3| - |\phi_1\, \bar{\phi}_4\, \bar{\phi}_2\, \phi_3|\}$$

$$[2b] \quad \Phi_T^1 = \frac{1}{2}\{|\bar{\phi}_1\, \phi_4\, \bar{\phi}_2\, \phi_3| - |\phi_1\, \bar{\phi}_4\, \phi_2\, \bar{\phi}_3| + |\phi_1\, \bar{\phi}_4\, \bar{\phi}_2\, \phi_3| - |\bar{\phi}_1\, \phi_4\, \phi_2\, \bar{\phi}_3|\}$$

$$[2c] \quad \Phi_T^2 = \frac{1}{\sqrt{2}}\{|\bar{\phi}_1\, \bar{\phi}_4\, \phi_2\, \phi_3| - |\phi_1\, \phi_4\, \bar{\phi}_2\, \bar{\phi}_3|\}$$

It can be shown (4, 5) that the matrix element of Φ_S and Φ_S^1 is $\sqrt{3}$ times larger than that of Φ_T with Φ_T^1. On the basis of the second-order perturbation theory, it is shown that this leads to a stabilization which is three times larger for the singlet state than for the triplet state, provided that the energy denominators are equal. The matrix element of Φ_T with Φ_T^2 is negligibly small as compared with the above matrix elements: in the square cyclobutadiene in which ϕ_2 and ϕ_3 are the degenerate NBMO's, this matrix element is vanishing from the symmetry reasons. In addition, there are two more doubly excited configurations arising from the same electronic configuration, Φ_S^2 and Φ_T^3, which can mix with Φ_S and Φ_T respectively:

$$[3a] \quad \Phi_S^2 = \frac{1}{2}\{|\phi_1\, \bar{\phi}_4\, \phi_2\, \bar{\phi}_3| + |\bar{\phi}_1\, \phi_4\, \bar{\phi}_2\, \phi_3| - |\phi_1\, \bar{\phi}_4\, \bar{\phi}_2\, \phi_3| - |\bar{\phi}_1\, \phi_4\, \phi_2\, \bar{\phi}_3|\}$$

$$[3b] \quad \Phi_T^3 = \frac{1}{2}\{|\phi_1\, \bar{\phi}_4\, \phi_2\, \bar{\phi}_3| - |\bar{\phi}_1\, \phi_4\, \bar{\phi}_2\, \phi_3| + |\phi_1\, \bar{\phi}_4\, \bar{\phi}_2\, \phi_3| - |\bar{\phi}_1\, \phi_4\, \phi_2\, \bar{\phi}_3|\}$$

It can be shown, however, that the matrix element of Φ_S with Φ_S^2 and that of Φ_T with Φ_T^3 have the same value and that the energy gaps between Φ_S and Φ_S^2 and between Φ_T and Φ_T^3 are the same in general as far as Φ_S and Φ_T are written as eqs. [1*a*] and [1*b*]. Consequently, it is concluded that the energy separation between Φ_S and Φ_T is not affected by the inclusion of Φ_S^2 and Φ_T^3 in a CI-type treatment.

It is thus expected that in molecules in which the energy separation between Φ_S and Φ_T at the Hartree–Fock level is very small for certain reasons the SP effects which bring about the extra stabilization of Φ_S result in the violation of Hund's multiplicity rule such that Φ_S lies below Φ_T.

In larger molecules, there are in general many other doubly excited configurations like eqs. [2*a*]–[2*c*] responsible for the SP effects.

II. Results and discussion

1. Propalene

The ground state of propalene has two equilibrium structures with respect to C—C bond lengths, one being the delocalized structure with the D_{2h} symmetry corresponding to the saddle point of the potential energy surface, and the other the bond-alternating structure with the C_{2h} symmetry corresponding to the energy-minimum point (11). Geometrical structures of the two forms optimized by using the MNDO method (12, 13) by assuming the molecule to be planar are shown in Fig. 1, where only the C—C bond lengths are presented.

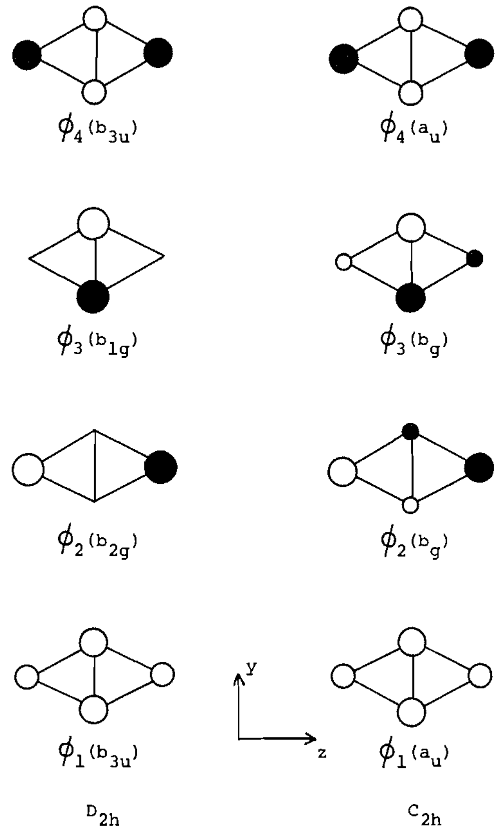

FIG. 2. The π molecular orbitals in the symmetrical (D_{2h}) and the distorted (C_{2h}) structure of propalene. White and black circles indicate the plus and minus signs of atomic-orbital coefficients, respectively.

In Fig. 2 are shown the schematic representations of π molecular orbitals for the two forms, together with orbital symmetries.

In the D_{2h} structure, the lowest excited singlet state (Φ_S) and the corresponding triplet state (Φ_T) arising from the electronic configuration $(b_{3u})^2(b_{2g})^1(b_{1g})^1$ belong to the B_{3g} irreducible representation. The singly occupied orbitals in the excited states, $\phi_2(b_{2g})$ and $\phi_3(b_{1g})$, are confined to the different carbon atoms from the symmetry reasons so that the exchange integral K_{23} responsible for the energy separation between Φ_S and Φ_T is expected to be very small: within the zero-differential overlap (ZDO) approximation the two states are degenerate (at the STO-3G level the energy separation is 0.124 eV). Thus, it is expected that $\Phi_S(B_{3g})$ lies well below $\Phi_T(B_{3g})$, provided that there exists a virtual orbital which can be used for constructing the doubly excited configuration relevant to the SP effects. Actually, $\phi_4(b_{3u})$ can be used as such a virtual orbital, and the resultant doubly excited configurations has the same symmetry (B_{3g}) as Φ_S and Φ_T.

On the other hand, in the C_{2h} structure, it is seen from the distributions of the atomic-orbital coefficients in ϕ_2 and ϕ_3 shown in Fig. 2 that the exchange integral K_{23} does not vanish even within the ZDO approximation. Actually, by using the PPP-type MO method, the energy difference between Φ_S and Φ_T is calculated to be 1.422 eV (3.934 eV at the STO-3G level). It is thus less possible that Hund's multiplicity rule can be violated in the C_{2h} structure.

In Table 1 are summarized the energy separations between Φ_S and Φ_T after the inclusion of electron correlation effects in both the structures calculated by using the second-order perturbation theory. The calculation methods used are (1) PPP+SP(RSPT), RSPT being the abbreviation of the Rayleigh–Schroedinger perturbation theory, (2) PPP+SDCI (RSPT) in which all the singly and doubly excited π configurations are included, and (3) STO-3G+CI(MR-BWPT) in which the singly and doubly excited configurations constructed from lower ten virtual orbitals (σ and π) and higher ten occupied ones and the main part of the triply and quadruply excited configurations are taken into account by using the multi-reference Brillouin–Wigner perturbation theory (MR-BWPT). For the PPP-type calculations, the geometrical structures optimized by using the PPP-type SCF MO method in conjunction with the variable bond-length technique (9–11, 15) are used, and for the *ab initio* MO calculations, those optimized by using the MNDO method (12, 13) are used.

TABLE 1. The calculated energy separations (in eV) of the lowest excited singlet–triplet pairs in nonalternant hydrocarbons[a]

Molecule	PPP	PPP+SP (RSPT)	PPP+SDCI (RSPT)	STO-3G+CI (MR-BWPT)
Propalene (D_{2h})	0	−0.366	−0.366	−0.248
Propalene (C_{2h})	1.422	1.155	0.223	1.974
Pentalene (D_{2h})	0.162	−0.400	−0.434	−0.534
Pentalene (C_{2h})	0.817	0.560	0.892	1.503
Heptalene (D_{2h})	0.140	−0.450	−0.471	
Heptalene (C_{2h})	0.661	0.394	0.905	

[a]The minus sign means that the singlet state is lower in energy than the triplet state.

As is expected, in the D_{2h} structure, the energy lowerings due to the inclusion of correlation effects turn out to be larger for $\Phi_S(B_{3g})$ than for $\Phi_T(B_{3g})$. On the other hand, in the C_{2h} structure, the PPP+SDCI and STO-3G+CI calculations indicate that the triplet state $\Phi_T(A_g)$ is lower in energy than the corresponding singlet state $\Phi_S(A_g)$, even though the lowering of $\Phi_S(A_g)$ (1.885 eV, PPP+SDCI; 9.03 eV, STO-3G+CI) is larger than that of $\Phi_T(A_g)$ (0.686 eV, PPP+SDCI; 7.04 eV, STO-3G+CI). This is due to the fact that $\Phi_T(A_g)$ is lower in energy than $\Phi_S(A_g)$ by a large amount before the inclusion of correlation effects.

It should be noted that the stabilization of $\Phi_S(B_{3g})$ in the D_{2h} structure (1.211 eV, PPP+SDCI) is due for the most part to the mixing with $\Phi_S^{\dagger}(B_{3g})$ (eq. [2*a*]) responsible for the SP effects, the stabilization energy due to this mixing being 0.974 eV, while that of $\Phi_S(A_g)$ in the C_{2h} structure (1.885 eV) is due substantially to the direct mixing with the doubly excited configurations (^1A_g), such as $(\phi_1)^2(\phi_3)^2$, which are not operative in lowering the energy of $\Phi_S(B_{3g})$ in the D_{2h} structure, the energy lowering of $\Phi_S(A_g)$ due to the mixing with $\Phi_S^{\dagger}(A_g)$ responsible for the SP effects being 0.518 eV.

It is added that the results obtained by using *ab initio* MO methods with extended basis sets are consistent at least qualitatively with the above results, though the energy separations, calculated by using 4-31G+CI(MR-BWPT) and 6-31G+CI (MR-BWPT), of the lowest excited singlet–triplet pair in the D_{2h} structure turn out to be considerably smaller (−0.038 eV and −0.055 eV, respectively).

The variations of the total energies of the various states of propalene with the nuclear distortion along the bond-alternating mode are shown in Fig. 3. The total energies taken to be the sum of the π-electron, σ-bond, and core-repulsion energies (10) were calculated at the PPP+SDCI(RSPT) level. It is seen that no molecular-symmetry reduction occurs in the excited

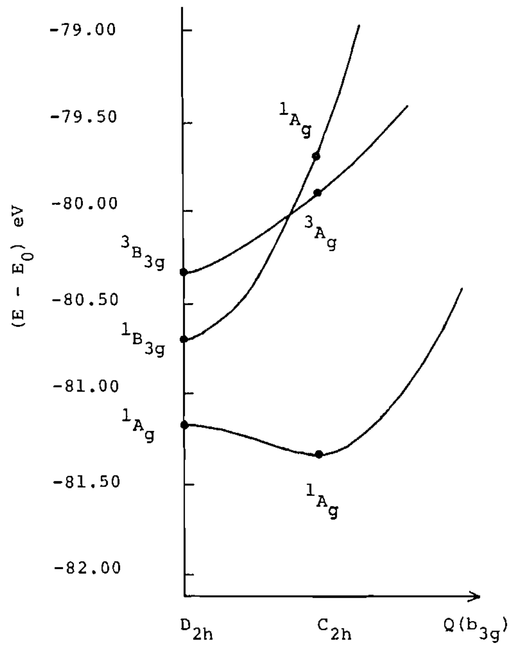

FIG. 3. The potential energy curves calculated by using the PPP+SDCI(RSPT) method of the ground state and the lowest $\pi \rightarrow \pi^*$ excited singlet and triplet states of propalene. E_0 is the sum of the σ-bond and core-repulsion energies at the D_{2h} structure (15).

states, Φ_S and Φ_T, and the potential energy curves for the two states intersect at a certain intermediate distorted nuclear arrangement.

2. Pentalene and heptalene

In these molecules, the HOMO and the LUMO originate from the doubly degenerate NBMO's of the corresponding $4n$ cyclic polyene, the HOMO's of propalene and heptalene and the LUMO of pentalene remaining still nonbonding. It is thus expected that in such molecules the exchange integral responsible for the energy separation between the excited singlet and triplet states originating from the electron jump HOMO $\rightarrow$ LUMO is rather small, and the SP effects lead to the violation of Hund's multiplicity rule.

Now it has well been known both theoretically (9–11, 14, 15) and experimentally (16–20) that the ground states of pentalene and heptalene undergo the molecular-symmetry reduction $D_{2h} \rightarrow C_{2h}$, as that of propalene does. The geometrical structures with respect to the C—C bond lengths of the symmetrical (D_{2h}) and distorted (C_{2h}) structures optimized by using the MNDO method are shown in Fig. 1.

The predicted energy lowerings of the lowest excited singlet–triplet pair due to the inclusion of correlation effects are listed in Table 1. In the D_{2h} structure of pentalene, the lowest excited triplet state $\Phi_T(B_{3g})$ is lower in energy than the corresponding singlet state $\Phi_S(B_{3g})$ by 0.162 eV (PPP) and 0.295 eV (STO-3G) before the inclusion of correlation effects, and the inclusion of correlation effects results in the violation of Hund's multiplicity rule such that $\Phi_S(B_{3g})$ is lower in energy than $\Phi_T(B_{3g})$ by 0.4–0.5 eV. In the D_{2h} structure of heptalene, the lowest triplet state $\Phi_T(B_{3g})$ is lower in energy than the corresponding singlet state $\Phi_S(B_{3g})$ only by 0.140 eV (PPP) before the inclusion of correlation effects. If we include these effects, it turns out that $\Phi_S(B_{3g})$ is lower than $\Phi_T(B_{3g})$ by ca. 0.5 eV.

By comparing the energy lowerings predicted by using the PPP+SP and PPP+SDCI methods, it is concluded that, as in the D_{2h} structure of propalene, the violation of Hund's multiplicity rule in the D_{2h} structures of pentalene and heptalene is due mainly to the SP effects. In the distorted structures (C_{2h}) of these molecules, Hund's multiplicity rule holds for the lowest excited singlet–triplet pair even after the inclusion of correlation effects.

It should be remarked that at the saddle points of the ground-state potential energy curves along the bond-alternating mode (the D_{2h} structures) of pentalene and heptalene, the energy lowering of the lowest excited singlet state ($^1B_{3g}$) is so large that this open-shell state lies most likely even below the closed-shell state (^1A_g) assumed to be the ground state before the inclusion of correlation effects. The *ab initio* MO calculations made by using the STO-3G+CI (MR-BWPT) method actually show that in pentalene the open-shell state ($^1B_{3g}$) is lower in energy than the closed-shell state (^1A_g) by 0.57 eV. Such a change of the nature of the ground state reduces considerably the energy difference between the energy-minimum state (C_{2h}) and the saddle point (D_{2h}) (21). In fact, all the energy differences so far calculated by assuming the ground state at the saddle point to be the closed-shell state (9–11, 14, 15) are too large to be comparable to the experimental activation energies for the isodynamic double-bond shift isomerization reaction in pentalene and heptalene (19, 20).

3. Alternant hydrocarbons

In alternant hydrocarbons, if the i-, j-, k-, and lth MO's are the next HOMO, the HOMO, the LUMO, and the next LUMO, respectively, the two singly excited configurations Φ_{ik} and Φ_{jl} are degenerate within the ZDO approximation owing to the pairing theorem.

$$[4a] \quad {}^{1,3}\Phi_{ik} = \frac{1}{\sqrt{2}}\{|\phi_i\,\bar{\phi}_k\,\phi_j\,\bar{\phi}_j| \mp |\bar{\phi}_i\,\phi_k\,\phi_j\,\bar{\phi}_j|\}$$

$$[4b] \quad {}^{1,3}\Phi_{jl} = \frac{1}{\sqrt{2}}\{|\phi_i\,\bar{\phi}_i\,\phi_j\,\bar{\phi}_l| \mp |\phi_i\,\bar{\phi}_i\,\bar{\phi}_j\,\phi_l|\}$$

The proper linear combinations of these degenerate configurations yield the two excited singlet and triplet states:

$$[5a] \quad {}^1\Phi^{\pm} = \frac{1}{\sqrt{2}}({}^1\Phi_{ik} \pm {}^1\Phi_{jl})$$

$$[5b] \quad {}^3\Phi^{\pm} = \frac{1}{\sqrt{2}}({}^3\Phi_{ik} \pm {}^3\Phi_{jl})$$

with the energies relative to the ground state given by

$$[6a] \quad {}^{1,3}E^{+} = \epsilon_k - \epsilon_i - J_{ik} + 2\,K_{ik} - K_{ij} \pm 2\,K_{ik}$$

$$[6b] \quad {}^{1,3}E^{-} = \epsilon_k - \epsilon_i - J_{ik} + K_{ij}$$

where ϵ_i is the orbital energy of the ith MO, and J_{ik} and K_{ik} are the Coulomb and exchange integrals between the ith and kth MO's, respectively.

In the lowest excited A_g states of linear polyenes and the lowest B_{2u} states of linear polyacenes treated in this paper, the relation that $2K_{ik} > K_{ij}$ holds (in larger linear polyacenes, the ith and lth MO's are not always the next HOMO and the next LUMO, respectively), and the energy ordering of the four excited states is such that ${}^3E^+ < {}^3E^- = {}^1E^- < {}^1E^+$ before the inclusion of correlation effects within the ZDO approximation. Since ${}^3\Phi^-$ and ${}^1\Phi^-$ are degenerate at this stage, it is expected that the inclusion of correlation effects lifts the degeneracy and leads to the energy ordering such that ${}^1\Phi^-$ lies below ${}^3\Phi^-$. Such

[a]In linear polyacenes, the yz-plane is taken to be the molecular plane, the y axis being parallel to the molecular long axis.
[b]The state energies are given by eqs. [6*a*] and [6*b*].
[c]The minus sign means that the singlet state is lower in energy than the triplet state.
[d]The notations in parentheses are due to Platt (24).

an energy ordering is considered as forming an exception to Hund's multiplicity rule, though $^3\Phi^-$ and $^1\Phi^-$ are represented by the mixture of the two monoexcited configurations and the rule holds for the singlet-triplet pairs of the component monoexcited configurations ($E(^3\Phi_{ik}) < E(^1\Phi_{ik})$ and $E(^3\Phi_{jl}) < E(^1\Phi_{jl})$).

As for the energy lowering of low-lying excited states due to the inclusion of correlation effects in alternant hydrocarbons, Čížek *et al.* (22) have proposed the qualitative rule which states that it will be most pronounced for the singlet "minus" states as compared with the singlet "plus" and both "plus"and "minus" triplet states. They have demonstrated the validity of this rule for a number of actual molecules, but they have treated only the energy orderings of singlet states. Here, we discuss the energy orderings of the singlet−triplet pairs of the "minus" and "plus" states in linear polyenes and polyacenes by using the same methods as used above for the nonalternant hydrocarbons, paying special attention to the role of the SP effects. However, the SP effects on the singlet−triplet pairs of the "minus" and "plus" excited states in these molecules are not so simple as those described in Section I, because an excited state in this case is written by the linear combination of the degenerate monoexcited states, one corresponding to the HOMO → the next LUMO and the other to the next HOMO → LUMO, and there are, in general, four types of doubly excited configurations responsible for the SP effects on the singlet−triplet pairs of the excited state. It cannot be shown without numerical calculations how the SP effects affect the energy orderings of the singlet−triplet pairs of the "minus" and "plus" excited states.

(a) Linear polyenes

In Table 2 are presented the predicted stabilization energies of the lowest excited $A_g^\pm$ states due to the inclusion of correlation effects. The data obtained by using the PPP+SDCI approximations indicate that in all the molecules examined the stabilization energies of the $^1A_g^-$ states are distinctly larger than those of the $^3A_g^-$ states, though the energy differences between the two states tend to be less pronounced as the molecular size increases. On the other hand, the stabilization energies of the "plus" states are larger for the triplet states than for the singlet states (except for butadiene), and Hund's multiplicity rule holds for these singlet−triplet pairs even after the inclusion of correlation effects.

It is interesting to note that in linear polyenes the large energy intervals between the $^1A_g^-$ and $^3A_g^-$ states are not attributable even qualitatively to the SP effects apart from butadiene: the stabilization energies due to the SP effects are larger for the $^3A_g^-$ state than for the $^1A_g^-$ state (except for butadiene). The most important configurations contributory to the large stabilizations of the $^1A_g^-$ states are the doubly excited singlet configurations of A_g symmetry ($mm \rightarrow nn$), particularly that corresponding to the electron jump from the HOMO to the LUMO, and this is true for butadiene also. On the other hand, it can be shown that the contribution of such doubly excited configurations to the stabilization of the $^1A_g^+$ state is very small: the matrix elements of $^1A_g^+$ with the doubly excited configurations, $jj \rightarrow kk$ and $ii \rightarrow ll$, are vanishing within the ZDO approximation. More precisely, the matrix elements of the component singly excited configurations of ^1A_g, Φ_{ik}, and Φ_{jl}, with the above doubly excited configurations have the same absolute value but are opposite in sign.

In order to examine the contributions of the higher-order configuration interactions, the stabilization energies of the lowest excited $A_g^\pm$ states of butadiene and octatetraene are calculated by using the STO-3G+CI(MR-BWPT) approximation (Table 3). The results obtained indicate again that the large stabilizations of the $^1A_g^-$ state are little due to the SP effects. The energy differences between the $^1A_g^-$ and $^3A_g^-$ states presented in Table 3 are appreciably large as compared with those listed in Table 2, but if we use a more extended basis set and make a larger-scale CI calculation, considerably smaller values could be obtained (23).

(b) Polyacenes

The stabilization energies due to the inclusion of correlation effects of the singlet−triplet pairs of the lowest $B_{2u}^\pm$ states in linear polyacenes (the lowest B_{2u}^- and E_{1u}^+ states in benzene) calculated within the semiempirical approach (PPP) are shown in Table 2. In this table the data for the lowest excited $A_1^\pm$ states of phenanthrene are also included.

By comparing the energy differences between the singlet and triplet "minus" states in linear polyacenes calculated by using the PPP+SDCI(RSPT) method with those calculated by using the PPP+SP(RSPT) one, it is revealed that the considerable part (about one half) of the energy difference is due to the SP effects.

It should be remarked that the stabilization energies of the singlet "minus" states obtained by using the PPP+SDCI approximations are so large that these states become very near in energy to the triplet "plus" states. This is in qualitative agreement with the fact that the singlet "minus" states are experimentally estimated to be slightly lower in energy (by 0.1 − 0.3 eV) than the triplet "plus" states (24). The predicted energy

[a]The minus sign means that the singlet state is lower in energy than the triplet state.
[b]The notations in parentheses are due to Platt (24).

difference between the singlet and triplet "minus" states in linear polyacenes tends to decrease with the molecular size. This is not in agreement with Platt's assumption that in polyacenes this energy separation can be taken to be constant (4000 cm^{-1}) except for that in benzene (5600 cm^{-1}) (24), apart from the fact that the predicted energy separations are considerably large as compared with Platt's values.

The stabilization energies calculated by using the PPP+SDCI methods for the singlet "plus" state (B_{2u}^+) (the E_{1u}^+ state in benzene and the A_1^+ state in phenanthrene) are almost the same as those for the corresponding triplet states in all the polyacenes examined. This indicates that the energy separations of the singlet−triplet pairs of the "plus" states calculated at the naive PPP level are little affected by the inclusion of correlation effects. The predicted energy separations are rather large as compared with the experimentally estimated values (1.74 eV, benzene; 1.24 eV, naphthalene; 1.05 eV, anthracene and naphthacene; 1.08 eV, pentacene; 1.20 eV, phenanthrene), the agreement between the theoretical and experimentally estimated values in linear polyacenes becoming better as the molecular size increases.

The stabilization energies of the excited states under consideration due to the inclusion of correlation effects in benzene and naphthalene are calculated also by using the STO-3G+CI(MR-BWPT) approximation. The obtained results are consistent with those obtained above, though the calculated values (Table 3) are considerably larger than those presented in Table 2 because of the use of the minimal basis set and the inclusion of the limited configuration interactions (25).

Conclusion

Propalene and its higher homologues, pentalene and heptalene, are the pertinent molecules for understanding how the SP effects affect the energy ordering of the electronically excited singlet−triplet pair. It is revealed that in these molecules Hund's multiplicity rule breaks down for the lowest excited singlet−triplet pair at the saddle point of the ground-state energy surface. Further, at the saddle points of pentalene and heptalene, the lowest excited singlet state (B_{3g}) is predicted to lie even below the closed-shell state (^1A_g), with the result that the open-shell state ($^1B_{3g}$) is really the ground state.

Hund's multiplicity rule breaks down also for the singlet−triplet pairs of the lowest excited "minus" states in linear polyenes and polyacenes. The energy separations of the singlet−triplet pairs in linear polyenes are due mostly to the mixing of the singlet state with the doubly excited configurations ($mm \rightarrow nn$), while the considerable part of the energy separations of the singlet−triplet pairs in polyacenes are due to the SP effects.

Hund's multiplicity rule breaks down most likely for an excited singlet−triplet pair whose energy separation at the Hartree−Fock level is rather small because of the smallness of the exchange integral responsible for the energy separation. An example of such an excited singlet−triplet pair is given by the singlet−triplet pair of an n $\rightarrow \pi^*$ transition besides those of $\pi \rightarrow \pi^*$ transitions treated in this paper. In this connection, it is interesting to note that the INDO+CI calculations of the electronic spectra of benzoic acid made by Ridley and Zerner (26) show that the lowest $^1(n,\pi^*)$ is lower in energy than the corresponding triplet state by 0.56 eV.

In view of the present results it is perhaps useful to note that the descriptions of the electronically excited states in the framework of the naive PPP approximation do not yield the correct energy ordering in general, particularly for the accidentally degenerate states. In order to obtain the correct energy ordering within this semiempirical approximation, one has to employ the empirical parameters for use in evaluating the energies of excited triplet states which are different from those used in evaluating the energies of excited singlet states (27).

Hoping that the poor quality of the basis sets and the limited CI used in the present *ab initio* MO calculations do not impair the main conclusions obtained in this paper, we are now considering more accurate calculations particularly for pentalene and heptalene.

Acknowledgements

All *ab initio* MO calculations have been performed by using the GAUSSIAN 70 and EFCI programs at the Computer Center of Tohoku University. The authors thank Professors K. Morokuma and S. Iwata for providing these programs, and Dr. M. Hanamura for assistance in carrying out the *ab initio* MO calculations. We thank also Professors M. Ito and D. M. Silver for helpful discussions. Le comportement cathodique et photocathodique d'électrodes de phtalocyanine sans métal, de cuivre et de fer (H_2Pc, CuPc et FePc) a été étudié en solutions acide, neutre et alcaline. Dans le noir, la courbe de polarisation de l'électrode de FePc présente deux pics de réduction qui n'ont pas été observés avec les autres phtalocyanines; ils sont associés à la réduction du cation central. L'illumination des électrodes semiconductrices n'a produit aucun effet sur la réaction du dégagement de l'hydrogène. L'analyse des courbes capacité–tension a révélé la présence de niveaux intermédiaires localisés à l'intérieur de la bande interdite des semiconducteurs et recouvrant environ 1% de leurs sites de surface. Les résultats sont expliqués en considérant les phtalocyanines comme des électrodes semiconductrices de type *p*. L'énergie des bandes et des états de surface a été illustrée dans un modèle d'interphase semiconducteur–électrolyte et la nature des transferts de charges inhibés par la présence de ces états interfaciaux a été discutée.

BENOÎT MARSAN, GUY BELANGER, and DOMINIQUE-LOUIS PIRON. Can. J. Chem. **63**, 1580 (1985).

The cathodic and photocathodic behavior of electrodes of phthalocyanines without metal or complexed to copper or iron (H_2Pc, CuPc, and FePc) has been studied in acidic, neutral, and alkaline media. In the dark, the polarization curve of the electrode of FePc shows two peaks of reduction which are not observed with the other phthalocyanines; these are associated with the reduction of the central cation. Lighting the semiconducting electrodes does not produce any effect on the reaction of production of hydrogen. An analysis of the curves of capacity vs. potential indicates the presence of intermediate levels localized within the forbidden band of the semiconductors and covering about 1% of their sites on the surface. The results can be explained if the phthalocyanines are considered to be semiconducting electrodes of type *p*. The energy of the bands and of the surface states can be depicted with a semiconductor–electrolyte interphase model and the nature of the charge transfers inhibited by the presence of these interfacial states is discussed.

[Journal translation]

1. Introduction

Les phtalocyanines ont récemment retenu beaucoup d'attention, en particulier sous forme de films minces. Leurs propriétés catalytiques, principalement vis-à-vis la réaction de réduction de l'oxygène (piles à combustible), ont été étudiées de façon approfondie (1–5). Les phtalocyanines sont des semiconducteurs organiques de type *p* (6) et leurs propriétés électriques ont été abondamment étudiées. La semiconductivité intrinsèque est associée aux électrons π mobiles des doubles liaisons conjuguées.

Le recouvrement important entre les orbitales π de la phtalocyanine et les orbitales *d* du métal suppose que ce dernier joue le rôle de pont lors d'un transfert électronique d'une molécule à une autre (7). Les impuretés ont également une influence sur la conductivité, en particulier l'oxygène qui diminue l'énergie d'activation de conduction des phtalocyanines (8). Ces dopants agissent comme pièges à électrons, entraînant la création d'un plus grand nombre de trous mobiles.

Étant donné que les phtalocyanines absorbent fortement dans la région visible du spectre solaire, avec une bande interdite de l'ordre de 1,8–2,1 eV (3), il a été suggéré de les utiliser dans des cellules photovoltaïques (9–16). Bien que le rendement de conversion de l'énergie solaire en énergie électrique soit très faible (<1%), à cause principalement du faible rendement quantique, certaines phtalocyanines (H_2Pc, CuPc, NiPc, MgPc) ont manifesté des activités intéressantes. Il a été observé que le rendement quantique peut être accru si les couches minces organiques sont exposées à l'air ambiant (11). Des études électrochimiques et photoélectrochimiques mettant en cause des électrodes de quelques phtalocyanines (H_2Pc, ZnPc, FePc, CuPc, NiPc) en couches minces ont également été rapportées (17, 18). De plus, des films de phtalocyanines ont été utilisés pour de la sensibilisation spectrale dans des cellules photoélectrochimiques (19–23).

Le présent travail se propose d'étudier le comportement électrochimique et photoélectrochimique des phtalocyanines sans métal, de cuivre et de fer évaporées en films minces dans des milieux acide, neutre et alcalin. Les résultats sont discutés en fonction des positions relatives des niveaux d'énergie des semiconducteurs, des couples $H^+(H_2O)/H_2$ et $O_2/H_2O(OH^-)$ en solution et des états de surface déterminés à partir des mesures de capacité différentielle.

2. Partie expérimentale

2.1 *Préparation des électrodes de phtalocyanine*

Une couche mince de H_2Pc, CuPc ou FePc provenant d'Eastman Kodak Co. et n'ayant été soumis à aucune autre purification ou autre traitement quelconque, d'une épaisseur approximative de 1000 Å, a été déposée par évaporation à 5×10^{-6} Torr (1 Torr = 133.3 Pa) sur un mince film d'or (~500 Å) préalablement formé sur une surface polie de cuivre dans une gaine de Kel-F (fig. 1). L'épaisseur des films a été évaluée par un contrôleur Varian modèle 980-6005. Les électrodes de phtalocyanine ont ensuite été chauffées dans une étuve à une température voisine de 100°C durant environ 2 h, puis exposées à l'air ambiant pendant 46 h avant leur immersion dans la solution, de manière à augmenter la conductivité des films semiconducteurs (17). Des évaporations successives d'or et de phtalocyanine (H_2Pc, CuPc ou FePc), formant des couches respectives d'une épaisseur voisine de 500 Å et 3000 Å, ont été effectuées sur une surface de graphite pour

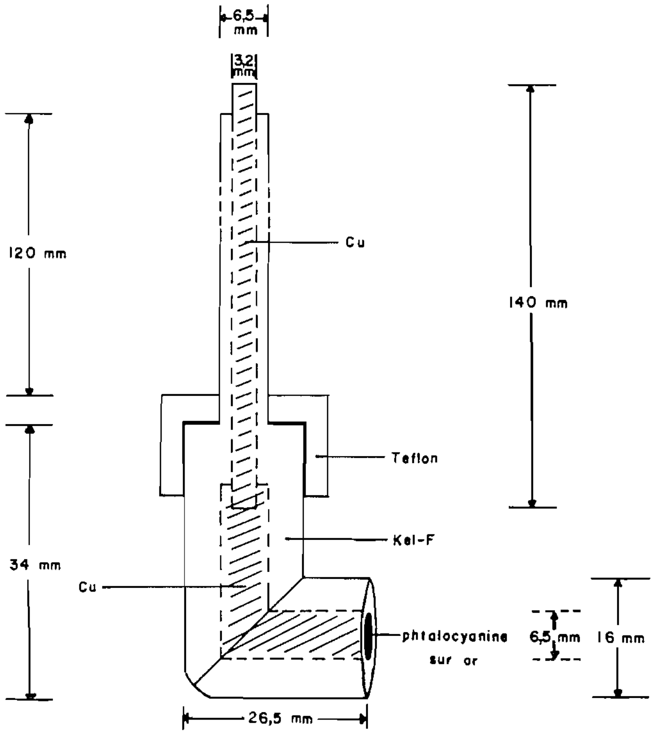

FIG. 1. Électrode de phtalocyanine utilisée pour les études photoélectrochimiques.

les mesures de capacité différentielle. Des traitements identiques à ceux subis par les électrodes employées pour les études potentiodynamiques ont par la suite été soumis aux électrodes avant leur immersion dans la solution.

Une cellule en Pyrex à trois compartiments séparés avec une électrode de travail (phtalocyanine), une électrode auxiliaire en platine et une électrode de référence réversible d'hydrogène, ERH, (électrode dans le même milieu que l'électrode de travail; milieux acide et neutre) ou Hg/HgO (milieu alcalin) a été utilisée pour les études photoélectrochimiques. La cellule est munie d'une fenêtre de quartz et une lampe au tungstène–halogène d'une puissance nominale de 650 W a été utilisée comme source lumineuse pour son spectre d'émission continu dans le proche ultraviolet et le visible.

2.2 *La préparation des essais*

Un barbotage d'hélium de 3 h a précédé l'immersion de l'électrode de phtalocyanine dans la solution appropriée, laquelle est demeurée sous atmosphère inerte pour toute la durée des essais. Les solutions préparées avec de l'eau triplement distillée possèdent les compositions suivantes: H_2SO_4 (Ultrex, J. T. Baker Chemical Co.) 0, 1 *N*; tampon KH_2PO_4 0,025 *M* – Na_2HPO_4 0,025 *M* (Fisher Scientific Co.); et KOH (Aristar, BDH Chemicals) 0,1 *N* dont le pH est de 1,4, 6,8 et 12,6 respectivement.

2.3 *Les techniques expérimentales utilisées*

Les courbes cyclovoltammétriques ont été obtenues par la méthode conventionnelle. Par ailleurs, la méthode utilisée pour les mesures de capacité différentielle est celle décrite par Morcos (24) et employant une perturbation à une fréquence de 200 Hz qui représente la fréquence optimale pour le système à l'étude.

3. Résultats expérimentaux et discussion

3.1 *Courbes capacité–tension*

Des films de H_2Pc, CuPc et FePc, polarisés anodiquement par intervalles d'environ 50 mV dans la région de potentiel correspondant à un courant résiduel négligeable, ont été soumis à des mesures d'impédance aux trois pH. Ainsi, les valeurs de capacité relevées représentent les capacités différentielles

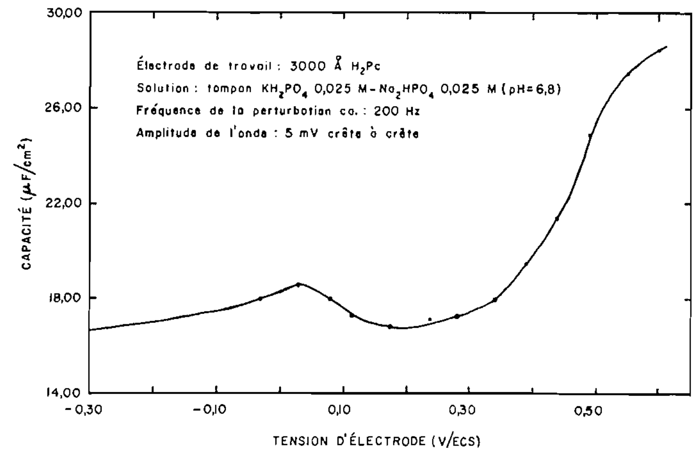

FIG. 2. Courbe capacité–tension pour la phtalocyanine sans métal (H_2Pc) en milieu neutre.

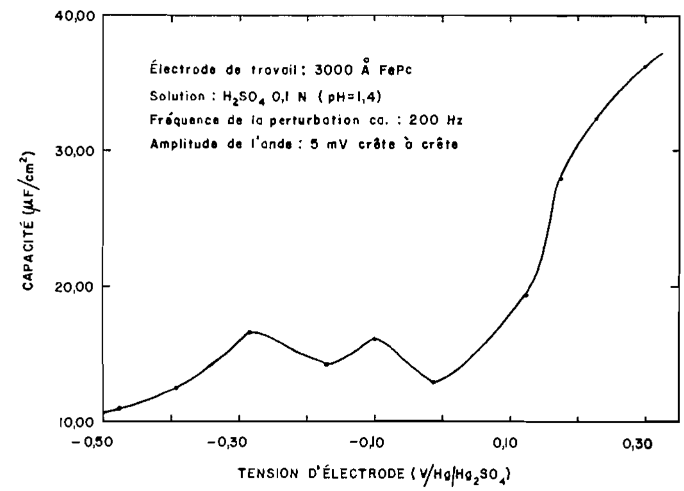

FIG. 3. Courbe capacité–tension pour la phtalocyanine de fer (FePc) en milieu acide.

de l'interface semiconducteur–électrolyte sans contribution faradique.

Comme l'illustre la fig. 2, la capacité différentielle de l'électrode de H_2Pc montre un maximum à 0,03 V/ECS. Cette caractéristique peut être expliquée en termes de niveaux intermédiaires situés à l'intérieur de la bande interdite du semiconducteur, lesquels augmentent la capacité différentielle en agissant comme réservoir de charges. Cela suggère donc une zone d'états de surface avec une densité maximale localisée à 0,27 V/ENH ou à une énergie de 4,77 eV sous le niveau du vide puisque l'énergie de Fermi standard du couple H^+/H_2 à l'équilibre (ENH) est approximativement de 4,5 eV sous le niveau du vide (25); cette valeur est comparable à celle obtenue par Fan et Faulkner (4,75 eV) (18). Une courbe similaire est obtenue avec l'électrode de CuPc et un second pic est observé dans le cas de la FePc (fig. 3).

L'analyse de ces courbes suggère une zone d'états de surface avec une densité maximale localisée à 0,40 V/ENH (−4,90 eV) pour la CuPc et deux zones d'états de surface dont la densité est maximale à 0,34 V/ENH (−4,84 eV) et à 0,52 V/ENH (−5,02 eV) pour la FePc; ces états de surface seront discutés plus loin. Il est à souligner qu'un changement de pH de la solution ne modifie pas l'allure des courbes capacité–tension.

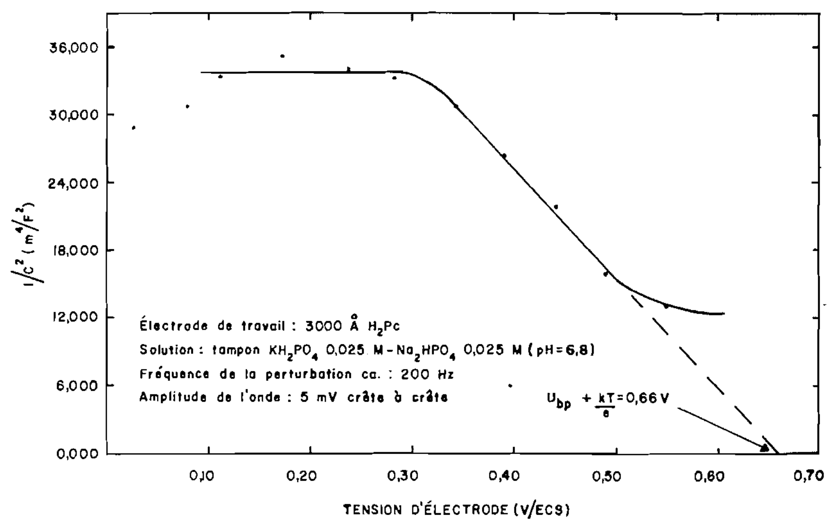

FIG. 4. Courbe Mott–Schottky pour la phtalocyanine sans métal (H_2Pc) en milieu neutre.

Une seconde évidence supportant l'idée de la présence d'états de surface est la valeur de la capacité différentielle qui est de l'ordre de 18 $\mu F/cm^2$ (H_2Pc), 20 $\mu F/cm^2$ (CuPc) et 13 $\mu F/cm^2$ (FePc) alors qu'elle est typiquement inférieure à 1 $\mu F/cm^2$ dans le cas d'une électrode semiconductrice (26). La densité maximale de ces états de surface (N_t) peut être estimée à partir de la hauteur de la capacité maximale des courbes capacité–tension (27):

$$[1] \quad C^0_{cs} \approx \left(\frac{e^2}{4kT}\right) N_t$$

où C^0_{cs} représente la capacité maximale à l'équilibre des états de surface; e, k et T correspondent respectivement à la charge de l'électron, la constante de Boltzmann et la température absolue. Les valeurs obtenues sont de l'ordre de $10^{13}/cm^2$, ce qui est équivalent à un recouvrement des sites de surface d'environ 1%.

3.2 *Courbes Mott–Schottky*

La connaissance du potentiel de bandes plates (U_{bp}) d'un semiconducteur nous indique si la photodécomposition de l'eau peut avoir lieu spontanément, c'est-à-dire sans l'application d'une tension à l'électrode semiconductrice en sus de l'illumination. Pour en déterminer la valeur, on applique en première approximation la relation de Mott–Schottky pour un semiconducteur non dégénéré, donnée par

$$[2] \quad \frac{1}{C_{sc}^2} = \frac{2}{e\epsilon\epsilon_0 N_A}\left(U_{appl} - U_{bp} - \frac{kT}{e}\right)$$

pour un semiconducteur du type p. Dans cette équation d'une droite, C_{sc} est la capacité de la région d'appauvrissement de charges à l'intérieur du semiconducteur, ϵ est la constante diélectrique du semiconducteur, ϵ_0 est la permitivité du vide, N_A est la concentration des accepteurs d'électrons et U_{appl} est la tension de l'électrode. La pente de la droite est proportionnelle à la concentration du dopant dans le semiconducteur et l'intersection avec l'axe des U_{appl} ($1/C_{sc}^2 = 0$) donne U_{bp} si le terme kT/e est négligé.

La courbe Mott–Schottky correspondant à une électrode de H_2Pc étudiée en milieu neutre est présentée dans la fig. 4, d'où l'on tire U_{bp} = 0,63 V/ECS (kT/e = 0,026 V à 24°C). Les valeurs obtenues pour les autres phtalocyanines sont données au tableau 1 qui indique également l'effet du pH sur ces valeurs. On remarque qu'une augmentation du pH de la solution tend à diminuer la valeur du potentiel de bandes plates, mais d'une façon très peu significative. Cette constatation suggère qu'aucune adsorption spécifique d'espèces ioniques ne se produit sur la surface des semiconducteurs qui permettrait de changer la chute de potentiel à travers la double couche d'Helmholtz lors d'une variation du pH de la solution, comme dans le cas de la plupart des semiconducteurs. Jaeger *et al.* (19) ont d'ailleurs observé que les niveaux d'énergie de H_2Pc demeuraient pratiquement inchangés lors d'une variation de pH.

TABLEAU 1. Variation de U_{bp} avec le pH et la phtalocyanine

pH (±0, 1)	U_{bp} (V/ENH) (±0,02 V)		
	H_2Pc	CuPc	FePc
1,4	0,92	0,87	0,84
6,8	0,88	0,83	0,80
12,6	0,85	0,81	*

*Instabilité de la FePc en milieu alcalin.

Le tableau met également en évidence l'effet de l'atome central de la molécule de phtalocyanine. On constate que la valeur du potentiel de bandes plates croît dans l'ordre FePc < CuPc < H_2Pc, bien que le changement soit à nouveau peu prononcé compte tenu de l'erreur expérimentale (±0,02 V). Dahlberg et Musser (12) ont mesuré les photovoltages à saturation dans des cellules photovoltaïques utilisant les mêmes électrodes de phtalocyanine et ils ont observé qu'ils croissaient suivant le même ordre. La valeur du photovoltage leur apparaît étroitement reliée à l'alignement de l'énergie des orbitales d du métal central avec la limite supérieure de la bande de valence de la phtalocyanine, déterminé à partir des spectres de photoémission de ces matériaux semiconducteurs. Ainsi, les orbitales $3d$ de symétrie e_g (d_{xz}, d_{yz}) de l'ion ferrique sont localisées au même niveau d'énergie que la plus haute orbitale occupée par des électrons π de la phtalocyanine et aucun photovoltage ne s'est manifesté avec la FePc. Par ailleurs, les orbitales $3d$ de l'ion cuivrique montrent une bonne séparation énergétique avec cette orbitale et un photovoltage légèrement

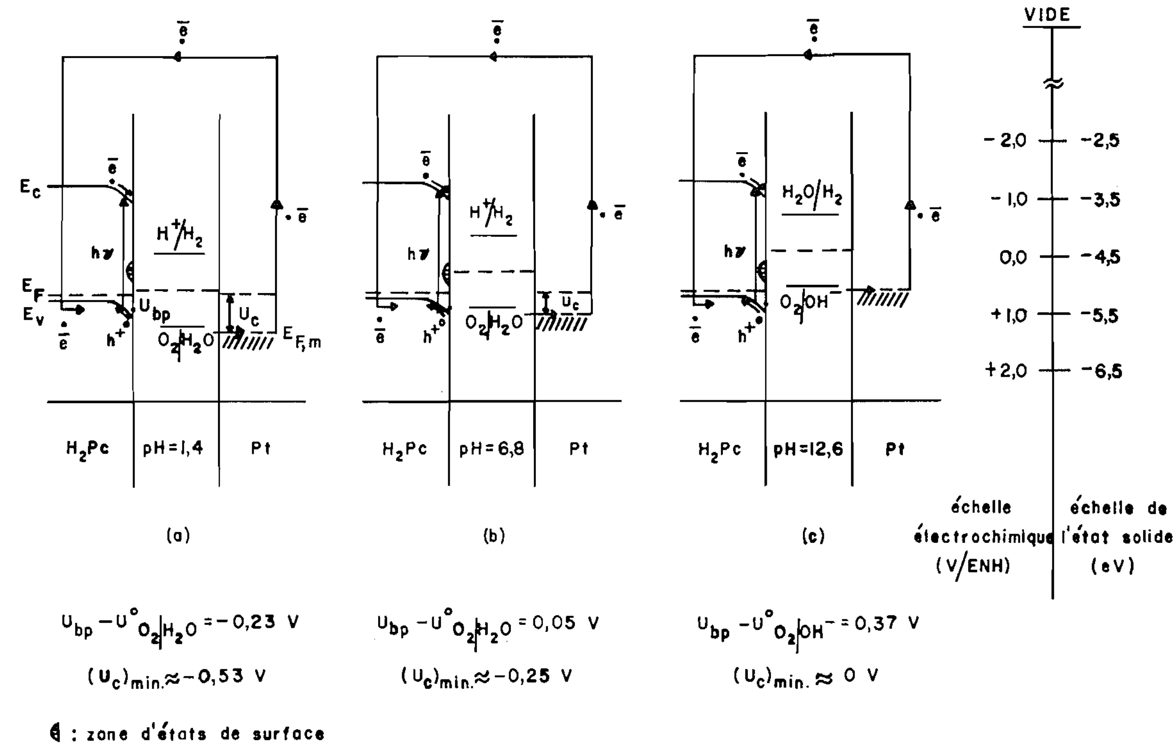

FIG. 5. Diagrammes de niveaux d'énergie pour la phtalocyanine sans métal (H_2Pc): (a) milieu acide; (b) milieu neutre; (c) milieu alcalin.

inférieur à celui présenté par la H_2Pc, ne possédant aucun électron *d*, a été observé avec la CuPc. Étant donné que la valeur du photovoltage à saturation correspond à la courbure des bandes du semiconducteur à l'équilibre (dans le noir), les raisons ci-haut mentionnées expliquent les différences obtenues dans les valeurs de potentiel de bandes plates.

La concentration des accepteurs d'électrons (N_A) déterminée à partir de la pente de l'équation Mott–Schottky est de l'ordre de $10^{21}/cm^3$ pour les trois phtalocyanines étudiées (ϵ mesurée = 3,8 ± 0,3); ceci représente une valeur très élevée, car les semiconducteurs hautement dopés possèdent des concentrations supérieures à $10^{18}/cm^3$. Ces résultats montrent le signe évident d'imperfections à la surface des phtalocyanines donnant lieu à des niveaux d'énergie discrets situés à l'intérieur de la bande interdite. Ces états de surface piègent les électrons provenant de la bande de valence en y créant un surplus de trous mobiles. Il est connu que les phtalocyanines sont activées lorsqu'elles absorbent l'oxygène, leur structure étant analogue à celle du groupe prosthétique de l'hémoglobine (28). De ce fait, l'oxygène doit être grandement responsable de la concentration élevée en porteurs majoritaires. Nos résultats sont en accord avec ceux obtenus précédemment par Crine[1] qui a utilisé la même méthode de mesure.

À la lumière des potentiels de bandes plates déduits des courbes Mott–Schottky, nous pouvons établir les diagrammes de niveaux d'énergie reliés aux cellules d'électrolyse photo-assistée de l'eau utilisant les électrodes de H_2Pc, CuPc et FePc, bien que l'on soit conscient des limitations de la mesure en raison de la présence des états de surface et de la seule fréquence utilisée (200 Hz). La figure 4 nous donne un potentiel de bandes plates de 0,63 V/ECS (−5,37 eV) pour H_2Pc étudiée en milieu neutre. Prenant une différence énergétique d'environ 0,1 eV entre la limite supérieure de la bande de valence et le niveau de Fermi (le semiconducteur est très dopé) et connaissant la valeur de la bande interdite des phtalocyanines (2,0 eV), on peut situer la limite inférieure de la bande de conduction à −3,47 eV (fig. 5(b)). Sur cette figure, la zone d'états de surface déduite de la courbe capacité–tension (fig. 2) possède une densité maximale localisée à −4,77 eV.

À pH 6,8, les couples H^+/H_2 et O_2/H_2O sont situés respectivement à 4,10 et 5,33 eV sous le niveau du vide. Étant donné que les concentrations d'hydrogène et d'oxygène dans la cellule sont nulles au début de l'électrolyse, le niveau de Fermi de l'électrolyte est fixé en plein centre des niveaux H^+/H_2 et O_2/H_2O, soit à −4,72 eV. Les potentiels de bandes plates déterminés en solutions acide et alcaline ont permis d'établir les diagrammes de niveaux d'énergie illustrés dans les figures 5(a) et 5(c). Des analyses similaires concernant les autres phtalocyanines (CuPc, FePc) ont mené aux diagrammes reproduits dans les figures 6 et 7.

3.3 *Courbes cyclovoltammétriques*

La voltamétrie cyclique a été utilisée pour caractériser le comportement électrochimique et photoélectrochimique des films de H_2Pc, CuPc et FePc vis-à-vis la réaction du dégagement de l'hydrogène. En l'absence de film phtalocyanine, l'électrode d'or montre une densité de courant beaucoup plus importante à partir de −0,40 V/ERH. Les courbes obtenues dans le noir révèlent un phénomène d'hystérésis entre les balayages d'aller et de retour, la densité de courant étant plus faible lors du balayage de retour (figures 8 et 9). L'irréversibilité du processus est attribuée à des espèces réductibles sur la surface du semiconducteur: au cours du balayage d'aller, la surface se nettoie par réduction irréversible des impuretés. Cet hystérésis diminue toutefois avec les cycles. La densité de courant correspondant à une tension d'électrode donnée diminue légèrement avec les cycles, ce qui peut être expliqué par la formation de bulles à la surface de l'électrode

lors du dégagement d'hydrogène, bloquant ainsi certains sites réactionnels. Notons que les électrodes de H_2Pc et CuPc présentent des courbes similaires.

La courbe de polarisation cathodique de l'électrode de FePc (fig. 9) présente deux pics de réduction, ce qui n'a pas été observé avec les autres phtalocyanines. Cela indique que ces pics ne sont pas associés à la réduction de la molécule organique de phtalocyanine, mais plutôt à celle du cation central. Compte tenu du traitement de l'électrode, le fer est probablement à l'état d'oxydation III donnant lieu au complexe à densité de spin élevé $Fe^{III}\ Pc^+\ O_2^-$. En effet, l'existence de Fe^{III} à l'état stable implique la présence d'un ligand supplémentaire

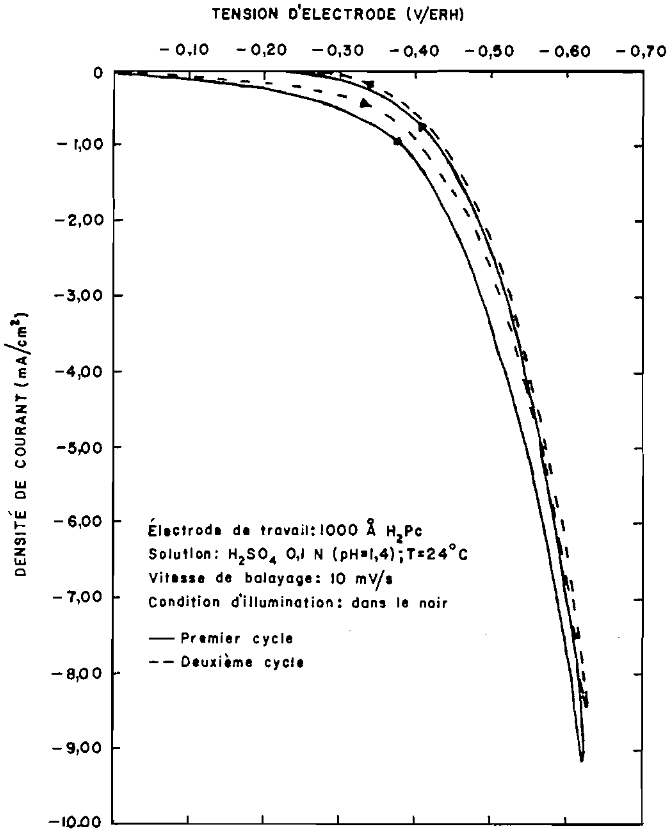

FIG. 8. Courbe de polarisation cyclovoltammétrique de la phtalocyanine sans métal (H_2Pc) en milieu acide.

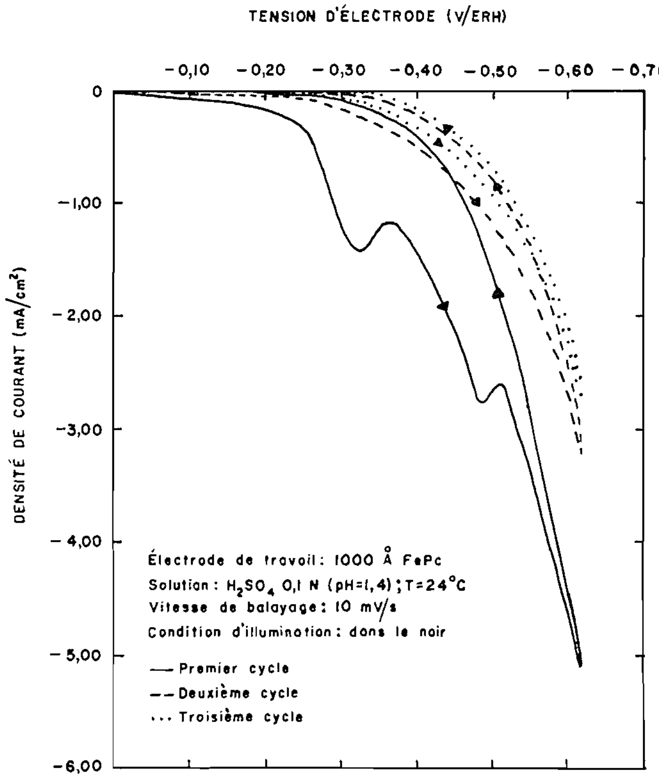

FIG. 9. Courbe de polarisation cyclovoltammétrique de la phtalocyanine de fer (FePc) en milieu acide.

accepteur (O_2) situé entre deux atomes de fer de deux molécules voisines pour des raisons de symétrie (29).

Les essais réalisés en solutions acide, neutre et alcaline ont permis d'étudier l'effet du pH de la solution: la densité de courant cathodique correspondant à une tension d'électrode donnée est réduite de façon appréciable en solution neutre (pH = 6,8), alors qu'elle varie peu lorsque le pH de la solution passe de 1,4 à 12,6. En solution neutre, la concentration ionique de l'électrolyte est plus faible et par conséquent la densité de courant cathodique mesurée est moins importante qu'en solutions acide et alcaline où les concentrations en ions H^+ et OH^- sont très élevées.

Lors de l'illumination des électrodes de phtalocyanine par une lampe au tungstène–halogène (150 mW/cm^2 *effectifs en surface de l'électrode*), aucun changement n'a été observé dans la variation de la densité de courant avec la tension imposée à l'électrode semiconductrice. Notre modèle d'interphase semiconducteur–électrolyte (figures 5–7) peut expliquer cette absence d'effet de la lumière sur le dégagement d'hydrogène.

Lorsqu'un photon est absorbé à l'électrode semiconductrice, une paire électron–trou est créée. Les paires photogénérées dans la région d'appauvrissement de charges sont immédiatement séparées par le champ électrique qui s'y trouve. Les électrons (porteurs minoritaires) sont dirigés vers la surface de l'électrode pour remplir des états interfaciaux qui agissent de médiateurs de transferts de charges à des accepteurs en solution (espèces oxydées) dont la densité des états d'énergie recouvre celle des états interfaciaux. Comme ces densités ne peuvent se recouvrir selon nos diagrammes de niveaux d'énergie (figures 5–7), les états de surface agissent plutôt comme centres de recombinaison, inhibant ainsi tout effet de lumière. Par ailleurs, la concentration très élevée en porteurs majoritaires confère aux phtalocyanines une région d'appauvrissement de charges relativement mince qui diminue de façon significative la quantité de photons absorbés.

En absence d'états de surface, le transfert d'électrons de la bande de conduction aux espèces oxydées H_3O^+ ou H_2O en solution serait facilité en milieu alcalin en raison du recouvrement plus important de la densité des états d'énergie de ces espèces (niveaux non occupés par des électrons) avec la bande de conduction; ce transfert devrait être plus appréciable dans le cas de l'électrode de H_2Pc en raison de la position moins élevée de ses bandes d'énergie. Par ailleurs, les diagrammes de niveaux d'énergie suggèrent un apport en énergie électrique moindre à pH alcalin pour initier la photodécomposition de l'eau, ce qui favorise un rendement de conversion de l'énergie optique en énergie chimique plus élevé. En effet, une tension cathodique (U_c) doit être appliquée à l'électrode de phtalocyanine en sus de l'illumination pour abaisser le niveau de Fermi de l'électrode auxiliaire métallique ($E_{F,m}$) au-dessous du niveau E_{O_2/H_2O} (E_{O_2/OH^-}) et ainsi assurer l'oxydation de l'eau. La tension minimale (théorique) requise pour mener cette réaction d'oxydation ($(U_c)_{min}$) diminue avec l'augmentation du pH de la solution, passant de 0,53 V (pH = 1,4) à 0,25 V (pH = 6,8) puis à 0 V (pH = 12,6) dans le cas de la cellule utilisant une électrode de H_2Pc (fig. 5). On peut remarquer qu'une courbure de bandes de l'ordre de 0,3 V, nécessaire à une séparation adéquate des paires électron–trou photogénérées par le champ électrique (30), a été respectée dans l'établissement des diagrammes de niveaux d'énergie.

En comparant les figures 5 à 7, on est en mesure de constater que l'apport en énergie électrique croîtrait dans l'ordre H_2Pc < CuPc < FePc, faisant état des différences dans les valeurs du potentiel de bandes plates. En effet, un potentiel plus négatif s'éloigne davantage de la tension U_{O_2/H_2O} (U_{O_2/OH^-}) exigeant par conséquent une tension supérieure pour amorcer l'oxydation de l'eau. Concernant l'électrode de FePc immergée en solution acide, la courbure de bandes résultant de la jonction semiconducteur–électrolyte est légèrement inférieure à 0,3 V, ce qui implique que l'illumination de cette électrode serait inefficace compte tenu du taux élevé de recombinaisons des paires électron–trou photogénérées.

4. Conclusion

L'illumination des électrodes de phtalocyanine n'a produit aucun effet sur la réaction du dégagement de l'hydrogène. Un modèle d'interphase semiconducteur–électrolyte établi à partir des mesures de capacité différentielle peut expliquer cette absence de photocourant. L'analyse des courbes capacité–tension a révélé la présence de niveaux intermédiaires localisés à l'intérieur de la bande interdite des semiconducteurs et recouvrant environ 1% de leurs sites de surface. Ces états interfaciaux qui piègent les électrons photogénérés dans la bande de conduction ne peuvent permettre leur transfert en solution en raison du non recouvrement de leur densité d'énergie avec la densité des états d'énergie des espèces oxydées H_3O^+ ou H_2O; ils agissent plutôt comme centres de recombinaison, empêchant la manifestation d'un photocourant. De plus, la concentration très élevée en porteurs majoritaires ($\sim 10^{21}/cm^3$) confère aux phtalocyanines une région d'appauvrissement de charges très mince qui diminue de façon significative la quantité de photons absorbés.

L'électrolyse photoassistée de l'eau deviendrait possible avec des électrodes de phtalocyanine qui absorbent fortement dans le visible par l'élimination des états de surface. Selon nos diagrammes de niveaux d'énergie, la réaction photocathodique du dégagement de l'hydrogène serait facilitée en milieu alcalin et avec une électrode semiconductrice de H_2Pc. Par ailleurs, l'apport en énergie électrique serait moins important dans ce même milieu et avec la même électrode de phtalocyanine pour initier la réaction anodique du dégagement de l'oxygène à l'électrode auxiliaire métallique, ce qui favoriserait également un rendement de conversion de l'énergie optique en énergie chimique supérieur; les rendements diminueraient dans l'ordre $H_2Pc > CuPc > FePc$. Une exposition moins prolongée des films de phtalocyanine à l'atmosphère atténuerait probablement la densité des états de surface, l'oxygène étant sans doute responsable de leur présence. Cependant, la grande résistivité des phtalocyanines (17) nécessite la présence d'une concentration suffisamment élevée d'oxygène jouant le rôle de dopant. En effet, il a été observé que le rendement quantique est accru lorsque les couches minces organiques sont exposées à l'air ambiant (11).

This paper is dedicated to Professor Camille Sandorfy on the occasion of his 65th birthday

M. M. ABO ALY, M. H. BARON, J. FAVROT, J. BELLOC, and M. REVAULT. Can. J. Chem. **63**, 1587 (1985).

Attempted vibrational assignments of (*E*,*E*)-2,4-hexadienal, (*E*,*E*,*E*)-2,4,6-octatrienal, and (*E*,*E*,*E*)-3-methyl-2,4,6-octatrienal are given between 3100 and 50 cm^{-1}. We particularly discuss spectroscopic effects of the aldehydic group presence, enlargement of the polyenal chain length, and methyl lateral substitution.

M. M. ABO ALY, M. H. BARON, J. FAVROT, J. BELLOC et M. REVAULT. Can. J. Chem. **63**, 1587 (1985).

L'attribution d'ensemble des spectres ir et Raman de trois polyénals: (*E*,*E*)-hexadièn-2,4-al-1, (*E*,*E*,*E*)-octatrièn-2,4,6-al-1 et (*E*,*E*,*E*)-methyl-3-octatrièn-2,4,6-al-1 est proposée. Elle permet de discuter les effets spectroscopiques liés à l'introduction d'un groupement aldéhydique, à l'allongement des chaînes conjuguées et à leur substitution par un groupement méthyle.

1. Introduction

This work is included in the general frame of studies on polyenes, polyenals, and phototransformation of retinal and its imine derivatives (1–6). Progress in technology permits new very interesting vibrational studies on molecules of biological interest; however, complete vibrational analysis is not often possible and this limits the full significance of the results. In recent papers on retinal and imine derivatives, we have pointed out that deconjugated products can be obtained by irradiation with various laser lines (1–3, 5). Raman spectra of these new products show that the deconjugation may occur, according to the experimental conditions, on the eighth or on the tenth carbon of the polyenic chain. They also indicate that each of these new compounds may be present as various stereoisomers. An accurate analysis of these spectra would allow a better knowledge of the structure of these photoproducts. However, there are no vibrational assignments of stereochemically well-defined model polyenals with two or three successive conjugated double bonds.

We have already shown, from a detailed analysis of the ir and Raman spectra of the three stereoisomers of 2,4-hexadiene, that there are general spectroscopic trends characteristic of the configuration of the double bonds (4). Concerning aldehydic compounds, there is only a nmr study on 2,4-hexadienal stereoisomers (7). In this paper we propose the vibrational analysis of all *trans* polyenals with two or three conjugated C═C bonds, (*E*,*E*)-2,4-hexadienal (HAL) and (*E*,*E*,*E*)-2,4,6-octatrienal (OAL), respectively. Modifications on vibrational spectra introduced by lateral methyl substitution have also been interpreted from the study of (*E*,*E*,*E*)-3-methyl-2,4,6-octatrienal (MOAL).

2. Materials and methods

2,4-Hexadienal is commercially available from Aldrich Corp. as a mixture of stereoisomers. (*E*,*E*)-2,4-hexadienal (HAL) was purified following the method of Albriktsen and Harris (8). The raw product is cooled at −60°C and transferred to a precooled filter funnel at −40°C. The noncrystalline products are drawn out. The crystalline products are melted at −20°C, recooled to −60°C, and filtered at −20°C. A product, still crystalline at −20°C, is recovered at −12°C. The nmr and ir spectra indicate a purity of 99% for the (*E*,*E*) stereoisomer in this sample (one aldehydic doublet δ = 9.53 ppm in CD_3CN solvent (8), mp −18°C, λ in ethanol = 271 nm) (9).

(*E*,*E*,*E*)-2,4,6-octatrienal (OAL) was prepared by the method proposed by Blout and Fields (9). In the last step, OAL was purified by several sublimations, instead of distillation, followed by crystallization in hexane. A hplc qualitative analysis indicates the purity of the (*E*,*E*,*E*) stereoisomer: only one elution peak at 320 nm, (mp 56°C, λ in ethanol = 315 nm) (9).

(*E*,*E*,*E*)-3-methyl-2,4,6-octatrienal (MOAL) was obtained from 3,5-heptadiene-2-one prepared by the method of Attenburrow *et al.* (10). The following steps are described by Weedon and Woods (11). Activated MnO_2 is used for the oxidation of 3-Me-2,4,6-octatrienol to obtain the corresponding aldehyde. Finally, the all-*trans* stereoisomer is separated from the others by the same low temperature crystallization method used for HAL. The nmr spectrum of the purified sample indicates a purity of 95% for the (*E*,*E*,*E*) compound (aldehydic doublet δ = 10.08 ppm in CD_3CN solvent, mp 19°C, λ in ethanol = 322 nm).

The ir spectra between 4000 and 200 cm^{-1} were recorded on Perkin–Elmer spectrophotometers (PE 180 and PE 983), with spectral slits of 1 cm^{-1} above 600 cm^{-1} and about 4 cm^{-1} below 600 cm^{-1}. Below 200 cm^{-1} an evacuable Brucker spectrophotometer IFS-113 was used with a resolution of 4 cm^{-1}. Liquid samples were inserted between two CsI windows or in polyethylene cells. Spectra of solid OAL were obtained by introducing the sample directly, or as Nujol mulls, between CsI or polyethylene plates.

The Raman spectrophotometer was a model RT Dilor equipped with a Kr^+ (λ_{exc} = 6471 Å) Spectra-Physics laser. Solids, neat liquids, and solutions were inserted in 2-mm diameter tubes. For polarization measurements the spectrophotometer response was calibrated over the 0 to 4000 cm^{-1} range by using a white light lamp.

3. Results and discussion

The three all-*trans* compounds belong to the C_s point group. The 39 normal modes of HAL are represented by 26 A′ and 13 A″, the 51 normal modes of OAL by 34 A′ and 17 A″, and the 60 normal modes of MOAL by 39 A′ and 21 A″. Vibrational assignments for HAL, OAL, and MOAL will be successively proposed. In a fourth part, the attribution of the aldehydic modes will be confirmed by analysis of the ir and Raman spectra of these compounds in solution in CCl_4 or CS_2. Wavenumbers and descriptions of Raman and ir bands relative to HAL, OAL, and MOAL are listed in Tables 1, 2 and 3 respectively and the corresponding spectra are reported in Fig. 1.

3-1. *(E,E)-2,4-hexadienal (HAL)* (Table 1, Fig. 1)

3-1-1. *Region 3100–2700 cm^{-1}*

Most assignments in this region are similar to those already given for (E,E)-2,4-hexadiene (4). However, a 2808-cm^{-1} band, which does not occur in (E,E)-2,4-hexadiene spectra, is assigned to the aldehydic CH stretching mode (ν CHa) (12–17). Another rather strong band at 2734 cm^{-1} corresponds to the overtone of the deformation mode of the same CH group (2 δ CHa), in Fermi resonance with the ν CHa (12–19).

3-1-2. *Region 1700–1000 cm^{-1}*

Classical assignments are given for the carbonyl stretching mode (ν CO) (20–22), the ethylenic modes (ν C=C), and methyl group CH deformations (δ_s', δ_a, and δ_s CH_3) (4, 23–25). For (E)-crotonaldehyde, δ_s CH_3 and δ CHa are assumed to be coupled (12). This may not be the case for HAL, where the CH_3 group is farther from the CHa group. We assign the weak ir and Raman line at 1394 cm^{-1} to δ CHa. Compared to (E,E)-2,4-hexadiene, the low frequency δ CHe at 1214 cm^{-1} may result from a coupling with an aldehydic motion, probably the δ CHa one The strong ir band and the Raman polarized line at 1166 cm^{-1} correspond to the central C—C stretching mode (ν C—C) (4). The stretching ν CCHO mode is observed at 1120 cm^{-1} as in acetaldehyde (15–17), slightly lower than for crotonaldehyde (12) and acrolein (26) and close to calculated and experimental frequencies obtained for retinal (27, 28).

Around 1000 cm^{-1}, the depolarized line at 1035 cm^{-1} is assigned to the A″ r CH_3 mode; both the r CH_3 and ν C—CH_3 are involved in the 1085 and 926-cm^{-1} A′ modes (polarized lines), as for other methylated products (12, 24, 25). We shall see, further, that this band also corresponds to a γ CHe mode, as in (E,E)-2,4-hexadiene (4). For crotonaldehyde, γ CHa has not been assigned (12). However, experimental results for this compound show that a band at 1011 cm^{-1} in the neat liquid moves to 1005 cm^{-1} in solution. With HAL, we observe the same experimental feature for a line at 1014 cm^{-1}, strong in the ir spectrum, weak and depolarized in the Raman one. We propose then to associate those bands with the γ CHa modes of the two enals.

3-1-3. *Region 1000–750 cm^{-1}*

Four bands in this range may be assigned to depolarized ethylenic out-of-plane CH motions (γ CHe). In the Raman spectrum, one has a medium intensity (863 cm^{-1}) and the three others are very weak (926 cm^{-1} (see above), 988, and 777 cm^{-1}). All of them have medium or strong intensity in the ir spectrum.

3-1-4. *Region 750–280 cm^{-1}*

Three kinds of carbon skeleton planar deformation modes are expected in this range: one δ CCO, one δ $CCCH_3$, and three δ CCC corresponding to central carbons. For crotonaldehyde, the deformation at higher frequency is the δ CCO mode (12). For (E,E)-2,4-hexadiene, among the four expected planar skeletal deformations, the two occurring at lower frequency correspond mainly to the δ $CCCH_3$ modes and the two at higher frequencies to the central δ CCC modes (4). For HAL, we clearly observe three polarized lines: one at 612 cm^{-1} is assigned to δ CCO, another at 298 cm^{-1} to δ $CCCH_3$, and the third one at 375 cm^{-1} to a central δ CCC. Two other ir bands (504 and 480 cm^{-1}), for which it was not possible to measure a depolarization ratio (not observed in Raman), are assigned to the two last δ CCC; those frequencies seem too high to correspond to out-of-plane torsion (t) modes (t C=C), the higher t C=C mode for (E,E)-2,4-hexadiene being proposed at 355 cm^{-1} (4).

3-1-5. *Region 300–50 cm^{-1}*

Although we have not been able to measure their depolarization ratio, all bands observed in this range should correspond to out-of-plane torsion modes for double and single bonds: two t C=C, one t C—C, one t CCH_3, and one t CCHO.

For (E)-2-butene (29) and (E)-crotonaldehyde (12), the t C=C, slightly coupled with a γ CHe, is observed at ca. 280 cm^{-1}. For (E)-1,3-pentadiene, it is given at 250 cm^{-1} (25). For (E,E)-2,4-hexadiene, one occurs at 355 cm^{-1}, the other at 235 cm^{-1} (4). For both dienes, the t C=C modes are configuration dependent, which suggests that t C=C motions are also coupled with out-of-plane motions. For HAL, the polarized 298 cm^{-1} line presents a shoulder which could correspond to the higher t C=C mode, the 242-cm^{-1} very weak ir and Raman band being an alternative assignment. The lower t C=C may account for the medium ir and very weak Raman peak at 200 cm^{-1}.

For propene (24, 30), pentadiene (25), (E)-2-butene (29, 31), and isoprene (32), t CCH_3 occurs also at ca. 200 cm^{-1}. Bands around 120 cm^{-1} are generally assigned to the t CCHO modes (12, 14, 26, 33) and the central t C—C modes are assumed to occur between 50 and 170 cm^{-1} (4, 25, 32–36). In our low frequency spectra, we clearly observe a medium ir line at 126 cm^{-1} and a shoulder at 145 cm^{-1}. As in (E,E)-2,4-hexadiene (4), t CCH_3 and t C—C may be coupled, and both contribute to these bands, however, the 126 cm^{-1} should also be assigned to t CCHO.

3-2. *(E,E,E)-2,4,6-octatrienal (OAL)* (Table 2, Fig. 1)

OAL is a solid at room temperature. Depolarization ratio measurements have been obtained from solution Raman spectra.

3-2-1. *Region 3100–2700 cm^{-1}*

Only four out of six expected ν CHe may be identified from the ir and Raman spectra. ν CHa and 2 δ CHa still in Fermi resonance are slightly higher than in HAL. An additional ir medium intensity band at 2716 cm^{-1} likely corresponds to a combination tone between ethylenic and aldehydic CH deformations; we shall see that a new δ CHe band occurs for OAL at 1334 cm^{-1}.

3-2-2. *Region 1700–1000 cm^{-1}*

The ν CO is assigned to the 1680-cm^{-1} Raman and 1670-cm^{-1} ir bands. The three ν C=C probably correspond to the 1638, 1604, and 1578 cm^{-1} bands (37, 38).

δ_s', δ_a, δ_s, r A′, r A″, δ CHa, ν CCHO, and γ CHa are observed at about the same frequencies for OAL and HAL. As expected, compared to HAL, there are two supplementary bands (1334 and 1256 cm^{-1}) in the δ CHe range. On the other hand, only one ν C—C is clearly observed at 1162 cm^{-1}, although two are expected as in hexatriene (37, 38). The second one may be assigned to a weak shoulder observed at ca. 1140 cm^{-1}. However, a slight amount of *cis* isomer would also give a band around this frequency (4).

3-2-3. *Region 1000–750 cm^{-1}*

For OAL, the ν CCH_3 is again assigned to a 929 cm^{-1} polarized line, but the close depolarized mode γ CHe at 938 cm^{-1} is well resolved in this case. The five other expected γ CHe observed in ir are very weak in Raman, except for the 892-cm^{-1} (dp) one, in analogy with the 863-cm^{-1} (dp) γ CHe of HAL.

3-2-4. *Region 750–280 cm^{-1}*

Seven bands are observed in this range. Four are polarized. That at the highest frequency is assigned to δ CCO, the lowest one to δ $CCCH_3$, and the two in the middle to two out of the five expected δ CCC. The three other bands are weak and their depolarization ratios have not been obtained. Those at 410 and 475 cm^{-1} are also assigned to the δ CCC modes. The 343-cm^{-1} band may correspond to a t C=C mode.

3-2-5. *Region 280–50 cm^{-1}*

As for the assignment of the HAL low frequency spectra, we think that the two higher frequency bands (240 and 190 cm^{-1}) correspond to two t C=C modes, the 160-cm^{-1} shoulder to the t CCH_3 mode, and the 138-cm^{-1} band to the t CCHO mode. A supplementary absorption observed at 92 cm^{-1} is assigned to one of the two t C—C modes of OAL.

3-3. (E,E,E)*-3-methyl-2,4,6-octatrienal (MOAL)* (Table 3, Fig. 1)

3-3-1. *Region 3100–2700 cm^{-1}*

Four out of the five expected ν CHe are identified at about the same frequencies as for OAL. The wavenumbers of peaks corresponding to ν_s', ν_a, and ν_s CH_3 do not change, nor those assigned to δ CH_3 harmonic and combination tones, despite the presence of the lateral (lat) methyl group. On the other hand, the ir spectrum is significantly different in the 2850 to 2700 cm^{-1} range. Making the same assignments for OAL and MOAL, replacement of the 2816, 2750, and 2716-cm^{-1} bands of OAL by 2835, 2770, and 2725 cm^{-1}, respectively, for

See Table 1 for abbreviations.

MOAL may be due to increased frequencies of the ν CHa and δ CHa modes when the polyenal is 3-methyl substituted. We shall see that it is in agreement with the assignment of the 1402-cm^{-1} band to the δ CHa mode of MOAL. Furthermore, intensity enhancement of the 2 δ_a CH_3 harmonic (2850 cm^{-1}) may be due to its peculiar proximity to the ν CHa mode in MOAL.

3-3-2. *Region 1700–1020 cm^{-1}*

The ν CO mode and two of the three ν C═C modes occur, respectively, at lower frequency than for OAL. δ'_s and δ_a of the two methyl groups of MOAL are not resolved. Both the δ_s CH_3 differ by only 4 cm^{-1}. The δ CHa is assigned to the 1402 cm^{-1}; although the intensity of this peak decreases as the purity of the (*E*,*E*,*E*) stereoisomer increases, it stays relatively intense (me-

dium in Raman) in the quasi pure product.

More important changes are expected below 1350 cm^{-1}. There must be: (*i*) one less δ CHe. As a matter of fact, a band at ca. 1310 cm^{-1} in the OAL spectra does not exist in the MOAL spectra; (*ii*) one more ν CCH_3. In isoprene (32) and 2-methylacrolein (12), where there is a lateral methyl group, ν C—C and ν C—CH_3 are coupled. According to retinal normal coordinates analysis (27, 28), δ C_{14}H also is coupled to ν C_{13}—CH_3 and ν C_{12}—C_{13}. In the MOAL spectra, new polarized bands appear at 1335 and 855 cm^{-1} and the intensity of the 1210 cm^{-1} is strongly enhanced relative to the 1205-cm^{-1} OAL band. These features resemble those for retinal (27, 28) and clearly point out the triple coupling among δ C_2H, ν C_3—C_4, and ν C_3CH_3 for this substituted octatrienal.

As for retinal (28), the r CH_3 modes of the lateral methyl group are assigned to the polarized line at 1020 cm^{-1} (A′) (medium in the Raman spectrum, very weak in the ir) and to the 1045-cm^{-1} peak (A″) (weak in ir). It should be noted that a band near 1020 cm^{-1} in the HAL and OAL spectra had to be assigned to the γ CHa mode, as it was depolarized. The γ CHa of MOAL may occur at lower frequency (27, 28).

Compared to OAL, other modes are not modified.

3-3-3. *Region 1000–700 cm^{-1}*

The ν CCH_3 mode of the lateral methyl group has already been assigned to the 855-cm^{-1} Raman polarized line, and the 930-cm^{-1} line corresponds, as for OAL, to ν CCH_3 of the terminal (ter) methyl group.

Compared to OAL, there is one less γ CHe mode. The γ CHa mode being assigned as for retinal (27, 28) to a shoulder at 996 cm^{-1}, the five observed depolarized bands have to be associated with the γ CHe modes.

3-3-4. *Region 750–280 cm^{-1}*

The polarized line at highest frequency (650 cm^{-1}) is assigned to δ CCO and the lowest one to both the δ $CCCH_3$ terminal and lateral modes. The four other polarized bands between these two correspond to four out of the five δ CCC expected. Among the two other weak bands for which depolarization ratios have not been obtained, the 570 cm^{-1} band has to be assigned to the fifth δ CCC. The other band at 465 cm^{-1} may be due to a t C═C mode, if we consider that the 3-methyl substituent of MOAL is in the *cis* position on the C_2═C_3 double bond relative to the C_1—C_2 bond (4).

3-3-5. *Region 280–50 cm^{-1}*

There are clearly not enough bands to assign all the expected out-of-plane torsional modes in this range. However, it seems relevant to assign one t C═C mode at ca. 200 cm^{-1}, one t C—C mode at 87 cm^{-1}, and the t CCHO mode at 131 cm^{-1}.

3-4. *Autoassociation effects on vibrational frequencies*

The differences in frequencies between spectra of solid and solution samples for OAL are more important than the observed differences between neat liquid and solution for HAL and MOAL. However, for the three products, the major shifts are obtained for bands associated with the vibrations of the aldehydic group: ν CO, δ CHa, ν CCHO, γ CHa, δ CCO. This confirms the assignment of these modes and proves that the aldehydic functions are more or less associated in the neat liquid and solid states. The γ CHe around 880–860 cm^{-1}, which is also dependent on the physical state of the sample, may be assigned to the C_2—H group in the three products.

Only for OAL one can observe a doublet at 1604 and 1617 cm^{-1} for the solid and neat liquid samples. The 1604-cm^{-1} band is the more intense in the solid state while the 1617-cm^{-1} band becomes the stronger in the neat liquid state spectra. To explain this effect, we propose a Fermi resonance between a ν C═C mode at ca. 1610 cm^{-1} and a combination tone whose frequency should depend on the physical state of OAL. The ν CCHO mode (1110 cm^{-1} in solution, 1120 cm^{-1} in the solid state) and the δ CCC mode (497 cm^{-1}) might give such a combination tone.

Vertical electronic spectra of the isovalent molecules H_2CNH, H_2SiNH, H_2CPH, and H_2SiPH on the basis of MRD-CI calculations

PABLO J. BRUNA, VOLKER KRUMBACH, and SIGRID D. PEYERIMHOFF

Lehrstuhl für Theoretische Chemie, Universität Bonn, Wegelerstraße 12, D-5300 Bonn 1, West Germany

Received August 16, 1984

This paper is dedicated to Professor Camille Sandorfy on the occasion of his 65th birthday

PABLO J. BRUNA, VOLKER KRUMBACH, and SIGRID D. PEYERIMHOFF. Can. J. Chem. **63**, 1594 (1985).

Large-scale multi-reference single and double-excitation configuration interaction (MRD-CI) calculations are employed for the study of the isovalent compounds H_2CNH, H_2SiNH, H_2CPH, and H_2SiPH in their ground state equilibrium geometry. The dipole moments and charge distributions are given. The vertical excitation energies to the intra-valence states $^{3,1}(n,\pi^*)$ and $^{3,1}(\pi,\pi^*)$ and to the first members of the Rydberg series originating from n and π MO's respectively are predicted; the first two ionization potentials and the Rydberg term values are also calculated. In H_2CNH, mixing of Rydberg and valence-shell states with CN stretching is analyzed. The trends in relative stability of electronic and ionized states can be directly related to increased orbital stability of n relative to π as soon as a first-row constituent is replaced by a second-row atom. The calculations explain the diffuse character of the uv spectrum of imines; they treat the molecules H_2SiNH and H_2SiPH for the first time and present a large number of data for all four molecules which can serve as a basis for future experimental investigations on these and related compounds.

PABLO J. BRUNA, VOLKER KRUMBACH et SIGRID D. PEYERIMHOFF. Can. J. Chem. **63**, 1594 (1985).

On a utilisé des calculs d'interaction de configuration sur une grande échelle, à référence multiple et à excitation simple ou double pour étudier les composés isovalents H_2CNH, H_2SiNH, H_2CPH et H_2SiPH dans la géométrie d'équilibre de leur état fondamental. On rapporte les moments dipôlaires et les distributions de charges. On prédit les valeurs des énergies d'excitations verticales vers les états intra-valences $^{3,1}(n,\pi^*)$ et $^{3,1}(\pi,\pi^*)$ et vers les premiers termes des séries de Rydberg qui commencent respectivement aux OM n et π; on a aussi calculé les deux premiers potentiels d'ionisation et les valeurs des termes de Rydberg. Dans le cas du H_2CNH, on a analysé le mélange d'états de Rydberg et de couches valentielles avec l'élongation CN. Dès que l'on remplace un constituant de la première rangée par un atome de la deuxième rangée, on peut établir une relation directe entre les tendances dans les stabilités relatives des états électroniques et ionisés et l'augmentation de la stabilité des orbitales n par rapport aux orbitales π. Les calculs expliquent le caractère diffus des spectres uv des imines; on rapporte les résultats de la première étude traitant des entités H_2SiNH et H_2SiPH et, relativement aux quatre molécules, on présente un grand nombre de données qui peuvent servir de base pour de futures études expérimentales sur ces composés et sur d'autres qui leurs sont apparentés.

[Traduit par le journal]

I. Introduction

In recent years considerable interest has arisen for molecules which possess atoms from both the first and the second row of the periodic table. Numerous experimental (1, 2) and theoretical (3–5) studies have been undertaken in order to understand the electronic structure and properties, in particular for systems in which the first-row atoms C, N, and O are replaced by Si, P, and S respectively and which contain CP, SiN, and SiP bonds instead of the CN functional group.

For the simple diatomics C_2, CSi, and Si_2, for example, it has been found (6, 7) that the ground state electronic configuration is entirely different for the three isovalent systems: it is $X^1\Sigma_g^+$ for C_2, $X^3\Pi$ for CSi with constituents from the first and second row, and $X^3\Sigma_g^-$ for the second-row member Si_2. As a result, the reaction properties and the electronic spectra are quite different in these three compounds. In a similar manner, calculations for CN, CP, SiN, and SiP (4, 6, 8, 9) and the corresponding positive ions predict different electronic configurations for the lowest states ($X^2\Sigma^+$ for CN, for example, and $X^2\Pi_i$ for the isovalent SiP), and this pattern is also known for the simple hydrides CH_2 and SiH_2, whereby CH_2 possesses a X^3B_1 ground state while it is X^1A_1 in SiH_2 (5). These examples clearly point out that drastic changes in the electronic structure can take place in a family of given compounds upon substitution of one or two first-row atoms by their second-row analogues. Many of these systems containing one or two atoms from the second row are not yet known experimentally and hence *ab initio* calculations are presently the most powerful tool for the study of such compounds and for providing guidelines for further experimental work in this area.

In the present work we have selected the five-atom molecules H_2CNH, H_2SiNH, H_2CPH, and H_2SiPH for a theoretical investigation. Even though the two carbon-containing compounds have already been isolated experimentally, very little information is available on their electronic spectra. The two silicon-containing compounds are entirely unknown and are studied here for the first time.

The vertical spectrum of H_2CNH was studied theoretically by Macaulay, Burnelle, and Sandorfy (10) some time ago but these authors have already assumed that their results were of limited quality due to the restriction in the theoretical treatment. In further work Sandorfy has called attention to a better theoretical study of this molecule (11), in particular with respect to the relative position of the Rydberg states, which can be helpful for the classification and (or) understanding of the rather diffuse and quite complicated spectra of higher alkyl R^1R^2—C=N—R^3 imines.

The goal of the present study is to obtain a reliable description of the vertical position of the most important valence states (n,π^*) and (π,π^*) and the first (n,s_R) and (π,s_R) Rydberg members in the isovalent family H_2CNH, H_2CPH, H_2SiNH, and H_2SiPH. The additional determination of the lowest ionization potentials in these compounds allows the prediction of the corresponding term values, key information which can then easily be transfered to analyze the spectra of larger compounds containing similar >A=B-chromophore groups.

II. Technical details of the calculations

Two different AO basis sets have been employed for each compound, namely one of pure valence character (Basis A) and a second (Basis B), derived from the first Basis A by adding diffuse Rydberg-type functions. In general, both bases are of double-zeta quality augmented by *d*-polarization functions for all heavy atoms and by *p*-functions for the hydrogen atoms. The carbon and nitrogen atoms are described by the Huzinaga primitive set (12) in the $[4s2p]$ contraction according to Dunning and Hay (13). For silicon and phosphorus in the compounds H_2SiPH and H_2CPH, the primitive gaussians determined by Veillard (14) are chosen in contraction eight of that work. The Si basis in silylimine H_2SiNH stems from Huzinaga (15), again in the contraction scheme given by Dunning (13). The exponents for the *d*-polarization functions are: 0.70 (C), 0.95 (N), 0.30 (Si), and 0.43 (P), respectively, as recommended by Roos and Siegbahn (16). The hydrogen functions are those given by Huzinaga (12); the exponent for the *p*-polarization function is 0.75. This Basis A (pure valence character) contains in summary the following number of contracted functions: 47 (H_2CNH), 55 (H_2CPH and H_2SiNH), and 63 (H_2SiPH), respectively.

The vertical spectra were analyzed in a more expanded AO basis which includes Rydberg-type functions always placed in the center of the respective AB bonds of H_2ABH. This Basis B contains ten functions more than Basis A. The functions added are of *s*-, *p*-, and *d*-character. In the ordering H_2CNH, H_2CPH, H_2SiNH, and H_2SiPH, the exponents used are, respectively: α_s (0.025; 0.022; 0.021; 0.018), α_p (0.023; 0.019; 0.018; 0.015), and α_d = 0.015 (for all systems).

The MRD-CI method employed in all calculations is well documented in the literature (17–19). In contrast to the simple SD-CI method in which single and double excitations are generated only with respect to a single determinant, the multireference treatment employed in the present work accounts also for the most important higher-than-double excitations. Since the MRD-CI space consisting of all single and double excitations relative to a set of reference configurations is generally quite large, only a selected subset of configurations (all those which contribute more than a given threshold *T* to the CI energy) is treated directly in the secular equation, while the contribution of all others is accounted for in a perturbation-like treatment (18). Finally, the contribution of higher-than-double excitations is estimated in analogy to the Langhoff–Davidson formula (20) as

$$E_{\text{full CI}} = E_{\text{MRD-CI}} + \left(1 - \sum_{\text{ref}} c_0^2\right)(E_{\text{MRD-CI}} - E_{\text{ref}})$$

whereby the sum is taken over all reference configurations.

In all calculations a frozen core (always doubly occupied MO's) is employed in the CI procedure. It contains the inner-shell MO's of each molecule, namely two in H_2CNH, six in both H_2CPH and H_2SiNH, and ten orbitals in the heavier H_2SiPH molecule. In addition, the two highest MO's of a' symmetry are discarded in the calculations for the three lighter molecules, while in H_2SiPH the ten highest MO's (complementary to the frozen core) are omitted from the CI. Thus the MRD-CI calculations are carried out by correlating 12 valence electrons, while 53 MO's are available for partial occupation in the CI (Basis B) in H_2CNH and H_2SiPH and 57 in H_2CPH and H_2SiNH respectively. Further technical details of the MRD-CI calculations such as size of the reference set, selection threshold *T*, size of MRD-CI space, and contribution of the reference set to the total wavefunction are always listed with the respective results.

Various SCF MO's have been chosen for the study of the electronically excited states. In general, the parent SCF MO's are most appropriate in the sense that they require only a small number of reference configurations. Other MO's generally call for a larger reference set but then lead to essentially the same energy, as it should be when the CI is carried to the limit of a full CI. In some cases it seemed advantageous to employ the same set of MO's for various states, and this information is then always given together with the results. The $^1A'$ ground state MO's are also employed for the calculation of the ionic states. For H_2SiPH, not only the ground and $^3(n,\pi^*)$ MO's have been used but also natural orbitals obtained by direct diagonalization of the first-order density matrix of the preceding MRD-CI step.

III. Ground state properties

A. Molecular geometries

The ground state $^1A'$ geometry was optimized at the SCF level (with Basis A) using the gradient technique of the Gaussian 80 package. The resulting equilibrium structural parameters are contained in Table 1, together with experimental (21, 22) and other theoretical results (10, 23) for H_2CNH and H_2CPH. The equilibrium geometry of the isovalent H_2GeNH molecule as reported in recent theoretical work (24) is also given for purposes of comparison.

The optimization was also carried out for the two experimentally known species H_2CNH and H_2CPH in order to estimate the degree of reliability of the SCF gradient results. According to the data of Table 1 the discrepancies between SCF equilibrium geometries and their experimental counterpart are quite acceptable; they are on the order of 0.01 au for all hydrogenic bond lengths and deviations in the angles are less than 2° when compared with the experimental values. The largest disagreement is noted for the bond distances between the heavy atoms AB. This situation was easily expected on the basis of the double bond character and the failure of the SCF method to give a correct description of this portion of the molecule. The SCF method predicts R_e (AB) values which are invariably shorter than the actual bond lengths (the experimental CN and CP distances in H_2CNH and H_2CPH, respectively, are ca. 0.035 au greater than the values predicted at the SCF level). The inclusion of correlation effects automatically introduces antibonding character into the wavefunctions, primarily due to contributions of the $\pi^2 \rightarrow \pi^{*2}$ and $\pi \rightarrow \pi^*$ excitations relative to the ground state configuration, and hence remedies the situation.

According to the parameters contained in Table 1, the inclusion of correlation effects produces an elongation of 0.09 ± 0.01 au in R_e (AB) for both silicon compounds relative to the SCF value. A similar increment of +0.087 au has been reported for the GeN equilibrium distance in the isovalent H_2GeNH compound when correlation effects are explicitly considered (24).

The ground state geometries for the experimentally unknown species H_2SiNH and H_2SiPH have been partially reoptimized at the MRD-CI level with respect to the distance $>$A=B, always using the valence Basis A. All other geometrical parameters were kept constant and equal to the optimal values obtained at the SCF level. The angles H(1)AB (H(1) is the hydrogen in *cis* position) lie within 124–129° for all species given in Table 1,

[a] The a' orbital is either σ or in-plane π character depending on the molecule under consideration.

while the angle H(2)AB is invariably somewhat smaller and ranges from 118 to 112°. The angle ABH(3) is reduced by a larger amount when one substitutes the nitrogen by the phosphorus atom.

Finally it is of interest to compare the equilibrium distances of the A═B frame with the corresponding diatomic AB and triatomic HAB (or ABH) species. A summary of experimental and (or) theoretical predictions (4, 9, 25–28) is contained in Table 2. The 9-valence electron diatomics CN, CP, SiN, and SiP are characterized by the low-lying electronic states $^2\Sigma^+$ $(\sigma\pi^4)$ and $^2\Pi_i$ $(\sigma^2\pi^3)$, respectively (4). The ground state is $^2\Sigma^+$ for the first three species and $^2\Pi_i$ for SiP, as recently reported in MRD-CI calculations (9). Because the π MO's possess bonding character and the last σ MO is only slightly involved in the AB bonding, the $^2\Pi_i$ states have larger equilibrium distances than the $^2\Sigma^+$ states. A comparison between the R_e (AB) values for corresponding AB and HAB compounds (Table 2) reveals that the internuclear separation in the triatomic molecules resembles that of the $^2\Sigma^+$ state in the diatomic. These findings can be explained by the common π^4 occupation in both the $^2\Sigma^+$ (AB) and $^1\Sigma^+$ (HAB) states, respectively.

In going from HAB to H_2ABH one formally occupies the in-plane component of the π^* MO, which is generally characterized as n (non-bonding with respect to AB) MO. Hence this MO has very little influence on the AB bond. The original π^4 in the linear triatomic HAB decomposes in the planar H_2ABH molecules into a'^2 and a''^2, respectively. The double occupation of the lower-lying σ and the out-of-plane π (a'') species is also present in the $^2\Pi_i$ $(\sigma^2\pi^3)$ states of the diatomics AB and for this reason one observes that the internuclear distances in H_2ABH are approximately the same as reported for the $^2\Pi_i$ states. In the case of the H_2CNH one finds a slightly larger distance as in the corresponding CN radical, but for all other species this rule works quite well.

B. *Molecular orbitals*

The H_2ABH molecules under discussion possess 12 valence electrons, whereby only one occupied MO is of a'' (π) symmetry. The highest occupied MO of a' symmetry $(5a')$ is invariably associated with the lone-pair of the heavy B atom and characterized as n, while the $4a'$ is generally of σ or in-plane π type, in analogy with isovalent H_2AB molecules, as for example H_2CO, H_2CS, H_2SiO, H_2SiS, etc.. The most important canonical energies and the total SCF energies are summarized in Table 3, while the relative separations between the MO involved in the vertical excitation (of valence character only) are diagrammatically shown in Fig. 1.

It is seen (Table 3 and Fig. 1) that only in H_2CNH is the non-bonding $5a'$ (n) the highest occupied MO while in all other H_2ABH systems the a'' (π) is always less stable. The relative energetics between the highest occupied MO's are thereby quite similar in both mixed compounds H_2SiNH and H_2CPH. In

TABLE 3. Total SCF and canonical energies (in atomic units) obtained for the most important valence orbitals at the corresponding SCF equilibrium geometries (Basis A).[a] The calculated dipole moments (debye) are also given

[a]The orbitals are labelled for the valence set only. Values in parentheses are $-\epsilon_i$ in eV.
[b]The molecular plane is (xy) and the AB bond collinear with the x-axis. The negative charge is concentrated around the atom B in all H_2ABH species. The first columns are MRD-CI (MO's) results at the corresponding equilibrium geometries, while the values in parentheses are SCF results (at the optimized SCF geometries). The data in the second column in H_2SiPH result from NO calculations.

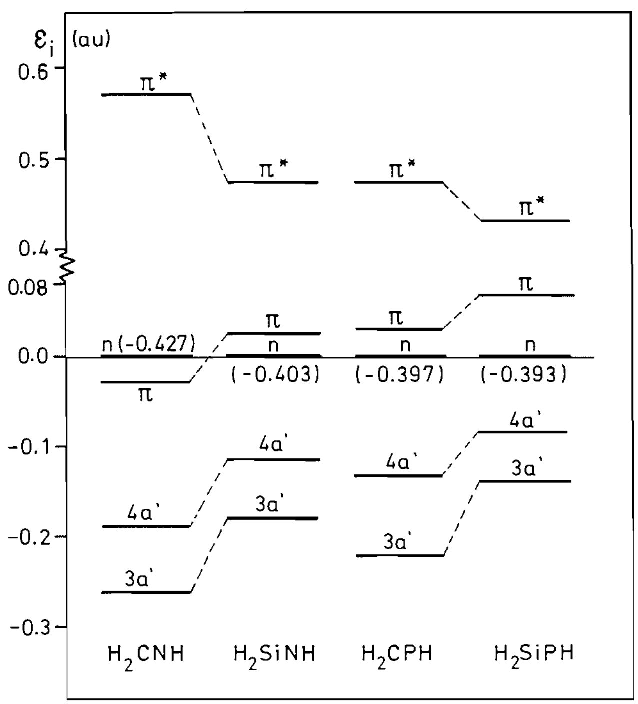

FIG. 1. Canonical orbital energies for the various species under consideration, obtained from the ground state SCF calculation.

H_2CNH one finds the situation familiar from H_2CO, while in H_2SiPH one observes a definite stabilization of the π^* (and n MO relative to the π MO's) and the opposite trend for the π MO which is shifted to higher canonical energies. Altogether the π^* becomes more stable upon substitution by a second-row atom relative to the original situation in H_2CNH (Fig. 1).

It should be pointed out that both the n and π^* orbitals correlate with the π^* (π_g-type) MO in the respective simple AB diatomics. Thus the in-plane n component achieves a considerably larger stabilization due to hydrogen admixture than its out-of-plane π^* counterpart, and this finally leads to a situation

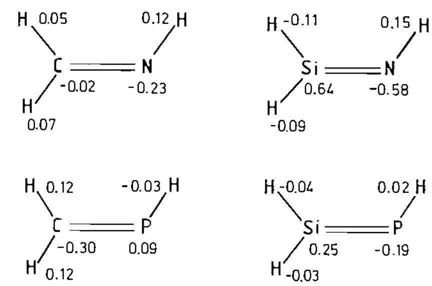

FIG. 2. Calculated net charge for the various compounds, obtained at the SCF level of treatment (Basis A).

in which the n orbital is placed even *below* the a'' MO which is originally associated with the π MO in the simple AB system. As a result one expects that the excitation energies for the $^{3,1}(n,\pi^*)$ and $^{3,1}(\pi,\pi^*)$ states are shifted to the red from H_2CNH to H_2SiPH, but that this effect is more pronounced for the $^{3,1}(\pi,\pi^*)$ multiplets.

C. *Charge distribution*

The Mulliken population analysis as well as the dipole moments give some insight into the charge distribution in the molecule. The population analysis has only been carried out at the SCF level of treatment (Basis A) and the results are indicated in Fig. 2. It is seen that the A atom is positive relative to B in the systems H_2CNH, H_2SiNH, and H_2SiPH, while in H_2CPH the situation is opposite and it is the phosphorus (atom B) which possesses the positive net charge in this analysis. In comparison with earlier results from the literature (29, 30), the charge separation is not as pronounced in the present work, however; Thomson (29) obtains a net charge of +0.38 for P and −0.35 for C in a STO-3G basis which changes to +0.31 (P) and −0.67 for C if the STO4-31G basis is employed (29, 30). Thus it is clear that the results are quite dependent on the quality of the AO basis.

The calculated dipole moments are also contained in Table 3. Generally the theoretical values are in relatively good agreement with the experimental data (22, 31) whereby the SCF value overestimates the dipole moment more than the MRD-CI result. All dipole moments indicate that the negative charge is concentrated in the BH region which is – with the exception of the H_2CPH system – in accordance with the Mulliken population analysis. The two spatial dipole moment components are almost equivalent in H_2CNH, while the direction is much closer to the Si=P bond in H_2SiPH ($\angle 18°$); the angles in the mixed compound (27° and 30°) lie, as expected, between the two extremes. The magnitude of μ is largest from H_2SiNH and almost the same as in the diatomic SiN radical (9).

IV. The Vertical Electronic Spectrum

One goal of the present work is to investigate the relative position of the valence $n \rightarrow \pi^*$ and $\pi \rightarrow \pi^*$ transitions in the various isovalent H_2ABH systems as well as that of the first $n \rightarrow s_R$ and $\pi \rightarrow s_R$ members of their Rydberg series. The calculation of the ionization potentials associated with $(n \rightarrow \infty)$ and $(\pi \rightarrow \infty)$ allows an estimate for the corresponding term values as well as for the respective quantum defects in the Rydberg series. The last point will be treated in Section V.

The H_2CNH molecule was analyzed in more detail than the other isovalent species. The potential energy curves for the lowest valence transitions are determined as a function of the CN internuclear separation in this case since it is well known from H_2CO or H_2CS that $n \rightarrow \pi^*$ and $\pi \rightarrow \pi^*$ excitations cause elongations of the AB bond. Additional Rydberg states are also treated for this molecule.

A. *Methylenimine H_2CNH*

There are earlier theoretical studies (10, 32–34) on the vertical spectrum of H_2CNH but all of them lack Rydberg-type AO as well as *d*-polarization functions on the heavy atoms. Another serious limitation of prior calculations is the inadequate treatment of the correlation energies, especially if one considers that only one reference configuration has been used in the older CI treatments.

We have studied this molecule in both Basis A and B. The study within the pure valence AO set could be considered as the *"diabatic valence"* portion of the potential curves (some of which possess valence-Rydberg character in the gas phase) or as the most likely potential curves of H_2CNH in condensed media. The valence transitions studied here are $^{3,1}(n,\pi^*)$, $^{3,1}(\pi,\pi^*)$, $^{3,1}(n,\sigma^*)$, $^{3,1}(\pi,\sigma^*)$, and $^{3,1}(\sigma,\pi^*)$, respectively. The first two multiplet pairs have also been studied in the more expanded Basis B, although it is to be expected that, with the exception of the high-lying $^1(\pi,\pi^*)$ state, both kinds of calculations give equivalent results.

The vertical transitions derived in the present work are contained in Tables 4 (Basis B) and 5 (Basis A), respectively, and in Fig. 3. In both cases a selection threshold of 5 μH (H, hartree) has been employed, leading to selected MRD-CI spaces ranging in order from 8000 to 12 000. The results for the MRD-CI and estimated full CI are given and show relatively little variance from one another; in the ensuing discussion the mean value of these will be used.

We analyse first the results obtained with the expanded AO basis. The lowest state in the vertical region is $^3(n,\pi^*)$, placed at 4.76 ± 0.03 eV, followed by the second triplet $^3(\pi,\pi^*)$ state, with an excitation energy of 5.10 ± 0.05 eV. The $^1(n,\pi^*)$ state is about 0.60–0.66 eV less stable than the corresponding triplet and located at ΔE = 5.42 ± 0.03 eV (Table 4).

According to Sandorfy and co-workers (10, 11, 36), the

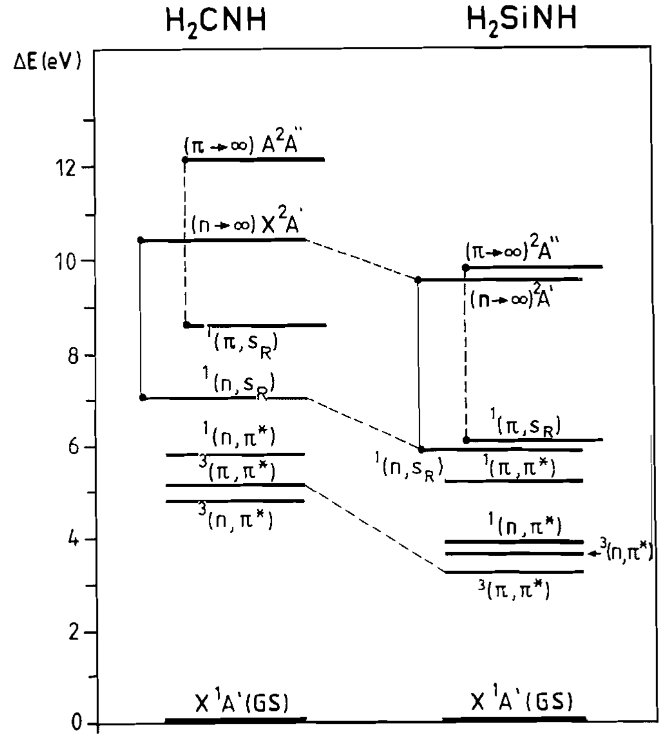

FIG. 3. Calculated vertical excitation energies (Basis B) in H_2CNH and H_2SiNH. Full CI results have been used.

$^1(n,\pi^*)$ transition is found between 41 000 and 43 000 cm^{-1} (i.e. 5.08–5.33 eV) for a series of azomethines. Our predicted value for the vertical excitation for the lowest singlet state in H_2CNH is in good agreement with this experimental finding since it is well known that the $^{3,1}(n,\pi^*)$ states acquire additional stabilization upon geometrical relaxation, i.e. elongation of the CN bond distance as well as loss of the C_s symmetry due to pyramidal-like structure in the excited states (10, 23). As discussed below, potential curves calculated at the MRD-CI level with respect to variations in the CN distance (and keeping all other geometrical parameters constant, however) find an extra stabilization of about 0.3–0.4 eV for the (n,π^*) multiplets, in comparison with the situation in the vertical region.

Although the earlier work of Macaulay *et al.* (10) has found a value for ΔE (ΔE = 4.68 eV) for the $^3(n,\pi^*)$ state quite comparable to the value reported in Table 4, by contrast the corresponding $^1(n,\pi^*)$ state was placed at an energy of 5.84 eV, i.e. ca. 0.40 eV higher than in the present study. Hence their predicted triplet–singlet splitting of 1.16 eV is too large when compared with our estimate of 0.66 ± 0.05 eV (see Table 4). Another theoretical study by Cimiraglia and Tomasi (32) locates the $^1(n,\pi^*)$ state slightly below the MRD-CI findings but places the $^3(n,\pi^*)$ state ca. 0.70 eV below the present value. This again leads to a splitting of 1.13 eV, quite similar to the value quoted in ref. 10. Other data for the $^1(n,\pi^*)$ states, also derived by theoretical methods, give 5.83 eV (34), while the excitation energy reported by Kitaura *et al.* (33) (i.e. 6.27 eV) seems to be definitely too high. The $^3(\pi,\pi^*)$ state is located vertically between the $^{3,1}(n,\pi^*)$ states around 5.10 ± 0.05 eV, i.e. ca. 4000 cm^{-1} above the prior estimate reported by Macaulay. The excitation energy of 3.93 eV cited in ref. 32 is apparently in error by more than 8000 cm^{-1}, however.

If one compares the $^{3,1}(n,\pi^*)$ states of H_2CNH with those of H_2CO one finds that the singlet–triplet splitting is comparable

TABLE 4. Calculated vertical excitation energies (in eV, Basis B) in H_2CNH and comparison with earlier work. Technical details of the MRD-CI treatment are also given

[a] The notation mMrR refers to m main or reference configurations while selection is carried out for r roots. The total MRD-CI space is of dimension DIM while the selected subspace treats only dim SAF's (indicated by DIM/dim in the column). The values in parentheses are the weight of the reference species ($\Sigma_{ref}\, c^2$) in percent. The MO basis employed is referred to as B1 to B5 corresponding to the SCF MO's of the ground state, $^3(n,\pi^*)$, $^3(\pi,\pi^*)$, $^3(n,s)$, and $^3(\pi,s)$ respectively.

[b] Total energies in hartree. T = 5 μH.

[c] Selection threshold used: T = 10 μH; E(GS) = −94.35319 au (MRD); −94.37490 au (full CI estimate). Using as nomenclature $A(\pi,p_\pi)$, $B(\pi,d_\pi)$, $C(\pi,d_\delta)$, and $D(\pi,\pi^*)$, the different roots have the composition:
(R1) 0.50 [A]; 0.25 [B]; 0.01 [C]; 0.13 [D]
(R2) 0.06 [A]; 0.13 [B]; 0.01 [C]; 0.65 [D]
(R3) 0.35 [A]; 0.54 [B]; 0.02 [D].

[d] Selection threshold used: T = 12.5 μH; E(GS) = −94.35131 au (MRD); −94.37280 au (full CI estimate). The composition of the different roots is:
(R1) 0.44 [A]; 0.11 [B]; 0.11 [C]; 0.13 [D]
(R2) 0.11 [A]; 0.29 [B]; 0.13 [C]; 0.36 [D]
(R3) 0.32 [A]; 0.50 [B]; 0.01 [C]; 0.07 [D]
(R4) 0.04 [A]; 0.02 [B]; 0.54 [C]; 0.31 [D].

(0.65 eV in H_2CNH and 0.40 eV in H_2CO) but that the absolute transition energies are shifted to higher values by 1.30–1.60 eV in H_2CNH. This behavior can be rationalized if one assumes that the hydrogen bound to the nitrogen atom stabilizes the n MO relative to the situation present in H_2CO.

There is no direct experimental information available about the location of the low-lying Rydberg states of H_2CNH. In the literature one can only find general trends on their relative

[b]Total energies in atomic units.

excitation energies, which are based on observations for higher azomethine compounds. According to Sandorfy (11) the spectra of imines are diffuse in nature and this makes the Rydberg states difficult to locate. The $(n\rightarrow s_R)$ band is expected between 48 000 and 50 000 cm^{-1} (i.e. 5.95–6.20 eV). A comparison with the Rydberg transition energy predicted in the present work for the lowest state (see Table 4) shows that the theoretical values are ca. 8000 cm^{-1} higher than the experimental expectations. The transition $^1(n,p\pi)$ is located here at 7.82 ± 0.05 eV (i.e. 63 000 cm^{-1}), again in greater discrepancy with the predictions of Sandorfy, who assumes smaller values of 55 000 – 58 000 cm^{-1} (between 6.82 and 7.19 eV) for both the $(n\rightarrow 3p)$ and $(\pi\rightarrow 3s)$ transitions. We calculate the $^1(\pi,s_R)$ state at 8.58 ± 0.04 eV (69 000 cm^{-1}), that is, approximately 1.60 eV (≈13 000 cm^{-1}) higher than the absorption region expected from simple correlation with experimental results in related imine compounds.

A closer analysis of the basis for the various predictions removes the apparent discrepancies with the theoretical results. The estimates of Sandorfy have been based on general trends for term values and on the known first two ionization potentials of diverse azomethine compounds. In the meantime it is clear from experiments and our calculations (Section V) that the ionization processes in the simplest methylenimine need much more energy than the corresponding ionization in the higher compounds. For example, while the IP associated with $(n\rightarrow\infty)$ is placed around 9.44 eV in the heavier imine molecules, in H_2CNH it is shifted to higher values by 1.08 eV according to the experimental IP of 10.52 eV (37). If one considers the next ionization band associated with $\pi\rightarrow\infty$, the destabilization of the π MO in going from H_2CNH to larger azomethines is even more dramatic, as exemplified by an IP $(\pi\rightarrow\infty)$ of 12.43 eV (37) in methylenimine compared with 10.48 eV observed for various $R^1R^2C{=}NR^3$ systems (36). This difference of 1.95 eV between the second ionization potentials in the simplest and the largest species must also occur between the first members of the respective $(\pi\rightarrow s_R)$ Rydberg series. In other words, the values expected by Sandorfy and co-workers for the location of the $^1(n,s_R)$ and $^1(\pi,s_R)$ transitions in H_2CNH (11) must be adjusted upwards by ca. 8800 and 15 000 cm^{-1}, respectively.

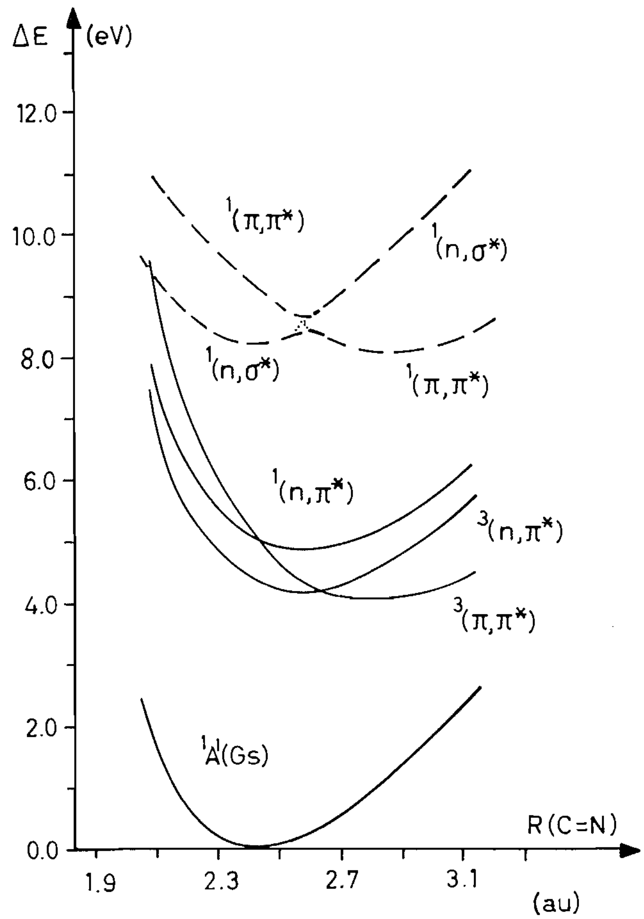

FIG. 4. Calculated potential energy curves as a function of C=N stretch for the lowest states of H_2CNH (Basis A). The $^1(\pi,\pi^*)$ and $^1(n,\pi^*)$ states are shown in dashed lines only because the actual behavior of potential energy curves is more complex as soon as Rydberg states are included (see Fig. 5).

After this shift, the experimental inferences and the present theoretical predictions are in good accord.

Before one analyzes the vertical transition energy for the $^1(\pi,\pi^*)$ state, the results obtained for variations in the CN distance in the lowest valence states $^{3,1}(n,\pi^*)$ and $^3(\pi,\pi^*)$, as well as in the ground state and the most important Rydberg states (Fig. 4), are of importance. All other internuclear geometrical parameters have been kept constant in these calculations.[1] The MO basis used in these CI investigations was obtained for the $^1A'$ ground state; the selection threshold was 12.5 μH, and leading to secular equations of the order 4000–6000. The results (Fig. 4) show that the $^3(\pi,\pi^*)$ state possesses the largest CN distance (about 2.8 au at equilibrium), while the other low-lying valence state curves for $^{3,1}(n,\pi^*)$ run parallel to each other and have a minimum at the somewhat shorter R(CN) ≈ 2.6 au. Similar results are reported by earlier SCF calculations (33). Both triplet states at their optimal geometries are in close energetic neighborhood and located around 4.0–4.2 eV above the ground state.

The $^1(\pi,\pi^*)$ state is placed within the restricted Basis A (of valence character only) at 9.30 ± 0.10 eV in the vertical region. A more refined treatment with the expanded Basis B leads to a more complicated picture: no unique state with predominant (π,π^*) composition is found any more. The lowest state of this symmetry is placed at 9.12 ± 0.08 eV and is fundamentally in nature 60% $\pi\rightarrow p\pi$ with ca. 20% contamination of the (π,π^*) configuration, while the next state contains more valence character, as given by the relative weights which are complementary to those in the lowest solution. The corresponding vertical excitation energy for the second state is 10.08 ± 0.08 eV. These results clearly demonstrate how the expansion of the AO basis by Rydberg functions splits the original "diabatic" eigenvalue of 9.30 eV into two states, one of them somewhat lowered with respect to it and with some degree of valence (π,π^*) character but essentially described by a Rydberg configuration, while the other component, placed around 81 000 cm^{-1}, contains the major portion of valence character.

The question of what happens with the $^1(\pi,\pi^*)$ state when the interatomic distance CN is increased has been investigated in two ways. First, only the valence-shell states are considered and the results are also contained in Fig. 4. The unperturbed $^1(\pi,\pi^*)$ configuration shows a similar CN stretch potential energy curve as the triplet counterpart with a minimum at relatively large CN separation (2.85 au). But in contrast to the situation for the $^3(\pi,\pi^*)$ state, which is located considerably *below* the $^3(n,\sigma^*)$ state according to Table 5, the singlet states show the reverse energetic ordering, leading to an interaction between both $^1(\pi,\pi^*)$ and $^1(n,\sigma^*)$ states as seen in Fig. 4. In other words, a stretching of the CN bond induces an avoided crossing between the (n,σ^*) and (π,π^*) configurations and will thus give rise to an irregular pattern in the vibrational structure of the ground state absorption.

The next step includes possible mixing of the $^1(\pi,\pi^*)$ state with Rydberg configurations. In this case only (π,π^*)-type configurations are considered which represent in the main the (π,π^*) valence-shell part and the $(\pi,p\pi_R)$ and $(\pi,d\pi_R)$ Rydberg states; since no $3d\pi$ functions are present in the AO basis, the higher π^*-type orbitals are only an approximation to such an MO. The results in Fig. 5 show a strong mixing among these configurations which is especially apparent at small CN separations. Generally the potential curves of the unperturbed Rydberg states should run essentially parallel to their ionic limit, also contained in Fig. 5. The strongly CN repulsive nature of the $^1(\pi,\pi^*)$ valence state perturbs this pattern; the $^1(\pi,\pi^*)$ valence potential energy curve crosses the $(\pi\rightarrow R)$ Rydberg manifold somewhat to the left of the Rydberg minima so that the valence character, present in the lowest $^1(\pi,\pi^*)$ state at large CN separation (for example 2.7 au), is gradually distributed among the $^1(\pi,\pi^*)$ states with decreasing CN values and is found in the third $^1(\pi,\pi^*)$ root at CN = 2.1 au. As a result, no single state with compact (π,π^*) character exists any more for CN values smaller than the equilibrium value of the X^1A' ground state, and considerable anomalies are expected in the energy levels and the intensity distribution of the absorption spectrum. To make the situation even more complicated, the $^1(\pi,\pi^*)$ state undergoes a further avoided crossing with the $^1(n,s_R)$ Rydberg state at CN values larger than 2.8 au. This behavior is also indicated in Fig. 5; the unperturbed $^1(n,s_R)$ potential energy curve would run strictly parallel to that of the $^2A'$ $(n\rightarrow\infty)$ molecular ion.

In summary, then, there is a manifold of states which couple with the $^1(\pi,\pi^*)$ whereby the interaction varies considerably

[1] The values reported by Macaulay *et al.* (10) for the internuclear angles and the hydrogenic bonds are taken for the calculation of the stretching potential curves; hence the starting geometry in the CN variations differs slightly from the best experimental data available (see Table 1).

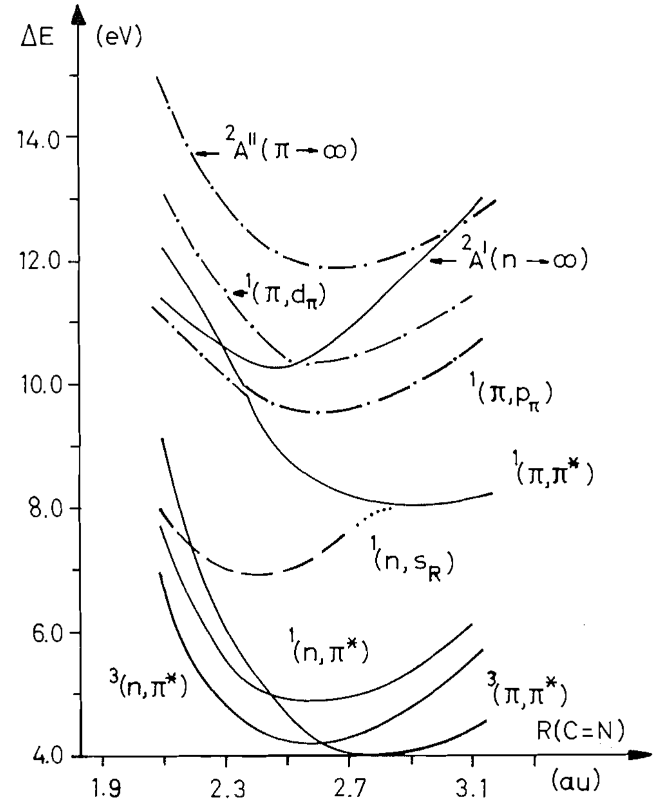

FIG. 5. Calculated mixing of Rydberg states of (π,π^*)-type symmetry as a function of CN stretch (Basis B).

with the change in CN bond length. It is thus not surprising that a quite diffuse and broad spectrum is obtained experimentally in this energy region.[2] This basic analysis can presumably be carried over to higher members in the $R^1R^2C{=}NR^3$ series and thus explains the complicated absorption and emission pattern in azomethines. The direct connection of the $^1(n,s_R)$ with $^1(\pi,\pi^*)$ potential curve shown in Fig. 5 is also in accordance with the observation by Sandorfy that the Rydberg states could be responsible for a part of the broad and highly asymmetrical low-wavenumber shoulder of the $^1(\pi,\pi^*)$ band in the spectra of imines.

Finally, if the results of the all-valence AO basis in Table 5 are compared with those obtained from the more flexible Basis B (Table 4) it is seen that the transition energies to the lowest $^{3,1}(n,\pi^*)$ and $^3(\pi,\pi^*)$ states are almost the same in both treatments, at least at the level of the estimated full CI. The $^{3,1}(n,\sigma^*)$ states are treated only in this basis (as are all other valence states) and are located at 8.06 ± 0.07 eV and 8.64 ± 0.08 eV (ca. 70 000 cm^{-1}) respectively. Even though the $^1(n,\sigma^*)$ is considerably above the first member of the Rydberg $^1(n,s_R)$ state at the ground state structure, this energy difference decreases with CN stretching until interaction of both states (Figs. 4, 5), as well as with the $^1(\pi,\pi^*)$ component, appears. Other valence states of interest are derived from the $\sigma\rightarrow\pi^*$ transition. They are characterized by the smallest singlet–triplet separation of the intravalence transitions studied so far. The highest states of (π,σ^*)-type are relatively close in energy to (σ,π^*) and show calculated excitation energies in the 10-eV region. Interactions of these states are also likely but have not been investigated in this work.

[2] Note that one can expect that the absorption maximum in this simplest H_2CNH imine is shifted to higher energies, when compared to the higher imines, for the same reason as discussed for the first members of the Rydberg series or the ionization potentials.

TABLE 6. Calculated relative energies for H_2SiNH (in eV)

B. *Silylimine H_2SiNH*

The relative energies predicted for the excited states of H_2SiNH in the vertical region are displayed in Table 6 and Fig. 3. The lowest excited state is found to be the $^3A'$ (π,π^*), in contrast to the situation of the first-row analogue H_2CNH, in which this state is placed (vertically) between the $^{3,1}(n,\pi^*)$ multiplets. The state has been studied in two different MO basis sets (see Table 6). Using the parent SCF MO's and one reference configuration, one obtains relative energies comparable to working with three reference configurations in the $^3(n,\pi^*)$ MO basis; the respective full CI estimates differ by only 0.04 eV, while the difference in MRD-CI values is 0.11 eV. The corresponding contribution of the reference configurations to the total wavefunction as measured by Σc^2 is 92.12% if the parent SCF MO's and 91.42% if the $^3(n,\pi^*)$ MO's are employed, compared to 90.55% achieved in the ground state treatment. This in turn signals that the calculated MRD-CI excitation energy employing the parent MO's is somewhat too low (3.04 eV) simply because the excited state is described slightly better than the ground state. A somewhat more balanced description between ground and excited states is obtained in the $^3(n,\pi^*)$ MO basis. This balance in Σc^2 is quite important for a good description of the relative energies, as pointed out in the literature (17*b*, 38). The full CI level of treatment leads to more reliable results because the differences in Σc^2 are essentially removed. This observation is valid for all vertical transitions reported in this work.

The $^{3,1}(n,\pi^*)$ states located at 3.68 eV and 3.93 eV re-

[a]The notation is the same as in Table 4; the selection threshold is $T = 5$ μH.
[b]These values are absolute energies in au.

spectively are shifted to *lower* energies by about 9000–12 000 cm^{-1} when compared with the similar transitions in the H_2CNH compound. The $^3A'$ (π,π^*) state is stabilized by ca. 16 000 cm^{-1} in going from methylenimine to silylimine, but the most drastic stabilization is found for the $^1A'$ (π,π^*) state: taking as vertical excitation energy for the strongly perturbed singlet (π,π^*) state of H_2CNH an approximate value of 9.5–10.0 eV, this vertical absorption band is shifted in the silicon compound by about 36 000 cm^{-1} to longer wavelengths. As a result the $^1(\pi,\pi^*)$ state is placed *below* both Rydberg series, even in the vertical region of the spectrum. This finding suggests that the absorption band associated with this transition must be simpler than in H_2CNH: although a broad band is expected due to the difference in the equilibrium geometries of ground and excited states, the strong Rydberg-valence mixing observed for H_2CNH is absent in the silicon compound. If perturbations are present, they are probably due to valence transitions, for example A' $^1(n,\pi^*)$ or A'' $^1(\pi,\sigma^*)$.

The $^{3,1}(n,\pi^*)$ splitting is smaller than the corresponding triplet–singlet energy separation in the (π,π^*) states. These trends are in line with the spatial distribution of the corresponding MO's involved in the transitions. Both π and π^* species have their charge distribution maxima perpendicular to the molecular plane, while the n MO is more concentrated in the molecular plane. Hence the respective exchange integrals are larger for the (π,π^*) configuration than for (n,π^*) and the triplet–singlet splittings follow these trends. Comparing the $>$C=N- with the $>$Si=N-group, one notices that all key MO's are more extended in space in the molecule with a second-row constituent, and this results in a systematic reduction in the triplet–singlet separations as soon as second-row atoms are included.

The first members of both Rydberg series are placed close together. According to the full CI data, the $^1(n,4s_R)$ is found vertically at 5.90 eV while the $^1(\pi,4s_R)$ lies only 0.17 eV (1400 cm^{-1}) above. Due to the different properties of the n and π MO's with respect to elongation of the Si=N bond, one can assume that the $^1(\pi,4s_R)$ state at its equilibrium is possibly just below the $^1(n,4s_R)$ state. A comparison of the Rydberg states in both H_2CNH and H_2SiNH reveals a general lowering in the excitation energies, of the order of 9500 cm^{-1} for the (n,s_R) state and a much larger effect (about 20 500 cm^{-1}) for the π-Rydberg series. These findings indicate that the π MO is relatively more *destabilized* (by about 11 000 cm^{-1} = 1.40 eV) than the n species after substitution of a carbon by the silicon atom, as already seen in Fig. 1.

C. *Methylenephosphine H_2CPH*

The H_2CPH molecule is the simplest phosphane-alkene; it has recently been observed (22, 39, 40) in the laboratory and its microwave spectrum has been analyzed (22). The lowest ionization potentials have also been measured.[3] This molecule is rather unstable, with a tendency towards dimerization.

Some theoretical work on H_2CPH is reported in the literature but to the best of our knowledge none of its excited states have been studied so far. The first work of Thomson (29) was limited to an estimate of the ground state equilibrium geometry at the SCF level (without *d*-polarization functions) and the ordering of n below π MO (Fig. 1) was noted for the first time. In another SCF study (30) the charge distribution of the different MO's was discussed and the π-bond energy has been estimated. In more recent work carried out by Lohr *et al.* (41), the proton affinity of H_2CPH was studied with a more expanded AO basis, also including correlation effects according to the Møeller–Plesset (in 4th order) scheme. The SCF energy obtained in that work is −380.29294 au and is comparable with our result of −380.3000 au. The final energy derived with the perturbative method is −380.57549 au and lies in between the values −380.57110 au (MRD-CI) and −380.59586 au (full CI estimate) reported in the present study (Table 7). These authors have found that the P-site protonation is favored over the C-site protonation by about 50 kJ/mol, whereby the resulting $H_2CPH_2^+$ radical possesses a C_{2v} planar equilibrium geometry. As illustration it can be mentioned that a similar protonation on H_2CNH to $H_2CNH_2^+$ indicates a value larger by 150 kJ/mol for the N-site protonation than for the C-site (41). This behavior in turn strongly supports the charge distribution reflected by the dipole moment calculation (Section III), i.e. a negative site at phosphorus, in contrast to what can be derived on the basis of the Mulliken population analysis.

The predicted locations of the excited states in H_2CPH are given in Table 7 while the relative separation is shown in Fig. 6, together with the H_2SiPH homologue.

The valence states $^{3,1}(\pi,\pi^*)$ and $^{3,1}(n,\pi^*)$ follow in the vertical region the same pattern as discussed for the H_2SiNH compound containing a second-row atom. The $^3(\pi,\pi^*)$ state lies at ca. 24 000 cm^{-1}, i.e. about 2000 cm^{-1} below the excitation energy assigned to the equivalent state of H_2SiNH (see Table 6). The $^{3,1}(n,\pi^*)$ states are located at 4.26 eV and 4.94 eV, respectively. The transition energies for the last mentioned multiplets, when compared with H_2CNH, are found about 4000 cm^{-1} lower, but ca. 5600 cm^{-1} higher as predicted here for the H_2SiNH molecule. In other words, the (n,π^*) states of H_2CPH are characterized by excitation energies lying between the cor-

[a]The notation is the same as in Table 4; the selection threshold is $T = 7.5$ μH.
[b]These values are absolute energies in au.

responding values assigned to H_2CNH and H_2SiNH, respectively. The $^1(\pi,\pi^*)$ state lies 52 000 cm^{-1} above the ground state and this implies a singlet–triplet splitting of 3.37 eV (27 000 cm^{-1}), much larger than the 2.0 eV established for H_2SiNH. Generally the triplet–singlet separations predicted for H_2CPH are greater than in the two silicon compounds.

The results of Table 7 show that in H_2CPH the Rydberg states are also placed close together as observed in H_2SiNH, but by contrast the $^1(\pi,s_R)$ state is located below the $^1(n,s_R)$ already in the vertical region. Surprisingly both $^1(n,s_R)$ states in H_2CNH and H_2CPH are in approximately the same absorption region (i.e. 56 000 ± 1000 cm^{-1}) and this finding is confirmed by the similarity in the corresponding $n\rightarrow\infty$ ionization potentials. The Rydberg (π,s_R) series is stabilized by about 15 000 cm^{-1} upon formal substitution of the nitrogen atom in H_2CNH by phosphorus and this behavior runs parallel to the strong lowering in the ionization energy $(\pi\rightarrow\infty)$ leading to the ground state of H_2CPH^+.

D. *H_2SiPH*

There is practically no information available for small molecules containing the SiP bond. Recently the first *ab initio* studies on the experimentally unknown simple molecules SiP (4) and SiP^+ (8), as well as on the isomer pairs HSiP–HPSi (9), were carried out in this laboratory and thus the present report on H_2SiPH is an expansion of this work to improve our knowledge of the bonding properties of silicon–phosphorus compounds.

The excitation energies obtained from the MRD-CI calculations are summarized in Table 8 and Fig. 6. The technical treatment differs somewhat from the previous cases because the various electronic states have been studied by employing an MO as well as an NO basis. In the first run, the CI calculations were carried out using the ground state or the $^3(n,\pi^*)$ MO's; the corresponding wavefunctions were transformed to an NO basis and the CI calculations repeated with a selection threshold of 5 μH, i.e. 2.5 μH smaller than in the first run.

As discussed in Section III, this molecule is characterized by the largest relative stabilization of the n species in comparison with the π MO's, while on the other hand the energy difference between both π and π^* MO's is the smallest of the present family of molecules (Fig. 1). This must be reflected in the corresponding excitation energies, as well as the state ordering, when compared with related molecules.

The $^3A'$ (π,π^*) level lies only 18 000 cm^{-1} above the ground state, which means a stabilization of ca. 7000–8000 cm^{-1} if one takes the corresponding values of H_2CPH or H_2SiNH as reference. The $^1(\pi,\pi^*)$ state is located practically at the same excitation energy as the $^1(n,\pi^*)$ state (around 36 500 ± 1000 cm^{-1}) and this finding suggests a broad band in the corresponding absorption spectrum. Due to the aforementioned relative stabilization of the n MO, the (n,π^*) multiplets are shifted to somewhat higher energies than in H_2SiNH. The rather small excitation energies found for the (n,π^*) and (π,π^*) states are also in agreement with the low-transition energies previously predicted for the $^4\Pi$, $^4\Sigma^+$, $^4\Delta$, and $^4\Sigma^-$ states of the parent SiP diatomic molecule (9).

By the same token, the first Rydberg state is clearly the $^1(\pi,s_R)$, lying around 44 000 cm^{-1}. The other Rydberg transition $^1(n,s_R)$ lies about 13 000 cm^{-1} above the lowest $^1(\pi,s_R)$ and one can expect that other terms $(\pi,4p_R)$ and $(\pi,3d_R)$ are just below the first member of the Rydberg series starting with the second highest n-orbital.

The results obtained by employing natural orbitals are collected in Table 9. In general the results are quite similar to those obtained in the MRD-CI calculations based on the two different types of SCF-MO orbitals. The advantage can primarily be seen in a somewhat more contracted (fewer reference configurations) MRD-CI expansion.

TABLE 9. Calculated relative energies for H_2SiPH (in eV) using NO's

Transition	Treatment[a]	MRD-CI	Full CI estimate
$^1A'$ (GS)	5M1R 192670/5219 (90.72%)	0.0 (−631.58345)[b]	0.0 (−631.60280)[b]

[a] The notation is the same as in Table 4; the selection threshold is $T = 5$ μH.
[b] These values are absolute energies in au.
[c] The NO basis used stems from the corresponding triplets.

V. Ionization potentials and term values

The electronic states of the positive ions H_2ABH^+ studied here are $^2A'$ (n,∞) and $^2A''$ (π,∞), respectively. Technical details of the calculations are presented in Table 10, together with the corresponding numerical results. The relative positions with respect to the neutral ground states as well as to the related Rydberg series are contained in Figs. 3 and 6.

According to the bonding characteristics of the molecular orbitals from which the ionization takes place, one can expect that the $^2A''$ (π,∞) ionic states have larger equilibrium AB distances than the corresponding values in the neutral molecules. This feature leads to vibrational progressions in this portion of the photo-ionization spectrum. The other ionization process (n,∞), by contrast, probably does not alter the internuclear AB distance to a larger extent and by this reason the corresponding PES peaks should be relatively sharp without structure.

Inspection of Table 10 shows that the theoretical values for the two IP's of H_2CNH are in quite good agreement with the experimental findings (37). The underestimation error of 0.20 eV in the case of $^2A''$ can be considered as typical for this kind of calculation and is probably also valid for the ionization potentials of the other compounds. Both IP's are close together in the vertical region for the mixed compounds H_2CPH and H_2SiNH. The $^2A''$ state of H_2CPH^+ is already the lowest ionic state vertically, while in the case of H_2SiNH^+ it lies somewhat above the $^2A'$ state. The extra stabilization due to elongation of the SiN distance probably leads to a final situation in which the ground state of H_2SiNH^+ also corresponds to $^2A''$ (π,∞). It is thus suggested that the PES spectra of both H_2CPH and H_2SiNH are more complex than experimentally reported for H_2CNH, in which the two first ionization regions are well separated.

For H_2SiPH the calculations predict a more simple (or normal) PES, with two well-characterized ionization processes in which without doubt the ground state of H_2SiPH^+ is the $^2A''$ state. The $^2A'$ (n,∞) has been shifted to higher energies by ca. 1.40 eV, a pattern observed before in the respective Rydberg series of H_2SiPH. Finally, it is of interest that the IP (π,∞) calculated for H_2SiPH is comparable with the values of 9.07 ± 0.02 eV ($HSiP^+$) and 9.00 ± 0.03 eV ($HPSi^+$) recently reported in a MRD-CI study of the ionization of the isomer pairs HSiP–HPSi in their corresponding $^1\Sigma^+$ $(\sigma^2\pi^4)$ ground states and leading to the $^2\Pi$ ionic states (9).

Finally, the calculated term values and the quantum defects for the various Rydberg series in the molecules are collected in Table 11. The results obtained for H_2CNH are close to the experimental findings on the HCN molecule (42, 43). The transitions $(1\pi\rightarrow 3s_R)$ and $(5\sigma\rightarrow 3s_R)$ in HCN are characterized by term values of 27 260 ± 500 cm^{-1} and they are comparable with the values 27 830 cm^{-1} $(n\rightarrow s)$ and 29 520 cm^{-1} $(\pi\rightarrow s)$ derived here for H_2CNH. The term values associated with the $(n\rightarrow p\pi)$ or $(\pi\rightarrow p\pi)$ transitions, namely 21 450 cm^{-1} (Table 11) are about 1000–2000 cm^{-1} higher than the experimental data reported in the equivalent transitions of HCN.

In H_2CPH the energy differences between the $^1(n,s_R)$ and $^1(\pi,s_R)$ states with respect to the corresponding ionization limits are found to be quite similar for both series (≈27 000 cm^{-1}), in accordance with general qualitative rules. The H_2SiNH molecule is apparently characterized by somewhat larger term values than found for the other species. The quantum defect and term value predicted for the (π,s_R) transition of H_2SiPH are in accordance with general expectations, while the transition involving the n orbital has a term value ca. 2000 cm^{-1} smaller.

We hope that the term values reported here could help to locate the Rydberg states of future experimental uv absorption spectra, not only of higher $R^1R^2A{=}BR^3$ compounds related to the simple parent molecules studied in the present work, but also for the simple diatomics CN, CP, SiN, and SiP, as well as the corresponding stable HAB isomers of the three last-mentioned AB radicals. To the best of our knowledge, nothing has been experimentally reported on this topic.

VI. Summary and conclusion

The present investigation on selected low-lying electronic states of H_2CNH, H_2CPH, H_2SiNH, and H_2SiPH gives further examples of a general trend in the electronic structure, already observed in a series of simpler compounds, built up from atoms exclusively of the first or the second row and possessing at the same time atoms of both rows. This trend can be directly related to orbital stability.

For all the atoms of the first row one finds that $\langle r \rangle$ for both $2s$–$2p$ AO's are very similar, while the $3s$–$3p$ subshell of second-row atoms are well separated in their spatial extension. As discussed in more detail elsewhere (9, 44), the two bonding σ MO's derived from $2s$ and $2p$ avoid each other, so that the higher of them $(p\sigma+p\sigma)$ is placed above the π MO. When a second-row atom is involved in the AB bond the splitting between the two σ MO's is reduced somewhat, and the $\sigma(p\sigma+p\sigma)$ MO is even placed below the π MO if both atoms A and B are second-row elements. In effect, this amounts to a considerable stabilization of the σ MO relative to the π if second-row atoms are introduced into the AB bond. At the same time the antibonding π^* MO becomes stabilized upon such substitution, which can be rationalized by the more diffuse charge distribution or alternatively by the primarily symmetric

TABLE 10. Vertical ionization potentials (in eV). Values in parentheses are full CI estimate energies

	$^2A'$ (n,∞)		$^2A''$ (π,∞)	
	Treatment[a]	MRD-CI (Full CI)	Treatment	MRD-CI (Full CI)

H_2SiPH^+ (NO's)	4M1R 226016/6233 (90.65%)	10.09 (10.11)	5M1R 250482/5911 (91.31%)	8.80 (8.87)

[a]The notation is the same as in Table 4. The MO's of the neutral ground state are used in each case ($T = 5\mu H$, except for H_2SiPH^+ (MO's), with $T = 7.5\ \mu H$).

TABLE 11. Calculated term values and quantum defects (δ) for the lowest Rydberg series (values in cm^{-1})

	H_2CNH		H_2CPH		H_2SiNH		H_2SiPH	
	Term value	δ	Term value	δ	Term value	δ	Term value	δ
$n\rightarrow s$	27830	0.99	27260	1.99	29680	2.08	24600	1.89
$n\rightarrow p_\pi$	21450	0.73						
$\pi\rightarrow s$	29520	1.07	27500	·2.00	30330	2.09	26580	1.97
$\pi\rightarrow p_\sigma$	23300	0.83						
$\pi\rightarrow p_\pi$	21450	0.73						

$\pi-\pi^*$ splitting relative to the separated $3p\pi$ value.

In diatomics these trends cause, for example, a decrease in the energy separation between $X^2\Sigma^+$ $(\sigma\pi^4)$ and $^2\Pi$ $(\sigma^2\pi^3)$ states in the series of diatomics CN, CP, SiN, and SiP (9) which is around 9000 cm^{-1} to 7000 cm^{-1} for CN and CP respectively, 1000 cm^{-1} in SiN, and negative in SiP, i.e. $X^2\Pi_i$ is the ground state in SiP, and $A^2\Sigma^+$ the low-lying excited state. Similar behavior was earlier reported (6) for the series C_2, CSi, and Si_2 with the states corresponding to the electronic configurations π^4, $\sigma\pi^3$, $\sigma^2\pi^2$ or the corresponding negative ions C_2^- (45), CSi^- (4, 46), and Si_2^- (5). The increased π^* stability can be seen from the relative separation between $^4\Pi$ $(\sigma^2\pi^2\pi^*)$ and $^4\Sigma^+$, $^4\Delta$, $^4\Sigma^-$ $(\sigma\pi^3\pi^*)$, which is of the order of 4.5–4.6 eV in the light CN radical, compared to 2.0–3.0 eV predicted for the silicon compounds SiN and SiP (9).

In the H_2ABH systems treated in the present work these general trends can be seen in the relative position and ordering of low-energy excited states as well as in the ionization potentials (Figs. 1, 3, 6). The complementary behavior of π and π^* (decrease and increase in stability) by replacement of a first by a second-row atom is quite apparent from Fig. 1. The n orbital as the in-plane π^* component is lower than the out-of-plane π^* due to hydrogen admixture but otherwise shows a similar behavior relative to π, as does π^* with the exchange of first by second-row atoms, and as a result the n MO is below π in all the compounds with the exception of H_2CNH. These relative orbital stabilities explain the following various features:

1. The $^3(n,\pi^*)$ is the first excited state only in the first-row compound H_2CNH whereas it is the $^3(\pi,\pi^*)$ which is the lowest excited species in the mixed and second-row molecules; the relative separation between $^3(\pi,\pi^*)$ and $^3(n,\pi^*)$ increases from H_2SiNH to H_2SiPH. The singlet states follow in principle the equivalent pattern whereby singlet–triplet splittings are larger for (π,π^*) than for (n,π^*) states and decrease with increase in the number of second-row constituent atoms.

2. The order of n and π ionization potentials is different in the first-row (H_2CNH^+, X^2A' (n,∞)) and second-row ions (H_2SiPH^+, X^2A'' (π,∞)); both ionic states are well separated, while in the mixed compounds n and π ionization is close in energy.

3. The Rydberg states associated with the $n\rightarrow s_R$ and $\pi\rightarrow s_R$ transitions are shifted relative to one another in analogy to the shift in the corresponding ionization limits. Only for H_2CNH a large interaction between the $^1(\pi,\pi^*)$ valence and the low-lying Rydberg states is found.

Comparison of H_2CNH with H_2CO on the one hand and H_2SiPH and H_2CS on the other shows a relatively large similarity. In H_2CO the $^1(\pi,\pi^*)$ state is found quite close to the $n\rightarrow\infty$ ionization limit, while this state is definitely below ionization in H_2CS (47) and $(CH_3)_2$ CS (48). Both studies have found that semidiffuse $3d\pi$ functions are to some extent important for the description of the $^1(\pi,\pi^*)$ state in the vertical energy range;

since no such functions are included in the present treatment, there might be some doubt as to the reliability of the $^1(\pi,\pi^*)$ energies. On the other hand, all Rydberg states in H_2CPH, H_2SiNH, and H_2SiPH are found above the $^1(\pi,\pi^*)$ state in the vertical energy region so that it is expected that $3d\pi$ functions are less important than in the sulfur compounds.

Finally, it should be mentioned that the magnitude of the ionization potentials and, with it, the absolute location of the Rydberg states depends quite substantially on the character of the atomic species or radicals attached to the C=N group: in higher azomethines the alkyl groups influence the relative position of the n and π MO's considerably, as deduced from the lower values of the IP's compared to that of the simplest member H_2CNH. Furthermore, the present work has treated only the nuclear arrangement H_2ABH in the comparative study and has entirely neglected the possibility of $HABH_2$ or other structures. Calculations carried out on various germanium species (24, 49) have indicated that the isomers $HGeNH_2$ or HGeOH are more stable, by about 32 kcal/mol or 20 kcal/mol respectively, than their H_2GeNH or H_2GeO counterparts.

Acknowledgments

The present authors as well as other members of this laboratory wish to thank Prof. C. Sandorfy for many pleasant and fruitful discussions over the past ten years and for his continuous interest in our work. The computer time necessary for the present study was supplied by the University of Bonn Computer Center, and for H_2SiPH by the Perkin–Elmer 3242 at Wuppertal sponsored by the Deutsche Forschungsgemeinschaft in the framework of the Sonderforschungsbereich 42.

Bonding in H_3AB compounds

MICHAEL W. SCHMIDT AND MARK S. GORDON
Department of Chemistry, North Dakota State University, Fargo, ND 58105, U.S.A.

Received August 16, 1984

This paper is dedicated to Professor Camille Sandorfy on the occasion of his 65th birthday

MICHAEL W. SCHMIDT and MARK S. GORDON. Can. J. Chem. **63**, 1609 (1985).

The nature of binding in the 14 valence electron H_3AB molecules is examined, where A and B are taken from the second and third rows. The AB bonding is inferred from the computed structures, *d* orbital populations, and localized orbitals. Near Hartree–Fock results are reported for the strongest bonding compounds, which are those with third row atoms A, and second row atoms B. Phosphine oxide, and to a lesser extent phosphine sulfide, are found to be effectively doubly bound. Amine oxide and sulfide are found to be ionic complexes. The thiazyl bond is confirmed as triple in nature. The exotic compound F_3IC is proposed as a synthetic target.

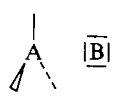
MICHAEL W. SCHMIDT et MARK S. GORDON. Can. J. Chem. **63**, 1609 (1985).

On a étudié le mode de liaison dans les molécules H_3AB à 14 électrons de valence dans lesquelles A et B sont des éléments des deuxième et troisième rangées. On déduit la nature de la liaison AB à partir des structures calculées, des populations des orbitales d et des orbitales localisées. On rapporte des résultats obtenus par une technique se rapprochant de celle de Hartree–Fock qui a été appliquée aux composés comportant les liaisons les plus fortes et qui sont ceux impliquant des atomes A de la troisième rangée et des atomes B de la deuxième rangée. On a trouvé que l'oxyde de phosphine et, à un degré moindre, le sulfure de phosphine comportent effectivement des doubles liaisons. On a trouvé que l'oxyde et le sulfure d'amine sont des complexes ioniques. On a confirmé que la liaison du thiazyle est triple. On suggère que le composé exotique F_3IC devrait s'avérer un but de synthèse intéressant.

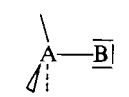
[Traduit par le journal]

Introduction

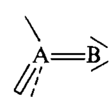
Recent investigations in our group (1–3) dealing with the bonding in phosphoryl compounds have centered in part on the degree of multiple bonding present. For a compound such as H_3AB, with 14 valence electrons, the following bonding schemes may be considered (nominal bond orders are given under each structure):



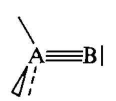
0



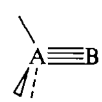
1



2



3



4

Structures **2**, **3**, and **4** contain hypervalent A atoms, which must use their *d* orbitals in binding in order to achieve the indicated expansion of their octets (4). The double and quadruple bonding structures shown above cannot be used in a description of binding, as the molecules to be considered here all possess three-fold rotational symmetry. Thus, any π binding present in addition to a σ bond is due to *e* symmetry orbitals, which of course come in pairs. Our findings for H_3PO (1, 3) and related substituted compounds (3) have shown that phosphine oxides are actually resonance hybrids between singly and triply bound structures. Thus, the effective (compromise) bond order in phosphine oxides was found to be somewhat less than two (3). In the present paper, we examine the bonding of phosphine oxide by comparison with a number of valence isoelectronic molecules.

Consider the following sequence of compounds: F_3SiF (tetrafluorosilane), F_3PO (trifluorophosphine oxide), and F_3SN (thiazyltrifluoride). The AB electronic structure in these molecules is usually depicted as single, double (5), or triple (6) bonding, respectively. These rather different bonding schemes are based on the normal valency of the atom B (F, O, or N), and on the experimental observation that the AB bond lengths decrease throughout this series. However, this sequence can be viewed in a more unified fashion, with each new member generated by transferring a proton from the nucleus of atom B to A. There are other similarities, as might be expected from their isoelectronic nature. All three compounds are gases at normal temperatures, and they possess quite strong AB bonds. The experimental SiF, PO, and SN bond strengths are 135 (7), 130 (7), and 93 (6) kcal/mol, respectively. (It is interesting that the bond strengths decrease in going from "single" to "double" to "triple".) The three compounds are also quite stable. For example, F_3SN will not react with metallic sodium below 300°C (6). In view of these similarities, and because of our finding (1, 3) that phosphine oxides possess bonding intermediate between single and triple bonding, one wonders whether or not the binding is similar in these compounds.

It is also obvious that the sequence F_3SiF, F_3PO, F_3SN of experimentally well characterized compounds may be extended in either direction, to hypothetical compounds. F_3AlNe contains a weak bond formed by donation of the rare gas lone pair to the σ accepting aluminum. An even more intriguing possibility is F_3ClC, an example of a "quadruply" bonded carbon at the exposed end of a molecule.

The atoms A and B in compounds such as these may also be chosen from different rows of the periodic table. For example phosphine sulfides and amine oxides are well known. We have considered most possible combinations of compounds with the atoms A and B chosen from the second and third rows of the periodic table. For simplicity the ligands to A have been chosen to be hydrogens, rather than fluorines.

Computational method

These compounds have been studied only at the Hartree–Fock level, and only the ground $^1A_1$ electronic states

[a] Distances in Å, angles in deg, energies in Hartrees, and vibrational frequencies in wavenumbers. All results are from basis I.

[b] This species is unstable with respect to a degenerate bend, as discussed in the text. All other species have positive definite force fields.

have been considered. The more exotic compounds, such as H_3ClC, have not been tested for the possibility of ground states of other space-spin symmetries. The stability of the singlet molecules was tested by calculation of the vibrational frequencies and normal coordinates.

Basis set I, used for structure determination, is the 3-21G basis (8), with polarization functions added to both atoms A and B. The d orbital exponents for second row atoms are taken from Hay and Dunning (9), and for the third row from Francl *et al.* (10). This basis, while it should give accurate structures, has three deficiencies: a relatively small sp basis on each atom, only one set of d orbitals on atom A to describe its possible hypervalent bonding, and no diffuse functions on atom B to describe its possible anionic character. These defects are ameliorated by basis II, which starts from the even-tempered bases of Schmidt and Ruedenberg (11). The hydrogen basis is $(4s/2s)$, scaled by 1.2. First row atomic bases are $(12s,6p/3s,2p)$ and third row atomic bases are $(16s,11p/4s,3p)$. These bases approach the atomic Hartree–Fock limits to within 5 millihartree. The single d exponent at atom A in basis I is split by the factors 0.4 and 1.4 to give two sets of d primitives at A, while atom B receives only a single set of d orbitals. The single d exponents are chosen as for basis I. s and p primitives, with exponents equal to the even-tempered parameter α, are added to the atom B so that the diffuse nature of a negatively charged B will be better represented. This basis is chosen so as to give very accurate Hartree–Fock electron densities for the AB bond. It describes the AH bonds less well due to the omission of p orbitals on hydrogen. For both bases the $3s$ contaminant of the Cartesian d orbitals was discarded.

The nature of the AB bonding is determined by means of Mulliken population analysis (12), and the determination of energy localized orbitals (13). Geometry optimizations and harmonic vibrational analysis were carried out using the GAUSSIAN 80 (14) series of programs. The ALIS program system (15) was used for energy and localized orbital calculations with basis II.

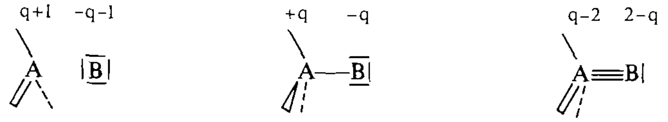
Results and discussion

Structures

The equilibrium geometries computed with basis I are shown in Table 1. The HAH angles may be readily obtained from the data in Table 1 by the formula

$$\angle HAH = \cos^{-1}[1 - 1.5\sin^2(180 - \angle HAB)]$$

In Table 1, q is the formal charge on atom A in the singly bound resonance structure. The value of q is also related to the formal charges present in the zero or triply bound structures:



The structures in Table 1 were computed using basis I, which contains d orbitals on both atoms A and B, as both sets do affect the AB length. Bases without d orbitals at hypervalent centers give rather inaccurate bond lengths (16). Using d orbitals at atom B does have an effect on the AB distance, although much smaller than those at A. For example, the 3-21G* basis set (16*a*), containing d orbitals only on P, gives a PO bond length of 1.470 Å for H_3PO (2). This shrinks further to 1.459 upon adding d orbitals at oxygen.

Consider first columns of constant q within Table 1. For the rare gas to AlH_3 or BH_3 complexes ($q = -1$), the AB distances are quite long, and the HAB angles nearly 90°, indicating little binding interaction. The strongest interaction is in H_3AlNe, whose AB distance is actually less than that in H_3BNe, and whose HAB angle departs most from a right angle. The AB bond strength can be made more quantitative. Basis I gives bond lengths of 1.190 and 1.585 for BH_3 and AlH_3, with total energies -26.24886 and -242.30990, respectively. These results give the following AB bond energies: H_3BNe, 4.9 kcal/mol; H_3AlNe, 8.1; H_3BAr, 0.9; and H_3AlAr, 1.6. Neon is a better σ donor, aluminum a better acceptor.

There are no surprises in the $q = 0$ column, where HAB angles are nearly tetrahedral, and bond lengths are easily rationalized as sums of atomic radii.

Examination of the $q = 1$ column is more interesting. When A is phosphorus, the HAB angle increases from the tetrahedral values in the preceding column, and the AB distance contracts. This may be explained by the mixing in of a certain amount of triple bond character which should shorten the AB bond. Also, as atom A expands its octet the HAH angles must decrease. If, however, A is nitrogen, the HAB angle remains nearly tetrahedral and the AB distance increases slightly from the $q = 0$ column. Their structures indicate that the amine chalconides are singly bound ionic complexes, while the phosphine chalconides acquire at least some multiple bond character.

The discrepancy between second and third row central atoms becomes even more pronounced upon entering the $q = 2$ column. Here the compounds with central oxygen atoms do not exist as minima on the SCF potential energy surfaces. Instead geometry optimizations of trial structures revert to the amine or phosphine oxide. The failure to find stable compounds is somewhat surprising. H_3ON seems less exotic if thought of as a complex of hydronium ion with a nitrogen anion. The compounds with central sulfur atoms are a different matter, as they continue the trend of shortening AB distances and greater HAB angles as the AB bonding gains yet more triple character.

Finally, there are two compounds with $q = 3$. In light of the failure to find molecules with central oxygens, no attempt was made to find the two compounds with central fluorines. The molecules with central chlorines have slightly longer AB bonds than in the previous column, thus ending the trend to ever shorter bond lengths. However, the HAB angles continue their increase. Thus the structures indicate binding in the $q = 3$ column is similar to that in the previous column. Compared to methylchloride in column 0, the ClC bond is very short. The vibrational analyses described below indicate that H_3ClSi is unstable with respect to a degenerate e symmetry bend, while H_3ClC is indeed a stable molecule.

Vibrational analysis

A complete normal coordinate analysis in the harmonic approximation for all the molecules considered here was performed using basis I. All of the molecules save H_3ClSi were found to possess all real frequencies. Thus all but one of these molecules correspond to a relative minimum on their SCF potential energy surfaces. These are therefore at the least thermodynamically stable, no matter how exotic some may seem, and may perhaps be kinetically stable.

The computed AB stretching frequencies have also been included in Table 1. The differing effective masses in each mode make comparison of the stretching frequencies wihin a given column impossible. However, it should be possible to compare the values for a given row of this table, where at least the atoms A and B have similar masses. Such a comparison indicates that the amine chalconides have weaker AB bonds than the methyl halides, while the phosphine chalconides possess greater stretching frequencies than the silyl halides. Furthermore, the compounds H_3SN and H_3ClC possess stretching frequencies greater than silylfluoride. Bond strengths cannot be directly inferred from stretching frequncies (recall that the experimental bond strengths are in the order $F_3SiF > F_3PO > F_3SN$). However, the stretching frequency for H_3ClC indicates a considerable strength for this bond. It is interesting to note that H_3SN and H_3ClC have greater stretching frequencies than do H_3NS and H_3CCl, in spite of having considerably higher energies. This is an expression of the multiple character of these bonds.

H_3ClSi has an imaginary degenerate bending frequency of $893i$ cm^{-1}. This means this molecule is unstable with respect to such bending, and is therefore unisolable. The lowest normal mode in H_3ClC is also a degenerate bend, but with a real frequency 589 cm^{-1}. The stability of the carbide with respect to bending in contrast to the silicide's instability is a reflection of the reluctance of silicon to hold a negative charge.

Charge distributions

Further enlightenment into the AB bonding can be gleaned from the charge distributions found in Table 2. First consider the d orbital populations given in parentheses. The d orbital population of atom A is invariably greater than that of B. This is to be expected, as A forms more bonds than B and thus deforms its electron density more. Furthermore, A uses its d orbitals to participate in any hypervalent bonding. (Remember though that the seemingly less important d orbitals on B do affect the AB bond lengths.) The d orbital populations of A reveal much the same information on the AB binding as did the structures discussed above. When A is a third row atom, the d population of A increases steadily across the rows, tailing off only at H_3ClC and H_3ClSi. This shows the same increase in hypervalence, and hence multiple bond character already indicated by the decreasing AB bond lengths and increasing HAB angles. However, the molecules H_3NO and H_3NS show no increase in the N d population over their carbon neighbors. This reflects the not surprising fact that the d orbitals of nitrogen are energetically nearly inaccessible for binding, in spite of their shortening effect on the NO and NS bond lengths. Note, however, that amine oxide shows more multiple character than amine sulfide.

The total charges given in Table 2 are more difficult to interpret. The idealized charges shown in the resonance structures above are altered in reality by (*i*) mixing of the zero, singly, and triply bound structures, and (*ii*) polarization within the bonds. When the vagaries of the arbitrary Mulliken par-

[b] See note *b* of Table 1.

titioning of the overlap populations is added, especially in the AH bonds, the total Mulliken charges are indeed difficult to interpret. The charge on atom B is a much better indicator of the AB charge separation than the charge on A, since the latter is also related to the AH charge separation.

In the $q = -1$ column, the charge on atom B is nearly zero rather than the +1 expected for a single bond. Thus, the bond order must be nearly zero. This is in keeping with the structural data and chemical intuition. Note that the most positive B occurs in H_3AlNe, which as already noted, does contain the strongest AB interaction.

The negative charges on B in the $q = 0$ column of Table 2 are more reasonably explained as a result of polarization of the single bonds in these compounds rather than admixture of the formally −2 B atoms in the triply bound resonance structure.

In the $q = 1$ column, atom B should possess a charge somewhere between the −1 value in the singly bound structure and the +1 value in the triply bound structure. As B possesses a substantial negative charge in all the compounds in this column, the singly bound contributor seems to dominate the position of the compromise between these resonance structures. Since these formal charges ignore the polarization of the bonds that certainly occurs, the charge populations reveal less about the bonding than do the structures and *d* orbital occupancies. The latter clearly indicate no appreciable multiple character for A = N, with at least some multiple bonding for A taken as phosphorus.

Were the bonding in the $q = 2$ column pure triple bonding, atom B would have zero charge. In fact the polarization of the SN bonds leads to a rather negative nitrogen, but less so than for oxygen in the previous column. Perhaps a fairer test is afforded by H_3SP, where the AB electronegativity difference is less than that for H_3SN. Phosphorus is indeed less negative here.

Although carbon and silicon should bear a unit of negative charge in the $q = 3$ column for triple AB binding, polarization of these bonds leads to considerably smaller negative charges. Note that silicon is able to carry only a very small negative charge in H_3ClSi, which no doubt contributes to the bending instability of this species.

Localized orbitals

A useful way of determining the nature of binding is the localization of the orbitals forming the SCF wavefunction. The concentration, or localization, of each electron pair into a particular spatial region of the molecule facilitates the interpretation of these pairs as bonds, nonbonding lone pairs, and so forth, while leaving the total many electron wavefunction unchanged. Since the bonding apparently changes dramatically from column to column, changes in the localized orbitals should reveal pictorially the changing nature of the AB bond. The molecules in the second row of Tables 1 and 2 contain the greatest potential for strong AB bonds. They have third row atoms A, possessing accessible *d* orbitals. They also have the more electronegative second row atoms B, favorable since the majority of these molecules have negatively charged atoms B. Thus, localized orbitals have been generated only for molecules in this row.

Calculations were carried out on these molecules with basis II and should represent near Hartree–Fock basis set limits for the electron densities. Hypervalent character in the AB bond should be well represented, as the atoms A possess twin *d* orbitals. Energies and Mulliken populations are shown in Table 3. Note that this basis gives *d* orbital populations approaching a full electron for the hypervalent H_3SN and H_3ClC. The *d* population of phosphorus in phosphine oxide is increased 54%

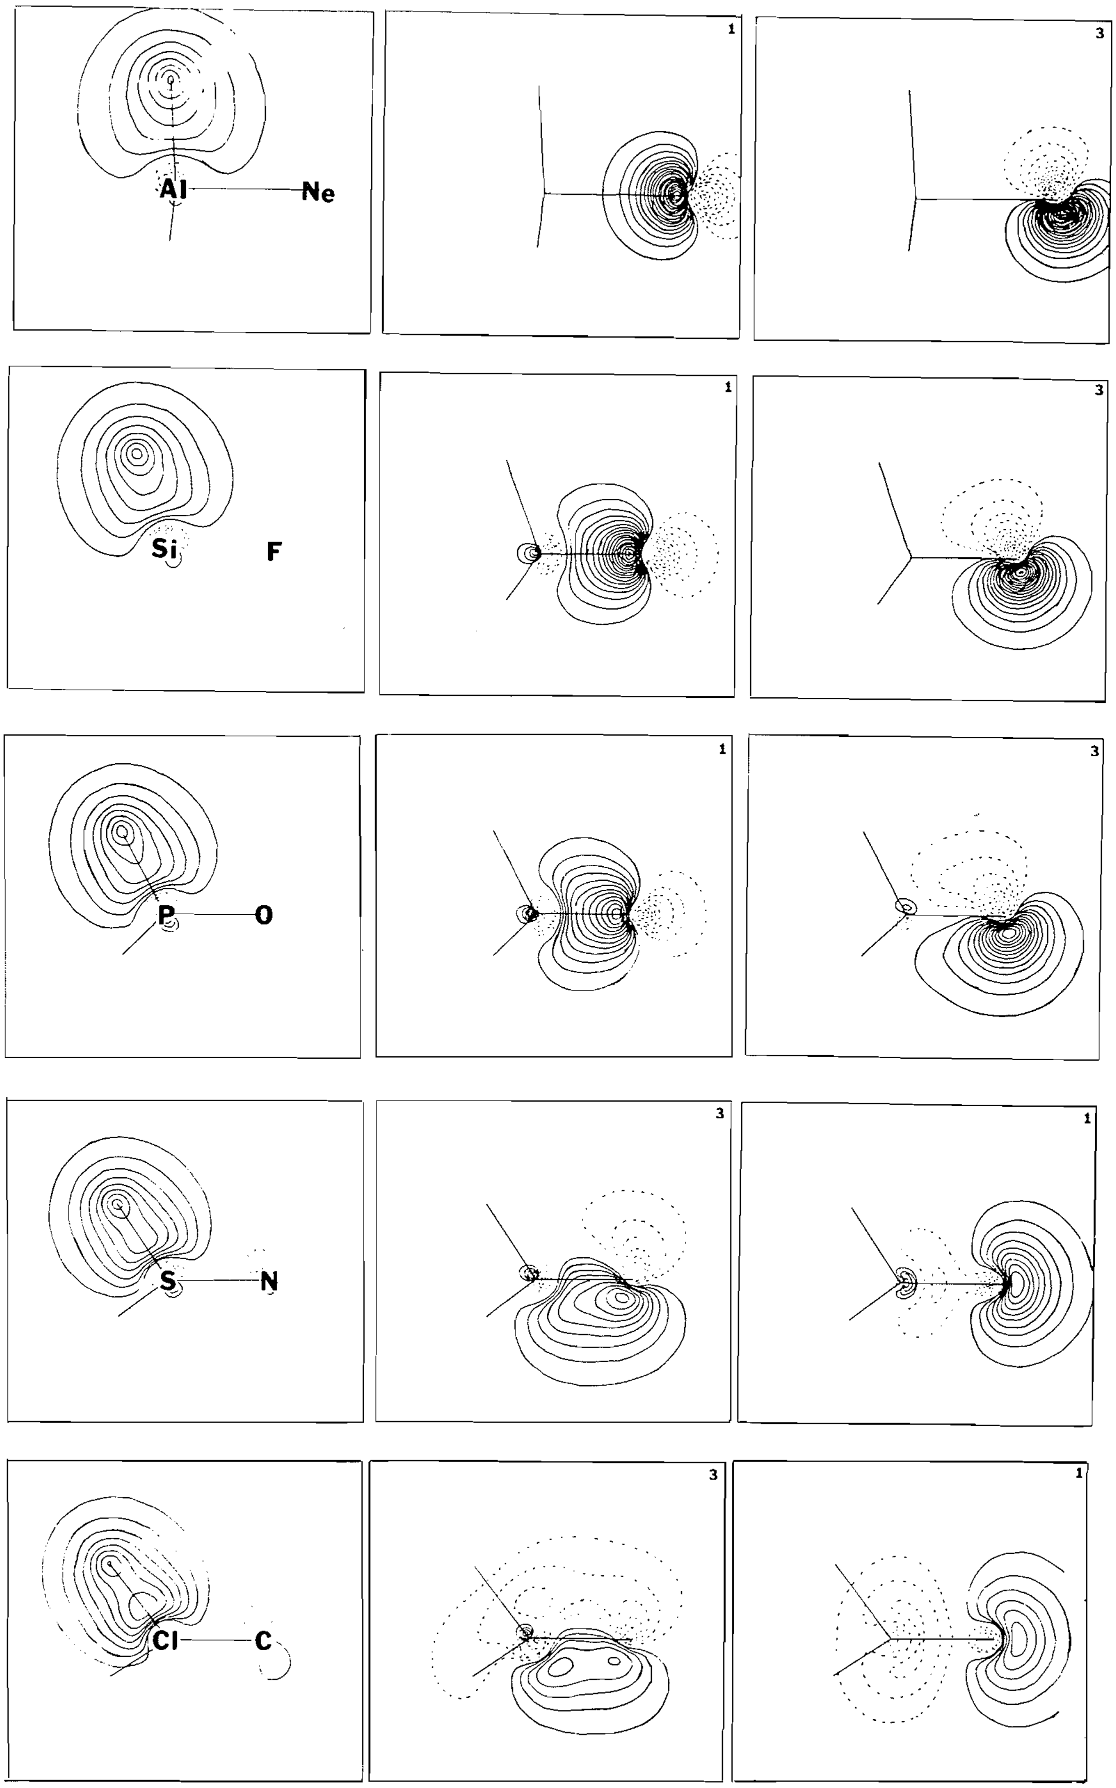

FIG. 1. Contour plots for energy localized orbitals, expanded in basis II. The increment between contours is 0.05 bohr$^{-3/2}$. The numerals indicate how many equivalent orbitals there are of each type.

[a] All results taken from basis II. Energies are in hartrees.
[b] Gross Mulliken atomic charge, with *d* orbital population in parentheses.

of the way from singly bound H_3SiF towards triply bound H_3SN.

The localized orbitals themselves are shown in Fig. 1. Care has been taken in these plots to use identical distance scales, with atom A centered. The contour increments are the same in all plots, to facilitate comparison. Positive amplitudes are shown as solid curves, and negative amplitudes as dashed lines. Nodes, or regions of zero amplitude, are shown as dotted lines. Electron densities are, of course, given by the square of the amplitudes.

The first column shows one of the three equivalent AH bonds. The increase in the HAB angles as A becomes more hypervalent is quite apparent. One can also see the polarization of the AH bond change as A becomes more electronegative.

The second column in the figure shows the orbitals responsible for the AB bonding. For H_3AlNe the orbital is completely polarized to neon. This is not really a bond at all, but rather a lone pair on neon donating a nearly invisible amount of electron density to the accepting *p* orbital of AlH_3. The σ bond in silyl fluoride is quite polarized. The σ bond in phosphine oxide is less polarized. Upon reaching H_3SN, the bonding changes in an apparently dramatic fashion, with three equivalent bond pairs, arranged staggered with respect to the three SH bonds. Thus the bonding in this molecule has become triple. H_3ClC closely resembles H_3SN, except that the bonds are more polarized to the central atom. Thus, the bonding in this molecule is also triple.

The final column of the figure shows the nonbonding orbitals on B. There are three on neon and fluorine, and one on nitrogen and carbon. It is not entirely accurate to describe the three lone pairs on oxygen in H_3PO as nonbonding for they clearly show some donation of electron density to phosphorus. This $p_\pi - d_\pi$ backdonation to the phosphorus is responsible for the great strength of the PO bond, and is discussed in detail elsewhere (3). The PO bond is clearly more than a single bond while not yet the triple bond found in H_3SN.

The transition from single to triple bonding begins to appear in H_3PO. If the three lone pairs on oxygen were to be tipped in towards P, so that they might share their electron density more effectively with P, one would arrive at orbitals much like the three bonding orbitals in H_3SN. If at the same time the positive bulk of the PO σ bond were diminished, while the negative lobe beyond the oxygen increased, this orbital would become the unique lone pair in H_3SN. In fact, we have shown (3) that the $p_\pi - d_\pi$ interaction increases as more electronegative ligands are attached at phosphorus. As a result of this increased backbonding for F_3PO the localized orbitals yield three bonding orbitals between P and O, and a single nonbonding orbital on oxygen. Thus the phosphine oxides appear intermediate between single and triple binding. Less electronegative ligands (H, CH_3, SiH_3) give localized orbitals resembling single bonds with some π interaction, while more electronegative ligands (OH, F) give just enough additional bonding to give orbitals resembling the triply bound H_3SN (3).

The geometry, *d* orbital populations, and localized orbitals presented here indicate phosphine oxide and sulfide are poised on the edge dividing singly and triply bound compounds such as H_3SiF and H_3SN. An appropriate way to view their bonding is as effectively double bonding, that is possessing roughly equal contributions from the two group theoretically allowed bonding schemes, single or triple. Phosphine sulfide has somewhat less hypervalent character than phosphine oxide.

The sequence of compounds whose localized orbitals were presented can be thought of as arising from the sequence AlF_3, SiF_4, PF_5, SF_6, and ClF_7, all of which exist save the last. The compounds we have considered can be formed by replacing 0, 1, 2, 3, or 4 fluorines with Ne, F, O, N, or C, and replacing the remaining fluorines with the less stabilizing ligand hydrogen. As shown in Table 1, H_3ClC is very much less stable than the conventional isomer H_3CCl. However, this does not preclude the existence of such carbides, as H_3ClC was shown here to be a relative energy minimum, with a strong ClC bond. After all, F_3SN exists and is quite stable, even though H_3SN is less stable than H_3NS. If a synthesis of a molecule in the H_3ClC family were attempted, efforts should be directed at F_3IC, whose parent interhalogen IF_7 is already known. Such a carbide would likely be very reactive, and might well demonstrate a unique chemistry.

Integrated dipole oscillator strengths and dipole properties for Ne, Ar, Kr, Xe, HF, HCl, and HBr

ASHOK KUMAR[1,2] AND WILLIAM J. MEATH[2]
Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 3B7

Received August 16, 1984

This paper is dedicated to Professor Camille Sandorfy on the occasion of his 65th birthday

ASHOK KUMAR and WILLIAM J. MEATH. Can. J. Chem. **63**, 1616 (1985).

Dipole oscillator strength distributions have been constructed, and used to evaluate integrated dipole oscillator strengths and a variety of dipole oscillator strength properties, for ground state Ne, Ar, Kr, Xe, HF, HCl, and HBr. Each distribution has been constructed by using experimental and theoretical photoabsorption cross sections and by subjecting the resulting dipole oscillator strength data to constraints provided by the Thomas–Reiche–Kuhn sum rule and molar refractivity or related data for the relevant dilute gases. The resulting dipole properties are generally the most or only reliable values available for the hydrogen halides, for the rare gases they largely augment reliable results for most of the properties already available in the literature. The results for HCl are used to discuss an interesting molecular effect in the photoabsorption spectrum of this molecule betwen ~200 eV and ~205 eV.

ASHOK KUMAR et WILLIAM J. MEATH. Can. J. Chem. **63**, 1616 (1985).

On a établi les distributions des forces d'oscillateurs dipolaires et on les a utilisé pour évaluer, pour les états fondamentaux de Ne, Ar, Kr, Xe, HF, HCl et HBr, les forces intégrées d'oscillateurs dipolaires ainsi qu'une variété de propriétés associées avec la force d'oscillateurs dipolaires. On a établi chaque distribution en faisant appel aux valeurs expérimentales et théoriques des sections droites de photoabsorption et en soumettant les données relatives aux forces d'oscillateurs dipolaires qui en résultent aux contraintes qui sont fournies par la règle des sommes de Thomas–Reiche–Kuhn et aux réfractivités molaires ou aux données apparentés pour les gaz dilués appropriés. Dans le cas des halogénures d'hydrogène, les propriétés dipolaires qui en résultent sont généralement les seules valeurs disponibles ou les plus fiables; pour les gaz rares, les résultats fiables sont grandement augmentés pour la plupart des propriétés qui sont déjà disponibles dans la littérature. On a utilisé les résultats obtenus avec le HCl pour discuter d'un effet moléculaire intéressant dans le spectre de photoabsorption de cette molécule entre environ 200 et 205 eV.

[Traduit par le journal]

1. Introduction

The accurate *ab initio* or direct experimental evaluation of many of the dipole properties for most atoms and molecules is a very difficult problem (1–7). On the other hand, a combination of experimental information and theoretical techniques can be used to evaluate many important dipole properties in a reliable way through the construction of globally reliable dipole oscillator strength distributions (1, 7–14). The main purpose of this paper is to present integrated dipole oscillator strengths and reliable values for the dipole oscillator strength sums S_k, $k = -10(1)-4, -3(\frac{1}{2})0$, 1, and 2, and the logarithmic dipole sums L_k, $k = -2(1)2$ for HF, HCl, HBr, Ne, Ar, Kr, and Xe.

The relationship between the dipole oscillator strength distribution (DOSD) and the dipole properties for a particular atom or molecule, and the method used to construct the DOSD are discussed in Section 2. The discussion includes a brief summary of various uses of the dipole properties and an outline of how experimental and theoretical dipole oscillator strength data, coupled with quantum mechanical constraint procedures using the Thomas–Reiche–Kuhn sum rule and molar refractivity or related data as constraints, can be used to evaluate reliable values for the dipole properties. The experimental and theoretical input data used to construct the DOSDs for the hydrogen halides, and the integrated oscillator strengths and the dipole properties for these molecules, are discussed and given in Section 3; the values for most of the dipole properties are the most reliable available. The results are used to augment and assess the molar refractivity data for these molecules as a function of wavelength λ and to discuss the oscillator strength data for HCl and HBr; of particular interest is a molecular effect occurring between ~200 eV and ~205 eV in the photoabsorption spectra of HCl. The adopted integrated DOSDs and dipole properties of the four rare gases studied here are given in Section 4. For common values of $k \le 0$ our results are usually in very good agreement with those of Leonard and Barker (11) and Leonard (15). Generally, significant improvements relative to their work is obtained only for $k > 0$. A discussion of our adopted results for the dipole properties of HF, HCl, HBr, Ne, Ar, Kr, and Xe, including a comparison with typical literature values, is given in Section 5. Literature results used explicitly to construct the DOSDs are discussed in Sections 3 and 4.

2. Relationship between DOSDs and the dipole properties

Properties

Knowledge of the dipole oscillator strength distribution (DOSD) for a molecule permits the evaluation of a variety of dipole properties for the molecule. Those of interest for this paper are the dipole sums S_k, the logarithmic dipole sums L_k, and the mean excitation energies I_k, defined by

$$[1]\quad S_k = \int_{E_0}^{\infty} \left(\frac{E}{2R}\right)^k \left(\frac{\mathrm{d}f}{\mathrm{d}E}\right) \mathrm{d}E$$

$$[2]\quad L_k = \int_{E_0}^{\infty} \left(\frac{E}{2R}\right)^k \left(\frac{\mathrm{d}f}{\mathrm{d}E}\right) \ln(E)\, \mathrm{d}E$$

$$[3]\quad I_k = 2R \exp\,[L_k/S_k]$$

where E_0 is taken to be the electronic absorption threshold, R

[1]On leave from the Department of Physics, Meerut University, Meerut, India.

[2]Associated with the Centre for Interdisciplinary Studies in Chemical Physics, University of Western Ontario, London, Ont., Canada N6A 3K7.

is the Rydberg constant of energy, (df/dE) is the differential dipole oscillator strength of the molecule for excitation energy E, and k can take on many different values (1, 7–14, 16, 17). Equations [1]–[3] are written for a continuous distribution of oscillator strengths. If the DOSD is made up of discrete and continuous parts these results should be modified such that, for example,

$$[4] \quad S_k = \sum_i \left(\frac{E_i}{2R}\right)^k f_i + \int_{E_0}^{\infty} \left(\frac{E}{2R}\right)^k \left(\frac{df}{dE}\right) dE$$

with a similar equation applying for L_k. In [4] the sum is over the discrete transitions for the molecule and E_0 is the absorption threshold for the continuum part of the DOSD. Usually the DOSD for a molecule is continuous in nature while that for an atom also contains a discrete part. The dipole properties defined by [1]–[4] are important in a variety of fields (1, 16, 17). For example, (a) the straggling (I_1, S_1), and the stopping (I_0), and the total (I_{-1}, S_{-1}) inelastic scattering cross sections, of fast charged particles in matter; (b) dipole polarizabilities $\alpha_d = a_0^3 S_{-2}$, where a_0 is the Bohr radius; (c) charge densities at nuclei (S_2); (d) Lamb shifts (I_2); (e) moments of the DOSD (S_{-2}, S_{-4}, S_{-6}, ...) occur in the Cauchy expansion of the frequency dependent polarizability or the molar refractivity (see below) of atoms or molecules; (f) S_{-1}, S_{-3}, $S_{-3/2}$, and L_{-2} can be used to obtain estimates for the dipole–dipole dispersion energies between atoms and molecules (12); and (g) the relevance of accurate results for the dipole properties in testing *ab initio*, non-empirical or other methods for evaluating the properties is well established (1, 5, 6, 12, 18), see also what follows.

Construction of DOSDs

The evaluation of the dipole properties is straightforward if reliable values for the dipole oscillator strengths (DOSs) are available from the absorption threshold to very large values of the excitation energy; for a discussion of the dependence of the dipole properties on the various spectral regions of the DOSD, see refs. 1, and 19 to 21. Unfortunately, there is often a lack of accurate DOS data over important photon energy regions for many interesting atoms and molecules. Also typical errors in DOS data ranges between 5–20% even for good oscillator strength data.

The procedure used to construct a dipole oscillator strength distribution for a given molecule from an initial data base of (df/dE) versus E values has been discussed in detail previously (13, 14), see also the discussion in ref. 22. The excitation energies for a given molecule are divided into N regions from the absorption threshold E_0 to very large values of E. The initial dipole oscillator strength data for the jth spectral region is modified according to

$$[5] \quad (df/dE)^j_{\text{mod}} = (1 + a_j)(df/dE)^j_{\text{initial}}, \qquad j = 1, 2, \ldots, N$$

so that the complete modified DOSD satisfies certain constraints through the choice of the a_j. If the input data contains discrete transitions, a parameter a_j is associated with each such transition.

The constraints used are furnished by the Thomas–Reiche–Kuhn sum rule (for a review of oscillator strength sum rules, see ref. 16), $S_0 = Z$ where Z is the number of electrons in the molecule, and preferably by two values of the molar refractivity R_λ of the relevant dilute gas corresponding to well separated wave lengths λ_1 and λ_2. If λ_2 and λ_1 are too close, $\Delta R_\lambda = R_{\lambda_2} - R_{\lambda_1}$ can become on the order of the experimental error in the refractivity data and the constrained least squares procedure used to determine the a_j cannot be carried out (19, 22). In such cases one value of R_λ, or the value of α_d or R_∞, can be used as a constraint with little loss in the reliability of many of the properties determined from the DOSD (22). The molar refractivity is related to the refractive index of the gas $n(\lambda)$, and to the frequency dependent or dynamic dipole polarizability $\alpha_d(\lambda)$ of the molecules making up the gas, by

$$[6] \quad R_\lambda = \frac{1}{\rho}\left[\frac{n^2(\lambda) - 1}{n^2(\lambda) + 2}\right] = \frac{4\pi}{3} N_A \alpha_d(\lambda)$$
$$= \frac{4\pi}{3} N_A (2R)^2 a_0^3 \int_{E_0}^{\infty} \frac{(df/dE)}{E^2 - (hc/\lambda)^2} dE$$

where ρ is the molar density of the gas, N_A is Avogadro's number, h is Planck's constant, and c is the speed of light. If the DOSD contains discrete transitions, [6] involves a sum over these as well as an integral over the continuum part of the DOSD, see, for example [4].

The constraints S_0 and R_λ are written as a sum of N terms (corresponding to discrete contributions from the discrete transitions and integrals for the continuum part of the DOSD), one for each a_j occurring in [5], and the parameters are determined for each initial DOSD by using the methods discussed in detail in ref. 13.

A DOSD can be constructed for each given initial data base for a given molecule. The total number of DOSDs constructed for a given molecule is given by

$$\prod_{k=1}^{N_{\text{input}}} N_k$$

where N_{input} is the number of input spectral regions and N_k is the number of independent sources of dipole oscillator strength data used for the kth input spectral region. If the N_k are large, choosing $N_{\text{input}} = N$ can lead to a very large number of distributions. In what follows this is reduced to manageable numbers by choosing N_{input} to be considerably less than N.

Each adopted DOSD is represented by a set of data points, E_l and $(df/dE)_l$, for $l = 1,\ldots,N_p \gg N$, and a set of interpolating functions to connect the points. For very high photon energies the differential dipole oscillator strengths are represented by the Born dipole formula (23), $AE^{-3.5}$. The dipole properties are readily evaluated using this representation of the DOSD.

3. DOSDs and dipole properties for HF, HCl, and HBr

The following photoabsorption and fast electron energy loss cross sections σ (proportional to (df/dE)) and dipole oscillator strength data were considered in the construction of the DOSDs:

HF: 8.0–150.0 eV (Carnovale and Brion (24)), 8.0–45.58 eV (Hitchcock and Brion (25)), 11.14–15.96 eV (Salama and Hasted (26)).

HCl: 5.64–11.82 eV (Myer and Samson (27)); 8.0–50 eV (Daviel *et al.* (28)), 200–280 eV (Ninomiya *et al.* (29)), 200–208.7 eV (Hayes and Brown (30)).

HBr: 5.39–7.0 eV (Huebert and Martin (31)), 7.0–100 eV (Brion and Thomson (32)).

For HF the energy loss cross sections (25, 26) have been normalized to the integrated oscillator strength obtained from Carnovale *et al.* (24) for common photon energy regions.

This experimental molecular data was augmented by employing the following mixture rules for relatively high photon energies:

$$[7] \quad \sigma(\text{HX}) = \tfrac{1}{2}\sigma(\text{H}_2) + \sigma(\text{X})$$

TABLE 1. Integrated dipole oscillator strengths for HF*, the absorption edge for HF occur at 684.7 eV [F_K] (34)

	Integrated dipole oscillator strengths		Integrated DOSs for original experimental and/or mixture rule data

*This table contains the oscillator strengths for the adopted DOSD, constrained to $\alpha_d = 5.601a_0^3$ and $S_0 = 10$, constructed by consideration of the initial unmodified experimental or mixture rule DOS data for HF. The references associated with the adopted DOSD indicates the source of the DOS data for the indicated spectral region. Also included are the integrated DOSs corresponding to the DOSD constrained to $\alpha_d = 5.330a_0^3$ and $S_0 = 10$.

where X = F, Cl, or Br. The cross sections for H_2 are taken from the recommended DOSD of Zeiss *et al.* (13) while those for the halides X are from Henke *et al.* (33) for 50–100 eV and Veigele (34) for 100 eV – 100 keV. Because of the structure (29, 30) in the experimental photoabsorption results for HCl for 200–208.7 eV, only the experimental input data is subjected to the constraint procedure for these photon energies. In all cases the Stobbe formula (35) is used to generate the oscillator strength data for $E > 100$ keV. The mixture rule is used explicitly to construct the DOSDs for $E > 150$ eV for HF and for $E > 50$ eV for HCl and HBr.

The number of input spectral regions is chosen to be $N_{\text{input}} \sim 20$. To provide flexibility in applying the constraint procedure discussed in Section 2 the number of parameters a_j was chosen to be ~60, that is $N \approx 60$ in [5]. For each molecule all possible initial DOSDs are employed in the constraint procedure based on the input data associated with $N_{\text{input}} \sim 20$; the total number of initial DOSDs considered varies from ~5200 for HF to 1024 for HCl and HBr. The adopted DOSD for each molecule is that corresponding to the least overall adjustment of the initial DOS input data considered in the constraint procedure as judged by the value of

$$(\text{STD}) = \left[\sum_{j=1}^{N} (a_j - \bar{a})^2/N\right]^{1/2}$$

It is important to emphasize that given DOS input can lead to DOSDs that differ considerably as a function of E while agreeing well globally in that they yield very similar results for a variety of dipole properties (13, 18, 36). The integrated dipole oscillator strengths for each molecule are provided for the input spectral regions.

DOSD and properties for HF

Although there is some refractivity data available for HF, see below, it is rather uncertain and therefore not well suited for providing constraints for the construction of the DOSD for this molecule. Rather, we use as a constraint the value of the static dipole polarizability or S_{-2} determined as described below.

Werner and Meyer (2, 37) have calculated the static dipole polarizabilities α_d for the isoelectronic series Ne, HF, H_2O, NH_3, and CH_4 using both the coupled electron pair approximation (CEPA) and the pseudo natural orbital configuration interaction (PNO-CI) method. Accurate values (Section 4 and refs. 13, 38, 39) of α_d for Ne, H_2O, NH_3, and CH_4 lie between the CEPA and PNO-CI results suggesting that α_d for HF should be between $5.500a_0^3$ (PNO-CI) and $5.670a_0^3$. A plot of the percentage deviation of the accurate values from the mean of the PNO-CI and CEPA results is a straight line for Ne, H_2O, and NH_3 and interpolation yields a result of $5.601a_0^3$ which we use as a constraint for constructing the DOSD for HF. This value agrees with that obtained by interpolation of a plot of the accurate values of α_d, for Ne, H_2O, NH_3, and CH_4, versus the number of protons in the molecule, see also Klein *et al.* (40), and used recently by Brobjer and Murrell (41).

As a check we have estimated S_{-1} for HF from a plot of reliable values (Section 4 and refs. (13, 39)) of S_{-1} for Ne, H_2O, NH_3, and CH_4 versus the number of protons in the molecules. Interpolation of this (essentially) straight line plot yields $S_{-1} = 5.50$ for HF which is in good agreement with the value evaluated from our adopted DOSD for HF, see Table 2.

Integrated dipole oscillator strengths for the adopted DOSD corresponding to the constraints $\alpha_d = 5.601a_0^3$, or $S_{-2} = 5.601$, and $S_0 = 10$ are given in Table 1 and the corresponding

TABLE 2. Some dipole properties S_k and L_k for HF, HBr, and HCl evaluated using the adopted DOSDs for the molecules, also included are the results corresponding to the DOSD for HF that is constrained to $\alpha_d = 5.330a_0^3$

Property	Value			
	HF			
	Adopted	$\alpha_d=5.330a_0^3$	HCl	HBr

dipole properties are given in Table 2.

The experimental situation regarding the refractive index of gaseous HF is summarized in Table 3, which contains results for the molar refractivity obtained from the work of Penning *et al.* (42) and Drummond (43). The few available experimental results are considerably lower than those evaluated from our adopted DOSD, see Table 3; the disagreement is well outside the estimated experimental errors of ~2% for Penning *et al.* (42) and ~5% for Drummond (43). The difficulties in obtaining reliable results for the refractive index of HF have been discussed by these authors and of particular importance is the elimination of dimerization effects.

If anything our adopted value of

$$\alpha_d = \left(\frac{3}{4\pi N_A}\right) R_\infty = 5.601 a_0^3$$

is too high. To illustrate the effect of a lower value of α_d on the results obtained from our constraint procedure we have repeated the calculation associated with our adopted DOSD using $\alpha_d = 5.330a_0^3$ obtained by increasing the value of R_λ obtained from Drummond's result by 5% and by assuming λ = 28 000 Å = ∞. This value of α_d is in reasonable agreement with an additivity estimate of $5.40a_0^3$ obtained by Clark (46) and referred to in Landolt-Bornstein (47).

The integrated DOSs, dipole properties, and R_λ values for the DOSD constrained to $\alpha_d = 5.330a_0^3$ are included in Tables 1–3, respectively. The DOS is affected markedly only for 12.8 eV < E < 16.0 eV and, as expected, this influences the results for the S_k and L_k significantly only for negative values of k. The results for the dipole properties corresponding to the DOSD constrained to $\alpha_d = 5.330a_0^3$ are lower than the adopted results corresponding to $\alpha_d = 5.601a_0^3$; the discrepancies are ~1% for $k = -1/2$, ~4.8% for $k = -2$, ~8% for $k = -4$ and they decrease as k decreases further since the differences between the two DOSDs decreases for E < 13 eV. We prefer the adopted results for the DOSD and the dipole properties for the reasons given previously. The other results for the properties can be regarded as an extreme possibility for lower bounds to our recommended results. A reasonable error estimate, ~±1%, for our adopted value for α_d(HF) is furnished by comparison of the PNO-CI and CEPA results of Werner and Meyer (37).

TABLE 3. Comparison of the values of R_λ, in cm³ mol⁻¹, for HF evaluated using the adopted DOSD with the experimental values obtained from Penning *et al.* (42). The result R (λ = 28 000 Å) = 1.898 cm³ mol⁻¹ has been obtained from Drummond *et al.* (43);[a] the corresponding result for our adopted DOSD is 2.0951 cm³ mol⁻¹; also included in the table are values of R_λ evaluated from the DOSD that is constrained to $\alpha_d = 5.330a_0^3$, see text for details

[a]The experimental refractivity results have been presented for 0°C and 1 atm assuming ideal behaviour. More complete corrections for non-ideal behaviour would probably lead to a reduction of the R_λ values obtained from the data in refs. 42 and 43; the article by Bosanac *et al.* (ref. 44, see also Redington (45)) contains a summary of available second virial coefficient data for HF.

DOSD and properties for HCl

There are apparently three sources of refractive index measurements for HCl, Cuthbertson and Cuthbertson (48) between 6707.9 Å and 4799.9 Å, Frivold (49) for 6564 Å to 4359 Å, and Larsen (50) between 5677.4 Å and 2302.8 Å. All are in very good agreement (within 0.2%) at the (essentially) common wavelength of 5462.25 Å. The Frivold data are used to generate molar refractivity constraints at 6564 Å and 4359 Å.

The integrated dipole oscillator strengths for the adopted DOSD are given in Table 4 and the properties evaluated from it are included in Table 2; our value of S_{-2} is identical to that obtained from the value of R_∞ given in Londolt-Bornstein (47). The values of R_λ calculated from the DOSD are in excellent agreement with the experimental values, see Table 5.

DOSD and properties for HBr

Refractive index data is available between 6707.9 Å and 2447.7 Å, see Cuthbertson and Cuthbertson (48) and Larsen (50). The results at λ = 6707.9 Å and 2675.8 Å were selected to provide the molar refractivity constraints for the construction of the DOSD for HBr. The integrated dipole oscillator strengths for the adopted DOSD are given in Table 6, the associated dipole properties in Table 2. Our result for S_{-2} is in excellent agreement with the value of 23.54 obtained from R_∞ given in ref. 47.

The molar refractivities evaluated from the adopted DOSD are compared with experiment in Table 7 and the agreement is excellent except in the case of R_λ values obtained from Larsen (50) for λ = 2464.8 Å and 2447.7 Å. Varying the molar

TABLE 4. Integrated dipole oscillator strengths for HCl (see also footnote for Table 1); the absorption edges occur at 208.7 eV (Cl_{L_2}) and 2822 eV (Cl_K) (34)

refractivity constraints had little influence on the calculated values of R_λ unless Larsen's (50) data for $\lambda \leq 2464.8$ Å were used; it appears that the experimental data for these values of λ are significantly too high, see Table 7.

Further discussion of the properties of the hydrogen halides is reserved for Section 5. However, comments on the DOSDs are relevant here, particularly concerning HCl and HBr.

The HCl experimental integrated oscillator strengths obtained from Hayes and Brown (30) and Ninomiya *et al.* (29) agree reasonably well for 200–205.3 eV, within the experimental error given in ref. 30, while the mixture rule result is some 50% higher. As E increases, between 205.3 and 208.7 eV, the integrated oscillator strengths obtained from ref. 30 and the mixture rule agree within the estimated experimental error whereas the results due to Ninomiya *et al.* (29) apparently become too low and this trend continues between 208.7 and 280 eV. It seems that the disagreement between the mixture rule and the experimental data between 200–205.3 eV, within ~3 eV of the Chlorine L_2 edge, is a nice example of a molecular photoabsorption effect occurring at high photon energies, see also ref. 52. Unfortunately this (possible) effect cannot be investigated at the K edge of HCl, or the absorption edges for HF and HBr, because of an apparent lack of molecular photoabsorption cross sections for these photon energies.

For $7 \leq E \leq 50$ eV the adopted integrated dipole oscillator strengths for HBr, see Table 6, agree with the input DOS results obtained by Brion and Thomson (32) within the estimated experimental error of ~25%. As E increases, however, the experimental results seem too low with respect to the mixture rule data which should become reliable for these values of the photon energies (except possibly near the absorption edges, see above). Further evidence of the reliability of the mixture rule can be found in Table 1 for HF between 100 and 150 eV, in Table 4 for HCl between 40 and 50 eV, and through the agreement of the mixture rule integrated oscillator strength for HCl between 5000 and 25000 eV with the molecular result of 5.440 (−1) obtained from Millar and Greening (53).

4. DOSDs and dipole properties for Ne, Ar, Kr, and Xe

Dipole oscillator strength distributions for the rare gases have been developed, in the context of evaluating reliable results for the dipole properties of these atoms, by several authors. Probably the most extensive treatment is due to Leonard and Barker (11), see also Barker and Leonard (54) and Leonard (15), and of course the pioneering work of Dalgarno and co-workers (9, 10, 55, 56) and Margenau (8) should also be mentioned. For a more complete discussion see refs. 11, 12, and 55.

Much more recently Berkowitz (57) has discussed the oscillator strength data for the rare gases and has used the Thomas–Reiche–Kuhn sum rule, experimental values of $\alpha_d = S_{-2}a_0^3$, and calculated or experimental values of S_{-1}, to help test and discriminate between the experimental DOS data considered.

The review of the experimental DOS data for the rare gases by Leonard and Barker (11), see also Leonard (15), was very extensive up to the time of the original work (~1967). Since then many new papers on the rare gas DOSs have appeared, many of which have been considered in ref. 57. It seems reasonable then to reconsider the rare gases in the light of the constrained least squares procedure discussed in Section 2 and to obtain a data base for these atoms analogous to our work on a variety of other atoms and molecules (13, 14, 18–20, 36, 39), including the hydrogen halides discussed in Section 3. We consider only the rare gases Ne, Ar, Kr, and Xe; effective dipole oscillator strength distributions for He are readily available in the literature (9, 11, 58). However, since most of the dipole properties obtained from our adopted DOSDs agree very

[a]The data has been corrected to ideal gas conditions in refs. 49 and 50.
[b]The results are obtained by converting the data ($n_d - 1$) given in (48) to ideal gas conditions by using ($n^0_{1.760} - 1$) = 1.00063($n_d - 1$) (see ref. 51).
[c]Used as constraints in the construction of the DOSD.

well with those of Leonard and Barker (11, 15), the details of the analysis will be suppressed substantially.

The initial or unmodified integrated oscillator strengths used explicitly in our analysis are given in Tables 8−11 for Ne, Ar, Kr, and Xe, respectively; all the appropriate references for the data are included in these tables. Molar refractivity data and $S_0 = Z$ are used as constraints for the construction of the DOSDs. The molar refractivity constraints are chosen to be: Ne − λ = 5462.25 Å and 2894.4 Å from Cuthbertson and Cuthbertson (108) correcting for non-ideal behaviour by using the second virial coefficient of Michels *et al.* (109); Ar − λ = 6329.9 Å and 4766.2 Å from Coulon *et al.* (110); Kr − λ = 2632.1 Å and 1770.9 Å from Smith *et al.* (111); Xe − λ = 2537.0 Å and 1702.0 Å from Bideau-Mehu *et al.* (112). A very useful review and critique of the refractive index data for the rare gases up to ~1970 can be found in Leonard (113); ref. 108 occurs in this review while refs. 110−112 are considerably more recent. In all cases the molar refractivity values calculated from our adopted DOSDs are in excellent agreement with the experimental values obtained from refs. 108−112 for all relevant values of λ; the agreement with other comparable experimental data is generally also very satisfactory.

Compared to the molecules considered in Section 3, the sources of DOS input data for the rare gases are immense. Potentially this data gives rise to millions of DOSDs if the approach used for the hydrogen halides is used here. To simplify matters we first used the oscillator strengths suggested by Berkowitz's (57) analysis of the DOS data for the rare gases, or by well intentioned interpretations or modifications of this data, to construct the DOSDs for Ne, Ar, Kr, and Xe. For example, we augmented the data considered by Berkowitz by recent DOS results for the auto-ionization region, by high energy DOS data generated by the Stobbe formula and by employing Henke's (33) more recent compilation of rare gas photoabsorption cross sections. In addition we have also constructed many additional DOSDs by making selective adjustments in the DOS input data, using the initial calculations as a guide, by employing other DOS data sources in order to attempt to minimize (STD). The adopted DOSD corresponds to the minimum value of (STD) obtained although we emphasize that not all possible combinations of DOS input data has been considered for this purpose. In all cases the STD fell from ~2−5 to ~0.5.

The integrated dipole oscillator strengths for the adopted DOSDs are given in Tables 8−11 for Ne, Ar, Kr, and Xe, respectively. While the corresponding results obtained from our initial calculations based on Berkowitz's analysis can differ locally, they usually agree with our adopted results globally in the sense of yielding very similar results for many of the dipole properties of the rare gases (some exceptions are discussed briefly in Section 5). The dipole properties S_k and L_k evaluated from our adopted DOSDs are given in Table 12. The values of S_{-2} resulting from our adopted DOSDs are in excellent agreement with the recommended values given in the review by Teachout and Pack (38) and Leonard (113).

5. Discussion

Some of the experimental and literature results for the dipole properties of the molecules and atoms considered in this paper have been compared with our adopted results in Sections 3 and 4 in the context of the evaluation of the properties. Also, very recently, a refined quantitative study of valence shell absolute photoabsorption cross sections for HF, including a discussion of experimental difficulties associated with this molecule, has been carried out by Hitchcock *et al.* (114). We begin this section with a comparison and brief discussion of other literature results, many of which are *ab initio* calculations for the hydrogen halides, for some of the dipole properties of HF, HCl, HBr, Ne, Ar, Kr, and Xe.

Hydrogen halides

The most studied dipole property of this group of molecules is the static dipole polarizability of HF. A recent discussion of correlation corrections to coupled Hartree−Fock calculations of the dipole polarizability of HF, together with an excellent calculation of α_d and a summary of previous work at the SCF and higher levels, can be found in Mukherjee *et al.* (4). All of the results at the SCF level quoted, except those of O'Hare and Hurst (115) which are ~4% higher than our recommended result, are substantially too low (by ≤12%). The addition of correlation effects generally increases the value of α_d but only a few calculations (116), including some of those of Mukherjee (4) aided by Padé approximant techniques, lead to results comparable in reliability to those of Werner and Meyer (37) used to construct the DOSD for HF in Section 3. Reference 4 contains excellent discussions and examples of the difficulties involved in obtaining reliable *ab initio* results for the polarizabilities of even moderately small species. Other recent work, not included in ref. 4, includes a recent study by

TABLE 6. Integrated dipole oscillator strengths for HBr (see also footnote for Table 1); the absorption edges occur at 1550 eV [Br_{L_3}], 1596 [Br_{L_2}], 1782 eV [Br_{L_1}] and 13 470 eV [Br_K] (34)

[a]The results are obtained by converting the data ($n_d - 1$) given in ref. 48 to ideal conditions by using ($n^0_{1.760} - 1$) = 1.00063 ($n_d - 1$) (see ref. 51).
[b]The data have been corrected to ideal gas conditions in ref. 50.
[c]Used as constraints in the construction of the DOSD.

Jorgensen *et al.* (117) using the coupled Hartree–Fock (CHF) or time dependent Hartree–Fock (TDHF) methods and the second order polarization propagator approximation (SOPPA) in length, mixed, and velocity forms. The TDHF results are significantly low (≲18%) while the SOPPA results in the length, mixed, and velocity representations are ~15%, 11%, and 4% lower, respectively, than the adopted result. Also relevant is a recent study (118) of the problem by an equation of motion approach involving the random phase, the Tamm–Danoff and the single-transition approximations using length, velocity, acceleration, and various mixed representations. The RPA results are of similar reliability to the TDHF calculations discussed previously while the theoretically poorer TDA and STA calculations can yield values for α_d(HF) that are in closer agreement with the recommended value of $5.60a_0^3$. An interesting recent discussion of the dependence of coupled Hartree–Fock results for α_d on the nature of the gaussian basis set used in the calculation can be found in ref. 119.

There are apparently few *ab initio* calculations for the other dipole properties considered in this paper for HF or for the dipole properties of HCl or HBr. The most recent *ab initio* study of the polarizability of HCl is apparently that due to Oddershede and Svendsen (120) who obtain a TDHF result of 17.14 a_0^3 and a SOPPA value of $18.06a_0^3$ compared to our adopted result of $17.39a_0^3$. The older SCF (finite field) and SCF-CI results of Williams and Amos (121) lie ~12% and 10% lower than the recommended value. The coupled Hartree–Fock result of Gianturco and Guidotti (122) agrees well (within ~1%) with that of ref. 120. The CNDO/2 finite perturbation plus polarization orbitals calculations of Rhee *et al.* (123) yield α_d = 5.39, 16.1, and $22.9a_0^3$ for HF, HCl, and HBr, respectively, which are ~3.8%, 7%, and 3.5% lower than our adopted results of Section 3.

The dipole properties S_k, for k = 2, 1, and −1, can be evaluated rigorously by taking an expectation value of an appropriate quantum mechanical operator with respect to the exact ground state wave function for the relevant atom or mole-

TABLE 8. Integrated dipole oscillator strengths for Ne (see also footnote for Table 1) for the adopted DOSD and for the initial DOS input data; the absorption edges occur at 48.5 eV (L_1) and 866.9 eV (K). The molar refractivity constraints used to construct the adopted DOSD are $R(\lambda = 5462.25$ Å$) = 1.00537$ and $R(\lambda = 2894.44$ Å$) = 1.02573$ cm^3 mol^{-1}

[a] Hartree–Fock (128): S_2(Ne) = 2.596(4), S_2(Ar) = 2.984(5), S_2(Kr) = 4.857(6); CI (129): S_2(Ne) = 2.599.
[b] Hartree–Fock (128): S_1(Ne) = 1.514(3), S_1(Ar) = 5.742(2), S_1(Kr) = 2.670(3); CI (129): S_1(Ne) = 1.544(2).
[c] Hartree–Fock (128): S_{-1}(Ne) = 4.055, S_{-1}(Ar) = 1.095(1), S_{-1}(Kr) = 1.575(1); CI: S_{-1}(Ne) = 3.761, ref. 129; S_{-1}(Ar) = 8.53, ref. 130.

cule (16, 17); estimates can be obtained by using approximate ground state wave functions (6, 124). *Ab initio* double-ζ SCF results (6) for HF are given by S_2 = 16050, S_1 = 119.8, and S_{-1} = 5.886 and are in reasonable agreement with our adopted values given in Table 2. S_2 is determined by the charge densities at the nuclei of the molecule of interest and the higher quality SCF values for these for HF obtained by Ransil and Sinai (125) leads to a result of S_2 = 16880 which is only 2% lower than our recommended value of 17220.

The value of the mean excitation energy I_0 for HF obtained by Wilson *et al.* (126) in the local plasma approximation (γ parameter chosen to be 1.2) is only 0.8% higher than our recommended result of I_0 = 95.6 eV obtained from [3] and the results for S_0 and L_0 given in Table 2. A discussion of the local plasma approximation, and its limitations, can be found in Johnson and Inokuti (127).

Rare gases

We begin with a comparison of our adopted results for the dipole properties of Ne, Ar, Kr, and Xe with those of Leonard and Barker (11) which are also listed in Table 12. The agreement between the two sets of values is very good in all cases for $-6 \lesssim k \lesssim -1$, especially for $-5 \lesssim k \lesssim -2$, and it should be noted in both sets of calculations $S_0 = Z$ by construction. The dipole properties S_k for large negative values of k, which are not of much direct physical significance, are dominated by the very low photon energy part of the DOSD and are largely unaffected by the constraints used in the calculations (1, 13, 19, 20).

The dipole properties S_2 and S_1, especially S_2, are dominated by the high photon energy part of the DOSD and S_2 is not very sensitive to the constraints used to construct the DOSD (1, 13, 19, 20). The differences between the results for these properties obtained here and in ref. 11 result from the different high energy DOS input used in the calculations. In Leonard and Barker (11) the Stobbe formula was used to provide the DOS data for $E > E_K$ whereas in the present work the more reliable photoelectric results of Veigele (34), obtained from mass attenuation coefficients by subtraction of scattering contributions as needed, are used between the K edge E_K and 100 keV (80 keV for Xe); Veigele's results were not available at the time the work in ref. 11 was completed. In all cases Leonard and Barker's results for S_2 and S_1 are lower than our recommended results, by ~8–11% for S_2 and ~2–4% for S_1. Similar, but slightly larger, discrepancies can be seen in Table 12 for L_2 and L_1 as well. The results for L_0 disagree by a smaller amount, from 2–4%, and it should be noted that L_0 is more sensitive to the high energy part of the DOSD than is S_0.

In some cases, namely Kr and Xe, our adopted results for S_{-1} differ appreciably (by ≳2%) with those obtained from ref. 11; S_{-1} is sensitive to the constraints used to construct the DOSD. These discrepancies, and other less significant differences in some of the results for the other dipole sums, are due to differences in DOS input data; often we have used more recent sources of data not available to ref. 11.

Prior to the present study the results for the dipole properties for Ne, Ar, Kr, and Xe obtained by Leonard and Barker (11) were probably the most generally reliable. It is clear our results for the S_k essentially augment their work for $k \leq 0$ and represent an improvement generally only for $k > 0$ (except for S_{-1} for Kr and Xe). Many workers have investigated the dipole properties of the rare gases and it is not possible to list or discuss all the results here. The results for the static dipole polarizabilities have been surveyed through ~1970 by Teachout and Pack (38), including both experimental and theoretical results. Barker and Leonard (11) compare their results with a variety of literature values through ~1971. More recently literature results for some of the dipole properties of Ne, Ar, and Kr have been summarized in the work of Dehmer *et al.* (21) and Cummings (128). Mention has already been made of the pioneering work of Dalgarno and his colleagues in this field.

It is known that Hartree–Fock or near Hartree–Fock quality ground state wave functions can give very reasonable results for S_2 and S_1, the corresponding calculation for S_{-1} is generally not nearly as reliable (6, 128). Hartree–Fock results (128) for S_2, S_1, and S_{-1} for Ne, Ar, and Kr are included as footnotes to Table 12; in all cases agreement with our adopted values for S_2 and S_1 is superior to that for Leonard and Barker's results. Fifty term CI wave function results (129) for these dipole sums are also included in Table 12 for Ne. The effect of CI on S_2 is very small and the agreement with our adopted result for S_{-1} is improved relative to the Hartree–Fock results. A CI result (130) for S_{-1}(Ar) is included in a footnote to Table 12 and is in considerably closer agreement with the recommended value than the Hartree–Fock value.

The dipole properties S_k obtained from the DOSDs based on Berkowitz's (57) analysis of the rare gas spectra, see Section 4, generally agree with our adopted results to within their estimated uncertainties (see later). Exceptions are $S_{-1/2}$ and S_{-1} for Xe where the discrepancies amount to 5% and 3% respectively. The (STD) corresponding to the DOSD for Xe based on Berkowitz's analysis is 5.0 and the DOS input data requires large modifications (between 10 to 24%) in the 80–150 eV, 300–790 eV, and 825–4800 eV energy regions which contribute significantly to $S_{-1/2}$ and to a lesser extent to S_{-1}; a discrepancy of ~5% also occurs for L_0 for the same reason. Large differences also arise when the L_k are small, that is ~3% for L_{-2}(Ne), ~13% for L_{-1}(Ar), ~49% for L_{-1}(Kr) and ~62% for L_{-1}(Xe). This is caused by a cancellation effect discussed by Kumar and Meath (22) and depends on the energy unit used in the definition of the L_k, see also ref. 131. Following (22) one can write

$$[8]\quad L_k(E/(1\text{ eV})) = (2R)^k[L_k(E/(2R)) + \ln(2R)S_k(E/(2R))]$$

It is clear that for $L_k(E/(2R))$ small, the error in $L_k(E/(1\text{ eV})$ is controlled by the error in $\ln(2R)S_k(E/(2R))$. Using the data given in Table 12, it can be seen that the discrepancies between the relevant L_k, with an energy unit of 1 eV, is reduced markedly (<1% in all cases) relative to those corresponding to an energy unit of $2R$.

Fewer results are available for the dipole properties L_k. Our values are in reasonable agreement with the higher quality results given in (15, 21, 56, 128, 129) for Ne, Ar, Kr, and Xe. Results obtained by differentiation of the S_k with respect to k can be unreliable if the input S_k are inaccurate or if the representation used for S_k as a function of k is poor, see also ref. 131.

In general reliable *ab initio* calculations of the dipole properties S_k, for $k \leq -1$, or for the L_k are very difficult to carry out. The difficulties in this type of calculation have been discussed in the context of the hydrogen halides earlier. In general, uncoupled and coupled Hartree–Fock calculations are not sufficient, see for example refs. 4, 37 and the discussion and results given in Werner and Meyer (2) for Ne.

The errors in our adopted results for the dipole properties of the hydrogen halides and the rare gases considered here have been estimated following the methods used previously, namely, by comparison with values obtained from DOSDs constructed from a variety of (reasonable) input DOS data. In all cases the S_k and L_k for $k \geq 1$, and particularly for $k = 2$, can have uncertainties of ~3% which are related to the errors in the high energy input DOS data used in the calculations.

For the hydrogen halides the uncertainty in the S_k is $\lesssim$1% for $-3 \lesssim k \lesssim 0$ and increases gradually as k decreases; it is ~2% for L_0, S_1, and S_{-4} and about the same as in the corresponding S_k values for L_{-1} and L_{-2} except in the cases of HF where L_{-1} and L_{-2} are fairly small. On a 1 eV energy scale L_{-1}(HF) and L_{-2}(HF) have uncertainties of $\lesssim$1%. For the rare gases the estimated errors in the S_k, for $-6 \lesssim k \lesssim 0$, are $\lesssim$1%. L_0 and S_1 are uncertain by ~2% and the errors in the other L_k are ~1% except where they are small. Recasting the results for these L_k on a 1 eV energy unit yields results reliable to $\lesssim$1%. The error estimates for the S_k and L_k for $k < 0$ are made under the assumption that the values of the molar refractivity constraints (the value of α_d for HF) used in the construction of the DOSDs are reliable (errors $\lesssim$0.5%).

An important use of globally reliable DOSDs lies in the evaluation of the dipole–dipole and the triple–dipole dispersion energies between atoms and molecules. These energies involve double or triple integrals over the DOSDs for the molecules involved in the interaction and can be evaluated directly by using the relevant distributions. A more efficient method for doing this is to use pseudo-DOSD techniques (132, 133) which require accurate results for the S_k as a function of k. The pseudo-DOSDs for the hydrogen halides and the rare gases will be presented elsewhere together with a variety of important dispersion energy constants.

The approach used in this work is a practical and reliable method for evaluating a wide variety of rotationally averaged or isotropic dipole molecular properties. The extension to anisotropic dipole properties or higher multipole properties is non-trivial due to a lack of the required oscillator strength data and/or reliable constraints for most species (1, 6). The extension to anisotropic properties is currently under investigation.

Acknowledgements

The authors wish to thank Professor C. E. Brion for making recent (28, 32) dipole oscillator strength data for HCl and HBr available to us before publication. This research was supported by a grant from the Natural Sciences and Engineering Research Council of Canada.

This paper is dedicated to Professor Camille Sandorfy on the occasion of his 65th birthday

V. P. BODART, J. DELHALLE, J. M. ANDRÉ, and J. ZYSS. Can. J. Chem. **63**, 1631 (1985).

The predictive use of scaled minimal basis sets calculations of electric polarizabilities for large hydrocarbons, proposed by Chablo and Hinchliffe, is further assessed by considering two series of oligomers, H—(CH═CH)$_n$—H and H—(C≡C)$_n$—H where n = 1, 2, 3, and 4. It is then applied to the yet experimentally untested vinylacetylene, 1,5-hexadiene-3-yne, and 1,5,9-decatriene-3,7-diyne for their polarizability.

V. P. BODART, J. DELHALLE, J. M. ANDRÉ et J. ZYSS. Can. J. Chem. **63**, 1631 (1985).

Utilisant deux séries d'oligomères, H—(CH═CH)$_n$—H et H—(C≡C)$_n$—H dans lesquels n = 1, 2, 3 et 4, on a réévalué l'utilité, comme méthode permettant de prédire correctement les polarisabilités électriques de grosses molécules, de la méthode proposée par Chablo et Hinchliffe et impliquant des calculs faisant appel à des ensembles de base restreints mais proportionnés. On a ensuite appliqué la méthode à la polarisabilité du vinylacétylène, de l'hexadiène-1,5 yne-3 et du décatriène-1,5,9 diyne-3,7 qui n'ont pas encore été testés expérimentalement.

[Traduit par le journal]

1. Introduction

Organic electrooptic and nonlinear optical materials are expected to be increasingly used in integrated optics and in optical communications. Though not being a sufficient condition, high values of α, β, and γ, respectively the electric polarizability, hyperpolarizability, and second order hyperpolarizability tensors of the constituting species (molecules, oligomers, chains), are essential for a given material to become a potential candidate for practical applications. Accordingly there is an obvious interest in prospective model calculations that could predict modified or novel organic structures having these desirable features. Among other factors, the existence and size of a delocalized π-system, the nature and position of substituents on the molecular framework are determining the numerical value of the components of α-, β-, and γ-tensors (1).

Simple theories such as the free-electron model and the Hückel method predict the π-electron polarizability, α, of a long chain molecule to be proportional to the cube of the molecular length (2, 3). Similarly, in a study of a family of donor–acceptor disubstituted phenyl polyene, the marked chain length influence on hyperpolarizability values has been pointed out (4). Thus chain length appears as a potentially useful parameter to consider in generating high values of α, β, and γ. However, both free-electron model and the simple Hückel method do not take into account Coulombic interactions explicitly, for example such as mediated by self-consistent field methods, a contribution which is likely to affect the above mentioned asymptotic relation. Additional investigations of the rate of increase of α with the size of chain molecules when interelectronic interactions are more explicitly included should be useful. Our preference is to perform *ab initio* calculations since other relevant properties such as equilibrium geometries can be consistenty evaluated within the limits of a chosen basis set. Unfortunately, to obtain quantitatively the polarizabilities from *ab initio* calculations substantially extended basis sets are needed. In spite of these dissuading results Chablo and Hinchliffe have reported on the feasibility of using predictively scaled minimal basis set results for large hydrocarbons (5).

The first aim of the present paper is to further test the validity of such a scaling procedure by comparing the longitudinal electric polarizability α_{zz}, calculated using STO-3G and 4-31G basis sets for two relevant series of oligomers, i.e. H—(CH═CH)$_n$—H and H—(C≡C)$_n$—H where n = 1, 2, 3, and 4. The second purpose is to use this procedure to predict the longitudinal polarizability of small molecules resulting from the combination of two reference moieties, —CH═CH— and —C≡C—.

2. Methodology

All the calculations reported in this work were done on a DEC 20-60 using a modified version of the GAUSSIAN 80 series of program (6). Standard STO-3G minimal (7*a*) and 4-31G split-valence (7*b*) basis sets were considered. Polarizabilities were calculated by the finite-field SCF method of Cohen and Roothaan (8) which is virtually equivalent to the analytic Coupled Hartree–Fock scheme. A term, $\mu \cdot E$, describing the interaction between the electric field, E, and the molecule is added to the unperturbed molecular Hamiltonian, H_0; μ is the total dipole moment of the molecule. At the Hartree–Fock level, the electric field appears explicitly in the one-electron part of the modified Fock operator, F(r),

$$[1] \quad F(r) = F_0(r) + e(r \cdot E)$$

where $F_0(r)$ is the molecular Fock operator in absence of electric field.

The numerical approach to the calculation of electric polarizabilities requires much higher accuracy of the total SCF energy than in standard applications. The convergence threshold on the density matrix elements was set up as 10^{-5}–10^{-6}. In this work we are only interested in the longitudinal component, α_{zz}, of the polarizability tensor α, the z-axis being directed along

TABLE 1. Theoretical and experimental longitudinal electric polarizabilities, α_{zz}, of acetylene and ethylene; the C—C bonds are directed along the z-axis

α_{zz} (au)	STO-3G	4-31G	Double-ζ	Exp.

[d]Reference 12.

the chain. The value of α_{zz} is obtained from the first derivative of the field-dependent dipole moment, $\mu(E)$, with respect to E_z in the limit of zero-field. In practice this is done numerically using

$$[2] \quad \alpha_{zz} = [\mu_z(E_z) - \mu_z(-E_z)]/2E_z$$

Polarizability calculations were carried out using eq. [2] with four values of the external field, −0.002, −0.001, +0.001, and +0.002 au. The Richardson extrapolation procedure (9) was applied to check the numerical stability of the results, a point which remains difficult in the finite field approach.

Ideally this investigation on the ability of minimal basis set calculations of polarizabilities should help compare the theoretical polarizabilities with experimental values, unfortunately these are missing except for the first terms of the series, acetylene and ethylene. Chablo and Hinchliffe have shown that double-ζ basis set used in Snyder and Basch book (10) yields calculated values in reasonably good agreement with experiment. We have repeated these calculations using the standard 4-31G basis and reached similar agreement, Table 1. Therefore we decided to use the 4-31G results as a reference to which STO-3G could be compared to assess the validity of a scaling procedure in the first part and then to predict "experimental" values for three molecules assembled from —CH=CH— and —C≡C—. It is worth pointing out that as found by Chablo and Hinchliffe, this procedure works only for the longitudinal component of the polarizability likely because of the lack of flexibility in the basis sets in the other two directions. As far as we are concerned, this is not a limitation since, for practical applications, the longitudinal component is the most interesting part. Molecular geometries are taken or adjusted from experiment as indicated at the bottom of the tables.

3. Scaling procedure

Longitudinal electric polarizability, α_{zz}, calculated with minimal STO-3G and split-valence 4-31G bases for both series of oligomers are listed in Table 2. The evolution of these data is graphically depicted in Fig. 1. It is to be pointed out that the difference between α_{zz} values for ethylene reported in Tables 1 and 2, respectively, stems from the fact that in the former the C=C bond is exactly set parallel to z-axis while in Table 2 this C=C bond has been oriented with respect to the z-axis (ca. 30 deg) as are the C=C bonds of the other terms in the H—(CH=CH)$_n$—H series.

The first observation is certainly that, in both series of compounds, α_{zz} is not yet stabilized after $n = 4$ since the increment from one term to the next is still increasing. Consequently future investigations of larger oligomers will be soon beyond normal computational possibilities if doublble-ζ basis sets are to be used. This fact motivates for substitutes like a scaling procedure. A more comprehensive analysis, including data from free-electron and Hückel methods, of the way α_{zz} increases with the size for a larger set of H—(CH=CH)$_n$—H oligomers is in progress.

As previously pointed out it is however gratifying to find the ratios $R_n = \alpha_{zz}(\text{STO-3G})/\alpha_{zz}(\text{4-31G})$ for $n = 1$ to 4 being roughly constant and similar in both series of compounds. The interval of variation of R_n for > 1 is typically 0.65 to 0.70, with R_n being close to 0.70 as the length of the oligomer increases. Therefore, when using the minimal STO-3G basis, a value of $R_n = 0.70$ can reasonably be chosen in studies related to unsaturated hydrocarbon chains.

Assuming that the ratio of $\alpha_{zz}(\text{4-31G})/\alpha_{zz}(\text{exp.}) = 0.9$ for acetylene and ethylene calculated from data in Table 1 will stay reasonably constant for other unsaturated hydrocarbon molecules, it is then possible to predict data at the scale of experimental observations by applying the multiplicative constant $1.57(1/(0.9 \times 0.7))$ to the corresponding STO-3G values. In the next section we apply these rules to predict α_{zz} of three molecules yet untested for their polarizabilities.

4. Longitudinal polarizabilities of small molecules assembled from —C≡C— and —CH=CH— fragments

Polydiacetylenes have received considerable attention lately owing to their linear and nonlinear optical properties (1). These are associated with the conjugated nature of their backbone which, in a way, can be considered as being built out of —(CH=CH)— and —(C≡C)— fragments. Like in the field of mechanical properties, where to a copolymer do not generally correspond values that are the weighted sum of their homopolymer contributions, it is likely that patterns of nonadditivity will similarly be observed for polarizabilities.

It is beyond the aim of this paper to investigate effects of various distributions of the units in increasing size oligomers, H—(CH=CH—C≡C)$_m$—R (R = H or —CH=CH$_2$), but, considering the availability of the scaling factors obtained in Section 3, it is nonetheless attractive to make preliminary attempts on three precursors. From Table 2 it can be observed that if α_{zz}(STO-3G) of ethylene, 17.47 au, is nearly equal to that of acetylene, 18.18 au, the rate of increase when regular oligomers are growing is in favour of the former as can be seen from the value of 1,3,5,7-*trans*-octatetraene, 174.56 au, compared to 145.47 au for 1,3,5,7-octatetrayne. How will the polarizability of mixed compounds compare with molecules in H—(CH=CH)$_n$—H and H—(C≡C)$_n$—H series and including the same number of carbon atoms? Vinylacetylene (**A**), 1,5-hexadiene-3-yne (**B**), and 1,5,9-decatriene-3,7-diyne (**C**) have been selected for this preliminary study. Their polarizability values are listed in Table 3. The right-hand side column provides figures obtained after multiplication of the STO-3G values by 1.57, they should be close to the experimental measures if these were available.

It is interesting to notice that vinylacetylene, **A**, has its longitudinal polarizability larger than the sum of acetylene and ethylene contributions. It is, however, slightly smaller than either 1,3-*trans*-butadiene or 1,3-butadiyne. The difference is more important in the next term (**B**), whose α_{zz}, 85.30 au, is substantially smaller than 1,3,5-*trans*-hexatriene or 1,3,5-hexatriyne, see Table 2. The last compound **C**, displays also a small value of α_{zz}, 183.69 au, which comes quite close to the one of 1,3,5,7-*trans*-octatetraene, 174.56 au, this compound having two carbon atoms less than in **C**. From these simple

TABLE 2. Comparison of STO-3G and 4-31G calculated longitudinal electric polarizabilities of two series of oligomers, H—(CH═CH)$_n$—H and H—(C≡C)$_n$—H; n = 1, 2, 3, and 4

[c]From the optimized geometry of the infinite chain (ref. 19).

TABLE 4. Longitudinal electric polarizabilities (α_{zz}) rescaled from STO-3G values

Compound	α_{zz}: anticipated experimental values (au)
Vinylacetylene	70.1
1,3-Butadiyne	79.6
1,3-*trans*-Butadiene	75.1
1,5-Hexadiene-3-yne	133.9
1,3,5-Hexatriyne	143.1
1,3,5-*trans*-Hexatriene	163.5
1,5,9-Decatriene-3,7-diyne	288.4
1,3,5,7,9-Decapentyne	324.5
1,3,5,7,9-Decapentene	341.1

manipulations it turns out that, in the idealized context of regular geometries, oligomeric structures H—(CH═CH—C≡C)$_n$—R (R = H or —CH═CH$_2$), H—(C≡C)$_{2n}$—H, and H—(CH═CH)$_{2n}$—H should be classified in that order of increasing longitudinal polarizability with the length of chains (Table 4).

5. Concluding remarks

From the present work it seems that a linear scaling procedure applied to minimal basis calculations is applicable to unsaturated hydrocarbon chains. This conclusion was drawn from the preassumed capability of double-ζ basis sets, to which the split-valence 4-31G basis belongs, to yield reasonably good values of the electric polarizabilities. It remains, however, that the field of electric polarizabilities and hyperpolarizabilities is badly missing the experimental data from which such a simple approach could and should be more appropriately tested.

In the course of testing we have experienced an extreme sensitivity of calculated polarizabilities to geometry changes and any attempt at using a scaling should be made consistently.

Finally, the results of Section 4 raise two questions for those who are attracted by prospective calculations with molecular engineering purposes: will mixed compounds inexorably lead to depleted polarizabilities? If this is not the case, then what are the type of moieties to be combined to enhance the resulting polarizability?

Acknowledgments

The authors are indebted to Dr. J. G. Fripiat for the implementation of the finite field method in the GAUSSIAN 80 series of programs and to Professor G. Berthier (ENSJF — Paris) and Mr. G. Baudoux for useful discussions. They acknowledge with appreciation the support of their collaboration under NATO grant #130.83. One of us (V.P.B.) is grateful to the Institut pour l'Encouragement de la Recherche Scientifique dans l'Industrie et l'Agriculture (IRSIA, Belgium) for financial support.

Réflexions multiples et prédissociations moléculaires

R. LEFEBVRE

Laboratoire de Photophysique Moléculaire,[1] Campus d'Orsay, 91405 Orsay, France

Reçu le 31 août 1984

Cet article est dédié au Professeur Camille Sandorfy à l'occasion de son 65^e anniversaire

R. LEFEBVRE. Can. J. Chem. **63**, 1635 (1985).

La méthode semi-classique met l'accent sur les réflexions multiples des ondes et les interférences qui en découlent. On utilise cette approche pour étudier un cas à deux canaux avec compétition entre résonance de forme et résonance de Feshbach. Dans la limite des faibles taux de prédissociation il y a additivité des deux effets.

R. LEFEBVRE. Can. J. Chem. **63**, 1635 (1985).

The semi-classical theory of molecular predissociation puts emphasis on the multiple reflections of waves and the resulting interferences. This approach is used to examine a case with two channels including a competition between a shape resonance and a Fesbach resonance. In the limit of low predissociation rates there is additivity of the two effects.

I. Introduction

La méthode semi-classique (voir par exemple la réf. 1) possède le mérite de donner une interprétation simple de nombreux problèmes de physique moléculaire. Un stade préalable est la définition des canaux décrivant l'interaction de deux entités moléculaires dans des états internes donnés. La fonction d'onde associée à chaque canal reçoit la forme JWKB. Il faut ensuite envisager l'effet sur les ondes de certains points ou régions critiques. Un point tournant produit une réflexion totale avec changement de phase approprié. Un croisement entre les potentiels de deux canaux produit un effet comparable à celui de la lame semi-transparente d'un interféromètre pour une onde lumineuse: il y a partition d'une onde incidente appartenant à un canal donné en deux termes associés aux deux canaux. Une barrière de potentiel produit une réflexion et une transmission partielles. Le système quantique se comporte de même manière qu'un système optique: une onde incidente subit des réflexions, des partitions et des transmissions successives. Les amplitudes des ondes émergentes permettent de définir la matrice **S** du problème. Les pôles de cette matrice donnent les états résonnants. Pour les énergies (complexes) de ces pôles, la fonction d'onde ne présente que des termes émergents.

Cet article examine un cas à deux canaux avec présence simultanée des deux mécanismes de prédissociation appelés types I et III par Herzberg (2). Un état quasilié se décompose soit par suite du croisement de son potentiel avec celui d'un état répulsif, soit par franchissement d'une barrière de potentiel. On parle aussi de résonance soit de Feshbach soit de forme. Cette situation a été envisagée dans le cas de l'ion O_2^+ par Helm *et al.* (3). Ces auteurs ont attribué à la présence simultanée des deux effets le fait que les largeurs observées pour les niveaux $v = 3$ de faible J de l'état $f^4\Pi_g$ ne peuvent s'expliquer par la seule interaction avec l'état $d^4\Sigma_g^+$. L'hypothèse d'une additivité des effets est implicitement admise.

La méthode semi-classique permet d'aboutir à une condition de quantification définissant les énergies des états résonnants. Dans la limite des faibles taux de dissociation (faible couplage intercanal, barrière de potentiel difficile à franchir) on peut démontrer l'additivité des deux mécanismes. Hors ce cas particulier (mais important), l'approche semi-classique montre qu'il y a des effets d'interférence. Une situation semblable a été étudiée par Sink et Bandrauk (4) dans le cas d'un potentiel attractif intersecté par plusieurs potentiels répulsifs. Là aussi la non-additivité est la règle et l'additivité n'est obtenue que comme cas limite.

A titre d'illustration de l'effet des réflexions multiples qui sont à l'origine du phénomène de résonance, nous examinons au préalable le problème classique du puits rectangulaire.

II. Réflexions multiples et résonances

Considérons une particule de masse μ astreinte à se mouvoir sur le demi-axe $0 < r \leq \infty$ et dont l'énergie potentielle possède la forme (puits rectangulaire):

[1] $$V(r) = -V_0(0 < r < r_0,\ V_0 > 0);\ V(r) = 0(r_0 < r)$$

L'espace autorisé pour la particule est ainsi divisée en une région interne et une région externe. Pour une énergie E, on peut définir les nombres d'onde correspondants par les relations:

[2] $$k_i^2 = 2\mu\hbar^{-2}(E + V_0);\ k_e^2 = 2\mu\hbar^{-2}E$$

Il est bien connu (5, 6) que la solution de l'équation d'onde s'obtient en imposant à la fonction d'onde d'avoir la forme:

[3a] $A \sin\ k_i r$ dans la région interne

[3b] $-e^{-ik_e r} + Se^{ik_e r}$ dans la région externe

On trouve ainsi pour l'amplitude de diffusion S l'expression:

[4] $$S = \frac{k_i \cos k_i r_0 + ik_e \sin k_i r_0}{k_i \cos k_i r_0 - ik_e \sin k_i r_0}\, e^{-2ik_e r_0}$$

Si l'énergie E est choisie à partir de la condition,

[5] $$\mathrm{tg}\ k_i r_0 = -ik_i/k_e$$

qui correspond à l'annulation du dénominateur de S, la fonction d'onde dans la région externe (eq. [3b]) est dominée par le terme émergent. Ceci peut se produire pour des énergies réelles négatives (états liés) mais aussi pour des énergies complexes de la forme $E = E_r - i\Gamma$. Ces énergies correspondent à des états résonnants qui sont autant de modes de fragmentation du système.

Il est intéressant de remarquer que l'amplitude de diffusion S (éq. [4]) peut aussi s'écrire identiquement:

[1] Laboratoire du CNRS associé à l'Université Paris-Sud.

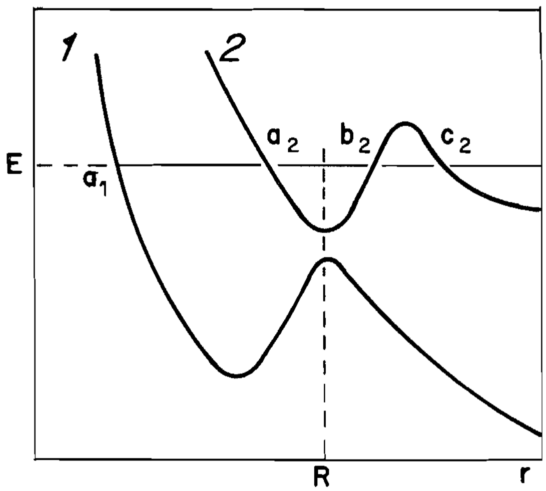

FIG. 1. Potentiels adiabatiques d'une situation comportant des prédissociations par franchissement d'une barrière de potentiel et par croisement de potentiels.

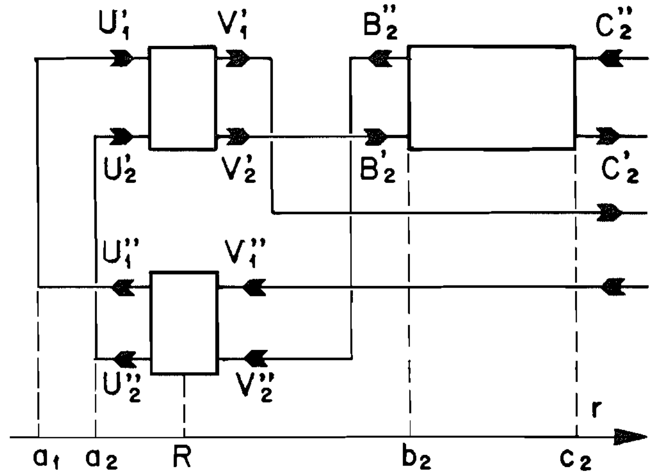

FIG. 2. Diagrammes des amplitudes JWKB entrantes et sortantes dans les régions classiquement accessibles. Les rectangles symbolisent l'effet du décroisement et de la barrière de potentiel sur les amplitudes.

[6] $$S = \left[\frac{k_i - k_e}{k_i + k_e}\,\mathrm{e}^{-2ik_e r_0}\right] + \left[\frac{2k_e}{k_i + k_e}\,\mathrm{e}^{i(k_i-k_e)r_0}\right] \times \left[\frac{2k_i}{k_i + k_e}\,\mathrm{e}^{i(k_i-k_e)r_0}\right] - \left[\frac{2k_e}{k_i + k_e}\,\mathrm{e}^{i(k_i-k_e)r_0}\right] \times \left[\frac{k_i - k_e}{k_i + k_e}\,\mathrm{e}^{2ik_i r_0}\right]\left[\frac{2k_i}{k_i + k_e}\,\mathrm{e}^{i(k_i-k_e)r_0}\right] + \left[\frac{2k_e}{k_i + k_e}\,\mathrm{e}^{i(k_i-k_e)r_0}\right]\left[\frac{k_i - k_e}{k_i + k_e}\,\mathrm{e}^{2ik_i r_0}\right]^2 \times \left[\frac{2k_i}{k_i + k_e}\,\mathrm{e}^{i(k_i-k_e)r_0}\right] - \ldots$$

expression que nous pouvons condenser en

[7] $$S = R + TT' - TR'T' + TR'^2T' - \ldots$$

Les amplitudes R, T, T' et R' sont définies par la comparaison des termes successifs de l'éq. [7] avec les quantités entre crochets du développement (éq. [6]). La signification de ces amplitudes est la suivante: R et T sont les amplitudes réfléchie et transmise correspondant à une onde d'amplitude unité incidente sur la discontinuité du potentiel en r_0, alors que R' et T' sont les amplitudes réfléchie et transmise correspondant à une onde émergente parvenant à cette discontinuité. Les termes successifs de l'éq. [7] correspondent aux évènements qui se produisent quand une onde incidente rencontre la région interne: (1) réflexion en r_0 (R); (2) transmission en r_0 (T), réflexion à l'origine et transmission en r_0 (T'); (3) transmission en r_0 (T), réflexion à l'origine, réflexion en r_0 (R'), réflexion à l'origine, transmission en r_0 (T'); etc.... La série figurant dans l'éq. [7] peut se sommer en

$$S = R + T\frac{1}{1 + R'}T'$$

et la condition $1 + R' = 0$ (pôles de S) redonne l'éq. [5]. On voit ainsi que ce sont les réflexions successives de l'onde dans la région interne qui sont à l'origine du phénomène de résonance.

La méthode semi-classique traite les problèmes moléculaires conduisant à des résonances de façon semblable. Ce sont les croisements et les barrières de potentiel qui jouent le rôle de la discontinuité de potentiel de l'exemple du puits rectangulaire. En dehors de ces régions les ondes se propagent librement sans réflexion, ainsi que l'admet l'approximation JWKB (7).

III. Condition de quantification semi-classique

Nous considérons maintenant la situation représentée sur la fig. 1. Les potentiels adiabatiques proviennent du décroisement par interaction de deux potentiels dont l'un présente une barrière de potentiel et l'autre est purement répulsif. Une méthode très efficace de traitement de ce type de problème a été donnée par Child (8). Les amplitudes JWKB sont définies dans chaque région classiquement accessible et loin des points tournants ou du point de décroisement R. Un diagramme tel que celui de la fig. 2 résume les "évènements" remarquables se produisant en raison des points tournants, du décroisement et de la barrière de potentiel. Les amplitudes U'_2 et U''_2 par exemple signifient que pour $r \ll R$ (mais $a_2 \ll r$) la fonction d'onde dans le canal 2 s'écrit:

[8] $$\psi_2(r) \sim [k_2(r)]^{-1/2}\left\{U'_2 \exp\left[i\int_R^r k_2(r')\,\mathrm{d}r'\right] + U''_2 \exp\left[-i\int_R^r k_2(r')\,\mathrm{d}r'\right]\right\}$$

Les rectangles figurant sur le diagramme symbolisent des transformations matricielles:

[9a] $$U'' = \mathbf{R}''V''$$

[9b] $$V' = \mathbf{R}'U'$$

[9c] $$C' = \mathbf{M}B''$$

Les points tournants à gauche a_1 et a_2 imposent en outre les relations:

[10] $$U'_1 = -i\mathrm{e}^{2i\alpha_1}U''_1; \qquad U'_2 = -i\mathrm{e}^{2i\alpha_2}U''_2$$

avec

$$\alpha_i = \int_{a_i}^{R} k_i(r)\,\mathrm{d}r$$

À noter qu'à la différence de Child (8) les notations 1 et 2 sont utilisées ici pour les potentiels adiabatiques, ce qui paraît préférable puisque la théorie semi-classique se formule entièrement à l'aide de ces potentiels (9). Une dernière information utile est le changement de phase subis dans le canal 2 entre R et b_2 soit:

[11] $V''_2 = B''_2 e^{i\beta_2}; \qquad B'_2 = V'_2 e^{i\beta_2}$

avec

[12] $\beta_2 = \int_R^{b_2} k_2(r)\, \mathrm{d}r$

Pour établir une condition de quantification, nous mettrons à profit le fait qu'il suffit de chercher les pôles d'un élément quelconque de la matrice **S** qui est ici une matrice 2 × 2, puisqu'avec le choix de l'énergie indiqué sur la fig. 1 il s'agit d'un problème à deux canaux ouverts.

La première étape du calcul est la prise en compte du décroisement et des points tournants de gauche. On peut, en utilisant successivement [9a], [11] et [9b] obtenir les amplitudes à la sortie du décroisement en fonction de celles imposées à l'entrée grâce à des relations linéaires dont la forme explicite n'est pas utile à ce stade:

[13a] $V'_1 = \mathcal{A}_{11} V''_1 + \mathcal{A}_{12} V''_2$

[13b] $V'_2 = \mathcal{A}_{12} V''_1 + \mathcal{A}_{22} V''_2$

Un choix possible pour les amplitudes des ondes incidentes est:

[14a] $V''_1 = -1$

[14b] $C''_2 = 0$

ce qui, compte tenu de [13b] et de [9c], conduit à

[15a] $V'_2 = -\mathcal{A}_{21} + \mathcal{A}_{22} V''_2$

[15b] $M_{21} B'_2 + M_{22} B''_2 = 0$

La condition [15b] est aussi, grâce à [11]:

[16] $M_{21} V'_2 e^{i\beta_2} + M_{22} V''_2 e^{-i\beta_2} = 0$

Les équations [15a] et [16] déterminent V'_2 et V''_2, donnant pour V''_2:

[17] $V''_2 = \dfrac{\mathcal{A}_{21}}{\mathcal{A}_{22} + M_{22} M_{21}^{-1} e^{-2i\beta_2}}$

V'_2 peut ensuite être écrit à l'aide de [16] en faisant apparaître le même dénominateur. Les éléments de la première colonne de la matrice de diffusion à courte portée $\mathbf{S}^{(s)}$ (réf 10) sont $S_{11}^{(s)} = V'_1$ et $S_{21}^{(s)} = C'_2$. Puisque

[18] $V'_1 = -\mathcal{A}_{11} + \mathcal{A}_{12} V''_2$

$C'_2 = M_{11} V'_2 e^{i\beta_2} + M_{12} V''_2 e^{-i\beta_2}$

le dénominateur résonant des éléments de la matrice **S** est identifiable à

[19] $\mathcal{A}_{22} + M_{22} M_{21}^{-1} e^{-2i\beta_2}$

Nous procèdons à un léger changement d'écriture pour formuler la condition de quantification semi-classique de ce problème

[20] $\boxed{1 + M_{21} M_{22}^{-1} \mathcal{A}_{22} e^{2i\beta_2} = 0}$

On a par ailleurs (conséquence de [9a], [11] et [9b]):

[21] $\mathcal{A}_{22} = -i e^{2i\alpha_1} R'_{21} R''_{12} - i e^{2i\alpha_2} R'_{22} R''_{22}$

la condition [20] et les formes données aux éléments des matrices **M**, **R**′ et **R**″ donnent en principe la solution de ce problème. Il est à remarquer que si l'on ne procède à aucune approximation justifiée par les conditions particulières d'un problème, il n'est guère possible d'aller au delà, sauf à utiliser des méthodes purement numériques. La section suivante examine le cas limite menant à une additivité des effets de barrière et de croisement de potentiel.

IV. Le cas limite des faibles taux de prédissociation

Les éléments des matrices **R**′, **R**″ et **M** dans la limite du faible couplage intercanal et d'une barrière difficilement franchissable peuvent être obtenus à partir d'expressions générales données par Child (8) (voir aussi Korsch (11)). On a ainsi:

[22] $R'_{22} = R''_{22} \rightarrow \sqrt{U} \exp\left[-i\dfrac{\pi}{4}\right]$

$R'_{21} = R''_{12} \rightarrow 1 - \dfrac{U}{2}$ et $R'_{21} R''_{12} \rightarrow 1 - U$

avec pour U (paramètre de Landau–Zener) l'expression:

[23] $U = \dfrac{2\pi\beta^2}{\hbar v \Delta F}$

β étant le couplage intercanal, v la vitesse classique et ΔF la différence des pentes des potentiels diabatiques, toutes ces quantités étant calculées au point de croisement diabatique. Par ailleurs:

[24] $M_{21} \rightarrow iK; \qquad M_{22} \rightarrow (1 + K^2)^{1/2}$

avec

[25] $K = \exp\left[\displaystyle\int_{b_2}^{c_2} |k_2(r')|\, \mathrm{d}r'\right]$

En conséquence:

[26] $M_{21} M_{22}^{-1} \rightarrow i(1 - 2^{-1} K^{-2})$

puisque dans ces hypothèses $K \gg 1$.

Définissons les deux angles:

[27] $\theta_d = \alpha_1 + \beta_2$ et $\theta'_a = \alpha_2 + \beta_2 - \dfrac{\pi}{4}$

Après multiplication de [20] par $\exp(-i\theta_d)$ et prise en compte de l'ensemble des relations [22]–[27], on obtient pour la condition de résonance:

[28] $$2 \cos \theta_d + 2U \exp[i(\theta'_a - \theta_d)] \cos \theta'_a - 2^{-1} K^{-2} \{U \exp[i(2\theta'_a - \theta_d)] + (1 - U) \exp[i\theta_d]\} = 0$$

Lorsque l'énergie est proche de celle d'un niveau d'énergie E_v du potentiel diabatique possèdant la barrière de potentiel, on a:

[29] $\theta_d \simeq \left(v + \dfrac{1}{2}\right)\pi$

ce qui permet d'utiliser les relations:

[30] $\cos \theta_d = (-1)^{v+1} \dfrac{\pi}{\hbar\omega_d}(E - E_v)$ et

$\exp[\pm i\theta_d] = \pm(-1)^v i$

En omettant le terme proportionnel à UK^{-2} on obtient comme solution de [28]:

$$[31] \quad E = E_v - i\frac{\hbar\omega_d}{\pi} U \cos\theta'_a \exp[i\theta'_a] - i\frac{\hbar\omega_d}{4\pi} K^{-2}$$

Le premier terme correctif à E_v se décompose en un déplacement et un élargissement qui sont ceux (8) de la limite diabatique du problème de prédissociation de type I. Le deuxième terme correctif représente l'élargissement dû à la barrière de potentiel. On a bien dans cette limite, comme attendu, une additivité des deux types d'effet.

Le terme proportionnel à UK^{-2} représente un effet d'interférence entre les deux types de prédissociations. Il contribue à l'énergie un terme correctif ΔE qui s'écrit:

$$[32] \quad \Delta E = i\frac{\hbar\omega_d}{2\pi} UK^{-2} e^{i\theta'_a} \cos\theta'_a$$

Ce terme contribue donc à la fois au déplacement et à l'élargissement. On constate en particulier que l'interférence joue dans le sens d'une diminution de l'élargissement. Ceci peut être attribué au fait qu'une ondelette parvenant soit au point de croisement, soit sur la barrière de potentiel a son amplitude affectée (diminuée) par le mécanisme de perte antérieur à celui considéré.

Signalons enfin comment le cas habituel de la prédissociation par croisement de potentiels se trouve inclus dans la situation examinée ici. La condition [16] peut aussi s'écrire:

$$[33] \quad V''_2 = -M_{21}M_{22}^{-1} e^{2i\beta_2} V'_2$$

Quand la barrière est infranchissable, $K \rightarrow +\infty$ et $M_{21}M_{22}^{-1} \rightarrow i$. La condition [33] devient celle imposée par un point tournant à droite.

V. Conclusion

L'exemple traité dans cet article vient s'ajouter à d'autres présentés dans la littérature pour illustrer la grande commodité de l'approche semi-classique. La fiabilité sur le plan numérique a été également maintes fois démontrée. L'aspect ondulatoire de la mécanique quantique se trouve mis à profit d'une manière particulièrement convaincante.

1,2-Difluorohydrazine represents a model for studying short-range discriminative interactions between two chiral radicals. Possible diastereomeric structures of the system were theoretically investigated by means of nonempirical SCF quantum chemical calculations. Four minima and six saddle points separating them were found on the potential energy surface. All the stable structures and one transition complex were completely optimized. Thermodynamic properties for the equilibrium between the two most stable conformers (*meso* and chiral) of difluorohydrazine are as follows (in kJ/mol): $\Delta H^0_{298.2} = -17.0$, $T\Delta S^0_{298.2} = -0.4$ (standard state: ideal gas at 101.325 kPa, 298 K).

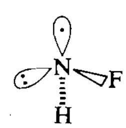
RUDOLF ZAHRADNÍK, BOHDAN SCHNEIDER, PAVEL HOBZA, ZDENĚK HAVLAS et HANSPETER HUBER. Can. J. Chem. **63**, 1639 (1985).

La difluoro-1,2 hydrazine représente un bon modèle pour étudier les interactions discriminatoires à courte distance entre deux radicaux chiraux. Utilisant des calculs non-empiriques de chimie quantique en champ auto-cohérent, on a étudié sur une base théorique les structures diastéréomères possibles du système. Sur la surface d'énergie, on peut déceler quatre minima et six points maxima. On a complètement optimisé toutes les structures stables et un complexe de transition. Les propriétés thermodynamiques de l'équilibre entre les deux conformères les plus stables (*méso* et chiral) de la difluorohydrazine sont les suivantes (en kJ/mol): $\Delta H^0_{298.2} = -17.0$, $T\Delta S^0_{298.2} = -0{,}4$ (état standard: gaz idéal à 101,325 kPa, 298 K).

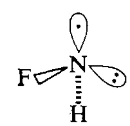
[Traduit par le journal]

The majority of important interactions in biological systems are highly selective or specific. Biological receptors do recognize absolutely a particular optical antipode derived from a certain chiral system. The discriminative nature of some terms of the perturbation interaction energy has been extensively and systematically studied by Craig and Mellor (1, 2). Mason has also published a review on this subject (3). It is now known that the discriminative power of chiral components was relatively small and that the enormous discriminative power of biological receptors is due to a different mechanism (4). In spite of this, it seems desirable to know more about the discriminative nature of weak intermolecular interactions because they occur in most important biological processes.

Systems derived formally by the combination of two chiral radicals represent useful models for studying short-range discriminative interactions. *Dextro* and *levo* methylcyanomethyl radicals, which can give *meso* and chiral isomers of 2,3-dicyanobutane, have been investigated theoretically by Craig, Radom, and Stiles (5). Isomers of 1,2-dimethylhydrazine, which is also a system with intramolecular discriminative interaction, have been studied extensively from both the theoretical and experimental point of view. Attention was paid to the abundance of conformers. Vibrational (6) and photoelectron (7) spectra, gas electron diffraction (8, 9), and microwave spectra (10) were studied and a nonempirical quantum chemical study was performed (9). However, chiral properties were not mentioned in the papers cited (6–10).



1



2

In this work, 1,2-difluorohydrazine (a formal product of interaction between *R*- and *S*-fluoroamidogens, **1**, **2**) is studied theoretically. The combination of **1** and **2** can yield a *meso* form **3** and chiral active forms **4** and **5**; **5** is a mirror image of **4**.

[a] For the sake of convenience, one additional geometric parameter is used.
[b] The same parameters are obtained for enantiomer M2 except the dihedral angles, which have opposite signs.
[c] The inversion group was assumed to be planar.

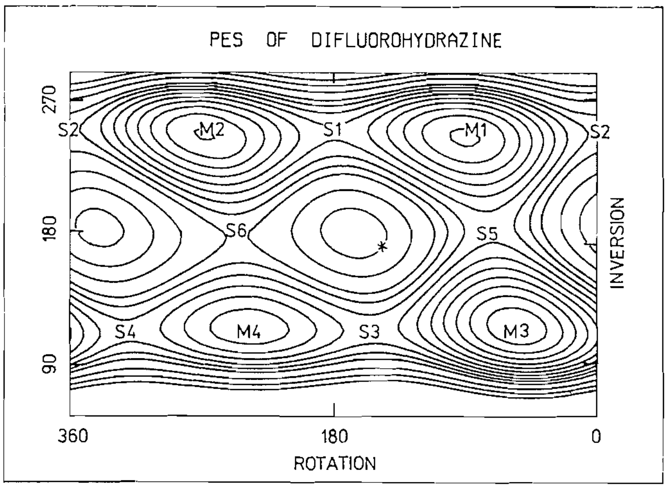

FIG. 1. Energy contour of PES cut for internal rotation around the N—N bond (torsion angle denoted as F3N2N1F5) and inversion of one of the NHF groups (angle F3N2N1H4). Absolute energy of the labeled contour line (*) is −307.000 au. The energy differences of the contour lines in the downhill direction are: 0.01, 0.01 au and then 0.005 au.

In a broader sense, the purpose of this study is to investigate the potential energy surface (PES) of the $N_2H_2F_2$ system. Particular attention has been paid to a special cut through the surface which contains the deepest minimum and its inversion product, including the respective saddle point.

Results and discussion

In order to get an idea about the internal rotation and inversion processes in 1,2-difluorohydrazine, a cut through the potential energy surface was studied. Calculations were performed by the Hartree–Fock SCF method with 3-21G basis set (11). A potential energy contour map constructed from 280 points is plotted in Fig. 1. On this cut of the PES, four minima (M) and six saddle points (S) are indicated. The minima M1 and M2 represent enantiomeric conformations of the *meso* form; they are asymmetric mirror images. These two minima are separated by saddle points possessing either symmetry plane (S1) or center of inversion (S2). The rotational barriers taken from the contour map are relatively high (65 and 95 kJ/mol); however, they do not guarantee the separability of the enantiomers at room temperature. The other two minima (M3 and M4) represent the chiral form, M4 being energetically significantly higher. These two minima are related by two rotational saddle points, S3 and S4, of a comparable height to those for the *meso* forms. It is worth mentioning that the inversional processes have almost the same barriers as the rotational ones. It seems that at room temperature there is no chance to isolate diastereomeric iosomers.

The energy profile of inversion M1 → S5 → M3 was studied in more detail, as well as minima M2 and M4. Geometry optimization of the stationary points with respect to all internal degrees of freedom was done by Hartree–Fock SCF calculations, using the Pople 3-21G basis set (11) and the FOGO method (12), with approximately DZ+P quality basis set.

Optimized bond lengths, and valence and dihedral angles obtained by *ab initio* SCF calculations (3-21G) and the FOGO method are summarized in Table 1. The nature of the located stationary points M1, M3, and S5 was ascertained by the number of negative eigenvalues of the Hessian. As expected, bond lengths and valence angles of the *meso* and chiral forms are very similar. The structure of the activated complex S5 fits the intuitive picture; the inversion group (N2F3H4) is almost planar (the deviation from planarity is about 10°) and all its bonds are shorter, in comparison with the bonds in either minima.

Energy characteristics are presented in Table 2 and Fig. 2. The inversion barrier for the process is found to be significantly higher than for the inversion of ammonia (about 28 kJ/mol) but much smaller than that for trifluoroammonia (328 kJ/mol; *ab initio* SCF with DZ+P basis set, ref. 13).

The thermodynamic calculation for the inversion process M1 ⇌ M3 is based on the rigid rotor – harmonic oscillator – ideal gas approximation (for details see, e.g., ref. 14). Vibrational frequencies of the systems were calculated by means of Wilson FG analysis (15) on the basis of 3-21G force constants. The thermodynamic characteristics for the equilibrium between the *meso* M1 and chiral M3 forms of difluorohydrazine (standard state: ideal gas at 101.325 kPa, 298 K) are (in kJ/mol) as follows: $\Delta H_0^0 = -16.9$, $\Delta H_{298.2}^0 = -17.0$, $T\Delta S_{298.2}^0 = -0.4$,

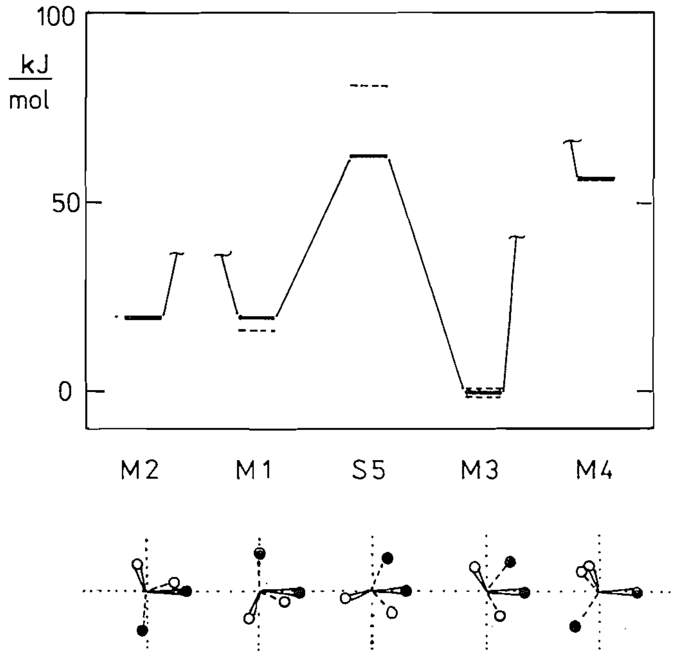

FIG. 2. Partial energy profile of the 1,2-difluorohydrazine system. Symbols: — 3-21G, ---- FOGO, ○ hydrogen atom, ● fluorine atom.

TABLE 2. Relative energies of the systems studied (kJ/mol)

System	3-21G	FOGO
meso M2	19.5	—
meso M1	19.5	16.0
Saddle point S5	62.6	80.1
Chiral M3	0.0[a]	0.0[b]
Chiral M4	50.6	—

[a] E(3-21G) = −307.07082 au.
[b] E(FOGO) = −308.3209 au.

$\Delta G^0_{298.2} = -16.6$. Equilibrium is controlled by the energy difference; the change in zero-point energy is small and the entropy change is negligible.

In conclusion, our calculations indicate that for the case of *intra*molecular discriminative interactions, the discriminative effects are small and not influenced by the entropy change: $\Delta E = -19.5$ kJ/mol; $\Delta H^0_{298.2} = -17.0$ kJ/mol; $\Delta G^0_{298.2} = -16.6$ kJ/mol. As a point of reference, the energy of thermal motion at 198.2 K is about 2.5 kJ/mol. Clearly, discriminative effects associated with *inter*molecular interactions are even smaller.

This paper is dedicated to Professor Camille Sandorfy on the occasion of his 65th birthday

DAVID JOHN MITCHELL, H. BERNHARD SCHLEGEL, SASON S. SHAIK, and SAUL WOLFE. Can. J. Chem. **63**, 1642 (1985).

At the 4-31G computational level, the intrinsic barriers of eight identity S_N2 reactions $X^- + CH_3X \rightarrow XCH_3 + X^-$ are less than the energies required to distort CH_3X from its ground state geometry to its transition state geometry by a constant 25 kcal/mol. The distortion energy and its C—X stretching and H—C—X bending components can be calculated directly, or, alternatively, estimated from the force constants and bond dissociation energies of CH_3X. Regardless of the mode of computation, the distortion energies are found to be dominated by the C—X stretching deformations, and these are linearly correlated with the intrinsic barriers. The total deformation energies are also linearly correlated with the intrinsic barriers. The transition vectors of the eight identity reactions have been calculated; each is dominated by the C—X stretch. The percentage of C—X stretching at the transition state, here termed the Distortion Index (DI), reflects the "tightness" or "looseness" of this structure. The intrinsic barrier increases as the DI increases, i.e., as the transition state becomes more "exploded". This result does not agree with the predictions of a More O'Ferrall – Jencks potential energy surface diagram. However, as shown in some detail, all of the computational results of the present work are in harmony with the surface crossing diagram model of the barrier. The essential feature of this model is the notion that the activation process in an identity S_N2 reaction is a result of the distortion that is required to transfer one electron from X^- to CH_3X.

DAVID JOHN MITCHELL, H. BERNHARD SCHLEGEL, SASON S. SHAIK et SAUL WOLFE. Can. J. Chem. **63**, 1642 (1985).

Des calculs au niveau 4-31G indiquent que les énergies des barrières intrinsèques de 8 réactions S_N2 d'identité: $X^- + CH_3X \rightarrow XCH_3 + X^-$ sont systématiquement 25 kcal/mol de moins que celles requises pour déformer le CH_3X de sa géométrie de l'état fondamental jusqu'à celle de l'état de transition. L'énergie de déformation, ainsi que ses composantes d'élongation C—X et de déformation H—C—X peuvent être calculées directement, ou évaluées, à partir des constantes de force et des énergies de dissociation des liaisons du CH_3X. Peu importe le mode de calcul, on a trouvé que les énergies de dissociation sont dominées par les déformations de l'élongation du C—X et celles-ci peuvent être reliées linéairement aux barrières intrinsèques. Les énergies de déformation totale sont également reliées linéairement aux barrières intrinsèques. On a calculé les vecteurs de transition des 8 réactions d'identité; chacune est dominée par l'élongation de C—X. Le pourcentage d'élongation de C—X au niveau de l'état de transition, que l'on appelle ici l'indice de distortion (ID), reflète la nature compacte ou lâche de cette structure. La barrière intrinsèque augmente avec l'ID, c'est-à-dire au fur et à mesure que l'on s'éloigne de l'état de transition. Ce résultat ne s'accorde pas avec les prédictions d'un diagramme de surface d'énergie potentielle de More O'Ferrall – Jencks. Cependant, tel que montré avec certains détails, tous les résultats obtenus par le calcul sont en accord avec le modèle de diagramme de croisement de surface de la barrière. La caractéristique essentielle de ce modèle réside dans le fait que le processus d'activation dans une réaction S_N2 est un résultat de la distorsion qui est requise pour transférer un électron de X^- à CH_3X.

[Traduit par le journal]

Introduction

The course of an S_N2 reaction $Y^- + CH_3X \rightarrow YCH_3 + X^-$ is attended by a number of changes in molecular geometry. A deformation of the H—C—H angles occurs as the configuration about the carbon atom is inverted, the C—X bond stretches and is broken, and the C—Y bond shortens and is formed. The changes in geometry are accompanied by changes in the total energy of the system. For a gas phase reaction, the nature of the latter has been discussed extensively (1, 2), and the reaction coordinate has been found to have the form shown in Fig. 1. In Fig. 1, $Y^- \ldots CH_3X$ and $YCH_3 \ldots X^-$ are reactant and product ion–molecule complexes (clusters), and $(Y—CH_3—X)^-$ is the S_N2 transition structure.

In an earlier communication (3), it was observed that linear relationships exist between stretching and bending geometrical parameters of $(Y—CH_3—X)^-$ transition structures and the thermochemistry of non-identity S_N2 reactions. One objective of the present work is to study the relationships between calculated geometrical parameters of identity S_N2 transition structures $(Y = X)$ and the calculated barriers $(\Delta E_0^{\neq})$ associated with such reactions (see Fig. 2). A second objective is to demonstrate that the Surface Crossing Diagram (SCD) model (4–6), which ascribes the origin of the S_N2 barrier to the energy required to transfer *one* electron from X^- to CH_3X, accounts for

all of the results.

For the reaction coordinate of Fig. 2, the region from cluster to cluster is of greatest interest, since it encompasses most of the geometrical changes. Because the fully optimized geometries and energies of $X^- \ldots CH_3X$ clusters and $(X—CH_3—X)^-$ transition structures were already available from HF/4-31G computations for X = H, HCC, NC, CN, HO, HS, F, Cl (2, 3, 7), a detailed examination of the relationships between these quantities was performed at this level. Additional computations were performed, as needed, using the 4-31G basis set and the GAUSSIAN 80 (8) or GAUSSIAN 82 (9) programmes.

Computational results

Table 1 summarizes the primary data: $\Delta E_0^{\ddagger}$ is the intrinsic barrier, R_1 is the C—X bond length of CH_3X in the cluster, R_2 is the C—X bond length in the transition structure, f_R is the calculated CH_3—X stretching force constant, f_θ is the calculated bending force constant for the umbrella deformation of the methyl group, and $f_{R\theta}$ is the stretch–bend interaction force constant.

The intrinsic barrier can be partitioned (10) into the energy required to deform the CH_3X moiety, and the interaction energy between X^- and the deformed CH_3X. An approximate estimate of the deformation energy can be obtained from the calculated force constants of CH_3X. To change CH_3X from its geometry in the cluster to its geometry in the transition state requires a stretch of the C—X bond by ΔR, and a bend of the H—C—X angle by $\Delta\theta$, as well as smaller changes in the rest of the molecule. Since stretching potentials are very anharmonic, it is not possible to estimate the energy associated with a C—X stretch from harmonic force constants alone. Therefore, to approximate the stretching anharmonicity, a Morse curve (11) was fitted to the calculated harmonic stretching force constant, f_R, and the experimental C—X bond dissociation energies, D, using eq. [1], where $\Delta R = R_2 - R_1$.

$$[1] \quad \Delta E_R^{approx} = D[1 - \exp(-\beta\Delta R)]^2; \quad \beta = (f_R/2D)^{1/2}$$

The data are shown in Table 2, and Fig. 3 is a plot of ΔE_R^{approx} versus $\Delta E_0^{\ddagger}$. The two quantities are linearly related (r = 0.975).

The energy required to bend an H—C—X angle can be estimated directly from the calculated harmonic force constant f_θ (eq. [2]), because the bond anharmonicity is small.

$$[2] \quad \Delta E_\theta^{approx} = \tfrac{1}{2} f_\theta(\Delta\theta)^2$$

The stretch–bend interaction must also be taken into account, because bending of the H—C—X angles is greatly facilitated by the stretch of the C—X bond. In the harmonic approximation, the stretch–bend interaction is given by eq. [3].

$$[3] \quad \Delta E_{R\theta}^{approx} = f_{R\theta}(\Delta R)(\Delta\theta)$$

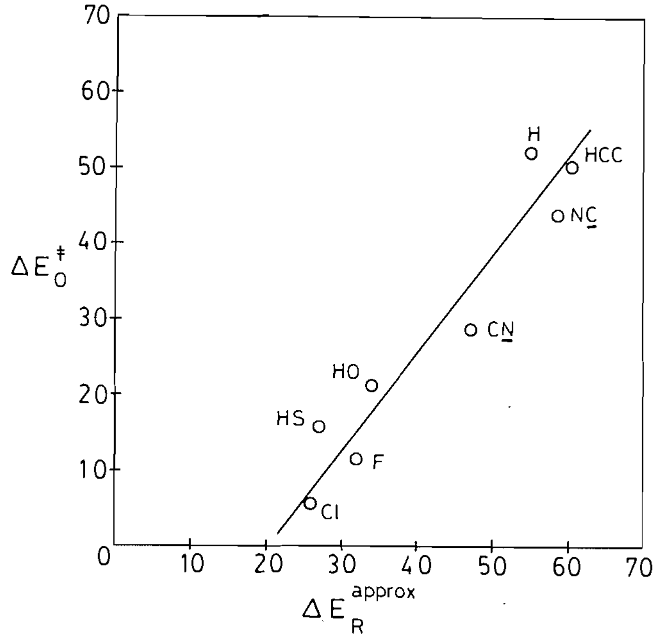

FIG. 3. A plot of $\Delta E_R^{\text{approx}}$ versus $\Delta E_0^{\ne}$ for eight identity S_N2 reactions. Energies are in kcal/mol.

In terms of the approximations of eqs. [1]–[3], the total deformation energy is given by eq. [4]. All of these quantities are included in Table 2.

$$[4] \quad \Delta E_{\text{def}}^{\text{approx}} = \Delta E_R^{\text{approx}} + \Delta E_\theta^{\text{approx}} + \Delta E_{R\theta}^{\text{approx}}$$

The deformation energies just described are approximations, because they are based on the calculated force constants and experimental dissociation energies of CH_3X. The actual deformation energies, ΔE_{def}, and their components can be calculated directly, as shown in Scheme 1. The stretching deformation energy, ΔE_R, is obtained from the energy difference between **3** and **1**, where **1** refers to CH_3X in the geometry of the cluster, and **3** is derived from **1** by a stretch of the C—X bond to its value in the transition structure **2**. The bending deformation energy, ΔE_θ, is obtained analogously from the energy difference between **1** and **4**, where **4** refers to bending of **1** to the bond angles of the transition structure. The total deformation energy is the energy difference between **1** and **2**. The quantities ΔE_{def}, ΔE_R, and ΔE_θ are collected in Table 3.[3]

Figures 4, 5, and 6 show, respectively, plots of ΔE_R, ΔE_θ, and ΔE_{def} versus $\Delta E_0^{\ne}$. The relationship between ΔE_R and $\Delta E_0^{\ne}$ is linear ($r = 0.954$), as is the relationship between ΔE_{def} and $\Delta E_0^{\ne}$ ($r = 0.979$), but ΔE_θ is poorly correlated with $\Delta E_0^{\ne}$. In addition, inspection of the data of Table 3 reveals that ΔE_{def} is dominated by the stretching deformation.

The most interesting observation is that the quantity ($\Delta E_{\text{def}} - \Delta E_0^{\ne}$) is constant. For this series of eight X's, at the HF/4-31G level, the difference is 25.1 ± 3.3 kcal/mol. *This is an important result. It implies that the differences in the intrinsic barriers result from the differences in* ΔE_{def}*; the effect of the anion* X^- *is approximately constant.* As will be discussed below, this finding, especially, constitutes strong support for the State Correlation Diagram (SCD) model of the S_N2 barrier.

[3] For X = F, the ΔE_{def} calculated from the energy difference between **1** and **2** is the same as the deformation energy obtained from a Morokuma analysis (10). The authors thank Dr. J. M. Lefour (Orsay) for checking this point.

[a] In kcal/mol.

As an additional probe of the identity S_N2 surface near the top of the barrier, vibrational frequency calculations were carried out for the eight transition states. Each structure has one imaginary frequency whose magnitude depends on the mass of X and on the curvature of the surface. The normal coordinate that corresponds to the imaginary frequency is the transition vector, which points along the intrinsic reaction path linking reactants and products. The transition vectors for the eight identity reactions are summarized in Table 4. To facilitate comparisons, in Fig. 7 the vectors have been shifted by an overall translation, to allow the central carbon atoms to remain stationary.

All of the transition vectors are very similar, despite the differences in the intrinsic barriers, and are dominated in each case by a C—X stretch. There is also a component of bend. Analysis of the force constants of the transition structures reveals that the bending potential has a positive curvature, and the stretching potential has a small positive or negative curvature; the stretch–bend interaction is always negative, and accounts for a sizeable fraction of the negative curvature. This analysis therefore indicates that the C—X stretch dominates the energetics associated with the barrier process, but the intrinsic reaction path requires the concerted action of stretching and bending at the transition state.

The foregoing computational results may be summarized as follows.

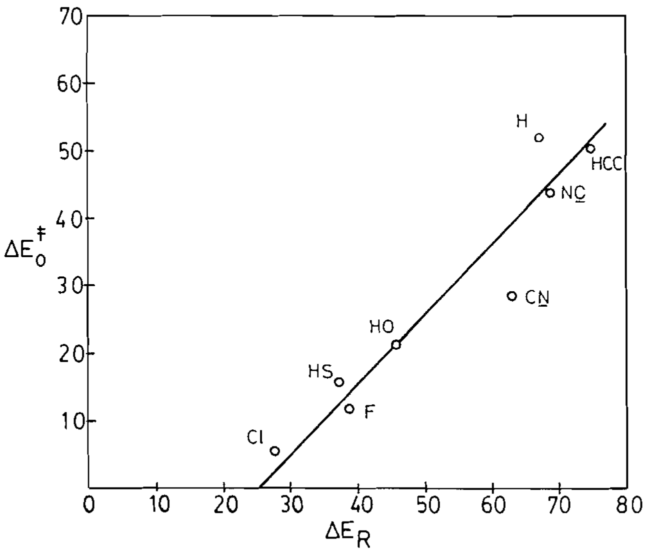

FIG. 4. A plot of ΔE_R versus $\Delta E_0^{\neq}$ for eight identity S_N2 reactions. Energies are in kcal/mol.

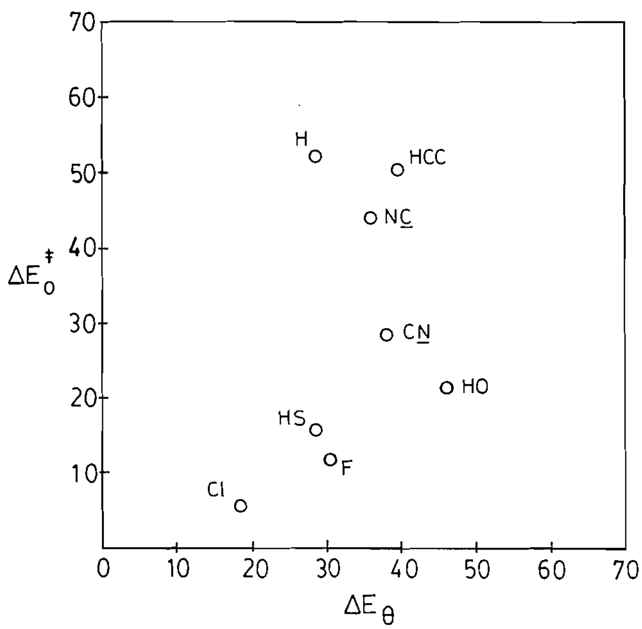

FIG. 5. A plot of ΔE_θ versus $\Delta E_0^{\neq}$ for eight identity S_N2 reactions. Energies are in kcal/mol

(a) The activation process of an identity S_N2 reaction is dominated by the deformation energy required to bring CH_3X from its geometry in the cluster to its geometry in the transition state.

(b) The deformation energy depends on the nature of X, and follows the order H ≃ HCC ≃ *C*N > *N*C > HO > HS > F > Cl.

(c) The C—X stretch is the distinguished deformation leading to the transition state.

(d) The C—X stretch required to achieve the transition state is linearly correlated with the intrinsic barrier.

Interpretation of the results in terms of the SCD model of the S_N2 barrier

An understanding of the activation process in the S_N2 reac-

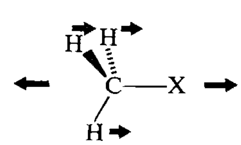
tion requires an understanding of the results just described. In the SCD model, the correlation diagram appropriate to an identity S_N2 reaction is shown in Fig. 8 (5*a*, *b*), whose anchor points are the two ground states and the two charge transfer states of the clusters. The transition state results from an avoided crossing of the two curves, and its geometry coincides with the crossing point.

At this point, the ground state $X\!:^-$R—X and the charge transfer state X·(R$\dot{—}$X)$^-$ have the same energy. Because of the energy gap that separates the two states at the beginning of the reaction, the crossing that achieves the transition state must be driven by molecular distortions (5, 13). The effects of these distortions are a destabilization of the ground state, and a concomitant stabilization of the charge transfer state.

That the ground state should be destabilized by the distortions depicted in **5** is self-evident. The charge transfer state is stabilized by the transformation of the (R$\dot{—}$X)$^-$ radical anion bond into a covalent X—R bond on the opposite side of R.



5

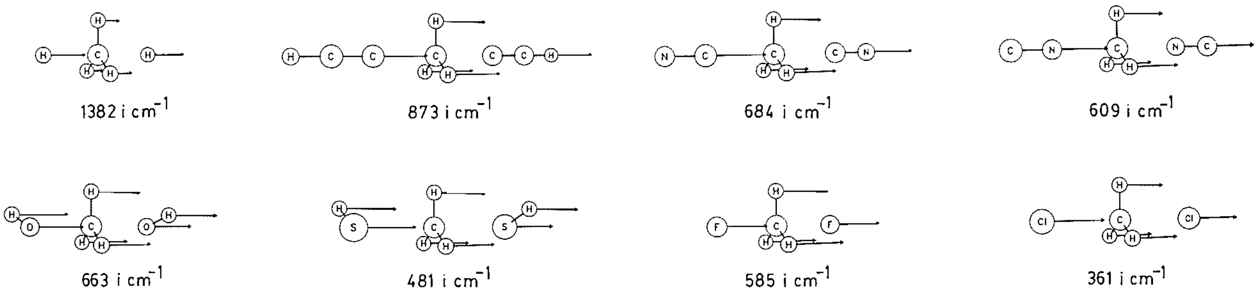


FIG. 7. Transition vectors for eight identity S_N2 transition structures. Calculations performed at the HF/4-31G level using GAUSSIAN 82.

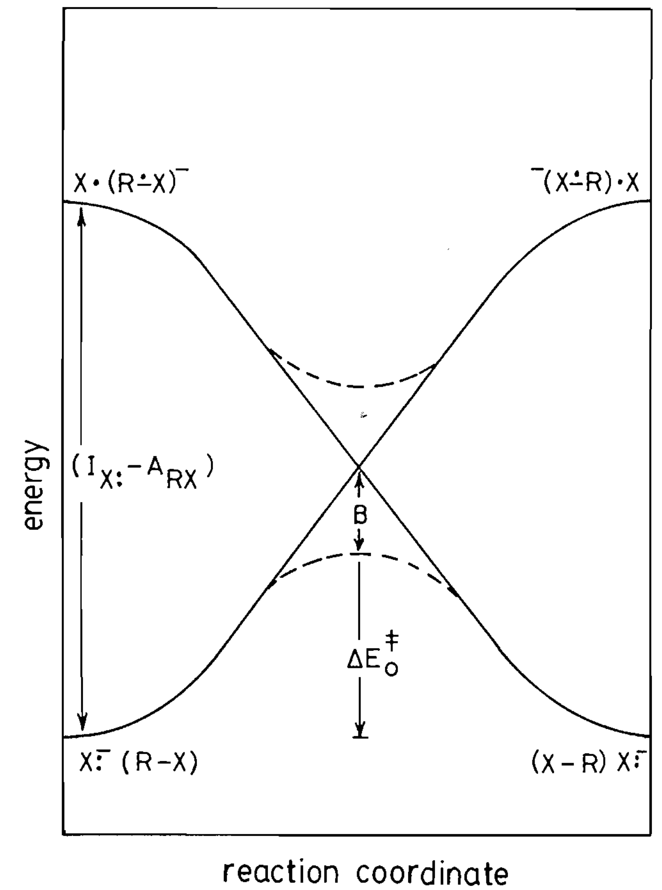

FIG. 8. State correlation diagram for the identity S_N2 reaction. The minima along the reaction coordinate refer to the ion–molecule clusters, and the maxima refer to the charge transfer states. The avoided crossing is given by B, $\Delta E_0^{\neq}$ is the central barrier, and $(I_X - A_{RX})$ is the electron transfer energy gap. The reaction coordinate can be defined as the difference between the X . . . R and R . . . X distances.

The conclusion that the S_N2 barrier results from the distortion required to reach the crossing point of the ground and charge transfer states provides a physical model for the correlation between $\Delta E_0^{\neq}$ and ΔE_{def}. In addition, two features of Fig. 8 allow the magnitudes of $\Delta E_0^{\neq}$ and ΔE_{def} to be estimated. One is the electron transfer energy gap (eq. [5]) that has to be overcome by the molecular distortions, where $I_{X:}$ is the ioniza-

$$[5] \quad \text{gap} = I_{X:} - A_{RX}$$

tion potential of X^- and A_{RX} is the electron affinity of RX. The second is the curvature of the functions that connect the ground and charge transfer states. When the distortion is inefficient, a shallow descent of the charge transfer state will be observed, as

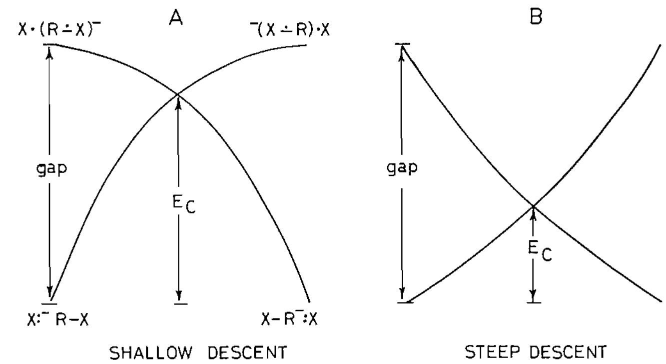

FIG. 9. (A) Shallow descent from the charge transfer state, a property of delocalized radical anions $(R\dot{-}X)^-$. (B) Steep descent from the charge transfer state, corresponding to efficient distortion of the charge transfer state.

shown in Fig. 9A. An efficient distortion will lead to a steep descent from the charge transfer state, as shown in Fig. 9B. For X's characterized by the same gap, the S_N2 barrier will decrease as the distortion becomes more efficient. As discussed elsewhere (5*a*, *b*, *d*, 6), the steepness or shallowness of descent in such cases is determined by the degree of delocalization of the odd electron in the radical anion $(R\dot{-}X)^-$. For example, delocalization in the radical anion results in a shallow descent for two reasons: (1) the distortion must overcome the delocalization energy; (2) the delocalization inhibits bond coupling between X· and $(R\dot{-}X)^-$.

A radical anion may possess two modes of delocalization, termed intralinkage and interlinkage. The intralinkage mode is defined by eq. [6], where $W_{R:}$ and $W_{X:}$ refer to the weights (i.e., the squares of the coefficients) of the resonance forms $R{:}^-{\cdot}X$ and $R{\cdot}{:}X^-$, respectively.

$$[6] \quad (R\dot{-}X)^- = W_{R:}(R{:}^-{\cdot}X) + W_{X:}(R{\cdot}{:}X^-); \quad W_{R:} + W_{X:} = 1$$

In a delocalized radical anion, $W_{R:}$ is large. This delocalizes the odd electron on X of $(R\dot{-}X)^-$ and leads to the inhibition of bond coupling noted above.

The interlinkage mode occurs whenever R bears two or more identical leaving groups X, as in CH_2Cl_2 or CH_4. In such cases the odd electron will be delocalized over all identical linkages (5*d*) as depicted in eq. [7] for $(CH_4)^{\dot{-}}$, where N is the normalization constant.

$$[7] \quad (CH_4)^{\dot{-}} = N[\text{H}\dot{-}\underset{\text{H}}{\overset{\text{H}}{\text{C}}}\text{—H} + \text{H—}\underset{\text{H}}{\overset{\text{H}}{\text{C}}}\dot{-}\text{H} + \ldots\ldots]$$

Since the odd electron may also exhibit intralinkage delocalization in the sense of eq. [6], such radical anions will be strongly delocalized; S_N2 reactions in these cases will be characterized by the shallow descent depicted in Fig. 9A.

The total index of delocalization $\bar{W}_{R:}$ can be taken as the product of the intralinkage index $W_{R:}$ and the interlinkage index. The latter is given by the inverse of the normalization constant of eq. [7], which takes into account the number of bonds that participate in delocalization. For example, in $(CH_4)^{\overset{\bullet}{-}}$ the interlinkage index is $(4)^{-1/2}$.

[8] $\bar{W}_{R:} = W_{R:}/N$

The deformation energy required to reach the transition state can be set approximately equal to the height of the crossing point E_C (Figs. 9A, 9B) above the cluster. As is evident from Figs. 8, 9A, and 9B, E_C is a fraction, f, of the energy gap ($I_{X:} - A_{RX}$), and this fraction is proportional to $\bar{W}_{R:}$, leading to eq. [9]. A similar expression holds for the barrier itself, with the modification that the avoided crossing B (Fig. 8) must be subtracted from E_C. This leads to eq. [10].

[9] $\Delta E_{def} \sim E_C = f(I_{X:} - A_{RX});\quad f \propto \bar{W}_{R:}$

[10] $\Delta E_0^{\neq} = f(I_{X:} - A_{RX}) - B;\quad f \propto \bar{W}_{R:}$

As discussed elsewhere (5, 6, 13), the avoided crossing is approximately constant for the identity reactions (B = 14 kcal/mol) (5*a*, *b*, *d*). This result is thus consistent with the HF/4-31G computational finding that ΔE_{def} differs from $\Delta E_0^{\neq}$ by a constant 25 kcal/mol. Equation [10] can be simplified further and given quantitative predictive ability by setting the proportionality constant between f and $\bar{W}_{R:}$ equal to unity (5) (eq. [11]).

[11] $\Delta E_0^{\neq}$ (kcal/mol) $= \bar{W}_{R:}(I_{X:} - A_{RX}) - 14$

Equations [9] and [11] reveal that trends in $\Delta E_0^{\neq}$ and in ΔE_{def} will be determined by the interplay between $\bar{W}_{R:}$ and ($I_{X:} - A_{RX}$). This point is illustrated by the data collected in Table 5, viz., the reactivity indices ($I_{X:} - A_{RX}$) and $\bar{W}_{R:}$, the calculated ΔE_{def}, the calculated $\Delta E_0^{\neq}$, and the $\Delta E_0^{\neq}$ given by eq. [11]. The deformation energy is large and the barrier is large when the electron transfer energy gap ($I_{X:} - A_{RX}$) is large, or when the shallowness index ($\bar{W}_{R:}$) is large. For example, in entries 1 and 2, $\bar{W}_{R:}$ is approximately constant; and the reaction $F^- + CH_3F$ has a higher $\Delta E_0^{\neq}$ and a higher ΔE_{def} than the reaction $Cl^- + CH_3Cl$ because the electron transfer energy is larger in the former case. Similarly, in entries 3, 4, and 5, $\bar{W}_{R:}$ is again approximately constant; in these cases as well, $\Delta E_0^{\neq}$ and ΔE_{def} increase as the electron transfer energy gap increases.

On the other hand, comparison of entries 1 and 4, for which the energy gap is approximately constant, shows that $HO^- + CH_3OH$, the reaction having the larger $\bar{W}_{R:}$, has the larger $\Delta E_0^{\neq}$ and the larger ΔE_{def}.

In summary, the Surface Crossing Diagram model (Fig. 8) and its quantitative representation (eq. [11]) reproduce the calculated trends in $\Delta E_0^{\neq}$ and ΔE_{def}. It follows that the activation process in an identity S_N2 reaction is a result of the distortion that is required to transfer one electron from $X:^-$ to CH_3X.

The availability of a physical model of the activation process allows the trends in the transition state geometries to be interpreted. In an identity S_N2 reaction, the distortion that distinguishes one X from another is $\Delta R = (R_2 - R_1)$, the change in the C—X bond length from the cluster to the transition state. The percentage of C—X lengthening at the transition state may be defined as the Distortion Index, DI (eq. [12]). This reflects the "tightness" or "looseness" of the transition state. A large DI corresponds to a looser or "exploded" (14) transition state.

TABLE 5. Reactivity indices, ΔE_{def}, $\Delta E_0^{\neq}$, and $\Delta E_0^{\neq}$ (eq. [11]), for $X^- + CH_3X \rightarrow XCH_3 + X^-$ reactions[a]

Entry	X	$I_{X:} - A_{RX}$[b]	$\bar{W}_{R:}$[b]	ΔE_{def}[c]	$\Delta E_0^{\neq}$	$\Delta E_0^{\neq}$ (eq. [11])[c]

[12] $DI = 100\Delta R/R_1$

The factors that control the DI are, again ($I_{X:} - A_{RX}$) and $\bar{W}_{R:}$. The first defines the energy gap that must be overcome by the distortion. The second reflects the ability of the distortion to decrease the energy of the charge transfer state. The following trends are predicted.

(a) For a series of reactions $X^- + CH_3X$ in which the degree of radical anion delocalization ($\bar{W}_{R:}$) remains constant, DI will increase as the energy gap increases, i.e., the transition state will become looser.

(b) For a series of $X^- + CH_3X$ reactions in which the energy gap remains constant, DI will increase as $\bar{W}_{R:}$ increases.

The data of Table 6 illustrate these points. From entries 1 and 2, which have the same $\bar{W}_{R:}$, it is seen that the looser transition state (larger DI) is obtained for $F^- + CH_3F$, which has the larger charge transfer energy gap. Similarly, in entries 3, 4, and 5, the looseness of the transition state again increases as the energy gap increases. On the other hand, entries 1 and 4 demonstrate that, for a constant gap, the transition state becomes looser as $\bar{W}_{R:}$ increases. Clearly, delocalization of the radical anion (larger $\bar{W}_{R:}$) leads to a loosening of the transition structure. The loosest transition state is thus observed for $H^- + CH_4$, because this leads to the most delocalized radical anion.

Table 6 also illustrates an additional correlation, between $\Delta E_0^{\neq}$ and the Distortion Index. The tightest transition state ($Cl^- + CH_3Cl$) has the lowest barrier, and the loosest transition state ($H^- + CH_4$) has the highest barrier.

What has thus emerged is a direct link between deformation energies, barriers, and transition state geometries, each of which is a consequence of the activation process in an S_N2 reaction. This unified insight has resulted from the notion that the activation process is itself a result of the distortion required to transfer a single electron from $X:^-$ to X across the CH_3 moiety of CH_3X.

The foregoing analysis of the trends in transition state geometries should be contrasted with the predictions of potential energy surface diagrams (PESD) (cf. Fig. 10) (15). For an identity S_N2 reaction the four corners of the PESD model represent reactants, products, the triple ion configuration ($X^- + CH_3^+ + X^-$), and the high energy hypervalent structure $(XCH_3X)^-$. The transition state lies at the midpoint between reactants and products, and changes in X can make the transi-

tion state tighter or looser, as indicated by the arrows in Fig. 10. Ignoring the effect of the high energy $(XCH_3X)^-$ corner, as is customary, leads to the following conclusion: if a change in X decreases the energy of the triple ion corner, the transition state will shift towards this corner, *and become looser*. For example, replacement of X = H by X = Cl should lead to a looser transition state, because $(Cl^- + CH_3^+ + Cl^-)$ is at least 40 kcal/mol more stable than $(H^- + CH_3^+ + H^-)$.

The trends of Table 5 are just the opposite of this important prediction of the PESD model. It is, therefore, not clear how the PESD model can be employed to rationalize the computational results of the present work.
