Reçu le 30 mars 1984

OTMANE BOUAB, GÉRARD LAMATY et CLAUDE MOREAU. Can. J. Chem. **63**, 816 (1985).

Les vitesse d'hydrolyse des orthoesters trioxa-2,7,8 bicyclo[3.2.1] octanes et trioxa-2,8,9 bicyclo[3.3.1] nonanes substitués en position 1 (R = H, CH_3, C_6H_5) ont été déterminées à deux températures dans un mélange eau/dioxanne 40:60 en volume. Ces nouveaux résultats confirment le comportement généralement observé dans l'hydrolyse des orthoesters ayant une conformation favorable pour s'hydrolyser avec contrôle stéréoélectronique.

OTMANE BOUAB, GÉRARD LAMATY, and CLAUDE MOREAU. Can. J. Chem. **63**, 816 (1985).

The rates of hydrolysis of 1-substituted 2,7,8-trioxabicyclo[3.2.1]octanes and 2,8,9-trioxabicyclo[3.3.1]nonanes (R = H, CH_3, C_6H_5) have been determined at two temperatures in dioxan/water (60:40 by volume). These new results confirm the behaviour generally observed in the hydrolysis of orthoesters which have a favourable conformation to hydrolyze under stereoelectronic control.

Introduction

Dans un précédent travail concernant l'hydrolyse des trioxa-2,4,10 adamantanes (1, 2) nous avons émis l'hypothèse que l'étape déterminant la vitesse de réaction était l'addition de l'eau sur l'ion carboxonium intermédiaire et non la formation de cet ion; en effet, l'encombrement stérique dû à la présence d'un cycle cyclohexanique est tel que le réaction favorisée est le retour vers l'acide conjugué du substrat (étape k_{-2}, schéma 1), hypothèse confirmée depuis par des travaux récents de McClelland (3).[1]

Afin de vérifier que le changement d'étape lente observé dans l'hydrolyse des trioxaadamantanes était dû à un encombrement stérique à l'approche de l'eau dans l'ion carboxonium intermédiaire, nous avons procédé à l'étude de modèles simples (4) et nous présentons maintenant l'étude réalisée sur deux séries de composés dont la structure est très voisine de celle des trioxaadamantanes – les trioxa-2,7,8 bicyclo[3.2.1] octanes substitués en position 1 : **1** (R = H), **2** (R = CH_3), **3** (R = C_6H_5) et les trioxa-2,8,9 bicyclo[3.3.1] nonanes substitués en position 1 : **4** (R = H), **5** (R = CH_3) et **6** (R = C_6H_5) – mais dans lesquels le retour interne vers l'acide conjugué du substrat à partir de l'ion carboxonium intermédiaire est fortement improbable (schéma 2), l'encombrement stérique d'une chaîne hydroxylée étant moindre que celui d'un cycle cyclohexanique.

Dans un premier temps, nous avons procédé à la synthèse des produits qui n'était pas connue pour quatre d'entre eux, **2**, **3**, **5** et **6**; dans un deuxième temps, nous avons procédé à l'analyse des produits de la réaction d'hydrolyse et à la détermination des constantes de vitesse d'hydrolyse et des grandeurs d'activation.

Résultats expérimentaux

Synthèse

Les orthoesters **1**, **2** et **3** ont été préparés par réaction de transestérification à partir du butanetriol-1,2,4 et des orthocarboxylates de triméthyle ou triéthyle correspondants; les orthoesters **4**, **5** et **6** ont été synthétisés, par réaction de transestérification également, à partir du pentanetriol-1,3,5 et des orthocarboxylates de triméthyle ou triéthyle correspondants. Les propriétés physico-chimiques des quatre nouveaux produits – **2**, **3**, **5** et **6** – sont données dans la partie expérimentale.

Analyse des produits de la réaction

L'analyse des produits d'hydrolyse peut apporter des renseignements utiles sur le sens d'ouverture des orthoesters. L'hydrolyse des orthoesters **1**, **2** et **3** peut conduire, tout en respectant les règles stéréoélectroniques, à trois produits (**10**, **11** et **12**, schéma 3); un seul produit d'hydrolyse (**10**) est observé. De même, l'hydrolyse des orthoesters **4**, **5** et **6** peut conduire, tout en respectant les mêmes règles stéréoélectroniques, à deux produits (**13** et **14**, schéma 4); là aussi, un seul produit d'hydrolyse est observé (**13**).

Ces aspects seront développés plus en détail dans la partie discussion.

SCHÉMA 2

Résultats cinétiques

L'hydrolyse acido-catalysée des trioxa-2,7,8 bicyclo[3.2.1] octanes substitués en position 1 et des trioxa-2,8,9 bicyclo-[3.3.1] nonanes substitués en position 1 a été effectuée dans le solvant eau/dioxanne 40:60 en volume et à deux températures. Les couples acide/base utilisés pour tamponner le milieu sont acide formique/formiate de sodium et acide acétique/acétate de sodium. La force ionique a été maintenue constante à 0,1 *M* par addition de chlorure de potassium. Les résultats cinétiques sont rassemblés dans les tableaux 1 et 2 (la reproductibilité moyenne est de 3%). Les constantes catalytiques $k_{H_3O^+}$, k_{HCOOH} et k_{CH_3COOH} ont été obtenues en exploitant les résultats des tableaux 1 et 2 et en tenant compte des effets dus à la présence du dioxanne (5, 6); ces constantes ainsi que les grandeurs d'activation sont reportées dans le tableau 3.

Interprétation des résultats expérimentaux

L'examen des tableaux 1 et 2 montre que l'hydrolyse des trioxa-2,7,8 bicyclo[3.2.1] octanes substitués en position 1 et des trioxa-2,8,9 bicyclo[3.3.1] nonanes substitués en position 1 est soumise à une catalyse acide générale, type de catalyse compatible avec le concept de contrôle stéréoélectronique qui implique que la rupture d'une liaison C—O—alkyle est favorisée si les deux autres hétéroatomes ont chacun une paire d'électrons libres antipériplanaire par rapport à cette liaison (7).

Par ailleurs, les résultats expérimentaux sont en accord avec un mécanisme dans lequel l'étape déterminant la vitesse de réaction est la formation d'un ion carboxonium intermédiaire (8, 9): les entropies d'activation sont du même ordre de grandeur que celles reportées dans l'hydrolyse d'autres systèmes cycliques (4), faiblement négatives dans la réaction catalysée par H_3O^+ (mécanisme unimoléculaire A1) et fortement négatives dans la réaction catalysée par les acides faibles (mécanisme bimoléculaire A S_E2); le remplacement d'un hydrogène par un méthyle où un phényle entraîne une augmentation de la vitesse de l'hydrolyse en accord avec une meilleure stabilisation de l'état de transition pour les produits substitués et en accord également avec l'absence d'empêchement stérique à la conjugaison dans les dérivés cycliques, empêchement stérique observé en série aliphatique (tableau 4) par Kresge et coll. (10).

Ces résultats font donc apparaître un comportement totalement différent de celui observé avec les trioxa-2,4,10 adamantanes substitués en position 3 (tableau 5) et confirment la particularité du système adamantyle.

SCHÉMA 4

Discussion

Sens d'ouverture dans l'hydrolyse des trioxa-2,7,8 bicyclo-[3.2.1] octanes substitués en position 1

En appliquant les règles stéréoélectroniques (11), l'hydrolyse des orthoesters **1**, **2** et **3** peut s'effectuer par rupture de l'une quelconque des liaisons C—O, C(1)—O(7), C(1)—O(8) ou C(1)—O(2) (schéma 5) pour donner les ions carboxoniums cycliques à 5, 6 ou 7 éléments et conduire aux produits d'hydrolyse **10**, **11** ou **12**. Expérimentalement, l'hydrolyse de l'orthoester **3** (R = C_6H_5) conduit à un seul produit (**10**) ce qui exclurait la formation de l'ion carboxonium cyclique à 7 éléments et donc la rupture, en particulier au cours de l'étape cinétique, de la liaison C(1)—O(8). Par ailleurs, si on élimine le facteur tension de cycle dans l'état initial, facteur qui favoriserait la rupture de la liaison C(1)—O(7) (10), il ne reste que les stabilités relatives des ions carboxonium pour trancher et les avis sont partagés; selon Paulsen (11), les ions dioxolénium-1,3 seraient plus stables que les ions dioxénium-1,3 alors que pour McClelland ce serait l'inverse (12).[2]

Sens d'ouverture dans l'hydrolyse des trioxa-2,8,9 bicyclo-[3.3.1] nonanes substitués en position 1

En ce qui concerne le sens d'ouverture des orthoesters **4**, **5** et **6**, la situation est moins complexe; deux ions cycliques peuvent se former tout en respectant les mêmes règles stéréoélectroniques (schéma 6); il ne peut y avoir que deux produits d'hydrolyse, **13** ou **14**. Expérimentalement, l'hydrolyse de l'orthoester **6** conduit au produit **13** ce qui exclurait la formation d'un ion carboxonium à 8 éléments et par conséquent la rupture cinétique de la liaison C(1)—O(9).

Position de l'état de transition

Nous avons montré dans un précédent travail (4) que les effets de substituant étaient un des critères qui permettaient d'élucider le mécanisme de l'hydrolyse des acétals et des orthoesters; le rapport $k_{C_6H_5}/k_{CH_3}$ permet, en particulier, de mieux apprécier la position de l'état de transition le long du chemin réactionnel: dans l'hydrolyse des orthoesters, ce rapport est voisin de l'unité, tantôt inférieur, tantôt supérieur, mais loin du rapport $k_{C_6H_5}/k_{CH_3}$ que l'on trouve dans l'hydrolyse des acétals ($k_{C_6H_5}/k_{CH_3} \simeq 30$).

Les rapports $k_{C_6H_5}/k_{CH_3}$ déterminés dans ce travail, ($k_{C_6H_5}/k_{CH_3}$ = 0,4 à 0,9 pour la série bicyclo[3.2.1] octane et $k_{C_6H_5}/k_{CH_3}$ = 0,7 à 1,1 pour la série bicyclo[3.3.1] nonane), confirment l'analyse que nous avions faite, à savoir que seul un état de transition ayant peu de caractère ion carboxonium peut conduire à un rapport $k_{C_6H_5}/k_{CH_3}$ inférieur à l'unité, les effets inductifs (+*I* pour CH_3 et −*I* pour C_6H_5) pouvant entrer en

compétition avec les effets mésomères (stabilisation de l'ion carboxonium à la fois par CH_3 et C_6H_5).

Réactivité

L'examen du tableau 3 montre qu'il n'existe pratiquement pas de différence de réactivité entre les séries bicyclo[3.2.1] octane et bicyclo[3.3.1] nonane pour un substituant donné, confirmant ainsi de façon plus précise les résultats obtenus par Hall *et al.* (12) pour les dérivés non substitués **1** et **4**.

L'introduction d'un cycle à cinq chaînons en série bicyclo[3.2.1] octane n'a donc pas de conséquence notable sur la réactivité des orthoesters. Des observations similaires ont déjà été faites antérieurement: il n'existe pas de différence de réactivité entre le diéthoxy-2,2 tétrahydrofuranne et le diéthoxy-2,2 tétrahydropyranne (7) pas plus qu'il n'en existe entre les méthoxy-2 dioxolannes-1,3 et les méthoxy-2 dioxannes-1,3 (4). De même un travail récent de Kresge en série bicyclo[2.2.1] heptane confirme l'absence de tension de cycle ou tension angulaire dues à la présence de cycles à cinq éléments dans l'hydrolyse des orthoesters (13).

Le fait que l'état de transition de la réaction soit peu avancé le long du chemin réactionnel n'est probablement pas étranger au "tassement" de la réactivité des orthoesters; cependant, une caractéristique commune à tous les orthoesters étudiés jusqu'à maintenant est une orientation favorable des paires d'électrons libres sur les atomes d'oxygène permettant l'hydrolyse avec contrôle stéréoélectronique.

Partie expérimentale

Les spectres de rmn ^{1}H ont été enregistrés sur un appareil Varian EM 390 (référence interne: TMS).

Synthèse

Les orthoesters **1**, **2**, **3**, **4**, **5** et **6** ont été préparés par réaction de transestérification à partir du butanetriol-1,2,4 (**1**, **2** et **3**) ou du pentanetriol-1,3,5 (**4**, **5** et **6**) et des orthocarboxylates de triméthyle ou

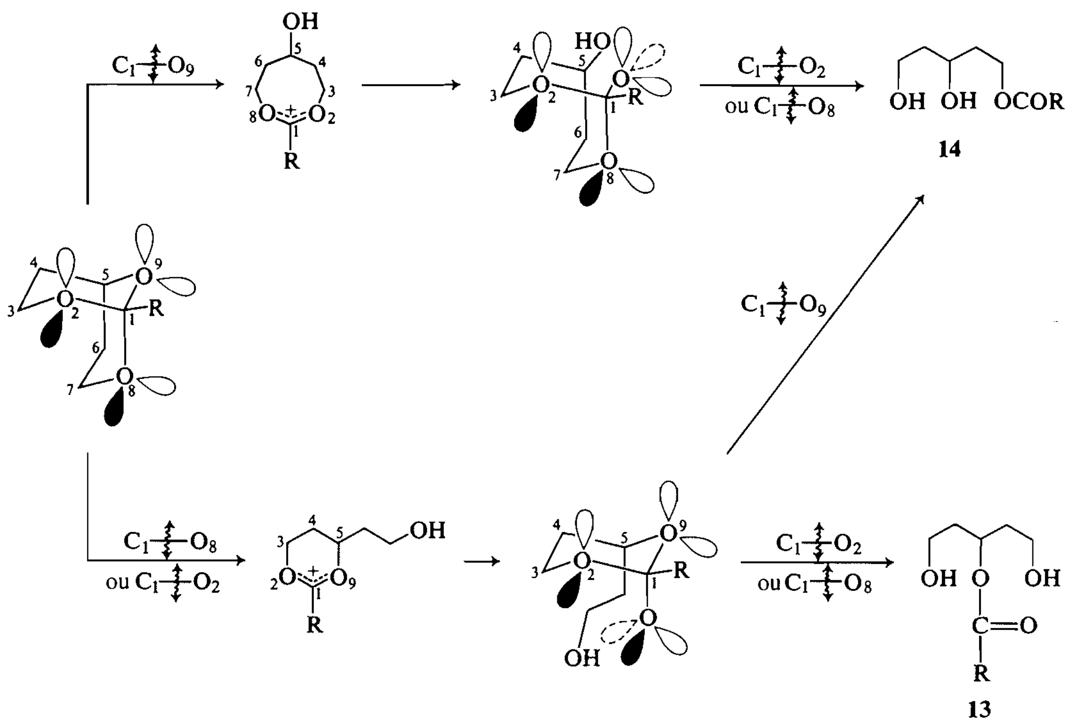

SCHÉMA 6

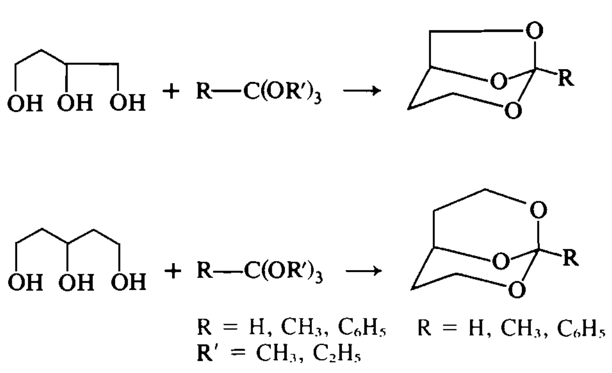

SCHÉMA 7

triéthyle correspondants (schéma 7).

1: La méthode reportée par Crank et Eastwood (14) conduit à des rendements médiocres. Ce produit a été obtenu en modifiant la procédure reportée par Hall *et al.* (12): un mélange de 14,8 g (0,1 mol) d'orthoformiate d'éthyle et 10,6 g de butanetriol-1,2,4 (Aldrich) est chauffé à 100°C pendant 3 h sous pression normale. On récupère ainsi les deux premières molécules d'alcool. La température est abaissée à 50°C et on fait barboter de l'acide chlorhydrique gazeux sec pendant 2 min. Le mélange est agité pendant 15 min et la pression abaissée à 20 Torr (1 Torr = 133.3 Pa). En chauffant progressivement, la troisième molécule d'éthanol est libérée et l'orthoester distillé. Une deuxième distillation soignée permet d'obtenir 6 g d'orthoester **1** pur; Eb. = 66–67°C/20 Torr; rendement: 52% (litt. (12) Eb. = 82°C/30 Torr; rendement: 70%); rmn ^{1}H ($CDCl_3$) δ: 1,2–1,4 (1H, deux multiplets, H4a), 2,1–2,5 (1H, multiplet symétrique, H4e), 3,6–4,1 (4H, multiplet, H méthyléniques sur C3 et C6), 4,5 (1H, multiplet, H5), 5,8 (1H, singulet, H1).

2: 16,2 g (0,1 mol) d'orthoacétate d'éthyle et 10,6 g de butane triol-1,2,4 (0,1 mol) sont dissous dans 50 mL d'alcool isobutylique anhydre. Ce mélange est chauffé progressivement jusqu'à 100°C. Une première fraction distille à 78°C; une deuxième fraction distille à 100°C; en abaissant la pression à 20 Torr on recueille l'orthoester entre 67°C et 72°C. Après redistillation, on obtient 5 g d'orthoester **2** pur; Eb. = 70°C/20 Torr; rendement: 38%; rmn ^{1}H ($CDCl_3$) δ: 1,2–1,5 (1H, deux multiplets, H4a), 1,58 (3H, singulet, méthyle sur C1), 2,2–2,5 (1H, multiplet symétrique, H4e), 3,7–4,2 (4H, multiplet, H méthyléniques sur C3 et C6), 4,6–4,8 (1H, multiplet, H5).

3: 3,7 g (0,02 mol) d'orthobenzoate de méthyle et 2,2 g (0,02 mol) de butanetriol-1,2,4 sont chauffés progressivement jusqu'à 140°C, période pendant laquelle on recueille du méthanol. Le résidu visqueux qui reste dans le ballon est distillé pour donner 2 g d'orthoester **3**; Eb. = 120°C/0,5 Torr; rendement: 60%; rmn ^{1}H ($CDCl_3$) δ: 1,3–1,6 (1H, deux multiplets, H4a), 2,2–2,6 (1H, multiplet symétrique, H4e), 3,9–4,5 (4H, multiplet, H méthyléniques sur C3 et C6), 4,80 (1H, multiplet, H5), 7,3–7,8 (3H, massif, H aromatiques).

4: Cet orthoester a été synthétisé suivant la procédure décrite par Hall *et al.* (12); Eb. = 78°C/10 Torr; rendement: 83% (litt. (12) Eb. = 78°C/ 10 Torr; rendement: 75%; rmn ^{1}H ($CDCl_3$) δ: 1,4–2,6 (4H, massif, H méthyléniques sur C4 et C6); 3,5–4,4 (5H, massif, H méthyléniques sur C3, C5 et C7), 5,78 (1H, singulet, H1).

5: Ce nouveau produit est préparé selon la procédure utilisée pour le composé **4**; Eb. = 125°C/0,03 Torr; rendement: 81%; rmn ^{1}H ($CDCl_3$) δ: 1,4–2,6 (3H, singulet à 1,45, méthyle sur C1; 4H, massif, H méthyléniques sur C4 et C6), 3,5–4,5 (5H, massif, H méthyléniques sur C3, C5 et C7).

6: 2,4 g (0,02 mol) de pentanetriol-1,3,5 et 3,7 g (0,02 mol) d'orthobenzoate de méthyle sont dissous dans 80 mL de xylène anhydre et portés à reflux pendant 48 h en présence de 100 mg d'acide paratoluènesulfonique. Au mélange refroidi on ajoute une solution saturée de carbonate de sodium. Après extraction du solvant, le produit brut est distillé. On obtient ainsi 1,5 g d'orthoester **6** pur; Eb. 111–113°C/0,08 Torr; rendement; 37%; rmn ^{1}H ($CDCl_3$) δ: 1,4–2,6 (4H, massif, H méthyléniques sur C4 et C6), 3,4–4,6 (5H, massif, H méthyléniques sur C3, C5 et C7), 7,2–7,7 (5H, massif, H aromatiques).

Analyse des produits d'hydrolyse

Après hydrolyse des orthoesters aromatiques **3** et **6** dans les conditions cinétiques, les produits d'hydrolyse sont analysés par rmn ^{1}H ($CDCl_3$). Dans les deux cas, la rmn ne révèle, aux erreurs d'intégration près, qu'un seul proton en α de la fonction benzoate. L'hydrolyse de **3** conduit donc essentiellement à l'ester **10** (cf. schéma 3) et l'hydrolyse de **6** conduit, quant à elle, uniquement à l'ester **13** (cf. schéma 4).

Caractéristiques rmn ^1H des produits d'hydrolyse ($CDCl_3$)

10: δ 1,8–2,4 (2H, massif, CH_2—CH_2OH), 2,85 (2H, massif, O—*H*), 3,8–4,2 (4H, massif, CH_2—O), 5,4–5,7 (1H, multiplet, *CH*—$OCOC_6H_5$), 7,3–7,6 et 7,9–8,1 (3H + 2H, deux multiplets, H aromatiques).

13: δ: 1,6–2,4 (4H, massif, CH_2—CH_2OH), 3,2–4,6 (6H, massif, CH_2OH), 5,1–5,4 (1H, multiplet, *CH*—$OCOC_6H_5$), 7,3–7,6 et 7,9–8,1 (3H + 2H, deux multiplets, H aromatiques).

Méthodes cinétiques

Les méthodes cinétiques sont analogues à celles décrites par ailleurs (2, 5).

γ-Phosphono-γ-lactones. The use of allyl esters as easily removable phosphonate protecting groups

MATTHIAS KAMBER AND GEORGE JUST[1]
Department of Chemistry, McGill University, Montreal, P.Q., Canada H3A 2K6

Received February 17, 1984

MATTHIAS KAMBER and GEORGE JUST. Can. J. Chem. **63**, 823 (1985).

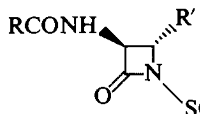
During the synthesis of γ-lactones bearing a phosphonic acid group at the γ-position, difficulties were encountered generating the free phosphonic acids from corresponding esters. A protecting group used for carboxylic acids was adapted to phosphonic acids, making this transformation easy.

MATTHIAS KAMBER et GEORGE JUST. Can. J. Chem. **63**, 823 (1985).

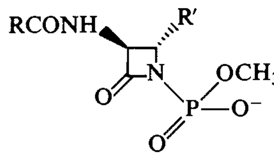
Lors d'une synthèse de γ-lactones ayant un acide phosphonique en position γ, nous avons éprouvé des difficultés à transformer des esters phosphoniques en acides libres. Cette transformation a été rendue facile par adaptation aux acides phosphoniques d'un groupe utilisé pour protéger les acides carboxyliques.

Introduction

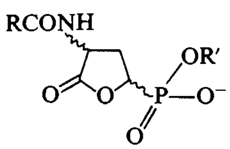
Some years ago (1), we pointed out that the steric strain responsible for the chemical reactivity and hence biological activity of the classical β-lactam antibiotics could be replaced by a strain generated by electron-withdrawing groups attached to the nitrogen atom of the β-lactam moiety. This concept was borne out by the discovery of monobactams (2) **1**, which are monocyclic β-lactams substituted by a sulfonic acid at the amidic nitrogen, and the synthesis of analogous monophosphams (3) of type **2**, of which the monomethyl ester **2** seemed to be the most active (3).



1 $R' = H, CH_3$



2



3*a* $R' = H, K^+$
b $R' = CH_3$

It occurred to us that the activated β-lactam function, $\nu \geq 1765\ cm^{-1}$, which most probably acts as an acylating agent (4), could be replaced by a γ-lactone, $\nu \simeq 1780\ cm^{-1}$, which should have similar acylating properties. We therefore decided to prepare γ-lactones **3***a and* **3***b*, the latter because of its similarity with monophospham **2**.

Synthesis of phosphonolactone 12

Glycine was transformed in 80% yield to its allyl ester hydrochloride, mp 68–71°C, using the recently described method of Brooks and Chan (5), and acylated in 80% yield with di-*tert*-butydicarbonate to **4**. Rearrangement of the bis-silylated dianion of **4** according to the procedure developed by Bartlett and Barstow (6) gave **6***a*, which was transformed to methyl ester **6***b*, using ethereal diazomethane.

Because of relatively low yields in the rearrangement step, and the necessity to esterify the carboxyl function with diazomethane on a large scale, carbobenzyloxyglycine was subjected to a similar sequence. Ester formation with allyl alcohol – trimethylsilyl chloride (Me_3SiCl) gave **5**, mp 36–37°C, and rearrangement of the bis-trimethylsilyl ether of the dianion of **5** gave crude acid **7***a*. Methylation with methanol–Me_3SiCl (5) gave **7***b*, mp 40–41°C, in 85% overall yield, based on carbobenzyloxyglycine.

Whereas the ozonolysis of analogous rearranged compounds derived from crotyl esters of type **7** to the corresponding aldehyde was apparently not possible (6), **7***b* could be easily ozonized at −78°C, using methylene chloride as solvent. Reductive work-up using dimethyl sulfide gave **8**, contaminated with a side-product which was difficult to remove.

Treatment of the crude aldehyde **8** with dimethyl phosphite in methylene chloride containing some triethylamine at 20°C overnight gave a mixture of the aldehyde-phosphonate adduct **13** and the cyclic phosphono-lactone **12** as a mixture of diastereoisomers. Stirring of the mixture in methylene chloride – trifluoroacetic acid (5:1) resulted in the complete conversion of the adduct **13** to the highly strained lactone **12**, $\nu = 1800\ cm^{-1}$.

Alternatively, phosphonolactone **12** was obtained, albeit in very low yield, in the following manner. Olefinic acid **7***a* was ozonolyzed to **9**, mp 139–142°C. Mesylation of **9** gave a mixture of mesylate **10** and chloride **11**. The latter was also obtained by treating **9** with thionyl chloride. Arbusov reaction of **11** with trimethyl phosphite gave **12** in very low yield.

Attempts to hydrolyse, partially or completely, dimethyl phosphonate **12** to monomethyl ester or diacid **3** ($R = OCH_2Ph$) failed. These attempts included (a) reaction with Me_3SiCl/KI or NaBr in acetonitrile (7, 8), which resulted either in opening of the lactone ring, or very slow reaction giving ill-defined products; (b) reaction with HBr/acetic acid (9), which gave polar products that did not provide starting material upon remethylation; (c) treatment with LiI/2,4,6-collidine in DMF (10) (similar to b); (d) reaction with thiourea (11): this gave what appeared to be the desired acid or acids, since remethylation provided starting material. However, the purification proved to be extremely difficult, and no clean acid could be isolated; (e) sodium bromide/benzyl triethylammonium chloride (12): the reaction was very slow, and no desired acid could be isolated.

It was clear that no good method was at hand, and that we required a phosphonic acid protecting group which could be removed under mild conditions, and where the requisite dialkyl or alkyl methyl phosphonate could be prepared and handled with relative ease. Furthermore, the resulting phosphonic acid

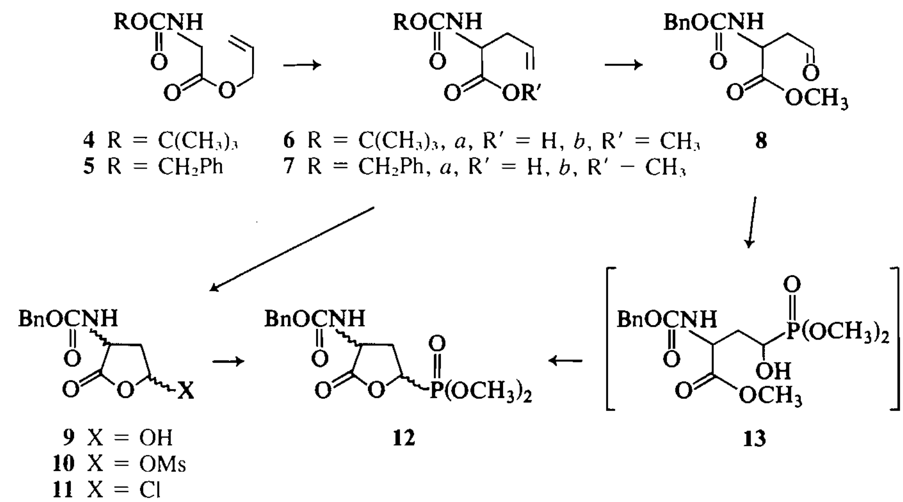
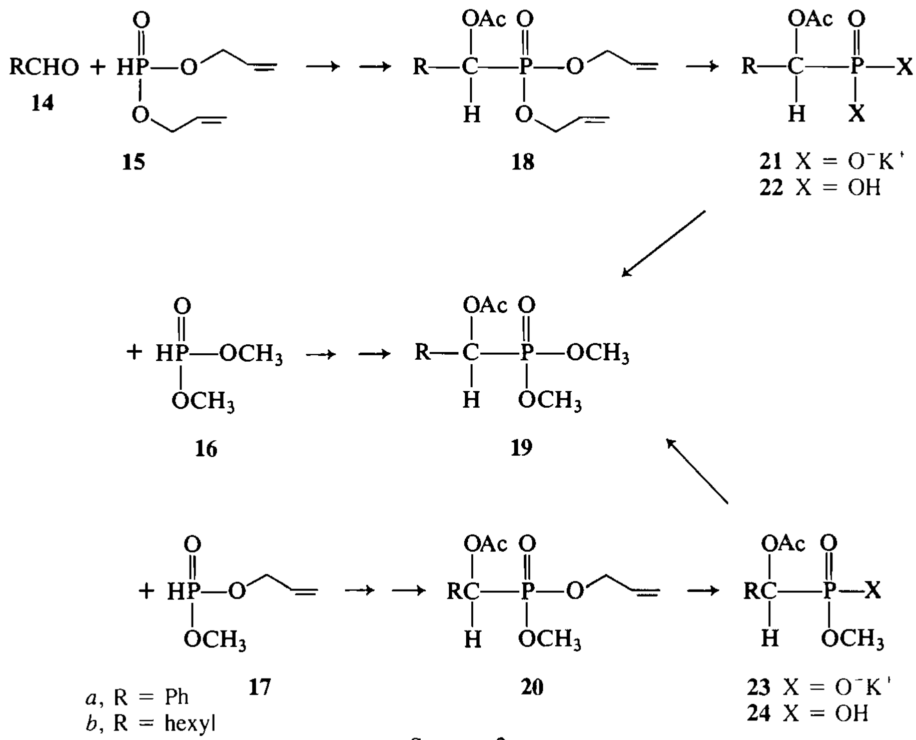


SCHEME 1



SCHEME 2

or salt should not require further purification beyond simple extraction or crystallization.

A variety of dialkyl phosphonates were investigated, and abandoned for the following reasons.

(a) Dibenzyl or benzyl methyl phosphonates are unstable compounds.

(b) Methyl trichloroethyl phosphonate is difficult to prepare, and trouble was anticipated in separating the free phosphonic acid from the zinc ions produced during Zn-mediated removal of the trichloroethyl group.

(c) Bis-trimethylsilylethyl phosphonate rearranges to trimethylsilyl phosphonate with extrusion of ethylene.

We then investigated the suitability of using diallyl and allyl methyl phosphonate as phosphonating agent. Diallyl phosphonate was prepared according to the general procedure described (13). After numerous trials (14, 15; also ref. 13, p. 28), allyl methyl phosphonate was prepared by reaction of allyl alcohol with phosphorus trichloride, and treating the resulting allyl phosphorodichloridite, bp 45–52°C (15 Torr; 1 Torr = 133.3 Pa), first with methanol–pyridine and then with water–pyridine.

For model studies, we prepared six α-acetoxyphosphonates **18**a, b, **19**a, b, and **20**a, b by treating benzaldehyde or heptanal with the appropriate diallyl, dimethyl, and allyl methyl phosphonates **15**, **16**, and **17**, and acetylating the resulting dialkyl hydroxyphosphonates. Three systems were used to try to remove the allyl group.

(1) Catalytic transfer hydrogenation using ammonium formate in methanol and 10% Pd/C (16). The results were not very reproducible, and methanolysis of the acetate group was observed.

(2) 3% $Pd(PPh_3)_4$/4–5%PPh_3/potassium 2-ethylhexanoate

in ethyl acetate (17). This system removed the allyl group smoothly to give potassium salts **21***a*, *b* and **23***a*, *b*. Their structures were proven by remethylation to give the dimethyl α-acetoxyphosphonates **19***a*, *b*. In each case, no starting materials **18***a*, *b* or **20***a*, *b* could be detected, and **19***a*, *b* was obtained as the major product (>90%), as established by tlc, and 200-MHz ^{1}H nmr in the case of **21***a*.

The isolation of the potasium salt was achieved by crystallization (**21***a*, 83%), or required evaporation to dryness, and washing with ether (**21***b*, **23***a*, **23***b*, 5–10% potassium 2-ethylhexanoate contamination). Other, more polar, diallyl phosphonates (see following paper) gave less soluble potassium salts which precipitated and were obtained in high yield and purity.

(3) Wilkinson's catalyst ($(Ph_3P)_3RhCl$). Heating to reflux of phosphonates **18***a*, **18***b*, **20***a*, and **20***b* in 15% aqueous acetonitrile containing 2–3% Wilkinson's catalyst for 1–2 hours (18) resulted in the disappearance of the starting material (tlc) and formation of **22***a*, **22***b*, **24***a*, and **24***b* in 71, 69, 86, and 78%, respectively. The work-up required evaporation of the solvent, dissolving the phosphonic acids in water, and separation from the precipitated Wilkinson's catalyst by filtration. Freeze-drying then gave the products. Their structures were proven by remethylation with ethereal diazomethane (tlc and, in the case of **24***a*, 200-MHz ^{1}H nmr).

None of the yields were optimized. Dimethyl phosphonates **19***a*, *b* were stable to the reaction conditions outlined under (2) and (3).

The application of this methodology to phosphono lactones **3** will be reported in due course.

Experimental

Thin-layer chromatography (tlc) was performed on Merck Silica Gel 60 F_{254} aluminum-backed plates. Flash chromatography was done on Woelm Silica (32–63 μm). Melting points (mp) were measured on a Gallenkamp block and are uncorrected, unless specified otherwise. The nmr spectra were recorded on Varian T-60, T-60A, and, where noted, XL-200 and Bruker WH-90 spectrometers. Infrared (ir) spectra were recorded on a Perkin Elmer 257 spectrophotometer. Abbreviations: br = broad, s = strong, m = medium, w = weak.

Mass spectra (ms) were obtained on HP 5984A or LKB 9000 spectrometers, in the direct inlet mode unless indicated otherwise.

Carbobenzyloxy (Cbz) glycine allyl ester 5

Cbz-glycine (6.3 g, 30 mmol) was dissolved in 35 mL allyl alcohol. Then Me_3SiCl (9.5 mL, 73 mmol) was added over a period of 5 min and the mixture left under a N_2 atmosphere at room temperature overnight (5). The solvent was evaporated and the product filtered through silica gel (short 3 × 5 cm column, methylene chloride). After crystallization from ether/petroleum ether, 7.20 g (28.9 mmol, 96%) of ester **5** was obtained, mp 36–37°C; ir ($CHCl_3$, cm^{-1}): 3860 m, 3620 m, 3450 m, 3020 s, 2990 m, 1745 s, 1725 s, 1515 m, 1420 m, 1210 s, 1050 m, 930 m, 750 s; ^{1}H nmr (60 MHz, $CDCl_3$) δ: 7.4 (s, 5H, C_6H_5), 6.2–5.6 (m, 2H, NH and =CH), 5.5–5.3 (m, 2H, H_2C=), 5.2 (s, 2H, Ar—CH_2—O), 4.7 (d, *J* = 6 Hz, 2H, O—CH_2—CH=CH_2), 4.1 (d, *J* = 6 Hz, 2H, CO—CH_2—N); ms (*m/z*, %): 249 (M^+, 6), 108 (41), 107 (31), 91 (100, 65 (11), 41 (17).

*Rearranged acid 7*a *(ref. 6)*

Hexamethyldisilazane (7 mL, 33 mmol) was dissolved in 100 mL dry tetrahydrofuran (THF) and cooled under N_2 to 0°C. Then n-butyllithium (20 mL, 1.55 *n* in hexane, 31 mmol) was added dropwise and after 10 min the solution was cooled to −78°C. The allyl ester **5** (3.75 g, 15.05 mmol, dissolved in 10 mL THF) was added over 5 min. After another 30 min, Me_3SiCl (4.2 mL, 33 mmol) was added, the mixture stirred for 15 min at −78°C, and then warmed up over 1 h to 20°C. The yellow solution was then warmed for 1–1.5 h to 55–60°C, cooled to 20°C, and diluted with 20 mL methanol. The solvents were evaporated to about 20% of their original volume, diluted with ether, and extracted 4 times with a 5% NaOH solution. Acidification of the combined water layers with cold 6 *N* HCl and extraction with methylene chloride (CH_2Cl_2) gave, after drying ($MgSO_4$) and evaporation, a quantitative yield of the crude acid **7***a* (7.5 g) as a yellowish oil. It was used without further purification; ir ($CHCl_3$, cm^{-1}): 3550–2500 br, m, 3440 m, 2950 m, 1720 s, 1500 m, 1340 m, 1050 m, 900 m; ^{1}H nmr (60 MHz, $CDCl_3$) δ: 10.5 (s, 1H, COOH), 7.3 (s, 5H, C_6H_5), 6.0–5.4 (m, 1H, =CH), 5.3–5.0 (m, approx. 3H, NH and H_2C=), 5.1 (s, 2H, Ar—CH_2—O), 4.4 (m, 1H, N—*CH*—COO), 2.6 (t, *J* = 6 Hz, 2H, CH_2—CH=CH_2); ms (*m/z*, %): 249 (M^+, 11), 208 (M^+ − 41, 2), 204 (M^+ − 45, 2), 108 (22), 107 (10), 91 (100), 79 (16), 65 (12), 41 (29).

*Methyl ester 7*b

Crude acid **7***a* (7.5 g) was dissolved in 30 mL methanol and Me_3SiCl (4.5 mL, 35.5 mmol) was added. Stirring overnight under N_2, evaporation to dryness, and recrystallization from ether/hexane gave the ester **7***b* as colourless crystals (3.47 g, 13.2 mmol, 88% from allylester **5**), mp 40–41°C; ir ($CHCl_3$, cm^{-1}): 3450 m, 2990 m, 1740 s, 1720 s, 1515 m, 1210 s, 1050 m, 920 m; ^{1}H nmr (60 MHz, $CDCl_3$) δ: 7.2 (s, 5H, C_6H_5), 5.9–5.3 (m, 2H, NH and =CH), 5.2–4.9 (m, 2H, H_2C=), 5.1 (s, 2H, Ar—CH_2—O), 4.4 (m, 1H, N—*CH*—COO), 3.7 (s, 3H, $COOCH_3$), 2.5 (t, *J* = 6 Hz, 2H, CH_2—CH=CH_2); ms (*m/z*, %): 263 (M^+, 17), 222 (M^+ − 41, 6) 204 (M^+ − 59, 4), 178 (4), 160 (4), 108 (8), 107 (3), 91 (100), 79 (4), 65 (8), 59 (2), 41 (5).

Aldehyde 8

The ester **7***b* (1.78 g, 6.75 mmol) was dissolved in CH_2Cl_2 and cooled to −78°C. Then ozone was bubbled through the solution until it turned blue. Excess ozone was removed with a steam of dry N_2. Dimethylsulfide (5 mL) was added and the reaction left at ~20°C overnight. The solvent was evaporated and the crude yellow oil partitioned between ether and saturated $NaHCO_3$ solution, and the ether layer dried over $MgSO_4$ and evaporated to give crude aldehyde **8** (1.73 g, 6.53 mmol, 96%) as a yellowish oil. The aldehyde **8** could be used without further purification; ir ($CHCl_3$, cm^{-1}): 3430 m, 2950 m, 2940 m, 1720 br s, 1500 s, 1430 m, 1330 m, 1050 m; ^{1}H nmr (60 MHz, $CDCl_3$) δ: 9.7 (s, 1H, CHO), 7.3 (s, approx. 5H, C_6H_5), 5.6 (m, 1H, NH), 5.2 (s, approx. 2H, Ar—CH_2—O), 4.7 (m, 1H, N—*CH*—COO), 3.7 (s, 3H, $COOCH_3$), 3.1 (d, *J* = 6 Hz, 2H, —CH_2—CHO); ms (*m/z*, %): 265 (M^+, 6), 206 (M^+ − 59, 3), 162 (M^+ − 59–44, 3), 115 (3), 108 (22), 107 (9), 91 (100), 79 (6), 77 (5), 69 (9), 65 (12), 59 (2), 55 (6), 44 (4), 43 (8), 41 (5).

Lactone 12

Crude aldehyde **8** (580 mg, 2.2 mmol) was dissolved in 1 mL CH_2Cl_2, dimethylphosphite (0.5 mL, 3.8 mmol) and triethylamine (0.1 mL) were added, and the mixture left overnight at ~20°C. The solvent was pumped off, 2.5 mL CH_2Cl_2 and 0.5 mL trifluoroacetic acid were added, and the mixture left for ~20 h. Flash chromatography (silica gel, ethyl acetate – hexane 5:1) gave 490 mg (1.43 mmol, 65%) of the lactone **12** as a mixture of 2 diastereoisomers; ir ($CHCl_3$, cm^{-1}): 3420 m, 2950 m, 2850 m, 1800 s, 1720 s, 1495 m, 1450 m, 1250 m, 1150 s, 1030 s; ^{1}H nmr (60 MHz, $CDCl_3$) δ: 7.3 (s, 5H, C_6H_5), 6.0–5.7 (m, 1H, NH), 5.1 (s, 2H, Ar—CH_2—O), 4.8–4.2 (m, 2H, P—CH and N—CH—COO), 3.8 (m, 6H, 2 P—O—CH_3), 2.9–2.1 (m, 2H, —CH_2—); ms (*m/z*, %): 343 (M^+, 19), 282 (3), 252 (17), 237 (7), 236 (76), 234 (2), 174 (4), 137 (13), 108 (10), 91 (100), 79 (11), 65 (11), 59 (4), 44 (6).

Allyl phosphorodichloridite

To 320 mmol PCl_3 at −75°C was added 320 mmol of freshly distilled allyl alcohol over a period of 5 h. The HCl formed was removed with a stream of dry N_2. The reaction mixture was warmed slowly to room temperature and kept stirring overnight (N_2 stream). Distillation was interrupted after 55 mmol (17%) allyl phosphorodichloridite, bp 35–40°C/10 Torr, was obtained because of reported spontaneous polymerization resulting in explosion of the mixture distilled to less than half of its volume.

Allyl methyl phosphonate 17

Allyl phosphorodichloridite (23.6 mmol) was dissolved in 80 mL dry THF and cooled under N_2 to −78°C. Then 23.6 mmol methanol and 23.6 mmol pyridine in 10 mL THF were added dropwise over a period of 30 min. Stirring was continued for another 1.5 h at −78°C, and for 2 h at 20–25°C. The reaction mixture was cooled to 0°C and 10 mL THF containing 25 mmol water and 26 mmol pyridine were added dropwise. The mixture was stirred 0.5 h at 0°C and then 2 h at 20–25°C. After filtration and evaporation, the crude yellow oil was dissolved in 2 mL of CH_2Cl_2 and filtered over 5 g silica gel using CH_2Cl_2 as eluant. After evaporation to dryness, the methyl allyl phosphonate **17** could be obtained as a clear oil (2.51 g, 18.5 mmol, 78.5%); ir ($CHCl_3$, cm^{-1}): 2440 (P—H), 1270–1180 (P=O, C—O); ^1H nmr (60 MHz, $CDCl_3$) δ: 6.85 (d, J = 700 Hz, 1H, PH), 6.2–5.7 (m, 1H, =CH), 5.6–5.1 (m, 2H, H_2C=), 4.7–4.4 (m, 2H, H_2COP), 3.8 (d, J = 12 Hz, 3H, H_3COP); ms (m/z, %): 137 (M^+ + 1, 0.5), 97 (29), 95 (M^+ − 41, 7), 80 (29), 79 (M^+ − 57, 100), 58 (66), 47 (25), 41 (27).

Diallyl phosphonate 15

Diallyl phosphonate was prepared in 86% yield from 1 equiv. phosphorus trichloride, 3 equiv. allyl alcohol, and 2 equiv. pyridine using the general procedure described (13); ir ($CHCl_3$, cm^{-1}): 2430 (P—H), 1270–1200 (P=O, C—O); ^1H nmr (60 MHz, $CDCl_3$) δ: 6.8 (d, J = 700 Hz, 1H, PH), 6.2–5.6 (m, 2H, =CH), 5.5–5.1 (m, 4H, H_2C=), 4.7–4.3 (m, 4H, H_2COP); ms (m/z, %): 121 (M^+ − 41 (C_3H_5), 51), 105 (M^+ − 57, 4), 83 (12), 80 (10), 79 (17), 65 (14), 58 (11), 57 (CH_2=$CHCH_2O$, 100), 41 (80).

Diallyl, methyl allyl, and dimethyl acetoxyphosphonates 18, 19, and 20

All six compounds were prepared in an identical manner, and their spectra were very similar. A representative example is described. To a methylene chloride (5 mL) solution of benzaldehyde **14***a* (2 mmol) was added diallyl phosphonate **15** (2.16 mmol) and 3 drops of triethylamine. After tlc indicated completion of the reaction (16 h), acetic anhydride (2 mL) and triethylamine (1 mL) were added at 0°C. After 2 h, diethyl ether and ice-water were added. Stirring for 0.5 h and washing to neutrality gave after drying ($MgSO_4$), evaporation, and flash chromatography (silica gel, petroleum ether – acetone 10:1) diallyl phosphonate **18***a* (1.36 mmol, 68%) as a clear oil.

18*a*: ir (film, cm^{-1}): 1755 (C=O), 1260 (P=O), 1220 (O—C), 1020 (P—O); ^1H nmr (60 MHz, $CDCl_3$) δ: 7.3 (m, 5H, C_6H_5), 6.1 (d, J = 13 Hz, approx. 1H, HCP), 6.1–5.5 (m, 2H, =CH), 5.4–5.0 (m, 4H, H_2C=), 4.6–4.3 (m, 4H, H_2COP), 2.1 (s, 3H, H_3CCO); ms (m/z, %): 310 (M^+, 0.2), 267 (M^+ − 43, 4), 162 ($HPO(OCH_2CH{=}CH_2)_2$, 10), 121 ($HPO_2OCH_2CH{=}CH_2$, 20), 107 (C_6H_5CHOH, 17), 77 (C_6H_5, 10), 57 ($H_2C{=}CHCH_2O$, 9), 43 ($COCH_3$, 100), 41 ($CH_2CH{=}CH_2$, 66).

Spectral characteristics of 18, 19, and 20

Dimethyl phosphonate **19***a*: 3.6 and 3.7 ppm (two d, J = 10 Hz, 6H, 2 CH_3OP); **19***b*: 3.78 and 3.80 ppm (two d, J = 10.6 Hz, 6H, 2 CH_3OP); allyl methyl phosphonate **20***a*: 3.6 and 3.7 ppm (two d, J 10 Hz, 3H, CH_3OP); **20***b*: 3.7 ppm (d, J = 10 Hz, 3H, CH_3OP); **18***a*, **19***a*, **20***a*: Ph—*CH*—*P*: J = 13 Hz, d; **18***b*, **19***b*, **20***b*: $C_5H_{11}CH_2$—*CH*—*P*: $J_{AX} + J_{BX}$ = 15 Hz, J(d) = 9 Hz. All mass spectra showed m/z for $HPO(OR)_2$; $HOP(OMe)_2$: **19***a* 110 (100%), **19***b* (97%); HOP(OM) ($OCH_2CH{=}CH_2$): **20***a* 136 (20%); **20***b* (80%); $HOP(OCH_2CH{=}CH_2)_2$: **18***a* 162 (10%); **18***b* (7%).

All phosphonate esters showed negligible (<0.4%) M^+ or $(M + 1)^+$ peaks except for **19***a*: M^+ 258.0664 (27.5%; calcd. 258.0657).

*Dipotassium salt 21*a

To 86 mg (0.28 mmol) of **18***a*, 1.33 mL 0.5 *M* (2.4 equiv.) potassium 2-ethylhexanoate in ethyl acetate, 20 mg (6.3 mol%) tetrakis-(triphenylphosphine)palladium(0), and 6 mg (8 mol%) triphenylphosphine were added. The reaction mixture was stirred at 20–25°C until all starting material had reacted (1.5 to 2 h). After addition of 2 mL acetone, the salt precipitated out as white crystals. Filtration gave 79 mg (83%) dipotassium salt **21***a*; ir (4% in KBr, cm^{-1}): 1705 (C=O), 1250 (P=O); ^1H nmr (60 MHz, CD_3OD) δ: 7.1 (m, 5H, C_6H_5), 5.5 (d, J = 13 Hz, 1H, HCP), 1.8 (s, 3H, H_3CCO), Dipotassium salt **21***a* was converted to its dimethyl ester **19***a* by dissolving it in methanol, and adding acidic ion-exchange resin (Amberlyte IR-120) and then ethereal diazomethane.

*Potassium salt 23*b

To 51 mg (0.17 mmol) **20***b*, 0.38 mL 0.5 *M* (1.12 equiv.) potassium 2-ethylhexanoate in ethyl acetate, 6 mg (3 mol%) tetrakis(triphenylphosphine)palladium(0), and 2 mg (4.5 mol%) triphenylphosphine were added and the mixture stirred at 20–25°C until all starting material had reacted (1.5 to 2 h). No crystals precipitated out, so the solvent was evaporated, and after the remaining yellowish oil was washed several times with ether, it solidified in the cold. Yield approximately 85–90%; ir ($CHCl_3$, cm^{-1}): 1725 (C=O), 1230 (P=O); ^1H nmr (60 MHz, $CDCl_3$) δ: 5.2 (m, 1H, HCP), 3.6 (d, J = 10 Hz, 3H, H_3COP), 2.2 (s, 3H, H_3CCO), 2.0–1.0 (br m, approx. 13H, alkyl) (^1H nmr spectrum shows approximately 5–8% impurities due to the remaining triphenylphosphine and 2-ethylhexanoate). The monopotassium salt **23***b* was converted to its dimethyl ester **19***b* as described earlier.

*Phosphonic acid 24*a

To a solution of 74 mg (0.26 mmol) **20***a* in 3 mL acetonitrile/ water (85:15), 5 mg (2 mol%) of Wilkinson's catalyst was added. After refluxing for 2 h all the starting material had reacted. The solvent was evaporated, and the residue stirred for 5 min in 5 mL of water. After filtration, the water layer was freeze-dried to give 65 mg (0.22 mmol, 86%) of the acid **24***a* as a yellow oil; ir ($CHCl_3$, cm^{-1}): 1740 (C=O), 1180 (P=O); ^1H nmr (60 MHz, $CDCl_3$) δ: 7.3 (br s, approx. 5H, C_6H_5), 6.1 (br s, 1H, HCP), 3.6 (br s, 3H, H_3COP), 2.2 (s, 3H, H_3CCO). The acid **24***a* was treated with ethereal diazomethane to give dimethyl ester **19***a*.

Received June 15, 1984

ABEYSINGHE A. PADMAPRIYA, GEORGE JUST, and NORMAN G. LEWIS. Can. J. Chem. **63**, 828 (1985).

Starting from tetrachloroacetone **1** and (carbomethoxymethylene)triphenylphosphorane **4**, the title compound **16** was prepared in five steps in 44% yield. Spectroscopic and chromatographic data indicated that this material was identical to a potent mutagen isolated from kraft pulp chlorination effluent. Various mutant *Salmonella typhimurium* strains (TA 98, 100, and 1537) behaved similarly when incubated with either **16** or the isolated mutagen.

ABEYSINGHE A. PADMAPRIYA, GEORGE JUST et NORMAN G. LEWIS. Can. J. Chem. **63**, 828 (1985).

A partir du tétrachloroacétone **1** et du triphénylphosphorane carboxyméthoxyméthylène **4**, le composé titre **16** a été préparé en cinq étapes dans un rendement de 44%. Cette substance était identique à un mutagène puissant isolé d'un effluent de chloration kraft. Différentes souches mutantes de *Salmonella typhimurium* (TA 98, 100 et 1537) ont réagi de façon semblable lorsque mises en incubation avec soit **16** ou le mutagène isolé.

Introduction

It is now firmly established that the effluent produced during the first chlorination stage of kraft and sulphite wood pulp bleaching is highly mutagenic (1−11). These findings generated considerable interest in the chemical structures of the mutagenic substances and various mutagens have now been identified, e.g. 2-chloropropenal and chlorinated acetones (4, 6, 7, 10, 11). In a related study it was reported that at least 30−50% of the total mutagenicity of kraft chlorination effluent was attributed to a single constituent (12, 13). This compound, tentatively proposed (12) to be the hydroxyfuranone **16** was highly mutagenic (~10^4 revertants/nmol) and, therefore, possibly carcinogenic (14).

In pulp manufacture, various effluent streams are required to remove unwanted materials formed at different stages of pulp production. These streams are subsequently combined prior to discharge into the receiving waters, and, *even* if biologically untreated, are only very weakly mutagenic (2, 5).

Nevertheless, the fate of the tentatively identified mutagen **16** deserves serious attention since its chemical stability, biodegradability, and bioaccumulation in aquatic organisms and plants is unknown.

As a first objective, therefore, a total synthesis of the hydroxyfuranone **16**, and a comparison of its mutagenicity to that of isolated effluent material was required.

Results and discussion

We considered that entry into the mutagen system could be achieved by the Wittig condensation of tetrachloroacetone **1** and (carbomethoxychloromethylene)triphenylphosphorane **7** or -phosphonate **5** (Scheme 1). Therefore, in a series of model studies, tetrachloroacetone **1** was condensed with phosphonates **2** and **3**, and phosphorane **4**. The reaction with the phosphonates proceeded slowly, and chromatography was required to obtain olefins **9** and **10** in 70−75% yield. However, phosphorane **4** reacted rapidly, with no subsequent chromatography needed, and **9** (80% yield) was crystallized directly from hexane.

[1]Authors to whom correspondence may be addressed.

Attempted hydrolysis of the ethyl ester **10**, with methanolic sodium hydroxide, afforded only the deconjugation product **11** based on nmr evidence; i.e., this compound had a one-proton singlet at δ 6.82 ($C\underline{H}Cl_2$) and a two-proton singlet at δ 3.66 ($\underline{CH_2}CO_2CH_2CH_3$). Further treatment of **11** gave a mixture of compounds that were not further investigated. In contrast, methyl ester **9** was converted to the desired acid **8**, as evidenced by nmr and ir, with no products of deconjugation being observed.

Having established that the condensation and hydrolysis of the methyl ester **9** proceeded without difficulty, we next turned our attention to the direct synthesis of the chloro-olefinic ester **13**.

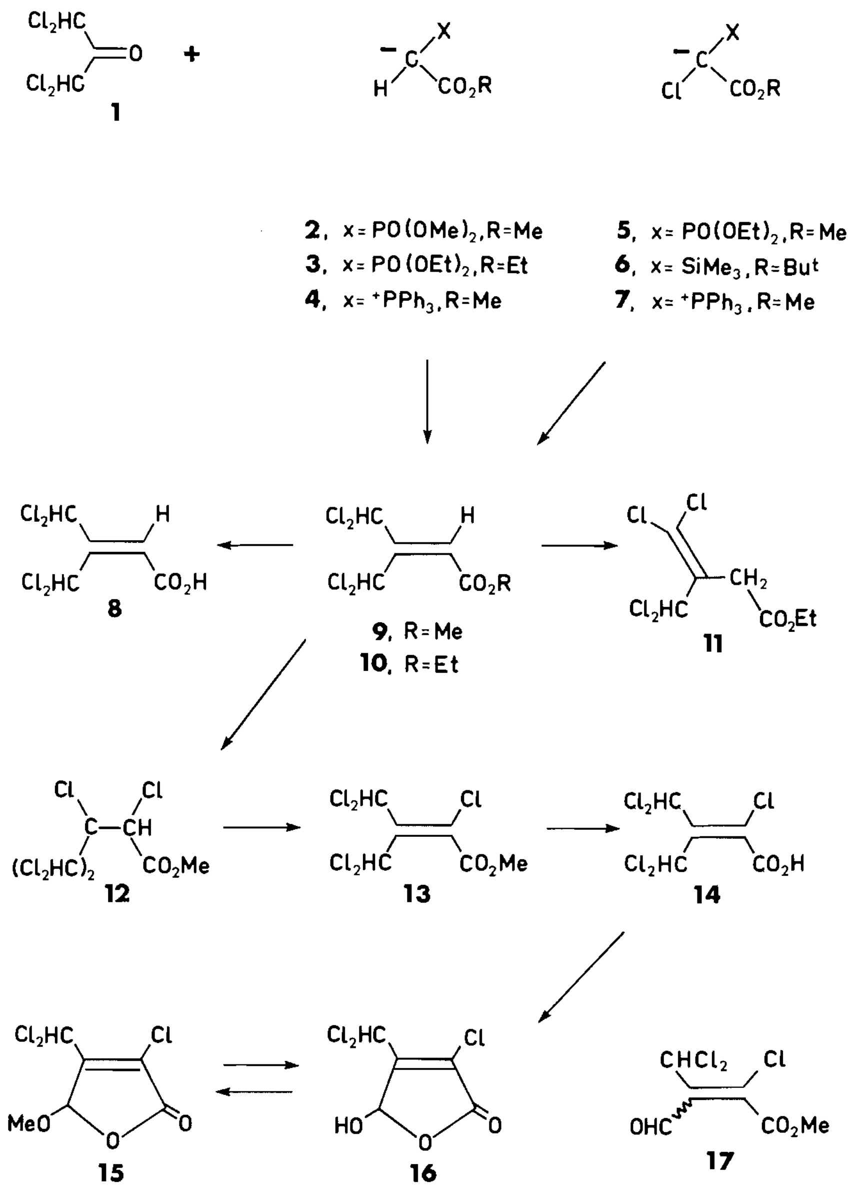
Chlorophosphonate anion **5**, obtained by treatment of triethyl dichlorophosphonoacetate with n-butyllithium (15), reacted with tetrachloroacetone **1** but did not produce the expected pentachloro condensation product **13**. Instead, only aldolization products resulting from the condensation of the anion of tetrachloroacetone **1** with **1** were obtained (mass spectrometric evidence only).

Reaction of the corresponding chlorophosphorane **7** (16) with **1** did not afford **13** either, but, surprisingly, gave the *tetra*chloro olefin **9** in approximately 50% yield. Further investigation of this interesting reaction revealed that pentachloroacetone **19** was being formed. It therefore seems (Scheme 2) that the sterically hindered Wittig reagent **7** abstracted a proton from tetrachloroacetone **1**, which in turn removed chlorine from the chlorophosphonium salt **18** to give pentachloroacetone **19** and (carbomethoxymethylene)triphenylphosphorane **4**.

An alternate approach to generate **13** by reaction of tetrachloroacetone **1** with the anion of *tert*-butyl chlorotrimethylsilyl acetate **6** (17) also failed.

We therefore treated the olefinic ester **9** with chlorine in CH_2Cl_2, in the presence of ferric chloride, for 18−24 h to produce the hexachloro compound **12**. An ethereal solution of **12**, when treated with triethylamine, gave the desired pentachloro-olefin **13** (80% yield based on **9**).

The nmr spectra for the tetrachloro- and pentachloro-olefins **9** and **13** were very informative: apart from the methoxy resonances, **9** had a vinylic proton at δ 8.03 and another singlet at δ 6.73, corresponding to the two protons adjacent to the chlo-



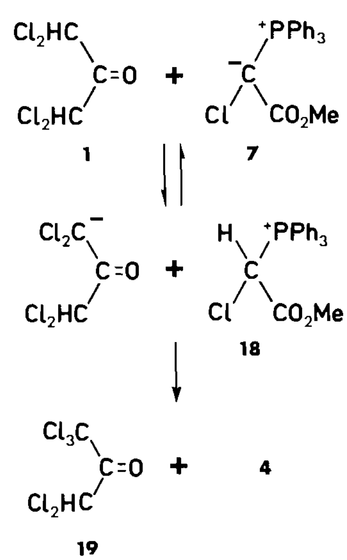
SCHEME 1

rine atoms. With **13**, only two one-proton singlets at δ 7.32 ($CHCl_2$ *cis* to $—CO_2CH_3$) and δ 6.72 ($CHCl_2$ *cis* to Cl) were observed. Mass spectra of both **9** and **13** were consistent with the structures assigned, but, under the conditions employed, no M^+ signal was evident. Only fragmentations due to the loss of at least one chlorine atom or the loss of a methoxy group were noted.

Unfortunately, conditions were not found for the direct conversion of ester **13** to the hydroxyfuranone **16**, e.g. treatment with two equivalents of lithium hydroxide gave a mixture of products that was not investigated further, and hydrolysis with potassium bicarbonate did not proceed at an acceptable rate.

However, hydroxyfuranone **16** was obtained as follows: reaction of **13** with one equivalent of lithium hydroxide (18) in tetrahydrofuran–water gave the carboxylic acid **14** in quantitative yield. Subsequent treatment of **14** with aqueous potassium carbonate afforded the hydroxyfuranone **16**, contaminated with very minor amounts of unidentified products.

The position of attachment of the dichloromethyl group was realized by simple inspection of the long range $^{13}C—^{1}H$ cou-



SCHEME 2

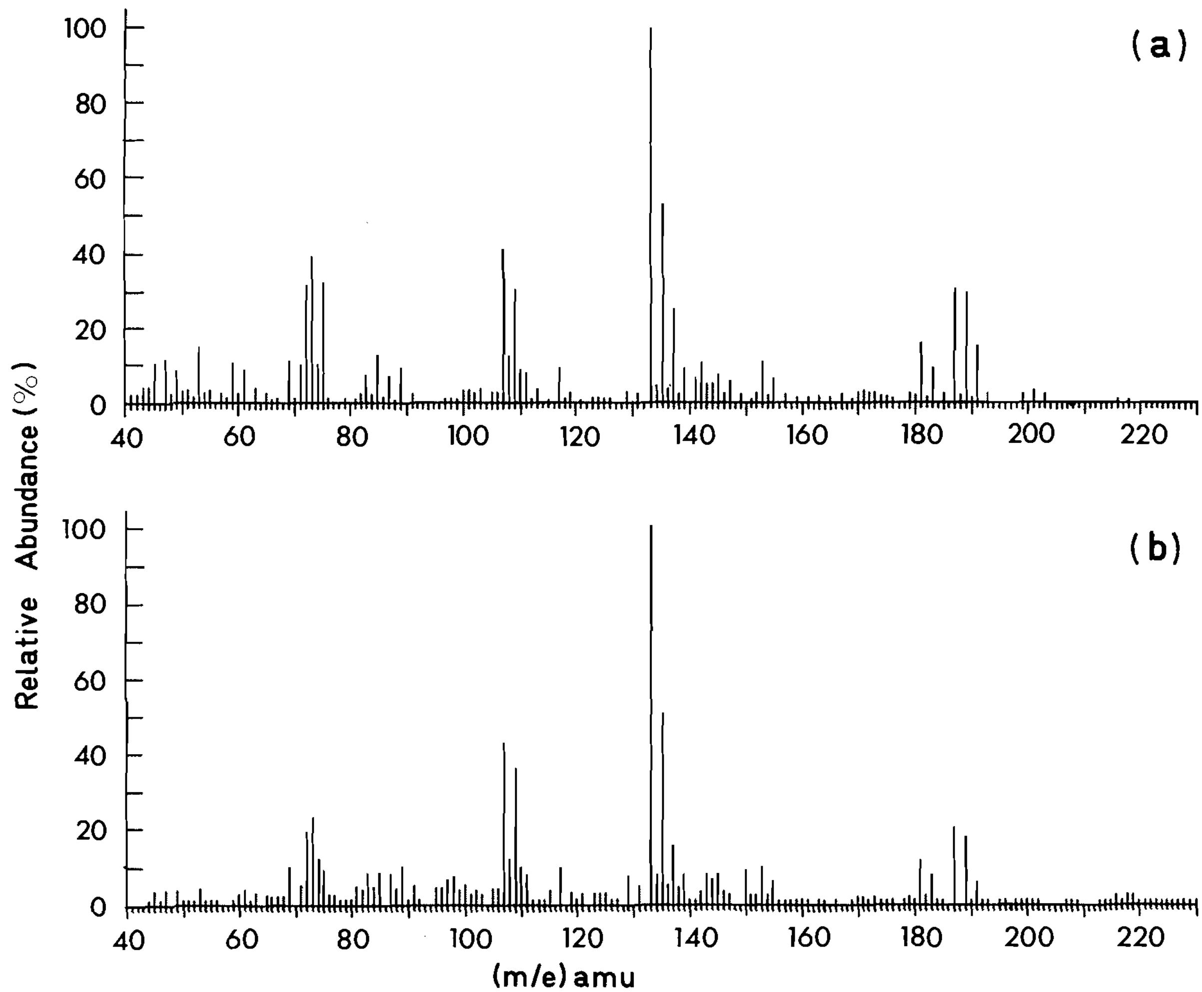


FIG. 1. Mass spectral fragmentation pattern of (a) synthetic hydroxyfuranone **16**, and (b) isolated mutagen. *Note*: The mass spectra of synthetic hydroxyfuranone **16** and the isolated mutagen were obtained on Hewlett–Packard quadrupole mass spectrometers 5980A and 5985A respectively. Both spectra were recorded in the electron impact mode.

pling in the nmr spectrum, e.g., the doublet at δ 164.51 (d, ^3J = 2.7 Hz, C═O) can only be rationalized by structure **16** since, if the other isomer were present, additional long range (^3J) coupling (CO—C—$CHCl_2$) would be observed.

Compound **16** had a retention time (gc, TMS derivative), uv spectrum, and a mass spectral fragmentation pattern (see Fig. 1) identical to that for the mutagen isolated from bleach plant effluent.

When acid **14** was submitted to the prolonged action of sodium hydroxide in methanol, a product was formed which appeared homogeneous by gc. However, gc/ms proved that it consisted of two products, the desired methyl ether **15** and what appeared to be **17**, of unknown geometry.

The methyl ether **15**, though, was smoothly obtained by the reaction of lactol **16** with methanolic hydrogen chloride. An identical gc retention time and mass spectral fragmentation pattern were recorded for this derivative, and the methyl ether previously produced from the isolated mutagen. Note also that lactol **16** could be regenerated from **15** by reaction with trifluoroacetic acid – THF–water.

Final confirmation of the mutagen's identity now required short-term bioassays with various mutant strains of *Salmonella typhimurium*. The mutagenic properties of synthetic trichlorolactol **16** are shown in Fig. 2. The corresponding test data for the isolated mutagen can be found in Fig. 6 of ref. 13.

When incubated with tester strain TA 100 (no metabolic activation), a strong mutagenic response occurred (~6000 revertants/nmol) in good agreement with previous observations for isolated material (13) (2,800–10,000 revertants/nmol). Further, when tester strain TA 100 was metabolically activated, neither the synthetic nor isolated mutagen produced a statistically significant number of revertants.

With tester strains TA 98 and TA 1537, synthetic **16** again behaved in a manner comparable to the effluent mutagen. In fact, the only difference observed was with strain TA 1535. Previously the effluent material had given a mild mutagenic effect but this was not observed for synthetic **16**. The reasons for this are not yet clear and require further investigation.

In conclusion, we have confirmed that the mutagen isolated from the chlorination effluent has the trichlorolactol structure **16**.

Experimental

General methods

Melting points were determined on a Gallenkamp MF-370 melting point apparatus and are uncorrected. Ultraviolet (uv) spectra were recorded on a Pye Unicam SP800 spectrophotometer in methanol solution. The wavelengths of absorption maxima are reported in nanometers (nm) with ε values in parentheses. Infrared (ir) spectra, measured on a Perkin–Elmer model 297 spectrophotometer, were

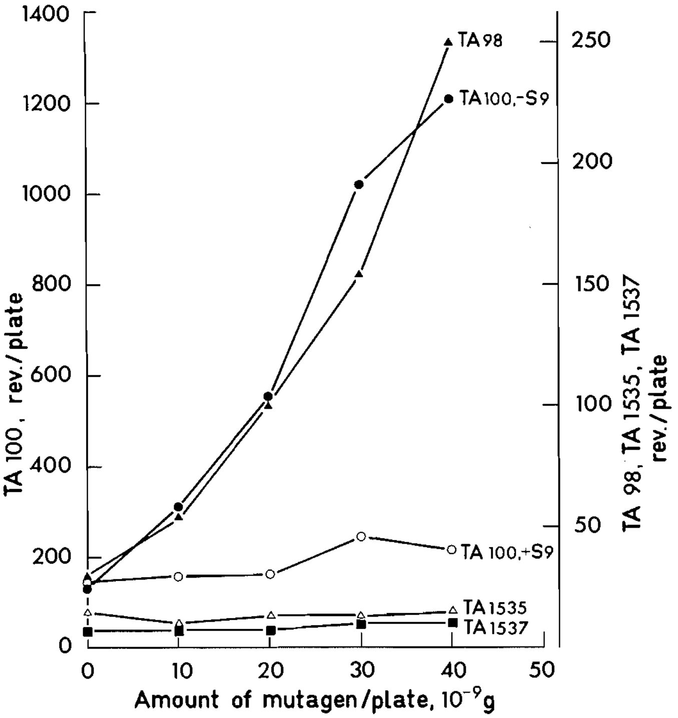

FIG. 2. Mutagenicity of synthetic hydroxyfuranone **16** on different test strains without metabolic activation. Testing against strain TA 100 was also made with metabolic activation (TA 100, +S9).

taken in chloroform solution, unless otherwise stated. The absorption maxima of each compound are reported in wavenumbers (cm^{-1}), and calibrated with respect to the absorption band of polystyrene at 1601 cm^{-1}. Proton magnetic resonance (^1H nmr) spectra were recorded on a Varian T-60 spectrometer, with TMS added as an internal standard. The integrated peak areas and proton assignments are given in parentheses. Carbon-13 magnetic resonance (^{13}C nmr) spectra were recorded in $CDCl_3$ solution on a Varian XL-300 spectrometer. Low resolution mass spectra (ms) were determined on a Hewlett–Packard model 5980A instrument and are reported in amu with relative abundances in parentheses. For simplicity, only the $^{35}Cl_n$ ion of the Cl_n cluster is reported. Microanalyses were carried out by Guelph Chemical Laboratories, Guelph, Ontario. Column chromatography utilized Merck (Kieselgel 60) silica gel (40–60 μm particle size). Thin layer chromatography utilized Merck art. 5554 alumina-backed silica gel 60 GF_{254} plates. As a matter of routine, all reagents and solvents were recrystallized or redistilled prior to use.

Ames mutagenicity testing was performed under contract by B.C. Research, Vancouver, B.C.

Methyl 3-(dichloromethyl)-4,4-dichlorocrotonate (9)

Methyl (triphenylphosphoranylidene)acetate (3.344 g, 10 mmol) and 1,1,3,3-tetrachloroacetone (1.96 g, 10 mmol) were dissolved in dry THF (10 mL), and the mixture stirred at room temperature for 14 h under nitrogen. The THF was then evaporated under reduced pressure and the residue dissolved in a minimum amount of CH_2Cl_2 (~ 3 mL). To this solution was added hexane (100 mL), with the resulting precipitate removed by filtration. The filtrate was evaporated and the residue recrystallized from hexane to give **9** (2.11 g, 84%), mp 50–51°C; ir ν_{max}: 3040, 3010, 1720, 1660; uv λ_{max}: 224(8464); ^1H nmr ($CDCl_3$) δ 3.90 (3H, s, CH_3), 6.73 (2H, s, 2 × $CHCl_2$), 8.03 (1H, s, CH); ms *m/e*: 219 (M^+ − OCH_3, 10%), 191 (M^+ − CO_2CH_3, 14%), 179 (M^+ − HCl, Cl, 100%). *Anal.* calcd. for $C_6H_6Cl_4O_2$: C 28.60, H 2.40, Cl 56.29; found: C 29.17, H 2.48, Cl 56.60.

Ethyl 3-(dichloromethyl)-4,4-dichlorocrotonate (10)

n-BuLi (1.5 *M*, 3.3 mL, 5 mmol) in hexane was added dropwise to a magnetically stirred solution of triethyl phosphonoacetate (0.92 mL, 5 mmol) in dry THF (4 mL) at −75°C under N_2. The reaction mixture was allowed to rise to room temperature, tetrachloroacetone (0.60 mL, 5 mmol) was added, and stirring was continued for 2 h. The mixture was then heated to reflux. After 14 h the reaction mixture was cooled, poured into cold water (20 mL), and extracted with hexane (3 × 25 mL). The organic extracts were dried (Na_2SO_4), and evaporated to give a brown oil. This was applied onto a silica gel column, and eluted carefully with Et_2O–hexane (5:95) by flash chromatography.

Selected eluent fractions were combined, and evaporated to give ester **10** (970 mg, 73%), mp 46–48°C; ir(KBr) ν_{max}: 3025, 2980, 1720, 1660, 780; uv λ_{max}: 223 (7528); ^1H nmr ($CDCl_3$) δ: 1.34 (3H, t, *J* = 6.5 Hz, CH_3), 4.28 (2H, q, *J* = 6.5 Hz, CH_2), 6.60 (2H, s, 2 × $CHCl_2$), 7.9 (1H, s, CH); ms *m/e*: 264 (M^+, 0.28%), 85 (100%).

Methyl 2,4,4-trichloro-2(dichloromethyl)crotonate (13)

A suspension of **9** (2.99 g, 11.9 mmol) and ferric chloride (5 mg) in CH_2Cl_2 (250 mL) was saturated with chlorine and allowed to stand at room temperature for 14 h. The solvent was then evaporated to give **12** (3.82 g, 100%) as a colorless oil; ir ν_{max}: 1752, 1340; ^1H nmr ($CDCl_3$) δ: 3.85 (3H, s, CH_3), 5.27 (1H, s, CHCl), 6.54 (1H, s, $CHCl_2$), and 6.64 (1H, s, $CHCl_2$).

To a magnetically stirred solution of **12** (3.82 g, 11.8 mmol) in dry Et_2O (30 mL) at room temperature was added triethylamine (2 mL, 14.3 mmol). Stirring was maintained for 30 min, and the organic mixture then removed and washed with water (3 × 10 mL). The organic solubles were dried (Na_2SO_4) and evaporated to give a light brown solid. Recrystallization from hexane gave **13** (2.72 g, 80%), mp 60–62°C; ir(KBr) ν_{max}: 3030, 3095, 2975, 1725, 1610, 1320, 805, 775, 725; uv λ_{max}: 232.5 (8244): ^1H nmr ($CDCl_3$) δ: 3.90 (3H, s, OCH_3), 6.72 (1H, s, $CHCl_2$, *trans* to CO_2CH_3), 7.32 (1H, s, $CHCl_2$, *trans* to Cl); ms *m/e*: 253 (M^+ − OCH_3, 5%), 250 (MH^+ − Cl, 22%), 248 (M^+ − HCl, 5%), 213 (M^+ − HCl, Cl, 100%). *Anal.* calcd. for $C_5H_5Cl_5O_2$: C 25.16, H 1.76, C 61.90; found: C 25.27, H 1.75, Cl 52.74. (No explanation has been found to account for the chlorine analyses.)

2,4,4-Trichloro-3-(dichloromethyl)-crotonic acid (14)

A solution of **13** (1 g, 3.49 mmol) and LiOH·H_2O (150 mg, 3.57 mmol) in THF–H_2O (7 mL, 6:1) was magnetically stirred at room temperature for 1 h. The solution was then concentrated (to ca. 2 mL), adjusted to pH 2 with 1 *M* hydrochloric acid, and extracted with ethyl acetate (3 × 10 mL). The organic solubles were dried (Na_2SO_4) and evaporated to give **14** (0.949 g, 99.8%), mp 118–120°C; ir (KBr) ν_{max}: 1690, 1610, 1600, 800, 770, 715; uv λ_{max}: 231 (7694); ^1H nmr ($CDCl_3$) δ: 6.80 (1H, s, $CHCl_2$, *cis* to CO_2H), 7.43 (1H, s, $CHCl_2$, *cis* to Cl), 11.05 (1H, s, CO_2H); ms *m/e*: 235 (M^+ − Cl, 17%), 199 (M^+ − HCl, − Cl, 37%), 44 (CO_2, 100%). *Anal.* calcd. for $C_5H_3Cl_5O_2$: C 22.05, H 1.11, Cl 65.09; found: C 22.21, H 1.16, Cl 65.24.

*3-Chloro-4-(dichloromethyl)-5-hydroxy-2(5*H*)-furanone (16)*

The acid **14** (0.79 g, 2.9 mmol) and $KHCO_3$ (0.581 g, 5.8 mmol) were dissolved in H_2O (25 mL) and heated for 3 h at 50°C under N_2. The reaction mixture was then cooled (to 20°C) and extracted with ethyl acetate (3 × 20 mL). The organic solubles were combined, dried (Na_2SO_4), and evaporated.

The crude product was applied to a silica gel column, and then carefully eluted with Et_2O–hexane (1:1) by flash chromatography. Trichlorolactol **16** (0.407 g, 65%) was obtained as a pale-yellow liquid by evaporation of selected chromatographic fractions; ir (neat) ν_{max}: 3400, 3000, 1780, 1660, 750, 690; uv λ_{max}: 224.5 (8129); ^1H nmr ($CDCl_3$) δ: 5.27 (1H, bs, OH), 6.40 (1H, s), 6.60 (1H, s); ^{13}C nmr ($CDCl_3$): 60.51 (d, $^1J_{C6-H6}$ = 181 Hz, $CHCl_2$), 96.55 (dt, $^1J_{C5-H5}$ = 178.8 Hz, $^2J_{C5-OH}$ = 3.85 Hz, CHOH), 125.19 (d, d, ^2J = 0.83 Hz, ^2J = 3.02 Hz, C=*C*—$CHCl_2$), 150.45 (bs, C3, =C—Cl), 164.51 (d, $^3J_{C2-H5}$, = 2.72 Hz, CO).

*3-Chloro-4-(dichloromethyl)-5-methoxy-2(5*H*)-furanone (15)*

To a solution of **16** (36 mg, 0.17 mmol) in methanol (0.2 mL) was added HCl-saturated methanol (3 drops), and the mixture was then stirred for 24 h at room temperature, under N_2. The solution was evaporated to give a residue which was redissolved in EtOAc (4 mL) and washed with water (1 × 2 mL). The organic solubles were dried (Na_2SO_4) and evaporated to give **15** (35 mg, 91%) as a colorless liquid; ir ν_{max}: 2930, 2840, 1795, 1725, 1655, 1600; uv λ_{max}: 226 (7781); ^{1}H nmr ($CDCl_3$) δ: 3.70 (3H, s, OCH_3), 6.05 (1H, s, C*H*OMe), 6.60 (1H, s, $CHCl_2$); ms *m/e*: 199 ($M^+ - OCH_3$, 32%).

*Conversion of **15** to **16***

A solution of **15** (40 mg, 1.73 mmol) in THF (0.6 mL) and trifluoroacetic acid (3 *N*, 0.4 mL) was stirred at room temperature for 96 h under N_2. The reaction mixture was then diluted with H_2O (3 mL) and extracted with ethyl acetate (3 × 10 mL). The organic extract was dried (Na_2SO_4) and evaporated. The crude product was applied to a silica gel column and carefully eluted with Et_2O−hexane (1:1) by flash column chromatography. Fractions containing the trichlorolactol were combined to give **16** (26 mg, 69%).

Formation threshold structures of some $[C_5H_7O]^+$ ions: use of general schemes for estimation of heats of formation of gas-phase organic ions

MEHRSHID ALAI, GIORGIO G. ATTARDO, AND ROBIN T. B. RYE[1]
Department of Chemistry, Concordia University, 1455 de Maisonneuve Blvd. W., Montreal, P.Q., Canada H3G 1M8

Received August 10, 1984

MEHRSHID ALAI, GIORGIO G. ATTARDO, and ROBIN T. B. RYE. Can. J. Chem. **63**, 833 (1985).

Recently published correlations between heat of formation and structure of gas-phase ions have been used to assign formation threshold structures to $[C_5H_7O]^+$ ions produced by methyl radical loss from molecular ions of mesityl oxide, 5-hexene-2-one, 3-methylcyclopentanone, and 2-cyclohexenol. An unambiguous structure assignment has been made for the $[C_5H_7O]^+$ daughter ion from mesityl oxide. For the three other precursors two common formation-threshold structures consistent with the thermochemical data are proposed.

MEHRSHID ALAI, GIORGIO G. ATTARDO et ROBIN T. B. RYE. Can. J. Chem. **63**, 833 (1985).

Des travaux publiés récemment ont établi des corrélations entre la chaleur de formation et la structure des ions en phase gazeuse; on a utilisé ces corrélations pour attribuer les structures, au niveau du seuil de formation, des ions $[C_5H_7O]^+$ qui se forment lorsque les ions de l'oxyde de mésityle, de l'hexène-5 one-2, de la méthyl-3 cyclopentanone ou du cyclohexène-2 ol perdent un radical méthyle. On a pu faire une attribution non ambigue de la structure de l'ion fille $[C_5H_7O]^+$ provenant de l'oxyde de mésityle. Pour les trois autres précursors, on propose deux structures communes, au niveau du seuil de formation, qui sont en accord avec les données thermodynamiques obtenues.

Introduction

Collisional activation (CA) mass spectrometry has achieved prominence as a method for the determination of the structure of gas-phase ionic species (1). In spite of the widespread use of this technique, thermochemical characterization of ions at their formation threshold remains an essential component of any complete structure determination. This is so because the CA technique samples ions with a range of internal energies; the structures determined may therefore be different than those at threshold if isomerization reaction channels with low energy requirements are available.

Two recent publications (2, 3) have outlined general methods for correlating ionic heats of formation with the threshold structures of gaseous odd and even electron ions. We have now utilized these techniques to assign configurations to $[C_5H_7O]^+$ ions generated by methyl radical loss from 4-methyl-3-penten-2-one (mesityl oxide) (**1**), 5-hexene-2-one (**2**), 3-methylcyclopentanone (**3**), and 2-cyclohexenol (**4**).

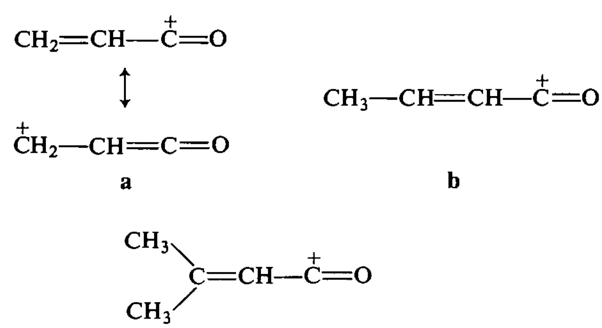
Experimental

The $[C_5H_7O]^+$ ions of interest were generated by dissociative ionization using a monoenergetic electron beam. Appearance energies (AE) were measured as described elsewhere (4). The heats of formation of the neutral precursors were taken from the literature or calculated by additivity.

Results and discussion

(a) *Mesityl oxide, 1*

Zwinselman *et al.* (5) proposed the molecular ion of **1** as an intermediate structure preceding the loss of methyl radical from 2-methyl-3,4-dien-2-ol, with the acylium ion **c** as the daughter ion generated. Ion **a**, readily produced by methyl radical loss from ionized methyl vinyl ketone (6), can be represented by the two canonical structures shown; thus **c** corresponds to double methyl substitution at a charge-bearing site of **a**. The other member of the series, **b**, can be generated by H loss from crotonaldehyde (7). If the structural assignments are correct,



a **b** **c**

then, following the conclusions of Holmes and Lossing (3), the heats of formation of **a**, **b**, and **c** given in Table 1 should lie on a straight line when plotted against log (no. of atoms), and this straight line should roughly parallel similar plots for other methyl substitutions at C-atoms bearing a formal charge. Inspection of Fig. 1 and the data in Table 1 shows that such is the case, with the least-squares line for **a**, **b**, and **c** approximately parallel to line A (methyl substitution on CH_2O) and line B (methyl substitution on CH_2OH). We propose, therefore, that **c** is the configuration of the $[C_5H_7O]^+$ ion formed from **1** by $\dot{C}H_3$ loss.

Additional information can be extracted from Fig. 1. It will be noted that the datum for **b** lies significantly above the line (dotted line, Fig. 1) joining the data points for **a** and **c**. The structure of **b** was clearly established by CA and analysis of metastable peak charcteristics (7); we conclude that the reported ΔH_f for **b** is too high. This is not surprising; a conventional electron impact source (such as used for **b**) is known to give AE measurements which are higher than those obtained with the monoenergetic electron beam used in the case of **a** and **c** (4*c*). We may thus revise the ΔH_f for **b** downwards by approximately 40 kJ mol^{-1} to a value of 645 kJ mol^{-1}.

(b) *5-Hexene-2-one, 2*

Loss of methyl from the molecular ion of **2** can occur via simple cleavage to give a $[C_5H_7O]^+$ ion of structure **d**. While **d** may be a plausible structure, it is by no means certain that it is the correct one. The heat of formation of **d** can be estimated

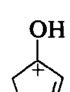
in the following manner. Ion **d** can be constructed by replacing the terminal CH_3 in $CH_3CH_2\overset{+}{C}{=}O$ with a $CH_2{=}CH{-}CH_2{-}$ group. It has been shown (2) that substitution on a site remote from the charge-bearing site has approximately the same effect on ΔH_f (ion) as on ΔH_f (neutral). The heats of formation of 2-propanone an **2** are −238.5 kJ mol^{-1} (8) and −153 kJ mol^{-1} (by additivity (9)), respectively. These data, when taken with a ΔH_f of 623 kJ mol^{-1} for $CH_3CH_2\overset{+}{C}{=}O$ (10), lead to a calculated heat of formation for **d** of 709 kJ mol^{-1}. The measured value (Table 1) of ΔH_f for $[C_5H_7O]^+$ from **2** is 628 kJ mol^{-1}, and it may therefore be concluded with some assurance that structure **d** is incorrect.

$H_2C{=}CH{-}CH_2{-}CH_2{-}\overset{+}{C}{=}O$

d

$H_3C{-}CH_2{-}CH{=}CH{-}\overset{+}{C}{=}O$

e



f

It is considerably more difficult to assign the correct structure, given the large number of possible configurations for $[C_5H_7O]^+$, but the estimation method can be used to determine whether proposed structures are consistent with the thermochemical data. The stabilizing effect of conjugation is well documented; we therefore wished to evaluate the conjugated ion **e** as a possible structure. The heat of formation of **e** can be estimated from the corrected ΔH_f for **b** (see Fig. 1 and text). Construction of **e** by replacement of the terminal CH_3 group in **b** wth CH_3CH_2 corresponds to substitution remote from the charge-bearing site and, as was done in the previous case, the effect of this substitution on ΔH_f (ion) was equated to the

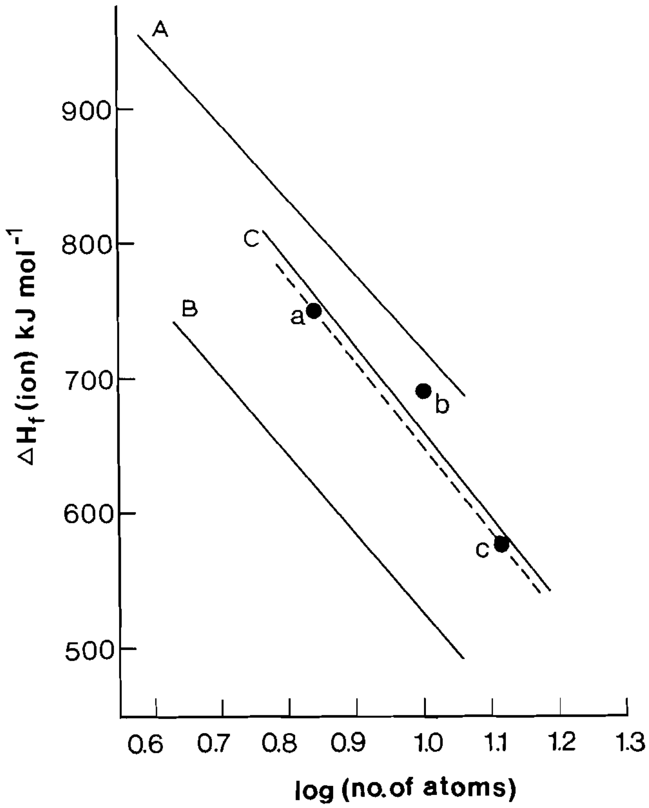


FIG. 1. Heats of formation vs. log (no. of atoms) for successive methyl substitution at charge-bearing site: **a**, [vinyl ketenium]$^+$; **b**, methyl-substituted vinyl ketenium cation; **c**, $[C_5H_7O]^+$ from mesityl oxide. Lines A, B, and C: see text.

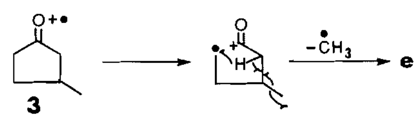
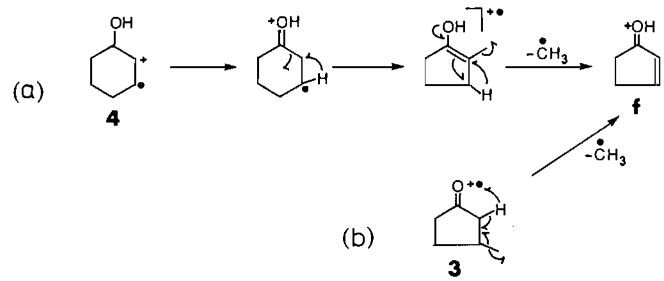


SCHEME. 1. Possible fragmentation pathways for production of ion **e** from the molecular ion of 3-methylcyclopentanone.

change in ΔH_f (neutral). This procedure leads to a calculated ΔH_f for **e** of 624 kJ mol^{-1}, in excellent agreement with the measured value. It would be unwise to conclude from this result that the ion structure has been unambiguously determined; this point is underlined by the results for **3** and **4** given below. It should also be noted that, at internal energies only slightly above threshold, other reaction channels and fragment ion structures may be involved. We have recently reported evidence (11) that this is the case for methyl radical loss from **2**.

(c) *3-Methylcyclopentanone,* **3**, *and 2-cyclohexene-1-ol,* **4**

The measured heat of formation of the $[C_5H_7O]^+$ ion from **3** and from **4** is the same, within experimental error, as that obtained with **2** as the precursor (Table 1). Formation of **e** from **3** can be easily rationalized in terms of CH_3 loss from α-cleaved molecular ion, as shown in Scheme 1. Methyl loss from **4** has been the subject of several reports (12–15). Buch and coworkers (14) studied the 70-eV spectra of **4** and a wide range of labelled analogues. Loss of CH_3 was observed to involve C(2) together with the hydrogen atoms from C(1), C(2), and C(3); a [1-hydroxy-cyclopentene-1]$^+$ ion with the charge located on C(2) was proposed as a plausible structure for the $[C_5H_7O]^+$ daughter ion. An alternative mechanism, based on



SCHEME. 2. Possible fragmentation pathways leading to ion **f** from the molecular ion of (a) 2-cyclohexenol (15) and (b) 3-methylcyclopentanone.

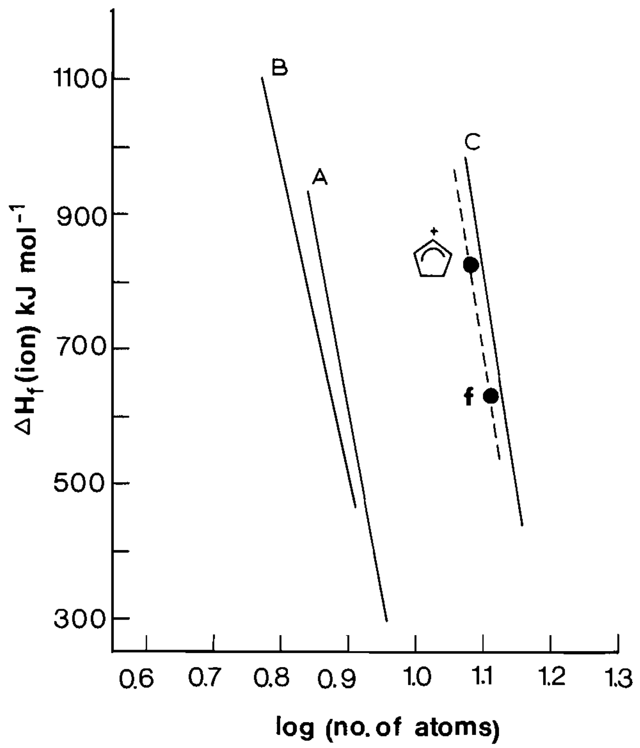


FIG. 2. Heats of formation vs. log (no. of atoms) for successive hydroxyl substitution at charge-bearing site: **f**, hydroxyl substitution on [cyclopentenium]$^+$ cation. Lines A, B, and C: see text.

the results of metastable ion studies, has been suggested by Lignac and Tabet (15). These authors propose that isomerization of the molecular ion of **4** to the enol form of methyl-2-cyclopentenol precedes methyl loss, with the latter process involving a shift of the hydrogen atom at C(4) (Scheme 2(a)). The $(M - CH_3)^+$ ion generated, **f**, is of interest because it could also be produced by methyl radical loss from **3**. A possible mechanism is shown in Scheme 2(b), although the 1,3-hydrogen shift indicated would imply an activation energy of at least 160 kJ mol^{-1} for this pathway (16). We wished to determine whether or not structure **f** was consistent with the measured ΔH_f for $[C_5H_7O]^+$ from **3** and **4**.

The procedure followed was analogous to that employed for **c**. Ion **f** can be viewed as resulting from —OH substitution on the charge-bearing site of the [cyclopentenium]$^+$ cation. It has been shown that plots of ΔH_f against log (no. of atoms) give roughy parallel lines for various series of successive —OH substitutions (3). The average value of the slopes of three such plots (lines A, B, and C, Fig. 2) was determined using the data in Table 1, the ΔH_f datum for [cyclopentenium]$^+$ (4*b*) used to calculate the intercept, and the estimated line for the effect of hydroxyl substitution on the charge-bearing a site of [cyclopentenium]$^+$ was plotted (dotted line, Fig. 2). The ΔH_f of **f** is estimated by this method to be 635 kJ/mol. Given the uncertainties associated with the above procedure, we conclude that threshold heat of formation measurements do not allow us to distinguish between ion structures **e** and **f**.

Summary

The methods developed by Holmes and Lossing have been used to assign the acylium structure **c** to the $[C_5H_7O]^+$ ion generated from **1** at the formation threshold.

For various series of both —OH and CH_3— substitutions at charge-bearing sites, roughly parallel plots of ΔH (ion) vs. log (no. of atoms) have been reported (3). This feature enables useful structural predictions to be made even in cases where only limited amounts of data are available. We have used this approach to show that at least two possible threshold configurations consistent with the thermochemical data, viz. **e** and **f**, are possible for the $[C_5H_7O]^+$ ion generated from **2**, **3**, and **4**.

Equilibrium structures, proton affinities, and ionization potentials of the fluoroacetones

SAI CHENG CHOI AND RUSSELL J. BOYD[1]

Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received July 9, 1984

SAI CHENG CHOI and RUSSELL J. BOYD. Can. J. Chem. **63**, 836 (1985).

Theoretical calculations on the fluoroacetones and their conjugate acids exhibit an inverse dependence of the proton affinity on the number of fluorine substituents. The good correlation between increasing proton affinity and decreasing ionization potential is attributed to the observation that the ionization of a nonbonding electron is essentially localized at a single atom which is also the site of protonation. The best quantitative agreement between the theoretical and experimental proton affinities is obtained at the 6-31G* level, while the STO-3G basis set leads to a satisfactory account of the additivity of fluorine substituents. The calculations corroborate the experimental interpretation of the preferred conformations of *p*-fluoroacetone molecules in terms of the presence of an intramolecular hydrogen bond between the carbonyl proton and the F on the adjacent carbon. Only one type of equilibrium conformation is predicted for the fluorinated acetones, whereas two types of equilibrium conformations are predicted for the conjugate bases.

SAI CHENG CHOI et RUSSELL J. BOYD. Can. J. Chem. **63**, 836 (1985).

D'après des calculs théoriques sur les fluoroacétones et sur leurs acides conjugués, l'affinité pour les protons varie d'une façon inverse avec le nombre de substituants fluor. C'est à l'observation que l'ionisation d'un électron non liant est essentiellement localisée sur un atome unique qui est aussi le site de la protonation que l'on attribue la bonne corrélation qui existe entre une augmentation de l'affinité pour les protons et la diminution du potentiel d'ionisation. C-est au niveau 6-31G* que l'on obtient les meilleurs accords quantitatifs entre les résultats expérimentaux et les valeurs calculées pour les affinités pour les protons; par ailleurs, l'utilisation de l'ensemble STO-3G conduit à une explication satisfaisante de l'additivité des substitutants fluor. Les calculs corroborent l'interprétation expérimentale des conformations privilégiées des molécules de *p*-fluoroacétones en fonction d'une liaison hydrogène intramoléculaire entre le proton du carbonyle et le F attaché au carbone voisin. Dans le cas des fluoroacétones, on ne prédit qu'un seul type d'équilibre conformationnel; toutefois, on prédit deux types d'équilibres conformationnels pour les bases conjuguées.

[Traduit par le journal]

Introduction

One of the major challenges of chemistry is to predict the effect of substituents on the properties of molecules and to develop models and theories which facilitate a better understanding of substituent effects. Most systematic studies of substituent effects have been carried out in solution, where the observed properties are often more a reflection of the effects of solvation than of the intrinsic properties of the species of interest. Recent advances in physical chemistry have provided several powerful methods for studying the reactions and structures of ions in the gas phase. Complementary information on the intrinsic properties of molecules and ions is provided, however, by *ab initio* molecular orbital theory.

Ion cyclotron resonance studies (1) of the gas-phase basicities of six fluorinated acetones have revealed a very regular decrease in proton affinity of 6.1 ± 0.4 kcal/mol for each successive fluorine substituent. This result has been interpreted in terms of a substituent effect which is almost purely inductive and correlates well with the group electronegativity of the methyl substituents. Furthermore, the linear dependence of the observed proton affinities on the number of fluorine substituents reveals a small stabilizing interaction of 2−3 kcal/mol in the protonated fluoroacetones, which is attributed to the formation of an intramolecular hydrogen bond. The additivity of fluorine substituent effects in the gas-phase basicities of fluorinated acetones stands in contrast to the less regular changes in acidities and basicities which are often associated, both in solution and in the gas phase, with multiple substitution in organic molecules (2, 3).

The Drummond and McMahon study of the fluorinated acetones is a remarkable application of one of the three techniques, namely high-pressure mass spectrometry (4, 5), flowing afterglow (6−8), and ion cyclotron resonance spectrometry (9−12), which yield reliable gas-phase data on the intrinsic acidities and basicities of molecules. Not only are the substituent effects additive, but up to six hydrogens in acetone can be replaced by fluorines. Furthermore, two isomers are possible for each of the di-, tri-, and tetrafluoro derivatives, and, therefore, a total of ten molecules are available for the study of multiple substituent effects. Given accurate proton affinities (1) for seven of these compounds, we have studied the ability of *ab initio* molecular orbital (MO) theory to account for the additivity of fluorine substituent effects in the acetone series. In this paper we focus our attention on equilibrium structures, proton affinities, and multiple substituent effects. We will present an analysis of intramolecular hydrogen bonding in the protonated fluoroacetones in a later paper (13).

Method

All computations were performed on a CDC CYBER 170-730 computer using the GAUSSIAN 76 program (14). In some cases an expanded version of the GAUSSIAN 76 program (15) was used. $CH_mF_{3-m}COCH_nF_{3-n}$ and their corresponding conjugate acids $CH_mF_{3-m}COHCH_nF^+_{3-n}$, where m and n are equal to 0, 1, 2, or 3 were optimized at the STO-3G level. For some species, in which the C—C bonds were found to be longer (1.56 to 1.63 Å) at the STO-3G level than normal ones (1.54 Å), partial 4-31G optimizations were carried out. The partial 4-31G optimizations are denoted by '4-31G' and consist of a 4-31G optimization on the C—C bonds followed by a minimal STO-3G optimization on the rest of the molecule. The '4-31G' optimization was employed on CH_2FCOCH_3, CHF_2COCH_3, CF_3COCH_3, CF_3COCF_3, and their corresponding conjugate acids. Partial optimizations with split-valence

basis sets have been shown (16) to yield good approximations to the full K-LMG optimizations in the case of *cis*-acetic acid and acetamide. A model geometry (r (C—H) = 1.085 Å and angle HCH = 108.2°) was used for all unsubstituted methyl groups. The STO-3G or '4-31G' equilibrium geometries of the fluorinated acetones and their conjugate acids are shown in Fig. 1.

Tables 1 and 2 list the STO-3G//STO-3G, 4-31G//STO-3G, 4-31G//'4-31G', and 6-31G*//STO-3G total energies and the point group symmetries of the equilibrium conformations in the neutral and protonated series, respectively. The theoretical proton affinities (PA), defined as the difference in total energies of the base and its conjugate acid, are listed in Table 5 together with the available experimental values. The zero-point energy and thermodynamic corrections have not been included. The latter are simply a function of the temperature, while the former should be essentially constant within a series of related molecules (16). Hence these omissions will not affect the chemical trends as significantly as the more serious basis set and correlation errors. Large basis sets and post Hartree–Fock calculations are impractical for the larger members of the series. Calculations at the 4-31G level are included for all members of the series, while the 6-31G* basis set has been used up to and including 1,1,1-trifluoroacetone and its conjugate acid.

Results and discussion

Equilibrium structures

The types of equilibrium conformations of the neutral and protonated series are shown in Fig. 2 where X and Y may be either hydrogen or fluorine. All neutral molecules show one type of conformation, namely that of type I, in which the unique atom occupies the X position. For CF_3COCH_3 and CF_3COCF_3, the question of the position of a unique atom does

not arise. As expected, those molecules with equal numbers of F atoms on each carbon have two equal C—C bonds. The reverse holds true, with the more highly substituted methyl group being associated with a longer C—C bond at both the STO-3G and '4-31G' levels.

In this work the site of protonation is assumed to be the carbonyl oxygen, in agreement with an earlier MNDO study (17) which showed that protonation at fluorine in CH_2FCOCH_3 is less stable by about 25 kcal/mol. In the two types of equilibrium conformation of the protonated series, position X on C_1 is always occupied by a F atom, thus forming a pseudo-five-membered ring. From Fig. 1, it is readily seen that five of the protonated molecules, $CH_3COHCH_3^+$, $CH_2FCOHCH_3^+$, $CHF_2COHCH_3^+$, $CF_3COHCH_3^+$, and $CF_3COHCF_3^+$, have type II equilibrium conformations while $CH_2FCOHCH_2F^+$, $CH_2FCOHCHF_2^+$, $CHF_2COHCHF_2^+$, $CF_3COHCH_2F^+$, and $CF_3COHCHF_2^+$, have type III equilibrium conformations. The apparent feature of the pseudo-five-membered ring in both types II and III equilibrium conformations indicates the presence of an intramolecular hydrogen bond between the carbonyl hydrogen and the F atom at C_1. This is in agreement with the experimental interpretation (1) of the dependence of the proton affinity on the number of fluorine substituents.[2] Note that in the protonated series, position X at C_3 is always occupied by a F atom, if possible, regardless of whether it is the unique atom or not. This is in contrast to that found in the neutral series. Figure 1 shows that, of the unsymmetrically substituted protonated

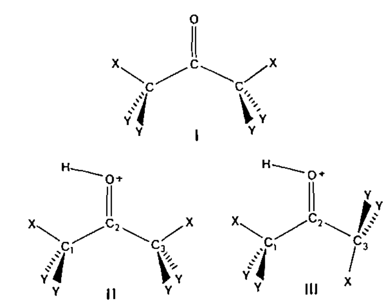

FIG. 2. Types of equilibrium conformations of the fluorinated acetones (I) and their conjugate acids (II and III).

acetones, the carbonyl proton is directed toward the carbon with the larger number of F substituents in the case of $CF_3COHCH_2F^+$, and toward the carbon atom with the smaller number of F substituents in the case of $CH_2FCOHCHF_2^+$ and $CF_3COHCHF_2^+$. With the exception of the latter two, the equilibrium conformations of the protonated species are characterized by an intramolecular hydrogen bond involving a F atom of the more highly substituted methyl group. Here it is interesting to note that Drummond and McMahon (1) have suggested that intramolecular hydrogen bond formation in pentafluoroacetone should occur to a fluorine in the CF_3 group rather than the CF_2H group, on the basis that the higher symmetry of the CF_3 group leads to a lower overall entropy associated with internal rotation, and thus the decrease in entropy due to restriction of the rotation should be less.

The equilibrium conformations of CH_3COCH_3, CH_2FCOCH_3, CF_3COCH_3, and CF_3COCF_3 remain unchanged upon

[2]Infrared studies (18, 19) of the protonated fluoroacetone and hexafluoroantimoniate salt (20) showed the absence of intramolecular hydrogen bonding when the halogen is fluorine.

protonation. In the case of CHF_2COCH_3 and CHF_2COCHF_2, protonation leads to a change in the conformation of the methyl group that is involved in the internal hydrogen bond. The conformation of the methyl group which is not involved in the internal hydrogen bond in CHF_2COCHF_2, $CH_2FCOCHF_2$, CHF_2COCHF_2, CF_3COCH_2F, and CF_3COCHF_2 remains unchanged upon protonation. Note that both methyl groups show changes in conformation upon protonation in the case of CHF_2COCHF_2.

The C—F bond length varies little from one molecule to another within the fluoroacetones, the range being from 1.370 Å (in CF_3COCH_2F) to 1.384 Å (in CH_2FCOCH_3) at the STO-3G level, whereas the C—H bond length shows a larger range of 0.025 Å. Previous studies (21, 22) have shown that the STO-3G basis set underestimates the effect of multiple substitution on the C—F bond lengths of the fluoromethanes. The bond angles in the neutral series are very close to the values typical of trigonally and tetrahedrally hybridized carbon. The only significant bond length variation is that of the C—C bond in both the neutral and protonated series. In general, at the minimal STO-3G level of optimization, the replacement of H by F results in the extension of the C—C bond (s). This is especially true in the protonated series. The degree of elongation in the protonated series is governed by the number of F atoms bonded to the adjacent carbon atom. In the case of the acetate anion, the C—C bond stretches by about 0.02 Å for each successive F substituent at the STO-3G level (16). This study shows similar elongation of the C—C bond(s) in both the neutral and protonated series. Relative to $CH_3COHCH_3^+$, the effect of a F substituent is to increase the adjacent C—C bond and to contract the opposite C—C bond of $CH_2FCOHCH_3^+$. In both the neutral and protonated series, the methyl carbon with a larger number of F atoms will have a longer C—C bond. With the increasing number of F substituents at both C_1 and C_3, the question arises as to whether such molecules are in fact on the verge of breaking up into two separate fragments. This is especially true in the case of $CF_3COHCF_3^+$. In short, the effect of fluorination in the protonated series can be summarized as shown in Table 3 with the $CH_3COHCH_3^+$ STO-3G structure as the reference. Use of a model methyl group is justified by the small changes of the optimized CH_3 group in CF_3COCH_3 as compared with that of CH_3COCH_3 at the STO-3G level.

As shown in Fig. 1, '4-31G' equilibrium structures were obtained for CH_2FCOCH_3, CHF_2COCH_3, CF_3COCH_3, CF_3COCF_3, and their corresponding acids. Analysis of the proton affinities and the total atomic charges at the 4-31G//'4-31G' level indicates only slight differences from the 4-31G//STO-3G values. Consequently, a significant improvement upon the STO-3G results for the two series is not expected as a result of reoptimization at the '4-31G' level. This is further justified by the poor agreement between the theoretical '4-31G' geometries of CF_3COCH_3 and CF_3COCF_3 with the experimental results of Adreassen and Bauer (23) and Bauer and co-workers (24), respectively.

This paper reports the first extensive theoretical study on the structures of the fluoroacetones and their conjugate acids. An *ab initio* study by Jost *et al.* (25) assumed model geometries for CH_3COCH_3, CH_2FCOCH_3, CH_2FCOCH_2F, and their corresponding conjugate acids based on the following parameters: C=O = 1.212 Å, C—H = 1.095 Å, C—C = 1.50 Å, C—F = 1.398 Å, and CCO = 121°. All other angles were assumed to be tetrahedral. On the basis of Del Bene and Vaccaro's work (26), Jost *et al.* argued that the C=O and $^+$O—H bond lengths and the COH^+ angle do not depend on the substituents and consequently do not require any optimization. Nevertheless, the present study clearly indicates that the number and positions of the F substituents do affect the geometry of the protonated species. This is especially noticeable in the pseudo-five-membered ring associated with the intramolecular hydrogen bond.

r (C_1—C_2)	1.578	1.593
r (C_2—C_3)	1.554	1.564
$\angle OC_2C_1$	122.1	112.4
$\angle OC_2C_3$	122.8	120.4
$\angle C_2C_1F$ or $\angle C_2C_3F$	111.3	101.2

A semi-empirical MNDO study (17) predicted a COH angle in the protonated species of about 120−125° and a slight increase in the O—H bond with the number of F substituents. However, this study shows an average COH angle of 104.9° at the STO-3G level. In addition, a large discrepancy is also observed for the O—H bond lengths: 1.026 Å on average at the STO-3G level versus 0.964 Å by MNDO. Nevertheless, the C=O bond in the protonated species is in close agreement, 1.277 and 1.273 Å according to the MNDO and STO-3G calculations, respectively. Table 4 summarizes the changes in structural parameters associated with protonation.

Proton affinities

Seven of the ten PA's are available from an ion cyclotron resonance (ICR) study (1). The extra three theoretical PA's are obtained from the three isomers of the di,- tri-, and tetrafluoroacetones. As shown in Table 5, the theoretical PA's decrease as the number of F substituents increases, in good agreement with the experimental observation. It is apparent that the minimal STO-3G basis set grossly overestimates the PA's by about 57 ± 3 kcal/mol. Since the amount of overestimation is fairly constant, the observed trends are well reproduced. The lack of experimental PA's for the three isomeric pairs precludes an assessment of the STO-3G prediction that maximizing the number of F's on one carbon decreases the basicity and hence increases the acidity of the protonated acetones.

PA's at the 4-31G//STO-3G level differ considerably from those at the STO-3G//STO-3G level, which does not in general provide reliable estimates of relative PA's of related bases (27, 28). The 4-31G//STO-3G calculations overestimate the PA of actone by about 7.4 kcal/mol and underestimate the

[a]All protons affinities are in kcal/mol.
[b]See ref. 1.
[c]See ref. 17.

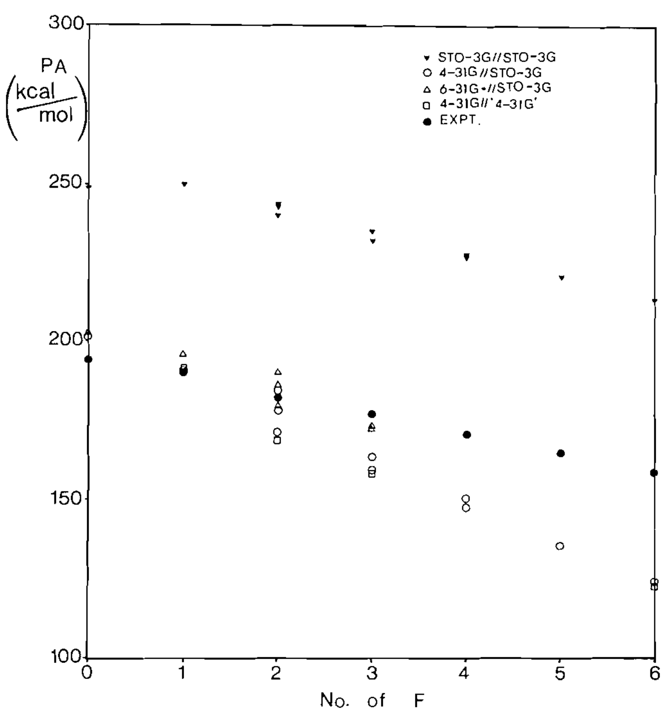

FIG. 3. Experimental and theoretical proton affinities (PA) versus the number of fluorine substituents in the fluoroacetones.

remaining PA's by up to 34.7 kcal/mol, with the error increasing as the number of F's increases. Note that, in the case of the tetrafluoroacetone pair of isomers, the prediction that maximizing the number of F's on one carbon atom increases the acidity of the protonated species does not hold at the 4-31G//STO-3G level. The slight difference between the 4-31G//'4-31G' and 4-31G//STO-3G results demonstrates that the application of partial split-valence optimizations does not significantly improve the PA's, in agreement with a study (16) of the carboxylate anions. However, at the 6-31G*//STO-3G level, a considerable improvement is observed, with the difference between the theoretical and experimental values not exceeding 10 kcal/mol. Even though the 6-31G*//STO-3G data are incomplete, it is obvious that the 6-31G* basis set gives the best estimate of the experimental PA's.

Figure 3 shows plots of the theoretical and experimental PA's versus the number of F substituents. The correlation coefficients (R^2) are 0.959, 0.979, 0.987, 0.904, and 0.991 for the STO-3G//STO-3G, 4-31G//STO-3G, 4-31G//'4-31G', 6-31G*//STO-3G, and experimental values, respectively. The correlation improves as the level of theory increases, with one exception, i.e. the 6-31G*//STO-3G data. Since only a few members of the series are included and they cover only a narrow range of n, the R^2 value for the 6-31G*//STO-3G data is insignificant. By comparison, the 4-31G//'4-31G' level gives the best R^2 value because the few PA values cover a larger range of n. Nevertheless, the R^2 value at the 4-31G//'4-31G' level is also insignificant due to the lack of a complete set of data. In fact the inability of the 4-31G basis set to account for the F substituent effect can be seen by making a comparison between the 4-31G and 6-31G* PA's at the STO-3G geometry. In acetone, the difference in PA between 4-31G//STO-3G and 6-31G*//STO-3G levels is only a small amount, 1 kcal/mol. With an increase in the number of F substituents, the difference in PA's between these two levels becomes excessive, indicating the inadequacy of the 4-31G basis set for the description of the effect of multiple F substituents.

Experimentally (1), a regular decrease of 6.1 kcal/mol in PA was observed with the addition of each F substituent. Least-squares fits to the data plotted in Fig. 3 yield 7.2, 13.7, 12.7, and 11.7 kcal/mol at the STO-3G//STO-3G, 4-31G//STO-3G, 4-31G//'4-31G', and 6-31G*//STO-3G levels, repectively. Hence the STO-3G//STO-3G calculations show an F substituent effect that is closest to the experimental result, while the larger basis sets show effects that are about twice as large. Even though the STO-3G//STO-3G calculations provide a more satisfactory account of multiple substituents, better quantitative agreement with experiment is obtained at the 6-31G*//STO-3G level.

A semi-empirical MNDO study by DeKock *et al.* (17) gave PA's that deviate considerably from the experimental results (see Table 5), with the deviations tending to increase as the number of F substituents increases. From a least-squares fit to the MNDO values (excluding acetone) in Table 5, we obtain a slope of 9.1 kcal/mol compared to the STO-3G and experimental values of 7.2 and 6.1 kcal/mol, respectively. A significant difference between the MNDO and *ab initio* results is evident from the equilibrium conformations. For the protonated species, all *ab initio* calculations yield equilibrium structures in which the carbonyl proton is directed toward a F on an adjacent methyl group. Thus the equilibrium structures are characterized by a pseudo-five-membered ring which is attributed to the formation of an intramolecular hydrogen bond. The MNDO results for protonated 1,1,1-trifluoroacetone place the energy

TABLE 6. Vertical ionization potentials[a]

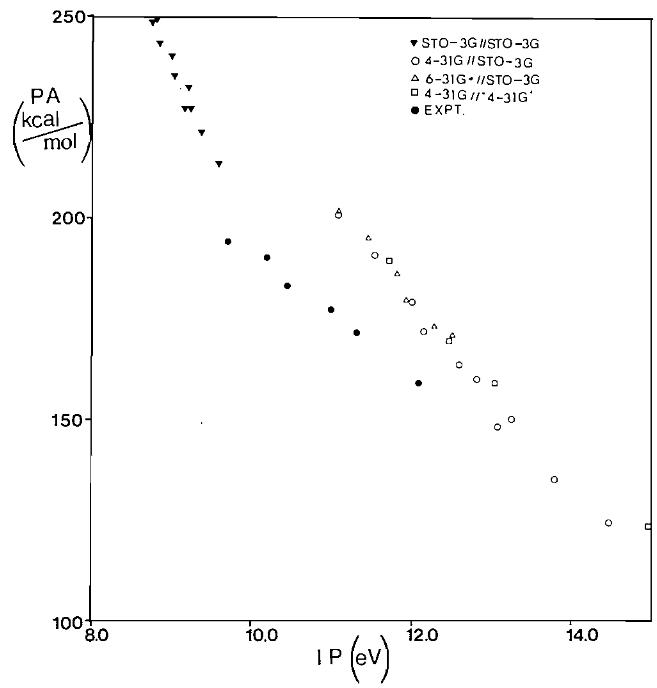

FIG. 4. Experimental and theoretical proton affinities (PA) versus the corresponding ionization potentials (IP) in the fluoroacetones.

of the hydrogen bonded conformation 1 kcal/mol above the conformation in which the carbonyl proton is directed toward the CH_3 group rather than the CF_3 group. At the 4-31G//4-31G level we find a difference of 1.7 kcal/mol in favour of the conformation which is interpreted in terms of a F---H—O intramolecular hydrogen bond. Thus our *ab initio* results are consistent with the original suggestion of Drummond and McMahon (1) and not with the MNDO results (17).

The overall free energy of stabilization of a protonated species due to the formation of an intramolecular hydrogen bond can be estimated from the difference between the acetone PA and the intercept obtained from a least-squares fit to the PA's of the fluoroacetones. This method leads to 7.7, 3.4, 6.0, 1.9, and 2.4 kcal/mol with the STO-3G//STO-3G, 4-31G//STO-3G, 6-31G*//STO-3G, experimental, and MNDO data, respectively. Thus the highly parameterized MNDO method leads to a better agreement with the experimental estimate of the stabilization due to the formation of an intramolecular hydrogen bond than do the *ab initio* calculations. Here it is interesting to note that the only previous *ab initio* study (25) of the proton affinities of acetone, monofluoroacetone, and 1,1-difluoroacetone attempted to assess the magnitude of the intramolecular hydrogen bond energy by comparing the energies of *syn* and *anti* conformations of the protonated forms. At the STO-3G and 4-31G levels with model geometries, Jost *et al.* (25) obtained 5.1 and 7.9 kcal/mol, respectively, for protonated monofluoroacetone. This is considerably higher than the 4-31G//4-31G value for protonated 1,1,1-trifluoroacetone (see the preceding paragraph). Such a procedure can not be applied, however, to the highly fluorinated acetones because a suitable *anti* conformation does not exist. We shall postpone a thorough discussion of the intramolecular hydrogen bond until a later paper (13) in which we will present a detailed analysis based on the topological properties of the charge density.

Ionization potentials

We wish to conclude our discussion by noting that there is a good correlation (see Fig. 4) between the theoretical values for the proton affinities and ionization potentials (IP) of the fluoroacetone bases. Similar correlations have been observed (29, 30) between experimental sets of data for a variety of systems, including the fluoroacetones (1), and in theoretical studies (27, 31, 32). The theoretical IP's for the fluoroacetones, as given by Koopmans' theorem (33), are tabulated in Table 6, together with the experimental (34) and MNDO (17) values. As expected, the STO-3G IP's are too low by about 1 to 2 eV, while the larger basis sets overestimate the IP's by similar amounts. Both theory and experiment indicate a correlation between increasing proton affinity and decreasing ionization potential for the fluoroacetones. The correlation is similar to that observed in other R_2CO molecules (32), and is expected in a related series of molecules in which ionization of a nonbonding electron is essentially localized at a single atom which is also the site of protonation. Del Bene has suggested (31) that the correlation between decreasing IP and increasing PA may arise from the common mechanism of stabilizing the resulting ions, which involves a polarization of electron density toward the basic site. The latter mechanism is a central feature of a model for the protonation of carbonyl bases (32).

Conclusion

The theoretical equilibrium structures are consistent with the interpretation of the gas-phase basicities in terms of the formation of an intramolecular hydrogen bond. The stereochemistry of the methyl group involved in the intramolecular hydrogen bond is always *cis* periplanar with the carbonyl group, whereas the other methyl group shows a preference for both *cis* and *trans* periplanar conformations. The fluoroacetones, like the parent molecule, are predicted to have equilibrium structures in which both methyl groups are *cis* periplanar with the carbonyl group, with the unique atom of the mono- and difluoromethyl groups lying in the carbonyl plane.

The theoretical PA's of the fluoroacetones have been shown to decrease as the number of F substituents increases, in agreement with the ICR study of Drummond and McMahon. The best quantitative agreement is obtained at the 6-31G*//STO-3G level, with the deviations being less than 10 kcal/mol. Although the minimal STO-3G basis overestimates the PA's by about 57 ± 3 kcal/mol, the minimal basis set provides a good estimate of the effect of each successive F substituent on the proton affinity: 7.2 kcal/mol versus the observed 6.1 kcal/mol. Larger basis sets lead to substituent effects which are about twice as great. Theoretical estimates of the intramolecular hydrogen bond energy have been obtained from the difference between the calculated PA of acetone and the intercept of a plot of the calculated PA's as a function of the number of F substituents. The STO-3G estimate is too high by nearly 6 kcal/mol whereas the 4-31G//STO-3G estimate is only 1.5 kcal/mol too high. In general, the *ab initio* calculations overestimate the effects of successive fluorine substituents. A good correlation between the theoretical proton affinities and ionization potentials of the fluoroacetones is consistent with the observation that the ionization of a nonbonding electron is essentially localized at a single atom which is also the site of protonation.

Intramolecular Michael-type additions. IV.[1] Synthesis of 2-azabicyclo[3.2.1]oct-3-enes from 4-chloroalkyl-1,4-dihydropyridines

BRIAN GREGORY,[2] ERIC BULLOCK, AND TENG-SONG CHEN

Department of Chemistry, Memorial University of Newfoundland, St. John's, Nfld., Canada A1B 3X7

Received June 20, 1984

BRIAN GREGORY, ERIC BULLOCK, and TENG-SONG CHEN. Can. J. Chem. **63**, 843 (1985).

2-Azabicyclo[3.2.1]oct-3-enes, including examples having a spiro centre at C(8), may be obtained by the reaction of anions derived from 1,3-diketones or cyclopentadiene with 4-chloroalkyl-1,4-dihydropyridines or with azepines. Intermediate 4,5-dihydro-1*H*-azepines have been isolated under milder conditions. The structures of the bicyclic compounds were established using infrared, ultraviolet, nuclear magnetic resonance, and mass spectrometry. Pharmacological examination of selected compounds revealed low antimicrobial and hypotensive activity.

BRIAN GREGORY, ERIC BULLOCK et TENG-SONG CHEN. Can. J. Chem. **63**, 843 (1985).

On peut obtenir des aza-2 bicyclo[3.2.1] octenes-3, y compris des exemples possédant un centre spiro en C(8), en faisant réagir des anions dérivant de dicétones-1,3 ou du cyclopentadiène avec des chloroalkyl-4 dihydro-1,4 pyridines ou avec des azépines. Utilisant des conditions expérimentales douces, on a pu isoler les dihydro-4,5 1*H*-azépines. On a déterminé les structures des composés bicycliques en faisant appel aux spectroscopies infrarouge et ultraviolette, à la rmn et à la spectrométrie de masse. Une étude pharmacologique de certains composés a permis d'établir qu'ils possèdent des activités hypotensive et antimicrobienne qui sont faibles.

[Traduit par le journal]

Saturated derivatives of 2-azabicyclo[3.2.1]octane are readily available through condensation reactions (2), from bicyclic ketones or their derived oximes using Schmidt or Beckmann reactions respectively (3−9), or by irradiation of bicycloheptane nitronate anions (10). Alkoxy derivatives have been obtained by the silver-(I) assisted solvolytic cyclization of a chloramine (11) and by photolytic decomposition of 1-azidonorbornane (12). The synthesis of 2-azabicyclo-[3.2.1]octenes and dienes has been achieved mainly through the reaction of norbornadiene with reagents such as benzenesulfonyl azide (13−17), cyanogen azide (18, 19), or nitrile oxides (20). Irradiation of 5-methylenenorbornene in the presence of nitrosamines gave 2-hydroxy-2-azabicyclo-[3.2.1]octa-3,6-dienes (21, 22), while 2-hydroxy-6-enes may be obtained by irradiation of cycloalkane nitronate anions (23). A 6-ene, in equilibrium with an isomeric cyclopentene, has been obtained by treatment of an equilibrium mixture of 2-oxabicyclo[3.2.1]octa-3,6-diene and *endo*-6-formylbicyclo-[3.1.0]hex-2-ene with methylamine (24). Spectroscopic evidence has recently been obtained using matrix isolation techniques for the photolytic preparation of the very reactive, anti-Bredt, bridgehead imine 2-azabicyclo[3.2.1]oct-1-ene (25). Only saturated derivatives appear to have been evaluated for pharmacological activity, prompted by structural relationships to pempidine (26) or the benzomorphan system (27). Reports describe assessment of hypotensive (28, 29), analgesic (30−32), narcotic antagonist (27), and ganglion-blocking activity (26).

Earlier, we have shown that 4-chloromethyl-1,4-dihydropyridines react with basic nucleophiles to give ring-expanded products (33) which may react further to give a variety of heterocyclic systems (34). Ashby and Eisner *et al.* have shown that the hydrosulfide anion reacts with the chloromethyldihydropyridine to give an 8-thia-2-azabicyclo[3.2.1]oct-3-ene, presumably through the intermediacy of a 4,5-dihydroazepine-4-thiol (35, 36). Other heteroatom bridged compounds prepared in this way include the 8-seleno-, 8-benzylamino-, and 8-oxa-2-azabicyclo[3.2.1]oct-3-enes (37, 38); use of thiourea followed by base affords 7-thia-2-azabicyclo[3.2.1]oct-3-enes (39), a reaction which does not involve nucleophile-induced ring expansion. It occurred to us that derivatives of 2-azabicyclo[3.2.1]oct-3-ene might be obtained by the action of a carbanion on a chloromethyl-1,4-dihydropyridine to give a 4-substituted-4,5-dihydro-1*H*-azepine, followed by intramolecular Michael addition as outlined in Scheme 1. The successful realization of this hypothesis is the subject of the present communication[3] and represents a departure from previous synthetic methodology, which mostly has involved ring expansion of preformed bicyclic skeleta. Further, the compounds available by this new route appeared interesting to screen for pharmacological activity.

Reaction of the 4-chloromethyl-1,4-dihydropyridine with sodium acetylacetonate in dimethylformamide at low temperatures afforded a crystalline product, $C_{17}H_{23}NO_6$, whose spectroscopic properties confirmed structure **3**. In particular, the ultraviolet absorption maxima at 231 nm (ϵ 12 100) and 329 nm (ϵ 12 300) were consistent with the presence of a 4,5-dihydroazepine-3,6-diester chromophore (33, 38), while the lack of a strong band at 250 nm[4] excluded the alternative structure **16**. In basic media, an additional strong absorption band at 297 nm (ϵ 26 300) was observed, due to the conversion of the β-diketone side chain to enolate. The failure to isolate the O-alkylation[5] product **16** may be due to the known propensity of dihydroazepines to lose 4-oxygen substituents to give the azepine **17** (37, 43), which is known to add nucleophiles (44), resulting in conversion to the more stable C-alkylation product **3**.

Reaction of **1**, **3**, or **17** with sodium acetylacetonate under

more vigorous conditions gave the 2-azabicyclo[3.2.1]oct-3-ene **7** whose structure follows from the presence of infrared bands due to NH (str), saturated ketone and ester, and unsaturated ester, and an ultraviolet spectrum showing an intense absorption at 289 nm similar to the 1,4,5,6-tetrahydronicotinic ester chromophore (45) in bridged systems (35–39).[6] The mass spectrum of **7** was dominated by a fragmentation pathway which involved loss of methyl acrylate and acetyl radical (Scheme 2) to give the substituted pyridinium ion at m/z 208. The [1]Hmr spectrum showed four methyl singlets at δ 1.79, 2.03, 2.14, and 2.27; the assignment of the signals at δ 1.79 and 2.27 to methyls at C(1) and C(3) respectively is based on a comparison with the [1]Hmr spectra of compounds **9–15** (see below) which lack signals due to acetyl methyl groups. The remaining signals in the spectrum were in good agreement with the assigned structure, although the signal due to the hydrogen at C(7) was obscured and an unequivocal assignment of the configuration of the methoxycarbonyl group was not possible. Since, based on [1]Hmr, the 7-methoxycarbonyl group of the 8,8-spirocyclopentadiene compounds **14** and **15** (see below) has an *endo*-configuration and we have shown earlier that, in an 8-thia analogue, the *exo*-7-methoxycarbonyl may be converted to *endo*-7-methoxycarbonyl by base-catalyzed equilibration (38), we believe the methoxycarbonyl group in **7** (and also in **8–13** below), which has a bridging group that is bulkier than sulfur, has an *endo*-configuration as shown. It is unlikely that under these conditions (6 h under basic conditions at 100°C in DMF) equilibration to the more stable epimer at C(7) had not taken place.

At room temperature, the action of sodium acetylacetonate on the chloroethyldihydropyridine **2** afforded a mixture of the dihydroazepine **4** (60%), whose methyl at C(5) is assigned a *trans*-configuration to the 4-diacetylmethyl group by analogy with earlier work (38), and the 2-azabicyclooctene **8** (13%). AT 100°C the bicyclic compound **8** was the major product, in 74% yield. These results indicate that the 4,5-dihydroazepine **4** is an intermediate in the formation of the 2-azabicyclooctene **8**, and this is supported by the observation that **8** is formed in 70% yield when sodium acetylacetonate or sodium methoxide is reacted with **4**. Further, it has been shown that the same azabicyclooctene **8** is formed in 80% yield when sodium acetylacetonate is reacted with the azepine **18** in DMF at 90°C. This reaction presumably involves Michael addition to C(4) in **18**, followed by intramolecular Michael addition. Thus, formation of **8** may involve the sequence **2** → **18** → **4** → **8**.[7] The *endo*-configuration of the methyl at C(6) in **8** is a necessary consequence of the *trans* stereochemistry at C(4,5) in the

[6]An alternative 9-oxa-2-azabicyclo[4.3.1]deca-3,7-diene structure **19**, formed by addition of the side chain enolate oxygen of **3** to C(2), would be expected to show an additional strong absorption band in the range 240–270 nm due to the additional 3-acetyl-5,6-dihydropyran chromophore (46, 47).

[7]Similar results also suggest the sequence **1** → **17** → **3** → **7**.

dihydroazepine **4** and is supported by ^{1}Hmr spectra of the spirocyclopentadiene compounds **14** and **15** (see below), while reasons for assigning *endo*-configuration for the 7-methoxycarbonyl group are given above. As with compound **7**, the mass spectrum was again dominated by the pyridinium ion at m/z 208, in this case arising by loss of methyl crotonate and acetyl radical. Although the mass spectra of **7** and **8** showed low abundance peaks at m/z 294 and 308 due to loss of acetyl radical, there is no evidence that loss of acetyl precedes loss of unsaturated ester in the formation of the pyridinium ion fragment. Indeed, since the mass spectra of the 8-thia analogues show loss of acrylate (35) or crotonate (38), we believe that loss of the unsaturated ester occurs prior to acetyl radical loss as shown in Scheme 2. The mass spectra of these compounds are being investigated further.

The use of sodium derivatives of cyclic 1,3-diketones, e.g. 1,3-cyclohexanedione or dimedone, afforded the novel spiro compounds **10**–**13** in yields of 60–90% at 65–90°C. In each case, the hydrogens at C(6,7) are obscured in the ^{1}Hmr spectrum and the configurations of the methyl and methoxycarbonyl groups are assigned by analogy (see above). Other spectroscopic features were consistent with the assigned structures.

The reaction has also been extended to the anion of cyclopentadiene in an attempt to provide compounds in which ^{1}Hmr signals due to protons at C(5) to C(7) may be seen clearly. Thus **1** or **2** afforded the spirocyclopentadienes **14** and **15** respectively. Although the expected ultraviolet absorption of the 5,5-dialkylcyclopentadiene chromophore at about 250 nm (48, 49) was hidden by the aminocrotonate absorption at 295 nm in **14**, it was apparent in **15**. In the infrared spectra, **14** and **15** showed saturated and unsaturated ester carbonyl and NH stretching absorptions. The ^{1}Hmr spectrum of **14** showed singlets at δ 1.21, 2.18, 3.62, and 3.71, due to methyls at C(1), C(3), and two methyl esters, respectively, a broad singlet at δ 4.28 (NH), and a four-proton multiplet at δ 6.31 due to the protons of the cyclopentadiene moiety.[8] In addition, the spectrum showed four multiplets consisting of a double doublet at δ 3.19 (J 4.9 and 11.8 Hz; this signal resembled the X part of an ABX system, and thus gave two coupling constants by direct measurement), a broadened doublet at δ 2.97 (J 5.8 and 1.0 Hz), and partly overlapping multiplets at δ 2.62 (J 4.9, 13.9, and 1.0 Hz) and δ 2.38 (J 11.8, 13.9, and 5.8 Hz). Examination of Dreiding models suggests that the dihedral angles subtended by C(5)—H with *exo* and *endo* C(6)—H are close to 30° and 90° respectively. Thus, the H at C(5) should be strongly coupled only to one proton, namely, *exo* H at C(6), and would be expected to be a doublet, J approx 6–7 Hz. Accordingly, the broadened doublet at δ 2.97 is assigned to the hydrogen at C(5); the broadening ($J \sim 1$ Hz) is due to coupling to the *endo*-hydrogen at C(6). The low field part (δ 2.62) of the higher field overlapping multiplets resembles the low field half of an AB system which is split by an additional proton, and consisted of 2 doublets with relative line intensities of approximately 1 : 1 : 3 : 3. The signals at δ 2.62 and 2.38 were therefore assigned to the two protons attached to C(6), and since only the latter signal shows a strong coupling (J 5.8 Hz) to C(5)—H, it must be due to the *exo*-hydrogen at C(6), while the δ 2.62 signal is due to the *endo*-hydrogen at C(6). The remaining signal, at δ 3.19, is consequently assigned to the hydrogen at C(7) and is *exo* (and the methoxycarbonyl is then *endo*) because it has a large coupling (J 11.8 Hz) to the *exo*-hydrogen at C(6) as required by the near zero dihedral angle. The assignments were confirmed by comparison with the ^{1}Hmr spectrum of **15** which, in particular, showed doublets at δ 1.07 (3H, J 6.5 Hz), 2.73 (1H, J 8.2 Hz), 2.97 (1H, J 5.2 Hz), and a multiplet at δ 3.08 (1H, J 5.2, 6.5, and 8.2 Hz) for the system —CH—CH(CH$_3$)—CH—. The doublet at δ 2.97 was assigned to the proton at C(5) and the size of the coupling indicated that it was coupled to *exo*-hydrogen at C(6), causing the methyl at C(6) to be assigned an *endo*-configuration. The doublet at δ 2.73 must then be due to *exo*-hydrogen at C(7) and this is confirmed by partial exchange using sodium methoxide in CH$_3$OD, when the NH signal disappeared and there was considerable diminution of intensity of the doublet at δ 2.73, while other signal intensities remained unchanged.

An interesting feature of the ^{1}Hmr spectrum of the bicyclooctenes is that in the compounds **7**, **8**, **10**–**13** derived from 1,3-diketones the signal due to the methyl at C(1) appears at

[8]The presence of 4 olefinic protons confirms that **14** and **15** are spiro-5,5-cyclopentadienes. Alkylation of cyclopentadienes with bis-alkylating agents such as dibromoethane is well known to produce 5,5-spirocyclopentadienes (48).

δ 1.61−1.79, while in spirodienes **14** and **15** it is found at δ 1.21 and 0.98 respectively. Since in the spirocyclopentane **9**, obtained by hydrogenation of **14**, the C(1) methyl signal is observed at δ 1.29, the above chemical shift variation must be due to deshielding by the carbonyl groups rather than shielding by the diene system.

Appropriate ring-opening of the tetrahydropyridine ring of spiro compounds **10**−**15** should furnish derivatives of the spiro[4,5]decane and spiro[4,5]nonane system and this is presently under investigation.

When the anion derived from diethyl malonate was reacted in tetrahydrofuran at 40°C with either chloromethyl compound **1** or chloroethyl compound **2**, substitution and ring expansion again took place to give the 4,5-dihydroazepines **5** and **6** respectively. In each case, the ^{1}Hmr signals due to ethyl esters (as with acetyl methyl groups in **3** and **4**) were non-equivalent and coupling constants between protons attached to C(4) and C(4′) were unusually high for substituted malonates (11 and 12 Hz in compounds **5** and **6** respectively), showing the lack of free rotation about C(4)—C(4′). Attempts to prepare the corresponding azabicyclo[3.2.1]octenes using more vigorous conditions, e.g. **1** or **2** with diethyl sodiomalonate in dimethylformamide at 120°C, were unsuccessful, yielding only **5** or **6**. The reasons for the failure to form the bicyclic compounds are not clear, but may involve prevention of the intramolecular Michael addition by the steric requirements of the two ethoxycarbonyl groups.

Three compounds were selected for evaluation in a broad pharmacological screen (see Acknowledgements). Compound **7** showed weak activity (MIC 100 μg/mL) against *Serratia marcescens* and *Klebsiella pneumoniae*. Compound **5** was active at a similar level against *S. marescens*, *K. pneumoniae*, and *Streptococcus fecalis*. It also exhibited activity at 100 mg/kg po (and slight activity at 25 mg/kg) in an antihypertensive assay using spontaneously hypertense rats. Low activity (MIC 50 μg/mL) against *Trichomonas vaginalis* was observed for compound **12**.

Experimental

Details concerning spectral measurements, analyses, etc., are provided in an earlier publication (34).

General method for preparation of 4,5-dihydroazepines or 2-azabicyclo[3.2.1]oct-3-enes

The 4-chloroalkyl compound **1** or **2** (0.01 mol) and the sodium enolate (or cyclopentadienylsodium) (0.022 mol) in dry dimethylformamide (10−30 mL per g of **1** or **2**) were stirred at the appropriate temperature for the specified time. The reaction mixture was then cooled, poured into 3.3 volumes of 10% aqueous ammonium chloride, and extracted three times with ether or chloroform. Evaporation of the organic solvent gave a crude product which was purified by column chromatography or recrystallization (see Table 1).

Dimethyl 4-(diacetylmethyl)-4,5-dihydro-2,7-dimethylazepine-3,6-dicarboxylate, **3**

Infrared ν_{max}: 3414 (NH), 1703 (ketone carbonyl), 1700 (unsaturated ester), and 1632 (C═C) cm^{-1}; uv (95% ethanol) λ_{max}: 231 nm (ε 12 100), 329 nm (ε 12 300); (0.01 *M* sodium hydroxide in 95% ethanol) λ_{max}: 234 nm (ε 11 900), 297 nm (ε 26 300), 326 nm (ε 12 100); ^{1}Hmr δ: 2.08 and 2.10 (s, s, acetyl methyls), 2.20 approx. (m, obscured by four methyl singlets), 2.25 and 2.33 (s, s, methyls at C(2), C(7)), 3.15 (dd, *J* 5.6 and 14.0 Hz, H at C(5)), 3.65 and 3.68 (s, s, methyl esters), 3.71 (d, *J* 11.0 Hz, —C*H*(COCH$_3$)$_2$), 4.29 (m, H at C(4) or C(5)), 5.68 (s, NH); ms *m/z*: 337(1.4, M$^+$), 237(50), 206(42), 205(40), 179(24), 178(91), 146(100), 118(39), 100(54), 85(60), 43(44), and 42(52).

*A−E represent 2,4-pentanedione, diethyl malonate, 1,3-cyclohexanedione, 5,5-dimethyl-1,3-cyclohexanedione, and cyclopentadiene, respectively.
†Solvents: DMF = dimethylformamide, E = diethyl ether, P = petroleum ether (boiling range 40−60°C), C = chloroform, THF = tetrahydrofuran.
‡Purification required column chromatography on silica gel H using benzene/ethyl acetate for elution.

Dimethyl 8,8-diacetyl-1,3-dimethyl-2-azabicyclo[3.2.1]oct-3-ene-4,7-dicarboxylate, 7

Infrared ν_{max} 3418 (NH), 1736 (saturated ester), 1721 (saturated ketone), and 1694 (unsaturated ester) cm^{-1}; uv λ_{max}: 289 nm (ϵ 13 600); ^{1}Hmr δ: 1.79 (s, methyl at C(1)), 2.03 and 2.14 (s, s, acetyl methyls), 2.27 (s, methyl at C(3)), 3.68 (s, ester methyl), 4.17 (s, NH), and, in addition, signals due to four protons between δ 1.4−3.9 which were partially obscured by signals due to methyl esters and C-methyl groups; ms m/z: 337(23, M^+), 306(10), 294(12), 208(100), and 43(21).

Alternate method

A solution of the 4,5-dihydroazepine **3** (6 mg) and sodium acetylacetonate (3 mg) in dry dimethylformamide (0.3 mL) was stirred at 60−65°C for 2 h and then worked up as above. The bicyclic product (4 mg, 66%) was obtained as white prisms, mp 192.5−193.5°C, and was shown to be identical with the product of the general method by mixed mp, uv, ir, and mass spectra.

Dimethyl 4-(diacetylmethyl)-4,5-dihydro-2,5,7-trimethylazepine-3,6-dicarboxylate, 4

Infrared ν_{max}: 3414 (NH), 1699 (saturated ketone and unsaturated ester), and 1631 (C=C) cm^{-1}; uv λ_{max}: 231 nm (ϵ 11 100), 328 nm (ϵ 12 700); ^{1}Hmr δ: 0.89 (d, J 6.8 Hz, methyl at C(5)), 2.08 and 2.10 (s, s, acetyl methyls), 2.29 and 2.30 (s, s, methyls at C(2) and C(7)), 3.25 (m, H at C(5)), 3.66 (d, J 11.0 Hz, CH($COCH_3)_2$), 3.67 and 3.70 (s, s, methyl esters), 4.07 (dd, J 5.5 and 11.0 Hz, H at C(4)), 5.76 (s, NH); ms m/z: 351 (9, M^+), 320(18), 319(9), 276(30), 252(54), 251(100), 220(81), 219(17), 211(19), 192(70), 179(80), 167(25), 160(35), 153(46), and 43(29).

Dimethyl 8,8-diacetyl-1,3,6-trimethyl-2-azabicyclo[3.2.1]oct-3-ene-4,7-dicarboxylate, 8

Infrared ν_{max}: 3436 (NH), 1733 (saturated ester), 1695 (unsaturated ester, saturated ketone), and 1668 (C=C) cm^{-1}; uv λ_{max}: 292 nm (ϵ 13 100); ^{1}Hmr (DMSO-d_6) δ: 0.84 (d, J 6.0 Hz, methyl at C(6)), 1.61 (s, methyl at C(1)), 2.03 and 2.08 (s, s, acetyl methyls), 2.27 (s, methyl at C(3)), 3.58 and 3.61 (s, s, methyl esters), 6.93 (s, NH); one ring proton at δ 3.6−3.8 was partially obscured by the methyl ester signals and the signals due to two other protons overlapped at δ 3.0−3.6; ms m/z: 351 (17, M^+), 320(8), 308(14), 276(6), 209(16), 208(100), 176(6), 148(6), and 43 (24).

Alternate method (a)

The 4,5-dihydroazepine **4** (10 mg) and sodium acetylacetonate (5 mg) in dry dimethylformamide (0.3 mL) were stirred at 60−65°C for 2 h. After being worked up as above, the bicyclic compound **8** (7 mg, 70%) was obtained as white prisms, mp 181−182°C.

Alternate method (b)

The 4H-azepine **18** (38) (160 mg) and sodium acetylacetonate (100 mg) in dry dimethylformamide (10 mL) were stirred at 90°C for 6 h and then worked up as above. The bicyclic compound **8** was obtained from ether − petroleum ether as white needles (180 mg, 80%), mp 180−181°C.

Dimethyl 1,3-dimethyl-2-azabicyclo[3.2.1]oct-3-ene-4,7-dicarboxylate-8-spiro-(2′,6′-dioxocyclohexane), 10

Infrared ν_{max}: 3416 (NH), 1725 (saturated ester), 1692 (unsaturated ester, saturated ketone), and 1659 (C=C) cm^{-1}; uv λ_{max}: 289 nm (ϵ 14 900); ^{1}Hmr δ: 1.75 (s, methyl at C(1)), 2.04 (s, methyl at C(3)), 3.68 and 3.69 (s, s, methyl esters), 4.20 (s, NH), and, in addition, one-proton signals at δ 3.5 and 3.8 were partially obscured by the ester methyl signal, while the other two ring protons and the six protons of the cyclohexanedione moiety appeared as overlapping multiplets at δ 1.2−3.3; ms m/z: 349(45, M^+), 318(24), 265(36), 231(20), 220(20), 207(55), 192(27), 179(100), and 165(22).

Dimethyl 1,3,6-trimethyl-2-azabicyclo[3.2.1]oct-3-ene-4,7-dicarboxylate-8-spiro(2′,6′-dioxocyclohexane), 11

Infrared ν_{max}: 3436 (NH), 1728 (saturated ester), 1695 (unsaturated ester, saturated ketone), and 1667 (C=C) cm^{-1}; uv λ_{max}: 292 nm (ϵ 15 250); ^{1}Hmr δ: 0.96 (d, J 7.0 Hz, methyl at C(6)), 1.65 (s, methyl at C(1)), 2.14 (s, methyl at C(3)), 3.69 and 3.71 (s, s, methyl esters), 3.85 (d, J 5.8 Hz, probably H at C(5)), 4.73 (s, NH), and a complex signal at δ 1.2−3.7 consisting of signals due to the remaining two ring protons and the six protons of the cyclohexanedione moiety; ms m/z: 363 (44, M^+), 332(21), 279(28), 220(23), 207(50), 192(32), 179(100), and 165(18).

Dimethyl 1,3-dimethyl-2-azabicyclo[3.2.1]oct-3-ene-4,7-dicarboxylate-8-spiro(4′,4′-dimethyl-2′,6′-dioxocyclohexane), 12

Infrared ν_{max}: 3416 (NH), 1727 (saturated ester), 1697 (unsaturated ester, saturated ketone), and 1662 (C=C) cm^{-1}; uv λ_{max}: 289 nm (ϵ 14 550); ^{1}Hmr δ: 0.84 and 1.19 (s, s, methyls of dimedone moiety), 1.73 (s, methyl at C(1)), 2.02 (s, methyl at C(3)), 3.68 (s, two ester methyls), 4.16 (s, NH), and complex signals between δ 1.6−3.9 due to eight additional protons; ms m/z: 377 (74, M^+), 346(28), 291(16), 259(34), 248(17), 220(26), 207(50), 179(100), 165(20), and 83(22).

Dimethyl 1,3,6-trimethyl-2-azabicyclo[3.2.1]oct-3-ene-4,7-dicarboxylate-8-spiro-(4′,4′-dimethyl-2′,6′-dioxocyclohexane), 13

Infrared ν_{max}: 3436 (NH), 1728 (saturated ester), 1696 (unsaturated ester, saturated ketone), and 1668 (C=C) cm^{-1}; uv λ_{max}: 292 nm (ϵ 15 050); ^{1}Hmr δ: 0.84 and 1.20 (s, s, methyls of dimedone moiety), 0.94 (d, J 7.0 Hz, methyl at C(6)), 1.63 (s, methyl at C(1)), 2.12 (s, methyl at C(3)), 3.64 and 3.67 (s, s, methyl esters), 3.80 (d, J 5.8 Hz, probably H at C(5)), 4.51 (s, NH), and a complex signal δ 1.8−3.7 consisting of the remaining two ring protons and four ring protons of the dimedone moiety; ms m/z: 391(77, M^+), 360(26), 279(14), 259(20), 248(17), 220(32), 207(50), 180(21), 179(100), 165(19), and 83(24).

Dimethyl 1,3-dimethyl-2-azabicyclo[3.2.1]oct-3-ene-4,7-dicarboxylate-8-spirocyclopentadiene, 14

Infrared ν_{max}: 3427 (NH), 1739 (saturated ester), and 1681 (unsaturated ester) cm^{-1}; uv λ_{max}: 295 nm (ϵ 16 200); ^{1}Hmr (HA 100) δ: 1.21 (s, methyl at C(1)), 2.18 (s, methyl at C(3)), 2.38 (m, J 5.8, 11.8, and 13.9 Hz, *exo*-H at C(6)), 2.62 (bdd, J 4.9, 13.9, and 1.0 Hz, *endo*-H at C(6)), 2.97 (bd, J 5.8 and approx 1.0 Hz, H at C(5)), 3.19 (dd, J 4.9 and 11.8 Hz, H at C(7)), 3.62 and 3.71 (s, s, methyl esters), 4.28 (s, NH), and 6.31 (m, cyclopentadiene ring protons); ms m/z: 303 (67, M^+), 288(13), 272(30), 244(100), 216(59), 212(27), 202(82), 184(34), 169(13), 158(63), 157(14), 156(16), 129(18), 128(19), 115(29), and 42(26).

Dimethyl 1,3-dimethyl-2-azabicyclo[3.2.1]oct-3-ene-4,7-dicarboxylate-8-spirocyclopentane, 9

The spirocyclopentadiene (250 mg) and platinum oxide (50 mg) in methanol (20 mL) were stirred under hydrogen at 1 atmosphere and room temperature. The hydrogen absorption required 0.5 h and stirring was continued for a further 0.5 h. The catalyst was removed by filtration and the solvent removed on the rotary evaporator. The spirocyclopentane was obtained after two recrystallizations from aqueous methanol as white prisms (242 mg, 96%), mp 212−213.5°C; ir ν_{max}: 3427 (NH), 1730 (saturated ester), and 1664 (unsaturated ester) cm^{-1}; uv λ_{max}: 296 nm (ϵ 16 950); ^{1}Hmr (HA 100) δ: 1.29 (s, methyl at C(1)), 1.62 (bs, eight cyclopentane ring protons), 2.10 (s, methyl at C(3)), 2.14 (m, J 5.5, 11.0, and 12.5 Hz, *exo*-hydrogen at C(6)), 2.35 (bdd, J 5.0, 12.5, and −0.5 Hz, *endo* hydrogen at C(6)), 2.70 (bd, J 5.5 and −0.5 Hz, H at C(5)), 2.94 (dd, J 11.0 and 5.0 Hz, H at C(7)), 3.64 and 3.68 (s, s, methyl esters), 4.04 (s, NH); ms m/z: 307 (48, M^+), 276(27), 248(14), 207(20), 206(100), 193(13), 192(37), and 179(32). *Anal.* calcd. for $C_{17}H_{25}NO_4$: *Mol. Wt.* 307, C 66.43, H 8.20, N 4.59; found: *Mol. Wt.* 307 (ms), C 66.27, H 8.22, N 4.69.

Dimethyl 1,3,6-trimethyl-2-azabicyclo[3.2.1]oct-3-ene-4,7-dicarboxylate-8-spirocyclopentadiene, 15

Infrared ν_{max}: 3422 (NH), 1728 (saturated ester), 1679 (unsaturated ester), and 1666 (C=C) cm^{-1}; uv λ_{max}: 241 nm (ϵ 3 100), 297 nm (ϵ 15 400); ^{1}Hmr (HA 100) δ: 0.98 (s, methyl at C(1)), 1.07 (d, J 6.5 Hz, methyl at C(6)), 2.26 (s, methyl at C(3)), 2.73 (d, J 8.2 Hz, H at C(7)), 2.97 (d, J 5.2 Hz, H at C(5)), 3.08 (m, J 5.2, 6.5, and 8.2 Hz, H at C(6)), 3.62 and 3.68 (s, s, methyl esters), 4.62 (s, NH), 6.10, 6.27, and 6.78 (each m, 1H, 2H, and 1H respectively, cyclopentadiene ring hydrogens); the 6-methyl doublet appeared as a singlet on irradiation at 308 Hz; ms m/z: 317 (46, M^+) 302(20), 286(16), 270(18), 258(56), 242(21), 226(22), 218(14), 217(80), 216(75), 203(19), 202(100), 198(18), 192(13), 184(17), 170(18), 158(25), 143(20), 142(15), 44(50), and 42(22).

Dimethyl 4-(diethoxycarbonylmethyl)-4,5-dihydro-2,7-dimethylazepine-3,6-dicarboxylate, ***5***

Infrared ν_{max}: 3417 (NH), 1750 (saturated ester), 1728 (saturated ester), 1705 (unsaturated ester), and 1633 (C=C) cm^{-1}; uv λ_{max}: 230 nm (ϵ 11 850) and 329 nm (ϵ 13 200); ^{1}Hmr δ: 1.19 and 1.24 (overlapping t, J 7.2 Hz, methyls of ethyl esters), 2.27 and 2.34 (s, s, methyls at C(2), C(7)), 3.30 (d, J 11.0 Hz, CH of malonate), 3.31 (dd partially obscured by signal at δ 3.30, J 16.0 and 6.0 Hz, H at C(5)), 3.65 and 3.69 (s, s, methyl esters), 4.06 and 4.15 (overlapping q, J 7.2 Hz, CH_2 of ethyl esters), 5.73 (s, NH); in addition, complex signals due to one proton at δ 2.0–2.4 and one proton at δ 4.15 were obscured by ring methyl and CH_2 of ethyl ester respectively; ms m/z: 397(4, M^+), 238(40), 237(82), 206(51), 205(42), 179(54), 178(97), 146(93), 133(72), 118(34), 115(100), and 43(80).

Dimethyl 4-(diethoxycarbonylmethyl)-4,5-dihydro-2,5,7-trimethylazepine-3,6-dicarboxylate, ***6***

Infrared ν_{max}: 3420 (NH), 1749 (saturated ester), 1727 (saturated ester), 1701 (unsaturated ester), and 1631 (C=C) cm^{-1}; uv λ_{max}: 230 nm (ϵ 11 800), 326 nm (ϵ 14 900); ^{1}Hmr δ: 0.93 (d, J 6.8 Hz, methyl at C(5)), 1.18 and 1.22 (overlapping t, J 7.3 and 7.2 Hz, methyls of ethyl esters), 2.32 (s, methyls at C(2) and C(7)), 3.21 (d, J 12.0 Hz, CH of malonate), 3.42 (m partially obscured by ester methyls and signal at δ 3.21, J 6.8, H at C(5)), 3.66 and 3.70 (s, s, methyl esters), 3.97 (dd, overlapping signals at δ 4.06, 4.14, J 6.0 and 12.0 Hz, H at C(4)), 4.06 and 4.14 (overlapping q, J 7.3 and 7.2 Hz, CH_2 of ethyl esters), 5.72 (s, NH); ms m/z: 411(3, M^+), 252(45), 251(87), 220(44), 192(39), 179(100), and 153(29).

Acknowledgements

The authors wish to thank Memorial University of Newfoundland and the Natural Sciences and Engineering Research Council of Canada for financial support and Memorial University for the award of a Fellowship to one of us (T.S.C.) In addition, the authors gratefully acknowledge the help of the late Dr. M. A. Davis and Ayerst Research Laboratories, Montreal, for arranging the pharmacological evaluation of compounds **5**, **7**, and **12**.

The ¹H and ¹³C spectra of mikanokryptin are unambiguously assigned using a variety of one-dimensional nmr experiments (selective homonuclear decoupling, use of inversion–recovery pulse sequences to reveal hidden peaks, and DEPT spectral editing) in conjunction with normal and "long range" two-dimensional heteronuclear correlated experiments. Detailed comparison of vicinal, allylic, and homoallylic ¹H—¹H coupling constants with dihedral angles determined from an earlier crystal structure determination indicates that solution and solid state configurations are similar.

Faisant appel à une variété d'expériences de rmn unidimensionnelle (découplage homonucléaire sélectif, séquences de pulsation avec inversion et récupération dans le but de révéler la présence de pics cachés et édition spectrale DEPT) ainsi qu'à des expériences hétéronucléaires en deux dimensions (normales ou à longue distance), on a pu faire une attribution non équivoque des signaux des spectres rmn du ¹H et du ¹³C de la mikanokryptine. Sur la base d'une comparaison détaillée des constantes de couplage ¹H—¹H viciniales, allyliques et homoallyliques avec les angles dièdres attribués antérieurement à l'aide de la structure cristalline, on a pu établir que les conformations à l'état solide et en solution sont semblables.

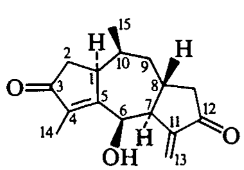
Introduction

Mikania mikrantha H.B.K. and a number of different plants of the genus *Aristolochia* share the popular name "guaco" in Mexican traditional medicine and are all purported to be effective for treatment of dermatological affections (1). As part of a continuing phytochemical investigation of plants which are used for this purpose in traditional medicine (2), we have undertaken an investigation of *Mikania mikrantha* H.B.K. The first compound isolated was mikanokryptin, **1**, a lactone derivative first reported by Herz *et al.* (3). The structure and stereochemistry of **1** has been established by X-ray diffraction techniques (4) and its ¹H spectrum has been partially assigned (3)



1

(more extensive assignments were reported for derivatives of **1** (3)).

In this manuscript, we report the complete and unambiguous assignment of ¹H and ¹³C spectra for **1**, using a variety of one- and two-dimensional nmr techniques. The solution and solid state conformations of **1** are also compared.

Results and discussion

(a) *¹H chemical shift assignments*

In the original report, five of the proton signals for **1** were obscured and two others overlapped (90 MHz $(CD_3)_2SO$ (3)). However, we found that in $CDCl_3$ (with ca. 5% $(CD_3)_2SO$ to promote solubility) at 200 MHz, $H(9)_\alpha$[1] was partially obscured by $C(14)H_3$, but all other peaks were clearly resolved (see Fig. 1(a) illustrating region 1.75–3.25). The multiplet structure for $H(9)_\alpha$ was resolved using a procedure first suggested by Hall and Preston (5). By utilizing a standard inversion–recovery pulse sequence and by choosing a delay time (0.88 s) for which the methyl signal is nulled, one can clearly observe the multiplet structure for $H(9)_\alpha$. (See Fig. 1(b); since the spin-lattice relaxation time, T_1, is significantly shorter for $H(9)_\alpha$ than for $C(14)H_3$, the former signal has almost completely recovered when the latter signal is nulled.) This approach has been surprisingly little used. However, it has some advantages even when compared to more sophisticated techniques such as homonuclear "*J* resolved" two-dimensional nmr spectra (6). Not only can the experiment be performed on routine spectrometers lacking the pulse programmer and large data storage capabilities necessary for 2D experiments but it will also succeed even when two signals have identical chemical shifts (provided they have different T_1 values). By contrast, homonuclear "*J* resolved" spectra cannot resolve peaks with identical shifts. Finally, the inversion–recovery spectra used to find the null provide useful qualitative relaxation information which

[1]Methylene protons are assigned as α or β on the basis of the known stereochemistry of **1** (4) plus the magnitudes of observed couplings to adjacent methine hydrogens. The two exocyclic methylene protons are labelled $H(13)_c$ and $H(13)_t$ depending on whether they are *cis* or *trans* to the lactone functionality.

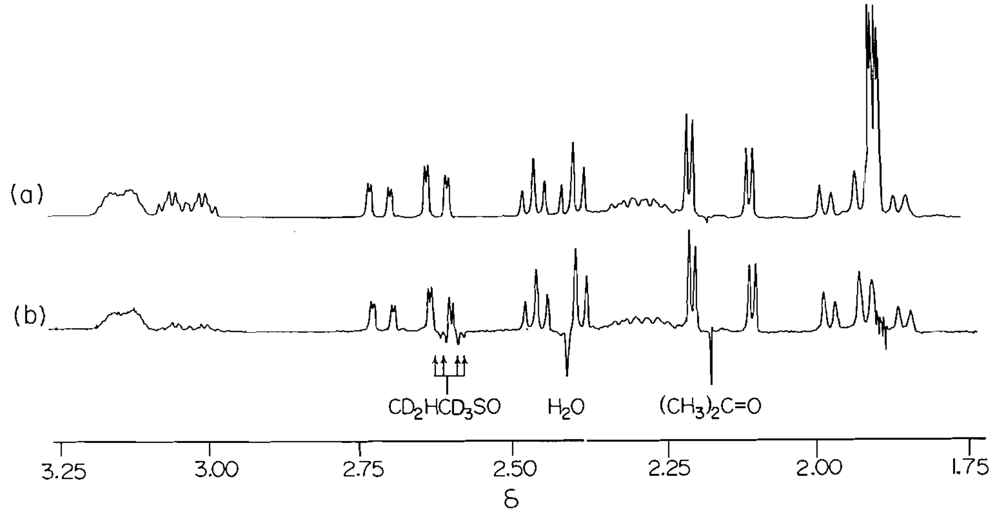


FIG. 1. Inversion–recovery ^{1}H spectra of **1** using the following delays betwen 180° (inverting) and 90° (sampling) pulses: (a) 2.25 s; (b) 0.88 s. The signal for $C(14)H_3$ is almost nulled with the shorter delay but nearly recovered with the longer delay. Also note that three small molecule impurity peaks (residual HCD_2CD_3SO, H_2O, and $(CH_3)_2C{=}O$ (solvent of crystallization)) which are inverted with the shorter delay are almost nulled with the longer delay, allowing clearer observation of $H(2)_\alpha$ and $H(9)_\beta$.

can aid in assigning peaks. For example, the low-field methylene proton (δ 6.40) was assigned as $H(13)_c$ on the basis of its longer relaxation time than $H(13)_t$ (δ 5.72). The latter proton is intramolecularly relaxed by dipole–dipole interactions with H(7), while there is no comparable proximate proton to relax $H(13)_c$.[2]

Remaining ^{1}H signals were assigned with the aid of a series of selective homonuclear decoupling experiments which established ^{1}H—^{1}H connectivities and also aided in determining the magnitudes of individual coupling constants. Final assignments of ^{1}H chemical shifts and coupling constants are given in Table 1. Allowing for differences due to solvent effects, the chemical shifts are consistent with the earlier partial assignment for **1** (3).

[d]$H(13)_c$ is *cis* to the lactone function while $H(13)_t$ is *trans* to the lactone function.

(b) *^{13}C chemical shift assignments for 1*

Initial ^{13}C assignments were based on normal ^{1}H-decoupled ^{13}C spectra plus CH, CH_2, and CH_3 subspectra obtained using DEPT spectral editing (7) (see Fig. 2). This allowed assignment of individual carbons in terms of numbers of attached carbons. In order to complete the assignment of individual peaks with a minimum of ambiguity, a pair of heteronuclear (^{13}C–^{1}H) correlated two-dimensional experiments were performed. The first was a standard heteronuclear correlated experiment using delay times optimized for direct ^{13}C–^{1}H coupling (8). This provided the ^{13}C spectra of protonated carbons along one frequency axis with the ^{1}H spectra of the corresponding directly bonded hydrogens along the second axis at right angles (see Fig. 3). This allowed unambiguous assignment of all protonated carbons on the basis of the previously assigned ^{1}H spectral peaks (see Table 2).

This left five non-protonated carbons to be assigned. Since these covered a wide chemical shift range (δ 136–208), partial assignment could be made on the basis of chemical shifts of related model compounds and (or) additive chemical shift parameters (9). In particular, the signal at δ 208.0 could be unambiguously assigned to the α,β-unsaturated carbonyl, C(3), while the signals at δ 143.5 and δ136.3 could be tentatively assigned as C(4) and C(11) respectively. However, while the peaks at δ 170.9 and δ 169.9 obviously were due to C(5) and C(12), it was unclear which signal was which. In order to resolve these ambiguities, a "long range" heteronuclear correlated experiment (10) was carried out. This used the same pulse sequence as the previous experiment but with delay times optimized for geminal ($^2J_{CH}$) and vicinal ($^3J_{CH}$) couplings, allowing assignment of non-protonated carbons from couplings to known ^{1}H signals on adjacent carbons. For example, the peak at δ 170.9 is coupled to $H(14)_3$ while the δ 169.9 peak shows coupling to $H(13)_c$ and $H(13)_t$ (all $^3J_{CH}$), allowing unambiguous assignment of the former as C(5) and the latter as C(12) (see Fig. 4). Similarly, the peak at δ 143.5 is coupled to $H(14)_3$ while the peak at δ 136.3 is coupled to $H(13)_c$ and H(7) (all $^2J_{CH}$), confirming the tentative assignment of the former as C(4) and the latter as C(11). Finally, the δ 208.0 peak shows coupling to $H(14)_3$, $H(2)_\alpha$, and $H(2)_\beta$, consistent with its as-

[2]This was confirmed by an nOe measurement.

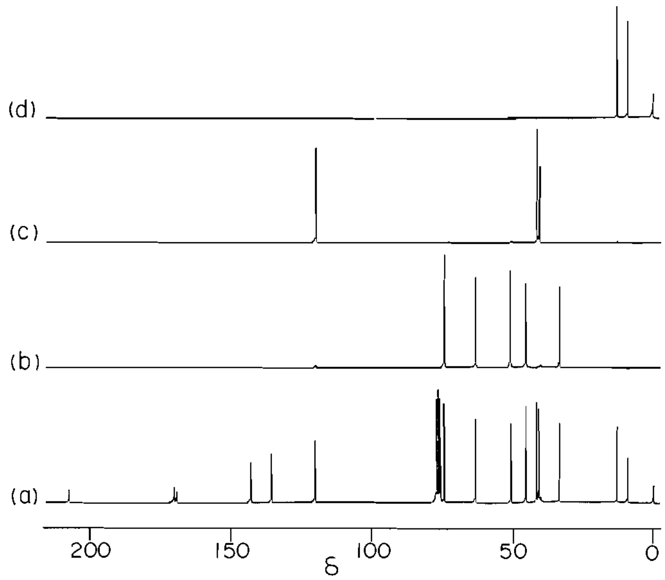

FIG. 2. (a) Normal ^{13}C spectrum of **1**; (b) edited (DEPT) spectrum for CH carbons only; (c) CH_2 only; (d) CH_3 only.

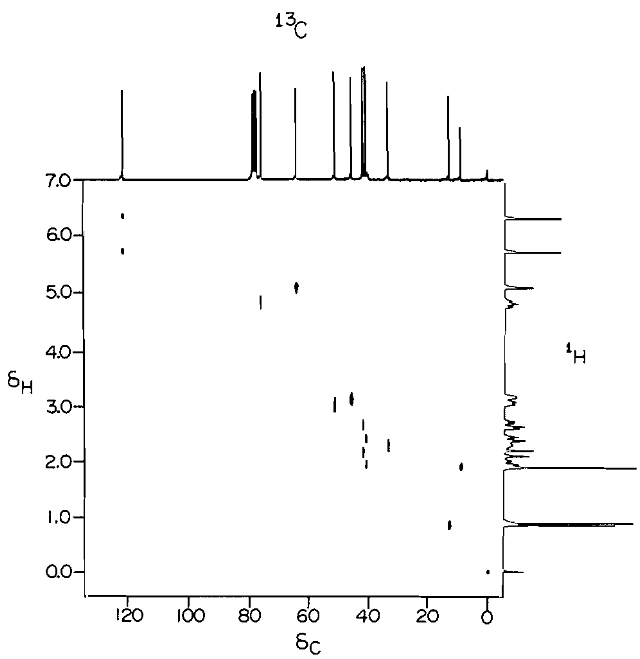

FIG. 3. Normal heteronuclear correlated spectrum of **1**, illustrating the protonated ^{13}C spectrum along the horizontal and the ^1H spectrum along the vertical.

signment of C(3). Note that the "long range" heteronuclear correlated experiment effectively divided the five non-protonated carbons into two subsets, the first (C(3), C(4), C(5)) coupled to $H(14)_3$ but not $H(13)_c$, and the second (C(11), C(12)) coupled to $H(13)_c$ but not $H(14)_3$ (see Fig. 4). Within each subset, chemical shift differences are sufficiently large ($\Delta\delta > 25$) to allow completely unambiguous assignment of individual peaks (see Table 2). This supports earlier evidence that "long range" heteronuclear correlated experiments provide an approach of considerable generality for assigning non-protonated ^{13}C peaks (10). This is important since the most obvious alternative, $^{13}C—^{13}C$ connectivity ("INADEQUATE") experiments (11), often cannot be carried out due to sensitivity limitations.

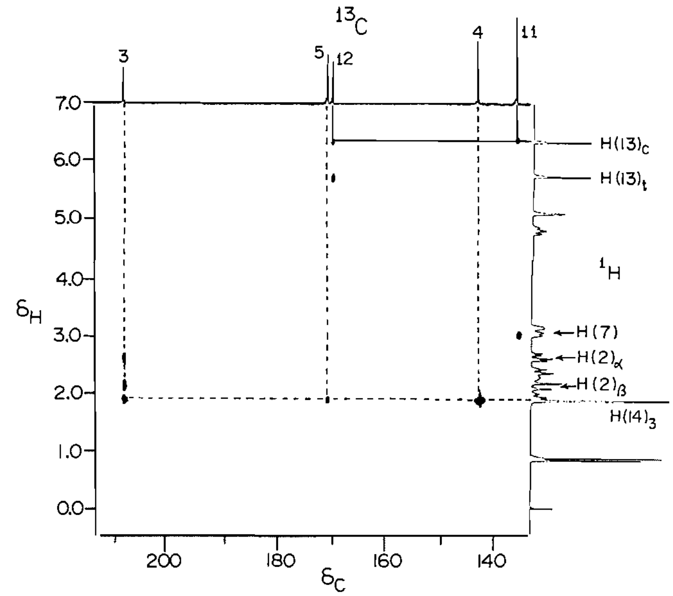

FIG. 4. "Long range" heteronuclear correlated spectrum of **1** with non-protonated ^{13}C spectrum along the horizontal and ^1H spectrum along the vertical; ------: connectivities of ^{13}C with $H(14)_3$; ——: connectivities of ^{13}C peaks with $H(13)_c$.

(c) *Comparison of the solution and solid state conformations of 1*

The publication reporting the crystal structure of **1** does not list any dihedral angles involving hydrogens (4).[3] However, these are easily calculated from the reported atomic coordinates (4) and are listed in Table 3, along with the corresponding $^1H—^1H$ coupling constants. Vicinal ($^3J_{H-H}$) coupling constants are also plotted against the corresponding solid state H—C—C—H dihedral angles in Fig. 5. These show a good Karplus relationship, indicating that are are no major changes in conformation on going from the solid state to solution. Even the H—O—C(6)—H(6) coupling constant is consistent with the observed dihedral angle in the solid state. However, this may be fortuitous since the orientation of the OH group in the solid state is influenced by intermolecular hydrogen bonding (4) and since the observed coupling constant is also consistent with that expected for a freely rotating OH group.

[3]However, ref. 4 provides a three-dimensional representation of the conformation of **1**, along with all C—C—C—C dihedral angles.

TABLE 3. Comparison of observed vicinal, allylic, or homoallylic $^{1}H-^{1}H$ coupling constants for **1** in solution with the corresponding dihedral angles in the crystalline state

Angle	<[a]	Coupling	J (Hz)[b]

		$^{4}J_{H(7)H(13)_t}$ (*cisoid*)	3.0
H(1)—C(1)—C(5)—C(4)	121	$^{5}J_{H(1)H(14)}$	2.0
H(6)—C(6)—C(5)—C(4)	54	$^{5}J_{H(6)H(14)}$	0.8

[a]Dihedral angle in degrees.
[b]Coupling constant (in hertz).

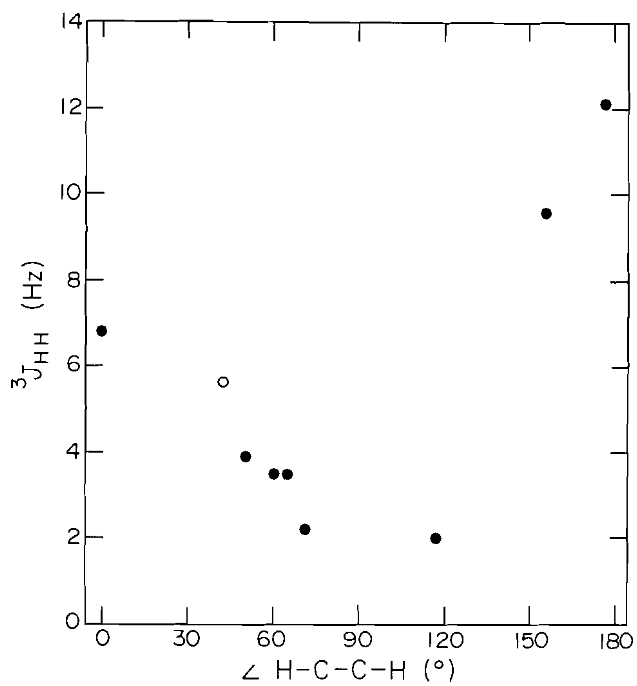

FIG. 5. Plot of vicinal $^{1}H—^{1}H$ coupling versus H—C—C—H dihedral angle. The open circle is the coupling to the OH proton.

Several of the observed long-range coupling constants are also consistent with the crystalline conformation. For example, the two allylic couplings involved H(7) and the exocyclic methylene protons are both $\geq$ 3 Hz. This is close to the maximum value for this type of coupling (12), as expected for the near-orthogonal orientations of H(7)—C(7) and C(11)—C(13) (allylic couplings show a maximum for <H—C—C=C $\simeq$ 90° (12)). The couplings of H(1) and H(6) to C(14)H_3 are respectively examples of *transoid* and *cisoid* homoallylic (H—C—C=C—C—H) couplings. Two factors probably account for the larger magnitude of the former coupling. First, *transoid* homoallylic couplings are generally larger than *cisoid* homoallylic couplings, e.g. the rotationally averaged homoallylic couplings in *cis* and *trans*-2-butene are respectively 1.20 Hz and 1.59 Hz (13). Second, homoallylic couplings are increased by having either C—H bond at right angles to the plane of the double bond (13). <H(1)—C(1)—C(5)—C(4) is closer to 90° than <H(6)—C(6)—C(5)—C(4), consistent with the larger magnitude of the former homoallylic coupling.

There is a small four-bond coupling between H(1) and H(6) and a five-bond coupling of similar magnitude between H(2)$_\alpha$ and H(6). However, no corresponding coupling is observed between H(2)$_\beta$ and H(6) (decoupling of H(6) gives no noticeable line narrowing for H(2)$_\beta$, suggesting $^{5}J_{H(2)_\beta H(6)} < 0.1$ Hz). The different couplings of H(2)$_\alpha$ and H(2)$_\beta$ to H(6) are surprising since the fragment C(2)—C(1)—C(5)—C(6) is almost planar (<C(2)—C(1)—C(5)—C(6) = 174°) and H(2)$_\alpha$—C(2) and H(2)$_\beta$—C(2) show fairly similar dihedral angles with respect to C(1)—C(5) (respectively 116° and 126°). Unfortunately, too little is known about the conformational dependence of this type of 5-bond coupling (14) to draw any conclusions concerning the reasons for these differences.

Finally, the large magnitude of the geminal coupling between H(2)$_\alpha$ and H(2)$_\beta$ (19.1 Hz) is consistent with a conformation in which the H—H axis is parallel to the π orbital of the adjacent carbonyl group (15), as indicated by the crystal structure (4).

In summary, we have used a variety of one-dimensional nmr techniques (selective decoupling, inversion–recovery sequences to reveal hidden resonances, and DEPT spectral editing) in conjunction with two-dimensional heteronuclear ($^{13}C—^{1}H$) correlated spectra to unambiguously assign the ^{1}H and ^{13}C spectra of mikanokryptin, **1**. Comparison of vicinal, allylic, and homoallylic $^{1}H—^{1}H$ coupling constants in solution with corresponding dihedral angles determined from the crystalline structure demonstrate that the solution and solid state conformations of **1** are similar.

Experimental

Specimens of *Mikania mikrantha* H.B.K. were harvested at Xanciutlalpan, Puebla, Mexico. Vouchers are on deposit at the IMSSM Herbarium (voucher numbers 3290, 3320, and 3452). Four hundred and fifty grams of dried, ground aerial parts (stems and leaves) were defatted with hexane by exhaustive maceration at room temperature, followed by extraction with methylene chloride (4 × 3 l) in a similar fashion. After *in vacuo* removal of solvent, 16 g of a residue were obtained. A solid separated spontaneously from this residue and was removed by filtration. Recrystallization from acetone–ethanol afforded crystals (mp 246–248°C) which were identified as mikanokryptin by comparison with previously reported ^{1}H nmr, uv, ir, and mass spectra data (3).

All nmr spectra were obtained on a Varian XL-200 nmr spectrometer, operating in pulsed Fourier transform mode at a probe temperature of 20°C. For ^1H spectra, ca. 5 mg of **1** were dissolved in 0.6 mL of 95% $CDCl_3$ − 5% $(CD_3)SO$ (with ca. 0.1% $(CH_3)_4Si$ as internal reference) and placed in a 5-mm tube. Spectra were obtained using 1600-Hz spectral widths and 16K data points (5-s acquisition time), zero filled to 32K (0.1-Hz data point resolution). Ninety degree pulses (7.5 μs) and 5-s recycle times were used and 32 transients were accumulated. For ^{13}C spectra, ca. 80 mg of **1** were dissolved in 2 mL of the same solvent mixture as for the ^1H spectra. Spectral widths of 12 000 and 1.33-s acquisition times (32K data points) were used for normal and DEPT spectra. For normal spectra, 45° (7.5 μs) pulses were used with a recycle time of 2 s and 10 000 transients were accumulated. Four DEPT spectra were obtained using θ pulses of 45°, 90°, 90°, and 135° (7) with 2500 transients for each spectrum. Edited subspectra were obtained using the editing program ADEPT incorporated in the standard Varian software (H release).

Normal and "long range" heteronuclear correlated spectra were obtained using a spectrum width of 11 000 Hz in the ^{13}C domain and 1500 Hz in the ^1H domain with 2048 data points for the former and 512 for the latter, 320 transients were collected per time increment with 128 time increments; 2-Hz line broadening was applied along each axis. For the normal spectrum, the delay times Δ_1 = 0.0036 s and Δ_2 = 0.0024 s were chosen, corresponding to optimum values for an average $^{13}C—^1H$ coupling of 140 Hz (6). For the long-range experiments, repeated preliminary measurements indicated best values of Δ_1 = 0.075 s and Δ_2 = 0.033 s. These are compromise values which are approximately optimized for both geminal and vicinal $^{13}C—^1H$ coupling involving methyl hydrogens (ca. 5 Hz (15)) and *anti*-vicinal $^{13}C—^1H$ coupling involving methylene and methine hydrogens (ca. 10 Hz (16)) (6).

Flow-tube studies of reactions of selected ions with cyanoacetylene

A. B. RAKSIT AND D. K. BOHME

Department of Chemistry and Centre for Research in Experimental Space Science, York University, Downsview, Ont., Canada M3J 1P3

Received August 10, 1984

A. B. RAKSIT and D. K. BOHME. Can. J. Chem. **63**, 854 (1985).

Rate constants and product distributions have been determined for ion/molecule reactions of cyanoacetylene (HC_3N) with He^+, $C^+(^2P)$, CH_3^+, C_2^+, C_2H^+, $C_2H_2^+$, CN^+, C_2N^+, $C_2N_2^+$, N_2^+, CO^+, H_3^+, N_2H^+, HCO^+, $C_2H_3^+$, H_3O^+, $CH_3NO_2H^+$, CH_3CNH^+, $(CH_3)_2COH^+$, i-$C_3H_7OH_2^+$, C_3H^+, and C_4N^+. The measurements were performed with the selected-ion flow-tube (SIFT) technique at 296 ± 2 K. The observed reactions exhibit a variety of pathways including charge transfer, proton transfer, condensation, and association. The condensation and association reactions are suited for molecular growth by ion/molecule reactions. Special consideration is given to the active role of cyanoacetylene in the possible molecular synthesis which occurs in dense interstellar gas clouds by ion/molecule reactions.

A. B. RAKSIT et D. K. BOHME. Can. J. Chem. **63**, 854 (1985).

On a déterminé les constantes de vitesse et les distributions des produits des réactions ions/molécules entre le cyanoacétylène (HC_3N) et les ions He^+, $C^+(^2P)$, CH_3^+, C_2^+, C_2H^+, $C_2H_2^+$, CN^+, C_2N^+, $C_2N_2^+$, N_2^+, CO^+, N_3^+, N_2H^+, HCO^+, $C_2H_3^+$, H_3O^+, $CH_3NO_2H^+$, CH_3CNH^+, $(CH_3)_2COH^+$, i-$C_3H_7OH_2^+$, C_3H^+ et C_4N^+. On a effectué les mesures à 296 ± 2 K en faisant appel à la technique des tubes à écoulement avec ions sélectifs (TEIS). Les réactions observées présentent une variété de voies réactionnelles, y compris des transferts de charges, des transferts de protons, des condensations et des associations. Les réactions de condensations et d'associations se prêtent bien à une croissance moléculaire par des réactions ions/molécules. On a accordé une considération spéciale au rôle actif que pourrait jouer le cyanoacétylène dans les synthèses moléculaires qui peuvent se produire, par des réactions ions/molécules, dans les nuages gazeux interstellaires denses.

[Traduit par le journal]

Introduction

Cyanoacetylene has attracted attention recently in astrochemistry as a consequence of its identification in the radiospectrum of several interstellar sources including cold dark molecular clouds and the circumstellar shells of late type stars (1). The molecular cloud TMC-1 is an example of such a source. This cloud also has been found to contain many related molecules such as the cyanopolyynes, $HC_{2n}CN$, with values of n up to 4, methylcyanoacetylene, CH_3C_2CN, and the radicals C_4H and C_3N (2). The concomitance of these molecules suggests that they have a common chemical lineage and that perhaps cyanoacetylene itself is a key progenitor. Here we report laboratory measurements of gas-phase reactions of various carbonaceous and organonitrogen ions with cyanoacetylene which begin to explore the latter possibility.

Gas-phase ion/molecule reactions have been invoked successfully in astrochemistry to account for the molecular synthesis of many simple molecules in interstellar clouds (3–5). Ion/molecule reactions are also expected to play an important role in the formation and destruction of larger and more complex molecules. The chemical paths to larger molecules become increasingly more difficult to track as the molecules become more complex and so they are not understood nearly as well. The studies reported here represent an attempt to identify such paths which are specific to cyanoacetylene.

A previous laboratory study of ion/molecule reactions with cyanoacetylene has led to the conclusion that the positive ion chemistry of cyanoacetylene is dominated by charge-transfer or proton-transfer reactions and is thus, by implication, of minor importance to the chemical synthesis of larger molecules (6). The observations reported here establish serious discrepancies with the earlier results for a number of key reactions and point towards an active rather than a passive role for cyanoacetylene in molecular growth by ion/molecule reactions.

Experimental

The measurements were performed with the selected-ion flow tube/flowing afterglow apparatus in the Ion Chemistry Laboratory at York University (7, 8). The reagent ions were derived from suitable parent gases by electron impact at low pressures. An axial electron impact ionizer (Extranuclear, Model 041-3) was used as the ion source. Typical ion injection energies were in the range 10 to 15 V. The carrier gas was either helium or hydrogen. To remove traces of water vapour the buffer gases were passed through zeolite traps (a 50:50 mixture of Union Carbide molecule sieves 4A and 13X) cooled to liquid nitrogen temperature. The cyanoacetylene was prepared in the laboratory from methyl propiolate (Aldrich) (9). Experiments with H_3^+ as the "chemical ionization" reagent indicated a purity of greater than 99%. All measurements were made at an ambient temperature of 296 ± 2 K.

Results

The reaction rate constants and product distributions obtained in this study for reactions of ions with cyanoacetylene are summarized in Table 1. Rate constants and product distributions were determined in the manner described previously (7, 10). Table 1 includes all the primary product ions which were observed to contribute more than 5% to the total product spectrum. The branching ratios have been rounded off to the nearest 5% and are accurate to ±30%. The experimental rate constants are compared with collision rate constants, k_c, derived according to a recent combined variational transition state theory/classical trajectory study of thermal energy ion polar molecule capture collisions (11) with an estimated polarizability for HC_3N of 5.29 Å^3 (12) and a dipole moment of 3.6 D (13).

He⁺

He^+ was derived from helium by electron impact at 26 eV and injected into helium buffer gas. Approximately 30% conversion to He_2^+ was observed at pressures of about 0.3 Torr. The conversion occurs by termolecular association along the length of the flow tube. The added cyanoacetylene was observed to react rapidly with both He^+ and He_2^+ although some of the observed decrease in the He_2^+ signal was due to depletion of the precursor He^+. Figure 1 shows the plethora of product

TABLE 1. Summary of rate constants (in units of 10^{-9} cm^3 molecule^{-1} s^{-1}) and product distributions measured for ion–molecule reactions with cyanoacetylene using the SIFT technique at 296 ± 2 K

Reactant ion	Products	Branching ratio	k_{exp}[a]	k_c[b]
He^+	C_2^+, C_3^+, C_2H^+, CN^+, C_2N^+, C_3N^+		6.9 (8.2)	9.0
C^+ (^2P)	$C_3H^+ + CN$	0.8	6.1 (8.7)	5.6
	$C_4N^+ + H$	0.2		
CH_3^+	$C_3H_3^+ + HCN$	0.6	4.2[c] (2.7)	5.1
	$CH_3^+ \cdot HC_3N$	0.4

[e]In hydrogen buffer gas at a total pressure of 0.185 Torr and concentration of 6.0×10^{15} molecules cm^{-3}.

[f]In helium buffer gas at a total pressure of 0.347 Torr and concentration of 1.1×10^{16} atoms cm^{-3}.

ions which appeared in response to these reactions. All of them can be derived by dissociative charge transfer. C^+, CH^+, and HCN^+ were also observed as primary product ions but they were produced in relatively small amounts and are not shown in Fig. 1. Also it should be noted that formation of HC_3N^+ itself was observed but the data analysis indicated that it could be accounted for entirely by secondary reactions. The secondary product spectrum was complex as would be expected from the high reactivity of all the primary product ions which is evident from the decays shown in Fig. 1. Several of these secondary reactions are elucidated in the following sections.

C^+

The C^+ ions were produced from C_2N_2 at an electron energy

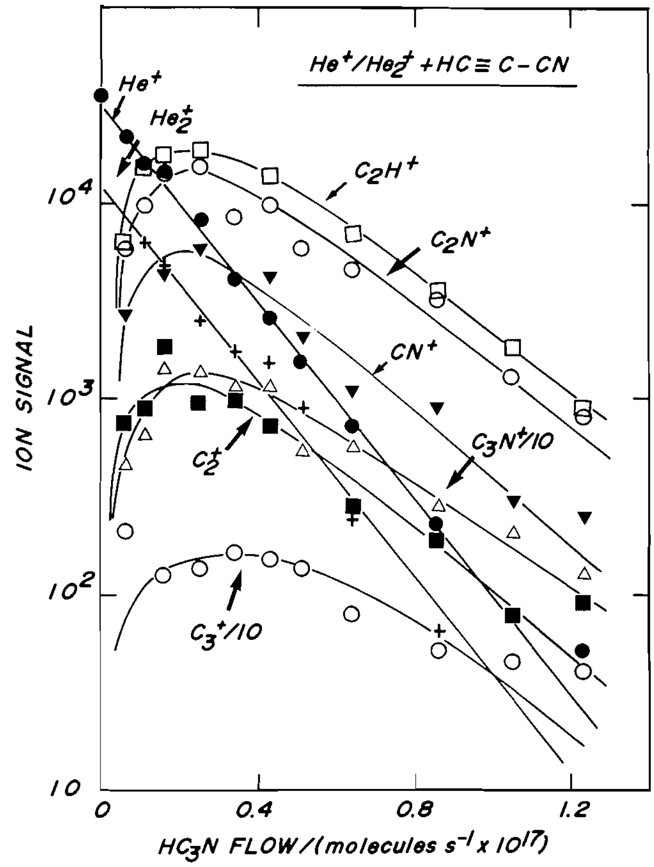

FIG. 1. The observed variations in ion signals recorded for the addition of HC_3N into the reaction region of the SIFT apparatus in which He^+ is initially established in helium buffer gas. P = 0.332 Torr, $\bar{v} = 7.4 \times 10^3$ cm s^{-1}, L = 46 cm, and T = 297 K. He^+ is derived from He at an electron energy of 25.7 eV.

of 32 eV and selected with an injection energy of 12.4 V. HCO^+ and C_2N^+ were two other ions observed in the C^+ spectrum downstream but with intensities less than 10% and 1% of the C^+ signal, respectively. Their origin can be attributed to reactions of C^+ with H_2O impurity in the buffer gas and with C_2N_2 which leaks through the selection quadrupole region. Separate experiments in which CO was added into the reaction region indicated that more than 95% of the C^+ generated in this fashion was in the ^2P ground state (14). Charge transfer to form CO^+ which is exothermic only with the excited ^4P state of C^+ was observed to proceed with less than 5% of the initial C^+ population.

Figure 2 shows data observed for the reaction of C^+ with HC_3N proceeding in our SIFT apparatus. The predominant primary product ion was identified as C_3H^+ and it was accompanied by some production of C_4N^+. The C_3H^+ and C_4N^+ ions may be formed by C—H insertion with elimination of CN and H, respectively. Formation of C_3^+ + HCN was not observed. Available heats of formation for C_3H^+ and C_3^+ (15, 16) indicate that formation of C_3^+ is approximately 30 kcal mol^{-1} less exothermic. The C_3H^+ product is likely to be the carbene cation $:\overset{+}{C}$—C≡CH whose chemistry we have investigated in detail in a separate study (8). The structure of the C_4N^+ product is uncertain as either $CCCCN^+$ or $CCCNC^+$ may be formed depending on which end of the molecule is attacked. Carbene character is also likely to be associated with this ion, as for example in $:\overset{+}{C}$—C≡C—CN. Figure 2 also shows rapid reac-

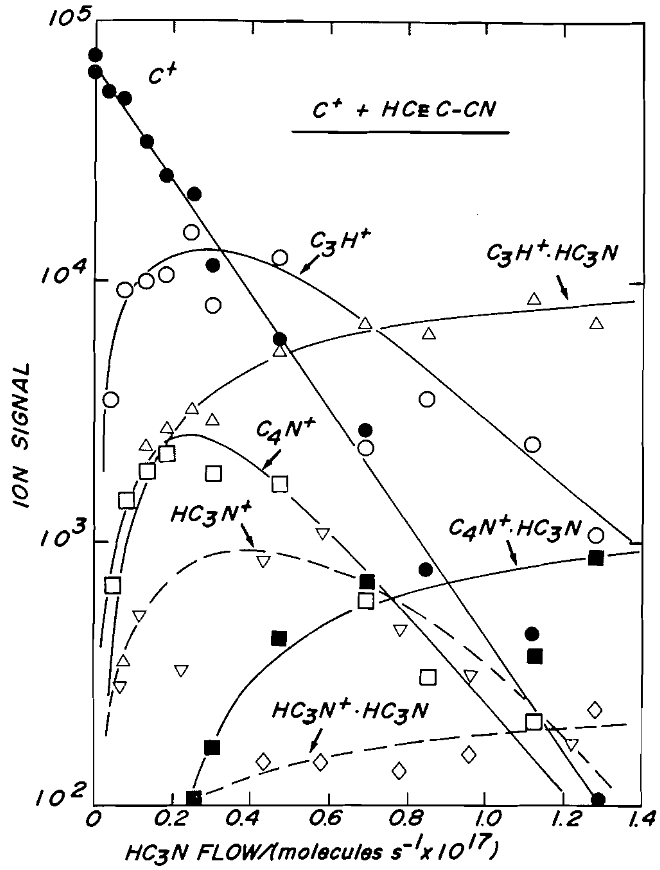

FIG. 2. The observed variations in ion signals recorded for the addition of HC_3N into the reaction region of the SIFT apparatus in which C^+ is initially established in helium carrier gas. P = 0.314 Torr, $\bar{v} = 7.2 \times 10^3$ cm s^{-1}, L = 46 cm, and T = 296 K. C^+ is derived from C_2N_2 at an electron energy of 32 eV.

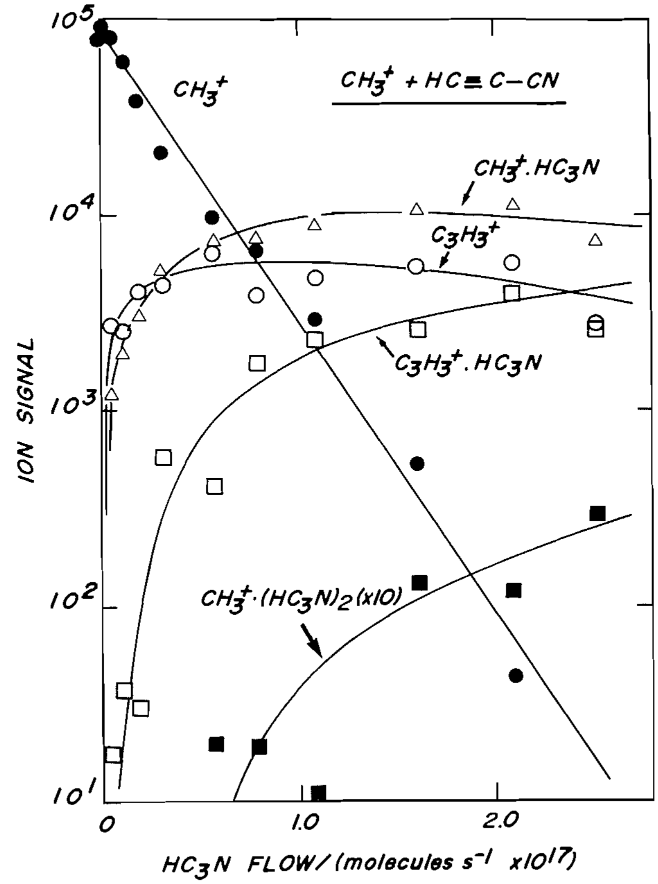

FIG. 3. The observed variations in ion signals recorded for the addition of HC_3N into the reaction region of the SIFT apparatus in which CH_3^+ is initially established in helium carrier gas. P = 0.311 Torr, $\bar{v} = 7.4 \times 10^3$ cm s^{-1}, L = 46 cm, and T = 295 K. CH_3^+ is derived from CH_4 at an electron energy of 24.1 eV.

tions of C_3H^+ and C_4N^+ with HC_3N to form the adducts $C_3H^+ \cdot HC_3N$ and $C_4N^+ \cdot HC_3N$. Also HC_3N^+ was produced as a primary ion and it reacted further to form the adduct $HC_3N^+ \cdot HC_3N$. The production of HC_3N^+, which accounts for about 5% of the initial C^+, may be attributed entirely to the excited ^4P component of C^+ which can react with HC_3N in an exothermic fashion by charge transfer. Not shown in Fig. 2 are the impurity ions at m/z 29 (HCO^+) and 38 (C_2N^+) which were present initially at levels of less than 10% and 1% of the initial C^+ signal, respectively. Separate experiments indicated that HCO^+ reacts by proton transfer to yield $H_2C_3N^+$ and that C_2N^+ produces C_3H^+. Also the observations allowed for some production (5%) of C_2N^+ directly from the reaction of C^+ with HC_3N.

CH_3^+

This ion was derived from CH_4 at 24 eV. Background ions were present at m/z = 19, 29, and 33. These were ascribed to H_3O^+, N_2H^+, and $CH_3^+ \cdot H_2O$. Figure 3 shows the appearance of the product ions which were assigned to the reaction of CH_3^+ with cyanoacetylene. Major primary products were observed at m/z = 39 and 66. Since formation of HC_2N^+ (m/z 39) + C_2H_3 is endothermic, the m/z 39 product must be $C_3H_3^+$. The ion with m/z 66 must be the adduct $CH_3^+ \cdot HC_3N$. Both product ions reacted further to form the adducts $C_3H_3^+ \cdot HC_3N$ and $CH_3^+ \cdot (HC_3N)_2$. An ion with m/z 52 was also observed in the product spectrum with an intensity up to 5% of the total product ions but its origin could be attributed entirely to proton-transfer reactions with the impurity ions.

The two primary product channels appear to reflect the position of attack on the cyanoacetylene molecule. Attack at the carbon α to the cyanogen group can lead to elimination of HCN and formation of the propargyl cation while attack at the β carbon would make HCN elimination less favourable and lead preferentially to an adduct which could be the cyanopropenylium ion, $CH_3\text{—}CH\text{=}\overset{+}{C}\text{—}CN$. However, neither of these structures can be considered to be established by these measurements. Alternatives include formation of the cyclopropenium isomer of $C_3H_3^+$ which is also exothermic and formation of an adduct which is electrostatically bound.

C_2^+

This ion was derived from C_2N_2 by electron impact at 50 eV. Background ions of known identity and origin were present at levels of less than 5% of the initial C_2^+ signal. Primary product ions with a contribution of more than 5% of the total observed included m/z 50 (C_3N^+), 74 (C_5N^+), 37 (C_3H^+), and 38 (C_2N^+). The corresponding reactions dictated by thermochemistry and their product distributions are indicated in Table 1. The predominant channel to produce C_3N^+ corresponds to hydride transfer. H atom elimination to form C_5N^+ leads to carbon chain lengthening. The mechanisms of the two remaining channels is less certain but they may arise from side-on attack by C_2^+. The adducts $C_3N^+ \cdot HC_3N$, $C_5N^+ \cdot HC_3N$, and $C_3H^+ \cdot HC_3N$ appeared to be formed rapidly by secondary reac-

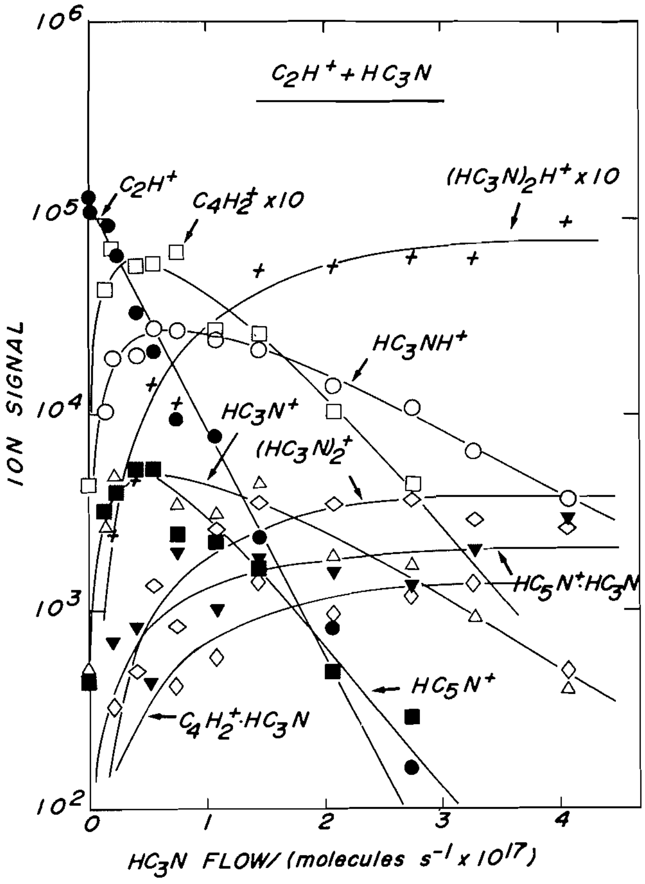

FIG. 4. The observed variations in ion signals recorded for the addition of HC_3N into the reaction region of the SIFT apparatus in which C_2H^+ is initially established in helium carrier gas. P = 0.339 Torr, v = 7.1 × 10^3 cm s^{-1}, L = 46 cm, and T = 297 K. C_2H^+ is derived from cyanoacetylene by electron impact at 31 eV.

tions with cyanoacetylene. Only the adduct of C_2N^+ was not observed. It is shown in a later section that this ion reacts with HC_3N to produce C_3H^+.

C_2H^+

This ion was generated from HC_3N by electron impact at 31 eV. The main impurity ions present initially were m/z 19 (H_3O^+), 26 ($C_2H_2^+$), and 42 ($H_2C_2O^+$) at 5%, 2%, and 2%, respectively, of the initial C_2H^+ signal. All three of these impurity ions have been shown in separate experiments to be derivatives of the reaction of C_2H^+ with H_2O impurity. Their presence was taken into account in the product analysis. The evolution of the product ions observed with addition of HC_3N is shown in Fig. 4. The predominant product channel corresponds to proton transfer and the minor channel apparently to charge transfer although CN transfer cannot be excluded. The two other intermediate channels both appear to result in C—C bond formation. The $C_4H_2^+$ product is likely to be ionized diacetylene which may arise by attack at the carbon α to CN while HC_5N^+, presumably ionized cyanodiacetylene, may be the result of attack at the β carbon with elimination of H. All four of the product ions reacted further with HC_3N to rapidly establish the adducts $(HC_3N)_2H^+$, $(HC_3N)_2^+$, $C_4H_2^+ \cdot HC_3N$, and $HC_5N^+ \cdot HC_3N$.

$C_2H_2^+$, $C_4H_2^+$

The $C_2H_2^+$ was derived from acetylene by electron impact at 31 to 51 eV. Major primary products were observed at m/z 50 and 77 which were assigned to $C_4H_2^+$ and $C_2H_2^+ \cdot HC_3N$, respectively. Production of m/z 50 = C_3N^+ is endothermic according to available heats of formation (16). The m/z 77 ion is produced exclusively from $C_2H_2^+$ and not from a secondary reaction of $C_4H_2^+$ with HC_3N which was shown in the C_2H^+ experiments to produce only the adduct $C_4H_2^+ \cdot HC_3N$. There was no indication for the formation of an ion at m/z 52 which would be indicative of proton transfer. Evidently carbon chain lengthening and association are the only two primary product channels. Proton transfer was identified as the only channel by earlier flowing afterglow measurements (6). It is possible that proton transfer is in fact endothermic although the energetics for proton transfer are not well known due to the uncertainty in the heat of formation of C_2H (17). Within the uncertainties of PA(C_2H) and PA(HC_3N) the change in enthalpy for the proton transfer is −4 ± 9 kcal mol^{-1}.

CN^+

CN^+ was derived from C_2N_2 by electron impact at ca. 55 eV. CN^+ reacts rapidly with H_2O and a number of ions derived from this reaction were present as impurity ions. The major reaction channel between CN^+ and HC_3N corresponds to charge transfer although C_2H transfer is also a possibility. Some production of an ion with m/z 50 was observed and it was ascribed to formation of C_3N^+ + HCN which may result from hydride transfer. Also an ion with m/z 52 (HC_3NH^+ or $C_2N_2^+$) was observed to be produced but its origin could be attributed entirely to a proton transfer between H_3O^+ and cyanoacetylene. The C_3N^+, HC_3N^+, and m/z 52 ions were all observed to undergo secondary reactions to form adducts with HC_3N.

C_2N^+

This ion was derived from cyanoacetylene at an electron energy of 35 eV. C_3H^+ was the only primary product observed and it reacted further to form the adduct $C_3H^+ \cdot HC_3N$. Separate experiments performed in our laboratory have shown that the C_2N^+ derived from HC_3N (and also from C_2N_2) is a mixture of at least two states. One component has been found to react rapidly with O_2 to form C_2NO^+ and O_2^+ and comprises about 5% of the total mixture. The remaining 95% was observed to be unreactive towards O_2. It is not clear whether the observed difference in reactivity is due to the two structural isomers C—N—C^+ and C—C—N^+ or whether singlet and triplet forms of this carbene cation are involved. Calculations have shown the C—N—C^+ isomer to be more stable than the C—C—N^+ isomer by ca. 30 kcal mol^{-1} (18).

H_3^+, N_2H^+, HCO^+, $C_2H_3^+$, H_3O^+

We have investigated proton transfer reactions with cyanoacetylene in a separate study directed towards a determination of the proton affinity of HC_3N by the bracketing technique (19). All five of the protonated species listed above were observed to react rapidly with HC_3N by proton transfer with rate constants in close agreement with predicted collision rate constants. The observations recorded for the fastest of these reactions, viz. the reaction with H_3^+, are shown in Fig. 5 which also includes the reactive behaviour of the impurity ions H_3O^+ and N_2H^+. The protonated cyanoacetylene reacts further to establish the protonated dimer.

$CH_3NO_2H^+$, NO^+

These two ions were generated by injecting $CH_3NO_2^+$ into H_2 buffer gas (19). At the injection energies employed (12.4 V) some NO^+ was present (≈ 10%) which is presumed to arise

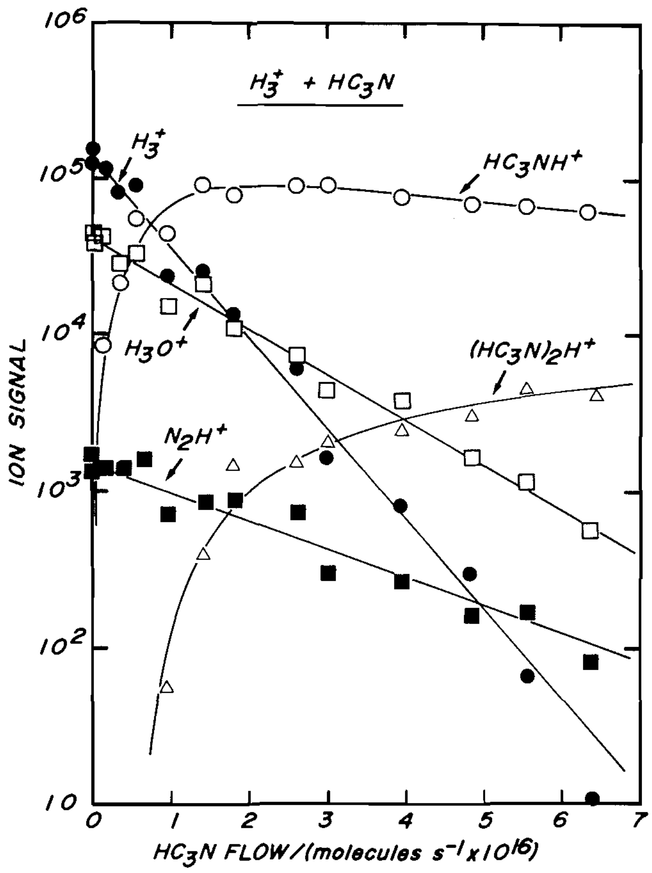

FIG. 5. The observed variations in ion signals recorded for the addition of HC_3N into the reaction region of the SIFT apparatus in which H_3^+ is initially established in hydrogen carrier gas. $P = 0.188$ Torr, $v = 6.5 \times 10^3$ cm s^{-1}, $L = 45$ cm, and $T = 296$ K. The selected ion is H_2^+ derived from H_2 by electron impact at 30 eV. H_3O^+ and N_2H^+ arise from reactions of H_3^+ with impurities in the carrier gas.

from collisional dissociation of $CH_3NO_2^+$. The NO^+ was observed to react only slowly to form the adduct $NO^+ \cdot HC_3N$. The rate constant for this association is estimated to be $< 1 \times 10^{-10}$ cm^3 $molecule^{-1}$ s^{-1} at a total pressure of 0.18 Torr and a hydrogen density of 5.9×10^{15} molecules cm^{-3}. The $CH_3NO_2H^+$ was observed to react rapidly to form two products in about equal proportions: an ion at m/z 52 which corresponds to protonated HC_3N and an ion at m/z 66 which may be $H_4C_4N^+$, $H_2C_4O^+$, or C_3NO^+. The possible m/z 66 product ions would involve concomitant production of the neutrals HNO_2, H_3N_2O, and H_5CNO, respectively. The first option appears most likely and could produce the cyanopropenylium ion as shown in reaction [1]

$$[1] \quad CH_3NO_2H^+ + HC{\equiv}C{-}CN \rightarrow CH_3{-}CH{=}\overset{+}{C}{-}CN + HNO_2$$

N_2^+, CO^+, $C_2N_2^+$

N_2^+ was derived from N_2 at an electron energy of 45 eV, $C_2N_2^+$ from C_2N_2 at 51 eV, and CO^+ from OCS at 34 eV. All these ions have recombination energies higher than the ionization energy of cyanoacetylene so that charge transfer was observed to be the dominant channel (>95%) for all three ions. Impurity ions were present at m/z 18 (H_2O^+), 19 (H_3O^+), and 29 (N_2H^+ or HCO^+) and these reacted predictably by proton transfer to establish HC_3NH^+. Both the HC_3N^+ produced by charge transfer and the HC_3NH^+ produced by proton transfer reacted further by addition of HC_3N to form $(HC_3N)_2^+$ and $(HC_3N)_2H^+$, respectively.

$(CH_3)_2COH^+$, CH_3CNH^+, i-$C_3H_7OH_2^+$

These three protonated species were observed to form adduct ions with cyanoacetylene. Each was generated in H_2 buffer gas by reaction [2]

$$[2] \quad X^+ + H_2 \rightarrow XH^+ + H$$

where X^+ was derived by electron impact of X = $(CH_3)_2CO$, CH_3CN, and i-C_3H_7OH, respectively (19). Table 1 shows that the association reactions with CH_3CNH^+ and i-$C_3H_7OH_2^+$ are quite rapid and about 10 times faster than the association reaction with $(CH_3)_2COH^+$. The adduct of CH_3CNH^+ was observed to react further with HC_3N in a manner which may be described by the solvated proton transfer reaction [3].

$$[3] \quad CH_3CNH^+ \cdot HC_3N + HC_3N \rightarrow HC_3NH^+ \cdot HC_3N + CH_3CN$$

The reverse of reaction [3] is actually the preferred direction. This was shown in a separate study in which $HC_3NH^+ \cdot HC_3N$ was generated in H_2 buffer gas by the reaction sequence [4] and [5]

$$[4] \quad H_2^+(H_3^+) + HC_3N \rightarrow HC_3NH^+ + H(H_2)$$

$$[5] \quad HC_3NH^+ + HC_3N \rightarrow HC_3NH^+ \cdot HC_3N$$

The $HC_3NH^+ \cdot HC_3N$ adduct was observed to react rapidly with CH_3CN by the reverse of reaction [3] with a rate constant of 1.9×10^{-9} cm^3 $molecule^{-1}$ s^{-1}. The analogue of reaction [3] was not observed for the adduct ions $(CH_3)_2COH^+ \cdot HC_3N$ and i-$C_3H_7OH_2^+ \cdot HC_3N$. The smaller rate constants for these two reactions are consistent with the larger intrinsic basicities of $(CH_3)_2CO$ (PA = 194 kcal mol^{-1}) and i-C_3H_7OH (PA = 190 kcal mol^{-1}). Finally, the observations indicated no measurable tendency of any of the adduct ions to add a second HC_3N molecule. The rate of addition of the second molecule of HC_3N is estimated to be at least 10 times slower than the rate of addition of the first. This difference in rate is likely to reflect a difference in the nature of the bonding in these adduct ions.

C_3H^+, C_4N^+

These two ions are likely to be the carbene cations with the linear structures $:\overset{+}{C}{-}C{\equiv}C{-}H$ and $:\overset{+}{C}{-}C{\equiv}C{-}CN$. When generated from the reaction of C^+ with HC_3N both ions were observed to add one molecule of HC_3N rapidly (see Fig. 2 and Table 1). Representative data for a separate study of the reaction of C_3H^+ with HC_3N where C_3H^+ is derived from electron impact of propylene is shown in Fig. 6. The two reactions were not investigated as a function of pressure. Stabilization of the adduct ions may proceed by collision with the buffer gas atoms but radiative association cannot be ruled out. The further addition of a second molecule of HC_3N was observed to proceed much more slowly.

Discussion and conclusions

The measurements reported here show that cyanoacetylene is very reactive towards ions at room temperature. The reactivity is manifested in a number of different ways. The moderate ionization potential of HC_3N and its moderately high proton affinity ensure that charge transfer and proton transfer can be effective. Cyanoacetylene also exhibits a range of interesting and rapid condensation and association reactions which are suited for molecular growth by ion/molecule reactions.

The ions selected in this study for reaction with cyano-

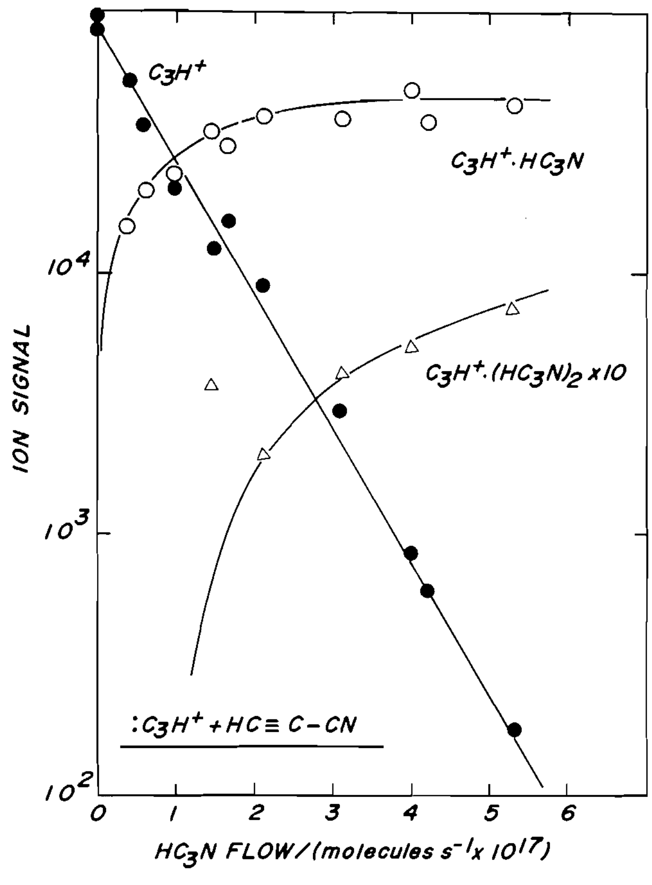

FIG. 6. The observed variations in ion signals recorded for the addition of HC_3N into the reaction region of the SIFT apparatus in which C_3H^+ is initially established in helium carrier gas. P = 0.347 Torr, $\bar{v} = 7.3 \times 10^3$ cm s^{-1}, L = 46 cm, and T = 296 K. C_3H^+ is derived from propylene by electron impact at 55 eV.

acetylene span a large range in recombination energy up to 24.6 eV for He^+. Charge transfer is exothermic for ions with a recombination energy greater than 11.60 ± 0.01 eV which is the ionization energy of HC_3N (20). Indeed charge transfer was an observed product channel with all of the ions which met this criterion, viz. He^+ (24.6), C^+ (^4P) (16.6), N_2^+ (15.6), CN^+ (15.1), CO^+ (14.0), $C_2N_2^+$ (13.4), and C_2H^+ (11.6), where the recombination energy is given in parentheses in eV (21). The charge transfer with He^+ was completely dissociative. For dissociative charge transfer to be exothermic to form any of the product ions indicated for He^+ in Table 1 the recombination energy of the ion must be greater than 17.7 eV and this is the case only for He^+. For the reactions of the other ions dissociative charge transfer is endothermic and was not observed. Charge transfer was observed to be only a minor channel with C_2H^+. The recombination energy of this ion is quite uncertain but appears to be very close to the ionization energy of cyanoacetylene. Values of 11.96 ± 0.05 eV (22), 11.6 ± 0.5 eV (17), 11.51 eV,[1] and 11.31 ± 0.13 eV (24) have been reported in the literature. Given this large uncertainty it is conceivable that charge transfer between C_2H^+ and HC_3N is in fact slightly endothermic at room temperature but this would still be consistent with our observation.

Freeman *et al.* (6) have reported flowing afterglow measurements of the charge transfer reactions of He^+, CN^+, and CO^+. The rate constants agree with those obtained in the SIFT study reported here within the combined error estimates of both experiments. However, Freeman *et al.* (6) did not report any dissociative charge transfer with He^+ and apparently also did not observe the small production of C_3N^+ from CN^+ which proceeds by hydride transfer. Furthermore these authors reported exclusive charge transfer for the reaction of C^+ with HC_3N which is not in agreement with our observations. Charge transfer between HC_3N and the $C^+(^2P)$ ground state is endothermic since the ionization energy of HC_3N (11.60 ± 0.01 eV) is higher than the recombination energy (11.260 eV) of $C^+(^2P)$. Charge transfer with C^+ should therefore not proceed rapidly at room temperature unless it is mostly in the (^4P) excited state. About 5% of the C^+ appeared to be in the (^4P) state in the SIFT experiments reported here and a charge transfer product was observed consistent with this population but the remaining 95% of the C^+ ions was seen to react to build up the carbon chain in the formation of C_3H^+ and C_4N^+.

Proton-transfer reactions with cyanoacetylene have been discussed in detail in a separate study directed towards a determination of the proton affinity of HC_3N (24). A value of 184 ± 4 kcal mol^{-1} was derived from bracketing measurements. Proton transfer was observed to proceed with H_3^+ (101), N_2H^+ (117), HCO^+ (141), $C_2H_3^+$ (153), H_3O^+ (166), and $CH_3NO_2H^+$ (180) but not with the CH_3CNH^+ (187) or $(CH_3)_2COH^+$ (194) where proton affinities are given in parentheses in kcal mol^{-1}. Proton transfer was observed by Freeman *et al.* (6) for H_3^+, N_2H^+, HCO^+, $C_2H_3^+$, and H_3O^+ and the rate constants obtained for these reactions with the two techniques again are in good accord. However, there are serious discrepancies for the reactions of CH_3^+ and $C_2H_2^+$ for which Freeman *et al.* (6) have also reported exclusive proton transfer. For these two ions the SIFT measurements indicate only condensation and association. The proton affinity of CH_2 can be calculated to be 197 kcal mol^{-1} from available thermochemical information (21) and this makes the proton transfer with HC_3N endothermic. The energetics of the proton-transfer reaction between $C_2H_2^+$ and HC_3N is less certain due to the uncertainty in the heat of formation of C_2H (17). Within the uncertainties of PA(C_2H) and PA(HC_3H) the change in enthalpy is −4 ± 9 kcal mol^{-1}. The SIFT measurements did not indicate occurrence of proton transfer which suggests that this channel is in fact endothermic also.

The remaining reactions which were investigated result predominantly in condensation and association and are of interest in chemical synthesis by ion/molecule reactions. Several condensation reactions lead to the buildup of purely carbonaceous ions as in the generation of C_3H^+ from C^+, $C_3H_3^+$ from CH_3^+, and $C_4H_2^+$ from C_2H^+ and $C_2H_2^+$. Others lead to the lengthening of the carbon backbone of the cyanoacetylene as in the formation of C_4N^+ from C^+, C_5N^+ from C_2^+, HC_5N^+ from C_2H^+ and possibly $H_4C_4N^+$ from $CH_3NO_2H^+$. The association reactions which were observed with HC_3N exhibited an interesting range in specific rate. The apparent bimolecular rate constants were generally $\geq 5 \times 10^{-11}$ cm^3 molecule^{-1} s^{-1} which is close to the collision limit. These are large values and as such are indicative of the formation "tight" adducts in which the bonding is quite strong (25, 26). Strong bonding is not entirely unexpected for the adducts observed. CH_3CNH^+, *i*-$C_3H_7OH_2^+$, and $(CH_3)_2COH^+$ should form proton bound adducts with HC_3N. The proton affinities of CH_3CN, *i*-C_3H_7OH, and $(CH_3)_2CO$ are within 10 kcal mol^{-1} of that for HC_3N. Charge delocalization is possible with $(CH_3)_2COH^+$ as is expressed in the resonance structures [6].

[1] S. I. Miller and J. Berkowitz. Referred to in ref. 22.

[6] 
This may result in a weaker proton bond in this case and thus account for the smaller rate constant observed for the formation of $(CH_3)_2COH^+ \cdot HC_3N$.

With C_3H^+ and C_4N^+ and possibly also $C_2H_2^+$ and $C_4H_2^+$ the bonding in the observed adducts is likely to be covalent. The carbene cations C_3H^+ and C_4N^+ should react with HC_3N by C—H σ bond insertion in a manner analogous to the bimolecular insertion reactions already reported for C_3H^+ (8, 27). Sigma bond insertion would lead to the product ions [7] and [8].

[7] $HC{\equiv}C{-}\overset{+}{C}H{-}C{\equiv}C{-}C{\equiv}N$

[8] $N{\equiv}C{-}C{\equiv}C{-}\overset{+}{C}H{-}C{\equiv}C{-}C{\equiv}N$

Charge delocalization is possible in these two ions and this may account for the observed decrease in the rate of addition of a second molecule of HC_3N. The nature of the bonding in the adducts $C_2H_2^+ \cdot HC_3N$ and $C_4H_2^+ \cdot HC_3N$ is less certain.

In ionized environments such as, for example, dense molecular interstellar clouds, ion/molecule reactions proceed in competition with neutralization reactions. Neutralization may proceed by electron-ion recombination (EIR), charge transfer (CT), or proton transfer (PT) and, when coupled to an ion/molecule reaction leading to bond formation in the ion, may result in the synthesis of a neutral molecule in which the new bond is preserved (23). For example, electron–ion recombination or proton-transfer reactions with the carbonaceous ions C_3H^+, $C_3H_3^+$, and $C_4H_2^+$ may establish the neutral molecules C_3, C_3H_2, and C_4H, and with $H_4C_4N^+$ may establish methylcyanoacetylene. $C_4H_2^+$ may neutralize by charge transfer to form diacetylene while HC_5N^+ may charge transfer to form cyanodiacetylene. The new bond may also be preserved directly in the neutral product of an ion/molecule reaction as in the reaction of C_2N^+ with HC_3N to form C_3H^+ where the neutral product must be C_2N_2.

For the specific case of the molecular cloud TMC-1 the results obtained in this study provide an indication of the possible role of cyanoacetylene in the synthesis of derivative molecules. Efficient routes are available for the synthesis of C_4H and C_4N according to reactions [9] and [10], respectively.

[9] $C_2H_2^+ \xrightarrow{HC_3N} C_4H_2^+ \xrightarrow[EIR]{PT} C_4H$

[10] $C^+ \xrightarrow{HC_3N} C_4N^+ \xrightarrow{CT} C_4N$

C^+ and $C_2H_2^+$ are attractive ionic precursors in models of interstellar ion chemistry as they react with H_2 only slowly by association (23). CH_3^+ is attractive for the same reason. With cyanoacetylene it yields the propargyl cation which may neutralize to form the carbene $H_2C{=}C{=}C{:}$ as shown in reaction [11].

[11] $CH_3^+ \xrightarrow{HC_3N} C_3H_3^+ \xrightarrow{PT} C_3H_2$

The $CH_3^+ \cdot HC_3N$ adduct observed in the laboratory may form in the molecular cloud by radiative association and then neutralize to form methylcyanoacetylene according to reaction [12].

[12] $CH_3^+ \xrightarrow{HC_3N} CH_3{-}CH{=}\overset{+}{C}{-}CN \xrightarrow[EIR]{PT} CH_3C_2CN$

Another possible route towards methylcyanoacetylene is reaction [13]

[13] $CH_3NO_2H^+ \xrightarrow{HC_3N} CH_3{-}CH{=}\overset{+}{C}{-}CN \xrightarrow[EIR]{PT} CH_3C_2CN$

but this route is less attractive for TMC-1 as CH_3NO_2 has not been identified. Plausible routes are also available for the synthesis of cyanopolyynes. Cyanodiacetylene may be produced directly from C_2H^+ according to reaction [14].

[14] $C_2H^+ \xrightarrow{HC_3N} HC_5N^+ \xrightarrow{CT} HC_5N$

Several of the primary product ions allow build up of the cyanopolyynes in secondary reactions. For example, recent measurements of the reaction of C_4N^+ with CH_4 in our laboratory indicate a channel leading the $H_2C_5N^+$ which may neutralize to form cyanodiacethylene. Other intriguing possibilities include the neutralization of the adducts $C_2H_2^+ \cdot HC_3N$ and $C_4H_2^+ \cdot HC_3N$ to form HC_5N and HC_7N, respectively, by elimination of H_2. Also the radiative recombination counterparts of the adduct formation observed in the flow tube for the carbene cations C_3H^+ and C_4N^+ expressed in reactions [15] and [16]

[15] $C_3H^+ + HC_3N \rightarrow HC{\equiv}C{-}\overset{+}{C}H{-}C{\equiv}C{-}CN + h\nu$

[16] $C_4N^+ + HC_3N \rightarrow NC{-}C{\equiv}C{-}\overset{+}{C}H{-}C{\equiv}C{-}CN + h\nu$

may provide direct routes for the synthesis in the interstellar medium of the large neutral carbenes $:C(C_2H)C_2CN$ and $:C(C_2CN)_2$. These may form on neutralization by proton transfer or electron–ion recombination. They constitute a new class of complex organonitrogen molecules whose presence may provide still further opportunities for molecular growth in the interstellar medium.

The crystal structure of *syn*-[4.4.3]propella-2,4,12-trien-11-ol 3,5-dinitrobenzoate, **2**, has been determined by single crystal X-ray diffraction and refined to an R value of 0.051. The crystal structure is triclinic with $a = 10.208(2)$, $b = 13.355(2)$, $c = 7.068(1)$ Å, $\alpha = 99.35(1)°$, $\beta = 100.63(1)°$, $\gamma = 100.79(1)°$, and the space group is $P\bar{1}$ with two molecules per cell, $D_{(calcd)} = 1.39$ g cm^{-3}. The unsaturated five-membered ring resides in an envelope conformation with C6—C11—C12—C13 lying essentially in a plane. The fifth atom, C1, is positioned 0.47 Å out of this plane on the side opposite O1. The latter is situated 1.38 Å away and projects the 3,5-dinitrobenzoate group above the central portion of the cyclohexadiene unit. Four contiguous carbon atoms in the latter ring are mutually coplanar and the fused cyclohexane ring adopts a chair conformation. The overall molecular geometry is reconcilable with its solvolytic behavior in aqueous acetone.

JUDITH C. GALLUCCI, KATSUO OHKATA, et LEO. A. PAQUETTE. Can. J. Chem. **63**, 862 (1985).

On a déterminé la structure cristalline du dinitro-3,5 benzoate du [4.4.3] propellatriène-2,4,12 ol-11-*syn*, **2**, par diffraction de rayons-X sur un cristal unique et on l'a affinée jusqu'à une valeur de $R = 0{,}051$. Le cristal est triclinique avec $a = 10{,}208(2)$, $b = 13{,}355(2)$, $c = 7{,}068(1)$ Å, $\alpha = 99{,}35(1)°$, $\beta = 100{,}63(1)°$, $\gamma = 100.79(1)°$. Le groupe d'espace est $P\bar{1}$ avec deux molécules par maille, $D_{(calc)} = 1{,}39$ g cm^{-3}. Le cycle insaturé à cinq chaînons existe dans une conformation enveloppe avec les 4 carbones C-6, C-11, C-12 et C-13 reposant essentiellement dans un plan. Le cinquième atome, C1, est situé à 0,47 Å hors de ce plan du côté opposé au O1. Ce dernier est à 1,38 Å plus loin et projette ainsi le groupe dinitro-3,5 benzoate au-dessus de la partie centrale de l'unité cyclohexadiénique. Quatre atomes de carbone contigus de ce dernier cycle sont mutuellement coplanaires et le noyau cyclohexanique qui lui est condensé adopte une conformation chaise. La géométrie moléculaire globale est en accord avec le comportement solvolytique dans l'acétone aqueuse.

[Traduit par le journal]

Introduction

The solvolytic behavior of the epimeric 3,5-dinitrobenzoates **1** and **2** in aqueous acetone has proven to be particularly informative with regard to the question of long-range charge delocalization (1). Despite the fact that the two molecules give rise to identical product distributions within experimental error, *anti* isomer **1** ionizes 100 times more rapidly than **2**. This widely divergent kinetic response was interpreted to be an indication of substantial π participation during rate-determining C—O bond heterolysis in **1** which fosters direct conversion to delocalized carbocation **3**. Because the *syn* isomer does not enjoy a comparably favorable stereochemical alignment, the initial ionization event leads to a simpler allyl cation. Only subsequently does the allyl → bishomotropylium electronic reorganization occur. The development of heightened charge delocalization as in **3** is almost certain to require disrotatory folding of the three- and unsaturated four-carbon bridges for the purpose of achieving through-space interaction and maximizing orbital overlap.

When the *anti/syn* rate ratio of 100 is compared to that previously determined for **4** and **5** (*exo/endo* = 12) (2), it becomes apparent that the presence of an additional fused cyclohexane ring is either more conducive to the development of bishomoaromatic character (see **3**) within **1** or less favorable to the ionization of **2**. For these reasons, we became interested in establishing the conformational preference of **2** and report here the results of its X-ray determined crystal structure.

X-ray structure results

Experimental

Preliminary precession photographs with MoKα radiation failed to find any Laue symmetry higher than $\bar{1}$; hence the space group possibilities are restricted to $P1$ and $P\bar{1}$. The pale yellow crystal used for data collection was a many-sided lump cut from a larger crystal and measured approximately 0.36 mm × 0.40 mm × 0.44 mm in size. The unit cell con-

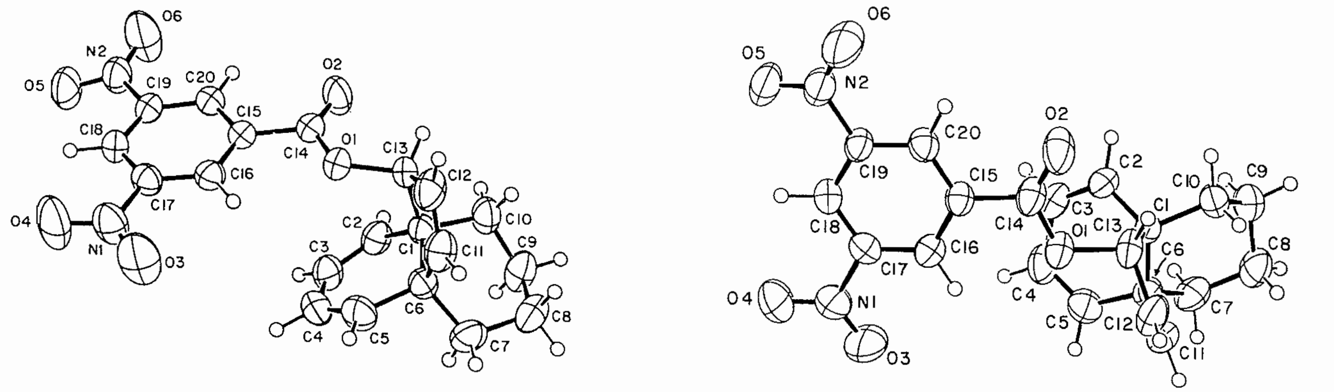

FIG. 1. ORTEP drawings of the molecular structure of **2** (left: side view; right: top view). The hydrogen atoms are drawn with an artificial radius for clarity; the nonhydrogen atoms are presented as 50% probability thermal ellipsoids.

stants a = 10.208(2), b = 13.355(2), c = 7.068(1) Å, α = 99.35(1)°, β = 100.63(1)°, and γ = 100.79(1)° were determined by the least-squares fit of the diffractometer setting angles for 26 reflections in the 2θ range 16 to 30° with MoKα radiation (λ(K$\bar{\alpha}$) = 0.71069 Å).

Data were collected at 21(1)°C by the $\theta-2\theta$ scan technique on a Syntex P$\bar{1}$ diffractometer equipped with graphite-monochromated MoKα radiation. The data were corrected for Lorentz and polarization effects and put on an absolute scale by means of a Wilson plot (3);[1] no absorption correction was applied. Five reflections saturated the detector during the data collection, the (0$\bar{1}$1), (101), (200), (3$\bar{1}\bar{1}$), and (30$\bar{1}$), and were not included in the data set. Six standard reflections were measured after every 100 reflections and gave no evidence of decay.

The additional pertinent crystallographic details are: $C_{20}H_{18}N_2O_6$ fw = 382.38 Triclinic, space group $P\bar{1}$, cell volume = 911 Å^3, Z = 2, $D_{(calcd)}$ = 1.39 g cm^{-3}, linear absorption coefficient = 0.98 cm^{-1}, 2θ limits = 4° ≤ 2θ ≤ 50°, scan speed = 2.0 to 24.0 deg min^{-1} in 2θ, background time/scan time = 0.5, scan range = 1.0° below Kα_1 to 1.2° above Kα_2, data collected = $+h$, $\pm k$, $\pm l$, unique data = 3219, unique data with $F_o^2 > 2\sigma(F_o^2)$ = 2083, final number of variables = 253, $R(F)$ = 0.051, $R_w(F)$ = 0.044, error in observation of unit weight = 1.80 e. ($R(F) = \Sigma||F_o| - |F_c||/\Sigma|F_o|$ and $R_w(F) = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$ with $w = 1/\sigma^2(F_o)$.)

Structure determination

Initial attempts to solve the structure with MULTAN 80 (4) in space group $P\bar{1}$ failed in that a pattern of planar hexagons was generated consistently in the E-maps. The structure was ultimately solved with MULTAN 80 with the following modifications: the two largest E-values were removed from the NORMAL file (these values are 4.6 and 4.5 for the (8$\bar{8}$3) and (833) reflections, respectively, and are significantly larger than the third largest value of 3.8) and the statistically weighted tangent refinement option was used. The resulting E-map clearly contained all the nonhydrogen atoms.

The SHELX-76 package (5) was used for full-matrix least-squares refinements; the function $\Sigma w(|F_o| - |F_c|)^2$ was minimized where $w = 1/\sigma^2(F_o)$. Isotropic refinement of the nonhydrogen atoms converged to an R index of 0.173. After one cycle of anisotropic refinement, a difference electron density map revealed the positions of all the hydrogen atoms. The hydrogens were then included in the model as fixed contributions at their calculated positions with C—H = 1.00 Å and $B_H = B_{C(iso)} + 1.0$ Å.^{2} The final refinement cycle on the anisotropic nonhydrogen atoms yielded agreement indices of $R(F)$ = 0.051 and $R_w(F)$ = 0.044 for the 2083 intensities with $F_o^2 > 2\sigma(F_o^2)$ and the 253 variables. The final cycle had a maximum shift/esd of 0.03. The final difference electron density map contains maximum and minimum peak heights of 0.15 and −0.18 e Å^{-3}. Scattering factors for the carbon, nitrogen, and oxygen atoms (6a) and for the hydrogen atoms (6b) are from the usual sources. The anisotropic thermal parameters,

the hydrogen atom parameters, and the structure factors have been placed in the Depository of Unpublished Data.[2]

Discussion

The final positional parameters of the nonhydrogen atoms of **2** are presented in Table 1. ORTEP drawings of the molecule (7) giving the numbering system we have used are shown in Fig. 1. No unusual bond lengths (Table 2) or bond angles (Table 3) have been noted. Only one intermolecular contact significantly less than the sum of van der Waals radii (C 1.7, N 1.5, O 1.4, H 1.2 Å) was observed: O2···H20 = 2.41 Å where H20 is a phenyl ring hydrogen. Consequently, the geometry reported in Fig. 1 can be assumed, to a first approximation, to be that of the isolated molecule. A stereoscopic view of the unit cell is shown in Fig. 2.

The torsion angles of the five-membered ring (Table 4) disclose that the four atoms C6—C11—C12—C13 are closest to being coplanar (Table 5). The fifth atom of this ring, C1, lies 0.47 Å out of this plane and comprises the flap of the envelope.

[2]Copies of these tables may be obtained, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

[a]The plane is described in the crystal coordinate system according to the method given in ref. 9.

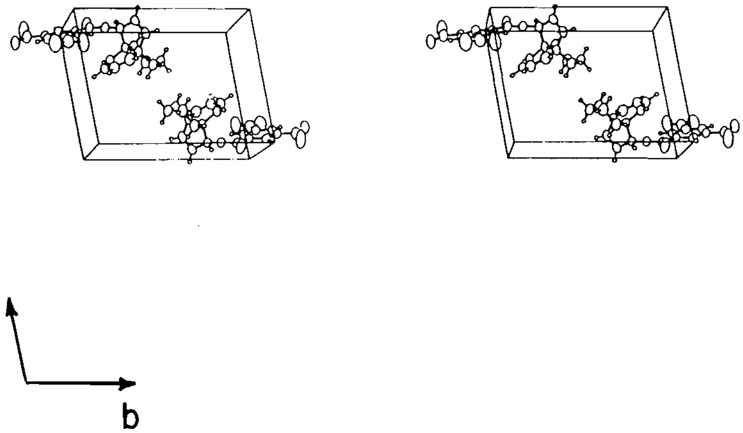

FIG. 2. Stereoscopic view of the unit cell for **2**.

Atom O1 lies on the opposite side of this four-atom plane and at a distance of 1.38 Å from it. The resulting cant projects the C13—O1 bond of the 3,5-dinitrobenzoate moiety directly over the central portion of the cyclohexadiene ring.

As concerns the latter, the data reveal that the four atoms C3—C4—C5—C6 most nearly define a plane. The remaining two atoms, C1 and C2, lie 0.52 Å and 0.20 Å, respectively, from this plane, and on the same side. The remaining cyclohexane ring is in a chair conformation. When a least-squares plane is fitted to the C6—C7—C9—C10 atoms, the C1 atom is 0.53 Å away from this plane, while the C8 atom is positioned 0.72 Å away and on the opposite side of this plane.

In view of the geometry characteristics of **2**, it is possible to conclude that its ionization is not sterically or torsionally impeded. Most notably, the three carbon atoms of the incipient allyl cation are not misaligned for eventual favorable interaction with the cyclohexadiene fragment. We presume therefore that the *exo/endo* rate differential which distinguishes **1/2** from **4/5** is most reasonably attributed to the facilitation of the direct conversion of **1** to **3** by the fused cyclohexane ring. The X-ray structure of molecule **1** might shed some light on this last point.

Ambident nucleophiles. III. N-bonded vs. C-bonded adduct formation on reaction of imidazolide anions with 1,3,5-trinitrobenzene

M. P. SIMONNIN, J. C. HALLE, F. TERRIER, AND M. J. POUET

Laboratoire de Spectroscopie et de Physicochimie des Solutions, U.A. 403 du CNRS, E.N.S.C.P., 11 Rue Pierre et Marie Curie, 75231 Paris, Cedex 05, France

Received July 6, 1984

M. P. SIMONNIN, J. C. HALLE, F. TERRIER, and M. J. POUET. Can. J. Chem. **63**, 866 (1985).

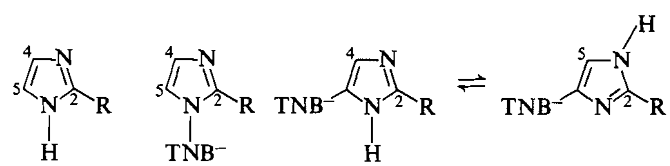
Imidazolide anions of imidazole, 2- and 4-methylimidazoles, 4,5-dimethyl and 4,5-diphenylimidazoles react with 1,3,5-trinitrobenzene (TNB) in dimethylsulfoxide (DMSO) to yield, initially, N-bonded σ-adducts under kinetic control. These undergo a subsequent conversion to C-adducts, which are the thermodynamically stable products. The formation of N,C-diadducts from the reversible attack of a second TNB molecule on the imidazolide moiety of the C-adducts is also observed. Provided that the corresponding position of the parent imidazolide anion is free, the formation of C-adducts occurs preferentially at the C-4 or C-5 carbon atom. However, C-2 substitution is observed in 4,5-disubstituted derivatives. Structures and preferred conformations of some adducts and diadducts are deduced from nOe experiments. The mechanisms of the various reactions are discussed. Evidence is presented that adduct formation results in a low-field shift of methyl groups located in a position adjacent to the substitution site, while all the other protons move upfield. This unusual deshielding presumably reflects a proximity effect between a methyl group and the hydrogen atom attached to the sp^3 carbon of the adducts.

M. P. SIMONNIN, J. C. HALLE, F. TERRIER et M. J. POUET. Can. J. Chem. **63**, 866 (1985).

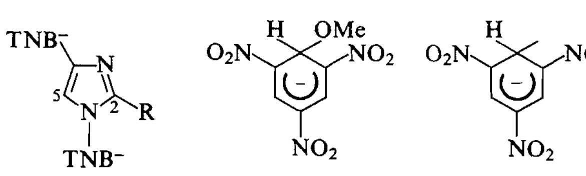
Dans le diméthylsulfoxyde (DMSO), le trinitro-1,3,5 benzène (TNB) réagit avec les anions imidazolate, méthyl-2 et méthyl-4 imidazolate, diméthyl-4,5 et diphényl-4,5 imidazolate pour donner initialement des complexes-σ azotés. Ces derniers disparaissent peu à peu au profit de complexes-σ carbonés qui sont les produits thermodynamiquement stables de la réaction. La formation de N,C-diadduits par attaque d'une seconde molécule de TNB sur la forme anionique des C-adduits est aussi observée. Le mécanisme des réactions est discuté. Il apparaît que les complexes carbonés résultent préférentiellement d'une attaque du TNB sur les carbones-4 ou -5 du noyau imidazole mais, dans les dérivés disubstitués-4,5 où ces positions sont occupées, la substitution électrophile se produit sur le carbone-2. Les structures et les conformations les plus favorisées des complexes ont été établies sur la base d'expériences nOe. Les études rmn montrent également, que, contrairement à ce qui se passe pour tous les autres protons, la formation des complexes entraîne un déplacement à champ faible d'un groupe méthyle adjacent au site de substitution. Ce résultat inattendu est probablement dû à un effet de proximité entre le groupe méthyle et l'hydrogène porté par le carbone sp^3 du complexe.

Imidazolide anions are known to be potential ambident nucleophiles, being able to undergo electrophilic attack by conventional electrophiles at a nitrogen or at a carbon atom (1, 2). Depending on the structures of the parent imidazoles and the experimental conditions, carbon attack may occur at C-2, C-4, or C-5.

In a recent communication (3), we have shown that unsubstituted imidazole anion $\mathbf{1}^-$ also acts as an ambifunctional nucleophile towards electron-deficient aromatics like 1,3,5-trinitrobenzene (TNB). In this case, the N-adduct **2** appears to form under kinetic control but the C-adduct **3**, which exists in the two tautomeric forms **3***a* and **3***b*, is the thermodynamically stable product. More significantly, the N,C-diadduct **4** was also observed. Inasmuch as this reaction provided the first example of the ambident reactivity of an imidazolide anion



R = H, **1** 2 **3***a* **3***b*
R = Me, **6** **7** **8***a* **8***b*



R = H, **4** **5** TNB⁻
R = Me, **9**

towards electrophilic aromatics, we thought it of interest to extend our study to differently substituted imidazolide anions. The results that we now report show that both N-1 and N-3 positions may be involved in the N-attack process when the anions are unsymmetrical. Moreover, TNB addition may take place at the three carbon positions of the imidazole ring.

Results

The reaction of TNB with imidazolide anions from 2-methyl, 4-methyl, 4,5-dimethyl, and 4,5-diphenyl imidazoles was studied in dimethylsulphoxide (DMSO) solution. The anions were generated first by adding an equimolar amount of methanolic potassium methoxide (5.54 *M*) to a solution of the parent imidazoles (0.3 *M*) in DMSO. Then, the resulting solution was added to a DMSO solution of TNB (0.3 *M*). Strong colors typical of TNB σ-adducts develop immediately. The course of the reactions was followed by ^{1}H nmr. An unambiguous distinction between N-bonded and C-bonded adducts could be made on the following grounds: (1) provided it could be observed, the presence of a broad NH signal at low field (~11 ppm) is typical of the C-adducts; (2) the observation that the AX_2 systems due to the cyclohexadienyl protons appear at higher field in the C-adducts than in the N-adducts, in agreement with electronegativity arguments and with previously reported results[1] (5–8). The cyclohexadienyl protons are noted $H_{1'}$, $H_{3'}$, $H_{5'}$ in the N-adducts and $H_{1''}$, $H_{3''}$, $H_{5''}$ in the C-adducts. In those instances where two N-bonded adducts were initially observed, nOe (nuclear Overhauser effect) experiments were carried out to determine structures. Also to be noted is the

[1] For recent reviews on Meisenheimer adducts, see ref. 4.

initial presence of some amounts of unreacted imidazoles and of the TNB-methoxide adduct **5** in all experiments; the reasons for this formation will be discussed in the forthcoming section.

2-Methylimidazole 6

In a general way, the reactivity of 2-methylimidazolide anion $\mathbf{6}^-$ towards TNB resembles that of unsubstituted imidazolide anion $\mathbf{1}^-$ (3). Nuclear magnetic resonance (nmr) spectra showed the initial formation of the N-adduct **7**. With time, **7** disappeared while two new species, which may be identified as the C-adduct **8** and the N,C-diadduct **9**, appeared. After a few weeks, **8** was the only species which existed in the solution. Table 1 allows the comparison of nmr data for the adducts from **1** and **6**. Peculiar features of interest are the following. While the three imidazolic protons of the N-adduct **2** give an AMX system which provides an unambiguous assignment of these protons, the two imidazolic protons of **7** give an AB system. In this case, the existence of a long-range coupling $J_{H_AH_{1'}} = 0.4$ Hz allows us to assign the low-field signal (H_A) to H_5. Accordingly, H_5 is deshielded relative to H_4 in both N-adducts **2** and **7**.

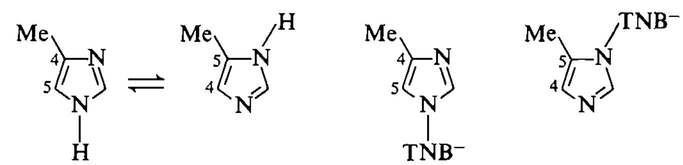
The observation of a broad signal at δ = 6.65 ppm for the imidazolic proton $H_{4(5)}$ of the C-adduct **8** indicates the existence of a tautomeric exchange **8***a* ⇄ **8***b* which prevents the detection of the NH signal. A similar tautomery was observed between **3***a* and **3***b* (3).

The structure of the diadduct **9** was assigned by analogy with the results for **4** (3). In this latter case, the observed coupling constant of 1.4 Hz was only consistent with a $^4J_{25}$ coupling, and therefore with structure **4**. Note that steric reasons are also expected to favor **4** or **9** rather than diadduct structures with two vicinal TNB^- moieties.

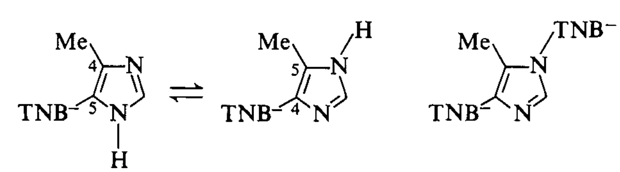
The nOe experiments were performed on the N-adduct **7**, the C-adduct **8**, and the N,C-diadduct **9**. Irradiation of the methyl signal of **7** resulted in a 15% enhancement of the integrated intensity of $H_{1'}$. In contrast, no nOe enhancement was detected between $H_{1'}$ and H_5. On the other hand, irradiation of the $H_{1''}$ signal of the C-adduct **8** resulted in a 17% enhancement of the integrated intensity of the imidazolic proton of **8**. Similarly, a 20% enhancement of H_5 of the N,C-diadduct **9** was observed when irradiating the $H_{1''}$ signal of **9**. The implications of these results in terms of preferred conformations of these adducts are discussed in the subsequent section (see Scheme 2).

4(5)-Methylimidazole 10

Due to its dissymmetrical structure, 4-methylimidazolide anion $\mathbf{10}^-$ may attack TNB via either of the nitrogen atoms N-1 or N-3. Indeed, the two N-adducts **11** and **12** were initially observed, though in quite different proportions, i.e. ~80:20. The spectra showed the presence of two very close AX_2 systems and two sets of two imidazolic protons and of methyl signals, with distinct chemical shifts (Table 2). These were assigned by nOe experiments, which indicated that the major species is **11** and the minor one **12**. In the case of **11**, irradiation of the $H_{1'}$ signal enhanced the integrated intensity of the H_2 signal by 20%. On the other hand, irradiation of the methyl signal of **12** enhanced the integrated intensity of the $H_{1'}$ signal by 17% (see Scheme 2).



10*a* **10***b* **11** **12**



13*a* **13***b* **14**

Conversion of **11** and **12** into the C-adducts **13** was nearly complete in several days. The spectrum of **13** showed the presence of only one imidazolic proton at δ = 7.28 ppm and a broad NH signal at 11.6 ppm. A broad signal was also observed

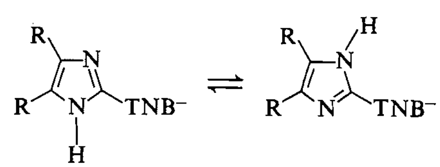
for the methyl group, suggesting the existence of a tautomeric equilibrium **13*a*** ⇄ **13*b***. An amount of the N,C-diadduct **14** was also evidenced by nmr, and its concentration was strongly increased by addition of a second equivalent of methoxide ion and of TNB. In addition to the two expected AX_2 systems, the spectrum of **14** showed only one imidazolic proton, the resonance of which gave a singlet. The structure **14** was attributed to this diadduct on steric grounds and confirmed by nOe experiments. Irradiation of the methyl signal of **14** enhanced the integrated intensities of $H_{1'}$ and $H_{1''}$ signals by 17% and 20% respectively. These effects unambiguously show that the two TNB^- moieties are not in a vicinal position, i.e. the diadduct corresponds to the tautomer **13*b*** of the C-adduct (see Scheme 2).

*4,5-Dimethyl and 4,5-diphenylimidazoles **15** and **18***

4,5-Dimethylimidazolide anion **15**$^-$ reacted with TNB to give the kinetically favored N-adduct **16**. The absence of a NH

R = Me, **15** R = Ph, **18**   **16** **19*** *Not observed



17*a* **20*a***   **17*b*** **20*b***

signal, the observation of a low-field imidazolic proton H-2, and the presence of two distinct methyl resonances with equal intensities are features typical of the dissymmetrical structure **16** (Table 3). With time, **16** disappeared and the C-adduct **17**, which has no imidazolic proton but a low-field NH signal, was formed. The observation of a single signal for the two methyl groups implies the existence of a rapid tautomeric exchange **17*a*** ⇄ **17*b***.

In contrast with its 4,5-dimethyl analog, 4,5-diphenylimidazolide anion **18**$^-$ does not form a N-adduct, i.e. **19**, on reaction with TNB. Only the formation of **5** with the concomitant recovery of the parent imidazole **18** was initially observed. Then, the nmr spectra showed the progressive formation of the C-adduct **20**, which was characterized by its cyclohexadienylic AX_2 system, a low-field NH signal at 11.5 ppm, and the absence of the H-2 imidazolic proton.

To be noted is that no N,C-diadduct formation could be detected, even under forcing conditions, i.e. with excess of methoxide ion and TNB, in these two 4,5-disubstituted imidazolic systems. Such adducts, which would necessarily have two vicinal cyclohexadienyl moieties, are expected to be disfavored on steric grounds. This conclusion is supported by the structure **14**, unambiguously established for the N,C-diadduct of 4(5)-methylimidazole (*vide supra*).

Discussion

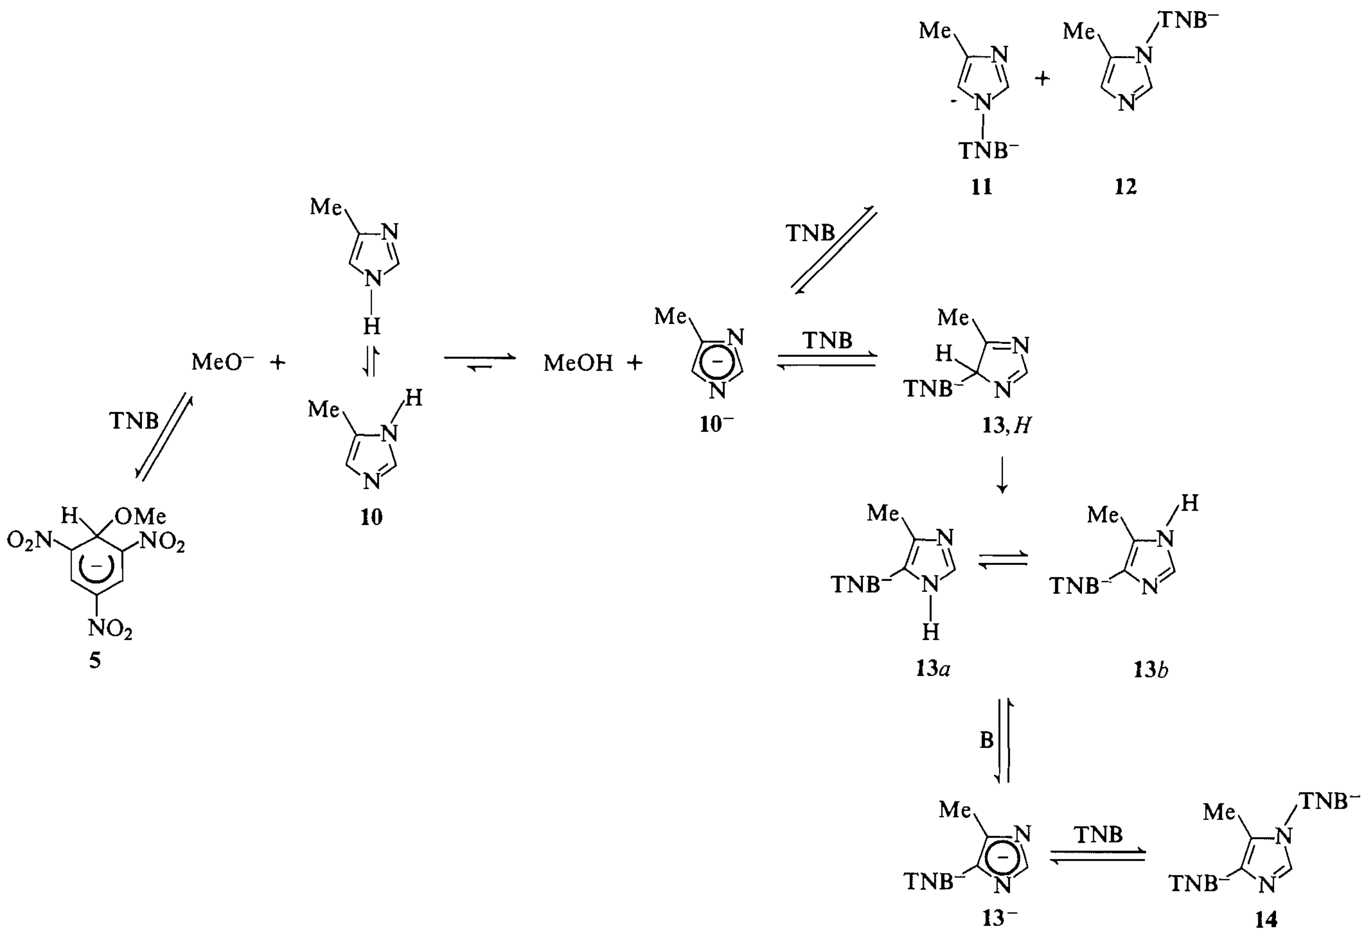
Mechanism of adduct formation

pK_a measurements of various imidazoles have shown that these derivatives are relatively acidic in H_2O–DMSO mixtures rich in DMSO and may be completely ionized by hydroxide ion in these media (9).[2] For instance, imidazole, 2-methylimidazole, and 4,5-diphenylimidazole have pK_a values of 17.15, 18.08, and 15.55, respectively, at 20°C in 5% H_2O – 95% DMSO (v/v), which are much lower than the ionic product of this mixture (pK_s = 24) (ref. 10). A similar situation prevails in H_2O–DMSO mixtures with >95% DMSO, as well as in methoxide solutions in DMSO–MeOH mixtures. On this ground, the most reasonable mechanism describing the interaction between TNB and the various imidazole anions is depicted in Scheme 1, which refers to the 4(5)-methylimidazole – TNB system.

Since the π-electron system of the imidazole ring is not interrupted by bond making at a nitrogen atom while it is at a carbon atom, the reaction of TNB with all imidazolide anions except **18**$^-$ results in the initial and reversible formation of the N-adducts, e.g. **11** and **12**, under kinetic control. Although the equilibrium concentration of MeO^- ions is small, the reversible formation of the methoxide complex **5** competes with that of the N-adducts, as a result of the well-known highly favored kinetic and thermodynamic factors associated with the formation of **5** from TNB and MeO^- (4*c*, 11). This latter adduct is the only one initially formed in the 4,5-diphenylimidazolide anion – TNB system. In this case, the nonobservation of the N-adduct **19** may be accounted for in terms of severe steric compression.

The formation of the C-adduct occurs in an essentially irreversible two-step sequence. The first step is the reversible formation of an imidazolenine intermediate, e.g. **13**, H, which subsequently rearranges to give the thermodynamically stable C-adduct, e.g. **13**. The non-observation of the imidazolenine intermediates suggest that they are not stable and that their rearomatization into the C-adducts is very fast. Indeed, this behavior is similar to that encountered in the case of the formation of the C-adducts of TNB and pyrroles or indoles (6). As previously discussed, on the basis of the absence of reaction between TNB and N-methylimidazole under the same basic

[2] Also, J. C. Halle and F. Terrier, unpublished results.



SCHEME 1

conditions as those used in this work (3), C-adduct formation from direct attack of carbanionic species of imidazoles may be safely excluded (12).

The negatively charged trinitrocyclohexadienate moiety is known to exhibit an appreciable acidifying effect (13–16). As a result, the NH group of the C-adducts is more acidic than that of the parent imidazoles and is deprotonated to some extent either by the equilibrium concentration of methoxide ions or by the imidazolide ions. Then, the resulting anions, e.g. **13⁻**, can attack free TNB, accounting for the reversible formation, under kinetic control, of the observed N,C-diadducts, e.g. **14**. As long as the experiments were performed in a 1 : 1 stoichiometry (1 equiv. Im^-/1 equiv. TNB), we observed that these N,C-diadducts ultimately disappear to give only the C-adducts. Clearly, the latter are thermodynamically more stable than the former. However, the N,C-diadducts could be regenerated by adding an equimolar mixture of MeO^- and TNB to the solutions of the C-adducts.

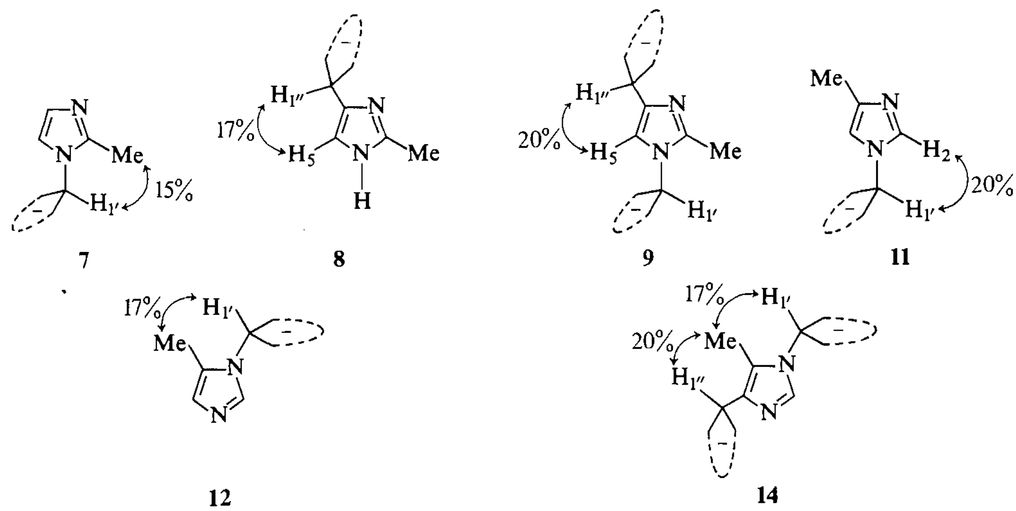
Although they are not thermodynamically stable products, the N-adducts may be isolated as crystalline potassium salts, provided that the experiments be done in acetonitrile instead of DMSO. Addition of ether precipitates red crystals, which rapidly turn to a gummy dark material if no care is taken to avoid contact with ambient moisture. Dissolution of these crystals in DMSO gives spectra similar to those observed from the *in situ* generation of the N-adducts. Similarly, we succeeded in precipitating the C-adducts by ether from the DMSO solution, when the isomerization of the N-adducts was essentially complete (see experimental section).

Preferred conformation of the adducts

Scheme 2 summarizes the results of the nOe experiments performed on various adducts. These suggest that the N- and C-adducts assume peculiar preferred conformations around their N—$C_{1'}$ or C—$C_{1''}$ bonds. In the case of the N-adduct **7** of 2-methylimidazole, the important effect between the 2-methyl group and $H_{1'}$ indicates a preferred conformation where $H_{1'}$ is spatially close to the methyl group, ie. where the TNB^- moiety is far removed from this group. In the corresponding C-adduct **8** and N,C-diadduct **9**, the nOe enhancements observed between $H_{1''}$ and H_5 suggest that, in their favored conformation, the C-TNB^- moiety lies in the vicinity of N-3. On the other hand, the N-TNB^- moiety of **9** presumably keeps the same orientation as in **7**.

However, the most interesting conformational results relate to the adducts of 4(5)-methylimidazole. Thus the nOe results show that the preferred conformation of the major N-adduct **11** is similar to that of **7**, despite the absence of a vicinal methyl group. In contrast, the $H_{1'}$ proton of the TNB^- moiety of the minor N-adduct **12** lies in the vicinity of the methyl group. Consequently, the H_2 proton of **12** is located in the proximity of the cyclohexadienate ring. A similar situation prevails in the favored conformation of the N,C-diadduct **14** where there is a proximal relationship between the 5-methyl group and each of the $H_{1'}$ and $H_{1''}$ protons.

The above results point out that the presence of a methyl substituent tends to favor a conformation where it is far away from the TNB^- moiety(ies). Such a situation was probably to be expected on the basis of steric grounds.



SCHEME 2

Proton chemical shifts

The imidazolic protons are more shielded in the N- and C-monoadducts than in the parent imidazoles. A further shielding occurs on formation of the N,C-diadducts. Similar trends are observed for the methyl groups when they are not attached at a carbon adjacent to the site of nucleophilic attack. In contrast, the methyl groups which are vicinal to a C-TNB^- or N-TNB^- moiety are deshielded relative to the parent imidazole. Moreover, in the N,C-diadduct **14**, where the methyl group is adjacent to both a N-TNB^- and a C-TNB^- moiety, an additional deshielding is observed relative to the N-adduct **12** or to the C-adduct **13**, suggesting that the effect is somewhat cumulative. Significantly, the deshielded methyl groups are those which are involved in a nOe enhancement, and consequently are spatially located close to the $H_{1'}$ or $H_{1''}$ protons bonded to the sp^3 carbons of the TNB^- moieties. This observation tends to indicate that the low-field shifts observed are related to a proximity effect (17, 18).[3] It is on this ground that we have attributed the two methyl resonances of the N-adduct **16** of 4,5-dimethylimidazole.

Experimental

Nuclear magnetic resonance spectra

The ^1H nmr spectra were recorded at 100 MHz (Varian XL 100) in the CW mode, using TMS as an internal standard. The nOe experiments were performed immediately after degassing the DMSO solutions by bubbling argon for 5 min.

Isolable adducts

Potassium salts of the C-adducts **3** and **13** of imidazole and 4-methylimidazole were precipitated from the DMSO solutions by addition of anhydrous diethyl ether (Et_2O). The purple crystals which formed were filtered, ground to a fine powder under an argon atmosphere, washed with copious amounts of anhydrous ether, and dried *in vacuo* to eliminate any associated solvent. The two adducts do not melt but decompose between 180 and 200°C. The ^1H nmr spectra of the isolated salts in DMSO-d_6 are similar to those observed in the *in situ* generation of **3** and **13**.

[3] A referee has suggested that another possible interpretation of this deshielding might be in terms of polarization of the methyl group (C-Me^+) by the adjacent and oppositively oriented dipole.

1,*n*-Radical ions. Photosensitized (electron transfer) and electrochemical oxidation of 1,1,2,2-tetraphenylcyclopropane[1]

DANIAL D. M. WAYNER AND DONALD R. ARNOLD[2]
Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received June 28, 1984

DANIAL D. M. WAYNER, and DONALD R. ARNOLD. Can. J. Chem. **63**, 871 (1985).

The photosensitized (electron transfer) and the electrochemical oxidation of 1,1,2,2-tetraphenylcyclopropane (**1**) have been studied. The products obtained from the photosensitized (electron transfer) study are 1,1,3,3-tetraphenylpropene (**2**), 1,3,3-triphenylindene (**3**), tetraphenylallene (**4**), and 3-methoxy-1,1,3,3-tetraphenylpropene (**8**). The product ratios are dramatically dependent upon the reaction conditions, particularly sensitizer (aromatic nitriles, tetracyanoethylene, chloranil, and 2,3-dichloro-5,6-dicyanobenzoquinone were used), and solvent. The variations in product ratios are attributed to variations in the redox behaviour of the sensitizer radical anion and upon the basicity and nucleophilicity of the medium. The products in the electrochemical study are **3**, **4**, and **8**. Common intermediates have been identified and a mechanism for the formation of products is proposed.

DANIAL D. M. WAYNER et DONALD R. ARNOLD. Can. J. Chem. **63**, 871 (1985).

On a étudié les oxydations photosensibilisées (transferts d'électrons) et électrochimiques du tétraphényl-1,1,2,2 cyclopropane (**1**). Les produits formés lors de l'étude photosensibilisée (transferts d'électrons) sont: le tétraphényl-1,1,3,3 propène (**2**), le triphényl-1,3,3 indène (**3**), le tétraphénylallène (**4**) et le méthoxy-3 tétraphényl-1,1,3,3 propène (**8**). Les rapports des produits formés varient d'une façon dramatique avec les conditions de la réaction et, en particulier, avec la nature du sensibilisateur (on a utilisé des nitriles aromatiques, le tétracyanoéthylène, le chloranil et la dichloro-2,3 dicyano-5,6 benzoquinone) ainsi qu'avec la nature du solvant. On attribue les variations observées dans les rapports des produits aux variations dans le comportement rédox de l'anion radicalaire du sensibilisateur et à la basicité ainsi qu'au caractère plus ou moins nucléophile du milieu. Lors des études électrochimiques, il y a formation de **3**, de **4** et de **8**. On a identifié la nature des intermédiaires communs et on propose un mécanisme pour la formation des produits.

[Traduit par le journal]

Introduction

The generation of radical ions in solution by photosensitization (electron transfer) is now recognized as a general reaction (3). There is intense research activity in this area, especially for the study of the formation and subsequent reactions of the radical cations (3). It is already apparent, however, that the observed reactions may not reflect the intrinsic reactivity of the radical cation: the nature of the acceptor radical anion often plays an important role, even in highly polar solvents where radical ion pair separation should be a fast process. Two recently reported examples, which involve initial formation of 1,3-radical cations, will illustrate this point.

The ultimate reaction of the 1,2-diphenylcyclopropane radical cation – sensitizer radical anion pair depends upon the sensitizer. When 1,4-dicyanonaphthalene is used as the electron accepting sensitizer, *cis–trans* isomerization of the 1,2-diphenylcyclopropane is observed (4). The proposed mechanism for this reaction, based upon a study involving photochemically induced dynamic nuclear polarization (CIDNP), indicates that back electron transfer from the sensitizer radical anion to the radical cation gives the 1,2-diphenylcyclopropane triplet (the trimethylene) which subsequently isomerizes. The energy of the donor–acceptor radical ion pair is greater than that of the triplet energy of 1,2-diphenylcyclopropane. On the other hand, when chloranil is used as the electron acceptor, no *cis–trans* isomerization occurs; CIDNP studies indicate the 1,2-diphenylcyclopropane radical cation is formed as before, but in this case back electron transfer yields only the sensitizer triplet, which is of lower energy than that of the 1,2-diphenylcyclopropane (4*b*). Apparently, *cis–trans* isomerization of the 1,2-diphenylcyclopropane radical cation is slow enough that it cannot compete with the back electron transfer process (5). In this case the critical factors which influence the reaction are the triplet energy of the radical ion pair and the triplet energy of the sensitizer relative to the triplet energy of the trimethylene.

In a closely related reaction, photosensitization (electron transfer) of phenylcyclopropane in methanol, using 1,4-dicyanobenzene as the acceptor, gives an almost equal mixture of the anti-Markownikoff addition product, methyl-3-phenylpropylether, and the photosubstitution product, 3-methoxy-1-(4-cyanophenyl)-1-phenyl propane (6). When 1,1-diphenylcyclopropane is subjected to these conditions, none of the analogous photosubstitution product is obtained; methyl-3,3-diphenylpropylether is formed in almost quantitative yield.

In both cases, the initial reaction of the radical cation is to add methanol to form the benzylic- or diphenylmethyl-type radical intermediate. In the case of phenylcyclopropane, coupling between the benzylic-type radical and the dicyanobenzene radical anion competes with the back electron transfer; i.e., reduction of the radical. With 1,1-diphenylcyclopropane, coupling between the diphenylmethyl-type radical and the dicyanobenzene radical anion cannot compete with reduction of the radical. The difference in reactivity is attributed to the differences in reduction potential of the intermediate radicals. The diphenylmethyl-type radical is considerably easier to reduce than the benzyl-type radical. While the reduction potential of this benzylic radical is not known, it will certainly be greater than that of the benzyl radical (−1.43 V vs. saturated calomel electrode (SCE), HMPA–THF, ref. 7) and may, in fact, be comparable to that of 1,4-dicyanobenzene (−1.6 V vs. SCE, acetonitrile, ref. 3). It therefore seems likely that the benzylic-type radical and anion will be in equilibrium with the dicyanobenzene radical anion and dicyanobenzene, while in the diphenylmethyl analogue ($E_{1/2}$ = −1.16 V vs. SCE, HMPA–THF, ref. 7) the equilibrium will be largely in favor of the anion. So, in this case, it is the reduction potential of the

[1]Portions of this work have been reported in preliminary communications (1, 2).
[2]Author to whom correspondence should be addressed.

sensitizer that ultimately determines the reactivity of the radical cation – radical anion pair.[3] A similar competition between addition of methanol and photosubstitution has been observed for olefin radical cations (8).

Another important characteristic of the sensitizer radical anion that can influence the fate of the radical cation is basicity; the radical cation may deprotonate, with the radical anion serving as base. The observed reaction will then depend upon the reactivity of the radical pair. The electron transfer process greatly increases the acidity of the donor (9) and the basicity of the acceptor, so proton transfer should frequently be favourable. Apparently, proton transfer is not always rapid enough to compete with other reactions or this process would be much more common.

Our awareness of the importance of these considerations originally developed from observations of the reactivity of 1,1,2,2-tetraphenylcyclopropane (**1**) radical cation that were apparently inconsistent. We have reported that the photosensitized (electron transfer) reaction of **1** in acetonitrile solution, using 1,4-dicyanonaphthalene as the electron accepting sensitizer, gave 1,1,3,3-tetraphenylpropene (**2**) in good yield (reaction [1] and ref. 1). In contrast, when tetracyanoethylene was used as the acceptor, 1,3,3-triphenylindene (**3**) was the only product (reaction [2]) (ref. 1). The mechanistic scheme we proposed for these reactions involved the 1,3-radical cation as a common intermediate which partitioned between two reaction pathways. Indene formation was thought to involve the 1,1,3,3-tetraphenylpropenyl cation. Yet it was known that this cation, generated by treatment of the alcohol precursor with acid, gave good yields of tetraphenylallene (**4**) (Reaction [3]) (ref. 10), and, the allene was not detected in either of these photosensitized reactions.

[1] 
[2] 
[3] 
[4] 
[5] 
A further complication was obvious from the work of Rao and Hixson which was reported about the same time as our results (6). As mentioned previously, 1,1-diphenylcyclopropane gives the methanol addition product upon irradiation in methanol with 1,4-dicyanobenzene as the electron acceptor. Similar irradiation of 1,1,2,2-tetraphenylcyclopropane gave good yields of the 1,1,3,3-tetraphenylpropene (**2**); no 1-methoxy-1,1,3,3-tetraphenylpropane (**6**) was detected (reaction [4]) (ref. 6). If the 1,1,3,3-tetraphenylpropenyl cation were involved in this reaction, 3-methoxy-1,1,3,3-tetraphenylpropene (**8**) should have been formed (reaction [5]).

These results were particularly surprising, not only because the 1-methoxy-1,1,3,3-tetraphenylpropane was not formed, but also because the 1,1,3,3-tetraphenylpropene was apparently stable under these conditions. We have shown that 1,1-diphenylethylene and other phenyl alkenes yield the product from the anti-Markownikoff addition of alcohol under these conditions (11), and, by analogy, 1,1,3,3-tetraphenylpropene should give 2-methoxy-1,1,3,3-tetraphenylpropane (**7**). However, this product also was not observed.

This plethora of possible products, six in all (**2–4**, **6–8**), from one relatively simple starting material, in fact, may not be unusual for reactions of this type. We were intrigued by the possibility that we could understand this complex behavior to the point where we could direct the reaction toward a specific product through seemingly minor variation in reaction conditions. Such an understanding is essential to the development of synthetically useful reactions in this area in general.

TABLE 1. Calculated free-energy change for electron transfer from **1**[a]

Acceptor	E_{00} (kcal mol^{-1})	E_{red} (V vs. SCE)	ΔG_{ET}[b] (kcal mol^{-1})
1,4-Dicyanobenzene (DCB)	98.6[c]	−1.60	−31.7
1,4-Dicyanonaphthalene (DCN)	79.6[c]	−1.28	−17.6
9,10-Dicyanoanthracene (DCA)	66.6[c]	−0.89	−14.6

[a]The oxidation potential of **1** is 1.36 V (E_p) in acetonitrile (1, 2).
[b]Calculated using the Weller equation (12) using $e^2/\epsilon\alpha$ = 0.06 eV.
[c]Reference 3.
[d]In these cases formation of a charge-transfer complex was indicated by a new adsorption band at long wavelength. The energy at the onset of the long wavelength charge-transfer absorption band is approximately 50 kcal mol^{-1}.

Results

*Photosensitized (electron transfer) irradiation of **1***

The pertinent characteristics of the electron accepting sensitizers used in this study are listed in Table 1. The reduction potentials were determined by cyclic voltammetry and, since analysis of the waves indicates the electrode processes are reversible, these values are thermodynamically significant. The anodic oxidation of **1**, however, is not reversible, so there is some uncertainty in the oxidation potential (2). The free energies for the electron transfer were calculated using the Weller equation (eq. [6]) (ref. 12).

$$[6] \quad \Delta G^0_{ET} = 23.06\,(E_{ox}(\text{donor}) - E_{red}\,(\text{acceptor}) - e^2/\epsilon\alpha) - E_{00}$$

The results of the irradiations are summarized in Table 2. Sensitizers 1,4-dicyanobenzene (DCB), 1,4-dicyanonaphthalene (DCN), 9,10-dicyanoanthracene (DCA), and methyl-4-

[3]Steric factors may also influence this reaction; it would be more difficult for the more hindered diphenylmethyl-type radical to couple with the dicyanobenzene radical anion.

cyanobenzoate (MCB) all lead to formation of 1,1,3,3-tetraphenylpropene (**2**) in acetonitrile solution (reaction [1]).

Rao and Hixson (6) have reported that **2** also was formed from **1** upon irradiation in methanol solution. We have confirmed this observation; when the irradiation is carried out in acetonitrile–methanol (3:1, v/v) only **2** is produced. No product resulting from the addition of methanol (neither **7** nor **8**) was detected. When this irradiation is carried out in acetonitrile – methanol – O-*d*, the product (**2**) has deuterium (>95%) incorporated at the allylic position. Extended irradiation of **2** under these conditions does *not* cause incorporation of deuterium nor methanol addition (7).

Using tetracyanoethylene (TCNE) as the acceptor, irradiation, in acetonitrile, of the charge-transfer band leads to the formation of 1,3,3-triphenylindene (**3**) (1). Careful analysis of this reaction mixture by high pressure liquid chromatography (hplc) indicates the presence of a trace of tetraphenylallene (**4**) (the ratio of indene (**3**) to allene (**4**) is 19:1) which was not detected in the previous work. Similar irradiation of this mixture, but with tetraethylammonium perchlorate (TEAP, 0.1 *M*) added, gives the same products in the same ratio.

On the other hand, with chloranil (TCQ) as the electron acceptor, irradiation of the charge-transfer complex in acetonitrile leads to the formation of tetraphenylallene (**4**) as the major product. Analysis of the reaction mixture by hplc indicates the ratio of **3** to **4** is 1:9 with this sensitizer. This ratio also does not change when the irradiation is carried out in acetonitrile containing 0.1 *M* TEAP. When this irradiation was carried out in acetonitrile–methanol (3:1, v/v) the product is 3-methoxy-1,1,3,3-tetraphenylpropene (**8**, reaction [5]).

When 2,3-dichloro-5,6-dicyanobenzoquinone (DDQ) is used as the electron accepting sensitizer, irradiation of the charge-transfer band, in acetonitrile solution, leads to the formation of substantial amounts of both **3** and **4** (1:3.5).

Controlled potential electrolysis of 1

The results from the controlled potential oxidation of **1** under various conditions are summarized in Table 3. The anodic oxidation of **1** in acetonitrile (0.1 *M*, TEAP) at 1.3 V (vs. SCE) leads to the formation of 1,3,3-triphenylindene (**3**) (2); tetraphenylallene (**4**) was not detected. When the electrolysis is carried out under similar conditions, but with 2,6-lutidine (0.1 *M*) added to the anolyte, the product is predominantly **4**; only a trace (<3%) of **3** is present under these conditions. Electrolysis of **1** in acetonitrile–methanol (3:1, v/v) results in the formation of 3-methoxy-1,1,3,3-tetraphenylpropene (**8**, reaction [6]).

Electrochemical measurements of 1

Cyclic voltammetric studies were carried out in both acetonitrile (0.1 *M* TEAP), and dichloromethane (0.1 *M* tetrabutylammonium perchlorate, TBAP) (2). In acetonitrile, two irreversible anodic waves are observed at E_p = 1.36 V and E_p = 1.58 V, at a sweep rate of 400 mV s^{-1}. As the sweep rate increases from 50 mV s^{-1}, the relative height of the second wave decreases and it is not detected at sweep rates faster than 1.0 V s^{-1} (Table 4).

The cyclic voltammogram of 1,3,3-triphenylindene (**3**) reveals a sharp anodic wave ($E_p - E_p/2$ = 40 mV) at 1.58 V at a sweep rate of 400 mV s^{-1}. The cyclic voltammogram of this solution after an equimolar amount of **1** has been added does not exhibit the wave at 1.36 V. The peak current for the wave at 1.58 V, on the other hand, doubles in value for this mixture (Fig. 1).

The cathodic sweep reveals the presence of a reversible wave at $E_{1/2}$ = 0.34 V and an irreversible wave at E_p = 0.17 V. The intensity of the reversible wave decreases if the cathodic sweep is delayed.

At the onset of oxidation of **1**, the acetonitrile solution around the anode turns visibly purple. A solution of 1,1,3,3-tetraphenylpropenol (**5**) in acetonitrile (0.1 *M* TEAP) containing trifluoroacetic acid (5×10^{-3} *M*) turns the same colour. The cyclic voltammogram of this solution also reveals a reversible wave at $E_{1/2}$ = 0.34 V.

Cyclic voltammetric studies in dichloromethane (0.1 *M* TBAP) were similar to those in acetonitrile, the main difference being that while there is an anodic wave at 1.36 V, the second anodic wave at 1.58 V is not observed. There is a quasi-reversible wave at $E_{1/2}$ = 0.37 V. The onset of oxidation again is accompanied by the development of a purple colour near the surface of the electrode, as was the case in acetonitrile.

Spectroelectrochemical measurements

The anolyte turns purple as soon as the potential is applied. The visible absorption spectrum of this solution shows three broad absorption maxima (λ_{max} = 568 nm, 459 nm, 382 nm) of

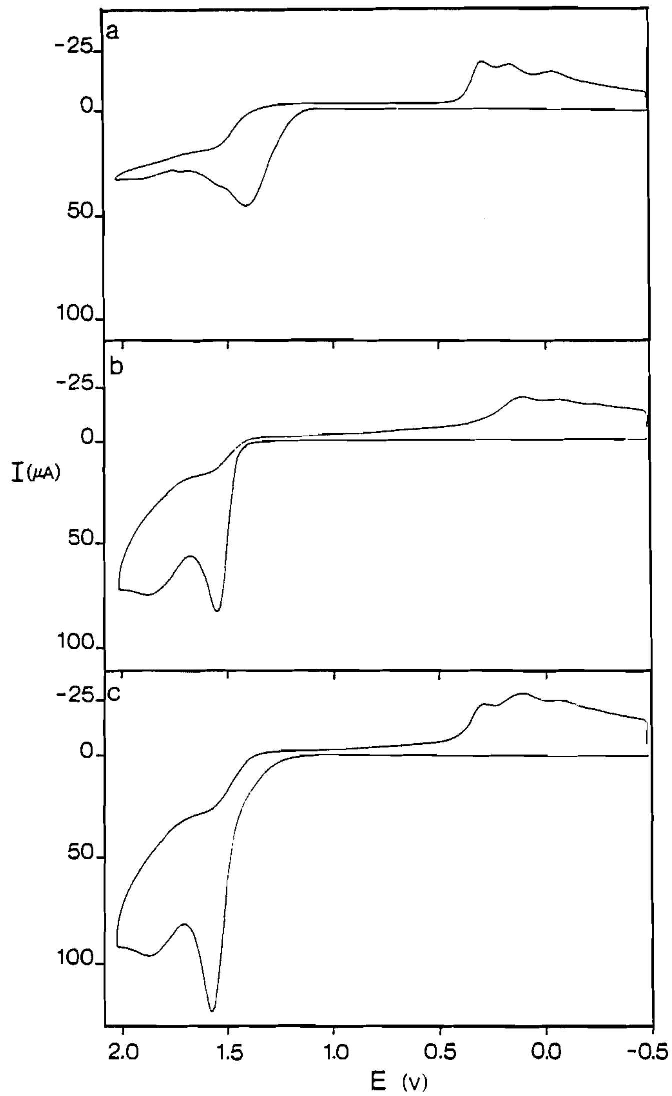

FIG. 1. Cyclic voltammograms in acetonitrile, 0.1 M TEAP at 400 mV s^{-1} of (a) **1** (1.5×10^{-3} M), (b) **3** (1.5×10^{-3} M), and (c) **1** (1.5×10^{-3} M) and **3** (1.5×10^{-3} M) illustrating that the adsorbed **3** insulates the electrode from the solution until the discharge potential of 1.58 V is reached.

approximately equal intensity. This spectrum is essentially identical to the spectrum obtained from the 1,1,3,3-tetraphenylpropenol in acetonitrile (0.1 M TEAP) to which trifluoroacetic acid has been added. The irradiation of the charge-transfer band between **1** and TCNE, TCQ, or DDQ results in the development of a coloured intermediate with a similar visible absorption spectrum, within a few seconds of irradiation. This colour slowly disappears if the vessel is removed from the irradiation source.

The rate of disappearance of the coloured intermediate can be measured using an electrolysis cell fitted with Pyrex windows (see Experimental). The rate of disappearance of the colour follows first-order kinetics with a rate constant of 2.87×10^{-2} s^{-1} at 23°C. The same rate constant is obtained whether monitoring the absorption at 460 nm or 570 nm (at 380 nm background absorption interferes with the measurement). Furthermore, the rate is independent of electrolyte concentration over the range 0.1 to 0.001 M TEAP (cell resistance precluded measurements at lower concentrations).

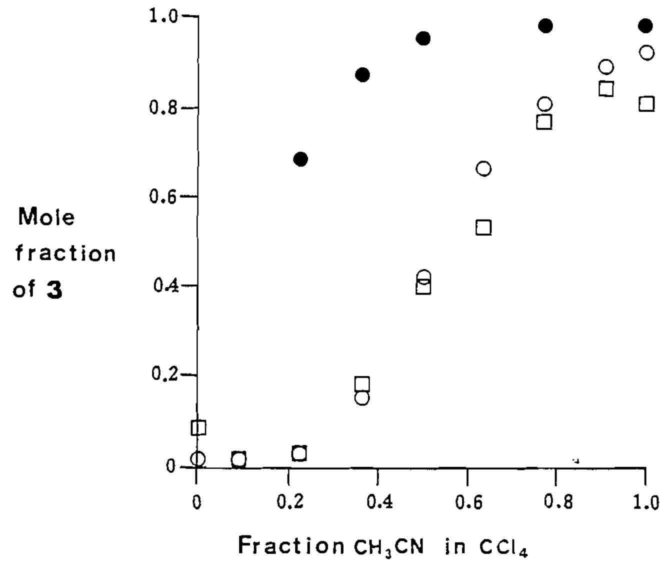

FIG. 2. Mole fraction of **3** (the remainder is **4**) versus the fraction (by volume) of acetonitrile in carbon tetrachloride from the reaction of **5** with (a) ● toluenesulphonic acid, (b) □ trifluoroacetic acid, and (c) ○ trichloroacetic acid.

TABLE 5. Effect of temperature on the rate of the unimolecular reaction of 1,1,3,3-tetraphenylpropenyl cation in acetonitrile (0.1 M TEAP)

T (°C)[a]	k_{obs} (s^{-1})
37.6	0.15±0.01
33.2	0.092±0.001
28.3	0.053±0.001
23.2	0.029±0.002
19.6	0.017±0.002
11.9	0.0063±0.0001

[a]±0.1°C.

The temperature dependence of the rate constant (Table 5) leads to an estimate of the activation energy for loss of the intermediate of 21.8±0.6 kcal mol^{-1} and a preexponential factor (log A) of 14.5 ± 0.4.

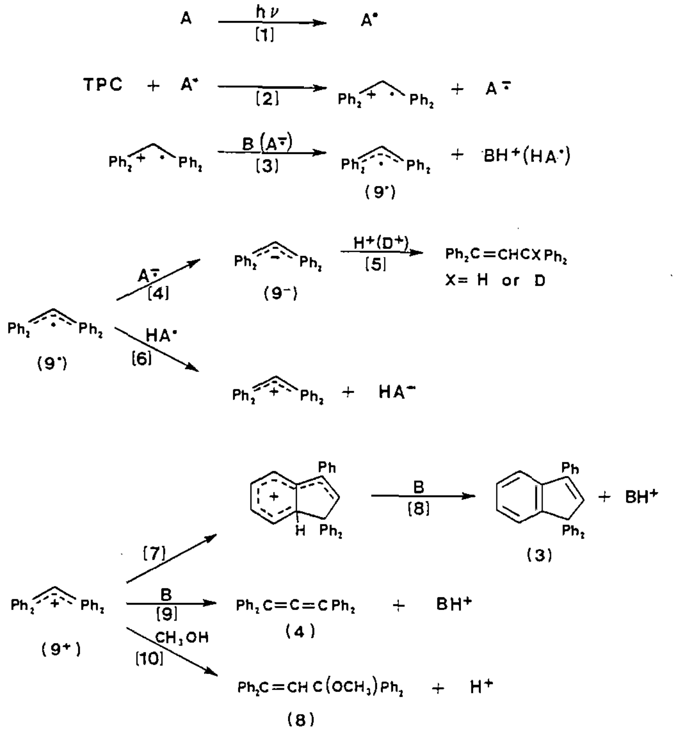
Solvent and acid effects on the ratio 3/4

The products obtained by treatment of **5** in mixtures of acetonitrile and carbon tetrachloride with an acid are **3** and **4**. These products are obtained in chemical yields greater than 90%. The ratio (**3**/**4**) decreases as the percentage of acetonitrile decreases (Fig. 2). While there appear to be no significant differences between trifluoroacetic acid and trichloroacetic acid, p-toluenesulphonic acid gives a significantly higher ratio (**3**/**4**) in all solvent mixtures.

Discussion

The products obtained upon photosensitized (electron transfer) oxidation of **1** are remarkably dependent upon reaction conditions, particularly solvent and sensitizer. Although some of these observations were reported several years ago (1, 6), the mechanism has never been discussed in detail. The sequence outlined in Scheme 1 can account for all the results.

The first two steps, initial excitation of the electron accepting sensitizer and electron transfer to give $1^{\cdot+}$ and $A^{\cdot-}$, are well established. All of the irradiations were carried out through



SCHEME 1

Pyrex, so wavelengths shorter than 290 nm are absorbed by the vessel. The sensitizers have appreciable absorption at longer wavelengths, while **1** is essentially transparent beyond 300 nm. The electron transfer step is thermodynamically favourable in every case (Table 2). Table 1 lists the free-energy change for this process as estimated by the Weller equation (12). With the quinone sensitizers (DDQ and TCQ) the triplet state is undoubtedly involved because of the rapid intersystem crossing in these cases. When the sensitizer forms a charge-transfer complex with **1** (TCNE, TCQ, DDQ) irradiation in the wavelength region of the charge-transfer transition can lead directly to the radical ion pair.

The deprotonation of $\mathbf{1}^{\cdot +}$ (Scheme 1, Step 3) dominates the chemistry after the electron transfer has occurred. In many instances in the literature, when a mechanism involving the deprotonation of a radical cation is proposed, the fate of the proton is essentially ignored until it is needed again to protonate another intermediate. In some cases the deprotonation does not seem to occur when it is predicted that it should, while in other cases the anion radical is thought to serve as the base. It is of fundamental importance to understand what is occurring and why. The first requirement is to estimate the pK_a of $\mathbf{1}^{\cdot +}$.

We have developed several thermochemical cycles which can be used to estimate the pK_a of a radical cation from available thermochemical data (9). An estimate can be made if the oxidation potential of RH (E^0_{RH}) and the bond dissociation energy of R—H (ΔG_{BDE}) are known. In this case, eq. [7] can be used,

$$[7] \quad pK_a = 0.73\,(-FE^0_{RH} + \Delta G^0_{BDE} + \Delta G^0_{tr(H^+)} + \Delta G^0_{f(H)} + \Delta G^0_{isom})$$

where $\Delta G_{tr(H^+)sol}$ is the free-energy associated with the transfer of a proton from water to the solvent of interest, $\Delta G_{f(H)g}$ is the free-energy of formation of a hydrogen atom and, ΔG_{isom} is the free-energy associated with the isomerization of the cyclopropyl radical to the allyl radical, Fig. 3.

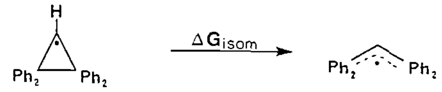


FIG. 3. The isomerization of 2,2,3,3-tetraphenylcyclopropyl radical to 1,1,3,3-tetraphenylpropenyl radical.

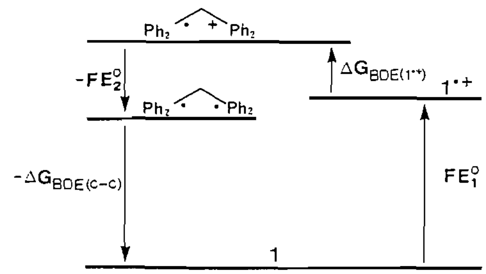

FIG. 4. Thermochemical cycle to estimate the strength of the one-electron, two-centre bond in $\mathbf{1}^{\cdot +}$.

To determine the pK_a of $\mathbf{1}^{\cdot +}$, the value of E^0_{RH} is estimated from the E_{ox} (1.48 V vs. NHE); $\Delta G_{tr(H^+)sol}$ is 11 kcal mol^{-1} for acetonitrile (13); $\Delta G_{f(H)g}$ is 48.6 kcal mol^{-1}, and $\Delta G_{BDE(RH)}$ is approximately 96±3 kcal mol^{-1} (14). The free-energy change associated with the isomerization from the cyclopropyl to the allylic structure must also be estimated. In the unsubstituted $C_3H_5^{\cdot}$ radical this value is approximately −25 kcal mol^{-1} (14). The extra stabilization associated with the four phenyl groups[4] should not account for more than −14±3 kcal mol^{-1}, so ΔG_{isom} should then be approximately −39±3 kcal mol^{-1}. Substitution of these values into eq. [7] gives an estimate of −11±4 for the pK_a of $\mathbf{1}^{\cdot +}$.

Another approach can be used to obtain an estimate of this number. The pK_a of the 1,1-diphenylethyl cation (in water) is approximately −6 (16). The pK_a value in acetonitrile, based on the free-energy of transfer of the proton (11 kcal mol^{-1}) and the hydrocarbon fragments (−2±2 kcal mol^{-1}), should be about 0.6±1. This number must be corrected for the allylic stabilization gained upon deprotonation (14±3 kcal mol^{-1}) and the strength of the one-electron two-centre bond being broken. An estimate of the strength of this bond may be obtained from the cycle shown in Fig. 4. The value of ΔG_{BDE} (C—C) is estimated from the activation barrier to thermal isomerization, which is about 30 kcal mol^{-1} (17). The oxidation potential E^0_2 should be approximately the same as the oxidation potential of the 1,1-diphenylethyl radical (approx. 0.42 V vs. NHE) (18) and the oxidation potential of **1** is given above. This gives an estimate of 6 kcal mol^{-1} for the strength of the one-electron two-centre bond of $\mathbf{1}^{\cdot +}$. Therefore, the pK_a of $\mathbf{1}^{\cdot +}$ should be:

$$pK_a = 0.6\pm1 - 0.728\,(14\pm3 - 6) = -5\pm3$$

It is, therefore, not surprising that $\mathbf{1}^{\cdot +}$ deprotonates. Furthermore, this process should be rapid because the C—H bond being broken can be parallel to the vacant *p*-orbital.

It is reasonable to assume that the sensitizer radical anion could serve as the base for the deprotonation of $\mathbf{1}^{\cdot +}$. In those cases where the sensitizer is reduced (TCNE, TCQ, and DDQ) this occurs. In fact, even in those cases where the sensitizer is not reduced (DCN, DCB, DCA, and MCB), and **2** is the

[4]This is based on ΔG^0_{BDE} (C—H) in diphenylmethane relative to the ΔG^0_{BDE} (C—H) in ethane (15).

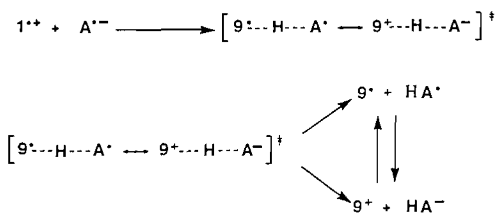
product, protonation of the sensitizer radical anion still may be favourable.[5] However, in these cases, Scheme 1, Step 4 requires the radical anion to reduce $\mathbf{9}^{\cdot}$. If proton transfer to these radical anions is slow, the radical cation, $\mathbf{1}^{\cdot+}$, is acidic enough to protonate the solvent. There are other possible mechanisms for the formation of **2** which involve $HA^{\cdot}$, disproportionation of the radical $\mathbf{9}^{\cdot}$, for example. However, the observed deuterium incorporation in **2**, from methanol-O-*d*, argues against this alternative.

The next step in the reaction scheme, Step 4, involves a reduction of $\mathbf{9}^{\cdot}$ by the sensitizer radical anion. The reduction potential of $\mathbf{9}^{\cdot}$ is known (−0.94 V vs. SCE, ref. 21). Table 1, which lists the reduction potentials of the sensitizers, clearly indicates that the radical anions of all of the aromatic nitriles are capable of reducing $\mathbf{9}^{\cdot}$ to $\mathbf{9}^{-}$; even DCA, where the electron transfer is almost isoenergetic. Furthermore, the radical anions of the other sensitizers (TCNE, TCQ, and DDQ), which do not give **2** as a product, are *not* capable of reducing $\mathbf{9}^{\cdot}$. Following the reduction of $\mathbf{9}^{\cdot}$, protonation of $\mathbf{9}^{-}$ (Scheme 1, Step 5) completes the mechanism for the formation of **2**.

The reduction of $\mathbf{9}^{\cdot}$ and subsequent protonation of $\mathbf{9}^{-}$ explains the high degree of incorporation of deuterium at the allylic position with no scrambling. The absence of observable isotopic scrambling in **2** also rules out reversibility for the deprotonation of $\mathbf{1}^{\cdot+}$ (9).

An alternative mechanism for the incorporation of deuterium in **2** might be deprotonation of $\mathbf{2}^{\cdot+}$ to form $\mathbf{9}^{\cdot}$ followed by reduction and subsequent deuteration. However, when a solution of **2** and 1,4-dicyanonaphthalene (DCN) are irradiated in acetonitrile − methanol-O-*d*, no deuterium exchange is observed.

This result raises several new questions. Since the formation of the highly stabilized radical, $\mathbf{9}^{\cdot}$, should be a driving force for deprotonation of $\mathbf{2}^{\cdot+}$, it is not immediately obvious why $\mathbf{1}^{\cdot+}$ deprotonates while $\mathbf{2}^{\cdot+}$ does not[6]. Furthermore, the inability of both $\mathbf{1}^{\cdot+}$ and $\mathbf{2}^{\cdot+}$ to react with methanol is unexpected (3, 8), especially in the case of $\mathbf{2}^{\cdot+}$ since 1,1-diphenylethylene under similar conditions reacts to form the anti-Markownikoff



SCHEME 2

addition product in high yield (11). Also, 1,1-diphenylcyclopropane and phenylcyclopropane react to add methanol. Products resulting from the deprotonation of the radical cation of 1,1-diphenylcyclopropane or phenylcyclopropane were not reported in these cases either (6).

The radical cation $\mathbf{1}^{\cdot+}$ must preferentially deprotonate. The bulky phenyl groups will inhibit the addition of methanol, allowing the deprotonation to compete effectively. The addition of methanol to $\mathbf{2}^{\cdot+}$ must also be hindered. It is known that the rate of addition of methanol to olefin radical cations decreases markedly as the olefin becomes more heavily substituted (3, 18). The preferred conformation of the diphenylmethyl group in **2** (and presumably $\mathbf{2}^{\cdot+}$) has the C—H bond perpendicular to the olefinic π-bond.[7] The phenyl groups, therefore, effectively hinder the addition of methanol. This conformational preference, which has been observed in other systems (23), also accounts for the apparent lack of acidity of $\mathbf{2}^{\cdot+}$.

Consider next, Scheme 1, Step 6, the oxidation of $\mathbf{9}^{\cdot}$. It is clear that the deprotonation of $\mathbf{1}^{\cdot+}$ to $A^{\cdot-}$ (Step 3) and electron transfer (Step 6) can occur simultaneously, and that this process is equivalent to hydrogen atom transfer from $\mathbf{1}^{\cdot+}$ by $A^{\cdot-}$ (Scheme 2). In effect, the transition state can be more or less polar. Nevertheless, it is useful to consider these various steps independently in order to assess the energetics of the overall process.

If proton transfer were to occur between $\mathbf{1}^{\cdot+}$ and $\mathbf{A}^{\cdot-}$, then, if the reduction potential of $HA^{\cdot}$ is greater than the oxidation potential of $\mathbf{9}^{\cdot}$ (i.e., $E_{ox}(\mathbf{9}^{\cdot}) - E_{red}(HA^{\cdot}) < 0$), the subsequent electron transfer to form $\mathbf{9}^{+}$ would be fast. On the other hand, if $E_{ox}(\mathbf{9}^{\cdot}) - E_{red}(HA^{\cdot}) > 0$, then, even if hydrogen atom transfer were to occur, the ion pair would undergo an electron transfer to generate the radical pair.

There is independent evidence, at least in the case of TCQ, where $\mathbf{9}^{+}$ is observed, that $E_{ox}(\mathbf{9}^{\cdot}) - E_{red}(HA^{\cdot}) < 0$. The electrochemistry of several quinones and hydroquinones (not DDQ or TCQ) has been studied previously (24). The oxidation of hydroquinones in the presence of bases such as pyrrolidine, 2,6-lutidine, and pyridine results in a new wave at about 0.7 V below the oxidation potential of the hydroquinone (25). In the case of 1,4-hydroquinone (QH_2), the anodic wave for the oxidation of the hydroquinone disappears upon addition of two equivalents of 2,6-lutidine to the anolyte (25*b*). Under these conditions, a new wave at $E_p = 0.67$ V was attributed to the

[5]Consider, for example, the protonation of $DCN^{\cdot-}$ by $\mathbf{1}^{\cdot+}$. The required values of ΔG^0_{BDE}, ΔG^0_{isom}, and E^0_{ox} have been discussed above. The value of E_{red} for DCN is in Table 1. Therefore, only an estimate of ΔG_{BDE} of the C—H bond to be made in $DCNH^{\cdot}$ is required. The enthalpy of reaction for 1,4-dihydronaphthalene to give naphthalene and two hydrogen atoms can be calculated (109.9 kcal mol^{-1}) from information in standard tables (19). The BDE of the C—H bond in 1,4-dihydronaphthalene is approximately 75±2 kcal mol^{-1} (15). This would give a BDE of 35±2 for the second C—H bond. It is known that a cyano group decreases the C—H BDE by approximately 6 kcal mol^{-1} (20). On the other hand, the other cyano group will stabilize the radical ($DCNH^{\cdot}$) to some degree, and both cyano groups will be conjugated in the product. The overall effect on the BDE may be as much as −4±2 kcal mol^{-1}. This would give a value of 22±3 kcal mol^{-1} for ΔG^0_{BDE} ($DCNH^{\cdot}$). The ΔG^0 for protonation of $DCN^{\cdot-}$ by $\mathbf{1}^{\cdot+}$ would then be −27±6 kcal mol^{-1}. Similar reasoning suggests that protonation of the radical anion of DCB, DCA, and MCB is also favourable.

[6]Using a thermochemical cycle similar to that above, the pK_a of $\mathbf{2}^{\cdot+}$ also may be calculated. The oxidation potential (E_{ox} of **2** is 1.80 V (vs. NHE) and the free energy associated with the bond dissociation is about 72 kcal mol^{-1}. The estimated pK_a of $\mathbf{2}^{\cdot+}$ is −5±2. Therefore, $\mathbf{2}^{\cdot+}$ should deprotonate in methanol. Since deprotonation of $\mathbf{2}^{\cdot+}$ is favourable from thermochemical considerations, the reason for the lack of apparent acidity must be kinetic in nature.

[7]Evidence for this conformational preference is based on observed vicinal $^1H-^1H$ coupling constants (16). The $^1H-^1H$ coupling in **2** is 10 Hz while in an analogous compound, 1,3-diphenylindene, where the dihedral angle is approximately 60 degrees, the $^1H-^1H$ coupling constant is only 2 Hz (17). The proton chemical shifts for the allylic and vinyl proton in **2** are δ 4.75 and δ 6.45 respectively. Those for 1,3-diphenylindene are δ 4.55 and δ 6.49 respectively.

oxidation of $QH^- \rightarrow Q + H^+ + 2e^-$.[8] Similarly, the oxidation of $TCQH_2$ in acetonitrile occurs at E_p = 1.56 V. Addition of 2,6-lutidine (1.5 equivalents) to the anolyte produces a new wave at E_p = 0.60 V attributable to the oxidation of $TCQH^-$.[9] Since E_{ox} ($9^\cdot$) − E_{red} ($TCQH^\cdot$) = −0.26 V, the observation of 9^+ is expected.

Irradiation of the charge-transfer complex between **1** and TCNE, DDQ, or TCQ results in the formation of mixtures of **3** and **4** as well as the reduced acceptors. The mechanism for the formation of **3** and **4** via 9^+ is shown in Scheme 1, Steps 7–9.

The proposed cyclization of the cation 9^+ is in apparent contradiction of reported behavior. Treatment of 1,1,3,3-tetraphenylpropenol (**5**) with *p*-toluenesulphonic acid in ethyl acetate gave an almost quantitative yield of **4** (10). We find, however, *that with acetonitrile as solvent*, treatment of **5** with *p*-toluenesulphonic acid leads to an almost quantitative yield of **3** (2). As the percentage of carbon tetrachloride in acetonitrile increases, the proportion of **4** progressively increases (Fig. 2). A weaker acid (trifluoroacetic acid or trichloroacetic acid) produces a much more dramatic effect than the strong acid (*p*-toluenesulphonic acid).

These results are rationalized by considering the effect of the solvent polarity on the strength of the acid (or it's conjugate base) (28). The dielectric constant of binary solvent mixtures of carbon tetrachloride and acetonitrile as a function of mole fraction of carbon tetrachloride is almost linear. As the solvent polarity decreases, the strength of the conjugate base increases, so the deprotonation of 9^+ becomes more favourable. The strong acid (*p*-toluenesulphonic acid) leads to a higher ratio of **3**/**4**. The pK_a of trichloroacetic acid is similar to that of trifluoroacetic acid, so it is not surprising that the plots obtained in Fig. 2 are similar.

This explanation may be oversimplified. Acid–base equilibria in aprotic solvents are complex. Besides the equilibrium for salt formation, equilibria for acid dimerization, $(HA)_2$, homoconjugate ion formation, $(A—H——A)^-$, and, in the case of **5**, the pK_{R^+}, are also important. In general, weaker acids dimerize more readily in aprotic media. On the other hand, homoconjugate ion formation is more favourable with stronger acids. The ability of the conjugate base to accept a proton, however, depends on its charge, size, polarizability, and, to some extent, steric factors (i.e. the same factors that are important in aqueous media). However, it is clear that relative pK_a's in aprotic solvents are very much attenuated, relative to those values measured in water (28). Most of this difference is a result of the heat of transfer of the proton from water to acetonitrile. (In the reaction of 9^+ in ethyl acetate, the solvent apparently acts as the base.)

The formation of indenes from the allylic cations has been reported. Pittman and Miller (29) have found that allylic cations such as the 1,1,3-triphenylpropenyl cation are stable at low temperature in strong acid. Warming these solutions induced cyclization to form stable solutions of the indanyl cation. Quenching with base led to an almost quantitative yield of the corresponding indene. In these solutions, the intermediate cyclohexatrienyl cations were not observed, which implies that Scheme 1, Step 8 is rapid, probably a result of the driving force for aromatization upon proton loss.

It is clear, therefore, that the ratio of **3** to **4** is sensitive to the basicity of the medium. The observed dependence of the ratio of **3** to **4** on the sensitizer (Table 2) may be explained on this basis. The ratio of **3** to **4** decreases in the order TCNE > TCQ > DDQ. This follows expected base strength of the anions HA^-. The difference in base strength of the anions (HA^-) can also account for the qualitative observation that the steady-state concentration of 9^+ is greater with TCNE as the sensitizer than with TCQ (see below).

The possibility that $9^\cdot$ may cyclize to lead, ultimately, to **3**, or, that $9^\cdot$ may disproportionate to give **4** should be considered. Dietz *et al.* (21) found that a stable solution of 9^- could be oxidized to form a stable solution of $9^\cdot$ (which gave a well-resolved esr spectrum). The solution of $9^\cdot$ could be reduced back to 9^- with no apparent reaction.

The irradiation of the charge-transfer complex between **1** and TCQ in acetonitrile–methanol (3:1, v/v) leads to the formation of **8** in good yield (based upon hplc analysis of the crude reaction mixture). The isolation of **8** is not straightforward; only half of this ether was eluted from a silica gel flash chromatographic column even though the compound was on the column for less than 30 min. The remainder of the material was recovered as **5** on elution with methanol. The formation of **8** is consistent with the existence of 9^+ along the reaction pathway. Treatment of **5** in acetonitrile–methanol (3:1, v/v) with trifluoroacetic acid (10^{-2} *M*) produces **8** in good yield, based upon proton magnetic resonance (^{1}Hmr) spectroscopy and hplc.

Strong support for many of the mechanistic considerations proposed in Scheme 1 can be derived from the electrochemical study of the oxidation of **1** (2). The oxidation of **1** at a spherical platinum electrode occurs at E_p = 1.36 V in acetonitrile (0.1 *M* TEAP) using a sweep rate of 400 mV s^{-1}. At sweep rates less than 1.0 V s^{-1} a second anodic wave (E_p = 1.58 V at 400 mV s^{-1}) is observed. The relative height of the second wave increases as the sweep rate decreases (Table 4). The second wave is attributable to the oxidation of **3**, adsorbed on the working electrode. The sweep rate dependence is a result of a slow chemical step. The strong adsorption of **3** to the working electrode is evident from Fig. 2. The sharp anodic wave at E_p = 1.58 V is obtained for the cyclic voltammogram of **3**. Addition of an equivalent amount of **1** to this solution only results in an increase in the peak current for the second anodic wave. The first wave at E_p = 1.36 V is not observed, indicating that the working electrode is insulated from the solution until the discharge potential of **3** is reached.

The appearance of an anodic wave attributable to the oxidation of **3** clearly indicates that the anodic wave at E_p = 1.36 V represents a two-electron process. Radical cations generally are more stable in dichloromethane than in acetonitrile (30), so this solvent was used in an attempt to detect the individual one-electron transfer steps upon oxidation of **1**. The first wave at E_p = 1.36 V in dichloromethane appears to be identical to the wave in acetonitrile. Even at sweep rates as fast as 20 V s^{-1}, no evidence for two one-electron transfers is obtained.

At the onset of oxidation (in acetonitrile), the solution near the surface of the electrode becomes visibly purple. The cathodic sweep reveals two waves. The first cathodic wave is reversible with $E_{1/2}$ = 0.34 V. The second wave is at E_p = 0.17 V and is irreversible. The irreversible wave may be the reduc-

[8]Recently, Laviron has measured the E^0 value for this oxidation ($QH^- \rightleftarrows QH^\cdot$, + 0.22 V vs. SCE, aqueous) (26).

[9]Addition of 2,6-di-*tert*-butylpyridine has a similar effect, except forty equivalents must be added before the wave at E_p = 1.56 V is not observed, and the new wave occurs at E_p = 0.87 V. These differences can be attributed to a steric effect with this hindered base (27).

tion of a proton which occurs at $E_{1/2}$ = 0.24 V (31) in water, i.e., the normal hydrogen electrode (NHE). A likely candidate for the coloured intermediate is **9**$^+$. When the cation **9**$^+$ is generated in the electrolysis cell from the alcohol **5** by the addition of trifluoroacetic acid, the voltammogram of the resulting purple solution has the same reversible reduction wave at $E_{1/2}$ = 0.34 V. Furthermore, the irreversible wave at E_p = 0.17 V, associated with the proton reduction, is also observed.

Some uncertainty still remains regarding the mechanistic sequence of the anodic oxidation of **1** to **9**$^+$. Two possible pathways are the ECE and the EEC process. For the ECE mechanism the deprotonation of **1**$^{\cdot +}$ is thermodynamically feasible even considering acetonitrile as the base (9), and the oxidation of **9**$^\cdot$ would be rapid at 1.1 V. The alternative pathway (EEC) requires that the oxidation of **1**$^{\cdot +}$ to **1**$^{++}$ occurs at 1.1 V (the onset of oxidation), followed by deprotonation to give **9**$^+$. An estimate of the oxidation potential of **1**$^{\cdot +}$ can be made; it should be between the oxidation potential of tetraphenylethylene radical cation (1.45 V) (32) and the oxidation potential of the 1,1-diphenylethyl radical (−0.2 V (18)). The strength of the one-electron two-centre bond in **1**$^{\cdot +}$ is small (5), so the oxidation potential of **1**$^{\cdot +}$ should be closer to the value for the 1,1-diphenylethyl radical. Obviously, both pathways are thermodynamically feasible.

Controlled potential electrolysis of **1** gives further support to the suggestion that **9**$^+$ lies on the reaction pathway (Table 3). Electrolysis in acetonitrile (0.1 *M* TEAP) gives **3** in good yield. Addition of a base (2,6-lutidine) diverts the reaction from the original pathway and **4** is now the major product (only a trace of **3** is detected). In acetonitrile–methanol (3:1, v/v) (0.1 *M* TEAP) the product obtained is **8**. This, of course, parallels the expected behavior of **9**$^+$.

It is interesting to compare the controlled potential electrolysis (in methanol) of **1** to that reported for 1,2-diphenylcyclopropane (*cis* and *trans*) (33). In the case of 1,2-diphenylcyclopropane the product from the electrolysis was 1,3-dimethoxy-1,3-diphenylpropane. It was proposed that the radical cation of the cyclopropane reacted with methanol to form the benzylic radical which oxidized to the cation and reacted once again with methanol (ECEC). The radical cation of 1,2-diphenylcyclopropane showed no propensity for deprotonation under these conditions (the allylic ether analogous to **8** was not detected). This, of course, is consistent with the photosensitized (electron transfer) results (1, 6).

The isolation of **8** from the electrolysis of **1** does not confirm unambiguously the intermediacy of **9**$^+$. If methanol were to react with **1**$^{\cdot +}$ (or **1**$^{++}$), the resulting diphenylethyl-type cation could simply deprotonate to give **8**. Furthermore, since an excess of protons is produced in this reaction, 1,3-dimethoxy-1,1,3,3-tetraphenylpropane may be produced, and subsequently react via an acid-catalyzed elimination of methanol. Analysis of the reaction by hplc indicates that **8** is the only product formed, even at low conversion (<5%). The photosensitized (electron transfer) reaction of **1** in acetonitrile–methanol (3:1, v/v) indicates that **1**$^{\cdot +}$ deprotonates much faster than it reacts with methanol. Certainly the dication **1**$^{++}$ will be as, or more, acidic under similar conditions. The formation of **8**, via **9**$^+$, under the electrolysis conditions is, therefore, reasonable.

Treatment of **5**, in acetonitrile (0.1 *M* TEAP), with trifluoroacetic acid, produces a coloured solution which exhibits three broad absorption maxima at 568 nm, 459 nm, and 382 nm attributed to **9**$^+$. This spectrum can be compared to the spectrum of **9**$^-$ which exhibits visible absorption maxima at 564 nm and 463 nm (14). Similarity is expected; the energy difference between the HOMO and the NBMO (non-bonding molecular orbital) in the cation is the same as the difference between the NBMO and the antibonding MO in the anion (34).

Electrolysis of a solution of **1** gives a coloured solution which exhibits absorption maxima at 570 nm, 461 nm, and 381 nm. Similarly, irradiation of the charge-transfer band between **1** and TCNE, DDQ, or TCQ in acetonitrile produces a coloured solution with absorption maxima at 566 nm and 458 nm. We suggest that all three spectra represent the same intermediate, **9**$^+$.

The stability of **9**$^+$, the ease with which it is generated electrochemically from **1**, and the ease with which it is detected spectrophotometrically make it possible to measure the rate of disappearance as a function of temperature (Table 5). The rate of disappearance of **9**$^+$ (measured at either 570 nm or 460 nm) follows first-order kinetics. The temperature dependence gives an apparent activation energy of 21.8±0.6 kcal mol^{-1} and a preexponential factor, log *A*, of 14.5 ± 0.4. It is clear from the simple mechanism in Scheme 1, Steps 7 and 8, that this rate constant represents the rate of formation of **3**. The rate at 23°C is independent of the concentration of electrolyte between 0.1 and 0.001 *M* TEAP. The ratio of **3**/**4** with TCNE as acceptor does not change significantly when 0.1 *M* TEAP is added to the solution. Similarly the product ratio is the same with or without 0.1 *M* TEAP when TCQ is the acceptor. It is reasonable to conclude, therefore, that the rate constant for the formation of **3** will be the same in the photochemical experiments.

Conclusions

1$^{\cdot +}$ can undergo several different reactions which depend on the acceptor used and on the reaction conditions. The reduction potential of **9**$^\cdot$ is −0.94 V (14). The reduction potentials of all of the acceptors which lead to the formation of **2** are greater than, or within 0.05 eV of, this value. Conversely, for the sensitizer radical anions which lead to the formation of **3** and **4**, all the radical anions are incapable of reducing **9**$^\cdot$. Only one, DDQ, is capable of oxidizing **9**$^\cdot$. It is possible, however, for the protonated radical anions (HA$^\cdot$) of TCQ, DDQ, and TCNE to oxidize **9**$^\cdot$ since **9**$^+$ is observed spectroscopically in these cases.

The partitioning between **9**$^-$ and **9**$^+$ is easily interpreted in terms of the reduction potential of the acceptor. The partitioning between **3** and **4** depends on the basicity of the medium. The implication is that HA$^-$ is the base, since in the absence of base (i.e. in the electrolysis of **1**) **4** is not formed. This indicates that **4** results from deprotonation to a base other than solvent.

The complex behaviour observed with this seemingly simple system must pertain in general for photosensitized (electron transfer) reactions. This complexity, in fact, offers an opportunity of dramatically increasing the synthetic utility of this type of reaction if the factors which influence the preference of one reaction pathway over another can be understood and controlled.

Experimental

Acetonitrile (Fisher ACS grade) for preparative photolysis and electrolysis, as well as for electrochemical measurements, was distilled successively from sodium hydride (1 g/L) and phosphorus pentoxide (2 g/L), followed by passing through a column of basic alumina (100 g/L), refluxing over calcium hydride for 24 h in an inert atmosphere, and, finally, fractional distillation. Acetonitrile for the electrochemical measurements was used immediately after distillation while that for preparative work was stored over 3A molecular sieves. Tetraethylammonium perchlorate (Aldrich) was recrystallized three times from 90% ethanol and dried in a vacuum desiccator. Tetracyanoethylene (Aldrich) was sublimed and recrystallized three times from chlorobenzene. Chloranil (Eastman) was purified by recrystallization four times from benzene. 2,3-Dichloro-2,6-dicyanobenzoquinone (Aldrich) was purified by recrystallization four times from chloroform–benzene (4:1). 1,4-Dicyanobenzene (Aldrich) was purified by sublimation followed by recrystallization three times from ethanol. 1,4-Dicyanonaphthalene was prepared by the method of Heiss, *et al.* (35) from the reaction of *o*-phenylenediacetonitrile and *N*,*N*'-di-*tert*-butylglyoxaldiimine. The 1,4-dicyanonaphthalene was purified by column chromatography followed by recrystallization from methanol (three times). Methyl-4-cyanobenzoate was prepared by the acid-catalysed esterification of 4-cyanobenzoic acid (Aldrich) and purified by recrystallization (ethanol). 9,10-Dicyanoanthracene was prepared by the reaction of cuprous cyanide with 9,10-dibromoanthracene (36) and was purified by column chromatography followed by recrystallization (twice from benzene). The preparations of 1,1,2,2-tetraphenylcyclopropane (17), 1,3,3-triphenylindene (37), and tetraphenylallene (10) have been described.

The ^{1}Hmr spectra were recorded on a Varian T60 spectrometer and are reported in parts per million downfield from TMS. Melting points were obtained on a Sybron Corporation Thermodyne hot stage and are uncorrected. The hplc analysis was performed using a Waters Associates M-45 solvent delivery system in conjunction with a Tracor 970 variable wavelength absorbance detector. The column (Merck, Lichrosorb RP-18) was prepared by suspending the packing (1.1 g) in a mixture of carbon tetrachloride (10 mL) and tetrabromoethane (8 mL) by sonication for 3 min. The slurry was poured into a pre-column (18 cm × 1.5 cm diameter) and immediately packed into the analytical column (10 cm × 0.6 cm diameter) with n-heptane at a pressure of 3450 psi (using a Haskel air-driven fluid pump). The eluant was progressively changed to chloroform, then methanol. The analysis was done at a flow rate of 1.2 mL/min with 83% methanol–water. The absorbance was monitored at 247 nm (the isobestic point of **3** and **4**).

To calibrate the hplc, the apparent mole fraction of **3** (based on relative peak heights) was converted to a true mole fraction with a working curve. The working curve was a plot of apparent versus true mole fraction, constructed with ten accurately weighed samples of mixtures of **3** and **4**.

Electrochemical cell and apparatus

Cyclic voltammetric measurements were performed in a three-electrode cell (10 mL volume) fitted with a cooling jacket and a scintered glass frit through which nitrogen was passed in order to deoxygenate and stir the solution prior to measurement. The working electrode was a spherical platinum electrode (1mm diameter) embedded in soft glass and contacted with a Nichrome wire through a mercury pool. The counter electrode was a platinum coil embedded in soft glass and inserted through a sidearm of the cell. The reference electrode was a saturated calomel electrode (SCE) which was isolated from the solution by a glass tube (inserted in another sidearm) which ended in a Luggin capillary placed 0.5 mm from the surface of the working electrode. The working electrode was immersed in concentrated nitric acid for 30 min prior to use, washed with 5% bicarbonate, water, and methanol, then dried in an oven at 60°C. The electrochemical cell was cleaned by immersion in concentrated nitric acid (2 h) followed by rinsing with water, 5% sodium bicarbonate, water, and acetone, and dried at 100°C.

Solutions were degassed with dry nitrogen (presaturated with solvent) for 5 min prior to each measurement, and, during the measurement, the nitrogen atmosphere was maintained above the solution. Substrate concentrations were typically 0.001 *M* in a total volume of 7 mL.

The spectroelectrochemical cell consisted of a 4-cm cylinder (1 cm diameter) with optically flat Pyrex windows sealed at each end. The cell was surrounded by a water jacket. The temperature of the solution in the cell was maintained using a Polyscience Corporation, Model 90 temperature controlled circulating bath. The solution in the cell was continuously stirred with a magnetic stirring bar, placed in a shallow well below the light path. The working electrode (platinum mesh, 4 cm × 0.5 cm), inserted via an opening in the top of the cell, was held against the inside wall of the cell in order to keep it out of the light path. A thermistor probe (Cary 219 spectrophotometer accessory) was placed in a second opening in the top of the cell and protruded only slightly, by approximately 2 mm, into the light path. The reference electrode and counter electrode were isolated from the solution in a separate compartment which contacted the working compartment through a scintered glass frit. This compartment was inserted through an opening in the side of the cell, ending with a ground glass joint. The entire assembly was placed in the sample compartment of a Varian–Cary 219 spectrophotometer.

The substrate concentrations were 2.9×10^{-3} *M*. During each run, approximately 0.5 C were passed at constant current (0.05 equivalents). The cell was then open-circuited and the absorbance of the solution monitored as a function of time. The solution was replaced with fresh solution after every third measurement. The temperature did not vary by more than ±0.1 degree during any given measurement.

Controlled potential electrolysis was performed with a standard H-cell (total volume 100 mL). Both the working electrode and counter electrode were platinum mesh (9 cm^2). The reference electrode was introduced via a Luggin capillary.

Cyclic voltammetric measurements were obtained with a PAR (Princeton Applied Research) 173 potentiostat in combination with a PAR 175 universal programmer and a PAR 179 digital coulometer. Controlled potential electrolyses and spectroelectrochemical measurements were performed with the use of the PAR 173 potentiostat.

Irradiations were carried out in acetonitrile or acetonitrile–methanol (3:1) at a substrate concentration of 0.1 *M*. Solutions were degassed by bubbling dry nitrogen for 10 min prior to irradiation. Irradiations were carried out in 2 cm id Pyrex tubes (large scale) or 5-mm Pyrex nmr tubes. Two irradiation systems were employed, a 1-kW medium pressure mercury lamp (General Electric Co.) with a quartz cooling jacket which was immersed in a constant temperature bath at 10°C, and a Hanovia 450-W lamp with a quartz cooling jacket. When the Hanovia lamp was used, the irradiation tubes were contained in a Pyrex cooling jacket connected to a Polyscience Model 90 temperature controlled circulating bath. This jacket also served as a short-wavelength (<280 nm) filter. Reaction mixtures were chromatographed on a flash chromatographic column or with a medium pressure (15 psi, helium) lc system (8).

*Photosensitized (electron transfer) irradiation of **1** using 1,4-dicyanonaphthalene in acetonitrile*

1 (100 mg, 2.9×10^{-4} mol) and 1,4-dicyanonaphthalene (10 mg, 5.8×10^{-5} mol) were dissolved in acetonitrile (3.0 mL), degassed by bubbling nitrogen for 10 min, and irradiated at 10°C (through a Pyrex filter) with a 1-kW lamp for 4 h. Analysis (hplc) indicated only one major product. The solvent was evaporated under reduced pressure and the reaction mixture separated by medium pressure chromatography (silica gel, hexanes–dichloromethane gradient). **2** (66 mg, 73%) was isolated and recrystallized from absolute ethanol to give colourless crystals which melted at 126–128°C (lit (38) mp 127–128°C). The ^{1}Hmr spectrum was identical to an authentic sample (δ, $CDCl_3$; 7.20 (m, 20 H), 6.52 (d, J = 10 Hz, 1H), 4.75 (d, J = 10 Hz, 1H)).

Other compounds isolated from the column were unreacted starting material (**1**, 10 mg) and unreacted sensitizer (DCN, 8 mg, 80% recovery).

*Photosensitized (electron transfer) irradiation of **1** using 1,4-dicyanonaphthalene in acetonitrile-methanol-O-*d

1 (30 mg, 8.7×10^{-5} mol) and DCN (3 mg, 1.7×10^{-5} mol) were dissolved in a mixture of acetonitrile and methanol-O-*d* (3:1, v/v, 1.0 mL), degassed by bubbling nitrogen for 5 min, and irradiated (through Pyrex) with a 1-kW lamp for 1.5 h (at 10°C). The solvent was removed under reduced pressure and **2** was isolated by medium pressure chromatography (silica gel, hexanes–dichloromethane gradient); ^{1}Hmr (Nicolet 360-MHz nmr spectrometer) showed only the resonances at δ 7.20 (m, 20H) and 6.52 (s, 1H). The ^{2}Dmr spectrum showed only a singlet at δ 4.78.

*Photosensitized (electron transfer) irradiation of **1** using tetracyanoethylene*

1 (100 mg, 2.98×10^{-4} mol) and tetracyanoethylene (38 mg, 3.0×10^{-4} mol) in acetonitrile (3.0 mL) were degassed by bubbling nitrogen for 10 min and then irradiated through a sodium nitrite filter (> 400 nm) at 10°C for 72 h. Within a few seconds of irradiation, the solution became dark purple. This colour slowly faded when the tube was removed from the irradiation bath. After the irradiation was complete (monitored by hplc) a colourless solid, which had precipitated, was filtered and the solvent was evaporated under reduced pressure.

The residue, after evaporation, exhibited an ^{1}Hmr spectrum (δ, $CDCl_3$: 4.90 (s)) and an ir spectrum (KBr (cm^{-1}): 2819, 2606, 2484, 2274, 1620, 1302, 1201, 996, 908, 561) identical to an authentic sample of dihydrotetracyanoethylene (39). The crude yield was 28 mg (74%).

The precipitate was combined with the residue from the evaporation of solvent and separated by medium pressure chromatography (silica gel, hexanes–dichloromethane gradient) to give **3** (58 mg, 67%), **4** (3 mg, 4%), and **1** (14 mg). The identity of **3** and **4** was confirmed by comparison to authentic samples of each (refs. 10, 37).

*Photosensitized (electron transfer) irradiation of **1** using chloranil in acetonitrile*

1 (100 mg, 2.9×10^{-4} mol) and chloranil (63 mg, 3.0×10^{-4} mol) in acetonitrile (2.0 mL) were degassed by bubbling nitrogen for 10 min, then irradiated through a sodium nitrite filter solution (> 400 m) at 10°C for 4 h. The solution became only slightly purple within a few seconds of irradiation. Analysis (hplc) indicated that **3** (minor) and **4** (major) were formed. The solvent was evaporated under reduced pressure, the residue was dissolved in dichloromethane, and the tetrachlorohydroquinone (insoluble in dichloromethane) was filtered (42 mg, 67%) and identified by mass spectrometry (M^+ (246) and characteristic M+2, M+4, M+6) and ir (KBr (cm^{-1}): 3410(s), 1415(s), 1312(s), 1205(s), 888(s), 720(m), 708(m)).

The dichloromethane was evaporated under reduced pressure and the residue was separated by medium pressure chromatography (silica gel, hexanes–dichloromethane gradient). Isolated from the column were **4** (47 mg, 67%), **3** (5 mg, 7%), and **1** (30 mg).

*Photosensitized (electron transfer) irradiation of **1** using 2,3-dichloro-5,6-dicyanobenzoquinone in acetonitrile*

1 (100 mg, 2.9×10^{-4} mol) and 2,3-dichloro-5,6-dicyanobenzoquinone (68 mg, 3.0×10^{-4} mol) in acetonitrile (2.0 mL) were degassed by bubbling nitrogen for 10 min, then irradiated through a sodium nitrite filter solution (> 400 nm) at 10°C for 4 h. The solution became dark purple within a few seconds of irradiation. The solvent was evaporated and the residue extracted into dichloromethane. The hydroquinone precipitate (reduction product) was filtered to give a crude yield of 32 mg, 47%, and identified by mass spectrometry (M^+ (228) and characteristic M+2, M+4) and ir (KBr (cm^{-1}): 3260(s), 2260(m), 1578(m), 1455(s), 1360(m), 1280(s), 1200(s), 1078(m), 892(s), 778(m), 748(m), 703(w), 690(w)).

The dichloromethane was evaporated under reduced pressure and the residue was separated by medium pressure chromatography (silica gel, hexanes–dichloromethane gradient) to give **3** (7 mg, 10%), **4** (25 mg, 35%), and **1** (29 mg).

*Photosensitized (electron transfer) irradiation of **1** using chloranil in acetonitrile–methanol (3:1, v/v)*

1 (100 mg, 2.9×10^{-4} mol) and chloranil (63 mg, 3.0×10^{-4} mol) in acetonitrile–methanol (3:1, v/v, 2.0 mL) were degassed by bubbling nitrogen for 10 min, then irradiated through a sodium nitrite filter solution (>400 nm) at 10°C for 5 h. The solvent was evaporated under reduced pressure and the residue was extracted with dichloromethane (to separate the hydroquinone from the reaction mixture). The hydroquinone precipitate was filtered (43 mg, 68%), and characterized as above.

The dichloromethane was removed under reduced pressure and separated by medium pressure chromatography (silica gel, hexanes–dichloromethane gradient) to give **4** (7 mg, 10%), **5** (54 mg, 77%), and **1** (33 mg). Analysis (hplc) of the original reaction mixture indicated that only **8** was present; neither **4** nor **5** were detected, indicating that these products were a result of decomposition of **8** on the silica gel column.

*Controlled potential electrolysis of **1** in acetonitrile*

Into the anodic compartment of the electrolysis cell, containing acetonitrile (0.1 *M* TEAP, 100 mL), **1** (250 mg, 7.2×10^{-4} mol) was dissolved. The solution was stirred and a constant potential of 1.3 V (vs. SCE) was applied. When 90.8 C had been consumed, the reaction was stopped. The solvent was removed under reduced pressure and the residue taken up into benzene to remove the electrolyte. After gravity filtration and removal of the benzene the mixture was separated by medium pressure lc (silica gel, hexane–dichloromethane gradient). The compounds isolated were **1** (84 mg) and **3** (142 mg, 85%). The identity of **3** was confirmed by comparison to an authentic sample (37).

*Controlled potential electrolysis of **1** in the presence of base*

1 (100 mg, 2.9×10^{-4} mol) was added to the anodic compartment of the electrolysis cell containing acetonitrile, 100 mL 0.1 *M* TEAP, and 0.1 *M* 2,6-lutidine. The solution was stirred and a controlled potential of 1.4 V was applied until 19.9 C were consumed. The solvent was removed under reduced pressure and the residue was dissolved in benzene. This solution was filtered (to remove TEAP) and the benzene was removed under reduced pressure. The mixture was separated by medium pressure chromatography (silica gel, hexane–dichloromethane gradient). The compounds isolated were **1** (77 mg) and **4** (13 mg, 57%). Analysis (hplc) of the fractions containing **4** indicated the presence of a trace (<3%) of **3**. The identity of **4** was confirmed by comparison to an authentic sample (10).

*Controlled potential electrolysis of **1** in acetonitrile–methanol*

1 (100 mg, 2.9×10^{-4} mol) was added to the anodic compartment of the electrolysis cell containing a mixture of acetonitrile and methanol (3:1, v/v, 0.1 *M* TEAP). The solution was stirred and a controlled potential of 1.4 V was applied until 60.1 C had been consumed. The solvent was evaporated and the residue dissolved in benzene. The benzene solution was filtered and the solvent was removed under reduced pressure. The mixture was separated by flash chromatography (silica gel, hexane–dichloromethane gradient). The products isolated were **1** (27 mg) and **8** (43 mg, 55%). Elution of the flash chromatographic column with methanol gave **5** (20 mg, 27%). **5** was not detected by hplc analysis of ^{1}Hmr of the reaction mixture.

Received June 26, 1984

David M. McKinnon, K. Ann Duncan, Aileen M. McKinnon, and Perry A. Spevack. Can. J. Chem. **63**, 882 (1985).

The treatment of di(2-amino-5-methylphenyl)methane with *N*-sulfinylmethanesulfonamide gives two materials, 3-(2-amino-5-methylphenyl)-5-methyl-2,1-benzisothiazole and what appears to be its tautomer, a 2,1-benzisothiazolo[2,3-*b*]-2,1-benzisothiazole derivative. Reaction of the former with methyl iodide gives mono-, di-, and trimethyl derivatives. The second of these also possesses the symmetrical 2,1-benzisothiazolo[2,3-*b*]-2,1-benzisothiazole structure. The structure of the other methylation product and of the acetylation products are discussed. Some 1,2-dithiol-3-ylidene-2-pyridylmethanes were made by condensation of 3-alkylthio-1,2-dithiolium salts with methyl 2-pyridylacetate. These demonstrate little sulfur–nitrogen interaction. 3-Methylthio-4-phenyl-1,2-dithiolium iodide reacts anomalously with methyl 2-pyridylacetate to form a quinolizinethione. 1,2-Benzisothiazolo[2,3-*a*]pyridinium triiodide was made by iodine oxidation of 2-(2-mercaptophenylpyridine).

David M. McKinnon, K. Ann Duncan, Aileen M. McKinnon et Perry A. Spevack. Can. J. Chem. **63**, 882 (1985).

La réaction du di(amino-2 méthyl-5 phényl) méthane avec le *N*-sulfinylméthanesulfonamide conduit à deux produits, le (amino-2 méthyl-5 phényl)-3 méthyl-5 benzisothiazole-2,1 et ce qui semble être son tautomère, un dérivé benzisothiazolo-2,1[2,3-*b*] benzisothiazole-2,1. La réaction du premier produit avec l'iodure de méthyle fournit des dérivés mono-, di- et triméthylés. Le deuxième de ces dérivés possède aussi la structure benzisothiazolo-2,1 [2,3-*b*] benzisothiazole. On discute de la structure des autres produits de méthylation et d'acétylation. On a préparé quelques dithiol-1,2 ylidène-3 pyridyl-2 méthanes par condensation de sels d'alkylthio-3 dithiolium-1,2 avec le pyridyl-2 acétate de méthyle. Ceci démontre qu'il n'y a que peu d'interaction entre le soufre et l'azote. L'iodure du méthylthio-3 phényl-4 dithiolium-1,2 réagit d'une façon anormale avec le pyridyl-2 acétate de méthyle; il en résulte la formation d'une quinolizinethione. On a préparé le triiodure du benzisothiazolo-1,2 [2,3-*a*] pyridinium par une oxydation à l'iode de la (mercaptophényl-2 pyridine)-2.

[Traduit par le journal]

Introduction

This paper will describe the preparation and properties of a number of fused systems containing actual or potential fused isothiazole rings which have been made as part of continuing studies on isothiazoles.

The 1,2-dithiolo[1,5-*b*]-1,2-dithioles[2] (**1**) are compounds in which the central sulfur atom possesses interesting valency properties, and many examples of compounds of this type have been described (1, 2). In fact many structural variations are possible to give compounds of analogous structure and properties, provided that the central atom is capable of valency shell expansion (1–3). Nevertheless, attempts to synthesize a dibenzo derivative of the system **1** have failed (4), although monobenzo derivatives are known. The most reasonable suggestion for this is that there is a steric repulsion of the interior *ortho* hydrogen atom on the benzo rings (2), since some dibenzo derivatives *linked* in the *ortho* positions do exist (5–7). Also, the 1,2-oxathiolo[1,5-*e*]-1,2-oxathiole system is known as the parent heterocycle, simple derivatives, a benzo, and as a dibenzo derivative (**2***b*) (8–11). In the dibenzo system the shortened S—O bond distances so change the geometry of the system that the *ortho* hydrogen atoms are no longer in a position for steric interference.

It was therefore of interest to construct isothiazole analogs of the dibenzo derivatives, i.e. the 2,1-benzisothiazolo[2,3-*b*]-2,1-benzisothiazole system (**2***c*), to further test this suggestion. Although some isothiazole analogs are known (12), these are of the parent heterocycle and simpler derivatives. No benzo derivatives appear to have been described.

We directed our attention to the compounds of type **3** as being some of the simplest with respect to nitrogen substitution because the ring substituents would provide both a suitable nmr probe and facilitate the *ortho–ortho* linking of an aromatic amine starting material. The diamine **4***a* was a suitable starting material since 2,1-benzisothiazoles have been prepared from *o*-toluidine derivatives by reaction with either thionyl chloride

[1] Author to whom correspondence may be addressed.

[2] These compounds have been named variously as thiathiophthenes or 1,6,6aλ^4-trithiapentalenes. Similarly the compound **2***c* could be named as a thiadiazaindenoindene. However, in this paper we will use the nomenclature systems of Chemical Abstracts. The naming of these compounds has been discussed by N. Losac'h (1).

(13, 14) or *N*-sulfinylmethanesulfonamide (15, 16), which is reported to give better yields. This diamine **4***a* had been prepared (17) by the rearrangement of the amine **5**, itself prepared from the amine **6**, but we found it simpler to prepare the diamine **4***a* directly by a modified procedure. Treatment of **4***a* with *N*-sulfinylmethanesulfonamide gave a reddish oil whose mass spectrum was consistent with a compound of formula $C_{15}H_{14}N_2S$, i.e. that of the compound **3***a*. The nmr spectrum indicated two equivalent methyl groups (at δ = 2.33 ppm). A broad peak at δ = 6.55 ppm may be due to NH protons. However, over several days this oil crystallized to a yellow solid, which was also the product obtained when attempts were made to purify the oil by chromatography. This material had an analysis and mass spectrum corresponding to $C_{15}H_{14}N_2S$, but since the nmr spectrum showed non-equivalency of the two methyl groups (at δ = 2.30 and 2.40 ppm), it appears that this compound is the isomeric 3-(2-amino-5-methylphenyl)-5-methyl-2,1-benzisothiazole (**7***a*). Since the methyl protons of 5-methyl-2,1-benzisothiazoles absorb at δ = 2.30–2.33 ppm (16, 17), it is likely that the protons at δ = 2.42 are those of the methyl group on the phenyl substituent. It therefore appears likely that **3***a* and **7***a* are tautomers. This compound exhibited a broad absorption at δ = 3.8 ppm which disappeared on shaking with deuterium oxide and is assigned to the amino group protons. Also, when the reddish oil was shaken with deuterium oxide, its spectrum changed to that of the yellow solid.

Since the tautomerism should be blocked by *N*-alkylation, the solid material was treated with methyl iodide, giving three products, corresponding to mono-, di-, and trimethyl derivatives. The second of these was a deep crimson crystalline solid whose nmr showed only two types of methyl peaks, at δ = 3.71 and 2.67 ppm, corresponding in chemical shift to *N*- and *C*-methyl groups respectively. In addition, the spectrum of the aromatic protons demonstrated a typical ABX pattern. The ^{13}C nmr spectrum of **3***b* demonstrated the presence of only nine types of carbon atom, four of which were quaternary. These properties are consistent with the symmetrical structure of 1,4,8,11-tetramethyl-2,1-benzisothiazolo[2,3-*b*]-2,1-benzisothiazoles (**3***b*). It thus appears that the shorter S—N bond lengths in **3***b*, like those in compounds of type **2***b*, so favorably affect the geometry compared to dithiole analogs that the interior *ortho* hydrogen atoms do not interfere with each other.

It should also be noted that the spectrum of the aromatic protons in the putative **3***a* resembled those of **3***b*.

The monomethylated material was a yellow solid whose nmr spectrum indicated three different methyl groups, one of which was in the range expected for an *N*-methyl group. Since the two others, at δ = 2.33 and 2.42 ppm, are in the range observed for the yellow compound **7***a*, we consider on this basis that it is 5-methyl-3-(2-methylamino-5-methylphenyl)-2,1-benzisothiazole (**7***b*). Three other structures, the imines **8***a* and *b* and the fused structure **3***c* are eliminated for the following reasons: the imines **8***a*,*b* are *o*-quinonoid structures, and expected to be unstable, and in the fused structure **3***c* the aromatic methyl groups would be expected to be much more equivalent than found, by comparison with the compounds **2***a* and *b*. It is recognized that **8***a* and *b* and **3***c* may be resonance contributors to a single structure. The third material, obtained only in small amounts, appears on the basis of its solubility, and that it contains iodine, to be a salt, probably 1-methyl-3-(2-dimethylaminophenyl)-2,1-benzisothiazolium iodide (**9**).

We also attempted to make the compound **3***b* from di(2-methylamino-5-methylphenyl)methane (**4***b*). The synthesis of this compound from *N*-methyl *p*-toluidine is reported (17) although no experimental details were given. We therefore made it from the amine **4***a* by conversion to its *bis*-trifluoroacetamide **4***c* (18). Although such amides are reported (19, 20) to give secondary amines directly on treatment with methyl iodide and potassium hydroxide, with this compound we isolated the *N*,*N'*-dimethyl *bis*-trifluoroacetamide (**4***d*) which afforded **4***b* on prolonged alkaline hydrolysis. When this was treated with *N*-sulfinylmethanesulfonamide we were unable to isolate any isothiazole products. In contrast to **4***a*, the compound **4***b* cannot form an *N*-sulfinylamine. It has been suggested (14) that *N*-sulfinylamines are necessary intermediates in the conversion of *o*-toluidines to 2,1-benzisothiazoles. It also seems likely that if the bicyclic structure **3***a* is indeed produced in the above reaction, it is formed by tautomerism of an initially formed 3-(2-amino-5-methylphenyl-5-methyl-2,1-benzisothiazole (**7***a*).

Treatment of the compound **3***a* with acetic anhydride gave two products, corresponding to mono- and diacetyl derivatives. Since the former showed only two methyl singlets in the ratio of 1:2, it therefore appears that the two aromatic methyl peaks are fortuitously equivalent. Two structures, **3***d* and **7***c*, are possible. Because of the close similarity of the methyl groups in the bicyclic structure **3***d* we are inclined to favor this structure. This material also exhibited a broad peak at δ = 6.75 ppm which, as noted above, may be indicative of an N—H group in the bicyclic structure. The diacetyl derivative possessed two non-equivalent aromatic methyl groups, ruling out a symmetrical structure, and the most likely possibility is therefore the imide **7***d*. Although satisfactory nmr and mass spectra were obtained for these materials, they appear to be too unstable for proper analysis. 2,1-Benzisothiazoles and 2,1-benzisoxazoles rearrange to oxazines on treatment with acetic anhydride (21, 22) but these types of reactions require structural features not present here.

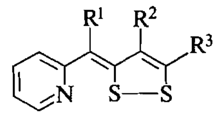
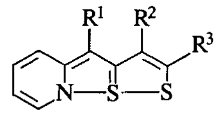
Other types of compounds containing interesting fused isothiazole type nuclei are the isothiazolo[2,3-*a*]pyridinium salts **10** and 1,2-benzisothiazolo[2,3-*a*]pyridinium salts **11**, some of which have been made by oxidation of suitable thiones (23) or acid treatment of certain thiocyanates (24). In this work 2-(2-aminophenyl)pyridine (**12***a*) was diazotized and converted via the xanthate **12***b* to 2-(2-mercaptophenyl)pyridine (**12***c*), which on iodine oxidation gave the salt **10***a*. Treatment of this with perchloric acid gave the known (24) perchlorate **10***b*.



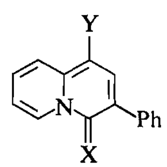
13



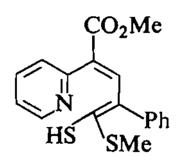
14

a $R^1 = CO_2Me$, $R^2 = H$, $R^3 = Ph$
b $R^1 = CO_2Me$, $R^2 = R^3 = Ph$
c $R^1 = CO_2Me$, $R^2 = R^3 = (CH{=}CH)_2$
d $R^1 = CO_2Me$, $R^2 = Ph$, $R^3 = H$
e $R^1 = R^2 = H$, $R^3 = Ph$
f $R^1 = H$, $R^2 = R^3 = Ph$
g $R^1 = CO_2Me$, $R^2 = Ph$, $R^3 = H$

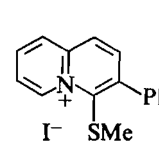
Other compounds which may possess to some extent a fused isothiazole structure are 1,2-dithiole-3-ylidine-2-pyridylmethanes (**13**), if possible resonance structures **14** are considered. These compounds are therefore analogous to compounds in which similar interaction between the nitrogen atom of a pyrimidine or pyridine ring and the sulfur atom of a thiadiazole ring has been demonstrated (25, 26), although crystal studies (27) on a more related compound, 3-methyl-6-(5-phenyl-1,2-dithiol-3-ylideneamino)pyridine have in fact demonstrated only slight sulfur–nitrogen interaction. These compounds **13***a*–*c* were made by condensation of methyl 2-pyridylacetate with the appropriate 3-alkylthio-1,2-dithiolium salts and, of these, **13***a*, *b* gave the compounds **13***e*, *f* on acidic hydrolysis. With **13***c* the hydrolysis proceeded more extensively, giving benzo-1,2-dithiole-3-one. An examination of the ^{13}C spectra of **13***e*, *f* showed no absorption in the region δ = 170–180 ppm, which appears to be fairly characteristic of a number of compounds possessing hypervalent sulfur (2), e.g. 1,2-dithiolo[1,5-*b*]-1,2-dithioles and related compounds, and it thus appears that these compounds too are best represented by structures **13**.



15



16



17

a X = S, Y = CO_2Me
b X = O, Y = CO_2Me
c X = S, Y = H

The reaction of 3-methylthio-4-phenyl-1,2-dithiolium iodide with methyl 2-pyridylacetate gave two compounds. One of these, obtained in low yield, corresponds to the condensation product **13***d*. The major product, a yellow crystalline solid, had properties consistent with a molecular formula of $C_{17}H_{13}NO_2S$ and appears to be a carboxylic ester. This is tentatively assigned the quinolizinethione structure **15***a* on the following basis: consideration of reaction mechanisms involving nucleophilic attack on the unhindered 5-position of the dithiolium salt would lead to the dithioester **16** or enethiol, which could form **15** by electrocyclization and loss of methanethiol. The ^{13}C nmr of the material exhibited an absorption at δ = 175.6 ppm, which is in the range exhibited by 2-pyridinethiones (29). Treatment of **15***a* with potassium permanganate in acetone afforded the quinolizinone **15***b*, and acid hydrolysis produced the quinolizinethione **15***b* which on methylation gave the salt **17**.

Experimental

The ^1H and ^{13}C nmr spectra were obtained in deuteriochloroform solution using tetramethylsilane as an internal standard, on a Varian model E.M. 360 spectrometer and on a Bruker model AM-300 spectrometer, respectively. Mass spectra were obtained on a Finnigan model 1015 spectrometer, and thick layer chromatography (tlc) was performed on Merck "Kieselgel 60 PF" silica gel. Where necessary, solutions were dried over anhydrous magnesium sulfate.

Di-p-toluidinylmethane (6)

This was prepared by the method of Eberhardt and Welter (28) and the product recrystallized from ethanol as pale yellow shiny leaflets, mp 85–87°C (lit. (28) mp 86°C).

Di-(2-amino-5-methylphenyl)methane (4a)

The method of Chakrabarti et al. (17) was modified as follows. Di-*p*-toluidinylmethane (**6**) (0.18 mol), *p*-toluidine hydrochloride (0.18 mol), and *p*-toluidine (1.8 mol) were mixed as solids, heated under nitrogen to 130°C, and stirred at this temperature for 14 h. On cooling, the mixture was neutralized with a slight excess of sodium hydroxide solution and *p*-toluidine was removed by steam distillation. The tarry residue was dissolved in warm 6 *M* hydrochloric acid, resinous material filtered off, and the filtrate slowly neutralized to pH 7 with sodium hydroxide solution. The brown amorphous mass which precipitated was kept at 5°C for 3 days and filtered. Recrystallization from hexane gave colorless needles, mp 93–94°C (lit. (17) mp 96°C).

Bis(2-trifluoroacetamido-5-methylphenyl)methane (4c)

The product was prepared from the diamine **3***a* by the method of Bruice et al. (19). Recrystallization from ethanol/water (1:3) gave colorless plates, mp 250–251°C.

*Bis(2-(*N*-methyltrifluoroacetamido)-5-methylphenyl)methane (4d)*

The method of Johnstone et al. (20) was modified as follows. The bis-trifluoroacetamide **4***c* (1.7 mmol), methyl iodide (9.4 mmol), and powdered potassium hydroxide (6.4 mmol) were added to dry acetone (20 mL) and the mixture refluxed for 30 min. Acetone and methyl iodide were removed *in vacuo*, and the resulting material dissolved in chloroform and filtered to remove potassium hydroxide. Evaporation of the filtrate gave a colorless viscous oil which crystallized on standing. Addition of petroleum ether gave colorless needles (83%), mp 100–101°C. This material was not analysed.

Di-(2-methylamino-5-methylphenyl)methane (4b)

The bis-*N*-methyltrifluoroacetamide **4***d* (1.5 mmol) was added to powdered potassium hydroxide (6.0 mmol) in water (10 mL) and methanol (5 mL), and the mixture refluxed for 17 h, cooled, acidified with 2 *N* hydrochloric acid, and extracted with chloroform. Drying followed by evaporation gave a colorless oil which crystallized on standing or upon addition of petroleum ether. Recrystallization from hexanes gave **4***b* as colorless prisms (77%), mp 88–89°C (lit. (17) mp 86°C).

*Reaction of di(2-amino-5-methylphenyl)methane (4a) with *N*-sulfinylmethane-sulfonamide to form 7a*

The procedure of Singerman (15) was used. Extraction of the final product with chloroform, followed by drying and evaporation, gave a viscous reddish oil which appears (tlc) to be substantially pure. This oil crystallized on standing several days and was further purified by chromatography. Isolation of a yellow band gave on work-up a deep yellow oil which crystallized on scratching. Recrystallization from hexane with rapid cooling gave deep yellow plates, mp 113–115°C (55%).

In some cases no reddish oil was obtained and the product gave yellow crystalline material directly on work-up. For the yellow material *7a*, The nmr spectrum, δ: 2.30 and 2.42 (two 3H singlets, the methyl groups), 3.75 (2H, broad, the NH_2 protons), 6.60–7.75 (6H bands, the aromatic protons) ppm. The mass spectrum M^+ 254, *M* calcd. 2.54. *Anal.* calcd. for $C_{15}H_{14}NS_2$: C 70.87, H 5.51, N 11.02, S 12.60; found: C 70.84, H 5.69, N 10.87, S. 12.41%.

For the reddish oil, tentatively **2***a*, the mass spectrum M^+ 254, *M* calcd. 254. The nmr spectrum, δ 2.35 ppm (two 3H singlets, the methyl groups), 6.55 (2H, broad, the two NH protons), 6.87–7.75 (6H bands, the aromatic protons) ppm. Treatment with D_2O gave a spectrum like that of **7***a*.

Reaction of 4b *with* N-*sulfinylmethanesulfonamide*

The procedure used was identical to that used for **3***a* (15). The final extraction showed no presence of the expected isothiazole **3***b* or of any other major product.

Reaction of 3a *with methyl iodide*

The 2,1-benzisothiazole **3***a* (0.4 mmol) and methyl iodide (5 mL) were heated under reflux for 20 h, methyl iodide removed *in vacuo*, and the resultant dark red solid chromatographed several times on silica in various chloroform/acetone blends. The monomethylation product **7** was a relatively non-polar yellow band which was isolated to give a yellow crystalline material (30%). Recrystallization from hexane gave deep yellow needles, mp 140–141°C. The nmr spectrum, δ: 2.33, 2.42 (two 3H singlets, the aromatic methyl groups), 2.82 (3H singlet, the *N*-methyl group), 3.75 (3H singlet, the *N*-methyl group), 3.75 ppm (1H, broad, the NH proton), 6.67–7.88 (6H bands, the aromatic protons) ppm. The mass spectrum M^+ 268, *M* calcd. 268. *Anal.* calcd. for $C_{16}H_{16}N_2S$: C 71.61, H 6.01, N 10.44, S 11.95; found: C 71.24, H 5.75, N 10.35, S 12.24%.

The dimethylation product **2***b* was a deep-red crystalline material and recrystallization from ethanol gave ruby colored prisms, mp 167–168°C. The nmr spectrum δ: 2.67 and 3.71 (two 6H's, the aromatic and *N*-methyl protons), 7.13–7.51 and 8.55–8.66 (4H, m and 2H, m respectively, the aromatic protons) ppm. When the peak at δ = 2.67 ppm was irradiated, the aromatic protons exhibited an ABX type pattern, J_{AB} = 8.5 Hz. The mass spectrum M^+ found: 282, *M* calcd.: 282. *Anal.* calcd. for $C_{17}H_{18}N_2S$: C 72.30, H 6.42, N 9.92, S 11.35; found: C 72.08, H 6.40, N 9.80, S 11.53%.

The third component, obtained in only a small amount (10 mg), was a highly polar deep yellow band which gave a dark yellow semi-crystalline oil on isolation. It was purified by crystallization from cyclopentanone followed by washing with small amounts of dry acetone. Deep amber prisms, mp 243–244°C, were obtained. This was not analyzed but appears to be salt-like and containes iodine. It is tentatively given the structure **9**.

Reaction of 2a *with acetic anhydride*

The isothiazole **2***a* (0.4 mmol) and acetic anhydride (5 mL) were refluxed for 20 min, cooled, extracted with chloroform, the chloroform extract washed with water, and dried. Evaporation gave an orange oil which was chromatographed on silica in a chloroform/acetone (6:1) mixture yielding 2 components.

The monoacetylation product **2***d* was a colorless fluorescent band (R_f 0.6) and gave a pale yellow oil (51%) which crystallized on standing. Recrystallization from methanol gave pale yellow needles, mp 164–165.5°C. The nmr spectrum, δ: 1.93 (3H, s, the acetyl methyl), 2.43 (two 3H, s, the aromatic methyl), 6.75 (1H broad, the NH), 7.10–8.25 (6H bands, the aromatic protons) ppm. The mass spectrum M^+ 292, *M* calcd. 292.

The diacetylation product **6***d* was a colorless band (R_f 1) with a bright blue fluorescence and gave a bright yellow oil (46%) upon isolation. The nmr spectrum, δ: 2.21 (6H, s, the acetyl methyls), 2.45, 2.57 (two CH_3, s, the aromatic methyls), 7.18–7.95 (6H bands, the aromatic protons) ppm. The mass spectrum M^+ 338, *M* calcd. 338. When the reaction time was increased to 1 h, the yield of **2***d* decreased to 11% while that of **6***d* increased to 87%.

These compounds begin to decompose after a few days and no satisfactory analyses were obtained.

*2-(2-Aminophenyl)pyridine (12*a*)*

2-(2-Nitrophenylpyridine) (ref. 30) (20 g, 0.1 mol) in 50% aqueous ethanol (50 mL) was warmed gently and sodium dithionite added slowly until the yellow color of the solution had disappeared. The solution was concentrated to remove ethanol and extracted with chloroform, which on evaporation gave the amine **10***a* as a colorless oil (80%).

*2-(2-Mercaptophenyl)pyridine (12*b*)*

2-(2-Aminophenylpyridine) (8.5 g, 0.05 mol) in dilute hydrochloric acid was diazotized and the mixture added to a warm (50°C) solution of potassium ethylxanthate (20 g) in water (100 mL). The mixture was allowed to cool and the oil extracted with chloroform. The dried chloroform extract was evaporated and the residual oil hydrolyzed in 20% aqueous sodium hydroxide solution at 100°C for 3 h. The mixture was treated with sodium dithionite (1 g) and refluxed 1 h more. The solution was separated from any unhydrolyzed material by decantation or filtration, adjusted to pH 7 with concentrated hydrochloric acid, and treated with ether. The dried ether extract gave the crude mercaptan as a yellow oil which was used directly in the next stage. Yield 2.5 g; 29%.

*2,1-Benzisothiazolo[2,3-*a*]pyridinium triodide (11*a*)*

The crude 2-(2-mercaptophenyl)pyridine (1.81 g, 0.01 mol) in ethanol (15 mL) was treated with a saturated solution of iodine in ethanol until precipitation of the crystalline product was complete. The product was filtered and recrystallized from nitromethane as brown needles, mp 166°C (60% based on crude starting material). *Anal.* calcd. for $C_{11}H_8NSI_3$: C 23.28, H 1.41, N 2.47, S 5.64, I 67.20; found: C 23.03, H 1.34, N 2.48, S 5.52, I. 67.07%. This material was treated in boiling acetic acid with perchloric acid and boiled to expel iodine, giving the perchlorate (**11***b*), mp 168°C (lit. (24) mp 168–169°C).

*Reaction of 1,2-dithiolium salts with methyl 2-pyridylacetate to form methyl 1,2-dithiol-3-ylidene-2-pyridylacetates (13*a–c*)*

The 3-methylthio-1,2-dithiolium salts (0.01 mol) and methyl 2-pyridylacetate (1.5 g) in acetonitrile (20 mL) were warmed gently for 5 min. The evolution of methanethiol was evident and the mixture became homogeneous. The solutions were diluted with water and extracted with chloroform, which was dried. Evaporation yielded red oils which crystallized on trituration with ethanol. Compounds were recrystallized from hexane–benzene, 1:1 mixtures. Results are summarized in Table 1.

*Hydrolysis of methyl 1,2-dithiol-3-ylidene-2-pyridylacetates to form 1,2-dithiol-3-ylidene-2-pyridylmethanes (13*c, f*)*

The esters (0.5 g) **12***a–c* were treated with amixture of acetic acid (5 mL) and concentrated hydrochloric acid (5 mL) under reflux for 24 h. Solutions were diluted with water and neutralized with sodium bicarbonate. The dried chloroform extracts were evaporated, giving the products as red or orange crystals which were recrystallized from toluene. Results are summarized in Table 1. Compound **12***c* gave only benzo-1,2-dithiole-3-one on hydrolysis.

*Reaction of 3-methylthio-4-phenyl-1,2-dithiolium iodide with methyl 2-pyridylacetate to form the quinolizenethione (15*a*)*

This reaction was performed as for the other 1,2-dithiolium salts. Work-up gave a viscous red oil which slowly crystallized under ethanol. The product (**15***a*) was collected and recrystallized from ethanol as fibrous yellow needles, mp, 166–168°C (61%). Work-up of the mother liquor gave more of this material and a small amount of the ester **13***g*.

For **15***a*, the ^{1}H nmr spectrum δ: 3.91 (3H, s, the methyl protons), 7.46–9.60 (10H bands, the aromatic and heterocyclic protons) ppm. The ^{13}C nmr spectrum, δ: 175.61 (C=S), 165.42 (C=O) ppm. The mass spectrum $M^+ - 1$ found: 294, $M - 1$ calcd.: 294. *Anal.* calcd. for $C_{17}H_{13}NSO_2$: C 69.15, H 4.41, N 4.75, S, 10.85; found: C 69.05, H 4.47, N 4.72, S 10.83%.

TABLE 1. Preparation of methyl 1,2-dithiol-3-ylidene-2-pyridylacetates (**12***a*–*c*) and 1,2-dithiol-3-ylidene-2-pyridylmethanes (**12***e*, *f*)

*This material appears (by nmr spectrum) to be a 3:1 mixture of two components, probably the two geometrical isomers. We have been unable to separate these by chromatography or crystallization.

*Preparation of methyl 3-phenyl-4-oxo-4*H*-quinolizine-1-carboxylate (15*b*)*

Methyl 3-phenyl-4-thio-4*H*-quinolizine-1-carboxylate (295 mg, 1 mmol) in acetone (10 mL) was titrated with a saturated solution of potassium permanganate in acetone until th solution just retained a purple color on standing. The mixture was filtered to remove manganese dioxide and purified by tlc using ether as an eluent. The product ran as a yellow band with a blue halo under uv light. Work-up and crystallization from an ethanol–benzene 1:1 mixture gave the product as bright yellow needles, mp 139.5–140.5°C (91%). The nmr spectrum, δ: 3.86 (3H, s, the methyl protons), 7.27–9.45 (10H bands, the aromatic and heterocyclic protons). The mass spectrum M^+ found: 279, *M* calcd.: 279. *Anal.* calcd. for $C_{17}H_{13}NO_3$: C 73.12, H 4.66, N 5.02; found: C 73.22, H 4.61, N 5.18%.

*Preparation of 3-phenyl-4*H*-quinolizine-4-thione (15*e*)*

The ester **15***a* (294 mg, 1 mmol) in acetic acid (10 mL), concentrated hydrochloric acid (10 mL), and water (10 mL) was refluxed 24 h. The yellow solution was neutralized with solid sodium bicarbonate and extracted with chloroform (3 × 50 mL). These extracts were dried and evaporated to give a yellow oil which was purified by chromatography. The material crystallized from ethanol as yellow needles, mp 135–136°C (91%). The mass spectrum, $M^+ - 1$ calcd.: 236, $M - 1$ found: 236. *Anal.* calcd. for $C_{15}H_{11}NS$: C 75.95, H 4.64, N 5.91, S 13.50; found: C 75.81, H 4.72, N 5.88, S 13.60%.

Preparation of 4-methylthio-3-phenylquinolizinium iodide (17)

3-Phenyl-4*H*-quinolizine-4-thione (118 mg, 0.5 mmol) was treated with methyl iodide (2 mL). The thione dissolved rapidly but soon precipitated a yellow oil which eventually crystallized. The material was collected and recrystallized from nitromethane with precipitation by ether as yellow needles, mp 146–148°C (97%). *Anal.* calcd. for $C_{16}H_{14}INS$: C 50.56, H 3.69, I 33.51, N 3.69, S, 8.44; found: C 50.47, H 3.81, I 33.45, N 3.69, S 8.81%.

Azides. Part V. A kinetic study of the formation of *N*-(*p*-toluenesulphonyl)-1*H*-azepine by thermolysis of *p*-toluenesulphonylazide in benzene under nitrogen pressure[1]

NAGARAJ R. AYYANGAR, RAMESH B. BAMBAL, DATTATRAYA D. NIKALJE, AND KUMAR V. SRINIVASAN
National Chemical Laboratory, Pune 411 008, India

Received July 6, 1984

NAGARAJ R. AYYANGAR, RAMESH B. BAMBAL, DATTATRAYA D. NIKALJE, and KUMAR V. SRINIVASAN. Can. J. Chem. **63**, 887 (1985).

The course of thermolysis of *p*-toluenesulphonylazide (**A**) in benzene at 160°C and 40.1 atm of nitrogen pressure was followed by analysis of the reactants and products in the reaction mixture by hplc. The rate measurements indicate that the reaction follows first-order kinetics with respect to the formation of *N*-(*p*-toluenesulphonyl)-1*H*-azepine (**B**) and *p*-toluenesulphonamide (**D**). The concentration–time profile is consistent with the formation of *p*-toluenesulphonylanilide (**C**) from the azepine (**B**). The rate constants indicate that the azepine (**B**) decomposes to the anilide (**C**) at the same rate at which it is formed.

NAGARAJ R. AYYANGAR, RAMESH B. BAMBAL, DATTATRAYA D. NIKALJE et KUMAR V. SRINIVASAN. Can. J. Chem. **63**, 887 (1985).

Faisant appel à la clhp pour analyser les réactifs et les produits présents dans les mélanges réactionnels, on a déterminé le cours de la thermolyse de l'azoture de *p*-toluènesulfonyle (**A**) en solution dans le benzène, à 160°C et sous 40,1 atmosphères d'azote. Les vitesses mesurées indiquent que la réaction est du premier ordre par rapport à la formation de la *N*-(*p*-toluènesulfonyl) 1*H*-azépine (**B**) et du *p*-toluènesulfonamide (**D**). Le profil concentration–temps est en accord avec une formation du *p*-toluènesulfonylanilide (**C**) à partir de l'azépine (**B**). Les constantes de vitesse indiquent que la vitesse de formation de l'azépine (**B**) est égale à sa vitesse de décomposition en anilide (**C**).

[Traduit par le journal]

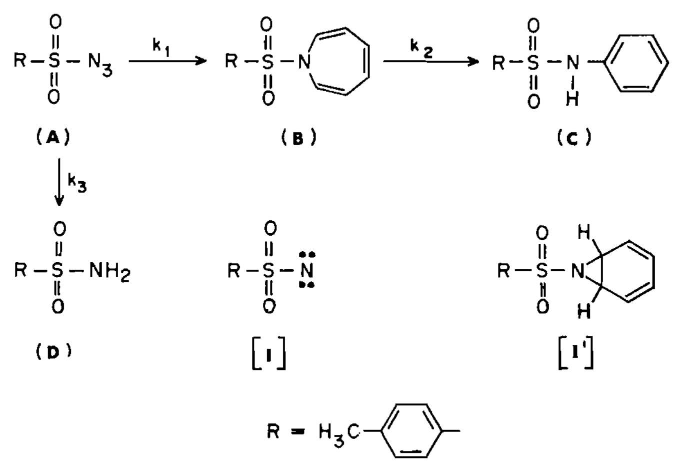
Introduction

Thermal decomposition of *p*-toluenesulphonylazide in dimethyl terephthalate at atmospheric pressure has been shown to result in the formation of 2-*p*-toluenesulphonamidoterephthalate and *N*-*p*-toluenesulphonyl-2,5-dicarbomethoxy-1*H*-azepine in 5% and 15% yields, respectively (1). Electron-withdrawing functional groups such as carbomethoxy, acetyl, and nitro lead preferentially to the formation of *N*-sulphonylazepines, whereas electron-donating groups such as methyl predominantly yield the sulphonanilides. This has been attributed to the influence of the substituents on the stability of the benzaziridine intermediate complex formed initially (2). It has been reported that, in the thermolysis mixture of methyl sulphonylazide in benzene, mainly the sulphonanilide (C—H insertion product) and the sulphonamide (hydrogen abstraction product) could be detected. Methyl sulphonylazepine, the ring expansion product (C═C insertion product) was not isolated, although its formation was evident and it was trapped as its tetracyanoethylene adduct (3).

Recently, the facile synthesis of *N*-sulphonyl-1*H*-azepines in good yields by the nitrene insertion reaction under nitrogen pressure has been reported by us, in which it was also shown that pressure has a remarkable effect on such insertion product formation involving ring expansion (4). This communication deals with the course of this reaction, which was followed kinetically by estimating the unreacted azide (**A**), the azepine (**B**), the sulphonanilide (**C**), and the sulphonamide (**D**) in the reaction mixture at various intervals of time by high performance liquid chromatography (hplc). The kinetic data indicated the reaction pathway as shown in Scheme 1.

The sulphonanilide (**C**) is exclusively formed from the azepine (**B**), by a consecutive reaction in series, viz. **A** → **B** → **C**. The sulphonamide derivative (**D**) is formed by abstraction of two hydrogens by the sulphonylnitrene (**I**), in a parallel reaction.

In contrast, when the thermolysis was carried out at atmo-



SCHEME I

spheric pressure and reflux temperature of benzene, the sulphonylazepine (**B**) was isolated only in poor yield (less than 1.5%). It was also shown that azepine formation increases with an increase in pressure. Furthermore, the reaction temperature of 155–160°C appeared to be critical. In one experiment, when the reaction was carried out at 140–145°C under otherwise similar reaction conditions, no sulphonylazepine (**B**) could be isolated. The use of nitrogen positive pressure serves the dual purpose of attaining the necessary critical temperature for the spontaneous irreversible thermolytic decomposition of the tosylazide (**A**) to the singlet nitrene (**I**), and of keeping the benzene in the liquid phase for a homogeneous reaction.

The interest in the azepine ring systems has been generated because of their presence in a number of drugs (5). The rhoeadine alkaloids have benzazepine as the basic structure (6). The sulphonyl azepines described here and elsewhere may exhibit promising biological activity.

Results and discussion

para-Toluenesulphonylazide was thermolysed in an excess

[1] NCL Communication No. 3403.

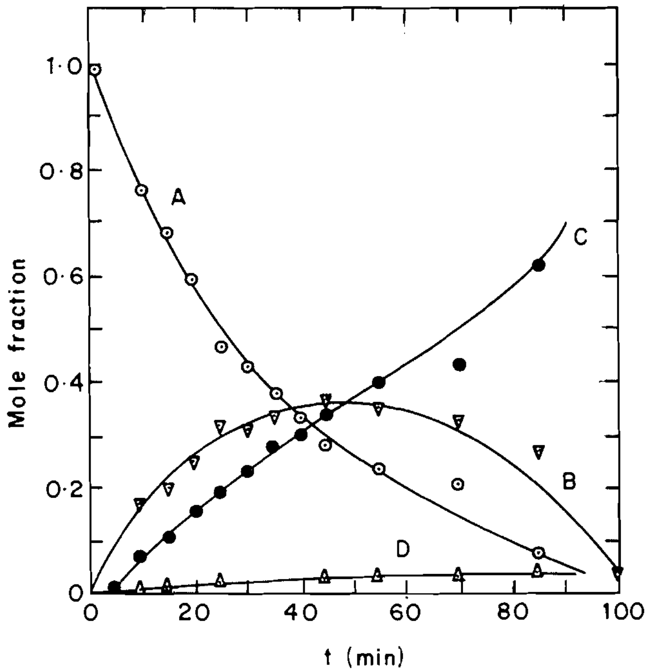


FIG. 1. Concentration–time curves.

of benzene at 160°C and 40.1 atm (1 atm = 101.3 kPa) of nitrogen pressure in a Parr autoclave. Aliquots of the reaction mixture were withdrawn at various intervals of time. They were subjected to hplc analysis for the estimations of the unconverted azide (**A**), and relative amounts of azepine (**B**), anilide (**C**), and amide (**D**), formed in the reaction (Table 1). Since benzene, one of the reactants, was in large excess, the reaction is zero order with respect to it. As such, it was removed from the samples before analysis. Preliminary investigations revealed that the reaction was initiated for a measurable conversion of the azide (**A**) to the nitrene (**I**) only at 160°C. Under the reaction conditions, this temperature was attained 50 min from the time the heating was started. This was taken to be the zero time of the reaction. The concentration vs. time curves for the azide (**A**), azepine (**B**), anilide (**C**), and amide (**D**) respectively are shown in Fig. 1. These are typical of those reported for consecutive first-order reactions (7). Since at the end of the reaction no azide (**A**) was present and the reaction could be carried out to complete conversion of the azepine (**B**) to the anilide (**C**), the thermolysis of *p*-toluenesulphonylazide (**A**) in benzene is a first-order consecutive irreversible reaction in series as shown in Scheme 1. The overall specific reaction rate ($k_1 + k_3$) for the thermal decomposition of the azide in benzene is the sum of the specific reaction rate for the formation of the azepine (**B**) (k_1) and that for the formation of the sulphonamide (**D**) (k_3) by a parallel reaction. Both reactions involve the nitrene (**I**) as intermediate.

The linear plot of $-\ln X_A$ vs. time t (Table 2, Fig. 2) indicated that the thermal decomposition of the azide **A** is a first-order reaction with an overall specific reaction rate

$$[1] \quad k_1 + k_3 = 0.028 \text{ min}^{-1}$$

The slope of the linear plot of X_B vs. X_D (Fig. 3) gives the value

$$[2] \quad k_1/k_3 = 5.349$$

45	0.278	1.28
55	0.219	1.52
70	0.210	1.56
85	0.082	2.50

Solving eq. [2] simultaneously with eq. [1], the values of k_1 and k_3 were evaluated as 0.0235 ± 0.0007 min^{-1} and 0.0044 ± 0.0001 min^{-1} respectively. To evaluate the value of k_2, the differential equation

$$[3] \quad \frac{dX_B}{dt} + k_2X_B = k_1e^{-k_1t}$$

for first-order consecutive irreversible reaction was simplified to

$$[4] \quad -\ln X_{B_{max}} = k_2t_{max}$$

Substituting the values for $X_{B_{max}}$ and t_{max} as 0.356 and 45 respectively from Fig. 1 and Table 1 in eq. [4], the value of k_2 was evaluated as 0.0228 ± 0.0006 min^{-1}. The second step of the series reaction was also confirmed to be first order by carrying out the reaction starting from different initial concentrations of the azide (**A**), under identical conditions. The mole fraction of the azepine (**B**) at t_{max}, i.e. $X_{B_{max}}$ remains constant and was independent of the initial azide concentration. Thus the results indicate that k_1 is nearly equal to k_2, in which case $X_{B_{max}} = 1/e = 0.368, \ldots$ from eq. [3]. The calculated value of $X_{B_{max}}$ as derived above matches well with the experimental value of 0.356 for $X_{B_{max}}$ (Fig. 1).

The kinetic data generated by us clearly indicate that the nitrene insertion in benzene at 160°C under pressure preferentially forms the sulphonyl azepine (**B**), possibly via the ben-

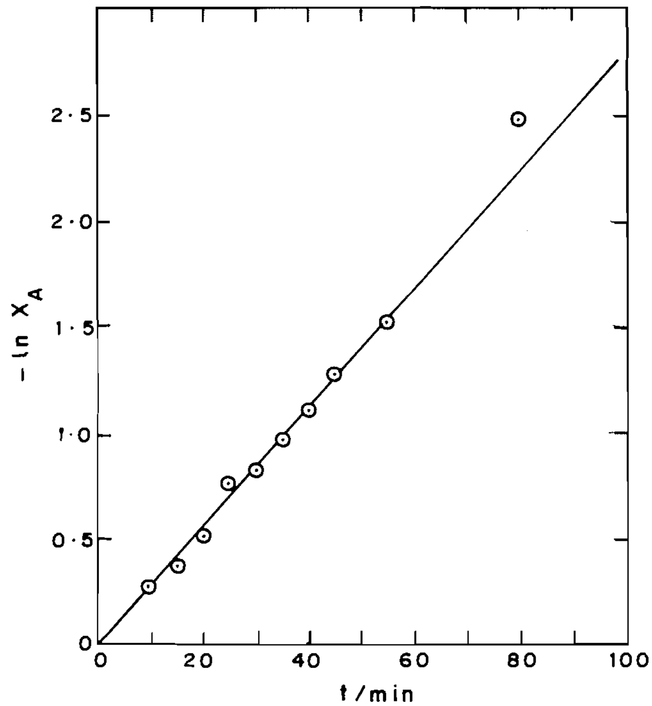

FIG. 2. First-order plot for the decomposition of azide **A** in benzene.

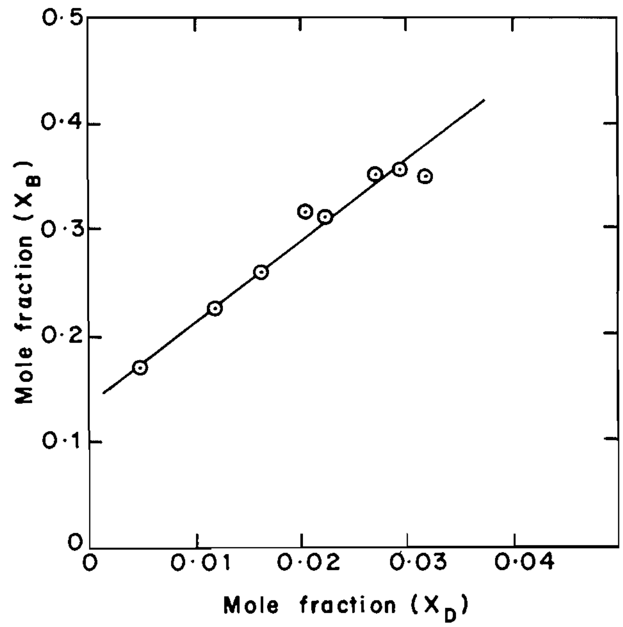

FIG. 3. Linear plot for the determination of k_1/k_3.

zaziridine intermediate (**I′**). The sulphonylazepine (**B**) then rearranges to the sulphonanilide (**C**) in a concerted manner, possibly involving a carbon–carbon σ-bond formation followed by aromatization. The rate constant evaluations show that the azepine (**B**) rearranges to the anilide (**C**) at the same rate at which it is formed. This indicates that, under the conditions of the reaction, both steps, viz. the formation of the azepine (**B**) and subsequent conversion to the sulphonanilide (**C**), are kinetically controlled.

Experimental

Melting points were recorded in capillary tubes. Benzene used for the reaction was distilled on phosphorous pentoxide. Petroleum ether used was of the boiling range 60–80°C unless otherwise specified. Reactions were carried out in a Parr bench-top mini reactor of 300-mL capacity provided with a heater, stirrer, pressure gauge, thermocouple, and temperature controller. A sample removal system in the form of a loop with inlet and outlet valves, fabricated out of a copper tube of 22 in. × 0.1 in. id, was fixed to the sampling point of the reactor. Reaction samples were analysed by reverse phase liquid chromatography on a Spectra-Physics SP 8000 high performance liquid chromatograph connected to a uv detector at 254 nm using an ODS (Spectra-Physics) column (250 mm × 4.6 mm id). The ir spectra were recorded as Nujol mulls using a Perkin–Elmer 221 spectrometer, the nmr spectra on a Varian T-60 spectrometer using tetramethyl silane as internal standard, and mass spectra on a CEC-21-110B mass spectrometer.

General procedure for the thermolysis of p-*toluenesulphonylazide in benzene*

In a typical run, the azide **A** (4.0 g, 0.005 mol) and benzene (200 g, 2.56 mol) were charged into the autoclave already purged with nitrogen. The reactor was pressurized to 27.2 atm with nitrogen and heated slowly to raise the temperature to 160°C in 1 h. The final pressure recorded on the gauge at 160°C was 40.1 atm, the generated nitrogen and the vapour pressure of benzene at reaction temperature contributing towards the increase in pressure. The first sample was removed at 145°C at 55 min and the rest at 160°C at various intervals of time (Table 1).

Procedure for sample removal

During each sample removal, the outlet valve of the sample tube was closed and the inlet valve opened to let the reaction mixture enter inside the loop. The inlet valve was then closed immediately. The loop was cooled externally by dipping in cold water and then the outlet valve opened to remove the reaction mixture inside the loop. Before removal of the next sample, the same operation was repeated to flush the inside of the loop free of the previous sampling. Each time nearly 10 mL of the sample was removed. The pressure drop noticed during each sample removal was compensated for by pressuring the system back to 40.1 atm with nitrogen every time.

High performance liquid chromatographic (hplc) analysis

Excess benzene was distilled off and the crude solid dissolved in methanol. The methanolic solution was filtered prior to analysis by hplc with the following operating parameters: detector at 254 nm at a sensitivity of 0.18 amp; mobile phase of methanol–water (6:4); flow rate of 2 mL/min; column inlet pressure of 1619 psi (1 psi = 6.89 kPa); and a chart speed of 1 cm/min; 10 μL of the sample were injected each time. The composition of the reactant and the products in the reaction mixture was then determined using the external standard quantitation method with the aid of the data processor unit present in the instrument. The order of elution of the components with their retention time(s) in parentheses are as follows: (1) *p*-toluenesulphonamide (**D**) (208); (2) *p*-toluenesulphonylanilide (**C**) (444); (3) *p*-toluenesulphonylazide (**A**) (534); and (4) *p*-toluenesulphonylazepine (**B**) (592). The analysis of the samples withdrawn at various intervals of time has been given in Table 1.

Preparation of standard compounds

The standard compounds were prepared according to methods reported in literature: (**A**) *p*-toluenesulphonylazide (8); (**B**) *p*-toluenesulphonyl-1*H*-azepine, mp 167°C (dec.) (lit. (4) mp 167°C); (**C**) *p*-toluenesulphonanilide, mp 103°C (lit. (9) mp 103°C); (**D**) *p*-toluenesulphonamide, mp 136°C (lit. (10) mp 136°C). All the products were characterized further by spectral and elemental analyses.

A study on the electrochemical reduction of acetylbenzoyl on a mercury electrode has been carried out in the pH range 0–9 in buffered aqueous solutions. The effect of pH, drop time, temperature, and acetylbenzoyl concentration on polarographic and kinetic parameters has been studied. The occurrence of adsorption phenomena is inferred from the recordings of $C-E$ curves. Tafel slopes and reaction orders have been obtained at potentials corresponding to the foot of the wave. On the basis of these experimental data, a reaction mechanism is proposed for the zone of potentials where Tafel's law is satisfied.

J. M. RODRÍGUEZ-MELLADO, J. L. AVILA et J. J. RUIZ. Can. J. Chem. **63**, 891 (1985).

Utilisant des solutions aqueuses tamponées et opérant à des pH allant de 0 à 9, on a étudié la réduction électrochimique de l'acétylbenzoyle sur une électrode à mercure. On a étudié l'effet du pH, du temps de chute, de la température et de la concentration de l'acétylbenzoyle sur les paramètres polarographiques et cinétiques. Sur la base des enregistrements de courbes $C-E$, on croit qu'il existe des phénomènes d'adsorption. On a obtenu les pentes de Tafel et les ordres de la réaction à des potentiels correspondants au pied de la vague. Sur la base de ces données expérimentales, on propose un mécanisme réactionnel pour la zone de potentiels qui satisfait à la loi de Tafel.

[Traduit par le journal]

Introduction

There are only two papers in the chemical literature dealing with the electrochemical reduction of acetylbenzoyl, showing great discrepancies with respect to one another.

Thus, a paper by Arai (1) reports the occurrence of one or two reduction waves (depending on the pH of the medium) over the pH range 0–10, finding no waves above pH 10. According to this author, a dimerization process corresponds to the first wave found.

On the other hand, Fedoronko and Hudekova (2) state that acetylbenzoyl shows one, two, or three polarographic waves (also depending on the pH of the medium) over the pH range 0–12 and attribute them to the reduction of the unhydrated species, the monohydrate protonated form, and the monohydrate itself, respectively. These authors carried out a potential-controlled electrolysis at potentials corresponding to the limiting current (i_L) of the first wave, subsequently isolating the reaction product and identifying it as phenylacetylcarbinol by ir spectroscopy.

In any case, the reduction mechanism of acetylbenzoyl has not yet been discussed. Therefore, the aim of this paper has been to carry out a polarographic study of this compound, as well as to determine some kinetic parameters at potentials corresponding to the foot of the polarographic wave ($i/i_L < 0.05$), on the basis of which the reaction mechanism can be discussed.

Experimental

All reagents used were Merck p.a. grade. A buffered solution with the following components and concentrations was used as supporting electrolyte: 0.05 M CH_3COOH and 0.05 M H_3PO_4 for pH < 8, and 0.05 M H_3PO_4 and 0.05 M $NaHCO_3$ for pH > 8. The ionic strength was adjusted to 0.2 M with $NaNO_3$.

An electronic system made up of an Amel 551 potentiostat, a Hewlett–Packard 7045-A recorder, and a Hewlett–Packard 3310-A wave generator was used. All measurements were made in a thermostatted Amel 494 cell.

The working electrode was a Radiometer B 400 capillary with flux, $m = 2$ mg s^{-1} and drop time, $t = 4.19$ s, both parameters being measured in 0.05 M phosphate buffer at pH 2 and open circuit, the height of the mercury reservoir being 40 cm. A saturated Ingold 303-NS calomel electrode was used as reference and a platinum Ingold Pt-4805 acted as auxiliary.

Differential capacity–potential curves were recorded automatically by fitting our electronic system to a circuit devised by Roldán *et al.* (3). A Telequipment D-1011 oscilloscope was also used. The capillary was an Amel EA 1019/2 with $m = 1.02$ mg s^{-1}, its drop time being set at 4.8 s.

Both the voltammetric measurements and the determination of the number of electrons were performed by means of a Metrohm EA 290 hanging-drop mercury electrode. Differential pulse polarograms were recorded by using a Metrohm-Herisau 626 polarograph.

All measurements were made in a nitrogen medium at 25 ± 0.1°C, with the exception of those corresponding to the study of the effect brought about by a temperature change. All other experimental conditions were identical to those described in ref. 4.

Results and discussion

Polarographic behaviour

Acetylbenzoyl shows one or two reduction waves (depending on the pH) by DC polarography. The first one occurs over the whole pH range under study (0–9), whereas the second one can only be observed within the pH range 2–9. The sum of the heights of the two waves remains practically constant throughout the pH range studied (Fig. 1).

The limiting current of the first reduction wave is dependent on the pH of the solution. Figure 1 shows the variation of the former as a function of the latter. Above pH 10, the limiting current decreases with time (the higher the pH, the sharper the decrease) due to the instability of acetylbenzoyl in alkaline solutions.

An increase in pH shifts the $E_{1/2}$ of this first wave towards more negative potentials. The plot of $E_{1/2}$ vs. pH is linear with a slope of −58 mV per pH unit.

Below pH 1 and at potentials corresponding to the limiting current the process is controlled by diffusion, as is evident from the value of the temperature coefficient (1.4%/°C) and the slopes of the plots of log i_L vs. log t (0.19) and log i_L vs. log h (0.5) (h is the height of the mercury reservoir). Between pH

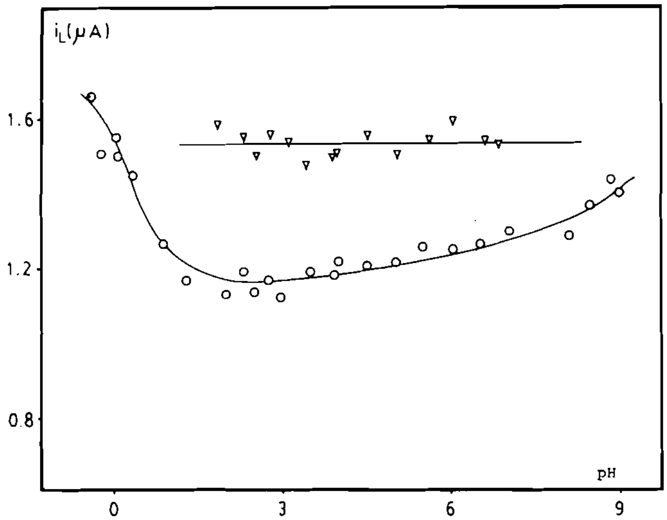

FIG. 1. Variation of i_L with pH. ○ First wave. △ Total limiting current.

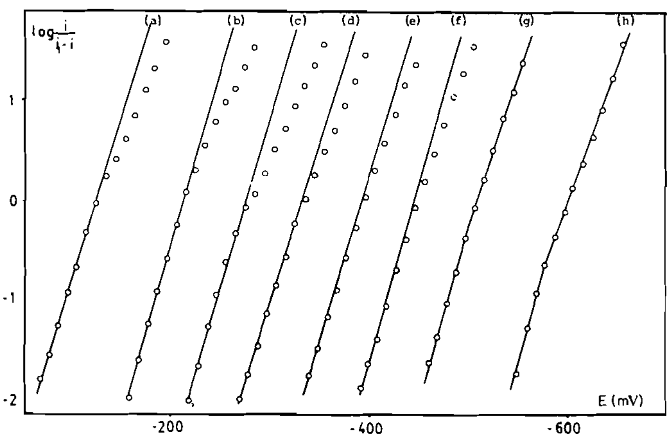

FIG. 2. Logarithmic analysis. pH: (a) 1.19; (b) 1.97; (c) 2.95; (d) 3.97; (e) 5.00; (f) 6.01; (g) 7.00; (h) 8.62.

1 and 9 the wave exhibits a certain kinetic character (at pH 4 the temperature coefficient is 2.8%/°C, $\partial\log i_L/\partial\log t = 0.25$, and $\partial\log i_L/\partial\log h = 0.42$). The variation of these parameters with pH, resembling that found for other α-dicarbonyl compounds (5), indicates that in the potential region corresponding to the plateau of the wave the process is partly controlled by the dehydration of the carbonyl group, a chemical reaction prior to the transfer process and subject to general acid–base catalysis. In order to show this kinetic character, we have plotted log $[i_L/(i_D - i_L)]$ vs. log t. The results so obtained satisfied the Koutecky equation (6), which, as modified for maximum current, reads:

$$[1] \quad i_L/(i_D - i_L) = 1.386\,(k_1K^2t)^{0.546}$$

The straight line obtained has a slope of 0.56 at pH 4, the value of k_1K^2 being 8.3 s^{-1}.

A logarithmic study of the first wave has been carried out over the whole pH range under study, its results being displayed in Fig. 2. The logarithmic study shows a linear segment corresponding to the lower part of the wave, whereas a deviation from linearity is observed for higher i values. The wave fulfils the Sluyters equation (7), derived for a weak adsorption of depolarizer, negligible for both products and intermediates.

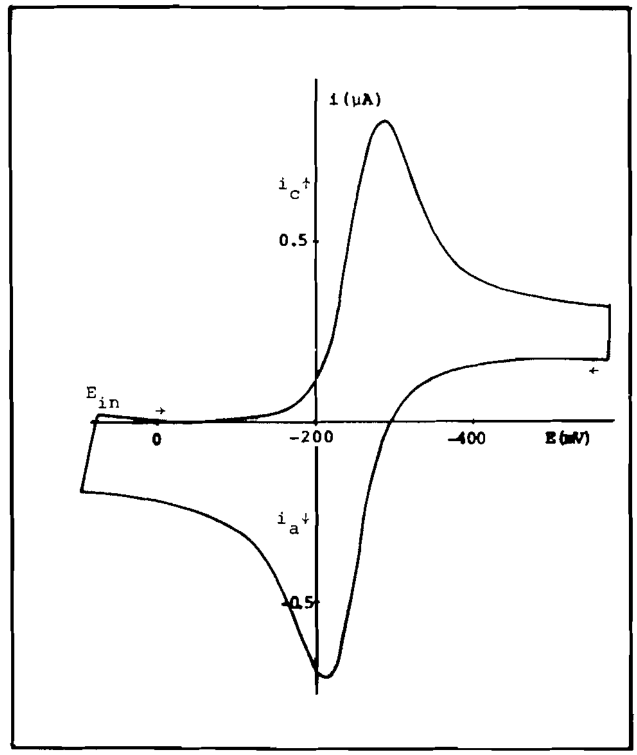

FIG. 3. Voltammograms. Sweep-rate = 400 mV s^{-1}. pH 2.12 ($E_p^{anodic} - E_p^{cathodic}$ = 82 mV). E_{in} indicates the potential initial.

The slope of the linear segment, −29 mV, indicates that the electron transfer is a reversible process, at least at potentials corresponding to the foot of the polarographic wave. In order to determine whether the overall reaction was reversible or postkinetic at these potentials, the influence of drop time on potential was studied at a constant i value corresponding to the foot of the wave, finding a slope of 15 mV for the linear plot of E vs. log t, which shows the overall process to be postkinetic. This conclusion is corroborated by the fact that the intensity is independent of the height of the mercury reservoir at potentials corresponding to the foot of the wave.

A voltammetric study has been carried out over the sweep range of 100–1000 mV s^{-1}. Figure 3 shows a typical voltammogram. The corresponding anodic peak is observed in addition to the cathodic one. The former can be attributed to the oxidation of the enol form of phenylacetylcarbinol. The difference between both peak potentials is greater than 2.303 $RT/2F$, which indicates that the overall process is not reversible. Above pH 7, the height of the anodic peak decreases with increase in pH, disappearing above pH 9.

With regard to the second reduction wave, its $E_{1/2}$ shifts towards more negative potentials (−110 mV/pH) with increase in pH. The value of the temperature coefficient (1.5%/°C) and the variation of the limiting current with the drop time ($\partial\log i_L/\partial\log t = 0.19$) and the height of the mercury reservoir ($\partial\log i_L/\partial\log h = 0.5$) show that the wave is governed by diffusion at potentials corresponding to the limiting current and is observable within the whole pH range.

A study of acetylbenzoyl reduction has been performed by differential pulse polarography, indicating that the peak corresponding to the second wave observed by DC polarography decreases in intensity between pH 4 and 6 and that a new peak appears at slightly more negative potentials. The variation of the area of both peaks with pH is the same shape as a titration

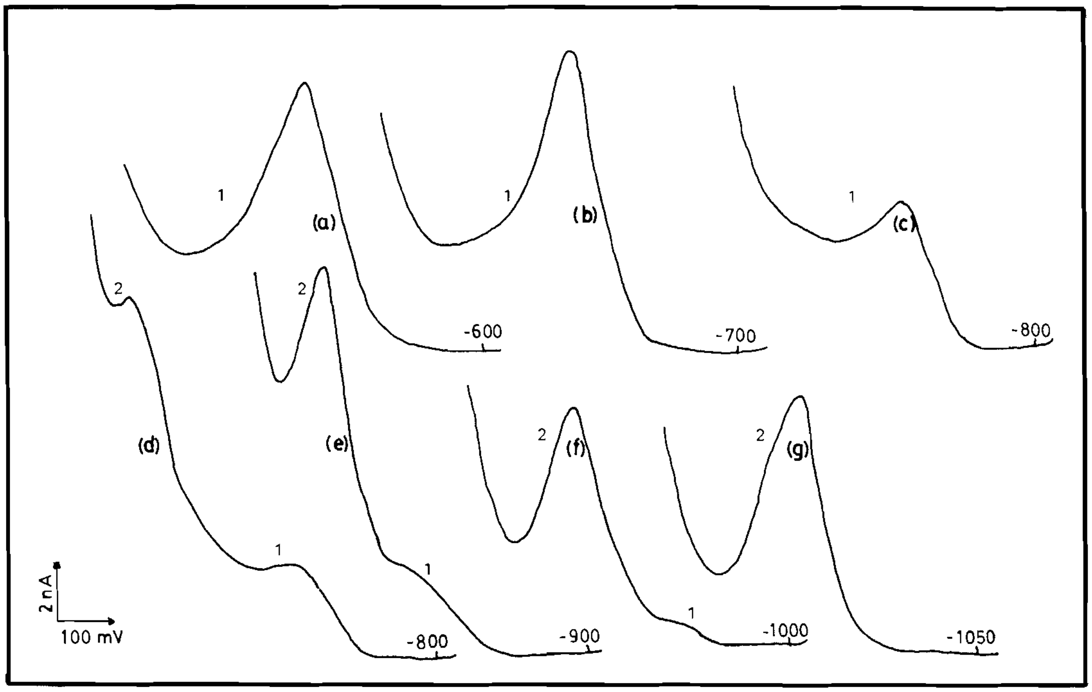

FIG. 4. Differential pulse polarograms. Second wave. Variation with pH. pH: (a) 3.01; (b) 3.51; (c) 4.02; (d) 4.49; (e) 5.09; (f) 5.49; (g) 6.00.

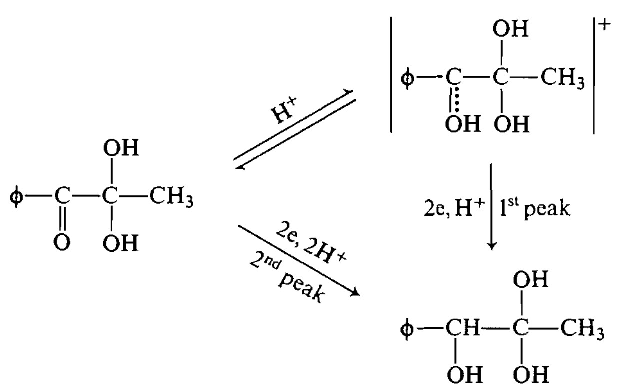
curve. Some of the recordings obtained are shown in Fig. 4.

The potentials of these peaks are the same as those corresponding to the second and third waves obtained by Fedoronko and Hudekova (2) by DC polarography. Moreover, we should indicate that the variation with pH of both the height and the potential of the aforementioned waves coincide exactly with the behaviour observed by us as regards the pH effect on the peaks obtained by DP polarography, and which should be, in our opinion, attributed to the processes suggested by Fedoronko and Hudekova for the second and third waves:



Determination of the number of electrons

The determination of the number of electrons taking part in the overall reduction reaction per mol of acetylbenzoyl was carried out by constant-potential chronoamperometry, using a hanging-drop electrode. One set of measurements was made at pH 0 and the potential corresponding to the limiting current of the first wave, and another set of measurements was performed at pH 4 and the potential corresponding to the limiting current of the second wave. A value of about 2 was found in every case.

$C-E$ *curves*

Capacity–potential curves were recorded for acetylbenzoyl

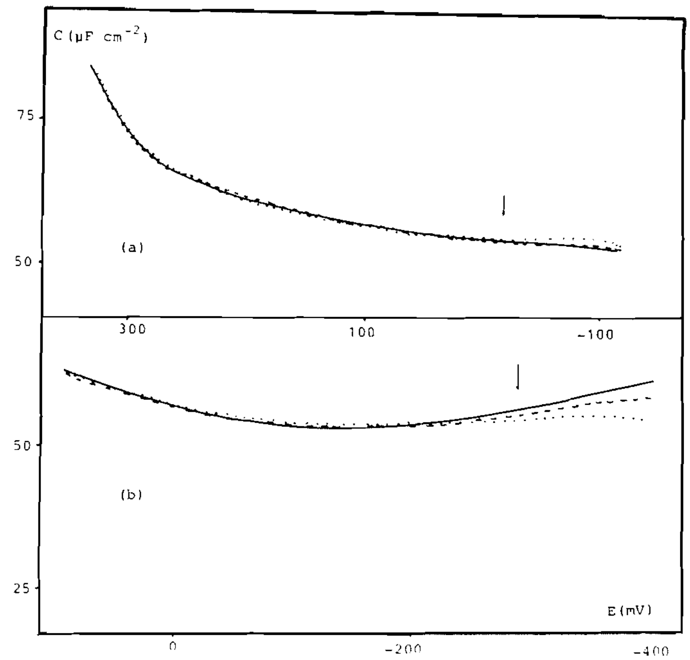


FIG. 5. Capacity–potential curves. (a) pH = 0; (b) pH = 4. ——— Supporting electrolyte. ----- Acetylbenzoyl 5×10^{-5} M. ······· Acetylbenzoyl 2×10^{-4} M. (Arrow indicates the potential of initiation of the reduction.)

at both the working concentration (2×10^{-4} M) and at 5×10^{-5} M. These recordings, performed at pH 0 and 4, together with those corresponding to the supporting electrolyte, are shown in Fig. 5. At pH 0 and 4 no practical difference can be observed between the three curves. Consequently, acetylbenzoyl adsorption must be very weak (and therefore unappreciable in the $C-E$ recordings) or nonexistent.

Nevertheless, the $C-E$ curves recorded at pH 10.3 do show the occurrence of adsorption, even at potentials corresponding to the beginning of the reduction process (around −650 mV).

Since the $C-E$ curves recorded below pH 9 do not show any extent of adsorption, we may consider that the reduction occurs in an homogeneous phase.

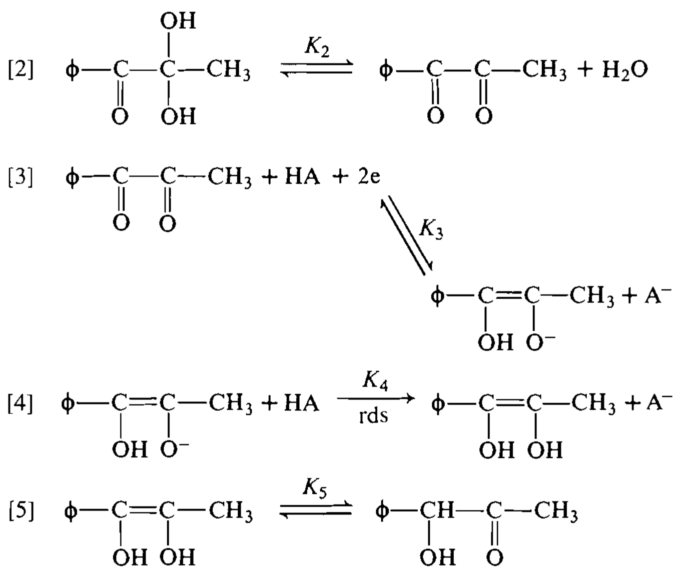
Tafel curves and reaction orders

Regarding $i-E$ polarization curves traced at potentials corresponding to the foot of the first polarographic wave, a study has been carried out on their variation with the concentration of reactants.

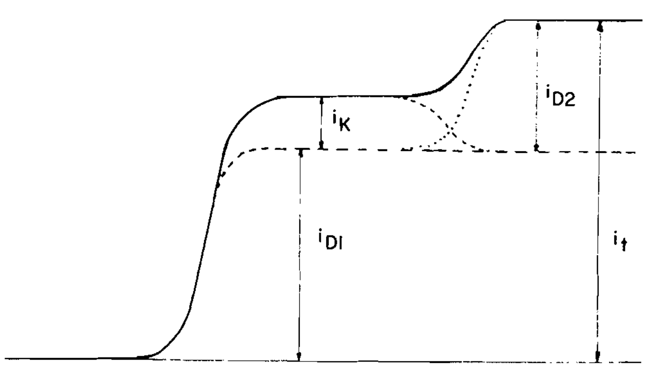
From the variation of $\log i$ with the concentration of reactants at a constant potential, the corresponding reaction orders were obtained. Figures 6 and 7 show some of the results. The average value of the Tafel slopes was −30 mV, while the reaction orders with respect to acetylbenzoyl and H^+ ion were 1.0 and 2.0 respectively.

With the aim of studying the influence of other proton donors of the solution on the reaction mechanism, the reaction orders corresponding to the buffer components were determined at varying pH and a constant ionic strength, indicating that this influence is only appreciable for high concentrations of the proton donors.

The following reaction mechanism, in agreement with the Tafel slopes and reaction orders found, is proposed for potentials corresponding to the foot of the wave:



SCHEME 1



SCHEME 2

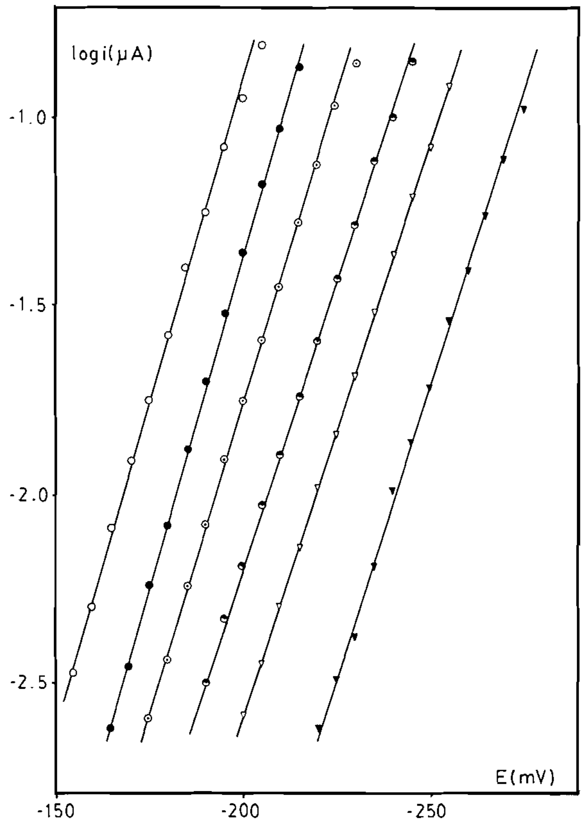


FIG. 6. Tafel plots at varying pH values. pH: ○ 1.69; ● 1.97; ⊙ 2.29; ◒ 2.48; △ 2.71; ▲ 3.04.

where HA represents any acidic species present in the interphase.[3]

Assuming reaction [4] to be the rate-determining step, the value of the cathodic current at the foot of the wave can be expressed as:

$$[6] \quad i = 2FKK'C\,C_H\,(k_H C_H + \sum_i k_{HA_i} C_{HA_i})\, e^{-2FE/RT}$$

where C and C_H stand for the concentration of acetylbenzoyl and H^+ ion, respectively; C_{HA_i} for the concentration of each acidic species (except H^+) present in the interphase; E for

[3]During the revision of this paper, it was suggested to us that reaction [3] should be written as 3 discrete steps:

[3*a*] $PhCOCOCH_3 + e^- = (PhCOCOCH_3)^{\cdot -}$

[3*b*] $(PhCOCOCH_3)^{\cdot -} + HA = (PhCOCOHCH_3)^{\cdot} + A^-$

[3*c*] $(PhCOCOHCH_3)^{\cdot} + AB^{\cdot -} = (PhCOCOHCH_3)^- + AB$

However, our experimental data prevent us from establishing the sequence of the elementary steps, in quasi-equilibrium, which precede the rate-determining step. Hence, we have opted for writing the sum of all these steps in reaction [3].

On the other hand, it could be considered that reactions such as [4] are generally very fast and often diffusion controlled and thus it is difficult to accept this as the rate-controlling step in the reaction. As a matter of fact, these reactions are generally fast, but our results clearly indicate the occurrence of a non-zero reaction order with respect to the proton donors of the supporting electrolyte, which indicates that these proton donors are involved in the rate-determining step. The occurrence of a protonation reaction as rate-determining step is, therefore, plausible.

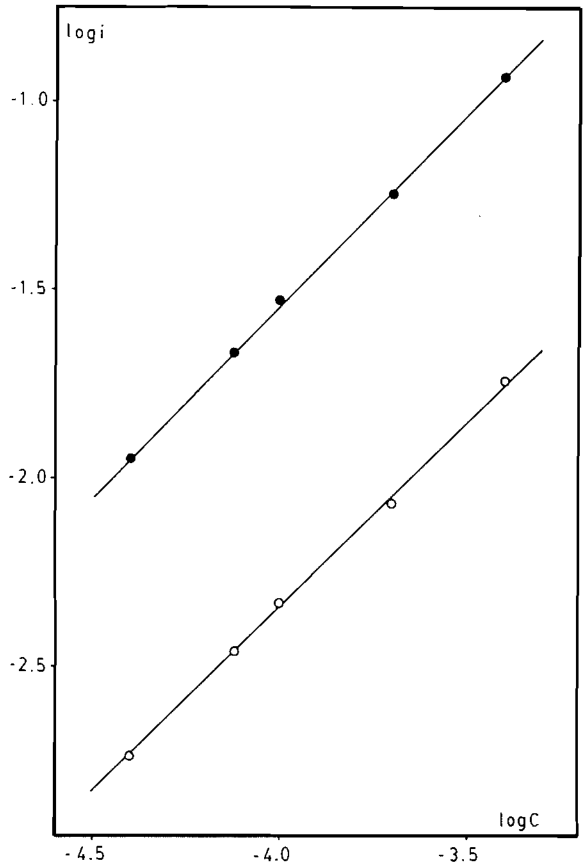

FIG. 7. Electrochemical order with respect to acetylbenzoyl. pH 4.00; ○ E = −275 mV; ● E = −300 mV.

potential applied; K for the product of the equilibrium constants of the stages prior to the rds; k_H and k_{HA_i} for the rate constants corresponding to the reaction of protonation by H^+ ion and HA_i species, respectively; and K' for $\exp(2F\Delta\Phi_{ref}/RT)$, $\Delta\Phi_{ref}$ being the potential of the reference electrode. The term $\sum_i k_{HA_i}C_{HA_i}$ takes into account the contribution of all acidic species present in the interphase, except the H^+ ion.

In the case of protonation by phosphoric acid, and according to eq. [6], the log i vs. log [HA] plot (where [HA] = $[H_2PO_4^-]$ + $[HPO_4^{2-}]$) should give rise (as is experimentally confirmed) to a curve with a slope approaching 1 or 0, depending on whether $k_{H_2PO_4^-}[H_2PO_4^-] + k_{HPO_4^{2-}}[HPO_4^{2-}]$ is much larger or smaller than k_HC_H, respectively. Furthermore, the plot of i vs. [HA] is linear (Fig. 8). The ratio between the slope and the intercept for this plot is independent of the potential, as may be expected from eq. [6], and clearly indicates that both H^+ ion and phosphoric acid are involved in the anion protonation (step [4]).

Since the $\sum_i k_{HA_i}C_{HA_i}$ term contribution is negligible at the values of the working buffer concentration, the reaction order with respect to H^+ ion can be expected to be close to 2, as it indeed happens to be.

Since the wave satisfies closely the Sluyters equation, the process must be complicated with adsorption phenomena. However, these deviations are not significant at potentials

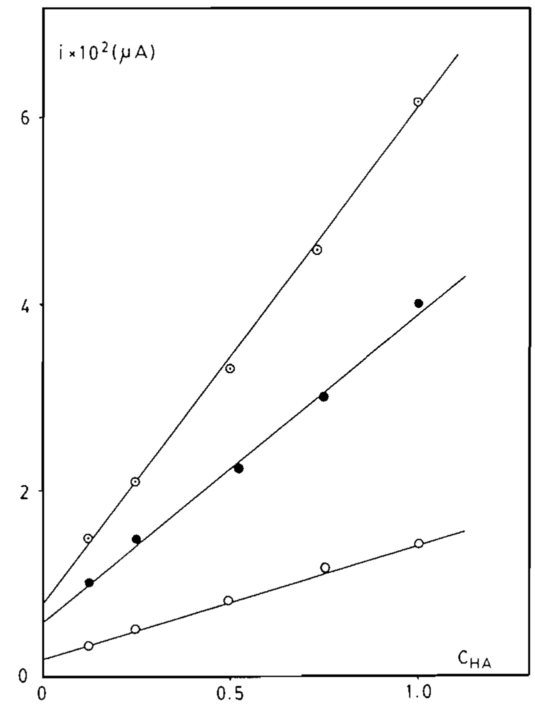

FIG. 8. Plot of i vs. $\{[H_2PO_4^-] + [HPO_4^{2-}]\}$ at pH 7.12. ○ E = −400 mV; ● E = −465 mV; ⊙ E = −480 mV.

corresponding to the foot of the wave.

The calculation of the polarographic and kinetic parameters corresponding to the second wave cannot be accomplished since, at potentials corresponding to the limiting current of the first wave, the reduction of both the unhydrated molecules already existing in the solution and those arising from the dehydration of the monohydrated form in the interphase takes place.

On the other hand, at potentials corresponding to any part of the second wave, the process involves the reduction of the monohydrate (a reaction allowed by the values of the potential) and the unhydrated species arising by diffusion from the bulk of the solution. This fact has prevented us from determining the limiting current for the first wave in the zone of potentials where the second one appears and, consequently, the value of the current for the latter. Therefore it is impossible to obtain electrochemical data for this process. Scheme 2 shows what has been stated above.

Pyrrole chemistry. XXVIII. Substitution reactions of 1-(phenylsulfonyl)pyrrole and some derivatives

HUGH J. ANDERSON, CHARLES E. LOADER,[1] RU XUN XU, NGHIA LÊ, NIALL J. GOGAN, ROBERT MCDONALD, AND LOUISE G. EDWARDS

Chemistry Department, Memorial University of Newfoundland, St. John's, Newfoundland, Canada A1B 3X7

Received August 13, 1984

HUGH J. ANDERSON, CHARLES E. LOADER, RU XUN XU, NGHIA LÊ, NIALL J. GOGAN, ROBERT MCDONALD, and LOUISE G. EDWARDS. Can. J. Chem. **63**, 896 (1985).

The preparative value of the 1-(phenylsulfonyl) *N*-blocking and directing group for the synthesis of 3-acylpyrroles has been further evaluated. Acetylation and benzoylation are strongly regiospecific and give good yields. However, the regiospecificity is not general and other substitution reactions give mixtures of 2- and 3-substitution or even mostly 2-substitution. Friedel and Crafts *tert*-butylation gives 3-*tert*-butyl-1-(phenylsulfonyl)pyrrole and provides a useful route to *tert*-butylpyrrole, but ethylation and isopropylation give mixtures. Acylations of 2- and 3-alkyl-1-(phenylsulfonyl)pyrroles show little evidence of useful regiospecificity.

HUGH J. ANDERSON, CHARLES E. LOADER, RU XUN XU, NGHIA LÊ, NIALL J. GOGAN, ROBERT MCDONALD et LOUISE G. EDWARDS. Can. J. Chem. **63**, 896 (1985).

On a évalué à nouveau l'utilité préparative du groupement phénysulfonyl-1 comme agent *N*-bloqueur et comme groupe directeur pour la synthèse d'acyl-3 pyrroles. L'acylation et la benzoylation sont très régiospécifiques et se produisent avec de bons rendements. Toutefois, la régiospécificité n'est pas générale et d'autres réactions de substitutions conduisent à des mélanges de produits substitués en 2 ou en 3 ou même à des produits qui sont principalement substitués en position 2. La réaction de *tert*-butylation selon Friedel et Crafts fournit le *tert*-butyl-3 (phénylsulfonyl)-1 pyrrole et cette réaction s'avère une route utile pour préparer du *tert*-butylpyrrole; toutefois les réactions d'éthylation ou d'isopropylation conduisent à des mélanges. Les réactions d'acylation des alkyl-2 (ou -3) (phénylsulfonyl)-1 pyrroles ne semblent pas présenter de régiospécificité utile.

[Traduit par le journal]

Recently, Kakushima *et al.* (1) provided a detailed account of their exploration of the Friedel–Crafts acylation of 1-(phenylsulfonyl)pyrrole.[2] Earlier, we (4) and they (5) had reported that this reaction gave mostly, and in some cases only, 3-substitution on the pyrrole ring, consequently affording a useful three-step synthesis of 3-acylpyrroles from pyrrole. Nevertheless, changes in the amount (4) and the nature (1) of the Lewis acid catalyst have been found to lead to more, or even exclusive, 2-substitution.

In contrast, the acylation of pyrroles having other electron-withdrawing groups on the nitrogen, such as the 1-alkoxycarbonyl, leads to almost exclusive 2-substitution (6). A closer model, 1-benzoylpyrrole, was also found to be acetylated at the 2-position. These acyl groups do have a trigonal carbon attached to the ring nitrogen and can occupy less space than the groups about the tetrahedrally substituted sulfur atom, particularly if complexation of the Friedel–Crafts catalyst with the *N*-substituent is important.

While the acetylation reaction was used to explore the potential of this acylation, most of our preparative efforts using the method have been directed toward the synthesis of some 3-aroylpyrroles that were of interest in other studies. These syntheses were generally carried through the acylation and hydrolysis steps without interruption to give the desired 3-aroylpyrrole in good yield where all steps were optimized (Table 1).

In the earlier communication (4) we reported that both formylation using dichloromethyl butyl ether/$AlCl_3$ or dimethylformamide/phosphorus oxychloride, and cyanation using cyanogen bromide/$AlCl_3$ or chlorosulfonyl isocyanate, resulted in 2-substitution of 1-(phenylsulfonyl)pyrrole. The Vilsmeier reaction gave a poor yield of product even under vigorous conditions. This contrasted strongly with the excellent 2-formylation of methyl 1-pyrrolecarboxylate (8). The cyanation reaction using chlorosulfonyl isocyanate was also relatively slow, but gave an almost quantitative yield of the 2-cyano derivative that was easily hydrolyzed to afford pyrrole-2-carbonitrile (69%) in three steps from pyrrole. However, a 73% yield may be obtained from the reaction of chlorosulfonyl isocyanate with pyrrole itself (9).

Kakushima *et al.* (1) found that oxalyl chloride/$AlCl_3$ gave 2-substitution (as the —COCl group) and they drew attention to the fact that a variety of one-carbon acylations all attacked the 2-position, in contrast to the 3-acylation of 1-(phenylsulfonyl)pyrrole obtained with acetyl and larger groups. However, the reaction of *S*-ethyl chlorothioformate/$AlCl_3$ gave a 65% yield of *S*-ethyl 1-(phenylsulfonyl)pyrrole-3-thiocarboxylate. It was hoped that this product would then afford easy access to pyrrole-3-carboxaldehyde, but stirring with Raney nickel under a variety of conditions (10, 11) produced no reaction or caused the loss of the entire thiol ester group. Removal of the 1-phenylsulfonyl group with KOH/methanol gave a good yield of methyl pyrrole-3-carboxylate contaminated with a small amount of *S*-ethyl pyrrole-3-thiocarboxylate. Similarly, aqueous base rapidly removed the phenylsulfonyl group but hydrolyzed the thiol ester more slowly.

Nitration of 1-(phenylsulfonyl)pyrrole with nitric acid/acetic anhydride under a variety of conditions gave a low yield of a crude oil that was a mixture of mostly 3- and some 2-nitrated product (nmr). The reaction caused considerable destruction of pyrrolic material. Crystallization from methanol

[1]Author to whom correspondence should be addressed.

[2]The phase transfer method of Illi (2) using powdered sodium hydroxide gave a 71% yield of 1-(phenylsulfonyl)pyrrole from pyrrole, while 50% aqueous sodium hydroxide afforded 84% of a very pure product (see Experimental). Either method is more convenient to use on a large scale than the original synthesis using pyrrolylpotassium (3).

TABLE 1. 3-Aroylpyrroles from 1-(phenylsulfonyl)pyrrole

3-Substituent	Yield (mp (°C))	Infrared (cm^{-1} ($CHCl_3$))	^1H nmr (ppm)
4-Methylbenzoyl-	45% (128–129.2)	1634	2.37 (3H, s), 6.68 (2H, m), 7.13 (2H, d), 7.23 (1H, m), 7.64 (2H, d), 9.53 (1H, b)
2-Methylbenzoyl-	57% (94.2–96.6)	1635	2.39 (3H, s), 6.60 (2H, m), 6.93 (1H, m), 7.16 (4H, m), 9.43 (1H, b)

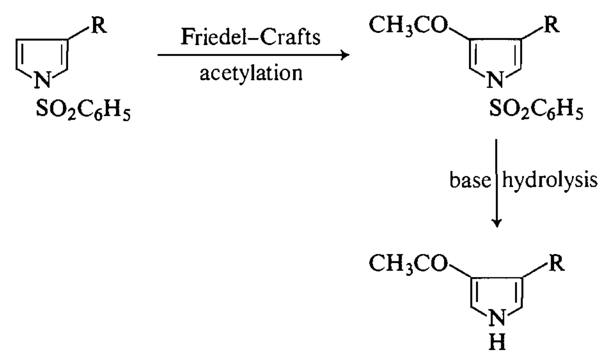

SCHEME 1

easily gave pure 3-nitro-1-(phenylsulfonyl)pyrrole. Although the yield was modest (20%), the purification and hydrolysis to 3-nitropyrrole seemed to make it a possible synthesis of the compound. An earlier preparation required chromatography to obtain a similar yield of 3-nitropyrrole (12). However, the recent method of Muchowski and Solas (13) affords close to 80% of 3-nitropyrrole in three steps from pyrrole.

Trichloroacetylation of 1-(phenylsulfonyl)pyrrole could not be obtained under any of the conditions tried. although it was possible to detect in both nmr and mass spectra trace amounts of the desired product following vigorous reactions. As trichloroacetylation does succeed with pyrrole-2-carbonitrile, the ring must be considerably deactivated. Further examples of the deactivated nature of 1-(phenylsulfonyl)pyrrole were: the failure of the HIO_3/I_2 iodination, a reaction that gives a modest yield with pyrrole-2-carboxaldehyde (14, 15), and of formylation with *N,N*-dimethylformamide/triphenylphosphinyl bromide perbromide (16) and with ethyl orthoformate/trifluoracetic anhydride (17).

The Friedel–Crafts alkylation of 1-(phenylsulfonyl)pyrrole with *tert*-butyl chloride and aluminum chloride catalyst afforded 3-*tert*-butyl-1-(phenylsulfonyl)pyrrole in excellent yield with only a trace of the 2-*tert*-butylated isomer (not isolated). Isopropylation with isopropyl chloride gave a mixture of the 2- (~55%) and 3- (~45%) isopropyl-1-(phenylsulfonyl)pyrrole. Separation of these isomers was fairly difficult using column chromatography, but was achieved with good recovery using medium pressure liquid chromatography (18) on silica gel. Ethylation of 1-(phenylsulfonyl)pyrrole with ethyl bromide in dichloromethane was very slow, giving a low yield contaminated with the product of the reaction with the solvent. This problem was overcome by using an excess of ethyl bromide as the solvent. The reaction was then fairly rapid but gave mostly 2-ethylation accompanied by the formation of considerable amounts of polymeric material. Under the conditions used, there was an almost complete lack of disubstitution during alkylations, even in the presence of a large excess of alkyl halide, again reflecting the low reactivity of 1-(phenylsulfonyl)pyrrole towards electrophilic attack.

The 2- or 3-alkyl-1-(phenylsulfonyl)pyrroles can be hydrolysed to the corresponding alkylpyrrole with base. The use of this path for the preparation of 3-*tert*-butylpyrrole has an advantage over the literature method (19) in that purification of the intermediate 1-phenylsulfonylated product is simple owing to the virtual absence of the other isomer. The separation of isomeric mixtures of 2- and 3-alkyl-1-(phenylsulfonyl)pyrroles is difficult, so the preparation of 3-ethylpyrrole by reduction/hydrolysis of 3-acetyl-(1-phenylsulfonyl)pyrrole as described below or by the reduction of the α-substituted succinonitriles with diisobutylaluminum hydride recently reported (20) (also suitable for 3-isopropylpyrrole) is preferable.

We were also interested in the effect of a 3-alkyl group on further Friedel–Crafts acetylation of the 1-phenylsulfonyl compounds. In general terms, would it be possible to extend the synthesis and obtain the 3,4-disubstituted pattern shown in Scheme 1.

To prepare 3-ethyl-1-(phenylsulfonyl)pyrrole for this investigation, attempts were made to reduce the carbonyl group on 3-acetyl-1-(phenylsulfonyl)pyrrole catalytically using Raney nickel, H_2/Pd, and $PdCl_2$/C. As well, hydrazine/tosyl hydrazide followed by reduction with $NaBH_4$ was tried, but these methods failed to give the desired product. As an alternative, the Huang–Minlon modification of the Wolff–Kishner reduction of 3-acetyl-1-(phenylsulfonyl)pyrrole gave 3-ethylpyrrole in one step and constitutes an efficient preparation of this compound (51% from pyrrole). The 1-phenylsulfonyl group was then replaced using its potassium salt (3). Later it was found possible to reduce 3-acetyl-1-(phenylsulfonyl)pyrrole directly to 3-ethyl-1-(phenylsulfonyl)pyrrole using the Clemmensen reduction.

These 3-alkyl-1-(phenylsulfonyl)pyrroles possessing groups of increasing size were subjected to Friedel–Crafts acetylation. However, instead of the 4-substitution hoped for, the products were all mixtures (as shown in Scheme 2) in which the predominant isomer arose from 5-substitution. As the alkyl group increased in size, the proportion of 2-substitution decreased. Some 4-substitution was observed (see Table 2).

Similarly, the cyanation of 3-*tert*-butyl-1-(phenylsulfonyl)-pyrrole gave mostly 5-cyanation, together with some 2-substitution, under the essentially neutral conditions of chlorosulfonyl isocyanate/*N,N*-dimethylformamide.

On the other hand, the Friedel–Crafts acetylation of

TABLE 2. The Friedel–Crafts acetylation of 3-alkyl-1-(phenylsulfonyl)pyrroles

	Product yield % (% of total isolated product)

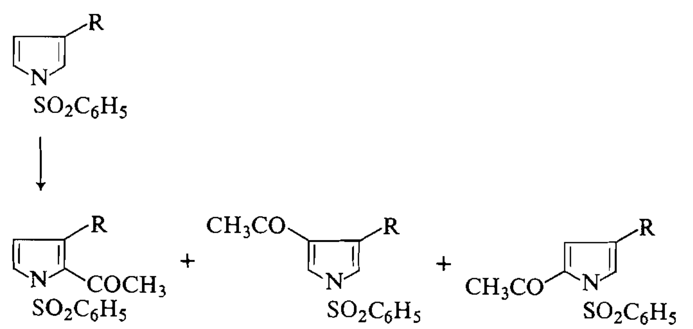
†$AlCl_3$ catalyst ($SnCl_4$ catalyst).



SCHEME 2

2-isopropyl-1-(phenylsulfonyl)pyrrole gave a mixture in which 4-substitution predominated, in contrast to the usual 5-attack on a 2-alkylpyrrole (21).

The product mixture obtained from the Friedel and Crafts reaction on the 3-alkyl-1-(phenylsulfonyl)pyrroles was very sensitive to reaction conditions and to the catalyst chosen for the reaction. Where a particular isomer is desired, careful choice of the reaction conditions can significantly improve its yield. The hoped-for high yields of the 4-substituted products were not obtained, but the procedure does offer a route to small amounts of some disubstituted pyrroles not easily obtainable by other methods.

Although the 1-(phenylsulfonyl) directing group does not provide a general pathway for the synthesis of 3-substituted pyrroles, it does afford a simple, efficient, and useful method for the synthesis of 3-acetylpyrrole and some other simple 3-acylpyrroles. In addition, useful yields of some 3-alkylpyrroles can be obtained. Other methods are available that are more selective and give better yields, but are often less convenient. The reason for the observed regiospecificity is unclear and we are continuing to investigate this aspect of the reaction. The fact that the presence of a 1-phenylsulfonyl group leads to "normal" (i.e. predominantly α-) substitution in the Friedel and Crafts acylation of 3-alkylpyrroles, while producing "abnormal" (i.e. mainly β-) substitution with 2-isopropylpyrrole, also needs explanation.

Experimental

Melting points are uncorrected. Elemental analyses were by Atlantic Microlabs, GA, U.S.A. The ir spectra were recorded on a Perkin–Elmer 237B or 1320 grating spectrophotometer as Nujol mulls unless otherwise stated. The ^1H nmr spectra (nmr) were determined using a Varian EM 360 or a Bruker WP-80 instrument and are expressed in ppm (δ values) relative to tetramethylsilane as internal reference in $CDCl_3$ unless otherwise stated. Low and high resolution mass spectra were recorded on a VG Micromass 7070HS spectrometer. Throughout, the term "petroleum" refers to the fraction of bp 60–80°C unless otherwise specified. The term "hexanes" refers to a mixture of isomers bp 65.8–69.0°C. For flash chromatography (22) "Baker Analyzed" silica gel, and for preparative thin-layer chromatography Whatman PLK5F plates, were used.

1-(Phenylsulfonyl)pyrrole

A mixture of pyrrole (52.8 g, 0.787 mol), dichloromethane (500 mL), tetrabutylammonium hydrogen sulfate (27.1 g), and sodium hydroxide solution (640 mL, 50% aqueous) was made in a 3-L 3-necked flask. The stirred mixture was cooled in cold water and phenylsulfonyl chloride (212 g) in dichloromethane (80 mL) was added fairly rapidly so that the mixture refluxed gently. When the addition was complete the mixture was stirred at room temperature for a further 20 h.

The inorganic precipitate was collected on a Celite pad by suction filtration and the filtrate was filtered through phase separation filter paper (Whatman IPS) to remove the aqueous layer. The organic filtrate was washed five times with water then dried ($MgSO_4$). The aqueous material that collected in the filter paper was diluted with an equal volume of water and then extracted with dichloromethane. The dichloromethane extracts were washed with water, combined with the organic material, and then dried ($MgSO_4$). The solvent was then removed to leave a thick oil that was crystallized from a dichloromethane/petroleum mixture affording off-white crystals. The product was recrystallized from methanol to give 1-(phenylsulfonyl)pyrrole (137 g, 84%), mp 88–89°C (lit. (3) mp 89–89.5°C).

Preparation of 3-benzoylpyrrole

Aluminum chloride (17.37 g, 130 mmol) was dissolved in the minimum amount of nitromethane and 1-(phenylsulfonyl)pyrrole (22.5 g, 109 mmol) in dichloromethane (600 mL) was added to the stirred mixture. Benzoyl chloride (18.3 g, 130 mmol) was then added over a period of 5 min and after a further 5 min stirring the mixture was poured slowly onto 600 mL of ice and water. The organic layer was separated and the aqueous layer was extracted with ether (3 × 75 mL). The combined organic extract was washed with sodium bicarbonate solution (2 × 75 mL, 5% aqueous), dried ($MgSO_4$), and the solvent removed. The medium-brown residue was added to a solution of potassium hydroxide (12.21 g) in aqueous methanol (120 mL water/120 mL methanol) and stirred overnight at 60°C. After cooling the methanol was flash-evaporated from the mixture, leaving a light-brown cloudy solution, which was extracted with dichloromethane (3 × 75 mL). The organic extract was dried ($MgSO_4$), and the solvent removed. Flash chromatography on silica gel of the light-brown gummy residue, using an ethyl acetate/hexanes mixture (15) as the eluting solvent, gave 3-benzoylpyrrole (9.44 g, 51% from 1-(phenylsulfonyl)pyrrole) as off-white crystals, mp. 98.5–99°C (lit. (23) mp 99.5–100°C), other properties identical with authentic material.

Other 3-aroylpyrroles prepared by this method are listed in Table 1.

2-Acetylpyrrole from 1-benzoylpyrrole

1-Benzoylpyrrole (0.71 g, 4.1 mmol) was dissolved in 1,2-dichloroethane (10 mL). To the stirred solution was added, at room temperature, aluminum chloride (1.22 g, 10 mmol) and acetic anhydride (0.45 mL, 4.3 mmol). After 2 h at room temperature the reaction mixture was poured into ice water (40 mL) and stirred vigorously. The layers were separated, the aqueous layers extracted three times with dichloroethane, and the combined layers washed with 5%

aqueous $NaHCO_3$, with saturated aqueous NaCl, dried ($MgSO_4$), and the solvent removed to give a dark oil. The ^1H nmr spectrum of the oil indicated almost entirely 2-acetyl-1-(phenylsulfonyl)pyrrole with less than 10% of 3-substitution.

The crude product was dissolved in a solution of methanol (30 mL) containing KOH (0.58 g, 10 mmol) and stirred at room temperature for 4 h. The solvent was flashed down and the product partitioned between water and ether. The aqueous layer was extracted 3 times with ether and the combined layers were washed with saturated aqueous NaCl and dried ($MgSO_4$). Removal of solvent gave 2-acetylpyrrole, (0.34, 75%). The sublimed product was identical to an authentic sample.

Vilsmeier formylation of 1-(phenylsulfonyl)pyrrole

1-(Phenylsulfonyl)pyrrole (500 mg, 2.4 mmol) was treated with a mixture of *N*,*N*-dimethylformamide (3 mL, 39 mmol) and $POCl_3$ (0.4 mL, 4.4 mmol) at 60°C for 48 h. The brown oil that formed was then cooled and dissolved in water. The aqueous solution was extracted with ether. The ether extracts were washed with water, dried ($CaCl_2$), and the solvent was removed. The residue was unchanged 1-(phenylsulfonyl)pyrrole. The aqueous layer was made strongly basic with 3 mol L^{-1} NaOH and stirred for 3 h. The yellow solution was then extracted with ether. The ether extracts were washed with water, dried (K_2CO_3), and the solvent was removed to leave a residue of pyrrole-2-carboxaldehyde (79 mg, 34%), identical with authentic material.

S-Ethyl 1-(phenylsulfonyl)pyrrole-3-thiocarboxylate

1-(Phenylsulfonyl)pyrrole (0.70 g, 3.4 mmol) was dissolved in 1,2-dichloroethane (10 mL). To the stirred solution at room temperature was added aluminum chloride (1.00 g, 7.5 mmol), followed by *S*-ethyl thiochloroformate (0.35 mL, 3.4 mmol). The solution was brought to the boiling point and stirred 1.5 h. The reaction mixture was poured into cold water (50 mL) and stirred vigorously. After the usual work-up, the dark solution was passed through a short column of Al_2O_3, eluting with dichloroethane. Removal of the solvent gave an oil that slowly crystallized. Recrystallization from dichloromethane/hexanes gave a colorless solid (0.65 g, 65%), mp. 67–68.5°C. Sublimation (which was very slow) gave mp 68–69°C; ir ν: 1650 cm^{-1}; nmr δ: 1.29 (3H, t, —CH_3), 3.00 (2H, q, —SCH_2-), 6.71 (1H, m, C-4), 7.16 (1H, m, C-5), 7.5–8.1 (6H, m, phenyl and C-2). *Exact Mass* calcd. for $C_{13}H_{13}NO_3S_2$: 295.03367; found: 295.0289, deviation 4.7 mmu.

3-Nitro-1-(phenylsulfonyl)pyrrole

Fuming nitric acid (0.35 mL) was added to ice-cold acetic anhydride (2 mL) and allowed to warm to room temperature. 1-(Phenylsulfonyl)pyrrole (1.081 g, 5.2 mmol) was dissolved in acetic anhydride (3 mL) and then cooled to −10°C. The solution of fuming nitric acid was then added dropwise to the stirred solution of 1-(phenylsulfonyl)pyrrole over about 5 min. The mixture was stirred for a further 1 h at −10°C and then poured onto about 150 g of ice. The aqueous mixture was extracted with ether, the organic extracts were combined, washed with water, dried ($CaCl_2$), and the solvent was removed. The ^1H nmr spectrum of the yellow residue showed that it contained about 30% of 3-nitro-1-(phenylsulfonyl)pyrrole and only a trace of the 2-nitro isomer. The residue in a little methanol was refrigerated overnight. The pale yellow crystals were collected, and washed with a small amount of cold methanol to give the product as a very pale yellow solid (321 mg, 24%), mp 102–103°C; nmr δ: 6.82 (1H, dd, C-4H), 7.13 (1H, dd, C-3H), 7.37–8.17 (6H, m); $J_{4,5}$ = 3.5, $J_{2,4}$ = 1.5, $J_{2,5}$ = 2.5 Hz; m/z = 252. *Anal.* calcd. for $C_{10}H_8N_2O_4S$: C 47.61, H 3.19, N 11.10; found: C 47.71, H 3.26, N 11.08.

3-Nitropyrrole

A solution of potassium hydroxide (1.2 g, 21 mmol) in methanol (25 mL) was added to the crude product of the nitration of 1-(phenylsulfonyl)pyrrole (1.081 g, 75 mmol) as above and the mixture was stirred at room temperature overnight. The solvent was then removed and water (100 mL) was added. The aqueous solution was extracted thoroughly with ether. The ether extracts were combined, washed with water, dried ($CaCl_2$), and the solvent was removed to leave a very pale yellow residue that was recrystallized from chloroform/petroleum to give 3-nitropyrrole (112 mg, 19% from 1-(phenylsulfonyl)pyrrole), mp 99.5–100.5°C (lit. (12) 99–101°C); nmr δ: 6.76 (2H, m), 7.68 (1H, dd). The aqueous layer from the extraction was made acid with 6 mol L^{-1} sulfuric acid and then again extracted with ether, which gave 302 mg of a yellow oil that contained only traces of 2- and 3-nitropyrrole. The bulk of this residue appeared to consist of products from the destruction of the 1-(phenylsulfonyl)pyrrole.

Similar hydrolysis of pure 3-nitro-1-(phenylsulfonyl)pyrrole (552 mg) gave pure 3-nitropyrrole (230 mg, 96%), mp. 99.5–100.5°C, as an almost colourless solid.

2-Cyano-1-(phenylsulfonyl)pyrrole

(a) 1-(Phenylsulfonyl)pyrrole (500 mg, 2.4 mmol) was dissolved in acetonitrile (5 mL) and cooled to 0°C in an ice bath. Chlorosulfonyl isocyanate (0.3 mL) was added dropwise to the stirred solution and then it was allowed to warm to room temperature and stirred for 5 h. *N*,*N*-Dimethylformamide (0.5 mL) was added to the mixture, stirring was continued for a further hour at room temperature, and the mixture was then poured onto ice. Solid 2-cyano-1-(phenylsulfonyl)pyrrole precipitated from the aqueous mixture as a light brown solid which was collected, washed with cold water, and air dried (556 mg, 99%). A sample of the almost pure crude product was sublimed for analysis (90°C, 0.1 Torr; 1 Torr = 133.3 Pa) to give the analytical sample, mp 94.5–95°C; ir ν: 2226 (CN) cm^{-1}; nmr δ: 6.27 (1H, q, C-4H), 6.90 (1H, q, C-3H), 7.46 (1H, q, C-5H), 7.41–8.16 (5H, m); m/z = 232. *Anal.* calcd. for $C_{11}H_8N_2O_2S$: C 56.88, H 3.47; found: C 56.91, H 3.50.

A sample of the product (329 mg) was hydrolysed as described above for 3-nitro-1-(phenylsulfonyl)pyrrole to give pyrrole-2-carbonitrile (90 mg, 69%), identical with an authentic sample.

(b) 1-(Phenylsulfonyl)pyrrole (1.035 g, 5 mmol) was dissolved in 1,2-dichloroethane (10 mL). To the stirred solution was added aluminum chloride (1.50 g, 22 mmol) and a solution of cyanogen bromide (0.53 g, 7 mmol) in 1,2-dichloroethane (5 mL) at room temperature; the solution was then stirred for 3 h. The reaction mixture was poured onto ice and stirred. The layers were separated and the aqueous layer was extracted three times with chloroform. The combined organic layers were washed with saturated aqueous NaCl and dried ($MgSO_4$). Removal of the solvent gave 1.15 g (99%) of light brown solid. A small sample was sublimed to give mp 94–95°C. A mixture mp with a sample from (a) was not depressed.

3-Ethylpyrrole

A mixture of 3-acetyl-1-(phenylsulfonyl)pyrrole (16.90 g, 67.8 mmol), KOH (16.90 g, 301 mmol), and $N_2H_4.H_2O$ (16.90 g, 338 mmol) in triethyleneglycol (170 mL) was stirred and refluxed for 1.5 h. Water was distilled from the mixture and it was refluxed for a further 4 h. Ether was added to the cooled mixture (ice and water) with stirring for 15 min. The organic layer was separated from the aqueous layer, which was extracted with ether (4 × 100 mL). The combined organic layer and extracts were washed once with water, dried ($MgSO_4$, 1 h), evaporated, and the residue vacuum distilled 86°C/20 Torr (lit. (24) bp 86–88°C/20 Torr), to give 3-ethylpyrrole (3.30 g, 51%). The ^1H nmr chemical shifts were identical to those of an authentic sample.

3-Ethyl-1-(phenylsulfonyl)pyrrole

(a) *From 3-ethylpyrrole*

3-Ethylpyrrole (3.30 g, 34.7 mmol) was dissolved in dry tetrahydrofuran (75 mL, freshly distilled) and then potassium metal was added slowly (excluding moisture) until an excess was present and the hydrogen evolution ceased. A solution of phenylsulfonyl chloride (6.75 g, 38.2 mmol) in tetrahydrofuran (10 mL) was then added dropwise at room temperature. The mixture was stirred overnight, filtered, and the solvent was evaporated. The residue was dissolved in water and extracted with ether (4 × 150 mL). The combined ethereal layer and extracts were washed once with water and dried ($MgSO_4$). The ether was removed and the residue was vacuum distilled (125–135°C/0.1 Torr) to give 3-ethyl-1-(phenylsulfonyl)pyrrole (2.38 g, 29%), an oil which solidified just below room temperature; nmr δ: 1.10 (3H, t, —CH_3), 2.40 (2H, q, —CH_2), 6.10 (1H, dd), 6.80 (1H, m), 7.00 (1H, dd), 7.3–7.8 (5H, m). *Exact Mass* calcd. for $C_{12}H_{13}NO_2S$: 235.06669; found: 235.0682, deviation 1.5 mmu.

(b) *From 3-acetyl-1-(phenylsulfonyl)pyrrole*

Amalgamated zinc (prepared from zinc (3.66 g, 56 mmol granular) and a solution of mercuric chloride (0.37 g, 1.4 mmol) in water (5 mL) and concentrated hydrochloric acid (0.5 mL)) was placed in a flask, together with water (2.5 mL), concentrated HCl (6 mL), and a solution of 3-acetyl-1-(phenylsulfonyl)pyrrole (1.09 g, 4.4 mmol) in toluene (25 mL). The solution was refluxed for 7 h, when more concentrated HCl (3 mL) was added and reflux continued to a total of 24 h. After cooling, the layers were separated, the aqueous layer extracted twice more with toluene, and the combined organic layers washed with saturated aqueous NaCl and dried ($MgSO_4$). Evaporation of solvent gave a thick brown oil. Short-path distillation gave 3-ethyl-1-(phenylsulfonyl)pyrrole (0.63 g, 61%), with spectral properties identical to the product above.

2- and 3-ethyl-1-(phenylsulfonyl)pyrrole

1-(Phenylsulfonyl)pyrrole (3.2 g, 15 mmol) was dissolved in bromoethane (5.0 mL) and cooled in an ice bath. Aluminum chloride (6.4 g, 48 mmol) was added rapidly with stirring and the mixture was heated under gentle reflux for 4.5 h, when the mixture was cooled and poured into ice/water. Following the usual work-up, removal of the solvent gave a brown oil (2.93 g) that was a mixture of products and polymeric by-products (^{1}H nmr). Flash chromatography of the oil on silica gel with elution by a 2% ethyl ether/petroleum (60–80°C bp) mixture gave (poor separation) the following.

2,5-Diethyl-1-(phenylsulfonyl)pyrrole (135 mg, 3%), mp 40.5–41.5°C (from ethyl ether/petroleum); nmr δ: 1.21 (6H, t, —CH_3), 2.78 (4H, q, —CH_2), 5.92 (2H, dd, C3,4-H), 7.32–7.87 (5H, m). *Exact Mass* calcd. for $C_{14}H_{17}NO_2S$: 263.09799; found: 263.0973, deviation 0.7 mmu.

2-Ethyl-1-(phenylsulfonyl)pyrrole (974 mg, 26%), mp 57–58°C (from methanol); nmr δ: 1.13 (3H, t, —CH_3), 2.76 (2H, q, —CH_2), 5.93 (1H, dd, C3-H), 6.16 (1H, dd, C5-H), 7.25 (1H, dd, C4-H), 7.35–8.18 (5H, m); m/z = 235. *Anal.* calcd. for $C_{12}H_{13}NO_2S$: C 61.25, H 5.56, N 5.95; found: C 61.34, H 5.61, N 5.90.

A mixture of 2- and 3-isomers (204 mg, 5%).

3-Ethyl-1-(phenylsulfonyl)pyrrole (483 mg, 13%), identical with the material obtained above from the reduction of 3-acetyl-1-(phenylsulfonyl)pyrrole.

2- and 3-isopropyl-1-(phenylsulfonyl)pyrrole

Aluminum chloride (9.65 g, 72.4 mmol) was mixed with dichloromethane (25 mL) and cooled in an ice bath. 1-(Phenylsulfonyl)pyrrole (5.0 g, 24.1 mmol) in dichloromethane (25 mL) was then added, followed by isopropyl chloride (2.58 g, 328 mmol) in dichloromethane (25 mL) dropwise. The pale yellow mixture was stirred in the ice bath for a further 5 h. It was then poured onto ice (100 g). Following the usual work-up, the solvent was removed to leave an oily residue (5.8 g, 96% as mixture). The ^{1}H nmr spectrum of the product indicated that it contained almost equal proportions of the 2- and 3-isopropylated products. Medium pressure chromatography (18) of the product (1-g sample) on silica gel (Merck Kieselgel 60) gave on elution with 3% ether/cyclohexane, in order of elution, the following.

2-Isopropyl-1-(phenylsulfonyl)pyrrole[3] (0.46 g, 23%). The product crystallized on cooling but melted below room temperature; nmr δ: 1.17 (6H, d), 1.36 (1H, septet), 6.03 (1H, m), 6.2 (1H, dd), 7.24 (1H, dd), 7.37–7.87 (5H, m), $J_{4,5}$ = 3.4, $J_{3,5}$ = 1.8, $J_{3,4}$ = 3.2, $J_{3,\text{isopropyl H}}$ = 0.7, $J_{\text{isopropyl}}$ = 6.8 Hz. *Exact Mass* calcd. for $C_{13}H_{15}NO_2S$: 249.08234; found: 249.0830, deviation 0.7 mmu.

3-Isopropyl-1-(phenylsulfonyl)pyrrole (0.31 g, 15%). The product was obtained as a colourless oil that slowly crystallized below 0°C; nmr δ: (6H, d), 2.64 (1H, septet), 6.17 (1H, dd), 6.87 (1H, m), 7.21 (1H, dd), 7.31–7.97 (5H, m), $J_{4,5}$ = 3.3, $J_{2,5}$ = 1.7 Hz. *Exact Mass* calcd. for $C_{13}H_{15}NO_2S$: 249.0823; found: 235.0831, deviation 0.8 mmu.

*3-*tert*-Butyl-1-(phenylsulfonyl)pyrrole*

1-(Phenylsulfonyl)pyrrole (5.0 g, 24 mmol) was added to a stirred mixture of aluminum chloride (9.65 g, 72 mmol) and dichloromethane (25 mL) cooled in an ice bath. A solution of *tert*-butyl chloride (2.8 g, 30 mmol) in dichloromethane (25 mL) was then added dropwise and the mixture allowed to warm to room temperature, stirred for 4.5 h, and poured onto ice. Following the usual work-up, the solvent was removed to leave the product as a pale yellow oil (5.9 g) that slowly crystallized. Recrystallization from methanol gave 3-*tert*-butyl-1-(phenylsulfonyl)pyrrole (5.12 g, 80%); mp 42°C; nmr δ: 1.17 (9H, s), 6.21 (1H, dd), 6.86 (1H, dd), 7.03 (1H, dd), 7.26–7.93 (5H, m), $J_{2,4}$ = 1.8, $J_{4,5}$ = 3.4, $J_{2,5}$ = 2.4 Hz; m/z = 263. *Anal.* calcd. for $C_{14}H_{17}NO_2S$: C 63.85, H 6.50; found: C 63.88, H 6.52. Base hydrolysis (4) of 3-*tert*-butyl-1-(phenylsulfonyl)pyrrole gave 3-*tert*-butylpyrrole (54% yield) with spectra identical to those of authentic material (24).

Cyanation of tert*-butyl-1-(phenylsulfonyl)pyrrole*

Cyanation of 3-*tert*-butyl-1-(phenylsulfonyl)pyrrole with chlorosulfonyl isocyanate using the procedure described above for 2-cyano-1-(phenylsulfonyl)pyrrole gave a 93% mixture of the two possible α-substituted products that proved to be very difficult to separate. The ^{1}H nmr spectrum showed that 2- and 5-cyano-4-*tert*-butyl-1-(phenylsulfonyl)pyrrole were present in a ratio of about 3:2. Medium pressure liquid chromatography (18) of 0.40 g of the crude product on silica gel (eluent 10:1 hexane/ethyl acetate) gave, in order of elution, the following.

*2-Cyano-4-*tert*-butyl-1-(phenylsulfonyl)pyrrole* (191 mg), mp 90.5–91.5°C; ir ν: 2201 cm^{-1}; nmr δ: 1.16 (9H, s, —$C(CH_3)_3$), 6.89 (1H, d, C-4H), 7.21 (1H, d, C-4H), 7.5–8.3 (5H, m), $J_{2,4}$ = 1.8 Hz. *Anal.* calcd. for $C_{15}H_{16}N_2SO_2$: C 62.47, H 5.59, N 9.71; found: C 62.57, H 5.63, N 9.66.

*2-Cyano-3-*tert*-butyl-1-(phenylsulfonyl)pyrrole* (25 mg), mp 81.5–83°C; ir ν: 2218 cm^{-1}; nmr δ: 1.35 (9H, s, —$C(CH_3)_3$), 6.29 (1H, d, C-5H), 7.42 (1H, d, C-4H), 7.5–8.2 (5H, m), $J_{4,5}$ = 3.4 Hz. *Exact Mass* calcd. for $C_{15}H_{16}N_2O_2S$: 288.09324; found: 288.0926, deviation 0.6 mmu.

In addition, between the two pure fractions a mixture (84 mg) of the two products was obtained.

Acetylation of 3-alkyl-1-(phenylsulfonyl)pyrroles

One molar equivalent of the 3-alkyl-1-(phenylsulfonyl)pyrrole was dissolved in an appropriate amount of dichloromethane, the mixture was cooled in ice and water, and 3 times the molar equivalent of catalyst ($AlCl_3$ or $SnCl_4$) was added followed by vigorous stirring at 0°C for 30 min. Acetyl chloride (2 molar equivalents) in dichloromethane was then added dropwise at 0°C. The reaction mixture was allowed to warm to room temperature and then stirred for 42 h. The reaction was quenched by pouring the mixture into a beaker containing ice and water, followed by stirring for 1 h. The layers were then separated and the aqueous layer was extracted with dichloromethane. The organic layer and the extracts were combined and washed three times with water, twice with 5% aqueous $NaHCO_3$, dried ($MgSO_4$), and the solvent was then removed to leave the crude products.

Acetylation of 3-ethyl-1-(phenylsulfonyl)pyrrole

Acetylation of 3-ethyl-1-(phenylsulfonyl)pyrrole (560 mg, 1.5 mmol) as described, and the residue subjected to preparative thin-layer chromatography on silica gel, developed with 10% ethyl ether in petroleum, gave the following.

[3]2-Isopropyl-1-(phenylsulfonyl)pyrrole rapidly turned yellow when stored at room temperature in air and was less stable than the 3-isopropyl isomer. Both compounds can be stored without decomposition below 0°C in air.

Unchanged starting material, 3-ethyl-1-(phenylsulfonyl)pyrrole (64 mg).

2-Acetyl-3-ethyl-1-(phenylsulfonyl)pyrrole (36 mg, 5%), mp 98–99°C; ir ν: 1667 cm^{-1}; nmr δ: 1.22 (3H, t, CH_2CH_3), 2.50 (3H, s, —$COCH_3$), 2.70 (1H, q, CH_2CH_3), 6.20 (1H, dd, $J_{4,5}$ = 3.2 Hz), 7.40–7.90 (6H, m, aromatic H). *Exact Mass* calcd. for $C_{14}H_{15}NO_3S$: 277.07726; found: 277.0770, deviation 0.3 mmu. Hydrolysis of this isomer in KOH and methanol gave 2-acetyl-3-ethylpyrrole; nmr δ: 1.30 (3H, t, CH_2CH_3), 2.46 (3H, s, —$COCH_3$), 2.80 (1H, q, CH_2CH_3), 6.10 (1H, dd), 6.85 (1H, dd).

A mixture (321 mg, 48%) of 4-acetyl-3-ethyl-1-(phenylsulfonyl)-pyrrole (16% yield based on ^{1}H nmr) and 5-acetyl-3-ethyl-1-(phenylsulfonyl)pyrrole (32% based on ^{1}H nmr). Recrystallization from ethyl ether/petroleum (60–80°C bp) gave pure *5-acetyl-3-ethyl-1-(phenylsulfonyl)pyrrole* as colourless needles, mp 94–95°C; ir ν: 1669 cm^{-1}; nmr δ: 1.25 (3H, t, CH_2CH_3), 2.35 (3H, s, —$COCH_3$), 2.52 (1H, q, CH_2CH_3), 6.90 (1H, d, $J_{2,4}$ = 2.0 Hz), 7.35–8.10 (6H, m, aromatic H). *Exact Mass* calcd. for $C_{14}H_{15}NO_3S$: 277.07726; found: 277.0762, deviation 1.1 mmu. Hydrolysis of this isomer in KOH and methanol gave 2-acetyl-4-ethylpyrrole; nmr δ: 1.30 (3H, t, CH_2CH_3), 2.40 (3H, s, —$COCH_3$), 2.55 (1H, q, CH_2CH_3), 6.60–6.85 (2H, m).

Preparative thin-layer chromatography (developing the plate with 30% ethyl ether/petroleum) of the mother liquors from the recrystallization gave some additional 5-acetyl-3-ethyl-1-(phenylsulfonyl)pyrrole and *4-acetyl-3-ethyl-1-(phenylsulfonyl)pyrrole*, mp 98–99°C; ir ν: 1663 cm^{-1}; nmr δ: 1.24 (3H, t, CH_2CH_3), 2.33 (3H, s, —$COCH_3$), 2.52 (1H, q, CH_2CH_3), 6.93 (1H, d, $J_{2,5}$ = 1.8 Hz), 7.35–8.10 (6H, m, aromatic H). *Exact Mass* calcd. for $C_{14}H_{15}NO_3S$: 277.07726; found: 277.0758, deviation 1.4 mmu.

Acetylation of 3-isopropyl-1-(phenylsulfonyl)pyrrole

As described above, the usual procedure with 3-isopropyl-1-(phenylsulfonyl)pyrrole (300 mg) gave a mixture which was separated by preparative thin-layer chromatography on silica gel developed with 10% ethyl ether in petroleum. Obtained were the following.

Unchanged 3-isopropyl-1-(phenylsulfonyl)pyrrole (16 mg).

2-Acetyl-3-isopropyl-1-(phenylsulfonyl)pyrrole (36 mg, 10%), mp 74–74.5°C; ir ν: 1676 cm^{-1}; nmr δ: 1.14 (6H, d, —$CH(CH_3)_2$), 2.52 (3H, s, —$COCH_3$), 3.06 (1H, m, —$CH(CH_3)_2$), 6.24, 7.37 (each 1H, d, $J_{4,5}$ = 3.23 Hz), 7.45–8.05 (5H, m, aromatic H). *Exact Mass* calcd. for $C_{15}H_{17}NO_3S$: 291.0929; found: 291.0912, deviation 1.7 mmu.

5-Acetyl-3-isopropyl-1-(phenylsulfonyl)pyrrole (232 mg, 66%), mp 132–133°C; ir ν: 1667 cm^{-1}; nmr δ: 1.21 (6H, d, —$CH(CH_3)$, 2.28 (3H, s, —$COCH_3$), 2.79 (1H, m, —$CH(CH_3)_2$), 6.90 (1H, d, $J_{2,4}$ = 2.15 Hz), 7.25–8.00 (6H, m, aromatic H). *Anal.* calcd. for $C_{15}H_{17}O_3S$: C 61.83, H 5.88, N 4.80; found: C 61.74, H 5.92, N 4.76.

The mother liquors showed the presence (^{1}H nmr) of a further compound which was difficult to purify. Slow sublimation of the gummy material along a glass tube gave a sublimate containing the product which was recrystallized from ethyl ether/petroleum to give *4-acetyl-3-isopropyl-1-(phenylsulfonyl)pyrrole*, mp 75–77°C; ir ν: 1673 cm^{-1}; nmr δ: 1.10 (6H, d, —$CH(CH_3)_2$), 2.35 (3H, s, —$COCH_3$), 3.33 (1H, m, —$CH(CH_3)_2$), 6.88 (1H, d, $J_{2,5}$ = 2.42 Hz), 7.25–8.00 (6H, m. aromatic H). *Exact Mass* calcd. for $C_{15}H_{17}NO_3S$: 291.0929; found: 291.0923, deviation 0.6 mmu.

*Acetylation of 3-*tert*-butyl-1-(phenylsulfonyl)pyrrole*

As described above, the usual procedure with 3-*tert*-butyl-1-(phenylsulfonyl)pyrrole (500 mg) afforded a highly crystalline mixture which on recrystallization from an ethyl acetate/petroleum mixture gave 5-acetyl-3-*tert*-butyl-1-(phenylsulfonyl)pyrrole (144 mg). Preparative thin-layer chromatography (10% ethyl ether in petroleum) of the residue from the mother liquor allowed further separation of the products as follows.

Unchanged 3-*tert*-butyl-1-(phenylsulfonyl)pyrrole (75 mg).

*5-Acetyl-3-*tert*-butyl-1-(phenylsulfonyl)pyrrole* (192 mg, total 236 mg 40%), mp 184–185°C; ir ν: 1672 cm^{-1}; nmr δ: 1.28 (9H, s), 2.31 (3H, s, —$COCH_3$), 6.93 (1H, d, $J_{2,4}$ = 2.06 Hz), 7.40–8.05 (6H, m, aromatic H); m/z = 305. *Anal.* calcd. for $C_{16}H_{19}NO_3S$: C 62.95, H 6.33; found: C 63.08, H 6.33. Hydrolysis (KOH/methanol) gave the known 2-acetyl-4-*tert*-butylpyrrole, mp 133–134°C (lit. (25) mp 133–134°C), ^{1}H nmr spectra identical.

The mother liquors from the recrystallization of the 5-acetyl-3-*tert*-butyl-1-(phenylsulfonyl)pyrrole contained some *4-acetyl-3-*tert*-butyl-1-(phenylsulfonyl)pyrrole*, mp 183–183.5°C; ir ν: 1673 cm^{-1}; nmr δ: 1.29 (9H, s), 2.40 (3H, s, —$COCH_3$), 6.85 (1H, d, $J_{2,5}$ = 2.35 Hz), 7.5–8.0 (6H, m, aromatic H). *Exact Mass* calcd. for $C_{16}H_{19}NO_3S$: 305.10856; found: 305.1064, deviation 2.2 mmu.

Acetylation of 2-isopropyl-1-(phenylsulfonyl)pyrrole

A solution of 2-isopropyl-1-(phenylsulfonyl)pyrrole (100 mg, 0.40 mmol) was acetylated with acetyl chloride and aluminum chloride in dichloromethane. After about 5 min the mixture was poured onto ice and stirred for 1 h, then allowed to warm to room temperature. After a total of 3 h, the yellowish mixture was worked up in the usual manner. Following filtration through phase separation paper to remove suspended water and drying (Molecular Sieves, Davison grade 512), removal of the solvent gave a mixture of acetylated products as an oil (90.5 mg, 77%). The ^{1}H nmr of the oil showed that the mixture contained three compounds. Flash chromatography of the product on silica gel gave on elution with 30% ether/petroleum (60–80°C bp), in order of elution; the following.

3-Acetyl-2-isopropyl-1-(phenylsulfonyl)pyrrole (trace).

5-Acetyl-2-isopropyl-1-(phenylsulfonyl)pyrrole (trace). The product crystallized on cooling but melted below room temperature; nmr δ: 1.23 (6H, d, —$CH(CH_3)_2$, 2.50 (3H, s, —$COCH_3$), 3.59 (1H, septet, —$CH(CH_3)_2$), 6.13 and 6.88 (each 1H, d, pyrrole H, $J_{3,4}$ = 3.7 Hz), 7.47–8.27 (5H, m, aromatic H).

4-Acetyl-2-isopropyl-1-(phenylsulfonyl)pyrrole (82.4 mg, 70%), as an oil that slowly crystallized, mp 73–74°C; ir ν: 1666 cm^{-1}; nmr δ: 1.11 (6H, d, —$CH(CH_3)_2$, 2.39 (3H, s, —$COCH_3$), 3.14 (1H, septet, —$CH(CH_3)$, 6.42 (1H, dd, $J_{3,5}$ = 1.8 Hz), 7.40–7.94 (6H, m, aromatic H). *Anal.* calcd. for $C_{15}H_{17}O_3S$: C 61.83, H 5.88, N 4.80; found: C 61.91, H 5.88, N 4.77.

A sample of this last compound (82.2 mg, 0.30 mmol) was hydrolysed (4) to give 4-acetyl-2-isopropylpyrrole (27.7 mg, 64%), mp 72–73°C (lit. (25) mp 68.5–69.5°C. An authentic sample (25) had mp 71–71.5°C and the mixture melting point was undepressed); ir ν: 3220, 1635 cm^{-1}; nmr δ: 1.27 (6H, d, —$CH(CH_3)$, 2.42 (3H, s, —$COCH_3$), 2.93 (1H, septet, —$CH(CH_3)_2$), 6.38 (1H, dd, 3-H, $J_{3,5}$ = 1.8, $J_{3,\text{isopropyl H}}$ = 0.9 Hz), 7.37 (1H, dd, 5-H, $J_{1,5}$ = 3.2 Hz).

n–π Electron donor–acceptor complexes. II. Aliphatic amines with dinitrobenzenes

JOAQUÍN O. SINGH, JORGE D. ANUNZIATA, AND JUANA J. SILBER[1]

Departamento de Química y Física, Universidad Nacional de Río Cuarto, Estafeta 9, Río Cuarto, 5800 Córdoba, Argentina

Received June 14, 1984

JOAQUÍN O. SINGH, JORGE D. ANUNZIATA, and JUANA J. SILBER. Can. J. Chem. **63**, 903 (1985).

The interaction of several aliphatic amines as *n*-donors and dinitrobenzenes (DNB) as π-acceptors has been studied in n-hexane. The formation of electron donor – acceptor (EDA) complexes is proposed to explain the spectroscopic behaviour of the mixtures. The stability constants (K_s) for these complexes have been calculated by an iterative procedure. For a given acceptor, the donor strength of $RNH_2 > R_2NH > R_3N$ was found. This order is explained by considering the role that steric effect may play in the EDA complex formation. On the other hand, the fact that for a given donor K_s follows the order 1,2-DNB > 1,3-DNB > 1,4-DNB, and that 1,2-DNB reacts with primary amines, led to the proposal of orientational complexes. These EDA complexes may be considered intermediates in aromatic nucleophilic substitution reactions.

JOAQUÍN O. SINGH, JORGE D. ANUNZIATA et JUANA J. SILBER. Can. J. Chem. **63**, 903 (1985).

On a étudié l'interaction de pluseurs amines aliphatiques, comme donneurs *n* et dinitrobenzens (DNB), comme accepteurs π, dans n-hexane. On propose la formation de complexes electron-donneur – accepteur (EDA) pour expliquer le comportement spectroscopique des mélanges. La constante de stabilité (K_s) pour ces complexes a été calculée au moyen d'une procédure itérature. Pour un accepteur donné, on a observé que la force du donneur était $RNH_2 > R_2NH > R_3N$. Cela s'explique en considérant le role que jouent les effects stériques dans la formation de complexes EDA. D'ailleurs le fait que K_s, pour un donneur donné, ait l'ordre 1,2-DNB > 1,3-DNB > 1,4-DNB et que 1,2-DNB réagisse avec amines primaires, conduit a proposer des complexes orientationnels. Ces complexes EDA peuvent etre considérés des intermediaires dans les réactions de substitution nucléophilique aromátique.

Introduction

The importance of the study of *n*-π Electron-Donor–Acceptor (EDA) complexes, as well as the need of a systematic study of their thermodynamic properties and their correlation with the structure of the component molecules, has been previously discussed (1).

To follow this line, the interaction of several aliphatic amines with 1,2-, 1,3-, and 1,4-dinitrobenzenes (DNB) in n-hexane has been studied in this work.

Several types of interactions between nitro-substituted aromatic compounds and aliphatic amines have been identified (2–5). They depend on the structure of the amine molecule and, to a great extent, on the nature of the solvent. In this sense the most studied nitro aromatic compound is 1,3,5-trinitrobenzene (s-TNB), for which evidence has been adduced (6, 7) for the formation of EDA complexes with primary, secondary, and tertiary amines dissolved in alkane solvents. In polar aprotic solvents, tertiary amines form solely EDA complexes with s-TNB (8, 9). However, in these solvents, for primary and secondary amines the addition to the aromatic ring resulting in a σ complex has been fully recognized (4, 5, 9). In addition, for *ortho*-dinitro aromatics, such as 1,2,4-TNB and also for 1,2-DNB, even in a nonpolar solvent as benzene, aromatic nucleophilic substitutions (S_NAr) of the nitro group by piperidine has been reported (10). The role that EDA complexes may play in the formation of the σ adducts and in S_NAr is yet unknown. The occurrence of such reactions via EDA complexes was proposed several years ago (3, 11). Also, a possible EDA complex between the nucleophile, either an aliphatic or aromatic amine, and the aromatic substrate, has recently been suggested to form previous to the σ complex intermediate, in order to explain the second-order kinetics in the amine, for fluorine substitution of 2,4-dinitro-1-fluorobenzene (12). However, no kinetic evidence has been obtained for the participation of the EDA complexes in this reaction. This is probably due to the high rate coefficient expected for the formation of this type of EDA complex (13). In the course of this investigation, the stability constants (K_s) for the formation of EDA complexes between aliphatic amines and dinitrobenzene have been determined. In order to correlate the values of K_s with the structure of the amines and the acceptors, orientational complexes are proposed. These types of complexes may be considered intermediates in S_NAr reactions.

Experimental

n-Hexane (Carlo Erba, R.P.), diethyl (DEA), triethyl (TEA), n-butyl (n-BA), di-n-butyl (DBA), and tri-n-butyl (TBA) amines (Aldrich Chemical Co.) were purified as previously described (1). To obtain reproducible results special care should be taken to assure the purity of the amine. The latter was controlled by glc (Porapak Q.-Apiezon L.), and by the ultraviolet cut-off point. The solvent and the amines were degassed and distilled in a high vacuum line just before use to ensure anhydrous conditions. 1,2-DNB (Fluka), 1,3-DNB (Merck), and 1,4-DNB (Fluka) were twice recrystallized from ethanol and then sublimed under vacuum.

Spectra were obtained in thermostatted cells in a Cary 17 spectrophotometer. The working temperatures were 16°, 27°, and 40°C ± 0.1°C.

Solutions were prepared by weighing. The ranges of concentration used were 1×10^{-4} to 3×10^{-4} *M* for DNB and 0.2 to 3 *M* for the amines. All solutions were freshly prepared prior to use.

Data processing was performed on a Digital PDP11/34 computer.

Results

The spectral characteristics of the systems amine–DNB studied show the same general features as observed for amine–benzonitrile (1). Although no new band is observed, there is an appreciable deviation from additivity of the optical density with respect to those of the components alone in the region of λ = 290 nm to 320 nm.[2] Typical spectral results are shown in Fig. 1. The spectral characteristics were maintained during the time measurement, except for the system n-BA – 1,2-DNB. For the latter system, a new band was observed at

[1]Author to whom correspondence should be addressed.

[2]The high absorption of both the amine and the DNB prevented observations at λ shorter than 290 nm.

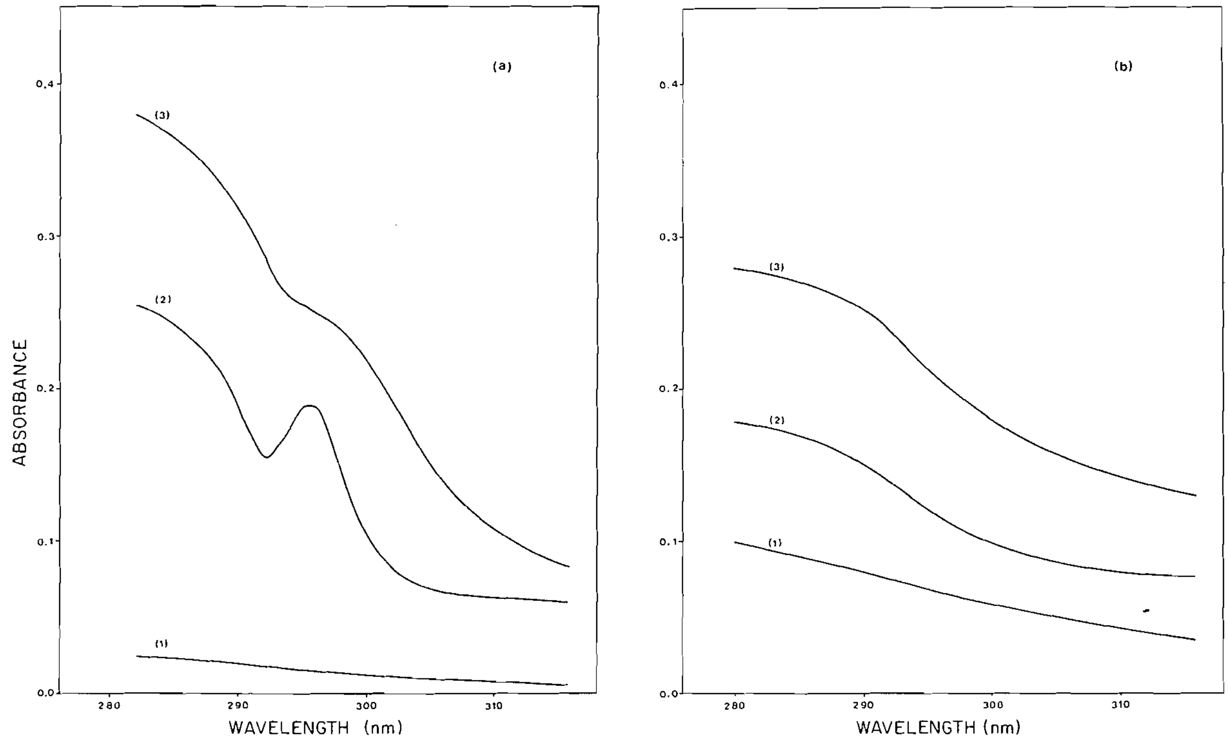

FIG. 1. Typical spectral results. (a) (1) n-BA 1.01 M; (2) 1,3-DNB 2.27×10^{-4} M; (3) mixture of n-BA 1.01 M and 1,3-DNB 2.27×10^{-4} M. (b) (1) DBA 1.19 M, (2), 1,2-DNB 1.21×10^{-4} M; (3) mixture of DBA 1.19 M and 1,2-DNB 1.21×10^{-4} M. Solvent: n-hexane. Temperature: 27 ± 0.1°C.

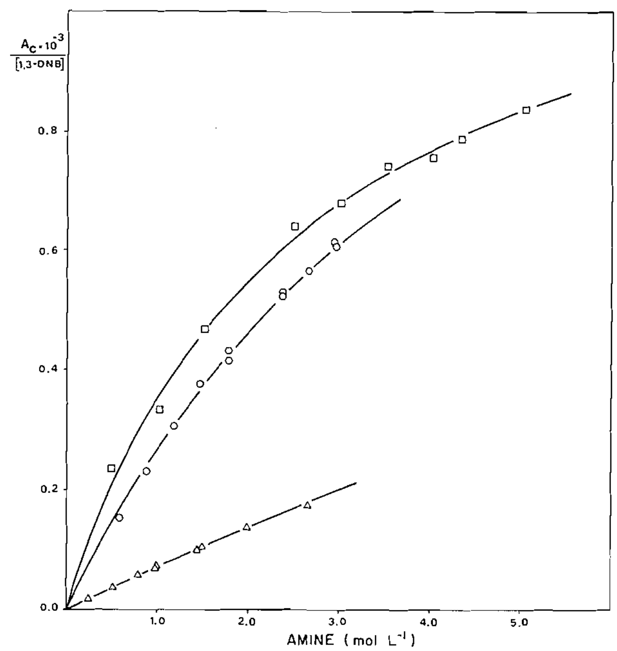

FIG. 2. Plots of $A_c/[A_0]$ vs. amine concentration for the systems. (□) 1,3-DNB − n-BA; (○) 1,3-DNB − DBA; (△) 1,3-DNB − TBA. The simulated curves are represented (see text) as a solid line.

$\lambda_{max} = 410$ nm immediately after mixing. This new band increased with time to a limited value depending on the 1,2-DNB concentration and it was assigned to the formation of N-n-butyl-2-nitroaniline, by S_NAr of the nitro group of 1,2-DNB by n-BA (14).

Actually, if the mixtures of the secondary amines with 1,2-DNB are allowed to stand for several hours, a new band also develops at around 400 nm, showing that these amines are also prone to produce S_NAr in 1,2-DNB. However, with the exception of the system n-BA − 1,2-DNB, these reactions are slow enough to allow the studies which are the purpose of this work. The enhanced absorbance for the systems amine−DNB was interpreted as due to a specific interaction, probably the formation of an EDA complex (1). Then, if a 1:1 complex is assumed, the observed absorbance, A_T, can be interpreted as the sum of three components (eq. [1])

$$[1] \quad A_T = A_A + A_D + A_{AD}$$

where A_A, A_D, and A_{AD} stand for the absorbance of the acceptor (DNB), the donor (amine), and the complex at equilibrium concentration.

An absorbance value, A_c, can now be defined as a function of the experimental values, A_T, and the corresponding values for the initial concentration of the acceptor, A_{A_0}, and the donor, A_{D_0}, (eq. [2])

$$[2] \quad A_c = A_T - (A_{A_0} + A_{D_0})$$

Then, A_c is a measure of the deviation from additivity of the mixtures. These values were determined for each system at 300 nm, which was the λ where they could be most accurately calculated. For every system, A_c was determined for different ratios of amine−DNB, in which the amine concentration $[D_0]$ was always at least 500-fold in excess with respect to the DNB concentration, $[A_0]$.

Typical plots of $A_c/[A_0]$ vs. amine concentration are shown in Fig. 2. For a given acceptor, the curvature of these plots is characteristic of a particular amine, giving a qualitative picture of the equilibrium conditions. The larger the deviation from a straight line, the greater the stability constant, K_s.

Approximate values of K_s and ϵ_c were determined graph-

TABLE 1. Results for K_s and ϵ_{AD} for amine–DNB complexes in n-hexane at 27°C and λ = 300 nm

Systems		Ratio	K_s	ϵ_{AD}	Correlation
Acceptor	Donor	$[D_0] \times 10^{-3}/[A_0]$	(L mol^{-1})[a]	(L mol^{-1} cm^{-1})[b]	coefficient
1,2-DNB	DBA	2.30–24.50	0.249±0.012	1661	0.9994
	TBA	1.73–13.75	0.098±0.010	1796	0.9996
1,3-DNB	n-BA	2.23–48.57	0.394±0.020	1764	0.9995
	DEA	2.05–25.10	0.243±0.012	2132	0.9993
	DBA	2.27–28.67	0.201±0.010	2133	0.9991
	TEA	3.05–16.13	0.089±0.009	2228	0.9983
	TBA	0.92–8.82	0.043±0.006	2267	0.9999
1,4-DNB	n-BA	2.96–29.56	0.356±0.008	3213	0.9992
	DBA	4.81–24.06	0.165±0.008	3295	0.9967
	TBA	0.52–4.60	0.032±0.005	6285	0.9938

[a]The error in K_s was calculated as in ref. 1.
[b]$\epsilon_{AD} = \epsilon_C + \epsilon_A + \epsilon_D$.

ically following eq. [3], derived (15) for the case where the absorption of the complex overlaps with that of the donor and the acceptor

$$[3] \quad \frac{[A_0][D_0]}{A_c([A_0] + [D_0])} = \frac{1}{K\epsilon_c}\frac{1}{([A_0] + [D_0])} + \frac{1}{\epsilon_c}$$

Then, the iterative procedure previously described (1) is used to calculate the final values of K_s and ϵ_c. In this procedure, K_s is varied to obtain the best fit to eq. [4].

$$[4] \quad A_c = \epsilon_c[AD]$$

[AD] being the equilibrium molar concentration of the complex. The fit to eq. [4] is measured by the correlation coefficient.

A further check to ensure the best values for K_s was developed. A computer simulation of the curves $A_c/[A_0]$ vs. $[D_0]$ was performed with the values of A_c calculated from the K_s obtained by the iterative procedure. A very good agreement between the experimental and the simulated curve was obtained, as is shown in Fig. 2. The results in K_s and ϵ_{AD} obtained for the systems studied are depicted in Table 1.

The behaviour of K_s with temperature was also studied for every system. Typical results are shown in Fig. 3. In general, as expected, small negative values of $-\Delta H$, around 8 kJ/mol, were found.

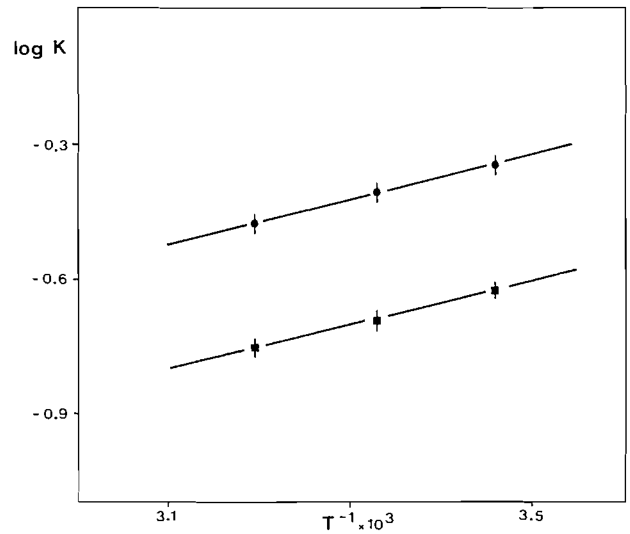

FIG. 3. Typical behavior of log K vs. T^{-1}: (●) n-BA – 1,3-DNB; (■) DBA – 1,3-DNB. Solvent: n-hexane.

Discussion

The fact that a value of K_s and a finite constant value of ϵ_{AD} could be determined from the enhanced absorbance of every mixture of amine–DNB in n-hexane can be taken as good evidence of formation of EDA complexes as was postulated for the same donors with benzonitrile, also in n-hexane (1).

Then, the difference in absorption of the mixture with respect to any single component may correspond (*i*) to broadening of a component band due to admixture of a component excited state with a charge transfer state (16); (*ii*) to an overlap with a new band of the EDA complexes. Although from the present experimental evidence it is not possible to distinguish between these two possibilities, the following considerations may favor (*ii*) as the more probable. It is expected that the maxima for the charge transfer band in these systems would lie in the ultraviolet region of the spectra (17), which is unreachable experimentally. These maxima are known to vary for similar sytems (1,3,5-TNB – aliphatic amines (6)) with the ionization potential (I_p) of the amine, in agreement with Mulliken's theory (18). In these systems it is observed that the lower the I_p of the electron donor, the smaller the transition energy ($h\nu_{AD}$) of the charge transfer band. Then, assuming that for the system DNB–amine the ϵ_{AD}(max) is not drastically different for the different amines, as was proposed for the systems benzonitrile–amines (1), it can be considered that the calculated ϵ_{AD} at 300 nm (see Table 1) represents the extinction coefficient of the tail of the charge transfer band. Consequently the difference in ϵ_{AD} would reflect the shift in ϵ_{AD} for any given acceptor, with the order $RNH_2 > R_2NH > R_3N$ as expected. On the other hand, and following the same reasoning, for a given donor the greatest value of ϵ_{AD} would be obtained for the acceptor with greatest electron affinities E_A (15). As can be seen in the table, for a given amine, ϵ_{AD} increases in the order 1,2-DNB < 1,3-DNB < 1,4-DNB which is also the order in which the E_A of the DNB increases (19). When the stability constant (K_s) values for a given acceptor are analyzed, it is clearly seen in the table that these follow the order $RNH_2 > R_2NH > R_3N$. This order is the inverse of the one that can be predicted from the inductive effects of the alkyl groups on the donor ability of the amines. There is a tendency, although it is only qualitative, for K_s to decrease with the dipole moment of the amine (20), which could suggest a contribution from dipolar association (21).

Actually the role of electrostatic force cannot be ruled out. It has been recently suggested that electrostatic interactions may make substantial contributions to the ground-state properties of EDA complexes (22). For the systems studied it is not possible, from the data, to establish the magnitude of this contribution, but it is not believed that it is the unique cause of the interactions. Previous studies in this laboratory, on solvatochromism in the ultraviolet spectra of π-acceptors such as benzonitrile (23) and nitrobenzene (24) as model compounds, have shown that the solvent effects on aliphatic amines cannot be accounted for only by dipolar interactions and that EDA complexation should be postulated. Similar considerations have been made to explain the mechanism of conductivity of triethylamine–nitrobenzene (25). Then, considering that the interaction is mostly through the EDA complex, the order of K_s with the amine structure could be explained through steric effects. Thus, for a given acceptor, the bulkier the substituents in the amine, the smaller the K_s. This consideration seems reasonable since the steric effects have been proposed to play an important role in EDA complexes having nitro aromatics as acceptors (26, 27). Moreover, in several types of EDA complexes having amines as donor, the effect of steric control on K_s (28–30) has been emphasized several times.

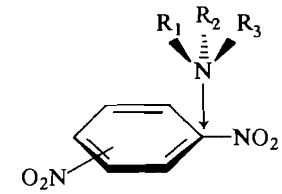
The values of K_s for the three DNBs studied are significantly greater than the values for the benzonitrile complexes with the same donor (1). These are expected results, since the presence of two nitro groups makes the aromatic ring more electron deficient and subsequently a better electron acceptor than benzonitrile.

The acceptor strength order generally observed for π–π complexes of these compounds (31) is 1,2-DNB $\sim$ 1,3-DNB $<$ 1,4-DNB. The explanation that has been given for these facts (32) does not seem to be satisfactory for the n–π complexes studied, since, for a given amine, the K_s follows the order of 1,2-DNB $>$ 1,3-DNB $>$ 1,4-DNB. The fact that both the donor and acceptor are unsymmetrical compounds suggests that there could be a preferred orientation of one molecule with respect to the other in the complex (33). Orientational complexes have been proposed for nitro aromatic complexes with indoles (33), methyl benzenes (34), and anilines (35).

Recently, energy changes calculated by CNDO/2 for complexing of ammonia, used as a model of an aliphatic amine donor, with quinones as acceptors (30) show that there are preferential sites of complexation at the midpoint of C(1)—C(2) on the quinone molecule. Nevertheless a stable complex is also predicted for any approach of the lone pair perpendicular to the quinone molecule.

In the present study, the fact that 1,2-DNB seems to be a better acceptor and at the same time gives S_NAr with the least sterically hindered amines suggests the possibility of formation of orientation complexes. In these complexes the amine nitrogen atom with its lone pair of electrons approachs the site of least electron density in the acceptor, which could be the carbon on the ring bonded to the nitro group (**I**). Such a type of complex has also been proposed as an intermediate in the reaction of amine with 1,3,5-TNB (36).

If such orientation is accepted, 1,2-DNB will probably be the better acceptor, due to the large inductive effect exerted by the *ortho* nitro group. This effect will be smaller for 1,3- and



I

1,4-DNB. It should be mentioned that similar arguments are proposed to explain the usually more powerfully activating effect of the *o*-nitro with respect to the *p*-nitro in S_NAr (37).

Étude physico-chimique des solutions concentrées en acide phosphorique par voie électrochimique. Propriétés acido-basiques et oxydo-réductrices

C. LOUIS ET J. BESSIÈRE

Laboratoire de Chimie et d'Électrochimie Analytique, Faculté des Sciences, Université de Nancy I, B.P. 239, 54506 Vandoeuvre Les Nancy, France

Reçu le 25 juin 1984

C. LOUIS et J. BESSIÈRE. Can. J. Chem. **63**, 908 (1985).

Les propriétés acido-basiques des milieux $H_2O-H_3PO_4$ (1 à 14 *M*) sont caractérisées par la fonction d'acidité R_0(H) et les fonctions basiques $R_0(H_2PO_4^-)$, $R_0(HPO_4^{2-})$, $R_0(PO_4^{3-})$ qui représentent respectivement l'activité du proton et le pouvoir donneur des particules $H_2PO_4^-$, HPO_4^{2-}, PO_4^{3-}. Les limites thermodynamiques du domaine de potentiel accessible ainsi que la nature de l'équilibre d'ionisation de l'acide sont précisées. Les niveaux d'acidité *H* et *R* des milieux phosphoriques sont comparés à ceux des milieux sulfurique, chlorhydrique et fluorhydrique. L'identité du niveau d'acidité R_0(H) de ces milieux pour une même valeur de l'acitvité en eau des solutions est montrée.

C. LOUIS and J. BESSIÈRE. Can. J. Chem. **63**, 908 (1985).

Acid–base properties in 1 to 14 *M* H_3PO_4 solutions are characterized with a R_0(H) acidity function and $R_0(H_2PO_4^-)$, $R_0(HPO_4^{2-})$, $R_0(PO_4^{3-})$ functions which respectively represent the H^+ activity in these media and their ability to give $H_2PO_4^-$, HPO_4^{2-}, PO_4^{3-} species. The thermodynamic limits of potential and the nature of the ionization equilibrium are studied. *H* and *R* acidity levels in phosphoric media are compared to those of sulfuric, hydrochloric, and hydrofluoric acid media. The identity of their R_0(H) acidity level for the same value of water activity is shown.

Introduction

L'acide phosphorique est un intermédiaire important dans la synthèse des engrais et dans l'élaboration de produits purs destinés à l'industrie alimentaire et au traitement de surface. La séparation des éléments valorisables (uranium, vanadium, terres rares) ou toxiques (cadmium, arsenic, molybdène, métaux lourds) qu'il contient est généralement réalisée par des opérations d'extraction liquide–liquide ou de précipitation. Les résines échangeuses d'ions et la flottation ionique ont également été envisagées à l'echelle du laboratoire et de l'installation pilote.

Le niveau d'acidité des milieux phosphoriques conditionne le pouvoir extractant des agents chélatants utilisés en milieu non miscible, la protonation des collecteurs de flottation ionique ainsi que le pouvoir oxydo-réducteur des solutés. Au cours de cet article, la variation du niveau d'acidité R_0(H) des milieux phosphoriques avec la concentration de l'acide (de 1 *M* à 14 *M*) et le diagramme potentiel–pH généralisé de ces milieux sont établis. Leur pouvoir donneur des espèces $H_2PO_4^-$, HPO_4^{2-}, PO_4^{3-} est caractérisé par les fonctions $R_0(H_2PO_4^-)$, $R_0(HPO_4^{2-})$, $R_0(PO_4^{3-})$, ce qui permet de préciser en particulier la nature de l'équilibre d'ionisation dans les milieux phosphoriques. L'importance du terme activité de l'eau dans la fixation du niveau d'acidité des milieux eau–acide est ensuite étudiée.

Experimental

Réactifs

Acide phosphorique: Prolabo; ferrocène: Sigma; indicateurs de Hammett: Aldrich; 1,4-benzoquinone et hydroquinone: Fluka.

Procédures et matériel

Les mesures potentiométriques à intensité nulle ont été faites au moyen du millivoltmètre Aries 10000 Tacussel. Les tracés polarographiques ont été obtenus sur le polarographe PRG 3 Tacussel.

Pour les tracés voltampérométriques sur électrode solide, réalisés avec l'ensemble Tipol EPL 2 Tacussel, un montage classique à trois électrodes a été utilisé. Le dégazage des milieux réactionnels est obtenu par passage d'azote.

L'électrode au calomel saturé aqueuse placée dans un compartiment séparé contenant H_3PO_4 0,1 *M* est en général utilisée comme électrode de référence (1).

REMARQUE: Elle a été comparée aux électrodes suivantes (2): électrode au calomel saturé aqueuse, électrode au calomel saturé préparée *in situ*, electrode AgCl/Ag, électrode Hg_2HPO_4/Hg, électrode $BiPO_4$/Bi.

L'électrode auxiliaire est constituée par un fil de platine. Les différentes électrodes de travail utilisées sont: électrode de platine EDI Controvit Tacussel (diamètre 1 mm) ou fil de platine (diamètre 0,8 mm) serti dans du verre ou du Teflon; électrode de carbone vitreux EDI Controvit Tacussel (diamètre 3 mm) ou barreau de carbone vitreux serti dans du verre (diamètre 2 mm). La vitesse de rotation est habituellement de 600 tours/min.

L'électrode à hydrogène est préparée selon la méthode préconisée par G. Charlot *et al.* (3).

Résultats et discussion

1. *Fonction d'acidité* $R_0(H)$ *des milieux* $H_2O-H_3PO_4$

La fonction d'acidité R_0(H) introduite par Strehlow et coll. pour caractériser le niveau d'acidité des solutions (4, 5) est déterminée expérimentalement à partir de la mesure du potentiel pris par une électrode indicatrice de pH en utilisant le système ferricinium/ferrocène comme référence de potentiel.

Dans le cas où l'électrode à hydrogène sert d'électrode indicatrice, la fonction d'acidité R_0(H) est donnée par la relation:

$$[1] \quad R_0(\mathrm{H}) = (E_0^{\mathrm{H_2O}} - E^{\mathrm{H_2O-H_3PO_4}})/0{,}058$$

où $E_0^{\mathrm{H_2O}} = -0{,}400$ V est le potentiel standard de l'électrode à hydrogène dans l'eau à 25°C et $E^{\mathrm{H_2O-H_3PO_4}}$ son potentiel dans une solution acide de composition donnée exprimé par rapport à Fc^+/Fc. Lorsque l'on utilise l'électrode 1,4-benzoquinone/hydroquinone saturée comme électrode indicatrice, la fonction R_0(H) est donnée par la relation:

$$[2] \quad R_0(\mathrm{H}) = (E_{\mathrm{Q_s/QH_{2s}}}^{\mathrm{H_2O}} - E_{\mathrm{Q_s/QH_{2s}}}^{\mathrm{H_2O-H_3PO_4}})/0{,}058$$

où $E_{\mathrm{Q_s/QH_{2s}}}^{\mathrm{H_2O}} = +0{,}316$ V est le potentiel standard du couple 1,4-benzoquinone saturée/hydroquinone saturée dans l'eau et $E_{\mathrm{Q_s/QH_{2s}}}^{\mathrm{H_2O-H_3PO_4}}$ son potentiel dans la solution acide exprimé par rapport à Fc^+/Fc.

La fonction R_0(H) s'identifie au pH si l'on admet que le potentiel standard du système ferricinium/ferrocène est indépendant de la nature du solvant. Dans la relation:

TABLEAU 1. Potentiels des systèmes Fc^+/Fc et H^+/H_2 dans les milieux $H_2O-H_3PO_4$ (mV vs. ECS dans H_3PO_4 0,1 *M*)

	H_3PO_4 *M*							
	0,1	1,02	2,04	5,10	7,15	10,0	12,0	14,0
$E_{1/2Fc^+/Fc} = E_0$ sur Hg (mV vs. ECS H_3PO_4 0,1 *M*)	+130	+80	+50	−30	−85	−190	−290	−380
E_{H^+/H_2} (mV vs. ECS H_3PO_4 0,1 *M*)	−347	−335	−337	−330	−327	−315	−300	−260

[3] $\mathrm{pH} = R_0(\mathrm{H}) + \log f_{Fc}/f_{Fc^+}$

les coefficients d'activité f_{Fc} et f_{Fc^+} sont alors égaux.

1.1. *Système de comparaison: ferricinium/ferrocène*

Le ferrocène (Fc) est peu soluble dans les milieux $H_2O-H_3PO_4$. Il s'oxyde en ferricinium (Fc^+) de coloration bleue sous l'action de l'oxygène ou des protons seuls lorsque le milieu est suffisamment concentré en acide.

Des réactions susceptibles de modifier le comportement redox du système Fc^+/Fc ont été mentionnées dans le cas d'autres milieux. Ainsi la protonation du ferrocène sur l'atome de métal a été mise en évidence par rmn dans les milieux H_2SO_4 concentrés (6). La complexation de l'ion ferricinium par les anions, qui a été montrée pour les chlorure, les perchlorate, les thiocyanate ainsi que pour les anions des acides carboxyliques, n'a pas lieu dans le cas des ions phosphate (7, 8). L'hydrolyse de l'ion ferricinium, qui peut se produire à température élevée (8), se fait lentement à température ambiante dans les milieux phosphoriques de concentration supérieure à 11,5 *M* où nous avons constaté l'apparition d'espèces Fe(II).

Etant donné les caractéristiques de rapidité et de réversibilité du système Fc^+/Fc dans les milieux $H_2O-H_3PO_4$, son potentiel normal est pris égal au potentiel de demi-vague de réduction de Fc^+ déterminé en polaragraphie. Les valeurs expérimentales des potentiels normaux du système Fc^+/Fc exprimées par rapport à l'électrode de référence ECS aqueuse dans un compartiment séparé contenant H_3PO_4 à la concentration 0,1 *M*, sont données dans le tableau 1.

1.2. *Système indicateur de H^+: H^+/H_2. Electrode à hydrogène*

Le bon fonctionnement de l'électrode à hydrogène dans les milieux phosphoriques peut en principe être vérifié en suivant la variation de son potentiel en fonction de la pression d'hydrogène. Mais l'analyse précise des voltampérogrammes est délicate car ils sont peu reproductibles. Leur allure générale est néanmoins en faveur d'un système rapide. La convergence de la fonction d'acidité calculée à partir de ces résultats et des fonctions d'acidité dont la détermination est fondée sur d'autres systèmes indicateurs de H^+ a confirmé a posteriori le fonctionnement correct de l'électrode à hydrogène dans les milieux phosphoriques. Les valeurs expérimentales de potentiel de l'électrode à hydrogène mesurées par rapport à l'électrode de référence ECS aqueuse dans H_3PO_4 0,1 *M* sont données dans le tableau 1.

1.3. *Système indicateur de H^+: 1,4-benzoquinone/hydroquinone*

Les deux composés 1,4-benzoquinone et hydroquinone sont solubles dans les milieux $H_2O-H_3PO_4$. Dans tout le domaine de concentration en H_3PO_4, les tracés voltampérométriques sur électrode de platine poli montrent que le système 1,4-benzoquinone/hydroquinone est lent. L'oxydation de l'hydroquinone est caractérisée par une vague de diffusion pure d'après le critère de Levich. Le signal correspondant à la réduction de la quinone n'a pas cette propriété et indique que l'espèce se transforme lentement.

TABLEAU 2. Potentiels des systèmes Q/QH_2 et Q_s/QH_{2s} dans les milieux $H_2O-H_3PO_4$ (mV vs. Fc^+/Fc)

	H_2O	H_3PO_4 *M*				
		2,0	5,5	8,0	11,5	14,0
$E_{0(Q/QH_2)}$ (mV vs. Fc^+/Fc)	+299	+328	+400	+460	+600	+720
$E_{Q_s/QH_{2s}}$ (mV vs. Fc^+/Fc)	+315	+320	+420	+505	+655	+780

Les études faites par potentiométrie à intensité nulle sur électrode de platine montrent que la loi de Nernst est vérifiée dans les différents milieux phosphoriques et que la pente des droites $E = f(\log[Q]/[QH_2])$ reste égale à 30 mV. Le système Q/QH_2 est donc reversible dans les milieux $H_2O-H_3PO_4$ selon le processus:

[4] $Q + 2H^+ + 2\,e^- \rightleftharpoons QH_2$

Les potentiels normaux du système Q/QH_2 ainsi que les potentiels mesurés à saturation des espèces Q et QH_2, exprimés par rapport au système Fc^+/Fc sont donnés dans le tableau 2.

1.4. *Fonction $R_0(H)$*

Les variations avec la concentration d'acide de la fonction $R_0(\mathrm{H})$ calculée à partir du système H^+/H_2 (relation [1]) et du système Q_s/QH_{2s} (relation [2]) sont présentées en fig. 1.

Les valeurs calculées à partir des deux systèmes indicateurs coïncident jusqu'à la concentration H_3PO_4 11,5 *M* (écart inférieur à 0,3 unité). Pour des concentrations d'acide comprises entre 11,5 et 14 *M*, nous utiliserons de préférence les valeurs déterminées à partir du système de l'hydrogène en raison de la modification de la quinone dans les milieux concentrés en acide.

La fonction d'acidité $R_0(\mathrm{H})$ qui caractérise l'acidité des milieux $H_2O-H_3PO_4$ présente une variation de 9 unités environ lorsque la concentration d'acide passe de 1,0 *M* à 14 *M*. L'écart entre les niveaux d'acidité des milieux phosphoriques correspondant aux concentrations industrielles 5,5 et 11,5 *M* est de 4 unités.

1.5. *Domaine de potentiel accessible dans les milieux $H_2O-H_3PO_4$. Diagramme potentiel–$R_0(H)$ du solvant*

D'un point de vue thermodynamique, le domaine des poten-

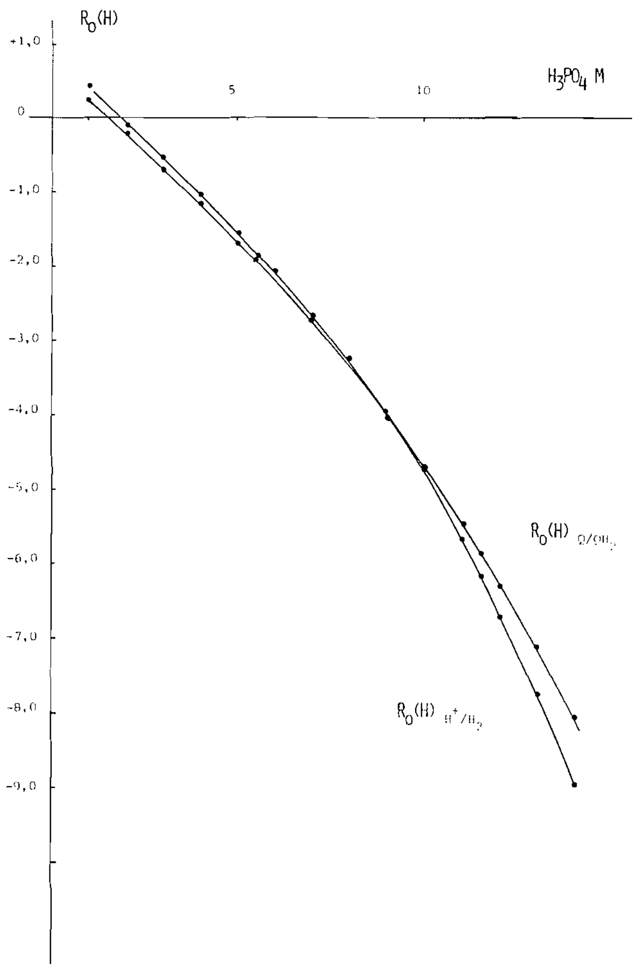

FIG. 1. Fonction R_0(H) en fonction de la concentration de H_3PO_4; (a) déterminée à partir du système H^+/H_2; (b) déterminée à partir du système Q_s/QH_{2s}.

tiels accessibles dans les milieux $H_2O-H_3PO_4$ est limité par les propriétés oxydantes du proton et les propriétés réductrices de l'eau. Les limites sont données par la variation des systèmes H^+/H_{2g} et O_{2g}/H_2O avec la concentration de l'acide.

Si l'on considère la réaction:

$$[5] \quad 2H^+ + 2e^- \rightleftharpoons H_{2g}$$

la variation du potentiel du système H^+/H_2 ne dépend que de la fonction d'acidité selon la relation [1].

Si l'on considère la réaction:

$$[6] \quad O_{2g} + 4H^+ + 4e^- \rightleftharpoons 2H_2O$$

la limite thermodynamique des potentiels accessibles en oxydation est donnée par la relation:

$$[7] \quad E = E^{H_2O}_{0_{O_2/H_2O}} - 0{,}058\ R_0(H) - 0{,}029 \log a_{H_2O}$$

avec $E^{H_2O}_{0_{O_2/H_2O}} = +0{,}829$ V. Elle dépend de l'acidité du milieu et de son activité en eau (9). L'étendue du domaine accessible en potentiel est donc donnée par la relation:

$$[8] \quad \Delta E = E^{H_2O}_{0_{O_2/H_2O}} - E^{H_2O}_{0_{H^+/H_2}} - 0{,}029 \log a_{H_2O}$$

Elle est pratiquement constante et égale à 1,23 V. En effet, le terme 0,029 log a_{H_2O} est négligeable jusqu'à une concentration d'acide de 8 *M* et sa valeur est de 28 mV dans les milieux les plus concentrés (tableau 3).

Le diagramme $E-R_0$(H) des milieux $H_2O-H_3PO_4$ est présenté en fig. 2.

REMARQUE: L'electrolyse sur électrode de platine de mélanges $H_2O-H_3PO_4$ donne O_2 et H_2 par décomposition de H_2O. Cependant, la formation d'ozone est sensible, même pour de faibles concentrations d'acide (10–12). Cette méthode a été préconisée pour la préparation de milieux concentrés d'acide phosphorique (12).

1.6. *Comparaison des fonctions d'acidité dans les milieux $H_2O-H_3PO_4$*

L'acidité des milieux $H_2O-H_3PO_4$ a été caractérisée par des fonctions *H*: H_0, H_0', H_0''', H_R, H_R' (13–16), ainsi que par des fonctions *R*: H_{GF} (8). Le tableau 4 présente les variations de ces différentes fonctions et permet de les comparer à la fonction R_0(H) que nous avons déterminée.

1.6.1. *Comparaison des fonctions* R_0*(H) et* H_0

Comme dans les autres milieux eau–acide, les fonctions d'acidité R_0(H) et H_0 présentent un écart sensible qui augmente avec la teneur en acide. Si l'on admet que la fonction R_0(H) traduit le mieux le niveau d'acidité du milieu du fait de la structure du système de comparaison Fc^+/Fc, d'après la relation:

$$[9] \quad pH = H_0 + \log f_I/f_{IH^+}$$

l'écart entre les deux fonctions mesure la quantité $\log f_I/f_{IH^+}$. Afin de préciser la part due à chacun des constituants du couple IH^+/I, nous avons étudié la variation de solvatation d'un indicateur de Hammett, l'anthraquinone I′, dont la protonation ne peut être réalisée dans les milieux phosphoriques, même concentrés.

En milieu 5,5 *M*, c'est la 4-chloro-2-nitroaniline I qui permet d'évaluer H_0 ($pK_{H_2O} = -0{,}9$). Les deux indicateurs de

TABLEAU 4. Fonctions d'acidité H et R dans les milieux $H_2O-H_3PO_4$

14,0	−3,55	−3,30	−5,5	−8,8	−7,9	−8,0	−8,9

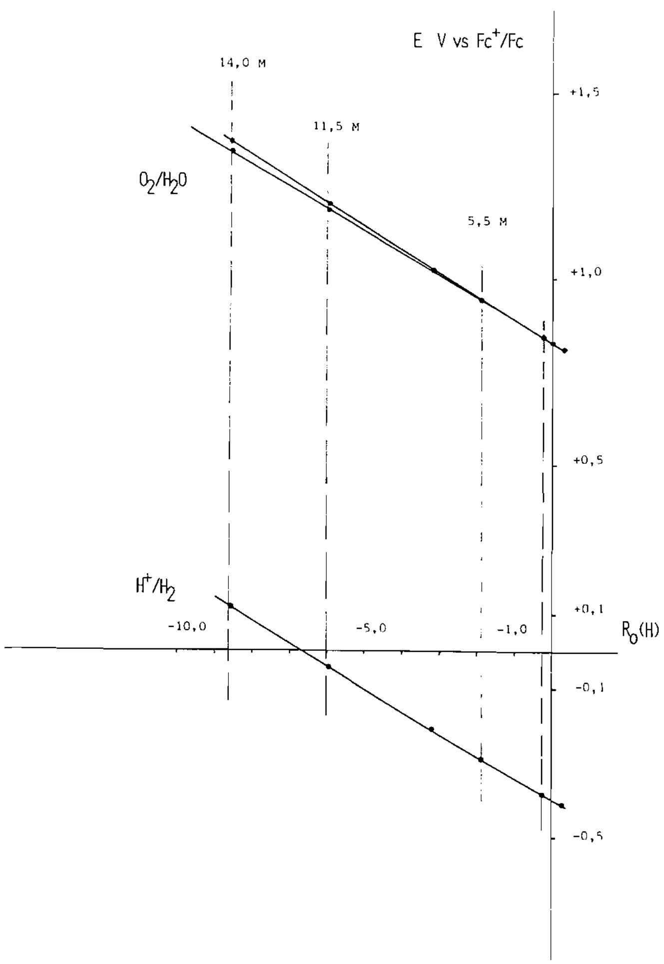

FIG. 2. Diagramme $E-R_0(H)$ des milieux $H_2O-H_3PO_4$.

Hammett obéissent à la relation:

[10] $f_I/f_{IH^+} = f_{I'}/f_{I'H^+}$

Or, la solubilité de l'anthraquinone ne varie pratiquement pas lorsque l'on passe de l'eau au milieu phosphorique 5,5 M. Donc, $f_{I'}$ est peu différent de 1 et la différence $R_0(H) - H_0$ mesure la quantité $-\log f_{I'H^+}$ (relation [9]). En milieu phosphorique 5,5 M, $-\log f_{I'H^+}$ est donc égal à $-1,2$. Cette valeur est voisine de celles trouvées pour les coefficients d'activité de cations monovalents qui ne subissent pas d'interaction spécifique avec les ions du solvant.[1]

Globalement, l'écart entre les fonctions $R_0(H)$ et H_0 est dû à une desolvatation rapide de IH^+ quand la teneur en acide augmente alors que la solvatation de la molécule neutre varie peu. Il semble que, du fait de leur structure, les indicateurs de Hammett soient plus sensibles aux effets de la solvatation par l'eau que les indicateurs conduisant aux fonctions $R_0(H)$ et H'_R.

1.6.2. *Comparaison des fonctions* $R_0(H)$, H_{GF} *et* H'_R

Les variations des fonctions d'acidité H_{GF} et $R_0(H)$ en fonction de la concentration de H_3PO_4 sont très voisines. Ceci valide indirectement l'utilisation de l'électrode de verre comme indicateur de niveau d'acidité. Contrairement aux électrodes à hydrogène et à quinhydrone dont le bon fonctionnement peut être vérifié, l'électrode de verre ne donne, pour chaque milieu, qu'une valeur de potentiel de membrane qui est fixé par la composition de la solution.

La concordance existant entre les fonctions H'_R et $R_0(H)$ est analogue à celle observée dans le cas des milieux $H_2O-H_2SO_4$ (17). Elle peut s'expliquer par le fait que les lois de variation des cofficients d'activité relatifs au ferrocène et au ferricinium sont très proches de celles observées pour les édifices hydrocarbonés insaturés, protonés ou non, conduisant à la fonction H'_R. Dans cette famille d'indicateurs, la présence de groupements substitués n'a pour effet que de modifier le pK_{H_2O} des couples indicateurs et n'a pratiquement pas d'influence sur la valeur du rapport des coefficients d'activité relatifs aux deux constituants du couple acide–base (18).

REMARQUE: À notre connaissance, l'exploitation des résultats existant concernant l'acidité des milieux phosphoriques pour le calcul d'une fonction d'acidité d'excès (19) n'a pas été faite.

2. *Fonctions* $R_0(H_2PO_4^-)$, $R_0(HPO_4^{2-})$ *et* $R_0(PO_4^{3-})$ *dans les milieux* $H_2O-H_3PO_4$

La fonction $R_0(H)$ traduit l'aptitude du milieu eau–acide à céder la particule H^+. Par analogie, les fonctions $R_0(H_2PO_4^-)$, $R_0(HPO_4^{2-})$ et $R_0(PO_4^{3-})$ sont définies pour caractériser l'ap-

[1] Le calcul et l'analyse des coefficients d'activité des anions et des cations dans les milieux phosphoriques seront présentés dans un article intitulé: Solvatation des espèces ioniques dans les milieux $H_2O-H_3PO_4$. À paraître. C. Louis et J. Bessière.

titude des milieux $H_2O-H_3PO_4$ à céder les particules $H_2PO_4^-$, HPO_4^{2-} et PO_4^{3-}.

Elles peuvent être déterminées expérimentalement à partir de la mesure du potentiel pris par une électrode M dont le fonctionnement fait intervenir un équilibre électrochimique engageant l'une des espèces phosphate et le composé insoluble correspondant. Ainsi, si l'on considère l'équilibre redox:

[11] $MHPO_{4s} + 2e^- \rightleftharpoons M_s + HPO_4^{2-}$

le potentiel du système $MHPO_{4s}/M_s$ dans les différents milieux est donné par la relation:

[12] $$E^{H_2O-H_3PO_4} = E_0^{H_2O} - \frac{0,058}{2} \log a_{HPO_4^{2-}}$$

Il ne dépend que de l'activité de l'espèce HPO_4^{2-} et la fonction

[13] $$R_0(HPO_4^{2-}) = \frac{E^{H_2O-H_3PO_4} - E_0^{H_2O}}{0,029}$$

est directement liée à l'écart des potentiels du système $MHPO_{4s}/M_s$ dans le milieu eau–acide et dans l'eau, ceux-ci étant exprimés par rapport au système de comparaison Fc^+/Fc.

Les fonctions $R_0(H_2PO_4^-)$ et $R_0(PO_4^{3-})$ peuvent être déterminées de la même manière. Néanmoins, elles ne sont pas indépendantes. En effet, en solution diluée, les activités des espèces participant aux équilibres:

[14] $H_2PO_4^- \rightleftharpoons H^+ + HPO_4^{2-}$ $\quad pK_2 = 7,2$

[15] $HPO_4^{2-} \rightleftharpoons H^+ + PO_4^{3-}$ $\quad pK_1 = 12,4$

sont liées au pH, à pK_1 et pK_2 par les relations:

[16] $pK_2 = pH + p(HPO_4^{2-}) - p(H_2PO_4^-)$

[17] $pK_1 = pH + p(PO_4^{3-}) - p(HPO_4^{2-})$

Dans les milieux concentrés, l'expression des constantes des équilibres de protonation reste la même et les trois fonctions sont liées par des relations formellement analogues à celles établies dans les milieux dilués:

[18] $pK_2 = R_0(H) + R_0(HPO_4^{2-}) - R_0(H_2PO_4^-)$

[19] $pK_1 = R_0(H) + R_0(PO_4^{3-}) - R_0(HPO_4^{2-})$

Ces fonctions permettent de préciser la nature de l'équilibre d'ionisation des mélanges $H_2O-H_3PO_4$ et de prévoir l'évolution de la solubilité d'un phosphate minéral avec la teneur en acide.

2.1. *Système Hg_2HPO_{4s}/Hg_s. Fonction* $R_0(HPO_4^{2-})$

L'oxydation électrochimique du mercure dans les milieux $H_2O-H_3PO_4$ se traduit par la formation d'un précipité qui a été identifié par diffraction X comme Hg_2HPO_4, quelle que soit la composition du milieu acide. La réaction d'oxydo-réduction est:

[20] $Hg_2HPO_{4s} + 2e^- \rightleftharpoons 2Hg_s + HPO_4^{2-}$

Le potentiel pris par une électrode au phosphate mercureux préparée *in situ* ne dépend donc que de l'activité des espèces HPO_4^{2-} (relation [12]). La fonction $R_0(HPO_4^{2-})$ est calculée d'après le relation [13] où $E^{H_2O} = -0,024$ V.

Les résultats sont présentés dans le tableau 5. Ils montrent que les propriétés réductrices du mercure en milieu $H_2O-H_3PO_4$ diminuent quand la concentration d'acide augmente.

2.2. *Système $BiPO_{4s}/Bi_s$. Fonction* $R_0(PO_4^{3-})$

Le phosphate de bismuth est peu soluble dans les milieux $H_2O-H_3PO_4$ et précipite uniquement sous la forme $BiPO_4$, quelle que soit la concentration de l'acide (20). $BiPO_4$ est réductible en bismuth métal selon le processus redox:

[21] $BiPO_{4s} + 3e^- \rightleftharpoons Bi_s + PO_4^{3-}$

Le potentiel E_{BiPO_{4s}/Bi_s} ne dépend que de l'acitvité des espèces PO_4^{3-}. Expérimentalement, il est donné par l'électrode de bismuth utilisée *in situ* (20). En effet, dans les différents milieux $H_2O-H_3PO_4$, l'électrode de bismuth se couvre instantanément d'une couche de phosphate de bismuth. La fonction $R_0(PO_4^{3-})$ est calculée d'après la relation:

[22] $$-\log a_{PO_4^{3-}} = R_0(PO_4^{3-}) = \frac{E^{H_2O-H_3PO_4} - E'^{H_2O}}{0,058/3}$$

où $E'^{H_2O} = -0,593$ V est le potentiel du système $BiPO_{4s}/Bi_s$ dans l'eau. Les résultats sont présentés dans le tableau 5.

REMARQUE: Les deux fonctions $R_0(HPO_4^{2-})$ et $R_0(PO_4^{3-})$ ont été déterminées indépendamment. Nous avons vérifié que la quantité:

$$R_0(H) + R_0(PO_4^{3-}) - R_0(HPO_4^{2-})$$

théoriquement égale à 12,4 (relation [19]), restait pratiquement constante et comprise entre 12,3 et 12,8, ce qui est satisfaisant puisque les fonctions R_0 sont déterminées chacune à 0,2 unité près.

2.3. *Fonction* $R_0(H_2PO_4^-)$

La fonction $R_0(H_2PO_4^-)$, calculée d'après la relation [18], figure également dans le tableau 5.

L'ensemble des propriétés acide–base des milieux $H_2O-H_3PO_4$ (1 *M* à 14 *M*) est présenté sous la forme d'un diagramme: $R_0(H_2PO_4^-)$, $R_0(HPO_4^{2-})$, $R_0(PO_4^{3-})$, $R_0(H)$, log a_{H_2O}, log $a_{H_3PO_4}$ en fonction de la concentration de H_3PO_4 (fig. 3).

2.4. *Application: équilibre d'ionisation dans les milieux $H_2O-H_3PO_4$*

Si l'équilibre:

[23] $H_3PO_4 + 4H_2O \rightleftharpoons H_9O_4^+ + H_2PO_4^-$

rend compte des phénomènes dans les milieux concentrés en acide, les fonctions $R_0(H)$ et $R_0(H_2PO_4^-)$, l'activité de l'eau a_{H_2O} et l'activité de l'acide $a_{H_3PO_4}$ sont liées par la relation:

[24] $R_0(H) + R_0(H_2PO_4^-) + \log a_{H_3PO_4} + 4 \log a_{H_2O} = 2,1$

A partir de nos résultats et des données de la littérature (9) nous avons calculé l'expression:

[25] $A_n = R_0(H) + R_0(H_2PO_4^-) + \log a_{H_3PO_4} + n \log a_{H_2O}$

en fonction de la concentration de l'acide pour $n = 4,2,1$. Les résultats sont donnés dans le tableau 6.

Il existe donc une concordance satisfaisante entre les données expérimentales et l'expression A_4 ($n = 4$) jusqu'à des concentrations d'acide voisines de 8 *M*. Pour des concentrations comprises entre 8 *M* et 12 *M*, la corrélation est bonne pour $n = 2$ puis $n = 1$. Ceci implique que le nombre des molécules d'eau solvatant le proton diminue à ces concentrations de H_3PO_4. L'équilibre de dissociation de H_3PO_4 est alors représenté par:

[26] $H_3PO_4 + H_2O \rightleftharpoons H_3O^+ + H_2PO_4^-$

Pour les milieux les plus concentrés (concentration supérieure à 12 *M*), l'expression [25] cesse d'être valable. Ceci peut être attribué à des phénomènes de dimérisation (21) ou de poly-

TABLEAU 5. Potentiels des systèmes Hg_2HPO_{4s}/Hg_s et $BiPO_{4s}/Bi_s$ dans les milieux $H_2O-H_3PO_4$. Fonctions $R_0(H_2PO_4^-)$, $R_0(HPO_4^{2-})$ et $R_0(PO_4^{3-})$

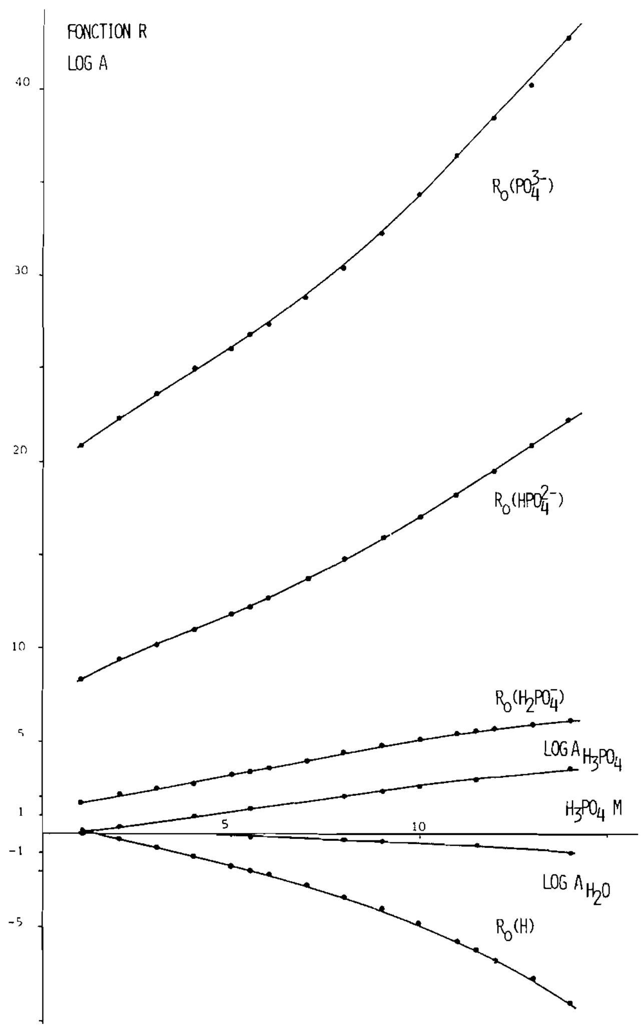

FIG. 3. Caractéristiques acide–base des milieux $H_2O-H_3PO_4$.

mérisation de l'acide phosphorique. L'équilibre [26] ne traduit plus à lui seul l'ionisation dans les milieux $H_2O-H_3PO_4$.

REMARQUE: Des phénomènes analogues ont été observés pour les milieux $H_2O-H_2SO_4$ et H_2O-HF. Des discontinuités au niveau des propriétés physiques (densité, conductivité) se manifestent à partir des concentrations $1H_2SO_4-2H_2O$ et $2HF-1H_2O$ (70% HF) (17, 22). Au delà de ces concentrations, il faut considérer les milieux comme des solvants différents dont les propriétés ne peuvent être déduites des lois concernant les mélanges.

3. *Comparaison de l'acidité de différents milieux eau–acide*

Les fonctions d'acidité d'excès apporteront probablement de nouveaux éléments dans la comparaison des milieux eau–acide (23). Nous avons, pour notre part, comparé les niveaux d'acidité $R_0(H)$ de différents milieux eau–acide pour des valeurs égales de leur activité en eau comme cela a été fait pour les fonctions d'acidité *H*.

3.1. *Comparaison de l'acidité à partir des fonctions* H_o

De nombreuses études ont porté sur l'analyse des relations susceptibles d'exister entre les valeurs des fonctions H_0 et l'activité de l'eau d'un mélange eau–acide de composition donnée. Ce sont principalement les travaux de Bascombe et Bell (24) et Wyatt (25) qui ont permis de préciser le rôle de l'activité de l'eau dans la fixation du niveau d'acidité H_0 des solutions acides.

3.1.1. *Cas des milieux eau–acides forts*

Dans le cas des acides forts, ces auteurs montrent que la fonction H_0 est la même pour des solutions ayant la même activité en eau. La relation entre la fonction d'acidité et l'activité de l'eau est:

$$[27] \quad H_0 = -5{,}02 + \log \frac{(1 + 20a_c + 150a_c^2 + 500a_c^3 + 625a_c^4)(1 - a_c)}{2a_c}$$

Elle s'applique avec une bonne précision aux mélanges $H_2O-HClO_4$, H_2O-HNO_3, $H_2O-H_2SO_4$, H_2O-HCl pour des teneurs inférieures à 60% en poids d'acide. Le modèle de Wyatt fait intervenir des équilibres successifs d'hydratation des différentes espèces participant à la réaction de protonation de l'indicateur. Ce résultat implique que, une fois l'activité de l'eau fixée, le terme $\log f_I/f_{IH^+}$ est indépendant de la nature des anions de l'acide et conduit à admettre que, dans les milieux eau–acide fort, les degrés d'aquation du proton, de I et de IH^+

TABLEAU 6. Calcul de l'expression [25] $A_n = R_0(\mathrm{H}) + R_0(\mathrm{H_2PO_4^-}) + \log a_{\mathrm{H_3PO_4}} + n \log a_{\mathrm{H_2O}}$ pour n = 4, 2, 1

[a] Valeur moyenne résultant du calcul de $R_0(H_2PO_4^-)$ d'une part à partir de la relation [18] (système Hg_2HPO_{4s}/Hg_s) et d'autre part de la combinaison des relations [18] et [19] (système $BiPO_{4s}/Bi_s$).

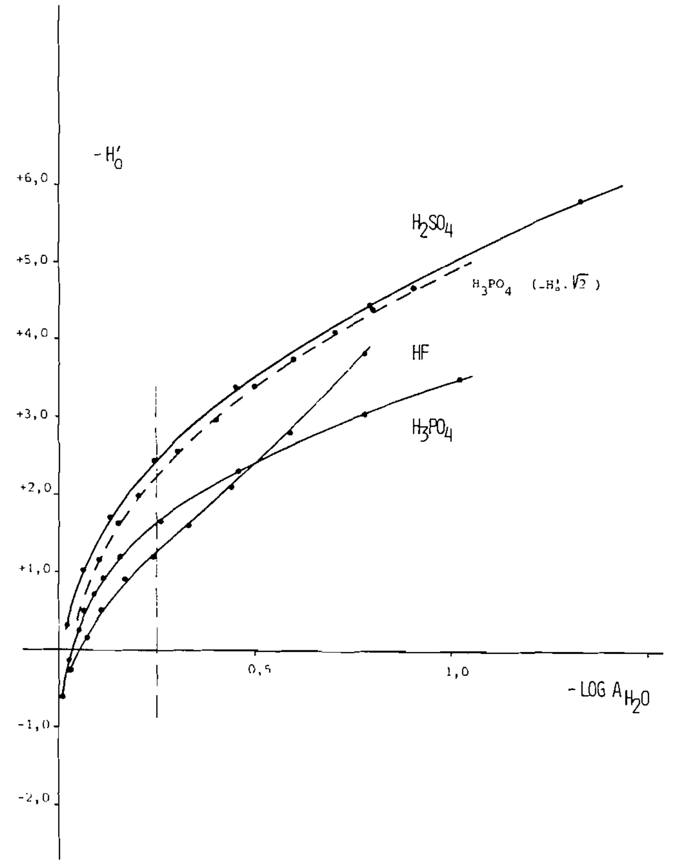

FIG. 4. Relation entre les fonctions H_0' et l'activité de l'eau dans les milieux $H_2O-H_2SO_4$, $H_2O-H_3PO_4$, H_2O-HF.

sont les mêmes et que les anions de l'acide ne participent pas à la solvatation de ces espèces.

3.1.2. *Cas des milieux eau–acides faibles*

Si l'on envisage le comportement d'acides faibles comme H_3PO_4 ou HF, on constate (fig. 4) que, pour une même activité de l'eau, le terme $-H_0$ est plus élevé dans le cas des acides forts que dans le cas d'un acide faible. Wyatt (25) a attribué cette différence au degré d'ionisation de l'acide d'après la relation:

$$[28] \quad H_0(\text{acide faible}) - H_0(\text{acide fort}) = \log \frac{1 + \alpha}{2\alpha}$$

Dans le cas de l'acide phosphorique, le coefficient α reste relativement faible. Il est de 0,126 pour H_3PO_4 42,5% (5,5 *M*)

TABLEAU 7. Calcul du coefficient d'ionisation [28] en fonction de la teneur (%) en acide pour H_3PO_4 et HF

$\log a_{H_2O}$	$C_{H_3PO_4}$ %	$C_{H_3PO_4}$ *M*	$\alpha_{H_3PO_4}$	C_{HF}	α_{HF}
−0,05	31	3,8	0,11	12	0,059
−0,1	42,5	5,5	0,126	19	0,046
−0,2	55	7,7	0,086	27,5	0,036
−0,3	62	9,2	0,059	34	0,028
−0,4	68	10,3	0,046	38,5	0,031
−0,5	72	11,3	0,036	42	0,036
−0,6	75	12,1	0,029	45	0,052
−0,7	79	12,7	0,025	48	0,086
−0,8	80	13,3	0,020		
−0,9	83	13,9	0,017		

et de 0,036 pour H_3PO_4 72,5% (11,5 *M*) (tableau 7). Contrairement aux solutions d'acides forts, les milieux $H_2O-H_3PO_4$ comportent à la fois des molécules d'eau et des molécules d'acide non dissociées susceptibles de participer à la solvatation des espèces H^+, I, IH^+. Ceci est confirmé par la conductibilité relativement faible de ces milieux par rapport à celle des milieux sulfuriques par exemple.

Le phénomène est probablement plus complexe dans le cas des milieux H_2O-HF où les molécules HF solvatent les ions F^- pour donner les espèces HF_2^- (22, 26–30). Ces équilibres secondaires perturbent les conditions d'application du modèle de Wyatt.

REMARQUE: Une analyse plus attentive des relations possibles entre l'activité de l'eau et la fonction H_0' dans les milieux $H_2O-H_3PO_4$ nous a conduit à constater que, dans tout le domaine de concentration envisagé, une solution phosphorique d'activité en eau donnée est caractérisée par un niveau d'acidité équivalent à celui d'une solution d'acide fort dont l'activité en eau est égale à la racine carrée de l'activité en eau de la solution phosphorique (fig. 4). Dans l'hypothèse où cette relation serait une propriété caractéristique des mélanges eau–acides faibles, elle devrait être vérifiée en particulier pour les milieux H_2O-HF. Or, d'après la fig. 4, nous voyons qu'il n'en est rien. Cependant, le comportement particulier des milieux H_2O-HF pourrait expliquer cette divergence et l'existence d'une relation entre les fonctions d'acidité H_0 des acides forts et des acides faibles n'est pas à exclure a priori. Elle devrait faire intervenir, en principe, les mêmes modèles que ceux utilisés dans les milieux $H_2O-H_2SO_4$ très concentrés (25, 31–34) où il existe des molécules d'acide non dissociées.

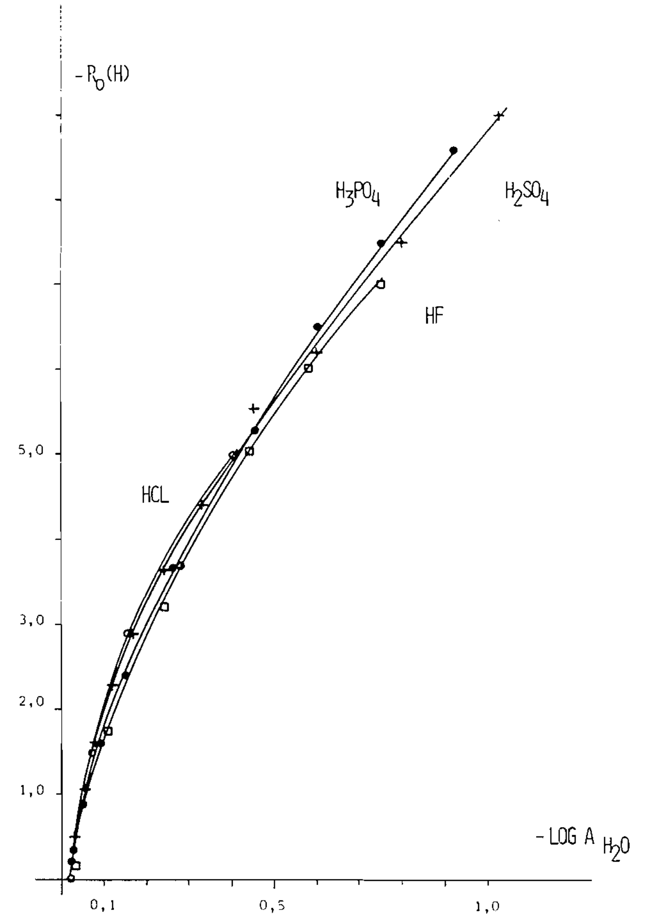

FIG. 5. Relation entre les fonctions R_0(H) et l'activité de l'eau dans les milieux $H_2O-H_2SO_4$, H_2O-HCl, $H_2O-H_3PO_4$, H_2O-HF.

3.2. *Comparaison de l'acidité à partir de la fonction* H'_R

Contrairement à ce qui a été observé avec les indicateurs de Hammett, il n'existe pas de relation univoque entre les fonctions H'_R et l'activité de l'eau dans les milieux eau–acides forts (35–41). Pour une même activité de l'eau, l'ordre de variation du terme $-H'_R$ est:

$$-H'_R(HCl) < -H'_R(H_2SO_4) < -H'_R(HNO_3) < -H'_R(HClO_4)$$

Les acides $HClO_4$ et HNO_3 ont un comportement voisin ($\Delta H'_R$ = 0,1 à 0,2 unités). Mais il existe un écart sensible dans tout le domaine de concentration entre le comportement des acides $HClO_4$ et HCl ($\Delta H'_R$ = 2 unités pour $-\log a_{H_2O}$ = 0,7).

D'autre part, les acides faibles comme H_3PO_4 (9, 16) ne se différencient pas nettement des acides forts. L'écart des fonctions H'_R pour les milieux H_2O-HCl, $H_2O-H_2SO_4$, $H_2O-H_3PO_4$ reste inférieur à 0,3 unités pour $-\log a_{H_2O}$ = 0,7.

3.3. *Comparaison de l'acidité à partir de la fonction* $R_o(H)$

La figure 5 présente les variations de la fonction R_0(H) avec l'activité en eau dans les milieux $H_2O-H_2SO_4$ (17), H_2O-HCl (42), H_2O-HF (26, 43), $H_2O-H_3PO_4$. Il apparaît que, dans le cas des acides forts H_2SO_4 et HCl, le niveau d'acidité est le même pour une même valeur de l'activité en eau. Ce résultat est analogue à celui obtenu avec les fonctions H_0 (25).

L'identité de la fonction R_0(H) à activité en eau donnée reste vraie dans le cas des acides faibles H_3PO_4 et HF. Il semble donc que les molécules non dissociées de H_3PO_4 ou de HF ne modifient pas le comportement du système de comparaison Fc^+/Fc comme elles le font dans le cas des indicateurs de Hammett. De plus, à activité en eau donnée, le niveau d'acidité R_0(H) est le même, que l'on soit en présence d'un acide fort ou d'un acide faible.

Ce résultat est important car il permet de comparer les solutions acides entre elles et d'apprécier, dans la modification de solvatation d'une espèce ionique ou moléculaire, la part due à l'activité en eau et celle qui peut être attribuée aux ions du milieu. Il sera appliqué en particulier à la comparaison des propriétés de solubilité des espèces et des caractéristiques d'oxydo-réduction de systèmes.[2]

Conclusion

Nous avons caractérisé le niveau d'acidité des milieux phosphoriques par la fonction d'acidité R_0(H). Sa variation est de 9 unités lorsque la concentration de l'acide passe de 1 à 14 *M* et de 4 unités entre les milieux industriels 5,5 et 11,5 *M*. Ces résultats permettront de préciser l'influence du niveau d'acidité sur le pouvoir oxydo-réducteur de nombreux systèmes, notamment de l'uranium.[3] Le diagramme potentiel – niveau d'acidité de ces milieux a été établi. L'étendue thermodynamique du domaine des potentiels accessibles reste proche de 1,23 V. Nous disposons ainsi des limites thermodynamiques de stabilité des oxydants et des réducteurs dans les milieux phosphoriques.

L'utilisation des systèmes électrochimiques du mercure et du bismuth nous a permis de déterminer les fonctions basiques $R_0(H_2PO_4^-)$, $R_0(HPO_4^{2-})$ et $R_0(PO_4^{3-})$. Elles seront utiles pour évaluer les variations thermodynamiques de solubilité des phosphates minéraux avec la teneur en acide.[4] L'analyse de la relation existant entre R_0(H), $R_0(H_2PO_4^-)$, les activités de l'eau et de l'acide phosphorique montre que l'équilibre d'ionisation de H_3PO_4 défini en solution aqueuse diluée reste valable pour les solutions concentrées en acide. Nous avons montré que le niveau d'acidité R_0(H) des milieux H_2O-HCl, $H_2O-H_2SO_4$, H_2O-HF et $H_2O-H_3PO_4$ était le même pour une même valeur du terme activité de l'eau. Ce résultat conduit à envisager la comparaison des propriétés d'oxydo-réduction et de complexation de systèmes, notamment ceux pour lesquels la solvatation spécifique des espèces mises en jeu par les anions du milieu n'est pas un facteur déterminant.

The photoreactions of tetraethylpyrophosphite, tetraphenylbiphosphine, diphenylphosphine oxide, and tetraethylbiphosphine disulphide with five quinones or quinonoid compounds have been studied by esr spectroscopy; $\dot{P}(O)Ph_2$ and $\dot{P}(O)(OEt)_2$ radicals add to both carbon–carbon and carbon–oxygen double bonds, whilst with $Ph_2\dot{P}$ and $\dot{P}(S)Et_2$ radicals only the species resulting from addition to a carbonyl group are observed. It is also reported that the photogenerated quinone triplets react with tetraethylpyrophosphite leading to the formation of diethoxyphosphonyl radicals, which in turn add to other ground state quinone molecules, the diethoxyphosphinyl adduct to a carbonyl group being also formed in the process.

ANGELO ALBERTI, ANDREW HUDSON, GIAN FRANCO PEDULLI, W. GRANT MCGIMPSEY et JEFFREY K. S. WAN. Can. J. Chem. **63**, 917 (1985).

Faisant appel à la spectroscopie rpe, on a étudié les photoréactions du tétraéthylpyrophosphite, de la tétraphénylbiphosphine, de l'oxyde de diphénylphosphine et du disulfure de la tétraéthylbiphosphine avec cinq quinones ou composés quinonoïdes; les radicaux $\dot{P}(O)Ph_2$ et $\dot{P}(O)(OEt)_2$ s'additionnent tant aux doubles liaisons carbone–carbone que carbone–oxygène alors que, avec les radicaux $Ph_2\dot{P}$ et $\dot{P}(S)Et_2$, on n'observe que la formation des produits résultant d'une addition sur le groupement carbonyle. On rapporte aussi que les triplets de quinones qui sont photogénérés réagissent avec le tétraéthylpyrophosphite en conduisant à la formation de radicaux diéthoxyphosphonyle qui s'additionnent à leur tour à l'état fondamental des molécules de quinones; l'adduit diéthoxyphosphinyle sur le groupement carbonyle se forme aussi dans ce processus.

[Traduit par le journal]

Introduction

The reactions of phosphorus-centered radicals with carbonyl compounds have received little attention to date. It has been reported that dialkylphosphinyl radicals $\dot{P}R_2$ (R = Me, Et) add to di-*tert*-butyl ketone to give $t\text{-}Bu_2\dot{C}OPR_2$ (1); similarly, the radical resulting from the addition of the photolytically generated $\dot{P}Ph_2$ to the less hindered oxygen atom of 2,6-di-*tert*-butyl-*p*-benzoquinone has been observed by one of us (2).

In order to achieve a deeper insight into the nature of the radical intermediates formed during the reactions of phosphorus-centred radicals with unsaturated derivatives containing the carbonyl function, we have undertaken an electron spin resonance (esr) investigation of the reactions between phosphinyl, phosphonyl, and thiophosphonyl radicals and a number of quinones.

There has been continuing controversy about radical addition to quinones and their analogs. This is mainly because of the two distinct reactive sites in these species. These substrates can in fact lead to different radical adducts depending on the pathway followed by the addition reaction, i.e. attack either at a carbon–carbon or a carbon–oxygen double bond by the incoming $R_n\dot{P}$ radicals. Analogous isomeric adducts have been actually observed in the addition of silyl and germyl radicals to unsaturated carbonyl derivatives such as maleic anhydride and other related compounds (3).

In the course of the present study both kinds of adducts were detected in the addition of phosphonyl radicals to most of the investigated quinones, while only the oxygen adducts could be observed with phosphinyl and thiophosphonyl radicals. We know of no previous reports of the addition of phosphonyl and thiophosphonyl radicals to the carbonyl function. It is hoped that these results will be useful to phosphorus chemists in their understanding of the reactions and reaction mechanisms involving phosphines, phosphites, and pyrophosphites.

Experimental

All phosphorus compounds were commercially available, as were quinones **1–3**; dithiolactone **4** (4) and dione **5** (5) were obtained as described in the literature.

The esr spectra were recorded on either a Varian E104 or a Bruker ER200 esr spectrometer equipped with an nmr gaussmeter (field calibration), a frequency counter (*g* factor determination), and standard variable temperature devices.

Benzene or *tert*-butylbenzene solutions of the appropriate quinone and tetraphenylbiphosphine (TPBP) or tetraethylbiphosphine disulphide (TPBPS) were irradiated within the cavity of the esr spectrometer by means of 1-kW or 200-W high pressure mercury lamps; di-*tert*-butyl peroxide (BOOB) solutions were used in the photoreactions of tetraethylpyrophosphite (TEP) and diphenylphosphine oxide (DPPO). A Bausch & Lomb grating monochromator was also used in some of the experiments.

Results and discussion

We have studied the reactions of diphenylphosphinyl, $\dot{P}Ph_2$;

5

diphenylphosphonyl, $O\dot{P}Ph_2$; diethoxyphosphonyl, $O\dot{P}(OEt)_2$; and diethylthiophosphonyl, $S\dot{P}Et_2$; radicals with *p*-benzoquinone (**1**, BQ), duroquinone (**2**, DQ), 2,6-di-*tert*-butyl-*p*-benzoquinone (**3**, DTBQ), 3,6-dimethylthieno[3,2-*b*]thiophen-2,5-dione (**4**, DMTTD), and benzo[1,2-*b*;5,4-*b*′]dithiophen-4,8-dione (**5**, BDTD).

Tetraphenylbiphosphine, P_2Ph_4, is known to be a good source of $\dot{P}Ph_2$ radicals when irradiated with uv light (2). Homolytic cleavage of the phosphorus–phosphorus bond presumably also occurs upon irradiation of TEBPS with formation of diethylthiophosphonyl radicals $S\dot{P}Et_2$. The diethoxyphosphonyl radical $O\dot{P}(OEt)_2$ has been generated by the displacement reaction [1] of photolytically produced *tert*-butoxyl radicals with TEP (6), and the diphenylphosphonyl radical $O\dot{P}Ph_2$ via hydrogen abstraction from DPPO by t-Bu$\dot{O}$ [2]:

[1] $[(EtO)_2P]_2O + t\text{-Bu}\dot{O} \rightarrow t\text{-BuOP(OEt)}_2 + O\dot{P}(OEt)_2$

[2] $Ph_2P(O)H + t\text{-Bu}\dot{O} \rightarrow t\text{-BuOH} + O\dot{P}Ph_2$

As mentioned in the introduction, phosphorus-centered radicals may react with carbonyl compounds by attacking the oxygen atom; in such quinones as DTBQ or BDTD, where the two carbonyl functions are inequivalent, isomeric adducts can be formed depending on which of the two oxygens undergoes addition. Moreover, quinones contain carbon–carbon double bonds which also are potential sites of addition for the incoming radicals. The formation of several kinds of spin adducts is therefore to be expected when reacting quinones with phosphorus-centered radicals.

p-Benzoquinones (1–3)

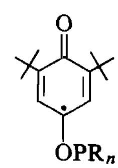
In principle, the addition reaction of $\dot{P}R_n$ radicals to BQ, DQ, and DTBQ can be schematized as outlined in eq. [3];

[3] 
(a) (b)

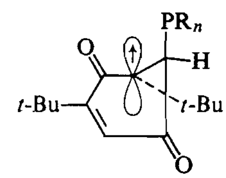
When using the unsubstituted derivative **1**, no adducts of either kind could be observed with $\dot{P}Ph_2$, $O\dot{P}Ph_2$, and $S\dot{P}Et_2$, while with $O\dot{P}(OEt)_2$ the species resulting from addition of the phosphonyl radical to a carbonyl group was detected. The low persistence of the possible adducts of BQ (**1***a*) and (**1***b*) likely makes these species difficult to detect. Since increasing the steric hindrance in the proximity of a radical centre usually leads to longer-lived paramagnetic species, the reaction was repeated using substituted quinones.

With DTBQ both the adducts **3***a* and **3***b* are obtained by reaction with $O\dot{P}Ph_2$ and $O\dot{P}(OEt)_2$, while $S\dot{P}Et_2$ and $\dot{P}Ph_2$ only give the oxygen adducts **3***a*. However, in the $\dot{P}Ph_2$ case the esr spectra also indicate the presence of a ring adduct **3***b* whose spectral parameters are identical with those exhibited by the corresponding species resulting through addition of $O\dot{P}Ph_2$ radicals to DTBQ. Because of the unsymmetrical nature of this quinone, two pairs of oxygen and ring adducts might be formed. The small triplet splitting (1.2–1.6 G) detected for radicals **3***a* clearly indicates that addition of $\dot{P}R_n$ radicals takes place at the less hindered carbonyl group. This assignment is confirmed in the case of $O\dot{P}Ph_2$ and $O\dot{P}(OEt)_2$ adducts by a comparison between the appropriate values collected in Table 1 and the hfs constants previously reported by Rieker for the authentic radicals **3***a* obtained by oxidation of the corresponding phenols (7). The detection of radical **3***a* (where PR_n is a $P(O)Ph_2$ group) in the thermal reaction of DTBQ with DPPO followed by oxidation has also been reported recently. (8).

The ring adducts of DTBQ originate from attack of $O\dot{P}R_2$ at an unsubstituted carbon of the quinone; addition to positions 2 or 6 would in fact result in the formation of a radical species which should show a ca. 20-G splitting from the single proton linked to the radical centre (3). We therefore assign the structure **3***b* to the ring adducts, although the actual values of the



3*a*



3*b*

β-proton and ^{31}P splittings (see Table 1) are, respectively, smaller and larger than expected. It seems that the presence of the bulky *tert*-butyl group α to the radical centre induces a significant distortion of the quinone ring, forcing the hydrogen atom into a quasi-equatorial position, i.e. into the nodal plane of the $2p_z$ orbital containing the unpaired electron, and the $P(O)R_2$ substituent closer to the axial position where the C—P bond can strongly overlap the singly occupied orbital. Similar trends have been previously reported for highly hindered cyclohexadienyl radicals (9, 10).

With duroquinone, only two adducts could be positively identified, i.e. the species **2***b* resulting from addition of $O\dot{P}Ph_2$ and $O\dot{P}(OEt)_2$ radicals to the ring of DQ. The identification of these radicals is straightforward, as their spectra consist of doublets, $a(^{31}P)$ = 33–38 G, of quartets, a(3H) = 23–24 G, further split into smaller quartets, a(3H) = 0.36 G, the magnitude of the couplings being consistent wth the presence of a methyl group α to a carbon radical centre and of another methyl group and a phosphorus nucleus β to it.

While the observed radicals are unambiguously identified, some questions concerning the nature of the initiating species may arise. We have therefore examined the photoreactions of 2,6-di-*tert*-butyl-*p*-benzoquinone, which was chosen because of the relatively high persistence of its radical adducts, upon irradiation in the regions of its uv absorption maxima, viz. 254 nm, 318 nm, and 446 nm (11). With BOOB-free solutions of

3 containing TEP a weak esr signal developed after awhile, its intensity, although increasing with time, never matching that of the spectra obtained by irradiation in the presence of peroxide. The signal clearly indicated the presence of three radical species: the ring- and oxygen-diethoxyphosphonyl adducts **3***a* and **3***b*, and a third species with a g factor 2.0047_5 and exhibiting coupling of the unpaired electron with two protons (a = 1.26 G) and a ^{31}P nucleus (a = 3.52 G). A probable mechanism accounting for the formation of $O\dot{P}(OEt)_2$ radicals involves

[4] 
attack of the photogenerated quinone triplet on the pyrophosphite, followed by α-fragmentation of the intermediate biradical. This mechanism also nicely accounts for the detection of a third radical species, whose esr couplings are consistent with the diethoxyphosphinyl adduct of DTBQ.

No esr signals were, however, detected when irradiating in the aforementioned regions solutions of **3** containing either TPBP or TEBPS, thus indicating that the reactions leading to the phosphinyl and thiophosphonyl adducts are not initiated by an excited state of the quinone. Although one would expect that irradiation at shorter wavelengths, where both TPBP and TEBPS absorb, would lead to the formation of $\dot{P}Ph_2$ and $S\dot{P}Et_2$ radicals, it is likely that the intensity of the radiation emerging from the monochromator is not sufficient for the cleavage of the P—P bond. Also in the case of DPPO, no signal from adducts **3***a* and **3***b* could be observed, unless BOOB was added to the solutions.

*3,6-Dimethylthieno[3,2-*b*]thiophen-2,5-dione (**4**)*

The reaction of both $O\dot{P}Ph_2$ and $O\dot{P}(OEt)_2$ radicals with the dione **4** leads to the simultaneous formation of the oxygen (**4***a*) and ring (**4***b*) adducts, the proton hyperfine splitting constants of the former species being similar to those of the analogous oxygen adducts with group IVB organometallic radicals (12). Attack at the ring might in principle occur at the carbons either in positions 3,6 or 4,5; in the former case the structure of the resulting adducts will be closely related to a substituted allylic system and a methyl splitting of ca. 10 G would be expected; in the other case addition would result in α-ketoalkyl radicals characterized by much larger methyl couplings (ca. 20 G), as for the DQ adducts. The ca. 8–9 G quartet splitting (see Table 2) clearly indicates that $O\dot{P}R_2$ radicals attack positions 3 or 6 of DMTTD.

Similarly to what was found with BQ, DQ, and DTBQ, the reaction of dione **4** with $S\dot{P}Et_2$ and $\dot{P}Ph_2$ radicals only led to the detection of the oxygen adducts **4***a*, although in the latter case esr evidence for the simultaneous formation of the $O\dot{P}Ph_2$ ring adduct **4***b* was also obtained.

*Benzo[1,2-*b*;5,4-*b*′]dithiophen-4,8-dione (**5**)*

On reaction of phosphorus-centered radicals with BDTD, addition seems to occur only at the oxygen atoms. Due to their inequivalence, two isomers **5***a* and **5***a*′ are expected to form, and indeed they have been observed with $\dot{P}Ph_2$, $O\dot{P}Ph_2$, and $O\dot{P}(OEt)_2$; surprisingly enough, with $S\dot{P}Et_2$ only isomer **5***a* could be detected. The identification of the isomers, accomplished by analogy with the related hydrogen and group IVB adducts (12), was based on the assumption that larger splittings at the protons 2,5 (see Table 3) should be observed for isomer (a), due to the possibility of delocalizing the unpaired electron on these positions. The relative concentration of isomer (a) increases along the sequence $PPh_2 < P(O)Ph_2 < P(O)(OEt)_2 < P(S)Et_2$; no traces of **5***a*′ could actually be observed for the last adduct.

General remarks

The $\dot{P}Ph_2$, $S\dot{P}Et_2$, and $O\dot{P}Ph_2$ radicals which lead to the observed spin adducts with quinones **1–5** are formed via ho-

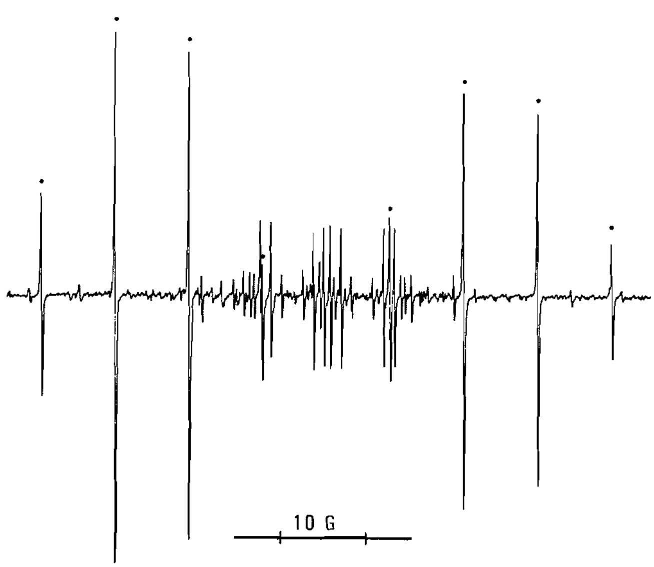

FIG. 1. The esr spectrum observed at 393 K upon uv irradiation of a solution of the dithiolactone **4** containing TEP and di-*tert*-butyl peroxide. The marked lines are due to the radical adduct **4***b*.

molysis of tetraphenylbiphosphine and tetraethylbiphosphine disulphide or by hydrogen abstraction from diphenylphosphine oxide by *tert*-butyl radicals. Diethoxyphosphonyls $\dot{O}P(OEt)_2$ may instead be formed through two alternative pathways, viz. reactions [1] and [4]. On the other hand, as it has been recently shown (13) that *t*-Bu$\dot{O}$ radicals react with pyrophosphite at a diffusion-controlled rate ($k_{[1]} = 2.85 \times 10^9\ M^{-1}\ s^{-1}$), we believe that in peroxide solutions the mechanism outlined in reaction [4] only plays a minor role. This seems to be further substantiated by the fact that the diethoxyphosphinyl oxygen adduct **3***a* was only detected when using peroxide-free solutions of DTBQ and TEP.

Reaction [4] is nevertheless an interesting and quite general process. Thus diethoxyphosphonyl adducts were detected in the absence of peroxide also with quinones **1**, **4**, and **5**, while intense esr signals from both $Ph_2\dot{C}OP(OEt)_2$ and $Ph_2\dot{C}OP(O)(OEt)_2$ were observed by irradiation of solutions of benzophenone and TEP (14).

Phosphinyl, phosphonyl, and thiophosphonyl radicals do not exhibit uniform behaviour in their reactions with compounds **1**–**4**; $\dot{O}P(OEt)_2$ and $\dot{O}PPh_2$ are in fact the only species for which adducts resulting from addition to the quinone ring could be observed along with those originating from addition to the carbonyl function. A knowledge of rates of addition of phosphorus-centered radicals to unsaturated and carbonyl compounds would of course be very useful in establishing whether the failure to observe a particular paramagnetic species is due to a slow rate of formation or to a fast rate of radical loss. Unfortunately, although the use of kinetic esr (15) and of laser flash photolysis techniques (16) has now made available a considerable amount of kinetic data for many radical reactions, only very few refer to processes involving phosphorus-centered radicals, and it would appear that attention has been mainly focussed on $\dot{O}P(OEt)_2$ (9, 17, 18). A substantial body of information is instead available on the reactivity of silyl radicals, whose reaction rates with various substrates have been determined (19). Although silicon- and phosphorus-centered radicals often react with the same substrates to give structurally related adducts, extrapolation of kinetic data is often dangerous. For example $\dot{O}P(OEt)_2$ and $\dot{S}iEt_3$ add to furan and thiophene with similar rates, while the reaction of silyl radicals with benzene is two orders of magnitude faster than that of diethoxyphosphonyls (13). Also, the silyl adduct to the double bond of maleic anhydride is detected at or below room temperature, but the oxygen adduct is the only observable species at higher temperature (3); the phosphonyl adducts **3**a, **3**b, **4**a, and **4**b are instead observed over a wide temperature range (−80 to +80°C), although in varying relative amounts.

All the observed $\dot{P}Ph_2$, $\dot{S}PEt_2$, $\dot{O}PPh_2$, and $\dot{O}P(OEt)_2$ radical adducts detected in this study are to be considered persistent (20), and, with the exceptions only of **1**a, **5**a, and **5**a', they could be observed over significant time intervals (several minutes to hours) when photolysis was interrupted. It is worth noting that in the case of the two phosphonyl derivatives **4**b the radical concentration can be increased or decreased reversibly in the absence of uv irradiation by simply raising or lowering the temperature, which clearly indicates that a monomer–dimer equilibrium is being observed.

Dione **5** represents a particular case; one might expect that the rates of addition to a ring and of decay of the resulting radicals did not differ drastically from the values determined in a laser flash photolysis experiment of the addition of $\dot{O}P(OEt)_2$ radicals to thiophene (13), i.e. $k_a = 1.7 \times 10^6\,M^{-1}\,s^{-1}$ and $2k_t = 10^9\,M^{-1}\,s^{-1}$ at −80°C, although a slight reduction of the rate of radical loss may be expected due to partial delocalization of the unpaired electron onto a carbonyl group. Although rates of addition of $\dot{P}R_n$ radicals to the carbonyl function are not available for comparison, it seems unlikely, at least in thermodynamic terms, that the incoming radicals add to one of the rings with consequent destruction of an aromatic system, when addition to one of the carbonyl groups would result in a stabilized phenoxyl radical.

A peculiar feature of the reactions of TPBP with quinones is that, besides the species resulting from addition of $\dot{P}Ph_2$ radicals to a carbonyl group, the $\dot{P}(O)Ph_2$ spin adducts to the ring of the quinone are detected; similar adducts were also formed when using diphenylphosphine to produce $\dot{P}Ph_2$ radicals. This is likely to be the result of contamination of TPBP or DPP by the corresponding oxides. It is in fact known that both secondary phosphines (21) and polyphosphines (22) are highly sensitive to oxidizing agents and, according to reactions [5] and [6], may lead to precursors of diphenylphosphonyl radicals.

$$[5]\quad 2Ph_2PH \xrightarrow{O_2} 2Ph_2P(O)H$$

$$[6]\quad Ph_2P\text{—}PPh_2 \xrightarrow{O_2} Ph_2(O)P\text{—}P(O)Ph_2$$

Received July 5, 1984

PIERO ZANELLO and PIERO LEONI. Can. J. Chem. **63**, 922 (1985).

The electrochemical behaviour of some copper(I) aminocarbonyl derivatives, namely, $[Cu(dien)(CO)]^+$ (dien = diethylenetriamine), $[Cu(Medpt)(CO)]^+$ (Medpt = *N,N*-bis(3-aminopropyl)methylamine), $[Cu_2(tmen)_2(\mu\text{-}PhCO_2)(\mu\text{-}CO)]^+$ (tmen = *N,N,N',N'*-tetramethylethylenediamine), has been studied in dimethyl sulfoxide solution at platinum electrodes by cyclic and dc voltammetry, and controlled potential coulometry. In all studied complexes each copper(I) centre undergoes one-electron charge transfers in both anodic and cathodic processes. The electrogenerated copper(II) complexes, fully characterized, can be reversibly reduced to the starting copper(I) carbonyl derivatives in the presence of carbon monoxide. The electron-transfer sequences in which these copper(I) complexes may be involved have been elucidated.

PIERO ZANELLO et PIERO LEONI. Can. J. Chem. **63**, 922 (1985).

Faisant appel à la voltamétrie cyclique et à cd ainsi qu'à la coulométrie à potentiel contrôlé et opérant en solution dans le diméthylsulfoxyde, on a étudié le comportement électrochimique de quelques dérivés aminocarbonyles du cuivre (I) au niveau d'électrodes de platine; on a examiné en particulier le $[Cu(dien)(CO)]^+$ (dien = diéthylènetriamine), $[Cu(Medpt)(CO)]^+$ (Medpt = *N,N*-bis(amino-3 propyl)méthylamine), $[Cu_2(tmen)_2(\mu\text{-}PhCO_2)(\mu\text{-}CO)]^+$ (tmen = *N,N,N',N'*-tétraméthyl-éthylènediamine). Dans tous les complexes étudiés, chaque centre de cuivre(I) subit un transfert de charge d'un électron, tant dans le processus anodique que cathodique. Les complexes de cuivre(II), générés d'une manière électrochimique, ont été complètement caractérisés et, en présence de monoxyde de carbone, ils peuvent facilement être reconvertis en dérivés aminocarbonyles de cuivre(I) de départ. On a élucidé les suites de transferts électroniques dans lesquels ces complexes de cuivre(I) peuvent être impliqués.

[Traduit par le journal]

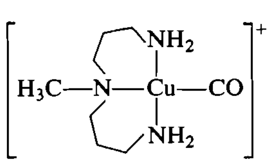
Introduction

The redox chemistry of copper(I) derivatives may serve to understand the function of a number of naturally occurring cuproproteins (1).

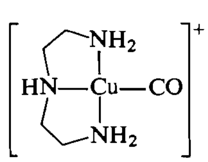
Increasing attention is paid to the electrochemistry of copper(I)/copper(II) redox couples of biological relevance (2–15). However, the electrochemical behaviour of copper(I) derivatives is seldom directly dealt (9, 11, 13). For the most part the redox properties of copper(II) derivatives are investigated, with a particular attention to the responses in the presence of carbon monoxide.

We present here the electrochemical behaviour in nonaqueous solvent of a number of copper(I) aminocarbonyl derivatives, $[Cu(Medpt)(CO)]^+$, $[Cu(dien)(CO)]^+$, and $[Cu_2(tmen)_2(\mu\text{-}PhCO_2)(\mu\text{-}CO)]^+$ (**I**, **II**, **III**), whose anodic oxidation leads to decarbonylated copper(II) species, $[Cu(Medpt)(S)]^{2+}$, $[Cu(dien)(S)]^{2+}$, and $[Cu_2(tmen)_2(\mu\text{-}PhCO_2)(S)]^{3+}$ (S = solvent) (**IV**, **V**, **VI**), able to be cathodically reduced to **I**, **II**, and **III**, respectively, in the presence of carbon monoxide.

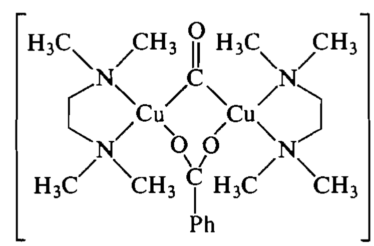
Because of the coordination geometry around copper, the nature of the donor atoms in **I**–**III**, the presence of a dicopper(I) unit in **III** which binds 1 CO/2 Cu, and the relatively



I



II



III

high electrode potentials for copper(I)/copper(II) charge transfers, this study can contribute to the elucidation of reversible oxidation and carbon monoxide binding processes in mononuclear and dinuclear copper proteins.

Results and discussion

In Fig. 1 the response at a platinum microelectrode, both in dc voltammetry at an electrode with periodical renewal of the diffusion layer (DLRPE) and in cyclic voltammetry, of **I** in dimethyl sulfoxide (DMSO) solution is reported.

As it can be seen the copper(I) complex gives rise to both an anodic and a cathodic process. Controlled potential coulometric tests at potentials corresponding to the limiting current of either oxidation or reduction process show that each process involves one electron per molecule of starting copper(I) compound. Quantitative deposition of copper metal occurs in the cathodic electrolysis.

As regards the anodic process, the analysis of CV responses with scan rate (16), from 0.02 to 5 V s^{-1} (at higher scan rates the response becomes ill-shaped), indicates the occurrence of an uncomplicated one-electron charge transfer quasi-reversible

[1]To whom all correspondence should be addressed.

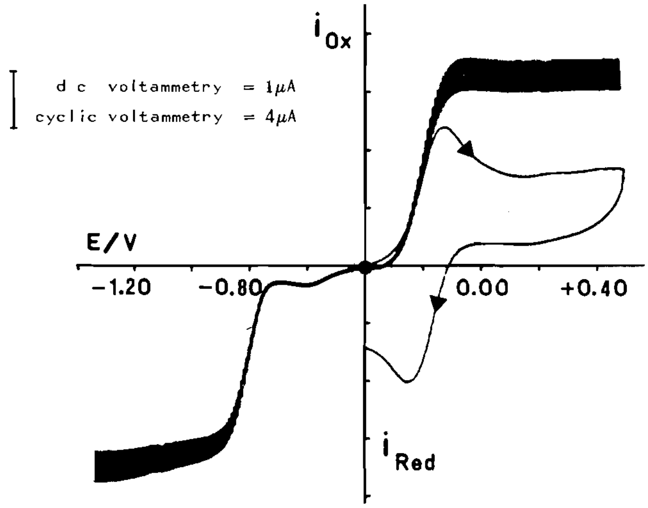


FIG. 1. Electrochemical behaviour of a DMSO solution containing $[NEt_4][ClO_4]$ (0.1 mol dm^{-3}) and $[Cu^I(Medpt)(CO)]BPh_4$ (8.2×10^{-4} mol dm^{-3}) in dc voltammetry and in cyclic voltammetry. Platinum working microelectrode. Cyclic voltammetric responses at 0.2 V s^{-1}. (●) Starting potential.

in character at a formal electrode potential $E^{0\prime} = -0.20$ V ($\Delta E_p = 160$ mV at $v = 0.2$ V s^{-1}). The dc voltammogram ($E_{1/2} = -0.20$ V) confirms the quasi-reversibility of the process in that it shows an ($E_{3/4} - E_{1/4}$) value of 75 mV and its logarithmic analysis gives a ratio $\Delta E/\Delta \log [i/(i_d - i)]$ of 72 mV. These data seemed to support the electrode formation of a previously unknown copper(II) carbonyl species. However, macroelectrolysis experiments performed at +0.2 V did not reveal any presence of copper(II) carbonyls; in fact, while the colourless copper(I) solution displays an ir spectrum with a CO band at 2045 cm^{-1}, the electrogenerated blue copper(II) solution shows no CO stretching frequencies. Notwithstanding coulometric experiments helped us in the elucidation of the electrode mechanisms involved in both anodic and cathodic processes. Figure 2 reports the CV responses after a series of exhaustive electrode oxidations and reductions of the starting copper(I) derivative.

The anodic oxidation of the copper(I) carbonyl species, $[Cu^I(CO)L]^+$ leads to a decarbonylated copper(II) derivative, $[Cu^{II}L]^{2+}$ (*vide infra*), able to display a voltammetric response at $E^{0\prime} = -0.20$ V, i.e. at the same potentials of the initial peak system A–B ($E^{0\prime} = -0.20$ V) (Fig. 2*b*). The $[Cu^{II}L]^{2+}$ compound can be reversibly reduced to the $[Cu^IL]^+$ analogue ($E_p^c = -0.27$ V) (Fig. 2*c*), which, in turn, can be reoxidized to the $[Cu^{II}L]^{2+}$ form ($E_p^a = -0.13$ V) (Fig. 2*d*). By saturation with CO, the $[Cu^{II}L]^{2+}$ species can be reduced to a copper(I) carbonyl derivative ($E_p^c = -0.20$ V) (Fig. 2*e*). As it can be seen this last step occurs at potentials more positive than the reduction to $[Cu^IL]^+$, in agreement with the well known behaviour of other copper(II) derivatives (4, 6, 7, 13). Infrared spectra on solutions from bulk electrolysis under CO atmosphere ($p = 1$ atm) of previously electrogenerated $[Cu^{II}L]^{2+}$ species show the starting copper(I) carbonyl compound to be restored.

In view of the tested quasi-reversibility of the $[Cu^{II}L]^{2+}/[Cu^IL]^+$ redox couple, and assuming the same degree of reversibility for the reduction of $[Cu^{II}L]^{2+}$ to $[Cu^I(CO)L]^+$, it is possible, following Gagné's suggestions (6), to compute the equilibrium constant for the reaction:

$$[Cu^IL]^+ + CO \overset{K^I}{\rightleftarrows} [Cu^I(CO)L]^+$$

on the basis of the anodic shift of the peak potentials (ΔE) of the reduction process copper(II)/copper(I) complex in the presence and in the absence of CO, through the simplified relation:

$$e^{\Delta E(nF/RT)} - 1 = K^I[CO]$$

A value of about 1.3×10^4 M^{-1} has been estimated.

Under nitrogen the decarbonylated copper(II) derivative can be further reduced to the corresponding copper(0) derivative $[Cu^0L]$ at the potentials of the peak system G–H ($E^{0\prime} = -0.55$ V) (Fig. 2*b–d*); decomposition to copper metal follows the charge transfer, as shown by the appearance of peaks E and F in the reverse scan, due to the charge transfers of electrodeposited copper metal to free copper(I) ion and of the copper(I) ion to free copper(II) ion, respectively. The reduction to $[Cu^0(CO)L]$ species of the starting $[Cu^I(CO)L]^+$ occurs at potentials of the peak system C–D ($E^{0\prime} = -0.64$ V), as shown in Fig. 2 *a* and *e*.

Ultimately the following scheme depicts the whole electrode activity of $[Cu^I(Medpt)(CO)]^+$:

$E_p^a = -0.13$ V

$[Cu^I(CO)L]^+ \xrightarrow{-e^-} [Cu^{II}(CO)L]^{2+} \xrightarrow[-CO]{\text{fast}} [Cu^{II}L]^{2+}$

$E^{0\prime} = -0.64$ V $+e^- \rightleftarrows -e^-$ +CO, $+e^-$ $E_p^c = -0.20$ V $+e^- \rightleftarrows -e^-$ $E^{0\prime} = -0.20$ V

$[Cu^0(CO)L]$ $[Cu^IL]^+$

$\downarrow t_{1/2} \cong 3$ s $+e^- \rightleftarrows -e^-$ $E^{0\prime} = -0.55$V

$Cu^0 + CO + L$ $[Cu^0L]$

$\downarrow t_{1/2} \cong 3$ s

$Cu^0 + L$

The decarbonylation step of $[Cu^{II}(CO)L]^{2+}$ could have been described as an equilibrium step; however, even in CO atmosphere ($p = 1$ atm) the anodic electrolysis of $[Cu^I(CO)L]^+$ did not lead to copper(II) carbonylated species.

Lifetimes reported have been obtained according to the Nicholson's method for a charge transfer followed by an irreversible first-order chemical reaction (17).

The fact that the anodic oxidation of starting $[Cu^I(CO)L]^+$

FIG. 2. FIG. 3. Dc voltammogram recorded on a DMSO solution containing $[Cu^I(dien)(CO)]BPh_4$ (1.38×10^{-3} mol dm^{-3}) and $[NEt_4]$-$[ClO_4]$ (0.1 mol dm^{-3}). Platinum working microelectrode.

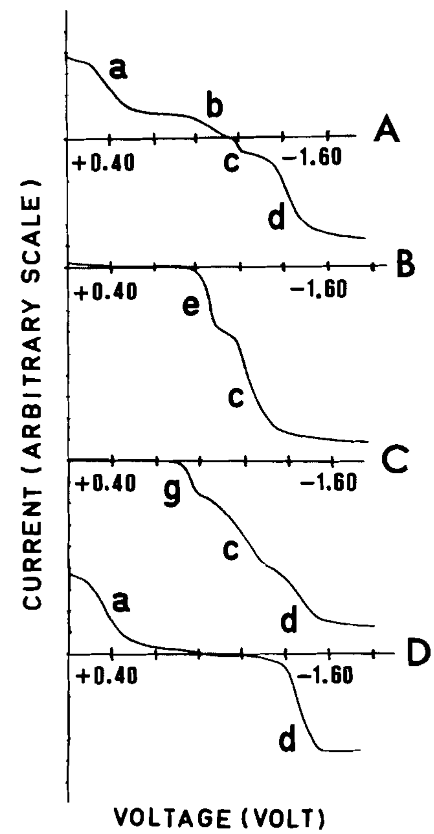

FIG. 4. Schematic dc voltammetric responses of a deaerated DMSO solution containing $[Cu^I(dien)(CO)]BPh_4$ (1.03×10^{-2} mol dm^{-3}) and $[NEt_4][ClO_4]$ (0.1 mol dm^{-3}) in the following experimental conditions: initial (*A*); after complete oxidation to copper(II) derivative at E_W = +0.6 V (*B*); in the same conditions of (*B*) but under CO atmosphere (p = 1 atm) (*C*); after re-reduction under CO atmosphere at E_W = −0.75 V of electrogenerated copper(II) species.

appears in cyclic voltammetry as an uncomplicated charge transfer must be attributed to the quickness of the decarbonylation reaction in comparison with the testable potential scan rates.

It must be said that **I** gives rise to a further anodic process at potentials higher than +1.0 V, but the closeness to the solvent discharge prevents any reliable investigation. Nevertheless its peak height in cyclic voltammetry about three times greater than that of the above reported one-electron oxidation, allowing us to disregard the formation of a copper(III)−amine compound, contrary to some tetraamine complexes (18), very likely suggests this process to be ligand based.

The electrochemical behaviour of **II** can be investigated less deeply than that of **I**, because cyclic voltammetric responses are hardly reproducible. However, dc voltammetry at a platinum DLPRE gives an exhaustive picture of the electron transfer processes in which this species can be involved. Figure 3 reports the dc voltammogram at a platinum electrode obtained from **II** in a deaerated DMSO solution. Two oxidation, *a* ($E_{1/2}$ = +0.38 V) and *b* ($E_{1/2}$ = −0.52 V), and two reduction processes, *c* ($E_{1/2}$ = −0.85 V) and *d* ($E_{1/2}$ = −1.27 V) are present. Controlled potential coulometric tests performed in correspondence to the limiting current of process *b* indicates the consumption of one electron per molecule of starting copper(I) compound; by performing the electrolysis at potentials corresponding to the limiting current of process *a* an overall consumption of one electron per molecule of starting copper(I) compound occurs too. This datum suggests that in DMSO solution an equilibrium exists between two copper(I) species, only one of which contains the Cu—CO unit (single CO stretching band at 2050 cm^{-1}). Coulometry at potentials corresponding to the limiting current of process *d* shows the overall consumption of one electron per molecule of starting copper(I) compound; electrodeposition of copper metal occurs.

Figure 4 schematizes the dc voltammetric responses from a series of exhaustive electrolyses on **II**.

Bulk electrolysis on a deaerated solution of starting copper(I) carbonyl compound $[Cu^I(CO)L]^+$ at potentials varying from −0.3 to 0.7V always leads to a blue copper(II) compound $[Cu^{II}L]^{2+}$, the ir spectrum of which shows no CO adsorption bands; this species can be electroreduced in two steps e ($E_{1/2}$ = −0.52 V), just located at the potentials of process b, and c ($E_{1/2}$ = −0.85 V) (Fig. 4B). As visible in Fig. 4C, under CO atmosphere (p = 1 atm) the voltammetric picture relevant to $[Cu^{II}L]^{2+}$ shows the process e to shift to more anodic potentials giving rise to the process g ($E_{1/2}$ = −0.33 V), attributable to the electrogeneration of a copper(I) carbonyl compound, followed by two processes at the same potentials of processes c and d. Under CO atmosphere the electrolysis of $[Cu^{II}L]^{2+}$ performed at potentials ranging between those corresponding to the limiting current of process g and those corresponding to the foot of process d (from −0.45 V to −0.8 V) gives rise to a copper(I) compound which substantially displays a response with one anodic and one cathodic process corresponding to processes a and d of the starting copper(I) compound, processes b and c being strongly lowered (Fig. 4D). In addition the ir spectrum of the so-electrogenerated copper(I) species is coincident with the one of starting **II**. This last step markedly throws light on the aforementioned equilibrium existing in DMSO solutions of **II**, which can be hence formulated as:

$$[Cu^I(dien)(CO)]^+ \xrightleftharpoons{+S\ (S\ =\ DMSO)} [Cu^I(dien)(S)]^+ + CO$$

In confirmation of this, the dc voltammogram of **II** under CO atmosphere appears as that of Fig. 4D.

An analogous equilibrium could not be detected in the case of **I** under the adopted experimental conditions. The more basic Medpt, which would strengthen the Cu—CO bond, as suggested by ir data, might be responsible for this different behaviour.

The voltammogram of **II** at p_{CO} = 1 atm allows us a reliable determination of the instability constant for copper(I) carbonyl compound in DMSO solvent simply from the limiting current values of the two copper(I) species; it results of the order of 1.6 × 10^{-4} M. Indeed this datum implies that the shift of the reduction potential of $[Cu^{II}(dien)]^{2+}$ towards more anodic potentials in the presence of CO had to be 52 mV instead of the measured value of 190 mV. We think the discrepancy must be attributed to the high degree of irreversibility of the electrode processes which makes unapplicable the previously cited Gagné's computation.

The irreversibility of the one-electron process a ($E_{1/2}$ = +0.38 V) is witnessed by an ($E_{3/4} - E_{1/4}$) value of 240 mV.

In conclusion, if one neglects the decarbonylation equilibrium due to DMSO solvent, the following scheme holds for the electrode activity of $[Cu^I(dien)(CO)]^+$:

$$E_{1/2} = +0.38\ V$$

$$[Cu^I(CO)L]^+ \xrightarrow[-e^-]{} [Cu^{II}(CO)L]^{2+} \rightarrow [Cu^{II}L]^{2+}$$

$$E_{1/2} = -1.27\ V \quad \downarrow +e^- \qquad +CO,\ +e^- \qquad +e^- \downarrow\uparrow -e^- \quad E^{0\prime} = -0.52\ V$$

$$[Cu^0(CO)L] \qquad E_{1/2} = -0.33\ V \qquad [Cu^IL]^+$$

$$\downarrow \qquad\qquad +e^- \downarrow \quad E_{1/2} = -0.85\ V$$

$$Cu^0 + CO + L \qquad\qquad [Cu^0L]$$

$$\downarrow$$

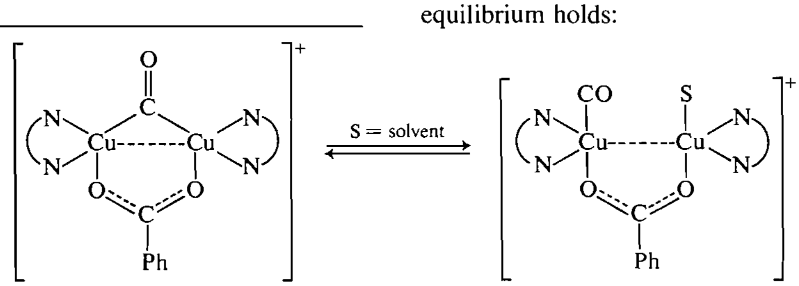
$$Cu^0 + L$$

It must be noted that no carbonyl copper(II) compound has been obtained even in macroelectrolysis tests at +0.7 V under CO atmosphere.

Also in this case ligand-centred anodic oxidation processes are present at potentials higher than +1.0 V.

At this stage the nature of the electrogenerated compound $[Cu^{II}L]^{2+}$ in the case of both **I** and **II** has to be discussed. In order to identify the oxidation product we synthesized several copper(II) complexes with different Cu/triamine ratios in DMSO. Their electrochemical behaviour was compared with that of the electrogenerated $[Cu^{II}L]^{2+}$ species. The voltammetric picture of the electrode oxidation product $[Cu^I(dien)(CO)]^+$ was paralleled by that of $[Cu(dien)(DMSO)_3]^{2+}$. This result was not unexpected, since for instance the possible rearrangement of $[Cu(dien)(CO)]^+$ to the common species $[Cu(dien)_2]^{2+}$ (19) should have involved the release of free copper ions easily detectable in voltammetry. The same pathway holds when dien is replaced by Medpt. This accounts for the formalism adopted in the description of the electrode activity of both **I** and **II**. It must be also pointed out that the cathodic reduction under CO atmosphere at the potentials of the first reduction step of both $[Cu(Medpt)(DMSO)_3]^{2+}$ and $[Cu(dien)(DMSO)_3]^{2+}$, chemically synthesized, leads to **I** and **II**, respectively, as shown by ir spectra.

As pointed out elsewhere (20), the existence of the complex **III** is limited to the solid state (bridging CO frequency at 1926 cm^{-1}), or in solution of nonpolar solvents (bridging CO frequency in toluene at 1945 cm^{-1}). In THF solution the following equilibrium holds:



III **III′**

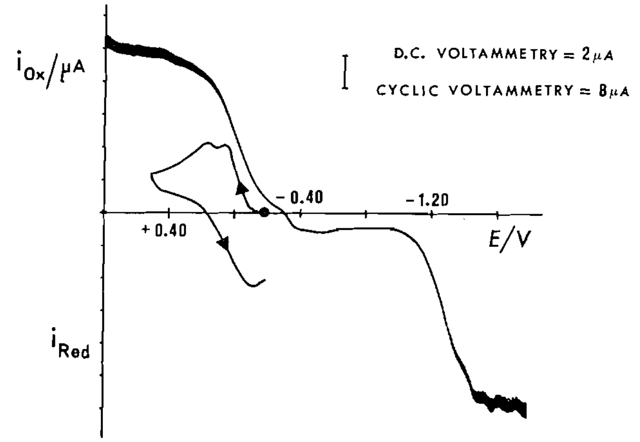


FIG. 5. Voltammetric responses of a DMSO solution containing $[NEt_4][ClO_4]$ (0.1 mol dm^{-3}) and $[Cu_2(tmen)_2(Ph—CO_2)(CO)(S)]$-$BPh_4$ (2.46 × 10^{-3} mol dm^{-3}). Platinum working microelectrode. (●) Starting potential for cyclic voltammetric response; scan rate 0.2 V s^{-1}.

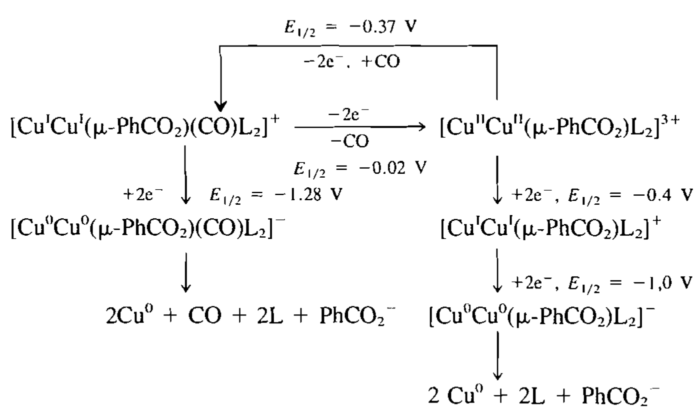
In fact, the ir spectrum shows both bridging (1930 cm^{-1}) and terminal (2060 cm^{-1}) CO bands. In DMSO the equilibrium is completely shifted to the right, as shown by the presence in the ir spectrum of only one CO stretching band at 2055 cm^{-1}. Therefore, the electrochemistry below discussed refers to this CO-unbridged form, **III′**. Figure 5 reports the voltammetric responses obtained from a **III′** solution at a platinum microelectrode.

As it can be seen the CV response shows the presence of two oxidation processes very close to each other (E_p^a = +0.04 V, +0.15 V), whereas dc voltammetry indicates the presence of only one oxidation process ($E_{1/2}$ = −0.02 V). Unfortunately the CV responses have a low degree of reproducibility, preventing any accurate study of the underlying electrode mechanisms. The cathodic reduction of the starting dicopper(I) complex occurs at $E_{1/2}$ = −1.28 V; cyclic voltammetry shows that the charge transfer is followed by decomposition of the electrogenerated zero-valent copper complex. Some amounts of air-oxidized product are also present, which undergoes a preceding reduction at $E_{1/2} \cong -0.3$ V. Also in this case the oxidation of the ligand occurs at potentials higher than +1.0 V, close to the solvent discharge. Controlled potential coulometric tests at +0.5 V indicate the consumption of 2 mol of electrons per mole of starting complex. Two mole of electrons per mole of starting complex are also consumed in the cathodic electrolysis at −1.7 V, which is followed by electrodeposition of copper metal. An ($E_{3/4} - E_{1/4}$) value of 200 mV for the anodic response indicates the irreversibility of the involved charge transfer. The presence of some inflexions on the rising part of the cathodic response prevents any graphical analysis of the relevant process. The clear detection of two subsequent oxidation processes in cyclic voltammetry suggests the mixed-valence $Cu^{II}Cu^{I}$ species (7) to exist only on the short-time scale. The available CV data do not allow us to distinguish the oxidation process of copper(I) carbonylated centre from that of copper(I) solvated centre. However, by analogy with the voltammetric behaviour of a series of dinuclear copper(I) complexes able to form monocarbonylated species (13), we are tempted by way of speculation to assign the less anodic peak of Fig. 4 to the oxidation of copper(I) carbonylated moiety and the more anodic peak to the oxidation of copper(I) solvated moiety.

Further information on electrode processes have been gained once again by dc voltammetry on solutions of **III′** exhaustively oxidized at the potential of +0.5 V. As expected the resulting blue dicopper(II) solution, which shows no carbonyl absorption band in its ir spectrum, is electroreduced in two successive steps schematically corresponding to the reduction of the dicopper centre from $Cu^{II}Cu^{II}$ to $Cu^{I}Cu^{I}$ ($E_{1/2} \cong -0.4$ V) and from $Cu^{I}Cu^{I}$ to $Cu^{0}Cu^{0}$ ($E_{1/2} \cong -1.0$ V), respectively. The less cathodic response is difficult to analyze because of the presence of a maximum of the first kind. Under CO atmosphere (p = 1 atm) this first step shifts anodically about 30 mV. The electrolytic reduction of the electrogenerated blue dicopper(II) species to dicopper(I) species at potentials varying from −0.35 V to −0.55 V, when performed under CO atmosphere, restores a pale green solution which displays a dc voltammogram identical to that reported in Fig. 5. In addition, the ir spectrum of this electrogenerated dicopper(I) species is coincident with that of the starting **III′**. In conclusion the electrode behaviour of the dinuclear copper(I) carbonyl complex $[Cu_2(tmen)_2(\mu\text{-}PhCO_2)(CO)(S)]^+$ can be best schematized:



Conclusions

The electron-transfer sequences in which **I**, **II**, and **III** may be involved have been studied in non-aqueous solvent. The anodic oxidation of **I**, **II**, **III** gives rise to the corresponding decarbonylated copper(II) derivatives, which in the presence of carbon monoxide can be quantitatively electroreduced to the starting copper(I) aminocarbonyl complexes, indicating that no irreversible change upon oxidation occurs in the skeleton of molecules **I**, **II**, and **III**.

A comparison between the electrode processes of **I** and **II** reveals that **I** is more easily oxidized to copper(II) species and more easily reduced to copper(0) species than **II**. It seems likely that the presence of the electron-donating methyl group in **I** favours the oxidation step, as well as the presence of a more flexible cavity, increased in size, favours the reduction step.

Finally it has to be underlined that the redox potentials of the copper(I)/copper(II) couples measured for **I**, **II**, and **III** are high enough to approach those of the copper sites in common cuproproteins (3, 7).

Experimental

Materials

[Cu(dien)(CO)]BPh_4, [Cu(Medpt)(CO)]BPh_4, and $[Cu_2(tmen)_2(\mu\text{-}PhCO_2)(\mu\text{-}CO)]BPh_4$ were prepared as previously described (20, 21). $[Cu(dien)(DMSO)_3]^{2+}$ and $[Cu(Medpt)(DMSO)_3]^{2+}$ were obtained as perchlorate salts by mixing in methanol equimolar amounts of $Cu(ClO_4)_2.6H_2O$ and the appropriate triamine in the presence of an excess of DMSO. The salts precipitated as blue microcrystalline solids and afforded satisfactory elemental analyses.

Reagent grade DMSO (Carlo Erba) was dried with 0.3-nm molecular sieves (Union Carbide). The supporting electrolyte tetraethylammonium perchlorate $[NEt_4][ClO_4]$ (Carlo Erba) was dried in a vacuum oven and used without further purification. Extra pure nitrogen was employed to remove oxygen from tested solutions. Carbon monoxide was passed through Oxy-Trap (Alltech Associates) to remove residual oxygen.

Apparatus

A PAR model 170 Electrochemistry System was used as polarizing unit; the recording devices were either a Houston Instruments model 2000 XY recorder or, for potential scan rates higher than 0.5 V s^{-1}, a Hewlett-Packard model 1123A storage oscilloscope.

Cyclic voltammetric tests were performed in a three electrode cell having a platinum sphere working microelectrode surrounded by a platinum-spiral counter electrode. The potential of the working microelectrode was probed by a Luggin capillary reference electrode compartment.

An electrode with periodical renewal of the diffusion layer (DLPRE) was obtained by moving the platinum electrode with a time-controlled knocker.

Controlled potential coulometric tests were performed in an H-shaped cell with anodic and cathodic compartments separated by a sintered glass disk. The working macroelectrode was a platinum gauze. In these tests an Amel potentiostat model 551, with an associated Amel model 558 coulometer integrator, were used.

Potential values refer to an aqueous saturated calomel reference electrode (sce). All experiments were carried out at 20 ± 0.1°C.

Infrared solution spectra were recorded on a Perkin-Elmer Model 597 spectrophotometer in the wavenumber range 4000–400 cm^{-1}.

Methods

Cyclic voltammetric current–potential curves have been analysed as a function of the scan rate, v, on the basis of the anodic, or cathodic peak potential (E_p^a, or E_p^c), the difference between the peak potential value of a response and that of the reverse one (($E_p^a - E_p^c$) for an anodic process, or ($E_p^c - E_p^a$) for a cathodic process), the quotient of the peaks current of the reverse and the direct response ((i_p^c/i_p^a) for an anodic process, or (i_p^a/i_p^c) for a cathodic process), the quotient of the peak current of the response and the square root of the scan rate ($i_p/v^{1/2}$). Unless otherwise specified, peak potential values refer at a scan rate of 0.2 V s^{-1}. Formal electrode potentials, $E^{0\prime}$, for quasi-reversible charge transfer have been computed as the average of the anodic (or cathodic) peak potential and the directly associated cathodic (or anodic) peak potential, under the usual assumption that the transfer coefficient α ranges between 0.3 and 0.7.

In dc voltammetry the location of irreversible charge transfer processes is expressed by $E_{1/2}$; for quasi-reversible process the $E^{0\prime}$ symbol has been used.

The solubility of CO in dimethylsulphoxide at P_{CO} = 1 atm has been taken as 1.1×10^{-3} mol dm^{-3} (20 ± 1°C) (22).

Complex formation between cuprous iodide and phenyl phosphine: a nuclear magnetic resonance and X-ray crystallographic study

RAYMOND J. BATCHELOR, THOMAS BIRCHALL,[1] AND ROMOLO FAGGIANI

Department of Chemistry and Institute for Materials Research, McMaster University, 1280 Main Street West, Hamilton, Ont., Canada L8S 4M1

Received July 27, 1984

RAYMOND J. BATCHELOR, THOMAS BIRCHALL, and ROMOLO FAGGIANI. Can. J. Chem. **63**, 928 (1985).

The X-ray crystal structure of di-μ-iodobis[bis(phenylphosphine)copper(I)] has been determined: $R_1 = 0.0460$. The crystals were monoclinic, space group *Cc*, $a = 10.625(2)$ Å, $b = 25.115(8)$ Å, $c = 11.361(2)$ Å, $\beta = 105.929(15)°$, fw = 821.28, and Z = 4. The molecular structure consists of two $CuI(C_6H_5PH_2)_2$ units bridged via the iodines so that each copper achieves tetrahedral coordination. Nuclear magnetic resonance data provides evidence that the phenylphosphines remain coordinated in solution but undergo rapid exchange at room temperature.

RAYMOND J. BATCHELOR, THOMAS BIRCHALL et ROMOLO FAGGIANI. Can. J. Chem. **63**, 928 (1985).

Faisant appel à la diffraction des rayons-X, on a déterminé la structure cristalline du di-μ-iodobis[bis(phénylphosphine)-cuivre(I)] jusqu'à une valeur de $R_1 = 0{,}0460$. Les cristaux sont monocliniques, groupe d'espace *Cc*, $a = 10{,}625(2)$, $b = 25{,}115(8)$ et $c = 11{,}361(2)$ Å, $\beta = 105{,}929(15)°$, mm = 821,28 et Z = 4. La structure moléculaire comporte deux unités $CuI(C_6H_5PH_2)_2$ qui sont reliées par les iodes d'une façon telle que chaque atome de cuivre atteint une coordination tétraédrique. Sur la base des données de la rmn, on peut affirmer que, en solution, les phénylphosphines restent coordinnées mais qu'elles subissent un échange rapide à la température ambiante.

Introduction

Although basicity and donor ability are well known properties of trivalent compounds of the group 5 elements there has been relatively little investigation of the coordination chemistry of hydrides and organohydrides of these elements other than nitrogen. Presumably this is because the tertiary derivatives, especially the triphenyl compounds, are much easier to work with and much less susceptible to oxidation. While it is reasonable to expect that the coordination chemistry of primary and secondary phosphines will be very similar to that of tertiary derivatives potential differences do exist. For example, there is evidence for the dissociation of P—H bonds with resultant formation of phosphido complexes (1). Also it has been noted that the order of basicity for phosphines is tertiary > secondary > primary > PH_3 (2).

The coordinating ability of a phosphine, however, depends on features other than simple basicity. For example, the extent to which π-acidity of the ligand can contribute to the stability of the coordinative interaction has been the centre of much controversy (3). It is unlikely that π-back donation into *d*-orbitals of the ligand is significant for tertiary organophosphines, but for PF_3 and for phosphites it is apparently important (4). Vibrational studies on the C—O stretching frequency of a carbonyl group *trans* to a given phosphine ligand indicate that PH_3 is intermediate in "π-accepting" ability between tertiary phosphines and phosphites (4).

It has also been shown that, for tertiary phosphines, the steric bulk of the ligand appears to be the deciding factor in the stability of the coordinative interactions between these ligands and transition metals (5–7) although there appear to be exceptions to this general rule (8). With much smaller phosphine ligands such as PH_3 or the primary phosphines, steric interactions should be greatly reduced (cf. the cone angles: PH_3 87°, $C_6H_6PH_2$ 101°, $P(C_6H_5)_3$ 145° (5)). For complexes containing small ligands, electronic factors should assume increased relative importance.

The systems $(CuX)_m(L)_n$ (X = halide, L = amine, phosphine, arsine) appeared to be potentially useful for investigations concerning the relative importance of steric and electronic factors because a large number of X-ray crystallographic studies have shown that the steric bulk of both the neutral ligands and the halides have a tremendous influence on the degree of association and resulting structure of such complexes (9, 10). Spectroscopic characterization of these complexes has proven to be somewhat problematic, however, and as a consequence of this they have been largely studied by X-ray crystallography (3, 10).

In early vapour pressure studies (11, 12) it was concluded that cuprous halides could form complexes with PH_3 in ratios of $CuX \cdot 2PH_3$ and $CuX \cdot PH_3$ but that these were unstable to loss of PH_3. Much later, Abel *et al.* (13) studied the complexes formed between $(C_6H_5)_2PH$ and cuprous halides in the hope that vibrational and ^1H nmr spectroscopy, with specific focus on the hydrogen bonded to phosphorus, would yield further information on the characterization of these kinds of complexes. These authors found complexes possessing most of the known stoichiometries for $(CuX)_m(PR_3)_n$, where $m/n = 1/3, 1/2, 2/3, 1/1$. However, while nmr and infrared spectroscopies could differentiate between free and complexed $(C_6H_5)_2PH$, these techniques could not discriminate between the different stoichiometries and structures of the complexes. These studies appear to be the only previous investigations of cuprous halide complexes of non-tertiary phosphines.

Here we report our results on the interaction of cuprous iodide with phenylphosphine and with phosphine. Nuclear magnetic resonance evidence is presented which indicates that complex formation takes place with both phenylphosphine and phosphine but only in the former case could solid complexes be isolated. One of these, $CuI \cdot 2C_6H_5PH_2$, has been subjected to analysis by single crystal X-ray diffraction and is shown to be dimeric, with bridging iodine atoms so that each copper achieves four coordination.

Experimental

Phosphorus-31 nmr spectra were recorded on a Bruker WH-90 spectrometer.

TABLE 1. Crystal and diffraction data acquisition parameters for $[CuI(C_6H_5PH_2)_2]_2$

Crystal parameters (at −65°C)[a]	
a = 10.625(2) Å	Monoclinic
b = 25.115(8) Å	Space group Cc
c = 11.361(2) Å	Z = 4
β = 105.929(15)°	fw = 821.28
V = 2914.6(12) Å^3	ρ_c = 1.8716(9) g cm^{-3}
$\mu(MoK_\alpha)$ = 38.5 cm^{-1}	ρ_o = 1.8(1) g cm^{-3}[b]
Conditions : hkl : $h+k = 2n$, $h0l$: $l = 2n$	
Crystal dimensions : 0.3 × 0.3 × 0.2 mm[c]	
Intensity measurements	
Radiation	MoK_α (λ = 0.71069 Å; graphite monochromator)
Scan mode	θ:2θ
Scan range	(K_{α_1} −1.0°) to (K_{α_2} +1.0°)
Scan rates[d]	5.86 to 29.30° min^{-1}
Reflections measured	$\pm h,k,\pm l$
Maximum 2θ	45°
Standard reflections[e]	5 −5 0 (esd 2.93%)
	4 −8 1 (esd 1.53%)
Details of refinement[f]	
Unique reflections	3820 (Friedel opposites not averaged)
"Unobserved reflections"	less than 3σ:381, zero intensity:36[g]
R factors[h]	R_1 = 0.0460, R_2 = 0.0593
Weighting scheme	$w = [\sigma_F^2 + 0.001741\ F^2]^{-1}$
"Secondary extinction"	$F^* = F(1-2.9 \times 10^{-8}F^2/\sin\theta)$
Final |shift/error|	Maximum 0.090, average 0.006
Highest peak[i] in final difference map	1.010 e Å^{-3}
Lowest trough in final difference map	−0.655 e Å^{-3}
$F(000)$ = 1583.9	

[a]15 reflections 20° ≤ 2θ ≤ 30° were used to determine the cell constants using MoK_{α_1} radiation (λ = 0.70926 Å).
[b]Neutral buoyancy in aqueous $ZnBr_2$.
[c]The crystal was a rectangular prism; the dimensions given are approximate; measurement of more precise crystal dimensions was unfortunately forestalled by decomposition and liquefaction of the crystal upon rewarming to room temperature after the acquisition of intensity data.
[d]Dependent on the intensity of a preliminary count.
[e]Measured after every 48 reflections; displayed no systematic deviations in intensity.
[f]Data reduction, including Lorentz and polarization corrections, was performed using programs from the XRAY-76 package of crystallographic programs (14). Absorption corrections were not applied (estimated maximum conceivable error in F is ~35%).
[g]Reflections of zero intensity were given a weight of zero in the refinement.
[h]$R_1 = \Sigma(|F_o| - |F_c|)/\Sigma(F_o)$; $R_2 = [\Sigma(w(|F_o| - |F_c|)^2)/\Sigma(wF_o^2)]^{1/2}$
[i]This peak occurs at (0.4035, 0.4229, 0.7104) which is 1.00 Å from I_1. The second most intense peak occurs at 1.09 Å from I_2.

X-ray crystallography

Crystals of $CuI \cdot 2C_6H_5PH_2$, suitable for single crystal X-ray analysis, were obtained by recrystallization from ethanol containing 5% tetrahydrofuran. The structure was initially solved using a partial set of intensity data collected at ambient temperature using a Syntex-Nicolet P2$_1$ diffractometer. The atomic temperature factors determined in this initial refinement were somewhat large, therefore a full data set was acquired at reduced temperature using an LT-1 low temperature attachment. Details of the crystal and diffraction data parameters are summarised in Table 1.

The symmetry and systematic absences of the weighted reciprocal lattice indicated that $C2/c$ and Cc were possible space groups for the crystal. The structure was solved by Patterson techniques and refined using the program SHELX 76 (14). The XRAY 76 package of programs (15) was used to perform data reduction and to create the ORTEP drawings of the structure. No solution to the Patterson map could be found in the centrosymmetric space group $C2/c$. Analysis of the normalized squared structure factors (E^2) gives an average value of $|E^2 - 1|$ of 0.82. A centrosymmetric structure would be expected to give a value of 0.97 and a non-centrosymmetric structure a value of 0.74 (14).

[b]Coordinates fixed arbitrarily to define the origin of the unit cell.

The structural solution in the non-centrosymmetric space group Cc was fully refined for all non-hydrogen atoms and included anisotropic temperature factors for Cu, I, and P. The hydrogen atoms associated with the carbon atoms of the phenyl rings were not well defined in the difference map: these atoms were fixed at positions 0.95 Å (16) from each carbon atom along a vector bisecting each C—C—C angle and in the plane defined by those atoms. Each hydrogen atom was assigned an isotropic temperature factor fixed at 1.5 times that of the carbon atom to which it was bonded. Because of these somewhat arbitrary constraints on the C—H groups, and as there is only passing interest in the phenyl groups themselves, no attempt was made to refine the carbon atoms anisotropically. The positions and temperature factors of the hydrogen atoms were recalculated after each cycle of refinement and were fixed at these new values for the subsequent cycle. The hydrogen atoms bonded to phosphorus could not be found in the electron difference map and were not included in the refinement.

The final positional parameters and equivalent isotropic temperature factors are given in Table 2. Anisotropic temperature factors for the heavy atoms are listed in Table 3. The calculated and observed structure factors and σ-values, selected least-squares planes and di-

Results and discussion

Description of the structure

The crystal consists of discrete molecular dimers, $[\{CuI(C_6H_5PH_2)_2\}_2]$, separated by normal van der Waals distances. Each molecule comprises one asymmetric unit of the structure.

The packing of the molecules in the unit cell, shown in Fig. 1, is particularly interesting because it demonstrates how the packing of structurally symmetric molecules can cause those molecules to assume asymmetric conformations. The molecules of $[\{CuI(C_6H_5PH_2)_2\}_2]$ pack so that three of the phenyl-groups, namely those bonded to P(1), P(3), and P(4), from each molecular unit are incorporated into infinite sliding stacks in which each ring is related to the ring three levels further along the stack by the *c*-centering operation. Therefore the axes of these "pseudo-graphitic" stacks are oriented parallel to the $[1,\bar{1},0]$ and $[1,1,0]$ directions. Stacks possessing these two different orientations are related to each other by the *c*-glide plane. Two of the crystallographically unique rings in a given stack are very nearly parallel to one another. The dihedral angle between them is 4.8°. The third ring is tilted somewhat with respect to the other two, giving dihedral angles of 20.6° and 21.4°. This tilting of the ring bonded to P(1) arises because the fourth crystallographically unique phenyl-ring, bonded to P(2) is situated between adjacent pseudo-graphitic stacks separated by unit translations along *a* and is in close contact with the former ring. This last phenyl ring is oriented approximately parallel to the axes of the neighbouring stacks and packs edge to edge with Cu_2I_2 rhombuses of adjacent molecules so that it is nearly coplanar with these latter fragments (Fig. 1). The dihedral angle between the plane of this ring and that of an adjacent Cu_2I_2 rhombus is 11.0°. The structure, therefore, contains sets of infinite "ribbons" parallel to $(1,\bar{1},0)$ and $(1,1,0)$ consisting of alternating phenyl-rings and Cu_2I_2 rhombuses. These "ribbons" are sandwiched between the "sliding stacks" of phenyl-rings and thus represent another facet of the same packing condition which gives rise to the orientations of the stacks. The absence of significant voids in this structure suggests that it represents an optimum packing geometry.

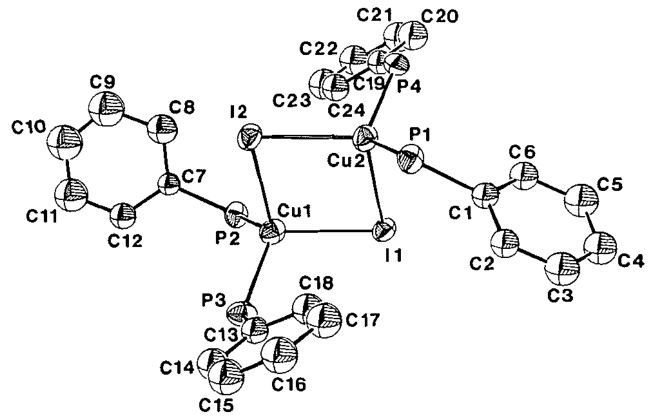

FIG. 2. The $[CuI(C_6H_5PH_2)_2]_2$ molecule viewed towards the *b,c* face.

Molecular structure

A diagram of an individual molecule is given in Fig. 2 and shows clearly the relative orientations of the phenyl-groups discussed above. There is a slight puckering of the Cu_2I_2 rhombus indicated by a dihedral angle of 5° between planes I1,Cu1,I2 and I1,Cu2,I2. Such puckering is commonly observed in structures of this type (17) and is no doubt attributable to packing forces. The interatomic distances and bond angles are listed in Table 4.

[2]Complete set of data is available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

The dimeric molecule contains two pseudotetrahedrally coordinated copper atoms bridged by two iodine atoms. The other coordination sites are occupied by the phosphorus atoms of the phenylphosphine ligands. This molecule may therefore be described as a "normal" dimer in that it has the most commonly occurring geometries about halogen and copper found in copper(I) halide – phosphine complexes. Although a number of compounds have been prepared which possess the same stoichiometric ratio of ligand to metal halide and which probably possess the same structure, no crystal structure has previously been reported for a simple "binary" dimeric complex of this stoichiometric ratio of CuI to monodentate phosphine ligand, nor has any similar structure been reported in which the phosphine ligands were not tertiary phosphines.

Recently the structures of a series of dimeric molecules based on the Cu_2I_2 unit have been reported (10). The neutral ligands in all of these cases were nitrogen bases. Two related structures of mixed-ligand dimeric $Cu_2I_2L_4$ complexes have been reported in which two neutral ligands are nitrogen bases and the other two coordinate via arsenic (18, 19). Two structures have been published (17) which consist of molecules possessing the Cu_2I_2 core and phosphorus-coordinating neutral ligands. Neither of these, however, is a simple $Cu_2I_2L_4$ complex. The one whose geometry most closely approaches that of the present structure is $[\{CuI[P(C_6H_5)_2CH_3]_2\}_2 \cdot SO_2]$ which has the same structural geometry as $[\{CuI(C_6H_5PH_2)_2\}_2]$ except that it contains a molecule of SO_2 which is weakly coordinated, via sulphur, to one of the bridging iodine atoms. The other complex is $[(CuI)_2\{P(C_6H_5)_3\}_3]$ in which one of the copper atoms is only pseudo-trigonally coordinated. Coordination of a fourth triphenylphosphine ligand in this molecule is thought to be prohibited as a consequence of the steric bulk of the triphenylphosphine ligands. The former compound containing $P(C_6H_5)_2CH_3$ ligands as well as the compound $[\{CuI(C_6H_5PH_2)_2\}_2]$, presented here, both demonstrate that the use of smaller phosphine ligands permits full tetrahedral coordination of the copper atoms.

Various authors have concluded that the molecular structures of cuprous halide – tertiary phosphine complexes are the net results of electronic, steric and packing factors (6, 9, 10, 17, 20). When the phosphine ligands and halide ions are large (e.g. $P(C_6H_5)_3$ and I^-) non-bonded intramolecular interactions are dominant in deciding the structural geometry and stoichiometry in concert with the metal–ligand and metal–halide bond distances which appear to be a function of the coordination number about the metal (9). The bond angles about copper and halogen appear to be quite variable and adopt values which presumably minimize steric interactions. In $[\{CuI(C_6H_5PH_2)_2\}_2]$, as well as in other compounds possessing Cu_2I_2 units, the geometry of this unit is apparently governed, to a large extent, by the minimum distance of mutual approach of the two iodine atoms (4.151(1) Å for $[\{CuI(C_6H_5PH_2)_2\}_2]$; 4.109(1) Å for $[\{CuI[(C_6H_5)_2CH_3]_2\}_2 \cdot SO_2]$; 4.302(1) Å for $[(CuI)_2\{P(C_6H_5)_3\}_3]$. Twice the accepted van der Waals radius of iodine is 4.30 Å (21).

Comparison with the nitrogen–donor adducts (10) shows that the change from phosphorus to nitrogen ligands is accompanied by expansion of the intramolecular I. . . I separation and the I—Cu—I angles along with corresponding contraction of the Cu---Cu separation and Cu—I—Cu angles. This may be related to the fact that the N—Cu—N angles are smaller than the corresponding P—Cu—P angles.

The Cu—Cu distance in $[\{CuI(C_6H_5PH_2)_2\}_2]$ is non-bonding (3.340(2) Å). The distance in Cu metal is 2.56 Å. However, separations of Cu atoms in similar compounds show a considerable range of values and can approach bonding distances. It has been postulated (22) that there may be a net "soft attractive" interaction between Cu atoms in such complexes rendering the structures relatively indifferent to the magnitude of the metal–metal separation. The result is that this distance is merely a consequence of the minimum halogen–halogen distance and normal Cu—X bond lengths.

The CuI bond lengths, average = 2.665(18) Å, are in the range normally found for tetrahedrally coordinated copper (I) (2.62–2.81 Å) (10, 17, 20). There do not appear to be any identifiable trends in these bond lengths with the nature of the neutral ligand. The Cu—P distances, average = 2.247(5) Å, are the same as those found with tertiary phosphines in similar structures, namely, 2.24 to 2.27 Å (17, 20). The phenylphosphine ligands display no unusual features in bond lengths or angles. The P—C bond lengths, average = 1.823(4) Å, are normal for a phosphorus–carbon single bond. The phosphorus atoms deviate very little from the planes of their associated phenyl rings. Apparent deviations in the C—C bond distances from the expected 1.395 Å, especially for those between *meta* and *para* carbon atoms, may result from systematic errors caused by rigid-body thermal motions. Specifically, wagging motions of the phenylphosphine groups may cause the C—C bond lengths furthest from the point of attachment of the ligand to the Cu atom to be systematically low (20).

Nuclear magnetic resonance of cuprous iodide – phosphine solutions

It has been demonstrated (6) that the steric bulk of a tertiary phosphine ligand is the dominant contributing factor to the dissociation of their complexes with cuprous halides in solution. Complexes between cuprous halides and the much smaller primary phosphines or PH_3 itself might reasonably be expected to be more stable since, in addition to their smaller cone angles (5), they have also been postulated to have greater π-acidity than tertiary phosphines (23). In fact a possible order of "complexing power" of P(III) ligands has been suggested to be as follows:

$$P(OR)_3 > PF_3 > PH_3 > PR_3 > P(OPh)_3 > PPh_3 \simeq PBu'_3$$

(4), though such a listing is of course somewhat arbitrary.

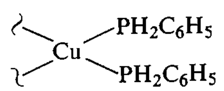
Earlier workers (11, 12) found that adducts between PH_3 and cuprous halides are unstable to loss of PH_3 under standard conditions. This suggests that ligand basicity is the dominant factor contributing to the energetics of the metal–phosphine interaction in the absence of steric effects.The relative basicities of PH_3 and the phenylphosphines, as given by the pK_a values of the conjugate phosphonium ions, are $P(C_6H_5)_3$, $pK_a = 2.73$; $P(C_6H_5)_2H$, $pK_a = 0.03$; $P(C_6H_5)H_2$, pK_a est. (−1.7); PH_3, $pK_a = -14$ (2). For compounds with Cu(I) it seems that π-back-donation into phosphorus d-orbitals is not sufficient to compensate for the weaker σ-donor ability of PH_3 relative to the phenyl-substituted phosphines. This may be due, in part, to the d^{10} filled-shell configuration of Cu(I).

To confirm the earlier conclusions regarding the interaction between PH_3 and CuI, solutions of PH_3 and CuI in THF were prepared and examined by ^{31}P nmr. It was found that indeed a considerable excess of PH_3 was required in the sealed nmr tubes in order to dissolve all of the cuprous iodide. ^{31}P nmr spectra of these solutions confirmed complex formation by revealing a complexation shift of approximately 20 ppm to low field and an increase in J_{PH} from 187 Hz for free PH_3 to approximately 233 Hz in the solution. The existence of only one ^{31}P signal, an ^1H-coupled quartet, regardless of the exact composition of the solution indicated that as with other phosphines the complexes undergo rapid ligand exchange in solution at room temperature. Raman spectra of the solutions confirmed this. A sharp band at 2307 cm^{-1}, attributed to the P—H stretching vibration of free PH_3, as well as a broader, possibly multiple, band centred at 2344 cm^{-1}, attributed to bound PH_3, were observed. Such an increase in P—H stretching frequency is in agreement with the observation that the P—H stretching frequency of $(C_6H_5)_2PH$ increases by about 33 to 41 cm^{-1} upon coordination to copper (I) (13). The nmr and vibrational results are consistent with a strengthening of the P—H bond upon complexation.

When low-temperature ^{31}P nmr spectra of the solutions were recorded, in an attempt to "freeze out" the ligand exchange process, a white solid precipitated and the time averaged ^{31}P nmr parameters shifted back towards those of free PH_3. This process was observed to be reversible and possibly indicates that $CuI-PH_3$ complex formation is endothermic. Crystals of the precipitated solid were shown by X-ray diffraction to be cuprous iodide (24).

The reaction of excess cuprous iodide with phenylphosphine in THF yielded a highly soluble product. The weight of unreacted CuI suggested that the stoichiometry of the soluble product was approximately $(CuI)_{0.8} \cdot C_6H_5PH_2$. The ^{31}P nmr spectrum of this solution consisted of a triplet at $\delta = -106.62(3)$ ppm having the spin–spin coupling $^{1}J_{PH} = 303(3)$ Hz. Below −70°C the ^{31}P resonance of the above solution broadens considerably; however, no new features were observed before the freezing point of the solution was reached. Since the observed room temperature chemical shift is to low field of that of free phenylphosphine by approximately 20 ppm and the P—H coupling constant is ~100 Hz greater than that of free phenylphosphine, it must be concluded that these nmr parameters represent a coordinated ligand. Perhaps these ligands undergo rapid exchange, at room temperature, between species of different geometry and degree of association as has been observed for tertiary phosphine adducts (7, 25). Attempts were made to isolate crystals suitable for X-ray crystallographic analysis from this solution, but although crystalline material was obtained we have not yet been able to characterise this product because of its tendency to decompose and release $C_6H_5PH_2$.

When two equivalents of phenylphosphine were allowed to react with cuprous iodide a crystalline product was obtained after recrystallization from ethanol containing 5% THF. A THF solution of the product yielded room temperature ^{31}P and ^{13}C nmr spectra which were essentially identical with those found for the previous solutions prepared using excess CuI. Upon cooling, however, the ^{31}P nmr spectrum initially displayed some broadening of the observed triplet until below −90°C further fine structure was resolved (Fig. 3). The low temperature spectrum can be accounted for by postulating a ^{31}P—^{31}P spin–spin coupling between two phenylphosphine ligands bound to the same coppper atom.



Although these two phosphorus atoms are chemically equivalent and thus have the same chemical shift, they are magnetically inequivalent by virtue of the strong coupling to the protons directly bound to them. Figure 3 includes a simulated spectrum which represents the best fit to the observed peak positions assuming only coupling between directly bound phosphorus and hydrogen ($^{1}J_{PH}$ = 299 Hz) and the two bond ^{31}P—^{31}P coupling ($^{2}J_{PP}$ = 107 Hz). The three bond ^{31}P—^{1}H coupling was fixed at zero for this simulation. The changes in ^{31}P chemical shift and one-bond ^{31}P—^{1}H coupling upon reducing the temperature were insignificant and no new resonances appeared. Therefore, it is apparent that at room temperature the bound phosphine ligands are being exchanged rapidly between different copper atoms. It is not possible to deduce whether this exchange is inter- or intramolecular. However, since it is known that these kinds of complexes may undergo ligand dissociation in solution (26), it is quite possible that the exchange is intermolecular in nature. The species in solution at low temperature could have the dimeric structure found in the solid state. Dimeric species are known to exist in benzene solutions of CuCl and $P(C_6H_5)_3$ or $PCH_3(C_6H_5)_2$ when the ligand to CuCl ratio is less than 3:1 (26). However, for the THF solutions of $[CuI(C_6H_5PH_2)_2]$ the possibility that a THF solvent molecule assumes one coordination position, and thus breaks-up the dimers, cannot be ruled out.

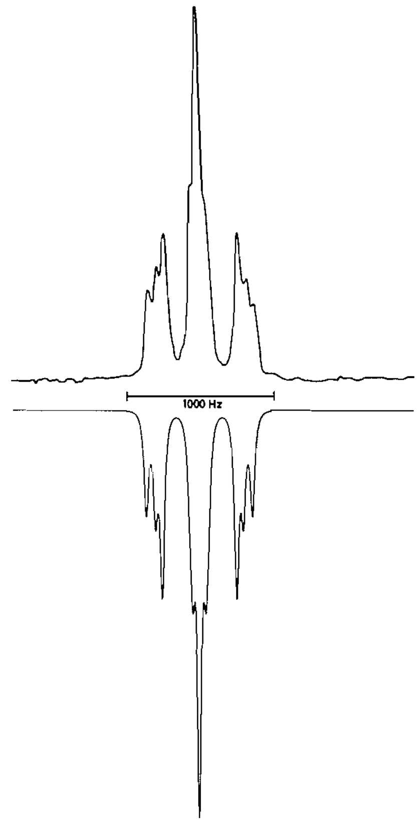


FIG. 3. ^{31}P nmr spectrum of $[CuI(C_6H_5PH_2)_2]_2$ in the THF solution at −99°C; upper, actual spectrum; lower, simulated spectrum.

High temperature potential/pH diagrams for the chlorine–water system

BARBARA KOLODZIEJ[1] AND FATHI HABASHI
Department of Mining and Metallurgy, Laval University, Quebec City, P.Q., Canada G1K 7P4

Received March 26, 1984[2]

BARBARA KOLODZIEJ and FATHI HABASHI. Can. J. Chem. **63**, 935 (1985).

Thermodynamic evidence supports the view that the reaction $2\,Cl^- + 2H^+ + \frac{1}{2}O_2 \rightarrow Cl_2(aq) + H_2O$ takes place above 127°C at pH = 0. An increase in HCl concentration and/or oxygen partial pressure allow the reaction to proceed at lower temperature.

BARBARA KOLODZIEJ et FATHI HABASHI. Can. J. Chem. **63**, 935 (1985).

Des données thermodynamiques suggérent que la réaction $2Cl^- + 2H^+ + \frac{1}{2}O_2 \rightarrow Cl_2(aq) + H_2O$ peut se produire à une température supérieure à 127°C et à un pH de 0. Si la concentration de HCl et/ou la pression partielle d'oxygène est augmentée, la réaction peut se produire à des températures plus basses.

[Traduit par le journal]

During the aqueous oxidation of some sulfide minerals at high temperature and pressure, it was observed that the rate of reaction in HCl solution is higher than that in H_2SO_4 solution of the same normality, all other factors being the same (1–4). This was explained to be due to the formation of chlorine according to the reaction

$$2Cl^- + 2H^+ + \tfrac{1}{2}O_2 \rightarrow Cl_2(aq) + H_2O$$

Aqueous chlorine is known to be a strong oxidant for sulfides; that is why its formation would enhance the dissolution. The present report is a thermodynamic analysis of the above reaction using E–pH diagrams prepared especially for elevated temperatures.

Method of calculation

Potential/pH diagrams for the chlorine–water system can be derived for temperatures up to 150°C by a method based largely on the Criss and Cobble Entropy Correspondence Principle (5). For representing equilibrium conditions in aqueous solutions we utilized the work by Pourbaix (6) which contains diagrams at 25°C. For easy comparison of the diagrams presented in the paper with those provided by Pourbaix we use his system of numbering of reactions.

The diagrams presented in this paper were constructed using the Correspondence Principle together with various other data from sources shown in Table 1. The reactions considered in the chlorine–water systems are shown in Table 2. All reactions were considered in the general form

$$[1] \quad aA + xH^+ + ze^- = bB + cH_2O$$

so that the reduction potential at temperature T becomes

$$[2] \quad E_T = E_T^0 + \frac{RT}{zF} \ln \frac{a_A^a a_{H^+}^x}{a_B^b a_{H_2O}^c}$$

If the activity of water is assumed to be equal to unity, the term $-\log a_{H^+}$ defined as pH, and with

$$[3] \quad \Delta G_T^0 = -zFE_T^0$$

it follows that

$$[4] \quad \frac{zFE_T}{2.303RT} = -\frac{\Delta G_T^0}{2.303RT} + \log \frac{a_A^a}{a_B^b} - x\ \mathrm{pH}$$

A change in free energy for each reaction at temperatures 90 and 150°C was calculated from the equation with T_1 = 298 K,

$$[5] \quad \Delta G_{T_2}^0 = \Delta G_{T_1}^0 - (T_2 - T_1)\Delta S_{T_1}^0 + (T_2 - T_1)\Delta \bar{C}_p^0]_{T_1}^{T_2} - T_2 \Delta \bar{C}_p^0]_{T_1}^{T_2} \ln (T_2/T_1)$$

using the G_{298}^0 and S_{298}^0 values shown in Table 1 and heat capacity data shown in Tables 3, 4. The ion heat-capacity functions have been presented by Criss and Cobble in the following form

$$[6] \quad \bar{C}_p^0]_{298}^{T_2} = a_{T_2} + b_{T_2} \cdot S_{298}^0 \text{ (absolute)}$$

where a_{T_2} and b_{T_2} are temperature dependent and S_{298}^0 (absolute) is the entropy based on $S_{H^+}^0 = -5.0$.

Results and conclusions

The equations for various reactions in the Cl–H_2O system presented in Table 2 were used in the construction of the potential/pH diagrams shown in Figs. 1, 2, 3, 4. The potential/pH equilibrium diagram for 25°C presented according to Pourbaix was supplemented with an expression related to equilibrium [31].

The equation presenting equilibrium [31] (Table 2) allows for the partial pressure of HCl over the aqueous 1 *M*, 3 *M* hydrochloric acid solution at 298, 363, and 423 K. Partial pressures of HCl in aqueous hydrochloric acid solutions at various concentrations and temperatures (10) are provided in Table 5. The diagrams presented in Figs. 1, 2, 3, 4 provide a suitable value of log p_{HCl} apart from the equilibrium line for reaction [31]. In order to determine the effect of hydrochloric acid concentration on the equilibria in question at 150°C also the potential/pH diagram for HCl was plotted (Fig. 4).

Analysis of the equilibria presented in the potential/pH diagrams at various temperatures shows that an increase in temperature results in a considerable decrease in the reaction potentials denoted in Table 2 by [3], [25], [35]. Thus, with the increasing temperature the area of thermodynamical stability of gaseous chlorine in equilibrium with gaseous HCl and Cl^- ions becomes enlarged and also the region of relative predominance of free chlorine Cl_2(aq) contained in hydrochloric acid solution becomes enlarged.

On the other hand, an increase in temperature results in an increase of the oxygen reduction potential

$$[7] \quad O_2 + 4H^+ + 4e^- = 2H_2O$$

which depends also on its partial pressure. By analyzing a possibility for reaction $2Cl^- = Cl_2(aq) + 2e^-$ (Table 4, reaction [3]) to occur, it was found on the grounds of the above mentioned relationships that at 25°C the potential of this reaction over the entire pH range lies above the reduction potential of O_2 to H_2O. Only a slight potential difference for reaction $2Cl^- = 2Cl(g) + 2e^-$ (Table 4, reaction [35]), and for reduction of oxygen of maximum 0.06 V for HCl solutions at pH $<$ 1.2 might indicate the oxidation reaction of Cl^- to Cl_2(g) to occur. An increase in temperature up to 90°C favours the oxidation reaction of Cl^- to Cl_2(g). At this temperature the difference in potentials between oxidation reaction of Cl^- ions to Cl_2(g) and reduction reaction of oxygen to H_2O in HCl solution at pH $<$ 2.2 is max. 0.17 V. On the other hand, for the course of reaction

$$[8] \quad 2Cl^- + \tfrac{1}{2}O_2 + 2H^+ = Cl_2(aq) + H_2O$$

the temperature of 90°C is still too low. Though for pH $<$ 1.4 the potential of oxidation reaction of Cl^- ions to Cl_2(aq) is slightly higher than that for reduction of oxygen but in this pH region, as shown by the diagram, one does not deal with the HCl solution. Analysis of equilibria for the same reactions at 150°C (Fig. 3) indicates that the course of oxidation reaction of

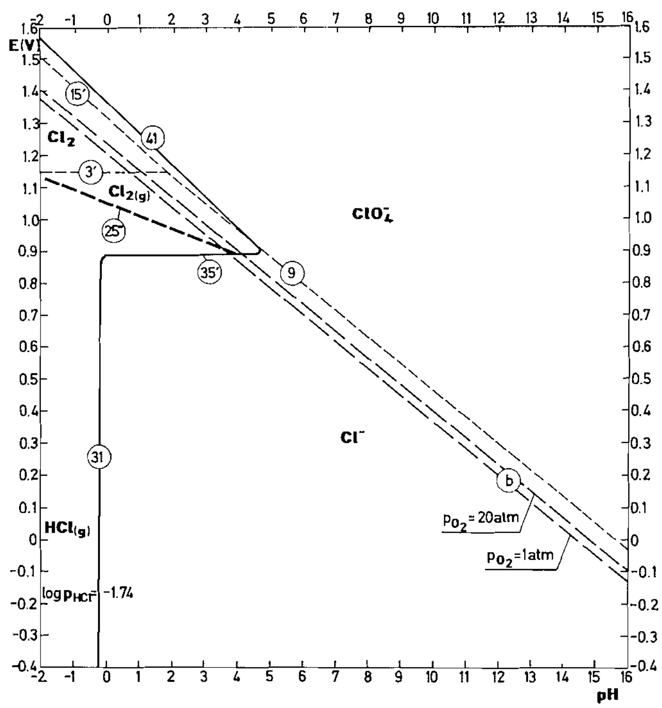

FIG. 3. Potential–pH equilibrium diagram for the system chlorine–water at 423 K, for solutions containing 1 g-atom Cl/L.

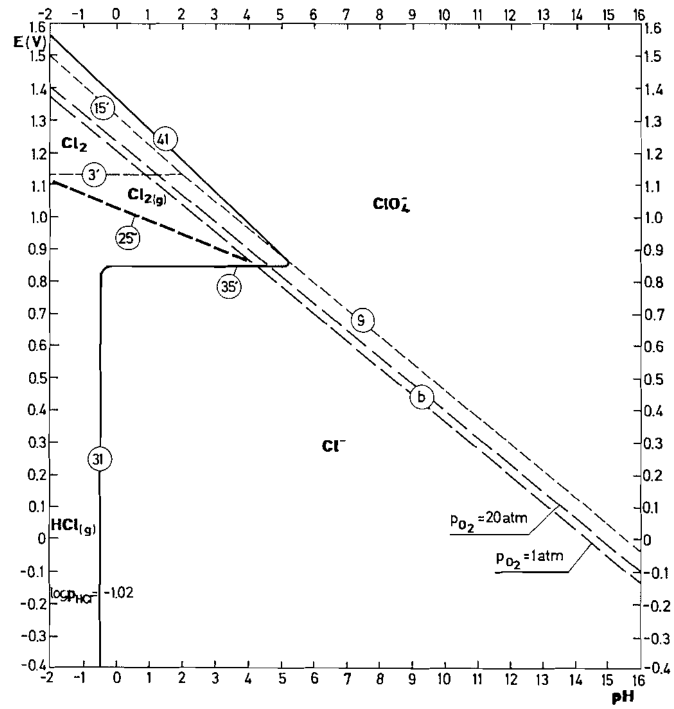

FIG. 4. Potential–pH equilibrium diagram for the system chlorine–water at 423 K, for solutions containing 3 g-atom Cl/L.

Cl^- ions to $Cl_2(aq)$ is thermodynamically justified. If the partial pressure of oxygen is 20 atm, the maximum difference of potentials for oxidation of Cl^- and reduction of oxygen in HCl solution at pH < 1 is 0.1 V for the reaction whose product is $Cl_2(g)$ and 0.37 V for the reaction which yields $Cl_2(aq)$, respectively. An increase in the hydrochloric acid concentration up to 3 M causes that under the same conditions the maximum potential difference increases up to 0.14 V and 0.43 V, respectively (Fig. 4). In order to estimate the temperature at which the course of oxidation reaction of Cl^- ions to $Cl_2(aq)$ becomes thermodynamically justified the following procedure was applied. The E_T potential of oxygen reduction was determined at 25, 90, and 150°C, assuming $P_{O_2} = 20$ atm and pH of solution equals 0. It amounts to 1.25, 1.24, 1.24 V, respectively. Because of such insignificant changes it was assumed that its value does not depend on temperature and is 1.24 V. Then the relation of E_T versus temperature for oxidation reaction of Cl^- ions to $Cl_2(aq)$ was determined. On this basis it was found that the E_T potential of this reaction assumes the

TABLE 5. Partial pressures (in atm) of HCl in aqueous hydrochloric acid solutions at various concentrations and temperatures

HCl	Temperature (K) 298	363	423
1 M	6.31×10^{-7}	2.48×10^{-4}	1.79×10^{-2}
3 M	7.0×10^{-6}	1.92×10^{-3}	9.42×10^{-2}

* Extrapolated values (on the grounds of $\log p_{HCl} = f(T)$).

value of 1.24 V at about 127°C. Thus one should infer that above this temperature the course of oxidation of the Cl^- ions to $Cl_2(aq)$ under oxygen pressure in HCl solution at pH = 0 is thermodynamically justified only at temperatures exceeding 127°C. Similar considerations carried out for solutions with varying pH and, hence, at various HCl concentrations indicate that an increase in HCl concentration allows this reaction to proceed at correspondingly lower temperatures. An increase in partial pressure of oxygen has a similar effect on the course of oxidation reaction of Cl^- ions to $Cl_2(aq)$: the higher the partial pressure of oxygen, the lower the temperature at which this reaction can take place.

Recent experimental work by Kiwi and Grätzel (11) has shown that chloride ion in acid medium can be oxidized in presence of solid catalysts. Thus, at pH ≈ 1, and 10^{-3} M Ce^{4+}, a solution of 10^{-3} M NaCl generates Cl_2 at the rate of 60 μM/L h in presence of ruthenium oxide, $RuO_2 \cdot xH_2O$. In view of the thermodynamic calculations presented here, the formation of Cl_2 during the aqueous oxidation of sulfide minerals in HCl medium seems plausible.

Appendix

The equilibrium between the two gaseous substances HCl(g) and $Cl_2(g)$ should be referred to in the chlorine–water system under consideration which contains also the Cl^- ions derived from dissociation of aqueous hydrochloric acid solution. Hence, in order to determine the limits of the domain of relative predominance of HCl(g) and $Cl_2(g)$ in the presence of the Cl^- ions one should consider two reactions denoted by [25] and [31] in the Table 4. The equilibrium of reaction [25] is described by the Nernst equation:

$$E_{(T)} = E_{0(T)} + \frac{2.303RT}{2F} \log \frac{p_{Cl_2}[H^+]^2}{p_{HCl}^2}$$

while that of reaction [31] by the equation

$$\log [Cl^-] = \log K_T + pH + \log p_{HCl}$$

where $K_T = [Cl^-][H^+]/p_{HCl}$

The following combination of the above two relationships:

$$E_{(T)} = E_{0(T)} + \frac{2.303RT}{2F} \log \frac{p_{Cl_2}}{p_{HCl}} + \frac{2.303RT}{2F} \log \frac{[H^+]^2}{p_{HCl}}$$

$$= E_{0(T)} + \frac{2.303RT}{2F} \log K_T - \frac{2.303RT}{2F} pH - \frac{2.303RT}{2F} \log [Cl^-]$$

yields an equation used for determination of the limits of the domains of relative predominance of the HCl(g) and $Cl_2(g)$ in the presence of the Cl^- ions. This equation is denoted by [25″] in Table 4 (according to the Pourbaix nomenclature) and is given for the respective temperatures 298, 363, and 423 K.

Synthesis of novel, highly reactive 1-oxyl-2,2,6,6-tetramethyl-1,2,5,6-tetrahydropyridine derivatives

JÓZSEF CSEKÖ, H. OLGA HANKOVSZKY, AND KÁLMÁN HIDEG[1]

Central Laboratory, Chemistry, University of Pécs, P.O. Box 99, H-7643 Pécs, Hungary

Received July 19, 1984

JOZSEF CSEKÖ, H. OLGA HANKOVSZKY, and KÁLMÁN HIDEG. Can. J. Chem. **63**, 940 (1985).

New multipurpose spin labels and synthons can be synthesized from 1-oxyl-2,2,6,6-tetramethyl-1,2,5,6-tetrahydropyridine-4-carboxylic acid (**1**). Either **1**, its pentafluorophenylester (**2**), or acylcarbonate (**3**) (prepared from **1** with ethyl chloroformate) can be reduced to 1-oxyl-2,2,6,6-tetramethyl-4-hydroxymethyl-1,2,5,6-tetrahydropyridine (**4**). The methanesulfonate (**6**) and the bromo compound (**7**) are highly reactive alkylating reagents due, in large part, to the allylic linkage in the nitroxide ring. The latter can be reacted with $KSSO_2CH_3$ to give methanethiolsulfonate (**9**). A novel side chain spin-labelled α-amino acid ester (**11**) is made by a phase-transfer alkylation of a Schiff base with **7**. Compound **11** can be coupled with the protected L-phenylalanine in the presence of dicyclohexylcarbodiimide (DCC) to produce the nitroxide dipeptide (**12**).

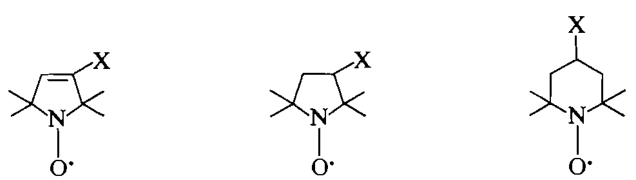
JOZSEF CSEKÖ, H. OLGA HANKOVSZKY et KÁLMÁN HIDEG. Can. J. Chem. **63**, 940 (1985).

On peut synthétiser de nouveaux synthons et de nouveaux marqueurs de spin à usage multiple à partir de l'acide oxyl-1 tétraméthyl-2,2,6,6 tétrahydro-1,2,5,6 pyridinecarboxylique-4 (**1**). On peut réduire soit le composé **1**, soit son ester pentafluorophényle (**2**) ou son acylcarbonate (**3**) (que l'on peut préparer à partir de **1** par réaction avec le chloroformate d'éthyle) en oxyl-1 tétraméthyl-2,2,6,6 hydroxyméthyl-4 tétrahydro-1,2,5,6 pyridine (**4**). Le méthanesulfonate (**6**) ainsi que le dérivé bromé (**7**) sont des réactifs alkylants très réactifs à cause, en grande partie, de la liaison allylique dans le cycle nitroxyde. On peut faire réagir le dérivé bromé avec le $KSSO_2CH_3$ pour obtenir le méthanethiosulfonate **9**. On a préparé le nouvel ester **11** d'un acide α-aminé portant un marqueur de spin sur la chaîne latérale en effectuant une alkylation par transfert de phase d'une base de Schiff par le composé **7**. Dans le but d'obtenir le nitroxyde dipeptide (**12**), on peut coupler le composé **11** avec une L-phénylalanine en présence de dicyclohexylcarbodiimide (DCC).

[Traduit par le journal]

Introduction

Reactive functional groups attached to stable nitroxide free radicals have been used as spin labels for studying biomolecules in recent decades (1). The most frequently used types of nitroxides are the pyrroline- the pyrrolidine-, and the piperidine-*N*-oxyls:



Hsia and co-workers reported the synthesis of 1-oxyl-2,2,6,6-tetramethyl-1,2,5,6-tetrahydropyridine-4-carboxylic acid (**1**) (2). We wish to report the reduction of the acid **1** to the alcohol **4** and the oxidation of **4** to the aldehyde **5**. The corresponding pyrroline derivatives have proved to be highly reactive and versatile synthons (3). The tetrahydropyridine derivative has opened further opportunities for spin-labelling molecules of biological interest.

Results and discussion

The synthesis of the acid **1** was achieved by the method of Hsia and co-workers (2). The alcohol **4** can be obtained either directly from **1** with sodium bis(2-methoxyethoxy)aluminium hydride (SMEAH) in toluene, from the reduction of the active ester **2**, or from the mixed anhydride ester **3** with sodium borohydride. The **4** can be oxidized to the unsaturated aldehyde **5** with activated manganese dioxide. The conversion of **4** to the mesylate (**6**) can be carried out with methanesulfonyl choride in the presence of triethylamine (TEA). Compound **6** with lithium bromide in acetone gives the bromo compound (**7**) in high yield. The bromo compound **7** shows high reactivity as observed in the corresponding pyrroline analogue (4), due to its allylic structure. The bromo compound **7** can be converted into the benzoate without allylic rearrangement because the same benzoate (**8**) can be obtained when the alcohol (**4**) is directly benzoylated with benzoyl chloride in pyridine. The methanethiolsulfonate derivative (**9**) can be prepared from **7** with potassium methanethiolsulfonate, utilizing the method described earlier for the synthesis of the pyrroline analogue (5). The importance of this method lies in the fact that α-amino acid derivatives can be prepared which bear the nitroxide moiety in the side-chain having no other chiral centre in the molecule.

The synthesis of a pyrroline α-amino acid (**10**) in our laboratory has been described earlier (6). Two reviews deal with synthesis and spin-labelling of α-amino acids and peptides (7, 8). We show here a synthesis of the new paramagnetic α-amino acid ester, **11**, utilizing O'Donnell's method (9) applied in our earlier work which described the synthesis of **10**. Amino ester **11** can be acylated with L-*N*-trifluoroacetyl phenylalanine (TFA-Phe) in the presence of dicyclohexylcarbodiimide (DCC) in dry tetrahydrofuran to give **12** (Scheme 1).

The presence of an allylic system in the nitroxide ring confers a substantial increase in reactivity upon halide derivatives of those nitroxides relative to the saturated ring nitroxides. This is of great importance for synthetic applications where these niroxides are coupled to biologically important, but often heat-labile molecules such as drugs, hormones, and macromolecules.

A second important aspect of our paper concerns the orientation of the nitroxide in a derivatized molecule. We emphasize that the five- and six-membered rings result in quite different alignments of the N—O$^\bullet$ bond of the nitroxide relative to a derivatized molecule. This can have a significant impact upon spectral analysis when a bound species is undergoing aniso-

tropic motion, e.g. in a biological membrane. Thus, the availability of allylic nitroxides for alkylation in addition to the α,β-unsaturated aldehydes for various reactions provides a needed versatility when synthesizing spin-labelled analogues which retain biological activity, and yields the best opportunities for interpretation of esr spectra.

Experimental

Melting points were measured using a Boetius micro instrument and are not corrected. The ir spectra were measured with a Zeiss Specord 75 type instrument. The esr spectra were obtained from a 10^{-3} M solution on a Zeiss ER9 spectrometer. All the monoradicals exhibited three equidistant lines with a_N = 14.8–15.0 G. The mass spectra were taken in a Varian-MAT-SM-1 instrument.

1-Oxyl-2,2,6,6-tetramethyl-1,2,5,6-tetrahydropyridine-4-carboxylic acid pentafluorophenyl ester (2)

To a stirred solution of carboxylic acid (**1**) (594 mg, 3 mmol) and pentafluorophenol (552 mg, 3 mmol) in dry ethyl acetate (10 mL), a solution of DCC (619 mg, 3 mmol) in dry ethyl acetate (3 mL) was added at 0°C. The mixture was stirred 3 h at room temperature. The dicyclohexylurea (DCU) was filtered off, the filtrate was extracted with 5% sodium hydrogen carbonate solution and with water, dried over anhydrous sodium sulfate, and evaporated to dryness. The pure yellow ester (**2**) was crystallized from chloroform/ether, yield: 820 mg (75%); mp 113–114°C; ir (Nujol): 1745 (CO) cm^{-1}. *Anal.* calcd. for $C_{16}H_{15}F_5NO_3$ (mol. wt. 364.3): C 52.75, H 4.15, N 3.85; found: C 52.40, H 4.22, N 3.80.

(Carbonic acid-1-oxyl-2,2,6,6-tetramethyl-1,2,5,6-tetrahydro-pyridine-4-carboxylic acid)anhydride ethyl ester (3)

To a stirred solution of **1** (1.98 g, 10 mmol) in ether (20 mL) triethylamine (TEA) (1.21 g, 12 mmol) was added, then the mixture was cooled to 0°C, and under stirring a solution of ethyl chloroformate (1.30 g, 12 mmol) in ether (10 mL) was added dropwise. After the addition had been completed, stirring was continued for 3 h at room temperature. TEA hydrochloride was filtered off, the filtrate was evaporated, then the residue was taken up in hexane and kept in a refrigerator. The crystals separated gave **3**, yield: 2.43 g (90%); mp 43–44°C; ir (Nujol): 1805, 1730 (COOCOO) cm^{-1}; ms, *m/e*: M^+ 270 (41), 196 (18), 182 (15), 168 (100). *Anal.* calcd. for $C_{13}H_{20}NO_5$ (mol. wt. 270.3): C 57.76, H 7.46, N 5.18; found: C 57.79, H 7.32, N 5.26.

1-Oxyl-4-hydroxymethyl-2,2,6,6-tetramethyl-1,2,5,6-tetrahydro-pyridine (4)

Method A

The active acid derivative (**2** or **3**) (10.0 mmol) was added to a stirred suspension of sodium borohydride (0.5 g) in ethanol (30 mL) at 0°C, stirred for 1 h, then the mixture evaporated to dryness. Water (10 mL) was added to the residue, extracted with chloroform (3 × 10 mL), the organic phase was dried, and evaporated to dryness. The solid residue was crystallized from ether/hexane; yield of **4** from **2**: 1.6 g (87%); from **3**: 1.63 (89%); mp 37–38°C; ir (Nujol): 3500–3100 (OH) cm^{-1}. *Anal.* calcd. for $C_{10}H_{18}NO_2$ (mol. wt. 184.3): C 65.19, H 9.84, N 7.60; found: C 65.39, H 9.70, N 7.89.

Method B

A toluene solution of sodium bis(2-methoxyethoxy)aluminium hydride (13.75 mL, 70%) was added dropwise to a stirred suspension of acid (**1**) (4.950 g, 25 mmol) in dry toluene (300 mL). The solution was refluxed for 2 h. The mixture was then added dropwise to a cooled and stirred 5% aqueous solution of sodium hydroxide (125 mL). The toluene phase was separated, dried, and evaporated to dryness, and the orange solid residue was crystallized from ether/hexane to give **4**, yield: 2.73 g (59%); mp 36–37°C. The product is identical with compound **4** obtained by Method A.

1-Oxyl-4-formyl-2,2,6,6-tetramethyl-1,2,5,6-tetrahydropyridine (5)

To a stirred solution of unsaturated alcohol (**4**) (1.84 g, 10 mmol) in tetrachloromethane (30 mL) was added active manganese dioxide (18 g); the solution was refluxed for 30 min, then filtered, and the filtrate was evaporated to dryness. The yellow residue was recrystallized from hexane to give pure aldehyde (**5**), yield: 1.21 g (66%); mp 69–70°C; ir (Nujol): 1670 (CO) cm^{-1}; ms, *m/e*: M^+ 182 (37), 168 (30), 152 (100). *Anal.* calcd. for $C_{10}H_{16}NO_2$ (mol. wt. 182.3): C 65.90, H 8.85, N 7.69; found: C 66.01, H 8.88, N 7.61.

1-Oxyl-2,2,6,6-tetramethyl-1,2,5,6-tetrahydropyridine-4-yl methyl sulfonate (6)

To a stirred solution of **4** (2.764 g, 15 mmol) and TEA (1.670 g, 16.5 mmol) in dichloromethane (25 mL) at −10°C, methanesulfonyl chloride (1.890 g, 16.5 mmol) was added dropwise, and stirred for 3 h at room temperature. The mixture was extracted with water (15 mL) and washed with a solution of 5% sodium hydrogen carbonate (20 mL). The organic phase was dried and evaporated to dryness. The product was a dark red oil (**6**), yield: 3.55 g (90%); ir (film): 1160 (OSO_2) cm^{-1}. *Anal.* calcd. for $C_{11}H_{20}NO_4S$ (mol. wt. 262.4): C 50.36, H 7.68, N 5.34, S 12.23; found: C 50.04, H 7.70, N 5.01, S 12.37.

1-Oxyl-4-bromomethyl-2,2,6,6-tetramethyl-1,2,5,6-tetrahydro-pyridine (7)

A solution of mesylate (**6**) (3.411 g, 13 mmol) and lithium bromide (3.387 g, 39 mmol) in dry acetone (20 mL) was refluxed for 30 min, diluted with water (10 mL), and extracted with ether (2 × 20 mL). The ether phase was dried and evaporated to dryness. The residual bromo compound (**7**) is a dark red oil, yield: 2.67 g (83%); ir (film): 1620 (C=C) cm^{-1}. *Anal.* calcd. for $C_{10}H_{17}BrNO$ (mol. wt. 247.2): C 48.59, H 6.93, N 5.67, Br 32.33; found: C 48.47, H 6.80, N 5.51, Br 32.77.

1-Oxyl-2,2,6,6-tetramethyl-1,2,5,6-tetrahydropyridine-4-yl methyl benzoate (8)

Method A

To the solution of **7** (247 mg, 1 mmol) in dry dimethylformamide (3 mL) sodium benzoate (173 mg, 1.2 mmol) was added. The mixture was heated (60°C) for 3 h, diluted with water (5 mL), and extracted with ether (3 × 10 mL). The organic phase was washed with water, dried, and evaporated. The residual **8** is a red oil, yield: 200 mg (69%); ir (film): 1720 (CO) cm^{-1}. *Anal.* calcd. for $C_{17}H_{22}NO_3$ (mol. wt. 288.4): C 70.81, H 7.69, N 4.86; found: C 70.75, H 7.58, N 4.49.

Method B

To a stirred solution of **4** (184 mg, 1.0 mmol) in dry pyridine, benzoylchloride (154 mg, 1.1 mmol) was added dropwise at 5°C. The mixture was allowed to stand for 3 h, then poured into crushed ice, and extracted with ether (3 × 10 mL). The organic phase was washed with 1 *N* hydrochloric acid, water, dried, and evaporated to dryness to give the **8** as an orange oil, yield: 220 mg (76%). The **8** was essentially the same as obtained by Method A.

(1-Oxyl-2,2,6,6-tetramethyl-1,2,5,6-tetrahydropyridine-4-methyl)-methanethiolsulfonate (9)

A solution of bromomethyl compound (**7**) (247 mg, 1.0 mmol) and potassium methanethiolsulfonate (150 mg, 1.0 mmol) in dry ethanol (10 mL) was refluxed for 3 h, then diluted with brine (10 mL), and extracted with ether (3 × 10 mL). The ether phase was dried and evaporated to dryness. The pure **9** was crystallized from ether/hexane, yield: 160 mg (57%); mp 38–40°C; ir (Nujol): 1325 (SO_2) cm^{-1}. *Anal.* calcd. for $C_{11}H_{20}NO_3S_2$ (mol. wt. 278.4): C 47.45, H 7.24, N 5.04, S 23.03; found: C 47.35, H 7.14, N 5.08, S 23.29.

Ethyl[2-amino-3-(1-oxyl-2,2,6,6-tetramethyl-1,2,5,6-tetrahydro-pyrid-4-yl)]propionate (11)

A solution of sodium hydroxide (2 *N*, 1.2 mL, 2.4 mmol) was added to a methylene chloride solution (3 mL) of the ethyl *N*-(diphenylmethylene)glycinate (10) (267 mg, 1.0 mmol), tetrabutylammonium hydrogen sulfate (TBAH) (407 mg, 1.2 mmol), and **7** (297 mg, 1.2 mmol) and stirred at room temperature for 3 h. The organic phase was evaporated, washed with water, dried, and evaporated to dryness. The residue was taken up in ether (30 mL) and filtered to remove quaternary bromide. The filtrate was evaporated to dryness. Aqueous citric acid (10%, 2 mL) was added to the tetrahydrofuran solution (2 mL) of the alkylated Schiff's base and stirred for 1 h. The reaction mixture was diluted with water (5 mL) and extracted with chloroform (2 × 10 mL) to remove the benzophenone. The aqueous phase was basified wth a solution of 2 *N* sodium hydroxide to pH 8, extracted with chloroform (3 × 10 mL), dried, and evaporated to dryness to give **11** as a red oil. The crude compound was subjected to preparative thin-layer chromatography (tlc) (Merck, Kieselgel 60; chloroform/MeOH, 9:1), the major band was eluted with ethyl acetate. Yield: 130 mg (48%); ir (film): 3400–3200 (NH_2), 1730 (CO) cm^{-1}; ms, *m/e*: M^+ 269 (9), 255 (14), 239 (23), 102 (100). *Anal.* calcd. for $C_{14}H_{25}N_2O_3$ (mol. wt. 269.4): C 62.43, H 9.36, N 10.40; found: C 62.09, H 9.25, N 10.47.

N-Trifluoroacetyl-L-phenylalanyl-2-amino-3-(1-oxyl-2,2,6,6-tetramethyl-1,2,5,6-tetrahydropyrid-4-yl) ethyl propionate (**12**)

To a stirred solution of L-*N*-trifluoroacetylphenylalanine (262 mg, 1.0 mmol) and **11** (269 mg, 1.0 mmol) in tetrahydrofuran (5 mL) was added a solution of DCC (206 mg, 1.0 mmol) in dry tetrahydrofuran (5 mL) at 0°C and stirred for 3 h at room temperature. The dicyclohexylurea (DCU) was filtered off, and the filtrate evaporated to dryness. The residue was taken up in ethylacetate (20 mL), washed with 1 *N* HCl at 0°C, then with 5% sodium hydrogen carbonate and water, dried, and evaporated to dryness. The pure product (**12**) was obtained with preparative tlc (Merck, Kieselgel 60; chloroform/ether, 9:1). Yield: 160 mg (31%); mp 57–59°C; ir (Nujol): 3400 (NH), 1730 (CO) cm^{-1}; ms, *m/e*: M^+ 512 (100), 482 (70), 346 (28). *Anal.* calcd. for $C_{25}H_{33}F_3N_3O_5$ (mol. wt. 512.6): C 58.58, H 6.49, N 8.20; found: C 58.32, H 6.52, N 8.25.

L'isomérisation de radicaux insaturés. II. Les radicaux α-éthallyles et α,γ-diméthallyles formés dans la photolyse de l'hexène-3 et du méthyl-4-pentène-2 à 147,0 et 184,9 nm

Reçu le 20 juin 1984

GUY J. COLLIN et HÉLÈNE DESLAURIERS. Can. J. Chem. **63**, 944 (1985).

Nous avons étudié la photodécomposition du *cis*-hexène-3 et du méthyl-4-*cis*-pentène-2 à 147,0 et 184,9 nm. La fragmentation de la molécule photoexcitée suit le mécanisme habituel. La rupture primaire a essentiellement lieu (≃80%) sur le lien C—C situé en position β par rapport à la double liaison. Des ruptures α(C—C), β(C—H) et α(C—H) viennent compléter ce panorama. La formation des radicaux α-éthallyles et α,γ-diméthallyles est donc importante dans chacun des deux cas, et nous avons pu montrer que ces deux radicaux doivent s'isomériser l'un dans l'autre pour pouvoir expliquer la formation d'une partie du pentadiène-1,3 dans le cas de l'hexène-3 et de la totalité du butadiène-1,3 dans le cas du méthyl-4-pentène-2. Cette isomérisation demande un transfert interne d'un atome d'hydrogène en 1,4.

GUY J. COLLIN and HÉLÈNE DESLAURIERS. Can. J. Chem. **63**, 944 (1985).

The photolysis of *cis*-3-hexene and 4-methyl-*cis*-2-pentene has been studied at 147.0 and 184.9 nm. The fragmentation pattern of the photoexcited molecule is normal: it requires, mainly, the split of a C—C bond located in the β position relative to the double bond (≃80%). Some α(C—C), β(C—H), and α(C—H) primary splits complete this mechanism. The formation of α-ethallyl and α,γ-dimethallyl radicals is important in 3-hexene and 4-methyl-2-pentene, respectively. An isomerization process, involving these two radicals, is necessary to explain the formation of part of the 1,3-pentadiene in the 3-hexene system and of all the 1,3-butadiene in the 4-methyl-2-pentene system. This process involves a 1,4-hydrogen atom transfer.

Introduction

Nous avons établi récemment que les radicaux excités α,α-diméthallyles s'isomérisent vers la structure α,β-diméthallyles et réciproquement par transfert interne 1,4 d'un atome d'hydrogène (1). La présente étude vise à observer le même processus avec les radicaux α-éthallyles et α,γ-diméthallyles. Pour ce faire, nous proposons d'étudier la photolyse du *cis*-hexène-3 et du méthyl-4-*cis*-pentène-2. En effet, il est connu que, dans la région de l'uv sous vide, ou de l'uv très lointain, la fragmentation la plus importante implique la rupture du lien β(C—C) (2, 3). Dans ces conditions, on peut s'attendre à obtenir les radicaux mentionnés plus haut avec des rendements importants.

Partie expérimentale

Les techniques utilisées dans ce travail sont classiques (1–3). La lampe émettant à 147,0 nm est une lampe de résonance à xénon (4) de fabrication domestique, l'autre est une lampe "basse pression" à mercure achetée chez Philipps. Les échantillons sont préparés dans un système en Pyrex dans lequel le vide est maintenu par deux pompes: une pompe à diffusion à huile (deux étages) est située en amont d'une pompe mécanique. Les analyses sont faites par chromatographie en phase gazeuse par deux appareils équipés de système de détection à double flamme ionisante et comprenant l'un une colonne de squalane (5) l'autre une colonne de UCON LB 550 × 20% (6). Les rendements quantiques sont obtenus par comparaison photochimique en éclairant dans les mêmes conditions le *cis*-butène-2.

Les échantillons de monomère sont des produits API. Les taux d'impuretés affichés sur ces échantillons sont: le *cis*-hexène-3, 0,086 ± 0,013% et le méthyl-4-*cis*-pentène-2, 0,08 ± 0,07%. Les analyses chromatographiques montrent que le *cis*-hexène-3 contient de l'hexène-1 (12 ± 0,5 ppm); on n'a pas mesuré le contenu d'hexène-2, ni celui en *trans*-hexène-3. Quant au méthyl-4-*cis*-pentène-2 il contient du méthyl-2-pentadiène-1,4 (10 ± 1 ppm), du méthyl-2-hexane (≃6 ppm), un composé inconnu en C_6 (10 ± 1 ppm). Ici, également, on n'a pu mesurer le contenu en isomère *trans*.

Résultats

Ceux-ci apparaissent sous forme de rendements quantiques dans les tableaux qui accompagnent le texte.

La photolyse du cis-*hexène-3 à 147 nm*

Les figures 1 et 2 montrent l'inverse du rendement des produits majeurs formés en présence d'oxygène: ce sont le butadiène-1,3, le pentadiène-1,3 (*cis* + *trans*) et l'éthylène. En présence d'oxygène moléculaire (+10%) les rendements en acétylène et en butyne-1 sont plutôt constants: $\Phi(C_2H_2)$ = $0{,}03_5 \pm 0{,}00_5$ et Φ(butyne-1) = 0,045 ± 0,005. En l'absence d'oxygène, les rendements en hydrocarbures saturés légers sont les suivants: $\Phi(CH_4)$ = 0,035 ± 0,01, $\Phi(C_2H_6)$ = 0,43 ± 0,05 et $\Phi(C_3H_8)$ = 0,10 ± 0,02 pourvu que la pression du monomère soit comprise entre 2 et 40 Torr (1 Torr = 133,3 Pa). On n'a pas observé de formation de méthyl-3-pentène-1 en l'absence d'oxygène.

La photolyse du cis-*hexène-3 à 184,9 nm*

Le tableau 1 donne un panorama complet des produits formés. Le butadiène-1,3 est encore le produit majeur formé en présence d'oxygène; son rendement est cependant plus faible que celui mesuré à 147 nm à pression égale. Il en est de même du pentadiène-1,3 et de l'éthylène. En l'absence d'oxygène, l'éthane est le produit majeur à toute pression. On observe aussi la formation de méthyl-3-pentène-1.

*La photolyse du méthyl-4-*cis-*pentène-2 à 147 nm*

Le tableau 2 donne une vue complète des produits formés auxquels il faut ajouter les diènes apparaissant dans les figures 3 et 4. Ces butadiène-1,3, pentadiènes-1,3 et isoprène ont des rendements qui décroissent avec l'augmentation de la pression. En présence d'oxygène, le propène et le pentadiène-2,3 ont des rendements qui décroissent aussi avec l'augmentation de la pression. Ainsi la valeur Φ(propène) passe de 0,11 à 1 Torr à 0,045 à 60 Torr et celle du pentadiène-2,3 de $0{,}02_3$ à $0{,}01_6$ sur le même intervalle de pression. Par contre, toujours en présence d'oxygène, les rendements en méthane, acétylène, propyne et méthyl-3-butyne-1 sont plutôt constants entre 5 et

[a]Le rendement quantique de ces produits se réduit à zéro en présence de 10% d'oxygène.
[b]Le rendement $\Phi(CH_4)$ est inférieur à 0,005 en présence de 10% d'oxygène.
[c]Voir texte: relation [B].
[d]Non mesuré.

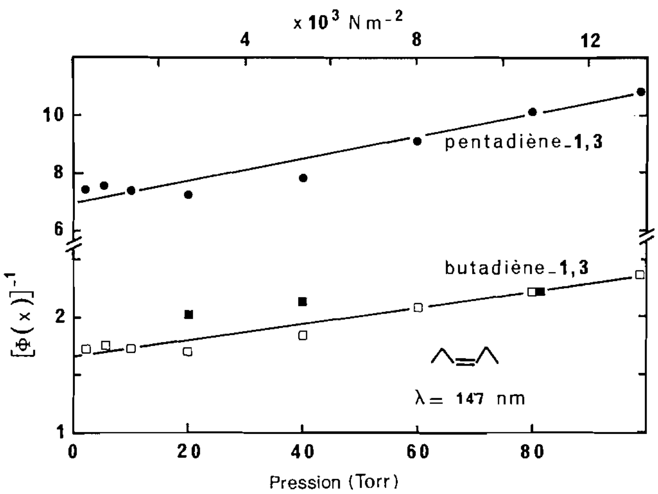

FIG. 1. Photolyse du *cis*-hexène-3 à 147,0 nm pure [□] ou en présence de 10% d'oxygène (●, ■). Inverse des rendements quantiques en fonction de la pression du monomère.

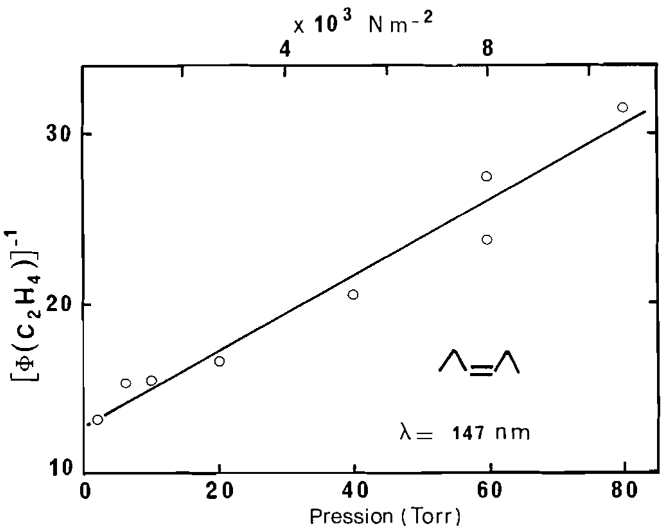

FIG. 2. Photolyse du *cis*-hexène-3 à 147,0 nm en présence de 10% d'oxygène. Inverse du rendement quantique de l'éthylène en fonction de la pression du monomère.

60 Torr: $\Phi(CH_4) = 0{,}03 \pm 0{,}01$, $\Phi(C_2H_2) = 0{,}04_0 \pm 0{,}00_4$, Φ(propyne) $= 0{,}015 \pm 0{,}005$ et $\Phi(C_5H_8) = 0{,}01_4 \pm 0{,}00_2$.

*La photolyse du méthyl-4-*cis*-pentène-2 à 184,9 nm*

Le tableau 3 indique qu'à cette longueur d'onde l'éthane est le produit majeur en l'absence d'oxygène et son rendement décroît avec la pression. En présence d'oxygène, le butadiène-1,3 et le pentadiène-1,3, dont les rendements sont similaires, sont les produits majeurs.

Enfin il faut signaler la formation de petites quantités de butène-1 (cas de l'hexène-3) et de propène, méthyl-3-butène-1 et pentène-2 (cas du méthyl-4-pentène-2) en présence de 10% d'oxygène. Le rendement quantique du butène-1 diminue de 0,02 sous une pression de 2 Torr à 0,01 sous une pression de 100 Torr. Celui du propène est similaire et ceux du méthylbutène et du pentène sont toujours inférieurs à 0,01 dans la même zone de pression. Ces produits sont probablement formés par décomposition des radicaux C_6H_{13} vibrationnellement excités. Ces derniers sont le résultat de l'addition des atomes d'hydrogène présents dans chacun des systèmes sur la double liaison du monomère (7, 8). Ce mécanisme ne sera pas discuté plus loin.

Discussion

La photolyse du cis-*hexène-3 (H3)*

(a) *À 147,0 nm*

La photofragmentation du *cis*-hexène-3 suit le mécanisme habituel déjà observé dans d'autres systèmes (2, 3). Ainsi la rupture prépondérante a lieu sur la liaison C—C située en position β par rapport à la double liaison. La molécule étant symétrique, deux liaisons C—C sont ainsi placées.

[1] $CH_3CH_2CH{=}CHCH_2CH_3 + h\nu \rightarrow CH_3CH_2CH{=}CHCH_2CH_3^{**}$

[2] $H3^{**} \rightarrow CH_3 + \dot{C}H_2\dot{C}H\dot{C}HCH_2CH_3^{*}$ $\quad \Delta H \simeq 295$ kJ mol^{-1} (réf. 9)

[3*a*] $\dot{C}H_2\dot{C}H\dot{C}HCH_2CH_3^{*} \xrightarrow{k_d} CH_3 + CH_2{=}CHCH{=}CH_2$ $\quad \Delta H \simeq 155$ kJ mol^{-1}

[3*b*] $\dot{C}H_2\dot{C}H\dot{C}HCH_2CH_3^{*} + M \xrightarrow{k_M} M + \dot{C}H_2\dot{C}H\dot{C}HCH_2CH_3$

L'énergie du photon incident est de 811 kJ Einstein^{-1}. A la température ordinaire, l'énergie vibrationnelle de la molécule est voisine de 14 kJ mol^{-1}, de telle sorte que la molécule photoexcitée, M**, contient environ 825 kJ mol^{-1}. Ainsi, après rupture du lien β(C—C) il reste encore 530 kJ mol^{-1} à distribuer entre les deux fragments. Le radical α-éthallyle, pourvu que la distribution de cet excédent soit convenable, a suffisamment d'énergie interne pour se fragmenter, à moins qu'une collision ne vienne lui en soustraire suffisamment auquel cas il est stabilisé. Ce simple mécanisme est du type

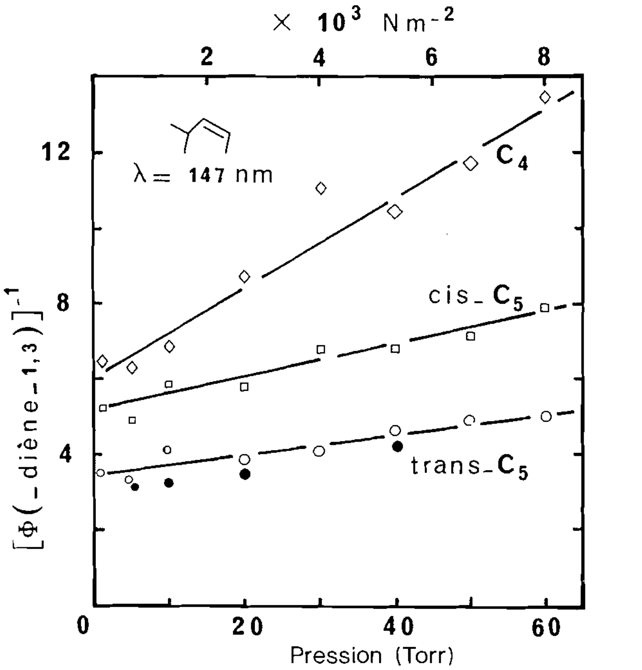

FIG. 3. Photolyse du méthyl-4-*cis*-pentène-2 à 147,0 nm pur (●) ou en présence de 10% d'oxygène (○, □, ◇). Inverse des rendements quantiques en fonction de la pression du monomère.

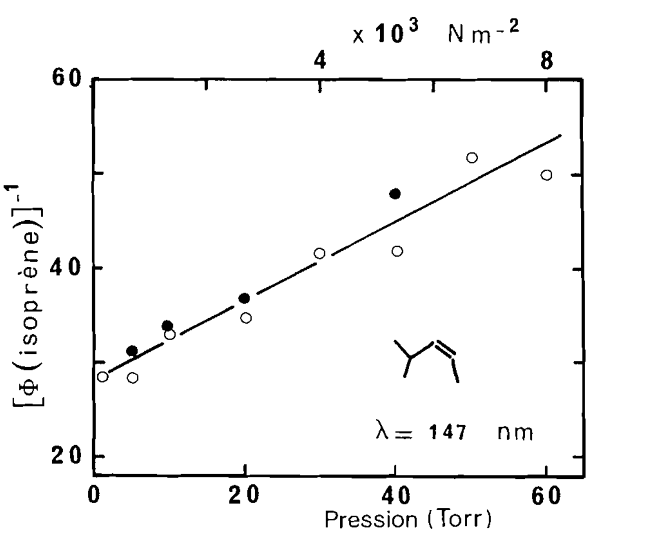

FIG. 4. Photolyse du méthyl-4-*cis*-pentène-2 à 147,0 nm pur (●) ou en présence de 10% d'oxygène (○). Inverse du rendement quantique de l'isoprène en fonction de la pression du monomère.

Stern–Volmer (10) et l'inverse du rendement quantique en butadiène-1,3 (B13) varie linéairement en fonction de la pression dans la chambre réactionnelle:

[A] $[\Phi(\mathrm{B13})]^{-1} = [\Phi_0(\mathrm{B13})]^{-1}(1 + k_s[\mathrm{M}]/k_d)$

La figure 1 montre la validité de la relation [A], et l'interception de la droite de Stern–Volmer à pression nulle donne la valeur maximum du rendement quantique en butadiène-1,3: Φ_0(butadiène-1,3) $\simeq 0{,}60_4$.

Le pentadiène-1,3 (*cis* + *trans*) a un comportement de type Stern–Volmer (fig. 1). Ce rendement est appréciable: Φ_0(pentadiène-1,3) = 0,145. Au moins deux routes peuvent être proposées pour leur formation. La première, et peut-être la plus importante, sera mieux circonscrite plus loin: elle réclame l'isomérisation du radical α-éthallyle vers la structure symétrique α,γ-diméthallyle par transfert interne 1,4 d'un atome d'hydrogène (11):

TABLEAU 2. Photolyse du méthyl-4-*cis*-pentène-2 pur à 147,0 nm. Rendements quantiques

Produits	Pression (Torr) 5	10	20	41

Propyne[b]	0,03	0,03	0,02	$0{,}02_4$
Butène-1[b]	$0{,}02_5$	$0{,}02_5$	$0{,}02_5$	$0{,}02_7$
Isobutane[a]	$0{,}03_6$	$0{,}03_4$	$0{,}02_7$	$0{,}03_1$
Méthyl-3-butyne-1[b] (?)	$0{,}01_8$	$0{,}01_6$	$0{,}01_6$	$0{,}01_5$
Isoprène[b]	$0{,}03_1$	$0{,}02_9$	$0{,}02_6$	$0{,}02_1$
Méthyl-2-pentane[a]	$0{,}04_7$	$0{,}03_0$	0,00	0,00
Diméthyl-2,4-pentène-2[a]	0,04	$0{,}01_6$	$0{,}02_4$	$0{,}01_1$
Diméthyl-2,4-pentane[a]	0,07	0,07	0,04	0,06
Diméthyl-2,3-pentane[a]	0,15	0,16	0,12	$0{,}12_6$

[a]Le rendement quantique de ces produits est essentiellement zéro en présence de 10% d'oxygène.
[b]Le rendement quantique de ces produits est essentiellement inchangé en présence de 10% d'oxygène.

[4] $CH_3CH_2\dot{C}H\dot{C}H\dot{C}H_2^* \rightarrow CH_3\dot{C}H\dot{C}H\dot{C}HCH_3^*$

$\Delta H = -14\ \mathrm{kJ\ mol^{-1}}$ (réf. 12)

[5*a*] $CH_3\dot{C}H\dot{C}H\dot{C}HCH_3^* \rightarrow CH_3CH{=}CHCH{=}CH_2 + H$

$\Delta H = 204\ \mathrm{kJ\ mol^{-1}}$

[5*b*] $CH_3\dot{C}H\dot{C}H\dot{C}HCH_3^* + M \rightarrow M + CH_3\dot{C}H\dot{C}H\dot{C}HCH_3$

L'autre mécanisme fait appel à la rupture primaire d'un lien C—H situé en position α par rapport à la double liaison:

[6] $H3^{**} \rightarrow CH_3CH_2\dot{C}H\dot{C}H\dot{C}HCH_3^* + H$

[7*a*] $CH_3CH_2\dot{C}H\dot{C}H\dot{C}HCH_3^* \rightarrow CH_3 + CH_2{=}CHCH{=}CHCH_3$

[7*b*] $CH_3CH_2\dot{C}H\dot{C}H\dot{C}HCH_3^* + M \rightarrow CH_3CH_2\dot{C}H\dot{C}H\dot{C}HCH_3$

De la même manière la rupture en α d'un lien C—C peut conduire à la formation d'éthylène (fig. 2) et aussi d'acétylène et de butyne-1:

[8] $H3^{**} \rightarrow CH_3CH_2^* + \dot{C}H{=}CHCH_2CH_3^*$

[9*a*] $CH_3CH_2^* \rightarrow C_2H_4 + H$

[9*b*] $CH_3CH_2^* + M \rightarrow M + C_2H_5$

[10*a*] $\dot{C}H{=}CHCH_2CH_3^* \rightarrow CH{\equiv}CH + C_2H_5$

[10*b*] $\dot{C}H{=}CHCH_2CH_3^* \rightarrow CH{\equiv}CCH_2CH_3 + H$

Le rendement minimum du processus [8] peut-être obtenu soit par la valeur du rendement en éthylène à pression nulle: $\Phi_0(C_2H_4) = 0{,}08$ (fig. 2), soit par la somme des rendements en acétylène et butyne-1: $\Phi(C_2H_2) + \Phi$(butyne-1) = 0,08 (voir résultats)!

La rupture d'un lien α(C—C) est très probablement plus facile que la rupture d'un lien α(C—H). En fait, à des énergies similaires, la fragmentation d'un lien α(C—C) semble à peu

[a]Le rendement quantique de ces produits s'annule en présence de 10% d'oxygène.
[b]Voir texte: relation [C].
[c]En présence de 10% d'oxygène, les rendements de ces produits sont ≈30% plus élevés.
[d]Non mesuré.

près aussi facile que celle d'un lien β(C—H) (13, 14). Cette remarque tend à montrer que la valeur $\phi([6])$ est inférieure à celle de $\phi([8])$, et la fragmentation en pentadiène-1,3 serait surtout le fait du mécanisme impliquant l'isomérisation du radical excité α-éthallyle.

Le bilan de la formation de tous les produits radicalaires est loin d'être complet. En particulier tous les produits de combinaison des radicaux en C_5 n'ont pas été mesurés. On peut cependant, sans démonstration élaborée, indiquer que le mécanisme ci-haut proposé est suffisant pour expliquer la formation de méthane, éthane et de propane en l'absence d'oxygène (voir résultats).

(*b*) *À 184,9 nm*

Le mécanisme discuté plus haut doit encore être valide. Cependant, l'énergie du photon est maintenant de 644 kJ Einstein^{-1}, on peut donc prévoir des fragmentations secondaires moins importantes et même, éventuellement, une stabilisation par collision de la molécule photoexcitée. Le tableau 1 montre la formation prépondérante du butadiène-1,3, avec encore un peu de pentadiène-1,3, mais de façon relativement beaucoup moins importante. Tout se passe comme si la diminution de l'énergie interne du radical α-éthallyle entraîne une diminution de l'importance de l'isomérisation et donc favorise sa stabilisation par collision.

Il faut ici relever la formation de méthyl-3-pentène-1. Celui-ci est tout probablement le résultat de la combinaison des radicaux méthyles et α-éthallyles:

[11*a*] $CH_3 + CH_3CH_2\dot{C}H\dot{C}H\dot{C}H_2 \rightarrow$ H3

[11*b*] $CH_3 + CH_3CH_2\dot{C}H\dot{C}H\dot{C}H_2 \rightarrow CH_3CH_2CH(CH_3)CH{=}CH_2$ (M3P1)

Le rapport des constantes de vitesse des réactions [11*a*] et [11*b*] n'est pas connu des auteurs. On peut cependant faire l'hypothèse que le rapport k_{11a}/k_{11b} est le même que celui observé lorsque le radical éthyle substitue le radical méthyle: soit k_{11a}/k_{11b} = 2,05 (15). On peut dès lors non seulement estimer le rendement des radicaux méthyles, mais encore celui des radicaux méthyles formés dans le processus primaire [2], $\Phi(CH_3')$, et ce à toute pression (tableau 1):

$$[B] \quad \Phi(CH_3') = 2\Phi(C_2H_6) + \Phi(C_3H_8) + 3{,}05\ \Phi(\mathrm{M3P1}) - \Phi(\mathrm{B13})$$

En effet, l'éthane est formé par la combinaison de deux radicaux méthyles, le propane et le méthyl-3-pentène-1 par celle d'un radical méthyle et d'un autre radical éthyle ou

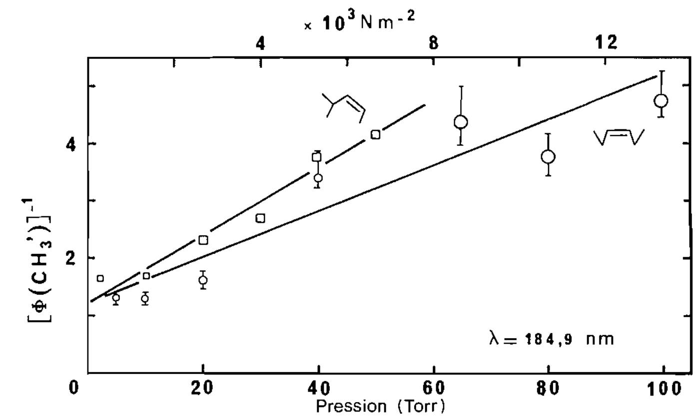

FIG. 5. Photolyse du *cis*-hexène-3 (○) et du méthyl-4-*cis*-pentène-2 (□) purs à 184,9 nm. Inverse du rendement quantique de la formation du radical méthyle primaire: formules [B] et [C]. L'incertitude expérimentale est représentée par une barre verticale.

α-éthallyle. Cependant, la formation de butadiène-1,3 libérant un second radical méthyle, il y a lieu de soustraire cette formation pour ne mesurer que le rendement de radicaux méthyles liés au processus primaire [2]. Les résultats de la relation [B] apparaissent dans le tableau 1. Traduits sous forme du mécanisme de Stern–Volmer, et ce malgré une incertitude expérimentale importante, ils permettent de mesurer ce rendement à pression nulle: $\Phi_0(CH_3') = 0{,}81_4\ (\pm 10\%)$ (fig. 5). Ainsi près de 80% de la molécule photoexcitée se fragmentent par rupture du lien β(C—C) à cette longueur d'onde.

Les autres produits apparaissant dans le tableau 1 ne demandent pas d'autres explications que celles déjà avancées à 147,0 nm. Tous ces résultats sont rassemblés dans le tableau 4. Ce dernier synthétise la photofragmentation de la molécule *cis*-hexène-3 photoexcitée.

*La photolyse du méthyl-4-*cis*-pentène-2 (M4cP2)*

(*a*) *À 147,0 nm*

A nouveau le mécanisme général de photofragmentation s'applique. On s'attend donc à obtenir principalement du pentadiène-1,3 (fig. 3): Φ_0 (pentadiène-1,3) = 0,47.

[12] $CH_3CH(CH_3)CH{=}CHCH_3 + h\nu \rightarrow CH_3CH(CH_3)\dot{C}H{=}CHCH_3^{**}$ (M4*c*P2**)

[13] M4*c*P2** $\rightarrow CH_3 + CH_3\dot{C}H\dot{C}H\dot{C}HCH_3^{*}$

[e]Le rendement total des réactions primaires de fragmentation est au moins égal, sinon supérieur, aux valeurs indiquées puisque celles-ci sont, en partie, déterminées par rapport aux rendements des réactions secondaires de fragmentation.

réactions suivies des réactions [5*a*] et [5*b*].

Il faut tout de suite ajouter que le butadiène-1,3 présente lui aussi un comportement de type Stern–Volmer avec un rendement à pression nulle fort appréciable: Φ_0(butadiène-1,3) = 0,16! Ici, la seule voie simple pour sa formation réside dans l'isomérisation du radical α,γ-diméthallyle vers la structure α-éthallyle.

La fragmentation primaire d'une liaison C—C située en position α par rapport à la double liaison conduit aux réactions suivantes:

[14] $M4cP2^{**} \rightarrow CH_3CH(CH_3)CH{=}\dot{C}H^{*} + CH_3$

[15*a*] $CH_3CH(CH_3)CH{=}\dot{C}H^{*} \rightarrow i\text{-}C_3H_7 + CH{\equiv}CH$

[15*b*] $CH_3CH(CH_3)CH{=}\dot{C}H^{*} \rightarrow CH_3\dot{C}(CH_3)\dot{C}H\dot{C}H_2^{*}$

[16] $CH_3\dot{C}(CH_3)\dot{C}H\dot{C}H^{*} \rightarrow H + CH_2{=}C(CH_3)CH{=}CH_2$

[17] $M4cP2^{**} \rightarrow i\text{-}C_3H_7^{*} + \dot{C}H{=}CHCH_3^{*}$

[18] $i\text{-}C_3H_7^{*} \rightarrow C_3H_6 + H$

[19] $\dot{C}H{=}CHCH_3^{*} \rightarrow CH_3 + CH{\equiv}CH$

réactions suivies ou en parallèles avec les réactions de stabilisation habituelles. Les formations d'acétylène et de propène sont aisément expliquées. Il faut ajouter que les produits moléculaires issus de la fragmentation de radicaux excités vinyliques ont des rendements quantiques peu sensibles à l'effet de pression. La formation d'isoprène est un peu plus complexe (fig. 4). L'isomérisation (transfert interne 1,3 d'une atome d'hydrogène) du radical méthyl-3-butènyl-1 vers la structure α,α-diméthallyle (16) est probablement assez facile étant donné la position tertiaire et allylique de l'atome d'hydrogène déplacé.[2] Finalement, les ruptures primaires de liens α(C—H) permettent d'expliquer les formations de

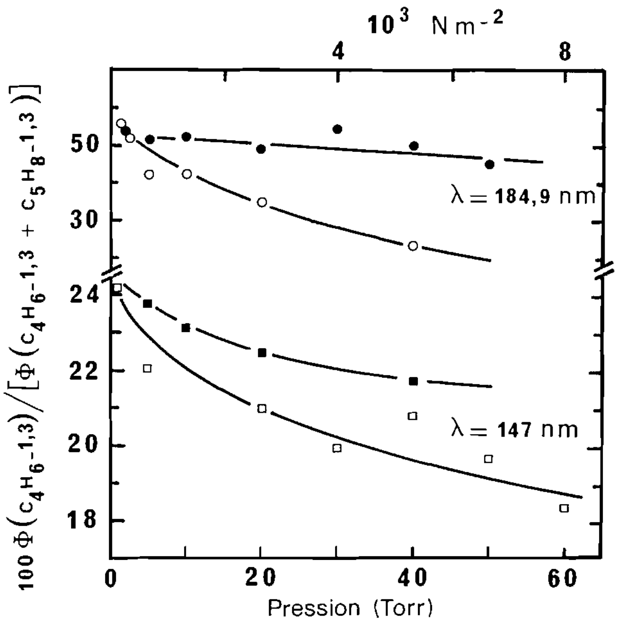

FIG. 6. Photolyse du méthyl-4-*cis*-pentène-2. Variation du rapport $\Phi(C_4H_6\text{-}1,3)/[\Phi(C_4H_6\text{-}1,3) + \Phi(C_5H_8\text{-}1,3)]$ en fonction de la pression du monomère en l'absence (■, ●) ou en présence de 10% d'oxygène (□, ○).

propyne, pentadiène-2,3 et méthyl-3-butyne-1 (tableau 2).

[20] $M4cP2^{**} \rightarrow H + CH_3CH(CH_3)CH{=}\dot{C}CH_3^{*}$

[21] $CH_3CH(CH_3)CH{=}\dot{C}CH_3^{*} \rightarrow i\text{-}C_3H_7 + CH_3C{\equiv}CH$

[22] $M4cP2^{**} \rightarrow H + CH_3CH(CH_3)\dot{C}{=}CHCH_3^{*}$

[23*a*] $CH_3CH(CH_3)\dot{C}{=}CHCH_3^{*} \rightarrow CH_3 + CH_3CH{=}C{=}CHCH_3$

[23*b*] $CH_3CH(CH_3)\dot{C}{=}CHCH_3^{*} \rightarrow CH_3CH(CH_3)C{\equiv}CH + CH_3$

Pour compléter ce mécanisme, il faudrait aussi proposer les réactions de ruptures primaires impliquant les liaisons β(C—H). Sans entrer dans le détail, ces réactions pourraient

[2]Ici, il faut mentionner que l'isomérisation du radical méthyl-3-butène-1-yl-1 vers la forme méthyl-2-butène-3-yl-1 a été observée (17*a*) et que cette dernière forme semble en équilibre avec le radical pentène-4-yl-1 (17*b*).

TABLEAU 5. Photofragmentation du méthyl-4-*cis*-pentène-2[a]

[d]Voir note *e*; tableau 2.

ajouter un peu de pentadiène-1,3 et de méthyl-3-pentadiène-1,3 (ce dernier produit n'ayant pas été mesuré).

(b) *À 184,9 nm*

Les résultats apparaissant dans le tableau 3 montrent encore la prépondérance du rendement en pentadiène: Φ_0(pentadiène-1,3) = 0,26. Cependant, par rapport aux rendements observés à 147,0 nm, le rendement en butadiène-1,3 a gagné de l'importance: Φ_0(butadiène-1,3) = 0,15$_4$. Quant aux autres réactions de fragmentation primaires, elles ne sont guère observables si ce n'est à travers la formation de quantités mineures de propène et de propyne.

De la même manière, les produits radicalaires (ceux dont la formation est inhibée par la présence d'oxygène) permettent d'évaluer qualitativement la présence de radicaux méthyles (formation de l'éthane) et isopropyles (formation d'isobutane). Malheureusement, la combinaison des radicaux méthyles et α,γ-diméthallyles reforme le monomère et celle impliquant les radicaux méthyles et α-éthallyles n'ont pu être mesurés. Il est dès lors hasardeux de vouloir établir le rendement quantique de formation des radicaux méthyles issus de la réaction de fragmentation primaire, réaction [13], puisque la relation suivante est incomplète:

$$[C] \quad \Phi(CH_3^{\cdot}) \geq 2\Phi(C_2H_6) + \Phi(\text{iso-}C_4H_{10}) - \Phi(\text{butadiène-1,3})$$

Cette relation donne une valeur minimum au rendement $\phi([13])$: $\phi([13]) \geq 0,60$ et son extrapolation à pression nulle attribue une valeur $\Phi_0(CH_3^{\cdot}) \simeq 0,79$ (tableau 3 et fig. 5).

L'isomérisation des radicaux α-éthallyles et α,γ-diméthallyles

Le tableau 4 montre, à partir des rendements de produits à pression nulle, que l'isomérisation (réaction [4]) est importante à 147,0 nm puisque le rapport Φ_0(pentadiène-1,3)/-Φ_0(butadiène-1,3) ≃ 0,24 et négligeable à 184,9 nm. Par contre, tableau 5, le rapport similaire est nettement plus important à 184,9 nm dans le cas du méthyl-pentène: Φ_0(butadiène-1,3)/Φ_0(pentadiène-1,3) = 0,59 à cette longueur d'onde comparativement à 0,34 à 147,0 nm (fig. 6). Cette dernière observation est, au prime abord, en désaccord avec la diminution d'énergie disponible lorsque la longueur d'onde croît entre 147,0 et 184,9 nm. On peut cependant proposer une explication simple pour cet apparent désaccord. On peut en effet admettre que, quelle que soit la longueur d'onde, le processus limitant n'est pas le processus primaire. En effet en tenant compte de l'énergie interne disponible à la température ordinaire, environ 658 kJ mol^{-1} sont disponibles, c'est-à-dire beaucoup plus que les 295 kJ mol^{-1} requis pour la rupture primaire. A 184,9 nm il ne reste donc qu'un maximum de 360 kJ mol^{-1} pour la fragmentation secondaire ou pour l'isomérisation.

La fragmentation du radical α-éthallyle (réaction [3*a*]) implique la rupture d'un lien β(C—C) tandis que celle du radical α,γ-diméthallyle (réaction [5*a*]) demande celle d'un lien β(C—H). Par conséquent, on peut admettre que l'énergie d'activation du processus [5*a*] est supérieure à celle du processus [3*a*]. Il s'ensuit que l'apparent équilibre observé ici en faveur de la formation du butadiène-1,3 est gouverné non pas par l'équilibre entre les deux formes radicalaires, mais plutôt par la facilité relative de chacun des deux radicaux à se fragmenter. La réaction [5a] est plus endothermique que la réaction [3a] de quelque 59 kJ mol^{-1}. La réaction [$-3a$] a une énergie d'activation d'environ 9 à 15 kJ mol^{-1} tandis que celle de la réaction [$-5a$] est de l'ordre de 5 kJ mol^{-1} (18). En tenant compte des facteurs de fréquence, encore à l'avantage de la réaction [3a], cette différence est insuffisante pour faire en sorte que la constante de vitesse de la réaction [5a] soit aussi rapide que celle de la réaction [3a].

Remerciements

Nous voulons exprimer nos remerciements et notre gratitude au Conseil de recherches en sciences naturelles et en génie du Canada et au Fonds pour la Formation de chercheurs et d'actions concertées du Québec pour l'aide accordée tout au long de ce travail.

Utilization of thiocarbonyl transfer reagents. Preparation of thioamides, mercapto esters, and thiapyran derivatives[1]

David N. Harpp,[2] J. Gavin MacDonald, and Charles Larsen[3]
Department of Chemistry, McGill University, Montreal, P.Q., Canada H3A 2K6

Received July 9, 1984

David N. Harpp, J. Gavin MacDonald, and Charles Larsen. Can. J. Chem. **63**, 951 (1985).

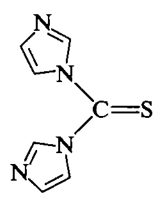
The reaction of 1,1′-thiocarbonyldiimidazole and 1,1′-thiocarbonylbis(1,2,4-triazole) with several aldonitrones has been found to afford thioamides in good yield. Several 1,1′-thiocarbonylbisazoles, which have been shown to undergo Diels–Alder additions with dienes to give cyclic and bicyclic adducts, can be further converted to mercapto esters, thiapyrans, and thiapyranones in good yield.

David N. Harpp, J. Gavin MacDonald et Charles Larsen. Can. J. Chem. **63**, 951 (1985).

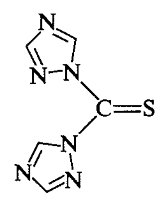
On a trouvé que la réaction du thiocarbonyl-1,1′ diimidazole ou du thiocarbonyl-1,1′ bis(triazole-1,2,4) avec plusieurs aldonitrones conduit aux thioacétamides, avec de bons rendements. Il est bien connu que plusieurs thiocarbonyl-1,1′ bisazoles peuvent subir des réactions de Diels–Alder, par additions de diènes, pour conduire à des adduits cycliques et bicycliques; on démontre que l'on peut transformer ces hétérocycles en mercapto esters, thiapyrannes et thiapyrones, avec de bons rendements.

[Traduit par le journal]

In recent years, heterocyclic thiocarbonyl transfer reagents (1) have found several important applications in the synthesis of new compounds (2). For instance, both 1,1′-thiocarbonyldiimidazole (**1**) and -1,2,4-triazole (**2**) react with various nucleophiles in a selective fashion, permitting the facile synthesis of unsymmetrically substituted thioureas and related compounds (3). They have also been used in a stereospecific olefin synthesis from 1,2-diols (4), and in the configurational assignment of olefins, diols, and epoxides (5).



1



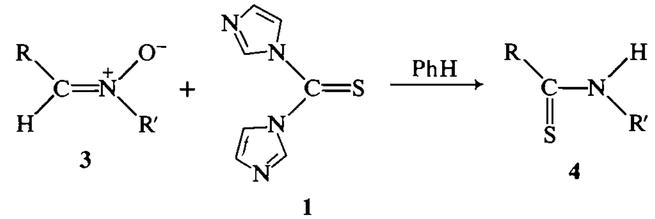
2

Our interest in utilizing thiocarbonyl transfer reagents in organic synthesis (5) is focused on the cycloaddition reactions of these systems with various nitrones and dienes. In this paper we wish to describe the preparation of thioamides (for a preliminary report, see ref. 6) from the reaction of aldonitrones with thiocarbonyl transfer reagents and to extend earlier work on the Diels–Alder adducts of these thiocarbonylazoles to the synthesis of thiapyrans, thiapyranones, and mercapto esters (7).

Results and discussion

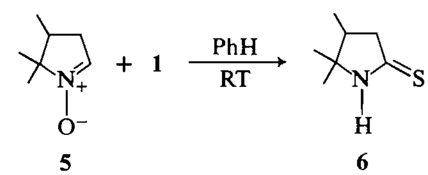
Although there are several methods in the literature for the preparation of thiocarbonyl transfer reagents, we have found that the trimethylsilylazoles offered the greatest potential for the one-pot synthesis of 1,1′-thiocarbonylbisazoles in excellent yields (3).

Treatment of a variety of nitrones (**3**) with 1,1′-thiocarbonyldiimidazole (**1**) or triazole derivative (**2**) in refluxing benzene provides thioamides (**4**) in good overall isolated yield (Table



1). The formation of **4** can be postulated[4] to arise by an initial 1,3-dipolar cycloaddition of the nitrone followed by elimination of 1,1′-carbonyldiimidazole.

It was found that treatment of 4,5,5-trimethyl-Δ′-pyrroline-1-oxide (**5**) with 1,1′-thiocarbonyldiimidazole (**1**) in benzene at room temperature gave 4,5,5-trimethylpyrroline-2-thione (**6**) in high yield.



The solvent polarity did not have an appreciable effect as reaction with benzene, chlorobenzene, or ethyl acetate all gave the product in similar yield. The presence of a trace amount of pyridine in the reaction mixture cut the reaction time in half (8 to 4 h) with no significant change in yield. It is likely that the base (B) assists in the elimination step (eq. [1]).

[4] To substantiate this, we found that benzonitrile oxide reacted with **2** to give the cycloadduct as a stable, white, crystalline product (see Experimental).

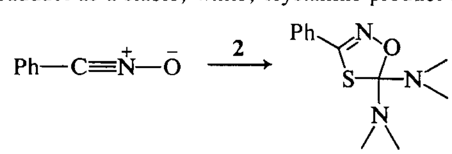

TABLE 1. Reaction of nitrones ($\mathrm{RHC{=}\overset{+}{N}(\overset{-}{O})R'}$) with **1** to give thioamides

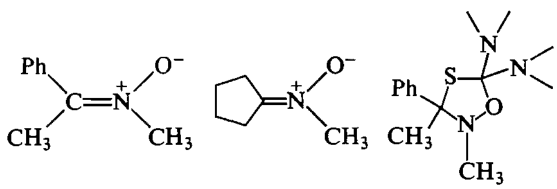
Product	R	R′	Isolated yield (%) of thioamide
4*a*	Ph	Me	75
4*b*		Me	68
4*c*		Me	67
4*d*	Ph	—CH_2Ph	70

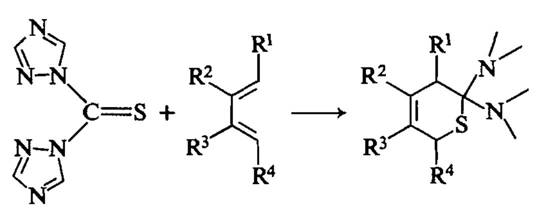
Reaction of thiocarbonylazole (**1**) with ketonitrones **7***a* and **7***b* in refluxing benzene gave no thioamide, with only starting material being recovered even after 3 days. Possibly some cycloadduct **8** is formed but there is no hydrogen on the ketonitrone carbon so the elimination step cannot take place as suggested for the aldonitrones in eq. [1]. The possibility that thioamide formation is light induced (8) was eliminated when **6** was formed in a dark reaction.



7*a* **7***b* **8**

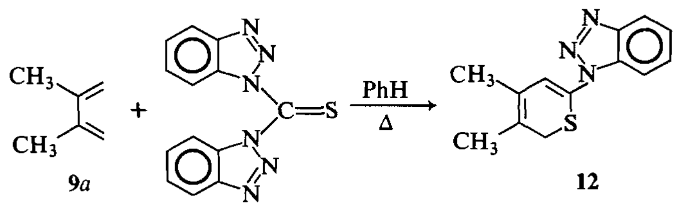
Examples of cycloaddition reactions between nitrones and thiocarbonyl compounds are not common (8, 9). Cyclic aldonitrones are reported to be converted to the related thiolactams by refluxing in carbon disulfide (10); however, noncyclic nitrones are instead isomerized by this method[5] (11). Reaction of *C*-phenyl-*N*-methylnitrone (**3***a*) with thiophosgene at room temperature in benzene gave only *N*-methylbenzamide, providing an interesting contrast with the related thiocarbonylazoles.

In addition to nitrone cycloadditions, the Diels–Alder reactions of thiocarbonyl transfer reagents with reactive dienes can be of broad utility in the construction of functionalized ring systems (7). Accordingly, we examined the [4 + 2] cycloaddition reaction of several thiocarbonylbisazoles with 2,3-dimethyl-1,3-butadiene (**9***a*) and 1,4-diphenyl-1,3-butadiene (**9***b*).



9*a*; R^1, R^4 = H; R^2, R^3 = CH_3 **10***a*
9*b*; R^1, R^4 = Ph; R^2, R^3 = H **10***b*

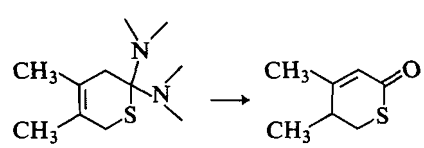
Treatment of 1,1′-thiocarbonylbis(1,2,4-triazole) (**2**) with 2,3-dimethyl-1,3-butadiene (**9***a*) in methylene chloride at room temperature for 10 h gave a nearly quantitative yield (98%) of 3,4-dimethyl-6,6-bis(1,2,4-triazol-1-yl)-5,6-dihydro-2*H*-thiopyran (**10***a*). Similarly, reaction of 1,4-diphenyl-1,3-butadiene (**9***b*) with the thiocarbonylbisazole (**2**) in refluxing benzene gave the corresponding dihydrothiapyran (**10***b*) in good yield. The cycloadducts of these thiocarbonylazoles are crystalline and moisture stable. This contrasts with the adducts formed by the parent thiophosgene (12), which tend to be unstable and must be stored in the cold. Interestingly, treatment of 2,3-dimethyl-1,3-butadiene (**9***a*) with 1,1′-thiocarbonyldibenzotriazole (**11**) in refluxing benzene for 8 h gave 3,4-dimethyl-6-(benzotriazol-1-yl)-2*H*-thiapyran (**12**). It is proposed that the cycloadduct is formed, which then eliminates one of the benzotriazole groups under the reaction conditions. In contrast to this, we found that similar reaction of butadiene (**9***a*) with 1,1′-thiocarbonyldibenzimidazole did not yield any product; only starting materials were isolated even after prolonged reflux.



9*a* **11** **12**

Several reviews of the Diels–Alder reaction involving thiocarbonyl dienophiles have been published (13) and illustrate that thiocarbonyl groups of all kinds are highly reactive as dienophiles, much more so than the corresponding carbonyl compound. Thioketones are effective dienophiles and add to most dienes in high yield at exceptionally low temperatures to afford stable adducts (14). The few reports on the regiochemical selectivity of thioketone additions to unsymmetrical dienes indicate that mixtures are obtained (15). *In situ* thioaldehydes also undergo Diels–Alder additions to dienes to yield stable thiapyran ring systems (7*b*, 16).

The chemistry of cycloadducts **10***a* and **10***b* has been investigated. The behavior of **10***a* and **10***b* under solvolytic conditions was found to be quite interesting. Refluxing dihydrothiapyran **10***a* in dilute hydrochloric acid for 1 h provided 3,4-dimethyl-3-hydro-2*H*-thiapyran-6-one (**13**) in high yield (80%). The structure of **13** was assigned on the basis of its physical and spectral data.



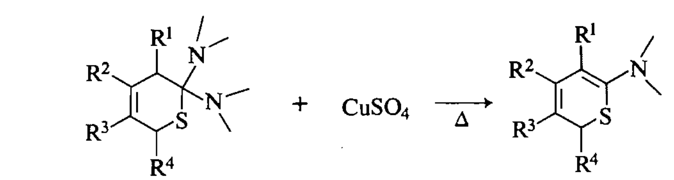
10*a* **13**

The formation of the thiapyranone presumably proceeds by way of acid-catalyzed elimination of the triazole groups with subsequent formation of the more stable conjugated enone system.

We have also observed that these dihydrothiapyran systems **10***a* and **10***b*, on treatment with cupric sulfate (0.5 equivalent) in a refluxing methanol–water mixture (4:1) for 1 h, gave the corresponding thiapyrans (**14**) in high yield.

Other cupric and cuprous salts (e.g. Cu^I I and Cu^{II} Cl_2) were also found to promote the elimination of one of the triazole groups under similar conditions. The copper cation was dem-

[5] Aldonitrones are known to rearrange to the isomeric amides by treatment with a variety of reagents such as phosgene, SO_2, PCl_3, and acetyl chloride.



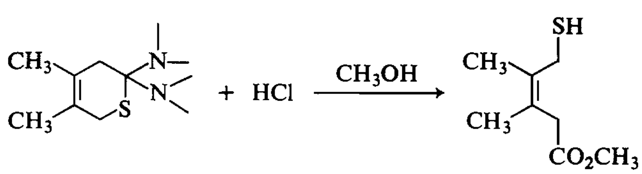
10*a*; R^1, R^4 = H; R^2, R^3 = CH_3 **14***a*
10*b*; R^1, R^4 = Ph; R^2, R^3 = H **14***b*

onstrated to be the active agent, as only starting material was recovered when ammonium sulfate was used, even after prolonged reflux. The copper ion is thought to complex with the triazole groups, thus assisting the elimination. While copper salts are well known to accelerate Diels–Alder additions (17), reports of copper-assisted eliminations do not appear to be common.

Treatment of 3,4-dimethyl-6,6-bis(1,2,4-triazol-1-yl)-5,6-dihydro-2*H*-thiapyran (**10***a*) or 2,5-diphenyl-6,6-bis(1,2,4-triazol-1-yl)-5,6-dihydro-2*H*-thiapyran (**10***b*) with methyl iodide in refluxing acetonitrile was also found to give the corresponding thiapyran (**14***a* or **14***b*) in high yield. The structure of the products was unambiguously confirmed by their physical and spectral data. Methyl iodide is thought to alkylate one of the triazole groups and thus activating it towards elimination under the solvolysis conditions.

Thiapyran (**14***a*) was also formed in high yield (95%) when 3,4-dimethyl-6,6-bis(1,2,4-triazol-1-yl)-5,6-dihydro-2*H*-thiapyran (**10***a*) was heated at reflux in a methanol solution containing one equivalent of phenol; presumably, phenol promotes the elimination of a triazole group by acid catalysis.

The solvolysis of these dihydrothiapyran systems in alcoholic solvents was found to depend on the acid concentration as well as the ratio of alcohol to water. Thus treatment of dihydrothiapyran **10***a* in refluxing methanol with dry HCl for 1 h gave the mercapto ester **15** in good yield[6] (18). In contrast, similar reaction of the dihydrothiapyran **10***a* in a 10:1 methanol–

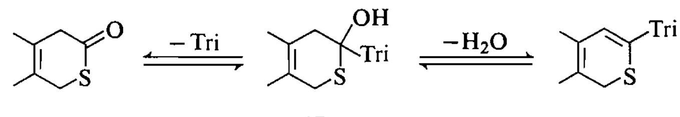


10*a* **15**

water mixture at reflux containing a small amount of acid gave a mixture of 3,4-dimethyl-6-(1,2,4-triazol-1-yl)-2*H*-thiapyran (**14***a*, 80%) and 3,4-dimethyl-5-hydro-2*H*-thiapyran-6-one

	14*a*	**16***a*
Ratio, 10:1	80%	10%
4:1	60%	33%

[6] Acyclic mercapto carboxylic acids have also been prepared by lithium/ammonia reduction of 2-thiophenecarboxylic acid.

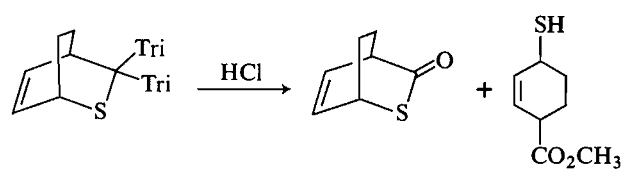


17

Tri = $C_2H_2N_3$

(**16***a*, 10%); this was easily separated by silica gel chromatography. Increasing the water concentration to a 4:1 mixture of methanol–water was found to increase the yield of the thiapyranone (**16***a*, 33%) at the expense of the thiapyran (**14***a*, 60%). As a working hypothesis, we propose that the mechanism involves competition between elimination of the second triazole group and dehydration of the intermediate[7] (17). Earlier studies also showed that product distribution was a function of alcohol used (7).

We also investigated the chemistry of the bicycloadduct (**18**) obtained from reaction of 1,3-cyclohexadiene with 1,1′-thiocarbonyl-bis(1,2,4-triazole) **2**. Treatment of **18** with an acidic methanol–water mixture (4:1) under reflux for 1 h gave a mixture of 2-thiabicyclo[2,2,2]oct-5-ene-3-one (**19**, 56%) and methyl 4-mercapto-2-cyclohexenecarboxylate (7) (**20**, 38%); these compounds were easily separated and characterized. In contrast, only the mercapto ester **20** was isolated in good yield when **18** was treated with cupric sulfate (0.25 equivalent) in a refluxing methanol–water mixture for 1 h. The observed difference in solvolysis between the bicyclic and cyclic systems is probably due to release of strain in the bicyclic case.



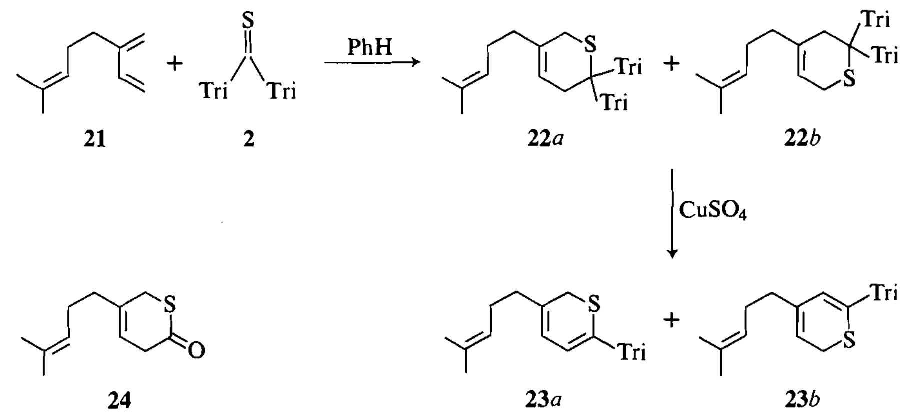
18 **19** **20**

We decided to further explore this copper-ion assisted solvolysis for the preparation of pure thiapyrans. A sample of myrcene (**21**) was reacted with 1,1′-thiocarbonylbis(1,2,4-triazole) (**2**) in refluxing benzene for 1 h to provide a mixture of the two isomeric cycloadducts **22***a*, *b* in high yield. Treatment of these dihydropyrans **22** with copper sulfate in a 4:1 methanol–water mixture at reflux for 1 h gave only the corresponding thiapyrans **23**[8] in good yield. It is interesting to note that similar treatment of **22** with an acidic methanol–water mixture (4:1) gave both thiapyrans **23** and thiapyranones **24**, as products. Thus, copper sulfate does appear to be a selective and general reagent for the preparation of thiapyrans from bis-triazole dihydrothiapyrans.

In summary, we have found that thiocarbonyl transfer reagents undergo ready cycloaddition with a variety of systems in synthetically useful yield. The cycloadducts of these reagents with dienes have been shown to undergo further reaction to

[7] Thiapyran **14***a* was shown not to be a precursor of thiapyranone **16***a* when a sample of **14***a* was refluxed in an acidic methanol–water mixture (4:1) for 4 h to yield only recovered starting material.

[8] We questioned whether thiapyran **23** might undergo internal Diels–Alder cycloaddition. Heating a benzene solution of **23** in a sealed tube at 180°C failed to yield any internal cycloadducts even after prolonged thermolysis; only slow decomposition was observed. Cycloaddition with maleic anhydride under similar conditions was also unsuccessful. This is likely due to the non-planarity of the thiapyran ring system.



give thiapyrans, thiapyranones, and mercapto esters under appropriate conditions. Further applications of the cycloaddition reactions of these compounds in organic sysnthesis are currently under investigation.

Experimental

All melting points and boiling points are uncorrected. Elemental analyses were performed by Guelph Chemical Laboratories Ltd., Guelph, Ontario. The infrared spectra were determined on a Perkin–Elmer 580 infrared spectrophotometer. The proton magnetic resonance spectra were determined at 60 MHz with a Varian Associates T-60A spectrometer. Mass spectra were obtained on a Du Pont 21-492B mass spectrometer, using a direct insertion probe. Apart from nitrones **3***d*(19), **5**(20), and **7***b*(21) all the others were easily prepared in high yield (ca. 98%) from the corresponding aldehyde or ketone with *N*-methylhydroxylamine hydrochloride in the presence of sodium acetate in ethanol at room temperature. All gave satisfactory physical and spectral data.

Reaction of C-*phenyl*-N-*methylnitrone (***3***a) with 1,1′-thiocarbonyldiimidazole (***1***)*

A mixture of 0.90 g (6.6 mmol) of *C*-phenyl-*N*-methylnitrone and 1.18 g (6.6 mmol) of 1,1′-thiocarbonyldiimidazole in 40 mL of dry benzene was heated at reflux under a nitrogen atmosphere for 8 h. The solvent was then removed under reduced pressure and the crude residue subjected to silica gel chromatography with a 50% ethyl acetate – hexane mixture as eluent. The major fraction isolated was a pale yellow crystalline solid (0.75 g, 75%) whose structure was assigned as *N*-methylthiobenzamide (**4***a*) on the basis of the following data: mp 79–80°C (lit. (22) mp 79–80°C); ir (Nujol): 3300, 1590, 1350, 1230, 1035, 1020, 992, 934, 914, and 765 cm^{-1}; nmr ($CDCl_3$) δ: 3.22 (d, 3H) and 7.7–7.2 (m, 6H); ms, *m/e*: 151 (M^+), 136, 121, and 77. *Anal.* calcd. for C_8H_9NS: C 63.54, H 6.00, N 9.26; found: C 63.62, H 5.99, N 9.12.

Reaction of C-*(2-furyl)*-N-*methylnitrone (***3***b) with 1,1′-thiocarbonyldiimidazole (***1***)*

A mixture of 0.50 g (3.9 mmol) of *C*-(2-furyl)-*N*-methylnitrone and 0.69 g (3.9 mmol) of 1,1′-thiocarbonyldiimidazole in 40 mL of dry benzene was heated at reflux under a nitrogen atmosphere for 8 h. The solvent was then removed under reduced pressure and the crude residue subjected to silica gel chromatography with a 50% ethyl acetate – hexane mixture as eluent. The major fraction isolated was a pale yellow crystalline solid (0.38 g, 68%) whose structure was assigned as *N*-methyl-2-thiofuramide (**4***b*) on the basis of the following data: mp 70–71°C (lit. (23) mp 71°C); ir (Nujol): 3220, 1580, 1510, 1330, 1275, 1157, 1031, 1010, 955, 865, 825, 745, and 700 cm^{-1}; nmr ($CDCl_3$) δ: 3.30 (d, 3H), 6.42 (m, 1H), and 7.33 (m, 2H); ms, *m/e*: 141 (M^+), 124, 111, 100. *Anal.* calcd. for C_6H_7NOS: C 51.04, H 4.99, N 9.92; found: C 51.00, H 4.93, N 9.84.

Reaction of C-*cyclohexyl*-N-*methylnitrone (***3***c) with 1,1′-thiocarbonyldiimidazole (***1***)*

A mixture of 2.55 g (18 mmol) of *C*-cyclohexyl-*N*-methylnitrone and 3.19 g (18 mmol) of 1,1′-thiocarbonyldiimidazole in 40 mL of dry benzene was heated at reflux under a nitrogen atmosphere for 8 h. The solvent was then removed under reduced pressure and the crude residue subjected to silica gel chromatography with a 50% ethyl acetate – hexane mixture as eluent. The major fraction isolated was a pale yellow crystalline solid (1.89 g, 67%) whose structure was assigned as *N*-methylthiocyclohexylamide (**4***c*) on the basis of the following data: mp 66–67°C; ir (Nujol): 3300, 1535, 1335, 1290, 1205, 1105, 1020, 975, 884, 843, 804, and 714 cm^{-1}; nmr ($CDCl_3$) δ: 1.3–2.0 (m, 11H) and 3.20 (d, 3H); ms, *m/e*: 157 (M^+), 142, 124, and 102. *Anal.* calcd. for $C_8H_{15}NS$: C 61.09, H 9.61, N 8.90; found: C 60.93, H 9.65, N 8.75.

Reaction of C-*phenyl*-N-*benzylnitrone (***3***d) with 1,1′-thiocarbonyldiimidazole (***1***)*

A mixture of 2.38 g (17 mmol) of *C*-phenyl-*N*-benzylnitrone and 3.0 g (17 mmol) 1,1′-thiocarbonyldiimidazole in 40 mL of dry benzene was heated at reflux under a nitrogen atmosphere for 8 h. The solvent was then removed under reduced pressure and the crude residue subjected to silica gel chromatography with a 60% ethyl acetate – hexane mixture as eluent. The major fraction isolated was a pale yellow crystalline solid (2.7 g, 70%) whose structure was assigned as *N*-(phenylmethylene)-benzenecarbothioamide (**4***d*) on the basis of the following data: mp 82–83°C; ir (Nujol): 3300, 3075, 3060, 3025, 1617, 1510, 1320, 1280, 1200, 1058, 1025, 916, 900, 760, and 740 cm^{-1}; nmr ($CDCl_3$) δ: 4.95 (d, 2H) and 7.0–7.8 (m, 10H); ms, *m/e*: 227 (M^+), 195, 165, 103, and 91; *Anal.* calcd. for $C_{14}H_{13}NS$: C 73.97, H 5.76, N 6.16; found: C 74.02, H 5.70, N 6.11.

*Reaction of 4,5,5-trimethyl-Δ′-pyrroline-1-oxide (***5***) with 1,1′-thiocarbonyldiimidazole (***1***)*

A mixture of 0.300 g (2.4 mmol) of 4,5,5-trimethyl-Δ′-pyrroline-1-oxide and 0.420 g (2.4 mmol) of 1,1′-thiocarbonyldiimidazole in 20 mL of dry benzene was stirred at room temperature under a nitrogen atmosphere for 8 h. The solvent was then removed under reduced pressure and the crude residue subjected to silica gel chromatography with a 10% ethyl acetate – hexane mixture as eluent. The major fraction isolated was a pale yellow crystalline solid (0.285 g, 84%) whose structure was assigned as 4,5,5-trimethyl-pyrroline-2-thione (**6**) on the basis of the following data: mp 144–145°C; nmr ($CDCl_3$) δ: 1.00 (d, 3H), 1.15 (s, 3H), 1.30 (s, 3H), and 2.2–3.2 (m, 3H); ms, *m/e*: 143 (M^+), 128, 95, and 58. *Anal.* calcd. for $C_7H_{13}NS$: C 9.15, H 9.15, N 9.78; found: C 58.98, H 9.55, N 9.30.

*Reaction of 1,1′thiocarbonylbis(1,2,4-triazole) (***2***) with* C-*phenyl*-N-*methylnitrone (***3***a),* C-*(2-furyl)*-N-*methylnitrone (***3***b), and* C-*phenyl*-N-*benzylnitrone (***3***d)*

In a similar fashion to the above reactions, a mixture of 1.4 mmol of 1,1′-thiocarbonylbis(1,2,4-triazole) and 1.4 mmol of the corresponding nitrone in 30 mL of dry benzene was stirred at room temperature under a nitrogen atmosphere for 8 h. Work-up was similar to that described with the imidazole experiments. The thioamides produced were found to be identical in every respect to those obtained by the thiocarbonyldiimidazole route. The isolated yields were *N*-

methylthiobenzamide (**4***a*), 62%; *N*-methyl-2-thiofuramide (**4***b*), 58%; and *N*-(phenylmethylene)-benzenecarbothioamide (**4***d*), 60%.

Reaction of N-*methyl*-C-*phenylnitrone (3*a*) with thiophosgene*

To a stirred solution of 0.30 g (2.2 mmol) *N*-methyl-*C*-phenylnitrone in 10 mL of dry benzene at room temperature was slowly added 0.25 g of thiophosgene in 5 mL of dry benzene. The thiophosgene solution was observed to decolorize immediately on contact with the nitrone solution. The resultant mixture was stirred for 2 h, after which the solvent was removed under reduced pressure. The crude residue was subjected to silica gel chromatography with a 50% ethyl acetate – hexane mixture was eluent. The major fraction isolated was a colorless crystalline solid (0.22 g, 73%) whose structure was assigned as *N*-methylbenzamide on the basis of the following data and by comparison with an authentic sample: mp 77–78°C (lit (24) mp 80–81°C); nmr ($CDCl_3$) δ: 3.00 (d, 3H), 6.8 (br s, 1H), and 7.2–7.8 (m, 5H); ms, *m/e*: 135 (M^+), 105, and 77.

Reaction of 1,1′-thiocarbonylbis(1,2,4-triazole) (2) with benzonitrile oxide

To a stirred solution of 0.22 g (1.4 mmol) benzohydroximoyl chloride (25) and 0.20 g (1.1 mmol) of 1,1′-thiocarbonylbis(1,2,4-triazole) in 20 mL of dry methylene chloride at 0°C was slowly added 0.4 g of trimethylamine. After the mixture was stirred for 2 h it was filtered and the solvent was removed under reduced pressure. The resulting residue was purified by silica gel chromatography with a 50% ethyl acetate – hexane mixture to give 0.284 g (87%) of 5,5-bis(1,2,4-triazol-1-yl)-5-phenyl-1,4,2-oxathiazole: mp 120–121°C; ir (Nujol): 3090, 1280, 1190, 1130, 995, 840, 755, and 670 cm^{-1}; nmr ($CDCl_3$) δ: 7.3–7.6 (m, 5H), 8.12 (s, 2H), and 8.53 (s, 2H); ms, *m/e*: 299 (M^+), 231, and 77.

Reaction of 2,3-dimethyl-1,3-butadiene with 1,1′-thiocarbonylbis-(1,2,4-triazole) (2)

A mixture of **2** (1.8 g, 0.01 mol) and 0.8 g (0.01 mol) of 2,3-dimethyl-1,3-butadiene in dry methylene chloride (35 mL) was stirred at room temperature for 10 h. Removal of the solvent under reduced pressure gave faint pink crystals. The product was recrystallized from benzene (or a mixture of benzene and cyclohexane) to give a nearly colorless product (2.6 g, 98%) with a melting point of 121–122°C. The product was assigned the structure 3,4-dimethyl-6,6-bis(1,2,4-triazol-1-yl)-5,6-dihydro-2*H*-thiapyran **10***a* on the basis of the following data: ir (Nujol): 3100, 1340, 1260, 1175, 1124, 990, 932, 843, 760, and 635 cm^{-1}; nmr ($CDCl_3$) δ: 1.76 (s, 6H), 3.25 (s, 2H), 3.72 (s, 2H), 8.02 (s, 2H), and 8.58 (s, 2H); ms, *m/e*: 194, 193, 178, 124, and 69. *Anal.* calcd. for $C_{11}H_{14}N_6S$: C 50.35, H 5.38, N 32.04; found: C 50.30, H 5.35, N 32.00.

*Reaction of 1,4-diphenyl-1,3-butadiene (9*b*) with 1,1′-thiocarbonylbis(1,2,4-triazole) (2)*

A mixture of 1.80 g (0.01 mol) of **2** and 2.06 g (0.01 mol) of 1,4-diphenyl-1,3-butadiene (**9***b*) in 40 mL of benzene was refluxed for 12 h. Removal of the solvent under reduced pressure gave a pale brown crystalline solid. The product was recrystallized from benzene to yield 2.6 g (67%) of colorless product with a melting point of 196–197°C. The structure of the product was assigned as 2,5-diphenyl-6,6-bis(1,2,4-triazol-1-yl)-5,6-dihydro-2*H*-thiapyran (**10***b*) on the basis of the following data: ir (Nujol): 3100, 1340, 1270, 1176, 1125, 980, 815, 734, and 665 cm^{-1}; nmr ($CDCl_3$) δ: 4.55 (d, 1H), 5.40 (m, 1H), 6.10 (m, 2H), 7.27 (s, 5H), 7.47 (s, 5H), 7.68 (s, 2H), 8.13 (s, 1H), and 8.87 (s, 1H). *Anal.* calcd. for $C_{21}H_{18}N_6S$: C 65.26, H 4.69, N 21.75; found: C 65.10, H 4.28, N 21.45.

Reaction of 1,3-cyclohexadiene with 1,1′-thiocarbonylbis(1,2,4-triazole) (2)

A mixture of 1.8 g (0.01 mol) of **2** and 0.8 g (0.01 mol) of 1,3-cyclohexadiene was heated at reflux for 10 h. Removal of the solvent under reduced pressure gave an almost colorless product. The crude product was recrystallized from cyclohexane to give a colorless crystalline product (2.44 g, 94%) with a melting point of 113–114°C. The structure of the product was assigned as 3,3-bis(1,2,4-triazol-1-yl)-2-thiabicyclo[2.2.2]oct-5-ene (**18**) on the basis of the following data: ir (Nujol): 3095, 1270, 1175, 1130, 1000, 940, 882, 830, 722, and 658 cm^{-1}; nmr ($CDCl_3$) δ: 1.57 (m, 4H), 3.88 (m, 1H), 4.53 (m, 1H), 6.10 (m, 1H), 6.65 (m, 1H), 7.85 (s, 1H), 7.93 (s, 1H), 8.45 (s, 1H), and 8.70 (s, 1H); ms, *m/e*: 260 (M^+), 191, 122, and 69. *Anal.* calcd. for $C_{11}H_{12}N_6S$: C 50.75, H 4.65, N 32.29; found: C 50.65, H 4.66, N 32.33.

Reaction of 1,1′-thiocarbonyldibenzotriazole (11) with 2,3-dimethyl-1,3-butadiene

A mixture of 2.0 g (7.2 mmol) of **11** and 0.59 g (7.2 mmol) of 2,3-dimethyl-1,3-butadiene in 30 mL of dry benzene was heated at reflux for 8 h. The solvent was then removed under reduced pressure and the crude residue subjected to silica gel chromatography with a 50% ethyl acetate – hexane mixture as eluent. The major fraction isolated was a pale yellow crystalline solid (1.0 g, 60%) whose structure was assigned as 3,4-dimethyl-6-(benzotriazol-1-yl)-2*H*-thiapyran (**12**) on the basis of the following data: mp 88–89°C; ir (Nujol): 1610, 1590, 1530, 1285, 1214, 1170, 1050, 1000, 970, and 860 cm^{-1}; nmr ($CDCl_3$) δ: 1.94 (s, 6H), 3.52 (s, 2H), 6.50 (s, 1H), and 7.2–8.0 (m, 4H); ms, *m/e*: 243 (M^+), 214, and 125.

*Reaction of 3,4-dimethyl-6,6-bis(1,2,4-triazol-1-yl)-5,6-dihydro-2*H*-thiapyran (10*a*) in dilute hydrochloric acid*

A suspension of 0.2 g (0.76 mmol) of **10***a* in 15 mL of water containing 8 drops of concentrated HCl was heated at reflux for 1 h. The resultant clear yellow solution was poured into 60 mL of cold water and the mixture extracted with methylene chloride (2 × 50 mL). The combined organic extracts were washed with water (100 mL), dried ($MgSO_4$), and the solvent removed under reduced pressure to yield a yellow oil. The crude residue was subjected to silica gel chromatography with a 10% ethyl acetate – hexane mixture as eluent. The major fraction isolated was a light yellow oil (87 mg, 80%) whose structure was assigned as 3,4-dimethyl-3-hydro-2*H*-thiopyran-6-one (**13**) on the basis of the following data: bp 60°C at 0.01 Torr (Kugelrohr) (1 Torr = 133.3 Pa); ir (neat): 2970, 2930, 2880, 1644, 1624, 1450, 1432, 1372, 1307, 1200, 1176, 1125, 1100, 1024, 846, and 700 cm^{-1}; nmr ($CDCl_3$) δ: 1.41 (d, 3H), 2.02 (s, 3H), 2.90 (m, 2H), 3.62 (dd, 1H, J = 12, 4 Hz), and 5.92 (br s, 1H); ms, *m/e*: 142 (M^+), 114, 99, and 67.

*Reaction of 3,4-dimethyl-6,6-bis(1,2,4-triazol-1-yl)-5,6-dihydro-2*H*-thiapyran (10*a*) with cupric sulfate*

A suspension of 0.2 g (0.76 mmol) 3,4-dimethyl-6,6-bis(1,2,4-triazol-1-yl)-5,6-dihydro-2*H*-thiapyran and 0.1 g (0.40 mmol) cupric sulfate in 20 mL of a 4:1 mixture of methanol–water was heated at reflux for 1 h. The mixture was then poured into 100 mL of water and the solution extracted with CH_2Cl_2 (2 × 20 mL). The combined organic extracts were washed with water, dried ($MgSO_4$), and the solvent removed under reduced pressure to yield pale yellow crystals. The crude product was subjected to silica gel chromatography with a 50% ethyl acetate – hexane mixture as eluent. The major fraction isolated was a white crystalline solid (0.12 g, 82%) whose structure was assigned as 3,4-dimethyl-6-(1,2,4-triazol-1-yl)-2*H*-thiapyran (**14***a*) on the basis of the following data: mp 96–97°C; ir (Nujol): 3100, 1620, 1580, 1415, 1292, 1270, 1210, 1145, 1100, 1000, 952, 900, 875, and 830 cm^{-1}; nmr ($CDCl_3$) δ: 1.94 (br s, 6H), 3.46 (s, 2H), 6.67 (s, 1H), 8.01 (s, 1H), and 8.42 (s, 1H); ms, *m/e*: 193 (M^+), 178, 124, and 91.

*Reaction of 2,5-diphenyl-6,6-bis(1,2,4-triazol-1-yl)-5,6-dihydro-2*H*-thiapyran (10*b*) with cupric sulfate*

A suspension of 0.6 g (1.55 mmol) of **10***b* and 0.5 g (2.00 mmol) cupric sulfate in 20 mL of a 4:1 mixture of methanol–water was heated at reflux for 1 h. The reaction mixture was then poured into 100 mL of water and the solution extracted with methylene chloride (2 × 20 mL). The combined organic extracts were washed with water (100 mL), dried ($MgSO_4$), and the solvent removed under reduced pressure to yield a light yellow solid. The crude product was easily purified by silica gel chromatography with a 20% ethyl acetate – hexane mixture as eluent to give 0.42 g (85%) of a white crystalline solid. The structure of the product was assigned as 2,5-diphenyl-6-(1,2,4-triazol-1-yl)-2*H*-thiapyran (**14***b*) on the basis of the following data: mp 121–122°C; ir (Nujol): 3108, 3058, 1620, 1594, 1486, 1400, 1352, 1274, 1200, 1124, 990, 942, 876, and 865 cm^{-1}; nmr ($CDCl_3$) δ: 5.08 (d, 1H, J = 5 Hz), 6.00 (dd, 2H, J = 10, 5 Hz), 6.66 (d, 1H, J = 10 Hz), 7.1–7.4 (m, 10H), 7.67 (s, 1H), and 7.90 (s, 1H); ms, *m/e*: 317 (M^+), 249, 172, and 149.

*Reaction of 3,4-dimethyl-6,6-bis(1,2,4-triazol-1-yl)-5,6-dihydro-2*H*-thiapyran (10*a*) with methyl iodide*

A mixture of 0.10 g (0.4 mmol) of **10***a* and 0.20 g (1.5 mmol) of methyl iodide in 10 mL of dry acetonitrile was heated at reflux for 1 h. The solvent was then removed under reduced pressure and the crude residue subjected to silica gel chromatography with a 50% ethyl acetate – hexane mixture as eluent. The major fraction isolated was a white crystalline solid (0.06 g, 82%) whose structure was assigned as 3,4-dimethyl-6-(1,2,4-triazol-1-yl)-2*H*-thiapyran (**14***a*) as its physical and spectral data were identical to a sample of **14***a* obtained in the $CuSO_4$ reaction.

*Reaction of 2,5-diphenyl-6,6-bis(1,2,4-triazol-1-yl)-5,6-dihydro-2*H*-thiapyran (10b) with methyl iodide*

A mixture of 0.5 g (1.3 mmol) of **10***b* and 0.5 g (3.5 mmol) of methyl iodide in 20 mL of dry acetonitrile was heated at reflux for 1 h. The solvent was then removed under reduced pressure and the crude residue subjected to silica gel chromatography with a 50% ethyl acetate – hexane mixture as eluent. The major fraction isolated was a white crystalline solid (0.3 g, 73%) whose structure was assigned as 2,5-diphenyl-6-(1,2,4-triazol-1-yl)-2*H*-thiapyran (**14***b*) on the basis of the following data: mp 121–122°C; ir (Nujol): 3080, 3057, 3022, 1625, 1594, 1558, 1487, 1400, 1352, 1274, 1200, 1124, 980, 875, and 867 cm^{-1}; nmr ($CDCl_3$) δ: 5.08 (d, 1H, J = 5 Hz), 6.02 (dd, 1H, J = 10, 5 Hz), 6.67 (d, 1H, J = 10 Hz), 7.0–7.6 (m, 10H), 7.70 (s, 1H), and 7.94 (s, 1H); ms, *m/e*: 317 (M^+), 249, 172, and 149.

*Reaction of 3,4-dimethyl-6,6-bis(1,2,4-triazol-1-yl)-5,6-dihydro-2*H*-thiapyran (10a) with phenol*

A mixture of 0.2 g (0.7 mmol) of **10***a* and 0.07 g (0.7 mmol) of phenol in 20 mL of acetone was heated at reflux for 3 h. The solvent was then removed under reduced pressure and the crude residue subjected to silica gel chromatography with a 50% ethyl acetate – hexane mixture as eluent. The major fraction isolated was assigned as 3,4-dimethyl-6-(1,2,4-triazol-1-yl)-2*H*-thiapyran (**14***a*) as its physical (including undepressed mixture mp) and spectral data were identical to a sample of **14***a* obtained with the $CuSO_4$ reaction.

*Acidic hydrolysis of 3,4-dimethyl-6,6-bis(1,2,4-triazol-1-yl)-5,6-dihydro-2*H*-thiapyran (10a)*

(a) *HCl in dry methanol*

Dry HCl was bubbled through a solution of 0.2 g (0.76 mmol) **10***a* in methanol (15 mL) at reflux for 40 min. Reflux was continued for an additional 60 min. The solvent was then removed under reduced pressure to yield a yellow oil. The crude product was easily purified by silica gel chromatography with a 10% ethyl acetate – hexane mixture as eluent. The colorless oil (0.10 g, 76%) was assigned as methyl 3,4-dimethyl-5-mercapto-3-pentenecarboxylate (**15**) on the basis of the following data: ir (neat): 2950, 2861, 2540, 1720, 1460, 1270, 1200, 1165, 1014, and 780 cm^{-1}; nmr ($CDCl_3$) δ: 1.60 (br s, 1H), 1.95 (s, 6H), 3.00 (s, 2H), 3.50 (m, 2H), and 3.9 (s, 3H); ms, *m/e*: 174 (M^+), 173, 159, 141, and 114.

(b) *HCl in a 10:1 methanol–water mixture*

A solution of 0.200 g (0.76 mmol) of **10***a* in 15 mL of a 10:1 methanol–water mixture containing 6 drops of concentrated hydrochloric acid was heated at reflux for 1 h. The cooled solution was poured into 50 mL of water and the mixture extracted with methylene chloride (2 × 20 mL). The combined organic extracts were washed with water (50 mL), dried ($MgSO_4$), and the solvent removed under reduced pressure. The crude residue was shown by tlc to contain two products which were easily separated and purified by silica gel chromatography with a 10% ethyl acetate – hexane mixture as eluent. The first fraction isolated was a colorless crystalline solid (120 mg, 80%) whose structure was assigned as 3,4-dimethyl-6-(1,2,4-triazol-1-yl)-2*H*-thiapyran (**14***a*) on the basis of the following data: mp 96–97°C; ir (Nujol): 3100, 1620, 1580, 1415, 1292, 1270, 1210, 1145, 1100, 1000, 952, 900, 875, and 830 cm^{-1}; nmr ($CDCl_3$) δ: 1.94 (br s, 6H), 3.46 (s, 2H), 6.67 (s, 1H), 8.01 (s, 1H), and 8.42 (s, 1H); ms, *m/e*: 193 (M^+), 178, 124, and 91.

The second fraction isolated was a colorless oil (10 mg, 10%) whose structure was assigned as 3,4-dimethyl-5-hydro-2*H*-thiopyran-6-one (**16***a*) on the basis of the following data: bp 68–70°C at 0.01 Torr (Kugelrohr); ir (neat): 2910, 2855, 1672, 1430, 1213, 1141, 1104, 1040, 903, and 742 cm^{-1}; nmr ($CDCl_3$) δ: 1.93 (s, 6H), 3.19 (s, 2H), and 3.63 (s, 2H); ms, *m/e*: 142 (M^+), 99, 82, and 67.

(c) *HCl in a 4:1 methanol–water mixture*

The above experiment was repeated; however, this time a 4:1 methanol–water mixture was used as solvent. Work-up as described gave 90 mg (60%) 3,4-dimethyl-6-(1,2,4-triazol-1-yl)-2*H*-thiapyran (**14***a*) and 35 mg (33%) 3,4-dimethyl-5-hydro-2*H*-thiapyran-6-one (**16***a*). The physical and spectral properties were identical to those described earlier.

Acidic hydrolysis of 3,3-bis(1,2,4-triazol-1-yl)-2-thiabicyclo[2.2.2]-oct-5-ene (18)

To a solution of 0.2 g (0.76 mmol) of **18** in 10 mL of a 4:1 mixture of methanol–water was added 3 drops concentrated HCl and the mixture heated at reflux for 3 h. The resultant solution was poured into 60 mL of water and the mixture extracted with CH_2Cl_2 (2 × 30 mL). The combined organic extracts were washed with water (50 mL), dried ($MgSO_4$), and the solvent removed under reduced pressure. The crude residue was subjected to silica gel chromatography using a 10% ethyl acetate – hexane mixture as eluent. The first fraction isolated was a colorless oil (50 mg, 38%) whose structure was assigned as methyl 4-mercapto-2-cyclohexenecarboxylate (**20**). The second fraction was a white crystalline solid (60 mg, 56%) whose structure was assigned as 2-thiabicyclo[2.2.2]oct-5-ene-3-one (**19**). Both these compounds were identified on the basis of their physical and spectral data: (**20**) ir (neat): 3030, 2900, 2725, 2560, 1728, 1430, 1290, 1265, 1195, 1165, 1030, 1014, 905, and 735 cm^{-1}; nmr ($CDCl_3$) δ: 1.78 (d, 1H), 2.02 (m, 4H), 3.13 (m, 1H), 3.75 (s, 3H), and 5.87 (m, 2H); ms, *m/e*: 172 (M^+), 139, 112, 108, and 79. (**19**) mp 73–74°C; ir (Nujol): 1680, 1618, 1350, 1330, 1180, 1070, 1010, 905, 880, 835, and 805 cm^{-1}; nmr ($CDCl_3$) δ: 2.0–2.6 (m, 4H), 3.98 (m, 1H), 4.50 (m, 1H), and 6.4–7.2 (m, 2H); ms, *m/e*: 140, 80, and 79.

Treatment of 3,3-bis(1,2,4-triazol-1-yl)-2-thiabicyclo[2.2.2]oct-5-ene (18) with cupric sulfate

A mixture of 100 mg (0.38 mmol) of **18** and 30 mg (0.12 mmol) of cupric sulfate in 20 mL of a 4:1 mixture of methanol–water was heated at reflux for 1 h. The cooled solution was poured into 50 mL of water and the mixture extracted with CH_2Cl_2 (2 × 20 mL). The combined organic extracts were washed with water (100 mL), dried ($MgSO_4$), and the solvent removed under reduced pressure. The crude residue was subjected to silica gel chromatography using a 10% ethyl acetate – hexane mixture as eluent. The major fraction isolated was a colorless liquid (62 mg, 93%) whose structure was assigned as methyl 4-mercapto-2-cyclohexenecarboxylate (**20**) as its physical and spectral data were identical to those described earlier.

Reaction of myrcene (21) with 1,1′-thiocarbonylbis(1,2,4-triazole) (2)

A mixture of 0.75 g (5.5 mmol) of myrcene and 1.0 g (5.5 mmol) of 1,1′-thiocarbonylbis(1,2,4-triazole) in 30 mL of dry benzene was heated at reflux under a nitrogen atmosphere for 1 h. On cooling, the solvent was removed under reduced pressure and the crude residue was subjected to silica gel chromatography with a 50% ethyl acetate – hexane mixture as eluent. The major fraction isolated was a colorless oil (7.5 g, 83%) which contained a 1:1 mixture of the two isomers 6,6-bis(1,2,4-triazol-1-yl)-5,6-dihydro-3-(4-methyl-pent-3-enyl)-2*H*-thiapyran (**22***a*) and its 4-(4-methyl-pent-3-enyl) isomer (**22***b*) identified on the basis of the following data: ir (neat): 3120, 2964, 2920, 2850, 1500, 1380, 1355, 1280, 1200, 1180, 1135, 1005, 950, 880, 820, and 750 cm^{-1}; nmr ($CDCl_3$) δ: 1.76 (br s, 6H), 2.20 (m, 4H), 3.34 (m, 2H), 3.87 (m, 2H), 5.07 (m, 1H), 5.66 (m, 1H), 7.98 (s, 2H), and 8.62 (s, 2H); ms, *m/e*: 316 (M^+), 248, and 136.

*Reaction of 6,6-bis(1,2,4-triazol-1-yl)-5,6-dihydro-3(and the 4 isomer)-(4-methyl-pent-3-enyl)-2*H*-thiapyran (22) with cupric sulfate*

A mixture of 0.60 g (1.9 mmol) of **22***a*, *b* and 0.16 g (0.66 mmol) of cupric sulfate in 10 mL of a 4:1 methanol–water mixture was heated at reflux for 1 h. The cooled reaction mixture was poured into 100 mL of water and the solution extracted with methylene chloride (2 × 50 mL). The combined organic extracts were washed with water (100 mL), dried ($MgSO_4$), and the solvent removed under reduced pressure. The crude residue was then subjected to silica gel chromatography with a 50% ethyl acetate – hexane mixture as eluent. The major fraction isolated was a pale yellow crystalline solid (0.42 g, 90%) which contained a 1:1 mixture of the two isomers, 4-(4-methyl-pent-3-enyl)-6-(1,2,4-triazol-1-yl)-2*H*-thiapyran (**23***b*) and its 3-(4-methyl-pent-3-enyl)- isomer (**23***a*). The structures were assigned on the basis of the following data: ir (Nujol) (**22***a* + **22***b*): 3120, 1645, 1570, 1500, 1270, 1200, 1134, and 100 cm^{-1}; nmr ($CDCl_3$) δ: 1.80 (s, 6H), 2.32 (s, 4H), 3.58 (m, 2H), 5.17 (m, 1H), 5.47 (m, 1H), 6.68 (s, 1H), 8.02 (s, 1H), and 8.46 (s, 1H); (**23***a*) δ: 1.70 (s, 6H), 2.38 (s, 4H), 3.54 (m, 2H), 5.17 (m, 1H), 5.98 (m, 2H), 8.02 (s, 1H), and 8.46 (s, 1H); ms, *m/e* (mixture): 247 (M^+), 232, 204, 178, and 79.

*Acidic hydrolysis of 6,6-bis(1,2,4-triazol-1-yl)-5,6-dihydro-3(and the 4 isomer)-4methyl-pent-3-enyl)-2*H*-thiapyran (22a, b)*

A solution of 0.86 g (2.7 mmol) of **22** in 30 mL of a 4:1 mixture of methanol–water was heated at reflux for 1 h. The cooled solution was poured into 100 mL of water and the mixture extracted with CH_2Cl_2 (2 × 30 mL). The combined organic extracts were washed with water (100 mL), dried ($MgSO_4$), and the solvent removed under reduced pressure. The crude residue was subjected to silica gel chromatography using a 50% ethyl acetate – hexane mixture as eluent. The first fraction isolated was a colorless oil (0.22 g, 41%) whose structure was assigned as 5-hydro-3(and the 4-isomer)-(4-methyl-pent-3-enyl)-2*H*-thiapyran-6-one (**24**) on the basis of the following spectral data: ir (neat): 2950, 2900, 1725, 1655, 1425, 1365, 1247, 1150, 1095, 1062, 1028, 880, 820, and 745 cm^{-1}; nmr ($CDCl_3$) δ: 1.73 (m, 12H), 2.25 (m, 8H), 3.17 (br s, 4H), 3.63 (br s, 2H), 3.78 (br s, 2H), 5.17 (br s, 2H), 5.72 (m, 1H), and 5.95 (m, 1H); ms, *m/e*: 196 (M^+), 168, 136, 128, and 79.

The second fraction isolated was a pale yellow crystalline solid (0.29 g, 43%) whose structure was assigned as 5-hydro-3(and the 4-isomer)-(4-methyl-pent-3-enyl)-6-(1,2,4-triazol-1-yl)-2*H*-thiapyran (**23**) on the basis of its spectral data and comparison with a sample reported earlier in the experimental section.

Stéréochimie des complexes du chlorure d'iode avec les bases carbonylées

MICHEL BERTHELOT, MARYVONNE HELBERT ET CHRISTIAN LAURENCE[1]

Laboratoire de Spectrochimie Moléculaire – U.E.R. de Chimie, Université de Nantes, 2, rue de la Houssinière, 44072 Nantes, France

Reçu le 13 juillet 1984

MICHEL BERTHELOT, MARYVONNE HELBERT et CHRISTIAN LAURENCE. Can. J. Chem. **63**, 958 (1985).

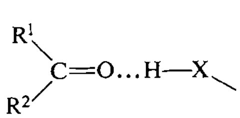
Le dédoublement des bandes ν(I—Cl) et ν(C═O) des complexes du chlorure d'iode avec des bases carbonylées en solution très diluée dans l'heptane a été attribué à l'existence de deux complexes 1 : 1 stéréoisomères: un complexe linéaire (ICl dans l'axe de la liaison carbonyle) et un complexe angulaire (ICl dans la direction d'une paire libre de l'oxygène). Dans les séries RCOOEt, RCOPh, RCO*t*-Bu, R_2CO, $RCONPh_2$ et $RCONMe_2$ où R = Me, Et, i-Pr ou *t*-Bu, on passe progressivement du complexe angulaire pour R = Me au complexe linéaire pour R = *t*-Bu car la présence de substituants encombrants sur le groupe carbonyle déstabilise le complexe angulaire. Dans les séries RCOH et RCOMe le complexe est angulaire quel que soit l'effet stérique de R car ICl se fixe sur la paire libre proche de H ou Me, substituants non encombrants. En présence d'un excès de ICl un complexe 1:2 apparaît.

MICHEL BERTHELOT, MARYVONNE HELBERT, and CHRISTIAN LAURENCE. Can. J. Chem. **63**, 958 (1985).

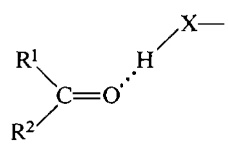
The splitting of the ν(I—Cl) and ν(C═O) bands of ICl complexes with carbonyl bases in highly diluted heptane solutions is explained by the existence of two 1 : 1 stereoisomeric complexes: a linear complex (ICl along the axis of the carbonyl bond) and an angular complex (ICl in the direction of a lone pair). In the series RCOOEt, RCOPh, RCO*t*-Bu, R_2CO, $RCONPh_2$, and $RCONMe_2$, where R = Me, Et, i-Pr, or *t*-Bu, the angular complex for R = Me transforms into the linear complex for R = *t*-Bu, since bulky substituents on the carbonyl group destabilize the angular arrangement. In the series RCOH and RCOMe the complex is angular whatever the steric effect of R, since ICl is located on the lone pair near the small H or Me substituents. When ICl is added in excess, a 1:2 complex appears.

Introduction

Dans un article précédent (1) nous avons mis en évidence deux complexes stéréoisomères (a) et (b) lors de la formation d'une liaison hydrogène sur le groupe carbonyle à partir du dédoublement de la vibration de valence ν(XH...). Dans le complexe (a) la géométrie est déterminée par une optimisation



(a)



(b)

de l'interaction électrostatique et dans le complexe (b) par une optimisation de l'interaction covalente. L'énergie de répulsion dépend de l'encombrement stérique du donneur de proton et des substituants R^1 et R^2 et est minimum dans la configuration (a).

Il est intéressant de savoir si d'autres acides de Lewis que les donneurs de proton présentent cette stéréoisomérie de complexation en solution. Parmi les acides de Lewis d'encombrement et de caractère électrostatique/covalent différents de ceux des donneurs de proton, le chlorure d'iode a été choisi dans ce travail car sa vibration de valence ν(I—Cl) (à 375,6 cm^{-1} dans l'heptane) s'abaisse fortement par complexation avec des bases de Lewis (2–6) et il donne des complexes suffisamment forts avec les bases carbonylées[2] pour provoquer également un abaissement important de la vibration ν(C═O) (7).

En confrontant les résultats obtenus par l'étude simultanée des vibrateurs ν(C═O) et ν(I—Cl) il est alors possible de mettre en évidence trois types de complexes (a), (b) et (c) dans les solutions d'ICl et de base carbonylée dans l'heptane.

[1]Auteur à qui toute correspondance doit être adressée.

[2]Les enthalpies de formation varient de −25,5 kJ mol^{-1} pour MeCOOEt (8) à −39,7 kJ mol^{-1} pour $MeCONEt_2$ (9).

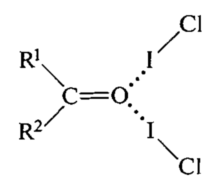
(b)



(c)

Partie expérimentale

Produits

La purification et la dessiccation de l'heptane et des bases carbonylées ont été précédemment décrites (1). Le chlorure d'iode Aldrich, garanti à 98%, est conservé et manipulé à l'abri de l'humidité.

Spectres

Ils sont enregistrés immédiatement après préparation de la solution sur un spectrophotomètre Perkin–Elmer 580B balayé par de l'air sec, travaillant à une résolution de 2 cm^{-1} dans les régions ν(CO) et ν(I—Cl). Les opérations de stockage, soustraction (des spectres du solvant et de ICl libre ou de la base libre), expansion et lissage des spectres sont effectuées sur une station de données PE 3500 grâce au logiciel PE 580.

Cellules et solutions

Les solutions sont effectuées dans l'heptane, solvant apolaire qui doit minimiser l'ionisation des complexes (5,6). Dans la région ν(I—Cl) une cellule en polyéthylène avec une cale d'épaisseur en Teflon permet d'éviter l'attaque des faces et de la cale par ICl. Une épaisseur de 6 mm permet de travailler avec des concentrations en ICl environ 10^{-2} *M* suffisamment faibles pour retarder d'éventuelles réactions d'halogénation de la base ou pour éviter la précipitation des complexes. La concentration de la base varie de 0,5 *M* à 10^{-2} *M* selon la stabilité du complexe. Dans la région ν(CO) une cellule CaF_2 de 1 mm permet de travailler avec des concentrations de l'ordre de celles de la région ν(I—Cl). Les solutions sont préparées et les cellules sont remplies en boîte sèche. Dans le spectrophotomètre les cellules sont thermorégulées à 20°C.

Décomposition des spectres

La soustraction de la bande ν(CO) libre ou de la bande ν(ICl) libre est effectuée directement sur la station de données, ce qui évite une décomposition mathématique du massif constitué par la superposition

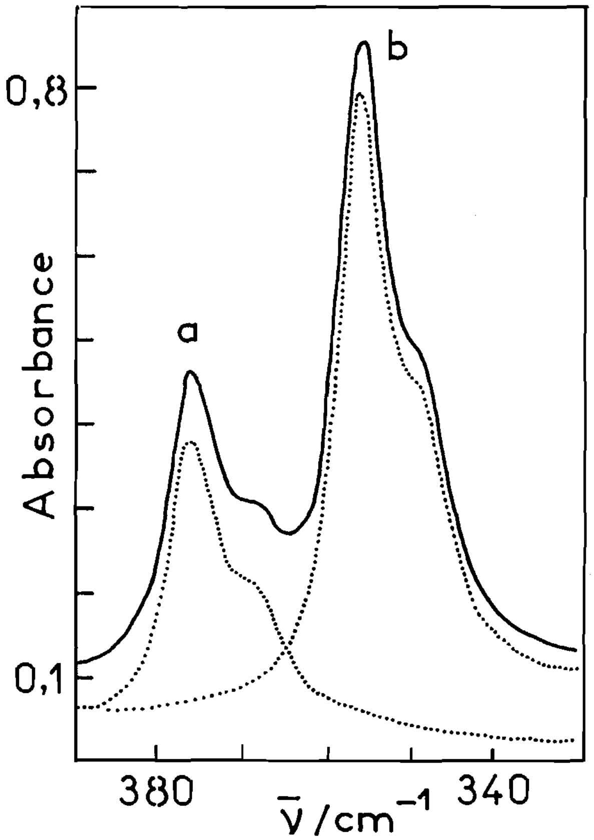


FIG. 1. Bandes ν(I—Cl) libre (a) et complexée (b) montrant la formation équilibrée d'un complexe cyclobutanone−ICl dans l'heptane. Concentrations: ICl ~0,01 *M* et cyclobutanone ~0,03 *M*.

des bandes du complexe et des molécules libres. Dans les cas où les bandes de plusieurs complexes se recouvrent la décomposition est effectuée mathématiquement comme précédemment (1).

Résultats

Région ν(I—Cl)

La bande d'absorption infrarouge ν(I—Cl) à 375,6 cm^{-1} dans l'heptane présente un épaulement aux basses fréquences attribué à l'isotope I^{37}Cl. Les rapports expérimentaux des fréquences et des absorbances au maximum des deux composantes du massif obtenues après décomposition sont en bon accord avec le rapport ν(I—^{37}Cl)/ν(I—^{35}Cl) = 0,9786 calculé dans l'approximation de l'oscillateur harmonique et avec l'abondance 24,5% de l'isotope ^{37}Cl.

Comme l'illustre la fig. 1, l'addition d'une base carbonylée à une solution de ICl dans l'heptane provoque, par formation équilibrée d'un complexe, l'apparition d'une nouvelle bande aux basses fréquences, déplacée de 3,5 cm^{-1} pour CF_3COOEt à 42,6 cm^{-1} pour la diméthyl-2,6-γ-pyrone.

Pour un certain nombre de cétones et d'esters, deux nouvelles bandes dénotées b (basse fréquence) et h (haute fréquence) apparaissent (fig. 2F, 2G). L'examen de l'évolution des fréquences et des intensités des deux nouvelles bandes dans les séries RCOOEt, RCOPh, RCO*t*-Bu et R_2CO, où R=Me puis Et puis i-Pr puis *t*-Bu, montre que c'est principalement la bande b qui est présente quand R=Me et la bande h quand R=*t*-Bu, alors que pour R=i-Pr ou Et, généralement les deux bandes b et h coexistent en proportions variables (fig. 2E à 2H).

Pour quelques complexes la bande ν(I—Cl) du complexe est plus fine que la bande ν(I—Cl) libre. Ceci provoque une meilleure résolution des deux isotopes et il apparaît, comme dans le cas précédent, deux bandes mais leurs fréquences et leurs intensités sont dans les rapports isotopiques 0,9786 et 24,5% ce qui permet de les attribuer aux deux isotopes et non aux bandes b et h précédentes (fig. 2H).

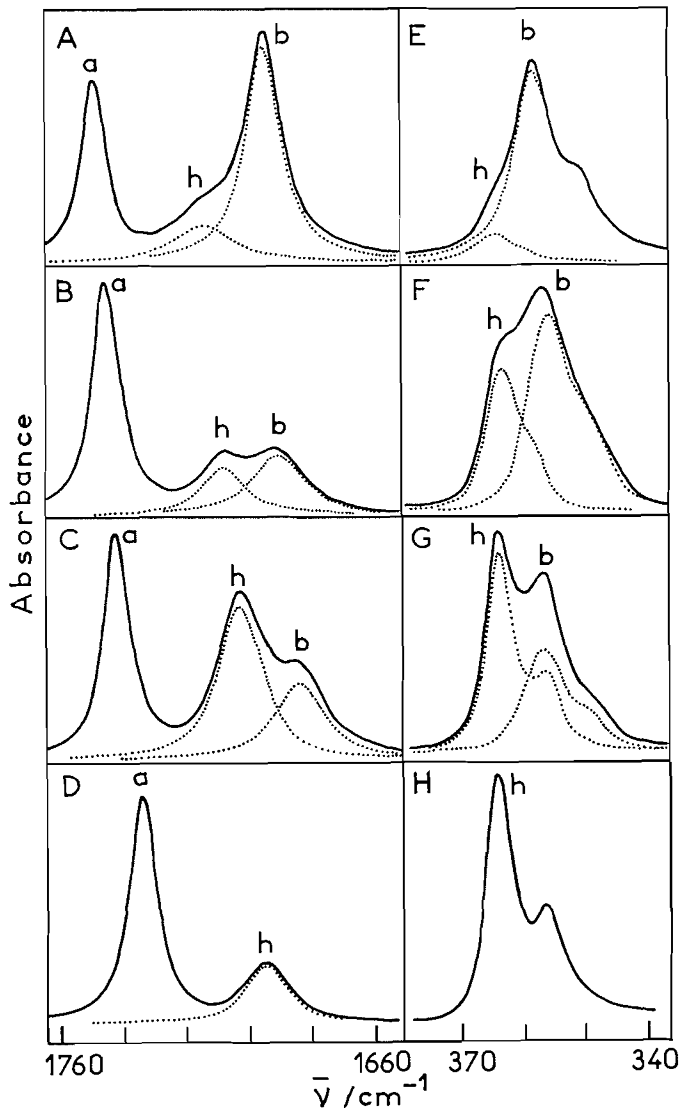

FIG. 2. Bandes ν(I—Cl) et ν(C=O) des complexes de ICl avec MeCOOEt (A et E), EtCOOEt (B et F), i-PrCOOEt (C et G) et *t*-BuCOOEt (D et H). Les bandes libres ont été soustraites dans la région ν(I—Cl). (a) Bande ν(C=O) libre, (h) complexe linéaire, (b) complexe angulaire.

Région ν(C=O)

L'addition de ICl à une solution de base carbonylée dans l'heptane provoque l'apparition d'une nouvelle bande aux basses fréquences, déplacée de 22 cm^{-1} pour MeCOH à 72 cm^{-1} pour $EtCONMe_2$.

Quand deux bandes b et h étaient apparues dans la région ν(I—Cl), on observe également deux nouvelles bandes dans la région ν(C=O) dans un rapport d'intensité voisin de celui observé pour ν(I—Cl) (fig. 2B et 2C).

Dans de rares cas deux nouvelles bandes apparaissent dans la région ν(C=O) par addition de ICl, alors qu'une seule nouvelle bande avait été observée dans la région ν(I—Cl) par addition de base carbonylée. La propension de la fondamentale

TABLEAU 1. Déplacements $\Delta\nu$(I—Cl) (cm^{-1}) pour les complexes linéaire (bande h) et angulaire (bande b) de ICl avec les bases carbonylées dans l'heptane

[a]Présence d'une bande h difficilement pointable.

ν(C=O) à entrer en résonance de Fermi avec des bandes harmoniques ou de combinaison dans ces molécules complexes généralement sans élément de symétrie peut expliquer cette discordance.

L'addition d'un excès de ICl, correspondant à la quasi-disparition de la bande ν(C=O) libre, permet d'observer dans de nombreux cas l'apparition d'une bande supplémentaire au massif ν(C=O) obtenu en solution diluée de ICl (fig. 3).

Les tableaux 1 et 2 rassemblent les déplacements de fréquence $\Delta\nu$(I—Cl) = ν(I—Cl)libre − ν(I—Cl)complexe et $\Delta\nu$(C=O) = ν(C=O)libre − ν(C=O)complexe, mesurés pour un certain nombre d'esters, carbonates, urées, carbamates, amides, aldéhydes et cétones. Ces $\Delta\nu$ se rapportent aux complexes b et/ou h, en fonction de la discussion ci-dessous.

Discussion

Complexe angulaire et complexe linéaire

Bien qu'aucun calcul théorique n'ait été effectué, à notre connaissance, sur les complexes de ICl avec les composés carbonylés, il est évident que trois principaux termes contribuent à l'énergie d'interaction entre ICl et une base carbonylée: un terme électrostatique (le moment dipolaire de ICl vaut 1,48 D dans le cyclohexane (10)), un terme covalent et un terme de répulsion. Il est clair que l'interaction électrostatique est optimisée dans la configuration linéaire $\overrightarrow{C{=}O}\ldots\overrightarrow{ICl}$. Il est probable que, comme pour les donneurs de proton, l'interaction covalente est optimisée lorsque ICl se place dans l'axe d'une paire libre. Une telle configuration angulaire a été trouvée, à l'état solide, pour le complexe acétone–dibrome (11). Il est enfin évident que la présence de groupes volumineux R^1 et R^2 sur le carbonyle augmente plus l'énergie de répulsion dans le complexe angulaire que dans le complexe linéaire.

La concordance entre les régions ν(C=O) et ν(I—Cl) et la dilution des solutions étudiées indiquent qu'il peut se former deux complexes 1:1 en solution. Par analogie avec les complexes des bases carbonylées avec des donneurs de proton (1),

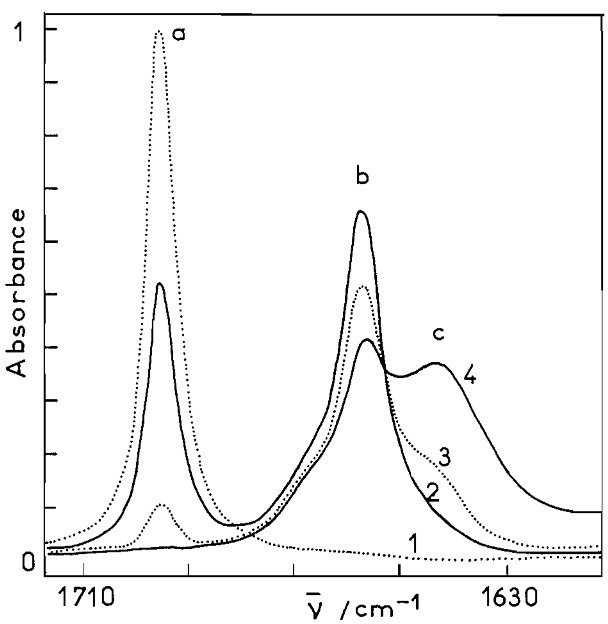

FIG. 3. Modification de la région $\nu(C{=}O)$ de l'acétophénone 0,015 *M* dans l'heptane par addition de quantités croissantes de ICl: (1) 0 (2) 0,03 *M* (3) 0,15 *M* (4) 0,5 *M*. (a) Bande libre, (b) complexe angulaire 1:1, (c) complexe 1:2.

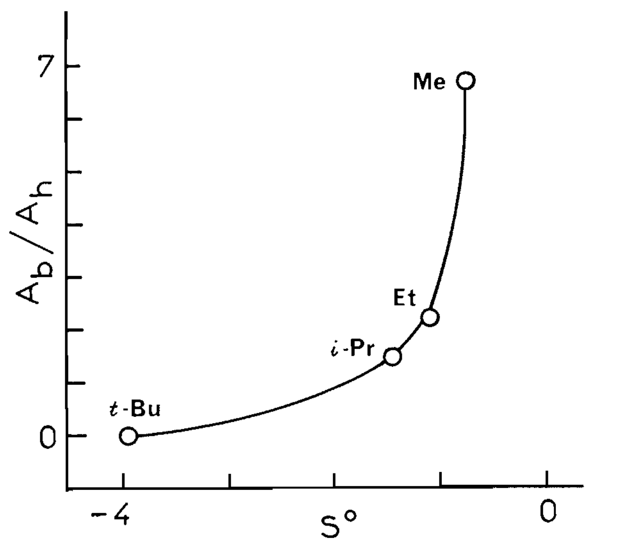

FIG. 4. Rapports d'intensité des bandes h et b (région $\nu(C{=}O)$) pour les complexes RCOOEt—ICl en fonction du paramètre stérique S^0 de R.

nous pensons que ces deux complexes sont l'un le complexe angulaire, l'autre le complexe linéaire.

*Attribution de la bande b au complexe angulaire et de la bande h au complexe linéaire par variation stérique dans les séries RCOOEt, RCOPh, RCO*t*-Bu et R_2CO*

La bande b disparaît au profit de la bande h dans les séries RCOOEt, RCOPh, RCO*t*-Bu et R_2CO quand l'encombrement du substituant variable R, mesuré par le paramètre stérique S^0(12), augmente en passant de Me à *t*-Bu (fig. 4). Les substituants constants OEt, Ph et *t*-Bu étant suffisamment volumineux ($S^0 = -1{,}36$, $-1{,}82$ et $-3{,}94$ respectivement) pour restreindre l'approche de ICl de leur côté, nous expliquons ce phénomène par un empêchement progressif de l'attaque angulaire de ICl sur la paire libre voisine de R, lorsqu'on passe de R = Me à R = *t*-Bu. Nous attribuons donc la bande b au complexe angulaire et, par voie de conséquence, la bande h au complexe linéaire, beaucoup moins sensible aux effets stériques.

Attribution angulaire ou linéaire dans le cas d'un complexe unique. Séries RCOMe, RCOH, $RCONMe_2$ et $RCONPh_2$

Dans les séries RCOMe et RCOH, on observe toujours un seul complexe quel que soit le volume stérique de R. De plus ce complexe ne change pas de structure pour R=Me, Et, i-Pr ou *t*-Bu puisque les déplacements $\Delta\nu(I{-}Cl)$ et $\Delta\nu(C{=}O)$ varient peu, ou régulièrement, dans ces séries (ce qui était attendu du fait des effets électriques voisins de ces quatre alkyles sur la basicité de l'oxygène). L'étude de la série RCO*t*-Bu ayant montré que pour MeCO*t*-Bu ce complexe est angulaire, il s'ensuit que pour MeCOEt, MeCOi-Pr et Me_2CO ce complexe est également angulaire car S^0(Me,Et ou i-Pr) < S^0(*t*-Bu). A fortiori HCOMe, HCOEt, HCOi-Pr et HCO*t*-Bu donnent aussi un complexe angulaire puisque S^0(H) < S^0(Me).

L'invariance de structure du complexe en dépit de l'évolution dramatique de l'encombrement stérique de R dans les séries RCOMe et RCOH provient à l'évidence de la fixation de ICl sur la paire libre restée dégagée du côté des petits substituants constants $H(S^0 = 0)$ et $Me(S^0 = -0{,}73)$.

Dans la série $RCONMe_2$ on observe également toujours un seul type de complexe. Mais les valeurs de $\Delta\nu$(I—Cl) montrent que l'on passe d'un complexe angulaire pour R=Me et Et ($\Delta\nu$ = 34,5 et 35,1 cm^{-1}) à un complexe linéaire pour R=i-Pr et *t*-Bu ($\Delta\nu$ = 25,3 cm^{-1}). Par analogie il est probable que la valeur $\Delta\nu$(I—Cl) = 30 cm^{-1} de $MeCONPh_2$ correspond au complexe angulaire et la valeur 22,5 cm^{-1} de i-Pr $CONPh_2$ au complexe linéaire.

Pour les autres bases carbonylées R^1COR^2 montrant des bandes ν(I—Cl) et ν(C=O) de complexe uniques, une tentative d'attribution "angulaire" ou "linéaire" est effectuée dans les tableaux sur la base (*i*) de l'encombrement des paires libres: les faibles valeurs de S^0 pour un substituant (séries $HCOR^2$, $ClCOR^2$ et $MeCOR^2$) et la cyclisation qui dégage les paires (carbonates cycliques, lactones, cycloalcanones, lactames) favorisent le complexe angulaire tandis que les fortes valeurs de S^0 pour les deux substituants R^1 et R^2 (urées, carbamates) et la conformation s-*cis*,s-*cis* des carbonates favorisent le complexe linéaire; (*ii*) des séquences de basicité obtenues précèdemment avec les donneurs de proton (1): ainsi $\Delta\nu$(I—Cl) = 11,5 et 16,5 cm^{-1} respectivement pour $C_6H_{11}COOMe$ et MeCOOMe alors que $C_6H_{11}COOMe$ apparaît plus basique vis-à-vis du méthanol; l'inversion est attribuée au passage d'un complexe angulaire pour MeCOOMe à un complexe linéaire pour $C_6H_{11}COOMe$.

Complexe 1:2.

Puisqu'une bande supplémentaire apparaît lorsque ICl est en excès par rapport à la base carbonylée, nous l'attribuons à un complexe d'ordre supérieur à 1:1. La possibilité pour une molécule de base oxygénée de fixer deux molécules d'acide de Lewis grâce aux deux paires libres de l'oxygène déjà été mise en évidence (*i*) pour les donneurs de proton avec les bases carbonylées (13), (*ii*) pour le cyanure d'iode avec l'oxyde de triphénylarsine (14) et (*iii*) pour l'iodophénylacétylène et l'iodocyanoacétylène avec l'oxyde de triphénylarsine (15). Nous attribuons donc cette bande supplémentaire au complexe 1:2 du type (c) représenté ci-dessus.

Mixed ruthenium(II) nitrosyls have been synthesized in yields larger than 60% by a general reaction of $[Ru(\eta^5\text{-}C_5H_5)(PPh_3)L]^+X^-$ (L = 2,2′-bipyridine or 1,10-phenanthroline, X^- = Cl^- or Br^-) or $[Ru(\eta^5\text{-}C_5H_5)(PPh_3)(L)X]$ (L = PPh_3, pyridine, 3-picoline, 4-picoline, $\frac{1}{2}$(2,2′-bipyridine), or $\frac{1}{2}$(1,10-phenanthroline); X^- = Cl^-, Br^-, I^-, CN^-, NCS^-, H^-, or $SnCl_3^-$) with $NOBr_3$ and N_2O_3. In these complexes NO seems to bind with the metal ion as NO^+. The reactions of N_2O_3 gave either nitrito or nitrosyl dinitrito complexes. The reactions of $NOBr_3$ with trichlorostannate complexes did not yield nitrosyl complexes, instead nitrito complexes were isolated in which spectroscopic evidence (ir, ^{1}H nmr) suggest π-interaction of one of the phenyl rings of the triphenylphosphine ligand to the ruthenium center. All products are characterised by elementary microanalyses, conductivity, magnetic moment measurements, electronic, ir, and ^{1}H nmr spectral data.

R. F. N. ASHOK, M. GUPTA, K. S. ARULSAMY et U. C. AGARWALA. Can. J. Chem. **63**, 963 (1985).

Faisant appel à une réaction générale du $[Ru(\eta^5\text{-}C_6H_5)(PPh_3)L]^+X^-$ (L = bipyridine-2,2′ ou phénanthroline-1,10, X^- = Cl^- ou Br^-) ou du $[Ru(\eta\text{-}C_5H_5)(PPh_3)(L)X]$ (L = PPh_3, pyridine, picoline-3, picoline-4, (1/2)(bipyridine-2,2′) ou (1/2)(phénanthroline); X^- = Cl^-, Br^-, I^-, CN^-, NCS^-, H^- ou $SnCl_3^-$) avec le $NOBr_3$ ou le N_2O_3, on a réussi à synthétiser des nitrosyles mixtes de ruthénium avec des rendements supérieurs à 60%. Dans ces complexes, il semble que le NO soit lié au métal sous la forme d'un ion NO^+. Les réactions impliquant le N_2O_3 conduisent à des complexes des types nitrito ou nitrosyl dinitrito. Les réactions du $NOBr_3$ avec les complexes trichlorostannates ne fournissent pas de complexes de type nitrosyle; on a plutôt isolé des complexes de type nitrito pour lesquels les données spectroscopiques (ir et rmn du ^{1}H) suggèrent l'existence d'une interaction-π de l'un des cycles phényles du ligand triphénylphosphine avec le centre ruthénium. On a caractérisé tous les produits grâce à leurs analyses élémentaires, à des mesures de conductivité et de moments dipolaires et à leurs spectres électroniques, ir et de rmn du ^{1}H.

[Traduit par le journal]

Introduction

During the course of our studies of the reactions of NOX′ (X′ = Cl^-, Br^-, Br_3^-, or NO_2^-) with various transition metal complexes (1−4), it has been found that these can be used as a good nitrosylating agent. In continuation with our investigations on the reactivities of some π-cyclopentadienyl ruthenium(II) complexes (5, 6), we report here a number of mixed ligand complexes $[Ru(NO)(PPh_3)LX_nY_{3-n}]$ ((X = Cl^-, Br^-, I^-, CN^-, NCS^-), (Y = Cl^-, Br^-, NO_2^-), n = 1−3), $[Ru(PPh_3)(NO_2)(SNCl_3)L]$ synthesized by the reactions of $[Ru(\eta^5\text{-}C_5H_5)(PPh_3)L]^+X^-$ (where L = 2,2′-bipyridine or 1,10-phenanthroline; X = Cl^- or Br^-) or $[Ru(\eta^5\text{-}C_5H_5)(PPh_3)(L)X]$ (where L = PPh_3, Py, 3-picoline, 4-picoline, $\frac{1}{2}$(2,2′-bipyridine) or $\frac{1}{2}$(1,10-phenanthroline); X = Cl^-, Br^-, I^-, H^-, CN^-, NCS^-, or $SnCl_3^-$) with $NOBr_3$ and N_2O_3 under homogeneous reaction conditions. It has also been shown that one of the phenyl rings of PPh_3 is π-bonded to ruthenium in $[Ru(NO_2)(PPh_3)(SnCl_3)L]\cdot xN_2O_3$ (x = 0−2). The yield of the complexes was found to be more than 60% in every reaction.

Experimental

All chemicals used were of Analar grade. The solvents were dried and distilled before use. The reactions were carried out under pure and dry nitrogen.

$NOBr_3$ and N_2O_3 were prepared by literature methods (7, 8) and used as saturated solution in dry dichloromethane.

The $[Ru(\eta\text{-}C_5H_5)(PPh_3)_2Cl]$ (9), $[Ru(\eta\text{-}C_5H_5)(PPh_3)_2Br]$, $[Ru(\eta\text{-}C_5H_5)(PPh_3)_2I]$, $[Ru(\eta\text{-}C_5H_5)(PPh_3)_2H]$, $[Ru(\eta\text{-}C_5H_5)(PPh_3)_2(CN)]$, $[Ru(\eta\text{-}C_5H_5)(PPh_3)(NCS)]$, $[Ru(\eta\text{-}C_5H_5)(PPh_3)_2(SnCl_3)]$ (10), and complexes $[Ru(\eta\text{-}C_5H_5)(PPh_3)(Py)Cl]$, $[Ru(\eta\text{-}C_5H_5)(PPh_3)(3\text{-}Pic)Cl]$, $[Ru(\eta\text{-}C_5H_5)(PPh_3)(4\text{-}Pic)Cl]$, $[Ru(\eta\text{-}C_5H_5)(PPh_3)(Bipy)]^+Cl^-$, $[Ru(\eta\text{-}C_5H_5)(PPh_3)(o\text{-phen})]^+Cl^-$, $[Ru(\eta\text{-}C_5H_5)(PPh_3)(Py)Br]$, $[Ru(\eta\text{-}C_5H_5)(PPh_3)(3\text{-}Pic)Br]$, $[Ru(\eta\text{-}C_5H_5)(PPh_3)(4\text{-}Pic)Br]$, $[Ru(\eta\text{-}C_5H_5)(PPh_3)(Bipy)]^+Br^-$, $[Ru(\eta\text{-}C_5H_5)(PPh_3)(o\text{-Phen})]^+Br^-$, $[Ru(\eta\text{-}C_5H_5)(PPh_3)(Py)I]$, $[Ru(\eta\text{-}C_5H_5)(PPh_3)(3\text{-}Pic)I]$, $[Ru(\eta\text{-}C_5H_5)(PPh_3)(4\text{-}Pic)I]$, $[Ru(\eta\text{-}C_5H_5)(PPh_3)(Bipy)_{1/2}I]$, $[Ru(\eta\text{-}C_5H_5)(PPh_3)(o\text{-Phen})_{1/2}I]$, $[Ru(\eta\text{-}C_5H_5)(PPh_3)(Py)(CN)]$, $[Ru(\eta\text{-}C_5H_5)(PPh_3)(3\text{-}Pic)(CN)]$, $[Ru(\eta\text{-}C_5H_5)(PPh_3)(4\text{-}Pic)(CN)]$, $[Ru(\eta\text{-}C_5H_5)(PPh_3)(Bipy)_{1/2}CN]$, $[Ru(\eta\text{-}C_5H_5)(PPh_3)(o\text{-Phen})_{1/2}(CN)]$, $[Ru(\eta\text{-}C_5H_5)(PPh_3)(Py)(NCS)]$, $[Ru(\eta\text{-}C_5H_5)(PPh_3)(3\text{-}Pic)(NCS)]$, $[Ru(\eta\text{-}C_5H_5)(PPh_3)(4\text{-}Pic)(NCS)]$, $[Ru(\eta\text{-}C_5H_5)(PPh_3)(Bipy)_{1/2}(NCS)]$, $[Ru(\eta\text{-}C_5H_5)(PPh_3)(o\text{-Phen})_{1/2}(NCS)]$, $[Ru(\eta\text{-}C_5H_5)(PPh_3)(Py)(SnCl_3)]$, $[Ru(\eta\text{-}C_5H_5)(PPh_3)(3\text{-}Pic)(SnCl_3)]$, $[Ru(\eta\text{-}C_5H_5)(PPh_3)(4\text{-}Pic)(SnCl_3)]$, $[Ru(\eta\text{-}C_5H_5)(PPh_3)(Bipy)_{1/2}(SnCl_3)]$, $[Ru(\eta\text{-}C_5H_5)(PPh_3)(o\text{-Phen})_{1/2}(SnCl_3)]$ were prepared as reported elsewhere (5).

[A] Reactions of NOX′ (X′ = Br_3^- or NO_2^-) with $[Ru(\eta^5\text{-}C_5H_5)(PPh_3)(L)^+X^-]$ (L = Bipy or 1,10-phen; X = Cl or Br), $[Ru(\eta^5\text{-}C_5H_5)(PPh_3)(L)X]$ (L = PPh_3, Py, 3-Pic or 4-Pic), or $[Ru(\eta^5\text{-}C_5H_5)(PPh_3)(L)X]$ (L = PPh_3, Py, 3-Pic or 4-Pic, $\frac{1}{2}$Bipy or $\frac{1}{2}$(1,10-Phen); X = I or NCS, $SnCl_3$)

A saturated solution of NOX′ in dichloromethane (*ca.* 5 mL) was very slowly added to a well stirred solution of the appropriate complex (*ca.* 0.6 mmol) in a mixed solvent containing 20 mL of dichloromethane and 40 mL of methanol at 30°C. The resulting mixture was heated under reflux for 10−15 min, whereupon microcrystals of the corresponding complex were separated. The product was filtered, washed with methanol, water, methanol, ether, and petroleum ether (40−60°C) and dried *in vacuo*. The samples were recrystallized from CH_2Cl_2/methanol mixture or CH_2Cl_2/petroleum ether, though the initial crop itself contained analytically pure complexes (yield, 70% approximately). These complexes were analyzed for the complexes whose compositions are shown in Table 1. In the case of the bromo

[1]For Part II, see ref. 6.

[2]The compound was synthesized in 1923. Though it has been formulated as $NOBr_3$, there is a possibility that it might be a mixture. For our reactions we have assumed it to be $NOBr_3$.

*These complexes are ionic having composition $[Ru(\eta^5\text{-}C_5H_5)(PPh_3)L]^+X^-$.

†B = Brown, OB = Orange Brown, YB = Yellowish Brown, G = Green, O = Orange, RB = Reddish Brown, YG = Yellowish Green, OR = Orange Red, OY = Orange Yellow, Y = Yellow. [A][B] = methods used for preparation.

‡^{1}H-nmr spectra showed broad multiplet resonance at around δ7.2 ppm due to phosphine and *N*-heterocyclic base protons. In addition, complexes **61–72** showed multiplet absorption at δ 6.2 due to π-bonded phenyl protons of the PPh_3 ligand. The complexes having picolines as coligands exhibited an additional signal in the region δ 1.8–2.0 for the methyl protons.

§Error limit ±1%. The complexes having NCS as one of the anionic ligands, analysed satisfactorily for sulphur.

complexes, the reaction mixture was stirred at room temperature for about half an hour, followed by the concentration of the resulting solution under reduced pressure to about 5 mL. The concentrate was centrifuged and the complex was precipitated by the addition of about 25 mL of *n*-hexane.

[B] Reactions of NOX′ (X′ = Br_3^- or NO_2^-) with [Ru(η^5-C_5H_5)(PPh_3)(L)X] (where L = PPh_3, Py, 3-Pic, ½(Bipy), or ½(1,10-Phen); X = CN^- or SCN^-)

The complex (150 mg, 0.2 mmol) was dissolved in a mixture of 10 mL of dichloromethane and 25 mL of methanol, followed by the addition of 2–3 mL of a saturated dichloromethane solution of NOX′. The reaction mixture was heated under reflux for about 30 min. The colour of the solution changed to blackish green. After the usual work-up (Method I, Bromocomplexes), an oily product was obtained from which a pure crystalline solid was difficult to separate. However, in a few cases the repeated process of dissolution of the oil in CH_2Cl_2 or $CHCl_3$, and precipitation with light petroleum (40–60°C) gave a dark green solid in rather low yield (*ca.* 15%) which was filtered, washed with *n*-hexane, and dried *in vacuo*.

If the foregoing procedure was slightly modified by adding about 25 mL of triphenylphosphine into the reaction mixture while under reflux, an instantaneous formation of an orange brown to orange yellow shining crystals in high yield (*ca.* 90%) was observed. These were separated, washed with methanol and ether, and finally dried *in vacuo*. The complexes contained bromide in place of CN^- or SCN^-).

[C] Reactions of NOX′ (X′ = Br_3^- or NO_2^-) with [Ru(η^5-C_5H_5)(PPh_3)$_2$H]

The bright yellow complex [Ru(η^5-C_5H_5)(PPh_3)$_2$H] when dissolved in CH_2Cl_2 or $CHCl_3$ gave the chloro complex, [Ru(η^5-C_5H_5)(PPh_3)$_2$Cl]; in $CHBr_3$ the bromo complex, [Ru(η^5-C_5H_5)(PPh_3)$_2$Br]. As a result, when NOX′ was reacted with the hydrido complex by method [A], the isolated products were found to be identical to those obtained from the chloro, or bromo complex, depending on the solvent chosen for dissolving the hydrido complex prior to its reaction with $NOBr_3$.

The melting points of the complexes were found on a Fisher-Johns melting point apparatus.

The electronic spectra (210–700 nm) of the complexes in chloroform solution were recorded on the Cary 17-D model spectrophotometer.

The ir spectra were recorded as KBr discs on a Perkin-Elmer 580 spectrophotometer in the range 200–400 cm^{-1}.

Magnetic moments were measured, by the Gouy method using $Hg[Co(NCS)_4]$ as the calibrant.

Nuclear magnetic resonance spectra of the complex were taken on the Perkin Elmer, HA-100 spectrometer.

All complexes exhibited bands due to protons of PPh_3 and heterocyclic bases around δ 7.0; of C_5H_5, around δ 4.0; and those of methyl protons of picolines, around δ 5.0.

Carbon, hydrogen, and nitrogen were estimated in the microanalytical laboratory of the I.I.T., Kanpur. The sulphur and halogen were estimated by the standard methods (11). The phosphorus in the complexes were estimated as mentioned elsewhere (12).

Results and discussion

The reactions of $NOBr_3$ or N_2O_3 with [Ru(η^5-C_5H_5)(PPh_3)(L)X] gave bright coloured air-stable mixed ligand complexes (yield 60%) having a general formula [Ru(NO)(PPh_3)X_nY_{3-n}L] (X^- = Cl^- or Br^-; Y^- = Br^-, NO_2^-; n = 1–3) except those with $SnCl_3$. In the latter case, the reaction products obtained have a general formula [Ru(NO_2)($SnCl_3$)(PPh_3)L]. The analytical data of these complexes are given in Table 1. They were found to be diamagnetic and non-conducting.

They were readily soluble in haloform solvents but were practically insoluble in alcohols and non-polar solvents. The products derived from the trichlorostannate complexes have poor solubility in haloform solvents too. In order to confirm the proposed formulation of the complexes, the spectral studies (uv, visible, ir, nmr) have been carried out on these complexes whose results are discussed under the following heads.

Infrared spectra

(1) Reactions with $NOBr_3$

The ir spectra of complexes having $SnCl_3^-$ as an anion differed from those of the remaining ones in three respects. (*i*) They failed to exhibit any band around 1850 cm^{-1}, indicating that $NOBr_3$ could not nitrosylate them. (*ii*) They showed four new bands characteristic of the coordinated NO_2^- (21) around 1340(s) cm^{-1}, 1320(m-w) cm^{-1}, 840(m-w) cm^{-1} and around 300(w) cm^{-1}. Since NO_2^- may co-ordinate both as nitro or nitrito group, the absence of the diagnostic band of the coordinated nitro group around 650 cm^{-1}, unless masked by the intense PPh_3 bands around 600 cm^{-1}, was tentatively taken as evidence for its being bonded to the metal ion through oxygen. (*iii*) They exhibited a characteristic pattern of five bands in the region 1500–1350 cm^{-1} which has previously been used as diagnostic of PPh_3 complexes where one of the phenyl groups of PPh_3 is π-bonded to the metal ion (5, 13–27). (*iv*) They also showed the presence of three bands in 690–820 cm^{-1} region, while PPh_3 coordinated through phosphorus exhibits only two bands around 690 and 740 cm^{-1}. In case the phenyl group of PPh_3 is π-bonded, it is also expected that the absorption bands due to out-of-plane C—H bending modes should show a shift in their positions. It has, therefore, been assumed that the third band around 790–800 cm^{-1} could arise because of the out-of-plane bending mode of C—H of the π-bonded phenyl ring.

The ir spectra of the remaining complexes (other than trichlorostannate ones) showed an intense absorption band in the region 1840–1880 cm^{-1} besides the bands due to other coligands (29–32). Since the position of ir frequency due to ν_{NO} corrected by Ibers rule (28) in the complexes has been found to be greater than 1620 cm^{-1}, these can be regarded as complexes between Ru(II) and NO^+.

During the course of reactions of cyanato and thiocyanato complexes, it has been noted that the reaction products invariably appeared as oils, from which all attempts to separate the crystalline product were not successful in most cases. In a few cases, however, a solid product could be isolated and its spectra showed bands due to CN or NCS groups around 2000 or 2100 cm^{-1}, respectively. As stated in the Experimental section the addition of a few milligrams of PPh_3 in the refluxing reaction mixture led to the separation of very pure product in relatively good yield in which CN^- or NCS^- had been substituted by Br^-. It is, however, difficult to assess the role which PPh_3 plays in the crystallization process.

Generation of sulfate ion during the course of the reaction with the thiocyanato complexes has also been detected by the analytical data of the product separated by evaporating the refluxed-solution to dryness, followed by washing the residue with ether or petroleum ether. In the spectra of these complexes, the exhibited typical absorption bands of bridged sulfato group (33) appeared at the appropriate positions (1200 cm^{-1}, 1050 cm^{-1}, 850 cm^{-1}, and 600 cm^{-1}) besides the bands of the other attached groups.

(2) Reaction with N_2O_3

Although N_2O_3 reacts with [Ru(η^5-C_5H_5)(PPh_3)(L)X] (where X = Cl, Br, I, CN, or NCS) to yield nitrosyls, the reaction products of complexes having $SnCl_3^-$ as anion were different in two respects: (*i*) NO group is not coordinated with the metal ion. (*ii*) The reaction products crystallised out with N_2O_3 as adducts. These differences have been indicated by their ir spectra which exhibited all the characteristic bands due to NO_2^- except that at 650 cm^{-1} (1340 cm^{-1}, 1320 cm^{-1}, 840 cm^{-1}, and 300 cm^{-1}) and those, due to N_2O_3 (1870, 1340, 1320, 840 cm^{-1}) with a slight unsystematic shifts in their positions. The absence of 650 cm^{-1} band suggested NO_2^- to be bonded as nitrito group. Although all the spectra have shown a band around 1850 cm^{-1}, but compared to the position of NO^+ band, its position in $SnCl_3$ complexes was shifted slightly towards higher wave numbers and it was relatively a broader band. Though 1850 cm^{-1} band may also indicate the presence of NO^+, but the presence of other characteristic bands of N_2O_3 around 1340, 1320, and 840 cm^{-1} suggested the absence of NO and further, the presence of bonded NO^+ group in the complexes will require an extra negative ion for balancing the charge on the complex. It was therefore envisaged that 1850 cm^{-1} band suggested the presence of N_2O_3 rather than NO^+. Besides their ir spectra also exhibited the characteristic pattern of five bands in the 1500–1350 cm^{-1} region, and three bands in 820–690 cm^{-1} region, suggesting the presence of π-interaction between ruthenium ion and one of the phenyl rings of PPh_3.

Interestingly, N_2O_3 adducts were formed only with the complexes in which ruthenium is coordinated with PPh_3 through π-interaction of one of its phenyl ring. Although the assignment of a reason for the interesting behaviour of these complexes will be speculative, literature indicates that a number of aromatic compounds like toluene, *m*-xylene, etc., form adducts with N_2O_3 by donating electron density from the aromatic ring to N_2O_3 (34). The formulation of these adducts as $[NOR]^+[NO_2]^-$ has also been discarded on the grounds of electrolytic conductivity (35). In the complexes, a weak acid–base interaction between uncoordinated phosphorus atom (base) and N_2O_3 (acid) could possibly explain the N_2O_3-adduct formation.

Though this simple explanation is highly speculative, it could be suggested that the triphenylphosphine molecule coordinated to the metal ion through π-interaction of the phenyl group is playing some role in the adduct formation.

¹H nmr spectra

All the complexes ¹H nmr spectra were studied to confirm the presence of the co-ligand molecules. These exhibited a poorly resolved broad multiplet due to the protons of the phenyl groups of PPh_3 and those of *N*-heteronuclear group in the region around δ 7.0 and an additional band due to methyl protons around δ 2.0 in the case of picolines. The absence of a sharp signal in δ 4.5 region, further confirmed the loss of η-C_5H_5 moiety during nitrosylation.

Owing to the low solubility of the $SnCl_3$ complexes, only low intensity, poorly-resolved spectra were obtained. However, a broad resonance around δ 7.2 and a weak multiplet around δ 5.2 were observed in every case. The latter signal has been assigned to the π-bonded phenyl ring of PPh_3 (17). The upfield shift of the band compared to that obtained in triphenylphosphine or P-bonded triphenylphosphine complexes is supportive of the π-interaction of the phenyl ring of PPh_3 with ruthenium. Though a single crystal X-ray study will ultimately give a conclusive proof for the π-arene interaction with the Ru atom, the present spectroscopic evidences (ir and ¹H nmr) nevertheless strongly suggest that the only structure of the nitrito chlorostannate complexes which is consistent with all the data is the one in which phenyl ring of triphenylphosphine is bound to metal with a π-arene type linkage (Fig. 1).

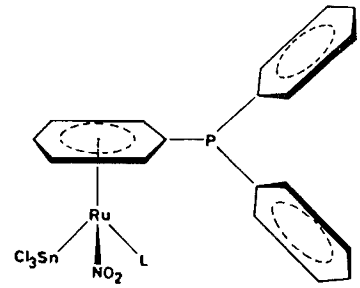

FIG. 1. Structure of cyclopentadienyl ruthenium complexes (L = PPh_3, pyridine, 3-picoline, 4-picoline, $\frac{1}{2}$(2,2′-bipyridine), or $\frac{1}{2}$(1,10-phenanthroline)).

Magnetic and uv, visible spectral data

All the complexes were diamagnetic in the solid state. This points towards an octahedral geometry of ligand atoms around the d^6 ruthenium ion in a strong ligand field causing a low spin configuration.

Table 1 lists the λ_{max} of the electronic spectra of the complexes obtained at room temperature in chloroform solution.

In order to seek some information about the π-interaction of one of the phenyl rings of phosphine molecules with the metal center, uv spectra of the $SnCl_3$ complexes were studied. But because of the presence of a number of π-bonded molecules like phosphine, pyridines, picolines, 2,2′-bipyridyl, 1,10-phenanthroline, NO_2^-, NO^+, SCN^-, or CN^- in the complexes, practically a continuous and strong absorption was observed beyond 350 nm. Hence no information could be gathered from their uv spectra, though in a few cases the positions of one or two shoulder bands around 270 nm did shift towards the higher energy side.

In the visible region a rather broad band of medium intensity, centering around 450 nm, was exhibited by all the complexes. As it is generally believed that d–d or the (MLCT) transition in ruthenium(II) octahedral complexes occur under a broad envelope at around 450 nm (36), the presence of a similar band in the present complexes suggested an octahedral geometry of ligands around Ru(II) ion. While comparing the spectral positions of this band with those of parent ones $[Ru(\eta^5\text{-}C_5H_5)(PPh_3)(L)X]$ (*ca.* 550 nm) a considerable band shift towards higher energy has been found in the nitrosyl or nitrito complexes. By taking into account the large number of donor groups which are capable of creating a stronger field around the metal ion an observed blue shift is quite understandable. Further, the position of the 450 nm band showed variation in its position for the series of Cl, Br, I, CN, $SnCl_3$, NCS complexes, in accordance with the ligand position in the spectrochemical series. The substitution of a phosphine ligand by a pyridine or picolines caused a red shift in consonance with their lower positions compared to phosphine in the spectrochemical series. The shift in 2,2′-bipyridine or 1,10-phenanthroline complexes was found to be erratic. Since 450 nm band seems to be ligand field dependent, it may be assigned to be arising due to MLCT. The probability of this band being due purely to a d–d transition is rather low, because of the availability of low lying empty π^* orbitals of the ligand.

Further the compositions of all the reaction products suggest an octahedral geometry. The complexes, being mixed ligand ones, may exist in a number of isomeric forms. However, no attempt has been made to assign any particular geometry to these complexes except that PPh_3 and L molecules may be *cis* to each other, if one assumes that no molecular rearrangement has taken place during the reaction.

A few of the complexes contain dichloromethane as a CH_2Cl_2 of crystallization. Since the number of protons in CH_2Cl_2 is two per molecule of CH_2Cl_2, it is difficult to observe these protons because of the solubility limitation of the complexes. However it has been observed that in a couple of cases (compounds **26** and **41**) where the solubility of the complexes was found to be rather large, a very weak band corresponding to one or two protons, around δ 4.2 was observed which has been assigned to CH_2Cl_2 bands.

Finally, it may be emphasized that although it is difficult to postulate any mechanistic path-way for these reactions, one may speculate the following tentative scheme of these reactions.

It is well known that the following equilibrium in the methanolic solution of $[Ru(\eta^5\text{-}C_5H_5)(PPh_3)_2X]$ exists:

$$[Ru(\eta^5\text{-}C_5H_5)(PPh_3)_2X] \rightleftharpoons [Ru(\eta^5\text{-}C_5H_5)(PPh_3)_2]^+ + X^-$$

It is, therefore, conceivable that the reacting species in these reactions could possibly be $[Ru(\eta^5\text{-}C_5H_5)(PPh_3)_2L]^+$ which interacts with $NOBr_3$ or N_2O_3 or NO^+ in a concerted or stepwise process to give an intermediate

$$[Ru(\eta^5\text{-}C_5H_5)(PPh_3)L(NO)]^{2+}$$

The latter subsequently undergoes substitution reaction with $X^- = Cl^-$, Br^-, NO_2^-, etc., to yield the final product $[Ru(NO)X_{3-n}Y_n(PPh_3)L]$.

The biosynthesis of cyclopropane fatty acids. III. pH Dependence of methyl hydrogen exchange: gas chromatographic – mass spectral studies

PETER H. BUIST AND JUDY M. FINDLAY
The Ottawa–Carleton Institute for Research and Graduate Studies in Chemistry, Carleton University, Ottawa, Ont., Canada K1S 5B6

Received August 28, 1984

PETER H. BUIST and JUDY M. FINDLAY. Can. J. Chem. **63**, 971 (1985).

L-Methionine-methyl-d_3 was administered to *Lactobacillus plantarum* and the deuterium content of the biosynthetic lactobacillic acid examined by gc–ms. By conducting the biosynthetic experiments in media of varying pH, it was shown that the production of d_1-cyclopropane fatty acid increases with decreasing pH. Factors such as culture age and total activity of cyclopropane synthetase do not directly influence the extent of exchange.

PETER H. BUIST et JUDY M. FINDLAY. Can. J. Chem. **63**, 971 (1985).

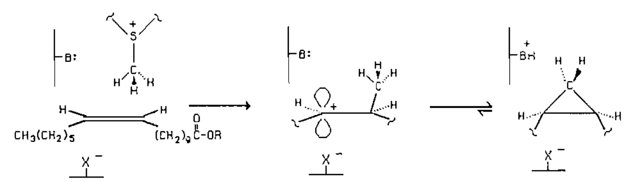
On a administré de la L-méthionine-méthyl-d_3 au *Lactobacillus plantarum* et, faisant appel à la cpg/sm, on a examiné le contenu en deutérium de l'acide lactobacillique biosynthétique. En effectuant les expériences de biosynthèse dans des milieux de pH variés, on a pu démontrer que la production d'acide gras comportant un cyclopropane-d_1 augmente avec une diminution du pH. Des facteurs comme l'age de la culture et l'activité totale de la synthésase de cyclopropane n'influencent pas directement le degré d'échange.

[Traduit par le journal]

Enzymic processes which take place in hydrophobic environments form an important subset of all biological reactions. The detailed mechanisms of these reactions are of interest since the chemical reactivity of species subjected to solvent-free environments is often startlingly different from their behaviour in solution. One important example of this type of chemistry is the biomethylenation of olefinic fatty acyl phospholipids as it takes place in many bacterial cell membranes (1). The methylene bridge is derived from *S*-adenosyl-L-methionine (S.A.M.) and the reaction is presumed to involve methyl transfer, formation of a carbocationic intermediate, and 1,3 proton elimination to give the cyclopropyl product. An active site model for this reaction has been presented previously (2) and the essential features are displayed in Scheme 1. The precise structure of the carbocationic intermediate is unknown. Feeding experiments using specifically deuterated substrates and the microorganism, *Lactobacillus plantarum*, have established that if a protonated cyclopropane (3) is involved, then it is sufficiently short-lived to preclude any significant scrambling of deuterium label, as determined by nmr experiments (2, 4). Fluorine substituent effect studies are currently underway in order to gain more insight into this intriguing biological reaction. (For a preliminary account, see ref. 5.)

Feeding experiments using methionine, bearing a trideutero methyl group, have also provided mechanistic information. Interestingly, up to 17% of a monodeuterated species is observed in the mass spectrum of biosynthetic cyclopropane fatty acid (lactobacillic acid) obtained in these feedings. After a complete analysis of the various possible pathways for hydrogen exchange, it was concluded that exchange at the methyl group was probably occurring as a consequence of the fact that the deprotonation step leading to cyclopropane formation is reversible (2).

Recently, the existence of the exchange process has been confirmed in every detail by running the simultaneously proton and deuterium decoupled ^{13}C nmr spectrum of biosynthetic lactobacillic acid derived from methionine-methyl-d_3, which was enriched with carbon-13 in the methyl group.[1] Again,



SCHEME 1

approximately 20% of a 1 : 1 mixture of the two possible diastereomeric d_1-species was observed in this experiment.

With the exchange phenomenon firmly documented by two independent analytical techniques, we decided to investigate this very unusual process more closely. Previously (2) it had been noted that the production of exchanged material seemed to increase with increasing culture age in feeding experiments with *Lactobacillus plantarum*. Since the pH of the culture medium also decreases with the extent of growth, due to lactic acid production, it was thought that the exchange process might be dependent on pH. We wish to report the results of experiments which show quite conclusively that this is, in fact, the case.

The simplest way to begin testing our hypothesis was to run the feeding experiments using methionine-methyl-d_3 in media of varying pH, and to analyze the biosynthetic cyclopropane for d_1-content by gc–ms. Two sets of feeding experiments were carried out, the results of which are shown in Table 1. In the first incubation, the pH of the culture was constantly adjusted during growth to the initial pH of 7, by the addition of sterile base to neutralize lactic acid produced by the organism (Expt. #1). In the second experiment, the incubation was started at a pH of 5 and allowed to drop to a final pH of 4.2 (Expt. #2). In this way, we were able to examine the exchange process in two complementary pH domains. We could not perform incubations where the initial pH of the culture was significantly greater than 7.0, since the microorganism cannot tolerate these conditions. In each case, a control experiment was performed (Controls #1 and #2), in which the pH of the medium was allowed to drop from an initial value of 7.0 to a value of approximately 4.0 at the end of the incubation. Experiment #3 refers to previously published work (2), in which the incubation

[1] Unpublished results, obtained in collaboration with A. G. McInnes, J. A. Walter and J. L. C. Wright.

TABLE 1. pH-Dependence of methyl group exchange during cyclopropane fatty acid biosynthesis

pH range (Ave. pH)	Cell yield[a] (mg/100 mL)	% Biomethylenation[b]	$\%d_2$[c]	$\%d_1$	$\%d_0$	$\%d_1/(\%d_1 + \%d_2)$

[a] The cell yields are given in terms of dry cell weight per 100 mL of culture.
[b] The fatty acids were extracted and analyzed by capillary gc to determine the % biomethylenation: [amt. cyclopropane/(amt. cyclopropane and amt. olefin)] × 100.
[c] For a discussion of errors in the determination of deuterium content, see the experimental section.

was carried out at uncontrolled pH, but part of the same culture was harvested during exponential phase (final pH 5.9) and the remaining portion in lag phase (final pH 4.4).

The following parameters were measured.

(1) Average pH at which biomethylenation was taking place. Our data shows that a substantial amount of cyclopropane formation occurs at all pH values.

(2) Cell yield, as an indication of extent of growth.

(3) % Biomethylenation, the % conversion of olefin to cyclopropane as a measure of the total activity of the cyclopropane synthetase.

(4) The extent of exchange, indicated by the amount of d_1-cyclopropane as a percentage of the total deuterated material. The contribution by d_0 species was neglected, as endogenous cyclopropane from the inoculum was always a major source of this material. Also, an inherent $M - 2$ peak in the mass spectrum of these compounds made it difficult to quantitate the d_0 species accurately. In any case, further loss of deuterium from a monodeuterated cyclopropane is expected to be small, due to a substantial intramolecular isotope effect (2).

When the extent of exchange given by the parameter $\%d_1/(\%d_1 + \%d_2)$ is plotted versus average pH of the medium, it is readily apparent that the extent of exchange increases with decreasing pH (see Fig. 1. At this stage we do not know the mathematical form of the pH dependence). The excellent reproducibility of the data is indicated by the results of Control #1 and Control #3. In contrast, the extent of exchange does not correlate in any obvious way with cell yield, as is readily seen by comparing the results of Expts. #2 and #3. It appears that the extent of exchange also increases with % biomethylenation (graph not shown). We believe that this latter correlation is an indirect one and is due to the fact that, in general, the total activity of cyclopropane synthetase is increased by a drop in pH due to a complex induction phenomenon, as discussed in further detail below.

Consideration of our active site model for this reaction may provide an explanation for the pH dependence of exchange (see

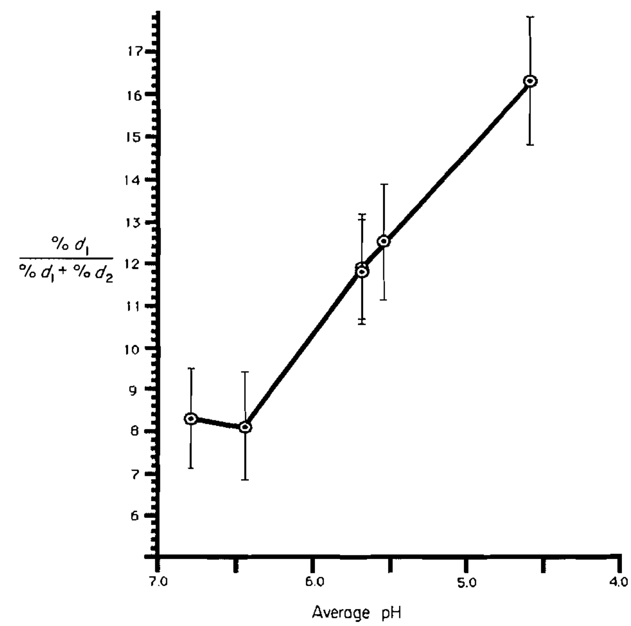

FIG. 1. Dependence of extent of methyl hydrogen exchange on pH.

Scheme 1). Using arguments first developed by Akhtar and Jones (6), we suggest that just as the sulfonium salt is activated by desolvation to allow delivery of a methyl group to an isolated double bond, so the equally unsolvated, conjugate acid (e.g. an ammonium group) is able to protonate the cyclopropane ring.

Assuming for the moment that this is the case, then one might intuitively expect that a lowering of external pH would cause an increase in d_1-cyclopropane production. At lower pH, the equilibrium between the base and its conjugate acid will be shifted to favour the conjugate acid form and hence favour reprotonation of the cyclopropane ring. This equilibrium may be established via one or more amino acid residues acting as a proton shuttle between the active site and the external environment. Thus the extent to which a dideutero-cyclopropane fatty acid is reopened will be greater under these "more acidic" conditions and thus lead to an enhanced production of exchanged material.

Another, perhaps less likely, explanation for the pH dependence of exchange might be that the tertiary structure of the cyclopropane synthetase is altered at lower pH so that the rate of product release is decreased relative to the rate of reprotonation of the cyclopropane.

Either of these effects may also lead to a decrease in specific acitivity of the enzyme. It is interesting to note in this connection that previous work with a cyclopropane synthetase from *Clostridium butyricum* has shown that the pH optimum for the enzyme is, in fact, 7.0 with a rather broad range of 3 pH units on either side of neutrality (7). Unfortunately, a pH profile for the enzyme from *Lactobacillus plantarum* has not been carried out; however, assays of this enzyme are routinely carried out at a pH of 7. The most recent enzymological work with a cyclopropane synthetase from *E. coli* also did not include a pH profile of enzyme activity (8). In vivo studies with *Lactobacillus plantarum* have shown that lowering of pH of the medium enhances lactobacillic acid production but that this effect involves protein synthesis (9), which indicates a more complex inductive effect than at first realized (10).

In summary, we have shown that the exchange at the methyl group in biomethylenation is pH dependent, and thus have provided a basis for further work using purified enzyme preparations buffered over a wider range of pH values. In this way, one should be able to determine the exact form of the pH dependence and gain some clues as to the nature of the base present in the active site. Also, it may be possible to monitor the in vitro exchange process directly by ^{13}C nmr, if S.A.M. enriched with carbon-13 in the methyl group is employed.

Methyl hydrogen exchange seems to be a general phenomenon in "difficult" biomethylations, i.e. methyl transfer to unactivated double bonds, particularly where elimination at the methyl group is the mode of collapse of the carbocationic intermediate (see ref. 2 for a complete discussion). We believe that the observance of exchange in these systems is a consequence of the high reactivity of separated ion pairs in the hydrophobic microenvironment required for these methyl transfers to proceed (6). A search for a similar pH dependence of methyl group exchange as found in this work is warranted in other systems.

Experimental

Apparatus, methods, and materials

L-Methionine-methyl-d_3 was purchased from Merck, Sharpe and Dohme, Pointe Claire, Quebec. Examination of the *bis*-TMS derivative of this material showed that it was essentially 100% trideuterated, with only traces of exchanged species present.

Mass spectrometric determination of deuterated species was performed on a VG 7070-E mass spectrometer, coupled to a DANI 3800 gas chromatograph which was equipped with a 6% OV 101 column and operated isothermally at 250°C. The mass spectrometer was operated at 70 eV, with an accelerating voltage of 6 kV. The ion source was heated at 210°C. Deuterium determinations were performed by injecting a 1% hexane solution of the biosynthetic fatty acids as their methyl esters, scanning the molecular ion cluster repetitively over the entire gc peak due to methyl lactobacillate, and summing the intensities of each individual peak. In this manner each deuterated species could be determined as a percentage with an absolute maximum error of ±1%. The resultant error in $\%d_1/(\%d_1 + \%d_2)$ was calculated in the usual way. In plotting this data, vertical error bars are used, since the error in the parameter plotted along the ordinate is considered to be much larger than the error in the parameter plotted along the abscissa.

The microorganism used in this study was *Lactobacillus plantarum* ATCC 8014 and was obtained from the American Type Culture Collection, Rockville, MD, U.S.A. The basal medium used for each feeding experiment was that of Henderson and Snell (11). The microorganism was grown without shaking at 37°C and harvested by centrifugation at 4°C at 5000 rpm. The cells were then freeze-dried and weighed. Fatty acids were isolated from the bacterial cells by saponification as described below and quantitated as their methyl esters by capillary gc analysis using a Varian Vista 6000 gas chromatograph equipped with a J. and W. DB-5, 0.25-μm capillary column and an FID detector.

Methionine-methyl-d_3 feedings: experiment #1 and control #1

L-Methionine-methyl-d_3 (25 mg) in 3 mL of 50% ethanol and a sterilized solution of biotin (2.5 μg) in 0.25 mL of water were added to 250 mL of filter sterilized basal medium (pH 7.0). Ninety milliliters of this medium were added to a Florence flask, which was then inoculated with a saline suspension (0.5 mL) of freshly grown cells and the culture grown for 26 h to give a final pH of 4.4. The cells were harvested and fatty acids extracted as usual.

One hundred and fifty milliliters of the same medium were transferred to a 250-mL beaker fitted with a 3-holed rubber stopper. A pH electrode was wiped with ethanol and inserted into the medium. An inlet tube connected via tubing to a burette filled with sterile 2 *N* KOH was also inserted. The third port was used to inoculate the medium. The beaker was placed in a constant temperature bath set to 37°C. As growth proceeded the pH of the medium was kept between 6.5 and 7.0 by adding base. After 26 h the cells were harvested and fatty acids extracted by the procedure described below.

Isolation of microbial fatty acids

The dried cells were hydrolyzed with 20 mL of 1 *M* KOH in 1:1 ethanol/water at reflux, under nitrogen, with stirring, for 2 h. The ethanol was then removed *in vacuo* at 40°C. The aqueous residue was transferred to a separatory funnel and washed once with 30 mL of ether. The aqueous layer was acidified with 50% H_2SO_4 and the pH was monitored with Congo Red paper. The fatty acids were extracted with 3 × 10 mL of ether and the combined ether layers were washed with 10 mL of water. After drying with 4 g of sodium sulphate, the ether layer was filtered and the solvent removed *in vacuo*. Residual water was removed as an azeotrope with acetone. The fatty acid residue was dissolved in 2 mL of ether contained in a 25-mL round-bottomed flask and a freshly prepared ethereal solution of diazomethane was distilled into the flask until the yellow colour of diazomethane persisted. The solvent was removed *in vacuo*.

The fatty acid methyl esters were stored in hexane solution in Teflon-capped vials.

Methionine-methyl-d_3 feedings: experiment #2 and control #2

L-Methionine-methyl-d_3 (40 mg) in 50% ethanol (4 mL) and biotin (4.0 μg) in 0.4 mL of sterile water were added to 400 mL of filter sterilized basal medium which was then divided into 200-mL portions between two Florence flasks. The pH of one portion was adjusted to 7.0 (Control #2) and the pH of the other portion was lowered to 5.0 (Expt. #2). Both flasks were inoculated with a 1.0-mL saline suspension of freshly grown cells. Growth was allowed to proceed for 48 h, after which the cells were harvested and fatty acids extracted as usual.

Mécanisme des réactions du chlorite et du dioxyde de chlore. 3. La dismutation du chlorite

GUY SCHMITZ ET HENRI ROOZE

Faculté des Sciences Appliquées, Université Libre de Bruxelles, 50, Avenue F. Roosevelt, 1050 – Bruxelles, Belgique

Reçu le 20 juin 1984

GUY SCHMITZ et HENRI ROOZE. Can. J. Chem. **63**, 975 (1985).

La dismutation du chlorite a été étudiée en solutions d'acide perchlorique 0,01 *M* à 1 *M*, à 25°C et pour une force ionique de 1 *M*. Les résultats impliquent au moins trois processus réactionnels. Le premier est catalysé par les ions Cl^-, le second donne une loi d'ordre deux et le troisième est catalysé par le fer. Sa loi cinétique est

$$\frac{d[ClO_2]}{dt} = \frac{[Fe^{3+}][ClO_2^-][HClO_2]}{[ClO_2]}\left(1{,}39 + \frac{0{,}11}{[H^+]}\right)$$

Elle peut être interprétée par la réaction réversible $ClO_2^- + Fe^{3+} \rightleftharpoons ClO_2 + Fe^{2+}$ suivie de deux étapes déterminantes $Fe^{2+} + HClO_2 \rightarrow$ produits et $Fe^{2+} + ClO_2^- \rightarrow$ produits. Nous déduisons de cette étude et de la précédente faite en présence d'*ortho*-tolidine, que la réaction d'ordre deux correspond à un mécanisme radicalaire en chaîne.

GUY SCHMITZ and HENRI ROOZE. Can. J. Chem. **63**, 975 (1985).

The disproportionation of chlorite was studied in 0.01 to 1 *M* perchloric acid solutions at 25°C and an ionic strength of 1 *M*. The results suggest at least three reaction paths. The first is catalysed by Cl^- ions, the second gives a second-order rate law, and the third is catalysed by iron. Its rate law is

$$\frac{d[ClO_2]}{dt} = \frac{[Fe^{3+}][ClO_2^-][HClO_2]}{[ClO_2]}\left(1.39 + \frac{0.11}{[H^+]}\right)$$

This can be interpreted by the reversible reaction $ClO_2^- + Fe^{3+} \rightleftharpoons ClO_2 + Fe^{2+}$ followed by two rate-determining reactions $Fe^{2+} + HClO_2 \rightarrow$ products, $Fe^{2+} + ClO_2^- \rightarrow$ products. From this study and the former, made with added *ortho*-tolidine, we conclude that the second-order reaction proceeds by a radical chain mechanism.

Introduction

La thermodynamique, la stoechiométrie et certains aspects de la cinétique de la dismutation du chlorite ont été discutés dans nos articles précédents (1, 2). Cette dismutation peut résulter d'au moins trois réactions.

(a) La réaction catalysée par les ions Cl^- (1). Elle peut intervenir même s'il n'y a pas d'ions Cl^- initialement, car la dismutation du chlorite en produit. Sa contribution n'est alors significative qu'aux acidités et conversions élevées. Elle peut être négligée lors de toutes les expériences discutées ci-après.

(b) La réaction classique d'ordre 2.

$$[1] \quad -d[HClO_2]/dt = k_1[HClO_2]^2$$

La loi [1], bien établie en milieux très acides, n'est plus vérifiée si $[H^+] \leq 0{,}2\ M$ (3).

(c) La réaction catalysée par des traces de fer dont nous avons étudié la cinétique en présence d'*ortho*-tolidine (2). Nous l'étudions ici en son absence. La technique expérimentale a été décrite antérieurement (1, 2). La concentration totale du chlorite, $[HClO_2] + [ClO_2^-]$, sera désignée par $[NaClO_2]$ et la concentration totale du fer ajouté par [Fe].

Résultats préliminaires

Nous avons confirmé l'observation de Kieffer et Gordon (3), la loi [1] n'est plus satisfaite si $[H^+] \leq 0{,}2\ M$, et en avons découvert la raison: la catalyse de la dismutation du chlorite par les traces de fer inévitablement présentes dans les réactifs. Rappelons (fig. 1 de la réf. 2) qu'en absence d'*ortho*-tolidine, si $[HClO_4] = 0{,}1\ M$, 5×10^{-6} mol/L de fer font plus que doubler la vitesse de formation du dioxyde de chlore. Cet effet du fer est très spécifique (4).

Lors de nos mesures préliminaires nous avons également observé un effet inhibiteur du dioxyde de chlore. Cet effet semblant contredire d'autres travaux, nous en donnons une preuve directe. La figure 1 montre l'évolution de la concentration du ClO_2 dans une solution de chlorite à pH = 2. On observe une diminution rapide de la vitesse qui ne peut résulter ni d'une perte de ClO_2 ni de la variation de la concentration du chlorite. Après 9 min la vitesse a diminué d'un facteur 3 environ, alors que la conversion est inférieure à 10%. La courbe (b) prouve que ceci résulte d'un effet inhibiteur du ClO_2 sur sa vitesse de formation. On a fait passer un courant d'azote pour chasser le ClO_2 dans une fraction de la solution donnant la courbe (a). Toutes autres choses étant égales, les vitesses sont plus grandes si $[ClO_2]$ est plus petit. D'autre part nous n'avons trouvé aucun effet du chlorate.

Résultats en présence de fer ajouté

Dans le domaine d'acidité étudié et sans chlorure ni fer ajouté, la stoechiométrie correspond assez bien à [2] avec une tendance à la formation d'un peu plus de chlorate (1, 3).

$$[2] \quad 4HClO_2 = 2ClO_2 + ClO_3^- + Cl^- + 2H^+ + H_2O$$

Nous avons vérifié qu'en présence de fer ajouté cette équation reste valable, les écarts semblant même moins importants qu'en son absence. Avec 3×10^{-4} mol/L de fer nous avons obtenu

$$[ClO_2]/\Delta[NaClO_2] = 0{,}49 \pm 0{,}02$$

rapport indépendant du chlorite initial, $[NaClO_2]_0 = 10^{-3}$ à $10^{-2}\ M$, et de l'acidité, $[HClO_4] = 10^{-2}$ à $2\ M$.

Pour une acidité fixée et une quantité de fer ajoutée suffisante (elle dépend de l'acidité et sera précisée plus loin) nous avons obtenu la loi cinétique [3]

$$[3] \quad \frac{d[ClO_2]}{dt} = k_3\frac{[NaClO_2]^2}{[ClO_2]}$$

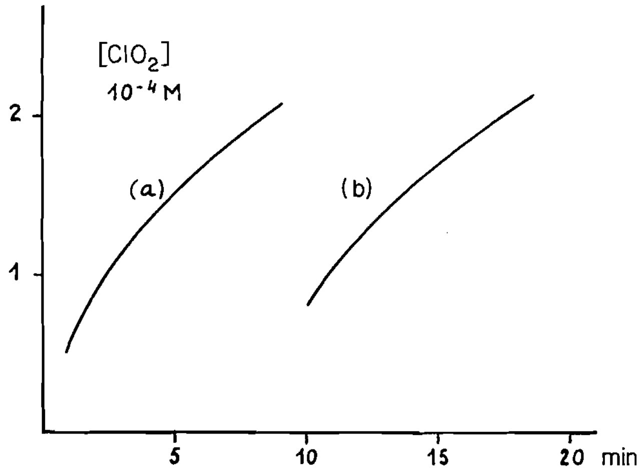

FIG. 1. Evolution de la concentration du ClO_2 dans deux fractions de la même solution; (a) sans barbotage d'azote; (b) après barbotage d'azote pendant 9 min. $[NaClO_2] = 5{,}4 \times 10^{-3}\ M$; $[HClO_4] = 9{,}0 \times 10^{-3}\ M$.

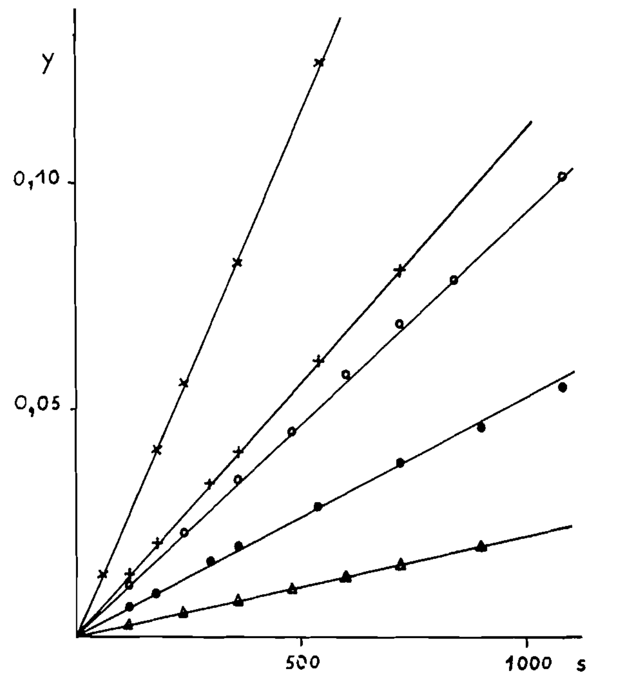

FIG. 2. Transformée Y de la conversion en fonction du temps; $[NaClO_2]_0 = 5{,}7 \times 10^{-3}\ M$. $4Y = [NaClO_2]_0/[NaClO_2] - 1 - \ln [NaClO_2]_0/[NaClO_2]$. $[H^+] = 0{,}0520\ M$, $[Fe] = 3{,}0 \times 10^{-4}\ M$ (X); $[H^+] = 0{,}0520\ M$, $[Fe] = 1{,}2 \times 10^{-4}\ M$ (+); $[H^+] = 0{,}0520\ M$, $[Fe] = 6{,}0 \times 10^{-5}\ M$ (●); $[H^+] = 0{,}208\ M$, $[Fe] = 6{,}0 \times 10^{-4}\ M$ (○); $[H^+] = 0{,}208\ M$, $[Fe] = 1{,}2 \times 10^{-4}\ M$ (△).

Par intégration, avec $[NaClO_2] = [NaClO_2]_0 - 2[ClO_2]$, on obtient [4].

$$[4] \quad \frac{[NaClO_2]_0}{[NaClO_2]} - 1 - \ln \frac{[NaClO_2]_0}{[NaClO_2]} = 4k_3t$$

La figure 2 donne quelques exemples de nos mesures et la figure 3 montre que la constante cinétique apparente k_3 est proportionnelle à la concentration du fer et indépendante de la valeur initiale du chlorite. L'effet de l'acidité sur k_3 apparaît dans le tableau 1 et conduit à expliciter [3] sous la forme [5].

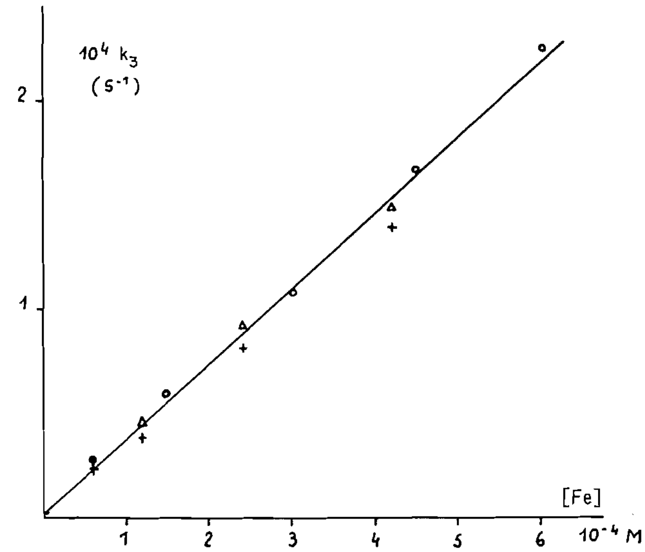

FIG. 3. Variation de k_3 en fonction du fer ajouté. $[H^+] = 0{,}104\ M$; $[NaClO_2]_0 = 3{,}2 \times 10^{-3}\ M$ (+), $5{,}7 \times 10^{-3}\ M$ (○), $8{,}0 \times 10^{-3}\ M$ (△), $1{,}6 \times 10^{-2}\ M$ (●).

TABLEAU 1. Effet de l'acidité sur k_3, 25°C, $I = 1\ M$

$[H^+]$ (M)[a]	$k_3/[Fe]$ $(M^{-1}\ s^{-1})$ Exp.	Calc.[b]
0,052	0,765	0,757
0,104	0,368	0,373
0,208	0,165	0,178
0,416	0,0866	0,0853
1,039	0,0334	0,0330

[a]Les valeurs de $[H^+]$ sont légèrement inférieures à celles de $[HClO_4]$ à cause de la formation de $[HClO_2]$.
[b]Valeurs calculées par [6].

$$[5] \quad \frac{d[ClO_2]}{dt} = \frac{[Fe][ClO_2^-]}{[ClO_2]}(k_5'[HClO_2] + k_5''[ClO_2^-])$$

On déduit de

$$[HClO_2] = \frac{[H^+]}{[H^+] + K_a}[NaClO_2];$$

$$[ClO_2^-] = \frac{K_a}{[H^+] + K_a}[NaClO_2]$$

la relation [6] entre k_3 et l'acidité.

$$[6] \quad \frac{k_3}{[Fe]}\frac{([H^+] + K_a)^2}{K_a} = k_5'[H^+] + k_5''K_a$$

En portant les valeurs du premier membre de [6], calculées avec $K_a = 2{,}4 \times 10^{-2}$ pour $T = 25$°C et une force ionique $I = 1\ M$ (2, 5), en fonction de $[H^+]$ on obtient une droite dont la pente et l'ordonnée à l'origine donnent:

$$k_5' = 1{,}39\ M^{-1}\ s^{-1}; \qquad k_5''K_a = 0{,}11\ s^{-1}$$

Résultats en absence de fer ajouté

En absence de fer ajouté la production de ClO_2 résulte à la fois de la réaction d'ordre deux et de celle catalysée par les traces de fer inévitablement présentes dans les réactifs (2, 4). Tant que la réaction catalysée par les ions Cl^- est négligeable, on obtient [7].

$$[7] \quad \frac{d[ClO_2]}{dt} = k_2[HClO_2]^2 + \frac{[Fe][ClO_2^-]}{[ClO_2]} \times (k_5'[HClO_2] + k_5''[ClO_2^-])$$

Pour une valeur donnée de la concentration du fer, la contribution du deuxième terme est d'autant plus petite que $[ClO_2]$ est grand. Elle diminue donc lorsque la conversion augmente. Cette contribution diminue également si l'acidité augmente, ce qui explique que Kieffer et Gordon (3) aient vérifié la loi d'ordre deux en milieux perchloriques 1,2 M mais pas en milieux moins acides.

Soit α un coefficient stoechiométrique valant 2 si [2] est exactement suivi, un peu supérieur si l'on forme un peu plus de chlorate.

$$[NaClO_2] = [NaClO_2]_0 - \alpha[ClO_2]$$

Si le deuxième terme de [7] était négligeable, on devrait vérifier la forme intégrée [8].

$$[8] \quad \frac{1}{[NaClO_2]} - \frac{1}{[NaClO_2]_0} = \alpha k_2' t$$

$$k_2' = k_2\left[\frac{[H^+]}{[H^+]+K_a}\right]^2$$

La figure 4(a) donne quelques exemples de nos résultats. La loi d'ordre deux n'est pas vérifiée aux faibles conversions parce que, conformément à [7], la réaction catalysée par le fer n'est pas négligeable. Elle ne le devient qu'à partir de conversions d'autant plus grandes que $[H^+]$ et $[NaClO_2]_0$ sont petits. Dans le domaine où $1/[NaClO_2]$ varie linéairement en fonction du temps, nous obtenons à 25°C

$$k_2 = 5{,}1 \pm 0{,}2 \times 10^{-3}\ M^{-1}\ s^{-1}$$

valeur indépendante du chlorite, $[NaClO_2]_0 = 10^{-3}$ à 10^{-2} M, et de l'acidité, $[HClO_4] = 0{,}2$ à 1,2 M. Nous avons utilisé $\alpha = 2$. Avec α un peu plus grand on calculerait $[NaClO_2]$ un peu plus petit, $\alpha k_2'$ un peu plus grand et par un effet de compensation pratiquement la même valeur de k_2. Hong et Rapson (5) ont obtenu $k_2 = 5{,}5 \times 10^{-3}$ et Kieffer et Gordon (3) $\alpha k_2 = 1{,}17 \times 10^{-2}$.

Les importances relatives des deux termes de [7] correspondent bien aux teneurs en fer des réactifs déterminées par spectroscopie d'émission de plasma (4). Par exemple pour l'expérience de la figure 4(a) faite avec $[HClO_4] = 1{,}2$ M et $[NaClO_2]_0 = 2{,}18 \times 10^{-3}$ M on peut estimer que l'on avait $[Fe] \sim 2 \times 10^{-6}$ M. On en déduit avec les constantes cinétiques ci-dessus $r(\text{fer})/r(\text{ordre 2}) = 1{,}2 \times 10^{-5}/[ClO_2]$ ou encore $r(\text{fer}) = r(\text{ordre 2})$ si $[NaClO_2]^{-1} - [NaClO_2]_0^{-1} = 5$ en bon accord avec l'expérience.

L'équation [7], basée sur nos mesures de la production de ClO_2, est en accord avec les mesures de Kieffer et Gordon (3) de la consommation du $NaClO_2$. La figure 4(b) en donne un exemple. En milieu acide perchlorique 1,2 M, pour lequel ils ont admis la loi d'ordre 2, on obtient bien une droite mais elle ne passe pas par l'origine. La présentation adoptée fait apparaître la contribution, petite mais significative, de la catalyse par le fer au début de cette expérience. Nous avons également vérifié que leurs résultats en milieux moins acides (par

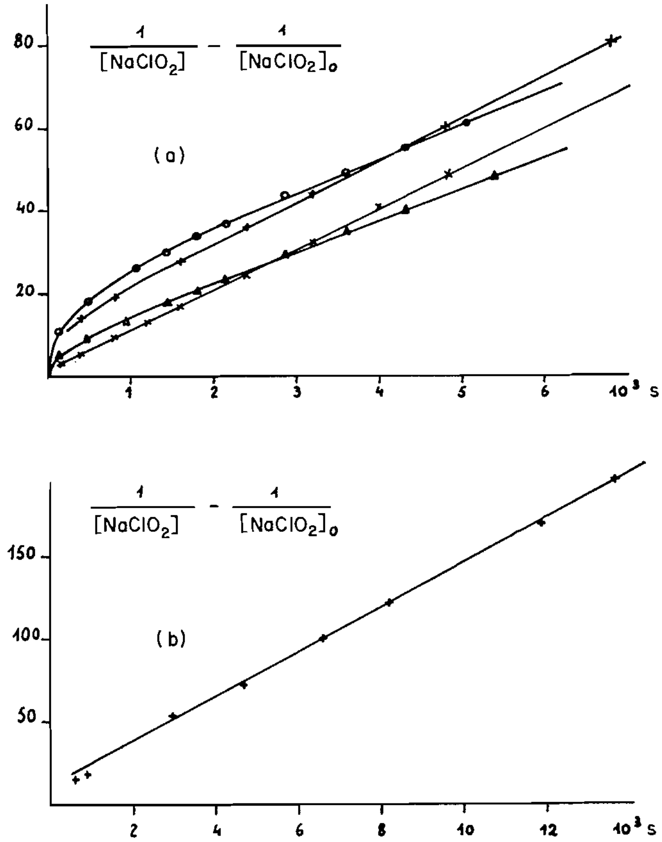

FIG. 4. (a) Résultats en absence de fer ajouté: $[H^+] = 1{,}2$ M, $[NaClO_2]_0 = 1{,}09 \times 10^{-2}$ M (X); $[H^+] = 1{,}2$ M, $[NaClO_2]_0 = 2{,}18 \times 10^{-3}$ M (+); $[H^+] = 0{,}2$ M, $[NaClO_2]_0 = 1{,}04 \times 10^{-2}$ M ($\triangle$); $[H^+] = 0{,}2$ M, $[NaClO_2]_0 = 4{,}15 \times 10^{-3}$ M ($\bigcirc$). (b) Résultats de Kieffer et Gordon (réf. 3, p. 243): $[H^+] = 1{,}2$ M, $[NaClO_2]_0 = 3{,}64 \times 10^{-3}$ M.

exemple p. 238 de la réf. 3; $[HClO_4] = 3{,}33 \times 10^{-3}$ M) satisfont la relation [4]. Dans ces milieux, la réaction catalysée par le fer présent dans les réactifs est prépondérante.

Interprétation des résultats

Catalyse par le fer

Pour interpréter nos résultats en présence d'*ortho*-tolidine nous avions admis (2) les réactions [9] et [10].

$$[9] \quad ClO_2^- + Fe^{3+} \rightleftharpoons ClO_2 + Fe^{2+}$$

$$[10'] \quad HClO_2 + Fe^{2+} \rightarrow ClO + Fe(OH)^{2+}$$

$$[10''] \quad ClO_2^- + Fe^{2+} + H_2O \rightarrow ClO + Fe(OH)_2^+$$

Ces mêmes réactions permettent d'interpréter la catalyse par le fer observée ici, la seule différence étant la réversibilité de [9]. L'*ortho*-tolidine réduisant très rapidement le ClO_2, en sa présence la réaction [9] est déterminante. Ici par contre, le ClO_2 est un produit de la réaction globale et [9] est un quasi-équilibre. On retrouve la loi [5] en admettant que les étapes déterminantes sont [10'] et [10''].

$$[Fe^{2+}] = K_9 \frac{[ClO_2^-][Fe^{3+}]}{[ClO_2]}$$

$$r_{10} = K_9 \frac{[ClO_2^-][Fe^{3+}]}{[ClO_2]} (k_{10}'[HClO_2] + k_{10}''[ClO_2^-])$$

Les constantes des équilibres d'hydrolyse

$$Fe^{3+} + H_2O \rightleftharpoons Fe(OH)^{2+} + H^+$$

$$Fe^{3+} + 2H_2O \rightleftharpoons Fe(OH)_2^+ + 2H^+$$

étant petites, respectivement 9×10^{-4} et $4,9 \times 10^{-7}$ (6, 7), les concentrations des formes hydroxylées sont négligeables dans le domaine d'acidité étudié. Celles des complexes avec les ions Cl^- le sont également (8). La valeur de la constante d'équilibre $K_9 = 2,7 \times 10^{-4}$ estimée en annexe implique que dès les plus faibles conversions observées, on a $[Fe^{2+}] \ll [Fe^{3+}]$ et par conséquent

$$[Fe^{3+}] = [Fe]$$

L'expression de r_{10} correspond bien à la loi expérimentale [5].

Réaction d'ordre deux

La réaction d'ordre deux étant supprimée par l'*ortho*-tolidine, nous avons souligné (2) que $2HClO_2 \rightarrow HClO + ClO_3^- + H^+$ n'est pas une réaction simple. Elle fait intervenir au moins un intermédiaire éliminé par l'*ortho*-tolidine. Ceci suggère un mécanisme radicalaire en chaîne de la forme générale suivante.

Initiation

[i] $HClO_2 + X \rightarrow R^1 + \ldots$

Chaîne

[c1] $HClO_2 + R^1 \rightarrow ClO_3^- + H^+ + R^2$

[c2] $HClO_2 + R^2 \rightarrow HClO + R^1$

Rupture

[r] $R^1 + X \rightarrow \ldots$

ou $R^2 + X \rightarrow \ldots$

La quasi-stationnarité des concentrations des radicaux R^1 et R^2 donne

$$k_i[HClO_2] = k_r[R^1] \text{ ou } k_r[R^2]$$

et une vitesse de la chaîne proportionnelle à $[HClO_2]^2$.

Admettons que la réaction d'initiation soit [10], c'est-à-dire $X \equiv Fe^{2+}$ et $R^1 \equiv ClO$. On obtient la chaîne [11], [12].

[11] $HClO_2 + ClO \rightarrow ClO_3^- + H^+ + Cl$

[12] $HClO_2 + Cl \rightarrow HClO + ClO$

La rupture peut être [13] ou [14].

[13] $Cl + Fe^{2+} \rightarrow Cl^- + Fe^{3+}$

[14] $ClO + Fe^{2+} \rightarrow ClO^- + Fe^{3+}$

D'autre part nous savons (1) que le HClO formé réagit très rapidement avec le chlorite suivant [15] et [16].

[15] $HClO + 2HClO_2 \rightarrow 2ClO_2 + Cl^- + H^+ + H_2O$

[16] $HClO + HClO_2 \rightarrow ClO_3^- + Cl^- + 2H^+$

Dans les milieux acides et riches en chlorite la réaction [15] est prépondérante.

La stoechiométrie de la chaîne résulte de [11] + [12] soit

$$2HClO_2 \rightarrow HClO + ClO_3^- + H^+$$

Si le HClO réagissait uniquement suivant [15] on obtiendrait exactement [2]. La petite contribution de [16] conduit à un excès de chlorate. On retrouve ainsi la stoechiométrie expérimentale.

Effet du choix de la réaction de rupture

A. Si on admet que la rupture de la chaîne se fait suivant [13] on obtient:

Initiation–rupture

Sa stoechiométrie résulte de 2 × [9] + [10] + [11] + [13] soit

$$4HClO_2 \rightarrow 2ClO_2 + ClO_3^- + Cl^- + 2H^+ + H_2O$$

Sa vitesse est donnée par l'expression de r_{10} ci-dessus. On retrouve bien la stoechiométrie et la cinétique de la réaction catalysée par le fer.

Chaîne

Nous venons de montrer que sa stoechiométrie est en accord avec l'expérience. Sa vitesse est obtenue en écrivant la relation de quasi-stationnarité:

$$k'_{10}[HClO_2][Fe^{2+}] + k''_{10}[ClO_2^-][Fe^{2+}] = k_{13}[Cl][Fe^{2+}]$$

d'où

$$r_{12} = \frac{k_{12}}{k_{13}}[HClO_2]^2\left(k'_{10} + k''_{10}\frac{K_a}{[H^+]}\right)$$

La comparaison de r_{10} avec la loi expérimentale [5] donne

$$\frac{k''_{10}K_a}{k'_{10}} = \frac{k''_5K_a}{k'_5} = 0,08$$

Dans les milieux acides où la réaction d'ordre deux est étudiée la contribution du terme en k''_{10} est petite et la cinétique correspond parfaitement à l'expression de r_{12}.

B. Si on admet que la rupture de la chaîne se fait suivant [14] on obtient:

Initiation–rupture

Sa stoechiométrie résulte de 2 × [9] + [10] + [14] soit

$$3HClO_2 \rightarrow 2ClO_2 + HClO + H_2O$$

suivi de [15] et [16]. Sa vitesse est donnée par l'expression de r_{10}.

Chaîne

Sa stoechiométrie est la même que ci-dessus. Sa vitesse est obtenue en écrivant la relation de quasi-stationnarité

$$k'_{10}[HClO_2][Fe^{2+}] + k''_{10}[ClO_2^-][Fe^{2+}] = k_{14}[ClO][Fe^{2+}]$$

d'où

$$r_{11} = \frac{k_{11}}{k_{14}}[HClO_2]^2\left[k'_{10} + k''_{10}\frac{K_a}{[H^+]}\right]$$

On retrouve également la loi cinétique de la réaction d'ordre deux.

La seule différence notable entre les deux hypothèses concerne la stoechiométrie de l'initiation–rupture. Avec [14], du fait de la prépondérance de [15] par rapport à [16], on prévoit une formation relative de ClO_2 beaucoup plus importante que celle obtenue expérimentalement pour la réaction catalysée par le fer. Nous admettons donc que, dans nos conditions, la rupture est [13]. Ce n'est pas nécessairement vrai en milieux moins acides. En effet lorsque la majorité du chlorite se trouve sous la forme ClO_2^-, le ClO produit par [10] pourrait réagir suivant [14] plutôt que suivant [11]. On expliquerait ainsi la forte proportion de ClO_2 obtenue par Kieffer et Gordon (3) si $[HClO_4] = 3,3 \times 10^{-3}$ *M*.

Comparaison avec les résultats de Ondrus et Gordon

Ondrus et Gordon (9) ont étudié la réduction du chlorite par un excès de Fe(II). L'étape déterminante correspond à l'échange d'un seul électron et leurs résultats sont interprétés par [10′] et [10″]. Nous avons recalculé leurs valeurs en prenant $K_a = 2,4 \times 10^{-2}$ et obtenu (2)

$$k'_{10} = 930\ M^{-1}\ s^{-1}$$

$$k''_{10}K_a = 64\ s^{-1}\ (25°C, I = 2\ M)$$

D'autre part la comparaison de [5] avec $d[ClO_2]/dt = 2r_{10}$ donne

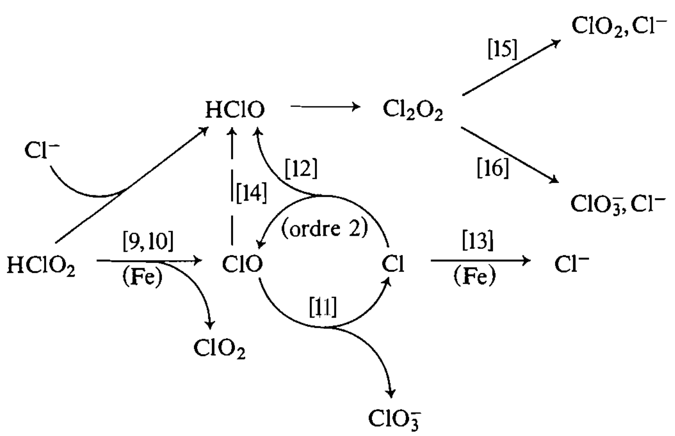
$$2K_9k'_{10} = 1,39\ M^{-1}\ s^{-1}$$

$$2K_9k''_{10}K_a = 0,11\ s^{-1}\ (25°C, I = 1\ M)$$

L'accord entre les deux séries de valeurs serait parfait avec $K_9 = 8 \times 10^{-4}$ au lieu de $K_9 = 2,7 \times 10^{-4}$ estimé en annexe. Comparant des constantes cinétiques déduites d'études très différentes et tenant compte de l'imprécision de l'estimation de K_9, due surtout aux effets de force ionique, il faut considérer que ceci confirme que [10] est l'étape déterminante de la dismutation du chlorite catalysée par le fer.

Conclusion et discussion

Ce qui apparaissait déjà dans le travail de Kieffer et Gordon a été confirmé et complété par nos mesures. La stoechiométrie et la cinétique de la dismutation du chlorite sont compliquées par des compétitions entre diverses réactions. Le mécanisme que nous proposons repose sur un très grand nombre de faits expérimentaux et peut être représenté par le schéma suivant.



On retrouve dans ce schéma les trois processus réactionnels cités dans l'introduction.

(a) La réaction catalysée par les ions Cl^- que nous avons étudiée antérieurement (1) correspond à la partie supérieure.

(b) Au centre on voit la chaîne donnant la loi d'ordre deux. Elle existe dans tout le domaine de pH étudié mais n'est prépondérante qu'en milieux assez acides et pour des conversions ni trop faibles (effet du fer) ni trop élevées (effet du chlorure).

(c) L'initiation–rupture de cette chaîne correspond à la réaction catalysée par le fer et inhibée par le dioxyde de chlore. Les traces de fer présentes dans l'acide perchlorique "pour analyses" ou dans le chlorite recristallisé plusieurs fois suffisent pour la faire apparaître. A pH = 0 elle devient négligeable par rapport à la réaction d'ordre 2 dès les faibles conversions; à pH = 2 elle reste importante jusqu'aux conversions très élevées.

Dans le premier article de cette série (1) nous avions laissé un fait expérimental étonnant inexpliqué. Lors de la réaction $HClO + HClO_2$ on peut obtenir plus de ClO_2 que le maximum prévu par [15]. Ceci avait également été observé par Emmenegger et Gordon (10) qui avaient suggéré que l'acide hypochloreux catalyse la dismutation du chlorite. Une telle catalyse peut se comprendre dans le cadre de notre mécanisme. Lorsque le HClO est présent dans le système en concentration macroscopique il faut tenir compte d'une réaction supplémentaire, $HClO + Fe^{2+} \rightarrow Cl + Fe(OH)^{2+}$, initiant la décomposition en chaîne de $HClO_2$ suivant [11] et [12].

Hong et Rapson (5) ont observé vers pH = 1 que lorsqu'on augmente la concentration des ions Cl^-, la vitesse de formation du ClO_2 passe par un minimum. Nous avons confirmé cette observation. L'augmentation de la vitesse après le minimum est évidemment due à la réaction catalysée par les ions Cl^-. L'interprétation de sa diminution avant le minimum donnée par ces auteurs ne peut être retenue car elle fait intervenir la réaction $HClO + Cl^- + H^+ \rightarrow Cl_2 + H_2O$ en exigeant qu'elle soit irréversible dans ces conditions, ce qui est exclu (11). Dans le cadre de notre mécanisme cette diminution peut s'expliquer simplement par la réaction $Cl + Cl^- \rightleftharpoons Cl_2^-$ (12). Si Cl_2^- disparait plutôt par une réaction de rupture que par une réaction analogue à [12], les ions Cl^- diminuent la vitesse de la décomposition en chaîne de $HClO_2$. Ces réactions n'ont pas été considérées ci-dessus car les données actuelles ne permettent pas un traitement quantitatif de cet effet.

Lorsqu'on augmente le pH, la vitesse de dismutation du chlorite passe par un maximum vers pH = 2 (3, 13). Ce fait ne peut être interprété simplement en remarquant que, pour une valeur donnée de $[NaClO_2]$, le produit $[ClO_2^-][HClO_2]$ passe par un maximum à ce pH. Il faut également tenir compte de la formation des formes hydroxylées $Fe(OH)^{2+}$ et $Fe(OH)_2^+$. Celles-ci semblent avoir également un effet catalytique en tampon acétate à pH = 4 (14).

Les travaux antérieurs avaient fait apparaître la complexité de la stoechiométrie et de la cinétique de la dismutation du chlorite. L'utilisation de l'*ortho*-tolidine nous a donné les clefs de leur interprétation: l'effet catalytique du fer et le fait que $2HClO_2 \rightarrow HClO + ClO_3^- + H^+$ ne soit pas une réaction élémentaire. Le mécanisme que nous proposons ici est en accord avec tous les faits expérimentaux connus entre pH = 0 et pH = 2. Son extension aux milieux moins acides nécessiterait de nouvelles expériences.

Annexe

Constante d'équilibre de [9]

Le potentiel standard E^0 du couple Fe^{3+}/Fe^{2+} vaut 0,771 V (15). Sa valeur apparente E' dépend du milieu et de la force ionique (16–18). En solutions perchloriques 1 M elle vaut 0,739 ± 0,002 V. Pour le couple ClO_2/ClO_2^- l'incertitude est plus grande. L'examen des sources nous ayant conduit à adopter 0,950 V (1) indique que cette valeur est une bonne estimation de E' en milieu perchlorique 1 M. Elle est supérieure au potentiel standard admis antérieurement $E^0 = 0{,}935$ V (19). L'effet de la force ionique sur ce potentiel est en accord avec celui observé par Hong et Rapson (5) sur la constante d'acidité K_a. En effet:

$$E' = E^0 - \frac{RT}{F} \ln \gamma^2_{HClO_2}$$

En prenant comme estimation du coefficient d'activité

$$\gamma^2_{HClO_2} = K_a^0/K_a'(1\ M) = 1{,}1/2{,}4$$

on obtient

$$E'(1\ M) - E^0 = 0{,}020$$

De $E'(Fe^{3+}/Fe^{2+}) = 0{,}739$ V et $E'(ClO_2/ClO_2^-) = 0{,}950$ V, on déduit

$$K_9 = \frac{[ClO_2][Fe^{2+}]}{[ClO_2^-][Fe^{3+}]} = 2{,}7 \times 10^{-4}$$

(25°C, milieu perchlorique 1 M)

Au cours de nos expériences on avait

$$\frac{[Fe^{2+}]}{[Fe^{3+}]} = 2{,}7 \times 10^{-4} \frac{[ClO_2^-]}{[ClO_2]} = \frac{6{,}5 \times 10^{-6}}{[H^+] + 2{,}4 \times 10^{-2}} \frac{[NaClO_2]}{[ClO_2]}$$

et $[Fe^{3+}] \gg [Fe^{2+}]$ dès les plus faibles conversions observées.

The mechanism of enzymic hydroxyl group removal from C-21 of tetrahydrodeoxycorticosterone

HERBERT L. HOLLAND AND ELLY RIEMLAND
Department of Chemistry, Brock University, St. Catharines, Ont., Canada L2S 3A1

Received August 2, 1984

HERBERT L. HOLLAND and ELLY RIEMLAND. Can. J. Chem. **63**, 981 (1985).

The C-21 hydroxyl group of C-17- and C-21-deuterium labelled tetrahydrodeoxycorticosterone is removed by the anaerobic intestinal bacterium *Eubacterium lentum* ATCC 25559 with retention of deuterium label at C-17α and loss of one of the two deuterium atoms originally present at C-21. Dehydroxylation at C-21 proceeds with an apparent primary kinetic isotope effect, K_H/K_D, at C-21 of 2.6. These data suggest a route for C-21 dehydroxylation involving a C-20(21)-enediol intermediate.

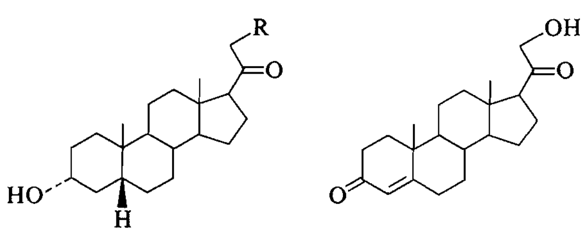
HERBERT L. HOLLAND et ELLY RIEMLAND. Can. J. Chem. **63**, 981 (1985).

Sous l'influence de la bactérie anaérobique intestinale *Eubacterium lentum* ATCC 25559, le groupement hydroxyle C-21 de la tétrahydrodéoxycorticostérone, marquée au deutérium dans les positions C-17 et C-21, est éliminé avec rétention du marqueur en C-17α et avec perte de l'un des deux atomes de deutérium originalement présents en position C-21. La déhydroxylation en C-21 se produit avec un effet isotopique cinétique primaire apparent, K_H/K_D, en C-21 qui est égal à 2,6. Ces données suggèrent que la déhydroxylation en C-21 implique un intermédiaire ènediol-C-20(21).

[Traduit par le journal]

Introduction

Those 21-hydroxycorticosteroids which undergo enterohepatic circulation in the body (passage through the intestines and reabsorption into the liver) are eventually excreted in a modified form lacking the C-21 hydroxyl group (1). In contrast, those which are directly excreted retain this functionality (2). The 21-dehydroxylation reaction is performed by the anaerobic intestinal microflora (3), the species responsible having been identified as *Eubacterium lentum* (4). This reaction can provide one of the major routes for the metabolism (and hence deactivation) of administered corticosteroids such as tetrahydrodeoxycorticosterone (**1***a*) (5) and aldosterone (6), and in view of its widespread relevance (in addition to any intrinsic chemical interest), we have undertaken a study of its mechanism.



1*a* R = OH
b R = H

2

Enzymological studies from Bokkenheuser's laboratory have established that the C-21 dehydroxylating enzyme from *E. lentum* requires a reduced flavin cofactor ($FMNH_2$) (4, 7), is inhibited by metal chelating agents (8), functions at pH 6.5–7.3 (1), and dehydroxylates only those substrates with a C-20 carbonyl function (1). Preliminary mechanistic work has also been carried out (9), which determined that C-21 dehydroxylation of ^{3}H labelled deoxycorticosterone (21-hydroxypregn-4-ene-3,20-dione, **2**) by human fecal flora proceeded with substantial but unreproducible loss of label from a site assumed to be C-21. However, this reference includes no details of the method of preparation of labelled substrate, or of the criteria used to establish the homogeneity or position of label, so the data must be interpreted with caution. Our data, discussed below, remove this ambiguity and expand upon the mechanistic details of the dehydroxylation.

Results and discussion

We have used the intestinal bacterium *E. lentum* ATCC 25559, in anaerobic mixed culture with *Esherichia coli*, to perform the conversion of **1***a* to **1***b*. The latter microorganism serves to generate the highly reducing environment necessary for *E. lentum* to carry out this biotransformation (1, 4). In our hands, this mixed but defined bacterial culture was not able to dehydroxylate **2** as previously reported in the case of undefined fecal bacteria (9) and the related bacterium *E. lentum* VPI 0255 (1), but **1***a* was quantitatively dehydroxylated at C-21 within seven days.

Labelled substrate **1***a* was prepared from unlabelled material by base catalysed exchange, using the method developed by Johnson for the preparation of side-chain labelled corticosteroids (10), and analysed by ^{1}H and ^{2}H nmr analysis. Product **1***b*, both of enzymic origin and as prepared by exchange, was additionally analysed by electron impact mass spectrometry. The latter technique could not be applied to labelled **1***a* because of the lack of an observable molecular ion: other mass spectral techniques (e.g. FAB) could not be used for quantitative deuterium estimation.

The deuterium content of **1***a* at C-21 was estimated by ^{1}H nmr using the C-3 hydrogen signal as internal reference, and thence at C-17 by the relative areas of the signals assigned to deuterium at C-21 and C-17 in the ^{2}H nmr spectrum. Reported values represent the average of ten integrations. The content and location of label in **1***b* were determined by mass spectral, ^{1}H and ^{2}H nmr data (see Experimental). The values obtained for starting material, biotransformation product, and control incubation samples are listed in Table 1.

Control experiments confirm that the integrity of label in **1***a* is maintained under the incubation conditions; thus **1***a* recovered from a pH 6.3 phosphate buffer after 7 days, and from a short (4 day) incubation at pH 6.2–6.5 with *E. lentum*, showed no appreciable loss or scrambling of label. Similarly, product **1***b* did not lose any label from C-17 or -21 during a seven-day exposure to an active culture of *E. lentum*/*E. coli*. Analysis of **1***b* produced from labelled **1***a*, however, clearly shows that the C-21 dehydroxylation reaction takes place without appreciable loss of label from C-17α, but with loss of one of the two labelled hydrogen atoms originally present at C-21.

‡Percentage of three deuterons.

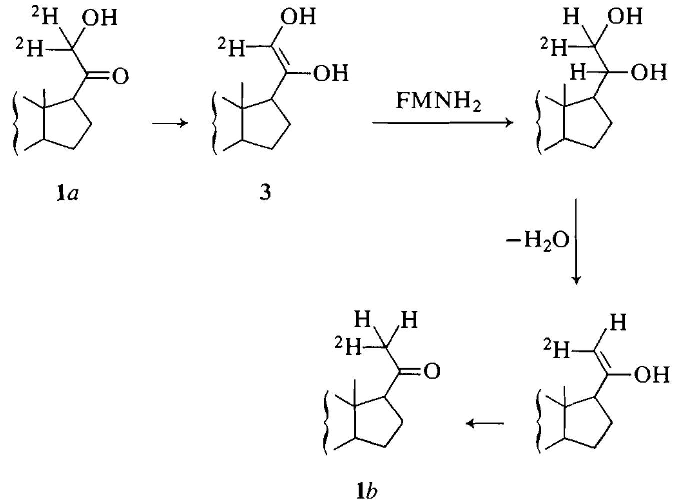
labelled and unlabelled **1***a* gave a sample of **1***b* whose deuterium content, following the assumption of the loss of one deuterium atom from C-21 during dehydroxylation, enabled the apparent primary kinetic isotope effect, K_H/K_D, for the reaction to be calculated using the equation (11):

$$K_H/K_D = \frac{\ln 1 - f\dfrac{1 + AD_0/AH_0}{1 + XD/XH}}{\ln 1 - rf\dfrac{1 + AD_0/AH_0}{1 + XD/XH}}$$

where AD_0/AH_0 = ratio of labelled to unlabelled substrate at time zero; XD/XH = ratio of products arising from labelled (XD) and unlabelled (XH) substrates; $r = (XD/XH)/(AD_0/AH_0)$; and $f = (XH + XD)/(AH_0 + AD_0)$ = fraction of conversion. Using the values $AD_0/AH_0 = 1$, $XD/XH = 0.54$, and $f = 0.52$ (see Experimental) the value of K_H/K_D is 2.6 ± 0.1. This value is similar to those observed for some other enzyme catalysed enolizations (12–14) and, together with the substrate and cofactor requirements discussed above, and a possible role for metal ions in the reaction, suggests the route for C-21 dehydroxylation proposed in Scheme 1.

During dehydroxylation, the substrate may bind irreversibly in the C-20(21)-enediol form **3** to an as yet unidentified metal ion of the enzyme. Metal ions are common binding sites in the enzymic coordination of α-ketols (e.g. glyoxalase (15)), and can provide Lewis acid activation for substrate enolization (16). Reduction of **3** by $FMNH_2$ may then be followed by metal catalysed dehydration (17) to release the product **1***b* in its enol form.

The route presented in Scheme 1 is somewhat similar to the routes established for the enzymic dehydroxylation of bile acids at C-7 (18, 19) and of 16α-hydroxyprogesterone at C-16 (20) by *Eubacteria*. In these cases, the reactions proceed by dehydration followed by reduction of the resultant carbon–carbon olefinic bond. Scheme 1 is consistent with all the available data on the C-21 dehydroxylation reaction. The nature of the metal ion and the stereochemical details of the deprotonation at C-21 remain to be investigated.



SCHEME 1. Proposed route for C-21 dehydroxylation by *E. lentum*.

Experimental

Apparatus, materials, and methods

Melting points were determined with a Gallenkamp apparatus and are uncorrected. The ^{1}H nmr spectra were obtained at 80 MHz on a Bruker WP-80CW using $CHCl_3$ as solvent and TMS as internal standard, and the ^{2}H nmr spectra at McMaster University, Hamilton, on a Bruker WM 250, using $CHCl_3$ as solvent and internal standard. Mass spectra were obtained with an AEI MS30 interfaced to a Kratos DS 55 data system. Deuterium content was determined by repeated scanning of the appropriate molecular ion and $M - H_2O$ regions and correction for natural isotopic abundances. Column chromatography was performed on silica gel (Merck 230–400 mesh) and thin layer chromatography on Merck silica gel 60F-254 (0.2 mm). *Eubacterium lentum* ATCC 25559 was maintained in continuous culture as described below.

Maintenance of E. lentum

Growth medium consisting of dehydrated brain heart infusion broth (Difco, 37 g/L) and cysteine hydrochloride (0.5 g/L) was autoclaved and cooled to room temperature under a continuous degassing stream of argon. The pH of the medium was 6.2–6.5. This medium was inoculated under anaerobic conditions with the stock *E. lentum* culture (12 mL per L of new medium) and allowed to grow out at 37°C. The culture was maintained by transfers at intervals not exceeding 14 days.

Synthesis of substrates

*5β-Pregnan-3α, 21-diol-20-one, 17,21,21-*d$_3$ *(***1***a)*

Unlabelled **1***a* (Sigma, 61.6 mg) was dissolved in methanol-OD (3 mL) and this solution added to a solution of tris(hydroxymethyl)-methylamine (1.05 g) in D_2O (25 mL) and methanol-OD (25 mL). The resulting mixture was maintained at 60°C for 24 h, then cooled and acidified with 35% DCl in D_2O to pH 5. The methanol was removed under reduced pressure and the aqueous residue extracted with dry ethyl acetate (3 × 25 mL). The extract was dried (Na_2SO_4) and evaporated to yield 61.7 mg of labelled **1***a*, identical in physical properties (mp, tlc) to unlabelled material. The ^{1}H nmr included signals at δ 0.63 (3H, s, C-18 H), 0.93 (3H, s, C-19 H), and 3.65 (1H, m, C-3 H) ppm. The area of the signal at δ 4.15 ppm was used to estimate the residual ^{1}H content at C-21 (5%, see Table 1). FAB mass spectral analysis gave a cluster of ions at m/e 334–337. The ^{2}H nmr included signals at δ 2.43 (C-17 H) and 4.12 (C-21 H) ppm.

*5β-Pregnan-3α-ol-20-one, 17,21,21,22,-*d$_4$ *(***1***b)*

To a solution of 5β-pregnan-3α-ol-20-one (0.1 g) and tetra-n-butyl ammonium bromide (0.1 g) in dry benzene (5 mL) was added a solution of NaOD in D_2O (5%, 10 mL). The resulting two-phase system was stirred and refluxed under protection from atmospheric moisture for 48 h. The reaction mixture was then cooled, and the organic layer separated, washed with pH 6.86 phosphate buffer (3 × 10 mL), dried, and evaporated to yield labelled **1***b* (81.5 mg), which had identical physical (mp and tlc) properties to an unlabelled sample. The ^1H nmr included signals at δ 0.58 (3H, s, C-18 H), 0.93 (3H, s, C-19 H), and 3.63 (1H, m, C-3 H) ppm. The ^2H nmr included signals at δ 2.07 (C-21 H) and 2.51 (C-17 H) ppm. Other spectral data (ir, ^{13}C nmr) were consistent with the proposed structure.

Exposure of labelled **1**a *to pH 6.3 buffer*

Labelled **1***a* (40 mg) was dissolved in ethanol (95%, 1 mL) and the resulting solution added to phosphate buffer (pH 6.3, 50 mL). The mixture was kept at 37°C for 7 days, then cooled, and extracted with chloroform (3 × 50 mL). The extract was dried and evaporated to give recovered **1***a* (37 mg). Deuterium content is listed in Table 1.

Incubations with E. lentum *(Table 1)*

The substrate (50 mg) was dissolved in ethanol (95%, 4 mL), and 1 mL portions of this solution added to each of four 250-mL aliquots of growth medium, prepared as described above. The medium was then autoclaved, cooled and degassed under argon, and each portion then inoculated with 3 mL of *E. lentum* stock culture (7 days old) and 3 mL of *E. coli* stock culture (Boreal). The cultures were then maintained at 37°C for 4–7 days (see Table 1). Products and recovered substrates were isolated as described (21), and purified by crystallization following column chromatography. Compounds were identified by physical (mp, tlc) and spectral (nmr) comparison with authentic samples. Details of recovery and yields are listed in Table 1.

For the mixed labelling isotope effect study, labelled and unlabelled **1***a* (37.5 mg each) were mixed and incubated as described above for 4 days. The product **1***b* (39 mg) was found by mass spectral analysis to have the following isotopic content: d_0, 70%; d_1, 18%; d_2, 12%. Based on the overall isotopic composition of the starting material (d_1 = 15%, d_2 = 47%, d_3 = 35%), the fraction XD/XH is calculated as below. Percent product arising from unlabelled substrate (XH) is $p.d_0$: % product arising from labelled substrate (XD) is $0.15\, q.d_0 + 0.47\, q.d_1 + 0.35\, q.d_2$ (assuming the loss of one deuterium on conversion). Total d_0 product is therefore $(p + 0.15q)$%, total d_1 product is $0.47q$%, and total d_2 product is $0.35\,q$%. Since $p + 0.15\,q = 70$, $0.47\,q = 18$, $0.35\,q = 12$, and $p + q = 100$, therefore $p = 65$, $q = 35$, and $XD/XH = q/p = 0.54$. The degree of conversion, f, was 0.52 based on the isolation of 38.9 mg of product. The remainder of the starting material was isolated unchanged, giving a quantitative recovery of steroid.

Extended basis *ab initio* calculations on conformers of propanal

V. P. GUPTA
Department of Physics, University of Jammu, Jammu Tawi – 180001, India

Received May 28, 1984

V. P. GUPTA. Can. J. Chem. **63**, 984 (1985).

Extended basis *ab initio* calculations on four conformations of propanal at the 4-31G and 6-31G** levels followed by many-body perturbative interaction calculations MP2 and MP3 have been conducted. Optimized geometries, heights of rotational barriers, dipole moments, ionisation potentials, and diagonal harmonic force constants have been reported. The *s-cis* conformer (dihedral angle CCCO = 0°) is found to be more stable than the *gauche* conformer (dihedral angle CCCO = 129.84°) by 5.07 kJ mol^{-1}. Torisonal potential barriers *s-cis/gauche*, *gauche/s-cis*, and *gauche/gauche* have values 8.81, 3.74, and 1.84 kJ mol^{-1}, respectively. It appears that meaningful values of rotational barriers can be obtained only after a careful optimization of the geometries of the conformations involved.

V. P. GUPTA. Can. J. Chem. **63**, 984 (1985).

Opérant aux niveaux 4-31G et 6-31G**, on a effectué des calculs *ab initio* sur quatre conformations du propanal; on a ensuite effectué des calculs MP2 et MP3 impliquant une interaction perturbative de plusieurs corps. On rapporte les géométries optimisées, les hauteurs des barrières à la rotation, les moments dipôlaires, les potentiels d'ionisation et les constantes de force harmonique diagonale. On a trouvé que le conformère *s-cis* (angle dièdre CCCO = O°) est plus stable que le conformère *gauche* (angle dièdre CCCO = 129,84°) par 5,07 kJ/mol. Les valeurs des barrières au potentiel de torsion sont respectivement 8,81, 3,74 et 1,84 kJ/mol pour *s-cis/gauche*, *gauche/s-cis* et *gauche/gauche*. Il semble que l'on ne peut obtenir de valeurs significatives pour les barrières à la rotation qu'après avoir effectué une optimisation adéquate des géométries des conformations impliquées.

Introduction

Several studies using different experimental techniques such as microwave (1–3), vibrational (4–8) and nmr (9) spectroscopy, and the theoretical techniques such as molecular dynamics (10) and molecular orbital calculations (11–14) have been reported in the literature for the determination of the conformation of propanal in gaseous and liquid phases. Some statistical mechanical calculations (15, 16) of the chemical and thermodynamic properties of propanal in the gaseous state have also been reported. All these studies indicate that propanal exists as a mixture of *s-cis* and *gauche* conformers with the methyl group eclipsing the carbonyl bond in the *s-cis* (**I**) conformation and skewed out of plane to a dihedral angle of ca. 130° in the *gauche* (**III**) conformer. In a separate communication (17), we have reported photorotamerisation studies on this molecule in low temperature argon and nitrogen matrices and have found that at 10 K the concentrations of the two conformers are 95% *s-cis* and 5% *gauche* which changes to 47% and 53% respectively, on irradiation with a broad band ir radiation. A considerable uncertainty exists in the literature about the conformations of the lowest energy conformer and also about the enthalpy difference between the two stable conformers (2, 4, 14, 17, 18). Similarly, different values have been reported in the literature for the potential energy barriers between conformers *s-cis/gauche* and *gauche/s-cis* and the dihedral angle φ_0 (C_1—C_2—C_3=O_4) in the *gauche* conformer (2, 4, 10).

Ab initio calculations on propanal were first reported by Radom *et al.* (11) who studied the variation of the RHF energy for the molecule with the change in the dihedral angle φ_0 (C_1—C_2—C_3=O_4). The calculations were performed using the 4-31G basis set and a model geometry as proposed by Pople *et al.* (19). However, no attempt was made to optimize the geometry of the molecule and as such the results were in large error from the experimental values. Allinger *et al.* (10) reported *ab initio* calculations using a $5s2p$ basis set of Gaussian orbitals (20) without a geometry optimization. They optimized geometries of the lowest energy conformations **I** and **III** by the method of molecular mechanics. In two recent studies (3, 33) that appeared after the present work was completed *ab initio* 4-21G results have been reported. In an earlier communication (17) we reported, in part, results of our *ab initio* calculations on propanal using the 4-31G extended basis set and the optimized geometries of the *s-cis* and *gauche* conformers.

In order to have a more complete understanding about the structure of propanal and for obtaining the diagonal force constants we carried out extended basis set 4-31G and 6-31G** *ab initio* calculations followed by many body Møller-Plesset perturbative interaction calculations MP2 and MP3.

Configurational notations and computational methods

The notations used in this paper for conformers of propanal are similar to those in alcohols (29, 30) as well as that published in our earlier communication (17). Propanal is a single rotor system in which different configurations can be obtained by rotation around the C_2—C_3 axis. The conformations with respect to the dihedral angle φ_0 (C_1—C_2—C_3=O_4) are denoted as **I** (or C; φ_0 = 0°), *II* (φ_0 = 72.9°), **III** (or G; φ_0 = 130°), and **IV** (φ_0 = 180°). Computer drawings of these conformations are given in Fig. 1. Rotation of the CH_3 group about the C_1—C_2 axis does not give any new conformer.

The calculations were carried out on computers Univac 1108, Burrough B7800, and Vax-11 using programmes Gaussian-76 (31) and Gaussian-80 (32). Geometries of all the four conformers were optimized in the 4-31G basis set by the usual iterative process using Gaussian-76. First, the coordinates of the *s-cis* (**I**) species (Fig. 1) were optimized, since this conformer was expected to be the lowest energy species. Then, using the *s-cis* geometry, the influence of the rotation of the CHO group in intervals of 10° was studied (i.e., varied from 0° to 180°); this calculation gave approximate φ_0 values for the maxima and minima. The geometries of the other three conformations (**III** corresponding to a minimum and **II** and **IV** corresponding to energy maxima) were then optimized. The

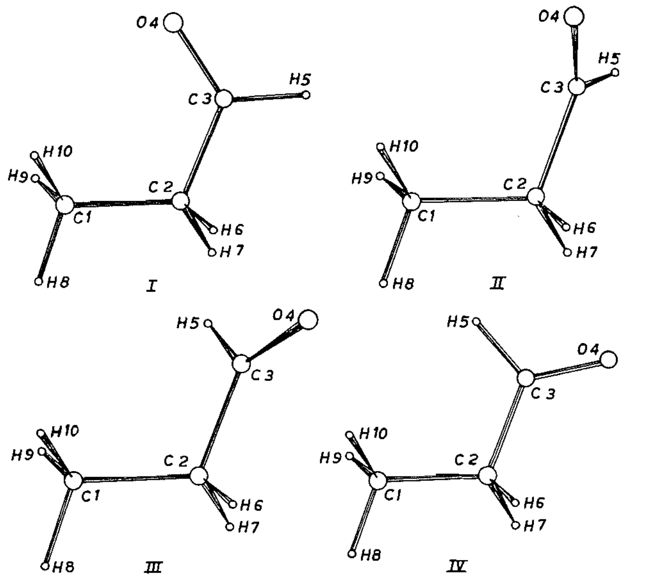

FIG. 1. Computer-drawn drawing of the conformations of propanal.

energy maxima do not seem to be first order saddle point. A semi-rigid 4-31G potential energy surface was constructed (cf. ref. (17)). For each calculated point on the curve, the geometry of the nearest optimized conformation was used. To obtain reliable results for the diagonal force constants, the geometries were carefully optimized till the bond lengths changed by no more than 0.2 pm (0.002 Å), angles no more than 0.2° and dihedral angles no more than 0.5°. Optimization of the angles required at least five iteration cycles. The optimizations of the minimum energy conformations **I** and **III** were verified by the gradient optimisation method of the program Gaussian 80 (31), in which case the residual forces on the cartesian coordinates were less than or equal to 1×10^{-3} mdyn. These optimized geometries were then used for the 6-31G** level calculations involving polarization functions at every atom. MP2 and MP3 level calculations also used the same geometries.

Results and discussion

The results of calculations are summarized in Tables 1 to 3. Table 1 contains the optimized geometries of all the four conformations in the 4-31G basis set. The energies of these conformations, rotational barriers; and the ionization potentials (based on Koopman's theorem), as obtained from the different levels calculations, are given in Table 2. The atomic and bond populations and the dipole moments obtained from 6-31G** calculations and the harmonic force constants obtained at the optimized geometries and at small displacements from these geometries for the *s-cis* and gauche conformations are included in Table 3.

From Tables 1 and 2 it follows that conformations **I** and **III** correspond to the energy minima and **II** and **IV** to the energy maxima. 6-31G** calculations elevate the energies of these conformations over their 4-31G values whereas the MP2 and MP3 calculations stabilize these values. The enthalpy difference between **I** and **III** from MP3 calculations is 5.07 kJ mol^{-1}. This value is higher than the experimental values 2.88 − 4.16 kJ mol^{-1} (2, 4, 9, 18, 21). The dihedral angle φ_0 (C_1—C_2—C_3=O_4) for conformation **III** obtained from 4-31G geometry optimization is 129.84° which lies within the experimental range 131 ± 6° suggested by Butcher and Wilson (2) from

microwave measurements and is quite close to the value 128.2° calculated by Allinger *et al.* (9) from molecular dynamics. The dihedral angle φ_0 (C_1—C_2—C_3=O_4) for conformation **II** is found to be 72.9° which is in agreement with a value of ca. 70° obtained by Pickett and Scroggin (1).

MP3 calculations predict **I** → **III** rotational barrier of 8.81 kJ mol^{-1} which is in agreement with the experimental value 8.80 kJ mol^{-1} estimated by Pickett *et al.* (1) from microwave studies. It may, however, be noted that a value of 15 kJ mol^{-1} calculated by Radom *et al.* (11) using a model geometry for the molecule in 4-31G basis set is very much higher than the experimental value as well as our calculated value. It thus appears that meaningful values for the torsional potential barriers through *ab initio* calculations can be obtained only after a careful geometry optimization. The calculated values of *gauche/s-cis* and *gauche/gauche* barriers are 3.74 and 1.84 kJ mol^{-1}, respectively.

It has been pointed out by earlier workers (22−24) that the calculated dipole moment at the 4-31G level overestimates the experimental value by about 25%. A similar situation is found in the case of the *s-cis* conformer of propanal where the calculated value of the dipole moment in the 4-31G level is 3.27 D as against the experimental value of 2.58 D (25). Extension of the basis set and introduction of polarisation functions at each atom, as in the 6-31G** level calculations, improves upon the value of the dipole moment. The 6-31G** value of dipole moment of *s-cis* propanal is thus found to be 3.01 D. The corresponding dipole moment for the *gauche* conformer is 3.23 D.

Experimental observations indicate that conformations involving a methyl group in *cis*-position to carbonyl have lower energy. Radom *et al.* (11) explain this observation by suggesting that a methyl group provides a polarizable group close to the highly intrinsic dipole of carbonyl. Our results seem to support this hypotheses. It is found that the population density

[a]Values based on 6-31G** level calculations.
[b]Values based on 4-31G level calculations. Other values in the force constant matrix can be obtained by writing to the author.
[c]Distances are in pm.
[d]Bond stretch force constants are in mdyn $Å^{-1} = 10^2$ N m^{-1}.
[e]Angle bending and torsional force constants are in mdyn $Å^{-1}$ $rad^{-2} = 10^{-18}$ Nm rad^{-2}.

of electron overlap between the atoms O_4 and H_9 or O_4 and H_{10} in conformation **I** is 0.0020 as against values between 0 and 0.0003 for the other three conformations.

It has been indicated by Pulay (26) that the *ab initio* calculations have a tendency to overestimate the diagonal force constants. However, trends in the values of the calculated force constants for molecules having similar structure are quite reliable and informative. Murto *et al.* (27) adopted scaling down procedure for using the STO-3G calculated force constants in the calculation of the frequencies of vibrations of fluoro- and chloroethanols. In the present case we have listed the unscaled diagonal force constants for the *cis* (**I**) and *gauche* (**III**) conformers of propanal in Table 3. It may be seen that the C═O stretching force constants for conformers **I** and **III** are 15.4968 and 15.3873 mdyn Å^{-1}, respectively, predicting a higher carbonyl stretching frequency in conformer **I**. This fact is confirmed from experiment where the C═O stretching absorption bands appear at 1743 cm^{-1} and 1727 cm^{-1} in conformers **I** and **III**, respectively, in argon matrix at 10 K (17). It is found that while diagonal force constants need to be scaled down by 15−20% to provide a good agreement with the experimental frequencies, the non-diagonal force constants (not reported here) do not need any scaling (28).

In quite recent study, Van Nuffel *et al.* (3) calculated the vibrational frequencies of *cis* (**I**) and *gauche* (**III**) conformers on the basis of a force field obtained through *ab initio* calculations using the 4-21G basis and predicted a higher frequency for C═O stretching vibration for conformer **III** (1756.2 cm^{-1}) than for conformer **I** (1754.7 cm^{-1}). This contradicts the experimental findings (17) and raises doubts about the unscaled values of their C═O stretching force constants (14.23 mdyn Å^{-1} for **I** and 14.24 mdyn Å^{-1} for **III**). Similarly, their predictions for several other frequencies of *cis* and *gauche* conformers do not agree with the experimental data (5, 17). However, they corroborate our conclusion regarding the magnitude of scaling down the *ab initio* diagonal force constants.

The product obtained from the reduction of potassium permanganate by trimethylamine in aqueous phosphate buffers has been identified as a soluble form of colloidal manganese dioxide which is stabilized in solution by adsorption of phosphate ions on its surface. The dependence of the rate of flocculation on several experimental variables has been studied. Phosphate ions have been found to increase the solubility of the colloid by increasing the apparent energy of activation of the flocculation process. This could explain the well-known capacity of those ions for retarding the precipitation of manganese dioxide.

FERNANDO MATA-PEREZ et JOAQUIN F. PEREZ-BENITO. Can. J. Chem. **63**, 988 (1985).

On a identifié le produit obtenu lors de la réduction du permanganate de potassium par de la triméthylamine dans des tampons aqueux de phosphates; il s'agit d'une forme colloïdale de dioxyde de manganèse qui est stabilisée en solution par une adsorption des ions phosphates sur sa surface. On a étudié la relation entre le taux de floculation et diverses variables expérimentales. On a trouvé que les ions phosphates augmentent la solubilité du colloïde par le biais d'une augmentation de l'énergie d'activation apparente du processus de floculation. Ceci pourrait expliquer la capacité bien connue de ces ions à retarder la précipitation du dioxyde de manganèse.

[Traduit par le journal]

Introduction

Manganese dioxide is a brown substance whose insolubility in water is well-known. However, its precipitation has been found to be substantially delayed in the presence of phosphate ions (1, 2). This property has made phosphate buffers useful for the study of a great variety of permanganate ion oxidations in aqueous medium. When they are present a soluble brown–yellow product, instead of a precipitate, is obtained. However, despite its extensive occurrence in permanganate ion oxidations performed in phosphate buffered solutions, the nature of that species has never been established.

Although it has been sometimes suggested that this soluble species could be $H_2MnO_4^{2-}$ (3*a*), H_2MnO_3 (4) or a phosphate complex (4, 5), we wish to report some spectrophotometric findings which strongly support that it is actually a soluble form of colloidal manganese dioxide stabilized in solution by the existence of phosphate ions on the surface of the colloidal particles.

The reducing agent used in this study was trimethylamine. The spectra recorded at the end of the reaction showed that the product is the same than those obtained using different reducing agents such as uracils (4), unsaturated acids (4), or dimethylamine (6), in phosphate buffers.

Although the organic products obtained from the permanganate ion oxidation of amines have been carefully determined (7–9), and some kinetic studies of the permanganate ion oxidation of trimethylamine in phosphate buffers have been published (10, 11), no identification of the soluble brown–yellow product has been reported. The present paper aims to resolve this missing point.

Experimental

The reactants were potassium permangante and trimethylammonium chloride (in excess). A buffer mixture $KH_2PO_4-K_2HPO_4$ was also used. Potassium chloride was added to the solutions to keep the ionic strength of the medium constant when necessary. The solvent was water twice distilled from potassium permanganate.

All the spectrophotometric operations (periodic scanning during reaction, recording of the spectra at the end of the reaction and monitoring of the flocculation process) were performed by means of a Hewlett-Packard UV-VIS Spectrophotometer, equipped with a temperature controlled cuvette holder.

The pH measurements were made by using a Corning Model 7 pH Meter, provided with a combined electrode.

To determine the oxidation state of manganese in the product, five solutions of $KMnO_4$ ($2 \times 10^{-4} - 1 \times 10^{-3}$ *M*) and $Me_3N \cdot HCl$ (3×10^{-2} *M*) were allowed to react in an aqueous buffered system. When the spectrophotometer showed that all the permanganate had been consumed, concentrated perchloric acid and an excess of potassium iodide were added to the solutions; the iodine released was titrated against standard thiosulfate solution, using starch as indicator.

Results

The iodometric technique previously used by other authors (4, 12, 13) allowed us to determine the oxidation state of manganese in the soluble brown–yellow product. An average value of 3.93 ± 0.13, which is quite consistent with a Mn(IV) species, was obtained.

On the other hand, when the reaction was scanned under the experimental conditions given in Fig. 1 no isosbestic point was found; instead the intersection of the successive spectra showed a shift to higher wavelengths as the reaction advanced. However, a 2.5-fold increase in the concentration of the buffer substances (all the other experimental conditions remaining constant) led to the observation of a sharp isosbestic point at 470 nm (see Fig. 2).

The spectrum of the soluble Mn(IV) species at the end of the reaction was also found to be dependent on the phosphate concentration; for the same Mn(IV) concentration the absorbance at every wavelength increases as the phosphate concentration decreases (see Fig. 3).

In order to establish the nature of the product more definitely, the influence of several experimental variables on the rate of conversion of the soluble Mn(IV) species into MnO_2 precipitate was studied. When sequential scans showed that all the permanganate had been reduced by trimethylamine, the evolution of the product was followed by monitoring the in-

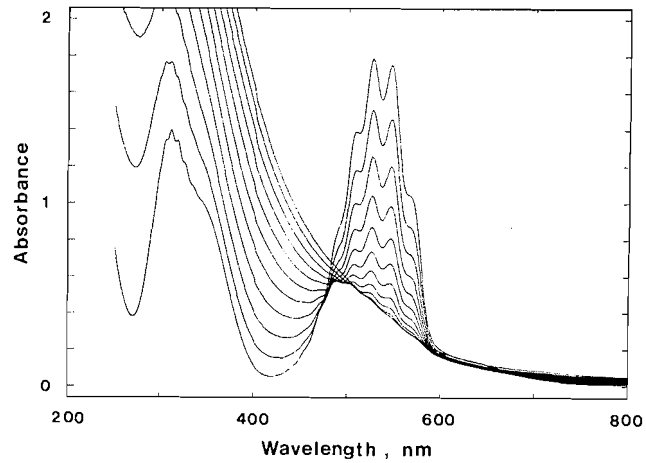

FIG. 1. Successive scans at 6 min intervals during the reaction between permanganate ion (8×10^{-4} M) and trimethylamine (3×10^{-2} M). [KH_2PO_4] = 2×10^{-2} M, [K_2HPO_4] = 2×10^{-2} M, ionic strength 0.23 M (KCl), pH 6.74, 45.0°C.

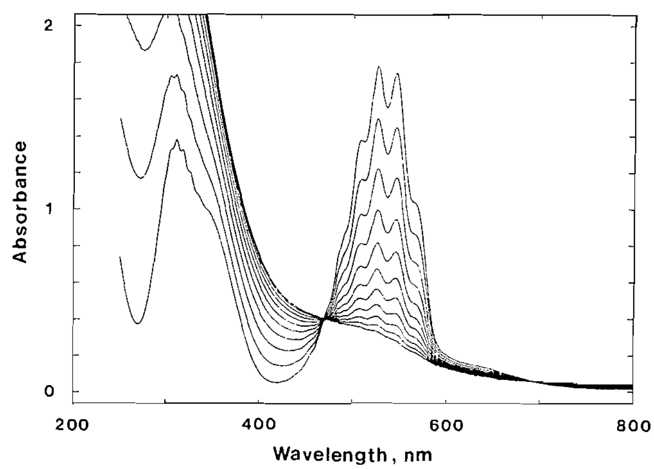

FIG. 2. Successive scans at 6 min intervals during the reaction between permanganate ion (8×10^{-4} M) and trimethylamine (3×10^{-2} M). [KH_2PO_4] = 5×10^{-2} M, [K_2HPO_4] = 5×10^{-2} M, ionic strength 0.23 M, pH 6.74, 45.0°C.

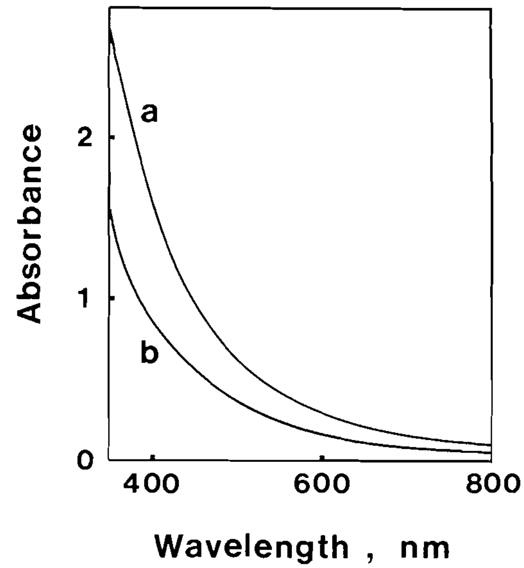

FIG. 3. Spectra at the end of the reaction between permanganate ion (8×10^{-4} M) and trimethylamine (3×10^{-2} M). Ionic strength 0.23 M (KCl), pH 6.74, 45.0°C. [KH_2PO_4] = [K_2HPO_4] = 2×10^{-2} M (a) and 5×10^{-2} M (b).

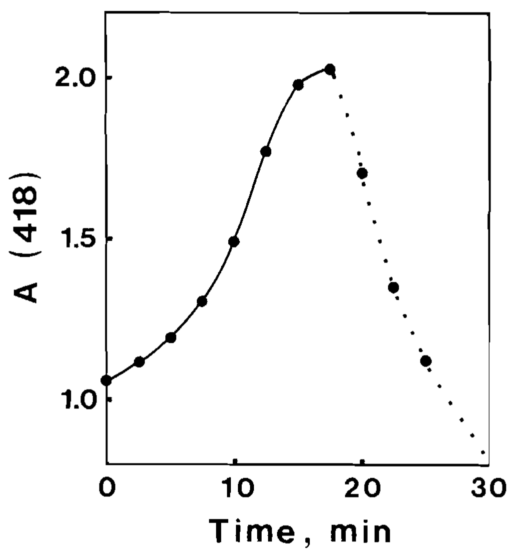

FIG. 4. Variation of the absorbance at 418 nm with time after the end of the reaction between permanganate ion (8×10^{-4} M) and trimethylamine (3×10^{-2} M). [KH_2PO_4] = 3×10^{-2} M, [K_2HPO_4] = 3×10^{-2} M, ionic strength 0.23 M (KCl), pH 6.74, 60.0°C. The dotted line shows when precipitation has already begun.

crease in absorbance at a chosen wavelength (for instance, at 418 nm) until a maximum was obtained. A typical example has been represented in Fig. 4. The highest value of the absorbance corresponded to the start of precipitation, and the subsequent decrease in that magnitude is due to the removal of MnO_2 from the solution by precipitation.

The time necessary for precipitation (t_p) was taken to be the period of time which elapsed between the end of the permanganate–trimethylamine reaction and the observation of a maximum in the absorbance at 418 nm. The inverse of t_p was selected as a way to estimate the rate of conversion of the soluble Mn(IV) species into MnO_2 precipitate.

By measuring t_p under different experimental conditions, it was found that the rate of conversion of the soluble Mn(IV) species into MnO_2 precipitate increases with the initial permanganate concentration in the system (Fig. 5) and also with the potassium chloride concentration (Fig. 6). On the contrary, phosphate ions inhibit the precipitation process, as Fig. 7 clearly shows.

Finally, t_p was found to decrease with temperature; these data are presented in Fig. 8 in an Arrhenius-type fashion. From the slopes of the ln $(1/t_p)$ vs. $1/T$ linear relationships apparent values of the energies of activation for the conversion of the soluble Mn(IV) species into MnO_2 precipitate at four different phosphate concentrations were determined, and the results have been listed in Table 1. We can see that an increase in the phosphate concentration results in an increase in the apparent energy of activation; i.e., precipitation is retarded.

Discussion

All the results obtained in this study can be adequately explained by accepting that the soluble Mn(IV) species is present in the system in the form of colloidal particles of manganese dioxide stabilized temporarily in solution by adsorption of

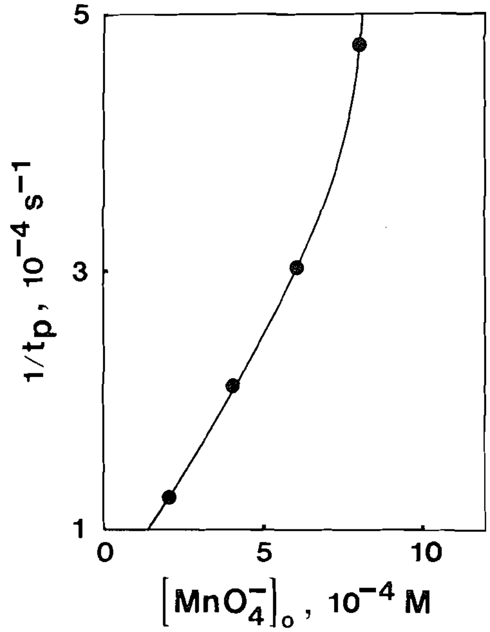

FIG. 5. Dependence of the rate of conversion of the soluble Mn(IV) species into MnO_2 precipitate on the initial permanganate concentration. [Me_3N] = 3 × 10^{-2} M, [KH_2PO_4] = 2 × 10^{-2} M, [K_2HPO_4] = 2 × 10^{-2} M, ionic strength 0.23 M (KCl), pH 6.74, 45.0°C.

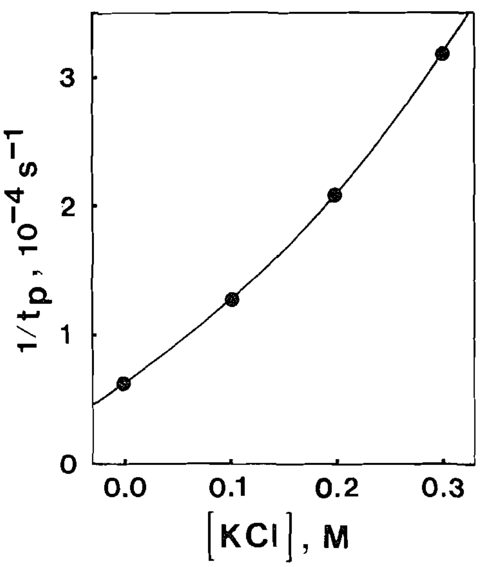

FIG. 6. Dependence of the rate of conversion of the soluble Mn(IV) species into MnO_2 precipitate on the potassium chloride concentration. [MnO_4^-]$_0$ = 8 × 10^{-4} M, [Me_3N] = 3 × 10^{-2} M, [KH_2PO_4] = 5 × 10^{-2} M, [K_2HPO_4] = 5 × 10^{-2} M, pH 6.74, 45.0°C.

phosphate ions on their surface. This hypothesis appears to be the only one which is consistent with the totality of experimental findings.

It has been found that for the soluble Mn(IV) species there is a good linear relationship between the logarithm of the absorbance and the logarithm of the wavelength, with the slope being slightly dependent on the experimental conditions and the amount of time elapsed after the end of the permanganate-trimethylamine reaction. The average slope for 54 different spectra recorded was 4.3 ± 0.6. This appears to be a reflection of Rayleigh's Law, according to which the absorbance due to

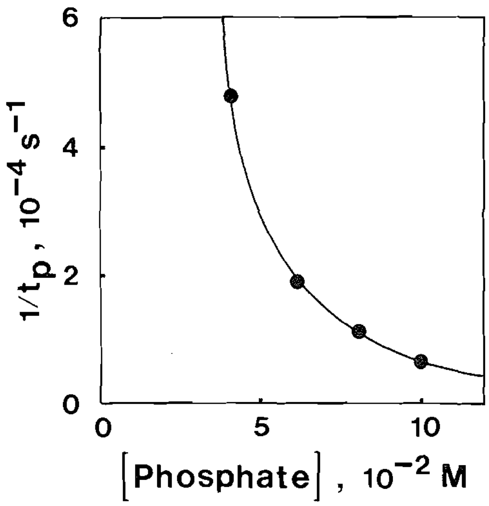

FIG. 7. Dependence of the rate of conversion of the soluble Mn(IV) species into MnO_2 precipitate on the total concentration of phosphate ions (equimolar amounts of KH_2PO_4 and K_2HPO_4). [MnO_4^-]$_0$ = 8 × 10^{-4} M, [Me_3N] = 3 × 10^{-2} M, ionic strength 0.23 M (KCl), pH 6.74, 45.0°C.

scattering of light by a solution of colloidal particles is inversely proportional to the fourth power of the wavelength (14). One of these linear relationships, in excellent agreement with Rayleigh's Law, is shown in Fig. 9.

The absence of an isosbestic point in Fig. 1 could be explained in principle as a consequence of the existence of some manganese intermediate between Mn(VII) and Mn(IV) in appreciable concentration; however, both Mn(VI) and Mn(V) are known to be instable in solutions buffered near neutrality (3b). Moreover, none of the characteristic bands of Mn(VI) or Mn(V) can be observed in Fig. 1. The lack of a good isosbestic point must then be due to an unfulfillment of Beer's Law by the soluble Mn(IV) species. However, this anomalous behavior cannot be due to an aggregative process of the soluble Mn(IV) species at the molecular level (such as dimerization), for a dimer could not produce a strong light-scattering phenomenon as is experimentally observed (see Fig. 9). The existence of a sharp isosbestic point at higher phosphate concentration (see Fig. 2) indicates that for these conditions Beer's Law is fulfilled.

To clarify this point, the absorbance at 526 nm for the experiments shown in Figs. 1 and 2 has been represented in Fig. 10 vs. the absorbance at 418 nm.

Since both permanganate ion and the soluble Mn(IV) species

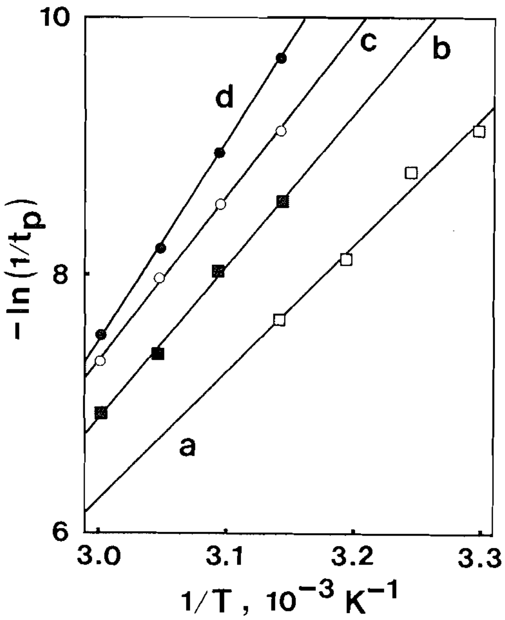

FIG. 8. Arrhenius-type plots for the conversion of the soluble Mn(IV) species into MnO_2 precipitate. $[MnO_4^-]_0 = 8 \times 10^{-4}$ *M*, $[Me_3N] = 3 \times 10^{-2}$ *M*, ionic strength 0.23 *M* (KCl), pH 6.74. $[KH_2PO_4] = [K_2HPO_4] = 2(a), 3(b), 4(c), 5(d) \times 10^{-2}$ *M*.

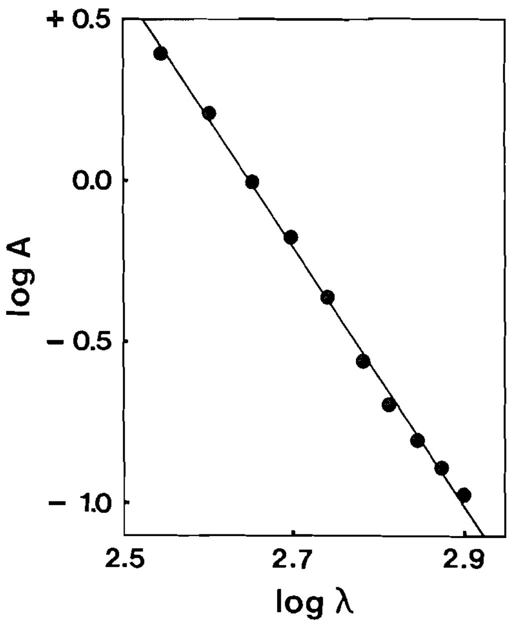

FIG. 9. Rayleigh's Law for the spectrum recorded an hour after the end of the reaction between permanganate ion (8×10^{-4} *M*) and trimethylamine (3×10^{-2} *M*). $[KH_2PO_4] = 2 \times 10^{-2}$ *M*, $[K_2HPO_4] = 2 \times 10^{-2}$ *M*, ionic strength 0.23 *M* (KCl), pH 6.74, 35.0°C. Slope = −3.99, r = 0.998.

absorb light at 526 nm, the absorbance at this wavelength can be written as follows:

[1] $A(526) = \epsilon_R^{526} c + \epsilon_P^{526}(c_0 - c)$

where ϵ_R^{526} and ϵ_P^{526} are respectively the extinction coefficients of reactant and product at 526 nm, and c is the permanganate concentration, its initial value being c_0. In eq. [1] it has been taken into consideration that the concentration of possible manganese intermediates between Mn(VII) and Mn(IV), if present

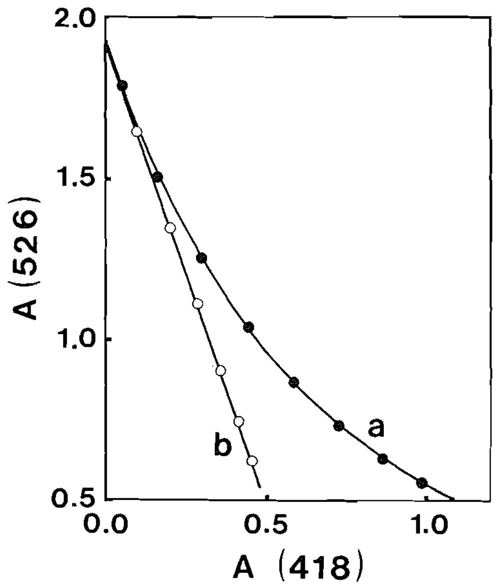

FIG. 10. Absorbance at 526 nm vs. absorbance at 418 nm during the reaction between permanganate ion (8×10^{-4} *M*) and trimethylamine (3×10^{-2} *M*). Ionic strength 0.23 *M* (KCl), pH 6.74, 45.0°C. $[KH_2PO_4] = [K_2HPO_4] = 2 \times 10^{-2}$ *M* (*a*) and 5×10^{-2} *M* (*b*).

at all, is negligible, as pointed out above.

Given that permanganate ion is transparent at 418 nm, the absorbance at this wavelength will be:

[2] $A(418) = \epsilon_P^{418}(c_0 - c)$

where ϵ_P^{418} is the extinction coefficient of the product at 418 nm.

From eqs. [1] and [2] we can deduce:

[3] $A(526) = \epsilon_R^{526} c_0 - [(\epsilon_R^{526} - \epsilon_P^{526})/\epsilon_P^{418}]A(418)$

Hence, a linear relationship would be expected for a plot of $A(526)$ vs. $A(418)$ during the course of reaction. However, as can be seen in Fig. 10 a linear plot is obtained only for the experiments completed at higher phosphate concentrations. Albeit we knew already from Fig. 1 that for the case of lower phosphate concentrations, the soluble Mn(IV) species does not fulfill Beer's Law, Fig. 10 provides an important information. We can observe for this case that the $A(526)$ vs. $A(418)$ relationship is actually a concave curve and that the linear relationship corresponding to higher phosphate concentration coincides with the tangent to the curve at the beginning of the reaction.

This concave curve is a consequence of the flocculation process. It is known that the intensity of radiation scattered by colloidal particles increases with the size of those particles (14). Hence, an increase in the size of the colloidal particles as the reaction is advancing will provoke an increase in the extinction coefficients of the product at 418 and 526 nm, and so a decrease in the absolute value of the slope of the $A(526)$ vs. $A(418)$ relationship (see eq. [3]). As a result, a concave curve, instead of a linear relationship, is found.

On the contrary, when the reaction is followed in the presence of a more concentrated buffer, phosphate ions will adsorb on the colloidal manganese dioxide in a greater proportion and the rate of flocculation will decrease because of the negative electrostatic charges accumulated on the colloid surface. Since the flocculation process is now much slower, the extinction coefficients of the product will be approximately constant and eq. [3] becomes a linear relationship.

The fact that this linear relationship is a tangent to the concave curve at the beginning of the reaction indicates that the size of the colloidal particles is initially the same in both cases. However, while the particles grow by flocculation throughout the reaction in the presence of a diluted phosphate buffer, the initial size of the colloidal particles is "frozen" in the presence of a more concentrated phosphate buffer.

The difference in the rate of flocculation explains the absence or presence of an isosbestic point in Figs. 1 and 2 respectively, and also the different intensity of the spectra recorded at the end of the reaction in both experiments (see Fig. 3). In the case of lower phosphate concentration the size of the colloidal particles is bigger as is the intensity of the radiation scattered by them.

The stabilization of colloids in solution by adsorption of anions on their surface is certainly a well-known phenomenon (15). Given that the experiments were made in systems near neutrality, the concentration of PO_4^{3-} ions was too small to be regarded as the stabilizing agent. Thus, either HPO_4^{2-} or $H_2PO_4^-$ must be responsible for that effect. Although both of them are probably stabilizing the colloidal particles, HPO_4^{2-} will likely account for a greater contribution, because of its greater charge.

Although the adsorption of phosphate ions greatly decreases the number of effective collisions between charged colloidal particles per unit of time, they will not be totally suppressed. Consequently, when all the permanganate has been reduced, flocculation will be made evident spectrophotometrically by a gradual increase in absorbance. Then, the start of the precipitation of manganese dioxide provokes a sudden decrease in that magnitude (see Fig. 4).

An explanation of the results shown in Fig. 5 is evident. An increase in the initial permanganate concentration will result in an increase in the concentration of the soluble Mn(IV) species at the end of the reaction and, accordingly, an increase in the number of colloidal particles of manganese dioxide. Since the collisions of colloidal particles per unit of time will increase parallelly, so will do the rate of flocculation.

The results summarized in Fig. 6 are a consequence of the well-known capacity of electrolytes for increasing the rate of flocculation of colloids (15).

Figure 7 confirms the fact already known from the analysis of Fig. 10, that phosphate ions inhibit the flocculation of colloidal particles and, so, delay the appearance of a precipitate of manganese dioxide.

The acceleration of the flocculation process with temperature shown in Fig. 8 is a consequence of an increase in the number of effective collisions between colloidal particles per unit of time. The fact that this is an activated process fulfilling an Arrhenius-type equation allows us to check the ideas so far developed. Since the stability of the colloidal particles in solution is due to the electrostatic charge that increases the energy necessary to surmount their mutual repulsion, and since this charge is originated by the selective adsorption of phosphate ions on the surface of colloidal manganese dioxide, an increase in the phosphate concentration will result in an increase in the amount of phosphate ions adsorbed and, so, in an increase in the apparent energy of activation of the flocculation process. This is in total agreement with the results compiled in Table 1.

On the other hand, the information presented in this paper might be useful to resolve a current controversy concerning a long-lived species detected in the permanganate oxidation of alkenes. The fact that the spectra recorded for this species are quite similar to the ones shown in Fig. 3 could support a Mn(IV) species, as suggested by some authors (4, 12, 13), rather than the widely accepted cyclic manganate(V) diester (16–24).

Acknowledgments

Discussions with Dr. D. G. Lee during the preparation of this manuscript, as well as the concession to J.F.P.B. by the Spanish Ministry of Education and Science of a grant to study at the University of Regina, Canada, where a part of the experimentation was made, are gratefully acknowledged.

Stereoselective total synthesis of (±)-sinularene and (±)-5-epi-sinularene are described. The sequence employs a "blocked" cyclopentadiene in which the cyclopropane unit also serves as a latent methyl group. Thus intramolecular [4+2] cycloaddition of the substituted methyl spiro[2.4]hepta-4,6-dien-1-yl)-2-pentenoate **11** affords 5-benzyloxy-6-isopropyl-8-carbomethoxy-tetracyclo[$5.4.0^{1,7}.0^{2,4}.0^{2,9}$]undec-10-ene (**12**) which after selective hydrogenolysis generates the tricyclo[$4.4.0^{1,6}.0^{2,8}$]decane (sinularene) ring system. Removal of the secondary hydroxyl function ($Ph_3P/CCl_4/CH_3CN$; $H_2/Pd/C$), reduction of the methyl ester ($LiAlH_4$), and introduction of the exocyclic double bond (acetate pyrolysis, 550°C) completes the synthesis of (±)-sinularene in 14 steps from cyclopentadiene. A parallel series of reactions employing the isopropyl epimer of **12** affords (±)-5-epi-sinularene.

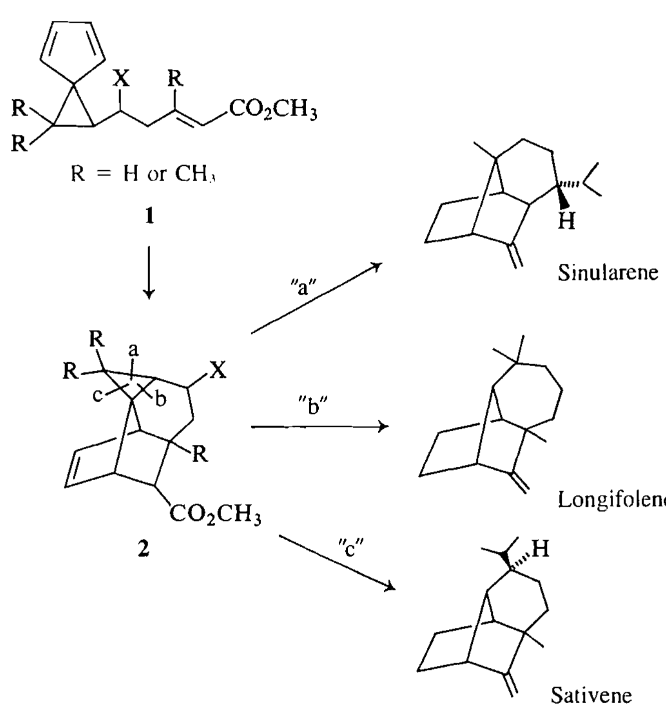
KAZIMIERZ ANTCZAK, JOHN F. KINGSTON et ALEX G. FALLIS. Can. J. Chem. **63**, 993 (1985).

On décrit des synthèses stéréosélectives totales du (±)-sinularène et du (±)-épi-5 sinularène. La synthèse implique l'utilisation d'un cyclopentadiène "bloqué" dans lequel l'unité cyclopropanique sert aussi de groupement méthyle latent. La cycloaddition intramoléculaire [4+2] du spiro[2.4]heptadiène-4,6 yl-1 pentène-2 oate de méthyle (**11**) conduit donc au benzyloxy-5 isopropyl-6 carbométhoxy-8 tétracyclo[$5.4.0^{1,7}.0^{2,4}.0^{2,9}$]undécène-10 (**12**) qui, après une hydrogènolyse sélective, conduit au système cyclique tricyclo[$4.4.0^{1,6}.0^{2,8}$]décane (sinularène). L'élimination de la fonction hydroxyle secondaire ($Ph_3P/CCl_4/CH_3CN$; $H_2/Pd/C$), la réduction de l'ester méthylique ($LiAlH_4$) et l'introduction de la double liaison exocyclique (pyrolyse de l'acétate à 550°C) complètent la synthèse du (±)-sinularène, en 14 étapes à partir du cyclopentadiène. Une série parallèle de réactions faisant appel à l'épimère isopropyle de **12** conduit au (±)-épi-5 sinularène.

[Traduit par le journal]

There is considerable current interest in the intramolecular Diels–Alder reaction and it has been applied to a number of natural product syntheses with notable success (1–4). Among the diverse structures produced in nature, the bridged sesquiterpenes sinularene (5, 6), longifolene (7, 8), and sativene (9, 10) occupy a prominent position. All have been the object of a variety of synthetic approaches and served as a challenge for new synthetic methodology (sinularene syntheses (11, 12),[1] longifolene syntheses (13–18), sativene syntheses (17–25)). In principle these structures could be synthesized via an intramolecular Diels–Alder reaction of an appropriate 5-alkylcyclopentadiene. In practice, however, as an early approach to longifolene showed (26), the propensity of substituted cyclopentadienes to undergo facile 1,5-sigmatropic rearrangement prior to cyclization takes precedence. Thus for this strategy to succeed, rearrangement must be blocked or conditions developed where cyclization can compete efficiently (27, 28). Unfortunately, blocking the sigmatropic reaction is not necessarily straightforward, since even chlorine migrates prior to cyclization in a related case (29).[2]

We report herein a successful solution to this problem, in which the sigmatropic rearrangement is blocked by the cyclopropane moiety present in the spiro[2.4]heptadiene system **1** (Scheme 1). Intramolecular cycloaddition affords a tetracyclic compound of type **2** and selective cyclopropane ring opening provides the requisite tricyclo[$4.4.0^{1,6}.0^{2,8}$]decane skeleton for the interesting marine natural product sinularene.



SCHEME 1

[1]After submission of this manuscript we learned of an additional sinularene synthesis by E. Piers and G. L. Jung (see following Communication). We are grateful to Professor Piers for a preprint of their paper.

[2]As we have pointed out elsewhere (38), an alternative solution employs a brexane intermediate followed by a ring expansion. This approach has been used by Snowden for the total synthesis of sativene (24).

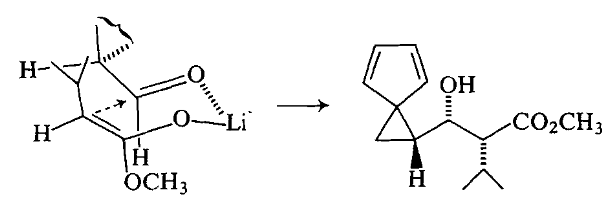
5-Epi-sinularene

With suitably substituted precursors, controlled cleavage of the other cyclopropane bonds should permit entry to the longifolene and sativene series as illustrated (30).

Our initial studies revealed (31) that a C5 oxygen substituent was essential to ensure that the desired intramolecular cycloaddition proceeded. In addition, by carrying the isopropyl function in the sidechain, it seemed likely that its stereochemistry could be controlled as a consequence of steric constraints in the Diels–Alder transition state. Thus the substituted triene **11** (Scheme 2) was selected as a suitable intermediate target. It is apparent that the nonbonded interactions between the developing *exo*-hydrogen and the isopropyl substituent are reduced in **4** compared to **3** and were expected to favour preferential cyclization to the natural stereoisomer.[3] Experimentally, the ether function (R = benzyl) was of greater significance and inhibited cyclization of the C5 (S) diastereomers.[4]

As outlined in Scheme 2, the substituted triene **11** was elaborated from a series of condensations commencing with the aldehyde **6**, obtained by oxidation of the known alcohol **5** (32, 33) (MnO_2, 83%). The initial coupling (LDA/THF, −78°C) with methyl 3-methylbutyrate generated the hydroxyl centre selectively (≃5:1) due to preferential attack on the aldehyde carbonyl from the less hindered direction. This led to a 93% yield of hydroxy-ester comprised of a 47:30:14:2 ratio of stereoisomers. The major diastereomer **8** (47%, illustrated)



7 8

arose from condensation with the Z(O) enolate as illustrated in **7** and was the isomer necessary for conversion to (±)-sinularene. The 30% component, produced from the *E*(O) enolate, differed in the orientation of the isopropyl group as required for (±)-5-epi-sinularene. The major diastereomer **8** was converted to the C4(R)C5(R) triene **11** as follows. The secondary alcohol was protected as a benzyl ether (80%, NaH, $PhCH_2Br$, DME) and the ester function reduced to the primary alcohol **9** (95%, $LiAlH_4$). Oxidation of **9** (PDC, 65%) gave the aldehyde **10** which was subjected to Wittig condensation with methyl (triphenylphosphoranylidene)acetate in refluxing THF. These conditions resulted in simultaneous cyclization of triene **11** to the tetracyclic ester **12** in 72% overall yield. A parallel series of

[3]All the compounds discussed are racemic but only the enantiomers leading to the natural configuration of sinularene and 5-epi-sinularene are illustrated, commencing with the *S* enantiomer of aldehyde **6**.

[4]For consistency and clarity the chiral centres are numbered according to the triene **11**.

reactions on the 30% diastereomer (isopropyl epimer of **8**) afforded the C4(S)C5(R) triene (not illustrated), which also cyclized at 67°C. In contrast, the related C5(S) triene isomers, failed to cyclize even in refluxing dichlorobenzene (180°C).

Thus the cycloaddition was specific, as confirmed by the success of the synthesis and X-ray analysis of the minor, crystalline isopropyl(S)-benzyl(R) adduct corresponding to **12** from which (±)-5-epi-sinularene was prepared. The nonbonded interactions in the transition state were clearly significant and find a partial parallel in the total synthesis of patchouli alcohol (34), in which only one diastereomer cyclized.

Consistent with our preliminary studies of related cyclopropyl ketones (30), hydrogenolysis of **12** cleaved the least substituted cyclopropane bond exclusively, to release the latent methyl group with concomitant removal of the benzyl function and hydrogenation of the double bond (H_2, 10% Pd/C, 85%). Attempted conversion of **13** to a secondary bromide with triphenylphosphinedibromide afforded a significant amount of the olefin **14** accompanied by unreacted alcohol. Elimination is known to compete with substitution in these cases (35) and, by conducting the reaction in acetonitrile with triphenylphosphine/carbon tetrachloride, the single olefin **14** was obtained in 97% yield (^{13}C nmr, 135.3, 128.9). Hydrogenation of **14** (H_2, 10% Pd/C, CH_3OH, 1 atm. (101.3 kPa), 99%) followed by lithium aluminum hydride reduction of the resulting ester provided the primary alcohol **15** quantitatively. Introduction of the exocyclic methylene using either selenoxide elimination or dehydrobromination proved impractical. Thus authentic (±)-sinularene was prepared from **15** *via* pyrolysis (550°C, 77%) of the acetate **16**, and possessed spectral features (^1H nmr, ir, ms) identical to those published for the natural product (5).

This completes a direct stereoselective synthesis of (±)-sinularene in 22% overall yield from the major aldol diastereomer **8** (9% from **5**) and 14 steps from cyclopentadiene, the same ultimate starting material as employed in the Australian (11) and Swiss (12) syntheses. A parallel series of reactions from the minor isopropyl(S) adduct corresponding to **12** afforded (±)-5-epi-sinularene.

These concepts and procedures are also applicable to the preparation of 12-acetoxysinularene (36, 37) and are currently being extended to an asymmetric synthesis of (+)-longifolene, utilizing this intramolecular Diels–Alder:cyclopropane ring opening strategy.

Thermal rearrangement of functionalized 6-*exo*-(1-alkenyl)bicyclo[3.1.0]hex-2-enes. A total synthesis of (±)-sinularene

EDWARD PIERS AND GRACE L. JUNG

Department of Chemistry, University of British Columbia, 2036 Main Mall, University Campus, Vancouver, B.C., Canada V6T 1Y6

Received November 30, 1984

EDWARD PIERS and GRACE L. JUNG. Can. J. Chem. **63**, 996 (1985).

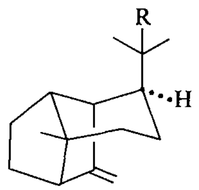
A total synthesis of the racemic form of the marine sesquiterpenoid (−)-sinularene (**1**) is described. The key step of the synthesis involved the stereoselective thermal rearrangement of the highly functionalized bicyclo[3.1.0]hexene **12** to provide, in 86% yield, the substituted bicyclo[3.2.1]octadiene **13**. Conversion of the latter substance into (±)-sinularene (**1**) was accomplished via an efficient 4-step sequence.

EDWARD PIERS et GRACE L. JUNG. Can. J. Chem. **63**, 996 (1985).

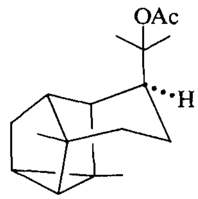
On décrit une synthèse totale de la forme racémique du sesquiterpénoïde marin, (−)-sinularène (**1**). L'étape clé de la synthèse implique la transposition thermique stéréosélective du bicyclo[3.1.0]hexène **12** hautement fonctionnalisé qui conduit au bicyclo[3.2.1]octadiène **13** substitué avec un rendement de 86%. On a opéré la transformation de **13** en (±)-sinularène (**1**) en faisant appel à une séquence très efficace de quatre réactions.

[Traduit par le journal]

In 1977, the constitution and absolute stereochemistry of the structurally unusual sesquiterpenoid (−)-sinularene, isolated from the soft coral *Sinularia mayi*, were determined to be as shown in **1** (1). Subsequently, two related natural products, 12-acetoxysinularene (**2**) and 12-acetoxycyclosinularene (**3**),



1 R = H
2 R = OAc



3

were obtained from a dichloromethane extract of *Clavularia inflata* (2). Up to the present time, two total syntheses of (±)-sinularene (**1**) have been reported (3, 4) and another has been completed.[1] In addition, the preparation of (±)-12-acetoxysinularene (**2**) has been described (5). We record herein our total synthesis of (±)-**1** via a route (summarized in Scheme 1) which is very different from those employed previously.

Reaction of 1-lithio-3-methyl-1-butyne with methacrolein (tetrahydrofuran, −30°C → room temperature, 1 h) provided the alcohol **4**[2] which, when treated with hot (130°C) triethyl orthoacetate in the presence of propionic acid (6), was converted stereoselectively into the ester **5** (58%). Transformation of the latter material into the diazoketone **6** (59% overall), followed by sequential carbenoid ring closure of **6** and hydrogenation (Lindlar's catalyst) of the resultant bicyclic alkyne **7**, provided cleanly the keto alkene **8** (62% from **6**).

Treatment of the trimethylsilyl enol ether of ketone **8** with $Pd(OAc)_2$ in acetonitrile (7) gave the enone **9** in 65% yield. When **9** was allowed to react with lithium divinylcuprate, the two epimeric conjugate addition products **10** and **11** were produced in a ratio of 9.4:1, respectively[3] (65% yield). These substances were separated by column chromatography. Evidence that the major (expected) product was the desired compound **10** was obtained by ^1H nmr spectroscopy. Thus, in a difference nOe experiment, irradiation at δ 2.15 (H_A, see **10**) caused enhancement of the signal (δ 2.91) due to the proton adjacent to the vinyl group (R in **10**).

In our overall synthetic plan, the key step was envisaged to be the thermal rearrangement of the enol silyl ether **12**, (hopefully) to produce the bicyclic triene **13**.[4] Presumably this process would involve isomerization of **12** to the epimer **17**, which would then undergo a Cope rearrangement (9). However, it should be pointed out that the thermally induced bond reorganization of **12** could proceed via an alternative pathway involving a homo-[1,5]-sigmatropic hydrogen migration (10) to provide (at least initially) the highly substituted cyclopentene **18**. In the anticipated transition state for the desired Cope process (see **A**), there is a significant destabilization due to steric repulsion between the isopropyl group and H_X. On the other hand, the presumed transition state for the sigmatropic

[1]Work by K. Antczak, J. F. Kingston, and A. G. Fallis. We are grateful to Professor Fallis for a preprint which describes their work (see preceding Communication).

[2]All compounds reported herein exhibited spectra (ir, ^1H nmr) in full accord with structural assignments. New substances gave satisfactory elemental analyses and (or) high resolution mass spectrometric molecular mass determinations.

[3]Interestingly, the reaction of **9** with vinylmagnesium bromide in the presence of $CuBr \cdot Me_2S$ (catalyst) was significantly less stereoselective, producing **10** and **11** in a ratio of 2.25:1 (63%).

[4]For previous reports concerning the synthesis of functionalized bicyclo[3.2.1]octane systems by thermolysis of 6-(1-alkenyl)bicyclo-[3.1.0]hex-2-enes, see ref. 8.

18 **B**

hydrogen shift suffers from a similar interaction involving the isopropyl group and H_Y (see **B**). Thus, it is difficult to make a clear-cut prediction as to which mode of rearrangement would be preferred.

Fortunately (and happily), thermolysis of **12** produced, in 86% yield, a single product, the spectra of which showed clearly that it was the desired triene **13**. Chemoselective hydroboration–oxidation of the latter compound, followed by treatment of the resultant alcohol **14** with *p*-toluenesulfonyl chloride in the presence of 4-dimethylaminopyridine, afforded directly the tricyclic ketone **15** (68% from **13**). Hydrogenation of **15** provided the ketone **16**, which was spectrally and chromatographically identical with the same compound prepared by Collins and Wege (3).[5]

Conversion of **16** into (±)-sinularene (**1**) has been accomplished previously via a three-step sequence (3). However, we have shown that this transformation can be carried out conveniently by treatment of **16** with methylenetriphenylphosphorane in refluxing tetrahydrofuran. Although the reaction was slow, it provided (±)-**1** cleanly (66% yield from **15**). Racemic sinularene (**1**) thus obtained was identical with an authentic sample.[5]

La réaction en phase gazeuse de l'azote activé avec le benzaldéhyde donne une réaction chimiluminescente attribuée essentiellement à la transition $T_1(n\pi^*) \rightarrow S_0$ du benzaldéhyde. Deux étapes dans le mécanisme de la réaction sont proposées.

ODILE DESSAUX, CHRISTIAN DUPRET, and PIERRE GOUDMAND. Can. J. Chem. **63**, 998 (1985).

The reaction of active nitrogen with benzaldehyde gives a chemiluminescent reaction mainly attributed to the $T_1(n\pi^*) \rightarrow S_0$ transition of benzaldehyde. Two steps of the mechanism are proposed.

Introduction

L'azote activé par décharge électrique microonde est un vecteur d'énergie de réactivité physicochimique très importante (1). Il constitue un milieu en évolution dynamique du fait du mécanisme complexe de recombinaison des atomes d'azote (2, 3) mettant en jeu des états moléculaires triplets ou singulet vibrationnellement excités (4). Le comportement de l'azote activé apparaît différent suivant l'état physique du réactif sur lequel il réagit: en phase gazeuse il entraîne, en général, une fragmentation de la cible moléculaire pour former des radicaux ou molécules mono, di ou triatomiques, pouvant être accompagnée d'une fixation d'azote atomique (1), tandis que ses réactions avec des matrices solides contenant un dérivé aromatique à faible température (77 K ou 4,2 K) ont pour effet essentiel une excitation à l'état triplet par transfert radiatif (5).

La possibilité de l'intervention de l'état triplet de la molécule cible comme intermédiaire primaire dans la réaction de l'azote activé est souvent postulée (1) sans aucune preuve directe: l'une des raisons essentielles de la difficulté de la mise en évidence d'une telle étape est le caractère fortement inhibiteur des atomes $N(^4S)$ pour des états triplets; c'est ainsi que s'interprète la faible concentration stationnaire de $N_2(^3\Sigma_u^+)$ dans le gaz activé où cette molécule à l'état triplet le plus bas est détruite par la réaction très rapide [1]:

$$[1] \quad N_2(^3\Sigma_u^+) + N(^4S) \rightarrow N_2(^1\Sigma_g^+) + N(^4S).$$

Nous rendons compte de la mise en évidence expérimentale de l'état triplet de la cible moléculaire dans la réaction chimiluminescente, en phase gazeuse, de l'azote activé sur le benzaldéhyde.

Partie expérimentale

L'azote activé est produit et réagit sur le benzaldéhyde C_6H_5CHO à l'aide d'un dispositif déjà décrit antérieurement (3). Les réactifs sont des produits chimiquement purs utilisés sans purification complémentaire. Le dispositif d'observation spectroscopique est constitué par la chaîne de détection et d'enregistrement: monochromateur "Coderg MSV" – photomultiplicateur "EMI 9558 QB" couplé à un enregistreur.

La réaction se présente comme une chimiluminescence bleue très localisée, dans la zone de mélange des deux flux gazeux. Ce phénomène ne peut être mis en évidence que dans des conditions très strictes de débit des deux réactifs qui impliquent la consommation complète des atomes d'azote qui se traduit par une disparition totale de la chimiluminescence jaune.

Le spectre d'émission de la chimiluminescence (fig. 1) présente essentiellement la transition triplet–singulet $T_1(n\pi^*) - S_0$ du benzaldéhyde. Les longueurs d'onde sont mesurées, avec une précision de 1 nm, à 460 nm, 426 nm et 397 nm, ce qui correspond avec une bonne précision à la vibration d'élongation de C=O dont la fréquence moyenne apparaît être de 1725 cm^{-1} dans notre travail. L'émission du système $^2\Sigma^+ - {}^2\Sigma^+$ du radical CN est également présente mais sous une intensité faible; la comparaison des spectres 1a et 1b montre qu'elle est présente sur le spectre d'un témoin enregistré après l'arrêt de l'arrivée du benzaldéhyde et semble indiquer que l'origine de cet émetteur très sensible est une impureté.

Discussion

Deux étapes mécanistiques de la réaction peuvent être dégagées dans ce travail préliminaire.

The reaction of active nitrogen with benzaldehyde gives a chemiluminescent reaction mainly attributed to the $T_1(n\pi^*) \rightarrow S_0$ transition of benzaldehyde. Two steps of the mechanism are proposed.

Introduction

L'azote activé par décharge électrique microonde est un vecteur d'énergie de réactivité physicochimique très importante (1). Il constitue un milieu en évolution dynamique du fait du mécanisme complexe de recombinaison des atomes d'azote (2, 3) mettant en jeu des états moléculaires triplets ou singulet vibrationnellement excités (4). Le comportement de l'azote activé apparaît différent suivant l'état physique du réactif sur lequel il réagit: en phase gazeuse il entraîne, en général, une fragmentation de la cible moléculaire pour former des radicaux ou molécules mono, di ou triatomiques, pouvant être accompagnée d'une fixation d'azote atomique (1), tandis que ses réactions avec des matrices solides contenant un dérivé aromatique à faible température (77 K ou 4,2 K) ont pour effet essentiel une excitation à l'état triplet par transfert radiatif (5).

La possibilité de l'intervention de l'état triplet de la molécule cible comme intermédiaire primaire dans la réaction de l'azote activé est souvent postulée (1) sans aucune preuve directe: l'une des raisons essentielles de la difficulté de la mise en évidence d'une telle étape est le caractère fortement inhibiteur des atomes $N(^4S)$ pour des états triplets; c'est ainsi que s'interprète la faible concentration stationnaire de $N_2(^3\Sigma_u^+)$ dans le gaz activé où cette molécule à l'état triplet le plus bas est détruite par la réaction très rapide [1]:

$$[1] \quad N_2(^3\Sigma_u^+) + N(^4S) \rightarrow N_2(^1\Sigma_g^+) + N(^4S).$$

Nous rendons compte de la mise en évidence expérimentale de l'état triplet de la cible moléculaire dans la réaction chimiluminescente, en phase gazeuse, de l'azote activé sur le benzaldéhyde.

Partie expérimentale

L'azote activé est produit et réagit sur le benzaldéhyde C_6H_5CHO à l'aide d'un dispositif déjà décrit antérieurement (3). Les réactifs sont des produits chimiquement purs utilisés sans purification complémentaire. Le dispositif d'observation spectroscopique est constitué par la chaîne de détection et d'enregistrement: monochromateur "Coderg MSV" – photomultiplicateur "EMI 9558 QB" couplé à un enregistreur.

La réaction se présente comme une chimiluminescence bleue très localisée, dans la zone de mélange des deux flux gazeux. Ce phénomène ne peut être mis en évidence que dans des conditions très strictes de débit des deux réactifs qui impliquent la consommation complète des atomes d'azote qui se traduit par une disparition totale de la chimiluminescence jaune.

Le spectre d'émission de la chimiluminescence (fig. 1) présente essentiellement la transition triplet–singulet $T_1(n\pi^*) - S_0$ du benzaldéhyde. Les longueurs d'onde sont mesurées, avec une précision de 1 nm, à 460 nm, 426 nm et 397 nm, ce qui correspond avec une bonne précision à la vibration d'élongation de C=O dont la fréquence moyenne apparaît être de 1725 cm^{-1} dans notre travail. L'émission du système $^2\Sigma^+ - {}^2\Sigma^+$ du radical CN est également présente mais sous une intensité faible; la comparaison des spectres 1a et 1b montre qu'elle est présente sur le spectre d'un témoin enregistré après l'arrêt de l'arrivée du benzaldéhyde et semble indiquer que l'origine de cet émetteur très sensible est une impureté.

Discussion

Deux étapes mécanistiques de la réaction peuvent être dégagées dans ce travail préliminaire.

[1]Auteur à qui adresser la correspondance.

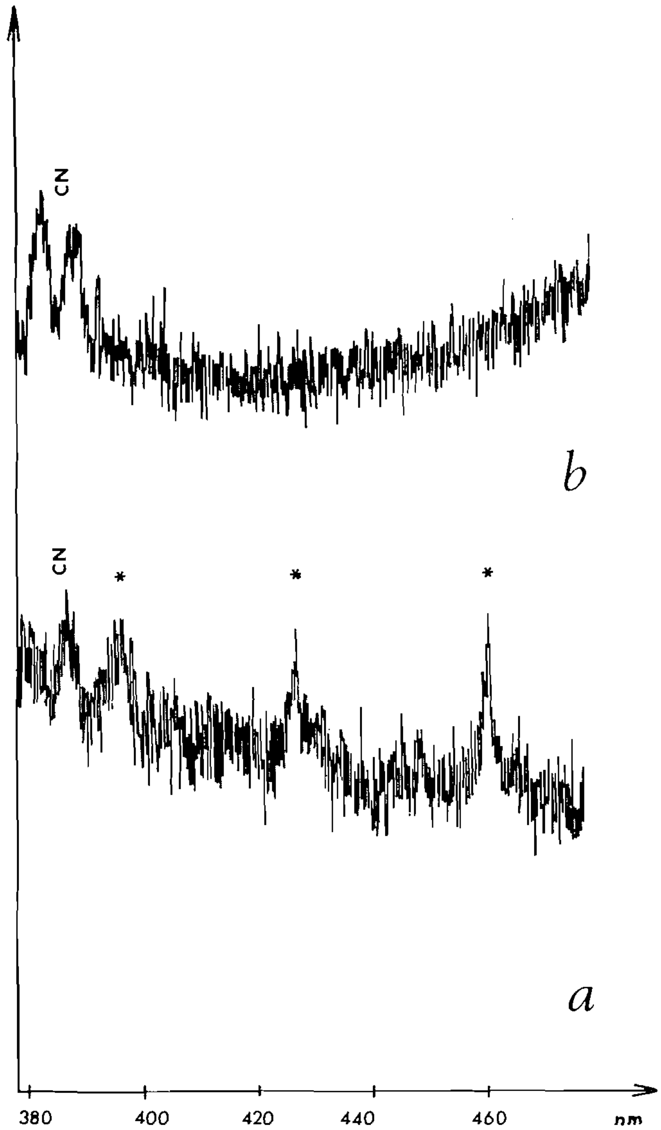

FIG. 1. (a) Enregistrement du spectre de la chimiluminescence du benzaldéhyde avec l'azote activé. (b) Enregistrement témoin en l'absence de benzaldéhyde.

(a) L'excitation de l'état $T_1(n\pi^*)$ du benzaldéhyde peut être interprétée, a priori; soit par un transfert d'énergie à partir de molécules d'azote présentes dans le milieu $N_2(^3\Pi_g)$: T_2 ou $N_2(^3\Sigma_u^+)$: T_1

[2] $N_2(T) + \phi CHO(S_0) \rightarrow N_2(S_0) + \phi CHO(T_1 n\pi^*)$

soit par une triple collision

[3] $N(^4S) + N(^4S) + \phi CHO(S_0) \rightarrow N_2(S_0) + \phi CHO(T_1 n\pi^*)$

Les réactions du modèle [2] ne sont efficaces que si elles sont très rapides, étant donné la court durée de vie des espèces $N_2(T)$ dans l'azote activé: $N_2(T_2)$, du fait de sa transition radiative permise vers $N_2(T_1)$, cette dernière à cause de la réaction [1]. La réaction [3] apparaît ainsi la plus probable comme responsable du peuplement de l'état triplet de ϕ-CHO. En tout état de cause les réactions [2] ou [3] de formation de $\phi CHO(T_1 n\pi^*)$ ne sont pas des réactions élémentaires et en particulier la réaction [3] peut mettre en jeu des états électroniquement excités de l'azote. Le diagramme énergétique (fig.

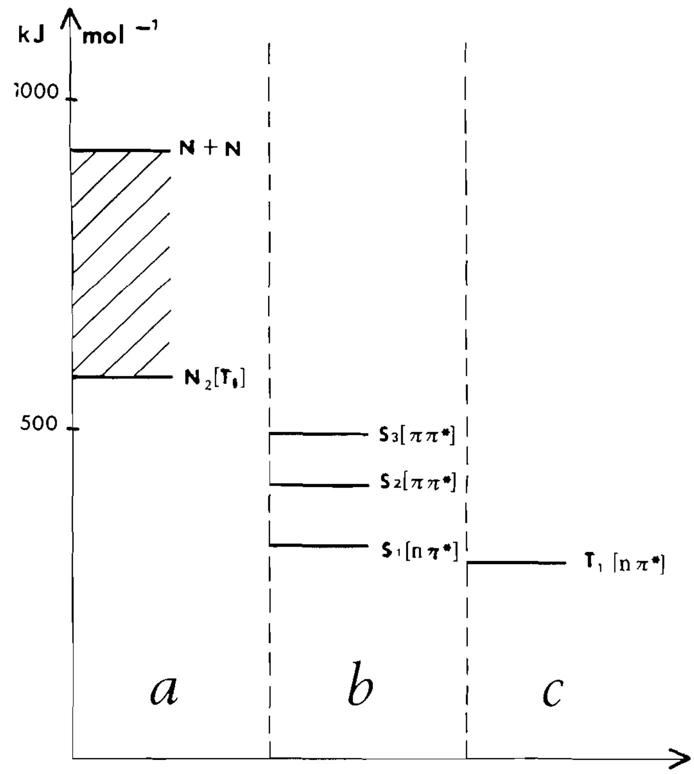

FIG. 2. Diagramme énergétique. (a) Niveaux d'énergie susceptibles d'être mis en jeu dans les réactions de l'azote activé. (b) Niveaux d'énergie des premiers singulets de ϕCHO. (c) Niveau d'énergie de l'état triplet de ϕCHO.

2) permet de comparer les énergies susceptibles d'être mises en jeu dans le transfert — qui doit se faire d'une manière isoénergétique: l'énergie de l'état triplet $T_1(n\pi^*)$ du benzaldéhyde, et celles de ses états excités singulets — qui constituent une limite supérieure pour l'énergie de l'état triplet correspondant. Ce schéma montre que l'état $T_1(n\pi^*)$ ne peut être produit qu'après un processus de relaxation énergétique important mettant en jeu des mécanismes de conversion interne (par cascade d'états triplets successifs), mais éventuellement aussi des conversions intersystèmes vers des états singulets.

(b) La nécessité d'opérer dans des conditions de disparition totale des atomes $N(^4S)$ étaye l'hypothèse d'une désactivation cinétique très rapide:

[4] $\phi CHO(T_1 n\pi^*) + N(^4S) \rightarrow \phi CHO(S_0) + N(^4S)$.

GÁBOR TÓTH, ATTILA ALMÁSY, LÁSZLÓ HAZAI, ANTAL SCHNITTA, and GYULA DEÁK. Can. J. Chem. **63**, 1001 (1985).

The stereochemistry of the adducts of isoquinolin-3(2*H*)-ones and maleimides was studied and ^{1}H and ^{13}C spectral parameters of the *endo* and *exo* stereoisomers were determined. The predominant rotamers generated by rotation about the C(7)—C(7a) and (C1)—C(1′) bonds were identified.

GÁBOR TÓTH, ATILLA ALMÁSY, LÁSZLÓ HAZAI, ANTAL SCHNITTA et GYULA DEÁK. Can. J. Chem. **63**, 1001 (1985).

On a étudié la stéréochimie des adduits obtenus par condensation des 2*H*-isoquinoléinones-3 sur les maléimides et on a déterminé les paramètres, en rmn du ^{1}H et du ^{13}C, des stéréoisomères *endo* et *exo*. On a identifié les rotamères prédominants qui sont générés par des rotations autour des liaisons C(7)—C(7a) et C(1)—C(1′).

[Traduit par le journal]

Introduction

Earlier, we reported that some isoquinolin-3(2*H*)-ones, prepared in our laboratory, which are partly present as their *ortho*-quinoidal lactam tautomer, are amenable to Diels–Alder reaction with active dienophiles (1–3). Thus, a number of adducts with maleic acid derivatives have been prepared employing *N*-phenyl- and *N*-carbamoyl-maleimide, as well as maleic anhydride, as dienophiles. The products contain various substituents, such as alkyl, aryl, aralkyl, and heteroaryl groups, and may be condensed with a benzene ring in positions (*f*), (*g*), or (*h*). The unsubstituted maleimide adduct **1** was prepared by an indirect route (1).

Results and discussion

The products may be of either *exo* or *endo* configuration. Usually only one adduct could be isolated, except in the case of **5** where both isomers could be separated (2). The numbering used in the assignment of nmr data is shown in the formula for *exo* **5*b*** (Scheme 2).

The earlier misconception that, in the *endo* isomers, the *ortho*-hydrogens of the condensed benzene ring (H-9a and H-9d) are highly shielded by the nearby imide carbonyl led to incorrect conclusions concerning the stereostructure of the above adducts and their congeners (4–6). It has been shown later that the two proton signals in question should rather be assigned to the *ortho*-hydrogens of the *N*-phenyl group (7–9). This assumption is supported by our present ^{1}H and selective ^{13}C{^{1}H} decoupling studies on compounds **1**–**6**. However, the assumption that increased shielding of the methyne protons is diagnostic for the *exo* stereoisomer (7) could not be confirmed.

Characteristic ^{1}H nmr data for compounds **1**–**7**, along with further Lis (Lanthanide induced shift) values for **5*a*** on addition of Eu(fod)$_3$ graphically interpolated to a 1:1 substrate/reagent ratio are compiled in Table 1.

We have found that the spectra of *exo* and *endo* isomers characteristically differ in the chemical shifts of the *ortho*-protons of the *N*-phenyl group, which in the latter are shifted upfield to 6.40 ppm owing to the diamagnetic anisotropic effect of the condensed benzene ring. The proton H-9a is in turn more

shielded in the *exo* isomers. When R^1 = CH_2Ph (**5***a* and **6**) diastereotopic methylene protons produce a broad singlet in the *endo* isomers, while an AB-type doublet in *exo* **5***b*. Lis measurements have revealed that, similar to 4-benzyl-1-phenyl-dihydro-3(2*H*)-isoquinolines (10), Eu(fod)$_3$ was associated with the amide carbonyl. Accordingly, highest induced shifts were observed at the methylene and *ortho*-hydrogens of the benzyl group. The accidental anisochrony of the methylene protons was lifted by the shift reagent, proving that the coincidence of chemical shifts was not due to averaging by fast

[b]Tentative assignment.

rotation around the C(1)—C(1′) bond. The Lis value (1.3 ppm) for the *ortho*-protons of the *N*-phenyl group at the same time supported the *endo* configuration in which *N*—Ph is remote from C(11)═O. Unequal Lis values for the angular H-2 and H-6 proton signals also confirm their assignment. ^{13}C chemical shifts for compounds **1**–**6** as well as of *cis*-4-benzyl-1-phenyl-1,4-dihydro-3(2*H*)-isoquinolinone **7**, used as a model, are shown in Table 2. Assignments were based on those for **7** (10). It has to be noted that, in view of recent data reviewed by Ewing (11), assignments for the *ortho*- and *meta*-carbons of the benzyl group had to be interchanged.

For *N*-phenyl-succinimides, some unassigned ^{13}C chemical shifts have been reported (12). *N*—Ph shifts can, however, be assigned by comparing the spectra of **1** and **2**. Selective $^{13}C\{^1H\}$ decoupling of the two-proton signal at 6.40 indicated that the signal at 126.3 belongs to C(4*b*). On N—H → N—Ph substitution the imide carbonyl signals were shifted upfield by 2.3–2.6 ppm. Identification of the close C(2) and C(6) methyne signals was possible by the appearance of a ^3J(C, H) = 3.6 Hz coupling in the former, arising by interaction with the 1-methyl group. ^1J(C, H) couplings were 142.8 and 141.0 Hz, respectively.

Assignment of the lower field signal to C(6) could also be substantiated by comparing data for **2** and **3**. By removing the methyl group in the γ-position, this signal was essentially unaffected, while that for C(2) shifted, as expected, upfield. Accordingly, the signal for the β-positioned C(11) moved upfield while that for the γ-positioned C(3) moved downfield. Changes caused in the signals of the condensed aromatic ring effected by $R^2 = CH_3$ substitution also corroborated their assignment.

In **4** ($R^1 = R^2 = CH_3$) interaction of the *peri* methyl groups resulted in a slight deformation of the molecular skeleton, which may explain small deviations of chemical shifts from those calculated by additivity rules for carbons in the vicinity of C(1) and C(9). Downfield shifts of the two methyl group signals due to a δ-effect are quite characteristic (13).

Replacement of $R^1 = CH_3$ (**2**) for CH_2Ph (**5***a*, **5***b*, and **6**) involves a characteristic downfield shift of the C(1) signals. For the C(2) signal, a marked upfield shift was observed in **5***a* and **6**, and a small downfield shift in **5***b*. This can be interpreted by considering the rotamers **x**, **y**, and **z**, generated by rotation around the C(1)—C(1′) bond. With **5***a* and **6** rotamer **x**, and with **5***b* rotamer **y** involve severe steric interaction and can thus be discounted as being predominant conformers. In both **x** and **y**, γ-gauche interaction between C(2) and Ph—C(1′) is expected, while the same groups are γ-anti disposed in **z**. In the light of the observed shifts (see above), the predominant conformer for **5***a* and **6** is **y**, while for **5***b* it is **z**. Differences in the C(1b) chemical shifts also reflect changes of conformation.

There is a notable difference of the C(7a) shifts in the *exo* and *endo* isomers which can also be traced back to conformational changes. In the *endo* series, steric interaction between C(5)═O and H_2-7b is avoided in rotamer **w**, in which the planes of C(7)-phenyl and of the condensed benzene ring are at about 30°, while in rotamer **u**, characteristic for *exo*-(**5***b*), this angle is about 90°.

This assumption is supported by an upfield shift of 0.5 ppm of the H-9d signal in **5***b* under the well-known anisotropic effect of the phenyl group, as compared with the values recorded for **5***a*.

The characteristic chemical shifts observed for the signals of the condensed aromatic ring of the dimethoxy compound **6** provided further evidence for our assignments. The close C(9a) and C(9d) signals were assigned with the aid of selective $^{13}C\{^{1}H\}$ decoupling.

Experimental

The ^{1}H and ^{13}C nmr spectra were recorded on a JEOL FX-100 nmr spectrometer in PFT mode (16 K data points for FID) at ambient temperature at 99.6 and 25.0 MHz, respectively, using tetramethylsilane as internal standard.

Received August 27, 1984

YASUO ABE, TAKAAKI DOHMARU, HIDEO HORII, and SETSUO TANIGUCHI. Can. J. Chem. **63**, 1005 (1985).

Kinetic studies of the oxidation of 2,3-dihydroxy-2-propenal (triose reductone, RH_2) by hexacyanoferrate(III), $[Fe(CN)_6]^{3-}$, were carried out in acidic media ($[H^+] = 0.02-0.1$ *M* (1 *M* = 1mol dm^{-3})) at various temperatures (10–30°C). The ionic strength of the media ($I = 0.04-0.4$ *M*) was adjusted using sodium perchlorate. The second-order rate constants in M^{-1} s^{-1} are (0.86 ± 0.06) – (2.83 ± 0.14) for the reactions of hexacyanoferrate(III) with RH_2 and [(4.16 ± 0.03) – (12.4 ± 0.2)] × 10^3 for those with RH^- ion. Activation parameters for the oxidation have been reported and compared with those of the oxidation of triose reductone with peroxodisulfate ion. A probable mechanism is proposed for the reaction.

YASUO ABE, TAKAAKI DOHMARU, HIDEO HORII et SETSUO TANIGUCHI. Can. J. Chem. **63**, 1005 (1985).

Opérant en milieu acide ($[H^+]$ = 0,02 à 0,1 *M* (1 *M* = 1 mol dm^{-3})) et à diverses températures allant de 10 à 30°C, on a effectué des études cinétiques sur l'oxydation du dihydroxy-2,3 propène-2 al (triose de la réductone, RH_2) par l'hexacyanoferrate(III), $[Fe(CN)_6]^{3-}$. On a ajusté la force ionique du milieu (*I* = 0,04 à 0,4 *M*) en utilisant du perchlorate de sodium. Les constantes de vitesse du second ordre (en M^{-1} s^{-1}) se situent entre 0,86 ± 0,06 et 2,83 ± 0,14 pour les réactions de l'hexacyanoferrate(III) avec RH_2 et entre (4,14 ± 0,03) × 10^3 et (12,4 ± 0,2) × 10^3 pour celles avec l'ion RH^-. On rapporte les paramètres d'activation pour l'oxydation et on les compare avec ceux obtenus pour l'oxydation du triose de la réductone par l'ion peroxodisulfate. On propose un mécanisme probable pour la réaction.

[Traduit par le journal]

Triose reductone (RH_2) has been well known for its reducing properties in aqueous solutions. The reductone is the simplest in structure of the compounds having an enediol group; the physiologically important L-ascorbic acid is a typical compound of this structure. Thus kinetic studies on the reaction of triose reductone would help to clarify the mechanisms of the physiological activities of enediol compounds. It has been reported that the rates of oxidation of RH_2 by molecular oxygen (1) and peroxodisulfate ($S_2O_8^{2-}$) (2) are dependent on the hydrogen ion concentrations. In the latter case, the mechanism was interpreted in terms of the successive one-electron transfers, while the rate constant for the triose reductone radicals was not determined. The existence of the triose reductone free radicals has been confirmed by pulse radiolysis of the reductone (3). Thus it is of current interest to get any kinetic information on the electron transfer reaction involving $RH^{\cdot}$. Hexacyanoferrate(III) is a typical one-electron oxidizing agent (4) and is often used in a model reaction of biologically important cytochrome c. In the present paper, we make kinetic studies of the oxidation reactions of RH_2 with hexacyanoferrate(III) in aqueous acidic solution, present the most probable reaction mechanism, and give the rate constants of some of the elementary reactions involved.

Experimental

Materials

Triose reductone was prepared and purified by the method described in the literature (5). Sodium perchlorate, potassium hexacyanoferrate(III), and potassium hexacyanoferrate(II) of analytical grade (E. Merck) were used without further purification. All the other chemicals were guaranteed reagents of the Wako Pure Chemicals Co. Ltd.

Reaction solution

The hexacyanoferrate(III) solution was prepared by dissolving 65.9 mg of the solid in 250 cm^3 of a dilute sulfuric acid solution containing 0.5 mmol of disodium dihydrogen ethylenediaminetetraacetate (EDTA) and a given weight of sodium perchlorate. EDTA was added to complex heavy metal ions which catalyse the oxidation of triose reductone (1) and which react with hexacyanoferrate(III) ion to produce complex precipitates. The triose reductone solution was prepared by dissolving 31.0 mg of the compound in 30 cm^3 of the same acid solution as described above. It was then saturated with argon (high-purity argon gas was bubbled through the solution to remove the dissolved oxygen).

Kinetic method

The hexacyanoferrate(III) solution (2.9 cm^3) was transferred into a gas-tight optical cell and argon gas was bubbled through the solution by means of injection needles and a septum cap for 0.5–1 h. The reaction was started by adding the triose reductone solution (0.1 cm^3). The temperature of the reaction solution was kept constant during the reaction. Kinetic data were obtained by following the decreasing absorption of hexacyanoferrate(III) at 420 nm (neither triose reductone nor hexacyanoferrate(II) absorbed light at this wavelength under the reaction conditions). The acidity was kept constant at a value in the range of 0.01–0.05 *M* in sulfuric acid. The temperature was controlled by circulating thermostated water around the cell housing. The pH values of the triose reductone solution in the course of the measurement of the pK_a values were corrected for various ionic strengths. The activity coefficients f_i for protons at varying ionic strengths (I) were obtained by using $\log f_i = -0.358 z_i^2 I^{1/2}/(1 + 10^8 a_i \times 0.2325 I^{1/2})$ with $10^8 a_i = 9$ and $z_i = 1$ (6). The activity coefficients used in this paper were 0.89 (0.04), 0.85 (0.1), 0.83 (0.2), and 0.80 (0.4): the ionic strength is given in parentheses.

Results and discussion

Stoichiometry

By maintaining a slight excess of oxidizing agent and by performing spectrophotometric measurements at 420 nm, the following stoichiometric equation was found:

[1] $2Fe(III) + RH_2 \rightarrow 2Fe(II) + DR + 2H^+$

where RH_2 and DR represent triose reductone and dehydroreductone, 1,2,3-propane-trione, respectively.

Dissociation constant of triose reductone

The pK_a values of the first dissociation of triose reductone (RH_2) for the equilibrium, $RH_2 \rightleftharpoons RH^- + H^+$, were determined by the spectrophotometric method reported previously (1) at an ionic strength of 0.4 *M* (with the temperature (°C) in paren-

theses): 4.95 (10), 4.91 (15), 4.86 (20), 4.82 (25), and 4.78 (30), and at 25°C (with the I in parentheses): 4.95 (0.04), 4.88 (0.1), 4.84 (0.2), and 4.82 (0.4).

Kinetics of the reaction

When pseudo-first-order conditions, $[TR]_0/[Fe(III)]_0 = 10$, were adopted, plots of log A_t vs. t were linear to at least 80% completion, where $[TR] = [RH_2] + [RH^-]$ and A_t indicates the absorbance of $K_3[Fe(CN)_6]$ at 420 nm at a certain time (t) of reaction. When second-order conditions, $[Fe(III)]_0/[TR]_0 = 2$, were adopted, second-order plots, $[Fe(III)]^{-1}$ vs. t, were also linear for 75% completion; some examples of the plots are given in Fig. 1. Thus, the following empirical rate law and the relationship between $[Fe(III)]^{-1}$ and t can be suggested, respectively:

$$[2]\quad -1/2\mathrm{d}[Fe(III)]/\mathrm{d}t = k_0[Fe(III)][TR]$$

$$[3]\quad [Fe(III)]^{-1} = k_0 t + [Fe(III)]_0^{-1}$$

Values of k_0 obtained at various temperatures, ionic strengths, and acidities are collected in Table 1.

The second-order rate constants k_0 increase with decreasing acidity. The conventional treatment of the reactions involving the acid dissociation equilibrium gives k_0 as in eq. [4],

$$[4]\quad k_0 = k_1 + (k_2 - k_1)K_a/([H^+] + K_a)$$

where k_1 and k_2 are the rate constants of the reactions of RH_2 and RH^- with Fe(III), respectively. In the present experiment, $[H^+]$ were much larger than K_a ($K_a = 10^{-5}$). Therefore, eq. [4] can be simplified to eq. [5],

$$[5]\quad k_0 = k_1 + (k_2 - k_1)K_a/[H^+]$$

The plots of k_0 vs. $[H^+]^{-1}$ showed a linear relationship; the plots are given in Figs. 2 and 3. The k_1 and k_2 values are listed in Table 2.

Effect of the reduced form

Some kinetic runs were performed in the presence of reduced species of metal complex, namely, hexacyanoferrate(II), in the same concentration as the corresponding oxidized form. No significant effect was observed on the calculated rate constants (see the values in parentheses in Table 1).

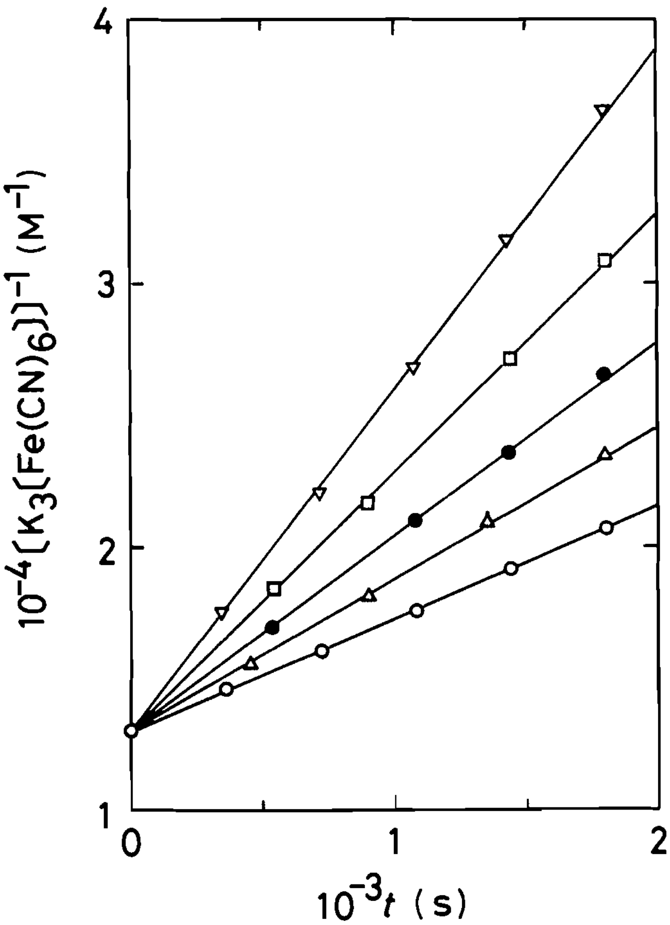

FIG. 1. Relation between 10^{-4} $[Fe(III)]^{-1}$ and time for the reduction of Fe(III) with triose reductone at I = 0.4 and various temperatures. ○: 10°C, △: 15°C, ●: 20°C, □: 25°C, ▽: 30°C.

Effect of ionic strength

In order to investigate the ionic-strength effect, kinetic runs were performed at 25°C with increasing addition of $NaClO_4$ up to 0.40 M. Values of second-order rate constants obtained for this portion of the investigation are listed in Table 2 and are

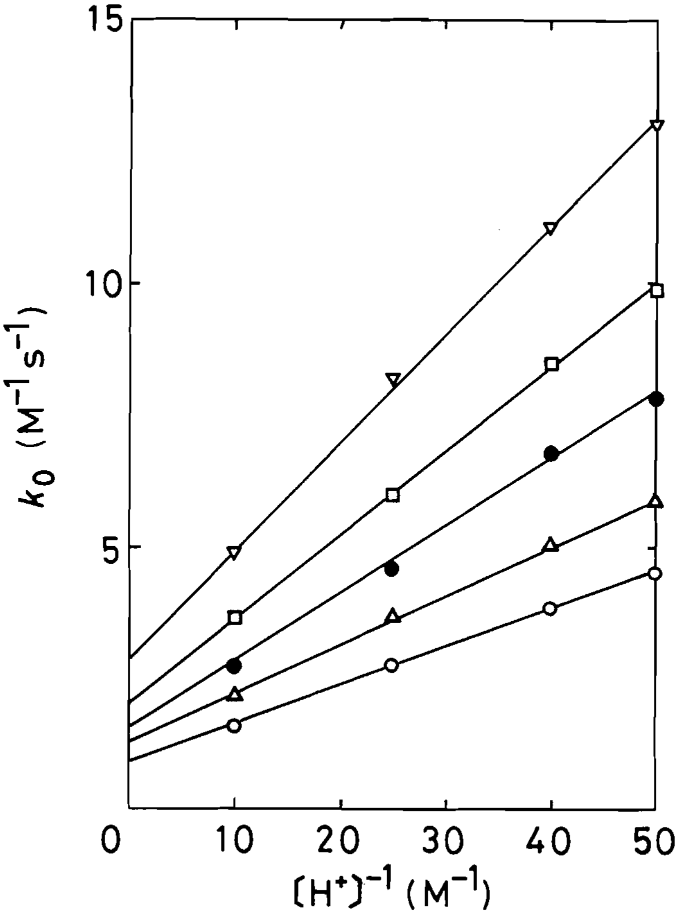

FIG. 2. Relation between k_1 and $[H^+]^{-1}$ for the oxidation of triose reductone with $K_3[Fe(CN)_6]$ at $I = 0.4$ and various temperatures. Each plot denotes the mean value of three experimental data. ○: 10°C, △: 15°C, ●: 20°C, □: 25°C, ▽: 30°C.

observed to increase with increasing ionic strength, as would be expected for reaction of the triose reductone monoanion with negatively charged oxidizing species.

Davies has normalized a great deal of kinetic data relating to specific cation effects by considering the effect of ion-pair formation between the specific cation and the reactants on the ionic strength or some function of the ionic strength by using the following equation (7),

$$[6] \quad \log k = \log k_0 + 2Az_az_bF(I)$$

$$F(I) = I^{1/2}/(1 + I^{1/2}) - 0.2I$$

where A is the Debye–Hückel coefficient, z_a and z_b are the charges on the reactant, and k_0 is the bimolecular rate constant at zero ionic strength. Swinehart applied Davies' equation to the reaction of hexacyanoferrate(III) with sulfite in the presence of sodium chloride and obtained a good relationship between rate constant and ionic strength (8).

The plots of log k_2 vs. $F(I)$ showed a straight line, with the relationship $\log k_2 = 3.17 \pm 0.05 + (2.75 \pm 0.21)F(I)$. This dependence is expected for the reaction between two ions of the same sign: the positive value of 2.75 is in good agreement with that of $z_az_b = 3.0$.

The fact that the ionic-strength dependence of rate constant in the reaction of triose reductone with peroxodisulfate in the presence of sodium perchlorate agreed with the Debye–Hückel equation (ref. 2) suggests that neither triose reductone anion

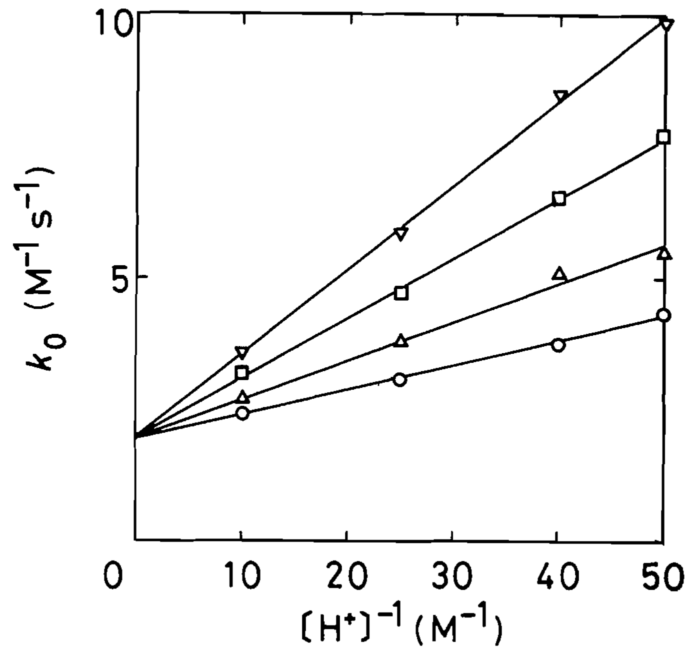

FIG. 3. Relation between k_1 and $[H^+]^{-1}$ for the oxidation of triose reductone with $K_3[Fe(CN)_6]$ at 25°C and various ionic strengths. Each plot denotes the mean value of three experimental data. ○: 0.04 M, △: 0.1 M, □: 0.2 M, ▽: 0.4 M.

TABLE 2. Temperature and ionic-strength dependence of rate constants and kinetic parameters

$\Delta S^{\ddagger}$ (J deg^{-1} mol^{-1})		−112±11	−97±3

nor peroxodisulfate anion form an ion pair. Therefore, it is suggested that hexacyanoferrate(III) forms an ion pair with sodium cation as indicated in eq. [7], although no empirical data has been reported in the literature.

$$[7] \quad [Fe(CN)_6]^{3-} + Na^+ \rightleftharpoons Na[Fe(CN)_6]^{2-}$$

The association constant of hexacyanoferrate(III) and potassium cation was estimated to be about 20 at 25°C (9). Assuming that a maximum value of the equilibrium constant for eq. [7] is 10^1 and that the activity coefficient of the ion pair is the same as for $[Fe(CN)_5NO]^{2-}$ (6), the fraction of the ion pair is expected to be less than 20% at the present reaction conditions.

Temperature dependence

The activation parameters corresponding to the specific rate

[1]Equilibrium constants for sodium ion-pair formation are usually less than half of those for potassium ion.

constants at $I = 0.4$ were calculated from the slope of the Eyring plot ($\ln k/T$ vs. $1/T$) and listed in Table 2. The absolute values of both enthalpy and entropy of activation for RH^- are less than those for the oxidation with peroxodisulfate ($\Delta H^\ddagger = 37 \pm 1$ kJ mol^{-1} and $\Delta S^\ddagger = -123 \pm 5$ J deg^{-1} mol^{-1}) (2) and also less than those for the oxidation of L-ascorbic acid with hexacyanoferrate(III) ($\Delta H^\ddagger = 45.2$ kJ mol^{-1} and $\Delta S^\ddagger = -166.5$ J deg^{-1} mol^{-1}) (10).

Mechanism of the reaction

From the results of ionic strength, it is suggested that the resulting ion pair has less oxidizing ability than hexacyanoferrate(III). Therefore, a mechanism consistent with the present experimental observation can now be written (eqs. [8]–[13]). The role of Na^+ has been ignored in the discussion that follows.

$$[8] \quad RH_2 \overset{K_a}{\rightleftharpoons} RH^- + H^+$$

$$[9] \quad [Fe(CN)_6]^{3-} + RH_2 \xrightarrow{k_1} RH^\cdot + [Fe(CN)_6]^{4-} + H^+$$

$$[10] \quad [Fe(CN)_6]^{3-} + RH^- \xrightarrow{k_2} RH^\cdot + [Fe(CN)_6]^{4-}$$

$$[11] \quad RH^\cdot \overset{K_2}{\rightleftharpoons} R^{-\cdot} + H^+$$

$$[12] \quad [Fe(CN)_6]^{3-} + RH^\cdot \xrightarrow{k_3} DR + H^+ + [Fe(CN)_6]^{4-} + H^+$$

$$[13] \quad [Fe(CN)_6]^{3-} + R^{-\cdot} \xrightarrow{k_4} DR + [Fe(CN)_6]^{4-}$$

The presence of free radicals in the oxidation of triose reductone was confirmed by esr measurement (11) and kinetic considerations (2). The linearity of pseudo-first-order plots and the absence of an effect of the presence of reduced species indicate that no reverse reactions are kinetically relevant.

Considering the K_2 value, which is estimated to be about 1.5 by us (unpublished result) at the equilibrium eq. [11], triose reductone free radicals exist in both forms $RH^\cdot$ and $R^{-\cdot}$ under the present conditions. Although absolute values of the rate constants k_3 and k_4 are unknown, the following experimental rate law [14] suggests that $k_3, k_4 \gg k_1, k_2$.

$$[14] \quad -1/2\, d[Fe(III)]/dt = (k_1 + k_2K_a/[H^+])[Fe(III)][TR]$$

Another mechanism for the consumption of triose reductone free radicals by disproportionation is also possible (3).

$$[15] \quad 2RH^\cdot \xrightarrow{k_5} RH_2 + DR$$

$$[16] \quad 2R^{-\cdot} + 2H^+ \xrightarrow{k_6} RH_2 + DR$$

If the radicals were eliminated only by the disproportionation, the rate law of the decrease of hexacyanoferrate(III) must be according to eq. [17].

$$[17] \quad -d[Fe(III)]/dt = (k_1 + k_2K_a/[H^+])[Fe(III)][TR]$$

The rate constant of the disproportionation was reported as $2 \times 10^8\ M^{-1}\ s^{-1}$ at pH 9.6 (3). Although the rate constant is much larger than the values of k_1 and k_2 even when the reaction conditions are different, the concentration of radicals at steady state is very small. Therefore, eqs. [15] and [16] can be neglected for the reaction mechanism of the oxidation of triose reductone, even though they might become important after 85% completion.

Relaxation and related ¹H nmr studies on "asperlin." Configuration and conformation of the epoxypropyl side-chain

PHOTIS DAIS AND ARTHUR S. PERLIN
Department of Chemistry, McGill University, Montreal, P.Q., Canada H3A 2A7
Received August 7, 1984

PHOTIS DAIS and ARTHUR S. PERLIN. Can. J. Chem. **63**, 1009 (1985).

Monoselective and biselective spin-lattice relaxation rates, together with nOe experiments, have been used to examine the configuration and conformation of the epoxypropyl side-chain of "asperlin" (**1**) in benzene solution. The data confirm earlier evidence that the oxirane ring is *trans*, and indicate that **1** is the 6*R*,7*S* diastereomer. Moreover, it is shown that in the most probable conformation of the side-chain about the C-5,C-6 bond, H-5 and H-6 are *anti*.

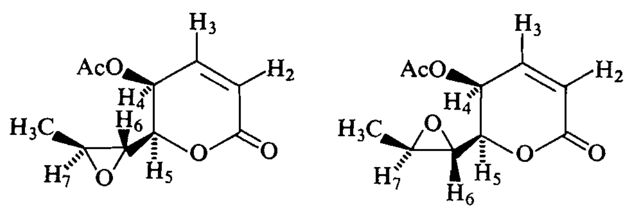
PHOTIS DAIS et ARTHUR S. PERLIN. Can. J. Chem. **63**, 1009 (1985).

Dans le but d'examiner la configuration et la conformation de la chaîne latérale époxypropyle de l' "asperline" (**1**) en solution dans le benzène, on a utilisé des vitesses de relaxation spin-réseau mono et bi-sélectives ainsi que des expériences d'effet nucléaire Overhauser. Les données confirment les indications antérieures à l'effet que le cycle oxiranne est *trans* et elles indiquent que le composé **1** est le diastéréomère 6*R*,7*S*. De plus, on démontre que dans la conformation la plus probable de la chaîne latérale autour de la liaison C-5,C-6, les hydrogènes H-5 et H-6 sont *anti*.

[Traduit par le journal]

Introduction

The structure of 5-acetoxy-5,6-dihydro-6-(1,2-epoxypropyl)-2-pyrone (**1**) ("asperlin"), a metabolite of *Aspergillus nidulans* (1), has been studied (2, 3) by ¹H and ¹³C nmr spectroscopy, using reference compounds derived mainly from carbohydrates of known stereochemistry, as well as by chemical synthesis (3). It was concluded that the pyrone ring of **1**



a *b*

1

assumes a semi-planar conformation, that the 4,5-substituents of the ring[1] have the L-*threo* configuration, and also that the exocyclic epoxypropyl moiety is *trans*. The present paper describes spin-lattice relaxation and nuclear Overhauser enhancement (nOe) measurements, carried out primarily to examine the configuration of the oxirane ring (i.e., as in diastereoisomer **1***a* or **1***b*),[2] as well as the conformation of the epoxypropyl side-chain.

Proton monoselective spin-lattice relaxation and nOe data, and (or) mono- and biselective experiments (4), provide a rigorous approach to the structure of molecules in solution, without the need of reference compounds. Obviously, this offers practical advantages when model compounds are not readily available or easily synthesized. The principle inherent in applying measurements of proton relaxation rates and nOe is the dependence of pairwise dipolar interactions on interatomic distances, viz., these interactions decrease approximately as a simple sixth power of the interatomic distance (5). Hence, by calculation of the pertinent interproton dimensions for a given molecule, structural and conformational features may be determined. Applied to asperlin, this general approach has afforded information about the most probable orientation of the epoxypropyl side-chain around the C-5,C-6 bond, and also about which of the two possible diastereoisomers (**1***a* or **1***b*) corresponds to the natural product.

[1]In keeping with the numbering used earlier (3) in correlating the stereochemistry of asperlin with that of carbohydrate models, the carbonyl carbon of **1** is herein designated C-1, and the α-proton, H-2.

[2]It has not proven feasible to determine the structure of asperlin by X-ray crystallography, because the only form of the compound available consists of twinned crystals (G. Donnay, private communication).

Experimental

¹H and ¹³C nuclear magnetic resonance spin-lattice relaxation and nOe measurements

All of the nmr experiments were conducted at 400 MHz (¹H) and 100 MHz (¹³C) with a Bruker-400 spectrometer, at 20°C. A 0.15 *M* solution of asperlin in benzene-d_6 was used for the ¹H experiments, and a 0.5 *M* solution in benzene-d_6 for the ¹³C experiments. Each sample was carefully degassed by using 5 to 6 "freeze–pump–thaw" cycles, following which the nmr tube was sealed. ¹³C spin-lattice relaxation times and ¹H nonselective relaxation rates were measured by the two-pulse inversion recovery technique. Details of the procedure used in the nonselective relaxation and nOe experiments are given elsewhere (6, 7). Statistical errors in the fit of semilogarithmic plots were within ±2% and ±5% for ¹H and ¹³C nmr relaxation rates.

Monoselective relaxation rates for H-4 to H-7 protons were measured by using a long (15–20 ms), weak pre-irradiation pulse which selectively inverted the required resonance frequency. The selective 180° pulse was provided by the decoupler channel. In performing bi-(double) selective experiments the computer of the spectrometer was used to control a train of two selective 180° pulses provided consecutively by the decoupler at the resonance frequencies of protons H-5 and H-7 and (or) H-4 and H-7. The time interval between the two pulses (~200 ns) and the total duration of the two pulses (~30 ms) were negligibly small compared to the long relaxation times of these protons, ensuring thereby the effectiveness of the experiment, i.e., no significant relaxation during excitation. Typical mono- and biselective inversions are shown in Fig. 1. Mono- and biselective partially relaxed spectra were obtained by the inversion recovery method. Typically 20 to 30 τ values covering the range ~0–2T_1 were used for the initial rate approximation. The total magnetization intensity for each resonance was processed by a two-parameter linear regression analysis to obtain selective relaxation rates. Each relaxation rate value presented is an average of 2 or 3 separate measurements. The statistical error and reproduciblity of the various relaxation rates were better than ±3% and ±5%, respectively.

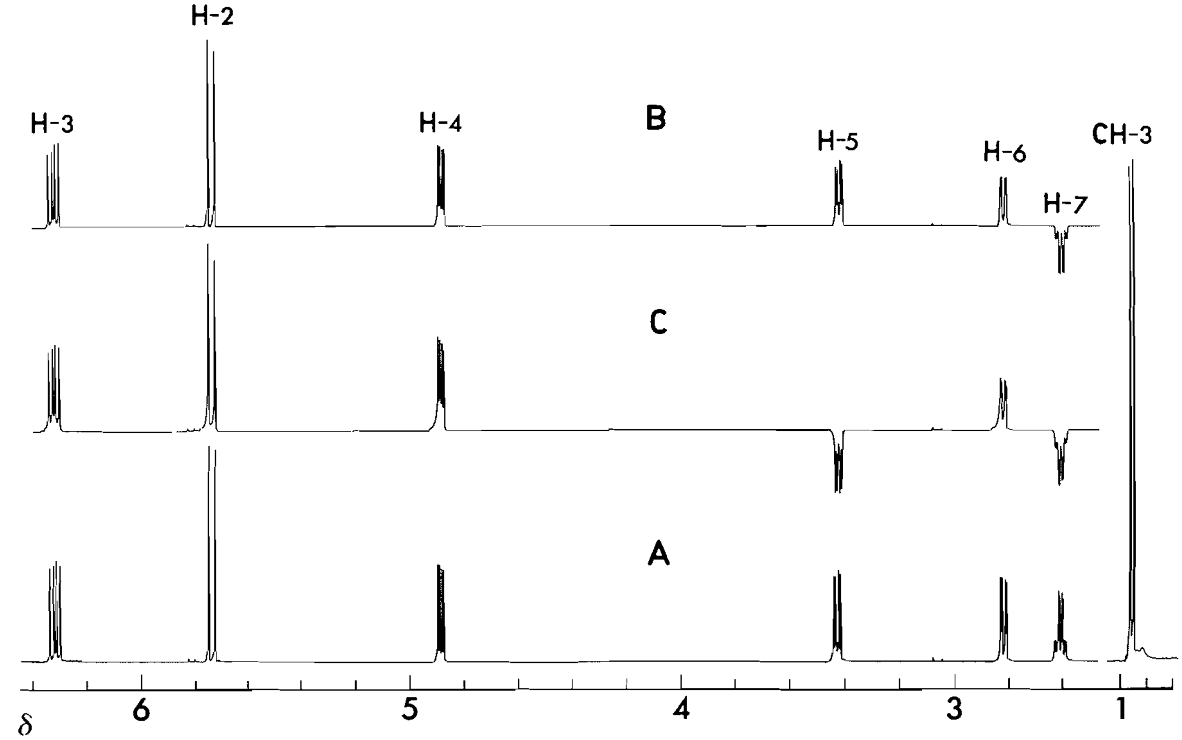


FIG. 1. (A) Normal ^{1}H nmr spectrum of **1** benzene-d_6 at 400 MHz; (B) representative ^{1}H monoselective spin-lattice relaxation experiment with **1**; the H-7 signal was inverted by a selective 180° pulse (~15 ms), τ = 0.01 s; (C) representative ^{1}H biselective spin-lattice relaxation experiment in which two signals, H-5 and H-7, were inverted simultaneously by two consecutive selective 180° pulses (~15 ms each) provided by the decoupler channel, τ = 0.1 s.

Results and discussion

At 400 MHz, with benzene-d_6 as the solvent, the ^{1}H nmr spectrum of **1** (Fig. 1A) is completely resolved. Whereas at lower field (3) the H-6 and H-7 signals overlapped, these signals now appear in slightly distorted form as a doublet of doublets and a quartet of doublets, respectively. Analysis of these signals, together with those of the methyl protons as an ABX_3 spectrum, gave the following parameters: J_{AB} = 1.95 Hz, J_{AX} = 0 Hz, J_{BX} = 5.20 Hz, ν_A = 559.17 Hz, ν_B = 516.84 Hz, and ν_X = 185.83 Hz, where A = H-6, B = H-7, and X_3 = CH_3. Proton chemical shifts and coupling constants are shown in Table 1. These nmr parameters, along with the ^{13}C chemical shifts, are in accord with previous (2, 3) interpretations of the stereochemistry of **1**.

The nonselective spin-lattice relaxation rates (R_1^{ns}) also shown in Table 1, give complementary information about the stereochemstry of **1**. For the ring protons, it can be seen that the R_1^{ns} values for H-4 and H-5 are the same, whereas the relaxation rates of H-2 and H-3 are lower by ~35% and 11%, respectively, and H-2 relaxes ~27% more slowly than H-3. Inspection of possible inter-ring relaxation pathways cannot satisfactorily explain these relaxation rates. For instance, H-3 and H-4 would be expected to have the fastest relaxation rates, due to the *gauche* and eclipsed disposition of their neighbouring protons. Moreover, the primary relaxation pathways for H-2 and H-5 are provided by H-3 and H-4, respectively, and al-

[b]Values in parentheses are standard deviations based on the measured intensities.

though the relative proximity of each pair of protons is nearly the same, the relaxation rate of H-5 is ~35% faster than that of H-2. In part, these variations reflect the sensitivity of proton relaxation rates to changes in the rates of anisotropic modes of reorientation of **1**. That is, ^{13}C spin-lattice relaxation measurements demonstrate that **1** tumbles anisotropically in benzene, inasmuch as the ^{13}C R_1 value for C-2 (Table 1) is smaller than those of the other ring carbons, which are nearly the same within experimental error. This difference, ~14%, indicates that **1** tumbles anisotropically about a preferential axis of rotation, which forms a small angle with the C-2, H-2 relaxation vector. The theory of dipole−dipole relaxation in anisotropically tumbling molecules shows (8) that relaxation vectors which lie on, or parallel to, the major axis of rotation are more efficient than vectors at an angle to this axis. It follows that the H-3,H-4 pathway is expected to be more efficient that those of H-2,H-3 and H-4,H-5. In addition, however, the fact that the relaxation rates of H-4 and H-5 are faster than for H-3 suggests that the two former protons interact with protons of the epoxypropyl moiety. Similarly, the methyl protons, which provide a primary relaxation pathway for vicinal H-7, should have an influence on H-6 commensurate with a *trans* configuration (2, 3) for the epoxide, as compared to a *cis* configuration in which the methyl protons and H-6 would be further apart. These considerations have a bearing on such questions as the configuration and conformation of this side chain, because of their relationship to molecular dimensions, as will now be discussed.

Interproton distances may be measured effectively from combinations of mono- (R_1^s) and biselective (R_1^{bs}) spin-lattice relaxation rates and nOe values. The experimentally determined interproton distances may then be compared with molecular models in order to assess stereochemical possibilities. Theory shows (4, 5, 9) that internuclear distances between spins i and j can be measured by combining monoselective relaxation rates and nOe values and (or) mono- and biselective relaxation rates, i.e.,

$$[1]\quad (r_{ij})^6 = \frac{0.5\,\gamma_i^2\gamma_j^2\hbar^2}{R_{1,i}^{s}\cdot f_i(j)}$$

and

$$[2]\quad R_{1,i}^{bs} = R_{1,i}^{s} + \sigma_{ij} \text{ and (or) } R_{1,j}^{bs} = R_{1,j}^{s} + \sigma_{ji}$$

where $\sigma_{ij} = \sigma_{ji}$ the cross-relaxation term given by

$$[3]\quad \sigma_{ij} = \frac{0.5\,\gamma_i^2\gamma_j^2\hbar^2}{(r_{ij})^6}\,\tau(ij)$$

$\tau(ij)$ is the rotational correlation time of the internuclear vector r_{ij}, $f_i(j)$ is the nOe value of spin i upon irradiation of spin j, and $R_{1,i}^2$, $R_{1,i}^{bs}$ are the mono- and biselective spin-latice relaxation rates of spin i, respectively. In the present study, intermolecular dipolar contributions were kept to a minimum by restricting the relaxation measurements to a degassed, dilute solution. Other competing relaxation mechanisms (e.g., spin-rotation, etc.) were found to be absent. This is demonstrated by the ratios of the nonselective rates to monoselective rates for the pertinent protons (Table 1), which are very close to the theoretical value 1.5 (5, 9) confirming the preponderance of dipole−dipole interactions in the relaxation of these protons. Problems associated with nonexponential decay of the magnetization vectors in the relaxation experiments (4, 9) were avoided by confining measurements to "initial" relaxation rates (4, 5, 9). Hence, three factors affecting relaxation rates, and thereby calculated interproton distances, were kept to a minimum.

Another factor to be assessed is motional anisotropy. Equations [1]−[3] hold under isotropic reorientation of the r_{ij} vector. In this case $\tau(ij)$ can be measured from ^{13}C spin-lattice relaxation experiments, assuming that the proton−proton correlation time is the same as the correlation time of the $^{13}C-^1H$ vector. For asperlin, the overall reorientation is anisotropic as evidenced by the ^{13}C T_1 values of the pyrone ring carbons (Table 1). The $\tau(ij)$ correlation time is, in fact, an effective correlation time containing contributions from the correlation times of molecular reorientation about the principle axes of the diffusion tensor. A study (10) of the motional behavior of **1** indicates that its rotational dynamics can be represented adequately by the diffusion of a prolate ellipsoid with the major axis passing through the C-2,H-2 bond. The correlation times for rotations about, and perpendicular to, the major axis were found to be $\tau_\parallel = 30.3 \pm 1.7$ ps and $\tau_\perp = 23.5 \pm 1.2$ ps. This ~22% difference in the correlation times for parallel and perpendicular rotations about the major axis leads to a reduction in the error in the calculated distances by a factor of six (see eqs. [1] and [3]). Therefore the estimated error in the calculations introduced by molecular anisotropy is ~4%, which is too small to invalidate the quantitative determination of internuclear distances.

By using the relaxation parameters in Table 1, the nOe values in Table 2, and eqs. [1]−[3], interatomic distances were calculated for the proton pairs H-4,H-6 and H-5,H-7 (Table 3). The other data in Table 3 are values of interatomic distances derived from stereochemical models[3] of the two diastereoisomeric forms of the *trans* epoxide (**1**a and **1**b), as well as those of the *cis* isomer, in which O-4 and H-5 are *anti* (3), and the dihedral angle between H-5 and H-6 is 180 ± 30°. This latter range is commensurate with the dihedral angle indicated by $^3J_{5,6}$ (6.85 Hz, Table 1), by reference to the Karplus relationship (11), whereas the alternate value of 0 ± 30° can be rejected because, as shown by the lack of a mutual nOe response between H-5 and H-6 (Table 2), these protons cannot have a *syn* relationship.

[3]HGS Molecular Models (Benjamin/Maruzen), using the "bent bonds" furnished to construct the oxirane ring of **1**.

TABLE 3. Interproton distances (Å) for "asperlin" from molecular models and nuclear magnetic resonance data

[a]The limits of error cited are the propagated errors in the various experimental quantities, including the error introduced by motional anisotropy.
[b]Corresponding to **1***a* and **1***b*, respectively.
[c]See footnote 3.

The interatomic distances taken from molecular models are regarded as approximations only. Although the structure of oxirane has been determined (12), we are uncertain as to dimensions of the angles and distances in the disubstituted oxirane structure comprising carbons 5 to 8 of **1**. With this reservation, a comparison of the experimentally determined values for the distance between H-4 and H-7 (~2.8 Å, Table 3), with those expected for the various diastereoisomeric forms, shows that the experimental value falls within the range for the two extreme orientations in **1***a*, whereas it lies well outside the range of values for the other *trans* isomer (**1***b*) and for both *cis* forms. Hence, the nmr measurements provide an independent proof that, as proposed earlier (2, 3), the epoxide ring of **1** is *trans*. An analogous comparison of distances between H-5 and H-7 finds no difference between **1***a* and **1***b* although in both instances the dimensions from models nearly overlap[4] the experimental value of ~2.8 Å.

Structures **1***a* and **1***b* may be compared in a different manner. According to the nmr measurements on **1**, H-4 and H-5 are equidistant from H-7 (~2.8 Å). By rotating the epoxypropyl side chain in a molecular model of **1***a* around the C-5,C-6 bond, so as to locate H-4, H-5, and H-7 in that fashion, H-6 becomes oriented *anti* with respect to H-5. This is in accord with the preceding comments on the significance of $^3J_{5,6}$. In marked contrast, however, when the analogous operation is applied to a model of **1***b*, the H-5,H-6 dihedral angle is found to be around 90°, i.e., requiring $^3J_{5,6} \simeq 0$ Hz.

Overall, then, the present findings are more fully compatible with structure **1***a* – the 6*R*,7*S* isomer – than with its diastereoisomeric structural alternatives. It is noteworthy that a tentative choice of **1***a* was made (13), on the basis of the minimal hindrance to epoxide formation expected, in the synthesis of (the D-enantiomer of) asperlin (3).

[4]Moreover, it may be noted that the molecular model afforded a value for the distance between H-4 and H-5 of the pyrone ring (having a more rigid geometry) that is ~9% smaller than the experimentally determined value (Table 3). With this "correction", isomer **1***a* also accommodates the H-5,H-7 interproton distance predicted by the nmr measurements.

Synthesis of D-norisomorphinans ((±)-[14α]-D-normorphinans)

JOHN P. YARDLEY[1] AND RICHARD W. REES
Wyeth Laboratories, Inc., P.O. Box 8299, Philadelphia, PA 19101, U.S.A.

Received March 28, 1984[2]

JOHN P. YARDLEY and RICHARD W. REES. Can. J. Chem. **63**, 1013 (1985).

A synthesis of the D-norisomorphinan ring system is described. Conversion of the initial synthetic target, *trans*-1,3,4,9,10,10a-hexahydro-6-methoxy-9-oxo-4a(2*H*)-phenanthrenecarboxamide (**10***c*) into the D-norisomorphinan (**6***b*) proved possible only after removal of the carboxamide ambident functionality. The successful route proceeds via hypobromous acid addition to *trans*-1,3,4,10a-tetrahydro-6-methoxy-4a(2*H*)-phenanthrenemethanamine (**21**) followed by a facile intramolecular cyclization to the D-norisomorphinan (**23**).

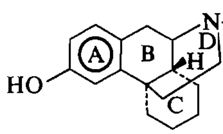
JOHN P. YARDLEY et RICHARD W. REES. Can. J. Chem. **63**, 1013 (1985).

On décrit une synthèse du système cyclique du D-norisomorphinane. On a d'abord obtenu l'hexahydro-1,3,4,9,10,10a méthoxy-6 oxo-9 2*H*-phénanthrène carboxamide-4a *trans* (**10***c*) comme première cible de la synthèse; ce n'est qu'après avoir éliminé la fonction carboxamide ambidente que l'on a pu transformer **10***c* et obtenir le D-norisomorphane (**6***b*). La voie permettant d'effectuer cette réalisation implique une addition d'acide hypobromeux sur la tétrahydro-1,3,4,10a méthoxy-6 2*H*-phénanthrène méthanamine-4a *trans* (**21**) suivie d'une cyclisation intramoléculaire facile en D-norisomorphinane (**23**).

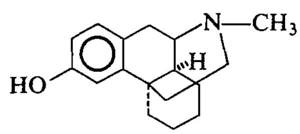
[Traduit par le journal]

Introduction

(−)3-Hydroxy-*N*-methyl-morphinan (**1**) has clinical utility as an analgesic, while potent analgesic activity has been uncovered in the corresponding B/C-*trans* fused or isomorphinan structure (**2**) (ref. 1). As part of a program to extend the



1

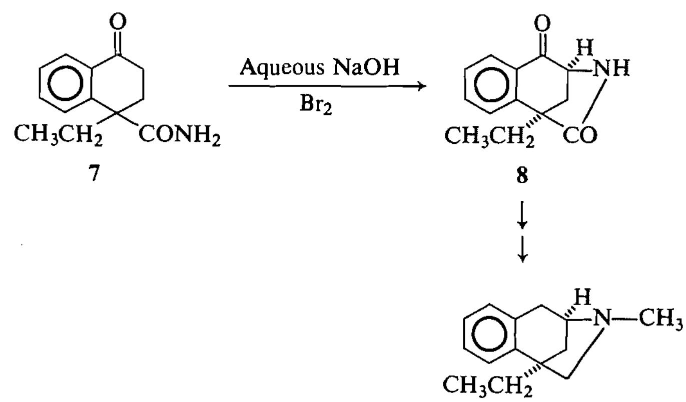


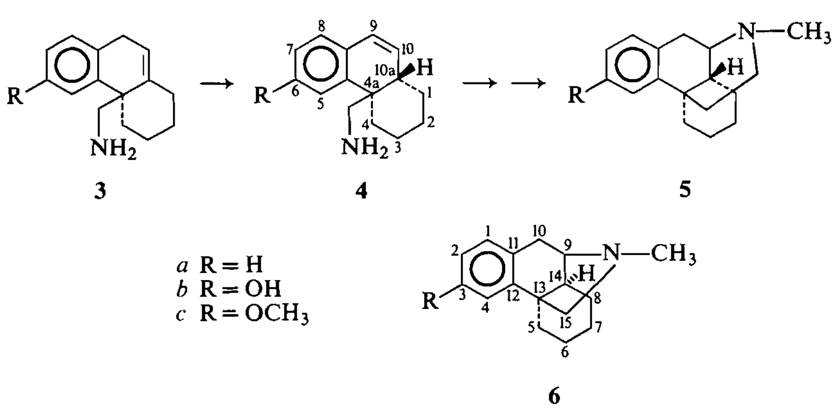
2

structure–activity relationships to the ring D-nor compounds, synthesis of the D-norisomorphinan ring system was required. Belleau, Conway, and co-workers have already described (2) a synthesis of the ring B/C *cis*-fused, D-normorphinan (**5***a*), which proceeds via 4a-aminomethyl-4a,10a-*cis*-1,2,3,4,10,-10a-hexahydrophenanthrene (**4***a*). Compound **4***a* was obtained by a base catalysed rearrangement of **3***a*; B/C-*trans* fused products were not observed. The synthesis described below passes through a 4a,10a-*trans* counterpart of **4***c* and leads to 3-hydroxy-*N*-methyl-D-norisomorphinan (**6***b*).

Results and discussion

At the outset it appeared that a viable synthesis of the D-normorphinan or D-norisomorphinan ring system could be modeled on Schenker's approach (3) to 2,3,4,5-tetrahydro-1,4-methano-1*H*-3-benzazepine (**9**), the key step of which was the cyclization of **7** to **8**. Thus a synthesis of **6** would require construction of the intermediate **10**. The synthesis of **10** is outlined in Scheme 2.





SCHEME 1

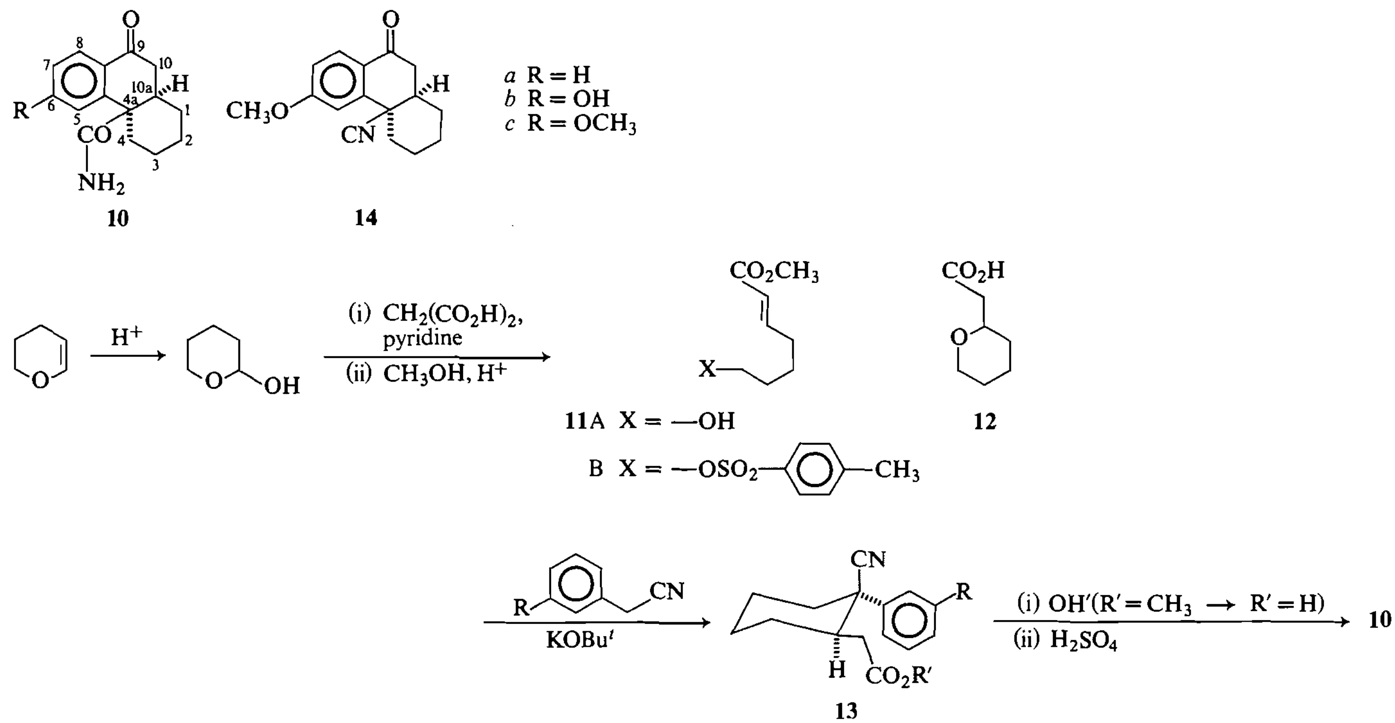
[2] Revision received October 19, 1984.



SCHEME 2

Methyl 7-hydroxy-*trans*-2-heptenoate (**11**A) is readily available by Raphael's procedure (4) starting from dihydropyran; in a minor modification, the intermediate 7-hydroxy-*trans*-2-heptenoic acid was not distilled but converted directly to the methyl ester using methanolic hydrogen chloride. In our hands, attempted distillation of the crude acid gave **12** as the predominant product. Cycloaddition was not a major problem in the distillation of **11**A, presumably due to the lower distillation pot temperatures involved. The oily tosylate (**11**B), together with *m*-methoxyphenylacetonitrile, added to a refluxing solution of potassium *tert*-butoxide in *tert*-butanol led, in a combined alkylation – Michael addition step, to **13***c* ($R^1 = CH_3$). **13***c* was not purified but hydrolysed to the acid **13***c* ($R^1 = H$) which in turn was cyclized directly to **10***c*. If the cyclization in sulfuric acid is conducted at 0°C rather than at room temperature, a small yield of the nitrile (**14**) may be isolated in addition to **10***c*, and this argues against participation of glutaric intermediates in the cyclization step. *para*-Activation is not required for cyclization, a virtually identical yield of **10***a* being obtained by a similar sequence from phenylacetonitrile.

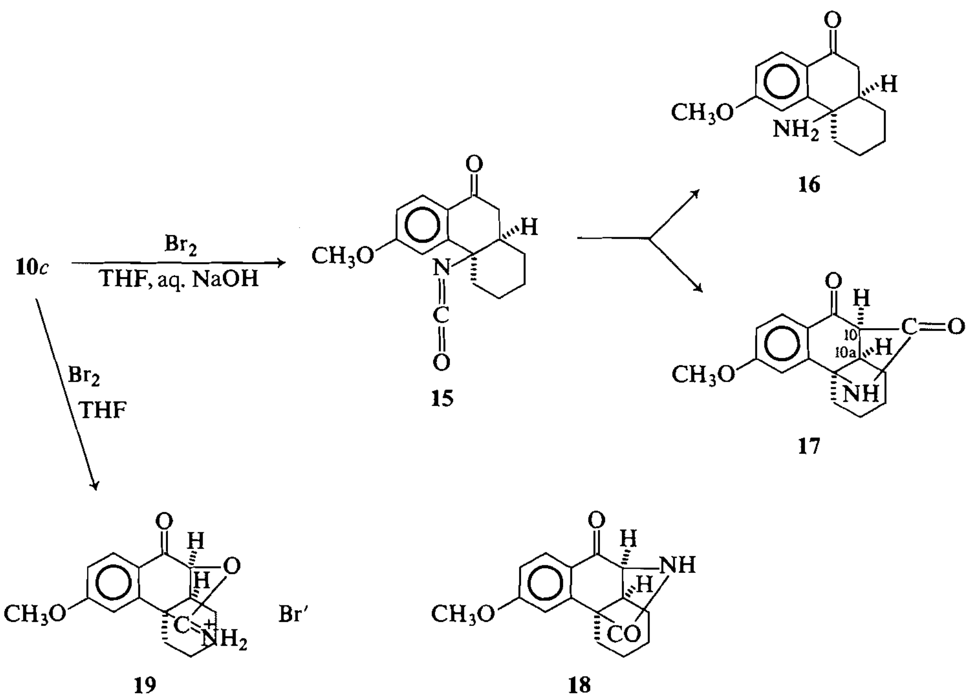
Compound **10***c* showed the appropriate mass ions at 273 (M^+) and 229 ($M^+ - CONH_2$), a 1,2,4-trisubstituted benzene ^{1}Hmr pattern, and primary amide and aryl ketone ir absorptions at 1690, 1660, 1595, and 1555 cm^{-1}. No trace of a second diasteriomer with B/C rings *cis* fused was detected and this deserves comment. Regardless of whether the Michael-addition step, a perpendicular attack on the conjugated system by a *m*-methoxyphenylacetonitrile anion, or nucleophilic displacement of the tosylate occurs first, the final step involves formation of a cyclohexane ring. The preferred transition state will presumably have the bulky *m*-methoxyphenyl and carboxymethyl groups in a low energy *trans* diequatorial relationship leading to **13***c* ($R^1 = CH_3$). Proof of the *trans* stereochemistry follows from the ^{1}Hmr of rigid transformation products, *vide infra*, all of which lack visible coupling between the H(9) and H(14) protons for which the Karplus equation predicts (5) a dihedral angle of 100°, in agreement with measurements from Dreiding models. The value for the corresponding B/C *cis*-fused, D-normorphinans J_{H9H14} is 5 Hz, in agreement with the observed dihedral angle $\phi_{H9H14} = 37°$ (2).

Bromination experiments

Schenker reports (3) the synthesis of **8** by a heterogeneous reaction of **7** in aqueous sodium hydroxide with bromine. Using the substrate **10***c* no reaction was observed, presumably a consequence of the extreme insolubility of **10***c*. Repetition of the reaction with the addition of tetrahydrofuran, initially added as a cosolvent, rather surprisingly afforded a two-phase system;[3] thin-layer chromatography indicated rapid loss of starting material. The product isolated in essentially quantitative yield was the Hofmann rearrangement product, the isocyanate (**15**), rather than the expected bromoketone (Scheme 3). If the isocyanate is not isolated, but the two-phase reaction mixture stirred overnight at room temperature, the products are the bridged structure (**17**) and a minor component – the amine (**16**). Compound **17** presumably arises via intramolecular attack of the enol form of **15** on the isocyanate moiety, formation of an α-enolate anion from this ketone with sodium hydroxide being unlikely. It is worth noting that **17** had the mass, mass spectral fragmentation pattern, and an ir expected for **18**. The ^{1}Hmr of **17** has a sharp one-proton singlet at 3.00 ppm, assigned to the H(10) proton. Lack of coupling with the H(10a) proton was the first evidence that rings B and C were *trans* fused.

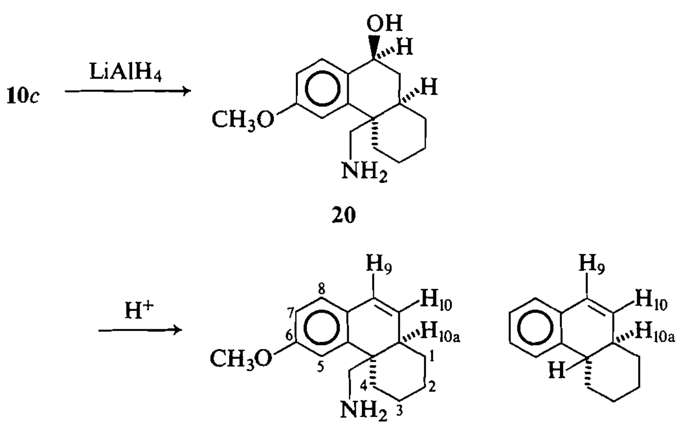
Bromination of **10***c* in anhydrous tetrahydrofuran with no added base afforded **19**. The appropriate mass ion at 271 (M^+) was observed and the ir showed typical ammonium bands. Again a peak at 5.39 ppm, assigned to the H(10) proton in the ^{1}Hmr was a sharp singlet. The isolation of **17** and **19** rather than

[3] The lowered solubility of tetrahydrofuran in strong alkali proved useful in the synthesis of both **15** and **23**.



SCHEME 3

18, while disappointing, suggested that the D-norisomorphinan would be obtainable once the ambident functionality of the amide was removed, e.g., by intramolecular cyclization of the aminomethyl compound **21**.



Conversion of **10***c* into **21** was achieved in two steps – a prolonged reduction with $LiAlH_4$ to the hydroxyamine (**20**), followed by formation of **21** by an acid-catalysed elimination of the benzylic hydroxyl. Compound **20** was isolated as a sharp-melting crystalline solid. Its isolation as a single isomer upon reduction reflects the lack of steric hindrance to α-face approach by the reducing agent. The quasi-equatorial stereochemical assignment for the ring hydroxyl was inferred from the broad width of the benzylic ^{1}Hmr proton signal at 4.8 ppm, reflecting the large diaxial interaction with the 10β proton. In practice, it proved convenient to convert the total crude reaction mixture directly to **21** using *p*-toluenesulfonic acid in benzene. Overall yields of 60% from **10***c* were obtained.

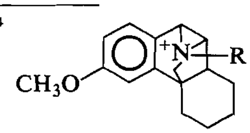
The ^{1}Hmr spectrum of **21** deserves comment; the C(10) olefinic proton is observed as the B portion of an ABX system. The Karplus equation (5) predicts a value $J_{H10H10a} \cong 0.1$ Hz for the 4a,10a-*trans* system where the dihedral angle, $\phi_{H10H10a} = 100°$ is found and, indeed, $J_{H10H10a} = 0–1$ Hz is observed in the model system (**22**) reported by Nelson *et al.* (6). In **21** the C(10) proton is observed as a doublet of doublets split by both H(9), $J_{H9H10} = 9$ Hz, and by H(10a), $J_{H10H10a} = 2.2$ Hz, suggesting a small increase in the $\phi_{H10H10a}$ dihedral angle.

A possible explanation may be made using Bucort's principles of conformational transmission, considering rings B and C as a *trans*-fused octalin system (see, for example, references to Bucorts' papers in ref. 7). The *syn* 1,3-diaxial interactions between the large aminomethyl group and the axial hydrogens at C(1) and C(3) are intensified by the ring B unsaturation. In opposition a decrease in steric pressure is obtained by a decrease in the dihedral angle formed by C(4)—C(4a)—C(10a)—C(1) and is not reflected in Dreiding models. The net result of the compromise is an increase in the $\phi_{H10H10a}$ angle.

Formation of the D*-norisomorphinan*

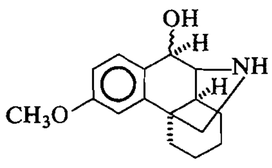
Two concurrent efforts to form the D-norisomorphinan ring system were made. One approach, an attempted synthesis of the azetidium structure[4] (**i**) by assisted solvolysis of an *N*-chloroamine derivative was unsuccessful. Lithium aluminum hydride reduction of **i** might be expected to afford a D-norisomorphinan. The other, a successful method, involved an attempt to prepare a 10α-bromo, 9ϵ-hydroxybromohydrin from **20** by treatment with *N*-bromoacetamide in aqueous tetrahydrofuran. α-Face attack by the bromonium ion is to be expected on both steric and electronic grounds, since the β-face is swept by the positively charged aminomethyl group. α-Face attack would presumably occur via perpendicular attack on the 9,10-olefin in a pre-boat form and lead to a 10α-bromo-

[4]

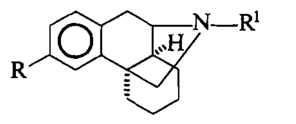


i

derivative, since solvent attack is to be expected at the benzylic position. After addition of excess sodium hydroxide the reaction mixture because two-phase and the product isolated after a 45-minute wait proved to be the D-norisomorphinan **23**. Bromohydrin formation is obviously followed by a facile intramolecular alkylation of the amine upon neutralization of the perchloric acid. Conversion of **23** to **24** by vigorous hydrogenolysis confirmed the benzylic location of the hydroxyl function. The benzylic proton of **23** appears in the nmr as a doublet, $J_{9/10}$ = 4.5 Hz, a value that is ambiguous with regard to configurational assignment.



23



24 R = OCH_3, R' = H
25 R = OCH_3, R' = $CO_2CH_2CH_3$
6*b* R = OH, R' = CH_3
6*c* R = OCH_3, R' = CH_3

Completion of the synthesis proved straightforward; **24** was converted to the *N*-methyl compound (**6*c***) via the intermediate urethane **25**. Demethylation of the aromatic methoxyl in **6*c*** proceeded smoothly, by brief treatment with hydrogen bromide at 140°C, affording 3-hydroxy-*N*-methyl-D-norisomorphinan **6*b***. Overall the synthetic route is represented by the sequence **10*c*** → **20** → **21** → **23** → **24** → **25** → **6*c*** → **6*b***.

Experimental

Melting points (uncorrected) were obtained on a Thomas–Hoover apparatus. The nmr and mass spectra were determined on Jeolco Model C-60HL and Associated Electrical Industries MS-9 spectrometers.

Methyl 7-hydroxy-trans-*2-heptenoate,* p-*toluenesulfonate (11B)*

Methyl 7-hydroxy-*trans*-2-heptenoate (85 g; 5.4 × 10^{-1} mol) in pyridine (450 mL) at 0°C was treated over 2 min with *p*-toluenesulfonyl chloride (123 g; 6.5 × 10^{-1} mol) and the mixture allowed to reach room temperature over 6 h. Ice was added and the mixture stirred for a further 45 min. After dilution with water the mixture was extracted with ether (2×) and the extracts washed successively with water, dilute sulfuric acid, water, $NaHCO_3$ solution, and brine and dried over Na_2SO_4. After evaporation of the solvent the oily tosylate was used directly; ir: 1730, 1660, 1600, 1360, 1180 cm^{-1}.

trans-*1,3,4,9,10,10a-Hexahydro-6-methoxy-9-oxo-4a(2*H*)-phenanthrenecarboxamide (10*c*)*

A mixture of *m*-methoxyphenylacetonitrile (20 g; 1.35 × 10^{-1} mol) and **11B** (39.6 g; 1.27 × 10^{-1} mol) in *tert*-butanol (550 mL) was added dropwise, during 3 h, to a refluxing solution of potassium *tert*-butoxide (16.4 g; 1.46 × 10^{-1} mol) in *tert*-butanol (300 mL). The reaction mixture was refluxed for a further 3 h under nitrogen and then stirred at room temperature overnight. Acetic acid (20 mL) was added and the reaction mixture stripped to a small volume, diluted with water, and extracted with diethyl ether (2×). The ether extracts were washed with water, brine, and evaporated; the residue in methanol (350 mL) was heated under reflux with 20% NaOH solution (100 mL; 5 × 10^{-1} mol) during 2.5 h. The reaction mixture was stripped to a small volume, diluted with water, and extracted with ether (rejected). The aqueous solution was acidified strongly with hydrochloric acid and extracted (2×) with ether. The ether extracts were washed with brine, dried (Na_2SO_4), and evaporated to a partially crystalline residue (35 g). The total residue was stirred with cold concentrated H_2SO_4 (1 L) overnight and poured onto ice. A highly crystalline product (14 g) precipitated and was recrystallized from acetone to yield **10*c*** (10 g, 29%), mp 225–228°C; ir: 3350 (s), 3140 (s), 1690 (s), 1660 (s), 1595 (s), 1555 infl. cm^{-1}; ^{1}H nmr (DMSO) δ: 3.71 (3H, s, —OCH_3), 6.75 (C(7)-H centre of a pair of d, $J_{5/7}$ 2.5 cps, $J_{7/8}$ 8.5 Hz), 6.99 (C(5)-H d, $J_{5/7}$ 2.5 Hz, $J_{5/8}$ 0 Hz), 7.62 (C(8)-H d, $J_{7/8}$ 8.5 Hz), 6.66 (2H, br m, $CONH_2$) ppm; ms *m/e*: 273 (M^+), 229 (M^+ – $CONH_2$), 187, 167. *Anal.* calcd. for $C_{16}H_{19}NO_3$: C 70.31, H 7.01, N 5.13; found: C 70.03, 70.54; H 7.04, 7.17; N 5.53, 5.15%.

If the concentrated sulfuric acid cyclization step in the above example is allowed to proceed at 0°C rather than at room temperature, small amounts of a more soluble (methanol), less polar, intermediate carbonitrile may be isolated: *trans*-1,3,4,9,10,10a-hexahydro-6-methoxy-9-oxo-4a(2*H*)-phenanthrenecarbonitrile (**14**), mp 174–177°C; ir: 2220 (very weak), 1685 (s), 1605 (s) cm^{-1}. *Anal.* calcd. for $C_{16}H_{17}NO_2$: C 75.21, H 6.71, N 5.49; found: C 75.06, H 6.71, N 5.49%.

Bromination experiments

trans-*2,3,4,4a,10,10a-Hexahydro-4a-isocyanato-6-methoxy-9(1*H*)-phenanthrenone (15)*

Bromine (144 μL, 0.45 g; 2.8 × 10^{-3} mol) was added to a stirred, two-phase solution prepared from **10*c*** (600 mg; 2.2 × 10^{-3} mol), sodium hydroxide (1 g), water (10 mL), and tetrahydrofuran (10 mL). Thin-layer chromatography indicated complete loss of starting material within 5 min. The reaction mixture was diluted with water and methylene chloride. The methylene chloride extract was washed with water (2×), brine, dried (Na_2SO_4), and concentrated to a residue. Crystallization from methylene chloride – hexane afforded **15** (500 mg, 84%), mp 112–113.5°C; ir: 2250 (s) cm^{-1}. *Anal.* calcd. for $C_{16}H_{17}NO_3$: C 70.83, H 6.32, N 5.16; found: C 70.60, H 6.45, N 5.04%.

trans-*4a-Amino-2,3,4,4a,10,10a-hexahydro-6-methoxy-9(1*H*)-phenanthrenone (16) and (4aα,10α,10aβ)-1,2,3,4,10,10a-hexahydro-6-methoxy-9*H*-4a,10(iminomethano)phenanthrene-9,11-dione (17)*

Bromine (720 μL, 2.23 g; 1.4 × 10^{-2} mol) was added over 10 min to a stirred two-phase solution prepared from **10*c*** (3 g; 1.1 × 10^{-2} mol), sodium hydroxide (3 g), water (40 mL), and tetrahydrofuran (45 mL). The reaction mixture was stirred at room temperature overnight, diluted with water, and extracted with methylene chloride. The methylene chloride extract was washed with water (2×), brine, dried (Na_2SO_4), and concentrated to a residue. Trituration of the residue with ether afforded a crystalline residue of **17** (1.24 g, 42%) that, after two recrystallizations from methylene chloride – methanol, had mp 239–243°C (dec.).

The ether triturate was evaporated and the residue recrystallized from ether–hexane (charcoal) and then methylene chloride – hexane to afford **16** (360 mg, 13%, mp 101–103°C. Compound **16**: ms *m/e*: 245 (M^+), 228, 202, 188. *Anal.* calcd. for $C_{15}H_{19}NO_2$: N 5.71; found: N 5.48, 5.49%. Compound **17**: ms *m/e*: 271 (M^+), 243, 228, 214. *Anal.* calcd. for $C_{16}H_{17}NO_3$: C 70.83, H 6.32, N 5.16; found: C 70.50, H 6.32, N 5.33%.

*(4aα,10α,10aβ)-1,2,3,4,10,10a-Hexahydro-12-imino-6-methoxy-9*H*-10,4a-(epoxymethano)phenanthren-9-one (19)*

Bromine (0.85 μL, 2.64 g; 1.7 × 10^{-2} mol) in tetrahydrofuran (40 mL) was added dropwise to a suspension of **10*c*** (4 g; 1.46 × 10^{-2} mol) in tetrahydrofuran (40 mL). Complete solution was followed by a voluminous precipitate of **19** (4.3 g, 83%). The analytical sample, mp 216–218°C (dec.), was obtained by rapid recrystallization from methanol–ether; ms *m/e*: 271 (M^+). *Anal.* calcd. for $C_{16}H_{17}NO_3 \cdot HBr$: C 54.56, H 5.15, N 3.98, Br 22.69; found: C 54.67, H 5.39, N 3.96, Br 22.06%.

(4aα,10aβ)-4a-Aminomethyl-1,2,3,4,4a,9,10,10a-octahydro-6-methoxy-9-phenanthrenol (20)

Compound **10*c*** (30 g) and lithium aluminum hydride (20 g) in tetrahydrofuran (3 L) were refluxed under nitrogen during 2 days. The cooled reaction mixture was treated dropwise with 100 mL, 3% NaOH solution, filtered, and evaporated to a crystalline residue of **20** (28 g) suitable for further transformation. An analytical sample, mp 149–151°C, was obtained by recrystallization from ethyl ether – hexane; ^{1}H nmr ($CDCl_3$–D_2O) δ: AB q of aminomethyl protons with *J* 13.5 Hz at 2.81 and 2.99, 3.84 (3H, s, OCH_3), 4.83 (1H center approximate t, C(9)-H) ppm; ms *m/e*: 243 ($M^+ - H_2O$). *Anal.* calcd. for $C_{16}H_{23}NO_2$: C 73.53, H 8.87, N 5.36; found: C 73.24, H 8.82, N 5.33%.

trans-*1,3,4,10a-Tetrahydro-6-methoxy-4a(2*H*)-phenanthrenemethanamine (21)*

Compound **20** (25 g; 8.5 × 10^{-2} mol) and *p*-toluenesulfonic acid monohydrate (18 g; 9.5 × 10^{-2} mol) in benzene (1 L) were heated under reflux using a Dean–Stark head; after 1 h the reaction mixture was stripped to a small volume, diluted with ether, and extracted with water. The aqueous phase together with a crystalline precipitate were washed with ether (rejected), basified strongly with NaOH solution, and extracted with ether (2×). The ether extracts were washed with brine, dried (Na_2SO_4), evaporated to a small volume, and filtered through a Woelm alumina column (Grade I, basic 120 g); the product (16 g) eluted with ether and was obtained as a colorless oil; ir: 1610, 1570 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 2.87 (2H, multiplet, $W_{1/2}$ H 5 Hz), 3.79 (3H, s, —OCH_3), AB q $J_{9/10}$ 9 Hz, protons centered at 5.48 (C(10)-H) and 6.36 (C(9)-H) further split by C(10a)-H, $J_{10a/10}$ 2.2 Hz, $J_{9/10a}$ 3 Hz ppm.

*(±)-(14α)-3-Methoxy-*D*-normorphinan-10-ol (23)*

Compound **21** (4.86 g; 2 × 10^{-2} mol) in tetrahydrofuran (150 mL) containing 0.5 *N* $HClO_4$ (80 mL; 4 × 10^{-2} mol) was cooled to 0°C and treated, under nitrogen, with *N*-bromoacetamide (3 g; 2.2 × 10^{-2} mol) added over 1–2 min. Thin-layer chromatography indicated that there was a rapid loss of starting material; after 20 min, excess NaOH solution (20 mL; 50%) and ice were added. The two-phase solution was stirred for 45 min. After dilution with benzene the organic layer was washed with water (2×), brine, dried (Na_2SO_4), and evaporated to a residue which readily crystallized on trituration with boiling ether to give the product (4 g; free base form), mp 140–143.5°C. Recrystallization from methanol–ether gave a higher mp form, mp 174–177°C; ^{1}H nmr ($CDCl_3$) δ: 2H, AB q, *J* 10 Hz, aminomethyl protons centered at 2.53 and 3.57; 2H, AB q, $J_{9/10}$ 4.5 Hz, $J_{9/14}$ 0 Hz centered at 3.24 (C(9)-H) and 4.66 (C(10)-H); 3.79 (3 Hs, —OCH_3) ppm. *Anal.* calcd. for $C_{16}H_{21}NO_2$: C 74.10, H 8.16, N 5.4; found: C 73.69, H 8.16, N 5.34%.

Salt (**23**·HCl), mp 244–245°C, crystallized from methanol–ether. *Anal.* calcd. for $C_{16}H_{22}NO_2Cl$: C 64.96, H 7.50, N 4.74, Cl 11.95; found: C 64.60, H 7.47, N 4.69, Cl 11.72%. In a repeat experiment, **21** (14.4 g) was converted into **23**·HCl (8.1 g, 46%), mp 243–245°C, without isolation or purification of the free base.

*(±)-(14α)-3-Methoxy-*D*-normorphinan (24)*

Compound **23** (5.0 g), acetic acid (80 mL), 70% perchloric acid (2 mL), and 5% Pd on $BaSO_4$ (2.0 g) were stirred at 80°C in an atmosphere of hydrogen overnight (1 mol uptake). After cooling, 30 mL of 10% K_2CO_3 solution were added and following filtration the reaction mixture was evaporated, basified with NaOH solution, taken into CH_2Cl_2, and washed with brine. After evaporation of the solvent, the residue in ether was dried (Na_2SO_4) and treated with isopropanolic hydrogen chloride to give a crystalline precipitate which after trituration with boiling acetone afforded **24**·HCl (4.14 g, 86%), mp 228–231°C (some previous decomposition). The analytical sample, mp 238°C (dec.), was obtained by recrystallization from acetone; ms *m/e*: 243 (M^+). *Anal.* calcd. for $C_{16}H_{22}NOCl \cdot \frac{1}{4} H_2O$: C 67.59, H 7.98, N 4.93, Cl 12.47; found: C 67.45, 67.35; H 7.75, 7.84; N 4.82, 4.67; Cl 12.97%.

*(±)-(14α)-3-Methoxy-17-methyl-*D*-normorphinan (6c)*

Compound **24** (4 g; 1.43 × 10^{-2} mol) in a stirred mixture of methylene chloride (300 mL) and saturated $NaHCO_3$ solution (300 mL) was treated with ethyl chloroformate (1.8 mL; 1.88 × 10^{-2} mol) at room temperature during 30 min. After standing overnight, the organic layer was separated and evaporated. The residue in ether was washed with dilute HCl, brine, dried (Na_2SO_4), and evaporated to give the urethane (**25**, 4.2 g). The urethane in ether–tetrahydrofuran (1 : 1, 400 mL) was heated under reflux with $LiAlH_4$ (2.5 g) during 4 h. After standing overnight the reaction mixture was treated with 12.5 mL 3% NaOH solution, filtered, and evaporated. The residue in ether was filtered through a Woelm alumina column (40 g, Grade I, basic) and eluted with ether. The total eluate was treated with isopropanolic hydrogen chloride and the precipitate, after crystallization from acetone, afforded **6***c*·HCl (2.9 g, 70%), mp 238–240°C; ^{1}H nmr ($CDCl_3$–D_2O) δ: 2.9 (3H, s, N-CH_3), 3.88 (3H, s, —OCH_3), 3.38 (ca. 2H, d, *J* = 3 Hz – actually center peaks of AB quartet (CH_2—N—CH_3)) ppm; ms *m/e*: 257 (M^+). *Anal.* calcd. for $C_{17}H_{24}NOCl$: C 69.49, H 8.23, N 4.77, Cl 12.07; found: C 69.30, H 8.29, N 4.64, Cl 12.35%.

*(±)-(14α)-17-Methyl-*D*-normorphinan-3-ol (6b)*

Compound **6***c*·HCl (1.8 g) and 47–49% aqueous hydrogen bromide (30 mL) were heated under reflux during 45 min. The cooled reaction was treated with ice and an excess of concentrated ammonium hydroxide to give a crystalline precipitate of the product (free base form). After aging (1 h) the precipitate (1.6 g) was filtered off. A small portion recrystallized from acetone had mp 223–225°C (dec.). *Anal.* calcd. for $C_{16}H_{21}NO$: C 78.97, H 8.70, N 5.76; found: C 78.93, H 8.91, N 5.73%.

The remainder in acetone was treated with a slight excess of isopropanolic hydrogen chloride and concentrated. The crystalline precipitate was recrystallized from methanol–ether; the product, **6***b*·HCl (1.15 g, 66%), had mp 255–258°C (with effervescence); ms *m/e*: 243 (M^+). *Anal.* calcd. for $C_{16}H_{22}NOCl$: C 68.68, H 7.93, N 5.01, Cl 12.67; found: C 68.17, H 7.86, N 4.85, Cl 11.97%.

Oxidation of hydrocarbons. 13. The oxidation of cinnamate ion by alkaline permanganate

DONALD G. LEE[1] AND KASINATHAN NAGARAJAN
Department of Chemistry, University of Regina, Regina, Sask., Canada S4S 0A2

Received April 17, 1984

DONALD G. LEE and KASINATHAN NAGARAJAN. Can. J. Chem. **63**, 1018 (1985).

The rates of oxidation of cinnamate ion by permanganate have been compared under conditions where distinctly different products (MnO_4^{2-} and MnO_2) are obtained. Since the rates of both reactions respond in similar ways to substituent effects, deuterium substitution on the double bond, and to temperature changes, it may be concluded that the different products are due to post transition state reactions. Reaction sequences that are consistent with this conclusion and with the observed stoichiometries have been suggested.

DONALD G. LEE et KASINATHAN NAGARAJAN. Can. J. Chem. **63**, 1018 (1985).

On a comparé les vitesses d'oxydation de l'ion cinnamate par le permanganate dans des conditions où l'on obtient d'une façon distincte deux produits différents (MnO_4^{2-} et MnO_2). Les vitesses des deux réactions répondent de la même manière aux effets de substituants, à l'introduction de deutérium sur la double liaison et à des changements de température; on en conclut que les différents produits proviennent de réactions se produisant après l'état de transition. On suggère des séries de réactions qui sont en accord avec cette conclusion et avec les stoïchiométries observées.

[Traduit par le journal]

Introduction

It has been assumed for almost one century that all permanganate–alkene reactions proceed by way of the same intermediate, a cyclic manganate(V) diester (1). This is a large assumption for a reaction in which the nature of the products is very sensitive to experimental conditions. Depending on the conditions employed, the organic products can be diols, ketols, or cleavage products, while the inorganic products are MnO_4^{2-}, MnO_2, or Mn^{3+} (2–4). Consequently, it is apparent that the assumption of a common intermediate should be carefully tested. In attempting to apply such a test, we have chosen to study the reaction under two sets of conditions that give distinctly different products, and to compare the effect of substituents, the effect of isotopic substitution and the effect of temperature changes on the rates of reaction.

Experimental

Materials

The oxidant was Fisher analyzed reagent grade potassium permanganate. The substituted *trans*-cinnamic acids were obtained from the Aldrich Chemical Co. and repeatedly recrystallized until they gave sharp melting points which agreed with those reported in the literature. The deuterated cinnamic acids were prepared using methods previously described (5). Water, collected from an all-glass still, was redistilled from alkaline permanganate (6).

Silicate solutions were prepared by dilution of commercial sodium silicate solutions (Harrisons and Crosfield) in the following way. A concentrated silicate solution (2 mL) was added to 1 L of distilled water and heated gently for 1 h with stirring. After cooling, the solution was centrifuged in portions, filtered, diluted to 2 L, and stored in polyethylene bottles. The density of this solution was 1.044 g/mL; its pH was 11.3. At this pH the product of the reaction is manganese(IV) oxide, which first flocculates and then precipitates (as MnO_2) if the reaction is carried out in an aqueous solution. However, the presence of silicate stabilizes manganese dioxide (7), prevents flocculation, and vastly improves the linearity of the kinetic rate plots.

When the reaction of permanganate with cinnamic acid is carried out in 0.50 *M* NaOH the product can be identified as MnO_4^{2-} from its spectrum (2). Under these conditions it is stable for a long period relative to the half-life of the reaction, thus making it possible to obtain reliable kinetic plots and to assign the observed spectral changes with high confidence.

TABLE 1. Rate constants for the oxidation of cinnamate ion by permanganate in 0.5 *M* NaOH[a]

[Cinnamate ion] ($M \times 10^3$)	k_1 (s^{-1})[b]	k_2 (M^{-1} s^{-1})[c]
8.11	7.01 ± 0.07	864 ± 9
14.9	12.1 ± 0.6	812 ± 40
20.3	16.4 ± 0.5	808 ± 24

[a]Temperature = 25.0 ± 0.1°C, $[MnO_4^-] = 3.8 \times 10^{-4}$ *M*.
[b]Pseudo-first-order rate constants (see Fig. 1).
[c]$k_2 = k_1$/[cinnamate ion].

Kinetic methods

The reactions were followed by monitoring spectral changes using a rapid-scan stopped-flow spectrophotometer (System 777-RS, supplied by Update Instruments Inc.). Reaction rates were determined under pseudo-first-order conditions by measuring the decrease in absorbance at 526 nm.

Results

Oxidations in 0.50 M NaOH

When the rate of oxidation was studied in 0.50 *M* NaOH using a large excess of the reductant, cinnamate ion, linear plots of $-\ln (A - A_f)$ vs. time were obtained (Fig. 1). This indicates that the rate of reaction is first order with respect to permanganate ion (8). The pseudo-first-order rate constants so obtained were found to be directly proportional to the cinnamate ion concentration, thus indicating that the reaction is also first order in reductant (Table 1).

Inverse secondary isotope effects were observed when the rates for *trans*-cinnamate ion-α-*d* and *trans*-cinnamate ion-β-*d* were compared with unlabelled *trans*-cinnamate ion (Table 2).

The rates of oxidation in 0.5 *M* NaOH were found to be quite insensitive to the presence of ring substituents (Table 3). A ρ value of 0.13 is obtained from a Hammett plot for the reaction, with a significantly better fit being obtained when σ^- substituent constants are used (Fig. 2).

Activation parameters for the reaction (Table 4) were deter-

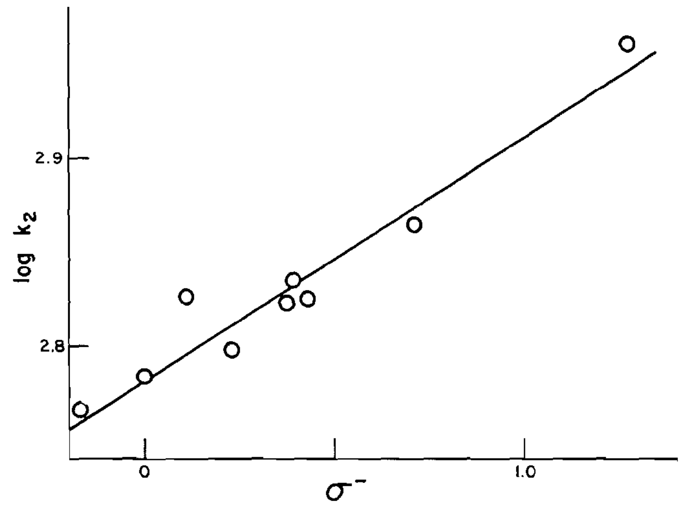

FIG. 2. Hammett plot for the oxidation of substituted cinnamate ions by permanganate in 0.5 M NaOH. Slope = 0.13, correlation coefficient = 0.97. When σ substituent values are used the slope increases to 0.16 and the correlation coefficient drops to 0.87.

mined from a plot of ln k_2/T vs. $1/T$. See Fig. 3.

With less than a ten-fold excess of cinnamate ion, good isosbestic points were observed at 469 and 577 nm when the solutions were successively scanned as the reaction progressed (Fig. 4), and one mole of manganate(VI) was formed for each mole of permanganate consumed. When larger excesses of cinnamate ion were used the isosbestic points were less sharply defined, and less than the calculated amount of manganate(VI) was formed. This suggests that manganate(VI) slowly reacts with cinnamate ion when it is present in large concentrations. Under all conditions manganate(VI) was slowly reduced to manganese dioxide on standing at room temperature.

Stoichiometric studies indicated that one mole of olefin consumed two moles of permanganate.[2]

Oxidations at pH 11.3

When the reaction was carried out in silicate solutions at pH 11.3 a stable pale brown solution (or suspension) was produced. Iodometric titrations showed that the manganese present was in the +4 oxidation state. A similar stabilization of manganese dioxide in silicate or phosphate solutions has previously been observed in other laboratories (7, 9).

An isosbestic point at 460 nm was observed when spectra were taken at intervals as the reaction progressed (Fig. 5). Stoichiometric studies indicated that 0.9 mole of permanganate was consumed for each mole of reductant present.[2]

[b]pH = 11.3, temperature = 25.0 ± 0.1°C, $[MnO_4^-] = 3.8 \times 10^{-4}\ M$, [substrate]/$[MnO_4^-]$ = 20.
[c][Substrate]/$[MnO_4^-]$ = 10.

[2]The initial product formed when cinnamate is oxidized proved to be somewhat reactive toward permanganate, thus making stoichiometric studies difficult. However, when other unsaturated carboxylates (such as 4-cyclohexene-1,2-dicarboxylate) were used, stable products were obtained and the stoichiometry could be established accurately and without difficulty.

The rate of reaction was found to be first order in both permanganate (Fig. 6) and cinnamate ion (Table 5). Inverse secondary deuterium isotope effects, similar in magnitude to those found when the reaction was studied in 0.5 M NaOH, were observed when the rates of cinnamate ion-α-d and cinnamate ion-β-d were compared with unlabelled substrate (Table 2).

A Hammett plot almost identical to that observed in 0.5 M NaOH was obtained (Fig. 7). Activation parameters obtained from a plot of ln k/T vs. $1/T$ (Fig. 3) have been summarized in Table 4.

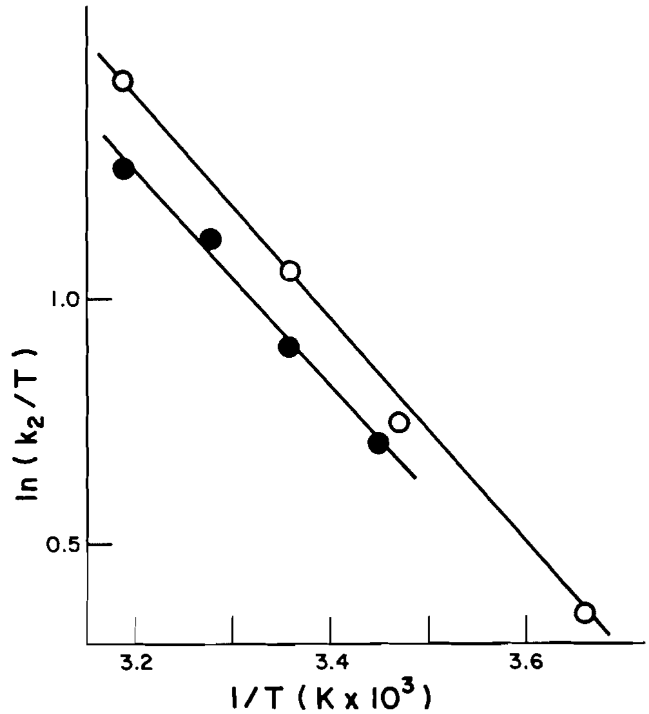

FIG. 3. Activation energy plots. ● 0.50 M NaOH. ○ silicate solutions (pH = 11.3).

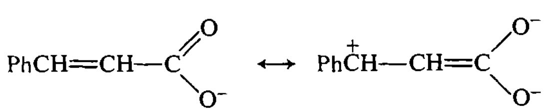
Discussion

The results obtained under both sets of conditions described above are consistent with a reaction that is initiated by formation of a cyclic manganate(V) diester in the rate-limiting step, as has previously been suggested by several authors (2, 3, 10):

[1] 
1

The small, positive ρ value may be associated with a stabilization of the ground state by electron-donating groups rather than an effect on the transition state. Stabilization by resonance of the type depicted in structures **2***a* and **2***b* would lead to reduced rates of reaction for those compounds bearing electron-donating substituents.



2*a* **2***b*

The inverse secondary deuterium isotope effects, which indicate a change in hybridization from sp^2 in the ground state to sp^3 in the transition state (11), are reminiscent of those obtained when the oxidation of cinnamic acid was studied in 1 M perchloric acid solutions (12). Consequently, it appears as if the transition state may be quite similar under acidic conditions as well. This suggestion is reinforced by noting that similar activation parameters are also obtained under basic, acidic, and nonaqueous conditions (Table 4). However, it is quite possible that a somewhat different transition state is obtained during the oxidation of methyl cinnamates by quaternary ammonium permanganate in nonaqueous solvents, where the observed rate constants are smaller, the substituent effects larger, and the isotope effects different (13).

If the rate-determining steps are the same under both sets of experimental conditions it follows that the different products obtained (MnO_4^{2-} and MnO_2) must be a consequence of post transition state reactions. In 0.5 M NaOH, where the product is MnO_4^{2-}, the stoichiometry indicates that two moles of permanganate are reduced. Consequently, it appears as if the cyclic manganate(V) diester formed in the rate-determining step must be oxidized by permanganate, giving two moles of manganate(VI). The exact point at which this oxidation takes place is, however, open to speculation and at least three possibilities can be considered. In one, the cyclic manganate(V) diester could be oxidized and then hydrolyzed as in eqs. [2] and [3] (2, 14).

[2] 

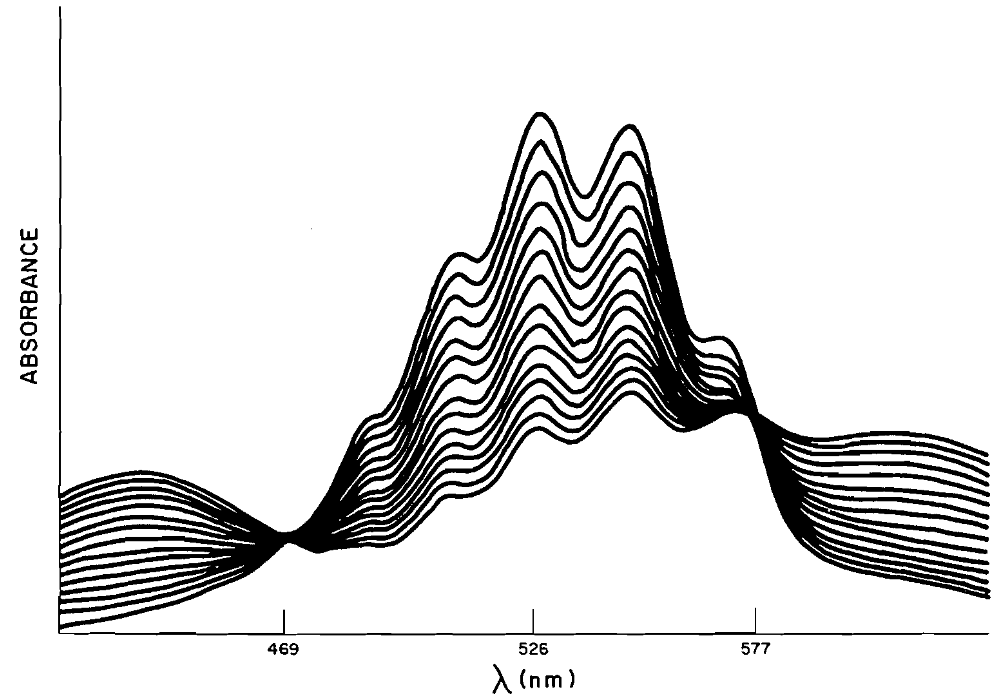


FIG. 4. Sequential scans obtained at 40-ms intervals during the oxidation of cinnamate ion (1.49×10^{-3} *M*) by permanganate (3.80×10^{-4} *M*) in 0.5 *M* NaOH at 25°C.

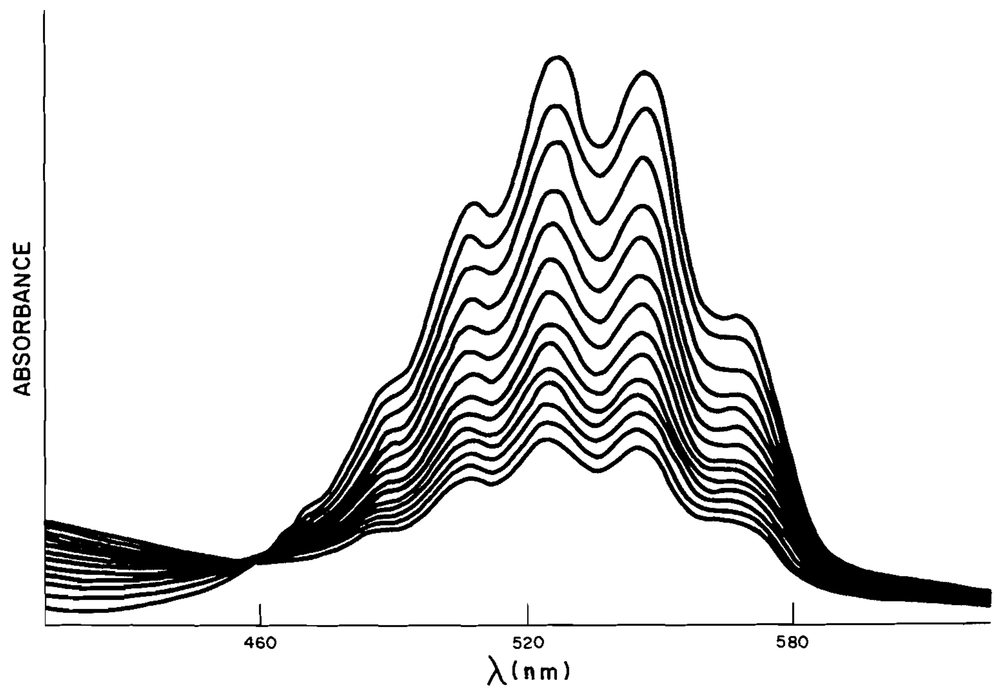

FIG. 5. Sequential scans obtained at 20-ms intervals during the oxidation of cinnamate ion (8.07×10^{-3} *M*) by permanganate (3.88×10^{-4} *M*) in a silicate solution (pH 11.3) at 17°C.

[3] 
An alternative possibility is suggested by reports that manganate(V) rapidly dimerizes in aqueous solutions (15, 16). Dimerization of **1** followed by oxidation and hydrolysis would also result in the formation of MnO_4^{2-} as the product:

[4] 

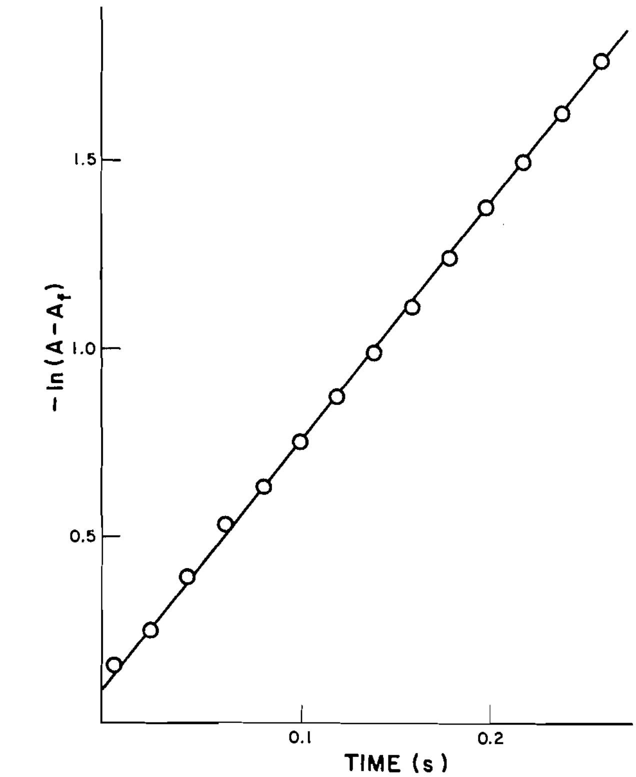

FIG. 6. Typical pseudo-first-order plot for the oxidation of cinnamate ion in silicate solutions. pH = 11.3. [Cinnamate ion] = 8.09 × 10^{-3} *M*. [$KMnO_4^-$] = 3.80 × 10^{-4} *M*. Temperature = 25°C. Slope = 6.10 s^{-1}. Correlation coefficient = 0.999.

[5] $2 + 2MnO_4^- + 2OH^-$

$\longrightarrow$  $+ 2MnO_4^{2-} + H_2O$

3

[6] $3 + 4OH^- \longrightarrow 2$  $+ 2MnO_4^{2-}$

However, the low concentration of intermediate present in these solutions would tend to suppress dimer formation (reaction [4]), as would the highly basic nature of the solutions.

A more likely possibility would be hydrolysis of the intermediate followed by oxidation of $HMnO_4^{2-}$ to MnO_4^{2-} as in eqs. [7] and [8].

[7] $1 + H_2O + OH^- \longrightarrow$  $+ HMnO_4^{2-}$

[8] $MnO_4^- + HMnO_4^{2-} + OH^- \longrightarrow 2MnO_4^{2-} + H_2O$

Whether the first or the third possibility would predominate depends on the relative magnitudes of the bimolecular rate constants for reactions [2] and [7], both of which would be expected to be large. However, the hydrolysis reaction would probably be faster because of the much larger concentration of hydroxide ions as compared to oxidant (0.5 *M* vs. 3 × 10^{-4} *M*). Consequently, although it is impossible to exactly specify the nature of fast reactions which follow the rate-limiting step, it seems most reasonable to propose a sequence consisting of reactions [1], [7], and [8].

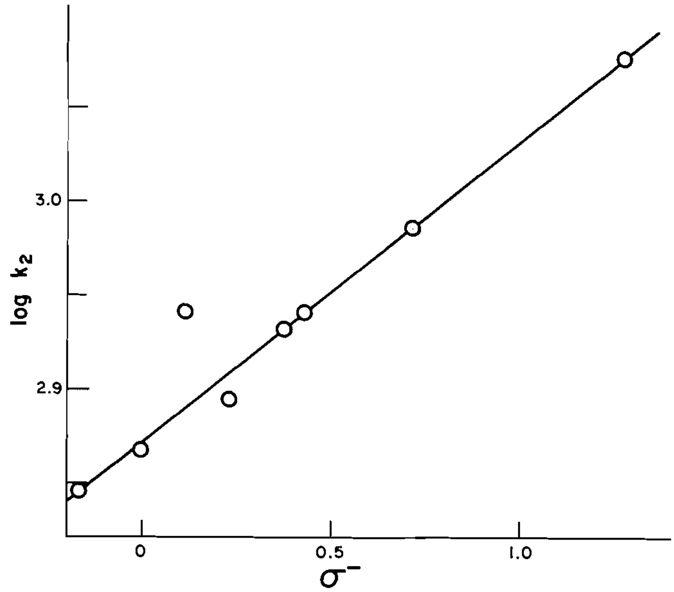

FIG. 7. Hammett plot for the oxidation of substituted cinnamate ions by permanganate in sodium silicate solutions (pH 11.3). Slope = 0.15, correlation coefficient = 0.96. When σ substituent values are used the slope increases to 0.20 and the correlation coefficient drops to 0.91.

TABLE 5. Rate constants for the oxidation of cinnamate ion by permanganate in silicate solutions at pH 11.3[a]

[Cinnamate ion] ($M \times 10^3$)	$k_1(s^{-1})$[b]	$k_2(M^{-1}\ s^{-1})$[c]
4.39	3.26 ± 0.02	742 ± 5
8.09	5.95 ± 0.15	736 ± 18
11.82	8.96 ± 0.26	758 ± 22

[a] Temperature = 25.0 ± 0.1°C, [MnO_4^-] = 3.8 × 10^{-4} *M*.
[b] Pseudo-first-order rate constants (see Fig. 6).
[c] $k_2 = k_1$/[cinnamate ion].

At pH 11.3, where the stoichiometry of the reaction is 0.9 : 1 and the product is manganese dioxide, a different sequence of reactions must follow the rate-determining step. The most likely possibility is that manganate(V), formed in reaction [7], is not stable under these less basic conditions and is immediately reduced to MnO_2 by reaction with the solvent as in eq. [9] (15, 17). This suggestion is consistent with the observation made by Carrington and Symons (17) that manganate(V) is stable only under very basic conditions; in more acidic solutions reduction to manganese dioxide is rapid and autocatalytic (15).

[9] $2HMnO_4^{2-} + H_2O \rightarrow 2MnO_2 + 1/2O_2 + 4OH^-$

This sequence of reactions requires a stoichiometry of $KMnO_4$/alkene = 1 : 1, which is slightly larger than the experimental value of 0.9 : 1. Consequently, there may be a competing reaction sequence that uses oxidant more efficiently. For example, the reaction at pH 11.3 could parallel that in 0.5 *M* NaOH, resulting in the formation of manganate(VI) which would also be unstable under these conditions (2, 17–19). Disproportionation of MnO_4^{2-} according to eq. [10] would lead to a stoichiometry of 0.66:1. A combination of these two sequences could then give the observed stoichiometry.

In order to test this possibility K_2MnO_4 was dissolved in 0.1 *M* NaOH and then diluted with either silicate solution or water to give two solutions of equal basicity. The solution containing silicate disproportionated rapidly according to eq. [10], while the solution not containing silicate reacted much

$$[10] \quad 3MnO_4^{2-} + 2H_2O \rightarrow 2MnO_4^- + MnO_2 + 4OH^-$$

more slowly. Consequently, the possibility exists that the reaction in silicate solutions at pH 11.3 could also consist of eqs. [1] and [7] followed by [8] and [10], or [9]. In any event, it must be assumed that the reactions following the rate-determining step are rapid because no long-lived intermediates were apparent under these conditions (Fig. 5).

In summary, it can be concluded that the formation of different products (MnO_4^{2-} and MnO_2) is not associated with any fundamental change in the mechanism of the reaction between permanganate and carbon–carbon double bonds. Instead, the change in products appears to be due to the greater reactivity of manganese(V) oxides in the less basic solution.

Viscosities and densities of binary liquid mixtures of *m*-cresol with substituted anilines. Part 3

RAMAMURTHY PALEPU,[1] JOAN OLIVER, AND BRIAN MACKINNON
Department of Chemistry, University College of Cape Breton, Sydney, N.S., Canada B1P 6L2

Received August 15, 1984

RAMAMURTHY PALEPU, JOAN OLIVER, and BRIAN MACKINNON. Can. J. Chem. **63**, 1024 (1985).

Densities and viscosities were determined for the binary systems of *m*-cresol with aniline, *N*-methylaniline, *N,N*-dimethylaniline, *N*-ethylaniline, and *N,N*-diethylaniline at five different temperatures. From the experimental results, the excess volume, excess viscosity, excess molar free energy of activation of flow, excess partial molar volume, and partial molar volumes were calculated. Also various thermodynamic parameters of activation of flow were calculated from the dependence of viscosity on temperature. The deviations from ideality of thermodynamic and transport functions are explained on the basis of molecular interactions between the components of the mixture.

RAMAMURTHY PALEPU, JOAN OLIVER et BRIAN MACKINNON. Can. J. Chem. **63**, 1024 (1985).

Opérant à cinq températures différentes, on a déterminé les densités et les viscosités des systèmes binaires formés d'une part de *m*-crésol et d'autre part d'aniline, de *N*-méthylaniline, de *N,N*-diméthylaniline, de *N*-éthylaniline et de *N,N*-diéthylaniline. A partir de ces résultats expérimentaux, on a calculé les volumes en excès, les viscosités en excès, les énergies libres molaires en excès pour l'activation de l'écoulement, les volumes molaires partiels en excès et les volumes molaires partiels. En se basant sur la variation de la viscosité avec la température, on aussi calculé divers paramètres thermodynamiques pour l'activation de l'écoulement. Il existe des déviations par rapport à l'idéalité des fonctions thermodynamiques et de transport que l'on explique en fonction d'interactions moléculaires entre les composantes des mélanges.

[Traduit par le journal]

Introduction

This paper deals with investigations of the thermodynamic and transport properties of binary liquid mixtures and is a continuation of our previous studies (1–4). The excess viscosity (η^E), excess volume (V^E), excess free energy of activation of flow (G^{*E}), and partial molar volumes ($\bar{V}_i$) have been computed from the experimental results on densities and viscosities for the systems *m*-cresol (MC) + aniline (A), *m*-cresol + *N*-methylaniline (MA), *m*-cresol + *N,N*-dimethylaniline (DMA), *m*-cresol + *N*-ethylaniline (EA), and *m*-cresol + *N,N*-diethylaniline (DEA) at five different temperatures.

Experimental

The methods used in the present investigation have been described previously (3, 4).

Materials and solutions

Chemicals used in the present study are either B.D.H. or Aldrich and purified by standard procedures (5). Only colourless middle fractions were collected and the mixtures were prepared by mixing weighed amounts of pure liquids. Caution was taken to prevent evaporation.

Results

The experimental results for pure liquids agree well with the values from literature (6, 7). Excess volumes for the systems MC + A and MC + DMA were reported by Solimo and Katz at 25°C (8), and the results of the present investigation are in excellent agreement with the published data. The experimental values for all systems at different temperatures[2] were used to calculate the excess thermodynamic functions with the following equations:

$$[1] \quad V = (X_1M_1 + X_2M_2)/\rho$$

$$[2] \quad V^E = V - (X_1V_1^* + X_2V_2^*)$$

$$[3] \quad \eta^E = \eta - (X_1\eta_1^* + X_2\eta_2^*)$$

$$[4] \quad G^{*E} = RT \ln \eta V - (X_1 \ln \eta_1^*V_1^* + X_2 \ln \eta_2^*V_2^*)$$

Here ρ, η, and V are the density, viscosity, and molar volume of the mixture, M_1, M_2, V_1^*, V_2^*, η_1^*, η_2^* are molecular masses, molar volumes, and viscosities of pure components 1 and 2, respectively, and X_i represents the mole fraction of the component i in the solution. The excess quantities Y^E were fitted to the Redlich–Kister (9) equation:

$$[5] \quad Y^E = X_1(1 - X_1)\sum_{j=1}^{n} a_j(1 - 2X_1)^{j-1}$$

Values of coefficients (a_j) of this equation, together with the standard error of estimate (σ) are summarized in Tables 1–3. Figures 1, 2, and 3 show the values of η^E, V^E, and G^{*E} as a function of the mole fraction of *m*-cresol.

The continuous curves were generated using a plotter (Watanabe Miplot), CBM 8032 microcomputer and the values of a_j from eq. [5]. Excess partial molar volumes (V_1^E) and the partial molar volume ($\bar{V}_1$) were computed using the equations:

$$[6] \quad (V_1^E) = (V^E)_{1,2} + (1 - X_1)\left[\frac{\partial(V^E)_{1,2}}{\partial X_1}\right]_{P,T}$$

$$[7] \quad (\bar{V}_1) = V_1^* + (V_1^E)$$

Figures 4 and 5 show the values of $(V_1)^E$, and $(\bar{V}_1)$ as a function of mole fraction of *m*-cresol. Continuous curves were generated with the aid of the plotter.

Various thermodynamic parameters of activation of viscous flow were determined using Eyring's equation (10). According to Eyring

$$[8] \quad \eta = \frac{hN}{V}\exp(\Delta H^{\ddagger}/RT - \Delta S^{\ddagger}/R)$$

where η is the viscosity of the solution, h, N, and V are Planck's constant, Avogadros number, and molar volume,

respectively.

When ln ($\eta V/hN$) is plotted against $1/T$, the slope is equal to $\Delta H^{\ddagger}/R$ and the intercept is equal to $-\Delta S^{\ddagger}/R$. Using both graphical and least-squares method, the activation parameters $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ were obtained and $\Delta G^{\ddagger}$ was obtained using the equation:

$$[9] \quad \Delta G^{\ddagger} = \Delta H^{\ddagger} - T\Delta S^{\ddagger}$$

Values obtained are presented in Table 4.

Discussion

Association of phenol and substituted phenols through inter-

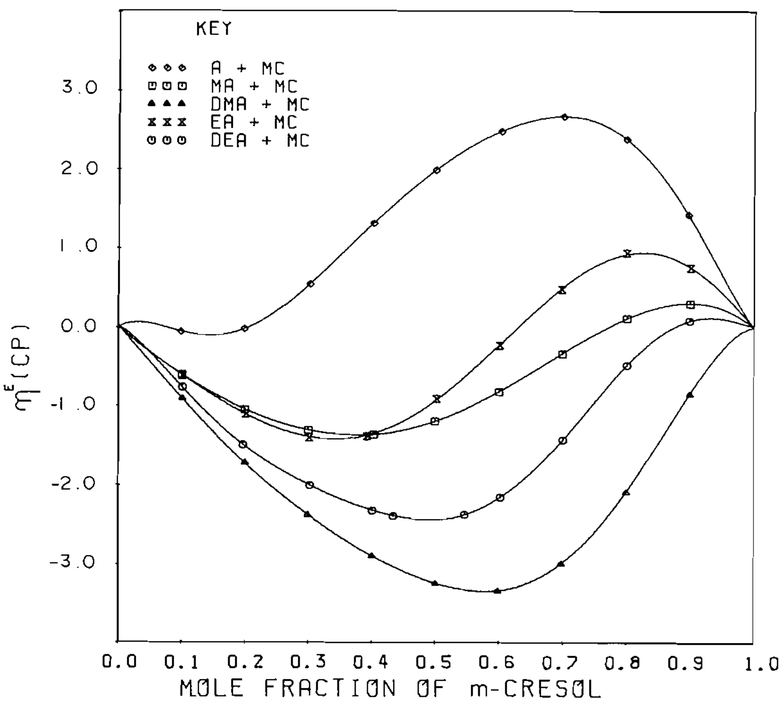

FIG. 1. Plot of excess viscosity vs. mole fraction of *m*-cresol.

molecular hydrogen bonding has been inferred on the basis of studies relating to physical properties (11). The hydrogen bond in the association of phenols is of O—H---O type, the strength of which is determined by the geometry of the molecules and the nature of the substituents in the phenol molecules. The choice of *m*-cresol was based on its ability to form intermolecular hydrogen bonds, compared to the limited ability of *o*-chlorophenol to form intermolecular hydrogen bonding. This is useful when comparing the present result to the results of *o*-chlorophenol with anilines (4). The above systems can be classified as both polar and associated systems (12). In nonelectrolyte systems, positive deviations from ideal behaviour are attributed to dispersion forces (13) and negative deviations to the geometric considerations (14). Attempts have been made to explain the behaviour of liquid mixtures on the basis of sign and magnitude of the excess viscosity and excess volume.

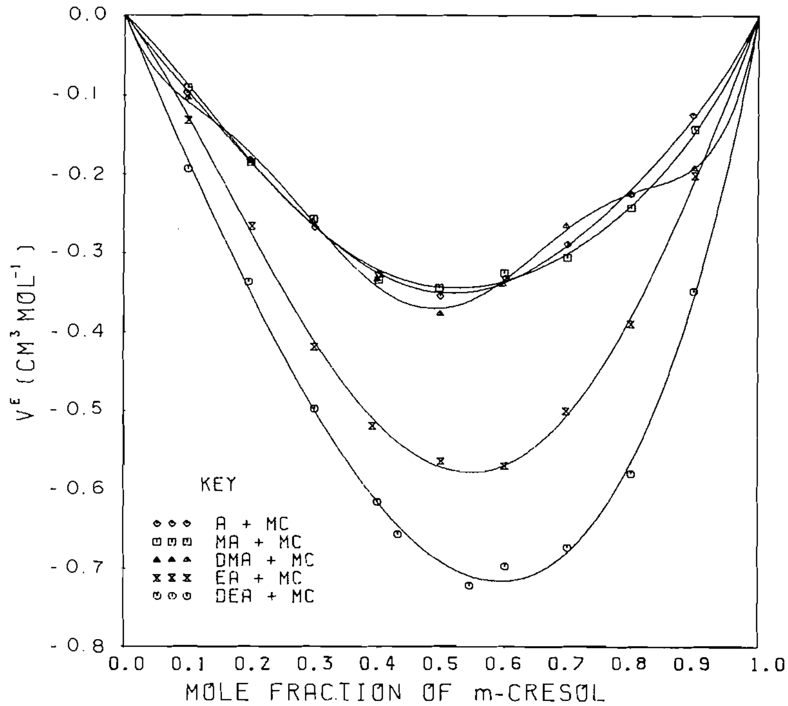

FIG. 2. Plot of excess volume vs. mole fraction of *m*-cresol.

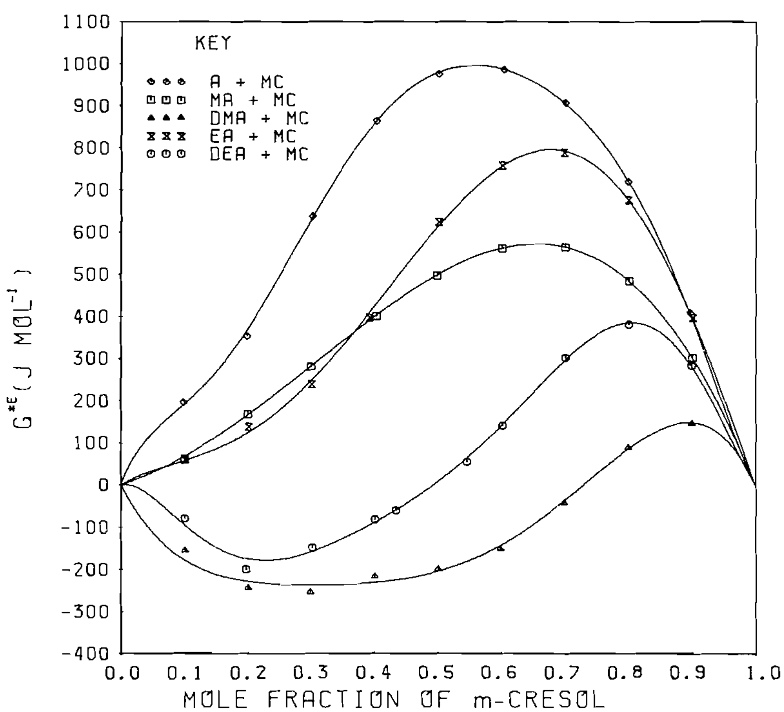

FIG. 3. Plot of excess free energy of activation vs. mole fraction of *m*-cresol.

Examination of Fig. 1 shows that the values of η^E become negative initially when MC is added and positive at higher mole fraction of MC. However, in the case of the system (DMA + MC) the η^E values remain negative in the entire range of composition. According to Fort and Moore (15) the values of η^E are negative for systems of different molecular size in which dispersion forces are dominant. The η^E values become less negative and then increasingly positive as the strength of the interaction increases. In the present study, all the chemical species are cyclic, so that small differences of size in the molecules are not important in the excess viscosity. The positive η^E values for the systems (A + MC), (MA + MC), and (EA + MC) indicate the strength of interaction increases at higher concentration of *m*-cresol probably due to association between *m*-cresol and anilines through hydrogen bonding. The values of η^E are equal to zero for all systems except (DEA + MC) at a definite mole fraction of MC. The composition at which η^E is equal to zero depends on the type of system and

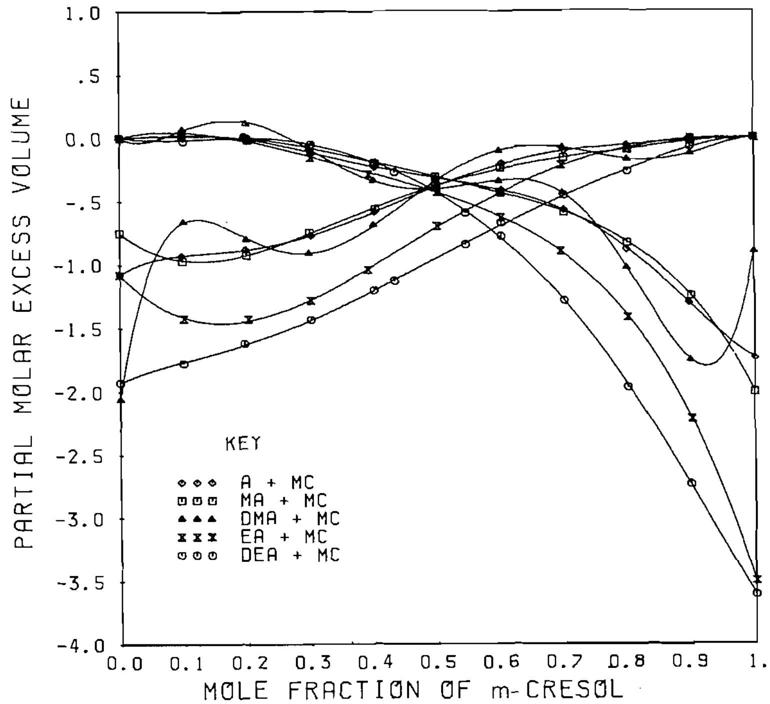

FIG. 4. Plot of partial molar excess volumes vs. mole fraction of *m*-cresol.

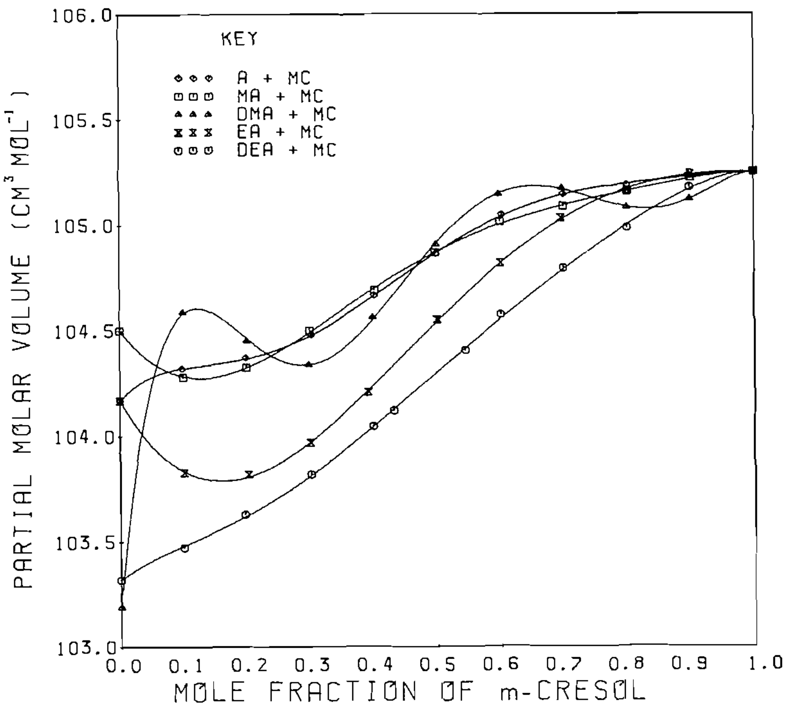

FIG. 5. Plot of partial molar volume vs. mole fraction of *m*-cresol.

whether or not the system behaves like an ideal one at this composition.

The negative values of V^E in Fig. 2 for the five systems are explained by Prigogine (16) in terms of different sizes of the molecules or the dipole–dipole interaction between them. The intermolecular association complex also contributes to these negative values. Since all the species are cyclic, the small differences of size in the molecules are not important in the excess molar volume. The minimum values of V^E for these systems can be explained in terms of acid–base interaction between *m*-cresol and anilines. The strength of the base follows the order DEA > EA > DMA > MA > A. The value at the minima for the system (A + MC) is slightly more negative than that of (MA + MC), and this may be due to the ability of aniline to form stronger hydrogen bonds with *m*-cresol than MA with MC. If H is defined as η/η_i where η is the experimental viscosity of the mixture and $\ln \eta_i = X_1 \ln \eta_1 + X_2 \ln \eta_2$ then according to Stairs (17), H is related to the ideal free

*Mole fraction of *m*-cresol, units: $\Delta H^{\ddagger}$, $\Delta G^{\ddagger}$ (kJ mol^{-1}), $\Delta S^{\ddagger}$ (J mol^{-1}).

volume (V_i) of the solution by the equation:

$$[10] \quad H^{-1} = (V_i + V^{E})/V_i$$

According to eq. [10], a plot of H^{-1} vs. V^{E} should be linear. However, when H^{-1} is plotted against V^{E}, a nonlinear plot was obtained in the present study. In our previous studies (3, 4) when ln H is plotted against G^{*E}, a single straight line with a zero intercept was obtained. This type of result is not unexpected, because the expression for G^{*E} takes into account both viscosity and volume.

All the systems involved in our previous studies exhibited positive η^E and negative V^E; however, in the present study when ln H is plotted against G^{*E}, a single straight line with nonzero intercept is obtained (Fig. 6). This behaviour is not unusual since in the present study the η^E values are both positive and negative and V^E values are negative. In the temperature range investigated, the values of $\Delta H^{\ddagger}$ are positive and vary in the order MC > A > EA > MA > DEA > DMA, indicating that association and dipole–dipole interactions increase the value of $\Delta H^{\ddagger}$. Except for DEA and DMA, the $\Delta S^{\ddagger}$ values are positive. The values of $\Delta H^{\ddagger}$ and $\Delta G^{\ddagger}$ for the mixtures are positive for each binary system studied and increase with increase in *m*-cresol concentration. Entropy of activation is positive for all systems except for DMA and DEA with MC in amine-rich regions.

According to Reed and Taylor (18) and Meyers *et al.* (19), the G^{*E} parameter may be considered a reliable measure to detect the presence of interaction between molecules. Positive values of G^{*E} can be seen in binary systems where specific interactions between molecules take place. G^{*E} values are positive at all compositions for the mixtures of MC with A, MA, and EA. For the other systems it is negative at low concentrations of MC and becomes positive at higher concentrations. From the values of G^{*E}, one can conclude that the strength of specific interactions varies in the order A + MC > EA + MC > MA + MC > DEA + MC > DMA + MC.

Examination of Fig. 5 reveals that the addition of 1 mol of *m*-cresol in a large volume of the different bases produces a volume contraction in the order MA < EA ≅ A < DEA < DMA. According to Somsen and co-workers (20) better information on interactions in binary mixtures can be deduced from the shape of the curve obtained when partial molar volume is plotted against composition. A pronounced minimum in the curve indicates the strength of the interactions.

From the analysis of the results one can conclude that the strength of specific interactions between *m*-cresol with substituted anilines varies in the order A + MC > EA + MC > MA + MC > DEA + MC > DMA + MC. The type of interactions are mainly acid–base interactions and hydrogen bonding. Also the strength of interactions is less pronounced in *m*-cresol compared to *o*-chlorophenol. This could be attributed to these facts: (*a*) *o*-chlorophenol is a stronger acid than *m*-cresol and (*b*) absence of polymerization through intermolecular hydrogen bonding in *o*-chlorophenol compared to *m*-cresol.

Dipole moments of some aromatic and aliphatic aldehydes. Their dependence on the solvent and the atomic polarization

CONSTANTINO GROSSE,[1] MAGDALENA MECHETTI, AND PEDRO BRITO

Instituto de Física, Facultad de Ciencias Exactas y Tecnología, Universidad Nacional de Tucumán, 4000 Tucumán, R. Argentina

Received May 2, 1984

CONSTANTINO GROSSE, MAGDALENA MECHETTI, and PEDRO BRITO. Can. J. Chem. **63**, 1031 (1985).

The dipole moments of 21 aromatic and aliphatic aldehydes were determined. Permittivity measurements were performed on highly diluted cyclohexane solutions at 20°C. The limiting forms of Debye's, Onsager's, and Bordewijk's expressions were used. The influence of the solvent on the dipole moment values was studied using decalin and heptane mixtures. Only the Debye's values presented an apparent solvent effect while the Onsager's and Bordewijk's values remained independent of the solvent. Dipole moment values obtained using the refractive indexes of the components were also compared with those derived using the refractive indexes of the mixtures. This permitted one to estimate in 0.07 the relation between atomic and electronic polarization.

CONSTANTINO GROSSE, MAGDALENA MECHETTI et PEDRO BRITO. Can. J. Chem. **63**, 1031 (1985).

On a mesuré les moments dipolaires de vingt et un aldéhydes aliphatiques et aromatiques. On a effectué les mesures de permitivité à 20°C, sur des solutions très diluées dans le cyclohexane. On a utilisé les formes limites des expressions de Debye, Onsager et Bordewijk. De plus, utilisant des mélanges de décaline et d'heptane, on a étudié l'influence des solvants sur les valeurs des moments dipolaires. Les valeurs obtenues à l'aide de l'expression de Debye sont les seules à présenter un effet apparent de solvant; les valeurs obtenues à l'aide des expressions de Onsager ou de Bordewijk sont indépendantes du solvant. On a aussi comparé les valeurs des moments dipolaires obtenues à l'aide des indices de réfraction des composantes avec les valeurs que l'on peut dériver des indices de réfraction des mélanges. Sur cette base, on peut évaluer à 0,07 la relation entre les polarisations atomique et électronique.

[Traduit par le journal]

1. Introduction

The main purpose of this work is to determine the dipole moments of a series of aromatic and aliphatic aldehydes. This was accomplished as usual (1, 2) by measuring the static dielectric permittivity of dilute polar − non-polar solutions.

A definite theoretical expression relating the solution permittivity with microscopic properties has not yet been obtained. Existing treatments generally assume an ideal behaviour neglecting correlations, complex formation, volume variations, and molecular anisotropies. In the high dilution limit, a linear variation of the static dielectric permittivity with concentration is expected. Different theories lead to different slopes and consequently, to different values for the dipole moment of the solute molecule. Despite its being an old problem this subject maintains a permanent interest as can be seen from the literature (3−7).

In this paper the high dilution limiting forms of the expressions due to Debye (1), Onsager (2), and Bordewijk (5), were used. In order to determine the importance of the solvent effect, some aldehydes were studied in three different solvents. Using measurements of the refractive indexes of these same mixtures, the values of the atomic polarization were also estimated.

2. Theoretical expressions for the static dielectric permittivity of solutions

The theoretical expressions most currently used to determine the molecular dipole moments in solution are those deduced by Debye and Onsager. In the limit of very low concentrations, they can be written, respectively, as

$$[1]\quad \epsilon_{1,2} = \epsilon_2 + K_1\left(\frac{N_1\mu^2_{\mathrm{Deb}}}{9\epsilon_0 kT}\right)\frac{(\epsilon_2+2)^2}{3} + K_1\frac{(\epsilon_{\infty 1}-\epsilon_2)(\epsilon_2+2)}{(\epsilon_{\infty 1}+2)}$$

$$[2]\quad \epsilon_{1,2} = \epsilon_2 + K_1\left(\frac{N_1\mu^2_{\mathrm{Ons}}}{9\epsilon_0 kT}\right)\frac{3\epsilon_2^2(\epsilon_{\infty 1}+2)^2}{(2\epsilon_2+\epsilon_{\infty 1})^2} + K_1\frac{(\epsilon_{\infty 1}-\epsilon_2)3\epsilon_2}{(2\epsilon_2+\epsilon_{\infty 1})}$$

where $\epsilon_{1,2}$ and ϵ_2 are the mixture and solvent permittivities, $\epsilon_{\infty 1}$ is the part of the solute permittivity associated with its total induced polarization, N_1 is the number of solute molecules per unit volume in pure state, and K_1 is the volume concentration. Equations [1] and [2] have been deduced in the framework of a continuum approach. A more rigorous expression for the permittivity has been obtained by Bordewijk (5). For polar−non-polar solutions of isotropic non-correlated molecules it writes as

$$[3]\quad \frac{(\epsilon_{1,2}-\epsilon_{\infty 1,2})(2\epsilon_{1,2}+\epsilon_{\infty 1,2})}{\epsilon_{1,2}(\epsilon_{\infty 1,2}+2)^2} = K_1\left(\frac{N_1\mu^2_{\mathrm{Bord}}}{9\epsilon_0 kT}\right)\left(\frac{3\epsilon_{\infty 1,2}(\epsilon_{\infty 1}+2)}{(2\epsilon_{\infty 1,2}+\epsilon_{\infty 1})(\epsilon_{\infty 1,2}+2)}\right)$$

where $\epsilon_{\infty 1,2}$ is the solution permittivity associated with the total induced polarization.

Before comparing the limiting form of eq. [3] with expressions [1] and [2], a functional relation between $\epsilon_{\infty 1,2}$ and $\epsilon_{\infty 1}$, ϵ_2, and K_1 is needed. Assuming that this relation is given by the Clausius−Mossotti equation (8, 9),

$$[4]\quad \frac{(\epsilon_{\infty 1,2}-\epsilon_2)}{(\epsilon_{\infty 1,2}+2)} = K_1\frac{(\epsilon_{\infty 1}-\epsilon_2)}{(\epsilon_{\infty 1}+2)}$$

the following result is obtained:

Hidrozimtaldehyde	134.18	1.01	6.10
n-Valeraldehyde	86.14	0.808	6.32

$$[5] \quad \epsilon_{1,2} = \epsilon_2 + K_1\left(\frac{N_1\mu^2_{\mathrm{Bord}}}{9\epsilon_0 kT}\right)\frac{3\epsilon_2^2(\epsilon_{\infty 1} + 2)^2}{(2\epsilon_2 + \epsilon_{\infty 1})^2} + K_1\frac{(\epsilon_{\infty 1} - \epsilon_2)(\epsilon_2 + 2)}{(\epsilon_{\infty 1} + 2)}$$

This expression combines the best features of eq. [1] and [2]: the non-dipolar part of Debye and the dipolar part of Onsager.

3. Experimental details

Static dielectric measurements were performed at the Microwave Laboratory of the Johannes Gutenberg University of Mainz, Germany, by one of us (C.G.). The apparatus and the experimental techniques used have been previously described (10, 11). For most measurements the solvent was cyclohexane which is, probably, the solvent best suited for dielectric studies (12). Heptane and decalin were also used to estimate the solvent effect.

The solvents, Table 1, were obtained from Merck and dried with 3 Å molecular seeds. The solutes, Table 2, in the highest purity available, usually purissimus grade, were obtained from Fluka. The solutions were also dried with molecular seeds. The data included in these tables, and later used in the calculation, were taken from the supplier's catalogs except for those in the last column in Table 2.

The parameters deduced from the measurements performed on highly diluted solutions are all linear functions of concentration. Therefore, the significant values are the corresponding slopes rather than the absolute values. In our case, the important quantity is the difference between the static dielectric permittivities of the solutions and of the pure solvent divided by the molar concentration: $(\epsilon_{1,2} - \epsilon_2)/x$.

In order to improve the precision of the results, measurements were performed at the following concentrations: x = 0.001, 0.002, 0.003, and 0.004, and the slopes were obtained by least-squares fits. The results obtained appear on Table 2, their accuracy being of the order of 1%.

4. Determination of the dipole moments

Before using eqs. [1], [2], and [5], in order to obtain the values of the dipole moments of the different solute molecules, the values of the permittivities $\epsilon_{\infty 1}$ must be assessed. They can not be directly measured since at high frequencies other absorption processes are present (13). Therefore, the induced polarization, $P_i = P_e + P_a$, where P_e is the electronic and P_a the atomic polarization, is often taken as being equal to P_e or proportional to it. The proportionality constant depends on the molecule considered and usually ranges between 1 and 1.15 (14). In this paper, both these extreme cases were considered. The dipole moments thus obtained are given in Table 3, where the first values in each column correspond to the case $\epsilon_{\infty 1} = n^2_{D1}$, while the second ones corresponds to

$$(\epsilon_{\infty 1} - 1)/(\epsilon_{\infty 1} + 2) = 1.15(n^2_{D1} - 1)/(n^2_{D1} + 2)$$

They are also compared to existing values (14) measured in solution at 20−25°C. When more than one dipole moment is reported the extreme values are indicated.

It is apparent from this table that the values of μ_{Ons} are very different from μ_{Deb}. These differences are, in general, greater than the experimental uncertainties in the determination of the dipole moments which are less than 1%. This shows the importance of choosing the best theoretical expression for μ. Table 3 also shows that the values of μ_{Ons} are almost equal to those of μ_{Bord}. The differences between the three dipole moment values can be estimated by writing $\epsilon_{\infty 1} = \epsilon_2 + \Delta$ and expanding eqs. [1], [2], and [5] in powers of Δ. This leads to

$$[6] \quad \mu_{\mathrm{Deb}} = \mu_{\mathrm{Ons}}\left[1 + \frac{2}{3}\Delta\frac{(\epsilon_2 - 1)}{\epsilon_2(\epsilon_2 + 2)}\right]$$

$$[7] \quad \mu_{\mathrm{Bord}} = \mu_{\mathrm{Ons}}\left[1 + \Delta^2\frac{(\epsilon_2 - 1)\epsilon_{1,2}(\epsilon_{\infty 1,2} + 2)^2}{(\epsilon_{1,2} - \epsilon_{\infty 1,2})(2\epsilon_{1,2} + \epsilon_{\infty 1,2})(\epsilon_2 + 2)^3}\right]$$

Equation [6] shows, in agreement with Table 3, that μ_{Deb} can be less or greater than μ_{Ons}, depending on the sign of Δ (6). On the contrary, the difference between μ_{Bord} and μ_{Ons} is independent of this sign, eq. [7], being one order smaller.

As for the variation of the moments obtained using extreme values of the atomic polarization, it is also comparable with the experimental error. The corresponding differences are smaller when Debye's expression is used increasing strongly with the use of Onsager's or Bordewijk's formulas.

5. Influence of the solvent

In order to estimate the influence of the solvent on the dipole moment values, additional measurements in heptane and decalin were performed on *ortho*, *meta*, and *para*-toluylaldehydes, Table 4. The results obtained with the three solvents appear on Table 5 and lead to the following conclusions. In view of the experimental uncertainties, no solvent effect could be detected for the substances considered when Onsager's or Bordewijk's formulas were used. On the contrary, Debye's formula leads to an apparent solvent effect since the corresponding variations with the solvent of the dipole moment values are roughly two

times greater than those for the other two expressions. All this is in agreement with the conclusions of ref. 6.

6. Estimation of the atomic polarization P_a

Equations [1] and [2] were obtained as low dilution limiting forms of the general formulae for the static dielectric permittivity, written as functions of the molecular parameters μ_i and α_i. The polarizabilities were then eliminated in terms of the high frequency permittivities of the pure compounds with the help of Clausius–Mossotti's expression.

On the contrary, Bordewijk's permittivity expression [3] is a function of the mixture high frequency permittivity $\epsilon_{\infty 1,2}$. This made it necessary to use the high frequency formula [4] in order to obtain the limiting result [5] comparable with eqs. [1] and [2]. This leads to the conclusion that, at least in the case of Bordewijk's formula, a better way to determine dipole moment values is to measure the permittivity variations with the concentration both at low, $(\epsilon_{1,2} - \epsilon_2)/x$, and high, $(\epsilon_{\infty 1,2} - \epsilon_2)/x$, frequencies.

In order to compare this procedure with the usual one, measurements of $(n^2_{D1,2} - n^2_{D2})/x$ for *o*-, *m*-, and *p*-toluylaldehyde in heptane, cyclohexane, and decalin were performed, Table 4. Dipole moment values were calculated by using the expressions:

$$[8] \quad \epsilon_{1,2} = \epsilon_{\infty 1,2} + K_1\left(\frac{N_1\mu^2_{Deb}}{9\epsilon_0 kT}\right)\frac{(\epsilon_2 + 2)^2}{3}$$

for the Debye model, and

$$[9] \quad \epsilon_{1,2} = \epsilon_{\infty 1,2} + K_1\left(\frac{N_1\mu^2_{Ons}}{9\epsilon_0 kT}\right)\frac{3\epsilon_2^2(\epsilon_{\infty 1} + 2)^2}{(2\epsilon_2 + \epsilon_{\infty 1})^2}$$

for both Onsager and Bordewijk's models.

As previously, the relation between $(\epsilon_{\infty 1,2} - \epsilon_2)/x$ and $(n^2_{D1,2} - n^2_{D2})/x$, was evaluated in the extreme cases:

$$[10] \quad \frac{\epsilon_{\infty 1,2} - \epsilon_2}{x} = \frac{n^2_{D1,2} - n^2_{D2}}{x}$$

and

$$[11] \quad \frac{\epsilon_{\infty 1,2} - \epsilon_2}{x} = 1.15\frac{n^2_{D1,2} - n^2_{D2}}{x} + 0.05\,(\epsilon_2 - 1)(\epsilon_2 + 2)$$

TABLE 6. Dipole moment values obtained using the mixture's refractive indexes

Substances	μ_{Deb}	μ_{Ons}, μ_{Bord}
o-Toluyaldehyde in		
Decalin	2.76−2.70	2.71−2.59
Cyclohexane	2.83−2.79	2.75−2.65
Heptane	2.79−2.73	2.70−2.58
m-Toluyaldehyde in		
Decalin	3.04−2.98	2.98−2.86
Cyclohexane	3.11−3.07	3.03−2.93
Heptane	3.10−3.05	3.00−2.89
p-Toluyaldehyde in		
Decalin	3.32−3.27	3.26−3.13
Cyclohexane	3.40−3.36	3.30−3.20
Heptane	3.40−3.35	3.28−3.17

The results obtained appear in Table 6, where the first values correspond to assumption [10] and the second ones to [11].

This table, when compared with Table 5, shows very similar values but appearing in each column in the inverse order. This means that the results obtained using expressions [1], [2], and [5], together with the assumption $P_a = 0$ ($P_a = 0.15P_e$) give approximately the same results as when using formulas [8] and [9] with condition [11] ([10]).

Therefore, the results of Tables 5 and 6 become compatible for intermediate $P_a = 0.07P_e$ values.

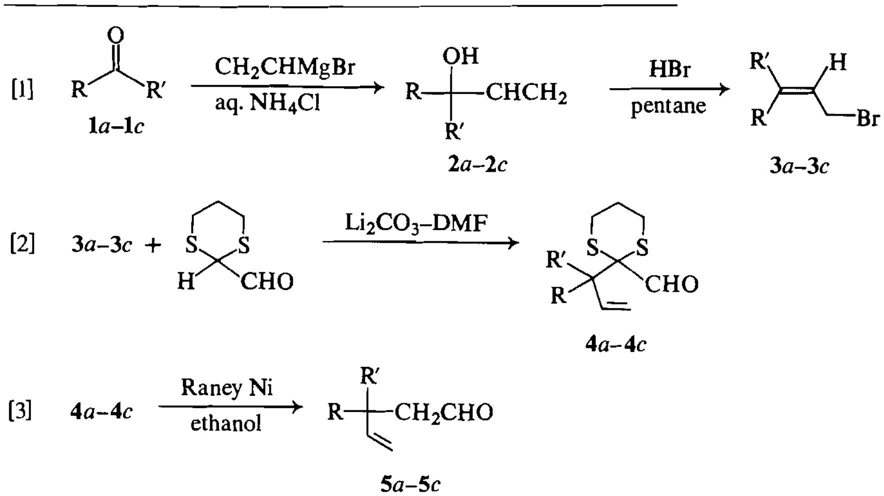
Introduction

Our ongoing investigation of catalytic asymmetric cyclization and decarbonylation reactions of pent-4-enals (1) has necessited the preparation of a series of racemic 3,3-disubstituted pent-4-enal substrates. Two methods have been reported (2) for the preparation of such compounds and the 2,3-disubstituted analogues. One method, of somewhat limited scope for synthesis of the 3,3-compounds, involves the conjugate addition of vinylcuprate(I) reagents to α,β-unsaturated aldehydes. The second, more versatile, reaction involves the addition of ethylene oxide to allylic Grignard reagents, followed by oxidation of the resulting alcohol. The methods are dependent on the availability and nature of the ultimate alkenic reagents and, for the latter method, the ease of oxidation of the alcohol precursor. We have developed an alternative approach to the desired substrates, one which involves the Raney nickel desulfurization of 2,2-(trimethylenedithio)pent-4-enal precursors. This paper reports the preparation and characterization of the new pent-4-enals **5***a*–**5***c*, their precursors **4***a*–**4***c*, and the compounds produced by the thermal rearrangement of these precursors (compounds **6***a*–**6***c*).

Results and discussion

The synthesis of the title compounds follows the reactions of eqs. [1]–[3] within Scheme 1. The preparation of the allylic bromides **3***a*–**3***c* is straightforward, and these compounds may



SCHEME 1. The preparation of **5***a*–**5***c* via **4***a*–**4***c*. (The substituents are as follows: (*a*) R = Me, R′ = Et; (*b*) R = Me, R′ = Ph; (*c*) R = Et, R′ = Ph).

be stored at 0°C for several days before use. Both *E* and *Z* isomers are present in **3***a*–**3***c*, the isomer ratio being dictated by the usual steric interactions (see experimental section). Reaction [2] also proceeds smoothly at room temperatures and good yields of **4***a*–**4***c* are obtained after ca. 5 days. These compounds are air-stable, white, crystalline solids which are readily isolated and purified by recrystallization. This feature makes 2-formyl-1,3-dithiane the thioacetal of choice in these reactions, as considerable difficulty was experienced in the purification of the liquid products derived from bis(ethylthio)acetal (these reactions were not pursued). From unsuccessful attempts to obtain other compounds of series **4**, we have discerned two features associated with reactions [1] and [2] which limit their synthetic generality and that of Scheme 1 as a whole. Firstly, the use of ketones with bulky substitutents (e.g. R = Me, R′ = 2,4,6-$Me_3C_6H_2$) can prevent initial reaction with vinylmagnesium bromide, presumably because the Grignard reagent is unable to approach the carbonyl carbon atom. Secondly, the use of ketones with two aryl substituents (e.g. R = Ph, R′ = *p*-$MeOC_6H_4$) enhances, following reaction [2], the rapid rearrangement of the series **4** product according to eq. [4]. Thus, when R = R′ = aryl, only products of series **6** are isolated by room temperature manipulations. Series **4** products of this type, however, may be accessible by suitable low temperature syntheses. Various analogs of **4***a*–**4***c* have been previously prepared by the *in situ* alkylation of 2-formyl-1,3-dithiane (3).

Compounds **4***a*–**4***c* are characterized by the following spectroscopic properties (see experimental section for details). In their infrared spectra, the compounds display characteristic absorptions at ca. 1700 ($\nu_{C=O}$), 1600 ($\nu_{C=C}$), and 600 (ν_{CSC}) cm^{-1}, while the mass spectra display peaks assignable to the molecular ion, a fragment formed by loss of CHO, the 2-formyl-1,3-dithianyl ion (m/e = 148), and cyclic disulfide ions (m/e = 107/106/105). The cyclic disulfide fragments have been observed also in the mass spectra of related 1-aryl-1,3-dithianes (4, 5). The 400-MHz ^1H nmr spectra of the compounds exhibit several features of interest; that of **4***c* (Fig. 1a) exemplifies the salient features for the series.[3] In all cases the resonances due to the aldehyde, vinyl, methyl, and aromatic protons are readily identified. As well, the spectra of **4***a* and **4***c* clearly display the diastereotopic nature of the methylene protons of the R′ and R groups, respectively. In **4***c*, two unique six-line resonances (δ_A 2.22, δ_B 2.53) are produced by the diastereotopic H_A and H_B protons (J_{AB} = 14.5 Hz, $^3J_{CH_3,A}$ = $^3J_{CH_3,B}$ = 7.5 Hz). The presence of the chiral centre in these molecules also dictates the inequivalence of the six heterocyclic ring protons and this is reflected in the observation of six unique resonances attributable to these protons (see Fig. 1a).

TABLE 1. Bond lengths in (*R*)-**4***c* with estimated standard deviations in parentheses

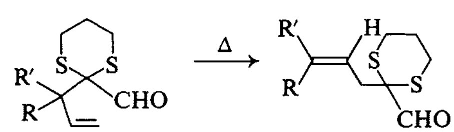
Bond	Length (Å)	Bond	Length (Å)
S(1)—C(2)	1.811(6)	C(4)—C(5)	1.319(9)
S(1)—C(6)	1.812(7)	C(6)—C(7)	1.531(9)
S(2)—C(2)	1.848(5)	C(7)—C(8)	1.489(10)
S(2)—C(8)	1.812(7)	C(9)—C(10)	1.490(9)
O —C(1)	1.128(11)	C(11)—C(12)	1.388(8)
C(1)—C(2)	1.508(9)	C(11)—C(16)	1.391(8)
C(2)—C(3)	1.583(7)	C(12)—C(13)	1.393(8)
C(3)—C(4)	1.539(8)	C(13)—C(14)	1.354(11)
C(3)—C(9)	1.540(8)	C(14)—C(15)	1.377(12)
C(3)—C(11)	1.537(7)	C(15)—C(16)	1.392(8)

The couplings observed for these ring protons[3] are consistent with the rings having a chair conformation in solution, a feature persistent in the solid state structure of (*R*)-**4***c* (see below). The ^{13}C-{^1H} nmr spectra of all compounds display the expected resonances, as detailed in the experimental section.

As confirmation of the spectroscopically derived formulations of **4***a*–**4***c*, the single crystal X-ray structure of (*R*)-**4***c* was determined. A stereoview of the molecule is given in Fig. 2. Pertinent bond lengths and angles are given in Tables 1 and 2, respectively. In this molecule the substituents of the adjacent quaternary carbon atoms C(2) and C(3) are in the least sterically encumbered staggered positions. Indeed, steric interactions appear to dictate the general conformations of all groups relative to their neighbours. On the (*R*)-C(3) atom the vinyl and ethyl substituents were unambiguously differentiated in the crystallographic study, the groups possessing bond lengths of 1.319(9) Å and 1.490(9) Å, respectively. The carbonyl group has a C—O bond length of 1.128(11) Å and the oxygen atom has close interatomic contacts with H(6a) (2.56 Å, C—H··O 121°) and H(8a) (2.70 Å, C—H··O 124°), and an intermolecular contact with H(8e) (−*x*, 1/2*y*, −*z*; 2.49 Å, C—H··O 140°). The trimethylenedithio ring possesses a chair conformation as found in solution by nmr. In the two structurally inequivalent C—S bonds, significantly different bond lengths of 1.811(6) and 1.848(5) Å are observed. Close intramolecular contacts are noted also between S(1)··H(92) (2.68 Å, C—H··S 110°), S(2)··H(91) (2.70 Å, C—H··S 110°), and S(2)··H(4) (2.62 Å, C—H··S 111°). The chair structure of the trimethylenedithio ring has been structurally characterized previously, for example in 2-phenyl-1,3-dithiane (6).

Intramolecular thermal rearrangement of **4***a*–**4***c* occurs readily at ca. 130°C, eq. [4]; the products that result from formal [1,3] sigmatropic shifts have been isolated and characterized as the trisubstituted alkenes **6***a*–**6***c*. Although we have not made a detailed study of the rates of rearrangement of

[4]



4*a*–**4***c* **6***a*–**6***c*

4*a*–**4***c*, it is clear from the observed reaction times (see experimental section) that **4***b* and **4***c* rearrange more readily than does **4***a*. Besides offering greater steric relief to the strained adjacent quaternary centers, rearrangement of **4***b* and **4***c* produces stabilized, more highly substituted (indeed, conjugated) alkenes. The lower steric strain of **4***a* and the absence of conjugate

[3] With the exception of the R groups, the numbering scheme used in Fig. 1 is applicable to all series **4**, **5**, and **6** compounds, i.e. C(1)—C(5) and C(6)—C(8) pertain to pent-4-enal and trimethylenedithio carbon atoms, respectively. In the nmr assignments of these compounds, protons are numbered according to the carbon atom to which they are bonded. The subscripts a = axial, e = equatorial, *g* = geminal, *t* = *trans*-, and *c* = *cis*- further specify the ring and olefinic protons and their couplings. The unique R group protons are identified separately. Typical proton coupling constants in the heterocyclic rings were $J_{6a6e} = J_{7a7e} = J_{8a8e}$ = 13.5 Hz, $J_{7a6e} = J_{7a8e}$ = 3.5 Hz, $J_{7e6e} = J_{7e8e}$ = 4.3 Hz, J_{6e8e} = 1.6 Hz, $J_{7e6a} = J_{7e8a}$ = 2.8 Hz, $J_{7a6a} = J_{7a8a}$ = 11.8 Hz. Other abbreviations used in the spectral data are: s = singlet, d = doublet, t = triplet, q = quartet, m = multiplet; ir, s = strong, m = medium, w = weak.

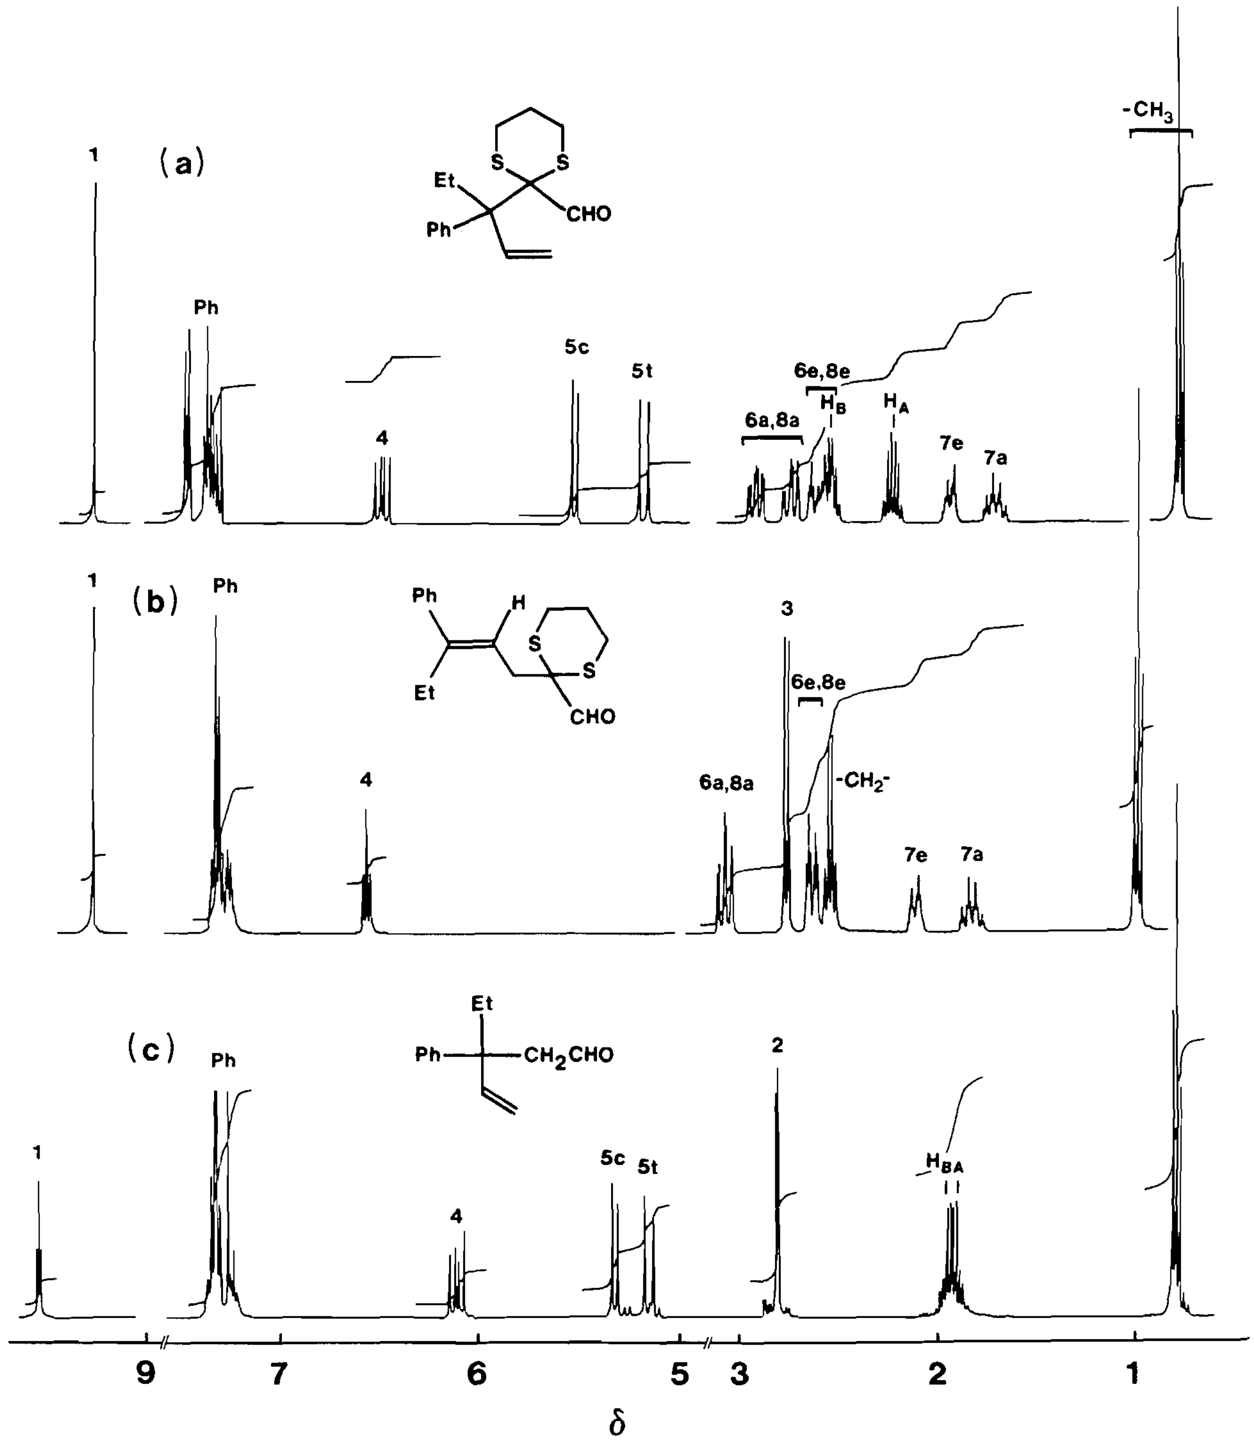


FIG. 1. The 400-MHz [1]H nmr spectra of (a) **4**c, (b) **6**c, and (c) **5**c, the archetypal members of the three classes of compounds described herein (see also footnote 3).

stabilization in **6**a lead to a slower rearrangement in this case. These rate-determining factors are consistent with the earlier mentioned room temperature rearrangement of 3,3-bis(aryl) compounds of series **4**. With the exception of the **4**a → **6**a rearrangement where both E- and Z-**6**a form, only the E isomer is formed during the rearrangement of **4**b and **4**c. A directly analogous rearrangement of 2,2-bis(ethylthio)-3,3-dimethylpent-4-enal has been studied recently by Bates and Ramaswamy (7), and their kinetic data were interpreted in terms of a biradical mechanism.

The loss of the chiral centre and its associated asymmetry upon the rearrangement of **4**a–**4**c lead to relatively simple nmr spectra for **6**a–**6**c. For example, in the [1]H nmr spectrum of **6**c (Fig. 1b), the diastereotopic methylene proton resonances and the six trimethylenedithio proton resonances of **4**c are replaced by a simple quartet resonance and a set of four ring proton resonances (due to H(7a),H(7e), and equivalent H(6a),H(8a) and H(6e),H(8e) pairs), respectively. Again, a chair conformation in the heterocyclic ring is indicated by the nmr data. The vinyl resonances of **4**c are replaced by triplet and doublet resonances due to the new alkene and β-methylene protons, respectively. Other spectral data are consistent with the pro-

TABLE 2. Bond angles in (*R*)-**4***c* with estimated standard deviations in parentheses

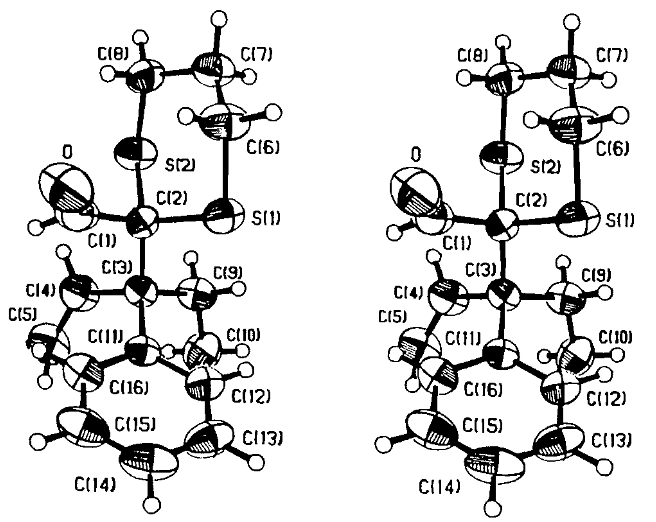

FIG. 2. ORTEP stereoview of (*R*)-**4***c* with the atom numbering scheme. Non-hydrogen atoms are shown as ellipsoids of 50% probability. Hydrogen atoms are spheres of convenient arbitrary size.

posed formulations.

The desulfurization of **4***a*–**4***c* leads to the formation of the desired pent-4-enal. This reaction is, however, critically dependent upon the nature of the Raney nickel used. In previous desulfurization studies (8–10), the possible concomitant reduction of functional groups such as aldehydes and alkenes by the Raney nickel has been noted. Only highly deactivated forms of Raney nickel (effected by a 2-h reflux in acetone (11)) have been found useful for the deuslfurization of **4***a*–**4***c*. The somewhat variable nature of the nickel makes monitoring by tlc the most reliable method of assessing the course of the reaction. Extensive reaction times or the use of highly activated nickel leads to sequential aldehyde, and then alkene, reduction. The pent-4-enals **5***a*–**5***c* are colourless liquids which are best stored under nitrogen at <0°C. Possible isomerization to the Prins product was not observed over a period of weeks (at room temperature, $CDCl_3$), although decomposition via autooxidation processes occurs over a period of several months.

The pent-4-enals exhibit infrared absorptions assignable to ν(C=O), ν(C=C), ν(=CH_2) as well as characteristic bands at ca. 768 and 705 cm^{-1}. The mass spectra exhibit peaks due to the molecular ion, and fragments resulting from the loss of CHO, CH_2CHO, and other substituent fragments. The 400-MHz ^{1}H nmr data of the compounds are summarized in the experimental section, and the spectrum of **5***c* is shown in Fig. 1c. With the exception of the R and R′ resonances, the nmr spectra of **5***a*–**5***c* display similar features due to the common pent-4-enal backbone. A characteristic vinyl group resonance is observed in the 5- to 6.5-ppm region (Fig. 1c), and a triplet resonance at ca. 9.5 ppm may be readily assigned to the CHO proton, which appears to be equally coupled ($^3J \sim 2.8$ Hz) to the two diastereotopic protons of the adjacent methylene group. The AB pattern associated with these CH_2 protons is displayed upon selective decoupling of the aldehyde proton. In **5***b* the significiantly different chemical shifts of these diastereotopic protons ($\Delta = 0.07$ ppm) produces a typical AB pattern in the CH_2 region, each peak being split by the small CHO coupling. However, the near equivalent chemical shifts of the diastereotopic protons in **5***c* ($\Delta = 0.02$ ppm) produce the triplet pattern and associated satellite peaks observed in Fig. 1c. The R and R′ resonances may be readily assigned and, where present, diastereotopic protons within these groups produce characteristic nmr resonances: e.g. the —CH_2CH_3 resonance of **5***c* results from the overlapping patterns of AB protons (J_{AB} = 15.6 Hz) equally coupled to the adjacent CH_3 protons. The small "duplicate" peaks in spectrum **1***c* indicate a small amount of a second rotamer in solutions of **5***c*.

In conclusion, we feel that the methodology described in this paper provides a general route to compounds of series **4**, **5**, and **6**. While our interest has been directed only at compounds where R ≠ R′, the synthesis of many other derivatives with R = R′ would be straightforward. We note again, however, the two conditions which limit the complete generality of this methodology: viz., the presence of bulky R and (or) R′ substituents, or R = R′ = aryl substituents. Substituents which contain functional groups that are reactive towards the reagents used in Scheme 1 may also prove to be problematic.

Experimental

Reagent grade solvents and chemicals were used without further purification unless otherwise stated. Liquid ketone starting materials were distilled prior to use. Tetrahydrofuran was distilled from sodium/benzophenone, and *N*,*N*-dimethylformamide was dried and stored over 4 Å molecular sieve. The acetone used was of spectroscopic grade. The method of Meyers and Strickland (11) was employed in the preparation of 2-formyl-1,3-dithiane. Thin layer chromatography was carried out on commercial silica gel plates (Bakerflex IB2-F, J.T. Baker Co.), while column chromatography employed 230–400 mesh silica gel (E. Merck). Plates were developed by 5% dodecamolybdophosphoric acid in ethanol.

Melting points were measured in air and are uncorrected. Infrared spectra were recorded on a Perkin Elmer Model 598 instrument as Nujol mulls or neat liquid samples. Nuclear magnetic resonance spectra were obtained on Brüker WH 400 (400 MHz, for ^{1}H) and Varian CFT-20 (19.9 MHz, for ^{13}C) spectrometers using tetramethylsilane as internal standard. Spectral assignments[3] were aided by routine decoupling experiments, computer simulation of the resonances and, for $^{13}C-\{^{1}H\}$ nmr, SFORD experiments. Mass spectra were recorded on a Varian MAT CH4-B spectrometer. Microanalyses were performed by Mr. P. Borda of this department.

Preparation of compounds

*4*a–*4*c

Bromoethene (6.41 g, 0.06 mol) in tetrahydrofuran (5 mL) was slowly added, at a rate which effected smooth boiling, to a mixture of magnesium turnings (2.5 g, 0.103 mol) in tetrahydrofuran (15 mL containing 4 drops of 1,2-dibromoethane activator) under an atmosphere of dinitrogen. A further 15 mL of tetrahydrofuran were added and the mixture allowed to stir for 45 min. The brown vinylmagnesium bromide mixture was cooled to 0°C and treated dropwise with the ketone (**1***a*–**1***c*, 0.06 mol). The mixture was sitrred at 0°C for 20 min, and then at room temperature for 40 min. It was then poured into a stirred saturated aqueous solution of NH_4Cl (150 mL) and upon dissolution of the magnesium was extracted with diethyl ether (3 × 50 mL). The combined ether extracts were washed with water, dried ($MgSO_4$), and the solvent removed *in vacuo*. The allylic alcohols **2***a*–**2***c* were obtained (identified by nmr).

The above product was dissolved in pentane (30 mL) and treated with 48% hydrobromic acid (7.5 mL). After stirring for 2 h, the pentane phase was washed with water (2 × 80 mL), dried ($MgSO_4$), and the solvent removed *in vacuo*. The allylic bromides **3***a*–**3***c* were obtained (identified by nmr). Isomeric ratios were, for **3***a*, 66% *E*, 34% *Z*; **3***b*, 77% *E*, 23% *Z*; **3***c*, 66% *E*, 34% *Z*.

A mixture of the above allylic bromide (0.05 mol), 2-formyl-1,3-dithiane (7.42 g, 0.05 mol), and lithium carbonate (5.55 g, 0.076 mol) in *N,N*-dimethylformamide (35 mL) was stirred under a slow flow of dinitrogen for 4–6 days (tlc monitor, 18% ethylacetate in petroleum ether 35–60°C bp). Diethyl ether (100 mL) was then added and the mixture washed with water (3 × 70 mL), 10% aqueous sodium hydroxide solution (3 × 60 mL), and then brine (2 × 60 mL). The ether solution was dried ($MgSO_4$) and the solvent removed under vacuum. For the high melting point solids (**4***b*, **4***c*), dissolution of the residue in ethanol/ether (~1:3) mixtures, followed by evaporation of the ether component, led to white crystals of product. These were collected, washed with ethanol, and vacuum dried. Low melting point **4***a* was purified by rapid distillation under vacuum (bp 100°C, 0.8 Torr (1 Torr = 133.3 Pa)). The purified liquid **4***a* solidified upon cooling. The products may also be purified by column chromatography (18% ethylacetate in petroleum ether 35–60°C bp).

*Compound 4*a

White crystalline solid, yield 8.0 g (70%), mp 38–40°C; ir (film, cm^{-1}): ν(C—H, CHO), 2840s, 2720s; ν(C=O), 1708s; ν(C=C) 1635w; ν(CSC), 620s; ^{1}H nmr ($CDCl_3$) δ: 0.77 (t, 3H, J = 7.5 Hz, CH_2CH_3), 1.24 (s, 3H, CH_3), 1.76 (m, 1H, H-7a), 1.85 (ABX_3, J_{AB} = 14.0 Hz, $J_{AX} = J_{BX}$ = 7.5 Hz, diast. CH_2 of Et), 1.99 (m, 1H, H-7e), 2.62, 2.66 (m's, 2H, H-6e,8e), 2.85, 2.95 (m's, 2H, H-6a,8a), 5.09 (dd, 1H, J_t = 17.6 Hz, J_g = 0.8 Hz, H-5*t*), 5.29 (dd, 1H, J_c = 11.2 Hz, J_g = 0.8 Hz, H-5*c*), 5.96 (dd, 1H, H-4), 9.35 (s, 1H, H-1); $^{13}C-\{^{1}H\}$ nmr ($CDCl_3$) δ: 8.13, 28.29 (CH_3CH_2), 17.39 (CH_3), 24.44, 26.97, 26.97 (C-7, C-6, and C-8), 47.16 (C-3), 68.19 (C-2), 116.73 (C-5), 139.57 (C-4), 190.69 (C-1); *m/e* (25°C): 232/231/230 (M^+), 203/202/201 (M − CHO), 150/149/148, 147, 107/106/105. *Anal.* calcd. for $C_{11}H_{18}OS_2$: C 57.35, H 7.88; found: C 57.2, H 8.0%.

*Compound 4*b

White crystalline solid, yield 11.8 g (85%), mp 53°C; ir (Nujol, cm^{-1}): ν(C—H, CHO) 2840s, 2720s; ν(C=O), 1695s; ν(CSC), 612s; ^{1}H nmr ($CDCl_3$) δ: 1.80 (s, 3H, CH_3), 1.70 (m, 1H, H-7a), 1.96 (m, 1H, H-7e), 2.59 (m, 2H, H-6e,8e) 2.78, 2.90 (m's, 2H, H-6a,8a), 5.16 (dd, 1H, J_t = 17.2 Hz, J_g = 0.8 Hz, H-5*t*), 5.35 (dd, 1H, J_c = 11.0 Hz, J_g = 0.8 Hz, H-5*c*), 5.75 (dd, 1H, H-4), 7.4 (m, 5H, Ph), 9.26 (s, 1H, H-1); $^{13}C-\{^{1}H\}$ nmr ($CDCl_3$) δ: 22.11 (CH_3), 23.89, 27.21, 27.21 (C-7, C-6, and C-8), 50.44 (C-3), 67.13 (C-2), 116.25 (C-5), 140.97 (C-4), 141.4–126.9 (Ph), 189.12 (C-1); *m/e* (65°C); 280/279/278 (M^+), 251/250/249 (M − CHO), 150/149/148, 147, 131, 107/106/105, 91. *Anal.* calcd. for $C_{15}H_{18}OS_2$: C 64.71, H 6.52; found: C 64.8, H 6.4%.

*Compound 4*c

White crystalline solid, yield 11.7 g (80%), mp 77°C; ir (Nujol, cm^{-1}): ν(C—H, CHO) 2840s, 2720s; ν(C=O), 1712s; ν(CSC), 620s; ^{1}H nmr ($CDCl_3$) δ: 0.78 (t, 3H, J = 7.5 Hz, CH_3), 2.22(A) and 2.53(B) (ABX_3, 2H, J_{AB} = 14.5 Hz, $J_{AX} = J_{BX}$ = 7.5 Hz, diast. CH_2 of Et) 1.71 (m, 1H, H-7a), 1.94 (m, 1H, H-7e), 2.54, 2.61 (m's, 2H, H-6e,8e), 2.75, 2.91 (m's, 2H, H-6a,8a), 5.15 (dd, 1H, J_t = 17.4 Hz, J_g = 1.3 Hz, H-5*t*), 5.49 (dd, 1H, J_c = 11.3 Hz, J_g = 1.3 Hz, H-5*c*), 6.46 (dd, 1H, H-4), 7.35 (m, 5H, Ph), 9.26 (s, 1H, H-1); $^{13}C-\{^{1}H\}$ nmr ($CDCl_3$) δ: 8.92, 24.62 (CH_3CH_2), 24.10, 27.46, 27.46 (C-7, C-6, and C-8), 55.95 (C-3), 68.41 (C-2), 118.76 (C-5), 127.55–137.00 (Ph), 136.62 (C-4), 189.07 (C-1); *m/e* (70°C): 294/293/292 (M^+), 265/264/263 (M − CHO), 150/149/148, 147, 145, 107/106/105, 91. *Anal.* calcd. for $C_{16}H_{20}OS_2$: C 65.71, H 6.89, O 5.50; found: C 65.5, H 7.0, O 5.5%.

*5*a–*5*c

Raney nickel (Aldrich Chemicals, 50-μ particle size, 30 g) was washed with water until the washings were neutral. The water was replaced by acetone (100 mL) and the mixture stirred under reflux for 2 h. The acetone was then replaced by an ethanol (anhydrous for **4***a*) solution of **4***a*–**4***c* (0.002 mol in 70 mL) and the mixture stirred for ca. 8 h (24 h for **4***a*. Monitor by tlc, 18% ethyl acetate/petroleum ether 35–60°C bp). Upon removal of the ethanol solvent (*in vacuo*), the residue was extracted with diethyl ether (3 × 100 mL). The combined extracts were filtered through Florisil, dried ($MgSO_4$), and reduced in volume to yield an oil. Column chromatography (18% ethyl acetate/petroleum ether 35–60°C bp) yields **5***a*–**5***c*.

*Compound 5*a

Volatile colourless liquid, difficult to free from solvent. Yield and analysis therefore precluded; ir (film, cm^{-1}): ν(C—H, CHO) 2810s, 2710s; ν(C=O) 1720s; ν(C=C) 1638m; ν(=CH_2) 920s, 768s; 705s; ^{1}H nmr ($CDCl_3$) δ: 0.84 (t, 3H, J = 7.4 Hz, CH_2CH_3), 1.12 (s, 3H, CH_3), 1.44(A) and 1.46(B) (ABX_3, 2H, J_{AB} = 14.0 Hz, $J_{AX} = J_{BX}$ = 7.4 Hz, diast. CH_2 of Et), 2.33 (d of AB quartets, 2H, δ_A = 2.29, δ_B = 2.37, J_{AB} = 15.0 Hz, J_{12} = 2.8 Hz, diast. *X-ray crystallographic study of (*R*)-4*c

A single crystal of what proved to be (*R*)-*4c* ($C_{16}H_{20}OS_2$, mol. wt. = 292.45), grown by the slow evaporation of a diethyl ether solution of **4c**, was selected for the crystallographic study. The crystal was monoclinic, space group $P2_1$, with a = 6.7224(9), b = 7.0172(3), and c = 16.269(2) Å, β = 98.443(6)°, and with d_{calcd} = 1.280 g cm^{-3} for Z = 2 and V = 759.1 $Å^3$. The intensity data were measured at 22°C on an Enraf–Nonius CAD4-F diffractometer (graphite monochromated Cu-K_α radiation, ω–2θ scans at a scan rate of 0.91–10.06° min^{-1} and scan range (deg in ω) of 0.90 + 0.14 tan θ). The size of the crystal used for data collection was approximately 0.16 × 0.30 × 0.31 mm. A total of 1698 unique reflections was measured for θ < 75° of which 1536 had $I \geq 3\sigma(I)$ (data collected for $+h$, $+k$, $\pm l$). The intensities of three check reflections, measured every hour throughout the data collection, showed only small random fluctuations. The data were processed[4] and corrected for absorption (12, 13) (μ = 30.3 cm^{-1}). The structure[5] was solved by conventional heavy-atom methods, the coordinates of the sulfur atoms being determined from the Patterson function and those of the oxygen and carbon atoms from subsequent difference maps. Hydrogen coordinates and thermal parameters were calculated (C(sp^3)—H = 0.98 Å, C(sp^2)—H = 0.97 Å) and included as fixed atoms. The non-hydrogen atoms were refined anisotropically to R = 0.071 and R_w = 0.091 (function minimized $\Sigma w(|F_o| - |F_c|)^2$ where $w = 1/\sigma^2(F)$; $\sigma^2(I) = S + 2B + [0.025(S - B)]^2$ where S = scan count and B = normalized background count). In the final cycle, the maximum parameter shift was 0.09 σ (mean Δ/σ = 0.01) and the residual electron density ranged from −1.0 to 0.58 e $Å^{-3}$. Refinement of the opposite enantiomorph resulted in higher values of R and R_w. The R value ratios (rejected enantiomorph/accepted enantiomorph) were 1.009 on R, and 1.011 on R_w, both significant at >99.5% probability level (14). The atomic scattering factors used were taken from Cromer and Mann (15) and (for hydrogens) Stewart *et al.* (16), and anomalous scattering factors (for S and O atoms) were taken from Cromer and Liberman (17).

[4] The computer programs used include locally written programs for data processing and locally modified versions of the following: ORFLS, full-matrix least-squares, and ORFFE, function and errors, by W. R. Busing, K. O. Martin and H. A. Levy; FORDAP, Patterson and Fourier syntheses, by A. Zalkin; ORTEP II, illustrations, by C. K. Johnson.

[5] A detailed account of the structure determination (Table 3), final atomic parameters (Tables 4 and, for hydrogen, 6), thermal parameters (Tables 5 and, for hydrogen, 6), torsion angles (Table 7), and a table of measured and calculated structure factor amplitudes (12 pages), are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

ANTONIO CERVILLA, JOSÉ A. RAMÍREZ, and ELISA LLOPIS. Can. J. Chem. **63**, 1041 (1985).

Complex formation occurring between *l*(−)malic acid and W(VI) has been investigated by polarimetric and cryoscopic measurements, and also by proton nmr spectroscopy. The complexing ability of malic acid depends on the metal–ligand ratio. With excess W(VI), four different complexes are formed. The pH of the medium is the principal variable controlling complex formation and the various interconversion equilibria. At high pH (>7.0), the stable complex is a monomer, while at lower pH values dimers predominate. Conditional dissociation constants of some species have been evaluated and they show that the complexes formed with excess W(VI) have a higher stability than those found when malic acid is in excess. Comparison of the proton coupling constants shows that the conformation of malic acid in its metal complexes depends on which reagent is in excess, and leads to a number of conclusions about the structure of the dimeric species.

ANTONIO CERVILLA, JOSÉ A. RAMÍREZ et ELISA LLOPIS. Can. J. Chem. **63**, 1041 (1985).

La formation de complexes entre l'acide malique et le W(VI) a été étudiée par polarimétrie, cryoscopie et spectroscopie ^{1}H nmr. Le pouvoir de coordination de l'acide malique dépend du rapport metal–ligande. Sous un excés de W(VI), quatre différents complexes sont formés; nous avons étudié leurs équilibres de formation et interconversion qui sont function du pH du milieu. Le complexe stable au plus haut valeur de pH est un monomére, tandis que les trois autres sont des diméres. Les constants conditionnelles de dissociation de quelques espéces ont été mesurées et leurs valeurs montrent que les complexes formés sous un excés de W(VI) sont plus stables que ceux qui sont formés en excés d'acide malique. La comparaison des constants de couplement du proton montre que la conformation de l'acide malique dépend du réactif qui est en excés et nous en tirons des conclusions sur la structure des espéces dimériques.

Introduction

The formation of complexes between W(VI) and *l*(−)malic acid (H_2L) has been investigated earlier by conductimetric, potentiometric, and polarimetric methods (ref. 1, and references therein).

In excess of H_2L, previous papers showed that malic acid can form, with W(VI) (1) or Mo(VI) (2), three different complexes which are similar to those formed by tartaric (3), oxalic (4), and lactic (5) acids: one monomeric 1:2 (metal/ligand) species and two dimeric species of stoichiometry 2:2, which are stable in a more acidic medium.

However, it is worth emphasizing that in contrast to what was observed for the above ligands and for the malonic acid (6) and sorbitol (7), the complexation behaviour of the malic acid depends on which reagent (W(VI) or H_2L) is in excess. As we shall see, with excess W(VI), the malic acid gives rise to other different complex species, pointing out that there must be some essential structural difference between the malic acid and the above ligands.

On the other hand, in a more recent paper, V. Gil *et al.* (8) have reported that the ^{1}H nmr spectra of a solution of Na_2WO_4 and H_2L show several X-type signals, arising from H—C—OD protons, that reveal the formation of three different complexes: two 1:2 metal/ligand monomeric species and one dimeric, of 2:2 stoichiometry. (A fourth 2:1 complex having an ABX spectrum whose X part was very broad and of low intensity could also be considered.) These authors also found that the conformation of the complex species depended on the pH and on which reagent was in excess; however, in spite of what would be expected, they found that the monomeric species were more stable at lower pH than the dimeric ones.

This paper tries to complete the study of the W(VI) – malic acid system and is directed, together with the data already published, toward elucidating the relationship between ligand structure and complex-formation ability for oxotungsten– and oxomolybdenum–ligand species.

Results and discussion

Evidence for the different complexes

In curve A of Fig. 1 we have plotted the changes in the rotatory power, $\hat{D}$, produced by the neutralization with NaOH of a solution 10^{-2} *M* in malic acid (H_2L). This curve was modified when the neutralization was carried out in the presence of Na_2WO_4, which forms stable complex species in solution. Curve C shows the effect produced by the addition of a constant Na_2WO_4 excess to the malic acid solution ($W(VI)/H_2L = 25$). In this curve, given that in the presence of a large excess of W(VI) we can assume that all the malic acid will be complexed, the only contributions to the rotatory power of the solution are those due to the complex species themselves. Five discontinuities can be distinguished: at pH = 10.00, 7.25, 5.50, 4.00, and 1.50. These discontinuities or breaks define five pH zones: (a) 10.00 > pH, the $\hat{D}$ values correspond to the free *l*(−)malate ions, meaning that there is no interaction between the WO_4^{2-} and L^{2-} ions; (b) 10.00 > pH > 7.25, the noticeable rotatory power increase by acidification must be due to the formation of a complex species, and at its maximum (pH = 7.25) we can consider that all the ligand will be forming this complex; (c) 7.25 > pH > 5.50, in this pH region the rotatory power fall can be related to the presence of a second complex in equilibrium with the first one; (d) 5.50 > pH > 4.00, in this pH interval there is a rotatory power increase, implying the existence of a third complex which produces a maximum of $\hat{D}$ at pH = 4.00; (e) 4.00 > pH > 1.50, finally, further acidification gives a drop of $\hat{D}$, which becomes stabilized at pH = 1.50. At this pH the $\hat{D}$ value is different from the one due to the free malic acid, showing the existence of a fourth complex in this pH medium.

On the other hand, curve B shows that the behaviour of this

[1] Revision received October 22, 1984.

TABLE 1. Rotatory power as a function of tungstate concentration[a]

v(mL)	$C_w(10^2)$ (M)	$\hat{D}$(degrees)	v(mL)	$C_w(10^2)$ (M)	$\hat{D}$(degrees)
0.50	2	0.116	3.00	12	0.298
0.75	3	0.152	3.50	14	0.309
1.00	4	0.179	4.00	16	0.322
1.50	6	0.227	4.50	18	0.328
2.00	8	0.258	5.00	20	0.335
2.50	10	0.282	6.00	24	0.347

[a] $\hat{D}_{\text{lim}} = 0.430$; pH = 7.40; λ = 436 nm; v_0 = 1 mL of H_2L ($a_0 = 0.25\ M$) v, mL of Na_2WO_4 ($b_0 = 1\ M$); V_T = 25 mL.

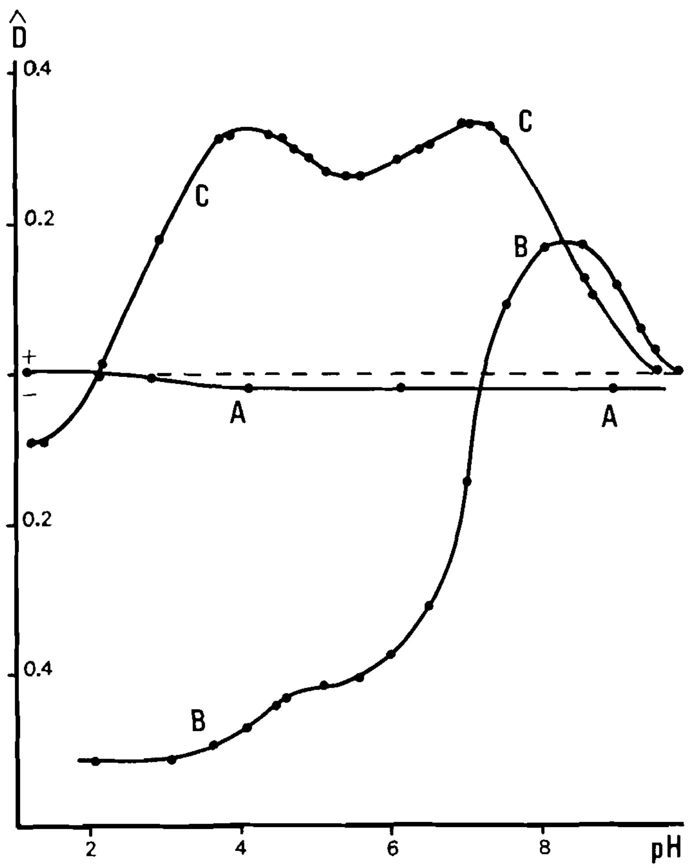

FIG. 1. Optical activity variations as a function of pH. Curve A: $10^{-2}\ M$ in malic acid; curve B: complexes formed with excess of H_2L, $10^{-2}\ M$ in Na_2WO_4 (L/W = 25); curve C: complexes formed with excess of W(VI), $10^{-2}\ M$ in H_2L (W/L = 25).

system when there is an excess of ligand in the solution is totally different from that observed when it is in deficit. When excess of ligand is present (H_2L/W(VI) = 25), the changes in the rotatory power with pH reveal the formation of three different complexes (one 1:2 and two 2:2) whose formation from tungstate and malate ions requires 2, 2, and 2.5 H^+ moles per mole of W(VI), respectively (1).

From the rotatory power data plotted in curves B and C it is seen that below pH 7.25 the complex species present when the ligand is in excess have a strong levorotatory character, while in excess of metal the complex species stable at lower pH (<2.0) has a slightly levorotatory character and the other three are dextrorotatory.

Stoichiometry and stability constants of the complexes

The above observations imply that the composition of these complexes cannot be determined by Job's method since its application requires that a single species is present in solution independent of which reagent is in excess (10).

In order to determine the stoichiometry and stability constants of the complexes formed in excess of W(VI), the generalized molar-ratio procedure (11) and Asmus "straight-line" method (12) were applied. For both methods, the presentation here will follow in detail these earlier papers, where any symbols or notations not defined in the present report will be found and explained.

A series of samples containing a constant amount of $l(-)$malic acid ($C_L = a_0 v_0/V_T$) and varying concentrations of W(VI) ($C_W = b_0 v/V_T$) was prepared by dilution of the appropriate amounts of the standard solutions (a_0, b_0) until V_T = 25 mL. All the solutions were made 1 M in $NaClO_4$ and their pH adjusted to the required value by adding appropriate amounts of concentrated NaOH and (or) $HClO_4$ (70%). The measured values of the rotatory power, $\hat{D}$ (degrees), of the solutions are given in Table 1 at pH = 7.40, first break.

For the application of the generalized Asmus' method, we may assume a general equilibrium of the type:

$$\delta L + n\delta\, W \rightleftarrows L_\delta W_{n\delta}$$

The mass action law can be written as:

$$K' = K_d^{1/\delta} = [L] \cdot [W]^n/[L_\delta W_{n\delta}]$$

and the following relation holds:

$$[1] \quad \frac{\hat{D}^{1/\delta}}{v^n} = \frac{a_0 b_0^n v_0}{V_T^{\,n+1}}\, \epsilon^{1/\delta} \frac{1}{K'} - \frac{(b_0)^n}{(V_T)^n}\, \delta\epsilon^{1/\delta - 1} \frac{1}{K'}\, \hat{D}$$

where ϵ denotes the specific molar rotation of the complex.

According to this relation the graphical plot of $\hat{D}^{1/\delta}/v^n$ vs. $\hat{D}$ is linear only when values δ and n are chosen correctly.

In Fig. 2 we show the plots obtained at pH = 5.60. The dimeric character of this complex (δ = 2) and its stoichiometric ratio 1:1 (n = 1) are clearly inferred from it. For this straight line the abscissa at the origin leads to the value (ϵ = 42.6)[2] which allows us to calculate from the slope the conditional stability constant K_d of the complex as $K_d = 3.41 \times 10^{-7}$.

From the data at pH = 7.40, the stoichiometric coefficients found for this complex are δ = 1 (monomeric species) and n = 1, with a conditional stability constant of $K_d = 5.51 \times 10^{-2}$.

On the other hand, the generalized molar-ratio method can also be applied using the data in Table 1. In this method, the formation of a single complex is described by an equilibrium of the type:

$$mL + nW \rightleftarrows L_m W_n$$

[2] In, deg mol^{-1} L dm.

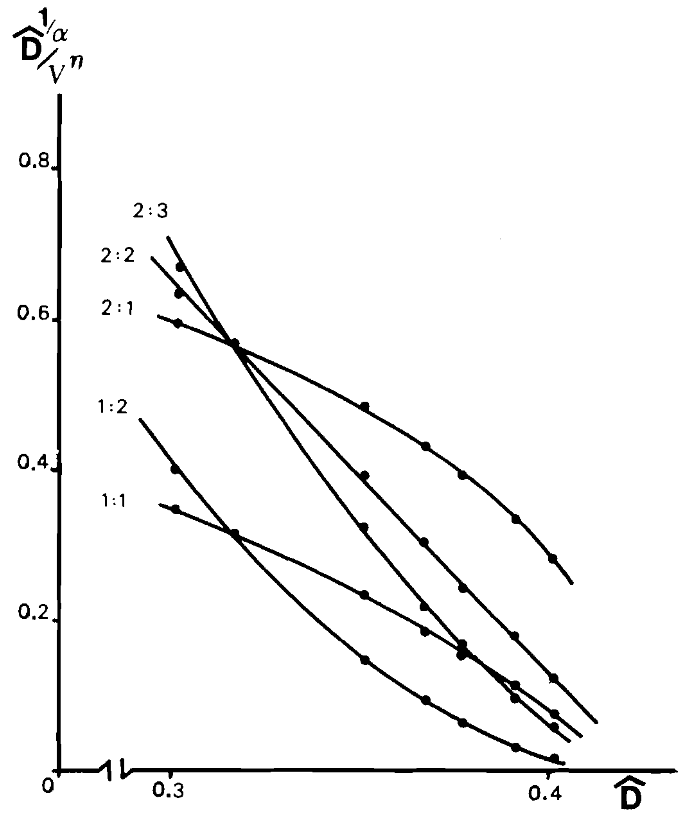

FIG. 2. Asmus modified method, pH = 5.60. ($\hat{D}^{1/\delta}/v^n$) vs. $\hat{D}$ for selected δ (degree of condensation) and n (stoichiometric ratio) values. Only when δ = 2 and n = 1 (stoichiometry 2:2) is a straight line obtained. $C_L^0 = 2 \times 10^{-2}$ M; v, mL of Na_2WO_4 0.25 M ($2.0 < v < 10.0$); V_T = 25 mL.

and now, the mass action law can be written as:

$$[2] \quad K^* = (1/K_{eq}C_L^{m-1})^{1/n} = \frac{C_W(x) - nC_Lx/m}{[x/m(1-x)^m]^{1/n}}$$

with $K_{eq} = 1/K_d$; C_L the concentration of ligand ($C_L = a_0v_0/V_T$), and C_W the metal concentration given by $[L_mW_n] = xC_L/m$ ($0 < x < 1$), where $x = \hat{D}/\hat{D}_{limit}$, and $\hat{D}_{limit}$ is equal to $\hat{D}$ of a solution having a large enough C_W/C_L ratio to assume that $[L_mW_n] = C_L/m$.

Plotting K^* against x, eq. [2] only leads to a horizontal line for the correct m and n values. As illustrated in Fig. 3, we have plotted the results obtained using the data given in Table 1 at pH = 7.40: $m = n = 1$, and the conditional stability constant is $K_d = 5.01 \times 10^{-2}$. At pH = 5.60 the m and n values found are $m = n = 2$, with the constant $K_d = 3.97 \times 10^{-7}$. These results are in excellent agreement with our Asmus' method results.

For the stoichiometries of the species present at lower pH, the above methods are unreliable because the high stability of the complexes makes the variation of the concentration of complex formed with the metal/ligand ratio negligible.

For these two species we have obtained indirect evidence of their stoichiometry from the ^1H nmr spectra. The low-pH ^1H nmr spectra recorded for a solution of 1:1 composition show a complete conversion of unbound to bound ligand resonances, and these complexes are so stable that a slight excess of ligand immediately gives rise to additional nmr signal corresponding to the free ligand. This fact points out that both species have a stoichiometric ratio W/L = 1. Furthermore, we shall present below additional polarimetric and cryoscopic results which provide a similar conclusion on the stoichiometry of these complexes.

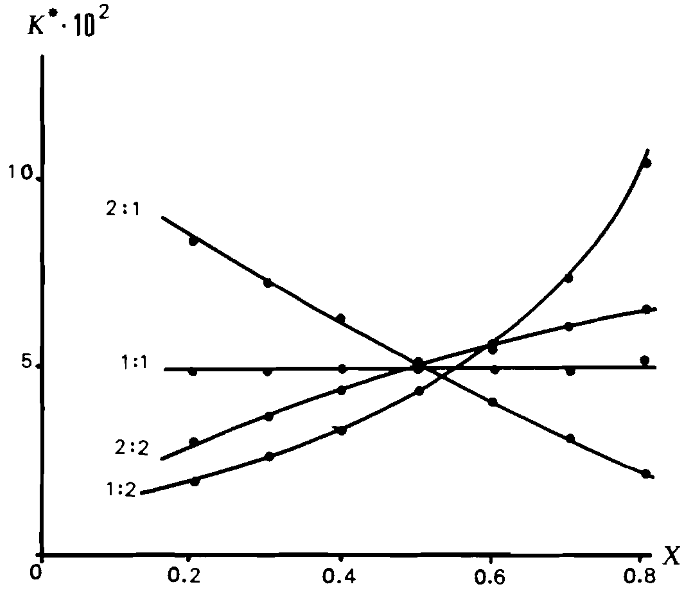

FIG. 3. Molar-ratio generalized method, pH = 7.40. K^* vs. x function only leads to a horizontal line for a stoichiometry 1:1.

Formation and interconversion equilibria

Given that all the complexes present when W(VI) is in excess have a 1:1 composition, the interconversion equilibria between different species can be written according to equilibria of the type:

$$[3] \quad \text{Complex A} + n\text{H}^+ \rightleftarrows 1/a \text{ Complex B}$$

in which the value of a is related to the degree of condensation of the complexes. For these equilibria we can write (9):

$$\text{constant} = \log(\beta^{1/a}/1 - \beta) + n\,\text{pH}$$

where constant = $\log K + 1/a \log a - \log C(1/a - 1)$, C being the initial concentration of the complex A and β the molar fraction of complex B formed.

Data in Fig. 1 (curve C) have been used to perform calculations which permit the determination of the coefficients n and a. As we have noted above, there are four pH zones, defined by the breaks, in which we can assume that an equilibrium of the type [3] takes place. For each of these intervals, the values of β can be calculated, for each pH, according to the relation:

$$[4] \quad \hat{D} = \hat{D}_B\beta + (1 - \beta)\hat{D}_A$$

where $\hat{D}$ is the value of the rotatory power at the pH mentioned and $\hat{D}_A$ and $\hat{D}_B$ the rotatory power corresponding to those pH values for which the curve C has the breaks, assuming that practically all the ligand is present in a single complex species.

Equation [4] implies that if we plot $\log(\beta^{1/a}/1 - \beta)$ as a function of pH for different values of $1/a$ we will obtain a linear relationship only for the correct value of a, and the slope of this straight line gives us the value of n. A summary of the results obtained is given in Table 2.

According to these data, and given that the stoichiometries of the complexes are known, we can write the following complexation equilibria, valid when W/L > 1:

TABLE 2. Calculated values of the a and n coefficients in the formation and interconversion reactions

pH zone	Proposed equilibrium	$\hat{D}$ limits values	a	n
9.50 > pH > 7.00	$W + L + nH^+ = 1/a$ I	$\hat{D}_{I} = 0.336$	1	1.07
7.00 > pH > 5.50	$I + zW + nH^+ = 1/a$ II	$\hat{D}_{II} = 0.267$	2	1.02
5.50 > pH > 4.00	$II + zW + nH^+ = 1/a$ III	$\hat{D}_{III} = 0.325$	1	2.05
4.00 > pH > 1.00	$III + zW + nH^+ = 1/a$ IV	$\hat{D}_{IV} = -0.090$	1	1.05

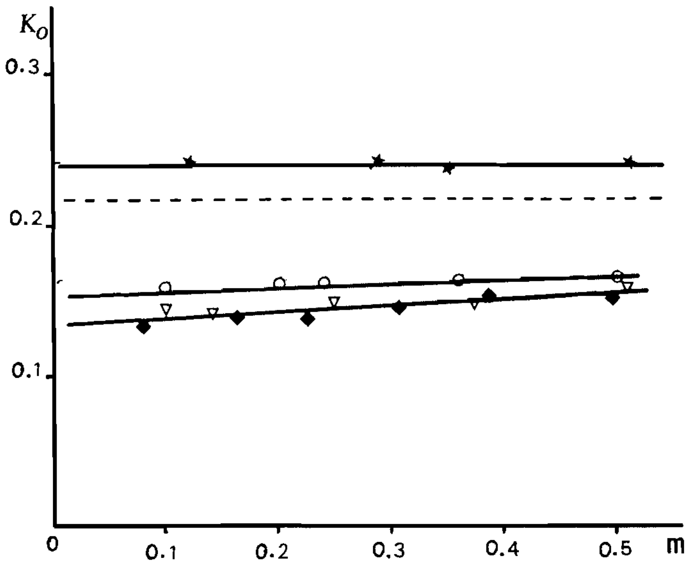

FIG. 4. Cryoscopic molal decreases K (°C) vs. molality (moles of W(VI)/kg of solvent). Malate/tungstate = 1, and (+) H^+/WO_4^{2-} = 1, (▽) H^+/WO_4^{2-} = 2, (◆) H^+/WO_4^{2-} = 3, (○) H^+/WO_4^{2-} = 3.5.

9.50 > pH > 7.00

$$WO_4^{2-} + C_4H_4O_5^{2-} + H^+ \rightleftarrows \{WO_2(C_4H_3O_5)(OH)_2\}^{3-}$$

7.00 > pH > 5.50

$$\{WO_2(C_4H_3O_5)(OH)_2\}^{3-} + H^+ \rightleftarrows 1/2\{[WO(OH)_2(C_4H_3O_5)]_2O\}^{4-} + 1/2H_2O$$

5.50 > pH > 4.00

$$\{[WO(OH)_2(C_4H_3O_5)]_2O\}^{4-} + 2H^+ \rightleftarrows \{[WO(OH)_2(C_4H_4O_5)]_2O\}^{2-}$$

4.00 > pH > 1.00

$$\{[WO(OH)_2(C_4H_4O_5)]_2O\}^{2-} + H^+ \rightleftarrows \{[WO(OH)(C_4H_4O_5)]_2O(OH)\}^{-} + H_2O$$

In summary, the formation of these complexes from WO_4^{2-} and $C_4H_4O_5^{2-}$ ions requires 1.0, 2.0, 3.0, and 3.5 equivalents of H^+ ions per each mole of W(VI) complexed, respectively, and the degree of condensation calculated agrees with those found by the stoichiometric methods.

Saline cryoscopy

In order to check the above polarimetric results we have applied an independent technique, saline cryoscopy in Glauber salt (13). The particular method used was the stationary state procedure (14).

It should be mentioned that the rotatory power of an equimolar solution of W(VI) and ligand has a dextrorotatory character, and the values of the rotatory power measured indicate that in this solution the ligand is predominantly involved in the formation of the complexes described when W(VI) is in excess (data not reported). This fact agrees with the higher stability constants found for these complex species.

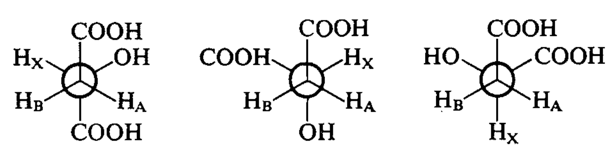
In Fig. 4 we have plotted the molal decrease (K) in the transition temperature of $Na_2SO_4 \cdot 10H_2O$ as a function of the molality of solutions (moles of W(VI)/kg of Glauber salt) for a series of samples containing malate/tungstate and H^+/tungstate ratios corresponding to the above deduced stoichiometries. H^+ ions were added to the solutions as $NaHSO_4$, according to Haase's observation (15). Urea was employed as a non-electrolyte to determine the cryoscopic constant of the apparatus, resulting in a value equal to 0.22°C/mol urea.

Extrapolation of the straight lines in Fig. 4 to infinite dilution leads to K_0, the molal decrease at the origin. These values can be used to calculate n, the number of cryoscopically active particles per W(VI) in the solutions since $n = K_0/0.22$. The results obtained agree with the polarimetric data.

Structural considerations

Since the vicinal H—H coupling constant J_{H-H} depends among other factors on the H—C—C—H bond angle, ^{1}H nmr spectroscopy has proved particularly suitable for the study of the conformation of malic acid in the complexes where the binding is inert.

For the free malic acid, the J_{H-H} values have been found to vary with pH, essentially as a result of conformational changes caused by electrostatic and steric effects. Those changes may be discussed in terms of the populations of the three staggered rotational isomers (16):



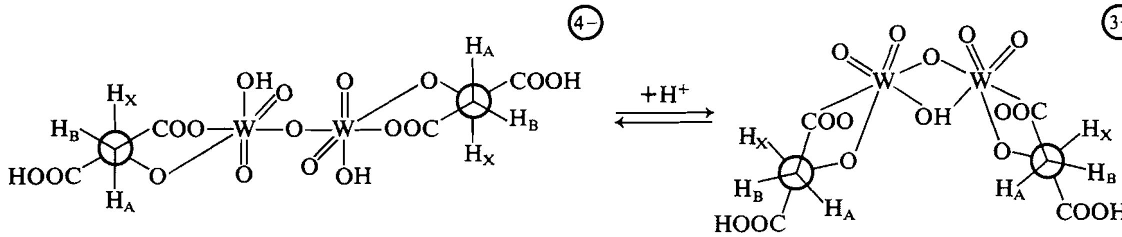
a **b** **c**

By assuming reasonable values for vicinal coupling constants in the three rotamers (J_{trans} = 16.0 Hz and J_{gauche} = 4.0 Hz) it has been possible to deduce, from the observed coupling constants, the relative populations of the isomers **a**, **b**, and **c** as a function of the pH (17, 18). The assignment of protons A and B has been based on the reasonable assumption that the malate ions exist mainly in form **a**, thus justifying $J_{AX} > J_{BX}$. Complexation with W(VI) leads to a negligible low shift of the AB pattern and a larger low field shift of the X multiplet.

In the presence of excess ligand, all spectra obtained for the complexes exhibit three broad peaks in the X-region that are nearly pH independent. This fact suggests that the conformation of the malic acid is fundamentally the same in all of them, but a complete analysis was not possible (see Table 3). Only $J_{AX} + J_{BX}$ = 12.5 Hz could be calculated for the complex present at pD = 5.00.

This agrees with the result obtained by Gil *et al.* (8), who found that, at pD = 5.50 using a 100 MHz spectrometer, the spectrum showed more lines, and separate values $J_{AX} = 10.5$ Hz and $J_{BX} = 2.4$ Hz could be calculated. According to these authors, the increase of J_{AX} and decrease of J_{BX} observed on going from the free ligand (malate ions at pD = 5.50; J_{AX} = 9.7 and J_{BX} = 3.3 Hz) to the complex with W(VI) shows that the formation of these complexes stabilizes conformation **a**. It was concluded that, in the presence of an excess ligand, the malic acid acts as bidentate ligand through a carboxylic acid centre and a β-positioned alcoholic group.

However, as mentioned in the Introduction, if we consider that these complexes are dimers with a $H_2L/W(VI) = 1$ ratio (1), and not monomers of 1:2 composition as indicated by Gil, the following structures can be proposed. In both structures, the ligand has the same **a** conformation:



Evidence for similar structures has been obtained for oxalate (4), malonate (6), lactate (5), tartrate (3), and sorbitol (7) derivatives, and the presence of a double bridge in protonated species has also been previously suggested.

In Fig. 5, ^{1}H nmr spectra when W(VI) is in excess are given at pD values where only one complex species is predominant. In this set of ABX spectra, the spectrum which does not appear is that recorded for the monomeric 1:1 complex (pH = 7.50), owing to the proximity of the X part to water which prevented a reliable measurement of the coupling constant.

Two aspects of these spectra are of interest. First, in agreement with our polarimetric findings, the ^{1}H nmr spectra show that for excess metal three 2:2 tungstate–malate complexes can be formed depending on pD. Second, these complexes give rise to room-temperature spectra with narrower lines than those obtained with excess ligand. This might indicate that, in agreement with the above calculated values of K_d, the complexes formed are more dissociated under these conditions. In fact, as has been already reported (8), on lowering the temperature the spectra in the presence of excess ligand become appreciably narrower and, accordingly, the broadening at room temperature may be assigned to ligand exchange.

In Table 3 are summarized the values of J_{AX} and J_{BX} obtained from ABX analysis of the spectrum of each of the three 2:2 complexes (19, 20). However, for the complex stable at pD = 2.60, due to the coincidence of peaks in its ABX spectrum, only ($J_{AX} + J_{BX}$) could be calculated.

The value of J_{BX} = 4.4 Hz obtained for the dimeric complex at higher pD is essentially a *gauche* coupling constant, whereas the value of J_{AX} = 8.6 Hz implies a mixture of *trans* and *gauche* arrangements for A and X. The conclusion is that, in this complex, forms **a** and **c** could have the most important contributions. However, since the complex is quite strong, ligand exchange is slow, and internal rotation of the ligand would be difficult in the complex. The observed coupling constant might better be interpreted in terms of a single conformation. Among the three staggered rotamers, conformation **a** is the one that is more in agreement with the observed J-values. However, J_{BX} is high and J_{AX} low enough to postulate a twisting of structure **a**, in the sense that the H_B—C—C—H_X dihedral angle increases with a concomitant decrease in H_A—C—C—H_X.

At pD = 4.50, according to Gil *et al.* (8), the observed values of J_{AX} = 1.2 Hz and J_{BX} = 6.3 Hz are close to the expected values for a conformation of the ligand in which the A and B protons are in a *gauche* arrangement with respect to the X proton. Thus **c**, or a conformation close to it, appears to be the preferred geometry in this case.

From these nmr results we can propose the following structures for the three 2:2 complexes formed in excess of W(VI):

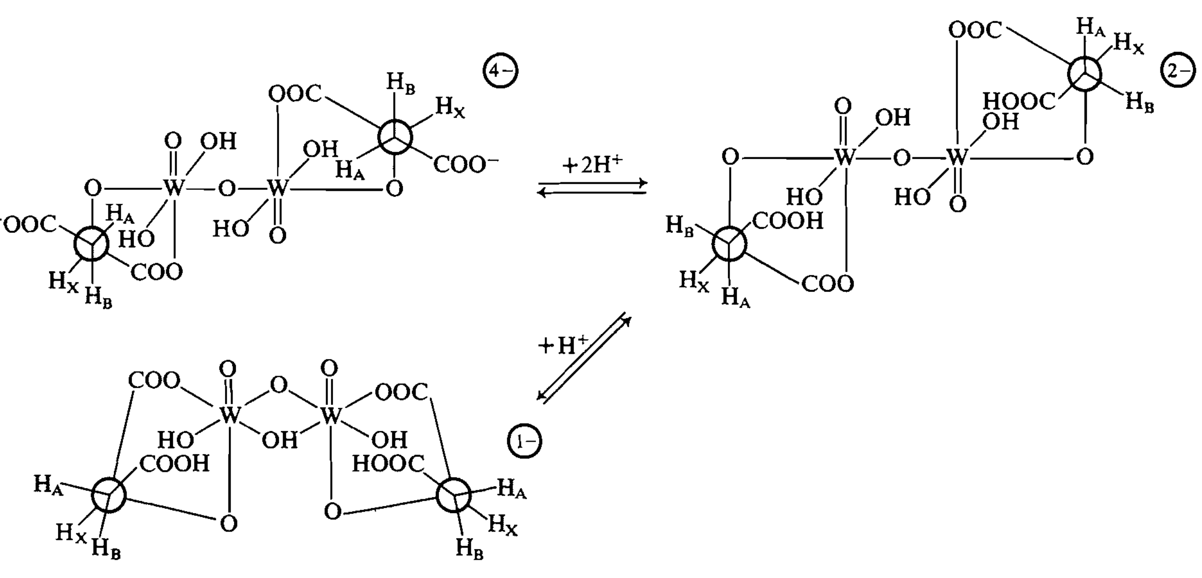


TABLE 3. Proton coupling constants and chemical shifts (in Hz) referred to *tert*-butanol, at 90 MHz[a]

Complex ion	pD	J_{AB}	$(J_{AX} + J_{BX})$	J_{AX}	J_{BX}	$(\nu_x - \nu_B)$	$(\nu_B - \nu_A)$
$\{[WO(C_4H_3O_5)(OH)_2]_2O^{4-}\}$	6.50	14.5	13.0	8.6	4.4	234.43	7.64
$\{[WO(C_4H_4O_5)(OH)_2]_2O^{2-}\}$	4.40	18.0	7.5	1.2	6.3	229.24	16.50
$\{[WO(C_4H_4O_5)(OH)]_2O(OH)^{1-}\}$	2.60	—	11.6	—	—		

[a] Spectra are shown in Fig. 5.

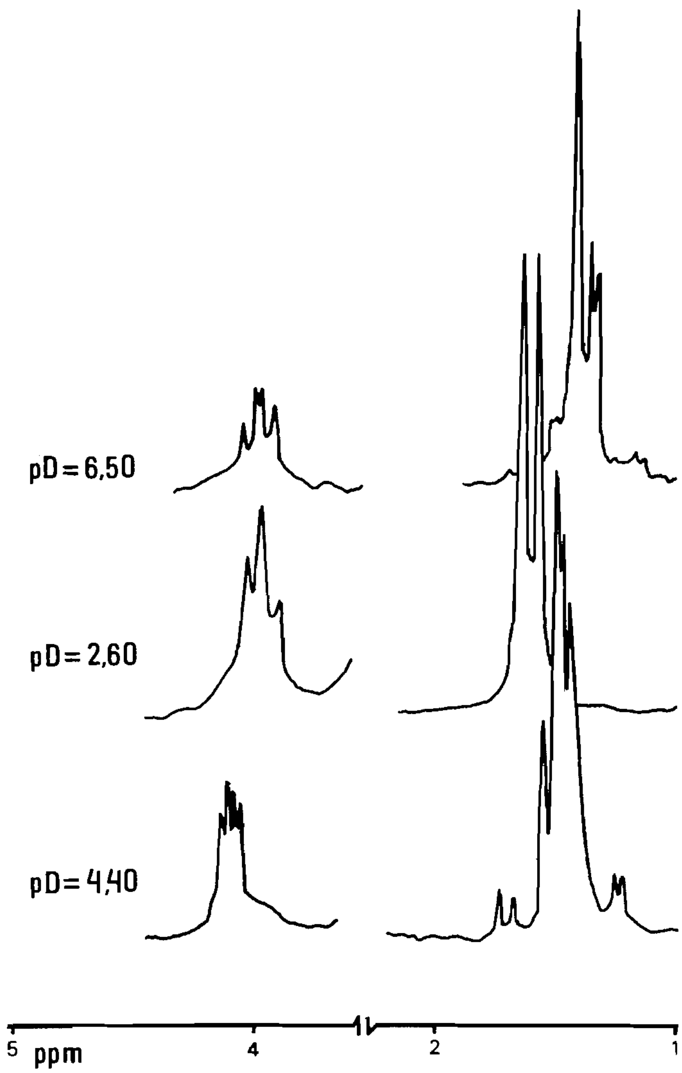

FIG. 5. 90-MHz Proton nmr spectra of a 4:1 solution of tungstate/malic acid in D_2O, for a range of pD values.

In all these structures we have assumed a bidentate complexing ability for the malic acid, which implies a chelation to each W atom through a carboxylic and an α-positioned alcoholic group. However, for the two last species which are stable at a lower pD, a facial tridentate coordination might also be expected. The five-membered rings in these complexes should be more stable than the six-membered rings formed in the complexes when ligand is in large excess. The higher stability of the former can thus be rationalized on the basis of the formation of five-membered, instead of six-membered, chelate rings. This feature would also account for previous reports of varying stabilities of the 2:2 Mo(VI)–ligand complexes with oxalic acid (4), malonic acid (6), and succinic acid (21). A dependence on the length of the carbon chain in the organic acid molecule, and thus chelate ring size, appears to exist. The oxalate complex is the most stable, the value of the dissociation constant for the malonate complex being two orders lower than for oxalate. No complex formation could be detected for the succinate complex (22).

Experimental

Solutions were prepared using analytical grade sodium tungstate and *l*(−)malic acid.

Rotatory power and pH were measured in a manner similar to that described previously (1). All samples were prepared to be 1 *M* in $NaClO_4$ to maintain the ionic strength of the medium and the pH was adjusted to the required value by adding the appropriate amounts of concentrated NaOH and (or) $HClO_4$ (70%).

The optical rotations of the solutions measured immediately and again after 24 h showed that immediate formation of stable complexes occurred.

For the cryoscopic measurements, a Knauer electronic measuring instrument was employed, using only a thermistor temperature probe. The standard sample volume was 0.15 mL and the reproducibility in the freezing point of the Glauber's salt was ±0.002°C. For concentrated solutions, the measuring error was smaller than 1%.

Samples for nmr spectroscopy were prepared by dissolving the appropriate amounts of Na_2WO_4 and *l*(−)malic acid in D_2O. In order to reduce the OH signal, the sample mixture was lyophilized from a D_2O solution and adjustment of the pD was done by dropwise addition of dilute DCl and NaOD solutions.

Proton nmr spectra were obtained at 90 MHz on a Perkin–Elmer R-32 spectrometer at a probe temperature of 35 ± 1°C.

$^{13}C-^{13}C$ connectivity (INADEQUATE) experiments have been used to reassign the ^{13}C spectrum of taraxasteryl acetate. This shows that there were ten errors in an earlier ^{13}C spectral assignment for this compound. An X-ray diffraction investigation of taraxasterol shows that ring E adopts a slightly distorted boat conformation. It is suggested that severe steric interactions in the chair form force it to adopt this unusual conformation. On the basis of the $^{1}H-^{1}H$ coupling constants, it is concluded that taraxasteryl acetate adopts a very similar conformation in solution. Crystals of taraxasterol–ethanol solvate are orthorhombic, space group $P2_12_12_1$ wih a = 7.447(1) Å, b = 17.637(2) Å, c = 22.269(4) Å, U = 2925 Å^3, and D_{calc} = 1.07 g cm^{-3} for Z = 4.

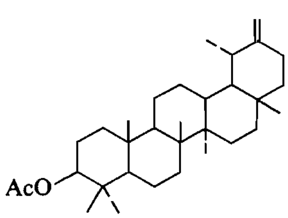
On a fait appel à des expériences de conjonction (INADEQUATE) du $^{13}C-^{13}C$ pour faire de nouvelles attributions du spectre du ^{13}C de l'acétate de taraxastéryle. Ces expériences ont permis de démontrer que la première interprétation du spectre du ^{13}C de ce composé comporte dix erreurs. Une étude par diffraction de rayons X du taraxastérol montre que le cycle E adopte une conformation bateau légèrement déformée. On suggère que c'est la présence de fortes interactions stériques dans la forme chaise qui oblige cette dernière à adopter cette conformation inhabituelle. En se basant sur les constantes de couplage $^{1}H-^{1}H$, on conclut que l'acétate de taraxastéryle adopte à peu près la même conformation en solution. Les cristaux du taraxastérol solvaté avec de l'éthanol appartiennent au groupe d'espace orthorhombique $P2_12_12_1$ avec a = 7.447(1) Å, b = 17.637(2) Å, c = 22.269(4) Å, U = 2925 Å^3, D_{calc} = 1.07 g cm^{-3} et Z = 4.

[Traduit par le journal]

Introduction

As part of an investigation of medicinal properties of natural products extracted from *Montanoa tomentosa* Cerv. (1), we isolated a white crystalline compound (mp 245–246°C) which, according to high resolution mass spectrometry, had the empirical formula $C_{32}H_{52}O_2$. Comparison with previously reported infrared (2), ^{1}H nmr (2), and ^{13}C nmr (3) spectral data and melting point data (2, 4) indicated that the compound was the pentacyclic triterpenoid taraxasteryl acetate, **1** (5). While this compound is known to occur in a wide variety of plants (2, 4), this represented the first report of its isolation from *Montanoa tomentosa*.



1

During the course of its characterization, we noted that there were at least six errors in the recently reported ^{13}C spectral assignments for **1** (3). Furthermore, certain of the coupling constants observed in the ^{1}H spectrum appeared to be inconsistent with the accepted stereochemistry (5) of **1**. Consequently, we undertook a more detailed nmr and X-ray diffraction investigation of **1** in order to obtain unambiguous spectral and stereochemical assignments. These investigations are reported below.

Results and discussion

(a) *Reassignment of the ^{13}C spectrum of 1*

As part of the characterizations of **1**, we applied spectral editing techniques to its ^{13}C spectrum. In Fig. 1, the ^{1}H-decoupled ^{13}C spectrum of the aliphatic region is reproduced, along with three edited subspectra (CH, CH_2, and CH_3), obtained using the pulse sequence DEPT (6). The latter spectra allow unambiguous assignment of ^{13}C peaks in terms of numbers of attached hydrogens. This revealed that there were at least six errors in the previously reported ^{13}C peak assignments (3) for **1** (see Table 1).

One possibility was simply that three pairs of carbons were interchanged (Table 1). However, it was uncertain whether these were the only incorrect assignments since spectral editing can only detect errors based on incorrect numbers of attached protons and not, for example, a pair of misassigned CH_3 groups. Consequently, we undertook a two-dimensional $^{13}C-^{13}C$ connectivity (INADEQUATE) experiment (7) in order to obtain an unambiguous total ^{13}C assignment of **1** based on carbon–carbon bond networks. The resultant spectrum is illus-

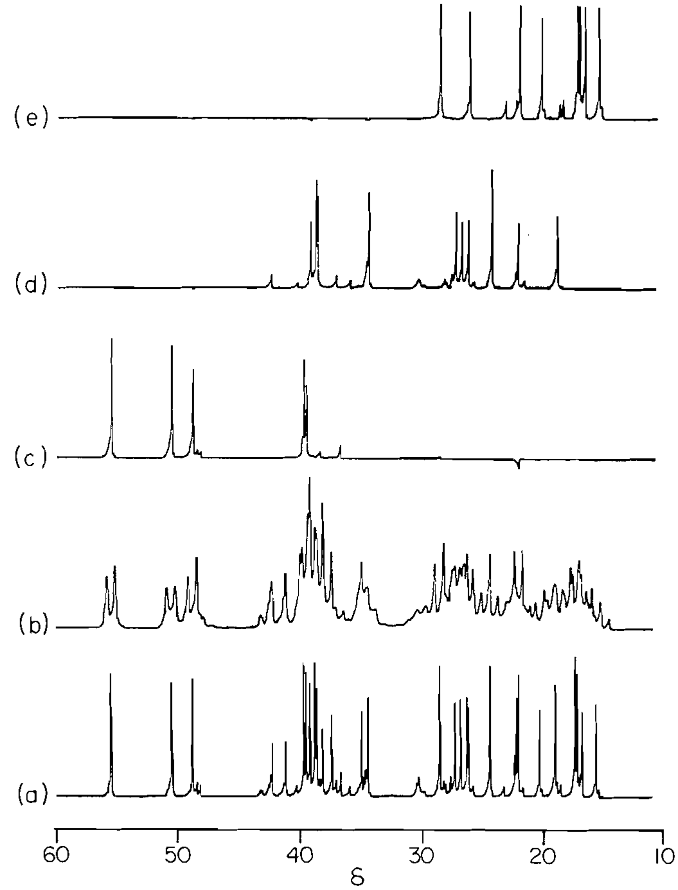


FIG. 1. (*a*) Normal ^{13}C spectrum of **1** for region δ 10–60; (*b*) SFORD spectrum; (*c*) subspectrum showing CH carbons only, obtained by DEPT spectral editing; (*d*) subspectrum showing CH_2 carbons only; (*e*) subspectrum showing CH_3 carbons only.

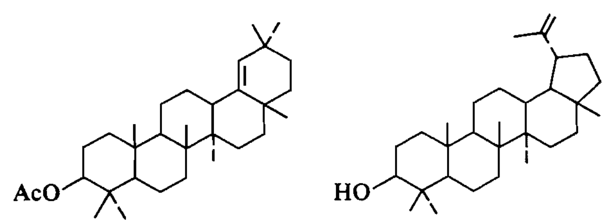
[a] ^{13}C chemical shifts in $CDCl_3$ (relative to $^{13}CH_3Si(CH_3)_3$). The first values are from this work while the values in brackets are from ref. 3.

[b] Number of attached protons for each ^{13}C peak as determined in this work by DEPT spectral editing. Incorrect values in brackets are from ref. 3 and were estimated from SFORD spectra.

trated in Fig. 2. Each directly bonded $^{13}C-^{13}C$ pair appears as a pair of AX or AB doublets having the same double quantum frequency, i.e. falling on the same horizontal line. Each doublet is centered about the corresponding chemical shift in the standard ^{1}H-decoupled ^{13}C spectrum with the doublet splitting, $^{1}J_{CC}$, typically being 35–70 Hz. Furthermore, each AX or AB spectrum must be symmetric about a line of slope 2 passing through the origin defined by the r.f. carrier (7). Due to these severe constraints, it is easy to distinguish data from artifacts and consequently establish the carbon–carbon connectivity pattern. The only unusual features in Fig. 2 concern the connectivities between C(20) and C(19) and C(21). The former peak is not observed since it lies outside the spectral window and digital filtering prevents folding in. However, C(20) still participates in double quantum coherence with C(19) and C(21). Based on the chemical shifts of these nuclei, the expected double quantum frequencies are, respectively, ca. 7300 Hz and 6150 Hz for C(19) and C(21). Since these lie outside the double quantum spectral window, these peaks appear folded in at respective double quantum frequencies of ca. −4700 Hz (doublet a in Fig. 2) and −5850 Hz (doublet b in Fig. 2). Note that there is no digital filtering in the double quantum dimension.

Final assignments are straightforward, based on the data in Fig. 2, and are given in Table 2. Individual carbons are also labelled on the stick diagram at the top of Fig. 2. These results reveal that there were ten misassigned ^{13}C peaks, all corresponding to protonated aliphatic carbons, in the earlier assignment (3). This represents over 40% of the 24 carbons of this type in **1**. There are at least two possible reasons for this disturbingly large number of misassignments. The first is that single frequency off-resonance decoupled (SFORD) spectra (obtained at 20 MHz) were used to assign ^{13}C peaks (3). However, even a 50.1-MHz SFORD ^{13}C spectrum for the aliphatic region of **1** (see Fig. 1) is far too complex to allow reliable assignments of all carbon multiplicities. Figure 1 provides a striking illustration of why this obsolete technique should be abandoned in favor of spectral editing techniques such as DEPT (6), INEPT (8), or APT (9). It should be noted that while DEPT and INEPT require a spectrometer with a sophisticated pulse programmer and phase shifters, APT can be implemented even on routine pulsed FT nmr spectrometers (9).

The second possible source of errors is in the use of model compounds as aids in assignment. This assumes (a) that the spectra of the model compounds are correctly assigned and (b) that they are sufficiently similar in structure and stereochemistry to the compound in question to be reliable models. In the case of **1**, germanicol acetate, **2**, (10) and lupeol, **3**, (11) were used as models. However, both **2** and **3** differ significantly from **1** in the structure of ring E. Interestingly, seven of the ten misassigned carbons are either ring D or E carbons or CH_3 groups bonded to ring D and (or) E (see Table 2). In addition, C(12) is spatially proximate to $C(29)H_3$. The significance of these observations will become apparent in part (b).



2 **3**

(b) *Determination of the relative configuration and conformation of taraxasteryl by X-ray diffraction methods*

The accepted structure for taraxasterol is 3β,18α,19α-

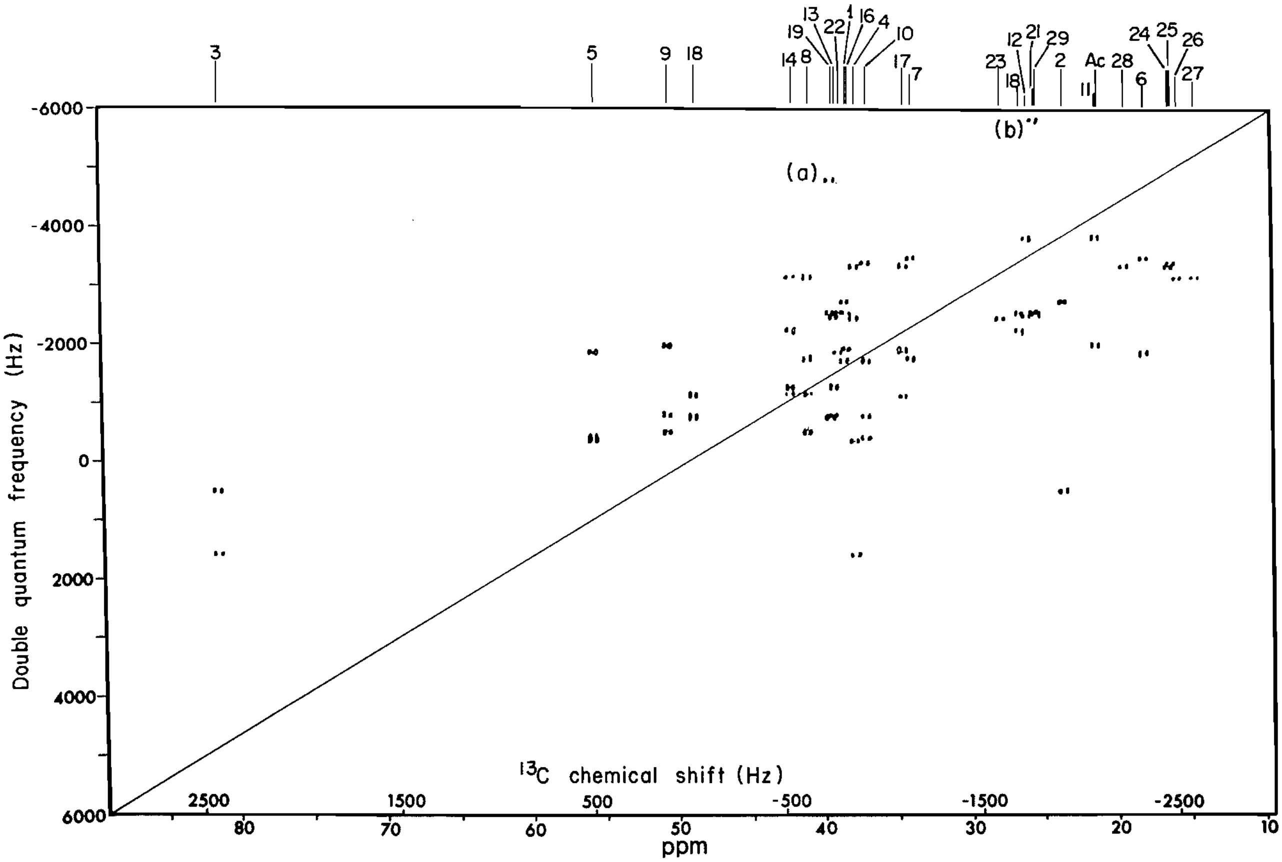


FIG. 2. Two-dimensional $^{13}C-^{13}C$ connectivity spectrum for **1**. Normal frequency axis is along the horizontal while the double quantum frequency is along the vertical. Peaks between coupled ^{13}C nuclei appear along the horizontal, distributed symmetrically with respect to the diagonal line. The final assignments are shown in the stick spectrum at the top. Doublets a (due to C(19)) and b (due to C(21)) are discussed in the text.

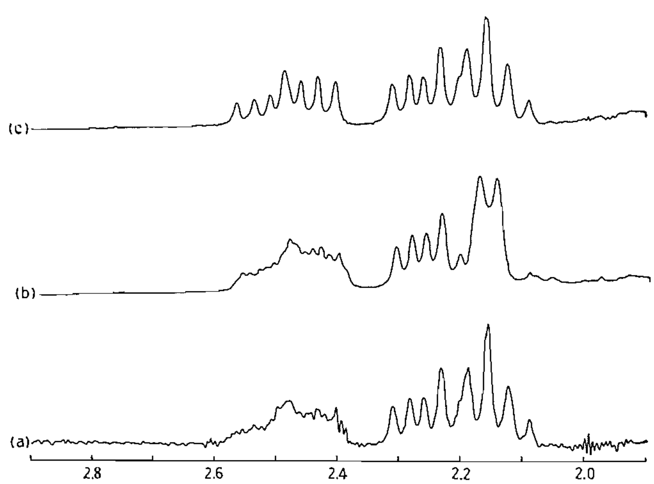

FIG. 3. ^1H spectrum of **1** in C_6D_6 showing allylic hydrogens. (*a*) Normal ^1H spectrum; (*b*) corresponding spectrum with decoupling of C(29) methyl doublet (δ 1.10); (*c*) corresponding spectrum with decoupling of exocyclic methylene protons (δ 4.92).

urs-20(30)-en-3-ol with the C(29) methyl group in an equatorial orientation in the assumed chair form of ring E (5, 12). However, the 200-MHz ^1H spectrum of **1** showed features which seemed inconsistent with this stereochemistry. In C_6D_6, the multiplets for protons allylic to the double bond are cleanly separated from other ^1H signals (see Fig. 3). Selective decoupling of the C(29) methyl doublet collapsed one of these multiplets to a doublet with $J_{HH} = 6.5$ Hz. This must be H(19) with the doublet reflecting vicinal coupling to H(18). This should be an *anti* (diaxial or a,a) coupling, according to the accepted structure. However, the magnitude of $J_{H(18)H(19)}$ seems more consistent with a *gauche* (axial–equatorial, a,e) coupling, e.g. $J_{H(a)H(a)} = 13.5$ Hz, $J_{H(a)H(e)} = 4–5$ Hz in methylenecyclohexane (13). Furthermore, selective decoupling of the methylene hydrogens reveals near-zero coupling of these protons to H(19). If H(19) is axially oriented, one would expect strong allylic coupling (ca. 2–3 Hz) to each of the methylene hydrogens, while this coupling should be near zero if H(19) is equatorial (14) (note that only one of the two C(21) protons (at δ 2.46 in Fig. 3) shows significant allylic coupling).

Both of these observations suggest that $C(29)H_3$ is in an axial or pseudo-axial orientation. One possible explanation is that the accepted structure for taraxasterol is incorrect and that it is actually 3β,18α,19β-urs-20(30)-en-3-ol. This would have $C(29)H_3$ axial and H(19) equatorial, assuming a chair form for ring E. In fact, the structure of taraxasterol has never been determined by an unambiguous technique such as X-ray diffraction. Rather, it was deduced from a complex series of isomerization and interconversion reactions (5). Consequently, we undertook an X-ray diffraction investigation of taraxasterol[1] in order to resolve these structural ambiguities.

The actual crystal structure of taraxasterol is shown in Fig.

[1] Taraxasterol was chosen for this investigation in preference to its acetate, **1**, since the former gave better crystals.

TABLE 2. Final assigned ^{13}C peaks for **1** from $^{13}C-^{13}C$ connectivity experiment

Carbon[a]	δ^b	Carbon	δ^b
C(1)	38.44 (38.4)	C(17)	34.53 (34.4)
C(2)	23.70 (23.6)	C(18)	48.63 (48.6)
C(3)	80.96 (80.8)	C(19)	39.28 (39.3, C(22))
C(4)	37.79 (37.7)	C(20)	154.64 (154.4)
C(5)	55.40 (55.4)	C(21)	25.61 (25.5, C(12))
C(6)	18.18 (18.1)	C(22)	38.85 (38.8, C(13))
C(7)	33.99 (33.9)	C(23)	27.94 (27.8)
C(8)	40.91 (40.8)	C(24)	16.51 (16.4)
C(9)	50.39 (50.3)	C(25)	16.34 (16.2, C(26))
C(10)	37.04 (37.0)	C(26)	15.89 (15.8, C(25))

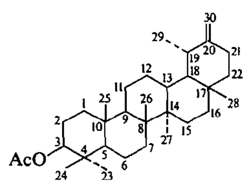
C(15)	26.64 (26.6)	CH_3—CO_2—	21.33 (21.1)
C(16)	38.29 (38.3, C(19))	CH_3—CO_2—	171.01 (170.8)

[a]Labelling as shown below.
[b]^{13}C chemical shifts in $CDCl_3$ (relative to internal $^{13}CH_3Si(CH_3)_3$). The first values are from this work while the values in brackets are from ref. 3. In cases where peaks were misassigned in ref. 3, the previous assignment is given after the δ value, e.g. (26.1, C(28)) illustrates that C(12) had previously been assigned as C(28).



Numbering of taraxasteryl acetate

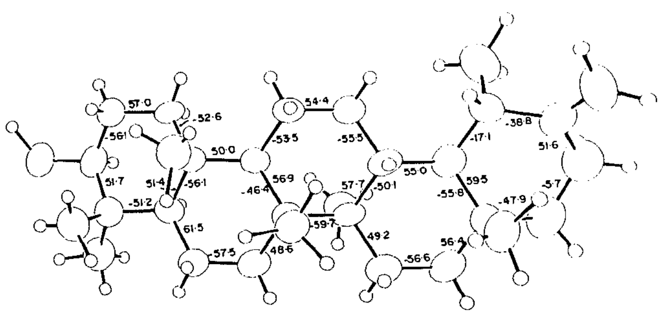


FIG. 4. ORTEP view of the molecular structure of taraxasterol. Thermal ellipsoids are drawn at the 50% probability level. The crystallographic numbering scheme corresponds to the chemical notation. The correct absolute configuration (using the inverted coordinates of Table 3) is indicated. Intraring C—C—C—C dihedral angles (°) are indicated for each ring. Note the close contact for $C(12)H_2$ and $C(29)H_3$.

4, while atomic coordinates are summarized in Table 3. In fact, the configuration of taraxasterol is identical to that previously proposed. However, while intraring dihedral angles for rings A–D (see Fig. 4) show that they exist in slightly flattened chair forms (an idealized chair would show alternating dihedral angles of +60° and −60°), ring E is in a distorted boat conformation (i.e. note the near zero values for ∠C(17)—C(18)—C(19)—C(20) and ∠C(17)—C(22)—C(21)—C(20)) with $C(29)H_3$ in a pseudo-axial orientation.

It is interesting to consider why ring E adopts the normally disfavored boat conformation. This cannot be primarily due to the presence of the exocyclic methylene group or to any steric interactions of $C(29)H_3$ with this group, since methylenecyclohexane prefers a slightly distorted chair form (15) while the methyl group in 1-methyl-2-methylenecyclohexane favors an equatorial orientation over an axial orientation by 1.0 kcal/mol (16). Rather, it appears that a steric interaction between $C(12)H_2$ and $C(29)H_3$ forces ring E into the boat conformation. Even in this conformation, the closest hydrogen–hydrogen separation between $C(12)H_2$ and $C(29)H_3$ is 2.46 Å, roughly the sum of hydrogen van der Waals radii. This distance would be significantly decreased if the molecules attempted to adopt a chair conformation for ring E.

The alternative possibility, that the ring E conformation results from crystal packing forces, can be conclusively ruled out on the basis of the X-ray and nmr data. The crystal packing diagram (see Fig. 5) shows a hydrogen bond O(1)—H(1) . . . . O(2) (O(1)—H(1) = 1.18 Å; O(2)—H(1) = 1.60 Å, ∠O(1)—H(1) - - - O(2) = 147.7°) involving the solvent. However, all other intermolecular contacts are weak. Furthermore, the ^1H nmr data indicate that **1** has a solution conformation which is very similar to the crystal structure conformation of taraxasterol. For example, the H(18)—C(18)—C(19)—H(19) dihedral angle of 142° in the crystal structure is consistent with $^3J_{H(18)H(19)}$ = 6.5 Hz in **1** while the H(19)—C(19)—C(20)—C(30) dihedral angle of 30° is also consistent with the near-zero allylic coupling of H(19) to the methylene protons. Thus the apparently inconsistent features in the ^1H spectrum of **1** can be rationalized in terms of a boat conformation for ring E. This also likely accounts for many of the misassigned ^{13}C peaks. For example, among the incorrectly assigned carbons are four of the five carbons in the sequence C(12)—C(13)—C(18)—C(19)—C(29) which is perturbed by the $C(12)H_2$—$C(29)H_3$ steric interaction. This clearly points out the risks in using

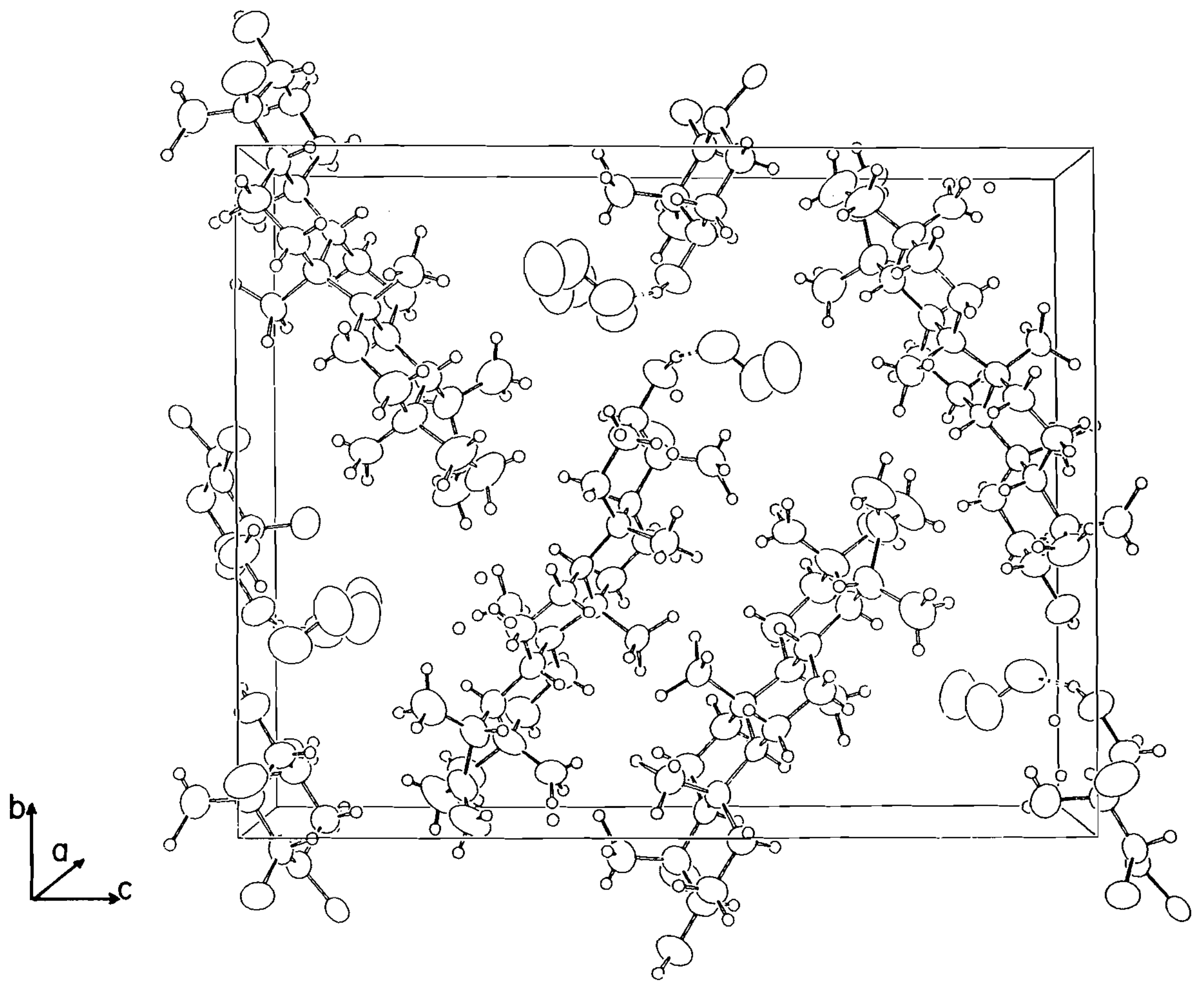

FIG. 5. Crystal packing diagram for taraxasterol–ethanol solvate.

model compounds to assign ^{13}C peaks in a compound of uncertain stereochemistry.

Conclusions

$^{13}C-^{13}C$ connectivity ("INADEQUATE") experiments have been used to unambiguously assign the ^{13}C signals in **1**. Comparison with a previous ^{13}C spectral assignment shows that 10 of 24 protonated aliphatic carbons had been incorrectly assigned (3). This is attributed to the use of an unreliable experimental method (SFORD) plus the use of inappropriate model compounds. It is concluded that SFORD spectra should be abandoned in favor of spectral editing (APT, INEPT, or DEPT) techniques while, at the very least, model compounds should only be used for assignment purposes when one is totally confident of the stereochemistries of both the model and target compounds. Wherever possible, one should use an unambiguous technique such as $^{13}C-^{13}C$ connectivity experiments for assignment of ^{13}C spectra (7). If this is impossible due to sensitivity limitations, it may often be possible to use heteronuclear correlated 2D spectra which are optimized for long-range $^{13}C-^{1}H$ couplings to unambiguously assign ^{13}C peaks (17).

Ring E of taraxasterol prefers a distorted boat conformation in the solid state, probably due to nonbonded interactions between $C(12)H_2$ and $C(29)H_3$. Taraxasteryl acetate, **1**, apparently has a very similar conformation in solution, accounting for the unexpected features in the ^{1}H spectrum of this compound.

Experimental

Dried ground leaves (1.2 kg) of *Montanoa tomentosa* Cerv. were macerated at room temperature with petroleum ether (bp 30–60°C) for periods of 48 h, three times. The extracts evaporated *in vacuo* were collected, yielding 87 g of syrupy residue. Twenty-five grams of this extract were chromatographed on a column of silica gel deactivated with 5% H_2O. Elution was carried out using 250-mL fractions of solution varying in concentration from pure hexane to 94% hexane/6% ethyl acetate (v/v%). Twenty-five fractions were collected in this way with **1** appearing in fractions 8–15. The collected fractions were rechromatographed under similar conditions, yielding 1.3 g of crude compound. Recrystallization from ethanol yielded 0.7 g of **1** (mp 245–246°C).

Most ^{1}H and ^{13}C spectra of **1** were obtained on a Varian XL-200 spectrometer operating in pulsed Fourier transform mode at a probe temperature of 20°C. ^{1}H spectra were recorded for C_6D_6 solutions containing ca. 5 mg of sample in 0.5 mL of solvent in a 5-mm tube with 0.1% tetramethylsilane as internal reference. Spectral width was 2000 Hz with 32K data points. 90° (7 μs) pulse widths were used with a repetition time of 8 s; 32 transients were collected. ^{13}C spectra were recorded for $CDCl_3$ solutions containing 150 mg of sample in 2.5 mL of solvent in a 10-mm tube. Spectral width was 10,000 Hz with 32K data points. 45° (7.5 μs) pulse widths were used with a repetition time of 1.6 s, and 4000 transients. Four DEPT spectra were collected using θ pulses of 45°, 90°, 90°, and 135° with 1200 transients for each

Anisotropically refined atoms are given in the form of the isotropic equivalent thermal parameter defined as: $(4/3)[a^2B(1,1) + b^2B(2,2) + c^2B(3,3) + ab(\cos\gamma)B(1,2) + ac(\cos\beta)B(1,3) + bc(\cos\alpha)B(2,3)]$.

spectrum (16 K data points, repetition rate = 1.6 s, [^{1}H] pulse width = 37 s). Edited subspectra were obtained using the subroutine ADEPT incorporated in the Varian software (H2 release).

The two-dimensional $^{13}C-^{13}C$ connectivity experiment was carried out with a Varian XL-300 nmr spectrometer using 300 mg of taraxasteryl acetate in 2.0 mL $CDCl_3$ and a 10-mm broadband probe tuned for ^{13}C at 75 MHz. The INADEQUATE pulse sequence (7) was set up to apply a final detection pulse of 135°. Broadband decoupling was applied continuously. The spectral width was 6000 Hz (80 ppm), the acquisition time was 0.170 s, and the resulting number of data points in the chemical shift dimension was 2048. The number of increments in the evolution time (delay between creation of double quantum coherence and observation of the signal) was 128, but zero-filling allowed second dimension Fourier Transformation using 256 data points in the double quantum frequency dimension. The first dimension FIDs were weighted by an exponential line-broadening function of 5 Hz; the second dimension interferograms were weighted by an exponential broadening function of 20 Hz.

Each increment was acquired for 320 pulse sequences, with a 3.0-s delay between sequences to allow substantial recovery of magnetization even for the quaternary carbons. This gave a total acquisition time of 36 h. The timing of the INADEQUATE sequence was calculated and set by the CCC2D program of the XL-300, based on the value of 37 Hz estimated for the average $^{13}C-^{13}C$ coupling constant.

Taraxasterol was prepared by hydrolyzing **1** in 0.1 *N* NaOH in 50% ethanol–water followed by neutralization, recovery of precipitated taraxasterol, and recrystallization from ethanol. The crystals were colorless blocks and needles. Precession photographs were used to obtain preliminary cell and space group information. Initially data were collected on an Enraf–Nonius CAD-4 diffractometer by the use of graphite monochromatized Mo K$\bar{\alpha}$ radiation (λ = 0.71069 Å). Subsequently a more extensive data set was obtained using Cu radiation (λ = 1.54184 Å) and a block-shaped crystal of overall dimensions 0.35 × 0.1875 × 0.1125 mm in the directions [1,0,0], [0,1,$\bar{1}$], and [0,1,1] respectively.

Crystal data

$C_{30}H_{50}O \cdot C_2H_6O$ fw = 472.8

Orthorhombic, space group $P2_12_12_1$ with a = 7.447(1) Å, b = 17.637(2) Å, c = 22.269(4) Å, U = 2925 Å^3, and D_c = 1.07 g cm^{-3} for Z = 4. Cu K$\bar{\alpha}$ radiation (λ = 1.54184 Å), μ(Cu K$\bar{\alpha}$) = 4.5 cm^{-1}.

Cell constants were obtained by least-squares refinement of the setting angles of 25 reflections within the range $9.6 < \theta < 20.4°$. Intensity data were collected at room temperature in coupled ω:2θ modes using scan ranges of 0.85 + 0.147 tan θ° within a maximum scan time of 95 s. For each reflection, backgrounds were obtained by extending the scan by 25% on either side of the peak and were measured for half the time taken to collect the peak. A total of 2986 reflections in the quadrant h,k,l with $2\theta \leq 130°$ was obtained. No significant variations in the intensities of 3 standard reflections monitored after every 8500 s of exposure time were observed.

Lorentz and polarization corrections were applied to all reflections. The rejection of systematically absent and zero F_{obs} data then gave a final data set of 2528 reflections. The structure was initially solved using direct methods (MULTAN 11) (18) on the data set collected with Mo radiation. Missing atoms and the presence of a molecule of ethanol solvent in the lattice were indicated in subsequent Fourier maps. Hydrogen atoms were placed in calculated positions or were located in difference Fourier maps (CH_3 groups) with fixed thermal parameters (B = 7.5 or 10.0 Å^2) but were not refined.

Least-squares refinement of the structure using the Cu data set and including an extinction correction g to the data converged (max. shift/error = 0.07) to the final residuals R_1 = 0.0773 (R_w = 0.0902) for 1941 reflections (308 variables) with $I > 1.5\sigma(I)$. The final value of g was 1.4(2) × 10^{-6} and weights were given by $1/\sigma(F)^2$ where $\sigma(F) = 4F^2/(\sigma(I)^2 + (0.07F^2)^2)^{1/2}$. A final difference Fourier contained no peak greater than 0.22 e Å^{-3}.

All calculations were performed on a PDP 11/23 computer using programs in the Enraf–Nonius structure determination package (19). Tables of positional parameters of the hydrogen atoms, anisotropic, thermal parameters, bond lengths, bond angles, and final structure factor amplitudes have been deposited as Supplementary Material.[2]

The dimethylphosphinate of manganese(II), $Mn[(CH_3)_2PO_2]_2$, and its dihydrate have been prepared and studied using magnetic susceptibility, differential scanning calorimetry, and electronic and vibrational spectroscopic methods. The dihydrate was obtained in crystalline form and a single crystal X-ray diffraction study revealed a polymeric structure.

Crystals of poly-bis(μ-dimethylphosphinato)diaquomanganese(II) are monoclinic, a = 20.722(3), b = 4.8652(2), c = 11.0689(14) Å, β = 102.209(7)°, Z = 4, space group $C2/c$. The structure was solved by conventional heavy-atom methods and was refined by full-matrix least-squares procedures to R = 0.030 and R_w = 0.033 for 983 reflections with $I \geq 3\sigma(I)$. The structure consists of infinite centrosymmetric chains of Mn(II) atoms linked by double phosphinate bridges and extending along the crystallographic b axis. The water molecules are involved in both interchain and bifurcated intrachain hydrogen bonding (O···O = 2.734(2), 2.899(3) and 3.120(3) Å). The coordination about Mn is slightly distorted octahedral with libration-corrected bond lengths Mn—O(phosphinato) = 2.156(2) and 2.212(2), Mn—OH_2 = 2.247(2) Å.

Magnetic susceptibility studies on the dihydrate from 300 to 4.2 K reveal a magnetic moment of ~5.9 BM over most of the range and give no evidence for significant magnetic exchange. The anhydrous compound, which is considered on the basis of indirect evidence to retain the double phosphinate bridged structure exhibited by the dihydrate, shows relatively strong antiferromagnetic behaviour. The data have been analyzed according to two theoretical models both of which employ the isotropic Heinsenberg Hamiltonian. The scaling model of Wagner and Friedberg gives $J = -2.94$ cm^{-1} and g = 2.02 and the interpolation scheme of Weng gives $J = -2.69$ cm^{-1} and g = 2.01. The magnitude of the exchange coupling is considered in relation to that observed in related manganese compounds and possible reasons for the observed damping of the exchange on hydration are discussed.

WALTER V. CICHA, JOHN S. HAYNES, KATHERINE W. OLIVER, STEVEN J. RETTIG, ROBERT C. THOMPSON et JAMES TROTTER. Can. J. Chem. **63**, 1055 (1985).

On a préparé le diméthylphosphinate de manganèse(II), $Mn[(CH_3)_2PO_2]_2$ ainsi que son hydrate double et on les a étudiés en faisant appel à la susceptibilité magnétique, à la calorimétrie à balayage différentiel et à la spectroscopie électronique et vibrationnelle. On a obtenu l'hydrate double sous forme cristalline et une étude par diffraction de rayons X sur un cristal unique révèle qu'il existe sous une forme polymérisée.

Les cristaux de poly-bis(μ-diméthylphosphinato)diaquomanganèse(II) appartiennent au groupe d'espace monoclinique $C2/c$, avec a = 20,722(3), b = 4,8652(2), c = 11,0689(14) Å, β = 102,209(7)°, Z = 4. On a résolu la structure par la méthode conventionnelle aux atomes lourds et on l'a affinée par la méthode des moindres carrés (matrice entière) jusqu'à des valeurs de R = 0,030 et de R_w = 0,033 pour 983 réflexions avec $I \geq 3\sigma(I)$. La structure comprend des chaînes centrosymétriques infinies d'atomes de Mn(II) liés par un double pont phosphinato et s'étendent le long de l'axe cristallographique b. Les molécules d'eau sont impliquées dans des liaisons hydrogènes interchaînes et intrachaînes bifurquées (O···O) = 2,734(2), 2,899(3) et 3,120(3) Å. La coordination autour du Mn est un octaédrique, légèrement déformée avec des longueurs de liaison, corrigées pour la libration, de Mn—O(phosphinato) = 2,156(2) et 2,212(2) et Mn—OH_2 = 2,247(2) Å.

Les études de susceptibilité magnétique, réalisées avec l'hydrate double à des températures allant de 300 à 4,2 K, révèlent la présence d'un moment magnétique de 5,9 BM environ sur presque tout l'intervalle considéré. Le composé anhydre, qui, d'après des preuves indirectes, conserverait la structure pontée double phosphinate qui existe dans le dihydrate, exhibe un comportement antiferromagnétique relativement fort. On a analysé les données selon deux modèles théoriques qui utilisent l'Hamiltonien isotrope de Heinsenberg. Le modèle proportionné de Wagner et Friedberg permet de prédire des valeurs de $J = -2{,}94$ cm^{-1} et g = 2,02 alors que le schéma d'interpolation de Weng conduit à des valeurs de $J = -2{,}69$ cm^{-1} et g = 2,01. On considère l'amplitude du couplage d'échange en rapport avec celui observé avec des composés apparentés du manganèse et on discute des raisons qui pourraient expliquer le fait que l'échange accompagnant l'hydratation est amoindri.

Introduction

The poly(metal phosphinates) are a class of inorganic coordination polymers in which metal centres are bridged by —OPR_2O— groups to form, typically, one-dimensional extended chains (1–6). These materials have generated interest from chemists and physicists alike over the past twenty years. Their polymeric nature leads generally to thermal and chemical stability as well as to some plastic and other properties of interest to industry (7) while the presence of paramagnetic transition metal sites throughout the polymeric lattice holds potential for the propagation of magnetic exchange and other interesting solid state properties (5, 6, 8). Earlier work on the dialkylphosphinates of copper(II) has shown that these compounds provide examples of both antiferromagnetic and ferromagnetic one-dimensional chains, the sign and magnitude of the exchange coupling in these compounds being related to relatively minor structural differences (6). To fully explore magneto-structural correlations in these systems we have been studying the effects of varying both the nature of the phosphinate bridge and the metal. In addition, in the present work we have discovered that hydration of the metal ion, in this instance at least, has a significant effect on the magnetic properties. We report here the synthesis and magnetic properties of the dimethylphosphinate of manganese(II), $Mn[(CH_3)_2PO_2]_2$,

[1] To whom all correspondence should be addressed.

and its dihydrate. The structure of the dihydrate was determined by single crystal X-ray diffraction methods. The existence of a monohydrate, reported earlier (9), was not confirmed in the present work.

Experimental

Preparations

Dimethylphosphinic acid, $(CH_3)_2PO_2H$

The synthetic route chosen involved the synthesis first of tetramethyldiphosphine disulfide, $(CH_3)_2P(S)P(S)(CH_3)_2$ according to a scaled-down version of Parshall's method (10) followed by oxidation and subsequent hydrolysis to the acid. Oxidation of the disulfide using hydrogen peroxide (11), chlorine (which gave dimethyltrichlorophosphorane, $(CH_3)_2PCl_3$, and which could be subsequently hydrolyzed to the acid) (12, 13) and mercuric oxide (14) all gave the desired product; however, the best yields were obtained by the method described in detail below involving oxidation with an excess of sulfuryl chloride to give dimethylphosphinic chloride, $(CH_3)_2POCl$, followed by hydrolysis to the acid.

The Grignard reaction between 1.65 mol of magnesium in 200 mL of dry ether and 1.50 mol of methyl iodide in 100 mL of dry ether was initiated by the addition of a few grains of iodine. The methyl iodide was added over 3 h at such a rate as to maintain a gentle reflux and when addition was complete, the mixture was refluxed for a further 1/2 h. The resulting solution was cooled in an ice bath and freshly distilled thiophosphoryl chloride (0.51 mol) in 50 mL dry ether was added slowly. A vigorous reaction resulted in the formation of a white precipitate. After addition was completed, the reaction mixture was cooled and poured over 350 g of ice after which 600 mL of 10% sulfuric acid was added and the mixture was stirred overnight. The resulting white precipitate was filtered from the solution and recrystallized from 5:1 (by volume) benzene–ethanol yielding 30.8 g of tetramethyldiphosphine disulfide (mp 226–227.5°C; lit. 227°C (10)).

Following the observation by Maier (14) that oxidation of tetraalkyldiphosphine disulfides with an excess of sulfuryl chloride results in the formation of dialkylphosphinic chloride, we added 0.49 mol of sulfuryl chloride dropwise, with stirring, to a cooled (0°C) benzene solution of $(CH_3)_4P_2S_2$ (0.10 mol). The solution immediately became cloudy yellow. After addition was complete the mixture was refluxed for 45 min, cooled, and the solvent, any remaining sulfuryl chloride and volatile reaction by-products were removed by pumping under vacuum. Crude $(CH_3)_2POCl$ was isolated from the dried reaction mixture by vacuum sublimation and was dissolved in water. The solution was filtered and the hydrochloric acid produced in the hydrolysis reaction was neutralized with aqueous sodium hydroxide. The residue from the evaporation of the aqueous solution was taken up in dry acetonitrile and filtered to remove sodium chloride. The desired acid was obtained in 89% yield by evaporation of the acetonitrile solution. Melting point 86–89°C (lit. 87.5–88.5 (15)). *Anal.* calcd. $C_2H_7PO_2$: C 25.54, H 7.50; found: C 25.50, H 7.63.

Poly-bis(μ-dimethylphosphinato)diaquomanganese(II), $Mn(H_2O)_2[(CH_3)_2PO_2]_2$

Manganese(II) acetate tetrahydrate (5.0 mmol) was dissolved in 400 mL of ethanol and the solution was then added dropwise with stirring to a solution of dimethylphosphinic acid (10.0 mmol) dissolved in 600 mL of ethanol. The resulting solution was stirred for about 2 days then the volume was reduced to about 300 mL by flash evaporation. Over the next 5 days small, pale pink crystals of the dihydrate, suitable for X-ray diffraction studies, were obtained. These were collected by filtration, washed with cold ethanol, and allowed to air dry. A further crop of crystals were obtained by reducing the volume of the filtrate by about a half and allowing the solution to stand for about a week (total yield, 26%). *Anal.* calcd. for $MnC_4H_{16}P_2O_6$: C 17.33, H 5.83, O 34.64; found: C 17.22, H 5.99, O 34.35.

In order to obtain pure crystals of the diaquo species it is necessary to crystallize slowly from dilute solutions as described above. More rapid crystallization yields non-crystalline materials of intermediate degrees of hydration. For example, when a solution of 7.5 mmol of manganese(II) acetate tetrahydrate in 250 mL ethanol was mixed with a solution of 15.1 mmol of dimethylphosphinic acid in 125 mL ethanol an immediate precipitate formed, the composition of which corresponded to a hemi-hydrate. *Anal.* calcd. for $MnC_4H_{13}P_2O_{4.5}$: C 19.21, H 5.24; found: C 19.14, H 5.25.

Poly-bis(μ-dimethylphosphinato)manganese(II), $Mn[(CH_3)_2PO_2]_2$

The anhydrous compound may be obtained by heating the diaquo compound or the hemi-hydrate to 60–70°C under vacuum for several hours. *Anal.* calcd. for $MnC_4H_{12}P_2O_4$: C 19.93, H 5.02, O 26.55; found: C 19.78, H 5.02, O 26.30.

Carbon, hydrogen, and oxygen were determined by P. Borda of the Department of Chemistry, The University of British Columbia.

Differential scanning calorimetry (DSC)

DSC studies were made using a Mettler DSC 20 cell and a Mettler TC10 TA processor.

$Mn(H_2O)_2[(CH_3)_2PO_2]_2$ exhibits an endothermic peak (ΔH = 343 J g^{-1}) at 107°C due to loss of water followed by a second endothermic event (ΔH = 40 J g^{-1}) at 208°C. $Mn[(CH_3)_2PO_2]_2$ exhibits an endothermic peak (ΔH = 41 J g^{-1}) at 200°C. Both materials undergo oxidative decomposition above 310°C.

Infrared spectra

Spectra in the range 4000 to 250 cm^{-1} were recorded on a Perkin-Elmer Model 598 spectrometer using samples mulled in Nujol as well as hexachlorobutadiene and pressed between KRS-5 plates (Harshaw Chemical Co.).

$Mn(H_2O)_2[(CH_3)_2PO_2]_2$: 3410 m br, 3160 m br, 2980 w, 2919 w, 1650 w br, 1425 w br, 1294 m, 1282 m, 1137 s, 1121 s, 1065 m, 1032 w sh, 903 w, 868 m, 735 m, 455 m.

$Mn[(CH_3)_2PO_2]_2$: 2985 w, 2920 w, 1424 w, 1302 m, 1288 m, 1123 s, 1031 s, 919 vw, 875 m sh, 867 m, 741 w, 726 vw sh, 497 w, 485 w, 455 w sh, 440 m (w = weak, m = medium, s = strong, v = very, br = broad, sh = shoulder).

Magnetic susceptibilities

Variable temperature magnetic susceptibilities were measured over the temperature range 4.2 to 300 K using equipment and methods described previously (6). The diamagnetic corrections used were −14, −42, and -13×10^{-6} cm^3 mol^{-1} for Mn^{2+}, $(CH_3)_2PO_2^-$, and H_2O, respectively.

X-ray crystallographic analysis of $Mn(H_2O)_2[(CH_3)_2PO_2]_2$

A crystal bounded by the eight faces (followed by their distances in mm from a common origin): ±(100), 0.031, ±(010), 0.244, ±(101), 0.063, ±(10 − 2), 0.075, was mounted in a general orientation. Unit-cell parameters were refined by least-squares on 2 sin θ/λ values for 25 reflections (2θ = 35–45°) measured on a diffractometer with Mo-K_α radiation ($\lambda(K_{\alpha_1})$ = 0.70930, $\lambda(K_{\alpha_2})$ = 0.71359 Å). Crystal data at 22°C are:

$C_4H_{16}MnO_6P_2$ fw = 277.05

Monoclinic, a = 20.722(3), b = 4.8652(2), c = 11.0689(14) Å, β = 102.209(7)°, V = 1090.7(2) Å^3, Z = 4, ρ_c = 1.687 g cm^{-3}, $F(000)$ = 572, μ(Mo-K_α) = 14.49 cm^{-1}. Absent reflections: hkl, $h + k$ odd, and $h0l$, l odd, space group $C2/c$ (C^6_{2h}, No. 15) from structure analysis.

Intensities were measured with graphite-monochromated MoK_α radiation on an Enraf-Nonius CAD4-F diffractometer. An ω–2θ scan at 0.87–6.71° min^{-1} over a range of (0.80 + 0.35 tan θ)° in ω (extended by 25% on both sides for background measurement) was employed. Data were measured to 2θ = 65°. The intensities of three check reflections, measured every hour throughout the data collection, showed only small random fluctuations. After data reduction,[2] an

* (1/3) trace U_{diag}.

absorption correction was applied using the Gaussian integration method (16, 17). Transmission factors ranged from 0.809 to 0.920 for 112 sampling points. Of the 1989 independent reflections measured, 983 (49.4%) had intensities greater than $3\sigma(I)$ above background where $\sigma^2(I) = S + 2B + (0.04(S - B))^2$ with S and B the normalized scan and background counts.

The centrosymmetric space group $C2/c$ was indicated by both the E-statistics and the Patterson function, from which the Mn and P coordinates were determined. The Mn atom is constrained to lie either on a twofold axis or at a centre of symmetry, the latter being the case. The coordinates of all remaining atoms were determined from subsequent difference maps. In the final stages of refinement the hydrogen atoms were refined with isotropic, and the non-hydrogen atoms with anisotropic thermal parameters. The scattering factors and anomalous scattering terms for Mn and P were taken from ref. 18. Convergence was reached at $R = 0.030$ and $R_w = 0.033$ for 983 reflections with $I \geq 3\sigma(I)$. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$ (where $w = 1/\sigma^2(F)$), $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$, $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$.

On the final cycle of refinement the mean and maximum parameter shifts corresponded to 0.002 and 0.02σ, respectively, and the mean error in an observation of unit weight was 1.286. The largest residuals on the final difference map (−0.69, +0.39 e Å^{-3}) were in the vicinity of P and Mn, respectively. The final positional and isotropic thermal parameters are given in Table 1. Anisotropic thermal parameters (Table 7) and measured and calculated structure factors have been placed in the Depository of Unpublished Data.[3]

Bond distances have been corrected for libration using the TLS model (19). The rms standard error in the temperature factors σU_{ij} (derived from the least-squares analyses) is 0.0010 Å^2. Two structural sub-units were analysed: the centrosymmetric MnO_6 unit and the O_2PC_2 fragment (rms σU_{ij} = 0.0024 and 0.0011 Å^2, respectively). Bond lengths corrected for libration (19, 20) appear in Table 2 along with the uncorrected distances. Bond angles, details of hydrogen bonding, and intraannular torsion angles are given in Tables 3–5, respectively.

Results and discussion

Although organophosphinates of manganese(II) have been reported in the literature (8, 9, 21–27), no detailed X-ray crystallographic or cryomagnetic studies on these compounds have been previously undertaken. We found that slow crystallization of the dimethylphosphinate derivative from dilute solution gave well-formed pale pink crystals which, according to elemental analysis and infrared studies, incorporate two molecules of water per manganese. The DSC thermogram for this material shows an endothermic event beginning around 60–70°C and peaking at about 107°C corresponding to the loss of the water molecules. Consistent with this, bulk samples of the hydrated derivative may be completely dehydrated by heating for several hours at 60 to 70°C under vacuum. There is no evidence in the thermogram for a stable monohydrate (9) or any other distinct hydrated phase. Whereas the variable temperature magnetic properties of the anhydrous material indicate a relatively strongly magnetically coupled system, the hydrated material gives little evidence for magnetic concentration (see below). In order to establish the manner in which the water molecules are incorporated and to determine whether we were dealing with a polymeric or molecular system, a single crystal X-ray diffraction study was undertaken on a crystal of the hydrate.

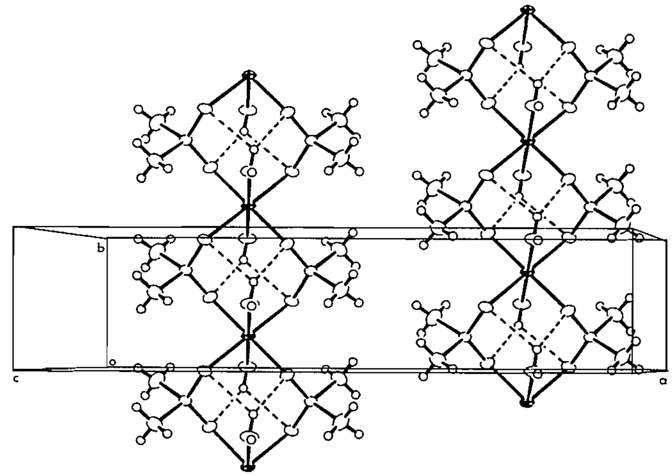

FIG. 1. View of $Mn(H_2O)_2[(CH_3)_2PO_2]_2$ showing two chains extending along the b axis. 50% probability thermal ellipsoids are shown for the non-hydrogen atoms; hydrogen atoms have been assigned arbitrarily small thermal parameters for the sake of clarity. Mn atoms are represented by shaded ellipses. Broken lines indicate hydrogen bonds.

The crystal structure of $Mn(H_2O)_2[(CH_3)_2PO_2]_2$ consists of closely packed infinite chains of identical cages (each having twelve vertices and six non-planar faces) propagating along the crystallographic b-axis (Fig. 1). The manganese atoms are connected in the chains by double phosphinate bridges with four oxygens from four different phosphinates forming a roughly square planar array around each manganese. Water molecules coordinated above and below this plane complete an MnO_6 chromophore. Atom labelling and the coordination geometry about Mn is shown in Fig. 2. Hydrogen atoms from the two water molecules coordinated to the same metal are involved in intrachain bifurcated hydrogen bonds with phosphinate oxygen atoms bonded to adjacent manganese atoms. These hydrogens together with the six chromophore oxygens make up eight of the cage vertices. The remaining four vertices are supplied by two phosphorus and two manganese atoms, the latter of which form shared corners between cages and hence serve as links in the infinite chains. The second hydrogen atom on each water molecule is involved in a strong hydrogen bond with a phos-

*Here and elsewhere in this report superscripts refer to the following symmetry operations: [1] $1/2 - x, 1/2 - y, -z$; [2] $x, y - 1, z$; [3] $1/2 - x, 3/2 - y, -z$; [4] $x, y + 1, z$; [5] $1/2 - x, y - 1/2, 1/2 - z$.

phinate oxygen on a neighbouring chain with the result that the chains are connected together in the *c* direction by two interchain hydrogen bonds per cage (Fig. 3). The overall structure can then be thought of as consisting of well-separated layers of cages stacked up approximately along the *a* axis. The strength of the hydrogen bonding interactions between adjacent chains is apparent from the differences between the intra and interchain hydrogen bonding parameters (Table 4). The shorter interchain distances suggest that hydrogen bonding is stronger between chains than within chains; this strong interchain interaction accounts, in part at least, for the relatively high crystal density of this material compared to, for example, that of copper(II) diethylphosphinate (5).

The intrachain distance between manganese atoms is 4.8652(2) Å and the minimum interchain distance is 6.046(1) Å. The intrachain distance is less than 0.1 Å shorter than the Cu—Cu distances in polymeric copper(II) phosphinates. The Mn—O bond distances of 2.156(2) and 2.212(2) Å are typical for this type of bond (28) and, as expected, are slightly longer than the Cu—O distances observed in the copper(II) phosphinates (4–6). Bond distances and angles involving the R_2PO_2 moieties are comparable to those found in other polymeric phosphinates (3–6) and exhibit no unusual features.

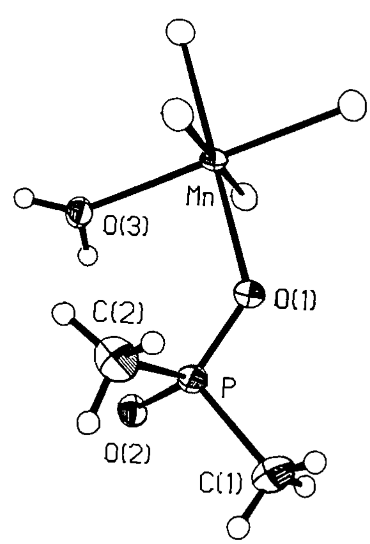

FIG. 2. View of $Mn(H_2O)_2[(CH_3)_2PO_2]_2$ showing the atom numbering scheme and the coordination about Mn.

Attempts to obtain crystals of anhydrous $Mn[(CH_3)_2PO_2]_2$ suitable for X-ray studies have not been successful. Certain conclusions regarding its structure may, however, be drawn from other evidence. It seems likely that the removal of the two water molecules on dehydration of the hydrate does not significantly alter the double phosphinate bridged backbone structure of the material. This is supported by the DSC thermogram which shows a single endothermic peak due to loss of water and no other thermal events which might accompany a major

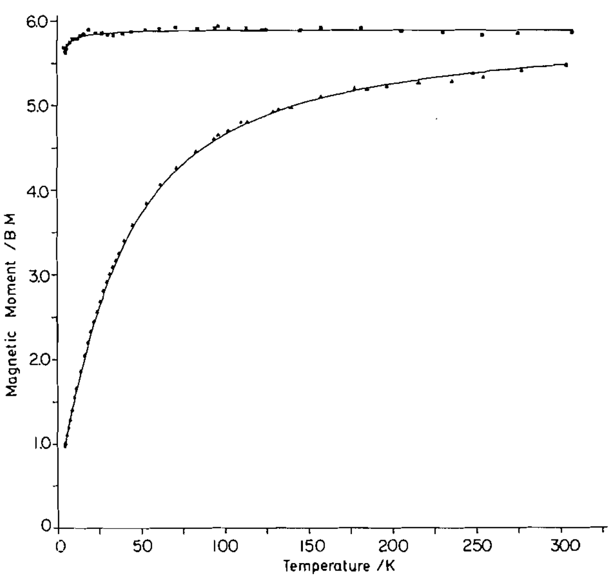

FIG. 4. Magnetic moment versus temperature plots for $Mn(H_2O)_2[(CH_3)_2PO_2]_2$ (■) and $Mn[(CH_3)_2PO_2]_2$ (▲). Solid lines are the best fit to the Wagner–Friedberg model.

change in structure up to ~195°C. The endothermic peak which appears near this temperature is not due to melting (visual observation on heating a sample in a melting point tube) and is probably due to a high temperature structural phase change. Further support for the contention that a polymeric lattice is maintained comes from solubility tests. The anhydrous compound was found to be only very sparingly soluble in methanol, ethanol, and acetone and insoluble in carbon tetrachloride, chloroform, and petroleum ether. Moreover the relatively strong magnetic exchange observed for this material is consistent with the presence of a polymeric lattice (see below) and not with a molecular species. It has been suggested that information regarding the mode of phosphinate coordination may be obtained from infrared studies particularly in the PO_2 stretching region (29). The antisymmetric and symmetric PO_2 stretching frequencies which occur at 1137 and 1065 cm^{-1} in the hydrated compound shift to 1123 and 1031 cm^{-1} on dehydration. A shift in frequencies would be expected as the hydrogen bonding interactions with the coordinated water molecules are removed. The increase in the separation between the two frequencies (from 72 cm^{-1} in the hydrate to 92 cm^{-1}) suggests that the phosphinate bridging may be more unsymmetrical in the anhydrous material (29). This might arise if, on dehydration, the phosphinate oxygens formerly involved in interchain hydrogen bonding now occupy axial positions vacated by the water molecules in a tetragonally distorted MnO_6 chromophore. The pale pink colour of the anhydrous material is consistent with such a chromophore or, in the limit of negligible interchain interactions, with a square planar environment about manganese (30).

TABLE 4. Hydrogen bond data (distances in Å and angles in deg)*

TABLE 5. Intra-annular torsion angles (deg) standard deviations in parentheses*

Atoms	Value (deg)
O(2)^3—Mn—O(1)—P	−107.61(15)
O(2)—P —O(1)—Mn	66.0(2)
O(1)—P —O(2)—Mn^4	49.1(2)
P —O(2)—Mn^4—O(1)^3	−89.81(13)

*Symmetry-related torsion angles have the opposite sign.

Magnetic susceptibility data are recorded in Table 6 and the magnetic moments are plotted in Fig. 4. The moment for $Mn[(CH_3)_2PO_2]_2$ varies from just above 5.4 BM at room temperature to about 1.0 BM at 4.2 K and the susceptibility versus temperature plot (Fig. 5) shows a broad maximum at 34 K. These properties suggest one-dimensional antiferromagnetic exchange as found, for example, in the triple chlorine bridged tetramethylammonium manganese(II) chloride (31).

Two models are available for the theoretical analysis of antiferromagnetic exchange in linear chain manganese(II) compounds, the scaling model of Wagner and Friedberg (32) and the interpolation scheme developed by Weng (33). Both models use the isotropic Heisenberg Hamiltonian, which is appropriate in the case of Mn^{2+} (^6S ground state). According to the Wagner and Friedberg model,

$$\chi_M = \frac{Ng^2\beta^2S(S+1)}{3kT}\cdot\frac{1+U}{1-U}$$

where $U = \coth K - 1/K$ and $K = 2JS(S+1)/kT$.

Hiller *et al.* have generated a series of coefficients for mag-

netic susceptibility to reproduce Weng's numerical results (34). Accordingly

$$\chi_M = \frac{Ng^2\beta^2}{kT}\,\frac{[A + BX^2]}{[1 + CX + DX^3]}$$

and for $S = 5/2$, $A = 2.9167$, $B = 208.04$, $C = 15.543$, $D = 2707.2$, and $X = |J|/kT$.

The experimental results were analyzed using both models with fits made to the susceptibility data with J and g as fitting parameters. Best fits were obtained by minimizing the function

$$F = \left[\frac{1}{n}\sum_i^n \left(\frac{\chi_i^{calc} - \chi_i^{obs}}{\chi_i^{obs}}\right)^2\right]^{1/2}$$

where n is the number of data points. The best fit values are $-2.69\ cm^{-1}$ for J, the exchange coupling constant, and 2.01 for g ($F = 0.0151$) using the Weng model and $-2.94\ cm^{-1}$ for J and 2.02 for g ($F = 0.0222$) using the Wagner–Friedberg model. As expected g is ~2.00 in both cases. For comparison, $[(CH_3)_4N]MnCl_3$ has $J = -4.38\ cm^{-1}$ (31) and $CsMnCl_3\cdot 2H_2O$, a single chloro-bridged chain, has $J = -2.16\ cm^{-1}$ (35). The magnetic interaction in the phosphinate compound is particularly interesting when one considers that although the exchange pathway involves a three-atom bridge, the magnitude of the exchange is at least comparable to that found in the chloro-bridged compounds.

A series of complexes with a similar bridging network to that found in the phosphinates are those of type $M(N_2H_5)_2(SO_4)_2$. The zinc compound has been shown to contain bidentate sulfate anions forming a double bridge between adjacent zinc ions to link them in a linear chain (36). The manganese compound (assumed to have the same structure) is antiferromagnetic with $J = -0.42\ cm^{-1}$ (37), seven times smaller than the J obtained for the phosphinate-bridged species. It is not obvious whether this difference in J's is due to the nature of the bridging anion (sulfate versus phosphinate) or due to the presence of extensive hydrogen bonding which is present in the sulfate-bridged com-

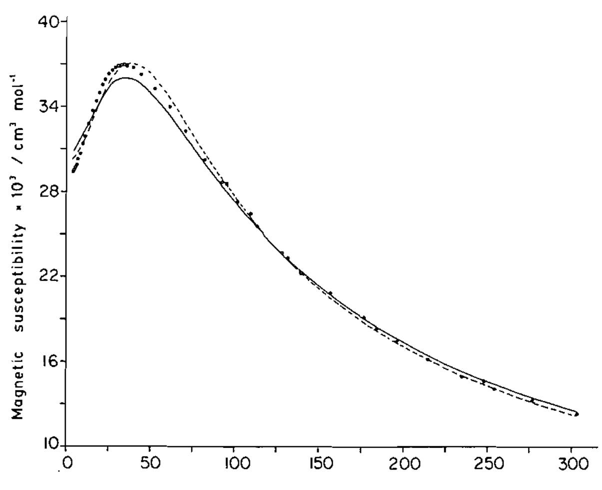

FIG. 5. Magnetic susceptibility versus temperature plots for $Mn[(CH_3)_2PO_2]_2$. Circles are experimental data. Solid line is the best fit to the Wagner–Friedberg model and the broken line is the best fit to the Weng model.

plex but absent in the phosphinate. Of relevance to this consideration is the fact that the hydrated manganese phosphinate derivative studied in the present work also has an extensive hydrogen bonded network and shows little, if any, magnetic exchange (see below).

Both theoretical models represent the experimental magnetic data reasonably well especially at temperatures above ~80 K. Discrepancies with both models are, however, seen at lower temperatures and, moreover, the Weng model does not reproduce the temperature of the rounded maximum in the χ_M plot as well as the other model (Fig. 5). Any or all of the following factors could account for the discrepancies. A small amount of paramagnetic impurity will affect the shape of the susceptibility versus temperature curve especially for antiferromagnets at lower temperatures. Both models ignore zero-field splitting effects (38) and although these should be small in the case of Mn(II) they may have a significant effect at low temperatures. Also, interchain interactions are ignored in both models. The possibility of some weak association between chains to raise the coordination number of manganese to six was discussed above. Unfortunately, without single crystal X-ray diffraction studies on this compound it is difficult to conclude whether such interactions are likely to be significant.

In contrast to the magnetic behaviour seen in the anhydrous compound, $Mn(H_2O)_2[(CH_3)_2PO_2]_2$ has a moment of ~5.9 BM over the range 300 to 10 K as expected for magnetically dilute, spin-free, manganese(II). There is a small decrease in moment from 10 to 4.2 K and while this can be fit to theory (Wagner and Friedberg model, $g = 2.00$ and $J = -0.02$ cm^{-1} (Fig. 4)), the fit should not be interpreted as definite evidence for exchange in this material; such small decreases in moment at low temperatures could be accounted for by zero-field splitting effects (38). Nonetheless, the fit does place an upper limit of -0.02 cm^{-1} on J and shows that any net exchange in the hydrate must be very weak indeed compared to that present in the anhydrous compound. Two possible explanations are suggested for this difference in magnetic properties. In the anhydrous compound relatively strong antiferromagnetic intrachain exchange takes place. On hydration the water molecules, through their coordination to manganese, will effectively decrease the metal's acidity towards the bridging phosphinate groups and, through hydrogen bonding to the phosphinate oxygens, they will effectively decrease the phosphinate basicity towards manganese. The net effect is weaker phosphinate–manganese bonds, poorer orbital overlap and weaker intrachain exchange. Another possible source of the effective damping of significant net magnetic exchange in the hydrate is suggested by the work on $MnCl_2 \cdot 2H_2O$ (39). This compound exhibits some structural similarities to the hydrate studied here. The compound has a chain structure with manganese atoms joined by double chloride bridges. Water molecules coordinated in axial positions form hydrogen bonds with chlorides in neighbouring chains. In this compound there is both intrachain antiferromagnetic exchange via the chlorides and interchain ferromagnetic exchange via the hydrogen-bonded water molecules with the magnitudes of the two almost equal. This raises the possibility that in $Mn(H_2O)_2[(CH_3)_2PO_2]_2$ antiferromagnetic intrachain exchange effects are also present but are roughly cancelled by interchain ferromagnetic exchange via the water molecules.

Preparation, crystal and molecular structures of $Ph_2CNSNSO$ and a comparison of the —SNSO and —SNSS chromophores

TRISTRAM CHIVERS,[1] RICHARD T. OAKLEY,[2] ROGER PIETERS, AND JOHN F. RICHARDSON
Department of Chemistry, University of Calgary, Calgary, Alta., Canada T2N 1N4

Received August 7, 1984

TRISTRAM CHIVERS, RICHARD T. OAKLEY, ROGER PIETERS, and JOHN F. RICHARDSON. Can. J. Chem. **63**, 1063 (1985).

The sulphenyl chloride, Ph_2CNSCl, prepared *in situ* from $Ph_2CNSiMe_3$ and sulphur dichloride, has been employed in the synthesis of $Ph_2CNSNSO$ and $Ph_2CNSNSNSNCPh_2$ by reaction with Me_3SiNSO and $Me_3SiNSNSiMe_3$, respectively. An X-ray structural determination of $Ph_2CNSNSO$ shows it to consist of a planar *cis–trans* chain. The crystals are triclinic and belong to the space group $P\bar{1}$, a = 9.9078(8), b = 10.0967(9), c = 15.1682(14) Å, α = 78.646(7), β = 71.065(7), γ = 63.449(7)°, V = 1281.5(5) Å^3, Z = 4. The final R and R_w values were 0.033 and 0.027, respectively. The $\pi^* \rightarrow \pi^*$ excitation energies for the RSNSO and RSNSS chromophores are compared for different R groups and discussed in the light of MNDO calculations on the model compounds HSNSX (X = S, O). The thermal decomposition of both $Ph_2CNSNSO$ and $Ph_2CNSNSNSNCPh_2$ produced S_4N_4 and Ph_2CO or $(Ph_2CN)_2S$, respectively.

TRISTRAM CHIVERS, RICHARD T. OAKLEY, ROGER PIETERS et JOHN F. RICHARDSON. Can. J. Chem. **63**, 1063 (1985).

On a utilisé le chlorure de sulfényle, Ph_2CNSCl, préparé *in situ* à partir du $Ph_2CNSiMe_3$ et du dichlorure de soufre, pour effectuer la synthèse du $Ph_2CNSNSO$ et du $Ph_2CNSNSNSNCPh_2$ par réaction avec soit du Me_3SiNSO ou du $Me_3SiNSNSiMe_3$. Une détermination de la structure du $Ph_2CNSNSO$ par diffraction des rayons-X a permis de montrer qu'il existe sous la forme d'une chaîne planaire *cis–trans*. Les cristaux sont tricliniques, groupe d'espace $P\bar{1}$, avec a = 9,9078(8), b = 10,0967(9), c = 15,1682(14) Å, α = 78,646(7), β = 71,065(7), γ = 63,449(7)°, V = 1281,5(5) Å^3 et Z = 4. Les valeurs finales de R et R_w sont respectivement 0,033 et 0,027. On a comparé les énergies d'excitation $\pi^* \rightarrow \pi^*$ pour les chromophores RSNSO et RSNSS portant différents groupements R et on en discute à la lumière de calculs MNDO sur les composés modéles HSNSX (X = S, O). Les décompositions thermiques de $Ph_2CNSNSO$ et $Ph_2CNSNSNSNCPh_2$ conduisent respectivement au S_4N_4 et Ph_2CO ou au $(Ph_2CN)_2S$.

[Traduit par le journal]

Introduction

Recently we have characterized a number of species containing the —SNSS chromophore (e.g. $SNSS^-$ (1), $SSNSS^-$ (2, 3), and $Ph_3PNSNSS$ (4)). We have also noted that π-donor ligands, R, induce a large bathochromic shift on the $\pi^* \rightarrow \pi^*$ transition of RSNSS derivatives and explained this effect in terms of qualitative MO considerations (5). Several compounds of the type RSNSO are known, e.g. CF_3SNSO (6) and Me_2NSNSO (7, 8), but quantitative data concerning their molecular structures or electronic spectra are lacking with the exception of $S(NSO)_2$ (9). In order to assess the effect of replacing a terminal sulphur atom by oxygen in these derivatives we have synthesized and determined the crystal and molecular structures of $Ph_2CNSNSO$. We have also carried out MNDO calculations on the model compound HSNSO and compared the results with those found for HSNSS. A secondary interest in RNSNSO compounds was that they might provide a convenient source of S_2N_2, and hence $(SN)_x$, via thermally induced elimination of RO in derivatives where R is a strong oxophile.

Experimental

Reagents and general procedures

Solvents were dried (methylene dichloride (P_2O_5) and acetonitrile (CaH_2 and P_2O_5)) and freshly distilled before use. All reactions were conducted under an atmosphere of nitrogen (99.98% purity passed through Ridox and silica gel). The progress of reactions involving trimethylsilyl reagents was monitored by ^1H nmr spectroscopy, and the non-volatile reaction products were analyzed initially by tlc on silica gel. Chemical analyses were performed by MHW Laboratories, Phoenix, AZ.

Sulphur dichloride (Thiokol/Ventron Division) was distilled before use and the following reagents were prepared by literature procedures: Ph_2CN_2 (10), S_4N_4 (11), $(Ph_2CN)_2S$ (12), $Ph_2CNSiMe_3$ (13), Me_3SiNSO (14), $Me_3SiNSNSiMe_3$ (15).

Instrumentation

Infrared spectra (4000–250 cm^{-1}) were recorded as Nujol mulls (CsI windows) on a Perkin-Elmer 467 grating spectrophotometer. Ultraviolet–visible spectra were obtained by use of a Cary 219 spectrophotometer. Routine ^1H nmr spectra were recorded on a Hitachi Perkin-Elmer R-24B instrument, and mass spectra were run on a Varian CH5 spectrometer (EI/70 eV) or a VG Micromass 7070F instrument (C.I./Ar).

Preparation of diphenylmethyleneamino(thionylimino)sulphide, $Ph_2CNSNSO$

$Ph_2CNSiMe_3$ (2.4 g, 9.3 mmol) in methylene dichloride (5 mL) was added dropwise to a solution of SCl_2 (0.96 g, 9.3 mmol) in methylene dichloride (20 mL) at −78°C. The reaction mixture was allowed to warm up slowly to −60°C during 3 h and then Me_3SiNSO (1.3 g, 9.3 mmol) in methylene dichloride (5 mL) was added at −78°C to the solution which was allowed to reach 23°C slowly. After 3 days solvent was removed from the orange solution *in vacuo* to give a very viscous residue which was redissolved in CH_2Cl_2–CH_3CN. Removal of solvent *in vacuo* produced a yellow solid which was dissolved in the minimum amount of toluene. A small amount of white precipitate, $Ph_2CNH_2^+Cl^-$ (ir spectrum), was removed by filtration. A tlc of the toluene solution indicated two major components which were separated by chromatography on a BioBeads SX-8 column. The first fraction yielded $(Ph_2CN)_2S$ (0.065 g, ir spectrum (12)). The residue obtained after removal of toluene from the second fraction was dissolved in the minimum amount of CH_2Cl_2 (ca. 10 mL) and then an excess of CH_3CN (ca. 40 mL) was added. After several days at −20°C this solution produced orange–red crystals of $Ph_2CNSNSO$ (0.94 g, 3.4 mmol) mp 95–96°C. *Anal.* calcd. for $C_{13}H_{10}N_2OS_2$: C 56.91, H 3.67, N 10.21, S. 23.37, O 5.83; found: C 56.21, H 3.71, N 10.12,

Ms: (E.I. source temperature 100°C) 274(100), 212(62), 180(76), 109(41), 77(87), 51(36), (C.I. source temperature 90°C) 274(19), 212(39), 180(53), 109(39), 104(28), 77(100).

Preparation of bis(diphenylmethylene)trisulphur tetranitride, $Ph_2CNSNSNSNCPh_2$

$Ph_2CNSiMe_3$ (8.3 g, 33 mmol) in CH_2Cl_2 (50 mL) was added dropwise to a solution of SCl_2 (3.4 g, 33 mmol) in CH_2Cl_2 (50 mL) at −78°C. After ca. 3 h a solution of $Me_3SiNSNSiMe_3$ in CH_2Cl_2 (50 mL) was added dropwise to the reaction mixture. The resulting red solution was allowed to reach 23°C slowly. Solvent was removed *in vacuo* and the dark red residue was recrystallized from acetonitrile to give pure (tlc) $Ph_2CNSNSNSNCPh_2$ (2.2 g, 4.5 mmol) λ_{max} 505 nm, $\epsilon = 2 \times 10^{-4}$ M^{-1} cm^{-1} (cf. lit: λ_{max} 508 nm (16)). The infrared spectrum was identical to that of an authentic sample prepared from Ph_2CN_2 and S_4N_4 (16, 17).

Thermolysis of $Ph_2CNSNSNSNCPh_2$

A solution of $Ph_2CNSNSNSNCPh_2$ (0.50 g, 1.0 mmol) in CH_3CN (50 mL) changed colour from deep red to pale orange during 48 h at reflux. After removal of solvent *in vacuo* the residue was dissolved in toluene and chromatographed on a Biobeads SX-8 column. Four fractions were collected and the following products were isolated: (*i*) an inseparable mixture of $Ph_2CNSNSNSNCPh_2$ and $(Ph_2CN)_2S$, (*ii*) and (*iii*) $(Ph_2CN)_2S$ (0.060 g, 0.22 mmol), and (*iv*) S_4N_4 (0.066 g, 0.36 mmol).

X-ray analysis of $Ph_2CNSNSO$

Crystal data

$C_{13}H_{10}N_2OS_2$ fw = 274.37
Space group $P\bar{1}$, $a = 9.9078(8)$, $b = 10.0967(9)$, $c = 15.1682(14)$ Å, $\alpha = 78.646(7)$, $\beta = 71.065(7)$, $\gamma = 63.449(7)°$, $V = 1281.5(5)$ Å^3, $Z = 4$, $\rho_c = 1.422$ g cm^{-3} (21(1)°C; MoKα, $\lambda = 0.71069$ Å, graphite monochromator) and μ(MoKα) = 3.95 cm^{-1}.

A red–orange sample of approximate dimensions 0.40 × 0.40 × 0.30 mm was cut from a large crystal and mounted on an Enraf-Nonius CAD4F diffractometer. Intensity data were collected at room temperature using the $\omega-2\theta$ scan technique with a scan range of 1.5(0.60 + 0.347 tan θ) and scan speeds varying from 0.6 to 5.0° min^{-1}. The intensity was calculated as $I = (P - 2(B1 + B2))Q$, where P is the central 64 steps of a 96 step scan, $B1$ and $B2$ are the background counts, and Q is the scan rate. The standard deviation of the intensity $\sigma(I) = [P + 4(B1 + B2)]^{1/2}Q$. Three standard reflections measured every 2000 s of X-ray exposure time showed no decomposition of the crystal had occurred during the data acquisition period. A total of 5866 unique reflections were measured for the octants $\pm h$, $+k$, $\pm l$ to a maximum $\theta = 27.5°$, of which 2932 were considered observed ($F_o > 3\sigma(F_o)$). The data were corrected for background, Lorentz and polarization effects but an absorption correction was not considered necessary. Extensive photographic studies of a number of crystals supported the choice of space group.

The coordinates of the CNSNSO fragment of one of the two molecules in the asymmetric unit were determined by direct methods (MULTAN 78) (18). Structure factor and difference Fourier calculations revealed the positions of the remaining non-hydrogen atoms. The structure was refined by full-matrix least-squares techniques based on F, minimizing the function $\Sigma w(|F_o| - |F_c|)^2$, where $w = [\sigma(F_o)^2]^{-1}$. All computations were performed using the XRAY 76 system of programs (19) implemented on a Honeywell computer with a Multics operating system. Scattering factors for non-hydrogen atoms were those of Cromer and Mann (20) and those for H were taken from ref. 21. Anomalous dispersion corrections were included for non-hydrogen atoms (22). H atoms were readily located from a difference Fourier map and included in the model in idealized positions (sp^2 at C, C—H = 0.95 Å) with isotropic thermal parameters set to 1.1 times B_{eq} of the atom to which they are bonded. H parameters were not refined. The model converged for 4332 reflections (observed reflections plus those for which $I_c > 3\sigma(I_o)$) and 325 variables with the agreement factors $R = \Sigma(||F_o| - |F_c||)/\Sigma|F_o| = 0.033$ and $R_w = [\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2]^{1/2} = 0.027$. In the final cycle the goodness of fit value was 0.82 and the largest peak of residual electron density was 0.28 e Å^{-3} and was of no chemical significance.

Tables giving the thermal parameters for non-hydrogen atoms (S I), positional and thermal parameters for hydrogen atoms (S II), and the structure factors for $Ph_2CNSNSO$ (S III) have been placed in the Depository of Unpublished Data.[3]

Computational method

The use of the MNDO (modified neglect of diatomic overlap) method (23) for the study of binary sulphur–nitride molecules has been reported by several groups (24–26).

Results and discussion

Preparation of $Ph_2CNSNSO$ and $Ph_2CNSNSNSNCPh_2$

Previous synthetic routes to RSNSO derivatives include the reactions of CF_3SNH_2 with SOF_2 (6), $Me_3SiNR'_2$ (R = Me, Et) with $S(NSO)_2$ (8), or Me_3SiNSO with R''_2NSCl (R″ = Me, Et, *n*-Pr, *i*-Pr) (7). In view of the ready availability of sulphenyl chlorides, the latter could constitute a general method and it has now been applied to the synthesis of $Ph_2CNSNSO$ via Ph_2CNSCl prepared *in situ* (reaction [1]).[4] Attempts to prepare related derivatives (R = Ph_3P, Ph_2S) were unsuccessful. However, this synthetic approach has been extended to provide an alternative preparation of $Ph_2CNSNSNSNCPh_2$ (reaction [2]), a member of a class of compounds which have been used as electrophotographic pigments (27).

$$Ph_2CNSiMe_3 + SCl_2 \xrightarrow{-Me_3SiCl} Ph_2CNSCl$$

[1] $$Ph_2CNSCl \xrightarrow[-Me_3SiCl]{Me_3SiNSO} Ph_2CNSNSO$$

[2] $$Ph_2CNSCl \xrightarrow[-2Me_3SiCl]{Me_3SiNSNSiMe_3} (Ph_2CNSN)_2S$$

Crystal and molecular structure of $Ph_2CNSNSO$

An ORTEP drawing of the molecule is shown in Fig. 1. Table 1 gives the positional parameters and Table 2 gives the bond lengths and bond angles for non-hydrogen atoms in the two different molecules of $Ph_2CNSNSO$ (**A** and **B**). The

[3] Tables S I – S III are available at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

[4] The reaction of Ph_2CNLi with SCl_2 to produce $(Ph_2CN)_2S$ has been reported (ref. 12).

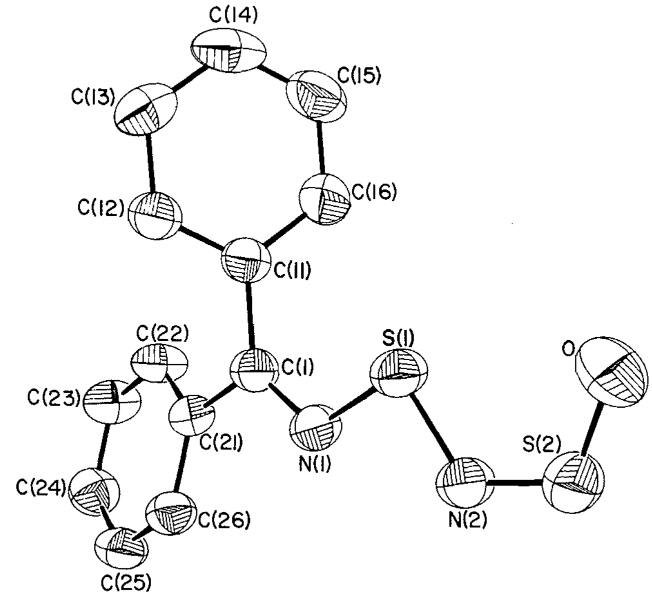

FIG. 1. An ORTEP drawing of $Ph_2CNSNSO$ showing the atomic numbering scheme for molecule **A**.

CNSNSO unit is an essentially planar, *cis–trans* chain,[5] the largest deviations from the best plane being 0.067 Å for S(1) in molecule **A** and −0.087 Å for S(1) in molecule **B** (Table 3). The detailed geometric arrangement bears a marked similarity to that found for the planar chain in OSNSNSO, which has a *cis, trans* geometry for both SNSO units (ref. 9, Table 4). The short C═N bond length (1.286(3) Å) and the alternation in the S—N bond lengths involving N(2) (1.644(2) and 1.529(3) Å) suggest that the valence bond structure **1** is a reasonable approximate representation for $Ph_2CNSNSO$. Furthermore the S(1)—N bond lengths (1.644(2) and 1.680(3)) Å and bond

1

2

angle at S(1) (96.9(1)°) are comparable to the corresponding values for $Ph_2CNSNCPh_2$ (d(S—N) = 1.675(2) Å and ∠NSN 94.7(1)°) (28), which are typical for two coordinate sulphur(II) (29). These data and a comparison of the structural parameters found for the thiosulphinyl derivative, **2** (4), suggest that delocalization of π electrons across S(1) is not well developed in **1**. In **2** the S—N bond lengths involving N(2) are equal (1.592(4) and 1.587(4) Å) and the bond angle at S(1) is 107.7(2)°.

The dihedral angles between the planes of the two phenyl groups attached to C(1) differ for the two molecules **A** and **B** (77.4 vs. 66.7°). Small differences are also observed in the dihedral angles between the individual phenyl groups and the CNSNSO plane (59.6 and 22.9° for **A** vs. 56.0 and 26.3° for **B**).

Electronic structure and uv–visible spectra of RSNSO derivatives

Ab initio HFS MO calculations on a model *cis*-$SNSS^-$ ion indicate that the ground state corresponds to a six π-electron system and that the strong absorption band at 470 nm represents a π* (HOMO) → π* (LUMO) excitation (1). Neutral molecules RSNSS also exhibit intense visible absorption bands attributed to π* → π* transitions and π donor ligands, R, induce a bathochromic shift on this absorption which is larger for soft ligands (e.g. S in $SSNSS^-$, λ_{max} 582 nm) (2) than for hard

[5] *Cis, trans* refers to the geometrical arrangement of the substituents attached to the S(1)—N(2) and S(1)—N(1) bonds, respectively.

ligands (e.g. Ph_3PN in $Ph_3PNSNSS$, λ_{max} 491) (4). This trend has been explained in terms of the change in the energies of the frontier orbitals of RSNSS caused by the substituent R (5), and it is expected to be qualitatively similar for the SNSO chromophore. In order to assess the effect of the replacement of a terminal sulphur atom by oxygen on the electronic structure of RSNSS we have carried out MNDO calculations for the model compounds HSNSO and HSNSS. As indicated in Fig. 2, the bonds are more polar in HSNSO than in HSNSS, but the bond orders are similar. The S—N bond orders of 1.08 and 1.48 for HSNSO are consistent with the observed bond lengths of 1.644(2) and 1.529(3) Å, respectively, for $Ph_2CNSNSO$ (*vide supra*). The corresponding bond orders of 1.11 and 1.50 for HSNSS do not corroborate the equal S—N bond lengths found for $Ph_3PNSNSS$ (4). It should be noted, however, that both "long–short" and "short–long" S—N bond sequences have been observed for $SSNSS^-$ (3), as predicted by *ab initio* MO calculations (2).

The energies and eigenvector coefficients of the π orbitals for planar HSNSO and HSNSS are compared in Table 5. The major difference is the higher energy of the LUMO (π_4) in HSNSO. Since the HOMO energies are similar, the π^* (HOMO) $\rightarrow$ π^* (LUMO) transition is expected to occur at higher energy for RSNSO compared to RSNSS. The experimental data given in Table 6 are consistent with this prediction, and a

TABLE 6. λ_{max} values (nm) for RSNSO and RSNSS derivatives

Compound	λ_{max}	Reference

$SSNSS^-$	582	2

[a]The appearance of two bands is the result of an excitonic coupling of the two chromophores.

similar trend has been observed for the $\pi \rightarrow \pi^*$ transition energies of carbonyls (30) and thiocarbonyls (31).

Thermal decomposition of $Ph_2CNSNSO$ and $Ph_2CNSNSNSNCPh_2$

Although $Ph_2CNSNSO$ exhibits moderate thermal stability, it does decompose at ca. 200°C in the solid state to give S_4N_4 and Ph_2CO (tlc). The formation of S_4N_4 is good evidence for the elimination of S_2N_2 (cf. thermolysis of $Ph_3As{=}N{-}S_3N_3$ (4)), but attempts to trap S_2N_2 using an apparatus described in ref. 4 were thwarted by co-sublimation of $Ph_2CNSNSO$. For comparison, the pyrolysis of $S(NSO)_2$ of 200–400°C under ultrahigh vacuum did not produce S_2N_2 (32).

The thermal decomposition of $Ph_2CNSNSNSNCPh_2$ in acetonitrile at reflux produced S_4N_4 in 72% yield (reaction [3]).

[3] $2Ph_2CNSNSNSNCPh_2 \rightarrow S_4N_4 + 2(Ph_2CN)_2S$

Conclusions

A comparison of RSNSO and RSNSS derivatives shows that they both adopt *cis, trans* chain structures, but the bonds are more polar and the $\pi^* \rightarrow \pi^*$ transition energy is higher in the former. The synthesis of RSNSO compounds (from RSCl) is more straightforward due to the availability of the reagent Me_3SiNSO.

Electrostatic effects on ionization equilibria: MNDO study of proton and hydrogen transfer reactions of 5-fluoropentanoic acid

ZDENEK FRIEDL[1]
Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received July 6, 1984

ZDENEK FRIEDL. Can. J. Chem. **63**, 1068 (1985).

Relative proton transfer enthalpies $\delta\Delta H^0$ and homolytic bond strengths $\delta\Delta H^0$ (A—H) of *sp* and *ap* conformers of 5-fluoropentanoic acid, as well as some related aliphatic and 4-X-bicyclo[2.2.2]octane-1-carboxylic halogenoacids, have been calculated by the MNDO method. The results, together with literature data concerning the gas phase acidities, were compared with the prediction of the electrostatic theory. It is shown that the substituent effects on acidities of carboxylic acids are largely due to substituent interactions in the anions and only to a smaller extent to interactions in the neutral acids. A small contribution (about one-eighth to one-fourth as large in magnitude but of opposite sign) is possibly also made by substituent effects on homolytic bond strengths DH^0 (A—H).

ZDENEK FRIEDL. Can. J. Chem. **63**, 1068 (1985).

Utilisant la méthode MNDO, on a calculé les enthalpies relatives de transferts de protons ($\delta\Delta H^0$) et les forces relatives des liaisons homolytiques ($\delta\Delta H^0$ (A—H)) des conformères *sp* et *ap* de l'acide fluoro-5 pentanoïque, de quelques halogénoacides aliphatiques apparentés et de quelques acides X-4 bicyclo[2.2.2] octanecarboxyliques-1. On a comparé les résultats obtenus ainsi que des données tirées de la littérature relatives aux acidités en phase gazeuse avec des prédictions obtenues à l'aide de la théorie électrostatique. On démontre que les effets des substituants sur les acidités des acides carboxyliques sont dus en grande partie à des interactions des substituants dans les anions alors que les interactions des substituants des acides neutres n'ont qu'une faible influence. Il est possible que les effets des substituants puissent faire une légère contribution (de l'ordre du huitième au quart de l'amplitude mais de signe inverse) sur les forces des liaisons homolytiques DH^0 (A—H).

[Traduit par le journal]

Introduction

Substituent effects on proton transfer reactions may be theoretically predicted within the framework of classical electrostatics. Considering ionization equilibria in the gas phase (1, 2), the electrostatic theory developed by Smallwood (3) seems to be more appropriate than the generally used theory of Kirkwood and Westheimer (4, 5). The second theory was created especially for the description of solvent effects on ionization equilibria in aqueous solutions. These effects are expressed by means of the effective relative permittivity ϵ_{ef}, which must be calculated from the solvent bulk permittivity ϵ_{ext} and the internal relative permittivity ϵ_{int} attributed to the solute molecule (4, 5). On the other hand, Smallwood (3) had cancelled all the solvation terms and considered the effect of the dipolar substituent X on the isodesmic reaction [1]

$$[1] \quad \text{X—A—H} + \text{A}^- = \text{X—A}^- + \text{A—H}$$

as the change of reaction enthalpy $\delta\Delta H^0$ in the gas phase.

Provided that effective relative permittivity ϵ_{ef} equals one for the gas phase, the electrostatic field effect F_D on the equilibrium [1] is expressed in both theories by the same equation, eq. [2]

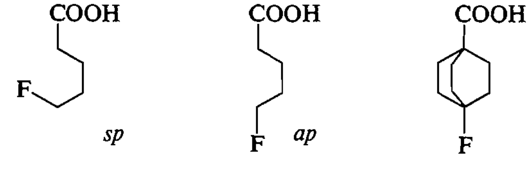
$$[2] \quad \delta\Delta H^0 \cong \delta\Delta E^0 = Ze\mu \cos\theta / r^2 \epsilon_{ef}(4\pi\epsilon_0)$$

where Z is the charge valence (± 1), e the electronic charge, μ is the dipole moment of substituent X, r the distance between charge Ze and μ, and θ is the angle between r and μ.

Equation [2] generally assumes that the remaining substituent effects have been eliminated by the proper choice of system (i.e., especially resonance R_π and steric S_D effects between the substituent X and the anion in X—A$^-$). Until now, great attention was paid to the testing of electrostatic theory from this point of view (2, 6) or simply changing of the geometrical variables r and θ in eq. [2] (refs. 2, 6–8). However, as we mentioned in our previous papers (9–12), two basic assumption of the theory still remain that have not been adequately tested: the equality of the homolytic bond strengths in the substituted and unsubstituted acids, and the consideration of the substituent effect as a direct field effect F_D acting exclusively on the ionizable proton in the neutral acid X—A—H.

At present there are only very limited experimental data about the changes of DH^0 (A—H) due to substitution from gas phase experiments (13–15), and none of them deal with carboxylic acids. In a similar way there are only a few papers (16–18) which consider the F_D effect in both the neutral acid and the anion.

For the reasons mentioned above, we decided to test the common assumption of the equality of homolytic bond strengths at a semiempirical quantum chemical level using the MNDO method. The *sp* and *ap* conformers of 5-fluoropentanoic acid (structure **1**) were chosen as model compounds, which allow us to test the F_D effects of the carbon–fluorine dipole even for the different geometrical parameters r and θ in eq. [2]. The applicability of the MNDO method (19, 20) for the



1 **2**

proton transfer reactions was checked on some related aliphatic and bicyclo[2.2.2]octane-1-carboxylic acids (structure **2**) whose gas phase acidities are known (13).[2]

Computational section

The quantum chemical calculations were made at the semi-empirical MNDO level (21) by using the MNDO (22) and MNDOC (23) programs. The standard geometry parameters (24) were used as a starting value for the geometry optimization, but the C—H bond lengths (109 pm) and the C—C—H bond angles (109.47°) were held constant. During the optimization the carboxyl group was kept coplanar with the carbon chain of the *sp* and *ap* conformers of **1**, and the most stable orientations were taken into account.

The geometrical constraints mentioned above were tested for the case of neutral and anionic forms of the *sp* and *ap* conformers of **1**. Despite this restriction, only a negligible influence upon $\delta\Delta H^0$ was found (less than 0.1 kJ mol^{-1}), in comparison with the fully optimized geometry.

The calculated heats of formation ΔH_f^0, the net atomic charges on the carboxyl proton q_H, and the sum of charges on the carboxylate oxygens q_O are given in Table 1 for all structures mentioned above. The same MNDO parameters for some aliphatic and bicyclo[2.2.2]octane-1-carboxylic acids are given in Table 2.

Electrostatic calculations

The relative electrostatic energies $\delta\Delta E^0$ were calculated from eq. [2] using $\epsilon_{cf} = 1$ and introducing the difference $\mu_X - \mu_H$ for μ. Standard bond moments (25) were used (in 10^{-30} C m): C—H, −1.0; C—F, 4.67; and C—Cl, 5.67. The geometrical parameters r and θ were both calculated from the MNDO optimized atomic coordinates and from the standard geometry parameters (24). In the second case, the ionizable proton of the carboxyl group was localized (4) at a distance of 145 pm from the carbonyl carbon in the direction of the prolonged bond C—C(O). The negative charge on the carboxylate anions was localized in both cases in the middle of the linkage of the carboxylate oxygens.

The electrostatic energies $\delta\Delta E^0$ for reaction [1] were calculated by means of eq. [2], taking charge valence $Z = +1$, while in the case of the relative electron affinities $\delta\Delta E^0$ (EA) the charge valence was taken as $Z = -1$. This means that $\delta\Delta E^0$ values express the energy change accompanying the removal of a proton from the neutral X—A—H molecule, while $\delta\Delta E^0$ (EA) predict the energy of removal of an electron from the electrostatic field due to a substituent dipole in the anion $X—A^-$.

The relative electrostatic energies $\delta\Delta E^0$ and electron affinities $\delta\Delta E^0$ (EA) calculated on the basis of optimized MNDO and standard geometry parameters are given in Table 3.

Discussion

Reynolds *et al.* have shown that *ab initio* molecular orbital calculations at the minimal basis set STO-3G level can be successfully used to predict substituent polar effects (6). This was illustrated, for example, on 4-substituted styrenes (26), 4-substituted benzoic acids (27), and substituted methylamines and pyridines (28). Since the investigated structures contained eight to twelve heavy atoms, the choice of fixed geometries (24) was necessitated by cost considerations. In this respect the semiempirical MNDO method (21) with the geometry opti-

mization can be considered as a promising approach (19, 20), especially as regards still important (2, 8) bicyclo[2.2.2]octane and 1-azabicyclo[2.2.2]octane systems in the future.

As mentioned in the introduction, there is a quite fundamental question as to whether the MNDO method is adequate for the description of the substituent effects on proton transfer reactions. For this reason we calculated MNDO $\delta\Delta H^0$ enthalpies for fluoroacetic, chloroacetic, 2-chloropropionic, 4-fluorobicyclo[2.2.2]octane-1-carboxylic (4-F-BCO), and 4-chlorobicyclo[2.2.2]octane-1-carboxylic (4-Cl-BCO) acids, as their experimental gas phase acidities $\delta\Delta H^0_{\mathrm{exptl}}$ are known (13).[2]

The consistency of the calculated and experimental data of Table 4 is reasonably good considering not only the electronegativity and polarizability effects (the chloro derivatives are stronger acids), but also the absolute $\delta\Delta H^0$ values. In particular, the satisfactory agreement of $\delta\Delta H^0$ values of the *ap* conformer of **1** and 4-F-BCO acid (structure **2**) with the experimental $\delta\Delta H^0_{\mathrm{exptl}}$ of 4-F-BCO acid (−16.2 and −16.7 kJ mol^{-1} versus −23.0 kJ mol^{-1}, Table 4) suggests that MNDO provides a proper description of the F_D effect on proton transfer reactions, because both acids have practically the same geometry parameters cos θ and *r* (see structure **1**), and thus the same theoretical magnitude of the F_D effect.

Comparison of the electrostatic theory with the MNDO calculations is presented in Tables 3 and 4. The problem is whether the gas phase acidities $\delta\Delta H^0$ are better predicted by the $\delta\Delta E^0$ or the $\delta\Delta E^0$ (EA) values.[3] In order to test this problem the following three types of isodesmic reactions [3] were formed,

[3] 
where R is either the carboxyl group COOH, carboxylate anion COO^-, or carboxyl radical $COO^\bullet$ in both *sp* and *ap* conformers of 5-fluoropentanoic acid. The effect of the substituent on acidity $\delta\Delta H^0$ (Table 4) is then given by the energy change for reaction [1], which is just the difference in the $\delta\Delta H_3^0$ energies for the COOH and COO^- groups. In a similar way, the substituent effects on the homolytic bond strengths δDH^0 (A—H) are given by the energy change for reaction [4]:

[4] $\mathrm{X{-}A{-}H + A^\bullet = X{-}A^\bullet + A{-}H}$

and eq. [5] expresses the substituent effects on electron affinity of the radical $\delta EA(A^\bullet)$:

[5] $\mathrm{X{-}A^- + A^\bullet = X{-}A^\bullet + A^-}$

The substituent effects on the gas phase acidity are then given with regard to eqs. [1], [4], and [5] by eq. [6]:

[6] $\delta\Delta H^0 = \delta DH^0\,(\mathrm{A{-}H}) - \delta EA\,(\mathrm{A^\bullet})$

TABLE 5. MNDO calculated $\delta\Delta H_3^0$ energies of reaction [3], homolytic bond strengths δDH^0 (A—H), and electron affinities δEA ($A^\bullet$) of eq. [6] (in kJ mol^{-1})

R	$\delta\Delta H_3^0$ *sp*	$\delta\Delta H_3^0$ *ap*	δDH^0 (A—H) *sp*	δDH^0 (A—H) *ap*	δEA ($A^\bullet$) *sp*	δEA ($A^\bullet$) *ap*
COOH	−0.6	−2.3	−1.0	2.2	−4.5	18.4
COO^-	−4.1	13.9	—	—	—	—
$COO^\bullet$	0.4	−4.5	—	—	—	—

The MNDO calculated $\delta\Delta H_3^0$ energies, the homolytic bond strengths δDH^0 (A—H), and electron affinities δEA ($A^\bullet$) are given in Table 5. When comparing these data, it is obvious that the predominant substituent effect on $\delta\Delta H^0$ is largely due to substituent interactions in the anions (16–18) and only to a smaller extent to interactions in the neutral acids and the carboxyl radicals.

In order to test the electrostatic theory we plotted the $\delta\Delta E^0$ and $\delta\Delta E^0$ (EA) values against the $\delta\Delta H^0$ energies. Figure 1 reveals that evidently the best agreement is with the MNDO geometry based $\delta\Delta E^0$ (EA) electron affinities. The electrostatic energies $\delta\Delta E^0$ generally underestimate $\delta\Delta H^0$, especially with respect to short-chain aliphatic halogenoacids (points 6–8, Fig. 1). The same pattern can be seen from the relative net atomic

[3] This approach differs slightly from Yoder's treatment (18) and, as regards the geometry used, is discussed below.

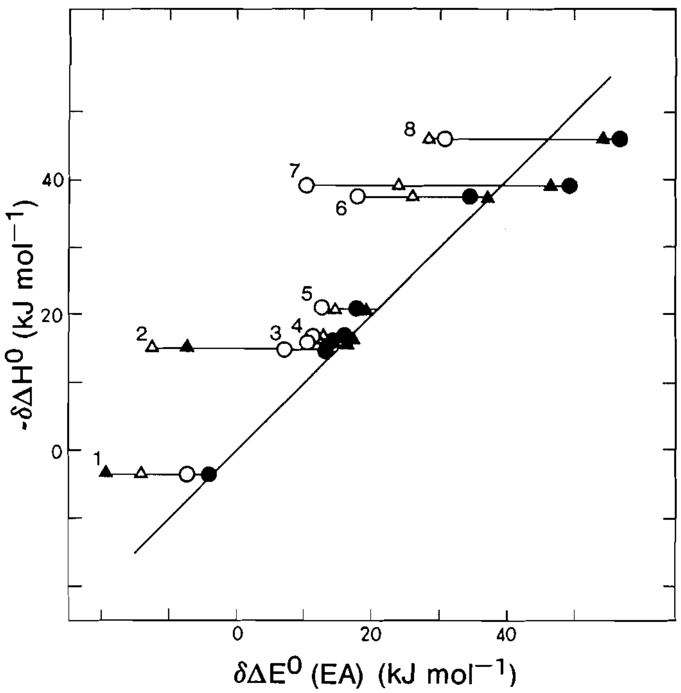

FIG. 1. Test of the electrostatic theory for variable halogenoacids. The MNDO $\delta\Delta H^0$ energies of various halogenoacids are plotted against $\delta\Delta E^0$ (○ MNDO, △ standard geometry) and (or) $\delta\Delta E^0$ (EA) (● MNDO, ▲ standard geometry). Parent acids: 1, *sp* 5-F-pentanoic; 2, *sp* 2-Cl-propionic; 3, *ap* 5-F-pentanoic; 4,4-F-BCO; 5,4-Cl-BCO; 6, *ap* 2-Cl-propionic; 7, fluoroacetic; 8, chloroacetic. The straight line has the theoretical slope.

charges δq_H and δq_O which are listed in Table 4. The ratio of $\rho(\delta q_O)/\rho(\delta q_H) = 3.3$ for the conformers of 5-fluoropentanoic acid, and for the related aliphatic halogenoacids it is even higher – approximately 10. In other words, these facts mean that the substituent effects on $\delta\Delta H^0$ are predominantly due to effects in the carboxylate anions so that the relative electron affinities $\delta\Delta E^0$ (EA) give a more appropriate description of the proton transfer reaction [1] at the empirical level of the electrostatic theory.

Note the failure of the standard geometry based $\delta\Delta E^0$ (EA) values (18) as regards a description of the reversed substituent effect in acids 1 and 2 (Fig. 1). In order to reach reasonable agreement with the $\delta\Delta H^0$ energies, the use of a corresponding fully optimized geometry is necessary.

The remaining problem is the possible substituent effects on homolytic bond strength DH^0 (A—H) during the proton transfer reaction [1]. If there was a set of experimental $\delta\Delta H^0$ and δEA (A$^\cdot$) values it would probably be possible to obtain δDH^0 (A—H) energies, even given their large uncertainty (29). Due to the lack of experimental data we tried to obtain δDH^0 (A—H) energies for reaction [4], at least at a MNDO method level.

The relevant data are assembled in Tables 4 and 5. When we compare $\delta\Delta H_3^0$ and $\delta\Delta H^0$ energies (Table 4) it is obvious that substituent effects on acidity are largely determined by effects in carboxylate anions, but their magnitudes in the corresponding neutral acids and carboxyl radicals are practically the same. Regardless of the small absolute values of δDH^0 (A—H), which are given in Table 5 (about one-eight (*ap*) to one-fourth (*sp*) as large in magnitude but of opposite sign), the general pattern of F_D effects on reaction [4] is quite reasonable: the lower the polarity of the O—H bond, the lower the δDH^0 (A—H) energy. Table 4 shows this relationship more explicitly in terms of the relative atomic charges δq_H, which predict an increase of electron density on the reaction centre of the *sp* conformer of 5-fluoropentanoic acid.

A somewhat less accurate approach based on the MNDO calculated IP (i.e., the negative HOMO energies of the anions X—A$^-$) gives δEA (A$^\cdot$) −2.9 kJ mol^{-1} for the *sp* and 18.4 kJ mol^{-1} for the *ap* conformer. Even so, the corresponding homolytic bond strengths (0.6 and 2.2 kJ mol^{-1}, respectively) agree fairly well with the δDH^0 (A—H) in Table 5.

The relative homolytic bond strength δDH^0 (A—H) is usually neglected within the framework of electrostatic theory (3–6). However, if the respective proton transfer reaction were transferred from the gas phase into solution, the magnitude of δDH^0 (A—H) would become more important for a predominant solvent effect on δEA (A$^\cdot$). For example, in the following reaction [7] we calculated that the $\delta\Delta H^0$ energies would

[7] $X—A—H + A^- \ldots H_2O = X—A^- \ldots H_2O + A—H$

decrease by 0.2 kJ mol^{-1} for the *sp* and 0.4 kJ mol^{-1} for the *ap* conformer of 5-fluoropentanoic acid. This trend agrees in general with the solvent attenuation factor (2) for the substituted acetic acids (SAF(aq) = $\rho_I(gas)/\rho_I(aq)$ = 4.1). Summarizing the present evidence, we can state that the homolytic bond strengths DH^0 (A—H) do not necessarily cancel, and that a competent experimental examination will be desirable in future studies.

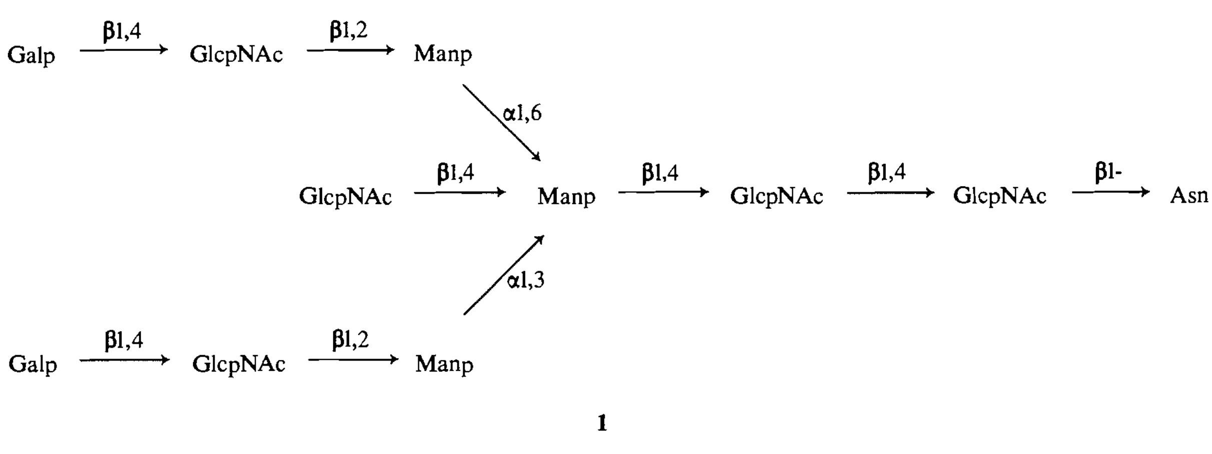
The synthesis of two trisaccharides and one disaccharide containing L-fucose and 2-acetamido-2-deoxy-D-glucose is reported. Methyl 3,6-di-*O*-benzyl-2-deoxy-2-phthalimido-β-D-glucopyranoside was glycosylated with a 3,4,6-tri-*O*-acetyl-2-deoxy-2-phthalimido-β-D-glucopyranosyl bromide. Removal of the phthalimido protecting groups by hydrazinolysis followed by *N*-acetylation and debenzylation yielded methyl *N*,*N*′-diacetylchitobioside 3′,4′,6′-triacetate. The latter was selectively fucosylated at the 6-position with 2,3,4-tri-*O*-benzyl-α-L-fucopyranosyl bromide to yield, after debenzylation and de-*O*-acetylation, methyl 2-acetamido-4-*O*-(2-acetamido-2-deoxy-β-D-glucopyranosyl)-2-deoxy-6-*O*-(α-L-fucopyranosyl)-β-D-glucopyranoside. When methyl 3-*O*-benzyl-2-deoxy-2-phthalimido-β-D-glucopyranoside was fucosylated, its 6-*O*- and 4,6-di-*O*-(α-L-fucopyranosyl) derivatives were obtained by use of 1 and 2 equivalents, respectively, of the protected fucosyl bromide.

DAVID A. SCHWARTZ, HO-HUAT LEE, JEREMY P. CARVER et JIRI J. KREPINSKY. Can. J. Chem. **63**, 1073 (1985).

On rapporte la synthèse de deux trisaccharides et d'un disaccharide contenant du L-fucose et de l'acétamido-2 déoxy-2 D-glucose. On a glycosylé le di-*O*-benzyl-3,6 déoxy-2 phtalimido-2 β-D-glucopyrannoside de méthyle avec le bromure de tri-*O*-acétyl-3,4,6 déoxy-2 phtalimido-2 β-D-glucopyrannosyle. L'hydrazinolyse du groupe protecteur phtalimido, suivie d'une *N*-acétylation et d'une débenzylation, conduit au N triacétate-3′,4′,6′ du *N*,*N*′-diacétylchitobioside de méthyle. La fucolisation sélective de ce dernier en position 6 à l'aide du bromure de tri-*O*-benzyl-2,3,4 α-L-fucopyrannosyle, conduit, après débenzylation et dé-*O*-acétylation, à l'acétamido-2 *O*-(acétamido-2 déoxy-2 β-D-glucopyrannosyl)-4 déoxy-2 *O*-(α-L-glucopyrannosyl)-6 β-D-glucopyrannoside de méthyle. La fucosylation du *O*-benzyl-3 déoxy-2 phtalimido-2 β-D-glucopyrannoside par 1 ou 2 équivalents de bromure de fucosyle protégé de méthyle permet d'obtenir les dérivés *O*-6 ou di-*O* (α-L-fucopyranosyle)-4,6.

[Traduit par le journal]

Glycoproteins containing N-linked oligosaccharides are ubiquitous on cell surfaces. All such oligosaccharides contain a core structure which is invariably attached through an *N*,*N*′-diacetylchitobiosyl linkage to L-asparagine (1), and in some cases this disaccharide moiety is glycosylated with L-fucose (2). We are studying the role of the three-dimensional structure of oligosaccharides such as **1** and **2** in biosynthetic pathways as well as in cell–cell recognition. In addition to this, the complete structures or their fragments can be used as determinants of artificial antigens which may be useful for the prep-



1

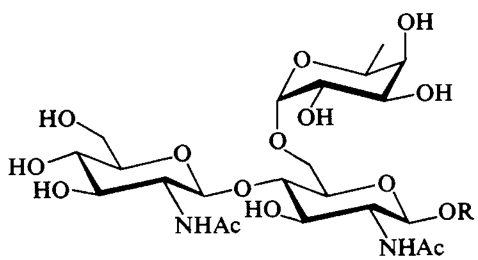
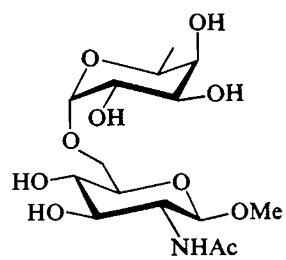
2

aration of diagnostic reagents (2, 3). In our overall synthetic strategy we sought to develop a methodology for the efficient syntheses of smaller oligosaccharides which can be linked together to form **1** or **2**. Thus we have previously reported the syntheses of the mannose-containing portion of the core (4, 5), and herein we describe an efficient and simple synthesis of the chitobiose-fucose part of **2**, i.e. the model trisaccharide **3***a*. We also wanted to prepare the disaccharide **4**, and in the course of this synthesis we observed that the reactivities of OH-6 and OH-4 differ sufficiently to allow a simple preparation of either **4** or **5**.

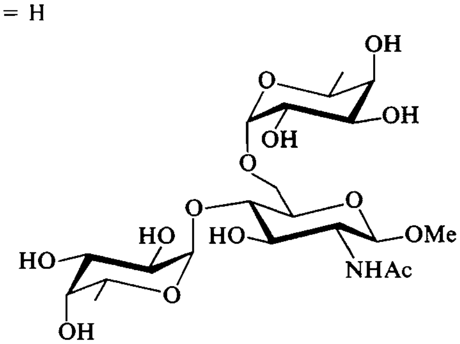
Trisaccharide **3***b* has already been synthesized (6) in a fairly complicated procedure employing 1,6-anhydro derivatives (20 steps in 1% overall yield). Since OH-4 is much more reactive in the latter than in the conventional $^4C_1$ conformation it seems advantageous to utilize this property for the formation of the 1,4-linkage of chitobiose. However, the use of 1,6-anhydro sugars is also extremely time-consuming, so we set out to design a shorter route which would allow the preparation of substantial quantities of **3***a* and related oligosaccharides relatively rapidly. The efficiency of the synthetic sequence is of particular importance because, eventually, isotopically labelled



3*a* R = Me
b R = H



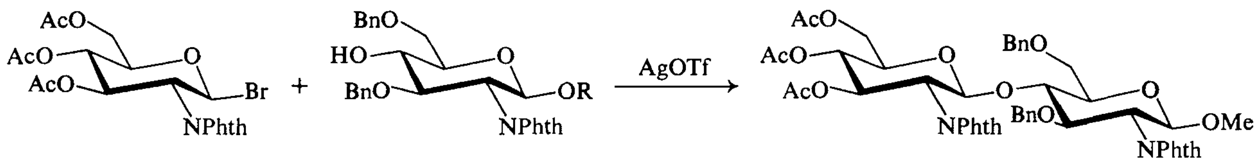
4



5

fucose is to be incorporated.

Lemieux *et al.* (7) have shown that the OH-4 in 2-amino-2-deoxyglucose is not so unreactive in the $^4C_1$ conformation as to warrant the use of 1,6-anhydro derivatives (8, 9). It was also shown previously (7, 11) that the protection of the amino function as its *N*-phthalimido derivative in glycosylating agents leads to exclusive formation of the desired β-anomer in similar situations. Moreover, in an aglycon moiety, the *N*-phthalimido group cannot participate in an imidate formation as the acetamido group does (10). We have therefore adopted the *N*-phthalimido approach to form a chitobiosyl derivative as, for instance, in the condensation of the aglycon **6***a* with the bromide **7** using silver triflate/collidine as a promoter, which resulted in a 60% yield of the disaccharide **8***a* (11).



7

6*a* R = CH_2CCl_3
b R = Me

8*a* R = CH_2CCl_3
b R = Me

The aglycon required for the synthesis of trisaccharide **3***a* should be a derivative of **8** in which the OH-6 is free. Therefore, any protection of this OH group should be removable in the presence of other blocking groups. First we considered the combinations **9** (R = Bn, R' = Ac) and **10** (R = *tert*-butyldimethylsilyl, R' = Ac).

Glycosylation of bromide **7** with methanol using silver triflate/collidine as promoter yielded **11** in 79% yield, with complete β-anomeric specificity (as determined by 360-MHz ^{1}H nmr spectroscopy). This glycosylation was subsequently accomplished more readily and in higher yield (95%) using silver zeolite (13) as the promoter with no loss of anomeric specificity.

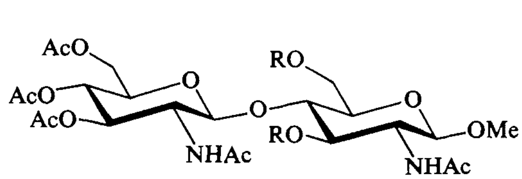
Zemplén deacetylation gave in 85% yield the triol **12** which after benzylidenation with α,α-dimethoxytoluene/*p*-toluenesulphonic acid gave **13** in 85% yield. Acetylation followed by hydrolysis of the benzylidene moiety gave the 3-acetyl derivative **15** in 80% yield. The structure of **15** was confirmed by its ^{1}H nmr spectrum which exhibited a signal at δ 5.63 characteristic of an acetylated H-3 (dd, J = 10.6 and 9.1 Hz).

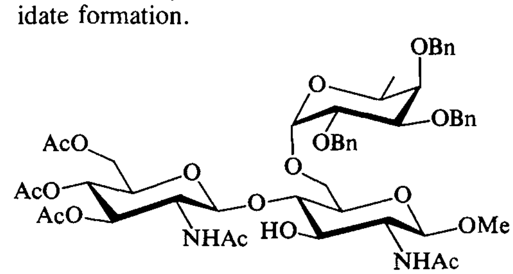
An attempt to synthesize **9** from diol **15** using phase transfer catalysis (14) resulted in isolation of **16** formed by migration of the secondary acetate group to the primary hydroxyl group. The stannylation technique of benzylation (11) yielded only the 6-benzyl derivative **17**, as the acetate was labile under the reaction conditions. We could not obtain the 3,6-dibenzyl derivative by this procedure as has been reported previously (15) for methyl α-D-mannopyranoside.

Unable to synthesize alcohol **9** we turned our attention to alcohol **10**. Direct silylation of diol **15** with *tert*-butyldimethylsilyl chloride and imidazole in DMF gave the desired alcohol **10** in 66% yield. Attempted glycosylation of alcohol **10** with bromide **7** using silver triflate/3,4-dihydro-2*H*-pyrido[1,2-*a*]-pyridinone-2-one (11, 16) in dichloroethane was unsuccessful, presumably because of the steric encumbrance of the bulky silyl protecting group.

Stymied by our previous approaches to make monosaccharides **9** and **10** with differential protection at the 3- and 6-positions of the glycon, we felt that the synthesis of disaccharide **20** (cf. ref. 11) or **8***b*, followed by their debenzylation, would lead to diols which could be selectively fucosylated at the desired, and more accessible, primary 6-position. Acetamido groups in **20** could be a potential problem as they can form an imidate in glycosidation reactions using strong promoters (10). However, it has been shown previously that in glycosidations in which mild promoters were used, certain bases present in the reaction mixture could be responsible for the imidate formation (e.g. Hünig's base, ref. 7*c*). The avoidance of such bases, particularly when the hydroxyl group to be glycosylated is the more reactive primary one (as would be the case in the standard, bromide ion-catalyzed fucosylation (12) of an *N*,*N'*-diacetylchitobiose derivative by tri-*O*-benzyl-α-L-fucopyranosyl bromide) should therefore suppress the imidate formation.



20 R = Bn
21 R = H



22

The synthesis of the starting alcohol **18** began from the benzylidene derivative **13** which was alkylated in 86% yield with sodium hydride and benzyl bromide in diethoxyethane to give **19** (11). Selective reduction of the benzylidene acetal in **19** using sodium cyanoborohydride (17) gave the desired alcohol **18** in 95% yield. The overall yield of **18** from **7** was 50%.

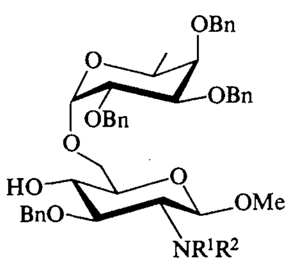
Glycosylation of alcohol **18** with bromide **7** to give the desired disaccharide **8***b* was accomplished in 46% yield using silver triflate/collidine in nitromethane. The ^{1}H nmr spectrum of **8***b* exhibited a doublet at δ 5.53, (J = 8.4 Hz, H-1) and a doublet at 4.87, (J = 8.3 Hz, H-1′). These assignments were confirmed by decoupling experiments (cf. also ref. 11).[3]

In order to synthesize the trisaccharide **3***a* starting from **8***b* we considered two approaches differing in whether the fucosylation would be performed on *N*-phthalimido or *N*-acetyl derivatives. As it as desirable to keep the number of synthetic steps after fucosylation to a minimum because, eventually, isotopically labelled fucose is to be incorporated, the latter was preferred.

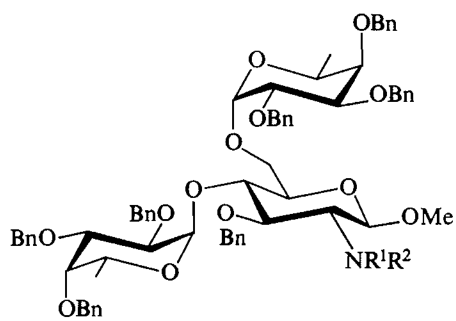
Hydrazinolysis of **8***b* and subsequent acetylation gave the desired *N,N′*-diacetylchitobiose derivative **20** in 75% yield. This disaccharide was debenzylated by hydrogenolysis over palladium-on-charcoal in methanol to give diol **21**. Diol **21** was selectively fucosylated in 65% yield with 1.2 equivalents of 2,3,4-tri-*O*-benzyl-α-L-fucopyranosyl bromide (18) using the halide ion-catalyzed procedure (12), i.e., tetraethylammonium bromide and 4A molecular sieves in dichloromethane/DMF. Trisaccharide **22** was deprotected by hydrogenolysis followed by Zemplén deacetylation to give trisaccharide **3***a* in 55% yield.

The structure of **3***a* was confirmed by its ^{1}H nmr spectrum, which exhibited three anomeric doublets: δ 4.91, (J = 3.8 Hz, H-1, α-fucopyranosyl moiety), 4.64, (J = 7.6 Hz, H′) and 4.43 (J = 8.0 Hz, H-1). The broadened quartet at δ 4.13, J = 6.3 Hz and <0.5 Hz is assigned to H-5 on the fucose moiety and is characteristic for a fucose substituted at the 6-position of *N,N′*-diacetylchitobiose (19).

Synthesis of saccharides **4** and **5** began with the hydrolysis of **19** in 60% aqueous acetic acid to give diol **23** in 88% yield. The protected disaccharide **24** was prepared from **23** by taking advantage of the higher reactivity of the primary hydroxyl group in **23** towards 2,3,4-tri-*O*-benzyl-α-L-fucopyranosyl bromide **28** (18) in comparison with the secondary hydroxyl. Consequently, the use of 1.2 equivalents of **28** for shorter periods of time leads to almost exclusive formation of **24**, while 2.4 equivalents or more of **28** and prolonged reaction times yield mostly the trisaccharide derivative **25**. It is, however, easy to separate **24** from **25** by chromatography.



24 R¹, R² = Phth
26 R¹ = Ac, R² = H



25 R¹, R² = Phth
27 R¹ = Ac, R² = H

Deprotection of both **24** and **25** by hydrazinolysis followed by *N*-acetylation and hydrogenolysis gave disaccharide **4** and trisaccharide **5**, respectively. The ^{1}H nmr spectra of **4** and **5** were in complete agreement with their structures. Thus, for example, **4** showed two anomeric proton resonances at δ 4.49 (d, J = 3.9 Hz, H-1′) and δ 4.45 (d, J = 8.5 Hz, H-1), a one-proton quartet at δ 4.14 (J = 6.5 Hz, J_2 < 0.5 Hz, H-5′), and a three-proton doublet at δ 1.23 (J = 6.6 Hz, H-6′). Similarly, **5** showed three anomeric proton resonances at δ 5.00 (J = 3.6 Hz, H-1′), 4.91 (J = 3.9 Hz, H-1″), and at 4.44 (J = 8.3, H-1), as well as two three-proton doublets at δ 1.22 and δ 1.14 (J = 6.6 Hz, H-6′ and H-6″).

Complete analysis of the nmr spectra of **3***a*, **4**, and **5** will be published elsewhere in connection with our conformational studies of these oligosaccharides.

Experimental

General methods

Melting points were determined on a Reichert Thermovar melting point apparatus and are uncorrected. Optical rotations were measured with a Perkin–Elmer polarimeter (Model 140) at 26 ± 1°C. Microanalyses were performed by the Microanalytical Laboratory Ltd., Markham, Ontario. The ^{1}H nmr spectra were recorded at 360 MHz with a Nicolet spectrometer at the Toronto Biomedical NMR Centre, University of Toronto. They were obtained at 23 ± 2°C either in $CDCl_3$ containing 1% TMS as the internal standard or in D_2O (99.996%, Merck, Sharp, and Dohme) with acetone (0.1%, 2.225 ppm relative to internal DSS) as the internal standard. FAB mass spectrometry was performed with a VG Analytical ZAB HF reverse geometry instrument (for general conditions cf. ref. 22 and references therein) at the Institute of Physiological Chemistry, University of Bonn.

Thin layer chromatography (tlc) was performed on silica gel $60F_{254}$ (Merck) plastic plates using the following solvent systems: A, hexane/ethyl acetate (1:1); B, ethyl acetate (100%); and visualized by quenching of ultraviolet fluorescence and (or) spraying with 50% aqueous sulfuric acid and heating at 100°C. Silica gel 60 (230–400 mesh; Merck was used for flash chromatography. All glycosylation reactions were performed under an argon atmosphere. All starting materials were dried overnight under vacuum (10^{-3} Torr; 1 Torr = 133.3 Pa) prior to use and all solvents were distilled from appropriate drying agents. Solutions were concentrated at water aspirator pressure unless indicated *in vacuo* (10^{-3} Torr).

The symbols ′ and ″ are used as follows:

$$\text{G}' \text{ (or F}') \xrightarrow[1,6]{1,4 \text{ or}} \text{G} \rightarrow \text{aglycon}$$

$$\begin{array}{ccccc} & & \text{F}'' & & \\ & & \downarrow{\scriptstyle 1,6} & & \\ \text{G}' & \xrightarrow{1,4} & \text{G} & \xrightarrow{1,6} & \text{aglycon} \end{array}$$

[3]Symbols used to distinguish monosaccharide units in oligosaccharides are defined in the experimental part.

F'' & \xrightarrow[1,4]{} & G & \xrightarrow{1,6} & \text{aglycon}
\end{array}
$$

where G represents an *N*-acetylglucosamine unit and F represents a fucose unit.

*Methyl 3,4,5-tri-*O*-acetyl-2-deoxy-2-phthalimido-β-D-glucopyranoside (11)*

Method A

To a cooled solution (−30°C) of methanol (0.9 mL), collidine (3.0 mL; 22.9 mmol), and silver triflate (5.80 g; 22.6 mmol) in nitromethane (25 mL) was added a solution of bromide **7**[4] (9.96 g; 20.0 mmol) in nitromethane (15 mL). The reaction mixture was stirred at −30°C for 1 h (tlc monitored), warmed to room temperature, and filtered through Celite. The filtrate was washed successively with 0.5 *N* aqueous HCl, saturated aqueous $NaHCO_3$, and brine. The organic extract was dried ($MgSO_4$) and concentrated to give a yellow oil from which **11** was crystallized after dilution with hexane/ethyl acetate (1:1) as a white solid (6.15 g in two crops; 79% yield).

Method B

To a stirred mixture of silver zeolite (20 g) (ref. 13), methanol (6 mL), and dichloromethane (75 mL) was added a solution of bromide (α or β) **7** (20.4 g; 40.9 mmol) in dichloromethane (50 mL). The reaction mixture was protected from light and was stirred at room temperature for 1 h, filtered through Celite, and the filtrate was concentrated to give a syrup (18.0 g) which after recrystallization from hexane/ethyl acetate (1:1) gave microcrystalline **11** (17.0 g; 95% yield from three crops); mp 155–157°C; $[\alpha]_D$ +42.2° (*c* 1.0, chloroform) (lit. (20) mp 160.5–162.0°C; $[\alpha]_D$ +44.7° (*c* 1.1, chloroform); (lit. (21) mp 156–157°C; $[\alpha]_D$ +45.5° (*c* 3.23, chloroform)); R_f(A) 0.3; ^{1}H nmr δ: 7.75–7.90 (m, 4H, $N(CO)_2C_6H_4$), 5.78 (dd, 1H, *J* = 10.6, 9.2 Hz, H-3), 5.30 (d, 1H, *J* = 8.5 Hz, H-1), 3.45 (s, 3H, OCH_3), 2.15, 2.05, and 1.88 (s, 9H, $COCH_3$).

Methyl 2-deoxy-2-phthalimido-β-D-glucopyranoside (12)

This compound was prepared in 85% yield from triacetate **11** and sodium methoxide in methanol according to ref. 20; mp 200–202°C; $[\alpha]_D$ −9.1° (*c* 1.0, methanol) (lit. (20) mp 202.5–204.5°C; $[\alpha]_{589}$ −8.62° (*c* 1.0, methanol)); R_f(A) 0.0, (B) 0.3; ^{1}H nmr δ: 7.85–7.95 (m, 4H, $N(CO)_2C_6H_4$), 5.17 (d, 1H, *J* = 8.3 Hz, H-1), 3.43 (s, 3H, OCH_3).

*Methyl 4,6-*O*-benzylidene-2-deoxy-2-phthalimido-β-D-glucopyranoside (13)*

Compound **13** was prepared in 85% yield from triol **12**, α,α-dimethoxytoluene, and *p*-toluenesulphonic acid in acetonitrile (7). After recrystallization from hexane/ethyl acetate (1:1) a colourless microcrystalline solid was isolated; mp 192–194°C; $[\alpha]_D$ +63.2° (*c* 1.0, chloroform); R_f(A) 0.43; ^{1}H nmr δ: 7.72–7.88 (m, 4H, $N(CO)_2C_6H_4$), 7.36–7.51 (m, 5H, C_6H_5CH), 5.60 (s, 1H, CHC_6H_5CH), 5.21 (d, 1H, *J* = 8.4 Hz, H-1), 3.45 (s, 3H, OCH_3), 2.38 (s, 1H, D_2O exch., *OH*). *Anal.* calcd. for $C_{22}H_{21}NO_7$: C 64.23, H 5.14, N 3.40; found: C 64.44, H 5.20, N 3.46.

*Methyl 3-*O*-acetyl-4,6-benzylidene-2-deoxy-2-phthalimido-β-D-glucopyranoside (14)*

Acetic anhydride (12.5 mL) was mixed with a cooled solution (0°C) of **13** (5.95 g; 14.4 mol) in pyridine (25 mL) and the reaction mixture was stirred overnight at room temperature. The colourless solution was poured onto crushed ice; the separated solid was collected by filtration, and dried *in vacuo*, to give **14** as an amorphous solid (5.90 g; 90% yield); $[\alpha]_D$ +4.0° (*c* 1.0, chloroform); R_f(A) 0.46; ^{1}H nmr δ: 7.7–7.9 (m, 4H, $N(CO)_2C_6H_4$)), 7.3–7.5 (m, 5H, C_6H_5CH), 5.88 (dd, 1H, *J* = 10.2 and 9 Hz, H-3), 5.55 (s, 1H, C_6H_5CH), 5.37 (d, 1H, *J* = 8.4 Hz, H-1), 3.45 (s, 3H, OCH_3). *Anal.* calcd. for $C_{24}H_{23}NO_8$: C 63.57, H 5.11, N 3.09; found: C 63.44, H 5.26, N 3.14.

[4]This compound and some other intermediates were purchased from Toronto Research Chemicals, 100 College St., Toronto, Ont., Canada M5G 1L5.

*Methyl 3-*O*-acetyl-2-deoxy-2-phthalimido-β-D-glucopyranoside (15)*

A solution of **14** (1.05 g; 2.31 mmol) in 60% acetic acid (50 mL) was heated at 100°C for 30 min (tlc monitored). The solvent was removed *in vacuo* to give diol **15** as a colourless solid (748 mg; 88% yield). Recrystallization from hexane/ethyl acetate gave **15** as a microcrystalline solid; mp 84–86°C; $[\alpha]_D$ +74.4° (*c* 1.0, chloroform); R_f(B) 0.45; ^{1}H nmr δ: 7.85–7.95 (m, 4H, $N(CO)_2C_6H_4$), 5.63 (dd, 1H, *J* = 10.6 and 9.1 Hz, H-3), 5.30 (d, 2H, *J* = 8.4 Hz, H-1), 3.45 (s, 3H, OCH_3), 2.8 (br s, 2H, *OH*), 1.95 (s, 3H, $COCH_3$).

*Methyl 6-*O*-acetyl-2-deoxy-2-phthalimido-β-D-glucopyranoside (16)*

A solution of diol **15** (200 mg; 0.54 mmol), tetra-*n*-butylammonium hydrogen sulfate (40 mg; 0.11 mmol), and benzyl bromide (0.1 mL; 0.82 mmol) in dichloromethane was added to a solution of aqueous NaOH (1 *M*; 0.65 mL; 0.65 mmol) in water (5 mL), and heated under reflux for 16 h. The organic phase was separated, dried ($MgSO_4$), filtered, and concentrated to a colourless oil. Flash chromatography on silica gel (hexane/ethyl acetate (35:65)) gave **16** as an amorphous solid; R_f(B) 0.44; ^{1}H nmr δ: 7.85–7.95 (m, 4H, $N(CO)_2C_6H_4$), 5.15 (d, 1H, *J* = 8.4 Hz, H-1), 4.67 (dd, 1H, *J* = 12.4 and 3.5 Hz, H-6), 4.29 (dd, *J* = 12.4 and 2.2 Hz, H-6′), 3.44 (s, 3H, OCH_3), 2.05 (s, 3H, $COCH_3$).

*Methyl 6-*O*-benzyl-2-deoxy-2-phthalimido-β-D-glucopyranoside (17)*

A solution of diol **15** (200 mg; 0.55 mmol) and bis(tri-*n*-butyl tin) oxide (0.30 mL; 0.58 mmol) in toluene (8 mL) was heated under reflux with continuous removal of water for 3 h. The solution was cooled to room temperature, the solvent was removed *in vacuo*, and the residue was dissolved in benzyl bromide (5 mL) and heated at 85°C for 18 h. After processing as described (11), the colourless residual oil was purified by flash chromatography on silica gel (ethyl acetate) to give **17** as an oil; R_f(B) 0.55; ^{1}H nmr δ: 7.85–7.95 (m, 4H, $N(CO)_2C_6H_4$), 6.82–7.03 (m, 5H, $C_6H_5CH_2$), 5.15 (d, 1H, *J* = 8.4 Hz, H-1), 3.85 (m, 2H, H-6), 3.43 (s, 3H, OCH_3).

*Methyl 3-*O*-acetyl-6-*O*-(*tert*-butyl)dimethylsilyl-2-deoxy-2-phthalimido-β-D-glucopyranoside (10)*

A solution of diol **14** (560 mg; 3.83 mmol) in DMF (5 mL) containing *tert*-butyldimethylsilyl chloride (277 mg; 1.84 mmol) and imidazole (260 mg; 3.83 mmol) was stirred overnight at room temperature. The colourless solution was diluted with ether, washed successively with water and brine, dried ($MgSO_4$), filtered, and concentrated. The residual oil was purified by flash chromatography on silica gel using hexane/ethyl acetate (1:1) as eluant; a colourless solid was isolated which was crystallized from hexane/ethyl acetate (490 mg; 66% yield); mp 138.5–140°C; $[\alpha]_D$ +0.6 (*c* 1.0, chloroform); R_f(A) 0.45; ^{1}H nmr δ: 7.85–7.95 (m, 4H, $N(CO)_2C_6H_4$), 5.65 (dd, 1H, *J* = 10.7, 8.3 Hz, H-3), 5.28 (d, 1H, *J* = 8.5 Hz, H-1); 3.45 (s, 3H, OCH_3), 1.95 (s, 3H, $COCH_3$), 1.6 (s, 1H, D_2O exch., *OH*), 0.95 (s, 9H, $(CH_3)_3C$), 0.10 (s, 6H, $SiCH_3$). *Anal.* calcd. for $C_{23}H_{33}NO_8Si$: C 57.60, H 6.93, N 2.92; found: C 57.71, H 7.04, N 2.90.

*Methyl 3-*O*-benzyl-4,6-benzylidene-2-deoxy-2-phthalimido-β-D-glucopyranoside (19)*

Compound **19** was prepared in 86% yield from alcohol **13**, sodium hydride, and benzyl bromide in dimethoxyethane as described (11). Following work-up, the residual oil was crystallized from hexane/ethyl acetate (1:1); mp 124–125°C; $[\alpha]_D$ +58.0° (*c* 1.0, chloroform); R_f(A) 0.55; ^{1}H nmr δ: 7.72 (br s, 4H, $N(CO)_2C_6H_4$), 7.42–7.6 (m, 5H, C_6H_5CH), 6.85–7.05 (m, 5H, $C_6H_5CH_2$), 5.63 (s, 1H, C_6H_5CH), 5.15 (d, 1H, *J* = 8.5 Hz, H-1), 4.20 (dd, 1H, *J* = 10.4 and 8.5 Hz, H-2), 3.40 (s, 3H, OCH_3). *Anal.* calcd. for $C_{29}H_{27}NO_7$: C 69.45, H 5.43, N 2.79; found: C 69.28, H 5.23, N 2.82.

*Methyl 3,6-di-*O*-benzyl-2-deoxy-2-phthalimido-β-D-glucopyranoside (18)*

To a mixture of compound **19** (1.0 g; 2.0 mmol), powdered molecular sieves (3A Linde; 25 g), and sodium cyanoborohydride (385 mg;

6.0 mmol) in THF (50 mL) was added dropwise a saturated solution of HCl in dry diethyl ether until the gas evolution ceased (17). The reaction mixture was stirred at room temperature until the starting material completely disappeared (1 h; tlc monitored). When compound **19** was present after 1 h, a small amount of ethereal HCl was added and stirring was continued. After the work-up as described (17), a colourless oil was isolated; $[\alpha]_D$ 39.4° (*c* 1.9, chloroform); R_f(A) 0.40; ^{1}H nmr δ: 7.6–7.75 (m, 4H, $N(CO)_2C_6H_4$), 7.2–7.4 (m, 5H, $C_6H_5CH_2$), 6.9–7.1 (m, 5H, $C_6H_5CH_2$), 5.06 (d, 1H, J = 8.3 Hz, H-1) 4.23 (dd, 1H, J = 10.7 and 8.3 Hz, H-3), 4.13 (dd, 1H, J = 10.7 and 8.3 Hz, H-2), 3.38 (s, 3H, OCH_3), 2.95 (s, 1H, D_2O exch., OH). *Anal.* calcd. for $C_{29}H_{29}NO_7$: C 69.17, H 5.80, N 2.78; found: C 68.92, H 5.63, N 2.69.

Methyl 3,6-di-O-benzyl-2-deoxy-2-phthalimido-4-O-(3,4,6-tri-O-acetyl-2-deoxy-2-phthalimido-β-D-glucopyranosyl)-β-D-glucopyranoside (8b)

To a solution of silver triflate (479 mg; 1.86 mmol), collidine (0.250 mL; 1.90 mmol), and alcohol **18** (875 mL; 1.74 mmol) in dry nitromethane (5 mL) cooled to −25°C was added a solution of bromide **7** (942 mg; 1.89 mmol) in dry nitromethane (3 mL). The reaction mixture was stirred at −25°C for 4 h, allowed to warm to room temperature, and a second equivalent of silver triflate (480 mg; 1.86 mmol) and collidine (0.250 mL; 1.90 mmol) was added followed by the addition of a solution of bromide **7** (950 mg; 1.97 mmol) in nitromethane (5 mL). The reaction mixture was protected from light, stirred overnight, and then filtered through Celite. The filtrate was diluted with dichloromethane (25 mL) and washed successively with 1 *N* aqueous HCl, saturated aqueous $NaHCO_3$, and brine, dried ($MgSO_4$), filtered, and concentrated to a brown syrup (2.8 g). Further purification by flash chromatography on silica gel using hexane/ethyl acetate (1:1) gave starting alcohol **18** (470 mg) and disaccharide **8*b*** as an oil (742 mg; 46% yield); $[\alpha]_D$ −8.6, (*c* 2.1, chloroform); R_f(A) 0.26; ^{1}H nmr δ: 7.75–7.95 (m, 4H, $N(CO)_2C_6H_4$), 7.65 (br s, 4H, $N(CO)_2C_6H_4$), 7.30–7.35 (m, 5H, $C_6H_5CH_2$), 6.80–7.05 (m, 5H, $C_6H_5CH_2$), 5.79 (dd 1H, J = 11.0 and 9.0 Hz, H-3'), 5.53 (d, 1H, J = 8.4 Hz, H-1), 4.87 (d, 1H, $J_{1,2}$ = 8.3 Hz, H-1'), 3.28 (s, 3H, OCH_3), 2.00, 1.97, and 1.84 (3s, 9H, $COCH_3$). *Anal.* calcd. for $C_{49}H_{48}N_2O_{16}$: C 63.91, H 5.25, N 3.04; found: C 63.70, H 5.41, N 2.90.

Methyl 2-acetamido-4-O-(2-acetamido-3,4,6-tri-O-acetyl-2-deoxy-β-D-glucopyranosyl)-3,6-di-O-benzyl-2-deoxy-β-D-glucopyranoside (20)

A solution of disaccharide **8*b*** (248 mg; 0.27 mmol), hydrazine hydrate (85%; 2 mL), and 95% aqueous ethanol (10 mL) was gently heated under reflux for 30 min. After cooling to 0°C the reaction mixture was filtered and the filtrate was evaporated to dryness (pale yellow solid, 230 mg). The residue was dissolved in pyridine (5 mL) and acetic anhydride (2 mL) and stirred overnight at room temperature. After the usual work-up the residue was triturated with hexane/ethyl acetate (1:1), the solid **20** was isolated by filtration (75 mg), and another portion of **20** (75 mg) was isolated by concentration of the filtrate followed by crystallization from hexane/ethyl acetate (1:1). The total yield of **20** was 75%; mp 246–248°C; $[\alpha]_D$ −10.6° (*c* 1.0, methanol); R_f(B) 0.64; ^{1}H nmr δ: 7.3–7.5 (m, 10H, $C_6H_5CH_2$), 6.15 (d, 1H, J = 9 Hz, $NHCOCH_3$), 5.19 (d, 1H, J =9 Hz, $NHCOCH_3$), 4.49 (d, 1H, J = 6.0 Hz, H-1), 4.36 (d, 1H, J = 8.4 Hz, H-1'), 3.43 (s, 3H, OCH_3), and 2.09, 2.04, 2.03, 2.01, and 1.96 (5s, 15H, $COCH_3$). *Anal.* calcd. for $C_{37}H_{48}N_2O_{14}$: C 59.67, H 6.50, N 3.76; found: C 59.50, H 6.39, N 3.69.

Methyl 2-acetamido-4-O-(2-acetamido-3,4,6-tri-O-acetyl-2-deoxy-β-D-glucopyranosyl)-2-deoxy-β-D-glucopyranoside (21)

Compound **20** (300 mg; 0.40 mmol) was hydrogenolyzed over palladium-on-carbon in methanol (10 mL) at atmospheric pressure for 16 h. After the usual work-up **21** was obtained as a colourless solid (235 mg; 87% yield). This product was used without further purification; $[\alpha]_D$ −21.7° (*c* 1.0, methanol); ^{1}H nmr δ: 5.10 (t, 1H, J = 8.6 Hz, H-3'), 5.04 (t, 1H, J = 8.6 Hz, H-4'), 4.62 (d, 1H, J = 8.6 Hz, H-1'), 4.42 (d, 1H, J = 8.3 Hz, H-1), 3.48 (s, 3H, OCH_3), 2.09, 2.04, 2.03, 2.01, and 1.96 (5s, 15H, $COCH_3$). *Anal.* calcd. for $C_{23}H_{36}N_2O_{14}$: C 48.93, H 6.43, N 4.96; found: C 49.03, H 6.55, N 5.03.

Methyl 2-acetamido-4-O-(2-acetamido-3,4,6-tri-O-acetyl-2-deoxy-β-D-glucopyranosyl)-6-O-(2,3,4-tri-O-benzyl-α-L-fucopyranosyl)-2-deoxy-β-D-glucopyranoside (22)

To a mixture of diol **21** (290 mg; 0.51 mmol), tetraethylammonium bromide (323 mg; 1.53 mmol), and powdered molecular sieves (4A Linde; 1.5 g) in dry dichloromethane (5 mL) and DMF (5 mL) was added a solution of tribenzylfucopyranosyl bromide (ref. 18) (310 mg; 0.624 mmol) in dichloromethane (5 mL). After stirring at room temperature for 16 h, the solids were removed by filtration and the filtrate was washed with water, dried ($MgSO_4$), filtered, and evaporated to dryness to give an amorphous white solid (600 mg) which after trituration with hexane/ethyl acetate (1:1) gave crystalline **22** (325 mg; 65% yield); mp 258–260°C; $[\alpha]_D$ −60.3° (*c* 1.0, methanol); R_f(B) 0.14; ^{1}H nmr δ: 7.2–7.6 (m, 15H, $C_6H_5CH_2$), 6.6 (d, 1H, J = 10.5 Hz, $NHCOCH_3$), 5.42 (d, 1H, J = 10.5 Hz, $NHCOCH_3$), 4.69 (d, 1H, J = 3.5 Hz, H-1''), 4.41 (d, 1H, J = 8.6 Hz, H-1'), 4.30 (d, 1H, J = 8.3 Hz, H-1), 3.41 (s, 3H, OCH_3), 2.09 (s, 3H, $COCH_3$), 2.0 (s, 6H, $COCH_3$), 2.02 (s, 3H, $COCH_3$), 1.77 (s, 3H, $COCH_3$), 1.12 (d, 3H, J = 6.4 Hz, H-6''). *Anal.* calcd. for $C_{50}H_{64}N_2O_{18}$: C 61.21, H 6.58, N 2.85; found: C 61.09, H 6.73, N 2.92.

Methyl 2-acetamido-4-O-(2-acetamido-2-deoxy-β-D-glucopyranosyl)-2-deoxy-6-O-(α-L-fucopyranosyl)-β-D-glucopyranoside (3a)

Compound **21** (280 mg; 0.48 mmol) was debenzylated by hydrogenolysis as described for **22**. The product was de-*O*-acetylated with sodium methoxide in methanol and neutralized with 10% aqueous acetic acid. Following evaporation of the solvent, the residue was dissolved in distilled water and passed through a column (150 mm × 15 mm) of mixed bed resin (BioRad AG501-X8). Trisaccharide **3*a*** was isolated as a white crystalline solid (85 mg, 55% yield). Recrystallization from ethanol/water gave an analytical sample; mp 298–300°C (dec.); $[\alpha]_D$ −4.3° (*c* 0.57, H_2O); ^{1}H nmr δ: 4.91 (d, 1H, J = 8.0 Hz, H-1''), 4.64 (d, 1H, J = 7.6 Hz, H-1'), 4.43 (d, 1H, J = 8.0 Hz, H-1), 4.13 (br q, 1H, J = 6.5, J_2 < 0.5 Hz, H-5''), 2.08 (s, 3H, $COCH_3$), 2.03 (s, 3H, $NHCOCH_3$), 1.23 (d, 3H, J = 6.6 Hz, H-6''); *m/e*: 583, $(M - 1)^-$. *Anal.* calcd. for $C_{23}H_{40}N_2O_{15}$: C 47.25, H 6.90, N 4.79; found: C 47.19, H 6.82, N 4.83.

Methyl 3-O-benzyl-2-deoxy-2-phthalimido-β-D-glucopyranoside (23)

A solution of **19** (4.10 g; 8.15 mmol) in 60% aqueous acetic acid (50 mL) was heated at 100°C for 30 min (tlc monitored). The solvents were removed *in vacuo* to give diol **23** accompanied by a small amount of the 6-acetate derivative. Pure **23** was obtained by flash chromatography on silica gel using ethyl acetate as a microcrystalline solid (2.90 g; 88% yield); mp 120.5–122°C; $[\alpha]_D$ +57.2° (*c* 1.0, chloroform); R_f(A) 0.12; ^{1}H nmr δ: 7.75 (br s, 4H, $N(CO)_2C_6H_4$), 7.0–7.15 (m, 5H, $C_6H_5CH_2$), 5.10 (d, 1H, J = 8.4 Hz, H-1), 3.40 (s, 3H, OCH_3). *Anal.* calcd. for $C_{22}H_{23}NO_7$: C 63.92, H 5.61, N 3.39; found: C 63.78, H 5.80, N 3.34.

Methyl 3-O-benzyl-2-deoxy-2-phthalimido-6-O-(2,3,4-tri-O-benzyl-α-L-fucopyranosyl)-β-D-glucopyranoside (24)

To a mixture of diol **23** (450 mg; 1.09 mmol), tetraethylammonium bromide (1.14 g; 5.4 mmol), and powdered molecular sieves (4A Linde; 2.5 g) in dichloromethane (10 mL) was added a solution of tribenzylfucosyl bromide (ref. 18) (650 mg; 1.3 mmol) in dichloromethane (5 mL). The reaction mixture was stirred at room temperature for 6 h and filtered through Celite. The filtrate was washed with water, dried ($MgSO_4$), filtered, and concentrated to give a colourless oil (1.2 g). Flash chromatography on silica gel (hexane/ethyl acetate (2:1)) gave **24** as a colourless oil (380 mg; 42% yield); $[\alpha]_D$ −7.0° (*c* 0.86, chloroform); R_f(A) 0.42; ^{1}H nmr δ: 7.6–7.8 (m, 4H, $N(CO)_2C_6H_4$), 7.2–7.6 (m, 15H, $C_6H_5CH_2$), 6.9–7.1 (m, 5H, $C_6H_5CH_2$), 5.01 (d, 1H, J = 8.4 Hz, H-1) 4.82 (d, 1H, J = 4.4 Hz, H-1'), 3.33 (s, 3H, OCH_3), 1.16 (d, 1H, J = 6.5 Hz, H-5'). *Anal.* calcd. for $C_{49}H_{51}NO_{11}$: C 70.91, H 6.19, N 1.69; found: C 70.80, H 6.22, N 1.73.

Methyl 3-O-benzyl-2-deoxy-2-phthalimido-4,6-di-O-(2,3,4-tri-O-benzyl-α-L-fucopyranosyl)-β-D-glucopyranoside (25)

To a mixture of diol **23** (625 mg; 1.51 mmol), tetraethylammonium bromide (1.59 g; 7.57 mmol), and powdered freshly activated molecular sieves (4A Linde; 1.50 g) in dichloromethane (10 mL) was added a solution of tribenzylfucosyl bromide (ref. 18) (1.45 g; 2.91 mmol) in dichloromethane (5 mL). The reaction mixture was stirred overnight at room temperature and filtered through Celite. The filtrate was washed with water, dried ($MgSO_4$), filtered, and concentrated to 2.2 g of a brown oil. Flash chromatography on silica gel using hexane/ethyl acetate (2:1) as eluant gave two major fractions. The more polar fraction, R_f(A) 0.42, was disaccharide **24** (365 mg; 30% yield).

The less polar fraction, R_f(A) 0.61, was trisaccharide **25** (425 mg) as a colourless oil; $[\alpha]_D$ −38.2° (*c* 0.6, chloroform); ^{1}H nmr δ: 7.6–7.8 (m, 4H, $N(CO)_2C_6H_4$), 7.2–7.5 (m, 30H, $C_6H_5CH_2$), 7.0 (m, 5H, $C_6H_5CH_2$), 5.35 (d, 1H, *J* = 3.2 Hz, H-1), 3.26 (s, 3H, OCH_3), 1.04 (d, 3H, *J* = 6.5 Hz, H-6′ or H-6″), 0.82 (d, 3H, *J* = 6.5 Hz, H-6′ or H-6″). *Anal.* calcd. for $C_{76}H_{79}NO_{15}$: C 73.23, H 6.39, N 1.12; found: C 73.11, H 6.45, N 1.01.

Methyl 2-acetamido-3-O-*benzyl-2-deoxy-6-*O-*(2,3,4-tri-*O-*benzyl-α-L-fucopyranosyl)-β-D-glucopyranoside (26)*

A solution of **24** (250 mg; 0.31 mmol) and hydrazine hydrate (85%; 2 mL) in 95% aqueous ethanol (10 mL) was gently heated under reflux for 20 min. The reaction mixture was concentrated to dryness to give a non-crystalline yellowish residue which was dissolved in a mixture of 50% aqueous methanol (10 mL) and acetic anhydride (3 mL) and sitrred at room temperature overnight. The precipitate which formed was isolated by filtration and dried *in vacuo* to give crystalline **26** (133 mg; 60% yield); mp 197–200°C; $[\alpha]_D$ −44.5° (*c* 0.7, chloroform); R_f(B) 0.48; ^{1}H nmr δ: 7.2–7.5 (m, 20H, $C_6H_5CH_2$), 5.37 (d, 1H, *J* = 9 Hz, N*H*COCH$_3$, 3.42 (s, 3H, OCH_3), 1.90 (s, 3H, $NHCOCH_3$), 1.17 (d, 3H, *J* = 6.5 Hz, H-6′). *Anal.* calcd. for $C_{43}H_{51}NO_{10}$: C 69.61, H 6.94, N 1.89; found: C 69.82, H 7.11, N 1.94.

*Methyl 2-acetamido-2-deoxy-6-*O-*(α-L-fucopyranosyl)-β-D-glucopyranoside (4)*

Compound **26** (210 mg; 0.28 mmol) was stirred with 10% palladium-on-charcoal (50 mg) in 75% aqueous methanol (10 mL) under hydrogen (1 atm (= 101.3 kPa)) for 18 h. Following filtration through Celite the filtrate was concentrated *in vacuo* and the resulting colourless solid was dissolved in water and passed through a column (150 mm × 15 mm) of mixed bed resin (BioRad AG501-X8) to give a desalted solution of disaccharide **4**. Pure **4** was obtained following lyophilization as an amorphous solid (89 mg; 83% yield); $[\alpha]_D$ −20.6° (*c* 0.38; H_2O); ^{1}H nmr δ: 4.94 (d, 1H, *J* = 3.9 Hz, H-1′), 4.45 (d, 1H, *J* = 8.5 Hz, H-1), 4.14 (br q, 1H, *J* = 6.5, J_2 < 0.5 Hz, H-5′), 3.50 (s, 3H, OCH_3), 2.04 (s, 3H, $NHCOCH_3$), 1.23 (d, 3H, *J* = 6.5 Hz, H-6′); *m*/*e*: 380 $(M-1)^-$. *Anal.* calcd. for $C_{15}H_{27}NO_{10}$: C 47.24, H 7.14, N 3.69; found: C 7.01, H 7.02, N 3.58.

*Methyl 2-acetamido-3-*O-*benzyl-2-deoxy-4,6-di-*O-*(2,3,4-tri-*O-*benzyl-α-D-fucopyranosyl)-β-D-glucopyranoside (27)*

A solution of compound **25** (248 mg; 0.21 mmol) and hydrazine hydrate (85%; 1 mL) in 95% aqueous ethanol (5 mL) was gently heated under reflux for 20 min. The reaction mixture was evaporated to dryness *in vacuo* and the resulting yellow amorphous residue was treated at room temperature with pyridine (5 mL) and acetic anhydride (1 mL). After the usual work-up a colourless oil (220 mg) was isolated. Flash chromatography on silica gel using hexane/ethyl acetate (2:3) gave **27** as a colourless oil (110 mg; 48% yield); $[\alpha]_D$ −41.5° (*c* 1.0, chloroform); R_f(A) 0.25; ^{1}H nmr δ: 7.1–7.5 (m, 35H, $C_6H_5CH_2$), 6.29 (d, 1H, *J* = 9.2 Hz, N*H*COCH$_3$, 5.29 (d, 1H, *J* = 3.1 Hz, H-1), 3.38 (s, 3H, OCH_3), 1.63 (s, 3H, $NHCOCH_3$), 1.03 (d, 3H, *J* = 6.4 Hz, H-6′ or H-6″), 0.96 (d, 3H, *J* = 6.4 Hz, H-6′ or H-6″).

*Methyl 2-acetamido-2-deoxy-4,6-di-*O-*(α-L-fucopyranosyl-β-D-glucopyranoside (5)*

Compound **27** (200 mg; 0.17 mmol) was deprotected to give **5** in a similar manner as it was used to prepare **4**. Trisaccharide **5** was a colourless amorphous solid (77 mg; 85% yield); $[\alpha]_D$ −3.8° (*c* 0.63, H_2O); ^{1}H nmr δ: 5.00 (d, 1H, *J* = 3.6 Hz, H-1′ or H-1″), 4.91 (d, 1H, *J* = 3.9 Hz, H-1′ or H-1″), 4.44 (d, 1H, *J* = 8.3 Hz, H-1), 4.34 (br q, 1H, *J* = 6.6 Hz, H-5′ or H-5″), 4.13 (br q, 1H, *J* = 6.6 Hz, H-5′ or H-5″), 3.49 (s, 3H, OCH_3), 1.22 (d, 3H, *J* = 6.6 Hz, H-6′ or H-6″), 1.14 (d, 3H, *J* = 6.6 Hz, H-6′ or H-6″).

Thermodynamic properties of the dilute solutions of silver chloride and aluminum trichloride in alkali chlorides by electromotive force measurements

P. J. TUMIDAJSKI AND S. N. FLENGAS

Department of Metallurgy and Materials Science, University of Toronto, Toronto, Ont., Canada M5S 1A4

Received March 5, 1984

P. J. TUMIDAJSKI and S. N. FLENGAS. Can. J. Chem. **63**, 1080 (1985).

Thermodynamic data for dilute solutions of AgCl and $AlCl_3$ in molten alkali chlorides were derived from the emf's of formation and of galvanic cells, respectively, given as, Ag/AgCl – ACl/C,Cl_2 and Ag/AgCl – ACl//$AlCl_3$ – ACl/Al. ACl represents NaCl, KCl, CsCl, or the equimolar mixtures of NaCl–CsCl and KCl–CsCl. It was found that the thermodynamic properties of the ternary melts could be predicted from the results of the binary melts using the relationship (17, 20, 21), $(\overline{\Delta Z})_{123} = (1 - t)\,(\overline{\Delta Z})_{12} + t(\overline{\Delta Z})_{13}$, where Z represents any partial molar property. The ternary solution is denoted by the subscript 1, 2, 3 while the two binaries are denoted by 1, 2 and 1, 3; t is a concentration variable given as $t = X_3/(X_2 + X_3)$. These expressions are valid when the binary and the ternary solutions have the same content of either AgCl or $AlCl_3$, respectively.

P. J. TUMIDAJSKI et S. N. FLENGAS. Can. J. Chem. **63**, 1080 (1985).

En se basant sur les fem de formation et des cellules galvaniques Ag/AgCl – ACl/C, Cl_2 et Ag/AgCl – ACl//$AlCl_3$ – ACl/Al dans lesquelles ACl représente NaCl, KCl, CsCl ou des mélanges équimolaires de NaCl–CsCl ou de KCl–CsCl, on a évalué les données thermodynamiques de solutions diluées de AgCl et de $AlCl_3$ dans des chlorures alcalins fondus. On a trouvé que l'on peut prédire les propriétés thermodynamiques des sels ternaires fondus en se basant sur les résultats obtenus avec des sels binaires fondus et en utilisant la relation (17, 20, 21) $(\overline{\Delta Z})_{123} = (1 - t)\,(\overline{\Delta Z})_{12} + t(\overline{\Delta Z})_{13}$, où Z représente n'importe quelle propriété molaire partielle. On utilise les indices 1, 2, 3 pour désigner la solution ternaire et les indices 1, 2 et 1, 3 pour désigner les deux solutions binaires; t est une variable de concentration que l'on représente par $t = X_3/(X_2 + X_3)$. Ces expressions sont valables quand les solutions ternaires contiennent chacune des quantités semblables de AgCl ou de $AlCl_3$.

[Traduit par le journal]

Introduction

The thermodynamic properties of the solutions of AgCl or $AlCl_3$ in alkali chloride melts have been the subject of several studies. For the former, the systems investigated include the binary solutions of AgCl–NaCl (1–3), AgCl–KCl (1, 3, 4), AgCl–CsCl (1, 3) and AgCl–RbCl (3), and the ternary solutions of AgCl–LiCl–KCl (5, 6), AgCl–NaCl–KCl (3), and AgCl–NaCl–CsCl (3). For the case of $AlCl_3$, the following systems have been studied: $AlCl_3$–NaCl (7–12), $AlCl_3$–KCl (7), $AlCl_3$–RbCl (7), $AlCl_3$–CsCl (7), and $AlCl_3$–NaCl–KCl (13). These measurements were taken with concentrated solutions of AgCl or $AlCl_3$. The behaviour of dilute solutions of AgCl or $AlCl_3$ where Henry's law is expected to be valid have not yet been investigated. The thermodynamic properties of the dilute solutions of AgCl in the binary systems AgCl–NaCl, AgCl–KCl, AgCl–CsCl, and in the ternary systems AgCl–NaCl–CsCl and AgCl–KCl–CsCl have been obtained from emf measurements on formation cells of the type, Ag/AgCl – ACl/C,Cl_2. The thermodynamic properties of the dilute solutions of $AlCl_3$ in the binary systems $AlCl_3$–NaCl, $AlCl_3$–KCl, $AlCl_3$–CsCl, and in the ternary systems $AlCl_3$–NaCl–CsCl and $AlCl_3$–KCl–CsCl have been obtained from emf measurements on galvanic cells of the type Al/$AlCl_3$ – ACl//AgCl – ACl/Ag. For both cells, ACl represents the salt components NaCl, KCl, CsCl, or the equimolar mixtures of NaCl–CsCl and KCl–CsCl.

Experimental

The AgCl and alkali chlorides used were reagent grade and were purified and dehydrated by treatment in an anhydrous HCl atmosphere at 673 K. The $AlCl_3$ was anhydrous of reagent grade. Iron contaminants were removed by vacuum sublimation. Aluminum trichloride was introduced into the alkali chloride salt by reacting an excess of the $AlCl_3$ vapor with a known quantity of alkali chloride in a two compartment non-isothermal cell described in detail elsewhere (14). The reaction is $AlCl_{3(g)} + ACl = A(AlCl_4)_{(l)}$. The weight gain of ACl following the reaction yields the exact stoichiometry of the product. Furthermore, A($AlCl_4$) type compounds have a lower decomposition vapor pressure compared to pure $AlCl_3$ (8, 15). Weighing, handling, and transfer of all chemicals were conducted in a drybox filled with anhydrous argon gas. All graphite used in the experiments was high density, research grade graphite (Aremco), and it was purified by chlorine treatment at 1273 K, as described previously (16, 17).

The design of the electrochemical cells employed in the present investigation are given in Figs. 1 and 2 for the AgCl and $AlCl_3$ systems, respectively. For the AgCl experiments, the cell consisted of the Ag indicator electrode and the Cl_2 gas reference electrode. The half cell compartments were separated by a diaphragm consisting of an asbestos fibre fused in quartz (16). The $AlCl_3$ cell contained the Al indicator electrode and the Ag/AgCl secondary reference electrode. The half cell compartments were separated by the asbestos diaphragm described previously.

At the beginning of a run, the appropriate weights of salts were transferred to the respective electrode compartments. Then the cell was heated in a furnace for 24 h while anhydrous argon gas passed over the salts to remove any remaining traces of moisture. Afterwards, the temperature was gradually raised above the melting point of the salts and emf measurements begun. After 2 h the emf's became stable and the potentials recorded. Reversibility was confirmed by temperature cycling and by polarization tests. For the latter, 1 mA was passed through the cell in each direction using an external dc source. After disconnecting the dc source, in each case the cell emf returned to the original value in less than 1 min. Cell emf's were stable and reproducible to within ±1 mV within the 24 h required for each run. The adjustment to the cell emf for the Ag—C thermoelectric potential was established by connecting the Ag and C electrode tips in the absence of the electrolyte and measuring the resulting emf.

The spontaneous reaction for the silver chloride formation cell is

$$Ag_{(s)} + \tfrac{1}{2}Cl_{2(g,\,1\,atm)} = \underline{AgCl}$$

The line under a salt species denotes a species in solution. The corresponding Nernst equation is:

$$[1] \qquad E_{cell} = E^0_{AgCl} - \frac{RT}{F}\ln\,(X_{AgCl}) - \frac{RT}{F}\ln\,(\gamma_{AgCl})$$

where E^0_{AgCl} is the standard formation cell potential of pure liquid AgCl. The values of E^0_{AgCl} used in this investigation were determined

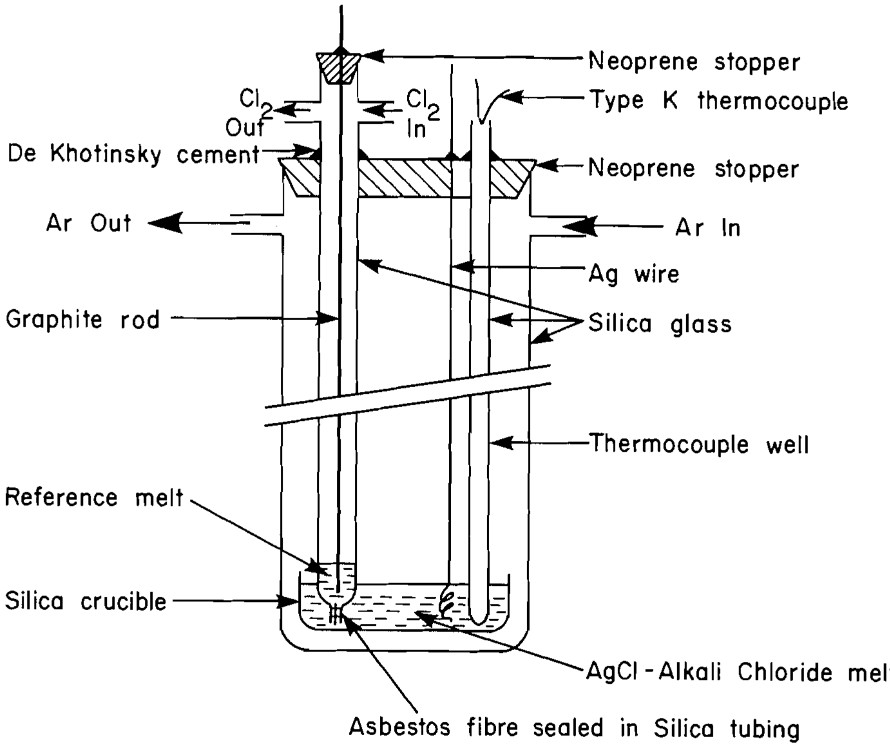

FIG. 1. Experimental cell for the AgCl experiments.

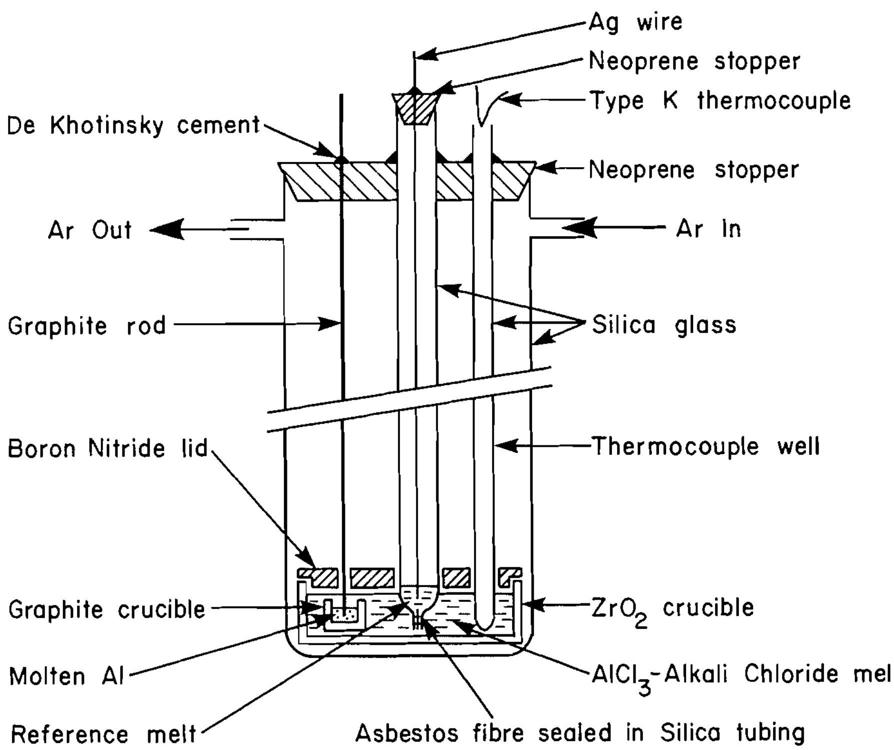

FIG. 2. Experimental cell for the $AlCl_3$ experiments.

previously in this laboratory (1). F is the Faraday's constant given as 96 487 J/V mol and R is the gas constant given as 8.3144 J/mol K. The standard state was chosen to be the pure liquid AgCl at the temperature of the experiments. For dilute compositions of AgCl, where Henry's law is expected to be valid, γ^{h}_{AgCl} should be constant. Accordingly, the formal potential of AgCl is defined as:

$$[2] \qquad E^{0}_{f(AgCl)} = E^{0}_{AgCl} - \frac{RT}{F} \ln (\gamma^{h}_{AgCl})$$

The final form of eq. [1] is

$$[3] \qquad E_{cell} = E^{0}_{f(AgCl)} - \frac{RT}{F} \ln (X_{AgCl})$$

and the plot of E_{cell} against log (X_{AgCl}) should be linear, having a slope of $2.303RT/F$, and an intercept equal to $E^{0}_{f(AgCl)}$.

The spontaneous cell reaction for the Al–Ag galvanic cell is

$$Al_{(l)} + 3\underline{AgCl} = \underline{AlCl_3} + 3Ag_{(s)}$$

The Nernst equation is

[4] $$E_{cell} = (E^0_{AlCl_3} - E^0_{AgCl}) - \frac{RT}{3F}\ln(X_{AlCl_3}/X^3_{AgCl}) - \frac{RT}{3F}\ln(\gamma_{AlCl_3}/\gamma^3_{AgCl})$$

where $E^0_{AlCl_3}$ is the standard formation cell potential of pure liquid $AlCl_3$. The values of $E^0_{AlCl_3}$ were available at 500 K from the thermochemical tables (18), and were calculated at higher temperatures assuming a temperature independent specific heat capacity. The uncertainty in $E^0_{AlCl_3}$ values is estimated to be ±5%. The standard state was chosen to be the pure molten chloride at the temperature of the experiments. For dilute solutions obeying Henry's law, $\gamma^h_{AlCl_3}$ and γ^h_{AgCl} are expected to be constant, and the formal potential should be:

[5a] $$E^0_{f(cell)} = E^0_{AlCl_3} - E^0_{AgCl} - \frac{RT}{3F}\ln(\gamma^h_{AlCl_3}/(\gamma^h_{AgCl})^3)$$

or

† Equimolar.

$$[5b]\quad E^0_{f(cell)} = E^0_{f(AlCl_3)} - E^0_{f(AgCl)}$$

where $E^0_{f(AgCl_3)}$ and $E^0_{f(AgCl)}$ are the formal potentials of $AlCl_3$ and AgCl respectively. Thus, eq. [4] can be written as

$$[6]\quad E_{cell} = E^0_{f(cell)} - \frac{RT}{3F}\ln\left(X_{AlCl_3}/X^3_{AgCl}\right)$$

Plotting E_{cell} against log (X_{AlCl_3}/X^3_{AgCl}), a straight line should be obtained with a slope of $-2.303RT/3F$ and an intercept equal to $E^0_{f(cell)}$. It should be mentioned that the formal potentials of eqs. [2] and [5] represent the free energy of a hypothetical state of unit mole fraction of solute, having in all respects the properties of the solute at its state in an infinitely diluted solution.

Results and discussion

Tables 1 and 2 summarize the measured cell emf's which have been expressed as least-squares lines of the form $E = AT + B$, where E is cell potential in V, and T is the temperature in K. Cell emf's have been corrected for the thermo-electric effects of Ag and C. Melt compositions are expressed in mole fractions of AgCl and $AlCl_3$, respectively. For ternary solutions, the composition variable t has been defined as

$$[7a]\quad t = X_{CsCl}/(X_{CsCl} + X_{NaCl})$$

or

$$[7b]\quad t = X_{CsCl}/(X_{CsCl} + X_{KCl})$$

The correlation coefficients in Tables 1 and 2 indicate that the plots of cell potential versus temperature should be linear. The estimate for the standard deviation of cell potential for the regression of cell potential on temperature is approximately 4 mV for all cases.

Nernst plots for the five AgCl – alkali chloride systems as expressed by eq. [2] are given in Fig. 3. The experimental data for AgCl indicate a one-electron electrode reaction, as expected. For the Ag–Al galvanic cell, plots of E_{cell} versus log (X_{AlCl_3}/X^3_{AgCl}) are given in Fig. 4. The curves are linear and correspond to a three-electron electrode reaction, as expected. Linear regression analysis for the Nernst plots gave correlation coefficients of almost unity for all cases. The linearity of the plots in Figs. 3 and 4 indicates that the dilute solutions of AgCl and $AlCl_3$ in molten alkali chlorides obey Henry's law. Values of $E^0_{f(AgCl)}$ and $E^0_{f(AlCl_3)}$ determined graphically as indicated in Figs. 3 and 4, are recorded in Tables 3 and 4 in accordance with the IUPAC convention (19). For both AgCl and $AlCl_3$, the magnitude of the values of the formal potentials increase as CsCl is added and decrease as the temperature is increased. Included in Tables 3 and 4 are the theoretical values for the formal potentials in the ternary solutions calculated from the equation which has been derived previously (17, 20, 21),

$$[8]\quad E^0_{f(123)} = (1-t)E^0_{f(12)} + tE^0_{f(13)}$$

where $E^0_{f(123)}$ is the formal potential of AgCl or $AlCl_3$ in a ternary solution and $E^0_{f(12)}$ and $E^0_{f(13)}$ are the formal potentials in the component binary systems. The t parameter was defined in eq. [7]. Figures 5 and 6 are the plots of $E^0_{f(AgCl)}$ and $E^0_{f(AlCl_3)}$ versus the t parameter at 1123 K for the AgCl – alkali chloride and $AlCl_3$ – alkali chloride systems, respectively. It is readily seen that the experimental results for $t = 1/2$ are in agreement

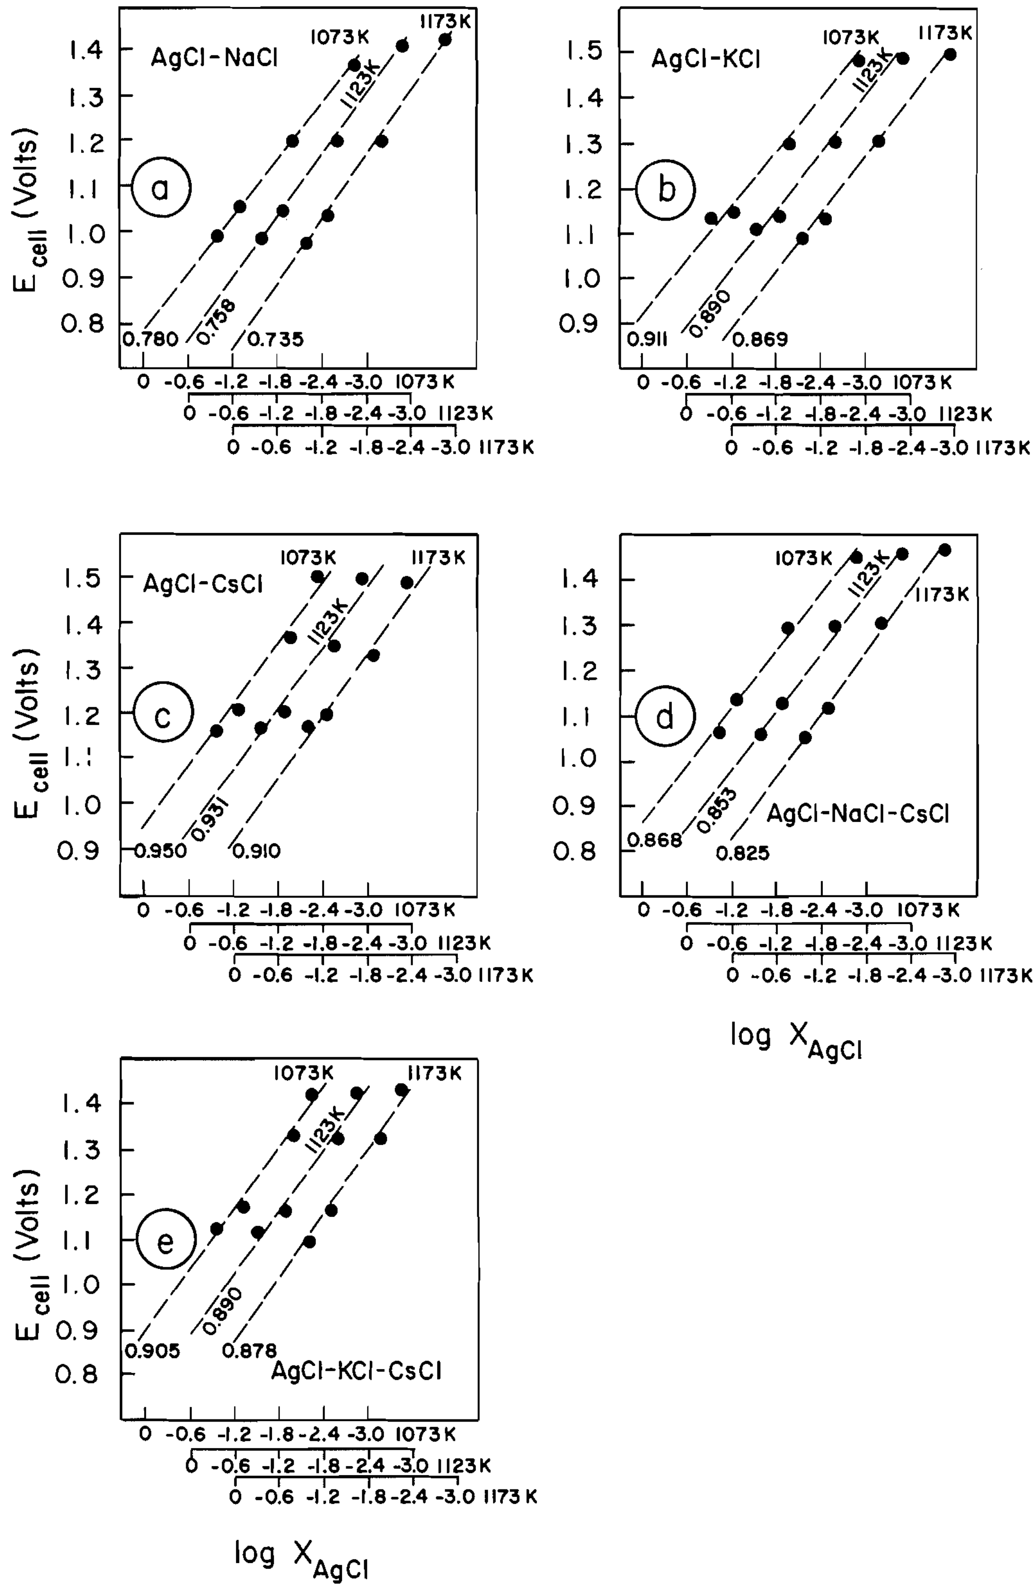

FIG. 3. Concentration dependence of E_{cell} in the AgCl – alkali chloride systems at 1073 K, 1123 K, and 1173 K.

to within 2% or better with the predicted values from eq. [8].

Activity coefficients for AgCl and $AlCl_3$, respectively, are summarized in Tables 5 and 6. The uncertainty in these values is estimated as ±5%. A comparison of the activity coefficients indicates the pronounced effect of CsCl in creating thermodynamically stable solutions. The large negative deviations from ideality shown by the magnitude of the activity coefficients of $AlCl_3$, indicates the strong tendency of the $AlCl_3$ to form complex species in these melts. Negative deviations from ideality have also been observed for the concentrated solutions of $AlCl_3$ in alkali chloride melts, and have been interpreted as indicating the presence of the complex species in solution (11,

12). For both the AgCl and $AlCl_3$ systems, the activity coefficients increase with temperature increase, indicating the dissociation of complexes at higher temperatures. The $AlCl_3$ – alkali chloride solutions could be suitable as electrolytes for the production of aluminum metal by fused salt electrolysis. The most thermodynamically stable systems appear to be the $AlCl_3$–CsCl binary and the $AlCl_3$–KCl–CsCl ternary solutions. Figures 7 and 8 are the plots of $\log \gamma^h_{AgCl}$ and $\log \gamma^h_{AlCl}$ versus the t parameter at 1123 K for the AgCl – alkali chloride and $AlCl_3$ – alkali chloride systems, respectively. The

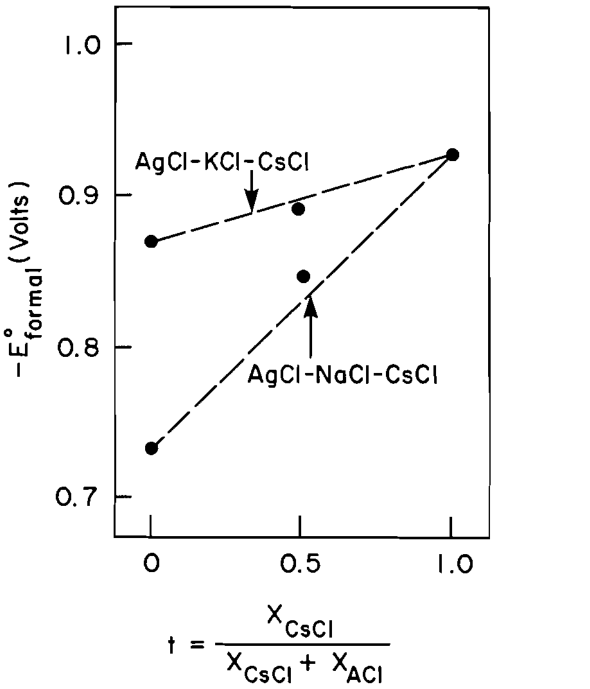

FIG. 5. $E^{0}_{f(AgCl)}$ versus t at 1123 K for the AgCl–NaCl–CsCl and AgCl–KCl–CsCl systems.

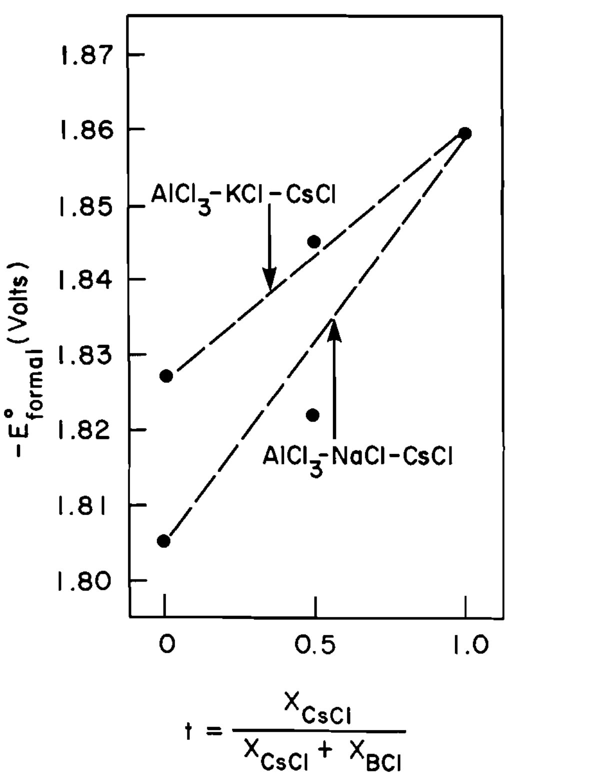

FIG. 6. $E^{0}_{f(AlCl_3)}$ versus t at 1123 K for the $AlCl_3$–NaCl–CsCl and $AlCl_3$–KCl–CsCl systems.

predicted values at $t = 1/2$ are in good agreement with those obtained experimentally.

The partial molar enthalpies and excess entropies of mixing for AgCl and $AlCl_3$ are given in Tables 5 and 6, respectively.

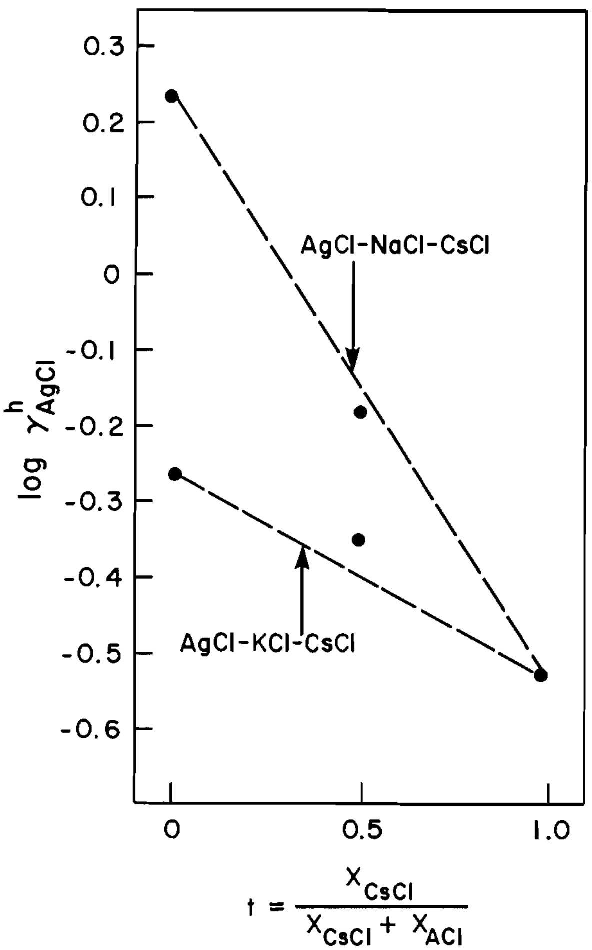

FIG. 7. $\log \gamma^{h}_{AgCl}$ versus t at 1123 K for the AgCl–NaCl–CsCl and AgCl–KCl–CsCl systems.

The error in the values of the enthalpies and entropies is approximately ±2.1 kJ/mol and ±2.1 J/mol K, respectively. The magnitude of the values of the enthalpies and entropies for $AlCl_3$ are much larger than the corresponding values for AgCl. This is consistent with the magnitude of the activity coefficients for $AlCl_3$, and with the pronounced reactivity of $AlCl_3$ with alkali chloride, and the subsequent formation of complex species in solution. For both AgCl and $AlCl_3$, the exothermicity increases as the size of the alkali metal cation in the alkali chloride solvent changes from Na^+ to Cs^+, indicating that in the presence of larger solvent cations there is an increase in the interaction between the silver or aluminum cation and the surrounding anions (22). The values of $(\overline{\Delta H})_{AgCl}$ or $(\overline{\Delta H})_{AlCl_3}$ in the ternary melts are in agreement to within 5% or better with those calculated from the previously derived expression (17, 20, 21) given as

$$[9] \quad (\overline{\Delta H})_{123} = (1 - t)(\overline{\Delta H})_{12} + t(\overline{\Delta H})_{13}$$

which is valid when the component binaries 1,2 and 1,3, respectively, and the ternary 1,2,3, contain the same amount of a reactive metal chloride like AgCl or $AlCl_3$, which are thought of as behaving like ligand acceptors.

The relationship is depicted schematically in Figs. 9 and 10 for the AgCl – alkali chloride and $AlCl_3$ – alkali chloride systems, respectively.

RUSSELL R. KING and ROY GREENHALGH. Can. J. Chem. **63**, 1089 (1985).

Reaction of triacetoxydeoxynivalenol (**3**) with hydrobromic acid – acetic acid at reflux temperatures yielded 3α,7α,13,15-tetraacetoxy-2-bromo apotrichothec-9-en-8-one (**5**) and 3α,7α,15-triacetoxy-13-bromo-12-hydroxytrichothec-9-en-8-one (**4**). Dehalohydrination of the 13,12-bromohydrin derivative with Zn – acetic acid followed by deacetylation with sodium ethoxide gave 3α,7α,15-trihydroxytrichothec-9,12-dien-8-one (**2**). This compound proved identical to the transformation product isolated from incubation of deoxynivalenol (vomitoxin) in vitro with rumen microorganisms.

RUSSEL R. KING et ROY GREENHALGH. Can. J. Chem. **63**, 1089 (1985).

La réaction du triacétoxydéoxynivalenol (**3**) lors d'un reflux avec un mélange d'acide hydrobromique et d'acide acétique fournit les produits: tétraacétoxy-3α,7α,13,15 bromo-2 ène-9, one-8 apotrichothec (**5**) et triacétoxy-3α,7α,15 bromo-13 ène-9, one-8 hydroxy-12 trichothec (**4**). D'autre part, la déhalohydrination du dérivé bromo-13 hydrin-12 à l'aide de zinc et d'acide acétique suivie de déacétylation avec l'éthoxide de sodium produit le trihydroxy-3α,7α,15 diène-9,12 one-8 trichothec (**2**). Le dérivé s'avère identique au produit de transformation récemment isolé lors de l'incubation in vitro du déoxynivalenol (vomitoxine) avec des microorganismes du rumen.

Deoxynivalenol (**1**) (3α,7α,15-trihydroxy-12,13-epoxy trichothec-9-en-8-one or vomitoxin) is one of the predominant trichothecene mycotoxins associated with infection of cereal grains by certain fusarium species (1). As a result of the consumption of such contaminated products, animals may suffer sublethal toxicoses (2). As yet, the exact metabolic fate of the toxin when ingested is unknown. Our recent investigations (3) involving incubation of deoxynivalenol in vitro with rumen microorganisms demonstrated that the predominant biotransformation consisted of deoxygenation of the 12,13-epoxide moiety to a 12,13-double bond. Yoshizawa *et al.* (4) have also observed a similar transformation when deoxynivalenol was administered to rats. Since there is good evidence to suggest that the toxicity of trichothecenes is conferred by the 12,13-epoxide group and that the elimination of it substantially detoxifies the substances (5), our primary interest was to prepare a sufficient quantity of the deoxygenated metabolite (i.e., 3α,7α,15-trihydroxytrichothec-9,12-dien-8-one (**2**)) in order to determine its relative toxicity.

Two standard approaches for transforming the 12,13-epoxide moiety to a double bond were investigated. One route was direct epoxide deoxygenation; the other, halohydrin formation (via epoxide cleavage) prior to dehalohydrination. Of the two approaches, only the latter eventually provided an acceptable measure of success.

Although Gutzwiller *et al.* (7) obtained low yields of the C-12,13 vinyl analogue of verrucarol (4β,15-diacetoxytrichothec-9,12-diene) on reaction with $LiAlH_4$, only complex mixtures (devoid of the vinyl derivative) were obtained on subjecting deoxynivalenol to similar reaction conditions. This result was not entirely unexpected and is presumably attributable to the presence of the reactive 9-en-8-one system. Attempted direct deoxygenation utilizing a Cu–Zn catalyst (8) (under a variety of reaction conditions) again did not elicit the required result.

Preliminary investigations involving a variety of reagents previously utilized for the deoxygenation of epoxides (9) (via halohydrin intermediates) also failed to bring about the desired reaction with deoxynivalenol. This behaviour may be ascribed to an inaccessibility towards the catalyst or to the possibility that conformational changes on cleavage of the epoxide group are energetically unfavourable and a thermodynamic driving force is required.

Eventually, it was determined that refluxing a solution of deoxynivalenol (**1**) and sodium iodide in acetic acid, prior to the addition of powdered zinc, furnished a quantity of the required diene (**2**). The yield was extremely small (<1%), however, and tlc analysis showed the reaction mixture contained many more substances than would be expected from a simple epoxide opening, followed by dehalohydrination. In an attempt to reduce unwanted side reactions, the triacetyl derivative (**3**) of deoxynivalenol was formed and hydrobromic acid was substituted for sodium iodide. Under these conditions, and although relatively longer reaction times were involved, tlc analysis confirmed that triacetoxydeoxynivalenol (**3**) was transformed into just two major compounds.

The new compounds were readily separated by preparative tlc and further purified by crystallization. The less polar of the two compounds (R_f 0.77, 19.4%) was found, by spectroscopic and chemical means, to exhibit properties consistent with those of the 13,12-bromohydrin derivative (**4**). For example (*i*) the tertiary nature of the hydroxyl group (indicated by ir) was confirmed by its lack of reactivity towards both chromic acid and trifluoroacetic anhydride; (*ii*) the parent ion from mass spectral determinations was increased by 81 *m/e*; and (*iii*) in the ^1H nmr spectrum (Table 1) no resonances ascribable to a spiro epoxide group were found. Compound **4** with the stereochemistry assigned is the product anticipated from a normal S_N2 epoxide opening (i.e., nucleophilic *trans* attack at the less highly substituted carbon atom) (10).

Identification of the other major product (R_f 0.68, 30.8%) from the reaction of triacetoxydeoxynivalenol (**3**) with hydrobromic acid – acetic acid proved more complex. First, the ir spectrum was devoid of hydroxyl absorptions. Secondly, both the mass spectrum and ^1H nmr spectrum indicated the presence of another acetoxyl group. Since its mass spectrum also dem-

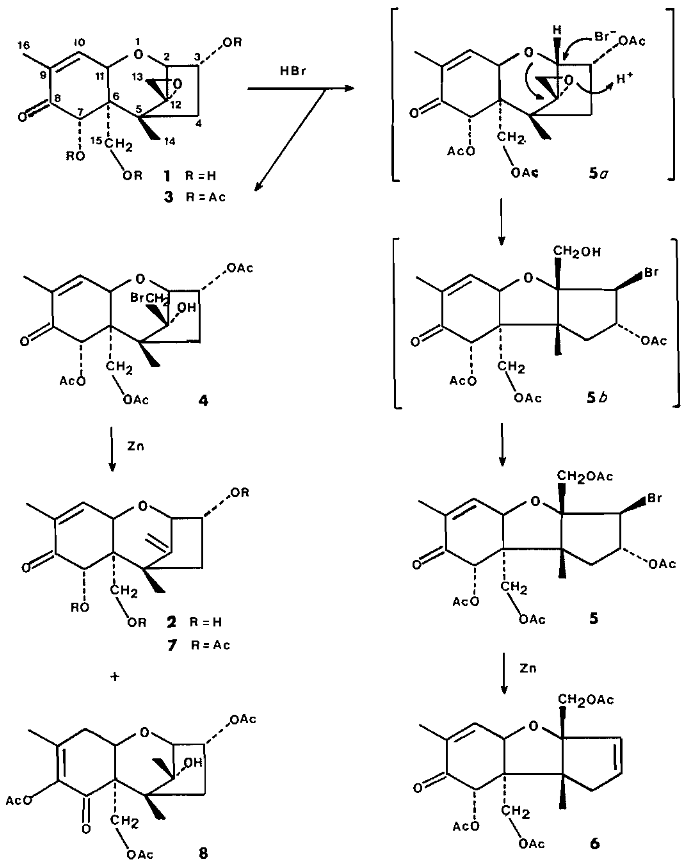

FIG. 1.

onstrated introduction of a bromine atom, and its ^{1}H nmr profile confirmed loss of epoxide-associated absorptions, the compound was initially formulated as a 13-acetoxy-12-bromo derivative. This compound was assumed to originate from acid-catalyzed acetylation of a 12-bromo-13-hydroxy precursor arising from an alternate mode of bromide attack on the 12,13-epoxide. In the light of a subsequent chemical transformation, however, it was established that skeletal rearrangement to an apotrichothecene ring system (11) (Fig. 1) had occurred, and the bromohydrin acetate was assigned the structure **5**. Again, it was assumed that acid-catalyzed acetylation takes place after the initial rearrangement.

Although acid-catalyzed rearrangements of the trichothecene to the apotrichothecene ring system are well documented (12), we believe this is the first such observation reported for the nivalenol series. This particular intramolecular process is thought to proceed by nucleophilic attack of the position one oxygen atom on the protonated epoxide moiety (i.e., **5***a*). Such a pathway obviously represents a comparable energy barrier to external nucleophilic attack by Br^- and, if our structural assignments are correct, is a severe limiting factor in our synthetic design.

Although neither of the bromo derivatives **4** and **5** were affected when treated with Zn in acetic acid at room temperature, they both reacted rapidly at reflux temperatures. The bromoapotrichothecene derivative (**5**) yielded just one major product (73.9%). As anticipated, mass spectral and ^{1}H nmr data confirmed elimination of bromine and an acetoxyl group (13). The ^{1}H nmr spectrum also indicated that resonances previously ascribed to the C-2, C-3 protons were replaced by signals representative of alkene protons in a 5-membered ring system (14). These data were considered supportive of the apotrichothec-2,9-diene structure (**6**) and are consistent with the rationale utilized to formulate the structure of its 2-bromo-apotrichothecene precursor (**5**).

In contrast to the bromoapotrichothecene compound (**5**), treatment of the 13-bromo-12α-hydroxy analogue (**4**) with Zn and acetic acid yielded one major and several minor compounds. The mass spectrum of the major compound (43.4%, isolated by preparative tlc) exhibited a molecular ion at m/e 406, suggesting the elimination of a bromine atom and a hydroxyl group. Its ^{1}H nmr had doublet resonances at δ 4.88 and 5.27 (each 1H, J = 1.0 Hz) which were assigned to terminal methylene protons at the C-13 position. Treatment of the compound with m-chloroperbenzoic acid in chloroform quantitatively converted it into triacetoxydeoxynivalenol (**3**). Based upon this data, the compound was assigned the 9,12-dien-8-one structure **7**. Accordingly, deacetylation with sodium ethoxide furnished the required 3α,7α,15-trihydroxy-trichothec-9,12-dien-8-one (**2**).

Of the minor products produced by treatment of the bromohydrin (**4**) with Zn − acetic acid, only one was isolated in quantities amenable to ready identification. Mass spectral data for this compound indicated loss of bromine and acquisition of a hydrogen atom. Its ^{1}H nmr spectrum exhibited a new 3-proton singlet at 1.50 and other changes (i.e., no resonances at δ 6.6 (H-10) or δ 6.05 (H-7), those for H-11 had moved upfield to δ 4.43, and a new two-proton quartet at δ 2.96, 2.55) were consistent with isomerization of the A-ring to an 8-acetoxy-8-en-7-one system (15). Based upon this data, the structure **8** was proposed for the compound. The formation of **8** from the bromohydrin **4** is possibly facilitated by proximity of the Zn−bromide−hydroxyl complex (16) to the 7β-hydrogen atom.

Experimental

Melting points are uncorrected and were determined on a Kofler hot stage microscope. Infrared (ir) spectra were determined on a Beckman IR-20A spectrophotometer in Nujol mulls. Nuclear magnetic resonance (nmr) spectra were obtained in $CDCl_3$ solutions with Me_4Si as an internal standard on a Bruker W.M. 250 nmr spectrophotometer at 250 MHz. The mass spectra were obtained on either of two systems, one a VG 7070H and the other a VG 12000 quadrupole instrument. Thin layer chromatograms were run on glass plates coated with silica gel GF (layer thickness 0.25 mm). Separated components were detected by ultraviolet fluorescence and (or) by charring after a spray of 5% sulfuric acid in ethanol.

3α,7α,15-Triacetoxy-12,13-epoxytrichothec-9-en-8-one (2)

A solution of *deoxynivalenol* (**1**, 400 mg) in acetic anhydride (3 mL) and pyridine (4 mL) was stirred overnight at room temperature and then neutralized by decantation into a cold saturated solution of sodium bicarbonate (80 mL). After extraction of the neutral solution with chloroform (2 × 80 mL) the chloroform extracts were concentrated under vacuum, and the residue crystallized from diethyl ether furnished *3α,7α,15-triacetoxy-12,13-epoxytrichothec-9-en-8-one* (**3**, 514 mg, R_f 0.70) (silica gel, hexane − ethyl acetate 1:1), mp 154−156°C (lit. (1) mp 155−157°C); ir (Nujol) ν_{max}: 1735 (acetates), 1680 (αβ-unsaturated ketone) cm^{-1}; ^{1}H nmr (see Table 1).

Reaction of 3α,7α,15-triacetoxy-12,13-epoxytrichothec-9-en-8-one (3) with hydrobromic acid/acetic acid

A solution of *3α,7α,15-triacetoxy-12,13-epoxytrichothec-9-en-8-one* (**3**, 380 mg) in glacial acetic acid (30 mL) was treated with an excess of 48% hydrobromic acid (0.25 mL) and refluxed with stirring until tlc studies (hexane − ethyl acetate 1:1) indicated that reaction was complete (4 h). The reaction solution was then cooled and the acetic acid removed *in vacuo*. The residue was subsequently purified by preparative thin layer chromatography (ethyl acetate − hexane 2:3). Crystallization of the major component (152 mg, R_f 0.68) from diethyl ether gave *3α,7α,13,15-tetraacetoxy-2-bromo apotrichothec-7-en-8-one* (**5**), mp 164−165°C; ir (Nujol) ν_{max}: 1740, 1725, and 1690 cm^{-1}; ^{1}H nmr (see Table 1). Mass spectrum m/e: 544.0933 (M^+); calculated for $C_{23}H_{29}Br^{79}O_{10}$: (m.wt.) 544.2628. Crystallization of the minor component (88 mg, R_f 0.77) from diethyl ether gave *3α,7α,15-triacetoxy-13-bromo-12-hydroxytrichothec-7-en-8-one* (**4**), mp 85−86°C; ir (Nujol) ν_{max}: 3460, 1748, 1735, 1716, and 1690 cm^{-1}; ^{1}H nmr (see Table 1). Mass spectrum m/e: 502.1387 (M^+); calculated for $C_{21}H_{27}Br^{79}O_9$: (m.wt.) 502.2392.

7α,13,15-Triacetoxyapotrichothec-2,9-dien-8-one (6)

3α,7α,13,15-Tetraacetoxy-2-bromo-apotrichothec-7-en-8-one (**5**, 60 mg) in glacial acetic acid (5 mL) was refluxed, with stirring, in the presence of powdered zinc (200 mg) for 5 min. The reaction solution was cooled, decanted into a rotary evaporator flask, and the acetic acid removed *in vacuo*.

The residue was taken up in chloroform (60 mL), washed with bicarbonate solution, and the chloroform removed *in vacuo*. Crystallization of the residue from ethanol furnished *7α,13,15-triacetoxy-apotrichothec-2,9-dien-8-one* (**6**, 33 mg, R_f 0.66), mp 120−121°C; ir (Nujol) ν_{max}: 1746, 1735, and 1692 cm^{-1}; ^{1}H nmr (see Table 1). Mass spectrum m/e: 406.1625 (M^+); calculated for $C_{21}H_{26}O_8$: (m.wt.) 406.1574.

Reaction of 3α,7α,15-triacetoxy-13-bromo-12-hydroxytrichothec-7-en-8-one (4) with zinc − acetic acid

3α,7α,15-Triacetoxy-13-bromo-12-hydroxytrichothec-7-en-8-one (**4**, 60 mg) in glacial acetic acid (10 mL) was refluxed, with stirring, in the presence of powdered zinc (200 mg) for 5 min. The reaction solution was cooled, decanted into a 100-mL rotary evaporator flask, and the acetic acid removed *in vacuo*. The residue was taken up in chloroform (60 mL), washed with bicarbonate solution, and the chloroform removed *in vacuo*. The residue was then purified by preparative thin layer chromatography (ethyl acetate − hexane 2:3). The minor component (5.2 mg, R_f 0.46) was crystallized from ether − hexane to yield *3α,8,15-triacetoxy-12-hydroxy-13-methyltrichothec-8-en-7-one* (**8**), mp 171−72°C; ir (Nujol) ν_{max}: 3410, 1758, 1735, 1718, 1655, and 1635 cm^{-1}; ^{1}H nmr (see Table 1). Mass spectrum m/e: 424.1752 (M^+); calculated for $C_{21}H_{28}O_9$: (m.wt.) 424.1734). The major component (21 mg, R_f 0.65), *3α7α,15-triacetoxytrichothec-9,12-dien-8-one* (**7**), had ir (Nujol) ν_{max}: 1735 and 1690 cm^{-1}; ^{1}H nmr (see Table 1). Compound **7** (20 mg) in absolute ethanol (5 mL) was treated for 15 min at room temperature with 0.1 M sodium ethoxide (5 mL). The reaction mixture was deionized with Amberlite IR-120 (H^+) ion-exchange resin and the ethanol removed *in vacuo*.

The residue was purified by preparative thin layer chromatography (ethyl acetate) and gave a compound (9.8 mg, R_f 0.51) as an amorphous solid; ir (Nujol) ν_{max}: 3360−3410, and 1672 cm^{-1}; ^{1}H nmr δ 1.46 (s, 3H, H-14), 1.88 (q, 3H, H-16), 2.18 (ABX, 2H, H-4), 3.85 (AB, 2H, H-15, J = 11.8), 4.25 (d, 1H, H-2, J = 4.5), 4.30 (m, 1H, H-3), 4.75 (d, 1H, H-11, J = 6.0), 4.76 (d, 1H, H-7, J = 1.5), 5.11, 5.24 (2s, 2H, H-13), and 6.63 (d, d, 1H, H-10, J = 6.0). Mass spectrum m/e: 280.1455; calculated for $C_{15}H_{20}O_5$: (m.wt.) 280.1312. These data are compatible with the structure 3α,7α,15-trihydroxytrichothec-9,12-dien-8-one (**2**), which is identical to the transformation product isolated from incubation of deoxynivalenol (**1**) with rumen microorganisms.

Competitive photochlorination and kinetic isotope effects for hydrogen/deuterium abstraction from the methyl group in C_2H_6, C_2D_6, CH_3CHCl_2, CD_3CHCl_2, CH_3CCl_3, and CD_3CCl_3

E. TSCHUIKOW-ROUX, JAN NIEDZIELSKI, and F. FARAJI. Can. J. Chem. **63**, 1093 (1985).

The abstraction of hydrogen and deuterium from ethane, 1,1-dichloroethane, 1,1,1-trichloroethane, and some of their deuterated analogs by photochemically generated ground state chlorine atoms has been investigated in the temperature range 7–95°C using methane as competitor. Rate constants and their temperature coefficients are reported for the following reactions:

$$C_2H_6 + Cl \rightarrow CH_3CH_2 + HCl \quad k_1$$
$$C_2D_6 + Cl \rightarrow CD_3CD_2 + DCl \quad k_2$$
$$CH_3C\mathit{H}Cl_2 + Cl \rightarrow CH_3CCl_2 + HCl \quad k_3$$
$$C\mathit{H}_3CHCl_2 + Cl \rightarrow CH_2CHCl_2 + HCl \quad k_4$$
$$CD_3C\mathit{H}Cl_2 + Cl \rightarrow CD_3CCl_2 + HCl \quad k_5$$
$$C\mathit{D}_3CHCl_2 + Cl \rightarrow CD_2CHCl_2 + DCl \quad k_6$$
$$C\mathit{H}_3CCl_3 + Cl \rightarrow CH_2CCl_3 + HCl \quad k_7$$
$$C\mathit{D}_3CCl_3 + Cl \rightarrow CD_2CCl_3 + DCl \quad k_8$$

An Arrhenius law temperature dependence was observed in all cases. Mixed primary and α-secondary kinetic isotope effects are $k_1/k_2 = 2.79 \pm 0.27$, $k_4/k_6 = 4.13 \pm 0.32$, $k_7/k_8 = 1.46 \pm 0.12$ at 298 K and decrease to $k_1/k_2 = 2.53 \pm 0.22$, $k_4/k_6 = 4.06 \pm 0.28$, $k_7/k_8 = 1.45 \pm 0.09$ at 370 K, showing a "normal" temperature dependence. The kinetic isotope effect for H/D abstraction from the methyl group decreases with increasing number of chlorine substituents in the adjacent chloromethyl group. The β-secondary isotope effect, k_3/k_5, is close to unity and shows a slight inverse temperature dependence.

E. TSCHUIKOW-ROUX, JAN NIEDZIELSKI et F. FARAJI. Can. J. Chem. **63**, 1093 (1985).

Opérant à des températures allant de 7 à 95°C et utilisant le méthane comme produit de compétition, on a étudié la réaction d'enlèvement d'hydrogène ou de deutérium de l'éthane, du dichloro-1,1 éthane, du trichloro-1,1,1 éthane et de quelques-uns de leurs analogues deutérés par des atomes de chlore générés d'une façon photochimique et existants dans leur état fondamental. On rapporte les constantes de vitesse et les coefficients de température appropriés pour les réactions suivantes:

$$C_2H_6 + Cl \rightarrow CH_3CH_2 + HCl \quad k_1$$
$$C_2D_6 + Cl \rightarrow CD_3CD_2 + DCl \quad k_2$$
$$CH_3C\mathit{H}Cl_2 + Cl \rightarrow CH_3CCl_2 + HCl \quad k_3$$
$$C\mathit{H}_3CHCl_2 + Cl \rightarrow CH_2CHCl_2 + HCl \quad k_4$$
$$CD_3C\mathit{H}Cl_2 + Cl \rightarrow CD_3CCl_2 + HCl \quad k_5$$
$$C\mathit{D}_3CHCl_2 + Cl \rightarrow CD_2CHCl_2 + DCl \quad k_6$$
$$C\mathit{H}_3CCl_3 + Cl \rightarrow CH_2CCl_3 + HCl \quad k_7$$
$$C\mathit{D}_3CCl_3 + Cl \rightarrow CD_2CCl_3 + DCl \quad k_8$$

Dans tous ces cas, on a observé une relation du type d'Arrhénius entre les vitesses et la température. A 298 K, on a déterminé les effets isotopiques cinétiques mixtes, primaires et secondaires en α, $k_1/k_2 = 2{,}79 \pm 0{,}27$, $k_4/k_6 = 4{,}13 \pm 0{,}32$ et $k_7/k_8 = 1{,}46 \pm 0{,}12$ et, à 370 K, ces valeurs diminuent vers $k_1/k_2 = 2{,}53 \pm 0{,}22$, $k_4/k_6 = 4{,}06 \pm 0{,}28$, $k_7/k_8 = 1{,}45 \pm 0{,}09$; ces résultats sont en accord avec une relation "normale" avec la température. L'effet isotopique cinétique pour l'enlèvement des H/D de groupements méthyles diminue avec une augmentation du nombre de chlores qui sont présents dans le groupe chlorométhyle voisin. L'effet isotopique secondaire-β se rapproche de l'unité et il présente une légère dépendence inverse avec la température.

[Traduit par le journal]

Introduction

The abstraction of hydrogen by ground state chlorine atoms from partially chlorinated methanes and ethanes has been the subject of a number of investigations. Earlier competitive results have been reviewed by Fettis and Knox (1) and, lately, the data have been updated and revised (2, 3). Recent environmental concern regarding the indirect effect of chlorofluoromethane release on the stratospheric ozone balance (4) has resulted in an upsurge of interest in the reactivity of atomic chlorine with hydrogen-containing atmospheric constituents which may provide a sink for Cl atoms, thereby removing them from the Cl/ClO cycle which catalytically destroys odd oxygen in the stratosphere. Although the concentrations of chloroalkanes in the stratosphere are relatively low, they are not negligible, and this has prompted several studies using modern "direct" techniques. Clyne and Walker (5) investigated the reactions of Cl atoms with CH_3Cl, CH_2Cl_2, and $CHCl_3$ using a discharge flow – mass spectrometric technique, and Manning and Kurylo (6) reported on the reaction Cl + CH_3Cl employing the flash photolysis – resonance fluorescence method. Two direct studies have been reported on mono-, di-, and trichloroethanes by Wine *et al.* (7, 8), in which chlorine atoms were produced by 355-nm pulsed laser photolysis of Cl_2 and mon-

itored by time-resolved resonance fluorescence spectroscopy. Though, in principle, the direct studies are to be preferred, the technique employed of following the rate of decay of the chlorine atom concentration suffers from its inability to distinguish between the different types of hydrogen in the chloroethane molecule, and, moreover, it cannot match the internal accuracy of modern competitive measurements.

In a recent paper from this laboratory (9) the photochlorination of C_2H_5Cl and C_2D_5Cl was examined using the competitive method. Accurate rate parameters were obtained and, surprisingly, a marked difference was observed in the magnitude of the intermolecular isotope effect involving the α and β hydrogens. To better understand these results, the measurements are presently extended to include the photochlorination of 1,1-dichloro- and 1,1,1-trichloroethane and their deuterated analogs. The experiments on ethane and perdeuterated ethane were also included to check the reliability of the earlier data (10), and for the sake of consistency in searching for the trends in a set of related compounds.

Experimental

The apparatus, light source, and experimental procedures have been described previously (9). Photolyses were carried out in a static system over the temperature range 7−95°C using filtered visible light centered at 424 nm. Only chlorine absorbs at this wavelength, and the ensuing decomposition of an excited Cl_2 molecule yields Cl atoms which are in their ground electronic state for all practical purposes ($Cl(^2P_{3/2}) > 99.2\%$ $Cl(^2P_{1/2}) < 0.8\%$ at 298 K). The temperature of the reactor was kept uniform to within 0.2°C, and dark reactions were never observed.

Three systems were examined: C_2H_6/C_2D_6, CH_3CHCl_2/CD_3CHCl_2, and CH_3CCl_3/CD_3CCl_3. The complementary data for the system CH_3CH_2Cl/CD_3CH_2Cl were taken from our recent publications (11, 12). The only carbon-containing products observed were the primary chlorination products: C_2H_5Cl, C_2D_5Cl, CH_3CCl_3, $CH_2ClCHCl_2$, CD_3CCl_3, $CD_2ClCHCl_2$, CH_2ClCCl_3, CD_2ClCCl_3, and CH_3Cl, the latter originating from the competitor, CH_4. Analyses were performed by isothermal gas chromatography using a 2-m Durapak column and flame ionization detection, at temperature settings in the range 110−150°C depending on compound. Quantitative analysis involved corrections for the relative sensitivities of the F.I. detector response, which were accurately determined (see discussion).

All chemicals used in this study were obtained commercially: research grade chlorine and methane from Matheson; 1,1-dichloroethane from Eastman Organic Chemicals; 1,1,1-trichloroethane (with no stabilizers added) from Matheson, Coleman, and Bell, Manufacturing Chemists; and deuterated compounds from Merck, Sharp and Dohme (Canada). The overall purity of the samples was on the average about 99%. All reactants were purified by repeated distillations *in vacuo* at either methanol or toluene slush temperatures (∼−94°C) until the level of the most deleterious impurities (viz. CH_3Cl and those corresponding to the C_2-photochlorination products) was below the limit of detection. The residual impurities, not exceeding 0.2%, were innocuous and were tolerated. The isotopic purity of the deuterated samples stated by the manufacturer was above 98% in all cases, and was confirmed by mass-spectral analysis.

Results and discussion

The reagents (ethane or one of the chloroethanes, CH_4 as competitor, and Cl_2) were photolyzed at λ ∼424 nm over the temperature range 7−95°C at total pressures of about 21 Torr (1 Torr = 133.3 Pa). Competing reactants were used in at least twenty-fold excess over chlorine to satisfy the requirement of long chains and insure that chain termination is predominantly by radical combination. In several experiments the excess of competing reactants over Cl_2 was varied up to seventy-fold and was found to have no effect on the product ratios. As expected, neither had a factor of ∼10 variation in light intensity. The pertinent rate laws, as well as the verification of the long-chain assumption, have been presented elsewhere (9).

Under these conditions the relevant processes are the eight abstraction reactions

$$[1] \quad C_2H_6 + Cl \rightarrow CH_3CH_2 + HCl$$

$$[2] \quad C_2D_6 + Cl \rightarrow CD_3CD_2 + DCl$$

$$[3] \quad CH_3C\mathit{H}Cl_2 + Cl \rightarrow CH_3CCl_2 + HCl$$

$$[4] \quad C\mathit{H}_3CHCl_2 + Cl \rightarrow CH_2CHCl_2 + HCl$$

$$[5] \quad CD_3C\mathit{H}Cl_2 + Cl \rightarrow CD_3CCl_2 + HCl$$

$$[6] \quad C\mathit{D}_3CHCl_2 + Cl \rightarrow CD_2CHCl_2 + DCl$$

$$[7] \quad CH_3CCl_3 + Cl \rightarrow CH_2CCl_3 + HCl$$

$$[8] \quad CD_3CCl_3 + Cl \rightarrow CD_2CCl_3 + DCl$$

followed by:

$$[9] \quad R + Cl_2 \rightarrow RCl + Cl$$

where R denotes any of the ethyl or chloroethyl radicals formed in reactions [1]−[8]. Since the radicals R are thermal, they can neither decompose nor undergo any internal rearrangements prior to reaction with Cl_2. As has been shown previously in analogous cases (11), under the experimental conditions used, other side reactions involving free radicals such as metathetical hydrogen/deuterium and (or) chlorine exchange, or the abstraction of H or D from the product hydrogen chlorides, are unimportant. These conclusions are also valid for the present system.

In the absence of these complicating features, the rate constant ratio for the competitive photochlorination of RH with a reference compound R′H is given by

$$[10] \quad \frac{k}{k_r} = \frac{\ln\,[RH]_0 - \ln\,[RH]_f}{\ln\,[R'H]_0 - \ln\,[R'H]_f}$$

where the subscripts 0 and f denote initial and final concentrations. Equation [10] is exact, subject only to the long-chain assumption. Since the consumption method is experimentally inconvenient and, moreover, cannot distinguish between different types of H-atoms in the reactant, eq. [10] can be expressed in terms of the product yields.

$$[11] \quad \frac{k}{k_r} = \frac{\ln\,\{1 - [RCl]/[RH]_0\}}{\ln\,\{1 - [R'Cl]/[R'H]_0\}}$$

At very low conversions with respect to both RH and R′H, eq. [11] may be simplified without noticeable error to

$$[12] \quad \frac{k}{k_r} = \frac{[RCl]\,[R'H]_0}{[R'Cl]\,[RH]_0}$$

The approximations involved in the derivation of this expression have been discussed elsewhere and shown to be justified (9, 11).

Equation [12] was used to reduce the data in experiments on di- and trichloroethanes. In experiments on C_2H_6 and C_2D_6 the difference in reactivity between the ethanes and methane is very large. Consequently, CH_4 was necessarily used in large (80- to 150-fold) excess. Still, the conversion of ethane in these experiments was as high as 7−8% for C_2H_6 and about 3 times smaller for C_2D_6. In these cases the simplified eq. [12] was modified by applying a correction factor (13) which, in the

limit, reduces to eq. [11], but which does not require a direct determination of the ratio, $[RCl]/[RH]_0$, the latter being inconvenient and subject to experimental error. These corrections were small, on the level of 2–4%.

In all cases studied, the rate constant ratios conformed to the Arrhenius rate law over the temperature range of this investigation. The results are listed in Table 1, and are based on the usual least-squares treatment, where the quoted error limits are one standard deviation. For each compound examined two different reagent mixtures using two different batches of this compound were prepared. The agreement between these two sets of results was always satisfactory. The uncertainties stated in Table 1 for the pre-exponential factor ratios, A_i/A_j, and activation energy differences $(E_i - E_j)/R$, account for random errors only. These incorporate uncertainties in pressure measurements in the preparation of mixtures, errors in gas-chromatographic peak area determinations, and varying levels of trace impurities from one mixture to another, and from one sample to another.

The differences in flame ionization detector sensitivity towards the compounds of interest are the major contributing factors to systematic errors. These differences were established using authentic samples, and relative correction factors are tabulated in Table 2, with CH_3CHCl_2 arbitrarily chosen as a reference. These correction factors are very significant for the different chloroethanes: the sensitivity decreases markedly with chlorine substitution, and also depends on the position of the halogen(s) for geometric isomers. Further, a discernible isotope effect is observed: the sensitivity decreases with increasing deuterium substitution in the molecule. In two cases authentic samples of the deuterated compounds were not available ($CD_2ClCHCl_2$ and CD_2ClCCl_3). In this instance the correction factors were evaluated by interpolation (Table 2).

The sensitivity corrections which affect the pre-exponential factor ratios but not the activation energy differences have been allowed for in Table 1 under the heading $(A_i/A_j)_{corr}$. Other systematic errors, e.g. those due to the isotopic impurities, deviations from the true Gaussian distribution, and to the as-

[b]1,1-Dichloroethane was arbitrarily chosen as a reference.
[c]Estimate: C.F.($CD_2ClCHCl_2$) = C.F.($CH_2ClCHCl_2$) × C.F. (CD_2ClCH_2Cl)/C.F.(CH_2ClCH_2Cl).
[d]Estimate: C.F.(CD_2ClCCl_3) = C.F.(CH_2ClCCl_3) × C.F.(CD_2ClCH_2Cl)/C.F.(CH_2ClCH_2Cl).

sumptions inherent in the simplified reaction mechanism are estimated to be of little importance.

Rate constants and absolute Arrhenius parameters

Based on the relative rate parameters reported in Table 1, the absolute Arrhenius parameters were calculated and assembled in Table 3 using the absolute rate constant value ($cm^3\ s^{-1}$) for the chlorination of methane determined by Keyser (14) for the temperature range 291 to 423 K,

$$[13]\quad k_{CH_4} = (1.65 \pm 0.32) \times 10^{-11} \exp[-(1530 \pm 68)/T]$$

We consider this value to be more appropriate for our range of temperatures than that recommended by the NASA panel (3) in the range 200–300 K applicable to stratospheric temperatures. Our rate parameters for the photochlorination of C_2H_6 differ significantly from those recommended by the NASA panel. However, if their preferred value for the methane reference reaction were to be adopted, reasonable agreement is achieved. This may be taken as an indication that Keyser's values for the rate parameters are too large. Nevertheless, for the sake of consistency with our former data on chloroethane, Keyser's value for k_{CH_4} is retained, particularly since it overlaps our temperature range.

In the case of the other compounds reported here, data from other laboratories that could be compared with our results are sparse. Chiltz *et al.* (10) reported the rate constant ratios, k_1/k_2, at several temperatures in the range 302–433 K for the direct competition in C_2H_6/C_2D_6 mixtures using a mass spectrometric technique. Although these data show a high degree of scatter when plotted according to the Arrhenius rate law, an approximate temperature dependence is given by $\ln(k_1/k_2) = 0.53 + 137/T$, in satisfactory agreement with our value of $\ln(k_1/k_2) = 0.545 + 151/T$ based on the data in Table 1.

Cillien *et al.* (15) have reported the relative and absolute parameters for the chlorination of 1,1-dichloroethane, in the absence and presence of CH_3Cl as competitor. The values of the Arrhenius parameters for this reference reaction used in the

original work are no longer tenable. The reevaluated rate constant (cm^3 s^{-1}) for methyl chloride

$$[14] \quad k_{\mathrm{CH_3Cl}} = 3.4 \times 10^{-11} \exp\,[-(1260 \pm 200)/T]$$

recommended by the NASA panel (3) based on the preferred absolute measurements of Manning and Kurylo (6) agrees well with our competitive measurements against ethyl chloride (13)

$$[15] \quad k_{\mathrm{CH_3Cl}} = (3.02 \pm 0.61) \times 10^{-11} \exp\,[-(1221 \pm 68)/T]$$

Using these new values to recalculate the absolute rate parameters of Cillien *et al.* we obtain good agreement with respect to the activation energy (Table 3). It should be noted that $\mathrm{CH_3CHCl_2}$ represents an internally competitive system, and the product ratio determines the relative rate constants directly: $k_3/k_4 = [\mathrm{CH_3CCl_3}]/\mathrm{CH_2ClCHCl_2}]$. In the case of simultaneous internal competition against an external standard, eq. [12] is also valid for each identifiable product. The results are shown in Table 4 and compared with $\mathrm{CH_3CH_2Cl}$ and with the internal competition data for $\mathrm{CH_3CHCl_2}$ of Cillien *et al.* (15) over the temperature range 303–353 K. It should be noted that since no external competitor is involved, the uncertainties associated with the latter do not enter into this direct comparison. The agreement in the activation energy difference between tertiary and primary hydrogens in $\mathrm{CH_3CHCl_2}$ is excellent, while the ratio of pre-exponential factors differs by about 30%. This discrepancy could result if the differences in sensitivities of the detector response toward tri-substituted photolysis products were not accounted for in the earlier work. The only other report on the rate parameters for the chlorination of $\mathrm{CH_3CHCl_2}$ is by Wine and Semmes (8) based on laser flash photolysis – resonance fluorescence measurements. Unfortunately, as noted earlier, in this direct investigation no distinction can be made between the abstraction of tertiary and primary hydrogens in the molecule, since the reaction was followed by measuring only the rate of decay of Cl atoms. Their rate constant for the abstraction reaction is therefore a composite of two contributions. In the light of the Arrhenius parameters for the primary and tertiary hydrogen abstraction presented in Table 3, the activation energy for the "mixed" processes reported by Wine and Semmes seems to be too low.

The reaction of chlorine atoms with 1,1,1-trichloroethane has also been investigated competitively by Cillien *et al.* (15) and directly by Wine, Semmes, and Ravishankara (7). In this case only one type of hydrogen is available and the results of

[c]Ratios given per available C—H bond.

both methods should be comparable directly. Regrettably, due to the slow nature of the reaction and the onset of complicating features attributed to secondary processes at the higher temperatures, Wine *et al.* could only establish a lower limit for the activation energy (Table 3). Comparison among the competitive studies shows that the activation energy determined in this work agrees with the recalculated values of Cillien *et al.*, given the large uncertainty in the latter work. However, the pre-exponential factors are in marked disagreement and, in this case, can not be reconciled on the basis of detector sensitivity corrections.

Inspection of Table 3 shows that both the *A*-factors and the activation energies are affected by chlorine substitution. The dominant feature with respect to reactivity is, firstly, the progressive increase in activation energies, in both the α and β positions, with increasing Cl substitution on the same carbon atom. Secondly, hydrogen abstraction is faster from the *substituted* carbon atom in a molecule with the *same* number of chlorine atoms, viz., $k(CH_3C\mathit{H}_2Cl) > k(C\mathit{H}_3CH_2Cl)$; $k(CH_3C\mathit{H}Cl_2) > k(C\mathit{H}_3CHCl_2)$. The highest activation energy and the slowest rate are observed for CH_3CCl_3 where there are only primary hydrogens. Similar trends have also been found in the case of fluoroethanes (13, 16, 17). A plausible qualitative explanation of these observations may be sought in terms of repulsive and electron withdrawal effects by the bound chlorine atom(s). The general trend of increasing activation energy and hence lower reactivity with increasing number of chorine substituents may then be attributed to the repulsion of the approaching chlorine atom by the bonded chlorine(s). It would appear that such repulsion should be more pronounced at the chlorinated site, yet the attack on the secondary hydrogen in CH_3CH_2Cl and tertiary hydrogen in CH_3CHCl_2 is faster than on the vicinal methyl group. This may be attributed to the electron-withdrawing power of the electronegative chlorine: the electrons are drawn towards the bound Cl atom(s), thus weakening the C—H bonds in the methylene and methine groups, respectively. Thus there is evidently a concerted effect of repulsion and electron withdrawal by the bound chlorines. The fact that hydrogen abstraction from the chlorinated group in CH_3CHCl_2 is slower than in CH_3Cl_2Cl further suggests that the repulsive effect increases with the number of chlorine substituents.

Although the argument based on repulsion and electronegativity considerations is simple and adequate, an opposite point of view has been presented by Johnston and Goldfinger (18) to rationalize the strong disagreement between the observed trend of activation energy with bond energy for hydrogen abstraction by Cl atoms from chlorinated methanes and ethanes (based on the then available data) and that calculated from LEPS and BEBO potential energy surfaces. Seeking an explanation in terms of nonbonding interactions between the incident and bound chlorine atoms (considered as symmetrical groups), these authors evaluated the Lennard–Jones 6–12 potential function and showed that for the dimensions of their activated complexes the interactions were on the attractive part of the potential. Therefore, the observed activation energies were ascribed not to van der Waals repulsions, but to dynamic effects of attractive dispersion forces between bound and free chlorine atoms. According to Johnston and Goldfinger, the preferential attraction of the chlorine atom by the bound chlorine results in collision complexes of the form >CH—Cl---Cl predominating over those of the form >CCl—H---Cl; thus unless the approaching atom has a relatively high kinetic energy, the hydrogen atom transfer complex never forms. This rather curious conclusion must be questioned in the light of more recent data on the activation energies for H by Cl abstraction and C—H bond dissociation energies, at least in the case of the chloromethane series. A comparison of the activation energies (values in kcal mol^{-1}) in CH_3Cl (3.6), CH_2Cl_2 (2.9), $CHCl_3$ (2.8) reported by Clyne and Walker (5) shows a distinct trend, if not a one-to-one correspondence, with the C—H bond dissociation energies: 102.9; 100.6; 95.2 kcal mol^{-1}, respectively, reported most recently by Weissman and Benson (19). The activation energy for Cl + CH_3Cl determined by Clyne and Walker is higher than that reported by Manning and Kurylo (6) and may be subject to a systematic error (3); however, we have used it here for the sake of internal consistency in this comparison. It is tempting to provide a similar comparison for the chloroethane series. Unfortunately, to date, "measured" C—H bond dissociation energies are not available for most of the chloroethanes, except for $CHCl_2CHCl_2$ and C_2HCl_5 (20). It was based on these data and the known value of $D(C_2H_5$—H) that Franklin and Huybrechts (21) assumed that $D(R_{Cl}$—H) = 98.0, 96.7, and 95.4 kcal mol^{-1} for primary, secondary, and tertiary C—H bonds, respectively, in those chloroethanes for which experimental values are not available. This is inadequate for the present purpose, especially in view of the kinetic data for the chlorination of CH_3CCl_3. Wine and Semmes (8) have argued convincingly that the substitution of Cl on one carbon atom substantially increases the C—H bond strength on the adjacent carbon atom, citing in support of CH_3CCl_3 its fluorinated analog, CH_3CF_3, in which the C—H bond is known to be extremely strong, $D(CF_3CH_2-H) = 106.7$ kcal mol^{-1} (20). A similar view with respect to fluoroethanes has been expressed by McMillen and Golden (20). In fact, Wine and Semmes carried the analogy of the reactivity trends observed in the chloromethane series to the chloroethanes, and suggested that the substitution of Cl in the α-position not only strengthens the C—H bond on the β carbon but also weakens the remaining C—H bonds on the α-carbon. Our results on the chlorination of both chloroethanes and fluoroethanes (13) support this contention.

Isotope effects

Rate constant ratios for H/D atom abstraction from compounds of interest at four selected temperatures are listed in Table 5. A few literature values that are available are included for comparison in Table 6. It should be emphasized that the measured intermolecular hydrogen−deuterium kinetic isotope effects consist of contributions from the primary and secondary isotope effects. Secondary contributions arise since the isotopic composition of the residual ethyl or chloroethyl groups is different. Although the contributions from the α-secondary isotope effect are, as recently shown (22), small, but not negligible, the present results do not permit us to extricate these contributions.

Our data on the C_2H_6/C_2D_6 system are in close agreement with those of Chiltz *et al.* (10). The isotope effect is rather weak compared to the so-called "theoretical maximum", which is based on a one-dimensional three-particle model but which ignores any tunneling correction. According to this simplified treatment applicable to hydrogen atom transfer reactions, the maximum kinetic isotope effect is related to the zero-point energy difference of the atoms being transferred in the reactants (23):

$$[16] \quad (k_H/k_D)_{max} = \exp\,[(E_{Z,RH} - E_{Z,RD})/RT]$$

For the C_2H_6/C_2D_6 system, $(k_H/k_D)_{max} \approx 8$ at 298 K. The temperature dependence of the primary (plus α-secondary) kinetic isotope effects (KIE) for this and the three chlorine substituted systems is normal: the KIE decreases with temperature (Table 5). A comparison of the chlorinated pairs with C_2H_6/C_2D_6 shows a significant change: the KIE for H/D abstractions from the methyl group is ~2.2 times larger in the case of the monochlorinated species. With increasing chlorine substitution the KIE decreases markedly, such that for the CH_3CCl_3/CD_3CCl_3 system it is about 1/2 the value for C_2H_6/C_2D_6. A comparison of H/D abstraction associated with the methyl and methylene groups in the chloroethane pairs (Table 6) reveals that the KIE for the primary hydrogens is about 3 times larger. In this instance the qualitative generalization postulated by Lewis (23): "With two hydrogen atom transfers of equal exothermicity, the one of higher activation energy will have the more nearly symmetrical transition state and hence the higher isotope effect" is roughly obeyed, given the uncertainties in the heats of reaction. However, this conclusion cannot be extended to the KIE associated with the pairs CH_3CH_2Cl/CD_3CH_2Cl, CH_3CHCl_2/CD_3CHCl_2, and CH_3CCl_3/CD_3CCl_3 based on the thermochemical data and interpolations of Franklin and Huybrechts (21) which predict almost equal exothermicities for hydrogen abstraction by Cl atoms for the three chloroethanes (Table 6). Since the activation energy increases significantly in going from CH_3CH_2Cl to CH_3CHCl_2 to CH_3CCl_3 (Table 3) while the KIE shows a strong opposite trend (Table 6), either the generalization of Lewis breaks down in this case, or the thermochemical data are inadequate. Our results, taken in conjunction with those of Cillien *et al.* (15) and Wine *et al.* (7, 8) strongly suggest that the C—H bond energies in chloroethanes and the estimated heats of formation of chlorinated ethyl radicals are in need of revision.

Finally, it is worth noting that our results yield the magnitude of the β-secondary kinetic isotope effect in the system CH_3CHCl_2/CD_3CHCl_2, k_3/k_5. This weak effect is unity within the limits of experimental error. However, the pre-exponential factors and activation energies for reactions [3] and [5] are different. The difference is barely outside the quoted error limits but the trends confirm our former observations concerning β-secondary kinetic isotope effects in the photochlorination of ethyl chlorides (11, 12): both the A-factor and the activation energy decrease as a result of deuterium substitution in the adjacent group, i.e., in going from CH_3CHCl_2 to CD_3CHCl_2, the activation energy difference accounting for the inverse temperature dependence.

The sorption of uranyl species on a hematite sol[1]

C. H. HO AND D. C. DOERN

Research Chemistry Branch, Whiteshell Nuclear Research Establishment, Atomic Energy of Canada Limited, Pinawa, Man., Canada R0E 1L0

Received December 20, 1983[2]

C. H. HO and D. C. DOERN. Can. J. Chem. **63**, 1100 (1985).

The sorption of uranyl species on a hematite sol of narrow size distribution has been studied as a function of uranium concentration and solution pH. The adsorption increases with increasing uranium content in the solution. Raising the pH from 5 to about 6.2 markedly enhances the uptake of uranium. The enhanced uptake coincides with a proportional increase of $(UO_2)_3(OH)_5^+$. The sudden increase in adsorption around this pH region does not appear to be due to changes in surface charge of the hematite particles. It may be due to specific interactions between $(UO_2)_3(OH)_5^+$ and the hematite particles. Results of desorption experiments show that different binding sites may exist on the hematite surface.

C. H. HO et D. C. DOERN. Can. J. Chem. **63**, 1100 (1985).

On a étudié la variation de la sorption d'espèces d'uranyles, sur un sol d'hématite avec une distribution étroite de la taille des particules, en fonction de la concentration de l'uranium et du pH de la solution. L'adsorption augmente avec une augmentation de la concentration de l'uranium dans la solution. Une augmentation du pH de 5 à 6,2 fait augmenter l'adsorption d'uranium d'une façon importante. L'augmentation de l'adsorption coïncide avec une augmentation proportionnelle de la concentration du $(UO_2)_3(OH)_5^+$. L'augmentation subite de l'adsorption autour de cette région de pH ne semble pas due à des changements dans la charge de la surface des particules d'hématite. Elle pourrait être due à des interactions spécifiques entre le $(UO_2)_3(OH)_5^+$ et les particules d'hématite. Les résultats des expériences de désorption montrent qu'il pourrait exister différents sites de fixation sur la surface de l'hématite.

Introduction

The sorption of metal ions on oxide surfaces is important in many technical areas such as ore processing and environmental pollution studies. It is also important when considering the transport of radionuclides in a geological waste-disposal vault. Waste forms could be subjected to groundwater attack, and actinides such as uranium could be released into the groundwater and adsorbed onto mineral surfaces or particulates (such as iron oxyhydroxides) already in the groundwater (1).

We have chosen to study uranium as the first step in a more general study of actinide adsorption onto colloidal particles. A number of studies on adsorption of uranium from aqueous solution have been reported (2–4). Most have emphasized adsorption on natural geological materials such as clay and basalt. Because not enough is known about either the state of the adsorbed uranium or the sorption mechanism onto any specific adsorbent, it is difficult to predict accurately the effect of sorption on the mobility of uranium.

The present study was directed towards achieving a better understanding of the mechanism of uranium adsorption on hematite. Hematite is an important component of geological formations found in close association with uranium under natural conditions (5). Therefore, information about the adsorption of actinides onto hematite will help in assessing actinide mobility. To this end, a hematite sol of narrow size distribution was synthesized and characterized. The adsorption and desorption of uranium on this sol were investigated over a range of pH values ($3 \leq pH \leq 6.2$), with particular emphasis on the correlation of uranium adsorption with the uranyl species present over this pH range.

Experimental

Materials

Distilled water was passed through two ion-exchange columns and then redistilled in a grease-free Pyrex still. The ferric chloride was Baker Analyzed Reagent. All other chemicals were reagent grade and were used without further purification.

The hematite sol was prepared by hydrolysis at 100°C of ferric chloride for about 24 h, and the particles were examined in an International Scientific Instrument DS Model 130 scanning electron microscope equipped with a Tracor Northern Particle Recognition and Characterization device for particle size and size distribution analysis. Specific surface area measurements were obtained by the BET method, using nitrogen gas as the adsorbate. The composition of the particles was determined by X-ray diffraction. The isoelectric point was obtained using a Rank Brothers Microelectrophoresis Apparatus. Infrared spectra were obtained in KBr medium using a Nicolet Model MX-1 Fourier Transform Infrared Spectrometer.

Methods

Uranium adsorption was determined by measuring the depletion of uranyl ions in a supernatant solution with a Cary 210 Ultraviolet spectrophotometer, using 2-(5-bromo-2-pyridylazo)-5-diethylaminophenol as a chromogenic reagent (6). A constant particle concentration of 0.2 g dm^{-3} was used with a contact time of 16 h. Trial experiments showed that adsorption did not change significantly for a longer contact time of 40 h. The experimental procedure was as follows: A series of uranyl solutions and the hematite sol were prepared at the required concentration, pH, and ionic strength (using 5×10^{-4} mol dm^{-3} NaCl, NaOH, or HCl). Then 10 cm^3 of the hematite sol was transferred to a polycarbonate centrifuge bottle containing 10 cm^3 of uranyl nitrate solution. The mixture was shaken for 16 h in a water bath at 25 ± 0.1°C. The solid was separated from the liquid in a Beckman L8-55 Ultracentrifuge and the supernatant solution was analyzed for uranium content. The pH of the supernatant was also noted. A control without hematite was prepared, and duplicate runs were performed for each series of experiments. The electrophoretic mobility of the particles was determined after diluting a portion of uranium-loaded hematite particles with centrifuged supernatant to give a suitable concentration for observation. Only the pH of the supernatant solution was used in the results.

Desorption of uranium from loaded hematite was studied in two separate experiments. In the first, a portion of the supernatant solution was replaced by the same volume of fresh solution with the same pH and salt concentration as the adsorption solution. In the second, the pH

TABLE 1. Characteristics of the hematite particles

Characteristic	Value
Particle size (μm)	0.12
Specific surface area ($m^2\ g^{-1}$)	34
Chemical composition (% α-Fe_2O_3)	>98
Isoelectric point	7.6

of the mixture was lowered fom 6.19 to about 4 using concentrated HCl immediately after the adsorption process. After equilibrating the mixture for an appropriate time, aliquots of the supernatant were removed, and the uranium concentration was determined. The pH of the supernatant was also measured.

Results and discussion

Characterization

Table 1 shows the characteristics of the synthesized hematite particles. The particle shape is uniform and the size distribution is very narrow. X-ray diffraction data were consistent with the particles being α-Fe_2O_3 containing less than 2% β-FeO(OH).

Adsorption

Figure 1 shows the dependence of the amount of uranium adsorbed on the equilibrium solution concentration of uranium at various pH values of the media. Significant adsorption does occur, even though the hematite particles possess net positive charge in the pH range from 3 to 6.5. This suggests that there must be a non-electrostatic contribution to the overall free energy of adsorption that outweighs the repulsive coulombic and solvation forces. The adsorption was greatest at a pH of about 6.2 and decreased markedly at lower pH values.

In an earlier study, Borovec (3) used the Freundlich isothermal relation to interpret his experimental data for the adsorption of uranyl ions by fine clay. Borovec's data conformed well with the Freundlich equation for uranyl concentrations below 1×10^{-4} mol dm^{-3}. Recently, Langmuir (7) used the Langmuir equation to analyze his data for the adsorption of uranium on iron oxyhydroxide. He suggested that the non-linearity of the plot might be due to different adsorption mechanisms. However, in the present study, the experimental data were not analyzed by the conventional adsorption isotherms because (*i*) a number of uranyl species exist in the solution; (*ii*) one or more uranyl species may be involved in the adsorption process; and (*iii*) the proportions of uranyl species change with the total uranium content in the solution.

Several attempts have been made to explain the variation in adsorption of hydrolyzable cations with respect to pH. In general, hydrolysis of cations to form other soluble and/or insoluble species is assumed to be an important factor in this variation; however, quantitative data on the hydrolysis of uranium(VI) are scarce. Calculations based on Sillen and Martell's thermochemical data (8) have shown that the hydrolysis of uranium (VI) could form a variety of aquo complexes such as $UO_2(OH)^+$, $(UO_2)_2(OH)_2^{2+}$, and $(UO_2)_3(OH)_5^+$. The proportion of each species depends on the total uranyl ion concentration and solution pH. Recently, Toth and Begun (9) used Raman spectroscopy to detect different hydrolyzed uranium species in an aqueous medium, and found that the predominant species in the pH region 1.30 to 4.02 were UO_2^{2+}, $(UO_2)_2(OH)_2^{2+}$, and $(UO_2)_3(OH)_5^+$. Although their uranyl ion concentrations were higher than those of other workers, the results agree with the data from Sillen and Martell (8) and Baes and Mesmer (10).

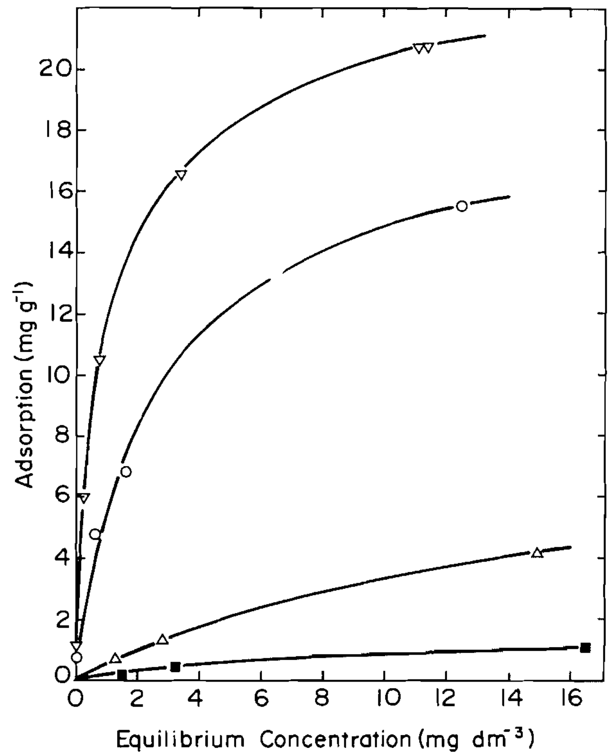

FIG. 1. Effect of pH on the adsorption of uranyl species on hematite at 25°C in 5×10^{-4} mol dm^{-3} NaCl: ∇, pH 5.95–6.19; $\bigcirc$, pH 5.26–5.45; $\triangle$, pH 4.51–4.58; $\blacksquare$, pH 3.04–3.06.

Figure 2 shows the fraction of uranium adsorbed as a function of pH, together with the hydrolysis data from Baes and Mesmer (10), at a uranyl ion concentration of 1×10^{-5} mol kg^{-1}. At pH < 4, where UO_2^{2+} is the predominant species, the adsorption is very small. This suggests that UO_2^{2+} is not the active species involved in adsorption. As the pH is increased, the adsorption of uranium increases abruptly. The sudden increase in adsorption around pH 5 could not be related to the surface charge of the hematite particles. As shown in Fig. 4, a change of solution pH from 4 to 6.2 results in only a slight decrease in the electrophoretic mobility of the hematite particles (dotted line). The reduction in the ζ potential of the hematite particles is considered to be too small to produce such a dramatic effect on the adsorption of uranium ions. However, this sudden increase in adsorption coincides with a marked increase in the amount of $(UO_2)_3(OH)_5^+$ and, therefore, $(UO_2)_3(OH)_5^+$ may be responsible for the increased uptake of uranium. The coulombic repulsion between $(UO_2)_3(OH)_5^+$ and the positively charged oxide surface is presumably less than for UO_2^{2+}, thereby permitting increased uptake of uranium. Moreover, the lowering of the ionic charge of hydrolyzed uranium (VI) ion would cause a decrease in secondary solvation energy, thereby enhancing the adsorption. Similar adsorption behaviour has been observed with other hydrolyzable cations. For instance, the adsorption of thorium(IV) (11) on silver iodide was observed to increase sharply as soon as hydrolysis became significant. Although other uranyl species such as UO_2OH^+ and $(UO_2)_2(OH)_2^{2+}$ are present in the pH region from 4 to 6, they are of minor importance when compared with $(UO_2)_3(OH)_5^+$ (see Fig. 2), and cannot account for the sudden increase in uptake of uranium.

In a recent paper, Maya and Begun (12) have demonstrated the existence of $(UO_2)_2CO_3(OH)_3^-$ in addition to $UO_2(CO_3)_2^{2-}$

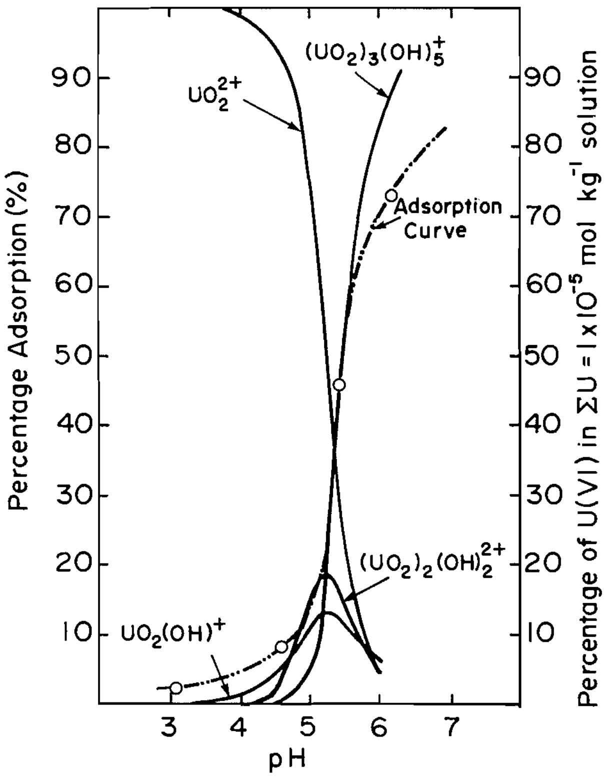

FIG. 2. Comparison of the pH dependence of the adsorption of uranyl species on hematite at 25°C with the percentage of the major hydrolysis products of U(VI) (ΣU = 1 × 10^{-5} mol kg^{-1}) (from ref. 10).

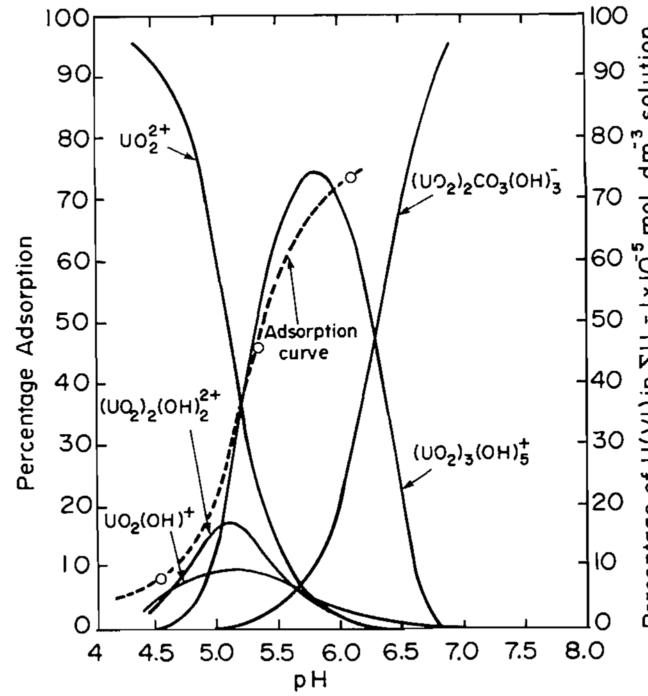

FIG. 3. Comparison of the pH dependence of the adsorption of uranyl species on hematite at 25°C with the percentage of the major hydrolysis products of U(VI) (ΣU = 1 × 10^{-5} mol dm^{-3}) from Lemire.

and $UO_2(CO_3)_3^{4-}$. Computer calculations that included these carbonate complexes (formed from dissolved atmospheric carbon dioxide) were performed by Lemire at Whiteshell Nuclear Research Establishment and the results are shown in Fig. 3. When the adsorption data are compared with the proportions of major hydrolysis products of U(VI) from Lemire's calculation (see Fig. 3), the agreement is very good, though the proportion of $(UO_2)_2CO_3(OH)_3^-$ begins to increase at a pH value of around 6.

The electrophoretic mobility results (see Fig. 4) show that the mobility of hematite depends on the amount of uranium adsorbed. For pH < 4, only a small amount of non-hydrolyzed UO_2^{2+} is adsorbed, and the electrophoretic mobility does not change significantly. As the pH is increased, a pronounced effect is observed, especially for solutions with higher uranium content. In each case, the isoelectric point tends to shift towards lower pH values. This behaviour is often observed for "specifically adsorbed" ions. As shown in the previous section, the proportion of $(UO_2)_3(OH)_5^+$ increases with pH. Such species contain more than one hydroxyl group per ion, and these hydroxyl groups can become attached to the positively charged hematite surface, lowering the overall surface charge of the particle. In fact, Matijevic and Janauer (13) have advanced the same idea to explain the reversal of charge of silver bromide sol by ferric ions.

One may question whether or not the above phenomenon can be explained by the interfacial precipitation model (14). This model would regard the adsorption as an interfacial precipitation of uranium(VI) oxide, which occurs at a pH lower than the bulk value. A comparison of the electrophoretic mobility data of the oxide with that of uranium-loaded hematite particles

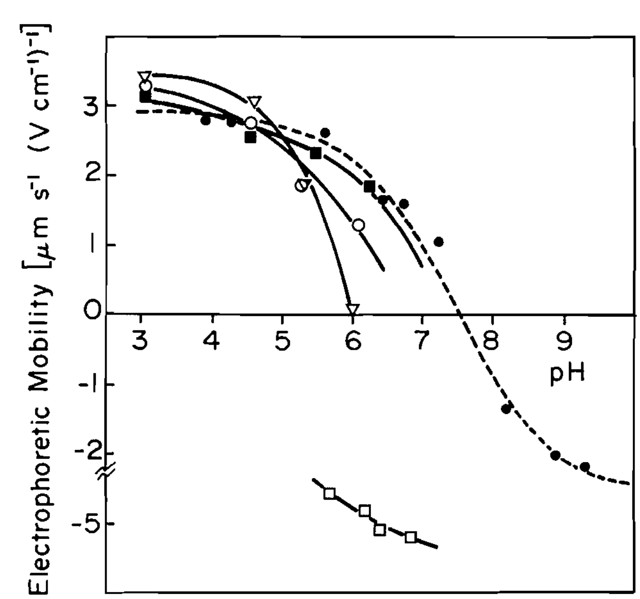

FIG. 4. Electrophoretic mobility of hematite sol in the absence and presence of uranyl species together with the electrophoretic mobility of U(VI) oxide as a function of pH at 25°C in 5 × 10^{-4} mol dm^{-3} NaCl: ∇, ΣU = 5 × 10^{-5} mol dm^{-3}; □, U(VI) oxide; ○, ΣU = 1 × 10^{-5} mol dm^{-3}; ●, hematite; ■, ΣU = 1 × 10^{-6} mol dm^{-3}.

should give some elucidation of the above question. A series of hydrolysis experiments were performed on aqueous UO_2^{2+} ions at slightly higher solution pH. The precipitates obtained were identified by electron diffraction to be U(VI) oxides. The variation of the electrophoretic mobility of the oxide with solution pH, as shown in Fig. 4, does not resemble that of the uranium-loaded hematite, indicating that the oxide is not the species involved in the adsorption.

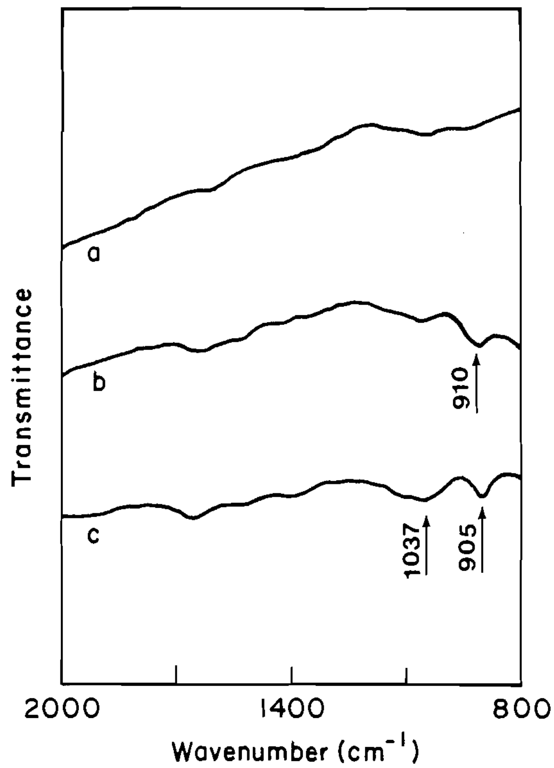

FIG. 5. Infrared spectra of (*a*) hematite,(*b*) hematite loaded with uranium at pH 4.30, and (*c*) hematite loaded with uranium at pH 6.08.

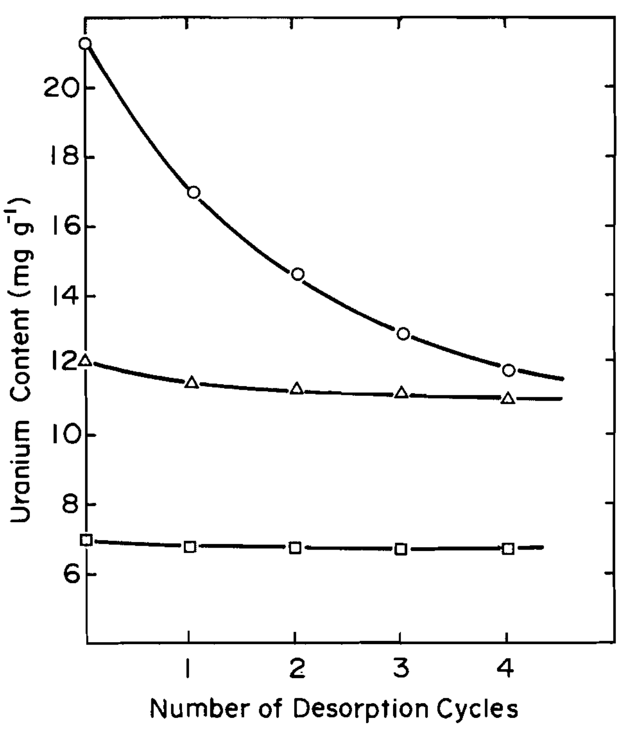

FIG. 6. Desorption of uranyl species from hematite sol as a function of desorption cycle at pH 6.2 in 5 × 10^{-4} mol dm^{-3} NaCl. The amounts of uranium adsorbed onto the hematite before desorption are ○, 21.17 mg g^{-1}; △, 12.10 mg g^{-1}; □, 6.97 mg g^{-1}.

Figure 5 shows the ir spectra (2000 cm^{-1} to 800 cm^{-1} range) of hematite and uranium-loaded hematites for two pH values. No defined bands were detected for hematite (Fig. 5*a*). For uranium-loaded hematites: at pH 4.30, UO_2^{2+} ions are adsorbed

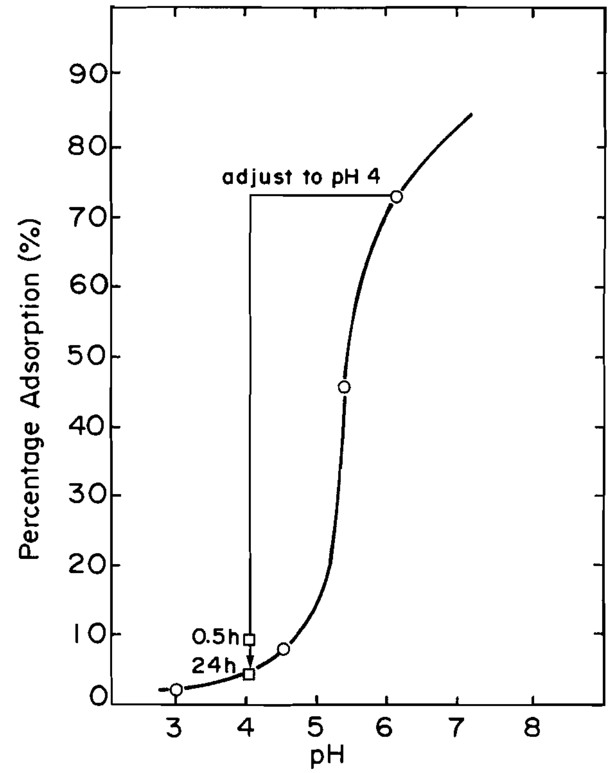

FIG. 7. The desorption of uranyl species from hematite sol.

and the characteristic uranium band appears at 910 cm^{-1} (Fig. 5*b*). The position of this band shifts to 905 cm^{-1} at pH 6.08 (Fig. 5*c*), indicating that the sorption product is different from UO_2^{2+}. From known hydrolysis data, this band can only be accounted for if $(UO_2)_3(OH)_5^+$ is adsorbed. The presence of an absorption band at 1037 cm^{-1} may be due to the hydroxyl groups in $(UO_2)_3(OH)_5^+$. The above results further substantiate our conclusion that $(UO_2)_3(OH)_5^+$ may be the major species involved in the adsorption.

Desorption

Desorption studies were carried out in two ways, using the uranium-loaded hematite particles immediately after the adsorption experiment. The results from successive desorption into water with the same pH and salt concentration as the adsorption solution are shown in Fig. 6. In most cases the adsorbed uranium is retained, even after several desorption cycles. At a pH of about 6.20, the predominant solution species is $(UO_2)_3(OH)_5^+$. It follows that this species may be adsorbed irreversibly. This is consistent with the behaviour of specifically adsorbed cations.

In addition, the amount of uranium desorbed depends on the initial amount of uranium adsorbed (Fig. 6), possibly because of different binding sites on the surface of the hematite. In a recent paper, Benjamin and Leckie (15) have shown that the surface of iron oxyhydroxide has different binding sites (Multiple-site Adsorption Model). The binding strength for cations may vary between sites by more than an order of magnitude. At high adsorption density, some cations are bound to weaker binding sites and these would come off first during desorption, however, at low adsorption density, most cations are bound to stronger binding sites and only a few would come off during desorption.

The effect of pH on the desorption process is shown in Fig. 7. The percentage of uranium adsorbed was plotted as a function of solution pH. After equilibrating the reaction system for 16 h at pH 6.2, the mixture was adjusted to pH 4. The results indicate a fast release of adsorbed uranium over a period of 30 min. Similar results were obtained when the solution pH was lowered to 3. Thus, it seems that the adsorption process is reversible with respect to solution pH. This can be explained if we assume that the added acid could alter the chemical form of the adsorbed species and/or destroy the bonding between the adsorbent and the adsorbate. As has already been mentioned, UO_2^{2+} is the predominant species at pH 4. A change in solution pH (to 4) could reverse the hydrolysis reaction:

$$3UO_2^{2+} + 5\ OH^- \rightarrow (UO_2)_3(OH)_5^+$$

Since the affinity of hematite for UO_2^{2+} is not high, most of the UO_2^{2+} is released from the surface of the oxide.

Cation transport in isomeric pentanes: effects of temperature, density, and molecular shape[1]

ISTVAN GYÖRGY, NORMAN GEE, AND GORDON R. FREEMAN
Chemistry Department, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received May 15, 1984

ISTVAN GYÖRGY, NORMAN GEE, and GORDON R. FREEMAN. Can. J. Chem. **63**, 1105 (1985).

The cation mobility μ_+ is measured in *n*-pentane, *iso*-pentane, *neo*-pentane, and mixtures of *n*- and *neo*-pentane over conditions from the normal liquid, through the critical fluid, to the low density gas. Most of the liquid data correlate with the reduced temperature T/T_c. The T/T_c reflects free volume and viscosity changes. Comparison is made to neutral molecule diffusion. The transition from viscosity control of mobility in the liquid to density control in the dilute gas occurs over the reduced viscosity region $3 > \eta/\eta_c > 0.6$, which corresponds to the reduced density region $1.9 > n/n_c > 0.5$. In the saturated gas $n\mu_+$ is similar in all pentanes, but *iso*- $\geqslant$ *n*- > *neo*-pentane. At constant density $d\mu_+/dT \geq 0$ for gases. The average momentum transfer cross sections in the *n*-/*neo*-pentane mixtures are similar to those in *neo*-pentane at low T but similar to those in *n*-pentane at high T. The present findings are combined with previous electron mobility data in addressing the effect of hydrocarbon molecular (external) shape on the electric breakdown strength of gases.

ISTVAN GYÖRGY, NORMAN GEE et GORDON R. FREEMAN. Can. J. Chem. **63**, 1105 (1985).

On a mesuré la mobilité μ_+ du cation dans le *n*-pentane, l'*iso*-pentane, le *néo*-pentane et dans les mélanges de *n*- et de *néo*-pentane dans des conditions allant du liquide normal, au fluide critique et finalement jusqu'au gaz de faible densité. Pour la plupart des données relatives au liquide, il existe une corrélation avec la température réduite T/T_c. Le rapport T/T_c reflète les variations du volume libre et de la viscosité. On a établi une comparaison avec la diffusion de molécules neutres. La transition, à partir du contrôle viscosimétrique de la mobilité du liquide jusqu'au contrôle de la densité du gaz dilué, se produit dans la région de viscosité réduite $3 > \eta/\eta_c > 0{,}6$ qui correspond à la région de densité réduite $1{,}9 > n/n_c > 0{,}5$. Dans les gas saturés, la valeur de $n\mu_+$ est identique dans tous les pentanes et elle varie suivant: *iso*- $\gtrsim$ *n*- > *néo*-pentane. Pour une densité constante, $d\mu_+/dT \geq 0$ pour les gaz. A basse température, les sections droites moyennes des transferts de moment dans les mélanges de *n*-/*néo*-pentane sont identiques à celles du *néo*-pentane; par ailleurs, à hautes températures, elles sont identiques à celles du *n*-pentane. On combine ces renseignements avec les données obtenues antérieurement sur la mobilité de l'électron pour étudier l'effet de la forme externe de l'hydrocarbure à l'état moléculaire sur la force de rupture électrique des gaz.

[Traduit par le journal]

Introduction

Ion mobilities in low density gases are limited by the gas density n, the molecular polarizability α, and the molecule–ion reduced mass M_r (1, 2). Gas density remains a dominating parameter up to the critical region (3–5). In the liquid phase, ion mobilities are limited by the viscosity η and the ion radius r (6). Stokes' law applies quite well at $\eta/\eta_c \gtrsim 2.5$, where η_c is the viscosity of the critical fluid (4, 5, 7). The transition from density to viscosity control of ion diffusion has previously been investigated in two ways. In argon gas at atmospheric pressure, ions have been clustered with increasing numbers m of water molecules until, with $m \gtrsim 1000$, the ionic radius was large enough, $\gtrsim 1.4$ nm, that Stokes' law applied in the gas phase (8). The other way was to increase the fluid density continuously from that of the low density gas to that of the dense liquid, and measure the change in mobility behavior (4, 5).

The possibility of an additional factor, that of molecular shape, emerges from a comparison of cation mobilities in *n*-hexane and cyclohexane (3*a*), or in benzene and toluene (3*b*), or in propane, propene, and cyclopropane (4). However, changes in polarizability might have complicated an apparent shape effect. In the present article, cation mobilities are reported for the isomeric series *n*-, *iso*-, and *neo*-pentane, and in mixtures of *n*- and *neo*-pentane, for which α is constant (9). The density was varied from the dilute gas through the critical region to the dense liquid.

Experimental

A. Materials

The pentanes were Phillips Research Grade. Further purification of the samples was effected in a grease-free vacuum line. After degassing, each pentane was stirred on sulfuric acid (>72 h), distilled onto potassium hydroxide pellets and stirred (>24 h), distilled onto a nearly equal volume of Davison Molecular Sieves 5A (>24 h), and finally distilled onto sodium–potassium alloy and stirred (>72 h). The acid removed traces of olefin, the hydroxide removed carbon dioxide and residual traces of sulfuric acid, the molecular sieves removed water, and the alloy removed residual traces of oxygen. The pentane was degassed by several freeze–pump–thaw cycles between each distillation. Prior to filling a cell, the liquid was subjected to a final distillation, transferred to a measuring burette, and the amount required to attain the critical fluid density at $T > T_c$ was distilled into the cell reservoir at 77 K. The cell was sealed with a flame after the cell pressure had been reduced to $<10^{-5}$ Pa.

B. Cells

The conductance cells had ~11 mm thick glass walls (10). Liquid phase measurements were performed in a cell in which the parallel plates were immersed in the liquid (10*a*) and gas phase in a cell in which the plates were above the liquid (10*b*). The cells were cut open at the end of the series of experiments, and the plate separations were measured with Do All models M-1 Minus measuring rods. The cell for the liquid phase had a drift distance of 3.10 mm; in the gas cell it was 3.20 mm.

C. Techniques

The samples were irradiated by 1 μs pulses of 1.7 MeV X-rays from a Van de Graaff generator. The electron drift times were <1% of those of the ions. The transient current was amplified with a Princeton Applied Research 113 preamplifier, integrated and stored in a Fabritek 1062 signal averager (4). The average of 16 or 32 signals was used to measure the ion drift time t_d (typically 10 to 1000 ms). The mobility is given by $\mu = l^2/t_d V$, where l is the drift distance and V the applied voltage. Voltages up to 6 kV were obtained from a Fluke 408B High Voltage Power Supply, and >6 kV from a Spellman High Voltage DC Supply.

The temperature was varied by heating the cell in a thermostated hot

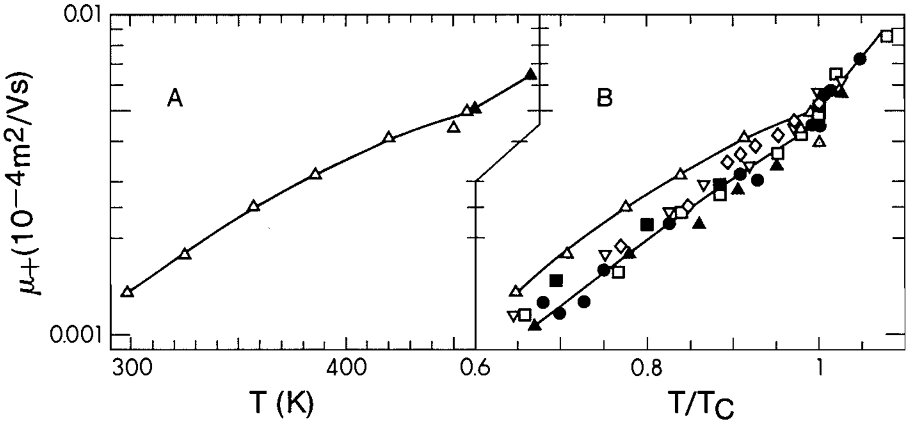

FIG. 1. Cation mobilities as functions of temperature (A) and reduced temperature (B) in the liquid and supercritical gas phases. A: *iso*-pentane, liquid under its vapor pressure (△), and gas at n_c (▲); B; *n*-pentane (■), *iso*-pentane (△), *neo*-pentane (●); *n*-pentane/*neo*-pentane mixtures containing 10 (◇), 25 (▲), 50 (□), and 75 (▽) mol% *n*-pentane.

air bath (10*a*). The cell temperature was monitored near the electrodes and at the end of the cell farthest from the electrode, by copper–constantan thermocouples (Thermo-electric Canada Ltd.). A third thermocouple in the bath was connected to the LFE Corp. Model 226-A21 temperature controller, which varied the current supplied to the heating coil of the Master Appliance Model AH-751 heat gun.

D. Physical properties

The critical constants and physical properties were obtained from refs. 11 and 12. No data were available for the mixtures; they were assumed to be ideal (13). The evaporation points and critical temperatures were visually monitored and no deviation from ideality was observed (13).

Viscosity data are available for *n*-pentane over a large range including the critical region (12, 14); the value of η_c is 26.7 μPa s. Data for *neo*-pentane are more sparse (15, 16); no critical region data were found. Data for liquid *iso*-pentane exist only for $T \leq 293$ K (17).

Results

A. Liquid phase

Data for the co-existence liquid and the supercritical gas of *iso*-pentane are plotted in Fig. 1*A*. The mobility μ_+ increases approximately as the exponential of the temperature. Such is also the case for *n*-pentane, *neo*-pentane, and mixtures of *n*-pentane/*neo*-pentane. Further, most of the differences between μ_+ in *n*-pentane, *neo*-pentane, and their mixtures disappear in a corresponding states plot (Fig. 1*B*).

B. Gas phase

Mobilities in *n*-pentane and *neo*-pentane gases are shown in Fig. 2, and those in *iso*-pentane and *n*-pentane/*neo*-pentane mixtures in Fig. 3. In each case μ_+ decreases along the co-existence curve as T increases, due to the concomitant increase of density n. However, at constant n the mobility is constant or increases with T. The relative increase is greater for a greater n.

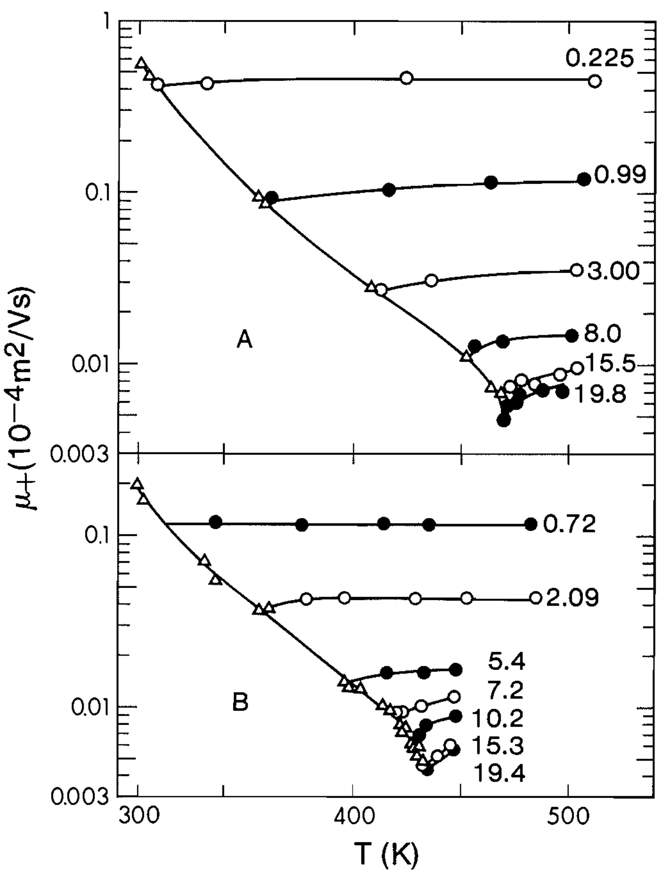

FIG. 2. Cation mobilities in the gas phase. △, coexistence vapor; circles, constant density n (10^{26} molecule/m^3). A: *n*-pentane; B: *neo*-pentane.

Discussion

A. Gas phase

1. Low density nonsaturated gas

At low gas densities, $d\mu/dT$ is near zero in all the pentane isomers and in the *n*-pentane/*neo*-pentane mixtures (Figs. 2 and 3). This is like the cation behavior in *n*-hexane (3*a*), benzene and toluene (3*b*) at $n \leq 3 \times 10^{25}$ molecules/m^3. In contrast, $d\mu/dT$ in cyclopentane and cyclohexane (3*a*) at $n \lesssim 5 \times 10^{25}$ molecules/m^3, or in the C_1–C_4 alkanes and alkenes at $\gtrsim 7 \times 10^{25}$ molecules/m^3 (4), is appreciably greater than zero, especially near the liquid–vapor co-existence curve. The value $d\mu/dT = 0$ implies that scattering is dominated by the long range attractive polarization potential (2). Combination of the Nernst–Einstein relation with the Chapman–Enskog diffusion expression gives (2)

$$[1] \quad n\mu_+ = \frac{3e\sqrt{\pi}}{8M_r}\left(\frac{2kT}{M_r}\right)^{5/2} \bigg/ \int_0^\infty v^5\sigma_m \exp\left(-M_r v^2/2kT\right) dv$$

where M_r is the ion–molecule reduced mass, v the relative velocity, k Boltzmann's constant, e the electronic charge, and σ_m the momentum transfer cross section. In terms of an average

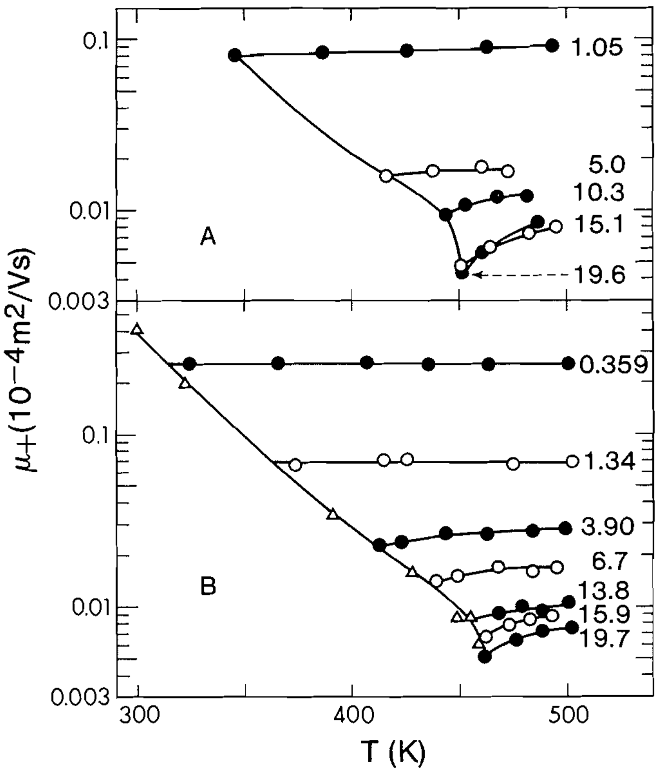

FIG. 3. Cation mobilities in the gas phase. Symbols as in Fig. 2. *A*: 50/50, *n*-pentane/*neo*-pentane; *B*: *iso*-pentane.

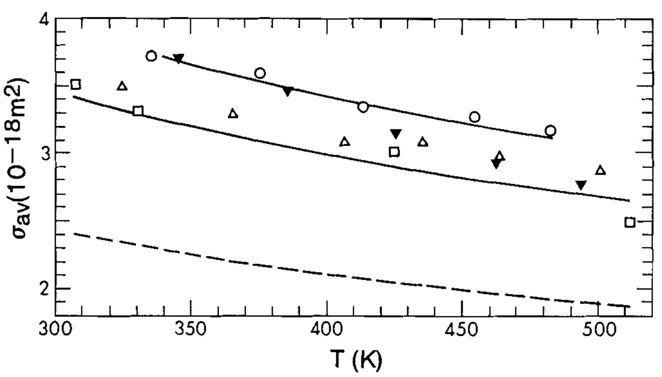

FIG. 4. Average scattering cross sections σ_{av} for cations in *neo*-pentane (○), *iso*-pentane (△), *n*-pentane (□), and 50 mol% *n*-pentane/*neo*-pentane mixture (▼), as functions of T. The values were calculated from eq. [4], using μ in the lowest constant density gases of Figs. 2 and 3, and assuming $M_r = M$. The solid lines serve as visual guides to the *neo*-pentane and *n*-pentane data. The dashed line indicates the polarization limit.

cross section σ_{av} (4*a*),

$$[2] \quad \sigma_{av} = \langle v^3\sigma_m\rangle/\langle v^3\rangle$$

$$[3] \quad = \left(\frac{3}{4}\right)\left(\frac{e}{M_r}\right)\frac{1}{\langle v\rangle n\mu_+}$$

with $\langle v\rangle = (8kT/\pi M_r)^{1/2}$, so that

$$[4] \quad \sigma_{av} = \frac{3}{8}\, e\left(\frac{\pi}{2M_rkT}\right)^{1/2}\frac{1}{n\mu_+}$$

For unclustered ions and molecules, M_r equals $M/2$, where M is the molecular mass. The radiolyses of *neo*-pentane (18) and *n*-pentane (19) initially generate C_1–C_5 cations. However, the smaller cations react rapidly with parent gas molecules, mainly by hydride transfer, so that the ions drifting in the cell would be C_5-cations (18, 19), probably clustered by molecules (4). For heavily clustered ions, M_r equals M. The latter was assumed in calculating the average cross sections in Fig. 4. The cross sections are largest for cations in *neo*-pentane and smallest for cations in *n*-pentane; the *iso*-pentane results are intermediate. The solid lines indicate the results for *neo*-pentane and for *n*-pentane if $d\mu/dT$ were zero. The cation cross sections in the *n*-pentane/*neo*-pentane mixture are similar to *neo*-pentane values at low temperatures, but decrease towards *n*-pentane values as T increases. The dashed line represents the polarization limit (2) for scattering by a molecule of average polarizability $\alpha = 10 \times 10^{-30}$ m^3, which is the value for each pentane (9). The line was obtained by calculating the Langevin small ion mobility (2) and combination of that with eq. [4]. All the pentane cross sections are larger than the polarization limit.

2. *Saturated gas*

As the gas density is increased along the vapor–liquid coexistence curve, the behavior is dominated by the fluid density (3–5). The product $n\mu_+$ varies by only ~25% on going from the low density gas to the critical fluid (Fig. 5). It passes through a shallow minimum at $n \approx 4 \times 10^{26}$ molecules/m^3, or $n/n_c \approx 0.2$. Data for ions in *iso*-pentane are shown in Fig. 5*A* to illustrate the behavior. Data for the three pentane isomers are given in Fig. 5*B* to permit comparison. The general behavior is similar for the three isomers, but the values of $n\mu_+$ are in the order *iso* $\gtrsim$ *n* $>$ *neo*. The slightly lower values in *neo*-pentane, which lacks flexibility in the molecular structure, suggests that molecular rigidity tends to increase the extent of clustering of molecules about the ion.

The increase of $n\mu_+$ at $n > 0.5n_c$ is attributed to the destructive interference of the multimolecular scattering interactions (5). At $n \gtrsim 1.9n_c$ the value of $n\mu_+$ decreases due to the restriction of motion by the reduction of free volume.

Similar behavior has been observed for ions in other liquids (3–5). The transition from normal gas phase behavior (density control) to normal liquid phase behavior (viscosity control) occurs in the region $0.5 \lesssim n/n_c \lesssim 1.9$.

B. *Liquid phase*

1. *Arguments against Arrhenius plots*

Traditionally, discussions of liquid phase diffusion coefficients (20–24) or ion mobilities (3) center around Arrhenius plots and the associated activation energies. Such procedures are unnecessary (25). Transport properties are describable in terms of temperature and density without emphasizing energy barriers or activation (26). Diffusion involves repeated small displacements, each much smaller than the diameter of a fluid molecule. The temperature has a small role but the dominant factor is the free volume ($V - V_0$), where V_0 is the lower limit of the volume V where the molecules are too crowded to permit diffusion or bulk flow (25–31).

The dispensibility of Arrhenius plots can be illustrated using the self diffusion coefficient D in liquid *n*-pentane. The data are presented in Fig. 6*A*, as in the original work (20). While the linear approximation (dashed line) is fair, plotting log D versus T (Fig. 6*B*) results in nearly as straight a line. The closest fit in either case is attained by a curve (solid line).

Values of log D in liquid *iso*-pentane and *neo*-pentane plotted against T likewise result in nearly straight lines (Fig. 6*B*). *Neo*-pentane data at $T > 299$ K of ref. 22 were abnormally high due to possible bubbling effects (23) and were not used. In a

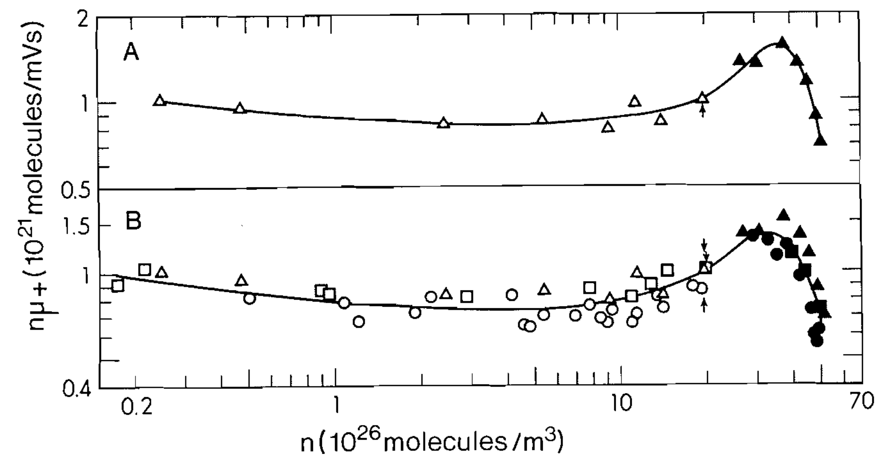

FIG. 5. Density dependence of $n\mu_+$ in the coexistence vapor and liquid of *iso*-pentane (△, ▲), *n*-pentane (□, ■), and *neo*-pentane (○, ●). Open symbols, vapor; closed symbols, liquid. The arrows indicate n_c.

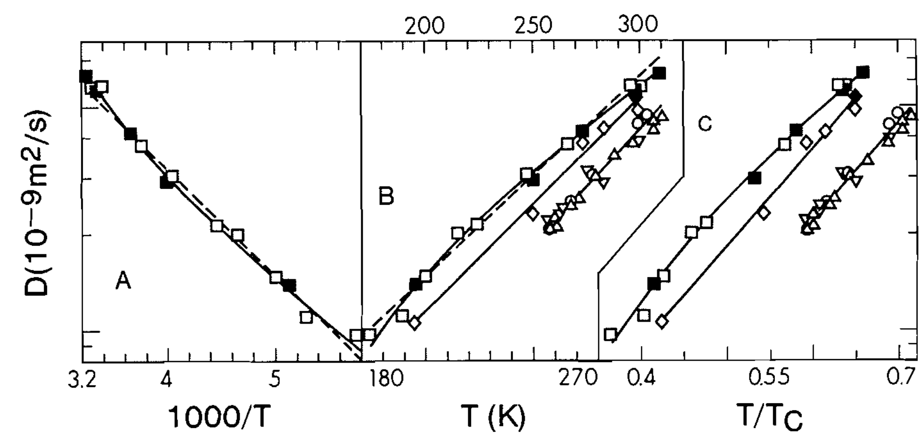

FIG. 6. Plot of log D versus: A, $1000/T$; B, T; C, T/T_c, where T_c is 433.8 K for *neo*-pentane, 460.4 K for *iso*-pentane, and 469.7 K for *n*-pentane. The liquids are (symbols, reference): *n*-pentane (□, 20), (■, 21); *iso*-pentane (◇, 21), (◆, 20*b*); *neo*-pentane (▽, 22), (△, 23), (○, 24).

corresponding states plot (Fig. 6*C*) the order remains *n*-pentane > *iso*-pentane > *neo*-pentane, unlike ion mobility where *iso*- > *n*- ≳ *neo*-pentane.

The log D versus T behavior largely reflects changes in $(V - V_0)$. The self-diffusion constant can be related to $(V - V_0)/V_0$, $T^{1/2}$, $M^{1/2}$, and the collision diameter (25, 28). If V_0 and the collision diameter are approximately constant, $D \propto T^{1/2}\,(V - V_0)/V_0$. For *n*-pentane a plot of D against $T^{1/2}\,(V - V_0)/V_0$ is slightly curved (Fig. 7). The curvature may be due to temperature dependence of V_0 or of the collision diameter (28).

In summary, a log D or log μ_+ versus T plot is preferred to an Arrhenius plot. The presentation of experimental data is more direct, and the attribution of the free volume effect to a hypothetical activation barrier is avoided. Therefore in this work log μ_+ versus T plots are used.

2. Possible molecular shape effect

Earlier studies (20–22), noted that at a given T/T_c, D is larger for the flexible molecules *n*-pentane than for the more rigid *neo*-pentane. The *iso*-pentane results are intermediate. These and related viscosity data (12, 14–17) lead to conjectures about the role of molecular shape (15, 21). The value of V/V_c is expected to be similar for the isomers at a given T/T_c. The values of V_c of the pentane isomers differ by only 2%, so each V should be similar at a given T/T_c. The diffusion data (Fig. 6*C*) then indicate that translation of a more rigid, sphere-like molecule at a given V is hindered with respect to the motion of a more flexible, chainlike molecule in accordance with theoretical expectation (32).

The ion mobility values in like manner are lower in the more rigid, sphere-like *neo*-pentane than in the more flexible *iso*-pentane at a given $T/T_c < 0.9$ (Fig. 1*B*). However, the values in *n*-pentane and in the *n*-pentane/*neo*-pentane mixtures are similar to those in *neo*-pentane, and they are lower than those in *iso*-pentane. At $T/T_c > 0.9$, the data for all liquids merge together. In contrast to neutral molecule diffusion, there is no clear shape effect for the motion of ions. The difference may lie in the effect of the charge on the local environment of the ion (32), and in the structures of the ions themselves.

3. Effect of viscosity

To connect the ion mobility to a physical property of the fluid, the mobility of ions in liquids has long been correlated with the viscosity η (6, 33–35). Values of $\eta\mu_+$ are presented in Fig. 8. The behavior is similar for each of the isomers wherever they can be compared. At $\eta > 100$ μPa s, $\eta\mu_+$ is constant. Using Stokes' law, the radius of the diffusing particle is

$$[5] \quad r = e/C\eta\mu_+$$
$$= 1.6 \times 10^{-19}/C\eta\mu_+, \text{ m}$$

where $\eta\mu_+$ is in kg m/V s^2 and the constant C is 6π for ions

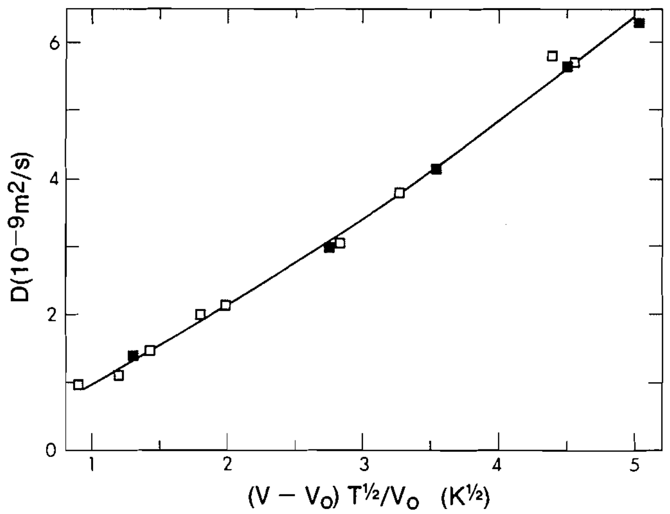

FIG. 7. Plot of D versus $(V - V_0)T^{1/2}/V_0$, where V_0 is 153×10^{-30} m^3/molecule (25*a*). Liquid symbols as Fig. 6.

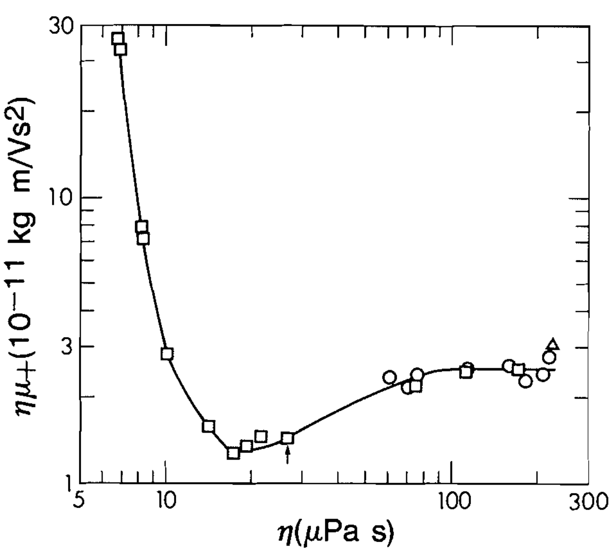

FIG. 8. Viscosity dependence of $\eta\mu_+$ in coexistence vapor and liquid *n*-pentane (□), *iso*-pentane (△) and *neo*-pentane (○). The arrow indicates η_c for *n*-pentane.

(stick condition). A radius of 3.3×10^{-10} m is inferred at $\eta >$ 100 μPa s in *n*- and *neo*-pentane, and of 2.8×10^{-10} m in *iso*-pentane. For a range of neutral molecules, C is near 4π (36). Assumption of 4π (slip condition) in eq. [5] in combination with the Nernst–Einstein relation gives radii in 10^{-10} m of 2.5 (*n*-pentane), 2.8 (*iso*-pentane), and 3.8 (*neo*-pentane) from D and η at 298 K. The ion and molecule radii are similar in size.

The decrease at $\eta < 80$ μPa s indicates breakdown of viscosity control and gives a limit $\eta/\eta_c \sim 3$ for normal liquid ion behavior. The $\eta\mu_+$ decreases through the critical region (arrow) to a minimum at $\eta \sim 18$ μPa s ($\eta/\eta_c \sim 0.7$) and increases at yet lower viscosity. The decrease as the critical region is approached has been ascribed to electrostriction exerting a greater effect as the compressibility of the fluid increases (4, 5, 7). The increase at $\eta < 16$ μPa s, $\eta/\eta_c < 0.6$, indicates the transition towards density control ($n\mu_+ \sim$ constant) and corresponds to $n/n_c < 0.5$ (Fig. 5). The transition region between density and viscosity control of ion transport in the pentanes is thus $0.5 \lesssim n/n_c \lesssim 1.9$, or equivalently $0.6 \lesssim \eta/\eta_c \lesssim 3$.

C. Application to dielectric breakdown strength

The present ion mobilities are reflected in the relative breakdown strength of pentane isomers. In an investigation of the breakdown strength of hydrocarbon gases, a structure dependence was observed but discounted (37). Chain branching increases the strength (*iso*- relative to *n*-butane; *neo*-relative to *iso*- and *n*-pentane). Hemispherical electrodes were used. In breakdown from a positive tip the electron mobility does not seem to be important; the initiation current depends on the cations (38–41). On the other hand, breakdown from a negative point is dependent upon the electron mobility. The present work indicates that at a given density the cation mobility is similar in all pentanes (Fig. 5). However, the slight differences are in the order indicated by the breakdown strength (37). In *n*-butane and *iso*-butane the cation mobilities are also similar (4). Further, the electron mobility depends on the physical shape of the molecules (12, 42) and is lower for a gas of more branched, more sphere-like molecules. Although the electrons are "hot" at the fields required for breakdown, a brief comparison of thermal electron mobilities indicates the tendencies. At a given low gas density, μ_e in *n*-butane is twice of that in *iso*-butane (42). For the pentanes, μ_e in *n*-pentane is 1.3 times that in *iso*-pentane and 3 times that in *neo*-pentane. The trends in the observed cation mobilities and the effect of increased sphericity on the electron mobility combine to confirm that dielectric breakdown strength is greater in gases of more branched, more sphere-like hydrocarbon molecules (37).

Magnetic concentration and polymorphism in di-n-octyl-, di-n-decyl-, and di-n-dodecylphosphinates of copper(II)

JOHN S. HAYNES, KATHERINE W. OLIVER, AND ROBERT C. THOMPSON
Department of Chemistry, University of British Columbia, 2036 Main Mall, Vancouver, B.C., Canada V6T 1Y6

Received September 27, 1984

JOHN S. HAYNES, KATHERINE W. OLIVER, and ROBERT C. THOMPSON. Can. J. Chem. **63**, 1111 (1985).

Phosphinates of copper(II) of the type $Cu(R_2PO_2)_2$ where R is n-octyl, n-decyl, and n-dodecyl have been synthesized and characterized by differential scanning calorimetry, vibrational and electronic spectroscopy, and variable temperature (300 to 4.2 K) magnetic susceptibility studies. Each of these compounds was obtained in distinct α and β structural forms. All materials appear to have the double phosphinate bridged extended chain structure and the magnetic data have been successfully analyzed according to the isotropic Heisenberg model for linear chains. The α forms exhibit antiferromagnetic behaviour with J values of -25, -29, and -29 cm^{-1} for the octyl, decyl, and dodecyl derivatives respectively. The β forms are ferromagnetic and have corresponding J values of 1.8, 2.1, and 2.3 cm^{-1} respectively. Magneto-structural correlations in these extended chain coordination polymers are discussed.

JOHN S. HAYNES, KATHERINE W. OLIVER et ROBERT C. THOMPSON. Can. J. Chem. **63**, 1111 (1985).

On a synthétisé des phosphinates de cuivre(II) du type $Cu(R_2PO_2)_2$ où R = n-octyle, n-décyle, et n-dodécyle et on les a caractérisés en faisant appel à la calorimétrie à balayage différentiel, aux spectroscopies vibrationnelle et électronique et à des études de susceptibilité magnétique à température variable (de 300 à 4,2 K). On a obtenu chacun de ces composés sous les deux formes structurales α et β. Tous les composés semblent avoir une structure en chaîne allongée avec deux ponts phosphinates. On a analysé avec succès les données magnétiques selon le modèle isotrope de Heisenberg pour les chaînes linéaires. Les formes α ont un comportement antiferromagnétique avec des valeurs de J de -25, -29 et -29 cm^{-1} respectivement pour les dérivés octyle, décyle et dodécyle. Les formes β sont ferromagnétiques et les valeurs correspondantes de J sont respectivement de 1,8, 2,1 et 2,3 cm^{-1}. On discute des corrélations magnéto-structurales dans ces chaînes allongées de polymères de coordination.

[Traduit par le journal]

Introduction

The diethyl-, di-n-butyl-, and di-n-hexylphosphinates of copper(II), $Cu(R_2PO_2)_2$, have been shown to be chain polymers with structures consisting of copper atoms with flattened tetrahedral coordination geometry (D_{2d} local symmetry) linked by double phosphinate bridges (1–3). Such structures provide the possibility of pathways for magnetic exchange; weak antiferromagnetic exchange was observed in the ethyl derivative while both the butyl and hexyl compounds showed ferromagnetic exchange (3). This dependence of the sign of the magnetic exchange on the type of alkyl group attached to phosphorus prompted the present extension of our studies to include phosphinates with longer chain alkyl groups. We were also encouraged in this particular direction by earlier observations of polymorphism in metal phosphinates (4–6) with the possibility that different forms of the same material might exhibit different magnetic properties.

We report here the synthesis and study of n-alkyl phosphinates $Cu(R_2PO_2)_2$, where R = n-C_8H_{17}, n-$C_{10}H_{21}$, and n-$C_{12}H_{25}$. Each of these may be obtained in a high melting (mp 120–130°C) α form from solution and a low melting (mp 90–100°C) β form from the melt. Each form shows distinct magnetic properties. Infrared, near-infrared, and visible spectra have been used to investigate structural similarities and differences in these materials, none of which can be obtained in crystalline form suitable for single crystal X-ray diffraction studies. The polymorphism exhibited by these compounds has been examined using differential scanning calorimetry (DSC).

Experimental

Synthesis of the phosphinic acids, di-n-octylphosphinic acid, (n-C_8H_{17})$_2PO_2H$

The phosphinic acids were synthesized by the peroxide catalyzed reaction between the appropriate 1-alkene and hypophosphorus acid (7). Di-n-octylphosphinic acid was prepared following the procedure of Peppard *et al.* (8), except that the quantities of the reactants used were reduced by one half, and recrystallization from acetone was required to remove a coating of light yellow oil from the crude product; mp 82–83.5°C (lit. (9) mp 85°C). *Anal.* calcd. for $C_{16}H_{35}PO_2$: C 66.17, H 12.15; found: C 66.34, H 12.09.

The n-decyl and n-dodecyl derivatives were prepared in a manner similar to the n-octyl compound; however, it was found that the procedure outlined (8) for the removal of the monosubstituted acid ((C_8H_{17})(H)(PO_2H) in the n-octyl case (by conversion to the sodium salt and subsequent extraction into aqueous sodium hydroxide) was not applicable to the ten- and twelve-carbon chain compounds. In the synthesis of these compounds the monosubstituted acids appeared to be the major products, despite attempts to promote the formation of the disubstituted derivatives by increasing the mole ratio of benzoyl peroxide to hypophosphorus acid (from 0.05:1.0 to 0.13:1.0) and by adding the peroxide in 4 portions over 9 h. However, the monosubstituted acids occurred as one component of an oil, which was easily removed from the solid disubstituted compounds by washing with cold ethanol or acetone, as described below.

Di-n-decylphosphinic acid, (n-$C_{10}H_{21}$)$_2PO_2H$

A mixture of 1-decene (0.50 mol), aqueous hypophosphorus acid (0.24 mol), water (24 mL), ethanol (170 mL), and benzoyl peroxide (a total of 28 mmol, one third being added in 3 portions, at 3-h intervals), contained in a round-bottomed flask, was refluxed for 26 h. When cooled, the mixture separated into two layers with a white solid in the top (organic) layer. The solution was extracted with 300 mL of benzene, after acidification with hydrochloric acid (500 mL of 1.0 *M* HCl). The benzene layer was scrubbed with two 125-mL portions of 1.0 *M* HCl, isolated, and evaporated, yielding a mixture of a white solid and an oil, which was removed by washing with cold ethanol. Recrystallization of the solid from benzene gave the desired di-n-decylphosphinic acid in 14% yield; mp 85.6°C (lit.(10) mp 87–88°C, (7) mp 87.7–88.3°C). *Anal.* calcd. for $C_{20}H_{43}PO_2$: C 69.32, H 12.51; found: C 69.07, H 12.70.

Di-n-dodecylphosphinic acid, (n-$C_{12}H_{25}$)$_2PO_2H$

After refluxing a mixture of 1-dodecene (0.29 mol), aqueous hypophosphorus acid (0.14 mol), water (10 mL), ethanol (45 mL), and benzoyl peroxide (16 mmol, added as described above for the n-decyl compound) for 24 h, the two-phase mixture was poured into 1.0 *M* HCl (250 mL) and thoroughly stirred. A total of 300 mL of benzene was needed to dissolve all the white solid that was present in the organic phase. This benzene was separated and the aqueous phase was extracted with a further 150 mL of benzene. The combined benzene layers were evaporated to a mixture of a solid and an oil, which was removed by washing with cold acetone. The crude acid was dissolved in chloroform and reprecipitated by the addition of acetone to yield di-n-dodecylphosphinic acid in 25% yield; mp 93.5°C (lit. (7) mp 93.8–94.8°C). *Anal.* calcd. for $C_{24}H_{51}PO_2$: C 71.59, H 12.77; found: C 71.54, H 12.75.

Synthesis of the copper(II) phosphinate α *forms*

A problem routinely encountered in the synthesis of the copper(II) phosphinate compounds under discussion was the formation of copolymers containing both the phosphinate ligand and the anion of the copper-containing starting material (usually the sulfate anion). It was found generally that dilution of the partially neutralized acid solution and (or) the reaction mixture with water prevented the copolymerization from occurring.

α-Poly-bis(μ-di-n-octylphosphinato)copper(II),
α-Cu[(n-C$_8$H$_{17}$)$_2$PO$_2$]$_2$

This compound was prepared in a manner analogous to that used by Gillman (4); however, dilution with water was needed to prevent the formation of the copolymer.

A solution of di-n-octylphosphinic acid (22 mmol) in methanol (500 mL) was partially neutralized (pH 6) with aqueous sodium hydroxide, then added dropwise with stirring to a solution of copper(II) sulfate pentahydrate (11 mmol) in 60% aqueous methanol (185 mL). Precipitation of a bright blue solid began immediately, and when the addition was complete, water (400 mL) was added and the mixture was stirred for 2 h. The solid was removed by filtration, washed with methanol, water, and, finally, methanol, and air dried. Yield: 98%. *Anal.* calcd. for $CuC_{32}H_{68}P_2O_4$: Cu 9.89, C 59.83, H 10.67; found: Cu 9.87, C 60.04, H 10.73.

α-Poly-bis(μ-di-n-decylphosphinato)copper(II),
α-Cu[(n-C$_{10}$H$_{21}$)$_2$PO$_2$]$_2$

This compound was prepared by essentially the same method as that previously reported for the n-hexyl derivative (3), although addition of water to the ethanolic acid solution, prior to the addition of the copper(II) solution, was required to prevent the formation of the copolymer in this case.

Di-n-decylphosphinic acid (9 mmol), dissolved in ethanol (500 mL), was partially neutralized with aqueous sodium hydroxide (8 mmol in 90 mL water). After filtration, water was added until the solution became cloudy (this cloudiness was, presumably, the water insoluble phosphinic acid, and was dispelled by the addition of a small volume of ethanol), giving a total volume of ca. 1 L. Copper(II) sulfate pentahydrate (4 mmol in 60 mL water) was added dropwise, with stirring, resulting in the precipitation of a bright blue solid. When the addition of the copper was complete, the reaction mixture was stirred for 1.5 h, after which the solid was removed by filtration, washed with ethanol, water, and, finally, ethanol, and air dried. Yield: 93%. *Anal.* calcd. for $CuC_{40}H_{84}P_2O_4$: Cu 8.42, C 63.87, H 11.22; found: Cu 8.33, C 63.84, H 11.12.

α-Poly-bis(μ-di-n-dodecylphosphinato)copper(II),
α-Cu[(n-C$_{12}$H$_{25}$)$_2$PO$_2$]$_2$

The preparation of two samples of the dodecyl compound, one the pure α form, and the other a mixture of the α and β forms (labelled α′), is described here. Whether some β isomer is formed in the synthesis of the α form appears to depend on the rate of formation of the product, which, in turn, depends on the concentrations of the reacting solutions, specifically, that of the phosphinic acid. Hence the α′ sample was obtained with rapid polymer formation from concentrated solutions. It is of note that Drinkard and Kosolapoff (10) appear to have formed the purely β-form of the copper n-decyl compound (on the basis of the melting point, 94°C (10) versus 92°C reported here), from a very concentrated aqueous solution of the phosphinic acid. The pure α-Cu[(n-C$_{12}$H$_{25}$)$_2$PO$_2$]$_2$ was synthesized in a manner analogous to that used to obtain the n-decyl derivative, with the exception that the solutions were more dilute.

Di-n-dodecylphosphinic acid (2.5 mmol), dissolved in ethanol (900 mL), was partially neutralized with sodium hydroxide (2.4 mmol in 75 mL water), and, after filtration, an additional 400 mL of water was added. Dropwise addition of aqueous copper(II) sulfate pentahydrate (1.2 mmol in 100 mL water) resulted in the precipitation of a very fine, blue solid. When the addition of Cu(II) was complete, a further 300 mL of water was added and the reaction mixture was stirred for 1.5 h. The solid was separated by filtration, washed with ethanol, and air dried. Yield 80%. *Anal.* calcd. for $CuC_{48}H_{100}P_2O_4$: Cu 7.33, C 66.51, H 11.63; found: Cu 7.28, C 66.40, H 11.43.

The α′-Cu[(n-C$_{12}$H$_{25}$)$_2$PO$_2$]$_2$ sample was prepared by the same method as described above for the pure α form; however, the partially neutralized phosphinic acid solution was much more concentrated (8 mmol in 1200 mL versus 2.5 mmol in ca. 1500 mL), and no water was added to the reaction mixture after the addition of the Cu(II) was complete. Yield 98%. *Anal.* found: Cu 7.37, C 66.51, H 11.70.

Synthesis of the copper(II) phosphinate β *forms*

The β isomers were obtained from the melt of samples of the analytically pure α forms. (Dissolution in, and subsequent evaporation of, an organic solvent such as chloroform also produces the β isomers.) In a typical conversion, the compound (ca. 1 g) was placed in a 100-mL Kjeldahl flask and melted in an oil bath at a temperature just above the appropriate melting point (given below). When judged, visually, to be completely melted, the sample was removed from the oil bath and allowed to freeze completely. It was then remelted and recooled, the process being repeated at least three times to ensure complete conversion of the α form to the β.

Experimental techniques

Infrared spectra were obtained on a Perkin–Elmer model 598 spectrophotometer. Samples were mulled in Nujol and pressed between KRS-5 plates (Harshaw Chemical Co.). Electronic spectra (from 3,800 to 30 000 cm^{-1}) were obtained on Nujol mulls using a Cary 14 spectrophotometer.

Magnetic susceptibilities over the range 125–4.2 K were measured using a P.A.R. Model 155 vibrating sample magnetometer and over the range 80–300 K using a Gouy balance. This equipment was described in detail earlier (3). Magnetic susceptibilities were corrected for the diamagnetism of all atoms. These corrections were (in 10^{-6} cm^3 mol^{-1}): copper, −11; $(n\text{-}C_8H_{17})_2PO_2^-$, −210; $(n\text{-}C_{10}H_{21})_2PO_2^-$, −257; $(n\text{-}C_{12}H_{25})_2PO_2^-$, −300. A value of 60×10^{-6} cm^3 mol^{-1} was used to correct for the temperature independent paramagnetism of copper(II).

Differential scanning calorimetry measurements were obtained with a Mettler DSC 20 Standard Cell, a Mettler TC10 TA Processor, and a Print Swiss Matrix RO-80 printer/plotter. Powered samples (2–4 mg) were sealed in standard aluminum pans (40 μL). Two small holes punched in the lid allowed for free access to the measuring cell atmosphere, in this case, air. The heating rate was 4°C/min. The temperature was calibrated from 25–600°C with standard indium, zinc, and lead samples. Heat flow calibration was achieved using carefully weighed samples of indium.

Carbon and hydrogen microanalyses were obtained by P. Borda of

[b] T_d represents the temperature at which oxidative decomposition begins.
[c] Sharp, broad, and doublet refer to the shape of the DSC curve; sh., shoulder, temp., temperature.

the Department of Chemistry, The University of British Columbia. Copper was determined by EDTA titration.

Solubilities

Qualitative solubility tests show β-$Cu[(n\text{-}C_8H_{17})_2PO_2]_2$ to be soluble (in excess of 0.1 g in 100 mL) in chloroform and slightly soluble in dichloromethane, carbon tetrachloride, and benzene. β-$Cu[(n\text{-}C_{10}H_{21})_2PO_2]_2$ is soluble in chloroform, slightly soluble in carbon tetrachloride, and insoluble in dichloromethane and benzene. The α forms of the above are slightly soluble in the chlorinated solvents and insoluble in benzene. Both α and β forms of $Cu[(n\text{-}C_{12}H_{25})_2PO_2]_2$ are slightly soluble in chloroform and dichloromethane and insoluble in carbon tetrachloride and benzene. All six of these compounds were found to be insoluble in petroleum ether, water, methanol, ethanol, and acetone.

Results and discussion

Syntheses, thermal properties, and solubilities

Reaction of a partially neutralized solution of di-n-octylphosphinic acid in methanol with an aqueous methanol solution of copper(II) sulfate pentahydrate gave a quantitative yield of α-$Cu[(n\text{-}C_8H_{17})_2PO_2]_2$. This material was first prepared, by a very similar method, by Gillman, who labelled it form I (4). Our observed melting point of 123.8°C and ΔH of 63 kJ mol^{-1} (Table 1) are in good agreement with the values obtained by Gillman. We found that remelting of the sample occurred at 89.4°C compared to Gillman's 81°C. The heat of fusion in this case also differs somewhat from that reported earlier. This second form, which we have labelled β-$Cu[(n\text{-}C_8H_{17})_2PO_2]_2$, is easily prepared in bulk by the repeated heating and cooling (135°C to room temperature) of a sample of the α form. We believe that this thermal cycling ensures complete conversion to the β form. This was not done in the earlier work and probably accounts for the differences observed in our β form and Gillman's form II.

Reaction of sodium di-n-decylphosphinate with copper(II) sulfate in aqueous ethanol yields α-$Cu[(n\text{-}C_{10}H_{21})_2PO_2]_2$. As for the octyl derivative, repeated heating to above the melting point of bulk samples of this material, followed by cooling to room temperature, results in complete conversion to the β form. In 1952 Drinkard and Kosolapoff (10) reported the preparation of what appears to have been the β form of this material (from the reported mp of 94°C); no mention of polymorphism was made in this early work.

No previous studies on copper(II) n-dodecylphosphinate have been reported. We obtained α and β forms by procedures identical to those used to obtain the corresponding decyl derivatives. In this instance we observed, however, that it is possible to have significant β contamination of the α form (the so-called α′ sample) if precipitation occurs too rapidly from concentrated solutions. The β contaminant was easily discernible in the DSC thermogram; whereas the pure α material shows a single endothermic peak at 125°C due to melting, the contaminated sample gave, in addition, an endothermic peak at 97.1°C due to melting of the β impurity.

The DSC data are given in Table 1. The heats of fusion, ΔH_{fus}, range from ~50 to 100 kJ mol^{-1}, for these long alkyl chain compounds. The values tend to decrease as the alkyl group gets shorter; this trend continues with the hexyl, butyl, and ethyl derivatives, where ΔH_{fus} values of 40, 28, and 13 kJ mol^{-1} respectively have been reported (3). This result suggests that the melting process involves the breakup of the interchain associative interactions and that these arise primarily from the intermeshing of alkyl groups on neighbouring chains (3). The extent of intermeshing would be expected to decrease as R gets smaller.

While the enthalpies of fusion tend to decrease as R gets smaller, the opposite trend is observed in the melting temperatures (compare the values in Table I to the values 109, 155, and 280°C reported for the hexyl, butyl, and ethyl derivatives (3)). This implies that while less energy is required to disrupt interchain interactions in the shorter R compounds, this effect is outweighed by the smaller increase in entropy on melting; therefore, a higher temperature of melting results.

Another effect of decreasing alkyl chain length in these polymeric phosphinates is to increase the oxidative stability. While the compounds studied here (and the hexyl derivative (3)) oxidatively decompose around 230–260°C, the ethyl and butyl derivatives decompose at 280°C (3). This effect has been observed before and has been attributed to the decreasing ease of oxidation of the alkyl group as R gets smaller (11, 12).

The accessibility of the polar inorganic backbone to polar solvents, as determined by the size of the alkyl groups attached to phosphorus, appears to be an important factor in determining the solubilities of these polymers. Hence, while the ethyl derivative is relatively soluble in polar solvents (3), the long alkyl chain compounds studied here are insoluble in water, methanol, ethanol, and acetone. Solubilities in chlorinated solvents, where presumably dipole-induced dipole interactions between the polymer backbone and the solvent are important, also tend to be slightly greater when R is small.

Electronic spectra

The α forms of the octyl, decyl, and dodecyl compounds exhibit broad absorption maxima at 12.3 × 10^3 cm^{-1} (±200

cm^{-1}) with shoulders at 14.3, 14.3, and 14.4 × 10^3 cm^{-1} (±400 cm^{-1}) respectively. Within the experimental uncertainty these spectra are identical to that reported previously for $Cu[(C_2H_5)_2PO_2]_2$ (2). The absorption maxima for the β forms are at 11.4, 11.4, and 11.6 × 10^3 cm^{-1} (±200 cm^{-1}) for the octyl, decyl, and dodecyl derivatives respectively; shoulders are observed at 13.2 × 10^3 cm^{-1} (±400 cm^{-1}) for all three. These spectra are indistinguishable from those of $Cu[(n\text{-}C_4H_9)_2PO_2]_2$ and $Cu[(n\text{-}C_6H_{13})_2PO_2]_2$ (3). As discussed previously (2), the principal absorption may be assigned to the $^2B_2 \rightarrow {}^2A_1$, ^2E transition and the shoulder to $^2B_2 \rightarrow {}^2B_1$ in D_{2d} symmetry.

It was shown (3) that the difference in the electronic spectra between the ethyl derivative, on the one hand, and the butyl and hexyl compounds, on the other, could be accounted for by slight differences in the geometries of the CuO_4 chromophores involved, the more compressed (towards square planar) geometry of the ethyl derivative shifting its absorptions to higher energies. It seems reasonable to conclude that the α forms studied here have CuO_4 chromophores which are similar in geometry to that found in $Cu[(C_2H_5)_2PO_2]_2$ and are more compressed towards square planar geometry than those of the β forms.

Infrared spectra

In view of the lack of precise structural data from X-ray diffraction studies, the infrared spectra were examined in some detail for indications of structural differences between the α and β forms. The most informative regions of the spectra were found to be those in which the P—O and P—C stretching vibrations occur and a listing of observed frequencies in these regions is given in Table 2. Absorptions in the 1000–1200 cm^{-1} region are readily assigned to PO_2 stretching vibrations of coordinated phosphinate groups (2). Although there is more structure associated with these absorptions for the octyl, decyl, and dodecyl compounds compared with the shorter alkyl chain derivatives, the principal bands in this region occur near 1110 cm^{-1} for the antisymmetric PO_2 vibration and 1045 cm^{-1} for the symmetric vibration in all compounds. Moreover, the separation between the bands of about 65 cm^{-1} falls into the range expected for equivalent P—O bonds (4, 6, 13). This supports the conclusion that all of these polymeric copper(II) phosphinates have the same basic inorganic backbone involving chains of copper ions joined by double bridging phosphinate groups. Other structures involving alternating single–triple phosphinate bridges, terminal phosphinate groups, or unsymmetrical bridging (non-equivalent P—O bonds) would be expected to give distinctly altered spectra in the PO_2 stretching region (4, 6, 13). Numerous shoulders of varying intensity are observed on the principal PO_2 absorptions of the compounds where R is large. This has been seen in other transition metal phosphinates and has been ascribed to overtones, combination bands, or PO_2 stretching frequencies caused by phosphinate structures not predominant in the bulk polymer (14, 15). Another possible cause is the presence of phosphinate groups in slightly different environments along the polymer chain. In the hexyl compound, for example, there are two crystallographically distinct rings; one ring has Cu—O—P—O—Cu moieties that involve one long (1.932 Å) and one short (1.896 Å) Cu—O bond while the other two Cu—O bonds are both relatively short (1.902 Å and 1.907 Å) (3). This difference in bonding results in two distinct types of phosphinate group and may be the cause of the structure seen in the PO_2 stretching region of this compound. By comparison, the Cu—O bonds are all nearly equivalent in the ethyl (1.916–1.922 Å) and butyl (1.916–1.926 Å) derivatives (2, 3) and for both of these, simple, unstructured two-band spectra are observed in the PO_2 stretching region.

Examination of the PC_2 stretching region (Table 2) reveals significant differences between the α and β forms. The former show a broad, medium intensity antisymmetric PC_2 stretch in the 770–775 cm^{-1} region, close to the frequency observed in the ethyl derivative. In contrast, in the β forms this band has shifted to about 805 cm^{-1} and become a relatively sharp, medium to strong absorption, comparable to the antisymmetric stretches observed in the butyl and hexyl derivatives. This particular band was seen in the spectrum of the preparation of the α-dodecyl derivative, which we concluded from DSC studies contained significant β impurity (so-called α′ material). The symmetric PC_2 stretch is virtually the same (~725 cm^{-1})

in all compounds, although in the ethyl and α derivatives this band is somewhat more intense than the antisymmetric stretch, while for the butyl, hexyl, and β forms it is generally less intense.

Other regions of the infrared spectra were generally less informative; however, there are features in the 450–600 cm^{-1} region, where angle bending modes of the C_2PO_2 groups normally occur (13, 16–21), which also group the β forms with the butyl and hexyl derivatives. These compounds all exhibit two relatively strong bands around 555 and 520 cm^{-1} with differing numbers of weaker bands depending on R. The α forms also exhibit two relatively strong bands but at higher frequencies (~585 and 550 cm^{-1}), as well as a number of weaker bands depending on R. In this instance the ethyl derivative is somewhat unique, exhibiting two medium intensity absorptions at lower energy than observed in the β forms (2). The region below 400 cm^{-1} contains bands due to Cu—O stretching and lattice vibrations. Most compounds studied here show a single medium intensity band around 360–380 cm^{-1} accompanied usually by several weaker bands. There are no clear features in this region that classify the compounds into distinct groups.

This analysis of the vibrational data has revealed spectral similarities among the ethyl and α derivatives on the one hand and the butyl, hexyl, and β derivatives on the other, and strongly suggests that there are important structural similarities within each group and differences between groups. Moreover, the greatest spectral differences between groups involve vibrations of the PC_2 moiety, suggesting that the differences primarily involve the orientations and inter- and intrachain packing of the alkyl groups while the inorganic Cu—O—P—O—Cu backbone remains relatively constant in all compounds (except for small differences in the CuO_4 geometry, as discussed above). This is consistent with the reported X-ray results on the shorter alkyl chain compounds (3). One of the structural features noted in this earlier work was that in the ethyl compound one of the $Cu(OPR_2O)_2Cu$ rings has two alkyl groups axial and two equatorial to the ring, whereas in the butyl and hexyl derivatives all alkyl groups are axial. Such differences likely occur in the α and β forms of the long alkyl chain compounds.

Magnetic properties

Magnetic susceptibilities from 4.2 to 300 K are given in Table 3[1] and magnetic moments are plotted as a function of temperature in Fig. 1. The strong spectral (and therefore, presumably, structural) correlation between $Cu[(C_2H_5)_2PO_2]_2$ and the α forms of the long alkyl chain compounds occurs also with the magnetic properties. In common with the ethyl compound, all α derivatives exhibit magnetic moments which decrease with temperature, behaviour indicative of antiferromagnetic coupling. As the temperature is lowered the magnetic susceptibility of α-$Cu[(n\text{-}C_{10}H_{21})_2PO_2]_2$ passes through a broad maximum at ~48 K and a minimum at ~16 K and then rises sharply with further decrease in temperature (Fig. 2). For both the α-octyl and α-dodecyl derivatives the low temperature rise in susceptibility occurs just below the temperature of the maximum and hence the maximum is not as well defined. This increase in susceptibility at the lowest temperatures is indicative of the presence of paramagnetic monomer impurity.

As before (3), the magnetic data were analyzed according to the isotropic Heisenberg model for exchange coupled linear chains employing the polynomial expression for the magnetic susceptibility developed by Hall (22, 23). Computer fits were made to the susceptibility data with J, g, and percent paramagnetic impurity as variables. For the purpose of these fits the paramagnetic contribution was assumed to follow Curie law and to have the same g value as that of the bulk antiferromagnetically coupled polymer. The criterion used for the best fit was that set of parameters which gave the minimum value of the function:[2]

$$F = \left[\frac{1}{n}\sum_i^n \left(\frac{\chi_i^{calc} - \chi_i^{obs}}{\chi_i^{obs}}\right)^2\right]^{1/2}$$

[2]This was the fitting function used in ref. 3 where it was termed the rms deviation. The values quoted in ref. 3 are in error; they should read 12×10^{-3}, 18×10^{-3}, and 13×10^{-3} for the ethyl, butyl, and hexyl derivatives respectively. The quantities are dimensionless.

where n is the number of data points and χ_i^{obs} and χ_i^{calc} are the experimental and calculated susceptibilities. We were not always able to obtain satisfactory agreement between experiment and theory over the entire temperature range from 4.2 to 300 K for the compounds studied in this work. In view of the inherent uncertainty, due to packing errors, in the absolute susceptibility determined by the Gouy method ($\sim\pm5\%$), we chose to fit the low temperature (<100 K) magnetometer data (estimated uncertainty in χ_M of $\pm2\%$) only. The best fit values of the magnetic parameters as well as the corresponding values of F for the various compounds are given in Table 4. The solid lines in Figs. 1 and 2 are calculated using these parameters and, as can be seen, the agreement with experiment is good, particularly over the low temperature region.

These long alkyl chain α derivatives differ from $Cu[(n\text{-}C_2H_5)_2PO_2]_2$ in two important ways. First, the magnetic data indicate the presence of paramagnetic impurities. This may reflect a small concentration of monomeric phosphinate in which the R_2PO_2 groups chelate or may reflect the effect of a smaller degree of polymerization and consequently a higher concentration of terminal copper atoms. In any event the microanalytical data suggest the impurity is "structural" rather than "chemical", reflecting the presence of a small amount of a paramagnetic form of copper(II) phosphinate different from that present in the bulk phosphinate bridged chain. The second way in which the α forms differ from the diethylphosphinate derivative is that the former have significantly larger absolute values of the exchange coupling constant J.

The β forms of the copper(II) dioctyl-, didecyl-, and didodecylphosphinates all exhibit ferromagnetic behaviour. The low temperature magnetic susceptibility data (4.2–100 K) were fit to theory employing the polynomial expression of Baker *et al.* for ferromagnetically coupled $S = 1/2$ chains (23, 24). Attempts to include paramagnetic impurity produced no improvement in agreement between experiment and theory in these cases. This may reflect the lack of such impurity; however, it must be appreciated that because of the large susceptibilities observed at low temperatures for ferromagnetic samples the detection of a small amount of paramagnetic impurity would be very difficult. Magnetic moments are shown compared to theory in Fig. 1 and best fit values of the magnetic parameters, as well as the corresponding values of the fitting parameter F, are listed in Table 4. An interesting feature of these results is that, in contrast to the results for the antiferromagnetic materials, the J values are all small ($\approx +2$ cm^{-1}) and very close to those observed for the ferromagnetic butyl and hexyl derivatives (3).

The sample of the α-dodecyl compound that DSC and infrared studies indicate contains significant β impurity (α' material) exhibits magnetic properties completely consistent with this conclusion. The magnetic moment, which decreases on lowering the temperature, shows a minimum at ~11 K, then increases again to 4.2 K (Fig. 1). This behaviour cannot be accounted for by paramagnetic impurity alone in an antiferromagnetic sample but is indicative of the presence of ferromagnetic impurity. In fact, the best fit was found assuming both paramagnetic and ferromagnetic impurity (Table 4). In fitting the data for this sample the value of J for the ferromagnetic impurity was fixed at the value observed for the pure β form. The values of g and J for the antiferromagnetic component that constitutes the major part of the sample (Table 4) obtained in the fit are in good agreement with the values obtained for the pure α form.

This work completes detailed magnetic studies on a series of straight chain dialkylphosphinates of copper(II). It has shown that, whereas the compounds containing short alkyl chains (C_2,C_4,C_6) exist in either antiferromagnetic or ferromagnetic forms, the longer alkyl chain compounds (C_8,C_{10},C_{12}) exhibit polymorphism and are readily obtainable in both forms. Spectroscopic evidence suggests all compounds have the same extended chain, double phosphinate bridged structure with differences involving the orientations of the alkyl groups with respect to the plane of the inorganic backbone. This in turn affects the packing of the chains and may result in the small differences observed in the detailed geometry of the CuO_4 chromophores. We suggested earlier (3) that both ferromagnetic and antiferromagnetic pathways for superexchange may be available in these compounds, with a feature such as the flattening of the CuO_4 chromophore favouring the latter pathway. These ideas may be taken further as a result of the current study. The exchange coupling constant is virtually the same in all of the ferromagnetic samples but $-J$ varies from ~1 cm^{-1} in the ethyl compound to ~30 cm^{-1} in the other antiferromagnetic materials. This suggests that the ferromagnetic pathway involves primarily σ-type orbital overlap, which is relatively insensitive to small changes in geometry, while the antiferromagnetic pathway involves the π-type orbital overlap, which is more sensitive to changes in geometry. Hence when the latter dominates, as it seems to do in the ethyl and α octyl, decyl, and dodecyl forms, greater differences in the magnitude of exchange coupling between compounds are observed.

Received September 19, 1984

Herbert L. Holland, Heike Pöpperl, Ronald W. Ninniss, and P. Chinna Chenchaiah. Can. J. Chem. **63**, 1118 (1985).

A series of *para*-substituted alkyl aryl sulphides has been transformed stereoselectively to the sulphoxide by incubation with the fungus *Mortierella isabellina*. The enantiomeric purity of the products was dependent on the nature of substitution in the aromatic ring and at sulphur. Comparisons of the enantiomeric purities obtained from sulphides with *para* substituents of the same steric size but different electronic properties indicate that the stereoselectivity of *S* oxidation is susceptible to electron withdrawing or donating factors. This conclusion lends credence to a stepwise oxidation mechanism involving an electron deficient sulphur intermediate.

Herbert L. Holland, Heike Pöpperl, Ronald W. Ninniss et P. Chinna Chenchaiah. Can. J. Chem. **63**, 1118 (1985).

Par incubation avec des champignons *Mortierella isabellina*, on a transformé stéréosélectivement en sulfoxydes une série de sulfures d'alkyles et d'aryles substitués en *para*. La pureté énantiomérique des produits dépend de la nature des substituants sur le noyau aromatique et au niveau du soufre. En se basant sur une comparaison des puretés énantiomériques obtenues avec des sulfures portant des substituants en *para* qui ont des encombrements stériques semblables mais des propriétés électroniques différentes, on peut déduire que la stéréosélectivité de l'oxydation du soufre est susceptible aux factuers électro-affinitaires ou électro-donneurs des substituants. Cette conclusion supporte le concept d'un mécanisme par étape impliquant un intermédiaire sulfuré déficient en électrons.

[Traduit par le journal]

In spite of the continued interest in chiral sulphoxides, both in the study of sulphur stereochemistry (1) and as intermediates in asymmetric synthesis (2), the best direct chemical methods for their generation from sulphides (3) have not yet achieved the high degree of enantiomeric purity desirable in modern asymmetric synthesis. High enantiomeric excesses (>35%) are routinely available for *p*-tolyl alkyl sulphoxides (only) by a modification (4) of the Anderson synthesis (5) using sulfinate esters, or by the use of biological oxidizing agents employing sulphides as substrates.

In the latter area, the use of actively growing or resting cultures of fungi has been the most widely used technique for the production of sulphoxides of good optical purity (6–8). Other methods of biotransformation, using enzymes of mammalian origin (9,10) or peroxide oxidation in the presence of enzyme templates (11), are not generally applicable to preparative scale work.

In an extension of our earlier work on the mechanism of alkyl aryl sulphide oxidation by the fungus *Mortierella isabellina* (12), in which we proposed that cytochrome P-450 dependent mono-oxygenase enzymes of the fungus were responsible for oxidation at sulphur, we have now studied the effects of substitution at the *para* position of the aromatic ring, and at sulphur, on the degree of enantiomeric enrichment of the resultant sulphoxide. The sulphides used in this study, **1** and **4**, gave the corresponding sulphoxides, **2** and **5**, respectively, as major products on incubation with *M. isabellina*; this is summarized in Table 1. In the case of methyl *p*-nitrophenyl sulphide (1*g*) and *p*-bromophenyl methyl sulphide (1*j*), the sulphones (3*a* and 3*b*, respectively) were also obtained. Fungal oxidation of sulphoxides to sulphones is well documented (13).

The enantiomeric enrichments reported in Table 1 were determined by the ^{1}H nmr chiral shift reagent method. In the presence of 0.25 molar equivalents of Eu(hfc)$_3$ the methyl singlets for the two enantiomers of **1**, the *S*-alkyl α hydrogen signals of 4*a*, 4*b*, and 4*d*, and the *S*-alkyl β hydrogen signals of 4*c* were well resolved (ΔΔδ ca. 0.2–0.4 ppm). In addition, the C-2 and C-6 aromatic hydrogen signals of **1** were also separated into a pair of half AB quartets whose relative areas

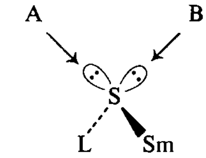
[b]Accompanied by sulphone (5%).

could be used as an internal check on the values obtained from the methyl singlets. The values for enantiomeric enrichments so obtained were checked where possible by optical rotation measurements. Our estimate of optical purity for the sulphoxide 1*b* differs from that previously reported by Sih and co-workers (8) for 1*b* obtained from the same fungus. The latter group, however, estimated their optical purity solely from rotation measurements; at least three different values for the specific rotation of (*R*)-1*b* appear in the literature (6,15).

The values reported in Table 1 for the enantiomeric enrichment of sulphoxides 2*g* and 2*j* may not be directly attributable to stereospecific sulphide oxidation. In these cases the formation of sulphone **3** was also obtained, raising the possibility that the values listed for the enrichments of 2*g* and 2*j* may be attributable at least in part to stereoselectivity in the oxidation of sulphoxide to sulphone (13). In an attempt to investigate this, racemic sulphoxides 2*g* and 2*j* were administered as substrates to *M. isabellina*, but under these conditions the formation of sulphone did not occur. It therefore seems likely that, in the case of sulphone formation from 2*g* and 2*j*, both oxidations occur without the substrate leaving the enzyme's active site; it may therefore not be possible to directly determine the stereoselectivity of the second oxidation. The assignment of absolute stereochemistry to the predominant sulphoxide enantiomers in Table 1 follows from the results reported for the absolute stereochemistry of alkyl aryl sulphoxides of known optical rotation (14,15,19,20).

Walsh and co-workers noted an intrinsic lack of stereospecificity in the cytochrome P-450 catalysed enzymic oxidation of *p*-tolyl ethyl sulphide to sulphoxide (21,22). A similar result has been recorded by others (23) and rationalized in terms of the diagram of Fig. 1. The alternatives are either specific binding with non-specific oxidation occurring at either A or B, or a non-specific binding mode in which oxidation occurs from only one of the directions shown. The latter interpretation has been proposed by Oae and co-workers (23) for the liver microsomal oxidation of sulphides on the basis of a change in absolute stereochemistry of the oxidation of PhSR where R = *tert*-butyl, compared with the stereochemistry observed for R = methyl, and the assumption that *tert*-butyl is sterically larger than phenyl.



L = large substituent
Sm = small substituent

FIG. 1. Stereoselectivity in enzymic sulphide oxidation

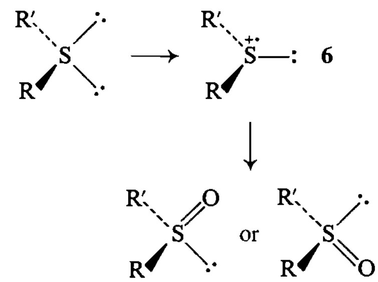


FIG. 2. Mechanism of enzymic sulphide oxidation (12,24)

This interpretation cannot hold in the present case, as all the sulphides listed in Table 1 gave sulphoxide of positive rotation (*R* stereochemistry; see above). We therefore prefer the earlier interpretation of Henbest and co-workers (6) of a specific binding mode and non-stereospecific oxidation. This proposal is also consistent with the conclusions of Walsh (21,22).

A non-stereospecific oxidation may be the result of a "loose" active site in which oxidation can occur from either direction (Fig. 1). In this event an additional possibility is raised by a consideration of the mechanism of oxidation at sulphur, and is presented in Fig. 2. Previous work (12,24) has indicated that this reaction is a stepwise process; the intermediate has been formulated as the radical cation (**6**) (Fig. 2) (24) or a similar species coordinated to the active site of the enzyme (12). In either case, the intermediate will not possess the regular tetrahedral geometry characteristic of sulphides or sulphoxides. Spectroscopic and theoretical studies of the related molecules H_2S and $H_2S^{+\cdot}$ indicate that the barrier to linearity is substantially reduced by ionization at sulphur (25,26) and that the ionized species can invert at room temperature (25).

Intermediate **6** will therefore not necessarily possess the stereochemical integrity of the substrate. The oxidation of **6** to sulphoxide is fast compared with the initial ionization step (12,27,28). The rates for similar reactions (e.g. C—H oxidation) catalysed by cytochrome P-450 dependent enzymes suggests that this rate can approach that of radical inversion (29), raising the possibility that the absolute stereochemistry of product may be determined, in part, by the stability of the radical cation **6**.

A comparison of the enantiomeric excesses (ee) of sulphoxides obtained from isosteric sulphides (Table 1) suggests that the ee is dependant at least in part on the electron density at sulphur. Thus with substrates 1*a*/1*h* (*para* H vs. *para* F), ee increases from 58 to 70%. A similar effect is found for 1*f* vs. 1*c* (72% to 90%), and 1*b* vs. 1*k* (46% to 80%), suggesting that, for these compounds, an increase in electron withdrawal by the aromatic ring and the resultant destabilization of the intermediate **6** has a positive effect on enantiomeric purity.

In the absence of more detailed information on reaction rates and intermediate structures this effect cannot be unambiguously attributed to a variation in radical lifetimes, but this hypothesis is an attractive one which is consistent with the data. It is, of course, not the only factor which affects enantiomeric excess. There clearly exist both *para* steric factors (cf. **1**, R = CH_3 vs. C_2H_5), and *S*-alkyl steric factors (cf. 1*a* vs. 4*a* and 4*d*), but in the results from the isosteric substrates described above these steric factors are minimized.

The data presented herein can therefore be rationalized in the following terms. The stereoselectivity of sulphoxide formation is determined largely by binding parameters, which are susceptible to steric factors (Fig. 1); in addition, there is an electronic effect of the substituent at the *para* position of the aromatic ring of **1** whose influence can be understood in terms of the stepwise mechanism of sulphoxidation presented in Fig. 2.

Experimental

Apparatus, materials, and methods

Melting points were determined on a Gallenkamp apparatus and are uncorrected. Infrared spectra were recorded on an Analect FX6260 FTIR spectrometer. Proton nmr spectra were obtained at 80 MHz with a Varian WP80CW instrument, using $CDCl_3$ as solvent and TMS as internal standard. Enantiomeric ratios were determined in a mixture of $CDCl_3$ and CCl_4 (1:4) in the presence of tris[3-(heptafluoropropylhydroxymethylene)-*d*-camphorato] europium(III). Mass spectra were obtained with an AEI MS30 interfaced to a Krato DS-55 data system. Column chromatography was performed on silica gel and thin layer chromatography on Merck silica gel 60F-254 (0.2 mm). Optical rotations were determined with a Perkin–Elmer 241MC polarimeter using chloroform as solvent. *Mortierella isabellina* NRRL 1757 was maintained as described previously (12).

Preparation of substrates

Thioanisole (1*a*) was a commercial sample. The methyl sulphides 1*b*–1*k* were prepared from the corresponding thiols as previously described (12). The alkyl sulphides 4*a*, 4*b*, and 4*d* were prepared by alkylation of the corresponding thiol with alkyl bromide (12), and 4*c* by addition of thiophenol to isobutene as described (30). Racemic sulphoxides 2*g* and 2*j* were prepared from the sulphide by oxidation with sodium metaperiodate (31). All compounds exhibited spectral and physical properties consistent with their structures.

Incubations with M. Isabellina

Mortierella isabellina NRRL 1757 was grown as described, and the incubations performed as previously detailed (12). Yields and enantiomeric purities of products are listed in Table 1.

Microbial hydroxylation of steroids. 10. Rearrangement during epoxidation and hydroxylation, and the stepwise nature of these enzymic reactions

HERBERT L. HOLLAND AND ELLY RIEMLAND
Department of Chemistry, Brock University, St. Catharines, Ont., Canada L2S 3A1

Received September 27, 1984

HERBERT L. HOLLAND and ELLY RIEMLAND. Can. J. Chem. **63**, 1121 (1985).

A series of unsaturated steroids has been incubated with fungi which are known to hydroxylate at a site corresponding to the allylic position in the analogous saturated steroids. In some cases, the anticipated hydroxylation occurred without rearrangement of the double bond. In a number of instances, however, products were obtained whose structures implied that allylic rearrangement had occurred during the reaction. The formation of these products is consistent with a stepwise mechanism of enzymatic oxidation. Possible routes for product formation are presented which incorporate this proposal.

HERBERT L. HOLLAND et ELLY RIEMLAND. Can. J. Chem. **63**, 1121 (1985).

On a fait incuber une série de stéroïdes non saturés avec des champignons connus pour hydroxyler à une site correspondant à la position allylique des stéroïdes saturés analogues. Dans quelques cas, l'hydroxylation prévue se produit sans transposition de la double liaison. Toutefois, dans un bon nombre de cas, on a obtenu des produits dont les structures impliquent que des transpositions allyliques se sont produites au cours de la réaction. La formation de ces produits est en accord avec un mécanisme de l'oxydation enzymatique qui impliquerait plusieurs étapes. On propose des voies réactionnelles possibles qui incorporent cette proposition.

[Traduit par le journal]

Introduction

The enzymatic conversion of a saturated carbon–hydrogen bond to hydroxyl, and the related enzymatic epoxidation of olefins, are most often catalyzed by cytochrome P-450 dependent mono-oxygenase enzymes (1). The mechanism of these oxidations is still in doubt, currently favoured possibilities being presented in Scheme 1 (for hydroxylation) and Scheme 2 (for epoxidation) (2).

Evidence has recently been accumulating which supports a stepwise route for both of these reactions (routes B, Schemes 1 and 2) (3–8). This has taken the form of epimerization during hydroxylation (4), the trapping of carbon radical intermediates (5, 6), the observation of inversion of olefin geometry during epoxidation (3), and the detection of rearrangements during olefin oxidation (7, 8).

The hydroxylation of steroids by fungi has been shown in many cases to be a cytochrome P-450 dependent mono-oxygenase reaction (9–12). In order to further study the mechanism of the enzymatic oxidation of steroid substrates, we have now investigated the metabolism of a series of unsaturated steroids by fungi which are known to hydroxylate analogous saturated steroids at a position corresponding to an allylic carbon (13). The putative existence of a radical intermediate such as those shown in routes B of Schemes 1 and 2 now allows for the possibility of allylic rearrangements in these cases, and it was this aspect of the problem which we set out to study.

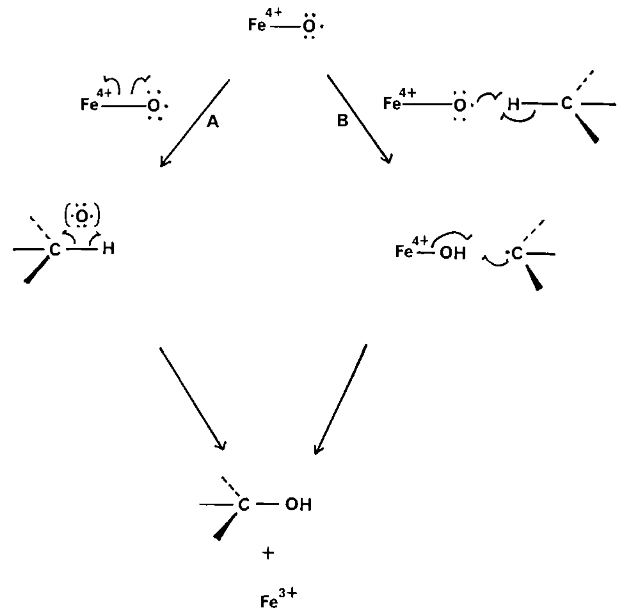
2 *a* $R^1 = H_2$, $R^2 = \alpha H, \beta OH$
b $R^1 = H_2$, $R^2 = 0$
c $R^1 = R^2 = \alpha H, \beta OH$

The substrates used in the main body of this work, **1**, **2*a***, **3**, and **4** were prepared by published procedures. The synthesis of **3** has been described only in outline, and is therefore presented

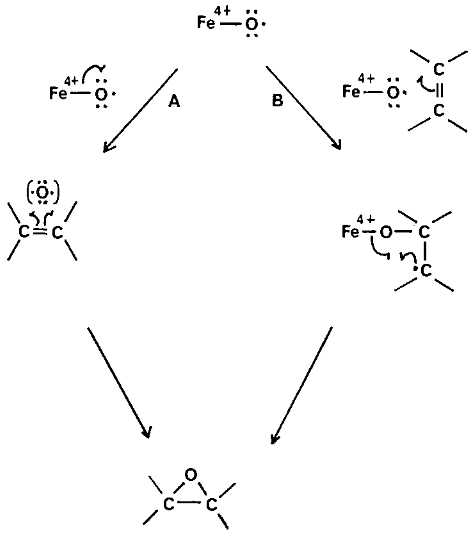


SCHEME 1. Possible routes for hydroxylation at saturated carbon by cytochrome P-450 dependent mono-oxygenases.

in detail herein. The ^{13}C nmr chemical shifts of these compounds, together with the ketone **2*b*** (which was prepared from **2*a*** by Jones oxidation to aid in chemical shift assignments) are presented in Table 1. The assignments were straightforward and were based on chemical shifts, multiplicity in off-resonance decoupled spectra, and published values for analogous steroids (14).

Results

The results of the incubations are summarized in Table 2. The $\Delta^{7,8}$ steroid **1** was recovered unchanged from incubation with *R. arrhizus*, a fungus known to hydroxylate Δ^4-3-keto-steroids at C-6β following the abstraction of the C-6β hydrogen (15). We attribute the absence of metabolism in this case to the failure of **1** to be bound by the enzyme's active site. The conjugated estradiene **2*a***, incubated with the C-11β hydroxy-



SCHEME 2. Possible routes for epoxidation of olefins by cytochrome P-450 dependent mono-oxygenases.

lating fungus *C. lunata*, gave only the product of 11β hydroxylation, **2***c*. No rearranged species were detected. The structure of **2***c* follows from its ^{13}C nmr spectrum (Table 3), which clearly shows the shifts anticipated for 11β hydroxlation (14) when applied to the spectrum of the unsubstituted substrate **2***a* (Table 1). Incubation of **2***a* with the C-11α hydroxylator *R. stolonifer* did not result in detectable metabolism.

The use of $\Delta^{8(9)}$-progesterone (**3**) as a substrate for fungi which hydroxylate progesterone (**14***a*) at C-7 or C-11 yielded some products whose structures indicate that the double bond is involved in their formation. Incubation of **3** with the 11α/7β hydroxylator *R. stolonifer* gave, in addition to normal 7β hydroxylation yielding **6**, a compound (**5**) which was assigned the structure shown. The ^{13}C and ^{1}H nmr spectra of **5** clearly show the presence of the $\Delta^{1,4}$-dien-3-one grouping and the lack of 17β acetyl side chain. The presence of the 9,11α epoxide can be deduced from ^{1}H nmr (the 11β hydrogen resonating at δ 3.38 ppm), and the presence of the shifts in the ^{13}C nmr spectrum (particularly at C-1 and C-7, and C-14) predicted for **5** on the basis of the application of shift parameters for a 9,11α epoxide (obtained from **4** and **12**) to **9**.

nmr was instrumental in structure assignment. The key shifts were those caused by γ *gauche* interactions (C-1, -7, -12, and -17), and the *trans*-antiperiplanar shift of C-18 caused by the presence of hydroxyl at C-14α (16, 17). The 7α hydroxylating fungus *M. griseocyanus*, when incubated with **3**, gave the product of 6β-hydroxylation and $\Delta^{9(11)}$ epoxide formation, **8**. The structure of **8** was deduced by nmr spectral analysis. The ^{13}C nmr spectrum showed shifts entirely in agreement with those calculated by applying the shift parameters for C-6β hydroxylation (14) and C-9,11 epoxidation (above) to the spectrum of **4**.

In order to allow for the possibility that $\Delta^{8(9)}$-progesterone, **3**, may contain the $\Delta^{9(11)}$ isomer **4** as a trace impurity produced during its preparation, a separate series of control incubations was performed using **4** as substrate. *R. stolonifer* gave only the product of ring A oxidation and side chain cleavage (**9**), together with a mixture of the 12-alcohols **10**. The structures of the

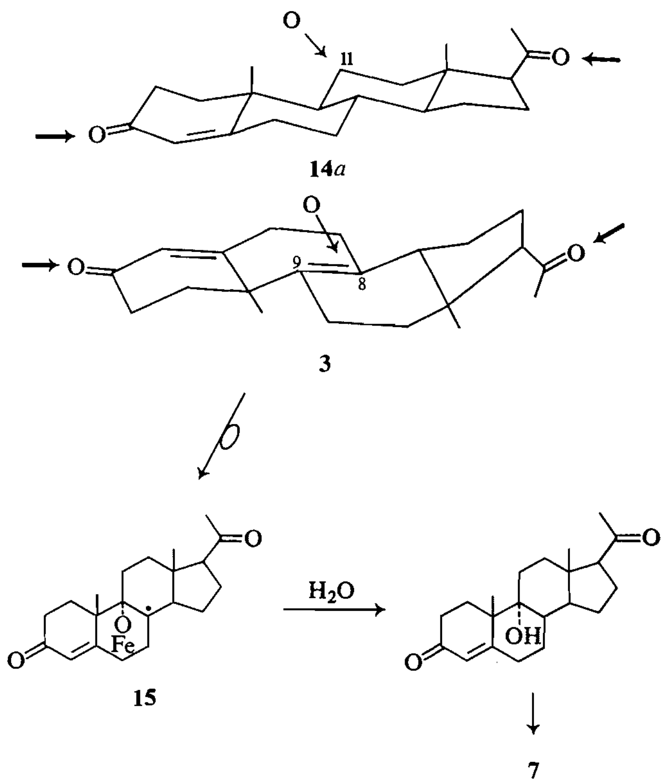


SCHEME 3. Possible route for hydroxylation of **3** at C-9α by *C. lunata*.

latter were confirmed by ^1H nmr decoupling experiments between the C-11 and C-12 hydrogens (see Experimental). This mixture could not be separated by any of the chromatographic techniques at our disposal. *C. lunata* gave only the reported (18) 9,11β epoxide on incubation with **4**, but *M. griseocyanus* gave a low yield of a complex mixture which, although chromatographically homogeneous (tlc), was shown by ^1H nmr analysis to contain at least three different steroids. The appearance of the characteristic C-11β hydrogen resonance as a doublet (J = 8 Hz) at δ 3.23 ppm indicated, however, that 9,11α epoxidation, probably producing **12**, had occurred.

Discussion

The oxidative removal of the C-17β acetyl side chain, and the introduction of Δ^1 unsaturation, has been reported to occur with several fungal species (19, 20), but not previously with *Rhizopus*. The introductions of hydroxyl at C-11β (in **2***c*) and C-14α (in **7**) by *C. lunata* represent normal modes of hydroxylation (13), as do the C-7β hydroxylation of **3** by *R. Stolonifer*, giving **6**, and the C-6β hydroxylation of **3** to give **8** (13). The hydroxylation of **4** at C-12 by *R. stolonifer* is not exceptional: the allylic C-12 position of the substrate is both activated (2) and adjacent to the normal site of hydroxylation (13).

The formation of the epoxides **5** and **8**, and the 9α hydroxylation giving **7**, cannot, however, be rationalized on the basis of simple oxidative metabolism. In the case of **7**, 9α-hydroxylation may occur via the route outlined in Scheme 3. The three-dimensional arrangement of binding (at C-3 and C-20) and hydroxylation (at C-11β) sites of progesterone, (**14***a*) (2), is also shown. Inspection of models shows that the $\Delta^{8(9)}$ substrate **3** best fits into this binding arrangement in an inverted manner. The "back-to-front" binding of steroid substrates for hydroxylation has been well documented by the Oxford group (2); "upside-down" binding has been proposed previously (21) to explain the results of some non-stereospecific hydroxylations at C-11.

Binding of **3** in the manner shown to the hydroxylase of *C. lunata* would expose the α face of the $\Delta^{8(9)}$ bond to the oxidizing site. Previous work has demonstrated that steroid hydroxylation and epoxidation can both be performed by the same enzyme (22, 23) and, in this event, the application of the stepwise mechanisms of Scheme 2 can result in 9α hydroxylation. The intermediate radical **15** does not collapse internally to epoxide in this case. The conformation of **15**, now that the restraining influence of the olefinic bond is removed, is such that the C-9α oxygen and the radical density of C-8 are rigidly *trans*-diaxial and therefore unable to recombine. Hydrogen transfer from solvent completes the process.

That the C-8β hydrogen of **7** is provided by the aqueous medium has been demonstrated by the incubation of **3** with *C. lunata* in the presence of 10% deuterium enriched water. The product thus isolated was examined by ^{2}H nmr and showed signals centered at 1.25 and 2.57 ppm. The latter were exchangeable and assigned to deuterium at enolic sites, but the former was not, and is close to the reported resonance position for the C-8β hydrogen of normal steroids (24).

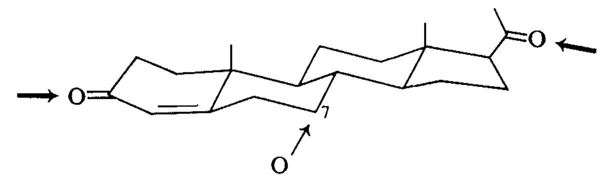
The epoxide grouping present in **5** and **8** must also be the result of a stepwise oxidation process. In the case of the metabolism of **3** by *M. griseocyanus*, a C-7α hydroxylator of normal steroids, inverse binding of **3** to the active site now exposes the C-11 position to the oxidizing species. Abstraction of a hydrogen from this position (cf. route B, Scheme 1) can produce the allylic radical **16**, which can rearrange to **17**, pick up hydrogen from the medium as above, and be epoxidized in the normal way (Scheme 4). The direct incubation of the $\Delta^{9(11)}$ steroid, **4**, with *M. griseocyanus* indicates that this epoxidation does indeed occur.

The formation of **5** from incubation of **3** with *R. stolonifer* can proceed in a similar manner, except that it is not necessary in this case to propose an inverted binding of substrate, as this fungus is a known C-11α hydroxylator. In this case, however, the $\Delta^{9(11)}$ olefin **4** is not itself directly epoxidized by *R. stolonifer*, suggesting that a preferred mode of reaction in this latter case is the removal of the side chain (giving **9**), after which the enzyme will not accept the androstene derivative as a substrate.

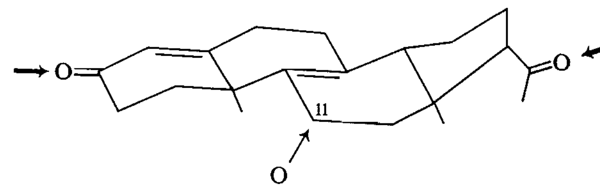
In an attempt to further confirm the radical nature of hydroxylation at C-11, we have also studied the competitive hydroxylations of progesterone (**14*a***) and its 11β-fluoro derivative (**14*b***) by *R. stolonifer*. The former yields only 11α-hydroxy progesterone (**14*d***), and we have previously demonstrated that the latter gives rise only to 11-keto progesterone (**14*c***), probably via a halohydrin intermediate (25). One might expect a rate retardation in the metabolism of **14*b*** compared with that of **14*a*** in the event that the reaction proceeded via a radical abstraction process (Scheme 1, route B). For a direct, concerted oxidation (Scheme 1, route A), with a transition state resembling substrate (2), the effect of the fluorine substituent should be minimal. In the event, the ratio of **14*c*** (from **14*b***) to **14*d*** (from **14*a***) observed from incubation of an equimolar mixture of these isosteric substrates with *R. arrhizus* was 1:12, indicating that **14*a*** is metabolized preferentially.

In the absence of information about the transport and binding of these substrates, these latter data are not conclusive. However, the results of this and the other incubations discussed herein generally support the stepwise, radical abstraction mechanisms of routes B, Schemes 1 and 2, for the hydroxylation and epoxidation of steroid substrates.

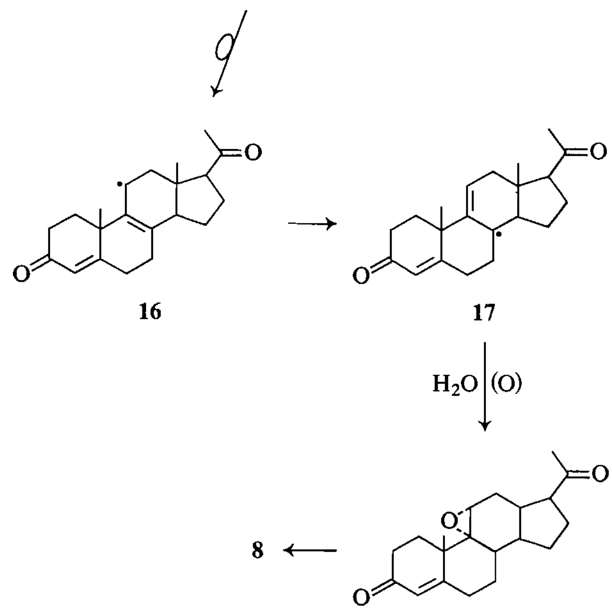
Other possible routes such as olefin hydration/dehydration have been considered for the formation of rearranged products and, in view of the fact that the products obtained result from



14*a*



3



SCHEME 4. Possible route for 9,11α epoxidation of **3** by *M. griseocyanus*.

whole organism metabolism, these possibilities cannot be entirely discounted. However, the available data on steroid hydroxylating fungi suggest that these rearrangements are not generally observed (13, 20) and we found no evidence for such rearrangement when not in concert with hydroxylation or epoxidation reactions.

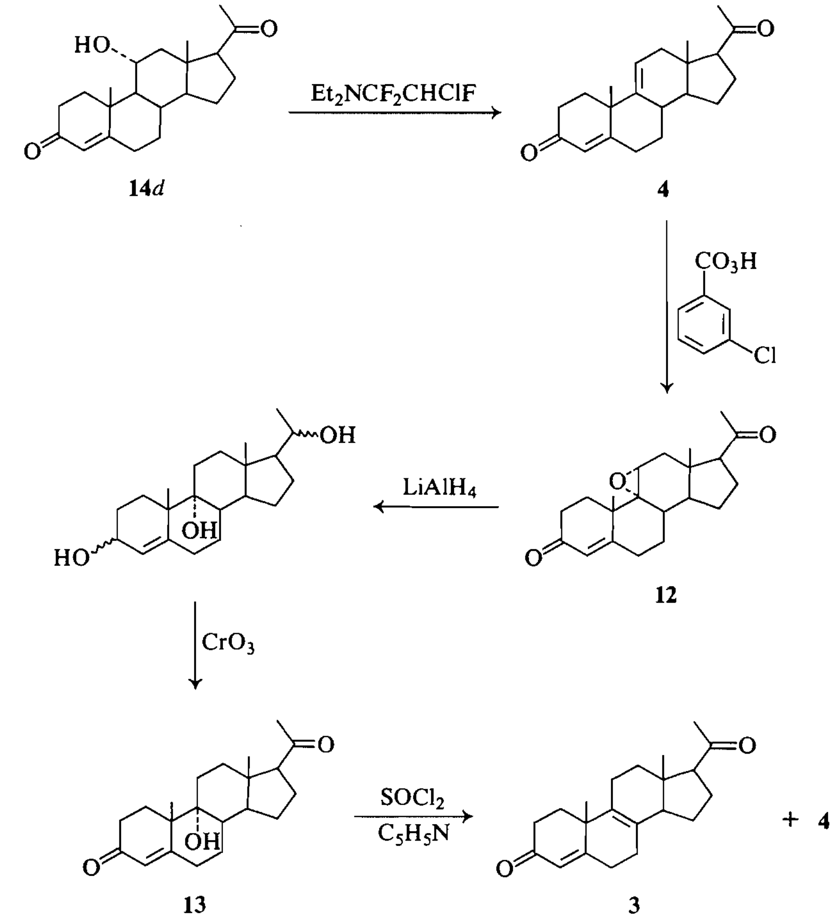
Experimental

Apparatus, materials, and methods

Melting points were determined on a Kofler heating stage and are uncorrected. Infrared spectra were recorded with a Perkin–Elmer 237B spectrometer. The nmr spectra were obtained with a Bruker WP60, WP80CW, or WH400 (at the Southwestern Ontario nmr Centre, Guelph) using $CDCl_3$ as solvent and TMS as internal standard. Mass spectra were obtained with an AEI MS 30 spectrometer fitted with a Kratos DS-55 data system. Thin layer chromatography was performed on Merck silica gel 60F-254 and column chromatography on Merck silica gel (230–400 mesh). Elemental analyses were performed by Guelph Chemical Laboratories, Guelph, Ontario.

Incubations with fungi

Curvularia lunata NRRL 2380 (26), *Mucor griseocyanus* ATCC 1207 (27), *Rhizopus arrhizus* ATCC 11145 (28), and *Rhizopus stolonifer* ATCC 6227b (28) were grown and the incubations performed as



SCHEME 5. Synthesis of pregna-4,8(9)-diene-3,20-dione (**3**) (ref. 32).

described. Details of times, products, and yields are summarized in Table 2.

Synthesis of substrates

The following compounds were prepared by the literature procedures, and gave satisfactory spectral and analytical data: androsta-4,7-dien-17β-ol-3-one (**1**) (29), estra-4,9(10)-dien-17β-ol-3-one (**2***a*) (30), and pregna-4,9(11)-diene-3,20-dione **4** (31). The ^{13}C nmr data are listed in Table 1.

Pregna-4,8(9)-diene-3,20-dione (3)

This compound was prepared by the route outlined by Schneider and Jackson (32) and presented in Scheme 5.

9,11α-Epoxypregn-4-ene-3,20-dione (12)

A solution of pregna-4,9(11)-diene-3,20-dione (**4**) (7.82 g) in chloroform (50 mL) was cooled to 5°C, and then a solution of *m*-chloroperoxybenzoic acid (5.1 g) in chloroform (50 mL) added. The resulting mixture was kept at 5°C for 6 h, then washed with aqueous sodium sulfite (3 × 100 mL), water, and dried over sodium sulfate. Evaporation gave a sample of **12** (7.01 g), mp 180–185°C (lit. (32) mp 180–192°C), which was used directly in the next step. The ^{13}C nmr data are listed in Table 3.

Pregn-4-ene-3β,9α,20β-triol

Lithium aluminum hydride (8.0 g) was added to dry ether (275 mL), and then a solution of **12** (7.0 g) in dry benzene (80 mL) added slowly with stirring. When the addition was complete, the resulting mixture was refluxed for 5 h, then cooled and the residual reducing agent decomposed (33). Work-up in the usual way gave a crude sample of the title compound (7.46 g) which was oxidized directly to **13** by the usual method (34, 35).

Pregna-4,8(9)-diene-3,20-dione (3)

A solution of **13** (4.5 g) in dry pyridine (100 mL) was cooled to 0°C. Thionyl chloride (5 mL), previously treated to remove traces of HCl and Cl_2, was then added at such a rate that the temperature was maintained below 5°C. The solution was then poured into ice water (500 mL), and extracted with ether (4 × 200 mL). The extract was washed with aqueous HCl (5%), then water, dried over sodium sulfate, and then evaporated. The residue was chromatographed (silica gel, benzene-to-ether stepwise gradient) to yield a sample (2.1 g) consisting of a mixture of the compound **3** and the $\Delta^{9(11)}$ isomer **4**. Crystallization from ethyl acetate/hexane gave pure **3** (1.05 g, 25%), mp 158–160°C (lit. (32) mp 162–167°C). The ^{1}H nmr included signals at δ 0.65 (3H, s, C-18H), 1.33 (3H, s, C-19H), 2.15 (3H, s, C-21H), and 5.72 (1H, s, C-4H) ppm. The ^{13}C nmr data are listed in Table 1. Also recovered was **4** (0.8 g) which was recycled in the synthesis.

Fungal metabolic products

Hitherto unreported data for the products of incubation of **2–4** with the fungi listed above are summarized below. The ^{13}C nmr data are listed in Table 3.

Estra-4,9(10)-diene-11β,17β-diol-3-one (2c)

Infrared ν_{max}: 1640, 2900, 3350 cm^{-1}; ^{1}H nmr included signals at δ 1.08 (3H, s, C-18H), 3.60 (1H, br m, C-11α, 17 H's), and 5.73 (1H, s, C-4H) ppm; ms *m/z* (%): 288 (36) 270 (100), 260 (30). M^+ 288.1701; $C_{18}H_{24}O_3$ requires M^+ 288.1725.

9,11α-Epoxyandrosta-1,4-diene-3,17-dione (5)

Melting point 196–198°C; ^{1}H nmr included signals at δ 0.98 (3H, s, C-18H), 1.53 (3H, s, C-19H), 3.38 (1H, m, C-11βH), 5.73 (1H, s, C-4H), 6.20 (1H, d, J = 10 Hz, C-2H), and 6.63 (1H, d, J = 10 Hz, C-1H) ppm; ms *m/z* (%): 298 (35), 282 (35), 256 (100), 241 (37). M^+ 298.1551; $C_{19}H_{22}O_3$ requires M^+ 298.1569.

Pregna-4,8-diene-3,20-dion-7β-ol (6)

Melting point 128–130°C. ir ν_{max}: 1620, 1665, 1720, 2929, 3430 cm^{-1}; ^{1}H nmr included signals at δ 0.55 (3H, s, C-18H), 1.33 (3H, s, C-19H), 2.13 (3H, s, C-21H), 4.53 (1H, t, J = 5 Hz, C-7αH), and 5.75 (1H, s, C-4H) ppm; ms m/z (%): 328 (60), 310 (25), 295 (31), 267 (28), 253 (16), 225 (100). M^+ 328.1989; $C_{21}H_{28}O_3$ requires M^+ 328.2039.

Pregn-4-ene-9α,14α-diol-3,20-dione (7)

Melting point 100–106°C; ^1H nmr included signals at δ 0.78 (3H, s, C-18H), 1.30 (3H, s, C-19H), 2.10 (3H, s, C-21H), and 5.83 (1H, s, C-4H) ppm; ms m/z (%): 346 (100%), 324 (55), 308 (52), 267 (93). M^+ 346.2162; $C_{21}H_{30}O_4$ requires M^+ 346.2144.

9,11α-Epoxypregn-4-ene-3,20-dion-6β-ol (8)

Melting point 177–179°C; ir ν_{max}: 1670, 1700, 2930, 3350 cm^{-1}; ^1H nmr included signals at δ 0.70 (3H, s, C-18H), 1.63 (3H, s, C-19H), 2.10 (3H, s, C-21H), 3.18 (1H, d, J = 5 Hz, C-11βH), 4.40 (1H, t, J = 4 Hz, C-6αH), and 5.90 (1H, s, C-4H) ppm; ms m/z (%): 344 (100), 326 (41), 311 (20), 301 (14), 283 (45), 267 (18). *Anal.* calcd. for $C_{21}H_{28}O_4$: C 73.23, H 8.19%; found: C 73.10, H 8.47%.

Androsta-1,4,9(11)-triene-3,17-dione (9)

Melting point 148–150°C; ir ν_{max}: 1625, 1665, 1740, 2940 cm^{-1}; ^1H nmr included signals at δ 0.93 (3H, s, C-18H), 1.43 (3H, s, C-19H), 5.55 (1H, br s, C-11H), 6.05 (1H, s, C-4H), 6.24 (1H, d, J = 10 Hz, C-2H), and 7.16 (1H, d, J = 10 Hz, C-1H) ppm; ms m/z (%): 282 (100), 267 (43), 239 (26). M^+ 282.1684; $C_{19}H_{22}O_2$ requires M^+ 282.1621.

Pregna-4,9(11)-diene-3,20-dione-12-α/β-ols (10)

Infrared ν_{max}: 1650, 1685, 1710, 2950, 3350 cm^{-1}; ^1H nmr included signals at δ 0.60 and 0.65 (each 3H, s, C-18H), 1.38 and 1.40 (each 3H, s, C-19H), 2.15 (3H, s, C-21H), 4.00 (1H, d, J = 6 Hz, C-12ξH), 4.43 (1H, d, J = 8 Hz, C-12ξH), 5.75 (1H, s, C-4H), 5.85 (1H, dd, J = 6, 8 Hz, C-11H) ppm. Irradiation at δ 5.85 caused collapse of the signals at δ 4.0 and 4.43 ppm to singlets. Mass spectra m/z (%): 328 (31), 313 (10), 311 (17), 295 (11), 284 (100).

9,11β-Epoxypregn-4-ene-3,20-dione (11)

Melting point 185–190°C; ^1H nmr included signals at δ 0.83 (3H, s, C-18H), 1.43 (3H, s, C-19H), 2.15 (3H, s, C-21H), 3.40 (1H, m, C-11αH), and 5.78 (1H, s, C-4H) ppm; ms m/z (%): 328 (100), 313 (66), 312 (51), 295 (68), 267 (98), 252 (45).

*Incubation of **3** with* C. lunata *in D_2O*

The fungus was grown in the normal way (26), collected by filtration, and resuspended in 10% (v/v) deuterium oxide in distilled water. The cells were allowed to equilibrate for 30 min in this environment, and then substrate (**3**) (0.45 g) was added in the normal manner (3). Subsequent incubation and work-up followed the procedure used for preparative incubations (see Table 2 and ref. 28). The product **7**, isolated by chromatography, was examined by ^2H nmr and showed signals centered at δ 1.25 and 2.57 ppm. Recovered substrate showed only natural abundance levels of deuterium.

Microbial hydroxylation of steroids. 11. Hydroxylation of *A*-nor-, *B*-homo-Δ^1-, and Δ^1-testosterone acetates by *Rhizopus arrhizus*

HERBERT L. HOLLAND AND P. CHINNA CHENCHAIAH

Department of Chemistry, Brock University, St. Catharines, Ont., Canada L2S 3A1

Received September 19, 1984

HERBERT L. HOLLAND and P. CHINNA CHENCHAIAH. Can. J. Chem. **63**, 1127 (1985).

The testosterone derivatives *A*-nortestosterone acetate and *B*-homo-Δ^1-testosterone acetate have been incubated with *Rhizopus arrhizus*, a fungus which hydroxylates testosterone at the C-6β and C-11α positions. These modes of hydroxylation were also observed for the *A*-nor steroid. The *B*-homo steroid, however, was oxidized at C-2β and concurrently hydroxylated at C-6β and C-7aβ (but not at C-11) by *R. arrhizus*. Δ^1 steroids of conventional skeleton were hydroxylated at C-11α by *R. arrhizus*; in addition, Δ^1-androstenedione was epoxidized at the 1,2β position. No C-6 hydroxylation of conventional $\Delta^{1,4}$-3-ketosteroids was observed.

HERBERT L. HOLLAND et P. CHINNA CHENCHAIAH. Can. J. Chem. **63**, 1127 (1985).

On a fait incuber les dérivés de la testostérone, acétates de *A*-nortestostérone et *B*-homo Δ^1-testostérone, avec le *Rhizopus arrhizus*, un champignon qui provoque des hydroxylations en positions C-6β et C-11α. On a aussi observé ces modes d'hydroxylation avec le *A*-nor stéroïde. Toutefois, le *R. arrhizus* provoque une oxydation du *B*-homostéroïde en C-2β ainsi qu'une hydroxylation concurente en C-6β et en C-7aβ (mais pas en C-11). Sous l'influence du *R. arrhizus*, les Δ^1-stéroïdes avec un squelette conventionnel sont hydroxylés en C-11α; de plus, la Δ^1-androstènedione subit une époxydation en position 1,2β. On n'a observé aucune hydroxylation en C-6 avec les $\Delta^{1,4}$ céto-3 stéroïdes conventionnels.

[Traduit par le journal]

A-norandrostanes have recently been found to be capable of interacting with estrogen and androgen receptor proteins in a specific way (1), while the naturally occurring plant hormone brassinolide is a steroid with a 7-membered B ring (2). In view of these developments, and as part of our continuing programme of investigation of steroid hydroxylations by *Rhizopus arrhizus* and other fungi (3), we have now studied *A*-nor and *B*-homo steroids as substrates. The microbial hydroxylations of *A*-nor steroids at C-1β, -6β, -7α, -9α, -11α, -11β, -12β, -14α, -16α, and -21 have been reported, representing in most cases normal modes of hydroxylation by the microorganisms concerned (4, 5); however, the incubations of *A*-nor or *B*-homo steroids with *R. arrhizus* have not been reported.

It was our intention to study the *A*-nor compound **2***a* and *B*-homotestosterone acetate as substrates; the former was readily synthesized, and the corresponding saturated *B*-homo steroid **7***a* was synthesized by Ringold's route (6). The analogous compound in the pregnane series has been converted to *B*-homoprogesterone by monobromination at C-4 followed by dehydrobromination (7) (an exceptional result, since the monobromination of 5α-3-ketosteroids normally occurs at C-2 (8)). When we applied the same procedures to **7***a*, however, we were unable to isolate any C-4 monobrominated product. Even in the presence of limiting bromine concentrations, the major product was the 2,4-dibromide **7***b*, which could be converted to the $\Delta^{1,4}$-dien-3-one **3** in moderate yield.

Faced with the dienone **3** as the only available *B*-homo steroid, we decided to study the $\Delta^{1,4}$-dien-3-ones of normal skeleton **1**, as substrates for the hydroxylating enzymes of *R. arrhizus*. Steroids of this structure have not previously been extensively examined for their ability to act as substrates in these reactions (4, 5).

The ^{13}C nmr spectra of substrates **1**–**3** are reported in Table 1. Product structures were deduced largely from ^{13}C and ^{1}H nmr data. The ^{13}C nmr spectrum of **1***c* has been previously reported; our assignments of resonances to C-7 and C-12 represent a reversal of the original literature values (9), and are based on the shifts predicted (10) from the wider range of substituents at C-17 now available to us. The assignment of resonances in **2***a* and **3** was straightforward and in agreement with those predicted from the values reported for analogous steroids of normal skeleton (10).

Hydroxylation of *A*-nortestosterone acetate **2***a* by *R. arrhizus* gave the C-11α and -6β hydroxysteroids **2***b* and **2***c* respectively. The structures of **2***b* and **2***c* follow from their ^{13}C nmr (Table 3) and ^{1}H nmr (Experimental) spectra, the former being particularly diagnostic in showing clearly the shifts for hydroxyl substitution at C-11α and C-6β anticipated from the published parameters (10).

In contrast, the $\Delta^{1,4}$-dien-3-ones **1** were not hydroxylated at C-6β by *R. arrhizus*, but gave the corresponding 11α-hydroxy derivatives, **4**, as major products (Table 2). Hydroxylations at C-6β and C-11α by *R. arrhizus* represent normal modes of oxidation of Δ^4-3-ketosteroids (4, 11). In the case of the dione **1***c*, however, a second product was also obtained in low yield, to which structure **5** has been assigned. The presence of an epoxy grouping at C-1,2 was indicated by the appearance in the ^{1}H nmr spectrum of an AB quartet at δ 3.37 and 3.62 ppm, one

half of which (3.37) was also coupled to the C-4 proton at δ 5.70 ppm. Both ^{13}C and ^{1}H nmr confirmed the absence of the Δ^1 olefinic bond, and the appearance of new ^{13}C resonances at 55.3 and 61.1 ppm is diagnostic of an epoxide (12).

The β stereochemistry of the 1,2 epoxide of **5** was deduced from ^{1}H nmr, where the downfield shift of the C-19 hydrogen signal indicates the presence of oxygen in a position 1,3-diaxial to the methyl group (13), and ord (optical rotatory dispersion) data (see Experimental), which show the presence of a weak negative $n \rightarrow \pi^*$ Cotton effect between 350 and 450 nm. Application of the octant rules for epoxy ketones (14, 15) predict that **5** should show a weak negative $n \rightarrow \pi^*$ Cotton effect, whereas the α isomer should show an effect of similar magnitude but opposite sign. This finding is in accord with the observed weak positive effect for 2β-hydroxy testosterone (16), and the fact that the epoxide grouping is known to be an "anti-octant" substituent (17).

The *B*-homo steroid **3** gave two products on incubation with *R. arrhizus*, assigned structures **6***a* and **6***b*. The ^{1}H and ^{13}C nmr spectra of **6***a* clearly showed the absence of the Δ^1 bond and the presence of two secondary alcohol groups in a *B*-homo-Δ^4-3-ketosteroid skeleton. One of the hydroxy groups was assigned to the C-2β position on the following rounds. The ^{13}C chemical shift (85.1 ppm) and ^{1}H shift of the associated methine hydro-

b R = Br

gen (4.12 ppm) locate the hydroxyl either adjacent to carbonyl or in an allylic position. The observation of the C-4 hydrogen as a doublet, coupled to the C-6β hydrogen (18), rules out the latter site of substitution. The β stereochemistry of substitution at C-2 follows from the downfield shift of the C-19 methyl group in both the ^{1}H and ^{13}C nmr spectra. Inspection of models of **6***a* and **6***b* (Fig. 1) shows that the C-2α hydrogen exactly bisects the C-1αH—C-1βH angle; the observed multiplicity of the C-2α hydrogen (triplet, J = 7.3 Hz) is in accord with this expectation. The conformation shown in Fig. 1 is different from that found for 2β-hydroxy-Δ^4-3-ketosteroids of normal skeleton (16), but the presence of the seven-membered B-ring in **6***a* and **6***b* introduces conformational restraints on ring A which are absent in normal steroids.

The location of the second hydroxyl group of **6***a* is not obvious, but the multiplicity and chemical shift of the associated methine hydrogen, and the ^{13}C nmr differences between **6***a* and **6***b* (see below), led to the location of this group at C-7aβ. The hydrogen now assigned as C-7aα has the multiplicity anticipated from the dihedral angles (ϕ C-7aαH—C-8H = 180°, ϕ C-7aαH—C-7αH = 90°, ϕ C-7aαH—C-7βH ≃ 145°) present in the predominant C-7 twist chair conformation of ring B shown in Fig. 2 (19). The ^{13}C nmr chemical shift assignments for **6***a* (Table 3) are also consistent with this structure. No other position of hydroxylation in ring B was consistent with these

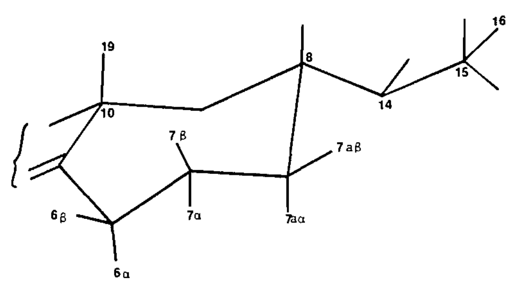

FIG. 3. Conformation of ring B of **6***b*.

values: rings C and D were clearly ruled out as sites of hydroxylation by the unambiguous observation of unperturbed ^{13}C nmr resonances at δ 22.9 (C-11), 24.2 (C-15), and 28.3 (C-16) ppm. *R. arrhizus* has been previously reported to hydroxylate normal steroids at C-7β (4).

The ^1H nmr spectrum of **6***b* clearly shows the presence of an additional hydroxyl group relative to **6***a*, and suggests its location at C-6β. This follows from the chemical shift of the associated methine hydrogen (δ 4.48 ppm) and the observation of the C-4 hydrogen signal as a sharp singlet (cf. **6***a* above), shifted downfield to δ 5.92 ppm. Closer examination of the ^{13}C nmr of **6***b* reveals the following: the C-19 signal, although downfield with respect to that of **6***a*, has not shifted to the extent normally associated with C-6β hydroxylation in normal steroids (10); there has been a 2-ppm downfield shift of the C-15 resonance, and the resonances at C-8 and C-9 show small downfield shifts. These facts are explicable by the assumption that ring B of **6***b* now adopts the alternative C-8 chair conformation shown in Fig. 3 (19). This conformation relieves the C-6β hydroxy – C-19 methyl interaction present in the alternative conformation of Fig. 2, and also has the effect of bringing the C-7aβ alcohol into close proximity with the C-15 hydrogens. In the conformation of Fig. 3, the steric relationship between C-15 and C-7aβ is identical to that of normal steroids, in which hydroxylation at C-7β causes an average downfield shift at C-15 of +2.8 ppm (10). This is not true of either C-7α hydroxylation, nor the presence of hydroxyl at C-7aβ in the conformation of **6***a* shown in Fig. 2. The observed multiplicity of the C-6α hydrogen signal of **6***b* is entirely consistent with that predicted from the C-6—C-7 dihedral angles estimated from the structure of Fig. 3 (C-6αH—C-7βH ≃ 160°, C-6αH—C-7αH ≃ 40°).

The remaining spectral data for **6***a* and **6***b* also accord with the structures discussed above. The absence of a molecular ion in the spectrum of **6***b*, and its low intensity in the spectrum of **6***a*, are probably attributable to a facile loss of water involving the C-2 alcohol, producing the cross conjugated keto group as a stable ion (and indeed as the base peak in the case of **6***b*).

We therefore conclude that, although hydroxylation of A-nortestosterone acetate by *R. arrhizus* shows no effects attributable to the lack of a carbon in the A-ring, the presence of an additional carbon in ring B (as in **3**), coupled with a Δ^1 bond, leads to a new site of oxidation, C-2β, in addition to the more usual hydroxylations at C-6 and C-7. The oxidation of **3** at C-2β is clearly not a conventional mono-oxygenase dependent hydroxylation of the type normally occurring at saturated carbon. However, direct conversion of steroid olefins to saturated alcohols has been observed during fungal hydroxylation,[1] and attributed to a variant of the normal enzymic epoxidation mechanism. It is therefore relevant that $\Delta^{1,4}$ steroids of normal skeleton can be epoxidized at the 1,2β position by *R. arrhizus*. The relationship, if any, between the epoxidation of **1***c* and the hydroxylation at C-2β of **3** will be the subject of future investigation.

[1] See the preceding paper of the series in this journal, ref. 3.

Experimental

Apparatus, materials, and methods

Melting points were determined on a Kofler heating stage and are uncorrected. Infrared spectra were recorded with an Analect 6260FX FTIR. The nmr spectra were obtained with a Bruker WP60 (^{13}C) or WP80CW (^{1}H) at Brock, or with a WM250 at McMaster University, using $CDCl_3$ as solvent and TMS as internal standard. Mass spectra were obtained with an AEI MS30 spectrometer fitted to a Kratos DS-55 data system. Thin layer chromatography was performed on Merck silica gel 60F-254, and column chromatography on silica gel (200–430 mesh). Optical rotation measurements were made at McMaster University using a Perkin–Elmer 241MC polarimeter. The solvent used was chloroform and the path length 1 dm. Elemental analyses were performed by Guelph Chemical Laboratories, Guelph, Ontario, or by the Pascher microanalytical Laboratory, Bonn, W. Germany.

Substrates

The following were commercial samples (Sigma): androsta-1,4-dien-17β-ol-3-one (**1***a*), androsta-1,4-dien-17β-ol-3-one acetate (**1***b*), and androsta-1,4-diene-3,17-dione (**1***c*). *A*-nortestosterone acetate (**2***a*) was prepared from testosterone by the published procedure (20, 21). *B*-homoandrosta-1,4-dien-17β-ol-3-one acetate (**3**) was prepared as outlined below.

*2ξ,4ξ-Dibromo-*B*-homo-5α-androstan-17β-ol-3-one acetate (***7*b*)

B-Homo-5α-androstan-17β-ol-3-one acetate (**7***a*) (100 mg) obtained by Ringold's synthesis (6) was treated with bromine in acetic acid by the procedure used by Himizu and Shichita in the synthesis of *B*-homoprogesterone (7). A single product, **7***b*, was obtained in 48% yield. No monobromo derivative was identified in the reaction mixture. Variation of stoichiometric ratio of reactants and time gave **7***b* and unreacted **7***a* as the only isolable steroids. The title compound had mp 171–172°C. *Anal.* calcd. for $C_{22}H_{32}Br_2O_3$: C 52.38, H 6.35, Br 31.75%; found: C 52.40, H 6.27, Br 32.10%.

B*-Homoandrosta-1,4-dien-17β-ol-3-one acetate (***3***)*

The dibromide **7***b* (0.135 g) was dissolved in DMF (7 mL) to which lithium chloride (0.135 g) had been added, and the mixture kept at 120°C under a nitrogen atmosphere for 16 h. Work-up in the usual way afforded a mixture which contained a single uv absorbing component (tlc). Column chromatography afforded **3** (0.035 g, 40%) as an oil which could not be induced to crystallize. The ^{1}H nmr included signals at δ 0.85 (3H, s, C-18H), 1.30 (3H, s, C-19H), 2.07 (3H, s, OAc), 4.57 (1H, t, J = 7 Hz, C-17αH), 6.07 (1H, s, C-4H), 6.15 and 7.05 (2H, ABq, J = 9 Hz, C-2 and -1 H's respectively); ^{13}C nmr, see Table 1; ms m/z (%): 342 (44), 320 (5), 300 (5), 286 (8), 282 (13), relative to 83 (100). M^+ 342.2322; $C_{22}H_{30}O_3$ requires M^+ 342.2195. *Anal.* calcd. for $C_{22}H_{30}O_3$: C 77.19, H 8.77%; found: C 77.51, H 8.62%.

Incubations with R. arrhizus *ATCC 11145*

Rhizopus arrhizus ATCC 11145 was maintained and incubations were performed as previously described (22), except that an incubation period of 72 h was used. Hitherto unreported spectral and physical data for products **2** and **4**–**6** are listed below. The ^{13}C nmr data are presented in Table 3.

A*-Norandrost-4-ene-11α,17β-diol-3-one, 17-acetate (***2**b*)

Oil; ir ν_{max}: 1682, 1731, 3443 cm^{-1}; ^{1}H nmr included signals at δ 0.88 (3H, s, C-18H), 1.26 (3H, s, C-19H), 2.05 (3H, s, OAc), 3.70–4.15 (1H, m, C-11βH), 4.65 (1H, t, J = 7 Hz, C-17αH), 5.77 (1H, s, C-4H) ppm; ms m/z (%): 332 (26), 314 (33), 304 (9), 286 (7), 279 (29) relative to 149 (100). M^+ 332.1938; $C_{20}H_{28}O_4$ requires M^+ 332.1988. *Anal.* calcd. for $C_{20}H_{28}O_4$: C 72.29, H 8.43%; found: C 72.10, H 8.12%.

A*-Norandrost-4-ene-6β,17β-diol-3-one, 17-acetate (***2**c*)

Melting point 189–191°C; ir ν_{max}: 1685, 1730, 2930, 3369 cm^{-1}; ^{1}H nmr included signals at δ 0.87 (3H, s, C-18H), 1.35 (3H, s, C-19H), 2.03 (3H, s, OAc), 2.25 (2H, br s, C-1H?), 4.65 (1H, t, J = 7 Hz, C-17αH), 4.85 (1H, t, J = 3 Hz, C-6αH), 5.78 (1H, s, C-4H) ppm; ms m/z (%): 332 (2), 316 (12), 288 (56), 274 (10), 256 (38) relative to 147 (100). M^+ 332.1929; $C_{20}H_{28}O_4$ requires M^+ 332.1988. *Anal.* calcd. for $C_{20}H_{28}O_4$: C 72.29, H 8.43%; found: C 72.64, H 8.18%.

*Androsta-1,4-diene-11α,17β-diol-3-one (***4**a*) and androsta-1,4-diene-3,17-dion-11α-ol (***4**c*)*

Spectral data for these compounds are in agreement with those previously published (23).

*Androsta-1,4-diene-11α,17β-diol-3-one, 17-acetate (***4**b*)

Oil; ^{1}H nmr included signals at δ 0.80 (3H, s, C-18H), 1.20 (3H, s, C-19H), 1.92 (3H, s, OAc), 4.0 (1H, d of t, J = 10, 6 Hz, C-11βH), 4.60 (1H, t, J = 8 Hz, C-17αH), 5.95 (1H, s, C-4H), 6.03 and 7.65 (2H, ABq, J = 10 Hz, C-2 and -1H's) ppm; ms m/z (%): 344 (12), 326 (2), 284 (2), 266 (4), 251 (3) based on 122 (100). M^+ 344.2031; $C_{21}H_{28}O_4$ requires M^+ 344.1987.

*1,2β-Epoxyandrost-4-ene-3,17-dione (***5***)*

Melting point 200–202°C; ir ν_{max}: 1663, 1738, 2956 cm^{-1} (no O—H stretch); $[\alpha]^{21}_{589}$ −79° (c = 0.31), $[\alpha]^{21}_{576}$ −85°, $[\alpha]^{21}_{546}$ −107°, $[\alpha]^{21}_{434}$ −331°, $[\alpha]^{21}_{404}$ −433°, $[\alpha]^{21}_{366}$ −201°; ^{1}H nmr included signals at δ 0.92 (3H, s, C-18H), 1.40 (3H, s, C-19H), 3.37 (dd, J = 2, 4 Hz) and 3.62 (d, J = 4 Hz) (each 1H, AB, C-2 and C-1 H's respectively), and 5.70 (1H, d, J = 2 Hz, C-4H) ppm; ms m/z (%): 300 (4), 284 (3), 272 (2), 226 (50), based on 57 (100). M^+ 300.1817; $C_{19}H_{24}O_3$ requires M^+ 300.1725. *Anal.* calcd. for $C_{19}H_{24}O_3$: C 76.0, H 8.0%; found: C 75.72, H 8.0%.

B*-Homoandrost-4-ene-2β,7aβ,17β-triol-3-one, 17-acetate (***6**a*)

Oil; ir ν_{max}: 1665, 1729, 2930, 3460 cm^{-1}; ^{1}H nmr included signals at δ 0.89 (3H, s, C-18H), 1.33 (3H, s, C-19H), 2.03 (3H, s, OAc), 3.90 (1H, d of t, J = 4, 11.5 Hz, C-7aαH), 4.12 (1H, t, J = 7.3 Hz, C-2αH), 4.64 (1H, t, J = 8 Hz, C-17αH), and 5.77 (1H, d, J = 1.4 Hz, C-4H) ppm; ms m/z (%): 374 (1.3), 358 (49), 343 (7), relative to 55 (100). $M^+ - H_2O$ 358.2124. $C_{22}H_{30}O_4$ ($M - H_2O$) requires 358.2144.

B*-Homoandrost-4-ene-2β,6β,7aβ,17β-tetrol-3-one, 17-acetate (***6**b*)

Oil; ir ν_{max}: 1663, 1729, 2931, 3430 cm^{-1}; ^{1}H nmr included signals at δ 0.89 (3H, s, C-18H), 1.46 (3H, s, C-19H), 2.02 (3H, s, OAc), 4.0 (1H, d of t, J = 3.5 and 11.5 Hz, C-7aαH), 4.15 (1H, t, J = 7.3 Hz, C-2αH), 4.48 (1H, d of d, J = 7.6, 9.6 Hz, C-6αH), 4.63 (1H, t, J = 8 Hz, C-17αH), and 5.92 (1H, s, C-4H) ppm; ms m/z (%): 374 (100), 359 (7), 332 (10), 314 (6). $M^+ - H_2O$ 374.2087. $C_{22}H_{30}O_5$ ($M^+ - H_2O$) requires 374.2093.

Surface tension and density of the molten $PbCl_2$–KCl–NaCl ternary system

T. FUJISAWA,[1] T. UTIGARD, AND J. M. TOGURI

Department of Metallurgy and Materials Science, University of Toronto, Toronto, Ont., Canada M5S 1A4

Received August 15, 1984

T. FUJISAWA, T. UTIGARD, and J. M. TOGURI. Can. J. Chem. **63**, 1132 (1985).

The maximum bubble pressure method was used to determine the surface tension and density of melts within the $PbCl_2$–KCl–NaCl system. The temperature range of this study was from 450 to 800°C. In all cases, the surface tension was found to decrease with increasing temperature. At constant molar ratios of KCl to NaCl, a minimum in the surface tension was observed at approximately 40 mol% $PbCl_2$. The ternary surface tension values were found to obey the simple additivity expression of the binary surface tensions of $PbCl_2$–KCl and $PbCl_2$–NaCl. Based on these findings, constant surface tension contours have been drawn.

The density obtained in the present study agree well with the previously determined densities using a bottom-balance Archimedean technique reported by this laboratory.

T. FUJISAWA, T. UTIGARD et J. M. TOGURI. Can. J. Chem. **63**, 1132 (1985).

On a utilisé la méthode de la pression maximale de la bulle pour déterminer la tension de surface et la densité de produits fondus dans le système $PbCl_2$–KCl–NaCl. On a effectué cette étude de 450 à 800°C. Dans tous les cas, la tension superficielle diminue avec une augmentation de la température. A des rapports constants de KCl/NaCl, on a trouvé qu'il existe un minimum dans la tension superficielle qui se situe à environ 40 mole pourcent de $PbCl_2$. On a trouvé que les valeurs des tensions superficielles tertiaires obéissent à une expression simple d'additivité des tensions superficielles binaires du $PbCl_2$–KCl et $PbCl_2$–NaCl. Sur la base de ces observations, on a pu établir des contours de tensions superficielles constantes.

La densité obtenue au cours du présent travail est en bon accord avec les densités déterminées antérieurement en utilisant une technique mise au point dans notre laboratoire et faisant appel à une balance d'Archimède.

Introduction

The present process for the extraction of lead from lead sulphide concentrates involves sintering followed by high temperature carbon reduction in a blast furnace. Although this process is effective for lead production from high grade lead sulphide concentrates, it does give rise to problems with respect to environmental concerns and to the treatment of complex lead ores. The public concern of the environmental effects of lead will no doubt introduce strict legislation controlling the emissions of heavy metals as well as sulphur dioxide.

In anticipation of such regulations, new processes have been proposed. One such process is the conversion of lead sulphide to a chloride followed by fused-salt electrolysis to produce metallic lead and chlorine (1–3). The chlorine produced is recycled directly or indirectly for the production of lead chloride. Various steps in this process are being actively investigated in Canada by CANMET.

Fused-salt electrolysis for the recovery of lead poses a number of problems. Lead chloride alone is not a good electrolyte. It has a high vapour pressure and exhibits poor current efficiency with respect to lead production. However, the addition of alkali chlorides decreases the fuming of lead chloride and improves the electrical conductivities. The favoured electrolyte composition appears to be the $PbCl_2$–KCl–LiCl ternary system. One problem with this system is the hygroscopic nature of LiCl. For this reason, the $PbCl_2$–KCl–NaCl ternary system has been suggested and serves as an alternative electrolyte in spite of its slightly lower molar conductivity.

Unfortunately, the physical properties of these ternary systems are scarce. Recently, the densities and molar volumes of melts in both the $PbCl_2$–KCl–NaCl and $PbCl_2$–KCl–LiCl ternary systems were determined in this laboratory (4). During this study, it was noted that alkali chloride melts containing $PbCl_2$ tended to creep up the crucible wall. Such observation suggests that the surface tension of these melts is quite low and could give rise to creeping of the electrolyte during cell operation. This phenomenon could lead to poor current efficiency. However, surface tension data on these systems are not available in the literature.

Consequently, the present study was undertaken to determine the surface tension of the molten salt system $PbCl_2$–KCl–NaCl as a function of composition and temperature in the range of interest for the electrolytic process of lead recovery.

Experimental

The maximum bubble pressure technique was selected as the method for the determination of the surface tension of the molten salts. With this method, the density of the liquid salt can be measured simultaneously with the surface tension. The maximum bubble pressure method at high temperatures has been used in many investigations (5–7) of the surface tension of molten salts and is known to give accurate and reproducible values. The principles of this method are well established. It involves the slow formation of a gas bubble at the tip of a capillary immersed in the liquid. Simultaneously, the pressure of the gas used to form the bubble is measured in order to determine the maximum pressure developed inside the bubble at the very instant it bursts. Schrödinger (8) developed the following relationship between the surface tension and the maximum bubble pressure.

$$[1] \quad \gamma = \frac{rP_\gamma}{2}\left[1 - (2/3)\left(\frac{r\rho g}{P_\gamma}\right) - (1/6)\left(\frac{r\rho g}{P_\gamma}\right)^2\right]$$

γ is the surface tension, r is the radius of the capillary, P_γ is the maximum pressure difference inside and outside the bubble at the level of the end of the tip, ρ is the density difference between the liquid salt and the gas, and g is the acceleration of gravity.

Apparatus

The overall apparatus used in this investigation is shown in Fig. 1. The furnace had a uniform temperature (2.5°C) region of 5 cm. The salt mixtures were contained in graphite crucibles with an inner diameter of 26 mm and a height of 47 mm under a purified argon

[1]Present address: Department of Metallurgy, Nagoya University, Nagoya, Japan.

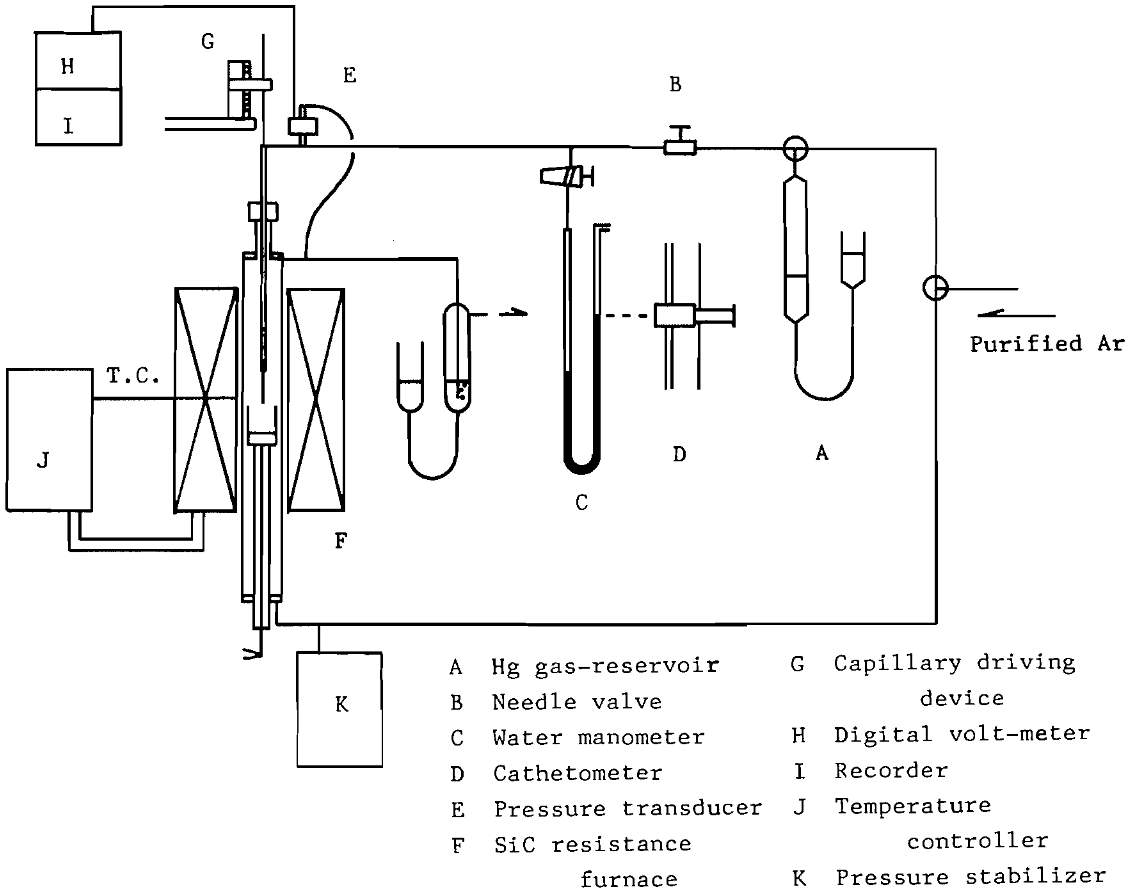

FIG. 1. Surface tension apparatus.

atmosphere. The capillary quartz tubes were 5 cm long, with an outer diameter of about 2.1 mm and with an inner diameter of about 1.03 mm. In order to obtain precise results, it was necessary to pay careful attention to the capillary tip. The bore must be as round as possible, the end flat and perpendicular to the axis of the capillary, and the edge of the orifice very sharp. A microscope was used to check the condition and the diameter of the orifice. All measurements were corrected for thermal expansion of the capillary orifice.

The quartz capillary tube was connected to an alumina tube with alumina cement (Ceramabond #503). This assembly was connected to a stainless steel tube which could be moved slowly (0.417 mm/min) up or down with a motor. The immersion depth of the capillary into the liquid was measured with a cathetometer and also calculated from the rotating speed of the motor. The pressure inside the capillary tube was measured with a pressure transducer (Model PL283TC-2.5-350, Stathan Instruments Inc., Los Angeles) with a sensitivity of 0.001 mV corresponding to 1 Pa. The high purity argon (99.999% min.) used to form the bubbles was passed through a copper getter furnace and through two drying columns packed with drierite and P_2O_5 to remove any possible traces of oxygen and water.

Materials

The potassium chloride (Fisher A.C.S. grade), the sodium chloride (Fisher U.S.P. grade), and the lead chloride (Baker Analysed reagent grade) were pre-dried in a vacuum oven at 150°C. As required, certain amounts of each salt were mixed together to form the desired salt mixture. This mixture was placed into a graphite crucible located in the purification furnace and kept at about 180°C under vacuum (1 Pa) for about 10 h. Argon was then introduced and the salt mixture heated to just above the melting point. Chlorine gas was bubbled through the melt for about 1 h. to remove any oxides. This was followed by bubbling of purified argon gas through the melt for about 1 h to remove any dissolved chlorine. The melt was then quenched and stored in a desiccator until required. The vaporization loss of lead chloride during the purification treatment was found to be negligibly small.

Procedure

A graphite crucible with the premixed, purified salt mixture was positioned inside the furnace. The capillary tip was cleaned with alcohol and dried with an argon gas jet before it was placed about 5 cm above the surface of the salt mixture. Each capillary tip was used for only one experiment. The furnace was then flushed with argon and slowly heated up to the desired temperature. Excess pressure was applied to the capillary while it was lowered towards the melt surface. The capillary was then lowered very slowly until a sudden pressure jump was registered by the pressure transducer as shown in Fig. 2, indicating that the capillary had touched the melt surface. The capillary was then stopped and the surface position was recorded. The bubbling rate was adjusted to about 1 bubble/min which was in the region where the transducer output was independent of the gas flow-rate. The pressure was increased linearly with the immersion depth until a bubble was released at the capillary tip followed by a sudden decrease in pressure. The capillary immersion depth was changed several times while the maximum bubble pressure was recorded. The pressure drop caused by the formation of a bubble at the capillary tip is the difference in the pressure just before the bubble bursts and after it has burst as shown by the sawtoothed curve in Fig. 2. By measuring the maximum bubble pressure at different immersion depths, the density of the salt can be calculated from the slope of the curve formed when the maximum pressure is plotted as a function of immersion depth as shown in Fig. 3. From the same plot, the pressure drop caused by the formation of the bubble can be found as the maximum pressure for zero immersion depth. Using this pressure value the surface tension of the salt mixture can be calculated using Schrodinger's equation. The temperature effect on the surface tension and the density

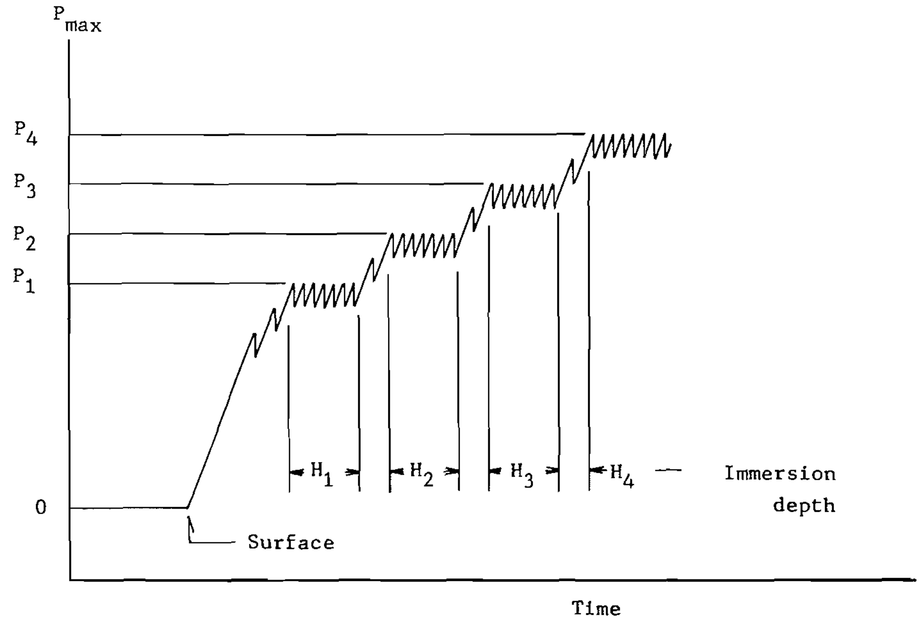

FIG. 2. Typical pressure transducer output.

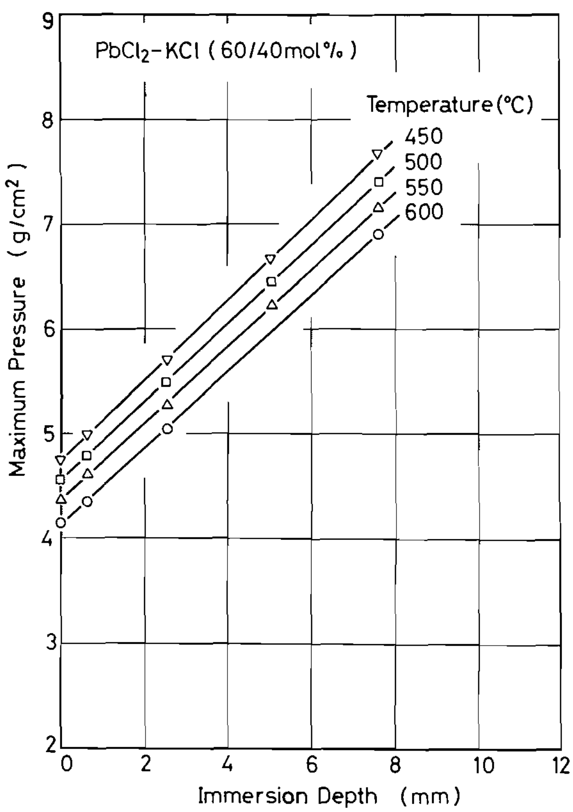

FIG. 3. Effect of immersion depth on the maximum pressure: $PbCl_2$–KCl system.

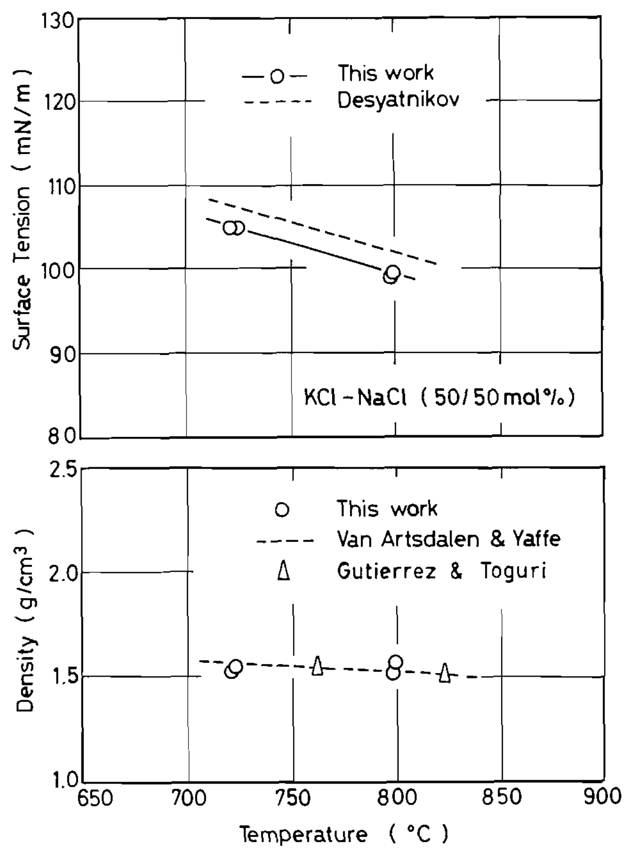

FIG. 4. Surface tension and density of KCl–NaCl (50/50 mole ratio) as a function of temperature.

were determined during both heating and cooling cycles.

A typical linear relationship between the maximum pressure and immersion depth is shown in Fig. 3 for a melt containing 60 mol% $PbCl_2$ and 40 mol% KCl. The effect of increasing the temperature is to decrease the maximum bubble pressure for a constant depth of immersion.

Results and discussion

The maximum bubble pressure apparatus was tested by measuring the surface tension and density of a 50 mol% mixture of NaCl–KCl. The results of this study are shown in Fig. 4. The surface tension obtained with the present apparatus is within 2.5% of the data of Desyatnikov (7) which are recommended by Janz *et al.* (9). Desyatnikov also used the maximum bubble pressure method. On the other hand, the density data obtained are in excellent agreement with both the recent data of

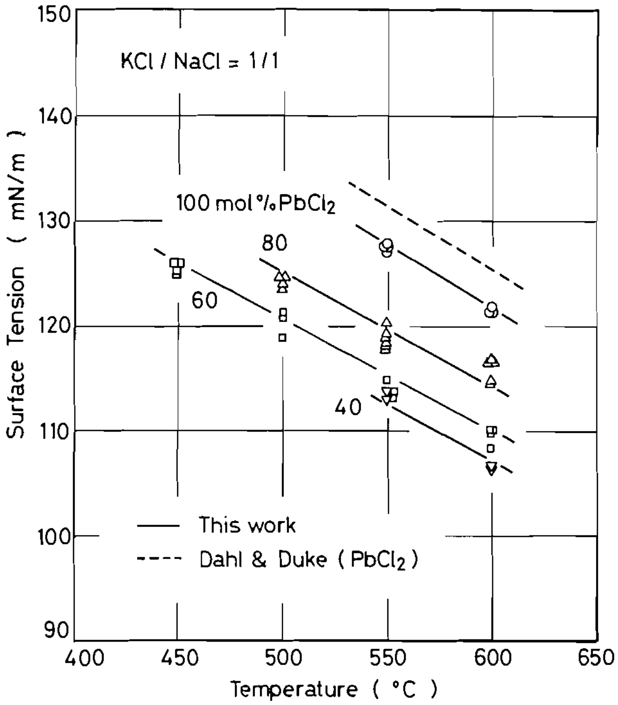

FIG. 5. Temperature dependency of surface tension at constant KCl/NaCl molar ratio in the $PbCl_2$–KCl–NaCl system.

Gutierrez and Toguri (4) and the older data of Van Artsdalen and Yaffe (10).

Based on these results, the surface tension and the density of pure $PbCl_2$ and the binary and ternary mixtures of $PbCl_2$, KCl, and NaCl have been measured within the temperature range of 450 to 600°C.

In the case of pure $PbCl_2$, the experiments were performed at two temperatures, 550 and 600°C. The upper limit was dictated by the vaporization loss of $PbCl_2$ and the lower limit by its melting point. Within the experimental temperature range the surface tension can be represented by the following equation:

$$[2] \quad \gamma = 227.9 - 0.122T \text{ (mN/m)}$$

As shown in Fig. 5, the present results are approximately 3.7% below those reported by Dahl and Duke (11) which are shown by the dotted line and which were obtained using the maximum bubble pressure method.

Our results both for the pure $PbCl_2$ and for the NaCl–KCl binary melts are approximately 2.5 to 3.7% below the reported values (7, 11). One likely systematic error is that as the quartz tube comes in contact with the liquid surface, the tube gets wetted and the liquid advances up the side of the tube. It has been estimated that due to this phenomenon, the true liquid surface falls approximately 0.1 mm in comparison with the surface detected when the capillary tube enters the liquid. The uncertainty in the measurements of the capillary immersion depth using a cathetometer is estimated to 0.15 mm giving a total of 0.25 mm with a corresponding uncertainty in the surface tension values of approximately 2%. With an additional error of approximately 1% caused by the measurements of the capillary radius and the maximum bubble pressure, the total uncertainty is estimated to be 3%.

The effect of temperature on the surface tension of melts containing equimolar mixtures of KCl and NaCl with varying amounts of $PbCl_2$ is also shown in Fig. 5. The results indicate

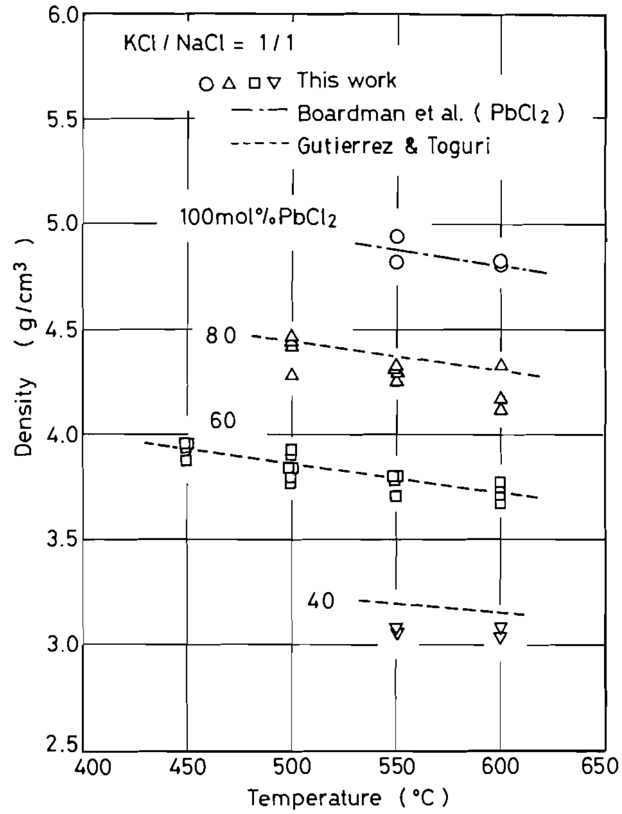

FIG. 6. Temperature dependency of density at constant KCl/NaCl molar ratio in the $PbCl_2$–KCl–NaCl system.

that the surface tension decreases linearly with increasing temperature and decreases with decreasing amount of $PbCl_2$ for melts containing more than 40 mol% $PbCl_2$. The corresponding density values are given in Fig. 6. The density for pure $PbCl_2$ obtained in the present study is in good agreement with that of Boardman *et al.* (12). The effect of temperature on the density of ternary melts is also illustrated and shows a linear decrease with increasing temperatures. Good agreement is found with the reported values of Gutierrez and Toguri (4) as shown by the dotted lines. Decreasing the concentration of $PbCl_2$ leads to a decrease in melt density.

The surface tension and the density were also measured for mixtures with a constant amount of $PbCl_2$ (60 mol%) and with varying amounts of KCl and NaCl. Figure 7 shows typical results for the effect of NaCl addition on the surface tension at various temperatures. Within the experimental accuracy, the surface tension increases linearly with increase in NaCl at constant $PbCl_2$ concentration. Increasing the temperature decreases the surface tension. The corresponding densities are illustrated in Fig. 8.

The surface tension of the binary mixture of $PbCl_2$–NaCl is higher than that of a mixture containing $PbCl_2$ and KCl. From the obtained data, an almost linear relation can be observed between the surface tension of the ternary mixtures and the ratio of KCl to NaCl at constant $PbCl_2$ contents. Similar relations are observed also for the density values with the highest density values in the $PbCl_2$–NaCl binary.

The compositions of the ternary system can be expressed by the parameters y and t, where

$$[3] \quad y = x_{PbCl_2}$$

$$[4] \quad t = x_{KCl}/(x_{KCl} + x_{NaCl})$$

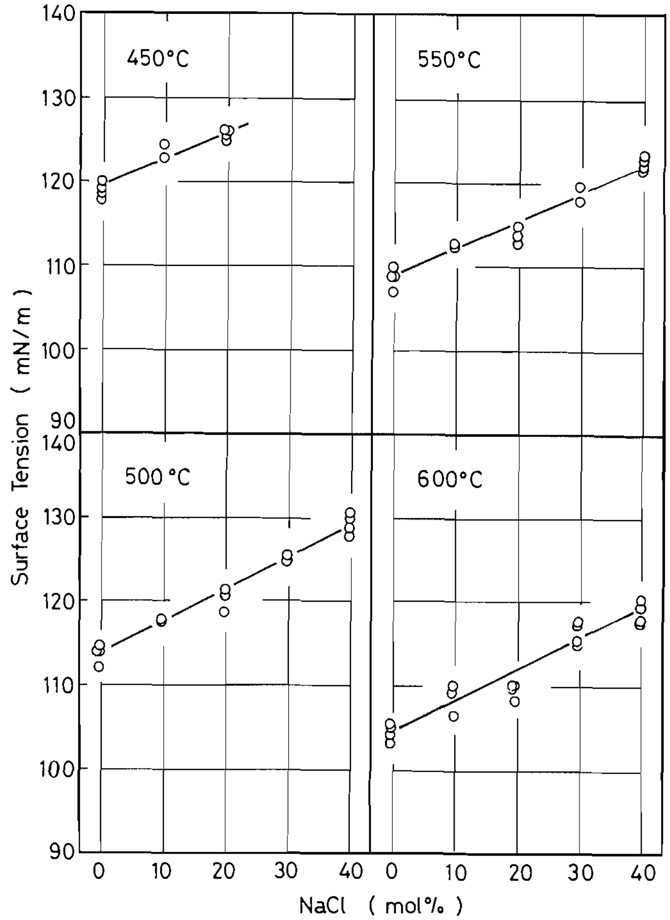

FIG. 7. Composition dependency of surface tension at constant $PbCl_2$ content (60 mol%) in the $PbCl_2$–KCl–NaCl ternary system.

The average surface tension values at each temperature and composition are given in Table 1 together with the fitted coefficients of the linear equation

$$[5] \quad \gamma = A + B^{*}T(\mathrm{K})\,(\mathrm{mN/m})$$

The corresponding average density values are given in Table 2 together with the fitted coefficients of the linear equation

$$[6] \quad \rho = C + D^{*}T(\mathrm{K})\,(\mathrm{g/cm^3})$$

Dahl and Duke (11) showed that the surface tension of the lead chloride-alkali chloride binary mixtures have a minimum value at approximately 40 mole percent $PbCl_2$. The extent of this minimum increases as the size of the alkali ion increases (from Na to Cs). A similar minimum in the surface tension was observed in this work. By extrapolating the values of the equimolar binary mixture of KCl and NaCl to 823 and 873 K, a pronounced minimum can be observed at a $PbCl_2$ content of approximately 40 mol%, as shown in Fig. 9. The plotted points are based on the average experimental values and the lines are the least-squares fitted second order polynomials. This behaviour corresponds well with that observed by Dahl and Duke (11) and by Sternberg *et al.* (13). This behaviour may be explained by the formation of surface active $PbCl_{2+n}^{n-}$ complexes, where the value of *n* may be 1, 2, or 4. Support for this suggestion comes from studies of Raman spectra (14), surface tension measurements (11), and density measurements (15). Similar complex formation has also been suggested in mixtures

of $CdCl_2$ with alkali chlorides based on surface tension measurements (16).

The surface tension of ternary mixtures with a given $PbCl_2$ mole fraction can be calculated, within experimental errors from the two binary systems $PbCl_2$–KCl and $PbCl_2$–NaCl by the following expression:

$$[7] \quad \gamma(\text{ternary}) = t^{*}\gamma_{12} + (1 - t)^{*}\gamma_{13}$$

where γ_{12} and γ_{13} are the surface tension of the binaries $PbCl_2$–KCl and $PbCl_2$–NaCl with the required $PbCl_2$ content. By assuming that this additive relation is valid throughout the ternary system, it is possible to calculate the surface tension of any mixture from the data of the two binaries $PbCl_2$–KCl and $PbCl_2$–NaCl. This additive behaviour has previously been

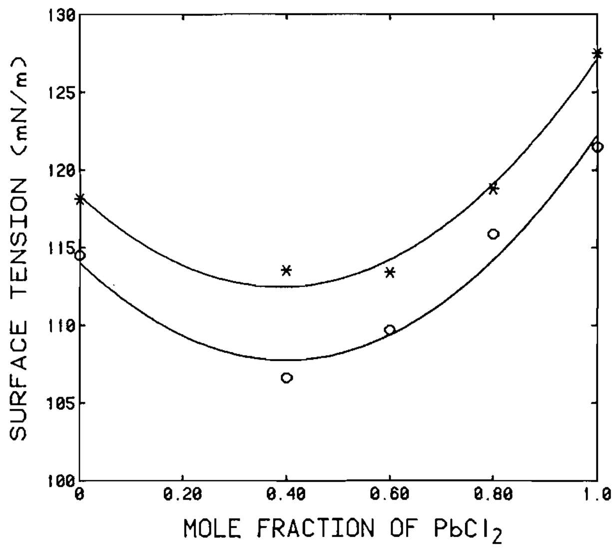

FIG. 9. Composition dependency of surface tension at constant KCl/NaCl molar ratio (50/50).

found (4) to be valid for the molar volumes of ternary mixtures of $PbCl_2$, KCl, and NaCl. By using reported (9) binary surface tension values, the following equations were found by a least squares curve fitting:

$PbCl_2$–KCl:

$$[8] \quad \gamma_{12} = 177.35 - 17.82*y + 73.49*y^2 - (6.44 + 5.94*y)*T$$

$PbCl_2$–NaCl:

$$[9] \quad \gamma_{13} = 218.45 - 39.2*y + 42.02*y^2 - (9.52 + 1.44*y)*T$$

$PbCl_2$–KCl–NaCl

$$[10] \quad \gamma = t*\gamma_{12} + (1 - t)*\gamma_{13}$$

By using these equations, constant surface tension lines can be calculated. Figure 10 shows the liquidus lines and the constant surface tension lines for the $PbCl_2$–KCl–NaCl ternary system at 873 K. For a constant $PbCl_2$ content the surface tension

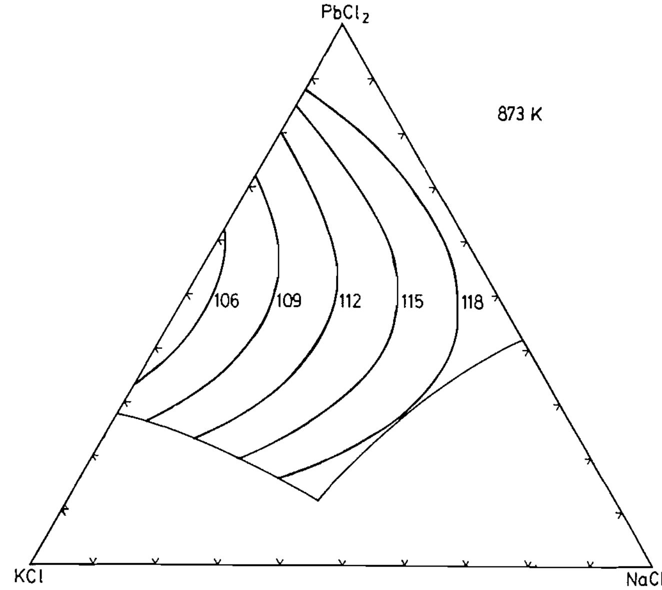

FIG. 10. Constant surface tension lines for the $PbCl_2$–KCl–NaCl ternary system at 873 K.

increases on going from the KCl- to the NaCl-rich side. For a given KCl-to-NaCl ratio a minimum in the surface tension is observed at approximately 45 mol% $PbCl_2$, which is slightly higher than that found in this study. The values measured in this work are all within 3% from those calculated by the above equations with the exception of the mixture of equimolar amounts of KCl and NaCl with 40 mol% $PbCl_2$ where the deviation is 4%. This is consistent with the present study in which the minimum in the surface tension was obtained for mixtures containing 40 mol% $PbCl_2$.

The density values obtained in this work using the maximum bubble pressure method are not expected to be of the same accuracy as those obtained by direct Archimedean methods. Nevertheless, the data obtained in the present study were in excellent agreement with those of Gutierrez and Toguri (4) who used a bottom-balance Archimedean technique.

Conclusions

(*1*) The surface tension and densities of the $PbCl_2$–KCl–NaCl ternary system have been determined over the temperature range 450 to 650°C by a maximum bubble pressure method.

(*2*) The surface tension of these melts were found to be additive at constant values of y and this behaviour could be described by the additivity rule with respect to t:

$$\gamma = t*\gamma_{12} + (1 - t)*\gamma_{13}$$

where the two binary systems, each containing $PbCl_2$, are denoted by the subscripts 12 and 13.

GILLES VILLEMURE, HIDEOMI KODAMA, and CHRISTIAN DETELLIER. Can. J. Chem. **63**, 1139 (1985).

A pH 7.0 solution of methyl viologen, tris(2,2′-bipyridyl)ruthenium(II) chloride and triethanolamine acting as a sacrificial donor, produces hydrogen when irradiated by visible light (>395 nm) in the presence of a montmorillonite. We have observed a maximum production of hydrogen corresponding to an optimum ratio methyl viologen/clay. Preferential adsorption studies have allowed us to relate this optimum ratio to a particular distribution of the dicationic organic species on the clay surface: methyl viologen is intercalated into the layers and shares the occupancy of the external surface area in a ratio three-to-one with tris(2,2′-bipyridyl)ruthenium(II). Nine different homoionic clays were prepared and, compared to the natural one, showed no drastic difference in the hydrogen production.

GILLES VILLEMURE, HIDEOMI KODAMA et CHRISTIAN DETELLIER. Can. J. Chem. **63**, 1139 (1985).

En présence d'une montmorillonite, soumise à l'irradiation par la lumière du visible (>395 nm), une solution de viologène de méthyle, de chlorure de tris(2,2′)-bipyridyle de ruthénium(II) et d'un donneur sacrificiel (la triéthanolamine), produit de l'hydrogène. Nous avons observé une production maximum d'hydrogène correspondant à un rapport optimum de viologène de méthyle/argile. Des études d'adsorption préférentielle ont permis de relier ce rapport optimum à une distribution particulière des espèces chargées dicationiques sur la surface de l'argile: le viologène de méthyle est intercalé entre les couches et partage l'occupation de la surface externe avec le bipyridyle de Ruthénium dans un rapport trois/un. Neuf argiles homoioniques différentes ont été préparées et ne montrent pas de différence notable pour ce qui est de la production d'hydrogène, lorsque comparées à l'argile naturelle.

Introduction

Montmorillonite is a naturally occurring aluminosilicate (1) with a layer structure. Each layer is built up of two tetrahedral Si—O_4 sheets with their vertices pointing inwards, between which cations, mainly Al(III), are octahedrally coordinated. Isomorphous replacement of aluminum(III) by magnesium(II) or iron(II) in the octahedral sheet and/or of silicon(IV) by aluminum(III) in the tetrahedral sheets results in a global negative charge which is balanced by aquated cations (Na^+ and/or Ca^{2+}) occupying the interlamellar space. Those cations are exchangeable and can be replaced by any positively charged organic or inorganic species. Interlamellar water molecules can also be exchanged with organic neutral molecules. Therefore, this fascinating material has known many applications. "Maya Blue", an acid, base, or temperature-resistant pigment was obtained by Mayas in the eighth century by incorporating an organic pigment (indigo) into a clay (attapulgite) (2, 3). Clays may have played an important role in the prebiotic formation of oligopeptides (4, 5). Recently, organic reactions effected by clay supported, or intercalated, reagents have been developed (6), and a rhodium catalyst intercalated into hectorite layers displays selectivity for olefin reduction (7). Clays play an important role in protecting ground water sources from contamination by capturing heavy metals (8) or organic herbicides such as paraquat (9, 10).

Paraquat (1,1′-dimethyl-4,4′-dipyridinium dichloride), also called methyl viologen, is used as an effective electron relay in the process of water photoreduction (11). Hydrogen production from water photosplitting by visible light is an important goal in solar energy conversion and storage. A system consisting of an electron relay, such as methyl viologen (MV^{2+}), a photosensitizer, such as tris(2,2′-bipyridine)ruthenium(II) ($Ru(bpy)_3^{2+}$), a sacrificial donor, such as triethanolamine (TEOA), and a catalyst, such as colloidal platinum, can effect water photoreduction (12). We have shown that this system in the absence of platinum, but in the presence of a natural clay, called Wyoming Bentonite, produces hydrogen, if irradiated by visible light, at pH 7.0 (13). Clay minerals (sepiolite or hectorite) have been used as a supporting material for a water photooxidation catalyst, RuO_2 (14), or as a simultaneous support for two catalysts, RuO_2 — in view of water photooxidation — and Pt — in view of water photoreduction (15). We show in this article how hydrogen is photoproduced in the presence of a natural clay, and we propose an interpretation for the role of the clay.

Experimental

Tris(2,2′-bipyridyl)ruthenium(II) chloride was purchased from Alfa, methyl viologen, triethanolamine, and sodium ethylene diamine tetraacetate (EDTA) from Aldrich, and were used without further purification. Buffers were Fisher solutions (monobasic potassium phosphate and sodium hydroxide for pH 7.0 and potassium biphthalate for pH 4.0). The clay was a Wyoming Bentonite from Clay Spur, Wyoming, USA. The <0.2 μm fraction of Wyoming Bentonite was separated using conventional techniques (gravitation).

Homoionic clays were prepared by saturating the original bentonite (mainly Na-form) with one of the following chloride solutions: Ni(II), Cu(II), Zn(II), Co(II), Mg(II), Ca(II), Sr(II), Li(I), or NH_4(I). Excess salts were removed by dialysis. The reaction mixtures used for the

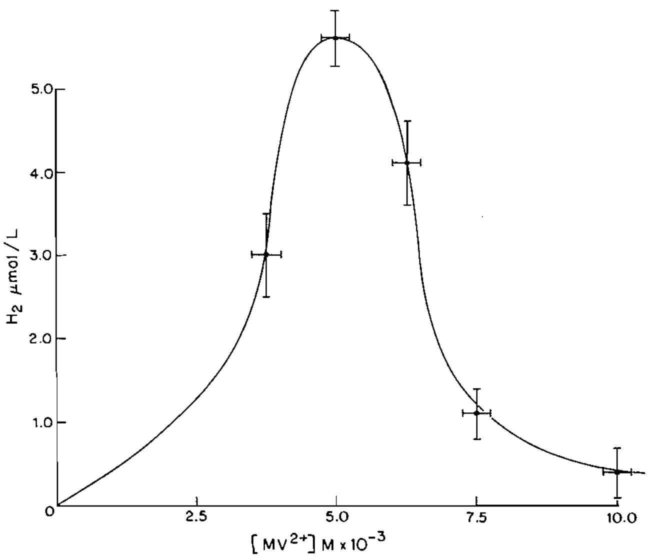

FIG. 1. Production of hydrogen as a function of MV^{2+} concentration (see Experimental part for description of the conditions).

experiment given in Fig. 1 were prepared in the following way, keeping the same order of addition of the various reagents under argon: 10 mL of the pH 7.0 buffered solution was added to 0.8 mL of TEOA, followed by the addition of 0.2 g of clay, a variable amount of MV^{2+}, 0.0192 g of $Ru(bpy)_3^{2+}$, and deoxygenated and deionized water in order to keep a constant total volume of 60 mL. Other experiments were based on the same typical procedure. The reaction mixture in a round bottom flask (cross-sectional area 75 cm^2) was then illuminated under argon with a 300 W tungsten–halogen lamp (at 25 cm from the center of the solution) through a 395 nm glass filter (Ealing, GG-395). Quantitative determinations of the hydrogen produced was effected by gas chromatographic analysis on a 5 Å molecular sieves column. Oriented thin films of clay which had been exchanged by MV^{2+} and $Ru(bpy)_3^{2+}$ were examined by an X-ray diffraction method to measure the change in d_{001}-spacing of the clay. The clay films were prepared by drying clay suspension (containing 20 mg sample) on glass slides. Diffraction patterns were recorded on a Scintag computer-automated X-ray diffractometer using Co radiation. Adsorption of methyl viologen or $Ru(bpy)_3^{2+}$ by montmorillonite was quantitatively measured by uv–visible spectra of the supernatant after 15 h stirring of the Na^+-exchanged clay in the methyl viologen (257.5 nm band) or $Ru(bpy)_3^{2+}$ (452 nm band) solutions.

Results and discussion

We have previously shown (13) that a solution of MV^{2+}, $Ru(bpy)_3^{2+}$, and TEOA at pH 7.0, in the presence of clay, produces a maximum amount of hydrogen at a given clay concentration. We have now checked that this maximum corresponds to an optimum value of the ratio MV^{2+}/clay and not to an opacity effect due to a too large clay concentration. Figure 1 shows the production of hydrogen as a function of methyl viologen concentration for a given amount of clay (3.3 g/L).[2] In the previously reported (13) experiment, and in this experiment, the maximum amount of hydrogen evolved corresponds to the same ratio [MV^{2+}]/[clay], equal to 1.5 mmol of MV^{2+}/g clay. This is three times higher than the typical cation exchange capacity of montmorillonite (100 mequiv./100 g) (10).

The production of hydrogen was also followed as a function of the concentration of clay and MV^{2+}, when their ratio was kept at a value close to the optimum observed value (Table 1). Since the concentration of $Ru(bpy)_3^{2+}$ was kept constant, the hydrogen production should increase with an increase in the MV^{2+} concentration. However, the observed hydrogen production increase depended only slightly upon the quantity of MV^{2+} in the experiment (Table 1). The opacity of the reaction mixture becomes important at high clay concentrations and can counterbalance a higher concentration of electron relay species. We checked that the system was independent of the nature of the cation with which the clay was saturated. That is for the nine different homoionic montmorillonites used (Table 2), we did not observe any synergistic effect between methyl viologen and the interlayer cation for the hydrogen production. The order of magnitude of the hydrogen production is the same as the one observed in the case of the original clay.

We determined the adsorption capacity of a homoionic clay (<0.2 μ) for MV^{2+} and $Ru(bpy)_3^{2+}$ (see Experimental). The maximum quantity of MV^{2+} and $Ru(bpy)_3^{2+}$ adsorbed by the clay were 89 ± 8 mequiv./100 g and 83 ± 5 mequiv./100 g, respectively. These values are in good agreement with literature data (10) for MV^{2+} (100 mequiv./100 g) and close to the exchange capacity of a typical montmorillonite (102 mequiv./100 g) (10). Figures 2 and 3 show the competitive adsorptions of MV^{2+} and $Ru(bpy)_3^{2+}$ by the montmorillonite.

When the two cations were added simultaneously to the clay suspension (Fig. 2), we observed a quasi-equal distribution of the cationic species between the two phases. At low $Ru(bpy)_3^{2+}/MV^{2+}$ ratios, no preferential adsorption is observed. The clay and the water phases contain the same molar ratio in $Ru(bpy)_3^{2+}$ vs. total concentration of charged organic species. At high $Ru(bpy)_3^{2+}$ concentrations a slight preferential adsorption of MV^{2+} is observed. In our experimental procedure Ru-

[a]H_2 produced after 20 h of illumination of a system containing MV^{2+} (2.5×10^{-3} M), $Ru(bpy)_3^{2+}$ (5.0×10^{-4} M), TEOA (1.0×10^{-1} M), clay (1.5 g/L) at pH 7.0 under argon.

[2]Under the same conditions, but at pH 4.0, using EDTA as the sacrificial donor, the hydrogen production is ten times higher.

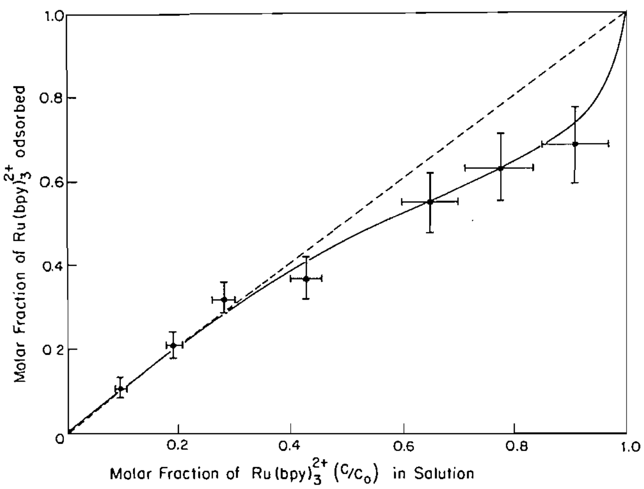

FIG. 2. Molar fraction of $Ru(bpy)_3^{2+}$ adsorbed on clay $[Ru(bpy)_3^{2+}]_{ads}/([Ru(bpy)_3^{2+}]_{ads} + [MV^{2+}]_{ads})$ as a function of molar fraction of $Ru(bpy)_3^{2+}$ in solution (see text).

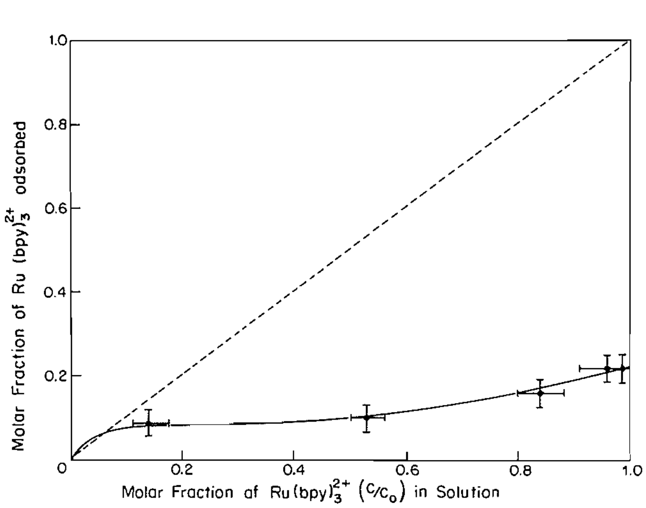

FIG. 3. Molar fraction of $Ru(bpy)_3^{2+}$ adsorbed on a clay on which MV^{2+} has been previously adsorbed, as a function of molar fraction of $Ru(bpy)_3^{2+}$ in solution (see text).

$(bpy)_3^{2+}$ was added to the system after MV^{2+}, when the clay interlamellar sodium has already been exchanged with MV^{2+}. The ability of $Ru(bpy)_3^{2+}$ to displace preadsorbed MV^{2+} was therefore studied (Fig. 3). $Ru(bpy)_3^{2+}$ can displace only a limited fraction of the MV^{2+}. Even with $Ru(bpy)_3^{2+}/MV^{2+}$ ratio equal to 10, only 22 ± 3% of the MV^{2+} is displaced (see Fig. 3). X-ray results showed that the d_{001} spacing was much smaller for MV^{2+} (12.55 Å) than for $Ru(bpy)_3^{2+}$ (17.4 Å) (Table 3). The thickness of the silicate layer being 9.6 Å, an interlamellar space of 2.95 Å accommodates methyl viologen. This space is too narrow by far to permit the incorporation of $Ru(bpy)_3^{2+}$. One can estimate the ratio between external areas and total areas of a montmorillonite to be about 30% (16). Therefore, small amounts of $Ru(bpy)_3^{2+}$ can be adsorbed on the external area of the clay, entering in competition with MV^{2+} for occupation of these sites, the internal sites not being available for $Ru(bpy)_3^{2+}$. This is in agreement with the optimum MV^{2+}/clay concentrations ratio observed for hydrogen production. When the MV^{2+} concentration is too high, the clay surface is saturated with MV^{2+} (Table 3).

All these observations lead us to a model for the active site

TABLE 3. Adsorption of MV^{2+} and $Ru(bpy)_3^{2+}$ by montmorillonite and X-ray determined basal spacings (see Experimental section)

Cation	Amount adsorbed (mequiv./g)	Basal spacings	
		Measured (Å)	Literature (Å)
Na^+	—	10.7	10.6(9)
MV^{2+}	0.89±0.08	12.6	12.4(10)
$Ru(bpy)_3^{2+}$	0.83±0.05	17.4	18.0(21)

responsible of the electron transfer to H^+: (*a*) MV^{2+} displaces Na^+, and/or any other interlamellar metal cations completely in such a way that the maximum exchange capacity of the clay has been attained. (*b*) The aggregate clay/MV^{2+} is particularly stable, with the dication probably adopting a flat conformation squeezed in a 2.95 Å intersheet distance. (*c*) $Ru(bpy)_3^{2+}$ can enter in competition with MV^{2+} adsorbed on external sites on the clay. The distribution of $Ru(bpy)_3^{2+}$ and MV^{2+} between external sites and the solution is not preferential. One dication out of three on the external sites is $Ru(bpy)_3^{2+}$, reflecting the organic cations solution ratio under our optimum experimental conditions. (*d*) MV^{2+} is reduced to $MV^{\dot{+}}$ on the external surface and/or on contact sites between external $Ru(bpy)_3^{2+}$ and intercalated MV^{2+}. Efficient charge separation can be achieved in aqueous suspensions of colloidal silica (17). Similarly the clay colloidal suspension suppress at least partially the reverse electron transfer between $Ru(bpy)_3^{2+}$ and $MV^{\dot{+}}$. The coexistence of electron acceptor sites, such as aluminum at the crystal edges (18) and electron donating sites, such as transition metals in the reduced states (18) can effect the electronic transfer to the protons, generated at the highly acidic montmorillonite surface (19). Titanium(III) exchanged zeolite A in water yields hydrogen under visible illumination (20). Local clay area containing titanium could be involved in the electronic transfer process.

HELMUT BEIERBECK, GEORGE KOTOVYCH, and MAKIKO SUGIURA. Can. J. Chem. **63**, 1143 (1985).

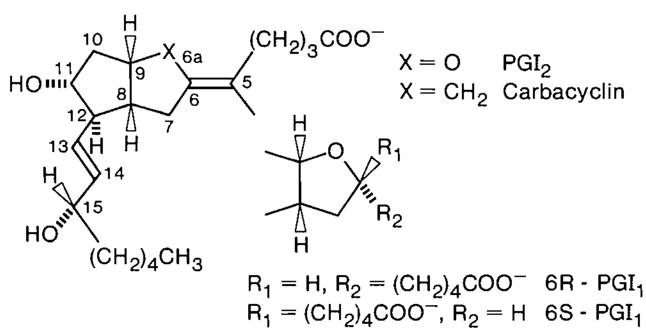
The conformations of prostacyclin, PGI_2, and three of its analogues, 6*R*- and 6*S*-PGI_1 and carbacyclin, were studied by high field ^1H nmr spectroscopy. The *cis*-bicyclo- and *cis*-oxabicyclo[3.3.0]octane ring conformations were completely assigned. The minima for the pseudorotational conformations are observed at $^7E/_{12}E$ for PGI_2, $^{6}_{6a}T/^{11}_{12}T$ for 6*R*-PGI_1, and $_6E/^{11}E$ for 6*S*-PGI_1 and carbacyclin. The data indicate that each molecule adopts a narrow pseudolibrational range, if not a single conformation. The α- and ω-side chain conformations were characterized, but not unambiguously. Vicinal coupling constants and nuclear Overhauser enhancements proved to be the most useful spectroscopic parameters in this study.

HELMUT BEIERBECK, GEORGE KOTOVYCH et MAKIKO SUGIURA. Can. J. Chem. **63**, 1143 (1985).

Faisant appel à la rmn du ^1H à haut champ, on a étudié les conformations de la prostacycline, PGI_2, et de trois de ses analogues, les 6*R*- et 6*S*-PGI_1 et la carbacycline. On a réussi à faire des attributions complètes pour les conformations des cycles *cis*-bicyclo et *cis*-oxabicyclo[3.3.0] octanes. On a observé les positions des minima des conformations pseudorotationnelles du PGI_2, 6*R*-PGI_1 ainsi que 6*S*-PGI_1 et carbacycline qui se situent respectivement à $^7E/_{12}E$, $^{6}_{6a}T/^{11}_{12}T$, et $_6E/^{11}E$. Ces données indiquent que les variations conformationnelles de chaque molécule sont limitées, mais qu'elles ne sont pas limitées à une seule conformation. On a caractérisé les conformations des chaînes latérales α et ω; toutefois ces caractérisations ne sont pas sans ambiguités. Les constantes de couplage vicinales et les effets Overhauser nucléaires se sont avérés les paramètres spectroscopiques les plus utiles de cette étude.

[Traduit par le journal]

In a recent series of articles (1–4) we reported ^1H nmr chemical shifts and coupling constants for prostacyclin and three of its derivatives, compounds of considerable pharmacological interest. Prostacyclin or PGI_2, first isolated in 1976, is a potent vasodilator and inhibitor of platelet aggregation (5, 6). It is rather unstable, however, and a number of biologically active analogues were developed (5), among them the isomeric 5,6-dihydroprostacyclins, 6*R*-PGI_1 and 6*S*-PGI_1, and carbacyclin, in which the ether oxygen is replaced by a methylene group. In the present study we have undertaken a detailed conformational analysis, based on ^1H nmr coupling constants and nuclear Overhauser effects, of this important group of prostaglandins.



Experimental

The samples of PGI_2, 6*S*-PGI_1, 6*R*-PGI_1, and carbacyclin used in this study were gifts from Drs. R. A. Johnson, J. E. Pike, and D. R. Morton of Upjohn, Kalamazoo. For the measurements of coupling constants in chloroform solution, CD_3OD was distilled into nmr tubes containing PGI_2 methyl ester or 6*S*-PGI_1, respectively, to exchange labile protons; the methanol was then evaporated and $CDCl_3$ added. The prostaglandin concentrations were ~0.005 *M*. The samples were sealed after four freeze–pump–thaw cycles. PGI_2 samples were prepared in glycine/D_2O buffer solutions at pH ≥ 10. Solutions were 0.005 *M* PGI_2 in a 0.20 *M* and 0.015 *M* buffer and 0.017 *M* in 0.02 *M* buffer to check for the effect of concentration on the T_1 data. The high pH was necessary to prevent PGI_2 hydrolysis. For 6*S*- and 6*R*-PGI_1, a 0.10 *M* phosphate/D_2O buffer of pH = 7.0 was used. The samples were weighed into nmr tubes, buffer solution added, the solvent evaporated, fresh 100% D_2O added, and oxygen removed in four freeze–pump–thaw cycles. 6*S*-PGI_1 concentrations were 0.005 *M*, 0.008 *M*, and 0.013 *M* while the 6*R*-PGI_1 solutions were 0.005 *M*. All glassware was cleaned extensively, including a nitric acid wash, to eliminate paramagnetic impurities.

All nmr measurements were carried out on a Bruker WH-400 FT nmr spectrometer equipped with an Aspect 2000 data system, using 16K, 32K, or 64K of memory, as required. The solvent deuterium resonances served as lock signal. All ^1H nmr spectra were run at ambient temperature, but the ^{13}C measurements were carried out at 277 K to minimize decomposition. The nonselective longitudinal ^1H relaxation times were determined using the $180°-t-90°$ pulse sequence as discussed previously (1).

Quantitative nOe's were determined as follows. The decoupler was set to the first of three or four multiplets and eight transients recorded in quadrature detection mode, the decoupler moved to the next multiplet, and finally far off resonance. The control free induction decay (FID) was subtracted from each nOe FID, and the decoupler reset to the first multiplet for the next cycle. Each multiplet was irradiated for a time $t \gtrsim 5T_1$ with sufficient power to just saturate that signal. The nOe's were derived from the integration curves of the signals of interest and the saturated signal in the difference spectrum. Each quoted nOe value is the average of at least three determinations.

The ^{13}C chemical shift assignments for PGI_2 are based on the spin-echo technique with gated decoupling and on selective $^{13}C-\{^1H\}$ decoupling experiments. With the exception of C_1 to C_3, our values are in good agreement with literature data for the PGI_2 methyl ester in

[1]Paper No. 10 in a series of high-field nmr studies on the prostaglandins and leukotrienes.

$CDCl_3$ (7). The 180°$-t-$90° pulse sequence was used in the ^{13}C T_1 experiments.

Calculations

Coupling constants

Vicinal coupling constants in $HR_1R_2C—CHR_3R_4$ segments were calculated with Altona's equation (ref. 8)

$$[1]\quad {}^3J_{HH} = 13.86 \cos^2 \phi - 0.81 \cos \phi + \sum_i^4 \Delta\chi_i\{0.56 - 2.32 \cos^2 (\xi_i\phi + 17{\cdot}9|\Delta\chi_i|)\}$$

where

ϕ = proton–proton torsion angle
$\Delta\chi_i$ = difference in Huggins electronegativities (9) between R_i and H ($\chi_C - \chi_H = 0{\cdot}4$, $\chi_O - \chi_H = 1.3$)
ξ_i = +1 and −1 for substituent R_i clockwise and counterclockwise from the coupled geminal proton.

Three- and four-bond vinyl–allylic coupling constants were estimated with Garbisch' equations (ref. 10)

$$[2]\quad {}^3J_{HH} = 6.6 \cos^2 \phi + 2.6 \sin^2\phi \qquad 0° \le \phi \le 90°$$
$$= 11.6 \cos^2\phi + 2.6 \sin^2\phi \qquad 90° \le \phi \le 180°$$

$$[3]\quad {}^4J_{HH} = 1.3 \cos^2\phi - 2.6 \sin^2\phi \qquad 0° \le \phi \le 90°$$
$$= -2.6 \sin^2\phi \qquad 90° \le \phi \le 180°$$

Nuclear Overhauser effects

For the case of isotropic motion and dipole–dipole relaxation the fractional enhancement $f_d(s)$ at nucleus d on saturating signal s is given (11) by

$$[4]\quad f_d(s) = A\left[\sum_s g_d(s) - \sum_{i\neq d,s} f_i(s)g_d(i)\right]$$
$$= -A \sum_{i\neq d} f_i(s)g_d(i), \qquad f_s(s) = -1$$

where

$g_d(i)$ = the geometric term
$= N_i\langle r_{di}^{-6}\rangle \Big/ \sum_j N_j\langle r_{dj}^{-6}\rangle$
N_j = number of magnetically equivalent nuclei j
r_{dj} = distance between protons d and j
A = the correlation term
$= [6\tau_C/(1 + 4\omega^2\tau_C^2) - \tau_C]/[\tau_c + 3\tau_c/(1 + \omega^2\tau_c^2) + 6\tau_c/(1 + 4\omega^2\tau_c^2)]$

The brackets in $\langle r_{dj}^{-6}\rangle$ indicate conformational averages (12), where appropriate. The nOe's for a given molecular conformation were obtained as follows. Coordinates for that conformation were generated as outlined below, proton–proton distances were derived from these coordinates, and the $g_d(i)$ in eq. [4] were evaluated. The nOe's were then obtained by an iterative fit of expression [4] to the observed values, calculating the constant A from an assumed correlation time or treating it as an adjustable variable in a least-squares fit.

Relaxation times

Nonselective ^1H relaxation times were calculated by a least-squares fit of eq. [5] (11) to the observed values, treating B as variable.

$$[5]\quad T_{1i} = B\Big/\left[\sum_{j\neq i} N_j\langle r_{ij}^{-6}\rangle + (N_i - 1)r_{ii}^{-6}\right]$$

where

$$B = 10/\{\hbar^2\gamma_H^4 \times [3\tau_C/(1 + \omega^2\tau_c^2) + 12\tau_c/(1 + 4\omega^2\tau_c^2)]\}$$

Ring conformations

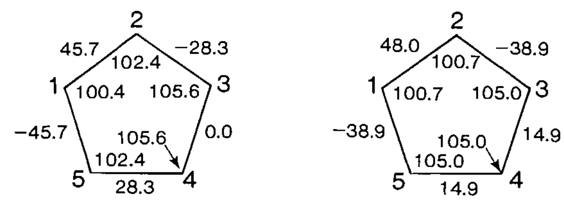
In order to simplify the pseudorotational analysis of the ring systems, PGI_2 and the PGI_1 isomers were assumed to be *cis*-bicyclo[3.3.0]octane derivatives like carbacyclin. The conformations of cyclopentane may be described by Altona's pseudorotation equation (ref. 13)

$$[6]\quad \phi_j = \phi_{max}\cos (p_k + 144j);\ j = 0, 1\ldots4$$

where

ϕ_j = C—C torsion angle about C_{j-1}—C_j
ϕ_{max} = maximum torsion angle
p_k = phase angle of pseudorotation
$= 18k$; $k = 0, 1\ldots19$

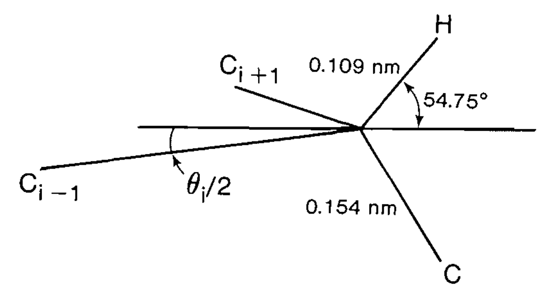
With ϕ_{max} = 48° the torsion angles in the twist and envelope conformations have the following values.



^1E $\qquad$ ^1_2T

The valency angles shown are Hendrickson's (14) values for Pitzer's (15) cyclopentane conformations, and were used in the derivation of ring coordinates.

In order to form *cis*-bicyclo[3.3.0]octane, two cyclopentane rings have to be joined at bonds with identical torsion angles. Since the rings may be combined up–up or up–down, 2×20 conformations are generated (the two combinations give identical results, when the torsion angle about the common bond is $\pm\phi_{max}$). Protons and carbon substituents were attached to the rings as shown.



Side chain conformations

Only coordinates and conformer populations for segment H_3-H_{17} were needed, since T_1's and nOe's were only available within the range H_5-H_{15}. The conformations of the abbreviated α- and ω-chains were built with C—C and C=C bond lengths of 0.154 and 0.134 nm, tetrahedral and trigonal bond angles, and eclipsed $C(sp^2)-C(sp^3)$ and staggered $C(sp^3)-C(sp^3)$ rotamers. Side chain conformations with *syn*-axial δ-interactions were excluded. The population χ_1 of a given chain conformation is the product of the populations p_{ik} of the rotational states of the constituent bonds (16)

$$[7]\quad \chi_1 = \prod_j^n p_{jk} \Big/ \sum_j^n \sum_k^3 \prod_j^n p_{jk}, \qquad 1 = 1, 2\ldots3^n$$

[a]Experiments carried out on the methyl ester. Side chain coupling constants (Hz): $J_{5,7\alpha} \simeq 0$, $J_{5,7\beta} = 1.7$, $J_{12,13} = 8.1$, $J_{13,14} = 15.3$, $J_{14,15} = 6.6$, $J_{15,16} \simeq J_{15,16^*} = 6.4$.

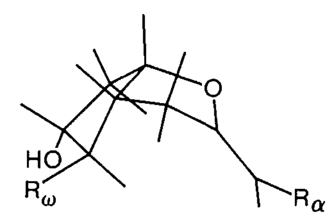
[b]ω-chain coupling constants are similar to $PGI_2/CDCl_3$ values.

where n = number of bonds with three rotational states. Rotamer populations were derived from coupling constants or treated as variables. The χ_i are the weighing factors for the r_{dj}^{-6}.

Results and discussion

The conformational analysis of PGI_2, the PGI_1's, and carbacyclin is based on two complimentary ^1H nmr parameters, namely coupling constants (Table 1), which define the orientation of vicinal protons, and nOe's (Table 2), which are sensitive probes of steric interactions. Relaxation times (Table 3) proved less informative, since conformational variations of internuclear distances tend to average in the sum of the relaxation contributions. For this reason, however, T_1's are useful motional probes, i.e. they define the molecular region in which the isotropic correlation time approximation for nOe's is justified. The nonselective relaxation times for PGI_2 and the PGI_1's are well reproduced for $H_5{-}H_{15}$ and $H_6{-}H_{15}$, respectively (Table 3), and the ^{13}C NT_1's for PGI_2 are approximately equal from C_5 to C_{15} (Table 4), as in $PGF_{2\alpha}$ (17, 18). The nOe expression [4] should therefore be applicable in this range, and indeed agreement is satisfactory (Table 2). Correlation times derived from the nOe's (τ_c = 0.24 ns) and T_1's (τ_c = 0.1 ns) are somewhat different, however. Relaxation times derived with τ_c = 0.24 ns are about 70% of the values obtained with τ_c = 0.1 ns. This discrepancy should not affect the conformational arguments.

The ring conformations for all four substrates are readily derived from the vicinal coupling constants. Plots of standard deviations between calculated and observed coupling constants vs. pseudorotational conformations (Figs. 1a and 1b) show well-defined minima at $^{7}E/_{12}E$ (PGI_2), $^{6}_{6a}T/^{11}_{12}T$ (6*R*-PGI_1), and $_{6}E/^{11}E$ (6*S*-PGI_1 and carbacyclin), indicating that each molecule adopts a narrow pseudolibrational range, if not a single conformation. In all cases the C_{11}—C_{12} torsion angle is at or near its maximum and the 11- and 12-substituents are pseudo-equatorial. The 6*R*-PGI_1 and carbacyclin conformation $_{6}E/^{11}E$ is the conformational minimum of *cis*-bicyclo[3.3.0]octane (19, 20).



PGI_2 Conformation $^{7}E/_{12}E$

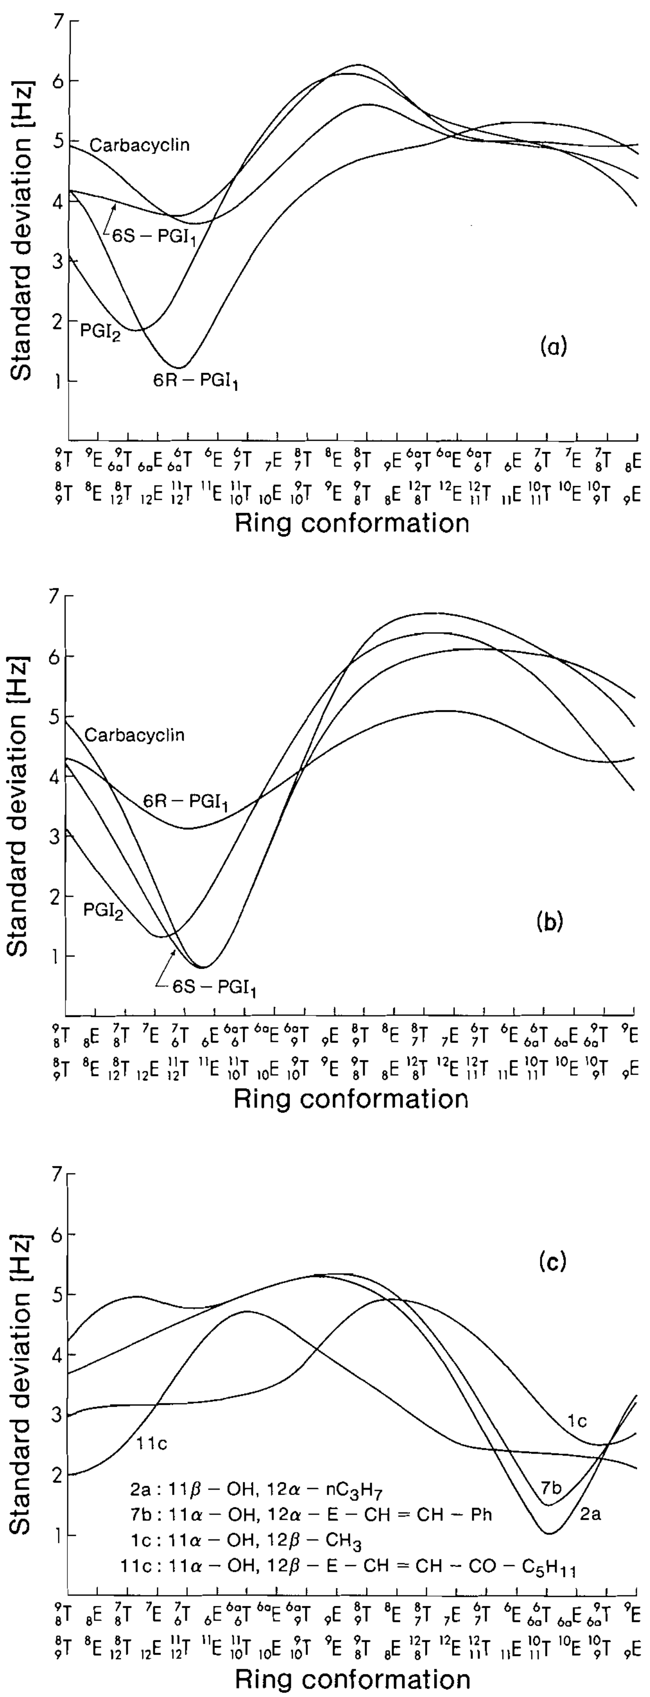

FIG. 1. Plots of standard deviations between calculated and observed vicinal proton coupling constants vs. pseudorotational conformations for PGI$_2$, 6R-PGI$_1$, 6S-PGI, and carbacyclin (1a and 1b), and for 11-hydroxy, 12-alkyloxabicyclo[3.3.0]octan-6-one data taken from ref. 21 (1c).

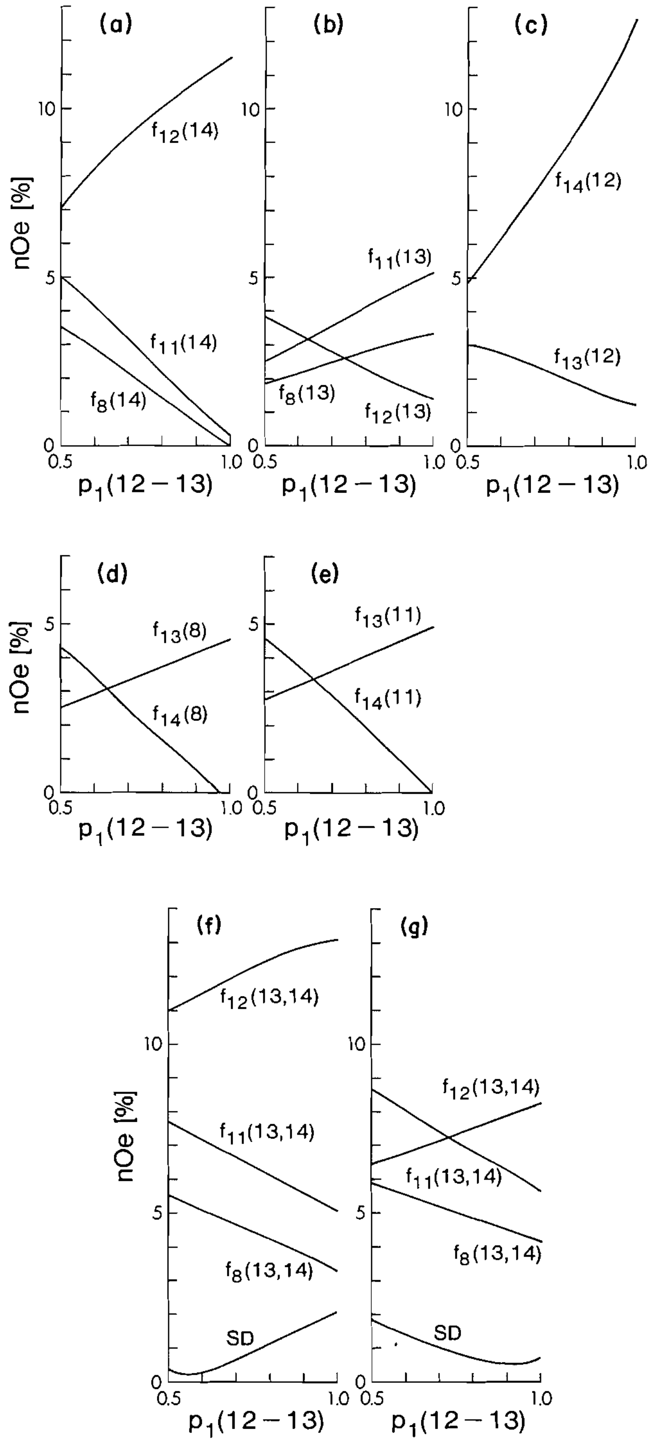

FIG. 2. Plots of calculated nuclear Overhauser effects and standard deviations (SD) between calculated and measured nOe's vs. the population of the principal C_{12}—C_{13} rotamer. Figs. 2a–2f: PGI$_2$; Fig. 2g: 6S-PGI$_1$.

The PGI$_2$ minimum in Fig. 1a is not much shallower than the minimum in Fig. 1b. Only two of the nine coupling constants of PGI$_2$, $J_{7\alpha,8}$ and $J_{7\beta,8}$, depend specifically on the ether ring conformation, and the minima in Figs. 1a and 1b are essentially determined by the cyclopentane ring conformation $_{12}E$. That the ether ring conformation is indeed ^{7}E (minimum in Fig. 1b), and not $_{6a}E$, is readily apparent from the vicinal coupling constants $J_{7\alpha,8}$ and $J_{7\beta,8}$,

	$J_{7\alpha,8}$	$J_{7\beta,8}$
${}_{6a}E/{}_{12}E$	3.9 Hz	11.0 Hz
${}^{7}E/{}_{12}E$	1.2 Hz	5.4 Hz
Exp.	~0	7.6 Hz

from the long range coupling constants $J_{5,7\alpha}$ and $J_{5,7\beta}$,

	$\phi_{5,7\alpha}$	$\phi_{5,7\beta}$	$\lvert J_{5,7\alpha}\rvert$	$\lvert J_{5,7\beta}\rvert$
${}_{6a}E/{}_{12}E$	−88.3°	31.7°	2.6 Hz	0.2 Hz
${}^{7}E/{}_{12}E$	−14.3°	105.7°	1.4 Hz	2.4 Hz
Exp.			0	1.6 Hz

and from the nOe's between H_5, $H_{7\alpha}$, and $H_{7\beta}$.

	$f_5(7\alpha)$	$f_5(7\beta)$	$f_{7\alpha}(5)$	$f_{7\beta}(5)$
${}_{6a}E/{}_{12}E$	0.5%	4.2%	0.2%	1.0%
${}^{7}E/{}_{12}E$	4.9%	0	1.4%	0
Exp.	5.0%	1.8%	3.0%	0

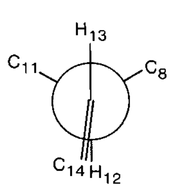
Nuclear Overhauser effects also provide convincing support for the 6S-PGI$_1$ conformation ${}_6E/{}^{11}E$ established on the basis of vicinal coupling constants (Fig. 1b).

	r_{6-12}	$g_6(12)$	$f_6(12)$	$g_{12}(6)$	$f_{12}(6)$	$r_{7\alpha-12}$	$g_{12}(7\alpha)$	$f_{12}(7\alpha)$
${}^{7}_{6}T/{}^{11}_{12}T$	0.202 nm	0.455	11.6%	0.497	12.6%	0.268 nm	0.091	1.9%
${}_6E/{}^{11}E$	0.239 nm	0.199	4.9%	0.241	5.7%	0.243 nm	0.218	5.1%
${}^{6a}_{6}T/{}^{11}_{10}T$	0.293 nm	0.048	0.9%	0.068	1.3%	0.219 nm	0.392	9.9%
Obs.			3.2%		4.0%			4.2%

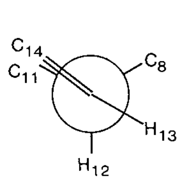
The H_6—H_{12} and, to a lesser extent, $H_{7\alpha}$—H_{12} distances are undoubtedly overestimated by using *cis*-bicyclo[3.3.0]octane as model. Nevertheless, the assignment seems unambiguous, since r_{6-12} and $r_{7\alpha-12}$ vary significantly and in opposite directions from one conformation to the next on the pseudorotation path.

De Clercq and Samson (21) published coupling constants for a series of synthetic lactone analogues of PGI$_2$, and it seemed worthwhile to look at the effect of replacing C_6=C_5 by C_6=O on the ring conformations. Surprisingly, no clear minimum could be found for the 11α-hydroxy, 12β-alkyl derivatives of oxabicyclo[3.3.0]octan-6-one (Fig. 1c), for which the authors (21) proposed the ${}^{10}_{11}T$ conformation (prostaglandin system). Averages over several contiguous conformations gave similar negative results. Interestingly, reasonably sharp minima at ${}^{6}_{6a}T/{}^{10}_{11}T$ were obtained for the 11α-hydroxy, 12α-alkyl and 11β-hydroxy, 12α-alkyl derivatives (Fig. 1c).

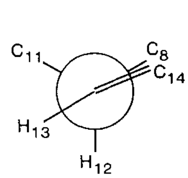
Acyclic C(sp^2)—C(sp^3) bonds like C_4—C_5 in PGI$_2$ or carbacyclin, C_{12}—C_{13} and C_{14}—C_{15} in the ω-chain, are known (see, for instance, ref. 22) to prefer rotational states in which the double bond eclipses a single bond. This is borne out in the crystal structures of prostaglandins (23−27), where the C_{12}—H and C_{15}—H bonds are more or less coplanar with C_{13}=C_{14}. However, the vicinal coupling constants in solution (e.g. $J_{12,13}$ = 8.1 Hz for PGI$_2$) certainly do not agree with an exclusive *trans* orientation, for which eq. [2] estimates a value of 11.6 Hz. Either C_{12}—C_{13} is in a rotational state with an H_{12}—H_{13} angle close to 150°, as suggested by Conover and Fried (17), or other eclipsed rotamers are significantly populated. If $J_{60°}$ = 3.6 Hz, C_{12}—C_{13} rotamers 2 and 3 would have to be occupied about half the time,



1



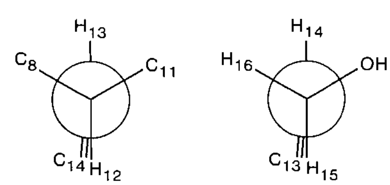
2



3

$$p_1 \times 11.6 + (1 - p_1) \times 3.6 = 8.1, \qquad p_1 = 0.56$$

although it is difficult to place confidence limits on that value. The nOe technique seemed well suited for estimating C_{12}—C_{13} rotamer populations, since H_8, H_{11}, and H_{12} provide close contacts for H_{13} and especially H_{14} at each stop on the C_{12}—C_{13} rotation path. Consequently the average distances, and therefore the nOe's, change significantly and in opposite directions on varying $p_1(12-13)$ (Figs. 2a−2e). Unfortunately H_{13} and H_{14} form an AB system and only the $f_i(13,14)$ are available, with contradictory results. The nOe's for PGI$_2$ confirm the coupling constant evidence, $p_1(12-13)$ = 0.6 (Fig. 2f), whereas, according to the $f_i(13,14)$ for 6R-PGI$_1$, there is essentially only one conformation, $p_1(12-13)$ = 0.9 (Fig. 2g). The nOe's and T_1's in Tables 2 and 3 were calculated with $p_1(12-13)$ = 0.5, but only a substrate with well-separated H_{13} and H_{14} signals is likely to provide an unambiguous answer.



The substitution pattern around C_{14}—C_{15} is similar to C_{12}—C_{13}, except for a replacement of carbon by oxygen. Equation [2] for vinyl−allylic coupling constants does not have a substituent term, but the electronegativity correction term of eq. [1]

$$(1.3 - 0.4)\{0.56 - 2.32\cos^2(-\phi + 17.9 \times (1.3 - 0.4)\}$$
$$= [-1.4(\phi = 180°) - 0.6(\phi = 60°)]/2 = 1.0 \text{ Hz}$$

accounts well for the observed difference $J_{14,15} - J_{12,13}$ = (6.6 − 7.8)Hz in 6S-PGI$_1$; i.e. the rotational behaviour about C_{14}—C_{15} is similar to C_{12}—C_{13}.

C_4 in PGI$_2$ or carbacyclin would be expected to occupy the skew positions, since eclipsing C_4—C_5 with the double bond

1 2 3

would introduce *syn*-axial δ-interactions with the ester oxygen or 6a-methylene bridge. Indeed, the observed H_4—H_5 coupling constants of 7.2 Hz for PGI_2/D_2O (1) and 6.7 Hz for carbacyclin/$CDCl_3$ (4) agree satisfactorily with 7.6 Hz, the value calculated with $p_2 = p_3 = 0.5$.

The coupling constants between H_{15} and the diastereotopic protons H_{16} and $H_{16'}$ are essentially equal, if not identical. With $J_{15,16}$ = 6.6 Hz (3) (6S-PGI_1/D_2O) the following rotamer populations are obtained.

$$p_1 = 0.13, p_2 = 0.47, p_3 = 0.40$$

The simpler model $p_1 = 0.0$, $p_2 = p_3 = 0.5$ was used in the nOe and T_1 calculations, which reproduces the coupling constants equally well, $J_{15,16}$ = 6.8 Hz, $J_{15,16'}$ = 7.6 Hz. A more detailed analysis on the basis of coupling constants seems unwarranted, and segmental motion as well as signal overlap eliminate nOe's. The situation is similar around C_5—C_6 in the PGI_1 series, where $J_{65} \simeq J_{65'}$ = 6.3 Hz (3). Again $p_2 = p_3$ = 0.5 was used in the calculations.

Finally, *trans* rotamer populations of 70% were assumed for all n-butane segments. For example, $J_{2,3}$ = 7.5 Hz (6S-PGI_1/D_2O) (3) gives $p_1(2-3) = 0.73$, in excellent agreement with the value of 0.72 obtained from the *gauche/trans* butane energy difference of 0.966 kcal/mol (28).

rived from this conformational model agree reasonably well with experiment, although some of the conformational details in the side chains remain to be worked out. The C_{12}—C_{13} rotamer problem in particular requires derivatives with well-resolved H_{13} and H_{14} signals. The conformations of the ring systems, on the other hand, are well defined. Not only is there good agreement between calculation and experiment, but alternative conformations could unambiguously be eliminated on the basis of nOe comparisons. Thus, as in the leukotriene series (29, 30), quantitative nuclear Overhauser effects and, to a lesser extent, relaxation time measurements proved useful complements to vicinal coupling constants in the conformational analysis of complex molecules of biological interest.

Substituent effects on benzyl radical hyperfine coupling (hfc) constants. Part 3. Comparison of the α-hfc for substituted benzyl radicals with the β-hfc for substituted cumyl radicals

DONALD R. ARNOLD,[1] A. MARTIN DE P. NICHOLAS, AND MILES S. SNOW
Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received August 16, 1984

DONALD R. ARNOLD, A. MARTIN DE P. NICHOLAS, and MILES S. SNOW. Can. J. Chem. **63**, 1150 (1985).

The electron spin resonance (esr) spectra of eighteen *para*-substituted cumyl radicals were analyzed. The relationship between the β-hyperfine coupling (β-hfc) constants of these cumyl radicals and the corresponding α-hfc constants of benzyl radicals was studied. Although there is a general trend for the α- and β-hfc values to vary in a similar manner, specific deviations from a linear correlation between these parameters were observed. These deviations were rationalized by considering charge effects on spin delocalization. The correlation coefficient for the linear regression analysis of these α- and β-hfc values was found to significantly improve when parameters reflecting charge effects on spin delocalization were included in an extended Hammett treatment of the spectral data.

DONALD R. ARNOLD, A. MARTIN DE P. NICHOLAS et MILES S. SNOW. Can. J. Chem. **63**, 1150 (1985).

On a analysé les spectres de résonance paramagnétique électronique (rpe) de dix-huit radicaux cumyles substitués en position *para*. On a étudié la relation existant entre la constante de couplage hyperfin-β (chf-β) de ces radicaux cumyles et les constantes chf-α correspondantes des radicaux benzyles. Les valeurs des chf-α et chf-β tendent généralement à varier de la même façon: cependant on observe des déviations spécifiques par rapport à la corrélation linéaire entre ces paramètres. On rationalise ces écarts en considérant les effets de la charge sur la délocalisation du spin. On a trouvé, que pour ces valeurs de chf-α et chf-β, le coefficient de corrélation de l'analyse de répression linéaire est amélioré d'une façon significative lorsque les paramètres qui reflètent les effets de la charge sur la délocalisation de spin sout inclus dans un traitement de Hammett élargi des données spectrales.

Introduction

The study of substituent effects on radical reactivity and stability is a topic of great interest. Several linear free-energy ($\sigma^{\cdot}$) scales based upon relative reactivity have been proposed (1, 2). Most of these scales have failed to unambiguously separate radical and polar effects. We have suggested that the $\sigma^{\cdot}_{\alpha}$ scale, based upon electron spin resonance (esr) α-hyperfine coupling constants (α-hfc), is a true reflection of the nature of the radical and is therefore free from complications caused by steric and polar effects inherent at a transition state (1). The validity and utility of the $\sigma^{\cdot}_{\alpha}$ scale was demonstrated by the satisfactory correlation obtained between $\sigma^{\cdot}_{\alpha}$ and the logarithm of the rate constant for the thermal isomerization of a series of 2-aryl-3,3-dimethylmethylenecyclopropanes studied by Creary (1, 3).

In Part 1 of this series (1), we defined $\sigma^{\cdot}_{\alpha}$, for a substituent x, from the benzylic α-hydrogen hyperfine coupling constant (α-hfc$_x$):

$$[1] \quad (\sigma^{\cdot}_{\alpha})_x = 1 - [(\alpha\text{-hfc}_x)/(\alpha\text{-hfc}_H)]$$

We believe that these $\sigma^{\cdot}_{\alpha}$ values represent the substituent effect on the component of energy that may be attributed to spin delocalization in these benzyl radicals. The $\sigma^{\cdot}_{\alpha}$ scale offers major advantages over other $\sigma^{\cdot}$ scales, because the substituent effects are attributable only to effects on the radical and not on any closed shell species. We have shown that the effects of charge on the stability of even relatively non-polar species, like hydrocarbons and hydrocarbon radicals, are not negligible (4). Consequently, the other $\sigma^{\cdot}$ scales, which have ignored effects on neutral closed shell species, cannot be used as an indication of radical stability.

In Part 2 of this series we extended the $\sigma^{\cdot}_{\alpha}$ scale to over thirty substituents. We also described in detail the mode of action of sulphur-containing substituents on benzyl radical delocalization. Several *para*-substituted benzyl radicals of the general form $R(O_n)SC_6H_4CH_2$. (n = 0, 1, 2; R = Me, Ph, Tol, COMe, OMe) were studied (2).

In this work[2] we extend our study of substituent effects on benzyl radical hfc values to the α,α-dimethylbenzyl (cumyl) system. This study is significant, because it enables the comparison of the substituent effects on the α-and β-hfc values of two closely related series of radicals. Since both α- and β-hfc values depend primarily on spin density they will correlate, if the major effect of substituents is on spin delocalization. Moreover, if such a correlation exists between these two parameters it will add considerable strength to the argument that the $\sigma^{\cdot}_{\alpha}$ scale is primarily a measure of spin density. It will give confidence to the $\sigma^{\cdot}_{\alpha}$ values that have already been established. In addition, if the substituent effect on both α- and β-hfc is in general the same, specific deviations from a linear correlation between these two parameters may provide valuable information about the factors which influence spin density and hence stabilization of a radical by spin delocalization. This understanding is required for the general application of $\sigma^{\cdot}_{\alpha}$ to benzylic radicals other then benzyl itself.

While the overall change in α-hfc values is large (>10%), the small effects (<0.03 G) caused by some substituents cannot be readily distinguished. It would therefore be useful to have a scale with a larger variation in hfc constants as a function of substitution. Studies of carbon based radicals containing hydrogens both α and β to the radical centre show that β-hfc values are frequently greater than the corresponding α-hfc values (5, 6). Consequently, we may find that the cumyl series, where

[d]Reference 2.

β-hfc values are being measured, will be more sensitive to changes in spin density. On the other hand, the significant decrease in the delocalization of spin into the ring, caused by the two α-methyl groups, will attenuate the substituent effect. The relative importance of these two opposing factors cannot be predicted a priori.

Results

The cumyl radicals were generated photochemically in the microwave cavity of the esr spectrometer, either by hydrogen atom abstraction from the corresponding cumene or by bromine atom abstraction from the appropriate cumyl bromide. The esr spectra were recorded with the aid of a signal averager and the hfc values were determined by computer simulation of the spectra.

The data (Table 1) represent a consistent series, produced under similar conditions. Typically, the best signal-to-noise ratio was obtained at the lowest temperature possible, above the freezing point of the solution. But most of the spectra were recorded at 253 K to maintain a consistency in the conditions. The esr spectra of two of these radicals have been reported previously (5); the agreement between our values and those reported is good. In several cases, the effect of variation of the spectra as a function of temperature was studied; the β-hfc was found to be independent of temperature over the range 213 to 333 K. Details are reported in the experimental section.

Discussion

In general, α-hfc is believed to arise primarily from a spin-polarization mechanism, while β-hfc results mostly from a hyperconjugative type of interaction (6–9). Thus, α- and β-hfc interactions need not show the same sensitivity to substituent effects. In fact, it has been shown that α- and β-hfc in hydrocarbon radicals are affected differently by such factors as deviation from planarity (i.e., the state of hybridization of the radical centre (6*b*)). β-Hfc values are also known to be very dependent on torsional angle, so conformation of the singly occupied orbital relative to the β-carbon–hydrogen bond is important (7).

Within a closely related series of substituted benzyl or cumyl radicals, factors other than spin density that could influence hfc should remain constant. In addition, the esr spectra of all the cumyl radicals studied showed a single hfc value for all the hydrogens of the α-methyl groups. This indicates that all of the methyl hydrogens are equilibrated, throughout the temperature range (213 to 333 K) used in this work. Thus, the methyl groups must be rapidly rotating so that torsional effects are averaged. Consequently, substituent effects on β-hfc values of the cumyl radical series can also be expected to be related primarily to spin delocalization.

In Table 2 the benzylic α-hfc constants of *para*-substituted benzyl radicals are compared with the β-hfc constants of the corresponding cumyl radicals. If both of these hfc values correlate, a constant ratio, α-hfc/β-hfc, is expected. Table 2 shows that for most substituents this ratio is close to the value for the unsubstituted radicals (α-hfc/β-hfc = 1.002). Thus there is a general trend for the β-hfc values in cumyl radicals to vary in a similar manner to that of the α-hfc values in benzyl radicals. However, Table 3 and Fig. 1 clearly show that significant deviations from a linear correlation between the α- and β-hfc values, much larger than the experimental error of ±0.03 G, are observed for some substituents. Because of these specific deviations, the correlation between the two types of hfc values is far from satisfactory (r = 0.92, 18 data points, see Fig. 1 and Table 3). In the plot shown in Fig. 1 the substituents that lie below (above) the least-squares regression line have a relatively lower (higher) ratio of α-hfc/β-hfc and hence show an unexpectedly large (small) effect in the cumyl series with

respect to the benzyl series. Figure 1 also shows that all electron-withdrawing (donating) groups cause a larger (smaller) spin delocalizing effect on the β-hfc in the cumyl than the α-hfc of the benzyl radical system.

Charge effects on spin delocalization have been discussed in terms of merostabilization (10) or capto-dative stabilization (11). Figure 2 shows how the electron-withdrawing nature of a *para*-substituent can affect spin delocalization.[3] These charge separated valence-bond structures show that α-substituents that can stabilize an incipient positive charge on the benzylic carbon will enhance spin delocalization by electron-withdrawing groups at the *para*-position. Therefore, the cumyl system, with two α-methyl substituents that stabilize a positive charge better than the α-hydrogens in the benzyl radicals, should be more sensitive than the corresponding benzyl system to charge effects. Hence, the deviations observed in Fig. 1 can be a result of a greater contribution of charge separated valence-bond structures, such as Figs. 2 (b) and (c), in the cumyl than in the benzyl radicals.

The specific deviation of each point from the correlation line shown in Fig. 1 is plotted against the Hammett substituent constant σ in Fig. 3. This parameter was chosen because a consistent set of values was available (12, 13).[4]

The sign of the slope of the line in Fig. 3 reflects the fact that electron-withdrawing groups generally have a greater influence increasing spin delocalization in the cumyl series relative to the benzyl series. This is consistent with a greater contribution of the charge separated valence-bond structures (Figs. 2 (b) and (c)) in the cumyl series.

We have defined the substituent effect on spin delocalization ($\sigma^{\bullet}_\alpha$) based upon the α-hfc of the benzyl radical. Of course, there must be *some* inherent charge effect on this system as well. A quantitative indication of the increased importance of charge effects on the cumyl radical series, relative to the benzyl series, can be obtained by plotting the β-hfc values against the two parameters α-hfc and σ (Fig. 4).[4]

The ρ_α value reflects the balance between the inherently larger β-hfc and the diminished delocalization into the ring, since considerable spin is distributed among the α-methyl groups.

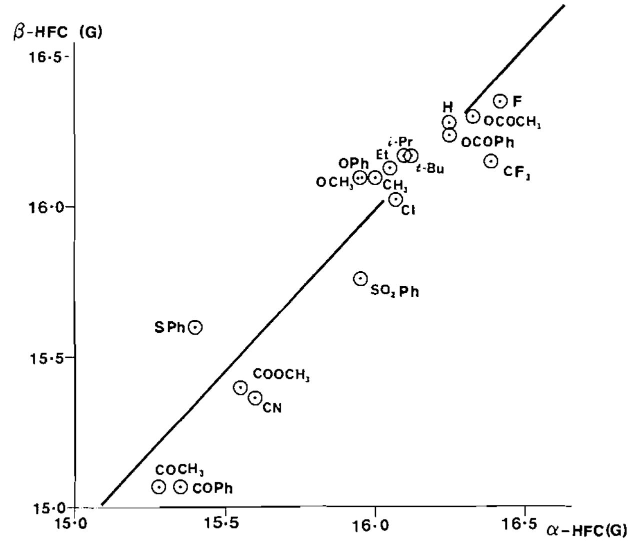

FIG. 1. A linear regression analysis of the relationship between β-hfc of cumyl radicals (a_β) and the benzylic α-hfc of benzyl radicals (a_α). $(a_\beta) = 1.06(a_\alpha) - 0.93$ ($r = 0.92$, 18 data points)

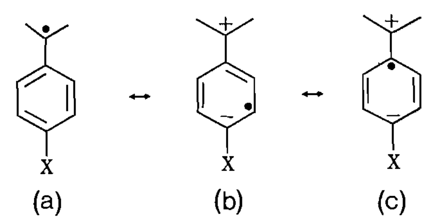

FIG. 2. Charge effects on spin delocalization in benzylic radicals.

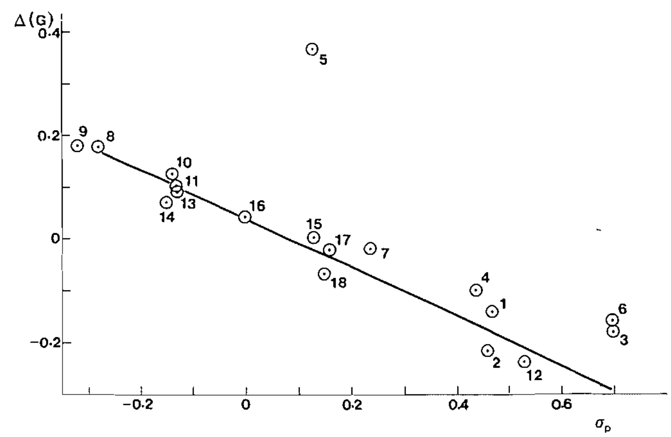

FIG. 3. A plot of Δ ($\Delta = a_\beta - 1.06(a_\alpha) + 0.93$), versus the Hammett substituent constant σ_p. Points are numbered according to Table 1.

The magnitude of ρ_σ indicates the increased importance of spin delocalization away from the benzylic position through a greater contribution of the valence-bond structures Figs 2(b) and (c), in the cumyl series relative to the benzyl series. The importance of charge effects on the relationship between the benzylic hfc values is now clear. Therefore it will be useful to determine if there are any other manifestations of charge effects on spin delocalization in the esr spectra of the cumyl radicals.

The valence-bond structures (b) and (c) in Fig. 2 clearly show that spin delocalization induced by charge effects will

[3]Effects resulting from the development of a negative charge on the benzylic carbon have been ignored in the absence of electron-withdrawing α-substituents. However, such effects, if present, will be opposite to the charge effects described in Figs. 2 (b) and (c).

[4]The correlation coefficient for the least-squares line in Fig. 3 is $r = 0.79$. σ^- Values are not available for all the substituents. For the data plotted in Fig. 4, the correlation coefficient is $r = 0.98$.

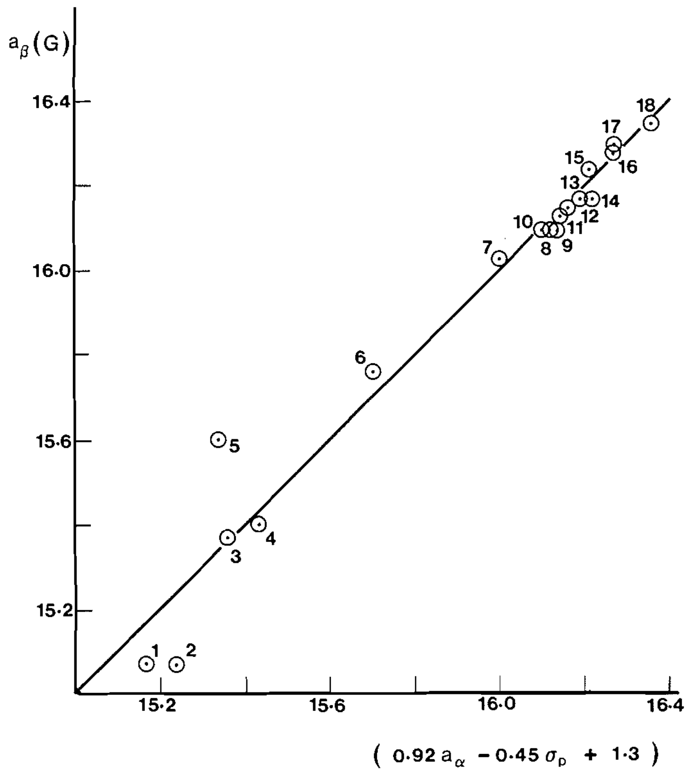

FIG. 4. Two-parameter Hammett correlation. A plot of β-hfc values of cumyl radicals (a_β) vs. (0.92 a_α(benzyl) − 0.45 σ_p + 1.3). Points are numbered according to Table 1.

cause an increase in α-spin[5] at the *meta*- and *ipso*-positions (14). This will result in a concomitant decrease in α-spin at the benzylic position. Moreover, such changes in spin distribution will decrease the absolute value of the hfc at the *ortho* and *meta* ring positions. In fact, all substituents displaying enhanced delocalizing effects in the cumyl system do have relatively lower $|a_o|$ and $|a_m|$ values. Moreover, the hypothesis that the variation in the $|a_o|$ and $|a_m|$ values are a manifestation of charge effects can be tested by the multiple linear regression analysis of α- and β-hfc values (denoted a_α and a_β respectively in Table 2), with the inclusion of an additional parameter, namely, the sum of the absolute values of the *ortho*- and *meta*-hyperfine coupling constants (i.e. $2(|a_o| + |a_m|)$).

This is admittedly a semi-quantitative approach to correct for charge effects on spin delocalization. However, the improvement in the correlation coefficient (r), corrected for the degrees of freedom (r = 0.92 becomes r = 0.94), suggests that this is a valid analysis (Table 3). Consequently, $2(|a_o| + |a_m|)$ may prove to be a useful parameter for describing the charge-related effects on spin delocalization.

The hypothesis that the α- and β-hfc values of benzylic radicals have the same functional dependence on spin density can be tested directly (free from charge effects) only if the relevant α- and β-hydrogens are on the same radical, such as the phenethyl radical system. Preliminary studies of this system indicate that the α- and β-hfc values do show the same functional dependence on spin density.[6] The complete study of this series is now underway.

[5]By convention, a radical is assumed to have excess α-spin.

Conclusion

The present study shows that there is a general trend: β-hfc values of cumyl radicals vary in a similar manner to the α-hfc values of benzyl radicals. However, specific deviations are observed from a linear correlation between these α- and β-hfc values. These deviations are rationalized by considering charge effects on spin delocalization. Electron-withdrawing (donating) substituents show a greater (smaller) delocalizing effect in the cumyl radicals relative to the benzyl radicals.

Charge effects on spin delocalization should be general, and should depend upon the electron-withdrawing and donating ability of the groups attached to the radical centre (11).

We have shown that the variations in the hfc values at the *ortho* and *meta* positions reflect the changes in the spin delocalizing efficiency of a substituent in the cumyl radicals relative to the corresponding benzyl system.

Since the extent of spin delocalization of a radical is inherently dependent upon charge effects, it will be difficult to assess the relative importance of radical stabilizing effects and polar factors from studies of relative reactivity.

Experimental

General information

The esr spectra were recorded on a Varian Associates E-109 B electron paramagnetic resonance spectrometer, equipped with a liquid nitrogen variable temperature accessory, at 0.5-mW microwave power and 0.5−0.8 G modulation amplitude. All spectra were recorded with the aid of a Nicolet 1170 signal averager. Typically, twelve, 100-G wide, scans were accumulated (0.5 min/scan). Coupling constants were measured directly from the oscilloscope and refined by computer simulation (15) using an IBM-PC.

The ^{1}Hmr spectra were recorded on a Varian CFT-20 spectrometer or a Nicolet Model 360 NB spectrometer, coupled to an Oxford Instruments superconducting magnet and a Nicolet 192 Kword data acquisition system, and are reported in parts per million downfield from TMS. Infrared spectra were recorded on either an air-purged Perkin−Elmer 180 grating infrared spectrometer, a Pye Unicam SP1000, or a Perkin−Elmer 283B or 237B infrared spectrometer and are reported in wavenumbers (relative to the 1601.8 cm^{-1} absorption of polystyrene). Mass spectra were obtained on a modified Du Pont CEC Model 21-104 mass spectrometer. Melting points, recorded on a Sybron Corporation Thermodyne hotstage apparatus, are corrected.

Substituted cumenes (liquids) were purified by gas chromatography using a 5 ft × 3/8 in. column packed with 5% SE-30 on Chromosorb-W (60/80) and helium as the carrier gas.

Materials

Di-*tert*-butyl peroxide (DTBP) and triethylsilane were obtained from Pfaltz and Bauer Inc. and were used without further purification. Hexamethylditin and hexabutylditin were obtained from Alpha Products and used without further purification. Chlorobenzene (J. T. Baker Chemicals Inc.) was stirred over concentrated sulphuric acid, washed successively with water, saturated sodium bicarbonate, and water, dried over anhydrous magnesium sulphate, and distilled through a Vigreux column. All solvents were distilled prior to use.

Synthesis

4-Isopropyldiphenyl ether

4-Isopropyldiphenyl ether was prepared by refluxing a mixture of 4-isopropylphenol, bromobenzene, cuprous oxide, and γ-collidine (2, 16). The yield of 4-isopropyldiphenyl ether was 87% as a colourless oil; ir PE 180 (neat) cm^{-1}: 1600, 1500, 1250, 875, 760; ^{1}Hmr (80 MHz, $CDCl_3$) δ: 7.34−6.87(m, 9H), 2.90(m, 1H), 1.24(d, 6H).

4-Isopropylacetophenone

4-Isopropylacetophenone was prepared by the reaction of cumene and acetyl chloride in the presence of aluminum chloride, using carbon disulphide as the solvent. The reaction mixture was purified by vacuum distillation. 4-Isopropylacetophenone was obtained as a colourless oil (17); ir SP1000 (neat) cm^{-1}: 1680, 1610, 830; ^{1}Hmr (361.1 MHz, $CDCl_3$) δ: 7.90(m,2H), 7.31(m,2H), 2.97(m,1H), 2.59(s,3H), 1.27(d,6H).

4-Isopropylbenzophenone

4-Isopropylbenzophenone was prepared by a procedure similar to that used for the acetophenone except using benzoyl chloride. Vacuum distillation afforded 4-isopropylbenzophenone as a colourless oil (18); ir SP1000 (neat) cm^{-1}: 1660, 1610, 850, 700; ^{1}Hmr (361.1 MHz, $CDCl_3$) δ: 7.32–7.81(m,9H), 2.99(m,1H), 1.29(d,6H).

4-Isopropyldiphenyl sulphone

4-Isopropyldiphenyl sulphone was prepared in essentially quantitative yield by the addition of 4-isopropylsulphonyl chloride to a solution of benzene and aluminum chloride (2). The sulphonyl chloride was prepared in 94% yield by the addition of chlorosulphonic acid to cumene at 0°C (19). Recrystallization of the crude product from alcohol, with added Norite, produced colourless needles, mp 101–101.5°C (lit. (30) mp. 98.5–99.5°C); ir PE 180 (KBr) cm^{-1}: 1610, 1325, 1170, 840, 760, 690, 650; ^{1}Hmr (80 MHz, $CDCl_3$) δ: 7.81–8.00(m,4H), 7.28–7.53(m,5H), 2.94(m,1H), 1.22(d,6H).

4-Isopropyldiphenyl sulphide

4-Isopropyldiphenyl sulphone, 2.0 g (7.7 mmol), was placed in a 50-mL round bottom flask equipped with a reflux condenser and septum inlet. The flask was purged with dry nitrogen and 5.5 g of diisobutylaluminum hydride (DIBAL-H) (38.7 mmol) in toluene (20 mL) was added through the septum via a syringe. The solution was refluxed under a nitrogen atmosphere until the reaction was complete (3–4 days). The reaction mixture was poured into aqueous ammonium chloride and extracted with ether. The combined organic layers were washed with a saturated salt solution, dried with magnesium sulphate, and evaporated (20). The residue was chromatographed on a silica gel column using methylene chloride as the eluent. The yield of the purified product was 1.57 g (90%); ir PE 180 (neat) cm^{-1}: 2980, 1595, 1490, 1450, 1395, 1375, 830, 745, 695; ^{1}Hmr (361.1 MHz, $CDCl_3$) δ: 7.16–7.32(m,9H), 2.88(m,1H), 1.24(d,6H).

Methyl 4-isopropylbenzoate

In a 250-mL 3-necked flask equipped with a magnetic stirrer, reflux condenser, and a constant pressure dropping funnel was placed 12.2 g (91 mmol) of aluminum chloride. To the aluminum chloride was added 10.0 g (83 mmol) of cumene dissolved in 175 mL of carbon disulphide. The flask was cooled in an ice bath; to the cooled mixture was added a solution of 11.6 g (91 mmol) of oxalyl chloride in 25 mL of carbon disulphide. After the evolution of gases (**caution: carbon monoxide!**) had ceased, the mixture was allowed to warm to room temperature. The mixture was then refluxed for 1.5 h and the cooled mixture was poured into 200 mL of methanol. The carbon disulphide was removed by distillation and the residue was poured into water and extracted with ether. The combined organic layers were washed with 5% sodium hydroxide, saturated salt solution, dried with magnesium sulphate, and evaporated. The yield of a pale yellow oil was 11.3 g (76%). The product was distilled under vacuum to yield a colourless oil (21); ir PE 283B (neat) cm^{-1}: 1735, 1620, 1285, 1120; ^{1}Hmr (80 MHz, $CDCl_3$) δ: 7.91–8.01(m,2H), 7.22–7.32(m,2H), 3.89(s,3H), 2.95(m,1H), 1.25(d,6H).

4-Fluorocumyl alcohol

4-Fluorocumyl alcohol was prepared by the reaction of ethyl 4-fluorobenzoate with methyl magnesium iodide, mp 36–37°C uncorrected (lit. (22) mp 37.8°C); ir 283B (neat) cm^{-1}: 3400, 1605, 1510, 1235, 1160, 835; ^{1}Hmr (80 MHz, $CDCl_3$) δ: 6.99–7.53(m,4H), 1.89(s,1H), 1.56(s,6H).

4-Trifluoromethylcumene

Method a: 4-trifluoromethylcumene was prepared by catalytic hydrogenation of 4-trifluoromethyl-α-methylstyrene using palladium-on-carbon (49% overall yield from the cumyl alcohol). The styrene was prepared by the acid catalyzed dehydration of 4-trifluoromethylcumyl alcohol (23, 24) using 4-tolunenesulphonic acid in refluxing benzene.

Method b: 4-trifluoromethylcumene was prepared by the reduction of 4-trifluoromethylcumyl alcohol using hydriodic acid and red phosphorus (refluxing overnight) (24). The yield was 58%; ir 283B (neat) cm^{-1}: 1625, 1335, 1175, 1135, 1080, 1020, 845; ^{1}Hmr (80 MHz, $CDCl_3$) δ: 7.18–7.59(m,4H), 2.96(m,1H), 1.25(d,6H).

4-Methylcumyl alcohol

4-Methylcumyl alcohol (22, 25) was prepared by the reaction of methyl 4-toluate with methyl magnesium iodide; ir 283B (neat) cm^{-1}: 3420, 1520, 1370, 960, 820; ^{1}Hmr (361.1 MHz, $CDCl_3$) δ: 7.37(m,2H), 7.15(m,2H), 2.34(s,3H), 1.79(s,1H), 1.57(s,6H).

4-Chlorocumene

4-Chlorocumene was prepared by a Sandmeyer reaction using the diazonium salt from 4-isopropylaniline and cuprous chloride (26); ir 283B (neat) cm^{-1}: 1500, 1100, 1020, 830; ^{1}Hmr (80 MHz, $CDCl_3$) δ: 7.06–7.32(m,4H), 2.87(m,1H), 1.21(d,6H); ms *m/e* (rel. intensity): 154(M^+,30), 139(100).

4-Isopropylphenyl benzoate

4-Isopropylphenyl benzoate was prepared by the reaction between 4-isopropylphenol and benzoyl chloride in 3 *M* aqueous sodium hydroxide (27); mp 75°C (lit. (28) mp 72–74°C); ir 283B cm^{-1}: 1735, 1200, 1055, 880, 720; ^{1}Hmr (361.1 MHz, $CDCl_3$) δ: 8.20(m,2H), 7.11–7.62(m,7H), 2.94(m,1H), 1.27(d,6H).

4-Isopropylphenyl acetate

4-Isopropylphenyl acetate (29) was prepared by a procedure similar to that used for the benzoate; ir 283B (neat) cm^{-1}: 1780, 1510, 1375, 1225, 1205, 1020, 915, 850; ^{1}Hmr (80 MHz, $CDCl_3$) δ: 6.92–7.28(m,4H), 2.90(m,1H), 2.27(s,3H), 1.23(d,6H).

4-Ethylcumyl alcohol

4-Ethylcumyl alcohol was prepared by the addition of 4-ethylacetophenone to methyl magnesium iodide (22); ir 283B (neat) cm^{-1}: 3400, 1510, 1460, 1365, 1170, 955, 830; ^{1}Hmr (80 MHz, $CDCl_3$) δ: 7.10–7.45(m,4H), 2.62(q,2H), 1.88(s,1H), 1.55(s,6H), 1.23(t,3H).

*4-*tert*-Butylcumyl alcohol*

4-*tert*-Butylcumyl alcohol was prepared by the addition of methyl 4-*tert*-butylbenzoate to a solution of methyl magnesium iodide; mp 78°C (lit. (22) mp 79°C); ir 283B (neat) cm^{-1}: 3350, 1370, 960, 830; ^{1}Hmr (80 MHz, $CDCl_3$) δ: 7.38(s,4H), 1.73(s,1H), 1.57(s,6H), 1.31(s,9H).

4-Cyanocumene

4-Cyanocumene (30) was prepared by a Sandmeyer reaction using the diazonium salt formed from 4-isopropylaniline and cuprous cyanide (27); ir 237B cm^{-1}: 2240; ^{1}Hmr (361.1 MHz, $CDCl_3$) δ: 7.59(m,2H), 7.33(m,2H), 2.97(m,1H), 1.27(d,6H).

4-Methoxycumene

4-Methoxycumene was prepared by the reaction of 4-isopropylphenol with dimethyl sulphate in 5% aqueous potassium hydroxide. The product was purified by column chromatography using silica gel; ir 283B (neat) cm^{-1}: 1620, 1520, 1250, 1040, 830; ^{1}Hmr (361.1 MHz, $CDCl_3$) δ: 7.15(m,2H), 6.85(m,2H), 3.79(s,3H), 2.86(m,1H), 1.23(d,6H).

Preparation of cumyl bromides

The method of Grice and Owen (31) was used for the conversion of substituted cumyl alcohols to the bromides. Typically, the cumyl alcohol (0.02 mol) was dissolved in pentane or benzene (100 mL). Hydrogen bromide gas was passed through the solution for 0.5 h. The solution was then dried over anhydrous magnesium sulphate, filtered, and the solvent removed at reduced pressure.

Electron spin resonance experiments

Cumenes

A static solution of DTBP (0.3 mL)[7] and the cumene (30–60 mg) was irradiated in the esr spectrometer cavity using filtered (methanol in a quartz tube) light from a 1-kW Hanovia Xe–Hg high-pressure lamp. All samples were purged with nitrogen for 5 min prior to

[7]To increase the solubility of the *para*-SO_2Ph derivative, 0.2 mL of benzene was added to the DTBP solution.

irradiation and examined at 253 K.

The observed spectrum of the 4-methoxycumyl radical, generated by this procedure, was complicated by the competitive hydrogen abstraction from the methoxy methyl group. Simulation indicated a ratio of cumyl to α-aryloxymethyl radical of ca. 1 : 1. The α-aryloxy radical was simulated by $a(CH_2)$ = 17.40 G.

Cumylbromides

Three procedures were used to generate the cumyl radicals from the bromide. In procedure 1, a static solution of DTBP (0.2 mL), triethylsilane (0.2 mL), and the bromide (50–100 mg), diluted if necessary with chlorobenzene, was purged with nitrogen and irradiated as described above in the esr spectrometer cavity. The 4-*tert*-butylcumyl radical was generated by this procedure at 233 K. In procedure 2, a solution of the bromide (50–100 mg) in *tert*-butylbenzene or chlorobenzene was continuously purged with nitrogen while hexamethylditin (0.1 mL) was injected via the purge tube. It was necessary to have a glass wool plug in the purge tube to filter the hexamethylditin. This solution was irradiated as described above. The use of chlorobenzene allowed cooling of the sample to temperatures as low as 233 K without precipitation of the hexamethylditin. The 4-fluoro and 4-ethyl derivatives were generated by this method at 263 K and 233 K, respectively. In procedure 3, the bromide (100 mg) was purged with nitrogen and hexabutylditin (0.1 mL) added in a glove box under an inert atmosphere. This solution was irradiated as described above. The 4-methyl derivative was generated by this method at 253 K.

Control experiments

Linearity of field was checked against the lines of $[Cr(NH_3)_5Cl]Cl_2$ doped with 2% $[Co(NH_3)_5Cl]Cl_2$ (32). Accuracy of the field was checked against the couplings for Wurster's blue perchlorate in ethanol (33). The effects of moderate temperature changes on the spectra of six representative cumyl radicals, 4-chloro, 4-isopropyl, 4-acetyl, 4-carbomethoxy, 4-benzoyl, and 4-phenylsulfonyl, were studied by recording the spectrum at 20-deg intervals from 213 to 273 K, and also at 333 K for 4-chloro and 4-acetyl, and at 293 K for 4-isopropyl, 4-benzoyloxy, and 4-phenylsulfonyl. In all cases the benzylic β-hfc value was invariant. However, for the 4-isopropyl derivative, a change in the hfc value for the isopropyl group with a lowering of temperature was observed, indicating the hindered rotation of the isopropyl group.

Novel coincidence effects in a bimetallic phase transfer catalyzed reaction. Biphasic reduction reactions catalyzed by rhodium carbonylmetallate clusters

FERENC JOÓ AND HOWARD ALPER[1]

Ottawa-Carleton Chemistry Institute, Department of Chemistry, University of Ottawa, Ottawa, Ont., Canada K1N 9B4

Received July 24, 1984

FERENC JOÓ and HOWARD ALPER. Can. J. Chem. **63**, 1157 (1985).

Bimetallic and cluster rhodium carbonyl complexes catalyze the biphasic reduction of nitro compounds under mild conditions (using CO/5 *M* NaOH, C_6H_6 or $PhCH_3$). Rate studies indicate the sensitivity of the reaction to the nature of the organic substrate, base concentration, and the temperature. A previously observed bimetallic ($Co_2(CO)_8$ and $(1,5\text{-HDRhCl})_2$) and phase transfer catalyzed [$R_4N^+X^-$] reduction of nitro compounds was found to be a consequence of the inhibition and reactivation of the true catalyst by the quaternary ammonium salt and cobalt carbonyl, respectively.

FERENC JOÓ et HOWARD ALPER. Can. J. Chem. **63**, 1157 (1985).

Opérant en deux phases et sous des conditions douces (utilisant CO/NaOH 5 *M*, C_6H_6 ou $PhCH_3$), les complexes, bimétalliques et sous forme d'agrégats, du rhodium carbonyle peuvent catalyser la réduction des composés nitrés. Des données cinétiques indiquent que la réaction est sensible à la nature du substrat organique, à la concentration en base et à la température. Une réduction, bimétallique et catalysée par un transfert de phase [$R_4N^+X^-$], des composés nitrés a été observée antérieurement; on a trouvé que cette réduction est une conséquence d'inhibition et de réactivation du vrai catalyseur qui sont respectivement provoquées par le sel d'ammonium quaternaire et le cobalt carbonyle.

[Traduit par le journal]

Group 8 metal complexes play an important role in the homogeneously catalyzed reduction of nitro compounds (1–4). One of us has demonstrated that by application of phase transfer techniques, the reaction conditions could be made significantly milder in the ruthenium carbonyl (3) and the dichlorotris(triphenylphosphine)ruthenium (5) catalyzed processes. Recently, the use of bimetallic phase transfer catalysis for the reduction of nitro compounds has been described, whereby the synergistic effect of cobalt carbonyl and chloro(1,5-hexadiene)rhodium(I) dimer $[1,5\text{-HDRhCl}]_2$ facilitates amine formation when dodecyltrimethylammonium chloride (DTAC) is the phase transfer agent in a mixture of 5 *N* sodium hydroxide and benzene, (reaction [1]). No reaction occurred when only one of the two metal catalysts were used under the phase

$$[1]\quad \mathrm{ArNO_2} \xrightarrow[\mathrm{Co_2(CO)_8,\,[1,5\text{-}HDRhCl]_2,\ rt,\ 1\ atm}]{\mathrm{CO,\ 5}\,M\,\mathrm{NaOH,\ C_6H_6,\ C_{12}H_{25}N(CH_3)_3{}^+Cl^-}} \mathrm{ArNH_2}$$

transfer conditions (6).

While there has been considerable interest in the use of two different metal complexes for catalyzing various organic transformations, little is understood about such processes. An investigation was therefore undertaken in order to gain some insight into the mechanism of the intriguing phase transfer reduction reaction. Several noteworthy findings were made which are reported herein: (*i*) rhodium carbonyl clusters are able to catalyze the nitro reduction in two-phase media in the *absence* of phase transfer agents and cobalt carbonyl; and (*ii*) the bimetallic nature of the above reaction ([1]) is a consequence of the coincidence of inhibition and reactivation of the true catalyst by the quaternary ammonium salt and cobalt carbonyl, respectively.

Results and discussion

When a nitro compound and a catalytic quantity of $[1,5\text{-HDRhCl}]_2$ or chlorodicarbonylrhodium(I) dimer, dissolved in a mixture of 5 *M* NaOH and either toluene or benzene, were placed under 1 atm of carbon monoxide at room temperatre ($[1,5\text{-HDRhCl}]_2$ is converted to $Rh(CO)_2Cl$ under these conditions), a relatively fast gas uptake began which corresponded to the nitro-amine conversion. The latter was verified by gas volumetry as well as by product isolation and characterization. However, *no* reaction was observed when a phase transfer catalyst was present [dodecyltrimethylammonium chloride, tetrabutylammonium chloride, tetrabutylammonium hydroxide].

The reactivity pattern (Table 1) is basically the same as that found with the $[1,5\text{-HDRhCl}]_2/Co_2(CO)_8$/DTAC catalyst system, i.e., the reaction is selective for the reduction of the nitro group in the presence of olefin, halogen, and carbonyl functionalities (6). The reaction of sterically hindered or aliphatic nitro compounds is slow compared to the non-hindered aromatic ones; nevertheless, it does occur.

Both temperature and base concentration are important for a favorable process to occur. At even slightly elevated temperatures (40°C), the catalyst is destroyed in the first few minutes of the reaction which then stops completely. At low base concentrations (0.1 *M*) a green aqueous phase is formed instead of the dark brown one in 5 *M* NaOH, and reaction is slow, if it occurs at all. A plot of the effect of hydroxide ion concentration on the rate of nitrobenzene reduction is illustrated in Fig. 1. The fastest reaction occurs at 3 *M* NaOH, while the rate is less at higher base concentrations. Variation in the base concentration will not only affect the solubility of the reactant species (including carbon monoxide), but also the ease of attack by hydroxide ion on coordinated carbonyl, and the interconversion of carbonylrhodates (discussed below). It is also noteworthy that deactivation of the catalyst is accompanied by uptake of carbon monoxide, and therefore a long pretreatment of the rhodium solutions with CO/H_2O should be avoided even at room temperature.

It is interesting to note that Alessio *et al.* (7) have found $Rh_6(CO)_{16}$ and chloro(1,5-cyclooctadiene)rhodium(I) completely inactive for the reduction of nitrobenzene in the absence of a chelating phenanthroline-type ligand by CO/H_2O in 95% ethanol at elevated pressure (30 atm) and temperature (165°C — no base was added). In the present study, however, $Rh_6(CO)_{16}$ or even aqueous $RhCl_3$ can be used as catalyst pre-

*Rates are expressed as mol RNO_2 reduced to RNH_2 per mol Rh per hour based on the conversion reached in the first 30 min. Biphasic systems: 15 mL 5 *M* NaOH, 20 mL toluene, 30°C, CO to 1 bar total pressure, and (*a*) 0.3 mmol substrate, 0.030 mmol Rh as [Rh(hexadiene)Cl]$_2$; (*b*) 1 mmol substrate, 0.033 mmol Rh as $[Rh(CO_2Cl]_2$; (*c*) 1 mmol substrate, 0.125 mmol Rh as $[Rh(CO)_2Cl]_2$; (*d*) 0.3 mmol substrate, 0.125 mmol Rh as $Rh_6(CO)_{16}$; (*e*) 1 mmol substrate, 0.100 mmol Rh as $RhCl_3 \cdot aq$; (*f*) 1 mmol substrate, 0.100 mmol Rh as $[Rh(CO)_2Cl]_2$; (*g*) as (*f*) but 500 mg NaOAc instead of 1 mL 5 *M* NaOH.

†Yield of isolated and chromatographically purified 4-aminochlorobenzene, 4-aminobenzophenone, and 4-amino-*trans*-stilbene (reaction time: 280, 65, and 260 min, respectively).

‡Homogeneous solutions: 9 mL MeOH, 1 mL H_2O, 1 mL 5 *M* NaOH, 30°C, CO to 1 bar total pressure.

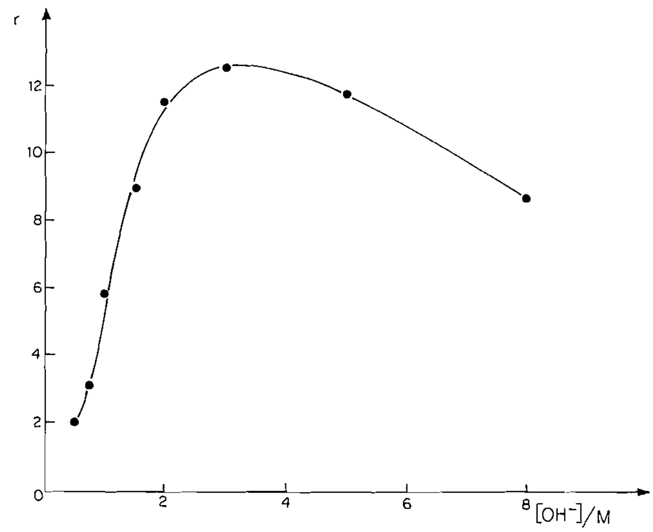

FIG. 1. Effect of base concentration on the rate of reduction of nitrobenzene. Conditions: 15 mL NaOH solution, 20 mL toluene, 0.03 mmol Rh as $[Rh(CO)_2Cl]_2$, 0.3 mmol $PhNO_2$, carbon monoxide up to 1 bar total pressure (30°C). Rates are calculated on the basis of gas uptake in the first 30 min of the reaction and are expressed as mol $PhNO_2$ reduced/mol Rh h.

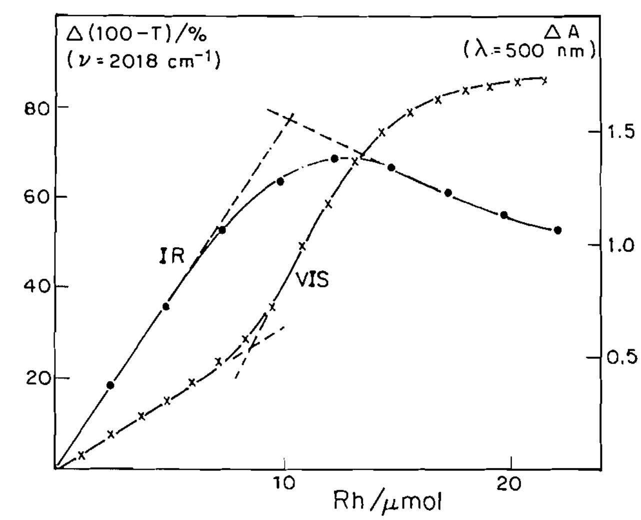

FIG. 2. Spectrophotometric titration of $Co(CO)_4^-$ with $[Rh(CO)_2Cl]_2$ under CO. Infrared: 9.50 μmol of $C_{12}H_{25}N(CH_3)_3^+Co(CO)_4^-$ in $PhCH_3$ titrated with 0.25 μmol Rh/μL solutions of $[Rh(CO)_2Cl]_2$ in $PhCH_3$. The break on the graph corresponds to 1.07 Rh/Co. VIS: 8.53 μmol $PPN^+Co(CO)_4^-$ in CH_2Cl_2 (3.0 mL) titrated with 0.12 μmol Rh/μL solutions of $[Rh(CO)_2Cl]_2$ in CH_2Cl_2. The break on the graph corresponds to 1.01 Rh/Co.

cursors (Table 1).

Pioneering work by Chini and co-workers[2] showed that various rhodium complexes can react with carbon monoxide and base to give a series of carbonylrhodates (via formation of $[Rh(CO)_2Cl]_2$ and $Rh_4(CO)_{12}$), including inter alia $[Rh_{12}(CO)_{30}]^{2-}$ (violet), $[Rh_5(CO)_{15}]^-$ (red–brown), $[Rh_7(CO)_{16}]^{3-}$ (green), and $[Rh_6(CO)_{14}]^{4-}$ (dark red). Furthermore, halo- and hydridocarbonylrhodates are also formed in the presence of halogen and hydrogen, respectively. Under the conditions employed by us, both $[1,5\text{-HDRhCl}]_2$ and $[Rh(CO)_2Cl]_2$ consume carbon monoxide up to the ratio of CO/Rh = 3.5, accompanied by the transfer of the rhodium containing species to the aqueous phase, forming a dark brown solution. The reaction is complex indeed, and the infrared spectra of the quaternary ammonium carbonylrhodate salts did not correlate well with the published spectral data of the noted carbonylrhodates. However, it was found that $Rh_{12}(CO)_{30}^{2-}$ (9) and $Rh_7(CO)_{16}^{3-}$ (10), prepared by the methods of Chini *et al.*, proved to be catalytically active for nitro reduction in homogeneous methanol/water solutions. As the reduction requires base, the slight activity of violet-red solutions of $Rh_{12}(CO)_{30}^{2-}$ (possibly also containing $Rh_5(CO)_{15}^-$) (11) may be due to the presence of some $Rh_7(CO)_{16}^{3-}$ as the real catalytic species. Use of the latter as catalyst results in the maintenance of a green color of the solution throughout the reaction; however, if one uses an excess of nitro compound compared to base, the color turns red when the OH^- ion is consumed, indicating that the nitro compound oxidized the green species (formal oxidation number −0.429) to the red one(s) (FON −0.166 and −0.2, respectively). The higher specific rates in aqueous alcohol than under biphasic conditions is probably a result of the homogeneous conditions. On the other hand, the low activity of the

[2] For an account of this subject, see ref. 8.

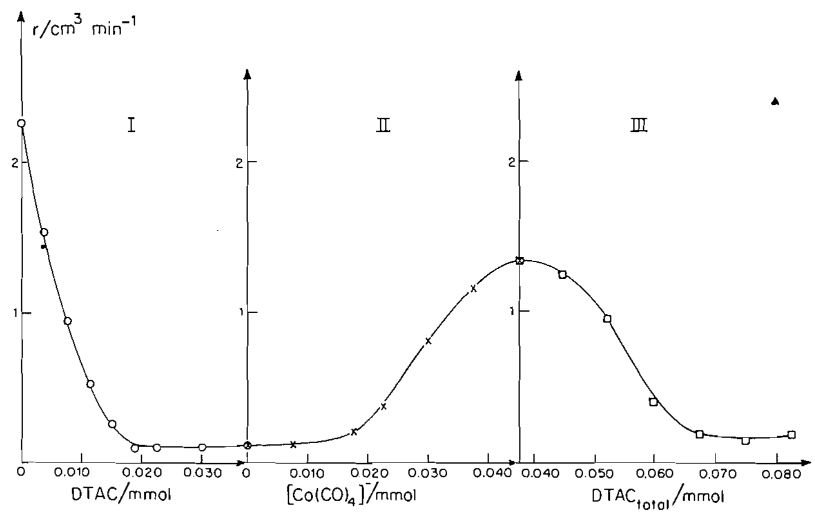

FIG. 3. Effect of (*I*) $C_{12}H_{25}N(CH_3)_3{}^+Cl^-$; (*II*) $Co(CO)_4{}^-$, formed from the added $Co_2(CO)_8$; and (*III*) $C_{12}H_{25}N(CH_3)_3{}^+Cl^-$ added subsequently, on the rate of reduction of $PhNO_2$ by CO/H_2O, catalyzed by $[Rh(CO)_2Cl]_2$. Conditions: 3 mmol $PhNO_2$, 0.10 mmol Rh, 15 mL 5 *M* NaOH, 20 mL $PhCH_3$, 30°C, 1 bar total pressure. The rate observed in the presence of 0.080 mmol of NaCl (and in the absence of $C_{12}H_{25}N(CH_3)_3{}^+Cl^-$) is also shown (▲).

green weakly basic aqueous solutions previously mentioned may be due to the low solubility of the aromatic nitro compounds in dilute aqueous base solutions, while 5 *M* NaOH is a reasonably good solvent for polar organic substrates.

Strongly basic aqueous solutions of rhodium carbonyls are known to catalyze the water gas shift reaction (1, 4, 12) and $Rh_{12}(CO)_{30}{}^{2-}$ was suggested as a catalytically active intermediate (13). We have also found that solutions of $[Rh(CO)_2Cl]_2$ in 5 *M* NaOH under carbon monoxide produce hydrogen at room temperature and 1 bar total pressure with a rate of about 0.1 mol H_2/mol Rh h.

In order to determine the cause of the synergistic effect of $[1,5\text{-HDRhCl}]_2$ and $Co_2(CO)_8$ in the phase transfer catalyzed reduction of nitro compounds by CO/H_2O (6) an investigation was made of the reaction of $[Rh(CO)_2Cl]_2$ and $R_4N^+Co(CO)_4{}^-$ in dry toluene. An intense red–brown color develops on the addition of $[Rh(CO)_2Cl]_2$ to $C_{12}H_{25}N(CH_3)_3{}^+Co(CO)_4{}^-$ in toluene or methylene chloride. The reaction can be followed by visible spectrophotometry at 500 nm and a plot of ΔA vs. [Rh] (Fig. 2) reveals the formation of a complex with a 1:1 Co/Rh ratio (not $Co_2Rh_2(CO)_{12}$).[3] Solutions of this composition show absorptions in the infrared region at 2062, 2018, 1986, 1948, and 1908 cm^{-1} (all strong — toluene solutions), and the formation of this complex is also established by ir spectrophotometric titration (Fig. 2). The structure of this complex may be $C_{12}H_{25}N(CH_3)_3{}^+Rh(CO)_2Cl(Co(CO)_4)^-$ in which $Co(CO)_4{}^-$ acts as a pseudohalide. The ir spectrum is in accord with this structure since there are only terminal carbonyl bands present, and the number of these bands is consistent with C_{2v} molecular symmetry with a staggered conformation. Attempts to obtain analytically pure materials have proved unsuccessful (15).

Addition of further amounts of $[Rh(CO)_2Cl]_2$ to the bimetallic anionic complex gives a new complex having a 2:1 Rh/Co ratio. This complex is much less stable in solution than the 1:1 complex. On addition of tetrabutylammonium chloride, the red–brown solution of the 1:1 Co/Rh complex turns light green, and the Co–Rh complex decomposes to give $Rh(CO)_2Cl_2{}^-$ (ir ν_{CO}: 2065 and 1988 cm^{-1}) and $Co(CO)_4{}^-$, in agreement with the anticipated higher nucleophilicity of Cl^- than that of $Co(CO)_4{}^-$.

The presumed bimetallic complex $R_4N^+Rh(CO)_2Cl\text{-}[Co(CO)_4]^-$ is destroyed by addition of either tetrabutylammonium hydroxide or 5 *M* NaOH to give $R_4N^+Co(CO)_4{}^-$, as can be readily observed by monitoring the characteristic absorption of cobalt tetracarbonyl anion at 1885 cm^{-1}. If there is an equivalent, or less, of R_4N^+ to $Co(CO)_4{}^-$ in the system, the rhodium-containing species formed by the action of base moves to the aqueous phase. However, when there is an excess of R_4N^+ compared to $Co(CO)_4{}^-$ the insoluble salts of the anionic carbonylrhodates are produced and are finely dispersed in the toluene phase, collecting at the interphase on standing. Addition of $Co_2(CO)_8$ gives $R_4N^+Co(CO)_4{}^-$ which migrates to the organic phase and forces the rhodium carbonyls back to the aqueous solution. This inhibition/reactivation sequence is illustrated in Fig. 3, which also indicates the formation of higher nuclearity rhodium clusters (inhibition by dodecyltrimethylammonium chloride occurs at much below the rhodium concentration). Separate experiments show that inhibition is not due to chloride ion.

In conclusion, the rhodium(I) biphasic reaction is a simple and selective homogeneously catalyzed nitro reduction process. The above results account for the "bimetallic" phase transfer reaction, and in particular establish the fascinating effects of a quaternary ammonium salt and a second metal complex catalyst on the rhodium catalyzed biphasic reaction.

Experimental section

The nitro compounds, rhodium and cobalt compounds, as well as phase transfer agents were commercial materials. Solutions of the violet $Rh_{12}(CO)_{30}{}^{2-}$ were prepared by reacting 19.5 mg (0.1 mmol Rh) of $[Rh(CO)_2Cl]_2$ with carbon monoxide in a 9:1 methanol–water solution (10 mL) containing 0.5 g of sodium acetate. When 1% water/tetrahydrofuran was used as the solvent, the initial violet color turned deep red in approximately 30 min, and an ir showed bands at 2070 w, 2042 vs, 2010 vs, 1870 m, 1840 m, and 1779 vs cm^{-1}, characteristic of $Rh_5(CO)_{15}{}^-$. Addition of 5 *M* NaOH (1.0 mL) to the above solutions gave rise to an intense green solution, and the

[3] The related, neutral complex $(PEt_3)_2(CO)RhCo(CO)_4$ has been successfully isolated from the reaction of *trans*-$RhCl(CO)(PEt_3)_2$ with $KCo(CO)_4$ (14).

$Rh_7(CO)_{16}^{3-}$ anion could be precipitated after dilution with water, as the Bu_4N^+ salt. This compound, owing to its extreme air-sensitivity, was characterized in acetonitrile solution: ir-ν_{CO} 1990 m, 1955 vs, 1905 m, 1815 w, and 1770 s cm^{-1}.

General procedure for the biphasic reduction of nitro compounds

A mixture of 5 *M* NaOH (15 mL), toluene or benzene (20 mL) and nitro compound (1.0 mmol) was degassed in a constant pressure, thermostatted manometric apparatus, which was finally filled with carbon monoxide. The rhodium catalyst (0.033 mmol) in toluene was added (by syringe). The mixture was stirred until the desired conversion had occurred (indicated by gas uptake) at which time stirring was stopped. The two phases were separated, the aqueous phase was extracted with toluene or ether (2 × 20 mL) and the combined organic solution was dried ($MgSO_4$) and concentrated. When there was less than 100% conversion, the product and starting material were separated by column chromatography on silica gel using toluene:ether (1:1) as eluant. Products were identified by comparison of R_f values (TLC) and spectral data with those of authentic materials.

Infrared and visible spectrophotometric studies

Visible spectrophotometric titrations were carried out under carbon monoxide using a screw-thread headed pyrex-glass cell closed with a silicone–rubber septum. For infrared measurements (Perkin-Elmer 783 spectrophotometer), stock solutions were prepared and mixed under carbon monoxide and samples were withdrawn by means of hypodermic syringes.

Illustrative preparation of $R_4N^+Co(CO)_4^-$ for ir spectrophotometric titrations: $Co_2(CO)_8$ (0.171 g, 1.0 mmol) and dodecyltrimethylammonium chloride (0.456 g of a 50% w/w $R_4N^+Cl^-$ in 1:1 H_2O-isopropanol) were dissolved in a degassed mixture of 5 *M* NaOH (25 mL) and toluene (40 mL) under carbon monoxide. The solution was stirred for 40 min, during which time it became almost colorless. The organic phase was removed (syringe) and dried ($MgSO_4$) under carbon monoxide. An infrared spectrum showed only one carbonyl band at 1885 cm^{-1}, characteristic of $Co(CO)_4^-$, the concentration of which was found, by the iodine oxidation method (16), to be 19 μmol Co/mL.

Bis(triphenylphosphine)iminium tetracarbonylcobaltate was prepared for visible studies. To 16 mL of a methylene chloride solution of $Bu_4N^+Co(CO)_4^-$ (containing 63 μmol Co/mL) was added 0.552 g of PPNCl followed by ether (40 mL). The desired compound was filtered, washed with hexane, and dried under nitrogen: ν_{CO} 1886 cm^{-1} (CH_2Cl_2). Yield: 0.465 g (68%).

Metabolites of *Lachnellula fuscosanguinea* (Rehm). Part 1. The isolation, structure determination, and synthesis of lachnelluloic acid[1]

WILLIAM A. AYER AND J. DANIEL FIGUEROA VILLAR

Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received September 27, 1985

WILLIAM A. AYER and J. DANIEL FIGUEROA VILLAR. Can. J. Chem. **63**, 1161 (1985).

The metabolites produced in liquid culture by the fungus *Lachnellula fuscosanguinea* (Rehm) Dennis have been examined and two antifungal agents, lachnelluloic acid and lachnellulone, have been isolated. The structure of lachnelluloic acid has been established as (−)-4-hydroxy-3-octanoyl-6-pentyl-5,6-dihydro-2-pyrone (**1**) by chemical and spectroscopic methods. The total synthesis of racemic lachnelluloic acid, starting from 6,8-tridecanedione (**6**) is reported. Lachnelluloic acid (**1**) shows strong antifungal activity against *Ceratocystis ulmi*, the causative agent of Dutch elm disease.

WILLIAM A. AYER et J. DANIEL FIGUEROA VILLAR. Can. J. Chem. **63**, 1161 (1985).

On a étudié les métabolites produits, au cours d'une culture liquide, par le champignon *Lachnellula fuscosanguinea* (Rehm) Dennis et on a isolé deux agents fongicides, l'acide lachnelluloïque et la lachnellulone. Faisant appel à des méthodes chimiques et spectroscopiques, on a démontré que la structure de l'acide lachnelluloïque correspond à celle de la (−)-hydroxy-4 octanoyl-3 pentyl-6 dihydro-5,6 pyrone-2 (**1**). On rapporte une synthèse totale de l'acide lachnelluloïque racémique faisant appel à la tridécanedione-6,8 (**6**) comme produit de départ. L'acide lachnelluloïque (**1**) présente une forte activité fongicide contre le *Ceratocystis ulmi*, l'agent provoquant la maladie de la tordeuse de bourgeons.

[Traduit par le journal]

The fungus *Lachnellula fuscosanguinea* (Rehm) Dennis (1, 2) has been shown to be antagonistic to the Dutch elm disease fungus *Ceratosystis ulmi* and to the wood rotting fungus *Fomes pini*.[2] Initial studies in our laboratories showed that a methylene chloride extract of liquid cultures of *L. fuscosanguinea* displayed antifungal activity against *C. ulmi*. We report here the isolation of two active antifungal agents and the structure (**1**) of one of these compounds, which we have named lachnelluloic acid.

Lachnelluloic acid (**1**) was isolated from the mycelium extract (CH_2Cl_2) of *L. fuscosanguinea* by flash chromatography followed by column chromatography on silica gel. The colorless, crystalline, low melting (39–40°C) substance possesses the molecular formula $C_{18}H_{30}O_4$ and gives a positive ferric chloride test. The infrared (ir) spectrum does not show OH absorption, but does show absorption at 1708, 1695, and 1555 cm^{-1}. The latter absorption band, and the lack of apparent OH absorption, is attributed to the strongly chelated enolized β-diketone functionality in **1**.

The ultraviolet spectrum of lachnelluloic acid shows strong absorption bands at 218 and 274 nm, shifted to 250 nm in the presence of base, very reminiscent of that of alternaric acid (**2**)

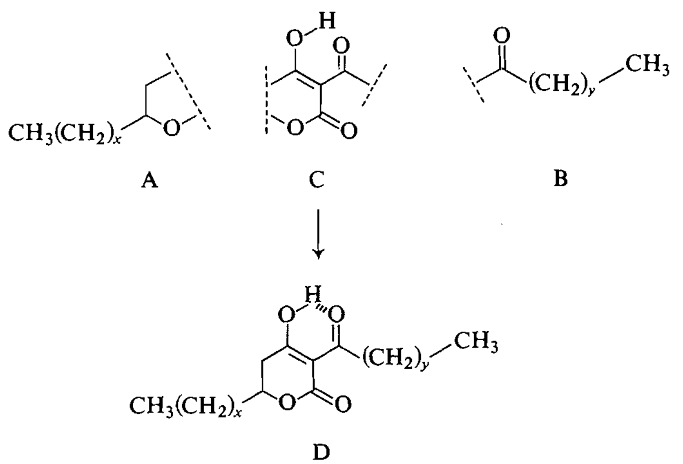
(**3**) and similar to that of dihydrodehydroacetic acid (**3**) (see below).

The ^1H nmr spectrum of **1** confirms the presence of the strongly H-bonded enolic proton, showing a signal at δ 17.9, similar to that observed in dihydrodehydroacetic acid (**3**). Homonuclear decoupling experiments suggested the partial structures A and B (Scheme 1) for lachnelluloic acid. Thus, simultaneous irradiation of the signal at δ 4.38 (proton *geminal* to the ethereal oxygen) induces decoupling of the *geminal* methylene protons at δ 2.68 and δ 2.58 (C-5 H's) as well as protons at δ 1.80 and δ 1.66, methylene protons of an alkyl side chain,

[1] The isolation and structure determination of lachnelluloic acid was first reported at the 9th Simposium Internacional de Química de Productos Naturales, Monterrey, Mexico, April 1982, Abstract no. 6. The synthesis of lachnelluloic acid was first presented at the Chemical Institute of Canada 66th Chemical Conference, Calgary, June 1982, Abstract OR 15-3.

[2] A. Tsuneda and Y. Hiratsuka, Northern Forest Research Centre, Canadian Forestry Service, Edmonton, personal communication. We thank Drs. Tsuneda and Hiratsuka for cultures of *L. fuscosanguinea*. The fungus was discovered growing on *Pinus contorta* in Jasper National Park and was identified by Dr. D.W. Minter, Commonwealth Mycological Institute (accession number CMI 250255).



SCHEME 1

suggestive of partial structure A. The *geminal* pair of protons at δ 3.06 and δ 2.96, α to a carbonyl, are coupled to protons at δ 1.66, also part of an alkyl side chain, in keeping with partial structure B (see Experimental for complete assignments).

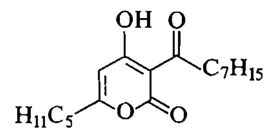
The ^{13}C nmr spectrum of **1** accounts for the 18 carbon atoms, two as methyl groups, eleven methylenes, one methine bearing oxygen, and four sp^2 hybridized carbons. The latter include a ketonic carbonyl at δ 204, a lactone or ester at δ 164, and the highly polarized double bond carbons of an enol at δ 195 and δ 103 (4, 5). In dihydrodehydroacetic acid (**3**) these signals appear at δ 201.2, 164.4, 195.0, and 103.4 (5).[3] This established the presence of part structure C in lachnelluloic acid.

Since lachnelluloic acid contains only four oxygen atoms, the part structures A, B, and C lead to structure D (Scheme 1) for lachnelluloic acid. The lengths of the side chains were deduced from the fragmentations observed in the electron impact mass spectrum of lachnelluloic acid. The base peak at m/z 239 corresponds to the loss of C_5H_{11} and represents the loss of the side chain *geminal* to the ethereal oxygen. A strong peak at m/z 226 ($M^+ - C_6H_{12}$) corresponds to McLafferty fragmentation of the acyl side chain. Thus in structure D, $x = 4$, and $y = 6$.

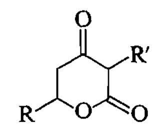
As a model for lachnelluloic acid, dihydrodehydroacetic acid (**3**) (6) was prepared by hydrogenation of dehydroacetic acid in benzene containing traces of pyridine. Compound **3** displays similar spectral characteristics (ir, uv, ^1H nmr, and ^{13}C nmr) to those of lachnelluloic acid (**1**). The direction of enolization in **3**, which must be the same as that in lachnelluloic acid, was determined to be as in **3** and not **4**, since the coupled ^{13}C nmr spectrum shows the lactone carbonyl as a broad singlet which is unaffected by deuterium exchange of the enolic hydrogen. Enolization as in **5**, although considered less likely, is not excluded by this datum (see also ref. 5).

In order to complete the assignment of the structure of lachnelluloic acid, racemic compound **1** was prepared by total synthesis as outlined in Scheme 2. Condensation of 6,8-tridecanedione (**6**), prepared by condensation of 2-heptanone and methyl hexanoate, with malonyl dichloride (**7**) afforded the pyrone **7** in 58% yield. Deacylation of **7** (90% H_2SO_4, 120–130°C) gave 4-hydroxy-6-pentyl-2-pyrone (**8**) in 87% yield. Hydrogenation of **8** over palladium–charcoal gives a quantitative yield of β-ketolactone **9** (spectral characteristics (see Experimental) and a negative ferric chloride test indicate that this compound exists in the unenolized form). Direct *C*-acylation of **9** with octanoyl chloride in refluxing trifluoroacetic acid (8) gave racemic lachnelluloic acid (**1**) in low (~10%) yield. Better results are obtained using Tanabe's method (9), which involves first *O*-acylation to provide **10** (~90% yield), followed by base-catalyzed thermal isomerization to provide racemic lachnelluloic acid (**1**) in 75% yield (34% overall yield from **6**), identical (ir, uv, nmr, ms) with the natural product. The absolute configuration of natural, levorotatory lachnelluloic acid has not been determined.

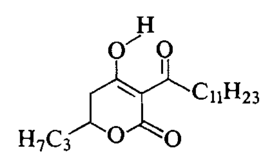
Direct acylation of the pyrone **8** with octanoyl chloride gave dehydrolachnelluloic acid **11** in high yield. All attempts to transform **11** into lachnelluloic acid by catalytic hydrogenation



11



12 R = C_5H_{11}, R′ = C_8H_{17}
13 R = CH_3, R′ = C_2H_5



14

(as was successful with dehydroacetic acid above) were unsuccessful. Hydrogenation over palladium–charcoal in ethyl acetate gave the deoxygenated β-ketone lactone **12** in virtually quantitative yield. Hydrogenation–hydrogenolysis of lachnelluloic acid under identical conditions also provided **12**, and similar hydrogenation of dehydroacetic acid gave **13**.

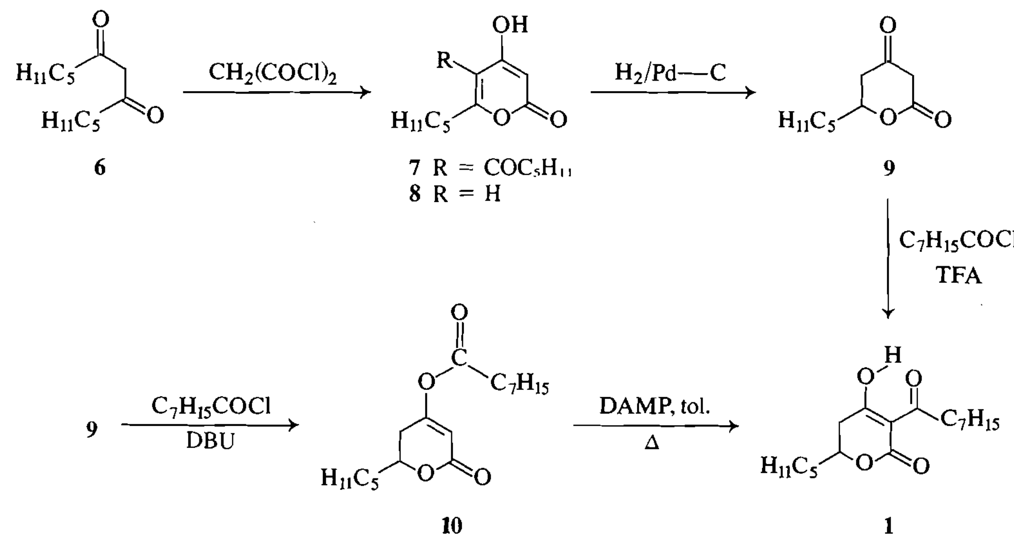
Lachnelluloic acid, which shows antifungal activity against *C. ulmi*, bears a structural similarity to the recently reported (10) podoblastins (e.g., podoblastin A (**14**)), compounds which also show antifungal activity. The structure of the second antifungal metabolite isolated from *L. fuscosanguinea*, lachnellulone, will be the subject of the next paper in this series.

Experimental

General

High resolution electron impact mass spectra (hreims) were recorded on an AEI MS-50 mass spectrometer. Chemical ionization mass spectra (cims) and low resolution electron impact mass spectra (lreims) were obtained using an AEI MS-4 mass spectrometer. Fast atom bombardment (FAB) spectra were obtained using an AEI MS-50 spectrometer. The data were processed in DS-50 and DS-9 computers. Fourier transform infrared (ftir) spectra were recorded as $CHCl_3$ casts on a Nicolet 7199 FT interferometer. Single scan infrared (ir) were recorded on a Perkin Elmer 297 spectrometer. Routine nmr spectra were obtained on a Varian A-56/60A spectrometer, a Bruker WP-80 spectrometer, and a Varian 4A-100 spectrometer with a Digilab FTS/NMR-3 data system. Tetramethylsilane was used as the internal standard. High field ^1H nmr and ^{13}C nmr spectra were recorded on Bruker WH-200 or WH-400 spectrometers with an Aspect 2000 computer system. Ultraviolet (uv) spectra were obtained on a Unicam SP 1700 spectrophotometer and optical rotations on a Perkin Elmer 141 polarimeter. Melting points are uncorrected and were determined on a Fisher–Johns melting point apparatus. E. Merck silica gel 60 (less than 230 mesh) was used for column chromatography, and E. Merck

[3] We wish to thank Prof. J.B. Stothers for valuable discussion and for performing a 2D INADEQUATE experiment on **3** (see ref. 5).



SCHEME 2

silica gel 60 (230–400 mesh) was used for flash chromatography. Preparative thin layer chromatography (ptlc) was carried out on Terochem silica gel G containing 1% Retma P-1 electronic phosphor (General Electric), 20 × 20 cm plates, 0.35–0.50 mm thickness. Analytical thin layer chromatography (tlc) was done on BDH precoated plates of silica gel 60 F-254. Visualization was carried out using uv light or iodine vapor (ptlc), and using 10% H_2SO_4 or 5% phosphomolybdic acid containing a trace of ceric sulfate in 5% sulfuric acid (tlc), followed by careful charring on a hot plate. All solvents were distilled prior to use. Skellysolve B refers to Skelly Oil Company light petroleum, bp 62–70°C.

Fermentations were carried out in a New Brunswick Scientific MF-214 microferm fermentor or a New Brunswick Scientific magnaferm fermentor.

Culturing of Lachnellula fuscoanguinea

Strain C-693 (Canadian Forestry Service, accession number of the Commonwealth Mycological Institute CMI 250255 and 250256) of *Lachnellula fuscosanguinea* was found growing on *Pinus contorta* on Maligne Lake Road, Jasper National Park, in 1979. A slant tube culture of this fungus was obtained from the Northern Forest Research Center, Edmonton. The original slant tube culture was transferred to potato dextrose agar (PDA) slant tubes which were kept as stock cultures at 4°C.

Shake cultures of the fungus were obtained by transferring small pieces of mycelium from the slant tubes to 300-mL Erlenmeyer flasks containing 150 mL of sterile potato dextrose broth (PDB). After two weeks at 17°C the shake cultures were ready to use as inoculum.

When a fermentor was used, 450 mL of inoculum was transferred to 10 L of sterile PDB in the fermentation tank. The conditions in the fermentor were kept as follows: temperature 20°C, air flow 1 L/min, pressure 4 psi (1 psi = 6.9 kPa), drive speed 170 rpm, and foam breaker speed 600 rpm. The fermentation was worked up after 3 weeks.

In the case of still culture, 25-mL aliquots of inoculum were transferred to 2.8-L Fernbach flasks, each containing 1 L of sterile PDB. The flasks were then kept at 17–20°C for at least 70 days.

Extraction of the metabolites

The culture mixture was separated into broth and mycelium by filtration through cheese cloth. The broth was extracted, without previous concentration, by CH_2Cl_2 liquid–liquid extraction (3 × 500 mL of CH_2Cl_2 for every 3 L of broth). The CH_2Cl_2 extract was then dried over anhydrous Na_2SO_4, filtered, and concentrated to dryness under reduced pressure at 35°C. Higher yields of extract were obtained when the broth was first concentrated (5 L to 500 mL, reduced pressure, 35°C) and then extracted with ethyl acetate in a continuous liquid–liquid extractor.

The mycelium was air dried for two days, then extracted with CH_2Cl_2 in a Soxhlet extractor. The CH_2Cl_2 extract was dried (anhydrous H_2SO_4) and concentrated.

Isolation of lachnelluloic acid (1)

A 50-mm diameter column was filled with 8 in. of silica gel for flash chromatography and packed using $CHCl_3$. The sample (1.5 g of crude extract) was applied as a concentrated solution in chloroform and the column was eluted with solvent at the rate of 2 in./min while collecting 50-mL fractions.

Fractions 20–30, eluted with $CHCl_3$, provided a waxy crystalline substance (305 mg). Column chromatography of this fraction (40 g of silica gel G mesh 270, 2-cm diameter column, Skellysolve B/$CHCl_3$, 1:1) gave a pure crystalline substance (204.2 mg), mp 39–40°C; $[\alpha]_D^{25}$ −26.6° (*c* 10, MeOH); tlc, R_f 0.5 (Skellysolve B/$CHCl_3$/HOAc, 50:50:1); ftir ($CHCl_3$, cast or solution): 2955, 2925, 2860, 1708, 1695, 1555, 1465, and 1065 cm^{-1}; uv (MeOH) λ_{max}: 218 (ϵ 700), 274 nm (ϵ 1090); uv (MeOH + NaOH) λ_{max}: 250 nm (ϵ 1375); uv (MeOH + HCl) λ_{max}: 275 nm (ϵ 1095); ^1H nmr (400 MHz, $CDCl_3$) δ: 17.9 (enolic H), 4.38 (H-6, dddd, J = 4.0, 5.0, 7.0 and 11.0 Hz, coupled to 2.58, 2.68, 1.80 and 1.66), 3.06 (H-13a, ddd, J = 6.5, 8.5, and 15.0 Hz, coupled to 1.66), 2.96 (H-13b, ddd, J = 6.5, 8.5, 15.0 Hz, coupled to 1.66), 2.68 (H-5a, dd, J = 11.0, 17.0 Hz, coupled to 4.38 and 2.58), 2.58 (H-5b, dd, J = 4.0, 17.0 Hz, coupled to 4.38 and 2.68), 1.80 (1H, dddd, J = 5.0, 7.0, 10.0, 13.0 Hz, coupled to 4.38, 1.66, and 1.53), 1.66 (3H, m, coupled to 4.38, 3.06, 2.96, and 1.80), 1.53 (1H, quintet, J = 5.0), 1.34–1.30 (14H, m, coupled to 0.90 and 0.92), 0.92 (3H, vt, J = 6.0, coupled to 1.34 and 1.30), 0.90 (3H, vt, J = 7.0, coupled to 1.34 and 1.30); ^{13}C nmr (100 MHz, $CDCl_3$) δ: 204.22 (s), 194.88 (s), 163.92 (s), 102.93 (s), 73.57 (d), 38.25 (t), 37.65 (t), 34.40 (t), 31.43 (t), 31.22 (t), 29.05 (t), 28.75 (t), 24.82 (t), 24.14 (t), 22.33 (t), 22.21 (t), 13.76 (q), and 13.66 (q); hreims *m/z* (formula, intensity, fragment): 310.2136 (calculated for $C_{18}H_{30}O_4$, 310.2144, 33, M^+), 292 ($C_{18}H_{28}O_3$, 6, M − H_2O), 240 ($C_{13}H_{20}O_4$, 15), 239 ($C_{13}H_{19}O_4$, 100.0, M − C_5H_{11}), 226 ($C_{12}H_{18}O_4$, 41, M − C_6H_{12}), 222 ($C_{13}H_{18}O_3$, 12) 221 ($C_{13}H_{17}O_3$, 62, M − $C_5H_{13}O$), 155 ($C_7H_7O_4$, 17), 129 ($C_5H_5O_4$, 10). The compound showed a positive ferric chloride test.

Isolation of lachnellulone[4]

Fractions 35–40 of the above mentioned flash chromatography of 1.5 g of crude extract of *L. fuscosanguinea*, eluant now 1% MeOH in $CHCl_3$, afforded a white crystalline material which was recrystallized from acetone/Skellysolve B to yield 20 mg of pure lachnellulone, mp

[4]The structure of lachnellulone will be discussed in part 2 of this series.

126–127°C; tlc, R_f 0.44 in $CHCl_3$; $[\alpha]_D^{25}$ +48.4 (*c* 10, CH_3OH). The spectral characteristics of lachnellulone will be described in the full paper.[4]

Hydrogenation of dehydroacetic acid

Dehydroacetic acid (1.0 g or 6 mmol) was mixed with 5% Pd–C (0.1 g) and benzene (20 mL) containing five drops of pyridine. The reaction mixture was then pressurized with hydrogen (60 psi) in a Parr hydrogenator for 40 h at room temperature. The reaction mixture was filtered to remove the catalyst and concentrated to dryness *in vacuo*. The solid residue was purified by crystallization from Skellysolve B/ethyl acetate to afford, in 95% yield, white crystals of dihydrodehydroacetic acid (**3**), mp 93–94°C; tlc, R_f 0.3 in $CHCl_3$/Skellysolve B/HOAc, 2:1:1; ftir (film): 2980, 2920, 1715, 1560, 1458, 1080, and 770 cm^{-1}; uv (MeOH) λ_{max}: (ϵ 20 700), 274 nm (ϵ 26 100); uv (MeOH + NaOH) λ_{max}: 208, 248 nm; ^1H nmr (200 MHz, $CDCl_3$) δ: 17.9 (1H, s), 4.52 (1H, m), 2.63 (2H, dd, *J* = 2.5, 6 Hz), 2.60 (3H, s), 1.44 (3H, d, *J* = 6 Hz); ^{13}C nmr (50 MHz, $CDCl_3$) δ: 201.18 (s), 195.04 (s), 164.35 (s), 103.43 (s), 70.25 (d), 39.45 (t), 26.47 (q), and 20.56 (q). The gated ^{13}C nmr spectra for deuterium-labelled (enolic H) dihydrodehydroacetic acid, δ: 201 (q, *J* = 6.5 Hz), 194 (m), 164 (bs), 103 (m), 70 (ddm, *J* = 147.5, 3.5 Hz), 39 (tbq, *J* = 130.0, 4.5 Hz), 26 (q, *J* = 230 Hz), and 20 (qq, *J* = 127.5, 2.0 Hz).

6,8-Tridecanedione (6)

Sodium amide (1 mol) was suspended in dry tetrahydrofuran (THF) (100 mL) in a 500-mL two-neck round bottom flask to which a dropping funnel and a reflux condenser ($CaCl_2$ drying tube) had been attached. 2-Heptanone (0.33 mol) in (THF) (50 mL) was added from the funnel over a period of 10 min. After 5 min stirring, methyl hexanoate (70 mL) in THF (50 mL) was added slowly to the reaction mixture. The viscous mixture was heated under reflux for 1 h and let cool to room temperature, then acidified with 10% HCl until all the precipitate had dissolved. The upper organic layer was separated, washed with distilled water, dried over anhydrous Na_2SO_4, filtered, and concentrated to yield a red liquid. Vacuum distillation (3 Torr; 1 Torr = 133.3 Pa) produced a fraction (130°C) containing the desired β-diketone, which was further purified by complexation with copper acetate (~100 mL of saturated solution). The copper complex was separated by filtration and washed with 95% EtOH. The green crystals of complex were then dissolved in $CHCl_3$ (100 mL) and decomposed with 10% H_2SO_4 (200 mL). The colorless $CHCl_3$ solution afforded, after drying and concentration, pure (by tlc) 6,8-tridecanedione (**6**), 35 g (54%), η_D^{20} 1.442; tlc, R_f 0.65 in Skellysolve B/ethyl acetate, 9:1; ir (cast): 2960, 2930, 2860, 1705 (w), 1610, 1460, 1150, 1110, 950, and 780 cm^{-1}; ^1H nmr (80 MHz, $CDCl_3$) δ: 15.40 (1H, bs), 5.50 (1H, s), 3.58 (fraction, s), 2.52 (fraction, t), 2.30 (4H, t), 1.62 (4H, bt), 1.30 (8H, m), 0.90 (6H, vt); hreims *m/z* (formula, intensity): 212.1775 (calculated for $C_{13}H_{24}O_2$, 212.1775, 11), 170 ($C_{10}H_{18}O_2$, 13), 156 ($C_9H_{16}O_2$, 34), 141 ($C_8H_{13}O_2$, 100), 100 ($C_5H_8O_2$, 50), and 99 ($C_6H_{11}O$, 77).

Condensation of 6,8-tridecanedione (6) with malonyl dichloride

6,8-Tridecanedione (24 mmol) was added to a round bottom flask connected to a dropping funnel and a gas outlet. Malonyl dichloride (24 mmol) was added slowly from the dropping funnel to the β-diketone and the reaction mixture was heated in a water bath at 80°C. A copious amount of hydrogen chloride, which was removed using a water aspirator, was produced in the darkening reaction mixture. When the evolution of HCl had stopped (30 min), the reaction mixture was dissolved in ether and washed with distilled water and then with brine. The ether extract was dried over anhydrous Na_2SO_4 and concentrated *in vacuo* to afford a red-brown solid residue which was recrystallized from hexane/ether (1:1) several times to give pale yellow flakes of 5-hexanoyl-4-hydroxy-6-pentyl-2-pyrone (**7**), 3.9 g (58% yield), mp 91–92°C; tlc, R_f 0.55 in 2% MeOH, 2% HOAc in $CHCl_3$; ftir (KBr): 3370, 2960, 2930, 2860, 2620, 2500, 1705, 1690, 1620, 1565, 1460, 1290, 985, and 830 cm^{-1}; uv (MeOH) λ_{max}: 225 (ϵ 6050); 261 (ϵ 5410), 288 nm (ϵ 5250); ^1H nmr (200 MHz, $CDCl_3$) δ: 16.71 (1H, bs), 5.56 (1H, s), 2.82 (2H, t, *J* = 7.5 Hz), 2.73 (2H, bt, *J* = 8.0 Hz), 1.70 (4H, m), 1.31 (8H, m), and 0.90 (6H, vt); ^{13}C nmr (50 MHz, $CDCl_3$) δ: 202.6 (s), 169.8 (s), 169.2 (s), 165.1 (s), 115.4 (s), 90.1 (d), 44.4 (t), 32.5 (t), 31.3 (t), 31.2 (t), 27.4 (t), 23.8 (t), 22.3 (t), 22.1 (t), 13.8 (q), and 13.7 (q); hreims *m/z* (formula, intensity, fragment): 280.1673 (calculated for $C_{16}H_{24}O_4$, 280.1675, 25, M^+), 252 ($C_{15}H_{24}O_3$, 22, M − CO), 237 ($C_{13}H_{17}O_4$, 15, M − C_3H_7), 224 ($C_{12}H_{16}O_4$, 18), 210 ($C_{11}H_{14}O_4$, 8), 209 ($C_{15}H_{13}O$, 100, M − C_5H_{11}), 206 ($C_{12}H_{14}O_3$, 27), 196 ($C_{11}H_{16}O_3$, 23), 181 ($C_9H_9O_4$, 14), 168 ($C_8H_8O_4$, 44), 153 ($C_7H_5O_4$, 26), and 99 ($C_6H_{11}O$, 67). *Anal.* calcd. for $C_{16}H_{24}O_4$: C 68.55, H 8.63; found: C 68.76, 68.92; H 8.70, 8.69.

Synthesis of 4-hydroxy-6-pentyl-2-pyrone (8)

5-Hexanoyl-4-hydroxy-6-pentyl-2-pyrone (**7**, 12.8 mmol) was dissolved in 90% H_2SO_4 (10 mL) and heated to 120–130°C for 60 min. The reaction mixture was cooled, diluted with 10% $NaHCO_3$, and extracted with ether. The ether extract was dried over anhydrous Na_2SO_4 and concentrated to yield an oil which crystallized under high vacuum. This compound was recrystallized from Skellysolve B/ether (1:1) to yield 1.8 g of the hydroxypyrone **8**. The mother liquors were purified by flash chromatography (30-mm diameter column, 2% MeOH, 2% HOAc in $CHCl_3$) to give, in fractions 9 to 13, 0.255 g of pyrone **8** (87% yield), mp 52–52.5°C; tlc, R_f 0.38 in 2% MeOH, 2% HOAc, 96% $CHCl_3$; ftir ($CHCl_3$ cast): 2960, 2930, 2845, 2520 (br), 1690 (w), 1640 (w), 1570, 1540, 1500, 1350, 1310, 1285, 1250, 1140, 920 (br), 885, 840, and 820 cm^{-1}; ^1H nmr (80 MHz, $CDCl_3$) δ: 10.9 (1H, bs), 6.1 (1H, s), 5.6 (1H, s), 2.5 (2H, t), 1.7 (2H, bt), 1.4 (4H, m), 0.9 (3H, vt); hreims *m/z* (formula, intensity, fragment): 182.0940 (calculated for $C_{10}H_{14}O_3$, 182.0942, 33, M^+), 164 ($C_{10}H_{12}O_2$, 2, M − H_2O), 154 ($C_9H_{14}O_2$, 7, M − CO), 141 ($C_8H_{13}O_2$, 10, M − C_2HO), 139 ($C_7H_7O_3$, 11, M − C_3H_7), 126 ($C_6H_6O_3$, 100, M − C_4H_8), 111 ($C_5H_3O_3$, 72), 98 ($C_5H_6O_2$, 44), and 84 ($C_4H_4O_2$, 64). *Anal.* calcd. for $C_{10}H_{14}O_3$: C 65.92, H 7.72; found: C 66.04, H 7.80.

Hydrogenation of 4-hydroxy-6-pentyl-2-pyrone (8)

4-Hydroxy-6-pentyl-2-pyrone (**8**, 1.37 mmol) was mixed with 5% Pd–C (30 mg) and ethyl acetate (20 mL) in a hydrogenation bottle. The reaction flask was connected to a Parr hydrogenator and pressurized to 70 psi with hydrogen. The reaction mixture was shaken for 24 h at room temperature. Filtration and concentration of the reaction mixture afforded 4-oxo-6-pentyl-3,4,5,6-tetrahydro-2-pyrone (**9**) in quantitative yield as a white solid (mp 64–65°C); tlc, R_f 0.33, 1% MeOH in $CHCl_3$; ftir ($CHCl_3$, cast): 3100, 2960, 2925, 2860, 2570, 1700 (w), 1595, 1390, 1290, 1040, 885, and 830 cm^{-1}; ^1H nmr (400 MHz, $CDCl_3$) δ: 4.62 (1H, dddd, *J* = 3, 5, 8, 12 Hz, coupled to δ 2.70, 2.47, 1.82, 1.71), 3.56 (1H, d, *J* = 19 Hz, coupled to δ 3.41), 3.41 (1H, d, *J* = 19 Hz, coupled to δ 3.56), 2.70 (1H, dd, *J* = 3, 18 Hz, coupled to δ 4.62, 2.47), 2.47 (1H, dd, *J* = 12, 18 Hz, coupled to δ 4.62, 2.70), 1.82 (1H, dddd, *J* = 5, 8, 9, 14 Hz, coupled to δ 4.62, 1.71, 1.56, 1.46), 1.71 (1H, dddd, *J* = 5, 5, 11, 18 Hz, coupled to δ 4.62, 1.82, 1.56, 1.46), 1.56 (1H, m), 1.46 (1H, m), 1.36 (4H, m) and 0.92 (3H, vt); hreims *m/z* (formula, intensity, fragment): 184.1098 (calculated for $C_{10}H_{16}O_3$, 184.1100, 5, M^+), 166 ($C_{10}H_{14}O_2$, 4, M − H_2O), 129 ($C_6H_9O_3$, 24, M − C_4H_7), 125 ($C_8H_{13}O$, 29, M − $C_2H_3O_2$), 115 ($C_5H_7O_3$, 17, M − C_5H_9), 113 ($C_5H_5O_3$, 100, M − C_5H_{11}), 111 ($C_6H_7O_2$, 19, M − C_4H_9O).

O-Acylation of 4-oxo-6-pentyl-3,4,5,6-tetrahydro-2-pyrone (9)

β-Ketolactone **9** (0.71 mmol) was dissolved in benzene (2 mL) containing 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) (0.73 mmol) and octanoyl chloride (0.73 mmol) at 0°C. This mixture was stirred in an ice-water bath for 3 h. The reaction mixture was treated with distilled water (20 mL) and extracted with benzene (2 × 10 mL). The combined benzene extracts were washed with 5% HCl (1 × 20 mL) and brine. The benzene solution was then dried over anhydrous Na_2SO_4 and concentrated to give an oil which was shown to be a single compound (tlc), the enol ester **10** (91% yield). This compound was unstable and was used immediately in the next step; ^1H nmr (200 MHz, $CDCl_3$) δ: 5.82 (1H, s), 4.40 (1H, m), 2.40 (2H, m).

Lachnelluloic acid (1)

6-Pentyl-4-oxyoctanoyl-5,6-dihydro-2-pyrone (**10**, 0.65 mmol) was dissolved in dry toluene (3 mL) and mixed with 4-*N*,*N*-dimethylaminopyridine (DMAP, catalytic amount). The resulting solution was heated under reflux for 5 h. The reaction mixture was worked up by adding water and extracting with toluene. The combined toluene extracts were washed with 5% HCl and brine. After drying over anhydrous Na_2SO_4 the solution was concentrated to give an oily residue. Flash chromatography of this residue (20-mm diameter column, Skellysolve B/EtOAc (95:5)) afforded, in fractions 7 to 11, pure racemic lachnelluloic acid (150 mg, 75% yield) as an oil, identical (tlc, ir, uv, ^{1}H nmr, hreims) with an authentic sample. *Anal.* calcd. for $C_{18}H_{30}O_4$: C 69.64, H 9.74, O 20.62; found: C 69.72, H 9.82.

Synthesis of dehydrolachnelluloic acid (11)

4-Hydroxy-6-pentyl-2-pyron (**8**, 1.38 mmol) was dissolved in trifluoroacetic acid (TFA) (10 mL) and mixed with octanoyl chloride (1.85 mmol). The reaction mixture was heated under reflux for 24 h. The resulting yellow solution was diluted to 100 mL with ether, extracted with 10% $NaHCO_3$ (2 × 200 mL), washed with water, dried over anhydrous Na_2SO_4, and concentrated to yield an oily residue. Flash chromatography of this residue (20-mm diameter column, Skellysolve B/chloroform (2:1)) afforded the pure crystalline dehydrolachnelluloic acid (0.4 g, 94%), mp 35–36°C; tlc, R_f 0.6 in chloroform/Skellysolve B (2:1); ftir ($CHCl_3$, cast): 3090 (w), 2960, 2930, 2830, 1725, 1635, 1605, 1560, 1445, 1225, 990, 850, and 700 cm^{-1}; ^{1}H nmr (200 MHz, $CDCl_3$) δ: 16.87 (1H, s), 5.92 (1H, s), 3.08 (2H, t, J = 7 Hz), 2.45 (2H, t, J = 8 Hz), 1.67 (4H, m), 1.35 (12H, m), 0.91 (3H, vt), and 0.89 (3H, vt); hreims m/z (formula, intensity, fragment): 308.1990 (calculated for $C_{18}H_{28}O_4$, 308.1988, 22, M$^+$), 290 ($C_{18}H_{26}O_3$, 8, M − H_2O), 252 ($C_{14}H_{20}O_4$, 3, M − C_4H_8), 237 ($C_{13}H_{17}O_4$, 64, M − C_5H_{11}), 224 ($C_{12}H_{16}O_4$, 100, M − C_6H_{12}), 210 ($C_{11}H_{14}O_4$, 41 M − C_7H_{14}), 204 ($C_{14}H_{20}O$, 31), 168 ($C_8H_8O_4$, 48), 153 ($C_7H_5O_4$, 10). *Anal.* calcd. for $C_{18}H_{28}O_4$: C 70.10, H 9.15; found: C 69.96, H 9.33.

Hydrogenation of dehydrolachnelluloic acid (11)

Dehydrolachnelluloic acid (0.78 mmol) was dissolved in ethyl acetate (20 mL) and transferred to a hydrogenation bottle containing 10% Pd–C catalyst (0.05 g). This mixture was pressurized to 60 psi of hydrogen in a Parr hydrogenator and shaken for 24 h. Thin layer chromatography of the reaction mixture showed the presence of a product different from lachnelluloic acid. After work-up the reaction product afforded the β-ketolactone **12**, in quantitative yield, as a viscous oil; tlc, R_f 0.2 in chloroform/Skellysolve B/HOAc (2:1:trace); ftir ($CHCl_3$, cast): 2960, 2930, 2865, 1610, 1384, 1250, 1120, 1040, and 740 cm^{-1}; ^{1}H nmr (200 MHz, $CDCl_3$) δ: 4.68 (1H, m, coupled to δ 2.73 and δ 2.42), 3.41 (1H, t, J = 7 Hz, coupled with δ 1.92, exchangeable with D_2O), 2.73 (1H, dd, J = 3, 18 Hz, coupled to δ 4.68 and δ 2.42), 2.42 (1H, dd, J = 12.0, 18.0 Hz, coupled to δ 4.68 and δ 2.73), 1.92 (2H, bt, coupled to δ 3.41 and δ 1.3), 1.3 (16H, m), and 0.90 (6H, vt); ^{13}C nmr (50 MHz, $CDCl_3$) δ: 201.05 (1.7), 169.07 (1.0), 73.81 (3.1), 56.49 (2.0), 43.42 (2.5), 34.23 (2.9), 31.60 (2.3), 31.18 (2.3), 29.44 (2.7), 29.08 (3.6), 29.00 (2.6), 27.02 (2.2), 24.17 (3.0), 22.90 (2.7), 22.40 (3.1), 22.20 (2.6), 13.82 (2.8), and 13.67 (3.4).

Hydrogenation of natural lachnelluloic acid (1)

Lachnelluloic acid (**1**, 3.1 mg) was mixed with 5% Pd–C (1 mg) and ethyl acetate (10 mL). The mixture was shaken at 60 psi of hydrogen for 24 h. The reaction mixture was filtered and concentrated to give a white solid which was purified by preparative tlc (20 × 20 cm, 0.35-mm thickness, $CHCl_3$) to afford β-ketolactone **12** (3 mg), identical (tlc, ftir, ^{1}H nmr, ms) with that prepared above.

Hydrogenation of dehydroacetic acid to give 13

Dehydroacetic acid (6 mmol) was mixed with 10% Pd–C catalyst (0.1 g) in a hydrogenation bottle, ethyl acetate (20 mL) was added to the mixture, and the flask was pressurized to 60 psi of hydrogen and shaken for 24 h at room temperature. Filtration and concentration of the reaction mixture afforded a yellow solid which was recrystallized from Skellysolve B/acetone to give white crystals of the β-ketolactone **13** in quantitative yield, mp 138–139°C. This compound gives a negative ferric chloride test; tlc, R_f 0.3 in Skellysolve B/$CHCl_3$/HOAc (30:70:1); ftir (film): 2960, 2930, 2860, 2540 (broad), 1603, 1385, 1270, 1120, 900 cm^{-1}; ir ($CHCl_3$): 1760 and 1720 cm^{-1}; hreims m/z (formula, intensity, fragment): 156.0788 (calculated for $C_8H_{12}O_3$, 156.0787, M$^+$), 128 ($C_6H_8O_3$, 53, M − C_2H_4), 87 ($C_4H_7O_2$, 9, M − C_4H_5O), 87 ($C_3H_3O_3$, 11, M − C_5H_9), and 55 (C_3H_3O, 100, M − $C_5H_9O_2$). *Anal.* calcd. for $C_8H_{12}O_3$: C 61.52, H 7.74; found: C 61.12, H 7.56.

Crystal structure determination of the conformation of two bicyclo[3.3.1]nonan-ones

JOHN F. RICHARDSON AND TED S. SORENSEN
The Department of Chemistry, University of Calgary, Calgary, Alta., Canada T2N 1N4

Received July 5, 1984

JOHN F. RICHARDSON and TED S. SORENSEN. Can. J. Chem. **63**, 1166 (1985).

The molecular structures of *exo*-7-methylbicyclo[3.3.1]nonan-3-one, **3**, and the *endo*-7-methyl isomer, **4**, have been determined using X-ray diffraction techniques. Compound **3** crystallizes in the space group $I\bar{4}$ with a = 15.115 (1), c = 7.677 (2) Å, and Z = 8 while **4** crystallizes in the space group $P2_1$, with a = 6.446 (1), b = 7.831 (1), c = 8.414 (2) Å, β = 94.42 (2)°, and Z = 2. The structures were solved by direct methods and refined to final agreement factors of R = 0.041 and R = 0.034 for **3** and **4** respectively. Compound **3** exists in a chair−chair conformation and there is no significant flattening of the chair rings. However, in **4**, the non-ketone ring is forced into a boat conformation.These results are significant in interpreting what conformations may be present in the related sp^2-hybridized carbocations.

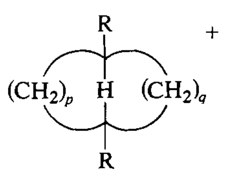
JOHN F. RICHARDSON et TED S. SORENSEN. Can. J. Chem. **63**, 1166 (1985).

Utilisant des techniques de diffraction des rayons-X, on a déterminé les structures moléculaires de la méthyl-7 *exo* bicyclo[3.3.1] nonanone-3, **3**, et de son isomère méthyl-7 *endo*, **4**. Le composé **3** cristallise dans le groupe d'espace $I\bar{4}$, avec a = 15,115(1), c = 7,677(2) Å et Z = 8 alors que **4** cristallise dans le groupe d'espace $P2_1$, avec a = 6,446(1), b = 7,831(1), c = 8,414(2) Å, β = 94,42(2)° et Z = 2. On a résolu les structures par des méthodes directes et on les a affinées jusqu'à des valeurs respectives de R de 0,041 et 0,034 pour les composés **3** et **4**. Le composé **3** existe dans une conformation chaise−chaise et il n'y a pas d'aplatissement notable des cycles en formes chaises. Toutefois, dans le composé **4**, le cycle qui ne porte pas la cétone est forcé de prendre une conformation bateau. Ces résultats sont importants pour interpréter la nature des conformations qui peuvent être présentes dans les carbocations apparentés qui ont une hybridation sp^2.

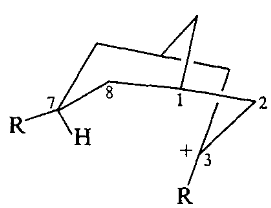
[Traduit par le journal]

A number of organic reactions, where a carbocation intermediate is involved, undergo a rearrangement reaction characterized by a n,1-hydride shift, where position 1 is the carbocation centre and n is a C—H function located at a separation of 2, 3, 4, 5.... carbon atoms distant.

In some recent examples where n = 5 and 6, it has been possible to directly observe a symmetrical μ-hydrido-bridged carbocation **1**, where p and q define a medium ring, i.e. p + q = 6, 7, 8, or 9 (1−3). In the case of p = q = 3, R = H, it has also been possible to show the existance of **1** as an intermediate in solvolysis or acid-catalysis reactions (4, 5).



1

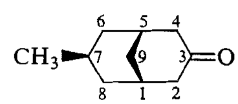


2

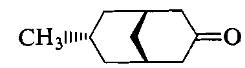
Like the simple ring compounds, the bicyclo[3.3.1]nonyl system **2** has been observed in many instances (6−8) to transfer a hydrogen between positions 3 and 7. However, the situation regarding a possible μ-hydrido-bridged carbocationic intermediate in solvolysis reactions has still not been definitively settled, although most of the evidence has been against such an intermediate. We have recently prepared the observable carbocation **2**, R = CH_3, and significantly, this is *not* a μ-hydrido-bridged structure,[1] involving instead a very rapid transfer of the hydrogen over a small barrier, i.e. a degenerate rearrangement involving a "normal" tertiary carbocation. The cation related to **2** but with an *endo*-methyl group was also prepared.[1]

The most likely cause of the difference between cations **1** and **2**, as discussed by Eakin *et al.* (6*a*), concerns the more rigid framework of the bicyclo[3.3.1]nonane ring system and the consequent difficulty in bringing C(3) and C(7) within "bonding" distance.

As an aid in the study of the observable carbocations, we were interested in getting structural data on the related ketones **3** and **4**. Ketone **3** was expected to be a di-chair structure and our principle interest was in looking at the expected "flattening" of the chairs because of transannular interactions. On the basis of nmr work, ketone **4** had been proposed to have a chair− boat structure (9). We were interested in confirming



3



4

this and in using **4** as a model for a "non-flattening" chair structure. The structure of **4** is also of interest in light of very recent work by Renzoni and Borden (10), in which a 7-*endo*-carbomethoxybicyclo[3.3.1]nonan-3-one is postulated to have a dichair structure.

In looking at base-catalyzed hydride transfer, Murray-Rust *et al.* (11) have determined the structure of *exo*-7-hydroxybicyclo[3.3.1]nonan-3-one, **5**, and the corresponding methyl ether, **6**, and both have a di-chair structure (the former has a slight disorder problem).

Experimental

X-Ray analysis

The ketones **3** and **4** were prepared as outlined in refs. 6*a* and 12, respectively. Ketone **4** was further purified by vpc and crystals of both isomers were obtained by slow sublimation. Due to the facile sublimation of the ketones, suitable crystals of each were quickly affixed to a goniometer head at room temperature and immediately placed in the cold stream on an Enraf−Nonius CAD4F automated diffractometer fitted with a low-temperature device. The crystal systems were identified as tetragonal and monoclinic, respectively, using the indexing routines of the instrument. The distribution of intensity data

and the systematic extinctions observed during data collection are consistent with the space groups $I4$, $I\bar{4}$, and $I4/m$ (hkl, $h + k + l = 2n + 1$) for **3** and $P2_1$ and $P2_1/m$ ($0k0$, $k = 2n + 1$) for **4**. The acentric distribution of E values (K curve) for **4** indicated $P2_1$; however, the distribution was ambiguous for **3**. The final choices of the space groups as $I\bar{4}$ and $P2_1$ were substantiated by the successful solution and refinement of the structures. All attempts to solve the structures in the centric space groups or to transform the indices of the molecular mirror plane to the appropriate crystallographic mirror plane ($z = 0$ for $P2_1$, $y = 1/4, 3/4$ for $I4/m$) were unsuccessful. The crystal data and experimental conditions are summarized in Table 1. Three standard reflections measured every 1500 s of X-ray exposure time showed no decomposition of the crystals had occurred during the data acquisition period. The data were corrected for background, Lorentz, and polarization effects but an absorption correction was not performed as it was impossible to accurately measure faces on the data crystals before sublimation had occurred.

The structures were solved by direct methods (MULTAN 78) (13) and refined by full-matrix least-squares techniques based on F, minimizing the function $\Sigma w(|F_o| - |F_c|)^2$. The weighting schemes used were $w = [\sigma^2(F_o) + 0.0001(F_o)^2]^{-1}$ and $w = [\sigma^2(F_o) + 0.0002(F_o)^2]^{-1}$, where $\sigma(F_o)$ was derived from counting statistics, for **3** and **4** respectively. All computations were performed using the XRAY 76 system of programs (14) implemented on a Honeywell computer with a MULTICS operating system. Scattering factors for non-hydrogen atoms were those of Cromer and Mann (15) and those for H were taken from ref. 16. Anomalous dispersion corrections were included for non-hydrogen atoms (17). H atoms were readily located from difference Fourier syntheses and included in the models in ideal positions (d(C—H) = 1.00 Å) with isotropic thermal parameters set to 1.1 times B_{equiv} of the C atoms to which they are bonded. H atom parameters were recalculated after each of the final cycles, but not refined. For each structure, the final difference Fourier map showed that the largest peak of residual electron density was 0.17 e Å^{-3} and

was of no chemical significance. Atomic coordinates and $B_{\text{equivalent}}$ values for non-hydrogen atoms are given in Table 2 and bond lengths and angles are summarized in Table 3.[2]

Results and discussion

The bicyclo[3.3.1]nonane skeleton has been the subject of numerous conformational analyses, mainly involving nmr spectroscopy or X-ray crystallography. We will restrict our discussion to those cases involving one keto centre at C-3.

The finding of a dichair structure for **3** (Fig. 1) is entirely expected. The deformations in this conformer are discussed in the next section. The chair–boat structure found for **4** (Fig. 2), with the ketone ring as the chair, is not unexpected, and serves to confirm the earlier analysis made by nmr spectroscopy (9). However, it is probable that the chair–boat and chair–chair conformers of **4** have quite similar energies since the corresponding *endo*-carbomethoxy compound is apparently a dichair (10). The steric bulk of a methyl group is generally considered to be somewhat larger than that of carbomethoxy (18), consistent with the observations, but also indicative of a fine dividing line here between conformations.

[2]A complete set of structure factor listings, anisotropic thermal parameters, and hydrogen atom parameters is available at a nominal charge, upon request from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ontario, Canada K1A 0S2.

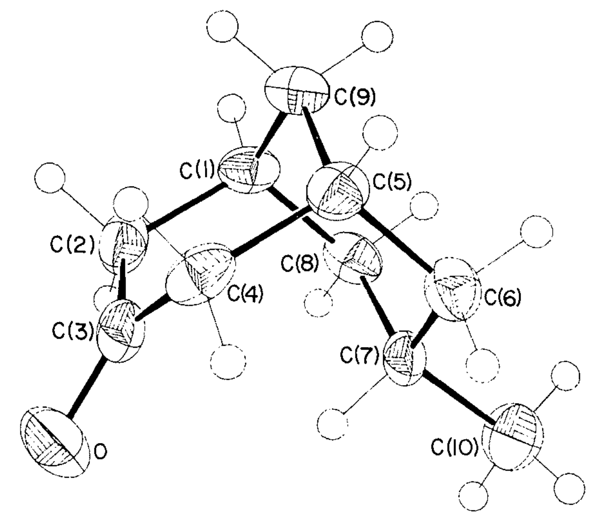

FIG. 1. A perspective view (Ortep) of the ketone **3** showing the atomic numbering scheme. Ellipsoids are drawn at the 50% probability level and hydrogens are included as spheres of radius 0.1 Å.

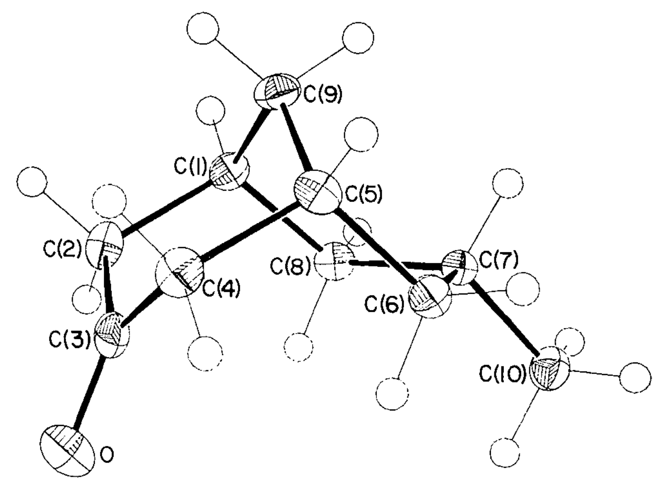

FIG. 2. A perspective view (Ortep) of the ketone **4** showing the atomic numbering scheme. Ellipsoids are drawn at the 50% probability level and hydrogens are included as spheres of radius 0.1 Å.

The crystal structures consist of discrete molecular units with the closest intermolecular contact being 2.54 Å for **3** (H10A(x, y, z) to H10C ($y - 1/2$, $1 - x$, $-z$)) and 2.38 Å for **4** (H10C (x, y, z) to H5 ($1 - x$, $1/2 + y$, $2 - z$)). Individual bond lengths and angles within the bicyclo[3.3.1]nonane skeletons of **3** and **4** show only minor deviations from the average values of 1.536(2) Å and 111.5° found in an electron diffraction study of the unsubstituted nonane (19). As one would expect, these deviations are greatest around atoms C(3) and C(7). A more detailed comparison between the present structures, **3** and **4**, and those determined by Murray-Rust *et al.* (11) **5** and **6**, is given in Table 4. The values are in general agreement within experimental error, with two minor exceptions: C_1—C_8(C_5—C_6) in **4** and the C=O distance for **5** are significantly longer than in the other structures. The latter has been ascribed to the disorder found in the crystal structure (11). The former could be a result of the chair–boat conformation which brings the *endo* H atoms on C(2), C(8) and C(4), C(6) closer than that found for **3** (avg. 2.43 Å for **3** vs. 2.34 Å for **4**). This is relieved in part by a slight lengthening of the C(1)—C(8)(C(5)—C(6)) and C(1)—C(2)(C(4)—C(5)) bonds.

†Boat conformation.

Ring deformations in 3

Repulsion between the C(3) and C(7) centres is expected to flatten both chairs in **3**. This deformation is most readily seen by looking at the $H_1C_1C_2H_2$ (*exo* or *endo*) and the H(1)C(1)-C(8)H(8) (*exo* or *endo*) dihedral angles. These are listed in Table 5. The best way to evaluate the flattening of the ketone chair in **3** is to compare the dihedral angles with those in **4**, where there is no C(3)—C(7) repulsion. This "extra" dihedral angle distortion is about 3–4° (Table 5). The other chair in **3** is also distorted from the theoretical 60° dihedrals by about 5°.

As a consequence of these distortions, the C(3)—C(7) distance in **3** is 3.004(5) Å and the *endo*-H(7)—C(3) distance is 2.43 Å. The details of the carbocation work on **2** and other 3-bicyclo[3.3.1]nonyl cations will be given in a separate paper. On the basis of the present structural work, it appears very probable that the undistorted C(3)—C(7) distance in a bicyclo[3.3.1]nonane is simply too long for the establishment of a μ-hydrido-bridged structure for **2**.

Bicyclization of aza-compounds by positive halide ions. I. Cyclic amines[1]

R. M. ELOFSON, F. F. GADALLAH, AND J. K. LAIDLER
Alberta Research Council, Edmonton, Alta., Canada T6G 2G2

Received January 9, 1984[2]

R. M. ELOFSON, F. F. GADALLAH, and J. K. LAIDLER. Can. J. Chem. **63**, 1170 (1985).

Cyclic amines are oxidized to the bicyclic compounds by electrochemical oxidation. The presence of halide ions is found necessary for the reaction to proceed and to produce any bicyclic products. It is postulated that a positive halide species, $X^{(+)}$, is produced electrochemically and stabilized under the specific reaction conditions. The $X^{(+)}$ ion forms a complex with the parent cyclic amine which decomposes to the bicyclic product and HX. An analogy between the Hofer–Moest reaction to produce $C^{(+)}$ and this reaction to produce $X^{(+)}$ is postulated

R. M. ELOFSON, F. F. GADALLAH et J. K. LAIDLER. Can. J. Chem. **63**, 1170 (1985).

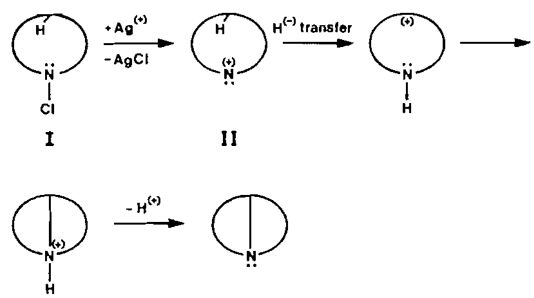
L'oxydation électrochimique des amines cycliques conduit à des composés bicycliques. On a trouvé que la présence d'ions halogénures est nécessaire pour que la réaction se produise et qu'elle conduise à des composés bicycliques. On fait le postulat qu'il y a production électrochimique d'un halogénure positif, X^+, qui est stabilisé dans les conditions spécifiques de la réaction. L'amine cyclique de base et l'ion X^+ formeraient un complexe qui se décomposerait en produit bicyclique et en HX. On fait le postulat qu'il existe une analogie entre la réaction de Hofer–Moest qui conduit à la formation de C^+ et cette réaction qui fournit des X^+.

[Traduit par le journal]

Introduction

Some time ago, Edwards and co-workers (1) succeeded in preparing indolizidine in 68% yield from *N*-chloroazacyclonane **1** in the presence of silver ions and aqueous dioxane. The reaction, as shown in [1], had every appearance of proceeding by way of a nitrenium ion **11**. After that discovery,

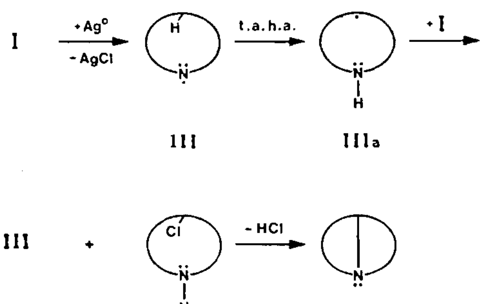
[1]



rapid development of nitrenium ion chemistry began, principally in Gassmann's laboratories (2).

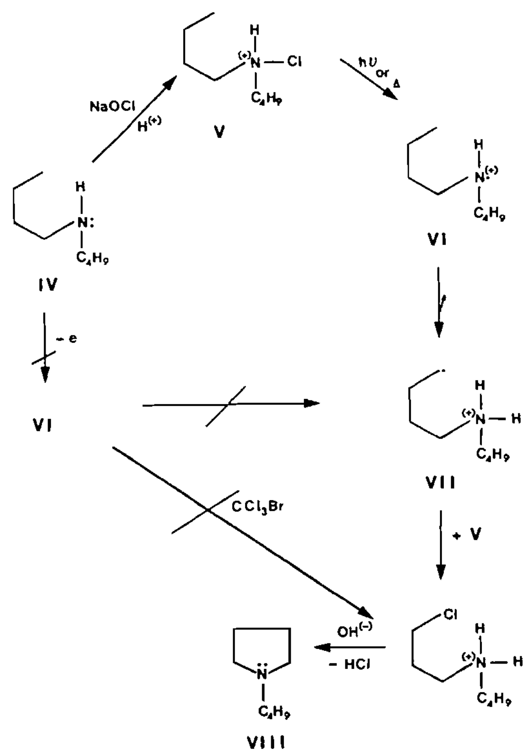
Later, Edwards and Vocelle (3) found that silver (Ag^0) also leads to bicyclization. They presented evidence that the bicyclization involves a free radical mechanism with a transannular hydrogen abstraction (t.a.h.a.) via a homolytic pathway, as illustrated in [2].

[2]



Earlier, Wawzonek and Culbertson (4) worked on a closely related problem. Those workers effected the cyclization of dibutylamine by irradiating chloramine **V**. As shown in [3],

[3]



the cation–radical intermediate, **VI**, was proposed. However, Wawzonek's later attempts (5) to produce the cyclicized product, **VIII**, by anodic oxidation of the amine, **IV**, in a methanol–water mixture containing tetramethylammonium tetrafluroborate were unsuccessful.

Later, Waegell and co-workers (6) achieved the production of *N*-chloro, *N*-methyl, 5-methylaminobicyclo[2.2.1]hept-2-ene in neutral medium. The authors verified that, under conditions thought to induce formation of nitrinium ions, only the homolytic reactions occurred.

Edward's (3) and Wawzonek's (4) mechanisms for cycliza-

[1]Alberta Research Council Contribution No. 1311. Parts of this paper were discussed in talks at The North American Chemical Congress, Mexico City, 1975; Electrochemical Society, Washington, DC, 1976; and 6th North American Meeting of Catalysis Society, Chicago, 1979.

[2]Revision received August 28, 1984.

TABLE 1. E (V) vs. sce (V) of amines, amides, and halide ions

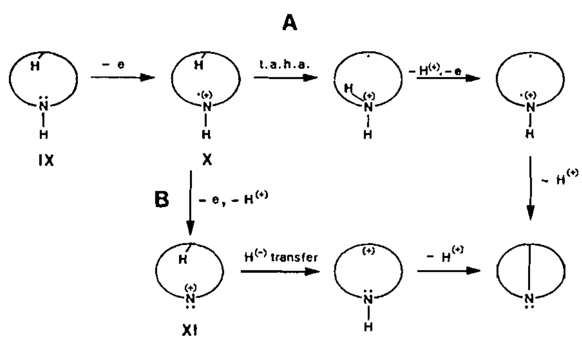
Species	E_1*	E_2*
Amines	+1.2 to 1.3	
$Cl^{(-)}$	+1.1	+1.7
$Br^{(-)}$	+1.03	+1.39
$I^{(-)}$	+0.25	+0.55

*E_1 and E_2 are half-wave potentials.

tion or bicyclization of haloamines are very similar in that they proceed via intramolecular hydrogen abstraction and the abstraction of Cl· from the starting material by a reactive intermediate, **III***a* or **VII**, respectively.

Starting with a cyclic amine, a prediction of the intermediate products is shown in [4]. The parent compounds **IX** would lose an electron on the anode to give a cation radical **X**. Route A or B would follow. Because the transannular hydrogen abstraction would have a faster rate than hydrogen abstraction from the solvent, route A was preferred over B. Since protonation is prevented in basic media, bicyclization would be encouraged. Reaction [4] shows the loss of two electrons and two protons in routes A and B.

[4]



Results and discussion

Attemps to carry out the oxidation of azacyclononane in acetonitrile, tetrabutylammonium fluoroborate or perchlorate as the electrolytic support and Pt, C, Hg, or stainless steel anodes at controlled potentials of 1.3 V corresponding to one electron oxidation or at controlled currents corresponding to much higher voltages of either the amine or the halide ions, Table 1, produced no detectable bicyclic products. Loss of starting material occurred due to other reactions. It seems that the cation radical as it was produced, abstracted hydrogen from (*a*) the solvent to produce electrochemically inactive ammonium ion, or (*b*) from an adjacent carbon leading to Schiff's base (7, 8). To discourage hydrogen abstraction from the solvent and to encourage proton removal, water was added to the reaction mixture, but no bicyclization occurred. This implies that t.a.h.a., which should produce bicyclic products via route A, did not occur. However, when a graphite anode was used in 10% water in acetonitrile in the presence of lithium chloride and 100 mA current, 3% bicyclic product was obtained. More bicyclic product, 64%, was obtained with lithium bromide using 20% of water as in [5].

We found that specific conditions have to be attained to produce the respectable yields for medium sized rings (C_7-C_9 amines) shown in Table 2. These specific conditions are (*1*) water, halide ion, and hydroxide ion or basic medium; and (*2*) a carbon anode and a current of 100 to 150 mA corresponding to a potential of approximately 2.3 V.

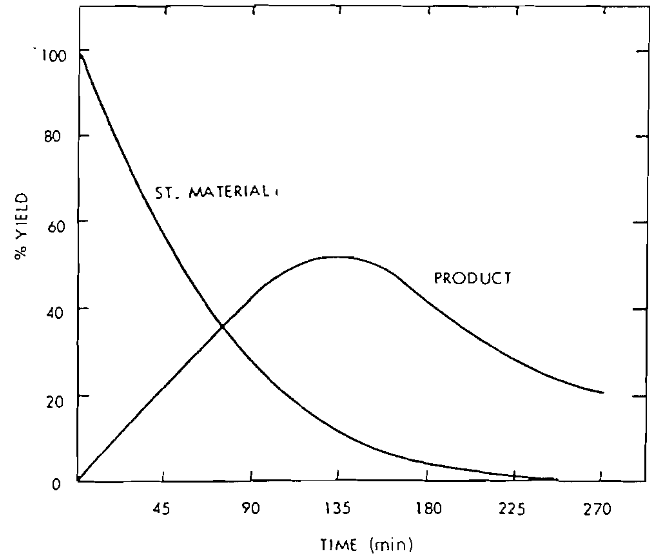


FIG. 1. Production and destruction of cyclic and bicyclic amines by further oxidation.

TABLE 2. Bicyclization of cyclic amines: 20% H_2O in CH_3CN, C anode, 0.1 *M* LiBr, 100 mA

Cyclic amine	Bicyclic product*		%	Time (h)
C_7NH_{15}	a		52	2.5
C_8NH_{17}	b		71	2.5
C_9NH_{19}	c		10	3.0
	d		3.5	

*a = azabicyclo [3.3.0] octane, b = azabicyclo [4.3.0] nonane, c = azabicyclo [4.4.0] decane, d = azabicyclo [5.3.0] decane.

However, high current and high voltage at the anode also cause the destruction of the starting material as well as the products. Figure 1 shows the time course of anodic oxidation of C_7 cyclic amine. The reaction must be monitored to obtain maximum yields.

The experimental conditions necessary to obtain significant yields are similar to those of the Kolbe acid oxidation (9) and specifically to the Hofer–Moest reaction (10). This implies a similar reaction mechanism. Beyond this, caution must be exercised in postulating a mechanism. As stated in a review on the Kolbe and Hofer–Moest reactions, "The course of a particular oxidation, thus, depends on both the nature of the intermediate radical and the experimental conditions, and the proper choice of reaction parameters frequently permits the predominant formation of either radical derived or cation derived products. As we can see, all aspects of the mechanism of these reactions are subject to controversy" (11). At this stage it is only possible to point out some analogies for a possible mechanism for the bicyclization of cyclic amines described here.

An explanation for the way in which these reactions proceed was found in Anson's studies on the pattern of ionic and molecular adsorption at a smooth platinum electrode in aqueous media (12). However, his findings could be extended to accommodate our system. Anson found that at high positive charge densities, such as in our system, the halide ions are strongly adsorbed. But neutral molecules such as amines are weakly adsorbed, and "the interaction energy of the water dipole with the electric field at the surface becomes so large that the water molecules are preferentially adsorbed and the organic molecules, i.e. amine, thereby desorbed from the surface" (12).

In the case of the Hofer–Moest reaction, caboxylate anions are adsorbed and oxidized at the anode first to an alkyl radical plus carbon dioxide. The alkyl radical, still at the carbon anode, loses another electron to produce a carbonium ion which upon desorption from the positively polarized anode undergoes further reaction to produce the varied products of this well known reaction. In the case of the bicyclization described here, it is clear from Anson's review that halide ions would be adsorbed and the cyclic amines would be desorbed at the high positive potentials in the partly aqueous media used. In analogy with the Hofer–Moest reaction, it is here suggested that the halide atoms may lose another electron before desorption from the anode whereupon reaction occurs with the amine, Table 1. If indeed a positive halide species is produced it would first be produced as a ground state triplet $X^{\uparrow\uparrow}$ (Hund's rule). This triplet would rapidly change to the hydrated singlet due to energy of solvation, although it might be stabilized at the carbon electrode for a short time. In any event there would appear to be a close relationship between the electrochemical bicyclizations caused by positive halide ion as proposed and the formation of a carbonium ion which was suggested by Koehl (13) to produce methyl acetate as the major product instead of ethane when carbon was used instead of platinum as anodic material in the oxidation of potassium acetate. Further work on these mechanisms remains to be done. It should be noted, however, that *N*-chloroamines were stable in the presence of the carbon anode but when current was passed through the system a little bicyclization (0.6%) occurred. When lithium bromide was added and current applied, 3.5% bicyclization occurred in 4 h. Under the standard electrochemical conditions described in Table 2, very good yields were obtained.

Experimental

Reagents

All reagents and solvents were purified by published methods (14) except as specified. Solid reagents and reference compounds were recrystallized and melting points agreed with literature values.

Cyclic and bicyclic amines

C_7 and C_8 cyclic amines were obtained from Aldrich. C_8—N—Cl was prepared by a method in ref. 3. C_{12} amine was prepared by $LiAlH_4$ reduction of the parent lactam and purified by distillation. C_9 cyclic and C_7–C_9 bicyclic amines were otained from Dr. O. E. Edwards, N.R.C., Ottawa.

Electrodes

Natural graphite (George F. Pettisos, Canada). Porous carbon, 60 (Union Carbide S2408-60). Porous carbon, 45 (Union Carbide S2584-45). All the above cut to 5 cm high and 1.5 cm diameter. Stainless steel 304, 1/8 in rod. Platinum in fine mesh in a cylinder 5 cm high and 1.5 cm diameter.

Procedure

A three-neck round bottle flask served as the electrolytic cell. The flask could be fitted with a side arm and a fine fritted glass disc to provide two compartments for the cathode and anode. However, separation of the electrodes did not produce any significant differences in the results.

Since each reaction has to be monitored to ensure maximum yield, samples were withdrawn periodically for analysis. Each sample (2.3 mL) was made alkaline enough in the cold to separate the organic and aqueous layer. The organic layer was separated and the aqueous solution washed with ether. The ether solutions were added to thc organic layer, dried, concentrated, and used for glc analysis.

The final reaction mixture was acidified, concentrated to 1/10 of its original volume, made alkaline, extracted with ether, and dried. The ether was concentrated to a known volume and then used for analysis.

Instrumental analysis

Gas liquid chromatography: Hewlett-Packard 810 Res. Chromatograph, dual column, T.C. detector. Mass spectrometry: Perkin-Elmer 270. Column, 10% SE30 on Chemosorb W.AW. DMCS 60/80 mesh, 1/8 in × 12 in, temperature programming 20°C/mt to 280°C.

The electronic absorption spectra of some coumarins. A molecular orbital treatment

RAFIE H. ABU-EITTAH AND BAHGAT ALI H. EL-TAWIL
Department of Chemistry, Faculty of Science, King Abdulaziz University, Jeddah, Saudi Arabia

Received June 14, 1984[1]

RAFIE H. ABU-EITTAH and BAHGAT ALI H. EL-TAWIL. Can. J. Chem. 63, 1173 (1985).

The electronic absorption spectra of coumarin and its derivatives umbelliferone (6-hydroxycoumarin), esculetin (6, 7-dihydroxycoumarin), and scopoletin (6-methoxy-7-hydroxycoumarin) were investigated. The $n \rightarrow \pi^*$ transition was not observed in the spectrum of coumarin but was observed in the spectra of some of its derivatives. Molecular orbital calculations, using the INDO procedures, were carried out on coumarin and some of its derivatives. The activities of the different sites of the molecules are discussed in terms of the coefficients of the atomic orbitals constituting the HOMO and the LUMO. The correspondence between the calculated and experimental transition energy and band intensity is satisfactory.

RAFIE H. ABU-EITTAH et BAHGAT ALI H. EL-TAWIL. Can. J. Chem. 63, 1173 (1985).

On a étudié les spectres d'absorption électronique de la coumarine et de ses dérivés, à savoir l'umbelliférone (hydroxy-6-couramine), l'esculétine (dihydroxy-6,7, coumarine) et la scopolétine (méthoxy-6-hydroxy-7 coumarine). On n'a pas observé de transition $n \rightarrow \pi^*$ dans le spectre de la coumarine mais on l'observe dans le spectre de certains dérivés. On a effectué des calculs d'orbitales moléculaires, selon les méthodes INDO, sur la coumarine et sur certains de ses dérivés. On discute de l'activité des différents sites des molécules en fonction des coefficients des orbitales atomiques haute occupée et basse vacante. On trouve satisfaisant la concordance entre les valeurs calculées et expérimentales des énergies de transition des intensités des bandes.

[Traduit par le journal]

Introduction

Coumarin and many of its derivatives have such marked physiological effects as active hypotoxicity, carcinogenicity, anticoagulant action, and antibiotic activity. Perhaps of the greatest fundamental biochemical interest is the photosensitizing effect on cells of certain linear furanocoumarins, which is intimately associated with their cross-linking of the strands of DNA.

An attempt to correlate the biological activities and electronic structures of some coumarins was made by Heathcote and Hibbert (1); Hückel molecular orbital calculations were performed and were used to extend previous calculations (2) performed on aromatic hydrocarbons.

Link's group (3) early examined 106 samples of 4-hydroxycoumarins and found dicoumarol to have a higher anticoagulant activity than any of the synthetic coumarins tested. The minimal structural requirement for such an activity was an intact 4-hydroxycoumarin residue.

Coumarins showed a varying inhibiting effect on enzymes. The structure of coumarin is responsible for the specific inhibition of the enzyme. Umbelliferon (7-hydroxycoumarin) had no inhibition effect, contrary to 4-hydroxycoumarin (4, 5). Dihydroxy derivatives were more effective than monohydroxy ones, especially when occupying vicinal positions. Electron transport processes were also inhibited by dihydroxycoumarins (5).

Wald and Feuer (6) conducted a structure–activity relationship study on the ability of coumarin and nine of its natural and synthetic derivatives to induce drug-metabolism enzymes in rat liver. They calculated σ and π-electron density at the various positions of the coumarin nucleus and related the enzyme induction to the calculated values.

Recent studies have indicated some antitumour activity by simple coumarins. Coumarin itself has been reported to be a moderately potent inhibitor of chemical carcinogen-induced neoplasia (7), and other related coumarins have antitumour activity (8, 9).

Coumarins are known by their lasing effect. The coumarin class of laser dyes has either an hydroxyl or amino group at C-7 of the coumarin nucleus. The effects of substituents on the lasing characteristics of these compounds have been reported (10–13). The synthesis of several new laser dyes and the effects of substituents on their fluorescence maxima and fluorescence quantum yields have also been reported (14).

Fluorescence spectra excited by 2-photon absorption of the 6943-A° line of a ruby laser was investigated (15*a*). Results show large single values of non-linear second-order optical susceptibility. Kobayashi (15*b*) studied the picosecond kinetics of 7-hydroxy-4-methylcoumarin in the lowest singlet excited state and confirmed that the excited anion of this coumarin system is formed through the excited state of the neutral molecule.

In spite of the vast biological importance of coumarins, a detailed study of their spectra and electronic structure is lacking in the literature. The reported spectral behaviour has only been for diagnostic purposes and the observed bands were assigned to the benzene and pyrone rings (16, 17). The spectra of hydroxycoumarins and many of their derivatives, have been reported (18). Useful for diagnostic purposes was the finding that acetylated phenolic coumarins show uv spectra similar to those of the corresponding parent hydrocarbons (19, 20).

The shifts observed when running the spectra of coumarins in alkaline media have been widely used for differentiation (21–23) and diagnostic purposes (24). Spectral shifts produced when other inorganic reagents are added to ethanolic solutions of certain coumarins are also of diagnostic value (25, 26).

The only MO calculations performed on coumarins were on its π-system or using the EHT procedures (27). In this work the electronic absorption spectra of some coumarins, namely, coumarin, umbelliferone (7-hydroxycoumarin), escoletin (6,7-dihydroxycoumarin), and scopoletin (6-methoxy-7-hydroxycoumarin) were investigated. Molecular orbital calculations using all valence electrons by means of the INDO procedure were performed on the above compounds as well as on some aminocoumarins. The calculated parameters, namely, total energy, transition energy, charge density, dipole moment, σ and π population analysis, etc. are not available in the literature and

[1]Revision received November 16, 1984.

are essential in understanding the electronic structure of the compounds studied.

Experimental

Ethanol (Koch light spectroscopic reagent grade) and dioxan (Merck reagent grade) were used without further purification.

Coumarin, umbelliferone, esculetin, and scopoletin were obtained from Sarsyntex Laboratories, Sarget. The purity of the samples was confirmed by tlc procedures.

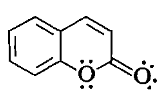
The spectra were recorded on a Cary-17 spectrophotometer using 1.0-cm^3 fused silica cells.

Results and discussion

A. *Electronic absorption spectra*

(i) Coumarin

The spectra of coumarin reported in the literature were not investigated further. The positions of band maxima, and their shift on varying the medium were used for identification purposes. The bands observed were sometimes assigned to transitions either on the benzene nucleus or on the pyrone nucleus. Such an interpretation is a rather crude one since the two chromophores, benzene and pyrone, are fused together and the



molecular orbitals will encompass the whole molecule and will not be localized on one of the chromophores. The π-electrons of the molecule are delocalized and the observed transitions should be assigned to the molecule as one unit. The method of "bisecting" the molecule to a number of non-interacting chromophores is an approximate one and has a meaning only if the chromophores are separated by more than one σ bond or if steric effects operate to distort the coplanarity of the different chromophores constituting the molecule. In the case of coumarin it is meaningless to bisect it into separate chromophores, and the observed spectral bands should be assigned to electronic transitions between molecular orbitals characteristic of the molecule.

The coumarin spectrum, in the accessible uv region, may show an $n \rightarrow \pi^*$ transition in addition to a number of $\pi \rightarrow \pi^*$ transitions. The $n \rightarrow \pi^*$ transition would be mainly localized on the C=O chromophore and may not be the lowest energy transition. The C—O—C bond angle in coumarin is 1.22°, indicating an sp^2 hybridization of the ring-oxygen atom (28). Hence, one of the lone pairs of electrons on that atom occupies a $2p_z$ atomic orbital and is a part of the π-system of the molecule.

Figure 1 shows the electronic absorption spectra of coumarin using ethanol and dioxan as solvents. Solvent polarity did not affect the position of band maxima, indicating that the polarity of the excited state is not significantly different from the polarity of the ground state. Electronic transitions which lead to polar states are stabilized in polar solvents, leading to a red shift of band maxima. The spectrum of coumarin shows three absorption bands none of which correspond to an $n \rightarrow \pi^*$ transition. This conclusion is supported by the high intensity (ϵ varied from 6,000 to 15,000) of the observed bands. Usually, $n \rightarrow \pi^*$ transitions are symmetry forbidden and ϵ is less than 100. Also, the absorption bands corresponding to $n \rightarrow \pi^*$ transitions are blue-shifted and blurred in polar solvent. The absorption band around 275 nm is asymmetric and the presence

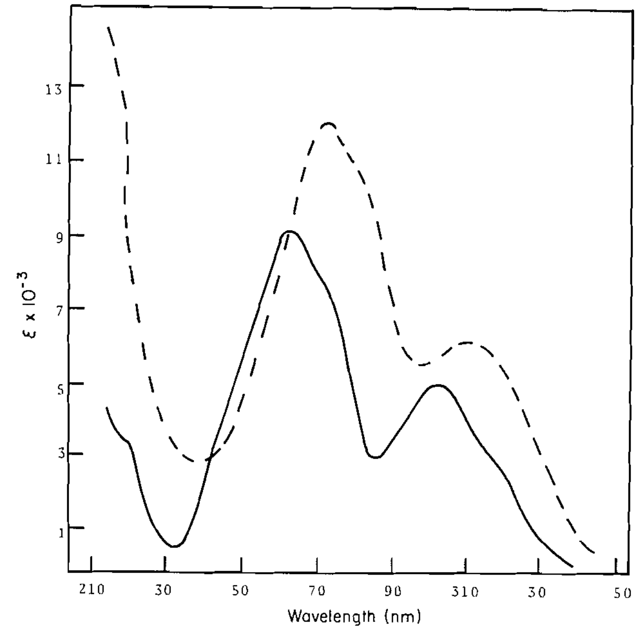


FIG. 1. The electronic absorption spectra of coumarin in dioxan (———); in ethanol (----).

TABLE 1. Numerical values of band maxima and intensities of the studied coumarins in ethanol

Compound	λ_{max} (nm)	ϵ (M^{-1} L^{-1})	f
Coumarin	310	6000	0.23
	285	10000	0.14
	274	12000	0.23
	220		
Umbeliferone	370	2200	0.04
	330	16830	0.43
	290	7300	0.15
	255, 240	4200, 5400	0.18
	220	14 290	—
Esculetin	400	3100	0.05
	350	11900	0.29
	300	5900	0.12
	260	5700	0.11
	230	16000	0.52
Scopoletin	400	3060	0.05
	345	12810	0.30
	300	5570	0.15
	253	6200	0.16
	230	15600	0.52

of a long wavelength shoulder is quite apparent. This observation may indicate that the band represents two overlapping electronic transitions; confirmation of such a conclusion will be by means of MO calculations.

The observed bands (Fig. 1) correspond to $\pi \rightarrow \pi^*$ transitions and the expected $n \rightarrow \pi^*$ transition is submerged under the strong $\pi \rightarrow \pi^*$ one. The position of the $n \rightarrow \pi^*$ transition will be predicted by MO calculations. As is evident, none of the observed $\pi \rightarrow \pi^*$ transitions can be assigned to the benzene or to the pyrone chromophores of the coumarin molecule. The observed bands correspond to transitions between MO's characteristic of the coumarin molecule.

Table 1 gives the values of band maxima, molar extinction coefficient, and oscillator strength of the observed bands.

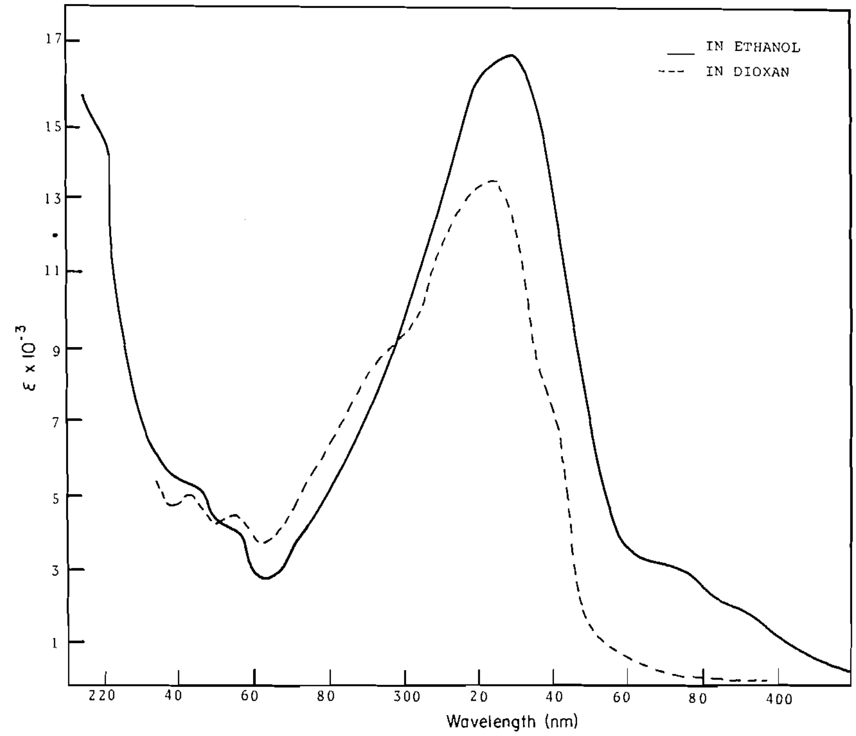

FIG. 2. The electronic absorption spectra of umbelliferone.

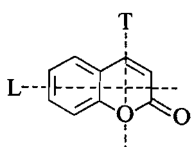
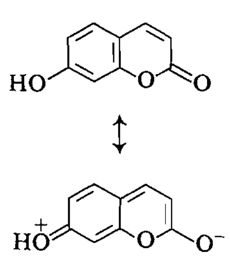
(ii) Substituted coumarins

Substitution in the coumarin nucleus by chromophores such as —OH, —OCH_3, —CH_3, and —NH_2 perturbs the electronic transitions of coumarin. The pertubation effect depends on



the extent of the interaction between the substituent and the π-system of the coumarin nucleus. The bands which will be perturbed depend on the position of the substituent, whether along the transverse, T, or the longitudinal, L, axis.

Figure 2 shows the electronic absorption spectra of umbelliferone (7-hydroxycoumarin). Substitution by an —OH group in the ring perturbed the spectrum significantly. Polar forms such as (b) are expected to contribute to the ground and mainly to the excited states. This contribution has resulted in a significant lowering of the energy levels as compared to those of coumarin. A pronounced red shift is encountered with all the

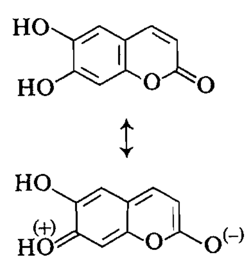


(a)

(b)

observed transitions; the lowest energy one appears in the region of 370 nm compared to 310 nm in coumarin, indicating that the contribution of tautomer (b) to the structure of umbelliferone is significant. The spectrum of umbelliferone shows at least five electronic transitions in the accessible uv region compared to the possibility of four electronic transitions for coumarin in the same region. The broad, intense and unsymmetric band in the region of 320 nm (Fig. 2) represents two overlapping transitions. The presence of a shoulder at the short wavelength end of the band is quite apparent. The observed bands represent $\pi \rightarrow \pi^*$ transitions, the weak $n \rightarrow \pi^*$ transition is submerged by the stronger $\pi - \pi^*$ one.

Substitution by another —OH group at C(6) facilitates the formation of the polar tautomer (c); hence one expects a further



(c)

red shift in band maxima. The bands of esculetin (6, 7-dihydroxycoumarin) are red-shifted (Fig. 3) compared to those of umbelliferone but the same electronic transitions are observed in both compounds. An interesting observation is that the two overlapping transitions (in the region of 300 nm) in the case of umbelliferone are resolved in the case of esculetin. The predominant contribution of tautomer (c) to the structure of esculetin explains the significant variation of its spectrum from that of coumarin.

The replacement of one of the —OH groups in esculetin with a methoxy group (scopoletin) produces a minor effect on the spectrum (Fig. 4). The methoxy group is a stronger electron donor than the hydroxy group but the extent of their interaction with the π-electron system of the coumarin nucleus is the same.

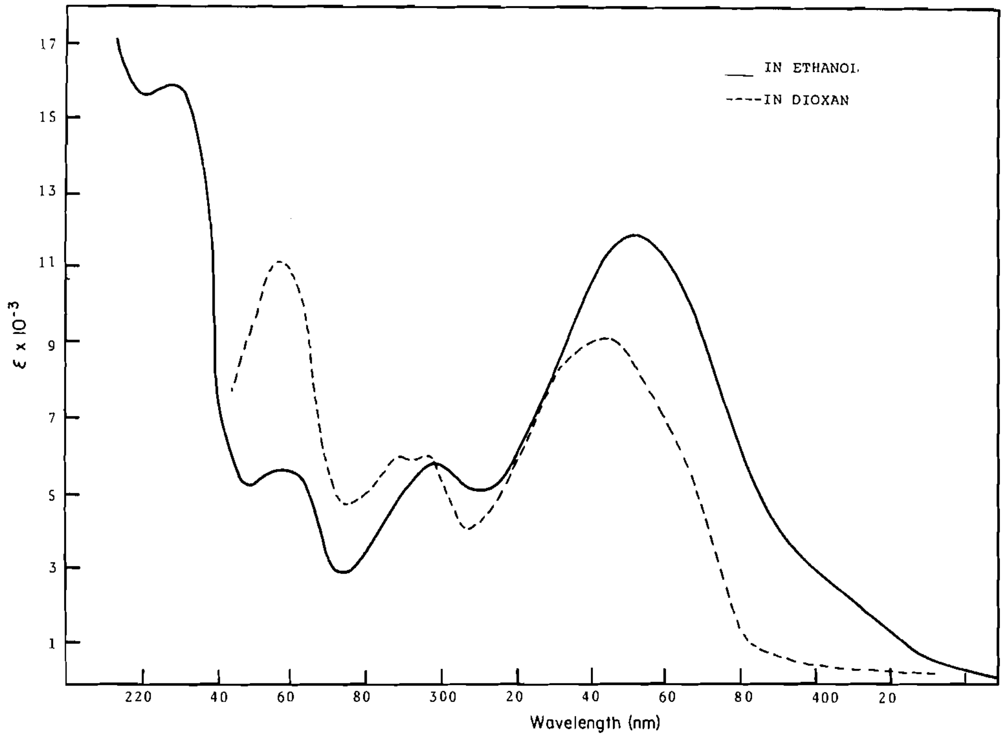


FIG. 3. The electronic absorption spectra of esculetin.

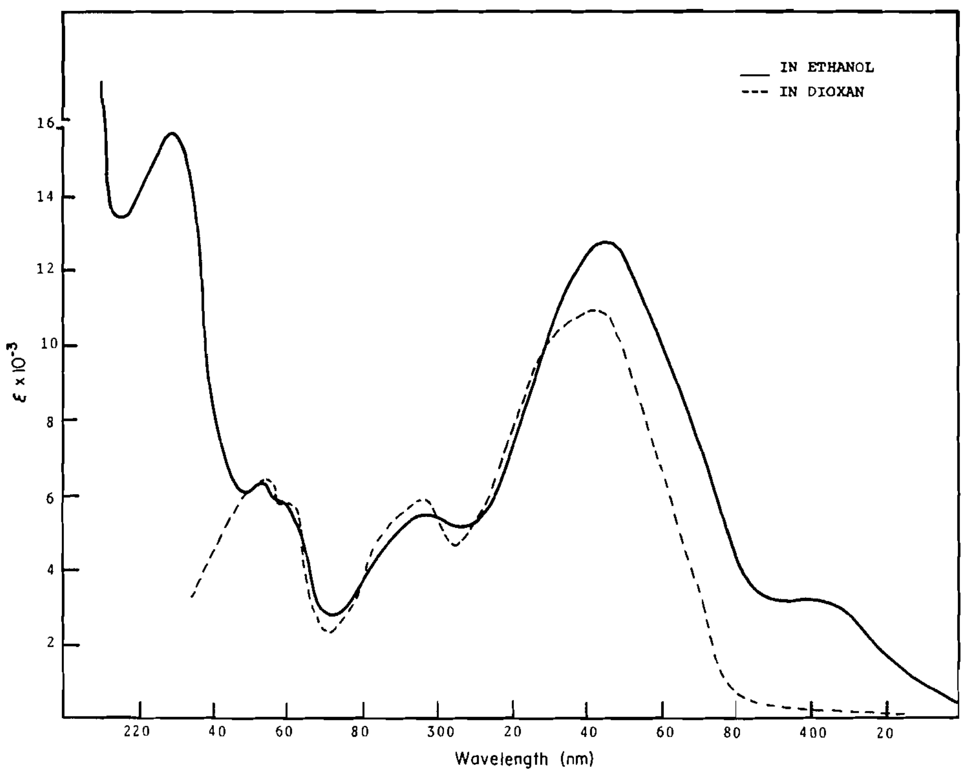

FIG. 4. The electronic absorption spectra of scopoletin.

This is seen when comparing the values of band maxima in the spectra of the two compounds; minor differences, if any, are detected. The values of band intensity confirm that all the observed transitions are $\pi \rightarrow \pi^*$ ones.

B. *Molecular orbital calculations*

It is established that a "structure–function" relationship exists for many biological compounds. The previously reported structural investigations considered only the "π" system of coumarins (1, 2, 27). In this work molecular orbital calculations were performed, using the INDO procedure, on coumarin and some of its derivatives, namely, 6-hydroxy-, 6,7-dihydroxy-, 6-amino-, 6,7-diamino-, 6-hydroxy-7-amino-, and 6-amino-7-hydroxycoumarins. Some of these coumarins and

their heteroanalogues are used as laser sources and information about their electronic structure is essential.

The formalism and parameterizations of the INDO procedure may be found in the literature (29, 30). The values of bond lengths and bond angles required to define the geometry of the compounds studied have been reported previously (28, 31). The configuration we used in our calculations is shown.

The results of computations are given in Tables 2 and 3. The numerical values of the coefficients of the atomic orbitals of the active sites C(2), C(3), C(4), and O(11), participating in the highest occupied and lowest vacant molecular orbitals, as well as the net charge on these sites are given in Table 2.

A comparison of the calculated parameters for some isomeric coumarins is given in Table 3. Table 4 compares the experimentally found transition energies and oscillator strengths with theoretically calculated ones.

Discussion and conclusions

The coumarins studied are strong dipoles, hence excitation

	5.39	5.10	0.52	0.27

of an electron is not expected to affect the polarity of the ground state. As a result, band maxima of the observed electronic transitions will not be apparently affected by solvent polarity. This result is evident when comparing the spectra of the coumarins studied in ethanol and dioxan.

The spectral behaviour of these coumarins indicates that substitution by an —OH group apparently affects the observed transitions. This result is evidence that tautomers such as (b) and (c) contribute significantly to the structures of hydroxycoumarins. The spectra of umbelliferon, esculetin, and scopoletin show a long wavelength shoulder which, most likely, corresponds to the forbidden $n \rightarrow \pi^*$ transition. The apparent high intensity of this transition results from its lying on the border of a relatively intense $\pi \rightarrow \pi^*$ transition. On the other hand, the coumarin spectrum does not show an isolated band (or shoulder) for the $n \rightarrow \pi^*$ transition. The solubility of the studied compounds is rather poor in non-polar solvents. Consequently, the weak $n \rightarrow \pi^*$ transitions were not clearly observed in dioxan. Molecular orbital calculations predicted the positions of the $n \rightarrow \pi^*$ transitions nicely (Table 4).

It is interesting to note that the electronic transitions which were overlapping in the spectrum of umbelliferone, in the region of 270–360 nm (Fig. 2), were nicely resolved in the spectrum of esculetin. This is evidence that tautomer (c) apparently contributes to the structure of that compound. Such a resolution appeared even better, when the —OH was replaced by an —OCH_3 group (scopoletin, Fig. 4).

Coumarins are α, β-unsaturated ketones. The active sites in the molecule are the C(2)═O(11) and C(3)═C(4). An important result of the performed calculations is the larger differences of the SCF-coefficients of these atoms in the HOMO than in the LUMO. In the former, the coefficient of the oxygen atom is significantly larger than that of C(2) and the coefficient of C(3) is larger than that of C(4). When considering the LUMO there is no significant difference in the values of the coefficients of C(2) and O(11) or between C(3) and C(4). Also, the charge on C(3) is always negative whereas that on C(4) is positive. The correspondence between the calculated and observed values of some parameters (transition energy and oscillator strength, Table 4) is satisfactory.

The spectra of amino- and hydroxyamino- coumarins are not available yet; our calculations indicate that their electronic spectra would not differ from their hydroxy analogues.

Molecular orbital calculations indicated that coumarin is a stronger dipole than hydroxycoumarins (Table 3). This result indicates that substitution by the —OH group creates a dipole in the opposite direction to that of the parent coumarin. The reverse behaviour is encountered on substitution by an —NH_2 group. It is found that amino-coumarins are stronger dipoles than coumarin, a result which means that substitution by the amino group creates a dipole in the same direction as that originally present in coumarin.

It may be interesting to compare some physical parameters for the isomers 6-hydroxy- and 7-hydroxy-coumarins; 6-amino- and 7-amino-coumarins; 6-hydroxy-7-amino- and 6-amino-7-hydroxy-coumarins (Table 3). No significant difference is detected in the total energy of any of the two isomers, and only slight differences are found in the lowest transition energy of any of the two isomers. However, significant differences in dipole moments are found between any of the two isomers.

Received April 6, 1984

ANIL K. PURI. Can. J. Chem. **63**, 1180 (1985).

Partial molar volume (ϕ_v^0), partial molar compressibility (ϕ_k^0), Jones–Dole viscosity *B* coefficient, and solute activation parameters of adenosine in water–DMSO mixtures in the presence of Ca^{2+} and K^+ ions have been calculated from ultrasonic, volumetric, and viscometric studies at 25, 30, 35, and 40°C (±0.01°C). The results are discussed in terms of the Jones–Dole viscosity *B* coefficients and the transition state parameters for viscous flow.

ANIL K. PURI. Can. J. Chem. **63**, 1180 (1985).

Utilisant les résultats d'études ultrasoniques, volumétriques et viscosimétriques effectuées à 25, 30, 35 et 40°C (±0.01°C), on a calculé les volumes molaires partiels (ϕ_v^0), les compressibilités molaires partielles (ϕ_k^0, les coefficients de viscosité *B* de Jones–Dole et les paramètres d'activation de solution de l'adénosine dans des mélanges eau/DMSO, en présence d'ions Ca^{2+} et K^+. On discute des résultats en fonction des coefficients de viscosté B de Jones–Dole et des paramètres de l'état de transition de l'écoulement visqueux.

Introduction

Adenosine is one of the most important nucleosides in the study of molecular biology (1). Conformational properties of adenosine, the interaction of its different functional groups with solvent molecules in solution and temperature dependence of these interactions play an important role in the understanding of the thermodynamic behaviour of biochemical processes in living cells. The ultrasonic velocity in solution can be used to study the solute–solvent and solute–solute interactions, which are determined by the chemical structure of the solute and solvent molecules. Ultrasonic velocity measurements are mostly limited to obtaining the hydration numbers in aqueous (2–5) and non aqueous solution (6). Hemmes *et al.* (1) made a successful attempt to study the dependence of solute–solvent interactions on the chemical structure of nucleic acid derivatives in an aqueous solution. Interaction studies of bivalent metal ions with uracil, thymine, and cytosine have been investigated potentiometrically (7–10). Many attempts have been made to study the solution properties of DMSO–water mixtures (11–14), since DMSO is particularly suitable for biophysico chemical processes. Excess thermodynamic properties of DMSO–water mixtures at 20, 30, 40, and 60°C have been discussed in terms of molecular interactions by Pandey and Tiwari (15). The interaction of DMSO with *N*-benzoyl amino acids has been recently shown by Fong and Grant (16) using the ^1H nmr technique. Results show that the intermolecular H-bonding between DMSO and the amino-hydrogen atom increases the effective steric size of the amino hydrogen. Recently kinetic studies of ligand substitution have been carried out in the DMSO–water system by Coetzee and Karakatsanis (17). Relative viscosity of solution of sodium and potassium bromides and iodides in DMSO–water at 25, 35, and 45°C have been reported by Feakins and Lawrence (18–20). Results are discussed in terms of Jones–Dole viscosity *B* coefficients and transition state treatment.

The present article deals with the results of ultrasonic, volumetric, and viscosity studies of adenosine in DMSO–water mixtures in the presence of K^+ and Ca^{2+} ion at 25, 30, 35, and 40°C (±0.01°C). Results have been discussed in terms of partial molar volume (ϕ_v^0), partial molar compressibility (ϕ_k^0), Jones–Dole viscosity *B* coefficient, and transition state theory.

[1]Present address: 2125 McKesson Drive, Richmond, VA 23235, U.S.A.

Experimental

Adenosine (supplied by Sigma chemicals, U.S.A.) was of extra pure "Grade-Reagent" quality. Purity was checked by tlc and paper chromatography according to well known methods (32).

Dimethyl sulphoxide (DMSO) was distilled in a stream of dry nitrogen over sodium hydroxide at a pressure of 2.6 kPa using a 50 cm column packed with Finskihelices. A conductivity cell was attached to the still head and solvent collected when the electrolytic conductivity (k) of distillate had fallen to 4×10^{-6} S m^{-1}. The solvent was stored, and all manipulations on the solutions were made in a nitrogen filled dry box. KCl was of AR grade while hydrated $CaCl_2 \cdot 2H_2O$ was dried at 110°C and stored in dessicator. A solution of adenosine (0.01 *M*) was prepared in DMSO solvent. Stock solutions of 0.1 *M* KCl and 0.1 *M* $CaCl_2$ were prepared in double distilled water.

Two sets of ten solutions each of adenosine–(water–DMSO)–Ca^{2+} and adenosine–(water–DMSO)–K^+ designated as system A and system B were prepared in varying composition from 10–75% by weight of DMSO.

The densities of solutions were determined with the help of a calibrated bicapillary pyknometer at 25, 30, 35, and 40°C (±0.01°C), respectively. The estimated error in the density measurements was of the order of ±0.05%.

Ultrasonic velocity (u) in different solutions were measured using variable temperature, ultrasonic interferometry with a quartz crystal having a frequency of 2 MHz. The estimated error was ±0.01%.

Viscosity measurements were carried out using a calibrated Ostwold viscometer at 25, 30, 35, 40°C, respectively, with maintained temperature of ±0.01°C. The time of flow for water was selected in the range of 15–25 s, while for dilute solutions at least 30 s or more was used. The estimated errors in viscosity measurements were of the order of ±0.004%.

Results

Density data for adenosine in the mixed solutions of electrolytes have been used for the calculation of apparent molar volume (ϕ_v^0) as a function of total molality of co-solute and water–DMSO solvent composition. The corresponding equation in terms of densities is

$$\phi_v = \frac{1000\,(\bar{d}^0 - d)}{m_t \bar{d}^0\, d} + \frac{\bar{M}}{\bar{d}^0}$$

where $\bar{d}^0$ and d are the densities of the DMSO–water solvent and adenosine solution respectively. The value of $\bar{d}^0$ was determined from $\bar{d} = \Sigma d_i y_i$ where y_i represents weight fraction, m_t is the total molality of the co-solute in DMSO–water solvent and can be determined by $m_t = \Sigma m_i$ where m_i is the molarity of ith component. The mean molecular weight of the two solutes ($\bar{M}$) was obtained from $\bar{M} = \Sigma M_i y_i$, here M_i is the molecular weight of component i. Apparent molar volume at infinite dilution (ϕ_v^0) has been evaluated from the equation.

$$[2] \quad \phi_v = \phi_v^0 + S_v\sqrt{m_t}$$

where S_v is the experimental slope of ϕ_v vs. $\sqrt{m_t}$ plot. Values of partial molar volume (ϕ_v^0) at different DMSO compositions and different temperatures are recorded in Table 1.

S_v values are given in Table 2 for systems A and B. From density and ultrasonic velocity the isentropic compressibility (β_s) of solution has been calculated from the relationship

TABLE 4. Viscosity *B* coefficient for adenosine–DMSO–water in the presence of K^+ and Ca^{2+} ions

35	0.0050	0.0070
40	0.0050	0.0056

$$[3] \quad \beta_s = \frac{1}{u^2 d}$$

where u is the ultrasonic velocity and d is the density of the medium. The isentropic aparent molar compressibility (ϕ_k) of solute was obtained from the relation

$$[4] \quad \phi_k = \frac{1000(\beta_s - \beta_0)}{m_t \bar{d}^0} + \beta_s\phi_v$$

where β_s and β_0 are the compressibilites of solution and solvent. Apparent molar compressibility at infinite dilution (ϕ_k^0) has been extrapolated from the linear plot of ϕ_k vs $\sqrt{m_t}$. Graphically estimated values of ϕ_k^0 are given in Table 3.

The experimental viscosity data were analysed in terms of the Jones–Dole equation (21) below which accounts for both solute–solvent and solute–solute interactions.

$$[5] \quad \frac{\eta^0}{\eta} = 1 + A\sqrt{m_t} + Bm_t$$

Here η^0/η is the relative viscosity of solution. The constants *A* and *B* are evaluated from the intercept and slope of the $(\eta^0/\eta - 1)/\sqrt{m_t}$ vs. $\sqrt{m_t}$ plot. The coefficient *A* represents the contribution from interionic electrolytic forces (22) and the coefficient *B* measures the order or disorder introduced by ions into the solvent structure. This constant is specific and approximates the additive property of electrolytes at a given temperature (23) although no satisfactory theoretical treatment has yet been given.

B coefficient values for systems A and B are given in Table 4. The viscosity and density data have been utilized for the calculation of activation parameter (24). The free energy of

activation for viscous flow (25, 33) is given by eq. [6],

$$[6]\quad \Delta\mu^* = RT \ln \frac{\eta^0 V}{hN}$$

where h is Planck constant and N is the Avogadro number, η^0 is the viscosity of solution, and V may be regarded as the volume of 1 mol of solution particles and is given by

$$V = \frac{1000}{n_1 + \nu n_2}\ \mathrm{cm}^3$$

where ν is the number of species into which a solute molecule dissociates and n_2 is the number of moles of solute per litre of solution. The number of moles n_1 of the solvent per litre of solution is given by

$$n_1 = \frac{1000\,\bar{d}^0 - n_2 \bar{M}_2}{\bar{M}_1}$$

where $\bar{M}_1$ and $\bar{M}_2$ are the molecular weights of co-solvent DMSO–water and co-solute adenosine and electrolytes, respectively. Furthermore, by measuring the B coefficient at different temperatures, enthalpies (ΔH^*), and entropies (ΔS^*) of activation can be obtained by using equations (24)

$$[7]\quad \Delta S^* = -\mathrm{d}(\Delta\mu^*)/\mathrm{d}T$$

$$[8]\quad \Delta H^* = \Delta\mu^* + \Delta S^*$$

Calculated values of $\Delta\mu^*$, ΔH^*, and ΔS^* are recorded in Tables 5 and 6 for sets A and B.

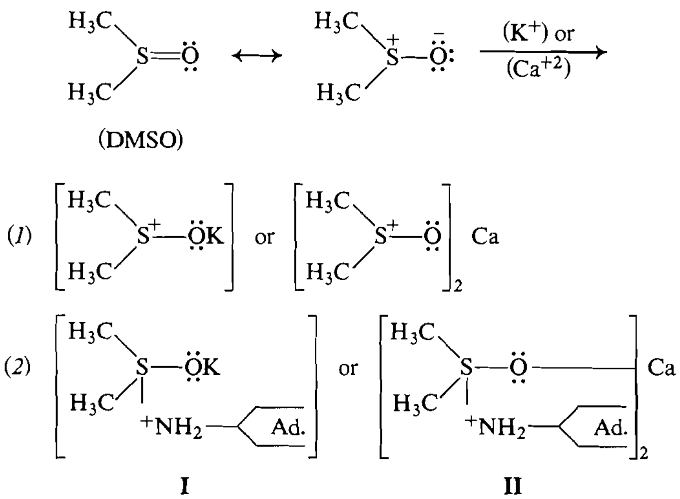
Discussion

The results in Table 1 reveal that the values of ϕ_v^0 (partial molar volume) gradually decrease with increase in temperature from 30 to 40°C for the system A and increase with temperature for system B for the whole range of solvent composition (10–75 wt.%). At the same time the positive S_v slopes for both the systems A and B gradually decrease with increasing temperature. It may therefore be concluded that ϕ_v^0 values correspond to a maximum for system B, thereby suggesting that solute–solvent interactions are stronger than solute–solute interactions in the temperature range 25–40°C. The increase in values of partial molal volume ϕ_v^0 for system B with increase in temperature are due to the dehydration of adenosine. S_v values are decreased with increase in temperature. It can be argued that solute–solute interactions can be affected by the influence of K^+ (system A) on the structure of DMSO as interionic attractions are stronger in DMSO (dipolar aprotic solvent) than in water because of the lower dielectric constant value of DMSO than water. The occurrence of maximum ϕ_v^0 values and lower S_v values in the case of system B is in agreement with the above inference.

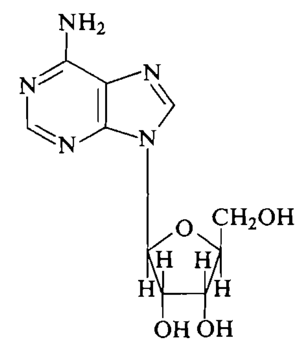
According to Kaulgud and Patil (26), negative ϕ_v^0 values are associated with the "promotion" of solvent structure, i.e., addition of adenosine in the presence of an electrolyte in DMSO–water may lead to an incipient structure that enhances the water structure. This result might be due to the accommodation of adenosine in the cavity created by the displacement of water molecule into the interstices.

Apparent partial molar compressibilities (ϕ_k^0) (Table 3) increase with increasing temperature for system A for solvent compositions varying from 10–75 wt. %. The same trend in ϕ_k^0 values observed for system B except at 40°C, where the value of ϕ_k^0 is significantly lower. It is evident from Table 3 that both systems A and B the values of (ϕ_k^0) are negative at all temperatures. It can be interpreted as due to the loss of structural compressibility of water on account of population increase of four bonded water molecules in the vicinity of adenosine molecules. Critical evaluation for all the available physicochemical studies of DMSO–water mixtures by Frank and Ives (27) led to the conclusion that there must be reinforcement of the water structure in the neighborhood of DMSO molecules in dilute solution. There is also a greater loss of structural compressibility of water employing a greater ordering effect by ions on solvent structure as in the case of systems A and B except at 40°C in system B.

Viscosity B coefficients of the Jones–Dole equation are positive for both systems. The B values gradually decrease with increasing temperature. Positive B values indicate strong alignment of solvent molecules with ions, i.e., strong DMSO interaction with K^+ or Ca^{2+} ions and with amino site of adenosine, which reveals the "structure-making" behaviour of solvent structure. The B values decrease with increasing temperature indicating that ion–solvent interactions are being influenced in the temperature range from 20 to 40°C. A number of factors are believed to contribute to the B values in solutions of K^+ and Ca^{2+} ions in DMSO–water mixture. Dimethylsulfphoxide, a dipolar aprotic solvent (19), is pyramidal in shape with two C-atoms, the O-atom, and S-atom at the vertices (28). The bonding characteristics of the sulphur atom have been explained by Burg (29). Both the sulphur and the oxygen atoms possess a lone pair of electrons and for sulphur the lone pair is tetrahedrally disposed to the methyl groups and oxygen atom. A strong electrostatic interaction between the positive charge on the cation and the lone pair on the oxygen of each solvent molecule is envisaged when a cation solvent complex is formed as shown by the following mechanism.



SCHEME 1. Possible mechanism: addition of metal ions with adenosine



Adenosine

The cation–solvent complex of K^+ and Ca^{2+} with adenosine in the presence of DMSO–water co-solvent are represented by **I** and **II**, respectively (Scheme 1). It is evident that DMSO interacts strongly with the cations and this is reflected by the values of B coefficent shown in Table 4.

The analysis of solute–activation parameters reveals (Tables 5 and 6) that ΔS^* and ΔH^* are negative for systems A and B and increase gradually with increasing composition of DMSO–water from 10–75 wt.%.

This fact indicates that in the solvent mixture the average transition state is associated with bond making and an increase in the order. The system B on the other hand with an increase in the percentage of DMSO from 55 to 75 wt.% in the mixture, the values of ΔS^* and ΔH^* are comparatively lower. In the latter case it can be assumed that the transition state for viscous flow is accompanied by the breaking and distortion of intermolecular bonds. Moreover, the smooth progression of the values of ΔS^* and ΔH^* found in system A and B, Tables 5 and 6 confirm the absence of structural enhancement of water by DMSO. In fact, when the water structure is increased by the addition of co-solvent, maxima or minima in the values of activation parameters of viscous flow were obtained for electrolytes in water–ethanol (30) and water–acetone (31) systems. It is evident from Table 5 that free energy of activation ($\Delta\mu^*$) is positive for all proportions of solvent composition and at all temperatures studied in the present investigation. The results show that adenosine is higher in free energy state, i.e. formation of the transition state is less favourable in

DMSO−water mixtures from 10−75 wt.%, suggesting that water has more affinity for adenosine in DMSO−water cosolvent mixture in the presence of K^+ and Ca^{2+}. Similarly, other activation parameters for adenosine as ΔH^* and ΔS^* show negative contribution in DMSO−water mixtures, suggesting that entropies (ΔS^*) are less effective in the presence of cations K^+ or Ca^{2+} ions, and therefore, the net amount of order created by cations in DMSO−water mixture is substantial.

Many methods have been employed for measuring the interactions of trace metals and humic materials but little consideration has been given to the magnitude of error in the resulting titration data. Most common metal-titration methods can be placed into one of three categories based on the chemical species that is most directly measured: free ionic metal, total labile metal, or ligand-bound metal. The propagation of random instrument error into a titration data set is not uniform throughout a titration and the pattern of propagation is shown to be characteristic of the category of method used. Standard deviations are determined for measurements by ion-selective electrodes, fluorescence quenching, and fixed potential amperometry (each representative of a category of methods). Error propagation in resulting titration data is quantified. No single titration method yields uniformly precise data in all concentration ranges and a combination of complementary methods yields the best characterization of metal binding to a humic material.

WILLIAM FISH et FRANÇOIS M. M. MOREL. Can. J. Chem. **63**, 1185 (1985).

Plusieurs méthodes ont été utilisées pour mesurer les interactions entre des métaux à l'état de trace et les substances humiques; toutefois, peu de cas a été fait de l'amplitude de l'erreur qui entache les données de titration qui en résultent. En se basant sur la nature des espèces chimiques qui sont mesurées le plus directement, on peut classer la plupart des méthodes usuelles de titrages des métaux dans l'une des trois catégories suivantes: soit les métaux ioniques libres, les métaux totaux labiles ou les métaux liés à des ligands. La propagation de l'erreur instrumentale au hasard dans un ensemble de données de titrage n'est pas uniforme dans l'ensemble d'un titrage et on montre que le schéma de propagation est une caractéristique de la catégorie de méthode utilisée. On a déterminé les écarts standards pour des mesures faisant appel aux électrodes sélectives pour des ions, au piégage de la fluorescence et à l'ampérométrie à potentiel fixe (chacune représentant une catégorie de méthodes). On quantifie la propagation de l'erreur dans les données de titrage qui en résultent. Aucune méthode de titrage simple ne fournit des données uniformément précises dans tous les intervalles de concentration et une combinaison de méthodes complémentaires s'avère la meilleure façon de caractériser la liaison d'un métal à une substance humique.

[Traduit par le journal]

Introduction

In recent years researchers have amassed a substantial body of information about the interactions of humic materials with trace metals. In gathering these data, many analytical methods have been used, each of which measures a single chemical quantity such as free or ligand-bound metal. The additional quantities necessary for mathematically modeling the system have been indirectly obtained by data transformations.

Valid comparisons among results of different methods are possible if each method yields, either directly or indirectly, the same concentration of a metal species for a particular system. Tuschall and Brezonik (1) applied this test to four commonly used analytical methods: ion-selective electrodes, anodic stripping voltammetry, fluorescence quenching, and continuous flow ultrafiltration. Saar and Weber (2) compared and intercalibrated ion selective electrode and fluorescence quenching data and Waite and Morel (3) compared fulvic acid titrations using ion-selective electrodes and fixed-potential amperometry. The results of these comparisons suggest that, over certain concentration ranges and with certain exceptions, the measurements of each chemical quantity by several different methods are in approximate agreement.

With the variety of apparently comparable techniques available, criteria are needed to guide the choice of methodologies appropriate to a particular application. In a review of the titration methods currently available, Saar and Weber (4) emphasized the special merits and problems associated with each technique, such as sensitivity, interferences, and the metals that can be measured. In addition to matching the experimental capabilities of the method to the system under study, it is important to recognize the differences in the precision of data obtained from each method as a result of the different chemical species that are measured. The distinctions are a consequence of the arithmetic manipulations needed to calculate indirectly a species concentration. Errors propagate, resulting in different degrees of uncertainty for the directly and indirectly measured quantities.

Previous comparisons of techniques have not fully considered the implications of errors in transformed data. Parameters that characterize humic materials, such as stability constants and equivalent ligand concentrations, vary widely in accuracy depending on the titration method and the metal concentrations used. Frequently, limitations of time and materials preclude repetitive titrations and error intervals are not determined for model parameters. An alternative to numerous replicate titrations is to measure the precision of the analytical methods and then quantify the propagation of error for each transformation of the data. The latter approach is employed in this study.

We examined the most useful analytical methods and grouped them into three classes based on the quantities they measure. We selected a representative method from each class and showed that this method, in addition to its particular practical limitations, is subject to predictable errors characteristic of its class and that these errors propagate through the transformations needed to model the experimental results. As a consequence, no single technique can yield a complete and optimally precise set of metal-binding data. Results from different methods were overlapped to yield data that possess minimal error over a wide titration range. We applied these principles to series of Cu(II) titrations of fulvic acid obtained with each representative method. The predicted region of minimal error for each method was demonstrated by comparing the standard deviations of conditional stability constants obtained.

Theory

Classes of methods

Commonly used titration techniques fall into three general classes, each defined by the quantity that is measured as a function of total metal added during the titration: free ionic metal, labile metal species, or bound metal species.

Free-ionic metal activity may be measured with a solid-state, ion-selective electrode (ISE). These Nernstian devices generate a potential proportional to the logarithm of the free-metal activity in solution. Because stability constants are conventionally written in terms of the free metal species, the output of an ISE titration is especially convenient to use in speciation models. Furthermore, the logarithmic scaling allows data to be collected over many orders of magnitude. This feature is useful for characterizing humic materials which typically have a wide range of apparent metal-binding strengths.

Ion-selective electrodes have several well-known practical limitations. While very low free-metal activity can be measured, the lowest *total* metal concentrations possible are at or above the average concentrations typically found in unpolluted natural waters. Cupric ISEs, which are the most commonly used means of studying metal—humic interactions, are also subject to a large, uncorrectable interference from chloride ions (5). To overcome these problems, ion exchange methods have been proposed for determining ionic activities of metals in titrations (6). Such procedures fall into this class because the metal that partitions onto the exchanger surface is proportional to free-metal activity. Unfortunately, these methods still require relatively high ligand concentrations and are difficult to calibrate and interpret because of ligand adsorption on the exchanger (7). Consequently, the ion-selective electrode, which is very reliable within its optimal operating range (in the absence of interferences), was chosen for this study as the representative method of its class.

The second class comprises methods that yield arithmetically scaled labile-metal concentrations. The labile-metal fraction is operationally defined for each method but is ideally taken to be the sum of all metal species except the organo-metallic complexes of interest. Anodic stripping voltammetry and fixed-potential amperometry (3) fall into this category as well as all titration techniques involving separations, such as dialysis (8), gel-permeation chromatography (9), and ultrafiltration (1). The separation techniques offer great flexibility in the choice of reactant metals and background electrolytes, but uncertain molecular-size cutoffs make unclear the composition of the labile-metal fraction.

Because of its sensitivity and convenience, anodic stripping voltammetry (ASV) has been the most widely used technique in this class. Yet it is not clear which metal species are electrochemically stable and which are decomposed as "labile" at the negative potentials employed in the plating step (1, 10, 11). Much debate has centered on the accuracy of ASV techniques and there is substantial reason to believe that characterizations of metal binding agents by ASV methods are ambiguous or subject to artifact.

Waite and Morel (3) describe fixed-potential amperometry (FPA) as a method of labile-copper analysis that appears to have a sensitivity comparable to ASV methods yet is free of the major artifacts associated with mercury electrodes operating in the negative potential region. The FPA method has been intercalibrated with cupric ISE data and is used in this study as the representative method for this class.

The third class of methods are those that directly measure the formation of organo-metallic complexes during the titration. Spectrophotometry is the classical technique in this category (12) but has been little used for humic substances because of the weak absorptivity of metal—humate complexes. Methods that extract organo-metallic complexes onto a hydrophobic column such as the C-18 Sep-Pak column procedure described by Mills and Quinn (13) also fall into this class. Such methods are useful in estimating the extent of organic metal-binding in natural samples but are poorly suited to detailed titrimetric procedures because the kinetics of humic complex formation and dissociation in the column are not well defined. Quenching of natural humic fluorescence by certain paramagnetic metals (such as Cu^{2+}) has been recently applied to metal binding studies with considerable success (1, 14). Fluorescence quenching (FQ) is relatively sensitive and provides a direct, arithmetically scaled measure of metal-complex concentration. It is employed here as the third representative method.

Error propagation in data transforms

Developing a thermodynamic equilibrium model of metal interactions with humic materials requires knowledge of the free ionic activity of the metal, [M], the ligand-bound metal concentration, [ML], and the unbound-ligand concentration, L_f, over a range of values. In practice, all three quantities are not measured directly or independently. One quantity is measured as a function of the total metal added to the system and the two remaining quantities are determined indirectly from conservation of mass considerations. Several transformations of the original data are necessary to obtain the three quantities used in an equilibrium model.

For example, in ISE titrations the electrode potential is converted to the logarithm of the metal activity by multiplying by a calibration factor (A). The log of activity is exponentiated to obtain the arithmetic metal activity, which in turn is multiplied by a proportionality constant (K_0) to generate the concentration of inorganic metal complexes, M_i. This value is subtracted from the total concentration of metal in solution to determine, indirectly, the concentration of ligand-bound metal. The value of L_f must be obtained by subtracting [ML] from the total ligand concentration, L_T. In each of these transformations the uncertainty in the quantity obtained increases as errors propagate through the data set. We can quantify this propagation by simple statistical methods, summarized in Table 1.

Examination of the error propagation equations leads to the observation that the least error in each quantity results from methods that most directly measure that quantity. Note also that many of the error terms are based on relative errors and that the absolute error in a derived quantity may be dependent on the magnitude of the terms used in the derivation. Uncertainty in the indirectly measured quantities may increase dramatically through the course of a titration as concentrations of total metal and the directly measured species increase. This effect can be demonstrated graphically by drawing calculated error bars on plots of titration data.

The plots in Fig. 1 are the so-called formation functions which depict bound metal as a function of the negative log of the free metal activity (pM). The underlying formation function is identical for the three plots and represents a simulated metal

titration of a hypothetical three-ligand mixture calculated with the computer-based equilibrium program MINEQL (15). The three ligands yield titration curves essentially the same as those of humic acid but can be used to generate titration data to an arbitrarily high degree of accuracy (16).

The standard deviations in the quantities measured by ISE, FPA, and FQ were calculated from experimental data obtained in this laboratory (as discussed below) and were translated through the propagation equations for each method. Error intervals of one standard deviation from the computer-calculated mean values for both pM and [ML] (the 68% confidence intervals) were drawn about each point in the calculated formation functions.

As noted earlier, the error intervals for each metal species are smallest for the methods that most directly measure that species: free metal for Classes I and II, bound metal for Class III. The wide error bars on the low pM values for the Class II (FPA-type) measurements (Fig. 1*b*) reflect the detection limit of this method for a solution in which the labile metal approximately equals the free-metal activity; a similar error region would also be observed in the Class I measurements if the titration were conducted below the detection limit of the electrode.

Above the detection limits, indirectly measured species exhibit the greatest error and the magnitude of this error varies widely across the titration range. For example, bound-metal errors increase greatly near the end of the titrations that measure unbound metal. This reflects the propagation of relative errors as well as the fact that errors become most severe when we attempt to calculate a species concentration by subtracting two relatively large numbers.

A mathematical model of humic binding is of greatest predictive value if it is fitted to the most precise data in any concentration range. For each class of methods there is a titration region of minimal error in determinations of both free and bound metal. Figure 1 indicates that the best approach to modeling entails fitting Class I titration data in the high to moderate pM range and Class III titration data in the moderate to low pM range. Class II titrations might also be desirable, because of the high sensitivity of FPA, or for calibrating a model to data from a high-chloride medium.

Before combining the results of different techniques, the methods should be intercalibrated so there is reasonable congruence among the data. Intercalibration can be achieved in the central region of the titrations where all three titration classes yield data of nearly equal precision. From this central region, the data set can be extended for both free- and bound-metal species in either concentration direction with data from the appropriate methods. If only a single method is used, careful consideration should be given to the poor precision of data in certain regions of the titration and the resulting errors in the modeling parameters derived for that region.

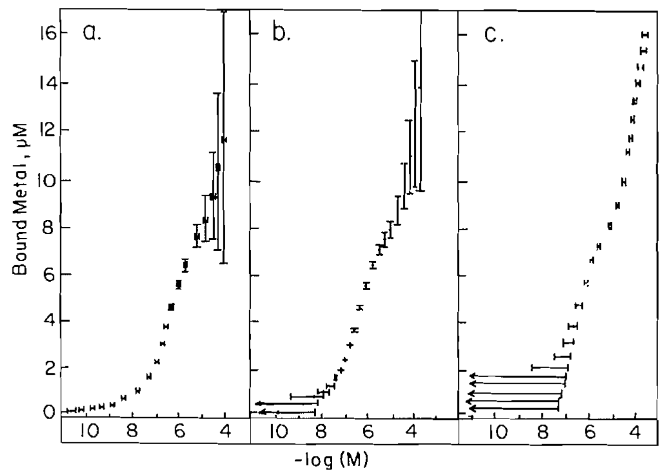

FIG. 1. A comparison of error propagation in hypothetical titration data: bound metal vs. −log free metal activity (formation functions). Error bars represent ± one standard deviation for: a. ion-selective electrode type data; b. fixed potential amperometry type data; c. fluorescence quenching type data.

Experimental

Fulvic acid was obtained from 20 L of Grassy Pond water (Bedford, MA) by adsorption onto XAD-8 resin according to the method of Thurman and Malcolm (17). The freeze-dried extract was 49% carbon by weight and this factor was used to prepare an aqueous stock solution of 50 mg-C/L of Grassy Pond fulvic acid (GP-FA). The stock solution was stored in a foil-covered flask (to exclude light) at 5°C and at pH 8. After preparation, stock solutions were allowed 48 h to dissolve and hydrolyze completely before any dilutions for titrations were made.

Solutions of fulvic acid for ion-selective electrode and fluorescence quenching titrations at 0.5, 1.0, and 5.0 mg-C/L were prepared with deionized water. Ionic strengths were adjusted using 1 *M* $NaClO_4$ to give an electrolyte concentration of 10^{-3} *M*. For fixed potential amperometry a background electrolyte of 0.5 *M* NaCl and 2 m*M* $NaHCO_3$ was used. The electrolyte was prepared from a 5 *M* NaCl, 20 m*M* $NaHCO_3$ stock solution that was passed through a Chelex resin column to remove contaminating trace metals according to the methods of Morel *et al.* (18).

Ion-selective electrode titrations were performed using a Radiometer F3000 Selectrode with a Cu(II) sensing membrane coupled with an Orion 90-02 double-junction reference electrode. The pH was monitored using a Fisher E5-A combination pH electrode and the pH was maintained by adjusting the alkalinity and bubbling with 1% CO_2/99% N_2 gas mixture. Electrode potentials were measured by a pair of Orion 801 Ionanalyzer meters. The ISE was calibrated with a series of copper solutions the day before each titration and was allowed to equilibrate overnight in a 1 m*M* Na_2EDTA/0.1 *M* TRIS buffer solution at pH 6.2. This procedure maximized electrode sensitivity in the low copper range. The fulvic acid solutions were titrated in 100-mL, water-jacketed beakers at 15°C with total copper concentrations ranging from 0.1 μ*M* to 100 μ*M*.

Fluorescence quenching titrations were performed using a Perkin–Elmer LS-5 Fluorescence spectrophotometer equipped with a 1-cm flow cell coupled by Teflon tubing and a peristaltic pump to a 50-mL, water-jacketed titration vessel maintained at 15°C. The pH was maintained with a CO_2/N_2 mixture as in the ISE titrations. Fulvic acid solutions were deoxygenated by several hours of bubbling with the CO_2/N_2 gas mixture in order to eliminate the minor quenching of the fulvic acid fluorescence by O_2. For GP-FA titrations the excitation and emission wavelengths were set for maximum fluorescence at 325 nm and 405 nm respectively. Slit widths were set at 10 nm. Kinetic studies indicated that quenching equilibrium was reached within 10 min at copper concentrations less than 1 μ*M* and in less than 5 min above 1 μ*M* copper. In subsequent titrations equilibration times were allowed, accordingly, before measurements were taken. Fulvic acid solutions were titrated over the same total copper range as in the ISE experiments: 0.1 μ*M* to 100 μ*M*.

Fixed potential amperometry was employed according to the methods of Waite and Morel (3). Measurements were made with an Environmental Science Associates (ESA) Model 3040 charge transfer analyzer equipped with a tubular pyrolytic graphite working electrode, a platinum wire counter electrode, and an Ag/AgCl, saturated NaCl reference electrode. The electrode potential was set at 90 mV and measurements were taken after a 10-min equilibration period following each copper addition. Titrations were performed with total copper ranging from 10 to 330 n*M*.

Results and discussion

Error analyses

The millivolt output of the ISE system was recorded to within 0.1 mV and analysis of five pairs of replicate titrations indicates that the standard deviation in electrode potential is ±0.5 mV. A slightly higher deviation is obtained at low Cu_T and pCu levels but, as an approximation, the standard deviation in potential was considered to be constant at ±0.5 mV.

The calibration factors for the electrode were determined by measurements of standard Cu(II) solutions. The deviation from Nernstian response allowed in the calibration slope was ±0.5 mV per decade pCu and the standard deviation was statistically derived from this spread to be ±0.4 mV per decade pCu.

The hydroxo and carbonato complexes of copper were calculated with stability constants selected from the literature. Stability constants and standard deviations for the carbonato complexes are given by Smith and Martell (19) as $\log \beta_1 = 6.75 \pm 0.02$ and $\log \beta_2 = 9.92 \pm 0.09$. There is greater variability in the constants for the hydroxo complex. For example, Smith and Martell (19) offer $\log \beta_1 = 6.3$ while Sunda and Hanson (20) reported $\log \beta_1 = 6.48$. The reported stability constants for the dihydroxo complex are particularly variable but, in two careful studies, values of $\log \beta_2 = 11.78$ (20) and 11.80 (21) were obtained. The mean of these is used in the present study. Standard deviations are not available for the hydroxo constants but it is reasonable to assume that both log β values are known to within ±0.10 log units. Because the concentrations of the hydroxide and the carbonate ions were held constant during the titrations, an aggregate proportionality factor, K_0, relating total inorganic and free ionic copper was calculated from the stability constants. The pH and $p(CO_3^{2-})$ were maintained within ±0.05 log units and incorporating all of these error terms in the calculation yielded $K_0 = 1.12 \pm 0.02$ for pH 6.0 and 170 ± 19 for pH 8.5.

The relative error associated with the calculation of inorganic copper becomes very significant when the inorganic copper concentration equals or exceeds the copper-fulvate concentration. This condition is dependent on both the metal/ligand ratio and the pH and is attained when either quantity is relatively high. Determinations of weak metal binding behavior by ion-selective electrode are therefore most accurate at low pH. Because apparent binding strength also decreases with pH, an appropriate compromise is to perform titrations near pH 6 where inorganic copper-complex concentrations and proton competition for the ligands are both acceptably small.

The standard deviation in the fluorescence measurements of a fulvic acid solution was uniform throughout the titration and equal to approximately 0.1% of the unquenched fluorescence. The relative fluorescence data are converted to bound-metal concentration by a calibration factor, *B*, linearly relating the percent-quenching (%*Q*) of fluorescence to the concentration of metal–fulvate complex. The simplest and most direct method for obtaining *B* is to plot percent quenching against the concentration of total metal added. If sufficiently small additions of Cu(II) (relative to the concentration of fulvic acid) are made, there is a region at the beginning of the titration in which there is a linear relationship between the metal added and the percent quenching. This region corresponds to the strong metal-binding portion of the titration in which essentially all of the metal added quantitatively binds to the fulvic acid. The slope of a least-squares fit of this region provides a quenching calibration factor for a given concentration of fulvic acid. This factor is assumed to be constant throughout the titration. The appropriateness of this assumption is discussed below.

The variation in the relative fluorescence translates into a standard deviation for the bound metal of ±0.1 × (calibration factor). For a typical titration of 5 mg-C/L GP-FA in which the calibration factor was 0.25 μ*M* bound Cu(II) per unit percent of quenching, the standard deviation on the bound copper measurements was ±0.025 μ*M*. The absolute error in bound metal is constant throughout so the relative error decreases as the titration advances. As a result, the relative error in the determination of free metal also decreases throughout the titration.

The labile copper measured by fixed potential amperometry includes all Cu(II) species that are reducible at the electrode potential, set in this system at +90 mV. At this potential only the hydrated cupric ion or the inorganic complexes are reduced and the current transferred over a fixed time interval, *U*, is proportional to the total inorganic copper in solution [Cu_i]. The proportionality factor, *C*, is obtained from a set of standard solutions. After systematic errors were corrected (3) we found the standard deviation in the current to be described by the equation:

$$[1] \quad S = \pm[S_x + S_{cr}(U)]$$

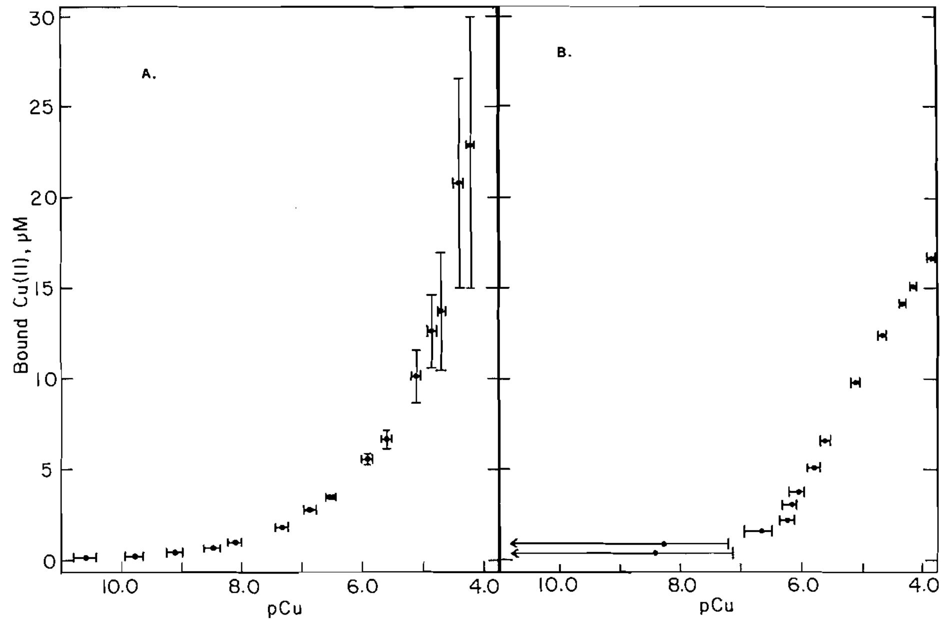

FIG. 2. Formation functions and standard deviations for Grassy Pond fulvic acid at 5.0 mg-C/L and pH 6.0. A. ISE titration; B. FQ titration.

in which S_x is a constant "background" error and $S_{cr}(U)$ represents the error that is proportional to the inorganic Cu(II) measured. For the experiments described here we found S_x = 0.4 nM and S_{cr} = 0.01; the latter value is the relative standard deviation in the proportionality factor. The minimum labile Cu(II) concentration accurately measurable was about 5 nM and the maximum copper concentration was about 350 nM.

The Davies equation was used to calculate the single-ion activity coefficients necessary for comparing the results of the FPA titrations to those of ISE titrations performed at lower ionic strength. Although there is significant uncertainty associated with these coefficients, the standard error could not be quantified and so is not incorporated in the error calculations.

Because total inorganic copper is directly measured by FPA, bound copper concentrations are more directly obtained with this method than by ISE. The inorganic copper concentration was converted to the cupric ion activity by the factor K_0 as defined earlier. For the solution conditions of the titration the minimum cupric ion activity measurable was about 0.01 nM or pCu = 11.0.

A summary of the standard deviations for the data from the three methods is presented in Table 1.

Comparison of titration results

Data from the ISE and FQ titrations of 1.0 and 5.0 mg-C/L solutions of Grassy Pond fulvic acid at pH 6.0 were converted by the arithmetic transformations described into both the directly and indirectly measured species concentrations. Plots of formation functions (bound metal vs. pCu) were prepared using the results of both techniques and are presented in Fig. 2 for comparison. The standard deviation for each data point was calculated with the error propagation equations, and error bars representing one standard deviation were placed around the symbols. The plots reveal systematic differences between the two methods as well as pronounced differences in the propagation of random error.

The formation functions demonstrate the limited sensitivity of fluorescence quenching for determining free-metal activity. Metal activity below 0.1 μM is measurable only by the ISE. The sensitivity of the ISE to low pCu allows the accurate calculation of stability constants or other model parameters for the strong binding region of the titration. Reliance on fluorescence quenching alone would preclude any quantification of this important property of humic materials.

The smallest amount of bound metal detectable in a fluorescence quenching titration is proportional to the smallest change in relative fluorescence distinguishable from noise. For the system described here that quantity is about 0.1 μM of bound copper and is independent of the total fulvic acid in solution. This amount is coincidentally the same as the smallest amount of strongly bound copper measurable with an ISE (equal to the minimum Cu_T).

Throughout the titration the ion-selective electrode provides relatively accurate measurements of pCu. Error propagation analysis reveals, however, that the accuracy of the ISE in measuring free metal does not translate into accurate bound-metal measurements over the entire titration range. The bound copper measured directly by fluorescence quenching exhibits higher accuracy than the indirect ISE data when [ML] > 2 μM. Accuracy in the high-metal region of the titration is critical for estimating the total ligand concentration, L_T.

In order to compare directly the species concentrations measured by these two methods, plots of the formation functions for both the ISE and the FQ titrations were overlaid (without error bars, for clarity) in Fig. 3.

In the low total-metal regions of the titrations, both ISE and FQ yield nearly identical bound metal values. The free-metal values in this region differ because of the poor precision with which fluorescence quenching measures unbound metal at low M_T. In the mid-range the formation functions overlap but, in the titration region corresponding to weak metal-binding, fluorescence quenching measures smaller bound-metal concentrations than does the ISE, a phenomenon observed in several other studies (1, 14). One explanation is that the weak binding sites have a different fluorescence efficiency than the stronger sites. Ryan and Weber (14) suggested that some of the weak binding occurs on molecules that have already been quenched by strongly bound Cu(II). Another explanation is simply that a greater proportion of the weaker binding is due to either sites not associated with fluorophores or a strictly electrostatic effect

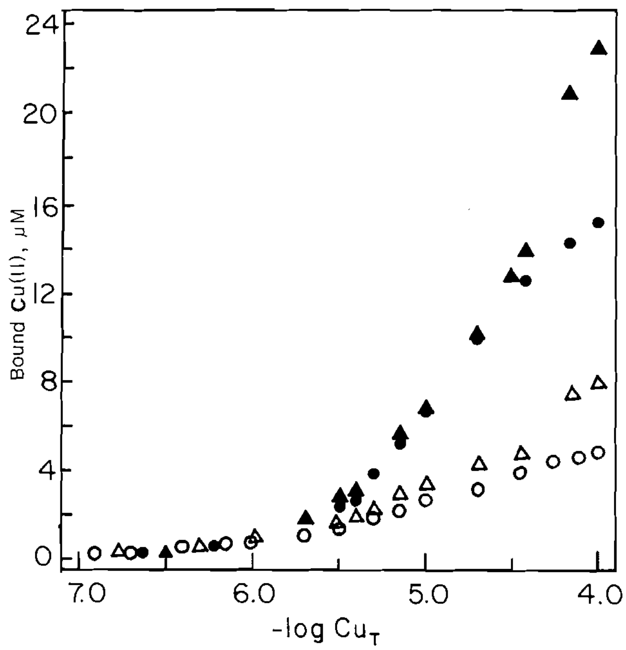

FIG. 3. Formation functions for Grassy Pond fulvic acid at pH 6.0. 5.0 mg-C/L: ISE (▲), FQ (●). 1.0 mg-C/L: ISE (△), FQ (○).

that does not involve the alteration of fluorescing electrons. No definitive explanation is currently possible and the discrepancy only adds greater uncertainty to the poorly defined end region of fulvic acid titrations.

The fulvic acid concentrations in these titrations are representative of many surface, freshwater systems but are perhaps an order of magnitude higher than in some deep groundwater or marine systems. The relatively high total copper concentrations required by the ISE seriously limit the usefulness of the method for characterizing humic matter at concentrations below 1 mg-C/L.

A fixed-potential amperometry titration of a 0.5 mg-C/L solution of Grassy Pond fulvic acid at pH 8.5 in 0.5 *M* NaCl demonstrates that FPA can quantify binding behavior for Cu(II)-fulvate present in concentrations below the sensitivity of other methods. The pH and background electrolyte furnish information about fulvic acid behavior under marine solution conditions.

The results of the FPA and ISE titrations were converted, as in the previous section, into both the directly and indirectly measured quantities and the data from both methods presented in comparative plots (Fig. 4). All activities were corrected to the lower ionic strength (I = 0.001) by coefficients calculated with the Davies equation. The formation functions demonstrate the relative merits of the two methods in the low-copper range. The ion-selective electrode is limited to measurements for which the total copper concentration is greater than about 0.1 μ*M* although the cupric-ion activity can be measured at less than 10^{-10} *M*. Total Cu(II) concentrations can be two orders of magnitude lower for the FPA titration than with the ISE, but FPA has the same sensitivity for both total and labile Cu(II). Therefore, the minimum cupric-ion activity measurable by FPA in the presence of strong binding agents is higher than for the ISE.

A comparison of the plots indicates good agreement in the cupric ion activities determined by both methods for pCu $\leq$ 9.2. At lower copper concentrations the activities measured by the ISE fall below the FPA data (Fig. 5). At these low total-

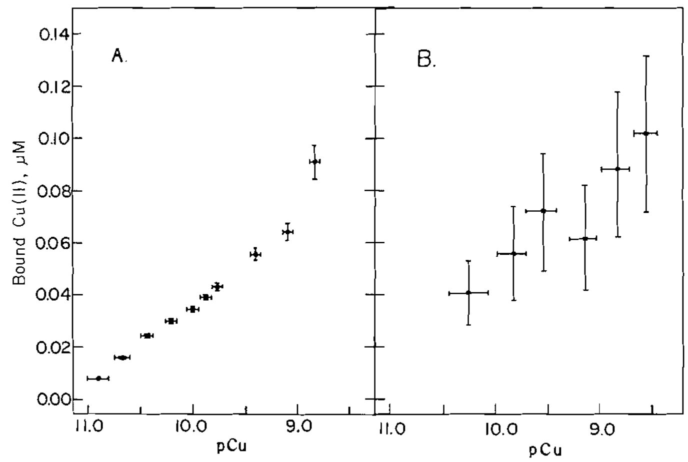

FIG. 4. Formation functions and standard deviations for Grassy Pond fulvic acid at 0.5 mg-C/L and pH 8.5. A. FPA titration; B. ISE titration.

copper concentrations the ISE is functioning below its optimal range and the equilibration time for the electrode is very slow, on the order of 2–10 h, depending on pH and pCu (low pCu and high pH have the slowest equilibration). Because the electrode potential drifts so slowly upward during this extended period it is likely the apparent equilibrium reached and recorded for these data points was short of true equilibration. Another likely problem was the loss of copper through surface adsorption at high pH, given the extended equilibration period. We estimated this quantity from atomic absorption spectrophotometry measurements of Cu_T in solution to be about 10% of total copper for Cu_T less than 1.0 μ*M*.

In the same Cu(II) concentration range, fixed-potential amperometry operates under optimal solution conditions and we expect the FPA data to be more accurate than those of the ISE operating outside its appropriate range. Measurements at the low metal/ligand ratios confirm the binding behavior observed in more concentrated fulvic acid solutions with other methods and are of great use in evaluating the metal complexing properties of marine waters.

Note also that the bound-metal data obtained by the ISE are particularly imprecise at the higher pH of this titration, compared to titrations at pH 6. The uncertainty in the inorganic complexation factor, K_0, is the primary cause. Recall that this constant is not needed in obtaining bound-copper values from FPA data because the total inorganic Cu(II) is measured directly by FPA.

The major limitations on FPA are the maximum permissible strong ligand concentration (about 0.1 μM), the maximum Cu(II) concentration (about 350 μM in the present system), and the need for relatively high chloride concentrations. These restrictions do not hinder the special usefulness of FPA for marine studies but indicate that the method cannot fully characterize humic material over a wide range of species concentrations, especially in the weak metal-binding region. While these problems are specific to FPA, all methods in Class II (linear, labile-metal) are hindered by the difficulty of collecting metal binding data over many orders of magnitude with a linearly responding method. As a class, these methods appear to be most useful for measuring a limited titration range under solution conditions that preclude the use of methods such as ISE and FQ.

The results of the fixed-potential amperometry titrations were not compared directly to the fluorescence quenching results because there is only a small region of overlap in the concentration ranges of the two methods. The overlap is in the region of least precision for free-metal measurements by fluorescence quenching. Hence, FPA and FQ, while complementary in the concentration ranges measured, cannot be directly intercalibrated.

Total ligand measurements

Determination of the total ligand concentration in solution is essential for defining conditional stability constants or parameters for other models of humic–metal interactions. If the bound-metal concentration in a plot of the complex-formation function levels off, the maximum concentration of bound metal is taken to equal L_T. Unfortunately, such unambiguous endpoints are rarely seen in Cu(II) titrations of humic materials. The large proportion of weak binding sites may not be fully saturated at the maximum metal activity in the titration. Formation of copper hydroxide solid at cupric ion activities greater than 10^{-4} M poses an upper limit for Cu(II) titrations, as does the flocculation of humic colloids (1).

The absence of a clear endpoint is exacerbated in ISE titrations by the scattered bound-metal data in the end region. Low ligand concentrations favor the likelihood of reaching the endpoint before pCu 4 and a low pH (less than 5) would permit continuing the titration to higher cupric-ion activities. However, L_T determinations are not improved by these conditions because the bound-metal concentration at the end of the titration in either case is smaller, while the error in the data remains about the same.

For Grassy Pond fulvic acid the best estimate of L_T, based on the ISE titration of 1.0 mg-C/L, is 6.0 ± 1.5 mequiv./mg-C (the standard deviation represents the variance in the bound-metal determination). For the fluorescence quenching titration of the same solution, L_T = 4.7 mequiv./mg-C. Although the uncertainty in the bound-metal measurements on which the latter figure is based is ±0.025 μM, the error in L_T is presumably greater than that because of uncertainty as to the degree of saturation of binding sites, coagulation effects, and uncertainty in the assumption that the FQ calibration factor is constant. Because the definition of endpoint remains rather arbitrary for all methods, the uncertainty cannot be quantified by replicate titrations. The error in L_T may be the single largest error in the calculation of metal–humic interactions. Many models of metal–humic interactions normalize bound-metal concentrations to L_T (i.e., $\bar{\nu} = [ML]/L_T$). Normalizing data to such a poorly defined quantity decreases the precision with which model parameters can be fitted.[1] Eliminating the L_T term from empirical binding models would obviate this analytically intractable problem.

In general, L_T is a difficult parameter to measure by any method, or, in fact, to properly define. The poor resolution of L_T has been little recognized in studies of metal–humic interactions and an examination of the literature indicates that most L_T values or "complexation capacities" are actually operationally defined endpoints that do not reflect the true concentrations of humic binding sites. The errors in titration end-regions also suggest that "total ligand concentration" or "binding capacity" should not be used as a descriptive parameter for comparing humic materials. The concentration of humic material, the method used, and the solution pH all have a dramatic effect on the maximum amount of metal binding observed.

Comparison of individual and combined data sets

Conditional stability constants for Cu(II)–fulvate complexes were derived from the results of the three exemplary methods by applying FITEQL, a computer-based, discrete-ligand optimization routine (22). The concentrations and stability constants obtained are, of course, only fitting parameters but they are useful for both reproducing the titration data and for comparing different data sets.

In order to compare the effects of error propagation, the standard deviations calculated for the titration data from each method were used to estimate confidence intervals for the derived stability constants and ligand concentrations. The solution scheme in FITEQL has provisions only for fixed relative standard deviations in the titration data. Since relative errors are not constant over the entire titration, the fitting optimizations were repeated for each ligand with the appropriate relative standard deviations substituted. The values used each time were the mean relative standard deviations for the titration region in which that ligand is predominant. The optimally fitted stability constants and equivalent ligand concentrations for all methods are presented in Table 2.

The results of applying a single analytical method to complicated mixtures such as fulvic acids are reflected in the diversity of standard deviations in the stability constants obtained. The regions of high error for each method translate predictably into poor accuracy for the conditional stability constants that predominate in those regions. This can be demonstrated by plotting the standard deviations associated with the ratios of bound metal to free metal for each titration (Fig. 6).

Prediction of bound-metal and free-metal concentrations is the goal of metal–humic speciation models and the error in the ratio of the two quantities is a convenient way of summarizing the errors expected in model calculations based on these data. The ratio is also proportional to the apparent stability constant that would be calculated at any point in the titration. In addition, the plot is a useful summary of the concentration ranges over which each method is operational.

The region in which the bound-metal/free-metal ratio is high

(the left-hand side of the plot) corresponds to the low Cu_T, strong-binding region of the titration. The ISE data here have much lower relative standard deviations than do the FQ data. Conversely, in the region of low bound-metal/free-metal ratios at the right-hand side (weak metal-binding), the FQ data are more precise. The entire range of the FPA titration lies in the high-ratio region and the method yields lower relative standard deviations in the strong-binding region than does the ISE.

The results in Fig. 6 also indicate that each method is more accurate at higher fulvic acid concentrations. Examination of the error propagation equations shows that higher ligand concentrations result in smaller relative errors in the bound-metal data, hence less error in stability constants.

Only a combination of several methods yields the most precise set of ligand parameters. Within any broad region of a titration only two of the three methods operate within their concentration limits and the more precise data of the two sets available can be used to create a combined-methods data set.

Conclusions

Any comprehensive study of the interactions of a humic material with one or more metals is subject to unnecessary imprecision if only a single analytical method is employed or if inappropriate methods are selected. Precision at high bound-metal/free-metal ratios is important for quantifying the strongest metal binding behavior of a humic substance while accuracy at low bound-metal/free-metal ratios is critical for assessing the total number of sites available for binding. We have demonstrated that analytical methods can be grouped according to the quantity that they most directly measure and that the precision of metal binding data over a wide range of solution conditions can be enhanced if methods from at least two different classes are used. Examining the error propagation associated with the formation-function plots for each class is helpful in choosing complementary methods that yield the most precise data throughout a wide titration range. If only a single method can be utilized, the variance calculations and error propagation equations listed in Table 1 can be used to estimate confidence intervals for species concentrations or model parameters.

An overall improvement in the precision of titration data leads to better predictive calculations of trace-metal speciation in natural waters. Quantification of the variance in the parameters used to describe metal−humic interactions allows for more useful and realistic comparisons among the results of different studies. Error analysis can also indicate which

ARNOLD JARCZEWSKI, MALGORZATA WALIGORSKA, and KENNETH T. LEFFEK. Can. J. Chem. **63**, 1194 (1985).

Rate constants for the β-elimination of HCl from 2,2-di(4-nitrophenyl)-1,1-dichloroethane (I) and 2,2-di(4-nitrophenyl)-1,1,1-trichloroethane (II) promoted by tetramethylguanidine in the aprotic solvents acetonitrile, tetrahydrofuran, and n-hexane have been measured. The activation parameters are characterized by small enthalpies of activation (4.1 to 7.3 kcal mol^{-1}) and large negative entropies of activation (-35 to -50 cal mol^{-1} deg^{-1}). The primary deuterium isotope effects at 20°C range from k_H/k_D = 4.8 to 10.3. The results are interpreted to indicate an $(EcB)_I$ mechanism for both substrates I and II in acetonitrile solvent and an E2H or mixed $(ElcB)_I$–E2H mechanism in the less polar solvents, tetrahydrofuran and n-hexane.

ARNOLD JARCZEWSKI, MALGORZATA WALIGORSKA et KENNETH T. LEFFEK. Can. J. Chem. **63**, 1194 (1985).

On a mesuré les constantes de vitesse des éliminations β de HCl du di(nitro-4 phényl)-2,2 dichloro-1,1 éthane (I) et du di(nitro-4 phényl)-2,2 trichloroéthane (II) sous l'influence de la tétraméthylguanidine dans des solvants aprotiques comme l'acétonitrile, le tétrahydrofuranne et le n-hexane. Les paramètres d'activation sont caractérisés par des enthalpies d'activation faibles (4,1 à 7,3 kcal mol^{-1}) et par des entropies d'activation importantes et négatives (-35 à -50 cal mol^{-1} deg^{-1}). A 20°C, les effets isotopiques primaires du deutérium s'étalent de k_H/k_D = 4,8 à 10,3. Sur la base des résultats obtenus, on croit que, dans l'acétonitrile comme solvant, les deux substrats I et II réagissent par un mécanisme $(EcB)_I$ alors que dans des solvants moins polaires, comme le tétrahydrofuranne et le n-hexane, les produits réagiraient par un mécanisme E2H ou par un mécanisme mixte $(ElcB)_I$–E2H.

[Traduit par le journal]

Introduction

The kinetics and mechanism of the β-elimination reaction of HCl from diarylchloroethanes with different bases in a variety of solvents have been examined by McLennan and Wong (1–5) and by Cristol *et al.* (6, 7). Also, a study of proton transfer reactions to yield stable carbanions has been used to assess the importance of this step in determining the reaction parameters of β-eliminations (8) or the contribution of the E1cB mechanism to the overall mechanism of elimination (9). Primary deuterium isotope effects have been found to be useful in defining the character of the mechanism.

In this study, therefore, arylchloroethanes in which different numbers of chlorine atoms on the α-carbon atom modify the acidity of the hydrogen on the β-carbon atom, have been used to investigate the influence of this acidity on the rate and mechanism of the β-elimination reaction. The effect of electron-withdrawing substituents in the phenyl rings (10, 11) has been investigated, using *p*-nitrophenyl groups to compare with the *p*-chlorophenyl groups previously studied (1–5).

In this paper the changes are examined in the activation parameters, isotope effects, and mechanism of the β-elimination reaction of HCl from 2,2-di(4-nitrophenyl)-1,1-dichloroethane (I) and 2,2-di(4-nitrophenyl)-1,1,1-trichloroethane (II) promoted by the base 1,1′,3,3′-tetramethylguanidine (TMG) in several solvents of different polarity.

Results and discussion

The second-order rate constants for the elimination of HCl from the substrates I and II are shown in Tables 1 and 2, together with the primary deuterium isotope effects. These rate constants increase with increasing polarity of the solvent as expected, except that the elimination of DCl from the deuterated substrates is slightly faster in tetrahydrofuran than it is in acetonitrile. The second-order rate constants in acetonitrile for both I and II are about 1×10^3 greater than the corresponding rate constants for the elimination of HCl from DDT and DDD by the same TMG base (12). This indicates a Hammett ρ value for this reaction of more than 5 if the σ^0 scale is assumed to apply (13, 14) or about 3 if the σ^- scale is used. In either case this is a greater value than the largest ρ value (2.0) which has been found for proton transfer reactions (13, 14). Values of 4 and 5 were reported (15) for the base catalyzed cleavage of a series of *trans* and *cis* 1-phenyl-2-arylcyclopropanols but, although the transition state for this does involve a proton transfer, the authors concluded that it, in fact, contains relatively little proton transfer. Thus, this reaction is controlled mainly by the rate for carbon–carbon bond cleavage.

No doubt the replacement of the *p*-chloro substitutent by the *p*-nitro group increases the acidity of the hydrogen on the β-carbon atom of I and II, but the effect on the rate of elimination is greater than can be ascribed to the acidity change alone. Thus, a change of mechanism is indicated by this result.

The activation parameters for the reactions were calculated from the second-order rate constants by a linear least-squares method and are collated in Tables 3 and 4. The enthalpies of activation are quite low for both substrates and all solvents, although slightly larger values are obtained in the more polar solvent acetonitrile than in the non-polar hexane solvent. The low $\Delta H^{\ddagger}$ values, compared to other β-elimination reactions (4, 5, 7, 12, 16–18), suggest that the mechanism may be of the E1cB-type and that $\Delta H^{\ddagger}$ is largely controlled by the energy requirement to break the initial state solvation shell and allow the proton to transfer to the base.

The entropies of activation are all large and negative, with

the values increasing as the polarity of the solvent is decreased, a trend previously observed by Cockerill (19). These results are consistent with an increase in the strength of the solvation shell during the activation process and that increase is greatest where the initial state solvation is weakest, in hexane solvent. The entropies of activation are generally consistent with a transition state of increased charge separation relative to the initial state.

The values of the primary deuterium isotope effect, given in Tables 1 and 2, are quite high for a β-elimination reaction, varying between k_H/k_D = 10.3 to 4.8 at 20°C. These show clearly that the rate-determining step involves the proton transfer. However, the isotope effect varies with the polarity of the solvent in the reverse manner to that observed for proton transfer reactions (20), in that the magnitude of the effect decreases with decreasing polarity of the solvent. This variation may not, therefore, be explained in terms of an increase in the active mass of the proton in polar solvents, as was suggested for the proton transfer reactions (19), but must be due to a variation in the mechanism. In the more polar acetonitrile solvent the $(E1cB)_I$ mechanism would be expected to be favoured, so that the full isotope effect would be observed. In the less polar solvents the mechanism should change to an E2H-type transition state, where the proton transfer is jointly rate controlling with the breaking of the bond to the leaving group, giving rise to the observation of a smaller deuterium isotope effect.

The isotope effects on the enthalpies of activation are about 1 kcal mol^{-1}, which would be expected for the loss of the carbon–hydrogen stretching frequency in the activation process, except for the reactions carried out in acetonitrile. In that solvent, where the mechanism is probably $(E1cB)_I$ (Scheme 1), the isotope effect on the enthalpies of activation of dichloro and trichloro substrates at 1.6 ± 0.2 and 2.3 ± 0.3 kcal mol^{-1} indicates that some proton tunnelling is probably taking place. The largest such isotope which can be accounted for by loss of the C—H stretching vibration and both C—H bending vibrations is about 2.1 kcal mol^{-1}. The absence of this evidence for tunnelling in the less polar solvents, where it is normally expected (20), is consistent with the operation of an E2H mechanism (Scheme 2), or a mixed E1cB–E2H mechanism.

The similarity of the second-order rate constants for the dichloro and trichloro substrates indicates that the effect of the chlorine atom on the acidity of the hydrogen on the β-carbon is very small. Therefore, the same mechanistic conclusions apply to both substrates.

In fact, in hexane solvent the trichloro substrate shows a slightly smaller second-order rate constant than the dichloro compound, showing no relationship with the acidity of the hydrogen on the β-carbon atom, in contrast to the findings for the analogous reactions of DDT and DDD (9).

Experimental

Materials

2,2-Diphenyl-1,1,1-trichloroethane was prepared by the method of McLennan and Wong (5) from acetophenone by chlorination with Cl_2 gas followed by reduction with $LiAlH_4$. The product 2,2-diphenyl-1,1,1-trichloroethane was recrystallized from methanol, mp 64.5–65°C (lit. (5) mp 64.5–65.5°C).

The ethane was nitrated by the method of Haskelberg and Lavie (21). The nitrated product had a mp 169°C (lit. (1, 21) mp 169°C); nmr, aliphatic proton, δ = 5.30 ppm (lit. (1) δ = 5.35 ppm).

2,2-Di(4-nitrophenyl)-1,1-dichloroethane was prepared according to McLennan and Wong (5) and Aston *et al.* (22). 1-Chloroacetophenone (20 g) in glacial acetic acid (150 g) was chlorinated by bubbling in Cl_2 gas for 7 h at 60°C under a 250-W lamp. The reaction mixture was poured onto crushed ice and the organic layer separated. The aqueous layer was extracted with diethyl ether and the ether extracts were added to the organic layer. After removal of the ether, the product 1,1-dichloroacetopheone was distilled at reduced pressure.

The 2,2-di(4-nitrophenyl)-1,1-dichloroethane was prepared from this ketone by the same procedure as for the trichloro compound, mp 179.5°C (lit. (1) mp 177–178°C); nmr, aliphatic proton, δ = 4.85 ppm (lit. (1) δ = 4.83 ppm).

The deuterated analogues of the two substrates were obtained using $LiAlD_4$ for the reduction of the ketones. The extent of deuteration was estimated to be at least 99% from the nmr spectra.

Reagent grade acetonitrile was purified by the method of O'Donnell *et al.* (23), with a final fractional distillation from P_2O_5. The fraction

which distilled at 82.0°C was collected.

Reagent grade tetrahydrofuran was purified by Paul's procedure (24). After work-up with NaOH and Al_2O_3, the solvent was fractionally distilled over sodium, with collection of the fraction distilling at 66.0°C.

Reagent grade hexane was purified by the method of Tonberg and Johnston (25). The hexane was shaken for 8 h with a mixture of H_2SO_4 (58%), HNO_3 (25%), and H_2O (17%) by weight. The solvent was then washed with concentrated H_2SO_4, then H_2O, and dried over a molecular sieve (4A). A final fractional distillation from sodium yielded a product, bp 68.7°C.

Tetramethylguanidine was dried over NaOH and fractionally distilled. The fraction distilling at 161°C was collected.

Product analyses

2,2-Di(4-nitrophenyl)-1,1,1-trichloroethane (0.5 g) was reacted in NaOEt in ethanol by refluxing the reaction mixture for 1 h. The mixture was cooled, poured into water, and the olefin product extracted with diethyl ether. The olefin was obtained by evaporation of the solvent and was recrystallized several times from ethanol, mp 172.5°C (lit. (1) mp 172–173°C).

The same method was used to prepare the olefin, 2,2-di(4-nitrophenyl)-1-chloroethene, from the dichloro substrate. After the solid products were recovered from the ether extract, they were separated by thin layer chromatography using benzene. The olefin was extracted from the tlc plate with isopropanol, mp 145°C (lit. (1) mp 145–146°C).

Kinetic measurements

The reactions were followed by monitoring the appearance of the olefin products at 324 nm using Specord uv–vis and VSU-2P spectrophotometers fitted with a constant temperature bath to control the temperature of the cell block within 0.1°C. In all three solvents the reaction went to 100% conversion to the olefin. The concentration of

Guggenheim analysis yields, $k_{obs} = 5.89 \times 10^{-3}$ s^{-1}

the base was always in large excess over that of the substrate, ensuring pseudo-first-order kinetics. Freshly prepared stock solutions were used to prepare the reaction mixtures in stoppered uv cells. Pseudo-first-order rate constants were calculated from the trace of absorbance vs. time using the Guggenheim method; an example run is given in Table 5. The second-order rate constants were calculated by a linear least-squares fit of the variation of k_{obs} with base.

The activation parameters were calculated using the transition state theory equation, again using a linear least-squares fit. The errors quoted in Tables 3 and 4 are the standard deviations.

Kinetics and mechanism of the oxidation of benzenediols and ascorbic acid by *bis*(1,4,7-triazacyclononane)nickel(III) in aqueous perchlorate media

A. McAuley, Lee Spencer, and P. R. West
Department of Chemistry, University of Victoria, Victoria, B.C., Canada V8W 2Y2

Received September 4, 1984

A. McAuley, Lee Spencer, and P. R. West. Can. J. Chem. **63**, 1198 (1985).

The reactions of the outer-sphere electron transfer reagent, $Ni(9\text{-aneN}_3)_2^{3+}$, (*bis*(1,4,7-triazacyclononane)nickel(III) ion) with ascorbic acid, hydroquinone, catechol, and resorcinol have been investigated. The absence of any proton related equilibria with the oxidant provides a means of ascribing the observed inverse hydrogen ion dependences to reactions of the dissociated ascorbate or quinolate ions, (HA^-). The data are consistent with the rate-determining one-electron transfer reactions:

$$Ni(9\text{-aneN}_3)_2^{3+} + H_2A \xrightarrow{k_1} Ni(9\text{-ane N}_3)_2^{2+} + H_2A^+$$

$$Ni(9\text{-aneN}_3)_2^{3+} + HA^- \xrightarrow{k_2} Ni(9\text{-ane N}_3)_2^{2+} + HA$$

followed by rapid oxidation of the radical ions formed. In the reaction with ascorbic acid, $k_1 \sim 0$ and k_2 (T = 25°C) = 5.2 × 10^6 M^{-1} s^{-1} ($\Delta H^{\ddagger}$ = 10.1 ± 2.5 kcal mol^{-1}, $\Delta S^{\ddagger}$ = 5.7 ± 5.1 cal mol^{-1} K^{-1}). For hydroquinone, catechol, and resorcinol, k_1 = 2.9 × 10^3, 2.8 × 10^2, and ~0 M^{-1} s^{-1} and k_2 = 6.9 × 10^9, 4.1 × 10^9, and 2.8 × 10^8 M^{-1} s^{-1}, respectively. These data have been combined with those from other similar reactions leading, by use of a Marcus correlation, to self-exchange rate constants for the $HAsc^-/HAsc^{\cdot}$ couple of 3.5 × 10^5 M^{-1} s^{-1} and for the $H_2Quin^{0/+}$ and $H_2cat^{0/+}$ systems of 5 × 10^7 and 2 × 10^7 M^{-1} s^{-1}, respectively. The importance of the effect of bond-reorganisation on electron transfer is discussed.

A. McAuley, Lee Spencer et P. R. West. Can. J. Chem. **63**, 1198 (1985).

On a étudié les réactions du réactif de transfert d'électron externe $Ni(Nonane\text{-}N_3)_2^{3+}$, (ion *bis*(triaza-1,4,7 cyclononane) nickel(III)) avec l'acide ascorbique, l'hydroquinone, le catéchol et le résorcinol. L'absence de tout proton relié à l'équilibre avec l'oxydant permet d'attribuer l'effet inverse observé pour l'ion hydrogène aux réactions des ions ascorbate et quinoléate dissociés (HA^-). Les données sont en accord avec des réactions impliquant un transfert à un électron comme étape déterminante

$$Ni(Nonane\text{-}N_3)_2^{3+} + H_2A \xrightarrow{k_1} Ni(Nonane\text{-}N_3)_2^{2+} + H_2A^+$$

$$Ni(Nonane\text{-}N_3)^{3+} + HA^- \xrightarrow{k_2} Ni(Nonane\text{-}N_3)_2^{2+} + HA$$

qui seraient suivies d'oxydations rapides des ions radicalaires formés. Pour la réaction avec l'acide ascorbique $k_1 \sim 0$ et k_2 (T = 25°C) = 5,2 × 10^6 M^{-1} s^{-1} ($\Delta H^{\ddagger}$ = 10,1 ± 2,5 kcal mol^{-1}, $\Delta S^{\ddagger}$ = 5,7 ± 5,1 cal mol^{-1} K^{-1}). Dans le cas de l'hydroquinone, du catéchol et du résorcinol, on a respectivement k_1 = 2,9 × 10^3, 2,8 × 10^2 et ~0 M^{-1} s^{-1} et k_2 = 6,9 × 10^9, 4,1 × 10^9 et 2,8 × 10^8 M^{-1} s^{-1}. On a combiné ces données à d'autres pour des réactions semblables afin d'obtenir, par l'emploi d'une corrélation de Marcus, une constante de vitesse d'autoéchange pour le couple $HAsc^-/HAsc^{\cdot}$ de 3,5 × 10^5 M^{-1} s^{-1} et pour les sytèmes $H_2Quin^{0/+}$ et $H_2cat^{0/+}$ de 5 × 10^7 et 2 × 10^7 M^{-1} s^{-1} respectivement. On discute de l'importance de la réorganisation de la liaison sur le transfert d'électron.

[Traduit par le journal]

Introduction

Although ascorbic acid (1–4) and other diols (5, 6) have been identified as reductants in biological processes, the recent interest (7–10) in electron transfer processes involving such species reflects the need for a precise understanding of the accompanying redox mechanisms. A feature of many of these reactions is the rate dependence on hydrogen ion concentration, normally associated with the varying degrees of protonation of the reductants. (In the case of ascorbic acid, for example, all three species H_2Asc, $HAsc^-$, and Asc^{2-} have been invoked as reactants in the oxidation by thioureapentacyanoferrate(III) ion (11)). Although early assessments (2) of the redox potentials for the H_2Asc^+/H_2Asc and $HAsc^{\cdot}/HAsc^-$ couples (~1.35 and 0.93 V, respectively) were based on large self exchange rates, more recent estimates (8, 12) are consistent with a value of 0.70–0.72 V for the ascorbate/ascorbate radical couple.

Investigations into the chemistry of nickel(III) species have led to the identification of species of considerable kinetic stability in aqueous media. In our laboratories, we have characterised recently (13) the *bis*(1,4,7-triazacyclononane)nickel(III) cation, ($Ni(9\text{-aneN}_3)_2^{3+}$) which, unlike other solvated tetraazanickel(III) macrocycles (14), shows only ~1% decomposition at pH ~ 3 over a 24 h period. Studies with several reducing systems have exhibited a lack of any pH dependence on electron transfer of this Ni(III)/(II) species and the reduction potential (0.945 V) renders it an appropriate outer-sphere reagent for examination of the kinetic parameters involved in redox reactions of organic substrates.

In this paper we wish to present data on the kinetics of oxidation of ascorbic acid and other benzene diols. From a knowledge of the self-exchange rate for the metal-ion couple, it is possible to derive information on the one-electron self-exchange processes for these organic reductants.

Experimental section

Materials

Bistriazacyclononanenickel(II) perchlorate (15), $[Ni(9\text{-aneN}_3)_2](ClO_4)_2$, was prepared using a modified preparation of the ligand as described (13). The corresponding nickel(III) salt was formed on addition of a slight stoichiometric excess of aquocobalt(III) (16) in ~1 M $HClO_4$. The resulting brown–green complex formed was recrystallised from ~10^{-3} M $HClO_4$. The solid was kept for months

TABLE 1. Rate data for the reaction of $[Ni(9\text{-}aneN_3)_2]^{3+}$ with ascorbic acid; $I = 1.00$ M (Li/H ClO_4), $\lambda = 350$ nm, $[H_2A] = (0.2-1.01) \times 10^{-3}$ M

$\Delta S^{\ddagger} = 5.7 \pm 5.1$ cal mol^{-1} K^{-1}

in a dessicator without any apparent decomposition. Hydroquinone (Aldrich), catechol (Fisher), resorcinol (MCB) were purified either by vacuum distillation or recrystallised from ethanol, dried with ether, and stored at 0°C. Ascorbic acid (Sigma) was used without further purification. Lithium perchlorate was prepared by neutralisation of Li_2CO_3 with ~3 M $HClO_4$ and recrystallised three times from distilled water.

Kinetic studies

Solutions of the benzene diols and of ascorbic acid were freshly prepared using nitrogen-saturated water and maintained under an inert atmosphere. For the oxidant, the required amount of solid $[Ni(9\text{-}aneN_3)_2](ClO_4)_3$ was added to a N_2-saturated, thermostatted solution prior to use. Kinetic experiments were carried out using a stopped-flow apparatus described previously (17). The reduction of $[Ni(III)]^{3+}$ (ca. $1-3 \times 10^{-5}$ M) was followed at 340–350 nm under pseudo first order conditions of excess reductant $(0.2-1.4) \times 10^{-3}$ M. At all pH's studied, plots of ln ΔOD against time were linear for at least three half-lives. Ionic strength and hydrogen ion concentration were maintained using $H^+/Li^+-ClO_4^-$ mixtures. At higher pH's (>3) acetate buffers (10^{-2} M) were used, with no observed kinetic dependence on the buffer concentration.

Results

(I) Reaction of $[Ni(9\text{-}aneN_3)_2]^{3+}$ with ascorbic acid (H_2Asc)

The green-coloured nickel(III) complex ($\lambda_{max} = 312$ nm, $\epsilon = 1.01 \times 10^4$ M^{-1} cm^{-1}) is reduced rapidly by ascorbic acid to yield the corresponding nickel(II) ion (λ_{max} 322 nm, $\epsilon = 11$ M^{-1} cm^{-1}). A spectrophotometric titration ($\lambda = 350$ nm) revealed an oxidant:reductant ratio of 2.02(±0.05):1 consistent with the overall reaction:

[1] $2Ni(III) + H_2Asc \rightarrow 2Ni(II) + Asc + 2H^+$

The reaction rate was observed to exhibit a first-order dependence on ascorbic acid concentration under all conditions used in conformity with the rate equation

[2] $-d[Ni(III)]/dt = 2k_0[Ni(III)][H_2Asc]$

Kinetic measurements were made at several reductant concentrations at each $[H^+]$ used. A summary of the data is presented in Table 1. The full details are available as supplementary material (Table S1).[1] At all temperatures, plots of the second order rate constant, k_0, against $[H^+]^{-1}$ were linear (Fig. 1) over the range studied. Intercepts of such plots did not vary statistically from zero.

Since there are no proton-related equilibria associated with the oxidant, a mechanism consistent with the observed data may be written as

[3] $H_2Asc \rightleftharpoons H^+ + HAsc^-$ (K_a)

[4] $Ni(9\text{-}aneN_3)_2^{3+} + HAsc^- \xrightarrow{k_2} Ni(9\text{-}aneN_3)_2^{2+} + HAsc^{\cdot}$

[5] $HAsc^{\cdot} \rightleftharpoons H^+ + Asc^{\cdot-}$

[6] $Ni(9\text{-}aneN_3)_2^{3+} + Asc^{\cdot-} \xrightarrow{\text{fast}} Ni(9\text{-}aneN_3)_2^{2+} + Asc$

The ascorbate radical intermediate $HAsc^{\cdot}$ is known to be a strong acid (16) ($pK_r(HAsc) = -0.45$) so that the predominant form under the present experimental conditions is $Asc^{\cdot-}$. The radical ion may then react with a second mole of nickel(III) to yield the de-hydroascorbic acid product. The large driving forces for reactions of this type ($E^0(Asc/Asc^{\cdot-}) = 0.14$ V (12)) have led to the suggestion (7) that reaction [6] is close to diffusion controlled. An alternative secondary step [7]

[7] $Asc^{\cdot-} + Asc^{\cdot-} \xrightarrow{H^+} H_2Asc + Asc$

must also be considered since the disproportionation reaction ($k_7 \geq 10^8$ M^{-1} s^{-1}) (18, 19) would result in the observed overall stoicheiometry.

Using the above mechanism, k_0 may be expressed in the form

[8] $$k_0 = \frac{k_1[H^+] + k_2K_a}{[H^+] + K_a}$$

where k_1 is the rate constant for the reaction of the nickel(III) species with the undissociated form of the acid, H_2Asc. From Fig. 1 and the data in Table 1 it is seen that $k_1[H^+] \ll k_2K_a$ and

$^a k_0$ values are the average of rate constants obtained using at least two and more usually three or four different substrate concentrations.

in the range $[H^+] = 0.005-1.00\ M$, $[H^+] \gg K_a$ ($pK_a = 3.96$) (20)), so that eq. [8] may be written as

$$[9] \quad k_0 = k_2K_a/[H^+]$$

as is observed (Fig. 1). The rate constants, k_2, evaluated from data on the temperature dependence of K_a at $I = 1.0\ M$ (20, 21) are presented in Table 1.

(2) Reaction of $[Ni(9\text{-aneN}_3)_2]^{3+}$ with hydroquinone, catechol, and resorcinol

Spectrophotometric titration at 350 nm (1.0 M $HClO_4$) revealed in all cases an oxidant:reductant ratio of 2(±0.1):1 corresponding to the overall reaction

$$[10] \quad 2[Ni(9\text{-aneN}_3)_2]^{3+} + H_2Q \rightarrow 2[Ni(9\text{-aneN}_3)_2]^{2+} + 2H^+ + Q$$

where H_2Q is the benzene diol and Q the corresponding quinone. As in the case of the ascorbic acid reaction, the rates were first order in both [Ni(III)] and $[H_2Q]$. No simple overall hydrogen ion dependence was observed over the range studied $[H^+] = 1.00\ M$ – pH 4.8, but two regimes were discernible. Representative rate data are presented in Table 2. Full details of rate data are provided in supplementary Table S2.[1]

(a) 0.1 M < $[H^+]$ < 1.0 M

In this range, for the substrates (hydroquinone and catechol) studied, a small but consistent retardation in rate was observed with increasing $[H^+]$. There is no spectroscopic evidence for any change in oxidant species under these conditions and in other redox systems (13, 22) where no protonation equilibria are involved there is no observed rate dependence of $[Ni(9\text{-aneN}_3)_2]^{3+}$ with $[H^+]$. The retardation may therefore be attributed to protonation of the quinol as is shown

$$[11] \quad H_3Q^+ \overset{K_b}{\rightleftharpoons} H_2Q + H^+$$

$$[12] \quad [Ni(9\text{-aneN}_3)_2]^{3+} + H_2Q \xrightarrow{k_3} [Ni(9\text{-aneN}_3)]^{2+} + SQ^{\cdot}$$

$$[13] \quad Ni(III) + SQ^{\cdot} \xrightarrow{\text{fast}} Ni(II) + Q$$

where $SQ^{\cdot}$ is the semiquinone radical with no assumption made as to the state of protonation of the species. A rate expression consistent with the reaction scheme may be written in the form

$$[14] \quad -d[Ni(III)]/dt = 2k_3[H_2Q][Ni(III)]\cdot K_b/([H^+] + K_b)$$

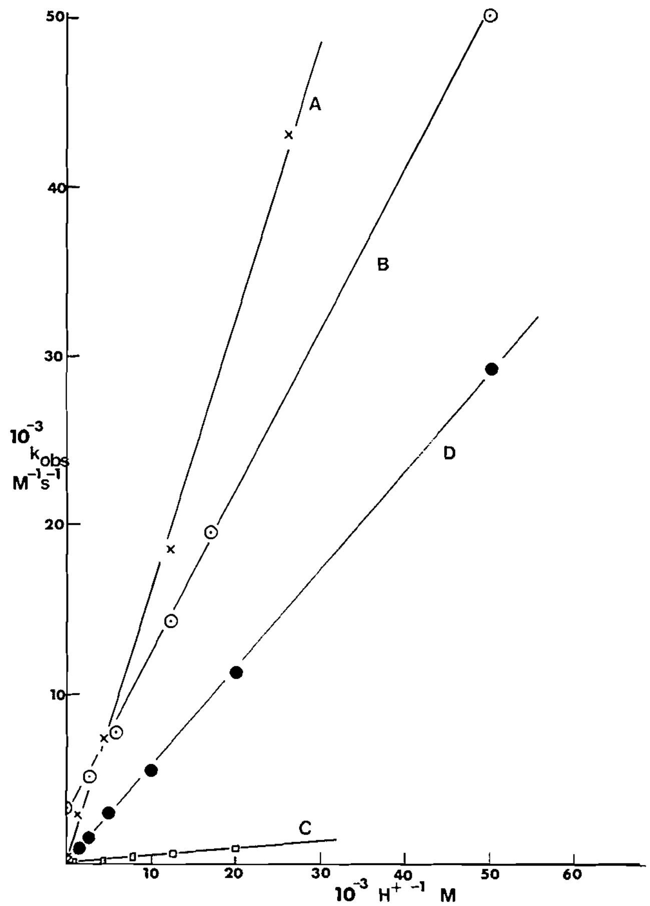

FIG. 1. Hydrogen ion dependences of the rates of oxidation of hydroquinone (*A*), catechol (*B*), and resorcinol (*C*), and ascorbic acid (*D*) ($T = 25°C$).

The observed second order rate constant, k_0, may be expressed as

$$[15] \quad k_0 = k_3K_b/([H^+] + K_b)$$

Equation [15] may be rearranged as

$$[16] \quad k_0 = k_3 - k_0[H^+]/K_b$$

such that a plot of k_0 against $k_0[H^+]$ should be linear with slope $-1/K_b$ and intercept k_3. Good linear plots were obtained for

TABLE 3. Rate constants for the reaction of $[Ni(9\text{-aneN}_3)_2]^{3+}$ with benzenediols and related anions

Reductant	K_b/M	$10^{10}K_a/M$	$10^{-3}k_3{}^a/M^{-1}\ s^{-1}$	$10^{-9}k_4/M^{-1}\ s^{-1}$
H_2Quin	4.2	1.40	2.9 (2.6)	6.9±0.3
H_2cat	1.8	3.55	0.28 (~0.2)	4.1±0.5[b]
H_2Res	—	1.55	~0	0.28±0.05[b]

[a]Values in parentheses are derived from higher pH conditions (see Fig. 2). More accurate values obtained at $[H^+] > 0.1\ M$.
[b]Corrections for diffusion related contributions lead to k_4 values of 3×10^{10} $M^{-1}\ s^{-1}$ ($Hcat^-$) and $3.1 \times 10^8\ M^{-1}\ s^{-1}$ ($HRes^-$), respectively. See text.

both reductants with (T = 25°C) $k_3 = 2.9 \times 10^3\ M^{-1}\ s^{-1}$ (hydroquinone) and $k_3 = 2.85 \times 10^2\ M^{-1}\ s^{-1}$ (catechol). Corresponding K_b values are $4.2 \pm 1.1\ M$ and $1.8 \pm 1.2\ M$, respectively. The rate data are consistent with the better reducing properties of hydroquinone. Similar behaviour to the above was observed in the oxidation by $Ni(cyclam)(H_2O)_2^{3+}$ (23) where the equilibrium data derived were $K_b = 4.5 \pm 1.2\ M$ (hydroquinone) and $3.3 \pm 0.9\ M$ (catechol) in good agreement with the present findings.

(b) $[H^+] < 0.1$ M

A marked increase in rate is observed with increasing pH which may be associated with the acid dissociation of the reductants, the almost identical pH profiles for each reaction reflecting the similarity of pK_a values for the substrates.

$$[17]\quad H_2Q \overset{K_a}{\rightleftharpoons} HQ^- + H^+$$

$$[18]\quad Ni(9\text{-aneN}_3)_2^{3+} + H_2Q \xrightarrow{k_3} Ni(9\text{-aneN}_3)_2^{2+} + SQ^{\bullet} + H^+$$

$$[19]\quad Ni(9\text{-aneN}_3)_2^{3+} + HQ^- \xrightarrow{k_4} Ni(9\text{-aneN}_3)_2^{2+} + SQ^{\bullet}$$

$$[20]\quad Ni(III) + SQ^{\bullet} \xrightarrow{\text{fast}} Ni(II) + Q$$

This mechanism is identical to that invoked in the ascorbic acid reduction and based on eq. [8] with the assumption that $[H^+] \gg K_a$ (pK_a = 9.5–11 for the reductants):

$$[21]\quad k_0 = k_3 + k_4K_a/[H^+]$$

Excellent linear plots of k_0 against $[H^+]$ were derived (Fig. 1). The individual rate constants are shown in Table 3. It may be noted that very good agreement is observed between k_3 values obtained at both high and low acid concentrations. In the case of resorcinol, however, there is no evidence within experimental error of any pathway attributable to k_3.

Discussion

The reactions of $[Ni(9\text{-aneN}_3)_2]^{3+}$ with the substrates under consideration may be assigned an outer-sphere mechanism since the oxidant is known to be substitution inert under the present experimental conditions. Two one-electron transfer steps may be expected in the oxidation of each substrate, the rate-determining process being the formation of the organic radical (or radical ion). Also, owing to the lack of any proton related equilibrium in the oxidant, the reactions of H_2A and HA^- may be attributed with a degree of certainty not often present in other oxidations. With aquo ions as reactants, the so-called "proton ambiguity" persists deriving from hydrolysis of the metal cations. The large difference in reactivity between the protonated ($k_3 \leq 10^3\ M^{-1}\ s^{-1}$) and dissociated forms ($k_4 \sim 10^7-10^9\ M^{-1}\ s^{-1}$) may be rationalised in terms of the redox potentials and self-exchange parameters. The rate constants for the reactions of $HQuin^-$ and $Hcat^-$ are very large and close to the limit of diffusion controlled systems. For the reaction of a 3+ ion of the type under consideration with a 1− anion, where an activated complex of radius ~10 Å is anticipated, a value of $k_{diff} \sim 4.7 \times 10^9\ M^{-1}\ s^{-1}$ may be estimated (24). It may be seen (Table 3) that the observed values for the reactions of $HQuin^-$ and $Hcat^-$ are of this order of magnitude and these systems must be considered as reacting predominantly via a diffusion controlled process. In the case of $HRes^-$, the rate constant is ~20-fold lower. The contribution to the observed value from diffusion may be eliminated (7) (eq. [22])

$$[22]\quad \frac{1}{k_{act}} = \frac{1}{k_4} - \frac{1}{k_{diff}}$$

where k_{act} and k_{diff} are the activation- and diffusion-controlled rate constants, respectively. Correction in this manner leads to k_4 values of $\sim 3 \times 10^{10}\ M^{-1}\ s^{-1}$ for the reaction with catecholate anion, $Hcat^-$, and $3.4 \times 10^8\ M^{-1}\ s^{-1}$ for the reaction involving $HRes^-$. The lower rate with the resorcinol anion may be interpreted in terms of the reduction of resonance stabilisation in the $HRes^{\bullet}$ radical formed on oxidation compared with that present in the $HQuin^{\bullet}$ or $Hcat^{\bullet}$ systems.

For the reactions under consideration, the cross-reaction rate constants are a function of the redox potentials of the reductants (25), consistent with the Marcus relationship. In terms of a recent modification of the theory (26), the rate constant for a cross reaction, k_{12}, is related to the rate constants for the component self-exchange reactions, k_{11} and k_{22}, and the equilibrium constant for the cross reaction, K_{12}, by

$$[23]\quad k_{12} = (k_{11}k_{22}K_{12}f_{12})^{1/2}W_{12}$$

where

$$[24]\quad \ln f_{12} = \frac{[\ln K_{12} + (W_{12} - W_{21})/RT]^2}{4\left[\ln\left(\frac{k_{11}k_{22}}{A_{11}A_{22}}\right) + \frac{W_{11} + W_{22}}{RT}\right]}$$

$$[25]\quad W_{12} = \exp\left[-(W_{12} + W_{21} - W_{11} - W_{22})/2RT\right]$$

$$[26]\quad W_{ij} = \frac{Z_iZ_je^2}{D_s\sigma_{ij}(1 + \beta\sigma_{ij}\sqrt{\mu})}$$

$$[27]\quad A_{ii} = \left[\frac{4\pi N\sigma^2\nu b\gamma r}{1000}\right]_{ii}$$

In these expressions W_{ij} is the work required to bring ions i and j (charges Z_i and Z_j) to the separation distance σ_{ij} (taken equal to the sum of a_i and a_j, the radii of ions i and j), $\beta = (8\pi Ne^2/1000D_skT)^{1/2}$, νb is the nuclear frequency that destroys the activated complex configuration ($\sim 9 \times 10^{12}\ s^{-1}$) (27), and γr is the thickness of the reaction layer (typically ~0.8 Å). Values of A/σ^2 are in the range $3-8 \times 10^{10}\ M^{-1}\ Å^{-2}\ s^{-1}$ and for the Ni(III) complex a value of $4.8 \times 10^{10}\ M^{-1}\ Å^{-2}\ s^{-1}$ has been derived (7). This value has been used in the present work.

The potentials of the H_2Q^+/H_2Q (E_1^0) and $HQ^{\bullet}/HQ^-$ (E_2^0) couples may be estimated using the expressions

$$[28]\quad E_1^0 = E_3^0 + 0.059\{pK_1 + pK_2 - pKr_1 - pKr_2\}$$

$$[29]\quad E_2^0 = E_3^0 + 0.059\{pK_2 - pKr_2\}$$

where E_3^0 represents the potential for the $Q^{\bullet-}/Q^{2-}$ couple (28) and pK_n and pKr_n are related to the dissociation of the diol or the corresponding radical.

Analysis of the data for $HRes^-$ (E_2^0 = 0.56 V), using k_{11}

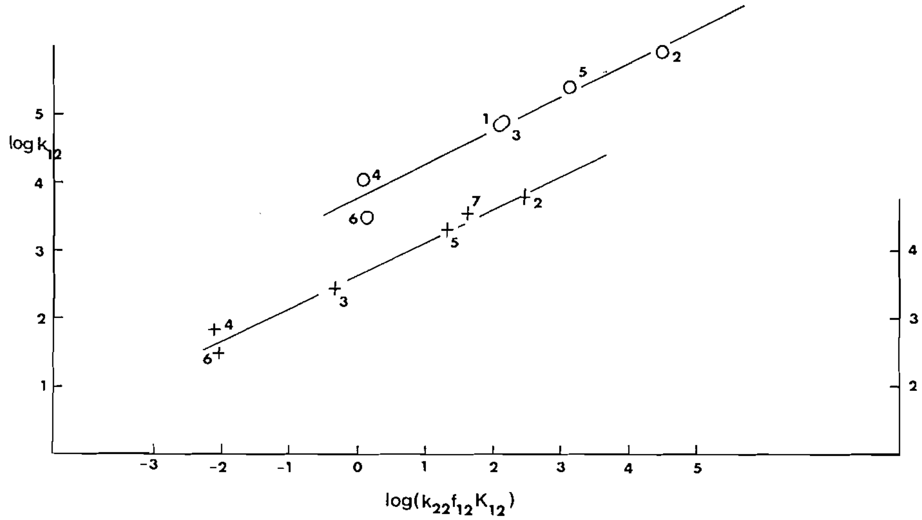

FIG. 2. Marcus correlations (plots of log k_{12} against log $f_{12}K_{12}k_{22}$) for the reactions of hydroquinone (○) and catechol (+) with various oxidants. *1*, $IrCl_6^{2+}$ (27); *2*, $[Ir(Cl_5)(OH_2)]^{3-}$ (26); *3*, $[IrBr_6]^{3-}$ (26); *4*, $[Ni(cyclam)(OH_2)_2]^{3+}$ (21); *5*, $[Ni(tet\text{-}c)(OH_2)_2]^{3+}$ (9); *6*, $[Ni(9\text{-aneN}_3)_2]^{3+}$; *7*, $Ni(tet\text{-}d)(OH_2)_2]^{3+}$ (9). Lines are drawn in accordance with a predicted slope of 0.50. Right hand ordinates refer to catechol data.

$(Ni(9\text{-aneN}_3)_2)^{3+/2+}$ = 6 × 10^3 M^{-1} s^{-1} (22) leads to a calculated value for the $HRes^-/HRes^{\cdot}$ self-exchange rate of 5.8 × 10^7 M^{-1} s^{-1} (ΔG^{*}_{22} ~ 4.4 kcal mol^{-1}).

In the case of the ascorbate ion, $HAsc^-$, a similar evaluation procedure leads to a self-exchange rate constant for the $HAsc^{\cdot}/HAsc^-$ couple of 3.5 × 10^5 M^{-1} s^{-1}. This is in excellent agreement with the value derived (1 × 10^5 M^{-1} s^{-1}) recently by Macartney and Sutin (7), confirming the outer-sphere character of the oxidant.

There are relatively few experimental data for the H_2Q^+/H_2Q couples. Using an analysis similar to that (eqs. [28], [29]) above, Pelizzetti *et al.* (29, 30) have evaluated redox potentials for the H_2Quin^+/H_2Quin and H_2cat^+/H_2cat couples (−1.14 and −1.25 V, respectively). The largest uncertainty in these values lies in the pKr_1 values ($H_2Q^+ \rightarrow HQ^{\cdot} + H^+$) where a value of 1− has been estimated. Using these data, we have plotted the results of several cross reactions using the form of the Marcus equation:

[30] $\log k_{12} = (1/2) \log k_{11} + (1/2) \log k_{22}K_{12}f_{12}$

where the work terms associated with the reaction of a neutral species approximate to zero. From eq. [30] it may be seen that a plot of log k_{12} against log $k_{22}f_{12}K_{12}$ should be linear with slope 0.50 and intercept (1/2) log k_{11}. The data for the oxidation of hydroquinone and catechol are shown in Fig. 2. Slopes are drawn as 0.5 leading to self-exchange rates of 5 × 10^7 M^{-1} s^{-1} (ΔG^* = 4.5 kcal mol^{-1}) and 2 × 10^7 M^{-1} s^{-1} (ΔG^* = 5.05 kcal mol^{-1}) for hydroquinone and catechol, respectively. These values are close to those derived previously (5). An uncertainty of a pK unit in the estimated value of pKr_1 would result in an uncertainty of about an order of magnitude in k_{11} (H_2Q/H_2Q^+).

The ratio of the rates of self-exchange of H_2Asc/H_2Asc (2 × 10^3 M^{-1} s^{-1}) (7) and $HAsc^-/HAsc^{\cdot}$ (3.5 × 10^5 M^{-1} s^{-1}) is ~6 × 10^{-3}. Using the rate of reaction of $Ni(9\text{-aneN}_3)_2^{3+}$ with $Hcat^-$, corrected for diffusion, (3 × 10^{10} M^{-1} s^{-1}) it is possible using (30) to derive a rough estimate of ~3.2 × 10^9 M^{-1} s^{-1} for the self-exchange rate involving the $Hcat/Hcat^{\cdot}$ couple. This is about two orders of magnitude greater than for the H_2cat/H_2cat^+ system. In the case of the ascorbate ion radical, however, the absolute rate is ~10^4 lower. This is probably the result of the extensive C—C and C═O bond re-organisation required on radical ion formation. A more facile electron redistribution with a minimum of bond length changes is possible for the $Hcat^-/Hcat^{\cdot}$ couple. The value for the corresponding resorcinol reaction is slower than that for catechol possibly owing to the lack of resonance stabilisation of the radical formed. However, it is clear that the benzenediol monoanions differ not only in the resonance delocalization which is uniquely available to *ortho*- and *para*-disubstituted aromatics (i.e. $Hcat^-/Hcat^{\cdot}$). The balance of the intermolecular and external hydrogen bonding forces in the two cases must be incor-

HCat⁻ 
 HRes⁻

porated. Such protic solvent effects play a substantial role in the position of keto−enol equilibrium, e.g., for acetylacetone (31). In general terms, differences in self exchange rates may well exhibit solvent trends reminiscent of Z values (or related solvatochromic scales) (32) where the energies of charge transfer bonds are related to solvation. It would be instructive to compare self exchange rates for the benzenediols in polar aprotic solvents (i.e., acetonitrile) and such studies are planned. Detailed analysis of these features must also await structural characterisation of the various radical species involved. It appears, however, that using coordination complexes employing outer sphere electron transfer pathways, it is possible to derive self-consistent data on organic redox couples where structural differences lead to significant variations in the electron-transfer parameters.

Isolation and structure of bryostatins 5−7[1]

GEORGE R. PETTIT,[2] YOSHIAKI KAMANO, CHERRY L. HERALD, AND MACHIKO TOZAWA[3]
Cancer Research Institute and Department of Chemistry, Arizona State University, Tempe, AZ 85287, U.S.A.

Received November 14, 1984

GEORGE R. PETTIT, YOSHIAKI KAMANO, CHERRY L. HERALD, and MACHIKO TOZAWA. Can. J. Chem. **63**, 1204 (1985).

American (Gulf of Mexico), Mexican (Gulf of California), and Japanese (Gulf of Sagami) specimens of the marine bryozoan *Bugula neritina* were found to contain in addition to bryostatin 4 (**3***a*) the new bryostatins 5−7 (**3***b*−*d*) as major antineoplastic components effective against the murine P388 lymphocytic leukemia. A total of 50 kg of wet *B. neritina* from the Northeastern Gulf of Mexico led to bryostatins 5−7 in 14.1, 61.9, and 31.2 mg yields respectively. The structural assignments for each of these potentially important substances were derived from detailed interpretation of the 400 MHz ^{1}H nmr and solution phase secondary ion mass spectral measurements, combined with the results of selective acid-catalyzed hydrolyses.

GEORGE R. PETTIT, YOSHIAKI KAMANO, CHERRY L. HERALD et MACHIKO TOZAWA. Can. J. Chem. **63**, 1204 (1985).

On a trouvé que les échantillons américains (Golfe du Mexique), mexicains (Golfe de la Californie) et japonais (Golfe de Sagami) du bryozoaire marin *Bugula neritina* contiennent, en plus de la bryostatine 4 (**3***a*), de nouvelles bryostatines 5−7 (**3***b*−*d*) qui sont des composants antinéoplastiques majeurs, efficaces contre la leucémie lymphocytique P388 murine. Un total de 50 kg de *B. neritina* humide, provenant du nord-est du Golfe du Mexique, a permis d'isoler 14,1, 61,9 et 31,2 mg respectivement des bryostatines 5−7. On a attribué les structures des chacune de ces substances potentiellement importantes en se basant sur une interprétation détaillée des spectres rmn du ^{1}H à 400 MHz et sur des mesures de spectrométrie de masse combinées aux résultats d'hydrolyses acido-catalysées sélectives.

[Traduit par le journal]

The bryozoan, *Bugula neritina* (Linnaeus) has proved to be a surprisingly productive reservoir of potentially useful anticancer constituents. A 15-year study (2) of this tiny marine animal in our laboratory has led to the discovery of bryostatins 1−3 (ref. 3, **1***a*, *b*, **2**) in Eastern Pacific Ocean specimens and bryostatin 4 (ref. 4, **3***a*) in Western Pacific Ocean, Gulf of California, and Gulf of Mexico samples. Each has exhibited activity against the U.S. National Cancer Institute's (NCI) murine P388 lymphocytic leukemia (PS system) at <46 μg/kg/inj. dose levels.

Further detailed investigations of *Bugula neritina* have now led to the isolation and structural elucidation of three new and potentially important bryostatins from Gulf of Mexico (Florida, USA), Gulf of California (Sonora, Mexico), and Gulf of Sagami (Japan) collections. Continuation of the bryostatin nomenclature (3*b*) has been employed to name these new PS cell growth inhibitory and antineoplastic substances bryostatin 5 (NSC-362616, PS cell line ED_{50}, 1.3×10^{-3} to 2.6×10^{-4} μg/mL, in vivo, 88% life extension at 185 μg/kg), bryostatin 6 (NSC-362617, PS cell line ED_{50}, 3.0×10^{-3} μg/mL, in vivo, 82% life extension at 185 μg/kg), and bryostatin 7 (NSC-362619, PS cell line ED_{50}, 2.6×10^{-5} μg/mL, in vivo 77% life extension at 92 μg/kg). Bryostatins 5−7 were discovered during a very careful examination of antineoplastic (PS) fractions leading to bryostatin 4 (4). In a typical approach, a Florida collection of *Bugula neritina* (50 kg wet wt) was extracted with methylene chloride − methanol−water and the methylene chloride phase was entered into an extensive separation procedure guided by bioassay using the PS leukemia. The biologically active methylene chloride fraction prepared (5) from the 9:1 → 4:1 methanol−water solvent partition sequence was subjected to detailed fractionation employing gel permeation (steric exclusion), silica gel and Sephadex (LH-20) partition, preparative layer, reverse phase, and high performance liquid (hplc) chromatography (4). Rigorous application of this improved separation sequence led to 44.5 mg of bryostatin 4 (**3***a*), bryostatin 5 (**3***b*, 14.1 mg), bryostatin 6 (**3***c*, 61.9 mg), and bryostatin 7 (**3***d*, 31.2 mg).

The reddish-purple color observed upon developing thin layer chromatograms of bryostatins 5−7 with anisaldehyde sulfuric acid reagent first suggested the relationship to bryostatin 4 and this superficial interpretation was further substantiated by careful interpretation of the high resolution (400 MHz) ^{1}H (Table 1) and ^{13}C nmr spectra (**3***b*) (Table 2). Except for the ester substituents at C-7 and C-20, all of the structural features characteristic of bryostatin 4 were apparent in the proton and carbon spectra of bryostatins 5−7. The solution phase secondary ion mass spectra of bryostatins 5−7 were quite revealing when the new techniques we developed (6) for detecting molecular ions of hitherto refractory substances were utilized. By this exceptionally useful method (employing an alkali metal iodide such as sodium iodide or silver tetrafluoroborate or thallium tetrafluoroborate in sulfolane) the molecular ions corresponding to bryostatins 5−7 were easily detected. Interpretation of the molecular ion with the few fragment ions produced proved to be very valuable; namely, for bryostatin 5, 889 $[M+Na]^+$, 871 $[M+Na-18]^+$, 829 $[M+Na-60]^+$, and 788 $[M+Na-102]^+$; bryostatin 6, 875 $[M+Na]^+$, 857 $(M+Na-18]^+$, 815 $[M+Na-60]^+$, and 787 $[M+Na-88]^+$; and bryostatin 7, 847 $[M+Na]^+$, 829 $[M+Na-18]^+$, and 787 $[M+Na-60]^+$. Loss of 60 and 102 mass units by mass spectral fragmentation of bryostatin 5 suggested acetate and valerate ester substituents. Similarly, loss of 60 and 88 from the bryostatin 6 molecular ion indicated acetate and butyrate esters. The cleavage of only 60 units from bryostatin 7 suggested a diacetate derivative.

Each of the preceding assumptions was further confirmed by completing the ^{1}H and ^{13}C nmr interpretations and these analyses were consistent with the mass spectral fragmentation results. Exact assignment for each of the ester substituents was achievable by the results of careful acid-hydrolysis experiments. As part of earlier structural studies involving bryostatins 1 (**1***a*) and 4 (**3***a*) it was found that the former substance

could be selectively hydrolyzed to bryostatin 2 (**1***b*) as major product, presumably because of steric hindrance in the vicinity of the C-20 ester. Analogously, hydrochloric acid (1% in aqueous methanol)-catalyzed hydrolysis (24 h at room temperature) of bryostatin 5 (1 mg) afforded C-20 acetate **3***e* (300 μg) as major product accompanied by a lesser quantity (100 μg) of C-7 *iso*-valerate **3***f*. Comparable results were obtained employing bryostatin 6 (1 mg) which led to C-20 acetate **3***e* (350 μg, identical with the acetate from bryostatin 5) as major product accompanied by C-7 butyrate (**3***g*, 150 μg). Also, hydrochloric acid-catalyzed hydrolysis of bryostatin 7 (1 mg) afforded only C-20 acetate **3***e*, which was the same product from bryostatins 5 and 6. The data obtained from the selective hydrolyses allowed assignment of structures **3***b* and **3***c* respectively to bryostatins 5 and 6. The structure of bryostatin 7 (**3***d*) was based entirely upon conclusions reached from analyzing nmr and mass spectra.

Structural elucidation of bryostatins 4–7 allowed the course of some reactions explored as initial chemical probes of the molecular geometry to be better understood. For example, acetylation of bryostatin 4 (**3***a*) with acetic acid – pyridine (2 h at room temperature) was found to be very selective and afforded C-26 acetate **3***h*. Presumably due to intramolecular hydrogen bonding, the hydroxyl group at C-3 was essentially unaffected. Location of the 26-acetate (**3***h*) was based on interpretation of the high resolution (400 MHz) ^1H nmr spectrum. The 26-proton usually observed at δ 3.77 was shifted downfield to δ 4.99 (m). Conversely the C-3 proton signal in acetate **3***h* at δ 4.13 (m) was essentially the same as that in bryostatin 4 (**3***a*) at δ 4.16.

Some of the biological implications apparent from inspecting the structures of bryostatins 4–7 are particularly noteworthy. From evidence now in hand, *Bugula neritina* indigenous to the U.S. West Coast seems to have a special ability for synthesis of the C-20 (*E*,*E*)-octa-2,4-dienoate ester. Interestingly, this substituent may be in part responsible for the reduced cytotoxicity of this series. While no evidence for even trace amounts of bryostatins 1–3 could be detected in the various Gulf specimens of *Bugula neritina*, we were able to find barely detectable (by thin layer chromatography) amounts of bryostatins 4–7 in the Eastern Pacific *Bugula neritina*. The trace amounts (tlc only) of bryostatins 4–7 came from about 500 kg (wet weight) of California *Bugula neritina*. Presently bryostatins 4–7 are being readied for further evaluation against the NCI key experimental tumor systems. The results and other on-going studies should allow a better view of structure/activity relationships among this fascinating group of marine animal anticancer components.

Experimental

All solvents employed for chromatographic purposes were redistilled. Column chromatography was performed using either Sephadex LH-20, from Pharmacia Fine Chemicals, AB, Uppsala, Sweden, or silica gel (70–230 mesh) from E. Merck, Darmstadt. The hplc columns (9.4 × 500 mm) employed were the Partisil-10 M-9-ODS-2 (C-18 reversed phase) and Partisil-10 M-9 columns from Whatman, Inc., Clifton, New Jersey. An Altex hplc unit with System Controller Model 420 and Model 110A pumps was utilized for final separations. Preparative and reversed phase (KC-18) tlc plates were Whatman products. Silica gel GF Uniplates were supplied by Analtech, Inc., Newark, Delaware. All tlc plates were developed by uv light and (or) detected by anisaldehyde – acetic acid – sulfuric acid spray (plates heated to about 150°C for 5 to 10 min). Fractions were collected with either Gilson FC-80 (microfractionator) or FC-220 (racetrack fractionator) equipment in conjunction with a Gilson uv monitor Model HM.

All melting points are uncorrected and were observed with a Kofler-type melting point apparatus. Ultraviolet spectra (methanol solution) were recorded with a Hewlett–Packard 8450A uv/vis spectrometer. Optical rotations (methanol solution) were observed using a Perkin–Elmer Model 214 polarimeter. Mass spectra were determined with a MAT-312 mass spectrometer equipped for solution phase secondary ion mass spectrometry (SP-SIMS) employing sodium iodide in sulfolane (6). Infrared spectra (KBr) were obtained with a Nicolet FTIR Model MX-1 spectrometer. The nmr spectra were measured with Bruker WH-90 and WH-400 instruments, and deuteriochloroform was employed as solvent with tetramethylsilane as internal standard.

Collection and extraction

A July 1982 re-collection of *Bugula neritina* from the Eastern Gulf of Mexico (Alligator Harbor, Franklin County, Florida) provided 50 kg (wet weight) of marine animal which was preserved in 2-propanol, extracted, and subjected to preliminary separation as described before (see ref. 4 for details). By this means 37.6 g of bryostatin-enriched methylene chloride extract (PS ED_{50}, 0.058 μg/mL) was obtained and subjected to a series of column chromatographic separations to yield bryostatin 4 (44.5 mg) and, as summarized below, bryostatins 5–7.

Bryostatin 5 (3b)

From the succession of silica gel and gel permeation (Sephadex LH-20) column chromatographic steps previously used (4) to concentrate bryostatin 4 (**3***a*), an active fraction (0.38 g) was isolated as a white amorphous powder (PS cell line ED_{50}, 1.6×10^{-3} μg/mL) containing bryostatins 4–7 (evidenced by tlc using 7:3 n-hexane – acetone and 2:3 n-hexane – ethyl acetate). By extensive dry column (2 × 60 cm) silica gel chromatographic methods with solvent gradients of n-hexane – acetone (5:1 → 1:1) and n-hexane – ethyl acetate (2:1 → 1:2), six fractions were selected for further purification. The first fraction contained bryostatin 4. The second, third, and fifth fractions were subjected to hplc using a Partisil C-18 reversed phase column with a 1:1 → 9:1 methanol–water gradient (flow rate of 2 mL/min). The second fraction (15 mg) yielded pure bryostatin 5 (14.1 mg), melting at 169–172°C (needles from methylene chloride – methanol): $[\alpha]_D^{27}$ +106.92 (*c* 0.028); uv λ_{max}: 226 nm (ε 36 300); ir: 3465, 2980–2935, 1740, 1725, 1660–1640, 1440, 1385, 1370, 1290, 1230, 1165, 1100, 1080, 1060, and 1000 cm^{-1}; SP SIMS (6) ms *m/z* 889 $[M + Na]^+$ for $C_{44}H_{66}O_{17}$. See Tables 1 and 2 for the nmr data and the discussion section for additional mass spectral ions.

Bryostatin 6 (3c)

The third fraction (65 mg) was subjected to the same hplc final purification procedures as summarized for obtaining bryostatin 5, to afford bryostatin 6 (61.9 mg) as needles from methylene chloride – methanol: mp 172–175°C $[\alpha]_D^{27}$ +39.92 (*c* 0.05); uv λ_{max}: 228 nm (ε 36 350); ir: 3460, 2980–2950, 1740, 1720, 1660–1650, 1440, 1380, 1370, 1280, 1240, 1160, 1100, 1080, 1060, and 1000 cm^{-1}; SP-SIMS (6) ms *m/z* 875 [M + Na] for $C_{41}H_{60}O_{17}$. The nmr data have been recorded in Tables 1 and 2 and mass fragmentation ions in the discussion.

Bryostatin 7 (3d)

The fifth fraction (33 mg) was also purified by hplc as above to yield bryostatin 7, 31.2 mg, mp 176–179°C (needles from CH_2Cl_2–CH_3OH); $[\alpha]_D^{27}$ +39.92 (*c* 0.05); uv λ_{max}: 228 nm (ε 36 350); ir (KBr): 3460, 2980–2950, 1740, 1720, 1660–1650, 1440, 1380, 1370, 1280, 1240, 1160, 1100, 1080, 1060, and 1000 cm^{-1}; SP-SIMS ms *m/z* 824 for $C_{41}H_{60}O_{17}$.

Acid-catalyzed hydrolysis of bryostatin 5 (3b)

A specimen of bryostatin 5 (**3***b*, 1 mg) was subjected to hydrolysis in 1% hydrochloric acid (0.5 mL) for 24 h at room temperature. The product obtained by extraction with methylene chloride was washed with water, dried (*in vacuo*), and separated by hplc reversed phase (C-18) column chromatography. A methanol–water gradient from 1:1 to 9:1 was employed to give C-20 acetate **3***e* (300 μg) and C-7 isovalerate **3***f* (100 μg).

The C-20 acetate (**3***e*) was obtained as an amorphous powder from aqueous methanol: mp 153–156°C: ir: 3475, 2980–2950, 1740, 1720, 1660–1638, 1435, 1380–1370, 1290, 1240, 1160, 1100, 1090, 1075, 1048, 1005, and 870 cm^{-1}; SP-SIMS (6) ms, *m/z* 805 $[M + Na]^+$ for $C_{39}H_{58}O_{16}$, 787 $[M + Na - 18]^+$ and 745 $[M + Na - 60]^+$.

The C-7 *iso*-valerate (**3***f*) was obtained as an amorphous solid melting at 147–152°C from aqueous methanol; ir: 3470, 3435, 2975–2950, 1738, 1720, 1660–1635, 1440, 1390–1370, 1290, 1240, 1160, 1100, 1075, 1050, 1000, and 870 cm^{-1}; SP-SIMS, ms, *m/z* 847 $[M + Na]^+$ for $C_{42}H_{64}O_{16}$, 829 $[M + Na - 18]^+$ and 745 $[M + Na - 102]^+$. The C-7 *iso*-valerate was found to be identical[4] with the compound (**3***f*) derived from bryostatin 4 (**3***a*) by analogous acid hydrolysis.

Acid-catalyzed hydrolysis of bryostatin 6

A specimen of bryostatin 6 (**3***c*, 1 mg) was hydrolyzed and the products separated by reversed phase hplc as described for bryostatin 5 to provide C-20 acetate **3***e* (350 μg), identical[4] to that obtained from bryostatin 5, and C-7 butyrate **3***g* (150 μg).

The C-7 butyrate (**3***g*) was obtained as an amorphous solid melting at 166–170°C; ir (KBr): 3475, 3430, 2975–2945, 1736, 1720, 1640, 1620, 1440, 1390, 1095, 1080, 1040, and 870 cm^{-1}; SP-SIMS (6) ms, *m/z* 833 $[M + Na]^+$ for $C_{41}H_{62}O_{16}$, 815 $[M + Na - 18]^+$ and 745 $[M + Na - 88]^+$.

Acid-catalyzed hydrolysis of bryostatin 7

A sample of bryostatin 7 (**3***d*, 1 mg) was hydrolyzed and the crude material purified by reversed phase hplc as outlined for bryostatin 5. The major product was 20-acetate **3***e* (370 μg) and it was found[4] to be the same product analogously obtained from bryostatin 5 (**3***b*).

Acetylation of bryostatin 4

A sample of bryostatin 4 (9.0 mg) was treated with acetic anhydride (0.14 mL) and pyridine (0.2 mL) at room temperature for 4 h. The mixture was poured into ice-water and extracted with methylene chloride. The extract was washed with dilute hydrochloric acid and water, concentrated, and dried under reduced pressure. The crude product (9.5 mg) was purified by reversed phase hplc using the same procedure as described above for bryostatin 5. Pure bryostatin 4 acetate (**3***h*, 8.0 mg, 88.9% yield) was obtained as colorless needles from methylene chloride – methanol: mp 159–162°; $[\alpha]_D^{27}$ +58.71 (*c* 0.034); uv λ_{max}: 227 nm (ε 36 600); ir: 3460, 2985–2935, 1745, 1730, 1660–1640, 1440, 1380, 1370, 1290, 1240, 1165, 1100, 1080, 1050, and 1000 cm^{-1}; SP-SIMS ms, *m/z* 959 $[M + Na]^+$ (*M* = 936 for $C_{48}H_{72}O_{18}$), 941 $[M + Na - 18]^+$, 899 $[M + Na - 60]^+$, $[M + Na - 88]^+$– and 857 $[M + Na - 102]^+$.

[4]By tlc and mass spectral comparisons.

Received July 9, 1984

JACK PASSMORE, GEORGE SUTHERLAND, TOM K. WHIDDEN, PETER S. WHITE, and CHI-MING WONG. Can. J. Chem. **63**, 1209 (1985).

S_7BrMF_6 (M = As, Sb) were prepared essentially quantitatively by a variety of similar routes to those that led to S_7IMF_6; and in addition, by the reaction of bromine and S_7IAsF_6. $(S_7Br)_4S_4(AsF_6)_6$ was prepared essentially quantitatively directly from sulphur, bromine, and arsenic pentafluoride in the appropriate ratios. Crystals of $(S_7Br)_4S_4(AsF_6)_6$ are isostructural with $(S_7I)_4S_4(AsF_6)_6$, space group $P4/n$, a = 19.19(3), c = 8.01(1) Å. The structure was refined from a low temperature set of data to a final R = 0.12. The salt contains a discrete planar S_4^{2+} and bromo-cycloheptasulphur (1+) cations, the latter having a similar geometry, sulphur–sulphur bond distances and an intra-cationic halogen–sulphur contact to that observed in S_7I^+.

JACK PASSMORE, GEORGE SUTHERLAND, TOM K. WHIDDEN, PETER S. WHITE et CHI-MING WONG. Can. J. Chem. **63**, 1209 (1985).

Utilisant diverses méthodes semblables à celles qui ont permis de préparer le S_7IMF_6, on a préparé le S_7BrMF_6 (M = As, Sb) avec un rendement pratiquement quantitatif; on l'a aussi obtenu par la réaction du brome et du S_7IAsF_6. Par réaction du soufre, du brome et du pentafluorure d'arsenic dans des proportions appropriés, on a préparé le $(S_7Br)_4S_4(AsF_6)_6$ avec un rendement essentiellement quantitatif. Les cristaux de $(S_7Br)_4S_4(AsF_6)_6$ sont isostructuraux avec ceux du $(S_7I)_4S_4(AsF_6)_6$, groupe d'espace $P4/n$, a = 19,19(3), c = 8,01(1) Å. On a affiné la structure, jusqu'à une valeur finale de R = 0,12, à l'aide d'un ensemble de données obtenues à basse température. Le sel contient des ions individuels S_4^{2+} plan et bromo-cycloheptasoufre (1+); la géométrie, les distances soufre–soufre et le contact intracationique halogène–soufre de ce dernier sont semblables à ce qui a été observé avec le cation S_7I^+.

[Traduit par le journal]

Introduction

We have recently prepared and determined the crystal structures of the sulphur iodine cations S_7IMF_6 (M = As, Sb) (1–3), $[(S_7I)_2I][SbF_6]_3 \cdot 2AsF_3$ (4, 5), $(S_7I)_4S_4(AsF_6)_6$ (4, 6), and $S_2I_4(AsF_6)_2$ (7). It was of interest to determine whether iodine was unique in its ability to form cations of this sort, therefore, we explored the analogous sulphur–bromine system, and the results are reported in detail below. A preliminary communication briefly mentioned $(S_7Br)_4S_4(AsF_6)$ (6). Prior to this work the known binary sulphur–bromine species were S_xBr_2 (x = 2 to ca. 10) (of which only S_2Br_2 is stable) (8), SBr_3MF_6 (M = As, Sb) (9) salts, and the rather unstable NH_4SBr (8).

Experimental

Chemicals and techniques have been described (5, 10), in addition bromine (Anachemia, Reagent Grade) was dried and stored over P_2O_5 prior to use. Elemental analyses were obtained from A. Bernhardt, W. Germany and Butterworth, Teddington, England. Table 1 includes experimental weights for experiments described below.

(1) Preparation of S_7BrMF_6

(A) Reaction of sulphur with arsenic pentafluoride and bromine. In a typical reaction, AsF_5 (2.40 g, 14.1 mmol) was condensed onto excess S_8 (2.79 g, 10.9 mmol) in AsF_3 (14.26 g) in a two-bulbed Pyrex vessel separated by a coarse sintered glass frit and equipped with a Rotaflo or J. Young Teflon-stemmed Pyrex valve. After 12 h, Br_2 (0.77 g, 4.81 mmol) was added and the mixture stirred for 2 h, yielding a red–brown solution containing solids. The products were separated by filtration and the volatile material removed. A noncrystalline soluble red–brown solid and unreacted S_8 were obtained. *Anal.* calcd. for S_7BrAsF_6 (the soluble product): S 45.50, Br 16.20, As 15.19, F 23.11; found: S 45.16, Br 16.52, As 15.03, F 22.90.

Other similar reactions with approximately stoichiometric amounts of S_8 were performed leading to microcrystalline products (weights given in Table 1). Reactions carried out by adding Br_2 before the AsF_5 gave material of very poor quality (i.e. containing S_xBr_2).

(B) Reaction of excess sulphur with antimony pentafluoride and bromine. In a typical reaction, SbF_5 (3.04 g, 14.0 mmol) was condensed onto S_8 (3.03 g, 11.8 mmol) in SO_2 (8.67 g) and the mixture stirred for 1 h. Br_2 (0.73 g, 4.56 mmol) was then added and the red–brown mixture stirred for 2 h. The soluble and insoluble products were separated by filtration and SO_2ClF (3.01 g) added to the solution to facilitate crystal formation. Removal of the volatile material at 0°C over a 12 h period yielded what appeared to be a highly crystalline red–brown soluble solid and a mixture of sulphur and a reduced antimony pentafluoride product, $(SbF_3)_3SbF_5$. Several well formed crystals of soluble product were examined by X-ray precession photography but were found to diffract X-rays very poorly. *Anal.* calcd. for S_7BrSbF_6 (the soluble crystalline product): S 41.55, Br 14.80, Sb 22.54, F 21.11; found (*1*) S 41.92, 41.86, Br 14.69, Sb 22.32, F 20.78; (*2*) (a different reaction) S 41.13, Br 14.89, Sb 22.50, F 20.99.

(C) Reaction of $S_x(AsF_6)_2$ (average x ca. 17), with bromine. In one reaction, excess S_8 (4.88 g, 19.1 mmol) was reacted with stirring with AsF_5 (3.05 g, 17.9 mmol) in SO_2 (11.86 g) for 12 h. Separation of the deep red soluble product from unreacted S_8 was followed by addition of Br_2 (1.03 g, 6.44 mmol). The section of the vessel containing the excess sulphur was previously flame sealed at a constriction to prevent reaction of the sulphur with Br_2. The weight of unreacted sulphur (1.56 g, 6.09 mmol) indicated that the average stoichiometry of the red sulphur polyatomic cation was $S_{17.4}^{2+}$. The red–brown solution was separated from the precipitated sulphur after 4 days, and removal of the volatile material over a 24 h period resulted in a red–brown microcrystalline soluble solid, and insoluble S_8.

(D) Reactions of S_7IAsF_6 with Br_2. In one reaction, AsF_5 (2.43 g, 14.3 mmol) was reacted with a mixture of S_8 (2.48 g, 9.68 mmol) and I_2 (4.66 g, 18.3 mmol) in SO_2 (11.60 g) for 2 h with vigorous agitation. The soluble and insoluble (excess S_8/I_2) materials were separated as in (*C*). The weight of excess S_8 and I_2 remaining was found to be 3.64 g (3.79 g calculated for formation of S_7IAsF_6 based on AsF_5). After 4 days Br_2 (0.82 g, 5.13 mmol) was condensed onto the solution resulting in a red–brown solution containing no precipitate. Subsequently, the solution was pumped to dryness over a 24 h period yielding a red–brown microcrystalline solid. *Anal.* calcd. for S_7BrAsF_6: S 45.50, Br 16.20, As 15.19, F 23.11; found: S 45.16, Br 16.49, As 15.50, F 23.05, I 0.00.

(E) Reaction of $S_8(AsF_6)_2$ with KBr. In one reaction, SO_2 (6.63 g) was condensed onto $S_8(AsF_6)_2$ (1.17 g, 1.85 mmol) in a previously

isolated section of the apparatus and the blue solution quantitatively added to KBr (0.22 g, 1.85 mmol). After 6 h the red–brown solution containing solids was filtered into a third bulb and SO_2ClF (2.80 g) added to facilitate crystal formation. Removal of the volatile material over a 4 h period resulted in a noncrystalline red soluble solid. The insoluble solid was identified as a mixture of S_8 and $KAsF_6$ by Raman spectroscopy and X-ray powder diffraction photography.

Identification of S_7BrMF_6 bulk material

X-ray powder photographs (Cu Kα radiation) of material from preparations 1(*A*) and 1(*C*) to 1(*E*) were obtained and all were found to be similar, showing three strong lines at $2\theta \simeq 18.3$, 22.5, and 29.0° ($I/I_0 = 100$, 20, and 50, respectively). In addition, some photographs showed other much less intense lines. Attempts at obtaining reproducible Raman spectra, using a spinning cell at −196°C, were unsuccessful.

Stability of S_7BrMF_6

Solid S_7BrAsF_6 decomposed after several days at room temperature while S_7BrSbF_6 was stable for several weeks. In addition, samples of both salts in concentrated (SO_2) solution deposited a yellow solid (presumably S_8) with evolution of a dark red liquid (presumably S_xBr_2) on standing for several weeks. Both salts were found to be stable in the solid phase for at least several months at −20°C. Redissolving solid samples in fresh SO_2 or AsF_3 resulted in decomposition.

(2) Preparation of $(S_7Br)_4S_4(AsF_6)_6$

In one reaction AsF_5 (2.18 g, 12.8 mmol) was condensed onto S_8 (1.34 g, 5.22 mmol) over SO_2 (8.95 g). Br_2 (0.48 g, 2.92 mmol) and SO_2ClF (2.95 g) were added after 1 h. On warming to room temperature a dark green–brown solution over a dark precipitate was obtained. (We found that slight excess of Br_2 and AsF_5 with addition of SO_2ClF yielded better quality crystals). After 12 h the solution was dark red, tinted somewhat with green. Most of the volatile material was slowly (~4 days) condensed to the other side of the reaction vessel with a temperature gradient of 10°C between the two bulbs. Red needle-shaped crystals were obtained. The crystals were washed quickly with a small amount of solvent and then the volatile material was removed. This and other similar preparations yielded crystals suitable for single crystal X-ray analysis.

Stability of $(S_7Br)_4S_4(AsF_6)_6$

A crystalline sample of $(S_7Br)_4S_4(AsF_6)_6$ showed no apparent loss of crystallinity on storage for several weeks at room temperature. The crystals were found to partially decompose to a red liquid on irradiation with X-rays (Mo-Kα).

X-ray crystal structure of $(S_7Br)_4S_4(AsF_6)_6$

Suitable crystals, manipulated in a Vacuum Atmosphere Corp. dry box with the aid of an externally mounted Wild M3 microscope of long focal length, were sealed under dry nitrogen in rigorously dried glass capillary tubes. An initial photographic investigation showed the crystals to be tetragonal, space group $P4/n$ and apparently isostructural with $(S_7I)_4S_4(AsF_6)_6$ (4, 6). Initial attempts at collecting intensity data were abandoned because of excessive crystal movement and it was observed that a layer of red liquid formed on the surface of the crystals on exposure to X-rays. A number of attempts were made to secure the crystals inside the capillaries, but none were successful. At this point it was decided to try and collect data at low temperature, thereby using the liquid decomposition product to freeze the crystal in place.

The crystal was mounted on a Picker FACS-I diffractometer equipped with a modified Enraf-Nonius low temperature attachment, using graphite monochromated MoKα radiation. The cell dimensions and an orientation matrix were determined by a least-squares fit to the centered coordinates of 12 Friedel pairs of reflections in the range 30° ≤ 2θ ≤ 45°. Intensity data for two unique sets of reflections were collected using an ω–2θ scan of 2° (2θ) corrected for dispersion of the Kα doublet, at a scan speed of 2° (2θ) min^{-1}. Backgrounds were measured for 1/10 scan-time at each end of a scan and if the peak was considered significant ($I > 2\sigma(I)$) an analysis of the peak profile was performed. Three reference reflections, measured every 100 reflections, showed no indication of sample decomposition during the data

[a]To approximate the disorder F(31) and F(32) were included with occupancies of 3/4.

collection. However, it was found necessary to redetermine the orientation matrix each time the liquid N_2 dewar was refilled (about every 12 h). Crystal data are given in Table 2.

An initial attempt to use the atomic positions from $(S_7I)_4S_4(AsF_6)_6$ (4, 6) was not successful so the structure was solved by the direct methods program MULTAN (11), from which all the S, Br, and As atomic positions were obtained. The fluorines were located in subsequent difference syntheses, those about As(1) and As(2) behaved normally. The environment about As(3) showed eight peaks, indicating a disordered AsF_6^- similar to that in $(S_7I)_4S_4(AsF_6)_6$. Attempts to fit a set of octahedral fluorine atom arrangements failed and the fluorine positions were approximated by assigning F's with 3/4 occupancies to the positions found in the original difference synthesis. After correction of the data for absorption by Gaussian integration (transmission coefficients 0.06–0.25), the structure was refined by least-squares techniques. A weighting scheme based on counter statistics was used, the function minimised was $\Sigma\omega(\Delta|F|)^2$. The final agreement factors were R $(=\Sigma|\Delta F|/\Sigma|F|)$ = 0.12 and R_ω $(=\Sigma\omega(\Delta|F|)^2/\Sigma\omega|F|^2)$ = 0.14, with all the atoms refined anisotropically. Such mediocre agreement factors are not unusual in compounds similar to this one, and can be attributed not only to the disorder of one AsF_6^- but to the high thermal motion of all the anions. This may have been exacerbated by errors in the absorption correction due to the crystal shape being modified by surface decomposition. A final difference synthesis showed no abnormal features, the maximum was 1.9e$^-$ in the region of Br. Scattering factors were taken from the International tables for crystallography (12) and were corrected for anomalous dispersion. Computations were performed using SHELX-76 (13). Final positional parameters are given in Table 3.

Discussion

Preparation of S_7BrMF_6 (M = As, Sb)

We have found that S_7BrMF_6 may be prepared essentially quantitatively in liquid sulphur dioxide according to reactions [1] to [5] below:

$$[1]\quad nS_8 + 3AsF_5 + Br_2 \rightarrow 2S_7BrAsF_6 + AsF_3 + \left(n - \frac{7}{4}\right) S_8 \quad \left(n \geq \frac{7}{4}\right)$$

$$[2]\quad nS_8 + 10SbF_5 + 3Br_2 \rightarrow 6S_7BrSbF_6 + (SbF_3)_3\cdot SbF_5\ (14) + \left(n - \frac{21}{4}\right) S_8 \quad \left(n \geq \frac{21}{4}\right)$$

$$[3]\quad S_x(AsF_6)_2\ (x \approx 17) + Br_2 \rightarrow 2S_7BrAsF_6 + \left(\frac{x-14}{8}\right) S_8$$

$$[4]\quad S_7IAsF_6 + \frac{1}{2}Br_2 \rightarrow S_7BrAsF_6 + \frac{1}{2}I_2$$

$$[5]\quad S_8(AsF_6)_2 + KBr \rightarrow S_7BrAsF_6 + KAsF_6 + \frac{1}{8}S_8$$

Experimental weight changes taken as a whole (Table 1), and analytical data (five separate analyses from four different preparations) support formation of S_7BrMF_6. Although evidence of this type may be misleading (c.f. S_{19}^{2+} (15, 16) and Te_6^{4+} (17–19)), in view of the well established (1–3) existence of S_7I^+ and the X-ray crystal structure determination of $(S_7Br)_4S_4(AsF_6)_6$ (see below) it is reasonable to conclude that S_7BrMF_6 was formed in all of these reactions. Thus S_7BrMF_6 can be prepared by a variety of routes.

It is noteworthy that the final product of these reactions was never S_8BrMF_6. Reactions [1] and [2] were carried out with excess sulphur (see Table 1), allowing for the formation of S_8BrMF_6, and, reasonably S_8Br^+ was initially formed in reaction [4] from S_8^{2+} and Br^-, which presumably disproportionates to the observed S_7Br^+ and elemental sulphur. Reactions [1] and [2] likely proceed wih initial formation of sulphur polyatomic cations. In a separate experiment, a mixture of sulphur polyatomic cations of average composition $S_{17.4}^{2+}$ were reacted with bromine to give S_7Br^+ and elemental sulphur (reaction [3]). In addition, it is noted that sulphur and arsenic and antimony pentafluorides react very rapidly in the presence of bromine to form sulphur polyatomic cations (6). Bromine cations are not likely intermediates in reaction [1] or [2] since bromine cations react with the solvent, sulphur dioxide, to give SO_2BrF (20). S_7BrAsF_6 was also formed by the reaction of S_7IAsF_6 and bromine. The enthalpies of atomisation of I_2(s) and Br_2(l) are essentially the same (Br, 26.7; I, 25.5 kcal/g atom 25°C (21)), and in two coordinate sulphur compounds the S—Br bond (ca. 56 kcal/mmol (8)) is stronger than the S—I bond (49 kcal/mmol (22)). Therefore reaction [4] is likely exothermic and is observed to proceed as indicated.

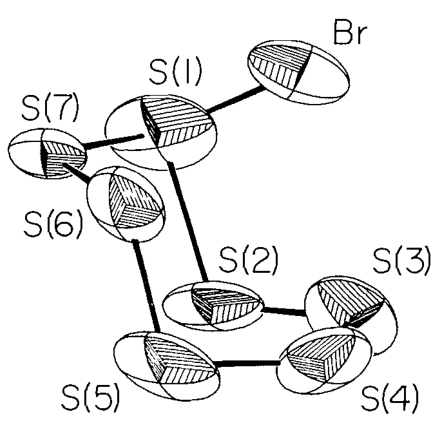

FIG. 1. The structure of the S_7Br^+ cation.

Preparation and characterization of $(S_7Br)_4S_4(AsF_6)_6$

This compound was prepared in ca. 90% yield (see Table 1) in sulphur dioxide solution according to reaction [6]:

$$[6] \quad 4S_8 + 2Br_2 + 9AsF_5 \rightarrow (S_7Br)_4S_4(AsF_6)_6 + 3AsF_3$$

X-ray powder diffraction photographs of this material were not inconsistent with the diffraction pattern calculated on the basis of single crystal diffractometer data. In addition, approximately 20 crystals from this preparation were identified as the title compound by single crystal X-ray precession photography. The experimental data are therefore consistent with the bulk of the material being $(S_7Br)_4S_4(AsF_6)_6$, and not a mixture of various species with this average stoichiometry.

It is noteworthy that $(S_7Br)_4S_4(AsF_6)_6$ is very soluble in the mixture of liquid SO_2 and AsF_3 present at the end of reaction [6], whereas $S_4(AsF_6)_2$ alone has low solubility. Thus, either the cations in solution are different from those in the solid state, or the solubility of $S_4(AsF_6)_2$ is greatly enhanced by the presence of S_7BrAsF_6.

The stabilities of the S_7Br^+*-containing salts*

The S_7Br^+-containing salts are less stable than the corresponding iodides. In addition, we were unable to prepare bro-

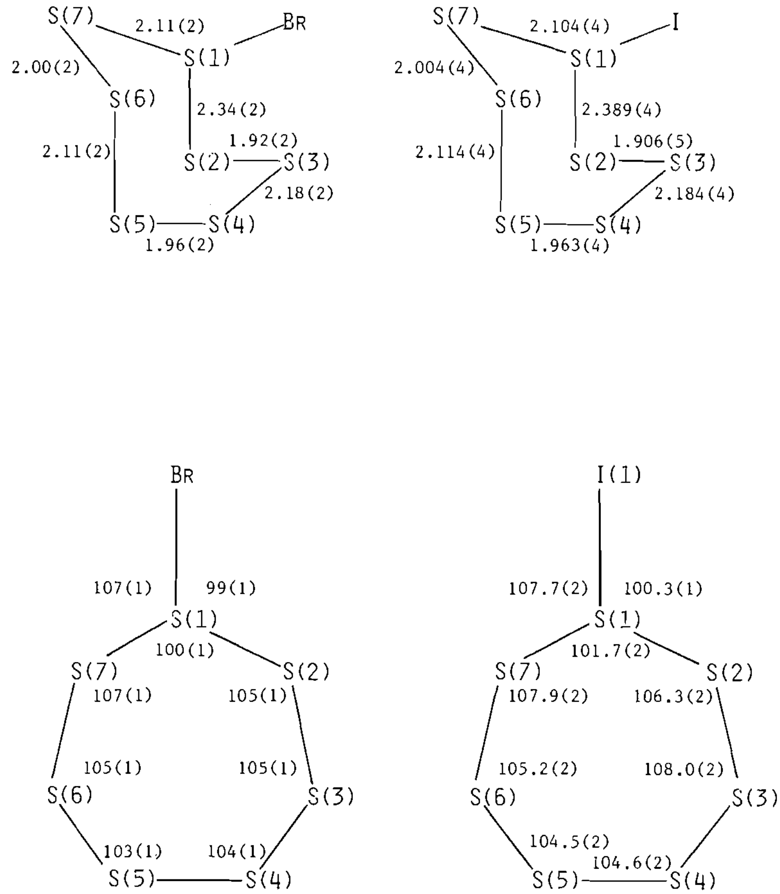

FIG. 2. A comparison of the bond distances (Å) and angles (deg) in S_7Br^+ with those in S_7I^+ in S_7ISbF_6 (3).

mine analogues of $(S_7I)_2I(SbF_6)_3 \cdot 2AsF_3$ (4, 5), and $S_2I_4(AsF_6)_2$ (7), or chlorine analogues of any of the sulphur–iodine cations. This is the opposite of what would be expected on the basis of the relative strengths of the sulphur–halogen bonds, and the relative stabilities of the hitherto known sulphur chlorides, bromides, and iodides, i.e. chlorides are more stable than bromides, which are more stable than iodides. This may, in part, be due to the greater stability of the products of disproportionation of the sulphur bromine (chlorine) cations, S_xBr_2 (S_xCl_2) and SBr_3^+ (9) (SCl_3^+). We note that SI_3^+ has not yet been identified, and S_xI_2 are not stable at room temperature. The relative stabilities of the sulphur bromine cations appears to decrease in the order $(S_7Br)_4S_4(AsF_6)_6 \geq S_7BrSbF_6 > S_7BrAsF_6$, a similar order to that of the corresponding iodides.

The crystal structure of $(S_7Br)_4S_4(AsF_6)_2$

The S_7Br^+ cation is illustrated in Fig. 1, and its geometry is compared to that of S_7I^+ (2, 3) in Fig. 2. Both S_7I^+ and S_7Br^+ have similar geometries to that of S_7O (23), with the sulphur ring having a distorted chair conformation. The neutral S_7 has a chair conformation of essentially C_s symmetry (24). Table 4 lists relevant bond distances and angles for S_7Br^+ and S_4^{2+}, and the ordered AsF_6^-'s. The sulphur–sulphur bond distances and angles within the cation are essentially identical to those of S_7I^+ (2, 3) (see Fig. 2), and the bond alternations within the ring are the same. As in S_7I^+, S(5)S(4)S(3)S(2) and BrS(1)S(2)S(3) are essentially planar, and the angle between the planes is 89.6°. The Br—S(3) contact (3.19(2) Å) is substantially less than the sum of the corresponding van der Waal's radii (3.80 Å) (25) indicating some Br—S(3) interaction. The S(1)—Br distance of 2.11(2) Å is somewhat shorter than the sum of the covalent radii of sulphur and bromine (2.18 Å) and other sulphur bromine bond distances (e.g. SO_2BrF, 2.155(6) (26); SBr_3^+, 2.16 (estimated in ref. 27); S_2Br_2, 2.164(5) (28); $SBrF_5$, 2.190(7) (29, 30); $(BrS)CS_2N_2^+Br_3^+$, 2.205(4) Å (31)). The shortest cation–anion contact is that to bromine, which is nearly linear (Br—F(23) = 2.81(3) Å, S(1)—Br—F(23) = 166(1)°). These features find a parallel in S_7I^+ (2, 3). The rather large standard deviations found for S_7Br^+ data do not allow a meaningful detailed comparison of the two structures. However, the average sulphur–sulphur bond distances and angles within the sulphur rings in S_7I^+ and S_7Br^+ are very similar (S_7I^+ in S_7ISbF_6, 2.095 Å, 105.5°; S_7Br^+, 2.09 Å, 104.1°; compare S_7, 2.066 Å, 104.95° (24)). It is noteworthy that the S_7X^+ unit has been identified in the crystal structures of $(S_7Br)_4S_4(AsF_6)_2$, S_7IMF_6 (M = As, Sb) (2, 3), $[(S_7I)_2I][SbF_6]_3 \cdot 2AsF_6$ (4, 5), and in $S_{19}(AsF_6)_2$ (16), whereas there is no evidence (3) for S_8X^+. Reasons why this might be the case have been suggested (3).

The S_4^{2+} cation is square and planar as is $S_4(AsF_6)_2 \cdot 0.6SO_2$ (6), and $(S_7I)_4S_4(AsF_6)_6$ (4, 6), with an S(8)—S(8') distance of 1.95(2) Å, not significantly different from those found in $S_4(AsF_6)_2 \cdot 0.6SO_2$ (2.015(3), 2.013(3) Å), and $(S_7I)_4S_4(AsF_6)_6$ (1.98(1) Å).[1]

[1] Complete set of data, which includes tables of anisotropic thermal parameters, torsional angles, and dihedral angles in S_7Br^+, and observed and calculated structure factors, may be obtained at a nominal charge, upon request, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

The title compound crystallizes in the monoclinic space group $P2_1$ with two independent molecules in the asymmetric unit (Z = 4). The unit cell dimensions are a = 11.861(2), b = 7.897(1), c = 14.527(3) Å, β = 91.28(1)°. X-ray intensity data were measured on a diffractometer, and the crystal structure was determined by direct methods. Least-squares refinement converged at R = 0.036 for 2980 reflections. The glycosidic torsion angle [C(2)—N(1)—C(1′)—O(1′)] is 53.9° in molecule A and 129.8° in molecule B. In both molecules, the orientation of C(1′)—O(1′) to C(2′)—O(2′) is *trans*. The conformations about C(3′)—C(4′) and C(4′)—C(5′) are different in each of the two molecules. These features are compared with those of acyclonucleoside analogues with antiviral activity. The conformation in aqueous medium was examined with the aid of high-resolution ^{1}H nmr spectroscopy, and the results are compared with those obtained from the X-ray analysis.

GEORGE I. BIRNBAUM, RYSZARD STOLARSKI, ZYGMUNT KAZIMIERCZUK et DAVID SHUGAR. Can. J. Chem. **63**, 1215 (1985).

Le composé mentionné dans le titre cristallise dans le groupe d'espace $P2_1$, avec deux molécules indépendantes dans l'unité asymétrique (Z = 4). Les dimensions de la maille unitaire sont a = 11,861(2), b = 7,897(1), c = 14,527(3) Å, β = 91,28(1)°. On a mesuré les données d'intensité à l'aide d'un diffractomètre et on a déterminé la structure cristalline par des méthodes directes. Un affinement par le méthode des moindres carrés conduit à une valeur de R = 0,036 pour 2980 réflexions. L'angle de torsion glycosidique [C(2)—N(1)—C(1′)—O(1′)] est égal à 53,9° dans la molécule A et 129,8° dans la molécule B. Dans chacune des molécules, l'orientation de C(1′)—O(1′) à C(2′)—O(2′) est *trans*. Les conformations autour de C(3′)—C(4′) et C(4′)—C(5′) sont différentes dans chacune des deux molécules. On compare ces caractéristiques avec celles d'analogues acyclonucléosides possédant une activité antivirale. On a étudié la conformation en solution aqueuse en faisant appel à la rmn du ^{1}H à haute résolution et on a comparé les résultats avec ceux obtenus par diffraction des rayons X.

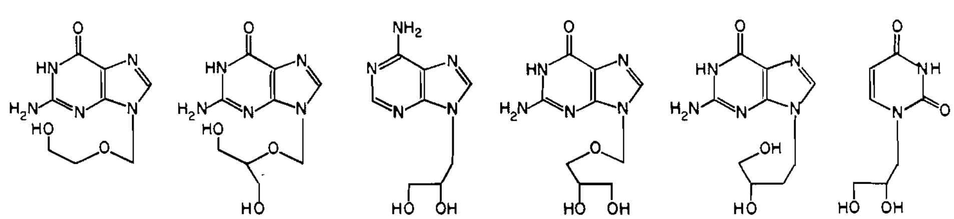
[Traduit par le journal]

Introduction

The 2′,3′-dialdehyde derivatives of ribonucleosides and ribonucleotides, obtained by periodate oxidation of the parent nucleosides and nucleotides, have been reasonably well characterized (1–3) and have been employed as affinity labels in a number of enzymatic systems (4, 5). Their subsequent reduction by borohydride leads to 2′,3′-seco analogues, which differ from the parent compounds only by the absence of the C(2′)—C(3′) bond. A number of such seconucleosides (and -nucleotides) have been prepared (6) and their biological activities examined (7, 8).

The foregoing take on added significance in relation to the known antiviral activities of other acyclonucleoside analogues in which the pentose ring is replaced by an acyclic chain. Interest in these originally stemmed from reports that acyclovir (ACV) is a potent antiherpes agent (9, 10), now licensed for treatment of herpes simplex type 2 virus infections. Subsequent members of this class include, amongst many others, 9-(1,3-dihydroxy-2-propoxymethyl)guanine (DHPG, 2′NDG), with in vitro antiviral activity superior to that of acyclovir (11–13), and others with lower activities, e.g. 9-(2,3-dihydroxypropyl)adenine (DHPA) (14), 9-(2,3-dihydroxy-1-propoxymethyl)guanine (DHPMG) (15, 16), and 9-(3,4-dihydroxybutyl)guanine (DHBG) (17).

Although the flexibility of the acyclic chains of these analogues would be expected to lead to equilibrium mixtures of conformers in solution, they are all capable of adopting conformations resembling a portion of the pentose rings, a factor

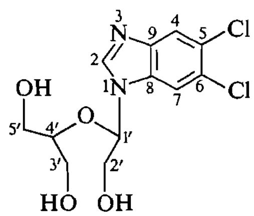


ACV DHPG DHPA DHPMG DHBG DHPU

[1] NRCC No. 24008.

which undoubtedly plays a role in their biological activities (18) and, in particular, in their reactions with enzyme systems involved in such activities. For example, yeast tRNA^{Phe}, in which the 3′-terminal AMP residue has been converted to the 2′,3′-seco form by oxidation–reduction, readily undergoes aminoacylation (19). Since it is the 3′-hydroxyl which is specifically aminoacylated in the unmodified tRNA (20), it may be inferred that the stereochemistry of this group in the seco-tRNA is retained, at least on interaction with the enzyme.

Although little is known about preferred solution conformations, the solid state structures and conformations of several of them have been determined (21–23; Hirschfield and Hoogsteen, unpublished). During the course of an investigation (24) on structure–activity relationships of 5,6-dichloro-1-β-D-ribofuranosylbenzimidazole (DRB), a known reversible inhibitor of nuclear RNA synthesis (25, 26) some analogues of which also possess antiviral activity (27), periodate oxidation and subsequent borohydride reduction gave the 2′,3′-seco derivative of DRB (seco-DRB) in the form of crystals suitable for X-ray diffraction. We report here on the solid-state and solution conformations of this analogue of acyclonucleosides. Such data should be of relevance to some of the reported activities in biological systems of oxidized–reduced nucleosides and nucleotides. In separate studies on the biological properties of such acyclonucleosides, now in progress, we have found that 2′,3′-secoguanosine is a more effective inhibitor of purine nucleoside phosphorylase than ACV or DHPG (unpublished observations).



Experimental

Seco-DRB was prepared according to the general procedure described by Lerner (6) and Rosenthal *et al.* (1). To 1 g (3 mmol) of DRB, dissolved by heating in 20 mL dioxane and 40 mL water, and then cooled to room temperature, was added 0.9 g (4 mmol) KIO_4 with stirring over a period of 30 min. The mixture was stirred for an additional hour and the reaction terminated by addition of 0.6 mL of ethylene glycol. The product was then reduced by addition of 2.2 g $NaBH_4$ and stirring for 3 h. Excess borohydride was decomposed by acidification to pH 1 and the solution was then brought to neutrality and loaded on a column (6 × 30 cm) of 100/200 XAD-4. Elution was with a 0–90% aqueous methanol linear gradient. The fractions between 70 and 80% methanol were pooled and brought to dryness below 35°C under vacuum to yield 0.64 g (65%) of seco-DRB. A portion was taken up in water at 80°C (50 mg/mL) and allowed to cool slowly to give four- and five-sided plates, mp 148°C.

The ^{1}H nmr spectrum of a single crystal of seco-DRB dissolved in 0.4 mL of 99.8 at.% D_2O at 310 K was recorded at 500 MHz. A Bruker AM-500 spectrometer was used with 32 K points for the free induction decay. Chemical shifts are expressed relative to the signal for HOD, δ 4.60 ppm at 310 K, which also corresponds to 1% dioxane at δ 3.71 ppm as the external reference. Gated presaturation of the HOD resonance was employed for solvent suppression, and homonuclear decoupling was conducted in combination with suppression of the HOD signal.

X-ray precession photographs indicated space group $P2_1$. A crystal fragment measuring 0.40 × 0.40 × 0.15 mm was mounted on a CAD4 diffractometer; the crystal data are as follows:

[a] All values were multiplied by 10^4.

$C_{12}H_{14}N_2O_4Cl_2$ fw = 321.2
Monoclinic, a = 11.861(2), b = 7.897(1), c = 14.527(3) Å, β = 91.28(1)°, V = 1360.35 Å^3, ρ_c = 1.57 g cm^{-3}, Z = 4 (20°C; MoKα_1, λ = 0.70930 Å); F(000) = 664, μ(MoKα) = 4.9 cm^{-1}.

Intensities were measured with monochromatized MoKα radiation, using ω/2θ scans with variable scan ranges and speeds. There were 3506 unique reflections with 2θ ≤ 56°; of those, 2985 had $I \geq 3\sigma(I)$ and were considered observed. The intensities were corrected for Lorentz and polarization factors; absorption corrections were considered unnecessary.

The structure was determined by direct methods with the aid of the computer program MULTAN78 (28). Of the 12 starting sets subjected to tangent refinement, the solution with the highest combined figure of merit yielded an E map on which 37 of the 40 nonhydrogen atoms in the asymmetric unit (two independent molecules, labelled A and B) could be located. The other three atoms were found on difference Fourier maps. The atomic parameters of these atoms were refined by block-diagonal least squares with anisotropic temperature parameters. All hydrogen atoms were located on difference Fourier maps and most were refined with isotropic temperature parameters. The atomic parameters of H(5″A) and the temperature parameters of seven other hydrogen atoms were not refined. The scattering factors were taken

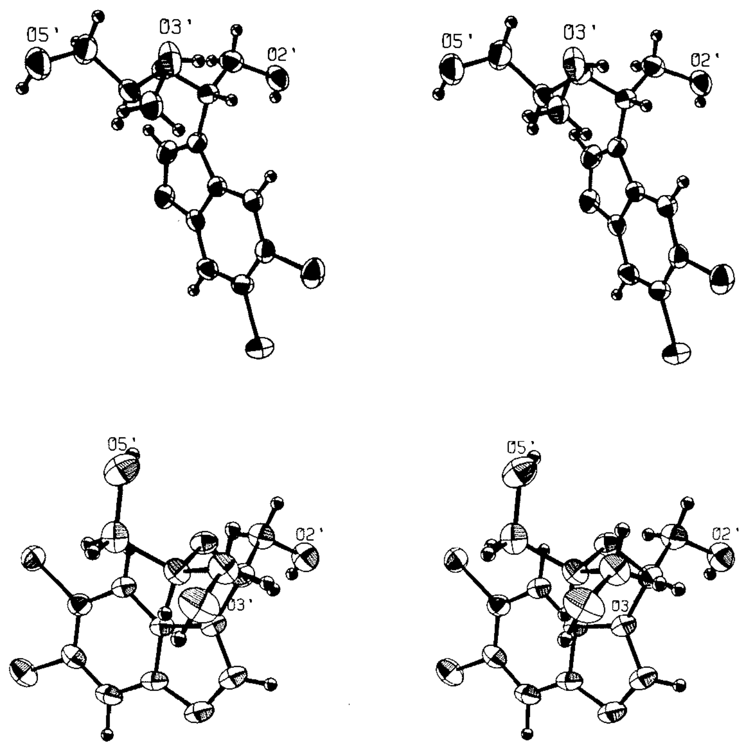

FIG. 1. Stereoscopic views of molecules A (top) and B (bottom) of seco-DRB; the thermal ellipsoids correspond to 50% probability.

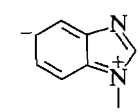
from the International Tables for X-Ray Crystallography (29) and the chlorine curve was corrected for anomalous dispersion. Throughout the refinement the function $\Sigma w(|F_o| - |F_c|)^2$ was minimized and a factor of 0.8 applied to all shifts. The following weighting scheme was used during the final stages: $w = w_1 \cdot w_2$, where $w_1 = 1$ for $|F_o| \leq 20$, $w_1 = 20/|F_o|$ for $|F_o| > 20$; and $w_2 = \sin^2\theta/0.2$ for $\sin^2\theta < 0.2$, $w_2 = 1$ for $\sin^2\theta \geq 0.2$. This scheme made the average values of $w(\Delta F^2)$ independent of $|F_o|$ and $\sin^2\theta$. After the final cycle the average parameter shift equalled 0.1σ and the largest one 0.4σ. The conventional residual index R is 0.036 and the weighted index R' is 0.043 for 2980 reflections (five reflections suffered from extinction and were given zero weights). A final difference Fourier map showed no significant features. The coordinates of nonhydrogen atoms are listed in Table 1. Anisotropic temperature parameters, hydrogen atom parameters, deviations of atoms from mean planes, and a list of observed and calculated structure factors are available.[2] Stereoscopic views of the two molecules are shown in Fig. 1.

Results and discussion

Benzimidazole moieties

In molecule A all atoms of the benzimidazole ring system are coplanar, the largest deviation from planarity (for C(2)) being 0.010(4) Å. Cl(6) lies in the mean plane but Cl(5) and C(1′) are displaced from it by 0.039(1) and 0.029(4) Å, respectively. In molecule B the imidazole ring is perfectly planar but the benzene ring has the shape of a shallow boat with C(5) and C(8) deviating from the mean plane by 0.013(4) and 0.011(3) Å, respectively. The displacements of the substituents are larger than in molecule A.

Most bond lengths and bond angles (Fig. 2) in the two molecules are in excellent agreement. The differences between the exocyclic angles at N(1) are undoubtedly due to the different conformations of the acyclic sugar moiety (see below), but there does not appear to be a reasonable explanation for the difference in the C(6)—C(7) bond length. Details of the geometry may be compared with values observed in unsubstituted benzimidazoles (30–32) and in two riboside derivatives (33, 34). A striking feature is the absence of symmetry in both groups of compounds. In the solid state, only one tautomer of the imidazole ring is observed, leading to asymmetry about a



line passing through C(2) and bisecting C(5)—C(6). Furthermore, there is no symmetry in the benzene rings, even in unsubstituted benzimidazoles. After averaging the bond lengths, we see that the longest ones are C(5)—C(6), C(8)—C(9), and C(7)—C(8). The shortest bond is C(6)—C(7), followed by C(4)—C(9). These results appear to indicate that, of the various charged resonance forms of benzimidazole, the one shown below is the most significant. The distribution of bond angles is also asymmetric. Thus, C(6)—C(7)—C(8) is the smallest angle in the benzene ring, C(9)—C(4)—C(5) being the next smaller one. The same pattern is also observed in some substituted benzimidazoles (33, 34). Cl substitution of the benzene ring would be expected to deform the bond angles by up to 1.2° (35) but disubstitution of two *ortho* atoms almost cancels this effect.

Sugar moieties

The conformation of the acyclic sugar moiety (Fig. 3) is different in each of the two molecules. The glycosidic torsion angle [C(2)—N(1)—C(1′)—O(1′)] is in the *syn* range in molecule A and in the *anti* range in molecule B. In each case an N—C bond is *gauche* to the C(1′)—O(1′) and the C(1′)—C(2′) bonds, while another N—C bond almost eclipses

[2]These tables may be obtained, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1S 0S2.

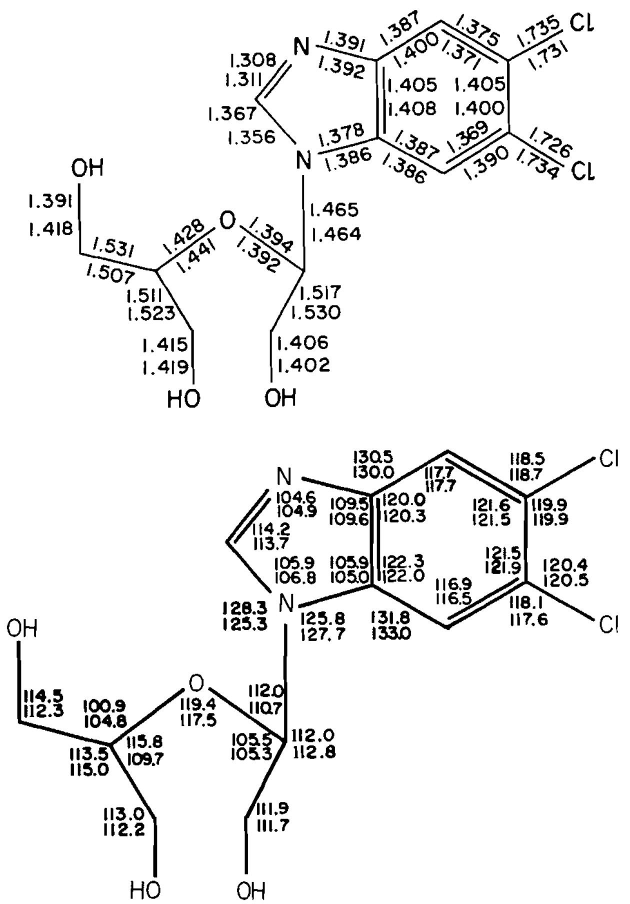


FIG. 2. (Top) Bond distances (in ångströms); their estimated standard deviations (esd's) are 0.003–0.005 Å, except for C(4′)—C(5′) and C(5′)—O(5′) in molecule A (0.006 Å). (Bottom) Bond angles (in degrees); their esd's are 0.2–0.3°. The upper and lower values refer to molecules A and B, respectively.

the C(1′)—H(1′) bond. It should be noted that in both molecules the O(1′)—C(1′)—N(1)—C torsion angle is smaller than C(2′)—C(1′)—N(1)—C. These are clearly the most stable conformations; their equivalence is illustrated by identical C(8)···H(1′) (mol. A) and C(2)···H(1′) (mol. B) distances (2.55–2.56 Å). We would predict that these conformations will be found in other acyclonucleoside analogues in which C(1′) is a tertiary carbon atom. On the other hand, in those analogues in which C(1′) is secondary, as in acyclovir (21), DHPG (Hirschfield and Hoogsteen, unpublished), *S*- and *RS*-DHPA (22), and in a derivative of 1-(2,3-dihydroxypropyl) uracil (DHPU) (23) the conformation about N—C(1′) is such that the C(1′)—X bond (where X is O(1′) or C(2′)) is approximately perpendicular (90 ± 20°) to the aglycon.

The orientation of the aglycon with respect to the sugar moiety appears unusual (Fig. 1), but a 120° rotation about the C(1′)—O(1′) bond brings about a conformation normal for β-nucleosides. In both molecules C(2′)—O(2′) is *trans* to C(1′)—O(1′). This is the conformation which is observed in ribofuranose rings with a C(2′)-*endo* pucker. C(3′)—O(3′) is *gauche*$^+$ with respect to C(4′)—O(1′) in molecule A and *trans* in molecule B. These conformations correspond to C(3′)-*endo* furanose rings with *xylo* and *ribo* configurations, respectively. Finally, C(5′)—O(5′) is *gauche*$^-$ to C(3′)—C(4′) in molecule A and *gauche*$^+$ in molecule B. Thus, of the six O—C—C—O interactions in the two molecules, four are found in *trans* and two in *gauche* conformations. As pointed out recently (18, 36), the *gauche* effect (37) is rather weak for C—O/C—O interactions and can be easily overcome by intermolecular hydrogen bonds or other packing forces. Nevertheless, its influence should become apparent when one surveys a large number of structures, because the effects of packing forces would be largely cancelled out. In the 1984 Cambridge Structural Database (38) we found 231 O—CH_2—CR_2—O fragments for which we calculated the O—C—C—O torsion angles. In the absence of the *gauche* effect, we would expect the *trans* rotamer, in which steric interactions are reduced, to be preferred over the two *gauche* conformers. In fact, we found only 53 *trans* rotamers, which confirms the existence, but also the weakness, of the *gauche* effect. These results are in general agreement with the observation of both *trans* and *gauche* conformations of C—OH bonds in acyclic polyols (39).

Most bond lengths in the two molecules are in very good agreement (Fig. 2), the only significant differences being at C(4′)—C(5′) and C(5′)—O(5′). The latter is most likely attributable to the different thermal parameters of O(5′). It is noteworthy that in this acyclic moiety C(1′)—O(1′) is significantly shorter than O(1′)—C(4′), a phenomenon generally observed in nucleosides. The bond angles at C(1′), C(2′), and C(3′) are not only the same in both molecules but also quite similar to those observed in ribofuranose rings. On the other hand, the angles at O(1′), C(4′), and C(5′) are different in both respects. C(1′)—O(1′)—C(4′) is unusually large, significantly larger than in acyclovir and in DHPG. It is possible that short intramolecular contacts between H(1′) and H(3′), 2.24–2.25 Å, are responsible for this (see Fig. 1). The differences between the angles at C(4′) are probably attributable to the different conformations about C(3′)—C(4′) and C(4′)—C(5′) (Fig. 3).

Hydrogen bonding and packing

Each molecule has three hydroxyl protons capable of participating in hydrogen bonds. The network formed by these bonds can be described as follows:

O(5′A)—H···O(2′B)—H···O(5′B)—H···N(3A)
O(3′B)—H···O(2′A)—H···O(3′A)—H···N(3B)

The geometry of the hydrogen bonds is given in Table 2. As commonly observed in X-ray analyses, the O—H bonds appear shorter than their real length. By extending the covalent bond lengths to their nominal value of 0.97 Å one obtains corrected H···*A* distances which reflect more accurately the strengths of these hydrogen bonds. The strongest bonds are seen to be those in which the proton donor also acts as an acceptor, a phenomenon known as the cooperativity effect (40). The O(2′B)—H···O(5′B) bond is unusually strong, particularly since it is part of a very short chain.

The molecules are packed so as to form pleated sheets, consisting of hydrophobic benzimidazole rings in molecules A and B and extending along *x* (Fig. 4). The dihedral angle between adjacent benzimidazoles is 121.4°. Located between the hydrophobic sheets are hydrophilic regions consisting of the carbohydrate moieties. The packing is stabilized by the hydrogen bond network described above.

Solution conformation

Solution conformations of 2′,3′-seconucleosides and -nucleotides have hitherto received relatively little attention. It was originally proposed by Cramer *et al.* (41), from an examination of CPK models, that a seconucleoside molecule should have a relatively rigid acyclic chain because of the steric effects of the

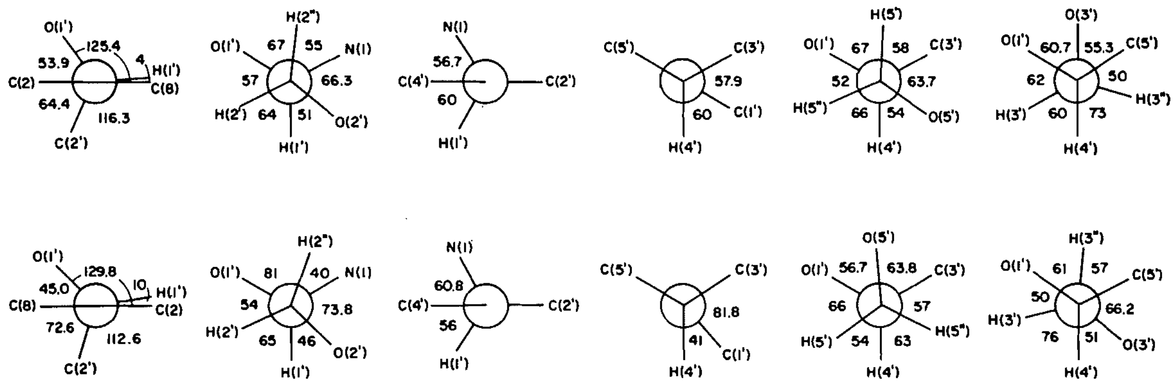

FIG. 3. Newman projections along N(1)—C(1′), C(1′)—C(2′), C(1′)—O(1′), O(1′)—C(4′), C(4′)—C(5′), and C(3′)—C(4′) in molecules A (top) and B (bottom).

D A	A at	Distances, Å $D\cdots A$	$H\cdots A$	$H\cdots A_{corr}$	Angles, deg D—$H\cdots A$
O(5′A)—H···O(2′B)	$-1+x, y, z$	2.861	1.93	1.90	169
O(2′B)—H···O(5′B)	$x, 1+y, z$	2.607	1.74	1.65	168
O(5′B)—H···N(3A)	$1+x, y, z$	2.888	2.12	1.92	175
O(3′B)—H···O(2′A)	x, y, z	2.862	2.04	1.90	170
O(2′A)—H···O(3′A)	$x, -1+y, z$	2.668	1.90	1.75	157
O(3′A)—H···N(3B)	x, y, z	2.758	2.07	1.82	162

additional hydrogens at C(2′) and C(3′). However, a subsequent examination of the ^{1}H nmr spectra of the seco-nucleotides derived from AMP and ATP (19) led to the conclusion that free rotation about the C(1′)—C(2′) bond is possible. An analogous conclusion was arrived at by Lowe and Beechey (2) from an analysis of the 360-MHz ^{1}H spectrum of seco-ATP. These authors further proposed that similar free rotation is possible about the C(3′)—C(4′) bond. However, only the H(1′) and H(2′) signals were resolved in the foregoing investigations, and no attempts were made to determine relative rotamer populations.

The conformation of seco-DRB in solution was examined with the aid of ^{1}H nmr spectroscopy. A 500-MHz spectrum of an aqueous solution yielded chemical shifts and coupling constants listed in Table 3. The population values of the staggered rotamers about the three C—C bonds in the acyclic moiety (Fig. 5) were evaluated from the Karplus relation, assuming a dynamic equilibrium between conformers and using the relationship with six parameters (three substituents other than protons on each C—C fragment) proposed by Haasnoot *et al.* (42). The proton–proton torsion angles were assumed to be ±60° or 180°. For each bond one can calculate rotamer populations for both the possible assignments of the AB protons in an ABX system. The results of these calculations are given in Table 4. While we cannot determine which of the two sets is the correct one, we can compare these values with the results of the X-ray analysis (Fig. 3) which, fortuitously, established the conformation of two independent molecules. In the case of the C(1′)—C(2′) bond, the first set of values indicates a 2:1:1 distribution of the *trans*, *gauche*$^+$, and *gauche*$^-$ rotamers, respectively, while the second one points to a preference of *gauche*$^+$. The X-ray analysis revealed a *trans* conformation in both molecules. For the C(3′)—C(4′) bond, both sets indicate a slight preference for the *gauche*$^+$ rotamer with a secondary preference for either *trans* or *gauche*$^-$. In the solid state we found one *gauche*$^+$ and one *trans* rotamer. Finally, for the C(4′)—C(5′) bond, there is a choice between equal populations of either *trans* and *gauche*$^-$ or *gauche*$^+$ and *gauche*$^-$ rotamers. In the crystal structure we observe one *trans* and one *gauche*$^-$ conformation. Thus, the first set of values in Table 4 is in better agreement with the results of the X-ray analysis than the second one. It should be pointed out that there is no dom-

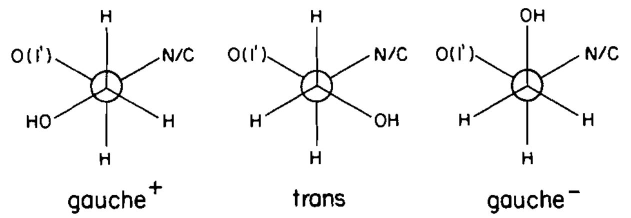

FIG. 5. *Gauche*$^+$, *trans*, and *gauche*$^-$ conformations about the C(1')—C(2'), C(3')—C(4'), or C(4')—C(5') bonds.

[a]For each bond, the values in the second row were obtained from reverse assignment of geminal AB protons.

inant conformation about any of these three bonds, indicating a relatively low energy barrier to rotation. We conclude, therefore, that the molecule can easily adopt whatever conformation is necessary for binding to an enzyme or other receptor.

We also obtained ^{1}H nmr spectra in DMSO-d_6 and in CD_3OD on a 100-MHz spectrometer. Owing to poor resolution, we were able to calculate relative populations only about the C(1')—C(2') bond. The results are in qualitative agreement with the values in Table 4.

Acknowledgements

We are very much indebted to Dr. David R. Bundle for recording the 500-MHz spectra and to Dr. Irena Ekiel for assistance with the nmr analysis. We are grateful to Dr. R. L. Tolman (Merck Sharp & Dohme Research Laboratories) for the results of the X-ray analysis of DHPG. Apart from the MULTAN system, all crystallographic calculations were carried out with programs written by Ahmed *et al.* (43). Figures 1 and 4 were drawn with the ORTEP program of Johnson (44).

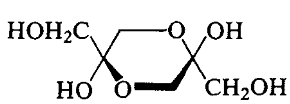
Labile 1,6-dihydroxy-2-hexanone (**4**) was prepared from the corresponding triol by selective di-*O*-tritylation, Collins oxidation, and careful detritylation of the resulting keto compound **3** under mild, acidic conditions. As shown by its ^{1}Hmr and ^{13}Cmr spectra, **4** exists as a 3:2 mixture of open-chain and cyclic forms, respectively, at equilibrium in deuterium oxide (25°C). Upon standing, **4** is slowly converted into a hemiacetalic dimer. Under acidic conditions, dehydrative dimerization takes place to give the corresponding tricyclic dianhydride, one or both of the possible isomers (1:1 mixture) of which being formed according to the presence or absence of water in the medium. The structure (*trans*) of the thermodynamic isomer **5** was firmly established by an X-ray crystallographic analysis.

WALTER A. SZAREK, OLIVIER R. MARTIN, ROBERT J. RAFKA et T. STANLEY CAMERON. Can. J. Chem. **63**, 1222 (1985).

La dihydroxy-1,6-hexanone-2 (**4**), un analogue simple et relativement instable des cétohexoses, a été préparée à partir du triol correspondant par di-*O*-tritylation sélective, oxidation de Collins, et détritylation acido-catalysée du composé cétonique protégé **3** dans des conditions très douces. D'après les spectres de rmn (^{1}H, ^{13}C), les deux formes tautomères ouverte et cyclique de **4** sont présentes en proportion 3:2 à l'équilibre dans l'eau lourde (25°C). Au repos, le composé **4** se transforme peu à peu en un dimère hémiacétalique. En milieu acide, **4** subit une dimérisation déshydratante pour conduire au dianhydride tricyclique correspondant, ce dernier étant obtenu sous la forme d'un seul ou des deux isomères possibles selon que le milieu contient de l'eau ou non. La structure (*trans*) de l'isomère thermodynamique **5** est établie sans ambiguité par une analyse cristallographique aux rayons X.

Introduction

In continuation of our studies related to the origin of the high sweet taste of D-fructose (1), we turned our attention to a very simple analog of the ketohexoses, namely 1,6-dihydroxy-2-hexanone, or 2-hydroxy-2-(hydroxymethyl)tetrahydropyran in its cyclic, hemiacetalic form. This compound was of interest because of the fact that, according to Shallenberger (2) and Kier (3), it contains, in its cyclic form, only the AH, B, γ (OH, CH_2OH, 6-CH_2) unit considered as the major site of binding of



I

D-fructose with the sweet taste receptor, and because of the fact that, according to Birch (4), it should be able to "polarize" on the receptor, in contrast to the slightly sweet, "symmetrical" dimer of dihydroxyacetone (I). The presence of a large proportion of non-cyclic form in the constitutional equilibrium of this "trideoxyketose", however, might impose serious limitations to the validity of sweetness evaluation tests.

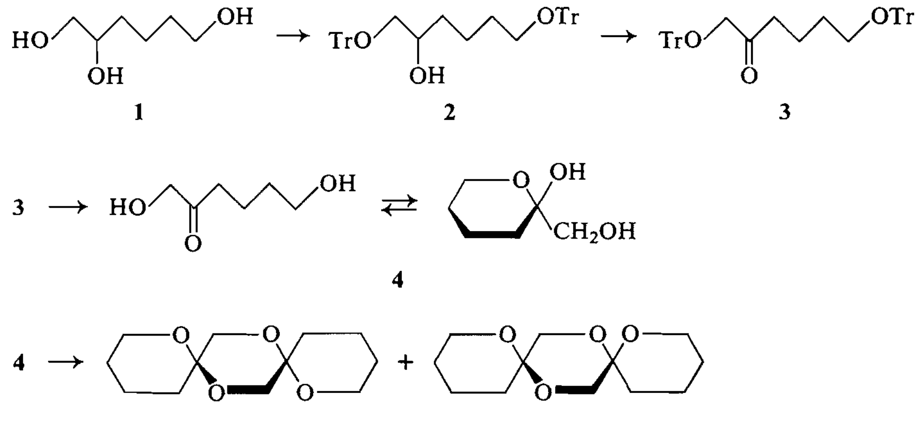
Previous ring-chain tautomerism studies of the simplest analogs of the ketoses (5) have established that 5-hydroxy-2-pentanone and 6-hydroxy-2-hexanone are less prone to exist in the cyclic form than the corresponding ω-hydroxyaldehydes (6), as expected from the lower reactivity of ketones as compared to aldehydes, and show a slight preference for the open-chain form in most organic solvents. If the presence of substituents on the ring stabilizes the cyclic form and increases the cyclic/open-chain ratio, the effect of a substituent (OH) at C(1) on this ratio was expected to be weak and a substantial proportion of open-chain form was anticipated for 1,6-dihydroxy-2-hexanone.

The only attempted preparation of 1,6-dihydroxy-2-hexanone has been reported by Owen and Peto (7). Ozonolysis of 2-methylene-1,6-hexanediol and treatment of the resulting ozonide with zinc and acetic acid gave a dianhydride which could not be cleaved to the expected dihydroxyketone. We describe in this article the first synthesis and the unusual properties of this "trideoxyketose" as well as an X-ray crystal structure determination of the corresponding *trans*-dianhydride **5**.

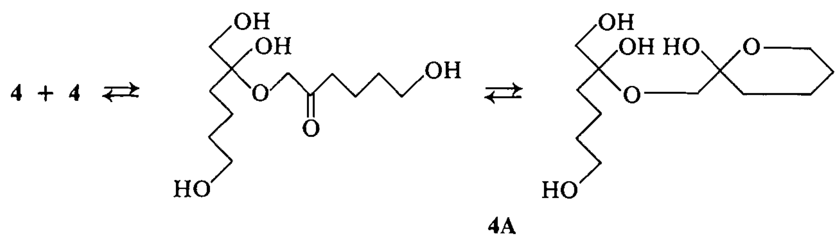
Results and discussion

The synthesis of 1,6-dihydroxy-2-hexanone (**4**) was realized in three steps from the corresponding triol **1** (Scheme 1). Commercially available **1** was selectively protected as its 1,6-di-*O*-trityl ether **2** and the secondary alcohol function of **2** oxidized, using $CrO_3 \cdot 2py - CH_2Cl_2$ (8), to the crystalline keto derivative **3** in excellent yield. The first attempts of detritylation of **3** rapidly revealed the unstable nature of **4**, and its formation from **3** constitutes the critical step of the synthesis. Catalytic hydrogenation of **3** did not give any satisfactory result, and the trityl groups of **3** had to be removed by acid-catalyzed hydrolysis. The best results were obtained by treating **3** in 7:2 (v/v) 1,4-dioxane – water (clear solution of **3**) with trifluoroacetic acid (final concentration ~6% (v/v)) at 55°C for 2 h, after which time the analysis of the mixture showed the presence of the expected product and triphenylcarbinol only. Upon processing under the mildest conditions (complete neutralization of the mixture with a basic ion-exchange resin before

[1] Revision received November 28, 1984.



SCHEME 1



SCHEME 2

any other operation is essential), homogeneous **4** could be isolated in 62% yield. Rapid chromatography on silica gel gave a very pure sample of syrupy 1,6-dihydroxy-2-hexanone (**4**).

The difficulties in obtaining clean detritylation of **3** arise mainly from the high tendency of **4** to form a tricyclic dianhydride under acidic conditions. Thus, for example, treatment of **3** with 80% acetic acid at reflux temperature gave a mixture of **4**, the dianhydride **5**, and two other compounds of intermediate mobility (tlc) which disappeared after addition of an aqueous base (most probably the 2-acetate of **4** and another acylhemiacetal); **4** and **5** were isolated in yields of 45% and 11%, respectively.

The complete dehydrative dimerization of **4** could be achieved, for example, in anhydrous 1,4-dioxane in the presence of trifluoroacetic acid; under these conditions, the two possible isomers **5** and **6** were formed in a 1 : 1 ratio, the former *trans*-isomer being identical to the dianhydride reported by Owen and Peto (7).

Finally, upon standing, 1,6-dihydroxy-2-hexanone (**4**) was found to give slowly, among other minor products, a slightly faster-moving (tlc) compound which was separated from the original material by column chromatography. Upon treatment with an aqueous acid, this compound yielded immediately and quantitatively the starting **4**, a behavior consistent with the dimeric, hemiacetalic constitution **4A** (Scheme 2).

Structural analysis

The ^{1}Hmr spectral analysis of **4** showed that the open-chain, keto form is slightly preponderant (55%) in deuterated dimethylsulfoxide, as in the case of 6-hydroxy-2-hexanone (5). However, the behavior of **4** in water is very different; as shown by the ^{1}Hmr spectrum, the proportion of the cyclic form of **4** is appreciable (40%), whereas no hemiacetalic form was observed for 6-hydroxy-2-hexanone in aqueous medium. The ^{13}Cmr spectrum of **4** in deuterium oxide is given in Fig. 1. The higher polarity of 2-hydroxy-2-(hydroxymethyl)tetrahydropyran as compared to 2-hydroxy-2-methyltetrahydropyran does not seem to be a sufficient reason to account for this result, no difference being observed between the two hydroxyketones in polar solvents such as dimethylsulfoxide; favorable hydrogen bonding with the solvent, involving a proton-donor and a proton-acceptor group, might also be a factor stabilizing the cyclic form of 1,6-dihydroxy-2-hexanone in water.

The electron-impact mass spectrum of **4** exhibits two major fragmentations which are driven by the high stability of the (di)oxonium cations derived from its cyclic form (see Scheme 3).

The tricyclic dianhydrides of **4** are the simplest analogs of the long-known diheterolevulosans I and IV, two of the di-D-fructose dianhydrides obtained by the action of concentrated acid on D-fructose (9, 10). The 1,4-dioxane ring of the C_i-symmetrical *trans*-isomer (see **5**, *trans*) is expected to adopt a stable chair conformation with both OR substituents (C(6)—O(1) and C(9)—O(10) bonds) in an axial disposition (anomeric effect, see ref. 11 for the conformation of a related di-D-fructose dianhydride) whereas the C_2-symmetrical *cis*-isomer (see **6**, *cis*) undergoes rapid interconversion between two identical chair conformers.

Name	X/a	Y/b	Z/c
C(1)	464(4)	4348(3)	1305(2)
C(2)	3928(5)	3431(4)	2110(3)
C(3)	3663(5)	3346(4)	3508(3)
C(4)	2080(5)	4515(3)	3744(3)
C(5)	79(5)	4360(3)	2701(3)
C(6)	−1448(4)	3990(3)	263(3)
O(1)	1992(3)	3261(2)	1160(2)
O(2)	1185(3)	5824(2)	1065(2)

The ^{1}Hmr spectra of the two isomers are very similar and exhibit in each case a typical AB system for the two equivalent pairs of protons of the 1,4-dioxane ring. The well-resolved signals of the protons at C(2), C(11) and C(5), C(14) of the *cis*-isomer **6** indicate that the tetrahydropyran rings of the tetraoxadispirohexadecane system probably adopt the chair conformation in which the C(6)—O(7) and C(9)—O(15) bonds are axially oriented with respect to these rings, the same conformation existing in the solid state (see Fig. 2).

The relative configurations of **5** and **6** cannot be assessed on the basis of their ^{1}Hmr spectra at room temperature. Although their thermodynamic stabilities strongly suggested the *trans*-diaxial configuration of **5** (see below), their structures were firmly established by an X-ray crystallographic analysis of the highly crystalline isomer **5**. Figure 2 shows a perspective view of the molecule; the atomic parameters are documented in Tables 1–3.

X-ray crystallographic analysis of **5**

Crystallographic numbering (see Fig. 2) has been used in this Section and in Tables 1–3.

$C_{12}H_{20}O_4$ fw = 228.29

Monoclinic $P2_1/c$, $a = 6.532(1)$, $b = 8.856(3)$, $c = 10.268(4)$ Å, $\beta = 102.30(2)°$, $V = 580.33$ Å^3, $Z = 2$, $\rho_c = 1.306$ g cm^{-3} (22 ± 1°C; MoKα_1, $\lambda = 0.70926$ Å (graphite monochromator) $\mu = 0.58$ cm^{-1}), $F(000) = 248$.

A crystal of about 0.3 × 0.4 × 0.6 mm was mounted along the long axis. The cell dimensions were refined from 25 general reflections with the Bragg angle θ in the range 12–14° on a CAD4 diffractometer. 1131 reflections were measured in the range θ 2–25° of which 578 had $I > \sigma(I)$. The data were reduced to a standard scale by routine procedures (12) and were corrected for Lorentz and polarization factors but not for extinction or absorption. Reflections with E 1.2 were used to solve the structure by an application of the tangent formula that examined 4096 (2^{12}) sets of starting phases and eliminated progressively all but the most likely combinations. This procedure is part of an X-ray system written by Sheldrick (13). The positions of all but the hydrogen atoms were found on the resultant E map.

The structure was refined by full-matrix, least-squares procedures, minimizing $\Sigma w(\Delta F)^2$ with isotropic temperature factors on all the atoms. The hydrogen atoms were located from a difference Fourier synthesis when R was 0.07. Refinement continued with anisotropic temperature factors on all but the hydrogen atoms, and it converged with $R = 0.041$. The stan-

dard deviation (σ) for each reflection was used for the weights during the refinement and the values of σ were determined from the diffractometer counting statistics.

Table 1 gives the final atomic coordinates.[2] The atomic scattering factors are taken from International Tables for X-ray Crystallography (1974). The interatomic distances, interbond angles, and torsional angles are given in Tables 2 and 3. Figure 2 shows a view of the molecule projected down *a*.

The crystal is constructed from isolated molecules of **5**, with the molecules themselves each containing a crystal symmetry center. There is no sign of disorder and thus **5** is confirmed to have the *trans* configuration. The C—C bond lengths are in the range 1.484(5)—1.519(4) Å, with C(2)—C(3) at 1.484(5) being possibly just significantly shorter than the others and with C(3)—C(4) at 1.519(4) just significantly longer. The C—O bond lengths are essentially equivalent with a range of 1.417(3)—1.431(4) Å. All three rings have the chair conformation; the torsional angles of the ring bonds in the central ring are 53.1(3), −52.5(3), and 55.0(3)° for the angles about C(6)—C(1), C(1)—O(2), and O(2)—C(6), respectively (the remaining three angles are related by the center of symmetry to the three already quoted, where they have the appropriate value with the opposite sign); the torsional angles in the external rings are −54.7(3), 57.9(4), −56.0(4), 52.6(4), −51.4(3), and 52.3(3)° for C(1)—O(1), O(1)—C(2) . . . . C(5)—C(1). In the central and external rings the mean torsional angles are ±53.5 and 54.1° which are somewhat less than ±55.9° that has been observed for cyclohexane (14).

Mechanistic aspects of dimer formation
