JAMES FREDERICK KING, JOHN HENRY HILLHOUSE, and KISHAN CHAND KHEMANI. Can. J. Chem. **63**, 1 (1985).

Reaction of thiirane 1,1-dioxide (**1**) with aqueous barium hydroxide gives chiefly barium ethanesulfonate (**3**) together with some ethylene and barium sulfite, and only a small amount (<5%) of barium 2-hydroxyethanesulfinate (**2**), the material previously described by Hesse *et al.* as the major product of this reaction. Reaction of **1** with potassium hydroxide proceeds analogously except for the formation of barium 2-sulfinatoethanesulfonate (**6**) from reaction of potassium sulfite with unreacted **1**. This revision, when taken with what is already known of the final step of the Ramberg–Bäcklund reaction, provides a consistent picture of the reaction of thiirane 1,1-dioxides with hydroxide. For this reaction we suggest a common intermediate with a pentacoordinated sulfur for formation of both the sulfonate anion and the olefin, though an attempt to confirm the existence of such a species using $H_2{}^{18}O$ was unsuccessful.

JAMES FREDERICK KING, JOHN HENRY HILLHOUSE et KISHAN CHAND KHEMANI. Can. J. Chem. **63**, 1 (1985).

La réaction du dioxyde-1,1 de thiiranne (**1**) avec l'hydroxyde de baryum aqueux donne principalement l'éthanesulfonate de baryum (**3**) avec un peu d'éthylène et de sulfite de baryum et une faible quantité (<5%) d'hydroxy-2 éthanesulfinate de baryum (**2**), le produit décrit antérieurement par Hesse *et al.*, comme produit principal de cette réaction. La réaction du composé **1** avec l'hydroxyde de potassium se produit d'une façon analogue, à l'exception du fait qu'il se forme du sulfinato-2 éthanesulfonate de baryum (**6**) qui provient de la réaction du sulfite de potassium avec le composé **1** qui n'aurait pas réagi. Cette nouvelle étude, entreprise à la lumière de ce qui est connu de la dernière étape de la réaction de Ramberg–Bäcklund, permet de développer une image cohérente de la réaction des dioxydes-1,1 de thiirannes avec l'hydroxyde. Nous suggérons donc que cette réaction implique un soufre pentacoordonné comme intermédiaire commun tant pour la formation de l'anion sulfonate que pour celle de l'oléfine et ce en dépit du fait qu'on n'a pas réussi à confirmer l'existence d'un tel intermédiaire en utilisant $H_2{}^{13}O$.

[Traduit par le journal]

In 1957 Hesse *et al.* (2) reported that thiirane 1,1-dioxide (ethylene sulfone) (**1**), on reaction with aqueous barium hydroxide, gave barium 2-hydroxyethanesulfinate (**2**) plus a small amount of ethylene and barium sulfite; the sulfinate (**2**) was described as being thermally unstable, decomposing rapidly to ethylene and barium sulfite above 50°C. Recently, while exploring possible routes to 2-hydroxyethanesulfonyl chloride (3), we had occasion to repeat some of these experiments and found them to be seriously in error; in particular, we found that **2** constitutes only a small part of product from **1** and, in addition, is thermally quite stable. We now describe our investigation and discuss its relevance to the mechanism of the final step of the Ramberg–Bäcklund reaction.

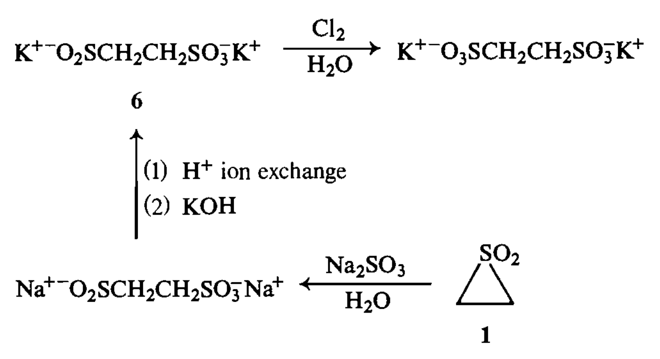
Results and discussion

Reaction products

Repetition of the reaction of **1** with aqueous barium hydroxide in our hands gave, as shown in Scheme 1 and Table 1, barium ethanesulfonate (**3**) as the major product, along with some ethylene and barium sulfite, plus a small quantity of the 2-hydroxyethanesulfinate (**2**). Similar reaction with potassium hydroxide gave potassium ethanesulfonate (**5**), ethylene, a small amount of the 2-hydroxyethanesulfinate (**4**), and a further product shown to be potassium 2-sulfinatoethanesulfonate (**6**).

Ethylene and barium sulfite were identified by comparison of ir spectra of the isolated products with those of authentic materials. The formation of barium ethanesulfonate (**3**) was proved by (a) the presence of the characteristic ^{1}Hmr and ^{13}Cmr signals of authentic **3** in the spectra of the reaction product, and (b) conversion of the crude reaction product via ethanesulfonyl chloride into crystalline ethanesulfon-*p*-toluidide, identical to a specimen prepared by a standard method. The presence of a small amount of the 2-hydroxyethanesulfinate salts (**2** and **4**) was indicated by a pair of triplets, at 2.60 and 3.92 ppm in the ^{1}Hmr spectrum, and by peaks at 65.9 and 59.1 ppm in the ^{13}Cmr spectrum of the crude product, the same signals having been observed already with authentic 2-hydroxyethanesulfinate (see experimental section and ref. 3).

An early indication that the crude potassium hydroxide product contained **6** was obtained by aqueous chlorination, which converted it into potassium 1,2-ethanedisulfonate, as shown by the replacement of the peaks ascribed to **6** by characteristic singlets in the ^{13}Cmr and ^{1}Hmr spectra, at 49.3 and 3.26 ppm, respectively. The 2-sulfinatoethanesulfonate anion was then characterized in the form of its potassium (**6**) and sodium salts. The latter was made simply by treating **1** with aqueous sodium sulfite; the recrystallized material showed appropriate ^{1}H and ^{13}Cmr and ir spectra and good elemental analyses. Conversion of this salt to the acid by ion exchange followed by neutralization with KOH gave **6**, which also gave correct elemental



analyses and the same ir and ^{13}Cmr and ^{1}Hmr spectra as the sodium salt. This preparation also, of course, provides the

See Table 1 for conversions and yields in individual runs

SCHEME 1

TABLE 1. The reaction of thiirane 1,1-dioxide (**1**) with aqueous barium and potassium hydroxides

Reactants and conditions[a]				Percentage yields of products (% conversions[b])			
M	[OH^-]	[**1**]	Time (h)	$CH_3CH_2SO_3^-M^+$ (**3** or **5**)	$CH_2{=}CH_2$[c]	$HOCH_2CH_2SO_2^-M^+$ (**2** or **4**)	Recovered **1**
Ba/2	0.33	0.16	24	49 (53)	14 (15)	3 (3)	7
	0.36	0.18	48	53 (53)	31 (31)	3 (3)	0
K	0.31[d]	0.28[d]	34	34 (48)	26 (37)	5 (6)	3
	0.45	0.45	42	28 (42)	24 (36)	3 (5)	10
	0.34[e]	0.17[e]	24	42 (54)	22 (28)	3 (4)	0

[a]At room temperature in 5 mL of H_2O, except as noted.
[b]That is, yield after correcting for recovered **1**, and, for the KOH reactions, the formation of potassium 2-sulfinatoethanesulfonate (**6**). Recovery of **1** is probably not quantitative and the conversions given are therefore likely somewhat underestimated.
[c]Ethylene production was not determined directly; the numbers given are the yields of the co-product, i.e. $BaSO_3$ from the $Ba(OH)_2$ reactions, and **6** from KOH.
[d]Ten millilitres of H_2O.
[e]At the end of the reaction the mixture was extracted with CH_2Cl_2 and the aqueous layer brought to pH 7.00 with 1 *M* HCl and worked up; the weight of the product (148 mg after drying) was corrected for the KCl present (estimated from the volume of HCl added) to give an estimated product weight (105 mg) which was used (with the ^{1}Hmr spectrum) in calculating these yields.

explanation for the difference in products found with the reaction of **1** with potassium and barium hydroxides. The reaction with hydroxide anion gives ethylene and sulfite anion in both cases, but whereas SO_3^{2-} simply precipitates as barium sulfite in the one case, it remains in solution and reacts with **1** in the other. Analogous ring opening of **1** by such nucleophiles as bromide or thiophenoxide ions has been reported by Vilsmaier and co-workers (4,5). The small amount of **2** and **4**, noted in the reactions of **1** with hydroxide presumably also arises similarly though, in accord with the pattern expected from hard–soft acid–base theory, this is only a very minor pathway with this nucleophile.

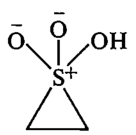
The numbers in Table 1 given as "percentage conversion" give the percentages of products after correction for unreacted **1** and, in the reaction with KOH, diversion of **1** to form **6**. Note that each molecule of $BaSO_3$ or **6** must be accompanied by a molecule of ethylene, and, as indicated in Table 1, it is on this basis that the (minimum) yields of ethylene are assigned. If in fact these reactions simply involve hydroxide anion without the countercations, we would expect the numbers under the above heading to be the same for both the barium and potassium hydroxides. The values in Table 1 indicate that the products from the two reagents are the same within the uncertainty of the rather complex and imprecise procedures used, and there is clearly no basis for suspecting any counterion effect.

Our experiments on the cleavage of **1** with hydroxide were carried out a number of times and found to be reproducible within the limits of the analytical method. Since we regard the identity of the products as established beyond reasonable doubt, it is pertinent to consider why Hesse *et al.* report such different results. Their elemental analyses, of course, fit **3** as well as **2**, but their assertion that their product above 50°C is rapidly decomposed into ethylene and barium sulfite is more difficult to explain. We have found that authentic **2** is not readily decomposed below 350°C (3) and is stable at 98°C for at least 5 h; **3** is also completely unaffected by temperatures much higher than 50°C. We note, however, that in our hands work-up of the reaction of **1** with $Ba(OH)_2$ after 1 h (the reaction time used by these authors) showed only partial reaction; specifically **3** was formed in <20% yield and a good deal of unreacted **1** was recovered. Noting also that their experiments were carried out before ^{1}Hmr or even ir spectra were generally used to examine crude reaction products, we are inclined to suspect that unreacted thiirane 1,1-dioxide (**1**), perhaps with residual base, is the source of the ethylene produced on heating above 50°C as reported by Hesse *et al.* (2).

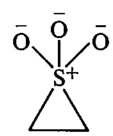
The mechanism of the final step of the Ramberg–Bäcklund reaction

Cleavage of a thiirane 1,1-dioxide (episulfone) is, of course, the final step in the well-known Bordwell mechanism (6,7) of the Ramberg–Bäcklund reaction (6–9). This process commonly gives an olefin (and presumably sulfite anion), though (saturated) sulfonate anions have been observed when (a) the original substrate has two or three α-halogen atoms (10,11), and (b) as a minor product in the reaction of chloromethyl ethyl sulfone (12). Whereas the report of Hesse *et al.* (2) describes behavior of the parent thiirane 1,1-dioxide entirely different from that of its alkylated derivatives, our findings fit well with the picture of episulfone cleavage adduced from study of the Ramberg–Bäcklund reaction. It would appear that up to one alkyl group (or else one or more halogen atoms) on the thiirane 1,1-dioxide permits a measure of cleavage to the sulfonate salt, whereas more alkyl groups lead more or less entirely to olefin formation.

Bordwell *et al.* have suggested that a species analogous to **7** is an intermediate in the methoxide-promoted desulfonylation[2] of *cis*-2,3-diphenylthiirane 1,1-dioxide (13), and Paquette (8) has proposed that formation of β-chloroalkanesulfonate anions arises by "attack of hydroxide at the sulfur atom with C–S bond cleavage to give more stable carbanion". We find it particularly attractive to combine these two pictures and to view the two sets of products as proceeding from a common species, e.g. **7** and (or) possibly **8**; a species such as **7**, by having two reaction pathways (other than reversal to starting material)



7



8

must therefore have a finite lifetime, and thus be a genuine intermediate. Although such hypervalent sulfur species have been subjects of discussion for many years and well-characterized oxygenated 10-S-5 anions have in fact been prepared (19,20), the existence of such species as actual intermediates in the reactions of ordinary sulfones or sulfonic or sulfuric esters has not been established. A good case for such intermediates has been presented by Kice (21), but, on the other hand, the conclusion in one recent examination of the reaction of aryl arenesulfonates is that the reaction probably does not proceed by way of an intermediate of finite lifetime (22).

The formation of such a hypervalent species (**7** or **8**) is expected (13) to be easy, relative to one from an unstrained precursor, owing to the release of considerable ring strain, provided that the form of **7** with one carbon apical and the other equatorial is formed.[3] It should be noted that this version of **7** is less symmetrical than **1** and that cleavage to the ethanesulfonate (**3** or **5**) might be expected to arise by cleavage of the relatively weak sulfur – apical carbon bond, probably in a general acid-promoted process akin to that suggested by Thibblin and Jencks (25) for the opening of cyclopropanols and related species. For the synthetically important extrusion to form the olefin, Bordwell *et al.* have suggested that the hypervalent intermediate cleaves by way of a short-lived biradical species. This proposal was made after the enunciation of orbital symmetry rules for cheletropic reactions but before the possibility of nonlinear cheletropic cleavage of three-membered rings had been put forward; in the light of Dewar's very recent pronouncement that "multibond reactions cannot normally be synchronous" (26), however, we would not presume to examine the mechanism of the cheletropic extrusion further at this stage.

In the hope of obtaining experimental verification of the existence of **7** as a species of finite lifetime, we tried carrying out the cleavage of **1** in ^{18}O-water. As with the others before us who have carried out related experiments (27,28), however, we found no incorporation of ^{18}O in the recovered starting sulfonyl compound. As has already been clearly noted by Kaiser (29), failure to observe ^{18}O-exchange does not rule out the intermediacy of the pentacoordinated species, but merely that if such a species (e.g. **7**) is formed, either equilibration of the oxygens or return to **1** must be slow relative to its further reaction.

[2]Although the thermal decomposition of episulfones has been extensively studied (see ref. 14 for a summary), it is evident that the relatively neglected base-promoted process is the important pathway under the usual conditions of the Ramberg–Bäcklund reaction. For example, although the conversion of *cis*-2,3-diphenylthiirane 1,1-dioxide to *cis*-stilbene is known to take place readily under mild conditions (e.g. in 1 h in CS_2 at 46°C) (13,15–17), for the reaction in methanol at 25°C Bordwell *et al.* note that "a [methoxide] concentration of 10^{-5} *M* is sufficient to make the half-lives of the first-order and second-order decompositions equal" (13). In agreement with Mock's activation data (18), which show the desulfonylation of neat **1** to be very slow at room temperature ($k = 2.1 \times 10^{-8}$ s^{-1} at 25°C), we find that the ^{1}Hmr signal of **1** in D_2O is undiminished after 1 week at room temperature; our base-promoted reactions were 90% complete within 5 min to 48 h depending on the hydroxide concentration.

[3]The C—S—C angle in **1** is reported to be 54.6° (23) in contrast to the "unstrained" angle in dimethyl sulfone of about 103° (24); conversion to this form of **7** would therefore effect a considerable reduction in ring strain since the C—S—C angle in the corresponding unstrained system would be expected to be around 90° or perhaps slightly less (cf. ref. 20).

Experimental

Reagent grade chemicals and solvents were used without additional purification unless otherwise noted. Melting points were determined on a Kofler Hot Stage and are uncorrected. Infrared spectra were obtained with a Beckman 4250 spectrophotometer and, unless otherwise stated, refer to KBr discs. The ^{1}Hmr spectra were obtained using Varian T60 and XL100 spectrometers, with all reported chemical shifts from the latter instrument; ^{13}Cmr spectra were determined on a Varian XL200 instrument using a sweep width of 5 K with 32 K transforms. Mass spectra were run on a Varian MAT-311A spectrometer. Solvent evaporation on work-up was carried out using a Büchi rotary evaporator connected to a water aspirator. Thiirane 1,1-dioxide (**1**) was prepared by the method of Hesse *et al.* (2) and purified by distillation (78°C/1.5 Torr; 1 Torr = 1.33 Pa). The colorless liquid so obtained gave, on cooling, white crystals, mp 18–19°C, and the following spectra: ir ($CHCl_3$) ν_{max}: 3100 (m), 3020 (m), 1390 (m), 1375 (m), 1325 (vs), 1210 (w), 1175 (vs), 1005 (m), 750 (m, br) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 3.15 (s); ^{13}Cmr ($CDCl_3$) δ: 31.6. The ^{1}Hmr spectra of a solution of **1** in D_2O (with TSP as the chemical shift and integration standard), before and after standing 1 week at room temperature, were identical. Sodium 2-hydroxyethanesulfinate, prepared as described previously (3), showed ^{13}Cmr signals at δ(D_2O) 65.8 and 59.0.

Reaction of thiirane 1,1-dioxide (1) with base

(a) *Potassium hydroxide*

A 10-mL round bottom flask containing thiirane 1,1-dioxide (**1**) (205 mg, 2.2 mmol) and KOH (125 mg, 2.2 mmol) dissolved in water (5 mL) was evacuated (2 Torr) and connected to an evacuated ir gas cell (NaCl plates, 10-cm path length) via an adaptor fitted with a stopcock which was opened from time to time over a 2-h period to collect the evolved gas in the cell. The ir spectrum showed peaks at ν_{max} 3120 (w), 3020 (vw), 1920 (w), 1440 (s), 945 (s) cm^{-1}, as observed also in the spectrum of authentic ethylene (Linde). The reaction mixture was allowed to react a further 40 h, after which it was extracted with CH_2Cl_2 (4 × 50 mL). The organic extracts were combined, dried with anhydrous $MgSO_4$, and the solvent evaporated to give unreacted **1** (20 mg, 0.22 mmol, 10%). The aqueous layer was evaporated and the last traces of water removed by azeotropic distillation with benzene and then by keeping under vacuum (5 Torr) for 24 h. The white powder (263 mg) thus obtained gave the following ^{1}Hmr spectrum (D_2O) δ: 1.27 (t), 2.92 (q), 2.59−3.22 (symmetrical A_2B_2 multiplet), 2.60 (t), 3.92 (t). The peaks were assigned from comparison with authentic spectra to potassium ethanesulfonate (**5**) (1.27 and 2.92 ppm), potassium 2-sulfinatoethanesulfonate (**6**) (2.59−3.22 ppm), and potassium 2-hydroxyethanesulfinate (**4**) (2.60 and 3.92 ppm), with the ratio of the peak areas coresponding to relative amounts of 50, 44, and 6% of **5**, **6**, and **4**, respectively. The ^{13}Cmr spectrum of this mixture confirmed the presence of these compounds with peaks at 57.7 and 46.8 assigned to **6**, at 48.2 and 11.2 due to **5**, and 65.9 and 59.1 ppm due to **4**. This material showed the presence of water (presumably of crystallization) in the ir spectrum; ν_{max}: 3400 (s, br), 2920 (w), 1620 (w), 1170 (vs, br), 1030 (s), 970 (w, br), 740 (m), 690 (w), 580 (w), 510 (w, br), 420 (w) cm^{-1}. Upon drying at 145°C/5 Torr for 36 h, the peak at 3400 cm^{-1} was largely removed, and the product mixture weighed 237 mg, which, when taken with the relative proportions deduced from the ^{1}Hmr spectrum, corresponds to yields of 24% of **6**, 28% of **5**, and 3% of **4**.

The presence of **6** in the reaction mixture was further demonstrated as follows. Chlorine gas was bubbled for 2 min into a solution of 50 mg of the reaction product in water (1 mL) at room temperature. The yellow solution so obtained was washed with CH_2Cl_2, the aqueous layer then evaporated, and the residual solid dried as before; the white powder (55 mg) thus obtained showed peaks at 3.3 in the ^{1}Hmr and 49.3 ppm in the ^{13}Cmr spectra characteristic of potassium 1,2-ethanedisulfonate (42%), in addition to those at 2.9 and 1.26 ppm (^{1}Hmr) and at 48.3 and 11.3 (^{13}Cmr) due to unchanged potassium ethanesulfonate (**5**) (58%). In a separate experiment, authentic **6** (27 mg, 0.12 mmol) was oxidized as above by bubbling chlorine (2 min) into a D_2O solution (0.5 mL) at room temperature. The ^{1}Hmr spectrum of the resulting solution showed peaks at 3.3(s) and 3.4−4.5 ppm (apparent A_2B_2). On standing (1 h), the complex set of peaks at 3.4−4.5 ppm almost completely disappeared, with corresponding growth of the singlet at 3.3 ppm (assigned, from comparison with authentic material, to potassium 1,2-ethanedisulfonate); the complex set of peaks at 3.4−4.5 is tentatively assigned to potassium 2-(chlorosulfonyl) ethanesulfonate, $K^+\bar{O}_3SCH_2CH_2SO_2Cl$, which hydrolyses on standing.

(b) *Barium hydroxide*

Thiirane 1,1-dioxide (**1**, 75 mg, 0.815 mmol), $Ba(OH)_2.8H_2O$ (257 mg, 0.815 mmol), and water (5 mL) were combined and the gas evolved collected over a 2-h interval and identified (as ethylene) as described above. The reaction mixture was allowed to react a further 22 h, after which the precipitated white solid was collected by filtration and dried (25 mg, 0.115 mmol, 14%); the ir spectum, with peaks at ν_{max} 1880 (w), 1630 (w), 1100 (w), 940 (vs, br), 640 (m), 500 (m) cm^{-1}, was identical to that of an authentic specimen of $BaSO_3$ (prepared by mixing solutions of Na_2SO_3 and $BaCl_2$ and collecting and drying the precipitate). The filtrate was extracted with CH_2Cl_2 (4 × 50 mL); the organic extracts were combined, dried with anhydrous $MgSO_4$, and the solvent evaporated to yield unreacted **1** (5 mg, 0.054 mmol, 7%). CO_2 was bubbled into the water layer and the precipitated $BaCO_3$ filtered off (and, after drying, identified by ir). The aqueous filtrate was then evaporated and the last traces of water removed as before. The white powder (95 mg) so obtained showed (a) ^{1}Hmr peaks at δ (D_2O) 1.29 (t, 3H), 2.95 (q, 2H), 2.60 (t, 2H), and 3.90 (t, 2H), indicating (by comparison with authentic spectra) the presence of **3** and **2** in relative proportions of 94% and 6% respectively, (b) the following ir spectrum, ν_{max}: 3400 (m, br), 2980 (w), 2940 (w), 1650 (w), 1450 (w), 1425 (w), 1200 (vs, br), 1050 (s), 780 (w), 750 (m), 520 (s) cm^{-1}, and (c) ^{13}Cmr peaks at δ (D_2O) 65.9 and 59.1 ppm assigned to **2**, and 48.2 and 11.2 ppm due to **3**. Upon drying at 145°C/5 Torr for 36 h, the peak at 3400 cm^{-1} was largely removed and the product mixture weighed 92 mg, which, when taken with the relative proportions deduced from the ^{1}Hmr spectrum and corrected for $BaCO_3$ present (see below), corresponds to 49% and 3% yields of **3** and **2** respectively. The $BaCO_3$ above apparently arose because of the solubility of $Ba(HCO_3)_2$; the quantity was estimated at 16 mg (of the 92 mg above) on the basis of a control experiment in which a known comparable amount of $Ba(OH)_2$ was treated with CO_2 as above and the weight of the precipitate (78%) and the material remaining in solution (22%) determined; the ir spectra of both (after drying) were identical to that of authentic $BaCO_3$.

In another experiment, **1** (1.2 g, 13 mmol) and $Ba(OH)_2.8H_2O$ (2.4 g, 7.6 mmol) in water (37 mL) were allowed to react for 1 h. Excess CO_2 was then bubbled into the mixture and the precipitate of $BaCO_3$ and $BaSO_3$ (as shown by ir) collected by filtration, and the filtrate evaporated (below 35°C) to yield a cream-coloured solid (0.92 g), the ^{1}Hmr spectrum (D_2O, T60) of which showed two singlets, a quartet, and a triplet (ratios roughly 12:6:2:3) corresponding to water, **1**, and **3** in the molar ratio 6:3:1, or about 400 mg (17% yield) of **3**. Attempts to remove the water completely considerably increased the ratio of **3** to **1**, presumably by volatilizing the latter; the ^{1}Hmr spectrum (XL100, D_2O), in addition to the peaks at 4.65 (s, HOD), 3.38 (s, **1**), 2.92 (q, **3**), and 1.27 (t, **3**), also showed peaks at 2.58 and 3.90 ppm corresponding to **2** (about 8 mol% of the amount of **3** or ~1% yield). An aqueous solution of this material was passed through a column of Rexyn 101 (H) and evaporated to yield a brown syrup. Thionyl chloride (50 mL) and a few drops of *N*,*N*-dimethylformamide were added and the mixture refluxed for 3 h, whereupon the excess $SOCl_2$ was removed by evaporation to give a brown liquid (0.4 g). To this liquid a solution of *p*-toluidine (0.5 g, 4.7 mmol) and triethylamine (1.0 mL, 7.2 mmol) in benzene (15 mL) was added. After standing overnight the solution was extracted with 1.0 *M* HCl (2 × 10 mL) and water (10 mL). The benzene layer was dried, filtered, and the solvent evaporated to yield a brown oil (0.16 g) which was recrystallized from benzene − petroleum ether (60−80°C) to yield off-white crystals (10 mg), mp 79−80°C; mixture mp with authentic etl.:nesulfon-*p*-toluidide gave no depression; ^{1}Hmr and ir were identical to those of an authentic specimen, mp 79−80°C (30).

(c) *$K^{18}OH$ in $H_2{}^{18}O$*

A solution of $K^{18}OH$ was made by dissolving small pieces of potassium (39 mg, 1 mmol) in 0.32 mL of $H_2{}^{18}O$ (97.5 at.% ^{18}O), supplied by MSD Isotopes division of Merck Frosst Canada Inc., Montreal, Canada, under a slow stream of nitrogen at 0°C. Thiirane 1,1-dioxide (**1**) (92 mg, 1 mmol) was then added to the above solution with stirring at room temperature. Gas evolution started immediately. After 30 s, the reaction mixture was extracted with CH_2Cl_2 (4 × 20 mL). The organic extracts were combined, dried with anhydrous $MgSO_4$, and the solvent evaporated to yield unreacted **1** (30 mg), which upon analysis by mass spectrometry showed SO_2 peaks at *m/e* 64 and 66 in the ratio 100 to 5.6; natural abundance thiirane 1,1-dioxide showed the same peaks in the ratio 100 to 5.2.

Preparation of sodium and potassium 2-sulfinatoethanesulfonates

Thiirane 1,1-dioxide (**1**) (191 mg, 2.08 mmol) and sodium sulfite (anhydrous, 225 mg, 1.79 mmol) dissolved in D_2O (0.5 mL) were allowed to react for 1.5 h, the reaction being monitored by ^{1}Hmr. The unchanged **1** was removed by extraction with chloroform, and the D_2O solution then evaporated and the white solid so obtained dried as before, to yield sodium 2-sulfinatoethanesulfonate (385 mg, 99% based on Na_2SO_3). The analytical specimen was recrystallized from ethanol−water and dried at 125°C/1 Torr for 24 h; mp >360°C (dec.); ir ν_{max}: 2910 (m), 2820 (w), 1190 (s), 1040 (s), 980 (w), 962 (w), 932 (w), 755 (m), 690 (w), 590 (w), 540 (w) cm^{-1}; ^{1}Hmr (D_2O) δ: 2.61−3.22 (m, A_2B_2); ^{13}Cmr (D_2O) δ: 57.6, 46.8. *Anal.* calcd. for $C_2H_4O_5S_2Na_2$: C 11.01, H 1.83, S 29.36; found: C 11.02, H 1.82, S 29.31.

A portion of the above salt was converted to the potassium salt (**6**) by passing the aqueous solution through Rexyn 101(H) (Fisher) cation exchange resin and neutralizing to pH 7.0 with 1 *M* KOH solution. Evaporation of the water gave a white solid which was recrystallized from ethanol−water and dried as before; mp 319−320°C (dec.); ir identical to that of the sodium salt. *Anal.* calcd. for $C_2H_4O_5S_2K_2$: C 9.59, H 1.60, S 25.56; found: C 9.63, H 1.57, S 25.43.

Preparation of potassium 1,2-ethanedisulfonate

This was made by the reaction of aqueous K_2SO_3 with 1,2-dibromoethane (31). The compound so obtained gave the following spectra: ir, ν_{max}: 3400 (m, br), 3020 (m), 2960 (w), 2940 (w), 1210 (vs, br), 1040 (s), 770 (s), 560 (s) cm^{-1}; ^{1}Hmr (D_2O) δ: 3.3 (s); ^{13}Cmr (D_2O) δ: 49.1.

Preparation of barium ethanesulfonate (3)

Ethanesulfonyl chloride (1.0 g, 7.8 mmol) was stirred with $Ba(OH)_2.8H_2O$ (2.3 g, 7.3 mmol) in water (100 mL) for 3 h at room temperature. The water was removed by evaporation and the off-white residue (2.0 g) so obtained recrystallized from 95% alcohol to give **3** as colorless needles, mp >395°C; ir (Nujol) ν_{max}: 1255 (m), 1220 (w), 1187 (s), 1162 (s), 1052 (s), 784 (m), 575 (m) cm^{-1}; ^{1}Hmr (D_2O) δ: 1.29 (t, 3H), 2.94 (q, 2H); ^{13}Cmr (D_2O) δ: 48.2, 11.2 ppm.

Stability of barium 2-hydroxyethanesulfinate (2)

Barium 2-hydroxyethanesulfinate (**2**) (49 mg, 0.28 mmol) prepared as described elsewhere (3) was kept at 98°C for 5 h, at the end of which time the ^{1}Hmr spectrum of the material (48 mg, 98%) was that of unchanged **2**; **2** shows no mp but decomposes above 350°C (3).

Steady-state γ-radiolysis of deaerated aqueous solutions of thymidine has been carried out in the presence of 2,2,6,6-tetramethyl-1,4-piperidone-*N*-oxyl (TAN), a well-known radiosensitizing agent. The eight main radiation-induced TAN addition products to thymidine have been isolated and characterized by ^{1}H and ^{13}C nmr, cd, and fast-atom bombardment mass spectrometry measurements.

MAURICE BERGER, JEAN CADET et JACQUES ULRICH. Can. J. Chem. **62**, 6 (1984).

La radiolyse γ en régime stationnaire de solutions aqueuses désaérées de thymidine a été effectuée en présence de tétraméthyl-2,2,6,6-pipéridone-4-*N*-oxyl (TAN) qui est un agent de radiosensibilisation. Les huit produits d'addition radio-induite de la molécule de TAN avec la thymidine ont été isolés et identifiés par diverses méthodes spectroscopiques: rmn ^{1}H et ^{13}C, dc et spectrométrie de masse par bombardement avec des atomes rapides.

Introduction

Various nitroxyl free radicals including nor-pseudopelletierine-*N*-oxyl (NPPN) and 2,2,6,6-tetramethyl-1,4-piperidone-*N*-oxyl (TAN) have been shown to sensitize hypoxic living cells to the lethal action of ionizing radiations (1, 2). The radiosensitizing ability of TAN appears to be higher in bacterial cells than in mammalian cells (3, 4). Two mechanisms which involve DNA as the major cellular target have been proposed for the biological action of several classes of radiosensitizers (5). The first postulates the oxidation of DNA anionic radicals (generated as anion–cation radical pairs by the direct action of ionizing radiation in purine and pyrimidine bases) through electron transfer reactions with TAN or NPPN. This would prevent the recombination of anion and cation radicals, resulting in permanent damage to the biopolymer. A second reaction is the covalent binding with radiation-induced DNA radicals (6). The formation of covalent TAN–DNA adducts has been reported upon irradiation either in aqueous solutions of DNA (7) or within living cells (8). Such lesions, the structures of which remain unknown, have been detected in Chinese hamster cells as *M. luteus* sensitive sites (9). Pulse radiolysis experiments have shown that the second-order reaction rate of TAN with the radicals resulting from the addition of OH radicals across the 5,6 bond of pyrimidine DNA components is an efficient process (10). The two main addition products of TAN to radiation-induced 5-hydroxy-5,6-dihydrothymin-6-yl and 6-hydroxy-5,6-dihydrothymin-5-yl radicals have been isolated and characterized (11). In the present study, thymidine has been used as a DNA model compound for a further investigation of the binding of TAN with the various nucleoside radicals induced by the water radiolysis species. We show that the bulk of the adducts result from the binding reaction of TAN with the radicals derived from addition of OH radicals at either carbon C(5) or carbon C(6).

Results

Steady-state γ-radiolysis of oxygen-free aqueous solutions of 1 m*M* thymidine containing 2 m*M* 2,2,6,6-tetramethyl-1,4-piperidone-*N*-oxyl (TAN) led to the formation of a complex mixture of nucleosides and thymine derivatives. These compounds were separated by two-dimensional thin-layer chromatography on silica gel plates (12). Eight nucleosides which exhibit high chromatographic mobility gave a coloration characteristic of carbonyl-containing compounds by spraying the chromatoplates with the 2,4-dinitrophenylhydrazine reagent (13). This is consistent with the presence of the piperidone moiety in the above nucleosides. These TAN–thymidine adducts were further purified and separated from the radiation-induced diastereoisomers of 5,6-dihydrothymidine and 5,6-dihydroxy-5,6-dihydrothymidine by preparative thin-layer chromatography on silica gel, followed by reversed–phase high performance liquid chromatography. These TAN–thymidine adducts, which represent about 50% of the overall radiation-induced degradation products (Table 1), were further characterized on the basis of various spectroscopic measurements. Further confirmation was provided by comparison with the adducts generated in alternate chemical routes.

The eight thymidine derivatives **2**–**9** showed no absorption around 260 nm, in line with the saturation of the 5,6-pyrimidine bond of these nucleosides (14). The six more stable thymidine–TAN adducts **2**–**7** were analyzed by fast-atom bombardment (FAB) mass spectrometry. This soft ionization technique is particularly suitable for the mass spectrometry measurement of polar and fragile molecules, such as the TAN adducts (Fig. 1). A prominent pseudo-molecular ion $(M + Na)^+$ at $m/z = 452$ was observed in the positive mass spectrum of each of the six nucleosides **2**–**7**. The pseudo-molecular ion $(M - H)^-$ exhibited in the negative ionization mode at $m/z = 428$ is of relatively low intensity. These spectroscopic data strongly suggest that these compounds result from the addition of a hydroxyl radical and of a TAN molecule to the starting thymidine. The same conclusions can be deduced from the observation of a pseudo-molecular ion in the field desorption (FD) and the desorption by chemical ionization (DCI) spectra of compounds **2** and **3** respectively. In addition, the fragmentation patterns of these adducts, particularly those obtained in

[a]Absorbed dose: 1.5 kGy; 1 mM thymidine and 2 mM TAN aqueous solutions.

[b]Number of molecules formed or destroyed per an absorbed dose of 1 Gy. The G values are the average of four independent measurements (accuracy to ±5%).

FD-ms, provide significant structural information. Thus the base peak at $m/z = 259$ corresponds to the loss of the TAN radical, whereas major fragments can be assigned to the TAN residue ($m/z = 170$) and the deoxyribose residue ($m/z = 117$) respectively. Mass spectrometric analyses of the two other nucleosides **8** and **9** were not so conclusive due to extensive thermal decomposition of the samples.

The 250-MHz ^{1}H nmr spectra of the thymidine–TAN adducts **2–7** in D_2O confirm the presence of the piperidine moiety. In particular, they exhibit four singlets in the range 1.04–1.44 ppm which correspond to the resonance signals of the methyl substituents of the piperidone ring. We also note the presence at a slightly higher field (1.55–1.70 ppm) of an additional singlet which was assigned as the pyrimidine methyl group. The chemical shift of this signal and those of the H(6) pyrimidine proton (5.23–5.40 ppm) are characteristic of 5,6-dihydrothymine derivatives. Similar ^{1}H nmr features are observed for the nucleosides **6** and **7**, suggesting an isomeric relationship for the adducts **2–7**. On the other hand, the two last products **8** and **9** have a different structure with a methylene group ($J_{gem} = -14$ Hz) at the C(6) carbon and the TAN residue attached to the C(5) carbon.

Site of attachment of the TAN moiety

Considerations of the ^{1}H nmr chemical shift values of the H(6) proton and of the thymine methyl group are not of interest for determining the site of attachment of the piperidone ring, either at the C(5) or the C(6) positions (Fig. 2). The comparison of the chemical shift values of H(6) for the adducts **2–7** does not show any significant differences which could be related to the α or β position of the TAN substituent. The lack of any selective downfield shift effect associated with other electronegative α substituents such as a hydroperoxide group has been previously noted for 5,6-dihydrothymidine derivatives (15). It must also be mentioned that the chemical shift of the pyrimidine H(6) proton is sensitive to the orientation of the aglycone about the *N*-glycosidic bond (16). On the other hand, ^{13}C nmr has been shown to be a suitable spectroscopic method for investigating the effects of substituents at carbons C(5) and C(6) in various 5,6-dihydrothymine derivatives (17). The relevant ^{13}C chemical shift values of the six thymidine–TAN adducts **2–7** and of various 5,6-dihydrothymidine derivatives are listed in Table 2. The comparison of the C(5) and C(6) chemical shifts of the compounds **2–7** with the corresponding carbons of the *cis* and *trans* diastereoisomers of 5,6-dihydroxy-5,6-dihydrothymidine shows that the C(6) resonance signal of compounds **2–5** is shifted downfield by about 9 or about 13 ppm. A similar deshielding effect is observed for the C(5) of the thymidine–TAN adducts **6** and **7**. This strongly suggests that the TAN substituent is at position 5 in nucleosides **6** and **7** and at position 6 in adducts **2–5**. The magnitude of the α effect of the TAN substituents (as determined by using 5-hydroxy-5,6-dihydrothymidine and 6-hydroxy-5,6-dihydrothymidine as the reference compounds) is 41–45 ppm for the C(6) carbon and about 38 ppm for the C(5) carbon. The lower value for the latter carbon may be due to the more severe crowding of this carbon which is suggested by the molecular model. The variation in the magnitude of the α effect at the C(6) carbon could be the result of changes in the *syn–anti* conformation of the nucleobase with respect to the sugar moiety, as discussed in more detail in the second paper (18). Polarization effects resulting from the close vicinity of the O(1′) atom with the C(6) carbon in compounds **2** and **5** would be at the origin of this shielding effect.

Further confirmation of the assignment of the position of the TAN substituent was provided by the radiation-induced synthesis of the various thymidine–TAN adducts **2–9** from 5,6-saturated thymidine derivatives. In the first series of reactions, the γ-radiolysis of oxygen-free aqueous solutions of (−)-*trans*-(5*S*,6*S*)-5-bromo-6-hydroxy-5,6-dihydrothymidine (**12**) (18) in the presence of 4.7 mM TAN and 0.1 M *tert*-butanol gives rise to the adduct **6**, whereas irradiation of the (+)-*trans*-5-bromo-6-hydroxy-5,6-dihydrothymidine (**13**) generates the adduct **7** (Fig. 3). A reasonable mechanism for their formation would involve, in the initial step of the reaction, the departure of the Br atom through an electron capture dissociation process (20). A recombination reaction between the resulting 6-hydroxy-5,6-dihydrothymid-5-yl radical and the TAN molecule would generate, with retention of configuration at the C(6) carbon (21), the adducts **6** and **7** respectively.

In the second series of reactions, evidence is provided for the adducts **2–5**. The two pairs of *cis* and *trans* diasteroisomers of C(6) addition products, **5**,**3** and **4**,**2** respectively, can be prepared in a selective way by using a radiation-induced procedure. γ-Irradiation of deaerated aqueous solutions of the 5*R* diasteroisomer of 5-hydroxy-5,6-dihydrothymidine (**11**) containing 2 mM TAN generates adducts **3**,**5**, whereas the two other adducts **2**,**4** are obtained from (5*S*)-5-hydroxy-5,6-dihydrothymidine (**10**). In addition, a mixture of both the 5*R** and 5*S** adducts, **8** and **9**, the absolute configuration of which has not been determined, is produced in both irradiated solutions. Under the experimental conditions used, the hydroxyl radical is the main radiolysis-reactive species which may abstract a hydrogen at carbon C(6) or lead to the loss of a hydroxyl group at carbon C(5). Similar abstraction of a hydroxyl group has been observed in X-irradiated 5-hydroxy-5-methylbarbituric acid (22). A recombination reaction of the resulting oxyl radical with TAN (23) gives rise to a pair of *cis* and *trans* diastereoisomers of C(6) adducts **5**,**3** or **4**,**2** with retention of the C(5) configuration (Fig. 4). It should be noted that the addition of the TAN molecule to the carbon C(6) is less stereoselective than to carbon C(5). This loss of stereospecificity is

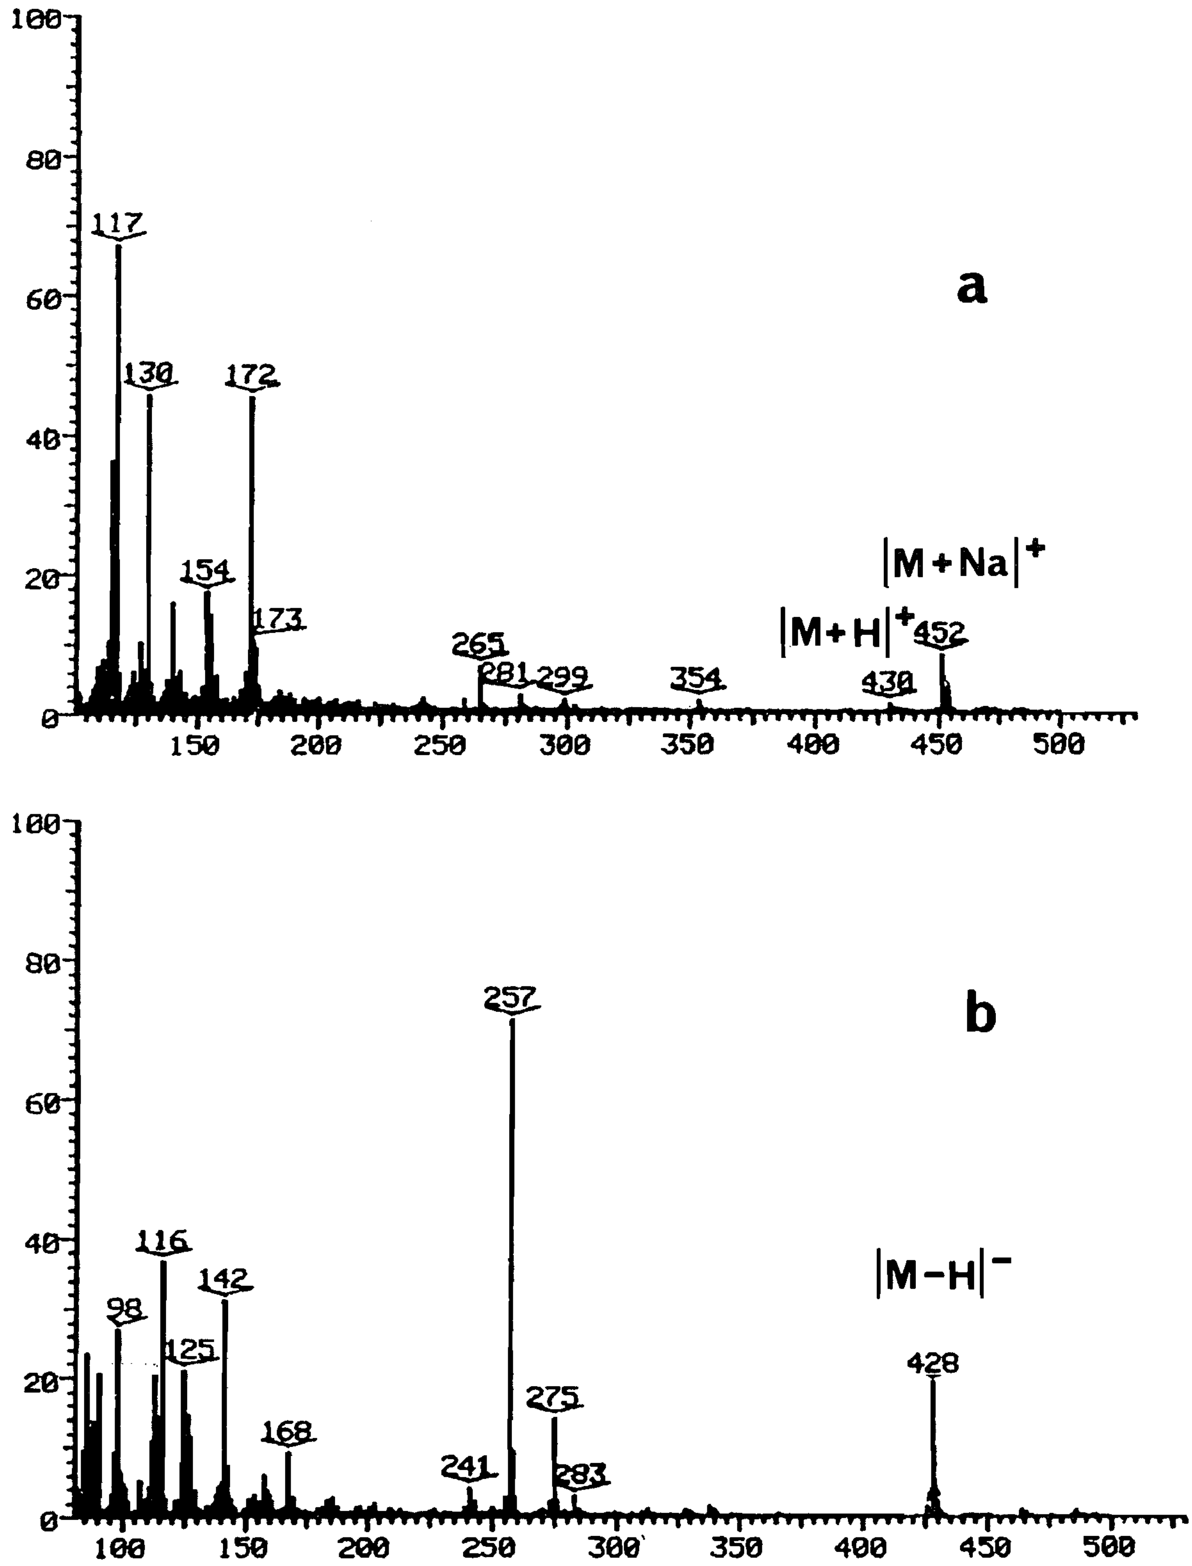

FIG. 1. FAB-ms spectra of the TAN−thymidine adduct **5**: (a) positive mode; (b) negative mode.

probably due to the presence of the two bulky substituents on the carbon C(5) preventing the preferential *trans* radical addition which is usually observed with respect to the 5- or 6-monosubstituted carbon within the pyrimidine ring (24).

Nature of the linkage to the TAN substituent

The covalent addition of nitroxyl radicals to carbon-centered radicals may generate either hydroxylamine derivatives (25) or *N*-oxide type compounds (26). Chemical transformations of the adducts **2**−**9** provided the most convincing evidence that the TAN moiety is linked via the nitroxyl oxygen to carbon C(6) in nucleosides **2**−**5** (hydroxylamine) and via the nitroxyl nitrogen to carbon C(5) in nucleosides **6**−**9** (*N*-oxide). Catalytic hydrogenation is expected to convert the substituted hydroxyl-

amine derivative to an alcohol and an amine through heterolysis of the N—O bond according to an S_N2 mechanism (27). Hydrogenolysis of the four adducts **2**–**5**, in the presence of Pd/C, generated in a quantitative way the thymidine glycols and the 2,2,4,4-tetramethylpiperidone. However, the two C(5) thymidine–TAN addition products **6** and **7** remain unchanged under these hydrogenolysis conditions.

The latter compounds **6** and **7** are unstable in solutions and undergo various transformations which can be rationalized on the basis of the postulated *N*-oxide structure. In particular, they show extensive decomposition after standing for 48 h in neutral

aqueous solution at 20°C. The major degradation product was characterized as 5-hydroxymethyl-2′-deoxyuridine (**14**) by comparison of some of its spectroscopic features (uv, EI-ms, ^1H and ^{13}C nmr) with those of the authentic sample synthesized according to Baker *et al.* (28). A likely mechanism for its formation would involve a Cope rearrangement, which is characteristic of *N*-oxide type compounds (29). Hydrogen abstraction from the methyl by the N—O function through a planar pentagonal transient state and subsequent departure of the piperidone substituent would generate a nucleoside with a methylene group (Fig. 5). Elimination of the hydroxyl at carbon C(6) would give rise to a reactive carbonium ion, which by reaction with water is converted to 5-hydroxymethyl-2′-deoxyuridine (**14**). In H_2O_2 the corresponding hydroperoxide **15** is obtained as the result of the nucleophilic attack by the perhydroxyl ion on the carbonium ion intermediate (30). It is interesting to note that similar reaction mechanisms have been proposed in the biosynthetic pathway of 5-hydroxy-

FIG. 5. Cope rearrangement of the thymidine–TAN adduct **6** or **7** to hydroxymethyl-2′-deoxyuridine (**14**) or hydroperoxymethyl-2′-deoxyuridine (**15**).

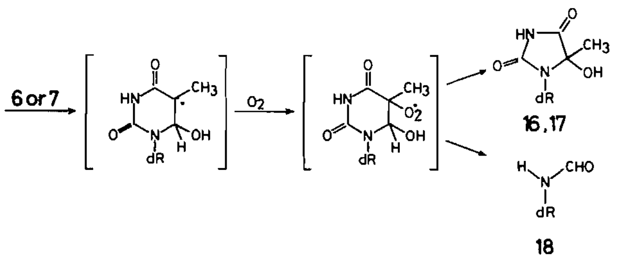

FIG. 6. Rearrangement of the thymidine–TAN adduct **6** or **7** to $5R^*$ and $5S^*$-1(2-deoxy-β-D-*erythro*-pentofuranosyl)-5-hydroxy-5-methyl hydantoin (**16**, **17**) and *N*-(2-deoxy-β-D-*erythro*-pentofuranosyl) formamide (**18**).

methyl-2′-deoxyuridine-5′-monophosphate which is catalyzed by dUMP hydroxymethylase (31). We may note that *N*-1-(2-deoxy-β-D-*erythro*-pentofuranosyl) barbituric acid (32), which would result from initial hydrogen abstraction reaction at carbon C(6), is produced, but in very low yield. This lower yield could be explained by the lack of planarity for the pentagonal transient state, due to the half-chair conformation of the 5,6-saturated pyrimidine ring. The formation of thymidine (**1**) from the other C(5) thymidine–TAN adducts **8** and **9** in aqueous solution would also strongly suggest a *N*-oxide type structure for these compounds. A Cope rearrangement appears as a likely mechanism for the generation of **1**.

Radical reactions, as the result of homolytic scission of the C—N bond of adduct **6** or **7** (*vide infra*) are predominant in aerated aqueous pyridine solutions. The major decomposition products were characterized as thymidine (**1**) (10%), the four *cis* and *trans* diastereoisomers of 5,6-dihydroxy-5,6-dihydrothymidine (20%), the *N*-(2-deoxy-β-D-*erythro*-pentofuranosyl) formamide (**18**) (33), and the $5R^*$ and $5S^*$ diastereoisomers of *N*-(2-deoxy-β-D-*erythro*-pentofuranosyl)-5-hydroxy-5-methylhydantoin (**16**, **17**) (34). The formation of the two latter classes of products may involve a Meisheimer mechanism (35) which would generate the 6-hydroxy-5,6-dihydrothymid-5-yl radical from homolytic scission of the C(5)—N bond. Subsequent fast reaction of this pyrimidine radical with molecular oxygen would give rise to the corresponding hydroxyhydroperoxyl thymidine radical (36). Disproportionation reactions between these peroxyl radicals are expected to produce oxyl radicals (37), which through subsequent β scission reactions would lead to the opening of the pyrimidine ring (Fig. 6). N^1-(2-deoxy-β-D-*erythro*-pentofuranosyl)-N^1-formyl-N^2-pyruvylurea is the expected product of this reaction. Hydrolysis of this unstable intermediate gives rise to the formamide compound **18** in 40% yield, whereas recyclization generates the hydantoin nucleosides **16**, **17** in about 20% yield.

The loss of oxygen from the molecular ion in electron impact mass spectrometric analysis may be diagnostic for the *N*-oxide structure (38). This particular ion ($M - 16$) has not been observed in the FAB mass spectrometry measurements of adducts **2**–**7**, which show little fragmentation.

Determination of the absolute configuration of adducts 2–7

As mentioned above, the radiation-induced degradation of the $5R$ diastereoisomer of 5-hydroxy-5,6-dihydrothymidine (**11**) in the presence of TAN gives rise to the *trans* and *cis* C(6) adducts **3** and **5** with retention of the initial $5R$ configuration. In the same way, the two $5S$ diastereoisomers **2** and **4** have been prepared from the ($5S$)-diastereoisomer of 5-hydroxy-5,6-dihydrothymidine (**10**) (39). The *cis* and *trans* configuration of the two nucleosides of each pair of $5R$ and $5S$ diastereoisomers could be deduced by considering the γ-effect of the C(6) TAN substituent on the ^{13}C nmr chemical shift value of the pyrimidine methyl group. An upfield shift effect of about 3 ppm is observed for the *trans* thymine glycol (11) and the corresponding 2′-deoxyribonucleoside derivatives (Table 2) when the C(6) hydroxyl group is in a *gauche* relationship with the C(5) methyl substituent. A similar upfield shift effect is noted for the adducts **2** and **3** by comparison with the second $5S$ and $5R$ diastereoisomers **4** and **5** respectively. The magnitude of this γ-effect is higher than for the 5,6-dihydroxy-5,6-thymidine, as expected for a bulky C(6) substituent. As a result, a $6R$ configuration and $6S$ configuration can be deduced for **3**,**4** and **2**,**5** respectively.

The assignment of the C(6) configuration of the TAN–thymidine adducts **6** and **7** is also based on their selective preparation in 90% yield from the corresponding ($5S$,$6S$) and ($5R$,$6R$) 5-bromo-6-hydroxy-5,6-dihydrothymidine (**12** and **13**). As discussed above, a *trans* addition of the TAN molecule to the 6-hydroxy-5,6-dihydrothymid-5-yl radical is expected to take place preferentially, giving rise to the ($5S$,$6S$) and ($5R$,$6R$) TAN–thymidine adducts **6** and **7**, respectively.

Mechanisms of the radiation-induced formation of the adducts 2–9

Interaction of the γ-rays with dilute aqueous solutions of thymidine and TAN leads to the formation of three reactive species (40): OH radicals ($G = 2.72$), solvated electrons ($G = 2.63$), and hydrogen atoms ($G = 0.55$). Under the experimental conditions used, about 40% of the OH radicals will react with thymidine (41): $k_{OH+dThd} = 3.9 \times 10^9\ M^{-1}\ s^{-1}$. The remaining 60% are scavenged by the TAN molecules (42): ($k_{OH+TAN} = 6.3 \times 10^9\ M^{-1}\ s^{-1}$). The pyrimidine ring of the nucleoside is the preferential site of reaction of the OH$^{\cdot}$ radicals through addition at the carbons C(5) and C(6) as shown by esr flow experiments (43). Recombination reactions of these radicals with the TAN molecule give rise to the C(5) adducts and the four *cis* and *trans* diastereoisomers of the C(6) addition products. The reaction of the solvated electrons with thymidine takes place mostly on the pyrimidine moiety (41). The resulting anionic radical is exposed to be quantitatively oxidized to the starting thymidine, since pulse radiolysis experiments have shown that electron transfer reaction from electron pyrimidine adduct to TAN is an efficient process (6, 8). The formation of the two adducts **8** and **9** may also be accounted for by the recombination reaction of 2,2,6,6-piperidone-*N*-oxyl with the radiation-induced 5,6-dihydrothymid-5-yl radical (42). This radical arises from the preferential addition of the hydrogen atom to the carbon C(6) within the thymine moiety (44). It should be noted that, in the present work, adducts with TAN covalently bound to the sugar moiety of thymidine were not detected. On the other hand, this latter class of adducts has been shown to be relatively important when purine 2′-deoxyribonucleosides are exposed to γ-rays in deaerated aqueous solution containing *N*-oxyl radicals (45).

Conclusion

The main radiation-induced TAN adducts to thymidine have been isolated and characterized as recombination products between TAN and transient 5-hydroxy-5,6-dihydrothymid-6-yl or 6-hydroxy-5,6-dihydrothymid-5-yl radicals. This constitutes a first step to further studies dealing with the radiation-induced binding of TAN to the thymine moiety within isolated DNA. In particular, the knowledge of the structure and chemical properties of these various thymidine−TAN adducts will facilitate their detection in enzymatic hydrolysates of DNA which has been irradiated in the presence of TAN.

Experimental

Materials

Thymidine was purchased from Sigma (St. Louis, Missouri) and used without further purification. 2,2,6,6-Tetramethylpiperidone was obtained from Aldrich (Beerse, Belgium). 2,2,6,6-Tetramethylpiperidone *N*-oxyl was synthesized according to Briere *et al.* (46). The two *trans* diastereoisomers of 5-bromo-6-hydroxy-5,6-dihydrothymidine (**12**, **13**) were prepared by addition of Br_2 to an aqueous solution of thymidine (19) and separated by preparative reversed-phase high performance liquid chromatography.

The four *cis* and *trans* diastereoisomers of 5,6-dihydroxy-5,6-dihydrothymidine (47), the two *cis* (5*S*,6*R*) and (5*R*,6*S*) diastereoisomers of 6-hydroxy-5,6-dihydrothymidine (48), and the 5*R* and 5*S* diastereoisomers of 5-hydroxy-5,6-dihydrothymidine (**11**, **10**) (49) were prepared according to literature procedures. The (−)-(5*S*)-dihydrothymidine has been obtained according to Kondo and Witkop (14), whereas the (+)-(5*R*)-diastereoisomer has been prepared by hydrogenation of an aqueous solution of thymidine in the presence of Pd/C as the catalyst (50). 5-Hydroxymethyl-2′-deoxyuridine has been synthesized according to Baker *et al.* (28). [^{14}CH$_3$]thymidine has been obtained from the Service des Molécules Marquées du Commissariat à l'Energie Atomique (Saclay, France). The radioactive nucleoside was purified prior to use on a Nucleosil octadecylsilyl silica gel column to remove self-radiolysis decomposition products.

Spectroscopic measurements

The uv absorption spectra were registered on a Beckman spectrophotometer Model 5230. The ir spectra using the KBr micropellet method were obtained on a Perkin−Elmer spectrophotometer Model 177. Field desorption mass spectra were obtained on a Varian-Mat 311 spectrometer. (The intensity of the current of desorption was 10 mA.) Fast-atom bombardment (FAB) mass spectrometry was carried out in a Model MS 50 spectrometer equipped with a commercially available FAB gun. Desorption of the molecules was obtained by exposure to a beam of 8-keV xenon atoms in a glycerol mull. Chemical ionization mass spectra using NH_3 as the reactant gas were performed on a Nermag R 10-10 C apparatus. The ^{1}H nmr and ^{13}C nmr spectra operating at 250 MHz and 62.83 MHz respectively were obtained on a CAMECA TSN 250 apparatus in the Fourier transform mode. Deuterium oxide was used as the solvent with 3-(trimethylsilyl)-propionate-2,2,3,3-*d*$_4$ as the internal reference. Circular dichroïsm spectra (cd) were registered on a Roussel Jouan III dichrograph using methanol as the solvent.

Irradiation procedure

The γ-radiolysis experiments were carried out with three ^{60}Co sources located in a pool. The dose rate, which was determined according to Fricke's method, was 110 Gy/min. The flasks which were used for the irradiation experiments were previously filled with bidistilled water (pH 6.5) and exposed to high doses of γ-rays (10^5Gy) in order to destroy the organic impurities within the glass. The aqueous solutions of thymidine were deaerated by bubbling nitrogen for 15 min prior to irradiation.

Chromatographic analyses

Analytical two-dimensional separations of radiation-induced decomposition products of thymidine were carried out on precoated silica gel 60 F_{254} plates (Merck, Darmstadt, G.F.R.) with the two following solvent systems (12): I. lower phase of chloroform−methanol−water (4:2:1) to which was added 5% of methanol; II. ethyl acetate − 2-propanol − water (75:16:9). Preparative thin-layer chromatography was performed on thick precoated silica gel plates (Merck). Detection of far-uv absorbing compounds was made by fluorescence quenching with a 254-nm emitting Desaga mineral lamp. The 2′-deoxyribonucleosides were visualized as pink spots after spraying the plates with the cysteine − sulfuric acid reagent and subsequent heating for 3 min at 100°C. The carbonyl-containing compounds were detected on the chromatogram by using the 2,4-dinitrophenylhydrazine spray reagent (13).

Quantitative analysis

The [^{14}C] radio-labelled compounds were detected on the thin-layer silica gel plates by autoradiography using Kodak NS-2T X-ray sensitive films. Detection of radioactivity as low as 0.01 μCi/cm^2 was made after overnight exposure. The detected radioactive compounds were further scraped off the silica gel and suspended in 1 mL water for 2 h. Under these conditions, the radioactive recovery was nearly quantitative. The β scintillation counting was accomplished on a Packard model 2425 Tricarb spectrometer.

Isolation and characterization of the radiation-induced TAN−thymidine adducts

A solution of 1 m*M* thymidine (484 mg) and 2 m*M* TAN (680 mg) in 2 L of deaerated water was irradiated for 45 min with ^{60}Co γ-rays (absorbed dose: 4950 Gy). The solution was evaporated to dryness under reduced pressure. The resulting residue was dissolved in 2 mL of aqueous methanol (1:1) and applied to 5 preparative thick-layer chromatoplates. The developing solvent was a mixture of chloroform and methanol (9:1). The faster-moving broad uv-absorbing zone (R_f 0.35), which gives rise to a yellow coloration with the 2,4-dinitrophenylhydrazine spray reagent, was extracted with 50% aqueous methanol (3 × 10 mL). Evaporation of the solution to dryness gave a syrup (129 mg) which was deposited on 5 thin-layer precoated silica gel plates. Two uv absorbing zones were resolved (R_f 0.53 and 0.43 respectively) by using chloroform−methanol (9:1) as the developer. The fastest eluting uv absorbing zone (R_f 0.53) was shown to contain a mixture of three thymidine−TAN adducts **4**, **8**, and **9** (46 mg) after being extracted with 50% aqueous methanol (3 × 6 mL). The slower eluting uv absorbing zone (R_f 0.43) was scraped off and the silica gel was further extracted with 50% aqueous methanol (3 × 6 mL). Evaporation to dryness of the resulting solution yielded 67 mg of a colorless syrup which contains the four thymidine−TAN adducts **2**, **3**, **5**, and **7**.

cis-*(5*S*,6*R*)-5-hydroxy-6-(2,2,6,6-tetramethyl-4-oxo-1-piperidinoxy)-5,6-dihydrothymidine (**4**)*

The oily residue (46 mg) which is a mixture of adducts **4**, **8**, and **9** was extracted from the faster uv-absorbing zone and applied to 3 precoated silica gel plates. The tlc plates were developed with ethyl acetate as the solvent. Two main zones which give a positive coloration with the cysteine−H_2SO_4 or the 2,4-dinitrophenylhydrazine spray reagents were detected by fluorescence quenching at 254 nm. The fastest eluting zone (R_f 0.62) was scraped off and the resulting silica gel was extracted with 3 × 5 mL of water−methanol (1:1). Evaporation to dryness of the filtrates yields 14 mg (1.7%) of an oily compound which was shown to be homogeneous by reversed-phase high performance liquid chromatography analysis on a C-18 Nucleosil column using a mixture of water−methanol (7:3) as the solvent (k' = 1.50); uv (λ_{max} H_2O): 206 nm; ^{1}H nmr (D_2O, TSP) δ: 1.14 (s, 3, CH_3), 1.21 (s, 3, CH_3), 1.32 (s, 3, CH_3), 1.44 (s, 3, CH_3), 1.59 (s, 3, CH_3 thymine), 2.42 (ddd, 1, H-2″), 2.94 (m, 1, H-2′), 3.74 (dd, 1, H-5″), 3.82 (dd, 1, H-5′), 4.0 (m, 1, H-4′), 4.47 (m, 1, H-3′), 5.41 (s, 1, H-6), 5.78 (dd, 1, H-1′); ^{13}C nmr (D_2O, TMS) δ: 19.8 (q, CH_3 thymine), 23.7, 24.3, 32.3, 33.8 (q, 4 × CH_3 piperidone), 38.7 (t, C-2′), 53.6 (t, CH_2 piperidone), 53.7 (t, CH_2 piperidone), 63.0 (t, C-5′), 66.1 (s, C-2, C-6 piperidone), 70.7 (s, C-5 thymine), 72.3 (d, C-3′), 87.0 (d, C-4′), 92.8 (d, C-1′), 93.7 (d, C-6 thymine); cd (*c* 1.4, methanol): $[\theta]_{280}$ ±0, $[\theta]_{270}$ −140, $[\theta]_{260}$ −1720, $[\theta]_{249}$ −4650, $[\theta]_{240}$ −1720, $[\theta]_{288}$ ±0, $[\theta]_{230}$ +3500; FAB-ms, *m/e* (relative intensity), positive mode: 452 (30, M^+ + Na), 430 (8, M^+ + H), 265 (20), 172 (15, TAN + 2H), 117 (58, 2-deoxyribose); negative mode: 428 (12, M^- − H), 283 (17), 257 (41, M^- − TAN), 241 (6, thymidine-H), 142 (15,5-hydroxy-5,6-dihydrothymine), 125 (18, thymine-H), 116 (14, 2-deoxyribose-H).

(5R) and (5S*)-5-(2,2,6,6-tetramethyl-4-oxo-1-piperidinyl-*N*-oxide)-5,6-dihydrothymidine (8, 9)*

Extraction of the slowest uv-absorbing zone (R_f 0.31) yielded 23 mg of a mixture of thymidine−TAN adducts **8** and **9** which were further separated on the C-18 Nucleosil octadecylsilyl silica gel column under the above conditions. Two main fractions corresponding to nucleosides **8** (k' = 4.36) and **9** (k' = 4.85) were collected. Evaporation to dryness of the aqueous methanol solutions gave respectively 9 mg of **8** (1.1%) and 8 mg of **9** (1%) as oily compounds.

Compound 8: ^{1}H nmr (D_2O, TSP) δ: 1.18 (s, 3, CH_3), 1.21 (s, 3, CH_3), 1.22 (s, 3, CH_3), 1.27 (s, 3, CH_3), 1.57 (s, 3, CH_3 thymine), 2.18 (ddd, 1, H-2″), 2.35 (ddd, 1, H-2′), 3.57 (d, 1, H-6a), 3.70 (dd, 1, H-5″), 3.76 (dd, 1, H-5′), 3.92 (m, 1, H-4′), 4.17 (d, 1, H-6b), 4.41 (m, 1, H-3′), 6.31 (dd, 1, H-1′).

Compound 9: ^{1}H nmr (D_2O, TSP) δ: 1.16 (s, 3, CH_3), 1.22 (s, 3, CH_3), 1.23 (s, 6, 2 × CH_3), 1.56 (s, 3, CH_3 thymine), 2.16 (ddd, 1, H-2″), 2.28 (ddd, 1, H-2′), 3.48 (d, 1, H-6a), 3.73 (dd, 1, H-5′), 3.76 (dd, 1, H-5″), 3.92 (m, 1, H-4′), 4.12 (d, 1, H-6b), 4.41 (m, 1, H-4′), 6.29 (dd, 1, H-1′).

cis-*(5R,6S)-5-hydroxy-6-(2,2,6,6-tetramethyl-4-oxo-1-piperidinoxy)-5,6-dihydrothymidine (5)*

The mixture (67 mg) of the four thymidine−TAN adducts **2**, **3**, **5**, and **7** was extracted from the second 2′-deoxyribonucleoside-containing band (R_f 0.42), applied to 5 silica gel precoated plates, and eluted with ethyl acetate as the solvent. Extraction of the fastest eluting band (R_f 0.61) provided a mixture (25 mg) of the TAN-addition products **5** and **7**, which were further separated by reversed-phase hplc on the C-18 Nucleosil column as reported above. Evaporation to dryness of the methanolic aqueous solution containing the fastest eluting compound (k' = 1.14) yielded 12 mg of **5** (1.4%) as an oily compound; uv (λ_{max} H_2O): 216 nm; ^{1}H nmr (D_2O, TSP) δ: 1.09 (s, 3, CH_3), 1.24 (s, 3, CH_3), 1.29 (s, 3, CH_3), 1.42 (s, 3, CH_3), 1.54 (s, 3, CH_3 thymine), 2.35 (ddd, 1, H-2″), 3.15 (ddd, 1, H-2′), 3.76 (m, 2, H-5′ and H-5″), 3.93 (m, 1, H-3′), 4.48 (m, 1, H-4′), 5.36 (dd, 1, H-1′); ^{13}C nmr (D_2O, TMS) δ: 24.0 (q, CH_3 thymine), 24.2 (q, 2, × CH_3 piperidone), 32.4 (q, 2 × CH_3 piperidone), 38.6 (t, C-2′), 53.5 (t, 2 × CH_2 piperidone), 63.0 (t, C-5′), 66.0 (s, C-2 and C-6 piperidone), 72.5 (d, C-3′), 73.6 (s, C-5 thymine), 85.5 (d, C-1′), 86.3 (d, C-4′), 89.1 (d, C-6 thymine); cd (*c* 1.2, methanol): $[\theta]_{310}$ ±0, $[\theta]_{280}$ +310, $[\theta]_{260}$ +2480, $[\theta]_{250}$ +6470, $[\theta]_{246}$ +7100, $[\theta]_{240}$ +4920, $[\theta]_{234}$ ±0; FAB-ms *m/e* (relative intensity), positive mode: 452 (10, M^+ + Na), 430 (3, M^+ + H), 265 (7), 172 (46 TAN + 2H), 117 (67, 2-deoxyribose); negative mode: 428 (20, M^- − H), 275 (16), 257 (73, M^- − TAN), 241 (4, thymidine-H), 142 (31, 5-hydroxy-5,6-dihydrothymine), 125 (22, thymine-H), 116 (37, 2-deoxyribose-H).

trans-*(5R,6R)-6-hydroxy-5-(2,2,6,6-tetramethyl-4-oxo-1-piperidinyl-*N*-oxide)-5,6-dihydrothymidine (7)*

The slowest eluting fractions (k' = 3.50) were collected and evaporated to dryness, yielding 11 mg of **7** (1.3%) as an oily compound; uv (λ_{max} H_2O): 215 nm; ^{1}H nmr (D_2O, TSP) δ: 1.08 (s, 6, 2 × CH_3), 1.17 (s, 3, CH_3), 1.29 (s, 3, CH_3), 1.64 (s, 3, CH_3 thymine), 2.27 (ddd, 1, H-2″), 2.36 (ddd, 1, H-2′), 3.74 (dd, 1, H-5″), 3.79 (dd, 1, H-5′), 3.95 (m, 1, H-4′), 4.44 (m, 1, H-3′), 5.32 (d, 1, H-6), 6.25 (dd, 1, H-1′); ^{13}C nmr (D_2O, TMS) δ: 15.0 (q, CH_3 thymine), 23.6 (q, CH_3), 23.7 (q, CH_3), 33.9 (q, CH_3), 34.0 (q, CH_3), 39.1 (t, C-2′), 53.9 (t, CH_2 piperidone), 54.3 (t, CH_2 piperidone), 62.6 (t, C-5′), 67.3 (s, C-2 or C-6 piperidone), 68.0 (s, C-6 or C-2 piperidone), 72.0 (d, C-3′), 80.1 (d, C-6), 80.8 (s, C-5), 86.2 (d, C-1′), 86.7 (d, C-4′); cd (*c* 1.6, methanol): $[\theta]_{320}$ ±0, $[\theta]_{300}$ −200, $[\theta]_{294}$ −220, $[\theta]_{289}$ ±0, $[\theta]_{270}$ +2900, $[\theta]_{253}$ +6230, $[\theta]_{240}$ 4450; FAB-ms *m/e* (relative intensity), positive mode: 452 (15, M^+ + Na), 430 (6, M^+ + H), 172 (48, TAN + 2H), 154 (18), 130 (48), 117 (2-deoxyribose); negative mode: 428 (22, M^- − H), 275 (18), 257 (76, M^- − TAN), 142 (32), 125 (22, thymine − H), 116 (36, 2-deoxyribose − H).

trans-*(5S,6S)-5-hydroxy-6-(2,2,6,6-tetramethyl-4-oxo-1-piperidinoxy)-5,6-dihydrothymidine (2)*

The silica gel containing the slowest eluting thymidine−TAN adducts **2** and **3** (R_f 0.30) was extracted with 50% aqueous methanol (3 × 6 mL). The evaporation of the resulting solution to dryness gave 26 mg of the two nucleosides **2** and **3** which were applied to the C-18 Nucleosil column and eluted with methanol−water (7:3) as the solvent. The fractions containing the fastest eluting nucleoside (k' = 3.43), as monitored by its uv absorption at 230 nm, were collected. Evaporation to dryness of the aqueous methanol solution yielded 15 mg of **2** (1.8%) as an oily compound; uv (λ_{max} H_2O): 206 nm; ^{1}H nmr (D_2O, TSP) δ: 1.04 (s, 3, CH_3), 1.07 (s, 3, CH_3), 1.23 (s, 3, CH_3), 1.43 (s, 3, CH_3), 1.69 (s, 3, CH_3 thymine), 2.34 (ddd, 1, H-2″), 3.14 (ddd, 1, H-2′), 3.72 (dd, 1, H-5″), 3.80 (dd, 1, H-5′), 3.88 (m, 1, H-4′), 4.47 (m, 1, H-3′), 5.24 (d, 1, H-6), 6.29 (dd, 1, H-1′); ^{13}C nmr (D_2O, TMS) δ: 20.1 (q, CH_3 thymine), 23.6 (q, 2 × CH_3), 32.8 (q, CH_3), 33.0 (q, CH_3), 53.8 (t, CH_2 piperidone), 53.9 (t, CH_2 piperidone), 62.5 (t, C-5′), 64.4 (s, C-2 or C-4 piperidone), 65.8 (s, C-4 or C-2 piperidone), 70.7 (s, C-5 thymine), 71.7 (d, C-3′), 85.5 (d, C-1′), 86.0 (d, C-4), 89.1 (d, C-6 thymine); cd (*c* 1.2, methanol): $[\theta]_{310}$ ±0, $[\theta]_{280}$ +190, $[\theta]_{260}$ +2840, $[\theta]_{253}$ +3800, $[\theta]_{246}$ +2830, $[\theta]_{240}$ ±0, $[\theta]_{230}$ −8400; FAB-ms, *m/e* (relative intensity), positive mode: 452 (35, M^+ + Na), 430 (12, M^+ + H), 354 (6), 265 (20), 172 (22, TAN + 2H), 117 (40, 2-deoxyribose); negative mode: 428 (22, M^- − H), 283 (15), 257 (42, M^- − TAN), 241 (8, thymidine − H), 142 (16, 5-hydroxy-5,6-dihydrothymine − H), 125 (16, thymine − H), 115 (15, 2-deoxyribose − H); FD-ms, *m/e* (relative intensity): 430 (40, M^+ + H), 259 (100, M^+ − TAN), 170 (75, TAN), 117 (15, 2-deoxyribose).

trans-*(5R,6R)-5-hydroxy-6-(2,2,6,6-tetramethyl-4-oxo-1-piperidinoxy)-5,6-dihydrothymidine (3)*

The fractions containing the slowest eluting thymidine−TAN adduct **3** (k' = 4.57) were collected and evaporated to dryness, yielding 14 mg (1.7%) of an oily compound; uv (λ_{max} H_2O): 214 nm; ^{1}H nmr (D_2O, TSP) δ: 1.07 (s, 3, CH_3), 1.17 (s, 3, CH_3), 1.26 (s, 3, CH_3), 1.44 (s, 3, CH_3), 1.66 (s, 3, CH_3 thymine), 2.42 (ddd, 1, H-2″), 2.96 (ddd, 1, H-2′), 3.73 (dd, 1, H-5″), 3.79 (dd, 1, H-5′), 3.99 (m, 1, H-4′), 4.45 (m, 1, H-3′), 5.34 (s, 1, H-6), 5.75 (dd, 1, H-1′); ^{13}C nmr (D_2O, TMS) δ: 19.8 (q, CH_3 thymine), 23.7 (q, CH_3), 24.3 (q, CH_3), 32.3 (q, CH_3), 33.8 (q, CH_3), 53.6 (t, CH_2 piperidone), 53.7 (t, CH_2 piperidone), 63.0 (t, C-5′), 66.1 (s, C-2 and C-6 piperidone), 70.7 (s, C-5 thymine), 72.3 (d, C-3′), 87.0 (d, C-4′), 92.8 (d, C-1′), 93.7 (d, C-6 thymine); cd (*c* 1.8, methanol): $[\theta]_{290}$ ±0, $[\theta]_{270}$ −300, $[\theta]_{260}$ −1480, $[\theta]_{255}$ −1780, $[\theta]_{249}$ −1290, $[\theta]_{244}$ ±0, $[\theta]_{230}$ +8200; FAB-ms, *m/e* (relative intensity), positive mode: 452 (28, M^+ + Na), 430 (11, M^+ + H), 265 (18), 172 (51, TAN + 2H), 117 (82, 2-deoxyribose); negative mode: 428 (29, M^- − H), 257 (58, M^- − TAN), 241 (8, thymidine − H), 142 (26, 5-hydroxy-5,6-dihydrothymine − H), 125 (37, thymine − H), 115 (25, 2-deoxyribose − H); DCI-ms (NH_3) *m/e* (relative intensity), positive mode: 430 (40, M^+ + H), 276 (10, M^+ − TAN + NH_3), 243 (11, thymidine + H), 172 (42, TAN + 2H).

trans-*(5S,6S)-6-hydroxy-5-(2,2,6,6-tetramethyl-4-oxo-1-piperidinyl-*N*-oxide)-5,6-dihydrothymidine (6)*

The main uv absorption band (R_f 0.22), which contained the starting thymidine (**1**) and the thymidine−TAN addition product **6**, was scraped off and the two nucleosides were extracted with 50% aqueous methanol (3 × 6 mL). The resulting solution was evaporated to dryness and applied to the C-18 Nucleosil reversed-phase column. The eluent was a mixture of water and methanol (7:3) and the detection of the nucleosides was monitored at 230 nm. The latest eluting nucleoside consisted of thymidine (k' = 1.05). The fractions containing the thymidine–TAN adduct (k' = 4.58) were collected and evaporated to dryness, giving 12 mg of a colorless oily compound (1.4%); uv (λ_{max} H_2O): 214; ^{1}H nmr (D_2O, TSP) δ: 1.10 (s, 6, 2 × CH_3), 1.21 (s, 3, CH_3), 1.31 (s, 3, CH_3), 1.65 (s, 3, CH_3 thymine), 2.20 (ddd, 1, H-2″), 2.44 (ddd, 1, H-2′), 3.74 (dd, 1, H-5″), 3.79 (dd, 1, H-5′), 3.96 (m, 1, H-4′), 4.46 (m, 1, H-3′), 5.39 (s, 1, H-6), 6.26 (dd, 1, H-1′); ^{13}C nmr (D_2O, TMS) δ: 14.6 (q, CH_3 thymine), 23.6 (q, 2 × CH_3), 33.8 (q, 2 × CH_3), 37.8 (t, C-2′), 53.8 (t, CH_2 piperidone), 54.3 (CH_2 piperidone), 63.1 (t, C-5′), 63.8 (s, C-2 or C-4 piperidone), 64.2 (C-4 or C-2 piperidone), 72.5 (d, C-3′), 79.5 (d, C-6 thymine), 80.9 (s, C-5 thymine), 85.1 (d, C-4′), 86.6 (d, C-1′); cd (c 1.3, methanol): $[\theta]_{319}$ ±0, $[\theta]_{309}$ +80, $[\theta]_{283}$ +600, $[\theta]_{276}$ ±0, $[\theta]_{269}$ −1500, $[\theta]_{240}$ −3870, $[\theta]_{229}$ −3760; FAB-ms m/e (relative intensity), positive mode: 452 (18, M^+ + Na), 430 (10, M^+ + H), 172 (40, TAN + 2H); negative mode: 428 (20, M^- − H), 257 (70, M^- − TAN), 116 (40, 2-deoxyribose − H).

*Decomposition studies of the adducts **2**–**7** in aqueous solutions*

The TAN–thymidine adduct **6** (45 mg) was dissolved in 100 mL of water (pH 6.5) and the resulting aerated solution was stirred for 48 h at 30°C. Two-dimensional thin-layer chromatographic analysis of an aliquot of the solution shows, besides the starting compound, the presence of a far-uv absorbing nucleoside. Preparative separation of this nucleoside was made on two thick silica gel tlc plates by using solvent system II. Extraction of the silica gel (R_f 0.35) with methanol (3 × 6 mL) provided 11.5 mg of a nucleoside which was characterized as 5-hydroxymethyl-2′-deoxyuridine (**14**) by comparison of its uv, ^{1}H nmr, and FAB mass spectrometric features with those of the authentic sample (28).

Under the same experimental conditions, the partial decomposition of **7** (~60%) generated 5-hydroxymethyl-2-deoxyuridine (**14**) in 45% yield as the major product.

It has to be pointed out that the other TAN–thymidine adducts **2**–**5** did not undergo any detectable degradation in the above conditions, even at a higher temperature (60°C).

*Conversion of the adducts **6** and **7** to 5-hydroperoxymethyl-2′-deoxyuridine (**15**)*

The solution of the adduct **6** (35 mg) in 80 mL of 30% aqueous hydrogen peroxide was stirred for 15 h at 30°C. The solution was evaporated to dryness under reduced pressure (10^{-3} Torr; 1 Torr = 133.3 Pa) to remove H_2O_2. The resulting residue was deposited on three thin-layer precoated silica gel plates which were further eluted with the solvent system II. The silica gel containing the main uv absorbing band (R_f 0.50), which gave a positive test for a peroxidic compound by spraying the chromatogram with a methanolic solution of KI, was scraped off and extracted with 3 × 6 mL of methanol. Evaporation of the methanolic solution yielded 8.8 mg of 5-hydroperoxymethyl-2′-deoxyuridine (39%), which showed uv and ^{1}H nmr spectroscopic properties identical to those of the authentic sample (30). Work-up in a similar way of the minor uv absorbing band gave 1.2 mg of 5-hydroxymethyl-2′-deoxyuridine (**14**) (5%).

Treatment of the adduct **7** under the above conditions yielded 5-hydroperoxy-2′-deoxyuridine (**15**) and 5-hydroxymethyl-2′-deoxyuridine (**14**) in 35% and 6% yields, respectively.

*Stability studies of the thymidine adducts **2**–**7** in pyridine–water solutions*

The TAN addition product to thymidine, **6** (85 mg), was dissolved in 100 mL of 50% aqueous pyridine. The resulting solution was stirred, open to the air, for 3 h at 60°C. The solution was evaporated to dryness and the resulting residue was applied on two precoated silica gel plates. Solvent system II was used as the developer. Six main bands, which gave a pink coloration after spraying the chromatoplates with the cysteine – sulfuric acid reagent, were extracted with 3 × 5 mL of methanol. Evaporation to dryness of the resulting solutions yielded six homogeneous nucleosides which were characterized by comparison of their uv, ^{1}H nmr, cd, and mass spectrometric features with those of the corresponding authentic samples: *N*-(2-deoxy-β-D-*erythro*-pentofuranosyl) formamide (**18**) (R_f 0.22; 22.2 mg, 40%); (+)-*cis*-(5*S*,6*R*)-5,6-dihydroxy-5,6-dihydrothymidine (R_f 0.30; 9.8 mg, 10%); (−)-*cis*-(5*R*,6*S*)-5,6-dihydroxy-5,6-dihydrothymidine (R_f 0.33; 9.4 mg, 10%); thymidine (**1**) (R_f 0.52; 7.9 mg, 9%); (+)-(5*R**)-1-(2-deoxy-β-D-*erythro*-pentofuranosyl)-5-hydroxy-5-methylhydantoin (**16**) (R_f 0.57; 7.9 mg, 9%); (−)-(5*S**)-1-(2-deoxy-β-D-*erythro*-pentofuranosyl)-5-hydroxy-5-methylhydantoin (**17**) (R_f 0.61; 8.5 mg, 10%).

Under similar experimental conditions, the degradation of the adduct **7** gave rise to the following compounds, which were separated by thin-layer chromatography on precoated silica gel plates as reported above: *N*-(2-deoxy-β-D-*erythro*-pentofuranosyl) formamide (**18**) (R_f 0.22; 29.3 mg, 41%); (+)-*cis*-(5*S*,6*R*)-5,6-dihydroxy-5,6-dihydrothymidine (R_f 0.30; 8.4 mg, 9%); (−)-*cis*-(5*R*,6*S*)-5,6-dihydroxy-5,6-dihydrothymidine (R_f 0.33; 8.6 mg, 9%); (+)-(5*R**)-1-(2-deoxy-β-D-*erythro*-pentofuranosyl)-5-hydroxy-5-methylhydantoin (**16**) (R_f 0.57; 7.7 mg, 9%); (−)-(5*S**)-1-(2-deoxy-β-D-*erythro*-pentofuranosyl)-5-hydroxy-5-methylhydantoin (**17**) (R_f 0.61; 8.4 mg, 10%).

The other adducts **2**–**5** are stable in pyridine–water at 60°C. In particular, no detectable decomposition of these adducts was observed after storage under the above conditions over a period of 24 h.

*γ-Radiolysis of deaerated aqueous solutions of 5-bromo-6-hydroxy-5,6-dihydrothymidine (**12**) or (**13**) in the presence of TAN*

A 0.1 *M* *tert*-butanol solution of 200 mg of (+)-*trans*-5-bromo-6-hydroxy-5,6-dihydrothymidine (**13**) and 200 mg of TAN in 250 mL of bi-distilled water (pH 6.5) was deaerated by bubbling with a stream of nitrogen for 15 min and subsequently exposed to γ-rays from the ^{60}Co source of 2.5 h (absorbed does 16.5 kGy). The solution was evaporated to dryness and the resulting residue was applied on a preparative high performance silica gel column SI 500 (Waters, Milford). Elution was carried out with solvent system II at a flow-rate of 50 mL per minute. The separation of the major adduct **7** from the starting bromohydrin and TAN was achieved after one recycle. Evaporation of the corresponding fraction (k' = 2.24) as detected by refractive index yielded 154 mg of **7** (61%) which was shown to be homogeneous by analytical reversed-phase high performance liquid chromatography and two-dimensional silica gel thin-layer chromatography (eluents I and II). Its ^{1}H nmr and FAB mass spectrometric data were identical to those obtained for the adduct **7** (*vide supra*).

γ-Irradiation of the aqueous solution of the (−)-*trans* diastereoisomers of 5-bromo-6-hydroxy-5,6-dihydrothymidine (**12**) in the presence of 4.7 m*M* TAN and 0.1 *M* *tert*-butanol gave rise to the TAN–thymidine adduct **6** in a 64% yield.

γ-Irradiation of an aqueous solution of 5-hydroxy-5,6-dihydrothymidine containing TAN

Two hundred milliliters of a degassed aqueous solution of 52 mg of (5*S*)-5-hydroxy-5,6-dihydrothymidine (**10**) and of 70 mg of TAN was irradiated with the γ-rays of ^{60}Co for 1 h (absorbed dose 6600 kGy). The solution was evaporated to dryness and the resulting syrup was deposited on a preparative silica gel thin-layer plate. The developing solvent was a mixture of chloroform and methanol (9:1). The broad band (R_f 0.42) which gave a positive coloration with both the 2,4-dinitrophenylhydrazine and cysteine – sulfuric acid sprays, which are characteristic of carbonyl containing compounds and 2′-deoxyribosides respectively, was extracted with 3 × 4 mL of methanol. Evaporation to dryness of the resulting solution yielded 11 mg of a yellow syrup. This residue was dissolved in 1 mL of 70% aqueous methanol and 0.2 mL of this solution was applied per analysis on the ODS-3 reversed-phase hplc column. Elution was carried out with a mixture of water and methanol (7:3) as the solvent. Four main fractions were detected by their uv absorption at 220 nm and collected. Evaporation to dryness yielded the four homogeneous TAN–thymidine adducts, which were characterized by comparison of their ^{1}H nmr and FAB mass spectroscopic features with those obtained for the authentic samples (*vide supra*): fraction 1 (k' = 1.50), 3.2 mg of

4; fraction 2 (k' = 3.42), 3.5 mg of **2**; fraction 3 (k' = 4.34), 1.2 mg of **8**; and fraction 4 (k' = 4.84), 1.4 mg of **9**.

Under similar experimental conditions, the γ-irradiation of 52 mg of the 5*R* diastereoisomer of 5-hydroxy-5,6-dihydrothymidine (**11**) in the presence of TAN generated four thymidine–TAN adducts. Initial thin-layer analysis, followed by reversed-phase high performance liquid chromatography, provided four main fractions: fraction 1 (k' = 1.15), 3.4 mg of **5**; fraction 2 (k' = 4.57), 3.7 mg of **3**; fraction 3 (k' = 4.35), 1.5 mg of **8**; and fraction 4 (k' = 4.85), 1.4 mg of **9**.

Hydrogenolysis of thymidine–TAN adducts

The nucleoside (10 mg) to be hydrogenolysed was dissolved in 10 mL of methanol; 300 mg of previously hydrogenated Pd/C (Merck, Darmstad, GFR) were added to this solution. Hydrogenolyses were carried out under 50 bars (1 bar = 100 kPa) for 5 h, while stirring the solution. The methanolic solution was then filtered through a Celite pad and evaporated to dryness. The oily residue was analyzed by tlc on silica gel and (or) hplc on the C-18 reversed phase column.

Acknowledgments

The authors thank H. Reutenauer (Centre Grenoblois de Résonance Magnétique Nucléaire) for carrying out the ^{1}H nmr experiments, and Dr. F. E. Hruska for fruitful discussions. They also acknowledge the "Association pour le Développement de la Recherche sur le Cancer" for partial support (Grant ADRC GR. 762.964).

FRANK E. HRUSKA, MAURICE BERGER, JEAN CADET, and MIECZYSLAW REMIN. Can. J. Chem. **63**, 15 (1985).

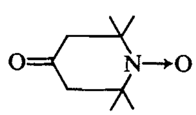
γ-Irradiation of oxygen-free, aqueous solutions of 2′-deoxythymidine in the presence of the organic nitroxide free radical, 2,2,6,6-tetramethyl-1,4-piperidone-*N*-oxyl (TAN), leads to a complex mixture of products in which the TAN moiety is linked to the C5 or C6 position of a 5,6-saturated thymine ring. Extensive [1]H and [13]C nmr data are provided for the eight TAN−dT adducts which are produced in the largest amounts. The results show that the conformational properties of the sugar moiety are dependent on the point of attachment of the TAN group and the configuration of the saturated thymine ring.

FRANK E. HRUSKA, MAURICE BERGER, JEAN CADET et MIECZYSLAW REMIN. Can. J. Chem. **63**, 15 (1985).

La radiolyse γ de solutions aqueuses de désoxy-2′-thymidine et d'un radical libre nitroxyde, la tétraméthyl-2,2,6,6 pipéridone-4 oxyle-1 (TAN), engendre un mélange complexe de produits qui résultent de l'addition de la molécule de TAN sur les carbones 5 ou 6 pyrimidiniques. Une étude détaillée de rmn [1]H et [13]C a été effectué par les huit dérivés d'addition radio-induite du TAN avec la thymidine. Les propriétés conformationnelles du fragment osidique de ces produits dépendent du site d'attachement de la molécule de TAN et de la configuration du carbone (6) du cycle pyrimidinique.

Introduction

The free radical reactions in γ-irradiated aqueous solutions of 2′-deoxythymidine (dT) in the presence of the organic nitroxide free radical, 2,2,6,6-tetramethyl-4-piperidone-*N*-oxyl (triacetoneamine-*N*-oxide, or TAN), lead to a complex array of products with the TAN moiety linked to a 5,6-saturated thymine base. In the previous, companion paper extensive chemical, mass spectrometric, and [1]H and [13]C nmr data were used for



structural and configurational assignments of several series of adducts with a TAN group at the C5 or C6 position of the pyrimidine ring (1). In vitro evidence (2,3) indicates that TAN, and other organic nitroxides, can react with hydroxyl radical-induced transients in DNA, but the nature of the products has not been determined. The adducts of the type described (1) are likely candidates, though addition of TAN to other bases, or to the sugar, cannot be discounted (4). The addition of the TAN group to the thymine base, with the concomitant 5,6-saturation of the ring, would have profound effects on its hydrogen bonding and stacking properties, and on the stereochemistry of the sugar phosphate backbone of a polynucleotide, but no information on its effects is available. Similarly, no structural data for any TAN adduct has been provided by X-ray crystallography. In this study we discuss [1]H and [13]C nmr data which provide information about the conformation of the TAN−dT adducts in aqueous solution and should contribute to our growing knowledge of modified nucleosides. Furthermore, our data should be useful for identifying any TAN adduct isolated from DNA.

[1]Permanent address: Chemistry Department, The University of Manitoba, Winnipeg, Manitoba, Canada.

In Fig. 1 are shown the four diastereoisomeric forms of 5-TAN-6-hydroxy-5,6-dihydro-2′-deoxythymidine (5T series) and the four diastereoisomeric forms of 5-hydroxy-6-TAN-5,6-dihydro-2′-deoxythymidine(6T series). Structures are shown for the adduct in each series, 5T1 and 6T1, which has the *R* configuration at C5 and C6. For the six remaining molecules only the C5—C6 fragment is given to show their configurations at C5 and C6: 5*S*,6*R* in 5T2 and 6T2; 5*R*,6*S* in 5T3 and 6T3; 5*S*, 6*S* in 5T4 and 6T4. It is important to note that evidence (1) points to linkage at C5 via the nitroxyl N-atom in the 5T series and at C6 via the nitroxyl O-atom in the 6T series. Note also that in each series (5T, 6T) the T1 and T4 bases constitute, in isolation, an enantiomeric pair with a *trans* relationship between the TAN and hydroxyl groups, whereas the T2 and T3 bases constitute a *cis* enantiomeric pair. As pointed out (1), the four 6T isomers, but only two of the 5T isomers, could be isolated in quantities sufficient for study; arguments were presented that the two are the *trans* isomers, 5T1 and 5T4. Space-filling models reveal more severe crowding of substituents on the pyrimidine ring in the 5T series. Thus, the absence of significant amounts of the *cis* isomers, 5T2 and 5T3, may be a reflection of the more critical stereochemical requirements for the formation of the 5T molecules. The *cis* isomers may, however, be present in the additional fraction of as yet unidentified products of γ-irradiation.

Figure 2 shows the structure of two additional adducts isolated in sufficient quantity, the diastereoisomers of 5-TAN-5,6-dihydro-2′-deoxythymidine with a TAN group linked to C5 via the nitroxyl N-atom and with a C6-*methylene* function. The molecules are denoted 5T*R* and 5T*S* according to their *R* or *S* configuration at C5, but we could make no absolute configurational assignment with the available spectroscopic data (1).

Essential for our discussion of the data for the 5T and 6T series are the four diastereoisomers of 5,6-dihydroxy-5,6-dihydro-2′-deoxythymidine which are major products of γ-irradiation of *aerated*, aqueous solutions of dT (5). They are

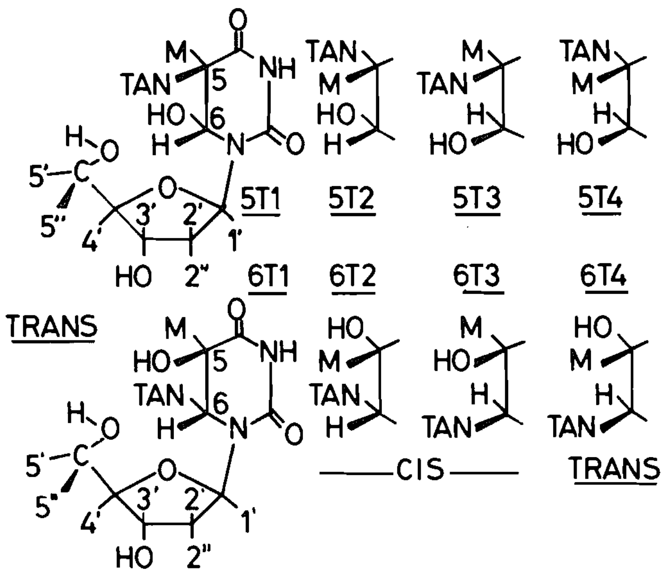


FIG. 1. Structures of the 5T and 6T series of 2′-deoxythymidine – TAN adducts. The linkage is to the nitroxyl N- and O-atoms in 5T and 6T, respectively. In each series the T1 and T4 bases are, in isolation, enantiomers with *trans*-oriented TAN and hydroxyl groups; the T2 and T3 bases are enantiomers with *cis*-oriented TAN and hydroxyl groups. The bases are represented in the *anti* conformer range about the *N*-glycosyl link; rotation by 180° makes them *syn*. M is CH_3. Absolute configurations of C5 and C6: T1 (*R*,*R*); T2 (*S*,*R*); T3 (*R*,*S*); T4 (*S*,*S*).

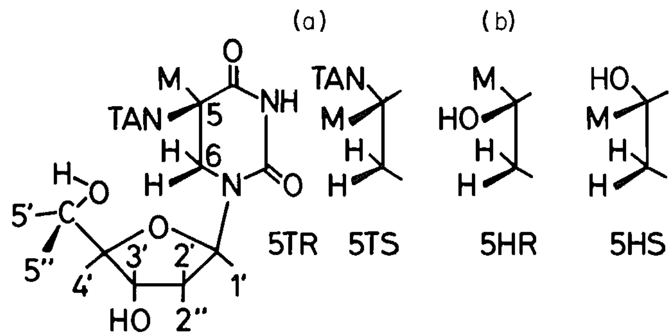

FIG. 2. Structures of (a) the 5T(*RS*) series of TAN adducts, 5T*R* and 5T*S* (linked via the nitroxyl N-atom), and (b) the 5H series of derivatives, 5H*R* and 5H*S*. M is CH_3. *R* and *S* refer to the C5 configuration. The bases are drawn in the *anti* conformer range about the *N*-glycosyl link. The absolute configurations have been determined for the 5H series but not for the 5T(*R*,*S*) series.

denoted D1, D2, D3, and D4, which have respectively the 5*R*,6*R*, 5*S*,6*R*, 5*R*,6*S*, and 5*S*,6*S* configurations at C5 and C6. Replace TAN by a hydroxyl group in the 5T (or 6T) series to obtain the correspondingly numbered D isomer (Fig. 1). Thus, 5T1, 6T1, and D1 all have the 5*R*,6*R* configuration, and so on. Note that the D1 – D4 and D2 – D3 base pairs in isolation are enantiomers with *trans* and *cis* oriented hydroxyl groups, respectively. ^{1}H nuclear magnetic resonance data have been reported for the D molecules (6). Similarly useful for comparison with the data of 5T*R* and 5T*S* are the two diastereoisomers of 5-hydroxy-5,6-dihydro-2′-deoxythymidine, generated also in γ-irradiated, aerated aqueous solutions and labelled 5H*R* and 5H*S* according to their configuration at C5 (Fig. 2). A detailed ^{1}H and ^{13}C nmr study of this 5H series has not been presented. In conjunction with the crystallographic structure available for the 5H*S* isomer (7), our solution spectroscopic data could be used to assign the configurations of the two 5H diastereoisomers (1).

Experimental

Materials

The 5T, 6T, and 5T (*RS*) series of TAN adducts (Figs. 1, 2) were prepared by γ-radiolysis of oxygen-free solutions of dT (1 m*M*) containing 2 m*M* TAN, and purified as described (1,8). The 5H*R* and 5H*S* isomers (Fig. 2) were prepared by γ-radiolysis of deaerated, aqueous solutions of dT (10 m*M*) containing 20 m*M* cysteine as described (9).

Nuclear magnetic resonance experiments

The nucleoside samples were lyophilized three times from 99.9% D_2O (Commissariat Energie Atomique, Saclay) and dissolved in 99.9% D_2O to a concentration of 0.1 *M*. (3-Trimethylsilyl)propionate-2,2,3,3-d_4 (TSP) was used as internal reference. Metal ions were removed using Chelex 100 resin columns (Bio-Rad, Richmond, CA). For the ^{1}H T_1 and nOe measurements the nmr tubes (5-mm od) were sealed under nitrogen. The ^{1}H nmr spectra were obtained at 250 MHz (Cameca TSN 250, FT mode, 20°C). Homonuclear decoupling experiments facilitated the spectral assignment. H2′ and H2″ were assigned following coupling constant arguments (10); H5′ and H5″ were assigned from chemical shift trends (11) and selective deuteration experiments (12). Spectral analysis (LAOCOON III) and computer-simulated spectra were the final test of the chemical shift (δ) and coupling constant (*J*) data, and are listed in Tables 1 and 2. The uncertainties in δ and *J* are estimated to be about 0.1 Hz at 250 MHz.

The proton T_1 data (30°C) were obtained by the inversion recovery pulse sequence ($180°-t-90°-T_d$) with a pulse delay of at least $5T_1$ between sequences (13). Ten spectra with delay times *t* in the range 0.1 s to 15 s were collected; peak heights as a function of *t* served as input for a least-squares computer program (probable uncertainty ~5%). The homonuclear ^{1}H nOe experiments were carried out as described elsewhere (14). The nOe enhancements were expressed as the percentage change in peak height of the H6 (or H1′) resonances upon saturation of the H1′ (or H6) resonances. The enhancements are averages of twenty measurements, reproducible to ±3%. The T_1 and nOe data are given in relevant sections below. Unfortunately, due to the rapid decomposition of the 5-TAN derivatives and the difficulties encountered in their synthesis and isolation, only their conventional ^{1}H (and ^{13}C) nmr spectra, but no T_1 or nOe data, were obtainable.

^{1}H-Decoupled ^{13}C nmr spectra were obtained at 25.1 MHz (Varian XL-100-15; 21°C) on aqueous solutions (~0.1 *M* in nucleoside containing about 1% dioxane as internal reference). The assignment of the spectra was made by comparison with published data (15, 16), off-resonance ^{1}H-decoupling, and, for C1′, C4′, and C6, selective ^{1}H-decoupling experiments. The $\delta(^{13}C)$ data in Table 3 are reported in ppm downfield from external TMS with internal dioxane measured at 67.86 ppm. With the available material, the weak carbonyl resonances could not be detected in reasonable times.

Results and discussion

Geometry of the pyrimidine and TAN rings

Evidence points to a distorted half-chair conformation for 5,6-saturated pyrimidines in which C5 and C6 lie on opposite sides of the mean plane defined by N1—C2—N3—C4 (7, 17 – 19). Of the molecules considered here, crystallographic data are available only for 5H*S*, which shows a half-chair with the 5-hydroxyl and 5-methyl groups in pseudo-axial and pseudo-equatorial positions, respectively (7). Conventional methods for determining solution conformations (vicinal *J*(HH)) are not applicable to the ring systems of the molecules under study (Figs. 1, 2). Space-filling models of the 6T molecules suggest a ring pucker with the bulky TAN group in an axial position. The models also suggest that, to accomodate the

[b]Estimated; not measurable when $\delta(5') \approx \delta(5'')$.

6-TAN group in this orientation, the torsion angle about the C6—O bond in the C5—C6—O—N fragment (which defines the relative orientation of the pyrimidine and TAN groups) must be in the antiperiplanar range (180° ± 30°). Rotation out of this range leads to severe crowding of the TAN methyl groups and the substituents on the base and sugar moieties. Crowding of groups is even more severe in the 5-TAN adducts since the TAN group is accompanied on C5 by the bulky 5-methyl group. (The absence of the *cis* adducts, 5T2 and 5T3, in the products of γ-radiolysis is probably a reflection of this more serious crowding.) Molecular models suggest that considerable distortion of the pyrimidine ring would be required to accommodate the 5-TAN group in the *trans* isomers, 5T1 and 5T4, as well as in 5T*R* and 5T*S*.

In the absence of vicinal H—H coupling interactions, only limited structural information about the TAN moiety can be

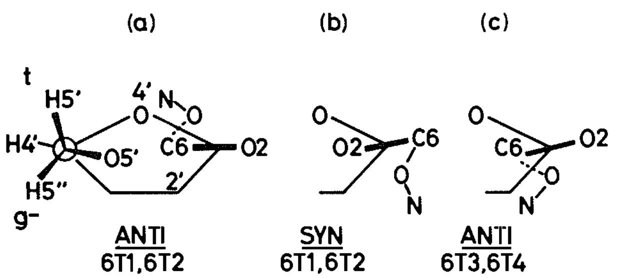

FIG. 3. View of the 6T molecules which shows the position of the 6-TAN group and 2-keto oxygen of the base relative to the sugar moiety in the *anti* and *syn* conformations. TAN is represented by O—N. The view of *syn* 6T3 and 6T4 (not shown) resembles *anti* 6T1 and 6T2 in the position of the TAN group. To obtain views of the correspondingly numbered 5T or D molecule, replace TAN by OH. The diagram on the left shows a projection along C4′—C5′ with the g^+ conformation. t and g^- give the location of O5′ in the t and g^- conformations.

gleaned from our ^1H nmr data. It is interesting that, in the —CH_2—CO—CH_2— portion of the spectrum (an ABXY pattern with geminal coupling constants of 13.5 Hz), a four-bond coupling of 2.2 Hz is noted between one pair of protons, with a smaller coupling of about 0.7 Hz between the other pair. This suggests that one of the four-bond H—C—C—C—H fragments approaches an all-*trans* conformation favorable for coupling (20), whereas the second fragment assumes a less favorable conformation. It is noteworthy that just this situation obtains in the twist-boat conformation found for the TAN molecule in organic solvents (21, 22).

Conformation about the N-*glycosyl bond* (χ)

Steric interactions involving the sugar ring with H6, the 2-keto oxygen, and the TAN methyl groups should have the largest direct role in determining the preferred conformations about the χ bond in the 6T series. Space-filling models suggest that, with an antiperiplanar C5—C6—O—N fragment, rotation about the *N*-glycosyl link is highly hindered and that relatively narrow ranges of χ angles are accessible to the 6T molecules. Thus for the 6*R* pair, 6T1 and 6T2, relatively few contacts are made in a conformation represented in Fig. 3(a) ($\chi \approx -130°$; *anti* domain) which places the TAN group off the sugar ring to its O4′ side. (See Davies and Dixon (23) for definitions of torsion angles.) A second conformation (Fig. 3(b); $\chi \approx 50°$; *syn* domain) places the TAN group off the sugar and near to the C2′ protons. For the 6*S* pair, 6T3 and 6T4, an acceptable conformation is found in the *anti* domain (Fig. 3(c); $\chi \approx -130°$) which places the TAN group near to the C2′ protons in a region similar to that in Fig. 3(b). A *syn* conformation for the 6*S* pair ($\chi \approx 50°$) also seems possible; a perspective is not given but it places the TAN group in a region near O4′, similar to that in Fig. 3(a). Other conformations, which place the 6-TAN group over the sugar ring, seem unlikely.

A variety of data lead us to conclude, in a qualitative way, that the 6*R* adducts, 6T1 and 6T2, prefer the *syn* domain of χ angles whereas the 6*S* pair, 6T3 and 6T4, prefer the *anti* domain. Thus, in nOe experiments in aqueous solution (30°C), saturation of H1′ of 6T1 or 6T2 led to an 11% enhancement of the integrated intensity of the corresponding H6 singlet; similar enhancements in H1′ intensity were noted when the H6 proton was saturated. This suggests proximity of the H6 and H1′ protons, which is achieved in the *syn* conformation (Fig. 3(b)) (24, 25). On the other hand, in the same experiments on the 6*S* pair, 6T3 and 6T4, no significant intensity changes (≈1%) were noted for either H1′ or H6, consistent with the separation of these atoms in the *anti* conformation (Fig. 3(c)).

Following the structural studies by ^1H spin-lattice relaxation time measurements of Preston and Hall (26) and Chachaty and Langlet (27), we find further evidence in Table 4 for the proximity of H1′ and H6. In dT, the parent, unsaturated nucleoside, a relatively long T_1 (H1′) is observed (≈3 s); saturation of the pyrimidine ring to form the D2 glycol leads to a small decrease

[b]Isochronous protons.

(17%) in T_1 (H1′). But formation of the 6T adducts leads to a sharp drop in T_1 (H1′) to 0.49 s − 1.15 s. This trend to shorter T_1 values for H1′ (and for the other protons on the nucleoside fragment, in general) is presumably a reflection, in part, of the longer correlation times for the heavier TAN adducts. However, much shorter T_1 (H1′) values are noted for 6T1 (0.67 s) and 6T2 (0.49 s) than for 6T3 (1.02 s) and 6T4 (1.15 s). This additional relaxation process in the *syn* 6*R* pair can be assigned to interactions with H6 which are not possible in the *anti* 6*S* pair. The striking difference between the 6*R* and 6*S* pairs is not, however, seen in the T_1 (H6) data. We think that, for two reasons, T_1 (H6) might be less sensitive to a *syn*, *anti* conversion. First, H6 should be most strongly relaxed by dipolar interactions with the TAN methyl and 5-methyl protons, which are independent of the χ angle. (Note that T_1 (H6) is always shorter than T_1 (H1′) (Table 4).) Second, the contribution to the H6 relaxation from H1′ in the *syn* conformation is replaced by a comparable contribution from H2′ in the *anti* conformation. (Table 4 also contains T_1 data for the remaining protons which serve to further characterize the molecules and may be of interest to readers).

With normal, unsaturated pyrimidine bases qualitative information about the χ angle has been obtained from chemical shift comparisons, particularly for the H2′ sugar proton, which experiences a large deshielding in the *syn* conformation due to the juxtaposition of the 2-keto oxygen (28−32). To show more clearly the effects of the TAN modification, correlation diagrams (Fig. 4) were constructed with the δ data for the methyl (M), H6, H1′, H2′, and H2″ protons of the 6T, 5T, and D molecules (Table 1 and ref. 6). Data for H3′, H4′, H5′, and H5″ are not given since they show smaller variations. Data are also shown for H1′, H2′, and H2″ of dT and m^{6}dU (6-methyl-2′-deoxyuridine), which prefer the *anti* and *syn* conformations, respectively, in the crystal and aqueous solution states (10, 29, 32, 33).

A striking feature of the diagram is the similarity, for 6T1 and 6T2 on the one hand and for 6T3 and 6T4 on the other hand, in the data for H1′, H2′, and H2″, the sugar protons of which are expected to sense most strongly the shielding effects of the TAN and base moieties. Within each pair the differences in δ are on average only 0.02 ppm, whereas differences in δ between the pairs is large (ca. 0.5, 0.2, and 0.08 ppm for H1′, H2′, and H2″, respectively). Particularly noteworthy are the large deshielding effects of H2′ relative to the data for the dT, D, and 5T molecules (ca. 0.5 ppm for the 6*R* pair and 0.7 ppm for the 6*S* pair) and the large shielding effects of H1′ for the 6*R* pair (ca. 0.5 ppm). In line with the T_1 and nOe measurements, these trends suggest a similarity in χ for 6T1 and 6T2, and for 6T3 and 6T4; that is, in the 6T series the conformation about the *N*-glycosyl bond depends strongly on the configuration at C6 but not at C5. Furthermore, in line with the proposal that 6T1 and 6T2 are *syn*, their H2′ protons resonate downfield by 0.55 ppm from dT and, in fact, only 0.01 ppm from H2′ of m^{6}dU. It is also interesting that the upfield shift of H1′ in the 6*R* pair relative to the 6*S* pair parallels the change in H1′ in m^{6}dU (*syn*) relative to dT (*anti*), though the effect is much larger in the TAN series (0.55 ppm versus 0.1 ppm). The relatively smaller variations in δ(H2″) are less useful as conformational probes.

The similarity in δ(H1′) for dT, 6T3, and 6T4 is in line with the proposed *anti* conformation for the 6*S* pair (Fig. 4). Of considerable concern, however, is the large deshielding (ca. 0.75 ppm) of their H2′ protons relative to dT. The effect is larger than that for the 6*R* pair and in isolation would have led us to assign a *syn* type conformation to the 6*S* pair as well. We attempt to reconcile this effect with the *anti* conformation in the following way. Space-filling models reveal that, with an antiperiplanar C5—C6—O—N fragment, H6 and the TAN methyl protons form a shallow cavity in which is located the nitroxyl nitrogen. In the *anti* conformation of the 6*S* pair, with the TAN group at the C2′ side of the sugar, H2′ can comfortably enter the cavity and approach the N-atom, which we propose is the origin of its strong deshielding. We are not aware of discussions of the shielding properties of N-atoms singly-bonded to three substituents, one of which is oxygen. However, evidence that N-atoms can strongly deshield a nearby proton is provided by the 2.1 ppm deshielding of the chloroform proton in its association with *N*-methylpyrrolidine (34). Of course, we do not suggest hydrogen bonding interactions for H2′, no more here than to the 2-keto oxygen in the *syn* conformation of the 6*R* pair.

Unfortunately, only conventional nmr spectra (but no nOe or T_1 data) could be obtained for the 5-TAN adducts since they are relatively unstable in solution. However, little variation (0.14 ppm or less) is seen in the shielding of any sugar proton for the entire collection of 5T, 5T(*R*,*S*), 5H, and D molecules (Table 1 and Fig. 4). Furthermore, the values for H1′ and H2′ are identical to the corresponding value in dT to within about 0.1 ppm, whereas the δ(H2″) values are typically only 0.1−0.2 ppm upfield from that of dT. Thus a predominantly *anti* conformation is assigned to this group of 5,6-saturated nucleosides. This conclusion is supported by the observation that 5H*S* is *anti* in the crystal state (7). It seems, then, that whereas the 6*S* to 6*R* configurational change in the 6T series effects a rotation from the *anti* to the *syn* conformation, no such effect is apparent for the 5T and D molecules. Thus, it seems that the 6-TAN can only be accommodated on the C2′ side of the sugar (Figs. 3(b), (c)), whereas the steric requirements of the smaller 6-hydroxyl group of the 5T and D molecules are much less critical.

Pucker of the sugar ring

The data in Table 2 show that the values of the *cis* coupling constant $J(1'2'')$ are remarkably similar for the majority of the 5,6-saturated systems (6.4−6.6 Hz) with slightly smaller values for 5T1 (6.0 Hz) and 5T4 (5.6 Hz). In the D series (6)

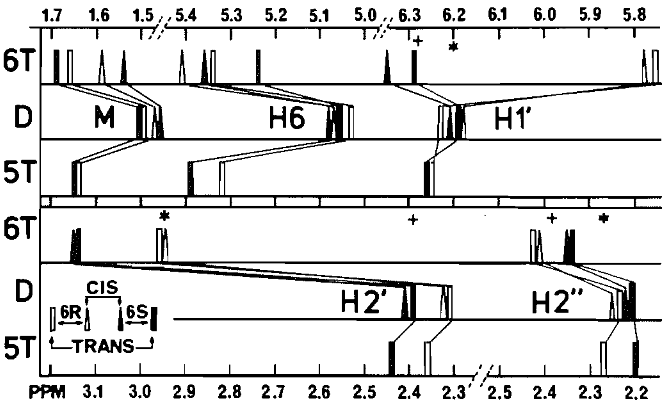

FIG. 4. Chemical shifts of the methyl (M), H6, H1′, H2′, and H2″ protons of the 6T, D, and 5T series. δ in ppm from TSP (Table 1). For each series: isomer 1 (open rectangle); isomer 2 (open triangle); isomer 3 (solid triangle); isomer 4 (solid rectangle). TABLE 5. Calculated populations of the 2′-*endo* (*S*) pucker[a] and of the g$^+$, t, g$^-$ rotamers about the C4′—C5′ bond[b]

Nucleoside	*S*	g$^+$	t	g$^-$
6T1	70	37	45	18
6T2	67	39	41	19
6T3	73	67	—	—
6T4	74	64	30	6
5T1	74	62	26	11
5T4	82	47	29	23
5T*R*	73	50	30	20
5T*S*	75	48	34	17
5H*R*	68	43	37	19
5H*S*	66	41	41	18
dU	60	51	37	12
m^{6}dU	44	35	51	14

[a]%*S* = (8.4 − *J*(3′4′))/7.3 as in ref. 41, which follows ref. 42, and 10*J*(3′4′) for m^{6}dU.
[b]Following ref. 43.

J(1′2′) lies in the range 6.1−6.7 Hz with D1 and D2 at the upper end of the range, and D3 and D4 at the lower end. The values of the *cis* coupling *J*(2′3′) are in the ranges 6.5−7.0 Hz for the 6T and 5H molecules and 5.9−6.3 Hz for the 5T and 5T(*R*,*S*) molecules. In the D series (6) *J*(2′3′) is in the range 6.4−7.0 Hz. Overall, only small changes in the *cis* couplings are seen relative to those of dU (2′-deoxyuridine) (*J*(1′2″) = 6.7 Hz; *J*(2′3′) = 6.8 Hz (35)), suggesting that the formation of the 5,6-saturated derivatives does not lead to large changes in the pseudorotational parameters (P, τ_m) (36, 37). That the *cis* couplings of dU are similar to those of 6T1 and 6T2 for which a *syn* conformation is proposed is interesting, since in the *syn* nucleoside m^{6}dU increases are observed in *J*(1′2″) (8.6 Hz) and *J*(2′3′) (8.2 Hz) (29). Such increases can be rationalized by shifts in the values of *P*(*N*) and *P*(*S*) towards to O4′-*endo* conformation (38). It may be that these changes in pucker, which do not accompany the *syn* 6T1 and 6T2 bases, are characteristic of 5,6-unsaturated pyrimidine nucleosides. A study of the 5,6-saturated derivatives of m^{6}dU could provide useful information about this possibility.

The *trans* coupling constants for the molecules in Table 2 (as well as for the D series (6)) show the overall trend *J*(1′2′) > *J*(2″3′) ≈ *J*(3′4′), which indicates a preference for the *S*(2′-*endo*) pucker over *N*(3′-*endo*) (Table 5) which is noted for normal 2′-deoxyribosides (39, 40). In less pronounced trends, the *J*(1′2′) couplings are similar in the 6T1, 6T2 pair (7.1 Hz, 7.2 Hz) and are similar in the 6T3, 6T4 pair (8.4 Hz, 8.1 Hz). A parallel trend is noticed for *J*(1′2′) in the D1, D2 pair (7.5 Hz, 7.2 Hz) and in the D3, D4 pair (8.5 Hz). For the remaining molecules *J*(1′2′) falls in the narrow range 7.8 ± 0.1 Hz, except for 5T4 (9.2 Hz). *J*(2″3′) and *J*(3′4′) fall into the narrow range 2.2−3.8 Hz and show the inverse correlation with *J*(1′2′) observed for normal 2′-deoxyribosides.

The calculated %*S* values in Table 5 show that, relative to dU, all of the 5,6-saturated systems show a greater bias for 2′-*endo*, the largest being 82% for 5T4. A similar trend toward higher %*S* in the 5,6-saturated system is also noted for the *ribosides*, uridine (U) and 5,6-dihydrouridine (h^{2}U) (19). In the *syn* nucleoside, m^{6}dU, a destabilization of 2′-*endo* occurs, and a bias now exists for 3′-*endo*. This shift towards 3′-*endo* is not seen for 6T1 and 6T2, suggesting again that in the *syn* conformation, 5,6-unsaturated and 5,6-saturated pyrimidine bases may, in general, have different effects on sugar pucker.

C4′—C5′ conformation

Interesting trends in the C4′—C5′ conformation (Fig. 3(a)) are apparent in the sum *J*(4′5′) + *J*(4′5″) (Σ) (Table 2). In one group of molecules Σ varies from 8.7 Hz to 9.9 Hz and is larger than the value for dU (8.5 Hz) (35) and dT (8.6 Hz) (10). At the upper extreme are the Σ values for 6T1 and 6T2, which are similar to that of m^{6}dU (10.1 Hz) (29, 30). In the second group, which comprises 5T1 and the 6S pair, 6T3 and 6T4, Σ is in the narrow range 7.2 ± 0.2 Hz and resembles the value for the riboside U (7.4 Hz) (44). Relative to dU, the molecules in the first group show a diminished contribution from the g$^+$ conformer (Table 5). The largest decrease is seen for 6T1 and 6T2 whose conformer distribution approaches that of m^{6}dU, where a bias for t over g$^+$ is noted. The destabilization of g$^+$ in *syn*, 5,6-unsaturated pyrimidine nucleosides has been attributed to repulsion of the 5′-hydroxyl and 2-keto groups (28−30). However, it is clear from, in particular, the data for 5H*S* that 5,6-saturation of an *anti* base can lead to comparable decreases in %g$^+$. The nmr studies also point to a destabilization of g$^+$ upon 5,6-saturation of pyrimidine *ribo*sides (19).

In contrast, the second group of 5,6-saturated derivatives (5T1, 6T3, 6T4) show an enhanced %g$^+$ relative to dU. A bias towards g$^+$ is apparent with an overall conformer distribution resembling that of U (g$^+$: 62%; t: 32%; g$^-$: 5%; calculated from data in ref. 44). No interactions which should enhance %g$^+$ are apparent to us in molecular models and thus we can only state the obvious: the overall conformation of these molecules is the result of complex steric and electronic factors. However, it is interesting to note that in the *anti* conformation of the 6*S* pair, 6T3 and 6T4, van der Waals contact is made between the 5′-hydroxyl group of the sugar and the protons of a TAN methyl group; in the *syn* conformation of the 6*R* pair, 6T1 and 6T2, this contact is prevented by the intervening 2-keto oxygen of the base. Also, with 5T4 aside, there is the prevailing trend in the TAN molecules for %g$^+$ to increase with increasing %S, the converse of a previously noted correlation (45).

The calculated values of %g$^-$ (Table 5) are interesting in the light of data for ribosides and other 2′-deoxyribosides (41, 46, 47). In both the ribose and deoxyribose series, the g$^-$ con-

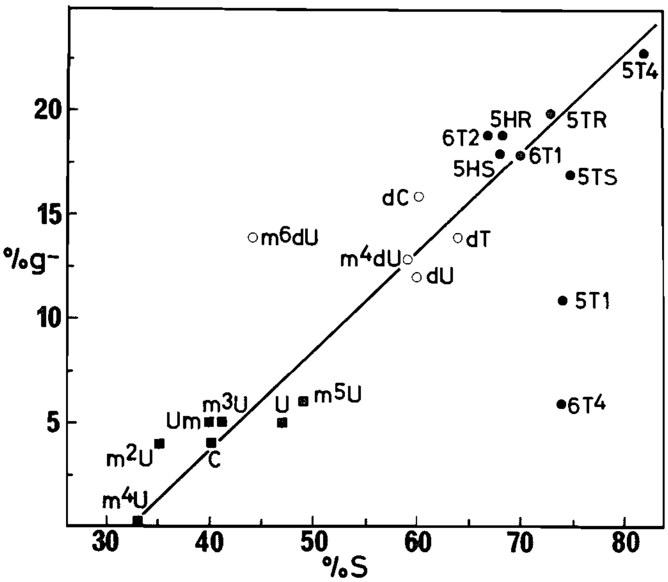

FIG. 5. Plot of %g⁻ versus %S for a series of pyrimidine nucleosides. Solid circles: 5,6-saturated TAN adducts. Open circles: 5,6-unsaturated 2′-deoxyribosides (data from refs. 41, 47). Solid squares: 5,6-unsaturated ribosides, cytidine (C), uridine (U), uridine methylated on the base (m^2U, m^3U, m^4U, m^5U), and at the 2′-position of the sugar (Um).

formation is the least likely, but g^- is more completely suppressed in the ribosides. Figure 5 shows that, with the exception of the data for m^6dU, 5T1, and 6T4, a reasonable correlation is obtained between %g^- and %*S*. The plot suggests that g^- is highly unlikely in a 3′-*endo* sugar. Extrapolation indicates that a maximum of about 40% can be obtained for g^- in a sugar which is 100% S. These solution studies agree with observations on crystalline nucleosides and tRNA which demonstrate that g^- is likely only for 2′-*endo* sugars (48, 49). The exclusion of g^- in 3′-*endo* sugars probably stems from crowding of the 3′- and 5′-hydroxyl groups, which is analogous to the unfavorable parallel 1,3-interactions between oxygens in acyclic sugar derivatives (50), the alleviation of which is an important conformational factor in these systems. (Presumably for similar reasons, the g^- conformation of the hydroxymethyl group of glucopyranosides is also unimportant (51–53).) The crowding of the hydroxyl groups in 3′-*endo*, g^- is removed by a change in the pucker, or by rotation into g^+ or t. A thorough analyses of the C4′—C5′ rotamer populations has been presented (41).

^{13}C chemical shifts

The effects of TAN modification and of configurational changes at C5 and C6 on the ^{13}C chemical shifts (Table 3) are more clearly seen in Fig. 6, which shows the data for the methyl (M), C5, C6, and C1′ carbons. Data for the remaining carbon atoms are not reproduced since they show smaller variations. Using the glycols (D series) as the reference points, one can note a number of interesting trends.

1. In the 6T series, TAN substitution has a small effect on δ(M) and δ(C5) (<1.5 ppm) relative to the corresponding D isomer. M is more shielded in the *trans* isomers (T1, T4) than in the *cis* isomers (T2, T3), by about 4 ppm in the 6T series and in the D series as well. Viewed differently, this means that, in the 6T and D series, the 5*R* to 5*S* configurational change causes a 4-ppm *deshielding* of M when C6 is *R* but a 4-ppm *shielding*

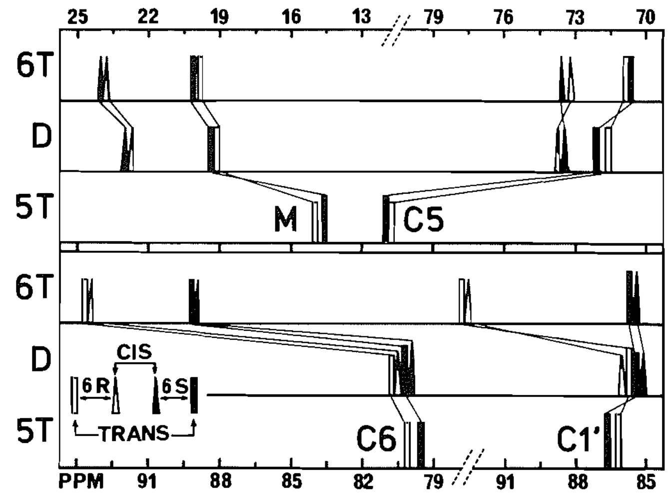

FIG. 6. Chemical shifts of the methyl (M), C5, C6, and C1′ carbons of the 6T, D, and 5T series in ppm from external TMS (Table 3). For each series: isomer 1 (open rectangle); isomer 2 (open triangle); isomer 3 (solid triangle); isomer 4 (solid rectangle). See also legend in lower left corner.

when C6 is *S*. Thus, δ(M) reflects significantly the configuration at C5 and C6, but less so the nature of the C6 substituent (OH or TAN). Similar but attenuated trends also develop in δ(C5).

2. In the D series, δ(C6) is essentially independent of the configuration at C5 and C6, with an overall spread of only 1 ppm for the four isomers. 6-TAN substitution effects a large deshielding of C6, the extent of which depends on the configuration of C6, i.e. 13 ppm for the 6*R* pair and 9 ppm for the 6*S* pair. Furthermore, the 6*R* to 6*S* change causes an upfield shift of about 4.5 ppm in C6, whereas a configurational change at C5 has little effect (compare 6T1 with 6T2, and 6T3 with 6T4). Thus, in contrast with δ(M) and δ(C5), δ(C6) in the 6T series reflects most strongly the nature of the 6-substituent (OH or TAN) and to a lesser extent the configuration at C6, with the configuration at C5 being unimportant.

3. In the D series, δ(C1′) is essentially independent of configuration at C5 or C6 with an overall spread of about 1 ppm for the four isomers. 6-TAN substitution in the 6*R* configuration deshields C1′ by about 7 ppm, but 6-TAN substitution in the 6*S* configuration has no effect on δ(C1′) (<1 ppm). Thus the change in configuration 6*R* to 6*S* causes an upfield shift of about 7 ppm in C1′, but configurational changes at C5 have minimal effect (<0.3 ppm). Though these ^{13}C shifts are not easily related to conformation, it is interesting to note that the *anti* conformation was assigned to the D isomers and the 6*S* pair of 6T isomers, but the *syn* conformation was assigned to the 6*R* pair.

4. A remarkable feature of Fig. 6 is that in the 6T series the M and C5 chemical shifts are "paired" according to the *cis* or *trans* geometry of the pyrimidine ring. That is, we see a similarity in δ(C5) for the *cis* isomers (6T2: 73.2 ppm; 6T3: 73.6 ppm) and for the *trans* isomers (6T1: 70.7 ppm; 6T4: 70.7 ppm), and a parallel behavior for δ(M). In striking contrast, δ(C6) and δ(C1′) are paired according to the configuration C6 rather than to the *cis* or *trans* nature of the ring. That is, we see a similarity in δ(C6) for the 6*R* pair (6T1: 93.7 ppm; 6T2: 93.4 ppm) and for the 6*S* pair (6T3: 89.1 ppm; 6T4: 89.1 ppm), with parallel behavior for δ(C1′). In a qualitative way, one can rationalize the presence of these two pairing

schemes by noting that in isolation the T1 and T4 bases are *trans* enantiomers, whereas the T2 and T3 bases are *cis* enantiomers (Fig. 1). In the absence of differential shielding effects from the sugar, corresponding base carbons in an "enantiomeric pair" will be identically shielded. The pairing of δ(M) and δ(C5) according to *cis* and *trans* geometries suggests the absence of significant shielding of C5 and M by the sugar, in line with the separation of the groups. The pairing of δ(C6) according to the *R* and *S* configurations at C6 indicates that, unlike C5 and M carbons, C6 experiences important shielding effects of the sugar. Furthermore, we are inclined to suggest that the pairing of δ(C6) is a reflection of the differences in conformation about the *N*-glycosyl link for the 6*R* pair (*syn*) and 6*S* pair (*anti*). This view is supported by the observation that the atoms of the *sugar moiety,* which are expected to sense configurational changes at C6 and conformational changes in the *N*-glycosyl link (C1′ (Fig. 6) as well as H1′, H2′, and H2″ (Fig. 4)), have chemical shifts paired in the same way as C6.

5. Comparing that data for 5T1 and 5T4 with the D isomers, we see that 5-TAN substitution causes a 9-ppm deshielding of the C5 carbon which is comparable to the effect of the 6-TAN group on C6 for 6T1 and 6T2 (~9 ppm) but less than the effect on C6 for 6T3 and 6T4 (~13 ppm). Comparison of these effects is complicated, however, because of the differences in conformation for 6*R* (*syn*) and 6*S* (*anti*) pairs of 6T isomers. 5-TAN substitution has a large shielding effect on the 5-methyl group (4−5 ppm), in contrast with the minor deshielding effect of a 6-TAN group (<1 ppm). C6 and C1′ (and the other carbons) experience only small changes upon 5-TAN substitution (>1 ppm). The similarity in the chemical shifts for corresponding carbons of 5T1 and 5T4 demonstrates that the sugar has no important configuration-dependent shielding effects on the base carbons.

The spin–spin coupling over six bonds between ${}^{19}F$ and ${}^{13}C$ nuclei on the sidechain in thirteen 4-fluorophenyl derivatives appears to be mediated by a $\sigma-\pi$ mechanism. Its magnitude depends somewhat on the hybridization state of the carbon atom carrying the coupled nucleus, as well as on the electronegativity of substituents attached to this carbon atom. A consistent behaviour of this coupling is observed if its value is assumed to be proportional to $\sin^2\theta$, where θ is the angle by which the bond carrying the coupled carbon nucleus twists out of the ring plane. However, in 4-fluorostyrene ${}^6J_p^{F,C}$ is a π electron coupling in the planar form, so that its magnitude decreases as the vinyl group twists out of the benzene plane. The $\sigma-\pi$ contribution to this coupling is smaller than the π component. ${}^6J_p^{F,C}$ is used to assess the conformational preferences of a number of compounds, including 4-fluoro-α-methylstyrene, 4,4′-difluorodiphenylmethane, 1,1-dichloro-2,2-bis(4-fluorophenyl)ethane, and 1-(4-fluorophenyl)-*N*-methylcyclohexylamine.

TED SCHAEFER, JAMES PEELING, GLENN H. PENNER, ALBERTA LEMIRE et RUDY SEBASTIAN. Can. J. Chem. **63**, 24 (1985).

Le couplage de spin à travers six liaisons entre les noyaux du ${}^{19}F$ et du ${}^{13}C$ des chaînes latérales de 13 dérivés fluoro-4 phényles semble être contrôlé par un mécanisme de type $\sigma-\pi$. Son amplitude dépend en partie de l'état d'hybridation de l'atome de carbone portant le noyau couplé et aussi de l'électronégativité des substituants fixés sur ce carbone. On observe un comportement consistant de ce couplage si on admet que sa valeur est proportionnelle à $\sin^2\theta$, où θ est l'angle de torsion hors plan de la liaison portant le noyau de carbone couplé. Cependant, dans le cas du fluoro-4 styrène, le couplage ${}^6J_p^{F,C}$ est un couplage d'électrons π dans une forme planaire; il en résulte que son amplitude diminue lorsque le groupe vinyle subit une torsion hors du plan du benzène. La contribution $\sigma-\pi$ à ce couplage est plus faible que celle de la composante π. On a utilisé la valeur de ${}^6J_p^{F,C}$ pour déterminer les préférences conformationnelles de plusieurs composés comprenant les fluoro-4 α-méthylstyrène, difluoro-4,4′ diphénylméthane, dichloro-1,1 bis(fluoro-4 phényl)-2,2 éthane et (fluoro-4 phényl)-1 *N*-méthylcyclohexylamine.

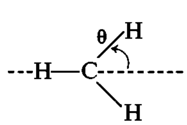
Introduction

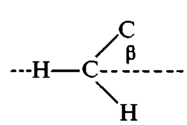
In the study of long-range spin–spin coupling constants, their mechanisms, and their application to conformational problems (1–16), it has been shown (5) that ${}^6J_p^{H,CH}$ varies as $\sin^2\theta$ in toluene derivatives. Here θ is the angle by which the α C—H bond twists out of the benzene plane. The coupling proceeds via a $\sigma-\pi$ mechanism and involves the sidechain proton and the *para* ring proton. Similarly, ${}^5J_p^{C,CH}$, the coupling between the sidechain proton and the *para* carbon-13 nucleus also varies as $\sin^2\theta$ (17, 18), implying that this parameter allows an extension (8) of the *J* method (1) as a conformational tool. In this method, a hindered rotor model provides a relationship between the expectation value of $\sin^2\theta$ and the barrier to rotation about the Csp^2—Csp^3 bond. The expectation value and the observed coupling are simply related by eq. [1], in which ${}^nJ$ can be ${}^6J_p^{H,CH}$ or ${}^5J_p^{C,CH}$ and ${}^nJ_{90}$ is the value of ${}^nJ$

$$[1] \quad {}^nJ = {}^nJ_{90}\langle\sin^2\theta\rangle$$

when θ is 90° in **1**. The *J* method can also discriminate among

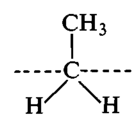


1

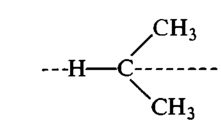


2

preferred ground-state conformations. For example, **3** and **4** can be established as the low-energy forms of ethylbenzene (19) and cumene (20), respectively.



3



4

${}^6J_p^{F,CH}$ has also been investigated as a conformational indicator for *p*-fluorotoluene derivatives (21). The conformational barriers obtained for identical sidechains differed somewhat from those found by the use of ${}^6J_p^{H,CH}$, although identical preferred conformations were identified. Part of the discrepancy possibly may be attributed to a non $\sigma-\pi$ component of ${}^6J_p^{F,CH}$, but this could not be proved. Perhaps a *para* fluorine substituent alters the barriers by altering hyperconjugative interactions of the sidechain C—H and C—C bonds with the benzene system. Another possibility is that the $\sigma-\pi$ component of ${}^6J_p^{F,CH}$ varies somewhat between compounds, ${}^6J_p^{F,CH_3}$ being more sensitive to ring substituent perturbations than is ${}^6J_p^{H,CH_3}$ (22).

It seems sensible, therefore, to extend the investigations to ${}^6J_p^{F,C} \equiv {}^6J$(C-β,F) in compounds of type **2**. The mechanism of this coupling might emerge and a comparison with ${}^6J_p^{H,CH}$, ${}^6J_p^{F,CH}$, and, indeed, ${}^5J_p^{C,CH}$ may establish its viability in conformational work. Because the coupling is measurable in the ${}^{13}C$ nmr spectrum under conditions where ${}^1H$ is decoupled, the experimental work is relatively simple and can be relatively easily done with low-field FT nmr spectrometers.

Experimental

Most of the compounds were obtained from Aldrich Chem. Co. The 4-fluoro-n-propylbenzene, and 4-fluoro-*tert*-butylbenzene were prepared from the *p*-amino derivatives via the diazonium salts. The 4-fluoroethylbenzene was synthesized from the 2-(4-fluorophenyl)-

ethanol via the bromide and its Grignard reagent. The ^{13}C nmr spectra were acquired at 305 K on a Bruker WH 90 FFT nmr spectrometer. A typical run involved 64 acquisitions into 16K and a spectral window of 400 Hz. The sample concentrations and solvents employed are noted in Table 1. The ^1H transitions were strongly irradiated in all these experiments, so that spectral analytical complexities did not arise.

However, the ^1H nmr spectrum of 4-fluoroethylbenzene had not been previously analyzed and yielded to a LAME analysis (23, 24).

The ^{13}C nmr spectrum of 4-fluorobenzyl cyanide was too broad to extract $^6J_p^{F,C}$, no doubt as a consequence of partially relaxed coupling to ^{14}N, whose spin-lattice relaxation time must fall into a range in which the T_2 of C-β becomes inconveniently short.

INDO MO FPT computations (25, 26) were done on an Amdahl V/8 system.

Results and discussion

(a) *Coupling parameters*

In Table 1 the observed $^nJ^{F,C}$ (n = 1–6) values are given for fourteen 4-fluorophenyl derivatives. In fluorobenzene the $^nJ^{F,C}$ values are −245.1, 21.02, 7.79, and 3.20 Hz for n = 1–4, respectively (28), and are no doubt of the same sign for the compounds in Table 1; the magnitudes vary only slightly from compound to compound. Coupling constants of this kind have been discussed previously in some detail (29). $^5J^{F,C}$ in 4-fluorotoluene is of unknown sign and, in view of previous discussions for $^5J_p^{F,H}$ in fluorobenzene (22, 30), may well contain σ and π components of opposite sign.[2] $^6J^{F,C}$ values are discussed in detail below.

Table 2 gives the ^1H nmr spectral parameters for 4-fluoroethylbenzene, not previously reported.

TABLE 2. The ^1H nmr spectral parameters for a solution of 4-fluoroethylbenzene in acetone-d_6 at 90.020 MHz and 305 K

Parameter	Value	Parameter	Value
$\nu_{CH_3}{}^{a,b}$	−76.668(14)	$^4J_o^{H,CH_2}$	−0.618(3)

(b) *The coupling mechanism of* $^6J^{F,C}$

Because $^6J_p^{H,CH}$ and $^5J_p^{C,CH}$ in toluene and its derivatives (5–8), $^6J_p^{H,CC\text{-}\beta}$ in an ethylbenzene derivative (8), and $^6J_p^{F,CH}$ in 4-fluorotoluene and its derivatives (21) are most likely dominated by a σ–π mechanism, it appears likely that $^6J_p^{F,C}$ will behave similarly.

Certainly, INDO MO FPT calculations of the above σ–π couplings confirm their $\sin^2\theta$ dependence (5, 8). Such calculations on 4-fluoroethylbenzene yield eq. [2] for standard geometries (27)

$$[2] \quad {}^6J_p^{F,C}\ \text{Hz} = 0.055 + 0.862\sin^2\theta$$

As argued for other couplings previously (5, 8), the number 0.055 is an artifact of the computation, so that eq. [2] should become eq. [3], where 0.055 Hz is subtracted from 0.862 Hz.

[2]The sign of $^5J^{F,C}$ in 4-fluorotoluene, as well as for analogous couplings in other 4-fluorophenyl derivatives, is under study here.

TABLE 3. Values of ${}^6J_{90}^{F,C}$ estimated from ${}^6J_p^{H,CH_2}$ and ${}^6J_p^{F,CH_2}$ in toluene derivatives

[d] Assuming ${}^6J_{90}^{H,CH_2} = -1.24$ Hz.
[e] $\langle\sin^2\theta\rangle_F^C = 1.5 - 2\langle\sin^2\theta\rangle_H^H$.
[f] In 4-fluorotoluene (21), 1.12 in CS_2, 1.15 Hz in acetone-d_6.
[g] In the 4-fluorotoluene derivatives.
[h] Assuming ${}^6J_{90}^{F,CH_2} = 2.28$ Hz.
[i] In 3,5-dibromoisopropylbenzene (20).
[j] $\langle\sin^2\theta\rangle_F^C = 0.75 - 0.5\langle\sin^2\theta\rangle_F^H$.

$$[3]\quad {}^6J_p^{F,C}\text{ Hz} = {}^6J_{90}^{F,C}\sin^2\theta = 0.807\sin^2\theta$$

In other words, INDO MO FPT computations imply a $\sigma-\pi$ mechanism for ${}^6J_p^{F,C}$, where θ is the angle by which the C—C bond of the sidechain twists out of the benzene plane. As expected on the basis of the known positive signs of ${}^6J_p^{F,CH}$ and ${}^5J_p^{CCH}$ (17, 22), ${}^6J_p^{F,C}$ is computed as positive.

However, ${}^6J_{90}^{F,C}$ is no doubt computed as too small in magnitude, just as is ${}^6J_{90}^{F,CH}$ in 4-fluorotoluene (5). This discrepancy has to do with the INDO parameterization, which should not perturb the functional form of eq. [3]. An artificial way of reproducing a correct ${}^6J_{90}^{F,C}$ would be to alter the C—F bond length, because such a coupling will depend on the overlap of the π orbitals at C-4 with the fluorine orbitals. In fact, ${}^6J_p^{F,C}$ depends exponentially on the C—F bond length, a situation previously noted for other $\sigma-\pi$ couplings, for example, ${}^6J_p^{H,BH}$ in a pyridine–borane complex (31). The discussion below suggests that eq. [4] agrees with experiment.

$$[4]\quad {}^6J_p^{F,C}\text{ Hz} = (1.29 \pm 0.06)\langle\sin^2\theta\rangle_F^C$$

A second question concerns the dependence of ${}^6J_{90}^{F,C}$ on a substituent attached to the coupled carbon. INDO MO FPT computations yield eq. [5] for 2-(4-fluorophenyl)ethanol, in which the electronegative hydroxyl group is attached to the coupled carbon atom.

$$[5]\quad {}^6J_p^{F,C}\text{ Hz} = 0.046 + 1.066\sin^2\theta$$

Relative to 4-fluoroethylbenzene the ${}^6J_{90}^{F,C}$ value has increased by 26%. As before, write eq. [6] in which the angle independent term is deleted on the basis of previous experience. The

$$[6]\quad {}^6J_p^{F,C}\text{ Hz} = 1.02\sin^2\theta$$

calculated increase in the presence of an electronegative substituent has its experimental counterpart in the increase of ${}^1J^{H,C}$ in methane derivatives, interpreted as originating in an enhanced s-electron density at the carbon-13 nucleus caused by the polar substituent (32).

The experimental deduction of ${}^6J_{90}^{F,C}$ now proceeds as follows. Table 3 contains ${}^6J_p^{H,CH}$ and ${}^6J_p^{F,CH}$ values and the $\langle\sin^2\theta\rangle$ values for a series of toluene derivatives in which the sidechain is CH_3, CH_2CH_3, $CH(CH_3)_2$, or $C(CH_3)_3$. The $\langle\sin^2\theta\rangle$ values are given on the assumption that ${}^6J_p^{H,CH}$ and ${}^6J_p^{F,CH}$ are $\sigma-\pi$ couplings and are obtained from ${}^6J$(observed) $= {}^6J_{90}\langle\sin^2\theta\rangle$, where $\langle\sin^2\theta\rangle$ is the expectation value of $\sin^2\theta$. The $\langle\sin^2\theta\rangle_F^C$ numbers follow from $\langle\sin^2\theta\rangle_F^C = 1.5 - 2\langle\sin^2\theta\rangle$ for ethyl substituents and from $\langle\sin^2\theta\rangle_F^C = 0.75 - 0.5\langle\sin^2\theta\rangle$ for isopropyl substituents if **3** and **4** are considered to be the preferred conformations of the two sidechains. The observed ${}^6J_p^{F,C}$ parameters then yield ${}^6J_{90}^{F,C}$ in the last column of Table 3.

The ${}^6J_p^{F,C}$ magnitudes range from 1.20 to 1.40 Hz, the eight values yielding an average of 1.29 ± 0.06 Hz, where 0.06 Hz is the standard deviation. In view of measurement errors in all the couplings involved and of the fact that 4-fluorophenyl are treated on the same footing as 3,5-dibromophenyl groups, a smaller uncertainty in ${}^6J_{90}^{F,C}$ is not expected. It might be argued, for example, that ${}^6J_{90}^{F,C}$ appears to decrease monotonically with an increase in the number of methyl substituents and that this implies an intrinsic dependence of ${}^6J_{90}^{F,C}$ on the substituent β to the coupled carbon, in constrast to the calculated increase above in ${}^6J_p^{C,F}$ caused by an α substituent on the coupled carbon. This dependence may exist but, in our opinion, is unproven and is difficult to establish from the present data set.

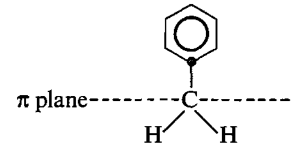
An example of the errors in the twofold barriers caused by the uncertainty in ${}^6J_{90}^{F,C}$ comes from ethylbenzene. A ${}^6J_{90}^{F,C}$ of 1.29 Hz implies a V_2 of 1.8 kcal/mol (1 cal ≡ 4.184 J), whereas 1.40 Hz leads to 1.2_5 kcal/mol. This last number, of course, is that deduced from ${}^6J_p^{H,CH}$ in 3,5-dibromoethylbenzene (19). If ${}^6J_p^{H,CH}$ is 0.45 Hz, as reported for ethylbenzene (33), then V_2 follows as 1.6 kcal/mol.

A conservative conclusion is that ${}^6J_{90}^{F,C}$ is predominantly a $\sigma-\pi$ coupling, and that it yields the preferred conformation of the sidechain and also a rough estimate of the barrier to internal rotation about the exocyclic carbon–carbon bond for these alkyl substituents.

(c) *Conformational applications of* ${}^6J_p^{F,C}$

(i) *4,4′-Difluorodiphenylmethane*

Here ${}^6J_p^{F,C}$ involves an sp^2 carbon atom in the second benzene ring, in contrast to the sp^3 carbon atoms discussed in the previous section. However, ${}^6J_p^{H,CH}$ and ${}^6J_p^{F,CH}$ have been used to study the preferred conformations of diphenylmethane derivatives (34), so that the following comparisons may be made. The latter couplings implied that the gable conformation, **5**, having



5

C_{2v} symmetry, obtained from a heavy-atom coplanar conformation by rotation of each benzene ring by 90° about the sp^2–sp^3 carbon–carbon bond, was preferred. In other words, C-1 of the second benzene ring lies preferably in a plane perpendicular to the plane of the first benzene ring. As far as $^6J_p^{F,C}$ is concerned, the preferred conformation is therefore analogous to **3** for ethylbenzene.

$^6J_{90}^{F,C}$ for 4,4′-difluorodiphenylmethane is 0.942(2) Hz. Therefore $\langle \sin^2 \theta \rangle_F^C$ is 0.942/1.29 or 0.730 ± 0.035, assuming $^6J_{90}^{F,C}$ as unaltered from its value for an sp^3 carbon and its error as 0.06 Hz. The V_2 is implied as $1.2_5 \pm 0.2_5$ kcal/mol for rotation about the sp^2–sp^3 bond. The temperature dependence of $^6J_p^{F,CH}$ yielded V_2 as $1.5_5 \pm 0.25$ kcal/mol, whereas $^6J_p^{H,CH}$ in 3,5-dibromodiphenylmethane gave V_2 as 1.1 ± 0.3 kcal/mol (34). These results imply that $^6J_{90}^{F,C}$ is not very sensitive to the hybridization state of the carbon atom carrying the coupled nucleus.

$^6J_p^{F,C}$ confirms that the preferred conformation of diphenylmethane has the C_1—C—C_1' plane perpendicular to the benzene planes. If the preferred conformation were one in which this plane lay *in* a benzene plane, then $^5J_p^{F,C}$ would most likely have a magnitude of less than 0.5 (1.29) or 0.65 Hz instead of the observed 0.94 Hz. See refs. 34 and 35 for a fuller discussion of other suggested conformations. The use of $^6J_p^{F,C}$ as an indicator of preferred conformations in *ortho*-substituted diphenylmethanes appears sensible, as it does for diphenylethanes.

(ii) *1,1-Dichloro-2,2-bis(4-fluorophenyl)ethane (DFDD)*

$^6J_p^{F,C}$ in DFDD is 0.801(2) Hz and again involves a carbon atom of the second benzene ring, suggesting a conformation closely related to that of diphenylmethane. In the crystal, the benzene rings do indeed lie in face-to-face positions (36) and corresponding atoms in these rings are related by reflection across a mirror plane containing the HCCH atoms of the aliphatic fragment. The latter has very nearly tetrahedral bond angles. If **5** corresponded to the preferred conformation in solution, that is, if θ_{min} were 90°, and if the rotation about the sp^2–sp^3 carbon–carbon bond were naively treated as twofold, then the internal barrier would be deduced as about 0.6 kcal/mol ($\langle \sin^2 \theta \rangle_F^C = 0.801/1.29$), about 1 kcal/mol lower than in the difluorodiphenylmethane above. That this interpretation would be erroneous can be seen as follows.

First, in solution the C—H bonds of the aliphatic fragment can also take on *gauche* conformations with respect to each other. Thus, in a 5 mol% solution in CCl_4 at 305 K, $^3J^{H,H}$ is only 7.76(8) Hz. The usual approach to the estimation of the magnitudes of the *trans* and *gauche* couplings (37–39), together with a $^3J_t^{H,H}$ of 10.5 Hz in sym-tetrachloroethane (40) and 11.3 Hz in sym-tetraphenylethane (41*a*), and a $^3J_g^{H,H}$ of 2.2 Hz in the former, implies a $^3J_t^{H,H}$ of about 10.9 Hz and a $^3J_g^{H,H}$ of 2.3 Hz in DFDD. A 2-site treatment then yields the *trans* population as 63%. In an acetone-d_6 solution the *trans* population increases to 82%, $^3J^{H,H}$ having increased to 9.35(3) Hz.

Furthermore, $^4J_o^{H,CH}$, $^5J_m^{H,CH}$, and $^6J_p^{F,CH}$ are −0.451(5), 0.233(3), and 0.25(2) Hz, respectively, in the acetone solution. These numbers imply (1, 7, 21) that not **5**, but a conformation with θ nearer 60°, is that of lowest energy. For a twofold barrier one may write (7) $^5J_m^{H,CH} = 0.336 \langle \sin^2 \theta \rangle_H^H + 0.188$, so that $\langle \sin^2 \theta \rangle_H^H$ becomes 0.134. Also (21), $^6J_p^{F,CH} = 2.27 \langle \sin^2 \theta \rangle_F^H$, yielding $\langle \sin^2 \theta \rangle_F^H$ as 0.110. The mean value is 0.122, implying a barrier of 2.9 kcal/mol. An empirical plot (41*b*) of $^4J_o^{H,CH}$ versus V_2 values suggests a twofold barrier of 3.0 kcal/mol. An estimate of $\langle \sin^2 \theta \rangle_F^C$ then follows as 0.75 − 0.5 (0.122), or 0.69, and $^6J_p^{F,C}$ becomes 0.69(1.29), or 0.89 Hz. The observed value is 0.80 Hz.

Of course, better agreement is not expected because the barrier can hardly be purely twofold, the *gauche* and *trans* conformations are treated as having the same conformation about sp^2–sp^3 bonds, and because the barriers in the two forms need not be the same. However, the argument does demonstrate DFDD as more rigid than 4,4′-difluorodiphenylmethane and that θ_{min} is much nearer 60° than 90°. A detailed investigation in which additional long-range couplings, such as $^nJ^{C,H}$ (8), are measured in solutions of varying polarity, may well lead to a sensible description of the internal dynamics of DFDD.

(iii) *2-(4-Fluorophenyl)ethanol and 1-(4-fluorophenyl)-propane*

In these compounds an electronegative substituent, hydroxy or methyl, is attached to the coupled carbon. The INDO MO FPT computations above imply a 26% increase in $^6J_{90}^{F,C}$ in the presence of the hydroxyl substituent. Assuming a linear dependence of $^6J_{90}^{F,C}$ on E_X, the electronegativity of the substituent, where $E_H = 2.1$, $E_{CH} = 2.5$, $E_{OH} = 3.5$, and assuming that $^6J_{90}^{F,C}$ is 1.29 Hz when X = H and 1.63 Hz when X = OH, leads to a $^6J_{90}^{F,C}$ of 1.39 Hz for X = CH_3.

In the propane derivative, $^6J_p^{F,C}$ is 1.11(1) Hz, implying $\langle \sin^2 \theta \rangle_F^C$ as 0.799 and V_2 as $1.8_5 \pm 0.3$ kcal/mol, based on a 0.06-Hz uncertainty in $^6J_{90}^{F,C}$. In the 3,5-dibromo derivative (42) of 1-phenylpropane, $^6J_p^{H,CH}$ is −0.428(2) Hz, leading to a barrier of 1.9 ± 0.2 kcal/mol. Of course, the existence of *gauche* and *trans* conformers about the sp^3–sp^3 carbon–carbon bond has been ignored in this comparison, which is meant only to suggest $^6J_{90}^{F,C}$ as a feasible conformational marker. The detailed discussion (42) of the barriers about the sp^2–sp^3 carbon–carbon bonds in the *trans* and *gauche* forms, given for $^6J_p^{H,CH}$ measurements, applies to $^6J_p^{F,C}$ also and need not be repeated here, except to note that the *gauche* is much larger than the *trans* barrier.

Turning to the ethanol derivative, one has $\langle \sin^2 \theta \rangle_F^C$ as 1.26/1.63 or 0.773 and therefore a V_2 of 1.6 ± 0.3 kcal/mol. In CS_2 solution, $^6J_p^{H,CH}$ in 2-(3,5-dibromophenyl)ethanol is −0.380(4) Hz (42) and leads to an average V_2 for the *trans* and *gauche* conformers of 3.1 ± 0.3 kcal/mol. Of course, in the CS_2 solution the proportion of *trans* and *gauche* forms varies with concentration (42), intermolecular self-association of 2-phenylethanol favoring the *trans* form.

For the fluorophenylethanol derivative, $^6J_p^{F,C}$ is here quoted for a 30 v/v % solution in acetone-d_6 (Table 1), in which the *trans* conformer will be favored strongly by intermolecular hydrogen bonding to solvent and other solute molecules. The *trans* form, of course, has a smaller barrier than does the *gauche* form, the latter having considerable steric hindrance to rotation due to the proximity of the phenyl and hydroxyl substituents. Consequently the average V_2 of 1.6 kcal/mol found from $^6J_{90}^{F,C}$ in acetone-d_6 solution is reasonable, implying, in fact (42), that 2-(4-fluorophenyl)ethanol exists predominantly in the *trans* conformation in acetone solution.[3] The *trans* form has a barrier of near 1.2 kcal/mol, while that in the *gauche* form must be greater than 4 kcal/mol (42) in CS_2 solution.

(iv) *4-Fluoro-α-methylstyrene and α-cyclopropyl-4-fluorostyrene*

These compounds do not have a proton necessary for the measurement of ${}^6J_p^{H,CH}$ or ${}^6J_p^{F,CH}$, so that ${}^6J_p^{F,C}$ remains as a conformational indicator. Now, although styrene is probably planar in the ground state (43, 44), the present compounds most likely are not, the α substituents entailing destabilization of a coplanar arrangement of the benzene and olefinic moieties. Furthermore, the internal rotational potential may not be twofold. Nevertheless, some conformational information is available from ${}^6J_p^{F,C}$.

In the α-methyl styrene, ${}^6J_p^{F,C}$ is 0.27 Hz. A *naive* approach, in which ${}^6J_p^{F,C}$ is taken to indicate *a* conformation, goes as follows. Assume ${}^6J_p^{F,C}$ is a σ–π coupling as suggested by INDO MO FPT calculations, also indicating that ${}^6J_p^{F,C}$ for this bonding situation is somewhat smaller than ${}^6J_p^{F,C}$ for an ethyl substituent, and that ${}^6J_{90}^{F,C}$ is therefore 1.13 Hz. It follows that $\sin^2\theta$ is 0.235 and that θ is 29°, the angle by which the CH_3 group twists out of plane. This number happens to agree with the 30° (45*a*) deduced from ultraviolet spectral extinction coefficients and from transition frequencies of the conjugation bands. Photoelectron spectral data imply a θ of 29 ± 6° in α-methylstyrene (45*b*). The same approach for the α-cyclopropylstyrene yields θ as 35°, employing a ${}^6J_p^{F,C}$ of 0.369(1) Hz (α-*tert*-butylstyrene (45*a*) apparently has θ = 64°).

If θ = 0° were to represent the preferred conformation and the internal barrier to rotation about the sp^2–sp^2 carbon–carbon bond were twofold, then the ${}^6J_p^{F,C}$ values would yield barriers of 1.4 and 0.8 kcal/mol for the methyl and cyclopropyl derivatives, respectively. That θ = 90° is not the preferred conformation is evident from the ${}^6J_p^{F,C}$ numbers, which are *less* than 0.5 $J_{90}^{F,C}$ for both compounds, the latter being the value in the limit of a vanishing barrier for a potential minimum at θ = 90°; this conclusion is independent of the barrier symmetry.

If a twofold steric barrier exists in the α-methylstyrene analogous to that in ethylbenzene of stable perpendicular form **3**, it opposes the twofold conjugational barrier favoring planarity. It may therefore be that the net barrier is lower than in styrene itself, estimated as twofold and ranging from 1.0 to 2.2 kcal/mol (43, 46), with an outlier at 0.5 kcal/mol.

No reliable value of V_2 is available for 4-fluorostyrene. ${}^6J_p^{F,C}$ is 2.24_5 (30) Hz. INDO MO FPT computations have it that ${}^6J_p^{F,C}$ is of maximum magnitude when θ is 0° and decreases as θ increases, no doubt because the coupling is dominated by a pure π mechanism involving the electrons of the olefinic double bond. The decrease goes as $\sin^2\theta$ and is calculated as

$$[7] \quad {}^6J_p^{F,C}\ \text{Hz} = 1.54 - 0.85 \sin^2\theta$$

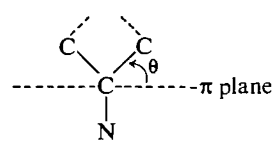
Of course, it may well be that a σ–π mechanism comes into play as θ increases from zero, so that this ${}^6J_p^{F,C}$ would not go to zero at θ = 90°. It is interesting, therefore, that ${}^6J_p^{FCH}(CH_3)$ in 4-fluoro-α-methylstyrene is computed as 0.71 Hz at θ = 90° (σ–π mechanism) whereas ${}^6J_p^{F,C}$ (=CH_2) is 0.69 Hz for eq. [7]. In other words, the INDO MO FPT computations imply that the coupling to the olefinic carbon nucleus consists of two positive contributions, both dependent on $\sin^2\theta$. The contributions differ by 90° in their maxima, the π component being the larger.

The important conclusion is that ${}^6J_p^{F,C}$ for the β-olefinic carbon nucleus decreases as θ increases, as observed for the α-methyl and α-cyclopropyl derivatives, being 1.57 and 1.42 Hz, respectively; this is smaller than the 2.24 Hz in 4-fluorostyrene, whose ground state conformation is presumably planar. These observations are in qualitative agreement with the indication above that the π is larger than the σ–π component of ${}^6J_p^{F,C}$.

The assumption of a twofold internal barrier, together with the harmonic approximation for the torsion about the exocyclic bond, leads to a V_2 of 0.5 or 1.0 kcal/mol from the microwave spectrum (44) of 4-fluorostyrene, and 1.0 kcal/mol from vibrational assignments in the 288-nm absorption spectrum (43). Heat capacity data (47) give V_2 as 2.87 kcal/mol. An MO calculation suggests 3.9 kcal/mol (48). The latter barrier would imply that the observed ${}^6J_p^{F,C}$ is within a few percent of its maximum value, that is, at θ = 0. Further work is needed, possibly involving long-range couplings from sidechain ^1H, ^{13}C nuclei and ^{19}F, ^1H, ^{13}C nuclei in the benzene ring.[4]

(v) *1-(4-Fluorophenyl)*-N-*methylcyclohexylamine*

In phenylcyclohexane the low-energy conformer contains the α C—H bond in the plane of the benzene ring, analogous to **4** for 2-phenylpropane, and ${}^6J_p^{H,CH}$ entails a twofold barrier to rotation about the exocyclic carbon–carbon bond of 2.1 ± 0.3 kcal/mol (49). In the presence of an *N*-methyl substituent on the α carbon atom, the phenyl group attached to this atom will most likely prefer a conformation obtained by a rotation of 90° from the bisected conformer in phenylcyclohexane, namely **6**. The angle θ will be 30° for a conformation in which the phenyl group is axial *or* equatorial.



6

${}^6J_p^{F,C}$ is 0.46_9 Hz and therefore $\langle\sin^2\theta\rangle_F^C$ is 0.364 ± 0.017 if ${}^6J_{90}^{F,C}$ is taken as 1.29 ± 0.06 Hz, as used above for tetrahedral carbon linkages. This value of $\langle\sin^2\theta\rangle_F^C$, being less than 0.5, confirms **5** as the preferred conformer and V_2 follows as 1.6 ± 0.3 kcal/mol. Whether the internal barrier is indeed twofold is not certain, so that this number must be treated with circumspection. The identification of **6** as the ground state seems certain, however.

(vi) *4-Fluorophenylacetic acid and 4-fluorophenylacetone*

In these compounds, ${}^6J_p^{F,C}$ involves a trigonal carbon atom

[3] Given sufficient sensitivity of the spectrometer, ${}^6J_p^{F,C}$ may therefore be the most convenient indicator of *trans*/*gauche* ratios in molecules of this kind, its measurement being straightforward compared to the analyses of spectra from complex spin systems.

[4] It is amusing that 1.57/2.24, the ratio of the couplings to the β olefinic carbon in the α-methyl derivative and the 4-fluorostyrene itself, yields 33° as the angle of twist in the former, as also deduced from the coupling to the methyl carbon (30°). For the α-cyclopropyl compound, θ is then 37°, compared to the 35° deduced from the ${}^6J_p^{F,C}$ for the coupling to the carbon nucleus in the 3-membered ring. These results may well indicate that the coupling to the β olefinic carbon nucleus is near zero at θ = 90°. However, a proper dynamical model is needed, together with a reliable potential energy profile for the internal rotation.

attached to electronegative substituents. Whatever the value of $^{6}J_{p}^{F,C}$ at $\theta = 90°$, from the values of 1.20 and 1.18 Hz for the ketone and acid, respectively, it is clear that the perpendicular form, of type **3**, is very stable. $^{6}J_{90}^{F,C}$ is expected to be larger than the 1.13 Hz assessed above for an olefinic carbon, by analogy with the 26% increase in $^{6}J_{90}^{F,C}$ for an aliphatic carbon caused by an attached electronegative substituent. If a similar increase applied to the carbonyl bond, $^{6}J_{90}$ would be 1.42 Hz. In that event, the barrier to rotation about the sp^2–sp^3 carbon–carbon bond, assumed twofold, would be about 2.3 kcal/mol for both the ketone and the acid. Obviously, this is a very rough estimate of V_2.

Therefore, $^{6}J_{p}^{F,CH}$ was measured for these two compounds in acetone-d_6, yielding 0.67(2) and 0.70(2) Hz for the ketone and acid, respectively. The electronegativity of the COOH group is 2.8 (50), and $^{6}J_{90}^{F,CH}$ is therefore estimated as 2.12 Hz by the procedure described for $^{6}J_{90}^{H,CH}$ (1). Then $\langle \sin^2 \theta \rangle_F^H$ is 0.323 ± 0.018 Hz and V_2 becomes 2.5 ± 0.5 kcal/mol, where $^{6}J_{p}^{F,CH}$ for the two compounds is averaged to $0.68_5 \pm 0.03$ Hz. It appears that $^{6}J^{F,C}$ and $^{6}J^{F,CH}$ yield similar conclusions about the conformational dynamics of these two compounds, agreeing that the low-energy conformer is analogous to **3**.

The radiation chemistry of 2-mercaptoethanol

MANOHAR LAL
Chemistry Division, Bhabha Atomic Research Centre, Bombay – 400085, India

AND

DAVID A. ARMSTRONG
Chemistry Department, University of Calgary, Calgary, Alta., Canada T2N 1N4

Received April 5, 1984

MANOHAR LAL and DAVID A. ARMSTRONG. Can. J. Chem. **63**, 30 (1985).

Hydrogen, hydrogen sulphide, mercaptoethanol disulphide, and ethanol yields from the radiolysis of 2-mercaptoethanol are consistent with the same mechanism postulated for other sulphydryl-containing molecules. In all cases studied g_H in neutral solution appears to be enhanced ($g_H = 0.7-0.9$ molecule per 100 eV). However, there is no basis for attributing this to reaction [10] which was postulated in earlier work:

[10] $e_{aq}^- + RSH \xrightarrow{H^+} RS\cdot + H_2$

but is not supported by independent data from H atom studies.

MANOHAR LAL et DAVID A. ARMSTRONG. Can. J. Chem. **63**, 30 (1985).

Les rendements en hydrogène, en sulfure d'hydrogène, en disulfure de mercaptoéthanol et en éthanol, obtenus lors de la radiolyse du mercapto-2 éthanol, sont en accord avec le mécanisme postulé pour d'autres molécules contenant des groupes sulfhydryles. Dans tous les cas étudiés, il semble que la valeur de g_H en solution neutre soit augmentée ($g_H = 0{,}7-0{,}9$ molécule par 100 eV). Toutefois, il n'y a aucune donnée expérimentale qui puisse permettre d'attribuer ce résultat à la réaction [10] qui avait été postulée dans un travail antérieur

[10] $e_{aq}^- + RSH \xrightarrow{H^+} RS\cdot + H_2$

mais ces résultats n'ont pas été confirmés par des données indépendantes obtenues à partir d'études sur des atomes d'hydrogènes.

[Traduit par le journal]

Introduction

Sulphydryl groups play an important role in many cellular processes (1). At the same time they are known to be highly susceptible to ionising radiation, and low molecular weight sulphydryl-containing molecules have been shown to act as sacrificial protectors (2). Their reactions with the free radicals formed in irradiated aqueous solutions are therefore of considerable interest. The following reaction mechanism, with RSH as the sulphydryl molecule, has been shown to adequately describe the products observed for cysteine (3, 4), penicillamine (5), and glutathione (6) in 1 to 10 mM aqueous solutions subjected to ^{60}Co or fast electron radiolysis. These are also the main primary reactions in

[1] $H_2O \rightsquigarrow 2.7\ \cdot OH + 2.6\ e_{aq}^- + 0.6\ \cdot H + 0.7\ H_2O_2 + 0.5\ H_2$

[2] $e_{aq}^- + H^+ \rightarrow \cdot H$

[3] $RSH + \cdot OH \rightarrow RS\cdot + H_2O$

[4] $RSH + \cdot H \rightarrow RS\cdot + H_2$

[5] $RSH + \cdot H \rightarrow R\cdot + H_2S$

[6] $RSH + e_{aq}^- \rightarrow R\cdot + SH^-$

[7] $RSH + R\cdot \rightarrow RS\cdot + RH$

[8] $RS\cdot + RS\cdot \rightarrow RSSR$

[9] $2RSH + H_2O_2 \rightarrow RSSR + 2H_2O_2$

dithiothreitol, but in that case there are some additional secondary reactions (7, 8). Reaction [9] is slow except at high pH and can usually be neglected in acid solutions (3, 9).

At pH 4–7 reaction [2] can be neglected and, since the contribution of reaction [5] is small in this pH range, the mechanism then predicts $G(H_2S) = G(RH) \simeq g_{e_{aq}^-}$ (3–6). While this was observed with the sulphydryl molecules noted above, the values of $G(H_2S)$ and $G(RH)$ from 2-mercaptoethanol, although equal, were reported to be only half of $g_{e_{aq}^-}$ (10). Jayson, Stirling, and Swallow attributed that observation to the occurrence of reaction [10]:

[10] $e_{aq}^- + RSH \xrightarrow{H^+} H_2 + RS\cdot$

Intuitively this seems to require the existence of a relatively long-lived RSH^- ion:

[11] $e_{aq}^- + RSH \rightarrow RSH^-$

[12] $RSH^- + H^+ \rightarrow RS\cdot + H_2$

and no evidence for that has been reported for aqueous systems.

The apparent difference between 2-mercaptoethanol and the other sulphydryl-containing molecules was obviously of fundamental interest. Also, since the former compound is often used as a model sulphydryl species, it is important that its mechanism of radiolysis be well understood. We have therefore reinvestigated the radiation chemistry of aqueous mercaptoethanol. A detailed study of the pH dependence of the hydrogen yields was made, since reaction [10] (or [11]–[12]) would significantly augment $G(H_2)$ in the pH range 4–7. Hydrogen sulphide, RSSR, and RH (i.e. ethanol) yields were also determined. Experiments were performed at both the Bhabha Atomic Research Centre (BARC) and at the University of Calgary.

Experimental

Materials

Mercaptoethanol (Sigma Chemical Co. pure grade) was subjected

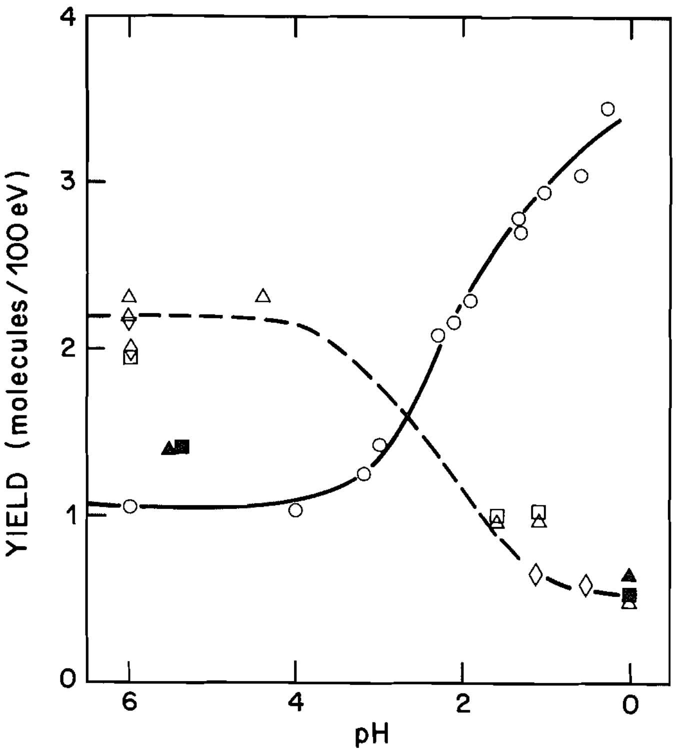

FIG. 1. Product yields as a function of pH for H_2 ○, EtOH □, H_2S △ in 10^{-2} *M* RSH and EtOH ◇ and H_2S ▽ in 2×10^{-3} *M* RSH, this study; filled symbols — as above from ref. 10.

to distillation under vacuum before use in the earlier experiments, but later it was found to be satisfactory to use it directly. Nitrogen used for preliminary deaeration of solutions at BARC, Bombay, was IOLAR-2 from the Indian Oxygen Co. Ltd. Water was triply distilled by standard methods. Fresh solutions were made for each experiment and final degassing was carried out by freeze, pump, thaw cycles (3).

Irradiations

These were performed in ^{60}Co sources, which gave dose rates of 40 or 9×10^{19} eV min^{-1} dm^{-3} (BARC, Bombay) and 7×10^{18} eV min^{-1} dm^{-3} (Calgary). Analyses were carried out immediately after irradiations.

Analyses

Hydrogen: Aliquots of degassed solution in cells fitted with break seals were connected to a vacuum system, which was used to extract the gases volatile at liquid nitrogen temperature (3) and collect them in a standard volume. Hydrogen was then analysed by gas chromatography with a 2 m × 0.66 cm diameter stainless steel column filled with 30–60 mesh SA molecular sieve at room temperature and with N_2 as carrier gas (BARC) or by following the drop in pressure when the hydrogen was allowed to diffuse through a heated palladium thimble (Calgary (3)).

Ethanol: This analysis was carried out by gas chromatography with N_2 carrier gas on a Carbowax number 6 column (10% chromosorb WAW) in a 1.6 m 0.66 cm diameter copper tube at 85°C.

Hydrogen sulphide: This was determined by both the ammonium molybdate and methylene blue methods (3).

Disulphide: Concentrations of RSSR in the irradiated solutions were obtained from the absorbances at 248 nm using an extinction coefficient of 324 M^{-1} cm^{-1}. In this case the ^{60}Co γ dose rate was 4×10^{20} eV min^{-1} dm^{-3}.

Results

As in the case of cysteine, product concentration versus dose plots were linear in the region below 10^{22} eV dm^{-3}. Yields of

products in molecules per 100 eV of radiation energy absorbed were obtained from their slopes. Hydrogen, H_2S, and ethanol yields for 2×10^{-3} and 10^{-2} *M* 2-mercaptoethanol solutions are presented as a function of pH in Fig. 1. Yields for more concentrated solutions are contained in Table 1.

Discussion

The effects of pH exhibited by the yields for high and low concentrations in Table 1 and Fig. 1 are similar, and the trends seen are in agreement with those observed with cysteine (3, 4). The yields of hydrogen sulphide and ethanol reported by Jayson, Stirling, and Swallow for 2-mercaptoethanol at pH 5.5 and 0.0 have been included in Fig. 1. Their results at the lower pH's are in good agreement with the present data. On the other hand, at pH 5.5 their values of $G(H_2S)$ and G(ethanol) are much less than the ones reported here for pH 4 to 6 in Fig. 1 and Table 1. The reason for this is not clear. However, if the lower yields of $G(H_2S)$ and G(ethanol) at pH ~5 *were* correct and reaction [10] had occurred to the extent postulated in ref. 10, the hydrogen yields would have been higher than $g_H + G^M_{H_2}$ (see below) by one molecule per 100 eV and close to 2 molecules per 100 eV. Clearly this is not the case. If g_H is taken as 3.6_5 at pH ≤ 1.3 (11) and $G^{H_2}_M$ as 0.3_0 in 10^{-2} *M* 2-mercaptoethanol solutions, then the mechanism given in the Introduction predicts $G(H_2S)$ or G(ethanol) + $G(H_2) = 3.6_5 + 0.3_0 = 3.9_5$ (11). The sum of the yields from the smoothed curves in Fig. 1 at pH 0.5 is 3.8_5, in reasonable agreement. Likewise k_4/k_5 is given by $(G(H_2) - 0.30_0)\,(G(H_2S))^{-1}$ (3). The value of 5 thus estimated from the 10^{-2} *M* solution yields at pH 0.5 is typical of primary sulphydryl compounds such as cysteine and methyl mercaptan (3, 12). The mechanism also predicts $G(\mathrm{RSSR}) = (1/2)\,[g_{e^-_{aq}} + g_H + g_{OH}]$, which is 3.1 molecules per 100 eV for 10^{-2} *M* RSH, taking into account the solute reactivity (5). The result obtained here at pH 6 was 3.4 molecules per 100 eV, which is in agreement, and is the same as the experimental yield reported in ref. 10. It was also similar to the disulphide yields from other sulphydryl molecules (3, 6).

The similarity to these other thiol compounds may be further demonstrated. At pH 6 the mechanism predicts that $\{G(H_2S)$ or G(ethanol) + $G(H_2)\}$ should be equal to $(g_e + g_H + G^M_{H_2})$ which is 3.2 + 0.30 = 3.6 (5). The sum of the experimental yields is $2.2_5 + 1.0_5 = 3.3$, which is also in satisfactory agreement. The yield of hydrogen should be equal to $G^M_{H_2} + g_H \times k_4/(k_4 + k_5)$. If $G^M_{H_2}$ is taken as 0.3 and $k_4/(k_4 + k_5)$ is assumed to be pH independent, then g_H must be ≃ 0.9 molecule per 100 eV. This is significantly larger than the normally accepted value of 0.6 (11). However, a similar discrepancy has been observed for cysteine and methyl mercaptan, for which the hydrogen yields in 10^{-2} *M* solutions are also ~1.0 molecule per 100 eV (3).

The origin of this extra hydrogen is not clear. Wilkening *et* *al.* (3) have argued against the occurrence of reaction [13] on the basis of Littman, Carr, and Brady's report (13) that reaction [14] is relatively efficient,

[13] $e^-_{aq} + RSH \rightarrow RS^- + H\cdot$

[14] $\cdot H + RS^- \rightarrow R\cdot + SH^-$

an observation which demonstrates that the exit channel to $R\cdot + SH^-$ is more favourable than that to $H\cdot + RS^-$. Alternative explanations of the excess hydrogen are the absorption of energy from subexcitation electrons (14) and the scavenging of dry electrons in reaction [15],

[15] $e^- + RSH \rightarrow RS^- + H\cdot$

for which the energetics would be different from [10]. Further experiments will be required to resolve this problem.

A nuclear magnetic resonance study of the formation and conformational equilibria of symmetrical and mixed disulfides of captopril

DALLAS L. RABENSTEIN[1] AND YVON THERIAULT
Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received March 8, 1984

DALLAS L. RABENSTEIN and YVON THERIAULT. Can. J. Chem. **63**, 33 (1985).

The oxidation of captopril (CpSH, 1-(D-3-mercapto-2-methylpropanoyl)-1-proline) by glutathione disulfide (GSSG) via thiol/disulfide exchange to form, in the first step, CpSSG and GSH and, in the second step, CpSSCp and GSH, has been studied in aqueous solution by ^{1}H nmr. Due to slow rotation around the amide bond(s) of CpSH and CpSSCp and of the captopril part of CpSSG, separate resonances are observed for the *cis* and *trans* conformations across these bonds. Conformational equilibrium constants were estimated as a function of pH for CpSH, CpSSCp, and CpSSG from the intensities of resonances for the *cis* and *trans* isomers. These equilibrium constants were used in the determination of equilibrium constants for the two steps in the oxidation of CpSH by GSSG. The results suggest that CpSH has a greater tendency to reduce disulfide bonds by thiol/disulfide exchange at physiological pH, and thus form mixed disulfides, than do the thiol groups in amino acids. Also, the conformational equilibrium constants indicate that, at physiological pH, approximately two thirds of the captopril, either free or in a disulfide form, has the *trans* conformation.

DALLAS L. RABENSTEIN et YVON THERIAULT. Can. J. Chem. **63**, 33 (1985).

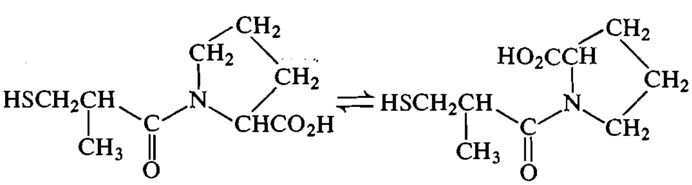
Faisant appel à la rmn du ^{1}H et opérant en solutions aqueuses, on a étudié l'oxydation du captoprile (CpSH, (D-mercapto-3 méthyl-2 propanoyl)-1 proline-1) par le disulfure de glutathion (GSSG) via un échange thio/disulfure qui permet de former le CpSSG et le GSH dans une première étape et le CpSSCp et le GSH dans une deuximème étape. A cause de la rotation lente autour des liaisons amide(s) du CpSH, du CpSSCp et de la partie captoprile du CpSSG, on a pu observer des résonances distinctes pour les conformations *cis* et *trans* par rapport à ces liaisons. Utilisant les intensités des résonances des isomères *cis* et *trans*, on a évalué les constantes d'équilibres conformationnels du CpSH, du CpSSCp et du CpSSG en fonction du pH. On a utilisé ces constantes d'équilibre pour déterminer les constantes d'équilibre des deux étapes de l'oxydation du CpSH par le GSSG. Les résultats suggèrent que, par comparaison avec les thiols des acides aminés, le CpSH a une plus grande tendance à réduire les liaisons disulfures, par un échange thiol/disulfure à pH physiologique, et ainsi à former des disulfures mixtes. Les constantes d'équilibres conformationnels indiquent également, à pH physiologique, qu'approximativement les deux tiers du captoprile, tant sous la forme libre que sous la forme de disulfure, existe sous une conformation *trans*.

[Traduit par le journal]

Introduction

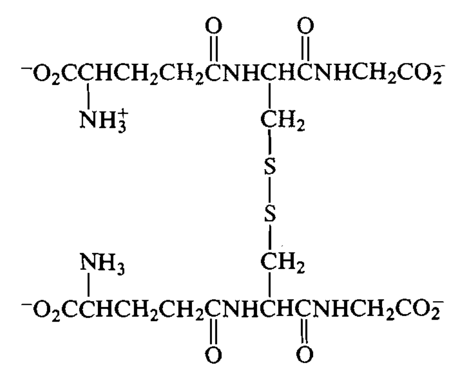
Captopril, 1-(D-3-mercapto-2-methylpropanoyl)-1-proline, is used clinically for the treatment of hypertension (1–3). Antihypertensive activity is thought to result from inhibition of angiotensin I-converting enzyme, with the thiol group of captopril binding to the active site of the enzyme (1–3). The thiol group is also the key functional group in the metabolism of captopril, with major metabolites being captopril disulfide and mixed disulfides with thiol-containing amino acids, peptides, and proteins (4–7).

Captopril exists in solution as an equilibrium mixture of *trans* (**1**) and *cis* (**2**) isomers with respect to the conformation



1 2

across the peptide bond (8). Although the conformational equilibrium of captopril has been characterized in detail (8), the chemistry of formation of disulfides from captopril and their conformational equilibria have not. This is of interest since it has been suggested that disulfide metabolites may play a role in determining the nature and time course of adverse reactions to captopril (9). In this paper, we report the results of an ^{1}H nmr study of the formation of symmetrical and mixed disulfides by



3

oxidation by glutathione disulfide (**3**) via thiol/disulfide exchange as described by eqs. [1] and [2].

[1] CpSH + GSSG ⇄ CpSSG + GSH

[2] CpSH + CpSSG ⇄ CpSSCp + GSH

where CpSH, CpSSCp, GSH, GSSG, and CpSSG are captopril, captopril disulfide, glutathione, glutathione disulfide, and captopril–glutathione mixed disulfide, respectively. As part of this study, the *cis–trans* conformational equilibrium across the amide bond(s) of CpSH and CpSSCp and the captopril part of CpSSG have also been characterized by ^{1}H nmr.

Glutathione disulfide was chosen for this study because it occurs naturally (10), captopril–glutathione mixed disulfide (CpSSG) has been detected as a metabolite of captopril (4, 5), and, with the cystine between two amino acid residues, GSSG

[1] Author to whom correspondence should be addressed.

serves to a first approximation as a model for disulfide bonds in proteins.

Experimental

The captopril and captopril disulfide used in this study were gifts from The Squibb Institute for Medical Research, Princeton, N.J. Glutathione disulfide was obtained from Sigma Chemical Co. The 99.7% D_2O, 40% NaOD in D_2O, and 35% DCl in D_2O were obtained from Merck Sharp and Dohme, Ltd.

The ^1H nmr spectra were measured at 360 MHz on a Bruker WM-360 spectrometer operating in the pulse/Fourier transform mode. The probe temperature was 25 ± 1°C. Chemical shifts were measured relative to internal *tert*-butyl alcohol and are reported relative to the methyl resonance of sodium 2,2-dimethyl-2-silapentane-5-sulfonate (DSS). The resolution was increased in some spectra with the Gaussian resolution enhancement routine in the Aspect 2000 software.

The pH measurements were made at 25°C with a Fisher Accumet pH meter equipped with a standard glass electrode and a fiber-tipped, saturated calomel reference electrode, or a microcombination electrode. Fisher certified standard solutions having nominal pH values of 4.00, 7.00, and 10.00 were used for calibrating the pH meter. The exact pH of each standard solution was determined by comparison with freshly prepared N.B.S. pH standard solutions (11). pH values reported are the meter readings; to indicate that pH readings for D_2O solutions were not corrected for the deuterium isotope effect (12), they are reported as pH*.

Solutions were prepared in 99.7% D_2O containing 1 *M* KCl and approximately 0.0001 *M* *tert*-butyl alcohol. Na_2H_2EDTA (0.003 *M*) was also added to solutions containing thiols, e.g. the equilibrium mixture resulting from the reaction of CpSH with GSSG, to complex traces of heavy metals which would catalyze the oxidation of the thiols (13). The solvent mixture was deoxygenated by bubbling with argon or nitrogen before addition of thiol to minimize oxidation by dissolved oxygen. Inert gas was also blown over the solution during adjustment of pH, and nmr tubes were flushed out with the gas before transfer of an aliquot of solution to the tube. To ensure that no air oxidation of thiol occurred in the measurement of equilibrium constants for thiol/disulfide exchange reactions of CpSH with GSSG, the sample solutions were degassed further by taking them, in an nmr tube, through at least three freeze–pump–thaw cycles on a vacuum line.

Results

In aqueous solution, captopril and its disulfides exist in a conformational equilibrium due to *cis/trans* isomerization across the captopril amide bond. To quantitatively characterize the oxidation of CpSH by GSSG, it was necessary to first characterize these conformational equilibria for CpSH, CpSSCp, and CpSSG.

Conformational equilibria

The 360-MHz ^1H nmr spectra of captopril and captopril disulfide are shown in Fig. 1. Each spectrum consists of two highly coupled spin systems: the —CH_2CHCH_3 spin system from the 3-mercapto-2-methylpropanoyl part and the —$CH_2CH_2CH_2CH$— spin system from the proline residue. The spectra are further complicated by the presence of *cis* and *trans* isomers with respect to the conformation across the amide bond. This results in a doubling of the resonances in the spectrum of captopril, as is clearly evident in the multiplet patterns at 3.4–3.9 and 4.26–4.39 ppm for the hydrogens on C_δ and C_α respectively of the proline residue and the methyl resonances at 1.12–1.17 ppm (Fig. 2). In the 3.4–3.9 ppm region, the resonances at 3.4–3.66 and 3.66–3.9 ppm are from the *cis* and *trans* isomers respectively (8). In the 4.26–4.39 and 1.12–1.17 ppm regions, the more intense multiplets are from the *trans* isomer. The assignment of the other resonances for captopril are: 1.8–2.4 ppm, the hydrogens on C_β and C_γ of the proline residue; 2.48–3.06 ppm, the two hydrogens on C3 and the one hydrogen on C2 of the 3-mercapto-2-methylpropanoyl part. The spectrum of captopril disulfide is composed of the spectrum for the captopril unit in four different environments due to the *cis–trans* isomerism: $CpSSCp_{(tt)}$ in which both amide bonds are *trans*, $CpSSCp_{(tc)}$ in which one amide bond is *cis* and the other is *trans*, and $CpSSCp_{(cc)}$ in which both amide bonds are *cis*. This results in an apparent lower resolution over the 1.9–2.4 and 3.2–3.8 ppm regions due to the overlap of resonances for the two *trans* environments ($CpSSCp_{(tt)}$ and $CpSSCp_{(tc)}$) and overlap of resonances for the two *cis* environments ($CpSSCp_{(tc)}$ and $CpSSCp_{(cc)}$). Four doublets from the four different environments are observed in the methyl region (Fig. 2). The assignments are given in Table 1; the basis of these assignments is discussed below.

Fractional concentrations of the two isomers of captopril were determined as a function of pH* from the relative intensities of the two methyl doublets and from the relative intensities of the resonances for the hydrogens on C_δ of the proline residue in the *cis* and *trans* isomers. The fractional concentrations of the *trans* isomer are 0.87 ± 0.01, 0.63 ± 0.01, and 0.71 ± 0.01 for the fully-protonated, monoprotonated, and deprotonated forms of captopril, which correspond to the equilibrium constants, $K_{1c/t} = [cis]/[trans]$, listed in Table 2.

The fractional concentrations of the three isomers of captopril disulfide were determined from the relative intensities of the methyl resonances (Fig. 2). Equations [3]–[6] describe the equilibria between the three forms of captopril disulfide.

TABLE 1. Identification of captopril-containing species

Species	Conformation of the captopril amide bond(s)	Species number
$CpSH_{(t)}$	*trans*	1
$CpSH_{(c)}$	*cis*	2
$CpSSCp_{(tt)}$	*trans, trans*	3
$CpSSCp_{(tc)}$	*trans, cis*	4
$CpSSCp_{(cc)}$	*cis, cis*	5
$CpSSG_{(t)}$	*trans*	6
$CpSSG_{(c)}$	*cis*	7

TABLE 2. *cis–trans* Conformational equilibrium constants for proline-containing molecules[a]

Compound	Low pH[b]	Neutral pH[c]	High pH[d]
Glycyl-L-proline[e]	0.19	0.54	0.72

[f]$K_{c/t} = [cis]_{total}/[trans]_{total}$.

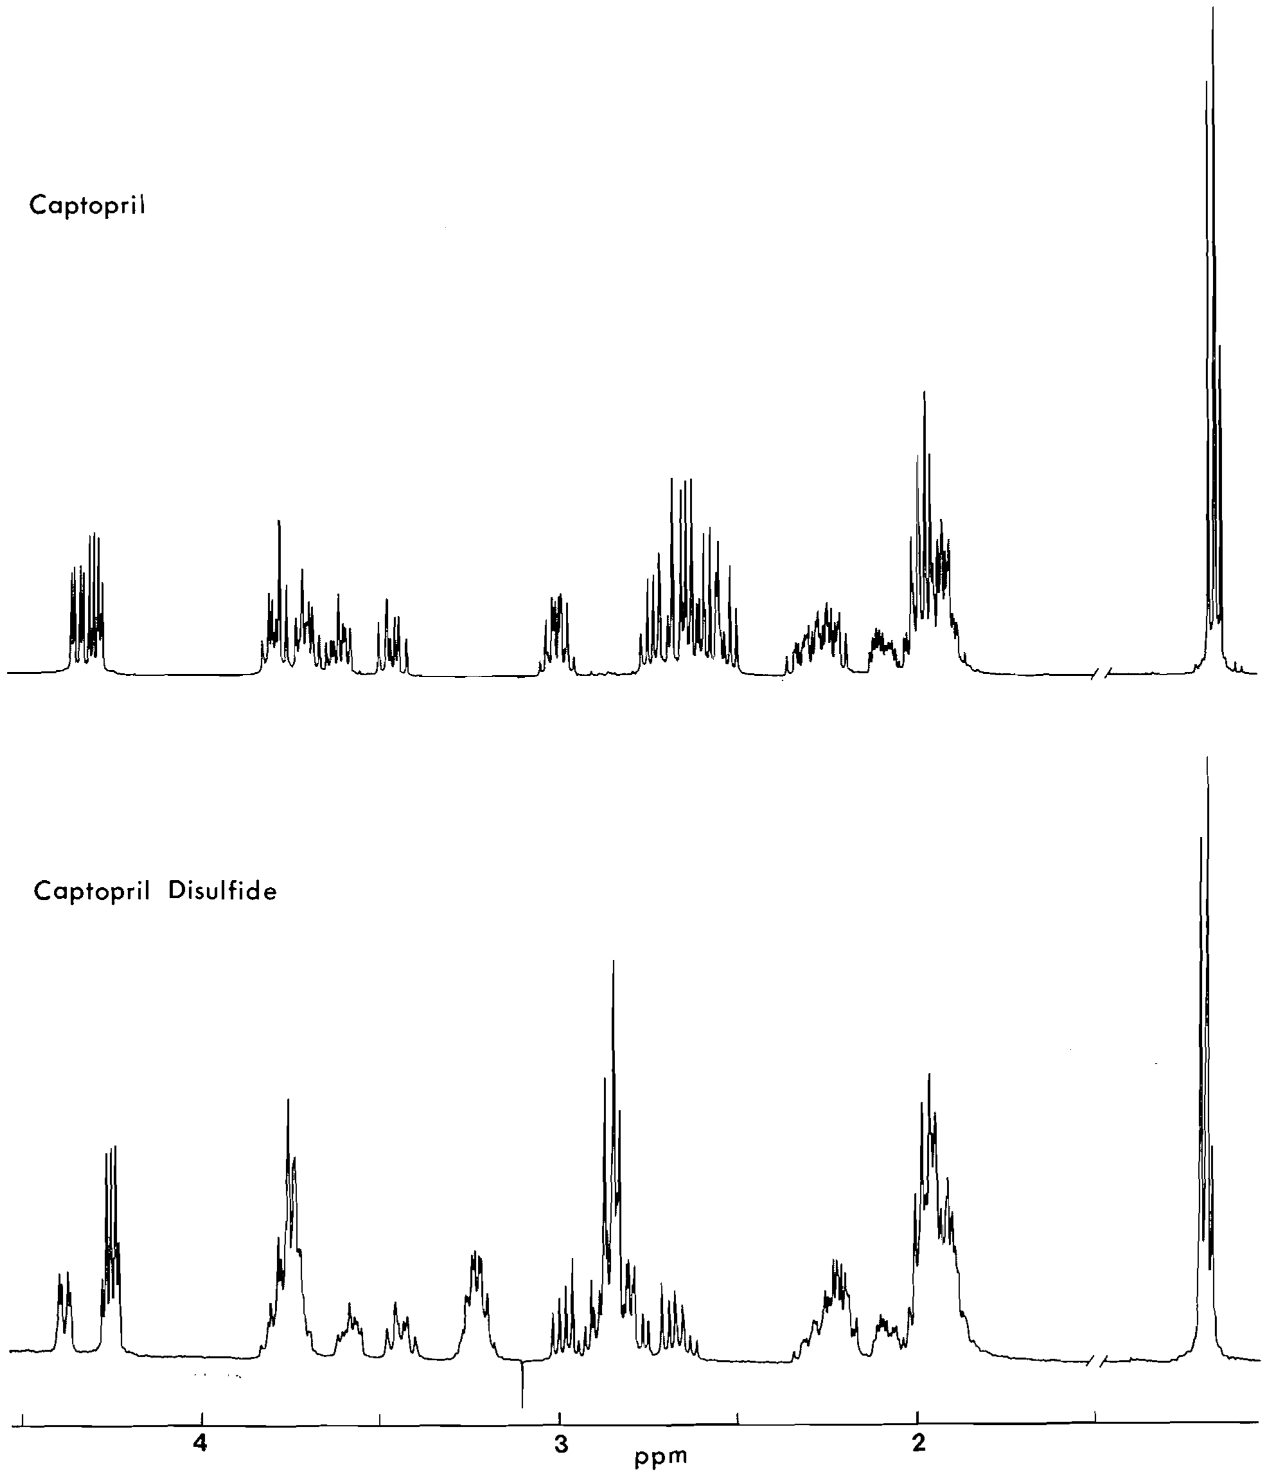

FIG. 1. The 360-MHz ^{1}H nmr spectra of 0.062 *M* captopril (pH* 6.0) and 0.042 *M* captopril disulfide (pH* 6.0). The gain was reduced by 2 in the 1–1.5-ppm region.

$$[3] \qquad \begin{array}{ccc} & \mathrm{CpSSCp}_{(tt)} & \\ \rightleftarrows & & \rightleftarrows \\ \mathrm{CpSSCp}_{(tc)} & \rightleftharpoons & \mathrm{CpSSCp}_{(cc)} \end{array}$$

$$[4] \qquad K_{cc/tt} = \frac{[\mathrm{CpSSCp}_{(cc)}]}{[\mathrm{CpSSCp}_{(tt)}]}$$

$$[5] \qquad K_{tc/tt} = \frac{[\mathrm{CpSSCp}_{(tc)}]}{[\mathrm{CpSSCp}_{(tt)}]}$$

$$[6] \qquad K_{cc/tc} = \frac{[\mathrm{CpSSCp}_{(cc)}]}{[\mathrm{CpSSCp}_{(tc)}]}$$

Equilibrium constants were determined at pH* 5.90, 5.99, and 6.10 and the results are: $K_{cc/tt} = 0.144 \pm 0.005$, $K_{tc/tt} = 0.84 \pm 0.01$, and $K_{cc/tc} = 0.171 \pm 0.006$. Total fractional concentrations of the *cis* and *trans* environments[2] were also deter-

[2] Fractional concentration of *trans* = $(2[\mathrm{CpSSCp}_{(tt)}] + [\mathrm{CpssCp}_{(tc)}])/2[\mathrm{CpSSCp}]_{\mathrm{total}}$.

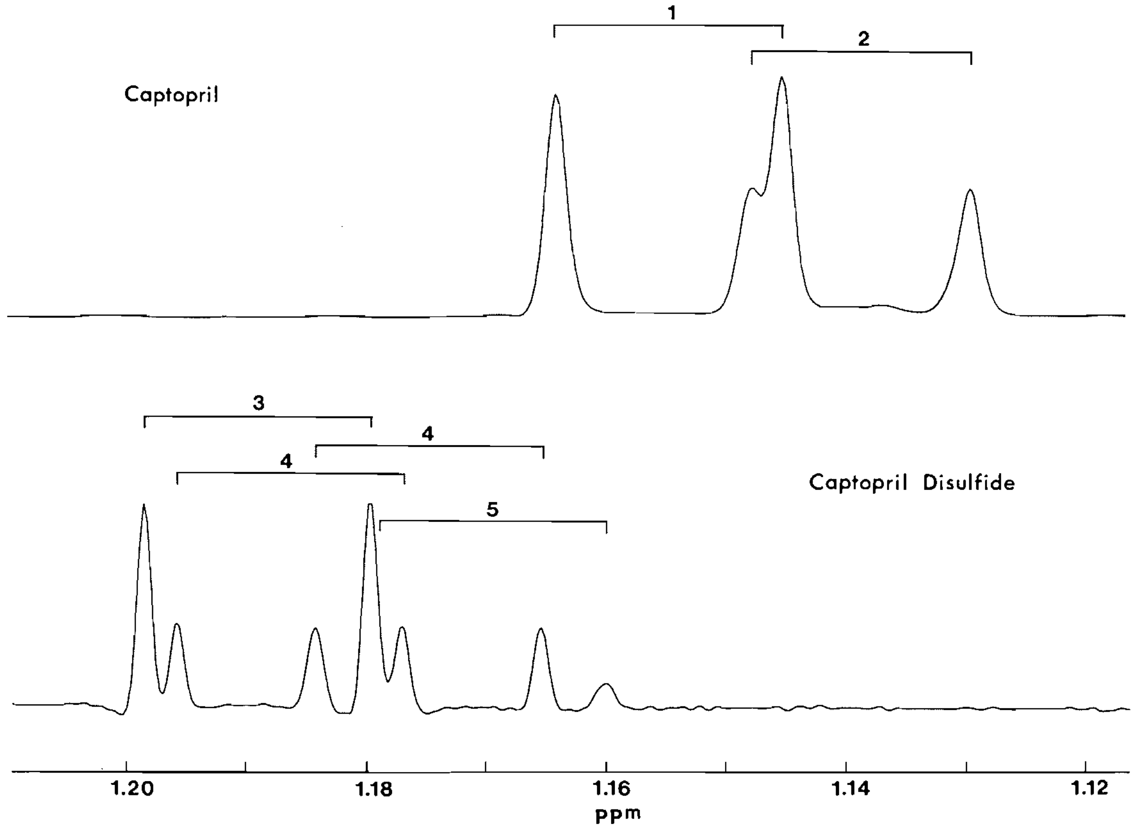

FIG. 2. The methyl resonances for the solutions described in the legend to Fig. 1. Resolution was enhanced by doing a Gaussian multiplication with the Bruker Aspect 2000 software. Resonance assignments are given in Table 1.

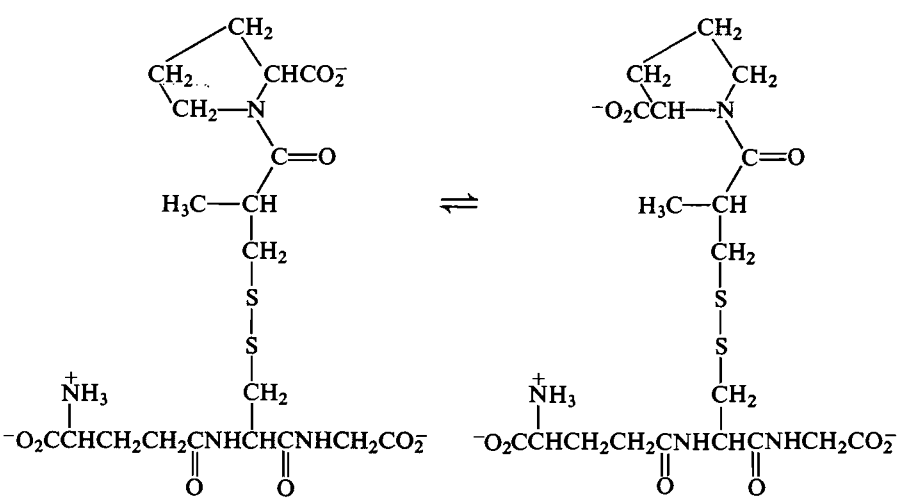
mined as a function of pH* directly from relative intensities of the *cis* and *trans* C_δ—H resonances. The fractional concentration of the *trans* conformation is 0.72 ± 0.03, independent of pH over the pH* range 3.75–11.02, corresponding to an equilibrium constant, $K_{c/t} = [cis]_{total}/[trans]_{total}$, of 0.39 ± 0.05. This is in excellent agreement with the value predicted by the above values for $K_{cc/tt}$, $K_{tc/tt}$, and $K_{cc/tc}$.[3] As the pH is decreased and the carboxylate groups are protonated, the fractional concentration of the *trans* isomer increases to 0.83 at pH* 0.75, corresponding to $K_{c/t} = 0.20$.

To obtain a solution containing CpSSG for the study of its conformational equilibrium (eq. [7]) 0.009 *M* CpSH was reacted with 0.18 *M* GSSG at pH* 7.1 in 1 *M* KCl solution. CpSSG, GSH, and CpSSCp were formed by thiol/disulfide exchange, as described by eqs. [1] and [2]. After reaction for 15 min, the solution was stirred in air for 18 days to oxidize CpSH to CpSSCp and GSH to GSSG to simplify the nmr spectrum. The methyl region of the ^1H nmr spectrum is shown in Fig. 3 and the assignments are given in Table 1. As indicated in Fig. 3, the dominant resonances are from CpSSG. Using the

[7]



[3] $K_{c/t} = (2K_{cc/tt} + K_{tc/tt})/(2 + K_{tc/tt})$.

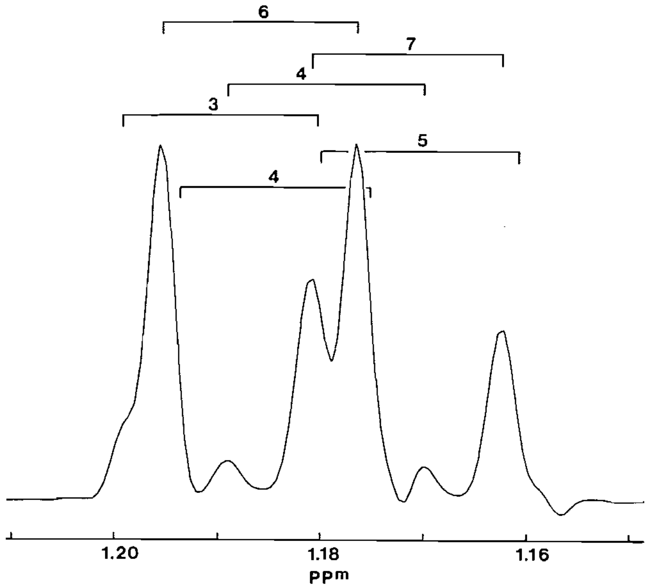


FIG. 3. The methyl region of the ^{1}H nmr spectrum of a pH* 7.0 solution contaning captopril–glutathione mixed disulfide and captopril disulfide. Details of the preparation of the mixed disulfide are given in the text. Resolution was enhanced by doing a Gaussian multiplication with the Bruker Aspect 2000 software.

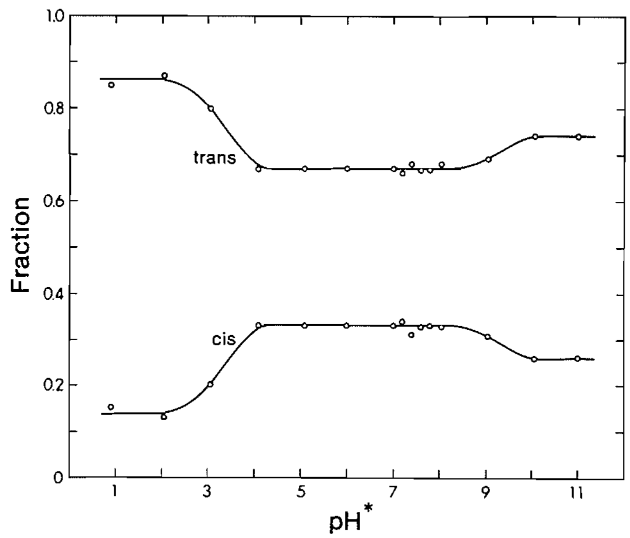

FIG. 4. The fractional concentrations of captopril–glutathione mixed disulfide in which the amide bond of the captopril part has the *trans* and *cis* conformations.

relative intensities of the methyl doublets for CpSSG, the fractional concentrations of the *trans* and *cis* forms of CpSSG were determined as a function of pH* over the pH* range 0.92–10.98 (Fig. 4). The equilibrium constants listed in Table 2 were obtained from these fractional concentrations.

Oxidation of CpSH by GSSG

To characterize the oxidation of CpSH by GSSG, equilibrium constants were determined for the reactions described by eqs. [1] and [2]. CpSH was reacted with GSSG in sealed nmr tubes, which had been degassed by the freeze–pump–thaw technique to minimize air oxidation, and then concentrations at equilibrium were determined by ^{1}H nmr. Figure 5 shows the methyl region of the nmr spectrum for a pH*

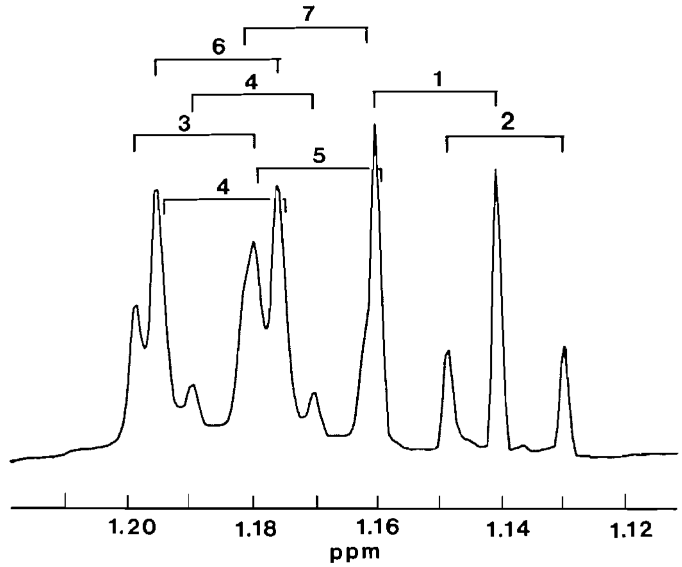

FIG. 5. The methyl region of the ^{1}H nmr spectrum of a solution prepared by reacting 0.045 *M* CpSH with 0.041 *M* GSSG at pH* 6.0 for 341 h in a degassed, sealed nmr tube. Resolution was enhanced by doing a Gaussian multiplication. Resonance assignments are given in Table 1.

6.0 solution at equilibrium; the spectrum was obtained 341 h after mixing the reactants to ensure that equilibrium had been achieved. As indicated in Fig. 5, the spectrum contains resonances for the *cis* and *trans* forms of CpSH, CpSSCp, and CpSSG. The concentrations of the various species were determined from the relative intensities of the resonances in Fig. 5 and the initial reactant concentrations. Using the determined concentrations, the conditional equilibrium constants, K_{1c} and K_{2c}, as defined by eqs. [8] and [9] and the equilibrium reactions in Fig. 6, were calculated.

$$[8] \quad K_{1c} = \frac{[\mathrm{CpSSG}]_{\mathrm{total}}[\mathrm{GSH}]}{[\mathrm{CpSH}]_{\mathrm{total}}[\mathrm{GSSG}]}$$

$$[9] \quad K_{2c} = \frac{[\mathrm{CpSSCp}]_{\mathrm{total}}[\mathrm{GSH}]}{[\mathrm{CpSH}]_{\mathrm{total}}[\mathrm{CpSSG}]_{\mathrm{total}}}$$

where $[\mathrm{CpSH}]_{\mathrm{total}}$, $[\mathrm{CpSSCp}]_{\mathrm{total}}$, and $[\mathrm{CpSSG}]_{\mathrm{total}}$ are the total concentration (*cis* + *trans*) of CpSH, CpSSCp, and CpSSG. The procedure involved determining the fractions of the total area of the methyl resonances due to CpSH, CpSSCp, and CpSSG. The total area of the resonances for CpSH was obtained by doubling the sum of the areas of its resonances at 1.13 and 1.14 ppm. That due to CpSSCp was calculated from the area of its resonances at 1.17 and 1.19 ppm and the values determined above for $K_{tc/tt}$, $K_{cc/tt}$, and $K_{cc/tc}$, and that for CpSSG was calculated as the difference between the total methyl resonance area and the areas for the CpSH and CpSSCp resonances. Using these fractions of the total methyl resonance area and the initial concentration of CpSH, the concentrations of CpSH, CpSSCp, and CpSSG were obtained. From these concentrations and the initial GSSG concentration, the concentrations of GSH and GSSG were calculated. The values calculated for K_{1c} and K_{2c} from three separate experiments in the pH* range 5.9–6.1 are 2.1 ± 0.1 and 1.5 ± 0.6 respectively. The rather large uncertainties reflect the accumulation of errors that results from obtaining concentrations by difference.

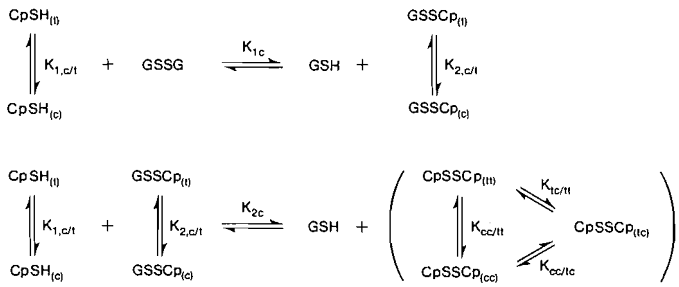

FIG. 6. The thiol/disulfide exchange equilibria and CpSH, CpSSCp, and CpSSG conformational equilibria occurring in a solution prepared by reacting CpSH and GSSG. The subscripts *t* and *c* indicate *trans* and *cis* conformations across the amide bond(s) of captopril in CpSH and CpSSCp or the captopril part of CpSSG.

Discussion

Conformational equilibria

Assignment of the *trans* conformation to the more abundant isomer(s) of CpSSCp and CpSSG is based on previous findings that the *trans* conformation is the more abundant for proline-containing dipeptides and related molecules, e.g. *tert*-butyloxycarbonyl-glycyl-L-proline-benzylester (14), glycyl-L-proline, glycyl-L-hydroxyproline, L-alanyl-L-proline, *N*-acetylsarcosine, glycylsarcosine (15), and captopril (8), and that the fractional concentration of the *trans* conformation increases when the carboxylate group is protonated (15). For example, the fractional concentration of the *trans* conformation of glycyl-L-proline increases from 0.65 to 0.84 when the carboxylate group is protonated (15), which is very similar to the increases found in this study for the more abundant isomers of CpSSCp and CpSSG.

The *cis/trans* equilibrium constants for the carboxyl-protonated (low pH) forms of CpSH, CpSSCp, and CpSSG are quite similar to each other and to those for dipeptides in which proline is the C-terminal residue, as indicated by the results in Table 2. The enhanced stability of the *trans* isomer at low pH probably results from intramolecular hydrogen bonding between the carboxylic acid hydrogen and the captopril amide carbonyl oxygen, which is not possible in the *cis* isomer. Evidence has been presented previously which indicates this to be the origin of the enhanced stability of the *trans* isomer of peptides in which protonated proline or sarcosine is the C-terminal residue (15–17). It is interesting to note that $K_{c/t}$ is approximately the same for the high pH forms of CpSH, CpSSCp, and CpSSC but is somewhat less than for the high pH forms of the proline-containing dipeptides. The origin of the enhanced stability of the *trans* conformation in the captopril unit at high pH is not obvious.

The magnitude of the *cis/trans* equilibrium constants for the neutral pH forms of CpSH, CpSSCp, and CpSSG suggests that, at physiological pH, approximately two thirds of the captopril has the *trans* conformation, regardless of whether it is free or in a disulfide form.

Oxidation of CpSH by GSSG

The reactive species in the oxidation of CpSH by GSSG via thiol/disulfide exchange (eqs. [1] and [2]) is presumably CpS^-, since it is well established that thiol/disulfide exchange proceeds via the thiolate anion (18–27). At pH 6, only a small fraction of CpSH is in the form of CpS^-, and thus the constants obtained in this work for eqs. [1] and [2] are conditional equilibrium constants. Conditional equilibrium constants for thiol/disulfide exchange in related systems are essentially pH independent up to pH values at which deprotonation of the thiol groups begins to occur (18), suggesting that the conditional equilibrium constants obtained in this work describe the reaction of CpSH with GSSG up to at least pH ~8.

The conditional equilibrium constant for the overall reaction (eq. [10])

[10] $2CpSH + GSSG \rightleftarrows CPSSCp + 2GSH$

K_{3c}, is calculated to be 3.2 ± 1.2 using the relation $K_{3c} = K_{1c}K_{2c}$. If the equilibrium position were governed by random distribution, K_{1c} and K_{2c} would be 2 and 0.5 respectively and K_{3c} would be 1. For comparison with the values for the reaction of CpSH with GSSG, $K_1 = 1.27$, $K_2 = 0.27$, and $K_3 = 0.34$ for the reaction of cysteine (CSH) with GSSG at pH 6.6 and 25°C (27) and $K_{1c} = 1.36$, $K_{2c} = 0.039$, and $K_{3c} = 0.053$ for the reaction of penicillamine (PSH) with GSSG at pH 7.4 and 25°C (18). The values for K_3 for the reactions involving CpSH and CSH are within a factor of 3 of the random distribution value, whereas that for PSH is somewhat smaller. PSH differs from CpSH and CSH in that it has two bulky methyl groups next to its thiol group, which hinders its reaction with penicillamine–glutathione mixed disulfide in the second step (18).

The overall equilibrium constant K_{3c} is related to the difference between the formal electrode potentials, $E^{0'}$, of the GSSG/GSH and CpSSCp/CpSH couples according to eq. [11].

[11] $$\Delta E^{0'} = E^{0'}_{GSSG/GSH} - E^{0'}_{CpSSCp/CpSH} = \frac{RT}{nF} \ln K_{3c}$$

With the value of 3.2 for K_{3c}, $\Delta E^{0'}$ is calculated to be 0.015 V. For comparison, $E^{0'}_{GSSG/GSH} - E^{0'}_{CSSC/CSH}$, where CSSC is cystine, is reported to be in the range −0.013 to −0.018 V at pH 6.6–7.0 (21, 23, 27) and $E^{0'}_{GSSG/GSH} - E^{0'}_{PSSP/PSH}$, where PSSP is penicillamine disulfide, is −0.0378 V at pH 7.4 (18). Values reported for $E^{0'}_{GSSG/GSH}$ are −0.205 V vs. the standard hydrogen electrode at 30°C and pH 7 (19) and −0.24 V at 40°C and pH 7 (28). These results indicate that CpSH has a greater tendency to reduce disulfide bonds by thiol/disulfide exchange than do the thiol groups in amino acids and that, if the disulfide bond in GSSG is similar to those in proteins, CpSH is capable of reducing protein disulfide bonds. These conclusions are supported by the finding that CpSH can activate papain by reduction of a disulfide bond at the active site and that CpSH is a more efficient activator of papain than is cysteine (29).

The anesthetic potency of *n*-alcohols exhibits a somewhat irregular dependence on the length of the hydrocarbon chain. An attempt has therefore been made to ascertain if this is related to the relative tendency for hydrogen bond formation by these alcohols. No such relationship was found. The result was rather that the degree of association by hydrogen bond formation of dissolved alcohols appears to be independent of the chain length, that is of the extent of other interactions that exist in these solutions.

LUCIE WILSON, R. BICCA DE ALENCASTRO et C. SANDORFY. Can. J. Chem. **63**, 40 (1985).

Le pouvoir anesthésique des alcools normaux dépend d'une manière quelque peu irrégulière de la longueur de la chaîne paraffinique. Nous avons par conséquent examiné la possibilité que cela soit lié à la tendance relative des alcools de former des liaisons hydrogène. Les résultats montrent que tel n'est pas le cas. Par contre il a pu être démontré que le degré d'association par liaisons hydrogène est indépendant de la longueur de leur chaîne paraffinique, c'est-à-dire des autres interactions intermoléculaires qui s'exercent dans ces solutions.

Introduction

The anesthetic potency of *n*-alcohols has been recognized by Posternak and Arnold in 1954 (1). This potency varies with the length of the paraffin chains of the *n*-alcohols, increasing steadily from methanol (C_1) to dodecanol (C_{12}). Then a surprising observation is made: tetradecanol (C_{14}) has no anesthetic potency at all. Tridecanol (C_{13}) has been reported to be intermediate between C_{12} and C_{14} or having no potency at all (2–5).

General anesthesia is known to be a matter of molecular associations. The current "hydrophobic theory" coupled with the "unitary hypothesis" stems from the Meyer–Overton rule which is based on the smooth relationship between anesthetic potency and solubility in lipids. According to this theory anesthetics exert their action in the hydrophobic part of the lipids in the neuron membranes. (For reviews see refs. 6–8.) We have challenged this view and proposed instead a pluralistic theory (9–12). According to it hydrophobic interactions can induce only weak anesthetic action while strong anesthetic action implies changes in polar interactions (hydrogen bonds) at ion-channels. Strong experimental indication for this on model gramicidin ion-channels has been provided by Urry and co-workers (13) (ion–channels are formed in proteins crossing the lipid membrane).

Whatever the case might be, it is of interest to examine the effects of alcohols on the neuron membrane. According to Richards and co-workers (2–4), *n*-alcohols with less than ten carbon atoms (C_1–C_9) decrease the gel to liquid crystal transition temperature (T_t) of the membrane and increase its fluidity. Alcohols with more than ten carbon atoms act in the opposite way: they increase the transition temperature and decrease the fluidity of the membrane. Decanol has no appreciable effect on either. These observations do not parallel anesthetic potency and cast doubt on the validity of the lipid solubility theories of anesthesia.

Miller and co-workers (5) took a different view. According to these authors, as well as Lawrence and Gill (14), the disordering effect of *n*-alcohols on the membrane decreases steadily with increasing chain length. They explain the cutoff by a rapid decrease, to below anesthetic levels, of the attainable concentration in the bilayer.

Now, alcohols can associate hydrophobically wih their hydrocarbon chains and by H-bonding using their OH groups. Since the possible role of H-bonding in the anesthetic properties of alcohols has not been considered by previous authors, we have undertaken a comparative study of H-bonding in *n*-alcohols from C_1 to C_{18}. While this work has not provided an explanation for the "cutoff" an intriguing result has been obtained which may have a bearing on our understanding of the anesthetic potency as well as of certain physicochemical properties of *n*-alcohols.

Outline of the work

The method used was infrared and near-infrared spectroscopy. The part of the spectrum due to the OH stretching vibrations was recorded for the *n*-alcohols from C_1 to C_{18} in carbon tetrachloride solutions. This was done at 23°C and then at 37°C, to approach physiological conditions and at 5°C where a larger proportion of the alcohol molecules is self-associated.

Subsequently we recorded the spectra of the alcohols using saturated hydrocarbons of different chain lengths as the solvent. This was done in order to explore the effect of solute–solvent interactions on the extent of self-association by H-bonding.

At the next stage binary mixtures of alcohols were studied. The alcohols were chosen in such a way that one of them had less than 10 and the other more than 10 carbons. As mentioned above (2–4), these should be antagonistic as to membrane disordering (fluidization) and the raising or lowering of the temperature of the membrane phase transition.

Finally spectra of mixtures of alcohols and carboxylic esters of different chain lengths were recorded. Esters contain a carbonyl group which, as a proton acceptor, is similar to those that alcohols might encounter if they enter the cell membrane.

Analogous measurements have been carried out in the near-infrared on ν(OH) overtones.

Experimental

Alcohols were purchased from the Aldrich Chemical Company or the Sigma Chemical Company and were 99% pure or better. They were further purified by distillation. The alkanes, from the Sigma Chemical Co. were passed through a silica gel column dried over magnesium sulfate and distilled under dry nitrogen atmosphere. The esters and *N,N*-diethylpalmitamide were Eastman products and were used without further purification.

Spectrograde carbon tetrachloride was supplied by A & C American Chemicals. Tetrachloroethylene (Eastman) was distilled under vacuum in order to eliminate traces of phosgene, and was protected from light.

The purity of the compounds was checked by recording their uv spectra or by gas phase chromatography. All samples were kept in a dry box under nitrogen atmosphere. Solutions were prepared gravimetrically and the spectra were recorded immediately afterwards.

The infrared spectra were recorded with a Perkin-Elmer model 621 instrument, using cells of 0.320 and 0.577 mm with silver chloride windows. The overtones were recorded on a Cary-17 instrument using silica cells of 1.07 and 3.00 cm. Resolution was about 2 cm^{-1} for both instruments.

Temperature was made constant by using a MGW Lauda-Thermostat. For maintaining 5°C a mechanical pump immersed in melting ice was used. Temperatures were measured by a copper–constantan thermocouple.

The spectrum of the solvent was recorded in the same cell and at the same temperature as the spectrum of the solution and was subtracted from the latter. The apparent molar absorption coefficients were computed by using the total alcohol concentration since the concentrations of the various monomer, dimer, . . . species cannot be determined with precision.

The calibration of the cells was regularly checked against benzene bands: 1960 cm^{-1} for cells whose optical path was less than 0.1 mm; for thicker cells the 845 cm^{-1} band was used.

Results and discussion

The ν(OH) bands in the solution spectra of alcohols have been the object of numerous investigations (refs. 15, 16, see ref. 17 for an early review). The "free" (non-hydrogen bonded) OH group has its band at about 3640 cm^{-1}, in methanol about 5–10 cm^{-1} higher. At higher concentration a band at about 3485 cm^{-1} belongs to the (linear) dimer. When the concentration is further increased the broad and intense "polymer" band appears, centered at about 3350 cm^{-1}, due to the internal OH groups which are both proton donors and proton acceptors. The end OH groups of dimers and polymers contribute to the apparent intensity of the free band. The dimer is well defined in a narrow concentration range only, since at higher concentration it is overlapped and covered by the broad and intense polymer band.

The relative intensities of the related overtones are very different. While in the fundamental region the polymer band is much more intense than the free band, in the overtone region the opposite usually holds (18–20). The reasons for this were the object of previous studies (21). (In H-bonded species mechanic and electric anharmonicities can make contributions of opposite sign to the intensity of the overtones.) In addition to the weakness of the overtones of H-bonded OH groups, we encounter another difficulty: this is the presence of strong ν(OH) + ν(CH) combination tones (22). Both CH and OH deuteration and low temperature measurements were needed in

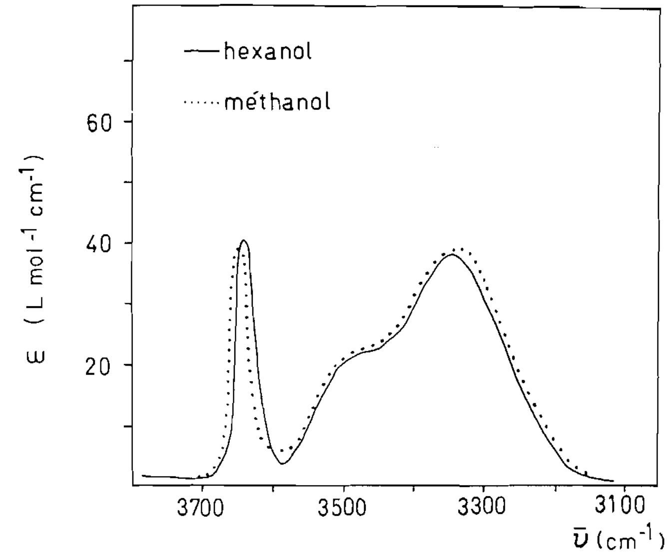

FIG. 1. The OH stretching region of the infrared spectra of methanol (dashed line) and *n*-hexanol (solid line) in 0.2 *M* carbon tetrachloride solutions.

order to assign the overtones for the H-bonded OH groups (20). For all these reasons only the free band was used in the work reported here. This free band is located near 7100 cm^{-1}. As the fundamental, it might receive contributions from the end OH groups of dimers and polymers.

Self-association of n-*alcohols* (C_1–C_{18})

Figure 1 shows the OH stretching region of the ir spectrum of a 0.20 *M* solution of *n*-hexanol in carbon tetrachloride. The monomer, dimer, and polymer bands are easily recognized at 3640, 3480, and 3345 cm^{-1}, respectively. The spectrum of methanol also given in Fig. 1 is slightly different. All the other *n*-alcohols from C_3 to C_{18} taken at 0.20 *M* concentration give spectra which are practically superimposable to that of *n*-hexanol. Thus, since both the free and polymer bands have evidently the same half-width from C_3 to C_{18}, the molar absorption coefficients may be considered proportional to the intensities. Table 1 lists the ϵ values for both bands for all the alcohols which were studied. Obviously, they are all equal within the limits of experimental error.

This result quite certainly does not constitute a basis for an explanation for the anesthetic "cutoff" observed. Nor does it make the changes in gel to liquid crystal transition temperature or the degree of fluidization that alcohols induce in the neuron membrane understandable.

This seems to indicate that the extent of H-bonding is not the fact underlying the variations of the anesthetic potency with chain length or of the membrane deforming effect of *n*-alcohols. The astonishing observation is that the extent of association by H-bond formation is independent of the number of carbon atoms in *n*-alcohols.

The spectra were also recorded at 37°C and at 5°C. The results are shown in Tables 2 and 3. While the values of the apparent molar absorption coefficients are, of course, different, from the point of view of the present discussion the result is the same: ϵ_A is independent of the number of carbons.

Only methanol and to a lesser extent, ethanol exhibits some slight differences; ϵ_A values of the free band are lower and those of the polymer band are higher than that of the alcohols C_3 to C_{18} indicating a somewhat higher degree of association (Table 1).

TABLE 1. Absorbances and apparent molar absorption coefficient (ϵ_A) of free (3640 cm^{-1}) and associated (3345 cm^{-1}) OH stretching vibrations of *n*-alcohols (0.2 *M* in CCl_4 at 23°C)

n-*Alcohols in* n-*alkanes of different chain length*

The question to which we sought an answer is as follows: is the extent of H-bond association of alcohols influenced by van der Waals interactions between the alkane solvent and the alcohols? For providing an answer the OH stretching region has been recorded for 0.2 *M* solutions of the alcohols C_4, C_6, C_8, C_{10}, C_{12}, and C_{13} in *n*-hexanol, *n*-dodecane, and *n*-tetradecane. Table 4 shows the results.

It is of interest to note that the mean molar absorption coefficient of the free band is 17.8 in *n*-heptane while it is 40.5 in CCl_4. As to the polymer band the corresponding values are $\epsilon_A = 68.7$ for *n*-heptane and 37.8 for CCl_4. This demonstrates the known fact (23–26) that in Cl-containing solvents the degree of H-bond self-association of alcohols is less than in hydrocarbon solvents.

A glance at Table 4 shows that the degree of H-bond self-association is independent of both the length of the chain of the *n*-alkane used as a solvent and the length of the chain in the alcohol.

Thus while halogenated solvents do interfere with H-bond formation, the latter appears to be independent of the length of the hydrocarbon chain.

Mixtures of "antagonistic" alcohols

If short chain alcohols (C_1 to C_9) on the one hand and alcohols having longer chains (C_{11} to C_{14}) on the other exert opposite influence on the physicochemical properties of lipid bilayers, it is logical to expect that binary mixtures of alcohols, one chosen from C_1–C_9 and the other from C_{11}–C_{14} will behave as antagonists as to their anesthetic action. Richards *et al.* found, however, that the effect in any of the pairs studied is

TABLE 4. Apparent molar absorption coefficients (ϵ_A) of the free (3640 cm^{-1}) and associated (3330 cm^{-1}) OH stretching vibrations of *n*-alcohols dissolved in different *n*-alkanes (0.2 *M* at 23°C)

n-Alcohols/ *n*-alcanes	ϵ_A of the free band (±3.2)	ϵ_A of the polymer band (±3.1)

Mean value of ϵ_A	40.6	37.9

additive, not antagonistic (2–4). In an attempt to ascertain whether or not there exists a parallel trend in the free/associated intensity ratio in the ir spectra we recorded (at 23°C) the OH stretching region for a number of such pairs in CCl_4 solutions, each of the components having a concentration of 0.1 *M*. The result obtained is that the intensities are perfectly additive. No indication has been found for antagonism. The results shown in Table 5 are practically the same as found for solutions containing a single alcohol at 0.2 *M* concentration (Table 1).

Mixtures of alcohols and esters or amides

Alcohols entering the lipid bilayer might form H-bonds of the O—H···:C=O type with the carbonyl groups of the lipids. In order to study this possibility (ref. 27 and references therein), we have examined the spectra of the ethyl esters of myristic, lauric, capric, and caprylic acids. The solutions contained 1.0 *M* of one of these esters and 0.2 *M* of an *n*-alcohol in CCl_4. Under these conditions the self-association of the alcohols diminishes considerably. Figure 2 gives as an example the spectrum of a solution containing *n*-heptanol and ethyl myristate. The polymer band at 3345 cm^{-1} has almost entirely disappeared. The free OH band has lost nearly half of its intensity. Instead, a new band appears at 3545 cm^{-1} which has been previously assigned to the OH stretching motion in the O—H···:O=C hydrogen bond (27). Its relatively high frequency indicates a weak H-bond. (The band at 3455 cm^{-1} is the first overtone of the carbonyl band whose fundamental is at 1735 cm^{-1}.)

All alcohols from C_3 to C_{18} behave in the same way, the spectra which we obtained are superimposable. This shows that at the same concentration the length of the chain has no appreciable influence on the degree of alcohol–ester H-bond formation. This is the same result as what has been obtained for alcohol–alcohol association.

Similar results have been obtained for amide–alcohol association. Only one example is given: that of *N*,*N*-diethylpalmitamide. Certain lipids, like sphingomyelin contain an amide group instead of an ester group. The H-bond is of the same type: O—H···:O=C. The length of the chain in the alcohols had no apparent influence on the OH stretching bands. Only methanol and ethanol exhibited slight differences with respect to the others (cf. Lesikar (28)).

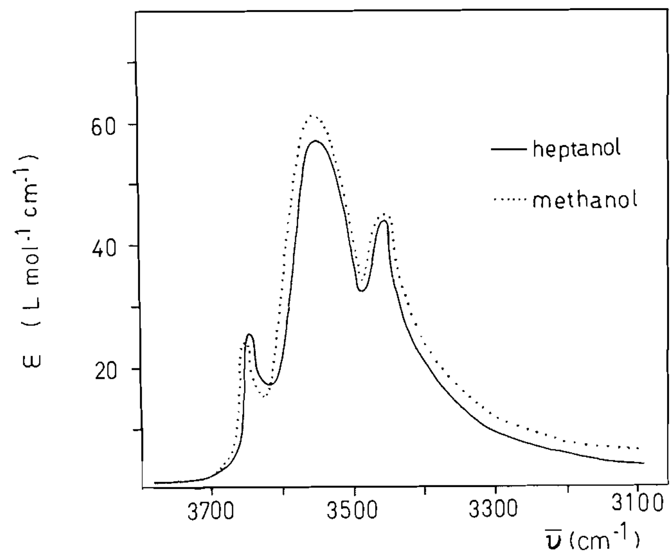

FIG. 2. The OH stretching region of the infrared spectra of a mixture of methanol (0.2 *M*) or *n*-heptanol (0.2 *M*) and ethyl myristate (1.0 *M*) in CCl_4 solution at 23°C.

In order to increase the chances of association the series of alcohol–ester spectra were also recorded at 5°C. Since at this temperature the free OH band disappears completely for 1.0 *M* solutions, the concentration of the esters was decreased to 0.5 *M* while that of the alcohols was kept at 0.2 *M*. Under the circumstances the O—H···:O=C band is found at 3520 instead of 3545 cm^{-1}. (The carbonyl overtone is at 3445 cm^{-1}.) The free OH band shifts from 3640 to 3635 cm^{-1}, the polymer band from 3345 to 3325 cm^{-1}. Typical examples are shown in Tables 6, 7, and 8 for esters at 23°C and at 5°C and for amides at 23°C, respectively. They exhibit no dependence on the length of the chain in the alcohols. The same applies to the chain length in the esters. Again methanol and ethanol exhibit slight differences with respect to the other alcohols.

Overtone studies

The first overtone of the free OH stretching vibration ($\nu = 0 \rightarrow \nu = 2$) of *n*-alcohols gives a well-defined band near 7100

cm^{-1}. An example is given in Fig. 3. The first overtone of the associated OH stretching vibration is very weak, broad, and ill-defined. In the present work only the first overtone of the free OH band has been used.

First, the OH overtones of 0.2 M solutions in tetrachloroethylene were recorded for the whole series. Unfortunately, the coincidence of the free OH overtone band with a CH_2 combination band introduces an additional source of error. (This band contains two quanta of a CH_2 stretching vibration and one quantum of the CH_2 scissoring vibration.) In the related n-alkanes the intensity of this CH_2 combination increases linearly with the number of CH_2 groups. Actually, when we subtracted

from the alcohol spectrum that of the respective alkane we found again that the intensity of the OH band is independent of the number of CH_2 groups in the alcohols. While this corroborates the results yielded by the fundamentals at the same concentration, this procedure is, for the above mentioned reason, less accurate. Therefore we renounce giving the numerical data.

The intrinsic intensity of the free band

The following objection could be made to the above interpretation of our results: it is conceivable that the intrinsic intensity of the free band decreases gradually with increasing chain length while that of the polymer band increases propor-

TABLE 9. Integrated band areas for the free OH band of 0.04 *M* solutions of *n*-alcohols in carbon tetrachloride

C_{15}	755±35	1.06±0.11	0.95±0.12

tionately and that these trends are compensated for by a parallel decrease in the H-bonded/free ratio as the chain length increases. (The opposite situation would also be conceivable.) In order to test this possibility, the integrated intensities of very dilute (0.04 *M*) solutions of ten of our alcohols were determined.

The solvent, carbon tetrachloride, was dried on anhydrous magnesium sulfate until complete disappearance of the infrared water bands. Two solutions were prepared for each alcohol and the spectrum was recorded several times between 3700 and 3200 cm^{-1}. The band areas, between 3660 and 3612 cm^{-1}, were determined with a polar compensation planimeter (model KP-27, Koizumi, Japan) calibrated with a rectangle of known surface area, close to that of the bands. The integration was carried out six times for each curve and the average of the results was taken. In view of the great similarity of all the bands, slit or wing corrections were not applied; the integration was extended from 3660 and 3612 cm^{-1} in all cases.

The results are given in Table 9. Clearly, the differences that are observed are within the limits of experimental error. If experimental error is disregarded, a trend appears whereby the intensity of the free band increases gradually until C_{10}, then it decreases until C_{17}. We cannot attach to this any significance at this stage although many years ago Mullins (29) found a similar trend in the activity coefficients. The cutoff at C_{14} certainly cannot be explained by these results.

Conclusions

We now have to answer the question: can the degree of H-bonding of alcohols be related to their anesthetic potency? The answer is clearly no in as much as self-association is concerned in either carbon tetrachloride or in paraffins of different lengths; the same applies to H-bonds between alcohols and esters or amides. An important observation can be made, however, the degree of association by H-bond formation in dissolved alcohols appears to be independent of the extent of other van der Waals or hydrophobic interactions that might exist in these solutions. The OH group does not seem to be the active factor in the anesthetic action of alcohols and one can speculate that their strong tendency for H-bond formation probably makes it difficult for them to reach the ion channels.

Neither hydrophilic, nor hydrophobic interactions seem to explain the curious dependence of the anesthetic potency of alcohols on their chain length. They are not so favorable a test case for the theories of anesthesia as they might appear to be at first sight.

Complexation du cuivre(II) par les phénylsérines *thréo* et *érythro*: étude thermodynamique

PATRICK SHARROCK

Département de chimie, Faculté des sciences, Université de Sherbrooke, Sherbrooke (Qué.), Canada J1K 2R1

Reçu le 24 avril 1984

PATRICK SHARROCK. Can. J. Chem. **63**, 46 (1985).

Les complexes cuivriques de la phénylsérine *thréo* et *érythro* ont été étudiés en solution par conductimétrie et potentiométrie. Les constantes de formation de complexes ont été obtenues en fonction de la température. La déprotonation en milieu basique du groupement OH des acides aminés β-hydroxylés est favorisée par la présence de l'ion métallique. La phénylsérine *thréo* a donné à 298 K les constantes de formation suivantes: Cu(L), K_1 = 7,99; Cu(L)$_2$, K_2 = 6,71; Cu(L$_2$H$_{-1}$), K_3 = −9,51; Cu(L$_2$H$_{-2}$), K_4 = −10,83. Les constantes correspondantes pour l'isomère *érythro* sont: K_1 = 7,70; K_2 = 6,70; K_3 = −9,82 et K_4 = −11,20. Les paramètres thermodynamiques pour la formation des complexes successifs Cu(L) et Cu(L)$_2$ sont: $-\Delta H$ = 21,3 et 44,7 kJ mol^{-1}; ΔS = 82 et 132 J K^{-1} mol^{-1}, respectivement, pour la forme *thréo* ainsi que $-\Delta H$ = 20,7 et 44,1; ΔS = 79 et 129 pour la forme *érythro*. Une enthalpie additionnelle de −21 kJ mol^{-1} correspond à la déprotonation des complexes. Ces résultats et les structures des complexes sont commentés.

PATRICK SHARROCK. Can. J. Chem. **63**, 46 (1985).

Conductimetric and potentiometric measurements in aqueous solution as a function of temperature show that cupric ions promote the deprotonation of the hydroxy side chain of *threo* and *erythro* β-phenylserines. The *threo* ligand yields at 298 K the formation constants: Cu(L), K_1 = 7.99; Cu(L)$_2$, K_2 = 6.71; Cu(L$_2$H$_{-1}$), K_3 = −9.51; Cu(L$_2$H$_{-2}$), K_4 = −10.83. The *erythro* isomer yields the corresponding constants: K_1 = 7.70, K_2 = 6.70, K_3 = −9.82, and K_4 = −11.20. Thermodynamic parameters for the first two complexation steps are $-\Delta H$ = 21.3 and 44.7 kJ mol^{-1}; ΔS = 82 and 132 J K^{-1} mol^{-1}, respectively, for the *threo* form and $-\Delta H$ = 20.7 and 44.1, ΔS = 79 and 129 for the *erythro* form. Deprotonation of the complexes corresponds to an additional enthalpy of −21 kJ mol^{-1}. These results and the structures of the complexes are discussed.

Introduction

La première synthèse de la phénylsérine fut décrite par Erlenmeyer en 1892 (1). La phénylsérine reste un acide aminé rare et a été peu étudiée en présence d'ions métalliques mis à part quelques travaux sur ses bases de Schiff utilisées comme modèles enzymatiques (2). Une étude rapporte la formation de complexes cuivriques avec la phénylsérine (3) mais comme il existe deux isomères de la phénylsérine, à savoir les formes *thréo* et *érythro*, il nous a paru utile de clarifier l'étude des complexes des phénylsérines pures, ce qui n'a encore jamais été fait. Shaw et Fox réussirent à séparer les deux isomères dès 1953 (4) et la *thréo* phénylsérine (L) fut reliée via une décarboxylation enzymatique à la (−) artérénol (5). Le chloramphénicol est un bactéricide dont la structure est reliée à celle de la phénylsérine, ce qui laisse présager des propriétés biologiques intéressantes pour cet acide aminé. Nous avons déjà décrit une synthèse de la *thréo* phénylsérine via une condensation catalysée par les ions cuivriques (6), synthèse qui passe par l'intermédiaire d'une isoxazolidine complexée aux ions cuivriques. Nous rapportons maintenant l'étude physicochimique en solution aqueuse de l'interaction des phénylsérines *thréo* et *érythro* avec les ions cuivriques.

Partie expérimentale

Synthèse

L'acide 2-amino, 3-hydroxy, 3-phénylpropanoïque, soit la phénylsérine, a été synthétisée par la méthode de Shaw et Fox (4) avec un rendement de 70%. La forme *érythro* a été obtenue avec une modification du protocole comme suit. Dans 150 mL d'eau on dissout 30 g de glycine et 24 g de NaOH. On ajoute 82 mL de benzaldéhyde et on refroidit la solution à 8°C. Un précipité se forme après 4 min et après 10 min, on laisse la température monter jusqu'à 20°C juste assez longtemps pour que tout le mélange se liquéfie. On refroidit de nouveau entre 8 et 10°C tout en agitant pendant 4 h. On acidifie lentement avec HCl glacé en mélangeant régulièrement. Les grosses boules de produit coagulé sont lavées avec 250 mL EtOH 95% froid, suivi d'éthanol absolu bouillant. À ce stade on a de la phénylsérine brute dont le rapport *thréo*/*érythro* (déterminé par rmn et chromatographie) est d'environ 1. L'isomère *thréo* recristallise dans 400 mL d'eau bouillante alors qu'après concentration et addition de 400 mL de dioxane–eau 50% on obtient l'isomère *érythro* avec un rendement de 47%.

Nous avons également obtenu les hydrochlorures des esters éthyliques des isomères *thréo* et *érythro* avec des rendements respectifs de 98 et 83% en partant des acides aminés hydratés, par la méthode de Fisher. Ces hydrochlorures d'ester sont intéressants car ils ne sont pas hydroscopiques et redonnent les acides aminés de départ par simple hydrolyse. L'hydrochlorure d'ester *thréo* est très soluble dans l'éthanol, tandis que celui de la forme *érythro* ne l'est pratiquement pas, ce qui permet de confirmer la séparation des deux isomères. Nous n'avons pas réussi à séparer les deux isomères de cette façon car la forme *érythro* devient soluble en présence de la forme *thréo*.

Mesures physiques

Les mesures de conductivité ont été effectuées avec une électrode CMO5g de Tacussel et un conductimètre de type CD6N de Solea (Lyon). Les surfaces de 5 mm^2 et distantes de 5 mm étaient fraîchement réactivées et calibrées avec du KCl 0,10 *M*.

Pour les mesures potentiométriques, nous avons préparé une solution NaOH ≈ 0,1 *M* dans de l'eau fraîchement distillée que nous avons conservé sous azote et standardisé avec KHP. L'acide nitrique utilisé pour abaisser le pH entre 2,2 et 2,5 avant les titrages a été titrée par la solution de NaOH. Les solutions d'acides aminés et de nitrate de cuivre ont été préparées immédiatement avant les titrages qui ont été effectués avec KNO_3 0,10 *M* comme électrolyte de support. Des rapports de ligand à métal de 1:1 à 2,5:1 ont été utilisés avec une concentration d'ions cuivriques de l'ordre de 0,01 *M*. La cellule de titrage thermostatée était munie d'un capuchon Metrohm par lequel passait des électrodes au calomel et de verre (Sargent Welch 150 MΩ) et une arrivée d'azote. Les lectures de pH effectuées avec un "Ionalyser Orion Research Model 801 Digital pH meter" étaient précises à ±0,002.

Nous avons délivré le titrant par l'intermédiaire d'un tube spécial en Teflon rigide provenant d'une seringue d'autoburette ABU 12 de Radiometer (Copenhagen). L'autoburette se lit au centième de millilitre et les résultats, enregistrés sur papier graphique avec un Fisher Recordall series 100, ont été accumulés entre 17 et 45°C par intervalle de 5°C en calibrant le pH-mètre à chaque température à pH 4 et pH 10. Les données en vue de l'affinement des constantes de formation ont été obtenus à partir des courbes de titrage avec un "Bendix datagrid digitizer" relié à un miniordinateur. Sur le coordinatographe, l'axe de pH était pris pour l'axe y et l'axe x était ajusté pour correspondre avec l'axe de volume. Les données x en fonction de y ont été prélevées par le coordinatographe avec des incréments mesurés le long des deux axes (mode $\Delta x + \Delta y$). Près des points équivalents, le mode Δx a été utilisé, ce qui diminue le nombre de points prélevés lors de grandes variations de pH. L'effet d'eventuelles erreurs analytiques est ainsi minimisé. Le programme SCØGS a été modifié afin que les matrices puissent accommoder jusqu'à 200 lectures par expérience. Nous avons utilisé un coefficient d'activité pour l'ion hydrogène de 0,78 et avons tenu compte de la variation avec la température de la valeur du produit ionique de l'eau.

Dans un premier temps les constantes K_1 et K_2 ont été affinées pour les ligands. Un graphique a été construit des logarithmes des constantes de dissociation en fonction de la température et les valeurs retenues comprenaient trois décimales et une erreur estimée à ±0,005. Dans un deuxième temps, ces constantes ont été utilisées en conjonction avec les estimés provenant de la méthode graphique de la fonction de formation ($\bar{n}$ α log A^-), pour affiner les valeurs des constantes de formation de complexes. Les deux premières constantes de formation ont été obtenues en éliminant les données à pH ≥ 10. Les données à pH basique ont été réintroduites en même temps que deux estimés pour les constantes de déprotonation des complexes. Ces deux dernières constantes ont été affinées indépendemment des quatre autres impliquées.

Les valeurs de ΔH et ΔS, ajustées par moindres carrés, ont été obtenues d'après la pente et l'intercept des graphiques de log K vs. $1/T$. Les courbes de distribution des espèces ont été dessinées d'après les résultats du programme SCØGS.

Résultats

Les courbes de titrages conductimétriques permettent généralement de mettre en évidence la formation successive de complexes 1:1 et 2:1. Cependant des titrages d'ions cuivriques par des solutions d'acide aminé de divers pH n'ont pas donné de bons résultats. Nous avons donc procédé au titrage conductimétrique de solutions contenant des rapports stoichiométriques ligand/métal de 2:1 par de la soude de titre connu. Ainsi, après correction pour les conductivités équivalentes des ions sodium ajoutés et correction pour les conductivités des ions H^+ et OH^- effectuées après mesure du pH, nous avons observé une augmentation de la résistance avec augmentation du pH, suivi d'une diminution en milieu basique. Les courbes de titrage présentées dans la fig. 1 montrent des brisures dans la pente des droites pour des rapports stoichiométriques des ions Na^+/Cu^{2+} de 1, 2 et 4.

Les courbes de titrages potentiométriques sont typiques des courbes observées lors de titrages de complexes cuivriques. Nous remarquons cependant que dans le cas d'un rapport ligand/métal de 1, on observe la formation d'un précipité d'hydroxyde cuivrique qui provoque un plateau vers pH neutre correspondant à la disproportionation en complexe 2:1 et en $Cu(OH)_2$ insoluble. Il est intéressant de noter la dissolution du précipité, ce qui conduit progressivement à une solution limpide en milieu fortement basique. Même s'il est impossible de calculer une constante de formation de complexe dans ces conditions, les données indiquent la formation d'une espèce distincte en milieu basique. Nous avons retenu la formation des complexes CuA^+, CuA_2, $CuH_{-1}A_2^-$ et $CuH_{-2}A_2^{2-}$ où H_2A représente le ligand protoné aux fonctions carboxyliques et aminées. Quelques titrages en fonction de la dilution n'ont pas permis de détecter la formation de dimères du genre M_2A_4.

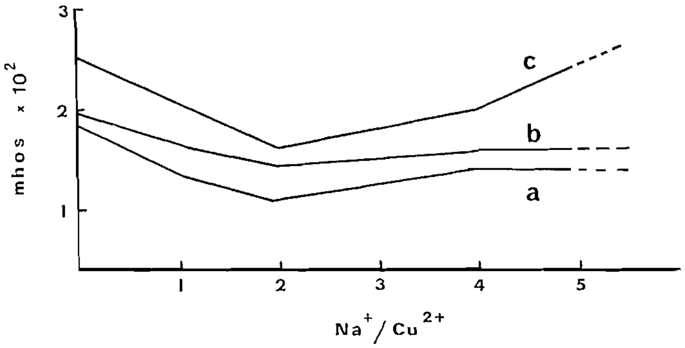

FIG. 1. Courbes de titrages conductimètriques pour les complexes cuivriques de la phénylsérine *thréo* (a) et *érythro* (b). La courbe (c) correspond au complexe de la sérine. Les concentrations de complexes sont ~0,01 *M*.

Les constantes de formation sont regroupées dans le tableau 1. On constate que les valeurs diminuent progressivement lorsque la température augmente et qu'elles sont légèrement plus petites pour la phénylsérine *érythro* que pour la forme *thréo*. Il est à noter que les constantes cumulatives log β_3 et log β_4 diminuent par rapport à log β_2. Ceci provient de la nature de log K_3 et log K_4 qui sont négatives car elles correspondent à des constantes de déprotonation des complexes.

Les courbes de distribution des espèces sont représentées à la fig. 2. La différence principale entre la complexation par l'isomère *thréo* et celle par l'isomère *érythro* réside dans le pH de formation des espèces déprotonées, celles-ci se formant plus facilement avec la *thréo* phénylsérine.

Les valeurs des paramètres thermodynamiques ΔG^0, ΔH^0 et ΔS^0 obtenues d'après la variation en fonction de la température des constantes d'équilibre paraissent dans le tableau 2. Dans ce tableau nous présentons aussi les enthalpies de formation des complexes CuA^+ et CuA_2 décomposées en termes électrostatiques et covalents d'après les équations [1] à [3]:

$$[1] \quad \Delta H_c = \Delta H - \Delta H_c$$

$$[2] \quad \Delta H_c = (T - \nu)(\Delta S + \Delta n\, R \ln 55.5)$$

$$[3] \quad \Delta G_c = -\nu(\Delta S + \Delta n\, R \ln 55.5)$$

ν est une constante obtenue à partir de la variation de la constante diélectrique du solvant en fonction de la température (ν = 219 K pour H_2O), Δn représente le changement dans le nombre de particules de soluté au cours de la réaction. De même ΔG_c, la contribution électrostatique à l'énergie libre qui

$$[4] \quad \Delta G = \Delta n\, RT \ln 55.5 + \Delta G_c + \Delta G_c$$

dépend de la température et ΔG_c, la contribution covalente invariable en fonction de la température sont données d'après [4]. Dans notre cas, la formule [5] permet de trouver la température T^0 ≥ 100°C et puisque nos réactions de formation de complexes sont exothermiques, log K diminue avec augmentation de la température et on s'attend à une importante

$$[5] \quad T^0 = \nu(1 + \Delta G_c/\Delta G^0_c)$$

contribution des forces covalentes. Nous remarquons dans le tableau 2 que les ΔH_c ne varient pas entre la formation du monochélate et du dichélate et sont caractéristiques des acides aminés utilisés. La variation observée dans ΔH pour les complexes successifs est donc attribuable à la variation dans ΔH_c. Pour préciser les résultats, nous avons corrigé la différence ΔG_r

TABLEAU 1. Constantes de formation des complexes cuivriques de la phénylsérine

Isomère *thréo*	Température (°C) 45	40	35	30,7	25	21,7	17,4

$(CuPS)^+$ + PS → $CuPS_2$	36,1	22,9	45	6,1	29,1
Cu^{2+} + 2PS → $CuPS_2$	80,4	43,9	122	14,9	58,8

[a] TPS = thréophénylsérine, EPS = érythrophénylsérine. SER et PS sont sérine et phénylsérine de la réf. 15.
[b] Les unités sont: ΔG et ΔH en kJ mol^{-1} et ΔS en J K^{-1} mol^{-1}. Les erreurs sont estimées à ±0,2 kJ mol^{-1} et ±1 J K^{-1} mol^{-1}.

$= \Delta G_1 - \Delta G_2$ pour tenir compte de l'effet statistique pour la réaction [6]

$$[6] \quad Cu^{2+} + CuL_2 \overset{K_r}{\rightleftharpoons} 2\,Cu\,L^+$$

K_{stat} serait la valeur de K_r si la réaction procédait suivant une loi purement statistique. Les équations utilisées sont [7] à [10] et les résultats sont consignés au tableau 3, avec $K_{stat} = 4$.

$$[7] \quad \Delta G_r = -RT \ln K_{stat} + \Delta G_{r,c} + \Delta G_{r,c}$$

$$[8] \quad \Delta H_{r,c} = (T - \nu)(\Delta S_r - R \ln K_{stat})$$

$$[9] \quad \Delta H_{r,c} = \Delta G_{r,c} = \Delta H_r - \Delta H_{r,c}$$

$$[10] \quad \Delta S_{r,t} = \Delta S_r - \Delta S_{stat}$$

Discussion

Les complexes cuivriques des phénylsérines ont des conductivités équivalentes faibles, ce qui indique qu'ils sont faiblement dissociés, en accord avec les constantes de formation trouvées assez grandes. Les phénylsérines agissent comme la sérine (7) et différemment de la glycine qui ne montre aucune discontinuité dans la valeur de la conductivité en fonction de la quantité de base ajoutée après le rapport molaire Na^+/Cu^{2+} 2:1. Ceci indique que dans le cas des acides aminés β-hydroxylés, il s'opère un changement particulier quand deux moles de base ont été ajoutées par mole d'acide aminé. Ceci peut s'expliquer par un changement dans la dimension ou la mobilité des complexes, ou par la formation de complexes déprotonés ou hydroxylés. Dans la mesure où la formation de complexes hydroxylés n'est pas détectée dans le cas de la glycine et qu'elle devrait dépendre du pH et non de la quantité stoechiométrique de base ajoutée, on peut affirmer qu'il y a déprotonation des fonctions β-hydroxylées et formation de complexes cuivriques anioniques.

TABLEAU 3. Comparaison des complexes successifs

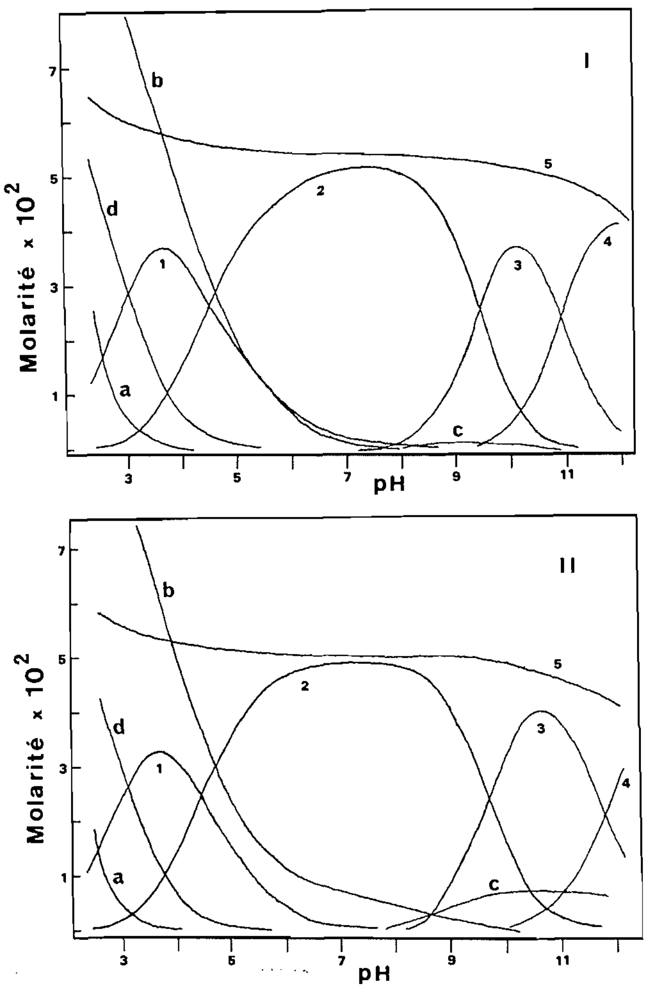

FIG. 2. Courbes de répartition des espèces en fonction du pH pour les complexes cuivriques de la phénylsérine *thréo* (I) et *érythro* (II). Les complexes sont 1: $[CuL]^+$; 2: CuL_2; 3: $[CuL_2H_{-1}]^-$ et 4: $[CuL_2H_{-2}]^{2-}$; 5: représente la concentration totale de cuivre et d, la concentration d'ions Cu^{2+} libres. a, b et c sont respectivement l'acide aminé protoné, le zwitterion et l'acide aminé déprotoné non complexés.

L'étude potentiométrique confirme la formation de plusieurs espèces. Les différences entre les titres calculés et observés sont minimisées avec le programme SØCGS en tenant compte des complexes CuA^+, CuA_2 et $CuH_{-1}\ A_2^-$ et $CuH_{-2}\ A_2^{2-}$. La détection de complexes déprotonés ou hydroxylés n'est pas nouvelle (7–10), ce phénomène ayant déjà été décrit pour la sérine et la thréonine. On ne s'attend pas à ce que des complexes hydroxylés soient solubles, ce qui favorise la conclusion qu'il s'agisse d'une déprotonation du ligand coordiné. Les ions cuivriques peuvent aussi déprotoner le carbone α dans des complexes analogues (11).

Pour les acides aminés, nous observons que les pK_1 et pK_2 sont plus petits pour la forme *érythro* (8,70 et 10,35) que pour la forme *thréo* (8,87 et 10,57) de la phénylsérine. Ceci est en accord avec les tendances générales observées et en particulier le cas de la thréonine et la allo-thréonine. L'ordre décroissant de pK_1 et pK_2 est sérine > thréonine > allo-thréonine > *thréo*-phénylsérine > *érythro*-phénylsérine. L'ordre de stabilité des complexes est Cu(thréonine)$^+$ > Cu(*thréo*-phénylserine)$^+$ > Cu(sérine)$^+$ > Cu(allo-thréonine)$^+$ > Cu(*érythro*-phénylsérine)$^+$; et aussi Cu(thréonine)$_2$ > Cu(*thréo*-phénylserine)$_2$ > Cu(sérine)$_2$ > Cu(*érythro*-phénylsérine)$_2$ > Cu(allo-thréonine)$_2$. Cet ordre n'est pas le même que l'ordre de basicité des ligands et on peut en déduire que les effets structuraux sont importants. En effet, par rapport aux complexes de la sérine (qui ne peut exister que sous une seule forme), les complexes avec les acides aminés substitués en position α sont plus stables lorsque la substitution donne une forme *thréo* et ils sont moins stables dans le cas d'une forme *érythro*. Ceci implique que la stabilité des complexes dépend non seulement de l'influence des groupes fonctionnels des ligands mais aussi de la géométrie globale des complexes résultants.

Des résultats thermodynamiques montrent que les paramètres ΔH et ΔS obtenus pour les complexes d'acides aminés hydroxylés sont semblables à ceux obtenus pour les acides aminés ordinaires. Raju et Mathur ont étudié les complexes de la sérine et de la thréonine avec une série de métaux de transition (12). Ils trouvèrent que les valeurs de ΔG et de ΔS étaient beaucoup plus grandes pour le cuivre qui formait des complexes plus stables. Par ailleurs, ils trouvèrent que c'était dans le cas du cuivre qu'il y avait la plus petite différence entre les valeurs observées pour la sérine et la α-alanine d'une part, et la thréonine et l'acide α-aminobutyrique d'autre part. Ils conclurent de ces observations que les complexes du cuivre étaient stabilisés par le champ cristallin et que le groupement OH n'entrait pas dans la première sphère de coordination. La comparaison de leurs résultats avec ceux de Stack et Skinner (13) révéla une différence anormalement large dans les valeurs de ΔH et ΔS pour la formation de Cu(sérine)$_2$. Ils trouvaient 40,1 kJ mol^{-1} et 142 J K^{-1} mol^{-1} alors que Stack et Skinner donnaient 58,9 kJ mol^{-1} et 79 J K^{-1} mol^{-1}, respectivement. Ils expliquèrent alors la différence comme étant attribuable aux conditions expérimentales. En effet, Stack et Skinner avaient utilisé un assez considérable excès d'acide aminé et avaient supposé la formation d'un complexe du cuivre avec plus de deux acides aminés. Ils avaient par conséquent appliqué une correction pour obtenir une valeur de ΔH correspondant exclusivement à la formation de CuA_2.

Thornton et Skinner étudièrent de nouveau les mêmes complexes (14) dans une série de mesures plus détaillées et se rendirent compte alors qu'il y avait un changement brusque dans ΔH dès que le pH dépassait 10. $-\Delta H$ était de l'ordre de 54 kJ mol^{-1} pour la formation de Cu(sérine)$_2$ et de Cu(thréonine)$_2$ à pH $\leq$ 10, ce qui se compare bien avec les valeurs pour Cu(glycine)$_2$ ($\simeq$ 56 kJ mol^{-1}) et pour Cu(alanine)$_2$ ($\simeq$ 48 kJ mol^{-1}). Ces valeurs montaient à 96 et 102 kJ mol^{-1} à pH = 12 pour la sérine et la thréonine respectivement. Donc, en milieu basique, les réactions étaient presque deux fois plus exothermiques. Ceci n'arrivait pas dans le cas des complexes de Ni ou du Zn, où des précipités apparaissaient en milieu basique. Les auteurs conclurent que leurs données démontraient la formation d'autres espèces en plus de Cu(sérine)$_2$ en milieu alcalin et proposèrent des complexes polyhydroxylés et polynucléaires. Cependant ils remarquèrent que le complexe Cu(glycine)$_2$ donnait un précipité en milieu basique et aucun changement de ΔH en fonction du pH et ne purent expliquer ces faits.

Letter et Bauman étudièrent les complexes du Cu et du Ni avec une série d'acides aminés reliés à la sérine (15) et à la tyrosine (16). Les enthalpies de formation des complexes successifs étaient toutes comprises entre 20 et 26 kJ mol^{-1}, la formation du deuxième complexe étant toujours un peu plus exothermique que la formation du premier (d'environ 2 kJ mol^{-1}). Les entropies variaient de 58 à 75 J K^{-1} mol^{-1} pour la formation du premier complexe et de 42 à 50 J K^{-1} mol^{-1} pour le deuxième. Ils expliquèrent leurs résultats comme suit:

1. L'enthalpie négative est attribuée principalement à la formation des liens cuivre–azote (la moitié des enthalpies de complexation du cuivre avec l'éthylènediamine étant de 27 kJ mol^{-1} pour CuL et de 26 kJ mol^{-1} pour CuL_2).

2. L'entropie positive est relié au départ des molécules d'eau coordonnées lors de la neutralisation des charges du cuivre par les groupements carboxyliques (la moitié de l'entropie de complexation de Cu^{2+} avec l'ion oxalate étant de 59 J K^{-1} mol^{-1}). Ils concluèrent que leurs données ne leur permettaient pas de retenir l'hypothèse de la formation de liens cuivre hydroxyles car les interactions cuivre–azote et cuivre – acide carboxylique semblaient adéquates et suffisantes.

Gergely *et al.* étudièrent de nouveau une série de complexes en partant du principe qu'il fallait considérer la possibilité des liaisons métal – groupement hydroxyle (17). Ils observèrent que tous les métaux étudiés (Co, Ni, Cu et Zn) et en particulier le cuivre, avaient une enthalpie de formation de complexe plus exothermique dans le cas de la sérine et de la thréonine que dans le cas de l'alanine et de l'acide α-aminobutyrique. Ils objectèrent à la comparaison de Letter et Bauman entre l'isosérine et les autres acides aminés hydroxylés, préférant baser leurs conclusions sur des comparaisons entre les acides aminés où —CH_2OH était remplacé par —CH_3.

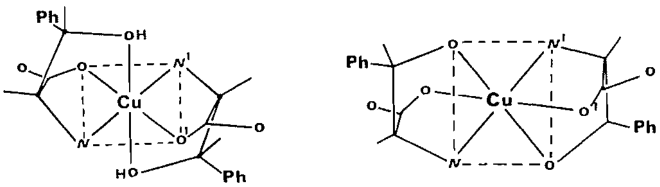
L'inspection des différences pH – log K montra que les complexes des acides aminés hydroxylés étaient relativement plus stables que ceux des acides aminés non hydroxylés. De plus, les complexes de la thréonine paraissaient encore plus stables que ceux de la sérine. Cette stabilité accrue se réflétait par des réactions plus exothermiques pour les acides aminés hydroxylés. Pourtant, l'effet inductif du groupement OH était naturellement d'affaiblir les liens Cu $\leftarrow$ N. Gergely *et al.* concluèrent donc: "The greater enthalpy change resulting in spite of this can be explained only by the formation of a further bond". Ils proposèrent par conséquent que les groupements OH non ionisés des acides aminés en question participaient à la formation de liens faibles à l'intérieur de la première sphère de coordination du métal.

D'autres auteurs ont étudié les complexes cuivriques de la sérine sans détecter les complexes déprotonés à pH basique (18 19). Nos résultats sur la phénylsérine *thréo* et *érythro* (voir tableau 2) sont semblables à ceux de Letter et Bauman sur la sérine et la phénylsérine. Nous remarquons que les ΔH_c sont caractéristiques des acides aminés et ne varient pas entre la formation du monochélate et du dichélate. Ces observations concordent avec les résultats de I et Nancollas (19). La variation observée dans ΔH pour les complexes successifs est donc attribuable à la variation dans ΔH_c.

Nous observons que $\Delta G_{r,c}$ est négatif, ce qui s'explique comme suit: les répulsions électrostatistiques entre ligands réduisent la stabilité des complexes dichélatés et favorisent la formation des monochélates. Par contre, les valeurs de $\Delta G_{r,c}$ (ou $\Delta H_{r,c}$) sont positives et reflètent les interactions covalentes et l'influence mutuelle des ligands. I et Nancollas (19) ont expliqué cet effet comme probablement relié à la plus grande facilité d'enlever l'eau de coordination du monocomplexe que de l'ion Cu^{2+}. Letter et Bauman ont montré que pour tous les complexes d'acides aminés, ΔH_2 est plus exothermique que ΔH_1. Ceci montre que la coordination du premier acide aminé facilite le départ des molécules d'eau restantes. Les changements d'entropie corroborent ces conclusions car ΔS_1 est beaucoup plus grand que ΔS_2. La formation du monocomplexe, comparé à la deuxième étape, correspond donc à la libération d'une plus grande quantité d'eau, avec un accroissement correspondant du désordre résultant. Les changements d'entropie positifs sont essentiellement reliés aux différences dans la solvatation des espèces participant aux réactions d'association.

Nancollas a considéré que la sérine était un acide aminé ordinaire (bidentate) mais il a remarqué que toutes les valeurs de $\Delta S_{r,t}$ étaient semblables à l'exception de celles pour les complexes de la sérine. Nos résultats montrent que la phénylsérine *thréo* et *érythro* ressemble à la sérine, c'est-à-dire qu'ils diffèrent eux aussi des valeurs observées pour les acides aminés ordinaires. Voici l'explication de Nancollas: "The lower value of $\Delta S_{r,t}$ for serine can be attributed to the electron-withdrawing property of the hydroxyl group in the β-position which renders the net positive charge on $Cu(ser)^+$ higher than for the other mono (amino acid) complexes. Interaction with the solvent will therefore be stronger in the case of $Cu(ser)^+$ resulting in a lower $\Delta S_{r,t}$". Cet argument est tendancieux, car si l'effet inductif est important dans le cas du monocomplexe, il doit être important aussi dans le cas de Cu(serine)$_2$. Autrement dit, on ne peut observer dans la différence qu'est $\Delta S_{r,t}$, aucune particularité attribuable à l'effet inductif, à moins que cet effet disparaisse dans le dichélate, ce qui semble douteux. A notre avis, les résultats thermodynamiques peuvent être expliqués raisonnablement si on postule que les acides aminés β-hydroxylés sont tridentates, avec le groupe OH en position axiale. Les structures proposées par les complexes sont présentées dans la fig. 3. On ne s'attend pas à une grande différence entre l'enthalpie d'un lien Cu—H_2O et d'un lien Cu—ROH où R représente le reste de l'acide aminé. Par conséquent, on peut même s'attendre à un équilibre, en solution aqueuse, entre des complexes avec soit H_2O, soit ROH coordonnés.

La question des changements d'entropie est plus délicate. En effet, la formation d'un chélate entraîne normalement un ΔS plus grand résultant en une plus grande stabilité d'un complexe



A B

FIG. 3. Structures proposées pour les complexes cuivriques de la phénylsérine. A à un pH neutre, B à un pH basique.

chélaté par rapport à un complexe analogue non cyclique. L'effet chélate est justement un effet d'entropie. Pourtant on observe encore une fois des valeurs de ΔS typiques de ligands bidentates seulement. Cependant, les acides aminés β-hydroxylés existent déjà sous forme cyclique en solution, (20–22), cycle formé par une liaison hydrogène entre les groupements OH et NH_3. Il est donc difficile d'interpréter les changements d'entropie lors de la formation du chélate métallique.

Conclusion

En conclusion, l'hypothèse que la sérine et la phénylsérine sont des acides aminés tridentates offre une meilleure explication des résultats thermodynamiques. Cette hypothèse explique pourquoi les acides aminés β-hydroxylés ont des ΔG (et des constantes de formation de complexes) proches des ΔG observés pour les acides aminés ordinaires. De plus elle suggère une bonne possibilité pour la formation des complexes déprotonés: la déprotonation du groupement OH coordonné et la formation d'un lien Cu–alcoxyde en milieu basique expliquerait l'augmentation de l'exothermicité de la réaction cuivre + acide aminé au dessus de pH 10. D'après la variation de log β_3 et log β_4 en fonction de la température, nous obtenons une valeur voisine de 21 kJ mol^{-1} pour chaque déprotonation (-23 et -19 ± 2 kJ mol^{-1} pour la phénylsérine *thréo* et *érythro*, respectivement). On retrouve donc l'augmentation totale de -42 kJ mol^{-1} découverte par Thornton et Skinner pour le cas des complexes de la sérine (14). Des études complémentaires par spectroscopie visible montrent un acroissement de la force du champ cristallin à pH basique. De plus des résultats rpe montrent l'apparition d'une structure hyperfine à 5 raies pour le complexe déprotonné, en accord avec la transformation de l'acide aminé en un ligand tridentate moins labile à pH basique. Les temps de relaxation en rmn concordent aussi avec les conclusions thermodynamiques et feront le sujet d'une autre publication.

Nos expériences sur la phénylsérine représentent la troisième occurrence de la détection de complexes déprotonés et tend à confirmer la généralité de ce phénomène pour les acides aminés β-hydroxylés.

Copper(II) acetates: from dimer to monomer

PATRICK SHARROCK
Département de chimie, Faculté des sciences, Université de Sherbrooke, Sherbrooke (Qué.), Canada J1K 2R1

AND

MILAN MELNÍK[1]
Department of Inorganic Chemistry, Slovak Technical University, CS 81237 Bratislava, Czechoslovakia

Received April 4, 1984

PATRICK SHARROCK and MILAN MELNÍK. Can. J. Chem. **63**, 52 (1985).

The epr spectra at various frequencies of copper(II) acetate anhydrous, monohydrate, monoacetic acid, and water – acetic acid adduct are presented and analysed. The presence of copper hyperfine splittings in the solid state epr spectra of this series of compounds is discussed. The frozen solution spectrum of copper(II) acetate in acetic acid solution containing ~2% water shows an exceptional resolution of $A_\perp$ hyperfine of 24 G. This is attributed to a key intermediate which explains the monomer–dimer dissociation mechanism. The influence of distortions on the structures of these compounds is presented.

PATRICK SHARROCK et MILAN MELNÍK. Can. J. Chem. **63**, 52 (1985).

Les spectres rpe à diverses fréquences de l'acétate cuivrique anhydre, monohydraté et des composés d'addition avec l'acide acétique et l'eau et l'acide acétique sont présentés et analysés. La présence de couplages hyperfins avec les noyaux ^{63}Cu et ^{65}Cu sont discutés. Le spectre rpe d'une solution gelée d'acétate cuivrique dans l'acide acétique contenant ~2% d'eau ont une résolution inhabituelle de $A_\perp$ de 24 G. Ceci est attribué à un intermédiaire clef qui explique bien le mécanisme de dissociation dimère–monomère. Nous présentons l'importance des distortions sur les structures de ces composés.

Introduction

Binuclear metal centers are known to be present in copper(II) carboxylates (1). The bridged binuclear structure, first documented by Van Niekerk and Schoening (2) for copper(II) acetate monohydrate, is now an ubiquitous feature in coordination chemistry. The magnetic properties of exchanged-coupled paramagnetic centers is of considerable interest (3). Bleaney and Bowers first recognized the triplet state epr spectrum of copper(II) acetate monohydrate (4) and solved the $S = 1$ spin Hamiltonian parameters. There is strong antiferromagnetic coupling in such dimers and a $-2J$ value of 298 ± 4 cm^{-1} was determined recently by direct spectroscopic measurements by neutron scattering (5).

A thermodynamic study (6) of solvation (in water/acetic acid) of copper(II) acetate shows that the dimer prefers coordination of water to that of acetic acid in the axial position. Also, water is reported to stabilize the dimer in solution despite the fact that water shifts the monomer–dimer equilibrium towards the monomer. Conflicting reports exist in the literature dealing with the presence or absence of epr signals for solutions of copper(II) acetate (7, 8), and even on the composition of the adducts present in water – acetic acid mixtures (6, 9).

We now wish to report the synthesis and characterization of copper(II) acetate adducts with acetic acid and water. We present the first epr spectrum for $Cu(OAc)_2 \cdot H_2O \cdot HOAc$ as well as a frozen solution spectrum with resolved hyperfine along $g_\perp$. We compare the spectroscopic parameters for the series of adducts.

Experimental

Preparation of compounds

Copper(II) acetate monohydrate was purchased from J.T. Baker Co. and used without further purification. The anhydrous compound was prepared by monitoring the weight loss on the monohydrate by gentle heating until constant weight. The sample was then sealed in the quartz epr tube.

Copper(II) acetate·acetic acid was prepared by adding acetic anhydride to a glacial acetic acid solution of copper(II) acetate. The solution was heated to dissolve the solids and put aside for crystallisation.

Copper(II) acetate·hydrate·acetic acid was prepared by equilibrating a suspension of copper(II) acetate monohydrate in acetic acid containing 1% water as measured by nmr. Following a one week period the solid product was filtered off and stored without drying in tightly sealed containers.

Physical measurements

Copper contents were checked by atomic absorption analyses. Thermal analyses were performed with a Setaram electrobalance and fully programmable oven. The samples weighed 100 mg and were under a nitrogen flow of 50 mL/min; the average heating rate was 2°/min.

Electron parameter resonance spectra were recorded on Varian E-9 spectrometers operating at X-band and Q-band and Jeol spectrometer at K-band. Standard cryostats and Varian temperature control units were used for the low temperatures.

Results

We found that careful dehydration of the monohydrate yields an anhydrous copper(II) acetate with only a small amount of mononuclear species. The acetic acid adduct also contains small amounts of mononuclear species and must be prepared in the rigorous absence of water and protected from atmospheric humidity. The water – acetic acid adduct cannot be dried in air without decomposition leading to formation of the monohydrate. This mixed-ligand adduct can only be obtained by a slow heterogeneous reaction as described in the Experimental section.

Atomic absorption and thermogravimetric analyses confirm the compositions of the compounds. *Anal.* calcd. for $Cu(CH_3COO)_2 \cdot CH_3COOH$: Cu 26.29; found: Cu 26.17. *Anal.* calcd. for $Cu(CH_3COO)_2 \cdot H_2O \cdot CH_3COOH$: Cu 24.46; found: Cu 24.32. All compounds begin to decompose at 250°C and yield copper metal mixed with small amounts of copper oxide. The acetic acid adduct loses its axial ligand readily beginning at temperatures as low as 40°C. Between 40 and 60°C the observed weight loss is 25.0%, which corresponds closely to the theoretical value of 24.85%. The monohydrate loses water near 100°C (observed weight loss of 9.1%, theoretical value

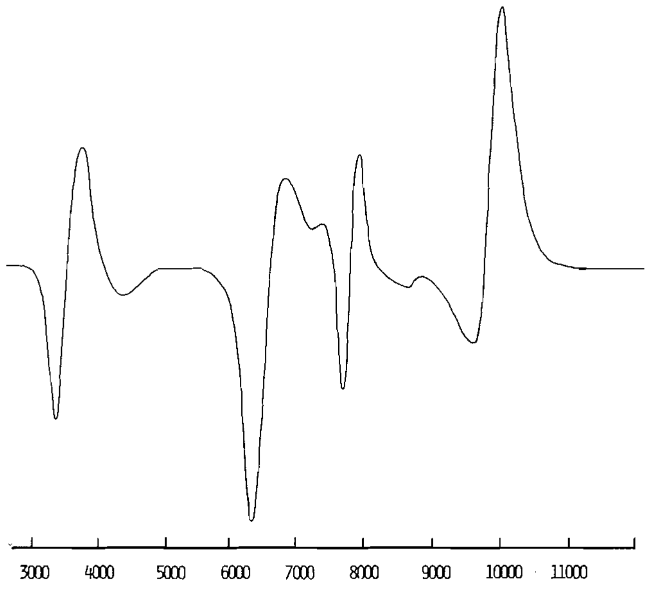

FIG. 1. K-band spectrum (24.725 GHz) of $[Cu(CH_3COO)_2 \cdot CH_3COOH]_2$ at room temperature.

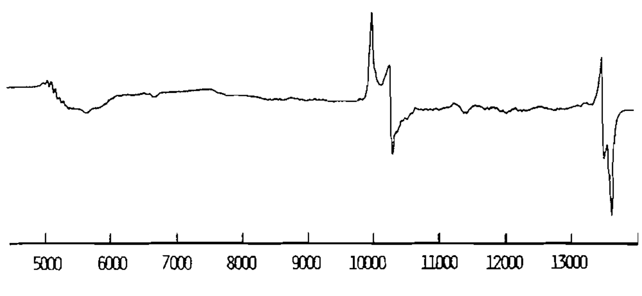

FIG. 2. Q-band spectrum (37.25 GHz) of $[Cu(CH_3COO)_2 \cdot H_2O \cdot CH_3COOH]_2$ at 110 K.

9.02%). Two steps were observed in the water – acetic acid adduct derivative of the decomposition curve between 40 and 100°C. The overall weight loss observed (29.4%) corresponds well with the calculated values for water and acetic acid (30.06%). Acetic acid is eliminated in the first step, followed by water in the second step. Reproducible results were obtained only by drying the compound to constant weight under a stream of dry nitrogen directly in the electrobalance sample holder immediately prior to the experiment.

At X-band frequencies and room temperature, powdered $Cu(OAc)_2 \cdot HOAc$ shows three broad absorption bands similar to those found in $Cu(OAc)_2 \cdot H_2O$. However, the anhydrous copper(II) acetate only shows one broad epr absorption near $g = 2$, and of peak-to-peak width of about 1 000 G. $Cu(OAc)_2 \cdot H_2O \cdot HOAc$ shows the three typical well-resolved absorption bands due to the triplet state transitions observable when $h\nu \simeq 0.3\ cm^{-1}$. These spectra are governed by the usual $S = 1$ spin Hamiltonian

$$\mathcal{H} = \beta H \cdot g \cdot S + D(S_z^2 - (1/3)S(S+1)) + E(S_x^2 - S_y^2)$$

where D and E are the zero-field splitting parameters which determine the energy levels along the three principal axes. The experimental D values are related to the interaction between the two coupled electrons by both the direct magnetic dipole–dipole interaction inversely dependant on the separation distance and by the pseudo dipolar interaction occuring via the bridging ligand's molecular orbitals. The E values reflect the rhombic component of the crystalline field. Of the six principal resonance field positions expected for $\Delta M_s = \pm 1$, the three corresponding to H_{z1}, $H_{\perp 2}$, and H_{z2} are detected at X-band. Increasing the quantum of energy allows a more complete observation of the spectrum as illustrated in Fig. 1.

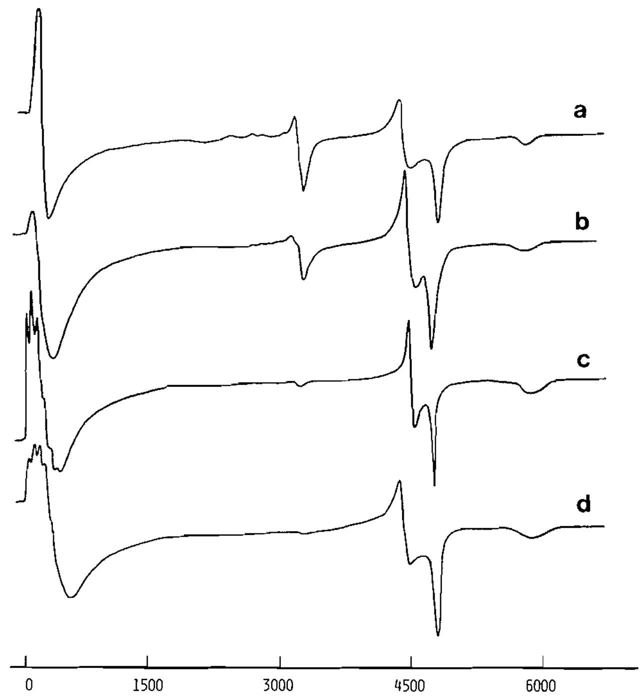

FIG. 3. X-band spectra (9.130 GHz) of $[Cu(CH_3COO)_2]_2$ (*A*), $[Cu(CH_3COO)_2 \cdot CH_3COOH]_2$ (*B*), $[Cu(CH_3COO)_2 \cdot H_2O \cdot CH_3COOH]_2$ (*C*), and $[Cu(CH_3COO)_2 \cdot H_2O]_2$ (*D*) at 110 K.

At K-band and room temperature (Fig. 1), $Cu(OAc)_2 \cdot HOAc$ shows a $\Delta M_s = \pm 2$ transition at 3 600 G in addition to the $H_{\perp 1}$ and $H_{\perp 2}$ transitions at 6 450 and 10 100 G, respectively. The absorption at 7 870 G is a $S = \frac{1}{2}$ monomer signal near $g = 2$. Lowering the temperature results in resolution of the rhombic field components. Figure 2 shows the low temperature Q-band epr spectrum of $Cu(OAc)_2 \cdot H_2O \cdot HOAc$. It also shows a $\Delta M_s = \pm 2$ transition with a seven-line dicopper nuclear hyperfine splitting in addition to the H_{x1}, H_{y1}, H_{x2}, and H_{y2} transitions. In this case, the weaker H_z absorptions were not detected because of the small sample size imposed at high frequency.

The epr spectra at 110 K obtained at X-band for the four copper(II) acetates studied are compared in Fig. 3. The four transitions observed are assigned to H_{z1}, H_{x2}, H_{y2}, and H_{z2} absorptions occurring from low to high field. The anhydrous compound which showed a featureless broad signal at room temperature shows a sharp peak for H_{z1}. $Cu(OAc)_2 \cdot HOAc$ has a H_{z1} absorption broadened by unresolved nuclear hyperfine structure, which was partly resolved, however, around 150 K. Both $Cu(OAc)_2 \cdot H_2O \cdot HOAc$ and $Cu(OAc)_2 \cdot H_2O$ show resolved seven-line splitting patterns on H_{z1}. The various spin Hamiltonian parameters derived from these spectra are listed in Table 1.

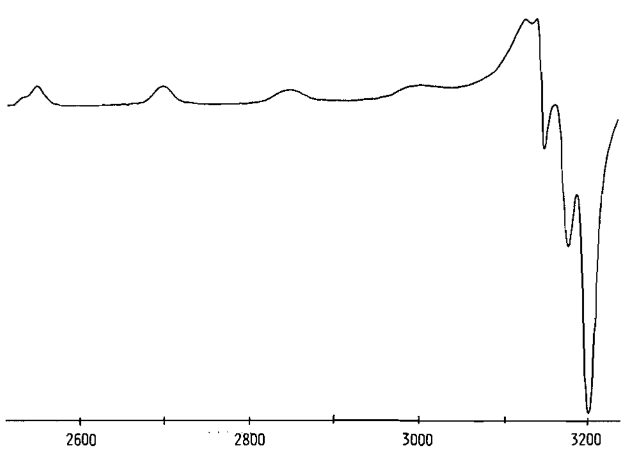

FIG. 4. Glassy state epr spectrum of $Cu(CH_3COO)_2$ in CH_3COOH with 1.88% H_2O at 110 K.

Solution spectra of copper(II) acetate at room temperature show no absorption in pure glacial acetic acid or very weak absorptions in DMSO, or ethyleneglycol. However, an ill-resolved four-line pattern appears when small amounts of water (or pyridine) are present in these solvents. Saturated copper(II) acetate in pure water shows an isotropic spectrum of 140 G peak-to-peak width, and a 0.01 M aqueous solution shows partly resolved hyperfine and $g_0 = 2.182$.

Frozen solution spectra of copper(II) acetate in water or ethyleneglycol only show $S = \frac{1}{2}$ transitions typical of mononuclear copper(II) complexes with metal hyperfine structure resolved along $g_\parallel$ and one strong absorption corresponding to $g_\perp$. In glacial acetic acid solutions, analogous features are found, but when small quantities of water (near 2% by volume) are present an exceptionally well-resolved spectrum yields $A_\parallel$, $A_\perp$, and partially separated ^{63}Cu and ^{65}Cu absorptions at low field (Fig. 4). The epr parameters calculated for the mononuclear copper(II) acetates are listed in Table 2. In glacial acetic acid solutions from 273 K to 77 K a triplet state spectrum similar to that obtained for the solid complex is observed with spin Hamiltonian parameters which show no variation with temperature and yield: $g_\parallel = 2.350$, $g_\perp = 2.066$, $g_{ave} = 2.165$, [D] = 0.326 cm^{-1}, E = 0.005 cm^{-1}.

Discussion

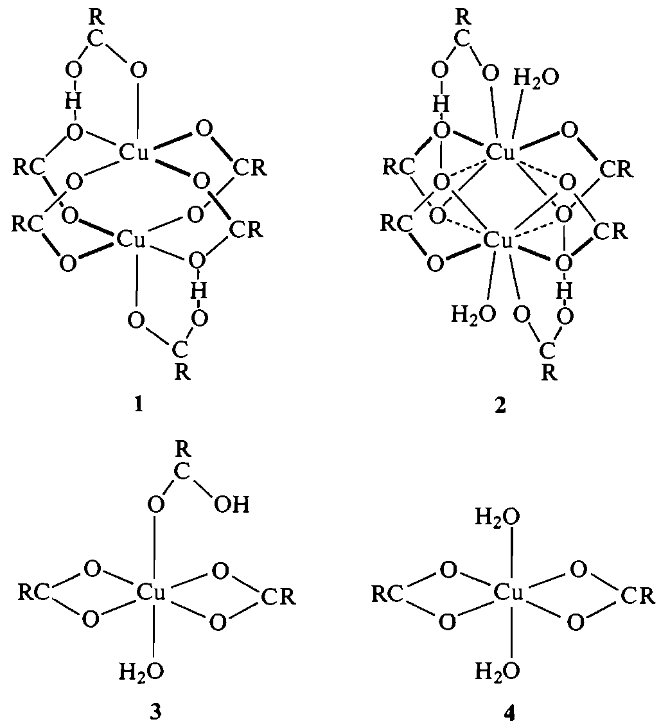
Copper(II) monohydrate (2) and acetic acid adduct (10) are both well-characterized. However, the water – acetic acid adduct has been previously formulated as $Cu_2(OAc)_4 \cdot H_2O \cdot HOAc$ (11) or as $Cu(OAc)_2 \cdot H_2O \cdot HOAc$ (6, 9). It is clear from both our thermogravimetric and atomic absorption analyses that the correct formula is the latter one. This compound has not been previously studied in the solid state because of difficulties in drying the compound without loss of acetic acid.

The epr spectra for the four compounds shown in Fig. 3 and the parameters listed in Table 1 are in good agreement with previous results (18). The broad single absorption observed for anhydrous copper(II) acetate is a common feature found in other anhydrous copper(II) carboxylates (19, 20). This broadening is attributed to interdimer magnetic interaction. It is known from the structure of copper(II) butyrate (21) that the axial sites are occupied by oxygen atoms of neighboring dimer molecules, providing a polymeric network and pathway for exchange. The [D] value of about 0.3 cm^{-1} is large compared to magnetic quantities (~3 000 G) but is small compared to vibrational frequencies. At room temperature nearly 50% of the dimers are in the thermally populated triplet state. Therefore interdimer dipolar couplings may also be expected to be significant at room temperature.

Figure 3 shows that all the compounds presented have axial symmetry with rhombic distortion. The anhydrous and acetic acid adduct do not show the seven-line hyperfine splitting on H_{z1}. This is also observed in a variety of other carboxylates with axial or rhombic symmetry, with or without axial ligands (22). From the observed narrow linewidth of 13 G (peak-to-peak of derivative) we conclude the absence of copper hyperfine is not due to inhomogeneous broadening but can be assigned to exchange interactions which, at low temperature are stronger than the hyperfine interaction but weaker than the g-anisotropy. The water and water – acetic acid adducts show resolved hyperfine splitting of about 60 G. As expected for exchange-coupled dimer systems this coupling is about half the value observed in monomer species. The resolution is attributed to isolation of the dimers by axial water ligands. In addition, a seven-line pattern is resolved in the low temperature Q-band spectrum (Fig. 2) on the $\Delta M_s = \pm 2$ transition which is observed only at higher frequencies.

The liquid solutions yield no epr absorption in solvents where copper(II) acetate retains the dinuclear structure. The $S = \frac{1}{2}$ spectra obtained in the presence of water are due to dissociation of the dimers. This is in agreement with excessive broadening of the triplet signal because of the large value of the anisotropic zero field splitting.

Frozen solution spectra reveal no significant variations in either the g values or appearance of the $A_{\parallel}$ hyperfine. The spectrum in Fig. 4 is unusual in showing resolved $A_{\perp}$ copper hyperfine. Well-resolved $A_{\perp}$ is often seen for other O-donor systems (23), but hyperfine structure along $g_{\perp}$ is absent in previous reports on copper carboxylates. This can be attributed to inhomogeneous broadening due to unresolved hyperfine and some sort of chemical exchange process leading to multiplicity of the complexes present. $Cu(H_2O)_4OAc_2$ has been proposed previously (9). Scheme 1 presents the various compounds present in solution. Compound **4**, with two coordinated water molecules exists in pure water or in other solvents containing water in the absence of other Lewis bases stronger than water. Compound **1** exists in glacial acetic acid solution and acetic acid axially coordinates to the dimer structure, leading to appreciable distortions as found in the solid state (10, 21). When the solvent is acetic acid containing ~2% water, compound **3** is found in equilibrium with compound **2**. Compound **2** is not expected to yield a visible triplet state spectrum and insufficient water is available to obtain **4**. This explains why **3** yields a well-resolved spectrum pertaining to one well-defined species. Furthermore, a compound of same composition as **2** can be isolated in the solid state and this is a key intermediate in explaining monomer–dimer equilibria. From Nyberg's data (17), the greatest line-width variation of the hyperfine lines is found precisely in acetic acid solutions containing 2% water, indicating a longer correlation time in a solvent of this composition. This was attributed to acetic acid replacing water as axial ligand in monomers, leading to large hydrodynamic radii (16), but should in fact be related to aggregation of **3** to form **2**. We propose for **2** similar distortions as known in compound **1**. The bridging acetate has one short Cu*—O* bond (darkline)



SCHEME 1

and one long Cu—O (dotted line). This long Cu—O bond can easily be broken with formation of a Cu*—O bond yielding chelating acetate ligands as shown by the thin lines (Scheme 1, compounds **2** and **3**).

Conclusion

Despite intensive study of copper(II) carboxylates, no comprehensive mechanism of formation or of dissociation of the dimer species had been presented yet. We believe our results point to distortions as the main factor governing the transformation. Our isolation of a complete series of copper(II) acetates clarifies the characterization of the species present both in solution and in the solid state and highlights the structural features which influence the epr spectra.

Received June 20, 1984

MILAN MELNÍK and PATRICK SHARROCK. Can. J. Chem. **63**, 57 (1985).

Niobium(IV) methoxide was synthesized by prolonged electroreduction of niobium pentachloride in methanol. Electron paramagnetic resonance spectra at room temperature and 77 K show the expected 10-line patterns of ^{93}Nb at $\bar{g} = 1.95$ and $\Delta M_s = 2$ absorptions indicating the presence of dimer species. The spectroscopic parameters obtained in the presence of a series of phosphorus donor ligands are presented and discussed in terms of mononuclear and dinuclear structures.

MILAN MELNÍK et PATRICK SHARROCK. Can. J. Chem. **63**, 57 (1985).

Nous avons préparé le tétraméthoxide de niobium(IV) par électroréduction lente du pentachlorure de niobium en solution méthanolique. Les spectres rpe à 298 K et 77 K montrent la structure hyperfine à 10 raies typique du ^{93}Nb à $\bar{g} = 1.95$ et aussi l'absorption $\Delta M_s = 2$ à $g = 4$ correspondant à des espèces dimères. Les paramètres rpe observés en présence d'une série de ligands phosphorylés sont présentés et discutés en termes de structures monomères et dimères pour les complexes du niobium(IV).

Introduction

Niobium(V) alkoxides are known to form dimeric, or polymeric compounds (1). Early transition metal alkoxides autoassociate in preference to complex formation with other ligands to reach coordination number six (2). Diamagnetic niobium(V) alkoxides were investigated by nmr (3) and factors controlling the coordination chemistry were discussed (4). Niobium(IV) alkoxides have been rarely investigated (5) and we now wish to report the first characterization of niobium alkoxide dimerisation observed by epr (6). We also present data demonstrating weak coordination of a variety of phosphine and phosphite ligands to the tetraalkoxoniobium species.

Experimental

Niobium pentachloride was purchased from Ventron, and kept under an atmosphere of dry nitrogen. All the phosphines used were of commercial origin (Organometallics, Inc. New Hampshire) and stored in Schlenk tubes.

Niobium tetramethoxide was prepared by dissolving niobium pentachloride in dry methanol and reducing the solution under a nitrogen atmosphere by electrolysis with graphite electrodes. Initially the deep wine–red to purple niobium(IV) chloro-methoxo species are formed, but after prolonged electroreduction in a cell equipped with a large porous-glass membrane separating the two electrode compartments, chloride ions migrate and are oxidized to chlorine gas as evidence by the appearance of the pale yellow–green solution in the other compartment. Following a three-day period with a large overpotential (5 to 8 V), the brown solution was filtered and concentrated under vacuum. A dark brown to black solid could be isolated with the characteristic infrared absorptions (ν(M—O) 870 cm^{-1}; ν(OCH_2) 985 and 1025 cm^{-1}) (7). Chloride ion determinations by silver nitrate titrations showed only 0.6% chloride by weight was present in the methoxide. Niobium content was determined as Nb_2O_5 after ignition in oxygen and confirmed isolation of $Nb(OCH_3)_4$. *Anal.* calcd.: Nb 42.8; found: Nb 42.2). *Anal.* calcd. for $Nb(OCH_3)_4$: C 22.14, H 5.57; found: C 21.86, H 5.61.

Samples for epr analysis were prepared and sealed under nitrogen in 3 mm quartz tubes. A varian E-9 spectrometer operating at X-band was used to obtain the epr spectra. Low temperatures were obtained using a cryostat technique previously reported (8). The frequency was measured with a digital frequency meter and the magnetic field calibrated with a Systron-Doner NMR gaussmeter.

Results

We observed that magnesium metal rapidly reduces niobium(V) in methanol, but the resulting products contain complex alkoxides. The formula $MgNb(OMe)_6$, analogous to the reported double alkoxide of niobium(V) (9), can be proposed for these compounds which were not further investigated. Electroreduction yields the desired tetramethoxoniobium(IV) which can be isolated as a dark brown solid insoluble in common organic solvents. It is relatively stable towards oxygen but hydrolyses readily in solution. It is insoluble in pure liquid phosphines but dissolves in liquid phosphites or toluene solutions of phosphites. A small amount of methanol is needed to dissolved niobium(IV) methoxide in toluene. The products of the reaction of niobium(IV) methoxide with phosphites are yellow to brown oils. With phosphines, brown to green viscous products are obtained which slowly separate out of the toluene solvent.

The room temperature epr spectrum of niobium(IV) methoxide is presented in Fig. 1. High gains and power and a strong modulation amplitude are needed to obtain spectrum (*a*) which shows a clearly resolved absorption near 1700 G in addition to the ten-line pattern centered near 3450 G. The spectrum (*b*) in Fig. 1 results when a small amount of dry HCl is bubbled into the same methanol solution used to obtain spectrum (*a*) (Fig. 1). This concentrated niobium(IV) solution does not show a half-field resonance but shows an intense absorption centered near $g = 2$. This somewhat distorted spectrum changes to the classical 10-line spectrum (*c*) as shown in Fig. 1, when diluted with toluene.

Oxygen-containing solvents tend to decompose niobium(IV) methoxide slowly but an epr spectrum could be obtained in THF, which consisted of a single broad resonance centered at $g = 2.0$. The spectroscopic parameters for the room-temperature spectra are listed in Table 1 together with data derived from the phosphine and phosphite ligands. Most of the phosphine adducts gave weak room-temperature signals and

[d] Weak signal.

showed half-field signals. In some cases no signal at all could be detected. For example triphenylphosphine, tri-*n*-butylphosphine, triethylphosphine in THF, or trimethylphosphine in DMF.

Trimethylphosphine, pure or diluted in toluene, yielded triplet ligand hyperfine splitting on each one of the ten niobium hyperfine lines. The dimethylphenylphosphine yielded phosphorus hyperfine partly resolved on the strongest niobium lines in the center of the spectrum, as shown in Fig. 2. Triethylphosphine gave a very broad and distorted 500 G peak-to-peak width absorption near g = 1.90.

Triphenylphosphine oxide gave a room-temperature spectrum identical to the ligand-free case. The phosphites used did not reveal ligand hyperfine structure in the epr of their niobium(IV) adducts. Dry HCl gas usually increased the intensity of the g = 2 spectra to the expense of the g = 4 absorptions, but with little improvement in the resolution.

The low temperature spectra of niobium(IV) methoxide showed features typical of anisotropic hyperfine with axial symmetry. Figure 3 showed the frozen-solution spectrum of niobium(IV) methoxide in methanol. The g = 4 feature at low field present in spectrum *a* disappears in spectrum *b* (Fig. 3), after HCl is introduced into the solution. Also the decrease in intensity in the central sharp peak is significant and is related to an absorption occuring together with the half-field line, as will be shown later. The frozen THF spectrum comprised a sharp peak at g = 2.0, the usual g =4 absorption and a strong and broad absorption centered at g = 2.7.

Difficulties were encountered in obtaining low-temperature epr signal for the phosphine adducts. For example, triethylphosphine produced a broad line with ill-resolved $A_{\perp}$. $A_{\parallel}$ was resolved and allowed the calculation of $g_{\parallel}$, but $g_{\perp}$ could not be obtained. When THF, acetone, methanol, or DMF was added to the phosphine adduct, the spectrum changed entirely to give a g = 4 absorption paired with a sharp axial-type absorption at g = 2.0. Figure 4 illustrates this pair of signals obtained in the case of tri-*n*-butyl phosphine. This spectrum could in turn be

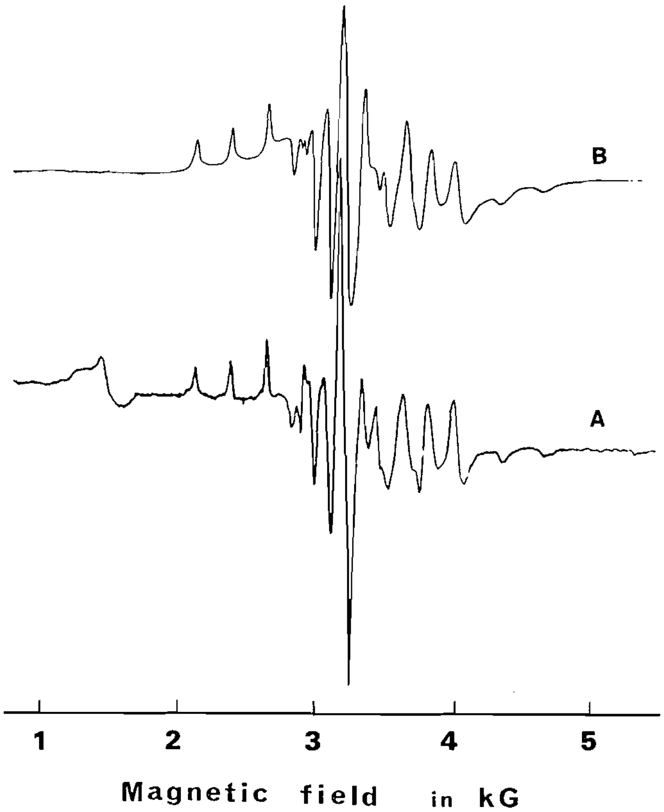

FIG. 3. The frozen-solution epr spectra of niobium(IV) methoxide; (*a*) in methanol solution, (*b*) same as (*a*) with a small amount of dry HCl.

eliminated by the addition of a small amount of HCl gas, but the spectra then reverted to those of the phosphine-free case.

Triphenylphosphine oxide showed a 77 K spectrum almost identical to the pure niobium methoxide, but a clearly resolved doublet on the lowest field $A_{\|}$ absorption demonstrated that two compounds are present with nearly identical epr parameters. The phosphite gave interesting results with tetraethyl pyrophosphite yielding two superimposed spectra. Figure 5 shows the epr spectrum obtained in the case of trimethylphosphite. The observed linewidths are significantly smaller than for the parent compound, illustrated in Fig. 3.

Discussion

Vanadium(IV) or vanadyl halide species form phosphine complexes which have been studied by epr (10). Few epr studies were conducted on niobium(IV) or tantalum complexes (11, 12), one problem being the loss of resolution observed for the heavier metals, attributed in part to the greater quadrupolar moment of their nuclei (13).

Electrolytically reduced niobium solutions have been reported in the literature (14–16), and niobium(IV) has also been produced by reduction with zinc (17) or aluminium foil (13). Discrepancies exist in the literature regarding the various species present in aqueous HCl or alcoholic HCl solutions. $NbCl_6^{2-}$ anion does not give an epr spectrum, indicating a pure octahedral configuration and a degenerate ground state (17). In tetrahedral organometallic niobium(IV) complexes the free electron lies in the $4d_{x^2-y^2}$ orbital and the epr spectrum is well-resolved (18). According to the Jahn–Teller Theorem and when the epr spectrum is observable at room and moderately low temperature, the free electron must lie in the d_{xy} non-

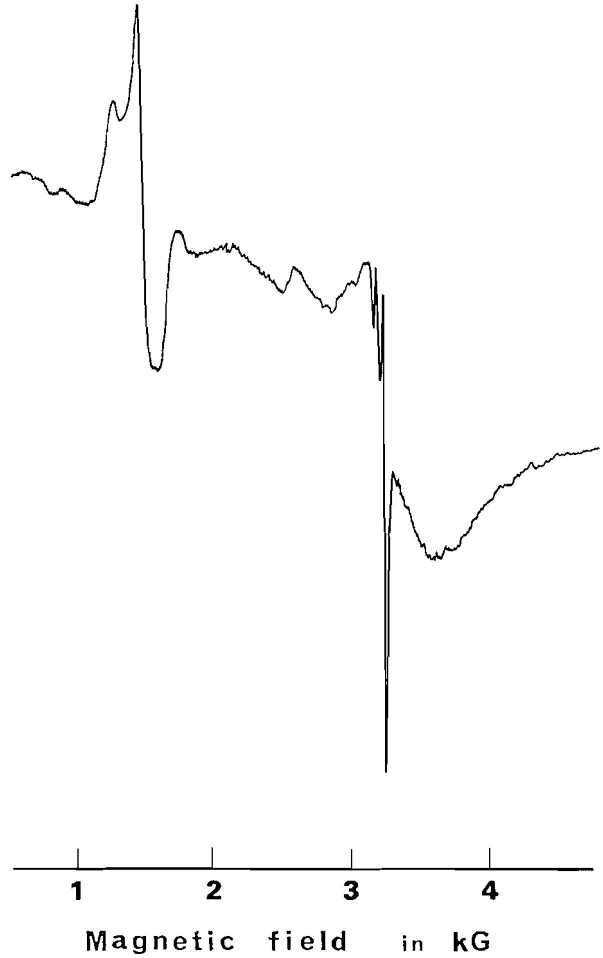

FIG. 4. The frozen-solution epr spectrum of niobium(IV) methoxide with tri-*n*-butylphosphine.

degenerate orbital in octahedral niobium(IV) complexes of D_{4h} molecular symmetry (19).

The ten-line room-temperature patterns observed for the complexes is consistent with the expected 100% ^{93}Nb metal hyperfine arising from nuclear spin $I = 9/2$. The coupling constant of about 180 G is in agreement with previous observations (13, 17). The low solubility of the parent complex and addition compounds points to the polymeric nature of the methoxide. The $g = 4$ signal can be attributed to a forbidden $\Delta M_s = 2$ absorption resulting from the presence of dimers held together by methoxo bridges. Many diamagnetic niobium(IV) complexes are known in the solid state (20) indicating polymeric compounds with strong magnetic interactions. This could also account for the absence of epr spectra or the weak signals observed in some of our solutions, despite the visible absorptions which demonstrate niobium(IV) complexation. The small value of the superhyperfine coupling constants shows weak niobium–phosphorus interactions. In analogy to the structure proposed for niobium(V) alkoxides, we propose the structures of Scheme 1. The triplet superhyperfine patterns are in agreement with two equivalent phosphine ligands coordinated in a *trans* axial geometry, but a *cis* geometry cannot be ruled out because of the absence of phosphorus splittings in the anisotropic spectra. In any case, the equilibrium is strongly in favor of the dimer, and only the smaller phosphines showed evidence for two coordinated ligands. Symmetry considerations rule out direct interaction of "σ" phosphorus orbitals

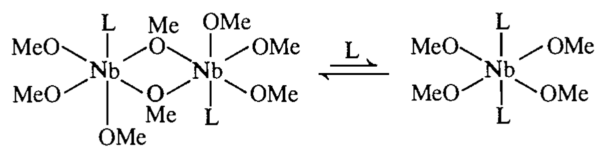
with the niobium d_{xy} orbital and spin-polarization may account for much of the coupling mechanism. Polar solvents shift the equilibrium towards dimer formation whereas HCl gas tends to destroy the dimers by formation of monomeric mixed chloromethoxo complexes. HCl also has the effect of eliminating excess phosphine used as solvent by producing phosphinium chlorides, and changing the dielectric constant. In agreement



SCHEME 1

with previous work on niobium(V) alkoxides (3), this has a pronounced effect on complex formation. However, niobium(IV) has a stronger tendency to form addition compounds than does niobium(V). The di-octahedral edge-shared dimer structure found for niobium(V) methoxide is coordinatively saturated whereas the same structure has room for one ligand (L in Scheme 1) in the case of niobium(IV). The bulkier phosphines fail to yield bis-adducts of monomer structure, and so do the bidentate phosphines used despite the expected chelate effect stabilization. We feel niobium(IV) methoxide is a polymer in the solid state, with each octahedral unit sharing two edges with neighboring molecules. Methanol may break up this insoluble structure and produce dimer or oligomer structures responsible for the $\Delta M_s = 2$ signals observed in solution. The axial peaks at $g = 2.0$ are so sharp they must be attributed to exchange-narrowed signals.

The low-temperature spectra can be explained assuming the same structures as presented in Scheme 1. The dimer or polymer signals at $g = 4$ and $g = 2$ are very strong, but superimposed on a broad absorption centered near 3300 G, as shown for example in Fig. 4. The sharp lines found for the trimethylphosphite adduct presented in Fig. 5 are attributed to slower methoxo group exchange in this species compared to the parent compound which shows broader features. Niobium(V) methoxide shows significant variations in its low-temperature nmr chemical shifts corresponding to various non-equivalent methoxide groups in exchange (21). The low temperature spectrum obtained for niobium(IV) methoxide in the presence of triphenylphosphine oxide shows spectroscopic parameters identical to the ligand free system, as listed in Table 2. However, the small but clearly visible splitting of the lowest field

$A_{\parallel}$ component indicates two similar compounds are present. Triphenylphosphine oxide is reported to react with niobium(V) alkoxide (1) to make an addition compound, but with niobium pentachloride, a niobium oxytrichloride adduct is formed by oxygen abstraction (5). Because triphenylphospine oxide is the only phosphorus-containing donor which we found to cause such a splitting, we may tentatively conclude it produces also a niobium oxymethoxocomplex. Tetraethylpyrophosphite yields two species which are attributed to the presence of excess phosphite which can thus form a *bis* complex and a *mono* adduct containing bidentate ligand.

In general, the phosphites produce larger $A_{\parallel}$ splitting constants than the phosphines. Inspection of the data listed in Table 2 also shows that the large hyperfines coincide with the smaller g values. This trend should follow variations in the strength of metal–ligand bonding but most of the spectra observed show great similarities in the spectroscopic parameters related to monomers. No differences are detected in spectra attributed to dimer species.

Conclusion

Niobium(IV) methoxide shows features analogous to niobium(V) alkoxides. The results point to a polymeric network for the structure of this compound, and a dimer structure in equilibrium with some monomer in solution. Weak interactions with phosphorus containing donors also result in the predominance of dimer adducts. Electron paramagnetic resonance spectra are useful in confirming that early transition metal alkoxides prefer to self-associate rather than form complexes with donor ligands. Further work showing stronger bonding in mixed niobium(IV) chloro-methoxo complexes will be reported elsewhere.

The photolysis of 2,3- and 3,3-dimethyl-1-butene at 147.0 and 184.9 nm

HÉLÈNE DESLAURIERS AND GUY J. COLLIN[1]

Département des Sciences Fondamentales, Université du Québec à Chicoutimi, Chicoutimi (Qué.), Canada G7H 2B1

HÉLÈNE DESLAURIERS and GUY J. COLLINS. Can. J. Chem. **63**, 62 (1985).

The photofragmentation of 2,3-dimethylbutene and 3,3-dimethylbutene has been studied at 147 and 184.9 nm in the gas phase. The main primary decomposition process at both wavelengths involves the rupture of a β(C—C) bond. The quantum yield for this process is higher than 0.7 at 147 nm and is probably even higher at 184.9 nm. All dimethallyl radicals formed at 147 nm in this process decompose at low pressure, but some of them isomerize from the α,β- to the α,α- structure (and vice versa) — via a 1,4-H transfer — before decomposition. At 184.9 nm, the same primary process is used to get a rough value for the lifetime of the photoexcited molecule, compared with the one made with RRKM calculations by assuming that all the photon energy resides in the vibrational framework of the fundamental electronic state. These lifetimes are about one nanosecond or less.

HÉLÈNE DESLAURIERS et GUY J. COLLINS. Can. J. Chem. **63**, 62 (1985).

On a étudié la photolyse des diméthyl-2,3- et -3,3-butène-1 à 147 et à 184,9 nm. Le principal mode de fragmentation de la molécule photoexcitée implique la rupture d'un lien C—C situé en position β. Le rendement quantique de ce processus primaire est supérieur à 0,7 à 147 nm et peut-être plus élevé encore à 184,9 nm. À 147 nm, tous les radicaux diméthallyles se décomposent à basse pression, mais certains le font après isomérisation par transfert interne 1,4 d'un atome d'hydrogène. À 184,9 nm le même processus primaire est utilisé pour déterminer le temps de vie de la molécule photoexcitée. Ce temps de vie, de l'ordre ou moins de la nanoseconde, est comparé avec celui que l'on peut obtenir à l'aide de calculs RRKM en supposant que toute l'énergie du photon est distribuée dans le tissu vibrationnel de la molécule.

Introduction

We have recently studied the gaseous photolysis of tetramethylethylene and 1-hexene at 184.9 nm. At low pressures (1 Torr = 1330 N m^{-2}), both photoexcited molecules decompose. The photoexcited 1-hexene molecule gives rise to the rupture of the β(C—C) bond (1) and that of the tetramethylethylene — a molecule without the β(C—C) bond — gives rise to the rupture of either a β(C—H) or a α(C—C) bond (2) with similar probability. Moreover, at high pressure (above 100 Torr), isomers are formed with rather high quantum yields in the tetramethylethylene case: Φ(isomers) = 0.34 in the presence of high propane pressure (3). Conversely, the isomerization processes are very low or not even observed in the 1-hexene case: Φ(isomers) ≤ 0.01 (1).

This work has two main purposes. First, we shall examine in other C_6 terminal olefins the validity of the rupture of the β(C—C) bond at low pressure, and, if possible, we shall estimate the lifetime of the photoexcited molecule. Second, we shall try to reconcile the apparent conflict observed above at high pressure: does the photoexcited molecule isomerize? We have chosen 2,3-dimethylbutene (23DMB) and 3,3-dimethylbutene (33DMB) for this study. It is hoped that any structural effect inside the C_6 family of terminal olefins will be exemplified.

Experimental section

Experimental details were essentially the same as those reported in previous papers from this laboratory (1–3). This include the Hg-lamp and actinometry (1). 23DMB and 33DMB are API products: 99.93 ± 0.03% and 99.98 ± 0.02%, respectively. All the irradiations were performed at room temperature (T ≃ 20°C). The analyses of the starting materials reveal only traces of lighter compounds (≤50 ppm). However, some C_6 hydrocarbons are present. They are 3- and 4-methyl-1-pentene (0.01%), 1-hexene (0.035%), and 2-methyl-2-pentene (0.055%) in 23DMB; 2,2-dimethylbutane (17.5 ppm) and 2,3-dimethyl-1,3-butadiene (?) (19.5 ppm) in 33DMB. The relatively large amount of impurity in 23DMB may be the result of an artifact: we observed an increase in impurity content (ca. 1%) when the gas chromatograph was used at T = 50°C. All these analyses were routinely made on two gas-chromatographs (dual flame ionization detector) one equipped with a squalane column (4) and the other one with a UCON column maintained at room temperature (23DMB case) or at 50°C (33DMB case) (5).

The RRKM calculations were made as reported in a previous paper from this laboratory (6). The vibrational models for 33DMB were taken from the literature (complex **2**) (7).

Results

The photolyses of 23DMB and 33DMB yield a number of hydrocarbon products which are reported in the tables along with their quantum yields. Within experimental conditions the percentage of conversion is kept well below 1%. Oxygen or nitric oxide at a sufficient concentration level (≃10%) remove free radicals from the reaction zone and does not significantly absorb the incident photon beam. Deuterium iodide was also used to scavenge free radicals. This technique was only possible with 33DMB. In the presence of 23DMB, the addition of DI results in an orange liquid formation.

At 147 nm

In both systems and in the presence of 10% oxygen, the main product is isoprene (Fig. 1) with pressure-dependant quantum yields between 0.35 and 0.8. A few other products, having lower quantum yield, are sensitive to an increase in the pressure. They are 1,2-butadiene (Fig. 2) and 2-methyl-2-butene formed in the 23DMB case: its quantum yield decreases from 0.03 at 5 Torr to 0.015 at 150 Torr. Several products formed with low yields are rather insensitive to an increase in pressure (Table 1). In the pure systems, the products are more numerous (Table 2). Ethane and 2,2,3-trimethylbutane are among the major ones. The addition of DI has substantially increased the methane yield (Table 3). Finally, isomers were not observed in either system in the presence of 10% oxygen.

At 184.9 nm

Except for isoprene (Fig. 3), all the quantum yields measured in the presence of oxygen are lower than 0.01. Table 4

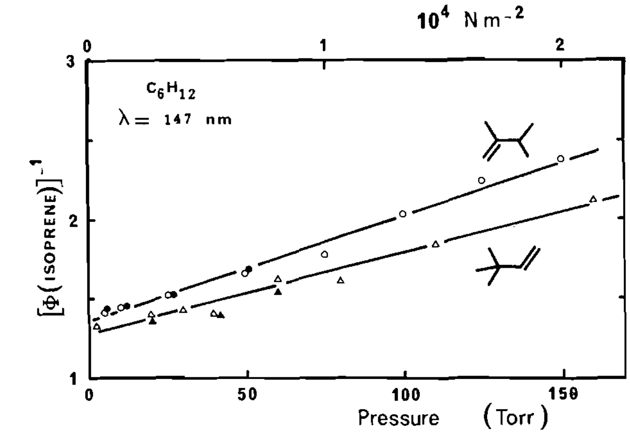

FIG. 1. Photolyses of 23DMB (○,●) and 33DMB (△,▲) at 147 nm either pure (○,△) or in the presence of 10% oxygen (●,▲). The straight lines are calculated from linear regressions: ○: $y = 1.358 + 0.0067x$, $r^2 = 0.983$; △: $y = 1.262 + 0.0051x$, $r^2 = 0.978$.

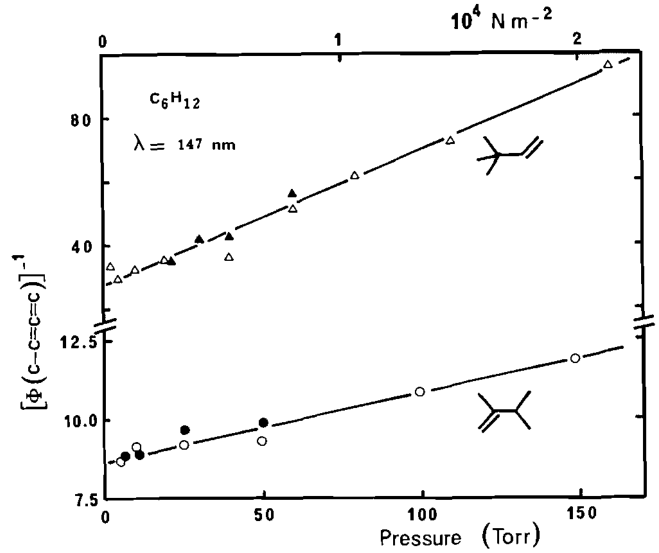

FIG. 2. Photolyses of 23DMB (○,●) and 33DMB (△,▲) at 147 nm either pure (○,△) or in the presence of 10% oxygen (●,▲). The straight lines are calculated from linear regressions: ○: $y = 8.6 + 0.021x$, $r^2 = 0.942$; △: $y = 27.6 + 0.41x$, $r^2 = 0.981$.

gives the main products formed in the pure systems. Again, isomers were not observed in the presence of 10% added oxygen even in the cases where 2–6 atm of propane were added to 50 Torr of monomer. Absorption coefficients of the 184.9 nm line were measured (base 10): ε(23DMB) = 7 200 (±5%) and ε(33DMB) = 5 900 (±5%) $dm^3\ mol^{-1}\ cm^{-1}$, in agreement with values taken from the literature (8).

Discussion

(a) Fragmentation of the photoexcited molecules and excited intermediates

At 147.0 nm

The energy of the incident photon at this wavelength is about 810 kJ $Einstein^{-1}$. Thus, the photoexcited molecules have much more internal energy than what it is needed for a C—C bond rupture. For example,

[1] 23DMB or 33DMB + $h\nu \rightarrow$ 23DMB** or 33DMB**

TABLE 1. Quantum yields of the photolyses of 23DMB and 33DMB in the presence of 10% oxygen at 147 nm[a]

Products	Quantum yield 23DMB	33DMB
Methane	0.03 ± 0.01	0.04 ± 0.01
Acetylene	$0.01_3 \pm 0.00_2$	$0.13 \pm 0.01_5$
Ethylene	0.04 ± 0.01	$0.04 \pm 0.01_5$

Propyne	0.10 ± 0.02	0.00
Allene	$0.05_5 \pm 0.01$	0.00
Isobutane	0.00	$0.02_4 \pm 0.00_5$
1,3-Butadiene	$0.01_5 \pm 0.00_5$	0.05 ± 0.01

[a] Pressure of the monomer is between 10 and 100 Torr; all quantum yields are the same in the pure systems except those of methane, propene, and isobutane (see Table 2).

[2] $23DMB^{**} \rightarrow CH_3^* + \underbrace{\overline{CH_2C(CH_3)CHCH_3}^*}_{A^*}$

[3] $33DMB^{**} \rightarrow CH_3^* + \underbrace{CH_3\overline{C(CH_3)CHCH_2}^*}_{B^*}$

$$\Delta H([2]) \simeq \Delta H([3]) \simeq 290 \text{ kJ mol}^{-1} \quad (9)$$

The excess energy is about 520 kJ mol^{-1} and must be shared between the fragments. Part of the C_5H_9* radicals (**A*** or **B***) carry away sufficient energy to overcome the energy barrier of the following process:

[4] **A*** or **B*** $\rightarrow H + CH_2{=}C(CH_3)CH{=}CH_2$ $\quad E_A \simeq 200$ kJ mol^{-1}

[5] **A*** or **B*** + M → M + **A** or **B**

This simple mechanism is known as a Stern–Volmer one (processes [1]–[5]) and the reverse of the isoprene quantum yield is a linear function of the pressure (10) (Fig. 1). At zero pressure, the Φ(isoprene) values, measured in the presence of 10% oxygen, are 0.74 and 0.79 in the 23DMB and 33DMB systems, respectively. Since the ϕ(process [2] or [3]) value is less than unity, the majority of **A*** or **B*** decomposes at zero pressure. Another compound observed in the presence of oxygen and having a Stern–Volmer behavior is 1,2-butadiene (Fig. 2). Its quantum yield is smaller than that of isoprene and smaller in the 33DMB than in the 23DMB system. Since allene is formed in the decomposition process of the excited β-methallyl radicals (11, 12), it may be proposed that the α,β-dimethallyl radicals also decompose only partially in 1,2-butadiene.

[6] $\overline{CH_2C(CH_3)CHCH_3}^* \rightarrow CH_2{=}C{=}CHCH_3 + CH_3$

[7] $\overline{CH_2C(CH_3)CHCH_3}^* + M \rightarrow M + \overline{CH_2C(CH_3)CHCH_3}$

Conversely, excited α-methallyl radicals are not known to decompose in allene. Thus, α,α-dimethallyl radicals are not expected to produce 1,2-butadiene. Moreover, a structural isomerization process must take place somewhere in order for this to happen. An easy way to explain such 1,2-butadiene formation is to assume an isomerization process involving **A*** and **B***.

Since these allylic radicals are far from cold, they have an internal energy probably sufficient to allow the occurrence of a 1,4-hydrogen atom transfer:

[8] **A*** ⇌ **B***

2-Ethyl-3-methyl-1-butene	0.01_7	0.03	0.03	0.00	0.00	0.00

[a]All quantum yields vanish in the presence of 10% oxygen except in the cases of methane, propene, and isobutane; see Table 1.
[b]Isobutene + 1-butene.

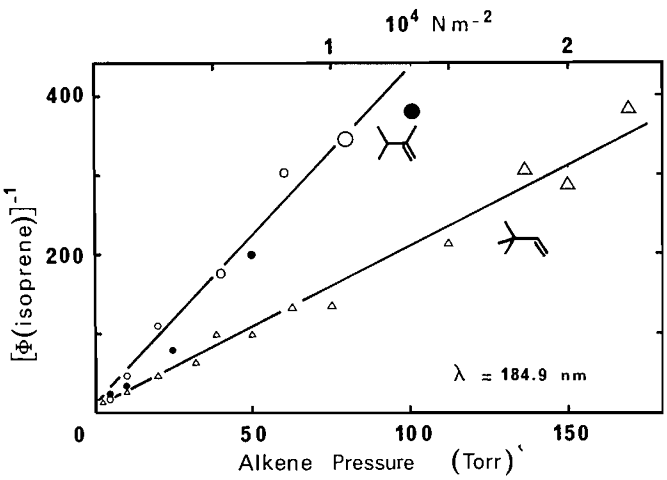

FIG. 3. Photolyses of 23DMB (○,●) and 33DMB (△,▲) at 184.9 nm either pure (○,△) or in the presence of 10% oxygen (●,▲). The straight lines are calculated from linear regressions: ○: $y = 16.19 + 4.03x$, $r^2 = 0.956$; △: $y = 7.0 + 2.0x$, $r^2 = 0.997$.

Other minor primary fragmentation processes must be proposed to take account of the results. For example, the occurrence of the rupture of a α(C—C) bond results in various compounds.

[9] $\quad 23DMB^{**} \rightarrow CH_3\dot{C}HCH_3^* + CH_2{=}\dot{C}CH_3^*$

[10] $\quad 33DMB^{**} \rightarrow t\text{-}C_4H_9^* + \dot{C}H{=}CH_2^*$

Again the major excess energy of the incident photon must be distributed among the fragments and the majority of them may decompose at low pressure. Thus, propylene (13), propyne, and allene (14), and acetylene (15) are expected even in the presence of oxygen (Table 1). At higher pressure and in the pure systems, propane and isobutene must be formed in the 23DMB system, as well as neopentane and propene in the 33DMB (Table 2). 1,3-Butadiene must be formed jointly with two methyl radicals since no ethane is formed in the presence of DI (Table 3). Finally, an unusual primary process seems to occur in the 33DMB system. In the presence of 10% oxygen,

tiny amounts of isobutane are formed.

[11] $\quad 33DMB^{**} \rightarrow iso\text{-}C_4H_{10} + C_2H_2$

At 184.9 nm

At this wavelength products are formed in lesser quantities than reported at 147 nm (Table 4). Figure 3 shows the variation of the reverse of the isoprene quantum yield versus the pressure. The Stern–Volmer behavior of these plots is similar to the observation made at 147 nm. However, the quantum yields measured at zero pressure are lower: $\Phi(\text{isoprene}) = 0.06_2$ and 0.27_6 in the 23DMB and 33DMB, respectively. In addition, the dependence of the pressure of these quantum yields is much stronger. Much more significant is the decrease of the methyl quantum yield with an increment of pressure. Compare for example Φ(ethane) in Tables 2 and 4 and Φ_{DI}(methane) in Table 3. By adding up the quantum yields of the products formed from methyl—methyl and methyl—**A** or —**B** radicals reactions, the $\Phi(CH_3)$ values may be estimated at each pressure. These values are reported in a Stern–Volmer way in Fig. 4. Again the $\Phi_0(CH_3)$ values measured at zero pressure are close to unity. In a first approximation, all the formation of methyl radicals may be ascribed to the primary processes. Thus Fig. 4 may be used to estimate the rate constant of the mono-

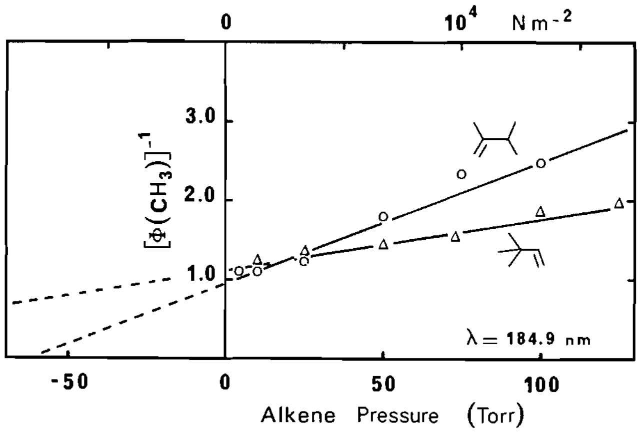

FIG. 4. Photolyses of pure 23DMB (○) and 33DMB (△) at 184.9 nm. The straight lines are calculated from linear regressions: ○: $y = 0.96 + 0.014x$, $r^2 = 0.95$; △: $y = 1.11 + 0.0065x$, $r^2 = 0.92$.

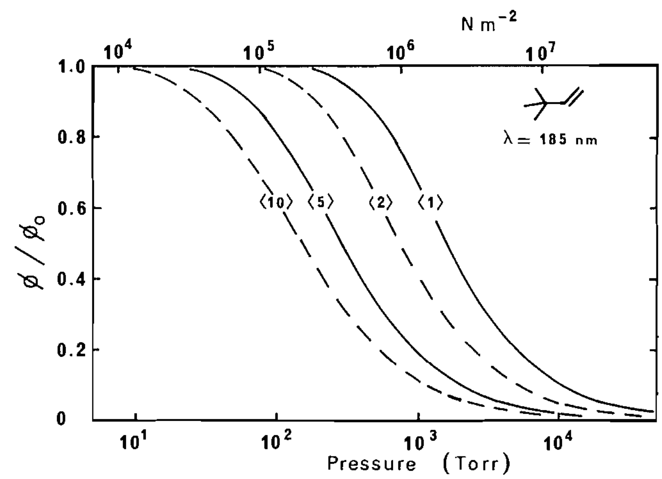

FIG. 5. Effect of the pressure on the fragmentation of 33DMB photoilluminated at 184.9 nm as determined through RRKM calculations. Stepladder models: ⟨10⟩ . . . are energies in kcal mol^{-1} transferred on each collision: see ref. 6.

molecular fragmentation process of the photoexcited molecule. In fact, the intercept of the Stern–Volmer plot with the pressure axis is a measure of the k_2/k_{12} and k_3/k_{12} ratios[2] (negative value: see Fig. 4).[3]

[12] $C_6H_{12}^{**} + M \rightarrow M + C_6H_{12}$

The intercepts are −60 and −170 Torr in the 23DMB and 33DMB systems, respectively. A similar value determined for the stabilization of photoexcited 1-hexene molecules was found about −30 Torr (1). The experimental k_{12} values are k_{12}(1-hexene) = 0.5 10^9, k_{12}(23DMB) = 1 10^9, and k_{12}(33DMB) = 2.75 10^9 s^{-1}. Thus in the C_6 1-alkene group, it appears that the lifetime of the photoexcited molecule decreases with an increase in the degree of ramification of the monomer. Figure 5 shows the results of RRKM calculations applied to process [9] of 33DMB (7). When a stepladder model is used for the stabilization of the photoexcited molecule where all the energy of the photon may be found in the vibrational framework of the ground state, it turns out that half of the excited molecules are stabilized at a pressure of 155 Torr, provided an energy step of 10 kcal mol^{-1} is chosen. The lessening of the lifetime of the vibrationally excited molecule is probably a direct consequence of the number of available reaction channels (1 in 1-hexene, 2 in 23DMB, and 3 in 33DMB) and also the slight decrease of activation energy with an increase of the ramification of the parent molecule (see footnote 3 and ref. 17).[3] The agreement with the experimental value is good, although it may be fortuitous. This constitutes an indication that the lifetime of the electronic excited states formed upon photoexcitation is much shorter.

(b) Radical reactions

At 147 nm

The effect of the addition of molecular oxygen has a drastic effect on the formation of various products (footnote *a*, Table 2). Thus it may be proposed that several products are formed in radical–radical reactions. The ethane quantum yield of 0.3 suggests a rather high yield for the methyl radical formation. Other radicals are also present. As seen in Table 2 as well as the DI experiments in Table 3, hydrogen atoms and allylic C_5H_9 radicals are formed. In fact, the H atom adds itself very efficiently to the double bond of the monomers and gives rise to the formation of a methyl-substituted C_6H_{13} radical (18). The combination of the latter with the methyl is responsible for the 2,2,3-trimethylbutane formation in both systems, 2,3- and 3,3-dimethylbutane are partly formed in disproportionation processes involving a C_6H_{13} and another radical.

---

[2] The rate constant subscripts refer to the reaction numbers.

[3] A referee made a valuable comment at that point. In the 23DMB case, the Stern–Volmer equation is

$$[\Phi(CH_3)]^{-1} = \phi_2^{-1} + \phi_2^{-1}(k_{12}/k_2)[M]$$

where ϕ_2 is the quantum yield of the primary process [2]. Since this ϕ_2 value is close or equal to 1, the slope, k_{12}/k_2, is the inverse of the negative intercept. Of course, the same comment applies in the 33DMB system.

[13] $H + 23DMB \rightarrow (CH_3)_2CCH(CH_3)_2$ **C**

[14] $H + 33DMB \rightarrow (CH_3)_3C\dot{C}HCH_3$ **D**

[15] **C** or **D** + $CH_3 \rightarrow (CH_3)_3CCH(CH_3)_2$

In experiments where DI is added, methyl radicals as well as **D**, abstract D atoms from DI: methane and 2,2-dimethylbutane are formed, respectively (19, 20). Obviously, allylic C_5H_9 radicals are also present: 3-methyl-2-pentene (*cis* + *trans*) and 2-methyl-2-pentene are the results of the combination of methyl and either α,β- or α,α-dimethallyl radicals in 23DMB and 33DMB, respectively.

[16*a*] $\overline{CH_2C(CH_3)CHCH_3} + CH_3 \rightarrow CH_3CH{=}C(CH_3)C_2H_5$

[16*b*] **A** $\rightarrow$ 23DMB

[17*a*] $CH_3\overline{C(CH_3)CHCH_2} + CH_3 \rightarrow (CH_3)_2C{=}CHC_2H_5$

[17*b*] **B** $\rightarrow$ 33DMB

[18] **A** or **B** + $CH_3 \rightarrow CH_4 + CH_2{=}C(CH_3)CH{=}CH_2$

The k_{16a}/k_{16b}, k_{17a}/k_{17b}, and $\Delta(CH_3,\mathbf{B})$ values were reported (16). They are 1.81 ± 0.04, 6.1 ± 0.6, and 0.1, respectively. Other radicals are formed in smaller amounts. For example, DI reveals the presence of methylsubstituted C_4H_9 radicals (19, 20) in the 33DMB system (Table 3) and their structure may be inferred from the neopentane formation (Table 2). In the 23DMB system, the presence of isopropyl radicals may be shown from the isobutane formation. Finally, β-isopropylallyl radicals probably appear in the 23DMB system. By combination reaction with methyl radicals they are responsible for the 2-ethyl-3-methyl-1-butene formation. They are probably formed through the abstraction reaction of an allylic hydrogen atom by a radical, although definitive proof is lacking. This reaction would explain part of the methane formation observed in the presence of oxygen (Table 1).

At this point it must be said that the above mechanism explains neither the formation of 2-methyl-2-pentene and 33DMB in the 23DMB system nor the formation of 3-methyl-2-pentene and 23DMB in the 33DMB system. An easy way to reconcile the observations with the above mechanism consists of calling upon the isomerization process involving the C_5H_9 radicals, and reported above (process [8]). One may add that this isomerization process is probably not at equilibrium, since a pressure effect is evident (Table 2). The amount of the isomerization decreases with an increase in the pressure.

At 184.9 nm

The main difference observed between experiments done at 147 and 184.9 nm is the relatively less yields of products at the longer wavelength: see for example, in Tables 2 and 4, the methane, ethane, . . . , 2,2,3-trimethylbutane quantum yields. However methyl as well as allylic C_5H_9 radicals are still present. One should add the absence of dimethylbutanes, 23DMB, and 33DMB. Thus it can be said either that hydrogen atoms are not formed or that their quantum yields are too low to measure. If the previously indicated mechanism for the fragmentation of the photoexcited molecules is still acceptable, hydrogen atoms are mainly formed in secondary processes. The excess energy of the photon is now reduced to ca. 350 kJ mol^{-1}. Then, excited $C_5H_9{}^*$ radicals bear away less internal energy at 184.9 nm compared to the situation described in the vacuum uv region. Their lifetime must be longer, so that stabilizing processes are more efficient. In the pure systems, at 147 nm, the isomeric 33DMB and 23DMB were assumed to be formed in radical processes following isomerization of the α,β-dimethallyl radicals towards the α,α- structure and vice versa. Again, the lower energy content of the $C_5H_9{}^*$ precludes this isomerization process, and these isomers are not observed at 184.9 nm.

$\Sigma =$	1.02_6	1.00_6

[a] All the quantum yields are indicated at zero pressure.

Conclusion

From the discussion given above, and the results shown in the tables, a fragmentation pattern may be proposed (Table 5). The total is close to unity, but uncertainties on values make the Σ value no more accurate than ±10%. A theoretical methyl radical quantum yield may be calculated: $\Phi(CH_3) = 1.1$ and 0.96 in 23DMB and 33DMB systems, respectively. As seen in Table 2, more precisely from the products formed in the methyl radical reactions, $\Phi(CH_3)$ values may be calculated and are close to unity at low pressure. Unfortunately, not all the pertinent disproportionation/combination ratios are available. However, a rough estimate leads to $\Phi_{meas}(CH_3)$ values such as 1.1 ± 0.2 and 1.0 ± 0.2 in each system. The agreement is particularly good. For the other radicals, similar calculations are much more difficult, and indeed impossible, since not all the pertinent products have been measured. For example, the measurements of the hydrogen atom quantum yield requires the measurements of all products coming from the C_6H_{13} radical reactions, and among them are the $C_{12}H_{26}$ molecules.

A calorimetric study of trimethylene oxide and its structure I and structure II clathrate hydrates in the temperature range 85 to 270 K[1]

Y. P. HANDA

Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R9

Received May 30, 1984

Y. P. HANDA. Can. J. Chem. **63**, 68 (1985).

Heat capacities and dissociation properties of trimethylene oxide and its structure I and structure II clathrate hydrates in the temperature range 85 to 270 K were determined using a Tian–Calvet heat flow calorimeter. The hydrates dissociate incongruently. The heat capacities of the hydrates are similar in magnitude to those observed for other structure I and structure II hydrates. For the structure I hydrate two thermal anomalies were observed. The one centered at 107 K can be identified as due to ordering of the trimethylene oxide dipoles along the $\bar{4}$ axes of the cages as suggested by the previous dielectric and nmr relaxation studies. The second centered at 168 K is interpreted as due to trimethylene oxide rich eutectic rather than due to some restructuring of the host lattice as has recently been suggested.

Y. P. HANDA. Can. J. Chem. **63**, 68 (1985).

Utilisant un calorimètre à écoulement de chaleur du type Tian–Calvet et opérant à des températures allant de 85 à 270 K, on a déterminé les capacités calorifiques et les propriétés de dissociation de l'oxyde de triméthylène et de ses hydrates de clathrates de structures I et II. Les modes de dissociation des hydrates ne sont pas congruents. Les capacités calorifiques des hydrates sont du même ordre de grandeur que celles observés pour d'autres hydrates de structures I ou II. On observe deux anomalies thermiques dans le cas de l'hydrate ayant la structure I. L'une d'elle est centrée à 107 K et on peut l'attribuer au fait que les dipoles de l'oxyde de triméthylène se réorientent le long des axes $\bar{4}$ de la cage, comme il a été suggéré par des études diélectriques et de relaxation en rmn qui ont été effectuées antérieurement. Contrairement à ce qui a été suggéré récemment, on croit que la deuxième anomalie, qui est centrée à 168 K, serait due à un eutectique riche en oxyde de triméthylène plutôt qu'à une certaine restructuration du réseau hôte.

[Traduit par le journal]

Introduction

Trimethylene oxide (TMO) is one of the few guest species known to form both structure I and II clathrate hydrates. This has been confirmed by X-ray diffraction studies (1–3). The compositions of the structures I and II are reported to be $TMO \cdot 7.67H_2O$ and $TMO \cdot 17H_2O$ respectively (2). The phase diagrams (4, 5), dielectric (2, 6, 7), continuous-wave nmr (2), and far infrared absorption (3, 8) studies for both structures and heat capacities (9) for structure I have also been reported.

The structure I TMO hydrate is the only clathrate hydrate for which two unique transitions, one relating to the guest and the other to the host lattice, have been reported. From their dielectric and nmr study, Gough *et al.* (2) suggested that at about 105 K, the TMO guest molecules undergo an ordering transition whereby below 105 K the nearest neighbour TMO dipoles acquire a predominantly parallel alignment along the $\bar{4}$ axes of the 14-hedral cages. This transition was not detected in any of the other studies. From their heat capacity measurements, Comper *et al.* (9) found a thermal anomaly at 169 K and attributed it to some restructuring of the host lattice. No such transition was detected in any of the studies on TMO hydrates. However, a metastable eutectic at 165 K corresponding to conversion of structure II hydrate and solid TMO into TMO-rich (81% by mass) liquid and a stable eutectic at 172 K corresponding to conversion of structure I hydrate and solid TMO into TMO-rich (93% by mass) liquid (4) has been reported. The absence of an independent evidence for any restructuring of the structure I host lattice leaves open the possibility that the transition observed by Comper *et al.* (9) may simply be due to eutectic melting. In the light of these reports, it was decided to re-examine the TMO hydrates.

In this paper the results of heat capacity and dissociation runs on pure TMO and on solid samples of composition $TMO \cdot 7.30H_2O$, $TMO \cdot 7.65H_2O$, $TMO \cdot 8.06H_2O$, and $TMO \cdot 17H_2O$ are presented and discussed in terms of the two transitions noted above. In view of the compositions of structures I and II hydrates (2) and the phase diagram of TMO–water mixture (4), sample $TMO \cdot 7.30H_2O$ should consist of solid TMO and structure I hydrate and sample $TMO \cdot 8.06H_2O$ should consist of a mixture of structures I and II hydrates.

Experimental

TMO was obtained from Fluka Chemical Corp. A gas chromatographic analysis showed it to contain methanol, ethanol, and 1-hexene as impurities. It was purified using a preparative gas chromatograph (F & M Model 775). The gas chromatographic analysis of the final sample did not show any detectable impurities. Water used was distilled and deionized. Solutions of composition $TMO \cdot 7.30H_2O$, $TMO \cdot 7.65H_2O$, $TMO \cdot 8.06H_2O$, and $TMO \cdot 17H_2O$ were prepared from degassed components directly in the calorimeter cells. The sample size in each case was about 5 g. Hydrates were prepared by keeping a sample about 1 K below its dissociation temperature (4, 5) for 2 days and then at a temperature about 10 K below it for another 2 days. This procedure was continued for 10 days after which the sample was kept at 235 K for another 50 days.

The calorimeter and its operating technique has been described elsewhere (10). It is a Tian–Calvet heat flow calorimeter (SETARAM, Model BT), the operation of which has been automated by connecting it to a computer and a data acquisition system. Before loading a sample, the calorimeter was cooled to 10 K below the dissociation temperature of the sample. It was subsequently cooled to 78 K over a period of 8 h and maintained at this temperature for 12 to 48 h before initiating a run. All measurements were made in the temperature scanning mode using scan rates of 9 K h^{-1} for the heat capacity and 3 K h^{-1} for the dissociation runs. The thermopile output was collected every 60 s for the heat capacity and every 15 s for the dissociation runs.

Results and discussion

TMO

For melting temperature, we obtained a value of (173.2 ±

[1]NRCC No. 23665.

TABLE 1. Experimental values of dissociation temperatures for various samples of TMO hydrates

Compound	T_{dso}/K 1st peak	2nd peak
$TMO\cdot7.30H_2O$	250.2	257.0
$TMO\cdot7.65H_2O$	250.9	256.3
$TMO\cdot8.06H_2O$	251.5	259.6
$TMO\cdot17H_2O$	251.1	262.4

0.1) K which is identical with the value reported in the literature (11). For enthalpy of melting, we obtained a value of (6.273 ± 0.050) kJ mol^{-1}. In the temperature range 85 to 160 K, the heat capacity, C_p, results were fitted by the method of least-squares to give the equation

$$[1]\quad C_p/(\mathrm{J\ K^{-1}\ mol^{-1}}) = 40.30 + 1.081 \times 10^{-2}\,(T/\mathrm{K}) + 1.581 \times 10^{-3}\,(T/\mathrm{K})^2$$

with a standard deviation of 0.50 J K^{-1} mol^{-1}. The heat capacity of the liquid in the range 185 to 195 K was virtually constant with a value of 98.6 J K^{-1} mol^{-1}. We are not aware of any literature data on enthalpy of melting and C_p of TMO to compare our results with.

TMO hydrates

The dissociation temperature, T_{dso}, observed for various samples are summarised in Table 1. For each hydrate sample two dissociation peaks were obtained. For the samples $TMO\cdot7.30H_2O$, $TMO\cdot7.65H_2O$, and $TMO\cdot8.06H_2O$ the temperature for the first peak corresponds to the peritectic point at which the structure I hydrate is converted into structure II hydrate and TMO-rich liquid. The temperature for the second peak corresponds to conversion of structure II hydrate into ice and TMO-rich liquid. For the sample $TMO\cdot17H_2O$, the first peak is due to the presence of a small amount of structure I hydrate as reflected by its T_{dso} value. The temperature for the second peak corresponds to the peritectic point at which the structure II hydrate is converted into ice and TMO-rich liquid. The present results are in good agreement with the literature values of 252.3 K (4) and 253 K (9) and of 264 K (4) for the incongruent dissociation of structures I and II hydrates, respectively.

The experimental results of heat capacity measurements are shown in Fig. 1 along with the heat capacities for $TMO\cdot7.67H_2O$ reported by Comper *et al.* (9). Since the C_p values were determined 0.15 K apart, the present results appear as continuous curves. The C_p values of the hydrates studied in this work are very close to each other and for the sake of clarity the curves for $TMO\cdot7.65H_2O$, $TMO\cdot8.06H_2O$, and $TMO\cdot17H_2O$ have been shifted downwards by 6, 8, and 8 J K^{-1} (mol $H_2O)^{-1}$, respectively. For the structure II hydrate, the C_p values are very similar to those for the structure II tetrahydrofuran hydrate (10). For the structure I hydrate, the C_p values are slightly higher than the structure I ethylene oxide hydrate (12). Such a result is to be expected in the light of the recent finding (13) that the C_p of the clathrate hydrates increases slightly with an increase in the unit cell size. The cubic cell parameter for structure I TMO hydrate is 12.02 Å at 143 K (2) and for ethylene oxide hydrate is 11.89 Å at 173 K (14). However, the C_p values of Comper *et al.* for $TMO\cdot7.67H_2O$ are, on the average, 35% higher than the present results for $TMO\cdot7.65H_2O$ at temperatures outside the transition regions.

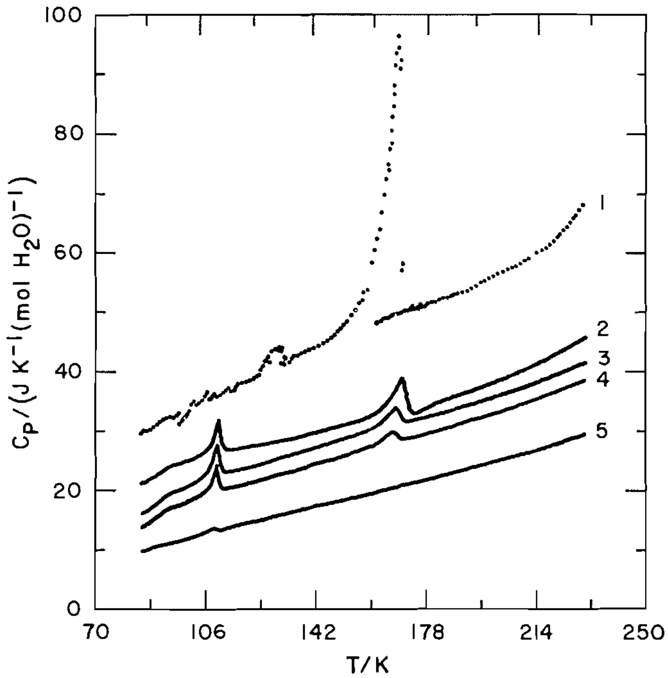

FIG. 1. Experimental heat capacities vs. temperature for trimethylene oxide hydrates. Curve *1*: $TMO\cdot7.67H_2O$ from ref. 9; curve *2*: $TMO\cdot7.30H_2O$; curve *3*: $TMO\cdot7.65H_2O$; curve *4*: $TMO\cdot8.06H_2O$; curve *5*: $TMO\cdot17H_2O$. Curves *3*, *4*, and *5* have been shifted downwards by 6, 8, and 8 J K^{-1} (mol $H_2O)^{-1}$, respectively.

As seen in Fig. 1, all the structure I samples show a transition at 162.6 K with the peak maximum temperature of 168.1 K. The corresponding values from the work of Comper *et al.* are 162 K and 169 K. The transition is very close to the solid TMO-structure I hydrate-TMO rich liquid eutectic observed at 172 K (4). The magnitude of the enthalpy of transition is maximum for $TMO\cdot7.30H_2O$ and corresponds to fusion of 0.042 mol of TMO whereas excess TMO present in the sample was 0.043 mol. The magnitude of the transition is smallest for $TMO\cdot8.06H_2O$ which contains a mixture of hydrates of structures I and II. No transition is observed for $TMO\cdot17H_2O$. The transition observed for $TMO\cdot7.65H_2O$ corresponds to the presence of about 2% unclathrated TMO. This suggests the presence of unreacted ice in the sample. However, the presence of ice can not be detected as according to the phase diagram (4), the melting of ice occurs in the same temperature range as the second dissociation peak observed in our work and thus any information related to melting of a small amount of ice will be buried in the main dissociation peak.

TMO occupies only the larger cages in both structure I and II hydrates. The mean free diameters of the 14-hedral cages which occur in structure I and the 16-hedral cages which occur in structure II are 5.8 Å and 6.6 Å, respectively (15) and the largest van der Waals diameter for TMO is about 6.2 Å (8). Thus whereas enclathration of TMO in the 16-hedral cages should be easy, the relatively large size of TMO makes it difficult to be incorporated in the 14-hedral cages of structure I. The difficulty of enclathration of TMO in the 14-hedral cages is further reflected by the slightly larger unit cell size of $TMO\cdot7.67H_2O$ as compared with other structure I hydrates (2). Thus even when one starts with a solution of proper composition, TMO + $7.67H_2O$, complete enclathration of TMO is not always guaranteed. This, in fact, is a general problem with clathrate hydrates and can occur even in cases where hydrate formation is supposed to take place rather easily, e.g., ethylene oxide and tetrahydrofuran hydrates (12). Since structure II hydrate is stable at a higher temperature than structure I hydrate, the formation of structure I hydrate may proceeed through formation of structure II hydrate first. Gough *et al.* (2) found that samples of structure I hydrate prepared from solution of composition TMO + $7.67H_2O$ always contained a small amount of structure II hydrate. This will lead to the presence of a small excess of unclathrated TMO. From these considerations and from the results presented above, we conclude that the transition observed at 168 K is due to TMO eutectic rather than due to any restructuring of the host lattice as suggested by Comper *et al.* (9).

For structure I hydrate, an order–disorder transition at about 105 K has been reported by Gough *et al.* (2) according to whom at temperatures below 105 K, the TMO dipoles in the 14-hedral cages align themselves parallel to the $\bar{4}$ axes of the cages. No such transition was observed in the structure II hydrate. As seen in Fig. 1, a transition is observed in the present C_p results at 107 K. A small transition peak seen in the structure II hydrate is due to the presence of a small amount of structure I hydrate in the sample as noted above. Similarly a slightly smaller magnitude of the transition observed in TMO·$8.06H_2O$ is due to the required presence of a small amount of structure II in the sample. The dielectric measurements (2) showed that the order–disorder transition process is quite slow and complete equilibrium was not attained even after a period of 12 days. In this work, the samples were conditioned at 78 K for 12 to 48 h and thus only qualitative results can be obtained from the transition peak. The enthalpy change associated with the transition at 107 K is calculated to be 140 J $(\text{mol TMO})^{-1}$ for TMO·$7.65H_2O$. The entropy change for the transition is 1.3 J K^{-1} $(\text{mol TMO})^{-1}$ which suggests that there are about 20% more orientations available to the TMO molecule in the cage above 107 K than below it.

Molecular orbital calculations for dialuminum and disilicon hydrides and related systems

N. COLIN BAIRD
Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received March 12, 1984

N. COLIN BAIRD. Can. J. Chem. **63**, 71 (1985).

Ab initio MO calculations for Si_2H_2 are reviewed and discussed in qualitative terms. New calculations are reported, by MNDO for Si_2H_2 and Si_2H_4, and using both MNDO and *ab initio* methods (including electron correlation at the MP2 level) for various possible structures for Al_2H_2 (**3**). As with the analogous silicon dihydride, a dibridged structure **3***a* is found to be superior to classical structures **3***b*, **3***c*, and **3***d*. MNDO calculations for derivatives of Al_2H_2 are reported. Finally, some implications of the calculations for the surface structures of partially-hydrogenated elemental aluminum and silicon are discussed.

N. COLIN BAIRD. Can. J. Chem. **63**, 71 (1985).

On a réévalué les calculs *ab initio* d'OM effectués sur le Si_2H_2 et on en discute sur une base qualitative. On rapporte de nouveaux calculs MNDO effectués sur le Si_2H_2 et sur le Si_2H_4 ainsi que d'autres, basés tant sur les méthodes MNDO qu'*ab initio* (incluant une corrélation électronique au niveau MP2), effectués sur diverses structures possibles du Al_2H_2 (**3**). Comme avec le dihydrure de silicium analogue, on a trouvé que la structure doublement pontée **3***a* est supérieure aux structures classiques **3***b*, **3***c* et **3***d*. On rapporte les résultats des calculs MNDO effectués sur des dérivés du Al_2H_2. On discute finalement des quelques implications des calculs pour les structures de surface de l'aluminium et du silicium élémentaire partiellement hydrogénés.

Introduction

Second-row analogs to the "saturated" first row hydrides A_2H_m are well-known. Thus for example H_3SiSiH_3, H_2PPH_2, and HSSH have long been known, and are analogs to ethane, hydrazine, and hydrogen peroxide. The situation with respect to "unsaturated" hydrides is much less well-developed. A few compounds are known which have silicon–silicon or phosphorus–phosphorus double bonds, but all are derivatives in which all hydrogen atoms are substituted by large organic groups (1).

Although the $R_2Si{=}SiR_2$ and RP=PR molecules synthesized to date have structures which resemble the corresponding $R_2C{=}CR_2$ and RN=NR systems, there are indications from recent theoretical calculations that the silicon analog of acetylene and perhaps other second row hydrides have unusual structures (2). These results have provoked our interest in the field, and we wish to report here some MO calculations (both *ab initio* and semiempirical) for the "double bonded" hydride of aluminum, Al_2H_2, as well as semiempirical explorations (to complement existing *ab initio* results) for Si_2H_2 and Si_2H_4. Finally, the results are used as a basis for some speculations concerning possible structures near the surface of partially-hydrogenated elemental aluminum and silicon.

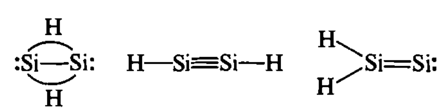
All *ab initio* calculations were performed using the methods and GAUSSIAN 82 computer program of Pople and coworkers. Geometry searches were performed using the 3-21G* basis for the aluminum atoms (3*a*) and the 31-G basis for hydrogen (3*b*); thus a set of Gaussian *d* orbitals is present on each Al atom, its other valence orbitals (3*s* and 3*p*) are each expanded by three GTOs (split into two sets) and the valence orbital of hydrogen is represented by four GTOs. Final energies were recomputed using the more sophisticated 6-31G* basis (3*c*). The major differential effects of electron correlation were incorporated by performing second-order perturbation calculations using the Moller–Plesset theory ("MP2") for the 6-31G* wavefunction (3*d*) obtained using the Hartree–Fock theory (unrestricted in the case of triplet states).

The MNDO calculations (4) were performed using Thiel's MNDOC computer program. (MNDO rather than the older but sometimes more reliable MINDO/3 method was employed since parameters for aluminum apparently are unavailable for the latter technique.) Our hope was that MNDO results would sufficiently parallel the *ab initio* results and experiment so that systems with three or more second-row atoms could be studied by the much less computationally-expensive semiempirical technique.

We have attempted to understand all the results by recourse to simple theoretical concepts such as bond strength, atomic promotion energy, and delocalization energies in the hope that non-theoreticians can usefully employ and generalize these computations.

Discussion and results

Recently a number of very sophisticated *ab initio* MO calculations, which include treatment of correlation energy, have been reported for Si_2H_2 (2). The global minimum is found to be the dibridged structure **1***a*, which contains a silicon–silicon single bond:



1*a* **1***b* **1***c*

This isomer is preferred energetically to the acetylene analog **1***b*, as well as to **1***c*. This preference can usefully be analyzed in simple terms. Structure **1***a* possesses two divalent, formally s^2p^2 silicon atoms, a single SiSi σ bond and two Si—H single bonds, each of which have been strengthened by delocalization of the bonding electron pair into an empty orbital of the other silicon. Structure **1***b* contains two tetravalent Si atoms (i.e. ones in which an *s* electron has formally been promoted to a *p* orbital to give the s^1p^3 configuration), one σ and two π SiSi bonds, and two localized SiH single bonds. Thus the strength of two π bonds here must be less than two times the sum of the

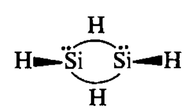
silicon promotion energy and the delocalization energy (of the SiH bond). Of course the opposite must be true for carbon, since only structures of type **1***b* are found in neutral hydrocarbons. The difference in behavior between the two elements is due primarily to the (expected) weakness of π bonds involving silicon and other atoms in its row of the Periodic Table. Structure **1***c* involves promotion for only one silicon, but compared to **1***a* only one π bond is gained and delocalization for both SiH bonds is lost. Nevertheless, the energy for **1***c* is only about 11 kcal mol^{-1} above that for **1***a*, whereas **1***b* lies about 40 kcal mol^{-1} above **1***a* (2*b*).

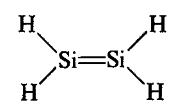
MNDO calculations (4) for Si_2H_2 which we have performed agree with the *ab initio* results in that **1***a* is predicted to be the minimum on the surface; type **1***b* structures collapse to **1***a* spontaneously. Structure **1***c* is calculated to be 33.1 kcal mol^{-1} less stable than **1***a* (see Table 1).

The optimum structure calculated by *ab initio* methods (which include correlation corrections) for Si_2H_4 is the ethylene analog **2***b*, although the SiH_2 groups are slightly flapped (5). The MNDO structure for **2***b* has a much greater angle of flap for the SiH_2 groups than does that from the *ab initio* calculations; the SiH_2 planes make a 44° angle with the SiSi vector according to MNDO. In the experimental structure for tetramesityldisilene, the corresponding angle is 18° (6).

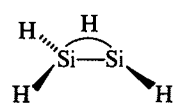
Structures for Si_2H_4 which do not involve *s* to *p* electron promotion at both silicons include **2***a* (neither Si promoted) and **2***c* and **2***d* (one Si promoted).



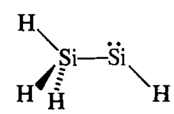
2*a*



2*b*



2*c*



2*d*

The contrast of **2***b* to **2***a* is formally identical to that of **1***b* to **1***a*, except that it is one σ and one π SiSi bond, rather than two π bonds, which are absent in the dibridged structure. Apparently the energetic superiority of σ over π SiSi bonds is sufficient to tip the balance here in favour of the classical structure. The *ab initio* calculations indicate that the classical structure **2***d* is in fact almost isoenergetic with **2***b* (3*a*); thus the π bond energy in **2***b* is not much greater than is the $s \rightarrow p$ promotion energy.

MNDO calculations we have performed predict that **2***a* is the global minimum on the Si_2H_4 surface. In contrast to **1***a*, the four-membered ring in **2***a* is predicted to be almost planar; the non-bridged hydrogens are located *cis* to each other. The preferred *cis* conformation in **2***a* is 1.0 kcal mol^{-1} more stable than the *trans*. The geometry at divalent, three-coordinate Si, and at univalent, two-coordinate Al, can be reconstructed qualitatively by requiring that one *p* orbital of the metal point toward each of the coordinated atoms. The predicted heat of formation for **2***a* is 33.1 kcal mol^{-1} superior to that for **2***b* and 18.1 kcal mol^{-1} superior to **2***c* — see Table 1. The **2***a* structure is predicted to be 50.2 kcal mol^{-1} more stable than two SiH_2 units, and 29.3 more stable than the classical structure **2***d*. (Apparently structures of type **2***a* were not considered in the previous MNDO calculations reported for Si_2H_4, since only **2***b* was discussed (7).)

Structure **2***c* is obtained from **2***d* by conversion of one of the three localized SiH bonds formed by the tetravalent silicon into a three-center Si--H--Si unit by delocalizing it into the empty 3*p* orbital of the divalent silicon. Although **2***c* is a minimum on the MNDO energy surface, it presumably represents the transition state between **2***b* and **2***d* on *ab initio* surfaces. Relative to *ab initio* results, MNDO appears to overestimate the energetic advantage of SiH bond delocalization and $s \rightarrow p$ promotion energies, and to underestimate the energy of SiSi bonds — compare results for **2***a* versus **2***b*, and **2***c* versus **2***b* and **2***d*.

Based upon the calculations and comparisons given above, we expect that the choice between structures having promoted

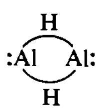
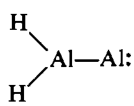
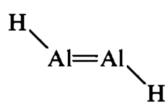
atoms which can form π bonds, and unpromoted, low-valent atoms which then form multicenter bonds using vacant *p* orbitals, will be determined by subtle electronic factors since apparently there is little difference energetically between them.

Given the above considerations, some rather intriguing chemistry is expected for compounds of silicon and aluminum, and perhaps even of magnesium, which have relatively low hydrogen-to-metal ratios. Thus, we have performed *ab initio* MO calculations (initially without any inclusion of configuration interaction or other correction for electron correlation) for Al_2H_2 in three possible structures **3***a*, **3***b*, and **3***c* and semi-empirical MNDO calculations for Al_2H_2 and also for other derivatives Al_2X_2.





3*a* 3*b* 3*c* 3*d*

Both the *ab initio* calculations (Table 2) and the MNDO (8) calculations (Table 1) predict that a planar dibridged structure **3***a* is the most stable structure for **3**. It is predicted to be 21.6 kcal mol^{-1} more stable than 2AlH monomers using the smaller basis set, 19.7 kcal mol^{-1} superior by the 6-31G* basis (using the same geometry), 28.2 superior by MP2 calculations with this basis, and 22.8 superior by MNDO. The optimum energy calculated for **3***c* is 13.5 kcal mol^{-1} less stable than for **3***a* according to MNDO. Using an assumed geometry (see Table 2), the estimated energy preference for **3***a* compared to **3***c* according to *ab initio* 6-31G* and MP2/6-31G* calculations is 19.8 and 23.4 kcal mol^{-1}, respectively. The calculated AlH distances in **3***a* are 1.817 Å and 1.638 Å respectively, and the AlHAl angles are 108.2° and 103.4°, respectively, according to *ab initio* and MNDO methods. (MNDO underestimates by 0.22 Å the bond distance in diatomic AlH, whereas using the present basis set *ab initio* predictions give 1.649 Å, which is in excellent agreement with the experimental value of 1.648 Å (8). Thus we expect the *ab initio* value for Al_2H_2 to be realistic, but the MNDO value to be rather too short.)

Although the linear double bond structure **3***b* appears favourable since the two singly-occupied π MOs produce a triplet state, it is predicted to be 10.6 (*ab initio*) or 49.5 (MNDO) kcal mol^{-1} less stable than is the dibridged singlet. MNDO calculations indicate that the optimum structure for the triplet in fact is not linear, but almost *cis* bent with HAlAl angles of 130.5° and a dihedral angle between the HAl vectors of 28°. One of the unpaired electrons occupies an MO which is best described as a combination of bonding π and antibonding σ; it contains substantial contributions from the 3*s* orbitals from the Al atoms. By the distortion from linearity, the 3*s* orbitals gain extra electron density (to yield a total of 1.45e) even at the expense of destruction of some of AlAl bonding, both σ and π. The energy improvement due to distortion from linearity is 8.1 kcal mol^{-1}. The *ab initio* results for the Al_2H_2 triplet are stable to these geometric distortions, but are unstable with respect to distortion to a planar *trans* structure with an HAlAl angle of 148°. As in the MNDO calculations, the incentive for nonlinearity is the increase in aluminum 3*s* orbital population which results. Clearly, though, both types of theory predict that AlAl π bonds are rather weak. The final energy for the nonlinear triplet at the optimum geometry is inferior to that for the dibridged singlet by 5.9 kcal mol^{-1} with the smaller basis, by 8.0 with 6-31G* and by 17.9 at the MP2/6-31G* level. The optimum AlAl distance in the linear triplet is 2.288 Å and in the *trans* is 2.38 Å; by comparison the single bond value obtained using the 3-21G* basis for Al_2 is 2.10 Å.

We have performed MNDO calculations for the dibridged and the classical X—Al=Al—X structures (closed shell singlet only) for Al_2F_2 and Al_2Cl_2 as well as Al_2H_2; the results are summarized in Table 3. In all three cases, the optimum classi-

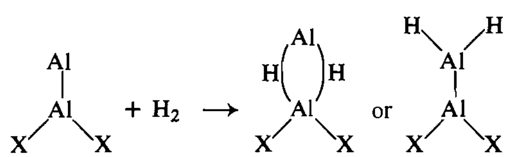
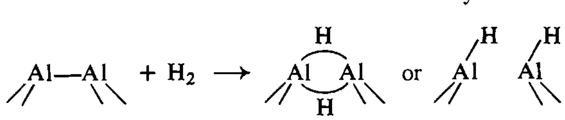
cal structure is the *trans* planar molecule, but this is less stable (by 30.4, 13.3 and 18.5 kcal mol^{-1}, respectively) than the dibridged structure. The dibridged dimers are more stable than two monomers by 31.0, 13.5, and 22.8 kcal mol^{-1}, respectively. Thus the classical structures are only slightly bound relative to the monomers; this is consistent with the long AlAl distances predicted for them by MNDO (Table 3). An *ab initio* structure for (singlet) **3***d* in the *trans* planar geometry gave a long AlAl bond, 2.67 Å, and an AlH distance and HAlAl angle of 1.61 Å and 121.0°, respectively. This classical double bond structure is 13.2 kcal mol^{-1} less stable than **3***a*, and by 13.5 and 14.0 at the 6-31G* and MP2/6-31G* levels, respectively.

The calculations for the disilicon and dialuminum hydrides have interesting implications regarding the surface structure for samples of elemental silicon and aluminum which have chemisorbed small amounts of hydrogen (though the possible dangers of extrapolation from results for two atoms to a multiatom surface are clear). For example, any univalent surface Al atoms can add H_2 to yield a dibridged structure **4***a* or a classical structure **4***b*:



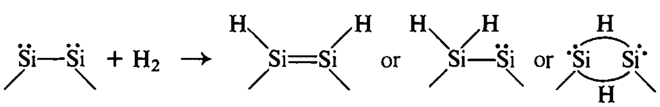
4*a* **4***b*

MNDO results for Al_2H_4 (i.e. **4** with X = H) predict the dibridged to be superior by 13.6 kcal mol^{-1}; however, this result could be spurious if MNDO's overestimate of the strength of delocalized Si—H bonds relative to Si—Si bonds (see S_2H_4 results above) extends also to aluminum. If two trivalent Al atoms at the surface are singly-bonded, an added H_2 could bridge the atoms (**5***a*) or add one hydrogen to each to give the classical structure **5***b*. MNDO calculations for Al_2H_6 and its monomers indicate that the dimer is preferred by 13.5 kcal mol^{-1} to two monomers. Thus from MNDO calculations we predict that hydrogen atoms will be always shared between aluminum atoms in a dibridged sense, whether or not this occurs between two Al atoms of the surface layer or between one of the first and one of the second layer.



5*a* **5***b*

With respect to the surface of silicon, it is clear that it could well consist of divalent silicon atoms, since the tendency of Si toward tetravalence is not nearly as acute as is that for carbon. If two Si atoms at the surface are singly-bonded to each other, and singly-bonded to (tetravalent) atoms in the next layer, one can conceive of hydrogen addition yielding classical structures in two ways; either one H to each of the Si atoms, to yield an ethylenic structure **6***b* with a formal double bond and the HSiSiH plane perpendicular to the surface plane, or both H atoms adding to the same Si atoms, to yield an analog **6***c* of the **2***d* structure. *Ab initio* calculations for Si_2H_4 indicate that these



6*b* **6***c* **6***a*

two structures will be preferred to bridged systems, and that the two will be almost equal in stability. On the other hand, MNDO calculations would presumably predict that the H atoms form a dibridged structure **6***a* with two surface silicon atoms, i.e., structure **2***a* with the classical, terminal *cis* SiH bonds replaced by SiSi bonds to two Si atoms in the second layer. High-quality *ab initio* calculations, including allowance for electron correlations effects, clearly are desirable for the *cis*, symmetrical dibridged structure **2***a* of Si_2H_4 in order to ascertain the real energy difference between it and the classical ethylene analog, since only such results can provide a realistic idea of the likelihood of finding dibridged hydrogen structures on the surface.

Conclusions

Both the semiempirical and *ab initio* calculations indicate that Al_2H_2, like Si_2H_2, has a dibridged singlet ground state rather than a classical multiply-bonded structure, and is bound relative to two AlH monomers. The driving forces which favour the nonclassical structures for these molecules include the weakness of π bonding between second row elements, and the energetic cost of $s \rightarrow p$ electron promotion. Unfortunately, MNDO calculations appear to overemphasize the strength of delocalized SiH bonds and to underemphasize the strength of SiSi bonds, and thus yield a nonclassical structure even for Si_2H_4. Further investigations concerning the structure of unsaturated aluminum or silicon hydrides should therefore use high quality *ab initio* calculations.

Intramolecular fluorescence energy transfer in nitrobenzoxadiazole derivatives of polyene antibiotics

NILS O. PETERSEN

Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received April 11, 1984

NILS O. PETERSEN. Can. J. Chem. **63**, 77 (1985).

Spectroscopic properties of the polyene antibiotic Nystatin and its nitrobenzoxadiazole derivative have been characterized by lifetime and quantum yield measurements. The data suggest that Nystatin and other polyene antibiotics exhibit spectral features common to other linear polyenes such as diphenylhexatriene and parinaric acid, and support the conclusion that the strong absorption (ϵ_{max} ~70 000 M^{-1} cm^{-1}; λ = 306 nm) is due to a symmetry-allowed transition to a higher excited state while the red-shifted emission occurs from a lower lying excited state through a weak, symmetry-forbidden transition.

Nitrobenzoxadiazole derivatives also exhibit efficient intramolecular fluorescence energy transfer from the polyene chromophore to the nitrobenzoxadiazole chromophore (λ_{em} = 535 nm). The lifetime and quantum yield measurements suggest that the predominant mechanism of energy transfer is via a Dexter type transfer in a fraction of molecules with appropriate conformations.

NILS O. PETERSEN. Can. J. Chem. **63**, 77 (1985).

Faisant appel à des mesures de rendements quantiques et de temps de demi-vie, on a caractérisé les propriétés spectroscopiques de l'antibiotique de nature polyénique, la Nystatine, ainsi que celles de son dérivé nitrobenzoxadiazole. Les donnés suggèrent que la Nystatine ainsi que les autres antibiotiques de nature polyéniques présentent des caractéristiques spectrales communes à celles des autres polyènes linéaires, comme le diphénylhexatriène et l'acide parinarique, et elles sont en accord avec la conclusion selon laquelle la forte absorption (ϵ_{max} d'environ 70 000 M^{-1} cm^{-1}; λ = 306 nm) est due à une transition, permise par la symétrie, vers un état plus excité tandis que l'émission dipolaire vers le rouge se produit à partir d'un état faiblement excité et par le biais d'une transition faible qui est prohibée en raison de symétrie.

Les dérivés nitrobenzoxadiazoles permettent également de transférer d'une façon efficace et intramoléculaire de l'énergie du chromophore du polyène vers le chromophore nitrobenzoxadiazole (λ_{em} = 535 nm). Les mesures de temps de demi-vie et de rendements quantiques suggèrent que le mécanisme prédominant du transfert d'énergie implique un transfert de type Dexter dans une fraction des molécules ayant des conformations appropriées.

Introduction

Polyene antibiotics (Fig. 1) are naturally-occurring compounds which can associate with sterols in membranes causing enhanced ion permeabilities (1). Some polyene antibiotics cause several physiological effects distinguishable by their dose response (2). *In vitro*, low doses stimulate DNA and RNA synthesis and are mitogenic, intermediate doses cause ion leakage, and high doses are cytotoxic (2–4). *In vivo*, many polyene antibiotics potentiate the effects of antitumor agents (5) and exhibit immunoadjuvant properties (6) in mice. It is possible that the multitude of effects originate from a single mechanism such as formation of specific pores (7, 8) through association with sterols, but it is likely that there are several sites in cell membranes where the polyene antibiotics can act. We are studying the membrane distribution and dynamics of a few polyene antibiotics, specifically Amphotericin B, Nystatin, and Pimaricin, in order to shed further light on their mechanism of action in culture cells. We are particularly interested in fluorescence photobleaching measurements of the dose dependence of the diffusion of these polyene antibiotics in cell membranes and have recently reported on the synthesis of a nitrobenzoxadiazole derivative of Amphotericin B (AmB) and its diffusion in L-cells at low doses (9). We also presented evidence suggesting that intramolecular fluorescence energy transfer could occur in this derivative. We have since prepared similar derivatives of Nystatin and Pimaricin and report here on quantum yield and lifetime measurements which provide evidence that intramolecular energy transfer in these three compounds occur principally by an electron exchange mechanism (Dexter transfer).

Experimental

Syntheses

N-Methyl-*N*-(7-nitrobenz-2-oxa-1,3-diazol-4-yl)-6-aminohexanoyl (NBD-6-MAHA) derivatives of Amphotericin B (NBD-AmB), Nystatin (NBD-Nys), and Pimaricin (NBD-Pim) were prepared, purified, and characterized as previously reported (9) with only minor modifications. The condensations with Nystatin and Pimaricin were carried out in dimethyl formamide (DMF) rather than dimethyl sulfoxide (DMSO) and their purification by high performance liquid chromatography were effected with slightly different proportions of the elution buffer.

Instrumentation

Fluorescence spectra were recorded as corrected spectra on either an MPF-4 or a model 650 fluorescence spectrophotometer (Perkin Elmer). Quantum yield measurements were made relative to 1.28 × 10^{-6} M quinine sulphate (recrystallized from water) in 0.1 N H_2SO_4 using the quantum yield of 0.52 (10). The quantum yields were corrected for refractive index differences between this solution and the particular solvent employed (10, 11). The quantum yields were calculated from areas of fluorescence emission curves by an integration program available in the Perkin Elmer 650 data station accessory. Absorbance spectra were measured on a Cary 219 UV-Visible spectrophotometer using more concentrated solutions (subsequently diluted accurately). No changes in extinction coefficient are observed upon dilution except for the case of AmB in water where changes in aggregation affect the spectrum above 10^{-6} M. Fluorescence lifetime measurements were made using single photon counting equipment in Professor W. R. Ware's laboratory. A picosecond laser system with frequency doublers were used for excitation in the 300 nm region while a Photochemical Research Associates Model 3000 nanosecond system was used for excitation in the 470 nm region. These systems have been described elsewhere (12). The laser system provides a cw

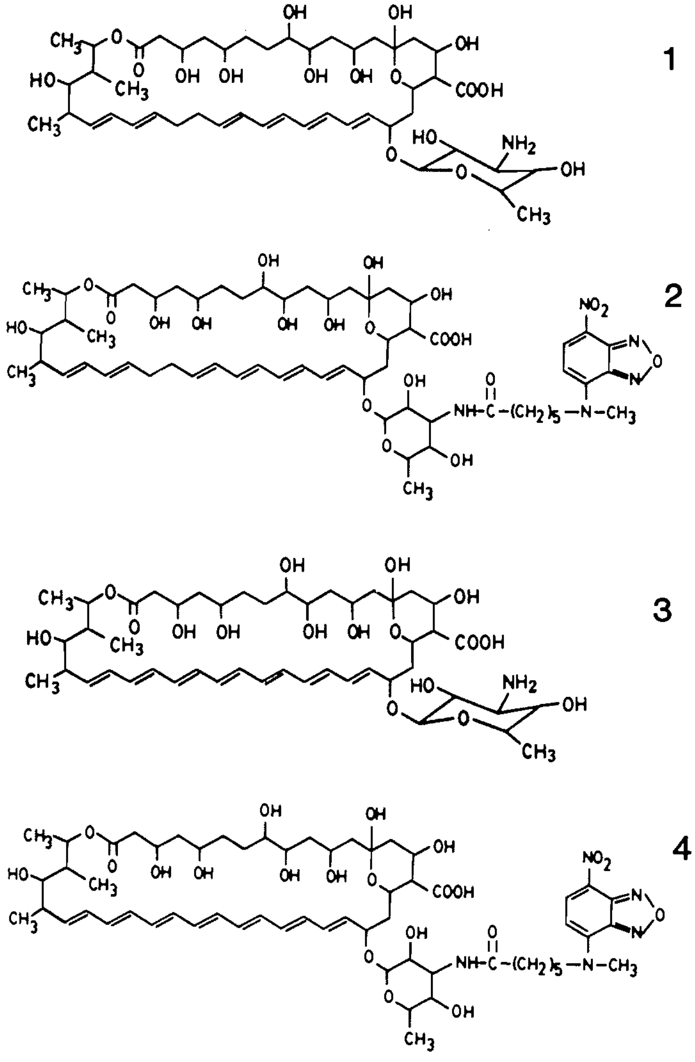

FIG. 1. Chemical structure of Nystatin (1), Amphotericin B (3) and their nitrobenzoxadiazole derivatives: NBD-Nys (2) and NBD-AmB (4). Note the polyene chromophore in the macrolide ring and the amphiphilic character of these molecules. Amphotericin B is a heptaene while Nystatin is spectroscopically a tetraene. The six carbon spacer and the mycosamine ring provide sufficient flexibility to permit close contact between the polyene chromophore and the nitrobenzoxadiazole ring in certain conformations.

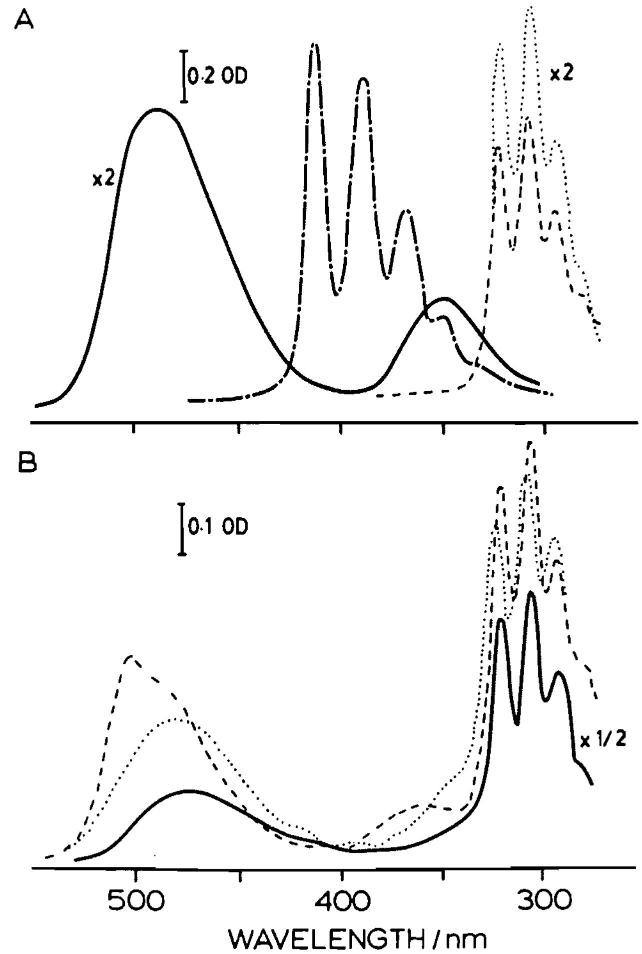

FIG. 2. (*A*) Absorbance spectra of 16 μ*M* Nystatin (---); 15 μ*M* Pimaricin (·····); 9 μ*M* Amphotericin B(-·-·-) and 25 μ*M* NBD-6-MAHA (—) all in DMF. (*B*) Absorbance spectra of 16 μ*M* NBD-Nys in THF (—); 14 μ*M* NBD-Nys in H_2O (---) and 14 μ*M* NBD-Nys in benzene (···). Note the characteristic red-shifted absorbance at 505 nm in H_2O.

power on the sample of less than about 10^3 W m^{-2} with pulse separations of 11 ns. Thus two-photon processes are unlikely in this system. The lifetimes were estimated from fitting by standard procedures of the fluorescence decay data to single or double exponential decays and the fits with reduced χ^2 values closest to unity were retained. De-oxygenating the samples by bubbling argon gas through the sample for 10–20 min had no measurable effects on either quantum yields or lifetimes.

Results

The optical spectra of the three polyene antibiotics prior to chemical modification are shown in Fig. 2, which also illustrates the solvent effect on the optical spectrum of NBD-Nys. Similar solvent shifts are found for all of the polyene antibiotics. The corresponding extinction coefficients are summarized in Table 1 which also shows the extinction coefficient of the NBD-6-MAHA intermediate used for preparing the fluorescent derivatives.

Representative fluorescence emission and excitation spectra of NBD-6-MAHA, Nystatin, NBD-Nys, and NBD-AmB are shown in Fig. 3. The emission corresponding to the NBD-chromophore is similar for all the derivatives. This emission is solvent sensitive and is red-shifted in more polar solvents (compare Fig. 3*c* and *d*). The excitation spectra (for emission at ~535 nm) are superpositions of the absorption spectra of the NBD-chromophore and the polyene chromophore but at different intensity ratios than observed in the absorption spectra of the derivatives. This suggests that absorption by the polyene chromophore results in emission from the NBD-chromophore, but this process occurs with less than unity efficiency.

The emission and excitation spectra are obtained from solutions of the derivative at very low concentrations (10^{-6} *M* and less) where intermolecular associations are unlikely. Moreover, the shape of the spectra, and therefore the relative intensities of the peaks in the excitation spectra, are insensitive to the concentration over a range from 4×10^{-6} *M* to 8×10^{-8} *M* except for small changes due to self-absorption at the higher concentrations. These latter effects are minimal for concentrations less than 10^{-6} *M*. These data suggest very strongly that the energy transfer process is *intramolecular*. In support of this conclusion, we can add that we have so far failed to

observe intermolecular energy transfer from the parent polyene antibiotic to either NBD-6-MAHA or NBD-MANC, the latter being a cholesterol derivative which should complex with the polyenes even at $10^{-5}-10^{-6}$ *M* concentrations ($K \sim 10^5\ M^{-1}$ (13)).

Figure 3 illustrates that in pure Nystatin there is an emission which peaks at λ = 405 nm. A similar fluorescence can be observed for Pimaricin but, as we have shown previously (14), pure Amphotericin B exhibits no detectable emission. One can, however, show (15) (data not presented) that the fluorescence and absorbance are both due to the Nystatin molecule since both are observed in the same peaks upon reverse-phase high performance liquid chromatography in several solvent systems. This is in contrast to Amphotericin B where a fluorescent species is clearly separated from the absorbance attributed to AmB (14). The quantum yield data presented below also indicate that the fluorescence emission at 405 nm for Nystatin arises from its polyene chromophore.

More careful analysis of emission spectra from purified Amphotericin B and the instrumental sensitivity show that the quantum yield is less than 0.002. In contrast, the quantum yield for Nystatin in THF is about 0.046. For these reasons, we have chosen to concentrate on characterizing the energy transfer process for NBD-Nys rather than NBD-AmB. It should be noted that even though the quantum yield for fluorescence of Amphotericin B is low, the energy transfer is still possible with reasonable efficiency as the spectra demonstrate (Fig. 3*c*).

Table 2 shows the fluorescence quantum yield and lifetimes

TABLE 2. Measured quantum yield and lifetime values and calculated rate constants for emission in THF at ambient temperature for Nystatin, NBD-6-MAHA, and NBD-Nys

	295	530	—	0.73	—	—

[a]Corrected for contribution from Nystatin emission in the region from 480–600 nm which overlaps the NBD emission.
[b]The best fit includes a very fast (0.1 ns) decay accounting for 10% of the intensity.

for Nystatin, NBD-6-MAHA, and NBD-Nys in THF at various combinations of excitation and emission wavelengths. The quantum yield measurements are relative to quinine sulphate in 0.1 N H_2SO_4 (ϕ = 0.52 (10)) and are corrected for the refractive index difference between 0.1 N H_2SO_4 and THF (10, 11). The emission spectra of Nystatin and of NBD-6-MAHA overlap in the region from about 480 nm to about 600 nm. The quantum yield of NBD-Nys emission for excitation at 306 nm was calculated allowing for this overlap correction. The lifetime measurements with excitation at 295 nm were done using a picosecond fluorescence lifetime apparatus by frequency doubling the emission at 590 nm from a Rhodamine dye laser pumped with a mode-locked argon ion laser tuned to 515 nm. The excitation at 295 nm minimizes overlap with the uv absorption of the NBD-chromophore which peaks at 340 nm. All tests show that the quantum yield for Nystatin is independent of the excitation wavelength between 290 nm and 323 nm. The 306 nm excitation used in the quantum yield measurements was the optimum choice based on three considerations: (*1*) it is the strongest absorption band thus giving the best signal-to-noise ratio, (*2*) it does not overlap severely with the 340 nm NBD absorption, and (*3*) the scattered light in these dilute solutions is sufficiently intense that it is detected at twice the wavelength (Fig. 3). For 306 nm excitation the light scattering peak is at 612 nm which is at the tail of the emission and therefore does not interfere seriously with the quantum yield measurements. For 295 nm excitation the light scattering peak is closer to the emission peak, increasing the uncertainty in the area measurement. (The light scattering peak was subtracted in all area measurements but this nevertheless introduces a small uncertainty.)

Several points can be made about the quantum yield data in Table 2. First, the quantum yields of emission for Nystatin and NBD-6-MAHA are similar. Second, the quantum yield of fluorescence from the NBD-chromophore arising from direct excitation at 470 nm is not affected by the chemical linkage to Nystatin (or to AmB). Third, in the NBD-Nystatin derivative the quantum yield for emission at 405 nm is decreased relative to that in pure Nystatin, while the quantum yield of new emission at 530 nm for excitation at 306 nm is approaching that of the NBD-chromophore when excited at 470 nm.

From these emission data we can calculate the quantum efficiency of energy transfer in two independent ways (16) as illustrated below for NBD-Nys in THF. First the transfer efficiency ϕ_{ET} may be calculated from the donor quantum yields in the absence (ϕ) and presence (ϕ') of the acceptor as

$$\phi_{ET} = 1 - \frac{\phi'}{\phi} = 1 - \frac{0.011}{0.046} = 0.76$$

Alternatively it may be calculated from the acceptor quantum yields in the absence (ϕ_A) and presence (ϕ'_A) of the donor as

$$\phi_{ET} = \frac{\phi'_A}{\phi_A} = \frac{0.040}{0.056} = 0.71$$

These are independent measures of the same quantity and the mutual agreement increases our confidence that the ϕ_{ET} measurement is accurate and therefore representative. These quantum yield measurements are determined from the areas of the fluorescence emission spectra. It is also possible to get an approximate estimate of the efficiency of energy transfer by measuring the *ratio* of the peak amplitudes in the corrected fluorescence excitation spectra and normalizing them to the appropriate extinction coefficients, i.e.,

$$\phi_{ET} = \frac{F_{306}/E_{306}}{F_{470}/E_{470}} = 0.70$$

This measurement is a third independent measurement of ϕ_{ET} and agrees well with the more correct area measurements. Utilizing the excitation spectra is particularly convenient for dilute solutions or highly scattering solutions if one can assume the absorption spectra are invariant. Obviously the measurement is extremely sensitive to self-absorption effects and requires good corrections for the spectrophotometer.

Table 2 also provides the lifetime measurements. These are from fits to single exponential decays in all cases but one, namely the emission from NBD-Nys at 405 nm when excited at 295 nm. In this case a small (~10%) but very rapid (~0.1 ns) component appeared. The major component decayed at 2.4 ns which is comparable to the lifetime of pure Nystatin at 2.6 ns. The lifetimes for emission at 530–535 nm are between 0.51 and 0.73 ns with the longest lifetime observed for the process involving the energy transfer process. Although the decay times have statistical uncertainties of less than 0.1 ns, it is likely that these processes have fundamentally the same decay rate.

The energy transfer efficiencies were measured in several solvents and are listed in Table 3. For the pure solvents there is a very large variation from 0.73 in THF to 0.04 in benzene.

TABLE 3. Fluorescence energy transfer efficiency for NBD-Nys in various solvents at ambient temperature

Solvent	ϕ_{ET}
THF	0.73
EtOH	0.57
DMF	0.33
H_2O	0.18
Benzene	0.04
100:0 EtOH:H_2O	0.60
60:40 EtOH:H_2O	0.60
40:60 EtOH:H_2O	0.62
20:80 EtOH:H_2O	0.45
2:98 EtOH:H_2O	0.31
0:100 EtOH:H_2O	0.18

The solvent-dependent changes in the optical spectra are smaller and cannot account for the variation in energy transfer efficiency through changes in the overlap integral. Interestingly enough, the energy transfer efficiency is lowest in benzene (0.04) where the quantum yield for emission by NBD-6-MAHA is the greatest. Table 3 also includes the variation in energy transfer efficiency with the composition of the solvent in mixtures of ethanol and water. It is evident that the efficiency is very sensitive to ethanol at low concentrations (2–20%) and fairly insensitive at higher concentrations of ethanol. We believe the solvent sensitivity arises from differences in conformation and state of aggregation of the NBD-Nys in each of the solvents. It should be noted that there appears to be no correlation between the efficiency of energy transfer and any of the standard solvatochromism scales (e.g. Z or E_T (17)).

The energy transfer efficiencies for NBD-AmB were measured by the ratio of emission areas at 535 nm by excitation at either 410 nm or 470 nm or by the ratio of the fluorescence intensities at 410 and 470 nm in the corrected excitation spectra (methods 2 and 3 above) in both cases correcting for the extinction ratio. In DMSO $\phi_{ET} = 0.05$ while in ethanol $\phi_{ET} = 0.07$. These are much smaller than the corresponding energy transfer efficiencies for NBD-Nystatin (in DMF and ethanol) which probably reflects a difference in the overlap integral in the two sets of chromophores. The energy transfer efficiency for NBD-Pim in ethanol is 0.49 which is slightly smaller than that for NBD-Nys (0.57). Since the spectral parameters are very similar, this difference likely represents a different conformational arrangement in the two molecules rather than a different overlap integral.

We have initiated studies of the energy transfer process in model membrane systems. Although these are incomplete, we have found that the energy transfer efficiency is greatest in dimyristoylphosphatidyl choline bilayers below the gel-to-liquid crystal transition ($\phi_{ET} = 0.90$) and lowest in dipalmitoyl phosphatidyl choline bilayers above the phase transition ($\phi_{ET} = 0.06$). It is difficult to get accurate measurements of the absorbance spectra in these samples because of the large amount of scattering from them due to the membrane suspension. Nevertheless, it is clear that the efficiency of energy transfer is greatest below the phase transition and greater in the less rigidly packed DMPC bilayer. Moreover, there is a shift in the excitation spectrum of the NBD-chromophore at higher temperatures which suggest a greater exposure to an aqueous environment. Thus the decrease in energy transfer efficiency is a combination of a change in bilayer structure and an increase in water content in the bilayer, both known to occur at the phase transition. At this point we cannot be certain which is the dominant effect.

Discussion

Nystatin spectroscopy

The photophysics of polyene antibiotics has not been studied in detail although their fluorescence properties have been utilized in several studies (18–20). Other polyenes, notably diphenylpolyenes such as diphenylhexatriene and diphenyloctatetraene and polyenic fatty acids such as *cis*- and *trans*-parinaric acid, have been studied intensively in part because of their utility in fluorescence depolarization measurements (21–24). Our results with Nystatin and other polyene antibiotics indicate that they share many of the characteristic spectroscopic features of other polyenes.

Diphenylpolyenes exhibit large Stoke's shifts and poor symmetry relations between the absorption and emission spectra (21, 22). The lifetimes measured by fluorescence decay are short (<5 ns) while the corresponding quantum yields are low (<0.1). The intrinsic or natural lifetimes are typically significantly longer than those estimated from the oscillator strength of the absorbance, i.e. from the integrated absorbance (21, 22). These observations have been interpreted in the past by considering two singlet excited states of different symmetry (^1B_u and ^1A_g in the $2/m$ (C_{2h}) group) where the ^1A_g state is at lower energy than the ^1B_u state. The ground state has ^1A_g symmetry, so the strong absorbance spectra (ϵ ~80–100000 M^{-1} cm^{-1}; $f \sim 1$) are associated with the $^1B_u \leftarrow {}^1A_g$ transition to the upper excited state. A rapid internal conversion causes relaxation to the excited ^1A_g state which is relatively long-lived because the $^1A_g \leftarrow {}^1A_g$ transition is symmetry forbidden. This ordering of the first two excited states accounts for the apparent discrepancy between the large oscillator strength and the long lifetime; for the large Stoke's shift (because the energy gap between the two excited states contributes to the red-shift of the emission) and for the loss of mirror symmetry between the absorption and emission spectra. The model has been confirmed in the case of diphenyloctatetraene in a glass at low temperatures by direct excitation of the $^1A_g \leftarrow {}^1A_g$ transition (22).

Parinaric acid (octadecatetranoic acid), specifically the isomers α(9,11,13,15-*cis*, *trans*, *trans*, *cis*) and β(9,11,13,15-*all-trans*) exhibit many of the spectroscopic features outlined above for the diphenylpolyenes (24). Although indirect, the evidence strongly supports an excited state ordering in the parinaric acids similar to that in the diphenylpolyenes. The data presented in this report for Nystatin are very similar to those of the parinaric acids. Specifically, their absorbance wavelength is solvent-sensitive while the emission wavelength is not; the emission is about 90 nm red-shifted (compared to 100 nm for parinaric acid); the intrinsic lifetime is about 57 ns (compared to 100 ns for parinaric acid) which is longer than the 8 ns estimated from the strong absorbance spectrum. The measured lifetime of 2.6 ns in THF is comparable to that of parinaric acid of 3.2 ns in dioxane; the quantum yield is 0.046 compared to 0.051 for parinaric acid. Considering these comparisons and accepting the conclusions about the excited state ordering for diphenylpolyenes and polyenic fatty acids, we conclude that the tetraene antibiotic Nystatin has similar excited state ordering and symmetry relationships between the states. Nystatin is a more complex molecule than either the diphenylpolyenes or the parinaric acids, so we are reluctant to attach the symmetry descriptions of ^1A_g and ^1B_u to the states. For the

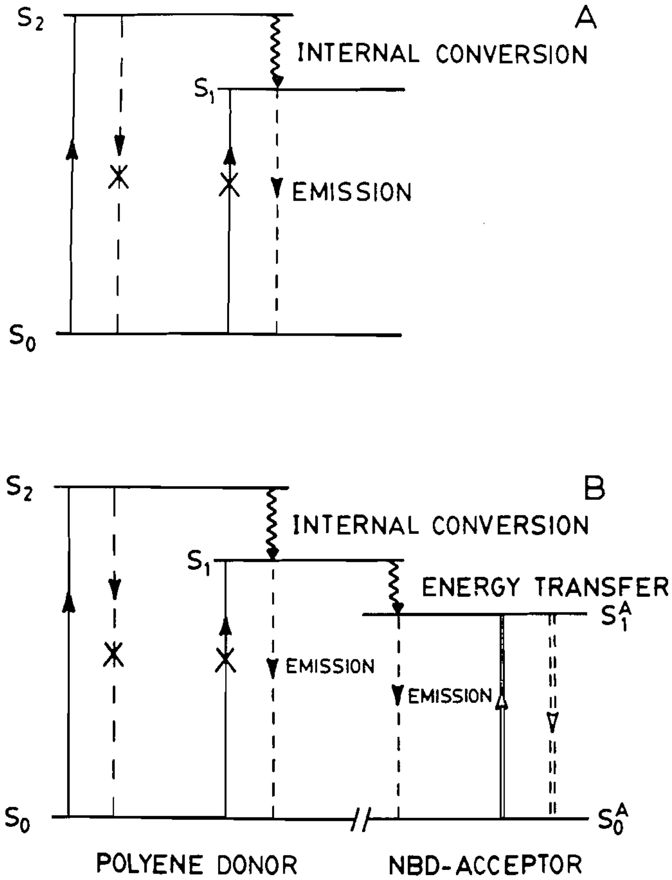

FIG. 4. *A*, Schematic representation of the transitions in the polyene chromophore of Nystatin. The emission from S_2 is not detected because of the rapid internal conversion to S_1. The direct absorption into S_1 is too weak to be detected. *B*, Schematic representation of the transitions in NBD-Nys. The polyene chromophore of Nystatin acts as a donor in the energy transfer from S_1 to the $S_1{}^A$ state of the NBD chromophore. The double arrows indicate the direct absorption and emission processes for the NBD chromophore. The energy transfer occurs rapidly in 70% of the molecules while the other 30% emit as in the parent Nystatin molecule.

purpose of the remainder of this discussion we will refer to the excited states as S_1 and S_2 with the understanding that S_2 is at higher energy than S_1 and that the $S_2 \leftarrow S_0$ transition is a symmetry-allowed transition observed in the absorption spectrum while the $S_0 \leftarrow S_1$ transition corresponds to a symmetry-forbidden transition observed in the emission spectrum. We will further presume that the internal conversion $S_1 \leftarrow S_2$ is rapid ($k_{IC} > 10^{12}\ s^{-1}$ (24)), so that energy transfer is most likely to occur from S_1. Figure 4*A* illustrates graphically the possible transitions in the Nystatin chromophore.

All the polyene antibiotics we have so far looked at (representing tetraenes (Nystatin, Etruscomycin, Pimaricin) and pentaenes (Chainin, Fungichromin (≡ lagosin ≡ cogomycin) (25)) and heptaenes (Amphotericin B)) exhibit the characteristically large Stoke's shifts and have very solvent-sensitive absorption spectra. Based on this limited evidence it is tempting to suggest that all the polyene antibiotics will follow the pattern of other polyenes including Nystatin. Of course, with the heptaenes the emission is so weak that any conclusions about the excited state ordering is dangerous.

NBD-Nystatin spectroscopy

The fluorescence emission spectrum of NBD-Nys in the region from 350 nm to 480 nm for excitation at 306 nm is the same as that of Nystatin except for a four-fold reduced quantum yield. Correspondingly, the excitation spectrum for emission at 405 nm is the same as that of Nystatin but with a four-fold lower intensity. These observations suggest that the state ordering of the Nystatin polyene chromophore is not affected by the conjugation of the NBD-chromophore. The reduction in quantum yield is due to energy transfer as discussed below. Moreover, the excitation spectrum in the region from 250 nm to 325 nm for emission at 535 nm is the same as that of Nystatin but with different intensities. This confirms that the emission from the NBD-chromophore is coupled to an energy transfer from the same excited states involved in the polyene spectroscopy. We suspect that the energy transfer occurs from S_1 in NBD-Nystatin.

The energy transfer process

The quantum yield and lifetime of acceptor (NBD) emission in NBD-Nys are similar to those in NBD-6-MAHA (Table 2) suggesting that there is no back-transfer from the NBD-chromophore to the polyene and that the radiative and non-radiative rate constants of the acceptor are essentially unaffected by the intramolecular interactions in NBD-Nys.

The emission at 535 nm arising from excitation at 306 nm is dependent on the kinetics of three consecutive processes, namely, internal conversion from S_2 to S_1 in the donor, energy transfer, and acceptor emission (Fig. 4*B*). Internal conversion is rapid and not rate-limiting. Standard kinetic arguments (26) predict an emission decay comparable to the slower and therefore rate-limiting of the two other processes. The measured lifetime for the total energy transfer and emission is only slightly larger than the lifetime of acceptor emission due to direct excitation (Table 2), suggesting that the emission step rather than the energy transfer step is rate-limiting. A consecutive reaction scheme also predicts an initial increase in the concentration of the intermediate which would be observed as an initial growth in the emission decay curve, unless the first step (energy transfer) is very rapid relative to the timescale of the measurement. The measured decay curve (Fig. 5) shows no evidence of an initial growth supporting the conclusion that energy transfer is rapid. From the data we estimate that the rate constant for energy transfer would have to exceed about $10^{10}\ s^{-1}$.

The donor emission quantum yield is about four times smaller in NBD-Nys than in Nystatin whereas the lifetime is about 10% smaller (Table 2). These data are mutually inconsistent or in conflict with the rapid energy transfer predicted by the acceptor emission data in any model which assumes that all molecules behave equivalently. Specifically, the measured quantum yield, ϕ, and lifetime, τ, of donor emission must change in proportion (16) since $\phi = k_F \cdot \tau = k_F/(k_F + k_{NR})$ in the absence of energy transfer and $\phi' = k'_F \cdot \tau' = k'_F/(k'_F + k'_{NR} + k'_{ET})$ with energy transfer. Here k_F, k_{NR}, and k_{ET} are the radiative, non-radiative, and energy transfer rate constants, respectively, and the primes indicate the values in the presence of energy transfer. If the donor radiative rate constant is not affected by the donor–acceptor interactions in NBD-Nys ($k'_F = k_F$), a four-fold decrease in quantum yield requires a four-fold decrease in lifetime. This is not observed. Conversely, the radiative rate constant would have to decrease about four-fold to accommodate the small change in lifetime actually observed. The resulting energy transfer rate constant of $3 \times 10^8\ s^{-1}$ is smaller than the rate of decay of the acceptor

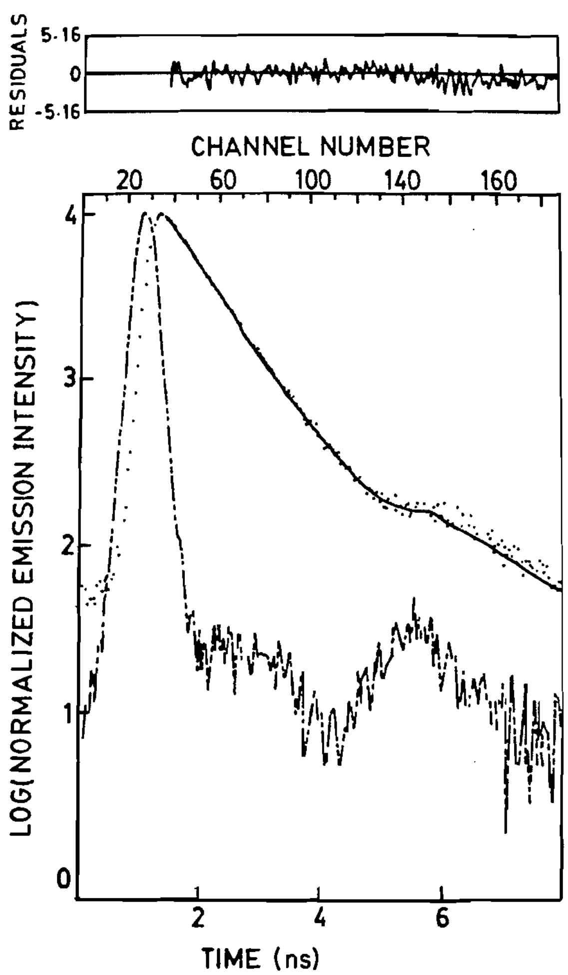

FIG. 5. Decay of emission from NBD-Nystatin measured at 530 nm while exciting at 295 nm. The dashed curve represents the laser pulse profile. Note the absence of a slow build-up as predicted for the Förster transfer process. The deconvolution yields a good fit to a single exponential decay with a time constant of 0.71. The residuals are shown above the curve.

emission ($k = 1.4 \times 10^9\ s^{-1}$) and much smaller than the energy transfer rate constant estimated from the acceptor emission data. Hence a decrease in radiative rate constant of donor emission would make the energy transfer process, rather than the acceptor emission, the rate-limiting step. This is contrary to the data for the acceptor emission (Fig. 5, Table 2). Furthermore, a large change in the radiative rate constant of the donor should be observable in its absorption spectrum since the integrated absorbance is related to the radiative lifetime (16).[1] Since there are no differences in extinction coefficients or wavelengths of maximum absorption of the polyene chromophore between Nystatin and NBD-Nys (Fig. 2) it is unlikely that the radiative rate constant is decreased significantly. Clearly, there are inconsistencies in the data whether or not we assume an invariant radiative rate constant. Models for the energy transfer process which assume that all molecules are affected equivalently must, therefore, be rejected for the NBD-Nys system.

The simplest alternative is the case where one population of molecules exhibits energy transfer exclusively and another population exhibits no energy transfer. The former do not contribute to the donor emission and are "dark-complexes" which still absorb and contribute to the observed acceptor emission. The latter are the only source of donor emission and since they are not affected by the energy transfer process, the measured lifetime of donor emission is unchanged. However, the measured quantum yield of donor emission must decrease to reflect the mole fraction, X, of unaffected molecules remaining. Specifically, the measured quantum yield will be

$$\phi' = X \cdot k_F/(k_F + k_{NR}) + (1 - X)k'_F/(k'_F + k'_{NR} + k'_{ET})$$

In the limit where $k'_{ET} \gg k'_F + k'_{NR}$, i.e., when energy transfer is rapid this reduces to $\phi' = X \cdot k_F/(k_F + k_{NR}) = X \cdot \phi$. The energy transfer efficiency becomes

$$\phi_{ET} = 1 - \frac{\phi'}{\phi} = 1 - X$$

and is now a direct measure of the mole fraction of the population of molecules which exhibit rapid energy transfer. The four-fold decrease in quantum yield then indicates approximately a 1:3 distribution of the two populations. The acceptor emission due to energy transfer arises from the population where energy transfer must be rapid so the acceptor emission step is rate-limiting and no growth in the decay curve is expected, in accord with the acceptor emission data (Table 2, Fig. 5). All the data are, therefore, wholly consistent with a system of two populations which are spectroscopically distinct and which interconvert slowly on the nanosecond time scale.

The conformational model

Examination of the structure of NBD-Nys (Fig. 1) suggests that two conformations could exist: a fully extended conformer in which the polyene and NBD-chromophore are separated by between 23 and 28 Å and a folded conformer in which the NBD-chromophore is positioned along the hydrophobic polyene-section of the macrolide ring. We propose that in THF these are the predominant conformers of NBD-Nys and that in the extended conformer energy transfer is inefficient because of the separation and relative orientation of the chromophores while in the folded conformer energy transfer occurs rapidly because of the proximity of the chromophores. The energy transfer efficiency then measures the mole fraction of the folded conformer and the large variation in energy transfer in different solvents (Table 3) reflects a different equilibrium between the conformers in each solvent.

Although this model will account for the quantum yield and lifetime data, three observations indicate that there likely is a small contribution to energy transfer from the extended conformer also. First, we have found no solvents in which the energy transfer could be completely suppressed. This could indicate that there is always at least some of the folded conformer present in solvents as different as H_2O or benzene, but it is also possible that the extended conformer is contributing to this emission. Second, the lifetime of donor emission decreases in THF by about 10%. This would be expected if energy transfer is a slow competing process in the extended conformer. Third, the separation of the chromophore in the extended conformer is small enough that some energy transfer by a Förster-type mechanism is expected.

It is possible to estimate the characteristic separation, R_0, at which 50% energy transfer would occur by a Förster mechanism since (27)

[1]This argument is complicated by the fact that the absorbing and emitting electronic states are different (Fig. 4) but some effects should be observed.

$$R_0 = C(\kappa^2 \cdot \phi \cdot \eta^{-4} \cdot J)^{1/6}$$

where C is a constant ($C = 9.786 \times 10^{-5}$), κ^2 is a factor dependent on the time-averaged relative orientation of the chromophores, ϕ is the quantum yield of donor emission, η is the refractive index of the medium, and J is the overlap integral given by (27, 28)

$$J = \frac{\int \epsilon(\lambda)F(\lambda)\lambda^4 d\lambda}{\int F(\lambda)d\lambda}$$

In this expression $\epsilon(\lambda)$ is the molar extinction coefficient of the acceptor, $F(\lambda)$ is the donor emission intensity, and λ is the wavelength. For the NBD–tetraene chromophore pair in THF we calculate

$$J = 3.10 \times 10^{-14} \text{ cm}^6 \text{ mmol}^{-1}$$

using a summation over 1 nm intervals. Assuming an orientation factor for an isotropic relative orientation ($\kappa^2 = 2/3$ (27, 28)) the characteristic separation is

$$R_0 = 25.8 \text{ Å}$$

It is likely that the intramolecular linkage would restrict the chromophore reorientations and the R_0 value could be an upper limit. Nevertheless, the extended conformer could in principle exhibit up to 50% energy transfer.

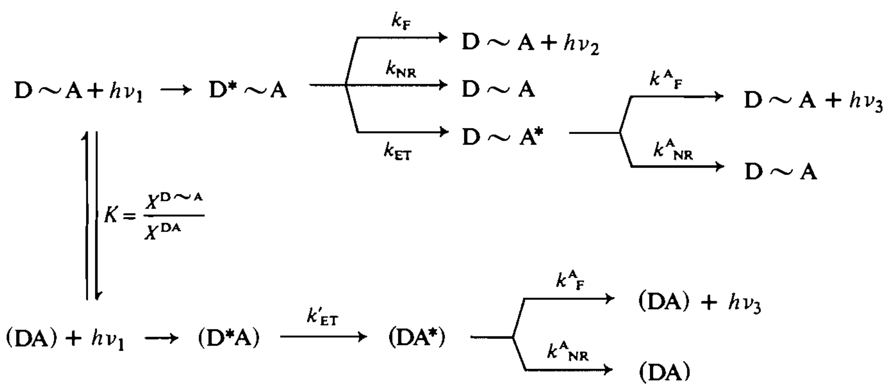
Given the likelihood that the extended conformer exhibits some energy transfer, we can use the observed decrease in lifetime to estimate the energy transfer rate constant, k_{ET}, and efficiency, ϕ_{ET}, in this conformer. Assuming no changes in radiative and non-radiative rate constants $\tau = 1/(k_F + k_{NR} + k_{ET})$ so $k_{ET} = 1/\tau - k_F - k_{NR} = (4.25 - 0.175 - 3.62) \times 10^8$ s^{-1} = 4.6×10^7 s^{-1} and $\phi_{ET} = k_{ET} \cdot \tau = 4.6 \times 10^7 \text{ s}^{-1}\, 2.35 \times 10^{-9} \text{ s} = 0.11$. Thus in THF the extended conformer may exhibit a slow energy transfer with an efficiency up to about 11%.

The folded conformer we postulate as one in which the NBD-chromophore has folded back over the mycosamine so that its π-ring system is parallel to the polyene chromophore. This will provide the close contact necessary for energy transfer by an electron-exchange mechanism. Because of the proximity we assume that energy transfer is occurring at unit efficiency by the Dexter-type mechanism. The total observed energy transfer is then given by the sum of the contribution from each conformer weighted by the respective mole fractions, i.e.,

$$\begin{aligned}\phi_{ET}\,(\text{total}) &= X \cdot \phi_{ET}\,(\text{extended}) + (1 - X)\phi_{ET}\,(\text{folded}) \\ &= X \cdot \phi_{ET}\,(\text{extended}) + (1 - X)\end{aligned}$$

For NBD-Nys in THF this yields (using ϕ_{ET} (extended) = 0.11), $X = 0.32$ and $(1 - X) = 0.68$. In other words, 32% of the NBD-Nys are in an extended conformation while 68% are folded.

The proposed conformational model for energy transfer in NBD-Nys is summarized in the following kinetic scheme where D represents the donor (Nystatin) and A the acceptor (NBD):



Here the internal conversion step ($S_2 \rightarrow S_1$) in the donor has been omitted for clarity. The extended conformer is represented by D ~ A. Upon excitation at $h\nu_1$, the donor can decay by emission of light (at $h\nu_2$), by non-radiative processes or by energy transfer to give D ~ A* which in turn can decay by acceptor emission (at $h\nu_3$). The folded conformer is represented by (DA). Upon excitation at $h\nu_1$, the donor transfers energy with unit efficiency to the acceptor which then decays by emission at $h\nu_3$. The conformers exist in equilibrium in the ground state, but the rate of interconversion is slower than the photophysical decay paths and therefore the conformers are observed as spectroscopically distinct species. We propose that the equilibrium constant is solvent dependent, which accounts for the variation in energy transfer efficiency (Table 3). We then interpret the variation in energy transfer efficiency in the mixed ethanol:water system and in the lipid membrane system as a reflection of changes in the equilibrium constant for the two predominant conformers. We hope to exploit this in studies of binding of steroids to NBD-Nys, since binding is likely to shift the equilibrium and thus alter the observed energy transfer efficiency.

Conclusions

Polyene antibiotics have intrinsic chromophores whose spectroscopic properties when properly understood may be exploited in studies of their mechanism of action in cell membranes. The photophysical behaviour of the tetraene Nystatin can be shown to resemble closely that of other polyenes, particularly the parinaric acids. On the basis of this comparison we suggest that the pattern of excited state ordering observed in other polyenes extends to the polyene antibiotics.

Nitrobenzoxadiazole derivatives of the polyene antibiotics exhibit efficient intramolecular energy transfer from the polyene chromophore to the nitrobenzoxadiazole chromophore. Lifetime and quantum efficiency measurements are consistent with a model in which there is an equilibrium between a fully extended conformer (D ~ A) and a folded conformer (DA). The former exhibit energy transfer by a Förster type energy transfer mechanism through Coulombic interactions of the transition dipoles. The latter exhibit energy transfer by a Dexter type energy transfer mechanism at a very fast rate. The total transfer efficiency depends on the relative proportion of the conformers which is sensitive to the solvent. For NBD-Nys in tetrahydrofuran the folded conformer represents about two-thirds of the molecules and accounts for more than 90% of the observed transfer. In other solvents the fraction of folded conformer is less.

The dependence of the energy transfer efficiency on the proportion of each conformer may provide a sensitive spectroscopic tool for studies of polyene−sterol interactions, since these are expected to affect the equilibrium distribution of extended and folded conformers (7, 8). Moreover, the spectroscopic properties of the chromophores suggest that it might be possible to observe intermolecular energy transfer between NBD-chromophores and polyene antibiotics if the complexes formed bring the chromophores within about 15−20 Å.

Reçu le 25 janvier 1984

JEAN-CLAUDE CHERTON, PAUL-LOUIS DESBENE, MARC BAZINET, MARC LANSON, ODILE CONVERT et JEAN-JACQUES BASSELIER. Can. J. Chem. **63**, 86 (1985).

La réaction du nucléophile azoture avec les triaryl-2,4,6 oxazinium-1,3 conduit en haut rendement aux β tétrazolo-*trans*-benzalacétophénones. La formation de ces tétrazoles implique l'intervention des azido-2 2*H*-oxazines-1,3 correspondantes. Un mécanisme de réarrangement de ces azides mettant en jeu deux tautoméries cycle–chaîne autour des intermédiaires iminoazides est proposé. Sous réserve que les azido-2 2*H*-oxazines-1,3 sont bien les produits cinétiques de l'attaque de N_3^-, les résultats présentés constituent un rare exemple de régiosélectivité de l'attaque d'un nucléophile sur le pôle C2 d'oxazinium-1,3.

Le problème de la réactivité du système oxazinium-1,3/azoture est discuté en référence au couple triphényl-2,4,6 pyrylium/N_3^-.

JEAN-CLAUDE CHERTON, PAUL-LOUIS DESBENE, MARC BAZINET, MARC LANSON, ODILE CONVERT, and JEAN-JACQUES BASSELIER. Can. J. Chem. **63**, 86 (1985).

Nucleophilic attack of sodium azide on 2,4,6-triaryl-1,3-oxazinium species gives high yields of β-tetrazolo-*trans*-benzalacetophenones from the corresponding 2-azido-1,3-oxazines. The rearrangement of the azido oxazines likely proceeds via tautomerism of the intermediate iminoazides. If the formation of the 2-azido-1,3-oxazines is under kinetic control, these results are a rare example of high regioselectivity in nucleophilic attack at the C2 carbon of 1,3-oxazinium species.

The reaction behaviour of the 1,3-oxazinium/N_3^- system is discussed, together with results obtained from the 2,4,6-triphenylpyrilium/N_3^-.

Nous nous intéressons depuis quelques années à la réaction du nucléophile azoture avec divers cations hétérocycliques aromatiques de type pyrylium. Les recherches ont ainsi été menées tant en raison de l'intérêt théorique de la réaction (1, 2) que des possibilités qu'elle offre sur le plan de la synthèse de composés hétérocycliques à sept chaînons (1, 3 à 9). (cf. schéma 1).

Les cations oxazinium-1,3 **1** ou azapyrylium-1,3 sont comme les cations pyrylium déficients en électrons, et comme tels réagissent avec de nombreux nucléophiles (10 à 13). A l'issue de ces réactions des oxaziniums-1,3, trois types d'oxazines: les 6*H*-oxazines **2**, les 4*H*-oxazines **3**, les 2*H*-oxazines **4** sont envisageables a priori en raison de la différenciation des pôles 2 et 6 en α de l'oxygène (cf. schéma 2).

Cependant, il ressort des travaux de R. R. Schmidt et coll. d'une part (10 et réf. citées) et de I. Shibuya et coll. d'autre part (11 à 13) que l'attaque d'une grande variété de nucléophiles sur le cation triphényl-2,4,6 oxazinium-1,3 **1***a* conduit exclusivement ou en prépondérance à des composés de type 6*H*-oxazine-1,3, c'est à dire de type **2** ou à des produits résultant de leur réarrangement (cf. schéma 2).

Le comportement du couple cation **1**/azoture n'avait pas encore été abordé. Compte tenu des résultats obtenus précédemment par nous mêmes en série pyrylium (1, 3 et 8) et par Schmidt et coll. (10) avec d'autres nucléophiles en série oxazinium-1,3, on pouvait attendre: soit une "non attaque" au sens covalent du terme avec formation d'un complexe de type donneur–accepteur comme observé dans le cas du couple triphényl-2,4,6 pyrylium/N_3^- (1, 3, 8); soit une attaque de N_3^- sur le pôle C6 du cation **1**. Au quel cas, l'evolution de l'azide covalent **2***a* (Nu = N_3) permettrait éventuellement l'accession à des homologues "aza" d'oxazépines-1,3, (cf. schéma 1) en l'occurence des *oxadiazépines* (14).

Nous présentons ici les premiers résultats concernant le comportement de triaryl-2,4,6 oxaziniums-1,3 **1** vis à vis du nucléophile azoture.

Résultats et discussion

L'action de l'azoture de sodium sur une solution de perchlorate de triphényl-2,4,6 oxazinium-1,3 **1***a* (10) dans l'acétonitrile anhydre se manifeste tout d'abord par une exaltation de coloration malheureusement trop brève pour être analysée par exemple par spectroscopie uv–visible, suivie d'une décoloration progressive du mélange réactionnel. Il s'agit donc d'une réaction d'attaque de N_3^-, mais la possibilité de formation transitoire ou simultanée d'un complexe donneur–accepteur, comme le laisse supposer l'exaltation de coloration n'est pas exclue. Au bout de quelques heures on isole un composé unique: le [diphényl-1,3 oxo-3 propène-1-yl (*E*)]-1 phényl-5 tétrazole que l'on dénommera désormais tétrazole **5***a* (Rdt 92%) (cf. schéma 2).

I. *Structure du tétrazole* 5a

Ce composé $C_{22}H_{16}N_4O$ résulte de l'incorporation de trois atomes d'azote au squellette du cation **1***a*. Toutefois les structures des produits primaires envisageables: **2***a*, **3***a* ou **4***a* (Nu = N_3, cf. schéma 2) sont à écarter en raison de l'absence de la bande d'absorption azido vers 2100 cm^{-1} dans le spectre infra-

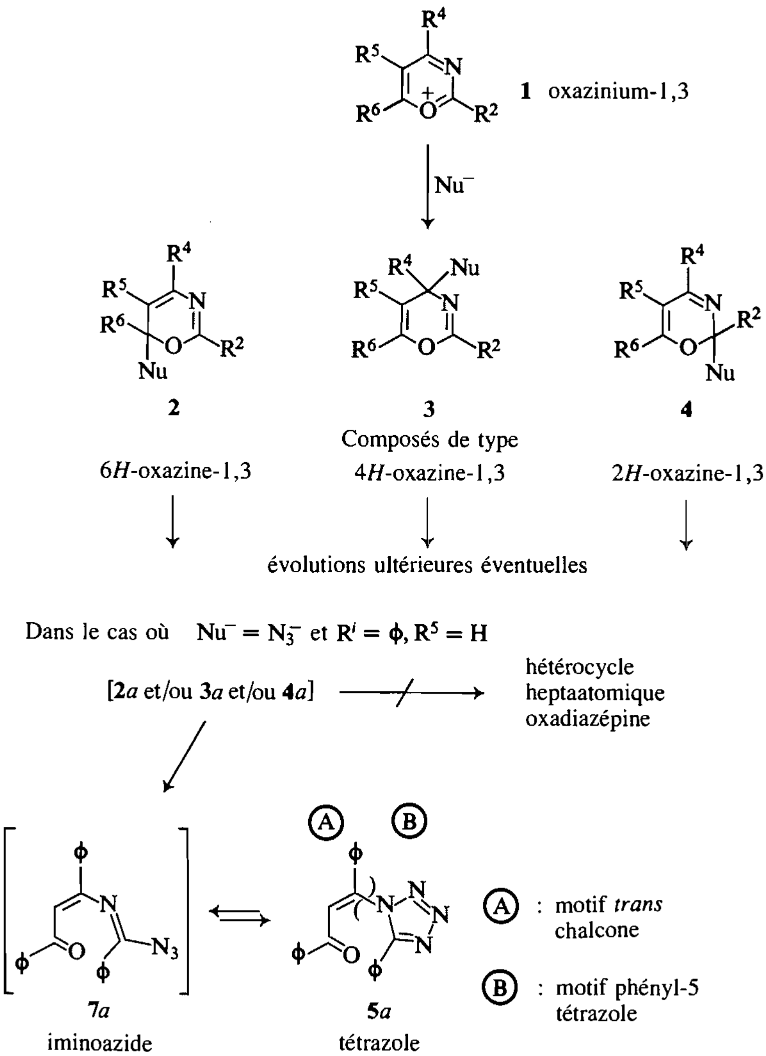

SCHÉMA 2

rouge (15). Après examen de ses propriétés chimiques[1] et spectroscopiques, nous avons attribué à ce composé la structure **5***a* associant les deux motifs: phényl-5 tétrazole et *trans* chalcone (cf. schéma 2).

Les arguments d'ordre spectroscopique sont les suivants: *la présence du motif* trans *chalcone* est établie par les analogies observées entre les spectres d'absorption uv–visible, infrarouge, de rmn ^{1}H et de rmn ^{13}C du composé **5***a* et ceux de la *trans* benzalacétophénone **6** (cf. partie expérimentale); le *motif tétrazole* est décelé en spectroscopie infra-rouge par l'observation d'un ensemble de bandes caractéristiques dans la région des empreintes (17, 18). En spectroscopie de masse, l'observation des ions moléculaires n'est pas possible par la technique de l'impact électronique I.E. à 70 eV ni même à plus basse énergie. L'ion de masse la plus élevée est alors celui résultant de la perte de N_2. Dans le cas du tétrazole **5***a*, une fragmentation $M^{+\cdot} - N_3^{\cdot}$ est également notée, elle conduit au cation oxazinium (M^+ 310, *Masse Exacte*). Pour les autres tétrazoles, les même hypothèses de fragmentations semblent raisonnables, d'autant que des observations similaires ont été faites dans le cas d'aryl et d'alkyl tétrazoles (19, 20). Le recours à l'ionisation chimique (IC) permet d'observer les ions quasi moléculaires (cf. partie expérimentale).

II. *Mécanisme d'obtention du tétrazole* 5a

La formation de ce tétrazole pose deux questions: celle du mécanisme d'isomérisation de l'azido-2 2*H*-oxazine-1,3 **4***a* dont il dérive manifestement – et celle de savoir si cette oxazine **4***a* est bien le produit cinétique de l'attaque de N_3^- sur l'oxazinium-1,3 **1***a*.

1. *Filiation oxazine 4*a *→ tétrazole 5*a

Nous proposons, pour rationaliser l'obtention du tétrazole **5***a*, deux tautoméries cycle–chaîne impliquant l'imino-azide **7***a* (1, 3, 8, 21, 22) (cf. schéma 2) jusqu'ici rencontrées séparément pour des systèmes voisins. (*i*) La tautomérie **4***a* $\leftrightarrows$ **7***a* s'apparente aux classiques équilibres diènone $\leftrightarrows$ α pyranne (cf. schéma 1) qui ont pu être notés lors de l'étude de l'action de nucléophiles (23) et en particulier de l'ion azoture (1, 3, 8) sur les cations pyrylium. (cf. schéma 1). (*ii*) La tautomérie **7***a* $\rightleftharpoons$ **5***a* est un équilibre du type iminoazide–tétrazole dont on connaît de nombreux exemples (21, 22).

L'obtention des tétrazoles **5***a* constitue une dérivation au schéma réactionnel initialement envisagé:

[1] L'étude détaillée du comportement thermique et photochimique des tétrazoles fait l'objet d'un article à part soumis pour publication au Can. J. Chem. (16).

produit cinétique de l'attaque de N_3^- sur l'oxazinium **1***a*, nous avons tenté de répondre en procédant à diverses démarches.

(a) *Action de NaN_3 sur* **1***a à basse température*

On ne décèle dans ces conditions aucune modification de la réaction: ni diminution notable du rendement en **5***a*, ni formation de nouveaux composés. Ce résultat signifie que l'oxazine **4***a* est probablement le produit cinétique de l'attaque.

(b) *Action de NaN_3 à basse température et en présence de triphényl phosphine*

Nous avons tenté d'intercepter à froid le précurseur du tétrazole **5***a* en procédant à l'attaque de l'oxazinium **1***a* par N_3^- en présence de $P(\phi)_3$. La triphénylphosphine est en effet connue pour capter les azides organiques en conduisant à des adduits 1 : 1 ou bien encore aux phosphoimines correspondantes par perte d'azote moléculaire (24).

Dans ces conditions, le cours "normal" de la réaction est modifié, une interception se produit effectivement puisqu'on observe: une diminution du rendement en tétrazole **5***a* de 92 à 47% (l'interception n'est que partielle), et la formation d'un composé phosphoré noté C.P. correspondant d'après l'analyse centésimale à la perte d'une molécule d'azote et à la fixation de $P(\phi)_3$ en partant d'une azidooxazine **2**, **3**, ou **4** ou de tout autre azide isomère (cf. schéma 3).

L'analyse centésimale n'a pu être réalisée que sur le composé C.P. brut car les essais de purification (recristallisation, chromatographie sur couche mince) conduisent immanquablement à une décomposition plus ou moins prononcée en mélange de $(\phi)_3PO$ et de triphényl 2,4,6-pyrimidine **8** (25) (cf. schéma 3). La fragilité de ce composé C.P. n'a pas facilité la détermination de sa structure. Cependant, aussi bien sa décomposition que diverses données spectroscopiques (comme: absence de carbonyle en infra-rouge, certaines fragmentations en spectrométrie de masse, présence dans le spectre de rmn ^{31}P d'un signal compatible avec un phosphore engagé dans un cycle (26)) nous conduisent à admettre pour ce composé C.P. une structure d'hétérocycle phosphoré. Dans le schéma 3 est représentée l'hypothèse la plus vraisemblable selon laquelle le précurseur intercepté à froid serait effectivement l'azido-2 2*H*-oxazine-1,3 **4***a*. Le produit de l'interception serait alors l'adduit $RN_3P(\phi)_3$ **9***a* sous forme ouverte ou cyclique dont le réarrangement direct ou par l'intermédiaire de la phosphoimine **10***a* (forme ouverte ou cyclique) conduirait au composé C.P. de structure **11***a* ou **12***a*.

Ces résultats confirment l'intervention d'un azide intermédiaire dans la formation du tétrazole **5***a* (cf. schéma 2) et s'accordent avec l'hypothèse de l'azido-2 2*H*-oxazine-1,3 **4** comme produit cinétique de l'attaque de N_3^-. Ils permettent d'écarter l'hypothèse d'un mécanisme concerté de l'attaque de N_3^- sur le pôle C2 de l'hétérocycle avec simultanéité de l'ouverture de cet hétérocycle et de la formation du cycle tétrazolique.

(c) *Effets de la substitution du pôle C2 sur la réactivité de N_3^- vis à vis des oxaziniums-1,3* **1**

Nous avons synthétisé de nouveaux oxaziniums-1,3

présentant en C2 un groupement aryle C_6H_4p-R^2 – soit électrodonneur et désactivant (**1***b*, $R^2 = OCH_3$) – soit électroattracteur (**1***c*, $R^2 = NO_2$), (cf. tableau 1).

De façon tout à fait qualitative, on constate que l'oxazinium anisylé **1***b* est moins réactif vis à vis de N_3^- que les sels **1***a* et **1***c*.

Le recours à le spectroscopie uv–visible comme moyen de comparaison des vitesses d'attaque des trois sels **1***a* à **1***c* n'a pas permis un classement plus précis de leurs réactivités. En effet, à de telles concentrations, intervient de façon non négligeable la réaction concurrente d'hydrolyse des sels, en particulier dans le cas de l'oxazinium nitré **1***c*, qui conduit aux "pseudo-bases" correspondantes: les β benzamido-*trans*-benzalacétophénones **13** (cf. partie expérimentale).

En revanche, le recours à des réactions compétitives d'attaque de N_3^- sur des mélanges de sels d'oxazinium **1** fournit le classement indicatif suivant (basé sur une analyse des mélanges réactionnels par rmn ^1H, cf. partie expérimentale): **1***c* ($R^2 = NO_2$), **1***a* ($R^2 = H$) > **1***b* ($R^2 = OCH_3$).

Cette séquence suggère l'hypothèse selon laquelle la réactivité de l'ion azoture vis à vis des oxaziniums serait tributaire dans une mesure restant à déterminer, de la charge du pôle C_2. En effet, l'examen a priori de la substitution R^2 sur les carbones hétérocycliques montre que l'effet mésomère du groupe nitro n'affecte pratiquement pas les pôles d'attaque, cependant que celui du groupe méthoxyle est désactivant. Il est évident que cette constatation ne constitue qu'une indication grossière de l'influence de la substitution et que bien sûr l'ensemble des effets électroniques doit être pris en compte.

Dans un premier temps, nous avons fait appel au déplacement chimique ^{13}C pour situer, de façon approchée, la densité électronique des différents pôles des cations oxazinium, sous réserve de la validité d'une telle relation pour ces cations (27). Néanmoins, nous avons montré que pour des cations hétérocycliques voisins: pyryliums et thiopyryliums, existait une relation linéaire δ ^{13}C et charge π.H.M.O (1, 8).

En ce qui concerne les oxaziniums-1,3 **1**, les données de la rmn ^{13}C (cf. tableau 1) semblent confirmer l'hypothèse d'une influence importante du facteur densité de charge des pôles éventuels d'attaque sur la réactivité de l'ion N_3^-. On observe en effet que le pôle C2 est le plus déblindé (voire le plus chargé) et qu'un certain parallélisme existe entre le δ ^{13}C du pôle C2 et la réactivité du cation correspondant vis à vis de N_3^- (cette dernière croissant du sel **1***b* au sel **1***c*).

Cette hypothèse amène à considérer comme moins favorable une attaque sur le pôle C4 qui s'avère être le moins déblindé voire le moins chargé des pôles d'attaque. En revanche, dans le cas de l'oxazinium nitré **1***c*, elle conduit à envisager la simultanéité d'une attaque de N_3^- sur les pôles C2 et C6 qui porteraient selon la rmn ^{13}C des charges voisines. Un composé supplémentaire a d'ailleurs été isolé en procédant à l'attaque du sel **1***c* à basse température. Son trop faible rendement n'a toutefois pas permis d'en préciser la structure ni, bien sûr, l'origine (attaque en C2 ou C6).

Un traitement théorique de la réactivité du système oxazinium-1,3/N_3^- analogue à celui déjà effectué dans le cas

de système pyrylium/N_3^- (1, 2) est actuellement entrepris. Tout d'abord il devrait permettre de vérifier la validité des hypothèses émises, comme celle d'une relation linéaire δ ^{13}C/densité de charges des pôles éventuels d'attaque des oxaziniums et celle d'une réactivité des cations **1** fortement tributaire des charges, selon laquelle les azido-2 oxazines-1,3 seraient les produits cinétique de l'attaque. Enfin, il devrait renseigner sur l'éventualité d'un complexe donneur–accepteur du type de ceux observés (1, 8) dans le cas de pyryliums peu encombrés, que nous avions envisagée pour interpréter l'exaltation de coloration observée au début de la réaction entre N_3^- et l'oxazinium **1***a*.

Partie expérimentale

Les spectres d'absorption ultraviolet–visible et infrarouge ont été respectivement enregistrés sur des appareils Hewlett Packard 8450 ou Philips SP8-250 et Philips SP3-200. Les spectres de rmn ^1H et rmn ^{13}C ont été enregistrés sur appareils Varian EM360 ou Bruker WP80 et sur appareils Bruker SY80 et WM250. Quant aux spectres de masse, ils ont été effectués par Mesdemoiselles J. Mercier et C. Lange que nous remercions, respectivement – au Centre de Mesures Physiques de Paris sur un spectromètre AEI MS50 – au laboratoire sur un spectrographe quadrupolaire NERMAG R10-10C. Les analyses élémentaires ont été effectuées par le Centre de Microanalyse du C.N.R.S. ou au Laboratoire de Microanalyse de l'Université Pierre et Marie Curie. Les points de fusion non corrigés ont été déterminés de façon instantanée au banc de Köfler.

1. *Synthèse et structure des triaryl-2,4,6 oxaziniums-1,3 1*

La structure des oxaziniums-1,3 **1** repose tant sur leurs propriétés spectroscopiques que sur celles de leurs précurseurs, les 4*H*-oxazines-1,3 **3** (Nu = H), et celles de leurs produits d'hydrolyse, les β-benzamido-*trans*-benzalacétophénones **13**. Une étude spectroscopique de ces trois classes de composés a donc été menée en recourant notamment à la rmn ^{13}C.

(a) *Propriétés des 4*H*-oxazines-1,3 3 (Nu = H)*

Les oxazines **3***a* et **3***b* étaient déjà connues (10, 28) ainsi que l'oxazine **14** (29) qui a servi de modèle pour les attributions de déplacements en rmn ^{13}C. *L'oxazine nitrée* **3***c* nouvelle a été préparée selon Schmidt (10): (60%); Fi 134°C (éther); ir cm^{-1} (KBr): 1690, 1640, 1605, 1580, 1520, 1500, 1455 et 1350; UV λ_{max} nm (ϵ_{max}), (éther): 214 (4,32), 272 (4,32); rmn ^1H ($CDCl_3$) δ ppm/TMS: 5,75 (syst. AB, 2H, J = 3 Hz). *Anal.* calc. pour $C_{22}H_{16}N_2O_3$: C 74,14, H 4,53, N 7,86; tr.: C 74,04, H 4,70, N 8,01. Spectre de masse: cf. tableau 2; rmn ^{13}C des oxazines: cf. tableau 3.

(b) *Obtention et propriétés des triaryl-2,4,6 oxaziniums-1,3 1*

Seul l'oxazinium **1***a* était connu (10). Les oxaziniums **1***b* et **1***c* ont été obtenus selon la même méthode (10) par oxydation des 4*H*-oxazines-1,3 **3** correspondantes.

*Perchlorate de diphényl-4,6 paraméthoxyphényl-2 oxazinium-1,3 1*b: (60%); Fi 265–267°C (CH_3CN, éther); ir cm^{-1} (KBr): 2850, 1615, 1590, 1530, 1095; uv–visible (CH_3CN) λ_{max} nm (log ϵ_{max}): 375

[a]Déplacements chimiques en ppm/TMS interne, solutions dans CD_3COCD_3.
[b]En raison de la compléxité des spectres, les carbones tertiaires des groupes aryles n'ont pas été attribués exceptés les carbones *para* (identifiables par leur intensité et pour 4′ par la substitution).
[c]Déplacements calculés par incrémentation (30) à partir des déplacements du composé **5***a*.
[d]*trans*-Benzalacétophénone **6** utilisée comme modèle du système énonique.
[e]**17** (35): modèle de tétrazoles.

(5,38), 436 (5,03); rmn ^{13}C: cf. tableau 4. *Anal.* calc. pour $C_{23}H_{18}N_1O_6$ Cl: C 62,80, H 4,13, N 3,18, Cl 8,06; tr.: C 62,49, H 4,23, N 3,30, Cl 7,83.

Perchlorate de diphényl-4,6 paranitrophényl-2 oxazinium-1,3 **1***c*: (85%); Fi 275–280°C (CH_3CN, éther); ir cm^{-1} (KBr): 1625, 1590, 1520, 1350, 1100; uv–visible (CH_3CN) λ_{max} nm (log ϵ_{max}): 274 (4,36), 352 (4,41), 404 (4,44); rmn ^{13}C: cf. tableau 4. *Analyse*: composé ne pouvant être isolé pur, cf. analyse centésimale de son produit d'hydrolyse la pseudobase **13***c*.

Pour les attributions des signaux δ ^{13}C des oxaziniums-1,3 **1** nous nous sommes basés sur la comparaison de l'oxazinium triphénylé **1***a* avec le pyrylium correspondant pour lequel δC4 < δC2 et δC6 (1, 8). Nous avons supposé que pour les oxaziniums-1,3 le même ordre était conservé et que le carbone C2 était le plus déblindé en raison de sa situation entre deux hétéroatomes. Ceci a été confirmé en procédant à l'enregistrement du spectre de **1***a* sans découplage des protons. On observe alors que le carbone le plus déblindé est le moins couplé (il s'agit de C2 qui apparaît sous forme de triplet), cependant que le signal suivant apparaît sous forme d'un quadruplet (C6 subit un couplage avec H2‴ et H6‴ et un couplage supplémentaire voisin avec H5). Pour les oxaziniums-2,4,6 triarylés la séquence des pôles éventuels d'attaque apparaît donc comme δC2 > δC6 > δC4. On constate que ces positions sont plus déblindées que celles des pyryliums (8, 32).

(c) β-*Benzamido* trans-*benzalacétophénones* **13**: *pseudo bases des oxaziniums* **1**

L'hydrolyse en milieu acétonitrile aqueux des oxaziniums **1***a* à **1***c* conduit aux pseudo bases **13***a* à **13***c* (33). Ces composés sont de configuration Z et présentent une liaison hydrogène intramoléculaire entre le carbonyle et le groupe amidique. Ceci se manifeste – en infra-rouge: bande de NH associé vers 3200 cm^{-1} et bande de C=O conjugué et associé vers 1620–1625 cm^{-1} – et en rmn ^{1}H: présence d'un signal très déblindé vers 13 ppm.

β-p-*Méthoxybenzamido*-trans-*benzalacétophénone* **13**b (70%); Fi 90–92°C (CH_3CN, éther); ir cm^{-1} (KBr): 3200, 2840, 1690, 1620, 1590, 1575; uv–visible (éther) λ_{max} nm (log ϵ_{max}): 213 (4,43), 283 (4,46) 344 (4,48); rmn ^{1}H ($CDCl_3$) δ ppm/TMS: 13,4 (s, 1H, éch. D_2O), 6,5 (s, 1H), 3,9 (s, 1H); rmn ^{13}C: cf. tableau 5). *Anal.* calc. pour $C_{23}H_{19}N_1O_3$: C 77,29, H 5,36, N 3,92; tr.: C 77,04, H 5,51, N 4,02; masse *m/e*: M^+ 357 (3), 252 (75), 207 (5), 135 (40), 92 (20), 77 (100).

β-p-*Nitrobenzamido*-trans-*benzalacétophénone* **13**c: (80%); Fi 192–194°C (CH_3CN, éther); ir cm^{-1} (KBr): 3200, 1690, 1625, 1590, 1350; rmn ^{1}H ($CDCl_3$) δ ppm/TMS: 13,4 (s, 1H, éch. D_2O), 6,5 (s, 1H); rmn ^{13}C: cf. tableau 5. *Anal.* calc. pour $C_{22}H_{16}N_2O_4$: C 77,29, H 5,36, N 3,92; tr.: C 77,04, H 5,51, N 4,02; masse *m/e*: M^+ 372 (1), 261 (21), 267 (100), 237 (20), 105 (40), 77 (60).

II. *Réaction de NaN_3 avec les triaryl-2,4,6 oxaziniums-1,3* **1**

A. *Obtention des tétrazoles* **5**

1. *Action de NaN_3 à température ambiante*

A une mmol de perchlorate de triaryl-2,4,6 oxazinium-1,3 **1***a* à **1***c* en solution dans 10 cm^3 d'acétonitrile sec est ajouté un excès de NaN_3 (2 à 3 fois la quantité stoechiométrique). Le mélange réactionnel est agité à la température ambiante sous atmosphère inerte et à l'obscurité pendant 2 h. Il est repris à l'eau, extrait à l'éther. La phase éthérée est séchée sur $MgSO_4$ puis évaporée à température ambiante sous vide.

Les tétrazoles *5a* à *5c* sont obtenus avec les rendements respectifs de 92%, 90% et 75%. Dans le cas de l'oxazinium **1***c*, on isole également 5% de pseudobase **13***c* ainsi qu'un composé supplémentaire non identifié lorsqu'on opère à froid (environ 5 mg).

2. *Action de NaN_3 à basse température*

A une solution de 100 mg (0,22 mmol) de sel **1***a* dans 5 cm^3 de CH_3CN sec sont ajoutés à froid (environ −40°C) 35 mg de NaN_3. Au bout de 48 h l'analyse par chromatographie sur couche mince de silice (ccm) n'indique qu'un seul produit. Le traitement habituel conduit à 84 mg (97%) de tétrazole **5***a*.

3. *Action de NaN_3 à basse température et en présence de $P(Ph)_3$*

A une solution de 100 mg (0,24 mmol) de sel **1***a* dans 5 cm^3 de CH_3CN sec sont ajoutés à froid ($\theta = -40$°C) 100 mg de $P(Ph)_3$ et 45 mg de NaN_3. Au bout de 48 h, le solvant est chassé et le résidu analysé par chromatographie préparative sur couche mince de silice, on isole dans l'ordre d'élution (cyclohexane/acétate d'éthyle 8:2): $P(\phi)_3$ en excès, le composé C.P. (100 mg) légèrement contaminé par $P(\phi)_3$, la triphényl-2,4,6 pyrimidine **8** (2,5 mg, 3,5%) identifiée à un échantillon authentique (10), le tétrazole **5***a* (40 mg, 48%), la pseudobase **13***a* (22 mg, 28%) et $P(\phi)_3O$ (3 mg, 3%) isolé par lavage à l'éther des 60 mg constituant le dépôt de ccm.

*Composé phosphoré C.P.: 11*a *ou 12*a: Fi ~ 190°C; ir (KBr) pas de carbonyle; rmn ^1H pas de signal caractéristique en dehors des H arom. *Anal.* calc. pour $C_{40}H_{31}OPN_2$ ($P(\phi)_3O$ + **8**): C 81,73, H 5,45, N 4,60; tr.: C 81,89, H 5,32, N 4,77. *Spectroscopie de masse*: impact électronique: on n'observe pas l'ion moléculaire $M^{+\cdot}$ 586 mais on retrouve l'intégralité des spectres de $P(Ph)_3O$ et de la pyrimidine **8**; *rmn ^{31}P* (101,25 MHz) δ ppm/H_3PO_4: 28,3 ($P\phi_3O$); −6,4 (C.P.).

4. *Classement de la réactivité des oxaziniums-1,3 1*a *à* c

Nous avons réalisé deux mélanges dans l'acétonitrile de sels ayant l'oxazinium anisylé **1***b* en commun (cf. schéma 4).

Sur chacun de ces mélanges il est procédé à l'action de NaN_3 pendant un court laps de temps (temps inférieur au temps nécessaire à la réaction totale du plus réactif). On procède alors à l'hydrolyse des sels n'ayant pas réagi. Les pseudobases **13** sont séparées (ccm) des tétrazoles **5** qui sont alors dosés par rmn ^1H en prenant comme référence les intégrations du signal méthoxyle du tétrazole **5***b* formé.

Il apparaît donc que le tétrazole **5***b* est obtenu en plus faible rendement que les tétrazoles **5***a* et **5***c*, ce qui signifie que le sel **1***b* réagit plus lentement avec N_3^- que les sels **1***a* et **1***c* qui ne peuvent toutefois pas être différenciés.

(B) *Propriétés spectroscopiques des tétrazoles*

Les données spectroscopiques: uv–visible, infra-rouge et masse sont consignées dans le tableau 6; *rmn ^{13}C* cf. tableau 7. L'interprétation des spectres des tétrazoles est facilitée par leur comparaison à ceux de deux composés modèles: la *trans*-benzalacétophénone **6** et les méthyl-1 aryl-5 tétrazoles **17** (35).

L'attribution des signaux voisins de 190 et 155 ppm se fait sans ambiguïté aux carbones notés C6 et C2. L'ordre des δ ^{13}C des carbones quaternaires notés C1′, C1″ et C1‴ pour le composé **5***a* découle de la comparaison avec les molécules modèles **6** et **17***a*. Les carbones C4′ et C4″ du composé **5***a* présentent des déplacements voisins de ceux des carbones correspondants des modèles **6** et **17***a*.

L'attribution du carbone C4 (δ = 142,7 ppm pour **5***a*) a été confirmée par l'enregistrement d'un spectre sans découplage des protons. C4 apparaît alors comme le plus couplé des carbones quaternaires: couplages avec H2″, H6″ et H5 et élargissement dû au voisinage de l'azote.

En conclusion, on est amené à considérer le motif tétrazole comme un groupement azoté très particulier: contrairement au motif benzamido, son introduction en position β sur la *trans*-benzalacétophénone n'a pratiquement pas d'influence sur le système ènonique.

A laser diffraction and nuclear magnetic resonance investigation of the cholesteric potassium *N*-dodecanoylalaninate mesophase system

KEITH RADLEY AND ALAN S. TRACEY
Department of Chemistry, Simon Fraser University, Burnaby, B.C., Canada V5A 1S6

Received February 28, 1984

KEITH RADLEY and ALAN S. TRACEY. Can. J. Chem. **63**, 95 (1985).

Nematic and twisted nematic mesophases have been prepared from various mixtures of potassium *N*-dodecanoyl-*l*-alaninate and its racemate. The induced pitch was determined as a function of optical purity as were nmr spectra from a variety of additives including several inorganic salts and *d,l*-alanine. Dipolar couplings from the $CHCH_3$ moiety of the alaninate headgroup were studied, as were quadrupole splittings from the N—D of the amido group and the D_2O of the water. It was proposed that with development of cholesteric behaviour on proceeding in a stepwise fashion from the *d,l* to *l* amphiphile, the individual disk-like micelles twisted into a chiral shape, then aggregated to form domain-like structures. The major axis of these aggregates is the axis along which the helix propagates and this local axis serves as the director axis for the aggregates. The individual aggregates reorient as a unit when placed in the magnetic field of an nmr spectrometer. As a consequence of this, the diamagnetic anisotropy of the mesophase prepared from the *l* amphiphile is positive in sign while that of the *d,l* analogue is negative. Despite this observed change in diamagnetic anisotropy, the alignment of the individual micelles is not different for the chiral and racemic materials.

KEITH RADLEY et ALAN S. TRACEY. Can. J. Chem. **63**, 95 (1985).

On a préparé des mésophases nématiques et nématiques croisées à partir de divers mélanges de *N*-dodécanoyl *l*-alaninate de potassium et de son racémate. On a déterminé le pas induit en fonction de la pureté optique ainsi que les spectres rmn obtenus par l'addition de divers produits incluant plusieurs sels inorganiques et la *d,l*-alanine. On a étudié les couplages dipolaires de la portion $CHCH_3$ de l'alaninate de tête ainsi que les couplages quadrupolaires N—D du groupe amido et du D_2O de l'eau. Il a été proposé que, si on développe le caractère cholestérique lorsqu'on procède par étape de l'amphiphile *d,l* vers le *l*, les micelles individuelles en forme de disques se croisent pour prendre une forme chirale et elles s'agglutinent ensuite pour former des structures en forme de domaines. L'axe principal de ces aggrégats est l'axe le long duquel l'hélice se propage et cet axe local sert d'axe directeur pour ces aggrégats. Les aggrégats individuels se réorientent sous forme d'unité lorsqu'ils sont placés dans le champ magnétique d'un spectromètre rmn. A cause de cette réorientation, l'anisotropie diamagnétique de la mésophase préparée à partir du *l*-amphiphile est de signe positif alors que celle de l'analogue *d,l* est négative. En dépit de ce changement observé dans l'anisotropie diamagnétique, il n'y a pas de différence dans l'alignement des micelles individuelles des substances chirales et racémiques.

[Traduit par le journal]

Introduction

The twisted nematic or cholesteric liquid crystalline materials were the first class of liquid crystals to be recognized (1). The term "cholesteric" designates the fact that early examples of this case of mesomorphic materials were prepared from derivatives of cholesterol. The most striking characteristic of these compounds is their selective reflection of incident light, thereby providing an intense irridescence. This behaviour derives from a helical arrangement of the constituent molecules induced by the specific interactions between chiral centres of adjacent molecules.

In the lyotropic mesophases employed in this study, cholesteric behaviour arises by a much more complex behaviour. The nematic state is characterized by micellar aggregates dispersed through an aqueous medium. In twisted nematics, the individual micelles are organized into a helical arrangement via interactions with other micelles. This implies that there must be a high degree of molecular order within each micelle, similar to that for the thermotropic twisted nematic mesophases, and that information concerning this molecular order is transferred from one micelle to another. The mechanism of transfer of this information is of interest. The interactions between micelles generate a helical axis giving rise to reflectance bands in the infrared rather than in the visible light region. The wavelength of reflected light, λ_0, is directly proportional to the pitch, P, of the helical axis and is dependent on the average of the refractive indices, $\eta_\parallel$ and $\eta_\perp$ so that eq. [1] is obtained. In this expression $\parallel$ and $\perp$ refer to an axis parallel or perpendicular to the helix

$$[1] \quad \lambda_0 = \frac{\eta_\parallel + \eta_\perp}{2} P$$

axis respectively.

The pitch of the helix can also be readily measured by microscopy (2); however, it is sometimes more convenient to use diffraction of laser light where the twist ($1/P$) is given by Bragg's Law for diffraction

$$[2] \quad 1/P = \sin \sigma/\lambda_0$$

where λ_0 is the frequency of the incident light and σ is the angle of light diffraction. Laser diffraction allows samples prepared for nuclear magnetic resonance (nmr) spectroscopy to be investigated without disturbing them. This is particularly convenient when samples have been homogeneously aligned by the magnetic field of the nmr spectrometer through their diamagnetic anisotropy, since the aligned samples give sharp diffraction bands.

Both twisted nematic and nematic lyotropic mesophases have been studied by microscopy using polarized light (2–6) and by nmr spectroscopy (6–9). The texture observed under the microscope is dependent on aggregate shape and thus microscopy can differentiate between nematic mesophases formed from the disk-like lamellar aggregates or the rod-shaped cylindrical aggregates (3). This information is necessary for the interpretation of the results from the nmr experiments.

The sign of the diamagnetic anisotropy of the individual micelles is important when studying twisted nematics. If this quantity is negative, the micellar aggregates align with their major axis perpendicular to the magnetic induction, B_0, which defines the z axis. Because B_0 is cylindrically symmetric, the helical arrangement is free to propagate along this axis. The symmetry in B_0, of course, may effectively be destroyed in the conventional iron-core magnet spectrometers by spinning the sample, thus providing a unique axis perpendicular to B_0. Such sample spinning will, in general, destroy the helical arrangement provided, of course, that aligning forces are stronger than twisting forces; if not, two-dimensional order of the micelles will then be obtained. If the diamagnetic anistropy of the micelles is of positive sign, they align with their major axis, the director, parallel to B_0. In this case, the cholesteric behaviour may be destroyed when the helical axis propagates perpendicular to the director.

Nuclear magnetic resonance spectroscopy is a powerful tool for investigating the details of interactions in liquid crystalline systems. Such information may be inferred from dipolar couplings and quadrupole splittings which provide information concerning molecular alignment (10, 11). This alignment, being determined by specific interactions, can be used to investigate those interactions. Of interest in this regard is the specificity of interactions between centres of optical activity, in particular the interactions between *d,l* isomers of simple molecules and an optically pure centre (*d* or *l*) of a micellar constituent. Work with *d* and *l* alanine in a mesophase prepared from optically resolved sodium decyl-2-sulphate has demonstrated the feasibility of this approach (7).

Recently, twisted nematic mesophases prepared from potassium *N*-dodecanoylalaninate have been described (4) and these materials provide suitable systems to work with. They are easily prepared in optically pure form and are readily obtained chemically pure by recrystallization.

Experimental

The *N*-dodecanoylalanine used in this study was prepared from commercially provided *l* and *d,l*-alanine by reaction with dodecanoyl chloride, as has been described (12), and that procedure differs little from the procedure utilized here. The purity of the amide was monitored by ^{13}C magnetic resonance, which indicated that several recrystallizations from petroleum ether (60–80) were required in order to remove dodecanoic acid. The product was made alkaline with KOH to provide the potassium *N*-dodecanoylalaninate, which was recrystallized three times from ethyl acetate/ethanol. It was necessary to take care that solutions were not made excessively basic since hydrolysis occurred to give potassium dodecanoate, which was not readily separated from the desired product by recrystallization. The purity of the product was checked by ^{13}C nmr and, if potassium dodecanoate was detected, the free amide was regenerated by acidification and purification carried out before recycling to the salt.

The liquid crystalline samples were prepared by weighing the various components into test tubes with a constriction in the centre. The tubes were then sealed and a homogeneous material formed by repetitively warming and centrifuging through the constriction. The liquid crystalline materials so prepared were transferred to nmr tubes, which were then sealed.

Table 1 provides the compositions of the various samples used in this study. For preparation B of this table, samples were prepared so that they proceeded from the racemic amphiphile to optically pure amphiphile in a stepwise manner. Two mesophases of composition C were prepared, C_1 from the racemic amphiphile and C_2 from the optically pure amphiphile.

The nmr measurements were made at 303 K. This slight warming of the samples allowed alignment in the nmr spectrometer to proceed at a relatively much more rapid pace, thus considerably shortening the spectrometer time required for this study. Variable temperature studies were performed on several samples and no unexpected behaviour was observed. For this study, ^1H, ^2H, alkali metal ion, and halide ion nmr spectra were obtained using a 400-MHz nmr spectrometer.

TABLE 1. Compositions used to form the various mesophases utilized in this study. Compositions are given in percentages by weight

Sample	KDDA[a]	Decanol	D_2O	Salt
A	22.70	6.38	70.92[b]	
B	27.81	5.94	66.25[b]	
C	26.85	6.04	60.40[c]	6.04 CsCl, 2.67 NaOAc

[a]KDDA refers to potassium *N*-dodecanoylalaninate which was changed in a stepwise manner from the racemate to the *l*-detergent.
[b]D_2O contains NaCl, 1%; LiCl, 0.67%; CsCl, 1.6%; RbCl, 1%; *d,l*-alanine, 0.5%; and *l*-alanine, 0.5% by weight.
[c]D_2O contains *d,l*-alanine, 0.67% and *l*-alanine, 0.17% by weight.

Various samples used in this study were investigated by microscopy using polarized light. All observations were made at ambient temperature ≈294 K and samples were contained in unsealed CAMLAB microslides or between a microscope slide and a cover slip. Concentration gradients were obtained when water evaporated at the exposed edge of the samples. This allowed mesophases that are adjacent, in the phase diagram, to the nematic (or twisted nematic) to be identified.

The pitches of the helical axis in the cholesteric materials were measured by laser diffraction. The wavelength of the light from the laser used was 6.328×10^{-5} cm. The samples used in the diffraction measurement were generally the same as those used for obtaining nmr spectra. Such highly aligned samples gave very sharp diffraction bands. The temperature of the samples was controlled by placing them in a brass block suitably drilled for water flow, sample placement, and an optical path. The temperature was then controlled with circulating water from a thermostated water bath. The temperature of the brass block was determined to within 0.1° using a calibrated thermocouple thermometer.

Results and discussion

Micelle structure

Two samples were prepared according to composition C of Table 1. One sample was prepared from potassium *N*-dodecanoyl-*d,l*-alaninate, the second from the corresponding *l* detergent. The samples were placed individually on microslides, covered with a coverslip, and investigated with a microscope. The first sample initially showed a schlieren texture which, following spontaneous alignment of the nematogen, became pseudo isotropic, characteristic of the nematic disk-like lamellar mesophase. The second sample provided the fingerprint texture associated with a twisted nematic mesophase. Both samples dried from the edges of the coverslip to give pseudo isotropic textures and oily, streak mosaic textures which are characteristic of lamellar layers. This indicates the nematic and twisted nematic mesophases are closely related to the lamellar phase, in accord with disk-like micelles (3). The pseudo isotropic textures of the nematic phases were investigated using a Bertrand lens and a full-wave retardation plate. The interference figures observed were consistent with positive birefringence, which is characteristic of disk-like rather than the cylindrical micelles (13). Similarly, investigation of the twisted nematic mesophase provided interference figures consistant with negative birefringence. This change in sign of birefringence with introduction of twist is characteristic of thermotropic materials (14).

The sign of the diamagnetic anisotropy of mesophases prepared from the resolved detergent was established by obtaining

TABLE 2. Quadrupole splittings and dipolar couplings observed from various components of the mesophase

Detergent[a,b]			Water[a,c]					
$\Delta\nu_{ND}$	D_{HCH_3}	D_{HH} (CH_3)	$\Delta\nu_{Li}$	$\Delta\nu_{Na}$	$\Delta\nu_{Cs}$	$\Delta\nu_{Cl}$	$\Delta\nu_{D_2O}$	D_{HH} (CH_3)
17.8	0.245	−0.535	0.49	5.30	0.25	2.17	0.27	0.056

[a]All splittings are in kHz. The maximum deviation from the average was ±5% for any component. Splittings are independent of the proportion of optical resolution of the chiral detergent.
[b]Detergent splittings were obtained for the headgroup only; signs of splittings are relative.
[c]The CH_3 dipolar coupling is from the alanine methyl group.

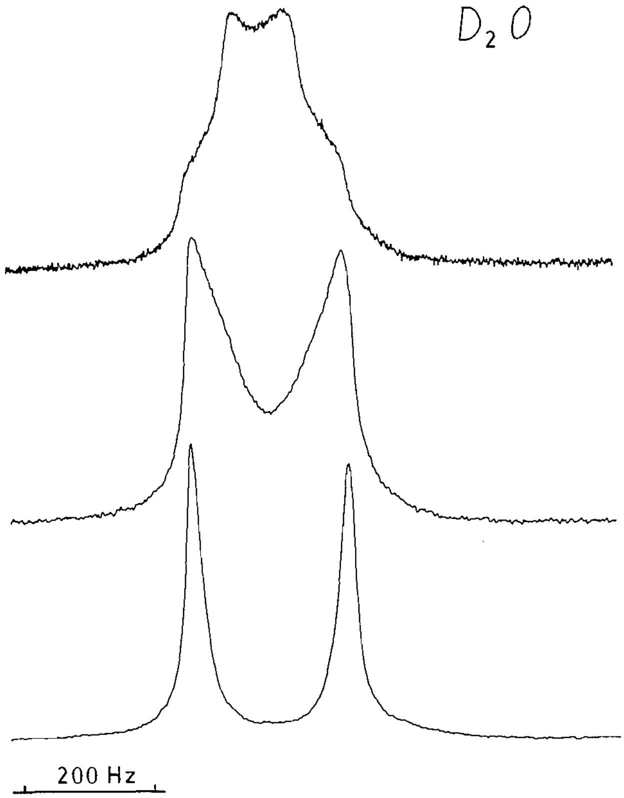

FIG. 1. Deuterium nmr spectra showing the change in deuterium signal as the twisted nematic mesophase progressively aligns in the magnetic field of the nmr spectrometer.

^{2}H nmr spectra from the D_2O immediately after placing a sample in the nmr spectrometer and at later time intervals. The first spectrum in a series typically showed a slight distortion from a true powder spectrum because a spectrum could not be obtained rapidly enough to eliminate all contributions from partially aligned material. Except for this, the first spectrum is characteristic of a random orientation of microcrystallites, while the others showed the development of signal intensity corresponding to alignment parallel to the magnetic field axis. The diamagnetic anistropy is therefore positive. Figure 1 shows the progressive effects of increasing alignment on the nmr powder spectrum. Signal intensity develops at the extremes of the spectrum, a result caused by the spontaneous alignment of the director along the magnetic field axis.

The above experiment could not be repeated for the racemate since it was found to align too quickly in the nmr spectrometer to provide a powder spectrum. However, when the sample was placed in an iron-core spectrometer and allowed to orient while spinning, a sharp D_2O doublet was obtained, as was a well-resolved alanine spectrum. This can only occur if the diamagnetic anistropy is negative, a result in accordance with that previously reported for this mesophase (4). The twisted nematic and nematic mesophase clearly are of opposite diamagnetic anisotropies. The mesophase prepared from the racemate consists of disk-like lamellar micelles of negative diamagnetic anisotropy, is nematic in character, and is designated as N_D^-.

An interesting aspect of these materials is the behaviour as a range of samples were prepared for which the amphiphile varied from pure potassium *N*-dodecanoyl-*l*-alaninate to the racemic compound. It was found that the samples prepared from the racemic detergent were highly fluid and aligned rapidly in the nmr spectrometer, while those prepared from the *l* material were significantly more viscous and aligned slowly in the spectrometer. Samples of intermediate compositions showed a gradual change in viscosity on proceeding stepwise from the racemic to the *l* detergent. It seems clear that this behaviour is related directly to the induced twist since measurements of the headgroup alignment, both at the amido position (given by the deuterium quadrupole splitting) and at the methyl group (given by the HH dipolar splitting), were constant throughout the range of *d,l* to *l* amphiphiles. Such constancy in alignment was also observed for the alkali metal and halide ions incorporated into the mesophase and for the D_2O solvent. The *d* and *l*-alanine also contained in the mesophase showed a constant average alignment although, in this case, *d* and *l*-alanine gave independent spectra that coalesced into one for the racemic detergent mesophase. The averages obtained for the various measured parameters are given in Table 2. Deviations from the average are less than 5%, dependent on the sample.

Figure 2 shows the change in twist ($1/P$) as a function of the proportion of *l* detergent and also the % change in alignment of the methyl group of the *d* and *l*-alanine from the averaged alignment for the two isomers, $\Delta s\%$. The behaviour of the twist with proportion of *l* detergent is similar to that previously reported (4). The change in pitch induced by change in temperature (Fig. 3) is quite surprising since the pitch increases with increase in temperature. This is in direct contrast with thermotropic cholesteric liquid crystals where, except in certain mixtures, the pitch always decreases with increase in temperature (14). It is also seen from Fig. 3 that the difference in the alignment of the *d* and *l*-alanines increases with increase in temperature.

For cholesteric thermotropic mesophases, two mechanisms have been proposed for the variation of twist with temperature (14). Both are based on the increase in thermal motion which leads to an increase in molar volume. This increase in molar volume affects the structure of the helix by either increasing (*i*) the intermolecular distance along the helix axis, thus increasing

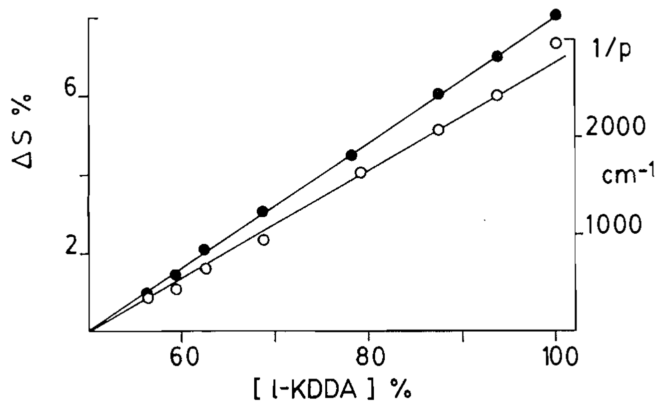

FIG. 2. The magnitude of the twist ($1/P$) induced in the mesophase as the amphiphile is changed in a stepwise manner from the racemate to the *l* derivative (○). The corresponding percentage change from the average alignment of the *d* and *l* isomers of alanine incorporated into the mesophase is also shown (●).

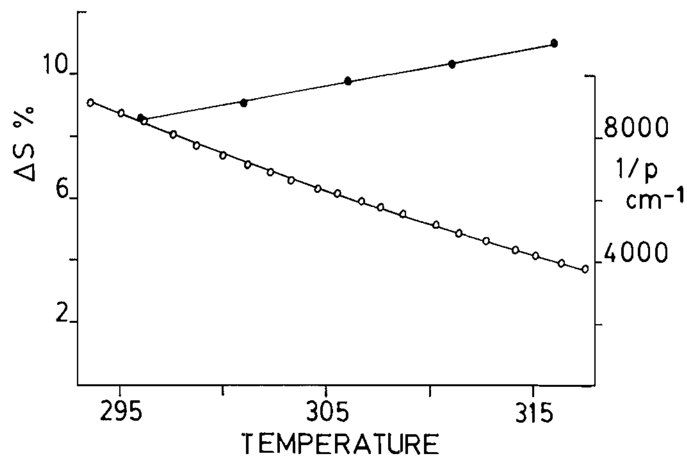

FIG. 3. The effect of temperature on twist (○) and on the difference in alignment of *d* and *l*-alanine is depicted (●).

the pitch, or (*ii*) by increasing the average displacement angle of the director of one nematogen with respect to the next, therefore decreasing the pitch. Although in principle the first mechanism could account for the observations obtained here, the explanation does not seem likely, at least on a molecular basis, because of the structure of a nematic lyotropic mesophase itself.

This mesophase consists of disk-like fragmented lamellae dispersed into an aqueous medium and interacting strongly with that medium via the polar headgroups of the individual detergent molecules. The individual micelles are separated by the interstitial water and will tend to stay separated since the micelles carry an electrostatic charge. If the effect of the asymmetry within one micelle is transmitted through the intervening aqueous solution to a second micelle by way of pairwise interactions (2) then a mechanism similar to the first, proposed for thermotropic mesophases, might be operative.

There is evidence to suggest that the micellar surface on the molecular level does not appear asymmetric from a distance. For instance, the individual components of racemic serine, tartaric acid, and other chiral molecules that are very hydrophilic in nature do not provide well-separated nmr spectra corresponding to the individual isomers.[1] On the other hand, slightly more hydrophobic species such as alanine do provide individual spectra. This indicates that the mechanism giving rise to the individual spectra is one of direct contact; a *d* to *l* interaction is different from an *l* to *l* interaction and this is reflected in the nmr spectrum where the dipolar coupling provides a direct measure of this difference.

On the basis of the argument advanced here, an increase in temperature of the mesophase should lead to a greater difference between the two spectra from *d* and *l*-alanine. As the temperature is increased, alanine will have an increased tendency to partition into the micelle and thus spend more time in contact with the optical centre of the individual amphiphiles. The increasing difference between the two spectra is clearly observed as shown by Fig. 3.

These results from solute molecules demonstrate that information concerning chirality within the micellar surface is not efficiently transmitted into the interstitial water of the mesophase. This conclusion provides little support for the pairwise interaction model, which suggests that specific interactions between molecules within different micelles generates the twist (2). The possibility of distorting a micelle into a chiral shape was also suggested by those authors but rejected tentatively on the basis of cholesteric behaviour versus distribution of chiral molecules within the micelle. However, a distortion model has been advanced by other workers (4) and distortion is supported by the work here.

The distortion model proposed here has the following salient features. The individual micelles are distorted into a chiral shape. Chiral micelles aggregate to form domains. The helical axis propagates along the major axis of the micellar aggregates. The twist characteristic of each domain is the same as that obtained by the twist measurements on the macroscopic sample.

The above characteristics are supported by several lines of evidence. The mesophase becomes progressively more viscous and requires longer periods of time in the nmr spectrometer before sharp nmr transitions are obtained as one proceeds in a stepwise fashion from the *d,l* to *l* amphiphile. This implies that increase in viscosity is caused by a progressive stabilization of a domain structure, although it could be a consequence of the different symmetry in the two materials. There is no evidence to suggest a significant change in micelle size. Indeed the constancy of the measured parameters in Table 2 seems to preclude such changes. The diamagnetic anisotropy determined for the mesophase prepared from the *l*-alaninate is opposite in sign to that determined for the racemate. Since the helical axis generated by the chiral amphiphile is parallel to the magnetic induction, it follows that the principle axis of the diamagnetic anisotropy tensor is parallel to the helical axis. This axis is the local alignment axis and as such is the director axis for the mesophase, rather than an axis attached to the individual micelles, as in the racemic material. This situation arises because the intermicellar forces generating the twist are strong enough that the micelles do not act as individuals when a magnetic field is applied; instead, the aggregates of micelles rearrange as the structural unit. The behaviour of the nematic and cholesteric materials is best pictured by considering two powder spectra, the first, derived from the racemic materials (nematic) having some specified width, the second, corresponding to the chiral material (cholesteric) having a width one-half that for the racemate. As alignment is allowed to

[1] A. S. Tracey and K. Radley, unpublished results.

proceed, the first powder spectrum grows at the maxima of the powder spectrum, 90° orientation, while the second spectrum grows at the extrema of the powder spectrum, corresponding to 0° orientation. When alignment is complete the two spectra are indistinguishable. This description is in accordance with all observations.

The decreasing pitch with decrease in temperature reflects the operation of a process similar to that of mechanism (*i*) described for the thermotropic mesophases. The individual twisted miceles within each domain pack closer together as temperature decreases. This shortens the pitch because the distance along the helix axis corresponding to one complete rotation of micelle directors is decreased as the micelles become closer together.

The decrease in mesophase viscosity with rise in temperature and the corresponding faster rates of alignment could reflect a smaller domain size as temperature is raised, but more probably it just reflects the fact that there is more thermal motion. This is supported by the fact that there is a memory associated with these materials. If a sample is aligned at 30°C in the nmr spectrometer, then removed, and laser diffraction used to measure its pitch (also measured at 30°C), a sharp diffraction pattern is obtained. With change in temperature, by say ±10°C, the diffraction bands are significantly broadened. When the sample is returned to 30°C, sharp diffraction bands are again obtained.

It is suggested that these liquid crystals be designated Ch_D^+ to specify that they are cholesteric mesophases of positive diamagnetic anisotropy originating from disk-like fragmented lamellae.

Conclusions

Lyotropic mesophases prepared from aqueous solutions of potassium *N*-dodecanoyl-*l*-alaninate and its racemate have been studied. A model for cholesteric behaviour in these systems has been proposed.

Microscope studies shows that the nematic mesophase prepared from the racemic amphiphile is composed of disk-like lamellae. With increasing optical purity of amphiphile, individual disk-like fragments develop a chiral shape which, through interactions with adjacent micelles, induces the formation of aggregates of micelles. In conjunction with this aggregation, the diamagnetic anisotropy changes from negative to positive. This change reflected the fact that the director for the mesophase has become the axis of the domain along which the helix propagates rather than the directors of the micelles themselves.

The alignment of the individual micelles is insensitive to the development of domains, a conclusion in accordance with the observation that quadrupole splittings and dipolar couplings from components incorporated into the aqueous region and from the amphiphiles of the micelles remain constant, independent of whether the amphiphile is racemic or optically resolved.

PETER JAMES SMITH, KANCHUGARAKOPPAL S. RANGAPPA, and KENNETH CHARLES WESTAWAY. Can. J. Chem. **63**, 100 (1985).

Secondary α-deuterium kinetic isotope effects have been determined for the elimination reactions of 2-phenylethyl halides with *tert*-butoxide in *tert*-butyl alcohol at 40°C in the presence and absence of the crown ether 18C6. The second-order rate constant k_2 and the normal $(k^H/k^D)_\alpha$ effect remained constant when the *tert*-butoxide concentration was varied for reaction of the iodo and bromo compounds. However, both the magnitude of k_2 and the secondary α-deuterium isotope effect were significantly dependent on [t-BuO$^-$] when chlorine and fluorine are the leaving groups. It is noteworthy that $(k^H/k^D)_\alpha$ is *inverse* for the reaction of both the chloro and fluoro compounds at "low" base concentrations and normal at "high" base concentrations. These results are discussed in terms of both *syn*- and *anti*-elimination pathways promoted by various associated and dissociated base species. It is suggested that the $(k^H/k^D)_\alpha$ effect may be useful as a criterion for determining the stereochemistry of E2 elimination reactions.

PETER JAMES SMITH, KANCHUGARAKOPPAL S. RANGAPPA et KENNETH CHARLES WESTAWAY. Can. J. Chem. **63**, 100 (1985).

Opérant à 40°C et en présence ou en l'absence de l'éther couronne 18C6, on a déterminé les effets isotopiques cinétiques secondaires des deutérium en α sur les réactions d'élimination des halogénures de phényl-2 éthyles par la *tert*-butylate dans l'alcool *tert*-butylique. Dans les cas des composés iodés ou bromés, la constante de vitesse du deuxième ordre (k_2) ainsi que l'effet normal $(k^H/k^D)_\alpha$ demeurent constants lorsqu'on fait varier la concentration du *tert*-butylate. Toutefois, lorsque les groupes nucléofuges sont soit le fluor ou le chlore, l'amplitude de k_2 ainsi que l'effet isotopique secondaire des deutérium en α varient d'une façon importante avec la concentration de l'ion *tert*-butylate. Il est notable que, pour les réactions des composés fluorés ou chlorés à de "basses" concentrations de base, la valeur $(k^H/k^D)_\alpha$ est *inverse*; toutefois, à des concentrations "élevées" de base, cette valeur est normale. On discute de ces résultats en fonction de voies d'éliminations *syn* et *anti* qui sont favorisées par diverses espèces basiques associées et dissociées. On suggère que l'effet $(k^H/k^D)_\alpha$ pourrait être un critère utile pour déterminer la stéréochimie des réactions d'éliminations E2.

[Traduit par le journal]

The elimination reaction of the 2-arylethyl derivatives with different leaving groups Y, $ArCH_2CH_2Y$, has been extensively studied (1–6) under a variety of solvent/base conditions. It has been established that the majority of the reactions proceed by way of the E2 mechanism following the *anti* pathway (5,7). Experimental studies (8–14) have demonstrated that the structures of the respective E2 transition states vary significantly in accord with theoretical predictions (15–20).

The reaction of the 2-arylethyl quaternary ammonium ions with base has been shown to have considerable carbanionic character at the E2 transition state (1,11,21), while the corresponding reaction of the 2-phenylethyl halides has been considered (11,16) to involve a more central E2 transition state where the extent of the carbon–hydrogen and carbon – leaving group bond rupture processes has progressed in a more synchronous fashion.

In order to gain a direct measure of the relative amount of hybridization change at the α carbon at the E2 transition state (double-bond character), we have determined the secondary α-deuterium kinetic isotope effects for the reaction of the 2-phenylethyl halides with *tert*-butoxide in *tert*-butyl alcohol at 40°C, eq. [1].

$$[1]\quad PHCH_2CH_2X + t\text{-BuO}^- \xrightarrow{t\text{-BuOH}} PHCH{=}CH_2$$
$$X = F, Cl, Br, I$$

[1]Author to whom correspondence should be addressed.

The reactions, which were shown to give the styrene product in 100 ± 1% yield, were studied under pseudo-first-order conditions where the *tert*-butoxide concentration was at least in twenty-fold excess. The progress of the reactions was determined by monitoring the product spectrophotometrically (λ_{max} = 248 nm). The analysis was done after the reaction solutions had been quenched at appropriate times with a dilute solution of sulfuric acid in 95% ethanol. This was done to eliminate the appreciable absorption of *tert*-butoxide ion at this wavelength. For reactions involving the crown ether 18C6, the reference cell in the spectrophotometer contained a solution of potassium *tert*-butoxide and the crown ether 18C6 in *tert*-butyl alcohol, both at the same concentrations as used in the kinetic experiments in order to compensate for the absorption of the complexed t-BuOK at 248 nm.

The second-order rate constants for the reaction of the 2-phenylethyl halides with different *tert*-butoxide concentrations in *tert*-butyl alcohol, both in the absence and presence of the crown ether 18C6, are given in Table 1 along with the observed values of the secondary α-deuterium kinetic isotope effects, $(k^H/k^D)_\alpha$. The theoretical maximum values (22–25) of the isotope effect corresponding to complete hybridization change from sp^3 to sp^2 at the transition state for the different leaving groups are also included.

It is generally considered that the reaction of the 2-phenylethyl halides with ethoxide in ethanol proceeds by way of the E2 mechanism (13,26–29). Since a plot of log k_2 (rate con-

*For two deuteriums.
†The error in the isotope effect is calculated using the formula:

$$\text{Error} = \pm(k^H/k^D)\,[(\Delta k^H/k^H)^2 + (\Delta k^D/k^D)^2]^{1/2}$$

where Δk^H and Δk^D are the standard deviations for the rate constants for the undeuterated and deuterated reactants, respectively.

stants found at "high" base concentration) for reaction with *tert*-butoxide in the present study against log k_2 (EtO$^-$) (30) is linear,[2] it is reasonable to conclude that reaction with *tert*-butoxide ion also proceeds via the concerted mechanism.

It is seen (Table 1) that the second-order rate constants for both the iodo and bromo[3] substrates do not change significantly when the [t-BuO$^-$] is doubled. However, there is a significant increase in k_2 in the reactions of the chloro and fluoro compounds when the *tert*-butoxide concentration is increased within certain limits; i.e., for the bromo compound, k_2 = 1.92×10^{-2} and 1.99×10^{-2} M^{-1} s^{-1} when [t-BuO$^-$] = 0.01688 and 0.03376 M, respectively, while for the fluoro compound $k_2 = 8.11 \times 10^{-5}$ and 9.80×10^{-5} M^{-1} s^{-1} when [t-BuO$^-$] = 0.1767 and 0.4066 M, respectively.

Addition of the crown ether 18C6 to the reaction of the chloro compound leads to the expected large increase in the magnitude of the second-order rate constant; i.e. $k_2 = 5.43 \times 10^{-4}$ M^{-1} s^{-1} when [t-BuO$^-$] = 0.01320 M while k_2 = 0.413 M^{-1} s^{-1} when [t-BuO$^-$] = 0.01296 M in the presence of 0.01377 M 18C6. It is known (31) that 18C6 complexes the potassium of t-BuOK converting the ion pair or larger aggregates to non-associated ions which are more effective (stronger) bases.

It is seen that the secondary α-deuterium isotope effects, like the k_2 values, do not vary with base concentration for the reactions of both the iodo and bromo compounds. On the other hand, both the α-deuterium isotope effects and the k_2 values, for the reactions of both the chloro and fluoro compounds with t-BuO$^-$ in the absence of 18C6, vary over a particular range of *tert*-butoxide concentrations. Of particular significance, however, is the observation that the secondary α-deuterium isotope effects are *inverse* at low base concentrations. To our knowledge, this is the first example of an inverse secondary α-deuterium isotope effect in an elimination reaction proceeding via the one-step concerted E2 pathway.

The reactions of both the chloro and fluoro substrates with *tert*-butoxide ion at the "higher" base concentrations, Table 1, have normal secondary α-deuterium isotope effects. As well, when the crown ether is added to the reaction solutions containing "low" concentrations of *tert*-butoxide, where inverse α-d_2 effects are found, the observed isotope effects are normal and are similar in magnitude to those found at "high" base concentrations.

An approximate measure of the degree of double bond formation (extent of C—X bond rupture) at the transition state for reaction of the four substrates can be determined by comparing the observed α-deuterium isotope effects, found for reaction carried out at "high" base concentrations, with the calculated theoretical maximum values for each leaving group, Table 1. The percent of the theoretical maxima for the leaving groups are 7, 51, 62, and 25 for F, Cl, Br, and I, respectively. This variation in the extent of double-bond formation with a change in leaving group can be rationalized in terms of the More O'Ferrall (17) – Jencks (19) energy surface diagrams if it is considered that the reaction of the fluoro compound proceeds via an E1cb-like E2 transition state while the iodo substrate reacts via a more central E2 activated complex.[4]

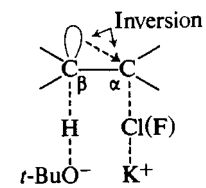
A reasonable explanation for the observed experimental results is that the reaction involving the best two leaving groups (I and Br) proceeds via the usual *anti* pathway at all base concentrations even though the extent of base association varies. The reactions involving the more electronegative (poorer) Cl and F leaving groups proceed via two distinct stereochemical pathways, the *anti* and *syn*, with the relative proportions of each pathway depending on the *tert*-butoxide concentration (32–34).

[2]The irreversible E1cb mechanism is also consistent with a linear plot. However, since it has been established (14, 39) that both the F and Br substrates react with t-BuO$^-$ in t-BuOH via the concerted E2 pathway, it is reasonable to conclude that all four substrates react via the same mechanism under these experimental conditions.

[3]Other workers (9, 39) also concluded that there was no significant drift in the second-order rate constants for reaction of the bromo compound in the t-BuO$^-$ in t-BuOH.

[4]A more detailed discussion can be found in a full paper to follow in this journal.

When the *tert*-butoxide concentration is "low" and *t*-BuOK exists to a significant degree as an associated base (ion pair), reaction of both the Cl and F substrates proceeds via a *syn*-elimination pathway where the loss of the leaving group and the β-hydrogen are assisted by the *t*-BuOK ion pair. For such a transition state **1**, which is expected to have considerable carbanionic character (35), sufficient negative charge could develop on the β-carbon so that inversion occurs at both C_β and C_α. Such a pathway is consistent with the observed inverse isotope effects which arise from an *increase* in the C_α—H out-of-plane bending frequencies at the transition state (22–25, 36, 37, and footnote 4).



1

The effect of *tert*-butoxide concentration on the magnitude of both k_2 and $(k^H/k^D)_\alpha$ is shown by the data in Table 1 for the reaction of the chloro substrate. It is seen that both the rate constant k_2 and the magnitude of $(k^H/k^D)_\alpha$ initially increase from their values at "low" base concentration, when *tert*-butoxide concentration is increased, and level off at "high" base concentration. A possible rationalization of these results is that an increase in *tert*-butoxide concentration leads to a decrease in the amount of associated base species (which favours *syn*-elimination) and an increase in the concentration of multiple ions such as negatively charged ion triplets, $(RO^-)_2M^+$, which may be considered as a free base (38). The bulky triple ion would presumably favour *anti*-elimination, for steric reasons, and a normal isotope effect and an increased rate of reaction would be observed because the triple ion is a stronger base than the associated species.

The effect of the addition of 18C6 to the reaction medium is consistent with the above explanation. The crown ether will complex the potassium ion and liberate a free *tert*-butoxide ion, an effective base, which removes the β-hydrogen via the *anti*-pathway. It is interesting to note that the magnitude of the secondary α-deuterium isotope effect is essentially the same for reaction of the chloro compound at "high" base concentration (triple ion as abstracting base) and under conditions of "low" base concentration in the presence of the crown ether where free *t*-BuO^- acts as the base. This suggests that the transition state structure is similar for reaction under the above conditions, in agreement with studies on the reaction of 2-phenylethyl bromide with dissociated and associated *tert*-butoxide ions (39). Finally, it appears that an inverse secondary α-deuterium kinetic isotope effect may be useful as a criterion for determining the stereochemistry of E2 elimination reactions; i.e., an inverse isotope effect is consistent with a *syn*-elimination and a normal kinetic isotope effect is diagnostic of a normal *anti*-coplanar E2 mechanism.

Conformational features of bisphenol-A polycarbonate

P. R. SUNDARARAJAN
Xerox Research Centre of Canada, 2660 Speakman Drive, Mississauga, Ont., Canada L5K 2L1

Received December 23, 1983

This paper is dedicated to the 10th anniversary of the Xerox Research Centre of Canada

P. R. SUNDARARAJAN. Can. J. Chem. **63**, 103 (1985).

Conformational energies have been estimated for the segments of the bisphenol polycarbonate chain, using the Lennard-Jones and Hill's empirical force field type of functions. It is found that the conformation of the carbonate group, defined by the torsion angle ζ, is restricted to the range of 45° to 65°. The rotations χ and χ' of the methyl groups also show similar limited flexibility. However, accessible conformations of the diphenyl propane (DPP) segment, defined by torsion angles ϕ and ψ, span a wide area of the (ϕ,ψ) surface, with the restriction that the rotations ϕ and ψ be synchronized such that $\phi + \psi \approx 90°$ or 270°. These features explain the slow thermal crystallization behaviour of the polycarbonate chains. The variability of the conformations of the repeat unit is illustrated with a series of figures.

P. R. SUNDARARAJAN. Can. J. Chem. **63**, 103 (1985).

Faisant appel aux fonctions empiriques de Lennard-Jones et Hill, de type champ de force, on a évalué les énergies conformationnelles de segments de la chaîne de polycarbonate de bisphénol. On a trouvé que la conformation du groupe carbonate, définie par l'angle de torsion ζ, est restreinte à l'intervalle de 45 à 65°. Les rotations χ et χ' des groupes méthyles présentent une flexibilité limitée analogue. Cependant, les conformations accesibles du segment diphénylpropane (DPP), telles que définies par les angles de torsion ϕ et ψ couvrent une plus grande proportion de la surface (ϕ,ψ); on doit toutefois imposer la restriction à l'effet que les rotations ϕ et ψ doivent être synchronisées de telle sorte que $\phi + \psi \approx 90°$ ou 270°. Ces caractéristiques expliquent le comportement des chaînes de polycarbonate lors de leur cristallisation thermique lente. On illustre la variabilité des conformations de l'unité de base à l'aide d'une série de figures.

Introduction

The bisphenol-A polycarbonate (BPAPC), represented schematically in Fig. 1, possesses a high T_g (~150°C) and T_m (~280°C). Its transparency in the film form and its dimensional stability contribute to its utility as a commercial material. Crystallization of BPAPC by thermal methods is difficult. Often, annealing for over 200 h at 190°C is required in order to crystallize it (1, 2). This inability to readily crystallize, combined with the dimensional stability, makes it a suitable material for various commercial applications.

The slow crystallizing tendency of BPAPC has been interpreted (3) as due to the fact that the thermal crystallization has to be preceded by certain morphological changes in the polymer matrix: preliminary ordering of the chains or a change in the polymer conformation. This characteristic of BPAPC makes it an ideal candidate for studies on the polymer glassy state. Several investigations on thermal transitions, molecular motion, etc., have been reported in the literature (4-6). Although thermal crystallization of BPAPC is a slow process, it crystallizes readily upon exposure to vapours of organic solvents such as acetone, carbon tetrachloride, methanol, etc. (7-9), or in the presence of plasticizers (10, 11).

Bonart (12) reported the crystal structure of BPAPC, with a unit cell of dimensions a = 12.3 Å, b = 10.1 Å, c (chain axis) = 20.8 Å, and γ = 84°. Two monomer units comprise the fiber identity period and four chains are contained in the unit cell, in the space group C_s^2.

Conformational energy calculations on segments of the BPAPC chain are reported here. These were undertaken in order to determine the extent of freedom of rotation enjoyed by the segments of the molecule and to verify if the concept of unhindered rotation for the phenyl and methyl groups is valid. Similar calculations have been reported by Tonelli (13). An appreciation of the accessible conformations and flexibility via the conformational energy calculations would lead to the understanding of not only the crystallization behavior, mechanical properties, etc., but also the type of interactions, at the short range level, which precipitate when the chain is associated with small molecule plasticizers. For example, Dulmage *et al.* (14) have studied the structure of the complex of aryl-substituted thiapyrylium salt with 4,4'-isopropylidenediphenyl-bis-phenyl carbonate, a model compound for BPAPC.

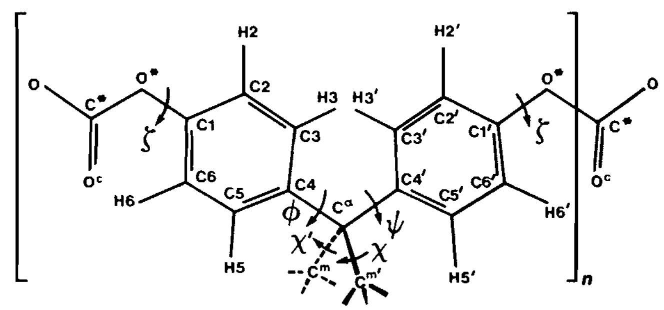

FIG. 1. Schematic representation of a segment of the BPAPC polycarbonate chain. The planar conformation is shown here. The relevant torsion angles are marked.

While this work was in progress, a paper on the optical anisotropy of polycarbonate analogs was published by Flory and co-workers (15). The calculations of optical anisotropy were based on the conformations of the carbonate and the diphenyl segments.

Energy calculations

1. *Geometrical parameters*

A portion of the polycarbonate chain is shown in Fig. 1, with the *trans-trans* conformation of the carbonate group. Calculations of Williams and Flory (16) indicate that the *cis-trans* or *trans-cis* forms are of low incidence. Hence, calculations described here were carried out with the *trans-trans* form exclusively. The bond lengths and bond angles used in this study are given in Table 1. These (Set I) were taken from

TABLE 1. Bond lengths and bond angles used in this study*†

	Length (Å)			Angle (deg)	
Bond	Set I	Set II	Atoms in bond	Set I	Set II

* See Fig. 1 for designation of atoms.
† Set I from refs. 16 and 17. Set II from ref. 15 and footnote 1.

Bowen and Sutton (17), and Williams and Flory (16). Also included (Set II) are the values used by Erman *et al.* (15) based on a crystal structure analysis of diphenyl carbonate.[1] Both sets of parameters have been used in the present calculations. The bond lengths and bond angles differ between Set I and Set II. The partial double bond character of the O—C* and C*—O* bonds leads to a bond length of 1.34 Å on the average (Set I). This distance was found to be 1.32 Å in the crystal structure of diphenyl carbonate.[1] The average of the O*—C1 bond length, taken from various structures, is 1.36 Å, whereas it is 1.42 Å in the above crystal structure. Quite significant are the differences in the bond angles of the carbonate group. Such large differences affect the results of the calculations, as discussed below. The geometrical parameters derived by Dulmage *et al.* (14) are not used here. Comparing them with the parameters reported by Erman *et al.* (15), it is found that there are appreciable differences in the bond angles of the carbonate group as well as the 2,2-diphenyl propane segment. The bond angles in the phenyl group, for example, vary from 120° to as small as 111.8°, and a pronounced nonplanarity of the phenyl is indicated.

The conformation of the carbonate group with respect to the phenyl was determined by varying the torsion angle ζ around the O*—C1 bonds (cf. Fig. 1). The planar *trans* conformation of the C*—O* and the C1—C2 bonds defines $\zeta = 0°$. The *trans* planarity about the C*—O* bond was maintained. The relative conformations of the contiguous phenyl groups were determined as a function of the rotations ϕ and ψ about the C4—C$^{\alpha}$ and C$^{\alpha}$—C4′ bonds. The eclipsed conformation of the C4—C3 and the C$^{\alpha}$—C4′ bonds corresponds to $\phi = 0°$. Likewise, for $\psi = 0°$, the C4—C$^{\alpha}$ bond eclipses the C4′—C3′. In these calculations, the minimum energy conformations of ζ and (ϕ,ψ) were determined independently.

Considering the appendage of the C$^{\alpha}$—C^{m} bonds, when the angle θ = C4—C$^{\alpha}$—C4′ is enlarged to 112°, if C^{m}—C$^{\alpha}$—C4 and C^{m}—C$^{\alpha}$—C4′ are kept at tetrahedral values, the angle C^{m}—C$^{\alpha}$—C$^{m'}$ would decrease to 106.7°. In order to distribute the strain equally between all the bond angles involving C^{m}, we impose the condition that C^{m} and C$^{m'}$ be attached to C$^{\alpha}$ such that the bond angles C^{m}—C$^{\alpha}$—C$^{m'}$, C^{m}—C$^{\alpha}$—C4, C^{m}—C$^{\alpha}$—C4′, C$^{m'}$—C$^{\alpha}$—C4, C$^{m'}$—C$^{\alpha}$—C4′ are equal, and denoted by θ'. Incorporating this condition in eq. 2 of Suter and Flory (18) leads to:

$$[1] \quad \cos\theta' = \frac{1 \pm \sqrt{1 + 4x}}{2x}$$

where:

$$[2] \quad x = \frac{4}{(1 + \cos\theta)}$$

With this formula, if $\theta = 112°$, θ' will be 108.96°. The methyl hydrogens were kept at mutually tetrahedral angles. One of the methyl hydrogens eclipsing the C$^{\alpha}$—C4 bond defines $\chi = 0°$. For each value of (ϕ,ψ), the torsion angles χ and χ' defining the positions of the methyl hydrogens were varied at intervals of 10° each and the positions corresponding to minimum energy were included in subsequent calculations.

TABLE 2. Parameters used for the potential energy functions

	L–J function			Hill's function	
Atom	α (Å^3)	N	R (Å)	ϵ (kcal mol^{-1})	$d^*/2$ (Å)
C	0.93	5	1.70	0.116	1.50
C^{ar}	1.23	5	1.85	0.060	1.95
C^{carb}	1.23	5	1.70	0.033	1.85
H	0.42	0.9	1.20	0.060	1.50
O	0.70	7	1.50	0.070	1.54
O^{carb}	0.84	7	1.50	0.070	1.54

2. *Energy functions*

The nonbonded interactions were estimated using the Lennard–Jones (L–J) 6–12 potential function and the Hill's empirical force-field function. The L–J function of the form:

$$[3] \quad E_{nb}(i, j) = -\frac{A_{ij}}{r_{ij}^{6}} + \frac{B_{ij}}{r_{ij}^{12}}$$

has been extensively used in the conformational analysis of various types of polymers (19–21). The parameters A_{ij} and B_{ij} were evaluated in the usual manner (19–21), using the polarizability (α), effective number of electrons (N), and the van der Waals radius (R_0). The values of α, N, and R_0 used in the present calculations are given in Table 2.

The Hill's function is similar to the Buckingham 6-exp function and is given by (22):

$$[4] \quad E_{nb} = \epsilon_{ij}\left[8.3 \times 10^{5} \exp\left(-13.6\frac{r_{ij}}{d_{ij}^*}\right) - 2.25\frac{r_{ij}}{d_{ij}^*}^{-6}\right]$$

Here ϵ_{ij} is an "energy" parameter which is taken to be the geometric mean of parameters ϵ_i and ϵ_j for the interacting atoms, and d_{ij}^* is the characteristic distance derived as an arithmetic mean of the diameters d_i^* and d_j^* assigned to the atoms.

The Hill's function was modified into a one-parameter function by Kitaigorodsky (23). The Hill's function has been widely used in the molecular mechanics calculations on organic small molecules (24) and has been incorporated in standard minimization computer programs. The parameters ϵ_i and d_i^* used in the present calculations are given in Table 2 and were taken

[1] D. Y. Yoon and P. J. Flory, cited in ref. 15.

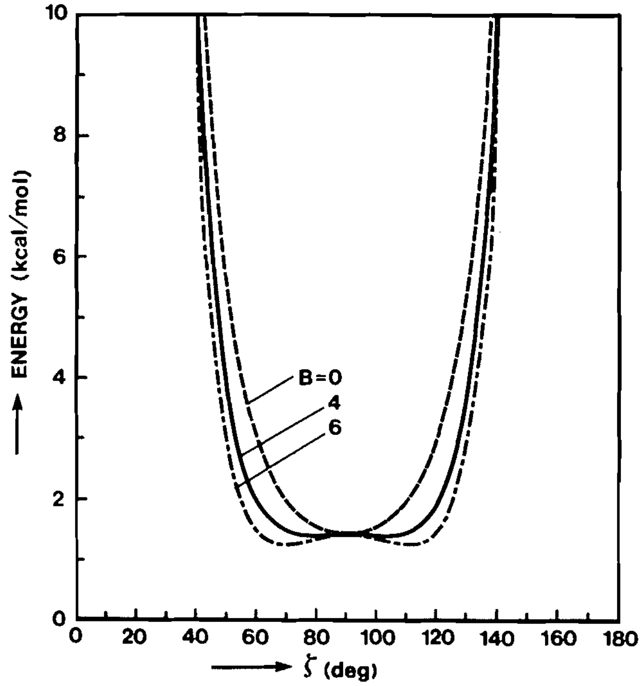

FIG. 2. The variation of energy with ζ is shown, for select values of *B*. The Lennard–Jones function was used here. The angle C*—O*—Cl is 113° (Set I parameters, see text).

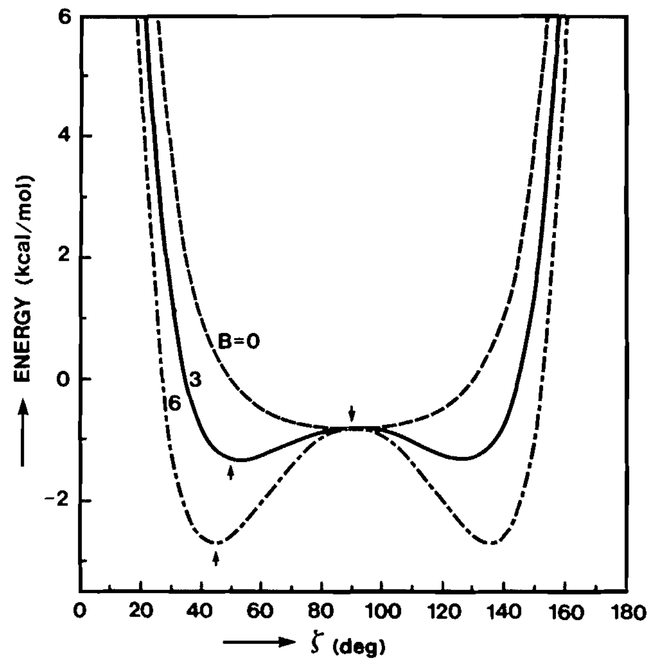

FIG. 3. The variation of energy with ζ is shown for select values of *B*. The Lennard–Jones function was used. The angle C*—O*—Cl is 121° (Set II parameters, see text).

from Allinger *et al.* (24), Hummel and Flory (25), and Andose and Mislow (26).

Another contribution to be considered for the estimation of the energies is that due to electron delocalization. The nonbonded interaction between O^c and the *ortho* hydrogen (H6 in Fig. 1) would oppose coplanarity of the carbonate group with the phenyl and would lead to a preferred value of $\zeta = 90°$. On the other hand, the electron delocalization would favour the planar conformation. Hence, the combined contribution due to both of these effects has to be included. The electron delocalization energy was estimated according to (25):

$$[5] \quad E_{\mathrm{deloc}} = -B\cos^2\zeta$$

where *B* is a parameter, in kcal mol^{-1}. An inherent threefold torsional potential with a barrier of 3 kcal mol^{-1} was assigned to the C—CH_3 bonds. The torsional potential was not included for rotations ϕ and ψ due to the negligible barrier for such a rotation in toluene.

Results and discussion

The calculations showed that the energies corresponding to ϕ and ψ in the accessible region are unaffected by the preferred ranges of ζ. Although the rotation of the phenyl via, for example, the ϕ would affect the carbonate group to the extent that its preferred relative disposition with respect to the phenyl has to be maintained, the interactions which arise between the two phenyl groups are determined by only the rotations ϕ and ψ. Hence the rotations (ϕ,ψ) and ζ can be treated independently, for the present discussion.

1. *The carbonate group*

The carbonate group is planar and predominantly *trans*. While the electronic delocalization would favour the coplanarity of the carbonate group with the plane of the phenyl, the steric repulsion between the carbonyl oxygen and the *ortho* CH group would oppose the coplanarity. In the crystal structure (27) of *p*-phenylenediacrylic acid diphenyl ester, $\zeta = 65°$, and in the structure of diphenyl carbonate,[1] $\zeta = 45°$.

The variation of energy with ζ, calculated with Set I geometry and L–J function, is shown in Fig. 2. The angle C*—O*—Cl is 113° here. While, as expected, the minimum in energy occurs at $\zeta = 90°$ with $B = 0$, it shifts to 80° and 70° with $B = 4$ and 6 kcal mol^{-1} respectively. Due to the predominant interaction between O^c and H6, a value of $B = 18$ is required in order to obtain the minimum at $\zeta \approx 50°$. The calculations of Hummel and Flory (25) on model compounds of *p*-phenylene polyesters and polyamides show that values of *B* in the range of 3 to 7 kcal mol^{-1} are required to reproduce the crystallographically observed torsion angles. A similar range of *B* can be expected to be valid for the carbonate group. The high value of 18 kcal mol^{-1} required to obtain a minimum at $\zeta = 50°$ is a consequence of the small value of 113° assigned to the angle C*—O*—Cl.

The variations of energy with ζ, calculated with Set II geometry (Flory parameters) using the L–J and Hill's functions, are shown in Figs. 3 and 4 respectively. The variations of some of the nonbonded distances with ζ are shown in Fig. 5. Note that with Set II geometry, the angle C*—O*—Cl is 121°. Comparison of Figs. 3 and 4 shows that with $B = 6$ kcal mol^{-1}, minima occur at $\zeta = 50°$ and 45° using the Hill's function and the L–J function, respectively. Figure 5 shows that the distances O^c - - - H6, C* - - - H6, and O* - - - C6 increase reasonably close to the sum of the van der Waals radii or the *characteristic* distance d^* in the range of $\zeta = 45$ to 55°. Comparison of the results obtained with Set I and Set II geometries shows that an enlargement of the angle C*—O*—Cl to nearly 121° is necessary to obtain the minimum in energy at $\zeta \approx 50°$, with values of *B* in the range of 4–6 kcal mol^{-1}. In the crystal structure[1] of diphenyl carbonate, the angle C*—O*—Cl is 121°, whereas it is 117.6° in the structure of *p*-phenylenediacrylic acid diphenyl ester (27). In any event, a value greater than 113° (which

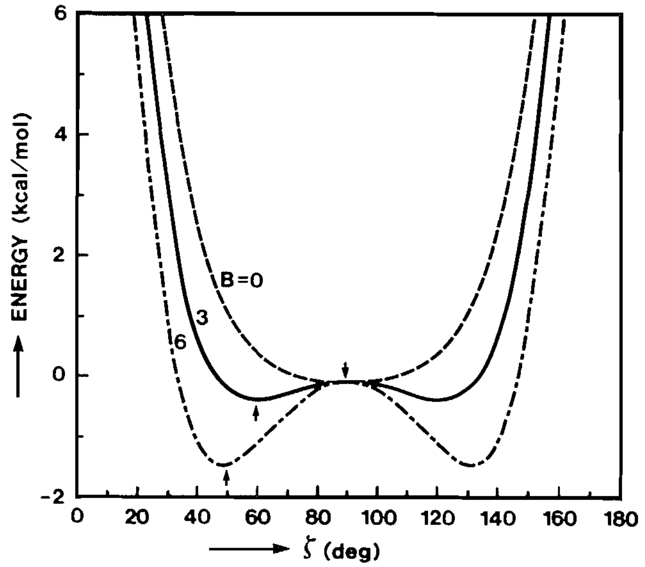

FIG. 4. Same as Fig. 3, but with Hill's functions for evaluating nonbonded interactions.

was used by Williams and Flory (16)) is indicated. The present calculations as well as the crystal structure studies cited above show that the preferred value of ζ is limited to 45–65°.

With B = 6 kcal mol^{-1}, and the Hill's function, the energy values at ζ = 0, 50, and 90° are 14, −1.5, and −0.1 kcal mol^{-1}, respectively, leading to a barrier of 15.5 kcal mol^{-1} at ζ = 0° and 1.4 kcal mol^{-1} at ζ = 90°. Similarly, with the L–J function and B = 6 kcal mol^{-1}, the energies at ζ = 0,45, and 90° are 20.2, −2.7, and −0.8 kcal mol^{-1}, respectively, resulting in a barrier of 22.9 kcal mol^{-1} at ζ = 0° and 1.9 kcal mol^{-1} at ζ = 90°. Adjustments of geometrical parameters could lower these energies somewhat. Pochan *et al.* (28), on the basis of dielectric relaxation measurements, deduced an activation energy of 17.7 kcal mol^{-1} for combined (sub T_g) β and γ relaxations of BPAPC and 8.1 kcal mol^{-1} for γ relaxation of bisphenol-A – diphenyl carbonate. The latter was associated with the carbonate group. Massa and Rusanowsky (29) reported a value of 9.8 kcal mol^{-1} for the γ relaxation. Although Yee and Smith (30) obtained 13 kcal mol^{-1} for the γ relaxation, they have shown that this relaxation is not attributable to the carbonate group exclusively, but rather to the monomer unit as a whole. Hence, it would seem that unambiguous comparison of the theoretical and experimental values of the barrier corresponding to the carbonate group is not possible at this time. However, the above experimental values for the activation energy can perhaps be accounted for by combining the energy barrier of ~2 kcal mol^{-1} mentioned above for the carbonate group at ζ = 90° and the barrier for the phenyl rotation discussed in the next section.

The results reported by Flory and co-workers (15) show that with the same geometrical parameters (Set II), and the Hill's function, the minimum occurs at ζ = 45° with B = 2 kcal mol^{-1}. However, according to our calculations shown in Fig. 4, when using a value of B = 2 kcal mol^{-1}, the minimum occurs at ζ = 65° and a value of B > 6 is needed to derive a minimum at ζ = 45°. It seems that these differences are due to the allowance made for bond angle variations for each ζ, in the work of Flory *et al.* (P. J. Flory, private communication).

2. *Conformation of the 2,2-diphenylpropane (DPP) segment*

The conformation of the DPP segment is defined by the

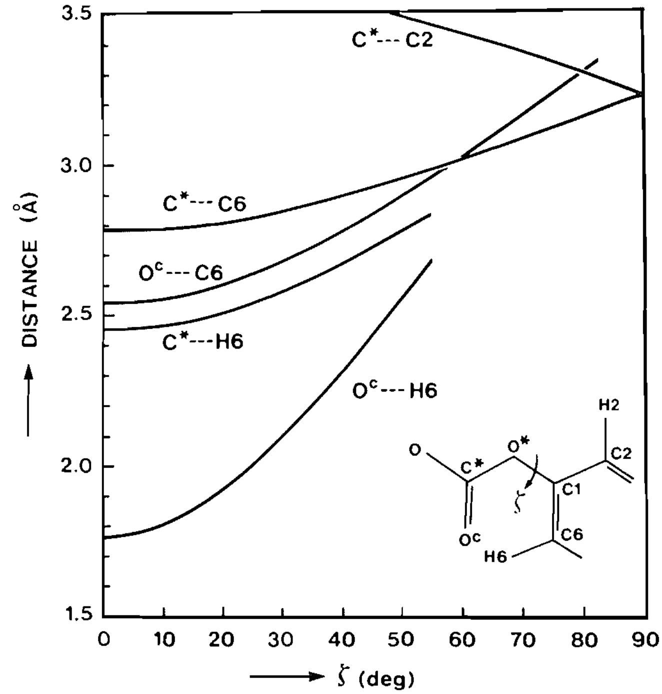

FIG. 5. The variations of significant nonbonded distances with ζ are shown here.

torsion angles ϕ and ψ (Fig. 1). The coplanar conformation of the phenyls incurs severe overlap of the *ortho* hydrogens. When $\phi = \psi$ = 0°, the distances H3---H3′, C3---H3′ (or C3′---H3) and C3---C3′ are 0.22, 1.3, and 2.2 Å respectively.

Energies calculated for the DPP segment in terms of ϕ and ψ are shown in Figs. 6 and 7, for the L–J and the Hill's functions respectively. The exact Flory geometry (Set II) was used. The torsion angles χ and χ' were varied for each (ϕ,ψ) and the methyl hydrogens were kept in their minimum energy conformation. It is seen from Figs. 6 and 7 that the minimum in energy occurs at (ϕ,ψ) = (45°,75°) and (75°,45°) with the L–J function and at (ϕ,ψ) = (25°,75°) and (75°,25°) with the Hill's function. Further, it is seen from Fig. 7 that all the conformations for which $\phi + \psi \approx$ 90° or 270° are within 1 kcal mol^{-1} from the minimum. The calculations with the L–J function (Fig. 6) also show a similar feature, with $\phi + \psi \approx$ 120° or 240°. The small variations in energy over a large domain are responsible for slight shifts in minima and the allowed range when different potential functions are compared. At the intervals of 5° in ϕ and ψ chosen for these maps, 35% of the conformational space is within 1 kcal mol^{-1} in Fig. 6 and 25% in Fig. 7. In the crystal structure (31) of diglycidyl ether of bisphenol-A, the values of (ϕ,ψ) are (64.3°,49°). This conformation occurs within the contour of 0.5 kcal mol^{-1} in Fig. 6. The energy corresponding to (ϕ,ψ) = (90°,90°) is 7.5 kcal mol^{-1} in Fig. 6 using the L–J function and 30.9 kcal mol^{-1} in Fig. 7, with Hill's function, relative to the respective minima. The value obtained with Hill's function is perhaps too high due to the higher emphasis that the parameters for this function place for the H---H interaction (see below). Combining the 7.5 kcal mol^{-1} for the barrier at (ϕ,ψ) = (90°,90°) and the ~2 kcal mol^{-1} derived for the barrier at ζ = 90°, the total energy is close to the value of ~9.0 kcal mol^{-1} deduced experimentally for γ relaxation. This theoretical energy is the maximum value of the barrier, as obtained by the present calcu-

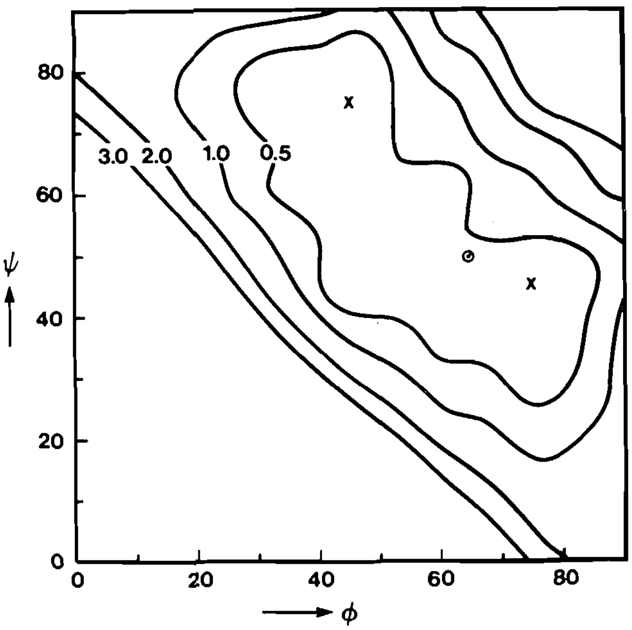

FIG. 6. The iso-energy contours are shown for the DPP segment, in terms of rotations φ and ψ, with respect to the minimum marked by ×. The L–J function was used. The symmetrically related part of the map can be seen as in Fig. 8. The conformation corresponding to the crystal structure of diglycidyl ether of bisphenol-A is marked by ⊙.

lations. A least-energy path for the conformational transition is possible, as discussed later.

Although intuitively one would expect the minimum to occur at (φ,ψ) = (60°,60°), the shifts of the minima from such a position in Figs. 6 and 7 need clarification. In Fig. 6, the difference in energy between (φ,ψ) = (45°,75°) and (60°,60°) is only 0.2 kcal mol^{-1}, and cannot be attributed to any unique predominant interaction. However, in Fig. 7, the energy difference between (φ,ψ) = (25°,75°) and (60°,60°) is 4.7 kcal mol^{-1}. The higher energy of the latter is not due to unfavorable interactions between the skeletal atoms but is due to those involving the methyl hydrogens. For purposes of discussion, let us denote the hydrogens attached to C^m by H_a, H_b, and H_c, and those appended to C^{m} by H_a', H_b', and H_c'. For (φ,ψ) = (25°,75°), with the hydrogens kept at positions corresponding to the minimum energy, the distances H_b---H_5', H_b'---H_5, and H_c---H3 are 2.13, 2.11, and 3.05 Å, respectively. These distances reduce to 2.01, 2.01, and 2.21 Å, respectively, at (φ,ψ) = (60°,60°), contributing to the energy difference of ~4 kcal mol^{-1}. Such a large contribution to the energy was traced to the nature of the Hill's function. The parameters chosen (24–26) (Table 2) for this function accentuate the interactions involving the hydrogen atoms, compared to the L–J function. For H---H interaction, R = 1.2 Å and $d^*/2$ = 1.5 Å are used. For a H---H distance of 2.4 Å, energies of −0.12 and 0.42 kcal mol^{-1} are obtained with L–J and Hill's functions respectively. However, at a distance of 2 Å, the energy is 0.36 kcal mol^{-1} with the L–J function and 4.2 kcal mol^{-1} with Hill's function. Thus, for the contact pairs listed above for (φ,ψ) = (25°,75°) and (60°,60°), the emphatic contribution to the energy of the latter is due to the nature of the Hill's function and the parameters chosen for the hydrogen atom. Adjustment of the parameters to establish correspondence between the two functions is not attempted here.

The (φ,ψ) map corresponding to a value of 112° for the

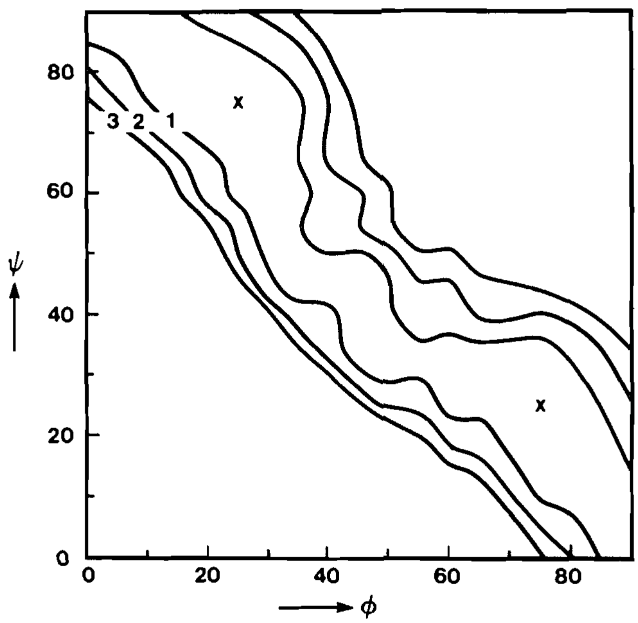

FIG. 7. Same as Fig. 6, but with Hill's function.

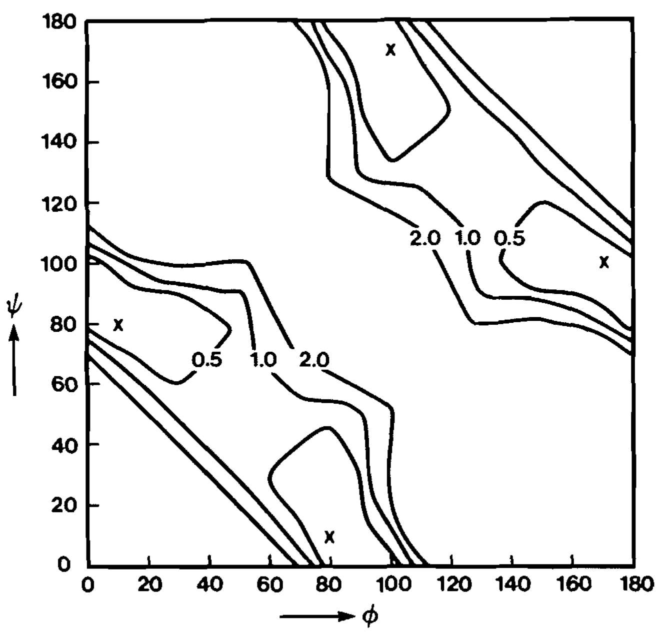

FIG. 8. Same as Fig. 6, but with a value of 112° for the C4—C^{α}—C4′ bond angle.

skeletal bond angle C4—C^{α}—C4′, constructed using the L–J function, is shown in Fig. 8. It is seen here that the minimum has shifted to (φ,ψ) = (10°,80°) and (80°,10°). The energy at (φ,ψ) = (90°,90°) is 7 kcal mol^{-1}. The large accessible area remains similar to those in Figs. 6 and 7. In fact, 49% of the conformations on the (φ,ψ) space are within 1 kcal mol^{-1} from the minimum. The small variation in energy (within 1 kcal mol^{-1}) over a large domain of the (φ,ψ) surface is responsible for the shift of the position of the minimum when either the potential functions or the geometrical parameters are changed.

The large accessible area on the (φ,ψ) surface qualifies the DPP segment to be classified as a fairly flexible portion of the polycarbonate chain. However, the rotations are *not* unhindered. The accessible conformations are such that the rota-

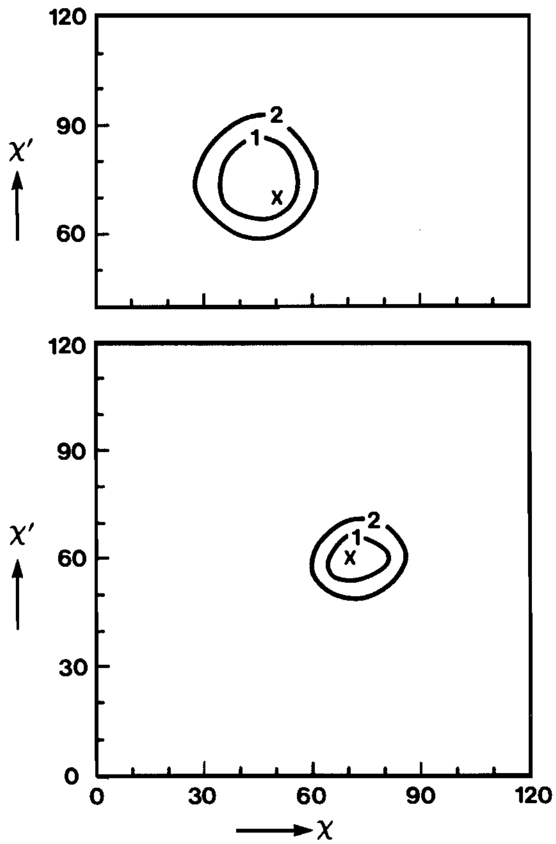

FIG. 9. The iso-energy contours are shown, for the methyl group rotation, in terms of χ and χ'. The (ϕ,ψ) values are (60°,40°) for the bottom figure and (0°,90°) for the top. The L–J function was used here.

tions ϕ and ψ have to be synchronized to meet the condition that $\phi + \psi \approx 90$–120° or 240–270°. In considering the molecular motion of the phenyls and their reorientation in BPAPC, the π flip or reorientation through small diffusive steps have been suggested as possibilities (32, 33). Figures 6–8 show that the reorientation of the phenyls can occur with coordinated rotations, along the path defined by $\phi + \psi \approx 90°$, without having to overcome a high energy barrier.

The energies associated with the rotations χ and χ' of the methyl groups are shown in Fig. 9, for two select values of (ϕ,ψ), using the L–J function. It is seen that with (ϕ,ψ) = (60°,40°), the minimum occurs at (χ,χ') = (70°,60°), which corresponds to the staggered disposition of the C—H bonds with respect to the contiguous skeletal bonds. With (ϕ,ψ) = (0°,90°), the minimum occurs at (χ,χ') = (50°,70°). The energy contours in Fig. 9 also show that within an energy of 2 kcal mol^{-1}, only a range of about 20° is accessible for χ and χ', for each (ϕ,ψ) conformation. The various values of (χ,χ') obtained with L–J and Hill's functions for conformations with $\phi + \psi = 90°$ are given in Table 3. This table shows that with the L–J function, χ and χ' vary from (50°,70°) to (70°,50°) as the values of (ϕ,ψ) change from (0°,90°) to (90°,0°). A larger range of (40°,80°) to (80°,40°) is obtained with the Hill's functon. In the above ranges, the energy of interaction of the methyl groups with the rest of the molecule varies very little with the L–J function, whereas a change in energy of 4.1 kcal mol^{-1} is noted with the Hill's function. These results show that while a certain range of conformations is accessible to the methyl hydrogens, the variations in χ and χ' depend on the values of ϕ and ψ.

TABLE 3. Values of χ and χ' derived for minimum energy positions of methyl hydrogens, for a few select values of ϕ and ψ

	L–J function		Hill's function	
ϕ,ψ (°)	χ,χ'	E*	χ,χ'	E*
0,90	50,70	0.2	40,80	0
10,80	50,70	0	50,80	1.1
20,70	50,70	0.2	50,80	2.0
30,60	60,70	0	60,80	2.8
40,50	70,70	0.3	70,80	4.1
50,40	70,70	0.3	80,70	4.1
60,30	70,60	0	80,60	2.8
70,20	70,50	0.2	80,50	2.0
80,10	70,50	0	80,50	1.1
90,0	70,50	0.2	80,40	0

* The energies, in kcal mol^{-1}, are given relative to the lowest energy (χ,χ') conformation in each case.

Garfield (34) suggested, based on the results of wide-line nmr studies, that the motions of the methyl groups and phenyls are cooperative. Jones and Bisceglia (5) arrived at the same conclusion.

The energy map for the DPP segment, reported by Flory *et al.* (Fig. 6 of ref. 15), shows that the minimum occurs at (ϕ,ψ) = (46°,46°) $(\psi_A,\psi_B$ in the notation of ref. 15). The contours therein also imply that the rotations ϕ,ψ are highly restricted. This is in contrast to Figs. 6–8 presented here, which show that a wide range of ϕ,ψ is accessible. This difference has been traced to the fact that Flory *et al.* used a constant value of $\chi = \chi' = 6°$ for constructing the energy map (P. J. Flory, private communication), whereas, in the present calculations, χ and χ' were minimized for each ϕ,ψ conformation. Since Flory *et al.* were concerned with the averages $\langle\cos^2 \phi\rangle$ and $\langle\cos^2 \psi\rangle$, this difference is not of significant consequence in their results on the optical anisotropy.

The inability of polycarbonate to crystallize readily is rationalized by the large accessible conformational domain derived from the present calculations. Further, the suggestion (3) that the chain has to adopt several intermediate conformations prior to crystallization is also supported by our work.

3. *Molecular shapes*

Robertson and co-workers (35) have discussed the nomenclature for the description of the conformations usually adopted by bridged diphenyls in crystal structures. These are generally described in terms of planar, butterfly, twist, and skew conformations as shown schematically in Fig. 10. None of the compounds studied so far by X-ray crystallography adopts the planar conformation, whatever the nature of the bridge atom: C, O, or S. This is mainly due to the repulsion between the *ortho* hydrogens as described earlier. Most diphenyls with ether linkage and sulfides adopt the skew and twist conformations; the ketones show only the twist conformation; the sulfoxides only the butterfly, sulfones the twist and butterfly, and methanes, the skew and twist. The reader is referred to the paper by Robertson and co-workers (35) for the identity of these compounds. These results show that the bridged diphenyls are found in a variety of conformations, depending upon both intra and intermolecular packing effects. The accessible conformations of the DPP segment of the BPAPC chain, discussed above, show that twist and skew conformations are

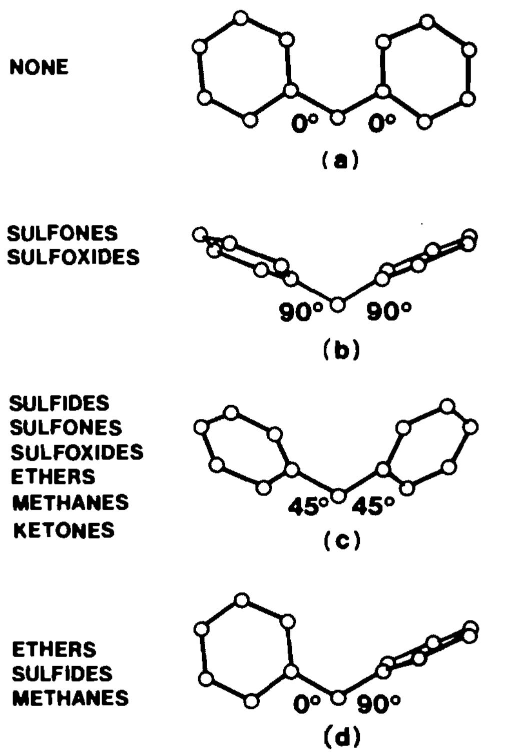

FIG. 10. Schematic representation of the nomenclature used for the description of the conformations of bridged diphenyls: (a) planar, (b) butterly, (c) twist, and (d) skew. The ideal (ϕ,ψ) values are marked (adapted from ref. 35).

possible. It is noteworthy that most of the compounds surveyed in ref. 35, with the C—C—C type linkage, occur along the zone defined by $\phi + \psi \approx 90°$.

The shapes of the segment of the BPAPC chain were drawn, in orthogonal projection, using a computer program developed for the Diablo Multiwriter. The shapes of one repeat unit of the BPAPC, for conformations with $\phi + \psi = 90°$, are shown in Fig. 11 (A–I). The (ϕ,ψ) corresponding to each shape is marked. These are only a few select conformations among those accessible to the repeat unit. Comparing with Fig. 10, the twist and skew shapes are obvious. Figure 11 clearly shows the variety of conformations which is accessible to the repeat unit in solution or in the amorphous state. With such a diversity of conformations, the long annealing time required for crystallization is understandable. The technique of molecular graphics is being used increasingly in conformational analysis of biopolymers, enzyme–substrate interactions, drug design, and organic synthetic chemistry. The variability in the shapes of the polycarbonate and similar chains can be best understood by such means.

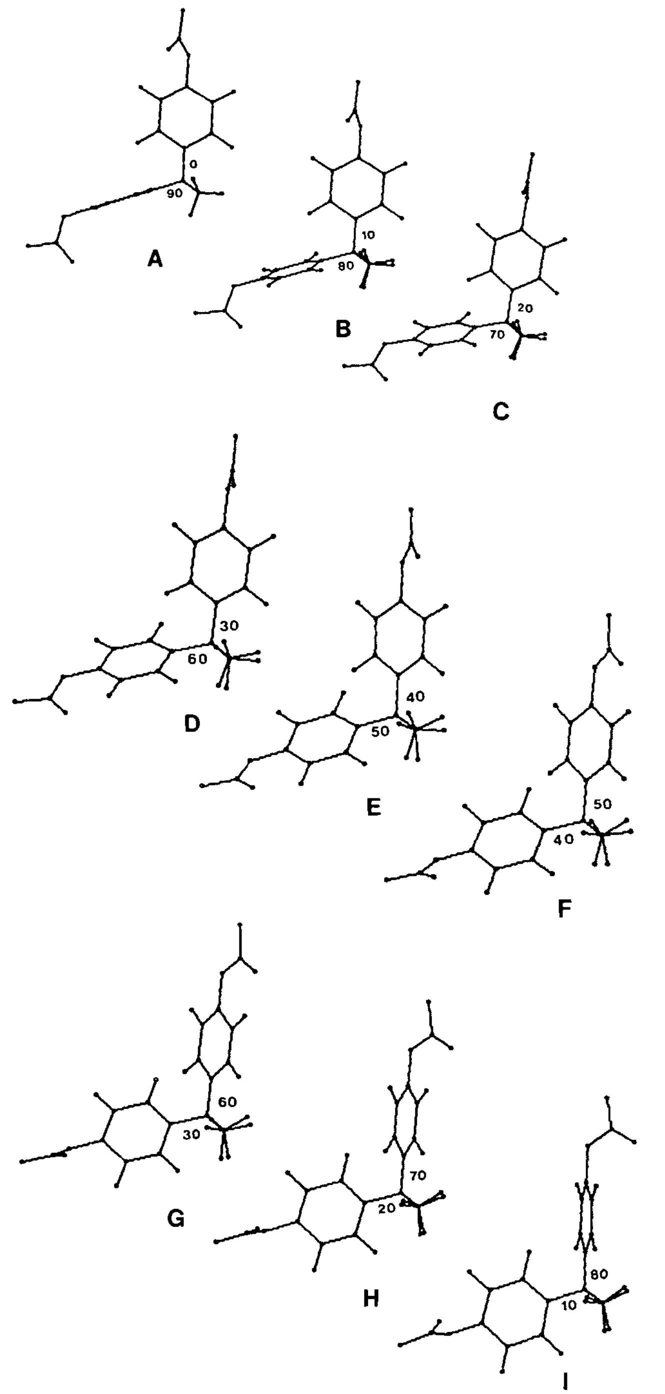

FIG. 11. (A–I): The variability of the conformation of the DPP segment is illustrated in terms of a series of shapes. The values of (ϕ,ψ) are marked. The molecule is shown in projection. The (χ,χ') conformations correspond to those derived using Hill's function (see Table 3).

Conclusions

The conformational calculations show that although the accessible area of the (ϕ,ψ) surface for the DPP segment is large, the rotations ϕ and ψ should be synchronized. Uninhibited free rotation is not possible. The carbonate group has a restricted freedom of rotation, to within 20°. The methyl group also has only a limited freedom of rotation. Free rotation is not indicated for these portions of the molecule. The slow crystallization upon annealing can be attributed to the conformational flexibility of the DPP segment, and the cooperativity needed for conformational rearrangement. The synchronized rotations of the phenyls can lead to diffusive reorientation. The general conformational features are discussed here and not the specific one pertaining to the crystal structure. The shapes of the repeat unit shown in Fig. 11 give pictorial representation to the stereochemical jargon.

CHRISTIANE COUTURE and ANTHONY JAMES PAINE. Can. J. Chem. **63**, 111 (1985).

The title reactions are an important class of copper mediated nucleophilic aromatic substitution processes, which constitute a useful tool in the molecular design and synthesis of small molecules. We report the results of extensive investigation of these processes, primarily focussing on cyanodeiodination (ArI + CuCN → CuI + ArCN). Among the interesting features of these processes are: (a) an unusual rate equation involving autocatalysis by CuI product; (b) retardation by both excess nucleophile (as KCN) and excess leaving group (as KI), which compete with ArX to complex with CuNu; (c) only cuprous nucleophiles are active (ligand exchanged products from cupric salts arise from prior redox equilibria which form CuNu); (d) the halogen effect is large ($k_I \sim 40-100\ k_{Br} \sim 300-5000\ k_{Cl}$) but the Hammett ρ value is zero; (e) *ortho*-alkyl groups do not hinder the reaction (and actually cause mild acceleration by relief of steric strain). Finally, the introduction of an *ortho*-COO^- group accelerates the reaction by a factor of 10^4-10^5, but the general features of the accelerated reactions are also the same, again indicating a common mechanism, with entropic acceleration by *ortho*-carboxylate. Both kinetic and thermodynamic factors were considered in detail, the latter apparently for the first time. Applications to practical syntheses are considered, and novel mechanistic models for these interesting processes are discussed.

CHRISTIANE COUTURE et ANTHONY JAMES PAINE. Can. J. Chem. **63**, 111 (1985).

Les réactions mentionnées dans le titre constituent une classe importante de réactions de substitutions nucléophiles aromatiques catalysées par le cuivre qui sont un outil utile pour la conception moléculaire et la synthèse des petites molécules. Nous rapportons les résultats d'une étude poussée de ces réactions au cours de laquelle on a mis l'accent, en premier lieu, sur la cyanodéiodation: (ArI + CuCN → CuI + ArCN). Parmi les caractéristiques intéressantes de ces réactions on peut noter, entre autre, le fait que: (a) ces réactions présentent une équation de vitesse inhabituelle qui implique une autocatalyse par le CuI qui est produit; (b) la vitesse de la réaction est retardée à la fois par un excès de nucléophile (comme le KCN) ou de nucléofuge (comme le KI) qui entre en compétition avec le composé ArX pour complexer le CuNu; (c) le fait que seuls les nucléophiles cuivreux soient actifs (les produits provenant d'un échange de ligands se forment au cours d'un équilibre rédox antérieur qui forme du CuNu; (d) l'effet des halogènes soit grand (k_I = 40 à 100 k_{Br} = 300 à 5000 k_{Cl}) alors que la valeur ρ de Hammett est égale à zéro; (e) les groupes alkyles en position *ortho* n'encombrent pas la réaction (et qu'ils provoquent en fait une légère accélération grâce à une diminution de la contrainte stérique). Finalement l'introduction d'un groupe COO^- en position *ortho* accélère la réaction par un facteur de 10^4 à 10^5; toutefois les caractéristiques générales des réactions accélérées sont les mêmes que les autres et ce fait indique l'existence d'un mécanisme commun qui subit une accélération entropique due à la présence du groupe carboxylate en *ortho*. On a considéré en détail les facteurs cinétiques et thermodynamiques; il semble que ces derniers ont été examinés pour la première fois. On considère les applications de ces réactions dans des synthèses pratiques et on discute de nouveaux modèles mécanistiques pour ces réactions intéressantes.

[Traduit par le journal]

Introduction

Aromatic substitution reactions are important tools in the molecular design and synthesis of small molecules. Substitution methodologies may be of electrophilic, nucleophilic, or radical character, the last of which is relatively rarely applied to synthetic problems. Electrophilic aromatic substitution (EAS) is the most common, and is supported by a wide literature. Nucleophilic aromatic substitution (NAS) usually requires a suitable leaving group, X, plus activation by electron-withdrawing substituents, which stabilize the intermediate negative charge in the classic addition–elimination mechanism (1). Nucleophilic aromatic substitution on unactivated rings is relatively rare, but may be effected in the presence of copper. There are two major classes of copper mediated reactions which are formal nucleophilic aromatic substitutions: copper catalysed reactions (known as Ullmann condensations), where copper is present as the metal, a salt, or an oxide; and copper ligand exchange reactions (1, 2). These reactions are fairly general, and some of the possibilities are shown in eqs. [1] and [2]. There is evidence that cuprous nucleophile species are intermediates in the catalytic reactions, and therefore, these processes likely share the same mechanism (3–5).

$$[1]\quad \mathrm{CuNu + ArX \rightarrow CuX + ArNu} \qquad \text{(ligand exchange)}$$

$$[2]\quad \mathrm{NuH + ArX \xrightarrow{Cu^+} ArNu + HX} \qquad \text{(catalysis)}$$

Nu = X, CN, SCN, OAc, OH, ArO, ArS, ArSe, ArNH, Ar_2N, Ar. . . .
X = I, Br, Cl.

Although these reactions have been known for many decades, there has been little systematic investigation of the reaction mechanism (2, 6, 7). The literature is characterized by questionable conclusions drawn with only a minimum of data, using relative yield measurements, or final product analyses (e.g. ref. 8) – techniques which cannot distinguish between rate and equilibrium effects (which, as will be shown, are quite important). In order to broaden mechanistic understanding of copper mediated NAS in general, and to improve its scope as a synthetic tool, we have begun by investigating the kinetically simpler ligand exchange reaction. In this case CuNu is a measurable reactant, rather than a hypothetical transient intermediate. In particular we focussed on copper mediated cy-

[1] Presented, in part at the 66th Canadian Chemical Conference, Calgary, Alberta as paper OR14-9 (June, 1983).
[2] Author to whom correspondence should be addressed.

anodeiodination (replacement of iodide with cyanide using cuprous cyanide) in detail, although we also examined a variety of other nucleophiles and leaving groups to ensure the generality of the work.

Experimental

Most substrates and products were commercially available and were purified by distillation or recrystallization to >99% purity by analytical hplc. 2,4,6-Tri-*tert*-butylbromobenzene was prepared by the method of Pearson *et al.* (9). Sodium salts of aromatic carboxylic acids were prepared by standard methods, and recrystallized from water.

Synthesis of 2,4,6-trimethyliodobenzene

Following the general procedure of Martin *et al.* (10), 2,4,6-trimethylbenzene (12.1 g; 0.10 mol), iodine (6.4 g; 0.025 mol), and ammonium persulfate (6.9 g; 0.031 mol) were added to a solvent consisting of acetic acid (135 mL), water (25 mL), and sulfuric acid (6 mL) in a 250-mL round bottom blask. The reaction mixture was stirred and heated at 80°C for 4 h, poured on ice (300 g), and worked up into methylene chloride. The coloured impurities were removed by elution through a short column of silica gel in hexane. The product was isolated from excess starting material by fractional distillation (bp 128°C/13 Torr) (1 Torr = 133.3 Pa) to give a low-melting white crystalline solid (7.1 g; 0.029 mol; 58% yield; mp 29.5–31°C (lit. (11) mp 29–30°C)). 2,4,6-Tri-*tert*-butyliodobenzene could not be prepared by this method.

*Synthesis of 2,4,6-tri-*tert*-butylbenzonitrile*

CuCN (0.48 g; 50 mmol) and 2,4,6-tri-*tert*-butylbromobenzene (0.20 g; 0.61 mmol) were heated in 50 mL DMA at 137°C for $4\frac{1}{2}$ days, then cooled and worked up into methylene chloride. The solvent was dried and evaporated to give a green oil which was chromatographed on silica gel, with hexane as eluent, to give impure white crystals (crude yield 0.10 g; 0.37 mmol; 60% yield). Pure product obtained by crystallization from MeOH (mp 150–151.5°C (lit. (12) mp 151–152°C)) had ir, ^{1}Hmr, Cmr, and ms consistent with the structure and the literature.

General kinetic method

Dimethylacetamide (DMA; Burdick and Jackson Company, Distilled in Glass grade) was the solvent selected. DMA from alternative suppliers gave the same results. Analytical hplc correction factors (KFs) were determined with reference to internal standard biphenyl (or *N,N*-diphenylformamide for the carboxylic substrate series), which gave the concentrations of substrate and product directly.

$$[\text{Compound}] = \frac{\text{Area counts compound} \times \text{KF compound} \times [\text{Internal STD}]}{\text{Area counts internal STD}}$$

Unfortunately, there was a relatively narrow operating window of reagent concentrations determined by the balance between the limited solubility of the cuprous nucleophiles and the requirement for moderately high iodobenzene concentrations to achieve a reasonable conversion rate. These windows were $[\text{CuCN}]_0 = 50–160$ mM and $[\text{PhI}]_0 = 15–45$ mM. Product cuprous iodide was less soluble and often precipitated from solution. For kinetic analysis, the following relationship was assumed: $[\text{CuNu}]_t = [\text{CuNu}]_0 - [\text{ArNu}]_t$.

Five or six reactions were usually conducted simultaneously in a temperature controlled oil bath fitted with independent magnetic stirrers. In a typical reaction CuCN (350 mg; 3.55 mmol) and biphenyl (internal standard; 3 mg; 0.02 mmol) were brought to temperature (usually 137°C) in 20 mL DMA. Iodobenzene (100 mg; 0.50 mmol in 1.00 mL DMA) was added and 10–20 aliquots (~50 μL) were taken from the reaction flask over 5–100% conversion. The aliquots were quenched in 68% CH_3CN/H_2O, filtered, and analysed by analytical hplc using a Varian 5020 liquid chromatograph, CDS 401 Vista data station, and 8055 auto-sampler (Column: Applied Science 3μ Excalibar adsorbosphere C_{18} or Spherisorb ODS reverse phase; 150 × 4.6 mm. Mobile phase: typically 68% CH_3CN/H_2O (+2% HOAc for carboxylate substrates); 1.5 mL/min. Detection: 254 nm and variable wavelength).

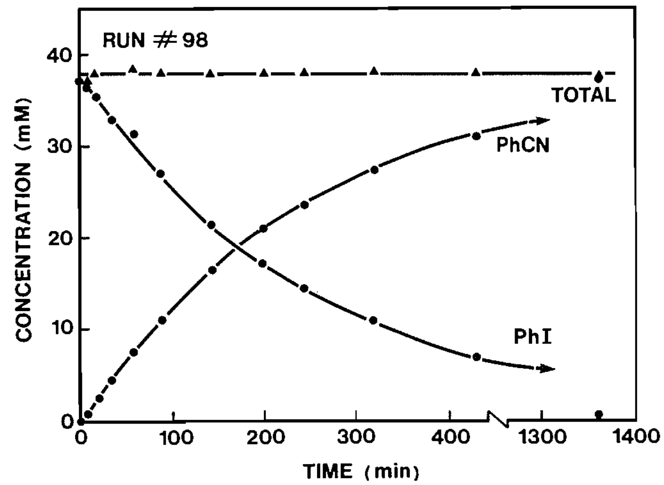

FIG. 1. Typical reaction profile for cyanodeiodination.

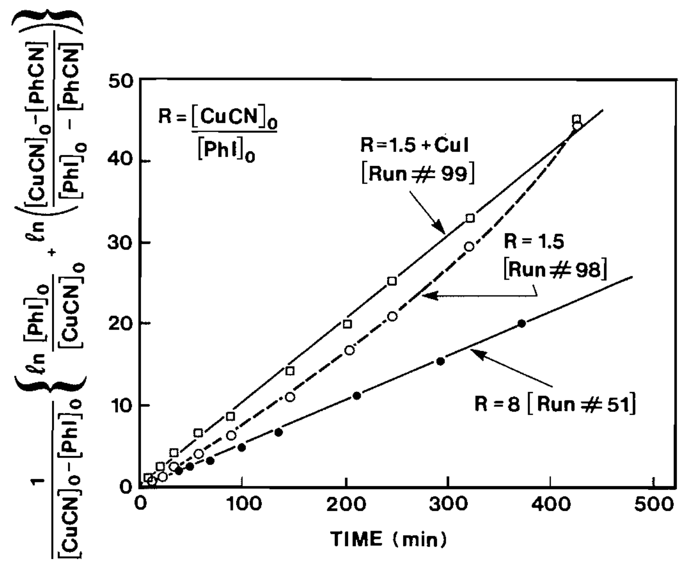

FIG. 2. Second-order kinetic plots for cyanodeiodination.

Analysis of kinetic results

The hplc data were corrected for thermal volume expansion of DMA (measured to be 1.2×10^{-3} K^{-1}) and used to prepare reaction profiles for over 170 runs (example in Fig. 1). These profiles were not well fit by the expected second-order kinetic expressions (see Fig. 2), so initial rates were determined over the first 10–30% of reaction from the slope, $k_{0,1}$, of plots of $-\ln [\text{ArX}]$ vs. time as follows.

$$[3] \quad \text{Initial rate} = (\text{d}[\text{ArCN}]/\text{d}t)_0 = k_{0,n+1}[\text{ArX}]_0[\text{CuCN}]_0^n$$

$$[4] \quad \text{Initial pseudo first-order rate constant} \equiv k_{0,1} = -\text{d}(\ln [\text{ArX}])/\text{d}t = \frac{(\text{d}[\text{ArCN}]/\text{d}t)_0}{[\text{ArX}]_0} = k_{0,n+1}[\text{CuCN}]_0^n$$

The order in CuCN, n, was determined from a log–log plot (Fig. 3) to be 0.64 ± 0.04. We have elected to represent the initial rate equation as 3/2 order ($n = 1/2$), so the initial 3/2-order rate constant is given by:

$$[5] \quad k_{0,3/2} = \frac{k_{0,1}}{[\text{CuCN}]_0^{1/2}} = \frac{-\text{d}(\ln[\text{ArX}])/\text{d}t}{[\text{CuCN}]_0^{1/2}}$$

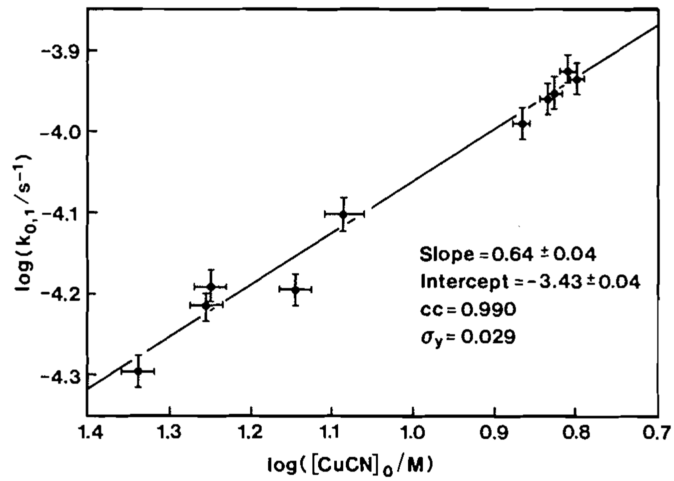

FIG. 3. Determination of the kinetic order in CuCN.

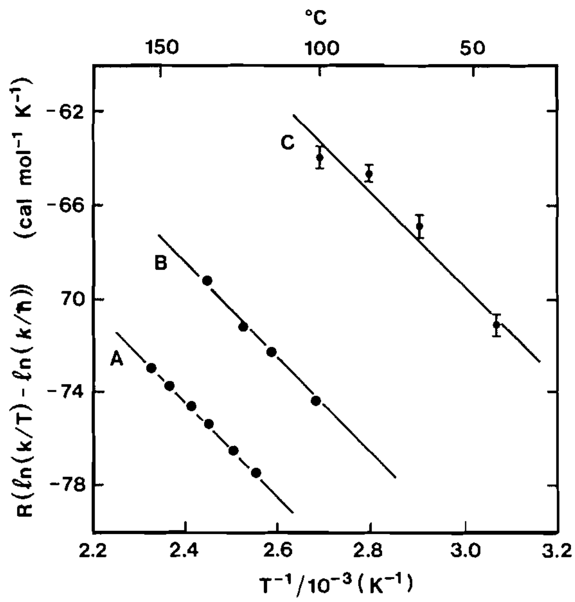

FIG. 4. Activation parameter plots for copper mediated cyanodehalogenations. (Labels A, B, and C correspond to the columns in Table 1.)

Unless otherwise noted, all rate constants presented in this work are the initial 3/2-order rate constants, $k_{0,3/2}$, in units of $L^{1/2}$ $mol^{-1/2}$ s^{-1}, and are designated simply as k, without subscripts.

Determination of activation parameters

Transition state theory gives the relation $k = \kappa(\mathrm{k}T/\hbar)$ [exp $(-\Delta G^{\ddagger}/RT)$], where k is the rate constant, κ the transmission coefficient, k the Boltzmann constant, and the other symbols have their usual meaning (13). Substitution of $\Delta G^{\ddagger}$ by $\Delta H^{\ddagger} - T\Delta S^{\ddagger}$, and reorganization of this equation leads to the linear relation in eq. [6], where the slope and intercept give the enthalpy and entropy of activation, respectively.

[6] $R[\ln (k/T) - \ln (\mathrm{k}/\hbar)] = (-\Delta H^{\ddagger}/T) + \Delta S^{\ddagger}$

$$y = mx + b; \quad x = 1/T$$

Activation parameter plots are shown in Fig. 4 and the results summarized in Table 1.

Competitive reactions

Some competitive reactions were performed in which the relative reactivity of A vs. B was obtained by extrapolating the measured product ratio $[P_A]/[P_B]$ back to time = 0, and correcting for the initial concentration of A and B as follows: $k_A/k_B = ([P_A]/[P_B])_0 \times ([B]_0/[A]_0)^m$, where $m = 1$ if A and B were aromatic halides, and $m = 1/2$ if A and B were cuprous nucleophiles.

TABLE 1. Summary of activation parameters for cyanodehalogenation

	A	B	C
ArX			$\Delta H^{\ddagger}$ (kcal mol^{-1})	20 ± 1	21 ± 3	19 ± 1
$\Delta S^{\ddagger}$ (cal mol^{-1} K^{-1})	−26 ± 2	−19 ± 5	−12 ± 4

Results

The rate equation

Second-order kinetic plots for cyanodeiodination exhibited upward curvature (see Fig. 2). This curvature is greater in reactions performed with nearly stoichiometric amounts of reagents ($R \equiv [CuCN]_0/[PhI]_0 \sim 1$) than in cases where a large excess of CuCN was employed (e.g. $R = 8$), which become almost pseudo-first order. Interestingly, the $R = 1.5$ (Run 98) and $R = 8$ (Run 51) lines in Fig. 2 appear to have the same *initial* slope, but the $R = 1.5$ line diverges upwards with time, indicating significant acceleration.

More than a dozen kinetic models were examined in an attempt to quantitatively describe the kinetics. Of these models, only two could rationalize upward curvature of this type:

[7] Model 1: $v = k_{3/2}[CuCN]^{1/2}[PhI]$; 3/2 order
RMS error ~ 1.5%

and (or)

[8] Model 2: $v = k_2[CuCN][PhI] + k_3[CuCN][PhI][CuI]$
RMS error ~ 0.3%

The 3/2-order model appears to best describe the initial rate, but the 3rd-order autocatalytic term in [CuI] in the second model (eq. [8]) is the only explanation for the slight accelerating effect of added CuI (*vide infra* and Table 2), as shown in Run 99 of Fig. 2. Run 99, saturated with added CuI, had an excellent 2nd-order plot ($v = k_{obs}[CuCN][PhI]$, where $k_{obs} = k_2 + k_3[CuI]_{sat}$). Integrating the Model 2 rate equation led to the result that ~35% of the $R = 1.5$ reaction proceeded via the 3rd-order term while less than ~12% of the $R = 8$ reaction went that way. The phenomenon of autocatalysis appears to be general: added CuBr also accelerates cyanodebromination of 2-bromobenzoic acid (for example, when [CuBr] ~ 16 × [2 BrPhCOOH], cyanodebromination is about twice as fast as in the absence of CuBr).

Other results

Reaction rates were compared in the presence and absence of various added substances, as shown in Table 2. Within experimental error, common electron or radical traps 1,1-diphenylethylene, 1,4-dinitrobenzene, and 1,6-di-*tert*-butyl-4-methylphenol had no effect on the rate of reaction between iodobenzene and CuCN, even when added in very large excess. Similar results were obtained for reaction of *o*-bromobenzoic acid with CuCN at 137°C in DMA (7.1 equiv. DNB gave a

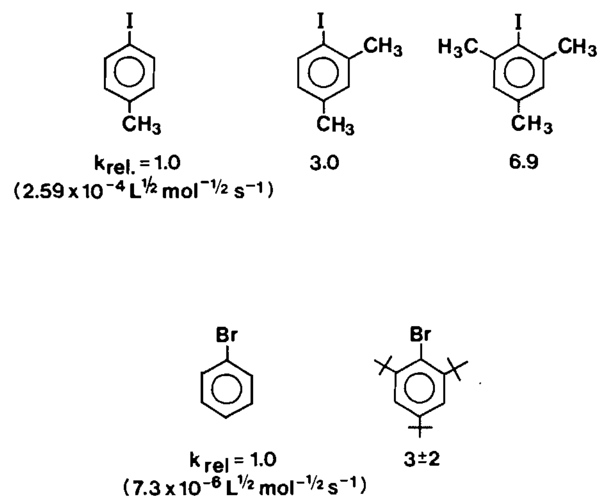


SCHEME 1. *ortho*-Substituent effects on cyanodehalogenation at 137°C in DMA.

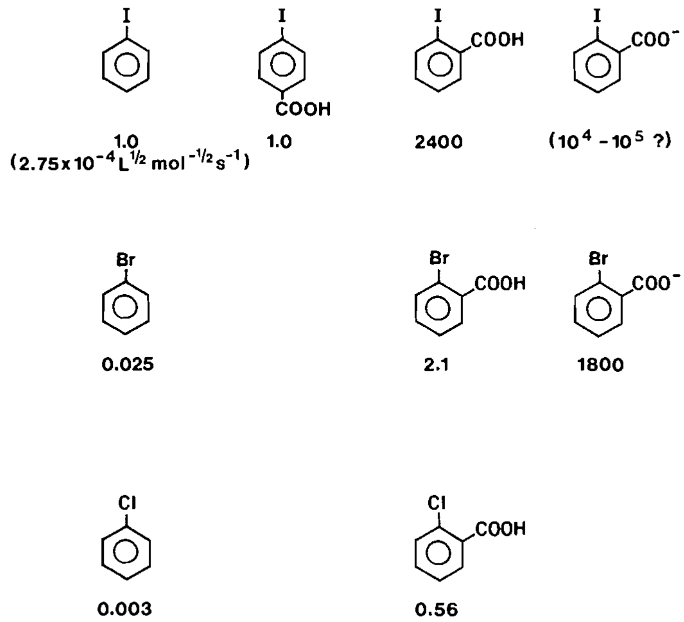
relative rate of 1.2 ± 0.25 (4 experiments)).

An equilibrium was observed for the reaction between iodobenzene and cuprous bromide (CuBr + PhI $\leftrightharpoons$ CuI + PhBr) at 137°C in DMA. Equilibrium was initially observed for a reaction, involving stoichiometric amounts of reagents, which stopped at only 85% conversion, and then confirmed by approach to equilibrium from the other direction. Unfortunately, the limited range of accessible compositions made it difficult to determine whether the equilibrium was bimolecular (K_2 = ([CuI][PhBr])/([CuBr][PhI])) or 3/2-order ($K_{3/2}$ = $([CuI]^{1/2} \times [PhBr])/([CuBr]^{1/2}[PhI])$). Equilibrium constants calculated for 5 runs performed at different compositions averaged 14 ± 3 for K_2, and 6.5 ± 1.4 for $K_{3/2}$. A single run of the same I/Br exchange in sodium *ortho*-halobenzoates was performed at 53°C, giving $K_2 \sim 6.3$ and $K_{3/2} \sim 3.1$. Cyanodeiodination, in contrast, goes to >99.99% conversion.

The effect of *para*-substituent on reactions of the type ArI + CuCN → ArCN + CuI was negligible (the Hammett plot in Fig. 5 has a ρ value of −0.02 ± 0.08), and *ortho*-methyl or even -*tert*-butyl groups have very little effect, causing a mild acceleration, as reflected in the data in Scheme 1. The relatively large error in the reaction rate for 2,4,6-tri-*tert*-butylbromobenzene is due to side reactions, apparently dealkylation, which destroy the mass balance.

Ortho- and *para*-diiodobenzene react sequentially, first forming the monosubstituted iodobenzonitrile, which builds up to 40–60% yield before conversion into the disubstituted product. Rate data for fits of these reaction profiles (not shown) are as follows: for *p*-diiodobenzene, k_1 (first substitution) = 1.24×10^{-3} and k_2 (second substitution) = 5.26×10^{-4}; for *o*-diiodobenzene, $k_1 = 5.48 \times 10^{-3}$ and $k_2 = 5.99 \times 10^{-4}$ $L^{1/2}$ $mol^{-1/2}$ s^{-1} at 137°C in DMA. These rate constants were determined by Runge–Kutta fits of the reaction profiles (RMS error ~2–3%), and are not initial rate constants.

In contrast to the relatively minor impact of all *para*-substituents and *ortho*-methyl, -*tert*-butyl, -iodo, and -cyano groups, there is an enormous *ortho*-carboxylate effect, and a



SCHEME 2. Relative rates of cyanodehalogenation at 137°C in DMA.

large halogen leaving group effect, as summarized in Scheme 2. The data in the scheme has been rendered to a common temperature, and the bracketted value for sodium 2-iodobenzoate has been estimated from the trend in the bromo series.

The reactivity of several cuprous salts was compared to CuCN to explore the effect of the nucleophile on the rate, and the results for nucleodeiodination are summarized in Table 3. Both CuBr and $CuBr_2$ react with PhI to form PhBr (Table 4). The addition of excess Br_2 to either reaction effectively inhibits the exchange, indicating an equilibrium of the type $CuBr_2 \rightleftarrows CuBr + 1/2\ Br_2$, where only CuBr is active in the ligand exchange reaction.

Discussion

Full reaction profiles, similar to the example in Fig. 1, were determined by analytical hplc, using an internal standard to test for the maintenance of a mass balance. Except where noted, the reactions were clean, and went to >99.99% conversion, with no side reactions detectable (hydrodehalogenation to form benzene: <0.5%; Ullmann coupling to form biphenyl: <0.02%). Mass balance failure occurred with some *ortho*-carboxylate systems and with 1,3,5-tri-*tert*-butylbromobenzene. These problems were attenuated somewhat by the use of initial rates.

Among the major identifiable classes of proposed mechanisms for copper mediated NAS reactions are the concerted mechanism, the benzyne mechanism, the $S_{RN}1$ radical chain mechanism (14), other non-chain electron transfer or radical mechanisms, and other forms of catalysed addition–elimination mechanisms. The concerted mechanism has frequently been proposed in the face of lack of evidence for any intermediates (particularly benzyne or radical ions (6, 7)). For example, the benzyne mechanism has been clearly ruled out by the well-known retention of position of substitution on the ring. Our unoriginal observation that copper mediated NAS is not inhibited by normal radical or electron traps rules out the $S_{RN}1$ mechanism (14) and any non-chain electron transfer or radical mechanism involving "free" radicals or radical ion intermediates. Furthermore, although we did observe weak esr signals at the beginning of a cyanodeiodination reaction, they were due to ~2% Cu^{2+} initially present in the CuCN (a common impurity in cuprous salts). The fact that cyanodeiodination of *o*- and *p*-diiodobenzene clearly occurs with the detectable buildup and decay of substantial amounts of the monocyano intermediate species also rules out the $S_{RN}1$ chain mechanism (14*a*, *c*).

TABLE 3. Relative reactivity of some cuprous nucleophiles in deiodinations

The rate equation

Second-order kinetics normally prevail for exchange reactions run under homogeneous conditions,[3] but Fig. 2 shows that second-order plots had upward curvature, consistent with the observed mild catalysis by cuprous iodide. Because *n*, the order in CuCN, at 0.64, was closer to 1/2 than to 1, and because the mechanistically significant *relative* rates were insensitive to variations in *n*, all results have been reported in terms of a simpler 3/2-order rate equation ($n = 1/2$) for the *initial* rate.

More than a dozen kinetic models were tested on individual runs, with the best fits obtained by two-term equations of the form $v = k_1[PhI][CuCN]^n + k_2[PhI][CuI][CuCN]^n$ for $n = 1/2$ or 1 (RMS error ~0.3%). One possible interpretation of $n = 1/2$ could be reversible dissociation of inactive, largely dimeric Cu_2CN_2:

$$[9]\quad \underset{\text{inactive}}{Cu_2CN_2} \overset{K}{\rightleftarrows} \underset{\text{active}}{2\ CuCN} \xrightarrow{PhI} PhCN + CuX$$

$$[10]\quad K = [CuCN]^2/[Cu_2CN_2]$$

$$[11]\quad v = k[PhI][CuCN] \sim k[PhI]\ (K[CuCN]_{stoich})^{1/2}$$

[3] Bacon and Hill found second-order kinetics to prevail in most copper mediated ligand exchange processes (using $R \sim 2-10$), except for cyanodeiodination, where their second-order rate constant also increased with time (6). They did not attempt to explain the observation.

TABLE 5. Results of competitive reactions performed in DMA at 137°C. The ratio of absolute rate constants (determined from ordinary experiments) is shown in the last column for comparative purposes

Reaction competitors A	B	Co-reagent	Ratio $[A]_0/[B]_0$	$[ArI]_{tot}$ (mM)	Ratio $R = [CuNu]_0/[ArI]_0$	k_{rel} k_A/k_B Competition	k_{rel} k_A/k_B Absolute
		CuCN	0.79	42.4	1.5	2.0	1.6
			0.83	15.7	7.9	2.1	1.7
CuBr	CuCN	PhI	0.86	40.0	1.1	1.0	6.1
			0.85	42.3	1.1	1.2	6.1
			0.90	16.5	8.0	1.6	6.5
			1.02	17.4	7.4	1.8	6.5

if the extent of dissociation is small. CuCN may dimerize at low temperatures, or in the solid state (15); however, at 137°C in DMA solution, dissociation should be extensive for entropy reasons. Detailed curve fitting of reaction profiles to general kinetic models allowing this dissociation, with K as a second adjustable parameter, gave worse results than the two-term models above. Furthermore, if CuCN actually dimerizes in solution, some consideration of potential Cu_2ICN species would be required, further complicating the quantitative analysis. For all these reasons, the rate equation was not pursued further, and the following discussion relies on the initial rate measurements using the empirical 3/2-order rate equation. Fortunately, *the broad conclusions drawn from these results are independent of the precise form of the initial rate equation.* Furthermore, the impact of the third-order term describing CuI autocatalysis could be attenuated significantly by comparing initial rates for reactions run with excess cuprous cyanide ($[CuCN]_0/[PhI]_0 \sim 8$, which approaches pseudo-first-order kinetics).

One of the interesting features of the $S_{RN}1$ mechanism in particular, and chain reactions in general, is the observation that relative rates measured in competitive reactions are very much different than relative rates determined by the ratio of absolute rate constants (14*b*). We applied this test of mechanism to these reactions (Table 5). In competition of *p*-nitro and *p*-methyliodobenzenes for cuprous cyanide, the competitive rate ratio was about the same as the ratio of absolute rate constants (2.05 vs. 1.65; both $\pm$ 15%). However, when CuBr and CuCN competed for iodobenzene, the competitive rate ratio was smaller than the absolute rate ratio (1–2 vs. 6–7). Since CuI catalyses CuCN reactions, the combination of two cuprous nucleophile species in the same solution may give rise to complex interaction effects, making it doubtful that this rate ratio discrepancy indicates a chain component to the reaction mechanism. The role of cuprous iodide autocatalysis may be assistance for removal of halide ion in the rate-limiting step, forming CuI_2^- as a superior leaving group.

Effect of other added substances

Basic mechanistic information may often be garnered from the effect various substances have on reaction rates. There is a rather strong solvent effect on copper mediated ligand exchange reactions which has been attributed to the ability to dissolve and solvate the cuprous species (6). For example, the rate in DMA was one-half that in DMF. The cuprous nucleophiles are insoluble in solvents like hydrocarbons, chlorocarbons, ethers, etc., so there is no reaction in those solvents. Table 2 lists the impact of various substances added at 10 to 20 times the initial iodobenzene concentration. 5% Water in DMA accelerates the reaction about 60%, probably a solvent effect. Benzoic acid, methyl benzoate, and benzonitrile have essentially no effect on cyanodeiodination. The absence of any effect with PhCOOH appears to contradict results of Cohen on reaction of *o*-iodo-*N*,*N*-dimethylbenzamide with CuCl and CuCN, where benzoic acid diverts the reaction to hydrodehalogenation (8). Unfortunately, Cohen gives no details on which to base a discussion of this difference. Interestingly, the addition of either excess nucleophile, in the form of KCN, or excess leaving group, as KI, retards the rate significantly. This observation effectively rules out any dissociative mechanisms, which should show common ion effects.

Other features

Scheme 2 summarizes the impact of halogen on cyanodehalogenation reactions. For both ordinary and *o*-COOH substituted systems, aryl iodides are about 40–100 times more reactive than aryl bromides, which, in turn, are more reactive than aryl chlorides. This series parallels leaving group ability of the halide ions ($I^- > Br^- > Cl^-$), and has been interpreted as indicative of rate limiting CX rupture (5, 6). It is noteworthy that the opposite order of reactivity is observed for unmediated nucleophilic aromatic substitution, proceeding via the well known addition–elimination mechanism with rate limiting attack by the nucleophile on the activated aromatic ring (16). In contrast to the relatively large aromatic halide leaving group effect, the cuprous nucleophile effect is quite small for soluble cuprous salts (Table 3), again consistent with rate limiting breakdown of an intermediate.

There is mounting evidence that only cuprous ion is active in copper mediated reactions, although cupric reagents may sometimes give product (5, 17).[4] In the case of ligand exchange observed with cupric bromide, the formation of bromobenzene from iodobenzene was traced to a redox equilibrium (eq. [12]), followed by subsequent reaction of cuprous bromide (eq. [13]). Crude thermodynamic estimates indicate that eq. [12] is probably thermoneutral at 140°C ($\Delta H^0 \sim 9$ kcal mol^{-1} (18) but $\Delta S^0 \sim 20$ cal mol^{-1} K^{-1} gives $\Delta G^0 \sim 0$).

[12] $CuBr_2 \leftrightharpoons CuBr + 1/2\ Br_2$

[13] $CuBr + PhI \rightarrow PhBr + CuI$

[4] Also A. J. Paine, unpublished data.

The Hammett ρ value for cyanodeiodination was found to be zero, within experimental error, for 7 *para*-substituents (Fig. 5). Copper mediated reactions typically have ρ values in the range 0–1 (6, 7, 19). This is also in marked contrast to unmediated nucleophilic aromatic substitution, where electron withdrawing groups like nitro are required to stabilize the incipient negative charge as it develops on the ring during attack by the nucleophile, leading to ρ values of 3–5 (7, 20). Clearly the copper mediation results in a mechanism which completely avoids the build-up of negative charge.

The effect of *ortho*-alkyl groups on the reaction was probed with the idea that steric retardation might indicate a concerted mechanism, because the transition state would be very crowded. Interestingly, both *o*-methyl and *o-tert*-butyl groups demonstrate a mild steric *acceleration*, perhaps indicative of relief of steric strain in the transition state. Thus, the overall absence of steric retardation appears to speak against a fully concerted mechanism.

ortho-*Carboxylate effect*

In spite of the fact that electronic substituent effects and *ortho*-alkyl steric effects are small, there is a widely recognized *ortho*-carboxylate effect (1, 2, 6): sodium *ortho*-iodobenzoate reacts ~10^4–10^5 times faster than iodobenzene (Scheme 2). *p*-Carboxylate has no effect, and the *ortho* salt is about 40–100 times more reactive than the free acid. The trend is the same in the bromo and chloro series as well. Of particular interest here is whether the *ortho*-carboxylate acceleration occurs via the same basic mechanism or by a completely new mechanism. This problem was considered in detail, and the general features of the *ortho*-acid series were found to parallel those in the simple haloaromatic series in all aspects: the rate equation, the halogen effect, the effect of added substances, cuprous iodide autocatalysis, etc. Thus we conclude that the accelerated reactions must have essentially the same mechanism. What then accounts for the huge rate difference?

It appears that the difference is primarily in the activation *entropy*. The plot of activation parameters in Fig. 4 shows that iodobenzene, *ortho*-bromobenzoic acid, and sodium *ortho*-bromobenzoate reactions with cuprous cyanide give three essentially parallel lines (same $\Delta H^{\ddagger}$) with different intercepts, $\Delta S^{\ddagger}$ (see Table 1). The $\Delta S^{\ddagger}$ obtained for the reaction of iodobenzene with CuCN is ~−26 entropy units, typical of second-order reactions, and is associated with the need for the reagents to diffuse together. On the other hand, a much more entropically neutral $\Delta S^{\ddagger} \sim -12$ eu for reaction of bromocarboxylate with CuCN suggests that the two reagents are already substantially associated in the ground state (perhaps by complexation of cuprous ion in the vicinity of the halide leaving group). On the other hand, the *enthalpy* of activation, corresponding to the bond breaking and forming steps, is the same as for the normal copper mediated reaction (19–21 kcal).

Thermodynamics and reversibility

Thus far, the discussion has considered the results of kinetic measurements and presented some pseudo-thermodynamic parameters. It is also useful to examine the thermodynamic parameters, particularly with regard to potential reversibility of these processes. Table 6 shows the reaction enthalpies, ΔH^0, calculated for generalized bimolecular copper ligand exchange equilibria of the type shown, using the relatively rare literature data on these compounds (18). Although they are quite crude, these appear to be the first such thermodynamic estimates, presently limited to the cases X, Y = F, Cl, Br, I, CN, N_3, and

TABLE 6. Estimated reaction enthalpies for assumed bimolecular ligand exchange reactions. (The standard states are the solid and liquid phases for the cuprous and aromatic species, respectively. The units are kcal mol^{-1}.)

○ Feasible ($\Delta H^0 \leq 0$)

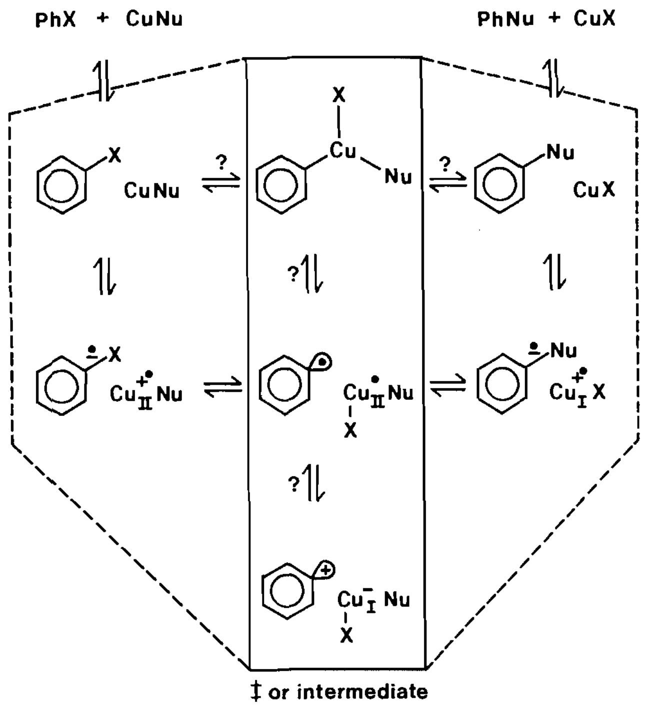
△ Possible ($0 \leq \Delta H^0 \leq 7$)

to solid or liquid standard states. The resulting table of 21 possible ligand exchange reactions is useful for correlation and prediction. For example, equilibrium constants, K_{eq}, may be estimated using the relation $\Delta H^0 \sim -RT \ln K_{eq}$ (assuming $\Delta S^0 \sim 0$). If ΔH is too large (>5 kcal mol^{-1}) then the reaction is predicted to be too endothermic to be feasible. If ΔH is negative, then the reaction becomes thermodynamically possible (but may still be kinetically slow). Synthetically useful reactions must be thermodynamically downhill, and, indeed, cyanodehalogenation is found to be so. In cases where $\Delta H \sim 0$, reversible equilibria may result, lowering the synthetic yield. For example, Table 6 predicts possible equilibria for Cl/Br or Br/I exchange, which was tested in the latter case, measuring $\Delta H^0 = -2.15$ kcal mol^{-1} (vs. prediction of -4 ± 2 in Table 6). This appears to be the first fully established case of reversibility in these reactions and it reinforces the notion that the proposed mechanism must have a *symmetrical*, high energy intermediate or transition state, which does not distinguish between the nucleophile and the leaving group.

The thermodynamic data in Table 6 show the following leaving group order: I > Br > Cl (> N_3 > CN > F); where the last 3 are usually endothermic. This series agrees with the kinetic leaving group ability. The thermodynamic nucleophilic reactivity is in the reverse order (obviously), but the kinetic nucleophile effects (SPh ≥ Br > CN ~ Cl, Table 3) are much smaller than the kinetic leaving group effects. This series differs from the kinetic nucleodebromination results of Bacon (6): Cl > Br > I > CN ~ SPh > SCN. Thus, it is evident that both thermodynamic considerations ($\Delta H < 0$) and kinetic considerations ($k_{ArI} > k_{ArBr}$) are required to design practical syntheses using copper mediated NAS.

Reaction mechanism

Any proposed mechanism must account for the following:



SCHEME 3. Intimate electron transfer mechanism for copper mediated NAS.

the halogen effect; the lack of *para*-substituent effect; the negligible *ortho* steric effect; entropic acceleration by *ortho*-carboxylate (but not by *para*-carboxylate); absence of radical chains or free radicals; cuprous iodide autocatalysis; and the retarding effect of potassium cyanide and postassium iodide. Finally, any proposed mechanism must obey the Principle of Microscopic Reversibility, and because of the symmetry of the ligand exchange, must involve a symmetrical transition state or intermediate which does not distinguish between the incoming nucleophile and the leaving group. It is in fact quite difficult to propose a chemically reasonable mechanism consistent with all these requirements, and this may explain why the literature abounds with concerted mechanisms. However, at this stage, we propose two fairly reasonable working hypotheses which are offered to stimulate further research.

Intimate electron transfer mechanism

The first alternative to a fully concerted mechanism is a special kind of electron transfer mechanism. More and more nucleophilic reactions are found to involve electron transfer instead of nucleophilic attack. In this system, however, the absence of any effect of electron traps means that electron transfers which do occur must be very rapidly reversible, or rapidly product generating, so that no "free" radical ions escape the solvent cage. Thus, a mechanism also capable of accounting for many of the results is shown in Scheme 3: cuprous nucleophile and aromatic halide drift around in solution until they come together in an encounter complex in a solvent cage. Such complexes have lifetimes of 500–1000 vibrations, during which time the action inside the large dotted area in the scheme must occur.

Suppose there were an electron transfer from the cuprous nucleophile to the aromatic halide. Such a transfer should be to the σ^* orbital, as opposed to a π^* orbital, because diiodo substrates first give monosubstituted products (a classical test to rule out the $S_{RN}1$ electron transfer mechanism (14*a*, *c*)). This radical ion then gives up a halide ion to form a cupric odd-electron species and a phenyl radical, still trapped in the same solvent cage. Presumably the interaction between these proximate unpaired electrons stabilizes the complex, and perhaps leads to bonding, giving rise to the possibility of the tri-substituted organocopper intermediate shown in the top centre of the scheme.[5] Whatever the form of the symmetrical intermediate shown in the central box, it merely reverses the formation process to give the ligand exchanged material.

This associative mechanism for ligand exchange has the advantage that leakage of phenyl radical can explain the benzene which is sometimes observed as a hydrodehalogenation side product (2). Also, cupric copper might further oxidize the phenyl radical to a cation, perhaps accounting for dealkyation in *tert*-butylated substrates. An electron transfer mechanism of this type might have less rigid stereochemical requirements than a concerted mechanism. Both KI and KCN retard the reaction by competing with ArX as ligands for the cuprous ion. Finally, the *entropic* role of the *ortho*-carboxylate substituent in this mechanism would be to complex the cuprous and cupric ions in the vicinity of the halide, thereby extending the lifetime of the encounter complex in the solvent cage, and increasing the probability of reaction. (The *enthalpic* role of *ortho*-carboxylate, if any, would be to stabilize the transition state by complexation with the copper.) On the other hand, the problems with this mechanism are: (a) the need for intimacy of electron transfer; and (b) the need for electron transfer to the σ^* vs. π^* orbital.

π-Complexed organocuprate intermediates

Another mechanism capable of rationalizing many of the experimental results is a refined version of Weingarten's proposal (5) involving π-complexed organocuprate intermediates (eq. [14]). The key intermediate in this process is the h^6, 18-electron complex between the cuprous nucleophile and the 6 π-electrons of the aryl halide (cuprous ion is d_{10}). From this complex, intramolecular attack of the nucleophile gives the tetrahedral intermediate, where the negative charge that would otherwise be borne in the ring, is neutralized by the 16-electron π-complexed copper atom, which sucks all of the excess electron density out of the ring (hence no substituent effect). The rate determining step would be loss of halide, followed by rapid collapse to final products.

[14] 
This mechanism offers a ready explanation for the retarding effect of KCN and KI, which are known to form higher coordinate anions ($Cu(CN)_2^-$ or $CuCNI^-$ (21)) which would be inactive in this model because they already have 14 electrons, and therefore cannot form the necessary h^6 18-electron complex.

This mechanism appears to be supported by parallels to nucleophilic aromatic substitution reactions in stable iron, chromium, molybdenum, and manganese arene carbonyl complexes known in the literature (5, 22). In fact, the tetrahedral

[5] A referee has noted that thermodynamic E^0 values for electron transfer from cuprous species to iodobenzenes are ~2 eV (i.e. at least twice as great as the enthalpy of activation of the ligand exchange process). However, the E^0 values refer to separated ions in solution, and stabilization within the cage (particularly if bonding is involved) could lower the activation energy from the E^0 value.

intermediate in eq. [15] has been isolated and characterized by X-ray crystallography (22c). Cuprous h^6 complexes are rare (23), but not unknown (24). Unfortunately, the arene carbonyl complexes undergo NAS with the following leaving group order: F > Cl > Br, opposite to that observed here (22). To account for this apparently conflicting order of reactivity, complexation of CuNu and ArX would have to be favoured in the order I ≫ Br ≫ Cl, in order to overcome the reactivity preference of the complex. If that were so, one would expect a larger substituent effect in general, because h^6 complexation should see the halide as just another substituent. Thus, this inconsistency diminishes the value of the parallel to other transition metal arene complexes.

[15] 
There are some minor problems with microscopic reversibility in the simple picture in eq. [14], but they can be overcome if the stereochemical integrity at the ipso carbon is allowed to scramble by reversible halide loss.

There are two possible explanations for the *ortho*-carboxylate effect in this reaction, both based on anchimeric assistance (25). The *ortho*-carboxylate may displace halide first, facilitating attack by cyanide (eq. [16]), or the carboxylate might assist removal of iodide, without ipso scrambling, through formation of a transient carboxyl hypoiodite (eq. [17]).

[16] 
[17] 
Neither of these possibilities is well supported at present: the first because of the strained 4-membered ring β-lactone intermediate (~25 kcal uphill (26)); and the second because of the extra electron density pushed into the ring upon formation of the hypoiodite. Furthermore, any anchimeric assistance mechanism is inconsistent with the *increased* (less negative) entropy of activation observed for *ortho*-carboxylate systems. $\Delta S^{\ddagger}$ should *decrease* for anchimeric assistance because of the loss of entropy on forming the 4- or 5-membered ring transition state or intermediate ($\Delta S^0_{\mathrm{cyclization}} \sim -(10-15)$ eu (26)), so the primary neighbouring group effect in this kind of reaction should be on $\Delta H^{\ddagger}$. Attractive though these anchimeric assistance explanations are for the *ortho*-carboxylate effect, they seem to be inconsistent with the observed activation parameter data.[6]

Thus, the problems with the π-complexed organocuprate intermediate mechanism are: (a) questionable parallels to NAS in other transition metal arene complexes; and (b) the inability to rationalize the *ortho*-carboxylate effect.

Final comments

Both of these mechanisms implicitly assume that CuNu is monomeric in solution. This is a crucial requirement for the *active* species in the π-complexed organocuprate proposal, but may be relaxed for the intimate electron transfer mechanism. Although the assumption is both reasonable and common, the problems with defining the rate equation serve as a reminder that this was an assumption, and may not be true.

A key mechanistic question is the nature of the initial interaction of ArX with CuNu: is it halogen complexation or π-type complexation? An obvious way to attempt to measure the relative affinity of cuprous ion for X or Ar in ArX would be through a systematic study of the solubility of cuprous salts in various ArX (e.g. PhH, PhI, PhBr, PhCl, 2,4,6-tri-*tert*-butylbromobenzene, etc.). If solubility were assumed a direct consequence of complexation, then trends in the solubilities would indicate the site of complexation. Attractive as this idea might seem, cuprous iodide was found to be insoluble in iodobenzene, for example, with a probable solubility of $<10^{-6}$ *M*, indicating an enthalpy barrier to dissolution and complexation of $> -RT \ln([\mathrm{CuI}]/[\mathrm{PhI}]) = 9.6$ kcal mol^{-1} at 25°C. (Compare to $\Delta H^0 \sim 2.9$ kcal for CuI in acetonitrile (35 g/kg solution (21))). These enthalpy numbers are *composite* figures, accounting for overcoming lattice energy *and* forming the complex, but the lattice energy term is the same for dissolution in either solvent, so complexation of CuI with PhI is >6.7 kcal more endothermic than complexation with CH_3CN. Thus it is not surprising that there is no reported spectroscopic evidence for complexed intermediates in these exchange reactions.

Although the 170 runs reported here probably constitute the most thorough investigation of copper mediated ligand exchange reactions to date, they are not adequate to completely specify the operable mechanism. Two working hypothesis mechanisms have emerged which should be further tested and refined. Further progress on this complex issue requires: a clarified rate equation from a clearer definition of the copper species in solution (monomer/dimer/oligomer and solvation state); more accurate thermodynamic estimates (particularly experimental data on other CuNu species); a better unravelling of entropy and enthalpy rate effects (via more accurate activation parameters); and measurement of association equilibria of CuNu with $ArCOO^-$. Furthermore, theoretical calculations may have some relevant input. The π-complexation mechanism may be tested by intramolecular reactions (systems which are sufficiently inflexible that CuNu cannot lie over the aromatic ring of ArX).[7]

Neither of the proposed mechanisms is completely satisfactory. Perhaps there is a combination process where initial halogen–copper complexation evolves into h^6 complexation. Given the plethora of mechanisms for unmediated NAS (28), it is possible that more than one mechanism operates in mediated reactions as well. These very interesting and useful processes pose an extremely complex and difficult problem, but new light has been shed on the issue and promising research directions identified.

[6] It may be that this inconsistency arises from the comparison of iodo and bromo aromatics in Fig. 4. A more accurate comparison would employ the same halogen.

[7] In fact, some intramolecular reactions are known (23, 27), but to interpret the results requires good models for intermolecular rates. Some of the known examples involve substrates which appear to be sufficiently flexible to position CuNu over the aromatic ring anyway.

This paper is dedicated to the 10th anniversary of the Xerox Research Centre of Canada

ROBERT A. MCCLELLAND, N. ESTHER SEAMAN, JAMES M. DUFF, and R. E. BRANSTON. Can. J. Chem. **63**, 121 (1985).

Kinetic studies are reported for the base hydrolysis to phthalamic acid anions (H) and ammonolysis to phthalamides (A) for seven phthalimides (P): **1**, unsubstituted; **2**, 4-NO_2; **3**, 4-Cl; **4**, 4-*t*Bu; **5**, 3-NO_2; **6**, 3-Me; **7**, 3-Me_3Si. The hydrolysis kinetics require two mechanisms, one which is first order in neutral imide and first order in hydroxide ion, and a second, which is important only in quite concentrated NaOH, which is first order in neutral phthalimide and second order in hydroxide ion. Ammonolysis kinetics for **1–5** revealed the rate law: Rate = k_N [Unionized phthalimide] $[NH_3][OH^-]$. A mechanism is proposed with rate-determining breakdown of the anionic form of the tetrahedral intermediate derived by addition of NH_3 to the phthalimide. The ammonolysis is reversible. The phthalamide hydrolyzes to the phthalamic acid via cyclization to an intermediate phthalimide, which is detected in concentrated base where its formation from phthalamide is more rapid than its subsequent hydrolysis. Rate constants for the cyclization follow the rate law: Rate = k_{cyc} [Phthalamide]$[OH^-]$. This reaction is the microscopic reverse of the ammonolysis, and the ratio k_N/k_{cyc} provides the equilibrium constant K_{eq} for the reaction P + NH_3 = A. Values for **1–5** lie in the range $2 \times 10^2 - 4 \times 10^3$. With 3-methylphthalimide, kinetics in aqueous ammonia do not obey a first-order relationship, but they could be analyzed by a scheme whereby the phthalimide is converted reversibly to the phthalamide and simultaneously undergoes an irreversible hydrolysis. The value of K_{eq} in the system is 1.8. With 3-trimethylsilylphthalimide the value of K_{eq} is further reduced to 0.01. The ammonolysis reaction does occur more quickly than hydrolysis but the equilibrium is so unfavorable that even in concentrated ammonia only a small amount of the phthalamide is ever formed.

ROBERT A. MCCLELLAND, N. ESTHER SEAMAN, JAMES M. DUFF et R. E. BRANSTON. Can. J. Chem. **63**, 121 (1985).

On rapporte des études cinétiques relatives à l'hydrolyse basique conduisant aux anions de l'acide phtalamique (H) ainsi qu'à l'ammonolyse conduisant aux phtalamides (A) de sept phtalimides (P) soit non substituée **1** ou substituées par des groupements NO_2-4 **2**, Cl-4 **3**, *t*-Bu-4 **4**, NO_2-3 **5**, Me-3 **6**, Me_3Si-3 **7**. Les cinétiques d'hydrolyse nécessitent deux mécanismes dont l'un est d'ordre un en imide neutre et d'ordre un en ions hydroxydes alors que le deuxième mécanisme, qui n'est important qu'en milieu très concentré en NaOH, est d'ordre un en phtalimide neutre et d'ordre deux en ion hydroxyde. La loi de vitesse des cinétiques d'ammonolyse des composés **1–5** peut être représentée par l'équation suivante: Vitesse = k_N [Phtalimide non ionisée]$[NH_3][OH^-]$. On propose un mécanisme dont l'étape déterminante est la rupture de la forme anionique de l'intermédiaire tétraédrique provenant de l'addition du NH_3 sur la phtalimide. L'ammonolyse est réversible. La phtalamide s'hydrolyse en acide phtalamique par le biais d'une cyclisation conduisant à une phtalimide intermédiaire que l'on peut déceler lorsque la réaction est réalisée en présence de base concentrée; dans ces conditions la formation de cet intermédiaire est plus rapide que son hydrolyse subséquente. Les constantes de vitesse pour la cyclisation peuvent être représentées par l'équation suivante: Vitesse = k_{cyc} [Phtalamide]$[OH^-]$. Sur une base microscopique, cette réaction constitue l'inverse de l'ammonolyse et le rapport k_N/k_{cyc} fournit la constante d'équilibre K_{eq} de la réaction P + NH_3 = A. Les valeurs de K_{eq} pour les composés **1** à **5** s'étalent de 2×10^2 à 4×10^3. Dans le cas de la méthyl-3 phtalimide en milieu ammoniacal aqueux, la cinétique n'obéit pas à la relation d'ordre un; on peut toutefois rationaliser ses données cinétiques en faisant appel à un mécanisme impliquant une transformation réversible de la phtalimide en phtalamide accompagnée d'une hydrolyse irréversible simultanée. La valeur de K_{eq} dans ce système est égale à 1,8. Dans le cas de la triméthylsilyl-3 phtalimide, la valeur de K_{eq} est réduite à 0,01. La réaction d'ammonolyse est plus rapide que celle d'hydrolyse mais l'équilibre est tellement défavorisé que, même en milieu ammoniacal concentré, il ne se forme que de très faibles quantités de phtalamide.

[Traduit par le journal]

Introduction

As well as being one of the most commonly used types of blue-green organic colourants, the phthalocyanine class of compounds are used in a number of electronic applications as a result of their well-known semiconductive properties (1). As part of a systematic investigation of the effect of substituents on the optical and electronic properties of phthalocyanines we have synthesized and characterized a variety of substituted phthalocyanines (J. M. Duff and R. E. Branston, unpublished results). The general route chosen involved as many as 6 steps (*o*-xylene → phthalic acid → phthalic anhydride → phthalimide → phthalamide → phthalonitrile → phthalocyanine), depending on the availability of starting materials. While most of these reactions proceeded as expected and we were able to devise optimized syntheses for most intermediates, a pronounced substituent effect, particularly at the 3-position, was found in the aqueous ammonolysis of phthalimide to phthalamide. Thus the unsubstituted phthalimide, all 4-substituted compounds studied, and the 3-nitro compound gave excellent yields of the corresponding diamide. The 3-methylphthalamide was finally synthesized in reasonable yield in a pressure reactor using liquid ammonia at 90°C. On the other hand, numerous attempts to convert the 3-trimethylsilylphthalimide to the amide in ammonia at a variety of pressures and temperatures afforded, at best, a few percent of amide (spectroscopically identified), which spontaneously formed the imide at room temperature.[1]

We report here a kinetic study of the aqueous ammonolysis (eq. [1]) undertaken in order to evaluate the effect of substituents on the course of the reaction, particularly substituents at the 3-position.

[1] 
Seven phthalimides have been subjected to investigations: X = H (**1**); 4-NO_2 (**2**); 4-Cl (**3**); 4-*t*-Bu (**4**); 3-NO_2 (**5**); 3-Me (**6**); 3-Me_3Si (**7**).

Results and discussion

Kinetic studies were conducted using uv spectroscopy, monitoring the disappearance (or appearance) of the phthalimide at its λ_{max} near 300 nm. As illustrated in Fig. 1, neither the phthalamide product of ammonolysis nor the phthalamic acid anion product of hydrolysis have significant absorbance at this wavelength (with the exception of the two nitro compounds). Imide concentrations were 10^{-3} molar or less, ensuring pseudo-first-order conditions of constant pH and ammonia concentration. Conditions in general were aqueous solutions at 25.0°C and 1 *M* ionic strength. The exception is the 3-Me_3Si derivative, which for solubility reasons was studied in 25% acetonitrile. The parent phthalimide was also studied in this solution for comparison purposes.

Hydrolysis kinetics

Hydrolysis of the phthalimides to phthalamic acids competes with ammonolysis under aqueous conditions, and its importance obviously needs to be evaluated. A number of studies of imide hydrolysis have appeared (4–7), although a detailed investigation involving a series of substituted phthalimides has not been carried out. The hydrolysis was investigated in sodium hydroxide solutions (pH > 11), carbonate buffers (pH 8.5–11), and phosphate buffers (pH 7.8–8.5). Excellent pseudo-first-order kinetic plots were obtained in all cases. Weak catalysis by the carbonate and phosphate buffers was observed. In these cases observed rate constants were extrapolated to zero buffer concentration or obtained in dilute buffers (0.005–0.01 *M*) where catalysis is unimportant. (Even in 0.5 *M* buffer solutions the contributions to the overall rate from the buffer catalysis is only of the order of 10–20%.) Typical plots showing the variation of the first-order rate constant with pH are shown in Fig. 2. Three separate regions can be observed in these profiles, a region A at low pH with a first-order dependence in hydroxide ion, which gives way in more concentrated base to a pH-independent region B, followed then in very concentrated base by a region C, again with a first-order dependence on hydroxide ion. The last region is most pronounced with electron-withdrawing substituents, and is not observed with the 3-Me_3Si substituent.

The general behaviour exhibited in weakly basic solutions,

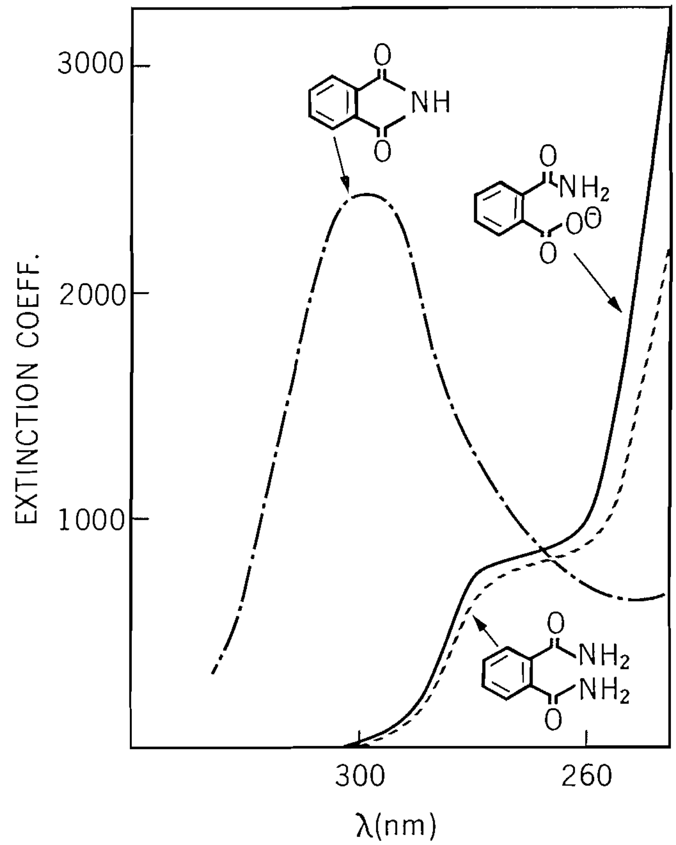

FIG. 1. Ultraviolet spectra of phthalimide and its products of ammonolysis and hydrolysis.

regions A and B, has been observed previously (4), and is explained by the reaction of hydroxide ion and the neutral phthalimide, with deprotonation of the imide occurring around pH 9–10, so that the rate constant levels, once the unreactive phthalimide ion is formed.

[2] 
The additional dependency on hydroxide ion observed in more concentrated base solution has been reported for the parent phthalimide on two occasions (5, 7). Butler (5) suggested that this was associated with the reaction of hydroxide ion with the phthalimide anion (k_2' process of eq. [2]), while Khan and Khan (6) favoured a kinetically equivalent reaction which is first order in unionized phthalimide and second order in hydroxide ion (k_3 process of eq. [2]). The latter interpretation seems more likely in light of the large number of studies of amide and anilide hydrolysis which have shown second-order terms in hydroxide ion (8). We have removed the ambiguity in

[1] These results are in conflict with those of Hopff and Gallegra (3), who describe the synthesis of both 3- and 4-trimethylsilylphthalamide in high yield using aqueous ammonia. Our results suggest that the 3-substituted amide was not formed as claimed and that the nitrile and phthalocyanine subsequently prepared from this material are of questionable existence.

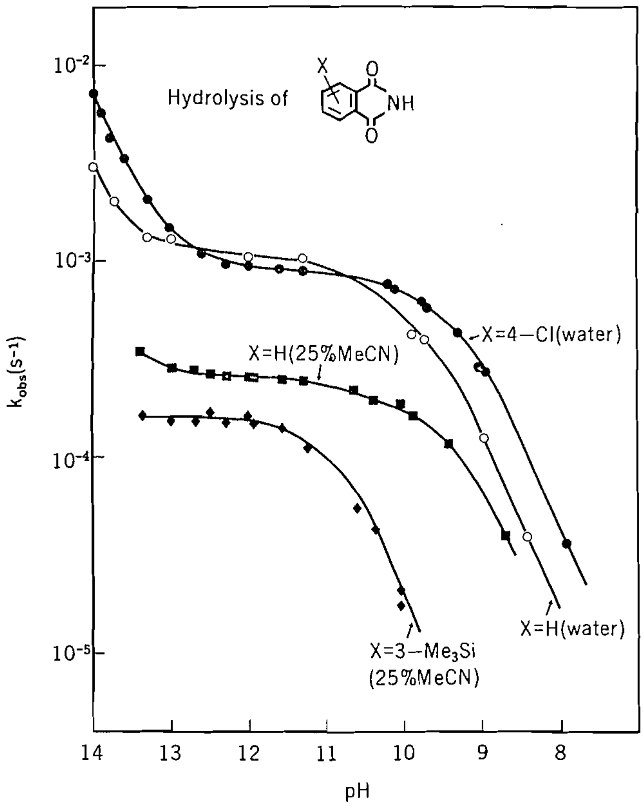

FIG. 2. Rate–pH profiles for phthalimide hydrolysis. Points are experimental. Curves are drawn according to eq. [4] using constants defined in Table 1.

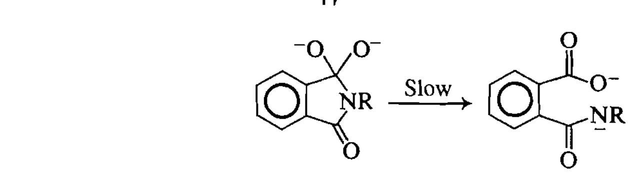
the present case by studying *N*-methylphthalimide, an imide which cannot ionize. First- and second-order terms in hydroxide ion are required in the rate law for this imide, eq. [3],

[3] $\text{Rate} = (k^2_{\text{OH}}[\text{OH}^-] + k^3_{\text{OH}}[\text{OH}^-]^2)\,(N\text{-methylphthalimide})$

with $k^2_{\text{OH}} = 22.8\ M^{-1}\ s^{-1}$ and $k^3_{\text{OH}} = 8.0\ M^{-1}\ s^{-1}$. Mechanistically the overall third-order process is explained (7, 8) by a rate-determining decomposition of the dianionic form of the tetrahedral intermediate.

[4]



The following rate expression accounts for the overall rate profiles in terms of constants defined in eq. [2].

[5] $$k_{\text{obs}} = \frac{k_2[\text{OH}^-] + k_3[\text{OH}^-]^2}{1 + (K_a/K_w)[\text{OH}^-]}$$

Using an iterative computer program, values of k_2, k_3, and K_a

TABLE 1. Rate constants for the hydrolysis of substituted phthalimides and kinetically determined dissociation constants (T = 25°C, ionic strength = 1.0)

Substituent	k_2, $M^{-1}\ s^{-1}$	k_3, $M^{-2}\ s^{-1}$	pK_a
4-NO_2	65.1	3.3×10^3	8.68
4-Cl	14.4	100	9.48
H	4.8	8.5	10.06
4-*t*Bu	2.9	4.4	10.21
3-NO_2	85.6	2.9×10^3	8.80
3-Me	1.69	1.50	10.49
3-Me_3Si (25% MeCN)	0.23	—	11.2
H (25% MeCN)	4.3	7.2	10.1

have been determined that provide the best fit to the experimental data. These are listed in Table 1. Hammett ρ values based on the data for the 4-substituted phthalimides[2] are 1.5 (±0.2) for k_2 and 3.4 (±0.2) for k_3. These reflect the different charge nature of the transition states for these two processes, a monoanionic transition state being involved with the k_2 process and the dianionic transition state of eq. [4] for k_3.

Ammonolysis kinetics – normal behaviour

In these experiments the disappearance of the phthalimide was monitored as a function of time in NH_4^+/NH_3 buffers. With the exception of the 3-Me and 3-Me_3Si phthalimides, excellent pseudo-first-order kinetic plots are observed, and in concentrated (1 *M*) buffers, the rate is significantly faster (by factors of about 10) than the hydrolysis rate at the same pH. This increase in rate can be attributed to the ammonolysis reaction of eq. [1]. The possibility does exist that some fraction of this rate increase is due to an ammonia-catalyzed hydrolysis, that is, ammonia acting as a general base, not a nucleophile. We feel, however, that this contribution cannot be very important. Excellent yields of phthalamides are obtained in aqueous ammonolysis. Moreover, general base catalysis by carbonate buffers is very small.

Serial buffer dilutions at constant pH were carried out for ammonia buffers with NH_4^+/NH_3 concentration ratios varying from 4:1 to 1:4. At constant pH the pseudo-first-order rate constant for phthalimide disappearance increases in a linear fashion with increasing NH_3 concentration (see Fig. 3).

$$K_{\text{obs}} = k^{\text{app}}_{\text{NH}_3}[\text{NH}_3] + k_0$$

The intercept rate constants k_0 obviously refer to hydrolysis, and these values do fit well into the hydrolysis rate profiles. The term in NH_3 represents the ammonolysis, and the feature of this is that the apparent second-order rate constants $k^{\text{app}}_{\text{NH}_3}$ are not constant, but increase with increasing pH (see insert to Fig. 3). This occurs in spite of a decreasing concentration of the neutral phthalimide, since the pH values of the ammonia buffers lie in the range 9–10 where the phthalimides are becoming ionized. The kinetics are, however, satisfied by a third-order ammonolysis, first order in neutral phthalimide, first order in ammonia, and first order in hydroxide ion. Taking into account the phthalimide ionization, the overall rate expression for ammonolysis becomes

[2] The σ values employed in determining this parameter are 0.76 (4-NO_2), 0.30 (4-Cl), 0 (H), and −0.14 (4-*t*Bu). These are the average of the *meta* and *para* values of the particular substituents. In the unsymmetrical phthalimides it was not determined to which carbonyl group the hydroxide anion or ammonia becomes attached.

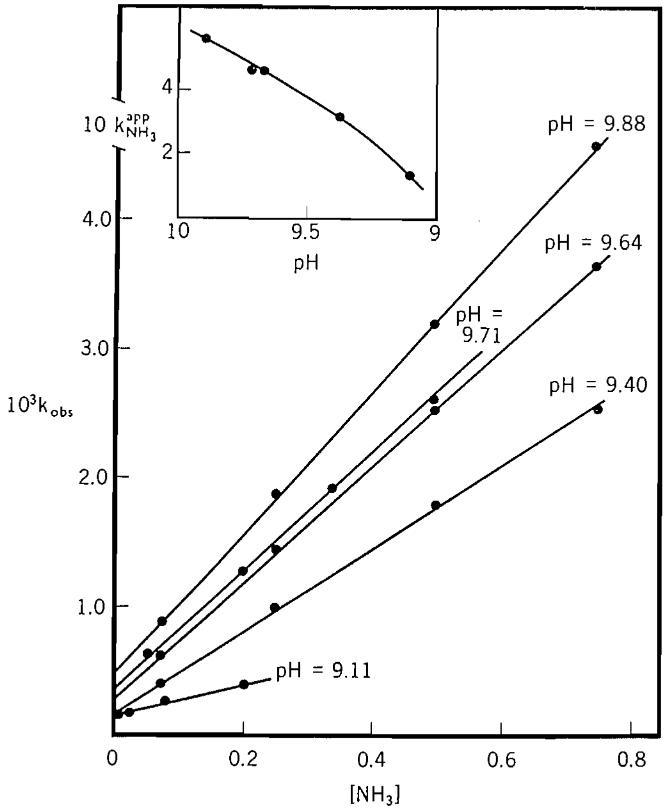


FIG. 3. Pseudo-first-order rate constants (s^{-1}, 25°C, ionic strength = 1.0) for disappearance of phthalimide in ammonia buffers. The insert plots the slopes $k^{app}_{NH_3}$ versus pH.

$$[6]\quad \text{Rate} = \frac{k_N[\text{Imide}][NH_3][OH^-]}{1 + (K_a/K_w)[OH^-]}$$

and the apparent second-order rate constant is

$$[7]\quad k^{app}_{NH_3} = \frac{k_N[OH^-]}{1 + (K_a/K_w)[OH^-]}$$

The third-order requirement for ammonolysis is reminiscent of the third-order hydrolysis and it signifies that the formation of a tetrahedral intermediate by addition of ammonia to the imide carbonyl cannot be rate limiting. We propose a scheme with rate-determining breakdown of the tetrahedral intermediate, involving ring opening of the anionic intermediate T^-.

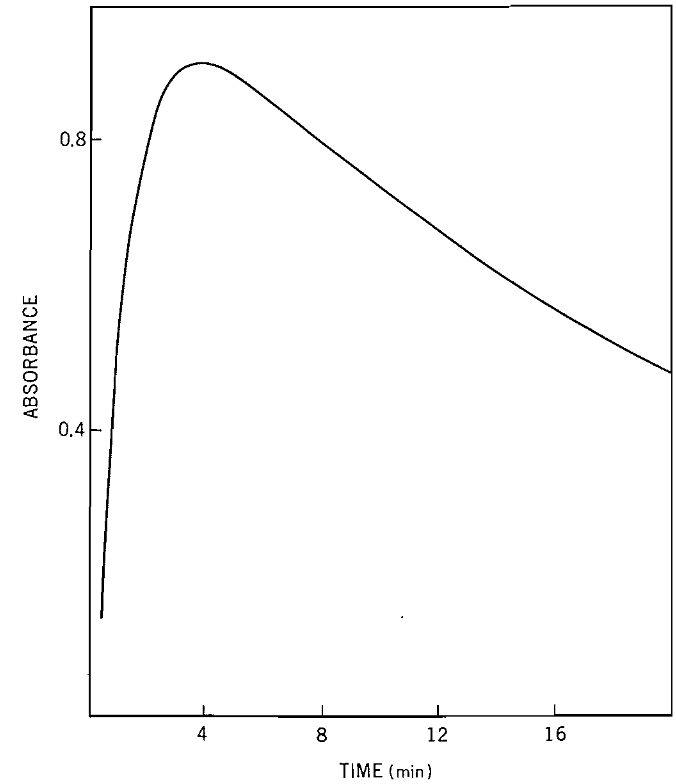

FIG. 4. Absorbance at 300 nm showing the formation and decay of phthalimide to acid on addition of phthalamide to 0.06 M NaOH.

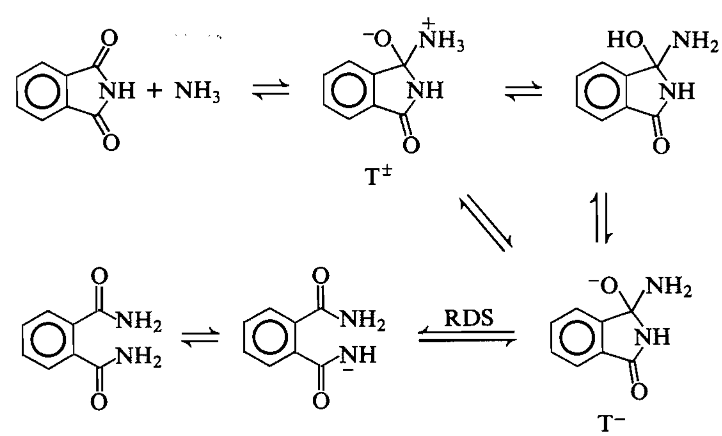
The term in hydroxide ion appears in the kinetic expression because of the requirement for deprotonation of the initially formed zwitterionic intermediate $T^{\pm}$ prior to the rate-determining step. An alternative interpretation involves a rate-determining formation of the anionic intermediate T^-, either in a concerted mechanism where hydroxide ion assists the addition of amonia by removing a proton as the carbon–nitrogen bond is formed, or in a "trapping" mechanism (9) where conversion of $T^{\pm}$ to T^- is rate-determining. These mechanisms have a proton transfer in the rate-determing step, so that hydroxide ion is acting as a general base. The argument against them is that general base catalysis by a second ammonia molecule is not observed. This requires a second-order term in ammonia,[3] and would appear as an upward curvature on plots

[8]



[3]The formation of an amide from an amine and ester occurs at high pH with the rate-determining formation of a tetrahedral intermediate, and does show general base catalysis by a second molecule of amine (ref. 2).

TABLE 2. Rate constants and equilibrium constants for the ammonolysis of substituted phthalimides (T = 25°C, ionic strength = 1.0)

Substituent	k_N, M^{-2} s^{-1}	k_{cyc}, M^{-1} s^{-1}	K_{eq}, M^{-1}
4-NO_2	3.7×10^3	2.78	1.3×10^3
4-Cl	2.3×10^2	0.59	3.9×10^2
H	70.6	0.29	2.4×10^2
4-*t*Bu	35.1	0.12	2.8×10^2
3-NO_2	2.9×10^3	3.6	8.1×10^2
3-Me	7.3	4.2	1.8
3-Me_3Si (25% MeCN)	0.3	24	0.01
H (25% MeCN)	14	0.4	35

of k_{obs} versus NH_3 concentration. A mechanism involving the addition of NH_2^- to the phthalimide is also excluded bcause of the extremely low concentration of this anion. It can also be noted that the conversion of trihaloacetones into acetamide and the halohydrin also exhibts third-order kinetics, with a term in hydroxide ion appearing in the rate law (10).

Values of k_N have been determined from eq. [7], using K_a values determined in the fit to the hydrolysis kinetics,[4] and are listed in Table 2. A substantial substituent effect (ρ = 2.3) is observed, consistent with the proposed anionic transition state. A comment can also be made about the competing hydrolysis. The ratio of the rate of ammonolysis of a phthalimide to the rate of its hydrolysis is simply $k_N[NH_3]/k_2$. This ratio is independent of pH, since both species require hydroxide ion, and proceed on unionized phthalimide. The relationship obviously breaks down at very high pH where hydrolysis is second-order in hydroxide ion. Using values determined here for k_N and k_2, one calculates for the parent phthalimide that reaction in a 1 M NH_3 solution will give 94% phthalamide and 6% hydrolysis product. In 10 M NH_3 the phthalamide yield goes to 99%.

Reversibility of phthalamide formation

As reported with the parent system by Crooy and Bruylants (11), phthalamides when placed in NaOH solutions show the rapid formation and subsequent decay of the phthalimide uv peak at 300 nm (Fig. 4). The decay rates are identical to those measured under the same conditions for the hydrolysis of the phthalimide. The formation process must therefore represent cyclization. The net result is the hydrolysis of one of the amide groups.

The cyclization of the phthalamide corresponds to the reverse of the phthalimide ammonolysis. Cyclization rate constants have been measured in concentrated NaOH solutions where the cyclization is much faster than the subsequent phthalimide hydrolysis. As noted by Crooy and Bruylants (11), the following rate law is observed.

$$[9] \quad \text{Rate} = k_{cyc}[\text{Phthalamide}][\text{OH}^-]$$

This is consistent with a mechanism which is the microscopic reverse of that proposed for phthalimide ammonolysis (eq. [8]) – pre-equilibrium deprotonation of one of the amide groups, followed by rate-limiting nucleophilic addition of the anion so-formed to the neighbouring amide. We were unable to detect any deviation from the rate law of eq. [9] even in 0.5 M NaOH solutions, and conclude therefore that the concentration of the deprotonated phthalamide remains small throughout.[5]

Values of k_{cyc} are listed in Table 2. The availability of the rate constants in both directions now means that the equilibrium constant for the system

[10] 
can be determined as the ratio of forward and reverse rate constants

$$K_{eq} = \frac{[\text{Phthalamide}]}{[\text{Phthalimide}][\text{NH}_3]} = \frac{k_N}{k_{cyc}}$$

Values of K_{eq} are also listed in Table 2. The equilibrium constants are large for the 4-substituted and 3-nitrophthalimides **1–5**, consistent with the ease of ammonolysis of these compounds.

A significant substituent effect is observed, electron-withdrawing substituents increasing the equilibrium concentration of phthalamide (ρ = +0.9 on K_{eq}). Electron-withdrawing groups should interact unfavourably with the carbonyl groups in both the phthalimide and phthalamide, and the indication therefore is that this interaction is less important in the amide form. A possible explanation is that the carbonyl groups in the amide are twisted with respect to the plane of the benzene ring, whereas the imide is constrained to be planar. This would mean that the phthalamide would have a diminished resonance interaction of the carbonyls and the 4-substituents. Another feature is the similarity of the 3-NO_2 and 4-NO_2 systems, this being particularly interesting in light of the results to be discussed with the two other 3-substituted imides. The implication is that the steric effect of the 3-NO_2 group is minimal. This may arise from a twisting of this group out of coplanarity with the benzene ring, so that the two oxygen atoms are directed away from the carbonyl groups. There also appears to be a significant solvent effect, the value of K_{eq} for the parent system being eight times smaller in 25% acetonitrile. There is no obvious explanation for this, but it seems to indicate that the phthalamide is a more polar molecule. It should also be noted that K_{eq} as defined in eq. [11] refers to neutral imide, and in base the equilibrium will shift significantly to the imide side because of its deprotonation. This is illustrated for the parent system in Table 3.

TABLE 3. Equilibrium concentrations of phthalamide and total phthalimide in 1 M NH_3 solutions

pH	Phthalamide / ([Phthalimide] + [Phthalimide anion])
7.06	240
8.06	238
9.06	218
10.06	120
11.06	22
12.06	2.4
13.06	0.2

[4] Values of k_N were also determined by fitting the experimental $k^{app}_{NH_3}$ data to eq. [7] with k_N and K_a as unknowns, and show good agreement. We preferred, however, to use the K_a determined in the hydrolysis kinetics, since a much greater pH range was covered in this study, so that the value of K_a should be more accurate.

[5] pK_a values for amide dissociation typically lie in this region. See ref. 19.

Ammonolysis kinetics – 3-methylphthalimide

When the ammonolysis of 3-methylphthalimide was investigated, decidely nonlinear first-order kinetic plots invariably resulted (see insert to Fig. 5). Imide disappearance occurs in two stages, an initial decrease followed by a somewhat slower decrease. This is explained by the following kinetic scheme,

$$\text{[12]}\quad \text{3-Methylphthalimides (I)} \begin{cases} \overset{k_1}{\underset{k_{-1}}{\rightleftharpoons}} \text{3-methylphthalamide (A)} \\ \xrightarrow{k_2} \text{3-methylphthalamic acid anion (H)} \end{cases}$$

with the imide being converted reversibly to the amide and irreversibly to the hydrolysis product. In simple terms, the initial rapid decrease represents the ammonolysis equilibration, where imide does not totally disappear since the equilibrium does not lie completely to the phthalamide side. The subsequent slower decrease corresponds to the hydrolysis of the imide in the imide–amide mixture, until only hydrolysis product remains. It can be noted that in any aqueous ammonolysis the latter product is the product of thermodynamic control.

In rigorous terms the analysis is more complex since the kinetic stages are not at all separated, signifying that the rate constants of eq. [12] are of the same order of magnitude so that all processes are occurring simultaneously. The differential equations for the kinetic system of eq. [12] can be solved (12). We have fitted the experimental curves of absorbance versus time to the appropriate equation[6] to obtain values of the constants k_1, k_{-1}, and k_2 which best satisfy the data. The constant k_2 refers to imide hydrolysis, and indeed the values obtained on the curve fitting were in excellent agreement with those directly measured for hydrolysis. The constants k_I and k_{-1} also take the appropriate form,[7] and provide values of k_N, k_{cyc}, and K_{eq} for the system (Table 2).

The value of K_{eq} is significantly decreased, being over 100-fold smaller than the value in the unsubstituted system. The decrease arises because of a 5-fold slower ammonolysis rate and a 40-fold faster cyclization rate. The effect arises because of greater steric congestion in the amide than in the imide, caused by the introduction of the 3-methyl group. This stabilization of a cyclic form relative to an acyclic one through the introduction of bulky substituents is fairly common (see, for example, ref. 13). In the present case, the phthalamide has three nonbonded groups on adjacent carbon atoms of the benzene ring. Cyclization to the imide releases some of the steric ocngestion caused by this arrangement.

Concentration–time profiles for the three species involved in the system are depicted in Fig. 6 for two aqueous ammonia solutions. The data shown in Fig. 6A represent the situation in the kinetics experiment. This shows that a maximum of only 35% 3-methylphthalamide is formed after 0.5 h, falling to only 12% after 3 h. As shown in Fig. 6B, however, quite high yields can be obtained in concentrated ammonia solutions.

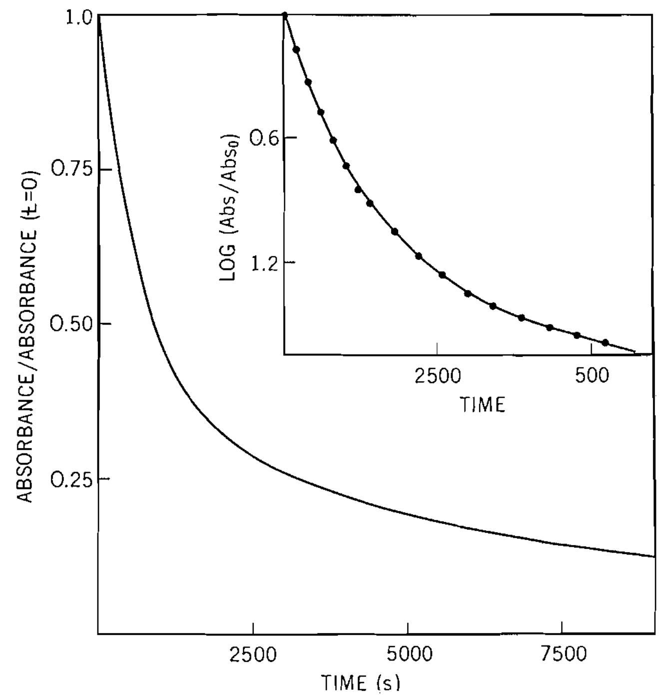


FIG. 5. 3-Methylphthalimide disappearance (λ = 305 nm) in a solution with $[NH_3]$ = 0.75, $[NH_4^+]$ – 0.25, pH = 9.88. Final absorbance is 0.00.

Reversibility is not as great a problem with the more reactive 4-substituted and 3-nitrophthalimides, **1–5**. The very favourable ammonolysis equilibrium drives the equilibrium to the phthalamide side and, particularly in concentrated aqueous ammonia, maintains it there so that the formation of hydrolysis product from the phthalimide is relatively unimportant.

Ammonolysis kinetics – 3-trimethylsilylphthalimide

With 3-trimethylsilylphthalimide, kinetic studies in the ammonia solutions used with the other compounds showed no acceleration in the rate beyond that of the hydrolysis reaction. This implies that ammonolysis is not occurring in these solutions and no phthalamide is forming. In more concentrated ammonia solutions, however, reproducible traces were obtained in which a more rapid initial decrease in absorbance is observed, accounting for about 5–10% of the total phthalimide, followed then by a slower absorbance decrease occurring at essentially the hydrolysis rate (Fig. 7). These curves are similar to those associated with the 3-methylphthalimide (Fig. 5), and they can be analyzed in the same way to provide rate and equilibrium constants for the ammonolysis (Table 2). The equilibrium constant is found to be very small here, being 100-fold smaller than the value for 3-methyl, and 3500 times smaller than the constant for the parent phthalimide in the same solvent. This effect is obviously associated with the increased steric bulk of the trimethylsilyl group, and is not unexpected on the basis of the results obtained with the smaller 3-methyl group. In kinetic terms, the 3500 factor is made up of a 50-fold slower ammonolysis rate coupled with a 65-fold faster cyclization. In terms of the ammonia solution in Fig. 6, the maximum yield of 3-trimethylphthalamide is only 6.5%, obtained after about 1000 s. Over 90% imide remains at this point, hydrolysis product accounting for only 2.4% of the mixture. Thus ammonolysis is more efficient than hydrolysis, but the equilibrium position is unfavourable.

---

[6] With the boundary conditions that at zero time $[I] = [I]_0$, $[A] = 0 = [H]$; then $[I]/[I]_0 = (\lambda_1 - k_{-1})\exp(-\lambda_1 t)/(\lambda_1 - \lambda_2) + (k_{-1} + \lambda_2)\exp(-\lambda_2 t)/(\lambda_1 - \lambda_2)$; $[A]/[I]_0 = k_I \exp(-\lambda_2 t)/(\lambda_1 - \lambda_2) - k_I \exp(\lambda_1 t)/(\lambda_1 - \lambda_2)$; $[H]/[I]_0 = 1 - (\lambda_1 - k_1 - k_{-1})\exp(-\lambda_1 t)/(\lambda_1 - \lambda_2) + (k_1 + k_{-1} - \lambda_2)\exp(-\lambda_2 t)/(\lambda_1 - \lambda_2)$.

[7] $k_I = k_I[NH_3][OH^-]/(1 + (k_w[OH^-]/k_a))$; $k_{-1} = k_{cyc}[OH^-]$.

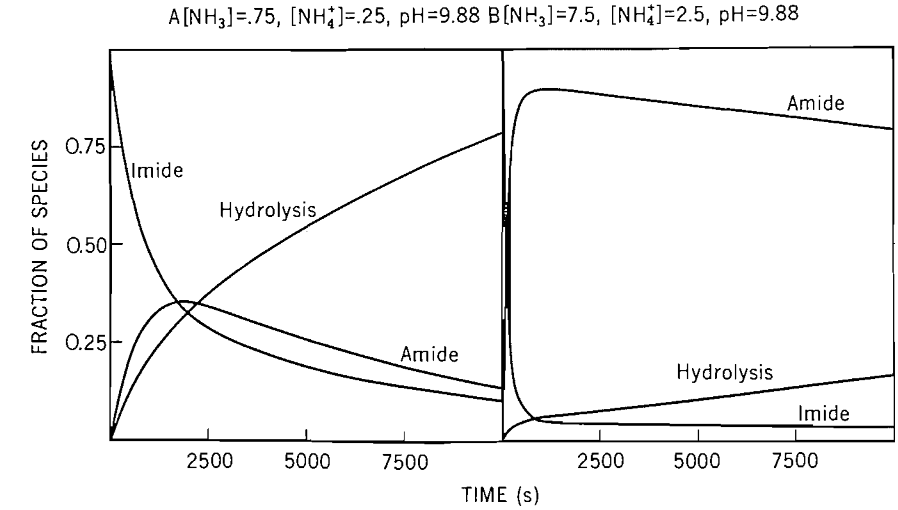

FIG. 6. Concentration of species as a function of time for 3-methylphthalimide in aqueous ammonia (A = dilute, B = concentrated).

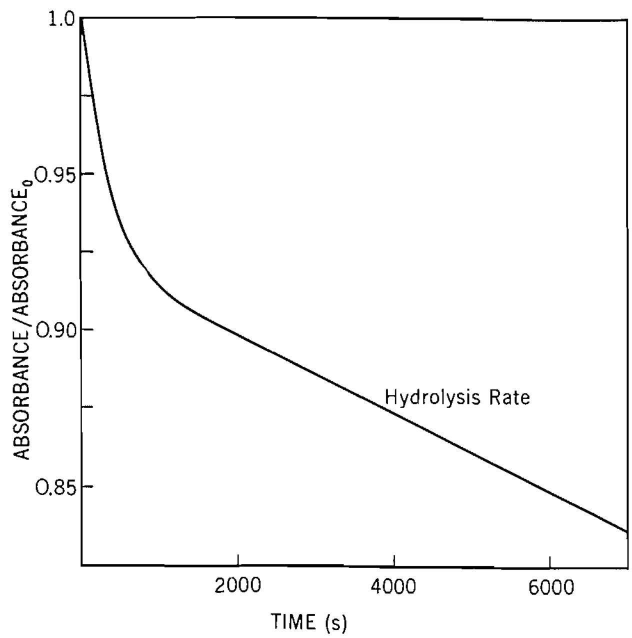

FIG. 7. Disappearance of 3-trimethylsilylphthalimide in concentrated aqueous ammonia $[NH_3] = 7.5$, $[NH_4^+] = 0.25$, pH = 10.6, 25% MeCN, 25°C).

Experimental

Synthesis of starting materials

Reagent grade phthalimide, 4-nitrophthalimide, 3-nitrophthalimide, and phthalamide were purchased from Fisher Scientific and were used without further purification. All products were characterized by ir (in Nujol) and ^{1}H or ^{13}C nmr spectroscopy using a Bruker 250 MHz instrument. Elemental analyses were performed by Galbraith Laboratoires, Knoxville, Tennessee.

4-Chlorophthalimide 3

A. 4-Chlorophthalic acid monosodium salt (100.01 g, 0.449 mol) was added to thionyl chloride (250 mL). The resultant solution was heated at reflux for 2 h, then the excess thionyl chloride was removed under reduced pressure. The remaining orange-yellow solid was heated with 2 L of boiling hexane and the hot suspension was filtered. The cooled filtrate afforded 57.4 g (70%) of 4-chlorophthalic acid anhydride, mp 67–68°C; ir cm^{-1}: 1860, 1790, 1760 (O=C—O—C=O).

B. The 4-chlorophthalic anhydride (55.9 g, 0.339 mol) was mixed with urea (17.8 g, 0.296 mol) and the mixture was gently heated with a Meker burner for 40 min. The liquid cooled to form a yellow solid, which was crushed and dissolved in 400 mL of DMF. Dropwise addition of water (800 mL in total) to the stirring DMF solution, followed by filtration and drying, gave 54.8 g (98%) of pale yellow crystals; mp 209–210°C (lit (14), mp 210°C); ir cm^{-1}: 3195 (N—H) 1787, 1705 (C=O).

3-Methylphthalimide 6

Urea (7.8 g, 0.130 mol) was mixed with 3-methylphthalic acid anhydride (24 g, 0.146 mol) and the mixture was gently heated with a Meker burner for 40 min. The melt was cooled, crushed, and suspended in water (200 mL) for 1 h. The brown solid was filtered off and dissolved in 100 mL of DMF to which decolorizing carbon (0.5 g) was added. The suspension was stirred for 1 h, then filtered. Dropwise addition of water (400 mL) to the DMF solution yielded 16.5 g (70%) of a beige solid; mp 186–188°C (lit (15) mp 188–189°C); ir cm^{-1}: 3220 (N—H), 1780, 1730 (C=O).

*4-*tert*-butylphthalimide, 4*

4-*tert*-Butylphthalic acid anhydride (61.4 g, 0.30 mol), prepared in three steps from *o*-xylene, was mixed with urea (18.0 g, 0.30 mol) and gently heated with a Meker burner for 30 min. The melt was cooled, and dissolved in 125 mL of DMF. Dropwise addition of water (375 mL) produced 57.8 g (94.5%) of a beige solid; mp 136–138°C (lit. (16) mp 131–132°C); ir cm^{-1}: 3220 (N—H), 1782, 1720 (C=O).

3-Trimethylsilylphthalimide, 7

3-Trimethylsilylphthalic acid anhydride (87.4 g, 0.397 mol), prepared in six steps from *o*-xylene (3) was mixed with urea (23.8 g, 0.397 mol). The reagents were kept in a nitrogen atmosphere, while being heated to produce a melt, for 30 min. The liquid melt was cooled, crushed, and stirred in water (600 mL) for 19 h. The crude product was filtered off, washed with water (500 mL), and dried in a vacuum oven for 4 h. The solid was dissolved in acetone (400 mL) and decolorizing carbon (2 g) was added to the solution. The suspension was filtered after 30 min. Dropwise addition of water (1.2 L) to the acetone solution, followed by filtration and water washing (3 × 500 mL), yielded 74 g (85%) of a white crystalline solid; mp 148.5–150.5°C; ir cm^{-1}: 3190 (N—H), 1769, 1722 (C=O). *Anal.* calcd. for $C_{11}H_{13}NO_2Si$: C 60.24, H 5.97, N 6.39, Si 12.81; found: C 60.44, H 5.93, N 6.48, Si 12.59.

4-Nitrophthalamide

4-Nitrophthalimide (100.5 g, 0.520 mol) was added to concentrated ammonium hydroxide (530 mL) and the suspension was stirred for 6 h, then cooled to 0°C for 19 h. The suspension was filtered and the product was washed with ether, then dried, yielding 107 g (99%) of a white powder; mp 196–198°C; ir cm^{-1}: 3440, 3440 (NH_2), 1668, 1587 (C=O).

4-Chlorophthalamide

4-Chlorophthalimide (53.2 g, 0.293 mol) was added to concentrated ammonium hydroxide and the suspension was stirred for 5 h, filtered, and dried, producing 41.6 g (72%) of a pale yellow powder; mp 196–198°C (lit. (17) mp 194–196°C); ir cm^{-1}: 3420, 3320, 3160 (NH_2), 1660, 1592 (C=O).

4-tert-Butylphthalamide

4-*tert*-Butylphthalimide (56.1 g, 0.274 mol) was suspended in concentrated ammonium hydroxide (825 mL). The stirred beige suspension quickly formed a dirty yellow solution which immediately became a milky suspension. At this point, more concentrated ammonium hydroxide (200 mL) was added since the mixture was too thick to stir, and stirring was continued for 3 h. The product was filtered off, washed with water (3 × 300 mL), and dried, giving 60.7 g (79.7%) of a white solid; mp 177–178°C (lit. (16) mp 180–181°C); ir cm^{-1}: 3300, 3190 (NH_2), 1670, 1595 (C=O).

3-Nitrophthalamide

3-Nitrophthalimide (256 g, 1.33 mol) was added to concentrated ammonium hydroxide (3225 mL). The yellow suspension gradually became white in color as the mixture was stirred, for 21 h. The reaction mixture was cooled to 0°C for 19 h, then filtered, washed with water (2 × 500 mL), and dried, giving 82.7 g (93%) of a white powder; mp 200–201°C (lit (18) mp 204–205°C); ir cm^{-1}: 3430, 3340, 3210 (NH_2), 1671 (C=O). *Anal.* calcd. for $C_8H_7N_3O_3$: C 45.94, H 3.38, N 20.08; found: C 45.69, H 3.48, N 19.94.

3-Methylphthalamide

3-Methylphthalimide (15 g, 0.084 mol) was added to liquid ammonia (100 mL) which had been condensed into a 300-mL Parr pressure reactor. The reactor was sealed and the temperature was raised to 90°C (840 psi; 1 psi = 6.89 kPa) in 1 h. The reaction mixture was stirred for 20 h, then cooled to less than −50°C. When the pressure in the reactor was close to 1 atm (101.3 kPa) the vessel was opened and the ammonia was allowed to evaporate off, producing a beige solid (15 g). An ir spectrum indicated the product was a mixture of 3-methylphthalimide and 3-methylphthalamide. A Soxhlet extraction of the crude product was carried out, with methylene chloride, for 23 h. The ir spectrum of the solid remaining in the thimble indicated there was only 9.17 g (56%) 3-methylphthalamide remaining. A sample (1.2 g) of the product was recrystallized from methanol; mp 182–184°C. *Anal.* calcd. for $C_9H_{10}N_2O_2$: C 60.66, H 5.66, N 15.72; found: C 60.79, H 5.78, N 15.54.

Attempt to synthesize 3-trimethylsilylphthalamide

3-Trimethylsilylphthalimide (15 g, 0.068 mol) was added to ammonia (150 mL) which had been condensed into a 300-mL Parr pressure reactor. The reactor was sealed, and heated to 90°C (860 psi) for 20 h. The vessel was then cooled to less than −50°C and the ammonia was allowed to evaporate away. A ^{13}C nmr spectra of the remaining beige solid (14.26 g) indicated that the product was ~90% starting material.

Kinetic methods

Kinetic measurements were made on a Unicam SP 1800 spectrophotometer, equipped with a jacketed multiple cell block maintained at 25.0 ± 0.01°C by an external water bath. A 3-μL solution of the phthalimide or phthalamide substrate was injected into 30 mL of the appropriate solution pre-thermostatted at 25°C, and the change in absorbance at 305 nm (330 nm for nitro compounds) monitored as a function of time. For phthalimide hydrolysis and ammonolyses, first-order rate constants were evaluated as slopes of plots of ln $(A - A_0)$ versus time. First-order rate constants for phthalimide appearance from phthalamide were determined using the Guggenheim method.

This paper is dedicated to the 10th anniversary of the Xerox Research Centre of Canada

MITCHELL A. WINNIK, ONDER PEKCAN, and M. D. CROUCHER. Can. J. Chem. **63**, 129 (1985).

Nonaqueous dispersions of poly(methyl methacrylate) (PMMA) particles, sterically stabilized with polyisobutylene (PIB), were prepared with naphthalene (N) groups covalently incorporated into the PMMA chains. These materials have a complex morphology of phase-separated PMMA and PIB microdomains, with the N groups in the PMMA microphases. The phosphorescence intensity and decay times of the N groups were measured as a function of temperature over the range 77–295 K for dispersions in methylcyclohexane and for freeze-dried powder samples. An Arrhenius treatment of the radiationless decay rate showed a change in slope at −35°C. The activation energy for the radiationless decay process is 3.8 kcal/mol in the −35 – +22°C temperature region, identical to that found for pure PMMA by nmr for chain motion associated with the α-methyl relaxation process. We believe that the phosphorescence experiment is sensitive to the diffusion of oxygen and other impurities in the sample. These rates increase as the temperature is raised, enhancing the rate of phosphorescence quenching. These experiments indicate that phosphorescence measurements on labelled samples are suitable for studying relaxation processes within individual microphases of a polyphasic composite material.

MITCHELL A. WINNIK, ONDER PEKCAN et M. D. CROUCHER. Can. J. Chem. **63**, 129 (1985).

On a préparé des dispersions non aqueuses de particules de poly(méthacrylate de méthyle) (PMAM) stabilisées stériquement par du polyisobutylène (PIB) et dans lesquelles des groupes naphtalènes (N) ont été incorporés d'une façon covalente dans les chaînes de PMAM. Ces composés ont une morphologie complexe comportant des microdomaines séparés de phases de PMAM et de PIB avec les groupes N situés dans les microphases de PMAM. Opérant à des températures allant de 77–295 K et pour des dispersions dans le méthylcyclohexane et des échantillons de poudres lyophilisées, on a mesuré l'intensité de la phosphorescence et le temps de décroissance de l'émission des groupes N en fonction de la température. Si on traite les vitesses de décroissance non radiative par le méthode d'Arrhénius, on observe un changement de pente à −35°C. L'énergie d'activation pour le processus de décroissance non radiative est de 3,8 kcal/mol dans l'intervalle allant de −35°C – +22°C; cette valeur est identique à celle trouvée par rmn, dans le cas du PMAM à l'état pur, pour le mouvement de chaîne associé au processus de relaxation du méthyle en α. Nous croyons que l'expérience de phosphorescence est sensible à la diffusion de l'oxygène et d'autres impuretés présentes dans l'échantillon. Ces vitesses augmentent avec la température, augmentant ainsi la vitesse avec laquelle la phosphorescence est piégée. Ces expériences indiquent que les mesures de phosphorescence sur des échantillons marqués conviennent bien à l'étude des processus de relaxation à l'intérieur de microphases individuelles d'un matériel composite à phases multiples.

[Traduit par le journal]

Phosphorescence measurements on polymer samples doped or labelled with appropriate dye molecules provide powerful means for studying properties of polymers in the solid state. Over the past 20 years various research groups have used these techniques to study the dynamics of gas permeability (1–3), and to detect various relaxation processes (4–7) in polymer films. A careful reading of these papers suggests that both the phosphorescence intensity of a dye and its phosphorescence decay time are sensitive to many of the processes which occur in the glassy state of polymers. One can observe the glass transition (at temperature T_g), the β transition (T_β), and in some instances the α′ transition due to local mode relaxation of the main polymer chain. Examples of sensitivity to sample history including hysteresis effects are known. Activation energies for polymer relaxation pathways can be determined, and these are comparable to those obtained by solid state nmr techniques.

One of the curious features of these experiments is that nearly all of them have been reported by research groups specializing in luminescence spectroscopy or photochemistry. Either the usefulness of these methods is not appreciated by the polymer community in general or they consider the techniques to be difficult, complex, or arcane. Perhaps it is felt that one needs optically transparent samples and sophisticated equipment. Our results reported here may serve as an incentive to others contemplating such experiments. We report phosphorescence intensity and decay measurements, obtained with rather primitive equipment, and with samples which are powders, suspensions, and dispersions, placed in cylindrical quartz tubes.

The system we are investigating is a particle ca. 2 μm in diameter, composed of two incompatible polymers, poly(methyl methacrylate) (PMMA) and polyisobutylene (PIB) (8–11). Nonaqueous dispersions of these particles have important industrial applications, particularly in electrostatic imaging technology (12). Although this material is commonly considered to have a "core-shell" structure, we have shown that its real morphology is more complex and more interesting. We have proposed a "microphase model" for its structure (10), with threads of PIB forming a connected interpenetrating network

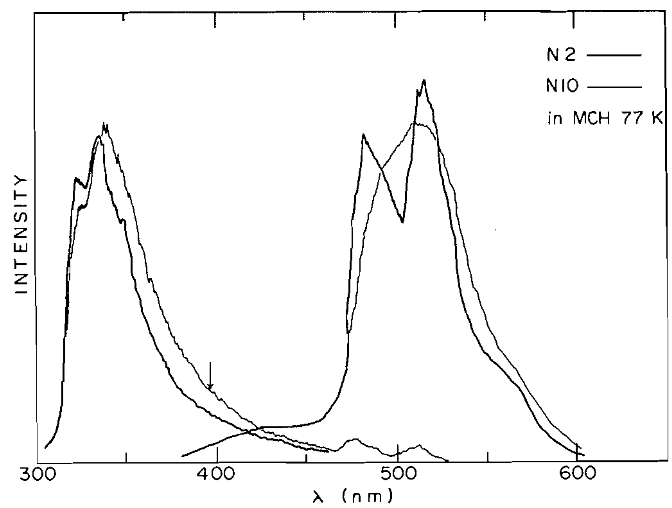

FIG. 1. The fluorescence and phosphorescence spectra of N2 and N10 dispersions in methylcyclohexane at 77 K.

throughout the interior of the particle.

This model was proposed to explain apparently contradictory results of fluorescence quenching experiments carried out on particles labelled in the PMMA chains with naphthalene (N) groups or anthracene (A) groups. The particles were dispersed in hydrocarbon solvents and small molecule quenchers were added to the liquid. When the quencher was very soluble in PIB and could communicate with the excited N* groups over substantial distances (e.g. 20–40 Å by a Förster energy transfer mechanism), we observed that quenching occurred within minutes of sample preparation, even for N groups deep within the core of the particle (8, 10). Quite different behavior was seen for quenchers that were soluble in PMMA and poorly soluble in PIB, particularly when quenching involved short range interactions (e.g. 4–5 Å, by exciplex formation) (11). Here it took days or weeks for the sorption process to come to equilibrium.

Because the N groups were introduced into the particle as an N-substituted methacrylate during a step in particle synthesis involving PMMA polymerization, the N groups must be covalently linked to the PMMA chains. Phosphorescence at room temperature from the particles indicates that the N groups are located in glassy PMMA phases. The N groups thus serve as molecular spies for events transpiring within the PMMA microdomains. Luminescence spectra of these labelled materials are shown in Fig. 1.

In this report we describe the phosphorescence intensity and phosphorescence decay times of these N-labelled PMMA particles as they are affected by changes in temperature and by the presence of hydrocarbon solvents. These experiments permit the α-methyl transition within the PMMA microphases to be identified.

Experimental

The synthesis and characterization of the particles have been reported previously (8–11). The particles, 2 μm in diameter, have compositions containing monomer units in mole ratios of isobutylene/methyl methacrylate/naphthylmethyl methacrylate of 13:100:2 and 13:100:10. We have referred to these materials as N2 and N10, respectively.

Phosphorescence measurements were carried out on a Hitachi–Perkin–Elmer MPF2 spectrofluorimeter. Intensity measurements were made in conjunction with a rotating mechanical chopper to remove prompt fluorescence. Phosphorescence decay measurements were made in a rather primitive fashion by blocking the excitation source of the spectrometer and recording the time profile of the intensity decay at 500 nm on a strip chart recorder (9, 13). These traces were digitized with a digitizing x,y-plotter and fitted to an exponential function by a nonlinear least-squares method. While reproducibility was excellent for decays on the order of 1–3 s, the method gives only the first decade of the intensity decay. Small departures from exponentiality would not have been detected (13).

Samples were prepared in quartz tubes fitted with a graded seal. Those samples in which oxygen was rigorously removed, by evacuating 3 – 5 h at 35°C on a vacuum line at 1×10^{-5} Torr (1 Torr = 133.3 Pa), were sealed under vacuum. Dispersions of N2 were prepared by weighing 6-mg samples of N2 into the sample tubes and adding 1 mL of methylcyclohexane. These were sonicated for ca. 1 min using a low-power ultrasonic cleaning bath.

Results and discussion

Spectroscopic considerations

Triplet states of organic molecules are extremely sensitive to quenching by oxygen and other impurities. As a consequence, phosphorescence is normally observed only in very viscous media – in crystalline hosts and glassy polymer films at ordinary temperatures, and in glassy matrices formed from organic solvents at low temperatures. Early sudies (14) focussed on two viscosity regimes in simple organic media: a low viscosity domain where the triplet lifetime ${}^3\tau$ was determined largely by diffusion processes involving quenchers, and a high viscosity region where ${}^3\tau$ depended upon the unimolecular rate constants for radiative (k_p) and non-radiative (k_{nr}) decay.

This view is somewhat oversimplified (15). If the impurity concentration is significant, static quenching can contribute to the radiationless decay rate. Similarly at high enough chromophore concentration, self-quenching becomes important (9), even in the absence of mass diffusion. When these bimolecular processes become dominant, one observes decreases in the phosphorescence quantum efficiency (ϕ_p) without concomitant changes in ${}^3\tau$: Some excited states, adjacent to a quencher, are quenched essentially instantaneously, and thus do not contribute to the signal used to determine ${}^3\tau$.

Extensive studies have shown that the unimolecular decay rates of aromatic triplet states are sensitive to temperature (1). Lifetimes decrease by about a factor of two between room temperature and 150 K. Below 150 K, both ${}^3\tau$ and ϕ_p remain constant. For many molecules, ϕ_p^0 (the superscript ^{0} implying the low temperature value) is quite small. For naphthalene, $\phi_p^0 = \phi_{ST}^0\, k_p/(k_p + k_{nr}^0) = 0.05$, where ϕ_{ST}^0, the triplet formation efficiency, is significantly larger than 0.05. Since k_p is independent of temperature (1, 15), this indicates that k_{nr} has both temperature-dependent and temperature-independent components.

The theory of radiationless triplet decay has been examined by a number of authors including Lin and Bersohn (16), Jortner and Berry (17), and Dexter and Powder (18). These groups give an expression for k_{nr} of the form

$$[1] \quad k_{nr} = k_{nr}^0\,(1 + A\mathrm{e}^{-E_a/kT})$$

which, in conjunction with the expression ${}^3\tau^{-1} = k_p + k_{nr}$, leads to the expression

$$[2] \quad \tau^0/\tau - 1 = a\mathrm{e}^{-(E_a/kT)}$$

The parameters A, a, and E_a are constants related to the vibrational levels of the matrix into which the excitation energy is dissipated.

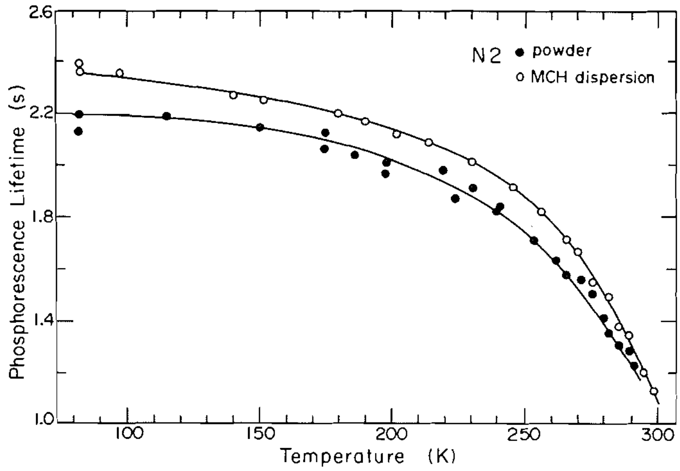

FIG. 2. Phosphorescence lifetimes of N2 as a function of temperature for (○) dispersions in methylcyclohexane and for (●) solid powder samples.

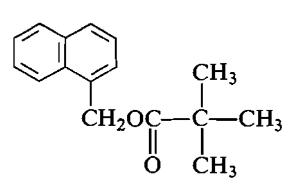
The case of naphthalene in PMMA has been investigated extensively by Jones and Siegel (1). They examined thin films (10 μm) which were carefully degassed and extensively annealed under vacuum. Exponential decays and simple Arrhenius behavior over the temperature range 77–300 K was observed only if these precautions were taken.

Oxygen was not the only quencher initially present in the sample. Residual monomer was also implicated. These authors treated their data according to eq. [2], taking the 77 K lifetime as the ${}^3\tau^0$ value. They found an E_a value of 500 cm^{-1} (1.4 kcal/mol). The temperature-dependent component of the radiationless decay was attributed to coupling of the decay to low-frequency bending vibrations in the PMMA matrix.

Through their care in removing quenching impurities, Jones and Siegel (1) simplified their experiments and data interpretation. Their ${}^3\tau$ values were insensitive to mechanical relaxation processes within the polymer film. If one takes less care in sample preparation, other factors, including diffusive quenching, contribute to the value of ${}^3\tau$. The magnitudes of these factors are sensitive to mechanical relaxation processes within the polymer. As we discuss below, impurities act to reveal, via phosphorescence quenching, various relaxation phenomena characteristic of the polymer matrix.

Triplet lifetime measurements in N2

Triplet lifetimes of freeze-dried N2 particles, in the powder form, were measured at temperatures between 77 K and room temperature. The samples were chilled rapidly in liquid nitrogen and measurements were taken from time to time as the sample warmed. Dispersions of N2 in methylcyclohexane were treated similarly. As Fig. 2 indicates, at temperatures below 150 K, the phosphorescence lifetimes are essentially independent of temperature.



1

One of the interesting features of the data is that the phosphorescence lifetimes depend upon the local concentration of N groups in the PMMA phase. This aspect has been examined in detail previously (9). Thus ${}^3\tau$ (N10) is shorter than ${}^3\tau$ (N2), which in turn is somewhat shorter than ${}^3\tau$ for a model compound, 1-naphthylmethyl pivalate (**1**), at 10^{-4} *M* in methylcyclohexane, or in a PMMA film at 77 K. The process of self-

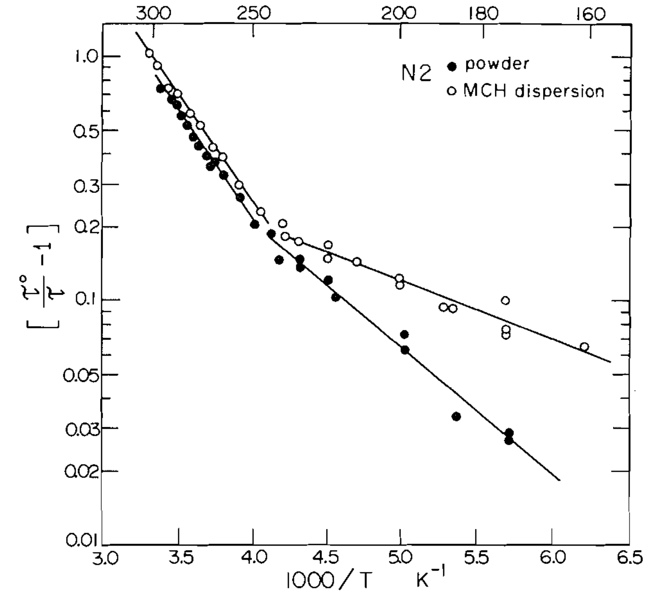


FIG. 3. Plot of log (τ^0/τ − 1) vs. $1/T$ for the data from Fig. 2.

[3] $N + N^* \rightarrow 2N$

quenching, eq. [3], provides an additional radiationless pathway, presumably via triplet excimer formation, to shorten the triplet lifetime.

The fact that ${}^3\tau$ in N2 is longer at 77 K in the methylcyclohexane dispersion than in the dry powder implies that the solvent acts to increase the mean separation between N groups in the particle. Curiously, the lifetime differences are exacerbated at low temperatures and disappear as the respective samples are allowed to warm. This result is in accord with separate observations on the fluoroescence of N groups in N2 and N10. One finds that the fluorescence lifetimes at room temperature are also sensitive to the local N concentration, but are nearly unchanged when N2 or N10 powders are dispersed in methylcyclohexane.[4]

Our interpretation of the triplet lifetime results is that the alkane solvent does not swell the PMMA microphases at room temperature. Rather it penetrates into various sites of free volume[5] and acts to retard the contraction of the PMMA phases as they are cooled.

The α-methyl relaxation process

The triplet lifetime data from N2 as a function of temperature are replotted in an Arrhenius fashion according to eq. [2] in Fig. 3. While the plots are curved, both are fit quite reasonably to two intersecting straight lines. The intersection temperature for both curves is approximately −35°C. This temperature corresponds to a relaxation process in PMMA as determined by wide-line ^{1}H nmr (20). This relaxation process corresponds to commencement of backbone methyl (α-methyl) group rotation in the polymer.

[4] O. Pekcan, unpublished observations.
[5] For an important discussion of non-solvent penetration into glassy polymers and its consequence on chain motion see ref. 19.

The activation energies E_a^{HT} of the high temperature portion of Fig. 3 are 1320 cm^{-1} (3.8 kcal/mol) for the N2 powder and 1460 cm^{-1} (4.2 kcal/mol) for the dispersion of N2 in methylcyclohexane. The former is very close to the value of 1260 cm^{-1} determined by Kawai (20*a*) from the temperature dependence of ^{1}H nmr correlation time for the α-methyl group relaxation process in solid PMMA.

In our opinion, the agreement of the phosphorescence experiments with the nmr data is not entirely coincidence. Rather, we believe that the $^3\tau$ values between −35°C and 25°C are sensitive to the conformational mobility of the backbone methyl groups in PMMA. The origin of this sensitivity is most likely related to the onset of diffusive quenching of N^{*3} by oxygen and other impurities in the matrix (22). Diffusion is enhanced by free volume fluctuations coupled to the increasing rotational mobility of the α-methyl groups at temperatures above −35°C.

These results pose a singular dilemma. Although the apparent onset temperature of −35°C from the phosphorescence lifetime measurements corresponds to $T_{\alpha\text{-Me}}$ determined by ^{1}H nmr for the α-methyl group rotation, the two experiments refer to very different time scales. The nmr experiment is sensitive to methyl group rotations in the megahertz frequency range (20, 21). The phosphorescence lifetimes are sensitive to impurity diffusion on the time scale of seconds. The 10^6 difference in experimental frequency should lead to a large (ca. 40°) difference in the value of $T_{\alpha\text{-Me}}$. The apparent E_a values for both measurements, however, should be the same.

This dilemma can be resolved by recognizing that the break in the Arrhenius plot in Fig. 3 does not necessarily represent a critical temperature of the system. Rather, it represents the temperature at which the rate of process with E_a = 1320 cm^{-1} overtakes the rate of a lower temperature process with E_a = 830 cm^{-1}. While impurity diffusion in a polymer matrix below T_g can lead to enhanced phosphorescence quenching, impurity diffusion itself is slow. Free volume increases which enhance the rate of α-methyl group rotation also enhance diffusion rates. Our experiments indicate that long range diffusion of impurities becomes efficient at reaching excited chromophores on a time scale of seconds when the free volume of the system is sufficient to permit α-methyl group rotation rates in the MHz range. The coincidence is that the break in the Arrhenius plot in Fig. 3 occurs at the same temperature as the $T_{\alpha\text{-Me}}$ found by ^{1}H nmr T_1 measurements.

Below −35°C, important differences appear in the phosphorescence decay times of N2 in the presence or absence of methylcyclohexane. The $^3\tau$ values decrease less with temperature in the alkane dispersion than in the dry powder. Activation energies are presented in Table 1. We have previously suggested that methylcyclohexane retards the volume contraction of the PMMA phase as the temperature is lowered. This implies some solvent penetration into the PMMA, although the details of the process are unclear.

If the preceding explanation is correct, bimolecular self-quenching ($N^{*3} + N \rightarrow 2N$) makes an important contribution to $^3\tau$ under these conditions, since contraction of the PMMA phases decreases the mean separation between N groups. This is a testable hypothesis, since self-quenching will no longer be important in particles containing less than 0.1% N groups. Particles of that composition are currently being prepared.

TABLE 1. Activation energies for radiationless decay rates for naphthalene groups in N2

	E_a (cm^{-1})	
Temperature range (°C)	Solid powder	Methylcyclohexane dispersion
−35 – 25	1320 ± 70	1470 ± 70
−180 – −35	830 ± 30	370 ± 20

Phosphorescence intensity measurements

While it is difficult to make quantitative luminescence intensity measurements on powder samples or turbid solutions, reasonable measurements of intensity versus temperature can be made on individual samples. We have carried out five sets of measurements on N phosphorescence as a function of temperature. These measurements involved N10 powder samples and N10 dispersions in methylcyclohexane, some samples degassed and sealed under vacuum, and other identical samples stoppered in the presence of air at room temperature. In addition we examined a dilute solution (10^{-4} *M*) of 1-naphthylmethyl pivalate (**1**) in methylcyclohexane. These samples were chilled rapidly to liquid nitrogen temperature. The phosphorescence intensity at 500 nm was monitored as the samples were allowed to warm.

These results are presented in Fig. 4. The top part (a) shows the intensity vs. temperature plots for the degassed N10 samples; (b), the same samples in the presence of air; and (c), the model compound **1** in aerated methylcyclohexane. There are numerous interesting and peculiar features present, not all of which can be interpreted at the present time.

The most straightforward to understand is that of **1** in methylcyclohexane. When chilled to 77 K, the solvent forms a transparent glass (T_g = 87 K) (23), where impurity diffusion is slow. As the sample warms, it begins to crystallize (24). The microcrystals formed serve to protect the chromophores from quenching, either by trapping them or by increasing the effective microscopic viscosity of the medium. At higher temperatures, (i.e. above −145°C) solvent mobility is such that larger crystals form, excluding both impurities and **1**. Quenching becomes more effective. Above the melting point of the solvent (−126°C), there is very little phosphorescence.

In the N10 powder samples, the intensity vs. temperature plots are rather featureless. The small dip at ca. −150°C seems to be reproducible. Whether or not it originates in some molecular relaxation process (25) in the PMMA is a matter of speculation. Phosphorescence persists to higher temperature in the degassed rather than the aerated samples.

The N10 dispersions show a number of peaks and valleys. These features are consistently reproducible. Their interpretation is difficult, and it is important to keep in mind that one cannot compare absolute intensities among different samples. The powder and dispersion samples, in Figs. 4(a) and (b), for example, have been normalized to equal intensity at 77 K. In our opinion, these features reflect aspects of quencher diffusion in the PMMA microdomains and interphase regions. Since these features do not appear in the phosphorescence lifetime experiments, quencher diffusion must be localized. It must occur on time scales much faster (less than 0.1 s) than our decay measurements permit us to detect.

Perhaps the most important aspect of these results is that the presence of a non-solvent for PMMA has such an influence on diffusive processes within the PMMA phases. The nature of this influence is still unclear and perhaps will become more apparent as our work progresses.

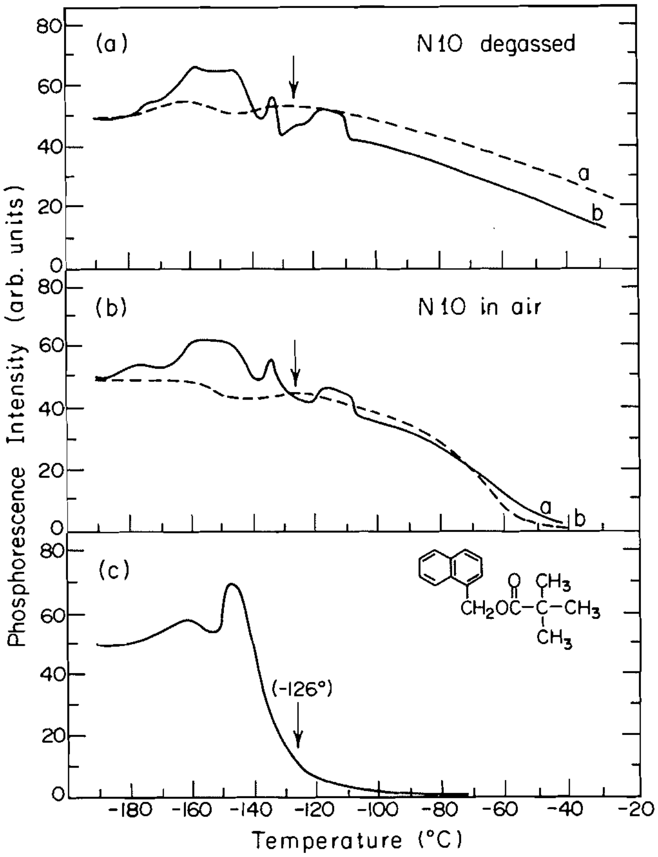

FIG. 4. Plot of phosphorescence intensity at 500 nm vs. temperature. (a) degassed samples of N10 (- - - - powder, —— dispersion in methylcyclohexane); (b) aerated samples of N10 (- - - - powder, —— dispersion); (c) aerated solution of 1-naphthylmethyl pivalate (**1**) in methylcyclohexane.

Conclusions

Phosphorescence decay times in PMMA phases labelled covalently with naphthalene groups are sensitive to mechanical relaxation processes in the glassy polymer. This sensitivity arises from impurity diffusion, which is coupled to the molecular motion of the polymer chains. The activation energy for diffusive quenching which we obtain corresponds to that previously determined by nmr methods for chain motion in PMMA (20). What is remarkable about our experiments is that the N groups were incorporated into the PMMA chains of a heterogeneous material composed of PMMA, polyisobutylene (PIB), and a graft of PMMA branches onto PIB. These results indicate that the PMMA chains demix into microphases. While the apparent T_g of this material has decreased to ca. 75°C compared to 105°C for pure PMMA, the activation energy for the α-methyl group relaxation within the PMMA microphase is unchanged from its value in the pure homopolymer.

These results offer encouragement that fluorescence and phosphorescence methods will provide means for studying relaxation processes within the individual microphases of blends and other composite polymer systems.

Received April 16, 1984

This paper is dedicated to the 10th anniversary of the Xerox Research Centre of Canada

ZORAN D. POPOVIC, RAFIK O. LOUTFY, and AH-MEE HOR. Can. J. Chem. **63**, 134 (1985).

Photoconductivity of a series of perylene tetracarboxyl-dimides has been studied by delayed-collection-field and electric field induced fluorescence quenching techniques. It has been shown that these materials exhibit both extrinsic (impurity controlled) and intrinsic carrier generation originating from the first excited singlet state. Perylene tetracarboxyl-diimides are photoactive in the visible spectral range and their carrier generation efficiencies compare well with generation efficiencies in the best known organic photoconductors. This makes them suitable for xerographic applications using visible light.

ZORAN D. POPOVIC, RAFIK O. LOUTFY et AH-MEE HOR. Can. J. Chem. **63**, 134 (1985).

Faisant appel à des techniques de piégeage de la fluorescence induite par un champ électrique et par un champ à collection retardée, on a étudié la photoconductivité d'une série de pérylènes tétracarboxyl-diimides. On montre que ces matériaux peuvent générer des transporteurs, à la fois d'une façon extrinsèque (controlée par les impuretés) et d'une façon intrinsèque; ces propriétés auraient leur origine dans le premier état singulet excité. Les pérylènes tétracarboxyl-diimides sont photoactifs dans la région du visible et leurs efficacités pour générer des transporteurs se compare bien avec les efficacités de génération des photoconducteurs organiques les mieux connus. On peut donc les considérer pour des applications xérographiques utilisant de la lumière visible.

[Traduit par le journal]

Introduction

In recent years the interest in photoconductivity in organic materials has ceased to be purely academic. This was mainly due to successful applications of organic photoconductors in xerography. After the pioneering work on the PVK–TNF system (1), many classes of photoconductive organic compounds have been found which can be used in xerographic photoreceptors. These include phthalocyanines (2), squaraines (3), thiopyrilium dyes (4), etc. Recently it has been shown that N,N'-bis-substituted perylene 3,4,9,10-tetracarboxyl-diimides exhibit high photoconductivity in both photovoltaic and xerographic applications (5). In the present study we have chosen to investigate in some depth the photoconductive behaviour of this class of compounds.

In a recent series of papers on X and β polymorphs of metal-free phthalocyanine, delayed-collection-field and electric field induced fluorescence quenching experiments were used to elucidate the mechanism of carrier generation (6–9). In the present work we will apply these techniques to study the carrier generation mechanism and also the influence of molecular structure and impurities on carrier generation in perylene derivatives.

Experimental

Materials

The chemical structures of the four compounds we investigated are given in Fig. 1. These materials were synthesized via the reaction of perylene 3,4,9,10-tetracarboxylic dianhydride with the desired amine. Products were purified by temperature gradient sublimation (10). The last compound (IV) is obtained as a mixture of two isomers shown in Fig. 1. The sublimed crystals therefore probably contained both isomers. The polymer binder used for fabrication of sandwich cells was polycarbonate (GE/Merlon) and the solvent used to prepare casting solutions was spectral grade methylene chloride.

Cell fabrication

Samples consisted of about 5 wt.% dispersion of the pigment in the polymer matrix draw-bar coated onto NESA glass slides. The coating solution was prepared by ball-milling the polymer, pigment, and solvent for 24 h. On top of the organic film Al was evaporated as the second electrode. Film thickness, which was between 1.5 μm and 2 μm, was determined from capacitance measurements assuming the composite relative dielectric constant of 2.9 (11). Optical micrographs of the cells showed that most of pigment particles were about 1 μm in size, with a few larger particles also present. The schematic representation of the sandwich cell is shown in Fig. 2.

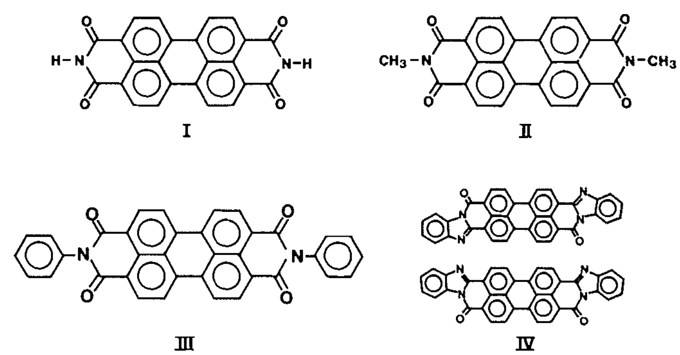

FIG. 1. Structural formulas of perylene diimides investigated in this work. In the text they are referred to as perylene I, II, III, and IV.

Measurements

Relative photoresponse, R, was determined by the delayed-collection-field technique (12). It was obtained as:

$$[1] \quad R = \frac{\Delta V}{I_{\text{light}}}$$

where ΔV is light induced voltage drop on the sample and I_{light} is the incident light intensity.

In the delayed-collection-field experiment the sample is illuminated with a short laser pulse (5 ns) under specified external voltage bias, which determines the electric field, E_{appl}, applied to the sample at the moment of illumination. After a short delay (typically 0.1 μs for our experimental set-up) a strong collection field, E_{coll}, is applied, which separates the photogenerated carriers. In order for the delayed-collection-field measurement to be meaningful, the relative photoresponse should saturate as the collection field is increased.

Electric field induced fluorescence quenching, $\Phi(E)$, is determined by the equation:

$$[2] \quad \Phi(E) = \frac{I_f(0) - I_f(E)}{I_f(0)}$$

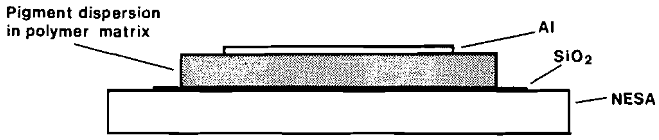

FIG. 2. Schematic diagram of the sandwich cell used in the measurements.

where $I_f(E)$ is the fluorescence signal normalized to the incident laser pulse intensity at the electric field E applied to the sample. Both R and Φ were measured simultaneously using a computerized signal averaging system described previously (8).

Fluorescence spectra were measured by exciting the sample by 5-ns light pulses from a Molectron nitrogen laser – dye laser system. The detection system consisted of a JY-20 monochromator, RCA C31034 GaAs photomultiplier tube, and PAR Model 162 boxcar integrator. For action spectra measurements (wavelength dependence of the photoresponse) Photochemical Research Associates Model 610C pulsed Xenon lamp and JY-20 monochromators were used providing 2.5-μs light pulses. All different instruments were controlled by a Cromemco System III microcomputer and every experimental point is typically an average of 100 measurements.

Results and discussion

In Figs. 3 and 4 action spectra and fluorescence spectra of compounds I–IV (Fig. 1) are presented. Action spectra were measured under the following electric field conditions: $E_{appl} = E_{coll} = E$. The apparent quantum efficiency, η', was obtained using the equation (13).

$$[3] \quad \eta' = \frac{C\Delta V}{eN_\Phi}\frac{1}{f_p}$$

where C is the total capacitance of the measuring circuit, ΔV is the voltage drop induced in the sample by pulsed illumination, e is the electron charge, N_Φ the number of light quanta falling on the sample, and f_p the relative volume of the sample occupied by photoconductive particles. As discussed in detail in ref. 13, the apparent quantum efficiency given by eq. [3] is approximately equal to the true carrier generation efficiency for illumination wavelengths which are strongly absorbed in photoconductive particles. It is interesting to note that there is a small but systematic discrepancy between sample photoresponse obtained for positive and negative bias of the semitransparent NESA electrode, with the negative bias giving consistently smaller photoresponse. This may be caused by either the existence of surface sensitized photoconductivity for holes or by slight differences in charge trapping and surface recombination parameters for electrons and holes. In general, action spectra (Figs. 3 and 4) resemble the absorption spectra (not shown) and the fluorescence appears as a mirror image of the absorption spectra.

In Fig. 5, the dependence of the relative photoresponse as a function of the collection field is given for samples I–III. These measurements were performed with no field applied to the sample at the moment of illumination $E_{appl} = 0$). As seen from Fig. 5, as the collection field is increased, the photoresponse saturates. In all subsequent experiments collection fields were chosen corresponding to the onset of saturation.

In Fig. 6 the dependence of the relative photoresponse on the collection field is given for sample no. IV for different fields, E_{appl}, applied at the time of illumination. In contrast to samples I–III, no clear saturation of the photoresponse is observed when $E_{appl} = 0$ (Fig. 6, curve (a)). However, there is a "distinct" shoulder around $E_{coll} = 10$ V/μm, after which photo-

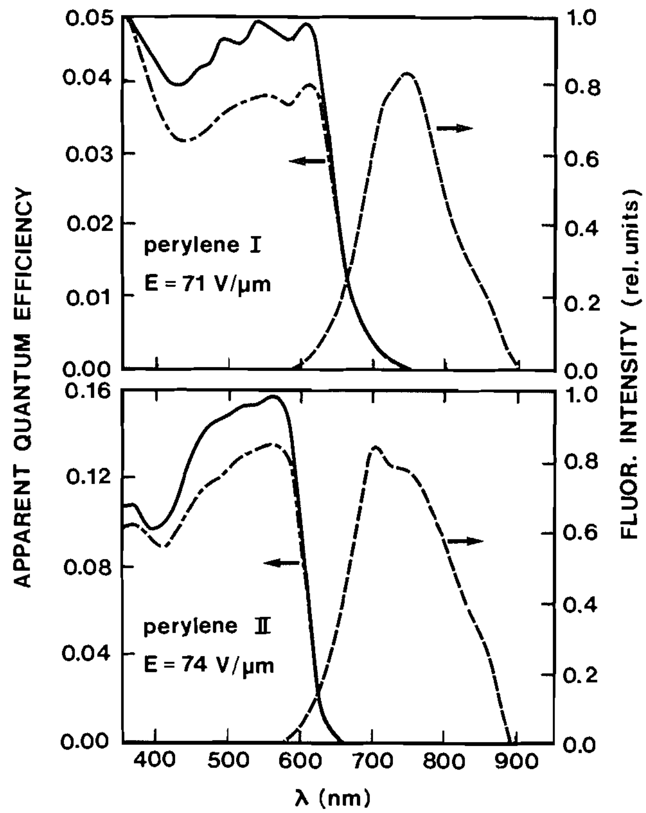

FIG. 3. Action spectra (—— NESA positive, ····· NESA negative) and fluorescence (– –) of perylenes I and II.

response increases relatively slowly. At higher E_{appl}, however, a clear saturation is observed for $E_{coll} > 10$ V/μm (Fig. 6, curves (b) and (c)). In subsequent measurements on this sample we have chosen $E_{coll} = 20$ V/μm, which is in the saturation range for higher fields.

At present we do not understand why sample no. IV behaves differently than samples I–III. It is interesting that only this compound has two structural isomers, which may be leading to increased trap density and to the observed anomalous behaviour in the photoresponse dependence on the collection field.

Before proceeding with discussion of further experimental data we will briefly discuss the correlation expected between fluorescence quenching and carrier generation in materials where the photoconductivity process occurs from the first excited singlet state. The fluorescence quenching efficiency (eq. [2]) is connected to the efficiency of the charge transfer state (geminate electron-hole pair) formation, η_{CT}, through the relation (7, 9)

$$[4] \quad \Phi(E) = \frac{\eta_{CT}(E) - \eta_{CT}(0)}{1 - \eta_{CT}(0)}$$

The carrier generation efficiency is given by

$$[5] \quad \eta(E) = \eta_{CT}(E) \cdot \Omega(E)$$

where $\Omega(E)$ is the probability that the CT dissociates into free carriers. At high fields $\Omega(E) = 1$ and linear correlation is expected between fluorescence quenching and carrier generation. As carrier generation is proportional to the relative photoresponse

$$[6] \quad \eta(E) = C \cdot R(E)$$

at high field we can write

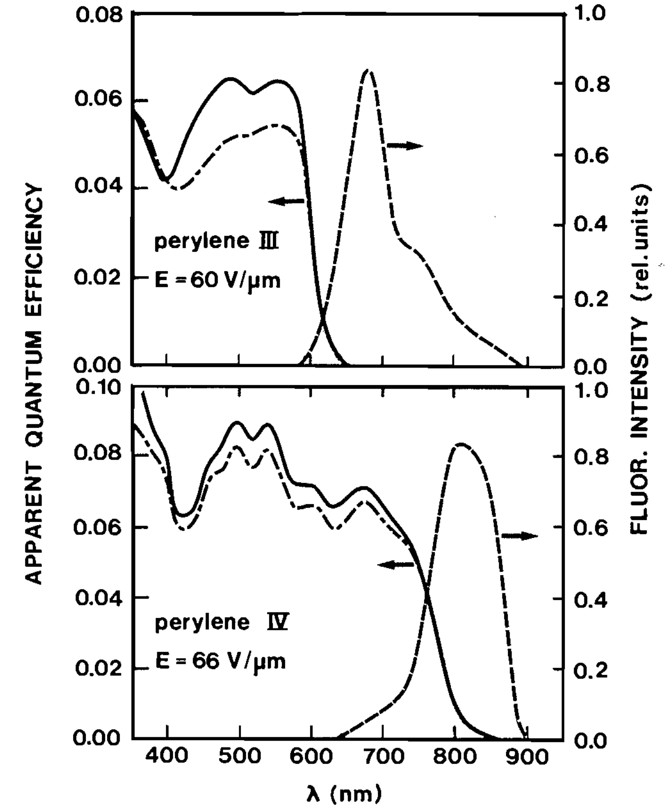

FIG. 4. Action spectra (—— NESA positive, ----- NESA negative) and fluorescence (– –) of perylenes III and IV.

$$[7] \quad \Phi(E) = \frac{C}{1 - \eta_{CT}(0)} R(E) - \frac{\eta_{CT}(0)}{1 - \eta_{CT}(0)}$$

If we now plot Φ as a function of R, from the intercept, i,

$$[8] \quad i = -\frac{\eta_{CT}(0)}{1 - \eta_{CT}(0)}$$

and slope, one can obtain both the proportionality constant C and $\eta_{CT}(0)$ and using [6] determine the true quantum efficiency $\eta(E)$. It is important to note that, alternatively, carrier generation efficiency can be calculated using eq. [3].

In Figs. 7a–10a the dependence of carrier generation efficiency and electric field induced fluorescence quenching on the applied field is given. For samples I and II, two material batches (before and after purification) have been studied. In Figs. 7b–10b correlation curves between fluorescence quenching efficiency and carrier generation are presented. Good correlation is observed in all cases, with some small discrepancies occuring at low fields. In Figs. 7–10 the scaling factor between R and η has been obtained as described in the preceding discussion.

It is interesting to compare carrier generation efficiencies obtained using combined fluorescence quenching and relative photoresponse measurements with the values obtained directly (as an absolute measurement) using eq. [3]. The comparison for purified materials is given in Table 1. The agreement between values obtained by the two methods is very good for samples II–IV, with only significant difference (a factor of two) observed in the case of sample I. For this sample optical microscopy reveals a relatively large proportion of large particles ($\gg$1 μm) which will not contribute significantly to the photoresponse, as they are larger than film thickness. There-

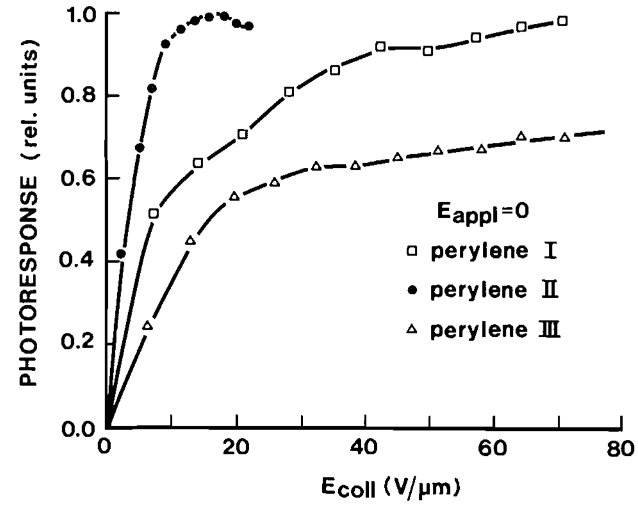

FIG. 5. Relative photoresponse obtained for zero field applied to the sample at the moment of illumination as a function of the collection field for perylenes I, II, and III.

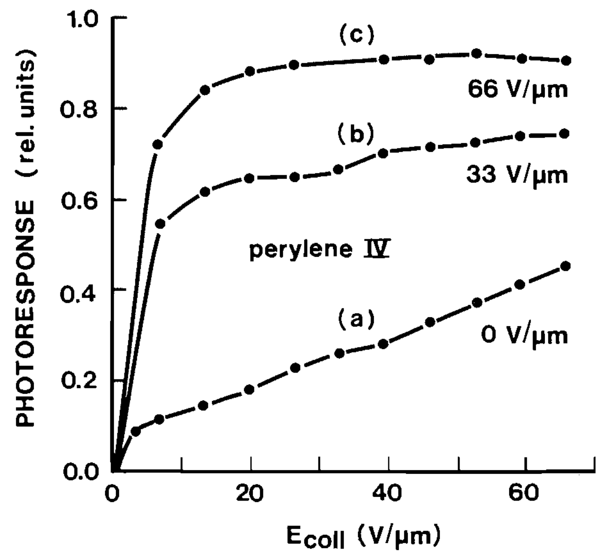

FIG. 6. The dependence of the relative photoresponse (at selected applied fields) on the collection field for perylene IV.

fore f_p in eq. [3] is overestimated, leading to the observed discrepancy.

A general feature of all fluorescence quenching curves is that they exhibit quadratic dependence at low applied fields. This can be easily understood in the framework of singlet decay (and concomitant fluorescence decrease) by production of CT states. Quadratic dependence is a direct consequence of possible formation of CT states in two opposite directions.

Some CT states are formed even at zero applied field. As they basically represent geminate electron-hole pairs, they can be separated by the application of a strong collection field in the delayed-collection-field experiment. Indeed, all our samples show non-zero carrier generation efficiency at no external field applied to the sample at the moment of illumination. As a rule in purified samples, the zero field carrier generation is relatively small. On the other hand, in non-purified samples it is much larger (Figs. 7 and 8). This enhancement of the zero field carrier generation must therefore be an impurity effect. It therefore appears that, in perylenes, both intrinsic and extrinsic

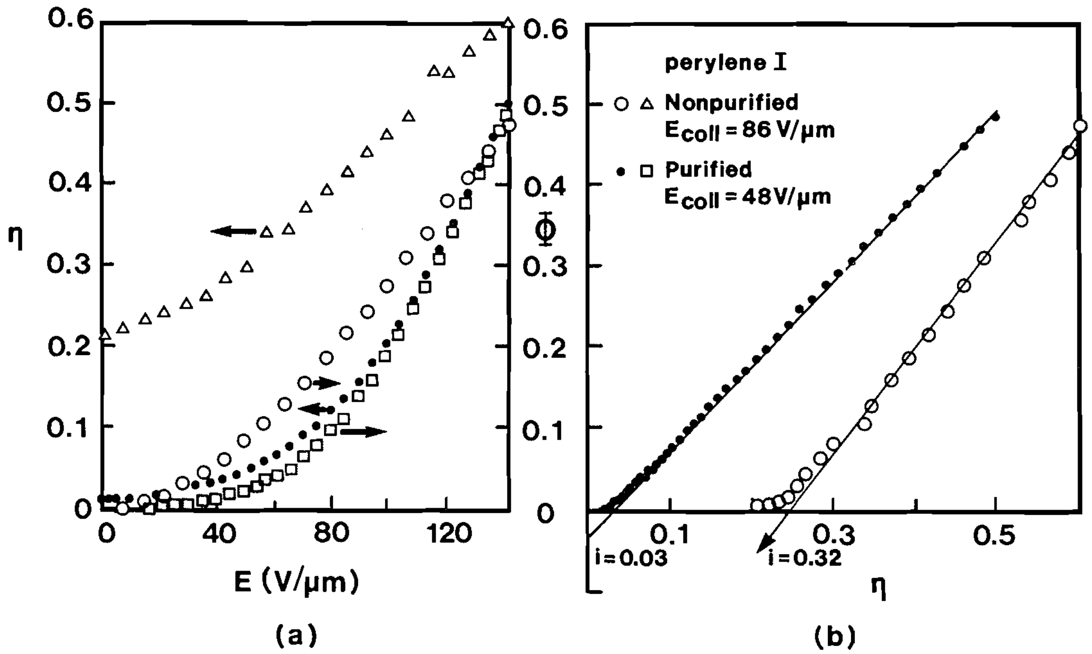

FIG. 7. Measurements on perylene I, before and after purification. (a) Field dependence of carrier generation efficiency and fluorescence quenching. (b) Correlation curves between fluorescence quenching and carrier generation.

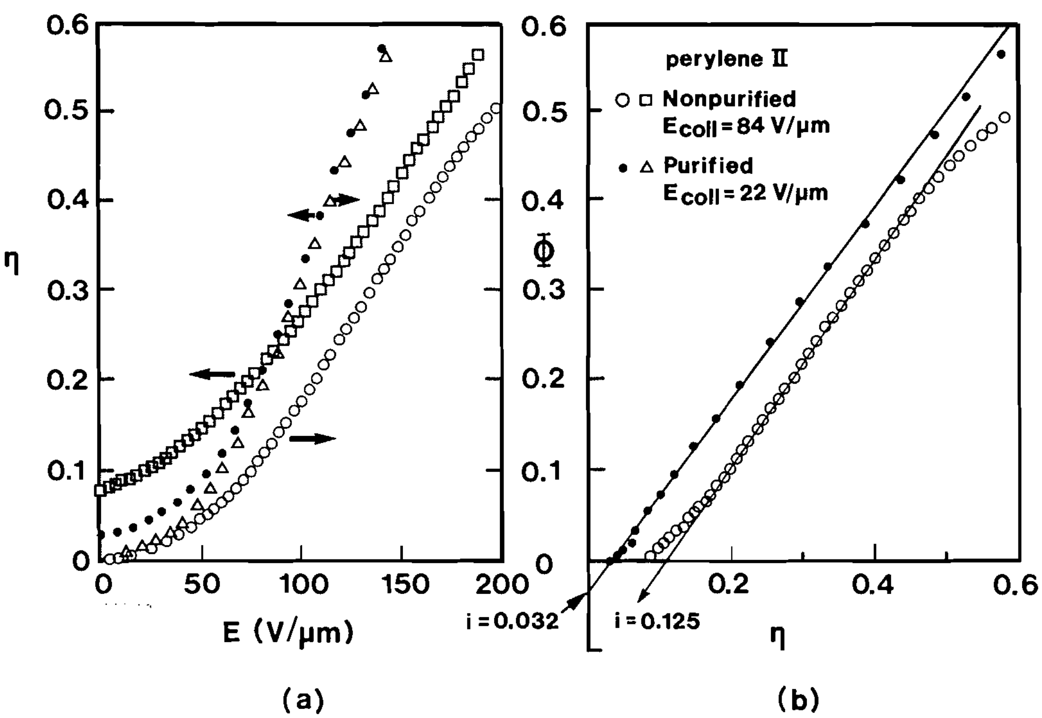

FIG. 8. Measurements on perylene II, before and after purification. (a) Field dependence of carrier generation and fluorescence quenching. (b) Correlation curves between fluorescence quenching and carrier generation.

(impurity controlled) carrier generation occurs. This is really not surprising, as the existence of sensitized photogeneration has been well documented in the literature (14).

From the point of view of practical applications like xerography, the existence of impurity controlled photogeneration can be quite detrimental, depending on the system. It is important to note that high fields are needed to separate carriers photogenerated at zero applied field. This, combined with the possibility that the carrier of one sign can be immobile, may lead to the increase in dark decay in subsequent xerographic cycles and accumulation of the trapped charge which increases background potential, and therefore decreases the contrast potential.

In xerography the shape of PIDC (photoinduced discharge curve) is predominantly governed by field dependence of carrier generation of the photoconductive component. This is strictly true when charge carriers have ranges of the order of photoreceptor thickness and, in dual layer structures, injection efficiency from the generator layer to the transport layer is

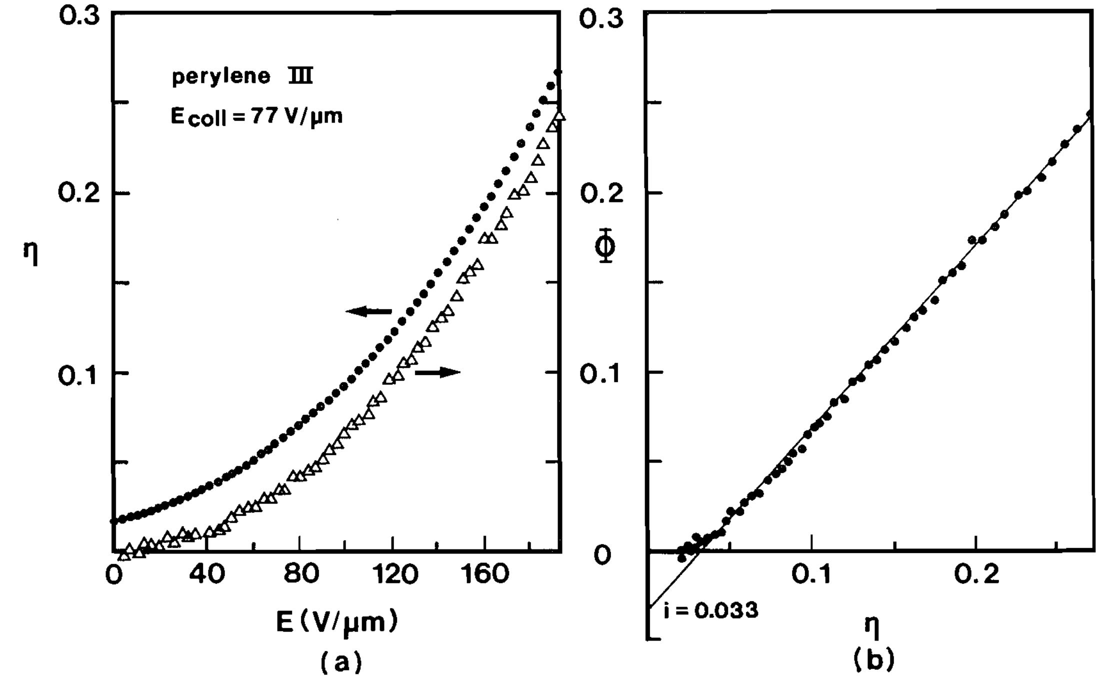

FIG. 9. Measurements on perylene III. (a) Field dependence of carrier generation and fluorescence quenching. (b) Correlation curve between fluorescence quenching and carrier generation.

IV	66	0.08–0.09	0.08

unity. Therefore the obtained carrier generation data shown in Figs. 7–10 can be used to predict the performance of these materials when incorporated in photoreceptor structures.

The comparison of generation efficiencies of the perylene derivatives with selected organic photoconductors is given in Table 2. Thiopyrylium aggregate photoreceptor, hydroxy squarylium, and x-metal-free phthalocyanine all exhibit carrier generation efficiencies approaching unity at electric fields larger than 100 V/µm. The perylenes studied in the present work also exhibit high carrier generation, although it is typically about 50% lower than the carrier generation in previously discussed compounds. Perylenes are, however, much more photoconductive than β-H_2Pc, PVK, and PVK–TNF systems.

TABLE 2. Comparison of carrier generation efficiencies in perylene diimides with selected organic photoconductors, at three different applied fields

Conclusions

We have applied pulsed photoconductivity and electric field induced fluorescence quenching techniques to study photogeneration in perylene diimides. Results showed that both extrinsic (impurity controlled) and intrinsic carrier generation exist in these materials. The intrinsic component of photoconductivity is consistent with the model of carrier generation in which the first excited singlet state is the direct precursor of the photogenerated carriers. This is manifested in excellent linear correlation between carrier generation and fluorescence quenching measured at different electric fields.

We have also demonstrated that simultaneous measurements of relative photoresponse and fluorescence quenching lead to determination of true carrier generation efficiency which is in good agreement with the values determined by absolute measurements on particle dispersions.

In summary, the data presented in this work show that perylene diimides are highly photoconductive in the visible spectral range and therefore represent useful materials for xerographic applications using visible light.

A matrix formulation of the conformational partition function is used to assess the influence of irregular structures on the formation of intramolecular antiparallel β sheets. An antiparallel sheet is considered to be irregular if any pair of contiguous strands has an unequal number of residues. The regular structures in the model consist of antiparallel sheets in which every strand contains the same number of residues. Aside from a growth parameter t, the model contains two parameters that account for the influence of edge effects. Each tight turn contributes a factor δ, and each residue in the sheet that does not have a partner in a preceding strand contributes a factor τ. When $\tau < \delta = 1$, preferred sheets consist of an extremely large number of very short strands. Such sheets resemble those found in cross-β fibers. Irregular structures increase the cooperativity of the formation of cross-β fibers. They cause the fibers that are formed to be longer (have more strands) and thicker (have more residues per strand) than if all antiparallel sheets were regular. A much different result is obtained if end effects are modified so that the antiparallel sheets formed resemble those found in globular proteins. Formation of antiparallel sheets remains cooperative, but irregular sheets now markedly reduce the cooperativity of the transition. At high antiparallel-sheet content, irregular structures cause typical antiparallel sheets to be smaller. The behavior of the conformational partition function shows that irregular structures make the dominant contribution to both transitions. Therefore, formulations that restrict consideration to regular structures may provide a misleading picture of antiparallel-sheet formation.

On a utilisé une formulation matricielle de la fonction de partition de conformation pour déterminer l'influence des structures irrégulières sur la formation de couches β intramoléculaires et antiparallèles. On considère qu'une structure feuilletée antiparallèle est irrégulière si l'une quelconque des paires de filaments contigues a un nombre inégal de résidus. Les structures régulières du modèle sont les couches antiparallèles dans lesquelles chaque filament contient le même nombre de résidus. En plus d'un paramètre de croissance, t, le modèle comporte deux paramètres qui tiennent compte de l'influence des effets d'arête. La contribution de chaque spire hermétique est un facteur δ et celle de chaque résidu dans la couche qui n'a pas de partenaire dans le filament précédent est un faceur τ. Lorsque $\tau < \delta = 1$, les couches privilégiées correspondent à un très grand nombre de filaments très courts. De telles couches ressemblent à celles trouvées dans des fibres réticulées de type β. Les structures irrégulières provoquent une augmentation de la coopérativité de formation de chaînes réticulées β. Les fibres qui se forment dans de telles conditions sont plus longues (il y a plus de filaments) et plus épaisses (il y a plus de résidus par filaments) que celles qui se forment lorsque toutes les couches antiparallèles sont régulières. On obtient un résultat très différent si les effets d'extrémités sont modifiés de telle sorte que les couches antiparallèles formées ressemblent à celles trouvées dans les protéines globulaires. La formation de couches antiparallèles reste soumise à l'effet de forces agissant dans le même sens, toutefois la présence de couches irrégulières réduit d'une façon importante la coopération de transition. Lorsque la teneur en couches antiparallèles est élevée, les structures irrégulières conduisent à la formation de couches antiparallèles typiques qui sont plus petites. Le comportement de la fonction de partition conformationnelle montre que les structures irrégulières contribuent de façon majoritaire aux deux transitions. En conséquence, les formulations qui se restreignent uniquement à une considération des structures régulières peuvent fournir une fausse image de la formation des couches antiparallèles.

[Traduit par le journal]

1. Introduction

The intramolecular antiparallel β sheet (1) is a structure commonly found in fibrous and globular proteins. We recently described a tractable matrix treatment for formation of intramolecular antiparallel β sheets with tight bends in homopolymers having a finite degree of polymerization (2). Three statistical weights are utilized. One, denoted by t, is assigned to every residue in the antiparallel sheet. The remaining two statistical weights, δ and τ, reflect the consequences of end effects. Each bend contributes a factor δ, and each residue that does not have a partner in a preceding strand contributes a factor τ. Previous illustrative calculations for homopolymers defined conditions that give rise to several different types of antiparallel sheets (2). Three types of particular interest here are (a) "sheets" consisting of isolated extended strands, (b) cross-β fibers, which are antiparallel sheets having a high axial ratio due to the presence of a large number of very short strands, and (c) antiparallel sheets composed of several strands in which the average strand contains approximately five residues. The third type of antiparallel sheet has a size and shape typical of those seen in globular proteins (3, 4). This type of sheet is not identical with those found in all globular proteins because it does not contain parallel strands, and contiguous strands cannot be connected by loops larger than tight bends. Cross-β fibers occur in several fibrous structures (5–7).

The general formulation (2) (which is easily extendible to specific-sequence heteropolymers) imposes no artificial constraints on the relationship between the numbers of residues in adjacent strands of the antiparallel sheet. However, the general treatment is easily modified so that every strand in a particular antiparallel sheet must have the same number of residues. In such antiparallel sheets, the number of residues in all strands is specified by the number of residues in the initial strand. These antiparallel sheets are described here as regular. In contrast, an antiparallel sheet in which any pair of adjacent strands has different numbers of residues will be designated as irregular. Several earlier descriptions of intramolecular antiparallel-sheet formation considered all antiparallel sheets to be regular (8–10). Two treatments (8, 9) employed antiparallel sheets in which all internal strands contained i residues, while the first and last strands had $i/2$ residues. These antiparallel sheets are defined here as being regular because the number of residues in all strands is specified by the number of residues in the first strand. It is of interest to establish the manner in which irregular antiparallel sheets contribute to statistical mechanical averages of conformational properties. The results presented here demonstrate that the presence of irregular antiparallel sheets has a profound influence on the formation of cross-β fibers and also on antiparallel sheets of the type found in globular proteins.

2. Calculations

The matrix formulation of the conformational partition function has been described in detail (2). The conformational partition function, Z, for a homopolymer comprised of n residues is written as

$$[1] \quad Z = \text{row}\,(1, \mathbf{0})\,\mathbf{U}^{n}\,\mathbf{U}\,\text{col}\,(1, \mathbf{0})$$

Here $\mathbf{U}$ is the statistical weight matrix, and $\mathbf{0}$ denotes a rectangular null submatrix whose dimensions are determined by the requirement that all matrices be conformable for multiplication. The terminating column, $\mathbf{U}$ col (1, $\mathbf{0}$), is identical with the first column in $\mathbf{U}$. All computations described here were performed for a homopolymer of 300 residues. A chain of 300 residues was selected because it is typical of that found in several large proteins. This number of residues is not sufficient to produce the behavior expected for an infinitely long chain when δ and τ are both small (11).

The statistical weight matrix is square and of dimensions $I(I + 3)/2$, where I is the maximum number of residues permitted in a strand. Ultimate interest is in the behavior of statistical mechanical averages in the limit where I goes to n. For most cases of interest here, that limit is attained in excellent approximation when I is 20. Special attention will be given in Section 6 to one circumstance in which a larger value for I would be required in order to produce a good approximation to the desired limit. For $I = 20$, the dimensions of $\mathbf{U}$ are 230 × 230, and the dimensions increase to 350 × 350 when I is 25. These large matrices are not constructed and manipulated in the computer. Instead a completely equivalent, but much more efficient, computation is performed by taking advantage of the sparseness of $\mathbf{U}$ and of summarizing rules which specify the locations of all nonzero elements (2). Conformational averages are extracted from Z by means of the usual statistical mechanical operations (12, 13).

The minimum number of residues per strand is two. Figure 1(A) depicts a regular antiparallel sheet containing six strands with two residues per strand. There are five bends. If one residue were to be removed from each strand, the resulting structure would be viewed as a single isolated strand of six residues and no bends. It is not considered to be an antiparallel sheet composed of six strands (each containing one residue) and five bends.

A disordered "c" residue is selected as the reference state and assigned a statistical weight of 1. The weighting scheme for

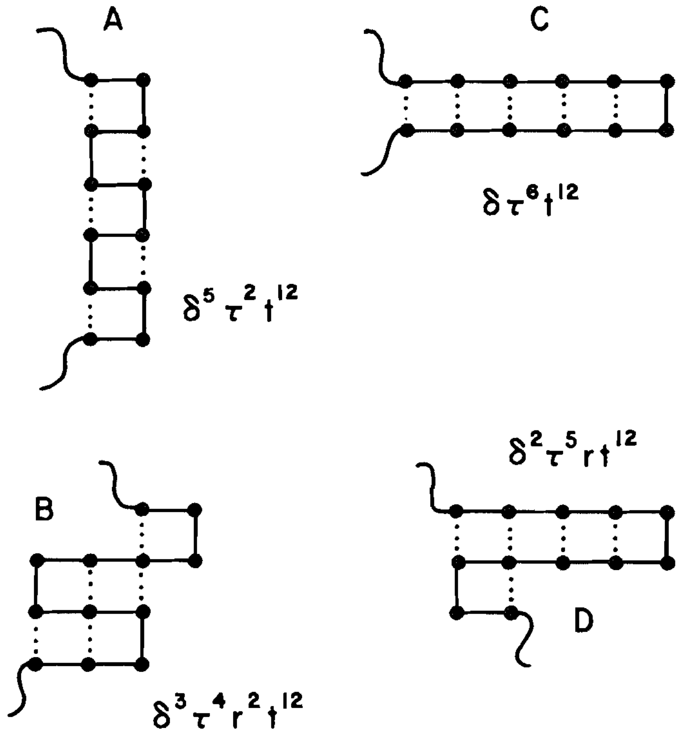

FIG. 1. Four illustrative antiparallel sheets of twelve residues, along with their statistical weights.

antiparallel sheets is illustrated in Fig. 1. This figure depicts four antiparallel sheets, two of which (A and C) are regular, while two (B and D) are irregular. The statistical weight is indicated for each antiparallel sheet. This weight can be written as

$$\delta^{n_{\mathrm{Bend}}/2}\,\tau^{n_{\mathrm{b}}}\,r^{n_{\mathrm{r}}}\,t^{n_{\mathrm{b+B}}}$$

Here $n_{\mathrm{b+B}}$ is the number of residues in the antiparallel sheet, n_{b} is the number of residues in the sheet that do not have a partner in the preceding strand, n_{r} is the number of pairs of contiguous strands which contain unequal numbers of residues, and n_{Bend} is the number of residues located at bends. Residues which contribute a factor τ are denoted by "b". The remaining residues in the antiparallel sheets are denoted by "B". Those residues situated at bends are considered to be part of the antiparallel sheet.

The value of n_{r} is of no consequence when $r = 1$. This assignment allows for the presence of both regular and irregular antiparallel sheets. All irregular antiparallel sheets are rejected when the assignment is changed from $r = 1$ to $r = 0$. Thus, if $r = 0$, the structures in Figs. 1B and 1D are rejected. There is no effect on the relative weighting of surviving antiparallel sheets because all regular antiparallel sheets have $n_{\mathrm{r}} = 0$ (we assume $x^0 = 1$ even when x is zero).

3. Transition from disordered chain to antiparallel sheet

Sheet formation in chains of 300 residues, arising from changes in t, is depicted in Fig. 2 for four combinations of δ and τ. A maximum of twenty residues is permitted in a strand. The transitions depicted by solid lines were initially described by Mattice and Scheraga (2).

Cooperativity provides a convenient means of classifying the transitions. The maximum of $\mathrm{d}f_{\mathrm{b+B}}/\mathrm{d}t$ (where $f_{\mathrm{b+B}}$ is the fraction of b + B states) will be taken as a measure of the cooperativity of a transition. A noncooperative transition is obtained

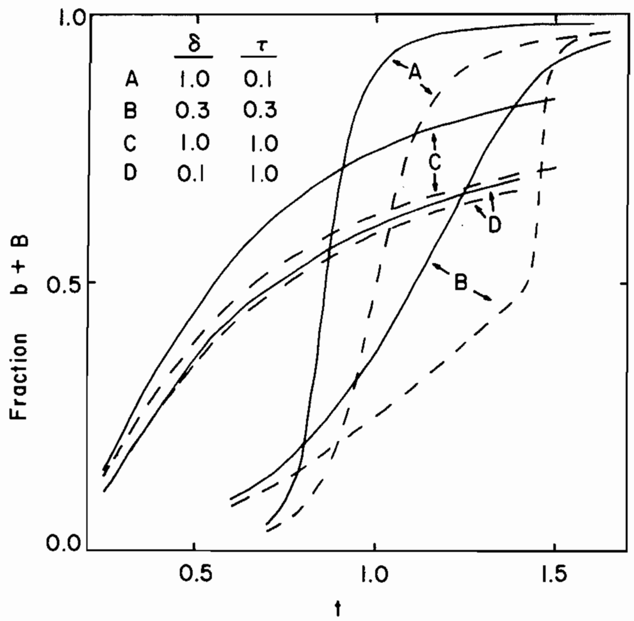

FIG. 2. Fraction of the residues in "b" or "B" states for the indicated values of δ and τ. Solid curves are obtained when there is no distinction between regular and irregular antiparallel sheets (r = 1), while dashed curves denote results obtained when all antiparallel sheets are regular (r = 0). All transitions were computed using n = 300 and l = 20.

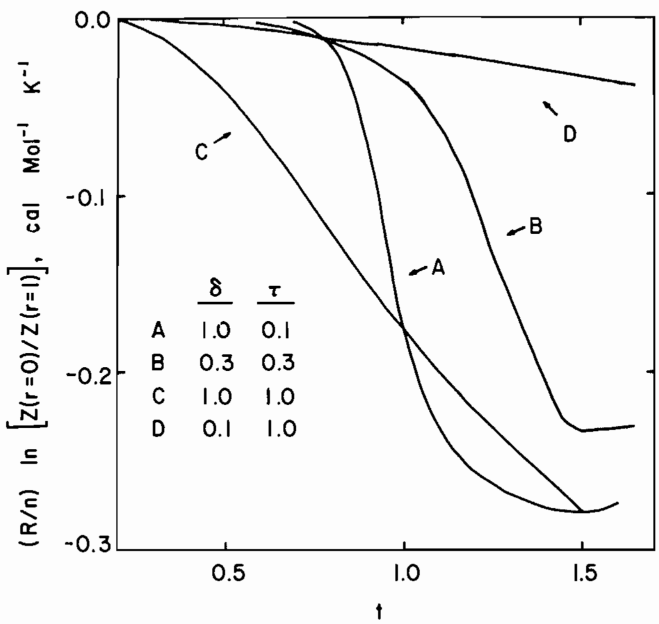

FIG. 3. $(R/n)\ln[Z(r = 0)/Z(r = 1)]$ for the indicated transitions when n = 300 and l = 20.

when δ = τ = 1. Comparison of curves C and D in Fig. 2 shows a similar lack of cooperativity when δ = 0.1, τ = 1. At a specified t, antiparallel sheet content in the noncooperative transitions is reduced if irregular antiparallel sheets are rejected. The reduction becomes less dramatic when δ is decreased from 1 to 0.1. In the limit where δ goes to zero, bends are completely suppressed and each "sheet" consists of an isolated extended strand (2). The statistical weight denoted by r is excluded from Z when δ is zero because no sheet contains multiple strands. Multistranded antiparallel sheets retain a small contribution to Z when δ is 0.1, and some of the antiparallel sheets are irregular. Consequently the change from r = 1 to r = 0 has a small effect when δ = 0.1. A larger effect is seen at δ = 1 because multistranded antiparallel sheets make a larger contribution to Z when bends are not penalized; hence, the effect of eliminating a significant number of irregular sheets is larger.

Sheet formation shows a higher degree of cooperativity when δ = 1, τ = 0.1, and when δ = τ = 0.3. The antiparallel sheets formed can be described as cross-β fibers in the former case (2). The initial strand is short because each residue in it is penalized when τ = 0.1. Many short strands can follow the initial strand without further penality because bends are not penalized when δ = 1. Antiparallel sheets resembling those found in globular proteins can be formed when δ = τ = 0.3. These antiparallel sheets contain several strands with about five residues per strand (3, 4). Onset of antiparallel sheet formation in the cooperative transitions demands a larger t if irregular antiparallel sheets are rejected. The cooperativity of the formation of cross-β fibers is slightly reduced if the fiber must be regular. In contrast, antiparallel sheet formation at δ = τ = 0.3 becomes significantly more cooperative when all antiparallel sheets are regular.

The greatest cooperativity is seen in the latter stages of the transition with δ = τ = 0.3, r = 0. A slightly greater cooperativity would be exhibited in the latter portion of this transition if the strands were allowed to contain more than twenty residues. Justification for this statement will be presented in Section 6. Additional calculations, the results of which are not presented here, show that the transition with δ = τ = 0.3, r = 0, at large t is the only one in Fig. 2 for which l = 20 does not provide an excellent approximation to the limit as l goes to 300.

Attention now turns to a consideration of the details of noncooperative antiparallel sheet formation (δ = τ = 1), cooperative cross-β fiber formation (δ = 1, τ = 0.1), and cooperative formation of the types of antiparallel sheets seen in globular proteins (δ = τ = 0.3).

4. Noncooperative sheet formation

Special interest attends the circumstance δ = τ = t = 1. All allowed conformations then have a statistical weight of one, and Z is simply the number of conformations. Numerical values of Z with n = 300 and l = 20 are 1×10^{90} when r = 1 and 4×10^{78} when r = 0. There are nearly 10^{12} conformations containing irregular antiparallel sheets for every conformation in which all antiparallel sheets are regular. If a large number of residues in a long chain is arranged in antiparallel sheets of the types seen in Fig. 1, the overwhelming majority of chain conformations will contain at least one sheet in which contiguous strands have different numbers of residues.

The relationship between Z at r = 1 and Z at r = 0 was evaluated for other values of t for the noncooperative transitions. Figure 3 depicts the results as $(R/n)\ln[Z(r = 0)/Z(r = 1)]$, which can be viewed as an entropic contribution expressed per mole of residues. It is on the order of -0.1 cal mol^{-1} K^{-1} at the midpoint of the transition to an antiparallel sheet (t near 0.6, Fig. 2) when δ = τ = 1. In contrast, it is on the order of -0.01 cal mol^{-1} K^{-1} at the midpoint of noncooperative antiparallel sheet formation when δ = 0.1 and τ = 1. The entropic effect is smaller in the latter case because the small value of δ/τ discourages formation of bends.

The average number of residues per antiparallel sheet is depicted in Fig. 4. The average antiparallel sheet is small when

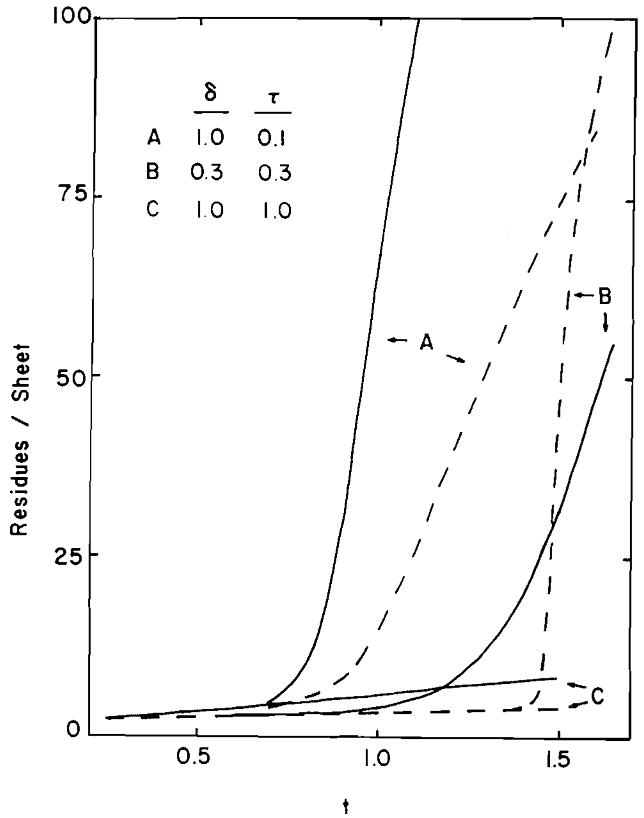

FIG. 4. Average number of residues per antiparallel sheet for the indicated values of δ and τ. Solid and dashed curves pertain to $r = 1$ and $r = 0$, respectively. All transitions were computed using $n = 300$ and $l = 20$.

$\delta = \tau = 1$. It becomes significantly smaller at large t if irregular antiparallel sheets are rejected. There is only a trivial effect on the number of residues per strand. At $t = 1.5$, the average number of residues per strand falls from 3.17 to 3.08 when irregular antiparallel sheets are eliminated. The change in the size of the average antiparallel sheet arises primarily from a reduction in the number of strands per antiparallel sheet, as shown in Fig. 5. At $t = 1.5$, there is an average of 2.72 strands per antiparallel sheet when irregular antiparallel sheets are allowed, but the average drops to 1.39 if irregular antiparallel sheets are excluded. The decrease in the number of strands per antiparallel sheet occurs because it is unlikely that adjacent strands will contain the same number of residues when antiparallel sheets form noncooperatively.

Differences in the average number of strands per antiparallel sheet have a large effect on the fraction of the residues situated at bends (Fig. 6). Rejection of irregular antiparallel sheets is accompanied by a large reduction in the number of bends because most of the surviving "sheets" consist of a single extended strand.

5. Cooperative cross-β fiber formation

An example of a set of end effects giving rise to cooperative formation of cross-β fibers is provided by the transition obtained with $\delta = 1$, $\tau = 0.1$. Comparison of Figs. 2 and 3 shows that $Z(r = 0)/Z(r = 1)$ undergoes a dramatic change as t passes through the region where fiber formation occurs. Differences in characteristics of the fibers are brought out in Figs. 4–7. If irregular antiparallel sheets are retained, the fibers are larger (contain more residues, Fig. 4), longer (have

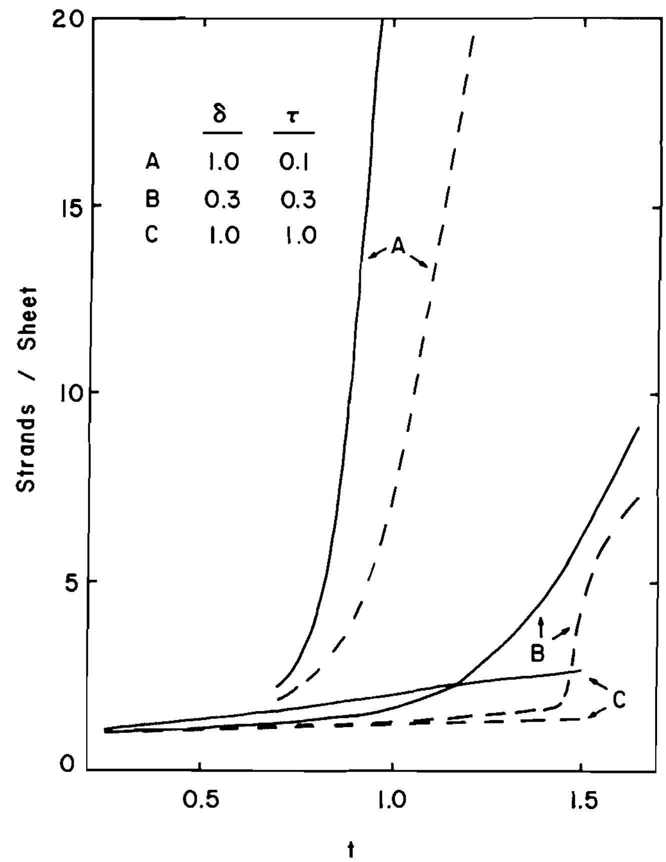

FIG. 5. Average number of strands per antiparallel sheet for the indicated values of δ and τ. Solid and dashed curves pertain to $r = 1$ and $r = 0$, respectively. All transitions were computed using $n = 300$ and $l = 20$.

more strands per antiparallel sheet, Fig. 5), and thicker (possess more residues per strand, Fig. 7). Differences in the average number of residues per strand are particularly important. There is an average of two residues per strand if irregular antiparallel sheets are rejected. Most antiparallel sheets then consist of a large number of in-register strands comprised of two residues each. Fig. 1(A) depicts a prototype of this fiber. All internal residues in this antiparallel sheet participate in bend formation. Consequently the fraction of residues situated at bends approaches 1 at large t (Fig. 6).

The average number of residues per strand approaches three when irregular antiparallel sheets are allowed (Fig. 7). Since the middle residue in a three-residue strand cannot participate in bend formation, the value of f_{Bend} at large t is considerably smaller than that when irregular antiparallel sheets are permitted (Fig. 6). While the average number of residues per strand is three, it would be incorrect to infer that the typical fiber consists of a large number of in-register strands containing exactly three residues each. If such fibers were truly to dominate the ensemble having $r = 1$, they would also dominate the ensemble with $r = 0$. Since they do not readily survive this change in r, the typical cross-β fiber occurs in a chain conformation which contains at least one pair of contiguous strands having unequal numbers of residues.

6. Cooperative sheet formation when $\delta = \tau = 0.3$

Antiparallel sheets resembling those commonly seen in globular proteins are formed when δ and τ are both less than one and

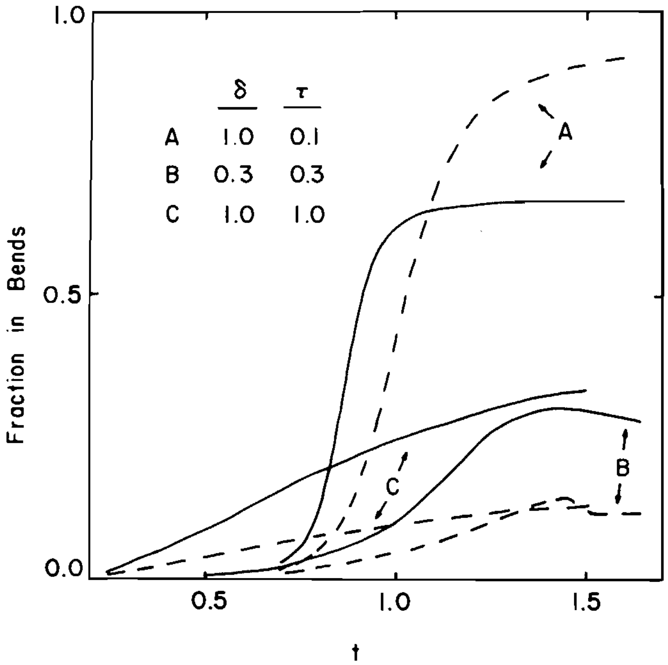

FIG. 6. Average number of residues located at bends for the indicated values of δ and τ. Solid and dashed curves pertain to $r = 1$ and $r = 0$, respectively. All transitons were computed using $n = 300$ and $I = 20$.

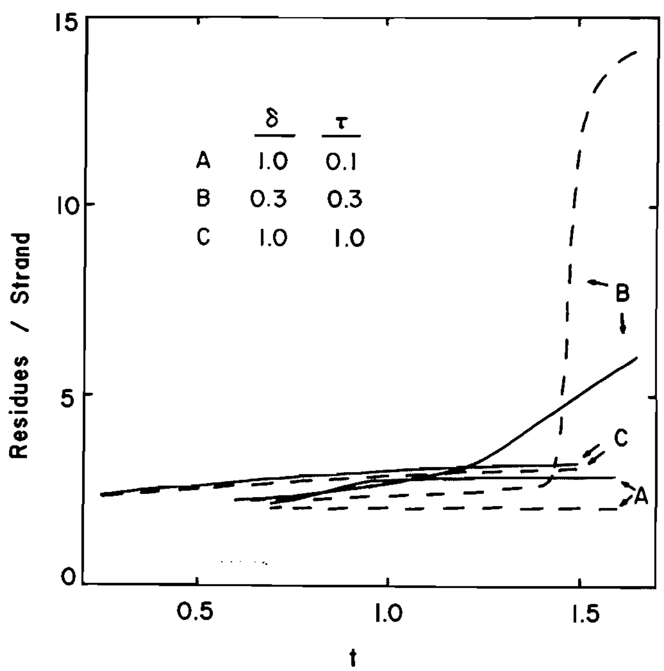

FIG. 7. Average number of residues per strand for the indicated values of δ and τ. Solid and dashed curves pertain to $r = 1$ and $r = 0$, respectively. All transitions were computed using $n = 300$ and $I = 20$.

not too different from one another (2). Comparison of curves depicted in Figs. 2 and 3 shows that (R/n) ln $[Z(r = 0)/Z(r = 1)]$ decreases as sheets are formed when $\delta = \tau = 0.3$. A striking feature of the transition obtained with $r = 0$ is the extremely sharp rise in f_{b+B} as t rises above 1.4. No comparable jump is seen when irregular antiparallel sheets contribute to the transition.

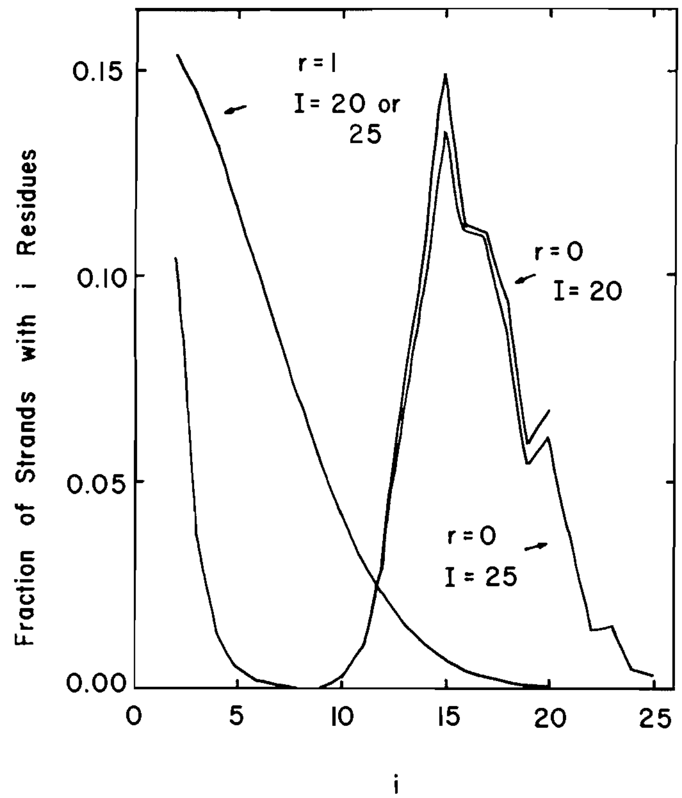

FIG. 8. Fraction of the strands containing the indicated number of residues when $\delta = \tau = 0.3$, $t = 1.6$, $n = 300$. The values of r and I are indicated for each curve.

The contrasting behaviors seen in Fig. 2 have their counterparts in the dimensions of the antiparallel sheets formed. Figure 4 shows that rejection of irregular antiparallel sheets is accompanied by a substantial reduction in the average number of residues per antiparallel sheet when t is in the range 1.0–1.4. However, the reverse becomes true as t approaches 1.5, due to an extremely rapid increase in the average size of the regular antiparallel sheets. This dramatic increase in the size of regular antiparallel sheets coincides with the rapid rise in f_{b+B} in Fig. 2. Inspection of Figs. 5 and 7 shows that the rapid rise in the size of regular antiparallel sheets has contributions from increases in the average number of strands per antiparallel sheet and average number of residues per strand.

In Section 2, it was stated that $I = 20$ provides a satisfactory approximation to the true behavior for all but one of the models considered here. The single exception is provided by regular antiparallel sheets formed at high t when $\delta = \tau = 0.3$. The basis for this statement is provided by examination of distribution functions for the number of residues per strand. Four distribution functions are depicted in Fig. 8. All are for $\delta = \tau = 0.3$ and a chain of 300 residues. The value of t is 1.6, which is slightly higher than the t that provides the maximum value of df_{b+B}/dt in Fig. 2.

Two distribution functions are for ensembles which retain irregular antiparallel sheets. The maximum number of residues permitted in a strand is 20 in one computation and 25 in the other. These two distribution functions resemble one another so closely that they are not distinguishable on the scale used in preparation of Fig. 8. Both distribution functions exhibit a monotonic decline as the length of the strands increases. They decay to very small values for chains containing as many as twenty residues per strand. The average number of residues per strand changes slightly (from 5.77 to 5.79) when l increases from 20 to 25.

Figure 8 also depicts a distribution function computed using $r = 0$ and $l = 20$. Two important differences are apparent upon comparison of the two distribution functions calculated using a maximum of 20 residues per strand. When irregular antiparallel sheets are present, the distribution function exhibits a monotonic decay at small values of i, but elimination of irregular antiparallel sheets causes the distribution function to become biphasic. The biphasic distribution function exhibits maxima for strands containing two and fifteen residues. At the beginning of Section 4, it was noted that the ensemble contains many more chain conformations when irregular sheets are allowed. Ensembles specified by $r = 0$ and $r = 1$ differ not only in the number of chain conformations, but also in the sizes of the strands that are present in these conformations. The presence of irregular structures causes a greater portion of the conformations to have sheets containing 6–9 residues per strand than would have been the case if all sheets were regular. The ensemble with $r = 1$ contains a greater fraction of conformations that are potential stable intermediates if δ and τ are assigned so that sheets contain more than 9 residues per strand as t becomes infinite. The presence of more stable intermediates causes the transition to have less of an "all or none" character when irregular sheets are present. The second difference is seen upon examination of the value of the distribution function for the longest (20 residues) allowed strand. The distribution function has decayed to a negligible value when irregular antiparallel sheets are retained, but it remains quite large when irregular antiparallel sheets are rejected. There is an implication that the ensemble with $r = 0$ would take advantage of the opportunity to form even longer strands if that opportunity were presented.

That implication is verified by the fourth distribution function, computed using $r = 0$ and $l = 25$. The increase in l from 20 to 25 causes the average number of residues per strand to rise from 13.87 to 14.27. When $r = 0$, the limiting behavior as l approaches n requires a value of l greater than 20. The consequences of the use of $l = 20$, rather than some larger value, can be summarized as follows: for $\delta = \tau = 0.3$, $r = 0$, and large t, the height and cooperativity of the sharp rise in f_{b+B} (Fig. 2), and the sizes of the resulting regular antiparallel sheets (Figs. 4, 5, and 7) are all underestimated.

Distribution functions were also examined using $t = 1.3$, which lies slightly before the marked rise in f_{b+B} in Fig. 2. At this value of t, all four distribution functions show a maximum for a strand of two residues, undergo a monotonic decay as one proceeds to longer strands, and fall to a negligible value when strands contain as many as twenty residues. These distribution functions are unaffected by changing l from 20 to 25.

An examination of the numerical values for Z facilitates an understanding of the origin of the effects seen in Fig. 8. The first two entries in Table 1 are for ensembles in which all antiparallel sheets are regular. The increase in l from 20 to 25 does not eliminate any conformations from the ensemble. Instead it adds chain conformations having 21–25 residues per strand. The added conformations cause Z to increase by a factor of 1.1.

No chains are eliminated from the ensemble if r is changed from 0 to 1 at constant l. Instead, conformations containing irregular antiparallel sheets are introduced into the ensemble. At $l = 20$ or 25, addition of the irregular antiparallel sheets

TABLE 1. Conformational partition functions when $n = 300$, $\delta = \tau = 0.3$, $t = 1.6$

r	l	Z
0	20	5.3×10^{44}
0	25	6.0×10^{44}
1	20	7.0×10^{59}
1	25	7.0×10^{59}

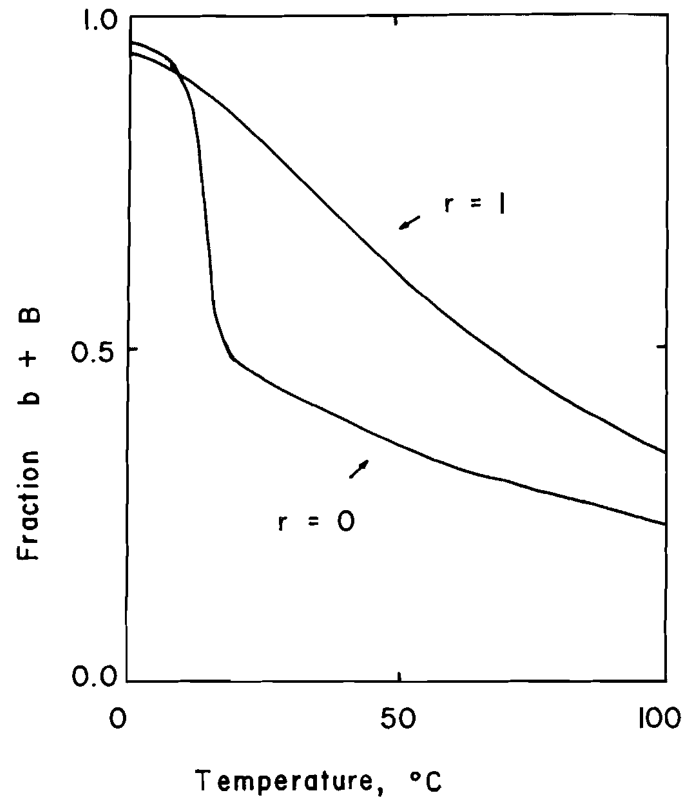

FIG. 9. Illustrative thermal transitions for the case where $n = 300$, $l = 20$, $\delta = \tau = 0.3$. The only temperature-dependent parameter is t. It is 1.6 at 0°C, with a temperature dependence corresponding to $\Delta H^0 = -1$ kcal mol^{-1}.

increases the value of Z by a factor of 10^{15}. The huge increase in the size of Z implies that completely regular antiparallel sheets have negligible influence on the properties of the new ensemble. Using "Σ_{irreg}" to denote the sum of the statistical weights for all chain conformations containing irregular sheets, we have

$$[2] \quad Z(r = 1) = Z(r = 0) + \Sigma_{\text{irreg}}$$

The last term exceeds $Z(r = 0)$ by a factor of 10^{15}. This factor would have been 10^{12} if all conformations were weighted equally (see Section 4). Conformations containing irregular antiparallel sheets completely dominate the ensemble due primarily to their overwhelming numbers, but in part due to the influence of the weighting of chain conformations. The presence of a multitude of chains containing irregular antiparallel sheets markedly reduces the cooperativity of the transition and the sizes of the antiparallel sheets formed.

Data depicted in Fig. 2 are replotted in Fig. 9 in a manner which emphasizes the potentially important consequences of irregular antiparallel sheets in thermally induced transitions. For purposes of illustration, all parameters except t are assumed to be independent of temperature. The value of t is assumed to be 1.6 at 0°C, with $d \ln t/d(1/T) = -\Delta H^0/R$ and ΔH^0 having the temperature-independent value of -1 kcal mol^{-1}. Irregular antiparallel sheets cause melting to extend continuously over a broader temperature range. If all antiparallel sheets must be regular, there is a rather sharp transition at low temperature, corresponding to the highly cooperative melting of the large regular antiparallel sheets, followed by a much less cooperative melting of small regular antiparallel sheets. The two melting curves are qualitatively different.

7. Conclusions

The number of irregular sheets accessible to a long chain far exceeds the number of regular sheets. Irregular structures make important contributions to average properties of two important classes of antiparallel sheets formed by homopolypeptides. They increase slightly the cooperativity of the formation of cross-β fibers. They also cause the fibers formed to be wider and longer. Irregular structures have a different effect on the transition which produces antiparallel sheets containing several strands with an average of about five residues per strand. Here, irregular structures bring about a dramatic reduction in the cooperativity of the transition and the size of the antiparallel sheets formed. Theoretical formulations in which all structures are regular may provide a misleading picture of antiparallel sheet formation in globular proteins.

Received February 10, 1984

This paper is dedicated to the 10th anniversary of the Xerox Research Centre of Canada

BENG S. ONG, BARKEV KEOSHKERIAN, TREVOR I. MARTIN, and GORDON K. HAMER. Can. J. Chem. **63**, 147 (1985).

2-Alkyltrinitrofluoren-9-ones **2** were conveniently synthesized by controlled nitration of 2-alkylfluoren-9-ones **5** with a mixture of red fuming HNO_3 and concentrated H_2SO_4 at 0–25°C. The precursors **5** were derived from the corresponding 2-acylfluorenes by appropriate reduction of the acyl function, followed by base-catalysed O_2-oxidation at the C-9 position. The regiochemistry of nitration was interesting: with a sterically bulky substituent in **5**, nitration occurred at C-4, -5, and -7 positions, affording 2-alkyl-4,5,7-trinitrofluoren-9-one in over 35% yield; on the other hand, **5** with a primary alkyl function underwent nitration predominantly at C-3, -5, and -7 positions. By virtue of its alkyl function, 2-alkyltrinitrofluoren-9-one **2** displayed better solubility and polymer compatibility characteristics than its non-alkylated analog, TNF. However, the charge transfer interactions of **2** with electron donors were weaker than those of TNF, despite the fact that they both have the same electron affinity. Both **2** and TNF exhibited good electron transport properties in poly(*N*-vinylcarbazole) matrices.

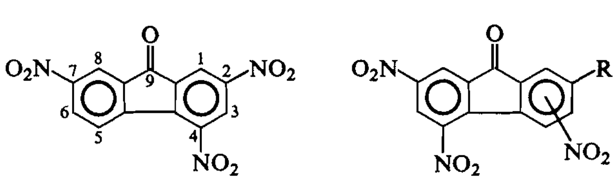
BENG S. ONG, BARKEV KEOSHKERIAN, TREVOR I. MARTIN et GORDON K. HAMER. Can. J. Chem. **63**, 147 (1985).

On a synthétisé les alkyl-2 trinitrofluorènones-9 (**2**) en procédant à une nitration contrôlée des alkyl-2 fluorènones-9 **5** à 25°C et à l'aide de HNO_3 fumant et de H_2SO_4 concentré. Les dérivés **5** sont obtenus par une réduction appropriée de la fonction acyle des acyl-2 fluorènes correspondants qui est suivie d'une oxydation par O_2, catalysée par les bases, de la position C-9. La régiochimie de la nitration est intéressante: si le composé **5** porte un substituant stériquement volumineux, la nitration se produit aux positions C-4, C-5 et C-7 et l'on obtient les alkyl-2 trinitro-4,5,7 fluorènones-9 avec un rendement dépassant 35%; par ailleurs, si le composé **5** porte un groupe alkyle primaire, la nitration se produit principalement dans les positions C-3, C-5 et C-7. Grâce à la présence de leurs fonctions alkyles, les alkyl-2 trinitrofluorènones-9 (**2**) sont plus solubles et plus compatibles avec les polymères que leurs analogues qui ne sont pas alkylés. Toutefois, les interactions de transfert de charge des composés **2** avec les produits donneurs d'électrons sont plus faibles que celles de la TNF et ce même si ces composés ont tous la même affinité électronique. Les composés **2** ainsi que la TNF présentent tous de bonnes propriétés comme transporteurs d'électrons dans des matrices de poly(*N*-vinylcarbazole).

[Traduit par le journal]

Nitrofluoren-9-ones and their derivatives have received growing interest as a unique class of electron acceptors. These molecules readily form charge-transfer complexes with electron donors (1–3) and have been extensively employed as photosensitizers and active constituents of photosensitive composites (4–7). Of this class of acceptors, 2,4,7-trinitrofluoren-9-one **1** (TNF) appears to be the most investigated molecule, presumably because of its relatively strong π-acid strength as well as its efficient photosensitization effect and electron transport capability (6, 7). Unfortunately, TNF has low solubility in organic solvents and exhibits poor compatibility with common matrix polymers; many applications requiring high concentrations of TNF cannot therefore be fulfilled. Moreover, TNF is mutagenic, and its use in the public domain is therefore discouraged.

In this paper we describe the synthesis, and molecular and electron transport properties of 2-alkyltrinitrofluoren-9-ones **2** – a structure which is expected to possess higher solubility characteristics than TNF by virtue of its alkyl substituent. The presence of a weakly electron-donating alkyl function in **2** and the difference in the regiochemistry of the nitro groups of **2** and that of TNF are not, however, expected to lead to a distinctive



1 **2**

[1] Author to whom correspondence should be addressed.

difference in their electronic properties, in particular, the energy of their LUMO's (i.e., electron affinities (8)). On the other hand, it is possible that the presence of an alkyl substituent in **2** may render the structure non-mutagenic.

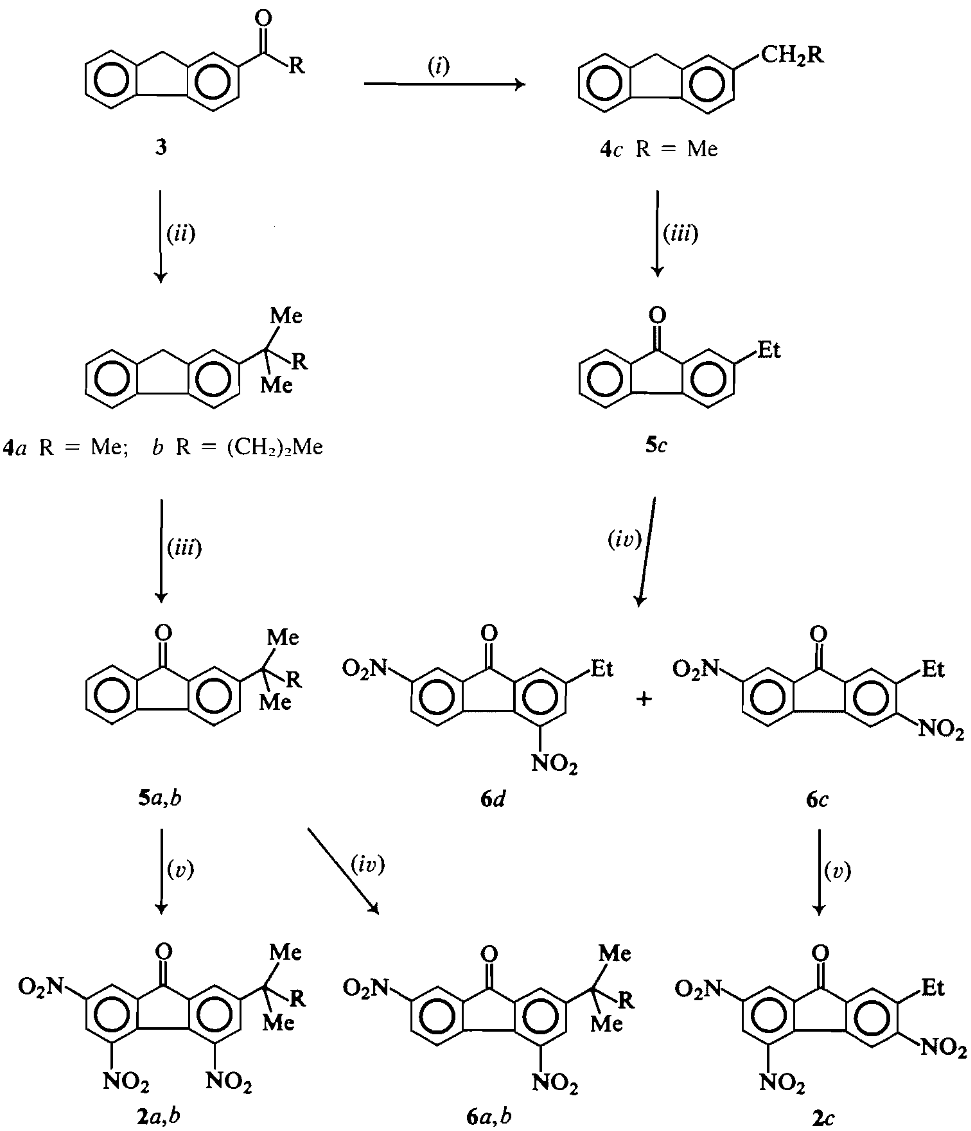
Results and discussion

Synthesis

While polynitration conditions are generally drastic, and oxidative degradations are common in these reactions, direct nitration of 2-alkylfluoren-9-one **5** appears to be the obvious route to **2**. What is required is a selective nitration reaction which is strong enough to trinitrate **5**, but mild enough not to cause significant degradation of its alkyl function. We felt that such a selective trinitration could be achieved by using a shorter reaction time and lower temperature conditions.

2-Alkylfluoren-9-one **5** was synthesized from 2-acylfluorene **3** by appropriate reduction of its acyl function to 2-alkylfluorene **4**, followed by oxidation at C-9 (Scheme 1). Thus, a Wolff–Kishner reduction of **3** with NH_2NH_2/KOH in ethylene glycol at 130–200°C afforded the corresponding 2-alkylfluorene **4***c* in good yield. On the other hand, the dimethylated species **4***a* or **4***b* was obtained by reductive methylation using the mild reductive methylating agent, $Al(CH_3)_3$ (9). Owing to the relatively high acidity of the C-9 protons ($pK_a \sim 23$, (10)), subsequent oxidation of **4** at C-9 was effectively accomplished by base-catalysed O_2-oxidation using Triton B in pyridine (11).

Nitration of 2-alkylfluoren-9-one **5** under standard polynitration conditions (e.g., 90% HNO_3/concentrated H_2SO_4, heat (12, 13)) did not yield the desired trinitro species. Under these conditions, **5** with a primary alkyl side chain (i.e., **5***c*) gave an intractable mixture of compounds, while **5***a* and **5***b*



Reaction conditions: (*i*) NH_2NH_2/KOH, 130–200°C; (*ii*) $Al(Me)_3$/cat. AcOH, 0–140°C; (*iii*) O_2/Triton B, pyridine; (*iv*) red fuming HNO_3, 0–25°C; (*v*) red fuming HNO_3/conc. H_2SO_4, 0–25°C.

SCHEME 1

with α-tertiary alkyl substituents afforded mainly 2,4,5,7-tetranitrofluoren-9-one. The latter apparently resulted from dealkylation of **5** and its nitrated intermediates during the course of the reaction. Even at room temperature and below, the desired product could not be detected in the reaction mixture. However, we found that the desired trinitration could be achieved by employing a stronger nitrating agent such as a mixture of red fuming HNO_3 and concentrated H_2SO_4. Thus, when **5***a* or **5***b* was treated with this nitrating agent, first at 0°C and then at room temperature, the trinitrated product, 2-alkyl-4,5,7-trinitrofluoren-9-one (**2***a* or **2***b*) was obtained in over 35% yield. The dinitro species, 2-alkyl-4,7-dinitrofluoren-9-one (**6***a*, *b*) could be isolated by terminating the reaction earlier or simply by treating **5** with red fuming HNO_3 at room temperature. The regiochemistry of the nitro functions in these products was unambiguously determined by nmr spectroscopy and is consistent with the reactivity of the fluoren-9-one structure in electrophilic substitution reactions (13). With **5***c*, the above conditions did not prove to be satisfactory; a complex mixture containing even the tetranitrated 2-alkylfluoren-9-one (as detected by mass spectrometry) was obtained. Nevertheless, if **5***c* was first treated with red fuming nitric acid at ice-bath temperature to generate the dinitro species, followed by addition of concentrated H_2SO_4 at room temperature, the desired trinitrated product, **2***c*, could be obtained in about 20% yield. Two other dinitrated compounds, namely 2-ethyl-3,7-dinitrofluoren-9-one **6***c* and 2-ethyl-4,7-dinitrofluoren-9-one **6***d* were also isolated in over 10% yields. The regiochemistry of nitration in this case is interesting; with a less bulky primary alkyl side chain, nitration also occurred at the weakly activated C-3 position. However, under the above conditions, it was difficult to nitrate the sterically congested C-4 and C-5 positions both at the same time. Accordingly, only **6***c* (and not **6***d*) was further nitrated at C-5 to give the corresponding trinitro derivative. The moderate

*Parameters for **2***c*, **6***c*, and **6***d* from the methylene proton-decoupled 250-MHz spectra.

yields of these 2-alkylnitrofluoren-9-ones are respectable in view of the extensive degradation commonly observed in polynitration reactions.

Spectroscopic properties

All the nitrofluoren-9-ones display ir absorptions at ~1345 and 1550 cm^{-1} typical of aromatic nitro compounds. The carbonyl absorption appears at approximately 1740 cm^{-1}, which is 30 cm^{-1} higher than that of fluoren-9-one; this is consistent with the electron-deficient carbonyl function of these compounds. Mass spectra of these molecules all exhibit molecular ions, together with fragmentations expected of the structures.

The ^{1}H nmr spectra of these compounds are regiochemically informative. The spectra of the trinitro derivatives display, besides their alkyl signals, two distinct AB quartets for their aromatic protons. Both **2***a* and **2***b* exhibit *meta*-coupling constants of ~1.9–2.2 Hz. Coupling constants for **2***c*, on the other hand, are 2.1 and 0.4 Hz for the *meta* and *para*-couplings respectively. The chemical shifts of the aromatic protons of **2** are extremely sensitive to solvent effects, particularly with benzene and dimethylformamide, which are capable of forming charge transfer complexes with **2**. The 80-MHz ^{1}H nmr spectra of the dinotro derivatives **6** are complex. While the disubstituted ring displays an AB (**6***d*) or AX (**6***c*) quartet (long-range coupling to the side-chain methylene protons is also observed), the proton signals of the monosubstituted ring are complex second-order ABC. However, at 250 MHz, the spectra are reduced to approximately first-order AMX, and the chemical shifts and coupling constants can be measured directly (Table 1).

Solubility and polymer compatibility characteristics

With an alkyl substituent in its structure, **2** was observed to display better molar solubility in organic solvents than its corresponding non-alkylated counterpart, TNF. The solubility characteristics of three trinitrofluoren-9-ones are summarized in Table 2.

TABLE 2. Solubilities of trinitrofluoren-9-ones in organic solvents at 22°C (mmol/mL)

	CH_3CN	CH_2Cl_2	$CHCl_3$	Acetone	EtOAc	THF
TNF	0.09	0.15	0.14	0.13	0.07	0.50
2*a*	0.13	0.34	0.33	0.21	0.13	0.65
2*b*	0.23	0.34	0.44	0.24	0.23	0.69

Although the trinitrofluoren-9-ones are compatible with strongly electron-donating polymers such as poly(*N*-vinylcarbazole), **2** generally displays better polymer compatibility characteristics than TNF with other common matrix polymers. For instance, while the solvent-cast films of TNF in Lexan (polycarbonate) and Flexiclad (polyester) at relatively high loadings of ~3 mmol/g of polymer exhibit signs of TNF crystallization on standing for a few days at room temperature, the same polymer matrices containing **2***a* and **2***b* under similar conditions are stable for months. Undoubtedly, the presence of an alkyl group, particularly one that is sterically bulky, imparts not only good solubility but also good polymer compatibility characteristics to the trinitrofluoren-9-one structure.

Electrochemical and charge-transfer properties

The electrochemical properties of nitrofluoren-9-ones were examined by cyclic voltammetric techniques. The cyclic voltammetric measurements were carried out in methylene chloride at room temperature using a hanging-mercury-drop working electrode and a Ag/AgCl reference electrode. Figure 1 depicts typical cyclic voltammograms for **2***b* and TNF under similar conditions. Both **2** and TNF exhibited two reversible one-electron reductions separated by ~0.3 V. The first half-wave reduction potentials of **2** and TNF are essentially identical. Their cyclic voltammograms showed a reversible re-

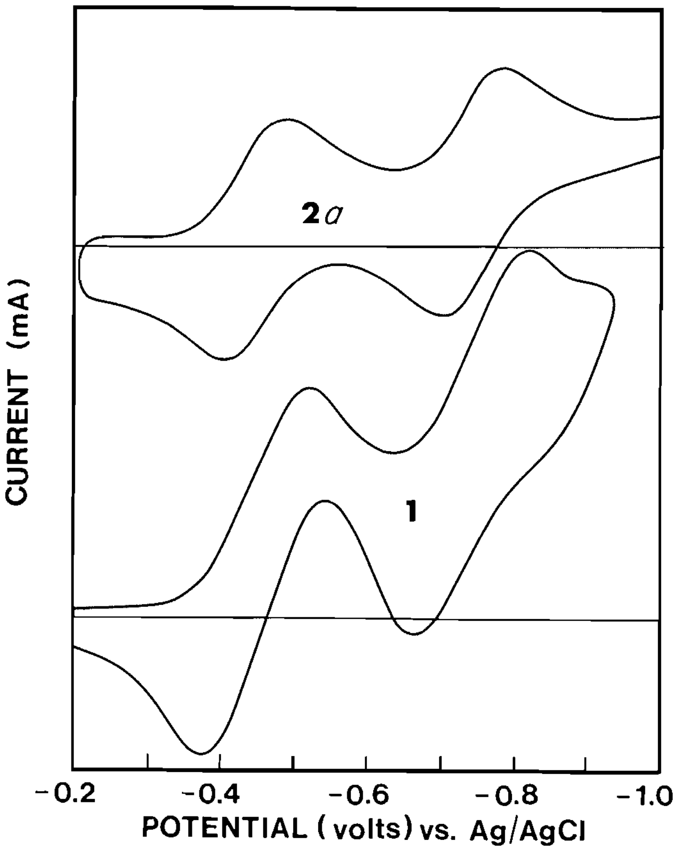

FIG. 1. Typical cyclic voltammograms of TNF (**1**) and 2-(1,1-dimethylbutyl)-4,5,7-trinitrofluoren-9-one (**2***b*) in methylene chloride at 25°C.

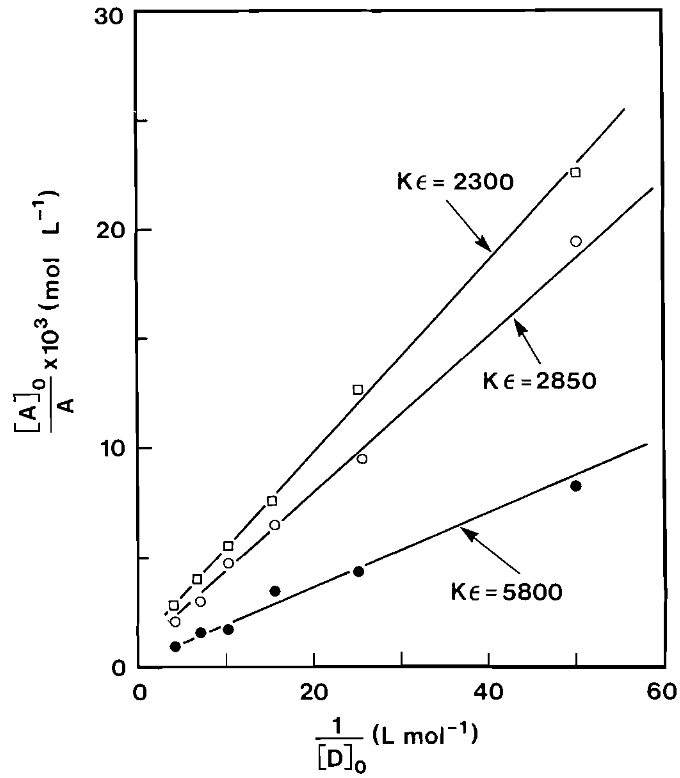

FIG. 2. Benesi–Hildebrand plots of charge-transfer interactions of TNF (**1**, ●), 2-*tert*-butyl-4,5,7-trinitrofluoren-9-one (**2***a*, ○), and 2-(1,1-dimethylbutyl)-4,5,7-trinitrofluoren-9-one (**2***b*, □) with *N*-ethylcarbazole in THF (λ_{max} ~ 435 nm, 1-cm cell, 25°C); $[A]_0$ = total acceptor concentration; [D] = total donor concentration; *A* = absorbance.

sponse, with a separation of 70 mV between cathodic and anodic peak potentials independent of scan rate (10–200 mV/s). These results indicate a simple, kinetically diffusion-controlled reduction of the molecules to the corresponding radical anions, which were stable within the time scale of measurement. Accordingly, it can be concluded that the presence of a weakly electron-donating alkyl substituent in **2** does not significantly perturb the energy of its LUMO from that of the basic trinitrofluoren-9-one structure. This is particularly important in that the electron transport capability of the structure depends profoundly on its electron affinity (14). From this perspective, **2** is therefore expected to be as good an electron transport system as TNF. Interestingly, the dinitro derivatives (e.g., **6***b*) also displayed two reversible one-electron reductions; the first reduction, however, occurred at −0.76 V.

Although **2** has the same electron affinity as TNF, it displays weaker charge-transfer interactions with electron donors than the latter. This is especially true in the case of **2***a* or **2***b* where a sterically demanding tertiary alkyl substituent is present. Figure 2 depicts the Benesi–Hildebrand plots of the charge-transfer interactions of **2** and TNF with *N*-ethylcarbazole. The selection of the latter as a donor was to ensure a strong CT interaction because of its reasonably high electron donor strength, structural planarity, as well as extended π-network. As can be noted, the product *K*ε's for **2** are significantly lower than that for TNF. For effective charge transfer interaction, a close spatial relationship of electron donor and acceptor is mandatory. The presence of a bulky group in **2***a* and **2***b* obviously hampers close association with donor molecules, and thus a weaker charge-transfer interaction results.

Electron Transport Properties

The electron transport properties of **2** and TNF were investigated by the xerographic discharge technique under space charge limited conditions (14–16). Figure 3 shows a schematic representation of the photoconductive layered device used in these studies. The device is comprised of a thin layer (0.5 μm) of amorphous selenium (a-Se) photogenerator, a relatively thick transport layer (10–15 μm) of a trinitrofluoren-9-one in poly(*N*-vinylcarbazole) (PVK), and a conductive substrate.

Figure 4 depicts the typical time-resolved photoinduced discharge curves (PIDC's) of **2***b* and, for comparison of TNF. The PIDC characteristics of **2***a*, **2***b*, and TNF are very similar, although a sharper initial discharge is noted in the case of **2**. This was probably the result of a better dispersion of **2** in the transport layer. The slight differences in the residual potentials for **2** and TNF are primarily due to variations in the thickness of the experimental devices. The estimated electron drift mobilities are tabulated in Table 3. It appears that under equivalent molar loading conditions, **2** has a higher electron drift mobility. Whether this is an intrinsic property of **2** or is merely due to the better dispersibility of **2** in the transport layer cannot be unambiguously answered.

Conclusions

We have shown that the direct nitration of 2-alkylfluoren-9-ones is a feasible route to the novel 2-alkyltrinitrofluoren-9-ones. The incorporation of an alkyl function into the basic trinitrofluoren-9-one structure not only results in an enhancement of its solubility but also its polymer compatibility

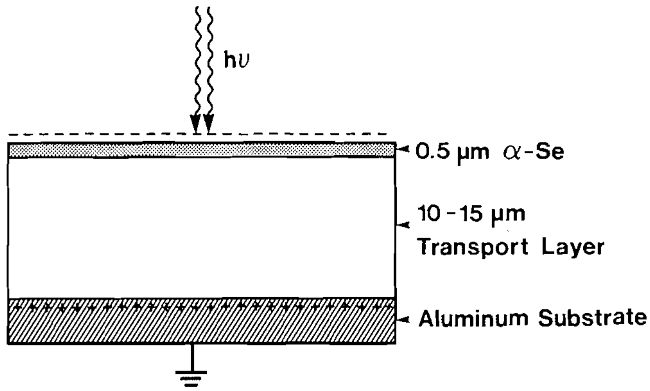

FIG. 3. Schematic diagram of the layered device for electrical characterization of trinitrofluoren-9-ones.

TABLE 3. Electron drift mobilities of trinitrofluoren-9-ones in poly(*N*-vinylcarbazole) matrices at applied electric field of 2×10^5 V/cm

Trinitrofluoren-9-one	Matrix loading (mol/g PVK)	Electron mobility (cm^2/V s)
TNF	3.2×10^{-3}	4×10^{-8}
2*a*	2.7×10^{-3}	1.4×10^{-8}
2*b*	3.2×10^{-3}	1×10^{-7}

characteristics. Of significance in this structural modification is that the electron affinity of the basic TNF structure is preserved in the alkylated analogs even though the regiochemistry of their nitro functions differs from that of TNF. In line with this, it is observed that both TNF and the alkylated analogs exhibit similar electron transport properties.

Experimental

All the solvents used in the reactions were Reagent Grade; unless otherwise stated, they were dried by refluxing with appropriate drying agents, followed by distillation before use (chlorinated solvents, xylene (P_2O_5); THF ($LiAlH_4$); pyridine (CaH_2)). Infrared spectra were recorded on a Beckmann IR-4250 spectrophotometer with polystyrene as the calibration standard; solid samples were taken as KBr pellets, liquid samples as thin films (neat). Electronic absorption spectra were obtained on Hewlett Packard 8450A uv/visible spectrophotometer. The ^{1}H nmr spectra were recorded in $CDCl_3$ on Bruker WP-80 and WM-250 spectrometers with tetramethylsilane as an internal standard. Mass spectra were obtained on a Finnigan 4000 quadrupole instrument. All melting points were measured on a Thomas–Hoover melting point apparatus and are uncorrected. Elemental analyses were performed by Galbraith Laboratories, Inc., Knoxville, Tennesse, U.S.A.

2-Acylfluorene (3)

2-Acylfluorene was prepared by Friedel–Crafts acylation of fluorene according to literature procedures (12). The reaction was conducted on a 0.6-mol scale with carboxylic anhydride/$AlCl_3$ as the acylating agent and dichloroethane as the reaction medium.

2-tert-Butylfluorene (4a)

A suspension of 2-acetylfluorene (4.16 g, 0.02 mol) in xylene (60 mL) and 5 drops of acetic acid was stirred at ice-bath temperature under a nitrogen atmosphere. 2 *M* trimethylaluminum solution in toluene (40 mL, 0.08 mol) was added slowly over a period of 15–20 min. After addition, the mixture was heated under reflux for 4 h. The reaction mixture was cooled, diluted with 50 mL ether, and hydrolyzed by pouring into a mixture of ether and dilute aqueous HCl solution. The aqueous layer was separated and extracted with ether. The combined organic solution was dried and evaporated to give the solid crude product. Column chromatography of the crude product on silica gel (hexane) gave the pure 2-*tert*-butylfluorene as a white crystalline solid (3.32 g, 75%), mp 115–116°C; ^{1}H nmr δ: 1.40 (s, 9H), 3.25 (s, 2H), 7.2–7.9 (m, 7H); ms (*m*/*e*): 222 (M^+). *Anal.* calcd. for $C_{17}H_{18}$: C 91.84, H 8.16; found: C 91.58, H 8.22.

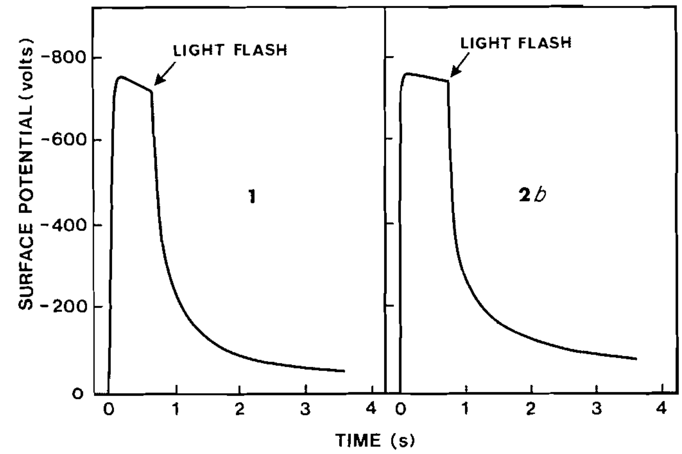

FIG. 4. Typical time-resolved photoinduced discharge curves for TNF (**1**) and 2-(1,1-dimethylbutyl)-4,5,7-trinitrofluoren-9-one (**2***b*)-based photoreceptors.

2-(1,1-Dimethylbutyl)fluorene (4b)

The title compound was prepared in a similar manner as **4***a*, in 82% yield. It was purified by recrystallization from methanol, mp 62–63°C; ^{1}H nmr δ: 0.80 (t, 3H), 1.10 (m, 2H), 1.35 (s, 6H), 3.85 (s, 2H), 7.20–7.80 (m, 7H). *Anal.* calcd. for $C_{19}H_{22}$: C 91.14, H 8.85; found: C 91.04, H 8.84.

2-Ethylfluorene (4c)

A mixture of 2-acetylfluorene (10.4 g, 0.05 mol), 85% NH_2NH_2 (5 g, 0.15 mol), and 8.4 g KOH in ethylene glycol (120 mL) was heated at 130–140°C for 2 h. Water generated from the reaction and excess NH_2NH_2 were removed by distillation at this temperature. The reaction mixture was then gradually brought to reflux over a period of 1 h and held at this temperature for another 4 h. After cooling and diluting with 65 mL of water, the mixture was poured into 100 mL dilute aqueous HCl solution. The solid product was collected, washed with water, and dried. Recrystallization from acetone–hexane afforded pure 2-ethylfluorene in 75% yield, mp 99–99.5°C; ^{1}H nmr δ: 1.30 (t, 3H), 2.70 (q, 2H), 3.85 (s, 2H), 7.1–7.8 (m, 7H); ms (*m*/*e*): 194 (M^+). *Anal.* calcd. for $C_{15}H_{14}$: C 92.74, H 7.26; found: C 92.68, H 7.18.

2-tert-Butylfluoren-9-one (5a)

A solution of 2-*tert*-butylfluorene **4***a* (2.83 g, 12.7 mmol) in dried pyridine (15 mL) was stirred in a 50-mL round-bottom flask under an oxygen atmosphere at room temperature. The reaction flask was connected separately to an oxygen source and a gas regulatory apparatus by means of rubber tubing such that the oxygen pressure in the system could be maintained at near atmospheric pressure during the reaction. A solution of 40% Triton B in pyridine (0.32 mL) was added to the reaction vessel by means of a syringe. An exothermic reaction was observed upon addition; the reaction mixture turned black instantaneously, and a fast consumption of oxygen was noted. The extent of reaction was conveniently monitored by tlc. After the reaction (~40 min), the mixture was pipetted into water with vigorous stirring. The yellow precipitate was collected, washed with water, and dried. Recrystallization from petroleum ether afforded pure **5***a* as a bright yellow solid (2.81 g, 94%), mp 99.5–100.5°C; ir (KBr): 1710 cm^{-1}; ^{1}H nmr δ: 1.35 (s, 9H), 7.2–7.7 (m, 7H); ms (*m*/*e*): 236 (M^+). *Anal.* calcd. for $C_{17}H_{16}O$: C 86.41, H 6.82; found: C 86.23, H 6.91.

2-(1,1-Dimethylbutyl)fluoren-9-one (5b)

The title compound was prepared from 2-(1,1-dimethylbutyl)-

fluorene *4b* in the same manner as *5a*. It was purified by column chromatography on silica gel using ethyl acetate – heptane (1:20) as the eluting solvent. Compound **5***b* was obtained as an oil in 86% yield; ir (neat): 1710 cm^{-1}; ^1H nmr δ: 0.80 (t, 3H), 1.10 (m, 2H), 1.30 (s, 6H), 1.60 (m, 2H), 7.2–7.7 (m, 7H). *Anal.* calcd. for $C_{19}H_{20}O$: C 86.32, H 5.81; found: C 86.25, H 5.69.

2-Ethylfluoren-9-one (5c)

The title compound was obtained from 2-ethylfluorene **4***c*, as in the case of **5***b*, in 92% yield; ir (neat): 1715 cm^{-1}; ^1H nmr δ: 1.20 (t, 3H), 2.60 (q, 2H), 7.0–7.7 (m, 7H); ms (*m/e*): 208 (M^+). *Anal.* calcd. for $C_{15}H_{12}O$: C 86.51, H 5.81; found: C 86.25, H 5.69.

2-tert-Butyl-4,5,7-trinitrofluoren-9-one (2a)

A mixture of red fuming HNO_3 (S.G. = 1.6, 40 mL) and concentrated H_2SO_4 (20 mL) was added slowly to 3.7 g (10 mmol) of powdered **5***a* in a 100-mL round-bottom flask at ice-bath temperature. The flask was constantly swirled during addition to ensure proper mixing of the reagents. The initial addition was carried out very slowly because of the highly exothermic reaction. After 20 mL of the nitrating agent was added, the mixture was removed from the ice bath, and the remaining nitrating agent then added. The resulting reaction mixture was further stirred at room temperature for 25 min before being pipetted into 500 mL of well-stirred ice-cold water. The solid yellow product was collected, washed with water, and air dried. Purification by preparative hplc on silica gel (methylene chloride – hexane 1:1) afforded 1.37 g (37%) of pure **2***a* as a bright yellow crystalline solid, mp 212–212.5°C; ir (KBr): 1345, 1550 (C—NO_2), 1742 (C═O) cm^{-1}; ms (*m/e*): 371 (M^+). *Anal.* calcd. for $C_{17}H_{13}N_3O_7$: C 54.99, H 3.53, N 11.32; found: C 55.12, H 3.47, N 11.21.

2-(1,1-Dimethylbutyl)-4,5,7-trinitrofluoren-9-one (2b)

The title compound was prepared from 2-(1,1-dimethylbutyl)-fluoren-9-one *4b* according to the same procedure as for *2a* on a 40-mmol scale in 43% yield, mp 188–190°C; ir (KBr): 1345, 1550 (C—NO_2), 1740 (C═O) cm^{-1}; *Anal.* calcd. for $C_{19}H_{17}N_3O_7$: C 57.14, H 4.29, N 10.51; found: C 56.88, H 4.34, N 10.31.

Nitration of 2-ethylfluoren-9-one (5c)

Red fuming nitric acid (16 mL) was added to 2-ethylfluoren-9-one **5***c* (0.416 g, 2 mmol) in a 50-mL round-bottom flask at ice-bath temperature with constant swirling over a period of 10 min. After addition, the mixture was stirred at room temperature for 1 h before 8 mL of concentrated H_2SO_4 was added. The mixture was allowed to react for another hour before being worked up as before. Preparative thin layer chromatography on silica gel (methylene chloride – hexane 2:1) yielded 0.15 g (22%) of 2-ethyl-3,5,7-trinitrofluoren-9-one **2***c* as a viscous oil (R_f 0.15); ir (neat): 1345, 1540 (C—NO_2), 1740 (C═O) cm^{-1}; ms (*m/e*): 343 (M^+); hplc analysis showed that the purity of **2***c* was about 95%, with some contamination from the dinitro derivatives.

Also isolated from the mixture were 0.065 g (11%) of 2-ethyl-3,7-dinitrofluoren-9-one **6***c* (R_f 0.24) and 0.083 g (14%) of 2-ethyl-4,7-dinitrofluoren-9-one **6***d* (R_f 0.39). Both of the products exhibit ir absorpitions at 1345, 1540, and 1740 cm^{-1}.

2-tert-Butyl-4,7-dinitrofluoren-9-one (6a)

Red fuming HNO_3 (20 mL) was added slowly to 1.0 g (4.2 mmol) of powdered **5***a* in a 50-mL round-bottom flask at ice-bath temperature over a period of 15 min with constant stirring. After addition, the reaction mixture was further stirred at room temperature for 20 min before being pipetted into 50 mL of ice-cold water. The yellow precipitate was collected, washed with water, and air dried. Column chromatography on silica gel (methylene chloride – hexane 2:1) gave 0.66 g (48%) of pure **6***a* as bright yellow crystals, mp 172–173°C; ir (KBr): 1345, 1540 (C—NO_2), 1740 (C═O) cm^{-1}. *Anal.* calcd. for $C_{17}H_{14}N_2O_5$: C 62.58, H 4.32, N 8.59; found: C 62.65, H 4.11, N 8.54.

2-(1,1-Dimethylbutyl)-4,7-dinitrofluoren-9-one (6b)

The title compound was prepared from 2-(1,1-dimethylbutyl)-fluoren-9-one **5***b*, in the same manner as **6***a*, in 53% yield as a bright yellow solid, mp 130.5–131.5°C; ir (KBr): 1345, 1540 (C—NO_2), 1740 (C═O) cm^{-1}. *Anal.* calcd. for $C_{19}H_{18}N_2O_5$: C 64.40, H 5.12, N 7.91; found: C 64.65, H 5.03, N 8.01.

Charge-transfer interaction

The charge-transfer measurements were performed on freshly prepared solutions in THF using a Hewlett Packard 8450A uv/visible spectrophotometer. The concentrations of the donor, *N*-ethylcarbazole, were varied from 2.0×10^{-2} *M* to 2.5×10^{-1} *M*, while those of trinitrofluoren-9-ones were kept constant at $\sim 2.2 \times 10^{-4}$ *M*. The λ_{max} of the CT band appeared at ~435 nm.

Electrochemical measurements

Electrochemical measurements were carried out on a PAR 174A polarographic analyzer connected to a PAR 175 universal programmer. A PAR model 303 static mercury drop electrode assembly was used. The system was equipped with a hanging-mercury-drop working electrode, a Ag/AgCl reference electrode, and a platimum wire auxiliary electrode. Sample concentrations were 10^{-3} *M*. Tetrabutylammonium perchlorate in methylene chloride was employed as the supporting electrolyte.

Electrical characterization

The electrical characterization of trinitrofluoren-9-ones as electron transport molecules was performed using the xerographic discharge technique under space charge limited conditions (14–16). The photoconductive layered device used for measurement was prepared as follows: a transport layer (10–15 μm) comprising a trinitrofluoren-9-one in PVK was solvent cast onto an aluminium substrate using a Bird film applicator. A 0.5-μm thick layer of amorphous selenium was vacuum evaporated on top of the transport layer to serve as the photogenerator. The device was corona charged to a negative surface potential and was discharged by exposing it to a light flash of wavelength of 4330 Å. The resulting photoinduced discharge of the device was monitored by a capacitively coupled probe. Under these conditions, one of the parameters controlling the rate of discharge is the electron mobility in the transport layer.

It is shown that the *tert*-butyloxycarbonylation of phenols, alcohols, enols, and thiols can be accomplished by reaction of these functionalities with di-*tert*-butyl dicarbonate under phase transfer conditions. The reactions proceed in high yield and can also be used for the introduction of *t*-BOC groups onto functionalized polymer backbones such as novolac or poly(*p*-hydroxystyrene). In addition, a study is made of the selectivity towards *tert*-butyloxycarbonylation of various polyfunctional compounds.

F. HOULIHAN, F. BOUCHARD, J. M. J. FRÉCHET et C. G. WILLSON. Can. J. Chem. **63**, 153 (1985).

On démontre que l'on peut effectuer une réaction de *tert*-butyloxycarbonylation des phénols, des alcools, des énols et des thiols en faisant réagir ces diverses fonctions avec du bicarbonate de di-*tert*-butyle dans des conditions de transfert de phase. Les réactions se produisent avec des rendements élevés et elles peuvent être utilisées pour introduire des groupements *t*-BOC sur les squelettes de polymères comme le novolac ou le poly(*p*-hydroxystyrène). De plus, on a étudié la sélectivité de divers composés polyfonctionnels par rapport à la réaction de *tert*-butyloxycarbonylation.

[Traduit par le journal]

Introduction

While the *tert*-butyloxycarbonyl group (*t*-BOC) is used widely as an amino protecting group, particularly in peptide synthesis following the work of Carpino and others (1–5), it has not, until recently, found any application as a protecting group for hydroxyl or thiol functionalities.

Our recent work on the preparation of poly(*p*-hydroxystyrene) (6) and poly(*p*-hydroxy-a-methylstyrene) (7) through the polymerization of the corresponding *t*-BOC protected vinyl phenols has shown the versatility of the *t*-BOC group for the protection of phenolic compounds. For example, the *t*-BOC group is resistant to both the conditions of the Wittig reaction and of cationic polymerization in liquid sulfur dioxide where other more classical protecting groups such as the acetoxy group fail. In addition, the unique ability of the *t*-BOC group to be removed by thermolysis or by the action of a catalytic amount of strong acid has proved critical in the preparation of pure poly(*p*-hydroxystyrene) (6) and is the basis for the use of poly(*p*-*t*-BOC-hydroxystyrene) in a new photoimaging system exhibiting the phenomenon of chemical amplification (8).

Results and discussion

Several different pathways have been tested for the *tert*-butyloxycarbonylation of hydroxyls and thiols (9–13); three of the most commonly used are shown in Scheme 1. All three are characterized by generally low yields and the use of extremely toxic or unstable reagents. In contrast to the paucity of methods for the preparation of *t*-BOC derivatives of alcohols, the preparation of *t*-BOC derivatives of amines has been studied extensively as the *t*-BOC group has proven extremely useful in peptide synthesis. In recent years numerous preparations have used di-*tert*-butyl dicarbonate as an *N*-*tert*-butyloxycarbonylation reagent due to the ease with which it reacts with amines to form the corresponding *t*-BOC derivatives in essentially quantitative yields. The reaction is accompanied by evolution of gas, as both carbon dioxide and isobutylene are released as the amine attacks the dicarbonate. Di-*tert*-butyl dicarbonate is a readily available crystalline reagent (14) which is safe and is easily handled. Our initial experiments were designed to explore the utility use of *t*-BOC groups for the protection of hydroxyls and involved the reaction of simple phenolates with di-*tert*-butyl dicarbonate.

tert-*Butyloxycarbonylation of phenols*

The reaction of phenols with di-*tert*-butyl dicarbonate (Scheme 2) proceeds readily under a variety of conditions and requires the presence of an equivalent amount of base. The reaction is fastest under phase transfer catalysis using liquid–liquid or liquid–solid reaction conditions. For example, phenol reacts very rapidly and quantitatively with di-*tert*-butyl dicarbonate in THF, ethyl acetate, or dichloromethane, in the presence of a catalytic amount of 18-crown-6 and an equivalent amount of powdered anhydrous potassium carbonate. Under liquid–liquid phase transfer conditions in dichloromethane solution, with aqueous sodium hydroxide or potassium carbonate as base and tetrabutyl ammonium hydrogen sulfate as catalyst, the reaction is also complete in an hour or less. Alternately, the phase transfer catalyst can be omitted completely for easier processing; the reaction with powdered anhydrous potassium carbonate and di-*tert*-butyl dicarbonate gives excellent yields of the desired product, albeit at much slower rates than the catalyzed reaction (Table 1). Phenolic substrates with functionalities such as aldehydes or ketones can be modified successfully without side reactions, as shown in the preparation of the *O*-*tert*-butyloxycarbonyl derivatives of *p*-hydroxybenzaldehyde and *p*-acetylphenol, **2***a* and **3***a* (Table 1), which are two useful precursors in the synthesis of reactive polymers (6,

SCHEME 2

7). The presence of substituents in the *ortho* position of the phenols causes a noticeable decrease in the reaction rate as the size of the substituent increases from methyl to *tert*-butyl. With 2,6-di-*tert*-butyl phenol, the reaction occurs, but at a very slow rate, and only a very low conversion (ca. 10%) is achieved, even in the presence of 18-crown-6 and after two days of stirring. While much of the 2,6-di-*tert*-butyl phenol remains unchanged in this reaction (ca. 70%), a significant amount of the diphenoquinone dimerization product is also isolated; such diphenoquinones are also obtained as by-products in the oxidative polymerization of phenols with bulky *ortho* substituents (15).

All of the low molecular weight aryl *tert*-butyl carbonates which were prepared by this method exhibit strong carbonyl bands near 1760 cm^{-1} in their infrared spectra. Their mass spectra all include a characteristic pattern for the loss of *t*-BOC (m/e 100) and a peak at m/e 57. Full spectral data are given in Table 4.

The *tert*-butyloxycarbonylation of phenolic polymers such as poly(*p*-hydroxystyrene) and novolac is also successful using the reaction conditions described above, faster reaction rates being observed in the presence of phase transfer catalysts. However, as the uncatalyzed reactions in the presence of powdered anhydrous potassium carbonate also give the *t*-BOC-substituted polymer in quantitative yield, it is the preferred method, as the purification of the final polymer is greatly simplified since no removal of the phase transfer catalyst from the precipitated polymer is necessary. With *m*-cresol novolacs containing *ortho–ortho* linkages, the reaction is slower than with the unhindered poly(*p*-hydroxystyrene) but proceeds nevertheless to completion even when no excess of dicarbonate reagent is present. Partial functionalization of a phenolic polymer is readily acomplished using less than a stoichiometric amount of dicarbonate; the dicarbonate is used quantitatively and without side reaction and this method is useful for the preparation of phenolic polymers containing varying proportions of free and *t*-BOC-protected hydroxyls.

In addition to analysis by nmr and ir spectroscopies, the *tert*-butyloxycarbonylated phenolic resins can be analyzed by thermogravimetry. This analytical technique is particularly useful in determining the exact degree of functionalization of partly *tert*-butyloxycarbonylated polymers, as the thermal reversion to the phenolic polymer occurs at 200°C with a sharp and easily measurable weight loss. For example, a novolac resin which had been allowed to react with 20% of the stoichiometric amount of di-*tert*-butyl dicarbonate lost 15% (100% of theory) of its weight upon heating to 200°C, confirming that 20% of the polymer's hydroxyl groups had been substituted in the reaction with the dicarbonate.

tert-Butyloxycarbonylation of alcohols

The reaction of alcohols with di-*tert*-butyl dicarbonate is much slower than that of phenols and requires the use of a phase transfer catalyst. Excellent results are obtained with liquid–liquid phase transfer catalysis using tetrabutyl ammonium hydrogen sulfate and aqueous sodium hydroxide; solid–liquid phase transfer catalysis is also suitable and affords essentially the same results. Allylic, benzylic, or primary alcohols react with the dicarbonate in a matter of hours, while secondary alcohols may require a day or more to react fully and tertiary alcohols are unreactive (Table 1). Reactions with the less reactive alcohols are best carried out using a 20% excess of the dicarbonate, as some of the reagent is slowly consumed in a side reaction with the aqueous sodium hydroxide. The infrared spectra of the carbonates show strong carbonyl bands near 1740 cm^{-1}, reflecting the lower energy of the carbonate bond of these alcohols compared to those of the phenolic compounds described above. Other spectral data are shown in Table 4.

tert-Butyloxycarbonylation of thiols

Both thiophenol and butanethiol react rapidly with di-*tert*-butyl dicarbonate under phase transfer conditions using the anhydrous potassium carbonate 18-crown-6 system, and afford good yields of the *t*-BOC derivatives. In contrast, the reaction with aqueous sodium hydroxide and tetrabutyl ammonium hydrogen sulfate does not lead to product, as the thiocarbonates which are formed are immediately hydrolyzed back to the starting thiols. Like phenol, thiophenol reacts with di-*tert*-butyl dicarbonate even in the absence of a phase transfer catalyst, provided anhydrous potassium carbonate is present. The reac-

tion with thiophenol can also be followed visually as it is accompanied by visible gas evolution. This evolution of carbon dioxide and 2-methyl propene is also observed in the reaction of di-*tert*-butyl dicarbonate with amines and in the reaction of phenol catalyzed by 18-crown-6, but is was not observed during reactions with alcohols or substituted phenols.

tert-*Butyloxycarbonylation of enols*

The *tert*-butyloxycarbonylation reaction was carried out with some readily enolizable compounds including acetyl acetone, ethyl acetoacetate, and acetophenone. Best results in these reactions (Table 2) were obtained using the crown ether – anhydrous potassium carbonate route. With ethyl acetoacetate, attack occurs exclusively at the acyl oxygen with formation of the (*E*) *t*-BOC derivative. Similar reactions of ethyl acetoacetate with acyl chlorides under phase transfer conditions are also known to give high percentages of the (*E*) *O*-acylated product (16). In contrast, acetyl acetone affords a 3 : 1 mixture of the (*E*) and (*Z*) *t*-BOC derivatives. Structural assignments for the two isomers of the *t*-BOC derivative of acetylacetone were made by a combination of spectral methods. Thus, it is known that the olefinic proton of similar compounds (11, 16) is observed at lower fields for the (*E*) isomer than for the (*Z*) isomer. In addition, a detailed FT-ir study shows that one of the isomers gives two carbonyl bands at 1704 and 1673 cm^{-1}, while the other isomer shows a single carbonyl band at 1702 cm^{-1}. An examination of molecular models confirms that while two possible orientations can occur for the (*Z*) isomer (structures A and B, Scheme 3), only one is likely for the (*E*) isomer (structure C, Scheme 3) as the other (D) is sterically hindered; therefore only one carbonyl band is expected for the (*E*) isomer. A similar result is obtained by consideration of the olefinic bands of the various isomers. This interpretation is further confirmed by the mass spectral data. Although the chemical ionization mass spectra of the isomers are nearly identical, that of the least abundant isomer shows an additional strong signal at m/e 127. This can be explained by a process in which the protonated cation resulting from loss of 2-methyl propene loses water and undergoes cyclization to form an aromatic cation (Scheme 4). This process is only possible with the (*Z*) isomer. Detailed spectral data can be found in Table 4.

The reaction with acetophenone gives best results when sodium hydride is used to form the enolate in a stoichiometric reaction, since the reaction under phase transfer catalysis, though successful, is too slow to be of practical value (Table 2).

Reactions with polyfunctional molecules

Having succeeded in the *tert*-butyloxycarbonylation of hydroxyls and thiols and enols, we looked briefly at the selectivity of the reaction by using polyfunctional molecules. A series of reactions was carried out with tyrosine ethyl ester, tyramine, *p*-aminophenol, and *p*-hydroxybenzyl alcohol. With *p*-aminophenol, excellent selectivity is observed as *N-tert*-butyloxycarbonylation is obtained in the absence of base, while in the presence of NaOH the reaction occurs mainly at oxygen (Table 3). This result is not unexpected since the nucleophilicity of the phenolate ion is much higher than that of the amino group of this substituted aniline.

As expected, different results are obtained with a molecule such as tyrosine, which has a more nucleophilic amino group as well as the reactive phenolic functionality. To simplify the reaction, tyrosine ethyl ester was chosen as the substrate. The reaction cannot be carried out with aqueous NaOH under phase

transfer conditions because the ester group is rapidly hydrolyzed. Reaction with the 18-crown-6 potassium carbonate system resulted in *N*-*tert*-butyloxycarbonylation. Selective *O*-*tert*-butyloxycarbonylation was not achieved. A similar reaction with tyramine using aqueous NaOH with tetrabutyl ammonium hydrogen sulfate resulted in protection at both the phenolic and the amino groups. Direct reaction of the phenolate of tyramine with di-*tert*-butyl dicarbonate afforded the same result, which confirms that selective *tert*-butylcarbonylation of the phenolic group cannot be achieved in the presence of strongly nucleophilic amino groups. In fact, the reaction affords a mixture of both the mono *N*-*tert*-butyloxycarbonyl and the di-*tert*-butyloxycarbonyl derivatives of tyramine even in the absence of added base, as the amino group of the tyramine acts as a base to assist in the *O*-*tert*-butyloxycarbonylation reaction. This result is not observed with *p*-aminophenol, which has a less basic amino group. Detailed spectral characteristics of the various *t*-BOC derivatives are given in Table 4.

To determine whether selectivity can be achieved in systems containing both phenol and aliphatic hydroxyl functionalities, the reaction of *m*-hydroxy-benzyl alcohol with di-*tert*-butyl dicarbonate was attempted under a variety of reaction conditions (Table 3). Aqueous NaOH in the presence of tetrabutyl ammonium hydrogen sulfate led to the formation of much disubstituted product. A higher percentage of reaction at the phenolic site was observed when the reaction was carried out with 18-crown-6 in the presence of powdered potassium carbonate; this limited selectivity was lost when the crown ether was omitted in the reaction with powdered potassium carbonate (Table 3). Finally, although the bis-*tert*-butyloxycarbonylation of L-cysteine has been accomplished previously (13) using *tert*-butyl chlorocarbonate, the reaction is much more convenient using di-*tert*-butyl dicarbonate.

Experimental

Infrared spectra were recorded using a Nicolet MX-1 Fourier-

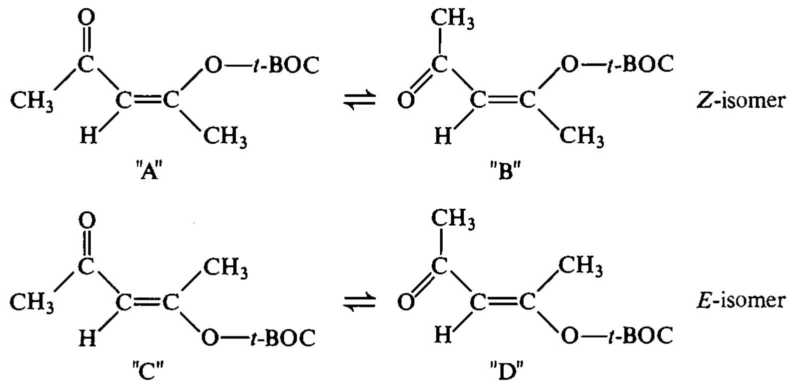
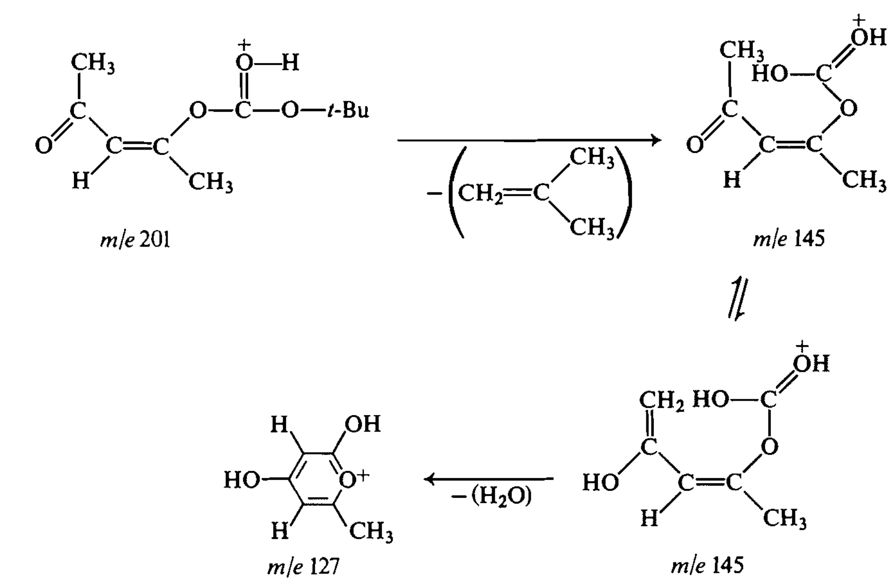
integration.

is given to compounds already reported.



SCHEME 3



SCHEME 4

Co. (resin M); the dark colored material had a broad molecular weight distribution with M_n approximately 6,000. Several grades of novolac obtained from Eastman Kodak were used successfully, most had molecular weights (M_n) less than 1000. All of the yields which are reported are for isolated compounds; in the case of polyfunctional molecules, Table 3 reports the %conversion for the dicarbonate as well as for the phenolic or thiol functionalities.

tert-*Butyloxycarbonylation of alcohols*

In a typical reaction, cinnamyl alcohol (1 g, 7.45 mmol) was dissolved in 2 mL dichloromethane containing di-*tert*-butyl dicarbonate (1.94 g, 8.89 mmol) and a catalytic amount of tetrabutyl ammonium hydrogen sulfate (0.073 g, 0.22 mmol). After cooling to 0°C, ice-cold 30% aqueous NaOH (3.7 mL) was added with vigorous stirring. After 90 min stirring, tlc indicated that the reaction was complete. The organic phase was diluted with dichloromethane, washed with a saturated brine solution, then dried over magnesium sulfate. After evaporation of the solvent, the product was purified by passing over a short silica gel column using 5% ethyl acetate in petroleum ether as eluting solvent; 1.65 g (93%) of the pure product was obtained as an oil; ir: carbonyl at 1741 cm^{-1}; ^{1}H nmr: 7.23 (s, phenyl), 6.66–6.23 (ABX_2 pattern, vinyl), 4.63 (d, CH_2), 1.47 (s, *tert*-butyl); mass spectrum: *M* + 234 (weak), 178 (strong, M − CH_2=$C(CH_3)_2$), 134 (medium, additional loss of CO_2), 133, 117, 57.

Similar reactions with other alcohols were carried out using a 10–15% excess of the dicarbonate reagent. The products which were obtained had spectral properties which are shown in Table 4.

tert-*Butyloxycarbonylation of phenols*

A suspension of 20.0 g anhydrous potassium carbonate in 20.0 mL dry THF containing 10.0 g phenol (0.1 mol) was cooled to 0°C, then treated with 23.2 g di-*tert*-butyl dicarbonate (0.1 mol) containing a catalytic amount of 18-crown-6. Chromatographic monitoring of the reaction showed that the dicarbonate was consumed in less than 1 h and the mixture was worked up as described above to afford 21 g (99% yield) of pure phenyl *tert*-butyl carbonate. The spectral characteristics of the product are given in Table 4. A parallel reaction done in the absence of 18-crown-6 proceeded somewhat more slowly, but afforded an excellent yield of the desired product.

tert-*Butyloxycarbonylation of novolac*

A solution of 5 g novolac in 20 mL ethyl acetate was treated with 3.5 g powdered anhydrous potassium carbonate and 4.55 g of di-*tert*-butyl dicarbonate. The mixture was stirred for 24 h at room temperature, then filtered. After evaporation of the solvent under reduced pressure, the residue was dissolved in a minimum of THF and the polymer was precipitated in water. After redissolution in dichloromethane, washing with water, and drying over anhydrous magnesium sulfate, the solvent was evaporated to yield the partly *tert*-butyloxycarbonylated novolac (6.7 g) as a hard foam. The *t*-BOC content of the polymer was 50% measured by nmr as well as by tga, as expected from the stoichiometry of the reaction. In other experiments the *t*-BOC content of the polymer was varied at will from a low of 3% to 100% by simple adjustments in the amount of di-*tert*-butyl dicarbonate available for the reaction. The functionalization reaction was also carried out using THF as a solvent; this resulted in an easier work-up as the polymer could be precipitated directly from the after-reaction mixture. The infrared spectra of the products show a carbonyl band at 1760 cm^{-1}, accompanied by a hydroxyl band at 3300 cm^{-1} in the case of the partly functionalized polymers only.

tert-Butyloxycarbonylation of poly(p-hydroxystyrene)

The reaction with resin M was carried out as described above for Novolac using 3.25 g of poly(*p*-hydroxystyrene) in 12 mL ethyl acetate with 4 g powdered anhydrous K_2CO_3 and 6 g di-*tert*-butyl dicarbonate to yield 5.5 g (93% yield) of fully substituted poly(*p-tert*-butyloxycarbonyl styrene). The polymer has spectral characteristics similar to those of an authentic sample (10). Partial *tert*-butyloxycarbonylation of poly(*p*-hydroxystyrene) can be accomplished readily as above, using less than a stoichiometric amount of the dicarbonate reagent.

tert-Butyloxycarbonylation of thiophenols

The reaction was carried out exactly as described above for the *tert*-butyloxycarbonylation of phenol. Effervescence occurred immediately upon addition of the dicarbonate and the reaction was complete within minutes. The desired product, obtained in 96% yield, has the spectral characteristics given in Table 4.

tert-Butyloxycarbonylation of enols

The reaction was carried out as above for the preparation of **1***a* but requires a longer reaction time. In typical cases most of the reaction is completed in 5–6 h and a small amount of colored tarry material is formed. This is removed by precipitation in petroleum ether followed by the usual work-up.

The spectral characteristics of the various products are given in Table 4.

tert-Butyloxycarbonylation of p-aminophenol

To a suspension of 1.00 g (9.16 mmol) of *p*-aminophenol in 5 mL dichloromethane was added 0.16 g (0.60 mmol) tetrabutyl ammonium hydrogen sulfate and 5.0 mL 30% aqueous NaOH. After stirring the mixture until a clear two-phase system is obtained and cooling to 0°C, 2.43 g (11.12 mmol) of di-*tert*-butyl dicarbonate was added. The stirred mixture turned dark and, after a few hours, chromatographic monitoring revealed that the reaction was over. After work-up, a mixture of two products was obtained. This mixture afforded 1.54 g of *O-tert*-butyloxycarbonyl-*p*-aminophenol **19***a* (80% yield) as well as 0.14 g of the *O,N*-bis-*tert*-butyloxycarbonylated derivative **19***b*. This result shows that 85% of the original phenolic groups have reacted, while conversion of the di-*tert*-butyl dicarbonate into the two isolated products reached 74%. A similar reaction carried out on the phenolate of *p*-aminophenol in homogeneous medium gave a slightly lower yield of **19***a* with only a trace (less than 1%) of **19***b*.

tert-Butyloxycarbonylation of tyramine

The reaction was carried out as above using 0.5 g (3.65 mmol) tyramine in 2 mL dichloromethane containing 0.05 g tetrabutyl ammonium hydrogen sulfate. After addition of an equal volume of 30% aqueous NaOH, the mixture was stirred until a clear two-phase system was obtained, 0.795 g di-*tert*-butyl dicarbonate was added, and the mixture was stirred rapidly at 0°C. The reaction was over in a few hours and the mixture was processed as above to yield 0.61 g of bis-*O,N-tert*-butyloxycarbonylated tyramine **20***a* (quantitative yield with respect to dicarbonate). A similar reaction using the preformed phenolate of tyramine and di-*tert*-butyl dicarbonate afforded the same di-protected product. In the absence of added base the reaction proceeded as follows: to 0.5 g tyramine (3.65 mmol) suspended in 2 mL THF at 0°C is added an equimolar amount (0.795 g) of di-*tert*-butyl dicarbonate. Effervescence occurred with complete dissolution of the solid materials. Work-up after 2 h of standing afforded 0.21 g of the bis-*t*-BOC derivative **20***a* (0.62 mmol) and 0.57 g of the *N-t*-BOC compound **20***b* (2.4 mmol). The overall conversion for this reaction was 100% for the dicarbonate and only 17% for the phenolic groups.

tert-Butyloxycarbonylation of m-hydroxybenzyl alcohol

The reaction was carried out as above with 1 g (8.05 mmol) *m*-hydroxybenzyl alcohol, 5 mL dichloromethane, 0.136 g tetrabutyl ammonium hydrogen sulfate, 5 mL 30% NaOH, and 2.108 g (9.66 mmol) di-*tert*-butyl dicarbonate at 0°C. The dicarbonate was consumed within 2 h and the mixture was subjected to the usual work-up to yield 0.96 g of the bis-*t*-BOC derivative **21***b* and 0.49 g of **21***a* for an overall conversion of 64% of the phenolic groups and 84% of the dicarbonate. A similar reaction carried out on equimolar amounts of *m*-hydroxy benzyl alcohol (1 g, 8.05 mmol) and di-*tert*-butyl dicarbonate (1.76 g) in 4 mL dichloromethane with 3 g anhydrous potassium carbonate and 0.4 mmol 18-crown-6 afforded a larger proportion of the mono-*t*-BOC derivative **21***a* (1.39 g) and a smaller amount (13 mol% of total or 0.31 g) of th bis-*t*-BOC derivative **21***b* with a quantitative conversion of the dicarbonate and 89% conversion of the phenolic groups.

tert-Butyloxycarbonylation of tyrosine ethyl ester

A suspension of 1.0 g (4.07 mmol) of tyrosine ethyl ester hydrochloride in 15 mL ethyl acetate was stirred with 0.050 g 18-crown-6 and 2.50 g anhydrous potassium carbonate until the tyrosine derivative was fully dissolved. Upon addition of 0.888 g (4.07 mmol) di-*tert*-butyl dicarbonate, effervescence was observed and the reaction mixture was processed immediately as above to yield *N-tert*-butyloxycarbonyl tyrosine ethyl ester (1.07 g, 85% yield) with mp 82–84°C. A similar reaction with two equivalents of the dicarbonate afforded the results listed in Table 3.

tert-Butyloxycarbonylation of a cysteine derivative

A solution of 1 g L-cysteine ethyl ester hydrochloride (5.4 mmol) in 2 mL water was treated with 4 g potassium carbonate. After addition of 2.36 g di-*tert*-butyl dicarbonate (10.8 mmol) and 0.13 g tetrabutyl ammonium hydroxide, the mixture was stirred. Heat was evolved and the reaction proceeded to completion very rapidly. After the usual work-up, the bis-protected cysteine ethyl ester was obtained as white crystals melting at 76.5–77.5°C.

Chemistry of spectinomycin: its total synthesis, stereocontrolled rearrangement, and analogs[1]

STEPHEN HANESSIAN AND RENÉ ROY[2]
Department of Chemistry, Université de Montréal, Montreal, P.Q., Canada H3C 3V1

Received March 9, 1984

This paper is dedicated to the 10th anniversary of the Xerox Research Centre of Canada

STEPHEN HANESSIAN and RENÉ ROY. Can. J. Chem. **63**, 163 (1985).

The total stereocontrolled synthesis of the antibiotic spectinomycin is described, based on the regiospecific functionalization and manipulation of appropriate starting materials. The tertiary ketol rearrangement of the antibiotic and its derivatives was studied and the stereochemical identity of spectinoic acid was established by chemical correlation. Dihydrospectinomycin derivatives undergo unusual solvolysis reactions.

STEPHEN HANESSIAN et RENÉ ROY. Can. J. Chem. **63**, 163 (1985).

La synthèse totale et stéréocontrôlée de l'antibiotique spectinomycine est décrite en se basant sur une stratégie de fonctionnalisation et manipulation spécifique de produits de départs appropriés. Le réarrangement des α-cétols tertiaires de la spectinomycine et ses dérivés a été étudié et l'identité stéréochimique de l'acide spectinoïque a été établie par des corrélations chimiques. Les dérivés de la dihydrospectinomycine donnent lieu à des réactions de solvolyses intéressantes.

Spectinomycin is a structurally unique antibiotic which is formally classified among the aminocyclitol group (1). Isolated from several fermentation broths in the early sixties, it was originally given the name actinospectacin (2; for a recent review on the chemistry of spectinomycin, see ref. 3) and is presently used in the veterinary area. It is also widely used in human medicine because of its potent activity against some strains of *Neisseria gonorrhoeae*. It may be the drug of choice against penicillin resistant strains of *Neisseria gonorrhoeae* (4) or for patients allergic to β-lactam antibiotics. Another interesting feature concerning the biological profile of spectinomycin is the fact that it exhibits a greater degree of therapeutic effect in infected animals than might be expected on the basis of its in vitro activities. Extensive studies concerned with structure modification in order to induce greater antibiotic activity were carried out in several laboratories (5, 6). Unfortunately, except for the recently announced 4-amino-4-(*R*)-dihydro derivative (7*a*), and some alkyl spectinomycin analogs (7*b*), efforts to improve the biological profile of spectinomycin have been somewhat disappointing.

The constitutional structure (8, 9), stereochemistry, and absolute configuration (10), as well as the biosynthesis (11) of spectinomycin have been the subject of elegant studies over the years. Its unique structural, conformational, and functional features are depicted in Scheme 1. The tricyclic structure harbors nine chiral carbon atoms, each of which bears at least one hetero atom. Stereoelectronic factors are dominant in view of the presence of three contiguous acetal type linkages (12) and the fused ring systems provide classical cases of the manifestation of natural anomeric stereoselection (13). This feature may be appreciated by considering the conformational depiction of spectinomycin in Scheme 1 where it can be seen that, in the solid state structure (10), one of the oxygen atoms at C4a and C10a has an axial disposition with respect to the other on the same carbon atom (*gauche* orientation), as dictated by the stereoelectronic requirements of the anomeric effect (for a discussion of the anomeric effect, see ref. 14). Deslongchamps, Descotes and their respective groups (15) have found that bicyclic acetals having an axial orientation of alkoxy anomeric substituents are stabilized by at least 1.5 kcal/mol compared to the alternate anomer.

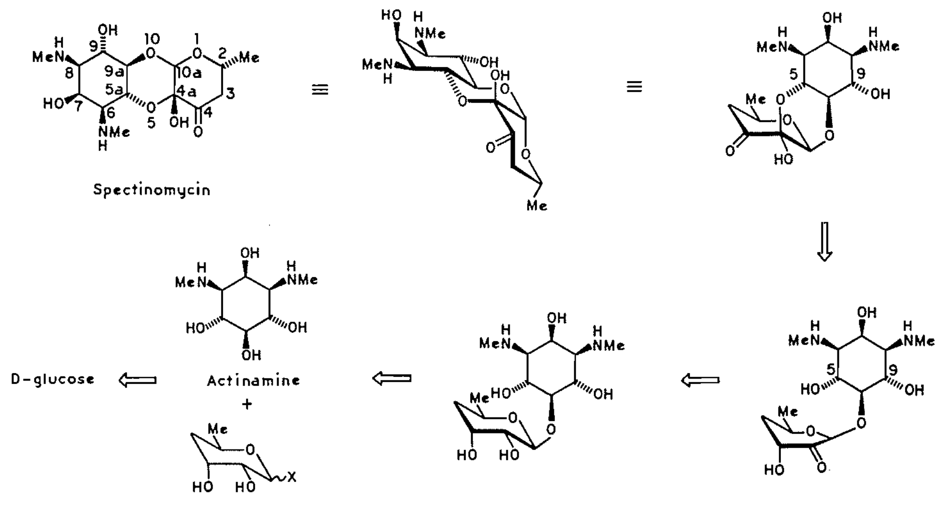
Spectinomycin adopts a "bent" shape in the solid state as well as in solution, and the resulting topological features in terms of functional groups, sidedness, and electronic properties may have an important bearing on its mode of action in inhibiting protein biosynthesis at the ribosomal level.

Surprisingly, little if any effort was reported on the total synthesis of spectinomycin prior to 1977. Thus, Suami *et al.* (16) reported on the synthesis of a tetrahydrospectinomycin derivative by glycosylation of a suitably protected actinamine. Several syntheses of actinamine, the cyclitol portion, were already available at the time (17; actinamine is also easily accessible from spectinomycin, see ref. 8) although by far the quickest access to this compound is by acidic hydrolysis of the antibiotic (9). In 1979, two independent and conceptually different total syntheses of spectinomycin were announced. The Upjohn synthesis (18) utilized L-glucose as starting material and involved a series of unique transformations. Our own synthesis, announced in preliminary form (13*b*, 19), was based on the systematic chemical manipulation of D-glucose and took advantage of some reactions anticipated to occur with a high degree of regiocontrol. It also relied in its final stages on a biomimetically-related process. Our strategy called for the synthesis of one of the four possible tetrahydrospectinomycins (20), namely, the 4*R*,4a*R* isomer (Scheme 1), which, by virtue of a predisposed arrangement of hydroxyl groups was expected to provide the necessary regio- and stereochemical control in subsequent operations leading to a pivotal 4a-keto derivative, and eventually to spectinomycin. With such a precursor in hand, we further expected the critical intramolecular ketalization to be diastereoselective because of the stereoelectronic requirements (12) of the anomeric effect (14).

In this paper, we give a full account of this synthesis, and we report on subsequent work (21) dealing with a unique stereocontrolled rearrangement of spectinomycin. The retrosynthetic analysis shown in Scheme 1 calls for the availability of a derivative of a 4,6-dideoxyhexose, which represents the chiral tetrahydropyran portion of the molecule. The fortuitous D-nature of the corresponding sugar directed our attention to D-glucose as a precursor. An initial objective, therefore, was to

[1] Taken in part from the Ph.D. thesis of René Roy, Université de Montréal, 1981.

[2] NSERCC Predoctoral fellow 1978–1981.



SCHEME 1

find expedient and practical methods to convert this readily available sugar into a dideoxy derivative with a predisposed orientation of hydroxyl groups at C-2 and C-3, as expressed in the structure of the glycoside **3** (Scheme 2). Note that the α-orientation of the *cis*-diol unit commits the synthetic scheme to proceed via a specific tetrahydrospectinomycin as dictated by our original strategy (Scheme 1). The availability of a two-step deoxygenation process (22) at C-4 and C-6 of methyl α-D-glucopyranoside via the intermediacy of the corresponding 4,6-dichloro derivative allowed us to have substantial quantities of the desired intermediate **1**. Attainment of the *cis*-diol orientation necessitated an inversion of configuration at C-3 and the most practical way was a two-step process involving oxidation at C-3 and reduction of the corresponding ketone. Thus, we were faced with the task of selective protection of the C-2 hydroxyl group, a process which was easily accomplished by taking advantage of the nucleophilic enhancement of oxygen atoms in trialkyltin ethers and their selective reaction with electrophiles (23, 24). Upon treatment of **1** with bis(tributyltin) oxide, the intermediate 2-*O*-tributlytin ether was formed selectively due to coordination with the anomeric methoxyl group (24). Reaction with benzoyl chloride gave the known 2-benzoate derivative (25) in 94% yield. Oxidation then gave the crystalline derivative **2** (25), which was reduced to **3**. The outcome of the reduction was predictable because of the α-orientation to the aglycone. Debenzoylation, acetolysis, and transformation into the glycosyl chloride were done in high-yielding steps to provide the reactive intermediate **5**. We were now faced with a stereocontrolled glycosidation with a suitably protected actinamine derivative, and the first of a series of protecting groups that would be compatible with the remainder of the synthetic sequence had to be chosen. Moreover, inspection of the structure of the intended glycoside intermediate placed some stringent requirements with regard to regio and stereocontrol. Thus, only the central hydroxyl group in the symmetrical actinamine molecule must be considered, in a condensation that should lead to a 1,2-*trans* orientation of substituents in the resulting glycoside. Such stereoselectivity can be expected by anticipating the intermediacy of 1,2-acyloxonium ions in the glycoside-forming step (for some reviews on glycoside synthesis, see ref. 26). The regioselectivity, on the other hand, could be achieved by appropriate protection–deprotection procedures so as to free the required hydroxyl group. Clearly this would unduly lengthen the synthesis. It was reasoned that by placing reasonably bulky substituents on the amino groups, the order of reactivity would greatly favor the hydroxyl group in question since it would be the least congested. Such was the case when *N,N'*-[(benzyloxy)carbonyl]-actinamine (16) was allowed to react with **5** in the presence of silver trifluoromethanesulfonate in dichloromethane at 40°C. Selective glycoside formation took place to give the expected product **6** in 60–65% yield. The choice of catalyst was evidently important (27), since a related glycosidation was accomplished in less than 10% yield when silver carbonate was used under typical Koenigs–Knorr conditions (16). Deacetylation of **6** gave the known *N,N'*-[(benzyloxy)carbonyl]-4(*R*),4a(*R*)-tetrahydrospectinomycin **7** (20).

Having thus secured the stereochemical identity of glycosidic linkage in our synthetic sample **6**, we considered various options for manipulating the hydroxyl groups en route to our next target, namely dihydrospectinomycin. To achieve this, it was necessary to set the stage for preferential oxidation at C-2 of the sugar and for intramolecular ketalization. The *cis*-diol unit in 7, comprising an axial–equatorial orientation of hydroxyl groups, proved to be a judicious choice for the synthetic operations to be performed. These called for the formation of a cyclic orthoester **9***b* which was expected to undergo a site-selective solvolysis to give the axial ester – equatorial alcohol **1***a* (28). At the same time the interplay between protecting groups and reaction conditions became, once again, an important issue. In order to achieve selective protection of the actinamine hydroxyl groups, **7** was first transformed into the corresponding isopropylidene derivative and a search for O-protecting groups was initiated, bearing in mind that the resulting derivative should withstand the rigors of aqueous acid,[3] while being susceptible to mild conditions of deprotection. The seldom used trichloroethoxycarbonate group (see, for example, ref. 29) was found to be ideal for these transformations. With these considerations in mind, we set out to test their outcome in the laboratory. The desired derivative **9** was easily prepared from the diol **7** by an uneventful sequence involving the isopropylidene derivative **8**, which upon acid hydrolysis gave the selectively protected diol. The latter was then transformed into

[3] In our original publication, we had used acetates as protecting groups. However, unless carefully controlled, their hydrolysis was accompanied by some intramolecular cyclic carbamate formation, ref. 19.

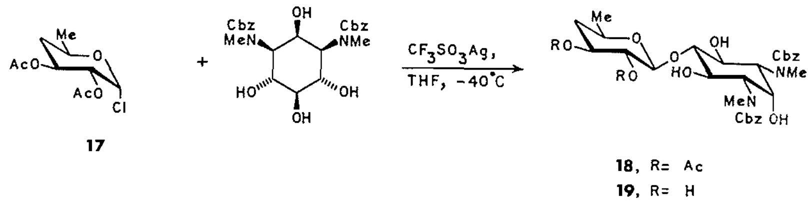
the orthoester **9**. Treatment of **9** with dilute acetic acid gave the amorphous monoacetate **10**, in which the acetate group was axial. Thus, the anticipated regiochemistry in the solvolysis of the orthoester ring had been indeed attained. Oxidation of **10** by a recent modification (30) of the Corey–Suggs procedure (31) gave the unstable keto derivative **11** as a syrup. Treatment of **11** with zinc dust in tetrahydrofuran cleanly removed the trichloroethoxycarbonyl groups and regenerated the triol system in the actinamine portion, with concomitant intramolecular ketalization, to give the monoacetyl derivative **12** in high yield. Mild base treatment then gave *N,N'*-[(benzyloxy)carbonyl]-4(*R*)-dihydrospectinomycin **13**, identical in all respects with authentic material. The corresponding acetonide **14** (13*a*, 32) was also easily prepared. Thus, the intermediate keto polyol underwent stereoselective ketalization with only one of the two possible, symmetrically disposed hydroxyl groups in the actinamine portion. This preference can be logically rationalized on stereoelectronic grounds (12, 14), much in the same way as for the free antibiotic itself (13, 18), and it is an anticipated event in this sequence.

Having reached this penultimate stage in our synthesis, we were in a position to address the next critical step in the sequence, namely, the oxidation of **13** to *N,N'*-[(benzyloxy)-carbonyl]spectinomycin **16**. The challenge that we faced was once more one of selectivity. How could one effect preferential oxidation of the 4(*R*)-hydroxyl group in the presence of a pair of axially (C-7) and equatorially (C-9) disposed hydroxyl groups, while maintaining the structural integrity of the molecule? Having explored a number of possible solutions to this problem, we turned once again to organotin chemistry where a unique opportunity for achieving a selective oxidation became evident, particularly in view of the *cis*-disposition of the vicinal diol unit. The oxidation of tributyltin ethers to carbonyl compounds (33) and of dibutyltin acetals to α-hydroxyketones (34) in the presence of bromine were known in the literature (23). This reaction appeared to be admirably suited to our needs,



SCHEME 3

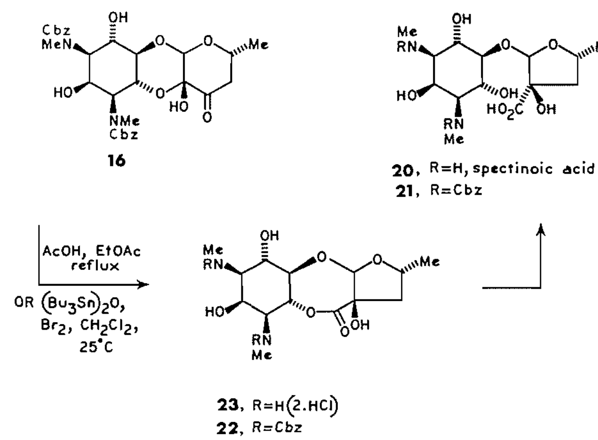
although its adaptation to acetals originating from tertiary and secondary hydroxyl groups was yet to be tested. Treatment of **13** with bis(tri-n-butyltin) oxide, followed by NBS, smoothly led to the desired *N,N'*-[(benzyloxy)carbonyl]spectinomycin **16** in high yield, presumably via the intermediacy of an intramolecularly coordinated tributyltin ether such as **15***a*. Alternatively, **13** could be transformed into the stannylidene acetal **15***b*, then treated with bromine to give the desired products. The former method was found to give cleaner products and could be better controlled, particularly in view of the tendency for the product to over-oxidize to give a by-product, which will be discussed later.

Vital to this successful oxidation was the original choice of a 4(*R*)-axial alcohol since, by its very nature the intermediate tin ether or acetal could only be oxidized at C-4, which has a favorably situated equatorial hydrogen atom.[4] Finally, hydrogenation of **16** under carefully monitored conditions led to the intended target, isolated as the crystalline dihydrochloride pentahydrate in high yield. This product was found to be identical to the natural product in all respects.

During the course of our studies, we also prepared the 4-epi tetrahydro *N,N'*-[(benzyloxy)carbonyl]tetrahydro-4(*S*),4a(*R*)-spectinomycin **19** (Scheme 3). Thus, acetolysis of **1** and glycosyl halide formation led to 2,3-di-*O*-acetyl-4,6-dideoxy-α-D-*xylo*-hexopyranosyl chloride **17** which, when condensed with *N,N'*-[(benzyloxy)carbonyl]actinamine as previously described, gave, after purification, the crystalline derivative **18** in 67% yield. Deacetylation at pH 8.5 gave the crystalline tetrol **19** (16), mp 260–265°C; $[\alpha]_D$ −3.2° ($CHCl_3$).

Stereocontrolled rearrangements

During the course of our oxidation studies of **13** in the presence of bis(dibutyltin) oxide and bromine, we had observed the formation of a secondary product which migrated close to the desired *N,N'*-[(benzyloxy)carbonyl]spectinomycin **16** (21). The same product was also formed when samples of **16** were treated with silica gel, or on prolonged standing in ethyl acetate. The spectroscopic properties of this new product were sufficiently different from those of **16** to warrant further inquiry, and it soon became apparent that a new entity was produced. The constitutional identity of this product was secured from chemical evidence and eventual correlation with a known degradation product of spectinomycin itself. Thus, treatment with sodium ethoxide in tetrahydrofuran led to a methyl ester, while treatment with aqueous sodium hydroxide followed by hydrogenolysis gave the known crystalline spectinoic acid dihydrochloride **20** (Scheme 4) (8). It was therefore evident that the new product was the seven-membered lactone **22**, which presumably arose by a process related to an α-ketol



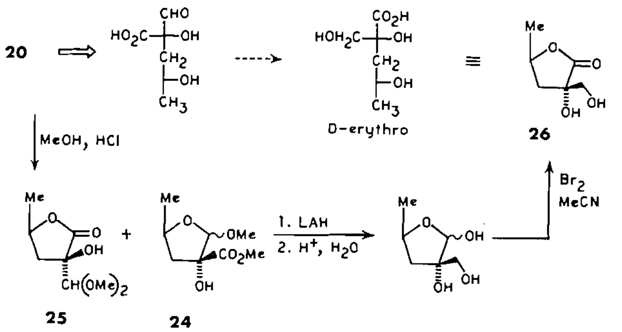
SCHEME 4

rearrangement (for a review, see ref. 35). Such rearrangements are well known to occur under acidic, basic, and solvolytic conditions and may be reversible processes (see, for example, ref. 36). However, many attempts to induce reversibility in our case were unsuccessful, possibly because of an unfavorable alignment of bonds in the lactone. The forward rearrangement process, however, can be nicely visualized to occur by activation of the C-4 carbonyl oxygen atom by an electrophile, and migration of the antiperiplanar C-4a—C-10 bond. The rearrangement did not occur with bis(dibutyltin) oxide or bromine alone, or when the substrate was converted to the 4,4-dimethylacetal derivative. It is therefore possible that the reaction is caused by initial formation of Bu_3SnOBr (33), which can supply a base as well as an electrophile. That a tertiary ketol rearrangement was indeed operative was also demonstrated when the same lactone was formed from **16** in the presence of 10% acetic acid in refluxing ethyl acetate.

Hydrogenolysis of the lactone **22** led to the corresponding amino derivative **23**, which was tested and found to be devoid of activity as an antibacterial agent. It is of interest to note in this regard that **23** is isomeric with spectinomycin and it can be considered as a variant in which the central ring has been expanded and the original α-ketol functionality transposed.

When spectinomycin was treated with strong base, there was formed an acidic degradation product which was called actinospectinoic acid (spectinoic acid) (9) and its formation was explained based on a tertiary ketol rearrangement. Although this substance was crystalline and a new asymmetric center was created at the carbon atom bearing the carboxyl group, no effort was made over the years to secure its configurational identity. The discovery of the acid-catalyzed rearrangement of **16** into the lactone **22** and its correlation with spectinoic acid **20** prompted us to establish the configurational identity of the latter. It had already been known (9) that methanolysis of spectinoic acid gave a mixture of methyl glycosides **24** and the lactone **25** (of unknown absolute configuration at C-2) (Scheme

[4] Vicinal *trans*-disposed stannylidene acetals are also subject to oxidation with bromine (ref. 34). It is also possible that we might be dealing with oligomeric ethers or acetals, rather than discrete derivatives such as **15***a,b*.



SCHEME 5

5). Thus if either product were successfully correlated with a known substance, then the task of assigning an absolute stereochemistry would be greatly simplified. We recognized the structural resemblance of α-D-isosaccharino-1,4-lactone to either methanolysis product **24** or **25**. In the hope of achieving structural and stereochemical convergence, we proceeded with a chemical modification program on two fronts. Thus, **24** was converted in three steps into the lactone **26** by standard methodology. The conversion of lactone **27**[5] derived from lactose (37) into our target required a deoxygenation at the terminal primary hydroxymethyl group, which was achieved in straightforward manner by a series of reactions shown in Scheme 6. Comparison of the physical properties of this crystalline *p*-nitrobenzoate ester **29**, derived from both the synthetic and degradation-derived lactone, established their complete convergence. The tertiary ketol rearrangement of spectinomycin therefore produces a single acid, whose absolute configuration at the newly formed asymmetric center is *R*. This, in fact, is the anticipated stereochemical result, based on a stereocontrolled migration of the C-4a—C-10 bond. With the establishment of the stereochemical identity of spectinoic acid some 23 years after its isolation, the last remaining structural problem concerning the parent antibiotic can be considered fully addressed.

In the course of our synthetic studies, we had become intrigued by the prospects of effecting a number of stereocontrolled fragmentation and substitution reactions, particularly with the unique anti-periplanar arrangement of bonds in 4-substituted dihydrospectinomycins (Scheme 7) (for examples of Grob-type fragmentations, see ref. 38). It was therefore of interest to attempt the experiments with the mesylate **31** derived from the 4-(*S*)-dihydro isomer **30** (Scheme 8). At first, heating the mesylate to its melting point did not result in the formation of new products. Consequently solvolytic studies were undertaken. Treatment of **31** with silver carbonate (39) in aqueous acetone gave the 4-(*R*)-dihydro isomer **13** in 47% yield, accompanied by *N,N'*-[(benzyloxy)carbonyl]actinamine. Clearly, solvolysis with net inversion has taken place under these conditions. When the same mesylate was treated with sodium acetate in anhydrous trifluoromethanol (40) at reflux temperature, there was formed the inverted acetate derivative **12** in 38% yield, accompanied by two unidentified side-products. Once again, apparent inversion of configuration had occurred in this reaction. However, when **31** was treated with sodium azide in 1.5% aqueous trifluoromethanol, the corresponding 4-(*S*)-azido derivative **32** was isolated in 30% yield, along with starting material and two unknown by-products. Thus, in this case a net retention of configuration was observed. Catalytic hydrogenation of **32** led to 4-amino-4-(*S*)-dihydrospectinomycin **33**, which was found to be devoid of antibacterial activity,[6] unlike its 4-(*R*) epimer **34** (7). Thus, what appeared to have been an alternative entry into the biologically active series was thwarted by the unexpected. Inspection of molecular models clearly indicates a severly restricted backside approach at C-4 in the conformationally rigid tricyclic system. Two possibilities can be considered for the displacement reactions. The mesylate could, in fact, react in the α-ketomesylate rather than the ketol form in which a much higher order of reactivity is expected (41) to give inverted products. In the case of the α-azido (Scheme 9) derivative, a subsequent base-catalyzed epimerization and subsequent intramolecular ketalization could take place to give the observed product. Alternatively, an intermediate epoxide can be envisaged to be transiently formed and attacked by the nucleophile, regiospecifically, with net retention of configuration. The results in the case of acetate ion and silver carbonate can be rationalized, based on attack of the α-keto mesylate followed by ketalization (without epimerization, or by another mechanism via initial attack on the carbonyl group, followed by an intramolecular reaction leading to the ejection of the mesylate and the formation of an intermediate acetoxonium ion).

These reactions were unsuccessful when the corresponding 4a-methoxy derivative was used, which strongly implies the involvement of the carbonyl group in the open form, or the tertiary hydroxyl group in a cyclic form.

Experimental

Melting points are uncorrected. Optical rotations were measured on a Perkin–Elmer automatic spectropolarimeter, model 141. The ^{1}H nmr spectra were recorded on Varian EM-360 and Bruker WH-90 and 400-MHz instruments using deuterochloroform as solvent unless otherwise stated. The ^{13}C nmr spectra were recorded at 22.6 MHz. Mass spectra were recorded on an AE1-902 mass spectrometer at low resolution unless otherwise indicated. Column chromatography was done using silica gel G254 with application of moderate suction or by the flash technique. Work-up with usual processing signifies extraction with an appropriate organic solvent, washing, drying the organic phase with magnesium sulfate, and evaporation.

*Methyl 2-O-benzoyl-4,6-dideoxy-α-D-*erythro*-hexopyranosid-3-ulose, 2*

A solution of **1** (22) (3.88 g, 24 mmol) in 100 mL of anhydrous toluene containing 9 mL (18 mmol, 0.75 equiv.) of bis(tributyltin) oxide was heated under reflux with a Dean–Stark trap. After 3 h, the solution was cooled to room temperature and benzoyl chloride (3.4 mL, 28 mmol) was added. After stirring 1 h, methanol was added and the solvent evaporated to give a residue which crystallized upon trituration with petroleum ether to give 6 g (94%) of the known 2-benzoate (25), mp 103–105°C; $[\alpha]_D$ +158.6 (*c* 1.21, $CHCl_3$).

A solution of this product (1.06 g, 4 mmol) was added to a suspension of pyridinium chlorochromate (16 mmol) and sodium acetate (656 mg, 8 mmol) in 50 mL of dichloromethane. After stirring for 15 h, ether was added to the dark suspension, the salts were filtered, and the filtrate was evaporated to a syrup (1.18 g; ~quantitative); $[\alpha]_D$ +65.2° (*c* 0.15, $CHCl_3$) (lit. (25) $[\alpha]_D$ +66°).

*Methyl 4,6-dideoxy-α-D-*ribo*-hexopyranoside, 3*

The preceding product (2.9 g, 11 mmol) in 100 mL of methanol was treated with sodium borohydride (492 mg, 13 mmol) and the solution was stirred for 10 min. Excess hydride was destroyed by addition of

[5] We thank Prof. R. B. Yeats, Bishop's University, Lennoxville, Quebec for a generous sample of **27**.

aqueous acetic acid to pH 6, the solution was evaporated to dryness, and the residue was extracted with ether. Usual processing gave a syrup which was dissolved in methanol and treated with sodium methoxide. After 24 h, the solution was treated with Dowex-50 (H^+), filtered, and the filtrate was evaporated to dryness. Flash column chromatography gave the pure product **3** as a colorless syrup in almost quantitative yield; $[\alpha]_D$ +112° (*c* 0.56, $CHCl_3$); ^1H nmr (60 MHz, ppm): 1.19 (d, Me, $J_{5,6}$ = 6 Hz), 1.37–2.21 (m, H-4'4', J = 13 Hz), 3.36 (OH), 3.42 (s, OMe), 3.50–4.30 (m, H2, H3, H5), 4.70 (d, H-1, $J_{1,2}$ = 1.3 Hz); ^{13}C nmr (22.6 MHz, ppm): 101.5, 68.8, 68.1, 58.8, 55.9, 39.06, 20.6.

1,2,3-Tri-O-acetyl-4,6-dideoxy-α-D-ribo-hexopyranose, 4

The preceding diol (840 mg, 5.2 mmol), acetic anhydride (5 mL), and $BF_3 \cdot Et_2O$ (0.3 mL) were stirred at 0°C for 24 h. The solution was poured into aqueous saturated sodium bicarbonate, and the solution extracted with chloroform and processed as usual to give a syrup which crystallized upon trituration with ethanol to give 563 mg (39%) of the crystalline β-anomeric acetate, mp 131.5–133°C (EtOH); $[\alpha]_D$ −53.3° (*c* 3.32, $CHCl_3$); ^1H nmr (60 MHz, ppm): 1.21 (d, C-Me, $J_{5,6}$ = 6 Hz), 1.77 (m, H-4,4', J = 13 Hz); 2.00, 2.07 (OAc); 4.14 (m, H5), 4.80 (dd, H-2, $J_{1,2}$ = 8 Hz; $J_{2,3}$ = 8 Hz), 5.44 (m, H-3), 6.01 (d, H-1); ms *m/e*: 215 (M^+ − OAc). The mother liquors were chromatographed on silica (hexanes – 10% ethyl acetate) to give 1.07 g (75%) of an anomeric mixture of acetates. *Anal.* calcd. for $C_{12}H_{18}O_7$: C 52.55, H 6.61; found: C 52.80, H 6.63.

2,3-Di-O-acetyl-4,6-dideoxy-α,β-D-ribo-hexopyranosyl chloride, 5

The mixture of anomeric triacetates **4** (500 mg, 1.82 mmol) was dried overnight under vacuum (desiccator). It was dissolved in 50 mL of ether (freshly distilled, LAH), cooled to 0°C, and a stream of HCl gas was bubbled through the solution during 2 h. The solvent was evaporated and the residue was repeatedly coevaporated with dry toluene. This product was kept under argon in THF solution. An aliquot was analyzed by ^{1}H nmr (60 MHz, ppm): 1.20 and 1.35 (d, C-Me, two anomers); 2.09, 2.13, 2.15, 2.17 (OAc, 2 anomers); 5.53 (d, H-1, $J_{1,2}$ = 8 Hz, β-anomer), 6.09 (d, H-1, $J_{1,2}$ = 4 Hz, α-anomer).

4,4a-Di-O-acetyl-N,N'-[(benzyloxy)carbonyl]-4(R),4a(R)-tetrahydrospectinomycin, ***6***

The chloride **5** prepared from 1 g (3.65 mmol) of triacetate **4** was transferred via a double-tip needle into a dry separatory funnel in a total volume of 40 mL of THF. A solution containing *N,N'*-[(benzyloxy)carbonyl]actinamine (2.6 g, 5.46 mmol, 1.5 equiv., previously dried from THF via Dean–Stark) and silver trifluoromethanesulfonate (1.4 g, 5.46 mmol, 1.5 equiv. (Fluka)), in 50 mL of dry THF was stirred at 0°C under argon. The temperature was lowered to −40°C, and the chloride added dropwise over a period of 1 h. The reaction mixture was stirred at −40°C for 3 h, then 1 g of sodium bicarbonate followed by 5 mL of aqueous saturated sodium chloride were added. The mixture was diluted with 150 mL of chloroform, filtered over Celite, and the organic layer was processed as usual to give a foam which was chromatographed over silica (hexanes–EtOAc, 3:7). Those fractions which showed a positive uv absorption test and a negative benzidine–periodate test were combined and processed to give 1.56 g (62%) of the title compound as an amorphous solid; $[\alpha]_D$ −8.2° (*c* 0.11, $CHCl_3$); ir ν_{max} ($CHCl_3$): 3480 (OH), 1750 (OAc), 1685 (Cbz) cm^{-1}; ^{1}H nmr (90 MHz, ppm): 1.26 (d, C-Me, J = 6 Hz), 1.78 (m, H-3,3'); 1.99, 2.05 (OAc); 3.09 (s, NMe_2), 4.81 (dd, H-4a, $J_{4a,10a}$ = 8 Hz, $J_{4a,4}$ = 3 Hz), 4.91 (d, H-10a, $J_{10a,4a}$ = 8 Hz), 5.15 (s, CH_2Ph), 5.52 (m, H-4), 7.35 (s, OH, Ph), etc. *Anal.* calcd. for $C_{34}H_{44}O_{13}$: C 59.29, H 6.44, N 4.07; found: C 58.98, H 6.39, N 3.98.

N,N'-[(benzyloxy)carbonyl]-4(R),4a(R)-tetrahydrospectinomycin, ***7***

A solution of **6** (700 mg, 1.02 mmol) in 10 mL of methanol was cooled to 0°C and treated with a small chip of sodium metal to give a pH ~ 8.5. After 15 min at 25°C, Dowex-50 (H$^+$) was added, the mixture filtered, and the filtrate was evaporated to dryness. Purification by chromatography (EtOAc) gave a solid which was recrystallized from acetone to give the title compound, (~quantitative), identical in all respects to authentic material (20) (mp, mixture mp, X-ray powder diffraction diagram, $[\alpha]_D$, ir, nmr); mp 189–192°C; $[\alpha]_D$ −31.3° (*c* 0.53, MeOH). *Anal.* calcd. for $C_{30}H_{40}N_2O_{11}$: C 59.59, H 6.67, N 4.63; found: C 59.55, H 6.78, N 4.46.

7,9-Tri-O-(2,2,2-trichloroethoxycarbonyl)-4,4a-O-isopropylidene-N,N'-[(benzyloxy)carbonyl]-4(R),4a(R)-tetrahydrospectinomycin, ***8***

The preceding compound (600 mg, 1 mmol) was suspended in 10 mL of benzene, 1 mL of 2,2-dimethoxypropane and 10 mg of *p*-TsOH were added, and the homogenous solution was stirred at 25°C for 1 h. The acid was neutralized with Dowex-1 (OH$^-$), the suspension filtered, and the filtrate was evaporated to dryness. Purification by silica gel chromatography (hexanes–EtOAc, 4:1, then 1:1) gave the expected acetonide derivative as colorless crystals (526 mg, 78%); mp 189–193°C; $[\alpha]_D$ −46.1° (*c* 0.94, $CHCl_3$); ir ν_{max} (KBr): 3450 (OH), 1680 (Cbz) cm^{-1}; ^{1}H nmr (90 MHz, ppm): 1.26 (d, C-Me); 1.37, 1.51 (s, CMe_2); 1.79 (dd, H-3,3'), 2.14 (d, H-3 eq.), 3.09 (s, NMe_2), 4.51 (d, H-10a, $J_{10a,4a}$ = 7 Hz), 5.14 (s, CH_2Ph), 7.35 (OH, Ph); ms *m/e*: 644 (M$^+$), 626 (M$^+$ − H_2O), etc. *Anal.* calcd. for $C_{33}H_{44}N_2O_{11}$: C 61.48, H 6.88, N 4.34; found: C 60.92, H 6.82, N 4.19.

A solution of the preceding compound (315 mg, 0.47 mmol) in 20 mL of dry pyridine containing 30 mg of *N,N*-dimethylaminopyridine was treated at 0°C with trichloromethyl chloroformate (1 mL, 7 mmol). The solution was left at 25°C overnight, excess reagent was destroyed by adding ice-water (30 min), and the mixture was evaporated in the presence of toluene to eliminate the pyridine. The residue was extracted with ether, the latter was washed successively with aqueous ammonium chloride, then water, and the organic phase was processed as usual. Chromatography over silica (hexanes–EtOAc, 7:3) gave the title compound as a glassy semi-crystalline solid (434 mg, 67%); mp 100–105°C; $[\alpha]_D$ −16.9° (*c* 1.16, $CHCl_3$); ir ν_{max} (KBr): 1765 (OCO_2), 1700 (Cbz) cm^{-1}; ^{1}H nmr (90 MHz, ppm): 1.22 (d, C-Me); 1.34, 1.49 (s, CMe_2); 2.80 (s, NMe_2), 4.48 (d, H-10a, $J_{10a,4a}$ = 7 Hz), 4.75 (s, CH_2CCl_3), 5.13 (s, CH_2Ph), etc. *Anal.* calcd. for $C_{42}H_{43}Cl_9N_2O_{17}$: C 43.23, H 3.71, Cl 27.34, N 2.40; found: C 43.78, H 4.27, Cl 27.19, N 2.38.

4-O-acetyl-7,9-O-(2,2,2-trichloroethoxycarbonyl)-N,N'-[(benzyloxy)carbonyl]-4(R),4a(R)-tetrahydrospectinomycin, ***10***

Compound **8** (300 mg, 0.22 mmol) was dissolved in a mixture of THF (5 mL) and 9:3 methanol–water (10 mL) containing 40 mg of *p*-TsOH. After stirring for 48 h the acid was neutralized with Dowex-1 (OH$^-$), the mixture was filtered, and the filtrate was evaporated to dryness to given an amorphous solid (280 mg); $[\alpha]_D$ −7.9° (*c* 0.26, $CHCl_3$); ir ν_{max} (KBr): 3450 (OH), 1765 (OCO_2), 1705 (Cbz) cm^{-1}; ^{1}H nmr (90 MHz, ppm): 1.19 (d, C-Me), 2.82 (s, NMe_2), 5.15 (s, CH_2Ph), 7.34 (s, Ph), etc.

The preceding compound (280 mg, 0.248 mmol), in 10 mL of benzene, was treated with 0.5 mL of trimethylorthoacetate and 10 mg of *p*-TsOH. The solution was stirred at 25°C for 1 h, the acid was neutralized with dry Dowex-1 (OH$^-$), and the suspension was filtered. Evaporation of the filtrate gave a syrup consisting of **9**, which was dissolved in 10 mL of 80% aqueous acetic acid, and the solution was stirred for 30 min. The solvent was evaporated and the residue treated with toluene several times (with evaporation), to give a syrup that was chromatographed (hexane–EtOAc, 7:3). The desired acetate was obtained as an amorphous solid (hexanes) (270 mg, ~quantitative); $[\alpha]_D$ −21.0° (*c* 0.63, $CHCl_3$); ir ν_{max} (KBr): 3500 (OH), 1770 (OCO_2), 1740 (OAc), 1710 (Cbz) cm^{-1}; ^{1}H nmr (90 MHz, ppm): 1.20 (d, C-Me), 2.11 (s, OAc), 2.82 (s, NMe_2), 3.41 (dd, H-4a, $J_{4a,10a}$ = 8 Hz, $J_{4a,4}$ = 4 Hz), 4.75 (s, CH_2CCl_3), 5.14 (s, CH_2Ph), 7.34 (s, OH, Ph). *Anal.* calcd. for $C_{41}H_{45}Cl_9N_2O_{13}$: C 41.99, H 3.87, N 2.39; found: C 41.53, H 3.85, N 2.31.

4-O-acetyl-N,N'-[(benzyloxy)carbonyl]-4(R)-dihydrospectinomycin, ***12***

(a) *From* ***10***

The preceding (160 mg, 0.14 mmol) was oxidized in the presence of PCC (90 mg, 6 equiv.) in refluxing benzene (10 mL) for 1 h. Excess ether was added, the suspension was filtered over "Florisil", and the filtrates and washing were processed as usual to give a syrup that was chromatographed (hexanes–EtOAc, 7:5). The unstable intermediate 4a-keto derivative **11** was collected in appropriate fractions, and immediately used in the next step. Thus, the resulting syrup was dissolved in 10 mL of glacial acetic acid, 130 mg of zinc dust (freshly activated by washing with 1 *N* HCl), and the mixture was stirred for 30 h. The reaction mixture was poured into aqueous saturated sodium bicarbonate – EtOAc, and the organic extracts were washed and processed as usual to give the title compound. This was purified by preparative thick layer chromatography on silica gel (EtOAc) (syrup, 60 mg, 64%), and was identical in all respects with material prepared from the natural product.

(b) *From N,N'-[(benzyloxy)carbonyl]-4(R)-dihydrospectinomycin*

The title compound (600 mg, 1 mmol), readily available from spectinomycin (13a, 32), was suspended in 15 mL of benzene, 1 mL of trimethylorthoacetate and 10 mg of *p*-TsOH were added, and the mixture was stirred for 1 h. The homogeneous solution was then treated with Dowex-1 (OH$^-$) and filtered. Processing the filtrate gave a syrup which was dissolved in 20 mL of 80% aqueous acetic acid (30 min). Evaporation and chromatography as previously described gave the 4-*O*-acetyl derivative **12** as a syrup (494 mg, 77%); $[\alpha]_D$ +27.2° (*c* 1.30, $CHCl_3$); ir ν_{max} ($CHCl_3$): 3600, 3640 (OH); 1730 (OAc), 1690 (Cbz) cm^{-1}; ^{1}H nmr (90 MHz, ppm): 1.26 (d, C-Me), 1.69 (m, H-3,3'), 2.14 (s, OAc); 3.04, 3.07 (s, NMe_2); 4.82 (s, H-10a), 4.95 (t, H-4), 5.15 (s, CH_2Ph), 7.34 (s, Ph).

N,N'-[(benzyloxy)carbonyl]-4(R)-dihydrospectinomycin, ***13***

The acetate **12** (100 mg, 0.155 mmol) was dissolved in 5 mL of methanol containing 0.05 mL of a 1 *N* sodium methoxide solution (pH ~8) and the solution was stirred at 25°C for 15 min. The base was neutralized with Dowex-50 (H^+), the mixture was filtered, and the filtrate was processed as usual to give an amorphous solid (93 mg, ~quantitative), mp 157–160°C; $[\alpha]_D$ +27.5° (*c* 0.50, $CHCl_3$); ir ν_{max} (KBr): 3420 (OH), 1680 (Cbz) cm^{-1}; ^1H nmr (90 MHz, ppm): 1.22 (d, C-Me), 1.69 (m, H-3,3′); 3.02, 3.07 (s, NMe_2); 4.84 (s, H-10a), 5.13 (s, CH_2Ph), 7.33 (OH, Ph).

This product was found to be identical with a sample prepared from spectinomycin (13*a*, 32) (tlc, $[\alpha]_D$, ir, nmr, ms).

Treatment of **13** (30 mg) with 2,2-dimethoxypropane in benzene containing *p*-TsOH gave the corresponding 4,4a-acetonide derivative **14** in 96% yield, identical with material prepared from spectinomycin; glassy amorphous solid, $[\alpha]_D$ +29.6° (*c* 0.27, $CHCl_3$) (lit. (13*a*, 32) $[\alpha]$ +31.17 ($CHCl_3$).

N,N′-*[(benzyloxy)carbonyl]spectinomycin (**16**)*

A solution containing 298 mg (1 equiv.) of bis(tri-n-butyltin) oxide and **13** (300 mg, 0.5 mmol) in 20 mL of benzene was stirred at 25°C for 1 h, then treated with NBS (134 mg, 1.5 equiv.). After stirring for 10 h, hexanes were added to precipitate the title compound in almost pure form as an amorphous solid (240 mg, 80%). Chromatography on silica gel (hexanes–EtOAc, 2:3) gave pure product, identical with a sample prepared from the antibiotic; $[\alpha]_D$ −4.6° (*c* 0.28, $CHCl_3$); ir ν_{max} (KBr): 3460 (OH), 1685 (Cbz) cm^{-1}; ^1H nmr (90 MHz, ppm): 1.41 (d, C-Me), 1.51 (m, H-3e), 1.65 (m, H-3a); 2.98, 3.08 (NMe_2); 4.70 (s, H-10a), 5.14 (s, CH_2Ph), 7.34 (OH, Ph), etc; ms *m/e*: 600 (M^+), 492 (M^+ − $PhCH_2OH$), 4.65 (M^+ − $PhCH_2OCO$), etc.

The oxidation of **13** (200 mg, 0.33 mmol) was also done in the presence of di-n-butyltin oxide (90 mg, 1.1 equiv.). The mixture was refluxed in methanol (10 mL) for 1 h, evaporated, benzene added, and the solution evaporated again to give a syrup. The stannylidene derivative was dissolved in 5 mL of dichloromethane containing 0.12 mL (1.1 equiv.) of tri-n-butyltin methoxide (24) and the solution was cooled to 0°C. This was treated with a solution of bromine (1.1 equiv., 2% in CH_2Cl_2) dropwise, over a period of 1 h. Residual bromine was destroyed with cyclohexene and the crude product was isolated by precipitation with hexanes to give an amorphous solid (184 mg, 92%). Chromatography as described above gave 139 mg (70%) of pure product.

(+)-Spectinomycin dihydrochloride

A solution of the previous compound (140 mg, 0.23 mmol) in a mixture of 2-propanol and water (~1:1, 5 mL) was hydrogenated in the presence of 100 mg of 5% palladium-on-charcoal, while monitoring the effluent gas for cessation of CO_2 evolution (aqueous $Ca(OH)_2$). The catalyst was filtered, the filtrate was evaporated, and the residue was dissolved in water (3 mL) and acidified with HCl to pH 3. Repeated evaporation with toluene gave a solid which was recrystallized from aqueous acetone (~5 mL). After standing at 0°C overnight, beautiful colorless needles of (+)-spectinomycin dihydrochloride·$5H_2O$ were obtained (104 mg, 90%), mp 205–207°C (dec.); $[\alpha]_D$ +14.8° (*c* 0.42, H_2O), identical to the authentic natural product (9); ir ν_{max} (KBr): 3300 (OH), 1740 (C=O, weak) cm^{-1}, etc.; ^1H nmr (90 MHz, ppm, D_2O): 1.25 (d, C-Me); 2.79, 2.82 (s, NMe_2); 4.86 (s, H-10a); ^{13}C nmr (22.6 MHz, ppm, D_2O): 94.4 (C4a, C10a), 92.6 (C4), 70.6 (C9a), 69.2 (C2), 66.9 (C9), 66.5 (C5a), 62.3 (C8), 60.3 (C7), 59.4 (C6), 42.6 (C3), 31.5 (N8-Me), 31.1 (N6-Me), 20.5 (C2-Me); see also ref. 11; X-ray Cu-powder diffraction diagram (mm distance, m, medium, s, strong): 16.1 m, 24.5 ms, 28 m, 29.2 m, 31.8 s, 42 m, 44.7 m, 51.0 m, 52.9 mm, 54.8 mm, 59.7.

N,N′-*[(benzyloxy)carbonyl]spectinoic acid, **21***

A solution of **16** (1 g, 1.67 mmol) in 25 mL of THF and 2.5 mL of *N* NaOH was stirred for 1 h, then the solution was neutralized with Dowex-50 (H^+). The resin was filtered, and the filtrate was evaporated to a syrup which was dissolved in ethyl acetate. Addition of hexanes gave the title compound as an amorphous solid (950 mg, 92%); $[\alpha]_D$ −47.3° (*c* 2.06, $CHCl_3$); ir ν_{max} ($CHCl_3$): 3440 (OH, CO_2H), 1730 (CO_2H), 1685 (Cbz) cm^{-1}; ^1H nmr (90 MHz, ppm): 1.36 (d, C-Me), 2.19 (m, H-4, 4′); 2.9, 2.04 (s, NMe_2); 5.30 (s, H-2), 5.10 (s, CH_2Ph), 7.30 (Ph), etc.; ms *m/e*: 600 (M^+ − H_2O).

Esterification of **21** with diazomethane in a mixture of ether and THF gave the corresponding methyl ester, isolated as an amorphous solid; $[\alpha]_D$ −48.2 (*c* 0.71, $CHCl_3$); ms *m/e*: 632 (M^+).

Alternatively, treatment of **16** (1 g, 1.67 mmol) with a solution of sodium methoxide (20 mL, pH 8.5, 30 min), followed by neutralization with Dowex-50 (H^+) and processing, gave the ester (787 mg, 75%) as an amorphous solid.

N,N′-*[(benzyloxy)carbonyl]spectinoic acid lactone, **22***

(a) *From **16** under acid catalysis*

A solution containing **16** (600 mg, 1 mmol) in 25 mL of EtOAc and 2 mL of glacial acetic acid was refluxed overnight. A new product was formed with a slightly higher tlc mobility ($CHCl_3$–MeOH, 9:1). The solution was evaporated to dryness in the presence of toluene and the residue was chromatographed over silica gel (hexanes–EtOAc, 2:3) to give 457 mg (76%) of the title lactone as an amorphous solid; $[\alpha]_D$ +67° (*c* 1.45, $CHCl_3$); ir ν_{max} ($CHCl_3$): 3360, 3320 (OH); 1750 (lactone), 1685 (Cbz) cm^{-1}; ^1H nmr (90 MHz, ppm, DMSO-d_6): 1.25 (d, C-Me), 2.20 (m, H-4,4′); 2.95, 299 (s, NMe_2); 5.35 (s, H-2); 5.13, 5.16 (s, CH_2Ph); 7.37 (s, Ph), etc.; ms *m/e*: 600 (M^+), 601 (M^+ + 1), etc.

(b) *From **16** in presence of $(Bu_3Sn)_2O$ and Br_2*

A mixture containing bis(tri-n-butyltin) oxide (596 mg, 1 mmol, 1 equiv.) and **16** (400 mg, 0.67 mmol) in 10 mL of dichloromethane was stirred for 2–3 min, then treated dropwise with 0.05 mL of bromine in 1 mL of dichloromethane under argon. The desired product was formed after 4 h at 25°C. The solution was evaporated to a small volume and the product was precipitated with hexanes, leaving the tin by-products in solution. The solid thus obtained was chromatographed to give 330 mg (83%) of lactone **22**.

(c) *From **13** in presence of bis(tri-n-butyltin) oxide and bromine*

A solution of **13** (200 mg, 0.33 mmol) and 258 mg (0.43 mmol, 1.3 equiv.) of the tin derivative in 10 mL of dichloromethane was treated with bromine (0.02 mL, 1.3 equiv. in 1 mL of dichloromethane) dropwise under argon. After similar treatment as described above, the desired lactone was obtained (170 mg, 85%).

*Chemical transformations of the lactone **22***

(a) *Methanolysis*

Treatment of **22** (105 mg, 0.18 mmol) in 15 mL of methanol containing 50 mg of potassium carbonate (or sodium methoxide), followed by neutralization with Dowex-50 (H^+), after 10 min gave the methyl ester of **21** (see above) (118 mg, ~quantitative); $[\alpha]_D$ −48.2° (*c* 0.48, $CHCl_3$).

(b) *Base hydrolysis*

A solution of the lactone **22** (500 mg, 0.67 mmol) in 10 mL of THF was cooled to 0°C and treated with *N* NaOH (1 mL, 1.5 equiv.); neutralization with Dowex-50 (H^+), followed by processing, gave **21** (413 mg, ~quantitative) as an amorphous solid.

*Spectinoic acid lactone dihydrochloride **23***

A solution of **22** (400 mg, 0.67 mmol) in 10 mL of 2-propanol containing 1 mL of water and 1.6 mL *N* HCl was hydrogenated in the presence of 10% palladium-on-charcoal (100 mg). After 1 h the catalyst was filtered, and the filtrate was processed as usual by coevaporation of the solvent with toluene to give an amorphous solid (225 mg, 83%); $[\alpha]_D$ −64.3° (*c* 1.12, H_2O); ir ν_{max} (KBr): 1720 (C=O) cm^{-1}; ^{13}C nmr (22.6 MHz, ppm, D_2O): 21.8, 31.7, 41.0, 60.1, 61.9, 68.1, 69.4, 77.8, 81.1, 86.9, 108.8, 174.9.

*Methanolysis of spectinoic acid. Isolation of **24** and **25***

This experiment was done essentially according to a literature procedure (8). A solution containing 10 g of spectinomycin free base (liberated from the salt with Dowex-1) and 20 g of barium hydroxide in 500 mL of water was stirred at room temperature for 24 h. The suspension was filtered, excess barium ions were precipitated with *N* H_2SO_4 until pH ~ 5.5, and the mixture was filtered over Celite. The filtrate was evaporated in the presence of methanol and the resulting spectinoic acid **20** was used in the next step. The residue was then dissolved in methanol (600 mL) containing 95 mL of acetyl chloride (**caution!**). After 48 h of stirring, ether was added to precipitate actinamine dihydrochloride (7 g). The filtrate was neutralized with sodium methoxide until pH 6–7, the salts were filtered off, and the filtrate was evaporated to dryness. The residue was extracted with ethyl acetate, washed with water, and the organic phase was processed as usual to give 3.06 g (58%) of a colorless syrup. Flash chromatography (hexanes–EtOAc, 3:2) gave an anomeric mixture of glycosides **24** (2.31 g, 75%) and the lactone **25** (0.77 g, 25%). The mixture of glycosides **24** (showed α_D −67.4° $CHCl_3$) (lit. (8) $[\alpha]_D$ −65.5° for a product distilled at 51–54°C (0.05 Torr; 1 Torr = 133.3 Pa)). The lactone **25** showed $[\alpha]_D$ +3.3° (*c* 0.55, $CHCl_3$); ir ν_{max} (film): 3400 (OH), 1770 (γ-lactone) cm^{-1}; ^1H nmr (90 MHz, ppm): 1.43 (d, C-Me); 1.85, 2.79 (dd, H-3, J_{gem} = 13 Hz, J_{vic} = 7.9 Hz); 3.53, 3.63 (s, OMe); 3.55 (s, OH), 4.40 (s, $CH(OMe)_2$), 4.63 (m, H4). The crystalline *p*-nitrobenzoate derivative (DMAP, *p*-nitrobenzoyl chloride) showed mp 123.5–125°C (ether–hexanes); $[\alpha]_D$ −20.0° (*c* 0.19, $CHCl_3$).

Transformation of ***24*** *into the lactone* ***26***

A solution containing the mixture of glycosides **24** (210 mg, 1.06 mmol) in 10 mL of ether was reduced with lithium aluminium hydride (130 mg, 2.67 mmol). After 30 min, water was carefully added to the cooled reaction mixture, then excess ether. The organic phase was separated and processed as usual to give a syrup (170 mg, 93%). This product was hydrolyzed in a mixture of THF and *N* HCl (10 mL, 1:1) by refluxing for 1.5 h. After neutralization with Dowex-1 (OH^-), filtration, and evaporation, a syrup was obtained which was purified by flash column chromatography ($CHCl_3$–MeOH, 95%) to give 130 mg (85%) of a chromatographically homogeneous product. Oxidation of a portion (90 mg, 0.60 mmol) in 7 mL acetonitrile, containing 166 mg (0.84 mmol) of barium carbonate, with 0.04 mL (0.72 mmol) of bromine diluted in 1 mL of acetonitrile gave, after 4 h, the desired lactone. Addition of cyclohexene, filtration, and evaporation gave a syrup corresponding to the lactone **26**. The crystalline *p*-nitrobenzoyl derivative **29** was prepared in the usual manner, mp 127–129°C (ether–hexanes); $[\alpha]_D$ +20.9° (*c* 0.87, $CHCl_3$); ir ν_{max} (KBr): 3500 (OH), 1745 (γ-lactone), 1729 (ester); 1520, 1340 (NO_2) cm^{-1}; ^1H nmr (90 MHz, ppm): 1.49 (d, C-Me); 2.02, 2.57 (dd, H-3,3′, J_{gem} = 14 Hz, J_{vic} = 6, 8 Hz); 3.03 (s, OH), 4.59 (d, CH_2OH), 4.88 (m, H-4), 8.26 (m, arom); ms *m/e*: 295 (M^+). *Anal.* calcd. for $C_{13}H_{13}NO_7$: C 52.86, H 4.44, N 4.74; found: C 52.66, H 4.54, N 4.59.

α-D-Isosaccharino-1,4-lactone acetonide, ***27***

α-D-Isosaccharino-1,4-lactone (37) (324 mg, 2 mmol) was dissolved in a 1:5 mixture of 2,2-dimethoxypropane and acetone, and 15 mg of *p*-TsOH was added. After stirring 1 h, the acid was neutralized with Dowex-15 (OH^-), the mixture filtered, and the filtrate was processed as usual to give the title compound as colorless crystals (398 mg, 99%), mp 53–55°C (ether–hexanes); $[\alpha]_D$ +41.5° (*c* 0.46, $CHCl_3$) (lit. (42) mp 56–57°C).

5-Chloro-5-deoxy-α-D-isosaccharino-1,4-lactone acetonide, ***28***

The preceding compound (311 mg, 1.54 mmol) was dissolved in 2 mL of $CHCl_3$ and 2 mL of pyridine, then heated with 0.2 mL of sulfuryl chloride at 0°C. After stirring overnight, the solution was diluted with water, then chloroform, and the organic phase was separated and processed. Evaporation gave a pale yellow syrup which was purified by column chromatography (hexanes–EtOAc, 7:3) to give 292 mg (86%) of the title product as a colorless syrup, $[\alpha]_D$ +28.8° (*c* 0.72, $CHCl_3$).

Transformation of ***28*** *into lactone* ***26***

An amount of the chloro derivative **28** (687 mg, 3.1 mmol) was dissolved in 30 mL of toluene and 3.27 mL (12.4 mmol) of tri-n-butyltin hydride was added, followed by 20 mg of azobisisobutyronitrile (AIBN). The mixture was refluxed for 4 h, cooled, the solvents evaporated, and the resulting oily residue was triturated with hexanes to remove a large portion of tin by-products. The residue was dissolved in acetonitrile, hexane added to deposit an oil, and the upper phase decanted. Evaporation of excess solvent gave the 5-deoxy derivative as a syrup (547 mg, 95%); $[\alpha]_D$ +31.7° (*c* 1.03, $CHCl_3$). Hydrolysis of the acetonide (547 mg, 2.94 mmol) was done with 80% aqueous acetic acid at 80°C for 30 min. Evaporation of the solvent and column chromatography gave the desired lactone **26** (430 mg); $[\alpha]_D$ +34.4° (*c* 0.22, $CHCl_3$). Transformation into the *p*-nitrobenzoate derivative **29** was done in the usual manner (DMAP) to give material identical in all respects with a sample obtained from the methanolysis and oxidation of spectinoic acid (mp, mixture mp, $[\alpha]_D$, ir, nmr).

4-O-methanesulfonyl-N,N′-[(benzyloxy)carbonyl]-4-(S)-dihydrospectinomycin, ***31***

To a solution of *N,N′*-[(benzyloxy)carbonyl]-4-(*S*)-dihydrospectinomycin **30**, readily available by catalytic hydrogenation of spectinomycin (43), followed by *N*-benzyloxycarbonylation (600 mg, 1 mmol) in 10 mL of pyridine, was added methanesulfonyl chloride (0.12 mL, 1.3 equiv.) at 0°C. The mixture was stirred at 0°C for 18 h, then ice-water was added, followed by extraction with ethyl acetate. Processing of the organic phase gave a residue which was chromatographed on silica gel ($CHCl_3$–MeOH, 97%) to give 530 mg (79%) of the title compound as an amorphous solid, $[\alpha]_D$ +2.60 (*c* 0.73, $CHCl_3$); ir ν_{max} ($CHCl_3$): 3560, 3390 (OH); 1685 (Cbz); 1340, 1170 (SO_2Me) cm^{-1}; ^1H nmr (90 MHz, ppm, DMSO-d_6): 1.21 (d, C-Me); 2.95, 2.97 (s, NMe_2); 3.20 (s, Ms), 4.62 (s, H-10a), 5.11 (s, CH_2Ph), 7.36 (O, H, Ph), etc.; ms *m/e*: 584 (M^+ − $MeSO_3H$). Calcd.: 584.236; found: 584.236.

Solvolysis studies with ***31***

(a) *With silver carbonate*

A solution of **31** (50 mg, 0.073 mmol) in 10 mL of 1:1 acetone–water mixture was refluxed in the presence of 100 mg of freshly prepared silver carbonate. The suspension was filtered over Celite, the filtrate was evaporated in the presence of 2-propanol, and the residue was chromatographed over thick layer plates (EtOAc). The major product, 21 mg (47%), was found to be *N,N′*-[(benzyloxy)carbonyl]-4-(*R*)-dihydrospectinomycin **13**, identical in all respects with authentic material. Another product (3 mg, 9%) was identified as *N,N′*-[(benzyloxy)carbonyl]actinamine.

(b) *With sodium acetate*

Compound **31** (50 mg, 0.073 mmol) was dissolved in 3 mL of anhydrous trifluoromethanol containing 96 mg (10 equiv.) of anhydrous sodium acetate. After refluxing for 18 h, the solvent was evaporated and the residue was chromatographed on thick layer plates (EtOAc). The major product (18 mg, 38%) was identified as the 4-*O*-acetyl derivative **12** (ir, $[\alpha]_D$, nmr). Deacetylation of this product gave **13**.

(c) *With sodium azide*

A solution of **31** (340 mg, 0.5 mmol) in 20 mL of trifluoromethanol containing 1.5% water was treated with finely powdered sodium azide (4.89 mg, 1.5 equiv.) and the mixture refluxed for 4 h. Filtration and evaporation gave a syrup which was chromatographed on silica (hexanes–EtOAc, 3:7) to give the 4-azido derivative **32** (syrup, 93 mg, 30%) and unreacted starting material (128 mg). The azide showed $[\alpha]_D$ +20.1° (*c* 0.38, $CHCl_3$); ir ν_{max} ($CHCl_3$): 3600, 3200 (OH); 2100 (N_3), 1685 (Cbz) cm^{-1}.

4-Amino-4-deoxy-(S)-dihydrospectinomycin dihydrochloride, ***33***

A solution containing 70 mg (0.11 mmol) of the azide **32** in 7 mL of ethanol and 0.1 mL of aqueous HCl was hydrogenated in the presence of 25 mg of 10% palladium-on-charcoal. After 3 h, the catalyst was filtered, and the filtrate was processed as usual to give a syrup. The latter was taken up in a small volume of ethanol and ether was added to precipitate the product. The hygroscopic solid was separated from the supernatant by decantation, then it was dried in a desiccator to give 45 mg (92%) of the title compound as an amorphous solid, mp 198–200°C (dec.); $[\alpha]_D$ +11.4° (*c* 0.49, H_2O); ^1H nmr (400 MHz, ppm, D_2O): 1.36 (d, C-Me), 1.77 (dd, H-3ax, $J_{3ax,3eq}$ = 12.7 Hz, $J_{3ax,4}$ = 3.9 Hz, $J_{3eq,2}$ = 1.7 Hz), 2.88 (s, NMe_2), 3.32 (dd, H-6, $J_{6,5a}$ = 10.1 Hz, $J_{6,7}$ = 2.9 Hz), 3.61 (dd, H-8, $J_{8,9}$ = 11.0 Hz, $J_{8,7}$ = 2.84 Hz), 3.71 (dd, H-4), 3.95 (m, H-2), 4.01 (dd, H5a, $J_{5a,9a}$ =

10.1 Hz), 4.11 (dd, H-9a, $J_{9a,9}$ = 10.0 Hz), 4.37 (dd, H-9), 4.79 (dd, H-7), 4.96 (s, H-10a); ms m/e: 334 (M^+ + 1, 315 ($M^+ - H_2O$), etc.

The crystal structures of cellulose polymorphs IV_I and IV_{II} have been determined by X-ray fiber diffraction analysis combined with stereochemical model refinement. Both structures crystallize in a two-chain unit cell of essentially identical parameters. The most probable space group in both cases is $P1$. The chain conformations, although close to two-fold helical, are marked by unequal rotational positions of the O(6) hydroxyl groups in adjacent residues. Despite identical unit cell parameters, the structures differ in chain polarity: in cellulose IV_I both chains of the unit cell are parallel, whereas in cellulose IV_{II} they are antiparallel. The difference in polarity is further substantiated by the results of chemical conversions which show that cellulose IV_I is converted to cellulose I, and cellulose IV_{II} is converted to cellulose II, via parallel and antiparallel cellulose triacetates, respectively. The reliability of the structure analyses is indicated by the residual $R'' = 0.115$ for cellulose IV_I and 0.094 for cellulose IV_{II}, for data sets of 41 and 43 reflections, respectively.

ERIC S. GARDINER et ANATOLE SARKO. Can. J. Chem. **63**, 173 (1985).

Faisant appel à une analyse de la diffraction des rayons-X par les fibres combinée avec une affinement du modèle stéréochimique, on a déterminé les structures cristallines des polymorphes IV_I et IV_{II} de la cellulose. Les deux structures cristallisent dans une cellule unitaire à deux chaînes et les paramètres de chacune de ces cellules sont essentiellement identiques. Dans chacun des cas, le groupe d'espace le plus probable est $P1$. Les conformations des chaînes sont pratiquement toutes les deux sous formes d'hélices binaires; toutefois, les groupes hydroxyles en (O)6 des résidus adjacents sont dans des positions rotationnelles différentes. Même si les paramètres de la cellule unitaire sont identiques, la polarité des chaînes diffère suivant les structures: dans la cellulose IV_I, les deux chaînes de l'unité cellulaires sont parallèles alors que dans la cellulose IV_{II} elles sont antiparallèles. La différence de polarité est confirmée par les résultats de conversions chimiques qui montrent que la cellulose IV_I peut être transformée en cellulose I et la cellulose IV_{II} est transformée en cellulose II par le biais de triacétates de cellulose qui sont respectivement parallèles et antiparallèles. La fiabilité des analyses structurales est indiquée par les valeurs de R'' qui sont 0,115 et 0,094 repectivement pour les celluloses IV_I et IV_{II} et qui sont basées sur des ensembles de données de 41 et 43 réflexions.

[Traduit par le journal]

Introduction

The existence of cellulose in the form of four polymorphic crystalline structures, designated celluloses I, II, III, and IV, has been known for some time (1). Of these polymorphs, only cellulose I is the native form, and all others are conversion products of it. However, only cellulose IV is obtained under high temperature conditions. This suggests a measure of stability for its structure, not unlike that of cellulose I and cellulose II (the most stable polymorph). Indeed, though celluloses I and II appear to be the most stable structures, cellulose IV can only be converted back to cellulose I or II by resorting to drastic treatments such as mercerization or boiling in acid (2). In contrast, the cellulose III polymorphs revert to celluloses I and II by simply warming in water.

Previous crystallographic analyses of various cellulose polymorphs have shown that their structures fall into two classes: one based on parallel chains (celluloses I and III_I), and the other on antiparallel chains (celluloses II and III_{II})[2] (3). Within each category there is reversibility between the polymorphs; however, the parallel to antiparallel conversion is irreversible.

Cellulose IV can be most easily prepared by heating cellulose III, and therefore, two polymorphs of it also exist — celluloses IV_I and IV_{II} — obtained, respectively, from celluloses III_I and III_{II} (4). The diffraction diagrams of both cellulose IV polymorphs are very similar (cf. Fig. 1). Nonetheless, reversible transformations to cellulose triacetate have shown that the two structures are not identical. Cellulose IV_I, upon heterogeneous acetylation, yields cellulose triacetate I (CTA I), whereas cellulose IV_{II} yields CTA II (5). Crystallographic structure analyses have shown that CTA I possesses a parallel-chain structure (6) while CTA II is antiparallel (7). It has further been shown that CTA I prepared from cellulose IV_I deacetylates to cellulose I while CTA II obtained from cellulose IV_{II} deacetylates to cellulose II (5). These observations strongly indicate that the two cellulose IV polymorphs differ in chain polarity.

A full crystallographic structure analysis of both polymorphs was undertaken in order to delineate their structural differences and to gain some understanding of their stability. From an industrial point of view, cellulose IV is an important minor component in various cellulose products, where it tends to modify their properties.

Experimental

Fibrous cellulose IV_I was prepared from ramie cellulose I by first converting the latter to cellulose III_I, followed by heating. The conversion to cellulose III_I was accomplished by swelling the fibers in 75% aqueous ethylene diamine for 5 h at 35°C, followed by washing with anhydrous methanol (8). The process was repeated three times. The conversion to cellulose IV_I was done by heating in glycerol, at 260°C for 20 min (9). Although cellulose IV_{II} can be prepared from cellulose III_{II} using the same method, the sample used here was a commercial one, produced by regenerating cellulose xanthate at 100°C. (This sample was provided by Dr. R. H. Marchessault of Xerox Research Centre of Canada.)

X-ray diffraction diagrams of both samples were recorded in an

evacuated Searle toroidal focusing camera, using Ni-filtered CuKα radiation and Ilford Type G Industrial X-ray Film. Multiple-film exposures were used for intensity determinations and powdered NaF was used for the calibration of the films intended for d-spacing measurements. The unit cell parameters were refined against measured d-spacings using least-squares procedures. The intensities were measured with a Joyce-Loebl recording microdensitometer, using straight-line scans along the layer lines. Overlapping intensity envelopes were resolved with a least-squares curve resolution program. The individual intensities were corrected for Lorentz and polarization factors, reflection arcing, distance of diffracted ray to film, tracing direction other than radial, and the Franklin artificial temperature factor (10), and were converted to relative structure factor amplitudes. A total of 16 observed structure factors were obtained for cellulose IV_I, which included the contributions of 30 planes. An additional 7 observed structure factors, representing 11 planes, were obtained in the same manner from intensities assigned one-half of the minimum observable intensity. For cellulose IV_{II}, the corresponding numbers were: 15 observed, 32 planes; 7 unobserved, 11 planes. Meridional reflections were not included in the measurements, because of the well-known difficulties in applying the necessary intensity corrections. During the structure refinement, most of the observed structure factors were equally weighted at 1.0, while the unobserved and some observed structure factors from weak and diffuse reflections were weighted at 0.5.

Results and discussion

Diffraction measurements

The diffraction diagrams of both polymorphs are shown in Fig. 1. Based on the d-spacing measurements of 15 reflections for cellulose IV_I and 16 reflections for cellulose IV_{II}, the unit cell parameters obtained by least-squares refinement are given in Table 1. The less than 1% difference in the parameters indicates the two unit cells to be identical within experimental error. Agreement between the measured and calculated d-spacings, also shown in Table 1, is good.

As previously observed with other cellulose structures, the space groups of the two cellulose IV polymorphs could not be determined unequivocally and were, therefore, assumed to be $P1$. The frequently used space group $P2_1$ with the screw axis in the chain direction was not considered because faint odd-order meridional reflections 001 and 003 were observable. However, as discussed later, the space group $P2_1$ with the screw axis at right angles to the chain axes was considered. As it turned out, after the completion of structure refinement, the space group $P1$ appeared to be the correct choice for both polymorphs.

Structure solution and refinement

As was done in all other cellulose crystal structure analyses, the method was one of model refinement. The generation of starting models was considerably simplified owing to the availability of detailed structural data for other cellulose polymorphs. The similarity of the unit cells of all cellulose structures indicates common conformational and packing features, viz., chains conforming exactly or nearly to a two-fold screw axis along the chain, and a crystalline packing marked by a sheet-like arrangement of chains in the $b-c$ plane of the unit cell. As is true of all other cellulose polymorphs, the calculated and observed densities (approx. 1.6 g/cm^3) dictate that two chains pass through each unit cell, with the most probable arrangement of one chain at the corner of the cell and the other in the center. With these constraints in place, the choice of

TABLE 2. Characteristics of possible models

Short contacts	0	0	0	0	0	0

[a]Chain 1 is the corner chain, chain 2 is the center chain. The 0° position of the chain rotation for space group $P1$ is when $O(4)_1$ is on the $-y$ axis for the corner chain (and in analogous position for the center chain). For $P2_1$, the corresponding positions are on the $-x$ axis. Chain 2 translation is measured relative to chain 1.

[b]O(6) rotations refer to the torsion angle O(5)—C(5)—C(6)—O(6). The 0° position is when atoms O(5) and O(6) are eclipsed. The first two angle values are for residues 1 and 2 (chain 1), the second two are for residues 3 and 4 (chain 2).

[c]ϕ = 0° when the bond sequence $H(1)_1$—$C(1)_1$—$O(4)_2$—$C(4)_2$ is *cis*; ψ = 0° when the bond sequence $C(1)_1$—$O(4)_2$—$C(4)_2$—$H(4)_2$ is *cis*. A positive angle is for the far bond clockwise relative to the near bond.

[d]The *virtual bond* (V.B.) is the vector connecting successive glycosidic oxygens (bridge oxygens, O(4)).

[e]The first number counts the intermolecular bonds, the second intramolecular bonds, per unit cell.

initial models was essentially limited to two: (1) both chains parallel, and (2) corner and center chains antiparallel. In the latter case, a further distinction into two models could be made: one in which both chains were independent, and another in which the chains were related by a two-fold screw axis along either the a or the b axis of the unit cell. In all models, the two glucopyranose residues comprising the fiber repeat were considered to be independent, i.e., the structures were assumed to be based on a cellobiose residue.

The model refinement procedure was identical with that used previously with other cellulose structures (11–13). Initially, all models were refined to acceptable stereochemical parameters, with all bond lengths, bond angles, torsion angles, and hydrogen bond lengths within the observed ranges as seen in carbohydrate crystal structures (14). The refinement was carried out with the molecular mechanics computer program PS79 (15), by minimizing the function

$$[1] \quad E = \sum[(a_i - a_{oi})/S.D._i]^2 + W \sum w_{ij}(d_{ij} - d_{oij})^2$$

where a_i are the bond lengths, bond angles, and torsion angles; a_{oi} and $S.D._i$ are the corresponding standard values and standard deviations, respectively; d_{ij} are the nonbonded distances; d_{oij} are the corresponding equilibrium distances; w_{ij} are appropriate weights; and W is the weight of the nonbonded repulsion term in the function. The standard values a_{oi} and d_{oij} have been previously published (15).

The stereochemically sound models were subsequently refined against the set of observed structure factor amplitudes, F_o, by minimizing the weighted crystallographic residual

$$[2] \quad R'' = \left[\sum w(|F_c| - |F_o|)^2/\sum w|F_o|^2\right]^{1/2}$$

(In this equation, F_c are the calculated structure factor amplitudes, and w are weights assigned to individual reflections.)

Because the number of reflections was relatively small, the refinable parameters during these refinement cycles included only the chain positioning parameters (i.e., rotation about the chain axes and translation along the c axis), all chain and ring torsion angles, and selected bond angles (bridge angles at the two glycosidic oxygens of the cellobiose residue and bond angles in the hydroxymethyl groups). All other bond angles and bond lengths remained invariant at values obtained by stereochemical refinement. During the final cycles of refinement, the function

$$[3] \quad \Phi = 100fR'' + (1 - f)E$$

was minimized, in order to forestall the development of short nonbonded contacts which may arise when refinement with a small number of reflections is attempted. (The fraction f ranged from 0.92 to 0.95, designed to weight both terms in eq. [3] equally.) In addition, during the final cycles of refinement, an overall, isotropic temperature factor of the form exp $(-B \sin^2 \theta/\lambda^2)$ was applied to the calculated structure factor amplitudes, with the term B included among the refinable parameters.

The results of the refinement of all three models for both cellulose IV_I and cellulose IV_{II} are shown in Table 2. As expected on the basis of virtually identical unit cells and diffraction diagrams, almost equally good parallel and antiparallel chain models were obtained in both cases. In the absence of any additional information, it would have been difficult to decide which of the models represented the correct structure solution. But, as described above, chemical conversion evidence, obtained through acetylation and deacetylation of the cellulose IV polymorphs, had definitely indicated that cellulose IV_I was a parallel and cellulose IV_{II} was an antiparallel structure. Therefore, of the three solutions shown in Table 2 for cellulose IV_I, only the parallel model should be correct, while it remained to be decided which of the two antiparallel models was the correct

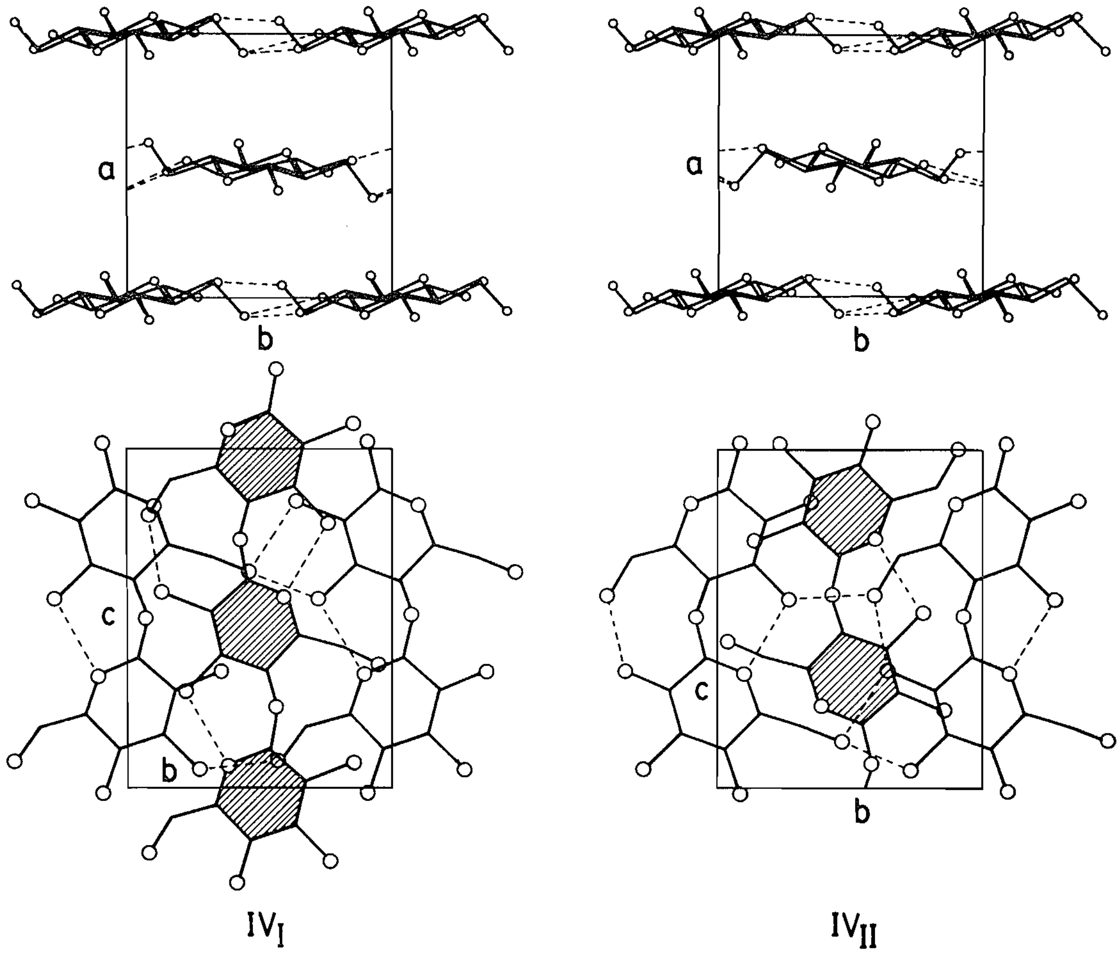

FIG. 2. Projections of the crystal structures of cellulose IV_I and IV_{II}. Hydrogen atoms are omitted and hydrogen bonds are shown by dashed lines.

solution for cellulose IV_{II}. Fortunately, in the case of cellulose IV_{II}, the decision could be made on the basis of the X-ray refinement which clearly favored the model in space group $P1$. The R'' index for the $P1$ structure was 0.094, while the index for the $P2_1$ structure was 0.120, or 28% higher. (This difference in the R''-factor is significant at a 75% confidence level, using the Hamilton statistical test as a criterion (16).)

A similar analysis failed for cellulose IV_I, for which both parallel and antiparallel models yielded an almost identical R'' index. As pointed out above, however, the parallel $P1$ structure should be the correct solution based on chemical conversion results.

The final structures of both polymorphs are shown in Fig. 2. Comparisons of calculated and observed structure factor amplitudes are given in Table 3, the atom coordinates are listed in Table 4, and the hydrogen bonds are shown in Table 5.

Structural characteristics

It is interesting that both cellulose IV polymorphs appear to crystallize in space group $P1$, i.e., they possess no symmetry. The lack of symmetry in the case of cellulose IV_I is clearly evident: the two chain rotations ("setting angles") differ by ~7°, and the O(6) rotation angles in adjacent residues differ by approximately 20° and 40° in the two chains, respectively. For cellulose IV_{II} the lack of symmetry is not as accentuated, but is observable in some other features of the structure. The chain setting angles are within approximately 3° of the position found for the model with $P2_1$ symmetry, i.e., with a two-fold screw axis parallel to the a axis of the unit cell. (To compare chain setting angles of $P2_1$ and $P1$ models, add 90° to the values of the latter.) Similarly, the translational positions of the two chains along the c axis differ by only 0.072 Å between the $P1$ and $P2_1$ models (4.562 to 2 × 2.317 Å; cf. Table 2). But the chain conformation angles (ϕ, ψ) and the O(6) rotation angles differ considerably more in this case.

In other respects, the cellulose IV_I and IV_{II} structures resemble other cellulose polymorphs. As an example, the chain conformations are very close to obeying two-fold screw symmetry — in all aspects but the O(6) rotation angles. This is shown by the generally similar ϕ, ψ, and τ (bridge) angles, and the lengths of the *virtual bonds* (V.B.) for the individual residues (cf. Table 2). The two-fold screw symmetry is definitely eliminated by the differences in the O(6) rotation, which probably arise because of a higher degree of hydrogen-bonding that this affords. For example, in the cellulose I structure where all O(6) rotations are nearly identical, eight intramolecular and four intermolecular hydrogen bonds, for a total of 12 per unit cell, are possible (11). In the cellulose IV_I and IV_{II} structures, where the unequal O(6) rotational positions allow essentially the same number of hydrogen bonds (12 and 13, respectively), there are more intermolecular bonds. In cellulose IV_{II}, there is even one intersheet hydrogen bond (cf. Table 5). This increased level of two- and three-dimensional hydrogen bonding must contribute to the stability of both polymorphs. A similar

situation exists in the cellulose II structure (12). The unequal O(6) rotations also account for the weak odd-order meridional reflections (001 and 003) that are visible in the diffraction diagrams of both polymorphs.

The general similarity of the ϕ, ψ angles in the two cellulose IV polymorphs, as well as their similarity to other cellulose structures, does not support the proposal by Hayashi *et al.* that the cellulose I and II families differ principally in measurable

[a]Subscripts 1 and 2 designate residues of corner chain, 3 and 4 of center chain.

differences in chain conformations (4).

As noted above, the two chains of the unit cell were placed at the corner and the center, respectively, in both structures. After completing refinement with this chain placement, the x and y parameters of the center chain axis were included as refinable parameters. This resulted in no significant movement of the chain in the $a-b$ plane and no further lowering of the R''-factor. It is concluded, therefore, that the second chain of the unit cell is centered in both cellulose IV polymorphs, as it appears to be in all other cellulose structures.

Stability of celluloses IV_I and IV_{II}

The stereochemical molecular mechanics techniques employed here had previously been used in an attempt to predict the unit cells of all cellulose polymorphs (17). The calculations were done on the assumption that the polymorphs resided in crystalline packing energy minima. The results generally supported this assumption, showing the existence of energy minima corresponding to celluloses I, II, III_I, III_{II}, and IV_{II}. Furthermore, cellulose II resided in a global minimum, in agreement with crystallographic and other experimental observations. Cellulose IV_{II} was predicted to reside in a reasonably deep energy minimum, which also agrees with experimental facts. Among the latter is the observation that single crystals of cellulose grow in the cellulose IV_{II} lattice at high temperatures rather than in the cellulose II lattice which occurs at low temperatures (18). In addition, it has been shown that cellulose IV_{II} can be converted to cellulose II, but only through a drastic treatment of boiling in hydrochloric acid (2).

A similar energy minimum for a parallel cellulose IV_I was not predicted; instead, the minimum coincided with the unit cell of cellulose I. The position of the cellulose IV_I unit cell was up-slope relative to cellulose I, which agrees with the experimental observation that cellulose IV_I can be converted to cellulose I (although, again, only be boiling HCl (2)). The claim that cellulose IV is not a unique crystalline polymorph but is a poorly crystalline mixture of two or more crystal lattices (19), is clearly not in accord with the results of crystallographic analysis and other observations. It is thus curious that even a shallow energy well corresponding to cellulose IV_I was not found. The energy surface in the region surrounding the unit cell of cellulose IV_I was recalculated on a finer grid, but the results were not significantly different. At best, a small "shelf" in the energy surface exists in that region. It is concluded that the stereochemical calculations used in our method either are not sufficiently sensitive or that there are contributions to stability that are not taken into account in the calculations. The latter alternative appears to be the more probable of the two.

Conclusions

With the completion of this study, all cellulose polymorphs except III_{II} have now been crystallographically analyzed. The results, which include the analyses of CTA I and CTA II, clearly support the conclusion that the cellulose crystal structures fall into two families that differ in chain polarity. The parallel-chain family, comprised of celluloses I, III_I, and IV_I, owes its existence solely to the mode of biosynthesis of cellulose I, as has been demonstrated by Brown and co-workers (20). In the biosynthetic mechanism, multiple cellulose chains are synthesized simultaneously and extended in parallel, apparently crystallizing immediately without rearrangement.

Regardless of the chain polarity, the crystal structures of all cellulose polymorphs are similar. The chain conformation is in all cases either exactly two-fold helical or is very close to it. The deviation from two-fold screw symmetry is principally caused by differences in the rotational positions of the O(6) hydroxyls. Even then, in all polymorphs including the present two, almost all of the O(6) rotational positions are not far from *tg*,[3] which for a long time was thought to be an unfavorable position because of its absence in carbohydrate crystal structures.

Other features of the cellulose crystal structures are, likewise, similar. The chains are arranged in sheets, with two-dimensional hydrogen-bonding within the sheets accounting for their stability. In all polymorphs, most of the hydrogen bonds are the intramolecular O(3)—O(5)′ and O(6)—O(2)′, and intermolecular O(3)—O(6). In all polymorphs except cellulose II (and to some extent, cellulose IV_{II}), intersheet hydrogen bonds are either lacking or are very weak. Consequently, the relative stagger of adjacent sheets along the *c* direction of the unit cell shows the most variability of all features among the different structures.

The unit cells of all polymorphs appear to be true two-chain cells and not sub-cells in a larger lattice. This is certainly true for the polymorphs that can be grown in single crystal form, such as cellulose II and IV_{II} (18). The possible exception may be *Valonia* cellulose which appears to crystallize in an eight-chain unit cell, although an alternative, two-chain, triclinic cell has been proposed (21). It is still of interest to determine the true unit cell of *Valonia* cellulose and the differences in its crystalline packing relative to other polymorphs.

The space groups of the crystalline celluloses are more difficult to determine with accuracy. For the most part, they appear to be $P1$, or in some cases, perhaps $P2_1$. Certainly, no more symmetry is evident in any of the structures than is afforded by the latter space group. Even in cases where $P2_1$ appears to be applicable, very weak odd-order meridional reflections can be detected.

The crystal structure analysis of celluloses, as well as of polymers in general, has made great strides during the past 10−15 years. To a large extent this is due to exhaustive model analysis made possible by computer methods. The next challenges in cellulose structure analysis lie in two broad areas. The first is in trying to gain a better understanding of the structure of the amorphous phase and the morphology of the cellulose fiber, and the second is in determining the mechanisms of cellulose interconversions, such as mercerization. Some work concerning the latter is in progress (22). Likewise, there is a challenge in trying to devise more accurate methods for predicting polysaccharide conformations and crystal lattices. As the case of cellulose IV_I illustrates, our methods in this regard may be inadequate. However, as a recent report by Pertsin *et al.* (24) points out, the use of more rigorous potential energy functions may be helpful, at least for the prediction of probable conformational models. Whether the same holds true for the prediction of complete crystal structures remains to be seen. In our hands, the results with respect to the latter have been inconclusive, regardless of the types of functions employed.

A series of random copolyesters containing two different aromatic ester triads and a decamethylene flexible spacer was prepared and characterized for the effect of comonomer composition on glass, crystalline and liquid crystalline state properties. The homopolymer of one of the triads was enantiotropic, but the other was not. However, a copolymer containing 90 mol% of the latter units and 10 mol% of the former showed thermotropic behaviour, which suggested that the latter homopolymer was probably monotropic. The effects of comonomer content on glass, melting and isotropization temperatures of the copolymers were very different for the three transitions.

Q.-F. ZHOU, J.-I. JIN et R. W. LENZ. Can. J. Chem. **63**, 181 (1985).

Dans le but de déterminer l'effet de la composition du comonomère sur les propriétés des états vitreux, cristallin et cristal liquide des copolyesters, on a préparé et caractérisé une série de copolyesters désordonnés contenant deux triades différentes d'esters aromatiques et un décaméthylène qui introduit un espacement flexible. L'homopolymère de l'une des triades est énantiotope, mais l'autre ne l'est pas. Cependant un copolymère contenant 90 mol% de ces dernières unités et 10 mol% des premières montre un comportement thermotrope qui suggère que le dernier homopolymère est probablement monotrope. L'effet de la teneur en comonomère sur l'état vitreux, les températures de fusion et d'isotropisation des copolymères est très différent dans les trois transitions.

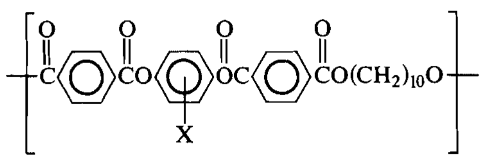
Introduction

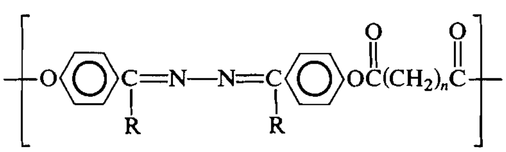
In a recent investigation in this laboratory, a series of thermotropic polyesters was prepared and characterized for the effect of lateral substituents on their liquid crystalline properties. The polymers contained an aromatic ester triad with a central hydroquinone unit, on which was placed a single substituent, and a decamethylene flexible spacer, as shown in the structure below (1, 2):



In this series, X was either a *n*-alkyl group (1) (C_nH_{2n+1}, n = 1–6, 8, 10) or a polar group (2), the latter including the CN, NO_2, Br, and OCH_3 groups.

Most of the polymers in this series showed nematic behaviour as indicated by their textures on the polarizing microscope. The exceptions were those polymers with the longer alkyl groups (n = 8 or 10) and, surprisingly, that with the methoxy group. It was possible, however, that these non-enantiotropic polymers were monotropic in their behaviour, but attempts to observe this property by controlled cooling experiments did not show clear evidence of thermotropic behaviour.

It was decided, therefore, to prepare a series of copolymers containing decreasing amounts of the non-enantiotropic methoxy units with one of the enantiotropic units (the cyano monomer unit) in order to estimate the possible isotropization temperature of the methoxy containing homopolymer if it was indeed monotropic. This approach had been taken with success by Iannelli, Roviello, and Sirigu (5) on two series of substituted benzalazine polymers containing flexible spacers, which were closely related to each other and had the following structures:



The homopolymers in which R was methyl and n = 8, 10, 12, or 14 were liquid crystalline, as indicated from their analysis by DSC and by polarizing microscopy, but none of the polymers in the series in which R was ethyl were thermotropic. For the latter, it was concluded that the polymers, most likely, were monotropic; that is, that their liquid crystalline behaviour and anisotropization transitions were masked or prevented by crystallization. By examining instead the copolymers containing units with R = CH_3 and with R = C_2H_5 groups having a single flexible spacer, an isotropization temperature could be estimated. This temperature was also confirmed by analyzing copolymers of R = C_2H_5 with two different flexible spacers. For both series of copolymers, isotropization temperatures could be observed in polymers of high ethyl group content because of depression of the melting point of the ethyl substituted homopolymer.

The former approach was taken in this study in that copolymers containing both cyano and methoxy substituted units, varying in composition from 0.5 to 0.9 mole fraction of the non-enantiotropic methoxy units, m, were prepared and characterized for their liquid crystalline properties.

Results and discussion

Thermal transition data as determined by DSC analysis, and confirmed by observations of the samples on the hot stage of a polarizing microscope, are collected in Table 1 for a series of copolymers of the following structure:

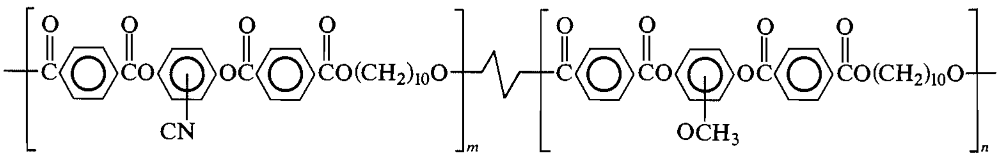
[2]Present address: Chemistry Department, Korea University, 1-Anam Dong Seoul 132, South Korea.



Transition temperatures

As shown by the data in Table 1, the glass transition temperatures, T_g, of the copolymers were all lower than those of either of the two homopolymers, and an apparently non-linear variation of T_g with composition was observed. The cause of this unusual relationship between copolymer composition and T_g is unknown, but the glass phases of these polymers and copolymers may well retain at least a partial nematic order, and it has been observed that a polymer with a mesophase glass has a different T_g value than with an amorphous glass (4).

The melting points, T_m, of the copolymers were found to vary in a uniform manner with composition, and the copolymers were crystalline over the entire range of compositions studied. The value of T_m of the methoxy unit polymer component decreased with increasing cyano unit content and probably passed through a minimum for the copolymer at or near the equimolar composition of the two different substituted hydroquinone units. The same type of behaviour was observed for the substituted benzalazine copolymers discussed above (3).

In contrast to the melting points, the isotropization temperatures (or clearing points), T_i, of the copolymers increased continuously, with increasing content of the mesogenic cyano unit throughout the composition range studied, and the thermal stability of the mesophase, ΔT, showed the same behaviour. In contrast, for the benzalazine copolymers discussed above, the equimolar copolymer showed that the widest temperature range of mesophase stability (3).

As clearly indicated by the data in Table 1, the effect of copolymerizing these two closely related, potentially mesogenic monomers on the transition temperatures of their copolymers is much greater on T_i than on T_m, and the two different transitions apparently follow different thermodynamic rules. Indeed, at this stage of our investigation very little is known, and no theory has yet been developed, about the thermodynamic behaviour of the liquid crystalline phase of main chain copolymers (5). Similar observations to these on differential effects on T_m and T_i have been made by Blumstein and co-workers on a series of main chain copolyesters containing azoxybenzene mesogenic units and flexible spacers (6).

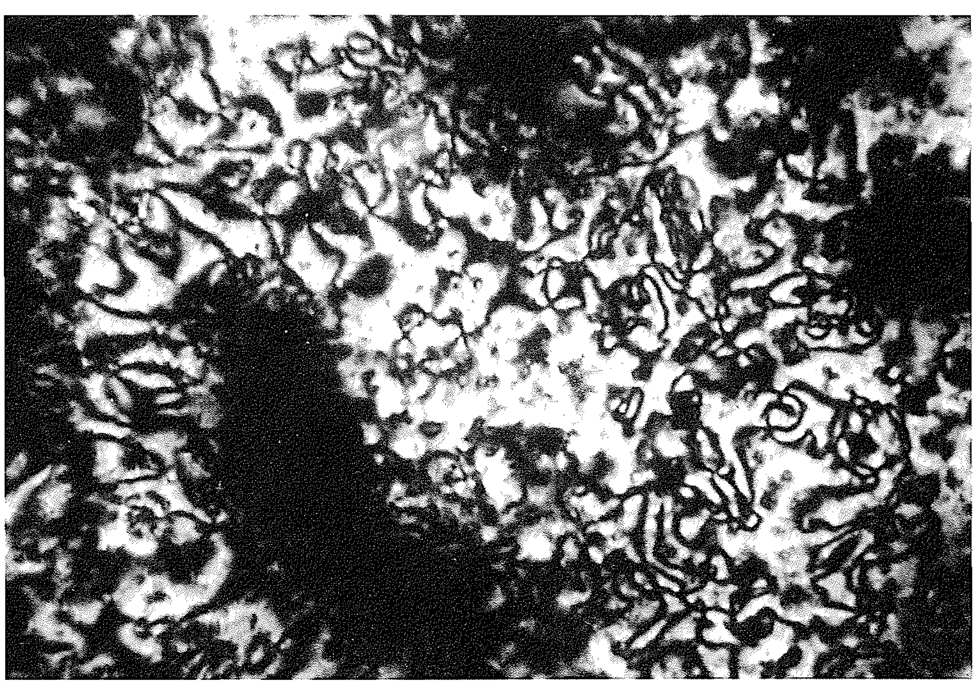

FIG. 1. Photomicrograph of copolymer with 0.90 mole fraction of methoxy triad units at 160°C; 320× magnification.

By extrapolating the relationship between T_i and methoxy unit content of the copolymers, a possible value of T_i for the homopolymer of that unit can be estimated, and it was found to be approximately 151°C. When only 10 mol% of the comonomer cyano units were inserted into the polymer, the melting point was depressed from 158 to 150°C, and the formation of a liquid crystalline phase on melting was observed. A photomicrograph of this phase, as observed on the polarizing microscope at 160°C, is shown in Fig. 1. The mesophase appears to be poorly organized, but the crude threaded Schlieren texture observed suggests the presence of a nematic phase. The occurrence of this type of monotropic behaviour was previously reported by this laboratory for polyesters containing dyad mesogenic units (7) and is well known for low molar mass liquid crystalline compounds (8).

In the DSC curve, the isotropization transition of the copolymer containing 10 mol% cyano units appeared only as a shoulder on the melting peak, but on cooling the sample from the isotropic melt state, a clearly separated exothermic deisotropization temperature, T_d, peak was observed at 148°C because of the normal supercooling of the crystallization process. That is the exothermic recrystallization peak for this copolymer was observed at 116°C, which is well below T_d.

It is also of interest to note that the copolymers containing 20 to 50 mol% of the cyano units showed little or no crystallization in the cooling cycle of the DSC curve. Instead crystallization occurred during the second heating cycle in most cases.

Experimental

The monomers were prepared by procedures previously described (2). A typical polymerization reaction was carried out in the following manner:

A solution of 1.143 g (2.25 *m*) of 1,10-*bis*(p-chloroformylbenzyloxy)decane in 15 mL of tetrachloromethane, TCE, was added dropwise with vigorous stirring to a solution of 2.25 *m* of the hydroquinone monomer in 5 mL of TCE and 5 mL of pyridine. The reaction was carried out at room temperature for 20–24 h under a nitrogen atmosphere, after which the mixture was poured into a large volume of acetone to precipitate the polymers. The solid product was washed successively with acetone, water, and acetone and dried under vacuum at room temperature.

Polymer characterization

The solution viscosities of the copolymers were measured with a Ubbelohde Viscometer at 40°C at a solution concentration of 0.5 g/dL in TCE. GPC analysis of one of the copolymer samples in a THF solution was made on a Waters instrument. The molecular weight and polydispersity index were determined by comparison with polystyrene standards. Thermal properties of the copolymers were studied using a Perkin-Elmer DSC II instrument under a nitrogen atmosphere with heating and cooling rates of 10°C/min. Thermotropic behaviour and optical textures of the polymers were examined on the hot stage (Mettler FP-2) of a polarizing microscope (Leitz, Orthoux).

Received January 31, 1984

This paper is dedicated to the 10th anniversary of the Xerox Research Centre of Canada

D. J. SANDERS. Can. J. Chem. **63**, 184 (1985).

The physical properties of thermal transfer materials are reviewed. Thermal conductivities and thermal contact resistances were measured for commercial Ink Donor Films (IDF's) with base films of condenser paper or polyethylene terephthalate, and for experimental base materials such as regenerated cellulose, polypropylene, and polyimide. Theoretical models of heat transport in IDF's are presented to demonstrate how the intrinsic thermal properties affect the IDF's performance in thermal transfer printing. To a first order approximation, the sensitivity of an IDF can be characterized by the time taken for heat to diffuse across it. Thermal transfer test patterns for commercial and experimental IDF's were evaluated for sensitivity, and the experimental results were compared to the theoretical predictions.

D. J. SANDERS. Can. J. Chem. **63**, 184 (1985).

On réexamine les propriétés physiques des matériaux de transfert thermique. On a mesuré les conductibilités thermiques et les résistances de contact thermique de Films Donneurs d'Encre commerciaux (IDF) portés par des films de base de papier de condensateur ou de téréphthalate de polyéthylène ainsi que celles des matériaux de base experimentale comme la cellulose regénérée, le polypropylène et la polyimide. On présente des modèles théoriques de transport de chaleur dans les IDF pour démontrer comment les propriétés thermiques intrinsèques affectent la performance des IDF dans l'impression par transfert thermique. En première approximation, on peut caractériser la sensibilité d'un IDF par le temps nécessaire pour que la chaleur puisse diffuser à travers du film. On a évalué les tendances observées lors des essais de transfert thermique effectués sur des IDF commerciaux et expérimentaux afin de déterminer la sensibilité et on a comparé les résultats expérimentaux avec les prédictions théoriques.

[Traduit par le journal]

I. Introduction

Thermal transfer printing (1–3) is a thermal printing process that uses plain paper rather than a specially coated thermal marking paper. Transfer printing employs an Ink Donor Film (IDF) consisting of a thin base film coated with a solid waxy ink. The ink side of the IDF is placed in contact with a plain paper receiver sheet and heat from a thermal printhead is applied to the base film. This locally melts the ink layer which then wets the receiver sheet and resolidifies. Since the receiver is usually much rougher than the smooth base film, the resolidified ink adheres preferentially to the receiver sheet. Subsequent separation of the sheets leaves transferred ink on the imaged areas of the plain paper.

The printing performance of a particular Ink Donor Film is determined by the physical properties of its constituent materials. The transferable ink is typically composed of Carnauba and other waxes with approximately 20% by weight carbon black pigment (1, 2). For high printing speeds and long printhead life, the temperature to which the printhead elements are cycled should be minimized. Therefore, the ink should have a low melting point, yet still be environmentally stable. Typically T_m is between 60 and 80°C (1–3). At the melting point, the ink viscosity should drop sharply to below 100 cP to promote wetting of the receiver sheet (1–3). Below T_m the ink should have a fairly high tensile strength so that it will not transfer under pressure to the receiver sheet without heating (2). The base material must be available as a film less than 50 μm thick. It should be smooth to promote release of the transferred ink, and it must be strong enough to be handled in a thermal printer without tearing. It must also be able to withstand high printhead temperatures for short periods (up to 300°C for several ms) without melting or charring. This requirement eliminates many polymeric materials.

Commercial IDF's use base films of polyethylene terephthalate (PET) (1–3), or "condenser" paper (3) of the type used in electrical capacitors. Typically the base film is 10–20 μm thick and the ink layer is 5–10 μm. Since the IDF is a one-use consumable item, the materials cost is also a factor in choosing a base film. Oki Electric Co. has developed a thermal transfer printer that uses a recoatable Ink Donor Film (4). The base film forms a continuous belt which is repeatedly passed through a heated inking system that reforms the ink layer. In this case, a heat-resistant 25 μm polyimide film was used (4).

This report concentrates on the thermal transport properties of the IDF. Since heat must be conducted from the thermal printhead to the surface of the ink layer, the total thermal resistance of the IDF should be minimized. This means it must be as thin as possible, it should have a high intrinsic thermal conductivity, and it should be smooth so as to minimize its thermal contact resistance with the printhead. The relationship between the thermal transport properties of the IDF and its printing performance has been examined for several commercial IDF's with condenser paper and PET base films, and various experimental IDF's with base films of regenerated cellulose, polypropylene, polyimide, and aluminum foil. In Section II, measurements of the thermal conductivites and other thermal parameters of the IDF materials are presented. Simple theoretical models of heat transport in thermal transfer printing are developed in Section III. The theoretical predictions are demonstrated experimentally in Section IV by measurements of the thermal printing sensitivities of the various IDF's.

II. Thermal properties of thermal transfer materials

The principal difficulty in measuring the thermal conductivity of a thin film is the problem of distinguishing between its bulk thermal conductivity and the thermal contact resistance between the film surface and the heating or cooling elements. This problem has been solved by using a pressure cell apparatus which is described in detail elsewhere (5). Basically, the cell

consists of two thermally insulated brass columns placed one on top of the other, each fitted with two temperature sensors. Heat is supplied at a known rate at the top of one column, and removed by water cooling at the bottom of the other, thus establishing a steady-state temperature gradient. The thin film sample is placed between the optically polished faces of the two columns, creating a discontinuity in the temperature gradient which represents the total temperature drop across the sample. Since the heat flux down the column is known, the apparent thermal resistivity of the sample can be calculated.

The top column is connected to a hydraulic piston so that the apparent resistivity R_T can be monitored as a function of the pressure P_0 applied to the sample up to a maximum pressure of 1700 psi. It has been shown (5) that this effectively eliminates the thermal contact resistance between the sample and brass surfaces. Therefore, the resistivity measured at high pressure represents the true bulk thermal resistivity R (inverse conductivity) of the sample. On the other hand, the total apparent resistivity at zero pressure is just

[1] $R_T = R + 2r/l$

where r is the coefficient of thermal contact resistance and l is the sample thickness. Since the contact resistance is due mainly to the roughness of the sample surface, it is useful to express it as the thickness of an equivalent air gap given by $g = K_a r$, where $K_a = 2.6 \times 10^{-4}$ W/cm °C is the thermal conductivity of air (6).

Typical results are illustrated by Fig. 1. The closed circles indicate the thermal resistivity of a commercial IDF with a 14 μm condenser paper base and a 5 μm ink layer. The open circles represent measurements for an uncoated sample of the base paper prepared by removing the ink layer with acetone. Since the complete IDF has a lower resistivity than the paper alone, this indicates that the ink has a higher thermal conductivity than condenser paper. The thermal conductivities and contact resistances of both the ink and the base paper can be calculated from these results (5). Similar measurements were performed for a PET based commercial IDF, for a typical office-grade bond paper receiver sheet, and for experimental base film materials such as cellulose, polypropylene, and polyimide.

These results are summarized in Table 1 along with other thermal parameters taken from various sources in the literature (6–8). The second column l represents the sample thickness,

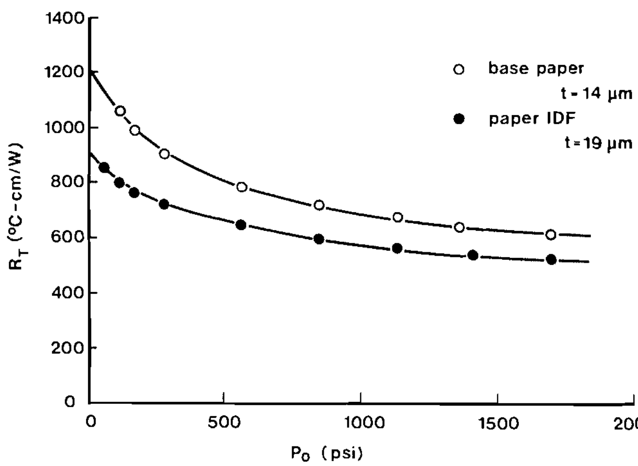

FIG. 1. Apparent thermal resistivity of a condenser paper based IDF. The closed circles represent the coated film, and the open circles represent the uncoated base paper.

ρ is the measured density, K is the bulk thermal conductivity, g is the effective air gap, T_m is the melting point or temperature of thermal decomposition, ρC is the heat capacity per unit volume, and $D = K/\rho C$ is the thermal diffusivity. All quantities listed without a reference were experimentally measured. The IDF ink has a heat of fusion $\rho\Delta H$ = 130 J/cm³ typical of paraffin waxes (9). This can be included as a temperature-dependent specific heat which rises from its base value of 2.5 J/cm³ °C (6) at 60°C to 28.5 J/cm³ °C at 70°C. The thermal diffusivity was calculated from the average specific heat ρC = 15.5 J/cm³ °C. The pressure cell is not suitable for measuring a thin film with a thermal conductivity greater than that of brass, so no attempt was made to measure the aluminum foil. The glass referred to in the last row of Table 1 is the protective overglaze coating which covers the resistive heating elements in a thermal printhead (10). Thus, reading from bottom to top, Table 1 represents the various layers through which heat must pass during thermal transfer printing. One can also compare the effective air gaps of the IDF materials. All the base films have roughnesses of 1 μm or less, while the receiver sheet is much rougher.

It is interesting to compare the thermal conductivities of the three cellulosic materials — receiver paper, condenser paper,

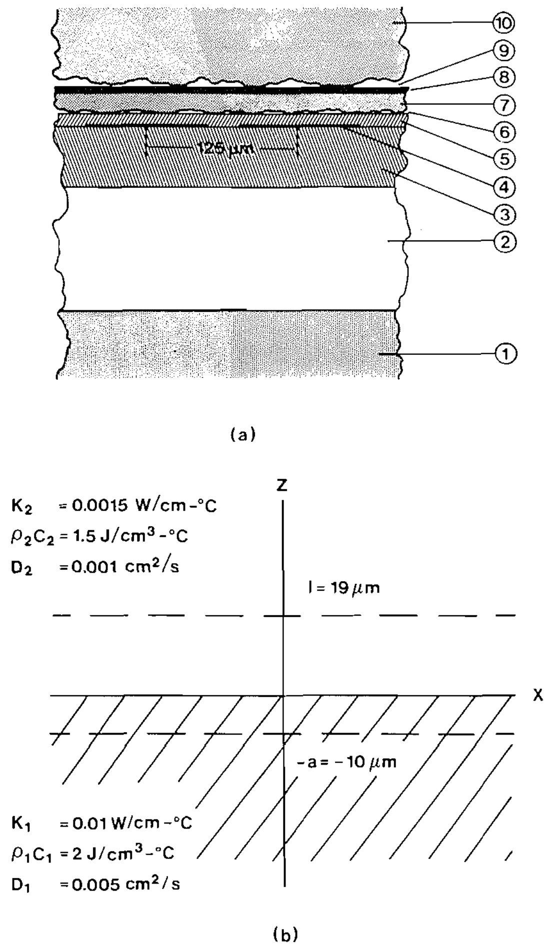

FIG. 2. Geometry of thermal transfer printing. (*a*) 200 spi thin-film thermal printhead. The layers are (*1*) 1 mm aluminum substrate, (*2*) 800 μm Al_2O_3 heat sink, (*3*) 50 μm glass underglaze, (*4*) 2 μm heating element, (*5*) 10 μm overglaze, (*6*) 1 μm air gap, (*7*) 14 μm base film, (*8*) 5 μm ink layer, (*9*) 5 μm air gap, (*10*) 100 μm receiver sheet. (*b*) Simplified two layer model for thermal transfer printing.

and cellulose film. Condenser paper is highly compressed so that it is almost as dense as the cellulose film, but its thermal conductivity is only 60% that of the regenerated film and in fact, is the same as the conductivity of the much less dense receiver sheet. This is because even a highly compressed paper has a structure of matted paper fibers. The principal direction of heat flow will be along the fibers, most of which are oriented in the plane of the sheet: In a regenerated film, however, the cellulose has been dissolved to a molecular level, so heat can flow directly across the thickness of the film.

III. Heat transport in IDF's

The heat flow in thermal transfer printing is more complicated than the steady-state heat flow used to measure thermal conductivity. Figure 2*a* illustrates the thermal printing geometry for a 200 spots/inch thin-film thermal printhead (10). The heating elements are deposited on top of a 50 μm glass underglaze layer which separates them from the ceramic and aluminum heat sinks, and are covered with a 10 μm protective overglaze layer. We wish to determine the transient response of this system to a pulse of heat applied to one of the heating elements.

The multilayered problem can only be solved numerically; however, the main features of the heat flow can be illustrated by a much simpler model that can be solved analytically. Shortly after the application of the heating pulse, all the heat will be concentrated in the layers close to the heating element. The thermal parameters of the overglaze and the glass underglaze are equal so they can be approximated by a single layer. Similarly, the thermal parameters of the IDF and the receiver paper are also nearly equal. Therefore, to a first order approximation, the system can be described by a two layer model. Since the heating element is wider (125 μm) than the thickness of the IDF (19 μm) or the underglaze (50 μm), the heat source is approximately planar. The simplified model is shown in Fig. 2*b*. Semi-infinite medium 1 (glass) extends below the *xy* plane, and medium 2 (paper) above it. At time $t = 0$ a heat source of q J/cm^2 is produced at the plane $z = -a$. According to Carslaw and Jaeger (11) the temperature rise T at any subsequent time t and any point z in either medium is given by

$$[2] \quad T_1(z, t) = \frac{q}{2\rho_1 C_1 \sqrt{\pi D_1 t}} \left\{ \exp\left[-(z + a)^2/4D_1 t\right] + \frac{d - k}{d + k} \exp\left[-(z - a)^2/4D_1 t\right] \right\}$$

and

$$[3] \quad T_2(z, t) = \frac{d^2}{d + k} \frac{q}{\rho_1 C_1 \sqrt{\pi D_2 t}} \exp\left[-(z + da)^2/4D_2 t\right]$$

where d and k are the ratios

$$d = \sqrt{D_2/D_1} \text{ and } k = K_2/K_1$$

In a thermal printhead, heat is not created instantaneously, but is generated during a pulse of width t_p. For a finite pulse, eqs. [2] and [3] must be modified to

$$[4] \quad T_1(z, t) = \frac{p}{2\rho_1 C_1 \sqrt{\pi D_1}} \left\{ \int_0^{t_0} \frac{\exp\left[-(z + a)^2/4D_1(t - t')\right]}{(t - t')^{1/2}} dt' + \frac{d - k}{d + k} \int_0^{t_0} \frac{\exp\left[-(z - a)^2/4D_1(t - t')\right]}{(t - t')^{1/2}} dt' \right\}$$

and

$$[5] \quad T_2(z, t) = \frac{d^2}{d + k} \frac{p}{\rho_1 C_1 \sqrt{\pi D_2}} \int_0^{t_0} \frac{\exp\left[-(z + da)^2/4D_2(t - t')\right]}{(t - t')^{1/2}} dt'$$

where

$$t_0 = t,\ t < t_p$$
$$= t_p,\ t > t_p$$

and $p = q/t_p$ is the power density supplied to the printhead.

Calculated temperature profiles in the printhead and IDF are shown in Fig. 3 for a pulse width of 1 ms. The thermal parameters for the printhead and IDF are those listed in Fig. 2*b*. The power density in the printhead was taken to be p = 1.9 mW/cm^2, as specified for a 200 spi printhead with a 1 ms pulse. With this choice of parameters, the calculation predicts a maximum printhead temperature of 300°C, which decays in about 10 ms.

The simple model can illustrate the effects of varying the IDF thermal parameters. Figure 4 shows how the temperature of the ink − receiver paper interface changes with time. The solid line corresponds to the parameters of Fig. 2*b*, i.e., an IDF with thickness l = 19 μm and the conductivity of paper K_2 =

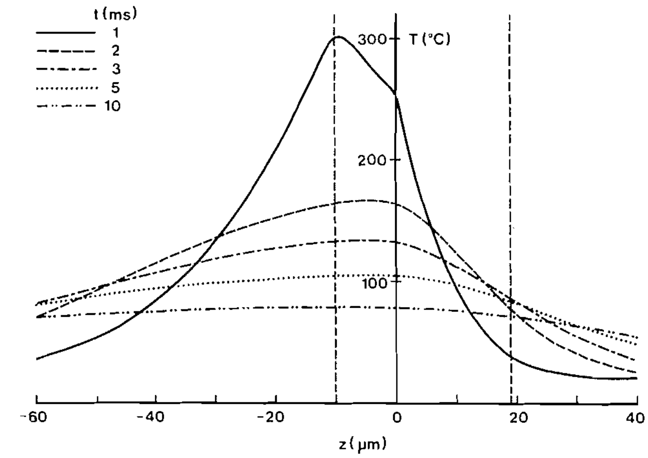

FIG. 3. Temperature profiles in a thermal printhead ($z < 0$) and ink donor film ($0 < z < 19$ μm) at various times after a 1 ms heating pulse at $z = -10$ μm.

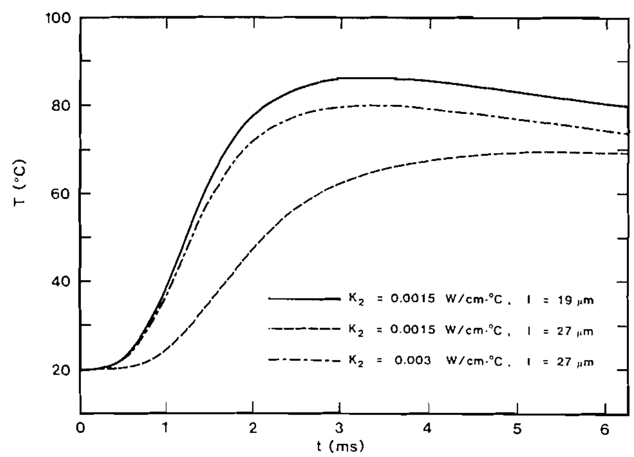

FIG. 4. Time evolution of the temperature at the IDF ink surface for various IDF thicknesses l and thermal conductivities K_2.

1.5 mW/cm °C. The ink temperature reaches a maximum of 86°C after a diffusion time $t_D = 3$ ms. If the IDF thickness were increased by a factor of $\sqrt{2}$ to 27 μm, the diffusion time increases to 5 ms as shown by the dashed line in Fig. 4. Moreover, since heat has more time to dissipate in the printhead, the ink temperature reaches a maximum of only 69°C. If the ink melting point is 70°C, this means that the thicker IDF would not transfer ink. However, if the IDF conductivity is doubled to $K_2 = 3$ mW/cm °C for a thickness of 27 μm, the situation is shown by the dash–dot line in Fig. 4. The diffusion time again is 3 ms and the maximum temperature is 80°C which is almost as high as the original case. Therefore, T_{max} is determined not by the thickness of the IDF, but rather by its effective thermal thickness as measured by its diffusion time t_D.

This can be demonstrated by the following approximations. Since T_{max} occurs after the heating pulse, the finite width of t_p can be neglected. From eq. [3], the temperature at the ink surface $z = l$ reaches a maximum after a diffusion time given by

$$[6] \quad t_D = (l + da)^2/2D_2$$

and the maximum temperature is

$$[7] \quad T_{max} = (2/e\pi)^{1/2} \frac{d^2}{d + k} \frac{q}{\rho_1 C_1 (l + da)}$$

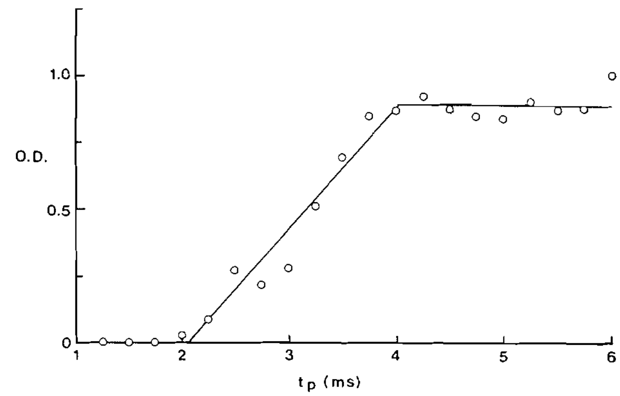

FIG. 5. Variation in optical density with heating pulse width for a thermal transfer test pattern. The IDF consists of a 14 μm condenser paper base with a 5 μm ink layer.

If $K_1\rho_1C_1 \gg K_2\rho_2C_2$, and $da \ll l$, this reduces to

$$[8] \quad T_{max} \simeq (2/e\pi)^{1/2}(D_2/K_1\rho_1C_1)^{1/2}q/l$$

But the diffusion time is just $t_D \simeq l^2/2D_2$. Therefore, for a given thermal printhead, the maximum ink surface temperature depends only on the heat density q, and the diffusion time t_D, i.e.

$$[9] \quad T_{max} \propto q/\sqrt{t_D}$$

IV. IDF sensitivity

The thermal transfer characteristics of a variety of IDF's were measured using a simple thermal imaging test fixture. This employs a printhead consisting of 10 elements arranged in a column with 60 spi spacing, producing a heated area of 0.4 × 4.0 mm. Under microcomputer control it creates a bar test pattern by energizing the printhead with voltage pulses of constant amplitude but progressively increasing pulse width. Figure 5 shows the results of measuring the optical densities of a typical test pattern with a scanning microdensitometer consisting of a Zeiss universal microscope with a photometer head. The O.D. was measured in reflection over a 0.1 × 1.0 mm slit. The test pattern of Fig. 5 was created with the standard IDF shown in Fig. 1, i.e., a 14 μm condenser paper base and a 5 μm ink layer. The power level was 2.6 W per element, and the pulse width t_p was increased from 1.25 to 6 ms in 0.25 ms steps. After a threshold is passed, the O.D. increases approximately linearly with pulse width until complete transfer occurs and the O.D. saturates.

Similar test patterns were created for a variety of commercial IDF's. To the naked eye, each pattern consists of a series of bars ranging from very faint to uniform black, as the amount of ink transfer increases. The sensitivity of each IDF was ranked relative to the standard IDF of Fig. 5 by shifting its test pattern relative to the standard pattern until bars of equal perceived optical density were aligned. The resulting shift in pulse width was translated into the difference in energy density Δq required to produce an image with each IDF relative to the standard. Results of these measurements are listed in Table 2. The base film thickness is l_f and the ink thickness is l_i. L is an effective thermal thickness for the IDF, defined as follows. From eq. [9], in order to produce a T_{max} equal to the ink melting temperature T_m, the heat density must be $q \propto T_m l/\sqrt{D}$. For a bilayer IDF this can be generalized to

$$[10] \quad q \propto T_m(l_f/\sqrt{D_f} + l_i/\sqrt{D_i}) = T_m L/\sqrt{D_f}$$

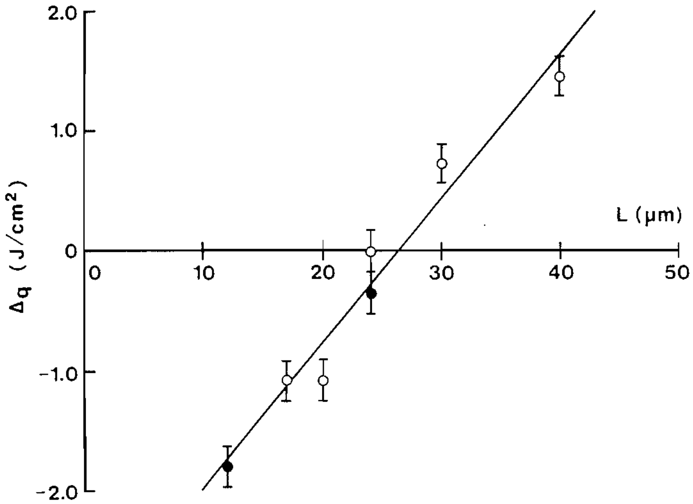

FIG. 6. Relative thermal transfer sensitivity Δq vs. effective thermal thickness L for 7 commercial IDF's. The open circles are condenser paper based IDF's, and the closed circles PET based.

TABLE 2. Relative sensitivities of commercial IDF's

Base material	l_f (μm)	l_i (μm)	L (μm)	Δq (J/cm^2)

6. Condenser paper	18	3	24	−0.36
7. Condenser paper	32	4	40	+1.44

TABLE 3. Relative sensitivities of experimental IDF's

Base material	l_f (μm)	l_i (μm)	L (μm)	Δq (J/cm^2)	$L/\sqrt{D_f}$ (s$^{1/2}$)
1. Condenser paper	13	13	30	0	0.123
2. Cellulose	19	12	47.4	+0.36	0.127
3. Polypropylene	13	9	27.8	+0.36	0.107
4. Polyimide	26	8	43.6	+2.88	0.125
5. Aluminum foil	9	10	602	+1.80	0.064

where $L = l_f + (D_f/D_i)^{1/2} l_i$ is the effective thermal thickness of the IDF. Using the data of Table 1, $L = l_f + 2l_i$ for both condenser paper and PET based IDF's. Because of its heat of fusion, the ink layer has a greater thermal thickness than an equal layer of base film, in spite of the higher thermal conductivity of the ink. The results listed in Table 2 are illustrated in Fig. 6. As predicted by eq. [10], there is a linear relationship between the IDF sensitivity as measured by Δq and the effective thermal thickness L.

Thermal transfer sensitivity was also measured for a series of experimental IDF's consisting of various base films coated in-house with a pigmented waxy ink. The results are listed in Table 3. Δq is a measure of the sensitivity of each IDF relative to the condenser paper based IDF. Since these materials have quite different thermal diffusivities, Δq does not correlate with the effective thickness L. However, eq. [10] predicts that Δq should correlate with the diffusion time given by $L/\sqrt{D_f}$. Comparing the last two columns of Table 3, it can be seen that this is true for the first three IDF's. They all have approximately equal sensitivities and equal diffusion times. In the case of the cellulose based IDF, the higher thermal conductivity of cellulose compensates for the greater film thickness. For the polypropylene IDF, the thinner ink layer compensates for the lower conductivity of the base film.

This correlation does not hold for the polyimide and aluminum foil based IDF's. In the case of the 26 μm polyimide film, it may be that the base film is too thick for a simple 1-dimensional heat flow analysis to be valid, and a numerical 3-dimensional analysis is required. This is certainly the case for aluminum foil. The transferred bars of the test pattern have a rounded appearance, indicating that heat has diffused laterally in the aluminum base film because it has a higher thermal conductivity than the printhead overglaze. This results in a loss of resolution and sensitivity.

In summary it can be stated that, for maximum sensitivity, an ink donor film should be as thin as possible, particularly the ink layer, and the base film should have a high thermal diffusivity, provided it is not higher than that of the printhead.

This paper is dedicated to the 10th anniversary of the Xerox Research Centre of Canada

ROBERT H. MARCHESSAULT, TERRY L. BLUHM, HRIRE M. GHARAPETIAN, and PUDUPADI R. SUNDARARAJAN. Can. J. Chem. **63**, 189 (1985).

The relationship between the dynamic thermoelastic behavior and molecular morphology of polyphasic polymer systems was studied. A sensitive tensometer equipped with a 50W/12V heating lamp provided uniform and controlled heat pulses to one side of the film. For various extension ratios, the stress change ($\Delta\sigma$) as a function of the sample temperature, was recorded, both for increasing and decreasing extension ratios.

The amount of increase in stress $\Delta\sigma$ with temperature was different for Kraton GX-6500 samples cast from either toluene, cyclohexane, or heptane. The variation of $\Delta\sigma$ with temperature was dependent on the extension ratio and was always greater for increasing extension. The slope of $\Delta\sigma$ with temperature decreased at 100–150% elongation in all Kraton GX-6500 samples during increasing extension. However, this slope increased at higher elongations. Small angle X-ray scattering studies on Kraton GX-6500 showed the presence of lamellar, rod shape, and spherical structures in samples cast from toluene, cyclohexane, and heptane solvents, respectively. The extreme dependence of elastomeric behavior on polyphasic morphology caused Kraton samples to show a strong decline in thermoelastic response with cycling.

X-ray studies on the films of Spandex, cast from dimethyl formamide, at different extension ratios showed the onset of crystallization at about 150% elongation. The thermoelastic studies performed on Spandex films also showed an increase in slope of $\Delta\sigma$ vs. T at 150–170% elongations, which was attributed to the influence of increased crystalline orientation on thermoelastic response. X-ray studies on unstretched and stretched Hytrel films showed the presence of crystallinity. The magnitude of $\Delta\sigma$ and variation with temperature for Hytrel films was greater than that of either Spandex, Kraton GX-6500, or cross-linked natural rubber.

By comparison with the latter, only Hytrel was superior in the magnitude of $\Delta\sigma$ variations with temperature. This was attributed to intrinsic crystallinity and the orientation which developed on stretching. At extension ratios $\lambda = 2$, $\Delta\sigma$ for Hytrel was an order of magnitude greater than for cross-linked natural rubber.

ROBERT H. MARCHESSAULT, TERRY L. BLUHM, HRIRE M. GHARAPETIAN, et PUDUPADI R. SUNDARARAJAN. Can. J. Chem. **63**, 189 (1985).

On a étudié la relation qui existe entre le comportement thermoélastique dynamique et la morphologie moléculaire de systèmes de polymères à plusieurs phases. Un tensomètre sensible, équipé d'une lampe chauffante 50W/12V, a permis d'appliquer des pulsations contrôlées et uniformes à une face du film. Pour divers rapports d'élongation, tant pour des rapports croissants que pour des rapports décroissants, on a enregistré le changement de stress ($\Delta\sigma$) en fonction de la température de l'échantillon.

Dans le cas d'échantillons de Kraton GX-6500, le taux d'augmentation du stress $\Delta\sigma$ avec la température varie suivant que le solvant utilisé pour préparer les échantillons est le toluène, le cyclohexane ou l'heptane. La variation du $\Delta\sigma$ avec la température dépend du rapport d'élongation et cette valeur est toujours plus élevée lorsque l'élongation est croissante. Avec tous les échantillons de Kraton GX-6500 examinés alors que l'élongation était croissante, la pente du $\Delta\sigma$ en fonction de la température diminue lorsque l'élongation est de 100 à 150%. Toutefois, cette pente augmente à nouveau lorsque les élongations sont plus élevées. Faisant appel à la diffraction des rayons-X à de petits angles, on a examiné divers échantillons de Kraton GX-6500; suivant que le solvant utilisé pour préparer les échantillons est le toluène, le cyclohexane ou l'heptane, on observe la présence de structures en lamelles, en forme de bâtonnets ou sous formes sphériques. La dépendance extrême du comportement élastomère sur la morphologie polyphasique fait que la réponse thermoélastique d'échantillons de Kraton subit une forte diminution.

Des films de Spandex, préparés à partir de solutions dans le diméthyl formamide, ont été étudiés par diffraction des rayons-X à différents rapports d'élongation; ces études ont permis de montrer que la cristallisation commence à environ 150% d'élongation. Les études thermoélastiques effectuées sur les films de Spandex ont aussi montré la présence d'une augmentation dans la courbe du $\Delta\sigma$ vs. T à des élongations de 150 à 170%; on attribue cette propriété à l'influence d'une orientation cristalline accrue sur la réponse thermoélastique. Des études par diffraction des rayons-X sur des films de Hytrel tendus et non-tendus ont permis de montrer la présence d'une cristallinité. Par comparaison avec les valeurs obtenues avec le Spandex, le Kraton GX-6500 ou le caoutchouc naturel réticulé, la valeur de l'amplitude du $\Delta\sigma$ — et sa variation avec la température — observée avec des films de Hytrel est beaucoup plus élevée.

Par comparaison avec les autres, le Hytrel est le seul à présenter une supériorité dans l'amplitude des variations du $\Delta\sigma$ avec la température. On attribue cette propriété à une cristallinité intrinsèque et à l'orientation qui se développe par élongation. A des rapports d'élongation $\lambda = 2$, la valeur du $\Delta\sigma$ est au moins dix fois plus élevée que celle du caoutchouc naturel réticulé.

Introduction

Thermoelasticity is an increase in force with temperature for strained elastomeric systems. This is opposite to the behavior of most solids, especially metals, and has long been recognized as a fundamental characteristic of elastomers. The possibility of using the thermoelastic phenomenon to convert heat into mechanical work has been explored (1, 2). The extent of the thermal contraction of elastomers under tension, is directly related to their molecular structure, chain configurations, and the morphology (3, 4). In the thermodynamic treatment of thermoelasticity, the tensile force (*f*) required to maintain a constant extension is presented as the sum of the internal energy and entropy (5). The thermoelastic properties are usually studied by following the temperature dependence of the tensile force at constant length, for various extensions, and under equilibrium conditions. The energetic and entropic components and their variation with extension in relation to the structure of the polymer can be derived from these data (5). In the present studies, the dynamic thermoelastic behavior of three thermoplastic elastomers and natural rubber were studied by applying uniform, controlled heat pulses of 10 s duration while recording the variation of tensile force with temperature at different extensions.

Usually, thermoplastic elastomers are block copolymers containing segregated chain segments of relatively low glass transition temperature. These segments, which are responsible for the elastomeric behavior of the copolymers, are referred to as "*soft*" segments. The other part of the copolymer chains consist of portions, which are capable of undergoing intermolecular association, thereby constraining the polymer chains without the need of covalent crosslinks. These parts are referred to as "*hard*" segments. At least two such hard segments per molecule are necessary for development of a three-dimensional pseudo-network structure.

Three thermoplastic elastomers, Kraton-GX6500, DTEX-Spandex, Hytrel-4056, and vulcanized natural rubber, as reference material, were used in the present studies. The elastomeric copolymers differ from one another not only in their molecular structure, but also in their morphologies. Kraton is not crystalline and does not crystallize under strain. Spandex is also not crystalline but exhibits strain-induced crystallization. Hytrel is crystalline in both unstretched and stretched states.

Kraton-GX6500 (Shell) is a hydrogenated, styrene–butadiene–styrene block copolymer containing 29 mol% of styrene. From small-angle X-ray scattering studies on solvent-cast Kraton films, it is known (6) that, depending on the casting solvent, the films possess spherical, cylindrical, or lamellar microdomains, which are obtained in the order of increasing solvent affinity for polystyrene. Thermo-mechanical studies (6) on Kraton, show that, under strain, films with spherical domains behave like natural rubber, while films with cylindrical and lamellar domains exhibit stress softening and yielding, respectively.

DTEX-Spandex fibres consist of polyurethane and inorganic fillers. Polyurethane elastomers may be considered block copolymers composed of relatively short areas of urethane "*hard*" segments and longer, flexible polyester or polyether "*soft*" blocks. The polarity of the "*hard*" segments may cause formation of hydrogen bonds, resulting in microphase separation (7). The "*soft*" blocks of some polymers have crystalline structure (8, 9), but other soft segments are amorphous and can undergo crystallization upon stretching, especially when the molecular weight is high. Linear polyether- or polyester-urethane elastomers based on aromatic diisocyanates and chain extended with low molecular weight diols under different extensions exhibit X-ray diffraction patterns corresponding to the onset of crystallization at about 150% elongation (10).

Hytrel (DuPont) is a thermoplastic elastomer. It is produced in a range of compositions of poly (tetramethyleneoxy) "*soft*" and tetramethylene terephthalate "*hard*" segments. Hytrel Type 4056 was used in the present studies. Mole fraction of the

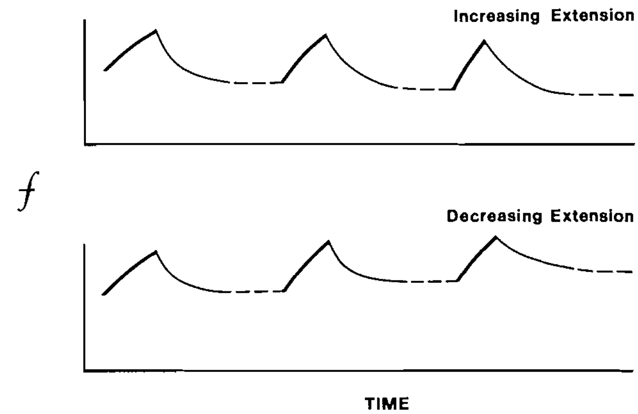

FIG. 1. Schematic of the variation of tensile force with time, for increasing and decreasing extensions. The heavy line represents the period when the heat lamp is on.

hard segments of this copolymer (11), determined by ^{13}C nmr has been reported to be 0.8. Electron microscopy studies have shown that Hytrel exhibits a two-phase morphology (12). The structure of the polymer consists of interpenetrating and continuous amorphous and crystalline phases rather than discrete domain structures as observed in styrene–butadiene copolymers (6). Small-angle light scattering and optical microscopy studies have shown that the crystalline phase is basically spherulitic (13). Application of stress to Hytrel produces orientation of the crystallites with their long axes perpendicular to the drawing direction (12). This orientation is most likely the effect of destructuring of the crystalline lamellae during drawing and is not recoverable upon the release of the applied force. It has also been observed that irreversible disruption of crystalline regions results in pronounced stress softening (12).

A sample of cross-linked natural rubber was also used in these studies for comparison. It is known that natural rubber is capable of undergoing strain-induced crystallization (3). However, the network structure of cross-linked natural rubber is affected by strain at much higher extensions than for thermoelastic elastomers.

Experimental

Thermoelasticity measurements

The thermoelasticity measurements were performed using a computerized tensometer setup. Each sample was initially subjected to stepwise increasing, followed by decreasing, extensions. At each extension, 4–6 heat pulses of 10 s duration, with 20 min relaxation time between each two consecutive pulses, were applied to the samples. The increase in the temperature for each heat pulse of 10 seconds duration was 31–33°C, which was measured by a thermocouple placed underneath the sample. The change in the tensile force during each thermal stimulation and after relaxation of 20 min was recorded.

It was observed that, for the initial 2–3 heat pulses applied at each extension, the tensile force after relaxation (f') was smaller than the tensile force before applying the previous heat pulse (f), if the pulse was applied after an increasing extension, and vice versa if the pulse was applied after a decreasing extension. However, the difference between f and f' decreased continuously at a given extension, and after 4–5 heat pulse–relaxation periods f' became almost equal to f. This is schematically shown in Fig. 1.

Preparation of the films

The films were cast by evenly coating the smooth surface of a Teflon block with a solution of the polymer. The coated block was placed horizontally in a chamber saturated with solvent vapour. The

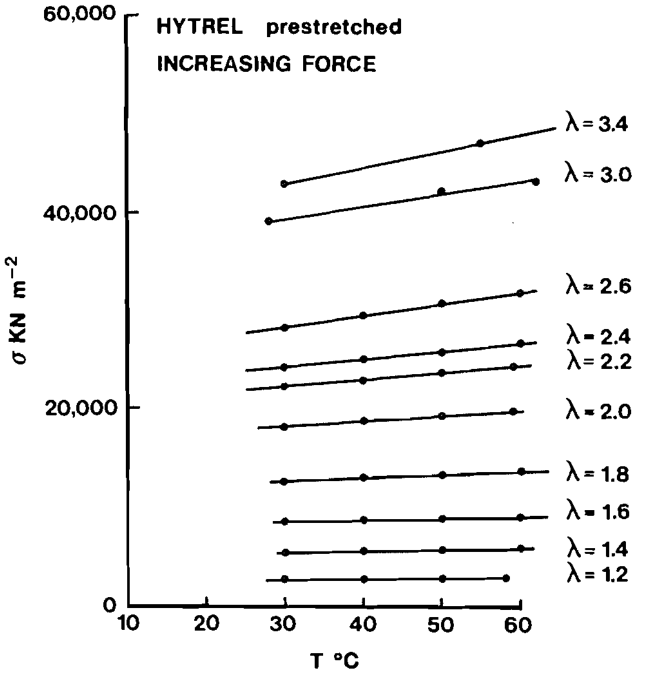

FIG. 2. Variation of stress (σ) with temperature, for different elongation ratios (λ) are shown for Hytrel.

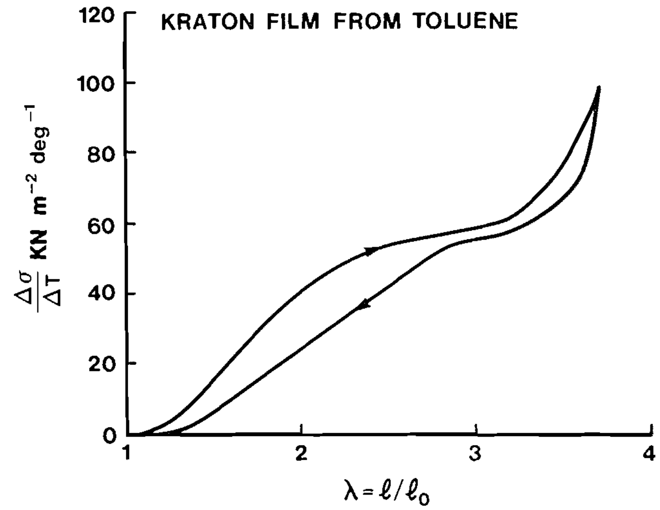

FIG. 3. Plots of variation of $\Delta\sigma$ with extension ratios (λ), for increasing and decreasing λ are shown for Kraton films cast from toluene.

vapour concentration was gradually lowered allowing the coating to dry slowly and form a uniform film. The films were then placed in an oven at about 100°C for 4 h. Rectangular samples, 130 mm × 70 mm in size, were cut from the films which were 0.1 to 0.2 mm thick. The thickness and width of the films were measured, at each extension, with a micrometer before applying the heat pulse.

The Hytrel films were prepared from the solution of the polymer in 1,2-dichloroethane, at room temperature. Toluene, cyclohexane, and heptane were used for Kraton. The Spandex solution was prepared by heating the Spandex fibres in dimethyl formamide at 100°C followed by removal of the inorganic fillers by sedimentation.

Hytrel films were also prepared by heat pressing the polymer granules between 2 mm thick Teflon sheets under a gradually applied pressure up to 6 psi at 160°C followed by rapid cooling to room temperature. Since these samples "necked" on stretching, all samples of Hytrel were cold-stretched until necking was completed (about 300-500%). X-ray examination showed a small degree of uniaxial orientation of the crystalline phase after this operation.

Small-angle X-ray scattering data were collected using a Kratky camera, equipped with a proportional counter, pulse height analyzer, and a step scanner. Wide-angle diffraction patterns were recorded using a Warhus flat plate camera. In both cases, CuK_α (λ = 1.5418 Å) radiation was used.

Results and discussion

In the thermoelasticity measurements, the variation of the stress (σ) with the rise in temperature (T) for the polymer films subjected to 10-s heat pulses at different extensions was recorded. At each extension (λ), 4–6 heat pulses were applied to the samples. However, only the data obtained from the last thermal stimulation at each extension were used in the present studies. Some typical results on variation of σ vs. T at different extensions are presented in Fig. 2. The data on the variation of σ with T for various values of λ was used to construct the curves of $\Delta\sigma/\Delta T$ vs. λ. Here, $\Delta\sigma/\Delta T$ is the change in the stress due to the change in the temperature from 30 to 50°C during the last heat pulse at an extension λ. The magnitude of $\Delta\sigma/\Delta T$ and the variation of the slopes of the plots of $\Delta\sigma/\Delta T$ vs. λ were correlated with sample microstructures derived by X-ray diffraction and scattering techniques as well as microscopic examination.

Small-angle X-ray scattering (SAXS) studies performed on solution-cast Kraton samples from toluene, cyclohexane, and heptane showed that these polymer films contained lamellar, cylindrical, and spherical structures, respectively, in agreement with previous conclusions (6).

Plots of $\Delta\sigma/\Delta T$ vs. λ for the Kraton samples are presented in Figs. 3–5. It is seen that the slopes in these cases decrease between 120–180% elongations.

SAXS curves recorded for the films cast from toluene, cyclohexane, and heptane are shown in Figs. 6, 7, and 8 respectively. In all cases, the data were collected before and after an extension of 125%. Fig. 6*a* shows a maximum at $s = (2 \sin \theta)/\lambda = 3.1 \times 10^{-3}$ Å^{-1}, which corresponds to a periodicity of about 320 Å in this film, which is known to possess lamellar structure. However, upon stretching 125%, this maximum vanishes. This phenomenon is reversible, i.e., when the film is relaxed, the maximum reappears. Accordingly, the phenomenon has been interpreted as due to the orientation of the lamellae in the plane of the film upon stretching. Since the plane of the X-ray beam is normal to the plane of the film, any periodicity normal to the plane of the film is not observed. Partial alignment of lamellar domains has been observed by other investigators (14). Figure 7*a*, corresponding to the cylindrical morphology, shows a maximum at $s = 3.4 \times 10^{-3}$ Å^{-1} and this results in an inter-cylinder distance of 290 Å. Upon stretching, this maximum is lost. However, another broad maximum is recorded at $s = 6.25 \times 10^{-3}$ Å^{-1} inter-cylinder distance of 150 Å. It is possible that, compared to the case of the unstretched sample, the alignment of the cylinders upon stretching reduces the inter-cylinder distance, following an affine deformation mechanism. The orientation is not nearly as complete as in the lamellar case , as evidenced by the continued presence of a scattering maximum, although it is greatly reduced in intensity. Figure 8 for the case of the spherical morphology shows that the dimensions increase in the direction of stretch, in direct correspondence with film extension.

Since orientation of the microstructure of the different Kraton samples at different extensions is observed by X-ray

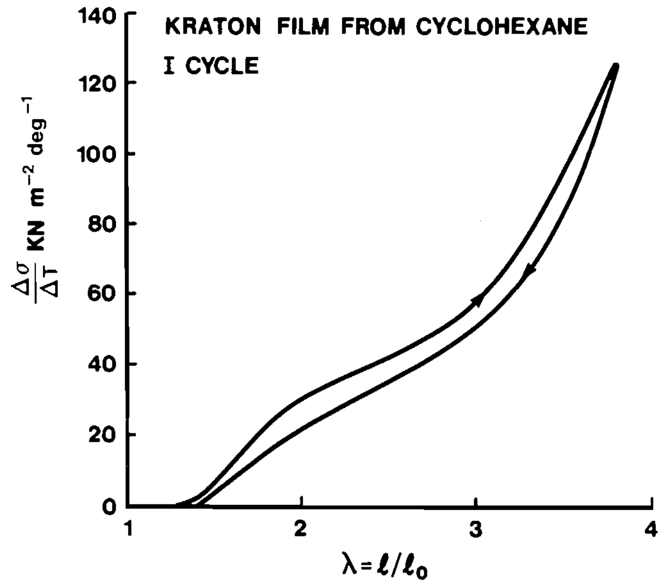

FIG. 4. Same as Fig. 3, but during the first cycle of measurement on Kraton film cast from cyclohexane (see also Fig. 9).

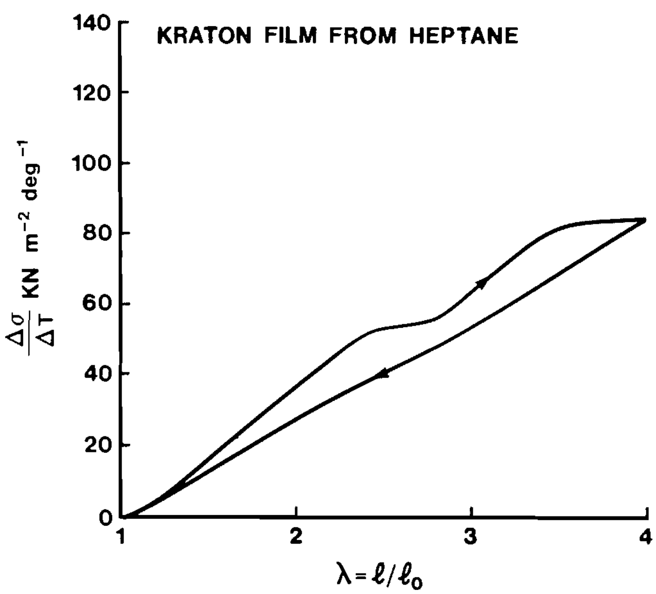

FIG. 5. Same as Fig. 3, but for Kraton film cast from heptane.

scattering studies, it is suggested that the decrease in the rate of increase of the $\Delta\sigma/\Delta T$ with λ (range of 120–180% elongation) is related to microdestructuring which negatively affects the thermoelasticity of these materials. At higher extensions, alignment of the stable domains is high and this sharply increases the slopes of the curves of $\Delta\sigma/\Delta T$ vs. λ. The extent of the "*low slope*" region was greatest for the sample cast from toluene and shortest for the one cast from heptane. The latter observation may be attributed to the linear extent of the lamellar and cylindrical microstructure and consequent orientation effects compared with the absence of microstructure anisotropy for the spherical domains during extension.

The rapid decrease in the slope of the curves of $\Delta\sigma/\Delta T$ vs. λ observed in the measurements performed during decreasing extensions were attributed to the orientation of the microstructure and stress softening during increasing extension of the samples. The plot of $\Delta\sigma/\Delta T$ vs. λ for the second cycle of

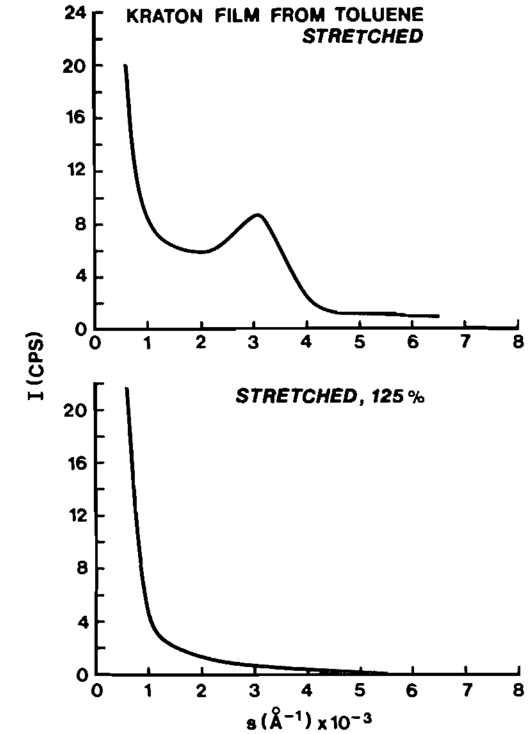

FIG. 6. Small-angle X-ray scattering curves for Kraton film cast from toluene, before and after stretching.

measurements, performed on the Kraton film cast from cyclohexane, is presented in Fig. 9. It was observed that the first cycle of studies considerably influences the thermoelastic properties of the material. The slope in the plot of $\Delta\sigma/\Delta T$ vs. λ, compressed to the first cycle, indicates partial destructuring of the polymeric microstructure after completion of the first cycle.

It is known that polyurethane undergoes strain-induced crystallization (11). X-ray scattering studies performed on the films prepared from Spandex fibres also showed strain-induced crystallization of the "*soft*" segments at an elongation of 150%. From thermoelastic measurements on the film cast from a solution of Spandex in dimethyl formamide, it is observed (Fig. 10) that the slope of the curve of $\Delta\sigma/\Delta T$ vs. λ increases rather abruptly at elongations of 140–160%. The generation of a crystalline phase in the strained Spandex sample is responsible for increasing the thermoelastic response of the sample above elongations of 140–160%. The increase in thermoelastic response can be attributed to thermally induced melting in the "*soft*" segments. The rapid drop in slope of $\Delta\sigma/\Delta T$ with λ during decreasing extensions is attributed to the reversal of strain-induced crystallization. In theory, the slope of the reverse curve is a function of rate of decrease of strain but this was not investigated in detail.

For both solution-cast and heat-pressed Hytrel films necking occurred during stretching, resulting in unidirectional orientation. For this reason the thermoelasticity measurements were performed on prestretched films. The extent of thermal contraction manifested by the magnitude of $\Delta\sigma/\Delta T$ at different extensions was greatest for Hytrel, compared with the other samples (cf. Fig. 11). The slopes of the curves of $\Delta\sigma/\Delta T$ vs. λ, for both Hytrel films, show a sharp increase above elongations of 120–140%. Wide angle X-ray diffraction patterns from prestretched (necked) and unstretched samples in the relaxed state show the presence of a crystalline phase in both

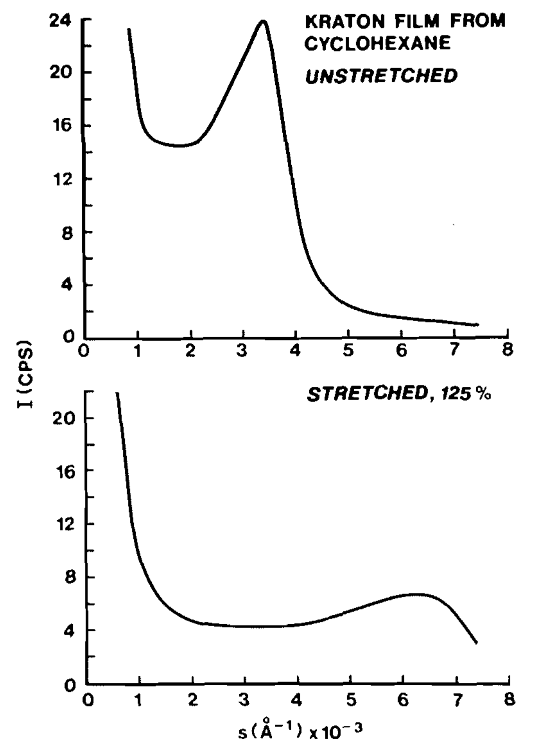

FIG. 7. Same as Fig. 6, but for Kraton film cast from cyclohexane.

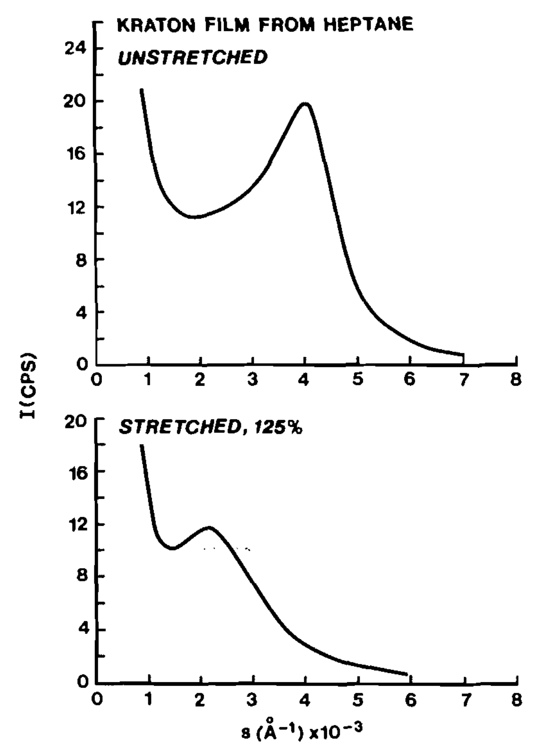

FIG. 8. Same as Fig. 6, but for Kraton film cast from heptane.

cases, and fibre-type orientation in prestretched samples. The superior thermoelastic response of Hytrel is attributed to the presence of homogeneously distributed, thermally stable, and partially oriented crystallites. The increase in the slope of the curves of $\Delta\sigma/\Delta T$ vs. λ at elongations of 120–140% could be due to the strain-induced crystallization.

The plot of $\Delta\sigma/\Delta T$ vs. λ for natural rubber is presented in

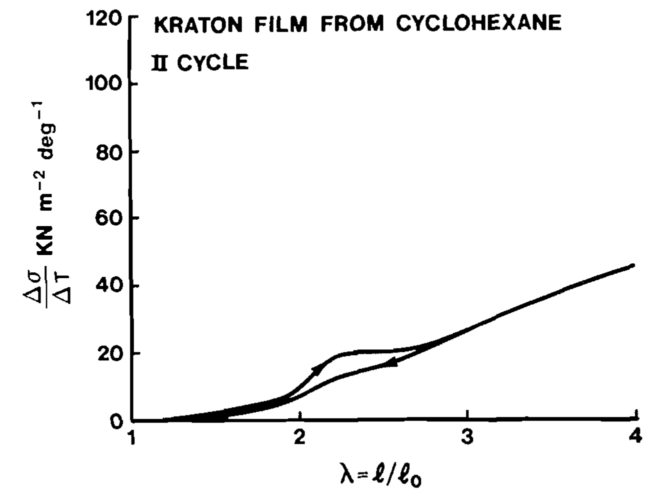

FIG. 9. Plots of variation of $\Delta\sigma$ with extension ratio (λ), for increasing and decreasing λ, are shown for the second cycle of measurement on Kraton film cast from cyclohexane (see also Fig. 4).

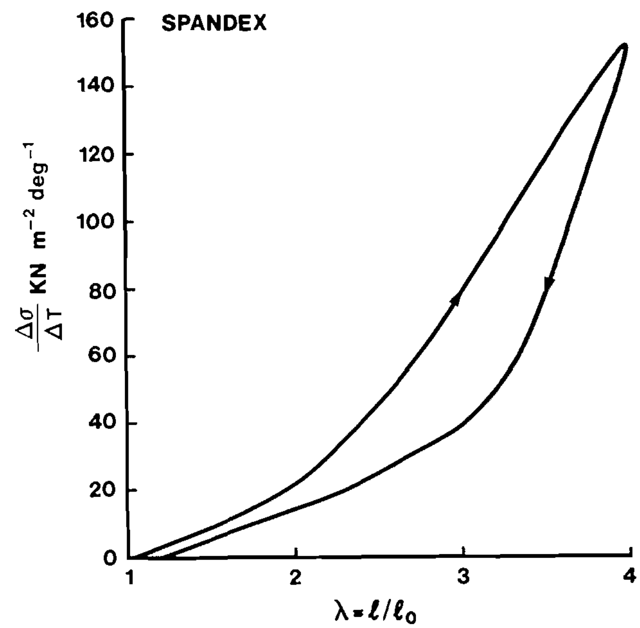

FIG. 10. Plots of variation of $\Delta\sigma$ with extension ratio (λ), for increasing and decreasing λ, for Spandex film cast from dimethyl formamide.

Fig. 12. It is observed that there is a relatively small change in the slope of the curve for increasing or decreasing extensions at elongations of about 120%. Compared with similar changes for films or Kraton, Hytrel, and Spandex, the changes for natural rubber are less significant, and this could be attributed to the affine behavior of an amorphous, covalently crosslinked structure, which undergoes very little textural change during extension. Also, it is well known that strain-induced crystallization does not occur in natural rubber at the low extension ratios employed here.

Conclusions

A comparison of the thermoelastic behavior of the four elastomers under investigation shows that increasing strain (with consequent orientation of microstructure and/or strain-induced crystallization of "soft" segments) has a positive influence on

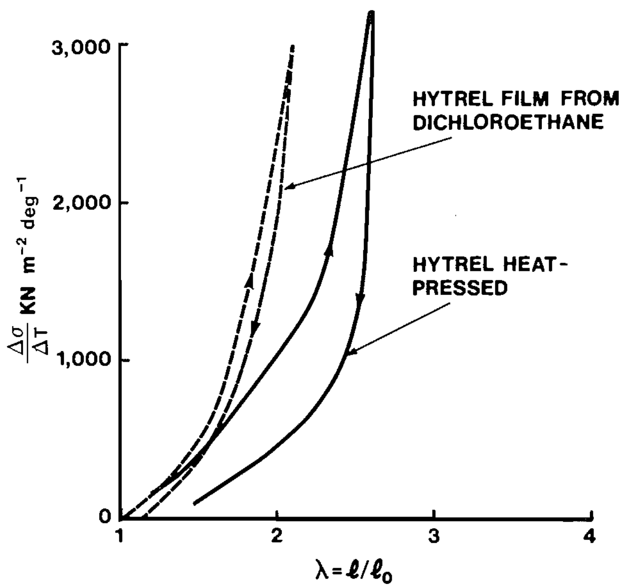

FIG. 11. Same as Fig. 10, but for heat-pressed and dichloroethane-cast films of Hytrel.

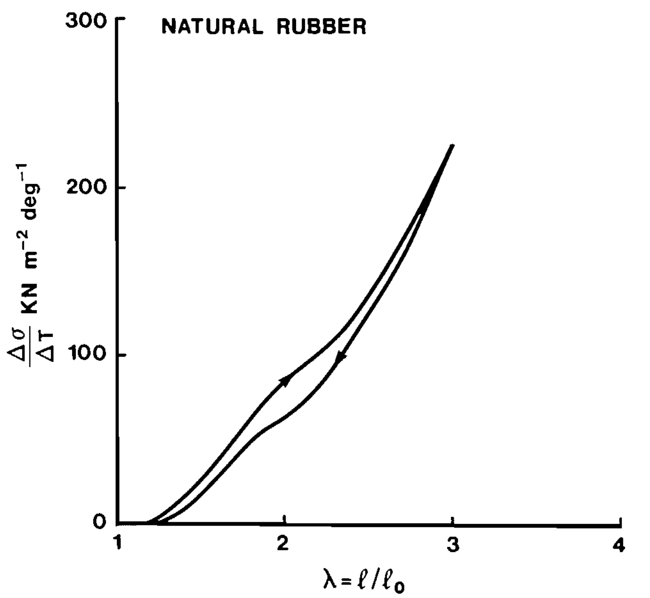

FIG. 12. Same as Fig. 11, but for natural rubber.

the extent of thermal contraction. Permanent orientation (e.g. prestretched Hytrel) also has a positive influence on thermoelastic properties probably because of removal of a spherulitic texture. Strain-induced crystallization of "soft" segments greatly increases the thermal response due to thermal melting of the crystallites and the concomitant increase in entropy during the application of a heat pulse.

Of the four materials, Hytrel best demonstrated the benefit to be derived from permanent crystallites ("hard" segments), preorientation and strain-induced crystallization of "soft" segments. Spandex also crystallizes upon stretching, but reversibly with stress. The "hard" segments in Spandex do not form a separate crystalline phase and hence permanent cross-links do not exist. Clearly, the permanent cross-links, oriented in the stretch direction, as in Hytrel, are the desirable contributors for a strong thermoelastic response.

In the case of natural rubber, the effect of moderate strains on thermoelastic behavior is well documented. The results of Fig. 12 are surprising only by comparison with the data for Hytrel, which at $\lambda = 2$ show a $\Delta\sigma/\Delta T$ which is an order of magnitude greater. The most obvious explanation is in terms of the above referenced cross-links. The near-reversibility of the curves in Fig. 11 suggests that strain encourages the development of intermolecular forces between Hytrel macromolecules to provide a pseudo-network with a distribution of crosslink strengths. This develops a network with a memory, at least up to strains of $\lambda = 2-3$ and probably well beyond.

In comparison to Hytrel, Kraton samples show less pronounced thermoelastic behavior. This can be attributed to a microtexture which is based on weak segment interaction, compared to crystallization forces. Entropy contributions to the thermoelasticity are low. Extension disrupts the microtexture and recovery is exceedingly time-dependent. Accordingly, the thermoelasticity of Kraton is difficult to exploit.

Again, in comparison to Hytrel, Spandex exhibits a softer thermoelastic behavior. It is probably optimized for comfort factors in garment application. Cross-linked natural rubber is similar in behavior and would probably show the rapid rise in thermoelastic response of Hytrel with extension but only at much higher λ where crystallization is known to develop. At that point both permanent and pseudo-crosslinks would be intermeshed.

In the case of the ideal rubber, stress-strain behavior is predictable if there is affine deformation and no intermolecular interaction. The present study suggests that maximum thermoelastic response is dependent on affine deformation with development of reversible intersegment forces as extension takes place. The very large difference in thermoelastic response of Hytrel compared to crosslinked natural rubber demonstrates the remarkable difference between crystallite networks vs. covalent networks in elastomers. Given the imagination of polymer chemists, the limits of elastomer technology are probably still far away.

For non-ideal elastomers there are both entropy and enthalpy contributions to the stress. The measurement of $\Delta\sigma/\Delta T$ provides one with a means of separating the entropy and enthalpy contributions to the stress at constant λ given by

$$\sigma_s = T(\delta\sigma/\delta T)_{p,l}$$

$$\sigma_e = (\delta H/\delta L)_{p,T} = \sigma - \sigma_s$$

where T is the absolute temperature, and p, s, H, and L represent the pressure, entropy, enthalpy, and length, respectively. Thus, thermoelastic data gathered using a tensometer as described here can be used to compare elastomers on the basis of these entropy contributions to the developed stress. Although these equations are only strictly accurate when constant pressure is replaced by constant volume, they are very nearly correct at small extensions, where affine deformations occur.

The surface chemistry and thermodynamics of the nucleation, growth, configuration, and host–guest interactions of small particles within softenable substrates is investigated. It is found that novel subsurface particle monolayers form rather generally when inorganic materials are appropriately deposited onto softened (or subsequently softened) organic polymer substrates; partially embedded structures are generally formed by organic particulate materials, although these can also be embedded by exposure to a solvent vapour. For both rigid preformed particles spread onto the polymer surface, and for flexible growing clusters (as occur in vacuum deposition), the tendency for complete immersion is thermodynamically determined by the same simple inequality among the surface and interfacial tensions. Modelling of the polymer molecule configurations in the vicinity of subsurface particles predicts a novel entropic force of sufficient magnitude to explain why the particles form a monolayer a few tens of nm below the surface, rather than dispersing throughout the polymer, and why this structure is remarkably stable on extended heating. With the convenient fabrication technique of vacuum deposition, subsurface formation is further limited kinetically, by growth mode and sinking rate considerations, to generally low melting point inorganics and to certain ranges of deposition conditions; once subsurface particles are formed, their subsequent growth during the deposition process generally occurs at constant (nearly close-packed) surface coverage by a combination of material-capture and coalescence. After these nearly monodisperse particles grow beyond ~0.4 μm, they begin to bridge into a continuous subsurface structure. These vacuum-deposition phenomena are quantitatively explained by kinetic models of the formation and growth mechanisms.

G. J. KOVACS et P. S. VINCETT. Can. J. Chem. **63**, 196 (1985).

On a étudié la chimie de surface et la thermodynamique de la nucléation, de la croissance, de la configuration et des interactions "hôte–récepteur" de petites particules à l'intérieur de substrats qui peuvent être ramollis. On a trouvé que, si des produits inorganiques sont déposés d'une façon appropriée sur des polymères organiques ramollis (ou qui ont subséquement été ramollis), il se forme d'une façon assez générale de nouvelles monocouches de particules sous la surface; généralement, les particules organiques forment des structures qui sont partiellement incrustées même si ces composés peuvent être incrustés par une simple exposition à des vapeurs de solvant. Tant pour les particules rigides préformées étendues sur la surface du polymère que pour les agglomérats flexibles croissants (qui se produisent par un dépot sous vide), la tendance à obtenir une immersion totale est déterminée par la même inégalité simple entre les tensions de surface et interfaciales. A l'aide de modèles des configurations de la molécule de polymère près des particules sous la surface, on peut prédire l'existence d'une nouvelle force entropique dont l'amplitude est telle qu'elle peut expliquer pourquoi les particules forment une monocouche à quelques nm sous la surface plutôt que de se disperser à travers tout le polymère et pourquoi cette structure est si stable lorsqu'on la chauffe d'une façon prolongée. Compte-tenu de l'existence, d'une part, de la technique commode de fabrication par dépot sous vide et, d'autre part, de considérations cinétiques relatives à la méthode de croissance et aux vitesses d'enfoncement, la formation sous la surface est généralement limitée à des composés inorganiques de bas point de fusion et à certaines conditions de dépot; lorsqu'il y a eu formation de particules sous la surface, une combinaison de capture de matériel et de coalescence fait que leur croissance subséquente, au cours du processus de dépot, se produit généralement avec une couverture de la surface qui est constante (pratiquement tassée). Lorsque ces particules pratiquement monodispersées atteignent des dimensions d'environ 0,4 μm, elles commencent à se joindre pour former une structure continue sous la surface. On peut expliquer quantitativement ces phénomènes de dépot sous vide en faisant appel à des modèles cinétiques pour les mécanismes de formation et de croissance.

1. Introduction

The surface chemistry of thin film formation during vacuum deposition onto rigid substrates has been studied extensively for the past half century (1). However, structures formed on/in softenable substrates have received very little consideration, save for one technologically important process involving the vacuum deposition of the photoconductive material Se (2). In this process, the substrate is a thermoplastic material which is heat-softened during Se deposition. Within a rather broad "window" of substrate temperature and deposition rate, the Se can form into a nearly close-packed monolayer of submicron, nearly monodisperse amorphous spheres embedded a few tens of nm under the polymer surface. This unique structure, illustrated in Fig. 1, is remarkably stable under extended heating. It can also readily be formed from a wide range of materials if they are incident as a smoke (3) onto a heated thermoplastic, or if appropriate particles are merely spread over the surface which is subsequently heat- or vapour-softened. However, with the very convenient technique of vacuum deposition onto heated thermoplastics, kinetic factors somewhat limit the formation of subsurface particles, usually to low-melting materials; even then, kinetic factors further limit it to certain ranges of substrate temperature and deposition rate. These unique vacuum-deposited structures possess other very unusual properties. The structure is very nearly independent of substrate temperature and deposition rate over very large ranges, within the "window" mentioned above. The diameter of the spheres can be varied from very low values up to at least ~0.4 μm *at constant surface (projected-area) coverage,* merely by varying the total quantity Q of material deposited per unit substrate area; this of course implies that a continual aggregation/coalescence process is occurring. Very strikingly, the diameter of the spheres is simply proportional to Q.

Structures of this kind may have major technological appli-

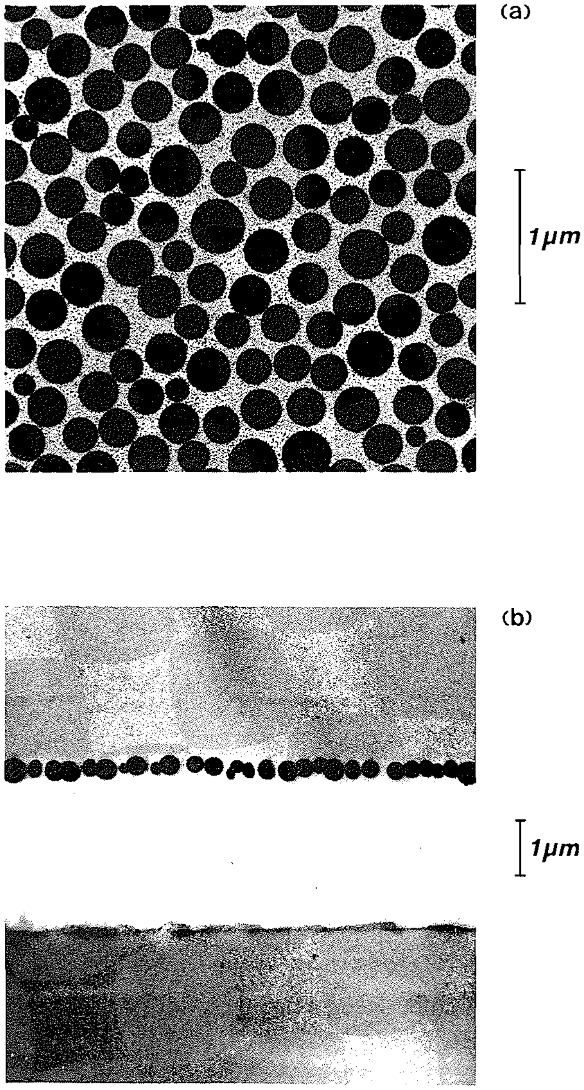

FIG. 1. TEM of Se, vacuum deposited onto heated thermoplastic, looking (*a*) normal to substrate surface, (*b*) parallel to substrate surface.

cations. For example, the Se material, shown in Fig. 1, has important uses as an electrophotographic film which is usually developed by a migration imaging process to form a visible image (2, 4–6). The many remarkable properties and demonstrated applications of this unique material have recently been reviewed (7).

In this paper we analyze the surface chemistry of the novel subsurface and related structures, including a detailed analysis of the interactions between particles and polymers; we also model the kinetics of the formation and growth mechanisms during vacuum deposition. The experimental observations are summarized in section 2. The roles of the surface and interfacial tensions of the particle and substrate materials in determining the thermodynamically most favourable structures are investigated in section 3. The configurations (8) of the polymer molecules and their interfacial interactions (9) with the particle surfaces are modelled in section 4, and are shown to result in a novel entropic force of sufficient magnitude to explain why particles form a monolayer rather than dispersing throughout the polymer, and why this structure is remarkably stable on extended heating. Kinetic models of the formation mechanism during vacuum deposition onto softenable substrates and also

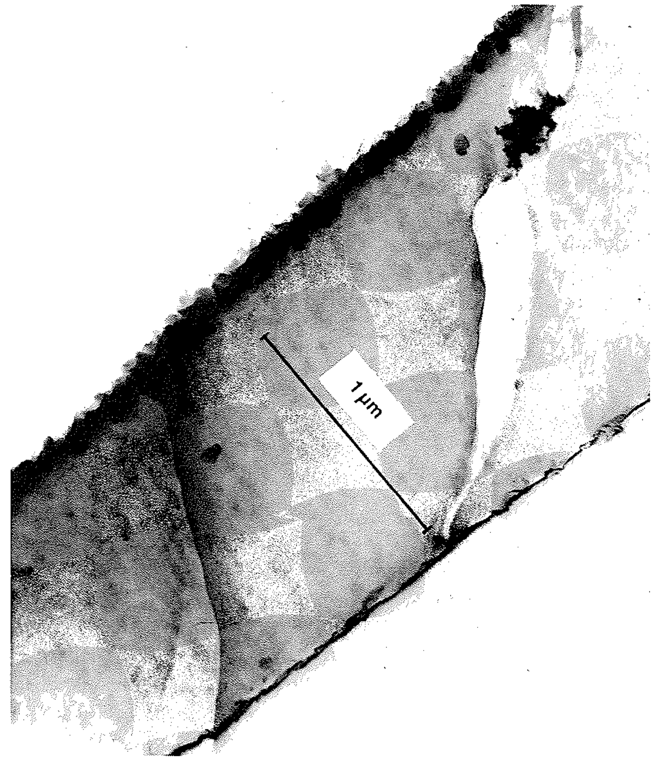

FIG. 2. TEM of vanadyl phthalocyanine, vacuum deposited onto heated thermoplastic, looking parallel to the substrate surface.

of the subsequent growth of subsurface particles are given in section 5.

2. Summary of experimental data

Apart from vacuum deposition, which we discuss below, there are several methods of forming subsurface structures from almost any particulate material. For example, we have formed such structures from both inorganic and organic materials (principally phthalocyanines), by a novel spreading technique. The phthalocyanine or other particulate is finely dispersed in a liquid (e.g. methanol) which is a non-solvent for the polymer substrate. The dispersion is then coated as a thin liquid film by a gravure coating technique. After the liquid evaporates, a thin powder film is left which can easily be wiped off and is therefore clearly above the substrate surface. If the substrate is now softened by heating, inorganic particles now form the subsurface monolayer. Organic particles, however, become partially embedded, much as in Fig. 2; in this state, a substantial amount of pigment can still be wiped off the film surface with a light paper tissue. However, if the polymer substrate is instead softened by exposure to a vapour which is a solvent for the polymer, complete embedding of the organic particles is achieved, generally within a few seconds. Typical solvents suitable for the styrene–hexylmethacrylate copolymer generally used in the technological applications (7) of the Se material are toluene, methylene chloride, and 1,1,1-trichloroethane. After vapour exposure, the polymer surface has a shiny glazed finish and since the particles are completely submerged the film can no longer be wiped off. Such embedded organic particulate structures, like their Se counterparts, have application as an electrophotographic film, in this case infrared-sensitive. In addition to vacuum deposition and the spreading technique, embedded particulate structures can also be made from a wide range of inorganic materials by a smoke (3) method. Material is evaporated in a high (atmospheric) background pressure of flowing nitrogen. Under these conditions, the material forms into a smoke which is carried by the gas flow onto a heated polymer substrate. The particle deposition can also be carried out by cascade and electrophoretic techniques. In the cascade technique, colloidal-size particles are produced by standard methods and are then picked up triboelectrically onto xerographic carrier beads. The beads are cascaded over the polymer substrate surface to deposit the particles. Particle sinking is then accomplished by either heat or vapour softening of the substrate, as discussed above. In the electrophoretic technique, the colloidal-size particles are suspended in an insulating liquid medium. They are then deposited onto the polymer substrate, which is in contact with the liquid, by applying an electric field through the liquid and thereby driving the naturally-charged particles to the polymer substrate. With appropriate suspending liquids, the particles may already become embedded at this stage. If not, after evaporation of the liquid, the polymer substrate may be either heat- or vapour-softened as above to effect embedding.

Turning now to the vacuum deposition technique, we have made a rather comprehensive experimental study of the formation of vacuum-deposited structures on heated thermoplastic substrates. The evaporants included a wide range of inorganic and organic materials and the experimental details have been given elsewhere (10). In general, two types of embedded structures have been observed, which appear to represent cases of thermodynamic equilibrium.

The first equilibrium structure, and by far the most important, is a monolayer of completely embedded spheres; an example is shown in the TEM of Fig. 1(*b*), for which the evaporant was Se and the substrate a heated styrene–hexylmethacrylate copolymer. The second equilibrium structure consists of partially embedded particles. This has been observed in the evaporation of vanadyl phthalocyanine onto the heated copolymer, the embedded lower portion of the particles being clearly seen in Fig. 2. The structure of Fig. 1(*b*) is readily obtained with low melting inorganic evaporants (10–12) but, at best, only partially submerged structures can be obtained with organic evaporants.

The subsurface monolayer structure was found to possess remarkable thermal stability. Continued heating of the polymer substrate at 115°C in vacuum for 3 days after formation of a subsurface Sn structure (similar to the Se structure in Fig. 1) failed to produce even the slightest migration of the nearly single-crystalline Sn particles into the polymer, as determined by electron microscopy of microtomed sections. A simple calculation (10) shows that this period of time should be more than ample for random Brownian motion to scatter the particles throughout the 1.5 μm-thick polymer matrix, in the absence of a restraining force.

The kinetics of subsurface particle formation (13–17) and growth (17) have also been determined for vacuum deposition. The formation data is summarized in Fig. 3, where the solid line gives the transition between surface and subsurface particle formation for Se on the well characterized (15) styrene–hexylmethacrylate copolymer substrate. The dashed lines represent the same transition for Sn on this copolymer substrate. At low deposition rates, the surface/subsurface transition lines for the two evaporants are nearly identical, with an activation energy of ~50 kcal/mol, which is also equal to the polymer's activation energy for viscous flow. At high deposition rates, the

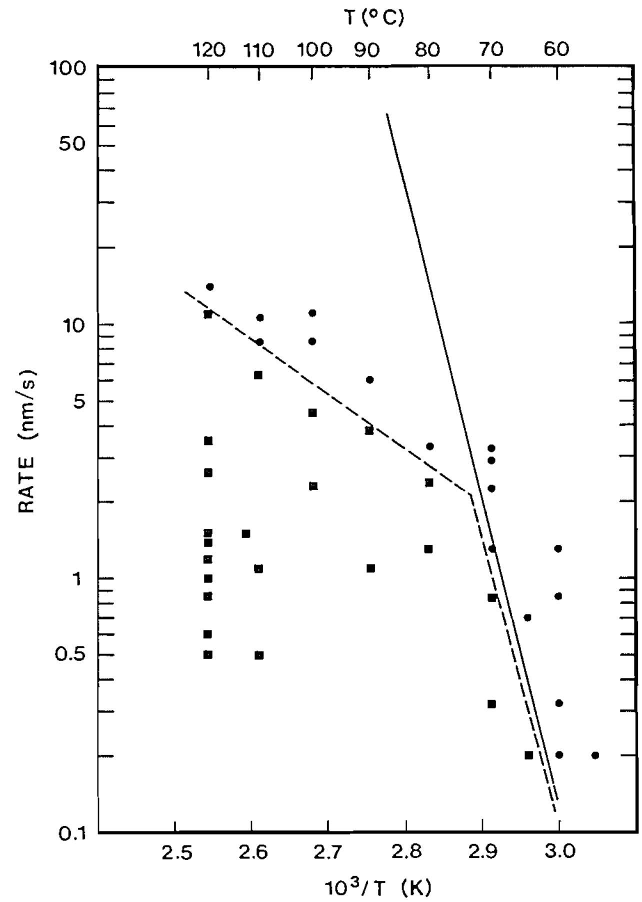

FIG. 3. Subsurface particle formation conditions for Se and Sn on our styrene-rich copolymer. Solid line separates region of surface film formation (right) and subsurface particle formation (left) for Se on the polymer. Dots represent surface Sn deposits and squares represent subsurface Sn deposits with the dashed curve dividing these two regions for Sn.

activation energy for the Se transition remains at 50 kcal/mol, but that for Sn drops to ~10 kcal/mol. Many other high-melting inorganic evaporants were studied, and formed only surface deposits under all accessible deposition conditions, as illustrated by the V deposit shown in Fig. 4. An interesting feature of this V film, common to virtually all above-surface deposits of inorganic materials on soft substrates, is that it consists of a thin continuous underlayer followed by superposed island structures. (The structure observed between the large dark islands is definitely due to a thin continuous film, since the underlying polymer has been dissolved away (10).) This normally-rare Stranski–Krastanov (S–K) growth mode (1) is thought to be one important factor limiting subsurface particle formation with inorganic evaporants (13).

The growth data for subsurface Se spheres is given in Fig. 7 of ref. 17. The projected area coverage $N\pi\langle a\rangle^2$ of the spheres remains remarkably constant over a rather large range. The average sphere radius, $\langle a\rangle$, and the number of particles per unit area, N, correlate with deposition time, t (at constant deposition rate), according to $\langle a\rangle \propto t$ and $N \propto t^{-2}$, at least up to a fairly large value of $\langle a\rangle$ ~0.2 μm. However, for larger values of $\langle a\rangle$, bridging of subsurface spheres begins, with eventual formation of a continuous *subsurface* film as shown in Fig. 5. The particulate structures obtained are almost independent of deposition rate and temperature over very large ranges, so long as one

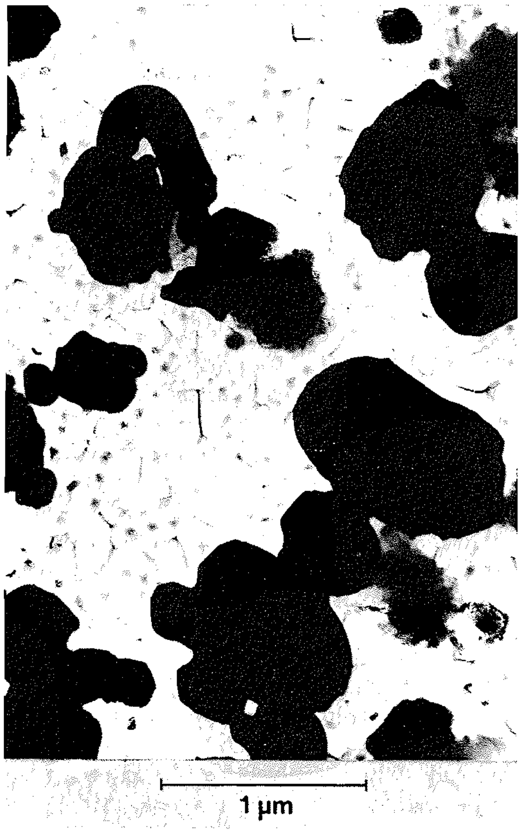

FIG. 4. TEM of V surface film deposited onto our heated styrene-rich copolymer, looking normal to the polymer surface.

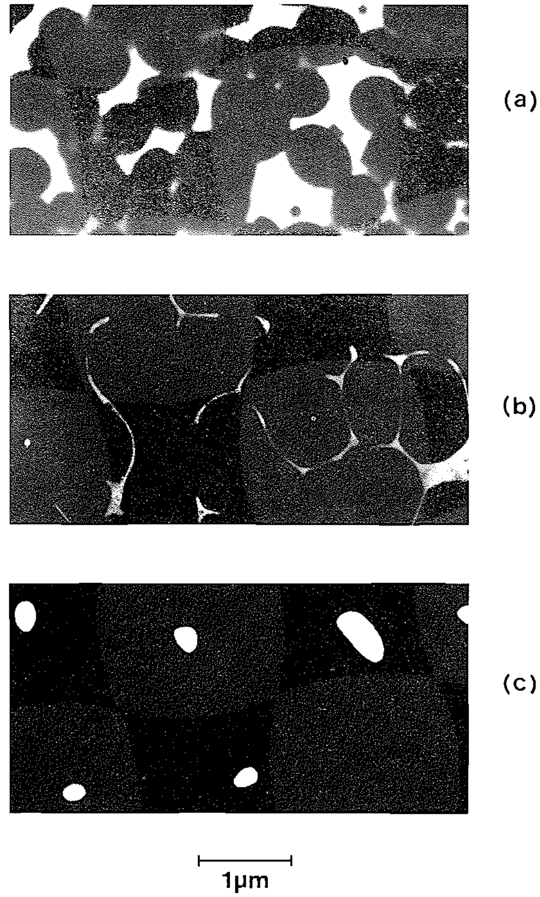

FIG. 5. TEM's of successive stages of the growth of subsurface Se spheres into a continuous surbsurface film.

remains within the "window" within which subsurface structures are formed at all.

3. Thermodynamic analysis of embedding

Thermodynamically, the most favourable state for any isochoric, isothermal system is the state with the lowest Helmholtz free energy, F (18). This free energy has both a volume and a surface contribution. We assume that the former is constant in our systems, corresponding to constant internal morphology within each material, so that only the surface contribution varies according to the particle-substrate configuration. To keep our analysis simple, we consider only homogeneous materials with isotropic surface tensions. For very small particles, gravitational forces are negligible compared with surface tension forces.

The surface free energy per unit area of a material is equivalent to its surface tension, γ, which is also equivalent to the isothermal work required to create a unit area of surface (19). The work of adhesion between two materials, W_{12}, is defined as the work necessary to separate the two materials at their interface. W_{12} is related to the surface tensions of the materials, γ_1, γ_2, by the relationship (19)

$$[1] \quad W_{12} = \gamma_1 + \gamma_2 - \gamma_{12}$$

where γ_{12} is the interfacial tension. It follows that the work of cohesion of a material, W_{11}, is simply $2\gamma_1$. It should also be noted that γ_{12} between two incompatible materials is positive. A negative γ_{12} implies a tendency for one material to dissolve in the other.

We start by considering subsurface structure formation by vacuum deposition. The case of a flexible cluster on a rigid substrate is generally taken as the starting point in treatments of thin film nucleation phenomena (1). The equilibrium cluster configuration is a spherical cap, with the contact angle determined by balancing the surface and interfacial tension components parallel to the rigid substrate, resulting in the well known Young equation (1). We restrict our discussion to the novel case of a soft substrate.

If the substrate is softened in the presence of a flexible cluster, the equilibrium cluster shape becomes a surface lens (20) as shown in Fig. 6. In this case, the surface tension components both parallel and normal to the substrate surface must be balanced at equilibrium. These two conditions give two equations which can be solved for the contact angles θ_1 and θ_2:

$$[2] \quad \cos\theta_2 = (\gamma_2^2 + \gamma_1^2 - \gamma_{12}^2)/2\gamma_2\gamma_1$$

and

$$[3] \quad \cos\theta_1 = (\gamma_2^2 + \gamma_{12}^2 - \gamma_1^2)/2\gamma_2\gamma_{12}$$

From Fig. 6, it is clear that the lens material will remain partially exposed above the substrate provided $\cos\theta_2 < 1$ (or equivalently $\cos\theta_1 > -1$). However, if the rhs of eq. [2] is >1 (or the rhs of eq. [3] is < -1), the lens material will become completely submerged into the substrate material and (for isotropic surface forces) will assume a spherical shape. From eqs. [2] and [3], these conditions for complete immersion reduce to the inequality

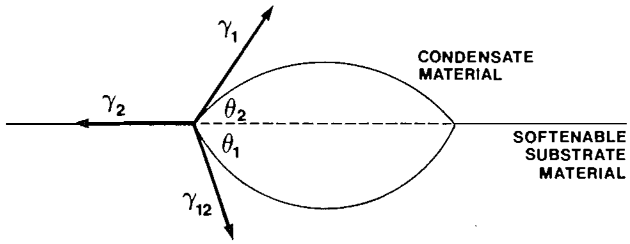

FIG. 6. Equilibrium lens configuration of a soft cluster in a soft substrate. The surface tension components both parallel and perpendicular to the substrate are in balance.

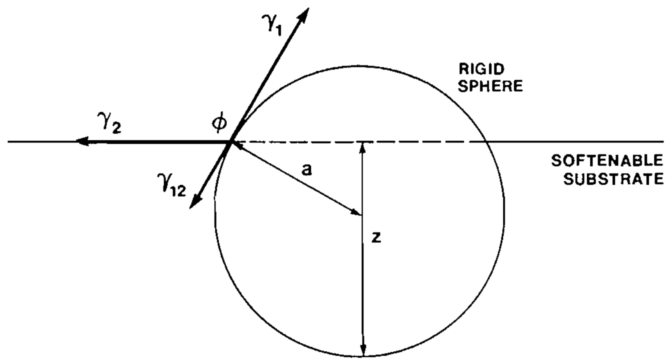

FIG. 7. Equilibrium position of a rigid sphere embedded in a soft substrate as determined by surface and interfacial tensions, related (as an example) according to $\gamma_1 = \gamma_2 = 2\gamma_{12}$.

$$[4] \quad \gamma_1 > \gamma_2 + \gamma_{12}$$

We now consider the case of a rigid preformed particle (for simplicity a sphere) in contact with a soft substrate (applicable to the case of structures formed by spreading, smoke, or electrophoretic techniques). For this case, the system will be in equilibrium when the surface tension components parallel to the *rigid* surface, i.e. parallel to the particle surface, are in balance. (The components perpendicular to the rigid surface remain unbalanced, analogous to the situation, described by the Young equation, of a liquid drop on a rigid substrate.) The situation is depicted in Fig. 7. The balance condition is given by

$$[5] \quad \gamma_1 + \gamma_2 \cos \varphi = \gamma_{12}$$

where φ is the angle between γ_2 and γ_1 on the line of contact between substrate and sphere surfaces. Since, for a sphere, the embedded depth z and the angle φ are geometrically related according to

$$[6] \quad z = a(1 - \cos \varphi)$$

where a is the radius of the sphere, the equilibrium embedded depth, z_{eq}, is seen to be given by

$$[7] \quad z_{eq} = a(\gamma_1 + \gamma_2 - \gamma_{12})/\gamma_2 \; (= 2aW_{12}/W_{22})$$

From eq. [7] it is readily seen that the equilibrium configuration is again a completely embedded sphere if and only if inequality [4] holds. It is a straightforward extension of the above analysis to show that inequality [4] is the general condition for complete immersion of an arbitrarily shaped rigid particle (21).

It can therefore be concluded that at equilibrium a particle, either rigid or soft, in contact with a soft substrate, will be completely embedded provided inequality [4] holds; otherwise, partial embedding represents the equilibrium configuration. It is interesting to note that inequality [4] can be expressed in terms of the relevant works of cohesion and adhesion as defined in eq. [1]. Inequality [4] is equivalent to the relationship, $W_{12} > W_{22}$. Therefore, a material will tend to completely embed itself in a soft substrate provided that the work of adhesion between the two materials is greater than the work of cohesion of the substrate, an intuitively reasonable result.

While the surface tensions of many materials are known, the interfacial tensions for most material combinations have not been determined. The dispersion force interaction theory developed by Fowkes (9) was used to calculate the interfacial tensions for systems of interest. In general, inequality [4] is found to hold for virtually any inorganic material on an organic polymer substrate (12, 21), but the reverse inequality holds in general for organic materials on organic polymer substrates (21).

These thermodynamic predictions are in fact confirmed by the experimental data. Completely embedded equilibrium structures as in Fig. 1 were formed by low melting inorganic evaporants where no kinetic limitations intervened, and by virtually any inorganic particulate when the spreading technique was used. Partially embedded structures as in Fig. 2 were formed by organic evaporants when no kinetic factors intervened, and by virtually any organic particulate when the spreading technique was used with only heat-softening. However if, instead, polymer solvent vapour exposure was used, then organic particulates as well as inorganic particulates would form a completely embedded structure.

The effect of polymer solvent vapour on particle embedding can be understood by noting that on vapour absorption the surface tension of the polymer–solvent system becomes that of the polymer solution. With sufficient uptake of a low surface tension solvent vapour, the surface tension of the polymer–solvent system approaches that of the pure solvent (21). In our experiments, the surface tension of the polymer (similar to polystyrene) is significantly higher than that of the solvent (e.g. toluene), so that absorption of a relatively small amount of solvent by the polymer can lower the surface tension of the substrate, γ_2, very close to that of the pure solvent (γ_{12} is not expected (21) to change appreciably). Therefore $\gamma_2 + \gamma_{12}$ can be lowered significantly by introduction of the solvent vapour, inequality [4] can now be satisfied, and complete immersion results.

4. Analysis of monolayer stability

In addition to the large free energy change associated with embedding an inorganic particle into the polymer as discussed in the previous section, there are at least two smaller contributions to the free energy; these vary with the depth of the sphere below the surface, and for convenience we reference them relative to a deeply embedded sphere. The first of these, ΔU_{VdW}, represents the Van der Waals attraction between the sphere and polymer half-space, which acts to pull the sphere deeper into the polymer. In addition we have attempted to treat the difficult problem of the detailed interactions between the sphere and polymer; this treatment suggests that there is a second (entropic) energy, $-T\Delta S$, tending to reject the particle. The sum of these two energy contributions with opposing gradients possesses a minimum for the sphere situated a specific distance below the polymer surface.

The Van der Waals (dispersion) interaction between the sphere and the polymer is a very long-range force. It the top of a sphere of radius a is located a distance l below the polymer surface, then by symmetry the net attractive force on the sphere by the polymer within the surface slab of thickness $2a + 2l$ is zero. However, all the polymer below this slab will exert an uncompensated attraction on the sphere. This interaction energy, ΔU_{vdW}, between a sphere and a half-space can be written down immediately (22):

$$[8] \quad \Delta U_{\mathrm{vdW}} = A_{12}/6\{(2 + 2x)/(2x + x^2) + \ln[x/(2 + x)]\}$$

where $x = l/a$ and A_{12} is the appropriate Hamaker constant describing the interaction between the sphere and polymer material. ΔU_{vdW} monotonically decreases to zero as the sphere moves away from the polymer surface.

As discussed in the previous section, when complete particle submersion is thermodynamically favourable, the work of adhesion of the polymer material to the particle is greater than the work of cohesion of the polymer ($W_{12} > W_{22}$). According to Fowkes' view of the interface, this implies that the polymer chain elements immediately adjacent to the particle surface should be in a state of compression with density slightly higher than the rest of the bulk polymer (12). Modern theories of polymer conformations (23) involving free volume effects also predict a higher polymer density at the particle surface. We shall make the simplifying assumption that the relaxation of this local high polymer density about the sphere surface can be described by random walk statistics (8), and we calculate the variation in entropy of the polymer as the sphere approaches the polymer–air (or polymer–vacuum) surface. Generally speaking, a compression of the polymer should reduce its entropy, and a long-chain material will not relax this compression for some considerable distance from the particle. Thus, we might expect the proximity of the air surface to diminish the extent of this compression, effectively allowing the compression to relax at the surface. In this case, the polymer's entropic contribution to the free energy of the system would tend to push the sphere toward the surface to maximize the entropy.

To calculate the internal entropy of the polymer, we use the diffusion equation approach (8, 24) with boundary conditions appropriate to the above view of the sphere–polymer interface. The details of this calculation may be found elsewhere (12). We give here only the final result for ΔS, the change in polymer entropy for a sphere at distance l from the polymer surface relative to the entropy when the sphere is deeply embedded:

$$[9] \quad \Delta S = kV_m(b^2/6)4\pi a\epsilon\left\{1 - \sinh\beta_0 \sum_{n=0}^{\infty} \exp\left[-\left(n + \frac{1}{2}\right)\beta_0\right] \Big/ \cosh\left[\left(n + \frac{1}{2}\right)\beta_0\right]\right\}$$

In eq. [9], k is Boltzmann's constant, V_m is the monomer volume, b is the average length of a link in the polymer chain (commonly called the Kuhn statistical length), ϵ is a positive dimensionless parameter related to the increased density at the sphere interface, and β_0 is given by $\sinh^{-1}\{[x(x + 2)]^{1/2}\}$. Numerical evaluation shows that ΔS steadily increases as the sphere moves toward the surface.

From eqs. [8], [9], the free energy variation with depth below the surface, ΔF_p, can be calculated according to the relation:

$$[10] \quad \Delta F_p = \Delta U_{\mathrm{vdW}} - T\Delta S$$

Parameters suitable for Se and Sn spheres in polystyrene have been determined (12) and the results for ΔF_p are given in Fig. 8 for spheres of radius $a = 0.15$ μm. The energy minima occur at the depths $l_{\min}(\mathrm{Se}) = 120$ nm and $l_{\min}(\mathrm{Sn}) = 98$ nm. The order of magnitude and relative size of these distances are in qualitative agreement with what is observed experimentally. The depths of the wells are 2.5×10^{-13} and 4.5×10^{-13} erg. These energies are about ten to twenty times $(kT/2)$ $(2.7 \times 10^{-14}$ erg) and should therefore be sufficient to stabilize a given sphere against random thermal fluctuations; this explains why the monolayer structure forms, and also its remarkable thermal stability on extended heating. Long range Van der Waals interactions of a given sphere with its neighbours should cause an additional self-stabilizing effect on the monolayer (12).

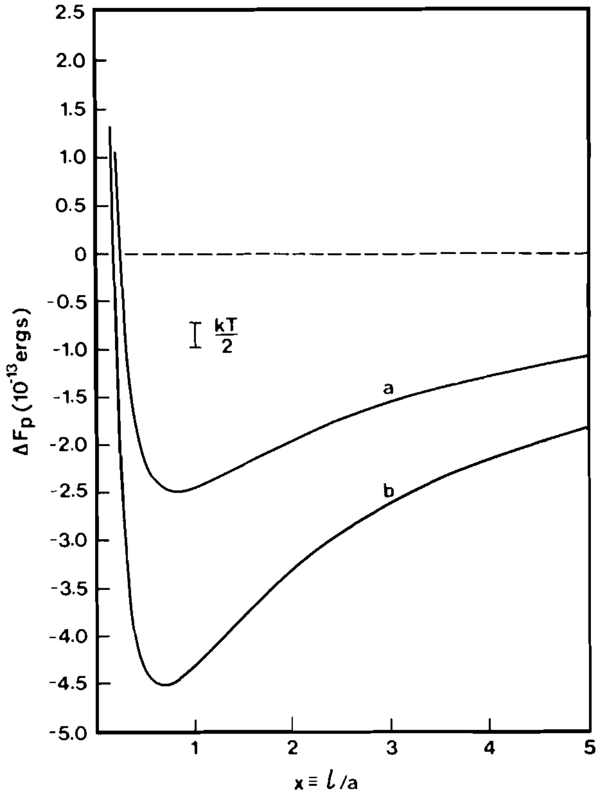

FIG. 8. Plots of ΔF_p given by eq. [10], as a function of the reduced depth of the sphere, $x = l/a$. Curves (a) and (b) were computed using the parameters given in ref. 12 appropriate for Se–polystyrene and Sn–polystyrene systems, respectively. The temperature in eq. [10] was taken as 120°C.

5. Kinetic analysis of formation and growth mechanisms during vacuum deposition

5.1 Formation mechanism

The Se transition curve in Fig. 3 is thought to be determined by particle sinking rate as controlled by polymer substrate viscosity and surface tension forces. If we assume the usual Volmer–Weber (V–W) growth mode (i.e. initial nucleation of the evaporant into an island structure) (1) with complete evaporant condensation into N spherical islands per unit area in a time negligible compared with that for island sinking, and also assume the viscous drag on a sinking sphere of radius a to be given by Stokes' formula (25), then the rate Ω at which material sinks below the surface is given by (13):

$$[11] \quad \Omega = (4\pi\gamma_2 Na^2/9\eta)\ln[(\gamma_1 + \gamma_2 - \gamma_{12})/(\gamma_1 - \gamma_2 - \gamma_{12})]$$

where η is the viscosity of the polymer. If the deposition rate

R is greater than Ω, an above surface film should form (i.e. the islands get buried by incoming evaporant before they can sink). Ω increases with surface coverage $N\pi a^2$ and should be a maximum at the largest practical surface coverage which does not impose significant additional restraints on sinking time. Using known values for η (15) and the γ's (12), and assuming $N\pi a^2 \sim 0.6$ (the result for randomly packed spheres (26)), an exact fit to the Se transition curve is obtained, using no disposable parameters.

A similar analysis gives a good description of the Sn transition curve in Fig. 3 for lower deposition rates; however, at high rates the transition from V–W to S–K growth (initial formation of the evaporant into a two-dimensional monolayer) gives initial continuous layers, which prevent subsurface Sn formation. (A similar transition is predicted for Se, but only at very high R values.) Theoretical considerations predict this transition when the saturation cluster density, N_s (the highest density of evaporant clusters reached on the polymer surface before neighbouring clusters begin to merge (27)), approaches the number of available adsorption sites/unit area N_0. That is, the transition is predicted when, at saturation, each cluster consists of only a few atoms (i.e. $\alpha = 0.1–0.5$ where α is defined as N_s/N_0) (28). This transition curve has an activation energy equal (28) to the surface diffusion energy E_d of the evaporant:

$$[12] \quad \ln (R/V_a) = \ln (\alpha^3 \delta q_0 \nu N_0/C) - E_d/kT$$

where V_a is the atomic volume, ν is a typical atomic vibration frequency $\sim 10^{12}$ s^{-1}, C is the number of nearest neighbour sites around a given adsorption site, and δ and q_0 are dimensionless parameters related to the rates at which stable nuclei grow into contact and stable clusters capture diffusing atoms, respectively (27).

To use eq. [12], we must estimate E_d. Now, if one considers the evaporant atoms to be adsorbed into the "tacky" polymer surface then one is able to account for an *adsorption* energy for Se equal to the unusually high value found experimentally (15). This tacky adsorption model also suggests a greatly increased surface diffusion energy E_d, and gives $E_d \sim 10$ kcal/mol for Sn. With this value of E_d, eq. [12] correctly predicts the slope of the high-R portion of the experimental Sn transition curve (Fig. 3). Moreover, using $\delta q_0 \sim 10^{-2}$ (appropriate for the diffusion-limited cluster growth process (27) thought to be applicable to low melting materials like Sn), we obtain agreement with the absolute values in Fig. 3 for $\alpha = 0.2$; this is well within the predicted range of 0.1–0.5. We thus have exact numerical agreement between theory and all parts of Fig. 3, essentially without the use of disposable parameters. Using $\delta q_0 \sim 10^{-7}$ (calculated (27) for the incorporation-limited cluster growth process, thought to be applicable to *high melting point* materials like Cr, Fe, V, etc.) we predict transition lines far below that of Sn, i.e., only the S–K growth mode is predicted to occur within accessible deposition conditions for these materials; this is exactly as observed experimentally (10). For such materials, calculations based on eq. [12] suggest that $T \geq 400$°C is necessary to give subsurface structures at $R \geq 0.1$ nm s^{-1}. Low surface tension polymers usually undergo severe degradation at such temperatures; in one case, however, we were indeed able to produce subsurface structures from a high melting material (Ag), by using relatively high values of T and special polymers (10).

5.2 *Growth mechanisms*

Let us now consider the *growth* of vacuum-deposited subsurface spheres, once a reasonably close-packed subsurface particulate monolayer is formed. In this situation, additional material impinging on the polymer surface will be captured by existing spheres, leading to their growth. When two adjacent spheres touch, a coalescence process will occur to form a new sphere in a time τ determined by their surface and bulk self-diffusivity (17). For Se, for example, at the temperatures used for the vacuum deposition process ($\sim$110°C), τ can be calculated to be generally very small ($\sim$ms), i.e. we have essentially instantaneous formation of the new sphere. In this case, the growth process can be considered as (a) growth of the stationary spheres (due to evaporant capture), leading to increase in the projected-area coverage $N\pi\langle a\rangle^2$ of the monolayer, and (b) continual random impaction and instant coalescence of neighbouring spheres, leading to a reduction in the coverage. Since the rate of sphere-sphere impingement will increase as the coverage increases, with no other dependence on the deposition rate, and since τ is negligible, it is clear that the situation will come to a dynamic equilibrium at a constant projected-area coverage, exactly as observed (section 2). That is to say:

$$[13] \quad N\pi\langle a\rangle^2 = \text{numerical constant}$$

The total volume of evaporant material (per unit area of substrate), Q, is of course given by:

$$[14] \quad N(4/3)\pi\langle a\rangle^3 = Q$$

Dividing eq. [14] by eq. [13] yields the extraordinarily simple proportionality between $\langle a\rangle$ and Q mentioned in section 1. Moreover, it is clear that in this regime the final structure will depend only on Q, not on the deposition rate or on temperature (so long as the subsurface structure is formed at all), also as observed. In addition, for constant deposition rate in this regime we have the relation $\langle a\rangle \propto t$, and (combining this with eq. [13]) $N \propto t^{-2}$. This is again exactly as observed (17).

Finally, it can be shown by consideration of the surface free energies (surface tensions) that, at high projected-area coverage, a continuous subsurface film is thermodynamically favourable compared with subsurface spheres (21). However, it is known from the previous discussion that the spheres grow at constant projected-area coverage with nearly instantaneous coalescence, over a rather large range. It therefore follows that a continuous film should be formed only after the coalescence time τ ceases to be negligible. In turn, since τ is expected to be proportional (17) to a^m ($m = 3$ or 4), this should only happen once the spheres exceed some minimum size. This is indeed observed in practice. With Se, for example, no deviation from sphericity is observed for sphere diameters up to about 0.4 μm; if more Se is deposited however, Fig. 5 shows that the structure becomes more and more two-dimensional, a continuous subsurface film eventually being formed.

Evidence is presented which demonstrates that titanium dioxide does in fact photogenerate H_2O_2 in the presence of the donor sodium formate. However, this H_2O_2 has only a transient existence in aqueous dispersions. This was confirmed by experiments in which H_2O_2 was injected into the dispersion. The reasons for the lability of H_2O_2 are discussed and possible mechanisms presented. Electron paramagnetic resonance experiments using spin traps reveal that photolysis of TiO_2 dispersion generates $\cdot OH$ radicals in the donor-free case while $\cdot CO_2^-$ radicals are observed in the presence of formate. These results are also consistent with H_2O_2 generation.

JOHN R. HARBOUR, JOHN TROMP et MICHAEL L. HAIR. Can. J. Chem. **63**, 204 (1985).

On présente des données qui indiquent que le dioxyde de titane, en présence d'un donneur comme le formate de sodium, provoque une photogénération du H_2O_2. Cependant, dans des dispersions dans l'eau, ce H_2O_2 n'existe que d'une façon transitoire. On a confirmé ce fait grâce à des expériences au cours desquelles on a injecté du H_2O_2 dans la dispersion. On discute de la cause de la labilité de ce H_2O_2 et on présente un mécanisme possible. Des expériences de résonance paramagnétique électronique, utilisant des capteurs de spin, révèlent que la photolyse d'une dispersion de TiO_2 génère des radicaux $\cdot OH$ dans le cas où il n'y a pas de donneur alors qu'on obtient des radicaux $\cdot CO_2$ en présence de formate. Les résultats sont également en accord avec la production de H_2O_2.

Introduction

In the past decade there has been a resurgence of interest in the photochemistry and photoelectrochemistry of semiconducting materials (1−15). Much of this work has been associated with solar energy applications and photochemical energy conversion devices. In particular, there has been much work done on titanium dioxide. Although this pigment would not be useful for solar energy conversion due to its large band gap (~3 eV), it is known to be quite stable when it is illuminated in contact with water. This is to be contrasted with other common semiconducting pigments such as ZnO, CdS, and GaAs which undergo photo-corrosion (4). It is well known that when aqueous dispersions of such pigments are irradiated with band gap radiation that hydrogen peroxide is formed in the external solution in measurable quantities. This does not appear to be the case, however, for unreduced titanium dioxide and, despite numerous experiments (2, 16−19), its photochemical formation has yet to be proven. Rao *et al.* (20), however, have demonstrated H_2O_2 generation using reduced TiO_2 while Pappas and Fischer (6) have reported H_2O_2 formation (using a surface treated TiO_2) detected with *o*-ansidine and horse radish peroxidase.

When semiconducting oxides are irradiated with light of energy greater than the semiconductor band gap then an electron from the valance band can be excited to the conduction band thus creating an electron−hole pair (21). These electrons and holes can then, if they do not recombine, reduce or oxidise species in the external electrolyte solution. The semiconductor thus acts as an electron pump driving electrons from a low to a higher energy level. The flat band potentials of zinc oxide and titanium dioxide are shown in Fig. 1 together with the redox energy levels of reactions potentially occurring in hydrogen peroxide synthesis. It is noted that the potentials of titanium dioxide and zinc oxide are very similar. As it is well established in the case of zinc oxide that hydrogen peroxide is formed as a result of the reduction of dissolved molecular oxygen by the conduction band electrons it is difficult to explain why hydrogen peroxide is not formed by a similar mechanism at the titanium dioxide − water interface.

In order to clarify some of the reaction mechanisms which are occurring, a series of experiments have been carried out utilizing the techniques of spin trapping, oxygen uptake from solution, and the transient detection of hydrogen peroxide during catalase injection. The results obtained with titanium dioxide are compared with similar data obtained for analogous zinc oxide systems.

Experimental

No convenient, non-destructive in situ method of H_2O_2 determination is known, thus it is not possible to monitor a system directly for H_2O_2 formation. However, addition of the enzyme catalase to a system containing H_2O_2 causes the dismutation of H_2O_2 to H_2O and oxygen. If the system is closed, the changes in oxygen concentration can be monitored and then doubled to get the H_2O_2 concentration. For this purpose a YSI model 5331 oxygen probe and YSI model 53 electronic unit were used and the oxygen concentration vs. time curves recorded on a strip chart recorder as described previously (8, 22). The oxygen probe used was a Clark type polarographic electrode with a semi-permeable membrane which allows the O_2 to diffuse to the electrode. The membrane is temperature-sensitive (~4% O_2/°C) and the whole system is enclosed within a constant temperature bath. The use of the oxygen electrode has the added advantage that changes in the dissolved oxygen concentration under illumination can also be measured. For example, it has previously been shown (8) that illumination of ZnO dispersions can result in a 1:1 relationship between oxygen consumption and H_2O_2 formation (3) if an electron donor such as formate ion is present in the solution.

Illumination for all systems was provided by a filtered G.E. Quartzline projection lamp. For the photon efficiency measurements, a 380 nm narrow band pass filter was used. For all other experiments a Corning CS 0-52 filter was used. During illumination the temperature of the oxygen monitor sample cells rose by up to 5°C, as seen by an apparent initial increase in the O_2 concentration after the start of illumination due to the temperature sensitivity of the probe (Fig. 2). This temperature increase in only temporary and the temperature falls when illumination is stopped.

All chemicals were used as received and were reagent quality. The anatase polymorph of TiO_2 was used as it is reported to be more photoactive than rutile and was obtained from Fisher. Its BET surface

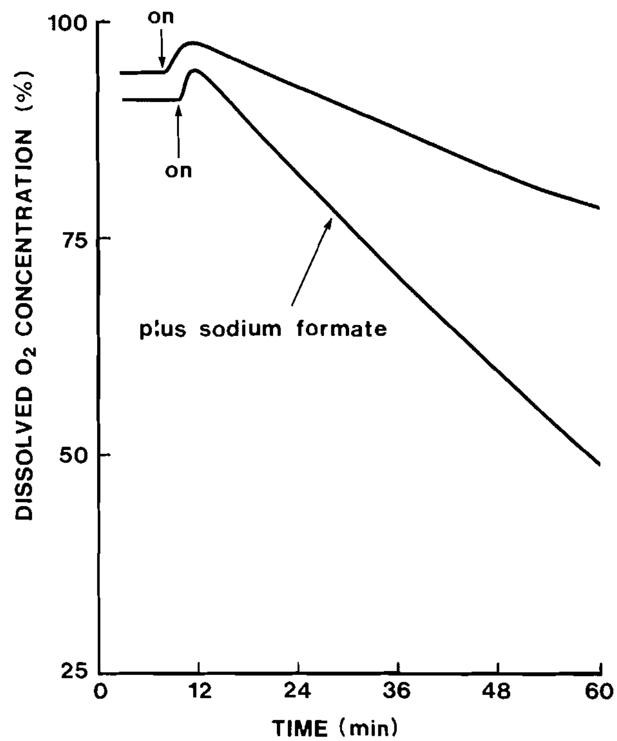

FIG. 2. Photo-induced oxygen uptake curves for TiO_2 in H_2O and TiO_2 in 0.1 *M* sodium formate solution.

area was determined to be 10.8 m^2/g. SEM showed the particle size to be between 0.2 and 0.5 μm.

Particle dispersions were prepared by adding TiO_2 and an appropriate amount of other reagents (usually to ~0.1 *M* concentration) to purified water and irradiating ultrasonically with a Heat System model 350 sonicator. Final TiO_2 concentration was 1 mg per 1 mL (pH = 6.5).

Spin trapping (23) experiments were carried out as described previously (8) using 5,5-dimethyl-1-pyrrolinyl-1-oxy (DMPO) (24) as the spin trap.

Results and discussion

(i) O_2 uptake

When an aqueous dispersion of TiO_2 (1 mg/1 mL) is illuminated such that a band-gap transition occurs (λ = 380 nm), the oxygen dissolved in the aqueous external solution is consumed. The rate of oxygen uptake (Fig. 2) in this closed system is 1.7%/min. (This is reported as the percentage decrease in the O_2 concentration of 5 mL of dispersion per min and corresponds to a photon efficiency of ~0.02.) If catalase is injected after illumination is stopped, no O_2 is liberated and therefore no H_2O_2 is free in solution. This is contrary to results with CdS or ZnO in which H_2O_2 is detected through catalase addition after illumination (7,8).

Addition of sodium formate at 0.1 *M* causes the rate of photoinduced O_2 uptake to increase to 4%/min or to a photon efficiency of ~0.05 (Fig. 2). Again, catalase addition *after* illumination ceased did not result in O_2 evolution. This lack of detection of H_2O_2 with TiO_2 is consistent with previous experiments (2, 16–19).

If H_2O_2 is being continuously generated in this system but is present only as a transient, then it is argued that injection of catalase at a point during illumination should reveal its presence. The catalase will cause dismutation of the H_2O_2 releasing oxygen and thus causing an apparent reduction in the rate of oxygen uptake. When this experiment was carried out in the donor-free system, no peak associated with O_2 evolution was observed. If anything, the rate of O_2 uptake increased slightly (depending on the amount of catalase injected). In any event, a reduction in the rate of O_2 uptake was not observed.

However, when the electron donor sodium formate was present in the system, addition of catalase at a point during illumination did provide evidence for H_2O_2 presence. At the point of injection, a small but reproducible peak associated with O_2 evolution was observed (Fig. 3). As expected, further additions of catalase or water as a control did not give this peak. After this peak of O_2 evolution, the rate of O_2 uptake was approximately halved (Fig. 3). This is the result one would expect if catalase causes the dismutation of transient H_2O_2 in this system. These results suggest that H_2O_2 is being generated when formate is present but, in the donor-free case, free H_2O_2 is not observed. (Similar results are obtained with the donor EDTA.)

If H_2O_2 (~10^{-4} *M*) is added to a TiO_2/H_2O dispersion during irradiation, evolution of oxygen is first observed and this gradually returns to oxygen consumption at the same initial rate. Addition of catalase at this point shows no change in the O_2 concentration demonstrating that all of the H_2O_2 had been removed from solution. Similar results were obtained in the presence of sodium formate (Fig. 4). These results show that H_2O_2 is not stable to the environment of illuminated TiO_2 either in the presence or absence of donor. Hence, it is not surprising that H_2O_2 is not readily detected in these systems since it is rapidly destroyed under these conditions.

In the formate case, illumination for 72 min of an O_2-saturated dispersion resulted in 65% of the total O_2 being consumed. For our 5 mL dispersion this amounts to a consumption of 1.9×10^{18} molecules of O_2. The surface area of the TiO_2 is

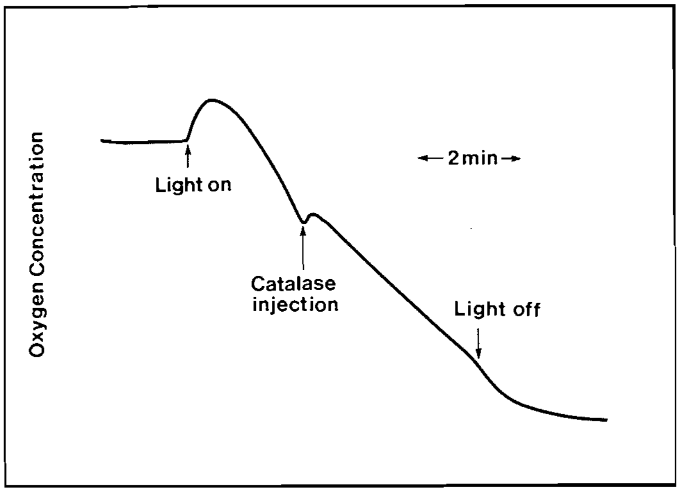

FIG. 3. The effect of injecting catalase during illumination of a TiO_2 dispersion of 0.1 *M* sodium formate.

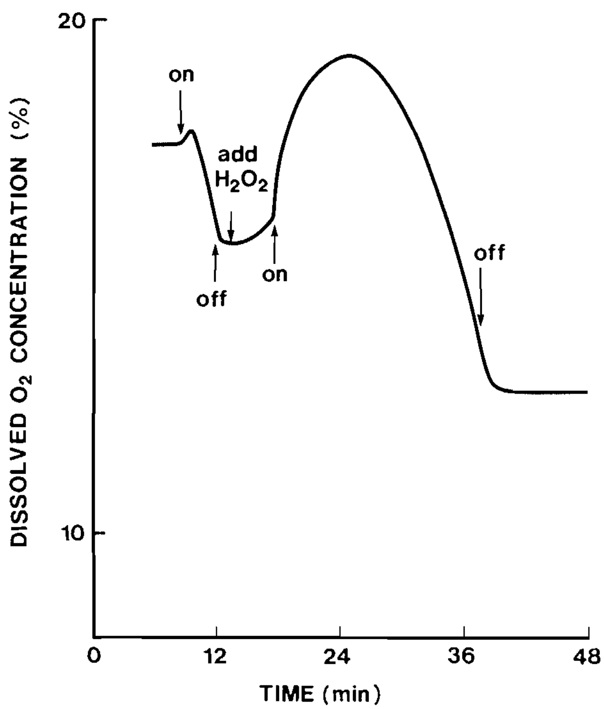

FIG. 4. Effect of adding H_2O_2 (~1 μmol) to a TiO_2 dispersion (5 mL) containing 0.1 *M* sodium formate. Note that the rate of O_2 uptake eventually returns to the value of the initial rate.

10.8 m^2/g and thus our 5 mg sample contributes 5.4×10^{18} Å^2 of surface. The oxygen uptake is thus equivalent to 35 molecules of H_2O_2 per 100 Å^2! In addition, the rate of uptake showed no sign of saturation which indicates that 35 molecules/100 Å^2 is certainly only a minimum value.

A similar experiment with the donor-free system showed that after 172 min, 40% of the total O_2 was consumed and the rate of O_2 uptake at this point was about half the initial value. This corresponds to 22 molecules H_2O_2 per 100 Å^2.

(ii) Electron spin resonance results

When the spin trap DMPO was added to the donor-free system and irradiation begun, an esr spectrum of the DMPO·OH radical adduct (25) was observed (Fig. 5) providing clear evidence that ·OH radicals are produced in this photo-

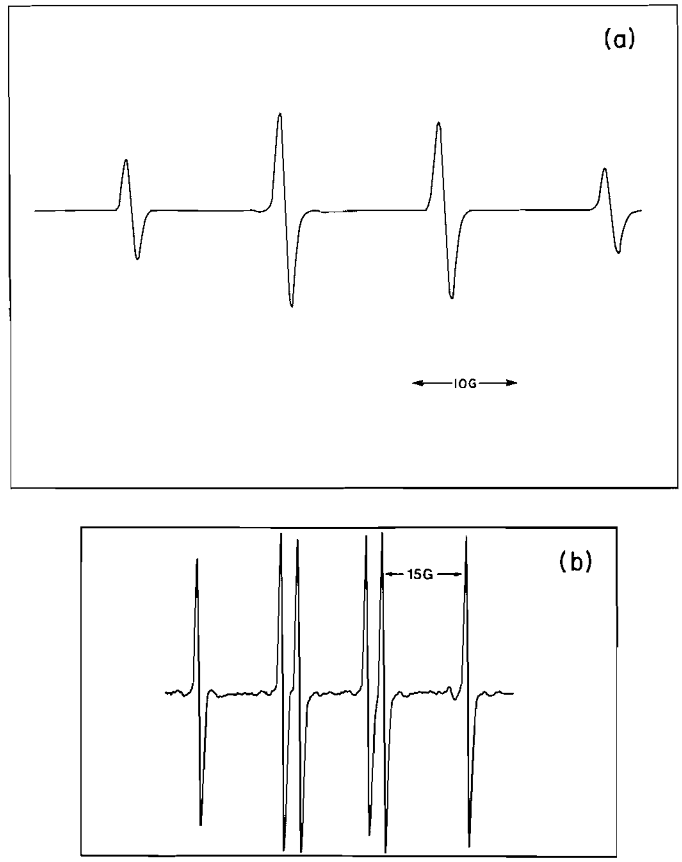

FIG. 5. The esr spectra of the (*a*) ·OH radical adduct of DMPO and (*b*) the $\cdot CO_2^-$ radical adduct of DMPO.

reaction. This production of ·OH radicals was a function of dissolved O_2 concentration. These results are analogous to those reported previously for ZnO suspensions. We found no evidence for the presence of O_2^- radicals in contradistinction to the results of Jaeger and Bard (26) who report the presence of trapped $HO_2\cdot$ and ·OH radicals when carrying out a similar experiment but using a different spin trap and *reduced* TiO_2.

In the case where formate was present, the spin trapping experiment revealed that excitation to TiO_2 produced the $\cdot CO_2^-$ radical adduct (27) (Fig. 5) while the hydroxyl radical adduct was no longer present. This has been observed (28) in other pigment systems (both CdS and ZnO) reflecting the oxidation of formate to $\cdot CO_2^-$ and/or the reaction of ·OH radicals with formate with a concomitant increase in H_2O_2 generation. Thus, the spin trapping experiments are also consistent with other systems in which H_2O_2 is being photogenerated. It is noted that the intensity of the signal is dependent on oxygen concentration and purging with nitrogen reduces both CO_2^- and ·OH signal to very small levels.

Boonstra and Mutsaers (29, 30) suggest that the photoactivity of titanium dioxide (in the gas phase) is described by the formation of a hydrogen radical rather than by formation of the hydroxyl radical which has been postulated in many previous studies. We would point out that in our spin trapping experiments at no time did we detect H· radical adduct.

It is clear from these results that in the presence of the donor, sodium formate, TiO_2 photocatalytically generates H_2O_2. The mechanism is summarized in reactions [1] — [10] (Table 1). However, in the case of TiO_2 without added donors, no evidence for H_2O_2 was found, yet oxygen is being consumed

TABLE 1. Reactions that generate or remove H_2O_2

Reduction	
[1]	$O_2 + e \rightarrow (O_2^-)_s$
[2]	$(O_2^-)_s + H^+ \leftrightharpoons (HO_2\cdot)_s$
[3]	$(HO_2\cdot)_s + e \rightarrow (HO_2^-)_s$
[4]	$(HO_2^-)_s + H^+ \leftrightharpoons (H_2O_2)_s$
or	
[5]	$2(HO_2\cdot)_s \rightarrow (H_2O_2)_s + O_2$
[6]	$(H_2O_2)_s \leftrightharpoons H_2O_2$
Oxidation	
[7]	$OH^- + h^+ \rightarrow \cdot OH$
	$\cdot OH$ + surface/impurities $\rightarrow$ oxidised product
or	
[8]	$Ti_sOH + h^+ \rightarrow Ti_s^r + \cdot OH$
For formate	
[9]	$HCO_2^- + \cdot OH \rightarrow H_2O + \cdot CO_2^-$
or	
[10]	$HCO_2^- + h^+ \rightarrow H^+ + \cdot CO_2^-$
H_2O_2 removal	
[11]	$H_2O_2 + 2e + 2H^+ \rightarrow 2H_2O$
[12]	$H_2O_2 + 2h^+ \rightarrow O_2 + 2H^+$
[13]	$Ti_s—O—Ti_s + H_2O_2 \rightarrow Ti_s—OH + Ti_sOOH$
[14]	$e + H_2O_2 \rightarrow \cdot OH + OH^-$
[15]	$\cdot CO_2^- + H_2O_2 \rightarrow \cdot OH + OH^- + CO_2$

during photolysis. Finally TiO_2, both with and without donor, destroys added H_2O_2 during photolysis.

There appears to be two plausible mechanisms for the photodestruction of H_2O_2. The first involves photoinduced redox reactions in which H_2O_2 can be reduced and/or oxidized by the electrons and holes. The second possibility involves an interaction of the TiO_2 surface with H_2O_2 which effectively consumes the H_2O_2 through a modification of the TiO_2 surface. Both of these mechanisms will be briefly discussed.

In the case of redox reactions, H_2O_2 can be reduced and/or oxidized at the TiO_2 surface (reactions [11], [12]). For reduction, the product would be H_2O (reaction [11]) and the O_2 uptake explained by the reduction of O_2 to H_2O_2 (reactions [1]–[6]) which is subsequently reduced to H_2O. On the other hand, oxidation of H_2O_2 would yield $2H^+$ and O_2. The fact that oxygen is evolved initially when TiO_2 is illuminated in the presence of added H_2O_2 suggests that oxidation of H_2O_2 is occurring. However, in order for oxygen uptake to be observed, the rate of reduction of H_2O_2 would have to exceed the rate of oxidation of H_2O_2. This is certainly plausible in the presence of a strong donor such as formate. It is also interesting to note that the measured photon efficiency is only 0.04 for TiO_2 compared to 0.70 previously reported for ZnO under similar conditions (8). This suggests that with TiO_2, much of the photocatalytic activity simply converts the generated product H_2O_2 back to water and oxygen.

Another redox reaction capable of removing H_2O_2 is given by reaction [15]. In this case $\cdot CO_2^-$ is the reducing agent. However, previous work (8) with aqueous ZnO dispersions has shown that $\cdot CO_2^-$ formation in no way diminishes the H_2O_2 which is photogenerated in that system. In fact, a conversion ratio of 1 is obtained (8). It therefore appears unlikely that reaction [15] plays any significant role in the destruction of H_2O_2.

The second possibility is the incorporation of H_2O_2 into the TiO_2 itself with the formation of a gel-like surface. This possibility appears to be most applicable to the donor-free case of TiO_2. It is well recognized that ZnO and TiO_2 have differing surface chemistry and, although it is difficult to speculate on the species which are formed and the exact surface structure that exists at the complex solid/solution interface, some insights may be obtained from the literature data generated on the gas/solid interface in the absence of donor (29–32). In particular the work of Boonstra and Mutsaers (30–32) is cited. These workers have examined the adsorption and thermal desorption of hydrogen peroxide in the presence of oxygen and water using both spectroscopic and volumetric techniques. It was found that hydrogen peroxide could be chemisorbed on a titania surface to a concentration of approximately 2×10^{14} molecules/cm^2 (2 H_2O_2 molecules/100 Å^2). H_2O_2 did not adsorb on zinc oxide. Boonstra and Mutsaers suggest that this difference in adsorption behaviour may explain why hydrogen peroxide is not detected when TiO_2 suspensions are irradiated and we agree that this behaviour could contribute to the observations in our experiments. Thus, it is suggested that the hydrogen peroxide formed from dissolved oxygen (reactions [1]–[4]) is either not able to desorb from the surface after it is formed (cf. reaction [6]) or, undergoes a reaction to become chemisorbed on adjacent sites. Unfortunately this facile utilisation of Boonstra and Mutsaers results cannot be correct in detail—the quantitative uptake numbers do not coincide. Thus Boonstra and Mutsaers observe an adsorption of 2 molecules of H_2O_2/nm^2. According to their proposed model the chemisorbed species is $Ti_s—O—O—H$ and thus 4 sites/nm^2 are involved (see reaction [13]).

In our simplest experiment with irradiation of the TiO_2/H_2O_2/O_2 suspension at least 1.2×10^{18} molecules of O_2 disappear from the system. This corresponds to 22 molecules of H_2O_2/nm^2, clearly an unlikely situation. It is therefore suggested that the TiO_2 surface becomes internally hydroxylated.

Further experimentation must be undertaken in order to determine which of these mechanisms is most important. In particular, changes in the chemical nature of the TiO_2 would be observed if incorporation of H_2O_2 into the surface/bulk is an important mechanism.

This paper is dedicated to the 10th anniversary of the Xerox Research Centre of Canada

KAR P. LOK and CHRISTOPHER K. OBER. Can. J. Chem. **63**, 209 (1985).

In a dispersion polymerization process, the reaction mixture starts out as a homogeneous solution and the resulting polymer precipitates as spherical particles, stabilized by a steric barrier of dissolved polymer. The final polymer particle size is determined by the inherent polymer aggregation behaviour under a given set of conditions. In the present study styrene polymerization was studied in various solvents using cellulosic derivatives as the steric stabilizer. Some of these solvents in certain combinations allowed the direct preparation of particles in the micron size and their size distribution appeared to be highly dependent on the monomer–solvent–initiator system. Investigations of these factors have suggested that monodisperse particles up to 12 μm can be prepared in a single step; studies of several systems are delineated.

KAR P. LOK et CHRISTOPHER K. OBER. Can. J. Chem. **63**, 209 (1985).

Dans un processus de polymérisation par dispersion, le mélange réactionnel de départ se présente sous forme d'une solution homogène et le polymère qui en résulte précipite sous forme de particules sphériques stabilisées par une barrière stérique du polymère dissous. Avec un ensemble donné de conditions de réactions, la grosseur des particules du polymère final est déterminée par un comportement inhérent au polymère vis-à-vis de l'aggrégation. Dans cette publication, nous étudions la polymérisation du styrène dans divers solvants en utilisant des dérivés de la cellulose comme stabilisateurs. Certaines combinaisons de ces solvants permettent de préparer directement des particules dont la taille est de l'ordre du micron; il semble que la répartition de leur taille dépende fortement du système monomère–solvant–initiateur. L'étude de ces facteurs suggère que l'on peut préparer, en une seule étape, des particules monodispersées dont la grosseur va jusqu'à 12 μm. On rapporte les résultats obtenus avec plusieurs systèmes.

[Traduit par le journal]

Introduction

There has been substantial interest in monodisperse polymer particles ever since J. W. Vanderhoff and E. B. Bradford announced their preparation of polystyrene particles with highly uniform particle size in 1955 (1). Monodisperse particles are finding a wide variety of applications including instrument calibration standards, standards for the determination of pore size and the efficiency of filters, column packing material for chromatographic separation, support materials for biochemicals, and so on. The level of success in each of these applications is ultimately dependent upon the particle size and its distribution, the morphology of the particles and the surface characteristics among numerous other factors.

Control of particle size and its uniformity has been a major area of interest; it proves to be particularly challenging to prepare monodisperse polymer particles in the micron size range (2–20 μm). Traditionally the attempt to prepare micron size particles has been to break up monomer droplets into the micron size range by homogenization in the presence of a stabilizer, and subsequently, polymerize the monomer by a suspension polymerization (2). This proves to be an inefficient method of achieving monodispersity because of the inherent size distribution in the mechanical homogenization step.

Monodisperse micron size polymer particles could not be prepared in reasonable quantities until Ugelstad *et al.* developed a method of growing sub-micron particles using a two-step swelling technique (3). In this method, submicron polymer seed particles are made by surfactant-free emulsion polymerization. The seed particles are subsequently suspended in a new medium and swelled by the addition of an emulsion of low molecular weight compound which diffuses from the emulsion droplets into the polymer particles. This small molecule is insoluble in water and does not normally diffuse through water, so a low boiling point water soluble aprotic solvent is used to facilitate the transport. The addition of the aprotic solvent permits the otherwise insoluble compound to diffuse and upon removal of the aprotic solvent, the small molecule is locked into the particle. Owing to the entropic dilution effect, this small molecule allows further swelling of the particle by monomer which, upon subsequent polymerization, gives rise to micron size particles as large as 50 μm. This technique provides a very elegant route to micron size particles but it is very tedious and difficult to carry out. There is sufficient interest in such particles that Vanderhoff and co-workers have been contemplating the growth of polymer particles to the micron size range aboard the space shuttle in microgravity (4, 5).

A second approach to preparing micron size particles is by dispersion polymerization. This method has been very thoroughly reviewed by Barrett (6) and it has been shown to produce particles with a very narrow size distribution. The process involves the polymerization of a monomer dissolved in a medium in the presence of a graft copolymer dispersant (or its precursor) to produce insoluble polymer dispersed in the medium. The graft copolymer functions as a steric stabilizer which can prevent flocculation and aggregation of the particles being formed. Since this method depends on incipient aggregation of the polymerizing species at the early stages of the polymerization, the number of particles are determined by these growing nuclei. The final size and distribution are largely determined by the amount of monomer introduced and the ability of the stabilizer to maintain the colloidal stability of the growing particles. Using a variation of this approach, M. Levy *et al.* have successfully prepared monodisperse polymer particles in the range of 1–6 μm (7). Their method involves the use of a polymeric steric stabilizer in combination with a quaternary ammonium salt which the authors claimed acts as an electrostatic co-stabilizer.

This paper discusses recent developments in the dispersion polymerization of styrene using nonionic cellulosic derivatives as steric stabilizers in a variety of solvent systems. Micron size

Surfactant	Present	None	None
Initial Homogeneity	Multiple phase	Single phase	Dual phase

particles can be prepared without the use of an electrostatic costabilizer, resulting in an uncharged dispersion. Such polymer particles can be made to be very uniform in size or to have a wider but defined particle size range, depending upon the solvency of the dispersion medium. In addition, the particle nucleation and growth mechanism will be delineated.

Experimental

The styrene monomer, dimethoxyethane, cellosolve, and benzoyl peroxide (BPO) were supplied by Aldrich. The methyl cellosolve came from several suppliers including J. T. Baker, Aldrich, and BDH. BDH *Omnisolve* ethanol was used, but other alcohols were obtained from Fisher Scientific. Tetrahydrofuran was stock from Caledon. The hydroxypropylcellulose (HPC, mw = 100 000), cellulose propionate and ethyl cellulose came from Scientific Polymer Products. All materials were used without further purification.

2.1. *Alcohol–ether/ethanol*

In a typical reaction, hydroxypropyl cellulose (HPC, 7.5 g) was dissolved in ethanol (EtOH, 175 mL) and methyl cellosolve (2-methoxyethanol, MeCell, 250 mL) under nitrogen in a three-necked round bottom flask with mechanical stirring over 30 min at 65°C. At that time, benzoyl peroxide (BPO, 3.0 g) dissolved in styrene monomer (75 mL) was added. The homogeneous mixture became cloudy after 5 min. After 2 h, the temperature of the reaction was raised to 75°C. The reaction was allowed to proceed for 24 h and then cooled. The particles were isolated by centrifuging the reaction mixture, decanting the supernatant, redispersing the particles in water, and finally freeze-drying them on a Labconco FreezeDry-12 giving a final product of monodisperse 10 μm spheres.

2.2. *Alcohol/water*

As an example, HPC (5.0 g) was dissolved in ethanol (500 mL) and water (300 mL) at 80°C using the flask and stirring conditions used above. Then solid BPO (1.0 g) was added. After 1 h, 50 mL of styrene monomer was added all at once, and heating was continued at 78°C for 7 h. A stable milky latex dispersion was obtained.

2.3. *Ether/ethanol*

In this reaction, HPC (7.5 g) was dissolved in THF (75 mL) and ethanol (350 mL) at 65°C. A solution of BPO (3.0 g) dissolved in styrene (75 mL) was added. After reacting for 48 h, a volume equal to 1.5 times the volume of THF present was distilled off using a rotary evaporator. A product with a particle size of approximately 8 μm resulted.

2.4. *Characterization*

Particle size measurements were performed on an optical microscope using calibrated photomicrographs for a given sample. In most cases these values were compared with those obtained using the ISI Mini-Scanning Electron Microscope. In addition, Coulter Counter measurements were performed on the samples with particle diameters 3 μm and above, and Nanosizer measurements were made on particles less than 3 μm.

Molecular weights were calculated using a Waters GPC (Model #M6000A, M440 and R401) operating at room temperature with columns in methyl ethyl ketone or THF solvent. Columns were packed with μ-Styragel with pore sizes of 100, 500, 10^5, 10^4, and 10^3 Å in diameter. A flow rate of 1.0 mL per min and both the uv and refractive index detectors were used.

Conversion kinetics were followed on a Varian GC Model 2830 using an FID detector. Helium was used as carrier gas in an isothermal experiment where the reaction mixture was injected directly into the instrument. The quantity of styrene monomer could be measured with respect to the solvent medium.

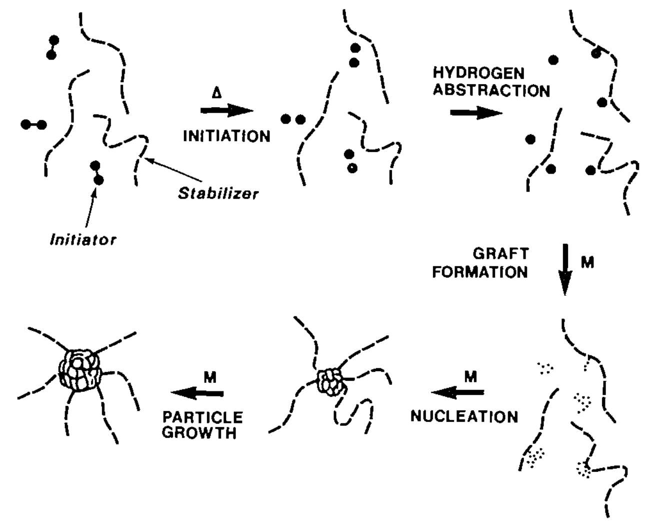

FIG. 1. Schematic representation of nucleation and growth in a dispersion polymerization.

3. Discussion

All of the different methods of particulate polymerization discussed in the introduction have properties that make them unique from each other. These differences are especially dependent on the way in which the reagents are located in the reaction medium as outlined in Table 1. The striking feature of dispersion polymerization is that there is initially only one phase and therefore the monomer is distributed throughout the reaction medium. In contrast, the other methods of polymerization start out as multiphase systems and as a result have different routes to nucleation and growth. Figure 1 shows a schematic for the nucleation and growth of sterically stabilized particles by dispersion polymerization.

Polystyrene particles can be prepared in a wide variety of solvent combinations by dispersion polymerization. The reaction requires that the monomer, initiator, and stabilizer are all soluble in the starting medium, and that the product polymer precipitates during the reaction. This puts certain constraints on the types of solvents that can be used in combination with the styrene monomer and stabilizer. However, once the polymer particles are formed, the initiator and monomer can be expected to partition between the solvent and polymer phases and the

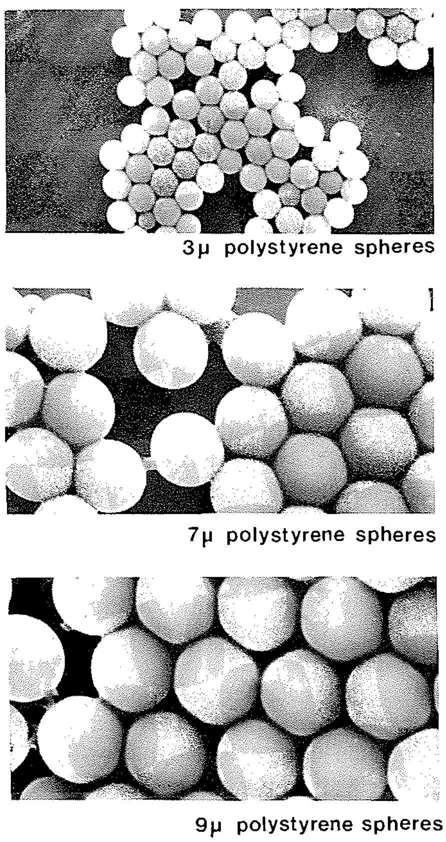

FIG. 2. Scanning electron micrograph of particles prepared with HPC stabilizer.

relative amount in each phase is determined by the choice of reaction conditions.

Particle size control is therefore a function of several thermodynamic and kinetic factors, and these include: (*1*) monomer–polymer solubility, (*2*) reactant composition, (*3*) temperature, and (*4*) solvent medium among others. Temperature, of course, influences both the thermodynamic factors such as solubility as well as the kinetics of initiator decomposition, which in turn determines the rate of polymerization and particle nucleation.

Several of these parameters controlling particle size were explored while preparing particles composed of a polystyrene core and cellulosic stabilizers. The solvent systems studied were water miscible, and could be classified as alcohols, ethers, and ether–alcohols. These materials possess a wide range of solubilities and systematic variations in the chemical structure, and this permits a better qualitative understanding of the effects of medium on the polymerizing mixture.

The properties of these liquids are listed in Table 2 and include their dielectric constant, dipole moment, and solubility parameter. Also included in the table is a three component parameter based upon covalent, dipolar, and hydrogen bonding forces, the presence of which is intended to show that even though the solubility parameter can be the same for two solvents, the contributing factors can be quite different. The solvents are ranked in increasing polarity according to their solubility parameter. As the table indicates, the least polar solvent used, and a solvent for polystyrene, was dimethoxyethane while the most polar liquid was water.

3.1. Ether–alcohol/alcohol mixtures

Methyl cellosolve (2-methoxyethanol or MeCell) is a member of the cellosolve or ether–alcohol family of commercial solvents, and is a solvent for hydroxypropyl cellulose (HPC) while being a non-solvent for polystyrene, the polymer prepared in the polymerization reaction. The solubility parameter, δ, of MeCell is 11.4 (14). In the systems studied, when MeCell was used alone, solvent-swollen 5 to 50 μm particles were obtained that could not be isolated without substantial coalescence, whereas ethanol (δ = 12.7) alone produced 0.5 to 3 μm particles.

The addition of ethanol, a stronger non-solvent for polystyrene, to MeCell enabled the preparation of particles in the 5–10 μm range. Both the ratio of the monomer to suspending medium was varied as well as the proportion of MeCell to ethanol. It was found that within a narrow window of relative concentrations it was possible to obtain particles with a monodisperse size distribution. By varying the relative amount of MeCell to ethanol the ultimate particle size could be controlled. Some of these monodisperse particles are illustrated in Fig. 2, and their molecular weights and diameters are listed in Table 3. The particles shown in Fig. 2 were taken from the unpurified reaction mixture which included ungrafted HPC as well as MeCell and ethanol. The bridging observed in the figure is due to excess HPC which can be easily removed during the washing

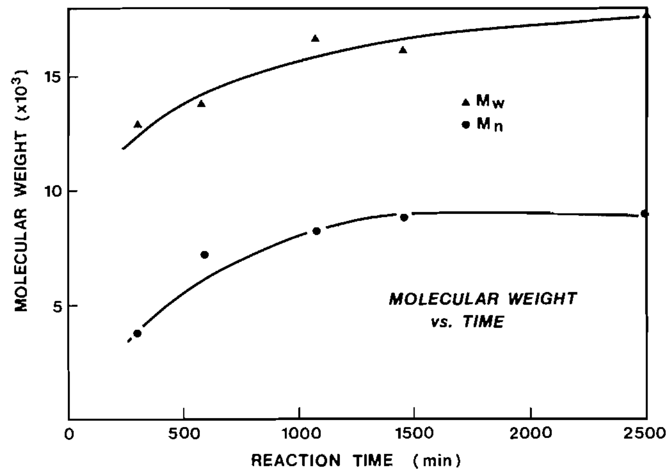

FIG. 3. Molecular weight changes as a function of time for polymerization in methylcellosolve/ethanol.

prior to the freeze-drying process. Once the HPC is removed, bridging has been found to be absent.

Shown in Table 4 are the reaction conditions used to produce monodisperse particles as well as those conditions producing polydisperse particles in MeCell–ethanol. As the amount of methyl cellosolve was increased, corresponding to a decrease in the polarity of the reaction medium, the size of the particles increased. Changes in styrene monomer concentration also led to polydispersity with more or less monomer producing larger particles. Interestingly, the amount of stabilizer had only a small effect on the final particle size. When the amount of HPC was halved, the resulting particles showed monodispersity of the large particles, but also the presence of some smaller particles. This suggests that stabilization may have been somewhat less effective with reduced HPC levels. Doubling the quantity of stabilizer produced effectively no change in particle size, indicating that the reaction is tolerant of excess stabilizer. In contrast, when less initiator was used, the resulting particles possessed a very large polydispersity and the rate of polymerization was much slower.

The molecular weight of both the HPC-stabilized polymer particles and the oligomer remaining in solution was determined by GPC in THF solvent. A plot of molecular weight versus time is shown in Fig. 3, and there it can be seen that as the reaction proceeds, the molecular weight of the particles increases initially and then levels off. This increase is probably an artifact of the particle isolation procedure at low conversions, and in fact particle molecular weight is level throughout the reaction. The molecular weights of the monodisperse particles produced in MeCell–EtOH are lower than those of polydisperse particles produced in the EtOH–water system discussed later and suggests that there are differences in the polymerization mechanism between the two systems at higher conversion.

The chromatograms of isolated particles, and the suspending medium at the end of the polymerization are given in Fig. 4. It is evident that the material left in solution (dashed line) was of lower molecular weight, except for the second peak appearing at lower elution volumes observable only on the RI detector. This material may be grafted HPC with enough styrene to give the material detectability by refractive index changes. The HPC remaining in solution and making up most of the dissolved polymer was otherwise not detected in either curve. The presence of the oligomer (peak maximum ~ 2500 MW) in solution shows that a critical molecular weight must be reached before nucleation can occur or else the polymer will remain in solution. This molecular weight is probably higher than 2 500 due to the larger amount of monomer at the beginning of the reaction causing increased solubility. A separate experiment has shown that polystyrene of 9 000 molecular weight is totally soluble in the starting reaction mixture while polystyrene of 35 000 molecular weight or more is insoluble. This observation indicates that the precipitating component has a molecular weight greater than 9 000. Interestingly, runs giving monodisperse and polydisperse particles both gave products with similar molecular weight properties.

Two other cellulosic stabilizers, ethyl cellulose and cellulose propionate, were studied in the MeCell–EtOH reaction medium. These polymeric stabilizers were soluble in the reaction medium and could be used to produce monodisperse particles. However, when the same conditions employed with HPC were used for these stabilizers the resulting particle sizes were quite different. The conditions used to generate 3 μm particles with

* 15% styrene at 65°C, 7.5 g HPC, 3.0 g BPO.

HPC stabilizer produced much larger particles (6 μm) with ethyl cellulose and cellulose propionate. Similarly when the conditions for the synthesis of 10 μm monodisperse HPC-stabilized particles were used, particles with a wide distribution and sizes ranging from 5 to 50 μm were produced with the other two stabilizers. Such differences between stabilizers may be due to changes in the degree of grafting expected to occur during the polymerization or in the solubility of the cellulosic function in the reaction medium. The ability of the stabilizer to inhibit coalescence would be affected in both cases.

Another ether–alcohol was investigated for its particle forming properties. Cellosolve (2-ethoxyethanol, $\delta = 10.5$) is chemically similar to methyl cellosolve, but cellosolve replaces the methoxy group of methyl cellosolve with an ethoxy group, making it somewhat less polar than methyl cellosolve. The size distribution of the cellosolve particles was perhaps the widest of those produced using the various solvent pairs, and was certainly never as narrow as that produced using methyl cellosolve. As shown in Table 5, increased amounts of ethanol produced smaller particles, in agreement with the MeCell–ethanol results.

3.2. Ether/alcohol mixtures

Two ether class solvents, dimethoxyethane (DME, $\delta = 8.6$) and tetrahydrofuran (THF, $\delta = 9.1$), were used in conjunction with ethanol as polymerization media. Of the solvents studied,

TABLE 6. Properties of particles prepared in alcohol media

Pure alcohol medium	δ_i $(cal/cm^3)^{1/2}$	Diameter (μm)*

these were the most non-polar and were both swelling solvents for polystyrene, the particle core. Using THF and ethanol, particles of about 10 μm could be prepared as shown in Table 5. Regardless of the final particle size, the particles were swollen by solvent which could be removed by distillation without leading to coalescence. While swollen particles had a smooth surface, the deswelled particles possessed a wrinkled surface. Small changes in the relative amount of THF to ethanol caused a much larger change in size and distribution than in the case of MeCell or cellosolve, but in no case was monodispersity observed even though a relatively narrow distribution was produced.

The even less polar solvent, DME, was used as a co-solvent with ethanol to produce polystyrene particles. Like the other solvent pairs, more ethanol led to smaller particles, and like the THF medium the particle size distribution was narrow but not monodisperse. It is probable that if different monomer levels were used, other effects on particle size and size distribution could be observed; however, the examples illustrate what can be expected when polymerization occurs in the presence of solvents for the polymer core.

3.3. Alcohol/water mixtures

Particles with a polystyrene core and HPC stabilizer could be made in methanol, ethanol, isopropanol, *tert*-butanol, or mixtures of these alcohols and water by dispersion polymerization. In pure alcohol, particle size increased from methanol ($\delta = 14.5$) to ethanol ($\delta = 12.7$) to *tert*-butanol ($\delta = 10.6$). In addition, the *tert*-butanol particle size distribution was also much wider. The smallest particle size was obtained in isopropanol ($\delta = 11.5$), as noted in Table 6. Based upon solubility alone, the isopropanol would have been expected to produce particles in the range between the ethanol and *tert*-butanol systems.

As one decreased the concentration of alcohol in ethanol–water systems, the particle size became smaller without much change in the polydispersity as shown in Table 7. This property was related to the polarity of the solvent system as observed in Table 2. By changing the systems shown in Table 8 from the most polar methanol–water system to ethanol–water to isopropanol–water and finally the least polar *tert*-butanol–water system, a similar trend of particle size in-

TABLE 8. The effect of changes of monomer concentration on particle size

Cosolvents (3:1 ratio)	Monomer concentration (vol. %)	δ_i $(cal/cm^3)^{1/2}$	Diameter* (μm)
MeOH–H_2O	12%	16.4	0.82 (1)
EtOH–H_2O	6%	15.7	0.61 (1)
	12%	15.4	1.05 (1)
	24%	14.7	2.14 (4)
	35%	14.0	2.85 (6)
iso-PrOH–H_2O	12%	14.8	1.11 (2)
tert-BuOH–H_2O	12%	14.3	1.64 (1)

crease was observed. The size increase from ethanol–water to isopropanol–water was relatively small compared with the increase from isopropanol–water to *tert*-butanol–water.

Monomer, since it is part of the initial solvent system, plays an important role in the resulting particle size. An increase in the initial monomer concentration leads to bigger particles and a wider size distribution. These effects, demonstrated with the ethanol–water system and shown in Table 8 and Fig. 5, can be summarized as follows: (*i*) increased monomer levels can sustain growth to give larger particles, (*ii*) solvency is changed since the monomer is in this case a solvent for its polymer, and (*iii*) the amount of monomer affects the equilibrium distribution of monomer between the polymer phase and the medium leading to a modification of the growth mode.

Another interesting observation is that both the molecular weight and the molecular weight distribution increase in the ethanol–water system as the polymerization proceeds as illustrated in Fig. 6. These are results that might be expected for a suspension polymerization and are quite different from those of an emulsion polymerization. The increase in molecular weight is also consistent with the Tromsdorf effect. This effect is quite strong in this solvent system, but not evident with MeCell–EtOH. In the latter case the Tromsdorf effect may be undetected due to polymerization in the medium, which masks an increase in the rate of polymerization expected to occur within the particles. In ethanol/water systems most of the monomer is located in the growing particle whereas in the ethanol/MeCell case, substantial quantities of monomer remain in the medium and these differences are reflected in the relative rates of polymerization.

In order to test the predictive properties of the solubility parameter, a solvent system having the same value as the MeCell–ethanol mixture was investigated. The solubility parameter value for isopropanol happens to be almost identical to that of MeCell, so two runs prepared by substituting isopropanol for MeCell with 15% monomer by volume were studied. The runs used a 50:50 isopropanol–ethanol (IPA–EtOH) mixture in the first case and a 70:30 IPA–EtOH mixture in the second case. The resulting particles (2.6 μm) were indeed found to be monodisperse in the first set of conditions, but quite a bit smaller than those particles prepared in MeCell–EtOH. In the second case the particles were somewhat larger (6 μm), but polydisperse. These observations show the importance of solubility to the ultimate particle size. However, the precise role of solvent polarity on final particle size is clouded somewhat by the observation that smaller particles are formed in the presence of isopropanol as compared to MeCell. Such inconsistencies demonstrate the existence of a different

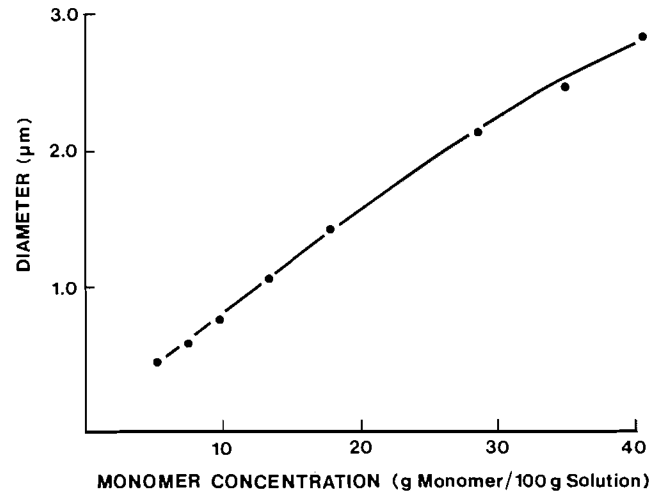

FIG. 5. Monomer concentration versus particle size in ethanol/water media.

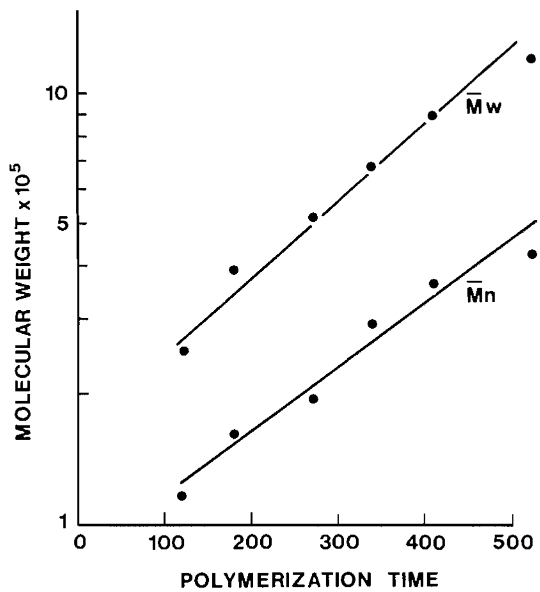

FIG. 6. Particle molecular weight versus conversion in ethanol/water media.

solvent property besides that reflected by the solubility parameter. The effect of solvent therefore is certainly not limited to solubility alone.

3.4. *Particle growth*

The unique feature of this polymerization technique is that it permits the direct polymerization of monodisperse micron-size particles when the appropriate conditions are used. The rate and mode of growth of these large monodisperse micron size particles are therefore of some interest and were studied quantitatively.

The current literature refers to several researchers who have dealt with monodisperse particles, but these particles were generally prepared in emulsion systems (8–13). In contrast to dispersion polymerization which entails nucleation from a homogeneous environment (11), emulsion polymerization begins as a multiphase system (8). Other differences are outlined in Table 1 and show the way that initiator and monomer is distributed differently in the two systems. In addition, it should be

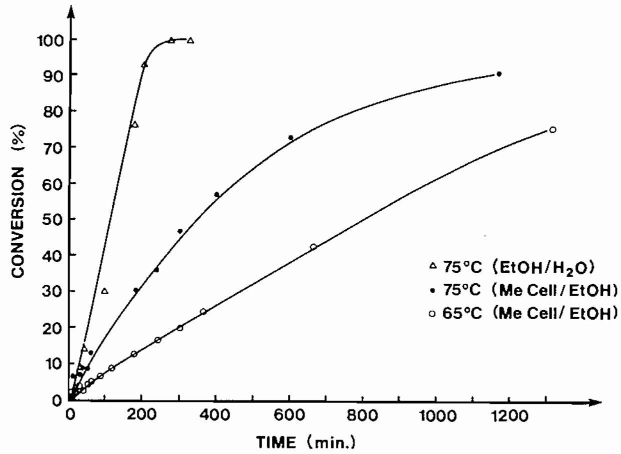

FIG. 7. Conversion versus time in particulate polymerization.

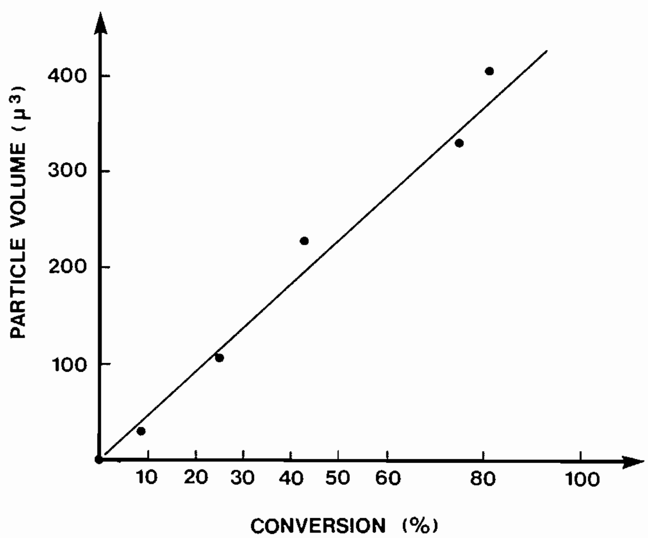

FIG. 8. Particle volume versus conversion during growth of monodisperse particles.

noted that oligomer formed in the homogeneous phase can be considered to either nucleate or be captured by growing emulsion particles, but may remain in solution in a dispersion polymerization depending on which reaction medium is used.

Figure 7 shows a plot of conversion (p) versus time (t) for two reactions in methyl cellosolve–ethanol at 65 and 75°C and for comparison a reaction in ethanol–water at 75°C is also shown. The conversion was measured by monitoring the disappearance of the monomer peak by gc as a function of time relative to the MeCell or ethanol peak. The ethanol–water system showed the highest rate of conversion indicating that there was a strong auto-acceleration or Tromsdorf effect typical of the kinetics of suspension polymerization and was consistent with the molecular weight results reported above. This could be related to the polarity of the solvent medium since in the ethanol–water system, both the non-polar styrene monomer and initiator quickly diffused into the particle nucleus and sustained faster particle growth. In the less polar MeCell–EtOH system, much slower rates resembling solution polymerization were observed, possibly because the monomer was present to a larger extent in both phases and the slower growth was determined by diffusion.

The final particle size depended on the amount of initiator and the temperature of reaction. If the amount of initiator was reduced, particle size and size dispersity increased. Temperature was also critical to the size distribution of the final product. Even though the reaction profiles of both runs in methyl cellosolve – ethanol at 75 and 65°C are similar, only the lower temperature run gave monodispersity. Starting temperatures of 75 and 55°C instead produced polydisperse samples. However, if the temperature was increased from 65 to 75°C after only 10% conversion the rate of polymerization could be increased without changing the dispersity of the product. This indicates that the temperature was critical to the particle formation stage, but not so crucial to the growth stage.

The increase in particle size during the course of the polymerization would be expected to be proportional to conversion provided that (a) all or a constant fraction of polymer was incorporated into the particles and (b) little or no coalescence occurred between particles of the same size. The relationship between particle volume (V_p) and conversion (p) is given in Fig. 8, which shows a plot of particle volume versus conversion for a monodisperse run where volume was calculated from the diameter of the particles as measured by optical microscopy. There is indeed an apparently linear relationship between particle volume and conversion. The linearity of the curve indicates that the number of particles is essentially constant from even the earliest stages of the reaction, and therefore nucleation must take place only in those early stages.

3.5. *Particle size control*

The initial medium solvency is important in determining the final particle size, since particle formation is restricted to the early stages of the polymerization. The ultimate particle size and distribution are also a function of the amount of coalescence that occurs during and after the particle formation stage. In the case of the monodisperse particles, coalescence between large particles is negligible and therefore a narrow size distribution is retained.

The importance of the initial solvency of the reaction medium can be seen in Table 4 where the solubility parameter (δ_i) of the starting reaction medium is listed. The solubility parameter is a value derived from the heat of vaporization of a solvent and its molar volume. All δ values reported here are in units of $(\mathrm{cal/cm^3})^{1/2}$. The solubility parameter was calculated as the root-mean-square volume weighted average of the solubility parameters of the cosolvents and monomer (15). The contributions of stabilizer and initiator were neglected because they were present in very low levels with respect to the other components.

The trend of particle size decrease with solvent polarity increase can be observed in this table, and was consistent for all observed reactions. The reaction conditions for MeCell–ethanol systems were plotted in Fig. 9, a three-coordinate plot where the axes are the volume percentages of ethanol, methyl cellosolve, and styrene. Also shown are two iso-solubility curves with δ equal to 11.5 and 11.9. Particles prepared at $\delta \geq 11.9$ were in the range of 3 μm diameter or less while those prepared at $\delta \leq 11.5$ were 10 μm or more. This observation was consistent over the range of monomer levels used, that is between 10 and 33% styrene. When monomer was reacted at concentrations as high as 50%, the polymerization system tended to gel and therefore no reactions are reported in this range. The three reaction mixtures represented by open circles are those that produced monodisperse particles. No satisfactory explanation can be presently offered as to why these

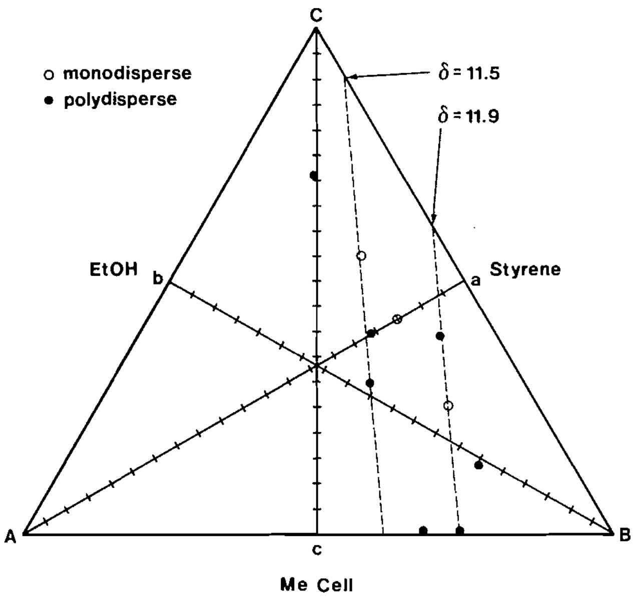

FIG. 9. Effect of composition of methyl cellosolve-ethanol-styrene reaction mixture on particle size and distribution.

particular reactions gave products with such narrow size distributions.

The initial solubility parameter of the other reported solvent systems was also calculated and is listed in Tables 5 to 8. The trend of particle size with polarity was consistent with the results reported above within a given solvent system. Note that a solubility parameter of 11.8 gave ~ 10 μm particles with THF–ethanol while the other systems in Tables 4 and 5 gave particles ranging from 1–4 μm to 7–9 μm with δ_i equal to 11.7. It is difficult therefore to correlate these results among substantially different solvent systems.

The reaction conditions listed in Tables 6, 7, and 8 also showed good consistency within a given system when comparing particle size with solubility. Comparing different systems again revealed that while particles of comparable size were produced at a given solubility parameter, direct comparison was not possible. These differences may be ascribed to the interaction that the solvent system has with the propagating free radical, and with the steric stabilizer. Differences in the chain transfer properties of the solvent, and the effect of solvent on the solubility of the stabilizer would both be expected to alter the ultimate particle size. This reconfirms the earlier observation that the effect of solvent on final particle size was not limited to solubility alone.

Anodic and cathodic processes for rf and dc excited plasmas of silane gas differ in the relative role of charged and neutral radical species. By studying the thickness distribution of films deposited on substrates immersed in the plasma, the relative importance of these species as contributors to the film thickness is assessed. In addition, the impact of the different deposition processes on the spin density in the deposited hydrogenated amorphous silicon films and a key photoelectronic property, the hole range, is discussed.

Les processus anodiques et cathodiques des plasmas de silanes gazeux excités par des f.r. et par du c.d. diffèrent par les rôles relatifs des espèces radicalaires neutres et chargées. L'étude de la répartition des épaisseurs des filmes déposés sur les substances immergés dans le plasma a permis d'établir l'importance relative de ces espèces en tant que responsables de l'épaisseur du film. De plus, on discute de l'impact des différents processus de dépôt sur la densité de spin des films amorphes de silicium hydrogéné déposés et sur une propriété photoélectronique fondamentale, la grandeur de la cavité.

[Traduit par le journal]

Introduction

Any physical vapor deposition process for thin films requires the generation of radicals which are transported to a substrate on which the film condenses. Condensable radicals are commonly generated by the vaporization of precursor solids and liquids in vacuum. Examples of such deposition techniques are thermal evaporation and sputtering. If the precursor material is already in gaseous form, condensable radicals can be created by thermal decomposition (CVD) or by plasma decomposition (plasma enhanced CVD) of an appropriate gas. The latter deposition method is also known as plasma or glow discharge deposition. This method has become increasingly important over the last decade because the use of gaseous starting materials offers significant and unique advantages over other physical vapor deposition methods. The glow discharge process is ideally suited for the uniform deposition of a wide variety of materials in single and multi-layers over large areas. In addition, materials that can be deposited by the glow discharge process often have unique properties which may be difficult if not impossible to duplicate by other fabrication processes. This is especially true for the alloys based on the group IV elements, such as amorphous hydrogenated silicon (a-Si:H), plasma silicon nitride (SiN_x), silicon oxide (SiO_x) and others. There is wide spread interest in devices based on these materials including solar cells, photoreceptors, and thin film transistors and correlations between process/material properties are therefore of considerable importance.

Despite this intense and growing interest in these materials and the considerable understanding of the physics of the devices which can be fabricated by the glow discharge process, relatively little is known about the mechanisms active during the deposition process itself. Diagnostic measurements such as mass spectroscopy and optical emission spectroscopy are commonly used to determine the presence of neutral and ionic species in glow discharge plasmas. These measurements have, in the case of silane, revealed the existence of a wide variety of such species in the plasma (1, 2) but have not been very useful in determining their importance and relative contribution to the growing film. It is generally assumed that the contribution of ions to the growth of a film in a plasma deposition process is much smaller than that of neutral radicals. The reasoning which leads to this consideration is based on the comparison of molecular dissociation and ionization energies where the first is generally much smaller than the latter. With a near Maxwellian distribution of electron energies, the generation rate for neutral radicals can be estimated to exceed the ionization rate by more than an order of magnitude for typical operating conditions. However, this argument may be misleading because the mass transport processes for ions and neutrals are fundamentally different. The relative concentrations of condensable neutrals and ions in the plasma are not necessarily simply related to the relative amounts of neutrals and ions which contribute to film growth.

Of special interest are the regions and plasma conditions close to the electrodes where, it is assumed, the film material of interest is deposited. These conditions are generally different at the cathode and the anode. As a consequence, the deposition rate and material properties of anodic and cathodic films are often different. Charged and neutral radical species arrive at the substrate surface with different energies and can impact various physical properties of the film due to differences in bonding, mechanical damage, or ablation. Differences in anodic and cathodic deposition rates can in principle be understood when charged condensable species contribute significantly to the deposition process. However, even if only neutral radicals contribute to the growing film, an imbalance in the cathodic and anodic deposition rate can result if the neutral species are not created uniformly in the gap.

Significantly different conditions can be externally and controllably imposed on any deposition system by the excitation mode of the plasma. Direct current (dc) and radio frequent (rf) plasma excitation are commonly used in capacitively coupled reactors. Very little is known about the relative deposition rates and the properties of the films deposited under these different conditions on the anode and the cathode.

The object of this paper is to compare and contrast the anodic and cathodic processes for rf and dc excited plasmas using information derived from the condensed species distribution in and across the discharge gap of a deposition reactor. In addition, measurements have been made of a key photoelectronic

parameter, viz the carrier range (3) for holes $\mu\tau_h$ (μ is the electronic drift mobility and τ_h is the deep trapping lifetime) for material produced under different conditions.

Experimental method

In a plasma, a variety of neutral and charged condensable radicals is created in the discharge gap by electron impact fragmentation of the precursor gas. To discriminate between the collective of neutral and the collective of ionic radical species, one can advantageously use the difference in the mass transfer mode of these species. The transport of charged species conforms primarily to the electric field lines whereas neutrals diffuse isotropically from their point of origin. A specific experimental arrangement which has been used in this work to study silane plasmas is shown in Fig. 1 and a more detailed drawing of the electrode area is presented in Fig. 2. A dielectric slab, S, called the "gap substrate" is placed in the discharge gap perpendicular to the parallel anode, A, and cathode, C, and parallel to the direction of gas flow. The dielectric plane is thin in order to minimize the flow disturbance. Its placement parallel with the electric field lines does not disturb the electric field distribution outside the slab. As convective transport is parallel to any of the surfaces under consideration, one can, to first order, neglect its effect on the thickness distribution of the condensed films. The line A'ACC' indicates the line over which the thickness of the deposited film was measured.

Characteristic hypothetical thickness distributions are shown in Fig. 3 for the extreme cases of deposition by exclusively neutral radicals (Fig. 3*a*) and exclusively ions (Fig. 3*b*). In the first case, neutral radicals are asumed to be uniformly created in the discharge gap by electron impact dissociation of gas molecules. These neutral radicals are transported to the walls of the confinement by diffusion. Even for the case of uniform radical generation in the discharge gap, the film thickness decreases close to the intersection lines of the electrodes and the gap substrate (points A and C in Fig. 3). The first reason for this decrease follows from geometrical considerations. Far away from the right angles between electrodes and the gap substrate, each point at the film surface receives vapor isotropically from the half space above it. Moving within distances d toward the right angles A and C, the half space contribution gradually diminishes to quarter space contribution in the corner. This geometrical effect causes therefore the film thickness to be half of the value which it would have without gap substrate. A second reason why the measured film thickness on the electrodes and the gap substrate decreases close to A and C is the sink effect of the walls on the condensable radicals. A concentration gradient between the neutral radical concentration in the plasma and the walls of the confinement is caused by the continuous disappearance of the condensable radicals close to the walls. This sink effect causes, just as the geometrical effect, gradients which extend over the order of the neutral radical diffusion length from A and C. These effects confound the interpretation of the measured thickness distributions and have to be taken into account. Mathematical modelling of the diffusion process is required to deconvolute the observed gap gap distribution in order to derive the gap distribution of neutrals. The mathematical formalisms have been developed by Chen (4) for various reactor geometries.

A significant simplification of the considerations results when only a small volume of space close to the intersection lines through A and C is considered. A volume can always be found in which the neutral radical distribution can be considered to be constant. In the case where only isotropic diffusion processes are active, the film thicknesses at A and C will be the same for the electrode and the gap substrate (Fig. 3*a*). This situation changes drastically when the predominant contribution to the deposition is by ionic species, a case which is schematically illustrated in Fig. 3*b*. Here, charged radicals of only one polarity are assumed to be created somewhere in the discharge gap by electron impact ionization. These ions are primarily transported along the electric field lines, thus contributing only to the buildup of material on one of the electrodes. The resulting thickness distribution pattern is quite different from the previous case and this difference can, at least in principle, be used to determine the relative contribution of neutral and charged radicals to the growing film.

It is emphasized that the previous considerations apply only to the idealized condition where the effects of self bias of the different surfaces in contact with the plasma are negligible with respect to the

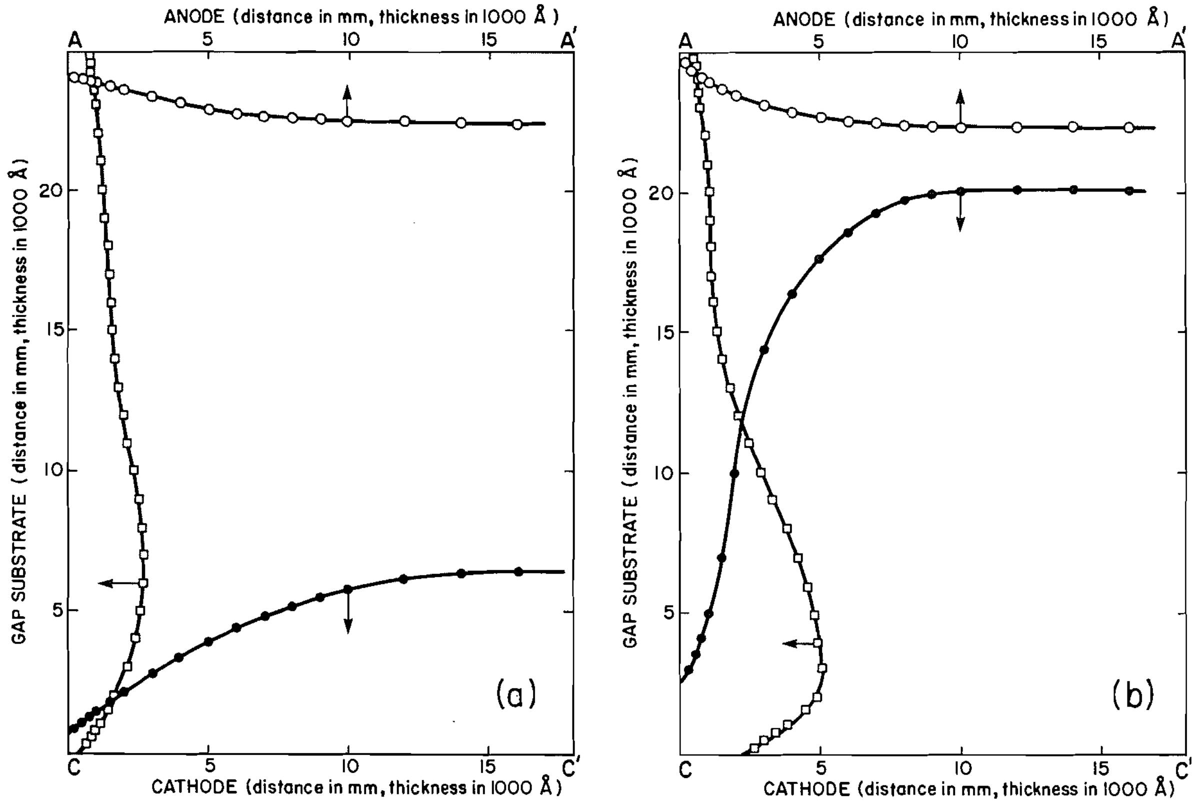

FIG. 4. (a) The film thickness distributions on the cathode (●), the anode (○), and the gap substrate (□) for a rf 10 min discharge of 100 sccm of silane at 250 mTorr and at a power input of 10 W; (b) The film thickness distributions on the cathode (●), anode (○), and gap substrate (□) for a 10 min dc discharge of 100 sccm of silane at 250 mTorr and at a current density of 0.1 mA/cm^2.

effects of the externally applied potentials. In reality, insulating surfaces, such as the gap substrate, assume a local potential which equalizes the electron and ion flux to the surface. Ions will then diffuse to this surface with an ambipolar diffusion coefficient which magnitude is of the order of the diffusion coefficient for neutral species. The contribution of ambipolar ion diffusion to the film thickness on the cross gap substrate has been neglected with respect to the combined effects of ion diffusion and ion drift in the externally applied electric field. Figure 3b is only an approximation of the practical situation and the deposition of a thin film on the gap substrate has to be expected.

In this paper the specific case of amorphous silicon deposition from silane gas has been studied. Knowledge about the condensable radical distribution in the discharge gap is essential for the realistic modeling of the mass transfer process active during deposition of this technologically important material. In addition, the effect of the externally applied bias on some of the properties of the deposited film have been determined. The spin density, as determined by electron spin resonance (esr) techniques, is generally taken as a measure for the dangling bond density. Furthermore, the range of photogenerated holes in the deposited films was measured by standard time of flight techniques (5) using samples ~10 μm thick. The hole range depends both on the mobility and the lifetime of these charge carriers, both of which parameters are related to the density of states in the forbidden gap of the material.

Experimental details and results

The entire electrode area (40 cm^2) of the anode and cathode of a small plasma deposition reactor was covered with glass with an electrically conductive film of indium-tin-oxide (ITO). The ITO film is hard enough to allow reliable thickness measurements to be made over grooved areas where the film has been removed by scratching of the material with a stainless steel pin. The electrical power was supplied to the electrodes and the ITO film. The interelectrode distance was kept constant at 2.5 cm. The electrode temperature was maintained at room temperature during deposition on substrates used for thickness measurements. Samples which were to be evaluated electrically were deposited on aluminum substrates at 230°C. The gap substrate was formed by a 100 μm thick glass plate mechanically clamped perpendicular to the electrodes at the anode. Silane gas was introduced into the reactor through a dispenser at a constant flow rate of 100 sccm. The gas was exhausted through a throttle valve arrangement such that its pressure was maintained at 250 mTorr. The deposition arrangement is schematically shown in Fig. 1.

The rf power and negative dc voltage, supplied between the cathode and grounded anode, were adjusted to a level where comparable amounts of polysilanes were formed by the discharge. The polysilane formation was measured by the rate of weight increase of a downstream filter and was of the order of 0.5 g/h under the present rf and dc operating conditions. The rf power was supplied at 5 W and 13.56 MHz whereas the dc current density was maintained at a level of 0.1 mA/cm^2 which corresponds to an intergap voltage of about 750 V.

Film thickness distributions were measured with a mechanical stylus instrument on the anode and cathode ITO substrates and the gap substrate over the line A′ACC′ as indicated in Fig. 2. The results are shown in Fig. 4. These results do not depend on which of the electrodes was used as anode or cathode, indicating uniformity of the gas flow in the gap area. The detailed shape of the thickness distributions and particularly the relative cathodic and anodic deposition rates depend somewhat on the reactor geometry, the interelectrode gap distance, and the pressure. The results obtained for different reactor geometries and operating conditions are qualitatively the same. The dc cathodic deposition rates are about a factor of 3–4 higher than the cathodic rf rates at comparable levels of polysilane formation. The anodic rates for dc and rf deposition are comparable under those circumstances and always smaller than the cathodic rates.

Table 1 lists the results of electron spin resonance measurements

TABLE 1. Hole range values for a-Si:H samples prepared in different plasmas

Plasma type	Electron spin resonance (cm^{-3})	Mobility*, $\mu(cm^2/V\ s)$	$\mu\tau_h$* (cm^2/V)
dc cathodic	5×10^{16}	5×10^{-4}	9×10^{-8}
dc anodic	5×10^{16}	3×10^{-4}	3×10^{-7}
rf cathodic	4×10^{16}	—	—
rf anodic	8×10^{15}	1.9×10^{-3}	1.3×10^{-6}

*These samples were made from SiH_4 admixed with 10 ppm B_2H_6.

and measurements of the hole range, $\mu\tau_h$, for samples made in rf and dc (anodic and cathodic) glow discharges.

Discussion

The differences between the measured and the hypothetical distribution of Fig. 3*b*, where ionic species were assumed to contribute primarily, include a significant film growth on the gap substrate and anode. This film growth is in the case of rf as well as dc discharges skewed towards the cathode where the electric field is expected to be relatively high. This indicates that, independent of the excitation mode, neutral radicals, rather than ions, are the dominant contributing species to the deposition process. Moreover, at A and C the film thickness on the gap substrate is the same as on the electrodes in all cases, again indicative of the diffusion of neutral species, the concentration of which is uniform close to A and C. Yet, the measured thickness distributions are quite different from the hypothetical distribution in Fig. 3*a*. The gap distributions are not symmetric with respect to the midgap position. This indicates that the neutral radicals are not uniformly created throughout the discharge gap as assumed for Fig. 3*a*. The fact that the cathodic deposition rates are always higher than the anodic rates is consistent with the fact that the generation of the neutral radicals takes placed relatively close to the cathode for both rf and dc discharges. However, there are significant and consistent differences in the film thickness distribution on the gap substrate between rf and dc excited plasma discharges. The gap substrate thickness is more uniformly distributed and the maximum is further away from the cathode for the case of an rf excited discharge. In the case of a dc discharge, the gap thickness distribution decreases only close to the cathode to about one half of the maximum value, which has to be expected from geometrical considerations alone. This is indicative of a high neutral radical distribution close to the dc cathode, consistent with the high cathodic deposition rates for that excitation mode.

The observed differences between the rf and dc discharge thickness distributions are compatible with the mechanisms through which these discharges are sustained. In the case of a rf discharge, the high frequency oscillation of electrons in the bulk of the plasma causes the molecular dissociation and ionization processes. This is in contrast to the case of a dc plasma which is sustained through secondary electron emission from ion impact on the cathode. The impacting ions do not contribute significantly to the thickness of the growing film. However, the electronic properties of the condensed film could critically depend on the effects of ion impact during growth. Even at ion concentrations which are three orders of magnitude smaller than the neutral radical concentration, the gap state density of the material would be of the order of 10^{18} cm^{-3} if each impacting ion could create a localized electronic state.

The anodic rf material consistently gives higher values of $\mu\tau_h$ compared with anodic or cathodic dc material. The relatively poor quality of the dc material may be associated with the bombardment of the film surface during the deposition process. Although damage of the material might be expected from the ion bombardment processes at the cathode, it is surprising that the anodic material, subject to predominantly electron bombardment, is of similar poor quality. At this point it can not be excluded that radiation damage associated with the dc process is responsible for the relatively high density of dangling bonds. Independent measurements of the drift mobility μ show that the mobility values for rf samples are consistently higher than dc samples whereas little difference is found between the dc cathodic and anodic samples. The primary change in the range, $\mu\tau_h$, for anodic and cathodic dc samples therefore appears associated with variation of the deep trapping lifetime τ_h, and hence the density of deep traps.

Conclusion

From the study of the film thickness distribution on substrates immersed in rf and dc silane plamas, it is concluded that in both types of discharge the predominant condensing species are neutral. These neutral radicals are in the case of dc discharges created closer to the cathode than for rf discharges. The dc cathodic deposition rate is therefore relatively high compared to an rf discharge at a comparable power level. This difference in the spatial distribution of condensable species in the discharge gap is compatible with the fact that rf discharges are predominantly sustained by electrons created in the bulk of the plasma whereas dc discharges are sustained by secondary electron emission from ion impact on the cathode. Although the impacting electrons do not contribute significantly to the thickness of the growing film, they do affect the electronic properties of the film by causing a relatively large concentration of deep gap states in dc cathodic films.

Molecular weight – viscosity relationships for a broad molecular weight distribution polymer

H. KH. MAHABADI AND L. ALEXANDRU
Xerox Research Centre of Canada, 2660 Speakman Drive, Mississauga, Ont., Canada L5K 2L1

Received February 28, 1984

This paper is dedicated to the 10th anniversary of the Xerox Research Centre of Canada

H. KH. MAHABADI and L. ALEXANDRU. Can. J. Chem. **63**, 221 (1985).

A novel and simple method is described for evaluation of molecular weight – viscosity relationships for a polymer where only broad molecular weight distribution samples are available. The method demands measurement of the intrinsic viscosity and GPC chromatograms of several samples. Results of applying the procedure to bisphenol A – Diethyleneglycol (50:50) copolycarbonate are presented.

H. KH. MAHABADI et L. ALEXANDRU. Can. J. Chem. **63**, 221 (1985).

On décrit une nouvelle méthode simple permettant d'évaluer les relations poids moléculaire vs viscosité de polymères pour lesquels on ne dispose que des échantillons pour lesquels la distribution des poids moléculaires est large. La méthode implique des mesures de viscosité intrinsèque et des chromatogrammes en phase gazeuse de plusieurs échantillons. On rapporte les résultats obtenus lorsqu'on a appliqué la méthode à un échantillon de polymère de bisphénol – A/diéthylèneglycol (50/50).

Introduction

In order to interpret a gel permeation chromatograph (GPC) of any polymer sample in terms of its molecular weight distribution, it is necessary to establish a quantitative relationship between molecular weight M and elution volume v. It is well-known that well-characterized narrow distribution polymer samples are the most appropriate for GPC calibration purposes. Such samples are, however, difficult to prepare with the exception of polystyrene, for which good standards are readily available. The $M-v$ relationship for any other polymer can be obtained using the familiar universal calibration procedure (1, 2) and a reliable pair of k and α constants for the Mark–Houwink–Sakurada equation.

The evaluation of the Mark–Houwink constants k and α for a particular polymer–solvent system normally requires the preparation of a series of samples having a wide range of molecular weights and their subsequent characterization by light scattering and dilute-solution viscosity. However, gel permeation chromatography (GPC), i.e., size exclusion chromatography can provide a convenient alternative route to k and α (3–10). In this case k and α can be estimated using unfractionated polymer samples of known $\bar{M}_n$ or $\bar{M}_w$ and intrinsic viscosity.

In this work a new and simple method which permits the facile determination of the Mark–Houwink constants using hydrodynamic average molecular weight, $\bar{M}_x$ (11), is presented. The method described uses a combination of gel permeation chromatography and intrinsic viscosity measurements for several broad molecular weight distribution samples.

As an example of the use of this method, molecular weight – viscosity relationships for bisphenol A – diethyleneglycol copolycarbonate were found.

Theory

In a recent publication by Rudin *et al.* (11), the use of a new molecular weight average, $\bar{M}_x$, to characterize polymer samples of heterogeneous composition have been proposed. $\bar{M}_x$, the hydrodynamic volume average, is defined according to

$$[1]\quad \bar{M}_x = \frac{\Sigma\omega_i[\eta]_iM_i}{\Sigma\omega_i[\eta]_i} = \frac{\Sigma\omega_iJ_i}{[\eta]}$$

where ω_i and $[\eta]_i$ are the weight fraction and intrinsic viscosity, respectively, of all species which exit the GPC columns with elution volume v_i. The denominator in eq. [1] is equal to the intrinsic viscosity $[\eta]$, of the whole sample GPC solvent. The values in numerator are available from GPC chromatogram and universal calibration curve. $J_i = [\eta]_iM_i$ can be read directly from the universal calibration curve and ω_i is equated to the ratio of the area of the GPC detector response at elution volume v_i to the total area under the GPC chromatogram.

For a polydisperse polymer, the Mark–Houwink equation relates $[\eta]$ to the viscosity average molecular weight $\bar{M}_v$

$$[2]\quad [\eta] = K\bar{M}_v^{\alpha}$$

If the whole polymer is considered to be composed of a mixture of monodisperse species each with molecular weight M_i, weight fraction ω_i, and intrinsic viscosity $[\eta]_i$ in GPC solvent, then

$$[3]\quad \bar{M}_v = (\Sigma\omega_iM_i^{\alpha})^{1/\alpha}$$

and

$$[4]\quad J_i = [\eta]_iM_i = KM_i^{\alpha+1}$$

Equation [2] can be written in terms of $\bar{M}_x$

$$[5]\quad [\eta] = K_x\bar{M}_x^{\alpha} = \delta K\bar{M}_x^{\alpha}$$

where δ is given by (12)

$$[6]\quad \delta = (\Sigma\omega_iJ_i^{\alpha/\alpha+1})^{\alpha+1}/(\Sigma\omega_iJ_i)^{\alpha}$$

If the parameter δ remains constant through the change of $[\eta]$ and $\bar{M}_x$, then a log–log plot of $[\eta]$ vs. $\bar{M}_x$ gives the expected straight line relationship. The constants α and K_x can be obtained from the slope and intercept of such lines, respectively. Then constant $k = K_x/\delta$ can be estimated utilizing eq. [7].

As reported earlier (12) δ, for polymer samples having the same polydispersity or having very broad MWD ($\bar{M}_w/\bar{M}_n \geq 4$), is constant.

Experimental

Copolycarbonate synthesis

Bisphenol A (BPA) – diethyleneglycol (DEG) copolycarbonates

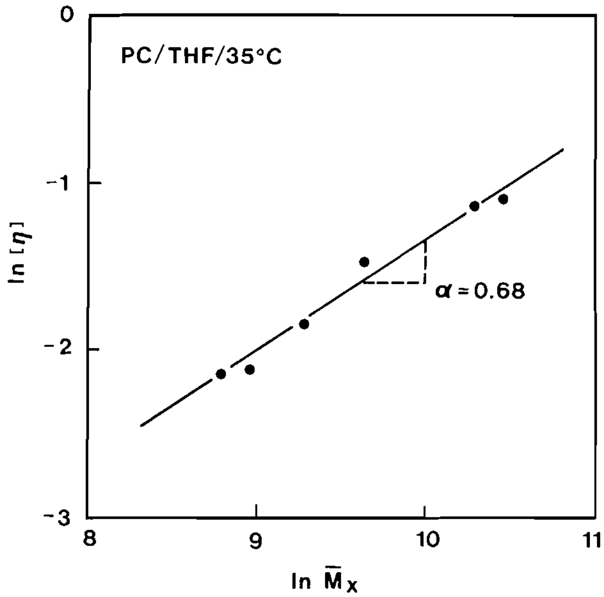

FIG. 1. ln [η] vs. ln $\bar{M}_x$ for cpc in THF at 35°C ($\bar{M}_w/\bar{M}_n \geq 4.5$).

were synthesized by solution polycondensation of BPA and DEG bischloroformate using CH_2Cl_2 as solvent and pyridine as the acid acceptor. The polymerization was carried out at low temperature and atmospheric pressure. The polymer molecular weight was changed by varying the concentration of DEG bischloroformate. All polymers synthesized are linear and have very broad molecular weight distribution ($\bar{M}_w/\bar{M}_n \geq 4.5$).

Gel permeation chromatography

A Water Associates GPC equipped with a high pressure solvent delivery (model 150C) was used. THF solutions of concentration less than 2 mg/mL were used. The flow rate, through a set of six μ styragel packed columns was 1 mL/min. The nominal size (in A) of μ styragel packings were 100, 500, 10^3, 10^4, 10^5, 10^6. A calibration curve based on elution volumes of 11 polystyrene standards from Pressure Chemical Company was constructed. The relation between molecular weight of PS and elution volume was obtained using a third degree polynomial. The coefficient of this polynomial was adusted for axial dispersion effects using an optimization method reported in the literature (13). Then, the corrected relationship between molecular weight of PS and elution volume was transferred to a universal calibration curve using the intrinsic viscosity of PS standards.

Intrinsic viscosity measurements

The intrinsic viscosities were determined using a Canon-Ubbelohde viscometer. All viscosities were obtained in THF and at 35°C (GPC conditions).

Results and discussion

The hydrodynamic volume average molecular weights of the polymer, $\bar{M}_x$, were estimated using eq. [1]. The right-hand side of eq. [1] was evaluated by treating the normalized GPC chromatogram data in a computer program. The calculated values of $\bar{M}_x$ along with [η] data were applied to eq. [5] and using least square analysis K_x and α were estimated. A log–log plot of [η] vs. $\bar{M}_x$ for BPA–DEG polycarbonate is shown in Fig. 1. Using GPC chromatogram and estimated value of α along with eq. [6], δ and therefore K for each sample was estimated. The results are summarized in Table 1. It is clear that variation for the calculated values of δ is less than 3%. The fact that δ is independent of MW and MWD of these samples indicate an accurate K and α estimation. The calculated values of K and α can be used to establish a relationship between [η] and molecular weight of copolycarbonate. This relationship can be written as:

TABLE 1. Calculated values of δ and k

Copolycarbonate samples	δ^a	$10^5 k^b$ (dL/g)
1	0.694	31.7
2	0.687	32.0
3	0.705	31.2
4	0.684	32.2
5	0.689	31.9
6	0.690	31.9
	$\delta = 0.692 \pm 0.007$	$\bar{K} = (31.8 \pm 0.3) \times 10^{-5}$

^{a}δ calculated from eq. [6] using α = 0.68.
^{b}K calculated from $K = k_x/\delta$ using K_x = 0.00022 dL/g.

TABLE 2. Viscosity results of copolycarbonate samples

Copolycarbonate samples	[η] measured (dL/g)	[η] calculated (dL/g)	% Difference
CPC 121	0.740	0.764	+3.2
CPC 108	0.139	0.130	−6.5

$$[7] \quad [\eta]\ \mathrm{dL/g} = 0.00032\ \bar{M}_x^{0.68}\ \mathrm{THF/35°C}$$

Using this relationship and universal calibration curve any average molecular weight of this copolymer can be calculated.

The precision of the proposed methods which use $\bar{M}_x$–[η] data to calculate K and α is tested here by comparing measured and calculated [η]. Two additional copolycarbonate samples were used for this purpose. Using the estimated values of K and α and GPC chromatogram, $\bar{M}_v$ and then [η] of these two samples were calculated. Good agreement is observed between measured and calculated [η] values as shown in Table 2. The difference between corresponding [η] values are small considering possible experimental uncertainties.

In summary, the proposed method for determination of molecular weight viscosity relationship outlined in this report has the advantage of being fast, convenient, and eliminates all fractionation problems related to monodisperse sample preparation and should be very useful for the characterization of highly specialized polymer products.

Inverse gas chromatography was used to investigate the miscibility behaviour of molten polystyrene–poly(2,6-dimethyl-1,4-phenylene oxide) blends as a function of composition (0, 25, 50, 75, 85, and 100 wt.% PS). Specific retention volumes were measured for various solutes in pure and mixed stationary phases of these polymers at 240°C. Infinite dilution weight fraction activity coefficients and Flory–Huggins polymer–solute (χ) and polymer–polymer (χ_{23}') interaction parameters were derived from these data.

Negative polymer–polymer interaction parameters were obtained for blends containing more than 60 wt.% PS, suggesting strong intermolecular interactions in the molten state. This is in accord with the well-known compatibility of PS–PPO blends. However, positive χ_{23}' values were observed for blends containing less than 60 wt.% PS. This suggests weak intermolecular interactions, and perhaps some microheterogeneity in PS–PPO blends with a low PS content. In view of the single, composition dependent T_g measured for each of these blends the microheterogeneity or microphase separation must be on a finer scale than that measured by the glass transition.

GIUSEPPA DIPAOLA-BARANYI, JOCELYN RICHER et WILLIAM M. PREST, JR. Can. J. Chem. **63**, 223 (1985).

On a utilisé la chromatographie en phase gazeuse inversée pour étudier le comportement, du point de vue de la miscibilité, de mélanges fondus de polystyrène–poly(diméthyl-2,6 oxyde de phénylène-1,4) en fonction de la composition (0, 25, 50, 75, 85 et 100% en poids de PS). Opérant à 240°C, on a mesuré, pour chacun des polymères, les volumes spécifiques de rétention de divers solutés dans des phases stationnaires pures et dans des phases stationnaires mixtes. A partir de ces données, on a déduit les coefficients d'activités de fraction en poids à dilution infinie ainsi que les paramètres d'interaction polymère–soluté (χ) et polymère–polymère (χ_{23}') de Flory–Huggins.

On a obtenu des paramètres d'interactions polymère–polymère négatifs pour les mélanges contenant plus de 60% en poids de PS; ceci suggère qu'il existe de fortes interactions moléculaires dans l'état fondu. Ceci est en accord avec la compatibilité bien connue des mélanges PS–PPO. Cependant, on a observé des valeurs positives de χ_{23}' pour des mélanges contenant moins de 60% en poids de PS. Cette observation suggère l'existence d'interactions moléculaires faibles et peut-être aussi quelques microhétérogénéités dans les mélanges de PS–PPO à faible teneur en PS. En se basant sur le fait que, pour chacun de ces mélanges, on ne mesure qu'une seule valeur de T_g, qui est indépendante de la composition, on peut croire que la micro-hétérogénéité ou la séparation de la microphase doit être dans une échelle plus précise que celle qui est mesurée par la transition du verre.

[Traduit par le journal]

Introduction

The technique of inverse gas chromatography (IGC) has recently been proven to be a very useful tool for obtaining polymer – small molecule and polymer–polymer interaction data (1–6). This method provides a fast and convenient route to reliable thermodynamic information on concentrated polymer systems in the molten state.

Polystyrene–poly(2,6-dimethyl-1,4-phenylene oxide) blends are classic examples of compatible polymer blends. However, recent calorimetric work by Prest suggests that there may be some microheterogeneity in PS–PPO blends with low PS content (7).

Therefore, a systematic study of PS–PPO blends was carried out over the whole composition range using IGC. The focal point of this work was the determination of polymer–polymer interaction parameters (χ_{23}') for various blend compositions. These data will be useful in evaluating the thermodynamic miscibility of these blends.

[1]Co-op student, Université de Sherbrooke, Quebec.

Experimental

Materials

All solutes were reagent or chromatoquality grade and were obtained from standard lab supply sources. Chromosorb G, AW-DMCS treated (70–80 mesh), was obtained from Johns-Manville. Polystyrene ($\bar{M}_w$: 110 000; $\bar{M}_w/\bar{M}_n < 1.06$) came from Polysciences Inc. The PPO sample was obtained from General Electric Co. ($\bar{M}_w$ = 69 000; $\bar{M}_w/\bar{M}_n$ = 2.1).

Column preparation

Coatings were prepared by coating the polymers onto Chromosorb G. Benzene (150 mL) was slowly evaporated from a solution containing polymer(s) (~2.7 g) and support (~23 g). The coated support was then dried in a vacuum oven (80°C) for 4 days and resieved before use (60/80 mesh). The percent loading of polymer on support (weight of polymer/weight of polymer plus support) was determined by calcination of 1–1.5 g of coating. A correction was made for the loss of volatiles from the uncoated support. The relative concentration of polymers in the blends was assumed to be identical with that in the original solution prior to deposition on the support. Columns were prepared from 1/4 in. o.d. copper tubing plugged at each end by silanized glass wool. To provide even packing, the column was constantly vibrated during filling. Columns were conditioned under N_2 at

TABLE 1. Stationary phase and column parameters

Polymer	Loading (wt.%)	Wt. polymer (g)	Column length (cm)
PS	7.45	1.1778	152
PPO	11.39	1.7624	140
PS/PPO blends			
25 wt.% PS	11.19	1.8076	147
50 wt.% PS	10.19	1.6551	152
75 wt.% PS	10.81	1.7726	147
85 wt.% PS	9.20	1.5229	152

250°C for 3 h before use. A complete description of the columns is given in Table 1.

Instrumentation

The IGC measurements were carried out with a Hewlett-Packard 5830A gas chromatograph equipped with a dual flame ionization detector. The oven temperature was measured with a precision of ±0.01°C with a Hewlett–Packard platinum resistance thermometer. Carrier gas (prepurified nitrogen) flow rates were measured from the end of the column with a water-jacketted soap bubble flowmeter. The net retention time of the probe (±0.01 min) was determined from the peak maxima retention times for the probe and methane (a marker to correct for dead volume in the column). Column inlet and outlet pressures were read from a mercury manometer (±0.05 mm Hg).

The solutes and marker were injected manually with a 10-μL Hamilton syringe (<0.01 μL). The solutes were characterized by symmetrical elution peaks and generally exhibited little sample size dependence at low injection volumes, low carrier gas flow rates (5–20 cm^3/min) and moderate column loading (7–10%). Galin and Rupprecht (22) have shown that under these conditions the opposite influences of surface adsorption and gas flow rate are nearly equivalent, so that the experimental V_g^0 value is quite close to the bulk V_g^0 value.

Data reduction

Specific retention volumes, V_g^0 (cm^3/g), were computed from the familiar expression of Littlewood *et al.* (8)

$$[1] \quad V_g^0 = t_N F J / w_L$$

where t_N is the net retention time for the probe, F is the carrier gas flow rate at 0°C and 1 atm (STP), J is a correction factor for gas compressibility, and w_L is the weight of polymer in the column.

At temperatures above T_g, the magnitude of V_g^0 is a measure of the solubility of the probe in the stationary phase. By applying thermodynamic theory to gas chromatography, one can relate the measured V_g^0 to the weight fraction activity coefficient at infinite dilution of the probe, $(a_1/w_1)^\infty$, a fundamental parameter of solution thermodynamics which indicates deviation from ideal solution behavior (9).

$$[2] \quad \ln (a_1/w_1)^\infty = \ln \frac{(273.16R)}{V_g^0 p_1^0 M_1} - \frac{p_1^0}{RT}(B_{11} - V_1)$$

where V_1, M_1, p_1^0 refer to the solute molar volume, molecular weight, and saturated vapor pressure respectively, R is the gas constant, T is the column temperature (K), and B_{11} is the second virial coefficient, which is used to correct for vapor phase nonideality of the probe. Values of B_{11} were estimated from corresponding equations of state (10, 11). Solute vapor pressures were obtained from Dreisbach's compilation (12). Solute densities were obtained from various sources, including the compilations by Orwoll and Flory (13) and Timmermans (14) as well as the International critical tables (15).

From the Flory–Huggins treatment of solution thermodynamics (16), one can obtain the χ parameter, which is a measure of the residual free energy of interaction between solute and polymer (9). χ is determined from the relationship

$$[3] \quad \chi_{12} = \ln (273.16 R v_2 / V_g^0 p_1^0 V_1) - (1 - V_1/V_2)\varphi_2 - p_1^0(B_{11} - V_1)/RT$$

TABLE 2. Specific retention volume, V_g^0 (cm^3/g), for various solutes in PS/PPO blends at 240°C

Solute	wt.% PS 0	25	50	75	85	100*

*Extrapolated from 170–190°C range.

where v_2, V_2, and φ_2 refer to the specific volume, molar volume, and volume fraction of the polymer. All other symbols have their usual meanings. For high molecular weight polymer and infinite dilution of probe the second term of eq. [3] (i.e., $(1 - V_1/V_2)\varphi_2$) approaches 1.

It has been shown (17) using Scott's ternary solution treatment (18) of Flory–Huggins theory that the overall interaction parameter between the volatile probe (1) and the binary stationary phase (2, 3) is given by

$$[4] \quad \chi_{1(23)} = \ln \frac{(273.16R(w_2 v_2 + w_3 v_3))}{V_g^0 p_1^0 V_1} - \left(1 - \frac{V_1}{V_2}\right)\varphi_2 - \left(1 - \frac{V_1}{V_3}\right)\varphi_3 - \frac{p_1^0}{RT}(B_{11} - V_1)$$

where w_2 and w_3 refer to the weight fractions of PS and PPO in the blend.

The volumetric data for the blends were determined by assuming that the specific volume of the blend is the weight average of the specific volumes of the parent homopolymers (19, 20).

Results and discussion

Specific retention volumes V_g^0 (cm^3/g) were measured for a variety of polar and apolar probes in molten PS, PPO, as well as four blends of varying ratios of these two homopolymers (i.e., 25, 50, 75, and 85 wt.% PS). In order to ensure the attainment of thermodynamic equilibrium for each polymer melt, measurements were carried out at 240°C, well above the glass transition of each homopolymer. The reliability of the V_g^0 values is better than 3%, except for 3,4,5-trimethylheptane for which the uncertainty is ±5%. Table 2 summarizes the measured V_g^0 values. The derived infinite dilution weight fraction activity coefficients $(a_1/w_1)^\infty$ are tabulated in Table 3.

Flory–Huggins χ parameters were determined from the measured retention data in order to examine the extent of polymer – small molecule (eg. probe) and polymer–polymer interaction in various PS–PPO mixtures. These values are summarized in Tables 4 and 5 at 240°C.

Polymer–probe miscibility

The data in Table 2 indicate that V_g^0 values for the probes investigated are consistently higher for PS than for PPO. These results indicate that the interaction between the aliphatic or aromatic probes and PS are stronger than with PPO. Figure 1 illustrates the dependence of V_g^0 on blend composition for six selected probes. With the exception of the 75% PS blend, higher values of V_g^0 are observed for these blends than would be predicted by addition of the homopolymer values.

Positive deviations of V_g^0 from linearity have previously been observed for some polystyrene–poly(*n*-butylmethacrylate) blends which are characterized by weak intermolecular interactions (4).

Values of $(a_1/w_1)^\infty$ are the highest for pure PPO irrespective of the solute used. This shows that the probes are less soluble in PPO than in PS. Measured values range from 4 to 16. The probe that shows highest $(a_1/w_1)^\infty$ in PPO is 3,4,5-trimethylheptane, 16.43 (i. e., a poor solvent). The lowest value in PPO, 4.67, is observed for cyclohexanol (i.e., a good solvent). In PS, the highest activity coefficient is observed for *n*-decane, 10.26, (i.e., a poor solvent), and the lowest value is 3.71, for

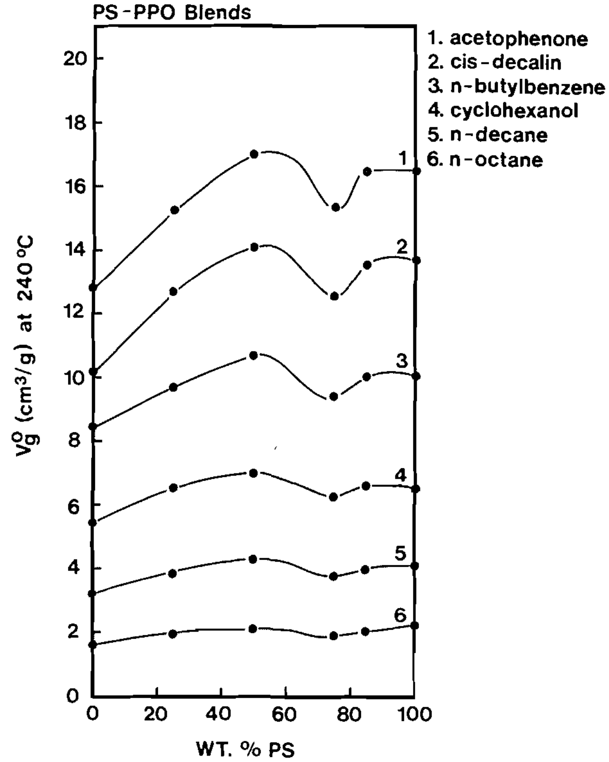

FIG. 1. Composition dependence of V_g^0 for various solutes in PS–PPO blends at 240°C.

chlorobenzene (i.e., a good solvent).

Flory–Huggins χ interaction parameters, which were derived from measured specific retention volumes, are summarized in Table 4. For any given solute, χ is larger (i.e., more positive) for pure PPO than for PS or its blends. This is consistent with the trend observed in the V_g^0 and $(a_1/w_1)^\infty$ data and indicates that the probe-polymer interaction is stronger for PS than for PPO. All χ parameters measured for these systems are greater than 0. Most of the χ values in PPO are greater than 0.5 (critical value) except for toluene, *n*-butylbenzene, chlorobenzene, and cyclohexanol. The reverse is true for PS. Most of the χ parameters here are less than 0.5 except for *n*-octane, *n*-decane, 3,4,5-trimethylheptane, and *n*-butylcyclohexane. Although the aromatic probes are good solvents for both PPO and PS, the interactions are more favorable with PS.

Polymer–polymer miscibility

Polymer–polymer interaction parameters (χ_{23}') were calculated from the measured polymer–probe interaction (Table 4) in corresponding pure and mixed stationary phases (4, 6).

$$[5] \quad \chi_{1(23)} = \chi_{12}\varphi_2 + \chi_{13}\varphi_3 + \chi_{23}'\varphi_2\varphi_3$$

where $\chi_{23}' = \chi_{23}V_1/V_2$.

The interaction parameter χ_{23}' is thus normalized to the size of the probe molecule. A negative interaction parameter is required in order to ensure miscibility of two high molecular weight polymers. Table 5 summarizes χ_{23}' values (240°C) obtained for the 10 probes for each of the four blend compositions.

As noted in previous chromatographic investigations of polymer–polymer miscibility (4, 6), probe-to-probe variations are observed. This is probably due to the assumptions inherent in eq. [5], i.e., random mixing of the two polymers in the stationary phase and/or random sensing of the polymer–

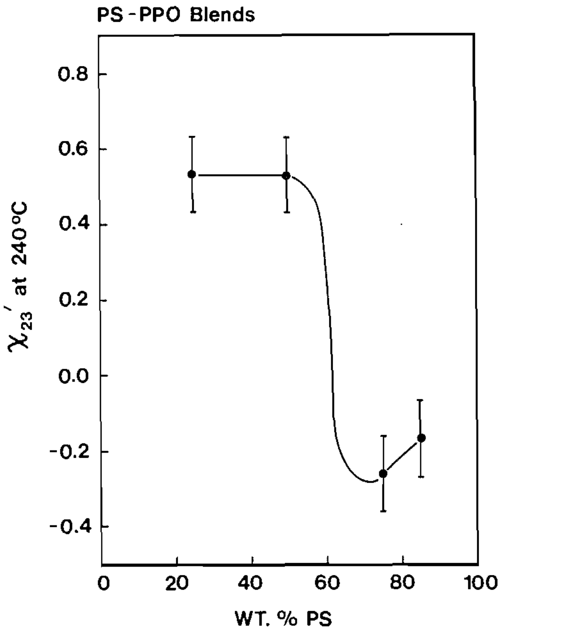

FIG. 2. Composition dependence of χ_{23}' in PS–PPO blends at 240°C.

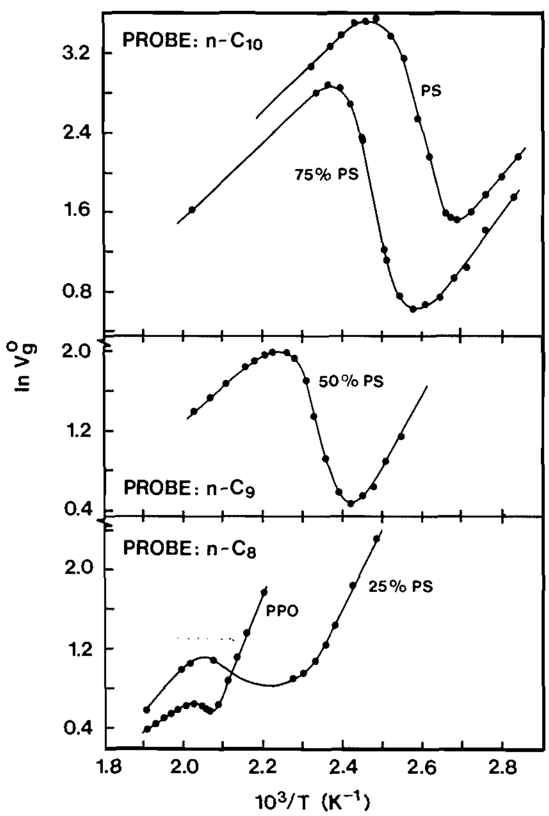

FIG. 3. Retention diagrams for PS–PPO blends of varying compositions.

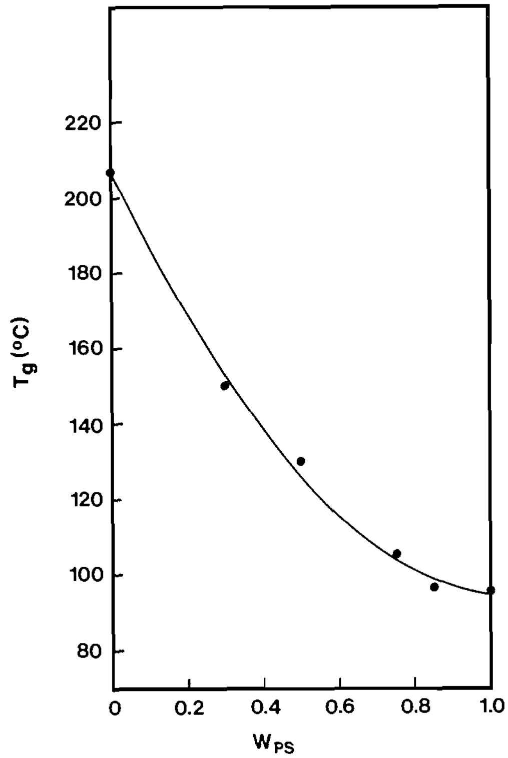

FIG. 4. Composition dependence of T_g.

polymer interaction by the probe.

For each blend composition, the measured χ_{23}' values were averaged for nine probes (3,4,5-trimethylheptane exhibits large deviations and was not considered in the averaging procedure) and are plotted in Fig. 2. In general, blends containing 25 and 50 wt.% PS exhibit positive χ_{23}' values (ca. 0.5); blends containing 75 and 85 wt.% PS exhibit negative χ_{23}' values (ca. −0.2). Thus PS–PPO blends with a high polystyrene content (>60 wt.% PS) are characterized by a strong specific interaction ($\chi_{23}' < 0$) in the molten state. This is in accord with the well-known compatibility of PS–PPO blends. Blends with a low polystyrene content (<60 wt.% PS) appear to exhibit weak intermolecular interactions at 240°C ($\chi_{23}' > 0$).

IGC studies show only one T_g for each blend over the whole composition range (Fig. 3 and 4), suggesting that PS and PPO are miscible at the segmental level.

However, Prest's DSC data indicate a broadening of the T_g transition with decreasing PS content which can be interpreted as increasing microheterogeneity in these blends (7). A similar conclusion was reached by MacKnight *et al.* (21) from dielectric relaxation studies.

The present thermodynamic data are in agreement with the postulate of increasing microheterogeneity in PS–PPO blends with decreasing PS content. The measured χ_{23}' values probably reflect interactions on a much finer scale than that reflected by the T_g transition. Electron microscopic studies should shed some further light on the level of miscibility in PS–PPO blends.

T. W. SCOTT and C. L. BRAUN. Can. J. Chem. **63**, 228 (1985).

The recombination dynamics of geminate cation−electron pairs in liquid hexane is studied by combining picosecond photoionization and infrared-stimulated charge dissociation measurements. The observed yield of free charge is determined by the product of the charge pair survival probability and the probability for infrared-stimulated charge dissociation. Experimental results are compared with transient solutions of the Smoluchowski equation governing diffusive recombination in a Coulomb well. Reasonable agreement with experiment can be reached by allowing for a radial distribution of initial pair separations. However, the stimulated dissociation yield exhibits a functional dependence on pair separation which complicates the analysis. A simple model of geminate charge pair dissociation by infrared stimulation is presented and its implications for these experiments are discussed.

T. W. SCOTT et C. L. BRAUN. Can. J. Chem. **63**, 228 (1985).

Faisant appel à une combinaison de mesures de photoionisations au niveau de la picoseconde et de dissociations de charges stimulées par l'infrarouge, on a étudié la dynamique de la recombinaison de paires de cation/électron géminées dans l'hexane liquide. On a déterminé le rendement observé de la charge libre en faisant le produit de la probabilité de survie de la paire chargée et de la probabilité de dissociation de charge stimulée par l'infrarouge. On compare les résultats expérimentaux avec des solutions transitoires de l'équation de Smoluchowski décrivant la recombinaison diffusante dans un puit de Coulomb. On peut obtenir un bon accord avec les résultats expérimentaux si l'on fait l'hypothèse qu'il se produit une distribution radiale des séparations initiales des paires. Toutefois, il existe une dépendance fonctionnelle du rendement de dissociation stimulée avec la séparation de la paire et ce fait complique l'analyse. On présente un modèle simple de la dissociation par stimulation infrarouge des paires chargées géminées et on discute des implications des ces expériences.

[Traduit par le journal]

Introduction

Photocarrier generation in organic materials frequently involves a transient charge pair as the immediate precursor of free charge carriers (1−6). Each pair consists of a parent positive ion and a localized photoelectron which are strongly correlated by their mutual coulombic attraction. The Onsager theory of geminate recombination gives the probability that a charge pair will dissociate into free carriers (7). In non-polar organic materials, at least for small values of the applied field, the separation probability is small and most pairs suffer rapid geminate annihilation. The influence of temperature and applied electric fields on the free carrier yield has been extensively studied in a large number of materials. In most cases the escape probability is well described by the Onsager model.

More recently, efforts to probe the time dependence of geminate recombination have been reported. The recombination dynamics of cation−anion pairs, where the anion is formed by electron attachment, has been studied using pulsed electron beam excitation (8−10). It has also been shown that the first half-life of electron−cation pairs is less than 100 ps in liquid hexane (11). A number of theoretical treatments of the time-dependent recombination process are also available. Following a series of approximate solutions (12), an exact treatment of geminate pair dynamics within the Onsager model is now available (13). This model assumes that the recombination process involves mutual diffusion of the geminate electron and cation through a uniform dielectric medium under the influence of their coulombic field. The work described here is an attempt to directly observe charge pair recombination dynamics in simple non-polar liquids and thereby test the validity of applying diffusion theory to this problem.

In a previous communication we reported picosecond recombination of photogenerated cation−electron pairs in liquid hexane (14). A new experimental approach was employed whereby geminate charge pairs are photodissociated by an intense infrared light pulse (15). With the improved time resolution attainable using mode locked lasers, we found that the first half-life in liquid hexane was no more than 9 ps. We report here a more detailed analysis of the geminate pair photodissociation process as well as a semiempirical fit of the observed charge pair annihilation dynamics in terms of transient solutions of the Brownian motion of the charge pair. In order that this diffusion theory (13) adequately fit the observed decay kinetics, it is necessary to assume that thermalization of the photogenerated electron results in a distribution of initial charge pair separations.

Experimental

Geminate charge pairs were formed in liquid n-hexane by resonant two-photon ionization of anthracene at 351 nm. The 351 nm light pulse with a 6−8 ps duration delivered 0.05 mJ of uv light over 2 mm^2 cross section of the sample. The uv pulses were obtained from the third harmonic of a mode locked Nd^{3+}-phosphate laser. After the arrival of the uv pulse, a 0.5 mJ probe pulse at 1053 nm interrogated the ionized sample for a period of 8− 10 ps. We recorded ionic photocurrent transients lasting several milliseconds after irradiation of the

[1]This work was completed during a post doctoral appointment at AT&T, Bell Laboratories, Murray Hill, NJ 07974, U.S.A.

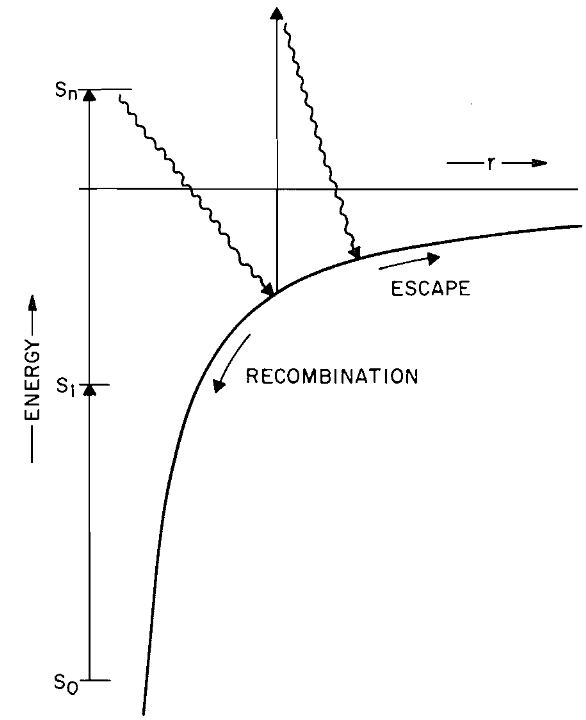

FIG. 1. A model for infrared-assisted dissociation of geminate electron–cation pairs. Two 351 nm photons generate a 7.1 eV singlet state of anthracene, S_n, which ionizes to form a geminate charge pair. Photoexcitation of the geminate electron initiates a second thermalization process which on average enhances the charge pair separation probability.

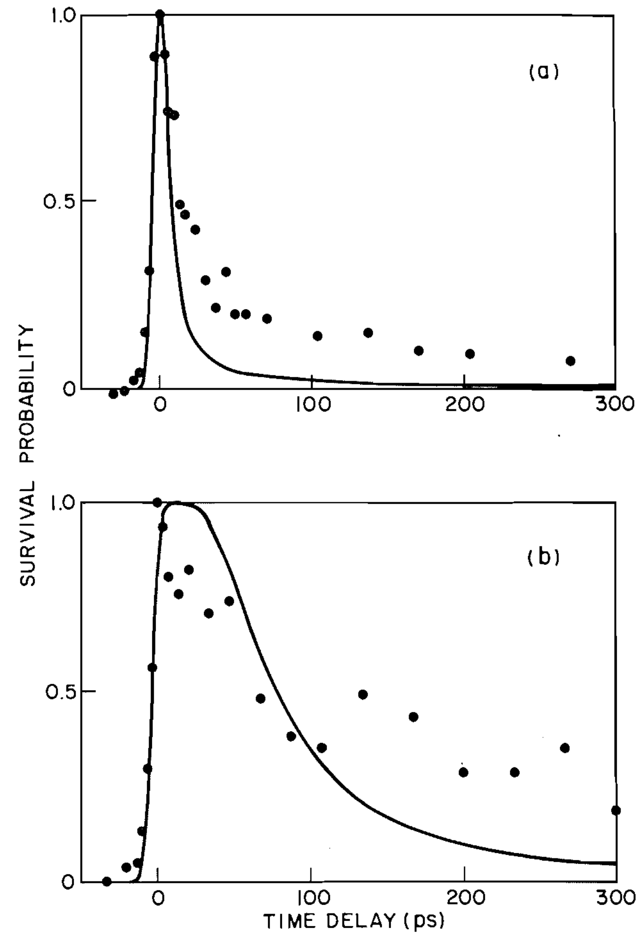

FIG. 2. Time dependence of ir-stimulated charge dissociation at 296 K (*a*) and 214 K (*b*). Each curve has been scaled to unity at its maximum. The solid curves are Hong and Noolandi's transient solutions of the Onsager problem for an initial charge pair radius of 45 Å. The dielectric constant used for hexane was 1.885 at 296 K and 2.01 at 214 K. The electron diffusion constant was 1.91×10^{-3} cm^2/s at 296 K and 9.4×10^{-5} cm^2/s at 214 K.

solution with a sequence of uv and ir pulses. The photocurrent amplitude was determined by the total number of free charge carriers generated by cooperative action of the two light pulses. The ir pulse enhances photoconduction by laser-assisted dissociation of the charge pairs formed by uv excitation. The time-dependent geminate pair survival probability was identified with the change in photocurrent amplitude as a function of the optical delay between the uv ionization pulse and the ir photodissociation pulse.

Zone-refined anthracene was dissolved in liquid hexane at a concentration of 7.5×10^{-6} mol L^{-1}. The solvent was dried over silica gel and passed through a 0.2 μm Teflon filter. A tandem photoconductivity cell allowed measurements of the charge carrier yield with and without ir excitation during each laser firing. The uv light pulse passed between two sets of parallel plate electrodes, each with an inter-electrode spacing of 3 mm and biased at 1500 V. The ir pulse overlapped the uv pulse in the first ionization cell, but was prevented from entering the second cell by an ir blocking color filter. The relative photoionization response of the two cells was determined by temporarily blocking the ir beam.

Discussion

Geminate charge pair annihilation dynamics were monitored by the process of infrared-enhanced photogeneration (14, 15). A schematic illustration of this technique is presented in Fig. 1. A uv photoionization pulse at 351 nm creates thermalized electron–cation pairs by resonant two-photon ionization of anthracene in liquid hexane. When only the uv pulse enters the sample, a photocurrent is observed from the fraction of charge pairs which surmount the Coulomb barrier and separate. When the uv pulse is folowed by an intense infrared pulse at 1053 nm, an increased yield of free charge is observed which depends strongly on the relative timing of the two optical pulses. It has been suggested (14, 15) that the infrared pulse acts by exciting the geminate electron which has an absorption cross-section of 3×10^{-17} cm^2 at 1053 nm (16). Since the ir photon has an energy of 1.2 eV while the Coulomb binding energy only amounts to 0.1–0.2 eV, ir excitation promotes the charge pair well above its dissociation limit. With the available infrared intensity of 10^{28} photons/cm^2 s the probability of exciting each geminate electron in the sample is near unity.

Apparently the subsequent dissociation of the infrared-excited geminate pair is an inefficient process. Typical thermal dissociation efficiencies of charge pairs in organic liquids are on the order of 0.1% (6). Anthracene in liquid hexane exhibits efficiencies of this size (15). Infrared excitation of the geminate electron is found to increase the dissociation yield by only a factor of 5 to 6. Enhancements on the order of 1000 would be expected if each optically excited geminate electron separated with unit probability. The smaller observed efficiencies can be rationalized by assuming that the optically excited electron re-thermalizes at an electron–cation separation where Coulomb driven charge annihilation remains the dominant decay mechanism (see Fig. 1).

Figure 2 shows how the cooperative ionization of anthracene in liquid hexane depends on the time delay between the uv and

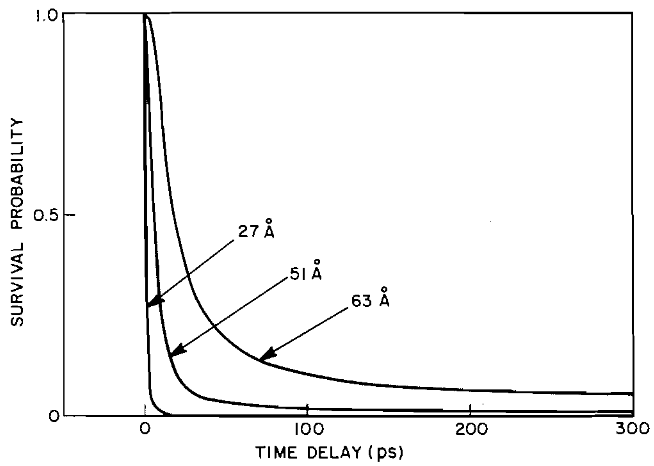

FIG. 3. Hong–Noolandi solutions of the time dependent charge pair survival probabilities for different initial separations at 296 K.

ir pulses at two temperatures. The vertical axis represents the difference in free charge yield when the uv pulse is accompanied by delayed ir excitation and when the uv pulse enters the sample alone. The steep rise and decay near time zero represents the recombination kinetics convoluted with the laser pulse width (8 ps at 1053 nm and 6 ps at 351 nm FWHM). The solid lines represent Hong and Noolandi's solutions (13) of the time-dependent Onsager problem for a single charge pair initially separated by 45 Å. Theoretical decay curves for other initial separations are shown in Fig. 3. The simulated decay curves in Fig. 2 take into account the finite laser pulse widths assuming Gaussian time profiles. It can be seen in Fig. 2 that cooling the solution from 296 to 214 K dramatically extends the first half-life. Each curve in Fig. 2 is normalized to unity at time zero. The actual magnitude of the infrared enhancement was seen to increase by a factor of five at low temperatures. The temperature dependence of the enhancement shows that the ir pulse generates at least some charge pairs with a larger separation than those formed by the uv pulse alone. This is consistent with the model presented in Fig. 1. The increased half-life seen upon cooling is captured by the Hong–Noolandi decay curves. We previously pointed out that the slower decay at 214 K results from the temperature dependence of the electron mobility in liquid hexane (14).

Although the theoretical decay curves shown in Fig. 2 agree qualitatively with experiment, it is apparent that the observed decay is faster at early times and slower at longer times than predicted for a 45 Å radius pair. This discrepancy can be rationalized by assuming that photoionization results in a distribution of charge pair separations. The radial distribution function

$$[1] \quad g(r) = r^2 \exp(-r/L)$$

when convoluted with Hong and Noolandi's theoretical decays gives good agreement with experiment at both temperatures for L = 14 Å (see Fig. 4). The mean charge pair radius occurs at $3L$ = 42 Å according to eq. [1]. This should be compared with the value of 45 Å obtained when temperature dependence studies are analyzed in terms of a single charge pair radius (15). Prior to convolution with the laser pulse width, the theoretical recombination curves give a half-life of approximately 3.5 ps at 298 K and 68 ps at 214 K.

The comparison of the time-dependent photodissociation

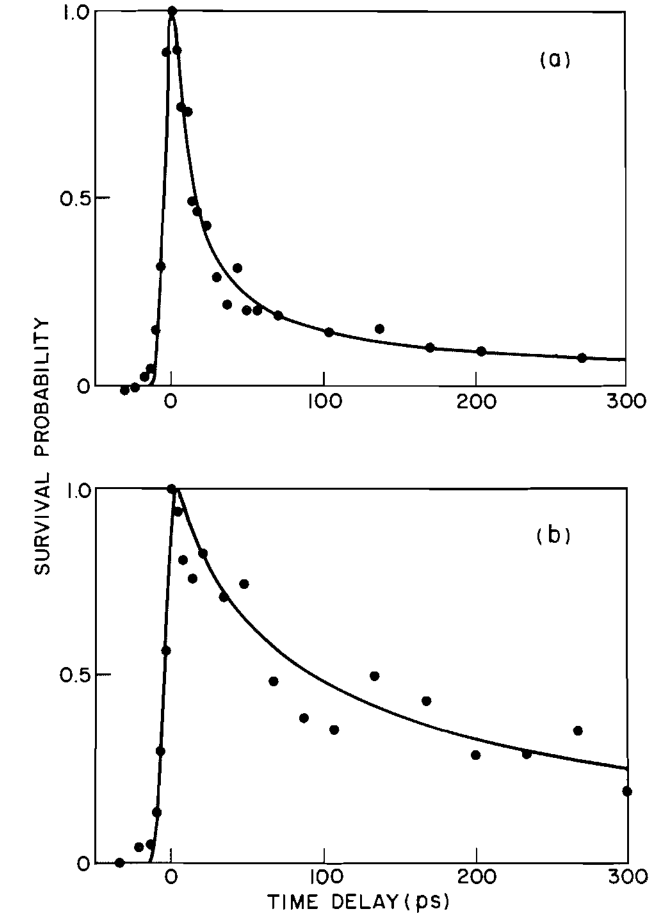

FIG. 4. Comparison of theoretical (—) survival probabilities and experimental (●) dissociation yields at 296 K (a) and at 214 K (b). Each curve has been scaled to unity at its maximum. The theoretical decay functions allow for a distribution of initial charge pair separations according to eq. [1] of the text. The simulations are shown for L = 14 Å (mean radius = 42 Å) at each temperature.

curves with transient solutions of the Onsager problem (Figs. 2, 4) assumes that the infrared-enhanced photogeneration process provides a direct measure of the charge pair survival probability. To test this assumption a simple analysis of the change in photocurrent due to infrared excitation of the geminate electron can be developed based on the model presented in Fig. 1. In the absence of the infrared photodissociation pulse, the escape probability (P_0) of a single charge pair at zero applied field is given by the well known relation (13).

$$[2] \quad P_0(r_0, T) = \exp(-r_c/r_0)$$

where r_0 is the initial charge pair separation and $r_c = e^2/4\pi\epsilon\epsilon_0 kT$ is the Onsager radius. Assuming that rethermalization after infrared excitation is not significantly perturbed by the Coulomb field of the cation, the probability of finding the rethermalized electron at some distance r from its initial position will be spherically symmetric about the original electron position. The new escape probability is then given by

$$[3] \quad P_{h\nu}(r_0, T) = \int g'(r)[\exp(-r_c/d)]r^2 \sin\theta \; dr d\theta d\phi$$

where (r, θ, ϕ) describes the position of the rethermalized electron in terms of a coordinate system centered at the initial

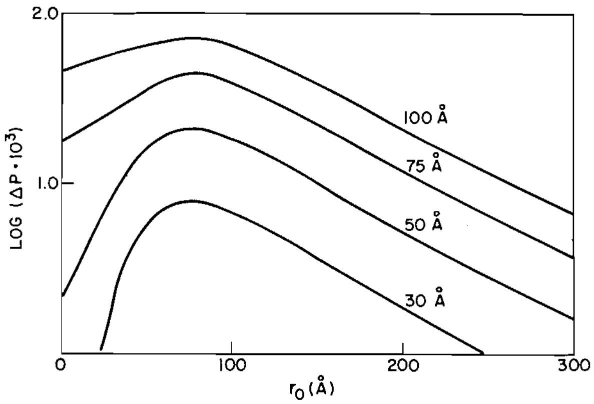

FIG. 5. Logarithm of the change in geminate pair escape probability, ΔP, after ir stimulation, as a function of initial pair separation, r_0. A series of curves are shown for different values of the secondary thermalization length at 296 K.

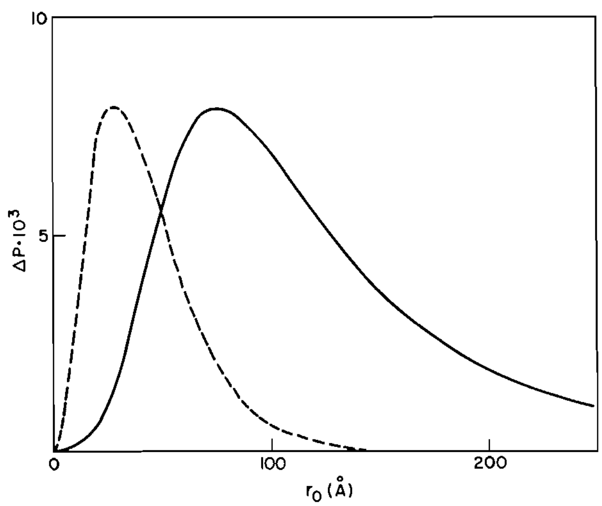

FIG. 6. Plot of the radial dependence of the initial pair distribution $g(r)$ for L = 14 Å (dashed line) and the change in escape probability for a secondary thermalization length of 30 Å (solid line). The vertical scale gives the numerical value of ΔP, while $g(r)$ has been scaled for ease of viewing.

position of the electron and where $g'(r)$ denotes the radial distribution of secondary thermalization lengths. The function $d(r,\theta,\phi)$ in eq. [3] is the distance between the cation and the rethermalized electron. (We note that the treatment of infrared photogeneration presented here differs from that in ref. 15 in that the previous work assumed that rethermalization would be symmetric about the parent cation.) In the absence of any detailed information on the secondary distribution of thermalization lengths, $g'(r)$, we will evaluate $P_{h\nu}$ for rethermalization on a spherical shell of radius r. Making the change of variables

$$x = [r^2 + r_0^2 - 2rr_0 \cos \theta]^{-1/2}$$

in eq. [3] we obtain

$$[4] \quad P_{h\nu}(r, r_0, T) = \frac{1}{2rr_0}\int_{|r_0+r|^{-1}}^{|r_0-r|^{-1}} \frac{1}{x^3} [\exp(-r_c x)]\mathrm{d}x$$

Numerical integration of eq. [4] shows how the infrared-enhanced escape probability $\Delta P = P_{h\nu} - P_0$ depends on the initial charge pair separation and the secondary thermalization length. Figure 5 shows a series of ΔP versus r_0 curves for different values of r. The enhancement shows a maximum in the range r_0 = 70–80 Å. ΔP goes to zero as r_0 becomes very large because both $P_{h\nu}$ and P_0 approach unity. For very small values of r_0, ΔP is again small unless the rethermalization lengths are large enough to substantially increase the charge pair separation.

A secondary thermalization length of ~30 Å accounts for the magnitude of the infrared enhancements seen in this work at both 296 K and 214 K. Figure 6 compares the radial dependence of ΔP with the distribution of initial separations described by eq. [1]. It is apparent that the measurement technique employed in this work does not sample all members of the initial distribution with equal probability and that the fit in Fig. 4 will be somewhat in error, particularly at early times. A more critical assessment of the importance of radial selectivity in geminate pair photodissociation will require an examination of the time evolution of the radial distribution of charge pairs (13).

Aknowledgements

The authors thank J. Noolandi, Xerox Research Center of Canada, and William J. McNeil for generating the theoretical decay curves shown in Figs. 2, 3, and 4. Grant DE-AC02-83ER13102 from the Department of Energy provided partial support for this work.

The structural changes occurring in poly(methylvinylketone) when exposed to high temperatures have been investigated by high-resolution ^{13}C solid-state nmr. The degradation proceeds via the aldol condensation of pendant ketone groups to form a cyclic β-hydroxy ketone which is dehydrated to the cyclic α,β-unsaturated ketone. As the degradation continues there is the formation of polycyclic structures and aromatization of the sample.

C. A. FYFE et M. S. MCKINNON. Can. J. Chem. **63**, 232 (1985).

Faisant appel à la rmn du ^{13}C à l'état solide, on a étudié la nature des changements structuraux qui se produisent lorsqu'on soumet de la poly(méthylvinyl cétone) à des températures élevées. La dégradation se produit par le biais d'une condensation aldolique de la fonction cétonique disponible qui conduit initialement à une β-hydroxycétone cyclique qui se déshydrate par la suite en une cétone cyclique α,β-insaturée. Au fur et à mesure de la dégradation, il y a formation de structures polycycliques et aromatisation de l'échantillon.

Introduction

The coloration which occurs during the thermally initiated degradation of poly(methylvinylketone) (PMVK) (**I**) was first reported by Marvel and co-worker (1). The chemical process was thought to be a cyclization resulting from an aldol condensation between pendant ketone groups. Previous workers (2–5) have employed uv and ir spectroscopy to study structural changes during the degradation, giving data in general agreement with this postulated reaction.

We wish to report the application of high resolution solid-state ^{13}C CP/MAS spectroscopy to study the structural changes which occur during the thermal degradation of PMVK. Schaefer and Stejskal (6) first demonstrated that by employing a combination of cross-polarization (7) and magic angle spinning (8) with high-power decoupling, spectra of moderate to good resolution could be obtained from solid materials (9). The spectra yield the isotropic average value of the chemical shift (for the solid state) and can be used for structural elucidations utilizing chemical shift correlations from solution nmr studies. This technique is particularly useful for samples which are insoluble or for amorphous materials where X-ray diffraction techniques are not applicable. It is also possible to separate the contributions to the spectra from protonated and non-protonated carbons in the sample by using a pulse sequence developed by Opella and Frey (10), giving additional structural information.

The purpose of this work is to follow the structural changes occurring during the thermal degradation of PMVK by ^{13}C CP/MAS nmr to determine the nature of the solid products formed and elucidate a degradation mechanism.

Experimental

^{13}C CP/MAS spectra were recorded at 22.6 MHz using a Bruker CXP 100 spectrometer equipped with a home-built probe. Samples were run as powders in spinners (capacity ~460 μL) constructed of KEL-F (polychlorotrifluoroethylene) in an Andrew-Beams type spinning apparatus. Samples were spun at ~3 kHz using air as a driving gas.

[1] To whom all correspondence should be addressed.

Poly(methylvinylketone) was a commercially available sample (Aldrich). Heat treatments were conducted in air for the times and temperatures specified in the text. After treatment, ^{13}C solid-state spectra were recorded using CP/MAS techniques to obtain both the total spectra and those of the nonprotonated carbons using the non-protonated carbon selection procedure (10). All ^{13}C CP/MAS spectra were recorded using a 1 ms contact time and a 1 s delay between pulse sequences with a decoupling field of 12 G. The spectra are semi-quantitative under these conditions. Nonprotonated spectra were recorded under similar conditions but with the decoupler gated off for 50 μs between the cross-polarization sequence and the acquisition of the free induction decay. During the time when the decoupler is off the magnetizations of those carbons with directly bonded protons decay rapidly due to the large dipolar interactions and are not detected during the acquisition period.

Results and discussion

^{13}C solid-state chemical shift assignments were based on the ^{13}C solution chemical shifts of model compounds (cyclohexanone, cyclohexenone, 3-methylcyclohexenone). In cases where suitable model compounds could not be found, assignments were based on the expected shift for the particular functional group.

Figure 1 shows the spectra of poly(methylvinylketone) during the various stages of thermal degradation. In each case, the spectrum on the left is that of the simple CP/MAS experiment and the corresponding spectrum on the right was recorded employing the nonprotonated carbon selection experiment and therefore shows signals from only the nonproton bearing carbons in the system.

Figure 1, parts *A*, *B* show spectra of the solid, untreated polymer, with the chemical shifts indexed with respect to TMS. As indicated in Fig. 1 and in Table 1, the resonance at $\delta = 211$ ppm may be assigned to the ketone functionality and the absorption at $\delta = 49$ ppm to the methine carbons. The resonance at $\delta = 29$ ppm consists of two components, one due to the methylene carbons and one from the methyl carbons. The use of the nonprotonated carbon selection experiment discriminates between these two components, yielding the assignment given in the figure (methyl resonances still appear after this selection although with reduced intensity, due to their particular relax-

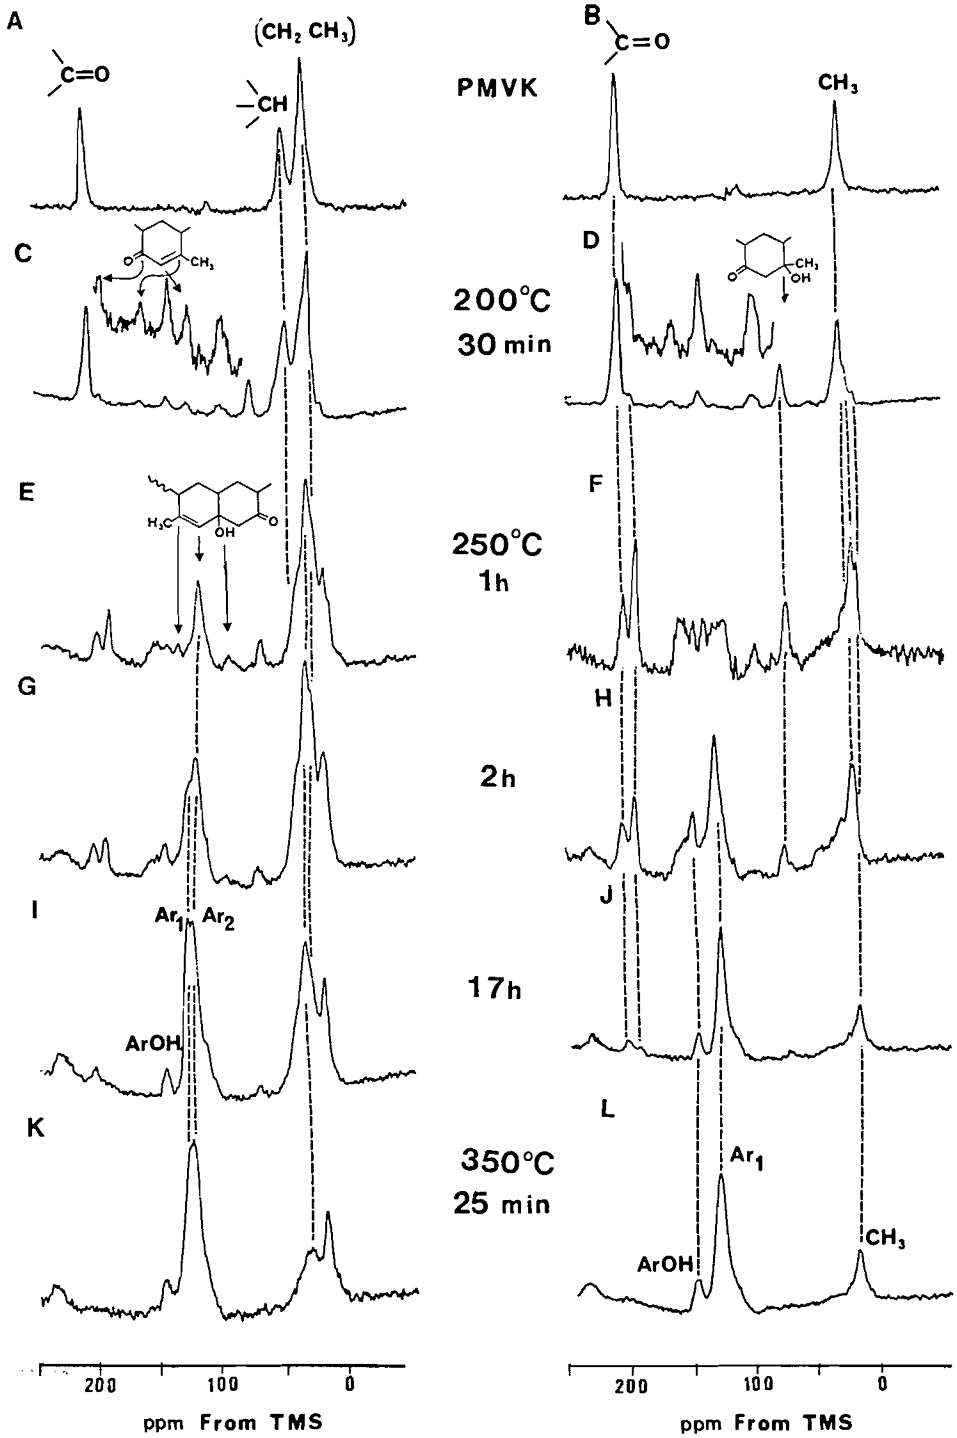

FIG. 1. ^{13}C CP/MAS spectra of PMVK during various stages of degradation. All spectra obtained with 1 ms contact and 1 s recycle delay: (*A*) undegraded polymer, 3 600 scans; (*B*) same sample as (*A*) only nonprotonated carbon selection, 16 000 scans; (*C*) spectrum of PMVK heated at 200°C in air for 30 min, 10 000 scans; (*D*) same sample as (*C*) only nonprotonated carbon selection, 33 000 scans; (*E*) spectrum of PMVK heated at 250°C in air for 1 h, 3 600 scans; (*F*) same sample as (*E*) only nonprotonated carbon selection, 6 000 scans; (*G*) spectrum of PMVK heated at 250°C in air for 2 h, 3 600 scans; (*H*) same sample as (*G*) only nonprotonated carbon selection, 13 000 scans; (*I*) spectrum of PMVK heated at 250°C in air for 17 h, 3 600 scans; (*J*) same sample as (*I*) only nonprotonated carbon selection, 6 800 scans; (*K*) spectrum of PMVK heated at 350°C in air for 25 min, 5 500 scans; (*L*) same as (*K*) only nonprotonated carbon selection, 6 000 scans.

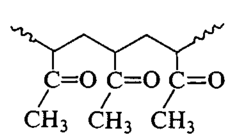
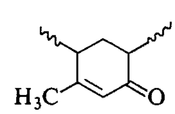
ation properties (10)).

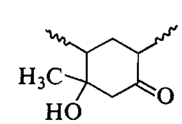
The effect of heating in air at 200°C for 30 min is illustrated in Fig. 1 parts *C* and *D*. The spectra indicate clearly that the degradation proceeds via the aldol condensation of adjacent $COCH_3$ groups. The small peak at δ = 201 ppm is due to a cyclic α,β-unsaturated ketone (**II**). This corresponds to the



I

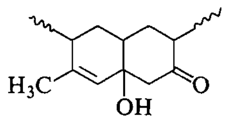


II



III

ketone group in 2-cyclohexen-1-one which absorbs at δ = 197.1 (11). The absorption at δ = 76 ppm is due to the hydroxyl bearing carbon of the cyclic β-hydroxy ketone (**III**). The resonance due to the carbonyl in this β-hydroxy ketone occurs at 211 ppm and is obscured by the large absorption due to the uncyclized ketone groups. Resonances at δ = 164 and 129 ppm are also assigned to the presence of the cyclic α,β-unsaturated ketone (**II**) as indicated in Fig. 1. The corresponding carbons in 3-methyl-2-cyclohexen-1-one give rise to absorptions at δ = 162 and δ = 126.5 (12). There is also a small absorption at 99 ppm thought to be due to the polycyclic alcohol (**IV**). The olefin in this structure is thought to give rise



IV

to the resonances at δ = 144 ppm and contributes to the absorption at δ = 129 ppm. From the nonprotonated spectra three types of methyls can be observed. The resonance at δ = 30 ppm is due to undegraded polymer, the absorption at δ = 22 ppm is due to methyl groups adjacent to a hydroxy-bearing carbon and the peak at δ = 19 ppm results from methyl groups adjacent to an olefinic group. Table 2 summarizes the chemical shift assignments for the degraded polymer.

Heating at 250°C (Fig. 1*E*, *F*) results in further degradation of the sample. There is a substantial loss in the carbonyl absorption at δ = 211 ppm and an increase in the absorption at δ = 201 ppm due to the cyclized ketone (**II**). The major component of the resonance at δ = 211 ppm is now due to the β-hydroxyketone (**III**). There is also the appearance of additional peaks at δ = 126 and 132 ppm indicating the formation of aromatic rings which must involve loss of hydrogen along the backbone of the polymer. A peak at δ = 154 ppm indicates the formation of phenol rings from the cyclic ketone. There is a large absorption due to methylene carbons from cyclized sections of the polymer as well as between cyclized sections at δ = 34 ppm. The intensity of the phenol resonance compared with the aliphatic absorption suggests that the terminal ketone rings are the first to be aromatized. As degradation continues there is an increase in the intensity of the absorptions in the aromatic region along with a corresponding loss in the aliphatic resonances (Fig. 1, *G*, *H*, *I*, and *J*), yielding a highly aromatic structure after 17 h.

At 350°C degradation is much more rapid. Figure 1 parts *K* and *L* show spectra of a sample heated at 350°C for 25 min. The sample is now mainly aromatic in nature and contains a number of phenol rings. There are also a number of methylene groups which form the links between the aromatic sections and methyl functionalities from the terminal rings at the opposite end of the cyclized sections from the phenol ring. At this stage the spectra of the degraded poly(methylvinylketone) resemble the spectra obtained from thermally degraded phenol–formaldehyde resins (13). This indicates a similarity in the types of functionalities formed during the degradation process. Thus, from the analysis of the ^{13}C solid-state nmr spectra considerable information is obtained on the nature of the degradation process and the mechanism of degradation summarized in Scheme 1. The initial step in the degradation appears to be an aldol condensation between pendant $COCH_3$ groups to form cyclic β-hydroxyketones. This is followed by dehydration to form the

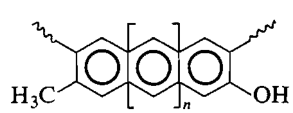
cyclic α,β-unsaturated ketone. The aldol condensation then continues to ultimately form polycyclic structures. This agrees in general with the ladder-type structures proposed by other workers.

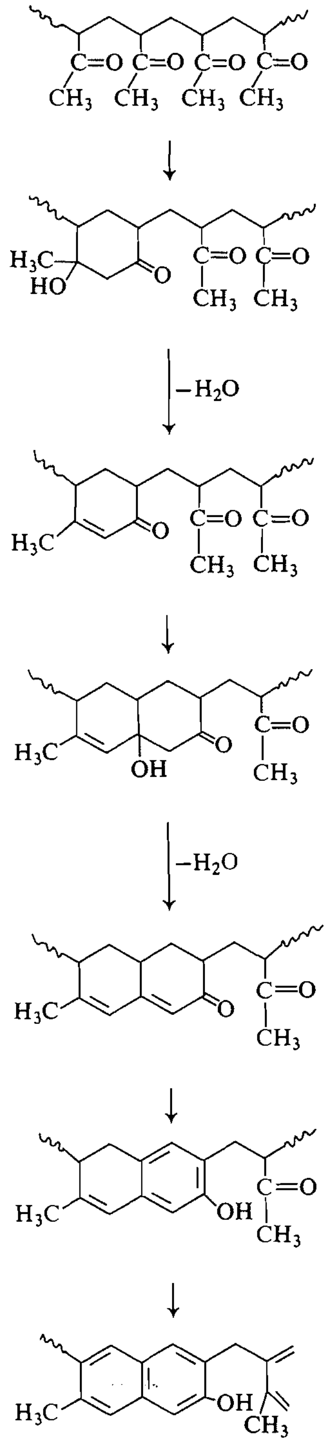
As degradation continues there appears to be formation of phenol rings, followed by a gradual aromatization of the sample. After heating at 350°C the sample consists of segments of aromatic rings (**V**). The ring at the ketone end of the segment will have a phenolic structure. At the opposite end of the segment the terminal ring will have a pendant methyl group. The sample also contains a number of methylene groups which link the aromatic sections.



V

Conclusions

By employing the techniques of high resolution solid-state ^{13}C nmr spectroscopy it is possible to follow the reactions



SCHEME 1

occurring during the thermal degradation of poly(methylvinylketone). The solid state spectra give considerable structural information on the nature of the solid products formed during the degradation process and on the mechanism of the degradation reaction itself.

The initial step appears to involve an aldol condensation between pendant ketone groups to form a cyclic β-hydroxy ketone, which is subsequently converted to the α,β-unsaturated ketone. The degradation continues to form polycyclic structures. At higher temperatures there is formation of phenol rings and a gradual aromatization of the sample. At 350°C the sample consists mainly of aromatic rings with a few linking methylene groups along with methyl groups.

CHARLES B. DUKE. Can. J. Chem. **63**, 236 (1985).

Polymers and molecular solids are characterized by two fundamental features: the retention of molecular identity in the solid state and the occurrence of relatively weak interactions between the individual molecular entities. The weak interactions lead to a high degree of disorder caused both by defects and by thermally induced motions of the molecules. A model of charges injected into polymers and molecular solids is developed. Photoemission and transport measurements are utilized to evaluate the parameters in this model. Results for metal free phthalocyanine are presented as an illustrative example. For molecular glasses and aromatic pendant-group polymers this analysis predicts that disorder causes injected charges to form a Fermi glass of self-trapped polarons, i.e., they occupy localized states characterized by a high degree of local atomic and electronic polarization. Successful interpretations of photoemission spectra, contact charge exchange, and injected carrier drift mobilities verify this prediction. The boundary of the Fermi-glass region of localized-state molecular-ion behavior is identified by consideration of molecular crystals in which injected charges may occupy extended energy-band states at low temperatures.

CHARLES B. DUKE. Can. J. Chem. **63**, 236 (1985).

Les polymères et les solides moléculaires présentent deux caractéristiques fondamentales: la rétention de leur identité moléculaire à l'état solide et l'existence d'interactions faibles entre les entités moléculaires individuelles. Les interactions faibles conduisent à beaucoup de désordre qui est causé tant par les défauts que par les mouvements induits thermiquement des molécules. On a développé un modèle des charges injectées dans les polymères et les solides moléculaires. On a utilisé des mesures de photoémission et de transport pour évaluer les paramètres de ce modèle. A titre d'exemple, on rapporte les résultats obtenus avec des phtalocyanines ne contenant pas de métal. Dans le cas des verres moléculaires et des polymères portant un groupe aromatique, cette analyse permet de prédire que, sous l'influence du désordre, les charges injectées forment un verre de Fermi composé de polarons auto-piégés, à savoir qu'ils occupent des états localisés caractérisés par un degré élevé de polarisation électronique et atomique locale. Des interprétations satisfaisantes de spectres de photoémission, d'échange de charge de contact et de mobilités de déplacement de substances ajoutées permettent de vérifier cette prédiction. On peut identifier la limite de la région du verre de Fermi du comportement ion-moléculaire de l'état localisé en considérant des cristaux moléculaires dans lesquels des charges injectées peuvent occuper, à basse température, des états étendus de bande d'énergie.

Introduction

This paper is devoted to the construction and validation of a model for the dynamics of charge carriers injected into polymers and molecular, especially organic, films. Our theme is that most organic materials which exhibit semiconducting behavior are *not* organic semiconductors in the traditional sense of energy-band theory. Misunderstandings of this topic have persisted for decades (1), thereby greatly delaying progress in the design of commercially useful organic semiconductors (2). Our results are of particular interest because they establish an explicit link between current ideas about the role of disorder in solid state physics and traditional chemical concepts concerning the molecular origin of the electronic properties of polymers and molecular solids (3, 4). Specifically, they establish the domain of model parameters called the Fermi-glass limit, for which injected charges form molecular ions (rather than occupy extended energy-band states) the spectroscopy and dynamics of which are governed by molecular-ion chemistry.

We proceed by first examining the distinguishing features of the molecular solid state and constructing models suitable for the description of injected charges therein. Then the validity of these models in the limit of strong disorder is verified by demonstrating that they provide quantitative descriptions of valence electron photoemission, contact charge exchange, and carrier drift mobilities in pendant-group polymers and molecular glasses. Finally, we discuss the boundary of the strong-disorder (Fermi-glass) limit by considering electron drift mobilities in single-crystal naphthalene.

The molecular solid state

Molecular solids are characterized by two fundamental features: the retention of molecular identity in the solid state and the occurrence of relatively weak interactions between the individual molecular entities. The weak interactions lead to a high degree of disorder caused both by defects and by thermally-induced motions of the molecules. In addition, the hopping integrals for an excess charge carrier to move from one molecule to its neighbors are small, typically about 0.01 eV, whereas the relaxation energy of these charges due to their polarization of both the molecules on which they reside and the surrounding dielectric medium is quite large, typically over 1 eV. The combination of large relaxation energies, small hopping integrals, and copious disorder suggests that charge carriers in organic solids form a Fermi glass of self-trapped polarons, i.e., they occupy localized states characterized by a high degree of local atomic and electronic polarization (4, 5).

Models of injected charges

One-electron models

The local or extended nature of molecular-ion states in molecular solids is determined by a competition between fluctuations in the local site energies of these states (which tend to localize them) and the hopping integrals for inter-site excitation transfer (which tend to delocalize them). In order to define this fluctuation-induced localization concept more precisely, consider the one-electron Hamiltonian

$$[1] \quad H = \sum_{i,\beta} \epsilon_i(\beta) a_{i\beta}{}^{+} a_{i\beta} + \sum_{i \neq i',\beta} (t_{ii'} a_{i'\beta}{}^{+} a_{i\beta} + \text{h.c.})$$

in which i is a site index; β indicates the molecular orbital; $t_{ii'}$ designate the intermolecular hopping integrals; and $a_{i\beta}$ is the annihilation operator for an electron occupying orbital β at site i. The important new feature of polymers and molecular glasses, not present in periodic crystal lattices, is that the site energies $\{\epsilon_i\}$ and the hopping integrals $\{t_{ij}\}$ form distributions. For example, the probability of finding an eigenvalue ϵ_i with value ϵ is typically taken to be (3, 4)

$$[2] \quad P(\epsilon) = (\pi\sigma^2)^{-1/2} \exp(-[\epsilon - \epsilon(\beta)]^2/\sigma^2)$$

in which σ^2 is the sum of a number of contributions associated with various types of disorder, and $\epsilon(\beta)$ is an average eigenvalue associated with the molecular-ion state labelled by the orbital index β. Because both the $\{\epsilon_i\}$ and $\{t_{ij}\}$ form distributions, the Hamiltonian [1] is specified statistically and hence can exhibit localized as well as extended eigenstates (2–5).

The eigenfunctions and eigenvalues of Hamiltonian [1] for prescribed (e.g., experimentally measured) distributions of the $\{\epsilon_i\}$ and $\{t_{ij}\}$ cannot be determined analytically at the present time. Some qualitative results have, however, been established numerically. The features of interest here can be specified in terms of a mean site energy, ϵ, the rms deviation from this mean, $\Delta = [\langle(\epsilon_i - \epsilon)^2\rangle_{AV}]^{1/2}$, and a mean hopping integral, t (5). Injected charges are localized, i.e., they form molecular cations or anions with the solid, if

$$[3] \quad \Delta > czt \equiv cW$$

in which W is the one-electron band width and c is a dimensionless number of the order of unity which depends both on the connectivity (i.e., dimensionality) of the system and on the distribution of the $\{t_{ij}\}$. Typically $c \sim 2.5$ for (isotropic) three-dimensional systems, 1.5 for two-dimensional systems, and zero for one-dimensional systems, although some confusion currently exists in the case of two dimensions (6). Inequality [3] is believed to be satisfied in molecular glasses and in certain aromatic polymers (3–5). In these cases electrons and holes injected into the material form local, molecular radical anions and cations, respectively, rather than extended states like those characteristic of crystalline covalent semiconductors. Consequently, under these circumstances the electrons and holes are more accurately visualized as molecular ions in solution which move by carrier hopping rather than by ionic diffusion.

The traditional energy-band model describes the opposite limit when $\Delta \equiv 0$. A schematic diagram of the nature of the eigenvalue spectrum associated with eq. [1] in the various limiting cases of relative magnitudes of Δ and W is given in Fig. 1. Different classes of polymers and molecular solids exhibit systematically distinct ranges of values of Δ and W. For typical pendant-group and molecularly doped polymers, 0.1 eV $\leq \Delta \leq$ 1 eV, and $W \ll 0.1$ eV. Therefore, $\Delta \gg cW$ is clearly satisfied for these materials and, as noted above, injected charges form intrinsic local molecular ion states in pendant-group polymers or analogous extrinsic states in molecularly doped polymers. This "Fermi-glass" limit is described in panel (c) of Fig. 1. For polymers with larger hopping integrals within the individual macromolecular chains, e.g., polyacetylene, polyethylene, and polyphenylene, Δ is less than W for motion along the chain. If interchain hopping were neglected, injected charges still would be localized in these materials because c = 0 for one-dimensional systems. If strong interchain hopping

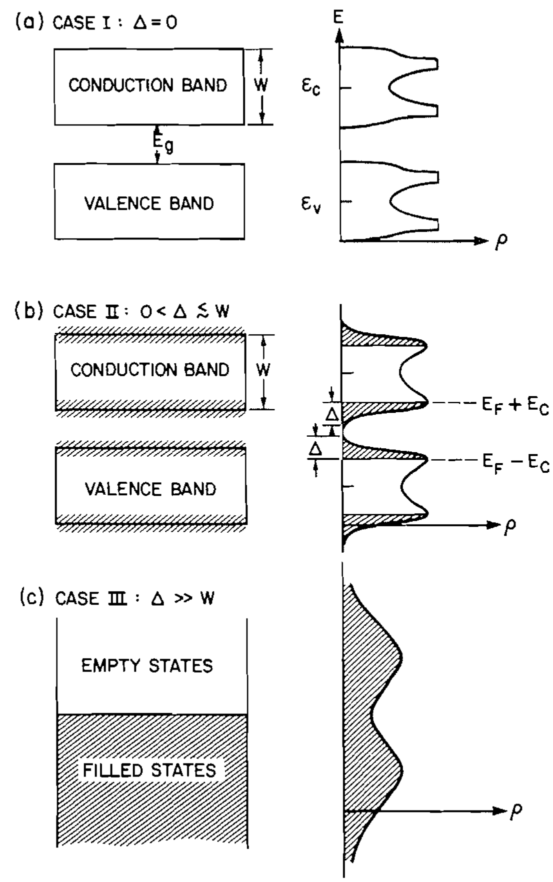

FIG. 1. Schematic indication of the consequences of static diagonal disorder (i.e., $\Delta \neq 0$, see text above inequality [3]) on the localization of one-electron states in a nominally three-dimensional solid. The symbol ρ designates the one-electron density of states. Panel (a): Case I, $\Delta = 0$, describes the traditional energy-band model. Panel (b): Case II, $\Delta < W$, where W is the one-electron bandwidth, describes the localization of electronic states at the edges of the band but not the center. E_c designates the mobility edge and E_F the bulk electrochemical potential. States closer to the band centers are extended whereas those further removed are localized. The localized states are indicated by shaded areas in the figure. Panel (c): Case III, $\Delta \gg W$, describes the situation in which all electronic states are localized and the concept of energy bands has lost its meaning (the Fermi glass model).

occurs, the polymer can become two- or three-dimensional, depending upon the packing of the macromolecular chains. This situation is described in panel (b) of Fig. 1. Such interchain interactions are thought to occur in polymers that exhibit metallic conductivity, e.g., polythiazyl, $[SN]_n$, and heavily doped polyacetylene (2).

Molecular orbital models

Since the molecular ions of interest in practical xerographic materials are "large" (i.e., azepines, benzidines, pendant-group polymers like polystyrene and poly(2-vinyl pyridine)) a description of their electronic properties requires the use of semiempirical molecular orbital methods. A spectroscopic CNDO-level model is used both for large molecules (7) and for macromolecules, i.e., polymers (8). This model affords a quantitative description of the photoemission and uv absorption spectra of over 100 polymers and large molecules (7, 8) and hence is useful for screening large classes of materials. It provides the starting point for constructing quantitative models of the electronic structure of molecular solids (4), triboelectric charge transfer (3), and transport in pendant-group and molecularly-doped polymers (9). Thus, the model affords a practical and reliable vehicle for describing the properties which are essential in electrophotographic applications. It also provides a useful way to calculate electron–molecular-vibration coupling constants (10): a critical ingredient in models of photoemission and transport in molecular solids (4, 9). A typical example of the application of the model to calculate the molecular cation density of states for comparison with photoemission (PES) data is shown in Fig. 2 for metal-free phthalocyanine, a molecule used as a photogenerator material in organic photoconductors (2).

Electron–vibration coupling: dynamic disorder and polarons

Given the existence of localized molecular ions in molecular solids, their small-polaron dynamics is established primarily by the interaction of the excess charge with those induced in the polymer matrix (4, 9). For such a purpose the Hamiltonian of eq. [1] must be extended to become

$$[4]\quad H = \sum \epsilon_i a_i^+ a_i^+ + \sum_{i \neq j} (t_{ij} a_i^+ a_j + h.c.) + \sum_{i,n} g_{in} \hbar\omega_n a_i^+ a_i (b_n + b_n^+) + \sum \hbar\omega_n (b_n^+ b_n + 1/2)$$

In eq. [4], a_i^+ designates the creation operator of an electron in an orbital of energy ϵ_i at site i, and b_n^+ that of a normal mode of vibration of energy $\hbar\omega_n$ coupled to the electronic state labelled by i via the dimensionless coupling constant g_{in}. The most obvious $\hbar\omega_n$ are the intramolecular vibrations of the molecular ions themselves (10). More important, however, are the dielectrically active normal modes of the molecular medium in which we envision the sites to be embedded. The $\hbar\omega_n$ associated with these "longitudinal polarization fluctuation" modes are obtained from the measured dielectric response of the polymer and g_{in} are specified in terms of a classical electrostatics analysis of the interaction of a charge in a prescribed molecular orbital with the dielectrically active normal modes (4). This model has been applied successfully to interpret valence-electron photoemission and uv absorption spectra of polystyrene and poly(2-vinyl pyridine), as well as photoemission from a wide variety of molecular glasses (4). Transport data are less widely available, but the model is consistent with the limited data base currently in the literature (4, 9). We conclude, therefore, that in molecular glasses (e.g., condensed ethyl benzene), pendant-group polymers (e.g., polystyrene), and molecularly-doped polymers (e.g., polycarbonate doped with trinitrofluorenone) the model defined by eq. [4] with the $\{g_{in}\}$ and $\{\hbar\omega_n\}$ obtained from measured polymer dielectric response is both necessary and sufficient for the description of the small-polaron dynamics of charges injected into these materials.

Valence electron photoemission

The main evidence for the validity of the relaxation-localization model defined by eq. [4] arises from the analysis of valence electron photoemission: a measure of eigenvalue spectrum of photogenerated molecular cations. In the Fermi-glass limit (Case III, panel (*c*), Fig. 1) the model makes three observable predictions (4). First, for molecules whose radical cation geometries are expected to be the same in the gaseous and solid phases, the valence electron photoemission spectrum in the solid state is predicted to be shifted rigidly to lower binding energies by an intermolecular relaxation energy 1 eV $\lesssim E_r$ (inter) $\lesssim$ 2 eV and broadened considerably. Second, in contrast to traditional models of solvation energies, E_r is predicted to be identical for polar and non-polar isoelectronic molecules. Third, the broadening of the spectra, although dominated by static disorder, should exhibit a characteristic temperature dependence associated with the excitation of low-frequency molecular motions upon the photogeneration of the radical cation from the neutral molecule. All three predictions have been verified, as indicated below.

Valence electron photoemission spectra from both gas-phase (11) and thin-film (12, 13) metal-free phthalocyanine are shown in Fig. 3. The fact that to within experimental reproducibility the thin film spectra are rigidly shifted and broadened versions of the gas-phase spectra is evident from the figure. In addition, all of these spectra are well described by the CNDO/S3 model (7) whose predictions already were shown in Fig. 2. Thus, we see for this particular case of a xerographic photogenerator the validity of the first prediction of the Fermi-glass limit of eq. [4]. This result also has been established for other molecular solids comprised of relatively rigid molecules (14, 15). In the case of less rigid molecules, e.g., triphenylamine and phenylenediamines, the geometry of the molecular cations can change between the gaseous and solid states, so that more complex differences occur between the valence electron photoelectron spectra characteristic of these two phases (16). Even in these cases, however, the spectra of condensed molecular films are essentially those of localized molecular cations. Therefore the task of any model of molecular cation states in condensed media (both glassy and crystalline) is the prediction of the relaxation energy shifts and large increases in widths of the photoionization lines in the condensed relative to the gaseous phase.

It might be anticipated that the intermolecular relaxation energies would be simply the static polarization energies of a molecular cation in the condensed medium given, for example, by the Born model of solvation (17). That such cannot be the case is immediately evident upon noting that nonpolar polystyrene and condensed ethyl-benzene exhibit the same relaxation-energy shifts, E_r(inter) = 1.5 eV, as polar poly(2-vinyl pyridine) and condensed 2-ethyl pyridine (4). The static dielectric constants of the polar materials are over twice those of the non-polar ones, demonstrating that static models of the relaxation energy are clearly incompatible with the observations. The relaxation-localization model specified by eq. [4] correctly predicts this result by revealing that only the high-frequency electronic branches of the longitudinal polarization spectrum, contribute to E_r(inter).

The analysis of the widths, σ, of the condensed phase photoionization lines is more complex because both static and dynamic disorder contribute to σ. Schematically, we can write

$$[5]\quad \sigma^2 = \sigma^2(\text{ins}) + \sigma^2(\text{intra}) + \sigma^2(\text{inhom}) + \sigma^2(\text{hom})$$

The instrumental width, σ(ins), is typically less than about 0.02 eV for a well designed ultraviolet photoemission spectrometer (4). The intramolecular contributions to the widths, σ(intra), vary from one molecular-ion state to another, lying in the range 0.2 eV $\lesssim \sigma$(intra) $\lesssim$ 0.4 eV (4). Usually the predominant contribution to the width in the condensed state is the inhomogeneous width σ(inhom), caused by spatial fluctuations of the electronic contributions to the relaxation energy. Typically 0.4 eV $\lesssim \sigma$(inhom) $\lesssim$ 0.6 eV depending upon sample

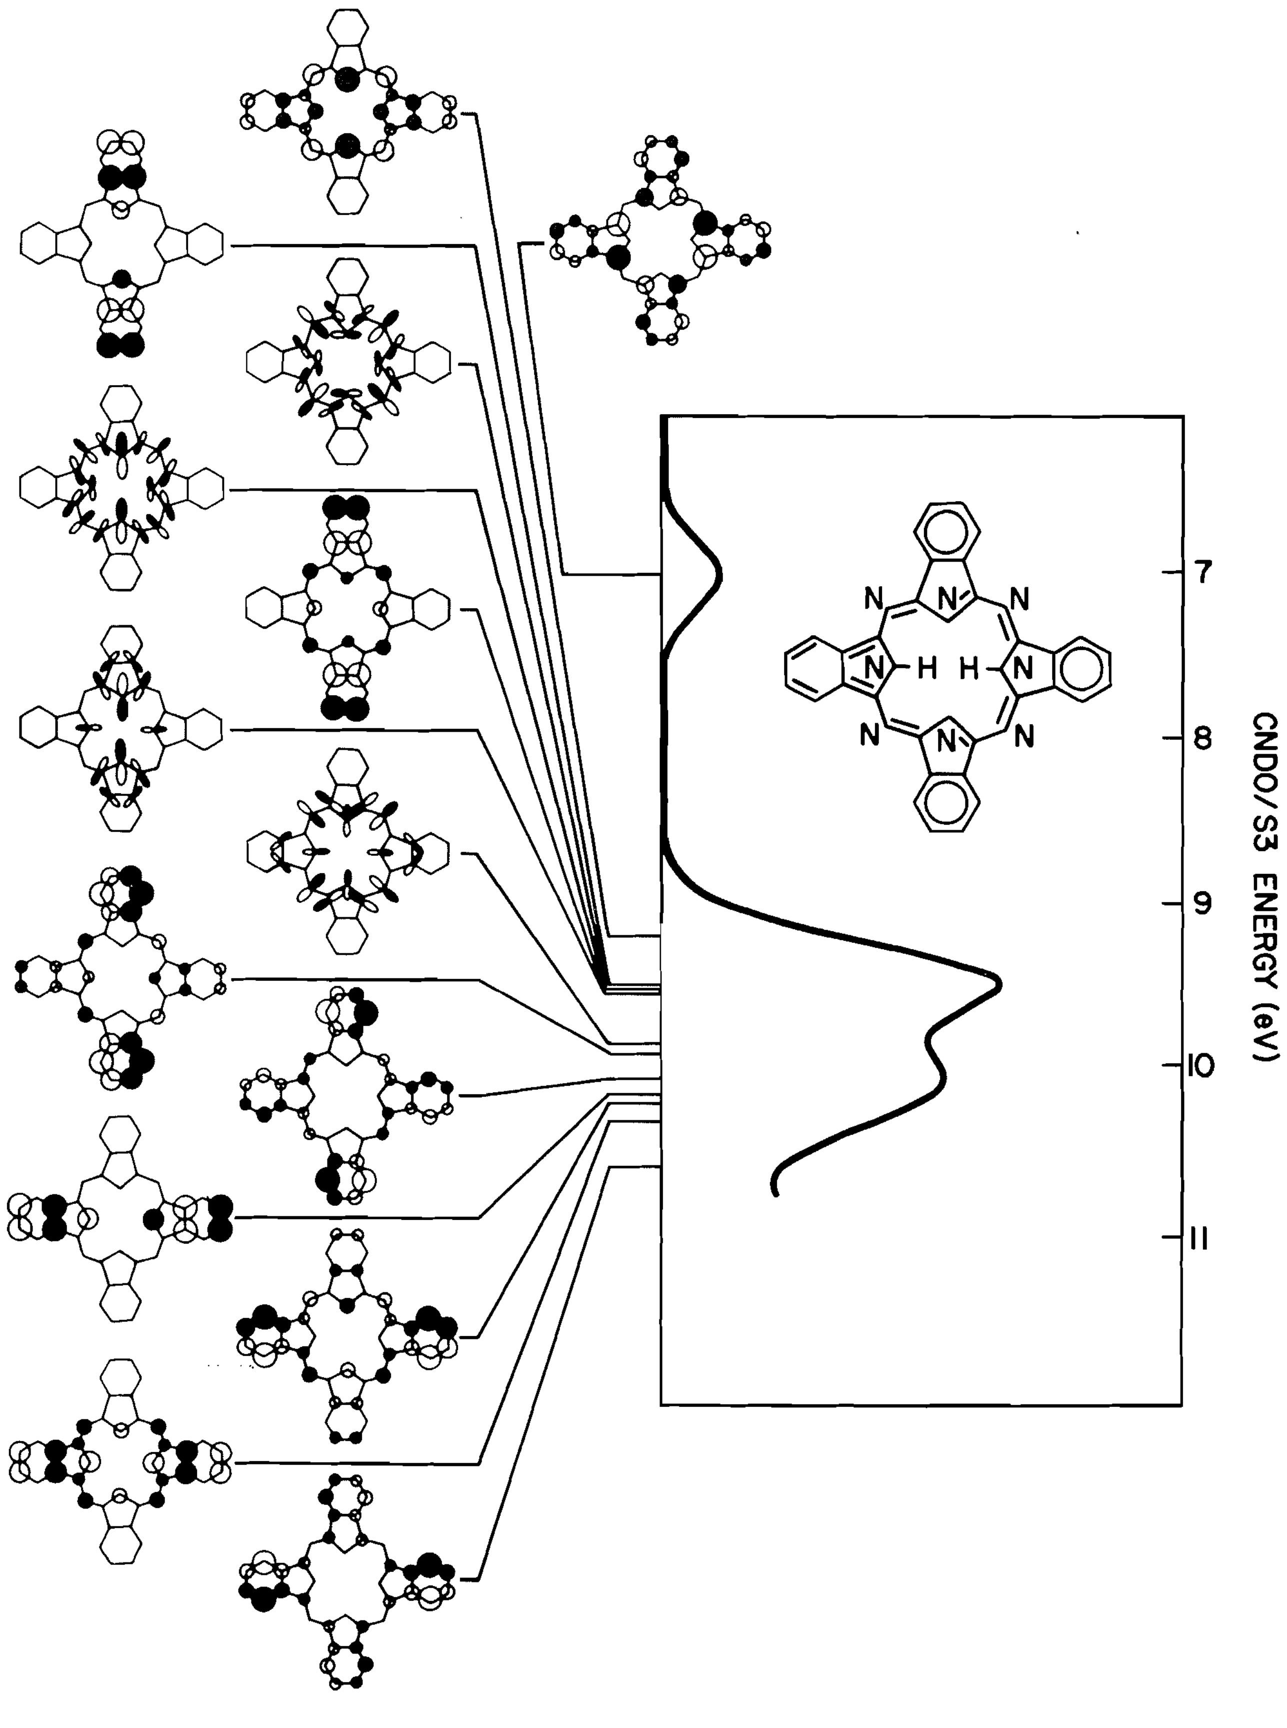

FIG. 2. Molecular-ion-state orbitals, eigenvalues, and density of states for metal free phthalocyanine predicted by the CNDO/S3 molecular orbital model (7).

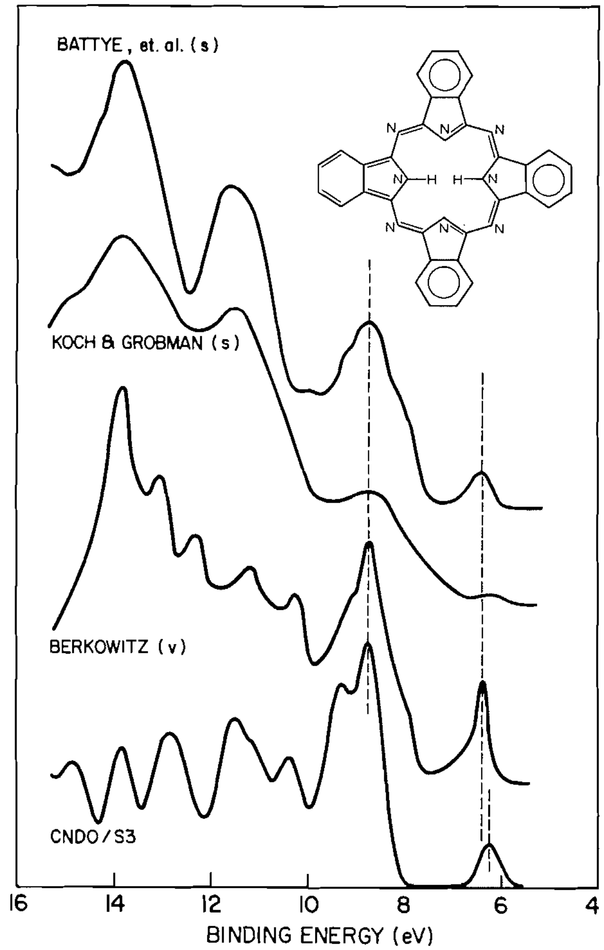

FIG. 3. Comparison of measured photoemission spectra from condensed thin-film (top two panels (12, 13)) and vapor-phase (third panel (11)) metal free phthalocyanine with the density of states calculated using the CNDO/S3 model (7). All spectra have been shifted to align the peak 8.75 eV with the vapor-phase spectrum. This procedure yields a relaxation energy shift of 5.0 eV for the thin film spectrum of Battye *et al.* (12) and of 1.3 eV for that of Koch and Grobman (13).

preparation conditions. Finally, the homogeneous contributions may be written as

$$[6] \quad \sigma^2(\text{hom}) = \sigma^2(\text{ir}) + c^2\,\kappa T$$

in which κ is Boltzmann's constant and T is the temperature. The first term arises from infrared active vibrations on all molecules including the one on which the molecular ion is formed. The second is caused by thermally excited longitudinal polarization fluctuations. It was predicted by the relaxation-localization model *a priori* (18), and subsequently observed for condensed isopropyl benzene (19) and violanthrene A (20). The model predicts 0.1 eV $\lesssim \sigma(\text{ir}) \lesssim$ 0.3 eV, but the contributions to σ from $\sigma(\text{ir})$ and $\sigma(\text{inhom})$ have not yet been separated experimentally.

Charge transport

Drift mobilities in pendant-group polymers and molecular glasses: the Fermi-glass limit

The relaxation-localization model has been applied to derive explicit expressions for electron (hole) transfer probabilities between two molecular sites in pendant-group and molecularly-doped polymers (9). These probabilities are the input data used in multiple-hopping models of measured transport properties, e.g., drift mobilities and photoconductivity. Consequently, they constitute the link between observed transport properties and the microscopic electronic structure of polymers. In particular, the model has proven useful in quantifying the trade-offs between the electrical and mechanical properties of polymers used in electrophotographic copying machines and in suggesting improved materials for such applications (9).

The model's important prediction is that of the influence of each of the different branches of the longitudinal polarization fluctuation spectrum on the electron-transfer probability. The high-frequency electronic branches, which are responsible for the photoemission relaxation energies, exert only a minor influence on electron-transfer by virtue of a temperature-independent prefactor. The low-frequency branches contribute to the activation energy for the electron transfer process as well as to the temperature-dependent widths of photoemission lines via eq. [6]. The ir branches cause the apparent activation energies to increase with increasing temperature. Thus, the model has clarified the physical basis of electron-transfer processes in condensed media as well as provided a new, more accurate mathematical expression for the transfer probabilities themselves. Its predictions are consistent with available experimental data (9).

Contact charge exchange between polymers

Although over a century of research has been devoted to contact charge exchange between insulators, prior to 1978 no model had been proposed which successfully predicted the quantitative magnitude of this charge exchange. That year a phenomenological version of the relaxation-localization model was proposed which predicted quantitatively the polymer–polymer charge exchange among various copolymers of polystyrene and poly(methyl methacrylate) in terms of effective spatially-averaged densities of molecular ion-states per unit energy, $\rho(E)$, for each polymer determined from metal-polymer contact charge exchange experiments (3). This model also predicted correctly the difference in contact charge exchange between pigmented and unpigmented polymers, and later was extended to encompass copolymers of polystyrene and poly(methyl methacrylate) with poly(2-vinyl pyridine), and copolymers of $(C_2F_3Cl)_m$ and $(C_2H_3F)_n$ (i.e., "Kel F-800") (21, 22). In addition, new data for polystyrene, poly(methyl methacrylate), and polyethylene subsequently were reported which purportedly contradicted the relaxation-localization average-density-of-states model interpretation (23). The differences between the data sets were attributed to the presence of extrinsic states and to the absence of a sufficient number of contacts to achieve adequate spatial averaging (24), however, so the original model thus far has withstood the test of time.

The relationship between the chemical properties of the polymers in question and the steady-state contact charge exchange is embedded in the parameters characteristic of the average density of states $\rho(E)$. Typically $\rho(E)$ is the form (3, 9):

$$[7] \quad \rho(E) = \rho_A(E) + \rho_D(E)$$

in which the $\rho_i(E)$ are given by eq. [2], D designates electron donors and A electron acceptors. Good donors exhibit small radical cation energies, ϵ_D, and good acceptors large radical anion energies, ϵ_A. Polar media lead to σ_i which are large and which have a temperature dependence as described in eq. [6] with large values of c. The structure of the polymer host enters

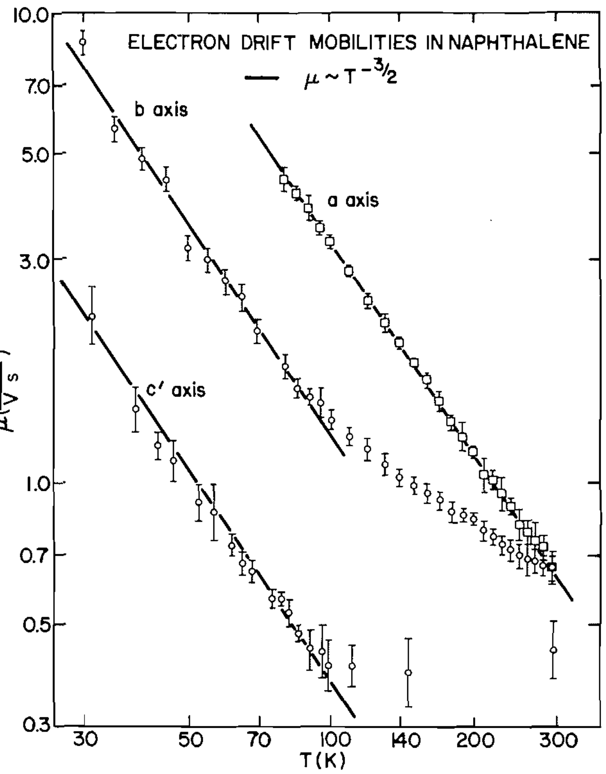

FIG. 4. Measured electron drift mobilities along the a, b, and c' directions in naphthalene as functions of temperature. The error bars are obtained as the averages of repeated runs under nominally identical conditions. The solid lines indicating $\mu \sim T^{-3/2}$ are the predictions of a Boltzmann equation analysis in which injected electrons occupy Bloch energy band states and their motion is limited via scattering by acoustical lattice vibrations (i.e., phonons) (after Andersen, Duke, and Kenkre (33), courtesy of the American Physical Society).

by virtue of more rigid (e.g., crystalline) materials tending to reduce ϵ_A, to increase ϵ_D, and to reduce σ_i^2 for a given acceptor or donor species, *ceteris paribus*. The correlation of the resulting contact charge exchange properties with measures of chemical reactivity and molecular structure have been discussed elsewhere (25). These correlations are consistent with triboelectric charge transfer occurring between relaxed molecular-ion states, typically intrinsic states localized on the pendant group moieties for polymers like polystyrene, poly(methyl methacrylate), and poly(2-vinyl pyridine).

Drift mobilities in naphthalene: the localized-extended-state boundary

The theory of the drift mobilities of charge carriers injected into semiconducting organic crystals has been a subject of debate for many years because of the occurrence in several materials of temperature and field independent mobilities (26–28) which initially proved inexplicable by either band or hopping models (26, 29). Interest in this subject was greatly stimulated when it was discovered that for exceptionally pure and perfect crystals of naphthalene the electron mobilities in the c' direction began to rise rapidly with decreasing temperature below $T \simeq 100$ K: a phenomenon interpreted as evidence for the long-anticipated band-to-hopping transition because in these materials $\Delta^2 \sim \kappa T$ so that a transition from the situation described by panel (b) in Fig. 1 to that described by panel (c) is expected with increasing temperature (30). Subsequently, additional drift-mobility data were accumulated for naphthalene, rendering it by far the most comprehensively characterized organic crystal in this regard, but the original interpretation (30) of the c' direction mobility data was questioned by virtue of the construction of a model in which the behavior exhibited by these mobilities was attributed to hopping between quasi-one-dimensional chains of naphthalene molecules (31). Thus, it seemed possible that naphthalene exhibited quasi-one-dimensional injected electron motion along the a axis at all temperatures rather than exhibiting a band-to-hopping transition at $T \simeq 100$ K for motion in the b and c' directions (29, 31, 32).

Although this saga is not yet over, its latest episode consists of a reinterpretation of the original drift mobility data in light of the recently expanded data base to reveal that a model embodying three-dimensional band motion is uniquely compatible with all the data for $T < 100$ K (33). These data and their description by acoustical-phonon-scattering limited band motion, i.e., $\mu \sim T^{3/2}$, for $T < 100$ K in all directions are shown in Fig. 4. A transition in the character of the electron motion at $T \simeq 100$ K is evident from these data which are compatible with the quasi-one-dimensional motion model for $T \gtrsim 300$ K (32). This transition is thought to constitute the boundary between localized and extended states specified by inequality [3]. The data for $T > 100$ K remain incomplete, however, so no quantitative analysis thereof is possible at this time (33).

Synopsis

Disorder-induced localization constitutes the bridge between solid-state physics and molecular-ion chemistry in condensed molecular media. Practical organic "semiconductors" typically are characterized by the Fermi-glass limit (Fig. 1, Case III, panel (c)) in which injected charges form localized molecular ions rather than occupy extended Bloch energy band states characteristic of traditional semiconductors. This fact renders local molecular-ion chemistry rather than energy-band models the appropriate predictors of the behavior of charges injected into xerographic materials. The boundary of the Fermi-glass region remains imprecisely defined, however, as revealed by the example of electron mobilities in naphthalene.

X-ray methods for quantitative determination of inorganic fillers in paper

TERRY L. BLUHM, ARTHUR Y. JONES, AND YVES DESLANDES
Xerox Research Centre of Canada, 2660 Speakman Drive, Mississauga, Ont., Canada L5K 2L1

Received December 30, 1983

TERRY L. BLUHM, ARTHUR Y. JONES, and YVES DESLANDES. Can. J. Chem. **63**, 243 (1985).

X-ray diffraction methods have been investigated as means of quantifying filler contents of paper. Both an "internal standard method" and an "absorption−diffraction method" were applied. Because of preferential orientation of the filler particles in commercial paper samples, the "internal standard method" was modified to include an empirical evaluation of the proportionality constant, K. Values of K specific for each filler material investigated (clay, calcite, talc, and titanium dioxide) were obtained by X-ray diffraction intensity measurements on standard papers containing different amounts of each filler. These values of K were then used to calculate the filler content of various commercial papers. The filler contents of these same commercial papers were also determined using the X-ray "absorption−diffraction method" and ash determination. Comparisons made among results from all these methods indicated that both X-ray methods give acceptable agreement with ash determination, but that the "absorption−diffraction method" is preferred due to its ease of application. In addition, the X-ray methods are more rapid and versatile than ash determination.

TERRY L. BLUHM, ARTHUR Y. JONES et YVES DESLANDES. Can. J. Chem. **63**, 243 (1985).

Deux méthodes de diffraction des rayons-X, "méthode du standard interne" et "absorption−diffraction," ont été utilisées pour la quantification des pigments inorganiques dans le papier. A cause de la présence d'une orientation préférentielle des particules de pigments dans des feuilles de papier commerciaux, la "méthode du standard interne" a été modifiée en utilisant une évaluation empirique de la constante de proportionalité K. Pour chaque pigment étudié (argile, calcite, talc et dioxide de titane) une valeur de K a été obtenue par la mesure des intensités rayons-X obtenus de papiers expérimentaux qui contenaient différentes quantités de pigments. Ces valeurs de K ont ensuite été utilisées pour évaluer la quantité en pigments dans des papiers commerciaux. Les contenus en pigments de ces derniers ont également été déterminés par la méthode "absorption−diffraction" et par détermination des cendres. Après comparaison des résultats obtenus par ces trois méthodes, il apparaît que la méthode "absorption−diffraction" soit préférée à cause de sa facilité d'application. De plus, les méthodes utilisant la diffraction des rayons-X sont plus rapides et plus versatiles que la méthode classique de détermination des cendres.

Introduction

Paper is composed of a mat of wood fibers bonded together by surface hydrogen bonds. It also contains some filler materials, usually incorporated to improve the optical properties (whiteness, opacity, etc.) of the sheet (1, 2). Typical plain xerographic paper made in North America consists of about 80% wood fiber, of which one quarter is softwood and three quarters are hardwood. The sheet also contains about 10% clay fillers and titanium dioxide, 5% starch, 5% water, and small amounts of various chemical additives such as rosin size and retention aids. However, the materials used as fillers around the world vary according to their availability and economic factors. Important considerations for the selection of a filler include optical properties, low cost, and compatibility with the paper-making process.

Most xerographic papers made in North America contain approximately 10% kaolin ($Al_2O_3 \cdot 2SiO_2 \cdot 2H_2O$), which is commonly known as clay, a naturally occuring, fine grain, well crystallized mineral composed of platelet-like particles. This hydrated aluminum silicate is extracted from the ground in various grades. Small amounts of titanium dioxide particles (~1 μm in diameter) are incorporated in paper to increase the whiteness of the sheet. The "anatase" crystal form is usually used in paper since it is cheaper than the "rutile" form. TiO_2 is, however, more expensive than clay and is therefore usually found only in small quantities in paper.

In Europe, calcite ($CaCO_3$) is extensively used as filler. European xerographic papers contain large quantities of calcite which is relatively inexpensive and compatible with the alkaline sizing treatment widely used in Europe. Particle size may vary from 1 to 10 μm. Calcium carbonates can be found occurring naturally or precipitated from limestone.

Most Japanese papers contain significant quantities of talc as filler. In Japan, talc costs about 50% less than clay. The designation of talc covers a wide range of natural products. The theoretical formula corresponds to a weight ratio of MgO to SiO_2 of about 1:2, but in actual samples this ratio may reach 1:1. Since the composition of talc is variable, it is understandable that there are many grades offered as commercial pigments.

In view of the large variety of fillers that are found in various xerographic as well as non-xerographic papers, we have undertaken a study examining the usefulness of X-ray analytical techniques for the quantitative determination of inorganic fillers in paper. It is clear that other analytical methods have been known for many years, but they suffer from various drawbacks. For example, ash determination (3), currently used in the paper industry, provides only the value of total ash, independent of the chemical composition. For analysis of each individual component, a complex "wet" chemistry method must be used (3), making the whole process very time consuming unless the laboratory is well equipped for continuous analysis. More sophisticated techniques such as energy dispersive X-ray analysis (EDAX) can be extremely accurate, but they do not provide an overall measure of filler content since EDAX is a surface technique (penetration of 3 μm only). X-ray fluorescence is a valuable method for elemental determination of fillers in paper, however, quantitative determination of the actual individual mineral phases cannot be made. For instance, the rutile and anatase forms of TiO_2 cannot be distinguished using this method, and since both clay and talc contain silicon atoms, these phases cannot be uniquely determined. The combination of X-ray diffraction and EDAX methods has been used successfully for the identification of both crystalline and amorphous fillers (4). Finally, fillers have also been analyzed by microscopic methods. However, these methods only provide qualitative information (5).

X-ray diffraction methods (6) have been used for a long time as a qualitative means of identification of inorganic fillers in paper and are extensively used for quantitative determination of mixed crystalline powder phases. Therefore, we have sought to extend these quantitative methods to the analysis of paper sheets. We report here results using two methods of X-ray quantitative analysis; (*i*) an internal standard method and (*ii*) absorption–diffraction method, for determination of inorganic fillers in cut paper sheets.

Methods

It has been widely observed that the intensity of diffraction peaks arising from various crystalline components in a mixture are greatly affected by the X-ray absorptivity of the components in the mixture. Peaks of the weakly absorbing component appear relatively weak and those of the strongly absorbing species are relatively stronger. Alexander and Klug (7) first arrived at a mathematical relationship relating the intensity of diffraction lines to the absorptivity of the sample as follows:

$$[1] \quad I_{iJ} = \frac{K_{iJ}x_J}{\rho_J\mu^*}$$

where I_{iJ} = intensity of peak i of component J of a mixture, x_J = weight fraction of component J in a mixture, ρ_J = density of solid component J, μ^* = mass absorption coefficient of the sample, and K_{iJ} = a constant depending on the nature of component J and the geometry of the diffractometer. The mass absorption coefficient of the sample, μ^*, can be related to the mass absorption coefficient of the Jth component, μ^*_J and that of the matrix surrounding the Jth component, μ^*_M, as follows:

$$[2] \quad \mu^* = x_J\mu^*_J + (1 - x_J)\mu^*_M$$

For paper where the Jth component is a filler $\mu^*_J \neq \mu^*_M$. μ^*_J can be calculated from a table of mass absorption coefficients for the various elements assuming that the elemental composition of the Jth component is known:

$$[3] \quad \mu^*_J = \sum x_i\mu^*_i$$

where the x_i are the weight fraction of the elements and the μ^*_i are the mass absorption coefficients for the elements in the compound J. However, μ^*_M can not be calculated as the composition of the matrix is not known. These circumstances necessitate the use of indirect methods of analysis by use of an internal standard.

Internal standard method

In using the internal standard method a known amount of a standard component, S_1 is added to the sample. Without going into the mathematics, a detailed discussion of which can be found in ref. 7, the following equations are obtained:

$$[4] \quad \frac{I_{iJ}}{I_{kS}} = K\frac{x_J}{x_S}$$

where I_{iJ} = intensity of the ith peak of component J in the matrix, I_{kS} = intensity of the kth peak of the internal standard in the mixture, x_J = weight fraction of component J, x_S = weight fraction of the internal standard added, and K = constant dependent on the mass absorption coefficients of the matrix and Jth component.

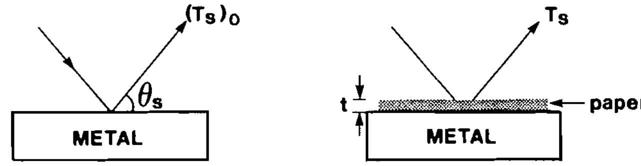

FIG. 1. Schematic of the arrangement used for the absorption–diffraction method.

$$[5] \quad K = \frac{(I_{iJ})_0\mu_J}{(I_{kS})_0\mu_S}$$

where μ_J = mass absorption coefficient of component J, μ_S = mass absorption coefficient of internal standard, $(I_{iJ})_0$ = intensity of ith peak of pure component J, and $(I_{kS})_0$ = intensity of kth peak of pure internal standard.

Equation [5] presented above is valid only when the particles in the sample are small (<3–5 μm) and no preferred orientation of particles is present in the sample. In paper, filler particles are often larger than 3–5 μm in size and they can not be ground to smaller size without completely destroying the paper sheet. Also, in the case of some fillers (i.e., kaolin and talc) the particle shape is anisotropic and some preferred orientation of the particles along the oriented wood fiber network is often present (8). Therefore, we chose to use a semi-empirical approach to the problem. Instead of calculating the value of K by using eq. [5], several sheets of paper were made containing various fillers, as described in the Experimental section, and K was determined from the slope of plots of x_J/x_S vs. I_{iJ}/I_{kS}. The value of K determined in this manner will henceforth be referred to as K'.

Absorption–diffraction technique

From eq. [1] it can be shown that

$$[6] \quad x_J = \frac{\mu^* I_{iJ}}{\mu_J^*(I_{iJ})_0}$$

In this equation the only unknown quantity is μ^*, the mass absorption coefficient of the mixture. If μ^* can be measured for the mixture using an X-ray powder diffractometer in the same geometry as that with which I_{iJ} and $(I_{iJ})_0$ are measured, the weight fraction, x_J, of a component can be determined. A method has been developed (9) using a thin layer of powder mounted on the surface of a fine grained metal where diffracted X-rays from the metal are attenuated by the powder (Fig. 1). The ratio of the intensities of a metal diffraction peak with, and without, the powder layer in place is given by the following equation;

$$[7] \quad \frac{T_s}{(T_s)_0} = e^{-2t\mu^*\rho/\sin\theta_s}$$

where T_s = intensity of metal diffraction with powder layer, $(T_s)_0$ = intensity of metal diffraction without powder layer, t = thickness of the powder layer, ρ = bulk density, θ_s = Bragg angle of the diffraction peak, and μ^* = mass absorption coefficient of the powder.

Combining eqs. [6] and [7] and introducing the parameters, A, the cross-sectional area of the beam at the sample; B, the area of the sample illuminated; and W, the weight of the paper sample illuminated, one obtains

$$[8] \quad x_J = \frac{-I_{iJ}}{(I_{iJ})_0} \times \frac{B\sin\theta_s}{AW} \times \frac{\log\,[T_s/(T_s)_0]}{1 - [T_s/(T_s)_0]^r}$$

in which $r = \sin\theta_s/\sin\theta_{iJ}$.

If we define

$$[9] \quad P_{iJ} = (I_{iJ})_0 \frac{A}{B}$$

then

$$[10] \quad x_J = \frac{-I_{iJ}\sin\theta_s}{WP_{iJ}} \times \frac{\log\,[T_s/(T_s)_0]}{1-[T_s/(T_s)_0]^r}$$

and P_{iJ} is constant for a given diffraction peak i of component J when A and B are invariant.

Paper is an ideal sample for the absorption–diffraction technique since the thickness is uniform and easily measured. Use of this method also eliminates the need to add an internal standard to the paper sheets which is often troublesome and introduces inaccuracy to the measurement.

Experimental

Three sets of standard papers were prepared using the Centrifugal Dynamic Vertical Sheet Former (Allimand 38140, Rives, France) which allows the preparation of papers having filler distributions similar to commercial papers (10). The basic furnish consisted of a 70:30 mixture of hardwood kraft pulp and softwood kraft pulp. Each set of papers consisted of five sheets with each sheet containing different amounts of fillers. The first set of papers contained varying amounts of calcite and clay (kaolin), the second set contained calcite and talc, while the third set contained calcite and titanium dioxide (anatase). These standard sets were used for the determination of K' values described in the Method section above. In our model papers, calcite was always present because we wanted to use the X-ray methods for determination of at least two fillers in the presence of each other. The quantity of filler added to a paper furnish is not totally retained in the final paper sheet. Therefore, the filler content actually present in the finished paper sheet was determined by ashing. Since calcite liberates CO_2 at around 600°C, it is possible to determine the percentage of both fillers by ashing at 575°C and at 925°C. Also, the four materials examined, clay, calcite, talc, and titanium dioxide, are the most commonly found fillers in xerographic papers.

X-ray diffraction data were collected using a Philips Automated X-ray Powder Diffractometer Model PW 1050/80 fitted with a proportional counter, pulse-height analyzer, and a graphite crystal monochromator placed in the diffracted beam. The design of the powder diffractometer is shown schematically in Fig. 2. The radiation used was Ni filtered CuK_α ($\lambda = 0.1542$ nm).

For the internal standard method, the internal standard chosen was finely ground NaCl producing a strong diffraction line at $2\theta = 31.7°$, not overlapping with lines from any of the filler analytes. The internal standard was added to the paper by pressing the finely divided powder into the surface of the sheet. The amount of sodium chloride added to each sheet was determined by weighing. Sample stacks consisting of four sheets each cut into squares 3 cm on a side were used for X-ray measurements. These paper squares were placed in a standard X-ray powder diffractometer sample holder as provided by Philips Electronics.

In the X-ray absorption–diffraction method of analysis no internal standard was required. The standard silicon wafer provided with the X-ray powder diffractometer was used for standard intensity measurement of the $2\theta = 26.1°$ diffraction line. Single thickness paper sheets cut approximately 2 cm × 2 cm were placed on top of the silicon wafer for measurement of diffraction line intensities as described in the Methods section. All intensities were determined by scanning across the diffraction peak at a 2θ scan rate of 1 deg per min and collecting the total number of counts recorded by the proportional counter. Background corrections were made by adding the number of counts collected during one-half of the scan time at each side of the diffraction peak and, subsequently, subtracting this total from the number of counts obtained while scanning across the peak.

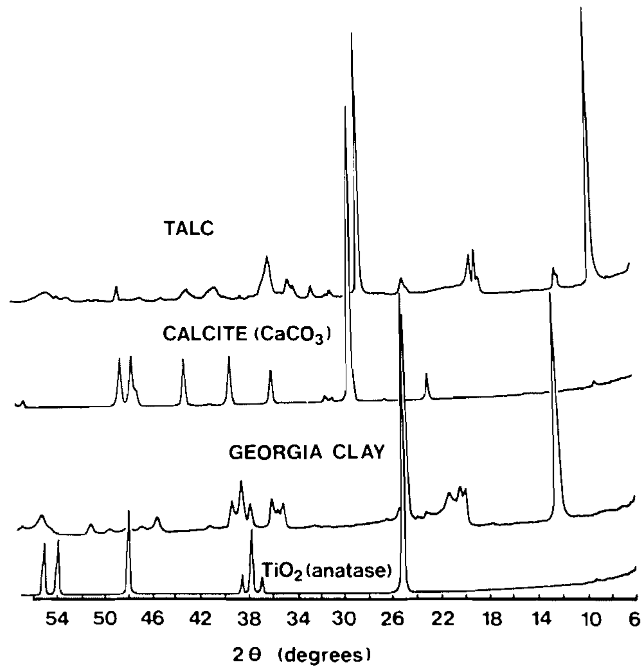

FIG. 3. X-ray diffraction traces of common paper fillers.

Results

Figure 3 shows the X-ray powder diffractometer traces of the four most widely encountered fillers in paper. Each material is characterized by a unique trace with peaks observed at specific values of 2θ. It is possible to use these traces to identify the components present in the sheet, and then, by measuring the intensity of the selected peaks, to estimate the quantity of each inorganic material.

(a) Internal standard method

Figures 4 to 6 represent X-ray powder diffractometer traces of representative samples for each of the three standard paper sets described in the Experimental section. On these traces, it is possible to identify the peaks due to cellulose, the major component of wood, and the peaks due to the filler materials. Only the peaks used for the quantification are identified on the figures.

Table 1 summarizes the data obtained from these control sheets. Diffraction peaks for measurement of I_{iJ} were chosen so as not to overlap severely with the peak of NaCl at $2\theta = 31.7°$. In these measurements, since a proportional counter was used, the errors in the I_{iJ} values are equal to $(I_{iJ})^{1/2}$.

of the filler (as determined by ashing) to the weight fraction of the internal standard (as determined by gravimetric analysis) are shown in Figs. 7 to 10. Values of K', which are determined by calculating the slope of these curves, are tabulated in Table 2. These values of K' can now be used in the determination of unknown filler content in other paper sheets.

The measured values of K' were then used to determine the amount of fillers in five selected samples of xerographic papers again using NaCl as internal standard. Diffractometer traces of these samples, labelled sample A, B, C, D, and E, are shown in Fig. 11. The total filler content of these papers was also obtained by ash determination. The results of this analysis along with results of ash determination are shown in Table 3. In the cases where more than one filler component was found in the paper, only the total filler content can be determined by ash determination.

(b) Absorption–diffraction method

The absorption–diffraction method was evaluated by determining the filler content of the same xerographic papers listed above. Values of P_{iJ} were calculated from the known geometrical parameters of the diffractometer and using values of $(I_{iJ})_0$ measured under the same conditions as for measurement of I_{iJ} values. The standard anatase, calcite, clay, and talc samples used were the same as those commonly used in the paper-making process. Equation [10] was used for calculation of the weight fraction of fillers. Values of A, B, $(I_{iJ})_0$, and P_{iJ} are reported in Table 4. The filler content in the five xerographic

papers determined using this method are reported in Table 5 along with those from ash determination.

Conclusions

Quantitative results of the method using an internal standard are very comparable with results obtained from the absorption–diffraction technique. Also, in almost all papers investigated, the agreement between ash and X-ray results is fairly good with the exception of sample B where high values of calcite content are found by both the absorption–diffraction and internal standard X-ray methods. Since this paper is made in Europe, it is possible that differences in crystallinity exist between calcite used in Europe and in North America. Since the evaluation of K' for the internal standard method and of $(I_{iJ})_0$ for the absorption–diffraction method were made using papers containing North American calcite, it is possible that these values cannot be used to analyze papers made with a calcite from different sources. This observation points to the fact that one should determine the parameters mentioned above with the same fillers as are actually used in the analyzed papers.

The average deviation between results from X-ray diffraction analysis and results from ash determination for both meth-

	Talc	0.004		
Sample E	Clay	0.098	0.100	0.096
	Talc	0.002		

ods of X-ray analysis is 15%, which seems acceptable in view of the heterogeneity of paper and its fluctuating water content. However, in our view the use of an internal standard is more difficult in practice since great care must be used in adding the internal standard and it is necessary to prepare a set of standard papers. Use of eq. [5] for calculation of K' was not successful, presumably because of preferred orientation and microabsorption effects in the paper samples.

TABLE 4. Values of the parameters used in the absorption–diffraction method

Filler	A (cm^2)	B (cm^2)	$(I_{ij})_0$ (counts)	P_{ij} (× 10^3)
Anatase	0.45	2.10	18629	3.99
Calcite	0.45	1.78	20104	5.08
Clay	0.45	2.10	26638	5.71
Talc	0.45	3.00	10310	1.55

TABLE 5. Filler concentration in five commercial xerographic papers as determined by X-ray diffraction (absorption–diffraction method) and ash determination

Xerographic paper	Filler	x_j (X-ray)		x_j (ash)
Sample A	Clay	0.013	0.115	0.093
	Talc	0.102		
Sample B	Calcite	0.246		0.190
Sample C	Clay	0.102		0.094
Sample D	Anatase	0.011	0.094	0.101
	Clay	0.066		
	Talc	0.017		
Sample E	Clay	0.079	0.084	0.096
	Talc	0.005		

Therefore, we conclude that the absorption–diffraction method of quantitative analysis using X-rays provides a rapid and moderately accurate method of determination of inorganic fillers in paper. This method is preferred over the use of an internal standard.

Styrene/butadiene block copolymer micelles in heptane

T. L. BLUHM AND M. D. WHITMORE[1]

Xerox Research Centre of Canada, 2660 Speakman Drive, Mississauga, Ont., Canada L5K 2L1

Received May 24, 1984

This paper is dedicated to the 10th anniversary of the Xerox Research Centre of Canada

T. L. BLUHM and M. D. WHITMORE. Can. J. Chem. **63**, 249 (1985).

The radius of gyration of poly(styrene-*b*-butadiene) block copolymer micelles in *n*-heptane is measured by small angle X-ray scattering (SAXS). The results are compared with theoretical predictions, and good agreement is found, particularly for the appropriate scaling relations. It is argued that the radius of gyration of the micelles depends on both the molecular weight and the composition of the copolymers. The dominant factors which determine the micelle core and corona dimensions are identified.

T. L. BLUHM et M. D. WHITMORE. Can. J. Chem. **63**, 249 (1985).

Faisant appel à la dispersion des rayons-X à petits angles (DXPA), on a mesuré les rayons de giration des micelles de copolymères en bloc de poly(styrène-*b*-butadiène) dans le *n*-heptane. On a comparé les résultats avec les prévisions théoriques et l'accord est satisfaisant, particulièrement pour les relations d'échelles appropriées. On pense que le rayon de giration des micelles dépend à la fois du poids moléculaire et de la composition des polymères. On a identifié les facteurs principaux qui déterminent le centre de la micelle et les dimensions de la couronne.

[Traduit par le journal]

Introduction

In the recent past, much experimental work has been done on diblock copolymer micelle formation in both selective solvents (1–5), and in a homopolymer corresponding to one of the copolymer blocks (6). More recently, a theoretical model has been developed for predicting the structural properties of these systems from equilibrium statistical mechanics (7, 8). For given molecular weights and chemical compositions of the copolymers and of the solvent or the homopolymer, the properties of interest include the sizes of the insoluble core and soluble corona, their swelling by the solvent or homopolymer, the stretching of each block of the copolymer, and the number of copolymer molecules per micelle. In addition to the overall magnitudes of the quantities, the ways in which they scale with the molecular weights of each block of the copolymer and of the homopolymer (if present), and with temperature, are of particular interest.

In this paper, we consider a system consisting of poly(styrene-*b*-butadiene) block copolymers in *n*-heptane, a selective solvent for the butadiene. In earlier work, Plestil and Baldrian (2) used small-angle X-ray scattering (SAXS) to determine the micelle parameters in this system over the temperature range 18 to 50°C, for copolymers of number average molecular weight $\bar{M}_N$ = 64 700 with 24% polystyrene by weight. Noolandi and Hong (7) developed a simple model involving one fitted Flory interaction parameter; their calculations were in good agreement with these results, including the temperature dependence.

A similar system has been studied by small angle neutron scattering (SANS), namely poly(styrene-*b*-butadiene) copolymers in polybutadiene homopolymer (6). In that work, four copolymers of different molecular weights and compositions, and three different molecular weight homopolymers were used. The measured quantity was the radius of the core, l_B, which was found to increase with increasing mw of the styrene block of the copolymer (or the homopolymer), but decreases with increasing mw of the butadiene block. In an extension and refinement of the model of ref. 7, Whitmore and Noolandi (8) obtained theoretical values for l_B which were in good overall agreement with these experiments and in particular, the scaling of l_B with the molecular weights of *each* block of the copolymer and with the homopolymer agreed very well. There were no fitted parameters in that case.

For the present work, we had available block copolymers of narrow dispersity and three different molecular weights and compositions. We have made room temperature SAXS measurements of the radius of gyration of the micelles formed in *n*-heptane, R_M, and extracted the dependence of R_M on the molecular weights of each block. This provides a test of the theoretical model which is complementary to the earlier work; we have a measure of the overall micelle size through R_M (not just the core radius l_B), and how it varies with the individual block molecular weights (not temperature). In addition, using the model we develop additional insight into the experimental results.

Experimental

The three poly(styrene-*b*-butadiene) copolymers used in this study were obtained from Professor Dale Meier, Michigan Molecular Institute, Midland, MI. They are materials originally supplied by Shell Development Company (9). The three polymers were designated by the code number SB(22-55), SB(12-71), and SB(12.5-93) referring to diblock copolymers with block molecular weights in thousands corresponding to the initials in the code. For example, SB(22-55) is the code for a styrene-butadiene block copolymer with a 22 000 molecular weight styrene block and a 55 000 molecular weight butadiene block. The Shell product numbers corresponding to these polymers are TR-41-2673, 967-250, and 982-250, respectively. The polydispersities in all cases are narrow (9) (Pd < 1.1).

Solutions of these copolymers were prepared in *n*-heptane (reagent grade) at room temperature and allowed to stand overnight before SAXS curves were measured. The solutions were turbid and remained stable for several weeks. Several solutions of each polymer were prepared with concentrations varying from 2 to 10 g L^{-1}. Radii of gyration obtained from the SAXS data were extrapolated to zero concentration to remove any concentration effect. All samples were run twice in order to ascertain the experimental errors. Small angle X-ray scattering curves were obtained using a Kratky camera with a 40 μm entrance slit, a 75 μm receiving slit and CuKα radiation (λ = 1.5418 Å). Scattered intensity was measured by means of a propor-

$\varphi_{CB}^{(1)}$	0.92	0.93	0.93
$\varphi_{CA}^{(2)}$	0.14	0.12	0.11
d (Å)	5.4	5.3	5.3

tional counter equipped with a pulse height analyzer. The solutions were placed in beryllium glass capillaries (2.0 mm diameter) and the data were collected at room temperature. The intensity scattered by a solvent blank was subtracted in each case. Sufficient counts were measured at each point during step-scanning so that the counting error was less than 1%. Radii of gyration were then determined from Guinier plots constructed using the slit smeared intensity data directly.

Guinier's approximation (10) of the scattering curve at very small angles can be written as:

$$[1] \quad I(h) = I(O)\exp(-h^2 R_M^2/3)$$

where

$$[2] \quad h = \frac{4\pi\theta}{\lambda}$$

θ equals one-half the scattering angle and λ is the wavelength of the incident radiation. The radius of gyration, R_M, is obtained from the slope of a plot of ln $I(h)$ versus h^2. It should be noted that this treatment according to Guinier's Law is valid only for $h^2R_M^2 \ll 1$ and that the radius of gyration obtained is a *z*-average radius. The radii of gyration measured for the three copolymer micelle systems are reported in Table 1. The Guinier plots in all cases are linear indicating that the micelles are most probably spherical and monodisperse (see Fig. 1) as one might expect from nearly monodisperse copolymers. The presence of the monodisperse micelles allows us to make direct comparisons with theory developed for monodisperse systems.

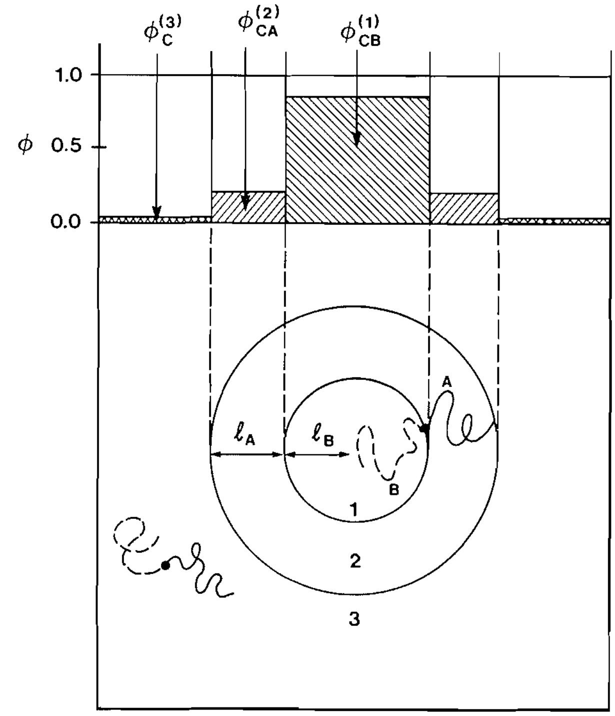

FIG. 2. Cross section of the model micelle, consisting of diblock copolymers in solvent. The core region, of radius l_B, is assumed to consist of B blocks of the copolymer (volume fraction $\varphi_{CB}^{(1)}$) plus solvent; the corona, of thickness l_A, consists of A blocks of the copolymer (volume fraction $\varphi_{CA}^{(2)}$) plus solvent; the outer region is calculated to consist almost enirely of solvent (although the model does allow for a finite copolymer volume fraction $\varphi_C^{(3)}$ in this region). Each of the three regions is assumed to be uniform.

Analysis

The results reported in Table 1 are now used to test the model referred to earlier, which in turn is then used to further analyze these results and deduce additional structural properties of the micelles. This model is essentially that developed originally by Noolandi and Hong (7); it incorporates the refinements introduced by Whitmore and Noolandi (8), but they turn out to be unimportant for this case. The model is fully described in refs. 7 and 8; here we describe it only briefly, generally writing out equations only when they differ from those in refs. 7 and 8. The model micelle is shown schematically in Fig. 2.

Each micelle is assumed to consist of a uniform core, referred to as region 1, and a uniform corona, region 2. The core consists of polystyrene blocks of the copolymer (B blocks) and solvent, with volume fractions $\varphi_{CB}^{(1)}$ and $\varphi_S^{(1)}$, respectively. Similarly, the uniform corona consists of polybutadiene blocks of the copolymer (A block) and solvent, with volume fractions $\varphi_{CA}^{(2)}$ and $\varphi_S^{(2)}$. Region 3, lying between the micelles, contains randomly distributed copolymers $\varphi_C^{(3)}$ and solvent $\varphi_S^{(3)}$. It is also assumed that the system is incompressible, so that in each region the volume fractions sum to unity.

In the procedure, the first step consists of obtaining an expression for the free energy of this system with micelles relative to the random state,

$$[3] \quad \Delta g = \frac{G_{\text{micelle}} - G_{\text{random}}}{\rho_{OS} k_B T V}$$

Here V is the volume of the system, T the temperature, k_B is Boltzmann's constant, and ρ_{OS} a reference density taken to be that of the pure solvent. The free energy difference depends on the degrees of polymerization of each of the two blocks of the copolymers, Z_{CB} (core) and Z_{CA} (corona), the densities of each of the corresponding pure systems (ρ_{OS}, ρ_{OB}, ρ_{OA}), three Flory interaction parameters and the overall copolymer volume fraction $\varphi_C{}^0$. In addition, Δg depends on four independent parameters which specify the structural properties of the micelles. They are the radius of the core, which we call l_B, the corona thickness l_A, the unit cell radius R, and the fraction of copolymers which condenses to form the micelles, $F_M{}^C$. (The remaining fraction $F_3{}^C = 1 - F_M{}^C$ remains in solution between the micelles.) The equilibrium values of these four parameters are the set that minimize Δg; the procedure thus consists of minimizing Δg with respect to them.

We express Δg as a sum of six terms. The first is the change in interaction energy.

$$[4] \quad \Delta g_{\text{int}} = -\chi_{AB} f_A f_B (\varphi_C{}^O)^2 [1 - (F_3{}^C)^2/G_3{}^V]$$
$$-\chi_{AS} f_A \varphi_C{}^O \varphi_S{}^O [1 - F_2{}^S F_M{}^C/G_2{}^V - F_3{}^S F_3{}^C/G_3{}^V]$$
$$-\chi_{BS} f_B \varphi_C{}^O \varphi_S{}^O [1 - F_1{}^S F_M{}^C/G_1{}^V - F_3{}^S F_3{}^C/G_3{}^V]$$

In eq. [4], $f_K = (Z_{CK}\rho_{OC})/(Z_C \rho_{OK})$ for each component with $Z_C = Z_{CA} + Z_{CB}$, and ρ_{OC} is given by $(Z_C/\rho_{OC}) = (Z_{CA}/\rho_{OA}) + (Z_{CB}/\rho_{OB})$. $F_i{}^S$ is the fraction of solvent in region i, and $G_i{}^V$ is the fraction of the total volume occupied by region i. The room temperature molar densities were taken to be $\rho_{OA} = 0.0165$ cm^{-3} (11), $\rho_{OB} = 0.0103$ cm^{-3} (12), and $\rho_{OS} = 0.00684$ cm^{-3} (2). Choosing ρ_{OS} for the reference density, the Flory χ parameters are $\chi_{AB} = 0.24$ (8, 13), $\chi_{AS} = 0.53$ (7), and $\chi_{BS} = 1.9$ (7).

The core-corona interface of each micelle contributes an interfacial energy, which has the form

$$[5] \quad g_I = \frac{\gamma}{\rho_{OS} k_B T} \frac{3 l_B{}^2}{R^3}$$

with the interfacial tension given as a simple function of $\varphi_{CB}{}^{(1)}$ and $\varphi_{CA}{}^{(2)}$ as well as the Flory χ parameters. The width of the interface, d, is given approximately by

$$[6] \quad \frac{d}{b} = \left(\frac{\varphi_{CB}{}^{(1)} + \varphi_{CA}{}^{(2)}}{6}\right) \left(\frac{\gamma}{\rho_{OS} k_B T}\right)^{-1}$$

when b is an average Kuhn statistical length. For the present case, the lengths (11) are $b_A = 6.8$ Å and $b_B = 7.1$ Å.

The third and fourth contributions are due to the reduction in entropy when fractions of each component are restricted to the different regions, including the localization of the copolymer joints to the interface. The stretching of the copolymer blocks is incorporated via the Flory expression for the elastic energy and depends on the relative extension of each block α_A and α_B, defined by $\alpha_K = (3/Z_{CK})^{1/2}\, l_K/b_K$ in each case. Finally, the small term which is due to the translational entropy of the micelles constitutes the sixth contribution to Δg.

The model as described provides theoretical values for the micelle parameters. For direct comparison with the experimental results, the radius of gyration of the micelles was calculated (2).

$$[7] \quad R_M{}^2 = \frac{3}{5} \frac{a_A(l_M{}^5 - l_B{}^5)/(l_M{}^3 - l_B{}^3) + a_B(f_B/f_A)\, l_B{}^2}{a_A + (f_B/f_A) a_B}$$

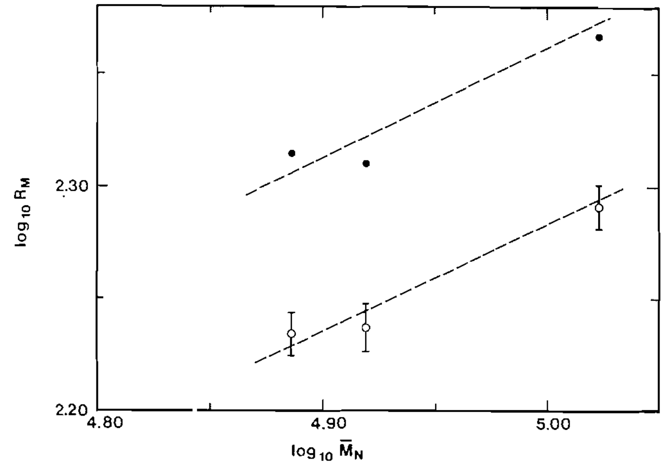

FIG. 3. Micelle radii of gyration as a function of $\bar{M}_N$ for the copolymers studied. The upper points are the theoretical values, and the lower ones are the experimental. As argued in the text, due to the different compositions of the blocks the two sets of points are not expected to lie on straight lines. However calculating the slopes of the straight lines as shown gives an overall power law of $R_M \propto \bar{M}_N{}^{0.44}$ both theoretically and experimentally.

where $l_M = l_A + l_B$, and a_A and a_B represent the density of "excess" electrons of polybutadiene and polystyrene, respectively.

These theoretical values of R_M are included in Table 1. The first point to note is the reasonable overall agreement with the measurements being consistently about 20% larger. (Recall that there are no fitted parameters.) Second, the overall general increase in R_M with molecular weight is in agreement. Finally, note that for the second sample, R_M is predicted to be slightly *less* than for the first, even though the molecular weight is somewhat *greater*. This, in fact, is not inconsistent with the measurements; a decrease of this small magnitude is well within the estimated error.

This last observation further illustrates a point emphasized in ref. 8, namely, that even the total micelle radius (or R_M) is determined by the degree of polymerization of each block of the copolymer, Z_{CA} and Z_{CB}, not just the total d.p. Z_C; it is clear from Table 1 that Z_C and the total molecular weight are larger for sample 2 than for sample 1.

Although the experimental uncertainty precludes verification of the prediction of a slightly smaller R_M for sample SB(12-71) as compared with SB(22-55), we can quantify the comparison of the theory and experiment by least-squares fitting a straight line to the two sets of points. Based on the above argument, we *expect* that the points should not lie on a straight line, but this procedure does act as a test of the model. The result is illustrated in Fig. 3; remarkably (and no doubt fortuitously), both theory and experiment give an average overall dependence of $R_M \propto \bar{M}_N{}^{0.44}$. This agreement implies the model predicts well the scaling of the entire micelle size. Furthermore, Whitmore and Noolandi found good agreement for the scaling of the core of the micelles (in homopolymer). We are thus lead to have considerable confidence in the scaling laws predicted by this model.

Based on this evidence, we can extract from the model some additional features. Table 1 lists the theoretical values for the radii (or thicknesses), stretching parameters and copolymer volume fractions in each region of the micelles, and the widths of the interfacial regions, d. Due to the somewhat large values of R_M obtained theoretically one or both of l_B and l_A is presumably overestimated, with corresponding effects on α_B and α_A. The small values of $\varphi_{CA}^{(2)}$ are largely due to geometry; even if the A blocks were unstretched, for the values of l_B found we would have $\varphi_{CA}^{(2)} \simeq 0.3$. We point out that the copolymer volume fraction remaining in solution is always very small, $\varphi_C^{(3)} < 10^{-10}$.

Next, we examine the scaling of l_B and l_A. Over the range of Z_{CB} and Z_{CA} used in these measurements, we find (theoretically),

[8*a*] $l_B \propto Z_{CB}^{0.67} Z_{CA}^{-0.01}$

[8*b*] $l_A \propto Z_{CA}^{0.54} Z_{CB}^{0.12}$

The picture that emerges is thus very similar to that found when a homopolymer was present in place of the solvent. The dominant behaviour is that the core radius scales with Z_{CB}, with a power very close to 2/3, and the corona thickness with Z_{CA} with a power somewhat larger than 1/2. These two scaling laws are perfectly consistent with a decrease in R_M with increasing $\bar{M}_N$ or Z_C, if the composition also changes. As well, they are certainly consistent with the average scaling $R_M \propto \bar{M}_N^{0.44}$, since the composition changes over the range.

It is also interesting to compare the A block stretching found here with the case of the AB copolymer in the A type homopolymer. In that case, there is no increase in interaction energy when the homopolymer penetrates the corona, leading to more stretching and hence a larger α_A than found in the present case.

One of these copolymers, SB(22-55), has been investigated using a new technique involving degradation of the polybutadiene matrix surrounding the polystyrene core (14). The degradation is achieved using ozone produced by an ozone generator. Thin copolymer films were first cast from octane solution, producing spherical structures, placed on stainless electron microscope grids, and then exposed to ozone. The result was polystyrene cores, separated completely from any matrix materials, which could then be shadowed with Pt—C and observed in the transmission electron microscope. The resulting micrographs obtained from SB(22-55) so treated revealed polystyrene cores with radii of approximately 115 Å in excellent agreement with the predicted values of l_B in Table 1. However, it should be pointed out that values of l_B from electron micrographs of stained copolymer films were found in the same study to range from 130 to 200 Å.

Conclusion

We have measured the radius of gyration of polystyrene/polybutadiene block copolymer micelles in *n*-heptane, and found an *average* power law dependence $R_M \propto \bar{M}_N^{0.44}$. We have modelled the system theoretically, and found the same power law dependence. However, it is argued that the composition of the blocks is also important, and that we should *not* expect all data points to obey this relationship because of their varying composition, a conclusion which is consistent with the measurements. Theoretically, we find the scaling of the core radius and corona thickness to be approximately $Z_{CB}^{2/3}$ and $Z_{CA}^{1/2}$, respectively, and that these relations are consistent with the average dependence of R_M on $\bar{M}_N$ found experimentally.

L. H. GARCIA-RUBIO and N. RO. Can. J. Chem. **63**, 253 (1985).

A method is demonstrated for the interpretation of the ultraviolet spectra of styrene-containing copolymers. This method is based on the use of model molecules to approximate the absorption behaviour of the known chromophores and on the statistical estimation of the average spectra of the unknown chromophores. The analysis yields directly the copolymer composition and an estimate of the background spectra which arise from the different arrangements of the styril units along the polymer chains. It is shown that reliable composition estimates are obtained for styrene – methyl methacrylate and styrene–acrylonitrile copolymers. The results from the interpretation of the spectra are discussed and compared with results obtained from the statistical copolymerization models.

On présente une méthode permettant d'interpréter les spectres ultraviolets de copolymères contenant du styrène. Cette méthode est basée sur l'utilisation de molécules modèles qui permettent de déterminer approximativement le comportement, vis-à-vis de l'absorption, de chromophores connus ainsi que sur l'évaluation statistique du spectre moyen de chromophores inconnus. L'analyse permet d'obtenir directement la composition du copolymère et d'évaluer les spectres de fond qui découlent des différents arrangements des unités styriles le long des chaînes de polymères. On démontre que, pour les copolymères styrène/méthacrylate de méthyle et styrène/acrylonitrile, on obtient des évaluations fiables de la compositions. On discute des résultats obtenus par l'interprétation des spectres et on les compare avec les résultats obtenus à partir de modèles statistiques de la copolymérisation.

[Traduit par le journal]

Introduction

The application of ultraviolet spectroscopy to the analysis of styrene-containing copolymers has been extensively reported in the literature (1–13). Band shifts, solvent effects, and hypochromic effects have been observed as functions of the copolymer composition and the microstructure of the polymer chains (2–8). The band shifts, solvent effects, and other anomalies observed in the absorption behaviour of polymers have precluded the development of analytical techniques which can yield composition estimates directly from the uv spectra (4). Existing techniques have to resort to assumptions regarding the copolymerization kinetics or to independent measurements of the copolymer microstructure (8–11). In this paper, a method is demonstrated which yields directly both the copolymer composition and an estimate of the background spectra which arise from the different arrangements of the styril units along the polymer chains. The method proposed is based on the use of model molecules to approximate the absorption patterns of the known chromophores and on the statistical estimation of the average spectra of the unknown chromophores. The technique reported is shown to give reliable estimates of the copolymer composition for styrene – methyl methacrylate and styrene–acrylonitrile copolymers. The preliminary assignment of absorption patterns is discussed and compared with previous literature reports and with the results of statistical copolymerization models.

Literature review

Studies on the absorption behaviour of styrene-containing copolymers have shown significant deviations from Beer's Law and from the assumption of additivity of the absorption of the individual components. These deviations have been attributed to the microstructure of the polymer chains (3, 4, 8, 10, 11) and in some cases to the conformation of the molecules in solution (2, 6, 9). Vala and Rice (2) observed that the extinction coefficient of isotactic polystyrene at certain wavelengths is smaller than the corresponding extinction coefficients for atactic polystyrene. This reduction in extinction coefficient (hypochromism) was attributed to the anisotropic effect of the phenyl rings. A similar hypochromic effect on the steric isomerism has been observed in the case of polymethyl methacrylate (14) and poly(2-methylbutyl methacrylate) (15). Hypochromic effects on styrene copolymers were first reported by O'Driscoll *et al.* (3) from observations made in the analysis of styrene – methyl methacrylate copolymers (SMMA). These authors suggested that the differences in the extinction coefficients were due to differences in the length of the styrene sequences present in the polymer chains. Brussau and Stein (4) investigated the effect of the sequence length of the uv absorption of styrene–butadiene (SB), styrene – maleic anhydride (SMA), and styrene–acrylonitrile (SAN) copolymers at several wavelengths in chloroform and THF. They also concluded that the response of the uv detector appears to be a function of the length of the styrene sequences. Stutzel *et al.* (8) investigated SMMA copolymers in THF and dioxane solutions. From their analysis using styrene dimers they concluded that the hypochromic effects are probably not due to differences in conformation. Rather, they suggested that hypochromic effects arise from the sequential arrangement of the monomer units in the chain, in agreement with O'Driscoll's and Brussau's conclusions.

More recently, the assumption that the extinction coefficient is correlated with the sequence length has been used by Gruber and Knell (10) in the analysis of styrene – butyl acrylate and styrene – *n*-butyl methacrylate copolymers and by Garcia-Rubio *et al.* (11) for the development of the GPC (gel permeation chromatography) technique for the analysis of SAN

copolymers.

Russo and co-workers (6, 7)[3] concluded, from studies on the hypochromism of SMMA copolymers in ester solutions, that the hypochromism in SMMA copolymers seems to be produced by inter- and intramolecular interactions between carbonyl groups and the phenyl rings and, therefore, it is governed by the number (sequence length) and intensity (solvent dielectric constant) of such interactions. These authors experimentally demonstrated that the hypochromism in SMMA copolymers can be effectively eliminated at 269.2 nm by using ester-type solvents. Recent studies (12, 13) on the estimation of copolymer extinction coefficients have also shown that, within the limits of experimental error, Beer's Law and the assumption of additivity of chromophores appear to be valid for a variety of styrene homopolymers and copolymers. This suggests that the hypochromic effects and the deviations from Beer's Law are due to unidentified chromophores present in the polymer molecules. The general concensus, however, favours the hypothesis that recognizes the length of the styrene sequences as the most important factor in explaining the observed deviations from Beer's Law. This implies that uv spectrophotometers cannot be used as concentration detectors for copolymer analysis without prior calibrations, which include the necessary corrections for the copolymer microstructure (4, 8, 11) or, alternatively, that a suitable solvent system should be found for each copolymer system, which will minimize the microstructure effects on the absorption behavior of the polymer. Either approach is unsatisfactory for chromatography experiments, where it would be desirable to interpret the detector responses directly, without having to make assumptions regarding the microstructure of the copolymer or without having to collect fractions for further analysis. Therefore, there is incentive for the development of the necessary methodology for the interpretation of the uv spectra.

Method of analysis

The estimation of copolymer compositions from uv spectroscopy data can be divided into several aspects: 1. the identification and quantification of chromophores embedded along the polymer chains that may have different absorption patterns, depending on their local environment and position in the chain; 2. the selection of model molecules which can adequately represent at least some of the chromophores present; 3. the statistical estimation of the polymer compositions and an average representation of the unidentified chromophores.

Based on the recent reports which suggest that: (a) Beer's Law is valid for chromophores present in the polymer molecules (12) and (b) that model compounds can be used to represent equivalent chromophores attached to the polymer molecules (13), the first problem can be postulated as a statistical identification process, where the objective is to obtain an accurate representation of the spectra of all the species present in the polymer molecules. The simplest criterion for the identification is to select those model molecules that best predict the spectra of the unknown mixture of chromophores, i.e. to eliminate statistically those components that, within the limits of the experimental error, cannot reduce the residual sum of squares between the measured and the calculated spectra. The calculated spectra are obtained from Beer's Law applied to all the concentrations over all the measured wavelengths, i.e.:

[3]M. Nencioni and S. Russo. Private communication.

$$[1] \quad A_j = \sum_{n=1}^{N} \epsilon_{nj} p_n C l$$

The objective function for the minimization process is given by:

$$[2] \quad \text{Min: } \sum_i \sum_j \frac{\phi^2_{ij}}{\sigma^2_{ij}}$$

where

$$\phi_{ij} = A_{ij} - \sum_n^N \epsilon_{nj} p_n C_i l$$

$$\sigma^2_{ij} = \text{var}\,(A_{ij}) + \sum_n^N [l C_i p_n]^2 \text{ var}\,(\epsilon_{n,j}) + \left[l \sum_n^N p_n \epsilon_{nj}\right]^2 \text{var } C_i$$

Alternatively, the differences between the measured (ϵ_j^{o}) and calculated extinction coefficients can also be used in the objective function. For this case, eq. [2] becomes:

$$[3] \quad \text{Min: } \sum_j^{\lambda} \left[\left(\epsilon_j^{\text{o}} - \sum_n^N \epsilon_{nj} p_n\right)^2 \Big/ \text{var}\,(\epsilon_j^{\text{o}}) + \sum_n^N p_n^2 \text{ var}\,(\epsilon_{nj})\right]$$

where the variances of the extinction coefficients are estimated from the absorption measurements. The solution of the nonlinear equations [2] or [3] for the identified number of components yields the composition estimates, as shown for the initiator fragments present in polystyrene molecules (13).

In the case of copolymers and other complex polymers, the spectra (ϵ_{nj}) which correspond to some of the species present can be obtained directly from the homopolymers of the monomers used to synthesize the polymer. If there are no effects on the absorption behaviour due to inter- and intramolecular interactions between the functionalities present in the solvent and in the polymer molecule, the direct application of [2] or [3] together with the spectra of the homopolymers and the initiator fragments should yield the copolymer composition estimates. However, if interactions are present, as in the case of styrene copolymerized with polar comonomers (4), the spectra of the chromophores present may be altered in an, as yet unknown, fashion. In order to aid the identification of the effects due to interactions, it is desirable to estimate the spectrum of the distorted or the unknown species. For this purpose the following assumptions are made.

(a) The distorted spectra of chromophores which result from interactions with the comonomer or with the solvent are considered to be separate species obeying Beer's Law.

(b) The spectra of the identified species are assumed to be independent of both the microstructure and the copolymer composition.

Given these two assumptions, it follows that if $N - 1$ species have been identified, or are known to be present in the polymer, it is possible, by applying simultaneously eqs. [2] or [3] to K different polymer samples, to obtain estimates of the composition for the K samples and the extinction coefficients for the Nth species (i.e. ϵ_{nj}: $j = 1, \ldots, \lambda$).

In other words, it is possible to obtain the composition estimates and an estimate of the extinction coefficient for the Nth component conditional upon the identification of $N - 1$ components, and the availability of K different polymer samples.

*The standard error for the nmr measurements is 1.75% (refs. 17, 18 and 26).
†The standard error for the gc measurements is 1.0% (ref. 18).

The total number of parameters to be estimated in this case is given by:

$$[4] \quad N_p = \lambda + KN$$

The total number of observations available from K samples measured at I concentrations and λ wavelengths is given by:

$$[5] \quad N_{ob} = \lambda KI$$

If eq. [3] is applied, then the number of observations becomes:

$$[6] \quad N_{ob} = \lambda K$$

A necessary condition for the estimation of N_p parameters is:

$$[7] \quad N_p \leq N_{ob}$$

It follows from eq. [7] that:

$$[8] \quad K > \frac{\lambda}{\lambda - N}$$

Therefore, if $\lambda \gg N$, a minimum of two samples should suffice to estimate the N_p parameters. The solution to the nonlinear eq. [2] or [3] for N_p parameters can be accomplished using any of the nonlinear least-squares estimation techniques (16). From the estimated background, the appropriate model molecule may be selected, or alternatively the estimated absorption pattern may be used directly for the estimation of composition in other samples.

Experimental

Materials

The model molecules butylbenzene, *tert*-butylbenzene, and ethyl benzoate were purchased from Eastman Kodak and Aldrich Chemicals respectively. The solvent, spectral grade tetrahydrofuran, was obtained from Burdick and Jackson Laboratories. The polymer samples were synthesized via free radical polymerization using benzoyl peroxide and 2,2′-azobisisobutyronitrile as initiators in the temperature range of 40 to 60°C (17, 18). Table 1 lists the properties of the materials investigated.

Measurements

The uv spectra for the polymers and model compounds in THF were determined in a H.P. Diode array 8450 uv/vis spectrophotometer at room temperature with a 1-cm path length cell. Up to seven concentrations plus replicates were used to obtain good estimates of the extinction coefficients as well as the measurement errors. Special care was taken to ensure that the measurements were always within the linear range of the instrument. The raw absorption data were transferred to a Data General S-230 Eclipse computer for further processing. The linear behaviour of the absorption with respect to concentration was statistically verified for all the substances used. Estimation of the extinction coefficients was done on a weight basis to minimize propagation of the experimental error (13).

Analysis of all the polymer samples was restricted to the spectral region between 250–300 nm. This was done to reduce the dimensionality of the statistical estimation problem when using eq. [2] or [3].

Results and discussion

Ultraviolet spectra of polystyrene and model compounds

Comparison of the absorption spectra of polystyrene with two similar chromophores, butylbenzene and its stereoisomer, *tert*-butylbenzene (Figs. 1 and 2), indicates the importance of steric effects in modifying the absorption pattern of a single chromophore. It seems that the ability of the phenyl rings, or the molecules containing them, to align themselves in the presence of the uv light has a definite effect on both the absorption pattern and the magnitude of the extinction coefficient. The fact that the absorption behavior of butylbenzene and polystyrene is very similar in form and intensity suggests that the phenyl groups in the polystyrene molecules are arranged in an oderly structure that maximizes the interaction between the phenyl rings. As the steric hindrance for such an arrangement increases (*tert*-butylbenzene), the absorption pattern changes and the absorption intensity decreases (Fig. 2). A similar observation has been made by Stutzel and Miyamoto from their studies on *meso*- and *d,l*-2,4-diphenylpentanes and isotactic and syndiotactic rich polystyrenes (8). These authors also show that the

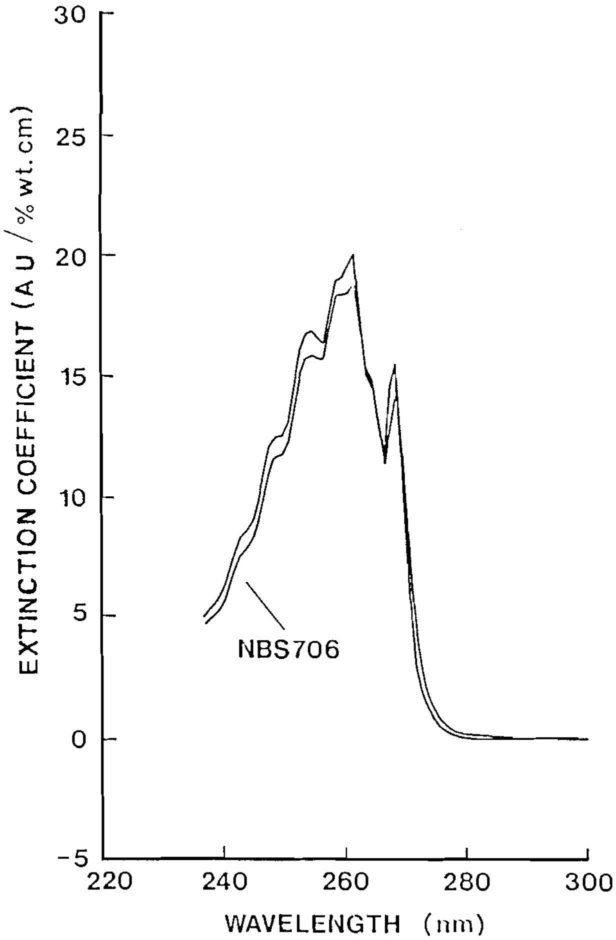

FIG. 1. Absorption spectra of butylbenzene and the National Bureau of Standards polystyrene NBS706.

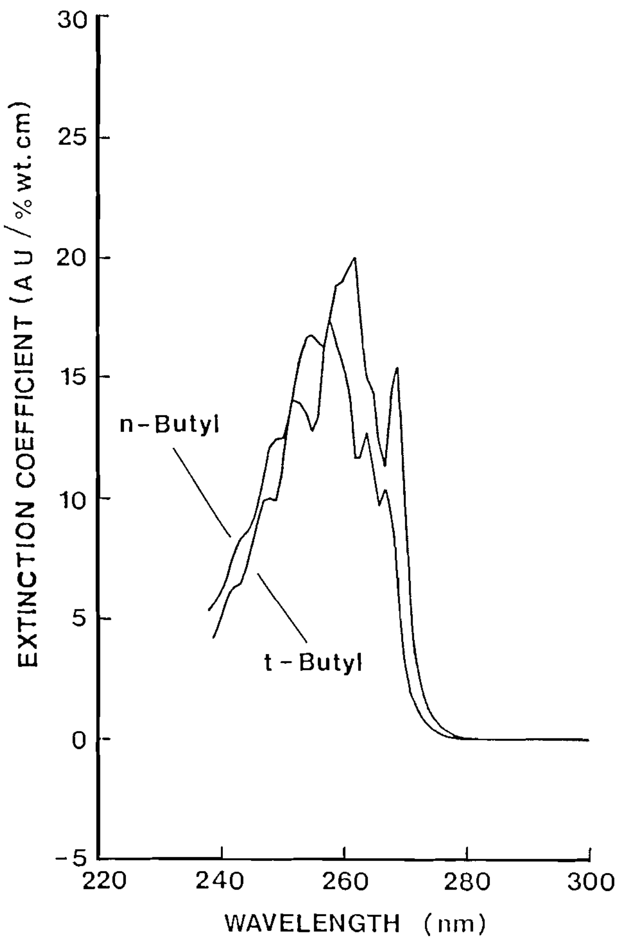

FIG. 2. Comparison of the absorption spectra of butylbenzene and *tert*-butylbenzene.

spectra of the polystyrenes and of the isomers decrease in intensity with increasing temperatures and converge to a shape similar to the *tert*-butyl benzene absorption pattern. The conclusion from the above observations is that the mutual position in space of adjacent phenyl rings seems to control the extinction coefficient as well as the shape and the form of the absorption spectrum. Therefore, depending on the chemical and steric nature of the comonomer, an absorption pattern intermediate between polystyrene and *tert*-butyl benzene could be expected as a result of the statistical estimation process.

Analysis of styrene – methyl methacrylate copolymers

The analysis of the SMMA copolymers shown in Table 1 was conducted in two stages. In the first stage the least-squares solution of eq. [3], using the data from samples SMMA01 to SMMA06 (Fig. 3) and the model molecules of polystyrene, *tert*-butylbenzene, and ethyl benzoate, gave the corresponding copolymer compositions (Table 2) and an average spectrum of the unidentified background (Fig. 4). Using the estimated background and the same model molecules, the analysis of the remaining samples (i.e. SMMA07-10) was done applying eq. [3] directly to each sample.

The estimation of the background was done conditional upon the following assumptions.

(a) The spectrum of polystyrene adequately represents some of the styril units present in polystyrene sequences, particularly those present in long styrene sequences.

(b) The spectrum of *tert*-butylbenzene can be used as a good approximation of the styril units that are either isolated or sterically hindered. This assumption was made based on the similarity between the spectrum of *tert*-butylbenzene and the spectra of high methyl methacrylate SMMA copolymers (compare Figs. 2 and 3).

(c) The spectrum of ethyl benzoate was used to approximate the benzoate groups resulting from the decomposition of benzoyl peroxide (13).

The initial guesses for the simultaneous solution of eq. [3] in the first stage (samples 01–06) were obtained directly from the same equation applied to each individual polymer using only three components: polystyrene, *tert*-butylbenzene, and ethyl benzoate. (Methyl methacrylate has negligible absorption in the wavelength region of interest, 230–300 nm.) Subsequently, several combinations of initial guesses were used to ensure that a global minimum, and therefore the solution to eq. [3], had been found. The estimated absorption pattern for the unknown chromophores is shown in Fig. 4. The compositions for samples 07–10 were obtained using the previously estimated absorption pattern (S_3) and the spectra of polystyrene NBS706 (S_1), *tert*-butyl benzene (S_2), and ethyl benzoate. The copolymer compositions obtained are reported in Table 2. Very good agreement between the measured and the calculated spectra was obtained in every case, as shown in Figs. 5 and 6. Comparison of the columns labelled total styrene and nmr in Table 2 indicates that the estimates of the styrene content by uv spectroscopy are within the limits of the experimental error for nmr measurements. The standard error for the

*Standard error for the uv measurements is 0.4% on a weight basis. Standard error for the nmr measurements is 1.75% on a weight basis.

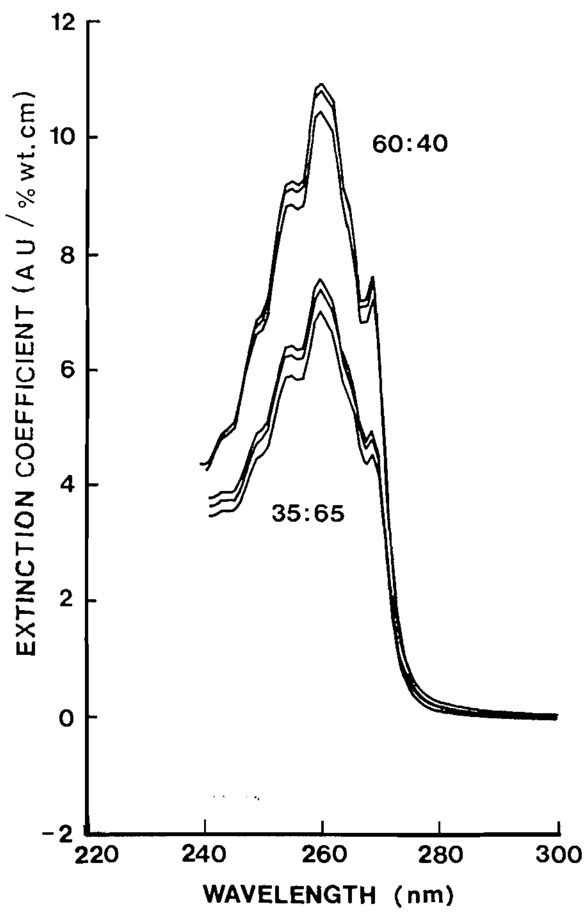

FIG. 3. Absorption spectra of styrene – methyl methacrylate copolymers. Feed compositions as indicated (styrene/methyl methacrylate).

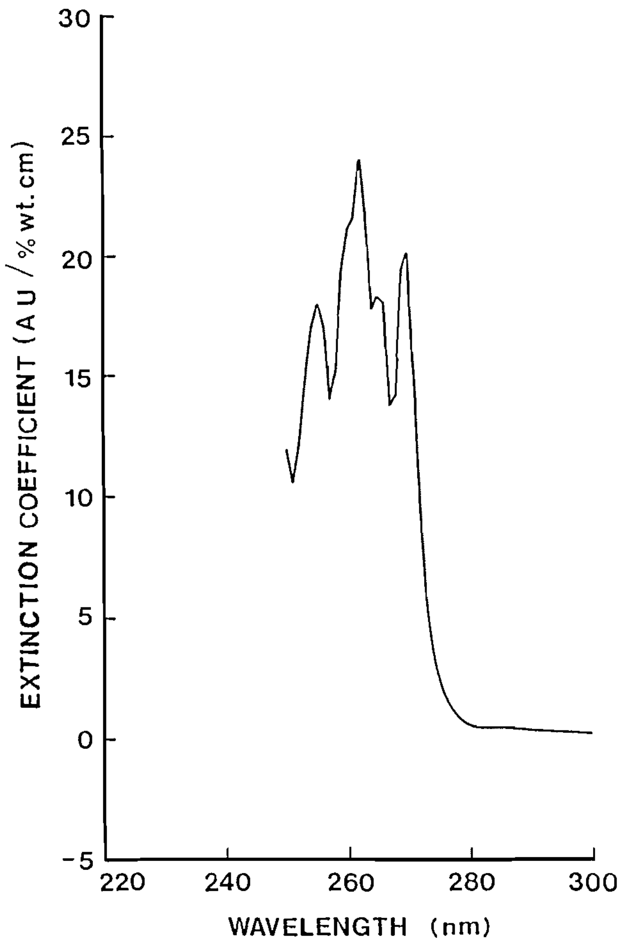

FIG. 4. Estimated background spectra for styrene – methyl methacrylate copolymers (S_3).

styrene content obtained from the pooled variance of replicate uv measurements is ±0.4 on a wt.% basis, whereas for the nmr the standard error was estimated at ±1.75 on the same basis. (Note that the standard error for the nmr measurements is in good agreement with previously reported values (19, 26)). Clearly, the approach suggested here can yield reliable quantitative information on the styrene content for SMMA copolymers.

Interpretation of the results for styrene – methyl methacrylate copolymers

As a first step in the interpretation of the results, the reactivity ratios from the composition data shown in Table 1 were estimated using the "Error in variables" models applied to the integrated form of the Mayo and Lewis equation (18, 20). The values obtained, r_1 = 0.4971, r_2 = 0.4639, were used to compute the concentration of monads, diads, triads, etc., from

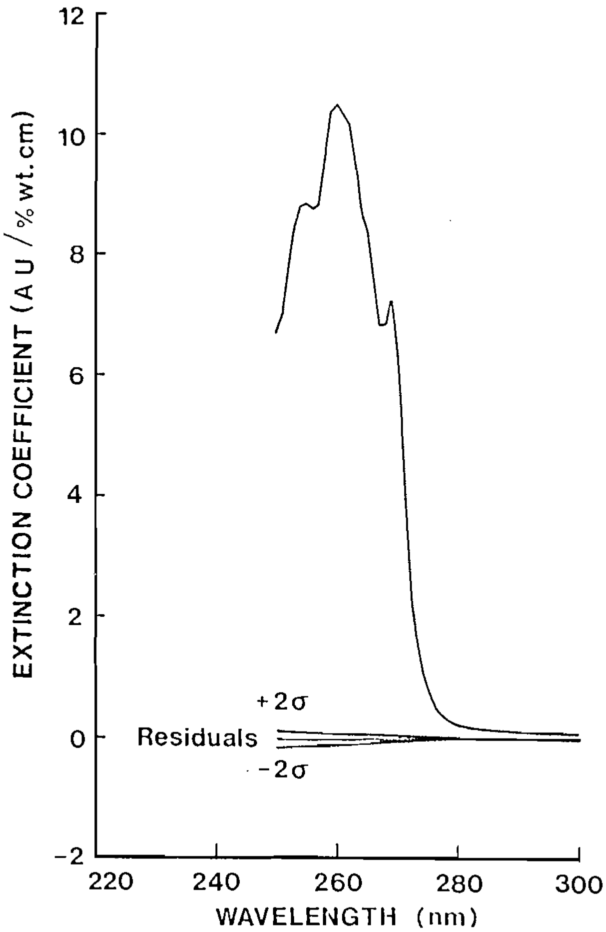

FIG. 5. Comparison between measured and calculated spectra for sample SMMA04. The residuals from the estimation and the 95% confidence interval on the measurements are indicated.

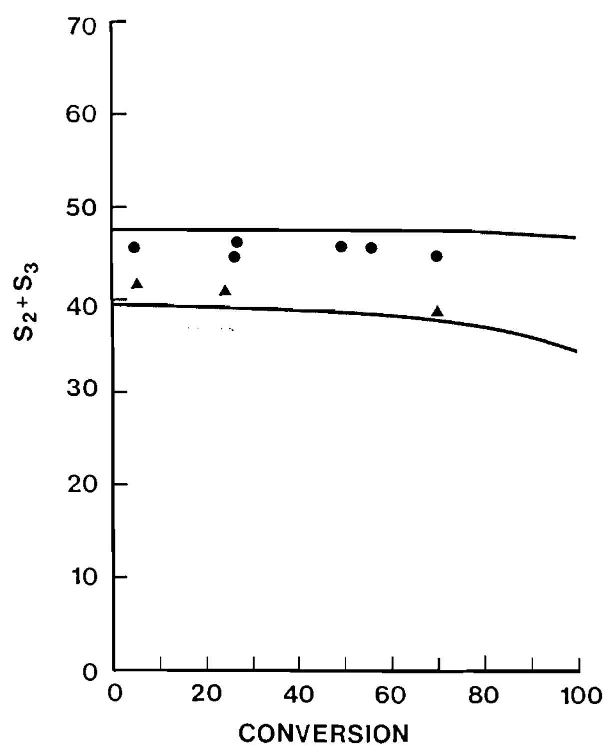

FIG. 6. Comparison between the measured and the calculated spectra for sample SMMA02.

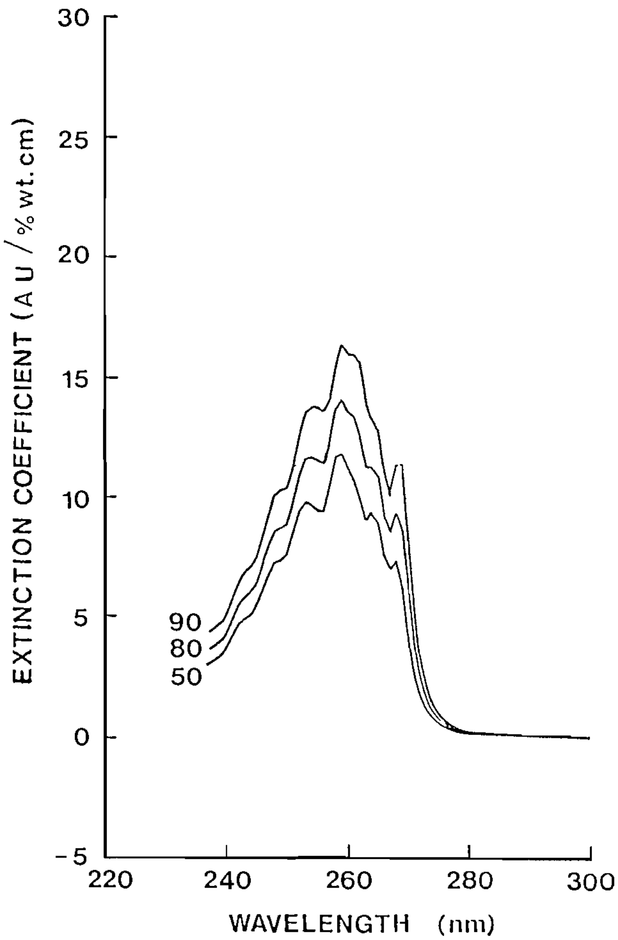

FIG. 7. Weight fraction of styrene contained in styrene − methyl methacrylate links as function of the weight conversion. Feed composition: (○) 60:40, (△) 35:65 styrene/methyl methacrylate. Solid lines, calculated values with $r_1 = 0.4971$ and $r_2 = 0.4639$.

the standard probability equations integrated as functions of conversion (18). The calculated concentrations were then compared with those obtained from the uv analysis: the results reported by Stutzel and Miyamoto (8) suggested good agreement between the calculated styrene centered triads (MSM, MSS, and SSS) and the uv measured concentrations. This, however, was not the case. Concentration differences beyond the limits of the experimental error were observed in all cases. Closer inspection of the estimated background spectrum (Fig. 4) indicates a red shift in the peaks at approximatley 267 and 272 nm relative to polystyrene's 264 and 269 nm. Since these red shifts are normally associated with solvent or substituent effects (21), we assume that the estimated background arises from styril units close to the carbonyl moiety of the methyl methacrylate units. That is, the estimated spectrum (Fig. 4) arises from coisotactic styrene − methyl methacrylate linkages. If it is further assumed that the species represented by *tert*-butylbenzene correspond to cosyndiotactic placements, then the sum of these two species (columns S_2 and S_3 in Table 2) represents the total concentration of styrene in styrene − methyl methacrylate diads, and the ratio $\sigma_{AB} = S_3/(S_2 + S_3)$ represents the fraction of the Sty−MMA diads which are coisotactic.

The mass fraction of styrene contained in Sty−MMA and MMA−Sty diads can be readily calculated from the standard

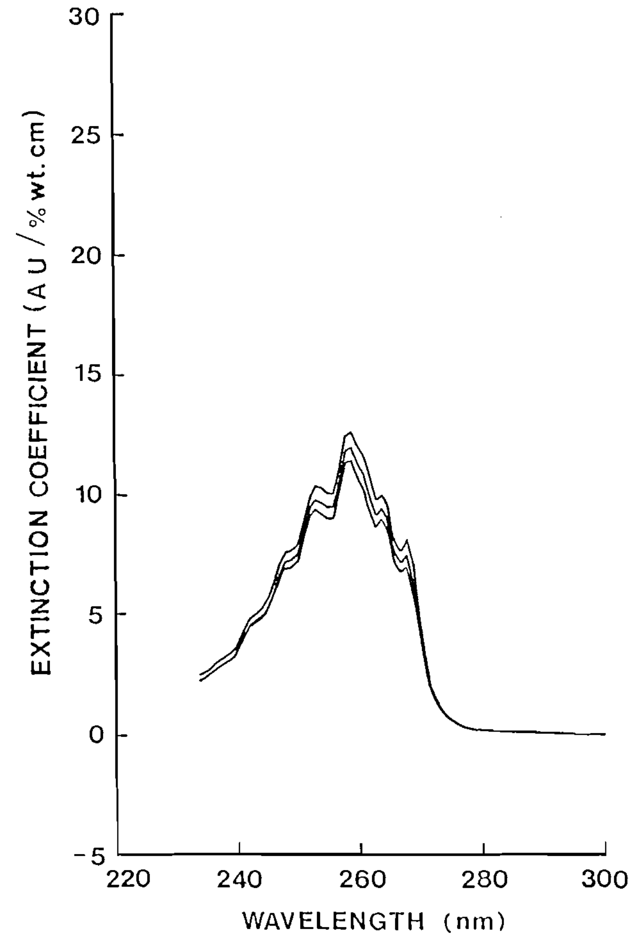

FIG. 8. Absorption spectra of bulk polymerization styrene–acrylonitrile copolymers. Feed composition as indicated in mol% styrene.

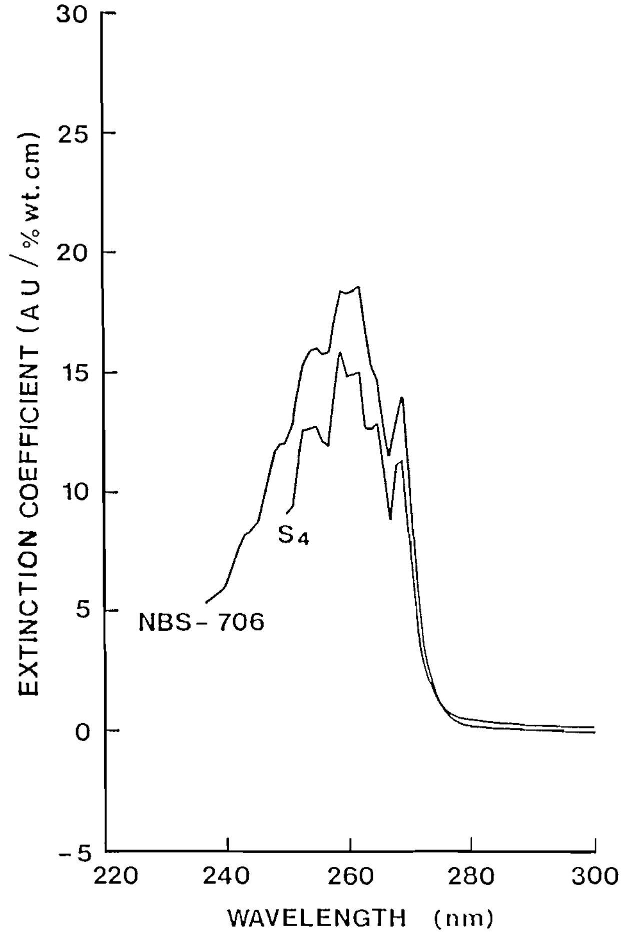

FIG. 9. Absorption spectra of commercial samples of styrene–acrylonitrile copolymers.

probability approach (22):

$$[9] \quad A_{AB} = \frac{1 - Paa^2}{1 + \dfrac{Pab}{Pba}}$$

where:

$$Pab = \frac{f_A}{r_b f_B + f_A}; \quad Paa = 1 - Pba$$

$$Pba = \frac{f_A}{r_B f_B + f_A}; \quad Pbb = 1 - Pba$$

Equation [9] can be numerically integrated along the conversion trajectory to give the cumulative concentration of styrene contained in Sty–MMA links:

$$[10] \quad A_{AB}(X) = \frac{1}{X}\int_0^X A_{AB}(X')\,dX'$$

Figure 7 shows the comparison between the measured fractions ($S_2 + S_3$) and the values calculated from eq. [10]. The agreement is satisfactory considering that only the total styrene content was used for the estimation of the reactivity ratios (20).

There is also very good agreement between the values for the coisotacticity parameter calculated from the uv measurements (Table 2) and the literature value of $\sigma_{AB} = 0.47 \pm 0.02$ (23–25) obtained from the ^{1}H nmr analysis of the methoxy resonance bands. This agreement supports the assignment of the S_2 to the cosyndiotactic Sty–MMA placements and S_3 to the coisotactic diads. Note that since the Sequence Length Distribution is proportional to the number of Sty–MMA diads, these assignments also explain previously reported correlations between the moments of the Sequence Length Distribution and the hypochromic effects (3, 8, 10, 11).

Analysis of styrene–acrylonitrile copolymers

The analysis of styrene–acrylonitrile (SAN) copolymers was, as in the case of SMMA copolymers, divided into two stages.

(a) The background spectrum and the compositions were estimated simultaneously for samples SAN90, SAN80, and SAN50 (Fig. 8) for which the conversion and composition were known (18).

(b) Using the estimated spectrum (Fig. 10), the compositions for the commercially available copolymers SAN 01–03 (Fig. 9) were obtained directly from the application of eq. [3] to each individual sample.

The assumptions made in the analysis were the same ones previously made for SMMA copolymers. That is, species S_1 and S_2, approximated by the spectrum of NBS-706 polystyrene and *tert*-butylbenzene respectively, are also present in SAN copolymers. The compositions obtained from the optimization procedure are reported in Table 3. Figure 10 shows the estimated absorption pattern for the unidentified chromophores, and Figs. 11 and 12 show typical comparisons between mea-

sured and calculated spectra for samples SAN90 and SAN02 (the highest and the lowest in styrene content). Clearly, the total styrene content measured by uv spectroscopy is in good agreement with the values reported from other measurement techniques (see Tables 1 and 3). In addition, there is very good agreement, within the limits of the experimental error, between the measured and the calculated uv spectra. This indicates that the estimated spectrum constitutes a good average representation of the unidentified chromophores.

Interpretation of the results for SAN copolymers

Close inspection of the estimated background spectrum (Fig. 10) shows that it has common features with the spectrum of isotactic polystyrene (8). This suggests that the presence of the acrylonitrile units may induce tacticity in the styrene sequences, or, as in the case of Sty–MMA copolymers, the observed absorption pattern may arise from coisotactic styrene/acrylonitrile diads. In order to assign the envelopes S_1, S_2, and S_4, the analysis done for SMMA copolymers with eqs. [9] and [10] was repeated. The reactivity ratios used were those for bulk styrene – acrylonitrile polymerizations (18) (i.e., $r_A = 0.37$ and $r_B = 0.0664$). As in the case of SMMA, no correspondence between a specific sequence length fraction and the uv-measured compositions could be obtained. A significant difference between the measured and calculated concentration of styrene in styrene–acrylonitrile diads was also observed (see Table 3 under Terminal). Therefore the esti-

TABLE 4. Microstructure parameters for SAN copolymers

Sample	Terminal model				Penultimate model			
	P_{IW} calc.	A_{ABw}	σ_{AB}	σ_{AA}	P_{IW} calc.	A_{ABw}	σ_{AB}	σ_{AA}
SAN90	94.29	20.99	0.336	0.275	94.3	20.0	0.303	0.284
SAN80	85.08	53.26	0.515	0.444	85.03	51.25	0.479	0.397
SAN50	71.60	66.38	0.435	0.493	72.04	61.71	0.412	0.707

mated background cannot be attributed to coisotactic styrene–acrylonitrile diads if the copolymerization kinetics follow the terminal copolymerization model. Recent ^{13}C nmr studies on the mechanism of styrene–acrylonitrile copolymerization suggest that the molecular microstructure is better described by the Penultimate copolymerization model (22). Using this model, the total concentration of styrene in styrene–acrylonitrile diads is given by:

$$[11] \quad A_{AB} = \frac{1 + Pbaa}{\dfrac{Pbaa}{Paab} + 2 + \dfrac{Pabb}{Pbba}}$$

where:

$$Paab = \frac{f_B}{r_A f_A + f_B}; \quad Pbba = \frac{f_B}{r_B f_B + f_A}$$

$$Pbaa = \frac{r'_A f_A}{r'_A f_A + f_B}; \quad Pabb = \frac{r'_B f_B}{r'_B f_B + f_A}$$

Replacing eq. [9] with eq. [11], the concentration of styrene groups which are next to a nitrile group can be evaluated as a function of conversion. The values obtained for samples SAN 90, 80, and 50 are reported in Table 3 under "Penultimate". The reactivity ratios were those recently reported by Hill *et al.* (26), $r_A = 0.229$, $r'_A = 0.634$, $r_B = 0.039$, and $r'_B = 0.091$. The predicted concentrations based on the penultimate model are also smaller than the uv measured values. This indicates that the observed concentrations cannot be completely explained by either the Terminal or the Penultimate copolymerization model. Therefore another explanation for the observed background must be found. Based on the similar spectral features of isotactic polystyrene and the estimated background, it can be assumed that the estimated spectrum is an average representation of the coisotactic styrene/acrylonitrile and styrene/styrene diads. Under this assumption it is possible to calculate both the coisotacticity parameter σ_{AB} and the styrene isotacticity parameter σ_{AA}:

$$[12] \quad \sigma_{AB} = 1 - \frac{S_2}{A_{ABw}}$$

$$[13] \quad \sigma_{AB} = 1 - \frac{S_2}{P_{IW} - A_{ABw}}$$

where P_{IW} is the total weight fraction of styrene in the copolymer, and A_{ABw} is the weight fraction of styrene in Sty–AN diads (eqs. [10] and [11]). The values for σ_{AB} and σ_{AA} calculated from the copolymerization equations and the uv measurements are reported in Table 4 for the Terminal and the Penultimate copolymerization models. Both the Terminal and the Penultimate copolymerization models predict that the concentration of the S_1 species should drop with the styrene content in the copolymer (or the corresponding feed compositions) to a value close to zero as the Number Average Sequence length

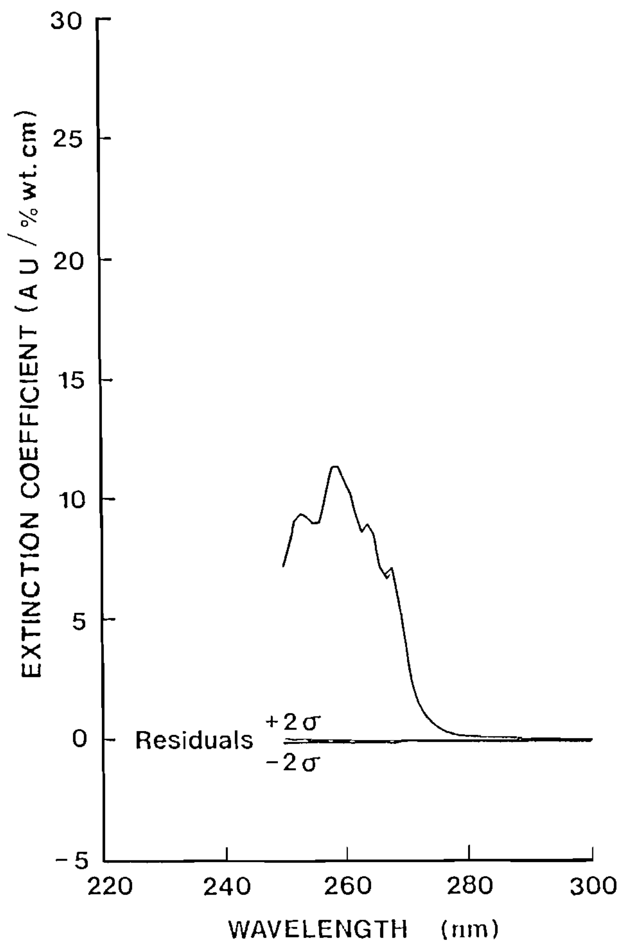

FIG. 12. Comparison between the measured and the calculated spectra of the commercial styrene–acrylonitrile sample SAN02.

approaches 1. Figure 13 shows that the variation of the species S_1, S_2, and S_4 is consistent with this assumption. Based on the above, the envelope S_4 can be tentatively assigned to the sum of the coisotactic Sty–AN and the isotactic Sty–Sty diads. The validity of the proposed assignments can be tested by demonstrating consistency between the uv concentrations and the corresponding assignments on the nmr spectrum of SAN copolymers. Work in this area is ongoing and it will be reported separately.

Summary and conclusions

A method has been proposed for the analysis of styrene-containing copolymers which yields the composition estimates directly from ultraviolet spectroscopy data. The compositions obtained from the uv measurements for styrene – methyl methacrylate and styrene–acrylonitrile copolymers have been com-

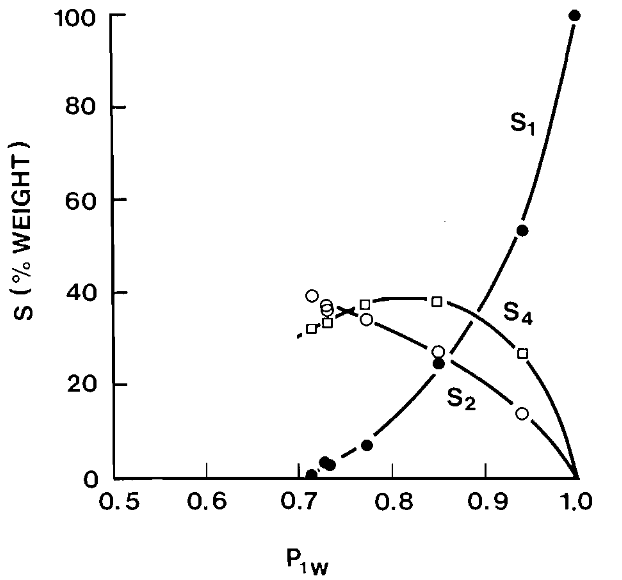

FIG. 13. Variation of the weight fraction of the styrene configurations S_1, S_2, and S_4 as function of styrene content in styrene–acrylonitrile copolymers.

pared with composition values determined with other measurement techniques. The agreement found was satisfactory within the limits of experimental error for the techniques involved. As a result of applying the proposed technique, an estimate of the spectrum of the unidentified chromophores is also obtained. This spectrum can be applied directly to the estimation of compositions in unknown samples and to the identification of the unknown structures giving rise to the measured spectrum. A tentative assignment of the estimated spectra has been made based on the well-known copolymerization models and published values of the coisotacticity parameter. In the case of SMMA, good agreement was found between the coisotacticity parameter estimates for uv spectroscopy and published ^{1}H nmr results. In the case of SAN copolymers there are no quantitative experimental data reported that allow the confirmation of the assignments. However, the concentrations of the species identified follow expected behaviour as a function of the copolymer composition.

The approach proposed here gives results which depend upon the model compounds selected to approximate the absorption of the known chromophores. The choice of the model molecules can, nevertheless, be verified by the consistency between the uv results and other measurement techniques such as ^{1}H and ^{13}C nmr. Once the model molecules and the residual spectra have been identified they can be used, routinely, for the analysis of unknown samples, as demonstrated in the analysis of the commercial SAN copolymers. The extension of this technique to GPC or SEC (size exclusion chromatography) experiments is therefore straightforward. It is clear that the uv spectra of polymers contain significant amounts of structural information which is yet to be explored. The use of the method demonstrated here in conjunction with other spectroscopy techniques appears to be a very promising tool for the elucidation of polymer microstructure and for the study of the conformation of molecules in solution.

The cationic polymerization of 1,3-dioxolane and 1,3-dioxepane has been investigated to prepare "living" polymers and then to use them for copolymerization. Carbenium hexafluoroantimonate salts that are good initiators for tetrahydrofuran polymerization have been tested but produce unsatisfactory results with these acetals. In contrast, triflic anhydride, another good initiator for tetrahydrofuran polymerization, allows molecular weight control. Attempts to prepare block copolymers of two acetals by adding the second one to the first one under living conditions were unsuccessful because of randomization through transacetalization. Block copolymers containing a central block of polydioxepane and outer blocks of 1,2-dimethoxyethylene could be prepared by addition of the latter to living polydioxepane. Active polydioxolane reacts readily with polystyrene and leads to the formation of graft copolymers in the absence of gel.

Nous avons étudié la polymérisation cationique d'acétals cycliques tels que le dioxolanne-1,3 et le dioxepanne-1,3 en vue de préparer des systèmes vivants et, partant de là, d'obtenir des copolymères. Les sels (hexafluoroantimoniates) de carbénium qui s'étaient avérés être de bons amorceurs pour la polymérisation du tétrahydrofuranne donnent des résultats décevants avec les acétals cycliques. Par contre l'emploi de l'anhydride de l'acide triflique, un autre bon amorceur de la polymérisation du tétrahydrofuranne, permet de contrôler la masse moléculaire des polyacétals formés. Nous avons tenté d'obtenir des copolymères séquencés de deux acétals cycliques en préparant d'abord un poly-acétal vivant avec l'un des monomères et en ajoutant ensuite le deuxième acétal cyclique. Cependant le copolymère obtenu présente une distribution statistique des deux monomères due aux réactions de transacétalisation. Par contre un copolymère triséquencé ayant une séquence centrale de polydioxepanne a pu être préparé en faisant réagir sur du polydioxepanne-α,ω vivant du diméthoxy-1,2 éthylène. Des copolymères greffés ont également été obtenus en faisant réagir du polydioxolanne, porteur d'un site actif par chaîne polymère, sur du polystyrène.

Introduction

Tetrahydrofuran (THF) has been known to polymerize through an oxonium active site which remains stable, provided that the counter anion is stable (e.g., SbF_6^-, PF_6^-, $CF_3SO_3^-$). We have shown that organic halides of various types, when reacted with a silver salt such as silver hexafluoroantimonate, induce by addition a fast, quantitative initiation of the THF polymerization. This is true for mono- and plurifunctional aliphatic and aromatic acyl halides as well as for allyl iodide, 2-iodopropane, chlorodiphenylmethane, etc. (1). We have also studied in detail the mechanism of initiation and shown that, for some other halides,initiation is slow either because of the slow formation of the initiating carbenium ions or because though the formation of the latter is fast, even quantitative (e.g. tertiobutyl iodide), they undergo immediate proton elimination; the protons formed are slow initiators and, besides, not suitable for our purpose because if the particular halide studied is carried by a polymer they lead to homopolymers instead of the desired copolymers.

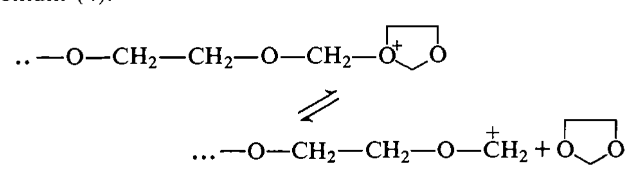
These findings obtained from model molecules have been applied in the preparation of block and graft copolymers: it has been shown that acyl halides carried by a backbone are very good initiators (2), just like the model acyl halide studied. But when the model molecules exhibit proton elimination it has been shown that the corresponding polymers exhibit proton elimination to an even greater extent, probably because of increased steric hindrance (3).

We have tried to use the same approach for the polymerization of cyclic acetals, which have some common character with a cyclic ether such as THF but still differ from it in many ways which we tried to utilize. First, in order to initiate the polymerization of these acetals, we used some carbocations that were successful in the case of THF; then we tried triflic anhydride. In a second series of experiments we made use of the results obtained to prepare block and graft copolymers.

Cyclic acetal homopolymerization

It has been shown that THF polymerization proceeds through a cyclic tertiary oxonium ion, but for dioxolane[2] the structure of the growing center has been proposed to exist under two different forms in equilibrium, namely, oxonium and alkoxy carbenium (4):

[1]



the equilibrium being shifted very strongly to the left so that propagation occurs mostly through oxonium-type ions. The dual nature of the active sites introduces a new feature as compared to THF, since one can expect active poly-DXL to be able to induce other reactions because of the higher electro-

1,3-Dioxolane (DXL) 1,3-Dioxepane (DXP)

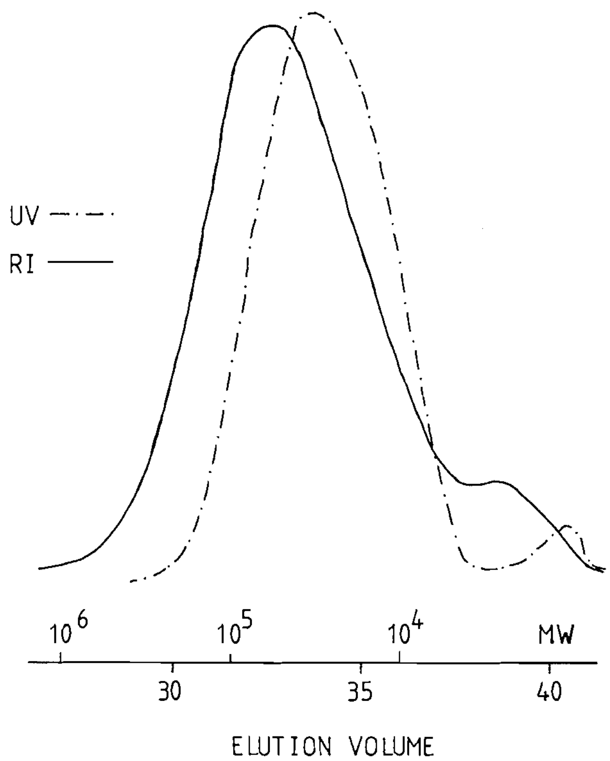

FIG. 1. The GPC curves of poly-DXL initiated by the diphenylmethylium cation; refractometric (RI) and ultraviolet (UV) detection at 260 nm (2 Shodex A-80 M columns; THF solvent; 1 mL/min flow rate).

philicity of the alkoxycarbenium ion. But, before such synthetic application can be envisioned, it is important to find the proper conditions to produce living poly-DXL systems where initiation is fast and quantitative and propagation is without transfer to monomer and without termination. Molecular weights can then be controlled and new synthetic routes are open.

1,3-Dioxolane (DXL) or 1,3-dioxepane[2] are known to produce side reactions (4); transfer to polymer is important and causes extensive formation of small rings by intramolecular and intermolecular transfer.

We are going to present our results concerning several initiators in relation to our search for living poly-DXL and apply the results to the preparation of block and graft copolymers using different comonomers and various methods.

Carbocations as initiators for DXL

Chlorodiphenylmethane has been reacted with silver hexafluoroantimonate stoichiometrically in the presence of DXL (5.2 *M*) at −55°C in CH_2Cl_2 solvent for 1 h. The polymer is recovered by precipitation in methanol at −30°C; the precipitated polymer is characterized by gel permeation (GPC) chromatography using the universal calibration; the soluble part is recovered after evaporation and characterized by vapor phase chromatography coupled to a mass spectrometer. The yield is ≃87%.

The precipitated fraction exhibits a number average molecular weight of 15 000 whereas the theoretical $\bar{M}_n$ is 55 000 and UV determinations show that only 70% of the initial chromophore has been incorporated.

The GPC determinations using both differential refractive index, RI, and UV detections (Fig. 1) show that the chromophore is present in all of the sample except for the lower molecular weight fraction: this could be an indication that it is composed of cycles. The UV peak at very low molecular weight corresponds probably to diphenylmethane but this has not been checked. After normalization of the curves a plot is made of the ratio of the UV absorption to the RI absorption multiplied by the $\bar{M}_n$ determined by GPC; the plot of ln $|\bar{M}_n \times (UV/RI)|$ obtained versus time of elution (Fig. 2) is an efficient way to estimate the relative incorporation of the chromophore into the polymer; if a particular polymer carries a chromophore at the chain end, the polydispersity of the sample will make the plot − using this representation − a straight horizontal line. This ideal situation is very close to that observed; it means that the chromophore is equally present on smaller and longer poly-DXL samples. Nevertheless, considering that only 70% of the chromophore is incorporated and that the experimental $\bar{M}_n$ is way below the theoretical one, we have to admit that some chain transfer occurred, probably involving the monomer through some unknown reaction, and that this side reaction was equally active on smaller and longer poly-DXL chains.

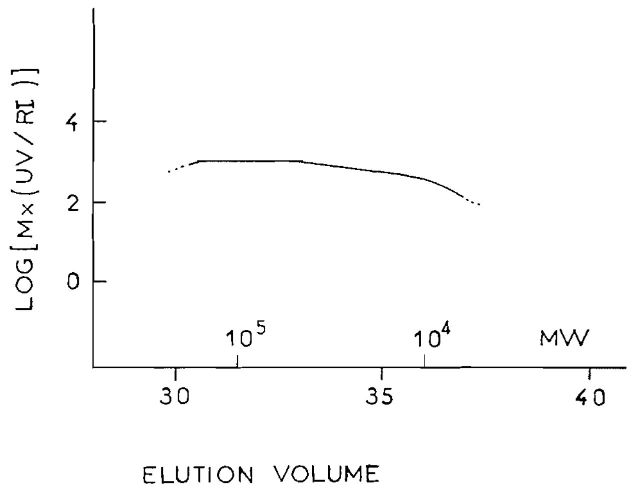

FIG. 2. Relative incorportion of the initiator moiety per polymer chain as a function of the chain length (RI, UV: normalized refractometric and ultraviolet signals; MW: molecular weight as given by the GPC universal calibration).

The soluble fraction analyzed by vp (vapor phase) chromatography and mass spectroscopy shows the presence of diphenylmethane: about 30% of the initially present chlorodiphenylmethane is present in this latter (eq. [2]). This suggests that initiation through hydride abstraction is quite significant:

[2] 
[3] 
TABLE 1. Polymerization of DXL by reacting organic halides with silver hexafluoroantimonate in CH_2Cl_2

Organic halide	Concentration of the halide (mol L^{-1})	Temperature and time of polymerization	Polymer yield (%)	$\bar{M}_{n.exp.}$ (GPC)	$\bar{M}_{n.th.}$
Chlorodiphenylmethane	5×10^{-3}	−55°C 1 h	87	15 000	55 000
2-Iodopropane	10^{-3}	−55°C 1 h	76	5 000	140 000
Benzyl bromide	13×10^{-3}	−15°C 1 h	79	10 000	32 000

From these observations, one can conclude that diphenylmethylium hexafluoroantimonate initiates the polymerization of DXL through two distinct mechanisms: addition and hydride abstraction (eq. [4]). Besides, extensive side reactions create smaller chains, just after initiation, and transfer takes place during propagation: an explanation of these findings is to be found in the lower nucleophilicity of dioxolane as compared to THF; the equilibrium is shifted to the left (as compared to the THF case)

[4] 
and the competition between the two processes − addition or hydride abstraction − makes the latter important. This is to be compared to the situation with THF where ϕ_2CH^+ is an excellent initiator by addition and ϕ_3C^+ initiates mostly through hydride abstraction. This result can be compared to that obtained when trityl salts react on THF: long ago it was established that hydride abstraction occurs in quantitative yield (5) and proposed that the tetrahydrofuran-2 ylium formed loses a proton (6) that is the true initiator of the THF polymerization.

The reaction of *2-iodopropane* with silver hexafluoroantimonate produced another good initiator of THF; we tried it also for DXL. 2-Iodopropane was reacted with the same silver salt, stoichiometrically in the presence of DXL (2.5 *M*), in methylene chloride at −55°C for 1 h to induce polymerization; deactivation was carried out with an excess of sodium benzylate (Table 1).

The solvent and unreacted monomer were evaporated: yield was 76%. The sample obtained was precipitated in methanol at −30°C, which separates the polymer from some low molecular weight material in solution. The recovered sample represented 77% of the starting sample and was characterized by GPC:

$$\bar{M}_{n.exp.GPC} = 5\,000$$
$$\bar{M}_{w.exp.GPC} = 88\,000$$
$$\bar{M}_{n.theor.} = 140\,000$$
$$\bar{M}_{n.exp.UV} = 40\,000 \text{ after excess benzylate elimination}$$

$\bar{M}_n$ determined by GPC is much lower than the theoretical value of 140 000, equal to the molar ratio of monomer consumed to initial 2-iodopropane; the polydispersity is quite high. The $\bar{M}_{n.exp.UV}$ which was determined by UV spectrometry is much higher than the $\bar{M}_{n.exp.GPC}$, which is an indication that very few active chains reacted with the deactivation agent. Double detection GPC (RI and UV) shows, as for diphenylmethylium, that the chromophore is present in all of the sample and also fairly regularly distributed.

Here again one observes that transfer to monomer prevails and that no living contribution can be found.

Benzylium hexafluoroantimonate was prepared by reaction of *benzylbromide* with $AgSbF_6$ stoichiometrically in the presence of DXL (7 *M*) in CH_2Cl_2 at −15°C, and the reaction proceeded for 1 h; termination was carried out with an excess of sodium methanolate. The yield was 79% (Table 1); the product was precipitated in methanol at −30°C where 74% was recovered as a high poymer, the rest (26%) was soluble.

Molecular weights were determined by GPC and by UV spectroscopy making use of the initiating chromophore; we found:

$$\bar{M}_{n.exp.GPC} = 10\,000$$
$$\bar{M}_{n.exp.UV} = 56\,000$$
$$\bar{M}_{n.theor.} = 32\,000$$

Here again the experimental $\bar{M}_n$ determined by GPC is much lower than the theoretical one, assuming complete initiation and absence of side reactions; i.e., transfer occurred. The high value of $\bar{M}_n$ determined by UV spectroscopy shows that only a small percentage (16%) of the initial chromophore has been incorporated into the polymer chains; the rest remains in the methanol-soluble fraction under various forms that we did not try to identify.

In conclusion, our attempts to use initiators containing the hexafluoroantimonate counter-ion − that had proved successful for THF polymerization − for the polymerization of dioxolane, ended without finding the proper conditions to obtain living samples; initiation was incomplete, and transfer significant.

Triflic anhydride as initiator

Penczek and co-workers (7) used triflic anhydride as an initiator for the polymerization of DXL and DXP; they showed that the concentration of active sites determined by a trapping agent (e.g. Ph_3P) corresponds to the initial concentration of initiator used within a few percent error. They also determined that the experimental $\bar{M}_n$'s agree with the theoretical ones so that they concluded that these systems are living; i.e. the total concentration of all active species is equal to the initial concentration of initiator. Since we needed well-defined polyacetals for copolymer synthesis we investigated this system and present below our findings.

Our main goal was to define experimental conditions where the theoretical and experimental $\bar{M}_n$'s would agree and where oligomer concentration would be minimal. We changed the initial monomer concentration, the temperature, and the reaction time. The GPC was used to determine the proportion of oligomers present and to calculate the $\bar{M}_n$'s of the higher molecular weight fraction, without taking into account the oligomers.

†Determined on the higher molecular weight fraction by GPC using the universal calibration.

The molecular weight determination by GPC is based on the universal calibration. The experiments described have been carried out with DXP. Table 2 shows our results.

Reactions carried out around −70°C are far from satisfactory since the molecular weights determined by GPC are markedly higher than the theoretical ones and large quantities of oligomers, probably rings, are present.

Reactions at −40°C give better results: molecular weights are close to the expected ones. The proportion of oligomers is very small (<5%). When monomer concentration is higher (e.g. 3 mol L^{-1}) viscosity increases considerably so that, in order to be able to stir, a compromise has to be found, and for our later experiments we chose initial monomer concentrations between 1 and 1.5 mol L^{-1}.

We used also an efficient proton scavenger, 2,6-ditertiobutyl-4-methylpyridine, in order to determine whether protons were involved in the initiation or propagation. Table 2 shows that no significant difference was found, and we can conclude that protons do not interfere with the polymerization.

When the reaction mixture is left standing for longer periods of time (e.g. 25 h) the molecular weight distribution changes very much; one observes an important increase of the proportion of oligomers and the $\bar{M}_n$ of the polymer increases drastically (e.g. from 50 000 to 350 000, Table 2). The polydispersity of the poly-DXP formed is quite important in every experiment and varies from 1.7 to 3.3.

In conclusion, we found that triflic anhydride can be used to prepare poly-DXP under conditions in which the molecular weights are controlled and only a small percentage of oligomers is present. This implies a careful choice of the temperature, of the time of reaction, and of the initial monomer concentration.

Copolymer synthesis

Penczek and co-workers have shown that the use of triflic anhydride leads to the formation of living poly-DXP (7); this was demonstrated by nmr, applying the ion trapping technique. We have seen above that one can control the molecular weight of the polymer formed; we can then try various possibilities to prepare block and graft copolymers.

Copolymers of two cyclic acetals

When DXL has been polymerized to prepare a dicationically living polymer, a small percentage of cycles are present because of the particular thermodynamic conditions. After addition of a second acetal, 1,3-dioxepane, polymerization ensues:

TABLE 3. Living polyacetals + vinylic monomers

Monomer		$10^{-3} \times \bar{M}_n$, I Stage		$10^{-3} \times \bar{M}_n$, II Stage		Yield* (%)
I	II	calcd.	found	calcd.	found	
DXP	DME	30.2	37.7	73.1	77.5	50
DXP	n.BVE	46.4	34.8	111.4	30.9	~100
DXP	St.	50.0	47.5		45.5	0
DXP	α-MeSt	91.2			87.0	0
DXP	Indene	73.5	87.7		81.0	0

*II stage. DME: 1,2-dimethoxyethylene; n.BVE: n.butylvinylether; St.: styrene; α-MeSt: α-methylstyrene.

removal of the lower molecular weight fraction of the macrocyclics leaves a copolymer which has a $\bar{M}_n$ close to the theoretical one — assuming a living copolymerization — within 10−15%.

The analysis of the microstructure (by ^1H and ^{13}C nmr) shows that, after the second monomer has been added, some block formation takes place but that these convert rapidly into random copolymer (7, 8). Clearly one cannot expect to prepare block copolymers using two acetals under living conditions because of the fast transacetalization occurring.

Copolymers using a vinylic comonomer

In order to avoid randomization through this side reaction we have used a second monomer whose active species are sufficiently stabilized to be unable to attack the polyacetal already formed during the second stage of the polymerization.

The first stage of the polymerization is always relative to poly-1,3-dioxepane initiated with triflic anhydride under the living conditions described above. After about 20 h the second monomer was added and left for 123 h. The polymers were then recovered and analyzed. Results are shown in Table 3.

Living cyclic DXP cannot initiate the polymerization of styrene, α-methylstyrene, and indene but can initiate the polymerization of n-butylvinyl ether, where a 100% conversion is observed. The molecular weights determined, nevertheless, do not correspond to the theoretical ones assuming a side reaction free system; the lower $\bar{M}_n$ observed in stage II stems from transfer to monomer so that, besides the copolymer formed, extensive transfer leads to homo-n-butylvinyl ether.

1,2-Dimethoxyethylene is an interesting case: the yield under our experimental conditions is usually of the order of 50%

TABLE 4. Reaction of active polydioxolane with various polymers

V	Polyvinyl-mesitylene	1.4	133000	83	Poly-DXL	99	Polyvinylmesitylene + traces of poly-DXL

*As compared to the initial phenyl-containing polymer introduced.

and it is not clear whether or not this comes from spontaneous deactivation. The samples obtained have been characterized by GPC, which shows a mononodal distribution, and membrane osmometry; the $\bar{M}_n$'s determined agree closely with the calculated ones (e.g. 77 500 and 73 100 respectively); fractionation with methylene chloride as solvent and iso-octane as nonsolvent has been carried out; each fraction obtained has been characterized by ^{1}H nmr to determine its content in both blocks, and selective solvent extraction has been carried out. It appears that no extractible homopolymer is present and that each fraction contains both DXP and DME. This demonstrates that direct initiation of a vinylic monomer by a living polyacetal is possible and that it can lead to a true block copolymer formation in the absence of homopolymer (9). Nevertheless the application of the method remains limited in its scope.

"Grafting onto" experiments

We have tried to make use of the dual nature of the active sites by reacting living polyacetal samples onto polystyrene, expecting to obtain a new way to prepare graft copolymers because of the possible Friedel–Crafts type reaction of the alkoxycarbenium onto the phenyl rings. Some preliminary experiments were carried out using diphenylmethylium hexafluoroantimonate as the initiator for dioxolane polymerization: we observed that a large fraction of the polystyrene was transformed into an insoluble network and that some poly-DXL was grafted on some soluble polystyrene. This finding definitely showed that growing poly-DXL has a reactivity much higher than that of oxonium ions since these latter are not capable of attacking a phenyl ring. This corroborated the possibility of existence of the proposed alkoxycarbenium.

The initiator used in the preliminary experiments has been shown since then to be poor for DXL polymerization so we turned to benzoylium hexafluoroantimonate, which, according to Kubisa and Penczek, is a satisfactory initiator (10).

The reactions were carried out in two steps: first, preparation of a growing poly-DXL which was characterized on an aliquot sample, then division of the batch into five parts which were reacted separately with a polymer containing phenyl rings; each experiment was then treated the same way and the products analyzed.

Preparation of an active poly-dioxolane

Benzoyl chloride (1.9×10^{-2} *mol* L^{-1}) was reacted stoichiometrically with silver hexafluoroantimonate in methylene chloride at −15°C in the presence of DXL (3.8 *M*); the reaction proceeded for 2 h. A sample aliquot was taken out and the reaction terminated with sodium methanolate: silver chloride was eliminated by centrifugation, the solvent and monomer left evaporated, and the product characterized by GPC. One peak plus some (<10%) oligomers were observed. The molecular weight was calculated without taking into account the oligomers; we found:

yield in polymer: 56%
$\bar{M}_n$: 13 500
$\bar{M}_w$: 22 500
$\bar{M}_{theor.}$: 8 500

Reaction of active poly-dioxolane onto various backbones

The solution of active poly-DXL was divided into five different aliquot samples, each containing the desired quantity of active sites for each particular experiment. The poly-DXL was then poured into five flasks containing the various polymers to be studied as backbones; after addition the concentration in DXL was 2.9 mol L^{-1}.

The reactions were carried out for 24 h at −15°C. Then sodium methanolate was added to terminate the reactions; silver chloride was centrifuged out. When some insoluble material was present it was isolated by filtration and treated with THF in a Soxhlet-type apparatus to remove the soluble fraction. The solvent was evaporated, the polymers dried and characterized by ^{1}H nmr and GPC.

Polystyrene, poly α-methylstyrene, and polyvinylmesitylene samples are used as polymers containing phenyl rings. The results are collected in Table 4. Refluxing 2-methoxyethanol, a solvent for poly-DXL and a nonsolvent for polystyrene, was used to separate homopolystyrene; refluxing ethanol was used to separate homopoly-DXL. Experiment I where the number of active poly-DXL sites per polystyrene chain is high ($\psi = \lvert O^+ \rvert / \lvert PS \rvert = 63$) yields mostly an insoluble network, but experiments II and III where ψ is much smaller show that the grafting efficiency for the polystyrene is 100%; only 20% of the poly-DXL present has been grafted.

In experiment IV the soluble fraction shows that it contains poly-DXL and some higher molecular weight material corresponding to ill-defined grafted poly α-methylstyrene.

Experiment V is relative to polyvinylmesitylene; 99% is recovered as an insoluble network and exemplifies the influence of a hindered phenyl ring.

In order to rationalize these results we propose that, when active poly-DXL is reacted on the polymers tested, two reactions are in competition, namely, a Friedel and Crafts attack of the alkoxycarbenium ion on the benzene ring, which leads to grafting, as in experiments I, II, III, and IV; hydride abstraction from the benzylic position can also occur and give a benzylic ion which can then attack a phenyl ring on another macromolecule, leading eventually to a network formation. This latter mechanism operates in experiments I and V.

In the case of poly α-methylstyrene, when there is no benzylic hydrogen, this process cannot take place and only the first one is operative: the existence of some small fraction of insoluble polymer could be explained by the Friedel–Crafts type attack of the benzenium onto a phenyl. An alternate explanation would involve some transfer to polymer involving the polyacetal itself, as has been observed in the case of poly THF.

In experiment I, both mechanisms are operative: grafting is observed because of the first one and network formation because of the second one, the number of active poly-DXL sites per polystyrene chain being high (63): the reason why experiments II and III do not exhibit this undesirable side reaction resting on the smaller number of active sites per chain.

In conclusion, the reaction of active poly-DXL on phenyl-carrying polymers can lead to graft copolymer formation in high yield, provided that experimental conditions are properly chosen, especially concerning the concentration of active sites per chain, which should remain small.

The ^{13}C nmr spectra of solids, acquired using the Cross Polarization/Magic Angle Spinning (CP/MAS) technique, are very sensitive to the detailed nature of crystalline packing. These effects are illustrated in the CP/MAS spectra of the α and β anomers of methyl-D-xylopyranoside. In the spectrum of the α anomer, which crystallizes with two molecules per unit cell, individual spectra can be resolved for the two molecules in the asymmetric unit of this crystal.

Introduction

Nuclear magnetic resonance has been widely applied to the study of carbohydrates. The solution ^{1}H and ^{13}C nmr spectra provide details of the chemical structures and conformational features. It is also possible to obtain high resolution ^{13}C spectra of solid carbohydrates using the Cross Polarization/Magic Angle Spinning (CP/MAS) technique (1). The CP/MAS spectra are similar to the corresponding solution spectra, although the resolution achieved in the solid state is generally lower. The ability to observe spectra of solids promises to be useful in the study of insoluble carbohydrate polymers, especially in relation to their native, solid states. For many biopolymers, insolubility in water must be the result of simultaneous or near-simultaneous biosynthesis and crystallization, a phenomenon which may well result in a non-minimum energy state in the native material.

The chemical shifts observed in solution are characteristic of the time-averaged, isotropic environments of the nuclei. Isotropic shifts are also observed in the solid state, under magic angle spinning. However, in the solid state, the chemical shifts can be influenced by features due to the manner in which the materials crystallize. For example, crystallization may "*lock in*" conformational features which alter the chemical shifts. In addition, interactions with near neighbors depend on the crystalline conformation. Solid state effects on chemical shifts have been noted in a number of systems, including carbohydrates (2, 3). The manifestation can be in terms of simple displacement of a given signal as a function of polymorphic form or it can be in terms of multiplicities which are seen for some, but not necessarily all, of the signals. In general multiplicities will be seen if: (*i*) the site symmetry in the crystal is less than the molecular symmetry for the isolated molecule; (*ii*) the unit cell contains more than one chemically equivalent molecule. In short, one should see a signal for each atom whose position must be specified in order to define the unit cell.

In the case of simple carbohydrates where a crystal can contain more than one isomer, the technique has proven to be a valuable supplement for the crystallographer (2, 3). In the case of homopolysaccharides where a disaccharide is often the crystallographic repeat, the method can provide direct evidence of small conformational and (or) crystal field effect differences between the two chemically equivalent units.

To add to our understanding of the factors which affect chemical shift, we have examined the ^{13}C CP/MAS spectra of the methyl α- and β-D-xylopyranosides. The crystal structures of these sugars are known (4–6) and are quite different. In particular, the β-xyloside crystallizes with one molecule in the asymmetric unit, while the α-xyloside has two independent molecules in the asymmetric unit.

Experimental

Crystals of both compounds were crystallized from alcohol/water mixtures. Solution state ^{13}C nmr (7) was used to verify the anomeric identity of each sugar. The crystals were then ground into homogeneous powders. X-ray powder diffractometry indicated the unit cell dimensions previously found (4–6). Solid state ^{13}C nmr spectra were obtained at 50.3 MHz using a Bruker CXP-200 spectrometer. The spectra were acquired with dipolar decoupling and cross polarization with radio frequency field strengths of approximately 65 kHz for Hartmann–Hahn matching and proton decoupling. Recycle times of 20 s were used in the cross-polarization pulse sequence. A rotor of the Andrew–Beams design was used for Magic Angle Spinning at approximately 4 kHz. The setting of the Magic Angle was monitored by

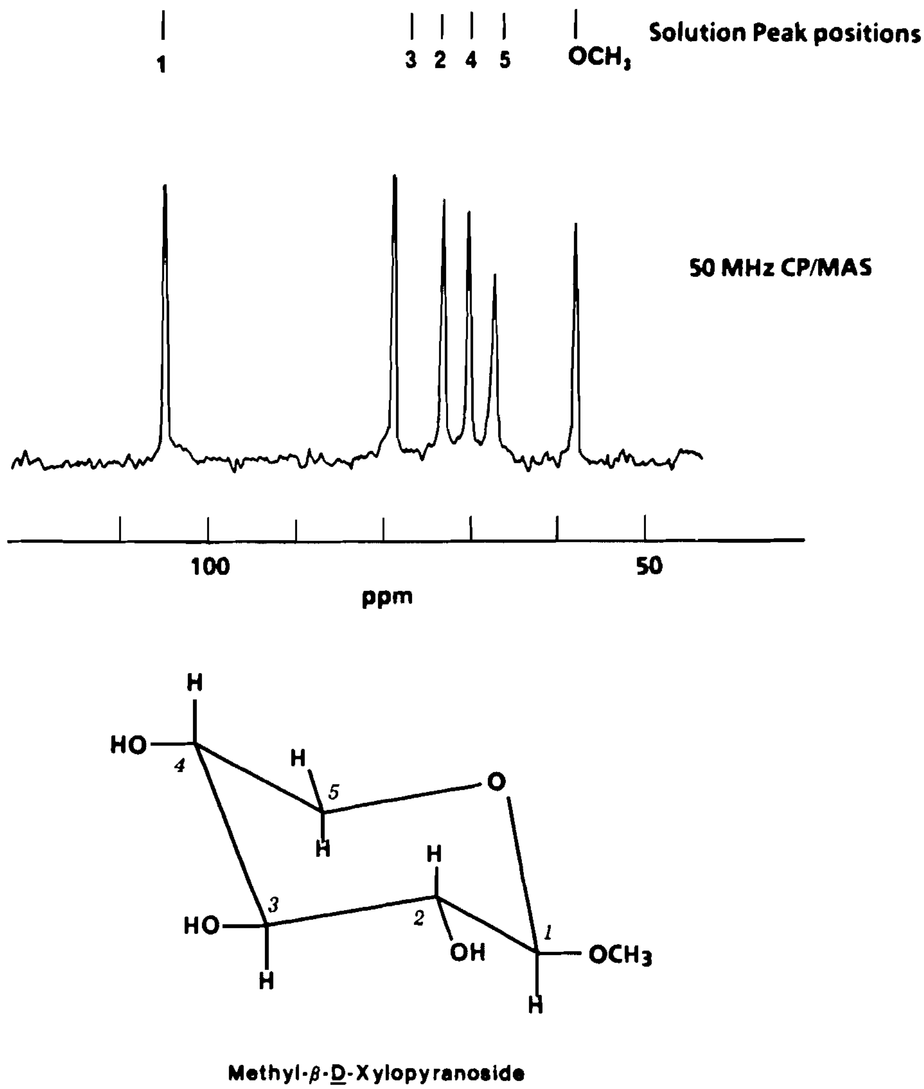

FIG. 1. Structure and ^{13}C CP/MAS nmr spectrum of methyl β-D-xylopyranoside. The solution chemical shifts (7) are included at the top of the figure.

the ^{79}Br nmr spectrum of KBr (8) incorporated in the rotor. A small amount of linear polyethylene ($\delta^{13}C$ = 33.6 ppm) was also included in the sample to provide a chemical shift reference (9).

Results and discussion

The ^{13}C CP/MAS spectra of solid samples of the methyl β- and α-D-xylopyranosides are shown in Figs. 1 and 2, respectively. In both figures, the solution state chemical shifts (7) are included for reference. The observed chemical shifts are given in Table 1. In the spectrum of the β anomer, a well-resolved six-line spectrum is observed. In the spectrum of the α anomer, eleven lines are resolved. The resonance multiplicity in the spectrum of the α anomer reflects the inequivalence of the two molecules in the asymmetric unit of this crystal. The magnetic environments of chemically equivalent carbon sites in the two molecules are different, so that individual resonances are resolved for each molecule.

A recent paper on the crystal structure of lactulose (2) convincingly showed how configurational multiplicity derived from solid state nmr was invaluable in arriving at the full three-dimensional crystal structure. In the present case, we

TABLE 1. ^{13}C chemical shifts of methyl α- and β-D-xylopyranosides*

α-Methylxylopyranoside		β-Methylxylopyranoside	
Solid state	Solution assignment	Solid state	Solution assignment
101.7 100.3	C-1	105.1	C-1
74.5 73.5 72.6 71.6 69.8	C-3, C-2, C-4	79.1 73.4 70.4	C-3 C-2 C-4
62.7 61.7	C-5	67.6	C-5
57.9 55.4	CH_3	58.3	CH_3

*Solid state shifts are measured relative to linear polyethylene at δ = 33.6 ppm. Solution assignments (7) may not correspond exactly to the solid state shifts due to differences in isotropic shifts in the two states.

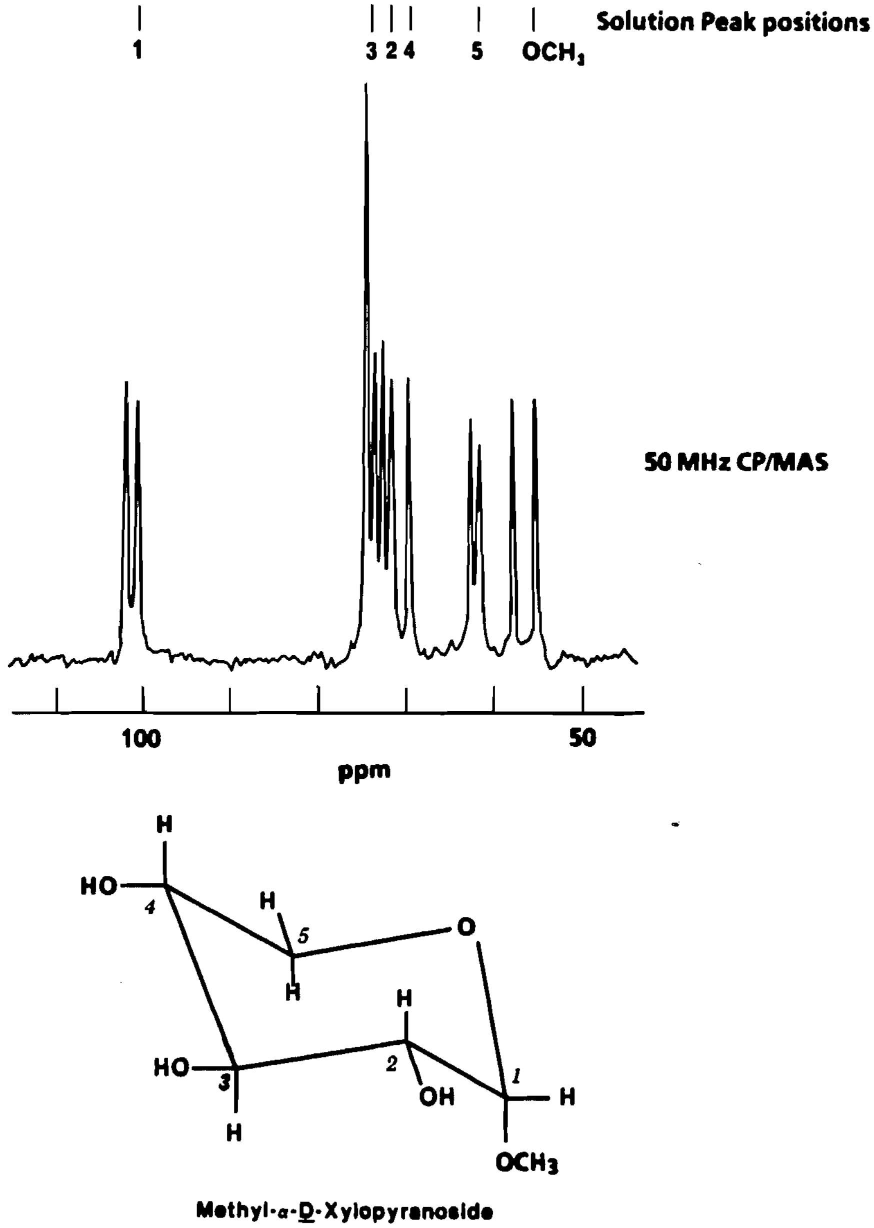

FIG. 2. Structure and ^{13}C CP/MAS nmr spectrum of methyl α-D-xylopyranoside. The solution chemical shifts (7) are included at the top of the figure.

have examined materials which have been well characterized by X-ray and neutron diffraction and the CP/MAS spectra serve to confirm the X-ray diffraction data. However, the remarkable sensitivity of this spectroscopic tool to the small differences in the shapes of the two molecules in the methyl α-xyloside is to be noted. The X-ray diffraction data (4) indicate that the only large conformational difference between the two crystalline forms of the α-xyloside is in the ϕ dihedral angle (O-5—C-1—O—CH_3). The small conformational differences, along with variations in intermolecular interactions, are sufficient to result in significantly different chemical shifts for chemically equivalent carbon sites in the two molecules. The methyl group shifts are particularly sensitive to the crystallographic inequivalence of the two molecules. The examination of other well-characterized systems may provide at least qualitative trends for the effects of the variation of crystal structure on the ^{13}C CP/MAS nmr spectra. It has been shown that a correlation exists between the C-6 chemical shift and the exocyclic C-5—C-6 torsion angle (10) in a number of sugars. It may be possible to derive other empirical relationships between the CP/MAS spectra and solid state conformational properties. Such information would be useful in aiding in the interpretation of the solid state spectra of material such as cellulose, where the spectra show characteristic features dependent on polymorphic form or the natural source of the material (11).

Oxidation of elemental mercury by hydroperoxides in aqueous solution

DONALD C. WIGFIELD AND SHERRY L. PERKINS
The Ottawa-Carleton Institute for Research and Graduate Studies in Chemistry, Department of Chemistry, Carleton University, Ottawa, Ont., Canada K1S 5B6

Received February 8, 1984

DONALD C. WIGFIELD and SHERRY L. PERKINS. Can. J. Chem. **63**, 275 (1985).

The recent development of techniques in this and other laboratories has allowed the exploration of elemental mercury oxidations by compounds bearing the —O—O—H moiety. The peracid group appears to be a far more effective oxidant of mercury than the peroxide group, and both peracetic acid and *m*-chloroperbenzoic acid oxidize mercury at the trace level to both mercurous and mercuric forms.

DONALD C. WIGFIELD et SHERRY L. PERKINS. Can. J. Chem. **63**, 275 (1985).

La mise au point de nouvelles techniques, tant dans notre laboratoire qu'ailleurs, a permis d'étudier l'oxydation du mercure élémentaire par des composés portant l'unité —O—O—H. Par rapport au groupe peroxyde, le groupe peracide semble être un oxydant beaucoup plus efficace du mercure: les acides paracétique et *m*-chloroperbenzoïque oxydent tous les deux le mercure à l'état de trace pour le transformer en composés mercureux et mercuriques.

[Traduit per lar jounral]

In recent communications we have shown that mercury signals in the cold vapor atomic absorption analysis (c.v.a.a.) under non-reducing conditions arise from elemental mercury and the mercurous ion, but not from mercuric ion, and furthermore that the signals from elemental mercury cannot exceed those corresponding to the solubility limit of mercury in water (63 ppb) (1−3). A signal in the c.v.a.a. under non-reducing conditions that exceeds 63 ppb may therefore be assigned as being due, at least in part, to the mercurous ion (3), and we have recently shown that, although most mercury oxidations do not display such a signal, oxidation by peracetic acid does (3). This observation, coupled with the development of the signal assignment mentioned above, allows the exploration of previously inaccessible mercury-peroxide chemistry at the trace level. This article reports our findings in this area.

Results and discussion

The combination of cold vapor atomic absorption analysis (c.v.a.a.) of mercury, together with the so-called "uptake" experiments involving the diffusion of mercury from the side-arm of a Thunberg flask, has been a particularly powerful methodology for studying metabolic oxidation of elemental mercury. This technique, devised by Magos, Clarkson, and their collaborators (4) involves having mercury in the side-arm of a Thunberg flask, separated from potential oxidants in aqueous solution which are located in the main body of the flask. Reaction and oxidation of the mercury is achieved by the mercury diffusing to the main body of the flask, thus eliminating the problem of trying to dissolve elemental mercury in aqueous solution. The contents of the flask are subsequently analysed by c.v.a.a. This analysis can be done either with the addition of stannous chloride, to reduce all forms of mercury to elemental mercury and thus give the total mercury content of solution, or in the absence of reducing agent, in which case the analysis is specifically for volatile mercury. These aspects have previously been fully described elsewhere (1, 4−6).

Although we have reported studies of mercury oxidation under fully homogeneous conditions (5), these studies are clearly limited to having a mercury concentration of less than 63 ppb (solubility limit of mercury in water). In this regard the non-homogeneous side-arm diffusion method offers a distinct advantage, and allows not only the possibility of a far greater concentration of mercury diffusing from the side-arm and being oxidized in solution, but also the opportunity of observing the signal, under non-reducing conditions, exceeding 63 ppb, indicative of the presence of mercurous ion. Using this mercury diffusion − c.v.a.a. technique with various peroxides as the oxidant in the main body of the flask, we have been able to explore mercury-peroxide reactions. The commercially available compounds which incorporate the —O—O—H functionality are hydrogen peroxide, ethyl hydroperoxide, *tert*-butyl hydroperoxide, peracetic acid, and *m*-chloroperbenzoic acid. Oxidations of mercury by all of these reagents at various concentrations have been studied, and the results are summarized in Table 1.

Perusal of these data reveals a number of interesting points. Firstly, the reactions with H_2O_2, C_2H_5OOH, and t-C_4H_9OOH show little oxidation and the results of these experiments are basically the diffusion-controlled formation of a Hg^0 aqueous solution coupled with a small amount of oxidation. In some cases (e.g. *t*-BuOOH, 20.7×10^{-5} M) the total mercury in solution is greater than 63 ppb, but this is mostly in the mercuric ion form, and there is no suggestion of the non-reducing c.v.a.a. signal exceeding, or approaching this value. These observations are consistent with our previous chemical and enzymic oxidations of mercury (3). Secondly, the oxidations by the two peracids, in contrast, give substantial uptake and oxidation of mercury, in some cases approaching 2000 ppb. Thirdly, although most of this mercury signal appears only on the c.v.a.a. analysis under reducing conditions, and is therefore mercury in the Hg^{2+} oxidation state (1, 2), oxidations, both peracetic acid and by *m*-chloroperbenzoic acid at several concentrations show c.v.a.a. signals under non-reducing conditions substantially in excess of 63 ppb. This observation shows the presence of the mercurous ion in these oxidations. Finally, within the concentration range studied, there appears to be an interesting contrast between oxidations by peracetic acid and by *m*-chloroperbenzoic acid. Oxidations by peracetic acid show the formation of mercurous ion at $[CH_3CO_3H] = 10.5 \times 10^{-5}$ M and at higher concentrations this mercurous signal continues to increase. In contrast, the oxidations with *m*-chloroperbenzoic acid also show the mercurous ion becoming evident at approximately $[RCO_3H] = 10 \times 10^{-5}$ M, but then rising to a maximum value at approximately $[RCO_3H] = 20 \times 10^{-5}$ M and dropping at higher $[RCO_3H]$. At very high $[RCO_3H]$ the signal is once again submerged below the solu-

*The signal under non-reducing conditions can sometimes appear to exceed that under reducing conditions due to unavoidable time lag between determinations and resulting loss of Hg^0. This is of consequence only where Hg(total) is very small.

bility limit of Hg^0.

A number of conclusions appear to follow from these observations. Firstly, the peracids are evidently far more effective oxidants than the peroxides and, since these "acids" are not particularly acidic (pK_a 7.1−8.2 (7)), it appears likely that the carbonyl group may well be playing a role in the peracid oxidations. Although a cyclic mechanism involving mercury and the carbonyl group, such as shown in Fig. 1 is an attractive notion, and one which would be restricted to the peracids, there are certainly other mechanistic possibilities which would account for the greater oxidative capability of the peracid group. Oxidation to the mercurous ion is also an intriguing mechanistic question. Clearly the technique used in this study, while allowing chemistry to be delineated, does not permit any mechanistic insight to be gained.

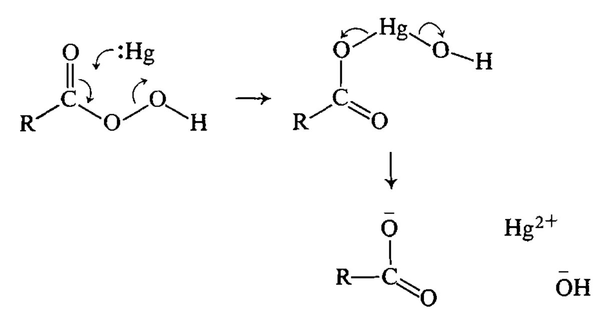

FIG. 1. Cyclic mechanism for mercury oxidation.

Experimental

Solutions and reagents

t-*Butyl hydrogen proxide*: *t*-butyl hydrogen peroxide solutions were prepared by serial dilution of *t*-butyl hydroperoxide-70 (Wallace and Tiernan Inc., Buffalo, NY).

Ethyl hydrogen peroxide: solutions were prepared by serial dilutions of 10% aqueous ethyl hydrogen peroxide (Polysciences Inc., Warrington, PA).

Peracetic acid: 40% peracetic acid (FMC Corporation, Buffalo, NY) was sequentially diluted to produce reagent solutions.

Hydrogen peroxide: 30% A.C.S. reagent grade hydrogen peroxide (Anachemia, Montreal, Canada) was serially diluted to produce reagent solutions.

m-*Chloroperoxybenzoic acid*: 0.5 g *m*-chloroperoxybenzoic acid (Aldrich Chemical Company, Milwaukee, WI) was dissolved in 10.0 mL absolute ethanol (Consolidated Alcohols Ltd., Toronto, Canada). Reagent solutions were prepared by serial dilutions of this stock solution with distilled water.

Incubation and analysis

Distilled water (3.0 mL) was placed in the main body of each Thunberg flask. The test reagent (20 μL) was added and the flasks were stoppered with a side-arm containing metallic mercury (0.1 mL). The flasks were incubated overnight in a metabolic shaker. At the end of the incubation period the side-arms were removed, flasks were sealed with parafilm, and solutions were analyzed by double Magos determination (1).

Control experiments

Oxidations with carboxylic acids were tested (see Table 1) in order to ensure that oxidations with peracids were not proceeding by initial reduction to the carboxylic acid which in turn acted as the main oxidant.

Errors

Error limits quoted are standard deviations on triplicate determinations.

Etude de l'anharmonicité électrique dans $^{12}C^{16}O_2$

PHILIPPE MILLIÉ
Département de Physico-Chimie, CEN/SACLAY, 91191 Gif-sur-Yvette Cedex, France

Reçu le 24 avril 1984

PHILIPPE MILLIÉ. Can. J. Chem. **63**, 278 (1985).

Le développement du moment dipolaire dans la molécule $^{12}C^{16}O_2$ en fonction des coordonnées normales est déterminé jusqu'au quatrième ordre par ajustement sur les valeurs expérimentales des intensités de transition. La convergence du développement est rapide, mais les termes d'ordre trois jouent un rôle très important si on veut obtenir une précision de l'ordre de 20%.

PHILIPPE MILLIÉ. Can. J. Chem. **63**, 278 (1985).

The dipole moment derivatives up to the fourth order are determined for the $^{12}C^{16}O_2$ molecule by fitting the experimental values of several transition intensities. The convergence is fast, but the third order is significant in order to obtain an acceptable accuracy (~20%).

Introduction

Le moment dipolaire d'une molécule polyatomique peut être décrit dans n'importe quel système de coordonnées représentant le déplacement des atomes par rapport à la configuration d'équilibre. Cependant, en général, on utilise un développement en puissance en fonction des coordonnées normales sans dimension (q_s)

$$[1]\quad M^\alpha = M_e^\alpha + \sum_s P_s^\alpha q_s + \frac{1}{2}\sum_{s,s'} P_{ss'}^\alpha q_s q_{s'} + \ldots$$

avec

$$P_s^\alpha = \left(\frac{\partial M^\alpha}{\partial q_s}\right)_e, \quad P_{ss'}^\alpha = \left(\frac{\partial^2 M^\alpha}{\partial q_s \partial q_{s'}}\right)_e \ldots \quad \alpha = x,y,z$$

La question essentielle est la rapidité de convergence d'un tel développement, c'est-à-dire le rôle de l'anharmonicité électrique dans les intensités de transition.

La molécule de bioxyde de carbone se prête particulièrement bien à une telle étude, car d'une part, sa fonction potentiel est bien connue (1), d'autre part, l'intensité d'un grand nombre de ses transitions a été déterminée (2).

Cette étude se distingue des études précédentes (3, 4) sur le même sujet sur trois plans: (*i*) l'utilisation d'une fonction potentiel plus raffinée, (*ii*) le nombre de transitions utilisées pour déterminer les coefficients P_s, P_{ss}, etc.., beaucoup plus grand (7 à 10 fois), et (*iii*) la fonctionnelle utilisée: on a cherché à reproduire au mieux les intensités de transition et non les moments dipolaires.

L'emploi de ces derniers pose en effet le problème du signe des valeurs expérimentales, et oblige, soit à tester tous les jeux de signe possibles, soit à ne garder que les transitions les plus intenses pour lesquelles le signe est certain (3), ce qui restreint l'échantillonnage dans les deux cas.

Considérations théoriques

1. *Principe général*

L'intensité d'une transition donnée entre deux états vibrationnels ψ_i et ψ_j est proportionnelle à

$$\langle\psi_i|M|\psi_j\rangle^2$$

Compte tenu de l'éq. [1], on obtient:

$$\langle\psi_i|M^\alpha|\psi_j\rangle^2 = \left[\sum_s P_s^\alpha \langle\psi_i|q_s|\psi_j\rangle + \frac{1}{2}\sum_{s,s'} P_{ss'}^\alpha \times \langle\psi_i|q_s q_{s'}|\psi_j\rangle + \ldots\right]^2$$

Si on connaît par ailleurs les fonctions d'ondes ψ_i et ψ_j, on peut aisément calculer $\langle\psi_i|q_s|\psi_j\rangle$, $\langle\psi_i|q_s q_{s'}|\psi_j\rangle$, etc. $\langle\psi_i|M^\alpha|\psi_j\rangle^2$ devient une fonction des seuls paramètres P_s^α, P_{ss}^α, etc.. et ces derniers sont alors obtenus à partir d'un échantillonnage de valeurs expérimentales de $\langle\psi_i|M^\alpha|\psi_j\rangle^2$.

2. *Obtention des fonctions d'ondes*

Elle consiste à écrire les fonctions d'ondes comme des produits des fonctions harmoniques et à diagonaliser l'hamiltonien $T + V$ dans cette base. Le potentiel utilisé est celui déterminé par A. Chedin (1). La validité de ce potentiel, la convergence des fonctions d'ondes et des éléments de matrice de l'opérateur moment dipolaire ont été discutées dans un article précédent (5). La dimension de la base utilisée est de 246 pour chacune des symétries Σ_g^+, Σ_u^+, Π_g, Π_u, Δ_g, Δ_u alors que les intensités des transitions utilisées ne font intervenir au maximum que les vingt premiers niveaux dans chaque symétrie.

3. *Développement du moment dipolaire*

Le développement, au quatrième ordre, en fonction des coordonnées normales sans dimension compte tenu des restrictions dues à la symétrie, s'écrit sous la forme (*i*) pour les transitions parallèles ($\Sigma_g^+ \leftrightarrow \Sigma_u^+$, $\Pi_g \leftrightarrow \Pi_u$, $\Delta_g \leftrightarrow \Delta_u$)

$$M_\parallel = P_3 q_3 + P_{13} q_1 q_3 + P_{113} q_1^2 q_3 + P_{223} q_2^2 q_3 + P_{333} q_3^3 + P_{1113} q_1^3 q_3 + P_{1223} q_1 q_2^2 q_3 + P_{1333} q_1 q_3^3$$

(*ii*) pour les transitions perpendiculaires ($\Pi_{g,u} \leftrightarrow \Sigma_{u,g}^+$, $\Delta_{g,u} \leftrightarrow \Pi_{u,g}$), si on utilise les coordonnées polaires ρ et φ, on obtient:

$$M_\perp = e^{i\varphi}(P_2\rho + P_{12} q_1\rho + P_{112} q_1^2\rho + P_{233}\rho q_3^2 + P_{222}\rho^3 + P_{1112} q_1^3\rho + P_{1233} q_1\rho q_3^2 + P_{1222} q_1\rho^3)$$

Conduite du calcul et résultats

1. *Choix de l'échantillonnage*

Bien qu'on ne puisse pas définir un critère absolu de choix, cet échantillonnage doit répondre aux qualités suivantes:

(a) Le nombre d'echantillons doit être nettement supérieur au nombre de paramètres, ici huit.

(b) Les transitions choisies doivent permettre une détermination significative des paramètres. Elles doivent donc faire intervenir ces derniers avec des poids comparables sur l'ensemble à déterminer. Il est notamment nécessaire pour cela de choisir aussi bien des transitions intenses que des transitions très faibles.

(c) On doit éliminer les transitions faisant intervenir des états vibrationnels très fortement perturbés par interaction de Coriolis (puisqu'on a négligé cette dernière dans l'hamiltonien) ainsi que celles pour lesquelles les erreurs expérimentales sont trop importantes.

On arrive ainsi à un total de 100 (après en avoir éliminé huit par le critère (c) pour les transitions parallèles et de 66 pour les perpendiculaires (après en avoir éliminé six) (à comparer à 9 pour la réf. 3 et à 15 pour la réf. 4).

2. *Choix de la fonctionnelle et conduite du calcul*

Soit expe(k) et theor(k) les valeurs expérimentales et théoriques du carré du moment dipolaire de la $K^{\text{ième}}$ transition considérée.

On recherche, par la méthode de Newton, les valeurs des paramètres P_1, P_2... qui minimisent la fonctionnelle

$$F = \frac{1}{n} \sum_{k=1}^{n} (\text{theor}(k) - \text{expe}(k))^2/\text{theor}(k) \cdot \text{expe}(k)$$

c'est-à-dire la somme des carrés des erreurs relatives. Les valeurs expérimentales sont tirées de la référence 2.

Pour s'assurer que l'on atteint le minimum minimorum, le processus itératif de Newton est répété pour un certain nombre de valeurs de départ différentes des paramètres.

On obtient, par cette méthode, la valeur absolue et le signe de chaque paramètre à condition d'attribuer un signe au paramètre le plus grand (P_1 ou P_2). La détermination antérieure de ce signe (3) permet de lever totalement l'ambiguité.

Discussion des résultats

Les résultats sont rassemblés dans les tableaux 1 (transitions parallèles) et 2 (transitions perpendiculaires).

On peut remarquer: (*i*) le bon accord entre cette détermination et les déterminations antérieures pour le premier terme aussi bien pour les transitions parallèles que pour les perpendiculaires; (*ii*) la rapide décroissance (environ un facteur 10 à chaque ordre) des termes successifs, notamment dans le cas des transitions perpendiculaires, où l'ordre quatre est pratiquement négligeable, ce qui justifie le choix d'un développement en fonction des coordonnées normales; (*iii*) l'amé-

lioration très nette de la valeur minimale de la fonctionnelle F en fonction du nombre de paramètres et notamment l'importance du troisième ordre pour obtenir une erreur relative moyenne inférieure à 30%; (*iv*) la bonne fiabilité des résultats obtenus en fonction des erreurs expérimentales: un changement aléatoire de toutes les valeurs expérimentales (limitée à 15% au maximum) ne modifie que peu les valeurs obtenues, même les plus faibles (comparer les colonnes 4 et 5 des tableaux 1 et 2). On peut ainsi estimer notre erreur à 1% sur le 1er terme et à 5% sur les autres. (*v*) le bon accord que l'on obtient avec les valeurs expérimentales aussi bien pour des transitions très intenses que pour des transitions de très faible intensité (huit ordres de grandeur) (voir tableau 3).

Conclusion

Comme il a été déjà discuté (5), le potentiel utilisé dans ce travail semble apte à reproduire théoriquement les intensités de transition observées. Le large échantillonnage utilisé permet d'améliorer la fiabilité du développement du moment dipolaire, notamment pour les plus petits termes qui jouent un rôle important pour les transitions presque interdites.

Une évaluation a priori, d'intensités de transitions non encore observées dans CO_2, semble maintenant possible avec une précision de l'ordre de 20%.

The gas phase ion molecule reactions of a number of anions, X^-, with diborane, B_2H_6, have been investigated using ion cyclotron resonance spectroscopy. Two distinct reaction channels are observed in addition to simple proton transfer. The first of these is production of BH_4^- and BH_2X while the second is formation of BH_3X^- and BH_3. In order to determine the importance of thermodynamic factors in the course of reaction *ab initio* calculations have been carried out on the species involved to obtain the relative stabilities of the two possible pairs of products. The 4-31+G basis set incorporating additional flat *s* and *p* functions has been used since this basis set has been demonstrated to give the most accurate description of anions to date. The results obtained indicate that the thermochemical factors are instrumental in determining the reaction pathway.

O. EISENSTEIN, M. KAYSER, M. ROY et T. B. MCMAHON. Can. J. Chem. **63**, 281 (1985).

Faisant appel à la spectroscopie de résonance de l'ion dans un cyclotron, on a étudié les réactions ion molécule en phase gazeuse d'un certain nombre d'anions, X^-, avec le diborane B_2H_6. On a observé deux voies distinctes de réaction en plus du simple transfert de proton. La première voie conduit à la formation de BH_4^- et de BH_2X alors que la seconde fournit du BH_3X^- et du BH_3. Dans le but de déterminer l'importance des facteurs thermodynamiques pendant la réaction, on a effectué des calculs *ab initio* sur les espèces impliquées afin d'obtenir les stabilités relatives des deux paires possibles de produits. On a utilisé l'ensemble de base 4-31+G incluant des fonctions additionnelles *s* et *p* planes puisque cet ensemble de base a donné jusqu'à présent la description la plus correcte des anions. Les résultats obtenus indiquent que les facteurs thermodynamiques contribuent à déterminer le processus réactionnel.

[Traduit par le journal]

Introduction

Despite the widespread synthetic utility of borohydride reductions the details of the mechanism by which BH_4^- reacts with carbonyl groups is not well understood (1–3). Recent *ab initio* calculations (4) have shown that the reaction of isolated BH_4^- with formaldehyde to produce methoxide ion and BH_3, reaction [1],

[1] $BH_4^- + CH_2O \rightarrow CH_3O^- + BH_3$

should be *endothermic* by 36 kcal mol^{-1}. In addition, exploration of the potential energy surface for this reaction also revealed a substantial activation barrier. This is in considerable contrast to the experimental observations which show that in solution borohydride reductions of carbonyl groups proceed rapidly with little or no activation energy and with evolution of substantial quantities of heat.

In order to explore the mechanism of reaction between naked BH_4^- and CH_2O we undertook an investigation of the gas phase reactions of BH_4^- with CH_2O using ion cyclotron resonance spectroscopy (ICR) (5). As predicted by *ab initio* calculations (4) no hydride transfer occurred. Furthermore, even in the case of reaction of BH_4^- with CF_2O, in which the carbonyl group is substantially activated, no hydride transfer was observed, reaction [2].

[2] $BH_4^- + F_2CO \rightarrow F_2CHO^- + BH_3$

In the course of our study reactions of BH_4^- with a wide variety of aliphatic aldehydes and ketones were also attempted and, while no hydride transfer was observed an extremely interesting new reaction was discovered.

Borohydride ion, BH_4^-, was generated in our system by reaction of F^- with diborane, B_2H_6, reaction [3].

[3a] $F^- + B_2H_6 \rightarrow BH_4^- + BH_2F$

[3b] $F^- + B_2H_6 \rightarrow BH_3F^- + BH_3$

Under usual experimental conditions proton abstraction by F^- from the aldehyde or ketone under investigation was also observed in those species possessing an α hydrogen. For example, with acetone the acetone enolate ion was readily formed, reaction [4]

[4] 
This ion was observed to subsequently react with diborane to produce a new species of boron enolate, reaction [5].

[4] To whom all correspondence should be addressed.

Trialkyl boron enolates are well known synthetic reagents for important reactions such as stereoselective aldol condensations (6, 7).

Having observed reaction [5], and to a smaller extent the analogous reaction of F^-, reaction [3*b*], it was felt that the reaction of CH_3O^- with diborane might then yield $CH_3OBH_3^-$, the postulated intermediate in the borohydride reduction of formaldehyde. However, when CH_3O^- was reacted with B_2H_6 the only product observed was BH_4^-, reaction [6].

$$[6] \quad CH_3O^- + B_2H_6 \rightarrow BH_4^- + CH_3OBH_2$$

The realization that there are two very different ways in which anions can react with diborane, reactions [7] and [8] led us to investigate a large number of anion–diborane reactions to

$$[7] \quad X^- + B_2H_6 \rightarrow BH_4^- + BH_2X$$
$$[8] \quad X^- + B_2H_6 \rightarrow XBH_3^- + BH_3$$

determine the factors affecting the species produced in these two general pathways. In order to determine the importance of the relative thermodynamic stabilities of the two sets of products on the product distribution, *ab initio* calculations for several key reactions representing different extents of pathways [7] and [8] were carried out. The results reported in the present study show an excellent agreement between theoretical calculations and experimental findings and provide strong evidence for thermochemical control in gas phase anion–diborane reactions.

Experimental

All experiments were carried out using an ion cyclotron resonance spectrometer of basic Varian V-5900 design extensively modified to permit routine operation in both conventional drift and trapped ion modes (8). Ion cyclotron resonance spectroscopic techniques have been described in detail elsewhere (9, 10).

Pure gaseous diborane was generated according to a modified method described by Dunbar (11) in which finely powdered KBH_4 (0.32 g) was added to 85% phosphoric acid (6 mL) which was frozen in liquid nitrogen. The reaction flask was then attached to a vacuum line, evacuated, and allowed to warm to room temperature. The B_2H_6 product was collected continuously by pumping through a dry-ice acetone trap into a liquid nitrogen trap. Mass spectrometric analysis revealed no higher boron hydrides and no other impurities.

All other chemicals were commercial materials of highest purity obtainable and were used without further purification other than degassing by successive freeze–pump–thaw cycles.

Although Dunbar (11) has reported that BH_4^- is obtained by dissociative electron impact on diborane, reaction [9], at the pressures

$$[9] \quad B_2H_6 + e^- \rightarrow BH_4^- + BH_2$$

at which our experiments were carried out the cross section for formation of BH_4^- by this mode relative to those for formations of the other anions of interest was so low that no direct production of BH_4^- was observed. Fluoride ion, F^-, was produced by dissociative electron attachment to NF_3; alkoxide ions, RO^-, were generated by dissociative attachment to alkyl nitrites, RONO; and CN^- by electron impact on cyanogen iodide, ICN. All other anions studied were generated by proton abstraction from the appropriate conjugate acid, by either F^- or CH_3O^-, reaction [10].

$$[10] \quad X^- + AH \rightarrow A^- + HX$$

Computational method

Ab initio molecular orbital calculations were carried out using the GAUSSIAN 80 program package (12). All calculations on molecules and ions were at the SCF level. All structures were fully optimized using the 4-31+G basis set described by Schleyer and co-workers (13) using an analytical gradient technique (14). The only geometric constraint imposed was freezing of rotation about the B—O bond in $CH_3OBH_3^-$ such that the ion was constrained to the most stable, staggered configuration.

The 4-31+G basis set with additional flat *s* and *p* Gaussian functions on all heavy atoms has been shown by Schleyer and co-workers (13, 14) to give a much more accurate description of energetics of anions than other split valence basis sets previously used.

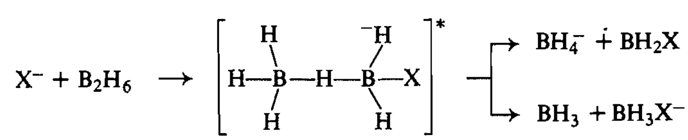
TABLE 1. Products observed for reactions of anions with diborane

BH_4^- only	BH_4^- and XBH_3^-	XBH_3^- only
CH_3O^-	F^-	CF_3^-
$C_2H_5O^-$	CH_3S^-	CF_3O^-
i-$C_3H_7O^-$		$CH_2NO_2^-$
t-$C_4H_9O^-$		CH_2CN^-
$CF_3CH_2O^-$		$CH_3CO_2^-$
		CN^-
		NO_2^-
				
		$CH_3—C\equiv C^-$

Results and discussion

The reactions of anions, X^-, with diborane can be divided into three broad categories: (*i*) those producing only BH_4^-; (*ii*) those producing both BH_4^- and XBH_3^- in varying proportions; (*iii*) those producing only XBH_3^-. The results obtained for the anions investigated in the present work are summarized in Table 1 according to these categories. Representative data are shown in Fig. 1 for reaction of CH_3O^- with B_2H_6, in Fig. 2 for reactions of F^- with B_2H_6, and in Fig. 3 for reaction of CN^- with B_2H_6.

These results suggest that the reactions of anions with B_2H_6 may be interpreted as occurring through a common, intermediate $XB_2H_6^-$ complex from which dissociation to products may occur as shown in Scheme 1. The structure of the inter-



SCHEME 1

mediate complex with a linear B—H—B bond is chosen by analogy to the $B_2H_7^-$ anion which has been shown by X-ray crystallographic (15) and *ab initio* studies (16–18) to have a symmetrical structure with a single, linear B—H—B bridge bond. The decomposition path will then depend upon the position of the central hydrogen atom in the B—H—B linkage, which, in turn, is dictated by the electronic properties of the X substituent. When X is a strongly electron donating substituent the central H will be displaced towards the boron to which X

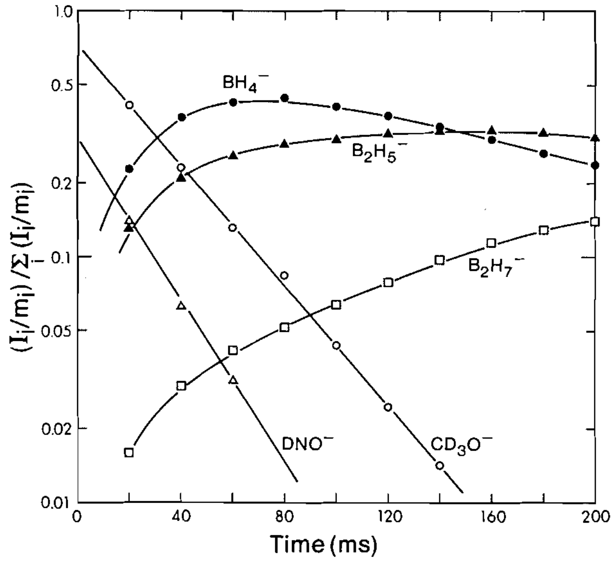


FIG. 1. Variation of relative ionic abundances with reaction time for a 2:1 mixture of CH_3ONO and B_2H_6 at total pressure of 1.5×10^{-6} Torr following a 5 ms, 70 eV electron beam pulse. Products of reactions of anions with CD_3ONO are omitted for clarity.

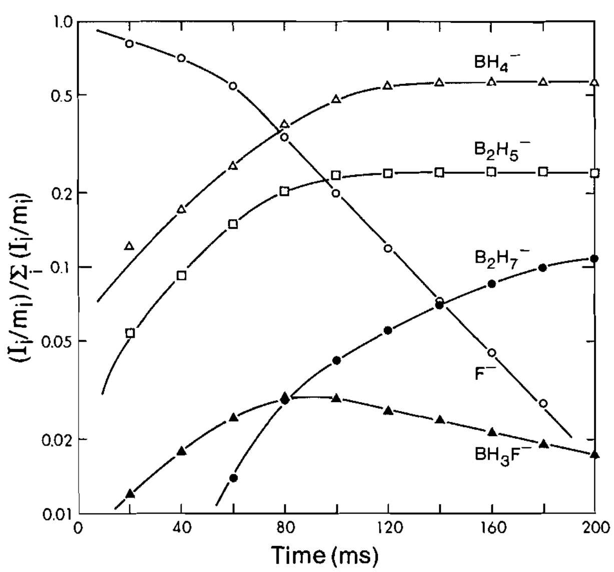

FIG. 2. Variation of relative ionic abundances with reaction time for a 3.3:1 mixture of NF_3 and B_2H_6 at a total pressure of 1.7×10^{-6} Torr following a 5 ms, 70 eV electron beam pulse.

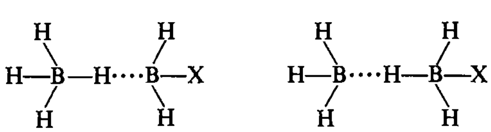
is not bound, as in **I**, thus facilitating a decomposition to produce BH_4^- and BH_2X. Conversely, when X is an electron-withdrawing group the central hydrogen atom will be displaced toward the boron to which X is bonded, as in **II**, thus favoring



I **II**

a dissociation to BH_3 and BH_3X^-. Finally, substituents which are neither intrinsically good electron-withdrawing nor donating groups will yield intermediates in which the central hydrogen atom remains close to the center of the bond, giving rise to

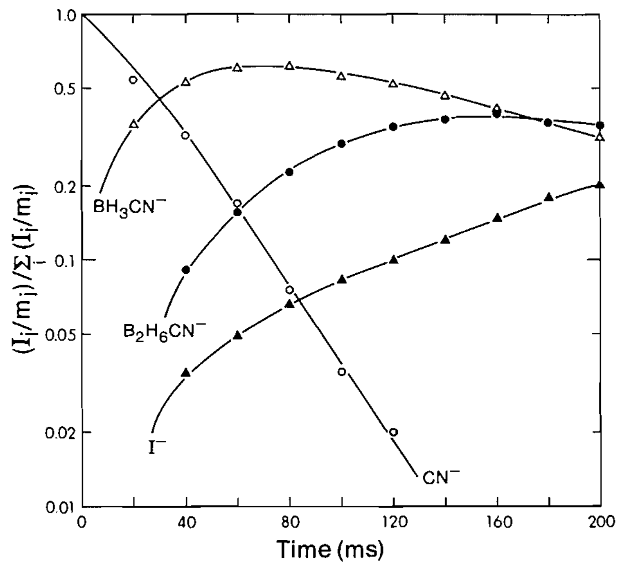


FIG. 3. Variation of relative ionic abundances with reaction time for a 1.4:1 mixture of ICN and B_2H_6 at a total pressure of 1.9×10^{-6} Torr following a 5 ms, 70 eV electron beam pulse.

a mixture of products. It is interesting to note that according to this classification F must be regarded as a more electron donating than withdrawing substituent on boron since 95% of the products of reaction of F^- are BH_4^- + BH_2F. This result is

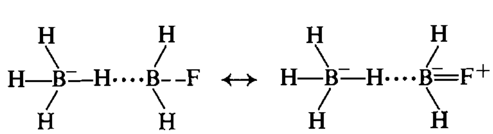
consistent with previous ICR investigations of isoelectronic gaseous carbonium ions (19, 20) which show F is a strongly stabilizing substituent by virtue of donation of F $2p$ electron density into the vacant $2p$ lobe of a carbonium ion center. The borane groups in this work are isoelectronic analogues of substituted methyl cations and it is then logical that stabilization of intermediates and products by F via $p-\pi$ donation can occur. This situation may be regarded formally as resulting from contributions from the valence bond structures **III** and **IV**.



III **IV**

It is also of interest to note the change in product distribution as the degree of charge delocalization is varied in a series of similar substituents. For example, the CH_3O^- ion yields only BH_4^- as a product ion whereas the CF_3O^-, in which negative charge is dispersed by inductive withdrawal through the σ framework of the molecule, yields only $CF_3OBH_3^-$. Similarly, a comparison of acetaldehyde, acetone, and trifluoroacetone enolates and acetate ion reveals that the least delocalized species, $HCOCH_2^-$, produces over 90% BH_4^- while the more delocalized, $CH_3COCH_2^-$, yields 70% BH_4^- and 30% $CH_3COCH_2BH_3^-$. As the degree of negative charge delocalization increases still further in $CF_3COCH_2^-$ and $CH_3CO_2^-$, no BH_4^- is observed and only XBH_3^- product is formed.

The factors affecting the stability of the intermediate complexes also apply to the product species and thus the competition between the two reactions might be regarded as the result of thermodynamic control. The three different situations may be represented by the three reaction coordinate diagrams shown in Fig. 4. In every case formation of both sets of products is exothermic; however, when there is a large difference in

exothermicity of formation of the two sets of products the more stable products are formed virtually exclusively (Fig. 4*a* and 4*b*). Conversely, when the exothermicities of both reactions are comparable (Fig. 4*c*) both pairs of products are produced, with the slightly more energetically favored pathway giving rise to somewhat more product.

In order to investigate this possibility of thermochemical control of the product distribution high quality *ab initio* calculations were carried out for products of reaction of CH_3O^-, F^-, and CN^-. These anions are representative of each of the three possible situations above. The optimized geometries of each of the possible ionic and neutral products are summarized in Table 2. The total energies obtained using the 4-31+G basis set and optimized geometries are listed in Table 3. The degree to which thermodynamic control operates in these reactions is seen most easily from an examination of the isodesmic hydride transfer reaction, eq. [11]. Energy changes for each of the situations

$$[11] \quad XBH_3^- + BH_3 \rightarrow BH_4^- + XBH_2$$

examined are shown in Table 4. As expected, when the enthalpy change for reaction [11] is large and negative as for CH_3O^-, reaction [7] producing exclusively BH_4^- is the only reaction observed. When the enthalpy change for reaction [11] is large and positive, as for CN^-, reaction [8], producing exclusively BH_3CN^-, is the only reaction observed. However, when the enthalpy change for reaction [11] is relatively small and either positive or negative both possible products might be expected. This situation is illustrated by the reaction of F^- with B_2H_6 where both BH_4^- (95%) and BH_3F^- (5%) are produced. According to the calculations at the 4-31+G level production of BH_3F^- is found to be 2.9 kcal mol^{-1} more energetically favorable than BH_4^- production. Thus from the *ab initio* results a *reverse* order of product abundances would have been predicted. This is most likely a consequence of slight deficiencies of the 4-31+G basis set which lead to a poorer representation of fluorine-containing neutrals relative to anions. As can be seen from the data in the Appendix the 6-31G* basis set predicts a B—F bond length of 1.29 Å in BH_2F while our 4-31+G calculations yield a B—F bond length of 1.36 Å. In order to test this possibility the energy change for the isodesmic reaction [11] where X = F was also determined at the 6-31G* level and BH_4^- was found to be slightly favored as the ionic product. In

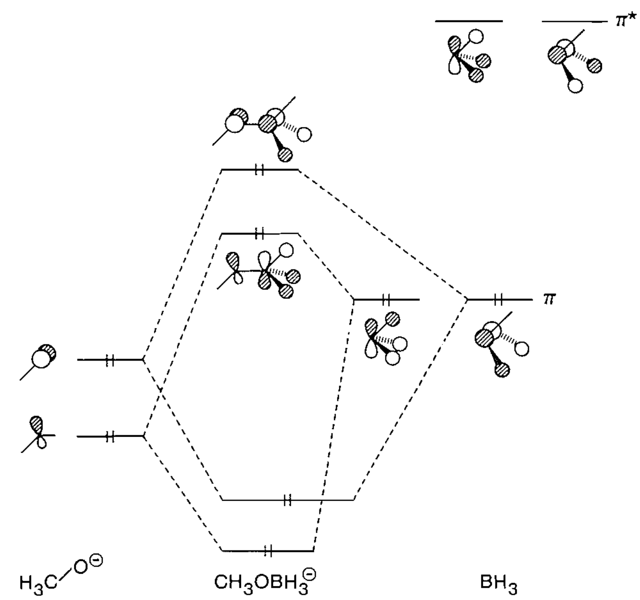

FIG. 5. Orbital interactions between CH_3O^- and the BH_3 fragment in $CH_3OBH_3^-$. Only those orbitals contributing to the destabilization of species are illustrated.

the absence of experimental data for the geometry of BH_2F it is not possible to say which basis set more adequately describes BH_2F; however, our experimental data clearly show that BH_4^- is the more energetically favorable product. In cases such as this where the energetic difference between possible products is very small it thus seems likely that *ab initio* calculations will have difficulty in determining the more stable products. It is important to note that in all cases *ab initio* calculation predicts that production of *both* sets of products is exothermic. These results are thus clear evidence of the importance of thermodynamic control in determination of product distribution in the reaction of anions with diborane.

An alternative method of analysing the above ion molecule reactions is to examine the orbital interactions stabilizing or destabilizing all possible products. The inspection of the anionic products listed in Table 1 shows that we can discriminate between the two types of BH_3X^- anions: those in which BH_3 fragment is linked to a non-stabilized anion with high energy orbitals (example, —OCH_3) and those in which BH_3 is attached to an anion possessing the low-lying empty orbitals.

An examination of the interactions between BH_3 and X^- fragments in the BH_3X^- anions shows that the BH_3 group contains a degenerate set of π_{BH_3} and $\pi^*_{BH_3}$ orbitals (Fig. 5). The latter set (π^*) is of high energy due to the low electronegative character of the boron atom, and consequently may be neglected. Thus, the only interactions of importance are those between the π_{BH_3} and the occupied and empty orbitals of X^- fragment.

When X^- has a *high energy HOMO and no accessible LUMO* orbitals as is the case of CH_3O^-, the interaction of X^- with BH_3 leads to a four electron repulsion between the two fragments. Such a limiting case is illustrated by the $CH_3OBH_3^-$ anion as shown in Fig. 5. Here, the methoxy anion has three lone pairs, one of which is implicated in the σ bonding with BH_3. The remaining two interact in an antibonding fashion with symmetry compatible π_{BH_3} orbitals (Fig. 5). On the other hand, if X^- is characterized by low-lying occupied orbitals, as well as *low-lying empty* orbitals, for example CN^- or NO_2^-, the

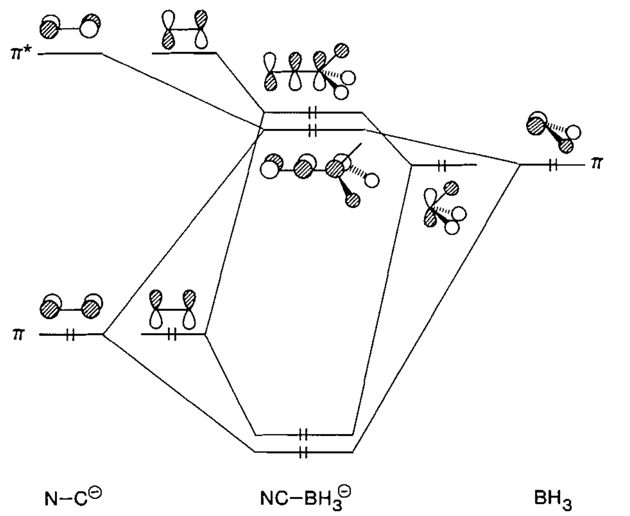

FIG. 6. Orbital interactions between CN^- and the BH_3 fragment in $NCBH_3^-$. Only those orbitals contributing to the stabilization and destabilization of the species are illustrated.

TABLE 5. Energies of the highest occupied molecular orbitals (HOMO) of the calculated XBH_3^- anions

Anion XBH_3^-	HOMO ϵ(au)
HBH_3^-	−0.19001
$NCBH_3^-$	−0.22265
FBH_3^-	−0.20029
$CH_3OBH_3^-$	−0.16315

effect of the four electron repulsion is minimal, while the system is stabilized by the two electron interaction between π_{BH_3} and the LUMO of the anionic fragment (Fig. 6).

The above analysis is confirmed by the relative energy levels of the highest occupied molecular orbitals (HOMO) of the calculated anions listed in Table 5. The highest HOMO (Fig. 5, Table 5) is found in the most destabilized species — $CH_3OBH_3^-$, while the $NCBH_3^-$, the most stabilized anion, possesses a low-lying HOMO (Fig. 6, Table 5). The HOMO of our reference anion BH_4^- is situated in-between those two extreme cases. This illustrates the absence of the stabilizing or destabilizing effects in the BH_4^- anion.

The stability of the neutral species (XBH_2) is the result of the electronic back donation from the occupied orbital of X fragment into the empty orbital of BH_2 fragment. The magnitude of this effect is related to the energy level of the occupied orbital of the X group and consequently is larger for CH_3OBH_2 than for $NCBH_2$.

The above orbital considerations also correspond closely to the gas-phase, ion–molecule reaction results shown in Table 1. Alkoxides, thiolates, and fluoride ion, characterized by high energy lone pair and inaccessible empty orbitals yield predominantly XBH_2 and BH_4^- products. On the other hand, the strongly stabilized anions such as CF_3O^-, cyclopentadienyl, and trifluoro acetone enolate which possess low-lying orbitals give XBH_3^- and BH_3 as products. In between those two extremes lie enolates, benzyl, and the slightly less stabilized anions such as $(CH_3)_2FSiCH_2^-$.

Conclusion

The experimental results presented above show that two possible competitive reaction channels exist for reactions of anions with diborane. The uniformity of these reaction pathways suggests that both reactions occur via a common $XB_2H_6^-$ complex reaction intermediate. The *ab initio* calculations performed reveal that the relative stabilities of the two possible products controls the reaction channel. This conclusion is further supported by considerations of the electronic donating and withdrawing properties of various substituent groups X and considerations of orbital interactions betwen X^- and BH_3. This, and similar studies, reveal the tremendous value to be gained from the parallel investigation of gas phase ion molecule reactions by both experimental and *ab initio* methods.

Appendix

Geometries

Since these are the first calculations of which we are aware employing the 4-31+G basis set on the species described here, it is of some interest to compare the geometries obtained with results using other basis sets.

1. BH_3. The B—H bond length is found to vary 1.16 Å (STO-3G) to 1.22 Å in a double zeta quality calculation (21–23). At the 6-31G** level the B—H bond length was found to be 1.1822 Å (24), in excellent agreement with the present value of 1.1836 Å.

2. BH_4^-. The borohydride ion, BH_4^-, has received a great deal of theoretical attention. Experimental results show a B—H bond length of 1.25 Å. Calculations at the 4-31G* level give 1.239 Å (25) and at the 6-31G level a value of 1.247 Å (26). Our value of 1.200 Å is thus in good agreement.

3. BH_2F. At the 6-31G* level the B—F bond length in BH_2F is found to be 1.293 Å (21, 23) while the present 4-31+G calculations yield 1.362 Å. Differences are also noted in the H—B—F bond angle 121.0° at the 6-31G* level and 117.3° at the 4-31+G level.

4. BH_3F^-. In BH_3F^-, as expected, the B—F bond length is considerably lengthened relative to BH_2F. At the 4-31G level the B—F bond length is 1.482 Å (25) while at the 4-31+G level 1.517 Å is found. B—H bond lengths for BH_2F and BH_3F^- are similar for all basis sets. This suggests that the B—F bond is very sensitive to the basis set used. In the absence of any experimental data for BH_3F^- it is not possible to determine which basis set provides the best description of B—F bonding.

5. BH_2CN and BH_3CN^-. Recently Marynick and co-workers (27) have carried out calculations using the 4-31G basis set for BH_3CN^- and its isomer BH_3NC^-. They found BH_3CN^- to be the more stable species and obtained a partially optimized geometry in good agreement with our present fully optimized geometry. To our knowledge no calculations on BH_2CN have been carried out. As expected the B—C bond length in the neutral molecule is shorter than that in the anion.

6. CH_3OBH_2 and $CH_3OBH_3^-$. No previous studies of either of these species could be found, however, a comparison to the corresponding hydroxy derivatives is of interest. Both BH_2OH (21, 23) and the BH_2OC— fragment are found to be planar. A staggered configuration in the CH_3 group was assumed. The B—O bond length in BH_2OH was found to be 1.334 Å (23) in good agreement with that found here for CH_3OBH_2 of 1.355 Å. The B—H bonds in CH_3OBH_2 were found to be slightly longer than those in BH_2OH. Calculations at the 4-31G level give a B—O bond length in BH_3OH^- of 1.522 Å, in exact accord with that found here for $CH_3OBH_3^-$.

The influence of a base on the methylation of aminoalcohols

CHOJI KASHIMA,[1] KAZUO HARADA, AND YOSHIMORI OMOTE

Received May 14, 1984

This paper is dedicated to Professor Peter Yates on the occasion of his 60th birthday

CHOJI KASHIMA, KAZUO HARADA, and YOSHIMORI OMOTE. Can. J. Chem. **63**, 288 (1985).

A selective methylation towards N and O atoms on aminoalcohols was observed using metal hydride reagents as the base, and the predominant factors for the selectivity were investigated in detail.

CHOJI KASHIMA, KAZUO HARADA et YOSHIMORI OMOTE. Can. J. Chem. **63**, 288 (1985).

Lorsqu'on utilise des hydrures métalliques comme bases, on observe une sélectivité de la réaction de méthylation pour les sites N et O d'amino-alcools. On a étudié en détail les facteurs prépondérants qui déterminent cette sélectivité.

[Traduit par le journal]

We reported previously on the selective alkylation towards N and O atoms of hydroxylamine in the presence of various bases (1). Here, in relation to the above, the methylation of aminoalcohols, which are the methylene analogues of hydroxylamine, was carried out using metal hydride reagents such as NaH, LiH, and CaH_2, and a selectivity in the methylation towards N and O atoms was observed.

The methylation of aminoalcohols was carried out as shown in Scheme 1. To a THF solution of the aminoalcohols, a molar equivalent amount of NaH, LiH, or CaH_2 was added and stirred at room temperature for an hour. To this mixture, a molar equivalent amount of dimethyl sulfate was added and stirred for another hour. After usual work-up, the yields were determined by means of gas chromatography. In the case of methyl iodide as the electrophile, the yields were generally lower.

The methylation of 2-aminoethanol (**1***a*) using NaH led mainly to O-methylated products (**4***a*, **5***a*, and **6***a*), while the use of LiH and CaH_2 led exclusively to N-methylated products (**2***a* and **3***a*) (Scheme 1, Table 1). The stirring with supersonic vibration, the higher reaction temperature, the use of various amounts of the base, the concentration of the substrates, and the polarity of the solvent were all ineffective in the selectivity of the methylation.

In order to clarify the predominant factor controlling the selectivity, the ability of the lithium cation to form a complex with aminoalcohols was measured by ^{7}Li nmr (2). 2-Aminoethanol (**1***a*), which possesses an ethyl alcohol moiety and an ethylamine moiety intramolecularly, was added to an ethanol solution of lithium ethoxide, and the signal of lithium ethoxide was shifted downfield. On the other hand, no remarkable shift could be observed in a mixture of lithium ethoxide and diethylamine, where an alcohol moiety and an amine moiety exist intermolecularly. These data suggested the formation of complexes due to the chelation between the aminoalcohol and the lithium cation. Similarly, 3-aminopropanol (**2***a*), 5-aminopentanol (**7**), and the N- and O-methylated derivatives of 2-aminoethanol (**2***a*–**6***a*) caused the downfield shifts summarized in Table 2. From Table 2, the magnitude of the shift was largest in 2-aminoethanol and decreased by the introduction of methyl groups on **1***a*, especially on the O atom. However, 1-phenyl-1,3-butanedione (**8**), where the stability constant (log *K*) of its lithium complex is reported to be 5.95 (3), showed a very large downfield shift. Therefore, even in the case of 2-aminoethanol, the complexation should be a very weak one.

TABLE 1. Methylation of 2-aminoethanol (**1***a*)

$$NH_2CH_2CH_2OH + Me_2SO_4 \xrightarrow{\text{Base}}$$

	Conv. (%)	N-Me:O-Me*
NaH	69	4:96
LiH	53	100:0
CaH_2	64	100:0
MeLi	66	100:0
MeMgI	65	100:0
No base	60	100:0

*The ratios of (**2***a* + **3***a*):**4***a* are shown.

The ratio of N-methylated products (**2***b* and **3***b*) to the O-methylated product (**4***b*) in ther methylation reaction of 3-aminopropanol (**1***b*) by the use of NaH, LiH, and CaH_2 were 23:77, 100:0, and 100:0, respectively (Scheme 1, Table 3). Next, the methylation of an equimolar mixture of 2-phenylethylamine (**9**) and 2-phenylethanol (**10**) (Scheme 2), where the influence of chelation is excluded, was carried out by the use of equimolar amounts of dimethyl sulfate. The ratios of N-methylated products (**11** and **12**) to O-methylated products (**13**) using NaH, LiH, and CaH_2 were 37:63, 100:0, and 100:0, respectively (Table 3). These results are very similar to those of the 2-aminoethanol (**1***c*) (Table 1), indicating that the complexation does not take part in the selective methylation.

Furthermore, the amount of hydrogen released in the methylation of 2-aminoethanol (**1***a*) in the presence of a metal hydride was measured, and the results are shown in Fig. 1. When NaH was used as the base, on addition of 2-aminoethanol (**1***a*) to the hydride, a vigorous evolution of hydrogen was observed simultaneously, and no hydrogen was released on addition of dimethyl sulfate. On the contrary, in the case of LiH and CaH_2, hydrogen was released only after the addition of dimethyl sulfate.[2] That is, although NaH reacted vigorously with 2-aminoethanol (**1***a*) to form aminoalkoxide anion, the reaction of LiH and CaH_2 with 2-aminoethanol (**1***a*) did not seem to occur at all. Since alkyllithiums are homogeneous and much

more active as lithiating reagents, the formation of aminoalkoxide was attempted using methyllithium as the base. Actually, a drastic reaction occurred by the treatment of 2-aminoethanol (**1***a*) with methyllithium accompanied by temperature elevation and gas evolution. However, the ratio for the N- and O-methylated products in this reaction was very similar to that of LiH (Table 1).

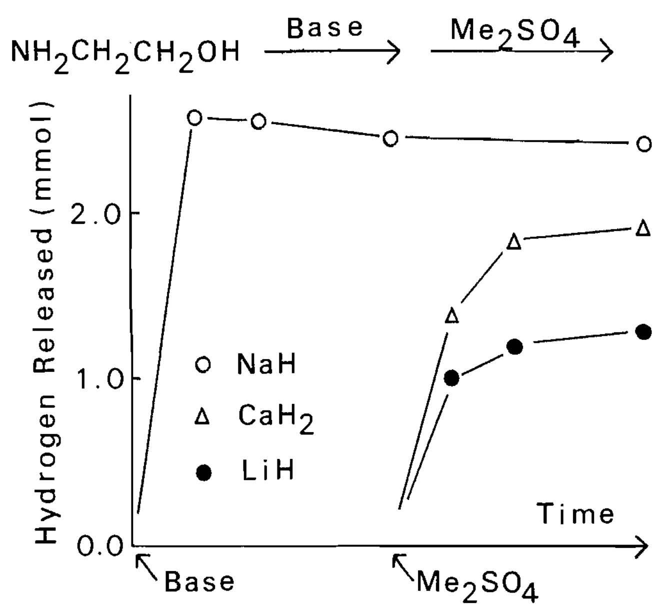

FIG. 1. Hydrogen released in the methylation of 2-aminoethanol (**1***a*).

The results of the methylation reactions, using hydride reagents alone, may be interpreted simply as the difference in basicity of the hydride reagents (4). However, in the methylation reactions using MeLi and MeMgI, gas evolution similar to the case of NaH was observed, while the product ratio resembled that of LiH. Therefore at the present stage no consistent explanation which stands for all the above results can be proposed. However, it is very interesting that NaH and LiH showed such a remarkable difference in selectivity in the methylation reaction.

Experimental

Methylation of aminoalcohols with metal hydrides

To a solution of the aminoalcohol (4 mmol) in 5 mL of THF, a molar equivalent amount of NaH, LiH, or CaH_2 was added and stirred at room temperature for 1 h. To this mixture a molar equivalent amount of dimethyl sulfate or methyl iodide was added and stirred for another hour. The reaction was quenched with ethanol, and an aqueous 10% sodium hydroxide solution was added in the case of 2-aminoethanol. The yields were determined by gas chromatography on a Shimadzu GC-4CM gas chromatograph using *N,N*-dimethylaniline as an internal standard. 10% PEG 20M and 5% KOH on Celite 545 was used as the stationary phase, and the column temperature was raised from 60 to 150°C at 10°/min.

Methylation of ethanolamine with methyl lithium and methyl magnesium iodide

A THF solution of ethanolamine (10 mmol) was added dropwise to a molar equivalent amount of MeLi or MeMgI in ether, which was accompanied by vigorous gas evolution. After stirring at room temperature for 2.5 h, a molar equivalent amount of dimethyl sulfate in THF was added and stirred for another 1.5 h. The reaction was quenched first with ethanol, and next with a 10% aqueous sodium hydroxide solution. The yields were determined by gas chromatography as described above.

*Measurement of the hydrogen released in the methylation of 2-aminoethanol (**1**a)*

The metal hydride (4 mmol) was placed in a flask fitted with a gas burette. A solution of 2-aminoethanol (**1***a*) (4 mmol) in 7 mL of THF was added and stirred at room temperature for 30 min. Next, a solution of dimethyl sulfate (2 mmol) in 3 mL of THF was added and stirred for another 30 min. As a control experiment, the above procedure was carried out in the absence of 2-aminoethanol (**1***a*). The amount of hydrogen released was measured by a gas burette with time, and the values were plotted as shown in Fig. 1.

Measurements of ^{7}Li nuclear magnetic resonance

The ^{7}Li nmr measurements were carried out on a JEOL-100 spectrometer at 30°C employing a D-lock to avoid any slight magnetic field drifts. The chemical shift measurements were made in spinning 10-mm tubes, and a solution of lithium chloride in D_2O was used as an external standard. The samples were prepared by addition of a molar equivalent of the substrate to an ethanol solution of lithium ethoxide (0.25 mmol of lithium hydride/mL of dry ethanol). The $\Delta\delta$ values shown in Table 2 are the differences in the chemical shifts of the samples and those of lithium ethoxide. Since all substrates exhibited a downfield shift based on the chemical shift of lithium ethoxide, the downfield direction was specified as plus.

Brown algal polyphenols: synthesis of "fucophlorethol A" octamethyl ether (2,2′,4,6,6′-pentamethoxy-4′-(2,4,6-trimethoxyphenoxy)biphenyl)

Mark A. Ragan

Atlantic Research Laboratory, National Research Council of Canada, 1411 Oxford Street, Halifax, N.S., Canada B3H 3Z1

Received February 27, 1984

Mark A. Ragan. Can. J. Chem. **63**, 291 (1985).

Vanadium tetrachloride-catalyzed dimerization of 3,5-dimethoxyphenol yields the key intermediate 2,2′,6,6′-tetramethoxy-4,4′-dihydroxybiphenyl, from which the octamethyl ether of the brown algal metabolite "fucophlorethol A" (2,2′,4,6,6′-pentamethoxy-4′-(2,4,6-trimethoxyphenoxy)biphenyl, **6**) is synthesized by Ullmann condensation and Hakomori methylation.

Mark A. Ragan. Can. J. Chem. **63**, 291 (1985).

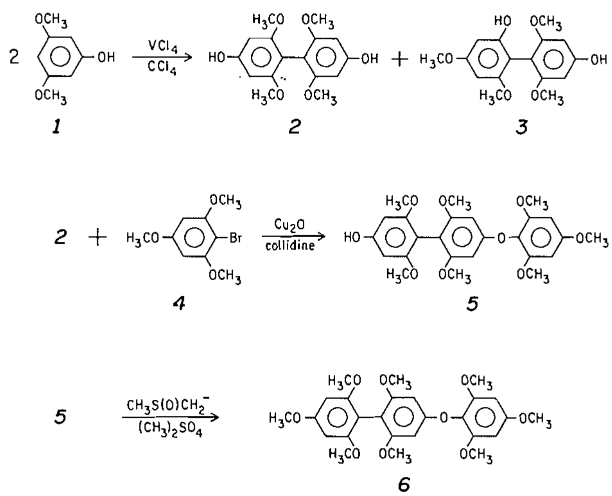
La dimérisation du diméthoxy-3,5 phénol, catalysée par la tétrachlorure de vanadium, conduit au tétraméthoxy-2,2′,6,6′ dihydroxy-4,4′ biphényle, un intermédiaire clé à partir duquel on a synthétisé, par une condensation de Ullmann et une méthylation de Hakomori, l'éther octaméthylique du "fucophloréthol A" (pentaméthoxy-2,2′,4,6,6′ (triméthoxy-2,4,6 phénoxy)-4′ biphényle, **6**), un métabolite extrait d'algues brunes.

[Traduit par le journal]

Introduction

Marine brown algae (class Phaeophyceae) accumulate large quantities of polyphenolic materials which may help protect the alga against predators or epiphytes (1). Most of these materials exist as intermediate-molecular weight "oligomers" (mol. wt. $\approx 10^3-10^4$) and high-molecular weight "polymers" (mol. wt. $\geq 10^4$) based on phloroglucinol (2–6); low-molecular weight congeners such as phloroglucinol itself, "dimers" (e.g. 2,2′,4,4′,6,6′-hexahydroxybiphenyl and 2,3′,4,5′,6-pentahydroxybiphenyl ether), "trimers", etc. (7, 8) are usually present in much smaller amounts. In Nova Scotian *Fucus vesiculosus* L., the "trimeric" polyphloroglucinol fraction consists almost exclusively of 2,2′,4,6,6′-pentahydroxy-4′-(2,4,6-trihydroxyphenoxyl)biphenyl (9), which has been given the trivial name "fucophlorethol A" (10).

Until now no synthesis has been reported for fucophlorethol A, nor for its isomer fucophlorethol B (8, 10) or for higher congeners (8, 10) in the fucophlorethol series. The commercial availability of bromo-2,4,6-trimethoxybenzene (**4**) made it appealing to approach the problem as an Ullmann ether synthesis (condensing **4** with 2,2′,6,6′-tetramethoxy-4,4′-dihydroxybiphenyl (**2**); see diagram), thereby taking advantage of the relatively low yields of the Ullmann ether reaction (11) to limit 4,4′-diphenoxy ether formation. Synthesis of **2** was more problematic; the Ullmann biaryl synthesis (by far the best standard procedure for forming 2,2′,6,6′-tetrasubstituted biphenyls) is incompatible with free or lightly protected 4,4′-hydroxyl groups, while biaryl syntheses based on Kharasch reactions (12, 13), the Wurtz reaction (14), organothallium intermediates (15), organoboranes (16), or various transition metal complexes (reviewed briefly in ref. 17) may have the same limitation and (or) fail to produce 2,2′,6,6′-tetrasubstituted products in significant yield.



On the other hand, reports of VCl_4- or $VOCl_3$-catalyzed dehydrodimerization predominantly in the *para* position of unprotected phenols (18, 19), including the production in one instance of 2,2′-dihydroxybinaphthyl (19), suggested that **2** might be directly synthesized by treating the commercially available 3,5-dimethoxyphenol (**1**) with VCl_4 or $VOCl_3$. The three-step synthesis of **6** reported herein should serve as a pattern for eventual synthetic approaches to the "tetrameric" fucodiphlorethol A and the higher homologues.

Experimental

Electron impact mass spectra were recorded, and accurate mass determination made by peak-matching with ions of perfluorokerosene, on a Dupont-CEC 21-110B instrument. The ^{1}H nmr and ^{13}C nmr spectra were recorded on Varian HA-100 and FT-80 spectrometers respectively. Elemental analyses were performed by Mikroanalytisches Laboratorium (Bonn, FRG) and Microanalysis Laboratories Ltd. (Markham, Ont.).

2,2′,6,6′-Tetramethoxy-4,4′-dihydroxybiphenyl (2) and 2,2′,4,6′-tetramethoxy-4′,6-dihydroxybiphenyl (3)

3,5-Dimethoxyphenol (**1**) (6.16 g, 40 mmol; Aldrich) was dissolved in CCl_4 (50 mL) under N_2 in a 500-mL 3-necked flask. VCl_4 (6.5 mL, 62 mmol; Alfa/Ventron) was added with stirring during 5 min, and the reaction mixture was stirred under N_2 at ≈25°C for 1 h.[2] Then 2 *N* aqueous H_2SO_4 (100 mL) was added, and the mixture was stirred vigorously under N_2 for 10 min (19). Partitioning between the acidic aqueous phase and $CHCl_3$ (75 mL) gave a yellow-brown organic layer,

[1]NRCC No. 23425.

[2]**CAUTION!** VCl_4 is toxic and corrosive. Use an efficient fume hood, and wear strong plastic-covered gloves and apron (VCl_4 attacks neoprene). VCl_4 is moisture sensitive. Spills may be neutralized with water. Physical data: see ref. 20.

a turquoise aqueous layer, and a water-insoluble, acetone-soluble precipitate. Thin-layer chromatography (tlc) on silica gel (75:20:5 by vol. hexane$-CH_2Cl_2-$isopropanol) revealed two major products, the more abundant (R_f 0.31) occurring in high concentration in the acetone-soluble precipitate, the less abundant (R_f 0.43) present in similar concentrations in both the precipitate and the $CHCl_3$ extract. Silica gel column chromatography (gradient 82:15:3 to 75:20:5 by vol. hexane$-CH_2Cl_2-$isopropanol) yielded the R_f 0.31 isomer (**2**; 512 mg) and the R_f 0.43 isomer (**3**; 133 mg).

2,2′,6,6′-Tetramethoxy-4,4′-dihydroxybiphenyl (2)

Crystallization from acetone gave colourless prisms, mp (cap., uncorr.) 285.0–291.0°C (dec.); ^{1}H nmr (acetone-d_6) δ: 6.14 (4H, ring H), 3.56 (12H, 2,2′,6,6′-OMe) ppm; ^{13}C nmr (acetone-d_6) δ_C: 160.3 (m; C-2,2′,6,6′), 158.8 ($^2J_{CH}$ ≈4 Hz, t; C-4,4′), 105.3 (poorly relaxed; C-1,1′), 93.2 ($^1J_{CH}$ = 157.8 Hz, d; $^3J_{CH}$ = 4.5 Hz, d; C-3,3′,5,5′), 55.8 ($^1J_{CH}$ = 143.1 Hz, q; 2,2′,6,6′-OMe) ppm; ms (250°C): 307.1139 ± 0.0009 (18%; required for $^{12}C_{15}{}^{13}CH_{18}O_6$, 307.1136), 306.1096 ± 0.0009 (M^+; 100%; required for $C_{16}H_{18}O_6$, 306.1103), 260 (18%), 167 (38%), 154 (13%), 153 (11%), 107 (11%), 69 (27%). *Anal.* calcd.: C 62.74, H 5.92, O 31.34; found: C 62.63, H 6.34, O 31.2.

2,2′,4,6′-Tetramethoxy-4′,6-dihydroxybiphenyl (3)

Crystallization from acetone or methanol gave tiny colourless prisms, mp (cap., uncorr.) 211.0–212.5°C; ^{1}H nmr (acetone-d_6) δ: 6.16 (2H; 3′,5′-H), 6.09 (2H; 3,5-H), 3.75 (3H, 4-OMe), 3.60 (9H; 2,2′,6′-OMe) ppm; ^{13}C nmr (acetone-d_6) δ_C: 161.4 (m; C-2), 160.7 (m; C-2′,6′), 160.4 ($^2J_{CH}$ ≈4? Hz, t; C-4), 159.6 ($^2J_{CH}$ ≈4.2 Hz, t; C-4′), 157.2 (m; C-6), 104.3 (poorly relaxed; C-1′), 102.8 (poorly relaxed; C-1), 94.3 ($^1J_{CH}$ ≈160 Hz, d; $^3J_{CH}$ poorly resolved d; C-3), 93.3 ($^1J_{CH}$ = 158.3 Hz, d; $^3J_{CH}$ = 4.7 Hz, d; C-3′,5′), 91.5 ($^1J_{CH}$ = 158.4 Hz, d; $^3J_{CH}$ = 5.2 Hz, d; C-5), 55.8 ($^1J_{CH}$ = 143.5 Hz, q; 2′,6′-OMe and 2-OMe), 55.3 ($^1J_{CH}$ = 143.5 Hz, q; 4-OMe) ppm; ms (195°C): 307.1139 ± 0.0009 (21%; required for $^{12}C_{15}{}^{13}CH_{18}O_6$, 307.1136), 306.1102 ± 0.0009 (M^+; 100%; required for $C_{16}H_{18}O_6$, 306.1103), 275 (12%), 260 (11%), 245 (12%), 167 (14%), 69 (22%). *Anal.* calcd.: C 62.74, H 5.92, O 31.34; found: C 61.45, H 5.99, O 31.35.

2,2′-6,6′-Tetramethoxy-4-hydroxy-4′-(2,4,6-trimethoxyphenoxy)biphenyl (5)

Bromo-2,4,6-trimethoxybenzene (**4**) (432 mg, 1.75 mmol), **2** (269 mg, 0.88 mmol), and dry Cu_2O (800 mg) were added to collidine (5 mL) in a 10-mL flask. Dry N_2 was bubbled through the suspension, then the mixture was heated to reflux for 44.5 h under N_2 (cf. ref. 12). The mixture was cooled, acidified (concentrated HCl – ice), and organic products were extracted into diethyl ether (3×) and ethyl acetate (3×), concentrated under N_2, and dried over Na_2SO_4. Vacuum sublimation at increasing temperatures yielded 1,3,5-trimethoxybenzene (≈10% of recovered organic matter), **4** (≈55%), **2** (≈15%), a major product (≈15%) having R_f 0.52 on silica gel (75:20:5 by vol. hexane$-CH_2Cl_2-$isopropanol), and numerous minor products (Σ ≈5%) including brominated (M^+ 384, 386) and dibrominated (M^+ 462, 464, 466) derivatives of **2**, a brominated derivative of **5** (M^+ 550, 552), a compound with M^+ 638 (presumably 2,2′,6,6′-tetramethoxy-4,4′-di(2,4,6-trimethoxyphenoxy)biphenyl), and its brominated derivative(s) (M^+ 716, 718). The R_f 0.52 material (**5**) was further purified by preparative silica gel tlc (Whatman PLK5F), and was crystallized from acetone + methanol. Yield isolated after three crystallizations, 15 mg (3.6% based on **2**); mp (biref. stage) 256.0–258.8°C; ^{1}H nmr (acetone-d_6) δ: 6.37 (2H; 3″, 5″-H), 6.15 (2H; 3,5-H), 6.09 (2H; 3′,5′-H), 3.83 (3H; 4″-OMe), 3.78 (6H; 2″,6″-OMe), 3.57 (6H; 2,6-OMe), 3.51 (6H; 2′,6′-OMe) ppm; ^{13}C nmr (acetone-d_6) δ_C: 160.8 (C-4′), 160.2 (C-2,6), 160.1 (C-2′,6′), 159.0 and 158.8 (C-4 and C-4″), 155.0 (C-2″,6″), 126.8 (poorly relaxed; C-1″), 105.0 (poorly relaxed; C-1 and C-1′), 93.2 (C-3,5), 92.8 (C-3′,5′?), 92.7 (C-3″,5″?), 56.4 (2″,6″-OMe?), 56.0 (2,6-OMe?), 55.8 (2′,6′-OMe? and 4″-OMe) ppm; ms (190°C): 473.1752 ± 0.0015 (23%; required for $^{12}C_{24}{}^{13}CH_{28}O_9$, 473.1766), 472.1735 ± 0.0015 (M^+; 100%; required for $C_{25}H_{28}O_9$, 472.1733), 303 (54%), 183 (13%), 155 (10%).

2,2′,4,6,6′-Pentamethoxy-4′-(2,4,6-trimethoxyphenoxy)biphenyl (fucophlorethol A octamethyl ether; 6)

Thrice-crystallized **5** (14 mg, ≈0.03 mmol) was dissolved in dry, redistilled DMSO (0.3 mL) under Ar. Sodium methylsulfinylcarbanion (22) was prepared from NaH (1.0 g of 80% dispersion in oil; BDH) and dry, redistilled DMSO (14 mL) under Ar by the method of Sjöberg (23), and 0.04 mL (0.06 mequiv.) was added under Ar to the solution of **5**. After 10 min of stirring, $(CH_3)_2SO_4$ (ca. 0.01 mL) was added; thereafter a white insoluble material formed in the reaction vessel. Additions of base (0.04 mL) and of $(CH_3)_2SO_4$ (≈0.01 mL) were repeated at 50 and 60 min, respectively. After a total of 270 min, the product was partitioned between CH_2Cl_2 and H_2O and, after further washings with H_2O, the organic phase was dried. Crystallization from absolute ethanol gave thin, elongated platelets, mp (biref. stage) 205.0–207.5°C. Yield isolated after three crystallizations, 96%; ^{1}H nmr ($CDCl_3$) δ: 6.22 (2H) and 6.21 (2H) (3,5-H and 3′,5′-H), 6.17 (2H; 3″,5″-H), 3.83 (3H) and 3.82 (3H) (4- and 4″-OMe), 3.80 (6H; 2″,6″-OMe), 3.68 (6H; 2,6-OMe), 3.60 (6H; 2′,6′-OMe) ppm; ^{13}C nmr ($CDCl_3$) δ_C: 160.5 ($^2J_{CH}$ ≈4 Hz, t; C-4′), 159.8 ($^2J_{CH}$ ≈5 Hz?, t; C-4), 159.2 (m; C-2,6), 159.0 (m; C-2′,6′), 157.6 ($^2J_{CH}$ ≈4.5 Hz, t; C-4″), 154.0 (m; C-2″,6″), 126.3 ($^2J_{CH}$ ≈8 Hz, t; C-1″), 105.5 and 105.4 (poorly relaxed; C-1 and C-1′), 92.2 ($^1J_{CH}$ = 159.8 Hz, d; $^3J_{CH}$ ≈5 Hz, d; C-3′,5′), 91.9 ($^1J_{CH}$ ≈159 Hz, d; $^3J_{CH}$ ≈5 Hz, d; C-3″,5″), 91.6 ($^1J_{CH}$ = 158.7 Hz, d; $^3J_{CH}$ ≈5 Hz, d; C-3,5), 56.3 ($^1J_{CH}$ = 144.4 Hz, q; 2″,6″-OMe), 56.2 ($^1J_{CH}$ = 143.3 Hz, q; 2,6-OMe), 56.0 ($^1J_{CH}$ = 143.6 Hz, q; 2′,6′-OMe), 55.5 q; 4-OMe) ppm (7); ms (145°C): 487.1917 ± 0.0015 (26%; required for $^{12}C_{25}{}^{13}CH_{30}O_9$, 487.1923), 486.1884 ± 0.0015 (M^+; 100%; required for $C_{26}H_{30}O_9$, 486.1890), 317 (16%). *Anal.* calcd.: C 64.19, H 6.21; found: C 64.15, H 6.07.

Assignments of ^{13}C nmr signals were made in the following manner: comparison of ^{13}C chemical shifts in **1** and 1,3,5-trimethoxybenzene allowed the effect of replacing one —OMe by —OH in this system to be calculated (*ipso*, +4.1 ppm; *ortho*, −1.6 ppm; *meta*, +0.1 ppm; *para*, −0.4 ppm; *meta*-OMe, −0.1 ppm). For **2**: these values, together with ^{13}C shifts for 2,2′,4,4′,6,6′-hexamethoxybiphenyl (cf. ref. 9), were used to calculate expected shifts for ^{13}C nuclei. The C-4,4′ signal was distinguished from that for C-2,2′,6,6′ by integration (recorded under a variety of conditions) and by its sharp symmetrical triplet in the nondecoupled spectrum. For **3**: signals for C-1′ through C-6′ were assigned by comparison with **2**, C-1 through C-6 by calculation from 2,2′,4,4′,6,6′-hexamethoxybiphenyl as above, and 4-OMe by integration and by comparison with 4,4′-OMe in 2,2′,4,4′,6,6′-hexamethoxybiphenyl. C-3′,5′ was distinguished from C-3 and C-5, and C-2′,6′ from C-4, by integration under a variety of conditions; C-4 and C-4′ gave sharp symmetrical triplets in the nondecoupled spectrum. Comparison of ^{13}C chemical shifts in **1** and 1,3,5-trimethoxy-2-(3,5-dimethoxyphenoxy)benzene (**7**; ref. 4, p. 83) allowed the effect of replacing —OH by 1,3,5-trimethoxyphenoxy to be calculated (*ipso*, +3.3 ppm; *ortho*, −1.0 ppm; *meta*, −0.2 ppm; *para*, +0.2 ppm; *meta*-OMe, −0.2 ppm). For **5**: these values, together with ^{13}C shifts for **2**, were used to calculate expected shifts for C-1′ through C-6′. Signals corresponding to C-1 through C-6 were assigned by comparison with **2**, and signals of the trimethoxyphenoxy group carbons (C-1″ through C-6″) by comparison with **7**. C-4, C-4′, and C-4″ were further distinguished from C-2,6, C-2′,6′, and C-2″,6″ by integration. Assignments for signals at 160.2 (C-2,6: expected, 160.3) and 160.1 (C-2′,6′: expected, 160.1 ppm) may be interchanged. For **6**: signals for C-1 through C-6 and C-1′ through C-6′ were assigned by comparison with 2,2′,4,4′,6,6′-hexamethoxybiphenyl, and C-1″ through C-6″ by comparison with **5** and **7**. C-4, C-4′, and C-4″ were further distinguished by integration and by the comparatively sharp triplets seen in the nondecoupled spectrum; assignments for signals at 56.3, 56.2, and 56.0 ppm may be interchanged.

Results and discussion

Vanadium tetrachloride-catalyzed dehydrodimerization of **1** under the conditions described above produces both the *para,para-* (**2**) and *ortho,para-* (**3**) coupled products, in approximately 4:1 ratio, with a combined isolated yield of 10.5% of theoretical. Although this is a modest yield, the major product **2** requires no further modification or deprotection prior to use in the Ullmann diaryl ether synthesis. The isolated yield (3.6%) of monocondensed product **5** from the diaryl ether synthesis compares reasonably well with the yield (9.9%) reported for the condensation of **4** with 3,4,5-trimethoxyphenol (11); moreover, the inefficiency of diaryl ether formation minimizes formation of 2,2′,6,6′-tetramethoxy-4,4′-di(2,4,6-trimethoxyphenoxy)biphenyl. Although the work of Sattler and Glombitza (11) suggests that diaryl ether formation could have been made more efficient by reacting 2,4,6-trimethoxyphenol with 2,2′,6,6′-tetramethoxy-4,4′-dibromobiphenyl, the latter is not directly available from Ullmann-type condensation, and would have to be synthesized indirectly through a tetramethoxybenzidine. The essentially quantitative methylation of **5** to **6** once again (see ref. 24) illustrates that the Hakomori procedure, normally used with carbohydrates (25), is ideal for methylation of polyphloroglucinols as well. Under the conditions described above, ring-methylation (24) was minimal.

Condensation of **2** with bromo-2,6-dimethoxy-4-(2,4,6-trimethoxyphenoxy)benzene would give "fucodiphlorethol A", the next higher homologue (8, 10) in this series of natural products.

The high molecular weight polyphloroglucinols of the marine brown alga *Fucus vesiculosus* L.: degradative analysis[1,2]

MARK A. RAGAN

Atlantic Research Laboratory, National Research Council of Canada, 1411 Oxford Street, Halifax, N.S., Canada B3H 3Z1

Received February 27, 1984

MARK A. RAGAN. Can. J. Chem. **63**, 294 (1985).

The high-molecular-weight polyphloroglucinol tannin of *Fucus vesiculosus* has been islated in pure form as judged by ^{1}H and ^{13}C nmr. Acetate and methyl derivatives were prepared and examined by uv and ir spectroscopy. Calcium – liquid ammonia degradation of the methyl ether derivative liberated numerous aryl compounds including fragments arising from ether-linked phloroglucinol end groups, internal *ortho*-, *meta*-, and *para*-oriented diethers, *vic*- and (tentatively identified) *sym*-triethers, internal phloroglucinol-derived biphenyls (three isomers), probable terminal biphenyls, terphenyl(s), and from quaterphenyl(s). No evidence was found for *vic*-trihydroxylated end groups. In all, 63 fragments were identified by gc–ms, and abundances of the major fragments were estimated by quantitative gc. The data indicate that the *F. vesiculosus* tannins – or at least the portion represented by these fragments – are highly branched structures consisting entirely of phloroglucinol units.

MARK A. RAGAN. Can. J. Chem. **63**, 294 (1985).

Si l'on se base sur les spectres rmn du ^{1}H et du ^{13}C, c'est à l'état pur que l'on a isolé du *Fucus vesiculosus* le tannin polyphloroglucinol de haut poids moléculaire. On en a préparé les dérivés acétate et méthylique et on les a étudiés par les spectroscopies uv et ir. La dégradation du dérivé méthylique par du calcium dans de l'ammoniac liquid libère plusieurs composés aromatiques dont des phloroglucinols terminaux qui étaient liés par des fonctions éthers, des diéthers internes orientés en positions *ortho*, *méta* et *para*, des triéthers *vic* et *syn* (attribution préliminaire), des biphényles internes dérivant du phloroglucinol (trois isomères), des biphényles qui sont probablement terminaux, des terphényles et des quaterphényles. On n'a pas pu mettre en évidence l'existence de groupes terminaux *vic*-trihydroxylés. Au total, on a identifié 63 fragments par cpg/sm et on a évalué les abondances relatives des fragments principaux en faisant appel à la cpg. Les données indiquent que les tannins du *F. vesiculosus* – ou du moins la portion représentée par ces fragments – ont des structures fortement ramifiées qui sont entièrement constituées d'unités phloroglucinol.

Introduction

Microscopic examination of the cells of brown algae (Phaeophyceae) reveals numerous small vesicles which stain intensely red with vanillin in strong mineral acid. Early investigators correctly concluded that these vesicles or "physodes" contain phloroglucinol or related compounds (1, 2). The roles (if any) of the physodes and their polyphenolic constituents in brown algal physiology remain unclear (3); however, at least some of these polyphenols possess antibacterial (4), antilarval (5), and antialgal (6, 7) activities, inhibit feeding by herbivores (8), and have properties of tannins (2, 9) and chelate ions of heavy metals (10, 11). The polyphenols are released into the surrounding seawater by living brown algae during stress (12) or solar irradiation (13), and by chelating toxic metal ions may influence the growth of phytoplankton (14) and other marine life.

Chemical investigation of the brown algal polyphenols has revealed a variety of low-, intermediate-, and high-molecular-weight compounds composed of phloroglucinol units. The low-molecular-weight fraction (operationally defined as those polyphenols which can be individually separated by chromatographic techniques) includes phloroglucinol itself (14, 15); "dimers" of phloroglucinol joined by direct carbon–carbon (e.g. 2,2′,4,4′,6,6′-hexahydroxybiphenyl) or ether bonds (e.g. 2,3′,4,5′,6-pentahydroxybiphenyl ether); and related "trimers", "tetramers", etc. similarly containing directly bonded and (or) ether- linked units (17, 18). Elaborations of this basic pattern include vicinal trihydroxylation (18), chloro substitution (19), esterification by sulfate (20, 21), and the presence of alkenyl side chains (22, 23).

Although the low-molecular-weight polyphenols have received much attention, they often constitute only a minor (<5%) portion of the total polyphenolic material of brown algae. The high-molecular-weight fraction (operationally defined as those soluble polyphenols remaining inside a dialysis tube during extended dialysis against distilled water) is by contrast the major fraction which has been isolated, comprising approximately 15–25% of the total extractable polyphenols (the intermediate-molecular-weight fraction, presumably the remaining 75% of the total polyphenols, is lost during dialysis and has never been directly examined). The high-molecular-weight fraction, although not particularly toxic to bacteria or yeasts (*vide infra*), is an excellent chelator of several heavy metal ions, particularly Cu^{2+} and Pb^{2+} (ref. 11; also, Guevremont and Ragan, unpublished), and is probably present in exudates from marine brown algae (24). The isolation, purification, preparation of derivatives, and degradative analyses of this high-molecular-weight polyphloroglucinol ("polymer") fraction are described in this report. The accompanying paper (25) describes direct investigations by nuclear magnetic resonance spectroscopy on the structure of the intact polymer.

Experimental

Fucus vesiculosus L. (25 kg f.w.), collected near Morris Point, Halifax Country on 15 July 1980, was transported on ice to the laboratory, where it was cleaned of macroscopic epiphytes and immediately frozen in liquid N_2. Portions were broken off, covered with EtOH (95%) in a large Waring Blendor (4.5 L), and macerated thoroughly. The green suspension was collected in large glass carboys, sparged exhaustively with N_2, and stored with occasional stirring under N_2 at 3°C in the dark for ≈48 h. Particles were removed on glass-wool filters to give 105 L of extract, which was concentrated *in vacuo* to 15 L using a 50-L continuous-flow "cyclone" evaporator.

[1] Issued as NRCC no. 23430.

[2] Part 4 in the series "Physodes and the phenolic compounds of brown algae". For part 3, see ref. 17.

The brownish, mostly aqueous concentrate was filtered (Whatman no. 1 paper), then was dialyzed to waste by cycling continuously through 2 m of $\frac{1}{4}$-in. diameter dialysis tubing (130 h, 3°C, N_2 atmosphere in reservoir; the returning, less-dense solution was carefully layered atop the liquid in the reservoir, and dense solution from the bottom of the reservoir was pumped to the dialysis tubing, to increase efficiency of operation). The dialyzed solution (≈23 L) was lyophilized, redissolved in distilled water (1.5 L), further dialyzed (48 h) against N_2-sparged distilled water, and again lyophilized to yield 84.6 g of crude polymer. Approximately 28-g portions were each dissolved in 50% aqueous MeOH (≈80 mL), sorbed onto "Avicel" microcrystalline cellulose, and loaded atop a dry-packed column (10 × 43 cm) of Avicel (16). Elution with MeOH–acetone (2:1 v/v) yielded a total of 68.2 g of purified polymer. Unless otherwise specified, all experiments reported herein were conducted on this preparation. Subsequent elution of the column with pyridine yielded only a further 2.7 g of highly discolored material which was not extensively analyzed.

Smaller batches of the polymer were prepared similarly (26, 27) from another collection of *F. vesiculosus* (Morris Point, Halifax County, 3 July 1974), from Nova Scotian *Ascophyllum nodosum* (L.) Le Jol. (Morris Point, 22 July 1975), and from Norwegian *A. nodosum* (Østmarkneset, Trondheim, 2 November 1976).

Purity of high-molecular-weight polyphloroglucinols prepared in this manner was indicated by the absence of all ^1H nmr signals except those in the range δ_H = 6.0–6.5 ppm, and the absence of all ^{13}C nmr signals except those in the ranges δ_C = 92–103, 123–131, and 148–162 ppm (11, 25). If carbohydrate signals were observed (^1H nmr: δ_H = 3.4–4.1 ppm; ^{13}C nmr: $\delta_C \approx$ 60–75 ppm), chromatography on Avicel columns was repeated to remove the contaminants.

Acetylation of the "polymer" (600 mg) was performed in excess Ac_2O (105°C, ≈1 h) with freshly fused NaOAc as catalyst. Remaining Ac_2O was destroyed with water (room temperature, 2 h), the $CHCl_3$-soluble product was washed by shaking against a saturated aqueous solution of NaCl, and residual HOAc was removed *in vacuo* (40°C); yield, 892 mg. Complete acetylation of —OH groups was confirmed by infrared spectrometry (Fig. 1).

Methylation was accomplished by a modification of the Hakomori (28) procedure. An aliquot of the polymer (600 mg) was dissolved in dry DMSO (redistilled from CaH_2; 10 mL) under N_2, and was cooled to 18 ± 1°C. Sodium dimethylsulfinylcarbanion (29) was prepared under a N_2 or Ar atmosphere by the method of Sjöberg (30). Additions (under N_2) of base and of $(CH_3)_2SO_4$ were made at intervals with stirring: methylsulfinylcarbanion base (1.40 mequiv. mL^{-1}; 14.0 mL, t = 0), $(CH_3)_2SO_4$ (1.8 mL, t = 30 min), base (8.0 mL, t = 4 h), and $(CH_3)_2SO_4$ (1.1 mL, t = 4.5 h). The temperature was allowed to increase slowly to 22°C (t = 30 min) and 25°C (t = 4.5 h), then was raised to 44°C for 1 h beginning at t = 24 h, and finally was reduced to ≈22°C. Careful attention to temperature was crucial for successful methylation. The product was placed into a wet dialysis tube, dialyzed against distilled water for 6–8 h, collected on a glass filter disc (GF/C, Whatman), and dried *in vacuo* (37°C) to constant weight (712 mg). Complete methylation of —OH groups was confirmed by infrared spectrometry (Fig. 1).

Esterification with diethyl phosphate groups was achieved by adding $CHCl_3$ (4.0 mL) to an efficiently cooled (≈25°C) solution of the polymer (210 mg) in diethyl phosphite (Aldrich; 3.0 mL) and Et_3N (1.1 mL), then stirring overnight at room temperature. The product was dialyzed repeatedly against distilled water (precipitates) and absolute EtOH (redissolves), and finally was dried *in vacuo* (37°C). The yellowish-brown, $CHCl_3$-soluble powder contained almost no free —OH groups (Fig. 1). Attempts to reduce the diethyl phosphate ester to the corresponding hydrocarbon (cf. ref. 31), and to cleave its ether bonds by treatment with alkali metals in NH_3, were unsuccessful.

Cleavage of aryl–aryl ether bonds was accomplished by dropwise addition of a solution of the methylated polymer (25 mg) in dry, redistilled THF (10 mL) to a stirred solution of Ca metal (BDH; 25–100 mg) in liquid NH_3 (≈15 mL). Additional Ca was added after 5–10 min to a total of 50–200 mg. After the blue color had persisted for 10–20 min, the solution was poured onto crushed ice in a separatory funnel, and carefully acidified (concentrated HCl – ice) to pH ≈2. Organic material was extracted into EtOAc, CH_2Cl_2, and (or) Et_2O, concentrated under N_2 at reduced temperature, and analyzed by tlc, gc, and gc–ms. Use of Na instead of Ca gave similar results. An alternative work-up procedure likewise gave similar results: the blue solution was transferred to a large Erlenmeyer flask, redistilled absolute EtOH (ref. 32; 30 mL) and solid CO_2 were added, the solution was clarified by centrifugation, and the products were concentrated under N_2 at reduced temperature prior to analysis by gc.

Products obtained from Ca–NH_3 cleavage were in some cases butylated by the Williamson procedure: an aliquot (e.g. 90%) of the organic phase from the cleavage reaction was dried under N_2, redissolved in NaOEt (0.32 g Na in 15 mL absolute EtOH), stirred under an atmosphere of N_2 for ≈10 min, then refluxed with n-butyl bromide (Anachemia; 2.8 mL) for ≈5 h; additional NaOEt (5 mL) and n-BuBr (1.0 mL) were added at t = 160 min. The product was cooled, filtered (GF/C), evaporated *in vacuo* (no external heating), then partitioned between CH_2Cl_2 and aqueous 6 N HCl. Butylation efficiency, estimated from capillary column gc, was ca. 98.5%. An aliquot of the product was subsequently treated once again with Ca in NH_3.

In other experiments, the fragments from Ca—NH_3 cleavage were trimethylsilylated (27) using "Tri-Sil" (Pierce).

Synthesis of reference compounds

The syntheses of 2,2′,6,6′-tetramethoxy-4,4′-dihydroxybiphenyl (33), 2,4′,6,6′-tetramethoxy-2′,4-dihydroxybiphenyl (33), 3,3′,-4,5,5′-pentamethoxybiphenyl ether (26), 2,2′,4,4′,6,6′-hexamethoxybiphenyl (16), and 2,2′,4,6,6′-pentamethoxy-4′-(2,4,6-trimethoxyphenoxy)biphenyl (33) have been described elsewhere. 2,4,6-Trimethoxyphenol and 1,2,3,5-tetramethoxybenzene were prepared by (partial) methylation of 2,6-dimethoxy-1,4-dihydroxybenzene (dissolved in acetone or DMSO) with CH_2N_2 (vigorous agitation, room temperature, 4 h), and were distinguished from 3,4,5-trimethoxyphenol by comparison with authentic 3,4,5-trimethoxyphenol on capillary column gc–ms (see below).

Iodo-2,2′,4,4′,6,6′-hexamethoxybiphenyl (**1**) was synthesized from 2,2′,4,4′,6,6′-hexamethoxybiphenyl (**2**) by Suzuki iodination (cf. ref. 34). Resublimed I_2 (2.06 g, 8.1 mmol), **2** (6.68 g, 20.0 mmol), and $HIO_4 \cdot 2H_2O$ (0.91 g, 4.0 mmol) were combined well. In a second flask, HOAc (67 mL), H_2O (11 mL), and concentrated H_2SO_4 (0.8 mL) were heated together (45°C), then were added to the solids in the first flask. The vigorously stirred solution was heated to 67°C during 150 min, then the reaction was quenched by pouring into ice water (ca. 250 mL), and the products were extracted into $CHCl_3$. The product **1** (≈60% of recovered organic matter) was separated from unreacted **2** (≈25%), diiodo-2,2′,4,4′,6,6′-hexamethoxybiphenyl(s) (M^+ 586; ≈10%), and more complex products by chromatography on silica gel (hexane–THF–CH_2Cl_2, gradient 80:10:10 v/v/v to 70:15:15 v/v/v). Crystallization from acetone gave tiny white crystals, mp (cap., uncorr.) 166–168°C; isolated yield, 22%; ^1H nmr ($CDCl_3$) δ_H: 6.37 (1H, H-5), 6.22 (2H, H-3′,5′), 3.90 (3H, 4-OCH_3), 3.84 (3H, 4′-OCH_3), 3.72 and 3.70 (9H, 2′,6,6′-OCH_3), 3.62 (3H, 2-OCH_3) ppm; ^{13}C nmr ($CDCl_3$) δ_C: 161.1 (m; C-4′), 160.0 (m; C-4), 159.7 (m; C-2), 159.0 (m; C-2′,6′), 158.8 (m; C-6), 111.0 (poorly relaxed; $^3J_{CH}$ = 5.4 Hz, d; C-1), 104.7 (poorly relaxed; $^3J_{CH}$ = 5.3 Hz, t; C-1′), 92.5 ($^1J_{CH}$ = 158.3 Hz, d; C-5), 90.9 ($^1J_{CH}$ = 159.0 Hz, d; $^3J_{CH}$ = 4.7 Hz, d; C-3′,5′), 73.4 ($^3J_{CH}$ = 7.4 Hz, d; C-3), 60.2 ($^1J_{CH}$ = 144.6, q; 2-OMe), 56.4 ($^1J_{CH}$ = 144.5 Hz, q; 4-OMe), 56.3 ($^1J_{CH}$ = 143.9 Hz, q; 6-OMe), 55.9 ($^1J_{CH}$ = 143.8 Hz, q; 2′,6′-OMe), 55.2 ($^1J_{CH}$ = 143.8 Hz, q; 4′-OMe) (assignments for C-2, C-4, C-4′, and C-6 are tentative) ppm; ms (190°C): 460 (M^+, 100%), 303 (11%), 302 (10%), 181 (9%), 69 (15%). *Anal.* calcd.: C 46.97, H 4.60, O 20.86, I 27.57; found: C 46.90, H 4.63, O 20.7, I 27.60.

2,2′,2″,4,4′,4″,6,6′,6″-Nonamethoxyterphenyl (**3**) and 2,2′,2″,2‴,-4,4′,4″,4‴,6,6′,6″,6‴-dodecamethoxy-(1,1′:3′,1″:3″:1‴)quaterphenyl (**4**) were synthesized by "crossed-Ullmann" reaction of **1** and iodo-2,4,6-trimethoxybenzene (16). Iodo-2,4,6-trimethoxybenzene (1.6 g, 5.5 mmol), **1** (2.0 g, 4.4 mmol), and 3.75 g EDTA-activated Cu

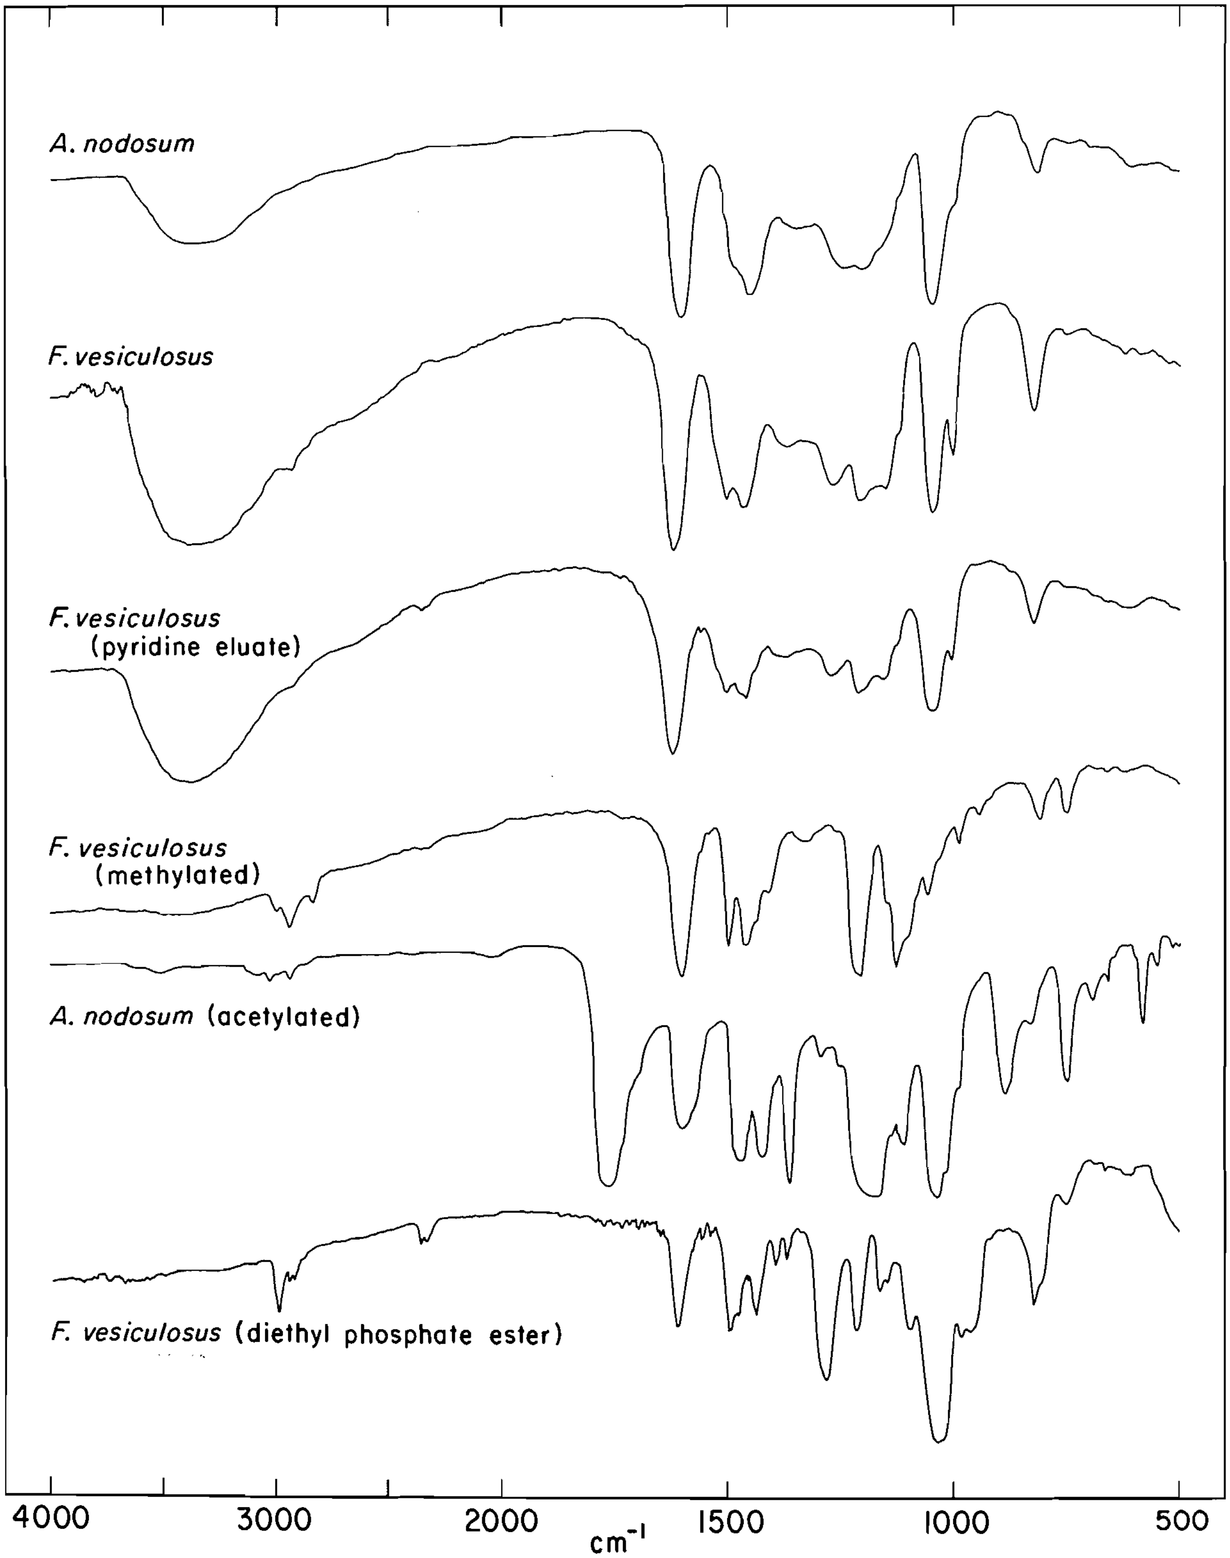

FIG. 1. Infrared spectra of high-molecular-weight polyphloroglucinols and derivatives.

powder (35) were combined thoroughly. The temperature was increased from 110°C to 295°C during 4.5 h while the reaction mixture was stirred vigorously with a heavy copper wire. Thereafter the mixture was cooled, crushed, and extracted with boiling EtOH (2 portions of 1 L). Column chromatography on silica gel (hexane–THF–CH_2Cl_2, gradient 80:10:10 v/v/v to 62.5:12.5:25 v/v/v) yielded **3** (≈30% of recovered organic products) and **4** (≈20%), together with **2** (≈30%), unreacted **1** (≈15%), and minor products (≈5%). Compounds **3** and **4** were further purified by preparative tlc (E. Merck silica gel 60F-254, 45:25:30 v/v/v hexane–THF–CH_2Cl_2). Isolated yields: 0.55 g of **3**, 0.34 g of **4**.

2,2′2″,4,4′,4″,6,6′,6″-Nonamethoxyterphenyl (3)

Crystallization from acetone gave white prisms, mp (birefringence stage) 209.5–210.0°C. ^1H nmr ($CDCl_3$) δ_H: 6.43 (1H, H-5′), 6.22 (4H, H-3,3″,5,5″), 3.82 (6H, 4,4″-OMe), 3.76 (6H, 4′,6′-OMe), 3.72

2,2′,2″,2‴,4,4′,4″,4‴,6,6′,6″,6‴-Dodecamethoxy-(1,1′:3′,1″:3″,1‴)quaterphenyl (4)

Crystallization from acetone or methyl ethyl ketone gave white prisms, mp (birefringence stage) 201.0–202.0°C. ^{1}H nmr ($CDCl_3$) δ_H: 6.43 (2H, H-5′,5″), 6.22 and 6.20 (4H; H-3,3‴,5,5‴), 3.82 (6H; 4,4‴-OMe), 3.78 (6H; 4′,6″- or 4″,6′-OMe), 3.74 (12H; 2,2‴,6,6‴-OMe), 3.62 (6H; 4′,6″- or 4″,6′-OMe), 3.24 (6H; 2′,2″-OMe) ppm; ^{13}C nmr ($CDCl_3$) δ_C: 160.6 (J_{CH} = 3.2 Hz, "q"; C-4,4‴), 159.2 (m; C-2′,2″), 159.12 and 159.09 (m; C-2,2‴,6,6‴), 158.25 and 158.15 (m; C-4′,6″ and C-4″,6′), 110.1 (poorly relaxed; $^3J_{CH}$ = 5.3 Hz, d; C-1″,3′), 109.3 (poorly relaxed; $^3J_{CH}$ = 5.1 Hz, d; C-1′,3″), 106.0 (poorly relaxed; $^3J_{CH}$ = 5.0 Hz, t; C-1,1‴), 91.7 ($^1J_{CH}$ = 156.3 Hz, d; C-5′,5″), 91.15 ($^1J_{CH}$ = 158.4 Hz, d; $^3J_{CH}$ = 4.4 Hz, d; C-3,3‴,5,5‴), 60.0 ($^1J_{CH}$ = 143.8 Hz, q; 2′,2″-OMe), 55.9 ($^1J_{CH}$ = 143.4 Hz, q; 2,2‴,6,6‴-OMe), 55.8 ($^1J_{CH}$ = 143.3 Hz, q; 6′,6″-OMe), 55.6 ($^1J_{CH}$ = 143.4 Hz, q; 4′,4″-OMe), 55.1 ($^1J_{CH}$ = 143.6 Hz, q; 4,4‴-OMe) ppm; ms (210°C): 666.2658 ± 0.0020 (M^+; 100%; required for $C_{36}H_{42}O_{12}$, 666.2673), 333 (16%). *Anal.* calcd.: C 64.85, H 6.35, O 28.80; found: C 63.52, H 6.43, O 29.25.

Compound **4** was also synthesized directly from **1**; **1** (3.0 g, 6.5 mmol) and EDTA-activated (35) Cu powder (2.6 g) were combined thoroughly, and the Ullmann condensation was conducted (heating from 125°C to 285°C during 5.5 h) and worked up as above. The product was further purified by chromatography on silica gel (as above) and was crystallized from acetone. Yield, 10%. The product co-chromatographed under a variety of conditions with **4** prepared by the crossed-Ullmann reaction.

A variety of acetylated and *n*-butylated reference compounds were prepared from the corresponding free phenols by the methods outlined above.

Gas chromatography was carried out on packed columns of 3% SE-30 (3.05 m × 3.2 mm id) with temperature programming from 100°C (held 2 min) to 280°C at 4 or 6°C min^{-1} using Hewlett–Packard 5731A and 5750 instruments with flame ionization detection. Mass spectra were recorded on a Dupont-CEC 21-110B instrument (70 eV) with electron-multiplier detection; high resolution mass measurements were made by peak matching, using perfluorokerosene as internal standard. Combined gc–ms was carried out (70 eV) on a Finnigan model 4000 instrument with an INCOS data system; gc–ms analysis of fragments from Ca– (or Na–)NH_3 degradation of the methylated polymer, and of reference compounds, utilized a high-capacity quartz capillary column (3% OV-1, ≈25 m, 0.3 mm id; Hewlett–Packard) with He carrier gas and a ≈10:1 injection splitter. The temperature was programmed from 75°C (held 1 min) to 275°C at 8° min^{-1}. Some gc–ms experiments utilized a packed column (3% SE-30, 3.05 m) with direct injection. Ultraviolet spectra were recorded on a Unicam SP8000 spectrophotometer using matched quartz 10-mm cuvettes. Infrared spectra were recorded on Perkin–Elmer model 283B and model 180 instruments; samples were prepared as films on AgCl discs. The ^{1}H and ^{13}C nmr spectra of reference compounds were recorded on a Varian FT-80 instrument using 5-mm or 10-mm sample tubes, internal ^{2}H pulse lock, and tetramethylsilane as internal reference; proton-noise-decoupled spectra were recorded using 8K data points, and high-resolution ("nondecoupled") spectra with 16K data points. Elemental analyses were done by Microanalytisches Laboratorium (Bonn, FRG) and by Microanalysis Laboratories Ltd. (Markham, Ontario). Metal analysis by plasma emission spectroscopy was done by Berringer Magenta Ltd. (Rexdale, Ontario). Determination of molecular weight by equilibrium ultracentrifugation was carried out on a Beckman model E instrument (0.1 *M* phosphate buffer, pH 7.00, 15°C, concentration ca. 0.2% w/v, 5.2×10^3 rpm ($\omega^2 = 2.965 \times 10^5$ rad^2 s^{-2})) equipped with Schlieren optics. Antibiotic screening was conducted by BioResearch Laboratories (Senneville, P.Q.), and antitumor testing by the U.S. National Cancer Institute (Bethesda, MD).

Results

Physical and spectroscopic properties

The purified high-molecular-weight polymer was a light-brown amorphous solid, extremely soluble (1 g mL^{-1}) in water, also soluble in DMSO, MeOH, and diethyl phosphite, and insoluble in other organic solvents or in SO_2 or NH_3. Aqueous solutions of the polymer gave reactions typical of tannins, e.g. precipitated proteins and alkaloids, tasted astringent, and formed insoluble complexes with excess Fe^{3+} ion. Colorimetric behaviour has been described elsewhere (36). Elemental analyses and apparent molecular weights are given in Table 1. Heterogeneity of molecular weights was indicated by the deviation from linearity of the plot of ln $(1/r)$ (dc/dr) vs. r^2, particularly at values of $r^2 > 50.3$ cm^2. Metal analysis showed Cu (10.7 ppm), Mg (231 ppm), and Si (10 ppm), while levels of Ag, Al, Ba, Be, Ca, Cd, Co, Cr, Fe, K, Mn, Mo, Na, Ni, P, Pb, Sr, Th, Ti, V, Zn, and Zr were below the limits of detection.

The ultraviolet spectrum (in H_2O) is dominated by "end-absorption", although a small absorption due to aromatic nuclei is present at λ = 268 nm; the $E^{1\%(w/v)}_{268\ nm}$ is 109 ± 10 units in distilled water (24). Infrared spectra of the purified polymers from *A. nodosum* and *F. vesiculosus* are virtually identical (Fig. 1), showing a strong bonded O—H stretching band (≈3400 cm^{-1}) which is removed by derivatization, as well as

[a]Ring-methylated methoxyphenols at rrt ≈0.803 and 0.827 were seen in commercial preparations of *m*-methoxyphenol; after butylation, ring-methylated methoxyphenyl butyl ethers were seen at rrt 1.185 and 1.192. Then, after subsequent re-treatment with Ca—NH_3, a trace of a possible fourth (debutylated) methyl-methoxyphenol was observed at rrt = 0.812.
[b]Probably 1,2-dihydroxy-3,5-dimethoxybenzene (see text).
[c]A possible monobutyl ether of methyl-dimethoxy-dihydroxybenzene was seen at rrt = 1.547.
[d]Probably methyl-1,3-dimethoxybenzene.
[e]Possibly 2,4-dimethylphenol (see text).
[f]Probably 2,4-dimethoxyphenol (see text).
[g]Probably 2,2′,4,6,6′-pentamethoxybiphenyl (see text).
[h]Probably 4-hydroxy-2,2,4′,6,6′-pentamethoxybiphenyl (see text).
[i]Not seen on capillary column but demonstrable (rrt ≈5.8) during packed-column gc.

bands arising from aromatic C—H stretching (≈2920, 2850 cm^{-1}, weak), aromatic ring skeletal vibrations (1605 cm^{-1}), aryl ether stretching (≈1470, 1200, 1050 cm^{-1}), and C—H out-of-plane bending in 1,3,5-substituted nuclei (815, 705 cm^{-1}) (37).

Derivatives

Acetylation of the high-molecular-weight polymer yielded a light-colored product soluble in $CHCl_3$, acetone, dioxane, THF, and Ac_2O/HOAc. No uv absorbance maximum (other than "end-absorption") was evident. Infrared spectroscopy (Fig. 1) demonstrated the absence of hydroxyl groups (loss of 3400 cm^{-1} band) and the presence of acetoxy groups (2935 cm^{-1}, acetate methyl C—H stretching; 1760 cm^{-1}, acetate carbonyl C=O stretching; 1185–1165 cm^{-1}, stretching), and in addition showed bands arising from aromatic C—H stretching (3090, 3025 cm^{-1}), aromatic ring skeletal vibrations (1605 cm^{-1}), aryl ether stretching (and aromatic nuclear in-plane bending?) (1475, 1140, 1110, 1035, 1020 cm^{-1}), and C—H out-of-plane bending in highly substituted (890 cm^{-1}) and 1,3,5-substituted (830, 695 cm^{-1}) nuclei.

Methylation of the purified polymer gave a light tan-colored product which was readily soluble in $CHCl_3$, CH_2Cl_2, and DMSO; soluble in THF and acetone; mostly soluble in dioxane; and insoluble in water, Et_3N, or NH_3. Infrared spectroscopy (Fig. 1) demonstrated the absence of hydroxyl groups, indicated the presence of methyl groups (C—H stretching, 2940 and (or) 2840 cm^{-1}; C—H bending, 1500 cm^{-1}), and showed bands arising from aromatic ring skeletal vibrations (1605 cm^{-1}), ether stretching (1465, 1440, 1220, 1205, 1125, 1055 cm^{-1}), and ring C—H out-of-plane bending (810 cm^{-1}).

Degradative analysis

Treatment of the methylated polymer with Ca in NH_3 (cf. ref. 38) produced a very complex mixture. Silica gel tlc (using a variety of solvent systems) allowed only partial resolution of ca. 15 components, but demonstrated the presence of relatively immobile (polar and (or) higher-molecular-weight) compounds which also absorbed at λ = 254 nm. Judging from the behaviour of reference compounds in these tlc systems and on gc, most of these relatively immobile fragments would not have been sufficiently volatile, even after butylation or trimethylsilylation, to have been seen during gc or gc–ms analysis.

A total of 63 fragments arising from the methylated polymer were identified by gc and gc–ms analysis of the Ca–NH_3 degradation product and the subsequent butylation mixture. Capillary gc–ms of the initial degradation product resolved at least 150 compounds, mostly of very minor abundance. Of the 123 most abundant in the reconstructed ion current (RIC) under these scanning and ionization conditions, 51 were identified as methoxylated and (or) methylated phenolic or aryl fragments (Table 2), 63 (mostly minor peaks, totalling 19.1 ± 7.2% of the total area of the RIC) were identified as column or septum bleed compounds, phthalate esters, etc., and 9 relatively small peaks could not be identified. The gc–ms of the *n*-butylated reaction mixture under the same conditions resolved at least 170 compounds; of the 150 most abundant, 59 were identified as methoxylated and (or) methylated aryl or phenyl butyl ether fragments (Table 2), 84 (almost entirely minor peaks) arose from column bleed, phthalate esters, etc., and 7 could not be identified. After further treatment of the butylated mixture with Ca–NH_3, gc–ms revealed an essentially identical pattern, with the exception that some debutylation had occurred. In all, 62 fragments arising from the methylated polymer were identified by gc–ms; the 63rd, **4** (Table 2), was insufficiently volatile for analysis on the capillary column, but was identified by its retention time on the packed SE-30 column. The permethoxy ether of a second phloroglucinol-related quaterphenyl reported (39) to occur in brown algae, 2,4,6-trimethoxy-1,3,5-*tris*-(2,4,6-trimethoxyphenyl)benzene, was not available for reference.

Identification of the former 62 fragments was made in the following manner. *Methoxyarenes* were initially located by scanning for expected molecular ions using the INCOS program "CHROMATOGRAM"; the individual methoxyarenes were then identified by comparison with reference compounds (when available; Supplementary Material[3]), examination of the

[3]This supplementary material is available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

mass spectra (with computer enhancement for the least abundant compounds), inferences drawn from ring-methylation (see below), and appearance of the compound at the same relative retention time (rrt) in chromatograms of the butylated reaction mixtures, both before and after the second $Ca-NH_3$ cleavage reaction. *Phenolic fragments* were identified similarly, except that the peak in the chromatogram of the initial reaction mixture was required to be absent from the butylation products, and instead to correspond to a new peak appearing at longer rrt and having an appropriate mass spectrum (including the molecular ion, major fragments of the parent phenol, and the required number of 56-amu fragmentations reflecting loss of butyl groups). The gc peak intensities from the butylated reaction mixture corresponded very well with intensities for the identical or parent compounds in the nonbutylated mixture. Problematic identifications are treated below.

The abundance of ring-methylated fragments, together with the total absence of infrared (see above) or nmr (25) evidence for any methyl groups in the native "polymer", indicates that extensive ring-methylation of the "polymer" had occurred, as expected from earlier studies (16). Although the presence of ring-methylated fragments greatly complicates the chromatograms, in some instances (abundances permitting) the pattern of ring-methylation provides useful corroboration of proposed structures as in the following instances.

(a) The appearance of only two mono- and only two dimethyl derivatives of the major fragment at rrt 1.090 (3,5-dimethoxyphenol) helps to rule out four of the six possible dimethoxyphenols: the 2,3-, 2,4-, 2,5-, and 3,4- dimethoxy isomers each should show three mono- and three di(ring-)methylated derivatives if all three ring positions were available for methylation in the native "polymer". The 2,6- (rrt 0.895) and 3,5- (rrt 1.091) isomers have only two possible mono- and two dimethyl derivatives.

(b) The presence of only two monomethyl derivatives of the abundant pentamethoxybiphenyl at rrt 2.057, together with the presence of **2** (rrt 2.297) and 2,2′,6,6′-tetramethoxy-4,4′-dihydroxybiphenyl (rrt 2.442), argues strongly that the former fragment has 2,2′,4,6,6′-methoxylation and was originally linked to the rest of the "polymer" by (at least) an ether bond at C-4′. If so, the hydroxypentamethoxybiphenyl at rrt 2.380 is probably 4-hydroxy-2,2′,4′,6,6′-pentamethoxybiphenyl.

(c) The obviously congeneric group of three methyl- and two dimethyl-tetramethoxydibutoxybiphenyls (rrts 2.770–2.791) may be provisionally correlated with 2,4′,6,6′-tetramethoxy-2′,4-dihydroxybiphenyl (three possible mono- and four di(ring-)methyl derivatives) at rrt 2.430 in the nonbutylated mixture, rather than with its 2,2′,6,6′-tetramethoxy-4,4′-dihydroxy isomer (one possible mono- and two dimethyl derivatives) at rrt 2.442.

Of the 24 parent (without ring-methylation) fragments found (Table 2), 21 were positively identified by the criteria described above. Both *m*- and *p*-methoxyphenols were found in the $Ca-NH_3$ reaction mixture and were positively identified by comparison of rrts and mass spectra with those of authentic compounds (Supplementary Material[3]), by computer matching with spectra in the 25409-compound National Bureau of Standards library,[4] and by their absence from the same positions in the chromatogram after butylation. The appearance of only one peak for butyl methoxyphenyl ether(s) after butylation (rrt 1.057) presumably results from the lack of resolution of *m* and *p* isomeric butyl methoxyphenyl ethers (Supplementary Material[3]). The three tentative identifications among parent fragments are a dimethoxydihydroxybenzene at rrt 1.145 (of modest abundance; no corresponding dimethoxydibutoxybenzene found), a hexamethoxybiphenyl at rrt 2.373 (of extremely minor abundance, incompletely resolved from the pentamethoxyhydroxybiphenyl at rrt 2.380), and a tetramethoxydihydroxybiphenyl at rrt 2.461 (of modest abundance and occurring in a very congested region of the chromatogram near two (other?) isomeric tetramethoxydihydroxybiphenyls and related ring-methylated compounds). One further problem involved the resolution of only one methyl-dimethoxybutoxybenzene peak despite the prior well-demonstrated presence of two ring-methylated 3,5-dimethoxyphenols. These and other problematic or tentative identifications (indcated by a "?" in Table 2) concern fragments of minor abundance, and the uncertainty of identification does not affect the subsequent discussion.

Semiquantitative estimation of the recovered fragments was made in the following manner: first, the 15 peaks resolved by packed column gc and detected by flame ionization were quantified using standard curves from reference compounds chromatographed under identical conditions. Second, the efficiency of recovering each fragment from the $Ca-NH_3$ reaction mixture was estimated, where possible, from the identical work-up of sham reactions spiked with known amounts of authentic references. Finally, the proportion of the total recovered fragments represented by these 15 peaks was approximated, by analysis of the reconstructed ion current distribution among the fragments resolved by capillary column gc–ms (Incos program "QUANTITATION"); the major fragments, together with their isomers and ring-methylated derivatives which were not separated by gc on packed columns, were responsible for 70.3 ± 1.7% of the total RIC under the scanning and ionization conditions employed. The results, summarized in Table 3, suggest that ca. 20% of the methylated "polymer" was released as mono-, di-, tri-, and tetranuclear fragments detectable by gc. Of these, ≈71% (by weight) are mononuclear (arising from ether-linked phloroglucinol units), ≈27% binuclear (arising from biphenyls linked to the remainder of the polymer by one or more ether bonds), and ≈2% tri- or tetranuclear.

Exact quantitation of the fragments was not possible. The efficiencies of recovery of fragments from the reaction mixture were variable (Table 3), with greatest variation seen among the most volatile fragments. Quantitative studies involving packed-column gc were complicated by incomplete resolution of fragments and by poor peak shape of phenolic components, while dependable quantitative results from capillary gc(–ms) were precluded by the use of an injection splitter.

Biological activity

The native, nonderivatized high-molecular-weight polymer was not significantly inhibitory at concentrations of 0.05–25 mg mL^{-1} to the growth of *Escherichia coli* (ATCC 10536), *Pseudomonas aeruginosa* (ATCC 15442), *Staphylococcus aureus* (ATCC 6538), *Streptococcus faecalis* (ATCC 10541), or *Saccharomyces cerevisiae* (ATCC 2601) in suspension cultures, and showed no activity against mouse P388 lymphocytic leukemia (5 daily injections of 12.5–200 mg kg^{-1} $injection^{-1}$).

Discussion

All spectroscopic and degradative data presented in this pa-

[4] Library as supplied by Finnigan-MAT Corp. (Sunnyvale, Calif.) and stated to be identical with the "EPA/NIH Mass Spectral Data Base" (see ref. 40).

TABLE 3. Recoveries and quantitation (using packed-column gc) of major fragments from Ca–NH_3 degradation of methylated "polymer"

Compound(s)[a]	rrt[b]	Rel. amt. ±s.d.[c]	n[d]	% Recovery[e]	n[d]	Estimate of amount released from 25 mg "polymer": mg	(wt%)
Dimethoxybenzenes	≈0.40	0.09[f]	1	34.5 ± 1.1[g]	4	0.1	(0.4%)
Methoxyphenols	≈0.62	0.10 ± 0.10[f]	3	31.0 ± 19.5[h]	2	0.1	(0.5%)

[a] Including unresolved isomers and ring-methylated derivatives.
[b] On 3% SE-30 on 60–80 mesh GasChrom Q; 3.05 m × 3.2 mm id columns; He flow 30 mL min^{-1}; flame ionization detection; temperature program 100°C (2 min) to 280°C (hold) at 6°/min.
[c] From standard curves of authentic reference compounds.
[d] Number of independent experiments from which quantitative data could be obtained.
[e] Recovery of internal reference (bromo-2,4,6-trimethoxybenzene) was 79.5 ± 3.7%.
[f] Occasionally seen in much larger quantities; *meta* isomers used for standardization.
[g] *meta*, 35.1 ± 0.2%; *ortho*, 33.9 ± 1.0%.
[h] *meta* Isomer.
[i] Much more abundant in capillary-column separations (RIC).
[j] Efficiency of recovery assumed to be 81%.
[k] From capillary-column separations, the minor fragments (not seen on packed-column gc) may be estimated to constitute a further ≈2.6% of the initial "polymer."

per suggest that the high-molecular-weight tannin of *F. vesiculosus* is based entirely on phloroglucinol. Previous hydrolytic experiments (16, 26) had revealed no carbohydrates and only traces of amino acids and ammonia; now, gc–ms analyses of the alkali metal – liquid ammonia degradations have revealed a variety of $(C_6)_n$-based fragments, but no C_6C_3 units which might be expected from a brown algal "lignin" (41–45), nor $C_6C_1C_6$ units characteristic of phloroglucinols in ferns and some higher plants (46), nor phenol or *o*-methoxyphenol as reported by Reznikov *et al.* (45). No evidence has been found for carboxy, alkenyl (cf. refs. 22, 23), or halo (cf. ref. 19) substitution in the polymer (although the Ca–NH_3 degradation would have caused dehalogenation). The efficient derivatizations by acetic anhydride and by sodium methylsulfinylcarbanion imply that all free hydroxyl groups (i.e. not involved in diaryl ether bonds) are readily "available" to the surrounding medium.

Both directly bonded and ether-linked units were demonstrated. Due to the low overall recovery of material from the Ca–NH_3 cleavage reaction, it is not possible to estimate the ratio of direct C—C to diaryl ether bonds in the parent molecule (see ref. 25); however, approximately 29% of the recovered phloroglucinol groups bore one or more direct C—C bonds (Table 3), whereas a minimum of 85% (71/1 + 27/2 + 2/3%) must have been linked to the rest of the molecule by one or more diaryl ether bonds. Oligoaryl regions donated a much smaller proportion (≈2%) of the recovered fragments. Thus to the extent that the results (Tables 2, 3) are characteristic of the entire polymer, it appears that the latter is composed of phloroglucinol units linked predominantly by ether bonds, with a smaller (but significant) proportion of direct C—C linkages.

It is also possible to identify certain fragments as having arisen from end groups (linked to the rest of the "polymer" by only one diaryl ether bond) and from "in-chain" groups (linked by two or more diaryl ether bonds). The only fragment unequivocally coming from end groups is 2,4,6-trimethoxy-*m*-xylene; however, as it is extremely unlikely (given the observed degree of ring-methylation) that every terminal phloroglucinol group would be methylated at both free ring positions, it is probable that much of the non- and mono-(ring-)-methylated 1,3,5-trimethoxybenzene observed also arose from end groups. Consistent with this conclusion is the absence of dihydroxytrimethoxybenzene fragments. If so, it becomes likely that most or all of the 2,4,6-trimethoxyphenol fragments have also arisen from terminal phloroglucinol groups. Other fragments perhaps arising from end groups include the pentamethoxy-, pentamethoxyhydroxy-, and hexamethoxybiphenyls (and their ring-methylated derivatives), although the only evidence bearing on their origin is the absence of dihydroxy derivatives in the reaction mixture.

"In-chain" groups include all those fragments bearing two hydroxy groups, and may be further categorized on the basis of the relative orientations of ether linkages: *para* (2,6-dimethoxy-1,4-dihydroxybenzene); *meta* (*m*-methoxyphenol, assuming its origin from a 1,3,5-trisubstituted group); *ortho* (the dimethoxydihydroxybenzene at rrt 1.145, which if possessing

1,3,5-substitution is probably 1,2-dihydroxy-3,5-dimethoxybenzene, as in the diether-linked ring of the 4-(2″-(2‴,-4‴,6‴-trihydroxyphenoxy)-4″,6″-dihydroxyphenoxy)-2,2′,4′,-6,6′-pentahydroxybiphenyl reported earlier (17), and the dimethoxyphenol (presumably 2,4-dimethoxyphenol) at rrt 0.867, which would arise from the same type of nucleus in the polymer); and possible *vic*- (*p*-methoxyphenol, assuming its origin from a 1,3,5-substituted unit) and *sym*-triethers (*p*-methoxyphenol; also, the presumed 2,4-dimethylphenol at rrt 0.577). The major fragment probably representing internal positions, 3,5-dimethoxyphenol, must arise from both *ortho*- and *para*-ether linked environments, because both possible mono- and both possible di-(ring-)methylated derivatives are present. In addition, and in contrast to the report by Glombitza and Lentz (47), evidence for internal biphenyl groups was found as well: three dihydroxytetramethoxybiphenyls, one tetramethoxyhydroxybiphenyl, and one tetramethoxybiphenyl (the latter two assumed to have arisen from 2,2′,4,4′,6,6′-hexasubstituted biphenyl nuclei), together with their ring-methylated derivatives.

Glombitza and Lentz (47) have studied a mixture of EtOAc-soluble "phlorotannins" (of unspecified medium to high molecular weights) from *F. vesiculosus* by $Na-NH_3$ cleavage and chromatography, finding six of the fragments reported here (1,3,5-trimethoxybenzene; 3,5-dimethoxyphenol; 2,4,6-trimethoxyphenol; **2**; 4-hydroxy-2,2′,4′,6,6′-pentamethoxybiphenyl; and 2,2′,4,6,6′-pentamethoxybiphenyl) as well as five biphenyl ethers and polar fragments relatively immobile during tlc. No biphenyl ethers could be demonstrated in the study reported herein. In agreement with the results of Glombitza and Lentz (47), no evidence was found here for the occurrence of *vic*-trihydroxy phenoxy end groups.

Information on the $Ca-NH_3$ cleavage reaction itself can also be deduced from the fragmentation observed: (a) cleavage of a diaryl ether bond *ortho* to two methoxy groups, and *para* to a third, liberates much more arene than phenol from that group, as also found by Glombitza and Lentz (47). Examples include the large quantity of 1,3,5-trimethoxybenzene (and its ring-methylated derivatives) produced, contrasted to the much smaller amount of 2,4,6-trimethoxyphenol recovered; and correspondingly, the large amount of **2** (and its ring-methylated derivatives) vis-à-vis the apparent absence of 2,2′,4,4′,6,6′-hexamethoxyhydroxybiphenyl from the fragments recovered.

(b) During cleavage of a 2,6-dimethoxy-1,4-diphenoxy group, the *meta* (4-) oxygen is retained intact whereas the *ortho* (1-) oxygen may or may not be lost. The presence of such units in the polymer is indicated by the appearance of 2,6-dimethoxy-1,4-dihydroxybenzene among the $Ca-NH_3$ reaction products. Some, but not all, of the 3,5-dimethoxyphenol fragments could have arisen from such units also (4-methylated and 2,4-dimethylated 3,5-dimethoxyphenols were observed); however, 2,6-dimethoxyphenol fragments were not seen. The 1,3-dimethoxybenzene observed could have arisen from loss of the 1,4-phenoxy oxygens, but given the absence of 2,6-dimethoxyphenol is more likely to be derived from 1,2-diphenoxy-3,5-dimethoxy groups.

(c) In contrast to the above, the *meta* (1-) oxygen of 1,2-diphenoxy-3,5-dimethoxy units may be lost during $Ca-NH_3$ cleavage, producing the presumed 2,4-dimethoxyphenol (rrt 0.867, see above). Loss of the 2-phenoxy oxygen could produce 3,5-dimethoxyphenol, and loss of both phenoxy oxygens, 1,3-dimethoxybenzene; however, each of the latter two fragments may have arisen from several different environments in the "polymer".

(d) Cleavage of the ether bond in a 4-phenoxy-2,2′,4′,6,6′-pentamethoxybiphenyl unit yields both 4-hydroxy-2,2′,4′,-6,6′-pentamethoxybiphenyl and 2,2′,4,6,6′-pentamethoxybiphenyl in approximately equal quantities (estimated from capillary column gc–ms experiments; on packed-column gc, the former fragment was found only in trace amounts).

High-molecular-weight polyphloroglucinols have been reported to occur in a variety of brown algae (26). The application of the methods described in this paper and similar methods independently developed by Glombitza and Lentz (47), together with ^{13}C nmr (25), may be expected to provide interesting structural and comparative data on these molecules.

A. GAVIN MCINNES, MARK A. RAGAN, DONALD G. SMITH, and JOHN A. WALTER. Can. J. Chem. **63**, 304 (1985).

^{1}H and ^{13}C nuclear magnetic resonance spectroscopy of the high-molecular-weight ($>10^4$) polyphenol fraction from *Fucus vesiculosus*, before and after acetylation or methylation, demonstrates that it is composed of phloroglucinol units (48.9 ± 3.5%) and 2,2′,4,4′,6,6′-hexahydroxybiphenyl, 2,2′,2″,4,4′,4″,6,6′,6″-nonahydroxy-1,1′:3′1″-terphenyl, and related quater- and polyphenyl groups (together, 51.1 ± 3.5%) linked by ether bonds, each bond involving the carbinol and methine carbons of different units and the formal loss of a molecule of hydrogen. The polymer is highly branched, with ca. 20–22% of the constituent units being chain termini; there is no evidence for large rings of units. Approximately 5–10% of the phloroglucinol and 54–82% of the directly bonded units occur on the exterior of the molecule, whereas the interior backbone consists predominantly of ether-linked phloroglucinol units.

A. GAVIN MCINNES, MARK A. RAGAN, DONALD G. SMITH et JOHN A. WALTER. Can. J. Chem. **63**, 304 (1985).

Sur la base des résultats obtenus à l'aide de la rmn du ^{1}H et du ^{13}C appliquée à la fraction polyphénolique (tant à l'état naturel qu'après une acétylation ou une méthylation) de poids moléculaire élevé ($>10^4$) isolée du *Fucus vesiculosus*, on peut conclure que ce produit est formé d'unités phloroglucinols (48,9 ± 3,5%), d'hexahydroxy-2,2′,4,4′,6,6′ biphényle, de nonahydroxy-2,2′,2″,4,4′,4″,6,6′,6″ terphényles et de groupements quater- et polyphényles qui leurs sont reliés (formant ensemble 51,1 ± 3,5%); toutes ces unités sont reliées par des liaisons éthers alors que chaque liaison implique le carbinol et les carbones méthines des différentes unités avec la perte formelle d'une molécule d'hydrogène. Le polymère est fortement ramifié et il comporte environ 20–22% d'unités constituantes qui terminent des chaînes; sur la base de nos données, il ne semble pas y avoir de grands arrangements cycliques des unités. Environ 5–10% du phloroglucinol et de 54–82% des unités qui sont directement attachées se retrouvent sur la partie extérieure de la molécule, alors que le squelette intérieur est formé principalement d'unités de phloroglucinol qui sont reliées par des liaisons éthers.

[Traduit par le journal]

Introduction

Polyphenols constitute as much as 15% of the dry matter of marine brown algae (Phaeophyceae) (1–3). Phloroglucinol, 2,2′,4,4′,6,6′-hexahydroxybiphenyl, and other MW (molecular weight) $<10^3$ phloroglucinol-based polyphenols have been identified as cellular constituents of *Fucus vesiculosus* (4–7) and other brown algae (4). However, as much as 95% of the total polyphenols of many brown algae have MW $>10^3$, and in *F. vesiculosus* approximately 25% have MW $>10^4$ (3, 5, 8). The gc–ms analysis of Ca–NH_3 degradation fragments of this highest MW fraction (9) has indicated that the molecules in this fraction contain phloroglucinol, 2,2′,4,4′,6,6′-hexahydroxybiphenyl, and smaller amounts of the corresponding hydroxyterphenyl and -quaterphenyl groups, linked together through oxygen. These observations suggest that the MW $>10^4$ polyphenols may be regarded as formally derived from phloroglucinol, although there is at present no supporting biosynthetic evidence. In this communication we present evidence from ^{13}C and ^{1}H nmr to characterize further the structure of the MW $>10^4$ polyphenols ("polymer") of *F. vesiculosus*.

Throughout this discussion, the term "unit" refers to hydroxylated benzene rings within the polymer, whereas the term "group" refers to two or more such units linked by direct carbon–carbon bonds to form hydroxy bi- or polyphenyls.

Experimental

Preparation of the polymer fraction, its derivatives, and reference compounds has been described in the previous paper (9). The additional reference compound hexaacetoxybenzene was synthesized from tetrahydroxy-*p*-quinone (Aldrich) by the procedure of Fatiadi and Sager (10) and was dissolved in trifluoroacetic acid-^{2}H for nmr. Unless otherwise specified, other nmr spectra were recorded in D_2O containing a small amount of DMSO as internal reference (for the native polymer and the corresponding reference compounds), or in $CDCl_3$ containing tetramethylsilane (TMS) (for acetoxyl and methoxyl derivatives). Chemical shifts are reported as ppm downfield from TSP (sodium 3-trimethylsilylpropionate 2,2,3,3-$^2H_4$) or TMS, respectively.

The ^{1}H nmr spectra were recorded at 80 and 100 MHz on Varian FT-80 and HA-100 instruments, respectively. The ^{13}C nmr spectra with broadband ^{1}H-decoupling were recorded at 20.11 MHz (Varian FT-80), 25.16 MHz (Varian XL-100), and 90.80 MHz (Nicolet Magnetics 360) at ambient temperatures, using an internal lock to ^{2}H. Conditions varied: flip angles 30°–55°, acquisition times 0.8–1.0 s, and delays between acquisitions 0–2.2 s. To ensure that spectral integrals were representative of the numbers of ^{13}C nuclei, in some experiments the relaxation reagents tris(ethylenediamine)chromium(III)chloride (CREN, 5 mg mL^{-1} D_2O solution) or chromium(III) acetylacetonate (10 mg mL^{-1} $CDCl_3$ solution) were used together with nOe suppression by "inverse-gated decoupling" (11) (decoupler off during the delay between acquisiitons). Within error, integrals were unchanged by these additional precautions, and hence may be taken as representative.

"EDIT" experiments (12) were carried out on Varian XL-100 (modified by addition of a Nicolet 1280 computer and 293B pulse programmer) and Nicolet Magnetics 360 instruments. The delay between 90° and 180° pulses at the ^{13}C frequency in the EDIT sequence was 2.99 ms, corresponding to an average $^1J_{CH}$ of 167 Hz.

Model structures used in the analysis of ^{13}C and ^{1}H spectra included the free hydroxy (suffix "*a*"), acetoxy (suffix "*b*"), and methoxy (suffix "*c*") forms of all possible phloroglucinol-based tri- (**1–3**), tetra- (**4–9**), penta- (**11–16**), and hexa-*O*-substituted (**18–21**) benzenes, tri- (**22–27**), tetra- (**28–35**), and penta-*O*-substituted (**36–41**) phenyl units, representative simple hydroxy ter- and quaterphenyls (**42–45**), and two other hydroxylated structures (**10, 17**) reported by

*"—" represents a direct (carbon–to–carbon) bond between phloroglucinol-based units. OH is replaced by CH_3CO or OCH_3 for the acetoxy or methoxy derivatives.

Glombitza and co-workers to be units of oligophloroglucinols in certain brown algae (although not *F. vesiculosus*). For structures whose chemical shifts were not available from reference compounds or from the literature, expected chemical shifts were calculated as before (7) using chemical shift substitutent effects derived from appropriate reference compounds. Full details are given in the Supplementary Material.[4] In general, no distinctions were made among different aryl (or aryloxy) substitutents for purposes of chemical shift calculations or symmetry considerations; this assumption was justified by the close similarities shown in substituent effects observed from different phloroglucinol-based substituents (Table 1).

Results

^{13}C nuclear magnetic resonance spectra

The ^{1}H-decoupled broadband ^{13}C nmr spectrum of the native polymer from *F. vesiculosus* (Fig. 1) shows three envelopes of signals which will be referred to as the high-frequency (δ_C 151.5–163.5), mid-frequency (126.0–128.5), and low-frequency (96.0–106.0 ppm) envelopes. Analysis of corresponding signals in the calculated or experimentally derived ^{13}C spectra of model structures **1***a*–**45***a* (Supplementary Material) demonstrates that the high-frequency envelope is composed of resonances from ^{13}C nuclei bearing hydroxy or aryloxy substituents and shielded by no more than one *ortho* oxy substituent (generally 149.3–163.9), and from oxy-substituted carbons shielded by two *ortho* and no *para* oxy substituents (141.6–152.4 ppm). Similarly, the mid-frequency envelope arises from the oxy-substituted carbons shielded by a *para* and two *ortho* oxy substituents, and the low-frequency envelope arises from directly bonded (as in C-1,1′ of biphenyl) and methine carbons shielded by a *para* and two *ortho* oxy substituents. The chemical shift ranges from ^{13}C nuclei in these environments in **1**–**45** and in the MW $>10^4$ polymer, both before and after acetylation or methylation (Table 2), are consistent with the hypothesis that the polymer is composed exclusively of phloroglucinol-based units.

This hypothesis also predicts that the combined integrated intensities I of the mid- (I_M) and low-frequency (I_L) envelopes should equal that of the high-frequency envelope (I_H). Analyses of ^{13}C spectra of the polymer and its acetoxy derivative (Table 3) confirmed these expectations: $I_H/(I_M + I_L)$ was 0.99 $\pm$ 0.01 when averaged over seven experiments designed (see Experimental) to minimize problems arising from differences in spin-lattice relaxation times and nOe.

A further test of the above hypothesis was available from the EDIT experiments. Signals in the mid- and high-frequency envelopes were all removed under conditions which suppressed signals from quaternary and methylene carbons, leaving only the methine carbon signals in the low-frequency envelope unaffected. Conversely, conditions which suppressed methyl and methine carbon resonances removed most of the signals in the low-frequency quaternary carbons (Fig. 1) having chemical shifts similar to those of the directly-bonded quaternary carbons (C-1) in **22**–**45** (see below). The completeness of suppression by the EDIT technique was confirmed by the absence of any residual methine carbon resonances in regions where they did not overlap quaternary carbon resonances. This technique permitted the direct measurement of the integrated in-

[4]The tabulated ^{13}C and ^{1}H chemical shifts for **1**–**45**, and full details of calculations, are available at a nominal charge from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

[a]N/A = shifts not available. N/O = not observed. Chemical shift ranges in polymer rounded to nearest 0.5 ppm. Signals in region from 104.0−121.0 ppm in spectrum of methylated polymer arise from *C*-methylated ring carbons.

tensity ratios I_{LQ}, I_{MQ}, and I_{HQ} of quaternary carbons within each envelope (Table 3).

Because the low-frequency quaternary signals arise from directly bonded carbons (C-1 in **22−45**), and because the high-frequency signals arise from exactly half of all ring carbons in the polymer (above), the proportion p_d of directly bonded units in the polymer may be estimated by $p_d = 100 \times 6I_{LQ}/2I_{HQ} = 52.5 \pm 3.3\%$. This estimate is an upper limit which does not take into consideration the presence of hydroxy ter-, quater-, and polyphenyl units. In order to make this correction, it is necessary to assign signals in the spectra of the polymer in much more detail.

Further details of the composition of the polymer were obtained by comparing chemical shifts (Fig. 1) and integrated intensities (Table 3) from the polymer spectra with those of the model units **1−45**. Chemical shift ranges expected for each type of ^{13}C nucleus in **1−45** already contain, in many cases, allowance for prediction error (for details, see Supplementary Material). Based on extensive experience, we estimate the accuracy of chemical shift comparisons between these model units and known model compounds to be ca. ±0.5 ppm. Thus, in the ensuing discussion, absence of a peak within the expected range, extended by 0.5 ppm on either end, is taken to indicate the absence of the corresponding unit from the polymer.

Using these criteria, 25 units may immediately be ruled out as components of the polymer: **3**, **9−20**, **27**, **29−32**, and **35−41** (Table 4). Unit **2** can be also ruled out because its characteristic ^{1}H nmr signal (**2***b* expected at δ_H 6.46−6.47 ppm) is absent, and **25** because the signal expected for C-1 of **25***b* (104.6−106.0 ppm) is absent from the appropriate EDIT spectrum. Seven further units (**1**, **6**, **7**, **23**, **26**, **33**, and **34**) not eliminated under these criteria are expected to exhibit signals in regions of the spectra where very small signals or tails from larger signals are found; these will be discussed individually below. With one exception (below), all remaining signals can be assigned to one or more of the remaining constituent units as described below.

vic-*Trihydroxylated units*

Absence of signals corresponding to C-2 of **10***a* and **10***c* (Table 4) indicates that **10** is not a component of the polymer, in agreement with results from Ca−NH_3 degradation (9). The *vic*-trihydroxylated unit **17** is discussed below with the other penta-*O*-substituted units.

*Penta-*O*-substituted units*

Absence of signals in the 141.6−151.5 ppm region of the polymer, and in the 142.3−150.1 region of its methoxy derivative, rules out the presence of penta-*O*-substituted units **11−17** and **36−41**. Most resonances from C-1, C-3, C-5 of **11−17**, and from C-2, C-4, C-6 of **36−41**, are expected to occur in these regions, and indeed do so in spectra of the corresponding MW $>10^4$ polyphloroglucinols from the brown algae *Chorda filum*, *Chordaria flagelliformis*, and *Dictyosiphon foeniculaceus* (13). The absence of these units was also indicated by the results from Ca−NH_3 degradation (9).

*Hexa-*O*-substituted units*

Absence of characteristic signals rules out the occurrence of hexa-*O*-substituted units **18−20** as constituents of the polymer (Table 4). The six identical carbons of **21***b* are expected at ca. 130.0−131.4 ppm, although this estimate is perhaps less certain than most due to the necessity of a solvent correction (see Supplementary Material). Although a small signal is apparent at 128−130.1 ppm, it is fully assignable to C-2 of **7***b* and (or) groups on substituent effects (all values in ppm)[a]

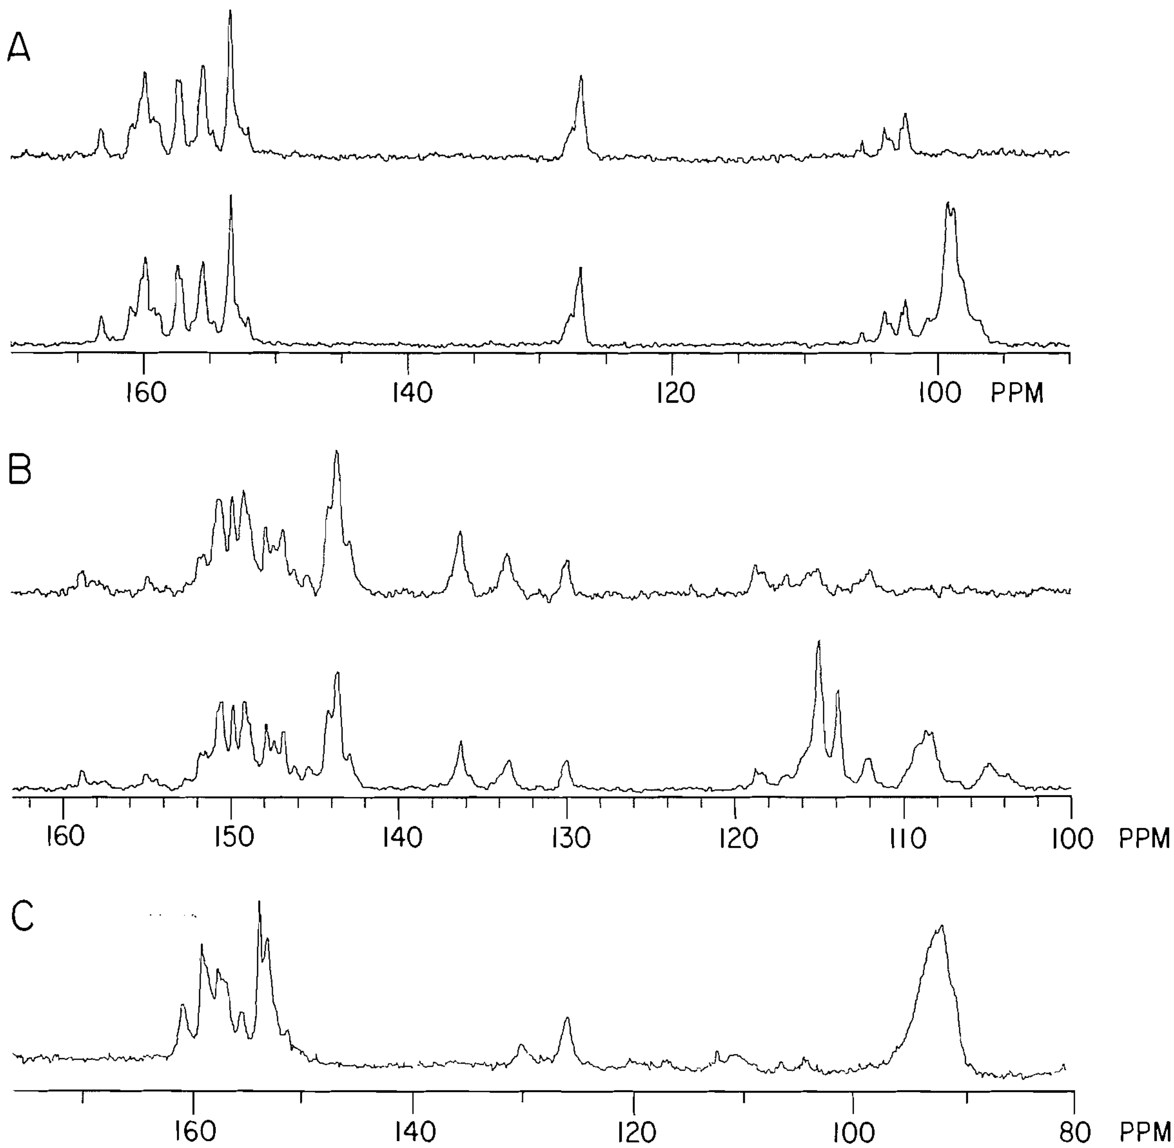

FIG. 1. The ^{13}C nmr spectra of the *Fucus vesiculosus* polymer. (A) Native hydroxy polymer, EDIT: quaternary carbons (above), and full spectrum (below). (B) Acetoxy polymer, EDIT: quaternary carbons (above) and full spectrum (below). (C) Methoxy polymer.

8*b* (below). Better evidence for the absence of **21** comes from integration of the three signal envelopes. The results displayed in Table 1 suggest that all six carbons of **21** will have almost identical chemical shifts, yet the results from signal envelope integration require that half the signals from each unit occur in the high-frequency envelope, and half in the mid- and (or) low-frequency envelopes. Therefore **21** cannot be a significant component of the polymer. This conclusion is reinforced by the absence of penta-*O*-substituted units (above), the lack of evidence from Ca—NH$_3$ degradation for hexa-*O*-substituted units (9), and the absence of precedent among lower-MW oligophloroglucinols for such units (4–7).

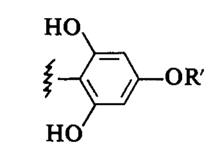
[a]Expressed as a fraction of the total integrated intensity from δ_C 166.0−94.0 (native polymer) or 160.0−100.0 ppm (acetylated polymer). Intensities used in text are from broadband-decoupled spectra, except for low-frequency quaternary signals (from EDIT).
[b]Effects of spin-lattice relaxation and nOe on relative intensity reduced by relaxation reagent (CREN or $Cr(acac)_3$) and use of 2-s delay between acquisitions.
[c]Results scaled so $I_{HQ} + I_{MQ} = I_H + I_M$ for each individual spectrum.
[d]Error shown here is from scatter of results for 2−4 spectra. Error of individual integrations ca. ±0.010 within each range.

Tri-O-substituted units

Units **2**, **3**, and **27** have already been ruled out as possible components of the polymer (Table 4 and above). Signals expected for C-1 and C-4 of **1***b*, and for C-2 of **23***a* and **23***b*, correspond to small peaks or tails of larger peaks which cannot necessarily be attributed to other units. Integration of the 108- to 110.2-ppm region of the EDIT spectrum of the acetoxy polymer (Table 3) indicates a maximum abundance of about 1% for **23** + **26** + **33**. Some indication of the maximum abundance of **1** (plus **2**) may be obtained from the high-frequency region of the spectrum of the methoxy polymer: the signal near 160.9 ppm could arise from C-1, C-3, C-5 of **1***c* and (or) **2***c*, and (or) it could represent C-4 of **22***c* and (or) **24***c*. The signal near 159.0 ppm could arise from twice as many carbons (C-2, C-6) of **22***c* and (or) **24***c*, as well as from C-2 (and perhaps also C-4,6) of the methoxy terphenyl **42***c*. Broadness and confluence of these signals preclude accurate integration, but the 160.9-ppm signal accounts for about 9.5−10% of the integral of the high-frequency envelope, and the 159.0-ppm signal, 22−23%. Correction for the contribution of **42** to the latter (below and Table 5) leaves a minimum of 19−20% corresponding to **22***c* and (or) **24***c*. Thus **22***c* and (or) **24***c* must be responsible for virtually all of the 160.9-ppm signal, and **1***c* and **2***c* must be virtually absent.

With units **1**−**3**, **26**, and **27** absent or negligibly minor, the signal at 163.1 ppm in the spectrum of the native polymer must arise from C-4 of **24***a* (expected: 162.5 ppm), and the signal near 158 ppm in the spectrum of the acetoxy derivative from C-4 of **24***b* (expected: 157.7−158.1 ppm). Repeated integration of these signals indicates an abundance of 14.4 ± 1.1% for **24** (Table 5).



22*a* R′ = H
24*a* R′ = R
(R = phloroglucinol-based unit)

With units **1**, **2**, **23**, **25**, **27** (above), and **43** (below) absent or negligible, the signal at 160.8 ppm in the spectrum of the native polymer must come from C-4 of **22***a* (expected: 160.3 ppm) and most of the integral remaining unaccounted for so far in the 157.9−162.0 ppm region of the spectrum of the methoxy derivative must come from C-4 of **22***c* (expected: 159.8−160.6 ppm); repeated integration and computer-aided deconvolution (using the Nicolet curve-resolution program NMRCAP) of these signals indicate an abundance of 18.6 ± 1.0% for **22** (Table 5).

Several independent checks on these estimates of **22** and **24** are available. The integral of the 158- to 162-ppm region of the spectrum of the methoxy polymer gives an estimate of 28.5−30.0% for **22** + **24** (see above). The integral of the

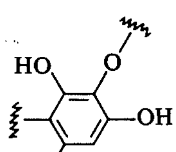
[a]Terminal units.
[b]Mean of four estimates (see text); **4**, maximum 3.4%.
[c]δ_C 105.5 ppm signal in native polymer spectrum (see text).

101.5- to 103.0-ppm region of the EDIT spectrum of the native polymer (Table 3) suggests an abundance of 18.0 ± 4.0% for **22**, although this estimate is complicated by the possible contribution of hydroxy polyphenyl units near this region. Finally, the integral of the 110.2- to 116.2-ppm region of the EDIT spectrum of the acetoxy polymer (Table 3) corresponds to an abundance of 35.4 ± 3.0% for units **22**, **24**, **34**, **43**, and **45**, in good agreement with the above estimate of 33.0 ± 2.1% for **22** + **24** and suggesting that units **34**, **43**, and **45** are at best minor components.

*Directly bonded tetra-*O*-substituted units*

Only one individual tetra-*O*-substituted unit can be readily identified from the ^{13}C nmr spectra: the signal at 118.2–118.5 ppm in the spectrum of the acetoxy polymer is characteristic of **28***b* (C-1 expected: 118.0–118.2 ppm), and integrates (Table 3) for an abundance of 10.5 ± 0.8%. Two other characteristic signals from this unit, those for C-2 of **28***a* (151.9, expected 151.4–151.6 ppm) and C-6 of **28***b* (145.2, expected 145.0–145.1 ppm), are not well resolved from larger neighboring signals, but integrals and computer-aided curve resolution indicate an abundance of 9.2 ± 1.5%.

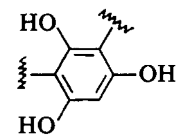


28*a*

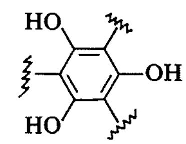
All other directly bonded tetra-*O*-substituted units have already been ruled out (**29**–**32** and **35**, above), or have been shown to be present in only trace amounts (**33** and **34**, above). Further confirmation of the low abundance of **33** and **34** may be inferred from the abundances of the corresponding non-phenoxylated units **25** and **26** (zero and <1%, respectively), from the lack of evidence from Ca–NH_3 degradation for **29**–**35** (9), and from the lack of precedent among known lower-MW polyphloroglucinols (4–7) for such structures in brown algae.

Hydroxy polyphenyl units

The ratio $6I_{LQ}/2I_{HQ}$ from EDITed ^{13}C nmr spectra (above) places a maximum (uncorrected) limit of 52.5 ± 3.3% on the abundance of directly bonded units in the polymer. Units **22**, **24**, and **28** have already accounted for 43.5 ± 2.9%, and **23**, **26**, **33**, and **34** for perhaps another 1%, leaving at most ca. 8.0 ± 6.2% (uncorrected) for hydroxyl polyphenyl units such as **42**–**45**. An estimate of **44** can be made from the integral of the small signal at 146.2 ppm in the acetoxy polymer spectrum (C-2,4,6 expected: 146.4–146.8 ppm), which indicates an abundance of 2.5 ± 0.5%, other units with resonances in this region having been eliminated or otherwise accounted for. Unit **42** exhibits only one characteristic ^{13}C nmr signal, at ca.



42*a*



44*a*

117 ppm in the acetoxy polymer EDIT spectrum. Integration and curve resolution yields 3.7 ± 1.0% for **42** (Table 3), but again the poor baseline and small, partially confluent signals in this region make this estimate questionable. These levels of **42** and **44** agree well, however, with the results from Ca–NH_3 degradation (9). Units **43** and **45** therefore probably amount to <2%.

The estimated abundance of directly bonded units can now be corrected for the presence of polyphenyl units: (52.5 ± 3.3) – (4/18)(3.7) – (6/24)(2.5) = 51.1 ± 3.5%. This estimate, which is again an upper limit, stands in good agreement with the sum of **22**, **24**, **28**, **33**, **34**, and **42**–**45** = ca. 49.7 ± 4.4% (Table 5). The difference, if real, may reflect the presence of small quantities of polyphenyl units other than **42**–**45**. In this regard it is interesting that the small signal at 105.5 ppm in the spectrum of the native polymer could not be assigned; it remained after suppression of ^{13}C—H resonances by the EDIT procedure, and presumably arises from C-1 of a minor unit (<2% abundance) having substituents or experiencing deshielding not considered here.

*Remaining tetra-*O*-substituted units*

The ca. 48.9 ± 3.5% of the units of the polymer which so far has not been considered are the tetra-*O*-substituted, entirely ether-linked structures **4**, **5**, **8**, and possibly **6** and **7** (Table 4). Four independent estimates of the abundance of these units are available: two (a and b) are direct, while two (c and d) require the absence of penta- and hexa-*O*-substituted units and supernumerary hydroxylation: (a) the integral of the 156.2- to 157.9-ppm region of the methoxy polymer spectrum (C-5 of **4***c*–**8***c*, corrected for C-2,4,6 of **44***c*) indicates an abundance

4*a*	H	H	H
5*a*	R	H	H
6*a*	H	R	H
7*a*	R	H	R
8*a*	R	R	H

(R = phloroglucinol-based unit)

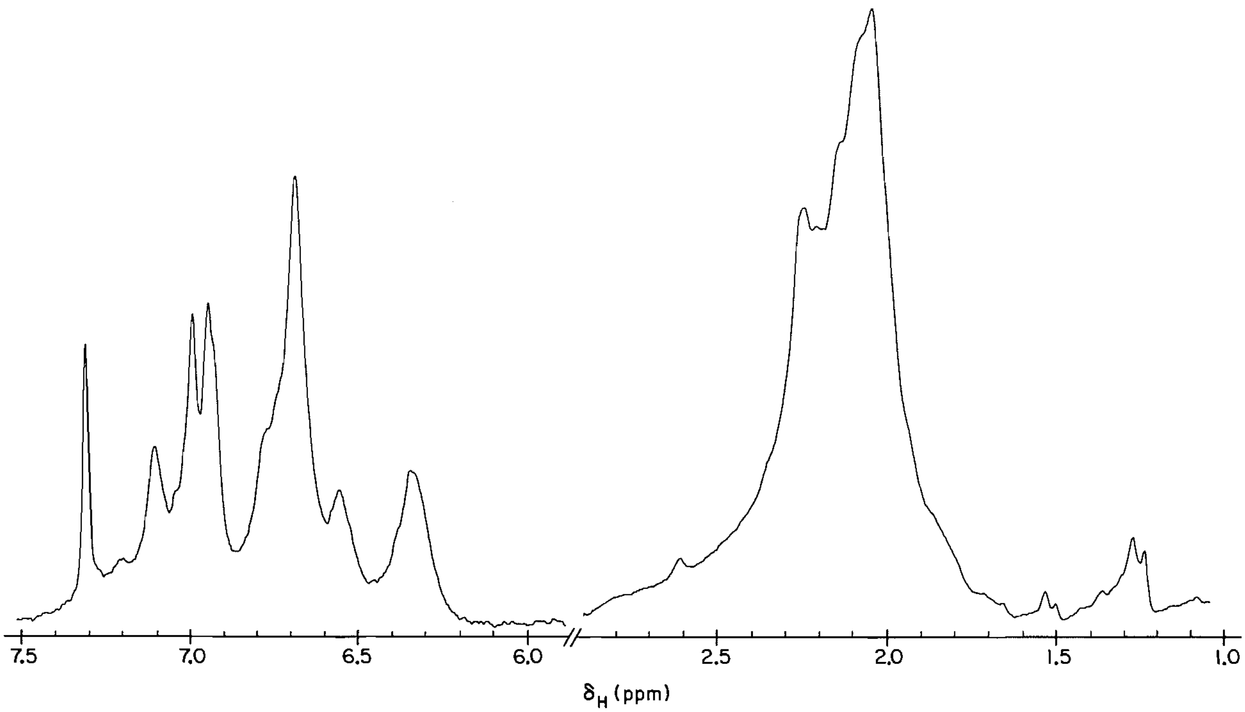

FIG. 2. The ^{1}H nmr spectrum of acetoxy polymer from *Fucus vesiculosus*.

of 53.7 ± 6.0% for **4**–**8**; (b) the integral of the 127.5- to 139.0-ppm region of the broadband-decoupled acetoxy polymer spectrum (Table 3; C-2 of **4***b*–**8***b*, possibly including small amounts of C-3 from **33***b* and **34***b*, and corrected for C-3 of **28***b*) indicates an abundance of 48.3 ± 3.8% for **4**–**8**; (c) from the integrals of the acetoxy methyl, acetoxy carbonyl, and methoxy ^{13}C nuclei in spectra of the acetoxy and methoxy polymer, there are 2.40 ± 0.07 derivatizable hydroxyls per unit in the native polymer, hence (after correction for **28**) 52 ± 7% of entirely ether-linked units; and (d) from the ratio of derivatizable hydroxyls to aromatic protons as determined by ^{1}H nmr, graphical analysis based on model compounds demonstrates that 53.5 ± 2.5% (corrected for **28**) of all units are entirely ether linked. These results (mean, 51.9 ± 3.6%) agree well with abundances of fragments present in the Ca–NH_3 degradation product of the methoxy polymer (9). Consideration of units **4**–**8** will therefore complete the roster of units allowable as components of the polymer.

Accurate assignment of the three signals in the mid-frequency region of the broadband-decoupled spectrum of the acetoxy polymer is crucial to a more detailed quantitative analysis of individual units **4**–**8**. The signal at 129.9 ppm clearly arises from C-2 of **7***b* (expected: 125.8–128.4 ppm) and **8***b* (expected: 129.0–129.3), as these are the only remaining possibilities (C-3 of **33***b* and **34***b*, expected at 129.1–129.8 ppm, may contribute slightly to this signal). The integral of this signal (Table 3) suggests an abundance of 15.0 ± 2.1% for these units; this may be a slight underestimate due to the presence of tails on this signal. The central signal, at 133.3 ppm, arises from C-2 of **5***b* (19.8 ± 2.0%; expected: 131.0–133.4 ppm), while the signal at 136.1 ppm (corresponding to 24.0 ± 3.0%) is due to C-2 of **4***b* (expected: 136.3–136.8 ppm) and C-3 of **28***b* (expected: 136.6–136.7 ppm).

Problems arise with C-2 of **6***b*, if present (Table 4). Its resonance is expected at 134.2–134.6 ppm, between the 133.3 and 136.1 peaks but slightly closer to the former. If it is assumed to be absent or to contribute to the 133.3-ppm signal, the 136.1-ppm peak would therefore arise entirely from **4***b* and **28***b*, and the abundance of **4** could be calculated by difference as 13.5 ± 3.8%. This is not possible for the following reason (see Discussion): in a large polymer, the proportion of terminal units cannot exceed the proportion of branching points. Here, the proportion of branching points (**7**, **8**, **43**–**45**, and perhaps some minor units: Table 5) is only ca. 22% at most, and the terminal unit **22** (18.6 ± 1.0%) already accounts for most of this. Therefore **4** can constitute at most 3.4% of the polymer, requiring that C-2 of **6***b* contribute to the 136.1-ppm signal in the spectrum of the acetoxy polymer and yielding 13.5 ± 3.8% for **4***b* + **6***b*.

With C-2 of **6***b* assigned to the 136.1-ppm signal, the integral of the 133.3-ppm peak, corresponding to 19.8 ± 2.0%, can be assigned entirely to **5***b*, a unit already encountered in a tetrameric phloroglucinol isolated earlier from *F. vesiculosus* (7). Further attempts to estimate **4** independently of **6**, and **7** independently of **8**, are subject to considerable uncertainty.

^{1}H nuclear magnetic resonance spectra

The ^{1}H nmr spectrum of the native polymer was recorded in H_2O (containing a small amount of D_2O) using selective gated saturation to suppress the solvent signal. Aromatic proton resonances appeared as a broad envelope (δ_H ca. 5.65–6.65 ppm) with poorly resolved maxima at ca. 6.11, 6.18–6.21, and 6.28 ppm. No signals attributable to the polymer were observed outside this region. When DMSO-$^2H_6$ was employed as solvent, the signals from the polymer were still very broad, but suggested a ratio of hydroxy to aromatic protons of ca. 1.55:1. After methylation of the polymer, the aromatic protons resonated in a broad envelope between ca. 5.60–6.75 ppm, with poorly resolved maxima at ca. 6.15 and 6.18 ppm; *O*-methyl protons were seen between ca. 3.00 and 4.20, with poorly resolved maxima at 3.63 and 3.74 and with a minor downfield tail extending beyond 4.50 ppm, and with the ratio of *O*-methyl

TABLE 6. Comparison of abundances of constituent units as estimated from ^{1}H and ^{13}C nuclear magnetic resonance

Unit(s) No.[a]	Abundance (^{1}H nmr)[b]	Abundance (^{13}C nmr)[c]
4 + **6** + **22** + **24**	45.7	46.5 ± 5.9
5	18.6	19.8 ± 2.0
7	16.5	<17.1
28	15.1	10.5 ± 0.8
42	4.1	3.7 ± 1.0
	100.0	<97.6 ± 9.7

[a]Units grouped as required by spectra.
[b]Values normalized assuming presence of only **4**–**7**, **22**, **24**, **28**, and **42**. Individual estimates in this column will therefore tend to be overestimates: see text. For estimate of error, see text.
[c]Values from Table 5.

groups to aromatic protons ca. 1.4:1. A small signal probably arising from *C*-methyl protons (introduced during the methylation procedure) occurred at 1.26 ppm. Little other information could be gleaned from these spectra because the resonances were broad and poorly resolved.

Aromatic protons in the acetoxy polymer, however, yielded relatively well-resolved signals (Fig. 2) which could be assigned by comparison with reference compounds (Supplementary Material). Because some units contain no aromatic protons (e.g. **44**, **45**) and because reference spectra were not available for others (most importantly **8***b*), quantitation of constituent units based on ^{1}H nmr could be only approximately (to within perhaps ±15% overall) congruent with quantitation based on ^{13}C nmr. Nonetheless, a similar quantitative picture emerged (Table 6). Tentative assignments are: δ_H 6.34 (**7***b*), 6.56 (H-6 of **5***b*), 6.69 (**6***b* and **24***b*), 6.78 (H-4 of **5***b*), 6.94 (**4***b*), 6.99 (**22***b*), 7.10 (**28***b*), and 7.20 ppm (**42***b*). Unit **2***b* (H-2 expected: 6.46–6.47 ppm) was absent.

Discussion

Some conclusions about the structure of the polymer can be drawn from the proportions of constituent units (Table 5). As mentioned earlier, in a sufficiently large polymer the proportion of terminal units cannot exceed the proportion of branching points. The proportion of branching points in the *F. vesiculosus* polymer cannot be determined exactly, but units contributing one branch point each (**7**, **8**, **26**, **43**, **44**) constitute about 17–18% of the units of the polymer, and units contributing two branch points (**33**, **34**, and **45**) add an indeterminate but small amount (Table 5). Even considering the possibility that the unidentified unit having C-1 at 105.5 ppm in the native polymer spectrum could hypothetically contribute a few percent more branching points, it is difficult to imagine that the total proportion of branching points could exceed about 22% on a per-unit basis. This is almost certainly completely matched by the abundances of the terminal units **22** (18.6 ± 1.0%), **4** (maximum 3.4%), and **1** if present. Physical properties of the polymer in solution make it extremely unlikely that any large interlocking or cross-linked rings of units occur, as there is no indication that the polymer or its derivatives form gels or viscoelastic solutions at any concentration in a variety of solvents; moreover, the native polymer is extremely soluble (>1 g mL^{-1} H_2O).

The 18.6 ± 1.0% abundance of **22** immediately requires that most of the directly bonded units in the polymer occur in

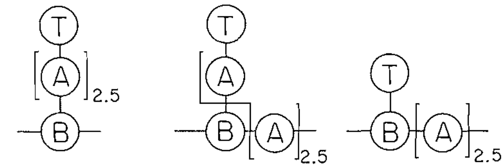

FIG. 3. Three possible average substructures (ignoring minor units) of the *Fucus vesiculosus* polymer. A = **5**, **6**, **24**, **28**, or **42**; B = **7**, **8**, **43**, **44**, or **45**; T = **4** or **22**.

terminal bi- or polyphenyl groups. The minimum proportion of such units would occur if all units **43**–**45** were internal, were directly bonded to a maximum number (**43** and **44**, one; **45**, two) of unit **22** each, and if no **22** was linked to any **42**; the maximum proportion would be found if all **22** and **42** contributed to terminal groups. These estimates, respectively, correspond to 54% to 82% of all directly bonded units being present in terminal bi- or polyphenyl groups, in qualitative agreement with results from Ca–NH_3 degradation (9). The corresponding estimate for terminal ether-linked units (**4**) is ca. 5–10%.

The existence of ca. 22% terminal (T) and ca. 22% branching (B) units (neglecting, for the moment, units **33**, **34**, and **45**) implies that on average there are (100 − 2(22) = 56)/22 = ca. 2.5 non-branching, non-terminal units for every terminus and every branch point. This situation corresponds to the "average" polymer substructures depicted in Fig. 3. If any regularity occurs in the structure of the polymer, it is only over a large scale, as may be deduced from the relatively low intensity of some signals and from the large number (≈65) of distinct aromatic ^{13}C resonances in the high-field (8.45 T) spectrum. The evidence points to the *F. vesiculosus* high-MW polyphloroglucinol fraction containing topologically linear polymers with numerous short branches, many of which terminate in hydroxy bi- or polyphenyl groups.

The occurrence, in approximately equivalent amounts, of directly bonded and exclusively ether-linked units establishes the *F. vesiculosus* polymer as distinct from the entirely ether-linked type found in *Chorda filum*, *Chordaria flagelliformis*, and *Dictyosiphon foeniculaceus*, and equally distinct from the almost exclusively carbon–carbon bonded type in *Pilayella littoralis* and *Spongonema tomentosum* (13). The absence of numerous potential candidate units from all of these polymers, the nonrandom distribution of ether-linked and directly bonded units within the *F. vesiculosus* polymer, the existence of different structural types of polymers within the brown algae, and the apparent correlation of these structural types with taxonomic position (13) strongly suggest that these polymers are produced by a nonrandomly directed assembly of smaller moieties.

Cyclotetraphosph(III)azanes: donor properties and ylide formation

KEITH D. GALLICANO AND NORMAN L. PADDOCK
Department of Chemistry, University of British Columbia, 2036 Main Mall, Vancouver, B.C., Canada V6T 1Y6

Received March 26, 1984

KEITH D. GALLICANO and NORMAN L. PADDOCK. Can. J. Chem. **63**, 314 (1985).

The ligand $(MeNPMe)_4$ (L) forms complexes $(L.CoCl^+)_2CoCl_4^{2-}$, $(L.CoCl)^+BPh_4^-$, $L.M(CO)_3$ (M = Cr, Mo, W, Mn^+), and a nickel complex $L.Ni_2(CO)_3$, which is easily oxidised to the phosphonimide $[MeNP(O)Me]_4$. Quaternary complexes $[LM(CO)_3R]^+I^-$ have been prepared both by quaternisation of the neutral complex (R = Me, CH_2CN, $CH_2C(O)NH_2$, M = Cr, Mo, W) and (R = Me) by reaction of the simple quaternary with the metal carbonyl. The quaternary complexes have been deprotonated to ylidic complexes, $L.M(CO)_3CH_2$ (M = Mo, W) in which the ylidic group has displaced one phosphine function. Chemical and structural features are discussed in terms of *d*-orbital contraction by acceptor groups. The phosphazane $(MeNPPh)_4$ has been prepared.

KEITH D. GALLICANO et NORMAN L. PADDOCK. Can. J. Chem. **63**, 314 (1985).

Le ligand $(MeNPMe)_4$ (L) forme des complexes $(L.CoCl^+)_2CoCl_4^{2-}$, $(L.CoCl)^+BPh_4^-$, $L.M(CO)_3$ (M = Cr, Mo, W, Mn^+) et un complexe de nickel $L.Ni_2(CO)_3$, qui s'oxyde facilement en phosphonimide de $[MeNP(O)Me]_4$. On a préparé des complexes quaternaires du type $[LM(CO)_3R]^+I^-$ soit par quaternisation du complexe neutre (R = Me, CH_2CN, $CH_2C(O)NH_2$, M = Cr, Mo, W) et (R = Me) ou par réaction du dérivé quaternaire simple avec le métal carbonyle. On a déprotoné les complexes quaternaires afin d'obtenir les complexes d'ylides, $L.M(CO)_3CH_2$ (M = Mo, W) dans lesquels le groupe ylide a remplacé une fonction phosphine. On discute des caractéristiques chimiques et structurales en fonction d'une contraction des orbitales *d* par les groupes accepteurs. On a également préparé le phosphazane $(MeNPPh)_4$.

Introduction

The chemistry of the cyclic phosphazanes $(R'NPR)_n$, recently reviewed by Keat (1), was significantly extended in 1977 by the synthesis of the tetrameric phosphazanes **1** (n = 4, R' = Me; *a*, *b*, R = Me, Et) by Zeiss and co-workers (2). The compound **1***a*, which has a crown conformation (2) similar to that of S_8, adds sulphur to give the trisulphide $(MeNPMe)_4S_3$ (3), forms new heterocyclic systems with acetylenes (4), and is quaternised by methyl iodide (**2***a*) (5). All the reactions, like that of **1***a* with $Mo(CO)_6$ (6), have special points of interest. This paper extends the study of the reactions of cyclotetraphosphazanes with acceptors, and describes the formation of ylidic metal carbonyl derivatives. The principal compounds referred to are illustrated in Fig. 1.

Experimental

All reactions and manipulations of air-sensitive products were carried out in an atmosphere of dry nitrogen. Solvents were distilled before use: tetrahydrofuran (THF) and toluene from sodium/benzophenone, acetonitrile from calcium hydride, and dimethylformamide (DMF) from potassium hydroxide.[1] In a typical photolysis experiment, the reaction mixture, in a silica vessel, was irradiated at a distance of 10–13 cm by a 450 W Hanovia mercury vapour lamp placed inside a quartz water-cooled jacket.

Infrared spectra, calibrated against polystyrene, were obtained from Nujol mulls on CsI plates using a Perkin Elmer 457 spectrophotometer. Mass spectra were recorded at 70 eV on a Varian (Atlas) CH4-B mass spectrometer. Nuclear magnetic resonance spectra were run on Varian XL-100 (^1H, 100 MHz; ^{31}P, 40.5 MHz) and Bruker WH-400 (^1H, 400 MHz) spectrometers. Positive chemical shifts are to low field of reference. Conductance measurements were made with a Wayne Kerr bridge Model B221A on solutions in nitromethane or water, concentrations near 10^{-3} *M*. Abbreviations: b, broad; m, medium; sh, sharp; shl, shoulder; st, strong; v, very; w, weak.

N-*Tetramethyl*-P-*tetraphenylcyclotetraphosph(III)azane* (**1***c*)

Phenyldichlorophosphine (10.73 g, 0.06 mol), purified by distillation over $AlCl_3$, was dissolved in 10 mL CH_3CN and added to heptamethyldisilazane (10.5 g, 0.06 mol). The mixture was heated under reflux with stirring for 3 h. Colourless crystals of **1***c* precipitated from the cooled reaction mixture, and were crystallised from chloroform; yield 15%, mp (decom.) 270–275°C. δ_P($CDCl_3$, ext. H_3PO_4) 107.6 ppm; δ_H($CDCl_3$, int. TMS) 3.18 (12H, NMe, multiplet), 7.4–7.7 (20 H PPh, multiplet). Major peaks in the mass spectrum: *m/e* 548 (M^+), 471 $(M - Ph)^+$, 411 $(MeNPPh)_3^+$, 274 $(MeNPPh)_2^+$, 197 $[PhP(NMe)_2P]^+$ (base peak). *Anal.* calcd. for $C_{28}H_{32}N_4P_4$: C 61.3, H 5.9, N 10.2; found: C 60.9, H 5.9, N 10.2.

Quaternisation reactions

Bromoacetophenone (0.131 g, 0.00066 mol) in 5 mL THF was added dropwise to **1***a* (0.097 g, 0.00032 mol) in 15 mL THF. After 1–5 min a heavy white precipitate formed, which was filtered off after stirring for 2 h at room temp. The hygroscopic solid was washed with 2 × 4 mL THF to give analytically pure $[(MeNPMe)_4CH_2C(O)Ph]^+Br^-$ (**2***b*) yield about 50% mp (decom.) 118–125°C under N_2. ν(C═O) 1678 cm^{-1}. *Anal.* calcd. for $C_{10}H_{31}BrN_4OP_4$: C 38.5, H 6.3, N 11.2, Br 16.0; found, C 38.4; H 6.4, N 11.0, Br 15.9. In a similar reaction of **1***a* with iodoacetamide, a 50% yield of $[(MeNPMe)_4CH_2C(O)NH_2]^+I^-$ (**2***c*) was obtained as a very hygroscopic solid, mp (decom.) 140–146°C under N_2 to a yellow liquid. *Anal.* calcd. for $C_{10}H_{28}IN_5OP_4$: C 24.8, H 5.8, N 14.4, I 26.2; found: C 24.9, H 5.8, N 14.2, I 26.0. The quaternary tetraphenylborate, from **2***a* and sodium tetraphenylborate in THF, was hydrolysed in damp air to bis(dimethylamino)dimethylphosphonium tetraphenylborate $[(MeNH)_2PMe_2]^+BPh_4^-$, δ_P($(CD_3)_2CO$, ext. H_3PO_4) + 53.7 ppm.[2] *Anal.* calcd. for $C_{28}H_{34}BN_2P$: C 76.4, H 7.8, N 6.4; found: C 76.1, H 7.8, N 6.4.

Complex formation with Co(II)

If a dilute solution of $CoCl_2$ in CH_3CN is added slowly to **1***a* in CH_3CN, an orange colour develops. If $CoCl_2$: **1***a* > 1.0, the green complex $[(MeNPMe)_4CoCl^+]_2CoCl_4^{2-}$ (**3***a*) is formed. **1***a* (0.115 g, 0.00038 mol) and $CoCl_2$ (0.100 g, 0.00077 mol) were dissolved in 5 mL hot acetonitrile, a green precipitate being formed immediately. The mixture was heated to boiling for 30 min, filtered, and the bright green product **3***a* washed with 2 × 5 mL CH_3CN (0.175 g, 93%, mp (decom.) > 270°C). ν[CoCl(in $CoCl_4^{2-}$)] (cm^{-1}) 311 (st), 298 (m).[3]

---

[1] Nitromethane was purified on an alumina column, dried over P_2O_5, and stored over molecular sieves.

[2] Cf. +54 ppm for $[Me_2N(NH_2)PMe_2]^+Cl^-$ (7).

[3] It is insoluble in organic solvents, but soluble in water, in which the anion (only) is hydrolysed.

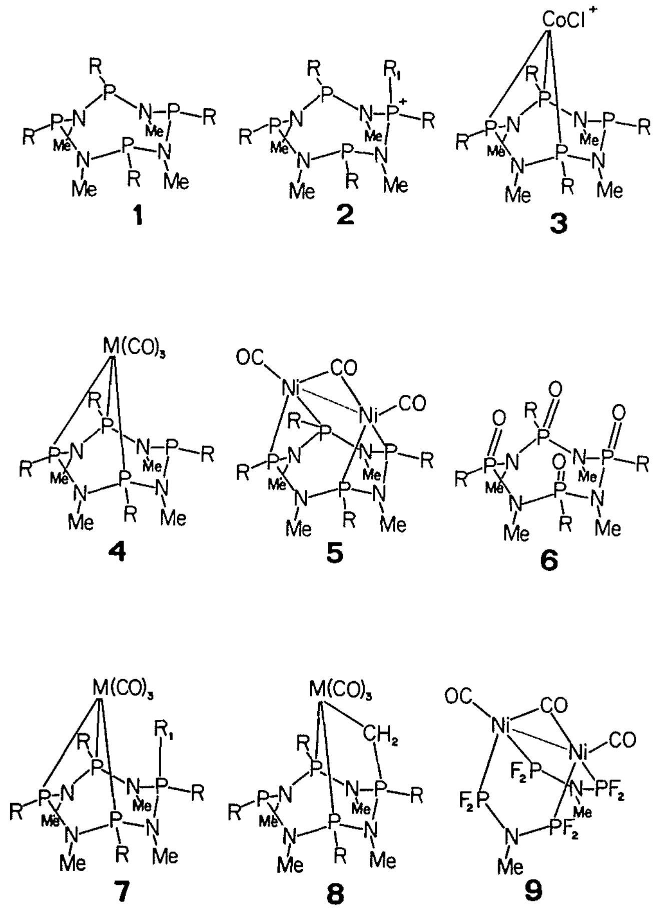

FIG. 1. **1**, *a*, R = Me; *b*, Et; *c*, Ph. **2**. R = Me: *a*, R_1 = Me; *b*, $PhC(O)CH_2$; *c*, $NH_2C(O)CH_2$. Anion I^- except **2***b*, Br^-. **3**, R = Me. **4**, R = Me: *a*, M = Mo; *b*, W; *c*, Cr; *e*, Mn^+ (anion Br^-); *f*, Mn^+ (anion $Mo(CO)_5^-$); *d*, R = Et, M = Mo. **5**, **6**, R = Me. **7**, anion I^-, R = Me for all, R_1 = Me: *a*, M = Mo; *b*, W; *c*, Cr; *d*, R_1 = $NH_2C(O)CH_2$, M = Cr; *e*, R_1 = $NCCH_2$, M = Cr; **8**, R = Me: *a*, M = Mo; *b*, W. **9**, adapted from ref. 16.

Anal. calcd. for $C_{16}H_{48}Cl_6Co_3N_8P_8$: C 19.4, H 4.9, N 11.3, Cl 21.5; found: C 19.7, H 4.9, N 11.3, Cl 21.4. On exposure to air, **3***a* forms a dihydrate. *Anal.* calcd. for $C_{16}H_{52}Cl_6Co_3N_8O_2P_8$: C 18.7, H 5.1, N 10.9; found: C 18.7, H 5.0, N 10.7. The tetraphenylborate $[(MeNPMe)_4CoCl]^+BPh_4^-$ (**3***b*) was precipitated as a lilac–green solid from an aqueous solution of **3***a* by the addition of $NaBPh_4$ and crystallised as needles from CH_3CN, mp (decom.) 225–270°C. It is soluble in DMF and $MeNO_2$; Λ_m ($MeNO_2$, 25°C) 68.8 ohm^{-1} cm^2 mol^{-1}. Its visible spectrum shows a strong charge transfer band at 386 nm (ϵ_{max} ~ 3600) and a broad band centred at ~672 nm. ν(Co—Cl) was not observed. *Anal.* calcd. for $C_{32}H_{44}BClCoN_4P_4$: C 53.8, H 6.2, N 7.9, Cl 5.0; found: C 53.6, H 6.3, N 7.8, Cl 4.8.

Reactions of **1***a*, **1***b with metal carbonyls*

The preparation of $(MeNPMe)_4Mo(CO)_3$ (**4***a*), already described (6), is better done photochemically in either THF or acetonitrile at 65°C (3 h for 200 mg of **1***a*) as described below for the tungsten complex. **1***a* (0.13 g, 0.00043 mol) and $W(CO)_6$ (0.154 g, 0.00044 mol) were dissolved in 15 mL hot, oxygen-free CH_3CN and irradiated at 60°C for 1 h. After a further 30 min at room temperature, yellow crystals appeared. The mixture was cooled to −30°C, and the crystals of $(MeNPMe)_4W(CO)_3$ (**4***b*) filtered off and washed with boiling CH_3CN; mp (decom.) >250°C, ν(C≡O) (cm^{-1}) 1922, sh; 1816 (side bands at 1775, 1848). The mass spectrum shows the parent ion at *m*/*e* 568 and stepwise loss of three CO groups. *Anal.* calcd. for $C_{11}H_{24}N_4O_3P_4W$: C 23.3, H 4.3, N 9.9; found: C 23.2, H 4.3, N 10.0. The chromium complex $(MeNPMe)_4Cr(CO)_3$ (**4***c*) was prepared similarly; mp (decom.) >280°C, ν(C≡O) (cm^{-1}) 1921, sh; 1813, 1824 b. The mass spectrum shows the parent ion at *m*/*e* 436 and stepwise loss of three CO groups. *Anal.* calcd. for $C_{11}H_{24}CrN_4O_3P_4$: C 30.3, H 5.6, N 12.8; found: C 30.1, H 5.4, N 12.9. **4***c* was also prepared in low yield by stirring equimolar quantities of **1***a* and $Cr(CO)_5$.THF in solution in THF for 3 days at room temperature. The complex $(MeNPEt)_4Mo(CO)_3$ (**4***d*) was prepared by heating a solution of **1***b* (0.092 g, 0.00026 mol) and $Mo(CO)_6$ (0.069 g, 0.00026 mol) in 15 mL toluene at 70°C for 1 h. Upon cooling, pale yellow crystals of **4***d* precipitated (0.084 g, 60%), which were recrystallized twice from toluene as tiny pale yellow needles, mp (decom.) 210–260°C; δ_P($CDCl_3$, ext. H_3PO_4) 111.0 ppm; δ_H($CDCl_3$, int. TMS) 2.89 (NMe, 5-line multiplet, J_{PH} 3.1 Hz), 1.96 ($PC\underline{H}_2CH_3$, quartet not split by P), 1.2 ($PCH_2C\underline{H}_3$, b); ν(C≡O) (cm^{-1}) 1921, 1835, 1819; solid state bands at 1941, 1787. The mass spectrum shows the parent ion at *m*/*e* 536 and the stepwise loss of three CO groups. *Anal.* calcd. for $C_{15}H_{32}MoN_4P_4O_3$: C 33.6, H 6.0, N 10.5; found: C 33.5, H 6.0, N 10.4. The manganese carbonyl complex $[(MeNPMe)_4Mn(CO)_3]^+$ Br^- (**4***e*) was prepared from **1***a* (0.162 g, 0.00054 mol) and $Mn(CO)_5Br$ (0.149 g, 0.00054 mol) in 15 mL THF at 60°C. After 2.5 h, the yellow **4***e* was filtered off (0.112 g, 40%) and washed with 3 × 5 mL THF: mp (decom.) 198–209°C. **4***e* soluble in H_2O, EtOH, CH_3CN, and slightly soluble in $CHCl_3$ in which it slowly decomposes. In nitromethane at 25°C, Λ_m = 79.0 ohm^{-1} cm^2 mol^{-1}, ν(C≡O) (cm^{-1}) 2030 (st, sh); 1929, (st, b); 1971 (m). *Anal.* calcd. for $C_{11}H_{24}BrMnN_4O_3P_4$: C 25.5, H 4.7, N 10.8, Br 15.4; found: C 25.3, H 4.8, N 10.5, Br 15.2. **4***e* forms a dihydrate, Λ_m($MeNO_2$, 25°C) 72.1 ohm^{-1} cm^2 mol^{-1}. *Anal.* calcd. for $C_{11}H_{28}BrMnN_4O_5P_4$: C 23.8, H 5.1, N 10.1, Br 14.4; found: C 23.5, H 5.1, N 9.9, Br 14.3. The same complex cation, with a different anion, was prepared by filtering a solution of $Mn_2(CO)_{10}$ (0.130 g, 0.00033 mol) in 5 mL toluene into a solution of **1***a* (0.100 g, 0.00033 mol) in 12 mL toluene. Evolution of CO began within 1 min. The clear yellow solution was stirred at room temperature for 18 h. The pale yellow product $[(MeNPMe)_4Mn(CO)_3]^+Mn(CO)_5^-$ (**4***f*) (0.127 g, 60%; 80% if the reaction is carried out photolytically) was filtered off and washed with toluene; mp (decom.) >250°C. Λ_m($MeNO_2$, 25°C) = 61.9 ohm^{-1} cm^2 mol^{-1}; ν(C≡O) (cm^{-1}) 2032 (st, sh); 1968, 1952 (st); 1899 (st, b), 1851 (st, vb). δ_H($(CD_3)_2CO$, int. TMS) 2.18 (PMe, b), 3.25 (NMe, b). *Anal.* calcd. for $C_{16}H_{24}Mn_2N_4O_8P_4$: C 30.3, H 3.8, N 8.8, O 20.2; found: C 30.2, H 4.0, N 8.9, O 19.9. The nickel complex $(MeNPMe)_4Ni_2(CO)_3$ (**5**) was prepared by filtering a solution of $(Ph_3P)_2Ni(CO)_2$ (0.499 g, 0.00078 mol) in 11 mL THF into a solution of **1***a* (0.117 g, 0.00039 mol) in THF. The yellow solution was irradiated at room temperature for 2 h (silica filter). After about 1 h the solution became orange–brown, and some brownish solid began to precipitate along with the yellow **5**, which was filtered off after a further 18 h in the dark at room temperature. The brown solid was removed by washing the residue with 2 × 15 mL CH_3CN. The bright yellow **5** (0.084 g, 43%, mp (decom.) >250°C) is slightly soluble in CH_3CN and acetone, in which it is relatively stable for short periods and moderately soluble in DMF. It is insoluble in THF and diethyl ether, and decomposes in $CHCl_3$. ν(C≡O) (cm^{-1}) 1972, 1946, 1775 (st, sh); weaker bands 2076 (w, sh), 1992 (m, sh), 1907 (sh, w), 1922 (shl). *Anal.* calcd. for $C_{11}H_{24}N_4Ni_2O_3P_4$: C 26.3, H 4.8, N 11.2, P 24.7, Ni 23.4; found: C 26.6, H 4.9, N 11.3, P 24.8, Ni 23.3. A new compound $[MeNP(O)Me]_4$ (**6**) was precipitated when a solution of **5** in DMF was oxidised in air. Filtration, followed by washing with DMF and pentane left analytically pure **6**, colourless blocks from acetonitrile, mp (decom.) >265°C. It is soluble in water, hot CH_3CN, and hot CH_3OH, insoluble in $CHCl_3$, CH_2Cl_2. Its mass spectrum shows the parent ion at *m*/*e* 364 and peaks arising from the loss of Me, MeN. ν(P=O) 1228 cm^{-1} (br, st). δ_P(CD_3OD, ext. H_3PO_4) +30.5. δ_H(CD_3OD, int. TMS) 1.86 (PMe, J_{PH} 15 Hz, doublet), 3.06 (NMe, J_{PH} 10.8 Hz, triplet). *Anal.* calcd. for $C_8H_{24}N_4O_4P_4$: C 26.4, H 6.6, N 15.4; found: C 26.5, H 6.6, N 15.1. A small yield of **6**, grossly contaminated with hydrolysis products, was obtained by the oxidation of **1***a* in THF with aqueous hydrogen peroxide.

Quaternary carbonyl complexes

The preparation and crystal structure of the complex $[Me(MeNPMe)_4Mo(CO)_3]^+I^-$ (7*a*) is described elsewhere (7). For the tungsten complex, 1*a* (0.115 g, 0.00038 mol) and $W(CO)_6$ (0.134 g, 0.00038 mol) were dissolved in 20 mL THF, and the clear colourless solution was irradiated at 65°C for 2 h. The mixture was cooled to room temperature and a large excess of MeI was added (about 1 mL). The mixture was heated under reflux for 18 h, during which time a pale yellow solid was precipitated from the red solution. It was filtered off and washed with 5 × 2 mL warm MeCN, leaving $[Me(MeNPMe)_4W(CO)_3]^+I^-$ (7*b*) as a very pale yellow solid (0.110 g, 41%, decomposing near 200°C). It is soluble in hot MeOH, DMSO, and pyridine, and can be crystallised as a 1 : 1 adduct from CH_3CN, to which the following results refer. ν(C≡O) (cm^{-1}) 1940 (st, sh); 1850, 1832 (st). δ_H(CD_3OD, ext. TMS) 1.82 (3H, doublet, J_{PH} 6.5 Hz), 2.12 (6H, b), 2.42 (3H, doublet, J_{PH} 12.5 Hz), 2.73 (3H, doublet, J_{PH} 13.2 Hz), 2.92 (6H, quintet, J_{PH} 4.5), 3.25 (6H, doublet split into virtual triplets, J_{PH} 10, 2.2 Hz). The ^1H nmr spectrum in DMSO was very similar, except that the group at lowest field formed a simple doublet. *Anal.* calcd. for $C_{14}H_{30}IN_5O_3P_4W$: C 22.4, H 4.0, N 9.3; found: C 22.3, H 4.1, N 9.2. The chromium complex $[Me(MeNPMe)_4Cr(CO)_3]^+I^-$ was prepared similarly and crystallised from CH_3CN as its hemi-adduct with CH_3CN (7*c*), mp (decom.) ~260°C, ν(C≡O) (cm^{-1}) 1935 (st, sh); 1847, 1829 (shl). *Anal.* calcd. for $C_{26}H_{57}Cr_2I_2N_9O_6P_8$: C 26.1, H 4.8, N 10.5, O 8.0; found: C 26.2, H 4.9, N 10.6, O 8.3. The complexes $[NH_2C(O)CH_2(MeNPMe)_4Cr(CO)_3]^+I^-$ (7*d*) and $[NCCH_2(MeNPMe)_4Cr(CO)_3]^+I^-$ (7*e*) were prepared similarly using iodoacetamide and iodoacetonitrile as quaternising agents. 7*d*, yellow–green crystals, mp (decom.) >250°C; ν(C≡O) (cm^{-1}) 1943, 1933; 1868 (shl), 1824 (st, sh); 1858, 1808 (st, sh). ν(C≡O) 1686 (m). *Anal.* calcd. for $C_{13}H_{28}CrIN_5O_4P_4$: C 25.1, H 4.5, N 11.3; found: C 25.1, H 4.5, N 11.3. 7*e*, pale yellow platelets, dark green ~200°C, mp (decomp.) >260°C; ν(C≡O) (cm^{-1}) 1945 (st, b); 1855 (st), 1828 (split, b). No ν(C≡N) observed. *Anal.* calcd. for $C_{13}H_{26}CrIN_5O_3P_4$: C 25.9, H 4.3, N 11.6; found: C 26.1, H 4.4, N 11.5. The carbonyl stretching bands are broadened in 7*e* and split into two sets in 7*d*, presumably a result of conformational or configurational isomerism caused by the bulky quaternising groups.

Ylides

A molybdenum carbonyl ylide was prepared by the addition of 2.2 equiv. of *n*BuLi (1.6 *M*) to 7*a* (0.135 g, 0.00022 mol) in 6 mL THF, with an immediate decrease in turbidity. The solution became yellow. After stirring for 45 min at room temperature, the mixture was filtered, the solid washed with MeCN until the washings were colourless, and then again with water until the washings were colourless. The residual pale yellow solid product $(MeNPMe)_4Mo(CO)_3CH_2$ (8*a*, 0.015 g, 14%) was recrystallised from hot DMSO; mp (decom.) >170°C. It is very soluble in warm DMF (very pale yellow solution) and in $MeNO_2$ (very bright yellow solution). Its mass spectrum (260°C) shows the parent ion *m/e* 494, the $(M - CH_2)^+$ ion, and the stepwise loss of three CO groups from each ion. ν(C≡O) (cm^{-1}) 1909 (st, sh); 1810, 1785 (st, split). CH_2 frequencies 975, 936 (m) (26). δ_H (DMSO-d_6, ext. TMS) −0.15 (2H, b), 1.48 (3H, doublet, J_{PH} 16.5 Hz), 1.74 (6H, singlet, b), 2.00 (3H, doublet, J_{PH} 12.5 Hz), 2.87 (12H, multiplet). *Anal.* calcd. for $C_{12}H_{26}MoN_4O_3P_4$: C 29.2, H 5.3, N 11.3; found: C 29.2, H 5.3, N 11.1. The tungsten ylide $(MeNPMe)_4W(CO)_3CH_2$ (8*b*) was prepared similarly as a bright yellow solid, mp (decom.) >180°C. It is soluble in hot DMSO (with slow decomposition), slightly soluble in hot MeCN, insoluble in H_2O, CH_2Cl_2, $CHCl_3$, acetone. Its mass spectrum (270°C) is similar to that of 8*a*. ν(C≡O) (cm^{-1}) 1900 (st, sh); 1800, 1775 (st). CH_2 frequencies 980, 934 (m). δ_H (DMSO-d_6, ext. TMS) 0.14 (2H, broad, with possible fine structure), 1.48 (3H, doublet, J_{PH} 16 Hz), 1.85 (6H, singlet, broad), 2.03 (3H, doublet, J_{PH} 12.8 Hz), 2.80 (12H, multiplet). *Anal.* calcd. for $C_{12}H_{26}N_4O_3P_4W$: C 24.8, H 4.5, N 9.6, O 8.3; found: C 24.9, H 4.5, N 9.4, O 8.5.

Results and discussion

The compounds 1*a*, *b* were obtained previously (2). One additional tetraphosphazane, the P-phenyl derivative 1*c*, has been prepared. Its ^{31}P and ^1H nmr spectra show that the phosphorus atoms and *N*-methyl groups are less shielded than they are in 1*a*, *b* (2), and it is possible that 1*c* was obtained in low and irreproducible yield because in $MeN(PhPCl)_2$, the main product in this and other work (8), the phosphorus atoms are weakly nucleophilic. No evidence of larger or smaller rings was obtained in any preparation of 1*a*–*c*. The following discussion is based mainly on the chemistry of 1*a*. Some of the nmr information is illustrated in Fig. 2.

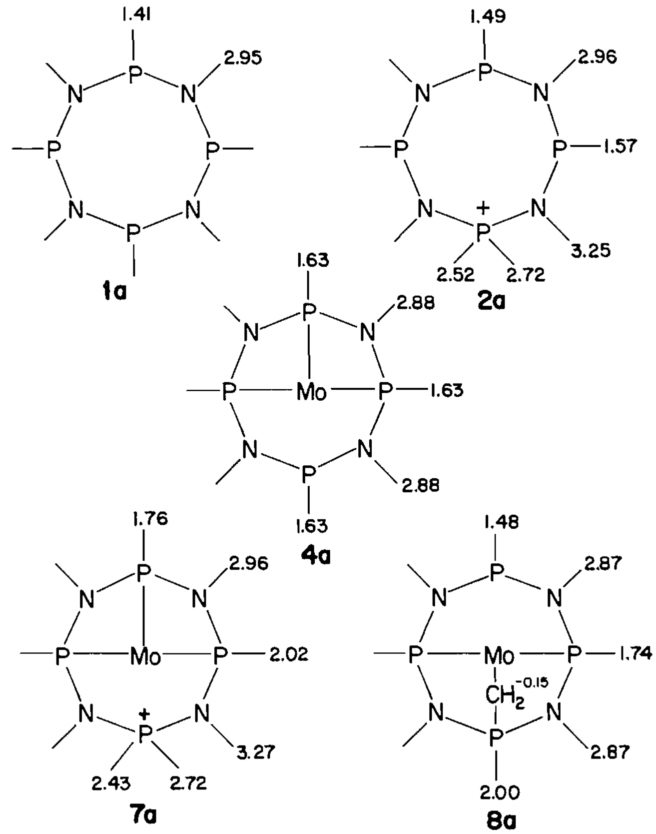

FIG. 2. ^1H chemical shifts of the methyl groups in 1*a* (2), its monomethyl quaternary ion 2*a* (5) (different assignments), its complex with $Mo(CO)_3$ (4*a*) (6), the quaternised complex 7*a* and the ylide 8*a* formed from it.

The electronic structures of the cyclic phosph(III)azanes $(R'NPR)_n$ are different from those of their P(V) isomeric phosphazenes $(NPRR')_n$; their skeletal structure is singly bonded, at least to a first approximation, and the phosphorus and nitrogen atoms each carry both a substituent and a formally unshared pair of electrons. The crown conformation of 1*a*, like that of S_8 (9) and $S_4(NMe)_4$ (10), is qualitatively compatible with the interaction of stereochemically active lone pairs (11), and the importance of steric interactions in other phosph(III)azanes has been stressed elsewhere (12, 13). Keat, especially, has associated conformational stability with the mutual perpendicularity of lone-pair directions at adjacent atoms (12). Important though these interactions are, the suggestion that they are not the whole story (6, 14) is confirmed and made specific by the present work.

The first point, recognised early for aminophosphines (15), is that electron release from nitrogen to phosphorus, indicated by the near-planarity of the groups attached to nitrogen (2), strengthens the donor function, so that the tetraphosphazanes are normally multidentate ligands. As a consequence, they can be expected to form cage complexes with a variety of acceptors. As an example of such complex formation by a transition metal ion, the complex cation **3**, with either $CoCl_4^{2-}$ or BPh_4^- as anion, seems likely to have the structure shown (Fig. 1), in which the phosphazane acts as a tridentate ligand. In the carbonyl complexes, too, the ligand is multidentate; attempts to prepare a derivative $LCr(CO)_5$ by the use of THF.$Cr(CO)_5$ were unsuccessful, leading to L.$Cr(CO)_3$ instead. Similar compounds **4** were obtained with $W(CO)_6$, $Mo(CO)_6$. All are fluxional at room temperature on the nmr time scale, but three carbonyl stretching frequencies are seen, two corresponding to the lifting of the degeneracy of the E band, compatibly with the structure shown.

The nickel carbonyl complex **5** is different. The evidence for the structure shown, in which the ligand is tetradentate, rests on the infrared spectrum, which shows ν(C≡O) corresponding to two terminal groups (1972, 1946 cm^{-1}) and a bridging group (1775 cm^{-1}). In an apparently related complex **9** of the stronger π-acceptor $MeN(PF_2)_2$ (16), the frequencies are higher (2070, 2055, 1891 cm^{-1}). Possibly as a result of smaller back-donation to phosphorus, **5** is sensitive to heat and is hardly stable in solution, in which it is easily oxidised to the oxophosph(V)azane **6**, an *N*-methylimide of methylphosphonic acid. The structure shown is to be expected if the oxidation is stereospecific, and is consistent with the nmr results, although the high symmetry might be attained statistically.

The ligand is also tetradentate in the complex quaternary salts **7**, which can be prepared by quaternisation of the neutral carbonyl complex; details of the crystal structure of **7***a* have been published (14) and are discussed further below.

By contrast, reaction of **1***a* with alkyl halides goes no further than the biquaternary stage. If the quaternising group is methyl, the monoquaternary cation is still a donor, and reacts (slowly) with metal carbonyls to give the quaternary carbonyls **7**. These, in turn, can be deprotonated by butyllithium, the quaternary carbonyl compounds **7***a*, *b*, leading to the ylides **8***a*, *b*, in which the molecule is stabilised by coordination of the ylide group to the metal, at the expense of the weaker phosphine donor.[4] The qualitative structure **8** is indicated by the ^{1}H nmr spectra (Fig. 2). The polar ylidic group, identified unambiguously in the spectrum by its integral, resonates at the highest field. The strong donor properties of the phosphazane are again noticeable, both in the need for two equivalents of base in the deprotonation reaction, and in the formation by the ylide of complexes with lithium salts (presumably through the fourth phosphorus atom), which need to be decomposed before pure **8***a*, *b* can be isolated. It is also likely that the (stereospecific) addition of more than three sulphur atoms to **1***a* (3) is restricted sterically rather than electronically; the three sulphur atoms are spaced out in the distorted ring, but a fourth sulphur atom, on P(4), would be unacceptably close to S(1) (1.9 Å).

Secondly, the donor properties of the phosphazane are likely to be limited by the transmission of electronic effects round the ring. The importance of this feature is shown by the pronounced inequalities in the lengths of the P—N bonds in the biquaternary ion $[(MeNPMe)_4Me_2]^{2+}$ (5) (mean 1.652, 1.749 (σ 0.005 Å) from the quaternary centres).[5] It is seen also in the easy hydrolysis of the $(MeNPMe)_4Me^+$ ion, nucleophilic attack (giving the $[Me_2P(NHMe)_2]^+$ ion) taking place not at the quaternary centre, but at the next nearest phosphorus atom. Again, if **1***a* is quaternised with either of the electron-withdrawing groups $[CH_2C(O)NH_2]^+$ or $[CH_2CN]^+$, no reaction takes place with metal carbonyls, presumably because the lone pairs have been significantly stabilised. In general, we can expect that, as a consequence of the transmission effect, σ-donation, at least, will become weaker as further acceptor molecules are added. If direct electrostatic effects are taken into account, it is not surprising that the quaternisation reaction stops at the second stage.

This view of the reactions is nevertheless incomplete, and the third point is the decisive effect of *d*-orbital occupancy on both the structures and chemistry of phosphazane derivatives. To some extent, the ^{1}H shifts of Fig. 2 can, indeed, be interpreted without explicit consideration of *d*-orbitals. Quaternisation of **1***a* deshields all the methyl groups, decreasingly from the positive centre (mean δ_H, (P)Me 1.97, (N)Me 3.11). Coordination of **1***a* to (fluxional) $Mo(CO)_3$ has a smaller effect (mean δ_H, (P)Me 1.63, (N)Me 2.88); in the quaternary complex **7***a* shielding is least (mean δ_H, (P)Me 2.19, (N)Me 3.12). The influence of the *d*-orbitals on the metal can be seen, possibly, in the smaller effect of $Mo(CO)_3$ compared with Me^+, and the fact that in the ylide **8***a*, in which the methylene group can donate no electrons to phosphorus, the phosphorus atoms are deshielded (mean δ_H, (P)Me 1.74, (N)Me 2.87) relative to those in **4***a*. It is seen convincingly in the properties of the $[L.Mn(CO)_3]^+$ ion (**4***e*) in which the positive charge restricts back-donation to both neighbouring atoms, raising ν(C≡O) and deshielding the ring atoms (fluxional; mean δ_H, (P)Me 2.18, (N)Me 3.25) compared to the $Mo(CO)_3$ complex. In the ylides **8**, the methylene group is unable to accept electrons, and ν(C≡O) is therefore reduced relative to L.$M(CO)_3$; for **8***a*, mean $\delta\nu = -23$ cm^{-1}. As a comparison, even lower frequencies are found in the tri-ylidic complex $(Ph_3PCH(Me))_3$-$Mo(CO)_3$, for which ν(C≡O) = 1898, 1799, 1767 cm^{-1} (19). The ligand is then more nearly a σ-donor, with a small decrease in shielding (mean δ_H, (P)Me 1.74, (N)Me 2.87) relative to **4***a*. Back-donation from the metal to the *d*-orbitals of phosphorus is important, but the net donor properties of the ligand are confirmed by the decrease in shielding of phosphorus on complex formation (δ_P, $(MeNPEt)_4$, 100(2); $(MeNPEt)_4Mo(CO)_3$ (**4***d*) 111.0).

The importance of *d*-orbital interactions is seen most directly in the transmission of electronic influences within the ligand, the energetics of its reactions with acceptors, and the changes in bond length which accompany the reactions. Earlier structural investigations[6] have shown that they are significant for the bonding in phosphazanes; the point of particular importance here is the sensitivity of *d*-orbitals to effective nuclear charge (20). The crystal structure of **7***a* (14) in comparison with those of **1***a* (2) and **4***a* (6), shows that the moderate strengthening of the C≡O bonds on quaternisation (mean $\delta\nu$(C≡O) 22 cm^{-1}) is accompanied by some strengthening of both the P—Mo and the P—N bonds (mean decrease in length 0.041, 0.012 Å). The dominant effect of the positive charge on the ring is therefore to make it, by *d*-orbital contraction, a better π-acceptor, though not as good (on similar evidence) as the PF_2 groups in $P[N(Ph)PF_2]_3Mo(CO)_3$ (21). The additional bond energy so

[4] For a review see ref. 17.

[5] As a comparison, the structural effects, at least, are less pronounced in C—N heterocyclics; protonation of a piperidine derivative (18) causes no significant changes in the lengths of the bonds meeting at N (σ 0.01 Å).

[6] For references, see ref. 14.

obtained makes the quaternary cation (thermodynamically speaking) a better donor than the neutral phosphazane.

We can apply these concepts to two reactions of **1***a* investigated earlier, with methyl iodide (5) and with sulphur (3). In both cases reaction with an acceptor facilitates further reaction; in the first, a monoquaternary salt easily disproportionates to a diquaternary and the neutral compound, in the second, the trisulphide is formed even with a deficit of sulphur. In an effort to reduce the nucleophilicity of a second phosphorus atom, we have quaternised **1***a* with the stronger acceptors phenacyl bromide and iodoacetamide. The monoquaternary derivatives were indeed obtained, even with an excess of these reagents, but their stability may depend on their insolubility, because disproportionation occurs in solution in CD_3OD. The stabilisation by the quaternary group of the formal lone pairs on phosphorus is more than compensated by the strengthening of the ring bonds by *d*-orbital contraction, and the same argument applies to the addition of sulphur atoms to the phosphazane ring. The strengthening is illustrated by the mean ring bond lengths, which decrease from 1.722 Å in $(MeNPMe)_4$ (2) to 1.700 Å in $(MeNPMe)_4Me_2^{2+}$ (5) and 1.701 Å in $(MeNPMe)_4S_3$ (3), comparable to the changes in the formation of **7***a*. Although the contraction effect is decisive here, it is likely that the energies are finely balanced, and disproportionation may not always occur. In carbonyl complexes of the related cyclodiphosph(III)azanes (22, 23) the ligand is apparently monodentate (23),[7] and all four sulphides $P_4(NMe)_6S_n$ ($n = 1-4$) have been obtained (25). Nevertheless, the work reported here shows clearly that the energy changes induced by *d*-orbital contraction have a significant effect on the properties of phosphazanes, and must be taken into account in discussions of their electronic structure.

[7] A cyclotetraphosphazane ring, complexed by two $M(CO)_5$ groups, is formed in the tetramerisation of a triazaphosphole (24). It is not strictly comparable with the compounds discussed here, because its centrosymmetric structure, forced by four fused triazaphosphole rings, prevents chelate complex formation.

As a result of an investigation undertaken to evaluate the acetamidomethyl group ($—CH_2NHCOCH_3$) as a water-solubilizing protecting group for thiolate ligands, a new type of oxotechnetium(V) complex was prepared. The compound oxobis(ethan-1,2-dithiolato-S,$\mu S'$)technetium(V)oxo(ethan-1,2-dithiolato-S,S')technetium(V), $[(TcO)_2(SCH_2CH_2S)_3]$, **1**, was synthesized by the reaction of $[TcOCl_4]^-$ with either an excess of bis(acetamidomethyl)ethanedithiol or 1.5 equiv. of ethanedithiol. The complex was characterized by field desorption mass spectrometry (m/e = 505(8), 507(2.8)) and its structure determined by single crystal X-ray diffraction. **1** has a monoclinic space group $P2_1/c$ with cell dimensions a = 8.833(2) Å, b = 15,034(3) Å, c = 11.350(2) Å, and β = 108.17(1)°, and has four formula units in the unit cell. Data were collected with the use of MoKα radiation and a Nicolet P3 diffractometer. The crystal structure was determined by standard methods and refined to R_1 = 0.0366 and R_2 = 0.0455 on the basis of 3312 independent reflections. The compound contains two technetium atoms. Two sulphur atoms of one square pyramidal $TcOS_4$ core are bonded to another $TcOS_2$ unit forming two square pyramids sharing an edge with an angle of 106.0(1) between the basal planes. The Tc—Tc distance is 3.654(1) Å. There are four distinct types of Tc—S bonds (range 2.256(2)—2.418(2) Å) and the Tc—O distances (1.66 Å) are normal.

A. DAVISON, B. V. DEPAMPHILIS, R. FAGGIANI, A. G. JONES, C. J. L. LOCK et C. ORVIG. Can. J. Chem. **63**, 319 (1985).

A la suite d'une étude entreprise dans le but d'évaluer l'utilité du groupe acétamidométhyle ($—CH_2NHCOCH_3$) comme groupe protecteur, soluble dans l'eau, des ligands thiolates, on a préparé un nouveau type de complexe oxotechnétium(V). On a synthétisé le complexe oxobis(éthanedithiolato-1,2-S,$\mu S'$)technétium(V)oxo(éthanedithiolato-1,2-S,S')technétium(V), $[(TcO)_2(SCH_2CH_2S)_3]$, **1**, par réaction du $[TcOCl_4]^-$ avec soit un excès de bis(acétamidométhyl)éthanedithiol ou 1,5 équiv. d'éthanedithiol. On a caractérisé le complexe par spectrométrie de masse par désorbtion de champ (m/e = 505(8), 507(2,8)) et on a déterminé sa structure par diffraction de rayons-X sur un cristal unique. Le composé **1** est monoclinique, groupe d'espace $P2_1/c$, dimensions de la maille unitaire a = 8,833(2), b = 15,034(3) et c = 11,350(2) Å et β = 108,17(1)° et la maille unitaire contient quatre unités. On a recueilli les données en utilisant la radiation MoKα et un diffractomètre Nicolet, modèle P3. La structure cristalline a été determinée par des méthodes standards et on l'a affinée jusqu'à des valeurs de R_1 = 0,0366 et de R_2 = 0,0455 sur la base de 3312 réflexions indépendantes. Le composé contient deux atomes de technétium. Les deux atomes de soufre d'une pyramide carrée de $TcOS_4$ formant le coeur de la structure sont liés à une autre unité de $TcOS_2$ formant deux pyramides carrées partageant un côté avec un angle de 106,0(1)° entre les plans de base. La distance Tc—Tc est égale à 3,654(1) Å. Il y a quatre types distincts de liaisons Tc—S (longueurs allant de 2,256(2) à 2,418(2) Å) et les distances Tc—O sont normales (1,66 Å).

[Traduit par le journal]

Introduction

Widespread use of technetium in the field of nuclear medicine has resulted (1) from the favorable nuclear properties of the metastable isotope ^{99m}Tc (λ = 140 keV, $t_{1/2}$ = 6 h). Concomitantly, a growing number of chemical studies using the readily available, long-lived isotope ^{99}Tc (β^- = 292 keV, $t_{1/2}$ = 2.12×10^5 y) are in the process of outlining the basic chemistry of the element (2). The pentavalent oxidation state (Tc(V), low spin d^2) has emerged as an important species in the reduction chemistry of pertechnetate (TcO_4^-), and the aqueous

chemistry of Tc(V) has been dominated by the TcO(3+) core and its affinity for sulfur-containing ligands (3). Sulfur can be used in combination with other ligating atoms and subsequently a series of $TcON_2S_2$ complexes was prepared (4), one of which undergoes rapid renal excretion (5). The fast renal clearance fostered an interest in simplifying the synthesis of this important series of compounds because the thiol-protecting benzoyl groups employed rendered the amide thiolate ligands water-insoluble, necessitating the use of biologically-compatible co-solvent, such as ethanol, in the preparation of the oxotechnetium complexes.

The acetamidomethyl functionality (acm)(—$CH_2NHCOCH_3$) is a useful protecting moiety for sulfhydryl groups in peptide synthesis (6, 7). The protection is particularly useful because acm is stable to acids such as liquid HF and to bases such as hydrazine, yet it is readily removed by the electrophilic attack of reagents such as Hg(II). In addition, water-solubility is imparted to thiols protected with acm. In order to test its effectiveness as a protecting group for thiols in the N_2S_2 system, bis(acetamidomethyl)ethanedithiol (edt(acm)$_2$) was prepared as a model and studied in its reactions with TcO_4^- and $[TcOCl_4]^-$. The desired product was the well-characterized (8, 9) $[TcO(edt)_2]^-$ ion, but, in addition, an apparent intermediate $[(TcO)_2(edt)_3]$ was isolated in the study. The same intermediate was isolated during ligand-exchange studies of oxotechnetium(V) complexes (10). We report here the full chemical and structural characterization of this intermediate.

Experimental section

Technetium as $NH_4{}^{99}TcO_4$ was obtained as a gift from New England Nuclear, Billerica, MA. All manipulations were carried out following precautions which have been detailed elsewhere (9). All reagents were used as received unless otherwise specified. Bis(acetamidomethyl)-ethanedithiol was prepared from ethanedithiol (Eastman) and N-hydroxymethylacetamide (11) in HCl. Literature procedures were followed to prepare [n-Bu_4N][$TcOCl_4$] (9) and [Ph_4As][$TcO(SCH_2CH_2S)_2$] (9). Elemental analyses were performed by Schwarzkopf Microanalytical Laboratories, Woodside, NY. and Spang Microanalytical Laboratory, Eagle Harbor, MI. Melting points were measured with a Mel-Temp apparatus and are uncorrected.

Infrared spectra were recorded with a Perkin-Elmer PE180 grating spectrophotometer from KBr pellets. Optical spectra were obtained in solution with a Cary 17 spectrophotometer. The high field proton nmr spectrum was recorded with a Bruker 250 MHz instrument. The positive ion field desorption mass spectrum was obtained with a Varian MAT 731 described elsewhere (12). Conductivity measurements were made with a Yellow Springs Model 3403 conductivity cell and a Serfass conductivity bridge. The acetonitrile used in this experiment was passed down a column of activated alumina immediately before use. (Woelm Neutral Activity Grade I supplied by ICN.)

Preparation of $[(TcO)_2(edt)_3]$

This orange solid was prepared by the reaction of $TcOCl_4^-$ with an excess of bis(acetamidomethyl)ethanedithiol (Method A) or with 1.5 equiv. of ethanedithiol (Method B). Both methods provide a ca. 80% yield of a microcrystalline orange solid which can be recrystallized in high yield from methylenechloride/hexane at −25°C to form orange blocks.

Method A

To a solution of 0.298 g [n-Bu_4N][$TcOCl_4$] (0.60 mmol) in 20 mL methanol was added a solution of 0.301 g edt(acm)$_2$ (1.27 mmol) in 30 mL methanol with stirring. Within 1 min after the addition, the resulting solution went from pale green to deep orange and became cloudy. This suspension deposited fine orange crystals over a period of 30 min. These were separated by suction filtration and dried *in*

vacuo for 4 h. The yield was 0.124 g, 82% based on Tc.

Method B

To a solution of 0.148 g [n-Bu_4N][$TcOCl_4$] (0.30 mmol) in 7 mL methanol was added 37 μL ethanedithiol (0.45 mmol). The green solution turned orange immediately and deposited fine orange crystals within 1 min. After stirring for 1 h, the orange solid was separated and dried as in method A. The yield was 0.060 g, 80% based on Tc. *Anal.* calcd. for $C_6H_{12}O_2S_6Tc_2$: C 14.23, H 2.39, S 37.99; found: C 14.76, H 2.63, S 36.85. Optical spectrum in CH_2Cl_2: 424 nm (ϵ = 6300 L mol^{-1} cm^{-1}), 286 (9600). Ir (KBr): ν(Tc=O) = 953, 946 cm^{-1} (both vs). Conductivity: neutral, 10^{-3} *M*, CH_3CN. FDMS: m/e = 505 (relative intensity 8), 507 (2.8). ^{1}H nmr, 250 MHz in $CDCl_3$: δ 3.22–3.34, δ 3.41–3.53 (total intensity 1, AA′BB′ multiplet); δ 3.53–4.12 (total intensity 2, ABCD multiplet). Mp 205–207°C (dec). The compound is soluble in methylene chloride, acetone, and acetonitrile. It is insoluble in nonpolar organic solvents and alcohols, except methanol in which it is slightly soluble.

Preparation of [TcO(edt)$_2$]$^-$ from edt(acm)$_2$

To a green solution of 0.125 g [n-Bu_4N][$TcOCl_4$] (0.25 mmol) in 10 mL methanol was added a solution of 0.15 g edt(acm)$_2$ (0.63 mmol) in 10 mL methanol, resulting in an orange suspension. To this suspension, 4 mL 1 *M* NaOH were added and the suspension refluxed for 6 h. Traces of $TcO_2 \cdot xH_2O$ were removed by filtration after cooling the orange solution to room temperature. To the orange filtrate was added 0.5 g $Ph_4AsCl \cdot H_2O$ in 10 mL water. This precipitated an orange solid which was redissolved by the addition of 40 mL acetone. The solution was placed aside for 24 h during which time orange needles of [Ph_4As][TcO(edt)$_2$] precipitated. These were separated by suction filtration, washed with 30 mL ether, and dried *in vacuo*. The yield was 0.145 g, 85% based on Tc. The identity of this product was confirmed by comparison of the infrared and optical spectra with those of an authentic sample (9).

Conversion of Tc_2O_2(edt)$_3$ to [TcO(edt)$_2$]$^-$

The compound Tc_2O_2(edt)$_3$ can be converted to [TcO(edt)$_2$]$^-$ by dissolution in acetone and addition of excess ethanedithiol. After stirring for 1 h, addition of $Ph_4AsCl \cdot H_2O$ in water and evaporation of the acetone precipitates [Ph_4As][TcO(edt)$_2$] quantitatively.

Collection of the X-ray data

Precession photographs showed the crystal was monoclinic and unit cell parameters were obtained from a least-squares fit of χ, φ, and 2θ for 15 reflections in the range 23.6° <2θ <34.4° recorded on a Nicolet P3 diffractometer using graphite-monochromated Mo$K\alpha_1$ radiation (λ 0.70926 Å at 22°C). Crystal data and other numbers related to data

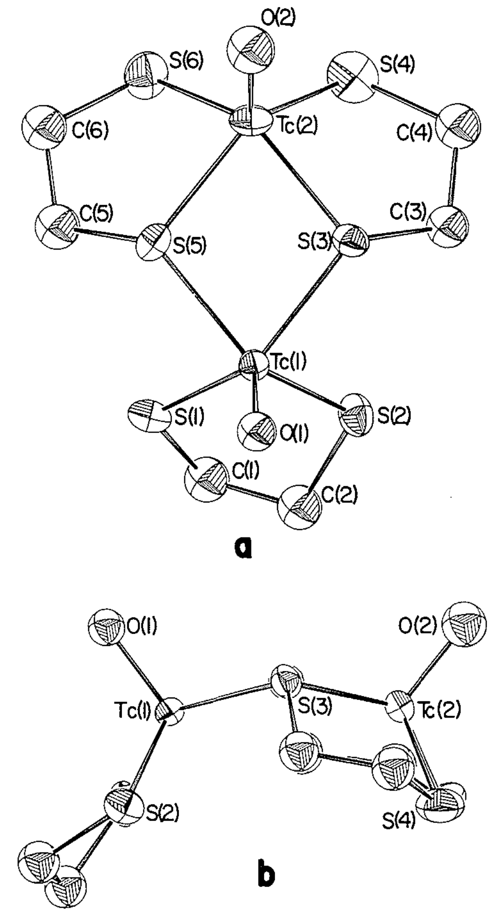

FIG. 1 (*a*) The molecule showing the atom numbering. (*b*) The molecule oriented to show the angle between the two square pyramids.

collection are summarized in Table 1. The density was obtained by flotation in a carbon tetrachloride – dibromoethane mixture. Intensities were measured on the P3 diffractometer using a coupled θ(crystal)–2θ (counter) scan. The methods of selection of scan rates and initial data treatment have been described (13, 14). Corrections were made for Lorentz polarization effects and absorption.

Solution of the structure

The coordinates of the technetium atom were found from a three-dimensional Patterson synthesis and a series of full-matrix least-squares refinements followed by three-dimensional electron density difference syntheses revealed all the atoms. At this stage the temperature factors of the technetium and sulfur atoms were made anisotropic. Tests were made to show the use of increased parameters was justified (15) except in the case of the hydrogen atoms. Further refinement, using full-matrix least-squares minimizing $\Sigma w(|F_o| - |F_c|)^2$, was terminated when the maximum shift/error was <0.04. Only x, y, z of hydrogen atoms were refined; temperature factors were fixed at roughly 50% greater than the atoms to which they were attached. Corrections were made for secondary extinction by the method of Larson (16). Throughout the refinement, the scattering curves were taken from ref. 17 and anomalous dispersion corrections from ref. 18 were applied to the curves for technetium and sulfur. The atom parameters for non-hydrogen atoms are listed in Table 2.[2]

[2] Lists of temperature factors, hydrogen atom positional parameters, best planes, dihedral and torsional angles and a listing of the moduli of the observed and calculated structure factor amplitudes and figure; unit cell packing are available from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

Results and discussion

The reaction of $[n\text{-}Bu_4N][TcOCl_4]$ with either 1.5 equiv. of ethanedithiol or 2 or more equiv. of bis(acetamidomethyl)-ethanedithiol at room temperature rapidly yields orange crystals of $[(TcO)_2(edt)_3]$, **I**, in high yield. It is possible to synthesize $[TcO(edt)_2]^-$ from $[TcOCl_4]^-$ and excess $edt(acm)_2$ by the addition of NaOH and heating the reaction mixture after **I** has been formed. The base must be added after the formation of **I** because of the tendency of $[TcOCl_4]^-$ to disproportionate (9) in aqueous or basic solution. While it is possible to synthesize $[TcO(edt)_2]^-$ from a preformed suspension of **I** with excess $edt(acm)_2$ in basic solution, it proved impossible to make either this complex or **I** via the reduction of pertechnetate in the presence of $edt(acm)_2$. Attempts were made with several reducing agents upon whose utility we have previously reported (19) in these types of systems.

The positive ion field desorption mass spectrum unequivocally identifies **I** as a 3:2 complex because of the presence of two peaks m/e = 505, 507 (from ^{32}S and ^{34}S, respectively) with appropriate intensities for six sulfur atoms in the molecular unit. Unfortunately, the complicated nmr spectrum does not yield any structural information, therefore a structure determination by single crystal X-ray diffraction was undertaken.

The molecule is shown in Fig. 1 and selected interatomic distances and angles are given in Table 3. The molecule contains two technetium atoms with similar near neighbour environments. Each technetium atom sits in the centre of a square pyramid, the base formed by four sulfur atoms, and the apex occupied by a tightly bonded (Tc—O(1) 1.665(3), Tc—O(2) 1.661(3) Å) oxygen atom. The technetium atoms are 0.7410(3) Å (Tc(1)) and 0.8025(4) Å (Tc(2)) above the sulfur atom planes values similar to those reported for other $TcOS_4$ systems (0.791 Å (20), 0.761 Å (21)) and for the molybdenum atom in corresponding $LMoS_4$ systems (0.66–0.83 Å) (22, 23).

When nearest neighbours are considered, the environments of the two technetium atoms are quite different. Tc(1) is bonded to both the sulfur atoms of one ethan-1,2-dithiolate group, S(1) and S(2), and to one sulfur atom of each of the other two ethan-1,2-dithiolate groups, S(3) and S(5). S(3) and S(5) also bond to Tc(2), acting as bridges. The remaining sulfur atoms, S(4) and S(6), are also bonded to Tc(2). This type of bridging sulfur has been observed previously for the $(NH_2CH_2CH_2S)^-$ ligand in the $[Ni_3(SCH_2CH_2NH_2)_4]^{2+}$ cation (24). The structure of **I** thus has four distinct types of Tc—S bonds. The bonds to the unique ethan-1,2-dithiolate group are quite short (Tc(1)—S(1) 2.260(1), Tc(1)—S(2) 2.256(2) Å), whereas the bridging bonds *trans* to the former are 0.15 Å longer (Tc(1)—S(3) 2.404(1), Tc(1)—S(5) 2.418(1) Å). The differences in the lengths of the two types of Tc—S bonds to the remaining ethan-1,2-dithiolate groups are less, but again the bridging bonds are longer (Tc(2)—S(3) 2.365(1), Tc(2)—S(5) 2.370(1) vs. Tc(2)—S(4) 2.277(2), Tc(2)—S(6) 2.283(2) Å). The Tc—S bonds are generally shorter than Mo—S bonds to the ethan-1,2-dithiolate ligand (edt) in *syn* and *anti*-(edt)MoS-$(\mu\text{-}S)_2$-MoS(edt), **II** and **III**, probably reflecting the stronger *trans* influence of the sulfide ligand (22).

The nearest neighbour S—S distances are in the normal range for transition metal complexes, where weak sulfur–sulfur interactions have been postulated. There are significant differences between these distances, but no consistent pattern of intra-ligand distances being shorter than inter-ligand distances or vice versa. The observed pattern can be explained if it is postulated that the strongest interaction (shortest distance, S(3)—S(5) 2.956(3) Å) between the bridging sulfur atoms causes weaker interactions (S(1)—S(5) 3.218(3), S(2)—S(3) 3.241(3), S(3)—S(4) 3.133(3), S(5)—S(6) 3.153(3) Å) in adjacent S—S systems, with consequent stronger interactions in the next nearest S—S systems (S(1)—S(2) 3.082(3), S(4)—S(6) 3.089(3) Å), regardless of whether they are intra- or inter-ligand.

The two square pyramidal systems are arranged in the *syn* configuration and, as can be seen in Fig. 1*b*, form the previously unknown structure **3** as defined by Bunzey and Enemark (22), where the dihedral angle between the sulfur atom planes, measured round from plane to plane on the oxo side is >180°. The actual value of 206.5(1)° agrees well with the predicted value of 210°. There was some doubt whether a Mo—Mo bond was present in **II** and **III**, but the present structure suggests this was the case. The Tc(1)—Tc(2) distance of 3.654(1) Å is substantially longer than the Mo—Mo distances of 2.79–2.92 Å. This results in much larger M—S—M angles (Tc, 100.03(5), 99.51(6)° vs. Mo, 76.2, 76.6, 77.62°) and consequent smaller S—M—S angles (Tc, 75.61(5), 77.25(5)° vs. Mo, 99.97, 99.72, 103.38°). We considered the possibility that the larger M—S—M angles in our compound might be because the bridging S atoms are three-coordinate, compared to the two-coordinate sulfide ions in **II** and **III**. However, Rh—S—Rh angles of 79.2, 80.2° are found in $Rh_2(SC_6H_5)_2(CO)_4$, where the bridging sulfur atoms are three-coordinate and the smaller values seem to be typical of systems where a metal–metal bond is present (25). The packing of the molecules in the unit cell shows no strong intermolecular interactions; all intermolecular distances are equal to or greater than van der Waals distances. The molecules are packed in a roughly hexagonal closed packed lattice.

The 3:2 complex was first observed spectrophotometrically (10), was subsequently isolated by both procedures described herein, and now has been unequivocally characterized by X-ray crystallography. We have isolated and spectrophotometrically observed the same type of dimer (10) in the reaction of $[TcOCl_4]^-$ with *excess* 1,3-propanedithiol while trying to prepare $[TcO(SCH_2CH_2CH_2S)_2]^-$, which was originally synthesized by Byrne and Smith (8) by $NaBH_4$ reduction of ethanolic TcO_4^- in the presence of propanedithiol. The titration of $[TcOCl_4]^-$ with 3,4-toluenedithiol (10), however, leads directly to the bis(dithiolato) monomer $[TcO(S_2C_6H_3(CH_3))_2]^-$ which we have previously reported (9).

These observations, taken together, raise the possibility of steric factors governing the reaction of $[TcOCl_4]^-$ with various dithiols. Indeed, molecular model studies suggest that steric hindrance prohibits the approach of the protected dithiol at the empty sixth coordination site (*trans* to the *oxo*) (10). The same rationale applies to the extra methylene group in the 1,3-propanedithiolato complex and explains the dimer formation in the presence of excess dithiol.

The electrophilicity of the oxotechnetium(V) core is adequate to remove the acetamidomethyl blocking group from edt(acm)$_2$. Subsequent experiments with a bis(acetamidomethyl) N_2S_2 amide thiolate (26) showed that the group functions in a more predictable manner in that system because TcO has the same electrophilicity, the ligand is much larger and tetradentate, and the final ligand:Tc ratio is 1:1. This allowed the formation of this important class of $TcON_2S_2$ anions in aqueous solution with no evidence for any intermediates.

IV. Order−disorder transitions: solid state kinetics, thermal analyses, X-ray diffraction and electrical conductivity studies in the $Ag_2SO_4-K_2SO_4$ system

M. SUNITHA KUMARI AND ETALO A. SECCO[1]
Chemistry Department, St. Francis Xavier University, Antigonish, N.S., Canada B2G 1CO

M. SUNITHA KUMARI and ETALO A. SECCO. Can. J. Chem. **63**, 324 (1985).

Order−disorder transitions occurring in the $Ag_2SO_4-K_2SO_4$ system were investigated by reaction kinetics, thermal analyses, X-ray diffraction, and electrical conductivity techniques. Solid−liquid and solid−solid phase diagrams are reported.

The conductivity data in the high temperature phase of the solid resemble superionic conductivity behavior. The higher conductivity of Ag_2SO_4 with K^+ presence relative to pure Ag_2SO_4 and $Ag_{2-x}Na_xSO_4$ compositions support a lattice expansion facilitating higher mobility of ions.

The reaction kinetics, X-ray diffraction, and electroconductivity results suggest a relatively open periodic SO_4^{2-} sublattice in the high-temperature phase of the sulfate-based systems studied in this series.

M. SUNITHA KUMARI et ETALO A. SECCO. Can. J. Chem. **63**, 324 (1985).

Faisant appel aux cinétiques de réaction et aux techniques d'analyse thermique, de diffraction de rayons-X et de conductivité électrique, on a étudié les transitions ordre-désordre qui se produisent dans le système $Ag_2SO_4-K_2SO_4$. On rapporte les diagrammes de phase solide-liquide et solide−solide.

Les donnés de conductivité thermique de la phase à haute température ressemblent à un comportement de conductivité superionique. Le fait que la conductivité du Ag_2SO_4, en présence de K^+, soit plus élevée que celle du Ag_2SO_4 à l'état pur ou de celles des compositions $Ag_{2-x}Na_xSO_4$ milite en faveur d'une expansion du réseau facilitant ainsi une mobilité plus grande des ions.

Les résultats observés avec les cinétiques de réaction, avec la diffraction de rayons-X et avec l'électroconductivité suggèrent la présence d'un sous-réseau périodique d'ions SO_4^{2-} qui est relativement ouvert dans la phase à haute température des systèmes à base de sulfates étudiés dans cette série.

[Traduit par le journal]

Introduction

Binary sulfates containing monovalent cations are members of a group of compounds which exhibit fast-ion or "superionic" conductivity in the high temperature phase (1). Such compounds are referred to as superionic conductors (SIC's) or solid electrolytes and have attracted considerable attention because of (*i*) their promise in applications in high-energy-density batteries and (*ii*) their unusual transport behavior.

The mechanism of fast-ion conduction is not completely understood although proposed models involve basically two structural types, viz. (*i*) layer structure as in β-alumina and (*ii*) channel structure as in α-AgI or in NASICON where an open network or skeleton framework of anions facilitates cation mobility (1). This paper is part of a continuing effort (2−4) to probe the nature of the phase transition, the structure of the high temperature phase and the effects of guest ions relating to the mechanism of fast-ion conductivity in binary sulfate systems.

Our earlier study on Na^+ presence in Ag_2SO_4 lattice revealed a decrease in conductivity in $Ag_{2-x}Na_xSO_4$ compositions attributed to lattice contraction resulting from $r_{Na^+} < r_{Ag^+}$. The interpretation suggested that incorporation of a slightly larger radius cation in the Ag_2SO_4 lattice would effect a higher conductivity. To test this hypothesis, the slightly larger radius K^+ was chosen, $r_{K^+} = 133$ pm versus $r_{Ag^+} = 126$ pm.

The high temperature form of Ag_2SO_4, II-Ag_2SO_4(α), hexagonal and space group $P6_3/mmc$ with unit cell dimensions $a_o = 5.519$ Å, $c_o = 7.504$ Å (5) is isomorphic with the high temperature form of K_2SO_4, α-K_2SO_4, with unit cell dimensions $a_o = 5.90$ Å, $c_o = 8.11$ Å, and $Z = 2$ (6). The structure of α-K_2SO_4 is described as disordered where the anions are evenly distributed among two oppositely directed orientations. Furthermore, the low temperature forms of Ag_2SO_4, I-Ag_2SO_4 (β) (7), and of K_2SO_4, β-K_2SO_4 (8), are isostructural orthorhombic with space groups *Fddd* and *Pnam*, respectively. To our knowledge, the only literature record of the Ag_2SO_4 phase diagram is the early report by Nacken (9) showing the existence of solid solutions and solid−solid phase transitions over the complete composition range.

This paper contains the results of a study on the condensed phase transitions in the $Ag_2SO_4-K_2SO_4$ system, the kinetics of the solid-state reaction between Ag_2SO_4 and K_2SO_4 and the conductivity of selected undoped and doped (Cd^{2+}), $Ag_{2-x}K_xSO_4$ compositions using thermal analyses, DSC, electroconductivity, and X-ray diffractometry techniques.

Experimental

Anhydrous Ag_2SO_4 and anhydrous K_2SO_4 were Alfa Products ultrapure grade; $CdSO_4$ was Fisher Certified grade. All $Ag_2SO_4-K_2SO_4$ samples were prepared by fusing the requisite composition mixture, previously well ground manually, of the respective sulfates in a Pt crucible.

DTA traces were recorded on a duPont 990 Thermal Analyzer in a flowing N_2 (ultrapure) atmosphere using ignited Al_2O_3 as reference material. The precision of a melting temperature was ±5°C whereas the transition temperature measurement was within ±2°C. The enthalpies of transformation were evaluated with the DSC accessory to the 990 DTA module using the heats of fusion or transition for In, Sn, Zn, AgI, CsCl as references; samples were encapsulated in Al containers — identical results within experimental error were obtained using Au containers.

X-ray diffraction patterns were obtained using a Norelco diffractometer with CuK_α radiation. Diffraction patterns at elevated temperatures were recorded with a Model X-86-N high temperature accessory (Materials Research Corp.) attached to the Norelco unit (10).

Electrical conductivity measurements were made on compressed polycrystalline sample in a stainless steel conductivity cell following the procedure described earlier (3, 11). The Ag_2SO_4-rich samples were in the form of a disc, 1 mm thick and 100 m^2 in surface area; other compositions were 1 mm thick and ~75 mm^2 in surface area of the crack-free portion recovered from the compressed disc.

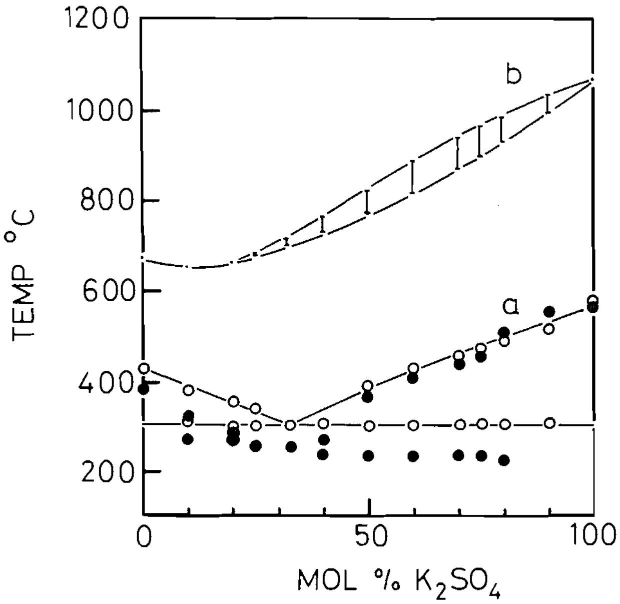

FIG. 1. (*a*) Solid−solid phase diagram of the $Ag_2SO_4-K_2SO_4$ system; ○, heat mode, ●, cool mode. (*b*) Solid−liquid phase diagram $Ag_2SO_4-K_2SO_4$ system, heat mode.

In the solid state kinetics measurements each sample of $Ag_2SO_4-K_2SO_4$ mixture, 2:1 mole ratio, of constant mass was ground manually to a uniform consistency; the sample was maintained at the set temperature in the DTA cell in the isothermal mode for the required time interval. The fraction of reaction of the 2:1 eutectoid, α, was evaluated by comparing the DSC enthalpic areas in the heat mode of the individual transitions for the final eutectoid state. The low degree of crystallinity of the samples did not permit a cross-check of the DSC kinetic data with X-ray diffraction data using the characteristic X-ray peak heights.

Results and discussion

Phase diagram

The transition temperatures recorded on DTA traces are plotted versus composition in Fig. 1 — Fig. 1(*a*) represents the solid−solid phase diagram and Fig. 1(*b*) represents the solid−liquid phase diagram. The Fig. 1(*b*) plot is in agreement with Nacken's report (9) but the Fig. 1(*a*) plot differs significantly from Nacken's — however, the relationship between our Fig. 1(*a*) cool mode data, filled circles, and Nacken's plot is apparent. Figure 2 gives the enthalpy change, ΔH_t, dependence on composition for the solid−solid transition.

The solid−liquid diagram is of the minimum type solid solution normally expected for isostructural binary systems with the noteworthy absence of the liquidus curve in the 80−100% Ag_2SO_4 region. Reisman (12) has done theoretical analyses of minimum type solid solutions using computer-derived models incorporating ΔH_f°, heat of fusion, and T_0, the melting temperature for each component. The minimum involves dimer−monomer transformation or dissociation of one component on melting which is displaced markedly toward the lower melting component when the higher melting component undergoes dissociation and vice versa. The minimum at 85% Ag_2SO_4 in Fig. 1(*b*) supports K_2SO_4 dissociation on melting as was found in the $Na_2SO_4-K_2SO_4$ system (2).

The solid state phase diagram, Fig. 1(*a*), displays solid solution behavior with the existence of an eutectoid at 305°C and 33 mol% K_2SO_4. The cool mode data, filled circles, show

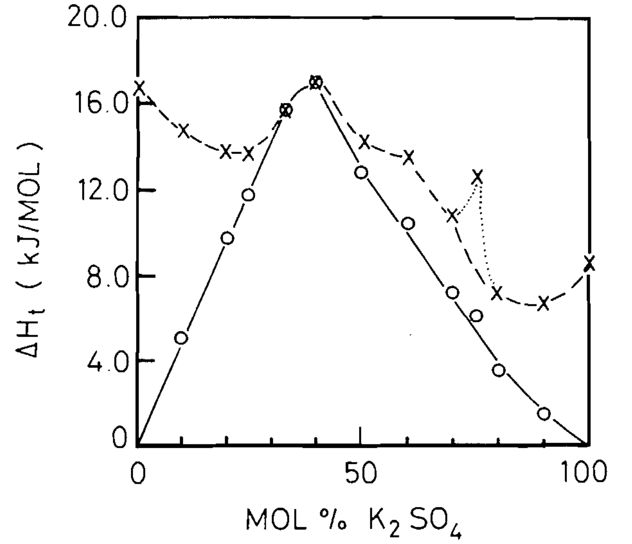

FIG. 2. Plot of enthalpy change for solid−solid phase transitions versus composition in $Ag_2SO_4-K_2SO_4$ system; ○, only 305°C transition value and ×, total sum.

irregular behavior and appreciable hysteresis effects relative to the heat mode data, open circles, for the eutectoid and Ag_2SO_4-rich compositions, i.e. >60%. The eutectoid composition was chosen at 33 mol% instead of 25 or 40% on the basis that a single thermal effect was reproducible on both heat and cool modes. It can be argued that the maximum ΔH_t value, Fig. 2, suggests 40% to be a more justifiable eutectoid composition. On the other hand, the maximum ΔH_t value may result from mixing or relative increased disorder — thus suggesting that 33% is the more ordered state with possible compound characteristics. The abnormal ΔH_t value for 75% K_2SO_4 is reproducible but unexplained — the only distinct feature of this datum being its broad temperature range, 385−485°C, for the solidus line transition. Thermal hysteresis effect, $\Delta T = T_p^f - T_p^r$, where T_p^f refers to the peak temperature on heating and T_p^r to the peak temperature on cooling, has been linked (13) to the co-existence mechanism of continuous transformations, the main factor controlling the hysteresis being the strain energy E_s, where $E_s \propto \Delta T \cdot \Delta S$ and ΔS is the entropy change for the transformation. Another basis for the hysteresis effect may be the disorder → order direction which imposes a configurational requirement of "long-range" order with the ordered migration of ions from one set of sites to another expressed by the relation $\Delta S = R \ln Q$ where Q is the ratio of the numbers of disordered states in the two phases (14).

X-ray diffraction

X-ray diffraction patterns at room temperature and above the transition temperature for Ag_2SO_4, K_2SO_4, 33 mol% K_2SO_4, 50 mol% K_2SO_4, and 70 mol% K_2SO_4 are presented in Fig. 3. The patterns confirm the solid phase structural transformation. The high temperature patterns of all compositions are simpler than their room temperature patterns. The high temperature pattern at 33 mol% K_2SO_4 closely resembles the Ag_2SO_4 high temperature pattern displaced to slightly higher "*d*" spacing. The characteristic high temperature peaks of 50 and 70 mol% K_2SO_4 appear at much higher "*d*" spacing relative to Ag_2SO_4. These patterns suggest that the low temperature structure of the $Ag_2SO_4-K_2SO_4$ solid state system undergoes a transformation to a phase resembling the II-Ag_2SO_4(α) form at high temperature. These results parallel the structural transformation behav-

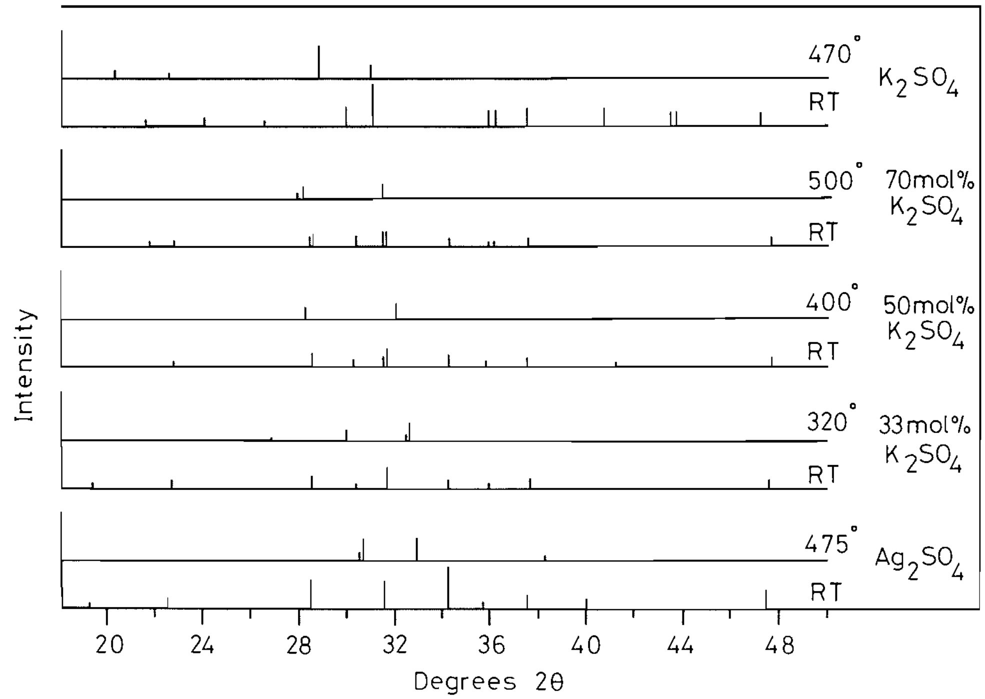

FIG. 3. X-ray diffraction line patterns, converted from diffractogram peaks, of relative intensity versus angle 2θ for Ag_2SO_4, 33, 50, 70 mol% K_2SO_4, and K_2SO_4 at room temperature (RT) and transition temperatures in °C.

ior observed for the $Na_2SO_4-Ag_2SO_4$ solid solution system (4) and $Na_2SO_4-K_2SO_4$ system (17).

Solid state kinetics

The best fit between the experimental results and the known kinetic equations, over the temperature range 323−369°C for reaction fraction α up to 0.8, was obtained for the second-order rate expression by Honig *et al.* (15) which at sufficiently large *t* takes the form

$$[1] \quad (1 - \alpha)^{-1} = 1 + \sigma G N_g t$$

where $(1 - \alpha)$ represents the unreacted fraction, σ is the shape factor, *G* is the lineal growth rate of the new phase, N_g is the initial density of germ nuclei, and *t* is the time. Equation [1] is also recognized as the integrated form of the second-order rate law, where integration of

$$d\alpha/dt = k(1 - \alpha)^2$$

yields

$$[2] \quad (1 - \alpha)^{-1} = 1 + kt$$

Plots of $(1 - \alpha)^{-1}$ versus time give straight lines for 2:1 mole ratio $Ag_2SO_4:K_2SO_4$, Fig. 4(*a*), whose slopes equal the formal rate constant *k* or the composite quantity $\sigma G N_g$, along with the intercept of unity. The slope of the standard Arrhenius plot of log *k* versus $T\,(K)^{-1}$, Fig. 4(*b*), yields an activation energy, E_a, of 96 ± 10 kJ/mol. This value is in contrast to the E_a values of 232 and 165 kJ/mol for $KNaSO_4$ and $K_3Na(SO_4)_2$, respectively.

The second-order rate behavior and the relatively high *k* values, i.e. $\sim 10^{-1}$, involving two solid reactants in solid state reactions is uncommon and the mechanism for such a reaction rate must incorporate highly mobile reacting species. The reaction mechanism is envisaged (2) to involve the cations as the effective reacting species in a sublattice of SO_4^{2-} units and the fundamental reaction step being the ordering of the cations on crystallographically preferential lattice sites which constitute a sublattice of superstructures or incommensurate structures (16). The model might be classified as involving a type of quasi-homogeneous solid state ionic reaction where a simple first-order dependence on the two principal reactants results in the overall second-order rate. The proposed model requires highly mobile cations, implying high ionic conductivity, in agreement with data reported in the following section.

Electrical conductivity

The temperature dependence of the ionic conductivity, σ, is interpreted in terms of the Arrhenius-type equation

$$\sigma = (\sigma_o/T) \exp(-Q_c/RT)$$

where σ_o represents a composite constant $(ne^2\lambda^2\nu/k)$, *n*, the number of ions per unit volume, *e*, the ionic charge, λ, the distance between the two jump positions, ν, the jump frequency, *k*, the Boltzmann constant, and Q_c is the activation energy for ionic motion, assuming the conductivity to be effectively ionic with negligible electronic or hole conductivity.

Plots of log (σ*T*) vs. $T(K)^{-1}$ for pure Ag_2SO_4 along with doped and undoped 33 mol% K_2SO_4 are presented in Fig. 5. In Fig. 6 are given plots of log (σ*T*) vs. $T(K)^{-1}$ for undoped 25 and 60 mol% K_2SO_4. The reproducibility of T_t for the major transition effect for the undoped compositions, 302−305°C, is in excellent agreement with T_t values from heat mode DTA, Fig. 1(*a*); the 2 mol% $CdSO_4$-doped sample (■,□) Fig. 5, shows a lower T_t of 292°C. A pronounced hysteresis effect occurs in all $Ag_2SO_4-K_2SO_4$ compositions plotted. While the 2 mol% $CdSO_4$-doped sample possesses a slightly higher conductivity prior to the transition than its undoped counterpart, the two samples show the same post-transition conductivity values. The predicted enhanced conductivity of Ag_2SO_4 containing K^+ on the basis of lattice expansion due to the larger K^+ radius is observed. On the other hand, the presence of 2 mol% Cd^{2+} with its attendant vacancies in the $Ag_2SO_4-K_2SO_4$ structure did not

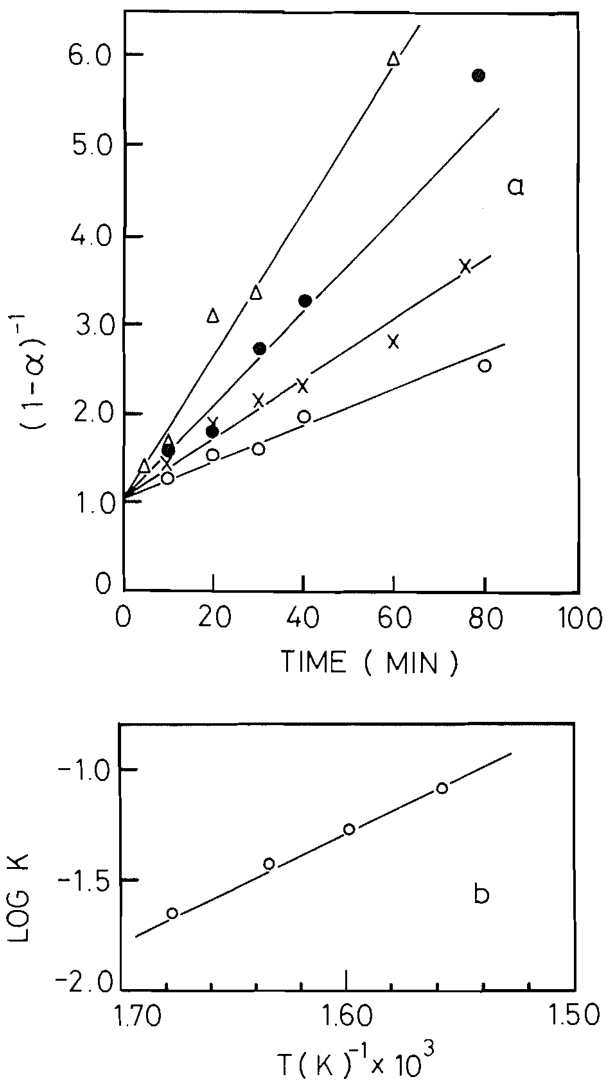

FIG. 4. (*a*) Plot of $(1-\alpha)^{-1}$ versus time, second order rate law; ○ 323°C, × 339°C, ● 353°C, △ 369°C. (*b*) Plot of log *k* versus T^{-1}.

increase the conductivity as expected. However, a counter balancing effect of lattice contraction by the smaller Cd^{2+}, $r_{Cd^{2+}}$ = 100 pm relative to r_{K^+} and r_{Ag^+} ~130 pm, might have militated against the anticipated increase as was found for the Ag_2SO_4–Na_2SO_4 system.

The $\sigma-T$ behavior of 25 and 60 mol% K_2SO_4 reveals along with erratic conductivity behavior in the post-transition region above 440°C. Such a decrease in conductivity versus temperature has been reported for Na_2SO_4 (18) and CsCl (19). The striking feature of such behavior is the recovery of the higher conductivity values and the regain of stability on the cool mode. The conductivity drop is interpreted in terms of collapse of the SO_4 framework, i.e. SO_4^{2-} sublattice, and its subsequent recovery on cooling implies restructuring of that sublattice. Contrast these effects with the "anti-hysteresis" effect observed in CD^{2+}-doped $KNaSO_4$ (3) and undoped 40 mol% Ag_2SO_4–Na_2SO_4 ascribed to vacancy–cation cluster formation analogous to that proposed for anion conductors (20).

The activation energy values for the ionic conductivity Q_c in the temperature region 525–650 K for 25, 33, and 60 mol% are tabulated in Table 1. The constant Q_c value, 41 ± 4 kJ/mol, in the two phases for 25 mol% K_2SO_4 and for doped and

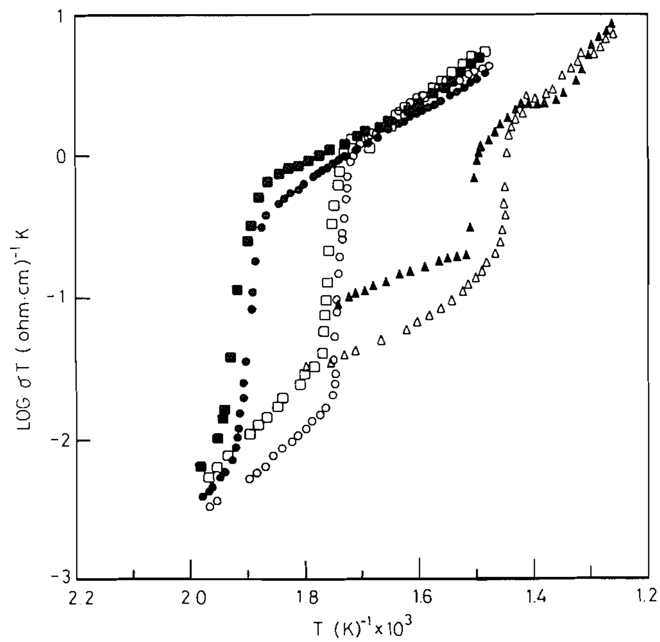

FIG. 5. Plots of log σT versus T^{-1}. Ag_2SO_4, △, ▲, heat and cool modes, respectively; 33 mol% K_2SO_4, ○, ●, heat and cool modes, respectively; 2 mol% Cd^{2+} in 33 mol% K_2SO_4, □, ■ heat and cool modes, respectively.

undoped 33 mol% K_2SO_4 suggests a common ionic species, viz. Ag^+ and conductivity mechanism. The higher Q_c and lower relative conductivity values in the two phases of 60 mol% K_2SO_4 suggest a smaller concentration of mobile ions

TABLE 1. Ionic conductivity activation energy values, Q_c, of various samples (% K_2SO_4)

Composition	Temperature region[a]	Q_c (kJ/mol) 25 mol%	33 mol%	60 mol%
Pure	A	76.8 ± 10	41.4 ± 4	90.2 ± 9
	B	1150 ± 100	1015 ± 100	1200 ± 100
	C	45.0 ± 4	44.2 ± 4	97.5 ± 10
2 mol% Cd^{2+}	A	—	36.8 ± 4	—
	B	—	966 ± 100	—
	C	—	46.0 ± 4	—

[a]A, ordered phase; B, transition; C, disordered phase.

or a larger ion, viz. K^+. These Q_c values are within limits of experimental error of the Q_c values observed in $KNaSO_4$ and $K_3Na(SO_4)_2$ (3), pure and doped Na_2SO_4 (4) and 40 mol% $Ag_2SO_4-Na_2SO_4$ system (4). The average Q_c of 1100 ± 100 kJ/mol for the phase transition of all compositions in Table 1 are in contrast with the average Q_c for Ag_2SO_4 and 40 mol% $Ag_2SO_4-Na_2SO_4$ (4) but compares with the Q_c and E_a activation energy values reported for phase transitions in $KNaSO_4$ and $K_3Na(SO_4)_2$ (2), K_2SO_4 (21), ZnS (22), and anthranilic acid (23).

The picture that emerges from the sulfate-based systems studied in this series is that a closely related structure of a relatively open periodic SO_4^{2-} sublattice exists in the high-temperature post-transition region. The open SO_4^{2-} framework facilitates the motion of the mobile cations contributing to the fast-ion or superionic conductivity in these systems. The superionic conductivity can be affected by contraction or expansion of the sublattice, within structural limits, effected by guest cations of different ionic radii relative to the host cation and/or by the presence of vacancies on cation lattice sites. This analysis further suggests that the presence of guest anions of different ionic radii and charges, e.g. WO_4^{2-}, TeO_4^{2-}, PO_4^{3-}, etc. in the SO_4^{2-} sublattice would effect similar or parallel behavior — this study is being considered in this series.

Halogenodephenylation of triphenyltin(IV) pseudohalides

P. C. SRIVASTAVA,[1] S. K. SRIVASTAVA, AND SUMAN B. SHARMA
Department of Chemistry, University of Lucknow, Lucknow – 226007, India

Received December 20, 1983[2]

P. C. SRIVASTAVA, S. K. SRIVASTAVA, and SUMAN B. SHARMA. Can. J. Chem. **63**, 329 (1985).

The halogenodephenylation of Ph_3SnX (X = NCO, NCS, and N_3) with IX′ (X′ = Cl and/or Br) yielded new $Ph_2Sn(X)X'$ and PhI. The diphenyltin mixed halide pseudohalides have been characterised by elemental analyses, molar conductance, molecular weight, tlc data, ir, and ^1H nmr spectral studies.

$Ph_2Sn(NCS)Br$ with DMSO forms $Ph_2Sn(NCS)Br\cdot 2DMSO$ complex.

P. C. SRIVASTAVA, S. K. SRIVASTAVA et SUMAN B. SHARMA. Can. J. Chem. **63**, 329 (1985).

L'halogénodéphénylation du Ph_3SnX (X = NCO, NCS et N_3) à l'aide de IX′ (X′ = Cl et/ou Br) conduit à du PhI et aux nouveaux composés $Ph_2Sn(X)X'$. On a caractérisé ces nouveaux composés en se basant sur des données d'analyse élémentaire, de conductivité molaire, de poids moléculaire et de C.C.M. ainsi que sur des études des spectres ir et rmn du ^1H.

Le $Ph_2Sn(NCS)Br$ et le DMSO forment le complexe $Ph_2Sn(NCS)Br\cdot 2DMSO$.

[Traduit par le journal]

Introduction

The cleavage reactions of tetraorganotins of the type $ArSnR_3$ (Ar = aryl, R = alkyl) have been extensively studied (1). There seems to be no report on the cleavage reactions of Ar_3SnX (X = pseudohalide). As a part of our studies on $Ph_3Sn(IV)$ pseudohalides (2–6), we report the halogenodephenylation of Ph_3SnX (X = NCO, NCS, and N_3) with ICl and/or IBr which yields hitherto unknown diphenyltin(IV) mixed halide pseudohalides; $Ph_2Sn(X)X'$ (X = NCS, X′ = Cl and Br; X = NCO, X′ = Cl; and X = N_3, X′ = Cl) and PhI. The $Ph_2Sn(X)X'$ have been characterised through elemental analyses, molar conductance, molecular weight, tlc data, ir, and ^1H nmr spectral studies.

$Ph_2Sn(NCS)Br$ with DMSO in acetone gives the complex $Ph_2Sn(NCS)Br\cdot 2DMSO$ which contains oxygen-bonded DMSO (ir evidence) and is non-electrolytic and monomeric in nitrobenzene.

Experimental

Materials and methods

Ph_3SnNCS (7), Ph_3SnNCO (8), Ph_3SnN_3 (9), and IBr (10) were prepared. ICl (Fluka) was procured commercially. The halides (Cl or Br) were estimated volumetrically (11) after decomposing the compounds with alcoholic KOH. All reactions and manipulations were carried out under nitrogen and the physicochemical measurements were done as before (4).

Halogenodephenylation reactions

Ph_3SnNCS with ICl (1:1): A solution of ICl (1.62 g, 0.01 mol) in $CHCl_3$ (25 mL) was added dropwise with vigorous stirring to a 50 mL chloroform solution of Ph_3SnNCS (4.08 g, 0.01 mol) at room temperature. This procedure was followed immediately by decolourisation. After complete addition, the mixture was refluxed for 2 h and concentrated by distilling off the excess of solvents at reduced pressure (10 mm Hg). It was then distilled to give PhI (1.32 g, 64.7%). To the residue 5 mL petroleum ether (40–60°C) was added and kept at 0°C. After 24 h a light yellow solid separated. This solid was washed with petroleum ether (40–60°C) and dried at 20°C/10 mm Hg and identified as $Ph_2Sn(NCS)Cl$ (1.65 g, 45%; mp 162°C).

Ph_3SnNCS with IBr (1:1): Under similar experimental conditions Ph_3SnNCS (4.08 g, 0.01 mol) with IBr (2.07 g, 0.01 mol) yielded PhI (1.45 g, 71.8%) and a light yellow solid, $Ph_2Sn(NCS)Br$ (2.05 g, 49.9%; mp 155°C).

Ph_3SnNCO with ICl (1:1): Reaction of Ph_3SnNCO (3.92 g, 0.01 mol) with ICl (1.62 g, 0.01 mol) in chloroform yielded PhI (1.73 g, 85%) and (1.75 g, 50%; mp 180°C) solid $Ph_2Sn(NCO)Cl$.

Ph_3SnN_3 with ICl (1:1): Reaction of Ph_3SnN_3 (3.92 g, 0.01 mol) with ICl (1.62 g, 0.01 mol) under similar conditions yielded PhI (1.63 g, 80%) and solid $Ph_2Sn(N_3)Cl$ (1.57 g, 45%; mp 167°C).

Preparation of complex $Ph_2Sn(NCS)Br\cdot 2DMSO$: To a solution of $Ph_2Sn(NCS)Br$ (4.11 g, 0.01 mol) in anhydrous acetone (20 mL) was added DMSO (1.56 g, 0.02 mol) ligand in 10 mL acetone. The mixture was refluxed for 3 h and excess solvent was distilled off. Petroleum ether (5 mL) (60–80°C) was added and the solution on concentration and cooling gave white crystalline solid which was washed with petroleum ether (60–80°C) and dried at 20°C/10 mm Hg and was identified as $Ph_2Sn(NCS)Br\cdot 2DMSO$ (3.97 g, 70%; mp 165°C).

Results and discussion

The phenyl group of Ph_3Sn pseudohalides is cleaved in preference to pseudohalide group by ICl and/or IBr and these reactions provide synthetic routes to hitherto unknown $Ph_2Sn(IV)$ mixed halide pseudohalides, $Ph_2Sn(X)X'$ (X = pseudohalide and X′ = Cl or Br). The recrystallisation of these compounds from CCl_4 and dichloromethane separately yielded the same product of same melting points indicating that these were pure compounds. Further, in tlc, the exhibition of a single spot by $Ph_2Sn(NCS)Cl$ (Rf. 0.47, ethyl acetate/*n*-propanol (3:2)), $Ph_2Sn(NCS)Br$ (Rf. 0.40, ethyl acetate/*n*-propanol (3:2)), $Ph_2Sn(NCO)Cl$ (Rf. 0.50, ethyl acetate/*n*-propanol (3:2)), and $Ph_2Sn(N_3)Cl$ (Rf. 0.80, chloroform/methanol (3:2)) and their parent compounds Ph_3SnNCS, Ph_3SnNCO, and Ph_3SnN_3 of Rf. 0.44, 0.64, and 0.60, respectively, in the stated solvent systems confirmed the purity of these compounds obtained after the halogenodephenylation reactions. The objective of complexing $Ph_2Sn(NCS)Br$ with DMSO were two-fold: (*i*) for checking the purity of the compound $Ph_2Sn(NCS)Br$ through ^1H nmr and (*ii*) the ease of formation of the adduct indicated that $Ph_2Sn(NCS)Br$ is as good acceptor as $Ph_2Sn(NCS)_2$, (7, 12). The molar conductance data in nitrobenzene indicate that they are non-electrolytes and molecular weight data in the same solvent show their monomeric character (Table 1). Further cleavage reactions of $Ph_3Sn(IV)$ pseudohalides with IN_3 and BrCN are in progress.

RICHARD G. BALL and RICHARD MACLEOD ELOFSON. Can. J. Chem. **63**, 332 (1985).

p-Diethylaminobenzenediazonium hexafluorophosphate, $C_{10}H_{14}N_3^+ \cdot PF_6^-$, crystallized in space group $P\bar{1}$ with a = 12.105(4), b = 12.340(5), c = 10.439(4) Å, α = 96.53(3), β = 104.11(3), γ = 64.44(3)°, and Z = 4. The structure was solved using direct methods and refined with full-matrix least-squares techniques on F, to a final R of 0.054 for 1917 reflections with $F^2 > 3\sigma(F^2)$. The mean bond lengths for the diazo group are: N—N 1.096(6); C—N 1.357(7) Å. The geometry of the molecule is discussed in terms of the possible resonance forms and it is shown to be consistent with a form in which the N—N triple bond is essentially intact and the aminobenzene moiety has "quinoidal" character.

RICHARD G. BALL et RICHARD MACLEOD ELOFSON. Can. J. Chem. **63**, 332 (1985).

L'hexafluorophosphate de *p*-diéthylaminobenzènediazonium, $C_{10}H_{14}N_3^+ \cdot PF_6^-$, cristallise dans le groupe d'espace $P\bar{1}$ avec a = 12,105(4), b = 12,340(5), c = 10,439(4) Å, α = 96,53(3), β = 104,11(3), γ = 64,44(3)° et Z = 4. On a résolu la structure par des méthodes directes et on l'a affinée par la méthode des moindres carrés (matrice complète) sur F jusqu'à une valeur finale de R = 0,054 pour 1917 réflexions avec $F^2 > 3\sigma(F^2)$. Les longueurs moyennes des liaisons du groupe diazo sont: N—N = 1,096(6); C—N = 1,357(7) Å. On discute de la géométrie de la molécule en fonction des formes possibles de résonance et on montre qu'elle est en accord avec une forme dans laquelle la triple liaison N—N est essentiellement intacte et l'unité aminobenzène a un caractère "quinoïdal".

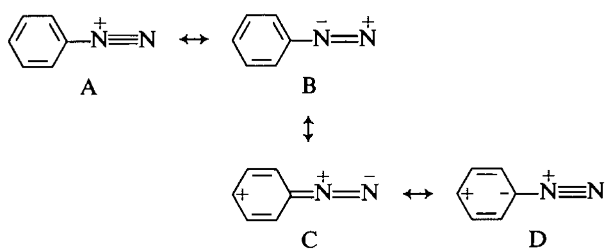
Introduction

The unusual properties of diazonium salts such as explosive decomposition under certain conditions, reaction with retention of nitrogen to produce industrially important products such as dyes, photochemical decomposition with loss of N_2 (the basis of the industrially important Diazolid process), etc., have fascinated chemists for over one hundred years.

Until 1960, resonance structures "A", "B", and "C" were



used routinely to accommodate the various properties of benzenediazonium salts. Subsequently, X-ray studies have consistently shown the N—N distance, regardless of substitution patterns or the nature of the anion, remains in the range 1.08 to 1.14 Å, which is indicative, when compared to the dinitrogen distance of 1.097 Å (1), of the N—N triple bond remaining largely intact in the ground state. In recent years ^{13}C and ^{15}N nmr studies (2, 3) have suggested that resonance form "D" is a major contributor to the ground state. An important compound for the purpose of correlating structural parameters and the spectroscopic results would be the salts of the *p*-diethylaminobenzenediazonium ion. This compound has been investigated as the chlorozincate salt (4) but the poor quality of the experimental results and the lack of agreement with other benzendiazonium compounds led us to undertake a re-examination of the crystal structure of *p*-diethylaminobenzenediazonium. Attempts were made to prepare suitable crystals first as the tetrafluoroborate and later as the hexafluorophosphate salts since these anions do not tend to strongly coordinate with the cation. However, success was not obtained until the *p*-diethyl derivative was crystallized as the hexafluorophosphate salt. The results of the structural analysis of this compound are presented herein and these, as expected, correlate closely with those of the similar compound *p*-morpholinobenzenediazonium tetrafluoroborate (5).

Experimental

Yellow crystals of *p*-*N*,*N*-diethylaminobenzenediazonium hexafluorophosphate were prepared by the method of Rutherford *et al.* (6) with the substitution of H_2SO_4 for HCl. Diffraction quality crystals were obtained by recrystallizing from methanol/diethyl ether.

Crystal data:
$C_{10}H_{14}N_3^+ \cdot PF_6^-$ fw = 321.21
Triclinic, $P\bar{1}$, a = 12.105(4), b = 12.340(5), c = 10.439(4) Å; α = 96.53(3), β = 104.11(3), γ = 64.44(3)°, V = 1364.2 Å^3, Z = 4, D_c = 1.56 g cm^{-1}, μ(MoKα) = 2.57 cm^{-1}.

Reflection data were collected at −70°C using an Enraf–Nonius CAD4 diffractometer. Reflections in the range $0 < 2\theta < 50°$ were measured using an $\omega-2\theta$ scan with $\Delta\omega = (0.80 + 0.35 \tan \theta)°$ and scan speeds varying from 1.7 to 5.0 deg min^{-1}. Two crystals, of approximate size 0.02 × 0.06 × 0.12 mm, were needed for data collection since the first crystal was lost when ice build-up on the goniometer head fractured the crystal from its glass fiber. 3873 reflections were measured from crystal 1 and 2175 from crystal 2. Over the course of data collection on both crystals two reflections, chosen as standards, were remeasured every 60 min of exposure time to monitor crystal and diffractometer stability. These intensities did not change by more than 11% for either crystal and no correction was applied to the data.

After correcting each data set separately for Lorentz, polarization, and background effects the two data sets were brought to a common

* Indicates an atom refined anisotropically. The equivalent isotropic thermal parameter is given by: $U = 1/3\,(U_{11} + U_{22} + U_{33} + 2U_{23}\cos\alpha + 2U_{13}\cos\beta + 2U_{12}\cos\gamma)$.

scale and merged to yield 4813 unique reflections. Of these 1917 had $I > 3\sigma(I)$ and were used in the structure refinement.

The structure was solved[2] using the direct methods program SHELX 84 and refined using full-matrix least-squares minimizing $\Sigma\omega(|F_o| - F_c|)^2$ where $\omega = 1/\sigma(I)$. Neutral atom scattering factors were calculated from the analytical expression for the scattering factor curves (8*a*) and the f' and f'' components of anomalous dispersion (8*b*) were included for all non-H atoms. In the final model the two PF_6 groups and the carbons of the four ethyl groups were refined with anisotropic thermal parameters, while the remaining non-H atoms were refined with isotropic thermal parameters for a total of 271 variables. The H atom contributions were included as fixed, isotropic atoms located at their "idealized" positions (C—H 0.95 Å and appropriate sp^2 or sp^3 geometry). No attempt was made to refine the H atom parameters because of the already low observations/variables ratio of 7.1:1.

Refinement converged with $R = 0.054$ ($R_w = 0.059$); the largest shift in any parameter was 0.7 times its esd. The highest peak in a final difference Fourier was 0.60(9) e Å^{-3} and was not considered chemically significant.

Final positional and thermal parameters are presented in Table 1.[3]

Discussion

The crystal structure comprises the two independent cations, depicted in Fig. 1, arranged in approximately parallel planes with the associated anions occupying spots near the cations, Fig. 2. Table 2 lists the interionic distances to 3.2 Å between the N and F atoms. There are six short contacts, <2.9 Å, and these are indicated in Fig. 2.

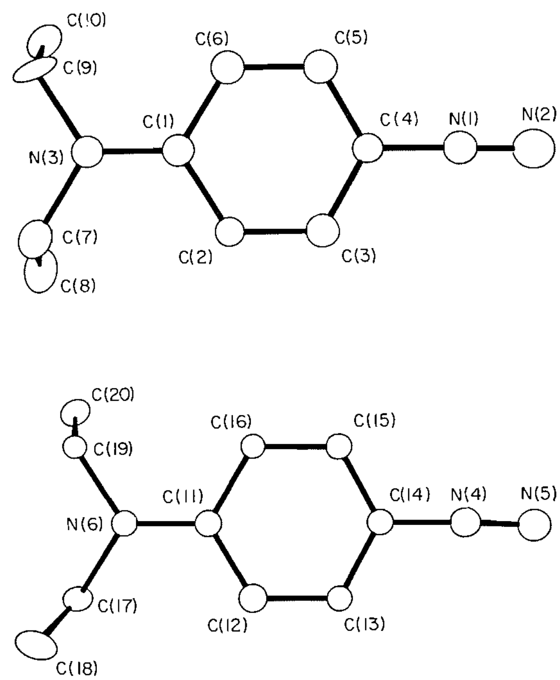

FIG. 1. Perspective view of the two independent cations showing the atom numbering scheme. Atoms are represented by thermal ellipsoids at the 50% probability level. For clarity the H atoms have been omitted.

Bond distances and angles are listed in Tables 3 and 4 respectively. The geometry of the anions is as expected, with P—F distances ranging from 1.573(4) to 1.601(4) Å for the anion based on P(1) and from 1.522(5) to 1.588(5) Å for the second anion. Since the second anion is the one involved in most of the interionic contacts, it is not surprising to see a larger range of P—F distances for this anion.

The two cations have essentially identical bond distances and angles with the only appreciable difference being the

[2] G.M. Sheldrick made available a pre-release version of SHELX 84 during a diffraction methods school in July, 1983. Other computer programs used in this analysis include the Enraf–Nonius Structure Determination Package (7) and several locally written or modified programs.

[3] Tables of anisotropic thermal parameters, derived H atom parameters, torsion angles, least-squares planes, and observed and calculated structure factors are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

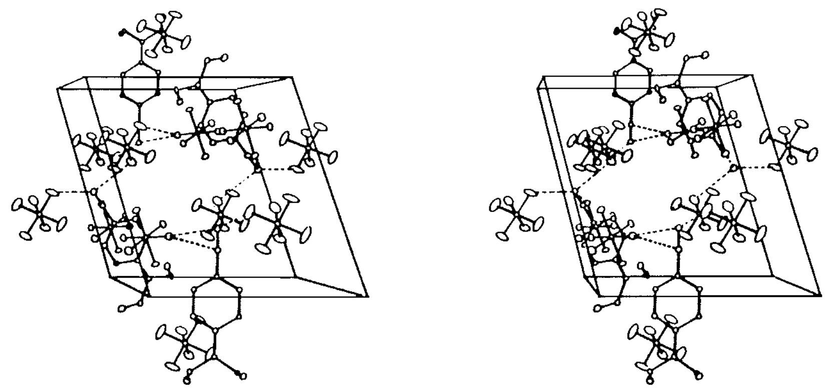

FIG. 2. Stereoview showing the ionic packing. The four cations in the cell are shown with more than one cell of anions. The F···N interionic distances less than 3.0 Å have been drawn as dashed lines. The unit cell has been oriented such that c runs left to right and b points toward the viewer.

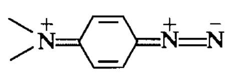
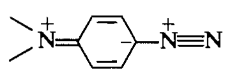
*Numbers in parentheses are estimated standard deviations in the least significant digits.

C(7)—C(8) bond which is shorter than the other three bonds of the same type. In fact it is the orientation of the ethyl groups which is the only feature distinguishing between the two cations; in one form both methyl groups point to the same side of the phenyl ring, while in the other they point to opposite sides.

The focus of this study is the geometry of the benzenediazonium moiety and how this geometry relates to the contribution of the resonance forms "A"–"D" to the ground state structure. For amino derivatives of benzenediazonium the resonance forms "C" and "D" can be drawn as



E



F

At the present time ^{13}C and ^{15}N nmr results (2, 3) indicate "F" should be the favoured structure. Table 5 presents the geometries of six structures, of roughly similar quality, containing benzenediazonium cations. For all the structures the N—N bond distance is essentially invariant and the values observed in the present study are in close agreement with the average value determined from the other structures. This observation is in accord with the conclusion of Sorriso (13*a*) that the N—N triple bond, as measured crystallographically, remains essentially intact in these types of compounds.

It is likely, by comparison with results of studies on C≡N bonds (14), that the mean N—N bond length observed in the X-ray structures is shorter by about 0.02 Å than the true internuclear N—N distance. If this is the case, then the bond order of the N—N interaction is slightly decreased from the full triple bond value and this should be reflected in a concomitant increase in the bond orders of both C(arene)—N bonds. Indeed these two distances (mean distances of 1.334(7) and 1.357(7) Å, for amino and diazo groups respectively) are both somewhat shorter than a usual C_{sp^2}—N single bond distance of approximately 1.42 Å and are in the range expected if there is some degree of double bonding between the ring and the diazo and amino groups. While the difference between these two distances is only just significant, it is interesting that the C(arene)—N(amino) distance is consistently shorter than the C(arene)—N(diazo) distance, which is what would be expected if both forms "E" and "F" contribute to the observed structure. These observations are supported by similar results observed in the structure of the morpholino derivative (5).

Observing the effect of a "quinoidal" form on the C—C distances in the benzene ring is somewhat more difficult due to the small differences involved compared to their associated standard deviations. Examination of the geometries presented in Table 5 shows that compounds **1** to **5**, in which the quinoid resonance forms may not be strong contributors, tend to have nearly equivalent distances around the ring while compounds **6**

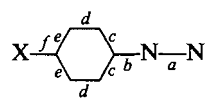
TABLE 5. Selected distances in benzenediazonium structures



Compound	—X	*a*	*b*	*c*	*d*	*e*	*f*	Reference
1	$—OCH_3$	1.099(2)	1.389(3)	1.389(3)	1.370(3)	1.399(3)	—	9
2	$—SO_3$	1.091(3)	1.410(4)	1.383(4)	1.375(4)	1.384(4)	—	10
3	—	1.093(7)	1.418(6)	1.386(8)	1.358(8)	1.399(10)	—	11
4	—	1.083(3)	1.415(3)	1.377(4)	1.382(4)	1.376(5)	—	12
5	—	1.093(2)	1.410(2)	1.396(2)	1.392(2)	1.395(2)	—	13*b*
6	$—NC_4H_8O$	1.100(1)	1.381(1)	1.395(1)	1.371(1)	1.424(1)	1.352(1)	5
7	$—NC_4H_{10}$	1.086(6)	1.360(7)	1.391(8)	1.356(8)	1.422(8)	1.329(7)	
		1.105(6)	1.354(7)	1.390(7)	1.374(7)	1.420(8)	1.339(7)	

and **7** do display an ordering of distances which is consistent with structures "E" and "F". This is in accord with the observation of greater electrophilicity of compounds **1–5** as compared to **6** and **7**, as measured by redox potentials or by the rate of coupling with suitable substrates (15, 16).

Thus, to date, the structural studies tend to support the spectroscopic evidence for resonance form "F" as an important contributor to the ground state structure of amino derivatives of benzenediazonium compounds. However, they also indicate at least a small contribution from form "E" in order to account for the consistently observed shortening of the arene–diazo bond distance from the usual single bond distance.

Enthalpies of interaction of ketones with organic solvents

W. KIRK STEPHENSON AND RICHARD FUCHS

Department of Chemistry, University of Houston, Houston, TX 77004, U.S.A.

Received April 17, 1984

W. KIRK STEPHENSON and RICHARD FUCHS. Can. J. Chem. **63**, 336 (1985).

Enthalpies of solution (ΔH_s) of a series of ketones (acetone, 2-butanone, 2-heptanone, 2-nonanone, 5-nonanone, 2,2,4,4-tetramethyl-3-pentanone, cyclohexanone) and alkane model compounds (*n*-heptane, *n*-nonane, 2,2,4,4-tetramethylpentane, cyclohexane) have been determined in 17 organic solvents (*n*-heptane, cyclohexane, CCl_4, α,α,α,-trifluorotoluene, 1,2-dichloroethane, triethylamine, butyl ether, ethyl acetate, DMF, DMSO, benzene, toluene, mesitylene, 1-octanol, methanol, *t*-butyl alcohol, 2,2,2-trifluoroethanol), and combined with heats of vaporization to give enthalpies of transfer from vapor to solvent ($\Delta H(\mathrm{v} \rightarrow \mathrm{S})$). These values have been used to evaluate ketone–solvent polar interactions ($\Delta\Delta H(\mathrm{v} \rightarrow \mathrm{S}) = \Delta H(\mathrm{v} \rightarrow \mathrm{S})(\mathrm{ketone}) - \Delta H(\mathrm{v} \rightarrow \mathrm{S})(\mathrm{alkane})$). The linear relationships between $\Delta\Delta H(\mathrm{v} \rightarrow \mathrm{S})$ and solvent dipolarity-polarizability (Taft-Kamlet π^* parameters) are derived. Based on the deviations from these correlations, ketone–CF_3CH_2OH enthalpies of hydrogen bond formation have been evaluated. The other alcohol solvents show no evidence of exothermic H-bond formation with ketones.

W. KIRK STEPHENSON et RICHARD FUCHS. Can. J. Chem. **63**, 336 (1985).

On a déterminé les enthalpies de solution (ΔH_s) d'une série de cétones (acétone, butanone-2 heptanone-2, nonanone-2, nonanone-5, tétraméthyl-2,2,4,4 pentanone-3, cyclohexanone) ainsi que d'alcanes modèles (*n*-heptane, *n*-nonane, tétraméthyl-2,2,4,4 pentane, cyclohexane) dans 17 solvants organiques (*n*-heptane, cyclohexane, CCl_4, α,α,α,-trifluorotoluène, dichloro-1,2 éthane, triéthylamine, éther butylique, acétate d'éthyle, DMF, DMSO, benzène, toluène, mésitylène, octanol-1, méthanol, alcool *tert*-butylique, trifluoro-2,2,2 éthanol) et on les a combinés avec les chaleurs de vaporisation pour obtenir les enthalpies de transfert de la vapeur au solvant ($\Delta H(\mathrm{v} \rightarrow \mathrm{S})$). On a utilisé ces valeurs pour évaluer les interactions polaires cétone-solvant ($\Delta\Delta H(\mathrm{v} \rightarrow \mathrm{S}) = \Delta H(\mathrm{v} \rightarrow \mathrm{S})(\mathrm{cétone}) - \Delta H(\mathrm{v} \rightarrow \mathrm{S})(\mathrm{alcane})$). On en a déduit la relation linéaire entre $\Delta\Delta H(\mathrm{v} \rightarrow \mathrm{S})$ et la polarité-polarisabilité du solvant (paramètres de π^* de Taft–Kamlet). En se basant sur les déviations par rapport à ces corrélations, on a évalué les enthalpies de formation de la liaison hydrogène cétone–CF_3CH_2OH. Il ne semble pas que les autres alcools étudiés comme solvant forment des liaisons hydrogènes exothermiques avec les cétones.

[Traduit par le journal]

Enthalpies of polar interaction of a series of ketones with methanol (MeOH), dimethylformamide (DMF), benzene, and cyclohexane (c-C_6) have been reported (1) using the solvation enthalpy, or $\Delta\Delta H(\mathrm{v} \rightarrow \mathrm{S})$, method. This method utilizes enthalpies of transfer of a solute from vapor to solvent,

$$[1] \quad \Delta H(\mathrm{v} \rightarrow \mathrm{S}) = \Delta H_s - \Delta H_v$$

where ΔH_s is the enthalpy of solution of the solute and ΔH_v denotes the solute heat of vaporization. $\Delta H(\mathrm{v} \rightarrow \mathrm{S})$ is often referred to as the solvation enthalpy, or the heat of solution of the gas. The enthalpy of polar interaction is taken as the difference in solvation enthalpies of a ketone (K) and an alkane model (M) with the same number of carbon atoms and a similar carbon skeleton:

$$[2] \quad \Delta H_p = \Delta\Delta H(\mathrm{v} \rightarrow \mathrm{S}) = \Delta H(\mathrm{v} \rightarrow \mathrm{S})(\mathrm{K}) - \Delta H(\mathrm{v} \rightarrow \mathrm{S})(\mathrm{M})$$

The model is used to cancel the ketone dispersion interactions and enthalpy of cavity formation within the solvent, thereby isolating the polar interactions,

$$[3] \quad \Delta\Delta H(\mathrm{v} \rightarrow \mathrm{S}) = \Delta\Delta H_c + \Delta\Delta H_d + \Delta H_p$$

where $\Delta\Delta H_c = \Delta H_c(\mathrm{K}) - \Delta H_c(\mathrm{M})$ ("c" denotes cavity) and $\Delta\Delta H_d = \Delta H_d(\mathrm{K}) - \Delta H_d(\mathrm{M})$ ("d" refers to dispersion). It is usually assumed that the $\Delta\Delta H_c$ and $\Delta\Delta H_d$ terms are equal to zero, or that the terms are non-zero but of opposite signs such that their sum is equal to zero, and eq. [3] simplifies to give eq. [2]. Failure of the model to cancel the cavity formation or dispersion interactions will be reflected in the ΔH_p values. In hydrogen-bond-donating (HBD) solvents, the formation of ketone–solvent hydrogen bonds may occur. Enthalpies of H-bond formation will be incorporated into the $\Delta\Delta H(\mathrm{v} \rightarrow \mathrm{S}) = \Delta H_p$ values.

Ketone–solvent polar interactions fall into two main classes: dipole–dipole and dipole – induced dipole. Using the Taft–Kamlet π^* solvatochromic parameters (2, 3) as a measure of solvent dipolarity-polarizability, one can obtain expressions in the form of eq. [4],

$$[4] \quad \Delta\Delta H(\mathrm{v} \rightarrow \mathrm{S})(\text{ketone vs. model}) = s\pi^* + y$$

where s is the π^* coefficient and y is the calculated $\Delta\Delta H(\mathrm{v} \rightarrow \mathrm{S})$ value in a solvent with $\pi^* = 0.00$ (i.e., y-intercept).

To investigate ketone–solvent interactions, $\Delta\Delta H(\mathrm{v} \rightarrow \mathrm{S})$ values for a series of ketones (acetone, 2-butanone, 2-heptanone, 4-heptanone, 2-nonanone, 5-nonanone, 2,2,4,4-tetramethyl-3-pentanone, and cyclohexanone) in 17 organic solvents of varying polarity will be reported. Dependencies of $\Delta\Delta H(\mathrm{v} \rightarrow \mathrm{S})$ on solvent dipolarity-polarizability will be evaluated via solvatochromic equations in π^* (eq. [4]). Ketone hydrogen bonding interactions with alcohol solvents will also be examined.

Experimental

Solutes and solvents were commercial samples in excess of 99% purity, which were dried over 4A molecular sieve, except for methanol and trifluoroethanol, which were dried over 3A sieve. Purities were established by gas chromatography using a Shimadzu Mini 2 gc with a glass-lined system, a 30 m × 0.25 mm id SE-30 silica capillary column, and a Hewlett-Packard 3390A integrator.

The calorimetric procedure and apparatus have previously been described (4). The vacuum jacketed calorimeter was immersed in a water bath at 25.00°C, with regulation to ±0.002°C. Liquid samples were introduced into 65–80 mL of solvent with 10-, 20-, or 50-μL syringes with immersed tips. Heats of solution were corrected (0.01–0.03 kcal/mol less endothermic) to allow for the heat capacity of the samples which were introduced at 21–23°C. The uncertainty intervals in ΔH_s (twice the standard deviation of the mean of three or more determinations) are 0.00–0.09 kcal/mol. No effect of concentration on ΔH_s was observed.

Results and discussion

Heats of vaporization, and heats of solution of acetone, 2-butanone, 2-heptanone, 4-heptanone, 2-nonanone, 5-nonanone, 2,2,4,4-tetramethyl-3-pentanone, and cyclohexanone in 17 solvents are listed in Table 1. Heats of vaporization and solution of *n*-heptane (*n*-C_7), *n*-nonane (*n*-C_9), 2,2,4,4-tetramethylpentane (Me_4C_5), and cyclohexane (*c*-C_6) are given in Table 2. Derived $\Delta\Delta H(\mathrm{v} \rightarrow \mathrm{S})$(ketone vs. alkane) values are shown in Table 3).

Methylene increments

Correlations of $\Delta H(\mathrm{v} \rightarrow \mathrm{S})$(ketone) vs. number of carbon atoms (n_c) for the series of 2-ketones are given in Table 4; correlation slopes (m) correspond to methylene increments. In all solvents, ketone solvation enthalpies increase exothermically with the addition of a methylene group, but the methylene increments are less exothermic for the more polar solvents. It is usually assumed that the dispersion interactions of a methylene (or alkyl) group do not vary significantly from solvent to solvent, so differences in $\Delta H(\mathrm{v} \rightarrow \mathrm{S})(CH_2)$ result from differences in ΔH_c. Since dipolarity-polarizability interactions between solutes and solvents increase with the π^* value of each (5), it is reasonable that solvent–solvent interactions are dependent on π^* of each solvent molecule, and that ΔH_c is primarily a function of $(\pi^*)^2$. The linear relationship of methylene group solvation enthalpies to solvent $(\pi^*)^2$ is:

$$[5] \quad \Delta H(\mathrm{v} \rightarrow \mathrm{S})(CH_2) = 0.443(\pi^*)^2 - 1.14 \text{ kcal/mol}$$

$$n = 17,\ r = 0.912,\ \text{see} = 0.06$$

where n is the number of solvents, r refers to the correlation coefficient, and see is the standard error of the estimate. However, correlation of the methylene increments of a series of *n*-alkanes (5) is considerably better:

$$[6] \quad \Delta H(\mathrm{v} \rightarrow \mathrm{S})(CH_2) = 0.399(\pi^*)^2 - 1.17 \text{ kcal/mol}$$

$$n = 20,\ r = 0.956,\ \text{see} = 0.04$$

The ketone methylene increment is more dependent on solvent $(\pi^*)^2$ because addition of a methylene group to a ketone not only increases dispersion interaction and cavity formation contributions to the solvation process (as is the case for alkanes), but also increases steric hindrance to carbonyl group dispersion interactions (1).

Methylene increments determined for the series of symmetrical ketones (acetone, 4-heptanone, 5-nonanone) are less exothermic than those of the 2-ketone series by 0.00–0.10 kcal/mol. For the symmetrical ketones:

$$[7] \quad \Delta H(\mathrm{v} \rightarrow \mathrm{S})(CH_2) = 0.521(\pi^*)^2 - 1.10 \text{ kcal/mol}$$

$$n = 17,\ r = 0.929,\ \text{see} = 0.06$$

Ketone polar interactions

$\Delta\Delta H(\mathrm{v} \rightarrow \mathrm{S})$(ketone vs. alkane) values, which provide a measure of ketone–solvent dipole–dipole or dipole – induced dipole interactions, are listed in Table 3. The values show a strong dependence on solvent dipolarity-polarizability, as illustrated by the π^* coefficient of the following correlation (ROH solvents omitted) for acetone (vs. *n*-propane) and Fig. 1.

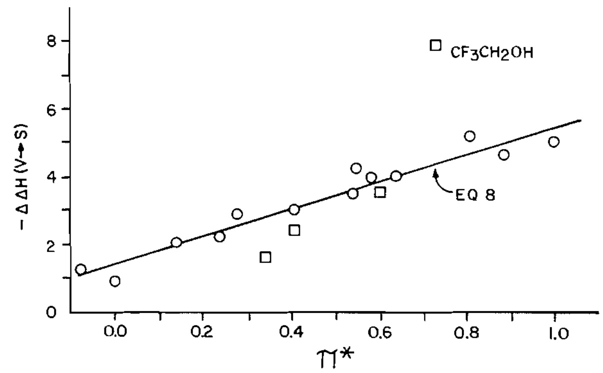

FIG. 1. $-\Delta\Delta H(\mathrm{v} \rightarrow \mathrm{S})$(acetone vs. *n*-propane) vs. solvent π^* for aprotic (○) and alcohol (□) solvents.

$$[8] \quad \Delta\Delta H(\mathrm{v} \rightarrow \mathrm{S})(\text{acetone vs. propane}) = 4.03\pi^* - 1.42 \text{ kcal/mol}$$

$$n = 13,\ r = 0.971,\ \text{see} = 0.35$$

The calculated value for cyclohexane ($\pi^* = 0.00$) is −1.42 kcal/mol (observed, −0.99 kcal/mol), and corresponds to the *y*-intercept. Because acetone (mv = 73.5 mL) is smaller than propane (mv = 88.1 mL), the $\Delta\Delta H_c$ term (eq. [3]) should be more exothermic for the more polar solvents; however, the points corresponding to DMF and DMSO are displaced endothermically from eq. [8] (Fig. 1). This suggests that the *y*-intercept does not result primarily from a solute – model cavity formation mismatch.

$\Delta\Delta H(\mathrm{v} \rightarrow c\text{-}C_6)$(acetone vs. propane) values have been attributed to carbonyl dipole – hydrocarbon solvent induced dipole interactions (6). This is consistent with the smaller $\Delta\Delta H(\mathrm{v} \rightarrow c\text{-}C_6)$(ketone vs. alkane) values of the larger ketones. The variation is fairly small and might be the result of different ketone – model cavity formation and dispersion interaction mismatches. Contrary to this explanation based on ketone–hydrocarbon induction interactions, $\Delta\Delta H(\mathrm{v} \rightarrow \mathrm{S})$ values of 5-nonanone and 2,2,4,4-tetramethyl-3-pentanone in *n*-heptane or in cyclohexane are in good agreement, but agreement is poor for polar solvents (aromatics, haloaliphatics) in which carbonyl dipole – solvent induced dipole interactions are operative. Solomonov and co-workers (7, 8) have estimated $\Delta H(\mathrm{v} \rightarrow c\text{-}C_6)$, usually to within 6% of the experimental value, for a wide variety of solutes based on the assumption that all compounds interact with alkane solvents through dispersion interactions only. It is probable that $\Delta\Delta H(\mathrm{v} \rightarrow c\text{-}C_6)$(acetone vs. propane) values result from larger dispersion interactions by a carbonyl group relative to a methylene group, consistent with the agreement between $\Delta\Delta H(\mathrm{v} \rightarrow \mathrm{S})$ for 5-nonanone and 2,2,4,4-tetramethyl-3-pentanone in the alkane solvents, and with Solomonov's findings. However, small contributions from induction forces or cavity formation mismatches cannot be ruled out.

Because acetone is a hydrogen-bond-accepting (HBA) compound, dissolution in an alcohol might be expected to be more exothermic than dissolution in a comparably polar but aprotic solvent, resulting in an exothermic displacement from eq. [8] (Fig. 1). Of the alcohol solvents used in this study, only CF_3CH_2OH is exothermically displaced; *t*-BuOH, MeOH, and

[a]In kcal/mol.
[b]$\Delta\Delta H(\mathrm{v} \rightarrow \mathrm{S})(\text{ketone vs. alkane}) = \Delta H(\mathrm{v} \rightarrow \mathrm{S})(\text{ketone}) - \Delta H(\mathrm{v} \rightarrow \mathrm{S})(\text{alkane})$.
[c]Me is methyl, Bu is butyl, Ph is phenyl.
[d]$\Delta H(\mathrm{v} \rightarrow \mathrm{S})(n\text{-}C_3)$ was estimated.
[e]$\Delta H(\mathrm{v} \rightarrow \mathrm{S})(n\text{-}C_4)$ was estimated.

1-octanol are not. This can be rationalized in terms of the relative hydrogen-bond-accepting basicities of the alcohols and acetone. The Taft–Kamlet β parameter (2, 3) will be used as a measure of HBA basicity. The CF_3CH_2OH oxygen (β = 0.00) is much less basic than the acetone carbonyl oxygen (β = 0.48), and solute–solvent H-bonds are preferred over solvent–solvent H-bonds. The other alcohols have oxygens which are better H-bond acceptors ($0.62 < \beta < 1.01$) than the carbonyl oxygen. Solvent–solvent H-bonds are not broken, and exothermic displacements are not observed. An alternative view is that solvent–solvent H-bonds are broken to form a solute cavity, but reassociate after the cavity is filled (9).

Dependencies on π^* similar to that of acetone are observed for the ketones listed in Table 3. Correlations of ketone $\Delta\Delta H$(v

$$2,2,4,4\text{-}Me_4C_5) = -2.69\pi^* - 1.00 \text{ kcal/mol}$$

$$n = 13,\ r = 0.953,\ \text{see} = 0.30$$

[15] $\Delta\Delta H(\text{v}\rightarrow\text{S})$(cyclohexanone vs. c-C_6)

$$= -3.75\pi^* - 1.60 \text{ kcal/mol}$$

$$n = 13,\ r = 0.963,\ \text{see} = 0.37$$

For all ketones, $\Delta\Delta H(\text{v}\rightarrow\text{S})$ becomes more exothermic with increasing solvent dipolarity-polarizability. Acetone (eq. [8]) shows the strongest dependence on π^*. The symmetrical ketones exhibit s values smaller than those of the corresponding 2-ketones. The carbonyl of 2,2,4,4-tetramethyl-3-pentanone is by far the most sterically hindered, eq. [14] having an s value of only −2.69. The most dipolar of the ketones, cyclohexanone (μ = 3.1 D) has a π^* dependency weaker than the 2-ketones (2.6 D < μ < 2.9 D). This is attributed to the larger π^* of the model compound cyclohexanone (π^* = 0.00) relative to the n-alkane models (π^* = −0.08). It has been found (10) in such cases that the s coefficient of π^* is dependent on the *difference* in π^* values of the polar compound vs. model. More of the polar interaction of cyclohexanone is cancelled by its model than is cancelled for 2-ketones by less polar alkane models.

For a given solvent, $\Delta\Delta H(\text{v}\rightarrow\text{S})$ will be largest for acetone or cyclohexanone (Table 3). Acetone values tend to be largest for the more polar solvents, a consequence of the large s value of eq. [8]. The larger cyclohexanone values in nonpolar or slightly polar solvents probably result from solute−model cavity formation and dispersion interaction mismatches. 2,2,4,4-Tetramethyl-3-pentanone $\Delta\Delta H(\text{v}\rightarrow\text{S})$ values represent minima in all solvents except n-heptane and 1-octanol, in which cases the values are within 0.01 kcal/mol of the minima. The relatively small values reflect the steric requirements of the large t-butyl groups, and the resulting hindrance to approach of solvent molecules to the carbonyl group.

2,2,2-Trifluoroethanol solvent − ketone solute enthalpies of hydrogen bond formation (ΔH_h), as measured by exothermic displacements of CF_3CH_2OH from the $\Delta\Delta H(\text{v}\rightarrow\text{S})$ vs. π^* correlations (Fig. 1), are:

ΔH_h(acetone) = −3.56 kcal/mol
ΔH_h(2-butanone) = −3.23 kcal/mol
ΔH_h(2-heptanone) = −2.99 kcal/mol
ΔH_h(4-heptanone) = −3.03 kcal/mol
ΔH_h(2-nonanone) = −3.02 kcal/mol
ΔH_h(5-nonanone) = −2.99 kcal/mol
ΔH_h(2,2,4,4-tetramethyl-3-pentanone)
= −2.88 kcal/mol
ΔH_h(cyclohexanone) = −3.71 kcal/mol

The values show an expected small dependence on steric factors due to the small size of the solvent hydroxyl group. 2-Heptanone, 4-heptanone, 2-nonanone, and 5-nonanone values are the same within experimental uncertainty (combined $\Delta\Delta H(\text{v}\rightarrow\text{S})$ uncertainty intervals), while the values for 2-butanone and acetone are progressively larger. ΔH_h(2,2,4,4-tetramethyl-3-pentanone) is slightly less exothermic than the isomer values. Hydrogen bonding is strongest with cyclohexanone, the ketone with the largest value of β. The $\Delta\Delta H(\text{v}\rightarrow\text{S})$ vs. π^* correlation see values range from 0.29−0.37 kcal/mol. If these large uncertainties are also considered in the overall uncertainties of the ΔH_h values, one may only conclude that acetone and cyclohexanone are stronger hydrogen-bond-acceptors than the other ketones, which have values within experimental uncertainty of each other.

Enthalpies of hydrogen bond formation of 1-octanol with aprotic organic solvents. A comparison of the solvation enthalpy, pure base, and non-hydrogen-bonding baseline methods

W. KIRK STEPHENSON AND RICHARD FUCHS[1]
Department of Chemistry, University of Houston, Houston, TX 77004, U.S.A.

Received April 30, 1984

W. KIRK STEPHENSON and RICHARD FUCHS. Can. J. Chem. **63**, 342 (1985).

Enthalpies of solution (ΔH_s) of 1-octanol and five model compounds (di-*n*-butyl ether, *n*-heptyl methyl ether, 1-fluorooctane, 1-chlorooctane, and *n*-octane) have been determined in 13 solvents (heptane, cyclohexane, CCl_4, 1,1,1-trichloroethane, 1,2-dichloroethane, triethylamine, butyl ether, ethyl acetate, DMF, DMSO, benzene, toluene, mesitylene), and combined with heats of vaporization to give enthalpies of transfer from vapor to solvent ($\Delta H(\mathrm{v} \rightarrow \mathrm{S})$). These values have been used to calculate the enthalpy of hydrogen bond formation (ΔH_h) of 1-octanol with each solvent, using the pure base (PB), solvation enthalpy (SE), and non-hydrogen-bonding baseline (NHBB) methods. Evidence is presented suggesting that (*a*) the SE method is susceptible to mismatches of the 1-octanol vs. model polar and dispersion interactions, (*b*) the PB method is sensitive to polar interaction mismatches, whereas (*c*) the NHBB method compensates for both polar and dispersion interactions mismatches. The (apparent) ΔH_h values determined by the SE and PB methods may be as much as several kcal/mol (nearly 50%) too large, because of the inclusion of other polar and dispersion interactions. The NHBB method is therefore preferred for determining enthalpies of H-bond formation from calorimetric data. However, apparent ΔH_h values from the SE and PB methods can be incorporated into total solvatochromic equations using Taft–Kamlet π^*, β, and ξ parameters, to provide enthalpies of H-bond formation in good agreement with ΔH_h (NHBB).

W. KIRK STEPHENSON et RICHARD FUCHS. Can. J. Chem. **63**, 342 (1985).

On a déterminé les enthalpies de solution (ΔH_s) de l'octanol-1 et de cinq composés modèles (éther di-*n*-butylique, méthoxy-1 heptane, fluoro-1 octane, chloro-1 octane et *n*-octane) dans treize solvants organiques (heptane, cyclohexane, CCl_4, trichloro-1,1,1 éthane, dichloro-1,2 éthane, triéthylamine, éther butylique, acétate d'éthyle, DMF, DMSO, benzène, toluène, mésitylène) et on a combiné ces valeurs avec les chaleurs de vaporisation afin d'obtenir les enthalpies de transfert de la phase vapeur au solvant ($\Delta H(\mathrm{v} \rightarrow \mathrm{S})$). On a utilisé ces valeurs pour calculer l'enthalpie de formation de la liaison hydrogène (ΔH_h) de l'octanol-1 avec chacun des solvants en utilisant les méthodes de la base pure (BP), de l'enthalpie de solvatation (ES) et de la ligne de base sans liaisons hydrogènes (LBSLH). Les données obtenues suggèrent que: (*a*) la méthode des ES peut être affectée si les interactions soit polaires ou de dispersion de l'octanol-1 sont mal assorties par rapport au composé modèle, (*b*) la méthode de la BP est sensible aux mauvais assortiments qui peuvent être dus aux interactions polaires tandis que (*c*) la méthode de la SLH permet de compenser aussi bien les mauvais assortiments dus aux interactions polaires que ceux dus aux interactions de dispersion. Les valeurs (apparentes) du ΔH_h, telles que déterminées par les méthodes des ES et de la BP, peuvent être surévaluées par plusieurs kcal/mol (presque 50%) à cause de l'inclusion d'autres interactions polaires et de dispersion. On préfère donc la méthode de la LBSLH pour déterminer les enthalpies de formation des liaisons hydrogènes à partir des donnés calorimétriques. Cependant, on peut incorporer les valeurs apparentes du ΔH_h obtenues à partir des méthodes des ES et de la BP dans les équations solvatochromiques totales en utilisant les paramètres π^*, β et ξ de Taft–Kamlet pour obtenir des enthalpies de formation de la liaison hydrogène qui sont en bon accord avec les valeurs de ΔH_h (LBSLH).

[Traduit par le journal]

Enthalpies of hydrogen bond formation of 1-octanol with several aromatic solvents have recently been determined by both the pure base and solvation enthalpy ($\Delta\Delta H(\mathrm{v} \rightarrow \mathrm{S})$) methods (1). In the pure base method (2, 3) the enthalpy of H-bond formation (ΔH_h) is taken as the difference in heats of solution of the alcohol (A) and a similarly polar but non-hydrogen-bond-donating model compound (M), in the "pure base" (H-bond acceptor) solvent (S), minus the difference of the heats of solution of A and M in an "inert" reference solvent (an alkane or CC_4):

$$[1] \quad \Delta H_h(\mathrm{PB}) = (\Delta H_s^A - \Delta H_s^M)_B - (\Delta H_s^A - \Delta H_s^M)_{\mathrm{ref}}$$

where PB refers to the use of the pure base method. The heats of vaporization of A and M need not be known.

The $\Delta\Delta H(\mathrm{v} \rightarrow \mathrm{S})$ method utilizes enthalpies of transfer from vapor to solvent($\Delta H(\mathrm{v} \rightarrow \mathrm{S})$) for each solute,

$$[2] \quad \Delta H(\mathrm{v} \rightarrow \mathrm{S}) = \Delta H_s - \Delta H_v$$

where ΔH_s is the enthalpy of solution of a liquid sample in the solvent at 25°C giving an "infinitely dilute" ($10^{-4}-10^{-2}$ *M*) solution, and ΔH_v is the solute heat of vaporization at 25°C. $\Delta H(\mathrm{v} \rightarrow \mathrm{S})$ is often referred to as the solvation enthalpy, or the heat of solution of the gas. The enthalpy of H-bond formation in a particular solvent is taken as the difference in solvation enthalpies of the alcohol (A) and model (M):

$$[3] \quad \Delta H_h(\mathrm{SE}) = \Delta\Delta H(\mathrm{v} \rightarrow \mathrm{S}) = \Delta H(\mathrm{v} \rightarrow \mathrm{S})^A - \Delta H(\mathrm{v} \rightarrow \mathrm{S})^M$$

where SE denotes the use of the $\Delta\Delta H(\mathrm{v} \rightarrow \mathrm{S})$ method (which utilizes solvation enthalpies).

From eqs. [1]–[3] it can be shown that

$$[4] \quad \Delta H_h(\mathrm{PB}) = \Delta H_h(\mathrm{SE}) - \Delta\Delta H(\mathrm{v} \rightarrow \mathrm{ref})$$

The two methods will be equivalent only when $\Delta\Delta H(\mathrm{v} \rightarrow \mathrm{ref}) = 0$. Typically, however, $\Delta\Delta H(\mathrm{v} \rightarrow \mathrm{ref})$ values range from +1.0 to −0.5 kcal/mol, and the two results differ.

Both methods utilize a model compound to cancel the non-hydrogen-bonding (dispersion and polar) interactions of the H-bond donor with the solvent, and the enthalpy of cavity formation within the solvent, thereby isolating the H-bonding interactions:

[a]Values and uncertainty intervals (2 × standard deviation of the mean) in kcal/mol.
[b]Uncertainty interval estimated.
[c]Estimated by interpolation.

$$[5] \quad \Delta H_h(\text{SE}) = \Delta\Delta H_c + \Delta\Delta H_d + \Delta\Delta H_p + \Delta\Delta H_h$$

and

$$[6] \quad \Delta H_h(\text{PB}) = (\Delta\Delta H_c + \Delta\Delta H_d + \Delta\Delta H_p + \Delta\Delta H_h) - (\Delta\Delta H_c' + \Delta\Delta H_d' + \Delta\Delta H_p')$$

where the prime refers to the reference solvent, $\Delta\Delta H_c = \Delta H_c^A - \Delta H_c^M$ ("c" denotes cavity), $\Delta\Delta H_d = \Delta H_d^A - \Delta H^M$ ("d" refers to dispersion), and $\Delta\Delta H_p = \Delta H_p^A - \Delta H_p^M$ ("p" denotes polar). Both methods assume that the $\Delta\Delta H_c$, $\Delta\Delta H_d$, and $\Delta\Delta H_p$ terms are equal to zero (or that $\Delta\Delta H_c + \Delta\Delta H_d$ are non-zero but of opposite sign such that the sum is equal to zero).

The choice of model compound is important because a failure of the model to cancel the non-hydrogen-bonding interactions will be reflected in the ΔH_h(PB) and ΔH_h(SE) values. In order to investigate the influence of the solute–model match and the validity of the usual assumptions, we will determine $\Delta\Delta H_h(\text{v} \rightarrow \text{S})$ values for 1-octanol (C_8OH) in various solvents using five different model compounds: di-n-butyl ether (Bu_2O), n-heptyl methyl ether ($MeOC_7$), 1-fluorooctane (FC_8), 1-chlorooctane (ClC_8), and n-octane (C_8). Two common reference solvents (cyclohexane (c-C_6) and carbon tetrachloride (CCl_4)) will be included in the study. We hope to gain insights into the nature of the $\Delta\Delta H(\text{v} \rightarrow \text{ref})$ term, the distinguishing feature between the pure base and solvation enthalpy methods. Finally, we will examine the use of the non-hydrogen-bonding baseline (NHBB) method (4), which uses correlations with the Taft–Kamlet solvent parameters π^*, β, and ξ, for determining the enthalpy of H-bond formation.

Experimental

n-Heptyl methyl ether was prepared by heating 1-bromoheptane with sodium methoxide in methanol solution. The other solutes and solvents were commercial samples in excess of 99% purity, which were dried over 4A molecular sieve. Heat of vaporization samples were 1-fluorooctane (99.77%) and n-heptyl methyl ether (99.9%). Purities of all solvents and solutes were established by gas chromatography using a Shimadzu Mini 2 gc with a glass lined system, a 30 m × 0.25 mm id SE-30 silica capillary column, and a Hewlett-Packard 3390A integrator.

The calorimetric procedure and apparatus have previously been described (5). The calorimeters were immersed in a water bath at 25.00°C, with regulation to ±0.002°C. Liquid samples were introduced into the calorimeters from 10-, 20-, or 50-μL syringes with immersed tips. Heats of solution were corrected (0.01–0.03 kcal/mol less endothermic) to allow for the heat capacity of the samples which were introduced at 21–23°C. The uncertainty intervals in ΔH_s (twice the standard deviation of the mean of three or more determinations) are 0.00–0.12 kcal/mol. No effect of concentration on ΔH_s was observed.

Heats of vaporization were determined by evaporating 100 μL samples at 6–7 Torr into a slow stream of nitrogen (0.5 mL/min) at 25°C, using the vaporization calorimeter and technique previously reported (1). Determinations were made on four samples. The uncertainties (2 × sdm) are 0.01–0.02 kcal/mol.

Results and discussion

Enthalpies of solution of C_8OH, Bu_2O, $MeOC_7$, FC_8, ClC_8, and C_8 in 13 solvents of varying polarity and hydrogen-bond-accepting (HBA) basicity are listed in Table 1. Solute heats of vaporization, molar volumes, and Hildebrand δ_H parameters (7) are given in Table 2. In Table 3 are listed the Taft–Kamlet π^*, β, and ξ parameters (4, 8), and Hildebrand δ_H values for each solvent (heptane, cyclohexane, CCl_4, 1,1,1-trichloroethane, 1,2-dichlorethane, triethylamine, butyl ether, ethyl acetate, dimethylformamide, dimethyl sulfoxide, benzene, toluene, mesitylene), where π^* is a measure of solvent dipolarity-polarizability, β indicates solvent HBA basicity, and ξ is the solvent coordinate covalency parameter (9). Derived $\Delta\Delta H(\text{v} \rightarrow \text{S})(C_8OH \text{ vs. model})$ values are also in Table 3.

Dependence of ΔH_h *on* C_8OH*-model polar interaction match*

A plot of $\Delta\Delta H(\text{v} \rightarrow \text{S})(C_8OH \text{ vs. } Bu_2O)$ vs. π^* (Fig. 1) illustrates relationship of ΔH_h(SE) and ΔH_h(PB) to solvent dipolarity-polarizability. The baseline for the solvation enthalpy method is the $\Delta\Delta H(\text{v} \rightarrow \text{S}) = 0.00$ kcal/mol line; the baseline for the pure base method (c-C_6 reference solvent) is the $\Delta\Delta H(\text{v} \rightarrow \text{S}) = \Delta\Delta H(\text{v} \rightarrow c\text{-}C_6) = -0.96$ kcal/mol line, as eq. [4] suggests. Both methods assume that exothermic displacements from the respective baselines are due entirely to H-bonding interactions. For example, in DMF solvent

$$[7] \quad \Delta H_h(\text{SE}) = \Delta\Delta H(\text{v} \rightarrow \text{DMF}) = -6.25 \text{ kcal/mol}$$

and

$$[8] \quad \Delta H_h(\text{PB}) = \Delta\Delta H(\text{v} \rightarrow \text{DMF}) - (-0.96) = 5.29 \text{ kcal/mol}$$

Of particular interest are the correlations of ΔH_h(SE) vs. π^* and ΔH_h(PB) vs. π^* for the non-hydrogen-bonding (NHB) solvents

$$[9] \quad \Delta H_h(\text{SE}) = -2.32\pi^* - 0.89 \text{ kcal/mol}$$

$$[10] \quad \Delta H_h(\text{PB}) = -2.32\pi^* + 0.07 \text{ kcal/mol}$$

where n (number of solvents) = 5, r (correlation coefficient) = 0.985, and see (standard error of the estimate) = 0.17 for both equations. Equations [9], [10], and Fig. 1 show that ΔH_h(SE) and ΔH_h(PB) values reflect not only H-bonding interactions, but also polar interactions, which result from the difference in solute (C_8OH) and model (Bu_2O) dipolarities. (It is noteworthy that monomeric 1-octanol solute appears to be more dipolar than associated 1-octanol solvent). The ΔH_p terms (eqs. [5], [6]) are nonzero (negative) and are incorporated into the ΔH_h(SE) and ΔH_h(PB) values. Correlations of ΔH_h(SE) and ΔH_h(PB) with π^* for the other C_8OH−model pairs are in Table 4. All show a strong dependence of ΔH_h(SE) and ΔH_h(PB) values on solvent polarity. The slope is largest when octane (C_8) is used as the model, because the alkane is completely nonpolar and does not even partially cancel C_8OH polar interactions.

We suggest that more accurate ΔH_h values can be obtained by measuring displacements from the $\Delta\Delta H(\text{v} \rightarrow \text{S})$(solute vs. model) vs. π^* line for the NHB solvents (4) (Fig. 1). This technique of evaluating H-bonding interactions will be referred to as the non-hydrogen-bonding baseline (NHBB) method and the resulting values denoted ΔH_h(NHBB). Use of this non-hydrogen-bonding baseline reduces or eliminates the contribution of the $\Delta\Delta H_p$ term to the ΔH_h(NHBB) value. It should be noted that the NHBB method is conceptually and formally similar to the "stepwise solvatochromic comparison method" for determining H-bonding contributions to uv/visible spectral shifts (10). For 1-octanol (Bu_2O model) in DMF solvent, ΔH_h(NHBB) is −3.32 kcal/mol. This value is much less exothermic than the corresponding ΔH_h(SE) and ΔH_h(PB) values (eqs. [7], [8]) which incorporate significant $\Delta\Delta H_p$ terms.

Dependence of ΔH_h *on* C_8OH*−model dispersion interaction match*

As previously stated (eq. [4]), the pure base and solvation

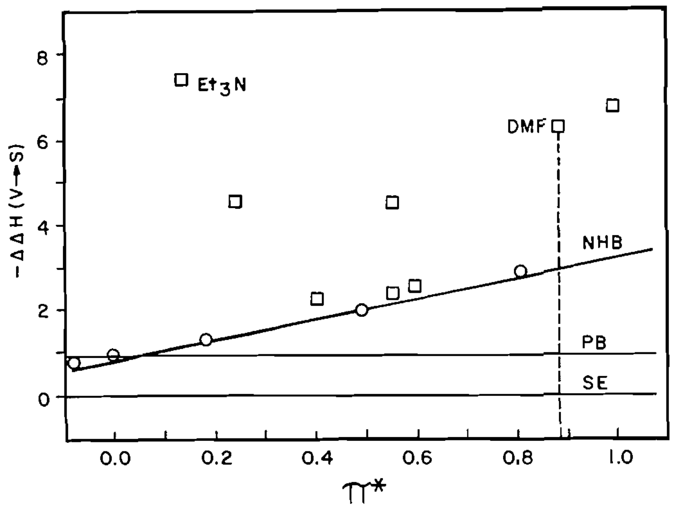

FIG. 1. $-\Delta\Delta H(\text{v} \rightarrow \text{S})$(1-octanol vs. n-Bu_2O) vs. solvent π^* for non-hydrogen-bonding (○) hydrogen-bond-accepting (□) solvents. Baselines for the non-hydrogen-bonding baseline, pure base, and solvation enthalpy methods are denoted NHB, PB, and SE, respectively.

enthalpy methods differ by an amount $\Delta\Delta H(\text{v} \rightarrow \text{ref})$. This $\Delta\Delta H(\text{v} \rightarrow \text{ref})$ term is reflected in the y-intercept values of the ΔH_h(SE) vs. π^* correlations for the NHB solvents in Table 4. The y-intercepts of the ΔH_h(PB) vs. π^* (NHB solvents) correlations are within a standard error of the estimate (see) of the origin. Determination of the factors which give rise to the y-intercept and $\Delta\Delta H(\text{v} \rightarrow \text{ref})$ values is crucial for an evaluation of the two methods.

Because the y-intercept corresponds to a hypothetical nonpolar ($\pi^* = 0$) solvent, it is logical that the y-intercept and $\Delta\Delta H(\text{v} \rightarrow \text{ref})$ are due to a C_8OH−model dispersion interaction or cavity formation mismatch rather than a polar interaction mismatch. To investigate this possibility enthalpies of dispersion interactions and of cavity formation of C_8OH in c-C_6 and CCl_4 have been estimated using the regular solution theory equations of Hildebrand and Scatchard (11, 12),

$$[11] \quad \Delta H_d = 2(\text{mv}_A)\delta_A\delta_S$$

and

$$[12] \quad \Delta H_c = (\text{mv}_A)\delta_S^2$$

where mv_A is the solute molar volume; δ_A, the solute solubility parameter (7) (Table 2); and δ_S, the solvent solubility parameter (Table 3). Calculated $\Delta\Delta H_d$(C_8OH vs. model) and $\Delta\Delta H_c$(C_8OH vs. model) values in c-C_6 and CCl_4 are given in Table 5.

The correlation of $\Delta\Delta H_d$(c-C_6 solvent) values with the y-intercepts of the NHB baselines for the ΔH_h(SE) vs. π^* correlations (Table 4) is

$$[13] \quad \Delta\Delta H_d(c\text{-}C_6 \text{ solvent}) = 1.328(y\text{-int}) - 0.24 \text{ kcal/mol}$$

where n = 5, r = 0.996, and see = 0.12. This excellent correlation suggests that the displacements of the y-intercepts from the origin are due primarily, if not totally, to a C_8OH−model dispersion interaction mismatch, rather than to H-bonding. Correlation of $\Delta\Delta H_d$ with $\Delta\Delta H(\text{v} \rightarrow c\text{-}C_6)$ gives

$$[14] \quad \Delta\Delta H_d(c\text{-}C_6 \text{ solvent}) = 1.350\Delta\Delta H(\text{v} \rightarrow c\text{-}C_6) - 0.09\text{kcal/mol}$$

TABLE 4. Correlations of $\Delta H_h(SE)$ and $\Delta H_h(PB)$ with π^* for NHB solvents

C_8OH model	ΔH_h vs. π^* correlation	n	r	see (kcal/mol)
Bu_2O	$\Delta H_h(SE) = -2.32\pi^* - 0.89$ kcal/mol	5	0.984	0.17
$MeOC_7$	$\Delta H_h(SE) = -1.81\pi^* - 0.48$	5	0.967	0.20
FC_8	$\Delta H_h(SE) = -1.89\pi^* - 0.13$	5	0.981	0.16
ClC_8	$\Delta H_h(SE) = -1.92\pi^* + 0.61$	5	0.998	0.05
C_8	$\Delta H_h(SE) = -4.13\pi^* - 1.73$	5	0.996	0.16
Bu_2O	$\Delta H_h(PB) = -2.32\pi^* + 0.07$	5	0.984	0.17
$MeOC_7$	$\Delta H_h(PB) = -1.81\pi^* + 0.17$	5	0.967	0.20
FC_8	$\Delta H_h(PB) = -1.89\pi^* + 0.15$	5	0.981	0.16
ClC_8	$\Delta H_h(PB) = -1.92\pi^* + 0.17$	5	0.998	0.05
C_8	$\Delta H_h(PB) = -4.13\pi^* + 0.06$	5	0.996	0.16

where $n = 5$, $r = 0.999$, and see $= 0.07$. Equation [14] supports the idea that the $\Delta\Delta H(v \rightarrow c\text{-}C_6)$ terms, the distinguishing feature between the pure base (c-C_6 reference solvent) and solvation enthalpy methods, can also be attributed to a C_8OH–model dispersion interaction mismatch. The $\Delta\Delta H_d$ term contained in the $\Delta H_h(SE)(C_8OH$ vs. model) values is eliminated or reduced in the pure base and NHBB baseline methods.

Comparison of eqs. [5] and [6] indicates that the $\Delta H_h(SE)$ value is composed of only one dispersion term, $\Delta\Delta H_d$, while the $\Delta H_h(PB)$ value is composed of two, $\Delta\Delta H_d$ and $-\Delta\Delta H_d'$ (prime refers to reference solvent). The solute–model dispersion interaction mismatch ($\Delta\Delta H_d$) in a given solvent is cancelled in the pure base method by the analogous term for the reference solvent ($-\Delta\Delta H_d'$). All $\Delta H_h(PB)$ vs. π^* (NHB solvents) correlations have y-intercepts within a standard error of the estimate of the origins. This requires that the solute–model dispersion interaction differences vary little with changing solvent.

The only $\Delta H_h(SE)(C_8OH$ vs. model) vs. π^* (NHB solvents) correlation having a y-intercept within a standard error of the estimate of the origin utilizes FC_8 as the model, suggesting that FC_8 is the best model for C_8OH with respect to dispersion interactions.

The correlation of calculated $\Delta\Delta H_d(CCl_4$ solvent) values with the y-intercepts ($\Delta H_h(SE)$ vs. π^* (NHB solvents)) is

$$[15]\quad \Delta\Delta H_d(CCl_4\ \text{solvent}) = 1.389\ (y\text{-int}) - 0.26\ \text{kcal/mol}$$

where $n = 5$, $r = 0.996$, see $= 0.12$. The correlation with $\Delta\Delta H(v \rightarrow CCl_4)$ is

$$[16]\quad \Delta\Delta H_d(CCl_4\ \text{solvent}) = 1.056\Delta\Delta H(v \rightarrow CCl_4) + 0.14\ \text{kcal/mol}$$

with $n = 5$, $r = 0.965$, and see $= 0.37$. This correlation coefficient is appreciably poorer, and the see value is at least three times larger than those of eq. [13] ($r = 0.996$), [14] ($r = 0.999$), and [15] ($r = 0.996$). This probably results from the difference in polar interaction of C_8OH and model ($\Delta\Delta H_p$) with CCl_4 ($\pi^* = 0.28$). For CCl_4 reference solvent, the C_8OH–model polar interaction mismatch will give rise to a $-\Delta\Delta H_p$ term (eq. [6]), which will cancel part of the $\Delta\Delta H_p$ term observed in solvents more polar than CCl_4 and will overcompensate for the $\Delta\Delta H_p$ term observed in solvents less polar than CCl_4.

Correlations of y-intercept ($\Delta H_h(SE)$ vs. π^* (NHB solvents))

TABLE 5. Calculated $\Delta\Delta H_d$ and $\Delta\Delta H_c$ values for 1-octanol vs. model in cyclohexane and carbon tetrachloride solvents[a]

C_8OH model	c-C_6 solvent		CCl_4 solvent	
	$\Delta\Delta H_d$[b]	$\Delta\Delta H_c$[c]	$\Delta\Delta H_d$[b]	$\Delta\Delta H_c$[c]
Bu_2O	−1.29	−0.81	−1.35	−0.88
$MeOC_7$	−1.00	−0.54	−1.04	−0.59
FC_8	−0.49	−0.39	−0.52	−0.42
ClC_8	+0.63	−0.86	+0.66	−0.94
C_8	−2.55	−0.35	−2.67	−0.37

[a]In kcal/mol.
[b]$\Delta\Delta H_d = \Delta H_d(C_8OH) - \Delta H_d$(model).
[c]$\Delta\Delta H_c = \Delta H_c(C_8OH) - \Delta H_c$(model); based on extrapolated values of $\delta_c(C_8OH)$ (Table 2).

or $\Delta\Delta H$(v → ref) values with calculated $\Delta\Delta H_c$ values are very poor ($r < 0.58$ for all equations), so mismatches in the cavity term ($\Delta\Delta H_c$) do not appear to be a problem in any of the methods.

These conclusions are based on $\Delta\Delta H_d$ and $\Delta\Delta H_c$ values calculated from simple regular solution theory equations. These values should be regarded as rough estimates when polar species are involved.

ΔH_h vs. β and ξ correlations

The relationship of calculated ΔH_h values to solvent H-bond basicity for the C_8OH-Bu_2O system are given in eqs. [17]–[19]

[17] $\Delta H_h(SE) = -6.668\beta - 1.052\xi - 1.58$

$n = 13, r = 0.973$, see $= 0.56$

[18] $\Delta H_h(PB) = -6.668\beta - 1.052\xi - 0.62$

$n = 13, r = 0.973$, see $= 0.56$

[19] $\Delta H_h(NHBB) = -4.929\beta - 2.842\xi + 0.06$

$n = 13, r = 0.996$, see $= 0.20$

where β is a measure of solvent HBA basicity, and ξ is the solvent coordinate covalency parameter, which allows for the "family dependent" nature of enthalpies of H-bond formation (9).

The correlation coefficient and standard error of the estimate for the NHBB method are substantially more favorable than the corresponding values for the solvation enthalpy and pure base methods. The y-intercepts of eqs. [17] and [18] are exothermically displaced from the origins by significant amounts while the intercept of eq. [19] is within a standard error of the estimate of the origin. This leads us to conclude that the NHBB method is superior to the solvation enthalpy and pure base methods for evaluating enthalpies of H-bond formation of 1-octanol, and probably of other H-bond donor solutes as well.

Total solvatochromic equations

Single expressions for the dependence of ΔH_h on π^*, β, and ξ may be determined through multiple parameter least squares correlations (4). The total solvatochromic equations for the C_8OH-Bu_2O solute–model pair are given by eqs. [20]–[22].

[20] $\Delta H_h(SE)$

$= -2.03\pi^* - 5.14\beta - 2.62\xi - 0.92$ kcal/mol

$n = 13, r = 0.997$, see $= 0.19$

TABLE 6. $b\beta + e\xi$ values for C_8OH–model pairs in DMF and Et_3N solvents[a]

Solvent	Model	$b\beta + e\xi$	$\Delta(b\beta + e\xi)$[b]	Overall see[c]
DMF	Bu_2O	−3.55		
	$MeOC_7$	−3.67	0.12	0.28
	FC_8	−3.33	−0.22	0.36
	ClC_8	−3.45	−0.10	0.34
	C_8	−2.93	−0.62	0.38
Et_3N	Bu_2O	−6.27		
	$MeOC_7$	−6.33	0.06	0.28
	FC_8	−6.13	−0.14	0.36
	ClC_8	−6.12	−0.15	0.34
	C_8	−6.15	−0.12	0.38

[a]In kcal/mol.
[b]$\Delta(b\beta + e\xi) = b\beta + e\xi$ (from eq. [22]) $- b\beta + e\xi$ (from eqs. [23], [24], [25], or [26]).
[c]Overall standard error of the estimate of the parent equations.

[21] $\Delta H_h(PB)$

$= -2.03\pi^* - 5.14\beta - 2.62\xi + 0.04$ kcal/mol

$n = 13, r = 0.997$, see $= 0.19$

[22] $\Delta H_h(NHBB)$

$= 0.28\pi^* - 5.14\beta - 2.62\xi - 0.03$ kcal/mol

$n = 13, r = 0.997$, see $= 0.19$

The y-intercepts, which result from the C_8OH-Bu_2O dispersion interaction mismatch ($\Delta\Delta H_d$), are small for eq. [21] and eq. [22] and relatively large for eq. [20]. The large π^* coefficients (s) of eqs. [20] and [21] result from incorporation of the polar interaction mismatch ($\Delta\Delta H_p$) into the ΔH_h(SE) and ΔH_h(PB) values, whereas the small s value of eq. [22] shows that the contribution of the $\Delta\Delta H_p$ term to the ΔH_h(NHBB) values is virtually nil. The β coefficients (b) of eqs. [20]–[22] are identical, as are the ξ coefficients (e). The b (and e) values of eqs. [20]–[22] are in good agreement with the b (and e) value of eq. [19] and in poor agreement with those of eqs. [17] and [18].

Analogous total solvatochromic equations for the other C_8OH–model pairs follow a similar trend. For a given solute–model pair (a) the y-intercepts of the ΔH_h(SE) equations are usually significantly displaced from the origin, while the y-intercepts of the ΔH_h(PB) and ΔH_h(NHBB) equations are not, (b) the π^* coefficients of the ΔH_h(SE) and ΔH_h(PB) equations are identical and much larger than that of the ΔH_h(NHBB) equation, and (c) the β and ξ coefficients are the same, or nearly so, for the ΔH_h(SE), ΔH_h(PB), ΔH_h(NHBB) equations.

Because the $s\pi^*$ and y-intercept terms reflect C_8OH–model polar and dispersion interaction mismatches, it is reasonable that the "true" enthalpy of H-bond formation is more accurately represented by the $b\beta + e\xi$ portion of the total solvatochromic equation, rather than by the entire equation.

Based on eqs. [20]–[22], the $b\beta + e\xi$ values for C_8OH (Bu_2O model) in DMF (β = 0.69, ξ = 0.00) are identical (−3.55 kcal/mol). Previously determined values for the solute–model pair in DMF are $\Delta H_h(SE) = -6.25$, $\Delta H_h(PB) = -5.29$, and $\Delta H_h(NHBB) = -3.32$ kcal/mol. The difference between the ΔH_h(SE) or ΔH_h(PB) and $b\beta + e\xi$ values are 2.70 and 1.74 kcal/mol, respectively, whereas the difference be-

TABLE 7. Average ΔH_h(SE), ΔH_h(PB), and ΔH_h(NHB) values for the five C_8OH–model pairs in organic solvents[a]

[a]Averages and uncertainty intervals in kcal/mol.

tween the ΔH_h(NHBB) and $b\beta + e\xi$ values (0.23 kcal/mol) is only slightly larger than the standard error of the estimate of eq. [22]. The analogous values in n-C_7 solvent (β = 0.00, ξ = 0.00) are $b\beta + e\xi$ = 0.00, ΔH_h(SE) = −0.76, ΔH_h(PB) = 0.20, and ΔH_h(NHBB) = −0.05 kcal/mol.

The other C_8OH–model pairs give rise to similar results. The agreement between $b\beta + e\xi$ and ΔH_h(SE) values is poor, except for the case of a relatively nonpolar solvent (π^* = small) *and* an unusually good solute–model dispersion interaction match (y-intercept = small). The agreement between $b\beta + e\xi$ and ΔH_h(PB) is poor for highly polar solvents (π^* = large) but improves with decreasing solvent polarity. The agreement between $b\beta + e\xi$ and ΔH_h(NHBB) values is good in all cases.

This demonstrates that C_8OH–solvent H-bonding interactions (i.e., $b\beta + e\xi$ values) can be extracted from the total solvatochromic equations of ΔH_h values calculated with the SE, PB, or NHBB methods, and that the difference between the ΔH_h(NHBB) and $b\beta + e\xi$ values will be small.

The β and ξ coefficients vary with changing model. ΔH_h(NHBB) total solvatochromic equations for the five C_8OH–model pairs are given by eqs. [22]–[26].

[23] ΔH_h(NHBB)(C_8OH vs. $MeOC_7$)

$$= 0.18\pi^* - 5.32\beta - 2.55\xi + 0.03 \text{ kcal/mol}$$

$$n = 13,\ r = 0.997,\ \text{see} = 0.20$$

[24] ΔH_h(NHBB)(C_8OH vs. FC_8)

$$= 0.31\pi^* - 4.82\beta - 2.71\xi + 0.08 \text{ kcal/mol}$$

$$n = 13,\ r = 0.991,\ \text{see} = 0.30$$

[25] ΔH_h(NHBB)(C_8OH vs. ClC_8)

$$= 0.19\pi^* - 5.00\beta - 2.57\xi + 0.12 \text{ kcal/mol}$$

$$n = 13,\ r = 0.993,\ \text{see} = 0.28$$

[26] ΔH_h(NHBB)(C_8OH vs. C_8)

$$= 0.36\pi^* - 4.24\beta - 3.14\xi + 0.04 \text{ kcal/mol}$$

$$n = 13,\ r = 0.989,\ \text{see} = 0.33$$

Comparison of eqs. [22]–[26] reveals that an increase (or decrease) in the β coefficient due to a model change is usually accompanied by a decrease (or increase) in the ξ coefficient. Differences between the $b\beta + e\xi$ value of the C_8OH–Bu_2O pair (eq. [22]) and those of the other pairs (eqs. [23]–[26]) for DMF solvent are shown in Table 6, as are the analogous values for Et_3N (β = 0.71, ξ = 1.00) solvent. The $b\beta + e\xi$ differences are usually within the combined uncertainties.

Average ΔH$_h$ *values*

Average ΔH_h(SE), ΔH_h(PB), and ΔH_h(NHBB) values for the five C_8OH–model pairs in 13 solvents are listed in Table 7. The uncertainty intervals of the average ΔH_h(SE) values for the NHB solvents range from 0.76 to 1.46 kcal/mol, while the uncertainty interval range for the corresponding ΔH_h(PB) averages is 0.00 to 0.77 kcal/mol. This supports the idea that the SE and PB methods are sensitive to the C_8OH–model match. The uncertainty intervals of the ΔH_h(NHBB) averages for the NHB solvents range from 0.04 to 0.12 kcal/mol. The same trend is observed for the HBA solvents; the uncertainty intervals of the ΔH_h(SE) averages are larger than those of the ΔH_h(PB) averages, which are in turn larger than the uncertainty intervals of the ΔH_h(NHBB) averages.

Summary

The solvation enthalpy method is very susceptible to C_8OH–model polar and dispersion interaction mismatches. The pure base method allows for a solute–model dispersion interaction mismatch but not for a polar interaction mismatch. The NHBB method compensates for both polar and dispersion interaction mismatches and is therefore the preferred method for determining enthalpies of hydrogen bond formation of 1-octanol. The NHBB method is the only method showing (within experimental uncertainty) no C_8OH polar or H-bonding interactions with nonpolar (π^* = 0.00) and NHB (β = 0.00) solvents. Also, $b\beta + e\xi$ values, which measure C_8OH–solvent H-bonding interactions and are in good agreement with ΔH_h(NHBB) values, can be extracted from the total solvatochromic equations of ΔH_h values calculated with the SE, PB, or NHBB methods.

Enthalpies of transfer of alkane solutes from the vapor state to organic solvents

RICHARD FUCHS AND W. KIRK STEPHENSON
Department of Chemistry, University of Houston, Houston, TX 77004, U.S.A.

Received June 18, 1984

RICHARD FUCHS and W. KIRK STEPHENSON. Can. J. Chem. **63**, 349 (1985).

Heats of solution of 5–8 C_5–C_{16} alkane liquids have been determined in each of 19 organic solvents covering the Taft–Kamlert π^* (dipolarity-polarizability) range −0.08 to 1.00. Enthalpies of alkane transfer from vapor to solvents have been calculated ($\Delta H(\text{v} \rightarrow \text{S}) = \Delta H_s - \Delta H_v$). The methylene increments in $\Delta H(\text{v} \rightarrow \text{S})$ in the 19 solvents and water (−1.18 to −0.67 kcal/mol) are not well correlated with the Hildebrand solubility parameter δ, but an empirical correlation exists with solvent π^* and polarizability:

$$\Delta H(\text{v} \rightarrow \text{S})(\text{CH}_2) = -0.879 + 0.385(\pi^*)^2 - 1.431((n^2 - 1)/(2n^2 + 1))$$

($n = 20$, $r = 0.977$, see = 0.032). By this criterion the small methylene increment in water appears to be associated with the high dipolarity and low polarizability of water.

RICHARD FUCHS et W. KIRK STEPHENSON. Can. J. Chem. **63**, 349 (1985).

On a déterminé les chaleurs de solution de 5–8 alcanes liquides en C_5–C_{16} dans 19 solvants organiques couvrant des valeurs de polarité/polarisabilité (π^* de Taft–Kamlet) allant de −0,08 à 1,00. On a calculé les enthalpies de transfert ($\Delta H(\text{v} \rightarrow \text{S}) = \Delta H_s - \Delta H_v$). Il n'y a pas de bonne corrélation entre, d'une part, les valeurs des incréments par méthylène pour le $\Delta H(\text{v} \rightarrow \text{S})$ dans les 19 solvants et l'eau (−1,18 à −0,67 kcal/mol) et, d'autre part, le paramètre de solubilité, δ, de Hildebrand; toutefois, il existe une corrélation empirique entre la valeur π^* du solvant et la polarisabilité:

$$\Delta H(\text{v} \rightarrow \text{S})(\text{CH}_2) = -0{,}879 + 0{,}385(\pi^*)^2 - 1{,}431((n^2 - 1)/(2n^2 + 1))$$

(où $n = 20$, $r = 0{,}977$, erreur st. = 0,032). En se basant sur ce critère, il semble que le faible incrément par méthylène dans l'eau soit associé à la polarité élevée et à la faible polarisabilité de l'eau.

[Traduit par le journal]

The free energy of transfer ($\Delta G(\text{v} \rightarrow \text{S})$) of nonpolar solutes from the gas to liquid water is highly unfavorable (endogenic), and this is particularly true of alkane solutes (1). However, for the rare gases, several inorganic gases (H_2, N_2, CO, O_2), and C_1–C_5 alkanes, the enthalpy contribution ($\Delta H(\text{v} \rightarrow \text{S})$) is actually more favorable for transfers to water than for transfers to organic solvents (1). Entropies of transfer ($T\Delta S(\text{v} \rightarrow \text{S})$) of these species to water are particularly unfavorable (negative), leading to the observed endogenic values of $\Delta G(\text{v} \rightarrow \text{S})$, and low solute solubility. Alkane $\Delta G(\text{v} \rightarrow \text{w})$ values reach a minimum at ethane, and become increasingly endogenic with alkane molecular weight (1) (C_2–C_7 methylene increment, 0.16 kcal/mol). The corresponding methylene increment in $\Delta H(\text{v} \rightarrow \text{w})$ is −0.67 kcal/mol, which Abraham (1) regarded as the net result of a "normal" solvent effect (−0.97 kcal/mol), and an unfavorable hydrophobic effect. He concluded that the hydrophobic contribution to the free energy, 0.54 kcal/mol, is more an enthalpic effect (0.30–0.44 kcal/mol) than an entropic effect (0.10–0.24 kcal/mol). The rare gases and inorganic gases were regarded as "normal" solutes in water, and this behavior was used (1, 2) to predict the "normal" solvent effect of alkanes in water. Differences between the "normal" and experimental values of $\Delta H(\text{v} \rightarrow \text{w})$ were attributed to a special (hydrophobic) effect. Calculations of solvent–solute interaction terms and scaled particle theory solvent cavity formation terms (3) also suggested that the enthalpy of methylene–water interaction is less exothermic than expected.

In examining the available enthalpy data on gas to solvent transfers (1) one notes that the C_2–C_5 alkane methylene increments in a given solvent are often quite inconsistent, and in substantial disagreement with increments derived from the higher alkanes. Our previous experience with C_5–C_{16} liquid hydrocarbons (4–6) suggests that increments in this range can be obtained quite precisely, from measured heats of solution of the liquids, and heats of vaporization ($\Delta H(\text{v} \rightarrow \text{S}) = \Delta H_s - \Delta H_v$). We have observed appreciable differences in the methylene increments among the several solvents we have examined previously, with some tendency toward less exothermic increments for the more "polar" solvents.

In the present study we will report the enthalpies of solution of liquid alkanes in polar and nonpolar aprotic and hydroxylic solvents. The objectives are to determine the methylene increments in a variety of solvents, to look for a relationship between the methylene increment and solvent properties, and to observe whether the methylene increment in water appears anomalous according to this relationship.

Experimental

Solutes and solvents were commercial materials in excess of 99% purity, which were dried with 4A molecular sieve, except for methanol and trifluoroethanol for which 3A sieve was used. Purities were established by gas chromatography using a Shimadzu Mini 2 gc with a glass lined system, a 30 m × 0.25 mm id SE-30 silica capillary column, and a Hewlett-Packard 3390A integrator.

The calorimetric procedure and apparatus have been described previously (7). The vacuum jacketed calorimeter was immersed in a 25.0°C water bath regulated to 0.002°C. Liquid samples were introduced with 10-, 20-, or 50-μL syringes at 21–23°C, and corrections were made (0.01–0.03 kcal/mol) for the sample heat capacity. The uncertainty interval in ΔH_s (twice the standard deviation of the mean) are 0.01–0.24 kcal/mol, with most falling in the range of 0.02–0.10 kcal/mol. Published heats of vaporization (4) were used to calculate $\Delta H(\text{v} \rightarrow \text{S})$.

Results and discussion

Enthalpies of solution of the C_5–C_{16} alkane liquids in 19 solvents are reported in Table 1, together with alkane heats of vaporization. These have been used to calculate the enthalpies of transfer from vapor to solvents in Table 2. The methylene

increment in $\Delta H(\mathrm{v} \rightarrow \mathrm{S})$, the Taft–Kamlet π^* value (8), and the polarizability function $(n^2 - 1)/(2n^2 + 1)$ are listed for each solvent in Table 3.

Abraham, Kamlet, and Taft (9) have correlated $\Delta G(\mathrm{v} \rightarrow \mathrm{S})$ of nonpolar solutes with δ_H, the Hildebrand solubility parameters (10) of solvents ($\delta_H = ((\Delta H_v - RT)/\text{molar volume})^{1/2}$), and $\Delta G(\mathrm{v} \rightarrow \mathrm{S})$ of polar solutes with combinations of δ_H and the dipolarity–polarizability parameter π^* ($\Delta G(\mathrm{v} \rightarrow \mathrm{S}) = g + h\delta_H\ (+\ s\pi^*)$). The rationale is that π^* describes the solvent–solute dipole–dipole interactions, whereas δ_H is an indication of solvent–solvent interactions and of the energy of cavity formation within the solvent. It was noted that the coefficient h increases with cavity size (solute molar volume), and s tends to become more negative with solute dipolarity (9, 11). This study involved only "select" solvents, which are aliphatic, non-hydrogen-bonded, non-halogenated compounds containing no more than one dipolar functional group, for which π^* is dependent on the dipole moment.

For alcohols δ_H does not properly predict the free energy or enthalpy of cavity formation, presumably because ΔH_v and δ_H reflect the loss of all hydrogen bonding, whereas cavity formation in alcohol solvents does not (12, 13). Correlational

[a]Based on correlations of carbon number vs. $\Delta H(v \rightarrow S)$ for alkanes. The standard error of the estimate and correlation coefficient are also indicated.
[b]Data from ref. 1. Values in addition to those in Table 2 used in determining the CH_2 increment are ethane, −4.72; propane, −5.38; and butane, −6.21 kcal/mol.
[c]π^* estimated by extrapolation of methanol to 1-butanol values in ref. 8.

values of solubility parameters (δ_C) have been proposed (13) for alcohols, which remove the H-bonding contribution to δ_H.

We have previously observed numerous correlations of $\Delta H(v \rightarrow S)$ of polar solutes with solvent π^*, *provided* that the enthalpy term considered is $\Delta H(v \rightarrow S)$ (polar solute) − $\Delta H(v \rightarrow S)$ (nonpolar model) (11). This largely avoids the need to account for cavity formation enthalpies in the various solvents, and the nonpolar solute−solvent forces, both of which are presumed similar for the polar solute and nonpolar model. In considering the methylene increment in $\Delta H(v \rightarrow S)$ for alkanes the situation is quite different. It has recently been stated (14, 15) that alkanes show no appreciable free energy or enthalpy of *polar* interactions with dipolar molecules. Unless a solute methylene group alters solvent structure in an enthalpically significant way, the methylene increment should depend only on ΔH_{cav} (endothermic) and ΔH_{disp} (exothermic). One might expect that ΔH_{cav} should be related to δ_H, and that ΔH_{disp} should depend on a solvent polarizability function such as $(n^2 - 1)/(2n^2 + 1)$. However, we have found only a fair correlation

$$[1] \quad \Delta H(v \rightarrow S)(CH_2) = -1.335 - 2.108((n^2 - 1)/(2n^2 + 1)) + 0.079\delta_H$$

$$n = 15,\ r = 0.934,\ \text{see} = 0.045\ \text{kcal/mol}$$

and this only by omitting alcohols and water from consideration. The hydroxylic solvents are poorly correlated whether δ_H or δ_C is used. The correlation is still poorer if the polarizability term is omitted. On the other hand, we have found an empirical correlation of the methylene increment with solvent π^*

$$[2] \quad \Delta H(v \rightarrow S)(CH_2) = -0.879 + 0.385(\pi^*)^2 - 1.431((n^2 - 1)/(2n^2 + 1))$$

$$n = 20,\ r = 0.977,\ \text{see} = 0.032\ \text{kcal/mol}$$

which includes all 19 organic solvents and water. This seems surprising for a process which presumably does not involve polar solute−solvent interactions. However, the $(\pi^*)^2$ term makes an *endothermic* contribution to the methylene increment. This suggests that the dipolarity and polarizability of a solvent, which cause it to have polar interactions with a polar solute, also tend to lead to enhanced solvent−solvent interactions and greater ΔH_{cav}. For nonpolar media including the gaseous state, perfluoroalkanes, *n*-alkanes, cycloalkanes, aromatic hydrocarbons, and CCl_4 δ_H depends on polarizability

$$[3] \quad \delta_H = 0.01 + 39.48((n^2 - 1)/(2n^2 + 1))$$

$$n = 12,\ r = 0.999,\ \text{see} = 0.14$$

π^* of nonpolar solvents also tends to increase with polarizability. Substantial dipolarity of a solvent leads to dipole−dipole association of the solvent, but does not contribute to methylene group solvation.

We acknowledge that eq. [2] predicts a methylene increment in perfluorodimethylcyclohexane (−1.05 kcal/mol) 0.20 kcal/mol larger than the observed (5). Also, the value of π^* at which the increment becomes zero is −1.50, whereas a mean value of −1.06 ± 0.10 has been reported for the gaseous state (16). The application of eq. [2] is therefore limited to solvents of $\pi^* > \sim 0$. However, such anomalies are far more severe using eq. [1].

It is of interest that eq. [2] predicts a methylene increment in water of −0.66 kcal/mol, compared with the experimental value −0.67 ± 0.15 kcal/mol, from which it appears that water does not have an anomalous increment. Equation [2] suggests that the difference in methylene increments of water and DMSO is due equally to the higher π^* and lower polarizability of water.

We are unable at this time to answer the question of why the methylene increment is not better correlated with the solubility parameter, or to derive a satisfactory theoretical basis for eq. [2]. In view of this we cannot claim that the equation unequivocally refutes Abraham's discussion of the methylene group hydrophobic effect (1).

Received May 10, 1984

MICHEL DROUIN and JOHN F. HARROD. Can. J. Chem. **63**, 353 (1985).

A family of complexes $IrH(CO)(Ph_3P)_2(ol)$, where ol is a monosubstituted ethylene, has been synthesized. Under an inert atmosphere the acrylonitrile complex undergoes clean decomposition to produce C_2H_5CN, half of the necessary hydrogen for the ligand reduction apparently being furnished by the phosphine ligand. The first step in the hydrogenation is insertion of the unsaturated ligand into the Ir—H bond. The alkyl product is unstable but may be trapped by O_2, to give the alkyl dioxygen complex, or by excess acrylonitrile to give the α-cyanoethyl acrylonitrile complex. Other ligands, such as CO and phosphines, displace the olefinic ligand more rapidly than insertion occurs. When ol = sytrene, the complex is very unstable with respect to styrene dissociation and very little insertion is observed. Under O_2, the styrene complex gives the first known hydridodioxygen complex $IrH(CO)(PPh_3)_2(O_2)$. The methyl acrylate complex exhibits behavior intermediate between that of the styrene and acrylonitrile analogues.

MICHEL DROUIN et JOHN F. HARROD. Can. J. Chem. **63**, 353 (1985).

On a synthétisé une famille de complexes $IrH(CO)(Ph_3P)_2(ol)$, où ol est un éthylène monosubstitué. Sous atmosphère inerte, le complexe d'acrylonitrile se décompose de façon nette pour produire du C_2H_5CN alors que la moietié de l'hydrogène nécessaire pour la réduction du ligand semble être fournie par le ligand phosphine. La première étape de l'hydrogénation consiste en une insertion du ligand insaturé dans la liaison Ir—H. Le produit alkylé est instable, mais il peut être piégé soit par O_2, pour donner le complexe d'alkyle dioxygéné, soit par de l'acrylonitrile en excès, pour donner le complexe α-cyanoéthyle acrylonitrile. Avec d'autres ligands, tels le CO et les phosphines, le déplacement du ligand oléfinique se produit plus rapidement que l'insertion. Lorsque ol = styrène, le complexe est très instable par rapport à la dissociation du styrène et on observe très peu d'insertion. Sous une atmosphère de O_2, le complexe de styrène conduit au premier complexe hydridodioxygène connu, soit le $IrH(CO)(PPh_3)_2(O_2)$. Le complexe, avec l'acrylate de méthyle, présente un comportement qui est intermédiaire entre celui du styrène et des analogues de l'acrylonitrile.

[Traduit par le journal]

Introduction

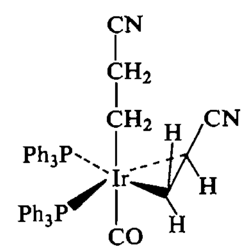
The insertion of an olefinic ligand into a metal–hydride bond is a key step in a large number of important catalytic reactions (see, for example, ref. 1). Despite a long history of experimental (2) and theoretical (3) investigations, and the synthesis of a large family of more or less stable hydridoolefin complexes (some representative references to hydridoolefin complexes are given in ref. 4), surprisingly little is known of the intimate mechanism of the hydridoolefin to alkyl transformation.

In the present paper we describe some reactions of a family of complexes: $IrH(CO)(PPh_3)_2(ol)$, where ol is a monosubstituted ethylene ligand. The reactions of these complexes, both in the presence and absence of reagents designed to trap the alkyl products of insertion, illustrate how the relative rates of olefin dissociation, olefin insertion, and trapping of alkyl products can greatly modify the mode of reaction.

Results

Synthesis of $IrH(CO)(PPh_3)_2(ol)$ complexes

Complexes of the type $IrH(CO)(PPh_3)_2(ol)$, where ol is a disubstituted ethylene with strongly electron withdrawing substituents, were first reported by Baddley and Fraser (5). These workers did not prepare any analogues with monosubstituted ethylenes, but tentatively concluded that the product of an attempted synthesis of the acrylonitrile (AN) complex was the compound **2**. In the present study the hydridoacrylonitrile complex was successfully prepared using a slight modification of the synthetic method of Baddley and Fraser (5). In fact, the reaction of $IrH_3(CO)(PPh_3)_2$ with pure olefinic ligand, followed by a stripping of the volatile olefin at low temperature, or by low temperature precipitation of product, proved to be a generally useful synthetic method for preparing the title compounds. In addition to the acrylonitrile complex, **1***a*, the methylacrylate (MA), **1***b*, and styrene (ST), **1***c*, complexes were also pre-



2

pared, isolated in a reasonably pure state and characterized by the usual physical and chemical methods. Other analogous compounds were detected in solution by ^{1}H-nmr, but were too unstable to isolate. All vinyl halide complexes were unstable with respect to transfer of halide to the metal under ambient conditions. However, several were observed at low temperature by nmr (see Table 1). The vinyl acetate complex, **1***d*, showed similar instability, but methyl vinyl ether did not form a complex.

With the exception of the vinyl chloride complex, **1***e*, all of the vinylic complexes observable by nmr showed the presence of two rotameric isomers, as previously observed by Fraser and Baddley for unsymmetrically disubstituted ethylenes (6) (see Table 1). The hydride resonances of the two rotamers (ethylene substituent in either the hydride or the carbonyl hemisphere) each appear as a pair of overlapping doublets due to the inequivalence of the two phosphine ligands.

Stability of the complexes $IrH(CO)(PPh_3)_2(ol)$ with respect to olefin dissociation

The three complexes **1***a*, *b*, *c*, span a range of stability with respect to olefin loss. Dissolution of the ST complex at room temperature rapidly produces free styrene and the products of the disproportionation of $IrH(CO)(PPh_3)_2$, **3** (7). On the other

[e] Not measured.

hand, the AN complex can be easily isolated at room temperature and dissolution of the pure solid at room temperature gives a very slow decomposition which does not produce free acrylonitrile (see below). The MA complex is intermediate between the ST and AN complexes in its behaviour.

The qualitative order of stability described above is confirmed by ^{1}H-nmr observations, of line widths for free and coordinated olefin, and of spin saturation transfer between the hydride resonances of one isomer and the other (9). At −20°C, the ST complex gives reasonably sharp lines for all resonances, but exhibits a strong spin saturation transfer between the hydride resonances of the two isomers. At 0°C, the resonances of this complex, and also those of the free styrene produced by ligand dissociation, are very broad. Both the MA and AN complexes give sharp resonances at room temperature, but spin saturation transfer is evident for both complexes. Quantitative treatment of the spin saturation transfer, using the methods described by Martin *et al.* (9), yielded average lifetimes of 12.5 s (−30°C), 4.3 s (20°C), and 1.5 s (20°C) for the ST, MA, and AN complexes, respectively.

Decomposition of $IrH(CO)(PPh_3)_2(ol)$ under inert atmosphere

Solutions of the AN complex in hydrocarbon solvents at room temperature decompose slowly (ca. 50% in 24 h) in a reaction which transforms all of the AN to propionitrile. Observation of the ^{1}H-nmr spectrum of the solution during this transformation shows that all of the starting hydride complex is eventually consumed and about 0.1 equiv. of $IrH(CO)(PPh_3)_3$, **4**, is produced. The latter product is most likely the result of AN ligand dissociation and disproportionation of the resulting $IrH(CO)(PPh_3)_2$. Deliberate addition of **4** at the beginning has no observable effect on the decomposition reaction. Addition of diphenylpicrylhydrazyl (DPPH) to the reaction led to a very slight increase in rate, while a spin trap (phenyl-*N*-butylnitrone, PBN) had no discernible effect on the rate. No incorporation of deuterium into the propionitrile occurred when the reaction was run in C_6D_6, but the decomposition of $IrD(CO)(PPh_3)_2(AN)$ gave propionitrile with a broad, poorly resolved ^{1}H-nmr spectrum, indicative of partial deuteration at both carbon positions.

The MA complex decomposes more slowly (25 to 30% in 24 h) under the same conditions, mainly by the loss of the ligand. Unlike the case of the AN complex, free olefin builds up in solution and only small amounts of the hydrogenation product, methyl propionate, are observed. Complete decomposition of the ST complex occurs in a few hours, almost entirely by olefin dissociation. Only traces of ethyl benzene are produced and the complex **4** appears rapidly, achieving a final concentration of ca. 30% of the total iridium. The rate of decomposition is reduced by either lowering the temperature, or by inclusion of an excess of olefin in the solution, but in neither case is the hydrogenation reaction increased relative to ligand dissociation. However, the presence of hydrogen in solution does lead to increased hydrogenation. For example, when the MA or ST complexes are prepared *in situ* by reaction of $IrH_3(CO)(PPh_3)_2$ with excess olefin in an nmr tube, the hydrogen liberated in the reaction forming the olefin complex is reconsumed by hydrogenation of free olefin.

The deuterio complexes, $IrD(CO)(PPh_3)_2(ol)$, where ol = AN, MA, and ST, were prepared by reaction of olefin with $IrD_3(CO)(PPh_3)_2$ of 90% isotopic purity. The isotopic purities of the products were found to be 85, 70, and 50%, respectively. The room temperature ^{1}H-nmr spectrum of a freshly prepared solution of $IrD(CO)(PPh_3)_2(AN)$ revealed a progressive increase in the concentration of $IrH(CO)(PPh_3)_2(AN)$. The rate of decomposition of the deuterio complex is considerably slower than that of the hydrido complex under the same conditions (ca. 25% conversion in 24 h).

Decomposition of $IrH(CO)(PPh_3)_2(ol)$ in the presence of dioxygen

The ^{1}H-nmr spectrum of a solution of the AN complex in C_6D_6 under an atmosphere of O_2 showed the disappearance of the reactant complex at about the same rate as under an inert atmosphere. However, instead of propionitrile, the disappearance of coordinated AN produces a new species with a sharp doublet at 1.40 ppm and a complex multiplet at 3.51 ppm. These two resonances are coupled and in the ratio of 3:1 (see Fig. 1). The presence of DPPH or PBN had no apparent effect on the reaction.

A reaction of $IrD(CO)(PPh_3)_2(AN)$ under the same conditions proceeded much more slowly (c.f. reaction under inert atmosphere) to give a product superficially similar to that of the H—Ir—AN reaction, but with changes in the multiplet at 3.51 ppm indicative of deuterium incorporation.

The product of the reaction of **1***a* with O_2 was made on a preparative scale to determine its structure. Although obtained as a crystalline material, the product did not yield to X-ray diffraction methods and its structural assignment rests on spectroscopic and chemical evidence. The conclusion that this compound has the structure **5** is based on the following evidence: (*1*) The ir spectrum of the compound shows bands due

5

to ν_{CN}, ν_{CO}, and ν_{O-O}, with frequencies and intensities comparable to those of analogous compounds (see Table 2). (*2*) The ^{1}H-nmr spectrum conforms to that of an α-cyanoethyl derivative. Decoupling of the methyl resonance simplifies the methine resonance to a pseudotriplet, due to coupling with two near-equivalent phosphorus nuclei. This coupling excludes the possibility that the compound is an alkylperoxo- complex and supports the direct bonding of the alkyl ligand to the metal. (*3*) The observation of two ^{31}P resonances of equal intensity which are attributed to the two diastereotopically inequivalent P ligands. (*4*) The compound reacts rapidly and cleanly with SO_2 to give a product whose ir spectrum shows a remarkable resemblance to the known compound $IrCl(CO)(PPh_3)_2(SO_4)$ (see Fig. 2) (10). The peaks at 1296 and 1160–1170 cm^{-1} (ν_3), 902 and 868 cm^{-1} (ν_1), and 694 cm^{-1} (ν_2) are highly characteristic of the chelating SO_4 group (11). Except for changes in chemical shifts, the ^{1}H-nmr features of the α-cyanoethyl group are the same as for the O_2 complex.

The reaction of the MA complex under oxygen, as under an inert atmosphere, proceeds primarily by olefin dissociation. However, the proton spectrum of a reaction carried out in an nmr tube showed the formation of a $—CH(COOCH_3)(CH_3)$ derivative in about 14% yield. Although this species (see Table 2 for ir and nmr data) is almost certainly the dioxygen complex, its instability and admixture with large amounts of other reaction products precluded its isolation as a pure compound.

The reaction of **1***c* with oxygen yields no detectable alkyl dioxygen compound. Instead, the disappearance of the hydride resonances of the reactant is accompanied by the appearance of a new hydride resonance (triplet, −14.5 ppm, C_6D_6). A preparative scale reaction in benzene afforded a yellow crystalline product whose analysis and spectroscopic properties (see Table 2) corresponded to $IrH(CO)(PPh_3)_2(O_2)$. In particular, the ratio of hydride to phenyl protons (1:29) and the J_{P-H} (18.5 Hz) confirm the presence of a hydride *cis* to two phosphine ligands. The presence of the dioxygen ligand is strongly suggested by the ir band at 823 cm^{-1}. The frequency of this band is very close to that observed for the methyl dioxygen analogue reported by Mason and Ibers (12) and somewhat lower than that of the analogues with more electron withdrawing ligands, such as halogen or α-cyanoethyl. Reaction of this compound with SO_2 led to the immediate disappearance of the hydride, possibly as a result of the insertion of the sulfate intermediate into the Ir—H bond. Resonances due to such an insertion were not observed, perhaps because of the strongly acidic character of the OH groups produced. A reaction of deuterio-**1***c* (about 50% of the hydride replaced by deuterium) with O_2 gave a product with an additional ν_{CO} at 2015 cm^{-1} due to CO *trans* to D.

Trapping of the insertion product by olefin

By heating the trisphosphine complex **4** with AN, Baddley and Fraser obtained an unstable compound to which they assigned the structure **2** on the basis of chemical analysis and ir spectrum (5). In view of the results described above, it appears more likely that an alkyl ligand, if present, would be the α-cyanoalkyl, rather than the β-cyanoalkyl. A second difficulty with the approach of Baddley and Fraser is that the method of synthesis liberates a phosphine ligand which can compete very effectively with the AN for a coordination site.

The problem of the presence of excess phosphine can be avoided by trapping the insertion product from **1***a* in AN as solvent. This reaction goes cleanly and to high conversion (>80%) in about 48 h. However, the ^{1}H-nmr spectrum of the product is very complicated. The source of this complication is evident when the structures of the most likely products **6***a* and **6***b* are considered. Since each of the isomers exists as two diastereomers, it is possible that there will be four sets of resonances for the alkyl and olefin ligands in the nmr spectra. In the proton spectrum there are two clearly identifiable doublets due to CH_3 at 0.50 ppm (J = 7.1 Hz) and 0.83 ppm (J = 7.3 Hz), and a multiplet resembling a pseudo-triplet at 1.5

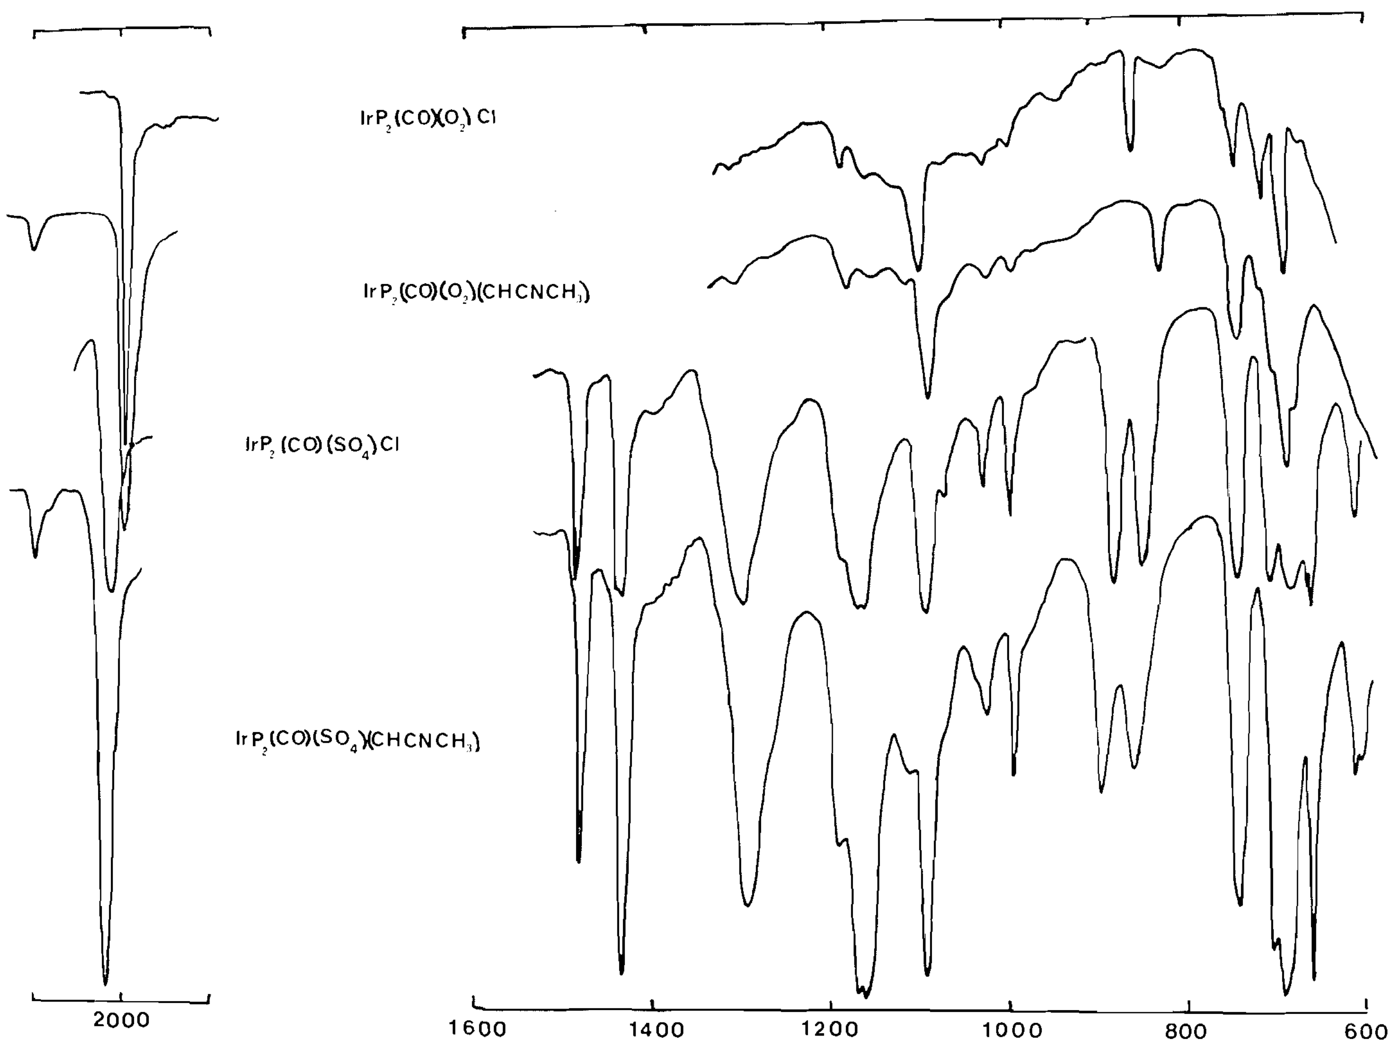

FIG. 2. Infrared spectra of the O_2 complexes $IrX(CO)(PPh_3)_2(O_2)$ (X = Cl and $CH(CN)CH_3$) and of their products of reaction with SO_2.

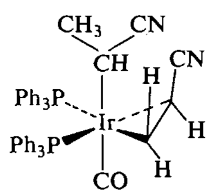
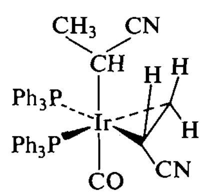


6a



6b

ppm. This latter resonance probably corresponds to two overlapping doublets. In addition there are two broad complex massifs at 2.0–2.3 ppm and 2.4–2.7 ppm due to the coordinated AN. The integrals for the CH_3 resonances and the AN resonances are in a ratio slightly greater than 1:1, most likely because the methine resonances are hidden in the multiplet at 1.5 ppm. The ^{31}P-nmr spectra are insensitive to the presence of diastereomers and, in the proton decoupled spectrum, four doublets at 0.8 and −7.6 ppm (J_{P-P} = 7.3 Hz) and 0.1 and −9.1 ppm (J_{P-P} = 9.8 Hz) were observed, a pattern very similar to that observed for **1***a*.

The proton spectrum, as expected, is simplified by replacement of acrylonitrile by ligands of higher symmetry. Fumaronitrile, which removes the possibility of rotamers, but still gives diastereomers, reacts in solution with **6** and simplifies the spectrum to two overlapping methyl doublets centred at 0.42 ppm, coupled to two methine multiplets at 2.0 and 2.4 ppm. Tetracyanoethylene, which can give neither rotamers nor diastereomers, gives a product with a doublet and multiplet at 0.98 and 3.8 ppm, respectively. Bubbling CO through a solution of **6** rapidly produces a product with two overlapping doublets at 1.93 ppm and a complex multiplet at 2.97 ppm. The presence of two different α-cyanoethyl resonances suggests that if the product is $Ir(CO)_2(PPh_3)_2[CH(CN)CH_3]$, as might be expected, it probably exists as two isomers. The ir spectrum of this product had no bands in the region typical of a metal acyl, excluding the possibility that insertion of CO into the Ir—C bond had occurred. Finally, bubbling O_2 through a solution of **6** under ambient conditions transforms it rapidly and completely to **5**.

Apart from O_2, AN proved to be the only neutral ligand with which the insertion product of **1***a* could be successfully trapped. Reaction of **1***a* with CO and phosphorus-containing ligands led to rapid substitution of the AN ligand. No evidence was obtained for a transformation of **1***b* or **1***c* into analogues of **6**.

Discussion

All of the observations in the present study conform to the widely held view that insertion of an olefin ligand will not occur if the double bond of the olefin is orthogonal to the M—H bond (3). The essentially constant rates of reaction for the AN complex, independent of trapping agent, the insensitivity of the reaction rates to a free radical trap and the appreciably slower rates of the Ir—D relative to Ir—H compounds, all point to the unimolecular insertion reaction as being the rate controlling process. The spectroscopic data are in accord with a structure in which the olefin ligand double bond is coplanar with the two phosphine ligands and perpendicular to the H—Ir—CO unit. This structure was previously demonstrated crystallographically for the fumaronitrile compound (6). It is therefore reasonable to suppose that the rate of insertion is controlled by the rate of the rotation of the olefinic double bond into coplanarity with the Ir—H bond.

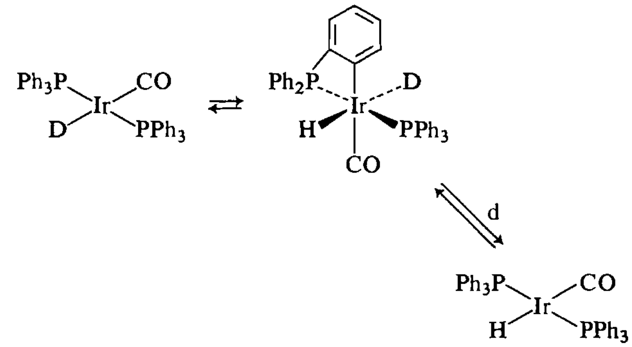
Whether or not insertion can be observed in the present systems depends on a delicate balance between the rates of olefin rotation and olefin dissociation. Even though the spin saturation transfer data and the general stability of compounds **1***a* and **1***b* suggest only modest differences in the rates at which they lose olefin, their abilities to give stable trapped insertion products are markedly different. Even without taking the irreversible disproportionation of **3** into account, the kinetic behavior of a system in which reversible olefin dissociation competes with an olefin rotation process, with at least two different potential minima, is very complicated and beyond the scope of the present results.

The relative rates of reaction of **1***a* with such neutral ligands as CO and PPh_3 and with O_2 are very different. In the case of CO and PPh_3 the reaction is complete in less than 1 h and the product results from the trapping of **3**, the product of olefin dissociation. For O_2, the reaction under the same conditions has a half life of about 24 h and the final product results from trapping the insertion product. Thus, in the case of **1***a* it appears that the combined rates of olefin dissociation and the reaction of **3** (present in very low concentration) with O_2 do not compete significantly with insertion. However, for **1***c*, the greater rate of olefin loss and the resulting higher concentration of **3** favours the reaction of **3** with O_2 and leads to the formation of the remarkable hydridodioxygen complex $IrH(CO)(PPh_3)_2(O_2)$. It is likely that this complex has a structure analogous to **1**, with the O_2 occupying the same position as the olefin. The comparative stability of this compound with respect to the insertion of the O_2 into the Ir—H bond is probably also due to the orthogonal disposition of the O—O and Ir—H bonds. This hydridodioxygen complex is also produced in small amounts in reactions of O_2 with other precursors of **3**, e.g. $IrH(CO)(PPh_3)_2$, $IrH(CO)(PPh_3)_3$, and **1***a* and **1***b*, but in these cases the rate of production of the dioxygen complex is comparable to its rate of decomposition in solution.

Only two examples of alkyldioxygen complexes have been previously reported (11, 12). Our attempts to use the method reported by Zecchin *et al.* for the synthesis of $Ir(CH_2CN)(CO)(PPh_3)_2$, were not successful for the higher α-cyanoalkyl derivatives. The presence of a β-hydrogen on the alkyl group, as is often the case, renders the product unstable. The trapping of the insertion products described above by O_2 thus remains a unique method for the synthesis of the higher alkyldioxygen compounds. To our knowledge, the hydridodioxygen complex reported above is the first of its kind. Such species may well participate in many reactions, either stoichiometric or catalytic, involving O_2 and organometallic complexes. The participation of a hydroperoxoiridium complex in a catalytic oxygenation reaction has recently been proposed by Atlay *et al.* (14).

The observed replacement of D by H in the $IrD(CO)(PPh_3)_2(ol)$ complexes is explained by H/D exchange within the transient square planar intermediate **3**. The orthometallation shown in [1] is a likely source of such an exchange and could

[1]



also furnish the additional hydrogen needed to effect complete hydrogenation of the acrylonitrile ligand, as observed. The D/H exchange cannot be attributed to a reversible insertion/β-elimination process since deuterated olefin is not observed until after much longer times than are required for considerable loss of Ir—D. In fact, the rate of H/D exchange is comparable to the rate of replacement of olefin by donor ligands and much faster than the rate of appearance of trapped insertion or hydrogenation products. Since the rate of hydrogenation of AN ligand, which occurs when **1***a* decomposes in solution under inert atmosphere, is very similar to the rate of production of insertion product trapped with O_2 or AN, it is reasonable to conclude that the rate controlling process in each case is the insertion of AN into the Ir—H bond. In the absence of trapping agent, the intermediate $Ir[CHCN(CH_3)](CO)(PPh_3)_2$ undergoes rapid hydrogenolysis, either by an intramolecular metallation analogous to [1] followed by reductive elimination of propionitrile, or by transfer of hydride from some other hydride complex in solution.

Experimental

All solvents were subjected to standard drying procedures and distilled prior to use. Deuterated solvents and $LiAlD_4$ were purchased from Merck, Sharp and Dohme, Canada Limited. Acrylonitrile (Matheson, Coleman and Bell), methyl acrylate (Aldrich Chemical Co.), and styrene (Kodak Chemical Co.) were freshly distilled under reduced pressure immediately before use. The iridium complexes $IrCl(CO)(PPh_3)_2$ (15), $IrH_3(CO)(PPh_3)_2$ (15), $IrD_3(CO)(PPh_3)_2$ (16), and $IrH(CO)(PPh_3)_3$ (17) were prepared by standard procedures.

^{1}H-nmr spectra were measured on a Varian XL-200 instrument operating in the FT mode at 200.06 MHz. ^{31}P spectra were recorded on a Brüker WH-90 instrument at 36.44 MHz. All proton shifts were measured relative to an internal tetramethylsilane standard and ^{31}P shifts were relative to an external 85% phosphoric acid standard. Infrared spectra were recorded on a Nicolet 7000 FT-IR machine at a resolution of 2 cm^{-1}.

Preparation of (η^2-acrylonitrile)carbonylhydridobis(triphenylphosphine)iridium(I)

A suspension of $IrH_3(CO)(PPh_3)_2$ (1.0 g; 1.34 mmol) in acrylonitrile (100 mL) was stirred at room temperature, with passage of a slow stream of nitrogen through the mixture. After several hours the solid had entirely dissolved and the volume of the solution was reduced to 20 mL by vacuum evaporation. Following filtration through celite, 45 mL of hexane was added and the solution was cooled to −20°C for several hours, filtered, and evaporated to dryness. The pale yellow solid was extracted with 12 mL of acrylonitrile and the white insoluble product recovered by centrifugation, washed with a further 8 mL of acrylonitrile and dried under vacuum. Yield: variable, but generally 20–35%. Decomp. 69–70°C. Ir (cm^{-1}): 2233(w), 2202(m), 2080(vs), 1958(vs). Nmr: see Table 1. *Anal.* calcd. for $C_{40}H_{34}IrNOP_2$: C 60.13, H 4.30, N 1.75, P 7.75; found: C 59.78, H 4.27, N 1.82, P 8.01.

(η^2-Methylacrylate)carbonylhydridobis(triphenylphosphine)-iridium(I)

Nitrogen was passed through a solution of $IrH_3(CO)(PPh_3)_2$ (1.33 g; 1.78 mmol) in 100 mL of methylacrylate for several hours. During this time almost all of the solid dissolved and the volume of the solution was reduced to ca. 10 mL. Following filtration through celite, the solution was evaporated to dryness under vacuum. The pale yellow, glassy residue was dissolved in 10 mL of benzene, filtered through celite into 6 mL of pentane, and evaporated to give a light yellow powder. It is essential that these last steps be performed as quickly as possible. The yield of product is variable between 80–90%. An analytically pure sample was obtained from a further recrystallization from methylacrylate at −20°C. Decomp. 72–75°C. Ir (cm^{-1}): 2067(vs), 1967(s), 1680(vs). Nmr: see Table 1. *Anal.* calcd. for $C_{41}H_{37}IrO_3P_2$: C 59.19, H 4.49, P 7.45; found: C 59.42, H 4.99, P 7.58.

(η^2-Styrene)carbonylhydridobis(triphenylphosphine)iridium(I) (18)

A stream of nitrogen was passed through a solution of $IrH_3(CO)(PPh_3)_2$ (0.35 g; 0.47 mmol) in 40 mL styrene, maintained at 40°C for 1 h. The solution volume was reduced to ca. 5.0 mL and, following filtration through celite, 8.0 mL of hexane was added. The solution was refiltered and quickly evaporated to dryness under vacuum. The product was obtained as a pale yellow powder in ca. 90% yield. Low temperature (<−20°C) recrystallization from a styrene/hexane mixture did not change the purity of the product which, from nmr and ir evidence, was greater than 95%. Ir (cm^{-1}): 2060(vs), 1941(vs). Nmr, see Table 1.

Preparation of deuterated analogues

The deuterated analogues of the AN, MA, and ST complexes were prepared by the same methods as the normal compounds, using $IrD_3(CO)(PPh_3)_2$ as reactant. Ir (cm^{-1}): AN complex 2197(w), 1998(sh), 1990(vs), 1513(w); MA complex 1963(vs), 1694(vs), 1496(w); ST complex 1975(vs).

Generation of the vinyl chloride complex

Vinyl chloride was bubbled through a solution of the styrene complex, **1***c*, at −25°C for 10 min. The sample was then left for 2 h at −25°C and the ^{1}H-nmr spectrum was recorded at −25°C (see Table 1). A similar experiment using AN gave the same nmr spectrum as that of an authentic sample of **1***a* prepared at room temperature.

Carbonyl(α-cyanoethyl)dioxygenbis(triphenylphosphine)iridium

The synthesis of the AN complex was followed as described above, up to the first filtration and then the solution was evaporated to dryness and the solid residue taken up in 25 mL of benzene. Oxygen was bubbled through the solution for 30 min and the mixture was stirred under an atmosphere of O_2 for a further 24 h. After periods of 5 and 10 h had elapsed, oxygen was bubbled through the solution for 10 min. The resulting green solution was evaporated to dryness and the product purified by elution as a yellow band from an alumina column with 1:1 acetone/hexane. An analytically pure sample was obtained as a dichloromethane solvate by recrystallization from dichloromethane/pentane. The presence of one molecule of CH_2Cl_2 per mole of complex was verified by ^{1}H-nmr and chemical analysis. Yields are variable between 40 and 50%. Decomp. 159–160°C. Ir and nmr, see Table 2. *Anal.* calcd. for $C_{40}H_{34}IrNO_3P_2.CH_2Cl_2$: C 53.77, H 3.97, P 6.76; found: C 54.17, H 3.92, P 7.06.

Carbonylhydridodioxygenbis(triphenylphosphine)iridium

Nitrogen was bubbled through a solution of $IrH_3(CO)(PPh_3)_2$ (0.40 g; 0.54 mmol) in 25 mL of styrene at 40°C for 1 h and the solution rapidly evaporated to dryness under vacuum. The yellow residue was dissolved in toluene at 0°C and O_2 gently bubbled through the solution for 24 h. During this time a yellow solid precipitated and the solution turned dark blue. The yellow product was filtered, washed several times with toluene at 0°C and dried under vacuum. A sample for analysis was recrystallized from CH_2Cl_2/pentane at −20°C. Yield ca. 30%. Decomp. 118°C. Ir and nmr, see Table 2. *Anal.* calcd. for $C_{37}H_{31}IrO_3P_2$: C 57.13, H 4.03, P 7.96; found: C 57.23, H 4.07, P 7.86.

Trapping experiments

The trapping of the insertion products was followed by ^{1}H-nmr. Such experiments were performed using a concentration of 2% of reactant complex in C_6D_6 and a cavity temperature of 20°C. In the case of the O_2 trapping experiment the solution was purged with pure O_2 for 5 min before the tube was sealed and put in the spectrometer cavity. In the case of AN trapping, the complex solution was treated with a ten-fold molar excess of AN before purging with argon and introduction into the spectrometer. After the reaction was completed the product solution was flash-evaporated to dryness and the solid redissolved in C_6D_6 containing either fumaronitrile or tetracyanoethylene in a two-fold molar excess over the original iridium complex. Under these conditions, the AN of **6** was completely displaced and the more heavily substituted cyanoolefin was fully coordinated.

Synthesis of derivatives of isoindole and of pyrazino[2,1-*a*]isoindole

JEAN-MARIE FERLAND,[1] CHRISTOPHER A. DEMERSON,[2] AND LESLIE G. HUMBER[2]
Ayerst Research Laboratories, Montréal, P.Q., Canada H4R 1J6

Received July 5, 1983[3]

JEAN-MARIE FERLAND, CHRISTOPHER A. DEMERSON, and LESLIE G. HUMBER. Can. J. Chem. **63**, 361 (1985).

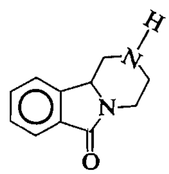
Amines were reacted with lactones **7** or with unsaturated nitro derivatives **8** to give isoindole and pyrazino[2,1-*a*]isoindole derivatives. The mechanisms of formation, proofs of structure, and stereochemistry are presented.

JEAN-MARIE FERLAND, CHRISTOPHER A. DEMERSON et LESLIE G. HUMBER. Can. J. Chem. **63**, 361 (1985).

La réaction d'amines avec les lactones et les dérivés nitro-insaturés du type **7** et **8** donne accès à des isoindoles et des pyrazino[2,1-*a*]isoindoles. Nous décrivons les mécanismes de formation ainsi que les preuves de structure et de stéréochimie.

The 1,2,3,4-tetrahydropyrazino[2,1-*a*]isoindole-6-one **1** was found to lower blood pressure in spontaneously hypertensive rats. In order to explore the structure–activity relationships in this type of compound, several analogs of the parent structure were synthesized. We envisioned different routes that would not only allow structural variations within the series but also give access to other heterocycles such as isoindole derivatives.

Some 1,2,3,4-tetrahydropyrazino[2,1-*a*]isoindole-6-(2*H*)-ones bearing a hydroxyl group at C-10a have been prepared (1,2,4) and the fully reduced ring system has also been described (3). However, none of those approaches (1–4) was general enough to provide access to the desired products.



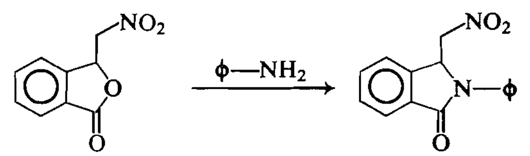
1

An interesting approach to isoindoles (3) has been published by Whelton and Huitric (6) involving the reaction of the nitrolactone **2** with bases (7). However, only weak bases such as aniline can be used (Scheme 1). With other amines the reactions followed a different pathway, leading to 1,3-dihydro-3-methylene-2*H*-isoindol-1-ones (**16**) (Scheme 3).

Kemp and Vellacio (8) have also shown that an amine can add in a Michael-type fashion to the double bond of the nitrostyrene derivative **4** to give **5**. This reaction is then followed by an acyl transfer from the phenol to the amine to give **6** (Scheme 2).

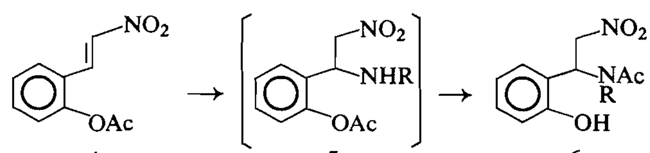
These two syntheses (Schemes 1 and 2) have been incorporated into a pathway that has led to the synthesis of a series of substituted isoindoles (Scheme 3). The nitrolactones **7** were transformed into the nitrostyrenes **8** (dimethyl sulfate/K_2CO_3). The latter reacted with bases such as methylamine, benzylamine, glycine ester, and aminoacetaldehyde diethyl acetal to give the nitroisoindole derivatives **9**. This approach proved to be very general (5).

As shown by nmr spectroscopy (see experimental), the lactone **7***b* exists as a mixture of stereoisomers. When transformed



2 **3**

SCHEME 1



4 **5** **6**

SCHEME 2

to the nitrostyrene **8***b*, a single isomer was obtained. Because of their high electronic densities, the nitro group and the benzene ring should be as far apart as possible, giving rise to a preferred stereochemistry. Only one conformation of the lactone would therefore be capable of displacing the CH_3 group of dimethyl sulfate in a *trans* diaxial or antiperiplanar fashion and the nitro group would end up being *trans* to the aromatic ring. This was confirmed through the examination of the nmr spectrum of **8***a*. Indeed, in this case the benzylic proton is centered at 8.7 ppm with a coupling constant equal to 12 Hz, a value indicative of a *trans* fusion (9).

The nitroisoindole derivatives **9***a* and *b* were then hydrogenated under neutral conditions to the corresponding amino derivatives **10***a* and *b*. Under similar conditions the isomers **9***f* and *g* yielded the amine derivatives **10***f* and *g*, which were separated by chromatography. Each isomer was then rehydrogenated in the presence of palladium under acidic conditions. This led to the generation of a free aldehyde group and subsequent reduction of the intermediate imine to give the 1,2,3,4-tetrahydropyrazino[2,1-*a*]isoindole-6-one derivatives **11** and **12** (Scheme 4). The methyl group of the isoindole derivative **11** appears at 1.53 ppm and must be equatorial to lie in the negative cone of the aromatic ring. The axial methyl of **12** is centered at 0.68 ppm. In **11**, the benzilic protons H_b and H_a are located respectively at 4.16 and 4.41 ppm and the coupling constant of the doublet for H_a is equal to 10 Hz. It agrees with an angle of 130–180°, indicative of a *trans* fusion. For product **12** the same protons are centered at 4.3[4] and 4.85 ppm and H_a appears as a doublet with J = 4 Hz. This is as

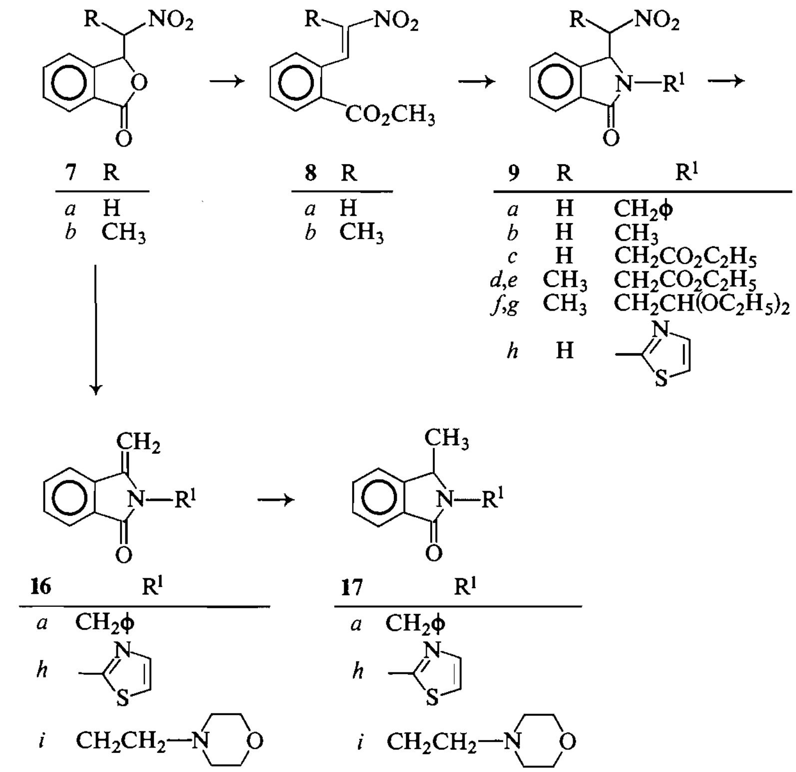
[4] On the spin decoupling experiment, irradiation of the CH_3 causes a coalescence of H_b at 4.3 ppm.



SCHEME 3

expected for a *cis* stereochemistry.

It is important to notice that a difference of 0.44 ppm is found in the location of the H_a of **11** and **12**. Such a difference arises from the anisotropic effect due to the β-substitution. A similar effect has been found in methyl cyclohexane (10). In this study, it was determined that an equatorial CH_3 would shield a β-axial proton by a value of 0.25 ppm while an axial CH_3 would deshield a β-equatorial proton by a value of 0.2 ppm for a total difference of 0.45 ppm. It constitutes an additional proof for the structures proposed for **11** and **12**.

The lactams **11** and **12** were reduced with diborane to the corresponding diamines **14** and **15**. These reactions are shown in Scheme 4.

As mentioned previously, when the nitrolactone **7***a* was treated wih a relatively strong amine such as benzylamine the novel 1,3-dihydro-3-methylene-2-phenylmethyl-2*H*-isoindol-1-one **16** was obtained. This structure was confirmed by nmr spectroscopy (the C=CH_2 appears as two doublets with a coupling constant equal to 2.5 Hz at 4.75 and 5.10 ppm), elemental analysis, and mass spectroscopy. The formation of such a compound can only be explained through the elimination of nitrous acid from the lactam **9***a*. A similar mechanism has already been proposed by Kloetzel (11). The mechanism and structure were further substantiated when **16** was again obtained when **9***a* was heated in the presence of benzylamine at reflux in toluene. The hydrogenation of the *exo* methylene derivative yielded the isoindol-1-one derivative **17***a*. Using another strongly basic amine such as *N*-(aminoethyl) morpholine, we observed the formation of the *exo* methylene derivative **16***i*. However, when a weakly basic amine such as aminothiazolidine was used, the nitrolactone **9***h* was isolated, as observed also by Huitric (6). The *exo* methylene derivative **14***h* was prepared on treatment with benzylamine. Both **16***h* and **16***i* were hydrogenated to yield **17***h* and **17***i*. These reactions are described in Scheme 3.

Some oxomethylene-isoindol-3-one derivatives have been reported in the literature (12). They were, however, obtained through a different pathway.

Experimental

Melting points are uncorrected. The ir spectra were taken on a Perkin–Elmer 225 ir spectrophotometer and nmr spectra were recorded on a Varian CFT-20 spectrophotometer operating at 80 MHz; TMS was used as an internal standard. The mass spectra were obtained on a LKB gc–ms 9000S instrument. Merck silica gel 60 (60–230 mesh) was used.

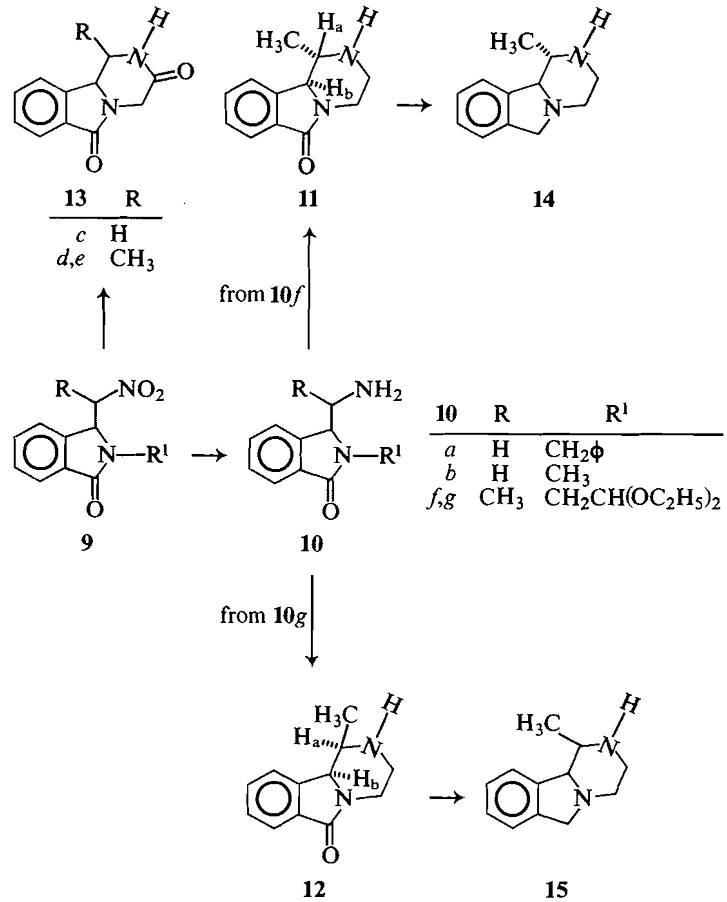
Preparation of the nitro lactones 7

3-(Nitromethyl)-isobenzofuran-1-(3*H*)-one (**7***a*) or the 3-(nitroethyl)lactone (**7***b*) are known products and were prepared according to methods described in literature (6, 7). Compound **7***a*, ms: 193 $(M)^+$, 132 $(M - HNO_2)^+$, and 133^+. Compound **7***b* exists as a mixture (2:1) of two isomers, the major one having its methyl centered at 1.1 ppm; nmr ($CDCl_3$): 1.1 and 1.63 (CH_3, 2d, J = 7 Hz), 5.8 (CHϕ, 0.66 H, d, J = 5 Hz), and 6.1 (CHϕ, 0.33 H, d, J = 3 Hz) ppm; ms: 207 $(M)^+$, 160 $(M - HNO_2)$, and 133^+.

*2-[(2-Methyl-2-nitro)ethylene]benzoic acid methyl ester (8*b*)*

Under anhydrous conditions a mixture of nitrolactone **7***b* (7) (2.0 g), dimethyl sulfate (1.6 mL), and K_2CO_3 (2.4 g) in acetone (50 mL) was stirred at room temperature for 18 h. The carbonate was removed by filtration and the filtrate evaporated. The residue was chromatographed on silica gel (50 g/g, toluene) to give product **8***b* (1.67 g) in 78% yield; ir ($CHCl_3$): 1715 and 1520 cm^{-1}; nmr ($CDCl_3$): 2.25 (CH_3, 3H), 3.91 (CO_2CH_3, 3H), 7.40 and 7.60 (Ar H, 3H, m), 8.18 (Ar H, 1H), and 8.50 (=CH) ppm; ms: 221 $(M)^+$, 190 $(M - OCH_3)^+$, 175 $(M - NO_2)^+$, 162 $(M - CO_2CH_3)^+$, and 129^+.

In a similar fashion was obtained **8***a* (from **7***a* (6)) in 65% yield, mp 87°C; nmr ($CDCl_3$): 3.8 (OCH_3, 3H, s), 7.0 (5H, m), and 8.7 (1H, d, J = 12 Hz) ppm; ms: 207 $(M)^+$, 176 $(M - OCH_3)^+$, 161 $(M - NO_2)^+$, 148 $(M - CO_2CH_3)$, and 129^+.



SCHEME 4

Formation of the nitro lactams 9

*2,3-Dihydro-3(nitromethyl)-2-(2-thiazolidinyl)-1*H*-isoindol-1-one (9*h*)*

A mixture of the nitrolactone **7***a* (20 g) and freshly crystallized 2-aminothiazole (20 g) in toluene (100 mL) was heated under reflux for 20 h. The dark orange mixture was diluted with more toluene and the organic solution washed with 10% HCl (3×), brine (4×), dried, and evaporated. The crude product obtained was taken into MeOH (200 mL) and the mixture heated under reflux for 1/2 h. After cooling, the solid obtained was filtered (9.4 g). The solid obtained after evaporation of the mother liquors was taken into EtOAc (100 mL) and heated at reflux for 1/2 h. The mixture was cooled and filtered to give a solid (5.2 g). The combined solids were crystallized from EtOAc/hexane to give the pure title product, in 50% yield, mp 146–147°C; ir ($CHCl_3$): 1715, 1555, and 1365 cm^{-1}; uv (MeOH) λ_{max}: 395, 235 and 228; ϵ: 12 160, 11 725, and 14 470; nmr ($CDCl_3$) 5.3 (CH_2NO_2, 2H, m), 5.9 (ϕCHN, 1H, m), and 7.55 (6 ArH, m) ppm; ms: 275 $(M)^+$, 229 $(M - NO_2)^+$ 215 $(M - CH_2NO_2)^+$. *Anal.* calcd. for $C_{12}H_9N_3O_3S$: C 52.35, H 3.29, N 15.26; found: C 52.19, H 3.15, N 15.25.

*2,3-Dihydro-3-(nitromethyl)-2-phenylmethyl-1*H*-isoindol-1-one (9*a*)*

A mixture of the nitroderivative **8***a* (1.0 g), benzylamine (0.57 g), and sodium acetate (0.45 g) was stirred vigorously in acetonitrile (20 mL) for 4 h. The salt was removed by filtration and the filtrate evaporated (bath temperature < 50°C). The residue was taken into EtOAc and th organic solution washed with 1 *N* HCl, brine, dried, and evaporated. The oil obtained (1.2 g) was used as such for the following reaction; nmr ($CDCl_3$): 4.80 (CH_2NO_2, 2H, d, J = 5 Hz), 5.0 (CH_2ϕ, 2H, s), 5.3 ($CHCH_2NO_2$, 1H, t, J = 5 Hz), 7.3 (5 Ar H), and 7.7 (4 Ar H) ppm. In a similar fashion were obtained the following.

*Compound 9*b

The reaction was carried out with **8***a* and aqueous methyl amine to give an oil in 60% yield; nmr ($CDCl_3$): 3.15 (N—CH_3, 3H, s), 4.80 (CH_2NO_2, 2H, d, J = 5 Hz), 5.18 (ϕCH, t, J = 5 Hz), and 7.7 (4 Ar H) ppm; ms: 206 $(M)^+$, 160 $(M - NO_2)^+$, and 159^+.

*Compounds 9*f *and* g

The reaction was carried out using **8***b* and aminoacetaldehyde diethyl acetal to give a mixture of isomers as an oil. It was used as such for the following reaction; nmr (DMSO): 4.3/4.6 ($CHNO_2$, 1/2H, m) and 5.5/5.8 ppm (CHϕ, 1/2H, m).

*2,3-Dihydro-3-nitromethyl-1-oxo-1*H*-isoindol-2-acetic acid ethyl ester (9*c*)*

To a suspension of glycine ethylester HCl (5.56 g) in acetonitrile (75 mL) was added Et_3N (4.04 g) and the mixture stirred at room temperature for 10 min. The unsaturated nitro derivative (**8***a*) (3.86 g) was added and the mixture stirred at room temperature for 22 h. The solvent was evaporated under reduced pressure (bath temperature < 50°C) and the residue dissolved in EtOAc. The organic solution was washed with 1 *N* HCl (2×), brine, dried, and evaporated. The crude product obtained (4.6 g) was chromatographed on silica gel (50 g/g, EtOAc/toluene 1:9) to give product **9***c* (2.4 g) in 44% yield; ir (Nujol): 1720, 1690, and 1550 cm^{-1}; nmr ($CDCl_3$): 1.3 (CH_3, 3H, t, J = 6 Hz), 4.4 (CH_2—CH_3, 2H, q, J = 6 Hz), 4.85 (CH_2NO_2, 2H, d, J = 5 Hz), 5.48 (CH—CH_2—NO_2, 1H, t, J = 5 Hz), and 7.3, 8.0 (4 Ar H) ppm; ms: 278 $(M)^+$, 232 $(M - NO_2)^+$, 205 $(M - CO_2Et)^+$, 158 $(\phi\overset{\overset{O}{\|}}{C}—N{=}CH_2)^+$. In a similar fashion were obtained the following.

*Compounds 9*d *and* e

The reaction was carried out using **8***b* and the crude product obtained chromatographed on silica gel (75 g/g, EtOAc/toluene, 1:9) to give **9***d* and *e* as a mixture of isomers in 21%/ yield; ir ($CHCl_3$): 1730, 1690, and 1550 cm^{-1}; nmr ($CDCl_3$): 1.2 (CH_3, 3H, m), 5.25 (ϕCH, 1/2H), 5.43 (ϕCH, 1/2H), and 7.1, 7.6 (4 Ar H) ppm; ms: 292 $(M)^+$, 246 $(M - NO_2)^+$, and 219^+.

*3-(Aminomethyl)-2-3-dihydro-2-(phenylmethyl)-1*H*-isoindol-1-one* (***10*****a**)

A solution of the nitro lactam **9***b* (1.2 g) in MeOH (75 mL) was hydrogenated over 10% Pd/C (0.5 g) at room temperature and atmospheric pressure. The catalyst was then removed by filtration and the filtrate evaporated. The crude product obtained was chromatographed on silica gel (50 g/g, $MeOH/CH_2Cl_2$, 1:9) to give 10*a* as an oil (1.0 g); ms: 223^+ and 30 $(CH_2NH_2)^+$.

The maleate was prepared in MeOH and recrystallized in EtOH/ether to give the analytical sample (0.7 g), mp 175–176°C; ir (Nujol): 2800, 1680, 1582, and 1355 cm^{-1}; uv (MeOH) λ_{max}: 277, 238, 228; ε: 1440, 9580, and 14 590; nmr (DMSO): 3.62 (CH_2NH_2, 2H, d, J = 3.5 Hz) 4.35 and 5.12 (ϕCH_2, 2H, 2d, J = 15 Hz), 4.72 (ϕCH, 1H, t, J = 3.5 Hz), 6.07 (=CH, 2H, s), 7.3 (5 Ar H), and 7.7 (4 Ar H) ppm. *Anal.* calcd. for $C_{20}H_{20}N_2O_5$: C 65.20, H 5.47, N 6.71; found: C 65.27, H 5.44, N 7.53.

In a similar fashion was obtained **10***b* as an oil; nmr ($CDCl_3$): 1.15 (NH_2), 3.15 (N—CH_3, 3H, s), 3.3 (CH_2, 2H, d, J = 3.5 Hz), 4.5 (CH, 1H, t, J = 3.5 Hz), and 7.7 (4 Ar H) ppm; ms: 147 $(M - CH_2NH_2)^+$, 146 $(M - CH_3NH_2)^+$, and 30 $(CH_2NH_2)^+$.

The maleate was prepared in MeOH and recrystallized from EtOH/ether to give the analytical sample in 40% from **9***b*; mp 165–167°C; ir (Nujol): 2880, 1660, 1577, and 1362 cm^{-1}; uv (MeOH) λ_{max}: 277, 267, 227; ε: 1350, 2340, 14 350. *Anal.* calcd. for $C_{14}H_{16}N_2O_5$: C 57.53, H 5.52, N 9.58; found: C 57.32, H 5.45, N 9.41.

*1α-Methyl-1,2,3,4,5,10b-hexahydropyrazino[2,1-*a*]isoindol-6-one (**11**) and its 1β-methyl isomer (**12**)*

A solution of the nitro lactam **9***f*, **9***g* (2.5 g) in acetic acid/water (4:1, 50 mL) was hydrogenated over 10% Pd/C, at room temperature and 50 psi (1 psi = 6.89 kPa) for 18 h. The catalyst was removed by filtration on the filtrate evaporated. The residue was taken into 2% HCl and extracted twice with ether. The aqueous solution was made basic (pH 9) with NH_4OH and extracted (3×) with EtOAc. The organic solution was dried and evaporated. The residue was chromatographed on silica gel (100 g/g, acetone/toluene, 2:3) to give isomer **10***f* (1.14 g), ir ($CHCl_3$): 1675, 1120, and 1050 cm^{-1} and isomer **10***g* (0.880 g), ir ($CHCl_3$): as for **10***f*.

A solution of the amine **10***f* (1.13 g) in MeOH (40 mL) and 1 *N* HCl (30 mL) was hydrogenated over 10% Pd/C at room temperature and atmospheric pressure for 48 h. The catalyst was removed by filtration, the filtrate neutralized with concentrated NH_4OH, and the methanol evaporated under reduced pressure. The water solution at pH 9 was salt saturated and extracted with EtOAc (3×). The organic solution was dried and evaporated to give **11** as an oil (0.648 g); ms: 202 $(M)^+$, 159^+, and 146^+.

The maleate salt was prepared in methanol and recrystallized twice from EtOH/ether to give the analytical sample (0.440 g), mp 181–182°C; ir (Nugol): 2800, 1690, 1615, 1575, and 1455 cm^{-1}; uv (MeOH) λ_{max}: 277, 269; ε: 1783, 2387; nmr (DMSO): 1.58 (CH_3, 3H, d, J = 6 Hz), 3.1 (CH_2N, 4H, m), 4.16 (CH_3—*CH*, m), 4.41 (ϕCH, d, J = 10.5 Hz), 5.9 (=CH), 7.4 (4 Ar H), and 11.0 (CO_2H and NH) ppm. *Anal.* calcd. for $C_{16}H_{18}N_2O_6$: C 60.37, H 5.70, N 8.80; found: C 60.25, H 5.68, N 8.79.

In a similar fashion, but hydrogenating the amine derivative **10***g*, was obtained the 1β-methyl isomer **12** as an oil; ms is identical to **11**.

The maleate salt was prepared in methanol and recrystallized twice from EtOH/ether to give the analytical sample in 40% yield from **10***g*, mp 190–191°C; nmr (DMSO): 0.68 (CH_3, 3H, d, J = 7 Hz), 3.2 (CH_2N, 3H, m), 4.3 (CH_3CH and CH_2N, 2H, m), 4.85 (ϕCH, d, J = 4 Hz), 5.9 (=CH), and 7.5 (4 Ar H) ppm; ms: as **11***h*. *Anal.* calcd. for $C_{16}H_{18}N_2O_6$: C 60.37, H 5.70, N 8.80; found: C 60.19, H 5.64, N 8.86.

*1α-Methyl-1,2,3,4,6,10b-hexahydropyrazino[2,1-*a*]isoindole (**14**)*

To a solution of the indolene derivative **11** (0.55 g) in dry THF at 0°C, under nitrogen, a 1 *M* solution of diborane in THF (136 mL) was added dropwise over a period of 10 min. The mixture was then heated under reflux for 18 h. The excess diborane was then destroyed with 10% HCl to pH 2 and the mixture distilled at atmospheric pressure until the distillate temperature reached 90°C. It was then neutralized to pH 12 and extracted (3×) with CH_2Cl_2. The organic solution was dried and evaporated to give **14** as an oil; ms: 188 $(M)^+$, 131^+, 118^+, and 117^+.

The maleate was prepared from the crude **14** and recrystallized twice from EtOH/ether to give the analytical sample (0.26 g), mp 144–145°C; ir (Nujol): 2800, 1620, and 1355 cm^{-1}; nmr (DMSO): 1.42 (CH_3, 3H, d, J = 6 Hz), 3.2 (CH_2N and CHN, 5H, m), 4.0 (ϕCH_2 and ϕCH, 3H, m), 6.1 (=CH, 2H), and 7.35 (4 Ar H) ppm. *Anal.* calcd. for $C_{16}H_{20}N_2O_4$: C 63.14, H 6.62, N 9.21; found: C 63.60, H 6.54, N 9.30.

In a similar fashion but starting from the lactone **12** was obtained the *1β-methyl-1,2,3,4,6,10b-hexahydropyrazino[2,1-*a*]-isoindole* ***15*** as an oil; ms: identical to **14**.

The maleate was prepared in MeOH and recrystallized from EtOH/ether to give the analytical sample in 50% yield from **12**, mp 135–137°C; nmr (DMSO): 1.2 (CH_3, 3H, d, J = 6.5 Hz), 2.7 and 4.4 (CH_2, CH, 8H, m), 6.08 (=CH, 2H), and 7.3 (4 Ar H) ppm. *Anal.* calcd. for $C_{16}H_{20}N_2O_4$: C 63.14, H 6.62, N 9.21; found: C 63.11, H 6.71, N 9.18.

*1,2,3,4,10b-Tetrahydropyrazino[2,1-*a*]isoindol-3,6(3*H*,6*H*)-dione (**13**c)*

A solution of the nitro lactam **9***e* (1.9 g) in methanol (100 mL) was hydrogenated over prehydrogenated PtO_2 (0.5 g) at room temperature and atmospheric pressure. The catalyst was removed by filtration and the filtrate evaporated. The residue was crystallized twice from acetone–water to give the dilactone **13***c* (0.70 g), mp 267–270°C; ir (Nujol): 3220, 3110, and 1680 cm^{-1}; ms: 202 $(M)^+$, 173 $(M - CH_2{=}NH)^+$, 145 $(173 - CO)^+$. *Anal.* calcd. for $C_{11}H_{10}N_2O_2$: C 65.38, H 4.98, N 13.86; found: C 65.47, H 5.16, N 13.76.

In a similar fashion were hydrogenated the nitro derivatives **9***d, e* to yield the dilactone derivatives **13***d* and *e* after chromatography on silica gel (50 g/g, i-propanol/toluene, 3:17). The two isomers were partially separated at a low yield (molecular ion present). However, only **13***e* was partially purified by crystallization from MeOH/ether, in 10% yield, mp 223–224°C; nmr (DMSO): 0.5 (CH_3, 3H, d, J = 6 Hz), 3.70 and 4.25 ($NCH_2C{=}O$, 2H, 2d, J = 17 Hz), 4.82 (ϕCHN, 1H, d, J = 4 Hz), and 7.40 (4 Ar H) ppm; ms: 216 $(M)^+$, 173 $(M - O{=}C{=}NH)^+$. *Anal.* calcd. for $C_{12}H_{12}N_2O_2$: C 66.65, H 5.60, N 12.96; found: C 66.30, H 5.56, N 12.99. (This product is unstable.)

*1,3-Dihydro-3-methylene-2-phenylmethyl-2*H*-isoindol-1-one (**16**a)*

Method A

A solution of the nitro lactone **7***a* (1.3 g) and benzylamine (1.3 mL) in benzene (50 mL) was heated under reflux for 18 h. The solvent was evaporated and the residue was chromatographed on silica gel (30 g/g, ether/hexane, 1:1). The residue was crystallized from ether/hexane to give the pure **16***a* (0.22 g), mp 116–117°C; uv (MeOH) λ_{max}: 305, 262, 254, 223, 217; ε: 7790, 12 940, 14 350, 37 315, 38 185; nmr ($CDCl_3$): 4.75 and 5.10 (=CH_2, 2H, 2d, J = 2.5 Hz), 5.0 ($CH_2\phi$, 2H, s), 7.22 (5 Ar H), and 7.65 (4 Ar H) ppm. *Anal.* calcd. for $C_{16}H_{13}NO$: C 81.68, H 5.57, N 5.95; found: C 81.58, H 5.48, N 5.94.

Method B

A solution of the nitro lactam **9***a* (0.95 g) and benzylamine (1 mL) in benzene (50 mL) was heated under reflux for 18 h. The product was isolated and purified as in Method A to give an identical product, mp 114–116°C (mixture mp 114–116°C), as shown by ir and nmr spectroscopy.

*1,3-Dihydro-3-methyl-2-phenylmethyl-2*H*-isoindole-1-one (**17**a)*

A solution of the *exo* methylene derivative **14***a* (1.5 g) in methanol (200 mL) was hydrogenated over 10% Pd/C (1.0 g) at atmospheric pressure and room temperature. The catalyst was removed by filtration and the filtrate evaporated. The residue was chromatographed on silica gel (30 g/g, ether/hexane, 1:3) to give **17***a* as an oil (1.0 g); nmr ($CDCl_3$): 1.42 (CH_3, 3H, d, J = 7 Hz), 4.25 and 5.32 (CH_2, 2H, 2d, J = 1.5 Hz), 4.35 (CH, 1H, q, J = 7 Hz), and 7.3 (9 Ar H) ppm; ms: 237 $(M)^+$, 146 $(M - CH_2\phi)^+$, 133 $(OCH_2—N{=}CO)^+$. *Anal.* calcd. for $C_{16}H_{15}NO$: C 80.98, H 6.37, N 5.90; found: C 80.88, H 6.37, N 5.84.

*1,3-Dihydro-3-methyl-2[2-(4-morpholinyl)ethyl]-2*H*-isoindol-1-one* ***17****i*

The *exo* methylene derivative **16***i* was obtained as in Method A and the crude product was hydrogenated as for **17***a*. The HCl salt was prepared directly from the crude mixture and crystallized 4 times from i-propanol/hexane to give the analytical sample in 17% yield, mp 208–209°C; nmr (DMSO: 1.45 (CH_3, 3H, d, J = 7 Hz), 3.6 (CH_2, 12H, m), 4.8 (ϕCHN, 1H, q, J = 7 Hz), and 7.6 (4 Ar H) ppm; ms: 260 $(M)^+$, 100^+, and 160^+. *Anal.* calcd. for $C_{15}H_{21}ClN_2O_2$: C 60.70, H 7.13, N 9.44; found: C 60.65, H 7.31, N 9.42.

*3-Methyl-1,3-dihydro-2-(2-thiazolyl)-2*H*-isoindol-1-one (17*h*)*

The *exo* methylene derivative **16***h* was obtained from **9***h* (10 g) as described in Method B. The benzene solution was washed with 2 *N* HCl, brine (3×), dried, and evaporated. The residue (3.5 g) in acetonitrile (300 mL) was hydrogenated over 10% Pd/C (1.75 g) at atmospheric pressure and room temperature. The catalyst was removed by filtration and the filtrate evaporated. The residue was chromatographed on silica gel (100 g/g, ether/hexane, 1:1) to give an oil (1.6 g). It was crystallized from benzene/i-propyl ether to give the pure **17***h*, mp 127–129°C; nmr ($CDCl_3$): 1.78 (CH_3, 3H, d, J = 7 Hz), 5.42 (CH, 1H, q, J = 7 Hz), 7.02 (=CHS, 1H, d, J = 4 Hz), 7.52 (4 Ar H), and 7.93 (1 Ar H) ppm; ms: 230 $(M)^+$, 215 $(M - CH_3)^+$. *Anal.* calcd. for $C_{12}H_{10}N_2OS$: C 62.58, H 4.38, N 12.17; found: C 62.61, H 4.47, N 12.31.

Autoxidation in micelles. Synergism of vitamin C with lipid-soluble vitamin E and water-soluble Trolox

LAWRENCE ROSS COATES BARCLAY,[1] STEVEN JEFFREY LOCKE, AND JOSEPH MARK MACNEIL
Department of Chemistry, Mount Allison University, Sackville, N.B., Canada E0A 3C0

Received May 23, 1984

LAWRENCE ROSS COATES BARCLAY, STEVEN JEFFREY LOCKE, and JOSEPH MARK MACNEIL. Can. J. Chem. **63**, 366 (1985).

A study was made of the effect of the inhibitors ascorbic acid (C), α-tocopherol (E), and 6-hydroxy-2,5,7,8-tetramethylchroman-2-carboxylate (Trolox, T) on the autoxidation of linoleic acid in 0.50 *M* sodium dodecyl sulfate (SDS) micelles at pH 7.0 in phosphate buffer. Reactions were thermally initiated at 30°C in the SDS micelles by a micelle-soluble initiator, di-*tert*-butylhyponitrite (DBHN). Although water-soluble C alone is an inefficient inhibitor, when combined with micelle-soluble E, it acts synergistically with the latter to extend the efficient antioxidant action of E beyond the sum of the induction periods of C and E acting separately. Similarly C acts synergistically with the water-soluble antioxidant, T. Quantitative studies of these effects under controlled rates of initiation (R_i) reveal that C functions to regenerate a mole of E (or T) per mole of C used. Kinetic studies show that the rate of autoxidation is first order in micellar linoleic acid and one-half order in micellar DBHN concentrations. Therefore, the classical rate law, $-dO_2/dt = k_p[R—H]\,(R_i)^{1/2}/(2k_t)^{1/2}$ is followed. The higher oxidizability ($k_p/2k_t^{1/2} = 4.48 \times 10^{-2}\ M^{-1/2}\ s^{-1/2}$) of linoleate in micelles compared to that in homogeneous solution in chlorobenzene ($k_p/2k_t^{1/2} = 2.30 \times 10^{-2}\ M^{-1/2}\ s^{-1/2}$) is interpreted in terms of the effect of the polar interfacial region of the micelles on a dipolar transition state, $R—\overset{-}{O}\overset{-}{O}{:}\ \overset{+}{H}\cdot R$, of the propagation reaction.

LAWRENCE ROSS COATES BARCLAY, STEVEN JEFFREY LOCKE et JOSEPH MARK MACNEIL. Can. J. Chem. **63**, 366 (1985).

On a étudié l'effet de l'acide ascorbique (C), de l'α-tocophérol (E) et de l'hydroxy-6 tétraméthyl-2,5,7,8 chromanecarboxylate-2 (Trolox, T) comme inhibiteurs de l'autoxydation de l'acide linoléique, dans des micelles à 0,50 *M* de dodécylsulfate de sodium (DSS) et dans un tampon de phosphate à un pH de 7,0. A 30°C, les réactions sont induites thermiquement dans les micelles de DSS en faisant appel à un initiateur soluble dans la micelle, le di-*tert*-butylhyponitrite (DBHN). Bien que C, qui est soluble dans l'eau, ne soit pas un inhibiteur efficace lorqu'on l'utilise seul, il agit d'une façon synergique lorsqu'on le combine à l'inhibiteur E, qui est soluble dans la micelle; il en résulte que l'action antioxydante efficace du composé E est prolongée au-delà de la somme des périodes d'induction des composés C et E agissant séparément. De la même manière, le composé C agit de façon synergique avec l'antioxydant qui est soluble dans l'eau. Des études quantitatives de ces effets, utilisant des vitesses d'initiation (R_i) contrôlées, révèlent que C regère une mole de composé E (ou T) par mole de C utilisée. Les études cinétiques montrent que la vitesse d'autoxydation est d'ordre un en acide linéloique micellaire et d'ordre une demie en concentration de DBHN micellaire. Donc, la réaction obéit à la loi classique de vitesse $-dO_2/dt = k_p[R—H]\,(R_i)^{1/2}/(2k_t)^{1/2}$. On interprète le fait que le linoléate dans les micelles est plus oxydable ($k_p/2k_t^{1/2} = 4{,}48 \times 10^{-2}\ M^{-1/2}\ s^{-1/2}$) qu'une solution homogène dans le chlorobenzène ($k_p/2k_t^{1/2} = 2{,}30 \times 10^{-2}\ M^{-1/2}\ s^{-1/2}$) en fonction de l'effet de la région interfaciale polaire des micelles sur un état de transition dipolaire $R—\overset{-}{O}\overset{-}{O}{:}\ \overset{+}{H}\cdot R$ de la réaction de propagation.

[Traduit par le journal]

Introduction

Important structural and functional properties of biomembranes are disrupted by the peroxidation of unsaturated membrane lipids. Autoxidation in biological systems is associated with important pathological events including aging (1, 2) and heart attack (3), and with the action of foreign toxic substances (4).[2]

We have shown that *quantitative* kinetic studies of autoxidation can be made in biologically important microenvironments such as bilayers (5) and micelles (6). Recently we have demonstrated that water-soluble initiators and inhibitors can be used to quantitatively study autoxidations in these systems (7). The kinetic data with aqueous initiator/inhibitor combinations were in agreement with those for lipid-soluble initiators and inhibitors, and with various lipid-soluble and aqueous-soluble initiator/inhibitor combinations. These results led us to extend our preliminary studies of synergism between lipid-soluble α-tocopherol and water-soluble ascorbate (6) to the present study of the interaction between ascorbate and both a lipid-soluble inhibitor (α-tocopherol) and a water-soluble inhibitor, 6-hydroxy-2,5,7,8-tetramethylchroman-2-carboxylate (Trolox).

This study was undertaken to answer two fundamental questions concerning autoxidation in microenvironments.

1. *Are combinations of water-soluble antioxidants (e.g. ascorbate and Trolox) more effective in inhibiting autoxidation than either alone, as was observed for ascorbate and the lipid-soluble α-tocopherol (6) and, if so, what is the quantitative nature of these synergistic effects?*

Recent outstanding publications by Ingold and Burton have finally established the key role of α-tocopherol as an antioxidant (8–10). While ascorbic acid is also implicated in a wide variety of biological phenomena and continues to attract a great deal of interest (11, 12), its role in lipid peroxidation is not well understood. In biological tissue, it is reported to act as either an inhibitor or as a catalyst of lipid peroxidation (13, 14). Quantitative data on its antioxidant activity is lacking. We hope that the present quantitative study on the interaction of ascorbate with other inhibitors will clarify its role as an antioxidant in micellar autoxidation. These results in turn have important implications for autoxidations in biological systems.

2. *Does autoxidation of a substrate solubilized in micelles follow the same classical rate law well known for homogeneous solutions?*

The autoxidation of organic substrates in homogeneous solu-

[1]Author to whom correspondence may be addressed. For a preliminary account of this work, see ref. 6.

[2]Reviews on this subject (4) include the effect of oxygen toxicity (I. Fridovich, Vol. I, Chapt. 6, p. 239), air pollutants (D.B. Menzel, Vol. II, Chapt. 6, p. 181, and J.B. Mudd, Vol. II, Chapt. 7, p. 203), and liver damage (E.S. Reynold and M.T. Moslen, Vol. IV, Chapt. 2, p. 49).

tion at oxygen pressures near 760 Torr (1 Torr = 133.3 Pa) is known to be a free-radical chain process which proceeds by the following reaction sequence (15–18).

[1] Initiation: formation of R· (or ROO·) rate = R_i

[2] Propagation: $R\cdot + O_2 \xrightarrow{\text{fast}} ROO\cdot$

[3] $ROO\cdot + RH \xrightarrow{k_p} ROOH + R\cdot$

[4] Termination: $ROO\cdot + ROO\cdot \xrightarrow{2k_t}$ nonradical products + O_2

The classical rate law for a system which follows these reactions is given by eq. [5]:

$$[5] \quad -\frac{d[O_2]}{dt} = \frac{k_p}{2k_t^{1/2}}[RH]R_i^{1/2}$$

where RH is the organic substrate, R_i the rate of chain initiation, k_p is the propagation rate constant, and k_t the termination rate constant. The ratio $k_p/(2k_t)^{1/2}$ is known as the "oxidizability" of the substrate. For our quantitative autoxidation studies, the rate of chain initiation (R_i) must be known and reproducible. This is accomplished by using azo initiators of known k_i. Because of the solvent "cage effect", the R_i must be determined, usually by the inhibitor method (19), using a phenolic antioxidant which terminates two chains by reacting with two peroxyls. Under these conditions:

$$[6] \quad R_i = 2[ArOH]/\tau$$

$$[7] \quad e = R_i/2k_i[R{-}N{=}N{-}R]$$

where τ is the length of time during which the reaction is inhibited and e is the efficiency of chain initiation.

Micelles (0.50 *M* SDS) were selected as microenvironments for these model quantitative studies for two main reasons: (1) such micelles are optically clear and concentrations of solubilized inhibitor and initiator can be measured directly by absorption spectral methods, and (2) α-tocopherol can be solubilized in micelles and this makes it possible for such micellar α-tocopherol to be transported to the site of autoxidation (6). Thus it should be possible to directly compare the antioxidant activity of lipid-soluble α-tocopherol with water-soluble Trolox and also to compare the effect of a combination of ascorbate with either of these inhibitors.

Results

1. *The antioxidant activity of ascorbate (C), and of combinations of C with α-tocopherol (E) and with Trolox (T)*

The system selected for synergism studies was linoleic acid in 0.50 *M* sodium dodecyl sulphate (SDS) micelles because this system gave convenient rates for our studies and the kinetics followed the classical rate law in the concentration range employed (*vide infra*). Reactions were initiated by using the lipid-soluble initiator, di-*tert*-butylhyponitrite (DBHN).

A new technique was required for quantitative studies using α-tocopherol as an antioxidant to inhibit autoxidation initiated in micelles. Previous sattempts to transport this excellent antioxidant through an aqueous phase were unsuccessful (5). However, for the present work we found that stock solutions of α-tocopherol could be prepared in 0.50 *M* SDS (1.2 × 10^{-2} molar in the micellar volume) by sonication and the concentration determined by ultraviolet spectroscopy. This greatly improved the precision of insertion of known amounts of this

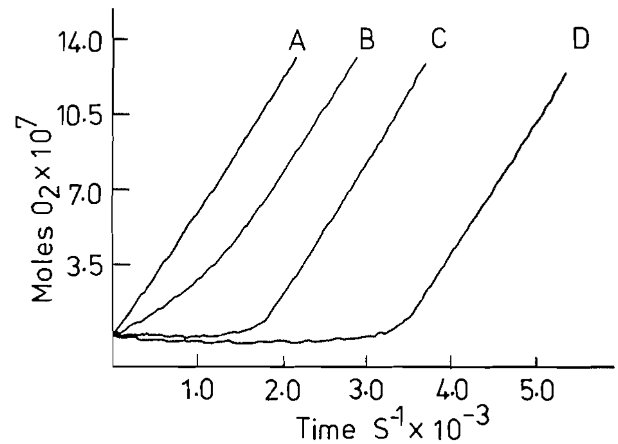

FIG. 1. Autoxidation of linoleic acid (6.43 × 10^{-5} mol) in 2.00 mL 0.50 *M* SDS – phosphate buffer (pH 7.0), initiated with DBHN (1.81 × 10^{-5} mol) at 30°C: A, uninhibited reaction; B, inhibited with ascorbic acid (4.80 × 10^{-8} mol); C, inhibited with α-tocopherol (2.34 × 10^{-8} mol); D, inhibited with ascorbic acid (4.80 × 10^{-8} mol) and α-tocopherol (2.34 × 10^{-8} mol).

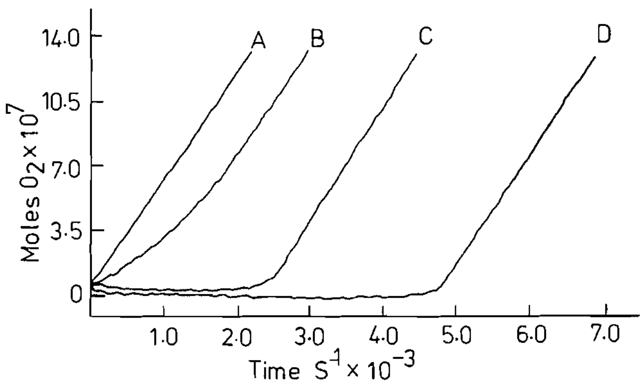

FIG. 2. Autoxidation of linoleic acid (6.43 × 10^{-5} mol) in 2.00 mL 0.50 *M* SDS – phosphate buffer (pH 7.0), initiated with DBHN (1.53 × 10^{-5} mol) at 30°C: A, uninhibited reaction; B, inhibited with ascorbic acid (4.77 × 10^{-8} mol); C, inhibited with Trolox (2.36 × 10^{-8} mol); D, inhibited with ascorbic acid (4.77 × 10^{-8} mol) and Trolox (2.36 × 10^{-8} mol).

antioxidant and it proved to be an effective inhibitor when introduced this way (see Fig. 1).

In the initial experiments, we compared the effect of the inhibitors C and E, and C and T, separately and in combinations, on the autoxidation of linoleic acid in SDS micelles. The results of a typical experiment are illustrated in Fig. 1 for C and E and in Fig. 2 for C and T and the data are summarized in Table 1.

A series of experiments was then conducted in order to *quantitatively* determine the effect of C on the inhibiting effect of E and of T. For this purpose, the ratio of C to E (or C to T) was kept constant in each experiment and the rate of initiation (R_i) determined immediately before and again after the determination of the extended induction period by the combination of these inhibitors. The results of these experiments are given in Tables 2 and 3.

2. *Kinetics of autoxidation in SDS micelles*

In order to use DBHN in our quantitative kinetic studies, it was necessary to have a convenient analytical procedure to determine its concentration in micellar solutions and also a

sorption agreed with literature values in homogeneous solution (5, 20).

A series of kinetic runs was carried out to measure the dependence of the rate of oxygen absorption on linoleic acid concentration [R—H] and on DBHN concentration.[4] Typically, the micellar substrate concentrations were varied by a factor of four (e.g. 0.0643 to 0.257 M) within a kinetic run by injecting linoleic acid into the reaction from a precision syringe. The DBHN micellar concentrations were varied six-fold (typically 0.86×10^{-2} to 5.08×10^{-2} M) in separate runs. The R_i and efficiency, e, in each experiment were determined by injecting α-tocopherol of known concentration in 0.50 M SDS into the system. A stoichiometric factor (n) of 2 for α-tocopherol was used (5, 8) for calculating the R_i. The results of these studies are outlined in Table 4.

Discussion

1. *Synergistic effects of ascorbate (C) on α-tocopherol (E) and on Trolox (T)*

The combination of inhibitors C with E, and C with T, exhibited two remarkable effects on the micellar autoxidation of linoleate.

(1) Although C is a relatively poor inhibitor when used alone (Fig. 1B), *the combination with E extends the typically efficient induction period observed for E alone* (Figs. 1C and D).

(2) The induction periods observed by combinations of E + C ($\tau_{(E+C)}$) *were longer than the sum of the separate induction periods* ($\tau_E + \tau_C$) for the same amounts of E and C (see Table 1). The amount of synergism observed in these experiments (i.e. as reflected in $\tau_{(E+C)} - (\tau_E + \tau_C)$, last column of Table 1) was typically in the range of 9–11%. Very similar behavior was exhibited when water-soluble inhibitors C and T were added to the aqueous phase. That is, the efficient induction period observed by Trolox was extended when used in combination with ascorbate. Furthermore, the combination of T + C gave induction periods ($\tau_{(T+C)}$) longer than the sum of the separate induction periods ($\tau_T + \tau_C$) (Table 1, last column). The amount of synergism observed here (ca. 20%) was significantly greater than that for C and E.

Two characteristics of the induction period during the combination of C and E clearly indicate that C functions so as to regenerate the E: (1) the *extended* induction period ($\tau_{(E+C)}$) observed for C and E combined exhibited the same efficient inhibition of autoxidation as observed for E (Fig. 1), and (2) high pressure liquid chromatography (hplc) analyses made during a typical $\tau_{(E+C)}$ induction period showed that the amount of E remained unchanged during the first half of the induction period. On the other hand, hplc analysis from a comparable run without C but the same amount of E indicated that the latter was being consumed as expected from the first of the induction period. Thus the interaction of E and C (and presumably T and C) involves a hydrogen transfer equilibrium of the type

$$\dot{E} + \bar{C} \rightleftharpoons E + \dot{\bar{C}} \text{ (or } \dot{T} + \bar{C} \rightleftharpoons T + \dot{\bar{C}}\text{)}$$

[4] A micellar reaction volume of 2.5×10^{-4} liters for 2.00 mL of 0.50 M SDS, estimated from density measurements (6, 21), was used in concentration calculations. The reaction volume calculated from the equation $v = 27.4 + 26.9n$ Å^3 (n = number of carbons) (22) gives a volume of 2.0×10^{-4} liters but this different volume does not change our results significantly.

[a] Concentrations are moles per liter of micelles, using a calculated volume of 2.5×10^{-4} L for 2.00 mL of 0.50 M SDS, and the amounts of DBHN and α-toc were measured spectrally.
[b] The R_i s were calculated using the e values measured for each run and k_i for DBHN = $3.2 \times 10^{-6}\ s^{-1}$.
[c] Corrected for the evolution of nitrogen from the initiator (DBHN).

The synergism observed is therefore analogous to the general type defined by Mahoney and Da Rouge (23, 24).

In our case, the magnitude of the synergistic effects will depend upon the favourable competition of ascorbate ($\dot{\bar{C}}$) with the generated peroxyl radical for the vitamin E radical, $\dot{E}$. That is, the effect observed will depend upon the rate constant ratio for:

$$\dot{E} + \bar{C}/\dot{E} + ROO\cdot$$

The rate constant for the hydrogen transfer reaction involved in $\dot{E} + \bar{C}$ has been measured ($1.55 \pm 0.2 \times 10^6\ M^{-1}\ s^{-1}$) (25), as has the rate constant for the reaction of α-tocopherol with peroxyl radicals ($ArOH + ROO\cdot \rightarrow ROOH + ArO\cdot$) ($3.24 \pm 0.15 \times 10^6\ M^{-1}\ s^{-1}$) (8). 4-Peroxycyclohexadienone adducts have been identified from the addition of peroxyl radicals to the α-tocopheryl radical (i.e. $E + ROO\cdot \rightarrow$ adduct) (26). We are not aware of a rate constant measurement for this reaction but the value is estimated to be approximately $7.3 \times 10^8\ M^{-1}\ s^{-1}$.[5] The successful competition of $\bar{C}$ for $\dot{E}$ observed here is attributed to the relatively high concentration of $\bar{C}$ (approximately 2.4×10^{-5} molar in the aqueous phase) and the probability that the polar phenoxyl head group of $\dot{E}$ is located near the polar micelle–water interface, allowing for effective hydrogen transfer between $\bar{C}$ and $\dot{E}$.

Niki *et al.* have reported electron spin resonance results to show that vitamin C regenerates vitamin E from the α-chromanoxyl radical (27) and, while this current work was in progress, they published an important paper to show that vitamin C and vitamin E are effective antioxidants *when used in combination* during the autoxidation of methyl linoleate (28). However, their results differ from ours in two important respects. Their studies were carried out in homogenous solution, and the inhibition period for C + E was lengthened to *the sum* of the inhibition period when either C or E was used alone; that is, they did not report a synergistic extension.

The results of our quantitative studies on the effects of varying the ratio of C/E and C/T on the induction periods give further insights into the efficiency with which ascorbate in the aqueous phase interacts to regenerate α-tocopherol in the micellar phase and likewise to regenerate Trolox in the aqueous phase. The results in Table 2 illustrate the *extension*, $\tau_{(E+C)} - \tau_E$, of the efficient induction periods ($\tau_{(E+C)}$) due to additions of known amounts of E and C in separate experiments where the rate of chain initiation (R_i) was controlled, by using known amounts of the lipid-soluble initiator DBHN, and monitored throughout each run by the measurement of induction periods (τ_E) with the known amounts of E. The extensions of the

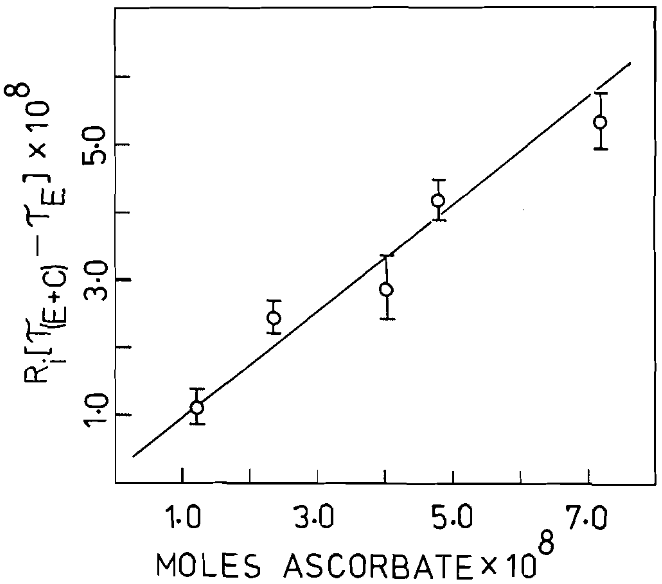

FIG. 3. Autoxidation of linoleic acid (6.43×10^{-5} mol) inhibited with α-tocopherol (E) and with ascorbate (C) in 2.00 mL 0.50 *M* SDS – phosphate buffer (pH 7.0), initiated with DBHN. Plot of the extension of the induction period × R_i versus the moles of ascorbate (see text and Table 2). The error bars represent standard deviations of 3 or 4 measurements.

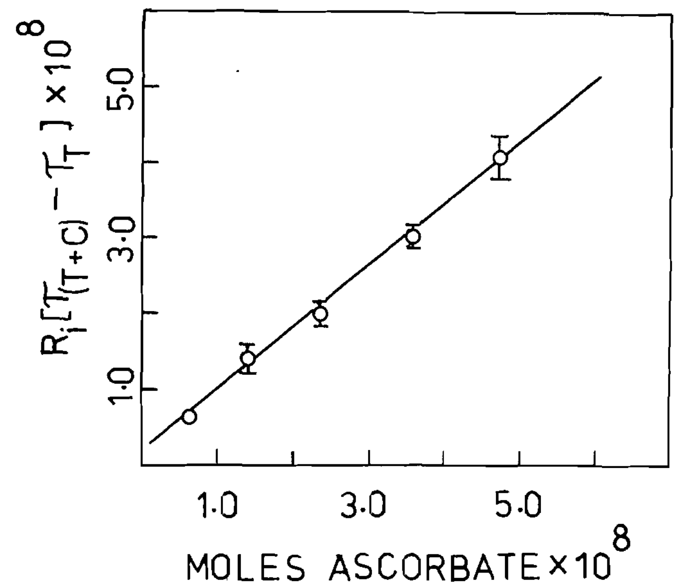

FIG. 4. Autoxidation of linoleic acid (6.43×10^{-5} mol) inhibited with Trolox (T) and with ascorbate (C) in 2.00 mL 0.50 *M* SDS – phosphate buffer (pH 7.0), initiated with DBHN. Plot of the extension of the induction period × R_i versus the moles of ascorbate (see text and Table 3). The error bars represent standard deviations of 3 or 4 measurements.

induction periods can be taken as an indication of the amount of vitamin E regenerated for a particular R_i and the product of R_i $[\tau_{(E+C)} - \tau_E]$ is thus a measure, indirectly obtained, of the amount of radicals trapped by C. When calculated per mole of C, one has a measure of the "stoichiometric factor" (n) for vitamin C *under these conditions*, in other words, a measure of the moles of vitamin E regenerated per mole of C. At lower combined induction periods ($\tau_{(E+C)}$), as in Runs 48, 54, and 56, a maximum stoichiometric factor of approximately one is observed. We find a near constancy of the value of n (the last column of Table 2) as the mole ratio of C to E was varied from 0.62 to 2.1. This is also illustrated in a near linear variation of R_i $[\tau_{(E+C)} - \tau_E]$ with C_{moles} as illustrated in Fig. 3 where the computed slope up to 5×10^{-8} moles of C is 0.78. At longer induction periods, usually corresponding to higher ascorbate, there appears to be a drop in n. This may be due to the loss of C in oxidation processes. Vitamin C does undergo slow oxidation under these conditions, and it is estimated that up to 20% of it would be consumed at higher combined induction periods (i.e. longer $\tau_{(E+C)}$).[6]

Remarkably similar quantitative results were obtained for the interaction of ascorbate with Trolox (T) as summarized in Table 3 and Fig. 4. That is, the stoichiometric factor, n, for the regeneration of T by C was approximately constant as the ratio C/T was varied from 0.264 to ca. 1.9. The value of n was approximately one at low C as in Runs 41, 42, and 43, and the slope of the plot (Fig. 4) of R_i $[\tau_{(T+C)} - \tau_T]$ versus C gives a value of $n = 0.82$ up to $C = 5 \times 10^{-8}$ moles. After longer extended induction periods ($\tau_{(T+C)} = 7.3 \times 10^3$ s), the value of n decreases, probably due to oxidation of C.[7]

2. *The rate law and oxidizability of linoleate in SDS micelles*

In order to determine the oxidizability of linoleate in SDS micelles, it is necessary to demonstrate that the rate of oxygen uptake follows the classical rate law given in eq. [5]. This means that the rate should be first order in substrate concentration in the micelles and one-half order in the R_i or initiator concentration in the micelles. For purposes of the calculations shown in Table 4, the assumption is made that the linoleate and the initiator, DBHN, are both completely partitioned into the micellar phase. This seems reasonable since DBHN is only very slightly soluble in water (5). We have not measured the partition coefficient of linoleic acid between the water–SDS phases, but is reasonable to assume that it is essentially all in the SDS phase, since the mole ratio of SDS to linoleate was never less than approximately 15:1. If the aggregation number of SDS is taken as 62 (30), this means there are, on the average, four linoleate molecules per SDS micelle for the most concentrated linoleate used (0.257 *M* in the micellar phase). The data in Table 4 indicate that the corrected rates follow very closely the classical first-order rate law for order in substrate. The actual value found for the order in [R—H] was 0.970 ± 0.077, averaged over six separate runs where the substrate was varied by a factor of four in each run. Figure 5 illustrates the linear relationships found for the variation of corrected rates with substrate concentration in the micelles for three typical runs with different DBHN concentrations. Correlation coefficients were better than 0.997 for all such runs.

The order with respect to initiator (DBHN) concentration in the micelle was more difficult to determine precisely. It is not possible to vary the DBHN concentration in a single experi-

[6] We have found the self-initiated rate of autoxidation of 5×10^{-3} molar ascorbate in the presence of 0.50 *M* SDS at pH 7.0 to be 1.55×10^{-7} *M* s^{-1} and the rate in the presence of DBHN (1.47×10^{-5} moles) under these conditions to be 2.01×10^{-7} *M* s^{-1}. This is somewhat higher than a reported rate of ca. 10^{-10} *M* s^{-1} (29) for 5×10^{-5} *M* ascorbate, when corrected for the concentration difference.

[7] Under our conditions, the limiting value of n is one for E + C and T + C. We recognize that a larger value might be applicable at lower R_i and high E/C (T/C) ratios. This condition is under investigation.

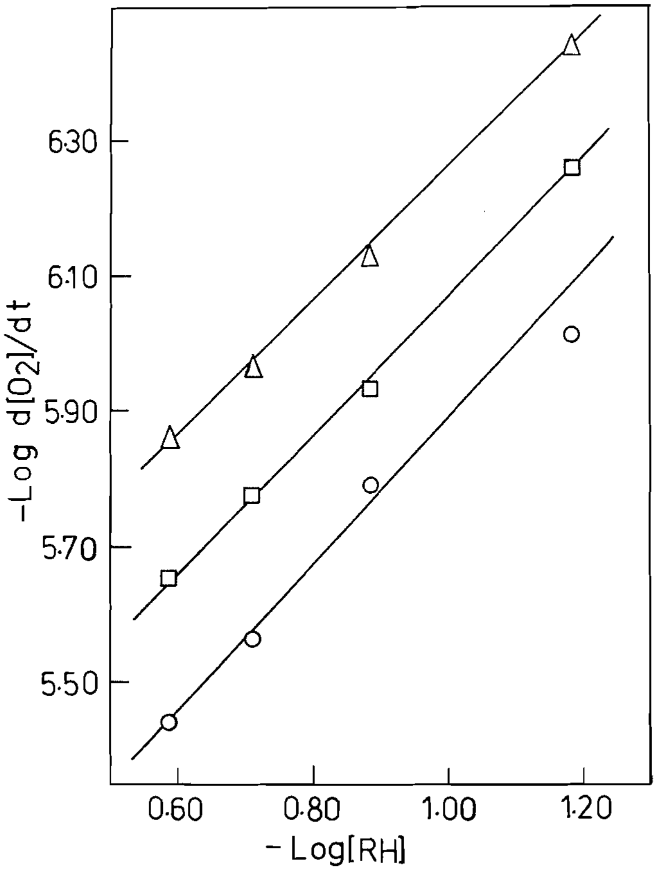

FIG. 5. Plot for the order in substrate for autoxidation of linoleic acid (0.0643 M to 0.257 M) in 2.00 mL 0.50 M SDS – phosphate buffer (pH 7.0): △, [DBHN] = 1.17×10^{-2} M; □, [DBHN] = 1.88 M; ○, [DBHN] = 5.14×10^{-2} M (taken from Table 4).

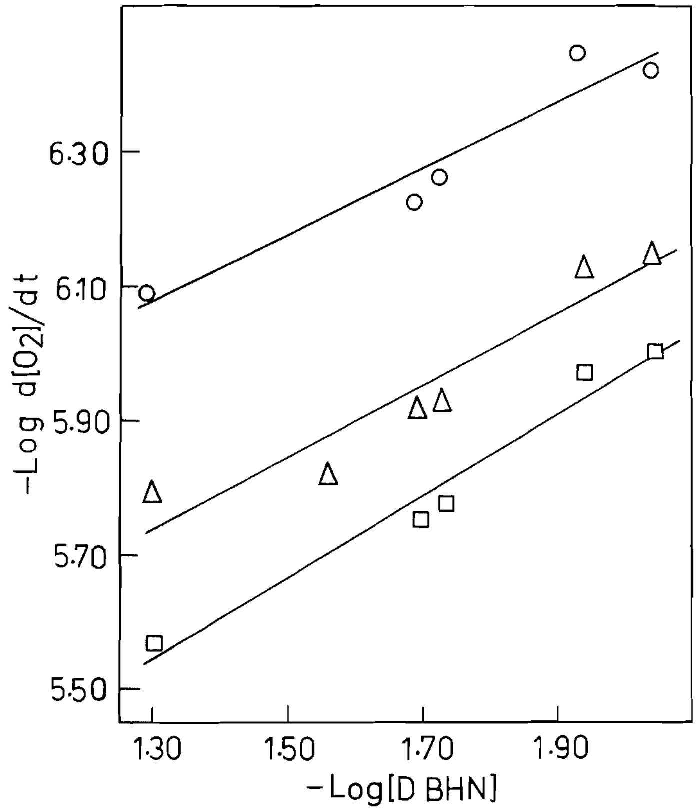

FIG. 6. Plot for the order in initiator (DBHN) for autoxidation of linoleic acid in 2.00 mL 0.50 M SDS – phosphate buffer (pH 7.0): ○, [R—H] = 0.0643 M; △, [R—H] = 0.129 M; □, [R—H] = 0.193 M (taken from table 4).

ment; therefore, measurements of the variation of corrected rates with [DBHN] were taken from separate experimental runs. Furthermore the [DBHN] was measured spectrally on diluted samples from these runs. There was a scatter of the points from plotting corrected rates versus [DBHN] as shown in Fig. 6, where the correlation coefficient was as low as 0.95. Nevertheless, the average order with respect to [DBHN] was 0.547 ± 0.050 and from this we conclude that the reaction is one-half order in [DBHN].

The efficiency, e, of chain initiation by DBHN in these 0.50 M SDS micelles (Table 4), is considerably lower (28.8 ± 2.5%) than that found in homogeneous solution in chlorobenzene (66%) (5). The lower e for DBHN in the micelles compared to that in chlorobenzene is attributed to the higher microviscosity of micelles. A reported microviscosity of 11.5 cP at 25°C (or 10 cP at 40°C) (31) contrasts with the bulk viscosity of 0.73 cP for chlorobenzene (5). Although there is no simple relationship between medium viscosity and initiator efficiencies (32), it is known that e for DBHN decreases as viscosity increases due to a larger proportion of free radical recombination within the solvent cage where they are formed (32). The e for DBHN in autoxidation initiated in bilayers, where the microviscosity is even higher, was further reduced to only 9.1% (5). Thus the lowering of e in micelles is expected and indeed serves to support the idea that these autoxidations are initiated in the micellar phase.

The near constancy of the oxidizability values for linoleate (last column of Table 4) also indicates that the classical rate law is followed for autoxidation in SDS micelles. The value obtained, $4.48 \pm 0.37 \times 10^{-2}$ $M^{-1/2}$ $s^{-1/2}$, is approximately *double* the reported value of 2.10×10^{-2} $M^{-1/2}$ $s^{-1/2}$ (33) measured in chlorobenzene.[8]

The increased substrate oxidizability of linoleate in SDS is attributed to the effect of the polarity of the micelles on the rate-determining step (i.e. the k_p) of the autoxidation. Solvent effects on the autoxidation of hydrocarbons are known to correlate with the dielectric constant of the medium (34, 35), apparently due to a general solvent effect on a transition state with dipolar character of the type

$$\text{R—O—O}\cdot + \text{H—R} \xrightarrow{k_p} [\text{R—O—O:}^- \ \text{H}\cdot\overset{+}{\text{R}}]$$

The local microenvironment can influence the physical and chemical behavior of solubilized species in micelles and even nonpolar hydrocarbons can be concentrated primarily near the micelle–water interface (36). Peroxyl radicals are known to be polar (5, 37) and are expected to reside mainly in or near the polar region at the interface.

The dielectric constant in this region of SDS micelles has been estimated from fluorescence studies (38) to be 45. Dielectric constant changes from 5.6 for chlorobenzene to 36 or 38 for solvents like nitromethane and acetonitrile have been

[8] We have recently determined the oxidizability of methyl linoleate ($2.26 \times 10^{-2} - 9.04 \times 10^{-2}M$) in chlorobenzene initiated by azobisisobutyronitrile to be 2.30 ± 0.30 $M^{-1/2}$ $s^{-1/2}$ (average of six measurements), which is in excellent agreement with the reported (33) result.

shown to approximately double the oxidizability of hydrocarbon substrates such as tetralin (34) and cyclohexene (35). This is in general agreement with the above postulate for an increase in linoleate oxidizability due to the location of the chain propagating free radicals in such a polar region of the micelle.[9]

Conclusions

1. Vitamin C has an important synergistic function in autoxidations and can act from the aqueous phase to regenerate a mole of α-tocopherol in the micellar phase per mole of ascorbate during the inhibited autoxidation of linoleate in a SDS microenvironment at pH 7.0.

2. Vitamin C also acts synergistically with a water-soluble inhibitor (Trolox) to inhibit the autoxidation of linoleate when the autoxidation is initiated in the micellar microenvironment.

3. The autoxidation of linoleate in 0.50 M SDS micelles follows the classical rate law for autoxidation since the rate of oxygen uptake was first order in substrate concentration and one-half order in initiator concentration in the micelles.

4. The higher oxidizability of linoleate in SDS micelles ($4.48 \times 10^{-2}\ M^{-1/2}\ s^{-1/2}$) compared to that in homogeneous solution in chlorobenzene ($2.30 \times 10^{-2}\ M^{-1/2}\ s^{-1/2}$) is attributed to the increased polarity of the micellar microenvironment. The polar peroxyl radicals, involved in the rate-propagating hydrogen abstraction reaction from the substrate, are expected to reside in the polar interface between the micellar core and the water. The higher dielectric of this region would provide a favourable solvent effect on a dipolar transition state for hydrogen abstraction.

These model experiments in micellar microenvironments have important implications for protective mechanisms in biological systems, especially from our findings which show that a water-soluble inhibitor can interact synergistically with a lipid-soluble one. We are currently extending these initial studies to other substrates in micellar systems and other inhibitors that may interact with vitamin E.

Experimental

1. *Materials and preparations*

Phosphate buffer

Solutions were prepared from 0.05 M of each of NaH_2PO_4 and Na_2HPO_4 in glass-distilled water containing 1×10^{-4} M EDTA. Immediately before use, this solution was passed through a Chelex-100 column (Bio-Rad 50–100 mesh) to remove traces of heavy metals (29).

Sodium dodecyl sulfate

The SDS was electrophoresis purity reagent (Bio-Rad).

Linoleic acid

The linoleic acid (Nu-Chek-Prep > 99%) was found to be free of hydroperoxides by tlc analysis on silica gel and testing with a *N,N*-dimethyl-*p*-phenylenediamine spray.

Initiators

DBHN, prepared by the method of Mendenhall (39), was recrystallized from cold methanol and stored as a solid at −30°C. Azobis(2-amidinopropane·HCl) was obtained from Polysciences, Inc. and stored at −30°C. The solutions of DBHN in 0.50 M SDS were prepared for each run by vortex stirring the DBHN (ca. 7 mg) with 5.00 mL of 0.50 M SDS for 20 min. This solution was gravity filtered; 1.00 mL was diluted to 50 mL with 1 : 1 methanol–water and analyzed for DBHN using the λ_{max} at 227 nm.

Inhibitors

α-Tocopherol (Eastman–Kodak) was stored in known concentrations in hexane under argon at −30°C. Solutions in SDS were prepared as follows. A 2.00-mL sample of the hexane solution (8.77×10^{-3} M in α-tocopherol) was evaporated to a thin film on the rotary evaporator under nitrogen. The 0.50 M SDS – phosphate buffer (12.00 mL) was added and this mixture was sonicated under argon in a Bransonic 220 bath sonicator at 20°C for 3 h. This stock solution could be stored under argon at least 1 week without a decrease in α-tocopherol concentration. When used as an inhibitor, the α-tocopherol concentration was checked by diluting a 1.00-mL sample to 50 mL in 1 : 1 methanol–water and measuring the absorbance at 292 nm. The Trolox was a gift from Hoffmann–LaRoche, Nutley, New Jersey. Freshly prepared standard solutions in phosphate buffer (pH 7.0) were used as an inhibitor. The ascorbic acid (L-(+)- from Anachemia) used was freshly prepared in phosphate buffer pH 7.0.

2. *Analyses*

Analyses for DBHN and α-tocopherol concentrations were made on a Varian–Cary 219 spectrophotometer. The hplc analyses were done on a Spectraphysics SP 8000 liquid chromatograph using a 4.6 mm × 25 cm Li Chrosorb NH_2 10-μm column and an ultraviolet detector set at 210 nm. For separation of components from an autoxidation sample, an aliquot was added to an acetanilide solution (internal standard); this was eluted on the column with 45:55 (v/v) acetonitrile – 2.5 mM NaH_2PO_4 buffer (pH 4.75) at 2.0 mL min^{-1} and 20°C for 9 min. The mobile phase was then changed over 2 min to 80:20 v/v acetonitrile–buffer. Under these conditions good resolution of acetanilide (3.4 *m*), DBHN (6.5 *m*), ascorbic acid (13 *m*), and α-tocopherol (24 *m*) was obtained. For identification, the DBHN and α-tocopherol were collected from the column and their ultraviolet spectra recorded.

3. *Autoxidation procedure*

Autoxidations were carried out at 30°C and 760 Torr of O_2 using a sensitive automatic recording gas absorption apparatus similar to that described (5). In a typical run, a 2.00-mL sample of the DBHN – 0.50 M SDS in phosphate buffer was equilibrated at 30°C. Then known amounts of linoleic acid were added from a precision syringe and the rates of oxygen uptake recorded after each addition. The per cent consumption of linoleic acid was generally less than 10%. Induction periods were obtained by adding α-tocopherol – SDS in phosphate buffer and the time was measured on the recorder until the uptake of oxygen resumed its original rate. For induction periods with both α-tocopherol and ascorbate, the solutions were added sequentially from separate syringes and the combined induction periods measured as before. In these cases, the rate of chain initiation (R_i) was followed by measuring the induction period with α-tocopherol alone, immediately before and again immediately after the combined induction periods found for α-tocopherol and ascorbate together.

Dihydro-9,14(4*H*)tripyrazolo(1,5-*a*:1′,5′-*d*:1″,5″-*g*)triazonine-1,4,7. Synthèse et étude par résonance magnétique nucléaire

ALAIN FRUCHIER,[1] BRIGITTE LUPO ET GEORGES TARRAGO
ERA au CNRS n° 169, Université des Sciences et Techniques du Languedoc, Place Eugène Bataillon, 34060 Montpellier Cedex, France

Reçu le 8 février 1984

ALAIN FRUCHIER, BRIGITTE LUPO et GEORGES TARRAGO. Can. J. Chem. **63**, 375 (1985).

Nous avons réalisé la synthèse selon une voie univoque de la triméthyl-2,7,12 dihydro-9,14(4*H*)tripyrazolo(1,5-*a*:1′,5′-*d*;1″,5″-*g*)triazonine-1,4,7. Une étude rmn de cette nouvelle molécule dans divers solvants a pour la première fois mis en évidence l'existence d'un équilibre conformationnel de type crown ⇌ saddle dans un dérivé du triazacyclononatriène.

ALAIN FRUCHIER, BRIGITTE LUPO, and GEORGES TARRAGO. Can. J. Chem. **63**, 375 (1985).

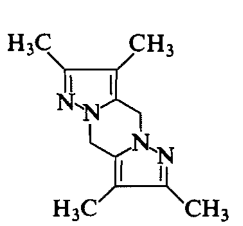
We have accomplished an unequivocal synthesis of 2,7,12-trimethyl-9,14-dihydro-1,5-*a*;1′,5′-*d*;1″,5″-*g*-(4*H*)tri-pyrazolo-1,4,7-triazonine. An nmr study of this new molecule in different solvents shows, for the first time, the existence of a crown ⇌ saddle conformationl equilibrium in a triazacyclononatriene derivative.

[Journal translation]

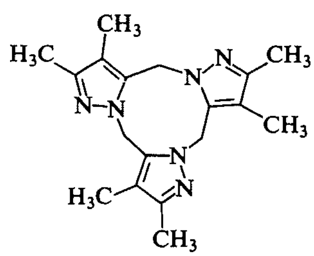
Introduction

Dans une publication précédente (1), nous avons montré que le composé obtenu par action du brome sur le sel d'argent du triméthyl-3,4,5 pyrazole ne pouvait avoir la structure **1** qui lui avait été attribuée (2).

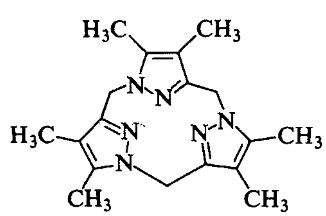
Sur la base de la masse moléculaire déterminée par spectrométrie de masse et du spectre de rmn dans le DMSO-d_6 indiquant une symétrie élevée, nous avions suggéré une structure cyclique tripyrazolique **2**. Cependant, étant donnée la méthode d'obtention, une structure de type **3** ne pouvait être absolument exclue.



1



2

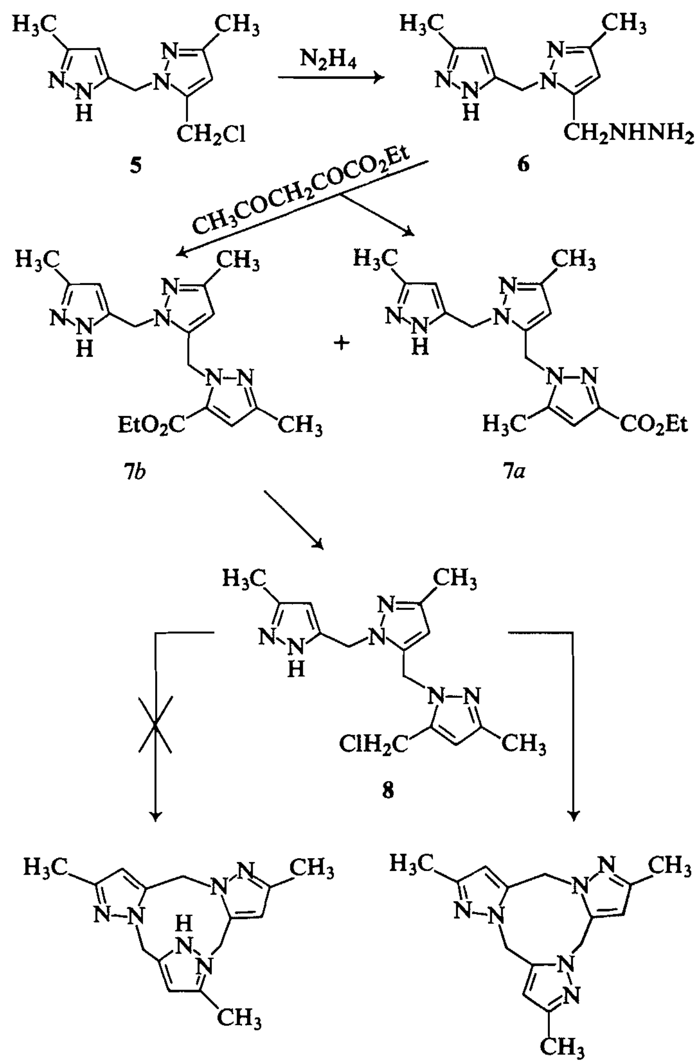


3

Nous présentons dans ce travail la synthèse univoque d'un composé analogue à **2**, la triméthyl-2,7,12 dihydro-9,14-(4*H*)tripyrazolo(1,5-*a*:1′,5′-*d*:1″,5″-*g*)triazonine-1,4,7 **4**, dont l'étude rmn prouve la structure proposée précédemment (1).

Résultats

La synthèse de **4** est effectuée selon le schéma réactionnel suivant:



Le composé **5**, dont nous avons déja décrit la synthèse (1), est traité par l'hydrazine pour donner **6**, qui par condensation avec l'acétylpyruvate d'éthyle conduit aux deux isomères **7***a* et **7***b*. Ces derniers sont séparés par chromatographie et identifiés par rmn sur la base du couplage entre les groupes méthyle-3(5) et les protons en position 4 des noyaux pyrazoliques (3). L'es-

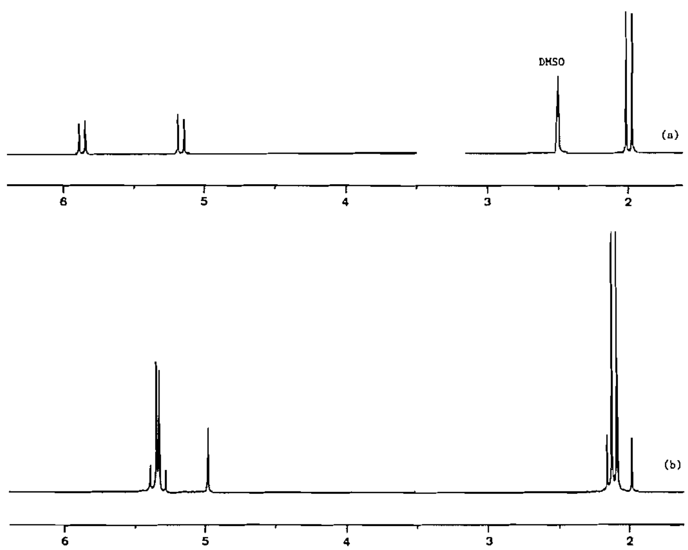

FIG. 1. Spectres en rmn de ¹H à 360 MHz de **2**. (a) DMSO-d_6; (b) $CDCl_3$.

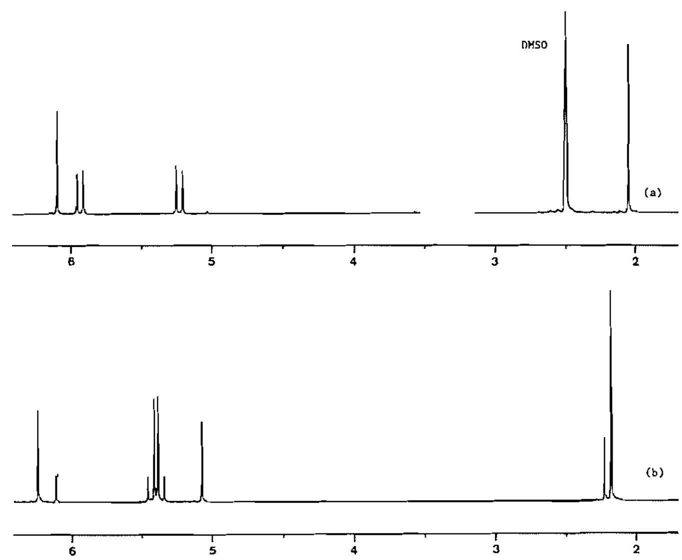

FIG. 2. Spectres en rmn de ¹H à 360 MHz de **4**. (a) DMSO-d_6; (b) $CDCl_3$.

ter **7***b* est ensuite réduit puis traité par le chlorure de thionyle pour donner **8**.

De par la présence de deux atomes d'azote nucléophiles dans le noyau pyrazole non *N*-substitué, la condensation du groupe chlorométhyle de **8** peut s'effectuer de deux façons et conduire à **4** et(ou) **9**. Cependant, soumis à un milieu basique fort dans les conditions de la catalyse par transfert de phase, **8** subit une cyclisation intramoléculaire par attaque du groupe chlorométhyle sur l'azote en β du substituant méthyle et donne le composé **4** avec un rendement de 38%. Si de nombreux autres produits sont formés au cours de la réaction, nous n'avons pu les identifier, le rendement de chacun d'eux étant inférieur à 3%.

Les spectres en rmn du proton de **2** et **4** dans $CDCl_3$ et DMSO-d_6 sont réunis dans les figures 1 et 2 respectivement, et les déplacements chimiques dans le tableau 1.

On notera une grande analogie, d'une part entre les spectres des deux composés dans le même solvant (fig. 1a et 2a, 1b et 2b), d'autre part en ce qui concerne l'effet du solvant sur un composé donné (fig. 1a et 1b, 2a et 2b). Pour chacun d'eux, le spectre dans le DMSO-d_6 est celui d'un composé unique de symétrie C_3 dont les protons méthyléniques sont fortement anisochrones, tandis que celui dans $CDCl_3$ correspond à un mélange de deux espèces en proportions inégales. La plus abondante est celle observée dans le DMSO, la moins abondante a la même symétrie mais ne montre aucune anisochronie des protons méthyléniques à 360 MHz.

Les produits **2** et **4** étant très peu solubles dans les deux solvants (étude de solutions saturées), et bien que chromatographiquement purs, la solubilisation sélective de deux espèces différentes dans les deux solvants ne pouvait être exclue. Cependant, cette hypothèse a pu être rejetée après étude de l'évolution du spectre d'une solution chloroformique lors de l'addition de DMSO-d_6 (fig. 3 et 4). Les composés **2** et **4** ont exactement le même comportement: dans les deux cas, l'addition de DMSO provoque la disparition progressive du produit et les pourcentages de forme C et S des composés **2**, **4** et **12**

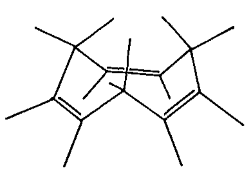
mineur, ainsi qu'une augmentation d'anisochronie des protons des méthylènes du produit majeur.

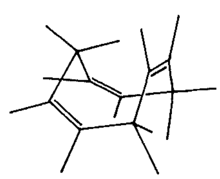
Discussion

La structure **9** pouvant être rejetée à cause de l'absence de symétrie qui conduirait à un spectre rmn plus complexe que celui de la figure 2a, le cycle central à neuf éléments de **4** explique son comportement en rmn.

En effet, il est connu (4) que le cyclononatriène-1,4,7 existe sous deux conformères C (crown) et S (saddle):



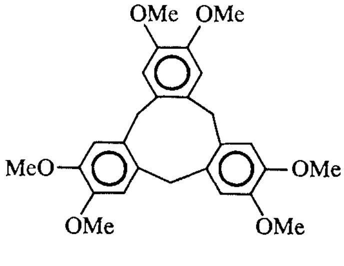
C



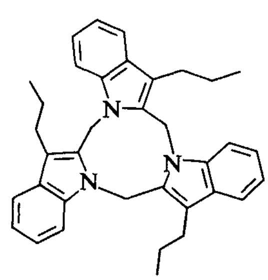
S

En rmn, seule la forme C est observée à basse température, tandis qu'à température ambiante ou élevée, le spectre correspond à un équilibre plus ou moins rapide entre les différentes formes possibles.

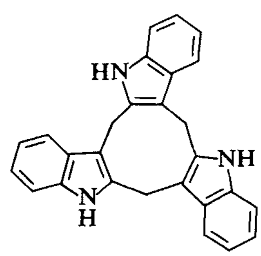
Dans le cas du cyclotrivératrylène (CTV) **10**, la forme C est seule observée (5), même à 200°C (absence de coalescence du système AB méthylénique). Dans tous les composés analogues cités (6), soit la forme C est seule présente, soit la forme S. Les



10



12



11

deux conformères ont été cependant signalés dans un même spectre rmn pour le produit **11** où le cycle benzénique est remplacé par un cycle à cinq éléments (7).

Le seul triazacyclononatriène-1,4,7 symétrique décrit à notre connaissance est le composé **12** (8) dans lequel les trois méthylènes sont isochrones dans le $CDCl_3$.

Il apparait donc que les spectres dans le DMSO-d_6 de **2** et **4** (fig. 1a et 2a) sont ceux d'une forme C (fig. 5): isochronie des protons situés sur les positions homologues des noyaux pyrazoliques et des groupes méthyléniques, indiquant la symétrie C_3, et anisochronie des protons à l'intérieur de chaque méthylène.

Dans le $CDCl_3$, par contre, si la forme C est encore majoritaire, il est raisonnable d'attribuer à la forme S les signaux du composé minoritaire. Cette structure n'ayant aucun élément de symétrie, conduirait à un spectre rmn complexe si elle n'était en équilibre rapide avec deux autres formes S équivalentes (4, 6, 8, 9).

La preuve que les formes majeure (C) et mineure (S) observées dans le spectre de **4** sont en équilibre conformationnel lent à température ambiante est apportée par l'évolution du spectre de **4** dans l'hexachloroacétone avec la température, montrant une coalescence des signaux des deux formes vers 140°C (fig. 6). La réversibilité du processus a été vérifiée lors du refroidissement.

En utilisant la méthode décrite dans la référence 10 pour les échanges entre sites inégalement peuplés, on peut évaluer le $\Delta G^{\neq}$ de l'équilibre C/S de **4** dans l'hexachloroacétone à 20 ± 1 kcal mol^{-1}. Cette barrière est inférieure à celle du CTV dans le même solvant: ce dernier se décompose à 200°C sans qu'il

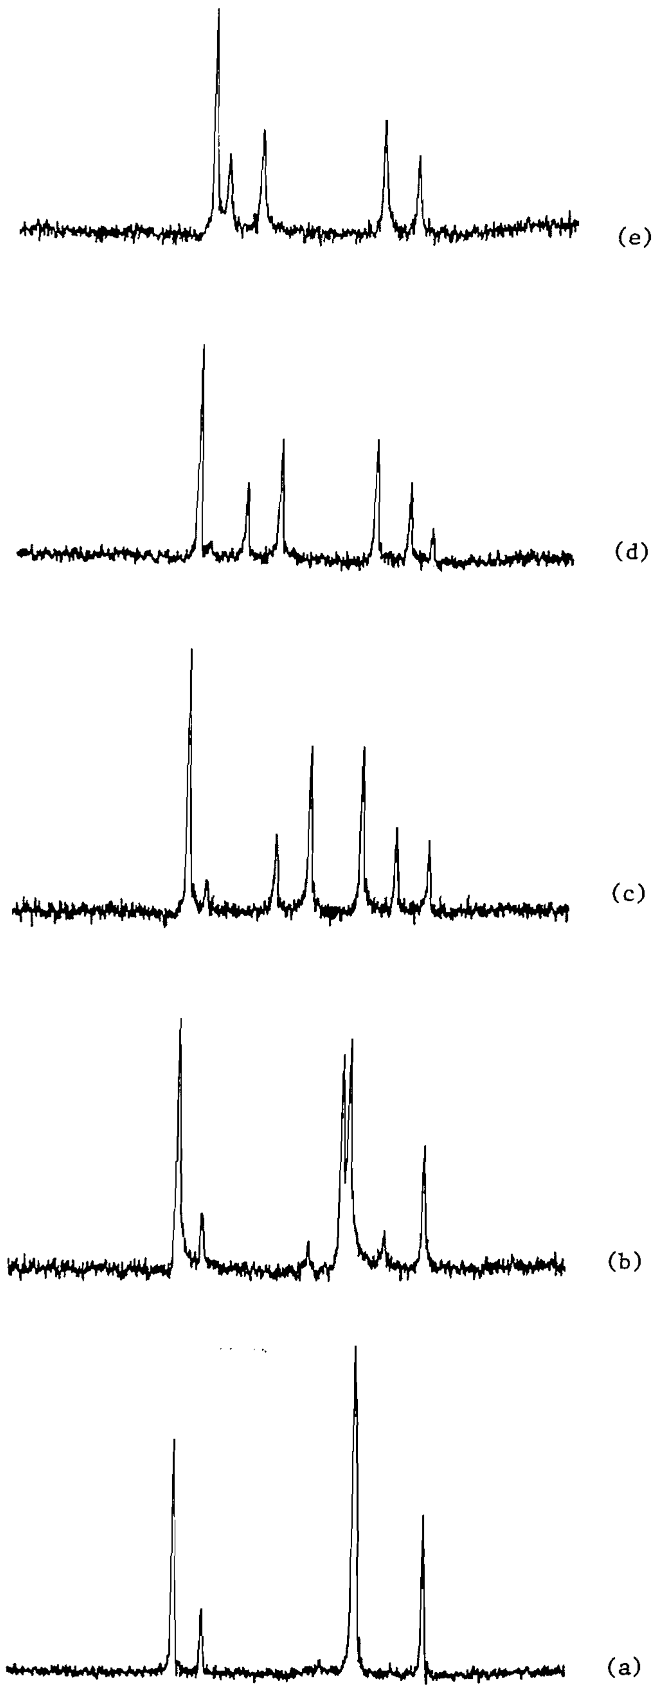


FIG. 3. Etude à 80 MHz de l'évolution du spectre de **4** par addition de DMSO-d_6 à une solution chloroformique (zone comprise entre 5 et 6,5 ppm); pourcentages $CDCl_3$/DMSO-d_6: (a) 100:0; (b) 90:10; (c) 85:15: (d) 80:20; (e) 0:100.

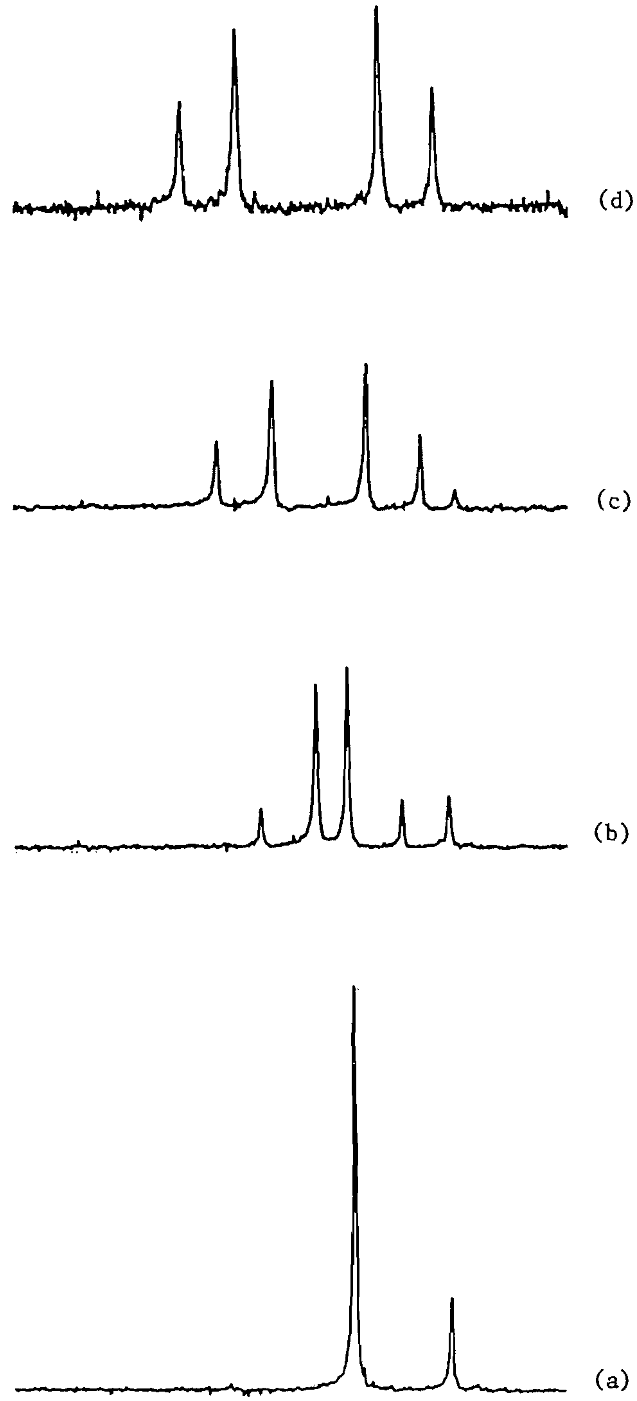

FIG. 4. Etude à 80 MHz de l'évolution du spectre de **2** par addition de DMSO-d_6 à une solution chloroformique (zone comprise entre 5 et 6 ppm); pourcentages $CDCl_3$/DMSO-d_6: (a) 100:0; (b) 84:16; (c) 80:20; (d) 0:100.

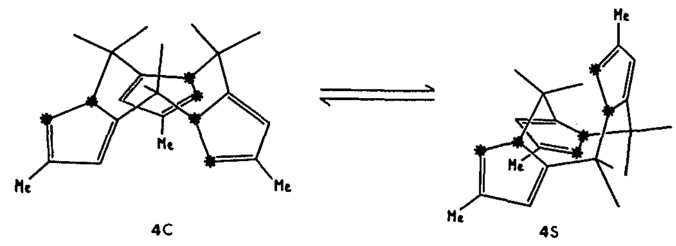

FIG. 5. Equilibre conformationnel crown ⇌ saddle du composé **4**.

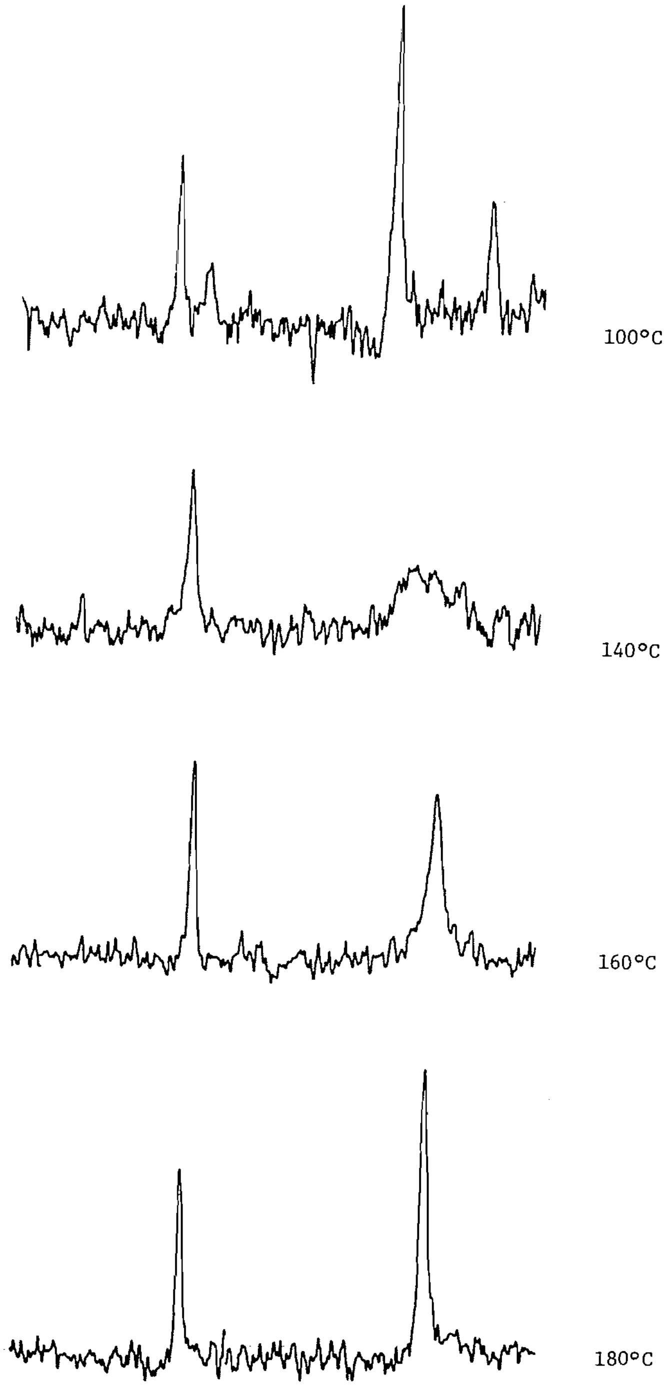

FIG. 6. Etude à 100 MHz de l'évolution avec la température du spectre de **4** dans l'hexachloroacétone (zone comprise entre 5.0 et 6.5 ppm).

y ait eu évolution du système AB méthylénique de la forme C seule visible (5). Par contre, aucun élargissement des signaux de la forme S n'est observé dans CD_2Cl_2 à −95°C. De toute évidence, et malgré que l'étude des deux équilibres ne soit pas possible dans le même solvant, la barrière de l'interconversion S/S est donc très inférieure à celle de l'équilibre C/S. En effet, le rôle du solvant est important. Par exemple, contrairement à ce qui est observé dans l'hexachloroacétone, le spectre de **4** dans le DMSO-d_6 à 140°C est identique à celui observé à température ambiante.

D'autre part, la différence de comportement de **2** et **4** dans $CDCl_3$ et DMSO-d_6 nous a incités à les étudier dans plusieurs autres solvants. Les déplacements chimiques sont réunis dans le tableau 1. On constate que dans les solvants tels que DMSO, benzène, méthanol, acétonitrile, acétone, l'équilibre est totalement déplacé en faveur de la forme C, mais que l'anisochronie des protons méthyléniques ainsi que le centre du système AB sont variables. Par contre, les solvants dans lesquels les deux conformères coexistent sont tous halogénés: chloroforme, dichlorométhane, bromoforme, hexachloroacétone. C'est aussi dans ces solvants que l'anisochronie des protons méthyléniques est la plus faible.

Enfin, des expériences réalisées à partir de mélanges $CDCl_3$/DMSO-d_6 et benzène/DMSO-d_6 ont mis en évidence la sensibilité plus grande d'un des deux protons méthyléniques à l'effet de solvant. Par exemple, lors de l'addition progressive de DMSO à une solution benzénique de **2** ou de **4**, le déplacement du système AB vers les fréquences élevées s'effectue avec croisement des signaux des protons méthyléniques.

Ces différentes observations sont en faveur d'une solvatation spécifique du conformère C, solvatation qui a déja été invoquée dans le cas du CTV (6, 9) pour expliquer la stabilisation de la forme C pourtant plus encombrée que la forme S. Ce dernier point est illustré dans notre série par le pourcentage de forme S qui passe de 20 (produit **4**) à 30 (produit **2**) puis à 50 (produit **12**) quand on remplace l'hydrogène de la position 4 des noyaux pyrazoliques par un méthyle (dans **2**) ou un brome (dans **12**) (tableau 1).

Conclusion

Dans la série du CTV, il a été montré (6) qu'au moins un des carbones sp^3 méthyléniques doit être remplacé par un carbone sp^2 pour qu'il y ait, dans l'échelle des temps de la rmn, équilibre entre conformères C et S. Dans tous les autres cas, c'est soit la forme C seule, soit la forme S seule qui est observé.

Nous venons de voir que cette condition n'est pas nécessaire dans la série de la tripyrazolotriazonine-1,4,7 où les formes C et S sont observées en même temps dans certains solvants.

D'autre part, étant donné que la différence observable entre formes S et C est l'anisochronie des hydrogènes méthyléniques de cette dernière, un spectre à haut-champ au moins sera souhaitable chaque fois que la forme S sera "vue" seule. Nous avons en effet montré que, dans certains solvants, l'anisochronie de la forme C peut être si faible qu'elle n'est pas mesurable à 80 ou 100 MHz.

Partie expérimentale

Les spectres rmn du proton ont été enregistrés sur les spectromètres suivants: Varian HA-100 et Bruker WP-80-DS du Laboratoire de Mesures Physiques de l'U.S.T.L., Bruker WM-250 de la Sadis Bruker à Wissembourg que nous remercions de son aide, Bruker WM-360-WB du Laboratoire de RMN à Haut-Champ de Montpellier. Tous les déplacements chimiques sont donnés en ppm par rapport au TMS pris comme référence interne.

Les spectres de masse ont été obtenus sur un spectromètre JEOL JMS D-100 au Laboratoire de Mesures Physiques de l'U.S.T.L.

Les points de fusion inférieurs à 250°C, non corrigés, ont été déterminés en tubes capillaires avec un appareil Tottoli, et ceux supérieurs à 250°C avec une platine chauffante Leitz.

Les analyses ont été effectuées par le Service Central de Microanalyses du C.N.R.S.

Les rendements indiqués correspondent à des produits ne présentant qu'une seule tache en chromatographie sur couche mince.

Hydrazinométhyl-5 diméthyl-3,5'(3') dipyrazolyl-1,3'(5') méthane **6**

Ce composé très instable a été préparé *in situ* pour éviter toute oxydation éventuelle (11). Un courant d'azote est envoyé sur une solution de 0,10 mol (26 g) du chlorhydrate de **5** (1) dans 500 mL d'éthanol puis 0,80 mol d'hydrate d'hydrazine (40 g) en solution dans 50 mL d'éthanol sont ajoutés. Le mélange est agité à température ambiante pendant 20 min puis refroidi jusqu'à apparition d'un précipité de chlorhydrate d'hydrazine que l'on filtre. Le filtrat est concentré sous atmosphère d'azote. L'huile obtenue est chauffée à 90°C sous 0,1 Torr (1 Torr = 133.3 Pa) afin d'éliminer le maximum d'hydrazine et est utilisée aussitôt pour l'étape suivante.

Carbéthoxy-5 triméthyl-3,3',5"(3") [pyrazole méthylène-3"(5")]-yl-1' dipyrazolyl-1,5' méthane 7b

Un mélange de 0,05 mol de **6** (11 g) et 0,06 mol d'acétylpyruvate d'éthyle (9,5 g) est chauffé à reflux 2 h sous atmosphère d'azote dans 500 mL d'éthanol. Après évaporation du solvant sous pression réduite, le résidu huileux est chromatographié sur alumine (ether/ethanol 98:2). A côté de produits non identifiés, les deux isomères suivants sont isolés.

Composé 7a, R_f = 0,10, avec un rendement de 10%; F = 120°C; spectre de masse (pic moléculaire): m/e = 342; rmn ($CDCl_3$): 6,52 (1H, s), 5,92 (1H, s), 5,67 (1H, s), 5,32 (2H, s), 5,28 (2H, s), 4,36 (2H, q), 2,20 (3H, d, J = 0,6 Hz: CH_3-5"), 2,16 (3H, d, J = 0,7 Hz: CH_3-5), 2,15 (3H, s, CH_3-3'), 1,34 (3H, t); rmn (C_6D_6): 6,43 (1H, s), 6,07 (2H, s), 5,88 (1H, s), 5,47 (1H, s), 5,24 (2H, s), 4,14 (2H, q), 2,06 (3H, s: CH_3-3'), 1,95 (3H, d, J = 0,6 Hz: CH_3-5"), 1,62 (3H, d, J = 0,7 Hz: CH_3-5), 1,03 (3H, t).

Composé 7b, R_f = 0,25, avec un rendement de 24%; F = 138°C; spectre de masse (pic moléculaire): m/e = 342; rmn ($CDCl_3$): 6,59 (1H, s), 5,88 (2H, s), 5,69 (2H, s), 5,42 (2H, s), 4,30 (2H, q), 2,24 (3H, d, J = 0,3 Hz: CH_3-3), 2,19 (3H, d, J = 0,6 Hz: CH_3-5"), 2,16 (3H, d, J = 0,3 Hz: CH_3-3'), 1,30 (3H, t); rmn (C_6D_6): 6,43 (1H, s), 6,03 (1H, s), 5,84 (1H, s), 5,65 (2H, s), 5,42 (2H, s), 3,92 (2H, q), 2,06 (3H, d, J = 0,3 Hz: CH_3-3), 2,03 (3H, d, J = 0.3 Hz: CH_3-3'), 1,83 (3H, d, J = 0,6 Hz: CH_3-5"), 1,02 (3H, t).

Hydroxyméthyl-5 triméthyl-3,3',5"(3") [pyrazole méthylène-3"(5")]-yl-1' dipyrazolyl-1,5' méthane

Cet alcool est obtenu par réduction de l'ester 7*b* par $AlLiH_4$ selon un protocole analogue à celui décrite dans la littérature pour l'homologue inférieur à deux noyaux pyrazole (1). Rendement 75%; F = 118–120°C; spectre de masse (pic moléculaire): m/e = 300; rmn ($CDCl_3$): 5,87 (1H, s), 5,82 (1H, s), 5,70 (1H, s), 5,23 (2H, s), 5,12 (2H, s), 4,42 (2H, s), 2,14 (3H, s: CH_3-3), 2,11 (3H, d, J = 0,6 Hz: CH_3-5"), 2.09 (3H, s: CH_3-3'); rmn (C_6D_6): 5,87 (1H, s), 5,83 (1H, s), 5,82 (1H, s), 5,22 (2H, s), 5,12 (2H, s), 4,38 (2H, s), 2,14 (3H, s: CH_3-3), 2,08 (3H, s: CH_3-3'), 1,81 (3H, d, J = 0,6 Hz: CH_3-5").

Chlorométhyl-5 triméthyl-3,3',5"(3") [pyrazole méthylène-3"(5")]-yl-1' dipyrazolyl-1,5' méthane 8

Ce composé est obtenu par action du chlorure de thionyle sur l'alcool précédent selon le même mode opératoire décrit pour l'homologue inférieur à deux noyaux pyrazoles (1). Rendement 65%; F = 80°C (décomposition); spectre de masse (pic moléculaire): m/e = 318; rmn ($CDCl_3$): 6,01 (1H, s), 5,92 (2H, s), 5,42 (2H, s), 5,34 (2H, s), 4,47 (2H, s), 2,32 (3H, d, J = 0,4 Hz: CH_3-5'), 2,19 (3H, s: CH_3-3), 2,17 (3H, s: CH_3-3'); rmn (C_6D_6): 5,80 (1H, s), 5,73 (1H, s), 5,71 (1H, s), 5,37 (2H, s), 5,23 (2H, s), 4,18 (2H, s), 2,10 (3H, s: CH_3-3), 2,09 (3H, s: CH_3-3'), 1,88 (3H, d, J = 0,4 Hz: CH_3-5").

*Triméthyl-2,7,12 dihydro-9,14 (4*H*)tripyrazolo(1,5-*a*:1',5'-*d*:1",5"-*g*)triazonine-1,4,7 4*

A 4 mL d'une solution de soude à 50% en poids sont ajoutés 2 × 10^{-4} mol de bromure de tétrabutylammonium et 300 mL de benzène en agitant vivement. Une solution de 0,005 mol de **8** dans 300 mL de benzène est alors ajoutée goutte à goutte au mélange précédent et le milieu réactionnel est chauffé au bain-marie à 60°C pendant 2 h.

Très rapidement, un précipité blanc, fin et floconneux apparait. En fin de réaction, ce précipité est filtré, lavé à l'eau puis extrait au chloroforme. La phase organique est séchée sur sulfate de sodium, filtrée puis le solvant évaporé. Le résidu solide est recristallisé dans un mélange eau/éthanol et donne **4** avec un rendement de 38%; F = 310°C; spectre de masse (pic moléculaire): m/e = 282. *Anal.* calc. pour $C_{15}H_{18}N_6$: C 63,89, H 6,43, N 29,80; trouvée: C 63,49, H 6,47, N 29,51; rmn, voir tableau 1.

*Tribromo-3,8,13 triméthyl-2,7,12 dihydro-9,14(4*H*)tripyrazolo-(1,5-*a*:1',5'-*d*:1",5"-*g*)triazonine-1,4,7* **12**

A 0,001 mol de **4** en solution dans le chloroforme est ajouté goutte à goutte 0,003 mol de brome en solution chloroformique. L'addition terminée, le mélange est porté à reflux pendant 1 h. Le bromohydrate de **12**, insoluble dans le chloroforme, précipite et le milieu est neutralisé par une solution aqueuse de Na_2CO_3. La phase organique est séparée, séchée et évaporée. Le solide blanc obtenu est recristallisé dans le chloroforme et conduit à **12** avec un rendement de 67%; F = 300°C; spectre de masse (pic moléculaire): m/e = 522. *Anal.* calc. pour $C_{15}H_{15}Br_3N_6$: C 34,71, H 2,91, N 16,19; trouvée: C 35,50, H 3,11, N 16,23; rmn, voir tableau 1.

*Hexaméthyl-2,3,7,8,12,13 dihydro-9,14 (4*H*)tripyrazolo-(1,5-*a*:1',5'-*d*:1",5"-*g*)triazonine-1,4,7 2*

Ce composé a été préparé selon les indications de la littérature (2). Le produit que nous avons isolé après recristallisation et sublimation possède les même caractéristiques que celles décrites dans la référence 2: Rendement 3% (litt. (2): 6%); F = 320°C (litt. (2): 325°C). *Anal.* calc. pour $C_{18}H_{24}N_6$: C 66,64, H 7,46, N 25,90; trouvée: C 66,59, H 7,38, N 25,58; rmn, voir tableau 1. La seule différence avec la littérature (2) est le pic moléculaire du spectre de masse à m/e = 324.

A simple reason for non-linear mixture rules in chemical kinetics. Part 1. Vibrational relaxation of diatomic molecules

CHRIS CARRUTHERS AND HESHEL TEITELBAUM
Ottawa–Carleton Institute for Research and Graduate Studies in Chemistry, University of Ottawa Campus, Ottawa, Ont., Canada K1N 9B4

Received January 4, 1984[1]

CHRIS CARRUTHERS and HESHEL TEITELBAUM. Can. J. Chem. **63**, 381 (1985).

The generalized rate law for the vibrational relaxation of diatomic molecules is extended to include inert collision partners. V–V energy transfer processes are accounted for explicitly as are thermal effects. The molecules are treated as Morse oscillators as far as energetics are concerned; however, the microscopic rate constants are Landau–Teller type. It is found that the phenomenon of non-linear mixture rules arises when experimental data are forced to fit a first-order rate law. The persistence of V–V processes at times well-advanced into the relaxation zone is responsible for deviations from linearity. The non-linearities are most pronounced at high temperatures, and can be avoided only by using extremely dilute mixtures. Several sources of ambiguity are pointed out. The type of excitation method influences the initial deviation from a Boltzmann distribution and plays a crucial role in determining the importance of V–V processes and hence the degree of non-linearity. Thus, when the initial distribution is Boltzmann as in shock waves, the mixture rule is found to be absolutely linear for the vibrational relaxation of diatomic molecules.

Several examples, heretofore not recognized as such, are pointed out in the literature.

CHRIS CARRUTHERS et HESHEL TEITELBAUM. Can. J. Chem. **63**, 381 (1985).

Dans le but d'inclure des partenaires inertes impliqués dans des collisions, on a étendu la loi généralisée de vitesse des relaxations vibrationnelles des molécules diatomiques. On peut interpréter explicitement tant les effets thermiques que les processus de transferts d'énergie V–V. En autant que les énergies sont concernées, on traite les molécules comme des oscillateurs de Morse; toutefois, les constantes microscopiques de vitesse sont du type Landau–Teller. Lorsqu'on force les données expérimentales à obéir à une loi de vitesse du premier ordre, on observe que le phénomène des règles de mélanges non-linéaires se développe. C'est la persistance des processus V–V, à des temps bien avancés dans la zone de relaxation, qui provoque des déviations de la linéarité. Les non-linéarités sont plus prononcées à hautes températures et on peut les éviter uniquement en utilisant des mélanges extrèmement dilués. On identifie plusieurs sources d'ambiguité. La méthode d'excitation influence la déviation initiale, par rapport à la distribution de Boltzmann, et elle joue un rôle crucial dans la détermination de l'importance des processus V–V et, par conséquent, dans le degré de non-linéarité. Donc, lorsque la distribution initiale est du type Boltzmann, comme dans les ondes de choc, on trouve que la règle des mélanges est absolument linéaire pour la relaxation vibrationnelle des molécules diatomiques.

On a relevé, dans la littérature, plusieurs exemples qui n'avaient pas été reconnus comme tels.

[Traduit par le journal]

A. Introduction

In the last 10 years interest has been aroused among theoreticians concerning the validity of the linear mixture rule for parallel rate processes (1–9). This rule states that if k_1 is the rate coefficient for $A + M_1 \rightarrow B + M_1$ and if k_2 is the rate coefficient for $A + M_2 \rightarrow B + M_2$ where M_1 and M_2 are species not undergoing any chemical change, then the overall rate coefficient, k, for the effective process $A \rightarrow B$ is $k = k_1x_1 + k_2x_2$ where x_1 and x_2 are the mole fractions of species M_1 and M_2, respectively. The above processes may represent vibrational relaxation or diatomic dissociation or unimolecular decomposition/isomerization at the low pressure limit. Even though this study concerns vibrational relaxation, we introduce the mixture rule in terms of familiar chemical kinetics concepts. It has been pointed out (1) that the linear mixture rule does not hold strictly except under very limited conditions. Neglecting complications due to fall-off behaviour, we can distinguish between two effects:

(*a*) *Mixed order kinetics*. The linear mixture rule will hold only if the products of, e.g., dissociation do not recombine, thus avoiding processes which are describable in terms of second-order kinetics. Furthermore, the linear mixture rule will hold only if A is infinitely diluted in a mixture with truly inert collision partners. Otherwise, A must be explicitly included as one of the collision partners. The rate law becomes $d[A]/dt = -k_1[M_1][A] - k_2[M_2][A] - k_A[A]^2$, and then it is clear that non-linearities are inherently built into the kinetics. It is impossible to define a quasi-first order effective rate coefficient. If the attempt is made, then a non-linear mixture rule is a necessary consequence. Unfortunately, the practice is widespread. This study points out the dangers involved.

(*b*) *Non-equilibrium kinetics*. Even when mixed-order kinetics is not in question, the linear mixture rule will hold only when the reaction is beyond the incubation period and only when local thermodynamic equilibrium can be said to exist (9). Clearly, if the above two processes are not elementary ones, but rather involve microscopic detail such as molecular energy transfer processes among vibrational levels which are not infinitely fast, then non-equilibrium kinetics prevail, and much depends on the relative ability of M_1 and M_2 to restore local equilibrium. The question here is whether the overall rate is a linear combination or a holistic combination of the two partial rates.

There are relatively uninteresting occasions when the rates are linearly additive: (*a*) there is only one quantum level in A, i.e., there is an undissociated A, and a product state B; (*b*) there are many levels in A, but the microscopic rate constants describing the energy transfer processes by M_1 and M_2 are all related by a constant factor (3). It is clear that in real systems neither of these criteria can be met absolutely. In general, then, the partial rates add non-linearly. When this happens, two significantly different mechanisms compete, one faster than the other, or one collider more efficient than the other (9). Each

[1] Revision received July 18, 1984.

competing route passes via several intermediates (e.g. vib/rot states), which may or may not be common to both of the routes. When one collision partner chooses one route and the other partner a second route we term this a non-cooperative pair. For example, during steady dissociation the closer a vibrational state is to the dissociation limit, the greater the deviation from Boltzmann population. The weaker the collider, the greater is the inability to restore thermal equilibrium. The extent of non-equilibrium depletion of the states below the dissociation limit depends non-linearly on the mixture composition, particularly if competing colliders are of different strengths. Therefore the rate of reaction (and hence the effective rate coefficient) depends non-linearly on the mixture composition (4). Thus, for non-cooperative routes the nonlinearity arises totally from the failure to additively account for the inability of each partner to restore thermal equilibrium. However, if the two routes communicate, i.e., if intermediates in each route are connected by yet a third process, then the slower of the two routes can be partially shunted. The very presence of an efficient route thus creates intermediates which obviate the need to move along part of the slow route, and thus helps to work around a potential bottleneck. We term this a synergistic system. An example of such a communicative process would be V–V energy transfer connecting two competing T–V routes.

A theoretical treatment by Troe (4) has given quantitative substance to the deviation from linearity of the mixture rule for polyatomic dissociation when the non-equilibrium criterion fails in a non-cooperative way. However, Troe concludes that the effect is barely within the experimentalist's detectability limits. Dove and Raynor (8) have also described non-cooperative effects for diatoms. In the latter study it was shown that non-equilibrium rotational distributions and vibrational distributions influence the additivity of vibrational relaxation and dissociation rates respectively. However, one could say that here cooperative effects are also involved (with V–RT processes acting as communicating routes). Both studies (refs. 4, 8) must be considered as involving A infinitely dilute in a mixture of inert M, since V–V processes are ignored. In this work we concentrate on mixtures containing finite amounts of A, without non-equilibrium phenomena, in which cooperative effects of A–A collisions can be demonstrated unambiguously.

Pritchard has shown that V–V (5) and/ or R–R (6) processes are responsible for non-linear rate laws in mixtures of finite composition. This was accomplished by direct numerical integration of the appropriate master equation. In the present work we demonstrate non-linear rate laws by analytical solution of the master equation for vibrational relaxation. In this way we may investigate the circumstances in which deviations might be observable, and we may suggest how to analyze experimental data in such cases.

Some experiments have come to light showing the non-linear effect markedly. Kiefer has pointed out (3) that H atoms and N atoms (10, 11) do not contribute linearly to the rate of their parent diatomic molecule's dissociation. This may not be too surprising since the atom–molecule interactions may give rise to distinctly different mechanisms than diatom–diatom or rare gas atom–diatom interactions. On the other hand, a systematic test of the mixture rule by Breshears *et al.* (12, 13) for the dissociation of H_2 and O_2 revealed no apparent non-linearities. The reason behind these apparent discrepancies is not known. However, we should note that the two effects (non-equilibrium distributions and mixed order kinetics) are not well separated in these cases. The situation is clearer for studies of vibrational relaxation where there is no complication due to dissociation depleting the vibrational level populations. A systematic test of the mixture rule for the vibrational relaxation of H_2 showed it to be linear (14) within experimental error. On the other hand, the NO/Ar system (15) showed very strong deviations from linearity at very high dilutions. Admittedly, Glänzer's graph is of log k vs. mole fraction. Nevertheless, even if Glänzer's graph is replotted on a linear scale, one would nevertheless be forced to conclude that a linear extrapolation of his data to zero mole fraction of NO leads to an overestimate of the argon contribution by orders of magnitude. Likewise, the only systematic test to date of the linear mixture rule for vibrational relaxation of a polyatomic molecule has shown strong deviations (16). All of these relaxation cases fall into the category of mixed-order kinetics in that the relaxing molecules may actively participate in their own relaxation. Hence they should all display non-linear mixture rules if one attempts to fit first order kinetics to the data. That they do not all do so may simply mean that measurements are not being made at sufficiently high dilutions nor at early enough times nor at high enough temperatures where the effect is most easily observed. This may also apply to the paucity of examples for dissociation (1). However, it is still not clear if the experimental technique itself plays a role. (Some techniques rely on measuring bulk vibrational energy profiles which are basically insensitive to second-order processes involving near-resonant V–V energy transfer steps.) It is also not clear whether there is a basic difference between diatomic molecules and polyatomic molecules due to the difference in vibrational state densities and in the number of vibrational degrees of freedom. For example, it is almost always thought (but not necessarily correctly, in general (17)) that the rate law for the vibrational relaxation of the vibrational energy, E, of a diatomic molecule obeys the rate law $dE/dt = -(E - E_\infty)/\tau$, where $1/\tau$ is an effective quasi-first-order rate constant obeying the linear mixture rule. On the other hand, if a polyatomic molecule is considered to consist of several independent normal oscillating modes, i, each obeying a similar rate law, then $dE/dt = -\Sigma_i(E_i - E_{i,\infty})/\tau_i$. Clearly there is no unique effective rate "constant". A phenomenological rate coefficient for such a system is time-dependent. However, the less dilute the mixture is, the greater the communication between parallel channels, i.e., the greater the influence of independence-destroying intermode-intermolecular V–V energy transfer processes. In the extreme limit of pure polyatomic gas it is conceivable that all τ_i could become identical — at which point a unique effective rate coefficient would exist. Thus, time- and mole-fraction-dependence become enmeshed.

In order to elucidate some of these points, we have carried out a study of the vibrational relaxation of diatomic molecules mixed with inert gases, which is valid for any conceivable type of excitation, and which solves the detailed master equation describing the vibrational level population changes as a function of time. Bimolecular V–V energy transfer steps are explicitly considered, and conditions for the validity of the linear mixture rule are examined. We follow on the model of our previous study which led to a non-exponential rate law for the rate of relaxation of vibrational energy of a pure diatomic gas (17). Here we generalize the model to include finite mixture compositions, and we study the effect of mole fraction on the phenomenological rate coefficient. We further show why some experiments show strictly linear mixture rules, while others must show non-linear mixture rules.

B. Relaxation model

For collisions of N_m diatomic molecules AB(m) in vibrational state m with other molecules in a mixture of AB and inert M molecules, the rate of change of the population, dN_m/dt, can be written in terms of T–V and V–V components

$$[1] \quad -\frac{dN_m}{dt} = -\left.\frac{dN_m}{dt}\right|_{T-V} - \left.\frac{dN_m}{dt}\right|_{V-V}$$

For T–V processes AB(m) may collide with any other AB in vibrational state $m = 0 \rightarrow m_*$, where m_* is the level just below the dissociation limit. AB(m) may also collide with the inert species M. The master equation describing the rate of change of the population of level m with time due to T–V processes is then given by

$$[2] \quad -\left.\frac{dN_m}{dt}\right|_{T-V} = (k^{AB}_{m,m+1}N_m + k^{AB}_{m,m-1}N_m - k^{AB}_{m+1,m}N_{m+1} - k^{AB}_{m-1,m}N_{m-1})\Sigma N_M + (k^{M}_{m,m+1}N_m + k^{M}_{m,m-1}N_m - k^{M}_{m+1,m}N_{m+1} - k^{M}_{m-1,m}N_{m-1})N_M$$

Here, $k^i_{m,n}$ is the rate constant for AB(m) $\rightarrow$ AB(n) upon collision with species i. In our previous study (17) we did not include collisions with the inert species M. The above rate equation assumes that (i) AB(m) can be excited or de-excited by one quantum, (ii) the various AB states are equally efficient at V–T de-excitation of AB(m) (but $k^{AB}_{i,j} \neq k^{M}_{i,j}$), and ($iii$) the rotational sublevels are equilibrated on a very short time scale, so that the rotational substructure need not be included explicitly.

We furthermore assume that the T–V rate constants can be scaled according to symmetrized Landau–Teller rules:

$$k^i_{m+1,m} = k^i_{1,0}(m+1)\, e^{-m\phi}$$

$$k^i_{m,m+1} = k^i_{0,1}(m+1)\, e^{m\phi}$$

where $\phi = h\nu_c\chi_c/kT$, and ν_c and χ_c are the Morse spectroscopic constants. These rate constants obey microscopic reversibility, and ensure the proper relative equilibrium populations. In [2] we gather coefficients of N_m, N_{m+1}, and N_{m-1}. We note that because the rate constants for different collision partners, i, depend in the same way on m, then [2] can be written in terms of $(k^{AB}_{0,1}N_{AB} + k^{M}_{0,1}N_M)$ and $(k^{AB}_{1,0}N_{AB} + k^{M}_{1,0}N_M)$. Since $k^i_{0,1}/k^i_{1,0}$ is just the Boltzmann factor, $\exp[-h\nu_c(1-2\chi_c)/kT]$, and is independent of the collision partner, i, then the concentration dependence in [2] can be written entirely in terms of the factor $(k^{AB}_{1,0}N_{AB} + k^{M}_{1,0}N_M)$. We follow the same procedure as in our previous study (17) and obtain an expression for the contribution of T–V processes to the rate of change of vibrational energy. Wherever $Nk_{1,0}$ appeared in that study involving pure AB it is now replaced by $(N_{AB}k^{AB}_{1,0} + N_M k^{M}_{1,0})$. We obtain, for Morse oscillators,

$$[3] \quad \left.\frac{dE}{dt}\right|_{T-V} = -(E - E_\infty)\,(N_{AB}k^{AB}_{1,0} + N_M k^{M}_{1,0}) \times [1 - \exp\{-h\nu_c(1-3\chi_c)/kT\}]$$

The effective rate constant, k, clearly is a simple linear combination of contributions by AB and M. This result is in perfect agreement with previous findings (9) that linear mixture rules are expected in quasi-first-order kinetic systems whenever the microscopic rate constants for different collision partners are all related by the same constant factor. In this case it is a consequence of the Landau–Teller rules. However, it is by no means guaranteed that even with these unique properties, the inclusion of V–V processes will not modify this conclusion for mixtures of finite mole fraction.

When V–V processes are included, it is only AB–AB collisions that affect $dN_m/dt|_{V-V}$. In our previous study we included all processes AB(m) + AB(n) $\rightleftarrows$ AB($m+1$) + AB($n-1$), and we scaled the individual rate constants according to Landau–Teller-like rules. The contribution of V–V processes to the rate of change of vibrational energy was found to be given by (17)

$$[4] \quad \left.\frac{dE}{dt}\right|_{V-V} = -N^2 k^{2,0}_{1,1}\chi'_c\,[2\bar{E}^2/h\nu' + \bar{E} - \overline{E^2}/h\nu']$$

where $k^{2,0}_{1,1}$ is the rate coefficient for the process

$$2AB(v=1) \rightarrow AB(v=2) + AB(v=0)$$

$\chi'_c = \chi_c/(1-\chi_c)$, $\nu' = \nu_c(1-\chi_c)$, $\bar{E}/h\nu' \equiv \Sigma m N_m/N$, and $\overline{E^2}/(h\nu')^2 \equiv \Sigma m^2 N_m/N$. In the present generalization we must explicitly recognize that only the AB–AB collisions can contribute to V–V processes. Thus N is identified here as N_{AB}. Our final rate law (consisting of two equations, one for $\bar{E}$ and one for $\overline{E^2}$) becomes, on a per molecule basis:

$$[5] \quad \frac{d\bar{E}}{dt} = -\frac{(\bar{E} - \bar{E}_\infty)}{\tau} - N_{AB}k^{2,0}_{1,1}\chi'_c\,[2\bar{E}^2/h\nu' + \bar{E} - \overline{E^2}/h\nu']$$

$$[6] \quad \frac{d\overline{E^2}}{dt} = (N_{AB}k^{AB}_{1,0} + N_M k^{M}_{1,0})\,[e^{\phi-\theta'/T} + (1 + 3e^{\phi-\theta'/T})\bar{E}/h\nu' - 2(1 - e^{\phi-\theta'/T})\overline{E^2}/(h\nu')^2](h\nu')^2 + N_{AB}k^{2,0}_{1,1}[2\bar{E}^2/h\nu' + \bar{E} - \overline{E^2}/h\nu']h\nu'$$

where $\theta' = h\nu'/k$ and $1/\tau = (N_{AB}k^{AB}_{1,0} + N_M k^{M}_{1,0})\,[1 - e^{2\phi-\theta'/T}]$. Therefore, with the following proviso, it would seem that all operations in our previous study (17) can be repeated simply by replacing $Nk_{1,0}$ by $(N_{AB}k^{AB}_{1,0} + N_M k^{M}_{1,0})$ and $Nk^{2,0}_{1,1}$ by $N_{AB}k^{2,0}_{1,1}$. The complication arises from thermal effects: as the vibrational energy changes, the translational–rotational energy changes correspondingly. $\bar{E}_\infty$, which depends on temperature, therefore changes during the relaxation, and $\bar{E}$ appears to approach equilibrium more quickly (18). In order to account for temperature variations we need to relate the vibrational energy to temperature or to translational energy. In other words, we need an expression for the conservation of energy, and then convert our differential equation into one involving temperature. From a practical point of view this is desirable anyway, since in many experiments it is not $\bar{E}$ but rather refractive index gradients which are measured. We consider the energy balance between the translational–rotational and the vibrational degrees of freedom. Shock tube experiments can be considered to be at constant pressure and enthalpy. This is an approximation, and indeed one analyzes data more carefully on a routine basis (12, 13). However, for a first-order determination of the influence of thermal effects on the non-linearity of the mixture rule, the approximation is good. The gas enthalpy

$$\bar{H} = \int_0^{T_e} \bar{C}\,dT$$

is a constant, where T_e is the true final (equilibrium) temperature, and $\bar{C}$ is the molar constant-pressure heat capacity = $\Sigma_i X_i \bar{C}_i$. $\bar{C}_i$ is the molar heat capacity of species i present with mole fraction X_i. This procedure is also valid for laser- or chemically-activated systems if heat loss to the walls of the cell is not significant. Then $\bar{C}$ would be a constant-pressure heat capacity only at relatively high pressures, but a constant-volume heat capacity at low pressures where the excitation energy diffuses over the whole cell. The relaxing molecules, AB, can release or take up heat from an inert buffer gas, depending on the type of experiment. In our previous study we did not include thermal effects because we considered them not to be a major effect, as far as determining the role of V–V processes was concerned. However, here we must consider thermal effects because they depend on mole fraction of the buffering gas.

C. Conservation of energy

The gas enthalpy is composed of translational and rotational contributions denoted by $\int(\bar{C} - \bar{C}_{\text{vib}})\mathrm{d}T$ plus a vibrational term $\bar{E}$ associated only with the diatomic molecule. In our relaxation model we do not exclude polyatomic colliders, M. However, for the sake of simplicity we give a detailed analysis here only for the case M = atom. Thus $\bar{C}_{\text{M}} = 5k/2$ (on a per molecule basis). Then, at constant pressure

$$[7] \quad \bar{C} - \bar{C}_{\text{vib}} = k(X_{\text{AB}} + 5/2)$$

where X_{AB} is the mole fraction of AB in the mixture $\equiv N_{\text{AB}}/(N_{\text{AB}} + N_{\text{M}})$. The conservation equation becomes

$$\bar{H} = \int(\bar{C} - \bar{C}_{\text{vib}})\mathrm{d}T + X_{\text{AB}}\bar{E} = \text{constant} = \int_0^{T_c} \bar{C}\mathrm{d}T$$

In differential form this becomes

$$[8] \quad X_{\text{AB}}\mathrm{d}\bar{E}/\mathrm{d}t = -(\bar{C} - \bar{C}_{\text{vib}})\mathrm{d}T/\mathrm{d}t$$

Phenomenological rate coefficient

Whenever the rate law is not that for pure first-order kinetics, it becomes important to specify the phenomenology, which is otherwise arbitrary. Here, as in ref. 17 the rate of relaxation is not purely exponential, and any arbitrarily defined rate coefficient will be time-dependent. The equivalence in eq. [8] suggests a definition which at least facilitates the comparison between shock tube and fluorescence experiments. One ought to get the same rate "constant" if ln $(\mathrm{d}E/\mathrm{d}T)$ or ln $(\mathrm{d}T/\mathrm{d}t)$ is plotted as a function of time. Thus we define τ'' as

$$[9] \quad -\frac{1}{\tau''} \equiv \frac{\mathrm{d}}{\mathrm{d}t} \ln(|\mathrm{d}\bar{E}/\mathrm{d}t|) \equiv \frac{\mathrm{d}}{\mathrm{d}t} \ln(|\mathrm{d}T/\mathrm{d}t|)$$

D. The generalized rate law for vibrational relaxation of diatomic molecules

Equations [5] and [6] can be combined by differentiating [5], eliminating $\mathrm{d}\overline{E^2}/\mathrm{d}t$, and obtaining an expression for $\overline{E^2}$ in terms of $\mathrm{d}\bar{E}/\mathrm{d}t$, $\mathrm{d}^2\bar{E}/\mathrm{d}t^2$, and $\bar{E}$. This result can then be resubstituted into [5] to obtain the final tractable rate law. Because of thermal effects the first stage in this procedure is not as straightforward as in ref. 17. We consider neither τ nor $k_{1,1}^{2,0}$ to depend strongly on temperature. However, the derivative of $\bar{E}_\infty$ becomes

$$\frac{\mathrm{d}\bar{E}_\infty}{\mathrm{d}t} = \frac{\mathrm{d}\bar{E}_\infty}{\mathrm{d}T}\frac{\mathrm{d}T}{\mathrm{d}t} = -\left(X_{\text{AB}}\frac{\mathrm{d}\bar{E}_\infty}{\mathrm{d}T}\right)\left(\frac{1}{\bar{C} - \bar{C}_{\text{vib}}}\right)\frac{\mathrm{d}\bar{E}}{\mathrm{d}t}$$

where we have used [8] explicitly. We further note that $X_{\text{AB}}\mathrm{d}\bar{E}_\infty/\mathrm{d}T$ is simply the contribution of the vibrational degree of freedom to $\bar{C}$. Thus, $\mathrm{d}\bar{E}_\infty/\mathrm{d}t = -[\bar{C}_{\text{vib}}/(\bar{C} - \bar{C}_{\text{vib}})]\mathrm{d}\bar{E}/\mathrm{d}t$.

Differentiation of [5] leads to

$$\frac{\mathrm{d}^2\bar{E}}{\mathrm{d}t^2} = -\frac{\mathrm{d}\bar{E}}{\mathrm{d}t}\left(\frac{1}{\tau_*} + N_{\text{AB}}k_{1,1}^{2,0}\chi_c'\right) - 4\chi_c'N_{\text{AB}}k_{1,1}^{2,0}\frac{\bar{E}}{h\nu'}\frac{\mathrm{d}\bar{E}}{\mathrm{d}t} + \frac{\chi_c'N_{\text{AB}}k_{1,1}^{2,0}}{h\nu'}\frac{\mathrm{d}\overline{E^2}}{\mathrm{d}t}$$

where

$$[10] \quad \frac{1}{\tau_*} = \frac{1}{\tau}\left(\frac{\bar{C}}{\bar{C} - \bar{C}_{\text{vib}}}\right)$$

Elimination of $\mathrm{d}\overline{E^2}/\mathrm{d}t$ leads to

$$\chi_c'N_{\text{AB}}k_{1,1}^{2,0}\frac{\overline{E^2}}{h\nu'}\left[N_{\text{AB}}k_{1,1}^{2,0} + \frac{2}{\tau}\right] = -\frac{\mathrm{d}\bar{E}}{\mathrm{d}t}\left[\frac{1}{\tau^*} + \chi_c'N_{\text{AB}}k_{1,1}^{2,0}\right] - 4\chi_c'N_{\text{AB}}k_{1,1}^{2,0}\frac{\bar{E}}{h\nu'}\frac{\mathrm{d}\bar{E}}{\mathrm{d}t} - \frac{\mathrm{d}^2\bar{E}}{\mathrm{d}t^2} + \chi_c'N_{\text{AB}}k_{1,1}^{2,0}h\nu' \times \left\{[N_{\text{AB}}k_{1,0}^{\text{AB}} + N_{\text{M}}k_{1,0}^{\text{M}}]\left[\mathrm{e}^{-u} + \frac{\bar{E}}{h\nu'}(1 + 3\mathrm{e}^{-u})\right] + N_{\text{AB}}k_{1,1}^{2,0}\frac{\bar{E}}{h\nu'}\left(1 + \frac{2\bar{E}}{h\nu'}\right)\right\}$$

where $u = h\nu_c(1 - 2\chi_c)/kT$. Substitution of this expression for $\overline{E^2}$ into [5] leads to

$$[11] \quad \frac{\mathrm{d}\bar{E}}{\mathrm{d}t}\left[\frac{N_{\text{AB}}k_{1,1}^{2,0}}{1 - \chi_c} + \frac{2}{\tau} + \frac{1}{\tau_*}\right] = -\frac{(\bar{E} - \bar{E}_\infty)}{\tau}\left[N_{\text{AB}}k_{1,1}^{2,0} + \frac{2}{\tau}\right] - \chi_c'N_{\text{AB}}k_{1,1}^{2,0}\left[\frac{(\bar{E} - \bar{E}_\infty)}{\tau}\left(1 + \frac{4\bar{E}}{h\nu'}\right) + \frac{4\bar{E}}{h\nu'}\frac{\mathrm{d}\bar{E}}{\mathrm{d}t}\right] - \frac{\mathrm{d}^2\bar{E}}{\mathrm{d}t^2}$$

This is the generalized rate law. It can be simplified by supposing a solution of the form

$$[12] \quad \frac{\mathrm{d}\bar{E}}{\mathrm{d}t} = -\frac{(\bar{E} - \bar{E}_\infty)}{\tau} + f(t)$$

Differentiating [12] and using $\mathrm{d}\bar{E}_\infty/\mathrm{d}t = -[\bar{C}_{\text{vib}}/(\bar{C} - \bar{C}_{\text{vib}})]\mathrm{d}\bar{E}/\mathrm{d}t$ we obtain

$$[13] \quad \frac{N_{\text{AB}}k_{1,1}^{2,0}}{1 - \chi_c} + \frac{2}{\tau} = -\chi_c'N_{\text{AB}}k_{1,1}^{2,0}\frac{4\bar{E}}{h\nu'} - \frac{\mathrm{d}\ln f}{\mathrm{d}t}$$

Just as in ref. 17 we are justified in neglecting the term $4\bar{E}\chi_c'/h\nu'$ compared with unity. Therefore

$$[14] \quad f(t) = f(0)\exp\left[-\left(\frac{N_{\text{AB}}k_{1,1}^{2,0}}{1 - \chi_c} + \frac{2}{\tau}\right)t\right]$$

Comparing eq. [12] with [5] we can easily deduce that

$$[15] \quad \left[\frac{2\bar{E}^2}{h\nu'} + \bar{E} - \frac{\overline{E^2}}{h\nu'}\right] = \left[\frac{2\bar{E}^2}{h\nu'} + \bar{E} - \frac{\overline{E^2}}{h\nu'}\right]_0 \exp\left[-\left(\frac{N_{\text{AB}}k_{1,1}^{2,0}}{1 - \chi_c} + \frac{2}{\tau}\right)t\right]$$

and

$$[16] \quad \frac{\mathrm{d}\bar{E}}{\mathrm{d}t} = -\frac{(\bar{E} - \bar{E}_\infty)}{\tau} - N_{\text{AB}}k_{1,1}^{2,0}\chi_c'\left[\frac{2\bar{E}^2}{h\nu'} + \bar{E} - \frac{\overline{E^2}}{h\nu'}\right]_0 \exp\left[-\left(\frac{N_{\text{AB}}k_{1,1}^{2,0}}{1 - \chi_c} + \frac{2}{\tau}\right)t\right]$$

There are some noteworthy features associated with this rate law:

(*a*) Thermal effects do not enter explicitly into [16], although they are implicitly contained in the time-variation of $\bar{E}_\infty$. (Of course, both τ and $k_{1,1}^{2,0}$ depend on temperature, the latter very weakly so. However, the temperature changes are usually only a few degrees K, and so we ignore this aspect.)

(*b*) The rate is not at all the same as supposed by experimentalists. Although $(\bar{E} - \bar{E}_\infty)$ relaxes nearly exponentially with a rate coefficient closely related to $1/\tau$ (see below), a second contribution relaxes somewhat faster. This term represents the effect of V–V processes. Whereas a relatively small amount of energy is associated with this term (the anharmonicity) compared with the main term, $N_{AB}k_{1,1}^{2,0}$ is usually $\gg 1/\tau$, and the amplitude of the V–V rate may be comparable to or even exceed the T–V rate, particularly since $[2\bar{E}^2/h\nu' + \bar{E} - \bar{E}^2/h\nu']_0$, the initial deviation from a Boltzmann distribution, can be arbitrarily large, depending on the type of excitation experiment. The V–V rate decays faster than the T–V rate; however, the large amplitude of the V–V term may contribute significantly to observed rates of relaxation.

(*c*) A unique relaxation time cannot be said to exist. It is only in the extreme limit of $N_{AB} \to 0$, or $k_{1,1}^{2,0} \to 0$ or $\chi_e \to 0$, or $[2\bar{E}^2/h\nu' + \bar{E} - \bar{E}^2/h\nu']_0 \to 0$ that the V–V term drops out and that a unique relaxation time results. In ref. 17 it was shown that $[2\bar{E}^2/h\nu' + \bar{E} - \bar{E}^2/h\nu']_0$ is zero when the initial population distribution is Boltzmann, such as in shock tube experiments. This predicts that the rate of vibrational relaxation of diatomic molecules measured in shock waves is exponential with a unique T–V relaxation time which obeys the linear mixture rule!

(*d*) In the limit that $N_{AB} \to 0$ the V–V term decays according to $e^{-2t/\tau}$. The factor of 2 seems reasonable, since if in the limit of $N_{AB} \to 0$, $\bar{E}$ decays according to $e^{-t/\tau}$, then functions of $\bar{E}^2$ ought to additionally decay according to $e^{-2t/\tau}$. Of course, the amplitude of the V–V term $\to 0$ in this limit. Alternatively, the $N_{AB}k_{1,1}^{2,0}$ term represents the V–V process $2AB(v = 1) \to AB(v = 0) + AB\ (v = 2)$. This can compete with the T–V process $AB(v = 1) \to AB(v = 0)$ only if the $v = 2$ state can also make its way back to $v = 0$. This is efficiently done by the T–V process $AB(v = 2) \to AB(v = 1)$ which is twice as fast as the $v = 1 \to 0$ step in our model (18) at the limit $N_{AB} \to 0$. Therefore $2/\tau$ must appear in conjunction with $N_{AB}k_{1,1}^{2,0}/(1 - \chi_e)$. This function has been known in the literature for many years. Rankin and Light (19), who used a V–V model very similar to ours, showed that the individual vibrational levels decay during early relaxation at more than twice the steady rate. Even the term $[\epsilon_0(1 + 2\epsilon_0) - \langle n^2\rangle_0]$ (essentially part of our pre-exponential term) appeared in their functions. Unfortunately, they neglected the molecular anharmonicity, and their energy rate law therefore reduced to the Bethe–Teller law.

E. Solution of the rate law

1. Shock tubes

As mentioned above, the rate law reduces simply to

$$[17]\quad \frac{d\bar{E}}{dt} = -\frac{(\bar{E} - \bar{E}_\infty)}{\tau}$$

In order to eliminate the time variation of $\bar{E}_\infty$, we differentiate eq. [17] and use $d\bar{E}_\infty/dt = [\bar{C}_{vib}/(\bar{C} - \bar{C}_{vib})]d\bar{E}/dt$ in order to obtain

$$[18]\quad \frac{d^2\bar{E}}{dt^2} = -\frac{1}{\tau_*}\frac{d\bar{E}}{dt}$$

We reintegrate in order to express the rate law in terms of final conditions. At $t \to \infty$; $d\bar{E}/dt \to 0$; $\bar{E}_\infty \to \bar{E}_{\infty,e}$, the true equilibrium energy. Therefore

$$[19]\quad \frac{d\bar{E}}{dt} = -\frac{1}{\tau_*}(\bar{E} - \bar{E}_{\infty,e})$$

The solution is a pure exponential, with time constant τ_*. The phenomenological time constant τ'' defined by [9] is simply $\tau'' = \tau_*$.

2. Laser excitation or chemical activation

At this point we should emphasize that, although this kind of experiment is amenable to monitoring individual vibrational level populations by narrow band fluorescence, in actual practice a broad-band fluorescence signal is measured which is proportional to $\Sigma nh\nu N_n$, i.e., to the total vibrational energy of an approximately harmonic oscillator mode (18). This is certainly the case for the experiments cited below.

In this general case we must integrate [16]. The same procedure is used as in the shock tube case to eliminate the time-dependence of $\bar{E}_\infty$. Setting

$$a = \left(\frac{N_{AB}k_{1,1}^{2,0}}{1 - \chi_e} + \frac{2}{\tau}\right)$$

and

$$b = h\nu_e\chi_e N_{AB}k_{1,1}^{2,0}\left[2\left(\frac{\bar{E}}{h\nu'}\right)^2 + \left(\frac{\bar{E}}{h\nu'}\right) - \frac{\bar{E}^2}{(h\nu')^2}\right]_0$$

and using eq. [9] we obtain

$$[20]\quad \bar{E} - \bar{E}_{\infty,e} = (\bar{E}_0 - \bar{E}_{\infty,e})\,e^{-t/\tau_*} + b(e^{-at} - e^{-t/\tau_*})/(a - 1/\tau_*)$$

and

$$[21]\quad \frac{\tau''}{\tau_*} = \frac{ab\tau_* e^{-at} + [(\bar{E}_0 - \bar{E}_{\infty,e})(a - 1/\tau_*) - b]e^{-t/\tau_*}}{a^2b\tau_*^2 e^{-at} + [(\bar{E}_0 - \bar{E}_{\infty,e})(a - 1/\tau_*) - b]e^{-t/\tau_*}}$$

In this study, we are interested in the dependence of τ'' on mole fraction, $X_{AB} \equiv N_{AB}/(N_{AB} + N_M)$. τ''/τ_* depends on five additional parameters:

$$\gamma \equiv k_{1,1}^{2,0}/(k_{1,0}^{AB} - k_{0,1}^{AB})$$

$$\phi_M \equiv (k_{1,0}^{M} - k_{0,1}^{M})/(k_{1,0}^{AB} - k_{0,1}^{AB})$$

$$\delta \equiv (\bar{E}_0 - \bar{E}_{\infty,e})/\{h\nu_e\chi_e[2(\bar{E}/h\nu')^2 + (\bar{E}/h\nu') - \bar{E}^2/(h\nu')^2]_0\}$$

$\lambda \equiv \bar{C}_{AB}/k$ and χ_e

One may look upon Figs. 1 and 2 as correction factors to be applied to measured relaxation times. Depending on the regime of t/τ_* studied, one measures τ'' which is far removed from the desired T–V τ_*. However, in order to apply these correction factors, one must know γ (the relative importance of V–V and T–V rate constants), ϕ_M (the relative T–V efficiencies of M and AB), δ (the deviation from equilibrium relative to the initial first and second moments of the vibrational energy) as well as λ and χ_e. It is not likely that γ and ϕ_M are known in advance of the measurements, and it is very difficult to measure δ. Therefore, it is unlikely that graphs such as Fig. 1 could ever be useful in this way. Furthermore, an experimentalist would not know unambiguously what his regime of t/τ_* is. If anything, he would measure τ'' and hence he would have an idea only of t/τ''. The dependence of the measured phenom-

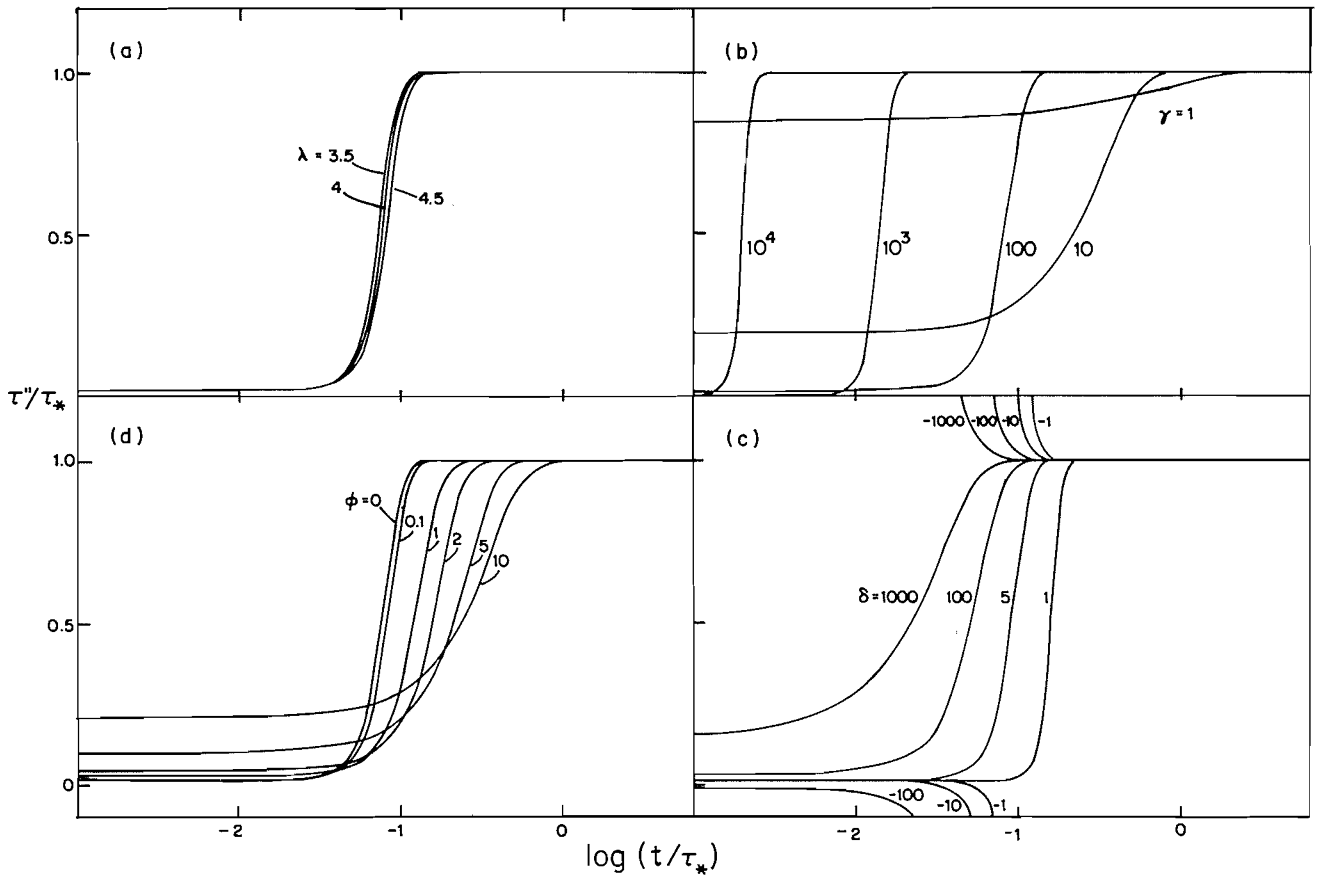

FIG. 1. Phenomenological relaxation times for the vibrational relaxation of diatomic molecules in gas mixtures as a function of reduced time, t/τ_*. (*a*) Effect of λ, i.e., of how nearly classical the oscillator is, for $X_{AB} = 0.5$, $\gamma = 100$, $\delta = 10$, $\chi_e = 0.01$, $\phi_M = 0.1$. For $\lambda = 4.5$, the vibration is classical; (*b*) effect of γ, i.e., of the relative importance of V–V and T–V rate coefficients, for $X_{AB} = 0.5$, $\delta = 10$, $\chi_e = 0.01$, $\phi_M = 0.1$, $\lambda = 4.5$; (*c*) effect of δ, i.e., of the deviation from equilibrium relative to that from a Boltzmann distribution. Here $X_{AB} = 0.5$, $\gamma = 100$, $\chi_e = 0.01$, $\phi_M = 0.1$, $\lambda = 4.5$. The discontinuities correspond to overshoots in energy; (*d*) effect of ϕ_M, i.e., of the relative efficiency of M and AB at equilibrating AB via T–V processes. Here $X_{AB} = 0.5$, $\gamma = 100$, $\delta = 10$, $\chi_e = 0.01$, $\lambda = 4.5$.

enological relaxation time on t/τ'' is even more complicated, as seen in Fig. 2*b*. In view of these difficulties it is advisable that workers report their measured values of $p\tau$ not only at given temperatures but also the measured time intervals of t/τ''. In this way, comparison between the results of different experimental techniques is facilitated.

In Fig. 1*b*, we note that the larger the γ, the earlier the V–V effects are over. However, it is also easy to calculate from [20] the percentage of energy change relaxed at a given time. We find that despite the rapidity of V–V processes, they are nevertheless important in some cases for late time measurements. For example, by the time $\tau'' = 0.95\tau_*$, 20% of the energy has already relaxed if $\gamma = 100$, $\delta = 10$, $\chi_e = 0.01$, $\lambda = 4.5$, $\phi_M = 0,1$, and $X_{AB} = 0.5$. (This might correspond to exciting Na_2 or Li_2 in the range $v = 2–6$ at some suitable temperature.)

When $\delta < 0$ the vibrational energy temporarily surpasses its equilibrium value. As shown in ref. 20 this manifests itself as an apparently negative τ until the maximum energy is reached. Beyond this point in time, the relaxation rate speeds up and approaches that controlled by the V–T processes. In terms of Treanor pumping, it is during this induction period that molecules pile up in high vibrational states. Thereafter, they relax at a relatively slow rate. The experimental conditions required for δ to be < 0 are difficult to obtain in studies designed to measure rate constants; and we therefore ignore this case here. Indeed, ref. 20 shows that for most, if not all laser- or chemically-activated molecules δ lies in the range 10–1000. For $\delta = 1000$, $\gamma = 100$, 6% of the energy change has relaxed by the time $\tau'' = 0.95\tau_*$; even for $\gamma = 10^4$, $\delta = 10$, as much as 10% change has occurred already. It seems that V–V processes make themselves felt on time scales that are up to 20 times greater than what one would have expected from the value of γ, i.e. the relative V–V/T–V rate constants, depending on the size of the perturbation, δ.

For collision partners which are as efficient as AB itself is at T–V excitation ($\phi_M = 1$), 25% of the energy has relaxed by the time $\tau'' = 0.95\tau_*$. The less efficient M is, the more important is V–V relative to T–V, and thus the earlier in time is the V–V effect over.

λ depends on how classical the oscillating molecule is (i.e. on the value of $h\nu/kT$). For a classical diatomic oscillator $\lambda = 9/2$; for the extreme case of a quantum oscillator $\lambda = 7/2$. Nevertheless, the nearness to classical oscillation plays little role in the transient behaviour.

Because the mole fraction, X_{AB}, affects not only the duration of V–V processes but also their amplitude, the dependence of this effect on X_{AB} is somewhat complicated: for $X_{AB} = 1$, $X_{AB} = 0.5$, $X_{AB} = 0.2$, $X_{AB} = 0.1$, $X_{AB} = 0.01$, $X_{AB} = 0.001$, the percentage of the vibrational energy relaxed by the time $\tau'' = 0.95\tau_*$ is 25%, 20%, 21%, 24%, 48%, and 56%, respectively. The mole fraction of AB must be as low as 10^{-4} before less than 5% of the energy has relaxed during the transient period when

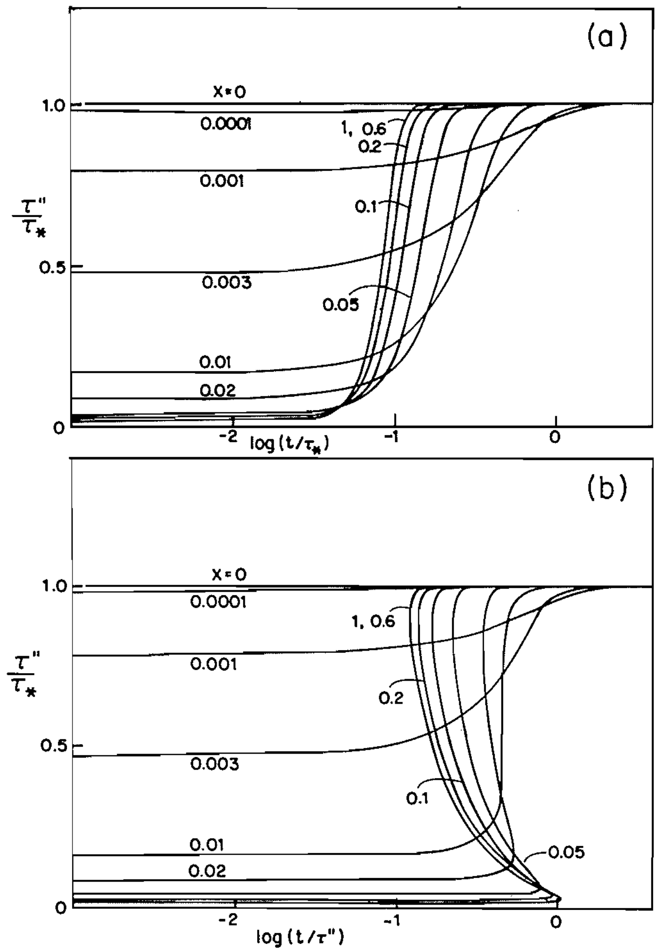

FIG. 2. Phenomenological relaxation times for the vibrational relaxation of diatomic molecules in gas mixtures as a function of reduced time and mole fraction. Here $\gamma = 100$, $\delta = 10$, $\lambda = 4.5$, $\chi_e = 0.01$, and $\phi_M = 0.1$. (*a*) t is normalized by dividing by the effective T–V time constant, τ_*; (*b*) t is normalized by dividing by the experimentally observed time constant, τ''.

$\gamma = 100$, $\delta = 10$. The mole fraction at which V–V effects are most felt is closely related to that at which the mixture rule deviates the most from linearity (see below). Therefore, despite the low mole fractions (10^{-3}) and the anharmonicity (10^{-2}), modest V–V processes ($\gamma = 100$) can have marked effects on measured rate coefficients! Great care is needed in interpreting vibrational relaxation data when $t < \tau_*$.

F. Mixture rules

The aim of this study was to see the effect of mole fraction on measured rate constants for relaxation, i.e., on $1/N\tau''$, or $1/p\tau''$. Using [21], [10], and the definition for τ, we obtain

$$\frac{1}{N\tau''} = \left(\frac{\bar{C}}{\bar{C} - \bar{C}_{\text{vib}}}\right) [X_{AB}(k_{1,0}^{AB} - k_{0,1}^{AB}) + X_M(k_{1,0}^{M} - k_{0,1}^{M})] \left(\frac{\tau_*}{\tau''}\right)$$

We note that the mole-fraction dependence is due to three factors: (*a*) thermal effects; (*b*) a linear dependence on relative efficiency of M; and (*c*) a non-linear factor due to the influence of V–V processes. We do not wish to confuse the issue by including thermal effects as a source of non-linearity, because experimentalists tend to account for them before attempting mixture rule plots. Therefore in Figs. 3 and 4 we include only the second and third factors, and plot the function

$$g = \left(\frac{1}{N\tau''}\right)\left(\frac{1}{k_{1,0}^{AB} - k_{0,1}^{AB}}\right)\left(\frac{\bar{C} - \bar{C}_{\text{vib}}}{\bar{C}}\right)$$

as a function of X_{AB}:

$$[22] \quad g = [X_{AB} + (1 - X_{AB})\phi_M] \times \left\{\frac{a^2 b\tau_*^2 e^{-at} + [(\bar{E}_0 - \bar{E}_{\infty,c})(a - 1/\tau_*) - b]e^{-t/\tau_*}}{ab\tau_* e^{-at} + [(\bar{E}_0 - \bar{E}_{\infty,c})(a - 1/\tau_*) - b]e^{-t/\tau_*}}\right\}$$

Not only does g depend on X_{AB}, but it also depends on time! It is here that we encounter at once both the crux of the matter and the experimentalists' dilemma. There is no unique choice for t/τ_*. Thus there is no unique mixture rule plot! Three reasonable choices are reflected in Figs. 3*a*, *b*, and *c*: (*a*) constant t/τ_*; (*b*) constant t/τ'', which is more readily estimable than t/τ_*; (*c*) constant absolute time, i.e. constant $Nt(k_{1,0}^{M} - k_{0,1}^{M})$, which is the most likely experimental situation (one is likely to measure at the earliest possible time permitted by electronic response regardless of X_{AB}). Of course, if Nt is fixed then t/τ_*, chosen in this way, also depends on X_{AB}: e.g., if we choose $t/\tau_* = n$ when $X_{AB} = 0$, then $Nt(k_{1,0}^{M} - k_{0,1}^{M}) = n$; and for fixed Nt,

$$\frac{t}{\tau_*} = \frac{n}{\phi_M}\{X_{AB} + (1 - X_{AB})\phi_M\}\left(\frac{\bar{C}}{\bar{C} - \bar{C}_{\text{vib}}}\right)$$

In Fig. 3 we have chosen typical parameters $\gamma = 100$, $\delta = 10$, $\chi_e = 0.01$, and $\phi_M = 0.1$. Since g has been normalized to give ϕ_M when $X_{AB} = 0$, i.e., the relative T–V efficiency of M:AB, then a linear mixture rule corresponds to a straight line connecting $g = 1$ (at $X_{AB} = 1$) with $g = 0.1$ (at $X_{AB} = 0$). It is only at or close to equilibrium that a linear mixture rule will be observed. At long times the relatively rapid V–V rate decays leaving only the T–V rates which do obey the linear mixture rule, as can be seen from [3]. At other times non-linearities are very evident. The danger lies in an experimenter's not measuring over the entire concentration range. Over any short range of mole fractions such plots will always appear to be linear — certainly within experimental error. The common procedure of extrapolating to $X_{AB} = 0$ and $X_{AB} = 1$ in order to extract the T–V rate constants for M and AB respectively is apparently wrong, except when measuring at equilibrium. We see that (*1*) linear extrapolations originating from a limited range of X_{AB} can give very large underestimates or overestimates of $k_{1,0}^{AB}$ and $k_{1,0}^{M}$. (*2*) It is only when measurements are made at $X_{AB} \lesssim 1/\gamma$ that linear extrapolations to $X_{AB} = 0$ can give a good estimate of $k_{1,0}^{M}$. In many cases, though, the large value γ (typically as large as 10^6) may make it impossible to properly estimate k_{10}^{M}. On the other hand, for those cases where curvature of the type in Fig. 3*a* can be observed experimentally, one has a good handle on the magnitude of γ. (*3*) When measurements are made in mixtures which are rich in relaxer, the mixture rule plots may be deceptively linear. However, linear extrapolation to $X_{AB} = 1$ will give effective rate constants which depend strongly on time. At earlier and earlier times the rate constants reflect more and more V–V character; but it is wrong to assume that in general they are V–V coefficients. Even at $t = 0$ they are at best a sum of V–V and T–V constants, $k_{1,1}^{2,0}/(1 - \chi_e) + 2(k_{1,0}^{AB} - k_{0,1}^{AB})$. At $t = \infty$, they are the T–V constants, $(k_{1,0}^{AB} - k_{0,1}^{AB})$. (*4*) The curvatures are markedly variable and depend on how the experimenter perceives his

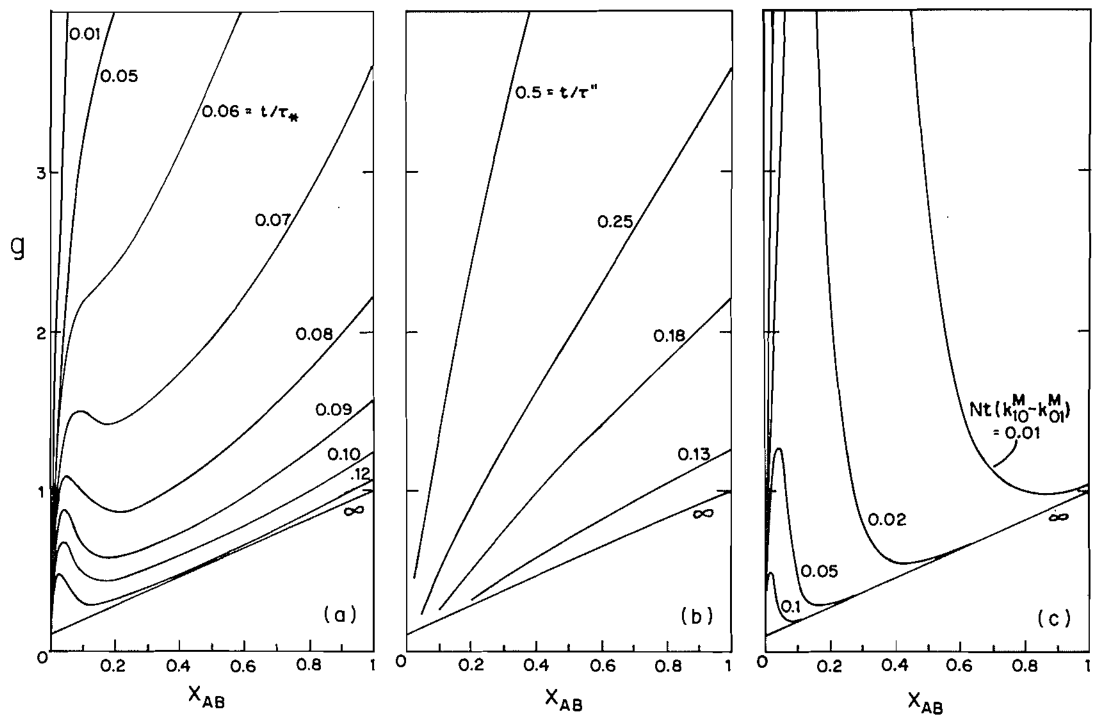

FIG. 3. Effective second order rate constant, g, as a function of mole fraction of the diatomic molecule, AB, undergoing vibrational relaxation. Typical conditions used here are $\gamma = 100$, $\delta = 10$, $\chi_c = 0.01$, $\lambda = 4.5$, and $\phi_M = 0.1$. The non-linearities are shown for three different choices of progress variable: (*a*) time reduced by the effective T–V time-constant; (*b*) time reduced by an effective relaxation time, as perceived by the experimenter; and (*c*) absolute time, or, time reduced by a mole-fraction-independent time-constant.

time scale. In Fig. 3*a* the rate coefficients are measured consistently at a fixed t/τ_*. Deviations from linearity are always present and are always positive. They must be positive when $\delta > 0$ because then V–V processes increase the rate of relaxation over that by T–V processes by introducing alternative mechanistic routes. Deviations are of two types: (*a*) monotonically varying; and (*b*) exhibiting a maximum. At early times only V–V processes are important, and they thus become monotonically more important as X_{AB} increases. The maximum manifests itself at later times even close to equilibrium. It exists because (as can be seen in Fig. 2 and in [16]) the smaller the mole fraction of AB, the smaller the amplitude of the V–V effect but the *longer* it takes relatively for the V–V effect to decay. These two properties compete, producing a maximum. We estimate the X_{AB} for maximum deviation from linearity, below. The X_{AB} at the maximum correlates well with the mole fraction at which the % energy change has relaxed the most by a fixed time via V–V processes. One should also note that an experimenter measuring in the region just beyond the maximum may get the erroneous impression that (since g decreases wih increasing X_{AB} here) AB appears to be *less* efficient than M is as a T–V collider even when it really is not ($\phi_M = 0.1$ here).

As mentioned earlier, if non-linearities are observed then it is because τ'' is not a unique quasi-first order time constant. Measurements are apparently being made in transient zones. Thus, the experimenter does not know the value of t/τ_*, merely that of t/τ''. Using that time scale the experimenter will obtain plots like those in Fig. 3*b* which are mildly curved, but still time-dependent. Note that there are actually three values of g possible for a given t/τ'' (see Fig. 2*b*). The fixed values of t/τ'' ($=[t/\tau_*][\tau_*/\tau'']$) chosen for Fig. 3*b* correspond to the transient zone where t/τ'' actually decreases while t/τ_* increases. Since the range of t/τ'' is restricted, then the range of X_{AB} is also restricted to that which results in transient zones falling within that time-scale window. (At times beyond this transient zone, when $\tau'' \approx \tau_*$, curves such as those in Fig. 3*a* are obtained.) The mildness of the curvature in Fig. 3*b* represents a very subtle danger to the experimenter, since he is then less likely to be aware of ambiguities.

In Fig. 3*c* the time scale has been divided by the characteristic time constant for T–V collisions of M, i.e., by $N(k^M_{10} - k^M_{01})$, which is independent of X_{AB}. This is essentially the same as choosing a fixed absolute time. At different mole fractions this fixed time corresponds to different t/τ_*. For example, measurements at $t = 1$ μs in mixtures with low mole fractions of AB may correspond to relatively early portions of the relaxation zone and hence have significant V–V character. On the other hand, in mixtures having large mole fractions, X_{AB}, which relax relatively faster, 1 μs may correspond to a relaxation very close to equilibrium where the T–V mechanism prevails. This choice of time scale is probably common in the literature, and could provide the most dramatic non-linear mixture effects.

Figure 4 shows the effect of the parameters δ, γ, λ, and ϕ_M on the mixture plots, for a fixed $t/\tau_* = 0.1$. The degree of closeness to classical oscillation, λ, affects only the residual thermal effects (the major thermal effect having been factored out earlier). However, these effects are weak. We also note from [16] and from Fig. 1*b* that the smaller the value of γ the smaller the amplitude of the V–V effects but the longer in time they last. This competition causes the deviation from linearity to be most pronounced at intermediate values of γ. In Fig. 4*c* when $\delta = 10$, the value of γ leading to worst deviation from linearity is for a modest $\gamma \sim 40$. Thus it is by no means certain that the larger the V–V rate constants are relative to the T–V rate constants the greater the non-linearity. In fact, it appears that the more important parameter for determining the degree

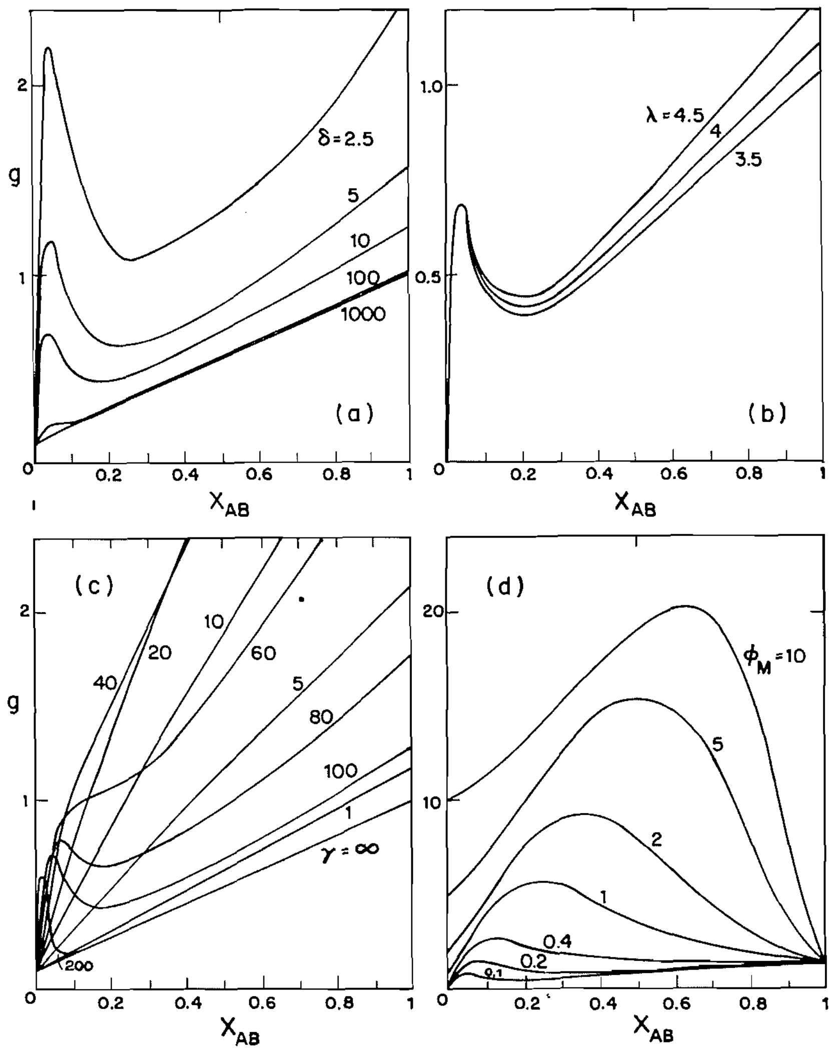

FIG. 4. Effective second order relaxation rate constant, g, as a function of mole fraction of the relaxing diatomic, AB, at $t/\tau_* = 0.1$. (a) Effect of δ, i.e., of the relative deviations from equilibrium and statistical distributions. Here $\gamma = 100$, $\chi_e = 0.01$, $\lambda = 4.5$, $\phi_M = 0.1$; (b) effect of λ, i.e., of how nearly classical the oscillator is. (At $\lambda = 4.5$ the oscillation is purely classical.) Here $\gamma = 100$, $\delta = 10$, $\chi_e = 0.01$, $\phi_M = 0.1$; (c) effect of γ, i.e., of the relative importance of V–V and T–V rate coefficients. Here $\delta = 10$, $\chi_e = 0.01$, $\lambda = 4.5$, $\phi_M = 0.1$; (d) effect of ϕ_M, i.e., of the relative efficiency of M and AB at T–V excitation. Here $\delta = 10$, $\gamma = 100$, $\chi_e = 0.01$, $\lambda = 4.5$.

of V–V character is δ. Figure 4a shows the sensitivity of non-linearity to δ. For $\delta = 1000$, the mixture rule is essentially linear. For $\delta = 10$, it is very non-linear. Reference 20 summarizes typical values of δ. For shock tube excitation (the initial population distribution is Boltzmann), $\delta = \infty$; the energy relaxes exponentially [19]; g is independent of time; $1/\tau'' = 1/\tau_*$, i.e. is a linear combination of T–V rate constants; and the mixture rule is always linear for this special kind of experiment. For laser-or-chemical excitation, $|\delta|$ is in the range 4–100, and we obtain non-linear mixture rules. In some of those cases, δ can also be negative (corresponding to energy overshoots or undershoots). We have not considered such cases in this study: an experimenter noting such overshoots would normally fit his data to a model including V–V and T–V processes.

It is also interesting to deduce the effect of temperature, T, on the non-linear mixture rule for a given experiment. As noted in ref. 20, δ does not seem to depend on temperature significantly. Therefore for fixed λ, δ, and ϕ_M we need only determine the temperature dependence of $\gamma = k_{1,1}^{2,0}/(k_{10}^{AB} - k_{01}^{AB})$. The V–V rate constant empirically is not significantly temperature dependent. If anything, it decreases with T. On the other hand, k_{10}^{AB} increases with T according to exp $(-cT^{-1/3})$ where c is a constant. Thus γ decreases with increasing T. We thus expect that for small $\delta < 100$ and $\gamma \gtrsim 40$, increasing the temperature decreases γ, and hence increases the non-linear effects. If the temperature is increased so much that $\gamma < 40$ then the non-linearities become less serious again. However, such high temperatures are rarely attained.

Finally, we note in Fig. 4d, where $\gamma = 100$, $\delta = 10$, that whereas the deviation from linearity is greatest when there is only 4% AB in the mixture if $\phi_M = 0.1$, the deviation is greatest at 63% AB if $\phi_M = 10$. Apparently, non-linearities manifest themselves in the mole fraction region corresponding to the *least* efficient collider. We also note that Fig. 4d is a way of expressing the use of a variety of different colliders to relax AB. In the mole fraction range $X_{AB} \sim 1$ linear extrapolations to $X_{AB} = 1$ give a common value regardless of the collider, as is reasonable. However, extrapolating from some intermediate range of X_{AB} (even if beyond the maximum) leads to problems.

Mild curvature prevents any two such extrapolations to lead to a common intercept. This should prove to be a useful diagnostic tool for detecting non-linearities when they are mild. The study of Miller and Hancock (21) is a good example, showing the existence of curvature indirectly. Admittedly their colliders were not inert atoms; nevertheless, the same principles are involved. It should be pointed out, however, that this is merely a necessary but insufficient test for linearity. Even if common intercepts are obtained they may not be easily interpretable unless the intercepts are time-independent as well.

It is interesting to investigate when the relaxation rate, $d\bar{E}/d(Nt)$ is least well described by a linear mixture rule. The first term on the right hand side of [16] is constructed from a linear combination of partial T–V rates with contributions from both colliders M and AB. The deviation from this linearity arises entirely from the second (V–V) rate term on the right hand side of [16]. This deviation from $(\bar{E} - \bar{E}_\infty)/N\tau$ is a maximum when

$$\left(\frac{X_{AB}k_{1,1}^{2,0}}{1-\chi_c}\right)\exp\left[-\left(\frac{N_{AB}k_{1,1}^{2,0}\tau}{1-\chi_c}+2\right)\frac{t}{\tau}\right]$$

reaches a maximum. We constrain ourselves to measurements made at fixed t/τ, such as in Figs. 3*a* and 4. Using the definition for τ, γ, and ϕ_M, the mole fraction of relaxer at the maximum, X, is given by

$$[23]\quad \frac{X\gamma(t/\tau)\phi_M}{[X+(1-X)\phi_M]^2(1-\chi_c)} = 1$$

As seen in Fig. 4, X does not depend on λ nor on δ. As an example, we choose the parameters of Fig. 4, where $t/\tau_* = 0.1$. $t/\tau \approx 0.1$ also, particularly when the mixture is dilute in AB. For $\gamma = 100$ (Fig. 4*d*) X varies between 0.012 and 0.404 in the range $\phi_M = 0.1 \to 10$. For $\phi_M = 0.1$ (Fig. 4*c*) X varies between 0 and 0.112 in the range $\gamma = \infty \to 80$. These are in qualitative agreement with the actual maxima in Fig. 4. However, we note that [23] corresponds to the deviations of *rates* from linearity; whereas Fig. 4 correspond to deviations of phenomenological *rate coefficients* from linearity.

Furthermore, in the likely case that $\gamma(t/\tau) \gg 1$, and $\phi_M \lesssim 1$, then $X \approx \phi_M/(\gamma t/\tau)$, i.e.

$$X = \frac{k_{1,0}^M - k_{0,1}^M}{k_{1,1}^{2,0}\,t/\tau}$$

In other words, the mole fraction at which non-linear deviations make themselves most felt is of the order of the relative T–V (collider M) rate constant to V–V rate constant. This is a very small number. However, more importantly the rate *coefficient* approaches to within 5% of the T–V limiting value only when X_{AB} is almost 100 times smaller yet. It puts *very* stringent requirements on an experimenter wishing to extract $k_{1,0}^M$ from data taken at finite mixture composition!

It is also useful to estimate the magnitude of the maximum deviation from linearity. We substitute [23] into an expression for the deviation from linearity divided by the linearly additive rate, i.e.

$$\frac{N_{AB}k_{1,1}^{2,0}h\nu_c\chi_c[2(\bar{E}/h\nu')^2 + (\bar{E}/h\nu') - \overline{E^2}/(h\nu')^2]_0 \exp[-(N_{AB}k_{1,1}^{2,0}\tau/\{1-\chi_c\}+2)t/\tau]}{(\bar{E}-\bar{E}_\infty)/\tau}$$

Noting that at early times $\bar{E} \approx \bar{E}_0$ and $\bar{E}_\infty \simeq \bar{E}_{\infty,c}$, and using the definition for δ, this maximum relative deviation becomes (for small X)

$$\frac{1-\chi_c}{\delta(t/\tau)}\,e^{-(1+2t/\tau)}$$

The relative deviation becomes more pronounced at earlier times and for smaller δ, i.e., the more non-Boltzmann the initial distribution is. For example, when $t/\tau = 0.1$ and $\delta = 5$, the rate of relaxation is more than 60% greater than it would have been without the non-linearities.

If, instead of choosing fixed t/τ, we consider experiments measured at fixed $N(k_{1,0}^M - k_{0,1}^M)t$, as in Fig. 3*c*, then X_{AB} at the maximum is given by

$$X = \frac{\phi_M}{N(k_{1,0}^M - k_{0,1}^M)t}[\gamma/(1-\chi_c) + 2(1-\phi_M)]^{-1}$$

Again, for the usual situation where γ is large, X is a small number,

$$X \approx \frac{(1-\chi_c)\phi_M}{\gamma}\cdot\frac{1}{N(k_{1,0}^M - k_{0,1}^M)t}$$

and the maximum relative deviation from linearly additive rates,

$$\frac{(1-\chi_c)e^{-1}}{\delta N(k_{10}^M - k_{01}^M)t},\ \text{can be} \gg 1$$

G. Suggestions for analyzing data

It appears that the safest experimental procedure (with respect to ambiguous interpretations) is to work as close as possible to equilibrium. In dilute mixtures ($X_{AB} \lesssim 1/\gamma$) linear extrapolation to $X_{AB} = 0$ leads to k_{10}^M. At $X_{AB} = 1$, one obtains k_{10}^{AB}. One should then measure $N\tau''$ as a function of time for $X_{AB} = 1$. Having already determined k_{10}^{AB} one can normalize $(1/N\tau'')$ by dividing by $(k_{10}^{AB} - k_{01}^{AB})$ to obtain g. Then, as can be seen from [22], when $X_{AB} = 1$

$$[24]\quad \frac{g-1}{a\tau_* - g} = a\tau_*\left[\frac{\delta(a\tau_* - 1)\bar{C}}{\gamma(\bar{C} - C_{vib})} - 1\right]^{-1} e^{-(a-1/\tau_*)t}$$

We note that $a\tau_* \sim \gamma$. At times far enough from equilibrium that some time-dependence in g is observable, but near enough to equilibrium that the variation is no more than a factor of 2 (i.e. $g \lesssim 2$), then $a\tau_* \gg g > 1$. Thus, a plot of ln $(g - 1)$ vs. time will give approximately a straight line with $(a - 1/\tau_*)$ as slope, i.e.

$$\frac{N_{AB}k_{1,1}^{2,0}}{1-\chi_c} + \frac{2}{\tau} - \frac{1}{\tau_*}$$

Having already determined k_{10}^{AB} and k_{10}^M (and therefore also τ and τ_*) as described above, $k_{1,1}^{2,0}$ is easily extracted. Alternatively, one can use the procedure given in ref. 20 (again for pure relaxer, AB) to determine $k_{1,0}^{AB}$ and $k_{1,1}^{2,0}$. However, in contradistinction to the above suggestion, where not even a knowledge of δ is required, the method of ref. 20 requires some knowledge of the population distributions. That procedure is based on the exponential decay of the function $2(\Sigma vN_v/N)^2 + \Sigma vN_v/N - \Sigma v^2 N_v/N$, as shown above (eq. [15]). The slope of a log plot of this function vs. time gives

$$\left(\frac{N_{AB}k_{1,1}^{2,0}}{1-\chi_c} + \frac{2}{\tau}\right)$$

Figure 1 shows that if measured at times sufficiently long ($\gtrsim 20\tau_*/\gamma$) then τ'' is just τ_*. Thus $N_{AB}k_{1,1}^{2,0}$ can be extracted by this method.

H. Comparison with experiment

The literature on the vibrational relaxation of molecules, pure or in mixtures with inert gases, is vast. We have not attempted an exhaustive search. Instead, we concentrate on two or three systems.

It appears that non-linearities are the rule rather than the exception for polyatomic molecules. We have observed them in our own laboratory for CH_4 (16), for N_2O and C_2H_2 (22) at mole fractions of the order of 0.01 in shock waves of Ar mixtures. In laser-induced experiments Moore and co-workers (23) have made measurements of the relaxation of H_2O diluted in Ar and in N_2. Slight curvature is evident for the ν_3 mode at mole fractions ~ 0.01. Wittig also (24) has studied the vibrational relaxation of the ν_1 and ν_3 modes of H_2O at mole fractions only as low as 0.05. However, extrapolations of his data to $X = 1$ using two different diluents do not give the same intercept. This is evidence for non-linearity, as discussed above. Since our model does not apply to polyatomics, we shall not discuss them further.

Diatomic molecules can be divided into two classes: according to whether the initial distributions are Boltzmann (shock tube experiments) or not. For the former class, we expect relaxation rates to be linearly additive. Indeed we have not found a single case contradicting this. Of some relevance is Glänzer's study of NO/Ar mixtures (15). In his shock wave experiments the $v = 0$, 1, and 2 vibrational level populations (in contradistinction to the total vibrational energy) did not decay or grow with linearly additive rates. Borrell's studies of CO mixtures with Ne (25) and with the hydrogen halides (26) seem to us to show the same behaviour. In analogy with the present study, the whole effect may be an artifact of the experimenter's imposition of quasi-first order kinetics onto the data, when the mechanism involves rapid second-order processes. Nevertheless, Glänzer's study showed that V–V effects can be eliminated by measuring at extremely low mole fractions $<10^{-4}$. It should serve as a warning to experimenters working far from equilibrium, particularly with molecules in the latter class. Unfortunately, fitting data to pure exponential functions is prevalent in the literature. V–T rate coefficients determined in this way are not likely to be unique rate *constants*, nor necessarily be interpretable as reported, unless $X \lesssim 10^{-4}$, or $\alpha \lesssim 10^{-4}$ (27).

In evaluating the second class of experiments, we concentrate on the hydrogen halides and on CO — molecules which have been the most extensively studied. It is evident to us that in the vast majority of these studies the mole fraction range was not sufficiently well covered, if at all. To complicate matters, in most studies neither the time regime used, t/τ, nor even the absolute time scale is ever cited. It is, moreover, extremely rare for the degree of excitation, α, to be mentioned. All of this is very important for diatomics where γ is expected to be much larger than for polyatomics. We expect that non-linearities should be most pronounced at $X \lesssim 10^{-3}$, as in Glänzer's study, far below the regime usually studied. Thus, very few studies show direct evidence of non-linearities in diatomic mixture rules: Hancock and Saunders discovered very strong non-linearities in their studies of DF relaxation at mole fractions as low as 0.0076. At the low temperatures involved it is probably dimerization which is responsible (28). Linear extrapolations of HF relaxation data, measured at mole fractions as low as 0.001, to $X = 1$ differ very much from the results for pure HF, thus indirectly indicating non-linearities (29). Similarly for H_2 (21). By measuring at very early times and at mole fractions as low as 0.002, Chen saw very strong non-linearities in the relaxation of HBr (30). The non-linearities in all of the above examples are consistently in the same direction as predicted by the present study.

Summarizing, we believe that the few experimental studies of mole-fraction dependence of relaxation times, as published in the literature, confirm the *predictions* of our study. However, it is not clear if experiments (particularly with hydrogen halides) confirm the scaling laws used in our basic model. Data on scaling relationships for V–V energy transfer in pure gases is surprisingly meagre (see ref. 31 for a thorough review). Only HCl and HF and CO have been studied in this respect. The consensus of opinion is that as v increases, the V–V channel becomes less able to compete with the V–T route. The data are considered to be substantially influenced by V–T processes (32), and we cannot conclude very much from this.

The question of the scaling of V–T rate constants is also not yet clear. On the one hand, the "V–T" rate constants are found to depend more strongly on v than linearly (33). On the other hand, our model, which accounts for a stronger variation by including an $e^{\Delta E/kT}$ term, (and presumably any model with "correct" scaling) would predict that the procedures used to draw such conclusions (i.e., treating the rates of population changes according to pure first order kinetics when α is as large as 0.01) are deficient. At the very best, such measurements lead to information on the sum of V–T and V–V rate constants; however, the possibility exists that they are artifacts, just as is the observed non-linear mixture rule. In other words, it is very hard for an experimenter to prove that so-called V–T rate constants are free of V–V character.

Notwithstanding these comments, some key experiments involving CO and DCl seem to confirm the scaling laws we used. Simpson and co-workers have shown that CO and DCl each relax via a continuous sequence of Boltzmann distributions behind shock waves (34, 35). This can only happen when V–T rate constants depend linearly on quantum number. The argument for this involves a discussion of canonical invariance, to which we now turn.

It has been shown by Shuler and co-workers (36, 37) that if the initial distribution of vibrational levels is Boltzmann, as in shock wave experiments, then equilibrium is approached via a continuous series of Boltzmann distributions, on condition that the harmonic oscillator molecules obey the Landau–Teller rules. The converse has also been proven (38, 39). As a corollary, Pritchard has stated that canonical invariance, linear mixture rules, and exponential decay all originate in the uniqueness of Landau–Teller sum rules (40). However, proofs of these properties have been given only for models where T–V are the only processes. There is as yet no satisfactory discussion in the literature on the question of canonical invariance for anharmonic molecules when V–V processes are involved: Osipov showed (41) that with V–V processes included and scaled according to Landau–Teller rules, then after the V–V transient period the distributions approach Boltzmann ones. However, he treated the molecules as harmonic oscillators and did not discuss the special case of an initial Boltzmann distribution. Rankin and Light did find canonical invariance even when V–V processes were considered (19). However, their model also used harmonic oscillators; we have already shown (17) that such a simplification essentially eliminates the influence of V–V processes on bulk measurements. The study which is closest to being satisfactory is Treanor's (42), who showed that, in general, canonical invariance is not valid. However, he used non-Landau–Teller scaling, and his result is thus expected. Moreover, Treanor did not consider the case which interests us here, namely, what happens if the initial distribution is Boltzmann? Therefore we still do not know whether or not the existence of canonical invariance implies Landau–Teller behaviour. Even our own study (20), which proved that energy-changes in a set of anharmonic oscillators decay exponentially when V–V and T–V rate constants scale according to Landau–Teller rules, does not prove canonical invariance (although we suspect that our study is a good starting point for a proof). We do not know whether exponential decay, linear mixture rules (and presumably canonical invariance) are a consequence of the unique sum rules or merely of an *initial* Boltzmann distribution, when V–V processes are involved.

In summary, the indications are that Simpson's experiments (made in a time regime where V–V effects have died out) show that T–V rate constants scale according to Landau–Teller rules.

I. Conclusion

We have shown that non-linear mixture rules can arise for the vibrational relaxation of diatomic molecules. Although we have evaluated the effect in detail for the atomic collision partner, M, the principle is the same for any inert collision partner. We have made a few reasonable approximations, such as isobaric relaxation, and we have neglected the temperature dependence of the microscopic rate constants. Except for thermal effects, it seems that non-linear mixture rules arise entirely as an artefact caused by the insistence of experimentalists on fitting measured data to first order kinetics, whereas a double exponential is more appropriate. The persistence of V–V energy transfer processes to times relatively advanced in the relaxation causes the rate law to be non-exponential and thus injects non-linearities into the analysis of data. Ambiguity is introduced by the experimentalist's conception of the time regime being probed. Some inconsistencies in choosing well-defined fixed or relative times accentuate the problem of the validity of the linear mixture rule. Such inconsistencies may lead to spurious results, e.g., in a plot of log $p\tau$ vs. $T^{-1/3}$, or at least lead to unnecessary scatter in the data. Even if a consistent time scale is chosen, linear extrapolations from curved mixture rule plots lead to wrong values for $k_{1,0}^{AB}$ and $k_{1,0}^{M}$. Furthermore, since the measured relaxation times are phenomenological in nature, different mixture rules may result depending on one's definition. For example, defining $\tau' \equiv -(\bar{E} - \bar{E}_\infty)/(\mathrm{d}\bar{E}/\mathrm{d}t)$ leads to different results than does use of [9] (20). We believe that, if our own suggestions for data analysis are not followed, then using definition [9] at least facilitates comparison between different experimental techniques such as fluorescence and schlieren methods, assuming that the regimes of t/τ'' and the degree of pertubation are reported.

We find that non-linearities are most evident at high temperatures, at early times, and in mixtures rich in the least efficient of the colliders. The larger the anharmonicity and the larger the degree of perturbation of the diatomic molecule the more pronounced the non-linearity becomes. Elimination of these non-linearities requires measurements at times up to 20 times longer and mole fractions up to 100 times smaller than expected on the basis of the magnitude of the V–V rate constant, depending on the initial conditions.

A special case was discovered where linear mixture rules are always expected — namely, shock tube measurements of the rate of vibrational relaxation of diatomic molecules. This results from the property that the initial distribution is Boltzmann. The same molecule at the same temperature using a different excitation method such as laser excitation would have relaxation times which disobey the linear mixture rule. However, we do not know if this result is due to the unique properties of Landau–Teller rate constants, i.e., if other scaling laws, which do not lead to canonical invariance, would also lead to the present result, or whether it is merely a consequence of the unique initial distribution in shock waves. Contrary to Pritchard's conclusion (40), obedience of Landau–Teller rules is now seen not to be sufficient to guarantee linear behaviour.

It is also instructive to interpret our results in terms of the synergism concept mentioned in the Introduction. Here, the two competing routes are (*1*) T–V processes by M, and (*2*) T–V processes by AB, each weighted by X_M and X_{AB}, respectively. The relatively slow T–V routes involve the steps $v = 0 \rightarrow v = 1 \rightarrow v = 2$. Even though in the present model the step $v = 1 \rightarrow v = 2$ is about twice as fast as $v = 0 \rightarrow v = 1$, the mere presence of AB in the mixture which allows for communicating V–V process $(v = 1) + (v = 1) \rightarrow (v = 0) + (v = 2)$ that may be more than 100 times as fast as $v = 0 \rightarrow v = 1$, obviates the need for T–V to accomplish $v = 1 \rightarrow 2$ at all. The role of T–V is relegated to restoring newly created $v = 0$ back to $v = 1$, a role which only T–V can accomplish. This symbiosis extends all the way up the vibrational ladder. However, the higher the vibrational level, the larger the T–V rate constants and the smaller the V–V constants. Thus the V–V route becomes relatively less important as a communicator. The synergism is most pronounced among the lower vibrational states. This idea has two consequences: (*1*) The whole effect depends on the initial conditions. The vibrational level to which the molecules are excited, the actual fraction excited, the closeness to equilibrium and hence need for communication, as well as the direction of relaxation (low $v \rightleftarrows$ high v) *all* determine the value of the all-important parameter δ. What may be an avoided bottleneck from one direction may not be so much of a bottleneck from the other direction, which has a different "average" vibrational quantum number and hence different δ. Indeed, as mentioned earlier, if enough molecules are produced in high vibrational states, δ can become < 0, and Treanor pumping will cause molecules to be trapped in high vibrational states and thus relax more slowly. (*2*) We can make a further prediction concerning the linear mixture rule. If the T–V rate constants depend less strongly on v than in the Landau–Teller model, then communication becomes even more important, and non-linearities become even more pronounced than found in this work. Conversely, if T–V constants depend more strongly on v than the Landau–Teller model, then the linear mixture rule will be better obeyed.

In our analysis, we implied that rotation of the diatomic molecule plays no role, or at least a passive role. Our analysis is valid only when the rotational levels have equilibrated on a much shorter time scale than that in question (43). Whereas this may be true with respect to the relatively improbable T–V processes, it may not be true with respect to the relatively probable V–V processes. A more proper treatment would have to involve the rotational substructure. As mentioned earlier, additional synergism can only lead to even greater nonlinearities. Work is now in progress in this direction.

Finally, we hope that this work will spur studies of vibrational relaxation to cover wide ranges of mole fraction.

Received April 2, 1984

PHILIP A. W. DEAN, JAGADESE J. VITTAL, and NICHOLAS C. PAYNE. Can. J. Chem. **63**, 394 (1985).

Stannous chloride, in solutions containing at least three mole equivalents of $NaEC_6H_5$, E = S and Se, forms triligated anions which crystallize readily as the tetraphenylarsonium salts, $[(C_6H_5)_4As][Sn(SC_6H_5)_3]$, **1**, and $[(C_6H_5)_4As][Sn(SeC_6H_5)_3]$, **2**. The crystals so formed are isomorphous, and their structures have been determined by single crystal X-ray diffractometry techniques. The salts crystallize in the monoclinic space group $P2_1/c$, with four formula units in unit cells of dimensions a = 10.760(1), b = 17.515(2), c = 20.247(3) Å, β = 104.71(1)° for **1**, and a = 10.885(2), b = 17.587(2), c = 20.612(2) Å, β = 105.47(1)°, for **2**. The structures have been refined by full-matrix least-squares techniques on F to agreement factors R = 0.024 (4780 observations with $F_o > 3\sigma(F_o)$) for **1**, and R = 0.030 (3442 observations with $F_o > 3\sigma(F_o)$) for **2**. The discrete $[Sn(EC_6H_5)_3]^-$ anions are isostructural; the three S or Se atoms form the base of a triangular pyramid whose apex is occupied by the Sn atom. Two Sn—S distances in **1** are 2.532(1) and the third 2.552(1) Å, while in **2** the Sn—Se distances are 2.649(1), 2.650(1), and 2.671(1) Å. Angles at the Sn atom are 89.91(3), 90.55(3), and 96.73(3)° in **1**, and 88.74(3), 89.72(3), and 97.27(3)° in **2**. In both anions all three phenyl groups adopt a propeller-like conformation and are disposed in equatorial positions above the basal plane of chalcogen atoms. These salts represent the first thiolato- and selenolatostannates(II) to be characterized structurally. Tin-119 nmr spectra confirm that the $[Sn(EC_6H_5)_3]^-$ ions are the same anionic Sn(II) species recently prepared *in situ* in solution.

PHILIP A. W. DEAN, JAGADESE J. VITTAL et NICHOLAS C. PAYNE. Can. J. Chem. **63**, 394 (1985).

Le chlorure stanneux, dans des solutions qui contiennent au moins trois équivalents molaires de $NaEC_6H_5$, E = S et Se, forme des anions triplement liés qui cristallisent facilement sous forme de sels de tétraphénylarsonium, $[(C_6H_5)_4As]$-$[Sn(SC_6H_5)_3]$ (**1**) et $[(C_6H_5)_4As][Sn(SeC_6H_5)_3]$ (**2**). Les cristaux qui se forment ainsi sont isomorphes et on a déterminé leurs structures par des techniques de diffraction des rayons-X sur des cristaux uniques. Les sels cristallisent sous forme monoclinique dans le groupe d'espace $P2_1/c$, avec quatre unités par unité et les dimensions de la maille sont a = 10,760(1), b = 17,515(2), c = 20,247(3) Å, β = 104,71(1)° pour **1** et a = 10,885(2), b = 17,587(2), c = 20,612(2) Å, β = 105,47(1)° pour **2**. On a affiné les structures par les techniques des moindres carrés (matrices complètes sur F) jusqu'à des facteurs d'accord R = 0,024 (pour 4780 observations avec $F_o > 3\sigma(F_o)$) et R = 0,030 (pour 3442 observations avec $F_o > 3\sigma(F_o)$) respectivement pour **1** et **2**. Les anions individuels $[Sn(EC_6H_5)_3]^-$ sont isostructuraux; les trois atomes de S (ou Se) forment la base d'une pyramide triangulaire dont le sommet est occupé par un atome de Sn. Deux des distances Sn—S dans **1** sont égales à 2,532(1) et la troisième est égale à 2,552(1) Å alors que dans **2** les distances Sn—Se sont égales à 2,649(1), 2,650(1) et 2,671(1) Å. Dans **1**, la valeur des angles au niveau de l'atome de Sn sont 89,91(3), 90,55(3) et 96,73(3)° alors que dans **2** les valeurs sont 88,74(3), 89,72(3) et 97,27(3)°. Dans chacun des anions, les trois groupes phényles adoptent une conformation hélicoïdale et ils occupent des positions équatoriales au-dessus du plan de base des atomes chalcogènes. Ces sels sont les premiers thiolato- et sélénolato-stannates(II) dont la structure a été caractérisée. Les spectres rmn du ^{119}Sn confirment que les ions $[Sn(EC_6H_5)_3]^-$ sont les mêmes espèces ioniques Sn(II) qui ont récemment été préparées *in situ* en solution.

Introduction

The structural chemistry of thiolato complexes of the *d*-block elements has been of intense interest in recent years. Thus, for example, complexes of the general type $[M(S\text{-Aryl})_4]^{2-}$ have been characterized structurally for M = Mn(II) (1), Fe(II), Co(II), Ni(II), Zn(II), and Cd(II) (2, 3), and Hg(II) (4). Similarly, the structures of polynuclear thiolato complexes have been described for a wide range of elements including Mn(II) (1), Fe(II) (5–8), Co(II) (9, 10), Zn(II) (11), Cd(II) (12), V(III) (13, 14), Mn(III) (15), Cu(I) (16, 17), and Ag(I) (18). By comparison, thiolato complexes of the *p*-block elements have received little attention. In particular, phenylthiolatostannates(II), together with the analogous selenolatostannates(II), the subject of the present paper, do not seem to have been investigated prior to a recent multinuclear solution nmr study from one of our laboratories (19), though salts of the $[Sn(SC_6F_5)_3]^-$ anion have been synthesized (20) and organometallic tin(IV) thiolates are well known (21).

In the previous nmr study (19), slow exchange ^{119}Sn and ^{77}Se nmr spectra could be obtained at reduced temperature for $C_6H_5S^-/C_6H_5Se^-/Sn(II)$ mixtures in methanol when $L_{total}/M <$ 3, allowing characterization in solution of the all of the species $[Sn(SC_6H_5)_x(SeC_6H_5)_{3-x}]^-$. As no structural data are currently available for either $[Sn(SR)_3]^-$ or $[Sn(SeR)_3]^-$ anions, we thought it desirable to isolate the parent complexes of this series and determine their structures; further we felt that comparison with the corresponding plumbates(II) for which we have recently presented structural data (22) would be of interest. Accordingly we report here the syntheses and X-ray structure analyses of $[(C_6H_5)_4As][Sn(EC_6H_5)_3]$ (E = S and Se). At the outset of our work no X-ray structural data were available for neutral stannous thiolates or selenolates. Very recently, however, the structures of two substituted benzene thiolates of tin(II) have been reported (23).

Experimental

All the chemicals were of reagent grade and used as received. Carbon and hydrogen analyses were performed by Guelph Chemical Laboratories Ltd.

Syntheses of the compounds were carried out under an argon atmosphere in a glove bag, using solvents that had been thoroughly deoxygenated with argon.

Synthesis of $[(C_6H_5)_4As][Sn(SC_6H_5)_3]$

Benzenethiol, 1.18 g (10.7 mmol), was added to 0.248 g (10.7 mmol) of sodium metal dissolved in 10 mL of methanol. The resultant

solution of $NaSC_6H_5$ was added to a stirred solution of 0.83 g (3.25 mmol) of $SnCl_2\cdot 2H_2O$ in 10 mL of water, producing a yellow precipitate. A solution containing 1.39 g (3.3 mmol) of tetraphenylarsonium chloride hydrate in 5 mL of methanol was added with stirring to the yellow precipitate followed by 50 mL of acetonitrile. The mixture was warmed to 70°C for 30 min giving a very pale yellow solution, filtered hot, and left to crystallize. The pale yellow crystals of diffraction quality obtained in a few hours were separated by decantation and washed with water, methanol, and carbon tetrachloride, then dried in a stream of argon. Concentration of the mother liquor provided a second crop of crystals. Yield: 500 mg. (18.5%). *Anal.* calcd. for $C_{42}H_{35}AsSnS_3$: C 60.81, H 4.25; found: C 60.63, H 4.36.

Synthesis of $[(C_6H_5)_4As][Sn(SeC_6H_5)_3]$

The preparation of this yellow compound was very similar to that of the sulfur analog but C_6H_5SeH was used instead of C_6H_5SH. The hot solution was sealed and refrigerated for a day to get lemon yellow crystals of diffraction quality. Yield: 150 mg (10%). *Anal.* calcd. for $C_{42}H_{35}AsSnSe_3$: C 51.99, H 3.64; found: C 51.91, H 3.73.

Physical measurements

^{119}Sn nuclear magnetic resonance spectra

The 296 K 149.2 MHz ^{119}Sn nmr spectra were measured and referenced to neat $SnMe_4$ as described previously (19). The samples were prepared in CH_2Cl_2 and were ~0.1 M and ~0.06 M for $[(C_6H_5)_4As][Sn(SC_6H_5)_3]$ and $[(C_6H_5)_4As][Sn(SeC_6H_5)_3]$, respectively.

Collection and reduction of X-ray data

Well developed, pale yellow crystals of equant habit were chosen for each salt. A preliminary photographic examination indicated the monoclinic space group $P2_1/c$ (24), and a careful examination of the films showed that the salts were isomorphous and isostructural. Crystal densities were determined by flotation in mixtures of 1,2-dibromoethane and carbon tetrachloride.

The analyses were carried out on an Enraf-Nonius CAD4F diffractometer using an incident beam monochromator and Mo radiation (25). The thiolate structure **1** was undertaken first. Cell constants and an orientation matrix were determined from reflections recorded on a rotation photograph, and refined using the angular settings for 25 high angle reflections with $40 < 2\theta < 50°$. ω-Scans of intense, low-angle reflections had an average width at the base of 0.80°, a satisfactory value (26). Crystal data for both salts are given in Table 1. Intensity data were recorded at variable scan speeds ranging from 4 to 0.9 deg min^{-1}, values chosen to optimize counting statistics within a maximum time per datum of 75 s. Background estimates were made by extending the scan by 25% on each side. Standard reflections 4 0 0, 0 4 0, and 0 0 10 were monitored every 166 min of X-ray exposure time, and showed an average 4.1% decay over the total period of 133.4 h. In all, 7551 observations were recorded, of which 204 were standards. Corrections were applied for Lorentz, monochromator and crystal polarization, and background radiation effects using the structure determination package (27) running on a PDP 11/23+ computer. Standard deviations were assigned based upon counting statistics, and a value chosen for p of 0.05 to avoid overweighting strong reflections (28). Fourteen crystal faces were identified by optical goniometry, and the crystal dimensions measured on a microscope equipped with a filar eyepiece. The data were corrected for absorption by the Gaussian method. A linear decay correction was applied, and the equivalent forms averaged, leaving 4780 unique data with $F_o > 3\sigma(F_o)$ for solution and refinement of the structure.

The same procedure was followed for the selenolate structure **2**. ω-Scans showed an average width at base of 0.58°. Variable scan speeds ranged from 4.0 to 0.9 deg min^{-1}, with a maximum time per datum of 75 s. A total of 136.7 h was required for recording the intensity data. The crystal chosen had eight faces, and an absorption correction was applied. A preliminary value of 0.04 was chosen for p. No decay correction was applied. In all, 3442 unique data with $F_o > 3\sigma(F_o)$ were available. Details of experimental procedures are given in Table 1 for both **1** and **2**.

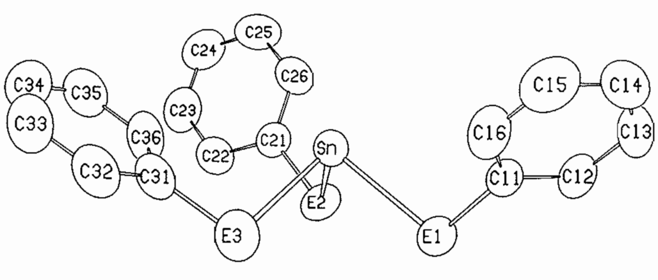

FIG. 1. A perspective view of an anion, showing the atom numbering scheme.

Solution and refinement of the structures

The atom positions for $[(C_6H_5)_4As][Pb(SC_6H_5)_3]$ (22) were used as a starting point for refinement of the structure of **1**. With all non-hydrogen atoms included, minimizing the function $\Sigma w(\|F_o| - |F_c\|)^2$, where F_o and F_c are the observed and calculated structure amplitudes, and the weight w is defined as $4F_o^2/\sigma^2(F_o^2)$, refinement converged at agreement factors $R_1 = \Sigma(\|F_o| - |F_c\|)/\Sigma|F_o|) = 0.037$ and $R_2 = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w F_o^2)^{1/2} = 0.055$. Scattering factors for neutral, non-hydrogen atoms were taken from ref. 24, and real dispersion corrections were included for all atoms (29). A difference Fourier synthesis showed clear evidence for all 35 H atoms on the phenyl rings, at peak heights ranging from 0.65(9) to 0.39(9) e Å^{-3}, so all were included in idealized positions (C—H 0.90 Å, sp^2 hybridization) with fixed isotropic thermal parameters arbitrarily set to 5 Å^2. The

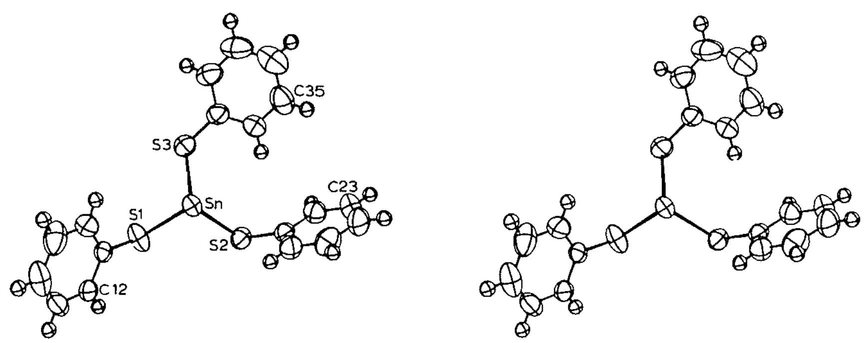

FIG. 2. A stereoview of the $[Sn(SC_6H_5)_3]^-$ anion.

scattering factor values were taken from Stewart *et al.* (30). With all non-hydrogen atoms assigned anisotropic thermal parameters, and hydrogen atom positions recalculated to maintain ideal geometries, refinement of 424 variables converged at $R_1 = 0.024$ and $R_2 = 0.033$ using 4780 observations with $F_o > 3\sigma(F_o)$. In a total difference Fourier synthesis there were eight peaks with electron density greater than 0.21(6) e Å^{-3}; of these, two were associated with the Sn atom, and the remainder were of no chemical significance. The error on an observation of unit weight was 1.022 electrons, and there were no parameter shifts in the final cycle. An analysis of R_2 in terms of F_o, $\lambda^{-1}\sin\theta$ and various combinations of Miller indices showed no unusual trends.

The positions for the thiolate structure were used as a starting point for refinement of the selenolate structure **2**. The 47 non-hydrogen atoms were refined with anisotropic thermal parameters and the refinement converged at agreement factors $R_1 = 0.040$ and $R_2 = 0.048$. Thirty four of the 35 hydrogen atoms were found from a difference Fourier synthesis, at peak heights ranging from 0.56(10) to 0.28(10) e Å^{-3}, so all were included in idealized positions. The refinement converged at $R_1 = 0.032$ and $R_2 = 0.035$. An inspection of F_o and F_c suggested that an extinction parameter should be refined. Employing 3442 observations with $F_o > 3\sigma(F_o)$ and a p factor of 0.05, refinement of 425 variables converged at agreement factors $R_1 = 0.030$ and $R_2 = 0.035$. Again, an analysis of R_2 in terms of F_o, $\lambda^{-1}\sin\theta$ and Miller indices combinations indicated a satisfactory weighting scheme. The error on an observation of unit weight is 1.011 electrons. The extinction parameter refined to $1.08(7) \times 10^{-7}$. In a final difference Fourier synthesis there were three peaks with electron density greater than 0.42(8) e Å^{-3}; these were associated with the tin and selenium atoms.

Positional and U_{eq} thermal parameters are given for the refined atoms of both structures in Table 2. Tables of hydrogen atom parameters, anisotropic thermal parameters, root-mean-square amplitudes of vibration, supplementary dimensions, weighted least-squares planes, torsion angles and structure amplitudes have been deposited.[2]

Results and discussion

General

The anions $[Sn(EC_6H_5)_3]^-$ (E = S or Se) produced by the reaction

$$Sn^{2+} + 3EC_6H_5^- \rightarrow [Sn(EC_6H_5)_3]^-$$

were isolated as their $[(C_6H_5)_4As]^+$ salts. The ^{119}Sn chemical shifts for $[(C_6H_5)_4As][Sn(SC_6H_5)_3]$ and $[(C_6H_5)_4As][Sn(SeC_6H_5)_3]$ in CH_2Cl_2 are 146 and 208 ppm, respectively, at

[2] Anisotropic thermal parameters, hydrogen atom parameters, root-mean-square amplitudes of vibration, additional bond distances and bond angles, weighted least-squares planes, selected torsion angles and structure amplitudes are available at a nominal charge from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

*Numbers in parentheses are estimated standard deviations in the least significant digits.

296 K. These values can be regarded as identical to those previously attributed to $[Sn(SC_6H_5)_3]^-$ and $[Sn(SeC_6H_5)_3]^-$ prepared *in situ* in methanol (140.0 and 207.0 ppm, respectively) (19), allowing for a small solvent effect on δ_{Sn} (31). Hence the earlier formulation is confirmed.

Description of the structures

The crystal structure of each compound consists of discrete cations and anions, the shortest cation . . anion As . . Sn distances being 5.020(3) and 4.972(1) Å in **1** and **2**, respectively. The shortest interionic distances are 2.54 and 2.55 Å between H44 and H74 in **1** and **2**, respectively. We note particularly that there are no interanionic interactions, the shortest Sn—Sn distances being 9.629(1) and 9.758(1) Å in **1** and **2**, respectively. Figure 1 gives the atom numbering scheme used and shows a perspective view of a $[Sn(EC_6H_5)_3]^-$ anion. Figure 2 shows a stereoview of the anion in **1**, with atoms plotted as 50% probability thermal ellipsoids. Selected bond distances and bond angles in the two compounds are listed in Table 3; those of the cations are unexceptional and are not discussed further.

It can be seen from the figures that the coordination about tin is trigonal pyramidal in both anions, as is commonly observed for $Sn^{II}L_3$ complexes of the VSEPR type AX_3E (see below). Overall, the four compounds $[(C_6H_5)_4As][M(EC_6H_5)_3]$, (M = Sn(II) or Pb(II), E = S or Se) are both isomorphous and isostructural. In contrast the compounds $[M(SAr')_2]_3$ (M = Sn(II) or Pb(II); Ar' = 2,6-diisopropylphenyl) are not isomorphous and are not considered to be isostructural (23).

The $[Sn(SC_6H_5)_3]^-$ anion

In the thiolato-complex the three sulfur atoms form the base of a trigonal pyramidal with the tin atom at the apex. The overall idealized symmetry of the SnS_3 kernel is C_{3v}, but two of the Sn—S distances are equal at 2.532(1) and shorter than the third distance of 2.552(1) Å, while the S—Sn—S angles are 89.91(3), 90.55(3), and 96.73(3)°. The largest angle, S2—Sn—S3, might be a result of repulsive steric interactions between the associated phenyl groups. There are short intramolecular non-bonded distances between H36 and C21 and C22: 2.862(3) and 2.920(4) Å in **1** and 2.913(6) and 2.972(7) in **2**. The Sn—S distances in **1** are intermediate between the short (terminal) Sn—S distance of 2.471(5) and the two longer (bridging) Sn—S distances of 2.643(4) and 2.583(4) Å found for the pyramidally coordinated Sn(II) centres in trimeric $[Sn(SAr')_2]_3$ (see above), but longer than the Sn—S distance of 2.435(1) Å found for monomeric $Sn(SAr)_2$ (Ar = 2,6-diisobutylphenyl) (23). The S—Sn—S angle of 85.4(1)° reported for $Sn(SAr)_2$ is less than any angle found in **1**.

As can be seen from Fig. 1, the phenyl groups all occupy equatorial positions above the three basal sulfur atoms. The dihedral angles Sn—S—CX1—CX6 are 51.9, 58.1, and 41.6° so that the phenyl rings are twisted into a propeller-like arrangement. Within the phenyl rings the C—C—C angles are in the range found in other phenylthiolates (4, 32, 33) and also in triphenylphosphines (34). The S—CX1—CX6 angles of 123.3(3), 122.2(3), and 122.8(3)° are systematically larger than the related S—CX1—CX2 angles of 118.7(2), 120.5(3), and 120.0(3)°; similar canting of the phenyl rings relative to the corresponding S—C vectors has been found in other arylthiolate complexes. At sulfur, M—S—CX1 angles of 102.1(1), 99.5(1), and 95.5(1)° are comparable to the values found for $[Pb(SC_6H_5)_3]^-$ (22), but are smaller than values found for terminal ligands in other arylthiolate complexes (e.g. 107.2(2) and 107.9(2)° in $[(CH_3)_4N]_2[Hg(S(4\text{-}C_6H_4Cl))_4]$ (4), and 107.8(4), 110.2(5), and 114.4(4)° in $[(C_6H_5)_4P]_2$-$[Cu(SC_6H_5)_3]$ (32).

The $[Sn(SeC_6H_5)_3]^-$ anion

This anion is isostructural with its sulfur analog. Two Sn—Se distances are equal at 2.649(1) Å, the third one is 2.671(1) Å and the Se—Sn—Se angles are 88.74(3), 89.72(3), and 97.3(3)°. Little information is available in the literature regarding Sn(II)—Se bond distances. To our knowledge the only previously reported data for Sn(II)—Se species is for tin(II) selenide (35). In SnSe, the tin atom is in a distorted octahedral environment with the three nearest selenium atoms at distances 2.77, 2.82, and 2.82 Å, all longer than the distances found here, though the corresponding Se—Sn—Se bond angles of 89, 89, and 96° are quite comparable to those found for **2**.

Comparison with other pyramidal Sn(II) compounds

Discrete triligated tin(II) species are of the VSEPR type AX_3E and are thus expected to have trigonal pyramidal coordination geometry about Sn(II), as described here for **1** and **2**. In earlier work, a trigonal pyramidal arrangement of the nearest atoms to tin(II) has been found in a variety of stannous compounds including, for example, $CsSnCl_3$, NH_4SnF_3, SnS, SnSe, $SnCl_2$, $SnSO_4$, and $K_3[Sn(HCO_2)_3]$ (21, 35, 36). Quite commonly in these compounds two of the Sn—X (X = F, Cl, S, or O) bonds of the trigonal pyramid are found to be equal or nearly equal in length, while the third one is significantly different, just as we find in the thiolato- and selenolatostannates; also the X—Sn—X angles are irregular as we find here. In many cases, as discussed for SnSe (above), in addition to three close contacts, Sn(II) enjoys additional long contacts to three atoms to complete a distorted octahedral environment. Such longer contacts are not found in either **1** or **2**, where the closest intermolecular Sn—E distances are 8.291(1) and 7.952(1) Å, respectively.

Several generalizations can be made regarding the structures of the two $[Sn(EC_6H_5)_3]^-$ anions. Firstly, they are both discrete and have the trigonal pyramidal coordination geometry expected for species of the VSEPR type AX_3E. Secondly, they both have all three phenyl groups in equatorial positions, and thirdly, they both have one Sn—E bond significantly longer than the other two with no apparent correlation with the angles at sulfur or selenium atoms. Finally, one Sn—E—CX1 angle is much larger than the other two. The same comments were made about the Pb structures (22), and we are inclined at present to attribute the variation in bond angles to packing forces, but we still have no explanation for the disparity in bond lengths.

Nitrooctaethylporphyrins: synthesis, optical and redox properties

LIANG-CHU GONG AND DAVID DOLPHIN
Department of Chemistry, The University of British Columbia, 2036 Main Mall, Vancouver, B.C., Canada V6T 1Y6

Received April 13, 1984

LIANG-CHU GONG and DAVID DOLPHIN. Can. J. Chem. **63**, 401 (1985).

The reaction of zinc octaethylporphyrin with N_2O_4 in dichloromethane gives, in a stepwise reaction, the zinc complexes of mono-, di-, tri-, and tetra-nitrooctaethylporphyrins. Demetallation, under acidic conditions, gives the corresponding free base porphyrins. The *meso*-nitro groups exert both steric and electronic effects on the porphyrin macrocycle. Thus N-protonation of the nitrated species causes a distortion of the ring and gives an optical spectrum similar to that of protonated *meso*-aryl-substituted porphyrins. In addition, the nitro groups make the oxidation of the porphyrin ring more difficult and at the same time facilitate the ring reductions.

LIANG-CHU GONG et DAVID DOLPHIN. Can. J. Chem. **63**, 401 (1985).

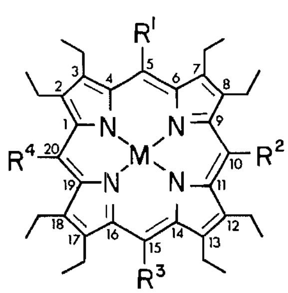
La réaction du sel de zinc de l'octaéthylporphyrine avec le N_2O_4 dans le dichlorométhane conduit, par l'intermédiaire d'une série de réactions, aux complexes de zinc des mono-, di-, tri- et tétra-nitrooctaéthylporphyrines. La démétalation, en utilisant des conditions acides, conduit aux porphyrines correspondantes qui existent sous forme de bases libres. Les groupes nitro en positions *méso* exercent des effets à la fois stériques et électroniques sur le macrocycle de porphyrine. La N-protonation des espèces nitrées provoque donc une distortion du cycle et fournit un spectre optique semblable à celui des porphyrines protonées portant des substituants aryles en position *méso*. De plus, les groupes nitro rendent le cycle porphyrine moins susceptible à l'oxydation et ils facilitent les réductions des cycles.

[Traduit par le journal]

Porphyrins, like most other aromatic systems, undergo electrophilic substitution. However, as with all heteroaromatic systems, the competition between the basicity of the heteroatom and the nucleophilicity of the aromatic π-system can prevent many substitution reactions from occurring. A striking example of this is the faster rate of *meso*-substitution of octaethylporphyrin (OEP) in CH_3CO_2D compared to CF_3CO_2D (1)!

Electrophilic substitution at the porphyrin periphery has been recently reviewed (2) and, while a wide variety of reactions have been described, few high-yield reactions have been reported. The usually large effort that must be expended to prepare any porphyrin, other than the trivially easy reactions to generate *meso*-arylporphyrins (3), requires that further manipulations should be as efficient as possible. We report here on the convenient preparation of the nitrooctaethylporphyrins and the effect the electron-withdrawing groups have on the redox properties of the free bases and some metal complexes.

The direct nitration of OEP in fuming nitric acid/acetic acid gives good yields of 5-nitrooctaethylporphyrin (5-(NO_2)OEP (**1**)) with considerably diminished yields of the dinitroporphyrins 5,10-$(NO)_2$OEP (**2**) and 5,15-(NO_2)OEP (**3**). Under more forcing conditions (HNO_3/H_2SO_4), 20% of the 5,10,15-trinitrooctaethylporphyrin (**4**) can be formed but isolable amounts of the 5,10,15,20-tetranitroporphyrin (**5**) are not observed (4).



Compound	R^1	R^2	R^3	R^4	M
1	NO_2	H	H	H	H,H
2	NO_2	NO_2	H	H	H,H
3	NO_2	H	NO_2	H	H,H
4	NO_2	NO_2	NO_2	H	H,H
5	NO_2	NO_2	NO_2	NO_2	H,H
7	NO_2	H	H	H	Zn
8	NO_2	H	NO_2	H	Zn
9	NO_2	NO_2	NO_2	H	Zn
10	NO_2	NO_2	NO_2	NO_2	Zn

Metallation of the porphyrin reduces the nitrogen basicity and can allow for preferential attack of an electrophile at the porphyrin periphery. Indeed, the nature of the metal can direct preferential pyrrolic- or *meso*-substitution. An example of the rate difference that may be observed upon metallation is that in neat CF_3CO_2D a half-life of 275 h at 90°C is observed for exchange of the *meso*-protons of OEP while Cu(OEP) undergoes almost complete exchange of the *meso*-protons in 1:1 $CF_3CO_2D/CHCl_3$ at room temperature within 20 min (5). Watanabe *et al.* (6) have shown that the nitration of zinc octaethylporphyrin (ZnOEP) using zinc nitrate in acetic anhydride proceeds in 2 min to give low yields of a mixture of **1**, **3**, and **4**, while after 3 h 57% of **5** is obtained.

Despite the fact that aromatic electrophilic substitution is normally thought to proceed via carbocation intermediates, there is growing evidence that such reactions proceed via an initial electron transfer followed by coupling of the resultant radicals (7). In fact, for the nitration of aromatic compounds, more reactive than toluene, by NO_2^+, electron transfer appears to be the principal route (7). If mesitylene with an oxidation potential of 1.62 V (vs. Ag/Ag^+, in CH_3CN) is nitrated via single electron transfer reactions, then metalloporphyrins with their first oxidation potentials of $\sim$1.0 V(8) must surely be nitrated by mechanisms involving electron transfer. Earlier we showed (9), that treatment of MgOEP with N_2O_4 caused a one-electron oxidation to give the corresponding π-cation radical (**6**) (10), which in the presence of excess NO_2 gives 5-(NO_2)MgOEP. The simplest rationale is that the radical **6** couples with NO_2, itself a radical, to give the isoporphyrin cation yielding a *meso*-nitroporphyrin upon deprotonation.

As each successive *meso* position is nitrated, the rate of further oxidation to a π-cation radical is decreased (due to the increase in redox potential as successive nitro groups are added, see below). Thus the extent of nitration can be conveniently controlled by simply varying the concentration of NO_2. Reaction of ZnOEP with thallium(III) nitrate gives nitroporphyrins (11). These reactions also initially generate the porphyrin π-cation radical, but it was suggested (11) that the radicals might not be the source of the nitroporphyrins. Be that as it may, the reactions of metalloporphyrins with NO_2 provides an excellent route to nitroporphyrins, as detailed below, providing the reaction conditions in the experimental section are carefully followed, since in the presence of dichloromethane (12) nitromethylation may occur.

In the present study we have chosen to use ZnOEP rather than pursue the initial studies (9) with MgOEP since the former is more robust, being less readily demetallated and less susceptible to photochemical decomposition. Care must be taken during demetallation since acid catalyzed *nucleophilic* substitution of the nitro groups can readily occur (24).

Free base porphyrins give unstable π-cation radicals and are thus unsuitable for the nitration studies described here.

[a]Chemical shifts δ (ppm) measured in dilute solutions of $CDCl_3$.
[b]All ethyl groups appeared as a quartet and a triplet with 8-Hz coupling.

Experimental

The nmr spectra were measured on a Varian XL-100 instrument, uv/vis spectra were recorded on a Cary 17 spectrometer, and the cyclic voltammograms were measured using tetra-*n*-propylammonium tetrafluoroborate in a three-electrode system as previously described (13). Oxidations were performed in CH_2Cl_2 (spectroscopic grade, distilled from calcium hydride) and reductions in DMF (reagent grade, dried over solid KOH, then distilled).

Zinc 5-nitrooctaethylporphyrin (**7**)

Octaethylporphyrin (2.34 g, 4.38 mmol) in dichloromethane (2340 mL) was treated with zinc acetate (2.14 g, 11.67 mmol) in methanol (13 mL). The mixture was stirred at room temperature for 1 h by which time metallation was complete (checked by tlc on silica gel using CH_2Cl_2/CCl_4 (1:3 v/v).

Thirty milliliters of a stock solution of 0.32 *N* NO_2 (Matheson Gas Products, Canada) in dichloromethane, determined titrimetrically (14), were diluted to 150 mL with dichloromethane and this dilute solution was added in one portion to the ZnOEP with rapid stirring at room temperature. The progress of the reaction was followed by tlc on silica gel (CH_2Cl_2/CCl_4 (1:3 v/v)). When all of the ZnOEP had been consumed (additional small aliquots of stock solution of NO_2 may need to be added to complete the reaction), the principal product was zinc 5-(NO_2)OEP (**7**). The reaction was stopped by the addition of 500 mL of saturated $NaHCO_3$. The organic phase was separated, washed with water (3 × 200 mL), and taken down to dryness on a rotary evaporator. The product was crystallized from $CHCl_3/CH_3OH$ and collected by filtration to give 1.46 g (52% yield). The filtrate may be used to make further nitrated products. *Anal.* calcd. for $C_{36}H_{43}N_5O_2Zn$: C 67.23, H 6.74, N 10.89; found: C 66.54, H 6.80, N 10.55.

Zinc 5,15-dinitrooctaethylporphyrin (**8**)

The same procedure as for **7**, above, was employed using 70 mL of the stock NO_2 solution to give 2.08 g (69% yield). The reaction was followed on silica gel tlc using CH_2Cl_2/CCl_4 (1:1 v/v). *Anal.* calcd. for $C_{36}H_{42}N_6O_4Zn$: C 62.83, H 6.15, N 12.21; found: C 62.87, H 6.13, N 12.06.

Zinc 5,10,15-trinitrooctaethylporphyrin (**9**)

The same procedure as for **8**, above, was employed using 140 mL of the stock NO_2 solution to give 1.59 g (49% yield). *Anal.* calcd. for $C_{36}H_{41}N_7O_6Zn{:}2CH_3OH$: C 57.25, H 6.20, N 12.30; found: C 56.60, H 6.05, N 12.71. The polar products **9** and **10** (below) crystallize with varying amounts of $CHCl_3$ and CH_3OH of crystallization.

Zinc 5,10,15,20-tetranitrooctaethylporphyrin (**10**)

The same procedure as for **3**, above, was employed using 170 mL of the stock NO_2 solution to give 3.24 g (95% yield). *Anal.* calcd. for $C_{36}H_{40}N_8O_8Zn{:}CH_3OH$: C 54.85, H 5.47, N 13.83; found: C 54.90, H 4.91, N 14.03.

5-Nitrooctraethylporphyrin (**1**)

Zinc 5-nitrooctaethylporphyrin (**7**) (100 mg) in glacial acetic acid (50 mL) was treated with concentrated hydrochloric acid (25 mL; 37%). After stirring at room temperature for half an hour, water (50 mL) was added. The organic layer was separated, washed with water (25 mL), saturated sodium bicarbonate (25 mL), and again with water (25 mL). The solvent was removed on a rotatory evaporator at room temperature and the residue was recrystallized from chloroform/methanol to give 72 mg (80%) of the product (**1**) identical, by electronic and mass spectra, to that previously reported (4).

5,15-Dinitrooctaethylporphyrin (**3**)

Zinc 5,15-dinitrooctaethylporphyrin (**8**) (103 mg) in methylene dichloride (100 mL) was treated with perchloric acid (10 mL, 72%). After stirring at room temperature for half an hour the solution was treated as for **1** above to give 78 mg of the product, **3**, identical, by electronic and mass spectra, to an authentic sample (4).

5,10-Dinitrooctaethylporphyrin (**2**)

The product was obtained from the filtrates, during the preparation of **3** reported above, by preparative tlc on silica gel (200 × 200 × 1 mm) using CH_2Cl_2/CCl_4 (1:3 v/v) to give less than 5% of material identical, by electronic and mass spectra, to an authentic sample (4).

5,10,15-Trinitrooctoethylporphyrin (**4**)

The same procedure as for **2** above gave 76 mg of the product (83%)

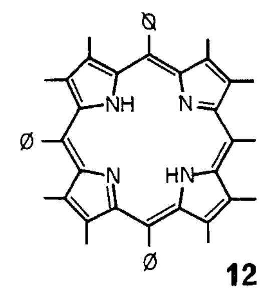
As for **2** above giving 81% of the product identical, by electronic and mass spectra, to an authentic sample (6).

Discussion

The powerfully electron-withdrawing nitro groups can be expected to modify the properties of the substituted porphyrins by decreasing the electron density in the aromatic π-system. However, the electron-withdrawing properties of the nitro group in such a sterically encumbered situation may be less than traditionally measured by the electrophilic substituent constants (σ). Indeed, even though σ_m for the nitro group (0.71) is greater than that of the cyano (0.56; ref. 15), the *meso*-protons of 5-cyano-OEP are more deshielded, as indicated by the ^{1}Hmr spectrum (δ 9.98 and 9.89; ref. 16), than those of **1** (10.25 and 10.10) which in turn are more deshielded than those of the parent OEP. This reflects both electronic and steric effects of the nitro group but it is clear from the nmr data (Table 1) that these effects are small and cannot be readily separated.

The optical spectra on the other hand (Table 2) show dramatic changes as the *meso*-positions are progressively substituted by nitro groups. In every case each additional nitro group causes both a bathochromic shift and weakening in intensity of all of the visible bands. While the Soret bands become weaker and broader with increasing substitution, an initial hypsochromic followed by a bathochromic shift was observed for the free bases. With the diprotonated species a bathochromic shift and decrease in intensity (associated with band broadening) was observed in all cases (Table 2). However, in the case of the zinc complexes the extent of both the bathochromic shifts and band broadening is far less (Table 2). This suggests that the major perturbations in all cases are steric rather than electronic. The zinc complexes, which are required to remain "essentially coplanar", will not allow the π-system of the nitro group to become coplanar with the aromatic π-system. However, with both the free bases and the diprotonated salts considerably more distortion may occur, as reflected by the optical spectra. The same effect is shown by the sterically crowded 2,3,7,8,12,13,17,18-octamethyl-5,10,15,20-tetraphenylporphyrin (**12**) (17) and the corresponding octaethyl derivative (18). Indeed, the optical spectra of **5** and **12** are quite similar (Fig. 1). A



12

major difference between *meso*-tetraarylporphyrins and octaalkyl-like porphyrins is that in the former case the diprotonated salts are green and the latter violet in solution. This dramatic change in color results from quite different optical spectra of the two classes of diprotonated salts. Figure 2 shows the spectra of the protonated forms of **5** and *meso*-tetra-*N*(methyl-4-pyridyl)porphyrin (**14**). The latter two compounds show similar spectra which are quite different from that of protonated OEP (Table 2). There has been much speculation as to the source of this difference upon protonation. But it is clear, from the above results and from an examination of the optical spectra of compounds such as $N_aN_bN_c$-trimethyl-*meso*-tetraphenylporphyrin iodide (19), that the major optical changes that *meso*-aryltetraphenylporphyrins and *meso*-nitrooctaethylporphyrins undergo upon protonations result from the distortion from planarity of the porphyrin macrocyle, aided both by the electrostatic repulsion of the positively charged inner nitrogens and the steric interaction between the *meso*- and β-substituents, a conclusion reached by Meot-Ner and Adler (20) and Bonnett

14

and Stephenson (4). A well-characterized example of this phenomenon was shown by the X-ray crystal studies of both protonated and distorted *meso*-tetraphenyl and *meso*-tetra-4-pyridylporphyrins (21).

While the electronic properties of the nitro groups do not have a major influence on the electronic spectra, they exert a major influence on the redox properties of both the free base and zinc complexes. The majority of metalloporphyrins show two sequential and reversible one-electron oxidation and reduction steps. Fuhrhop *et al.* (22) have noted, for a wide range of metallooctaethylporphyrins, that $E^{ox}_{1/2}(2) - E^{ox}_{1/2}(1)$ is roughly constant at about 300 mV for ring oxidations and is similarly constant for porphyrin ring reduction where $E^{red}_{1/2}(2) - E^{red}_{1/2}(1) = 0.4-0.5$ V. Furthermore, when only ring redox processes are involved, $E^{ox}_{1/2}(1) - E^{red}_{1/2}(2)$ is about 2 V. As can be seen from Table 3, all of the redox processes listed are close to these values, suggesting in each case that ring redox processes are being observed. However, the reduction waves in every case correspond to a two-electron process. All of the reductive electrode processes were quasi-reversible as were oxidations of the zinc complexes. But, as is often the case, the oxidation of the free bases was followed by a chemical reaction, making the process irreversible. It is clear that the nitro groups are exerting a considerable electronic effect in these redox processes, as can be seen from the monotonic increase in the oxidation potentials and decrease in the reduction potentials with increasing nitro substitution. The redox potentials of a large number of free-base porphyrins have recently been collected (23). It is interesting to note, for a variety of *meso*- and β-substituents, that the *meso*-tetra(*N*-methyl-4-pyridyl)porphyrin was the most readily reduced ($E^{red}_{1/2}(1) = -1.01$ V) and that, like our systems, it showed only a single two-electron reduction wave unlike the majority of porphyrins which show two one-electron waves.

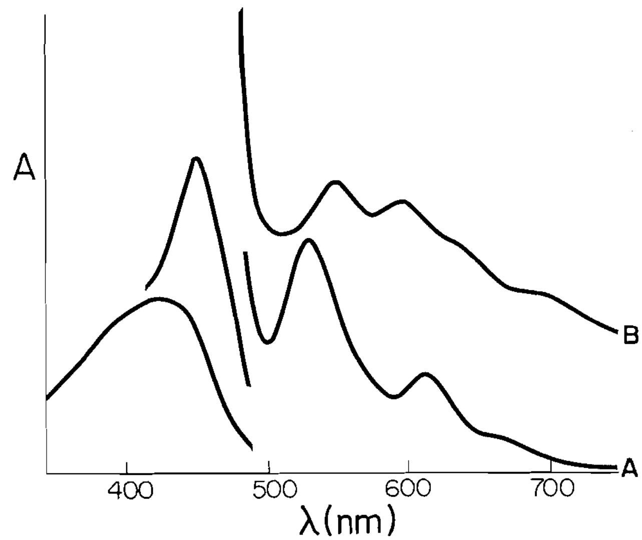

FIG. 1. Optical spectra (CH_2Cl_2) of A, *meso*-tetranitrooctaethylporphyrin (**5**), and B, *meso*-tetraphenyloctamethylporphyrin (**12**). Region below 500 nm was recorded at an attenuation of ten.

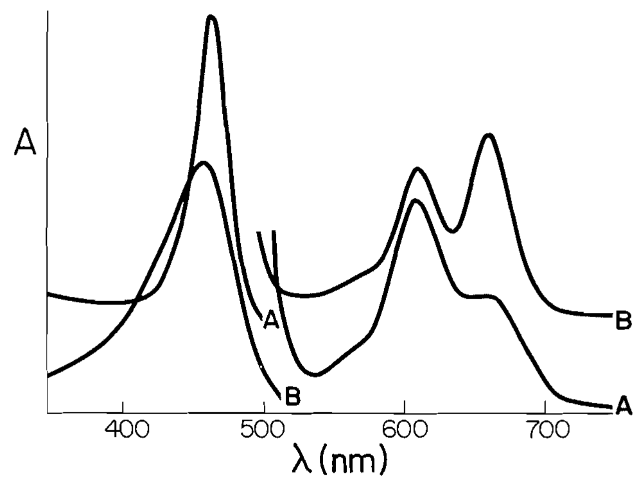

FIG. 2. Optical spectra (CH_2Cl_2, 1% TFA) of protonated **5** and protonated **14**. Region below 500 nm was recorded at an attenuation of ten.

We prepared these variously nitrated porphyrins anticipating that ring oxidations would become more difficult and ring reduction easier. Since this has proved to be the case we expect, for the future, that these systems may be useful for the preparation of metalloporphyrins having metals in unusually high oxidation states.

Nucleophilic substitution of *meso*-nitrooctaethylporphyrins

LIANG-CHU GONG AND DAVID DOLPHIN

Department of Chemistry, The University of British Columbia, 2036 Main Mall, Vancouver, B.C., Canada V6T 1Y6

Received April 13, 1984

LIANG-CHU GONG and DAVID DOLPHIN. Can. J. Chem. **63**, 406 (1985).

Nitrooctaethylporphyrins readily undergo nucleophilic aromatic substitution in the presence of HCl or HBr. In the presence of methoxide, nucleophilic addition to give a porphodimethane occurs, followed by autoxidation to the methoxyporphyrin. Unlike the nitrated complexes, the chlorosubstituted porphyrins exhibit redox potentials similar to those of unsubstituted analogs. *Meso*-halogenated porphyrins do, however, show steric distortion due to the bulk of the halogen atoms.

LIANG-CHU GONG et DAVID DOLPHIN. Can. J. Chem. **63**, 406 (1985).

En présence de HCl ou de HBr, les nitrooctaéthylporphyrines subissent facilement des réactions de substitutions aromatiques nucléophiles. En présence d'ions méthylates, il se produit une addition nucléophile conduisant à un porphodiméthane; cette réaction est suivie d'une auto-oxydation qui conduit à une méthoxyporphyrine. Contrairement au comportement observé avec les complexes nitrés, les potentiels rédox des chloroporphyrines sont semblables à ceux de leurs analogues qui ne sont pas substitués. Par contre, les porphyrines portant des halogènes dans les positions *méso* présentent une distortion stérique qui est due à l'encombrement des atomes d'halogènes.

[Traduit par le journal]

Introduction

The chemistry of porphyrins, like that of most aromatic systems, is dominated by electrophilic substitution (1) and, like most other aromatic systems nucleophilic substitution is far less frequently observed. Indeed, in porphyrin chemistry only one or two authentic examples of nucleophilic substitution are known and these occur under special circumstances, as with the relief of considerable steric strain (2). We have shown that when the porphyrin HOMO is depleted of both electrons, to give the π-dication, facile nucleophilic substitution occurs to give an intermediate isoporphyrin (3) which will either be stable or lose a proton to give a substituted porphyrin (4). Even when only one electron is removed from the HOMO, to give a porphyrin π-cation radical, nucleophilic substitution occurs but by more complex mechanisms (4–6). We report here on the nucleophilic substitution of free base porphyrins where, as with benzenoid systems, nucleophilic attack is aided by the powerfully electron-withdrawing nitro group.

Experimental

All chemicals were reagent grade; nitrooctaethylporphyrins were prepared as reported earlier (7). The ^{1}H nmr spectra were measured on a Varian XL-100 spectrometer with the exception of that of 5,10-dichloro-15-nitrooctaethylporphyrin, which was measured on a Bruker WH 400 spectrometer. Mass spectra were measured on a Varian MAT CH 4B instrument. Electronic spectra were measured on a Cary 17 spectrometer and the cyclic voltammograms were measured under the conditions previously described (7). Microanalyses were performed by Peter Borda (U.B.C.)

5-Chloro-10,15,20-trinitrooctaethylporphyrin (2)

5,10,15,20-Tetranitrooctaethylporphyrinato zinc (**1**) (7) (100 mg, 0.13 mmol) was placed in glacial acetic acid (100 mL) and dichloromethane (50 mL). The solution was cooled to 10°C and concentrated hydrochloric acid (10 mL, 37%) was added. The mixture was stirred at 10°C for 1 h. Dichloromethane (50 mL) was added and the organic layer was washed with water, saturated sodium bicarbonate, and then water. The organic phase was reduced in volume and the product crystallized by the addition of methanol to give **2** (52 mg, 57%). An analytical sample was recrystallized from dichloromethane/methanol; uv/vis CH_2Cl_2 (log ϵ): 255 sh (3.39), 270 (3.51), 436 (4.69), 538 (3.74), 568 sh (3.51), 617 (3.41), 682 (2.85); CH_2Cl_2/TFA (log ϵ): 268 sh (3.63), 293 (3.29), 467 (4.84), 560 sh (3.19), 615 (3.68), 678 (3.63); ^{1}H nmr: 1.18 (t, 6H), 1.23 (t, 6H), 1.25 (t, 12H), 3.30 (q, 12H), 3.69 (q, 4H); ms: 703 (80), 657 (75), 549 (100). *Anal.* calcd. for $C_{36}H_{42}N_7O_6Cl$: C 61.40, H 6.01, N 13.91, Cl 5.03; found: C 61.01, H 6.27, N 14.11, Cl 5.45.

Reaction of zinc tetranitrooctaethylporphyrin (1) with hydrofluoric acid

5,10,15,20-Tetranitrooctaethylporphyrinato zinc (**1**) (7) (100 mg, 0.13 mmol) was placed in a mixture of glacial acetic acid (100 mL), hydrofluoric acid (15 mL, 48.8%), and dichloromethane (500 mL). The mixture was stirred for 24 h, after which the organic layer was washed with water, saturated sodium bicarbonate, and then water. The organic layer was reduced in volume and chromatographed on a silica column using dichloromethane. The first fraction was unreacted starting material. The second fraction was rechromatographed on silica (200 × 200 × 1 mm) using CH_2Cl_2/CCl_4 (1:3 v/v) to give **2** (9.3 mg, 10%). Finally, elution of the column with methanol gave octaethylxanthoporphyrinogen (**3**) (20 mg, 26%). No fluorine-containing porphyrins were observed.

5,10-Dichloro-15,20-dinitrooctaethylporphyrin (4)

5,10,15,20-Tetranitrooctaethylporphyrinato zinc (**1**) (7) (100 mg) was placed in a mixture of glacial acetic acid (100 mL) and hydrochloric acid (15 mL, 37%). The mixture was stirred at room temperature for 1 h. Dichloromethane (50 mL) was added and the organic phase washed with water, saturated sodium bicarbonate, and then water. The solution was taken to dryness and the residue crystallized from chloroform/petroleum ether (30–60°C) to give 55 mg (55%) of product; uv/vis CH_2Cl_2 (log ε): 270 (3.39), 305 (3.99), 440 (4.84), 546 (3.80), 575 (3.73), 612 (3.65), 685 sh (2.98); CH_2Cl_2/TFA (log ε): 275 (3.98), 300 (3.99), 467 (5.06), 570 sh (3.40), 611 (3.84), 678 (3.84); ^{1}H nmr: 1.18 (t, 6H), 1.21 (t, 6H), 1.42 (t, 6H), 3.22 (q, 8H), 3.54 (q, 4H), 3.63 (q, 4H); ms: 692 (90), 547 (90), 602 (90), 565 (90), 564 (90), 549 (100). *Anal.* calcd. for $C_{36}N_{42}N_6O_4Cl_2$: C 62.33, H 6.10, N 12.12, Cl 10.22; found: C 62.26, H 6.03, N 11.85, Cl 9.90.

5,10,15-Trichloro-20-nitrooctaethylporphyrin (5)
