This paper is dedicated to Professor Camille Sandorfy on the occasion of his 65th birthday

WOLFGAND RETTIG and ANDRÉ KLOCK. Can. J. Chem. **63**, 1649 (1985).

The fluorescence of 6-aminocoumarine (A6C) is very weak and anomalously redshifted as compared to its 7-substituted analogues 4-methyl-7-aminocoumarine (A7C) and 4-methyl-7-diethylaminocoumarine (DEA7C). The solvatochromic redshift in homologous alcohols is much stronger for A6C, pointing to an increased dipole moment of the emitting state. A twisted intramolecular charge transfer (TICT) state with full charge separation is made responsible for this emission. This is rationalized by molecules-in-molecules calculations. The strong Stokes shift in n-hexane and in ethanol glass at 77 K suggests that A6C emits from a TICT state even under these conditions.

WOLFGAND RETTIG et ANDRÉ KLOCK. Can. J. Chem. **63**, 1649 (1985).

La fluorescence de l'amino-6 coumarine (A6C) est très faible et elle glisse de façon anormale vers le rouge si on fait une comparaison avec des composés analogues substitués en position-7 comme la méthyl-4 amino-7 coumarine (A7C) et la méthyl-4 diéthylamino-7 coumarine (DEA7C). Le glissement solvatochrome vers le rouge provoqué par les alcools homologues est plus prononcé avec le A6C et ceci suggère qu'il y a une augmentation du moment dipolaire de l'état qui émet. On attribue cette émission à un état de transfert de charge intramoléculaire croisé (TC1C) avec une séparation complète de charges. On rationalise ce fait en fonction des calculs sur des molécules dans des molécules. Le fort glissement de Stokes dans le n-hexane et dans l'éthanol à 77 K suggère que, même dans ces conditions, le A6C émet à partir de l'état TCIC.

[Traduit par le journal]

Introduction

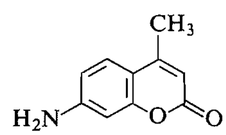
Lippert and co-workers (1–5) observed several types of adiabatic and diabatic photoreactions in dilute solutions of 7-hydroxycoumarine and related compounds as revealed from multiple fluorescence spectra.

Only those coumarine dyes which possess an electron donor substituent in the 7 position showed a rather high and tunable LASER efficiency, whereas donor substitution in the 6 position strongly reduces the fluorescence quantum yield. Even some 7-dialkylamino coumarines are prone to undergo fluorescence quenching in polar solvents. This has been traced back by Jones, Halpern *et al.* (6, 7) to an adiabatic photoreaction towards a nonemissive state.

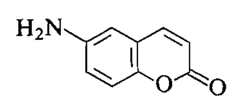
From the substituent and solvent dependence, this state was shown to be connected with the donor and acceptor properties of amine and coumarine moieties, and was assigned as a Twisted Intramolecular Charge Transfer (TICT) state (8) with the dialkylamino group twisted perpendicularly to the plane of the coumarine skeleton. By making this twisting motion unavailable through ring closure to the "rigidized structure" of Coumarine 102 or 153, the fluorescence quenching is suppressed (7). For the same reason, "rigidized" rhodamines show an enhanced fluorescence quantum yield at room temperature as compared to the nonrigidized strctures (rhodamine B vs. rhodamine 101 (9–11). Similarly, it has been shown that the extremely low fluorescence quantum yield of triphenyl methane dyes can be traced back to the formation of a charge-localized TICT state of very short lifetime (12), and that the comparatively low fluorescence quantum yield of 6-hydroxy-9-phenyl-fluoron (13), a close relative to fluorescein, can be understood on the same basis (rotation of the phenyl group).

In all of the above cases, the TICT state is found to be nonfluorescent. Emission from a TICT state seems to be more the exception than the rule. In the favourable cases of observable TICT emission, however, which often goes along with dual fluorescence (8, 14–19), this emission can yield important information on the properties of this state. Solvatochromic measurements show that the TICT state involves a complete charge separation even for symmetric compounds (18). Its photophysical properties are consistent with a forbidden radiative transition to the ground state (8, 20, 21).

Here, we report on the fluorescence of 6-aminocoumarine (A6C), which is weak (22) and strongly redshifted. The photophysical data are consistent with the emission from a TICT state.



A7C



A6C

Experimental

6-Aminocoumarine (A6C) was a gift from Bayer/Leverkusen and showed, after purification, a mp 162.5–163.0°C (lit. (22) mp 162.6–163.4°C). 4-Methyl-7-aminocoumarine (A7C) and 4-methyl-7-diethylaminocoumarine (DEA7C) were purchased from Eastman (Coumarin 120 and 1, respectively). All compounds were purified by repeated recrystallization and subsequent vacuum sublimation. The solvents used were of Merck Uvasol quality or Fluka puriss. and showed no impurity emission at the sensitivity levels used.

Absorption spectra were taken on a Cary 17 spectrometer, and corrected fluorescence and fluorescence excitation spectra on a FICA 55 MK II or a Perkin Elmer 650-60 spectrofluorimeter. Fluorescence quantum yields (optical densities < 0.15) were determined for aerated solutions relative to DEA7C in ethanol (ϕ_f = 0.59 (6)) and are corrected for refractive index changes of the solvent. Decay time measurements were made on aerated solutions using an Edinburgh instruments single photon counting device. Decays were found to be monoexponential over 3 decades.

Molecules-in-molecules (MIM) calculations were performed using a program written by P. Straub and described in ref. 23. Details were kept as described in ref. 24. Ideal geometries (all angles 120°, $r_{C—C}$

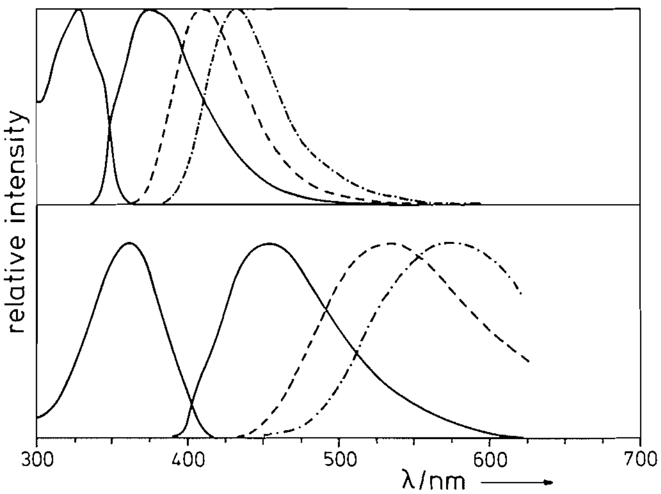


FIG. 1. Normalized fluorescence excitation and emission spectra (corrected for lamp profile and spectral sensitivity distribution) of A6C (lower part) and A7C (upper part) in n-hexane (—), and emission spectra in acetonitrile (- - -) and ethanol (-·-·-), at room temperature.

$= r_{C—O} = 1.40$, $r_{C—N} = 1.46$ Å) were assumed. The ionization potential of the dimethylamino group was taken to be 8.24 eV, the electron affinity of coumarine 0.482 eV. Nine locally excited coumarine states (each represented by linear combination of up to 3 configurations from a standard PPP-SCF-CI calculation) and 2 amino-to-coumarine charge transfer states were taken into consideration. For coumarine, Hückel MO's (heteroparameters taken from ref. 25) were used. A-factors for solvatochromic measurements were calculated using a program developed for the microstructural solvent interaction (MSI) model (16), with all bond lengths equal to 1.4 Å.

Results

Figure 1 shows the fluorescence excitation and emission spectra of A6C and A7C in hexane and the redshifted emission in ethanol and acetonitrile. Contrary to the excitation spectra, which do not differ strongly for the two compounds and which are identical to the absorption spectra, the emission spectra strongly differ but are independent of excitation wavelength and concentration. The Stokes shift $\Delta\tilde{\nu}_{St}$ (in cm^{-1}) is nearly doubled for A6C as compared to A7C, and the solvent polarity has much stronger effect in the case of A6C. This is shown more precisely by the fluorescence maxima in a series of homologous n-alcohols (Table 1).

The data of Table 1 can be converted into a solvatochromic plot (Fig. 2) using Lippert's equation [1] (26, 27).

$$[1] \quad \tilde{\nu}_a - \tilde{\nu}_e = \Delta\tilde{\nu}_{St} = \frac{2}{hc}\frac{(\mu_e - \mu_g)^2}{a^3} \cdot \Delta f + \text{const.}$$

where μ_g and μ_e are ground and excited state dipole moments, respectively, a is the Onsager radius, h and c are fundamental constants, and Δf is a solvent polarity function depending on dielectric constant ϵ and refractive index n (see Fig. 2). Although the Lippert equation does not take into account polarizability effects and the deviation from colinearity of $\boldsymbol{\mu}_g$ and μ_e, eq. [1] is used here, because the MIM calculations indicate the angle between μ_e and μ_g to be small.

The slopes and intercepts thus determined are collected in Table 2. For extracting $\Delta\mu = \mu_e - \mu_g$, the Onsager parameter a was taken as approximately 40% of the long axis of the molecules, a value suggested by Lippert for elongated nonspherical molecules (27). A more precise comparison of relative $\Delta\mu$ values can be obtained by using the microstructural solvent interaction (MSI) model (16) which takes into account the actual nonspherical shape of the molecule and its charge distribution differing from that of a point dipole. The resulting equation [2] closely resembles eq. [1] with the simple substitution of A_{MSI} for $1/a^3$.

$$[2] \quad \Delta\tilde{\nu}_{St} = k\, A_{MSI}\, (\mu_e - \mu_g)^2 \cdot \Delta f + \text{const.}$$

The values for $\Delta\mu$ determined by these two methods are also contained in Table 2.

Figure 3 shows the dependence of the fluorescence quantum yields ϕ_f on solvent polarity. For A6C, ϕ_f values are reduced by a factor of ~10 as compared to the other compounds and depend very strongly on solvent polarity. This dependence is

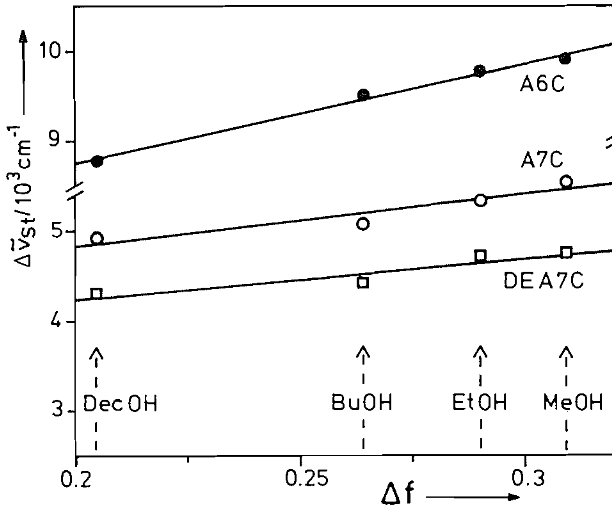

FIG. 2. Fluorescence solvatochromic plot for A6C, A7C, and DEA7C in homologous n-alcohols, $\Delta f = (\epsilon - 1)/(2\epsilon + 1) - (n^2 - 1)/(2n^2 + 1)$.

much weaker for DEA7C and nearly absent for A7C. Table 3 contains the observed decay times which, together with ϕ_f, yield values for the radiative rate constant k_f. k_f is strongly reduced for A6C ($\approx 1.6 \times 10^8\ s^{-1}$ for A7C and $\approx 1.7 \times 10^7\ s^{-1}$ for A6C in ethanol).

Figure 4 shows the fluorescence spectra of A6C in ethanol at different temperatures down to 77 K.

Discussion

Both A7C and DEA7C show high solvatochromic slopes indicative of a large excited state dipole moment (Table 2). The wave functions of the excited state are thus of intramolecular charge transfer (ICT) character, i.e. contain the coumarine locally excited (LE) state (C*) with a high weight of the charge transfer configuration $|N^+C^-\rangle$, where N stands for the amino group and C for the coumarine moiety (6, 7). Solvatochromic slope and excited state dipole moment μ_e are even larger for A6C.

A further prominent difference of A6C from A7C and DEA7C is the large Stokes shift $\Delta\tilde{\nu}_{St}$, which for A7C in methanol amounts to ~5500 cm^{-1} and increases to ~9900 cm^{-1} for A6C. This Stokes shift is comparable to that of TICT fluorescence bands (~13 400 cm^{-1} for *N,N*-dimethylaminobenzonitrile (DMABN) in methanol (14) or 9800 cm^{-1} for

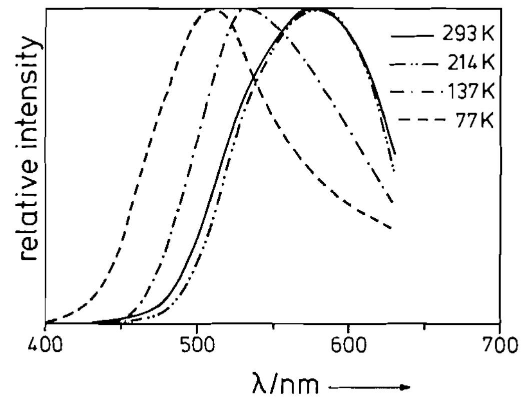

FIG. 4. Fluorescence spectra of A6C in ethanol at different temperatures.

bis(*N,N*-dimethylaminophenyl)-sulfone in methanol). Even in hexane, the strong difference from A7C in $\Delta\tilde{\nu}_{St}$ remains (see Fig. 1), consistent with the high intercept for A6C from the solvatochromic plot (Table 2). Thus, an excited state proton transfer mechaism can be excluded. Moreover, the halfwidth $\Delta\tilde{\nu}_{1/2}$ for the emission of A6C in methanol (3950 cm^{-1}) is much larger than that of A7C (2870 cm^{-1}).

We tentatively assign the emission of A6C as arising from a state with pure CT character, i.e. where the excited state wavefunction is represented by $\psi_e \approx |N^+C^-\rangle$ without admixture of $|C^*\rangle$. This is possible if $|C^*\rangle$ and $|N^+C^-\rangle$ belong to different irreducible symmetry representations and cannot interact in a configuration interaction sense. A way to achieve this is to twist the amino lone-pair axis into the plane of the coumarine skeleton, i.e. perpendicular to the coumarine p_z π-orbitals. This situation corresponds to what is known in the literature as the "Twisted Intramolecular Charge Transfer" (TICT) state (8) and is governed by the "minimum overlap rule" (8, 18): the increasing dipole moment for increasingly twisted geometries provides the driving force for the twist towards the TICT (90°) conformation with maximum charge separation via the polar solvent induced energetic stabilization (ΔE_{solv} in eq. [3] below).

By this same electrostatic interaction, the molecule is locked more or less flexibly in the perpendicular conformation.

The very low fluorescence quantum yield and its strong solvent polarity dependence for A6C (Fig. 4) can be interpreted using the above model. From a theoretical viewpoint, emission from a perpendicularly twisted TICT conformation is forbidden by symmetry. Moreover, nonradiative processes ("photochemical funneling") are enhanced for TICT-like structures because ground and excited states can come very closely together (28). The TICT emission thus has to derive from vibrationally excited levels of the S_1 (TICT) state (8), i.e. it corresponds to a hot fluorescence: vibronic coupling via the twisting motion around the perpendicular minimum can couple higher-lying allowed states to the transition moment. In the case of larger aromatics (anthracene, carbazole), a TICT fluorescence quantum yield of up to ~0.4 can thus be obtained (18, 29). The stronger the solvent interaction (more polar solvent), the more the molecule will be confined to a small angular range around ψ = 90° and, for solvent independent nonradiative TICT decay rates k_{nr}, reduced TICT fluorescence quantum yields are expected. For a more quantitative treatment, the solvent dependence of k_{nr} also has to be taken into account.

The very weak solvent dependence of ϕ_f (A7C), on the other

[c] $\Delta E = E(\text{TICT}) - E(\text{LE})$, with E(LE) of coumarine = 3.48 eV.

hand, points to essentially solvent polarity independent k_f and k_{nr} rate constants of the ICT state. ϕ_f (DEA7C) is quenched by a factor of 2.3 in going from decanol to methanol. This may be due to the beginning formation of a nonradiative TICT state in this case, in accordance with results of G. Jones *et al.* (7) who find a very strong TICT participation in polar solvents (i.e. fluorescnce quenching) when the acceptor strength of the coumarine is increased by a CF_3 group.

Although fluorescence quantum yields are low for A6C, the decay times are long, characteristic for a forbidden transition. The resultant radiative rate constant k_f is lower than that for A7C by a factor of ≈10.

The question arises as to why the substitutional isomers A6C and A7C behave so differently. This can be rationalized by a consideration of the changes of the TICT energy, which is given by eq. [3].

$$[3] \quad E(\text{TICT}) = \text{IP(D)} - \text{EA(A)} + C + \Delta E_{solv}$$

IP(D) is the ionization potential of the donor (amino group in this case), EA(A) is the electron affinity of the acceptor (coumarine in this case), C is the Coulomb stabilization due to the attraction of radical cation (ionized amino group) and radical anion (reduced coumarine), and ΔE_{solv} is the energy gained by solvating the TICT dipole. For positional isomers, only C and ΔE_{solv} change. As the theoretical TICT dipole moment is quite similar for both A6C and A7C, ΔE_{solv} will also be similar in a given solvent. The main changes are thus due to the Coulomb interaction term C. Table 4 contains the C values calculated for several substitutional isomers of dimethylaminocoumarine, the calculated TICT state energies for the gas phase, and the energy difference ΔE between lowest LE and TICT state. Negative ΔE values indicate that the TICT state is situated below the LE state. The 6-isomer has the lowest-, the 7-isomer the highest-lying TICT state. This is readily visualized by inspecting the lowest unoccupied molecular orbital of coumarine (Fig. 5), which shows a large coefficient at the 6 position and a small one at the 7 position.

A6C is a very unusual TICT state forming molecule insofar as it involves the unsubstituted amino group as a donor. The only other example known to date is 9-aminofluorene, which emits dual fluorescence (19), whereas neither 4-aminobenzonitrile nor *N*-methyl-4-aminobenzonitrile populate a TICT state. Thus, the relatively weak donor character of the NH_2 group is compensated by EA(A) and C in the case of the coumarines (eq. [3]). Judging from the fluorescence spectrum in n-hexane, part of the emission may be due to a TICT state even in this nonpolar solvent. Some other compounds are known to emit TICT fluorescence in alkanes (30, 31).

The low temperature fluorescence spectra of A6C in ethanol (Fig. 4) are virtually insensitive to temperature down to ≈200 K. On further lowering of the temperature, a blue shift is observed which can be ascribed to the incomplete relaxation of the solvent during the excited state lifetime (26). But even at 77 K an anomalously large Stokes redshift (6950 cm^{-1}) is retained. This may be ascribed to the small size of the amino group which even in this rigid matrix can relax to the TICT geometry, possibly by taking advantage of the free volume (32).

One-electron photooxidation of *N*-ethylcarbazole in the presence of carbon tetrachloride. Products and mechanism of the photochemical reaction

BOGUMIL ZELENT AND GILLES DUROCHER[1]

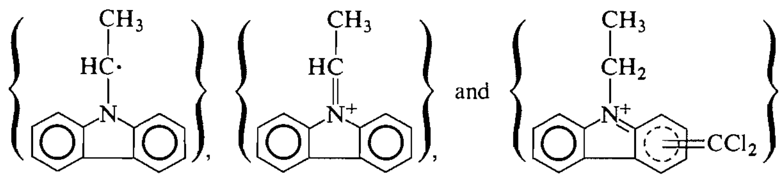
Département de Chimie, Université de Montréal, C.P. 6210, Succ. A, Montréal (Qué.), Canada H3C 3V1

Received September 25, 1984

This paper is dedicated to Professor Camille Sandorfy on the occasion of his 65th birthday

BOGUMIL ZELENT and GILLES DUROCHER. Can. J. Chem. **63**, 1654 (1985).

The mechanism of the photodecomposition of *N*-ethylcarbazole (NEC) in the presence of carbon tetrachloride has been discussed on the basis of the photoproducts identified. The photodissociation of the *N*-ethyl bond and the electron transfer in the transiently formed ex-CT complex, $^1(\mathrm{NEC}^{\delta+}\cdots\mathrm{CCl_4}^{\delta-})^*$, have been proposed as the primary photochemical processes involved in the singlet excited NEC molecule. The latter, treated as the main process, leads to the radical cation of NEC, chloride ion, and trichloromethyl radical in the solvent cage, $[\mathrm{NEC}^{+\cdot}\mathrm{Cl}^-\dot{\mathrm{C}}\mathrm{Cl_3}]$. The other reactions in the system studied are analysed following the decomposition of $\mathrm{NEC}^{+\cdot}$ in the presence of Cl^- and $\dot{\mathrm{C}}\mathrm{Cl_3}$, which can occur by the *N*-ethyl group and (or) by the aromatic ring. The formation of intermediate products such as

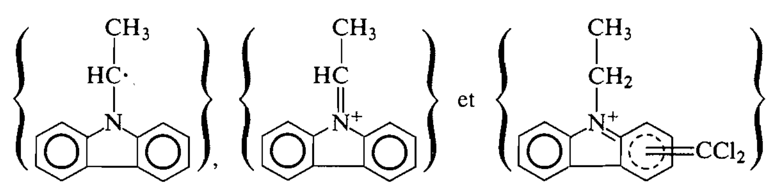


α_r α_k $\gamma_i'(i = 1, 2, 3, \text{or } 4)$

in the solvent cage gives rise to secondary photochemical reactions in the system studied. The polarity and chemical activity of the reaction media used strongly influence the nature of the secondary photochemical transformations both in and outside the solvent cage. The formation mechanism of the photochemical reaction products in CCl_4 when ammonia was used, after and during irradiation, has been explained mainly by the transformations of the radical α_r and cation α_k as well as by the carbazyl radical β, which is also formed in the reaction medium. On the other hand, reaction of the cation γ_i' explains the formation of the photoproducts in the irradiated solution of NEC with CCl_4 in ethanol. These photochemical results have been compared to the photochemical reactions involved in the carbazole–CCl_4 system.

BOGUMIL ZELENT et GILLES DUROCHER. Can. J. Chem. **63**, 1654 (1985).

Le mécanisme de la photodécomposition du éthyl-*N*-carbazole (NEC) en présence de tétrachlorure de carbone (CCl_4) est analysé suite à l'identification des photoproduits obtenus. La photodissociation du lien *N*-éthyl ainsi que le transfert électronique dans le complexe excité de transfer de charge $^1(\mathrm{NEC}^{\delta+}\cdots\mathrm{CCl_4}^{\delta-})^*$ peuvent être la cause de l'acte photochimique primaire suite à l'excitation du NEC dans son état premier singulet. Le phototransfert électronique conduit à l'apparition du radical cation du NEC, à l'anion chlorure et au radical trichlorométhyl dans la cage du solvant, $[\mathrm{NEC}^{+\cdot}\mathrm{Cl}^-\dot{\mathrm{C}}\mathrm{Cl_3}]$. La décomposition du radical cation en présence de Cl^- et de $\dot{\mathrm{C}}\mathrm{Cl_3}$ s'effectue par l'attaque du groupe *N*-éthyl ou par le noyau aromatique. Les produits intermédiaires suivants:



α_r α_k $\gamma_i'(i = 1, 2, 3, \text{ou } 4)$

dans la cage du solvant donnent lieu à l'ensemble des réactions photochimiques secondaires. La polarité ainsi que l'activité chimique du milieu réactionnel influencent fortement la nature des transformations photochimiques secondaires dans la cage du solvant et en dehors de celle-ci. Le mécanisme de formation des produits photochimiques dans le CCl_4 lorsque l'ammoniaque est ajouté au cours et après l'irradiation s'explique principalement par la transformation du radical α_r, du cation α_k et du radical carbazyl β qui est également présent dans le milieu réactionnel. Par ailleurs, la présence des cations γ_i' explique la formation des photoproduits du NEC dans les solutions d'éthanols auxquelles est ajouté du CCl_4. Ces résultats photochimiques ont été comparés à ceux obtenus pour le système carbazole–CCl_4.

Introduction

The photophysical properties of carbazole and its *N*-substituted derivatives (1–5) along with the photochemical reactions (6–8) have been the object of extensive studies in recent years. On the other hand, the electronic spectroscopic properties of carbazoles have also been thoroughly studied (9–12). Most of these investigations were correlated with the theoretical calculations which have been carried out in order to describe the ground and excited electronic states of carbazole (9, 13–15) and *N*-alkyl derivatives of carbazole (11, 16).

†Abbreviations: a, main product of the reaction studied (chemical yields between 5 and 20%); b, minor product of the reaction studied (chemical yields below 5%); s, remaining substrate.

Carbazole and its derivatives, like other aromatic amines in the presence of strong organic electron acceptors such as tetracyanoethylene, tetracyanoquinodimethane, 2,3-dichloro-5,6-dicyano-*p*-benzoquinone, trinitro and tetranitrofluorenones, *p*-chloranil, etc., form charge transfer (CT) complexes (17−22) with new asymmetric absorption bands in the visible region of the spectrum. The asymmetry of these new CT bands was interpreted (18, 19, 22) as being associated with the existence of two closely lying higher occupied molecular π-orbitals of carbazoles (12). The possibility of distinguishing two maxima in asymmetric absorption spectra of the complexes is due to the two CT transitions from the higher occupied molecular orbitals of carbazoles to the lowest vacant orbital of the acceptors. In these ground state CT interaction studies, much attention has been devoted to *N*-ethylcarbazole. The ionization potential of *N*-ethylcarbazole (21) obtained from CT complexes as well as the thermodynamic parameters of the formation of its CT complexes (18, 20) have also been presented and discussed. On the other hand, a singlet excited *N*-ethylcarbazole molecule in the presence of electron acceptor molecules is easily involved in electron transfer reaction, transforming itself to a radical cation (23, 24). The radical cation of *N*-ethylcarbazole in acetonitrile is well characterized by the absorption band at 780 nm (23, 24), which in nitrobenzene is at 800 nm (25).

Carbon tetrachloride is well known to be an efficient fluorescence quencher of a large variety of organic molecules (1, 2, 26−32). The fluorescence quenching process has usually been explained by the exciplex formation between the singlet excited molecule and the CCl_4 molecule. Such transient excited state interaction becomes an important step of photochemical reactions. The electronic excitation of donor molecules like aromatic amines, which possess comparatively low ionization potential in the presence of CCl_4, leads to electron transfer in the transiently formed exciplex (7, 33−35). This is accompanied by the heterolytic dissociation of a C—Cl bond in CCl_4. Such chemical activity in CCl_4 is connected not only with its significant electron affinity (2.12 eV) (28) but also with its comparatively low C—Cl bonding energy (231.2 kJ mol^{-1}) (36) and the low (~0) activation energy of the dissociative process for the electron attachment (37). Because of its properties, CCl_4 is frequently used as an active component in photochemical reactions.

The mechanism of photooxidation of carbazole in the presence of CCl_4 has been studied in our laboratory (7). The ethyl substitution in the carbazole molecule modifies the electronic structure of the aromatic ring system and the possibilities of the photochemical transformations of the molecule. This study proposes a mechanism which explains the photodecomposition of *N*-ethylcarbazole in the presence of CCl_4, based on the photoproducts identified. The mechanism presented will be compared to the photochemical reactions in the carbazole−CCl_4 system. These photochemical results along with the fluorescence spectra of the photoproducts also support the electron transfer mechanism proposed to explain the fluorescence quenching of carbazole and *N*-ethylcarbazole by halocarbons (1).

Results and discussion

In the *N*-ethylcarbazole (NEC) − carbon tetrachloride system the uv radiation absorbed in the ^1L_b band of NEC initiates a complex chemical reaction which leads to a large number of derivatives of carbazole. Table 1 shows the photoproducts obtained from the photodecomposition of NEC in the presence of CCl_4 when the photolyte was neutralized by ammonia gas after irradiation (first column) and during irradiation (second column) as well as when ethanol was used as a photochemical reaction medium (third column). Such products as carbazole (C), *N*-(trichlorovinyl)carbazole (**2**), *N*-(β-dichlorovinyl)-

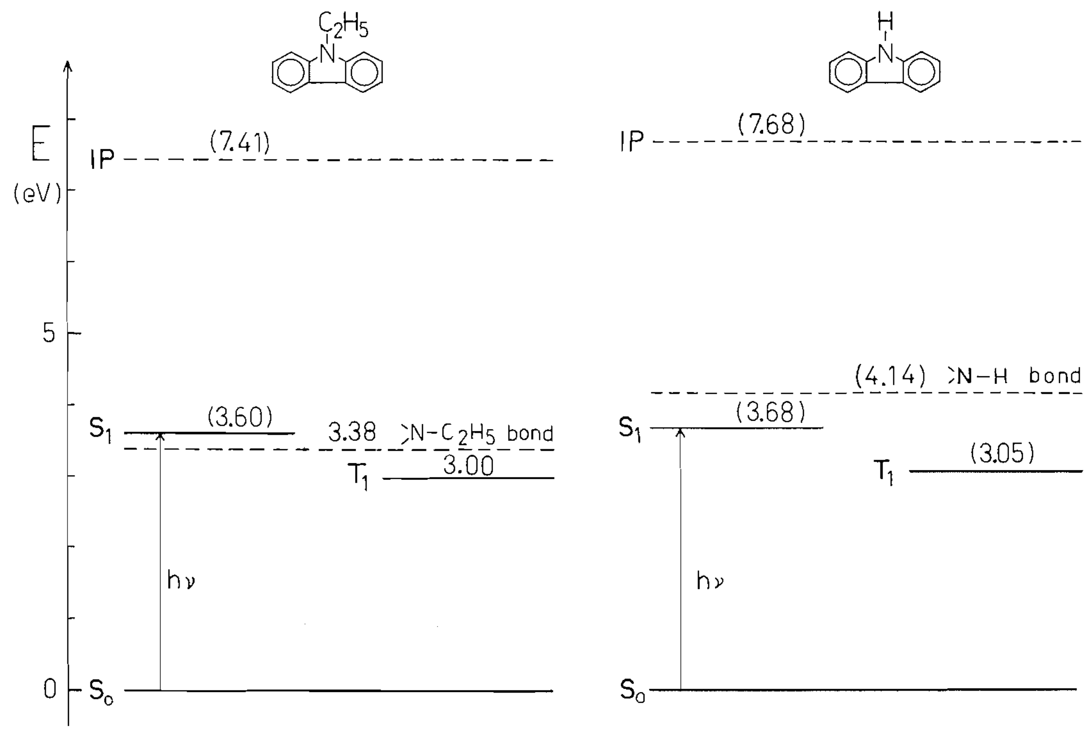

FIG. 1. Energy level diagram for *N*-ethylcarbazole and carbazole.

carbazole (**3**), *N*-(α-methyl-β-dichlorovinyl)carbazole (**4**), *N*-(2-trichloromethylpropenyl)carbazole (**5**), 1,1-di(*N*-carbazyl)-ethane (**6**), *N*-(α-trichloromethylvinyl)carbazole (**7**), and *N*-cyanocarbazole (**8**), as well as 1-cyanocarbazole (**9**) and 3-cyanocarbazole (**10**), indicate the possibilities of the photochemical transformations of NEC by the *N*-ethyl part of the molecule. On the other hand, the compounds **9**, **10**, and 3-cyano-*N*-ethylcarbazole (**11**), in addition to 3-(carboethoxy)-carbazole (**12**) and carboethoxy derivatives of NEC such as 1-(carboethoxy)-*N*-ethylcarbazole (**13**), 3-(carboethoxy)-*N*-ethylcarbazole (**14**), 4-(carboethoxy)-*N*-ethylcarbazole (**15**), 1,6-di(carboethoxy)-*N*-ethylcarbazole (**16**), 2,6-di(carboethoxy)-*N*-ethylcarbazole (**17**), 3,5-di(carboethoxy)-*N*-ethylcarbazole (**18**), 3,6-di(carboethoxy)-*N*-ethylcarbazole (**19**), and 1,5-di-(carboethoxy)-*N*-ethylcarbazole (**20**), which form in ethanol as a solvent, indicate also the participation of the aromatic ring of the NEC molecule in secondary reactions.

Figure 1 shows an energy level diagram for NEC and carbazole based on experimental data (6, 12, 38, 39). This simple energy level diagram indicates that the *N*-ethyl substituent decreases the ionization potential (IP) of the carbazole molecule, and the difference between the ionization potential and the energy of the first singlet state for the NEC molecule is lower than that of carbazole, $[\mathrm{IP(NEC)} - E_{S_1}(\mathrm{NEC})] < [\mathrm{IP(C)} - E_{S_1}(\mathrm{C})]$. Such a relation suggests that the formation of the excited CT complex between the singlet excited NEC molecule and CCl_4 is energetically more probable than it is in the case of carbazole. We also see in the diagram that the energy of the *N*-ethyl bond is lower than the energy of the first singlet state of NEC molecule. This energy diagram also indicates that there exists a certain probability for the photodissociation of the *N*-ethyl bond of the NEC molecule in its singlet excited state. In the case of carbazole, the energy of the first excited singlet state is lower than that of the N—H bond.

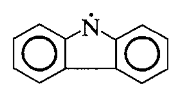
The photochemical reaction products obtained (Table 1) and the energy level diagram discussed (Fig. 1), along with the well-known photophysical (1, 26−30) and photochemical (7, 33−35) results in the aromatic electron donor − CCl_4 system, strongly suggest the following primary photophysical and photochemical processes of the NEC molecule in the presence of CCl_4:

$$\text{[1]}\quad \mathrm{NEC} + h\nu \longrightarrow {}^1\mathrm{NEC}^*$$

$$\text{[2]}\quad {}^1\mathrm{NEC}^* \longrightarrow \mathrm{NEC} + h\nu_F$$

$$\text{[3]}\quad {}^1\mathrm{NEC}^* + \mathrm{CCl_4} \rightsquigarrow \begin{cases} {}^3\mathrm{NEC}^* + \mathrm{CCl_4} \\ \mathrm{NEC} + \mathrm{CCl_4} \end{cases}$$

$$\text{[4]}\quad {}^1\mathrm{NEC}^* \rightsquigarrow$$



$$+ \dot{\mathrm{C}}_2\mathrm{H}_5$$

β

$$\text{[5]}\quad {}^1\mathrm{NEC}^* + \mathrm{CCl_4} \rightsquigarrow {}^1(\mathrm{NEC}^{\delta+}\cdots\mathrm{CCl_4}^{\delta-})^*_{\mathrm{solv}}$$

$$\text{[6]}\quad {}^1(\mathrm{NEC}^{\delta+}\cdots\mathrm{CCl_4}^{\delta-})^*_{\mathrm{solv}} \rightsquigarrow \begin{cases} {}^3\mathrm{NEC}^* + \mathrm{CCl_4} \\ {}^1\mathrm{NEC}^* + \mathrm{CCl_4} \\ \mathrm{NEC} + \mathrm{CCl_4} \end{cases}$$

$$\text{[7]}\quad {}^1(\mathrm{NEC}^{\delta+}\cdots\mathrm{CCl_4}^{\delta-})^*_{\mathrm{solv}} \rightsquigarrow \{\mathrm{NEC}^{+\cdot}\mathrm{Cl}^-\dot{\mathrm{C}}\mathrm{Cl}_3\}_{\mathrm{solv}}$$

The radiationless processes in the dissipation of the singlet excitation energy of the NEC molecule compete with fluorescence (eq. [2]). The photophysical processes can occur via the external spin orbital coupling with the CCl_4 molecule (eq. [3]) or via complexation (eqs. [5] and [6]). On the other hand, the photodissociation of the *N*-ethyl bond (eq. [4]) and the electron transfer in the excited CT complex (eq. [7]) are the photochemical processes.

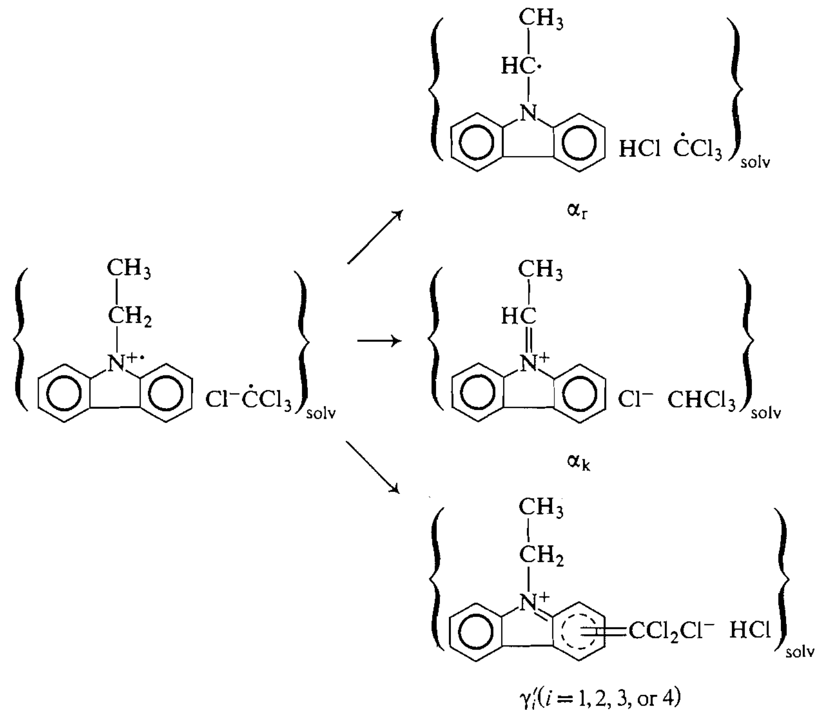
We propose that the electron transfer from singlet excited NEC molecule to CCl_4 molecule in the transient excited CT complex, ${}^1(\mathrm{NEC}^{\delta+}\cdots\mathrm{CCl_4}^{\delta-})^*$, is the main primary photochemical process which initiates a complex chemical reaction.

It leads to the radical cation of NEC, chloride ion, and trichloromethyl radical in the solvent cage. Similarly to the radical cation of carbazole (7), the further transformations of the radical cation of NEC are conditioned by the presence of Cl^- and $\dot{C}Cl_3$ in the solvent cage. These transformations result in other active species according to the following:

[8]

[9]

[10]



The formation of the α_r radical from the radical cation of NEC (eq. [8]) is promoted by the formation of thermodynamically stable hydrogen chloride. The reactions of the radical cation of NEC with the CCl_3 radical can lead to cation α_k and chloroform (eq. [9]) or cation γ_i' (eq. [10]).

The formation of radicals by abstraction of an α-proton from the radical cation of amine molecules has been postulated in reactions of chemical oxidation of *N*,*N*-dialkylanilines by benzoyl peroxide (40) and in photochemical oxidation of tertiary amines in the presence of halomethanes (41). On the other hand, in the reactions of benzoyl peroxide with *N*,*N*-dialkyl aromatic amine, the formation of the corresponding cations by the abstraction of a hydrogen atom from the radical cation of the amine molecule has also been postulated (42, 43). The proposed mechanism of the transformation of the radical cation of NEC in the solvent cage is consistent with earlier studies on the mechanism of the photochemical reactions in the aromatic amine – polychloromethane system (33, 34).

The formation of γ_i' (mainly with i = 1 or 3) is accompanied by the formation of hydrogen chloride. This reaction occurs with the participation of the aromatic ring system in the radical cation of NEC favoring the 1, 3, 6, and 8 positions. It is in good agreement with the charge density redistribution in the aromatic system. Indeed, theoretical calculations of the π electronic charge density in the carbazole molecule (8, 13, 14) show that the 1, 3, 6, 8, and 9 (N) positions are most favored. There exists a good correlation between the charge redistribution and the chemical properties of the carbazole radical cation and carbazyl radical. Such correlation has been confirmed by the products obtained from chemical (44, 45), electrochemical (14), and photochemical (7) reactions involving carbazole and carbazyl radical as well as by the products of the photochemical rearrangements of *N*-acetylcarbazole (8). On the other hand, it has also been exemplified in the literature that the alkyl substituent at nitrogen in carbazole influences the π electronic charge redistribution (11, 15, 16). The alkyl substituent increases the charge density in the ring system and decreases the electron density at the nitrogen atom in all electronic states of the molecule. There is an accompanying additional effect of polarization of the ring system, enhancing the electron density at the 1, 3, 6, and 8 positions and decreasing the electron density at the other positions.

The products presented in Table 1 show that the probability of transformations of the radical cation of NEC and further reactions of the intermediate species formed in the solvent cage strongly depends on the polarity and chemical activity of the reaction media used. The formation mechanism of the photochemical reaction products in nonpolar reaction medium like CCl_4 can be explained mainly by the secondary reactions of the radicals α_r, β, and $\dot{C}Cl_3$. On the other hand, intermediates γ_i' can explain the formation mechanism of the products in polar reaction medium like ethanol.

Reactions of cation α_k

Because of its electron acceptor properties, cation α_k can transform into the radical α_r in the presence of excited NEC molecule, such transformation resulting from the electron transfer in the excited charge transfer complex according to reaction (11):

[11] $^1NEC^* + \alpha_k \rightarrow {}^1(NEC^{\delta+} \cdots \alpha_k^{\delta-})^* \rightarrow NEC^{+\cdot} + \alpha_r$

In the presence of ammonia α_k cn also easily form the proper ammonium salt and decompose subsequently to give carbazole (eq. [12]).

[12] $Cl^{-}\alpha_k + NH_3 \rightarrow$  Cl^{-}

$\rightarrow C + CH_3CH{=}NH_2^{+}Cl^{-}$

The proposed mechanism of the formation and decomposition of the cation α_k in the reaction media studied here seems highly probable. Nevertheless this will obviously require further study.

Reactions of radical α_r

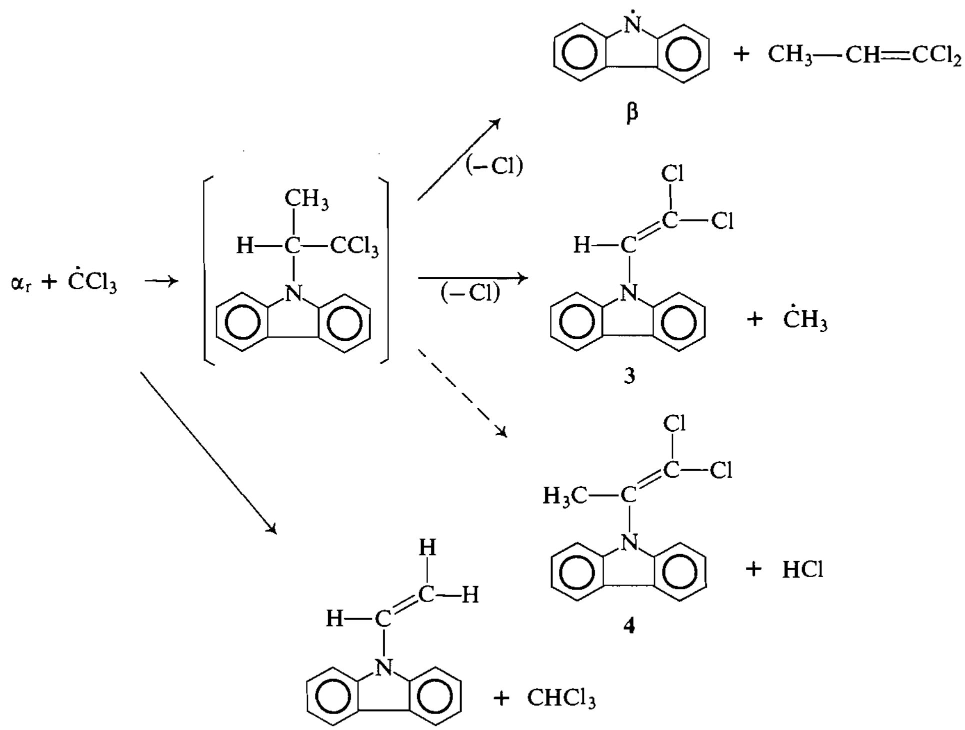
Apart from reactions [8] and [11] the radical α_r can also be formed by abstraction of α-hydrogen from the NEC molecule in the radical reaction medium. The interaction between radicals α_r and $\dot{C}Cl_3$ might be responsible for the appearance of such compounds as **3** and **4**, as well as radical β, by the decomposition of the intermediate product, *N*-(α-trichloromethylethyl)carbazole, unstable in the reaction medium (see eqs. [13]–[16]). Radical α_r in the presence of $\dot{C}Cl_3$ can transform to *N*-vinylcarbazole (eq. [16]). Similar reaction in the trialkylamine–polyhalomethane system (14) has been thoroughly studied. Nevertheless, *N*-vinylcarbazole in the photochemical reaction medium is highly unstable and will easily be

[13]

[14]

[15]

[16]



undergoing further transformation (17, 46–48). In the presence of CCl_4 and CCl_3 radicals the transiently formed *N*-vinylcarbazole probably becomes the precursor of **7** according to reaction [17]. In pure CCl_4 as the photochemical reaction medium, hexachloroethane (**1**), **3**, and **7** appear, among others, as the main products.

[17] 
7

When ethanol was used as a solvent, we identified **5**. The formation of **5**, along with the low chemical yield of **1** (see Table 1), indicates the active role played by ethanol. The participation of ethanol in the reactions of CCl_3 radicals suggests the complex formation mechanism of **5** (eq. [18]).

[18] α_r 
5

The reactions of CCl_3 radicals generated from CCl_4 with the primary alcohols are well known in the literature, where both α-hydrogen abstraction and chain reaction mechanism have been postulated (49, 50).

Reactions of radical β

The formation of carbazole and **6** as main products in CCl_4 when ammonia was used after and during irradiation (Table 1) (eqs. [19] and [20]) proves the existence of radicals β.

[19] 
[20] 
6

In an acid reaction medium, reaction [13] seems to be the main source of radical β. Comparatively low yield of carbazole when ethanol was used as a solvent and trace amount of carbazole obtained during irradiation of NEC in pure ethanol or in pure 3-methylpentane indicate that reaction [4] is not highly efficient. During irradiation of NEC in CCl_4 in the presence of ammonia gas the formation of radical β can be explained by the interaction of the radical cation of NEC with ammonia (eq. [21]). It has been found that interaction between the radical

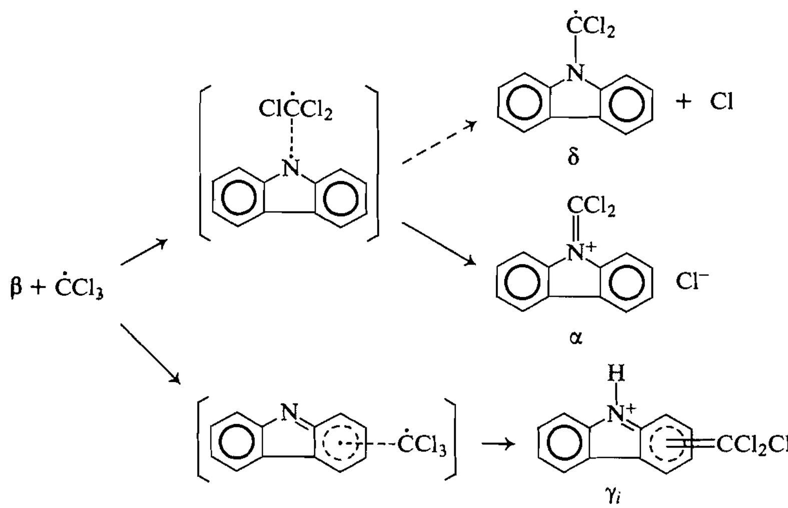
[21] 
cation of an aromatic amine and ammonia results in the corresponding radicals (7*c*, 33). The comparatively low yield of **6** in the acid reaction medium as compared to the yield of **6** in the ammonia reaction medium can be explained by the competing influence of reactions [13]–[16] in which radicals α_r are involved.

Such compounds as **2**, **8**, **9**, and **10** that are found in the photolyte after irradiation of NEC in CCl_4 strongly suggest the formation of the intermediate species δ, α and γ_i. These intermediates can be formed by the reaction of radical β with the CCl_3 radical (eqs. [22]–[24]).

[22]

[23]

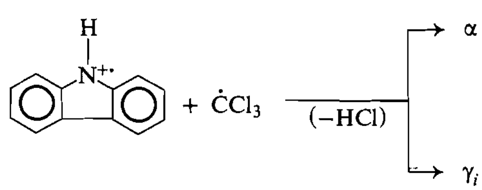
[24]



In an acid reaction medium, reaction [13] seems to be the main source of radical β. Comparatively low yield of carbazole reaction medium, intermediates α and γ_i can also be formed by reactions [26] and [27].

[25] 
[26]

[27]



The intermediates δ, α, and γ_i convincingly explain the formation mechanism of the products **2**, **8**, **9**, and **10** (8) as follows:

[28] 
2

[29] 
8

[30] 
9,10

Among the identified products, the **8** forms as the main compound.

Comment on the reactions of radical CCl_3

Apart from the reaction of radical–radical type in the system studied, the trichloromethyl radicals can also react with carbazole or NEC molecules through the aromatic ring, resulting in the corresponding γ_i and γ_i' intermediates (eq. [31]). Ionic

R = H or C_2H_5

[31] 
products γ_3 and γ_3' form mainly in the ammonia reaction medium by reaction [31]. This explains the formation mechanism of **10** and **11** according to reaction [30].

The relatively low bond energy of C—Cl in the CCl_4 molecule and the possibility of the formation of the stable hydrogen chloride molecule in the presence of CCl_4 and hydrogen donor molecules facilitate the chain reaction mechanism in CCl_4. Reaction [31] can constitute one of the links of the chain reaction in the NEC–CCl_4 system, such reaction being initiated by the CCl_3 radicals in the presence of CCl_4 as a good hydrogen acceptor.

TABLE 2. Fluorescence maxima of a series of (carboethoxy)-*N*-ethylcarbazole molecules in ethanol at room temperature excited at 340 nm

Molecule	λ_{max} (F) (nm)
N-Ethylcarbazole	365

3-(Carboethoxy)-*N*-ethylcarbazole	365
4-(Carboethoxy)-*N*-ethylcarbazole	437
1,6-Di(carboethoxy)-*N*-ethylcarbazole	395
2,6-Di(carboethoxy)-*N*-ethylcarbazole	405
3,5-Di(carboethoxy)-*N*-ethylcarbazole	412
3,6-Di(carboethoxy)-*N*-ethylcarbazole	361
1,5-Di(carboethoxy)-*N*-ethylcarbazole	430

Reactions of cation γ_i'

(Carboethoxy)-*N*-ethylcarbazoles are formed as the main photoproducts in the system NEC–CCl_4 when ethanol is used as a solvent (see Table 1). The formation mechanism of mono(carboethoxy)-*N*-ethylcarbazoles can only be explained by the reaction of ionic form γ_i' with ethanol (eq. [32]). In the photochemical reaction medium studied γ_i' can be formed in the solvent cage (eq. [10]) and out of it (eq. [31]).

[32] 
Mono(carboethoxy)-*N*-ethylcarbazoles formed during irradiation can also undergo photochemical reactions in the presence of CCl_4. This leads to di(carboethoxy)-*N*-ethylcarbazoles as follows:

[33] 

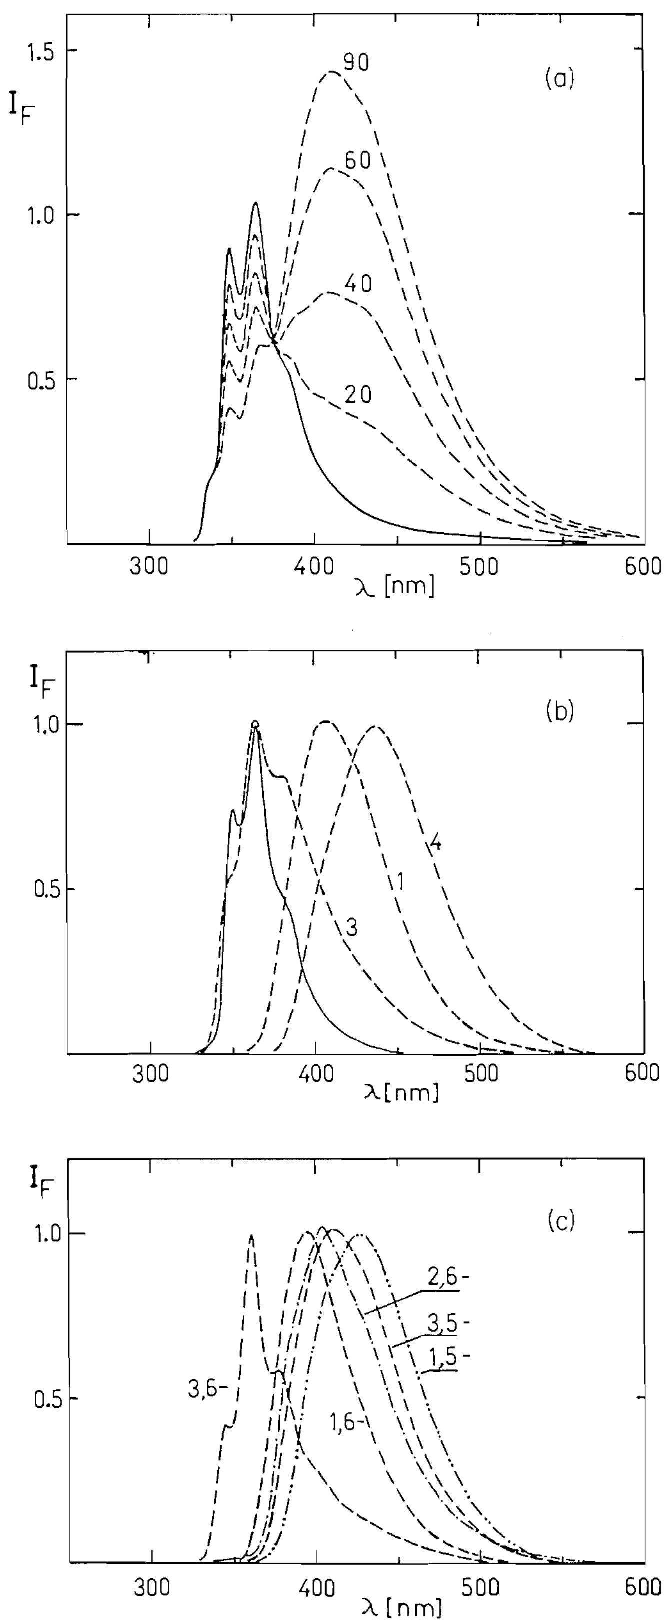

FIG. 2. Fluorescence spectra of an ethanol solution of (a) *N*-ethylcarbazole (1×10^{-4} *M*) in the presence of CCl_4 (0.1 *M*) before irradiation (_______), and after specified time of irradiation in seconds (– – –). The excitation wavelength was fixed at 340 nm; (b) *N*-ethylcarbazole (_______), and mono(carboethoxy)-*N*-ethylcarbazoles ($\sim 1 \times 10^{-4}$ *M*); (c) di(carboethoxy)-*N*-ethylcarbazoles ($\sim 1 \times 10^{-4}$ *M*).

The comparison between NEC and carbazole photochemistry

As shown in Fig. 1, the electron transfer from singlet excited NEC molecule to CCl_4 molecule in the ex-CT complex should be energetically more probable than that for cabazole, and from the same figure we can see that the photodissociation of the *N*-ethyl bond in the NEC molecule, as a primary photochemical process, is also possible.

The secondary photochemical reactions of NEC in CCl_4 which occur with the participation of cation α_k and radical α_r are peculiar only to NEC. On the other hand, the photochemical decomposition of the NEC molecule in the presence of CCl_4 in ethanol as a solvent is very similar to that of the carbazole molecule under the same conditions (7*b*). This has been well exemplified by the photoproducts identified, such as (carboethoxy)-*N*-ethylcarbazoles (see Table 1), which are formed in the same way as (carboethoxy)carbazoles from carbazole, as well as by the fluorescence spectra shown in Fig. 2. During irradiation of an ethanol solution of NEC in the presence of CCl_4 (Fig. 2a) the typical fluorescence of NEC decreases in intensity, while new fluorescences appear in the range 380–550 nm and increase in intensity. We have shown in Figs. 2b, 2c and Table 2 that mono and di(carboethoxy)-*N*-ethylcarbazoles in ethanol might all be responsible for the new fluorescence observed.

The observed changes in the fluorescence spectra of an ethanol solution of NEC in the presence of CCl_4 are similar to that of carbazole, and the maxima of the fluorescence bands are shifted to lower energy by about 8 nm. This is in good agreement with the substituent effect of the *N*-ethyl group.

The photodecomposition of NEC in CCl_4, can also lead to radical β, which in the presence of CCl_3 radical can transform to the same products as these observed in the photodecomposition of carbazole. This is indicated by the *N*- 1-, and 3-cyanocarbazoles as products, when ammonia was used as a scavenger of HCl. Radical β is one of the transient amine products that easily forms both in the photochemical reaction of carbazole and NEC in CCl_4. In the carbazole–CCl_4 system, radical β can only be formed from the radical cation of carbazole in the presence of chloride ion or ammonia (7). However, the photodecomposition of NEC in CCl_4 to radical β can occur by radical α_r in the presence of CCl_3 radical, the radical cation of NEC in the presence of ammonia, or by the photodissociation of the *N*-ethyl bond in the molecule. The formation mechanism of radical β from NEC molecule promoted by CCl_4 requires further study.

Experimental

Apparatus

The ^1H nmr spectra were determined with a Bruker WH-90 spectrometer operating at 90 MHz or a Bruker WP-80 spectrometer operating at 80 MHz. Chemical shift values are given in a δ scale with respect to TMS as an internal standard. Infrared spectra were recorded on a Perkin–Elmer 710B infrared spectrophotometer and mass spectra were taken with a VG Micromass 1212 mass spectrometer or a Kratos MS-9 mass spectrometer.

The absorption spectra were recorded on a Cary 17 spectrophotometer using 10-mm optical path cells. The emission spectra were recorded on a fluorescence spectrophotometer Model SF-1 "Fluorispec" (Baird-Atomic, Inc. Cambridge, MA). All solution examined in fluorescence were first deoxygenated with oxygen-free argon.

General procedure

N-Ethylcarbazole solutions (0.004 *M*) in pure carbon tetrachloride or 0.1 *M* carbon tetrachloride in ethanol were deoxygenated with

oxygen-free argon and irradiated in a Pyrex Hanovia immersion-well reactor for 30 min with an Hanovia 679A36 450-W medium-pressure mercury lamp. Hydrogen chloride generated during these reactions was neutralized. The irradiated solution of *N*-ethylcarbazole in pure carbon tetrachloride was saturated with ammonia gas. But only sodium carbonate was added to the irradiated *N*-ethylcarbazole solution with carbon tetrchloride in ethanol. The solution was mixed and then the sediment was separated by decantation. Following that, the solutions of photolytes were concentrated. *N*-Ethylcarbazole solution (0.004 *M*) in carbon tetrachloride was also irradiated (30 min) in the presence of ammonia. A slow stream of ammonia gas was bubbled through the solution before and during irradiation. Hydrogen chloride generated during the photochemical reaction was thus removed from the reaction medium. After irradiation, the solution of photolyte was concentrated.

The photochemical reaction products were then analysed by tlc detected by uv (using Eastman-Kodak tlc plates, silica gel 13181 with fluorescent indicator No 6060) and separated by column chromatography. The columns were packed with silica gel (Kieselgel 60, Merck, particle size 0.040–0.063 mm). Developing systems consisted of petroleum ether (low boiling fraction) and ethyl ether or benzene. The developed distance on the tlc plates was kept at 10 cm. Identified products, on the basis of their ^{1}H nmr, ir, and mass spectra, have been listed in Table 1 and their R_f values on tlc plates with silica gel are listed in Table 3.

Materials

N-Ethylcarbazole 99% was obtained from Aldrich Chemical Co. and was further twice recrystallized in pure ethanol and then purified by column chromatography with silica gel using a petroleum ether – ethyl ether mixture (1000:1 v/v) as a developing system. Carbazole (zone refined 99.999%) was obtained from James Hinton Co. and was used without any further purification. 1-Cyano-*N*-ethylcarbazole, 3-cyano-*N*-ethylcarbazole, 1-(carboethoxy)-*N*-ethylcarbazole, and 3-(carboethoxy)-*N*-ethylcarbazole were synthesized by *N*-ethylation of the corresponding N—H derivatives with ethyl bromide in the presence of caustic solution and benzyltriethylammonium chloride as a phase-transfer catalyst, as described in ref. 51. The compounds were purified by column chromatography with silica gel, using a petroleum ether – ethyl ether mixture as a developing system. The purity of these compounds was checked by tlc.

1-Cyano-N-ethylcarbazole: crystalline solid (R_f 0.55, petroleum ether – ethyl ether, 10:1). Infrared (film) $\tilde{\nu}_{max}$: 3050 (vw), 2960 (w), 2910 (vw), 2200 (s, C≡N), 1620 (vw), 1590 (w), 1575 (w), 1485 (s), 1470 (m), 1455 (m), 1440 (w), 1375 (vw), 1340 (w), 1315 (s), 1260 (vw), 1230 (w), 1215 (vs), 1160 (vw), 1125 (s), 1100 (vw), 1070 (w), 1040 (w), 1015 (vw), 930 (vw), 900 (vw), 850 (vw), 790 (s), 770 (w), 740 (vs) cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 1.55 (t, J = 8 Hz, 3H, methyl), 4.75 (q, J = 8 Hz, 2H, methylene), 7.16–7.80 (m, 5H, arom), 8.05–8.34 (m, 2H, arom). Mass spectrum (70 eV) (mol. wt. for $C_{15}H_{12}N_2$: 220.28), m/e: 220 (M^+, 41), 205(100), 192(8), 191(8), 178(5), 177(7), 165(10), 164(13), 151(13), 138(7).

3-Cyano-N-ethylcarbazole: crystalline solid (R_f 0.18, petroleum ether – ethyl ether, 10:1). Infrared (film) $\tilde{\nu}_{max}$: 3050 (vw), 2970 (w), 2920 (vw), 2200 (vs, C≡N), 1630 (m), 1595 (vs), 1495 (s), 1475 (vs), 1460 (m), 1385 (m), 1350 (s), 1330 (m), 1320 (m), 1290 (w), 1235 (vs), 1165 (vw), 1150 (m), 1125 (w), 1085 (w), 1060 (vw), 1020 (vw), 940 (vw), 885 (w), 845 (w), 800 (m), 775 (vw), 765 (vw), 740 (s), 720 (m) cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 1.47 (t, J = 8 Hz, 3H, methyl), 4.41 (q, J = 8 Hz, 2H, methylene), 7.22–7.80 (m, 5H, arom), 8.06–8.09, 8.15–8.18 (2m, 1H, arom), 8.39–8.41 (m, 1H, arom). Mass spectrum (70 eV) (mol. wt. for $C_{15}H_{12}N_2$: 220.28), m/e: 220 (M^+, 34), 205(100), 191(6), 177(6), 165(5), 164(7), 151(9).

1-(Carboethoxy)-N-*ethylcarbazole*: oil (R_f 0.60, petroleum ether – ethyl ether, 10:1). Infrared (film) $\tilde{\nu}_{max}$: 3050 (vw), 2970 (m), 2920 (w), 2900 (vw), 1715 (vs, C=O), 1610 (vw), 1590 (w), 1575 (m), 1490 (m), 1475 (s), 1450 (s), 1415 (s), 1380 (w), 1360 (w), 1330 (m), 1320 (m), 1310 (m), 1260 (vs), 1215 (m), 1195 (vs), 1155 (vw), 1135 (vs), 1090 (s), 1065 (vs) 1035 (vw), 1010 (w), 940 (vw), 910 (vw), 850 (vw), 780 (vw), 745 (vs), 720 (m) cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 1.17 and 1.27 (2t, J = 8 Hz, 6H, methyl), 4.29 and 4.36 (2q, J = 8 Hz, 4H, methylene), 6.94–7.35 (m, 4H, arom), 7.60–8.10, (m, 3H, arom). Mass spectrum (70 eV) (mol. wt. for $C_{17}H_{17}NO_2$: 267.33), m/e: 267 (M^+, 100), 252(69), 238(7), 224(48), 222(11), 220(23), 208(13), 206(23), 204(18), 196(14), 194(11), 193(23), 192(9), 168(55), 167(30), 166(30), 165(25), 164(23), 152(8), 140(16), 139(21), 138(9).

3-(Carboethoxy)-N-*ethylcarbazole*: oil (R_f 0.31, petroleum ether – ethyl ether, 10:1). Infrared (film) $\tilde{\nu}_{max}$: 3050 (vw), 2970 (m), 2925 (w), 2890 (vw), 1705 (vs, C=O), 1625 (m), 1595 (s), 1490 (m), 1470 (s), 1460 (m), 1445 (m), 1385 (m), 1365 (s), 1345 (m), 1335 (s), 1325 (s), 1300 (s), 1280 (s), 1245 (vs), 1220 (s), 1170 (vw), 1140 (m), 1130 (m), 1120 (w), 1095 (s), 1080 (s), 1050 (w), 1020 (m), 940 (vw), 905 (w), 880 (w), 850 (vw), 820 (w), 765 (s), 755 (m), 740 (m), 715 (s) cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 1.27 and 1.30 (2t, J = 8 Hz, 6H, methyl), 4.20 and 4.29 (2q, J = 8 Hz, 4H, methylene), 7.03–7.40 (m, 4H, arom), 6.95–8.10, (m, 2H, arom), 8.67, 8.68 (d, 1H, arom). Mass spectrum (70 eV) (mol. wt. for $C_{17}H_{17}NO_2$: 267.33), m/e: 267 (M^+, 100), 252(85), 239(7), 224(53), 222(50), 194(15), 179(31), 178(14), 165(10), 164(11), 152(13), 139(7), 138(5).

N-Vinylcarbazole was prepared from carbazole following the method described in the literature (52). The compound was purified by column chromatography with silica gel, using a low boiling fraction of petroleum ether as a developing system. The purity of this compound was checked by tlc (R_f 0.55, petroleum ether). The ^{1}H nmr ($CDCl_3$) spectrum of the synthesized compound was the same as described in ref. 53.

Carbon tetrachloride from American Chemicals was a Spectrograde quality solvent and it was first washed with a saturated sodium carbonate solution and then repeatedly with water, dried with calcium chloride and phosphorus pentoxide, and redistilled.

Ethanol was purified by refluxing with concentrated sulfuric acid for 24 h and then was fractionally distilled. Petroleum ether and benzene were distilled before use.

Spectral characteristics of the photochemical products

Carbazole (C): this compound was identified by comparison with an authentic sample (R_f, ^{1}H nmr and ir spectra). *Hexachloroethane* (**1**): single crystals and N-*(trichlorovinyl)carbazole* (**2**): crystalline solid were identified as described previously (7*ab*). N-*(β-Dichlorovinyl)carbazole* (**3**): crystalline solid: infrared (film) $\tilde{\nu}_{max}$: 3060 (m), 1620 (w), 1600 (m), 1485 (s), 1480 (s), 1455 (vs), 1445 (vs), 1420 (w), 1335 (vs), 1310 (s), 1225 (vs), 1155 (s), 1140 (m), 1115 (vw), 1080 (m), 1065 (vw), 1025 (vw), 995 (vw), 920 (m), 875 (m), 880 (s), 745 (vs), 715 (vs) cm^{-1}. ^{1}H nmr ($CDCl_3$) δ: 6.87 (s, 1H, C—H), 7.20–7.58 (m, 6H, arom), 7.94–8.18 (m, 2H, arom). Mass spectrum (70 eV) (mol. wt. for $C_{14}H_9NCl_2$: 262.14), *m/e*: 263 (M^+, 32.2), 261 (M^+, 46.3), 228(13.4), 226(36.6), 191(100), 190(66.6), 166(5.2), 165(8.8), 164(16.2), 163(14.2), 140(12.9), 139(10.6).

N-*(α-Methyl-β-dichlorovinyl)carbazole* (**4**): crystalline solid; ^{1}H nmr ($CDCl_3$) δ: 1.56 (s, 3H, methyl), 7.20–7.60 (m, 6H, arom), 7.98–8.20 (m, 2H, arom). Mass spectrum (70 eV) (mol. wt. for $C_{15}H_{11}NCl_2$: 276.17), *m/e*: 277 (M^+, 42), 275 (M^+, 73), 260(14), 242(10), 240(38), 227(36), 225(100), 205(87), 204(79), 190(10), 164(3).

N-*(2-Trichloromethylpropenyl)carbazole* (**5**): crystalline solid: infrared (film) $\tilde{\nu}_{max}$: 3050 (w), 2970 (m), 2920 (m), 1620 (w), 1590 (m), 1570 (w), 1490 (w), 1480 (m), 1470 (m), 1450 (s), 1420 (s), 1380 (w), 1335 (m), 1310 (m), 1260 (w), 1215 (vs), 1175 (w), 1155 (w), 1125 (m), 1110 (vw), 1075 (w), 1070 (w), 1040 (w), 1015 (w), 1000 (vw), 970 (w), 930 (w), 915 (s), 900 (w), 885 (vw), 870 (vw), 860 (m), 810 (m), 780 (m), 775 (w), 740 (vs), 720 (w) cm^{-1}. ^{1}H nmr ($CDCl_3$) δ: 1.27 (s, 3H, methyl), 7.10–7.45 (m, 6H, arom and 1H, C—H), 8.0–8.20 (m, 2H, arom). Mass spectrum (70 eV) (mol. wt. for $C_{16}H_{12}NCl_3$: 324.64), *m/e*: 328 (M^+, 2.3), 327 (M^+, 14.8), 325 (M^+, 47.5), 323 (M^+, 41.3), 312(5.9), 310(19.0), 308(18.9), 292(1.1), 290(5.6), 288(10.1), 277(5.0), 276(14.2), 275(30.1), 274(60.4), 273(51.5), 272(92.8), 241(5.4), 240(31.9), 239(17.5), 238(100).

*1,1-Di(*N*-carbazyl)ethane* (**6**): crystalline solid; infrared (film) ν_{max}: 3040 (m), 2920 (m), 2840 (m), 1620 (w), 1600 (m), 1560 (w), 1480 (m), 1450 (vs), 1420 (w), 1380 (w), 1325 (s), 1310 (m), 1240 (m), 1225 (m), 1215 (m), 1205 (m), 1190 (w), 1160 (m), 1135 (w), 1120 (w), 1100 (vw), 1065 (w), 1025 (w), 1000 (vw), 965 (vw), 910 (m), 885 (w), 800 (s), 780 (s), 745 (vs), 715 (s) cm^{-1}. ^{1}H nmr ($CDCl_3$) δ: 2.21 (d, J = 7 Hz, 3H, methyl), 5.53 (q, J = 7 Hz, 1H, C—H), 7.20–7.60 (m, 12H, arom), 7.85–8.18 (m, 4H, arom). Mass spectrum (70 eV) (mol. wt. for $C_{26}H_{20}N_2$: 360.46), *m/e*: 360 (M^+, non-observed), 194(100), 167(62.5), 166(31.8), 140(19.4), 139 (16.3).

N-*(α-Trichloromethylvinyl)carbazole* (**7**): crystalline solid; infrared (film) $\tilde{\nu}_{max}$: 3050 (w), 2920 (w), 2850 (vw), 1615 (w), 1600 (m), 1580 (vw), 1480 (m), 1450 (vs), 1365 (m), 1335 (m), 1310 (m), 1270 (w), 1230 (s), 1195 (vw), 1165 (vw), 1150 (vw), 1120 (vw), 1105 (vw), 1070 (vw), 1030 (vw), 1005 (m), 955 (w), 915 (m), 900 (w), 850 (vw), 805 (w), 780 (w), 750 (vs), 720 (s) cm^{-1}. ^{1}H nmr ($CDCl_3$) δ: 4.72 (s, 2H, ethene), 7.20–7.60 (m, 6H, arom), 8.07–8.20 (m, 2H, arom). Mass spectrum (70 eV) (mol. wt. for $C_{15}H_{10}NCl_3$: 310.61), *m/e*: 315 (M^+, 2.5), 313 (M^+, 34), 311 (M^+, 85), 309 (M^+, 83.5), 278(63), 241(5.5), 240(19.5), 239(19), 238(50), 204(39.5), 167(50), 166(17), 140(27), 139(32), 87(19), 85(92), 83(100).

N-*Cyanocarbazole* (**8**): crystalline solid, 1-*cyanocarbazole* (**9**): crystalline solid; and 3-*cyanocarbazole* (**10**): crystalline solid were identified as described previously (7*c*).

*3-Cyano-*N*-ethylcarbazole* (**11**): this compound was identified by comparison with an authentic sample (R_f, ^{1}H nmr and ir spectra).

3-(Carboethoxy)carbazole (**12**): crystalline solid. The compound was identified as described previously (7*a*, *b*).

*1-(Carboethoxy)-*N*-ethylcarbazole* (**13**) and *3-(carboethoxy)-*N*-ethylcarbazole* (**14**) were identified by comparison with authentic samples (R_f, ^{1}H nmr and ir spectra).

*4-(Carboethoxy-*N*-ethylcarbazole* (**15**): oil; infrared (film) $\tilde{\nu}_{max}$: 3040 (vw), 2960 (m), 2910 (w), 1710 (vs, C=O), 1615 (w), 1590 (m), 1570 (w), 1490 (m), 1470 (m), 1460 (s), 1430 (s), 1380 (w), 1360 (vw), 1345 (vw), 1320 (s), 1295 (m), 1270 (vs), 1255 (vs), 1220 (w), 1185 (m), 1150 (m), 1130 (s), 1095 (vs), 1070 (m), 1020 (m), 990 (w), 960 (vw), 920 (vw), 845 (vw), 790 (vw), 745 (vs), 710 (m) cm^{-1}. ^{1}H nmr ($CDCl_3$) δ: 1.44 and 1.51 (2t, J = 8 Hz, 6H, methyl), 4.43 and 4.56 (2q, J = 8 Hz, 4H, methylene), 7.25–7.92 (m, 6H, arom), 8.84 and 8.93 (2s, 1H, arom). Mass spectrum (70 eV) (mol. wt. for $C_{17}H_{17}NO_2$: 267.33), *m/e*: 267 (M^+, 100) 252(61.2), 224(22.3), 222(9.5), 194(5.5), 179(6.8), 165(2.6).

*1,6-Di(carboethoxy)-*N*-ethylcarbazole* (**16**): crystalline solid; infrared (film) $\tilde{\nu}_{max}$: 3050 (vw), 2970 (m), 2920 (w), 2890 (w), 2860 (vw), 1710 (vs, C=O), 1620 (m), 1590 (m), 1580 (m), 1490 (m), 1470 (m), 1450 (m), 1410 (m), 1380 (w), 1365 (m), 1335 (m), 1315 (w), 1300 (m), 1270 (s), 1260 (vs), 1250 (vs), 1245 (vs), 1215 (m), 1195 (s), 1170 (w), 1140 (s), 1095 (vs), 1060 (s), 1015 (m), 945 (vw), 925 (vw), 900 (vw), 875 (vw), 850 (vw), 810 (vw), 765 (m), 740 (m), 725 (w) cm^{-1}. ^{1}H nmr ($CDCl_3$) δ: 1.27–1.68 (m, 9H, methyl), 4.32–4.73 (m, 6H, methylene), 7.15–8.37 (complex m, 5H, arom), 8.83 (s, 1H, arom). Mass spectrum (70 eV) (mol. wt. for $C_{20}H_{21}NO_4$: 339.45), *m/e*: 339 (M^+, 100), 324(47), 311(28), 296(29), 294(26), 278(40), 268(7), 266(12), 264(15), 237(41), 222(18), 220(14), 194(6), 193(9), 192(10), 191(10), 168(16), 167(19), 166(21), 165(25), 164(29), 139(12), 138(8).

*2,6-Di(carboethoxy)-*N*-ethylcarbazole* (**17**): crystalline solid; infrared (film) $\tilde{\nu}_{max}$: 3040 (vw), 2970 (m), 2920 (m), 2890 (m), 2840 (w), 1710 (vs, C=O), 1625 (m), 1600 (w), 1570 (w), 1495 (w), 1470 (m), 1455 (m), 1440 (m), 1430 (m), 1390 (w), 1375 (m), 1365 (m), 1340 (m), 1310 (m), 1300 (m), 1280 (m) 1245 (vs), 1225 (s), 1170 (vw), 1140 (w), 1100 (s), 1080 (m), 1050 (vw), 1015 (m), 950 (vw), 925 (vw), 900 (vw), 875 (vw), 820 (vw), 770 (w), 755 (w), 740 (m), 715 (vw) cm^{-1}. ^{1}H nmr ($CDCl_3$) δ: 1.48 (t, J = 8 Hz, 9H, methyl), 4.43 (q, J = 8 Hz, 2H, methylene), 4.47 (q, J = 8 Hz, 4H, methylene), 7.15–7.50 and 7.80–8.30 (2m, 5H, arom), 8.87 (s, 1H, arom). Mass spectrum (70 eV) (mol. wt. for $C_{20}H_{21}NO_4$: 339.45), *m/e*: 339 (M^+, 72), 324(70), 311(8), 296(40), 294(44), 268(38), 266(40), 251(15), 238(22), 224(19), 223(63), 222(22), 221(24), 194(21), 193(35), 192(56), 191(35), 180(20), 178(74), 166(19), 165(42), 164(100).

*3,5-Di(carboethoxy)-*N*-ethylcarbazole* (**18**): crystalline solid; infrared (film) $\tilde{\nu}_{max}$: 3050 (vw), 2970 (s), 2920 (m), 2840 (w), 1710 (vs, C=O), 1615 (m), 1590 (s), 1570 (w), 1495 (w), 1460 (s), 1420 (m), 1385 (m), 1365 (s), 1335 (s), 1320 (vs), 1295 (s), 1290 (s), 1275 (vs), 1260 (vs), 1240 (vs), 1235 (vs), 1225 (s), 1180 (s), 1135 (s), 1095 (vs), 1070 (s), 1020 (s), 960 (vw), 925 (vw), 880 (vw), 860 (vw), 845 (vw), 810 (w), 795 (w), 765 (s), 745 (m), 715 (m) cm^{-1}. ^{1}H nmr ($CDCl_3$) δ: 1.27–1.66 (m, 9H, methyl), 4.33–4.68 (m, 6H, methylene), 7.26–8.32 (complex m, 5H, arom), 9.55 (s, 1H, arom). Mass spectrum (70 eV) (mol. wt. for $C_{20}H_{21}NO_4$: 339.45), *m/e*: 339 (M^+, 100), 324(63), 311(12), 296(33), 294(86), 268(30) 266(40), 251(8), 238(9), 221(26), 193(20), 191(10), 178(14), 165(13).

*3,6-Di(carboethoxy)-*N*-ethylcarbazole* (**19**): crystalline solid; infrared (film) $\tilde{\nu}_{max}$: 3050 (vw), 2970 (s), 2920 (m), 1705 (vs, C=O), 1625 (w), 1595 (s), 1575 (w), 1490 (m), 1480 (m), 1465 (m), 1450 (m), 1425 (w), 1385 (m), 1370 (s), 1335 (m), 1305 (s), 1285 (s), 1255 (vs), 1245 (vs), 1215 (s), 1180 (vw), 1145 (m), 1130 (w), 1100 (s), 1080 (m), 1050 (w), 1025 (s), 965 (vw), 945 (vw), 910 (vw), 895 (w), 870 (vw), 850 (vw), 835 (vw), 820 (w), 765 (s), 745 (w), 720 (m) cm^{-1}. ^{1}H nmr ($CDCl_3$) δ: 1.48 (t, J = 8 Hz, 9H, methyl), 4.42 (q, J = 8 Hz, 2H, methylene), 4.46 (q, J = 8 Hz, 4H, methylene), 7.40 and 7.49 (2s, 2H, arom), 8.19 and 8.29 (2d, J = 1.8 Hz, 2H, arom), 8.88–8.90 (m, 2H, arom). Conclusions

The irreversible electron transfer from singlet excited NEC molecule to CCl_4 molecule in the transient ex-CT complex, $^1(NEC^{\delta+}\cdots CCl_4^{\delta-})^*$, along with the photodissociation of the *N*-ethyl bond in the NEC molecule, have been proposed as the primary photochemical processes initiating the complex mechanism of secondary reactions in the system studied. Such intermediates as α_r, α_k, and γ'_i, formed by the transformation of the radical cation of NEC in the solvent cage, $[NEC^{+\cdot}Cl^-\dot{C}Cl_3]$, as well as carbazyl radical β, explain the formation mechanism of the photochemical reaction products depending on the reaction media used. The decomposition of $NEC^{+\cdot}$ in the presence of Cl^- and $\dot{C}Cl_3$ can occur by the *N*-ethyl group in a nonpolar solvent like CCl_4 or by the aromatic ring in a polar solvent like ethanol. This has been well exemplified by the photoproducts presented in Table 1.

When ethanol is used as a solvent, the photodecomposition of the NEC molecule in the presence of CCl_4 is similar to that already described for the carbazole molecule. Nevertheless, the secondary reactions in the system NEC−CCl_4, which occur with the participation of cation α_k and radical α_r, are characteristic of the NEC molecule only.

The scheme described for the transformation of $NEC^{+\cdot}$ in the solvent cage serves as a key for the explanation of the formation mechanism of all the photochemical reaction products in the NEC−CCl_4 system, depending on the reaction media used. On the contrary, these products, closely connected with the reactions of intermediates α_r, β, $\dot{C}Cl_3$, and γ'_i, strongly support the formation of the radical cation of NEC in the system studied.

All the results presented, along with our earlier studies on photochemical reactions in the carbazole−CCl_4 system, serves as chemical proof of the electron transfer mechanism used to explain the fluorescence quenching of carbazole and *N*-ethylcarbazole by halocarbons (1).

Received September 26, 1984

This paper is dedicated to Professor Camille Sandorfy on the occasion of his 65th birthday

B. A. Lombos. Can. J. Chem. **63**, 1666 (1985).

The role of deep-lying trapping centers in semi-insulating GaAs, polysilicon and polycrystalline tin oxide transparent electrode has been systematically investigated. It was demonstrated that some of the peculiar transport properties of these semiconductors can be elucidated by deep level compensation. A multilevel model is presented to determine the position of the Fermi level as a function of impurity concentrations. These include, quantitatively, the deep-lying levels which have been introduced by doping in the case of GaAs and by grain boundaries in the case of polycrystalline films. In the latter cases the dangling bonds, associated to lattice defects, are characterized by energy levels which are localized in the energy gap. These dangling bonds can act as electron traps when empty and hole traps when occupied. These are the deep levels.

In each of the investigated three cases, this concept permitted the elucidation of some of the transport properties of these semiconductors.

B. A. Lombos. Can. J. Chem. **63**, 1666 (1985).

On a étudié d'une façon systématique le rôle des centres profonds de piègeage dans le GaAs semi-isolant, dans le polysilicium et dans une électrode transparente d'oxyde d'étain polycristallin. On démontre que l'on peut élucider quelques unes des propriétés particulières de transport de ces semi-conducteurs en faisant appel à une compensation par des niveaux profonds. On présente un modèle à plusieurs niveaux pour déterminer la position du niveau de Fermi en fonction des concentrations des impuretés. Ceux-ci comprennent quantitativement les niveaux profonds que l'on a introduit par dopage dans le cas du GaAs et par les joints des grains dans le cas des films polycristallins. Dans ces derniers cas, les liaisons pendantes associées aux défauts du réseau sont associées à des niveaux d'énergie qui sont localisés dans la bande interdite. Ces liaisons pendantes peuvent agir comme piège d'électrons quand elles sont vides et comme piège de trous lorsqu'elles sont occupées. Ce sont les niveaux profonds.

Dans chacun des trois cas étudiés, ce concept permet d'élucider certaines propriétés de transport de ces semi-conducteurs.

[Traduit par le journal]

Introduction

The role of deep-lying impurity levels in semiconductors became important with the discovery of semi-insulating GaAs (SI GaAs) (1). This modification of the normally semiconducting GaAs resulted in the possibility of the realization of a number of solid state devices and integrated circuits by epitaxial technology. Due to the inherent electrical properties of GaAs, superior to those of silicon and germanium, the well-known classical active materials for the microelectronic industry, GaAs components have improved properties. These include their high frequency response, high temperature or power handling capacity, radiation hardness for satellite electronics, and the possibility for optoelectronic applications, such as solid state lasers. Some of these, naturally, could not have been realized with either silicon or germanium, since they are lower and indirect gap materials (2, 3). The extensive investigations of deep-lying levels, relative to room temperature thermal excitations, responsible for SI GaAs resistivities larger than 10^8 (ohm cm), were reviewed by Lin and co-workers (4, 5). Different compensation mechanisms were developed in the analyses of the experimental data. It was, however, *a priori* assumed that the material is semi-insulating in the calculations of the Fermi level (6, 7). Recently, a multilevel model without any *a priori* assumptions was employed, by considering the effect of all electrically active impurities in a quantitative explanation of the conditions required to realize semi-insulating GaAs (8).

This multilevel model was successfully used to analyze the transport properties of some polycrystalline thin film semiconductors as well.

Shockley (9) first recognized the importance of the dangling bonds associated with lattice defects and their acceptor behavior in the diamond structure. The theory has been worked out by Read (10), treating this dangling bond as having an unpaired electron. Then an electron in the conduction band of a semiconductor could diminish its energy by being paired to it. Consequently, an energy level, localized in the energy gap, can be expected to be associated with it (11). In the case of polysilicon, extensively used in the thin film form for microelectronics, this concept was used in the elucidation of its peculiar transport properties (12, 13). Here, the grain boundaries were the crystal defects, introducing deep levels. Then a compensation mechanism could account for the large change in room temperature resistivities, by a factor of 10^9 (ohm cm), of polysilicon films. In addition, the deep level concept could be extended to the formation of impurity bands elucidating the experimentally observed mobility minima in polysilicon (14). Following Mott's discussion of the Anderson transition (15), in the case of overlapping wave functions of the ionized impurities, a metallic impurity band can be formed in the band gap of the semiconductor. Then, when the Fermi level is in this impurity band, the propagation of the charge carriers is regarded as a diffusion process in a random system. As a result, the periodicity of the host lattice loses its role in the conduction process. This results in the replacement of the effective mass with the rest mass of the charge carriers, giving rise to characteristic low mobilities (16). Consequently, the observed mobility minima in polysilicon films can be quantitatively associated with the crossing of the Fermi level through the above mentioned metallic impurity band which has been created by the grain boundaries introduced deep-lying trapping centers (17).

Using the same model of deep levels, the measured transport properties of polycrystalline thin film of tin oxide could also be partially elucidated (18).

In this work the role of the deep-lying impurities will be treated with the analysis of some new results obtained in the case of chemical vapor deposited tin oxide films.

Multilevel model

The determination of the position of the Fermi level is of fundamental importance in solid state electronics for the characterization of the transport properties of semiconductors and devices. Following an elegant graphical method developed by Shockley (19) the Fermi energy E_f at any temperature, T; donor and acceptor concentrations, N_{dj} and N_{ai}; the impurity ionization energies, E_{dj} and E_{ai}; and band gap, E_g can be determined from the neutrality condition:

$$[1] \quad n + \sum_{i=1}^{l} N_{ai}^{-} = p + \sum_{j=1}^{m} N_{dj}^{+}$$

In large gap semiconductors the Fermi level is within the band gap several kT units away from the band edges, especially in the case of SI GaAs. Therefore Maxwellian statistics can be used. In this case the free electron concentration, n, is given by the well-known expression

$$[2] \quad n = 2(2\pi m_e k T/h^2)^{3/2} \exp\left(-\frac{E_g - E_f}{kT}\right)$$

here k is the Boltzmann constant, h is the Planck constant, and in the case of GaAs, $m_e = 0.069\, m_0$ (20) is the density of state effective mass of the electrons and the band gap is given by (20)

$$[3] \quad E_g(T) = 1.522 - \frac{5.8 \times 10^{-4}\, T^2}{T + 300}$$

The ionized acceptor concentration as the function of energy, E, can be determined by:

$$[4] \quad N_{ai}^{-} = N_{ai}\left(1 + 1/g \exp\frac{E_{ai} - E_f}{kT}\right)^{-1}$$

The expression describing the ionized donors' concentration is given by:

$$[5] \quad N_{dj}^{+} = N_{dj}\left(1 + g \exp\frac{E_{dj} + E_f - E_g}{kT}\right)^{-1}$$

The degeneracy factor, g, was taken to be 4 for the shallow acceptors, however, in the case of deep-lying acceptors a value of 2 was used as in the case of the donors. The hole concentration, p, is given by the equivalent expression to the one for the free electrons (2) by:

$$[6] \quad p = 2(2\pi m_h kT/h^2)^{3/2} \exp\left(-\frac{E_f}{kT}\right)$$

where in the case of GaAs,

$$m_p = 0.58\, m_0$$

The Fermi level can now be determined by plotting the terms in expression [1] as a function of energy, E, using the above given expressions in eqs. [2] to [6]. The running index, E, will be equal to the Fermi energy, E_f if the neutrality condition expressed in eq. [1] is satisfied. The position of the Fermi level, in turn, gives the corresponding free electron and hole concentrations of the material, then with the appropriate mobilities, the resistivity and the Hall coefficient can be computed and correlated to the experimentally measured ones.

The case of GaAs

In Table 1 the results of semiquantitative mass spectrographic analyses are collected for five GaAs single crystals, grown by a heat pipe assisted zone refiner using fused silica and boron nitride boats (21). The electrically active impurities in the case of GaAs are carbon shallow acceptor with $E_{ai} = 0.019$ eV, oxygen deep-lying donor, with $E_{dj} = 0.68$ eV, silicon shallow donor with $E_{dj} = 0.002$ eV, sulphur shallow donor with $E_{dj} = 0.006$ eV, and finally chromium deep-lying acceptor with $E_{ai} = 0.9$ eV, respectively. The ionization energies of the shallow impurities were taken from Sze's work (20) while the ones for the deep-lying levels were obtained from Lin's data (4, 5). To demonstrate the above described graphical method for the determination of the Fermi level and the corresponding free carrier concentrations, in Fig. 1 the calculated Shockley curves are given using the mass spectrographic data of sample 1 collected in Table 1. The limits of accuracy of the semi-quantitative spark source mass spectrographic analyses have been discussed in a previous publication (8). Figure 2 depicts the curves obtained using the results of sample 2 collected in the same table. It can clearly be seen that sample **1** is

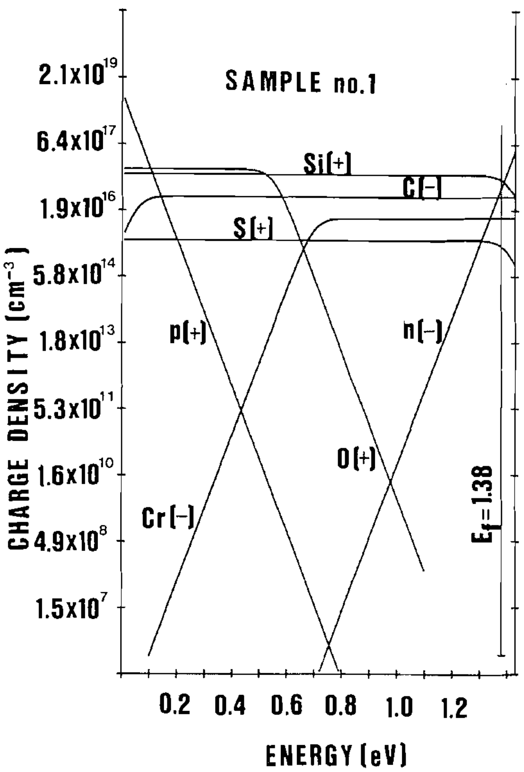

FIG. 1. Calculated Shockley curves for semiconducting GaAs, based on the mass spectrographic analyses, collected in Table 1, sample *1*.

a semiconductor having the Fermi level close to the conduction band, E_f = 1.38 eV above the valence band. This is to be compared with the room temperature band gap of GaAs E_g = 1.435 eV, according to the Varshany equation (3). In Fig. 2 the Fermi energy is close to the band gap center, E_g = 0.65 eV, resulting in a practically intrinsic material, due to the deep level compensation, characterized by a very low carrier concentration. The calculated and measured electron concentrations of this sample are 3.5×10^4 and 6.2×10^6 (cm^{-3}), respectively. These are to be compared to the ones of the semiconducting sample 1, characterized by calculated and measured electron concentrations of 6.4×10^{16} and 3.1×10^{17} (cm^{-3}), respectively. The ratio of the carrier concentrations of these two samples are in the range of 10^{11}, correctly reflecting a semiconducting and a semi-insulating GaAs crystal. The corresponding calculated and measured resistivities are in the range of 10^{-2}, 10^{-3} for the semiconductor and 10^8 (ohm cm) for the semi-insulator, respectively. For comparison purposes the measured and calculated data for the five crystals are collected in Table 2. It can clearly be seen that the calculations, in each of these cases, yield the proper semiconductor or semi-insulator character of the crystals. It is to be mentioned that even in relatively recent publications the role of deep-lying levels in the compensation mechanisms for semi-insulating GaAs results in some "intriguing" aspects related to semi-insulating and semi-intrinsic materials (22, 23). To clarify these problems, based on the results of the above described multilevel model, using Shockley's graphical method, the simple conditions for semiconducting and semi-insulating behavior can be given as follows. Assuming for simplicity, that the sum of the shallow-ionized donor and acceptor concentrations are N_D and N_A, while the deep-lying total donor and acceptor concentrations are N_{Dd} and N_{Ad}, respectively, the following four cases can be distinguished; based on the systematic comparison of the calculated (calcd.) and measured (obsd.) transport properties of five crystals, collected in Table 2:

(*I*) The material is n-type if

[7] $N_D - N_A > 0$

it is semi-insulating if

[8] $N_D - N_A < N_{Ad}$

it is semiconducting if

[9] $N_D - N_A > N_{Ad}$

In the case of n-type materials the deep-lying donors have negligible influence on the electrical properties of the crystal, as it can clearly be seen by examining the curves of Figs. 1 and 2.

(*II*) The material is p-type if

[10] $N_D - N_A < 0$

it is semi-insulating if

[11] $N_A - N_D < N_{Dd}$

it is semiconducting if

[12] $N_A - N_D > N_{Dd}$

In the case of p-type material the deep-lying acceptors have a

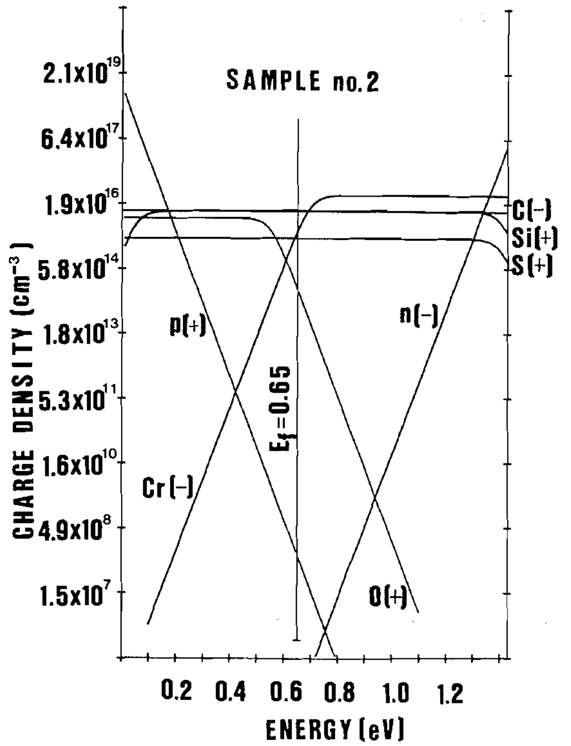

FIG. 2. Calculated Shockley curves for semi-insulating GaAs, based on the mass spectrographic analyses, collected in Table 1, sample 2.

correspondingly negligible influence on the electrical properties of the crystals. These conditions are in complete agreement with the results presented in Figs. 1 and 2 based on the measured mass spectrographic analyses collected in Table 1. The calculated and measured data are summarized in Table 2. The free carrier concentrations are determined by the position of the Fermi level, which is given by the corresponding impurity concentrations, introduced intentionally or unintentionally. The clarification and the understanding of the mechanisms for semi-insulating properties is necessary in order to determine the conditions for reproducible growth of SI GaAs. These crystals have a great potential as a substrate material for epitaxial GaAs integrated circuit and other solid state devices.

The case of polysilicon

This form, of the well-known semiconductor, has an increasing application in solid state electronics (24). A polycrystalline material is composed of small crystallites joined together by grain boundaries. The electrical properties of this type of system were first discussed by Shockley (9) and were treated theoretically by Read (10). Some recent experimental investigations, using Deep Level Transient Spectroscopy (DLTS), established the fact that crystal defects introduce deep-lying donor and acceptor states (25). Their electrical behaviours are similar to the ones introduced by impurities, discussed above in the case of GaAs.

Grain boundaries, characteristic of polycrystals, are complex structures. They are considered to consist of a few atomic layers of disordered surface atoms. These create a transition region between the different orientations of the neighboring crystallites. Inside each grain, the atoms are arranged in a periodic manner. A grain can therefore be considered as a small single crystal. The grain boundaries are characterized by incomplete atomic bonds. These result in hybridized surface dangling bonds, which are randomly distributed, characterizing a polycrystal. They can act as electron traps when empty and hole traps when occupied. Some direct evidence for carrier recombination at a tilt boundary in n-type germanium was presented by Vogel *et al.* (29). Following Shockley and Pearson (30), measurements have confirmed that the density of these surface states is in the order of the density of the surface atoms (31).

This dangling bond model permits the evaluation of the concentrations of the deep-lying levels. These can be computed by considering the average surface area of the grains, knowing their average sizes and assuming that one dangling bond exists per surface atom (12, 13, 17, 26). Then, considering the compensation effect of the deep-lying trapping centers, the position of the Fermi level can be determined, using the above described multilevel model.

In the case of polysilicon the position of acceptor traps was taken to be 0.37 eV below the conduction band, according to Seto (27). The position of the deep-lying donors has been valued at 0.37 eV above the valence band (28). Then, for example, if the average grain size, determined by scanning electron microscopy (13), is 3 μm and the characteristics dangling bond density in silicon (111) surface is 7.8×10^{14} cm^{-2}, the corresponding trapping center concentration, deep-lying donor in this case, can be calculated to be $N_{Dd} = 1.56 \times 10^{19}$ cm^{-3}. Now, if the position of the Fermi level is determined as a function of the doping shallow acceptor density N_A, it is found (12) that the Fermi energy will cross the deep-lying donor level at a characteristic acceptor concentration. It is of interest to note, that at this acceptor density a mobility minimum has been observed (17, 27). This can be interpreted by the concept of metallic impurity band conduction. According to Mott and co-workers (15, 16), if the average ionized impurity separation is commensurable with the Bohr radius then the wave functions of these impurities can overlap, forming an impurity band. This band is separated from the corresponding conduction or valence band edges by many kT's, especially in the case of deep-lying levels. In this case, if the Fermi level is in this impurity band then the conduction processes will be guided by its random system properties. Consequently, the effect of lattice periodicity looses its role in the transport properties of the solid. This results in the replacement of the effective mass of the free carriers in the impurity band, by the rest mass of the electron. Since the carrier mobilities are related to the effective mass, this phenomenon is characterized by low mobilities. These can be estimated by an expression given by Mott (16):

$$[13] \quad \mu_{min} < \frac{2\pi e R^2}{6h}$$

where R is the average impurity separation and e is the electronic charge.

The calculated value in the above mentioned case is 32 (cm^2 V^{-1} s^{-1}), which is of the same order of magnitude as the measured ones at the experimental mobility minima (12).

Finally, the position of the Fermi level determines the free carrier concentration, as it has been demonstrated in the case of GaAs (see Figs. 1 and 2). Thus knowing the carrier mobilities one can calculate the resistivity of polysilicon films as a function of the doping concentration. The results are collected in Fig. 3. Here, curves 1 and 2 depict the experimental and calculated values of Seto (27), curve 3 shows the calculated values

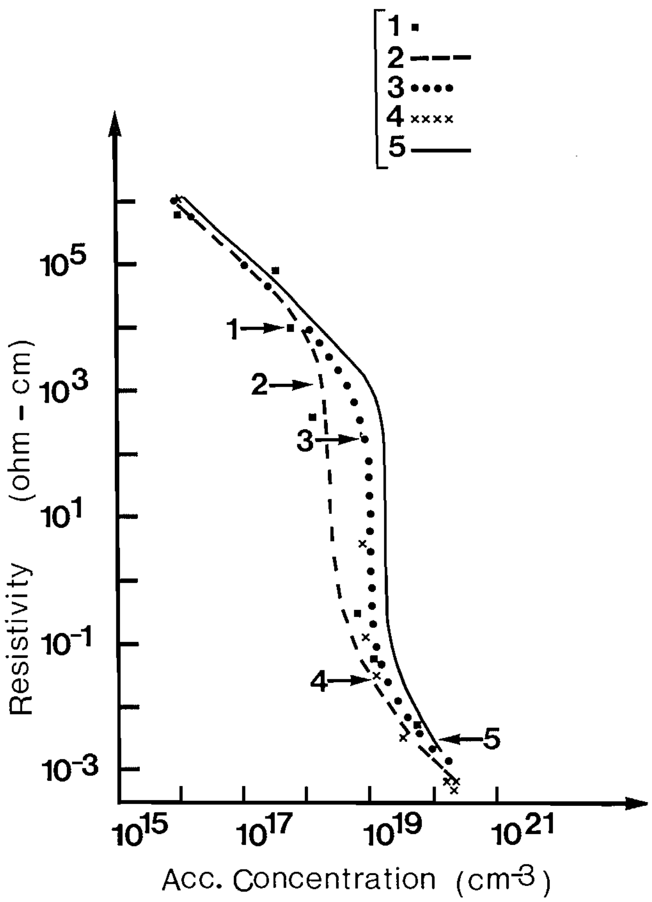

FIG. 3. Resistivities (ohm cm) as a function of doping concentration for *1*, experimental data of ref. 27; *2*, theoretical curve of ref. 27; *3*, calculated curve for p-type film; *4*, experimental points of p-type film; *5*, calculated curve of n-type film.

of p-type polysilicon using the multilevel model discussed above, curve 4 represents the experimental data of this investigation (12, 13) and curve 5 has been calculated in the case of an n-type film. In all cases good agreements can be seen between the experimental and calculated results. They represent, correctly, the characteristic large variation of the resistivities of polysilicon films. These are in the range of 10^9 (ohm cm) which were never observed in the case of single crystal silicons. It can be pointed out, that the existence of quasi semi-insulating polysilicon, in analogy to SI GaAs, is due to grain-boundaries-introduced deep-lying trapping centers compensation.

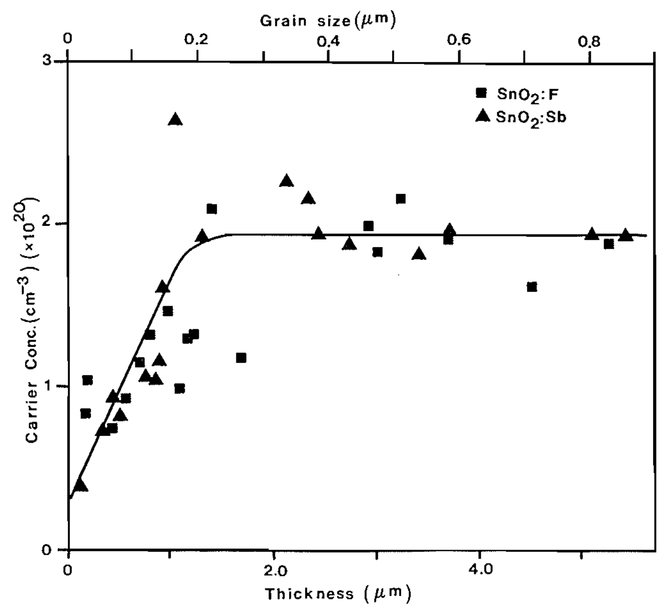

FIG. 4. Carrier concentration as a function of film thickness of CVD deposited tin oxide. Calculated curve, full line; experimental data of fluorine doped tin oxide, full squares; experimental data of antimony doped tin oxide, full triangles.

The case of tin oxide

These polycrystalline films are of interest as transparent electrodes for photovoltaic and photoelectrochemical solar energy converters. They combine high electrical conductivity with low optical absorption in the visible part of the spectrum (32). The films were grown by the technique of Chemical Vapor Deposition (CVD) (32). The transport properties of the transparent electrodes were determined by Hall effect measurements described previously (21). It was found that films doped for a free carrier density of 2×10^{20} (cm^{-3}) have thickness-dependent transport properties, below a layer thickness of 1 μm. Above this value, the carrier concentration, mobility, and consequently the film resistivity become layer thickness independent. The measured values of resistivities are shown in Fig. 4, where the triangles represent the data obtained in the case of antimony doping, while the squares are the ones for fluorine doping. It can be seen that the measured resistivities are also independent of the doping species. The obtained X-ray diffraction spectra suggest again the existence of grain boundaries introduced deep-lying trapping centers. In Table 3 the measured film thicknesses, d(μm); average grain sizes

l(μm); and the fraction of crystallites having different orientations, $F(110)$, $F(200)$, $F(211)$, $F(301)$, and $F(400)$, respectively, are collected based on previous works (18). This table includes the calculated trapping centers concentrations, $N(t)$ (cm^{-3}), and the resulting free carrier concentrations, at constant doping, using the above discussed deep-lying compensating impurity model. In this case, however, some characteristic properties of the grain boundaries in tin oxide have been taken into account. Following the results obtained by X-ray Photoconduction Spectroscopy (XPS) and Ultraviolet Photoconduction Spectroscopy (UPS) (32) it can be argued that grains of (200) (in the second order (400)) orientations do not participate in the trapping mechanisms (33). This was taken into account in the calculation of the trapping centers density, $N(t)$, using the fractions of the occurrence of different orientations, collected in Table 3, obtained from the X-ray diffraction spectra. Taking the measured average charge carriers mobility of tin oxide films to be 18 ($cm^2\ V^{-1}\ s^{-1}$), the resistivity as a function of the layer thickness, can be calculated. The results are shown in Fig. 4 by the curve drawn in full line. It can be seen that the calculated curve and the measured data are in good agreement. This indicates once more the validity of the deep-levels compensation model in the case of tin oxide as well.

Conclusions

The compensation mechanisms, due to deep-lying trapping centres, having been examined to elucidate some of the particular transport properties characteristic of semi-insulating GaAs, polysilicon, and polycrystalline tin oxide transparent electrodes. In the first case the deep-lying levels can be introduced by chromium or oxygen doping. In the case of polycrystals their origin could be related to dangling bonds created by the grain boundaries.

The determination of the Fermi level, based on complete mass spectrographic analyses, led to the establishment of the quantitative conditions required for deep levels compensation in the case of single crystal GaAs. Polysilicon films are characterized by peculiar mobility minima as a function of carrier concentrations and by a very large resistivity range compared to single crystals. The deep level compensation mechanisms, combined with metallic impurity conduction, have been used to analyze these phenomena. In the case of polycrystalline tin oxide films the measured thickness dependence of resistivities could be elucidated by this model applied with some relevant modifications.

Ab initio study of rotational isomerism in acrolein[1]

GEORGE R. DE MARÉ
Laboratoire de Chimie Physique Moléculaire, Faculté des Sciences, CP. 160, Ave. F. D. Roosevelt, 50 B. 1050 Brussels, Belgium

Received August 31, 1984

This paper is dedicated to Professor Camille Sandorfy on the occasion of his 65th birthday

GEORGE R. DE MARÉ. Can. J. Chem. **63**, 1672 (1985).

Analytic gradient (force) methods at the STO-3G, 3-21G, and 6-31G* basis set levels have been used to optimize the geometry of acrolein completely at each critical point (minima, maximum) in the torsional potential energy curves for rotation about the single C—C bond (dihedral angle θ). The STO-3G and 6-31G* optimizations predict the planar *trans* conformation (θ = 180°) to be more stable than the *cis* conformation (θ = 0°) by 1.87 and 6.97 kJ/mol, respectively. The 3-21G optimizations, in disagreement with experiment, place the planar *cis* structure below the *trans* by 4.5 J/mol. The predicted relative energy (Δ*E*) and position for the transition state (*TS*) for rotation from the *trans* conformer are Δ*E* = 22.35, 37.14, and 34.41 kJ/mol and θ = 91.8, 91.6, and 91.0° for the STO-3G, 3-21G, and 6-31G* optimizations, respectively. The computed and experimental geometries, relative energies, dipole moments, and coefficients for the torsional potential expansion are compared.

GEORGE R. DE MARÉ. Can. J. Chem. **63**, 1672 (1985).

La géométrie de l'acroléine a été optimisée complètement par la méthode force (gradients analytiques) avec les bases STO-3G, 3-21G et 6-31G* à chaque point critique (minima, maximum) de la courbe d'énergie potentielle pour la rotation autour de la liaison C—C simple (angle dièdre θ). Les optimisations avec les bases STO-3G et 6-31G* situent la forme plane *trans* (θ = 180°) à 1,87 et 6,97 kJ/mol, respectivement, en dessous de la forme plane *cis* (θ = 0°). Par contre les optimisations avec la base 3-21G placent le rotamère *trans* 4,5 J/mol au dessus du *cis*, en désaccord avec les données spectroscopiques. L'énergie (Δ*E*) et la position de l'état de transition (*TS*) pour la rotation *trans* → *cis* sont Δ*E* = 22,35, 37,14 et 34,41 kJ/mol et θ = 91,8, 91,6 et 91,0° pour les optimisations avec les bases STO-3G, 3-21G et 6-31G*, respectivement. Les géométries, énergies relatives, moments dipolaires, et coefficients de l'expansion en série du potentiel de torsion, obtenus dans ce travail, sont comparés avec les données expérimentales.

Introduction

Ab initio torsional potential energy curves for rotation about the C—C bond adjacent to the CH═X group in a number of R—CH═X compounds (where R = cyclopropyl, CH═CH_2 or CH═O and X = CH_2 or O) have been generated recently by De Maré and co-workers (1−4) using various basis sets and complete geometry optimization by analytic gradient methods. For 1,3-butadiene (3, 4) and vinylcyclopropane (1), optimization along the torsional potential energy curve with a larger than minimal basis set reveals a *gauche*/s-*trans*[2] conformer equilibrium in agreement with experiment (5, 6). In contrast, only the *cis* and *trans* positions represent minima in the torsional potential energy curves for the oxygen-containing compounds, regardless of the basis set used (2, 3). For these compounds, however, the predicted relative energies of the *cis*, *TS*, and *trans* structures are very basis set dependent (2, 3). For cyclopropanecarboxaldehyde (*CPCA*) (2), the predicted relative energies have been shown to depend more on the basis set used for the computations than on the basis set used for the geometry optimizations. The same conclusion applies to glyoxal (7) for which certain discrepancies between experimental and *ab initio* optimized geometrical parameters persist (8). Although good experimental estimates of the energy difference between the most stable acrolein conformer (*trans*) and a higher energy rotamer have been available for more than 10 years (9), the complete structure of the latter has been only just reported (10).

This paper presents a detailed study of the geometries and relative energies of the *trans*, *TS*, and *cis* acrolein structures (see Fig. 1) obtained with the minimal STO-3G, split-valence 3-21G, and 6-31G* basis sets.

Computational method

The references for the basis sets used in the present study are STO-3G (11), 3-21G (12), 3-21G** (13), 4-31G (14), 6-31G* (15), and 6-31G** (15). For the optimizations, non-planar acrolein structures (dihedral angles of 5°) with initial values of θ = 5, 90, or 175° (see Fig. 1) were constructed using bond lengths and valence angles deduced from the corresponding STO-3G, 3-21G, or 6-31G* optimized parameters in *CPCA* (2) and 1,3-butadiene (4). The optimizations were carried out within the Hartree−Fock formalism (16), using the analytic gradient (13) of the SCF energy with respect to the internal geometrical parameters (bond lengths, valence, and dihedral angles). The Optimally Conditioned (OC) minimization technique (17*a*)[3] was used to determine the optimal geometry at each minimum. The VA05AD sum of squares technique (18) was used for the *TS* optimizations and to confirm the order[4] of the stationary points revealed by the OC method.

All computations were performed with the MONSTERGAUSS *ab initio* program (19) on the CYBER 170/750 computer system at the University of Brussels.

[1]Presented in part at the 14ème Congrès des Chimistes Théoriciens d'Expression Latine, Louvain-la-Neuve, 1983 and 29th IUPAC Congress, Cologne, 1983.

[2]With the STO-3G basis set, complete optimization of the vinylcylopropane and 1,3-butadiene geometries along the torsional potential energy curves reveals only s-*cis* and s-*trans* minima (see refs. 1, 4). In the remainder of the text s-*cis* and s-*trans* will be denoted by *cis* and *trans*, respectively.

[3]The routine is described in ref. 17(*b*).

[4]The order of a critical point is equal to the number of negative eigenvalues of the Hessian or force constant matrix (second derivatives of the energy with respect to the internal geometrical parameters). The order of a minimum, maximum, second order, saddle point, … is 0, 1, 2, … .

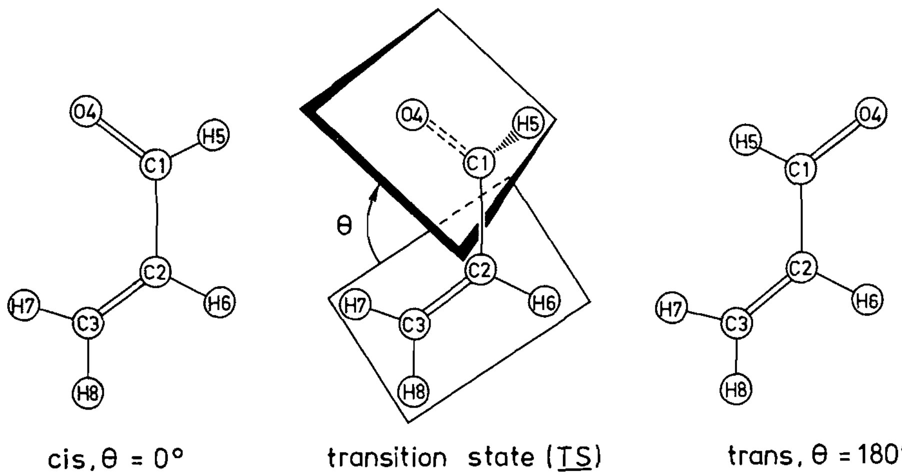

FIG. 1. Nomenclature and atom numbering used throughout the text. The atom numbering is the same as that used by Blom, Grassi, and Bauder (10).

Results and discussion

Critical point structures and potential energy curves

The optimized geometrical parameters, energy, dipole moment, and order obtained with the STO-3G, 3-21G, and 6-31G* basis sets for acrolein at each critical point in the torsional potential energy curves (see Fig. 2) are listed in Table 1.

Stable acrolein rotamers

The OC optimizations with all three basis sets and starting values of $\theta = 5$ and 175° lead to completely planar *cis* and *trans* structures, respectively. In each case the order of the Hessian is zero, as is required for an energy minimum.[4] The predicted positions of the minima are thus in agreement with experiment: the planar *trans* conformer has long been known to be the most stable (20) while the structure of the higher energy rotamer, first detected in 1971 (9) has recently been shown to be definitely *cis* planar (10, 21).

Although Devaquet, Townshend, and Hehre (22) used the STO-3G basis to optimize the geometries of *cis* and *trans* acrolein in 1976, they did not report the optimized geometrical parameters. They found energies of −188.30219 and −188.30284 hartree for the completely optimized *cis* and *trans* structures, respectively. These values are significantly higher than those found in this work (see Table 1). The discrepancies are probably the result of different cut-off criteria[5] since the relative energies of the rotamers differ by about 10% (1.87 (this work) compared to 1.71 (22) kJ/mol).

Whereas the STO-3G optimizations correctly predict the *trans* acrolein structure to be most stable, the above energy difference appears to be too small. (George, Bock, and Trachtman (23) have optimized the geometries of *cis* and *trans* acrolein completely with the 4-31G basis set and found an energy difference of −0.0013 au or 3.4 kJ/mol, which is also apparently too small. It is less than that obtained in 4-31G//BASIS1 computations in this study (see Table 2). Indeed,

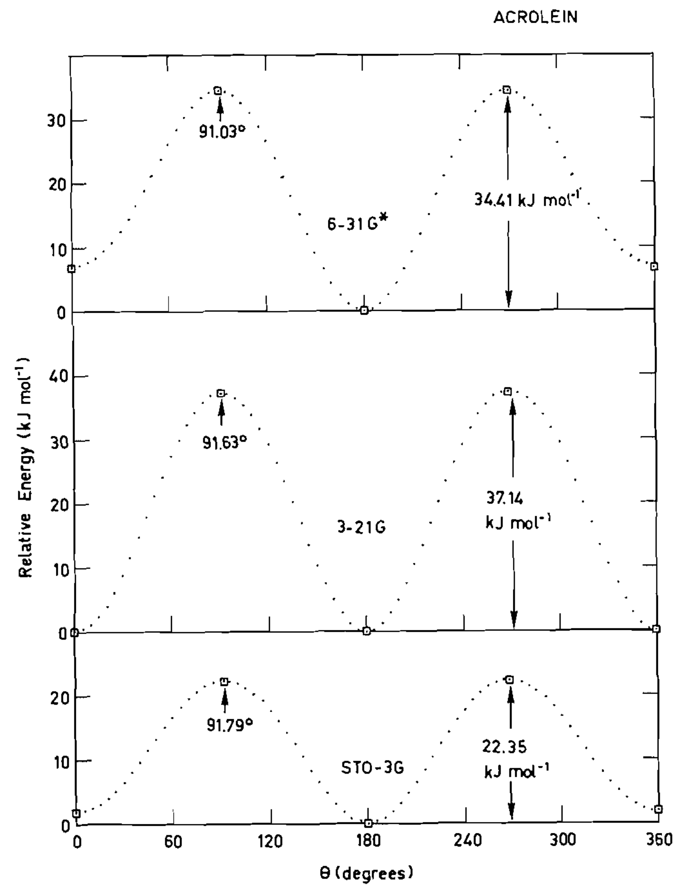

FIG. 2. Relative energies for rotation around the C—C single bond in acrolein. The *cis* conformation corresponds to dihedral angles of 0 and 360°, the *trans* conformation to 180°.

estimates obtained from gas-phase near ultraviolet (9) and Raman (24) spectroscopy lie in the range 570−700 cm^{-1} or 6.8−8.4 kJ/mol.[6] Thus only the 6-31G* optimizations yield a "reasonable" energy difference between the *cis* and *trans* acrolein conformers. *The 3-21G basis actually predicts the* cis *structure to be more stable than the* trans, even if only by

[5]In this work the optimizations were terminated when the gradient length, $|g| = \left[\sum_{i}^{n} (\delta E/\delta q_i)^2/n\right]^{1/2}$, was reduced below 5×10^{-4} mdyn. The q_i are the internal coordinates (bond lengths, bond angles and dihedral angles) and the sum is over the n optimized coordinates (25). The cut-off criterion generally yields energies stable below the μhartree level (25).

[6]The experimental error limits extend this range somewhat, but not enough to include the STO-3G or 4-31G predictions.

TABLE 1. STO-3G, 3-21G, and 6-31G* optimized parameters for acrolein (see Fig. 1 for atom numbering; bond lengths are in pm and angles in deg)

[a]Not computed.
[b]Barrier height from the *cis* structure = 37.14 kJ/mol.

4.5 J/mol. This failure of the 3-21G basis was unexpected since it has yielded apparently reliable relative energies, not only for optimized hydrocarbon structures (1, 4), but also for oxygen-containing species (i.e. CH_3CHO ground, triplet n → π* and n → 3*s* electronic states (25)).

In view of the present results, it is likely that the *cis−trans* energy difference in *CPCA* is nearer to 1.2 than to 7.0 kJ/mol (6-31G* and STO-3G optimized values, respectively (2)). Note that only the STO-3G basis computations (even with optimized geometries from the larger basis sets) gave a higher energy for *cis* than for *trans* CPCA (2).

Position and height of the TS

As previously observed for *CPCA* (2), the predicted position of the *TS* is remarkably basis set independent for acrolein. In going from the minimal STO-3G to the extended 6-31G* basis, the predicted location of the *TS* only ranges from 91.79 to 91.03°. The *TS* structure is thus very close to that with the double bonds perpendicular to one another. The situation in acrolein is therefore, as might have been expected, intermediate to those in 1,3-butadiene and glyoxal where the 6-31G* basis predicts the *TS* to be at θ = 101.5 (4) and 73.0° (3), respectively. For the latter two molecules, the minimal basis set optimizations predict the *TS* to lie closer to the perpendicular structure than does the 6-31G* basis (3, 4).

The barrier heights to rotation from the predicted most stable rotamer, obtained by the 3-21G, 6-31G*, and STO-3G optimizations, are 37.1, 34.4, and 22.3 kJ/mol, respectively. Thus although the trend is the same as that revealed in the *CPCA* study, the variation in the values (31.7, 24.3, and 13.8 kJ/mol, respectively) was much more pronounced for *CPCA* (2).

The experimentally determined values for the rotational *trans* → *cis* barrier in acrolein lie between those predicted by the STO-3G and 6-31G* optimizations. Carreira (24) found 2236 ± 135 cm^{-1} (26.76 ± 1.62 kJ/mol) by fitting the torsional overtones in the low frequency gas phase Raman spectrum of acrolein to a potential function of the form

$$[1]\quad V(\phi) = \sum_i (0.5V_i(1 - \cos i\phi))$$

where φ = 0 corresponds to the stable *trans* configuration. (The *cis−trans* energy difference derived from the same analysis is 584 ± 180 cm^{-1} (6.99 ± 2.15 kJ/mol) (24).) A slightly higher value, 2460 cm^{-1} (29.4 kJ/mol), for the barrier was deduced by De Groot and Lamb (26) from ultrasonic measurements on acrolein in the liquid phase.[7]

Dependence of the geometrical parameters on the basis set and on the dihedral angle θ; comparison of experimental and theoretical geometries

As mentioned above, George, Bock, and Trachtman (23) have optimized the geometries of *cis* and *trans* acrolein completely using gradient methods with the unscaled 4-31G basis set (14). For the optimization on *trans* acrolein, they report a total energy of −190.4693 hartree, a value much higher than that (−190.4798 hartree) obtained in an optimization with the 4-31G basis set or in 4-31G//BASIS1 computations reported in Table 2. The C—H bond lengths they obtain are longer than those obtained here (7). The comparison of their results and ours thus falls outside the scope of the present work.

Although comparison of theoretical and experimental parameters below the 1 pm/1° level may be dubious (27), it is nevertheless interesting to see if the observed trends in the data are consistent. Such a comparison is made in Table 3 where the experimental and predicted (6-31G*) differences in the parameters in *cis* and *trans* acrolein are given. The variation in the parameters will now be discussed in some detail.

∠H7C3C2, ∠H8C3C2, and ∠H7C3H8

The experimental trend for ∠H7C3C2 (*trans* > *cis* value by 1.2°) is reproduced and the computed differences (0.58 (STO-3G), 1.37 (3-21G), and 0.84° (6-31G* optimized values)) are reasonable. Both the STO-3G and 3-21G basis sets predict a small *increase* in ∠H8C3C2 in the *cis* compared to the *trans* conformer. Only the 6-31G* basis reproduces the experimental trend, predicting ∠H8C3C2 to be 0.26° smaller in *cis* acrolein (compared to an experimental Δ*ct* of 0.7° (Table 3)). The optimized values of ∠H7C3H8 change very little on going from the *trans* to the *TS* structure, then increase by 0.6 to 1.1° in the *cis* conformation. The *ab initio* and experimental results are again in agreement on the direction, but not on the magnitude, of the change in this angle.

∠C1C2C3

The contrast in the predicted behaviour of the CCC bond

[7]Although the *ab initio* values are comparable to the gas phase, note that De Groot and Lamb (26) obtained a *cis−trans* energy difference of 8.6 kJ/mol, within experimental error of the gas phase values.

[a] r_s structure determined from the microwave spectra of eleven isotopic acrolein species with C3—H7 assumed equal to C3—H8 (28).
[b] Average structure in the ground vibrational state determined by the combined use of the electron diffraction intensities and rotational constants (20).
[c] r_s structures determined by Blom, Grassi, and Bauder (10) from the microwave spectra of normal and highly enriched, singly D, ^{13}C, and ^{18}O substituted acrolein species. The error limits given are equal to three times the standard deviation from the least squares treatment (10).
[d] $(\Delta ct)_{exp.}$ and $(\Delta ct)_{theor.}$ are the differences between the values for the parameters in the *cis* and *trans* acrolein structures from ref. 10 and from the 6-31G* optimizations (Table 1), respectively.

angles in acrolein and 1,3-butadiene is striking. Whereas the ∠CCC's in *trans*-1,3-butadiene are found to be almost basis set independent (4), the ∠C1C2C3 obtained for *trans* acrolein with the STO-3G basis is more than 1° larger than the 3-21G or 6-31G* optimized values. Whereas the optimized CCC bond angles in 1,3-butadiene are predicted to be largest (by about 3°) for a near *cis*-structure (4), the optimized ∠C1C2C3 values for acrolein are largest in the *TS* structure. The differences in the values for this angle in the *cis* and *trans* conformers of acrolein are small and erratic. The 6-31G* optimizations reproduce the experimental trend but the predicted change is only about 20% of the experimental one.

C—H bond lengths

As is generally observed (see ref. 2), each C—H bond length for a given critical point structure varies according to STO-3G > 6-31G* > 3-21G optimized value. Also, as observed for *CPCA* (2), the STO-3G optimizations predict the aldehydic C—H bond to be longest in the *TS* whereas both the 3-21G and 6-31G* optimizations predict it to be longest in the *trans* conformer. The shorter C1—H5 optimized bond length in the *cis* compared to that in the *trans* acrolein rotamer reproduces the experimental trend. Note that the combined uncertainties in the experimental bond lengths are fairly large.

Excluding the C1—H5 bond length discussed above, all the optimized C—H bond lengths fall in the range 107.18−108.52 pm. For a given basis set and a given environment (see below), the variation in the C—H bond length is much smaller. The optimized values can therefore be used without optimization (or as excellent starting values for optimizations) in larger molecules.

In agreement with the small difference in the experimental values of the C3—H8 bond length in the *cis* and *trans* conformers (108.1 and 108.0 pm, respectively), all three basis sets give a C3—H8 bond length which is relatively independent of θ. The STO-3G values for C3—H7 vary according to *cis* > *trans* > *TS* value whereas for both the 3-21G and 6-31G* basis sets, the *trans* > *TS* > *cis* optimized values. This is sharp contradiction with the experimental finding that C3—H7 is 0.8 pm longer in the *cis* structure (10). One might expect that non-bonding interactions between H7 and the O-atom in the *cis* configuration would lead to a lengthening of the C3—H7 bond. Note also that the behaviour of the optimized values for C3—H7 with the larger basis sets parallels that predicted by the same basis sets for the corresponding C—H bonds in 1,3-butadiene where a repulsive interaction between the H-atoms destabilizes the *cis* structure (3, 4).

C=O and C=C bond lengths

As, expected, the optimized C=O and C=C bonds for a given basis set are predicted to be shortest in the *TS* structure. These bonds are predicted to be slightly shorter in the *trans* than in the *cis* conformer. This behaviour is similar to that found for the double bonds in 1,3-butadiene (+0.2 pm in the *cis* rotamer compared to the *trans* 6-31G* optimized value) (4). In *CPCA* the 6-31G* C=O optimized bond lengths are 118.88 and 119.14 pm in the *trans* and *cis* conformations, compared to 118.98 and 119.08 pm for acrolein. These theoretical results support the experimental findings that the C2=C3 bond is the same length in *trans* and *cis* acrolein while the C1=O4 bond is slightly longer in the *cis* structure ((10); see Table 3).

C1—C2 bond length

The results are very similar to those obtained for the bond joining the ring and CHO group in *CPCA* (2). The difference between the *cis* and *trans* optimized C1—C2 bond lengths increases with basis set size to 0.75 pm for the 6-31G* basis. These findings are in agreement with the microwave results of Blom *et al.* (10) which give 146.8 and 147.8 pm for the C1—C2 bond length in *trans* and *cis* acrolein, respectively.

TABLE 4. Computed net charges on the H5—C1—O4, H6—C2, and H7—C3—H8 groups (δ^1, δ^2, and δ^3, respectively) in the *trans*, *TS*, and *cis* acrolein structures; see Fig. 1 for the atom numbering

[a]From the final computation in the geometry optimization.
[b]From the 3-21G**//3-21G computation.
[c]From the 6-31G**//6-31G* computation.
[d]Calculated from the values given in ref. 23 for computations without dipole moment optimization.

The agreement between the theoretical and experimental trends in the C1—C2 bond on going from the *trans* to the *cis* acrolein conformers is in sharp contrast with the present situation for glyoxal (7, 8, 29).

Relative energies of acrolein structures computed using the optimized geometry from another basis set

The complete geometry optimization of the *trans*, *TS*, and *cis* acrolein structures with the 6-31G** basis set would be fairly costly in terms of computer time. Nevertheless, it would be interesting to investigate the effect of adding polarization functions on the H-atoms. Also, why are the relative energies obtained for *trans* and *cis* acrolein with the 3-21G basis set so different from those expected? For both *CPCA* (2) and 1,3-butadiene (4) BASIS2//BASIS1 computations (where BASIS2 is used for the computation with the BASIS1 optimized geometry) showed that the trends in the relative rotamer energies obtained by BASIS2 optimizations were satisfactorily reproduced. A series of BASIS2//BASIS1 computations is reported in Table 2.

For a given BASIS1, the relative energies of the *TS* or *cis* acrolein structures obtained with the 6-31G**//BASIS1 computations are slightly lower than (but well within 2% of) the relative energy obtained with the 6-31G*//BASIS1 computations. It is thus very unlikely that geometry optimization with the 6-31G** basis set would lead to relative energies or conformer stabilities which are meaningfully different from those obtained with the 6-31G** basis set in the present study.

For a given BASIS2, each set of BASIS2//BASIS1 computations gives relative energies for the *trans*, *TS*, and *cis* acrolein structures which are quite consistent, showing that the differences depend on the basis sets and not on the optimized geometry. It is apparent that complete optimization of the bond lengths and bond angles, even with the minimal STO-3G basis, leads to geometries which can be used with other basis sets to obtain reasonable relative energies (for the other basis sets and not necessarily compared to the real relative energies!).

With the 3-21G** basis set, the relative energies for the optimized *TS* and *cis* structures are closer than the 3-21G ones to those predicted by the 6-31G* computations. The relative energy for the *cis* conformer is still unsatisfactory, however. It is clear that, for oxygen-containing species, geometry optimization with the 3-21G basis set on several isomers should be followed by 6-31G* computations to check the 3-21G basis predictions for the relative energies.

Basis set dependence of the computed net charges from Mulliken population analysis

The computed net charges on the H5—C1—O4, C2—H6, and H7—C3—H8 groups (δ^1, δ^2, and δ^3, respectively) derived from the Mulliken population analysis (30) are given in Table 4.

The δ^1 values predicted by the 3-21G and 3-21G** basis sets are *positive*, just as the net charges on the CHO group in *CPCA* predicted by the 3-21G and 6-21G basis sets are positive. With the STO-3G, 4-31G, 6-31G*, and 6-31G** basis sets, *negative* δ^1 values are predicted for all the acrolein structures. With all the basis sets used in this study, the δ^1 values for the *TS* are less negative (thus more positive for the 3-21G and 3-21G** basis sets) than in the *trans* and *cis* conformers. The positive values of δ^1 obtained with the 3-21G and 3-21G** basis sets are apparently the result of a larger computed positive charge on the aldehydic H-atom with these basis sets. From the (7, 3) basis set results reported by Bock, George, and Trachtman (23), one obtains $\delta^1 = -0.003$ for the *trans* and +0.002 for the *cis* acrolein structures.[8] This variation may simply reflect the near balance of the sum of the charges on the atoms in the CHO group with the (7, 3) basis. Indeed, this type of behaviour has already been noted for the net charges computed for the CHO group in various *CPCA* rotamers with the 6-31G and 6-31G* basis sets (2). There the net charges are near zero and oscillate between negative and positive values.

With all the basis sets used in this study δ^2 is negative and δ^3 is positive for all the acrolein structures. This is in sharp contrast to the results obtained for 1,3-butadiene where the 3-21G and 6-21G basis sets consistently predicted a net positive charge on the CH_2 groups, while the 6-31G, 6-31G*, and 6-31G** basis sets predicted net negative charges on the CH_2 groups.

Whether hydrogen bonding or an electrostatic interaction in *cis* acrolein causes this rotamer to be relatively more stable than the *cis* rotamer or glyoxal (see below) has been discussed in detail by Bock, George, and Trachtman (23). For acrolein, 1,3-butadiene, and glyoxal, the *trans* conformer is the most stable and it is in equilibrium with a higher energy rotamer (the *cis*, except for 1,3-butadiene where a cisoid *gauche* rotamer lies about 3 kJ/mol below the *cis* (3, 4)). The energies of the

6-31G* optimized *TS* structures, relative to the *trans* conformer, are quite similar (34.4, 25.4, and 30.0 kJ/mol, respectively (Table 1; (3))). In contrast, one finds relative energies for the optimized *cis* structures of 7.0, 16.0, and 23.5 kJ/mol with the same basis set, compared to experimental values of 6.8−8.6, about 16, and 13.5 kJ/mol, respectively, for the higher energy rotamer. (The "low" relative energy for *cis* glyoxal (13.5 kJ/mol from spectroscopic measurements) compared to those obtained with double ζ or double ζ + polarization basis sets has been discussed by Osamura and Schaefer (8).) In spite of the discrepancy between the theoretical and experimental energy differences for *cis* and *trans* glyoxal, it is quite apparent that some additional stabilization process is present in *cis* acrolein.

If one compares only the charge distributions on the CH_2 group and the O-atom in *cis* and *trans* acrolein, there is little evidence for hydrogen bonding in the *cis* structure. (In contrast to the findings of Bock, George, and Trachtman (23) with a (7, 3) basis set, the charges on the O-atom in *cis* and *trans* acrolein are found to be equal in 6-31G**//6-31G* computations (Table 5).) A more detailed examination of the data is possible. In Table 5, the net charges on the atoms of the CH_2 groups in the *cis*, *TS*, and *trans* acrolein and 1,3-butadiene structures are given for comparison. The net charge on the C-atom is smallest in the *TS* for 1,3-butadiene and smallest in the *cis* rotamer of acrolein, respectively. The net "electron loss" on this atom on going from the *trans* to the *cis* acrolein structure was taken as direct evidence against hydrogen bonding in acrolein (23). The behaviour of the net charges on the hydrogen atoms, when compared to that in 1,3-butadiene, is probably more in favour of hydrogen bonding than previously supposed. Indeed, in the *TS* structure of each molecule the net charges on H8 and H7 are almost equal. Further, in 1,3-butadiene the net charges on H8 (and on H7) are almost equal in the *cis* and *trans* conformers with the net charge on H8 greater than that on H7. For acrolein, whereas the net charge on H8 is about 7% larger than that on H7 in the *trans* conformation, the situation is completely reversed in the *cis* rotamer with the net charge on H7 about 19% larger than that on H8. It would be very interesting to have detailed density plots in these molecules.

Fourier expansion of the torsional potential

The torsional potential energy curves obtained for acrolein have been simulated by a least-squares procedure using eq. [1]. The relationship between ϕ and θ is $\phi = 180 - \theta$, since V must be zero for $\phi = 0$ (this relationship was also used for the 3-21G torsional potential, neglecting the small energy difference between the *cis* and *trans* conformations). At least 21 additional data points (7 near each critical point) were computed for use in the least-squares simulation to ensure that the resulting torsional curves were "smooth". The coefficients are given in Table 6.

Although the coefficients for the 3-21G torsional potential curve simulation are given, they are probably only useful for reproducing the computed data since they reflect the unrealistic *cis−trans* energy difference (nearly zero) predicted by the basis. Also, because of this near zero energy difference, with the maximum very near the perpendicular position, a second solution with negative V_1 and positive V_3 and V_5 (but nearly identical absolute values of the V_i) exists. The first three terms of the expansion are the most important, as has been observed previously by Carreira (24) for the series derived to fit the Raman torsional overtone spectrum of acrolein. The V_1 term in the STO-3G series is very small compared to that in the 6-31G* series. Except for the high V_2 value in the 6-31G* simulation (which essentially reflects the *trans−cis* barrier) there is fairly good agreement between the V_i from the simulation of the 6-31G* optimal curve and the values obtained by Carreira.

[c]From the 6-31G**//6-31G* computation.
[d]From ref. 10.
[e]From ref. 34, calculated from $\mu_a = 3.06 \pm 0.04$ and $\mu_b = 0.54 \pm 0.14$ D.

The values of V^*, which is given by eq. [2] (see ref. 32),

$$[2] \quad V^* = \sum_{i=1}^{n} i^2 V_i$$

are also given in Table 6. Those derived from the *ab initio* torsional potential curves are higher than the "experimental" ones. Once again the largest deviations are observed where the barrier to rotation was predicted to be the highest.

Dipole moments

The dipole moments computed in the present study are given in Table 7 for comparison with those available in the literature.

For all of the basis sets used in this study, the dipole moment of *cis* acrolein is computed to be smaller than that for the *trans* conformation. The STO-3G values are too small, being 62 and 66% of the experimental values of the dipole moments for the *trans* ($\mu(trans)$) and *cis* ($\mu(cis)$) acrolein rotamers. This is very similar to the results obtained with the STO-3G basis set for the optimized *CPCA* structures where the computed $\mu(trans)$ and $\mu(cis)$ values are 60 and 64%, respectively, of the experimental values. The 3-21G**//3-21G computations give dipole moments which are very close to the experimental ones. For the 3-21G, 6-31G*, and 6-31G**//6-31G* computations, remarkably constant values of $\mu(trans)$ and $\mu(cis)$ are obtained. Whereas the 3-21G and 6-31G* computed values of the dipole moments for *trans* and *cis CPCA* were about 6−8% larger than the experimental ones (2), the differences observed for acrolein are slightly larger, being from 11 to 15%. This agreement is still quite satisfactory.

Conclusions

The geometry optimizations at the STO-3G, 3-21G, and 6-31G* basis set levels all predict a two-well torsional potential for acrolein with stable *cis* and *trans* rotamers, in agreement with experiment. Only the computations with the extended 6-31G* and 6-31G** basis sets yield satisfactory relative energies for these stable structures, however. The smaller basis sets used (STO-3G, 3-21G, 3-21G**, and 4-31G) all lead to *cis−trans* energy differences which are too small. As observed previously for *CPCA* (2) and 1,3-butadiene (4), the relative energies of the acrolein structures depend more on the basis set used for the computations than on that used for the optimizations.

The STO-3G optimized single and double bond lengths are all longer and shorter, respectively, than those obtained with the 3-21G and 6-31G* optimizations. The optimized values for ∠H7C3C2 are smaller in *cis-* than in *trans*-acrolein, in agreement with experiment. This decrease in ∠H7C3C2, as well as an observed increase in the C3—H7 bond length, in *cis-* compared to *trans*-acrolein, have been interpreted as reflecting an attraction between H7 and the oxygen atom in the *cis*-conformer (10). The 3-21G and 6-31G* optimizations predict the C3—H7 bond to be *shorter* in the *cis*-acrolein conformer, however, in apparent disagreement with experiment. Hydrogen bonding in the *cis* conformer may nevertheless be reflected by the computed net charges (31): the computed net charge on H7 is lower and higher than that on H8 in *trans-* and *cis*-acrolein, respectively.

As previously observed for *CPCA* (2), STO-3G values for the dipole moments of the acrolein rotamers are too small (about 65% of the observed ones). Those computed with the larger basis sets are quite satisfactory, however, all being within 15% of the experimental ones.

Acknowledgements

Dr. C. E. Blom (Justus-Liebig-Universität Giessen) is thanked for supplying a copy of the manuscript on the structure of *cis-* and *trans*-acrolein prior to its publication. It is also a pleasure to acknowledge the assistance of the staff of the Computing Center at the University of Brussels.

Un problème toujours d'actualité: trois électrons – trois centres

G. BERTHIER

Laboratoire de Biochimie Théorique, (L.A. n° 77), Institut de Biologie Physico-Chimique,
13, rue Pierre et Marie Curie, F-75005 Paris, France

Reçu le 6 août 1984

Cet article est dédié au Professeur Camille Sandorfy à l'occasion de son 65e anniversaire

G. BERTHIER. Can. J. Chem. **63**, 1681 (1985).

On discute l'état présent des calculs théoriques sur les radicaux libres en prenant l'allyle comme point de repère. La nature des produits atomiques de dissociation contenus dans une fonction d'onde en forme de déterminant adaptée à la symétrie fournit un critère heuristique utile en cas de brisure de symétrie.

G. BERTHIER. Can. J. Chem. **63**, 1681 (1985).

The present status of theoretical calculations on free radicals is discussed, taking allyl as a benchmark. The nature of the atomic dissociation products included in a symmetry-adapted determinantal wave function gives a useful, heuristic criterion for symmetry-breaking cases.

Depuis quarante ans environ, l'étude de la répartition de trois électrons entre trois atomes munis chacun d'une orbitale (au moins) est un thème récurrent en chimie théorique. Le radical allyle CH_2CHCH_2, avec ses trois carbones porteurs d'électrons π, constitue l'archétype des systèmes de ce genre, aussi bien dans les applications classiques de la théorie de Hückel ou celle de la mésomérie aux hydrocarbures conjugués (voir p. ex. 1–6) que dans le développement ultérieur de méthodes de calcul plus explicites.

L'allyle a servi d'exemple lors de la mise au point de traitements théoriques pour les systèmes à couches électroniques incomplètes comme les radicaux libres ou les biradicaux. Il en a été ainsi pour les deux variantes possibles de la méthode du champ self-consistant dans l'approximation LCAO-MO, celle dite "UHF, sans contrainte de spin S^2 (7–9), et celle dite "RHF", qui conserve la notion intuitive d'orbitales moléculaires dioccupées, puis mono-occupées pour les électrons non appariés (10, 11). Il en est de même de la méthode d'interaction de configuration, soit sous sa forme initiale (12), soit dans la version "atomes dans les molécules" (13). La méthode des orbitales moléculaires alternantes, où l'on réalise une interaction de configuration de forme prédeterminée à partir de spinorbitales de type UHF(14) a été aussi éprouvée sur l'exemple du système π de l'allyle (15).

Les travaux précédents ont eu, dans le domaine des structures moléculaires, des conséquences qui dépassent l'intérêt chimique d'un tel système: ils ont servi à illustrer la notion de densité de spin négative, dont la présence sur certains atomes joue un grand rôle en résonance paramagnétique électronique (16–18) et en diffraction des neutrons polarisés (19). Enfin, les configurations excitées dues au saut d'un électron π vers l'orbitale moléculaire non-liante ou vers l'orbitale anti-liante du système allyle (20, 21) forment la base de l'interprétation des transitions doublet–doublet caractéristiques des radicaux libres non-saturés (voir 22–25 et références jointes).

Au cours de la dernière décennie, le système à trois électrons réapparaît comme exemple-type, en théorie du champ self-consistant de difficultés dues à d'éventuelles brisures de symétrie durant la résolution des équations de Hartree–Fock (26). En général, celles-ci sont dues au fait que les contraintes de symétrie d'espace et de spin imposées aux fonctions d'onde, solutions du problème RHF à une particule ne sont – selon la reformulation du théorème de Delbrück (27) donnée par Ripka (28) – que des propriétés de self-consistance; cela n'exclut nullement la possibilité de solutions moins restrictives dans certains cas, mais qu'il convient de purifier de leurs composantes d'espace ou de spin indésirables, d'où le dilemne de symétrie de Löwdin (29). Parmi toutes les formes d'extremums locaux possibles (pour un exemple simple, voir la réf. 30), on dit, selon Thouless (31) qu'une fonction Hartree–Fock est instable si la dérivée seconde de l'énergie totale E par rapport à certaines orbitales est négative au lieu d'être définie, positive. Ces caractéristiques de la théorie du champ self-consistant, d'abord reconnues en physique des noyaux (32), sont maintenant bien comprises en physique atomique (33, 34) et moléculaire (35–40 et références jointes).

Un examen des fonctions d'onde moléculaires non-Delbrück qui ont été signalées dans la littérature (voir la réf. 41) montre que beaucoup des composés répertoriés peuvent être assimilés à des systèmes à trois électrons – trois centres. La liste de résultats présentée dans le tableau 1 comporte des types chimiques variés dans des états doublets et triplets, fondamentaux ou excités. Selon la terminologie usitée en chimie organique (42–44), il s'agit aussi bien de radicaux σ que π, l'électron non-apparié occupant dans la configuration de référence soit une orbitale de composantes atomiques s ou σ symétriques, soit une orbitale de composantes π antisymétriques par rapport au plan des trois centres.

Les propriétés d'instabilité des orbitales moléculaires de type Hückel trouvées par Paldus et Čižek (37) dans l'allyle subsistent quel que soit le niveau de l'approximation LCAO-MO utilisée, et pour une gamme très étendue de longueurs et angles de liaison: calculs avec davantage d'électrons de valence ou calculs complets en base minimale (45, 46), calculs en base étendue allant de distances internucléaires très grandes à la conformation d'équilibre (47, 48). Par rapport à un système d'orbitales adapté à la symétrie C_{2v} d'un squelette nucléaire à liaisons CC égales, on y constate que la perte de l'opération σ_v' (plan perpendiculaire au motif $C_1C_2C_3$) dans la fonction d'onde électronique entraîne un abaissement d'énergie qui s'amplifie quand on permet aux noyaux de suivre la brisure de symétrie du nuage électronique. Il s'agit en quelque sorte de "suivisme nucléaire",[1] qu'on peut interpréter comme une pseudo-distorsion de Jahn–Teller (49), aboutissant à la formation d'une structure de Lewis localisée, avec une double liaison entre les deux carbones de gauche et un électron non-apparié à droite, ou vice-versa. La tendance générale des systèmes d'électrons π à se localiser sous l'effet des brisures de symétrie (50) est tout à fait vérifiée par l'allyle. Il en résulte aussi que la surface d'énergie obtenue à partir d'orbitales moléculaires correspondant à des solutions instables qui restent adaptées à la symétrie nucléaire présente une discontinuité au passage du groupe ponctuel C_{2v} (liaisons CC égales) au groupe C_s (liaisons CC différentes), et que celle obtenue avec les solutions stables à symétrie brisée a un caractère non-analytique dans la même région (38). D'autres causes d'instabilité que la contrainte de symétrie σ_v' peuvent être étudiées concurremment ou indépendamment, telle l'hypothèse de la double occupation des orbitales moléculaires, dont la levée conduit à une fonction d'onde UHF non-exactement doublet, ou la symétrie d'alternance PPP des hydrocarbures conjugués (40, 51).

Les brisures de symétrie signalées pour les autres radicaux à trois centres proviennent généralement aussi d'une perte de symétrie gauche–droite, qu'il reste à concilier avec les résultats expérimentaux. Le cas du trihydrogène H_3, où l'on peut dire que la perte de symétrie obtenue dans les calculs Hartree–Fock préfigure l'état normal du système: une molécule H_2 liée à un atome H par interaction de van der Waals (52, 53) est particulier. Une solution souvent adoptée (54–57) consiste à effectuer une interaction de configuration avec les orbitales moléculaires de la symétrie la plus basse; mais en raison de possibles défauts d'analyticité on devrait, pour tenir compte correctement de la corrélation électronique, éliminer les composantes de symétrie indésirables des solutions sans contraintes des équations de Hartree–Fock avant le calcul variationnel lui-même, ce qui revient à un traitement de champ self-consistant multi-configurationnel (38). Dans le cas du radical allyle, il s'avère qu'un calcul MC-SCF direct à l'intérieur du sous-système π, suivi d'une interaction de configuration mettant en jeu les mono- et diexcitations, reproduit correctement les propriétés de symétrie C_{2v} des données expérimentales (58). Une autre ressource est l'interaction de "résonance" entre structures déformées gauche–droite et droite–gauche équivalentes (55, 59; voir aussi la réf. 60).

De tous les travaux précédents se dégage la nécessité d'avoir clairement notion des brisures de symétrie susceptibles de se manifester dans les calculs de surfaces d'énergie. Une étude rigoureuse du problème, basée par exemple sur le signe des valeurs propres des matrices d'instabilité (35–39) est souvent longue et coûteuse, et l'analyse de la fragmentation de la molécule considérée en fragments plus petits peut donner certains renseignements (48). Heureusement, une comparaison des produits de dissociation *atomiques* contenus dans les configurations avec différents types d'orbitales quand les distances internucléaires deviennent infiniment grandes, fournit rapidement une idée de la situation. Le critère proposé ici étend aux composés à trois électrons et plus l'explication bien connue selon laquelle un déterminant construit à partir d'une orbitale moléculaire doublement occupée de symétrie σ_g^+ ne représente pas correctement la molécule H_2 parce qu'il contient une contribution trop forte de structures ioniques, tandis qu'un déterminant formé de deux spinorbitales purement atomiques a un bon comportement asymptotique; cette situation demeure pour des molécules diatomiques plus compliquées (61, 62).

TABLEAU 2. Poids en % des structures ioniques et covalentes du système à trois électrons – trois centres

$\psi_{sym.ad.}$ (RHF)*		$\psi_{sym.ad.}$ (UHF)†		$\psi_{sym.br.}$	
$C^-A^\cdot - A^-C^\cdot$	25	$C^-A^\alpha - A^-C^\alpha$	16,66	$A^-C^\cdot$	25
$B^-A^\cdot - B^-C^\cdot$	25	$B^-A^\alpha - B^-C^\alpha$	33,33	$B^-C^\cdot$	25
$A^-B^\cdot - C^-B^\cdot$	12,5	$A^-B^\alpha - C^-B^\alpha$	8,33	$(A - B)\,C^\cdot$	50
$A^\cdot B^\cdot C^\cdot$	37,5	$A^\beta B^\alpha C^\alpha - A^\alpha B^\alpha C^\beta$	8,33		
		$A^\alpha B^\beta C^\alpha$	33,33		

*Orbitales de Hückel. L'expression détaillée des structures indiquées se trouve dans la réf. 13; $A^\cdot B^\cdot C^\cdot$ est l'une des fonctions doublets possibles pour le problème à trois spins (ici $A^\alpha B^\alpha C^\beta - 2A^\alpha B^\beta C^\alpha + A^\beta B^\alpha C^\alpha$).

†Orbitales de Hückel avec $\lambda = \sqrt{2}$ et $\mu = 1$.

Le tableau 2 donne pour trois centres A, B, C le résultat d'un développement tout à fait analogue au calcul classique mentionné plus haut pour le système AB avec deux fonctions de base χ_a et χ_b. Dans la première colonne sont indiqués les poids des formules ioniques et covalente contenues dans déterminant de la forme $\psi_{sym.ad.} = |\phi_1\alpha\phi_1\beta\phi_2\alpha|$, où ϕ_1 et ϕ_2 sont des orbitales moléculaires de type Hückel adaptées à la symétrie C_{2v} (ϕ_1: $\chi_a + \sqrt{2}\,\chi_b + \chi_c$; ϕ_2: $\chi_a - \chi_c$). Les coefficients de ces fonctions se trouvent dans des publications antérieures (13, 40). La troisième colonne contient les résultats correspondants pour le déterminant $\psi_{sym.br.}$, où ϕ_1 et ϕ_2 sont des orbitales de symétrie C_s, localisées l'une entre A et B, l'autre sur C ($\phi_1 = \chi_a + \chi_b$; $\phi_2 = \chi_c$). On voit immédiatement que pour des distances internucléaires très grandes le déterminant à symétrie brisée $\psi_{sym.br.}$ doit fournir une énergie plus basse, puisque le poids des structures ioniques y est moins fort (50% au lieu de 62,5% dans $\psi_{sym.ad.}$). Le même état de choses subsiste quand on passe d'une description RHF à symétrie d'espace et de spin adaptée à une description UHF à symétrie d'espace seulement, c'est à dire si l'on prend $\psi_{sym.ad.}$ (UHF) $= |\phi_1\alpha\phi_2\beta\phi_3\alpha|$ où ϕ_1 et ϕ_2 sont des orbitales de Hückel différentes (17, 63) selon le spin de l'électron considéré (ϕ_1: $\chi_a + \lambda\chi_b + \chi_c$; ϕ_2: $\chi_a + \mu\chi_b + \chi_c$; ϕ_3: $\chi_a - \chi_c$ avec $\lambda > \mu \simeq 1$). On trouve encore que le poids des structures ioniques dans le déterminant UHF reste prépondérant: 58,33% dans le cas $\mu = 1$. Il apparaît très nettement ici l'importance de l'opération σ_v' du groupe C_{2v} comme contrainte d'espace effective pour les systèmes à trois électrons – trois centres. On notera que le caractère σ ou π éventuel des orbitales atomiques χ n'intervient pas dans ce résultat; en outre, on constate que les systèmes à trois centres avec deux ou quatre électrons ne donnent aucun signe de brisure de symétrie dans leurs produits de dissociation atomiques.

[1] L'expression "suivisme nucléaire" est une transposition pour le cas des noyaux du terme "orbital following". Dans le cas des molécules A_3 ayant la forme d'un triangle équilatéral et où il existe un niveau monoélectronique doublement dégénéré, occupé par un seul électron, la distorsion $D_{3h} \rightarrow C_{2v}$ est un véritable effet Jahn–Teller.

L'examen des produits de dissociation ne saurait pourtant remplacer une analyse détaillée de l'origine des brisures de symétrie, comme l'indique le cas de la molécule H_2 elle-même où un déterminant RHF donne une description acceptable quand on se rapproche de la distance internucléaire d'équilibre. C'est seulement un critère heuristique commode qu'on peut sans doute généraliser à davantage d'électrons. Ainsi, si l'on prend comme modèle d'un biradical triplet dans l'état fondamental le système d'électrons π du triméthylèneméthane $(CH_2)_3$ C (64), on trouve que le déterminant construit à l'aide d'orbitales de Hückel adaptées à la symétrie D_{3h} avec deux électrons sur la première et un électron sur la seconde et la troisième contient 66,66% de structures ioniques, contre 50% dans le cas d'une description localisée de symétrie C_{2v} avec deux électrons formant liaison avec l'atome central A et un atome terminal B et deux électrons non appariés sur les deux autres atomes C, D. On pourrait traiter des systèmes plus compliqués en utilisant un algorithme de calcul sur ordinateur qui a été récemment developpé pour extraire les formules de valence contenues dans un déterminant de Slater (65, 66), et même étudier des situations multi-configurationnelles en profitant du fait que les programmes du genre ZDO avec interaction de configuration conviennent très bien pour les grandes distances interatomiques.

Remerciements

L'auteur dédie cet article au professeur Camille Sandorfy pour son soixante-cinquième anniversaire; il remercie ses collègues parisiens et grenoblois qui lui ont communiqué des résultats encore inédits.

La mécanique de la liaison hydrogène: résultats de spectroscopie infrarouge

Y. MARÉCHAL[1]

Centre d'Etudes Nucléaires de Grenoble, Département de Recherches Fondamentales, 85X, F 38041 Grenoble Cedex, France

Reçu le 6 août 1984

Cet article est dédié au Professeur Camille Sandorfy à l'occasion de son 65e anniversaire

Y. MARÉCHAL. Can. J. Chem. **63**, 1684 (1985).

Nous passons en revue la mécanique de la liaison hydrogène telle que nous la connaissons par la spectroscopie ir. Nous montrons comment traiter les différents couplages anharmoniques des vibrations ν_s (X—$\vec{H}$ . . . Y) de façon à éliminer les éléments parasites des spectres ir et de façon à ne garder que les éléments susceptibles de donner des informations sur la dynamique de la liaison hydrogène, telle que sa capacité de transférer des protons ou son mécanisme de rupture, qui sont des processus encore très mal connus. Nous décrivons aussi les possibilités de la spectroscopie vibrationnelle pour acquérir des informations sur ces mécanismes, qui peuvent avoir un rôle important en biologie.

Y. MARÉCHAL. Can. J. Chem. **63**, 1684 (1985).

We review the mechanics of H-bonds as revealed by ir spectroscopy and show how the various (strong) anharmonic couplings of the ν_s vibrations (X—$\vec{H}$ . . . Y) of H-bonds may be treated so as to eliminate the irrelevant features of the spectra and keep only those features which may give information on the still unknown dynamical quantities of the H-bonds, such as the transfer of protons through H-bonds or the mechanism of rupture of H-bonds. We also describe the possibilities offered by vibrational spectroscopy for studying these dynamical quantities, which may be important in biology.

La spectroscopie ir de la liaison hydrogène (LH) est un domaine de recherche où le Professeur C. Sandorfy a eu une contribution des plus éminentes. Il s'agit d'un domaine qui a connu pendant plus de deux décades un développement important, qui semble avoir cumulé vers les années 1980, et qui apparaît, en 1985, comme un sujet en plein mutation. Il peut donc être judicieux de saisir cette occasion du 65e anniversaire du Pr. C. Sandorfy pour faire le point de nos connaissances sur la mécanique de la LH telle que la spectroscopie ir nous l'a révélée, et pour préciser les perspectives de recherche dans ce domaine, telles qu'elles apparaissent aujourd'hui. Mais tout d'abord nous allons rapidement évoquer comment ce sujet s'est révélé dans les années 1955–1960.

Ce domaine de recherche sur la LH est apparu, il y a quelques 25 années (1) comme un domaine d'importance fondamentale pour comprendre la physique de nombreux mécanismes moléculaires. La LH est en effet une liaison dont l'énergie de formation est de quelques kT à l'ambiante, ce qui la distingue d'une liaison de valence ou d'une liaison de van der Waals. Cela lui donne une importance particulière dans les innombrables réactions se passant à la température ambiante, et en particulier les réactions aqueuses. Elle intervient aussi bien dans les domaines de la science des matériaux (les polymères en particulier) qu'en biologie où elle est vraiment la liaison-reine. C'est elle qui donne à un liquide aussi courant et répandu que l'eau ses propriétés physiques, chimiques et biologiques exceptionnelles.

On peut détecter et étudier cette LH essentiellement par des méthodes de spectroscopie vibrationnelle (ir, ir lointain, Raman, neutrons inélastiques . . .) et de rmn. Cependant, parmi ces méthodes, l'ir tient une place à part car elle présente une propriété frappante (2) que l'on retrouve dans toutes les LH X—H . . Y: la bande d'élongation de l'hydrogène ν_s (X—$\vec{H}$ . . . Y) a une intensité particulièrement grande (1 à 2 ordres de grandeur plus intense que la raie ν_{X-H} (X—$\vec{H}$) correspondante du composé X—H sans LH); de plus elle est large, structurée et décalée vers les basses fréquences. Un exemple en est donné dans le spectre de l'acide acétique en phase vapeur de la

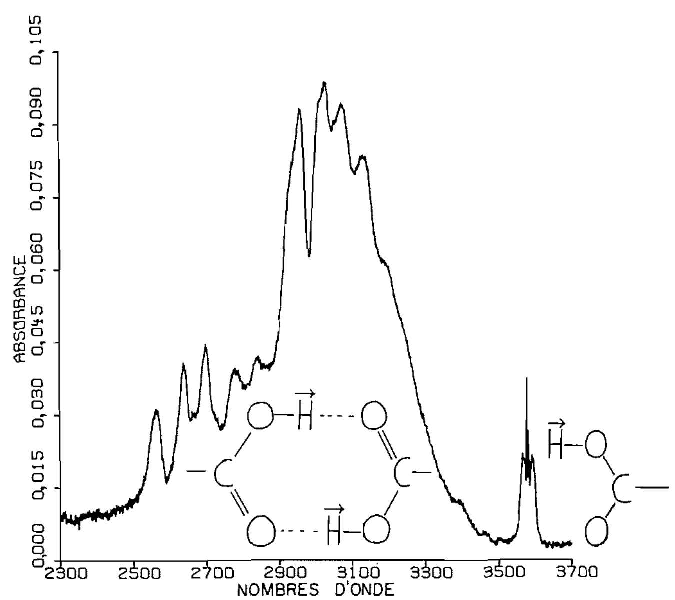

FIG. 1. Spectre ir de l'acide acétique en phase gazeuse à 300 K. La quantité de monomères et de dimères est équivalente.

fig. 1 où les quantités de monomères sans LH, CH_3COOH et de dimères cycliques liés par LH, $(CH_3COOH)_2$ sont équivalentes. Ces traits particuliers que l'on retrouve dans la fig. 1 sont caractéristiques de la LH.

Il est très vite apparu qu'il serait très utile de connaître l'origine de ces traits caractéristiques pour pouvoir tirer du spectre ir de la liaison hydrogène des informations précises sur la nature de cette liaison. Au congrès de Ljubljana (1957), une première réponse était donnée à ce problème,[2] avec la suggestion que la largeur et la structure particulières de ν_s étaient dues à deux forts couplages anharmoniques: le premier couple ν_3 avec les vibrations basse fréquence (50–200 cm^{-1}) de la LH (du type $\overleftrightarrow{X}$—$\vec{H}$ . . . $\overleftrightarrow{Y}$ ou X$\overset{H\cdot}{\uparrow}$·Y) et le second couple ν_s

[1]CNRS.

[2]S. Bratos et D. Hadzi, dans la réf. 1; N. Sheppard, aussi dans la réf. 1.

avec des niveaux de vibrations non accessibles optiquement et tombant en quasi-résonance avec ν_s. Ce dernier type de couplage de résonance est connu sous la dénomination de "résonances de Fermi". La responsabilité relative de ces deux couplages dans la forme, l'intensité et la position (en fréquence) de ν_s a été très longue à déterminer et a suscité de très nombreuses controverses. Celles-ci n'ont réellement pris fin qu'avec l'apparition de méthodes quantitatives permettant de séparer ces deux effets d'une manière précise. La mise au point de ces méthodes a en fait exigé de nombreuses expériences et analyses théoriques qui se sont poursuivies jusque vers les années 1980. Si cela a pris tant de temps, c'est parce que ces deux couplages anharmoniques sont en général tous les deux importants et de grandeur comparable (3–5) ce qui n'est apparu que lorsqu'on a pu les mesurer.

Nous allons décrire dans le prochain paragraphe le principe de ces approches quantitatives qui permettent de séparer ces deux effets, de les mesurer, et finalement d'éliminer du spectre ir de la LH les effets parasites, ce qui permet de ne garder que les informations susceptibles d'être utilisées pour comprendre le rôle que joue la LH à la température ambiante. Avant d'aborder ce paragraphe, notons cependant, que la spectroscopie ir de la LH, avec la puissance potentielle qui est la sienne, n'a pas attendu l'apparition de ces méthodes pour fournir de précieux renseignements sur la LH. C'est ainsi que des corrélations entre le centre de gravité de la bande ν_s et la distance X . . . Y dans la liaison X—H . . . Y ont été publiées (2). Elles permettent, après une simple mesure ir, d'estimer la longueur d'une LH, évitant ainsi tout le lourd travail d'analyse d'une structure par rayons X ou neutrons. Ce type de corrélation a été fortement développé et raffiné par A. Novak (6). De même, le Pr. C. Sandorfy et sa collaboratrice di Paolo (7) ont t-ils pu utiliser avec succès la présence de cette bande intense pour corréler la force anesthésiante des fluorocarbones à leur pouvoir de casser les LH, ce qui donne un point du vue intéressant sur le mécanisme de l'anesthésie.

Analyse de la bande ν_s

La première des caractéristiques frappantes de ν_s est sa très forte intensité, qui rend la spectroscopie ir si sensible à la LH. Cette intensité est due au déplacement des électrons nettement différent dans X—H . . . Y que dans X—H lorsqu'on allonge la distance X—H. L'origine physique de cette propriété n'est pas encore complètement claire, bien que des explications aient été avancées (8). Il faut dire que peu de résultats expérimentaux concernant les intensités des bandes ν_s ont été publiés. Ceci tient à la difficulté rencontrée pour mesurer des valeurs absolues d'intensités spectrales. Parmi les rares résultats expérimentaux, signalons cependant ceux concernant les intensités relatives $P_{\nu_s^H}/P_{\nu_s^D}$ des bandes ν_s pour les liaisons X—H . . . Y et X—D . . . Y correspondantes. Dans les dimères cycliques liés par LH, ce rapport prend une valeur anormalement grande (9), qui a été expliquée par la présence d'une forte anharmonicité électrique. Ce type d'anharmonicité semble être lui aussi général dans les LH (10), mais cela n'explique pas pourquoi cette valeur anormalement grande n'a été trouvée que dans les dimères cycliques (11).

Parmi les autres effets marquants caractérisant ν_s, le déplacement important de son centre de gravité vers les basses fréquences demande certainement aussi la connaissance précise de la structure électronique de la LH, bien qu'une théorie purement vibrationnelle (12) ait aussi permis d'en donner une explication satisfaisante. Les autres propriétés marquantes de ν_s peuvent s'expliquer par la présence des deux couplages anharmoniques dont nous avons parlé précédemment. Nous allons décrire leurs effets plus en détail.

Couplage ν_s – vibrations basse fréquence de la LH

Il s'agit, comme nous allons le voir, du couplage le plus intéressant en soi. Il a pu être étudié sur de (rares) systèmes où il est le seul couplage existant (13). On peut représenter très simplement ce type de couplage en supposant que le potentiel correspondant à ν_s est un potentiel harmonique dont la fréquence ω est modulée par l'une des vibrations basse fréquence de la LH ($\vec{\mathrm{X}}$—$\vec{\mathrm{H}}$ . . . $\overleftarrow{\mathrm{Y}}$ ou $\mathrm{X}\diagup\overset{\mathrm{H}\cdot}{\uparrow}\,\cdot\cdot\mathrm{Y}$) (9, 14, 16). Cette supposition est la plus simple et semble réaliste quand l'on sait que si la transition $0 \rightarrow 1$ en ν_s est très intense, les transitions $0 \rightarrow n$, elles, sont très faibles.[3] Dans le cas des LH fortes, cependant, cette supposition est moins exacte, et il peut être nécessaire (17) de considérer un potentiel anharmonique pour ν_s, dont les constantes sont modulées par ces vibrations basse fréquence. Pour une liaison faible ou intermédiaire, si l'on désigne par q la coordonnée représentant la vibration ν_s et par Q un des modes basse fréquence de la LH, le potentiel $V(q, Q)$ pour ces deux oscillateurs sera donc de la forme:

$$[1] \quad V(q, Q) = \frac{1}{2}m\omega^2(Q)q^2 + \frac{1}{2}M\Omega^2Q^2$$

m = masse du proton et M = masse réduite de l'oscillateur Q. Les fonctions d'onde $\psi(q, Q)$ correspondant à un tel potentiel seront très bien approchées par les fonctions d'onde adiabatique du type (14, 18):

$$[2] \quad \Psi(q, Q) = \phi_n(q, Q)\alpha_n^l(Q)$$

ou $\phi_n(q, Q)$ est la n-ème fonction d'onde ($n = 0, 1$) décrivant la vibration ν_s et $\alpha_n^l(Q)$ une fonction d'onde du vibrateur Q. Cette approximation se justifie par le fait que la fréquence ω est de l'ordre de 3000 cm^{-1} alors que Ω est de l'ordre de 150 cm^{-1}. On a donc un rapport entre ces fréquences aussi favorable que dans la séparation électrons–noyaux où cette approximation est une approximation de base. Elle revient à considérer que la vibration de l'hydrogène est suffisamment rapide pour pouvoir s'adapter immédiatement à toute nouvelle valeur de Q. L'oscillateur Q de son côté, est suffisamment lent pour ne voir que l'effet moyen de la vibration ν_s, si bien que son potentiel effectif $W_n(Q)$, qui dépend du degré d'excitation n de ν_s est:

$$[3] \quad W_n(Q) = \left\langle \phi_n(q, Q) \left| \frac{p^2}{2m} + V(q, Q) \right| \phi_n(q, Q) \right\rangle_q$$

$$= \frac{1}{2}M\Omega^2Q^2 + \left(n + \frac{1}{2}\right)\hbar\omega(Q)$$

$$p = -i\hbar\frac{\mathrm{d}}{\mathrm{d}q}$$

Dans le case du couplage électrons–noyaux, une telle situation donne lieu à des spectres du type "Franck–Condon", et c'est effectivement ce qu'il advient dans notre cas, lorsque ce couplage est le seul en jeu (19).

Avec un tel potentiel, on peut facilement montrer que le centre de gravité $\bar{\omega}$ de la bande ν_s ainsi que sa largeur quadratique moyenne σ s'écrivent:

---

[3]C. Sandorfy dans la réf. 15, chap. 13.

$$[4] \quad \bar{\omega} = \langle \omega(Q) \rangle_Q = \omega(\langle Q \rangle_Q) + \frac{1}{2}\frac{d^2\omega}{dQ^2} \times \langle (Q - \langle Q \rangle_Q)^2 \rangle_Q + \ldots$$

$$[5] \quad \sigma^2 = \left(\frac{d\omega}{dQ}\right)^2_{\langle Q \rangle} \langle (Q - \langle Q \rangle_Q)^2 \rangle_Q + \ldots$$

où $\langle\,\rangle_Q$ signifie que l'on prend la moyenne sur tous les états Q dont la population dépend de la température (selon une loi de Boltzmann par exemple) et que la dépendance de ω en Q est approchée par un développement en puissances de Q.

L'équation [4] est intéressante, car elle est valable même en présence de résonances de Fermi, et elle permet de comprendre la dérive de $\bar{\omega}$ avec la température. Celle-ci est très générale pour la LH et, à notre connaissance, toujours dans le même sens: lorsque la température augmente, $\bar{\omega}$ augmente. Deux types d'explications en ont été donnés: la première (20) fait jouer un rôle particulier à la quantité $\langle Q \rangle_Q$, qui représente alors la valeur moyenne de la longueur X . . . Y, quantité qui croît certainement avec la température (dilatation thermique). Q est donc la coordonnée de la vibration ν_σ ($\overleftarrow{\mathrm{X}}$—$\overrightarrow{\mathrm{H}}$ . . . $\overleftarrow{\mathrm{Y}}$). . Dans ce cas, on s'attend à ce que $d\bar{\omega}/dT$ soit positif, car $d\omega(Q)/dQ$ l'est certainement (plus la longueur moyenne X . . . Y est grande, plus $\bar{\omega}$ est grand (6)). La deuxième explication (21) suppose que l'effet de température sur $\bar{\omega}$ vient du dernier membre de l'éq. [4]. La quantité $\langle (Q - \langle Q \rangle_Q)^2 \rangle_Q$ représente le carré de l'amplitude de vibration de la vibration Q qui augmente avec la température (comme $1/\tanh \hbar\Omega/2kT$) pour un potentiel harmonique). Pour que $d\bar{\omega}/dT$ soit positif, il faut donc que $d^2\omega/dQ^2$ soit aussi positif, ce qui oblige à considérer que Q est alors la coordonnée de la vibration de torsion

(X╱H·↑·Y). En effet, d'après les courbes de Novak (6), un $d^2\omega(Q)/dQ^2$ positif est très improbable pour la vibration ν_σ. Nous avons testé ces deux hypothèses quantitativement (3, 4) pour les cristaux d'imidazole et d'acide adipique et en avons déduit que seule la deuxième explication est réaliste dans ces cas là: entre 77 K et 300 K la dilatation $\langle Q \rangle_Q$ de la distance X . . . Y telle qu'elle est mesurée aux neutrons ou rayons X n'est pas du tout suffisante pour expliquer cette dérive $d\bar{\omega}/dT$ (4, 22). C'est un résultat intéressant, car il permet de décrire avec précision la sensibilité thermique de certaines propriétés de la LH, ce qui peut avoir un impact non négligeable en biologie. De plus il met en lumière le rôle des vibrations basse

fréquence de torsion (X╱H··Y) de la LH. Ces vibrations ont peut-être un rôle plus important qu'on ne le croit d'ordinaire, en particulier dans le processus de rupture de la LH, qui peut être lui aussi très important en biologie.

L'équation [5] traduit le fait que la largeur σ de la bande ν_s pour ce processus dépend fortement de la température. Elle permet aussi d'expliquer pourquoi la bande ν_s de la liaison X—D . . . Y est plus étroite que celle de la liaison X—H . . . Y.

Résonances de Fermi

Il s'agit d'un processus d'intéraction entre le premier niveau excité de ν_s et un niveau non accessible optiquement, qui sera en pratique une combinaison binaire de premiers niveaux excités d'autres vibrations (q_δ) de la molécule X—H. Le potentiel V_F représentant une telle intéraction sera de la forme:

$$[6] \quad V_F = q \sum_{\delta,\delta'} F_{\delta,\delta'} q_\delta q_{\delta'}$$

Un potentiel décrivant un couplage anharmonique de cette forme a, en général, peu d'effet sur le spectre, sauf près de la résonance, c'est à dire lorsque l'énergie $\omega_\delta + \omega_{\delta'}$ du premier niveau excité en δ et δ' est de l'ordre de grandeur de ω. Dans ce cas le potentiel de ν_s sera $1/2\, m\omega^2 q^2$, avec ω indépendant de Q (résonances de Fermi pures). Si $V_F = 0$, le spectre consistera en une seule raie d'intensité I, de fréquence ω et de largeur nulle. Si V_F est différent de 0 le spectre se partagera alors en N raies (N = nombre de termes effectifs dans le $\sum_{\delta,\delta'}$ de l'éq. [6]) dont l'intensité totale sera encore I, le centre de gravité ω et la largeur quadratique moyenne égale à σ_F tel que:

$$[7] \quad \sigma_F^2 = \frac{\hbar}{8} \sum_{\delta,\delta'} F^2_{\delta,\delta'} \frac{1}{m_\delta \omega_\delta} \cdot \frac{1}{m_{\delta'} \omega_{\delta'}} \cdot \frac{1}{m\omega}$$

ou m_δ et ω_δ sont la masse effective et la fréquence de vibration du mode δ.

On voit donc que les résonances de Fermi n'ont aucun effet sur l'intensité et le centre de gravité de la bande ν_s. Ils ont un effet sur la largeur de ν_s mais cette largeur σ_F a la propriété d'être indépendante de la température. Ceci est dû à ce que ces résonances n'affectent pas l'état fondamental de ν_s, mais seulement son premier niveau excité qui est thermiquement inaccessible (3000 cm^{-1} = 4500 K).

Effet de ces deux couplages simultanés

Lorsque ces deux couplages anharmoniques sont présents, le potentiel correspondant est la somme $V(q, Q) + V_F$ (équations [1] et [6]). Il est alors aisé de montrer que le centre de gravité $\bar{\omega}$ de ν_s est toujours donné par l'éq. [4] (les résonances de Fermi n'ont aucune influence sur le centre de gravité) et que la largeur quadratique moyenne μ de ν_s est telle que (3, 4, 23):

$$[8] \quad \mu^2 = \sigma^2 + \sigma_F^2$$

où σ^2 et σ_F^2 sont donnés par les équations [5] et [7]. Dans cette équation la variation de μ avec la température vient uniquement de celle de σ (σ_F est indépendant de T). Les variations thermiques du centre de gravité $\bar{\omega}$ de ν_s et de sa largeur μ ne proviennent donc que du couplage de ν_s avec les vibrations basse fréquence de la LH. Cette propriété a permis de mesurer les grandeurs relatives de ces deux couplages par une analyse des variations des spectres de certains corps à LH entre 10 K et 300 K (3, 4). Cette analyse a alors montré que à température ambiante ces deux couplages étaient de grandeur comparable, alors qu'à 10 K, les résonances de Fermi étaient prédominantes.

On peut en fait pousser plus loin l'analyse de la forme de raie pour la transition $0 \rightarrow 1$ en ν_s lorsque le potentiel de ν_s est $V(q, Q) + V_F$. Une première approche à ce problème avait été décrite dans le cas particulier où la vibration basse fréquence Q n'est pas décrite quantiquement mais peut être traitée dans sa limite classique. C'est le cas, par exemple, d'une LH diluée dans un liquide sans LH, où une solution qualitativement satisfaisante pour la forme de raie a alors été obtenue (24). Le cas où la vibration Q ne peut être considérée dans sa limite classique est plus complexe. C'est celui très général des gaz ou des cristaux à LH. La transition $0 \rightarrow 1$ en ν_s pour une telle LH isolée est schématisée fig. 2: la transition ir s'effectue à partir d'un niveau du potentiel $W_0(Q)$ (eq. [3]) vers un niveau du potentiel $W_1(Q)$. Les niveaux de ce dernier ne sont cependant pas des niveaux propres du système de vibrations de la LH car ils sont en intéraction avec des niveaux (de résonance) définis par les potentiels $W_0(Q) + \hbar(\omega_\delta + \omega_{\delta'})$. Sur la fig. 2 nous n'avons dessiné, pour plus de commodité, que l'une de ces résonances δ, δ'. Ces niveaux de résonance ne peuvent pas être

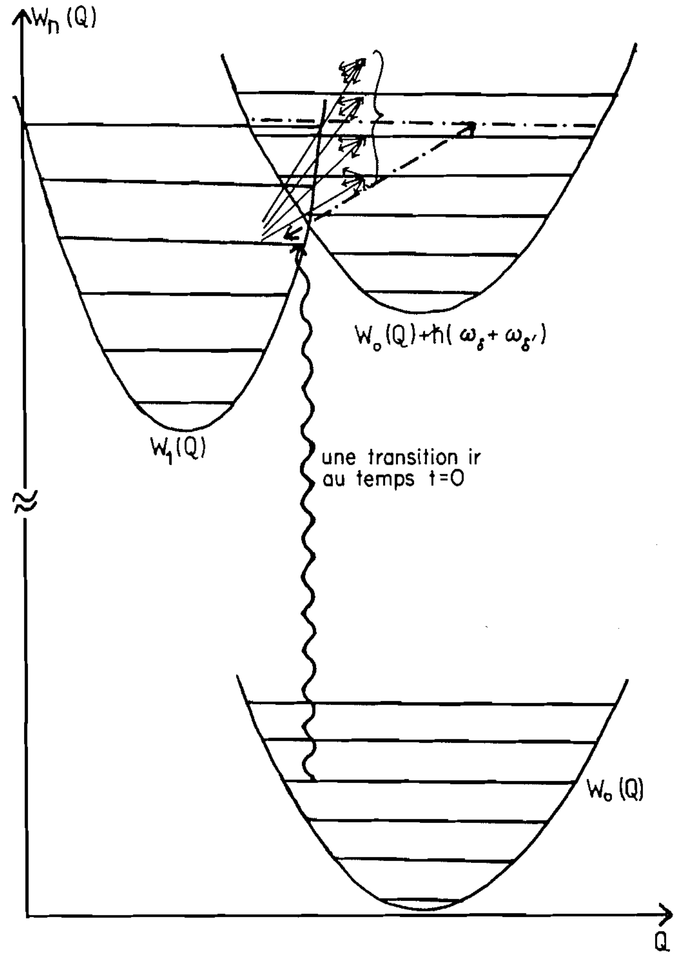

FIG. 2. Schéma de la transition $0 \rightarrow 1$ en ν_s.

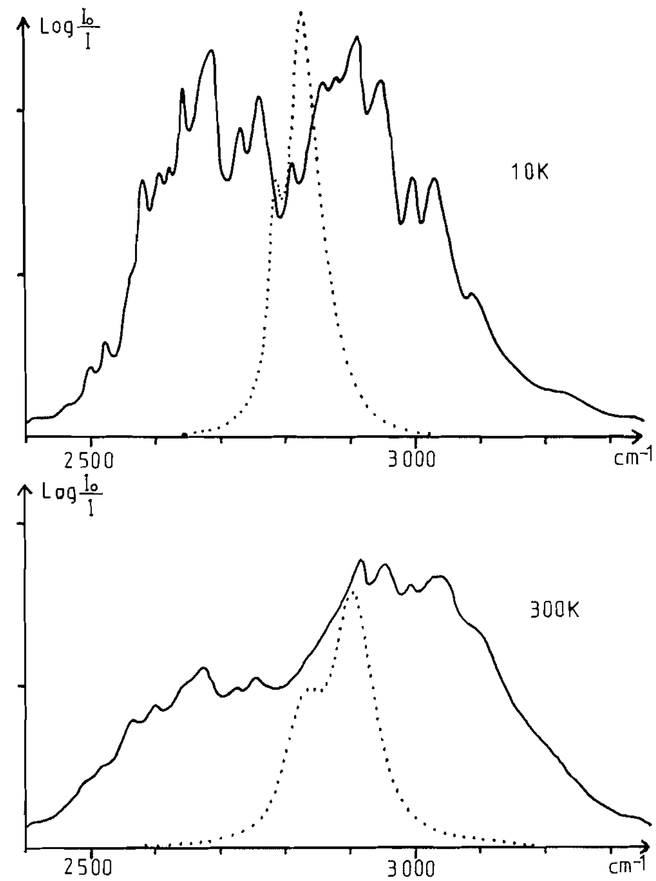

FIG. 3. Bande ν_s de monocristaux d'acide adipique H à 10 K et 300 K: spectre expérimental $\omega \cdot s(\omega)$ (en traits pleins —) et spectre calculé $\omega \cdot g(\omega)$ en pointillé . . .) après élimination des résonances de Fermi. Les échelles pour ces deux spectres sont différentes.

atteints directement par la transition ir. Cependant l'excitation créée par cette transition ir au temps $t = 0$ en $W_1(Q)$ passera, au bout d'un certain temps t sur des niveaux de $W_0(Q) + \hbar(\omega_\delta + \omega_{\delta'})$, puis reviendra sur des niveaux de $W_1(Q)$, etc. . . On peut simplifier considérablement le problème si on remplace l'ensemble des niveaux de Fermi $W_0(Q) + \hbar(\omega_\delta + \omega_{\delta'})$ atteints au bout du temps t par un niveau virtuel d'énergie égale à la moyenne des énergies des niveaux atteints (niveau ---- dans la fig. 2). Cette moyenne est indépendante du temps t. Pour tout niveau de Fermi défini par le couple δ, δ', on définit une telle moyenne. Le prix à payer pour une telle simplification se retrouve dans une perte de résolution, qui interdit de pouvoir inclure des éléments très fins du spectre. Cela revient à considérer que l'approximation faite en introduisant cette simplification est une approximation de temps court.

On peut alors définir (23), à partir de la forme $s(\omega)$ expérimentale de la bande ν_s (le spectre expérimental étant proportionnel à $\omega s(\omega)$), une forme $g(\omega)$, qui est la forme "épluchée" de ν_s, c'est-à-dire la forme qu'aurait ν_s si les résonances de Fermi étaient égales à zéro. Une relation simple, qui se prête particulièrement bien à une computation existe alors entre s et g. Nous montrons dans les figures 3 et 4 la forme $\omega g(\omega)$ du spectre pour les acides adipiques H et D à différentes températures, ainsi que le spectre expérimentale $\omega s(\omega)$ (les deux courbes $\omega s(\omega)$ et $\omega g(\omega)$ sont dessinées, pour des raisons de présentation à deux échelles différentes; elles ont même intensité intégrée). Les spectres $\omega g(\omega)$ pour l'imidazole et les acides carboxyliques en phase vapeur seront publiés prochainement. Nous voyons que l'élimination des résonances de Fermi simplifie considérablement les spectres, et qu'il est alors beaucoup plus facile d'en tirer des informations sur les couplages de ν_s avec les vibrations basse fréquence de la LH. Ces couplages sont, comme nous l'avons déjà mentionné, très intéressants à connaître en eux-mêmes, car ils sont à l'origine de la sensibilité de ν_s à la température, et peuvent aussi donner des indications sur les processus de rupture de la LH. Par contre les résonances de Fermi, que nous avons éliminées, apparaissent comme des effets parasites dans la bande ν_s: ce sont des effets qui ne se retrouvent que dans les niveaux excités de ν_s, qui sont thermiquement inaccessibles, et ne peuvent donc pas se manifester dans les propriétés de la LH à température ambiante. Ce sont en fait de purs artifices de la spectroscopie vibrationnelle.

Perspective de recherches

La spectroscopie ir est une technique puissante pour étudier la LH. Elle a cependant longtemps trainé ce problème de résonances de Fermi, qui ont empêché de l'utiliser à sa pleine puissance. Maintenant que l'interprétation des spectres peut être grandement simplifiée par l'élimination de ces résonances, les perspectives de la spectroscopie ir sont très intéressantes, en particulier pour étudier les propriétés dynamiques de la LH, telles que son mécanisme de rupture, sa capacité de transférer des protons, etc. . . De ces mécanismes nous ne connaissons que très peu de choses. Pourtant la rupture d'une LH dans l'eau constitue une source d'énergie de quelques kT à l'ambiante, qui

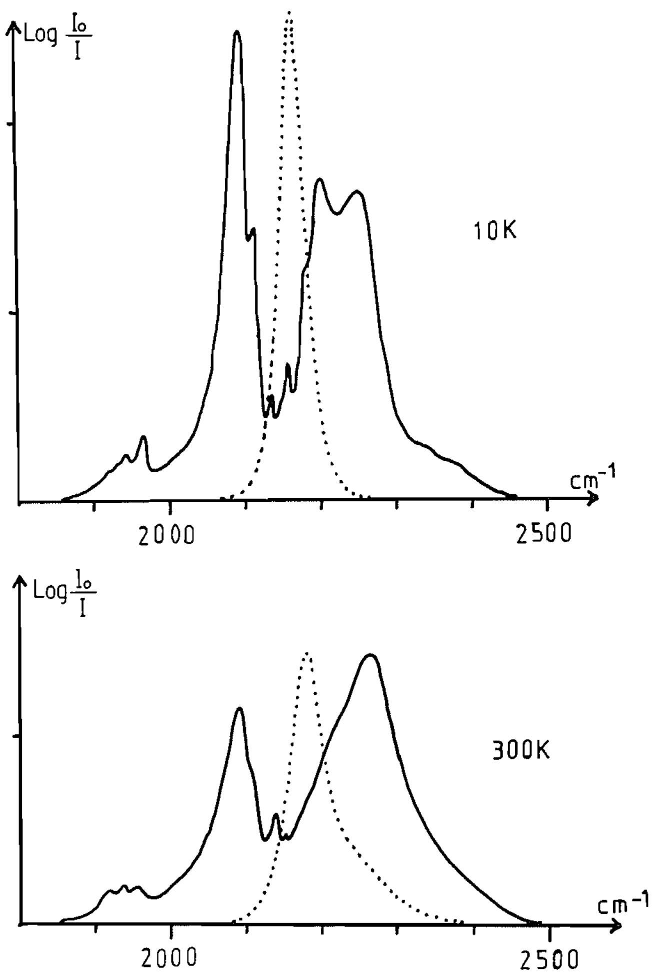

FIG. 4. Bande ν_s de monocristaux d'acide adipique D à 10 K et 300 K: spectre expérimental $\omega \cdot s(\omega)$ (en traits pleins —) et spectre calculé $\omega \cdot g(\omega)$ (en pointillé . . .) après élimination des résonances de Fermi. Les échelles pour ces deux spectres sont différentes.

semble capable de se déplacer très rapidement dans l'eau (25). Elle a une énergie très comparable à l'énergie d'une réaction ATP $\rightleftarrows$ ADP. Il n'est donc pas impossible qu'elle ait de ce fait un rôle important dans les mécanismes bio-énergétiques. Il semble donc extrêmement utile de connaître en détail les mécanismes de rupture de la LH, leur mode de propagation (exciton, soliton, . . ?) et bien sûr l'effet de la température sur ces mécanismes. De même le transfert des protons est certainement un mécanisme essentiel dans toutes les réactions aqueuses. L'eau est en effet un liquide présentant une densité de LH exceptionnelle (presque un ordre de grandeur plus élevée que pour les autres liquides à LH tels que méthanol, éthanol, etc . . .) où ce transfert peut être particulièrement efficace. On peut penser que c'est leur différence de capacité à transférer les protons ou deutérons qui donne à l'eau et à l'eau lourde leur si grande différence de propriétés biologiques.

Par sa grande densité de LH, l'eau est cependant un corps compliqué à étudier. De plus elle est pratiquement opaque en ir. C'est donc par d'autres techniques spectroscopiques (Raman, diffusion Rayleigh (25) ou de neutrons essentiellement) qu'elle pourra être abordée. Cependant l'ir sera une technique très précieuse si l'on veut aborder l'étude de ces mécanismes dynamiques dans la LH sur des corps plus simples que l'eau qui pourront alors servir de modèles de base pour l'eau. Nous pensons en particulier aux dimères cycliques des acides carboxyliques en phase vapeur ou des diacides carboxyliques en cristaux. Ces systèmes sont d'excellents modèles de LH simples, relativement faciles à manipuler, et une approche théorique des mécanismes de transferts de protons dans ces cycles dimériques a déjà été proposée (26).

Par ailleurs une extension de la spectroscopie ir vers l'ir lointain semble aussi actuellement pleine d'avenir. Ce type de spectroscopie a récemment accompli des progrès marquants avec l'apparition de nouveaux détecteurs plus sensibles et plus rapides. Nous avons vu le rôle qui jouent dans le spectre de ν_s les vibrations basse fréquence de la LH. La mécanique de ces vibrations basse fréquence, et en particulier leurs couplages anharmoniques sont encore très mal connus. Leur connaissance précise peut cependant être très utile pour connaître le rôle exact de la température dans tous les systèmes à LH, biologiques en particulier.

Nous voyons ainsi que la spectroscopie ir de la LH, qui a constitué un domaine important de recherche jusque vers les années 1980, a encore de nombreux sujets à étudier, qui concernent essentiellement la dynamique de la LH. On peut penser qu'il s'agit en fait d'un domaine nouveau très riche, qui est susceptible de fournir des constantes fondamentales pour la biologie ou la science des matériaux.

Potential energy hypersurfaces have been studied for the $CH(\tilde{X}^2\Pi) + C_2H_4(\tilde{X}^1A_g)$ addition and insertion reactions by *ab initio* molecular orbital theory. 6-31G basis set was used for complete geometry optimization of CH, C_2H_4, the cyclopropyl and allyl radicals as well as the reaction intermediates involved, with the RHF open shell SCF method. CI calculations were then performed at the SCF level optimized geometry. Analysis of the potential energy hypersurfaces predicts, in agreement with reported experimental data, a zero activation energy for the addition reaction via a non least motion, asymmetric reaction path, while the insertion reaction features a computed activation energy of 15 kcal mol^{-1}.

RATNAKAR K. GOSAVI, IMRE SAFARIK et OTTO P. STRAUSZ. Can. J. Chem. **63**, 1689 (1985).

Utilisant la théorie des orbitales moléculaires *ab initio*, on a étudié les hypersurfaces d'énergie potentielle pour les réactions d'addition et d'insertion $CH(\tilde{X}^2\Pi) + C_2H_4(\tilde{X}^1A_g)$. On a utilisé un ensemble de base 6-31G pour effectuer une optimisation des radicaux CH, C_2H_4, cyclopropyle et allyle; on a aussi effectué une optimisation des intermédiaires réactionnels en faisant appel à la méthode des couches ouvertes de RHF en champ auto-cohérent. On a alors effectué des calculs IC au niveau de la géométrie optimisée en champ auto-cohérent. Pour la réaction d'addition, une analyse des hypersurfaces d'énergie potentielle permet de prédire que l'énergie d'activation est égale à zéro et que la réaction se produit par le biais d'une réaction asymétrique ne procédant pas par une voie de moindre déplacement; ces prédictions sont en accord avec les données expérimentales existantes. Pour la réaction d'insertion, la même analyse permet de prédire que l'énergie d'activation est égale à 15 kcal/mol.

[Traduit par le journal]

Introduction

The chemistry of carbynes, the family of monovalent carbon radicals has been explored experimentally for the past quarter century (1) and in recent years, comparative rate data have become available for the reactions of ground $^2\Pi$ state diatomic methylidynes, CH (2, 3), CF, CCl, and CBr with C_2H_4 and alkanes (1, 4–6). Quantitative kinetic studies with the direct spectroscopic observation of the transient methylidyne species lead to the determination of absolute rate constant values and in some cases, the Arrhenius parameters. The mechanistic aspects of these reactions, however, have remained largely obscure owing to the complexity of the carbyne generating reactions, which in all cases, produce a variety of other reactive intermediates as well. Detailed mechanistic studies of a carbyne species have only been carried out on the solution phase reactions of carbethoxymethylidyne, C—COOEt (7) where it was shown that the doublet ground state methylidyne undergoes concerted stereospecific cycloaddition to olefins and regio selective insertion into the C—H bonds of paraffins and olefins. Hydrogen abstraction by the carbyne was not observed in these studies. On the basis of these results it can be assumed with reasonable confidence that all four diatomic carbynes studied to date, CH, CF, CCl, and CBr exhibit analogous reactivity in their doublet ground state with olefins and paraffins.

Theoretical studies of the ground and excited states of diatomic carbynes, CH (8, 9), CF (10, 11), and CCl (12, 13) have concordantly shown that in agreement with experiment they all have a $^2\Pi$ ground state with a low lying $^4\Sigma^-$ state as the lowest excited state. In contrast, a recent *ab initio* study of CLi (14) predicts the inversion of energy levels in this species with the lowest excited $^2\Pi$ state to lie ~34 kcal mol^{-1} above the $^4\Sigma^-$ ground state. Kim, So, and Schaefer (15) investigated the equilibrium geometries and relative energies of the low-lying electronic states of carbohydroxymethylidyne, HOC(=O)—C, — the parent species of carbethoxymethylidyne which had been studied experimentally — and its isomeric formoxymethylidyne, HC(=O)O—C, with the SCF and CI methods using double ζ and double ζ plus *d* basis sets. The results predict the *cis* $^2A''$ state to be the ground state for carbohydroxymethylidyne, closely followed by a $^2A'$ (10 kcal mol^{-1}) and a $^4A''$ (17 kcal mol^{-1}) states. The formoxymethylidyne, on the other hand, has a *trans* $^2A'$ ground state with the *cis* $^2A''$ and the $^4A''$ states lying at 12 and 70 kcal mol^{-1}, respectively, higher than the $^2A'$ ground state.

The first molecular orbital study of a methylidyne reaction was reported by Brooks and Schaefer (16). They investigated the potential energy surfaces for the insertion of doublet methylidyne into molecular hydrogen and abstraction of hydrogen by the quartet methylidyne. *Ab initio* molecular orbital studies with configuration interaction with double ζ and double ζ + polarization functions gave an energy barrier of ~75 kcal mol^{-1} for the least motion insertion reaction path, where the CH approach is perpendicular to the H—H bond at the center of the bond. In the non least motion insertion path, where the C—H axis is parallel with the H—H axis and the carbon atom approaches the center of the H—H bond, the energy barrier was only 4 kcal mol^{-1}. For H abstraction by the quartet methylidyne the computed barrier was ~11 kcal mol^{-1}.

In our previous molecular orbital studies on the reaction path of doublet methylidyne addition to ethylene (17), we calculated the potential energy surface at the SCF level with the Unrestricted Hartree Fock (UHF) method using the minimal STO-4G basis set. We had considered two reaction paths for the addition reaction; in one C—H is approaching at the center of the C=C bond from above the ethylene plane. This symmetric addition path has a small activation energy of ~7.7 kcal mol^{-1}. The other reaction surface studied was for the asymmetric approach where the C—H approaches off center again from above the ethylene plane. The potential energy surface for this asymmetric reaction path showed no activation energy and it was concluded that the addition of $CH(\tilde{X}^2\Pi)$ to ethylene ($\tilde{X}^1A_g$)

proceeds without any activation energy along the asymmetric path.

Here we report the results of another, higher quality *ab initio* molecular orbital study with limited configuration interaction on the potential energy surfaces of both the addition and insertion reactions of ($\tilde{X}^2\Pi$) ground state methylidyne to ethylene ($\tilde{X}^1A_g$).

Method

All the molecular geometrical parameters of ground state ethylene (^1A_g), CH($^2\Pi$), doublet cyclopropyl and allyl radicals, and the reaction intermediates involved were optimized at the SCF level by the energy gradient method (18, 19) with 6-31G basis set (for C, see ref. 20*a*; for H, see ref. 20*b*). The Restricted Hartree Fock (RHF) open shell SCF method was used for the doublet state radicals. Configuration interaction (CI) calculations include all singly and doubly excited configurations (CISD) with respect to the SCF configuration, and were done using the direct CI method (21) at the SCF level optimized geometry. Davidson's formula (22) was applied to the CI results to estimate the correction for the quadruple excitations (CISDQ). The lowest three orbitals corresponding to the core orbitals of carbon 1*s* were kept doubly occupied and frozen, and the top ten virtual orbitals were also kept frozen in the CI calculations. All the computations were performed with the "MONSTERGAUSS" Program (23) on an AMDAHL 5860 computer at the University of Alberta.

Results

The optimized C—H bond distance of 1.117 Å calculated for the $^2\Pi$ ground state of methylidyne is in good agreement with the experimental value of 1.120 Å (24). The optimized molecular parameters for ethylene (^1A_g) are summarized in Table 1 and the double ground state optimized geometry for the cyclopropyl radical, the product of the addition reaction is shown in Fig. 1. These values are in close agreement with the earlier optimized geometry with minimal (17, 26) and extended (4-31G) (27) basis sets. The radical center in the cyclopropyl radical is non planar with an out-of-plane angle between C_1H_{10} and the CCC ring, of 40.86°. The corresponding planar (C_{2v}) structure has the optimized geometry of $R(C_1—C_2) = 1.467$ Å, $R(C_2—C_3) = 1.539$ Å, $R(C_1—H_{10}) = 1.060$ Å, $R(C_2—H_6) = 1.076$ Å, $\angle H_6C_2H_7 = 113.36°$, $\angle C_3C_2H_6 = 117.86°$, and $H_6C_2C_3C_1$ out-of-plane $\angle = 109.06°$, with total energies: $E_{SCF} = -116.354881$ au, $E_{CISDQ} = -116.502782$ au. This transition state structure for the inversion motion of the radical center is 4.3 kcal mol^{-1} at the SCF and 9.0 kcal mol^{-1} at the CISDQ level higher in energy than the C_s symmetry lowest energy structure. The CH insertion into the ethylene C—H bond yields an allyl radical. The SCF optimized geometries of both C_s and C_{2v} structures are depicted in Fig. 2. Electron spin resonance studies (28) have shown that the allyl radical has a C_{2v} symmetry. Several theoretical studies on electronic structure (29, 30), doublet instability (31–34), and symmetry dilemma (35, 36) have been reported for the allyl radical. The RHF SCF geometry optimization for three center, three π electron systems usually overestimates the stability of structures containing one short and one long bond (C_s) (Fig. 2*a*) relative to the one with intermediate equal bond lengths (C_{2v}) (Fig. 2*b*). This problem has been solved by inclusion of the correlation energy (32, 33). The optimized geometry of the symmetric allyl radical is similar to the one obtained from 4-31G basis set

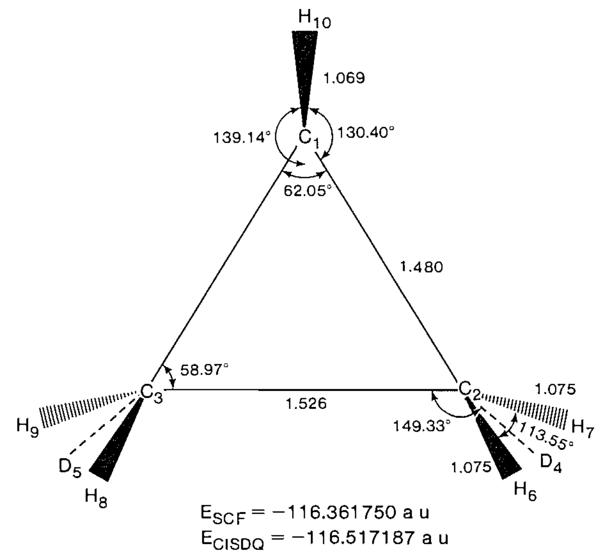

FIG. 1. Doublet ground state, RHF-SCF optimized geometry of the cyclopropyl radical. Bond distances are in Å and bond angles in degree.

TABLE 1. SCF-optimized molecular parameters of ethylene ($\tilde{X}^1A_g$) with 6-31G basis set

Molecular parameters	Calculated	Experimental[a]
R(C—C) (Å)	1.322	1.330
R(C—H) (Å)	1.074	1.076

[a]Reference 25.

calculations (29). As expected, at the SCF level the C_s symmetry radical is more stable — by 1.8 kcal mol^{-1} — than the C_{2v} structure but the inclusion of the correlation energy has the effect of lowering the energy of the C_{2v} structure below the C_s symmetry structure by 1.2 kcal mol^{-1}.

The addition reaction path

Two reaction paths for the addition of CH($^2\Pi$) to ethylene (^1A_g) have been studied; in both cases CH is approaching at the center of the C=C bond, from the plane perpendicular to the ethylene, Fig. 3. Total energies as a function of the $X_1—C_4$ distance (d, Fig. 3) have been calculated for the SCF level optimized geometry and CI calculations were then done on the SCF optimized geometry. In the first reaction path, C_4H_9 and X_1 are in the plane perpendicular to the $C_2C_3C_4$ plane .The single electron on the C_4 atom remains in the p_x orbital until the $X_1—C_4$ distance reaches 1.85 Å, and Localized Molecular Orbital (LMO) analysis shows ethylene and methylidyne as separate entities. At 1.85 Å distance partial bond formation between $C_4—C_2$ and $C_4—C_3$ takes place. Below this distance the single electron moves from the p_x orbital to the p_y orbital on C_4. This transition complex has a small energy barrier of 3 kcal mol^{-1} at the SCF level, Fig. 4, which disappears in the CISDQ potential energy surface, Fig. 5.

In the second reaction path, where the CH approach is in the plane of $C_2C_3C_4H_9$, the single electron remains always in the p_y orbital of C_4. LMO analysis of the reaction intermediates shows that CH and ethylene remain as separate entities until the $X_1—C_4$ distance again reaches 1.85 Å, at which point partial bond formation between $C_4—C_2$ and $C_4—C_3$ takes place. The

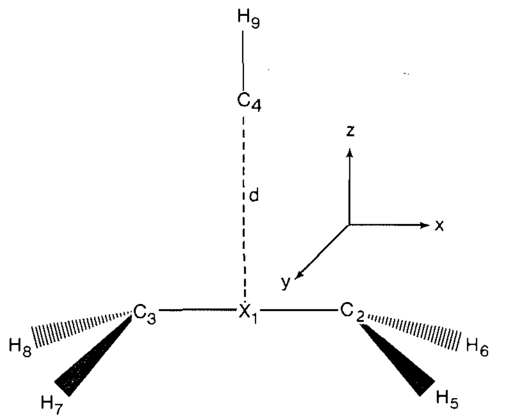

FIG. 3. Addition and insertion reaction path.

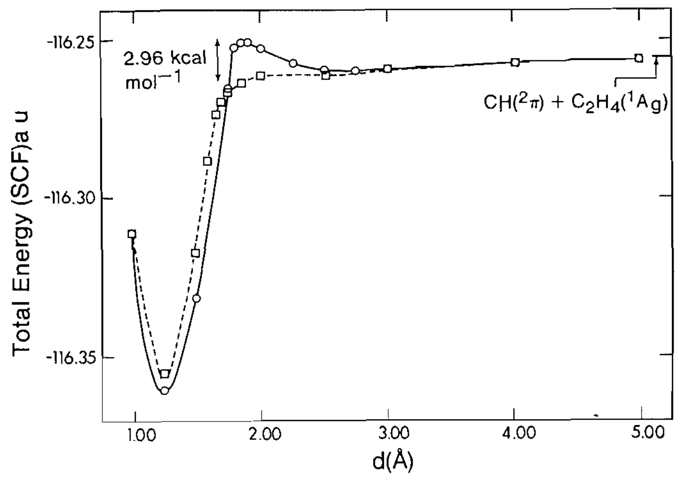

FIG. 4. Potential energy surface of lowest doublet state addition of CH + C_2H_4 reaction path at the SCF level. ○, perpendicular approach; □, planar approach of CH.

$C_2X_1C_4$ angle at this distance is 104.5° and the $X_1C_4H_9$ angle is 95.2°. The $C_2X_1C_4$ angle in the first reaction path remains at 90°, whereas in the second reaction path this angle is greater than 100° until the X_1—C_4 distance reaches a value of 1.60 Å. For this in-plane approach both the SCF and CI calculations predict no activation energy (Figs. 4 and 5).

The insertion reaction path

In the insertion reaction path CH is approaching in the plane of the ethylene molecule. The total energy of the $^2A''$ state as a function of the X_1—C_4 distance (*d*) has been calculated with optimizing all the rest of the molecular parameters, Fig. 6. The $C_2X_1C_4$ angle at large distances is small (e.g. at d = 5 Å, $\angle C_2X_1C_4$ = 42.6°) and increases as the distance decreases reaching a maximum of 99° at 2.5 Å. Then again it starts decreasing as *d* decreases to the final product of the allyl radical. LMO analysis shows that methylidyne and ethylene remain as separate entities until *d* reaches a value of 2.325 Å corresponding to the transition complex, Fig. 7, where C_2—C_4 bond formation starts to take place. At this transition state the C_4 atom is right above the C_2 carbon, i.e. $\angle C_3C_2C_4 \simeq 93°$ and H_6 is still bound to the C_2 atom. Below d = 2.325 Å the H_6 migrates from C_2 to C_4. The energy barrier at the SCF level is 29 kcal mol^{-1}. The configuration interaction studies on the potential energy surface with the SCF optimized geometries, Fig. 6, for the insertion reaction predicts an activation energy of ~15 kcal mol^{-1}.

Discussion

The first addition reaction path studied, where the CH is approaching in the plane perpendicular to the CCC plane is similar to the symmetric path we reported earlier (17). At the RHF open shell SCF level with 6-31G basis set, the energy barrier, 3 kcal mol^{-1}, is smaller than the minimal STO-4G UHF value of 7.7 kcal mol^{-1}. On inclusion of the correlation energy by configuration interaction computation, the energy barrier disappears completely (Fig. 5). The second reaction path, the in-plane approach, where C—H is approaching in the CCC plane, is close to the asymmetric approach reported earlier (17) where the reaction coordinate was the $C_2X_1C_4$ angle while in the present study we choose the X_1—C_4 distance as the reaction coordinate. This asymmetric approach, both at minimal STO-4G basis (UHF-SCF) and 6-31G basis (with RHF-SCF), predicts no energy barrier for the addition reaction even at the SCF level. On inclusion of correlation energy by the CI calculations, the energy along the addition reaction path decreases monotonically and again without any energy barrier (Fig. 5).

The LMO analysis at the critical level of 0.07 for bond identification shows partial bond formation between C_4—C_2 and C_4—C_3 at an X_1—C_4 distance of 1.85 Å in both reaction paths. Bond formation probably takes place by the p_z electrons

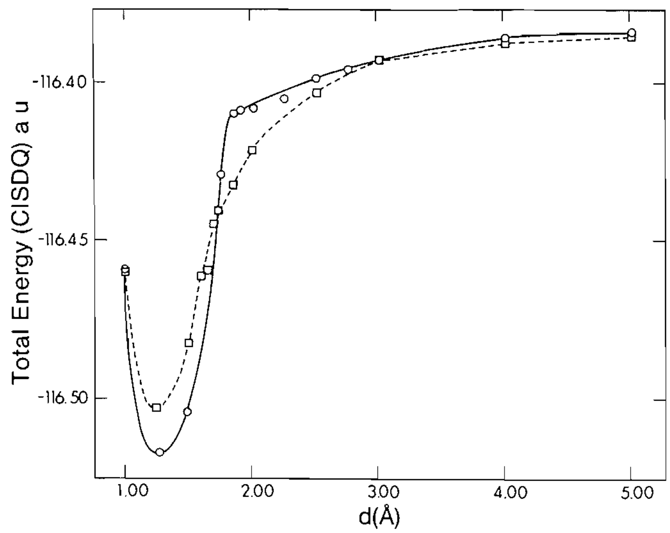

FIG. 5. Potential energy surface of lowest doublet state addition of CH + C_2H_4 reaction path at CISDQ level. ○, perpendicular approach; □, planar approach of CH.

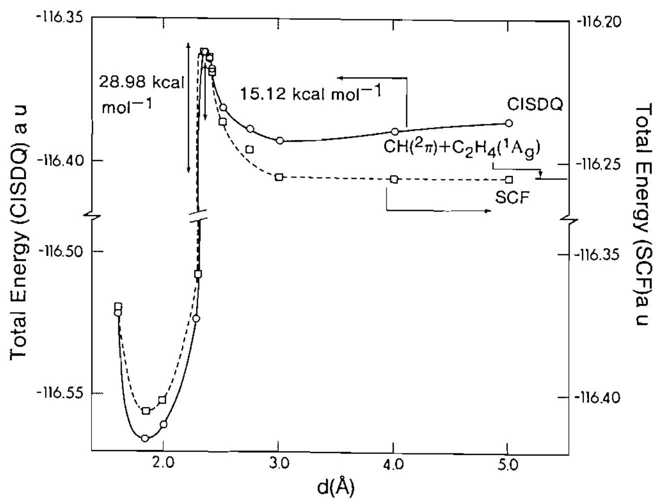

FIG. 6. Potential energy surface for CH insertion into ethylene. --- SCF; —— CISDQ level.

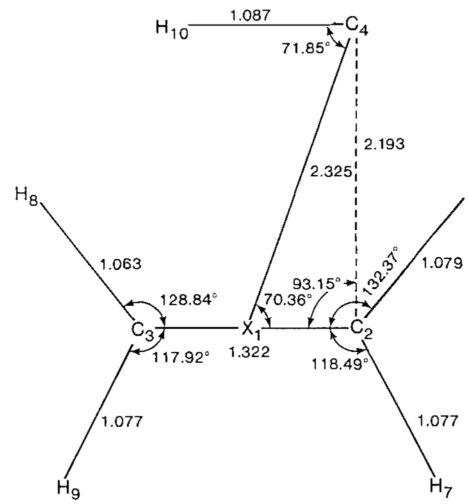
of the ethylene (C_2C_3) moving to the p_z in-plane empty orbital of methylidyne C_4 in both cases but back donation occurs from the lone pair of the p_x orbital of C_4 in path two and in path one the single p_x electron forms a partial bond with a carbon atom of ethylene. In the latter case, below d = 1.85 Å, one electron from the lone pair in the p_y orbital of methylidyne moves to the in-plane p_x orbital to complete the bond formation with ethylene. This electron rearrangement could perhaps be the reason why the asymmetric approach, reaction path two initially has a lower energy until d reaches a value of ~1.75 Å below which the symmetric path lies lower in energy leading to the cyclopropyl radical structure (Figs. 4 and 5). In either case the addition appears to be a one-step, concerted process, in agreement with the experimental stereospecific addition results obtained for the carbethoxymethylidyne. These potential energy surface calculations suggest that the addition of ($\tilde{X}^2\Pi$) ground state methylidyne to ethylene (^1A_g) follows the asymmetric path two in the early stages of the reactions until d = 1.75 Å, then crosses over to the symmetric path one, without any energy barrier. This asymmetric approach is in line with the predic-



$E_{SCF} = -116.209395$ a u
$E_{CISDQ} = -116.361519$ a u

FIG. 7. RHF-SCF optimized geometry of the transition complex of CH insertion into ethylene. Bond distance in Å and bond angles in degree.

tions of the molecular orbital studies of the reaction path for the addition of singlet ($^1A_1$) methylene to ethylene (37, 38) favoring the asymmetric approach without any activation energy. Asymmetric reaction paths were also predicted for several singlet ($^1A_1$) substituted carbene cycloaddition reactions with some activation energy (37, 39).

The present computational results' prediction of a zero activation energy for the addition reaction of CH($\tilde{X}^2\Pi$) to $C_2H_4(\tilde{X}^1A_g)$ compares well with the experimental value of −0.35 kcal mol^{-1} recently reported by Berman, Fleming, Harvey, and Lin (2).

The knowledge of the geometry of the activated complex makes it also possible to estimate a value for the preexponential factor of the reaction on the basis of transition state theory.

The preexponential factor of the reaction has been reported to be $1.34 \times 10^{11}\ M^{-1}\ s^{-1}$ (2). Assuming that the preexponential factor for the insertion reaction into the C—H bonds of ethylene is the same as the one measured for methane (3), $0.30 \times 10^{11}\ M^{-1}\ s^{-1}$, we correct the experimental value for the ethylene reaction by subtracting the experimental value for methane $1.34 \times 10^{11} - 0.30 \times 10^{11} = 1.04 \times 10^{11}\ M^{-1}\ s^{1}$.

From the above experimental A factor the entropy of activation at 300 K

$$\Delta S_c^{\ddagger} = R \ln\left(\frac{hA}{e^2kT}\right) = -12.11 \text{ eu}$$

and

$$\Delta S_p^{\ddagger} = \Delta S_c^{\ddagger} - \Delta n\, R \ln (RT) = -18.47 \text{ eu}$$

The standard entropy for the activated complex is obtained from the equation

$$\Delta S_p^{\ddagger} = S_p^0(\mathrm{AC}) - S_p^0(\mathrm{CH}) - S_p^0(\mathrm{C_2H_4})$$

Taking $S_p^0(\mathrm{CH})$ = 43.7 eu and $S_p^0(\mathrm{C_2H_4})$ = 52.4 eu (40) the entropy of activation calculated from the experimental A factor yields the value $S_p^0(\mathrm{AC})$ = 77.63 eu for the standard entropy of the activated complex.

Based on the similarity between the cyclopropyl radical and the optimized structure computed for the activated complex of the CH + C_2H_4 addition, the standard entropy for the activated complex, S_p^0(AC), can be estimated using Benson's method (40). Starting out with the standard entropy for the cyclopropyl radical, $S_p^0 = 60.4$ eu (40), the longer C(H)—C(H_2) bonds will give 1 eu additional rotational and 3−4 eu additional vibrational contributions for the entropy of the activated complex. The vibrational contribution is compensated somewhat by the increased frquencies of the CH_2 groups due to the shorter H_2C—CH_2 bond. Thus, the standard entropy for the activated complex is estimated to be about $S_p^0(AC) \simeq 65 \pm 2$ eu, in serious disagreement with the value derived from the experimental A factor. The A factor derived from the estimated S_p^0(AC) value lies in the range of $6.5 \times 10^7 - 4.9 \times 10^8\ M^{-1}\ s^{-1}$ which is over two orders of magnitude lower than the reported experimental value.

We are not able at present to rationalize this discrepancy.

Turning to the insertion reaction, the transition state complex at d = 2.325 Å still resembles the reactant state (Fig 7), with the methylidyne carbon C_4 being close to C_2 at an angle $C_3C_2C_4$ = 93°, and the C_2—C_3 distance being similar to ethylene. At d = 2.30 Å the H_6 hydrogen migrates from C_2 to C_4 and C_2—C_4 bond formation begins to take place with C_2—C_4 distance of 1.735 Å. The energy barrier is 15 kcal mol^{-1} which is higher than the measured activation energies for insertion into the C—H bonds which are all negative and have values in the order of 0.4−0.06 kcal mol^{-1} (3). The computed energy barrier is sensitive to the correlation energy and geometry optimization at the CI level would very likely have a significant decreasing effect on it. The computed energy barrier, 4 kcal mol^{-1}, for the insertion of CH($\tilde{X}^2\Pi$) into the hydrogen molecule (16) is also probably somewhat larger than the experimental value.

We propose a simple electrostatic model for the analysis of ligand binding to proteins. Besides a geometric fit electrostatic complementarity is also needed to allow favourable hydrogen bonding and ion-pair interactions. Nonpolar regions of the ligand and the biomacromolecule active site should match to reduce unfavourable hydrophobic effects, i.e., to lower the Gibbs free energy of the complex in aqueous solution. These principles are applied to the inhibition of dihydrofolate reductase by methotrexate. The enzyme active site is represented by an electrostatic lock which is derived from the macromolecular electrostatic potential and field at certain reference points. The key, defined similarly for the ligand, should fit into the lock to ensure complementarity, i.e., recognition. Hydrogen bonding and ion-pair interactions can be studied by the "potential key" while the "field key" accounts for hydrophobic complementarity. Analyzing the dihydrofolate reductase–methotrexate interaction in the light of the above principles the relative importance of various molecular fragments in binding can be determined.

PÉTER NAGY et GÁBOR NÁRAY-SZABÓ. Can. J. Chem. **63**, 1694 (1985).

Nous proposons un modèle électrostatique simple pour analyser les propriétés de liaison des ligands à des protéines. En plus d'un accord géométrique, une complémentarité électrostatique est nécessaire pour permettre l'existence de liaisons hydrogènes et d'interactions ion-paire favorables. Les régions non polaires du ligand et le site actif de la biomacromolécule doivent correspondre pour réduire les effets hydrophobes défavorables, c'est à dire pour diminuer l'énergie libre de Gibbs du complexe en solution aqueuse. On a appliqué ces principes à l'étude de l'inhibiteur de la réductase dihydrofolate par le méthotréxate. On représente le site actif de l'enzyme par un verrou électrostatique qui découle du potentiel et du champs électrostatique macromoléculaire, à certain points de référence. La clé, définie d'une façon analogue pour le ligand, doit s'adapter au verrou pour assurer la complémentarité, c'est à dire la reconnaissance. On peut étudier les liaison hydrogènes et les interactions ion-paire pour une "clé du potentiel" tandis que la "clé du champ" s'utilise pour la complémentarité hydrophobe. Une analyse de l'interaction réductase dihydrofolate–méthotréxate, à la lumière de ces principes, permet de déterminer l'importance relative des divers fragments moléculaires dans les liaisons.

[Traduit par le journal]

Introduction

The molecular basis of biological specificity is recognition of certain systems or parts of them by others. This process is pictorially modeled by the lock-and-key concept: locks (mostly crevices in proteins, nucleic acids, or other biomacromolecules) accommodate keys (inhibitors, substrates, or other ligands). Biological response is achieved if keys "fit" into the lock, a concept widely used but, in general, not unequivocally defined. The lock-and-key model is elegantly exploited in modern computer graphics (1–4) which, however, account only for close contacts between nonbonded atoms, i.e. excluded molecular configurations. There are at least two further requirements to be met: electrostatic complementarity and matching of nonpolar (hydrophobic) regions (5–7). In order to be recognized the ligand has to interact favourably with the active site and in biochemical systems interactions are mainly determined by electrostatic forces. Thus an electrostatic complementarity between the biopolymer and the ligand is also necessary to ensure binding. Finally, matching of nonpolar regions is required; this is a manifestation of the hydrophobic effect.

In this paper we propose a simple model which accounts for geometric, electrostatic, as well as hydrophobic complementarity. While the geometric requirement is considered conventionally, electrostatic and hydrophobic matching is studied in terms of the molecular electrostatic potential and field, respectively. The model is qualitative and certainly does not compete with up-to-date sophisticated numerical calculations which should, in principle, substitute experimental data. Rather, it is developed to analyze ligand binding in general, e.g., to recognize those fragments of the interacting molecules which are necessary for binding. Since numerical calculations yield figures which are often difficult to use for such analyses important trends may be overlooked. Ideally, the two types of approaches should complement each other: working hypotheses offered by the qualitative model could be checked numerically. In the next section we describe the model and later we illustrate its use on the inhibition of dihydrofolate reductase (DHFR) by methotrexate (MTX **1**).

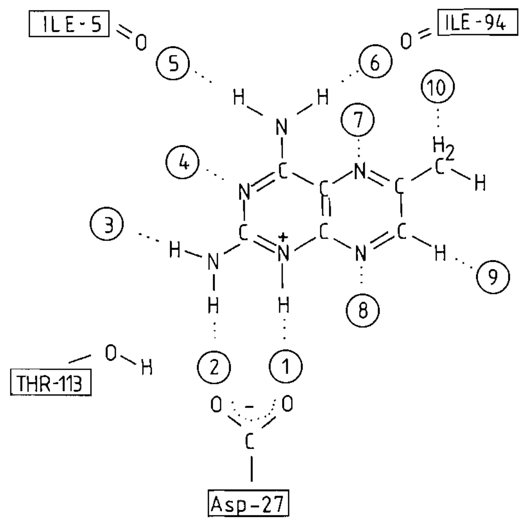

FIG. 1. Fragment A of MTX for calculation of atomic charges. Reference points, as defined in the text, are indicated by numbers in circles.

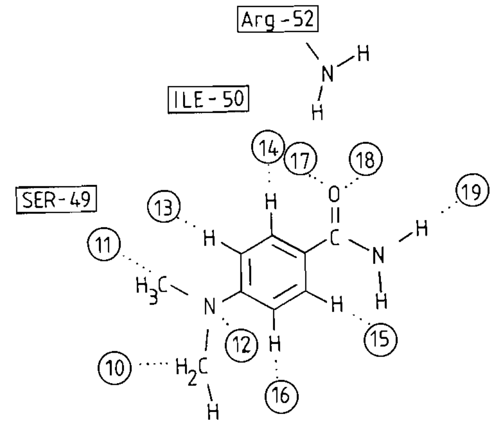

FIG. 2. The same as in Fig. 1 for fragment B of MTX.

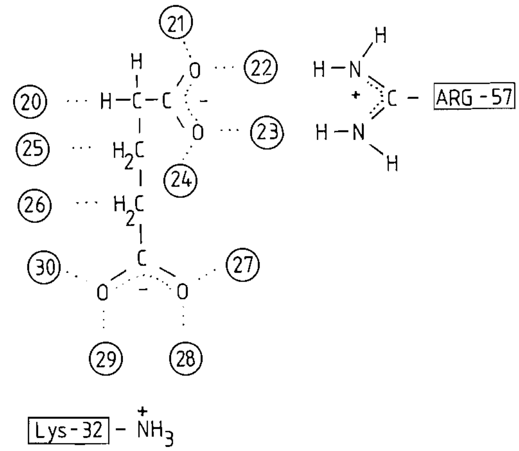

FIG. 3. The same as in Fig. 1 for fragment C of MTX.

Model and method

In this paper we model keys in two different ways. The "charge key" is simply the atomic charge pattern of the molecule which can be obtained from some quantum chemical, e.g. CNDO/2, calculations. A complementarity between the electrostatic lock and the charge key means that the approximate value of the interaction energy,

$$[1] \quad E_{\text{int}} = \sum_a V(\boldsymbol{r}_a)q_a$$

where $V_m(\boldsymbol{r}_a)$ is the electrostatic potential of the biomacromolecule at atom a bearing a net charge of q_a, is negative indicating binding (5). On the other hand, the definition of the "potential key" is based on a model by Douglas and Kollman (8) where the electrostatic potentials of the interacting systems at given reference points are used to estimate binding energies.

To study the matching of hydrophobic regions we use the "field lock" determined by the electrostatic field map of the enzyme. At a given site the molecular electrostatic field orients and interacts with point dipoles, modeling water molecules. The stronger the interaction the larger is the absolute value of the electrostatic field (9); thus hydrophobic regions around a molecule are indicated by small fields. Hydrophobic complementarity means matching of small field regions.

To determine the electrostatic lock of DHFR from *Escherichia coli* we considered all enzyme atoms. Coordinates were taken from the Protein Data Bank (10, 11). Because of the shielding effect of counter ions (12) we considered all surface side chains unionized. On the other hand, side chains of Asp-27, Lys-32, and Arg-57, located in the vicinity of the ionized inhibitor, were treated as charged (see, e.g., ref. 13).

We calculated the electrostatic potential of DHFR and MTX from bond contributions (14). This allows us to treat very large molecules with several thousands of atoms since, due to the approximate transferability of bond orbitals and neglect of non-orthogonality terms the computational work increases only linearly with the number of bonds. This is an advantage over empirical force field methods which are restricted to systems with at most 500 atoms (15). Further details of the calculation are given elsewhere (5, 12). Atomic point charges were calculated by the CNDO/2 method (16). Schematic arrangement of reference points for the potential key is depicted in Figs. 1−3. The distance of the reference points from the neighbouring atoms is 100 pm and the orientation is trigonal or tetrahedral, corresponding to hybridization. For C—H bonds chemically plausible orientations are considered and reference points lie 150 pm or 180 pm from the hydrogen or carbon atom, respectively. In some cases reference points may get too close to a neighbouring enzyme atom, thus a slight correction was necessary (cf. Table 1).

Results and discussion

The electrostatic potential lock for DHFR from *Escherichia coli* and the fit with the charge key of MTX is illustrated in Figs. 4−6. Fitting the potential lock with the potential key is seen in Figs. 7 and 8. Inspection of Figs. 4 and 7 indicates that most atoms of the pyrazine part in MTX (C6, C7, and N8 in Fig. 4, reference points 8 and 9 in Fig. 7) fit badly in the DHFR lock. This is in accord with the experience that the principal structural characteristics necessary for binding to DHFR is a 2,4-diaminopyrimidine or an *s*-triazine structure (3, 4, 13, 17−19). The unfavourable binding of the pyrazine moiety is also seen from the electrostatic interaction energies calculated from eq. [1]. E_{int} is −117 kJ/mol and +23 kJ/mol for the 2,4-diaminopyrimidine and pyrazine fragments, respectively. Another strongly binding region of MTX is the α-carboxyl group of glutamate (CT, O1, and O2 in Fig. 6, reference points

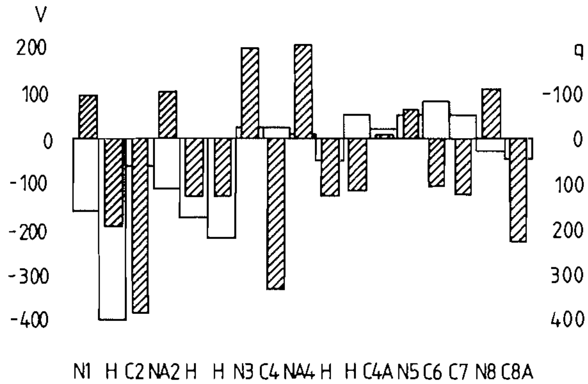

FIG. 4. Electrostatic potential lock of DHFR (open bars) and charge key of the MTX A fragment, Fig. 1 (hatched bars). Hydrogen atoms of C—H bonds are omitted. The V electrostatic potential is given in kJ/mol the q charge in millielectrons.

21, 22, 23, and 24 in Fig. 8). Ion-pair interaction (and hydrogen bonding) with the side chain of Arg-57 is very strong here. On the other hand, the terminal carboxyl of glutamate (CD, OE1, and OE2 in Fig. 6 and reference points 27, 28, 29, and 30 in Fig. 8) feels a much weaker attraction by the charged Lys-32 side chain. The OE1 . . . NZ(Lys-32) distance is as large as 627 pm. Elongation of the glutamate side chain by one or two methylene units should improve the fit between the lock and the key, thus enhancing the interaction between the enzyme and its inhibitor.

Figures 4–6 and 7 and 8 allow one to compare predictive (and illustrative) powers of the charge key and potential key concepts outlined in the Model and method section. The potential key is more illustrative. In fact, charge alternation (e.g. for atoms of a N—H bond) renders difficult to recognize good fits between the potential lock and its charge key. On the other hand, the possibility to estimate binding energy increments of certain molecular fragments is an attractive feature of the charge key concept.

Field locks are depicted in Figs. 9 and 10. Good fits are observed for the 2,4-diaminopyrimidine region (reference points 1–6) and for the α-carboxylate group (reference points 22 and 23). Here the strong field of the inhibitor finds its counterpart in the enzyme active site. This is completed by matching the potential lock and its key, with the formation of ion pairs or hydrogen bonds (cf. Figs. 1–3 and footnotes to Table 1). The complementarity of strong field regions indicate that favourable hydration has to be overbalanced by the attractive interaction between matching groups. This is indeed the

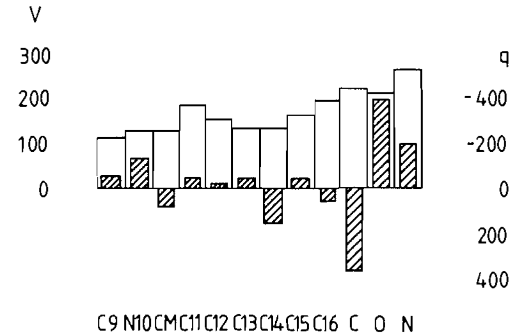

FIG. 5. The same as in Fig. 4 for the MTX B fragment (Fig. 2).

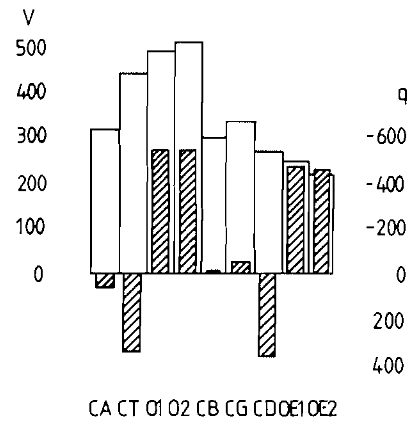

FIG. 6. The same as in Fig. 4 for the MTX C fragment (Fig. 3).

FIG. 7. Electrostatic potential lock of DHFR (open bars) and potential key of MTX (hatched bars) for reference points 1–19 (Figs. 1, 2). The V electrostatic potential is given in kJ/mol.

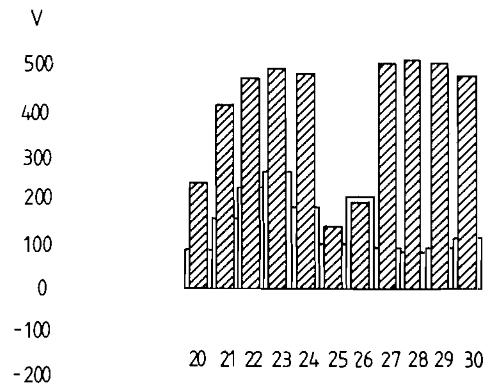

FIG. 8. The same as in Fig. 7 for reference points 20−30 (Fig. 3).

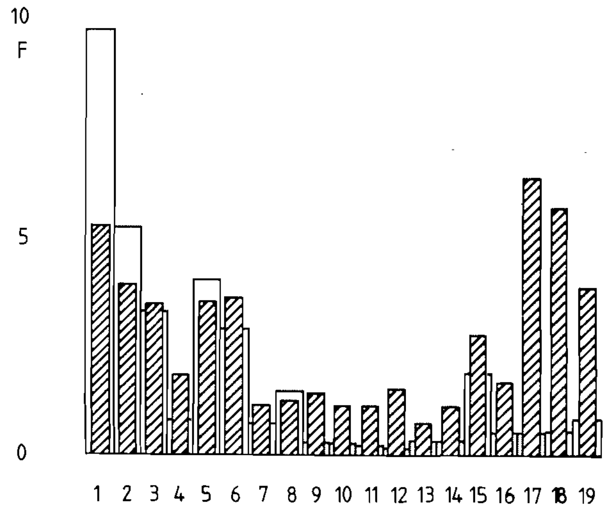

FIG. 9. Electrostatic field lock of DHFR (open bars) and field key of MTX (hatched bars) for reference points 1−19 (Figs. 1, 2). The F electrostatic field is given in V/nm.

case as indicated by the good fit of the potential key into its lock (Figs. 7 and 8).

Weak field regions ($F < 1.5$ V/nm) around the alkyl groups and the phenyl ring (reference points 9−11, 13, 14, 16, 20, and 25) match with the enzyme field lock, indicating that hydrophobic regions of the inhibitor are recognized by DHFR. The fit is bad for the amide region (reference points 17−19) and for the terminal carboxylate group of glutamate (reference points 28 and 29) where a small enzyme field finds a strong inhibitor field as counterpart. In both cases the bad fit is due to unfavourably large distances between atoms of a hydrogen (or ion-pair) bond. For the amide group the NH1(Arg-52) . . . O distance (356 pm) is large compared to the typical value (280 pm). As we have mentioned above the NZ(Lys-32) . . . OG1 distance is too large even for an ion-pair bond. Though both amide and terminal carboxylate groups contribute to the bonding of the inhibitor (cf. Figs 7 and 8) their favourable hydration is not balanced by the attraction between potentially matching regions of MTX and DHFR.

It is a bit astonishing that for reference point 15 of MTX both potential and field values are larger than expected for a hydrophobic group (cf. Figs. 7 and 9). This is due to the through-space electrostatic effect of the distant carboxylate group (cf. ref. 20). The same effect enhances the field in reference point 16. Interestingly, in spite of large distances from enzyme

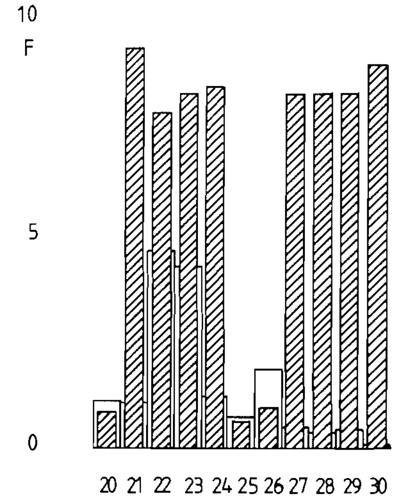

FIG. 10. The same as in Fig. 9 for reference points 20−30 (Fig. 3).

groups capable to form ion-pair or hydrogen bonds, the DHFR lock potential and field is relatively large at reference point 15, thus ensuring a good fit.

Conclusions

(*1*) Recognition of a ligand (key) by a biomacromolecule (lock) requires geometric fit and a complementarity between electrostatic potential and field patterns of the lock and its key. Matching potential patterns corresponds to optimal electrostatic interaction while an optimal field pattern fit should minimize unfavourable hydrophobic effects upon association of the biomacromolecule with the ligand.

(*2*) A simple way to define the electrostatic lock and its key is to calculate the potential and field at some characteristic reference points around the biomacromolecule and its ligand. In our case the quoted electrostatic potentials were calculated by an additive scheme using bond fragments.

(*3*) Applying the above principles to the dihydrofolate reductase−methotrexate complex it was found that the 2,4-diaminopyrimidine and α-carboxylate parts of the inhibitor are mainly responsible for binding to the enzyme. Furthermore, elongation of the glutamate side chain by one or two methylene units would improve the electrostatic fit, i.e. make binding stronger.

This paper is dedicated to Professor Camille Sandorfy on the occasion of his 65th birthday

PAUL DUPUIS and M. A. EL-SAYED. Can. J. Chem. **63**, 1699 (1985).

It is observed that the number of protons pumped per M_{412} formed in the bacteriorhodopsin photocycle almost doubles at high salt concentrations. In this paper, we studied the rates of deprotonation of tyrosine and of the two components of the protonated Schiff base at high salt concentrations, and at different pHs and temperatures. It is found that at pH = 7, increasing the salt concentration decreases the rates of deprotonation of the protonated Schiff base and tyrosine. This strongly suggests that the observed gain in the quantum yield of proton release per M_{412} formed when the salt concentration is increased is not a result of an increase in these rates. However, at high pH, e.g. 9.6, increasing the salt concentration increases the rate of deprotonation of the Schiff base by about 50%. Under all conditions, the slow component of the Schiff base is found to lose its proton prior to tyrosine.

PAUL DUPUIS et M. A. EL-SAYED. Can. J. Chem. **63**, 1699 (1985).

À de fortes concentrations en sel, le nombre de protons pompés pour chaque M_{412} formé au cours du photocycle de la bactériorhodopsine est pratiquement doublé. Dans cette publication, nous rapportons les résultats d'une étude, à des fortes concentrations en sel, à divers pH et à diverses températures, sur les vitesses de déprotonation de la tyrosine et des deux composantes de la base de Schiff protonée. On a trouvé qu'à un pH de 7 l'augmentation de la concentration en sel diminue les vitesses de déprotonation de la base de Schiff protonée et de la tyrosine. Ceci suggère fortement que l'augmentation observée du rendement quantique des protons libérés pour chaque M_{412} formé lorsqu'on augmente la concentration du sel n'est pas dû à une augmentation de ces vitesses. Cependant, si on opère à un pH d'environ 9,6 et que l'on augmente la concentration du sel, on provoque aussi une augmentation de la vitesse de déprotonation de la base de Schiff de l'ordre de 50%. On a trouvé que, quelles que soient les conditions, la composante lente de la base de Schiff perd son proton avant la tyrosine.

Introduction

Bacteriorhodopsin (bR), the only protein in the purple membrane of *Halobacterium Halobium*, contains one molecule of retinal covalently bound to the ϵ-amino group of a lysine residue via a protonated Schiff base (1, 2). When it absorbs light, it undergoes a photochemical cycle (3) with at least four intermediates appearing and decaying in a time scale that varies from picoseconds to milliseconds:

$$bR_{570} \rightarrow K_{610} \rightarrow L_{550} \rightarrow M_{412} \rightarrow O_{640} \rightarrow bR_{570}$$

During this cycle, protons are pumped from the inside to the outside of the cell, resulting in a pH gradient across the cell membrane. This proton gradient drives some metabolic processes such as ATP synthesis (4–9). The exact mechanism of the proton pump remains unclear. However, protons are ejected from the cell on a time scale comparable to the L_{550} to M_{412} transformation (10, 11). A good correlation has been found between the number of protons pumped by the purple membrane and the amount of the slow decaying form of M_{412} (12).

M_{412} is unique, as it is the only intermediate whose Schiff base is unprotonated, while the parent pigment and all the other intermediates are protonated (4, 13–17). Some studies have inferred that the Schiff base deprotonation is closely associated with the proton pump mechanism (18, 19) and the effect of chemically modified tyrosines on the rate of decay of M_{412} suggests a coupling between some tyrosines and M_{412} (20–24).

Recently, the kinetics of formation of both the tyrosinate ion absorption at 296 nm and the deprotonated Schiff base (M_{412}) absorption were studied simultaneously as a function of pH and temperature (25). The results show two formation rates for M_{412}, in agreement with previous observations (11, 18). The slow one is dominant under physiological conditions and is found to be slightly faster than that for the tyrosinate formation (25). This is in disagreement with the proposal that the tyrosinate formation is a prerequisite to the deprotonation of the Schiff base (18, 19). Furthermore, the ratio of the amplitudes of the fast and slow components of the M_{412} formation is found to be very sensitive to pH and, at any pH, can be used (25) to calculate a pK_A value of about 9.6. This is explained by having two different sites for the protonated Schiff base within the protein. In one site, the Schiff base is near an amino acid with a pK_A of 9.6, e.g. tyrosine, but lysine is also a possibility. This gives rise to the slow M_{412} component. In the second site, the Schiff base is near the conjugate base of the amino acid. This gives rise to the fast M_{412} component. The formations of the slow and fast components of M_{412} as well as that of the tyrosinate ion all have activation energies that are comparable to H-bond energies (25). These studies were performed on suspensions of bR in water; the pH was adjusted with phosphate buffers.

According to experiments on purple membrane sheets, the quantum yield of proton release depends on the medium. As salt concentrations increase, the quantum yield of M_{412} remains the same but the H^+/M_{412} ratio goes from 1 to >2 (26, 27). The purpose of this work is to carry out experiments similar to those of ref. 25, this time varying the salt concentration of the external medium to see how the formation rates and the relative amplitudes of the two M_{412} components, as well as those for the tyrosinate ion, are affected. We want to determine if the variation in any of these parameters can account for the change in the quantum yield of proton release.

At pH = 7.0, in a 0.5 *M* KCl solution, the rate constants and the relative amplitudes of the two M_{412} components are found

---

[1] Author to whom correspondence may be addressed.

to be the same as in a low salt solution. In a basal salt solution, the rate constants are smaller than in a low salt medium at pH = 7. The same observations are made for the tyrosine deprotonation. These results strongly indicate that the doubling of proton release per M_{412} formed is not a consequence of the change in the kinetics of deprotonation of the Schiff base or tyrosine at physiological pH. In salt solutions, however, as the pH increases, the sum of the weighted average values of the rate constants for the two M_{412} components increases. This is a result of a more rapid increase in the relative amplitude of the fast component, with pH, in the presence of high salt concentrations.

Experimental

Master slants of the ET1-001 strain of H. Halobium were provided by Dr. R. A. Bogomolni and Dr. W. Stoeckenius. The procedure for the growth and purification of the purple membrane was a combination of those outlined by Oesterhelt and Stoeckenius (28) and Becher and Cassim (29).

The experimental setup used to monitor the uv and visible absorption changes in bR is the same as the one used in ref. 25. Briefly, the monitoring wavelengths of 297 nm (for the tyrosinate ion) and 405 nmr (for M_{412}) were provided by the collimated output of a 1000-W Xe/Hg lamp (Canrad Hanovia, Newark, NJ) which was passed through a 5-cm water filter and focused onto the entrance slit of a 0.25-m monochromator (Jarrell–Ash, Waltham, MA) by a quartz lens. The light from the exit slit was passed through a 0.3 optical neutral density filter acting as a beam splitter, allowing 30% of the light to enter a reference RCA 1P28A photomultiplier tube while the remaining light was focused onto a 0.5 × 1.0 cm jacketed water-cooled quartz cell (Precision Cells, Hicksville, NY). The transmitted light was passed through a Corning 7-54 or 7-59 visible cutoff filter (Corning Glassworks, Corning, NY) and collected by the photocathode of the sampling RCA 1P28A phototube. The output of a differential oscilloscope displaying the transient absorbance was connected to a Biomation 805 Waveform Recorder which was interfaced to an Apple II computer. This computer was used to signal average the data and store it on magnetic floppy discs. For the tyrosinate signal, 512 scans were averaged while the M_{412} signal required only 128 scans. The data was then sent to a VAX computer and analysed and plotted via a special computer program.

Photolysis of the sample was accomplished with a focused 6-ns, 532-nm beam obtained from the frequency doubled output of a Nd:YAG laser (Quanta-Ray, Mountainview, CA), at a repetition rate of 10 Hz. Care was taken to insure that the photolysis beam overlapped with the probe beam so that the whole volume would be photolysed. Photolysis powers were kept at 50 mW by attentuating the laser beam with a 045 Corning filter.

For both the temperature and pH studies, the concentration of bR was approximately 1.6×10^{-5} M, assuming an extinction coefficient of 63000 M^{-1} cm^{-1} at 570 nm. The temperature was kept constant by using a temperature controlled cell connected to a water bath circulator and was monitored using a Markson pH/Temp meter. The bR was susepended in water containing 0.5 M KCl or in water containing most of the salts present when the bacteria are grown (NaCl, 4.3 M; KCl, 2.7×10^{-2} M; $CaCl_2$, 1.8×10^{-3} M). In addition, for the pH studies, the suspensions contained 0.1 M KH_2PO_4 buffers which were adjusted to the desired pH by addition of 0.2 M NaOH. The pHs of all suspensions were checked prior to the experiment.

Laser photolysis experiments were carried out for bR_{570} suspensions over the range $7.0 \leq pH \leq 10.0$ at 22°C. The temperature studies were conducted in the range 5.0–25°C by 5° increments. In all cases, identical conditions were maintained with respect to the bR concentration and laser pulse intensity.

Results and discussion

The present studies were done on bR suspensions in two different media: a medium containing KCl, 0.5 M, and a medium similar to the "basal salt" solution in which the bacterium grows: NaCl, 4.3 M; KCl, 2.7×10^{-2} M; $CaCl_2$, 1.8×10^{-3} M. $MgSO_4$ was not used because of the precipitate formed upon the addition of NaOH to change the pHs. In both of these solutions the quantum yield of proton release per M_{412} formed is approximately twice what it is in a medium having a very low salt concentration (26, 27). All the results will be discussed in comparison to the data obtained for bR suspensions in water, without any salt added besides the buffers (25).

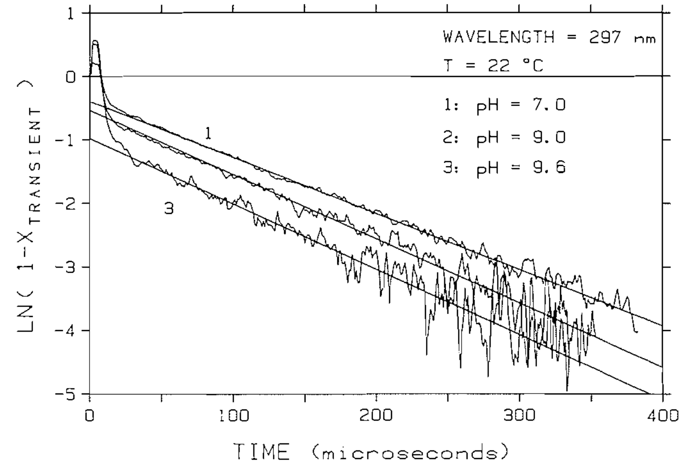

FIG. 1. A plot of ln $(1 - X_t)$ versus time for the absorbance change at 297 nm at pH = 7.0, 9.0, and 9.6 (bR suspensions in 0.5 M KCl). The fast component corresponds to changes in absorption of the retinal chromophore. The positive spike at $t = 0$ is caused by the scattering of the incident laser beam which was not totally filtered out.

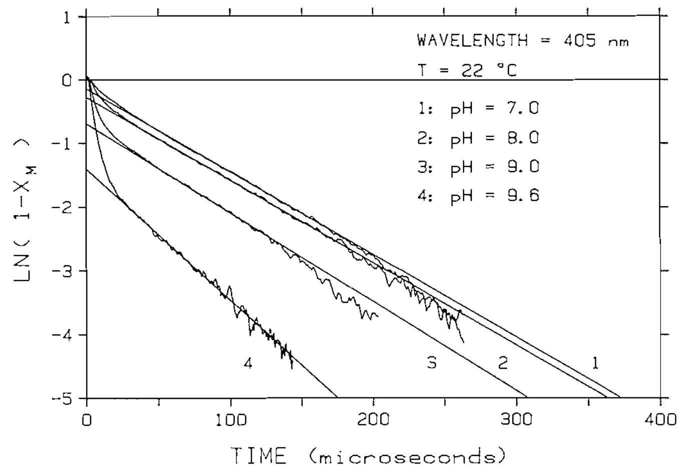

FIG. 2. A plot of ln $(1 - X_M)$ versus time for M_{412} at pH = 7.0, 8.0, 9.0, and 9.6 (bR suspensions in 0.5 M KCl). Note that the amplitude of the fast component becomes more important as the pH increases.

A. *Deprotonation kinetics of the Schiff base and tyrosine*

1. *In a 0.5* M *KCl solution*

Both the M_{412} and tyrosinate absorptions were normalized to the maximum absorbance change observed at 405 and 297 nm respectively. The normalized absorption of the transient is assumed to be proportional to its mole fraction, X_t, at time t, and $1 - X_t$ is the mole fraction of the precursor (L_{550} for M_{412} and tyrosine for tyrosinate).

Figures 1 and 2 show semilogarithmic plots (ln $(1 - X_t)$ vs. time) for the tyrosinate and M_{412} formations, respectively, at

different pHs. These plots, as expected, are very similar to those for bR suspensions in water without KCl (25). Both figures show the presence of two components.

In the case of the absorbance change monitored at 297 nm (Fig. 1), the very fast component corresponds to changes in the retinal absorption, which is also observed at this wavelength (30). The positive spike at $t = 0$ is caused by scattering from the laser beam which could not be completely filtered out. The slower component corresponds to the tyrosinate absorbance (30, 31). M_{412} shows a biphasic formation and the intensities of the slow and fast components depend on the pH of the external medium (Fig. 2). The corresponding change in the tyrosinate plot can be attributed to the fact that, as the pH increases, equilibrium favors the tyrosinate form, and there are fewer tyrosines that can deprotonate during the photocycle.

Table 1 shows the rate constant values for the formation of M_{412} ($k_{M\,fast}$ and $k_{M\,slow}$) and of the tyrosinate ion (k_{tyr}). For the sake of comparison, Table 2 shows the same rate constants for the experiment performed on suspensions of bR in low salt solutions (buffers present) (25).

In both sets of experiments, the pH was increased up to the point where we were unable to accurately determine the slow M_{412} component or the tyrosinate formation. In 0.5 *M* KCl, at pH > 9.8, the amplitude of the slow M_{412} component was too small to determine its rate constant, and for the tyrosinate ion, at pH > 9.8, most of the absorbance change at 297 nm was caused by the retinal absorption. In the low salt solutions, the experiment could be done up to pH = 10.6.

The first observation that can be made is that whether KCl is present or not, both components of the M_{412} generation process are still faster than the tyrosinate formation. Secondly, at the same pH, the amplitude of the fast M_{412} component increases as the KCl concentration increases. Finally, at pH < 9.4, all rate constants are about the same in both sets of experiments but, at pH ≥ 9.4, the rate constants for the slow M_{412} component are larger when KCl is present in the external medium. However, at pH ≥ 9.4, the amplitude of the fast component becomes more and more important and it is more and more difficult to resolve the pure slow component. This apparent increase in the rate constant of the slow component should be taken as an indication of the importance of the fast component rather than as representative of a major change in the real value of the constant itself.

We have previously discussed the Schiff base deprotonation in the following manner (25). It is proposed that two sites for the protonated Schiff base exist within the protein. In one site, the Schiff base is located near an amino acid (AH) with a pK_A of 9.6 and, in the other, it is located near the conjugate base (A^-). This describes the two different rise times for M_{412} as follows:

a. $L_{550}\,[=\overset{+}{N}H,\ AH] \rightarrow M_{412}$ slow

b. $L_{550}\,[=\overset{+}{N}H,\ A^-] \rightarrow M_{412}$ fast

One would then expect the time dependence of the M_{412} absorption to be given by:

$$[1]\quad \ln\,(1 - X_M) = \ln\,[C_1 \exp\,(-k_A t) + C_2 \exp\,(-k_{AH} t)]$$

This assumes: (a) two different independent chromophore populations, (b) the rate of $AH \rightleftharpoons A^- + H^+$ equilibration is slow compared to the rate of formation of L_{550} and M_{412}, and (c) M_{412} has the same absorption coefficient in the two sites. Obviously, the relative amplitudes (C_1, C_2) of the two components will depend on the pH. In Fig. 2, one observes that the contribution of the amplitude of the fast component of the generation process becomes greater as the pH of the external medium increases.

If this idea is valid, then the dissociation constant of the amino acid group could be determined from the rise curve of M_{412} (25).

The dissociation constant for the amino acid side chain is given by:

$$K_A = [H^+]\,[A^-]/[AH]$$

This results in the following equations (25):

$$[2]\quad pK_A = pH - \log\,[A^-]/[AH] = pH - \log C_1/C_2$$

where C_1 and C_2 are the constants given in eq. [1] corresponding to the concentrations or mole fractions of the chromophore near the deprotonated form (A^-) and the protonated form (AH) of the amino acid group. If tyrosine is assumed to be that titratable amino acid group, then C_1 and C_2 are the concentrations of the chromophore near the tyrosinate ion and tyrosine respectively. C_1 and C_2 can be determined from extrapolation at time $t = 0$ of the semilogarithmic plots of Fig. 2.

For the experiments performed in water without addition of salt, such a calculation yielded a value of about 9.6 (25) for the

pK_A of the amino acid controlling the formation of M_{412} (Table 2). This value is not very different from the pK_A of tyrosine.

For the medium containing KCl, at any given pH, the amplitude of the fast M_{412} component is more important than in a low salt solution. We expect the pK_A value calculated from eq. [2] to be smaller than those of Table 2. Indeed, Table 1 shows that eq. [2] yields a pK_A value around 8.9.

This is an unexpected result. It could be interpreted in two different ways: either another amino acid is controlling the appearance of M_{412} or something happened to tyrosine (or lysine) so that its pK_A is much lower in presence of KCl. The former possibility should be eliminated because the only amino acid with a pK_A remotely close to 8.9 is cysteine ($pK_A = 8.33$) and there is no cysteine in bacteriorhodopsin (32). Then how do we explain the decrease in pK_A of tyrosine? When the concentration of salt gets to be as high as 0.5 *M*, the ionic strength is not negligible and we have to take it into consideration when we calculate the pK_A of tyrosine. In eq. [2], we have used the absorbance change at 405 nm to estimate the concentrations of the fast and slow M_{412} components. Absorbance under these conditions of bR concentrations follows closely the Beer–Lambert equation and is directly proportional to the concentrations of M_{412}. But in our calculation for the pK_A of tyrosine we should use activities instead of concentrations. By using a pH meter for our pH measurements, we immediately get the activity of H^+. The activity coefficient of tyrosine should be close to 1 since it is a neutral species, but the activity coefficient of the tyrosinate ion depends on the ionic strength. For KCl, 0.5 *M*, the activity coefficient is 0.649 (33). The use of the Davies equation, as an alternate method to evaluate $\gamma_\pm$, yields a value of 0.750 when we take into account the ionic strength caused by KCl and the buffers.

We rewrite eq. [2] with the activity coefficient of the tyrosinate ion:

$$[3] \quad pK_A = pH - \log (C_1/C_2) - \log \gamma_{tyr^-}$$

We should subtract the value of $\log \gamma_{tyr^-}$ from the values calculated by eq. [2] to correct for the ionic strength of the solution. But, with the value of $\gamma_\pm$ found above (0.649), we can only increase the pK_A value to 9.0. In order to raise the pK_A value from 8.9 to 9.6, the activity coefficient of the tyrosinate ion should be around 0.2. Of course one has to be careful when using equilibrium constants and activity coefficients for a system such as bR, but it seems that we still need another explanation to account for the change in the pK_A of tyrosine.

This explanation is possibly found from the studies on deionized bR (34, 35). When the purple membrane is deionized on a cation exchange column or when it is washed first with >2 *N* NaCl followed by deionized water, its absorption maximum changes from 568 nm to about 600 nm. Elemental analysis shows that it contains no Ca^{2+} or Mg^{2+} ions while the native bR contains about 1 Ca^{2+} and 3 Mg^{2+} (35). Addition of salt to a suspension of the blue (deionized) membrane restores the 568 nm absorption maximum. What controls the change in absorption seems to be the cation, and any cation is capable of regenerating the purple color (34). However, when monovalent cations (e.g. K^+, Na^+, . . .) are used, subsequent dilution with deionized water reverses the effect, while Ca^{2+} or Mg^{2+}-restored purple membrane is not affected by dilution. Furthermore, a much higher concentration of K^+ or Na^+ is needed to obtain the purple color. This seems to indicate that Ca^{2+} or Mg^{2+} are tightly bound to the protein while monovalent cations are not. To change the absorption maximum of the retinal chromophore, the cations have to be in close proximity to it. These cations close to the chromophore may also be close to the tyrosine controlling the appearance of M_{412}. At low salt concentration (e.g. for bR suspensions in deionized water), the only cations close to the chromophore should be the tightly bound Ca^{2+} and Mg^{2+} ions. But in KCl, 0.5 *M* (or in a basal salt solution), some monovalent cations should also be near the chromophore and the presence of these additional positive charges might account for the lower pK_A calculated for tyrosine under these conditions.

TABLE 3. The values of $k_{M\,fast}$ and $k_{M\,slow}$ for M_{412} formation and k_{tyr} for tyrosinate formation obtained at each pH for bR suspended in a basal salt solution. $T = 22°C$

pH	$k_{M\,fast}$ ($10^4\ s^{-1}$)	$k_{M\,slow}$ ($10^4\ s^{-1}$)	k_{tyr} ($10^4\ s^{-1}$)	pK_A

9.6	18 ± 3 (0.85)	1.8 ± 0.2 (0.15)	0.82 ± 0.09	8.8

2. *In basal salt solution*

Table 3 shows the rate constants for the formation of M_{412} and the tyrosinate ion for the bR suspensions in a basal salt solution. When compared to the values of Table 1, all rate constants are smaller. It is clear that the rate constants are affected by the basal salt medium, but still the tyrosinate formation is slower than both components of the M_{412} appearance. There is no easy explanation for the slowing down of the rate constants, but it is interesting to note that vesicles loaded with and suspended in NaCl develop approximately twice the transmembrane electric potential found if KCl is present (36). So this change in the rate constants may have to do with the nature of the salts themselves.

The pK_A value of tyrosine calculated from eq. [2] is around 8.6. This value is lower than that determined in low salt or KCl solutions. This might be due to the presence of a much higher concentration of cations in the solution.

B. *Temperature studies*

1. *In KCl, 0.5* M

Table 4 shows the values for the different rate constants as a function of temperature. It also gives the corresponding activation energies. For the same experiment done in deionized water, the values were the following (25):

$$E_A(M_{412\,fast}) = 42 \pm 3 \text{ kJ/mol}$$

$$E_A(M_{412\,slow}) = 47 \pm 3 \text{ kJ/mol}$$

$$E_A(tyr^-) = 39 \pm \text{ kJ/mol}$$

Within experimental error, all these activation energies are the same whether KCl is present in the solution or not. In light of this fact, the difference in quantum yield of proton release in both mediums does not seem to have anything to do with the activation energy for the formation of M_{412}, in agreement with the small sensitivity of the rate constants to the presence of

TABLE 4. The values of $k_{M\,fast}$ and $k_{M\,slow}$ for M_{412} formation and k_{tyr} for tyrosinate formation obtained at each temperature for a bR suspension in a medium containing 0.5 *M* KCl. The activation energy of each transient at different pHs is also given

pH = 9.0	38 ± 2	58 ± 1	45 ± 1

KCl.

We checked if increasing the pH has any effect on the activation energies. As can be seen in Table 4, all activation energies increase with increasing pH.

2. *In basal salt solution*

Table 5 gives the same information as Table 4, but for the basal salt medium. The activation energies for the slow M_{412} component and the tyrosinate ion are about the same as before. On the other hand, the fast M_{412} component has a lower activation energy than in the previous experiments. This decrease in activation energy is surprising. However, the rate constant of the fast M_{412} is the most affected by the basal salt solution; then it is not unexpected that the resulting activation energy will be more affected than the others. Since the quantum yield of proton release is the same in KCl, 0.5 *M*, and in a basal salt solution (27), once again the major change in activation energy of the fast M_{412} component does not appear to be directly correlated to the proton pumping mechanism.

A study of the variation of the activation energy as a function of pH shows that the activation energies increase with increasing pH, as was the case for the KCl solution.

Conclusions

Bacteriorhodopsin suspensions in three different media were studied. Two media contained the high salt concentration for which it is reported that 2 protons are pumped per M_{412} formed. When compared to the results for a lower salt concentration, some differences are observed, but nothing that really seems to account for the differences in the quantum yield of proton release. The following are the important observations.

1. In all solutions studied, the M_{412} formation is faster than the tyrosinate ion formation; also, the rate of deprotonation for tyrosine is found to be the same or slightly smaller in the presence of salts. Therefore, the change in the quantum yield of proton release cannot be correlated to changes in the rate of deprotonation of tyrosine.

2. At pH = 7.0, the total rate of deprotonation from the slow and the fast components is 2.6×10^4 s^{-1}, 2.0×10^4 s^{-1}, and 2.9×10^4 s^{-1} in KCl, basal salt, and low salt solutions respectively. It shows that the salt does not increase the overall rate of deprotonation for the protonated Schiff base at physiological pH.

3. The total rate of deprotonation for the protonated Schiff base can be calculated from Table 2 for low salt solutions. At pH = 7.0, this rate is 2.9×10^4 s^{-1} while at pH = 9.6, it is 10.5×10^4 s^{-1}. This shows that the rate increases as the pH increases. This behavior is opposite to the observed efficiency of proton pumping, which is better at lower pH (12, 37). Again, this argues against any correlation between the quantum efficiency of pumping and the kinetics of deprotonation of the protonated Schiff base.

4. At pH = 9.6, the total rate of deprotonation is *larger* in a salty solution than in a low salt solution. This rate is 15.3×10^4 s^{-1}, 15.6×10^4 s^{-1}, and 10.6×10^4 s^{-1} in KCl, basal salt, and low salt solutions respectively. This shows that the addition of salt increases the rate of deprotonation by about 50% at pH = 9.6, while it decreases at pH = 7.0.

5. At pH = 7.0, the relative amplitudes of the slow M_{412} component are 0.88, 0.81, and 0.88 in KCl, basal salt, and low salt solutions respectively. The rate constants for this component are 1.3×10^4 s^{-1}, 1.0×10^4 s^{-1}, and 1.3×10^4 s^{-1} in the same solutions. These results show that the slow component does not change in kinetic behavior, again suggesting that these rate parameters do not account for the increase in the proton pumping yield.

6. The pK_A value for the amino acid which is proposed to be responsible for the two M_{412} components (25) is found to have a much lower value in salty solutions than in low salt solutions. This is explained in part by the effect of the ionic strength of the solutions, but mostly by the probable presence of some cations near the retinal chromophore.

7. The relative amplitude of the fast component increases in the presence of salt. Since the proton pump is more efficient at low pHs (12, 37) and since the slow forming M_{412} is dominant at low pH, the increase in the fast M_{412} component observed as the salt concentration increases can hardly account for the change in the number of protons pumped per M_{412} formed.

8. In the absence of buffers, all activation energies in the three media seem to be about the same except for the fast M_{412} component in the basal salt solution. In this case the activation energy decreased significantly. Once again, this does not seem to greatly affect the proton pumping efficiency.

9. The fact that the salt does not increase the rate of deprotonation of the protonated Schiff base and tyrosine at pH = 7, but increases the yield of proton pumping, might lead to one or both of the following conclusions: (a) a fraction of the protons pumped out of the cell comes from acids that are not being monitored by our probes, or (b) the salt affects the rate of proton transport *after* the deprotonation of the protonated Schiff base and tyrosine. The latter could result from a change in the electrochemical potential or the structure of the part of the membrane involved in the proton pumping process.

10. The activation energies increase as a function of pH. This might account for part of the decrease in proton pumping efficiency as the pH increases.

11. A comparison is now made between the results we obtained for the M_{412} formation in a basal salt solution with the results for its decay in a similar medium (12). For both the decay and the rise of M_{412}, the amplitudes of the slow and fast components are equal at a pH of about 8.5, but at pH = 7.0 the fast component of the decay is more important than the fast component of the formation. Also, at constant pH, for the formation of M_{412}, we do not observe a radical change in the amplitudes of both components as a function of temperature. In the decay, at temperatures higher than 25°C, the fast component becomes more important than the slow component. There is no clear correlation between the two components of each process. However, one should remember that the amplitudes of the two components determined from the rise time give the relative amount of the L_{550} intermediate in the two sites. In the decay, the amplitudes of the fast and slow decaying components give the relative amounts of the M_{412} intermediates in the two sites. During the L_{550} to M_{412} transformation, other processes (25), e.g. $AH \rightleftharpoons A^- + H^+$ equilibration, salt movements, and protein conformational changes, could have taken place to change both the nature and the relative concentrations of the two sites.

Received July 27, 1984

This paper is dedicated to Professor Camille Sandorfy on the occasion of his 65th birthday

U. P. AGARWAL, A. J. BARNES, and W. J. ORVILLE-THOMAS. Can. J. Chem. **63**, 1705 (1985).

Infrared spectra are reported of mixtures of hydrogen sulphide with chlorine or bromine in low-temperature argon or nitrogen matrices. The $H_2S \ldots Cl_2$ and $H_2S \ldots Br_2$ complexes were identified from the perturbed halogen stretching vibration. Absorptions due to the corresponding hydrogen halides provided evidence that reaction was occurring between the hydrogen sulphide and halogen (despite the use of a twin-jet deposition), and other reaction products were tentatively identified from the observed absorptions.

U. P. AGARWAL, A. J. BARNES et W. J. ORVILLE-THOMAS. Can. J. Chem. **63**, 1705 (1985).

Opérant à basses températures et dans des matrices d'argon ou d'azote, on a déterminé les spectres infrarouges de mélanges de sulfure d'hydrogène avec du chlore ou du brome. On a identifié les complexes $H_2S \ldots Cl_2$ et $H_2S \ldots Br_2$ en se basant sur la perturbation de la vibration d'élongation de l'halogène. Des absorptions dues aux halogénures d'hydrogène correspondants suggèrent qu'il se produit une réaction entre le sulfure d'hydrogène et les halogènes (en dépit du fait que les produits ont été déposés à l'aide de deux jets séparés); en se basant sur les absorptions observées, on a pu identifier d'autres produits de réactions sur une base préliminaire.

Introduction

Charge transfer complexes have been extensively studied in liquid solutions using a variety of techniques. However, vibrational spectra obtained from such solutions may be due to 1:2, 2:1, or even larger complexes, rather than the simple 1:1 complex. Matrix isolation spectroscopy provides a method of studying 1:1 complexes free from interactions with other donor or acceptor molecules (1). The technique also enables the study of interactions between molecules which react together under normal conditions, providing information about the structure of the reaction intermediate.

A number of halogen complexes have been studied in low-temperature matrices by infrared and uv/visible absorption spectroscopies (2–9) and also by Raman spectroscopy (10). The systems studied include the water–halogen complexes (2, 4) but the corresponding hydrogen sulphide complexes have not previously been reported. Hydrogen sulphide is known to react with chlorine or bromine, leading to the formation of a number of products (11). It was thus of interest to investigate the interaction between hydrogen sulphide and halogens using matrix isolation spectroscopy. Mixtures of hydrogen sulphide with chlorine or bromine in matrices were found to exhibit similar behaviour, whereas mixtures of hydrogen sulphide with iodine gave complicated spectra arising from a variety of reaction products (with no evidence for the presence of an $H_2S \ldots I_2$ complex). The present paper is thus confined to the interaction of hydrogen sulphide with chlorine and bromine.

Experimental

Since chlorine or bromine reacts rapidly with hydrogen sulphide at room temperature in the gas phase, matrix samples were prepared by simultaneous deposition of twin jets of hydrogen sulphide/matrix gas and halogen/matrix gas mixtures onto a cold caesium iodide window. The window was maintained at ca. 15 K using an Air Products Displex closed-cycle refrigerator. Infrared spectra (3000–200 cm^{-1}) were recorded using a Perkin-Elmer 225 spectrophotometer.

Hydrogen sulphide (Matheson) was dried over P_2O_5 before use. Chlorine and bromine were each degassed under vacuum. The matrix gases used were high purity argon and nitrogen, which were further dried by being passed through a liquid nitrogen cold trap. The matrix and solute gases were mixed in the desired proportions using standard manometric techniques.

Results

A number of spectra were recorded of mixtures of hydrogen sulphide with chlorine or bromine in argon or nitrogen matrices with an overall matrix:solute ratio of ca. 100 and an hydrogen sulphide:halogen ratio of ca. 1:1 or 1:2. Typical spectra are illustrated in Figs. 1 and 2, and the absorptions observed are listed in Tables 1 and 2. Little variation was found between the various spectra recorded, with the exception of changes in the relative intensities of the hydrogen sulphide monomer, dimer, and multimer bands. These were readily identified by comparison with previous studies of hydrogen sulphide in argon and nitrogen matrices (12–14).

As an aid to identification of the hydrogen sulphide – halogen complex absorptions, spectra were also recorded of water–chlorine and dimethyl sulphide – chlorine mixtures in argon matrices. The water–chlorine complex gave an absorption at 535 and 525 cm^{-1} (with the intensity ratio, 3:2, expected for $^{35}Cl_2$:$^{35}Cl^{37}Cl$ isotopic splitting) in good agreement with the previously reported value of 535.5 and 528.2 cm^{-1} in a nitrogen matrix (4). Dimethyl sulphide – chlorine mixtures were studied since, unlike hydrogen sulphide – chlorine mixtures, reaction cannot occur. An absorption due to the dimethyl sulphide – chlorine complex was observed at ca. 525 cm^{-1}.

Discussion

Hydrogen sulphide – halogen complexes

For hydrogen sulphide – chlorine mixtures, the strong bands at 518 and 510 cm^{-1} in an argon matrix and at 507 cm^{-1} in a nitrogen matrix are readily assigned to the chlorine stretching vibration of the hydrogen sulphide – chlorine complex. The doublet in the argon matrix is clearly due to isotopic splitting, which is only partially resolved in the nitrogen matrix. The

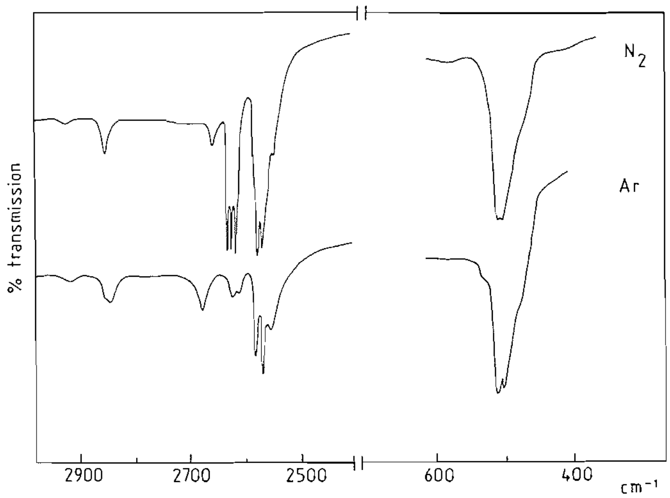

FIG. 1. Infrared spectra of hydrogen sulphide – chlorine mixtures in argon and nitrogen matrices.

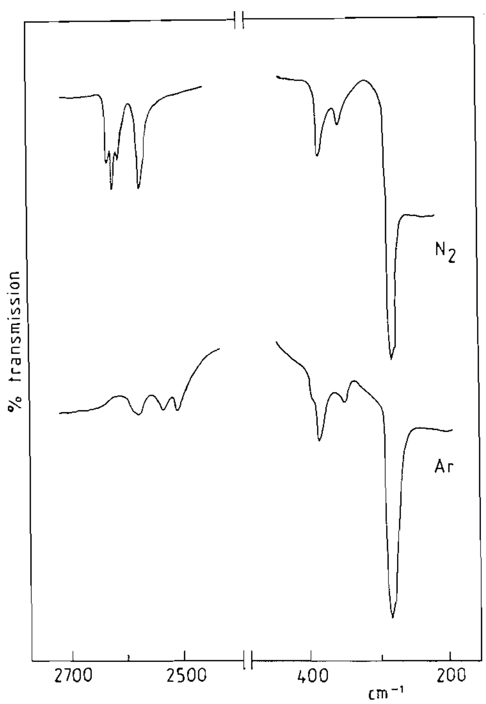

FIG. 2. Infrared spectra of hydrogen sulphide – bromine mixtures in argon and nitrogen matrices.

wavenumber of the chlorine stretching vibration is similar to that in the dimethyl sulphide – chlorine complex and in line with the general trend of other chlorine complexes (Table 3). The strength of the complex is rather greater than that with water, but much lower than that with ammonia. There were no additional bands in the hydrogen sulphide stretching region which could be attributed to the complexed hydrogen sulphide molecule.

Hydrogen sulphide – bromine mixtures exhibit a prominent band at 285 cm^{-1} in argon matrices and at 280 cm^{-1} in nitrogen matrices. This is clearly due to the bromine stretching mode of the hydrogen sulphide – bromine complex, and is again in line with the bromine stretching frequencies of related complexes (Table 3). As for the corresponding chlorine complex, no

perturbed hydrogen sulphide stretching vibrations could be identified.

Reaction products

Although a twin-jet deposition technique was used to obtain the hydrogen sulphide – halogen matrices, a number of other absorptions were apparent in the spectra which must be due to reaction products. Mixtures of hydrogen sulphide and chlorine in the gas or liquid phase react to give sulphur or sulphur chlorides (11):

$$Cl_2 + H_2S \rightarrow 2HCl + S$$

$$2Cl_2 + H_2S \rightarrow 2HCl + SCl_2$$

$$3Cl_2 + 2H_2S \rightarrow 4HCl + S_2Cl_2$$

Thiohypochlorous acid is proposed as an intermediate in the production of polysulphide species:

$$Cl_2 + H_2S \rightarrow HCl + HSCl$$

$$HSCl + H_2S \rightarrow HCl + H_2S_2$$

$$HSCl + H_2S_2 \rightarrow HCl + H_2S_3$$

etc.

Thiohypohalous acid species have not been isolated, although the hypohalous acids have been identified in low-temperature matrices (15).

The hydrogen sulphide – chlorine mixtures exhibited absorptions in the HCl stretching region, in particular a band at 2674

[a]This work.
[b]N_2 matrix.

cm^{-1} in argon matrices and 2660 cm^{-1} in nitrogen matrices which can be identified as the hydrogen sulphide – hydrogen chloride complex (16). Other weak bands in the region are probably due to isolated HCl or the chlorine – hydrogen chloride complex. Hydrogen sulphide – bromine mixtures in argon matrices exhibited weak absorptions in the HBr stretching region, although these did not correspond with previously reported HBr monomer or aggregate band positions (17). Possibly they are due to the bromine – hydrogen bromide complex. The hydrogen sulphide – hydrogen bromide complex (16) was not observed in these mixtures.

The presence of hydrogen halides in the matrices implies that other reaction products must also be present. In the hydrogen sulphide – chlorine mixtures, the only evidence of such species was a shoulder, at ca. 485 cm^{-1} (argon) or 470 cm^{-1} (nitrogen), on the low frequency side of the $H_2S \ldots Cl_2$ complex absorption. This does not correspond to the S—Cl stretching vibration of any reported sulphur–chlorine species. In particular, SCl_2 absorbs at ca. 520 cm^{-1} (18) and S_2Cl_2 at ca. 450 cm^{-1} (19). We attribute it tentatively to the S—Cl stretching mode of thiohypochlorous acid.

In the hydrogen sulphide – bromine mixtures, well-defined bands were observed in the S—Br stretching region at 385 and 355 cm^{-1}. The latter absorption corresponds approximately with the reported position of the SBr stretching modes of the S_2Br_2 molecule (19). We tentatively attribute the 385 cm^{-1} absorption to the S—Br stretching mode of thiohypobromous acid. However, the vibrational spectrum of SBr_2 has not been reported; conceivably the 385 cm^{-1} band could be due to this species.

Conclusions

Infrared spectra of mixtures of hydrogen sulphide and chlorine or bromine trapped in low-temperature matrices have shown that the hydrogen sulphide and halogen molecules interact to form a molecular complex $H_2S \ldots X_2$. This is presumably an intermediate in the reaction

$$H_2S + X_2 \rightarrow HX + HSX$$

Stable products can then be formed by reactions such as

$$HSX + X_2 \rightarrow HX + SX_2$$

$$HSX + SX_2 \rightarrow HX + S_2X_2$$

etc.

Received August 6, 1984

This paper is dedicated to Professor Camille Sandorfy on the occasion of his 65th birthday

HANS WOLFF and JERZY SZYDLOWSKI. Can. J. Chem. **63**, 1708 (1985).

The infrared spectra of gaseous, liquid, and solid C_2H_5SD, and the Raman spectrum of the liquid compound are analyzed and the corresponding spectra of C_2H_5SH were reinvestigated under improved conditions. In the deuterated compound the CH_2 rocking vibration does not interact with the SD bending vibration and therefore does not split into vibrations of the conformers. The measurements suggest for gaseous and liquid C_2H_5SH and C_2H_5SD the simultaneous presence of the *trans* and *gauche* conformers, appearing at room temperature in the ratio of the order of 1:3. In analogy to solid C_2H_5SH, the exclusive presence of the *gauche* conformers can be inferred for solid C_2H_5SD. The spectra reported in the literature for the C_2H_5SH molecules embedded in matrices at low temperatures permit a similar interpretation. The doublet structure observed for the vibrational bands, not only of pure solid C_2H_5SH and C_2H_5SD but also of their solid mixtures, may be due to non-equivalent sites of the unit cell.

HANS WOLFF et JERZY SZYDLOWSKI. Can. J. Chem. **63**, 1708 (1985).

On a analysé les spectres infrarouges du C_2H_5SD dans les états gazeux, liquide et solide, le spectre Raman du composé liquide ainsi que les spectres correspondants du C_2H_5SH qui ont été réexaminés dans des conditions améliorées. Dans le composé deutéré, la vibration de rocking du CH_2 n'interfère pas avec la vibration de déformation du SD; elle ne se sépare donc pas en vibrations des conformères. Dans les composés C_2H_5SH et C_2H_5SD gazeux ou liquides, les mesures à la température ambiante suggèrent que les conformères gauche et trans existent simultanément dans des rapports de 1:3. Par analogie avec les résultats obtenus avec la C_2H_5SH, on peut suggérer que le C_2H_5SD à l'état solide existe exclusivement sous la conformation gauche. Sur la base des spectres rapportés dans la littérature pour des molécules de C_2H_5SH imbriquées dans des matrices à basses températures, on peut proposer une interprétation semblable. La présence de doublets qui ont été observés dans les bandes vibrationnelles, non seulement du C_2H_5SH et du C_2H_5SD purs à l'état solide mais aussi dans leurs mélanges solides, pourrait être due à des sites qui ne sont pas équivalents dans la maille unitaire.

[Traduit par le journal]

A. Introduction and measurements

For ethanethiol one *trans* form and two equivalent *gauche* forms are to be considered. The manifestation of these forms in the vibrational spectra has been studied in low temperature infrared spectra including those of matrices and especially in infrared and Raman spectra in the range of torsional transitions (1−7). Some of these investigations have also been performed for C_2H_5SD. However, there has been no systematic infrared study of the deuterated compound. To fill in the blanks and to expand the investigations on rotational isomerism of ethanethiol, the infrared spectra of gaseous, liquid, and solid C_2H_5SD were measured. In addition, the Raman gas spectra known from the measurements of Durig *et al.* (7) were supplemented by determining the Raman liquid spectra. Further, the infrared spectra of crystallized mixtures of C_2H_5SH and C_2H_5SD were recorded. They were analyzed together with those of C_2H_5SH which in part were reinvestigated under improved conditions.

The infrared measurements were carried out with the Perkin-Elmer 225 spectrometer by using conventional methods for obtaining the gas and liquid spectra, and the method of Wagner and Hornig (8) for the solid phase spectra. The Raman liquid spectra were recorded with the Coderg PH 1 spectrometer with excitation with the 6328 Å line of the helium−neon laser. C_2H_5SH and C_2H_5SD were the highly purified products which had been utilized for the determination of the vapour pressure isotope effect of the two compounds (9).

B. Results and discussion

1. Gaseous compounds

Considering the relevant features of the spectra in Fig. 1, the infrared spectra of gaseous C_2H_5SD in the range of the SD stretching and bending vibrations are compared with the corresponding spectra of C_2H_5SH (measured wave numbers in Table 1). The spectra of C_2H_5SD show similar splittings as those of C_2H_5SH, as do in part the Raman spectra of the gaseous compounds (7). From the intensities of the Q-branches the high-frequency component of the doublets of the stretching vibrations is estimated to be markedly weaker than the low-frequency component. Relating the splitting to the presence of the conformers and considering the explanation which states the *gauche* forms are the dominant conformers in the gaseous state (2, 5, 7) (see below), it can be supposed that the high-frequency component belongs to the *trans* form. The low-frequency component, which is separated from the high-frequency satellite by 9 cm^{-1} for C_2H_5SH and by 6 cm^{-1} for C_2H_5SD, corresponds to the *gauche* forms.

For the purpose of comparison with C_2H_5SD, Fig. 2*a* represents the infrared spectrum obtained in the range of the CH_2 rocking vibration for gaseous C_2H_5SH. The spectrum shows in addition to the more intense band at 735 cm^{-1}, a less intense one at about 780 cm^{-1}. Smith, Devlin, and Scott (2) observed this splitting for liquid and glassy C_2H_5SH, and explained it by the assumption that the rocking vibration of the *gauche* forms is shifted to the wave number of 735 cm^{-1} owing to interaction with the SH bending vibration appearing at 875 cm^{-1}. The interaction does not occur with the rocking vibration of the *trans* form at 780 cm^{-1}, as that conformer belongs to the point group C_s and its rocking and bending vibrations are of different symmetry. With this in mind, the higher intensity of the band at 735 cm^{-1} confirms that the *gauche* forms are the dominant conformers in the gaseous state at room temperature. The missing of the band at 780 cm^{-1} in the Raman gas spectra (7) suggests an insufficient Raman activity.

[a]Abbreviations: w weak, m middle, s strong, sh shoulder, v very, g *gauche*, t *trans*; gt indicates that presumably both conformers contribute to the measured frequency; however, the *gauche* forms contribute more.

[b]The SH stretching vibrations measured for crystallized C_2H_5SH are 2544 and 2527 cm^{-1} (vs).

[c]SH bending vibration of the *trans* form of gaseous C_2H_5SH, being expected at 830–835 cm^{-1} (see text), may be unobserved not only because of the presence of this conformer in the ratio of merely 1:3, but also because of lower activity.

[d]CH_3 torsion of crystallized C_2H_5SH is found at 261 cm^{-1} (m).

Figure 3*a*, representing the infrared spectrum of gaseous C_2H_5SD, shows no band at 735 cm^{-1}, but one at the wave number 780 cm^{-1} at which in the infrared spectrum of C_2H_5SH the rocking vibration of the *trans* form is found. This wave number is therefore chosen for the rocking vibration of the *trans* form of C_2H_5SD and, as to be seen in the following, also for the vibration of the *gauche* forms.

The rocking vibration of the *gauche* forms of C_2H_5SH is observed on the low-frequency side of the vibration of the *trans* form. The rocking vibration of the *gauche* forms of C_2H_5SD should occur on the high-frequency side, if it would interact with the bending vibration of the sulfhydryl group appearing for the deuterated compound at 620 cm^{-1}. However, such a satellite is not observed. Assuming the rocking vibration of the *gauche* forms to occur near that of the *trans* form, the frequency distance from the bending vibration with 160 cm^{-1} is obviously too large. The corresponding distance for C_2H_5SH is only 40–50 cm^{-1} with the calculation based on the values of 780–785 and 830–835 cm^{-1} for the unperturbed vibrations.

2. *Liquids*

In the Raman gas spectra where the band at 780 cm^{-1} was not observed, a band at 696 cm^{-1} had been assigned to the rocking vibration of the *gauche* forms of C_2H_5SD. However, as stated in the preceding paragraph, the approximate coincidence of the rocking vibrations of the different conformers of C_2H_5SD near 780 cm^{-1} is suggested by observation of a weak band in the Raman spectrum of the liquid compound at 786 cm^{-1}. Because of the inactivity of the rocking vibration of the *trans* form, this band can only be assigned to the *gauche* forms. This assign-

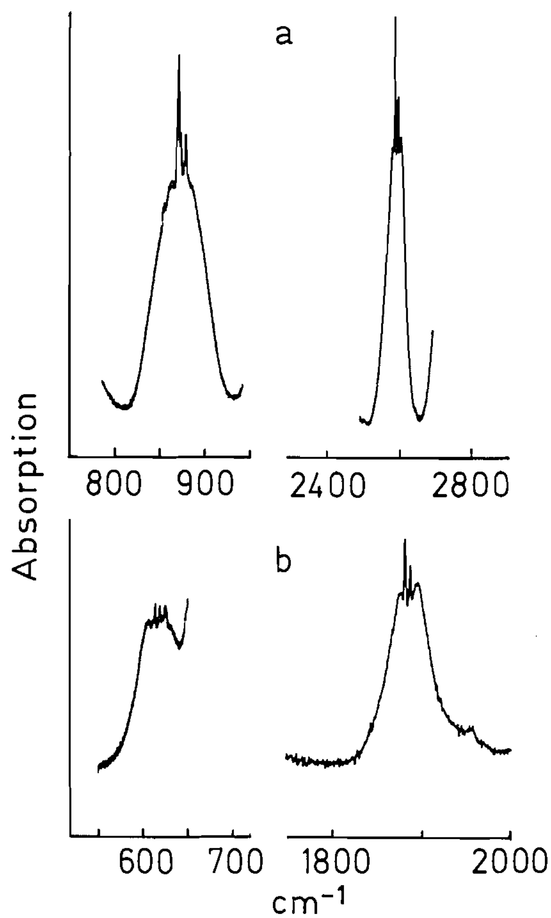

FIG. 1. (a) Splitting of the SH stretching and bending vibrations in the infrared spectrum of gaseous C_2H_5SH; (b) splitting of the SD stretching and bending vibrations in the infrared spectrum of gaseous C_2H_5SD.

ment is supported by the observation that the corresponding band of C_2H_5SH appears at 740 cm^{-1} (2) and, in agreement with the interpretation of the infrared spectra, belongs to the *gauche* forms vibration, which is shifted due to the interaction.

From the infrared spectrum of liquid C_2H_5SH reproduced in Fig. 2b, I_{trans}/I_{gauche}, the ratio of the integrated intensities of the two rocking bands, is determined to be about 1:3.2. Excluding a greater intensity change of the rocking vibration due to the interaction with the bending vibration, the ratio of the quantities of the *trans* and the *gauche* conformers present in the liquid at room temperature is therefore of the order of 1:3.

Under these circumstances the enthalpy difference between the two conformers of C_2H_5SH is obtained from

$$[1]\quad \Delta H = R\frac{T_1T_2}{T_2 - T_1}\ln\left[(I_{gauche}/I_{trans})_{T_1}/(I_{gauche}/I_{trans})_{T_2}\right]$$

where $(I_{trans}/I_{gauche})_{T_1}$ and $(I_{trans}/I_{gauche})_{T_2}$ are the ratios of the integrated intensities at the temperatures T_1 and T_2, and R is the universal gas constant. In addition to the value for I_{trans}/I_{gauche} from the spectrum of the liquid at the measuring temperature of 300–320 K, the value from the spectrum of the glass at liquid nitrogen temperature (Fig. 2c) is used for the calculation, considering the latter spectrum as that of the liquid at liquid nitrogen temperature. The average result for ΔH of somewhat more than 1400 J mol^{-1} is in the order of that of 1300 J mol^{-1} derived from thermodynamic measurements and agrees with the assumption of the gauche forms as the more stable conformers (2, 7).

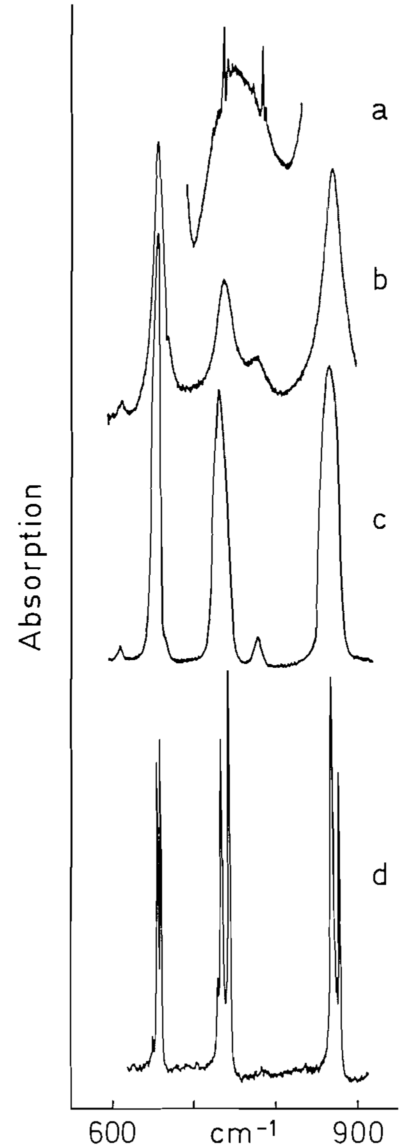

FIG. 2. Infrared absorption in the region of the CH_2 rocking vibration of (a) gaseous C_2H_5SH (350 Torr), (b) liquid C_2H_5SH (path length 0.025 mm), (c) and (d) glassy and solid C_2H_5SH at liquid nitrogen temperature.

The ratio I_{trans}/I_{gauche} for the gas at room temperature is similar to that of the liquid, and there is probably no large difference between the rotational isomerism of C_2H_5SH and C_2H_5SD. The above results for the liquid are therefore approximately valid also for the gas, and the results for C_2H_5SH also nearly for C_2H_5SD.

3. *Solids*

Like gaseous and liquid C_2H_5SD, the solid compound shows for the CH_2 rocking vibration merely the absorption at 780 cm^{-1} (Fig. 3c), while the band of solid C_2H_5SH appears at 735 cm^{-1} (2) (Fig. 2d). Assuming similar behaviour of C_2H_5SH and C_2H_5SD with regard to the rotational isomerism, however, unlike gaseous and liquid C_2H_5SD, the absorption of the solid compound can be solely assigned to the *gauche* conformers. In solid C_2H_5SH only these forms remain from the different conformers of the gaseous and of the liquid compound

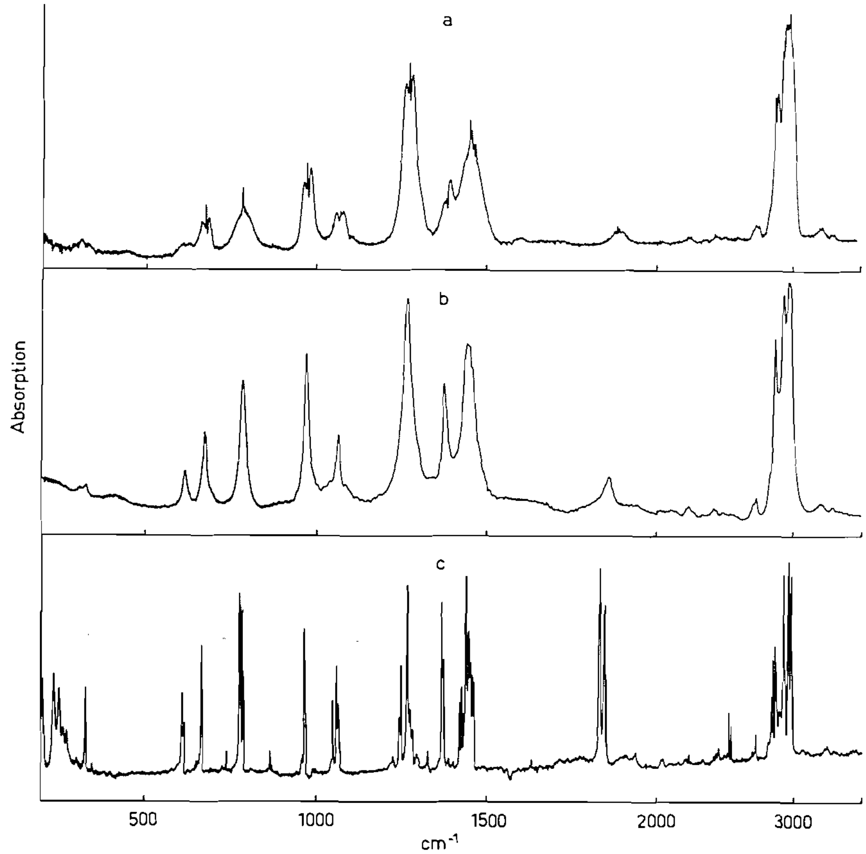

FIG. 3. Infrared spectra of (*a*) gaseous, (*b*) liquid, (*c*) solid C_2H_5SD.

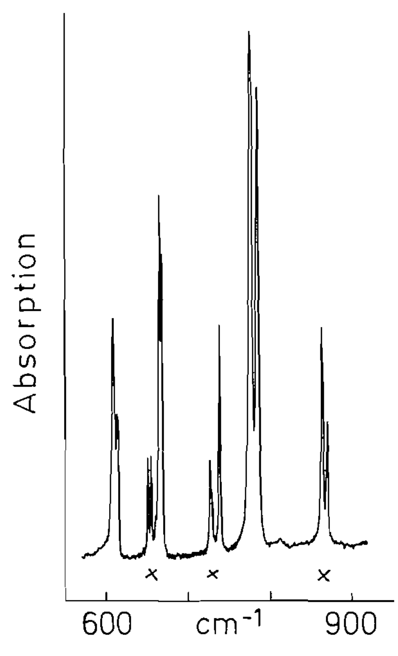

FIG. 4. Infrared bands of CS stretching, CH_2 rocking, and SH bending vibrations of C_2H_5SH in a solid mixture with C_2H_5SD (1:10). The doublets appearing for the vibrations of C_2H_5SH are indicated by crosses.

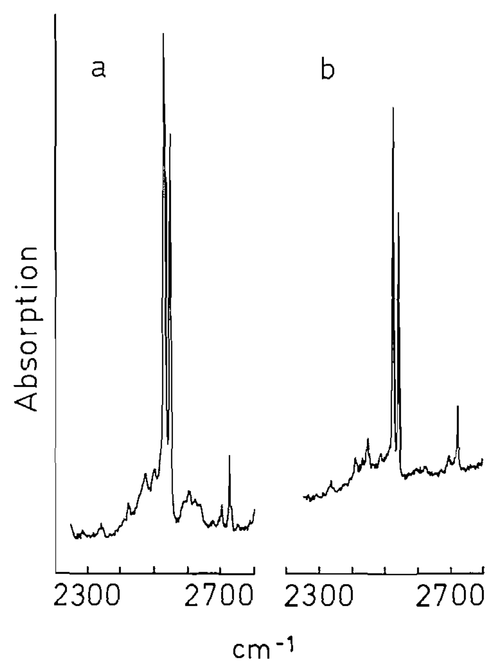

FIG. 5. Infrared band of the SH stretching vibration in (*a*) pure solid C_2H_5SH, (*b*) a solid mixture of C_2H_5SH with C_2H_5SD (1:10).

(2) (Fig. 2*a*–*d*).

Also, like the bands of solid C_2H_5SH (2), the band at 780 cm^{-1} and most other vibration bands of solid C_2H_5SD are split into mainly two components. In the spectra of the solid mixtures of C_2H_5SH and C_2H_5SD the doublets remain nearly uninfluenced by the isotopic dilution. This is shown in Fig. 4 in comparison with Fig. 2*d* for the CS stretching, for the CH_2 rocking, and for the SH bending vibration bands and in Fig. 5 for the SH stretching vibration band of C_2H_5SH. The intensity ratios of the doublet components are only insignificantly changed with the isotopic dilution, and the wave numbers of the doublets of the pure solid and of the solid mixture are nearly the same; they are in the sequence of the listed vibrations 659/656 and 658/654 cm^{-1}, 743/733 and 742/731 cm^{-1}, 877/868 and 874/868 cm^{-1}, and 2544/2527 and 2546/2530 cm^{-1}. The splittings may therefore arise from non-equivalent sites of the unit cell. Then separate frequencies corresponding to the different sites can be expected on isotopic dilution even for non-degenerate vibrations (10, 11).

In the infrared spectra obtained from C_2H_5SH on high dilution in an argon matrix, and analogously in other matrices, Barnes, Hallam, and Howells (4) found a doublet at 731.0 and 732.8 cm^{-1}, but no absorption at 780 cm^{-1}. Considering the intensity ratio of the doublet components and assuming that the equilibrium at room temperature is frozen out in the matrix, the authors assigned only the low-frequency component to the rocking vibration of the *gauche* conformers, but the high-frequency component to that of the *trans* conformer. One would, however, expect that with transition to 20 K merely the association equilibrium at room temperature freezes out and the equilibrium of rotational isomers at the low temperature is largely adjusted. Therefore, both doublet components may be assigned to the *gauche* conformers in agreement with the preceding explanations, the splitting of only 1.8 cm^{-1} (compared to 10 cm^{-1} in the pure solid) being due to matrix or other effects. The CH_2 rocking vibration of matrix-isolated C_2H_5SD has not been measured. Unlike the matrix isolation value of C_2H_5SH, but similar to the vibration of gaseous, liquid, and solid C_2H_5SD, it can however be expected to appear near 780 cm^{-1}.

The frequency shifts in the solids relative to the gases amount to 60−75 cm^{-1} for the SH and to 40−50 cm^{-1} for the SD stretching vibrations. The shift in the liquid compounds are not much greater than half of the values for the solids. The low magnitude of these shifts corresponds to the results of investigations on hydrogen bonding of other thiols and indicates the weakness of the H or D bonds of these compounds (4, 12). It is further to be noticed that in reasonable relation to the frequencies measured for the methyl torsion vibrations of gaseous C_2H_5SH and C_2H_5SD (7) the values of 261 and 254 cm^{-1} are found for the crystallized compounds. All other assignments can be taken from Table 1, or from the former investigations (2, 4, 7).

C. Conclusions

It is evident from the infrared investigation of C_2H_5SD that the conditions for interaction of the CH_2 rocking vibration with the bending vibration of the sulfhydryl group are satisfied for the *gauche* conformers of C_2H_5SH but not of C_2H_5SD. The observation of a single band for the rocking vibration of gaseous and liquid C_2H_5SD therefore supports the explanation for the splitting of C_2H_5SH through the interaction to which only the vibrations of the *gauche* conformers are subjected. The rocking vibration of the *trans* form is Raman-inactive, but the different wave numbers for the vibration of the *gauche* forms in the Raman spectra of C_2H_5SH and C_2H_5SD agree with the interpretation. The infrared intensities of the components of the rocking vibration of C_2H_5SH reveal for the gaseous and the liquid compounds at room temperature the appearance of the *trans* form and of the *gauche* forms in the ratio of about 1:3. In reasonable relation to other measurements and calculations a value of the order of 1400 J mol^{-1} results from the intensities of the rocking bands of C_2H_5SH for the enthalpy difference of the two forms. Analogously to C_2H_5SH, the exclusive appearance of the *gauche* conformers can be inferred for solid C_2H_5SD. The spectra reported in literature for the ethanethiol molecules embedded in matrices at low temperatures permit a similar interpretation. The doublet structure of the vibrational bands of the solids even on isotopic dilution most likely arises from non-equivalent sites of the unit cell.

Received August 10, 1984

This paper is dedicated to Professor Camille Sandorfy on the occasion of his 65th birthday

JUNZO UMEMURA, MUTSUO MATSUMOTO, TAKESHI KAWAI, and TOHRU TAKENAKA. Can. J. Chem. **63**, 1713 (1985).

Fourier transform infrared (FT-IR) spectra in the range 3800–2800 cm^{-1} have been recorded of the first and second black films in air prepared from aqueous solutions of sodium dodecylsulfate (SDS) without and with the addition of sodium chloride, respectively. It is found that in both films the methylene chains of SDS, which are located outside the aqueous core of the sandwich structure, are in an oriented liquid crystalline state. In a first black film, the thickness of the aqueous core is determined to be 9.6 nm, by recording polarized infrared spectra with various angles of incidence to the film surface, and by analyzing them with the aid of thin layer optics. It is found that this value varies in the range 5 ~ 10 nm from film to film. The extinction coefficients of the aqueous core are also examined. In the second black film, the thickness of the aqueous core is found to be about 1 nm. The OH stretching band of water in the second black film appears at appreciably higher wavenumbers (by 60 cm^{-1}) than those of the first black film, indicating a high ionic strength in the aqueous core. In both black films, there is no sign of molecular orientation or rigidified structure of water.

JUNZO UMEMURA, MUTSUO MATSUMOTO, TAKESHI KAWAI et TOHRU TAKENAKA. Can. J. Chem. **63**, 1713 (1985).

On a enregistré les spectres infrarouges par transformation de Fourier dans la région de 3800 à 2800 cm^{-1} des premier et deuxième films noirs dans l'air préparés à partir de solutions aqueuses de dodécylsulfate de sodium (DSS) respectivement avec et sans chlorure de sodium. On a trouvé que dans chacun de ces films, les chaînes méthylènes du DSS, qui sont situées à l'extérieur du noyeau aqueux de la structure en sandwiche, sont dans un état cristallin liquide orienté. En enregistrant les spectres infrarouges polarisés sous divers angles d'incidence par rapport à la surface du film et en les analysant à l'aide de principes d'optique pour les couches minces, on a évalué que l'épaisseur du noyeau aqueux du premier film noir est égale à 9,6 nm. On a trouvé que cette valeur varie de 5 à 10 nm suivant le film. On a aussi examiné les coefficients d'extinction des noyeaux aqueux. Dans le deuxième film noir, on a trouvé que l'épaisseur du noyeau aqueux est égale à 1 nm. Par rapport au premier film noir, la bande de vibration OH de l'eau du deuxième film noir se trouve à des nombres d'onde beaucoup plus élevés (environ 60 cm^{-1}); ce résultat indiquerait la présence d'une force ionique élevée dans le noyeau aqueux. Dans les deux films noirs, il n'existe aucun signe d'orientation moléculaire ou de structure rigidifiée de l'eau.

Introduction

By withdrawing a metal frame from soap solution to air through the interface, a single planar foam film can be easily prepared. At equilibrium, such a film is sufficiently thin (4–50 nm) to appear black by reflected light. Thus, the film is called "black soap film" or "black foam film" (1). The black soap film takes the sandwich structure consisting of a thin sheet of aqueous solution (aqueous core) enclosed by two surface monolayers of soap molecules. Such black films in air have been of great interest for centuries (1), because they provide easily formed, geometrically well-defined model systems for investigating the stability of foams. The black film is also a good model to study surface forces of the London-dispersion type (2) or of electrical double layers (3). Besides, black soap films in air have striking similarities, in various aspects, with bimolecular (black) lipid membranes in aqueous solution (4). Thus, the investigation of black soap films is closely related to the understanding of biological membranes.

Hitherto, the experimental methods used for studying the black soap films are limited to radioactive-tracer (5, 6), optical reflectance (7, 8), light scattering (9), X-ray diffraction (10, 11) techniques, and so on. Modern spectroscopic techniques such as infrared or nuclear magnetic resonance spectroscopy are principally expected to provide valuable structural informations on these films. In reality, however, these techniques have suffered from their poor detection limits, because of the minute amount of constituents in thin soap films. For example, the infrared spectra of multiple sheets of black soap films obtained by using a dispersion type instrument with a PbS detector (7) could only give a very rough estimate of the thickness of the aqueous core, whose accuracy is crucial to the theoretical investigation of the surface forces.

On the other hand, the innovation of the Fourier transform infrared (FT-IR) technique has enormously improved the detection limit of infrared measurements, and has made it possible to investigate the systems interesting to colloid and interface scientists, such as aqueous micellar solutions (12, 13), multibilayer lipid membranes in aqueous media (14, 15), Langmuir-Blodgett monomolecular film (16), and trace amounts of oriented water in a liquid crystalline matrix (17).

In the present work, the FT-IR technique has been applied to the study of black films in air prepared from aqueous solutions of sodium *n*-dodecylsulfate (SDS). Without the addition of inorganic electrolyte, the SDS solution at room temperature provides the "first black" film, whose equilibrium thickness is believed to be performed by a balance between van der Waals attraction and electrostatic double-layer repulsion (1). By adding a sufficient amount of inorganic electrolyte like NaCl, the SDS solution provides the "second black" film of about 4.4 nm (18). Both first and second black films have been investigated here with polarized infrared radiation to see the state and orientation of the surfactant and water molecules in the films.

Experimental

SDS (purity >99%) and NaCl (purity >99.9%) were purcased from Nakarai Cemicals, Ltd., Kyoto, Japan. Doubly distilled water was used for the preparation of aqueous solutions. The sample cell adopted in this experiment is illustrated in Fig. 1. The main cell body (75 mm internal diameter and 100 mm high) is made of polymethylmethacrylate. The rectangular frame of 51 mm wide and 38 mm high, which is made of a 1.2 mm ϕ platinum wire, was used to support soap films. In order to prepare the soap film, the frame was once dipped

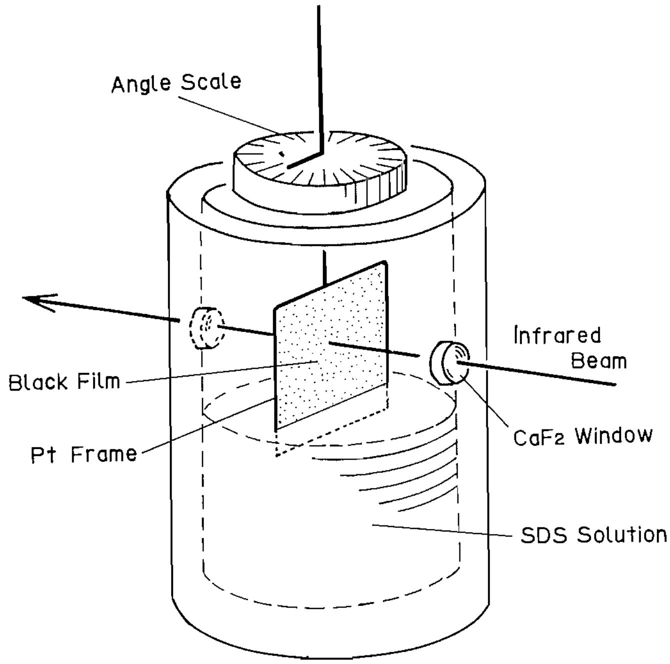

FIG. 1. Sample cell for FT-IR measurements of black films.

into the aqueous solution with SDS concentration larger than the critical micellization concentration (80 mM, ref. 19), and then it was slowly lifted up to air. The frame can be rotated around its center axis so that the angle of incidence of infrared radiation can be changed freely. The infrared radiation passed through the soap film and two CaF_2 windows (8 mm diameter) on the cell wall. In the case of normal incidence to the film surface, the spot of the infrared beam on the film was as small as about 0.5 mm ϕ. To achieve the equilibrium of temperature and vapor pressure inside the cell, prior to the withdrawal of the film, the cell was placed overnight in the sample compartment of the FT-IR spectrophotometer set in a temperature-controlled room, with a continuous supply of infrared radiation. Under these conditions, the temperature inside the cell was 29°C. Then the film was lifted up from the solution and was subjected to infrared measurements.

Infrared spectra were recorded on a Nicolet 6000 FT-IR spectrophotometer equipped with an InSb detector. Typically, 500 to 2000 interferograms collected with the maximum optical retardation of 0.25 cm were coadded, apodized with a Happ-Genzel function, and Fourier transformed with one-level of zero-filling to yield spectra of high S/N ratio with a resolution of 4 cm^{-1}. Polarization measurements were performed by using a wire-grid polarizer with AgBr substrate. Special attention was paid to the cancellation of the infrared bands due to atmospheric water and a slight amount of frost formed upon the detector surface. The latter is inevitable to commercial detectors cooled by liquid nitrogen. Since the amount of frost changes with time, the back ground spectra were recorded before and after a series of measurements for one film. Then, the background spectrum corresponding to each sample spectrum was obtained by a time-weighted average of the above two spectra.

For numerical calculations and graphical plottings of the results, a Facom M-180 II AD computer of this institute was utilized.

Results and discussion

1. *First black film*

When the film is drawn from the aqueous SDS solution, or more precisely from the surface of the solution, its initial thickness is fairly large. However, the aqueous core of the film immediately starts to thin by drainage, and the black film is first formed at the top of the film. The area of the black part

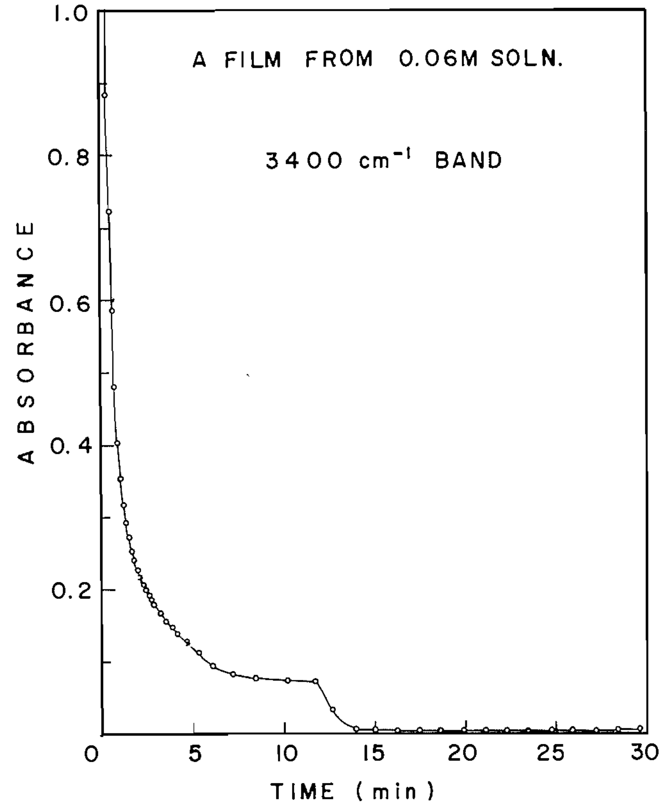

FIG. 2. Change in absorbance of water at 3400 cm^{-1} with time for a film drawn from 0.06 M aqueous solution of SDS.

gradually increases, the horizontal border between the black part and thicker part descending downwards. The feature of the thinning can be monitored by measuring the absorbance of the OH stretching band of water (3400 cm^{-1}) at a fixed position in the film. The typical result for the film drawn from the 0.06 M SDS solution is shown in Fig. 2, where each point represents the result of an accumulation of 10 scans. Within about 7 min, the absorbance becomes nearly constant at 0.075 which corresponds to a 88 nm thick aqueous core (see below for the evaluation of the thickness). At this stage, the film appears silvery. In 12 to 14 min, the part of the spot of the infrared beam becomes black, giving an absorbance of 0.0085. All of the film becomes black after 30 min. The infrared spectrum of this equilibrated black film is shown in Fig. 3*A*. The broad OH stretching band of water peaked at ~3400 cm^{-1} and weaker CH stretching bands of the methylene chain of SDS at 2960–2850 cm^{-1} are observed. The features of the 3400 cm^{-1} band (peak wavenumber, bandwidth, and contour) are very similar to those of bulk liquid water (20).

In Fig. 3*B* and *C*, the spectra of equilibrated black films obtained by different withdrawals from the same 0.06 M SDS solutions were also displayed. It is found from the absorbance of each film in Fig. 3*A–C* that the thickness of the outer SDS monolayers (monitored by the CH bands) are invariant in all the films, but the thickness of aqueous core (monitored by the water band) varies in each film. It is usually believed that the equilibrium thickness of the first black film is determined by the ionic strength in the aqueous core (18). However, the result in Fig. 3 indicates that the actual equilibrium thickness is also affected by the delicate difference in each experimental condition, such as that in minute quantities of surface-active impurities (1) which can be introduced by the dehydration of SDS

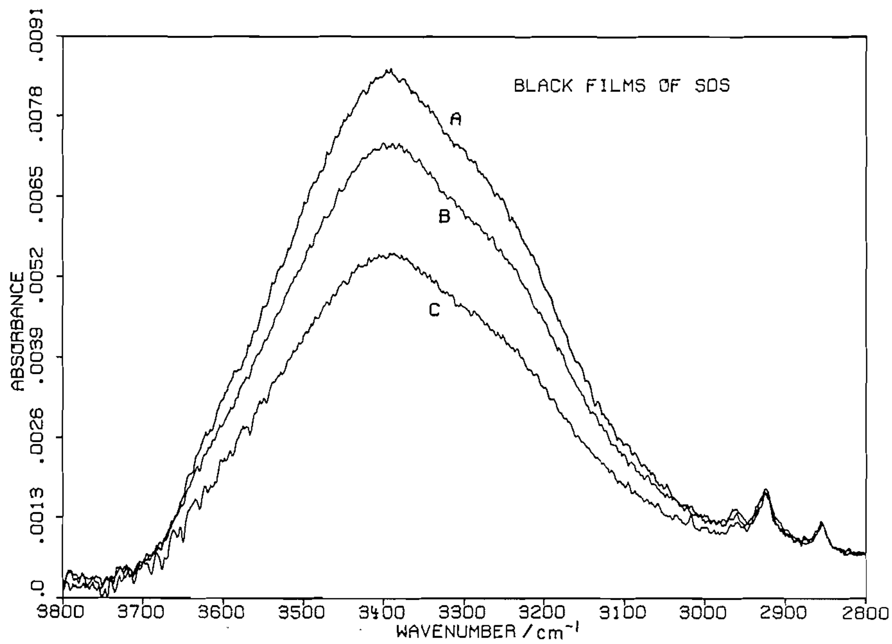

FIG. 3. Infrared spectra in the 3800–2800 cm^{-1} region of three different first black films drawn from 0.06 *M* aqueous solutions of SDS.

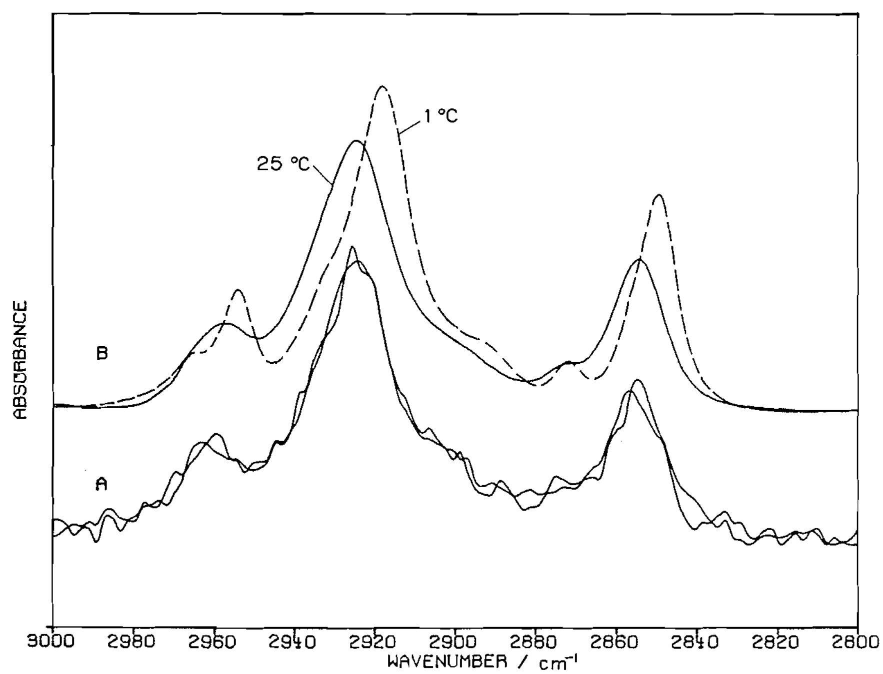

FIG. 4. Infrared spectra in the CH stretching region of SDS. *A*; Two different first black films drawn from 0.06 *M* aqueous solution. *B*; 1.5 *M* aqueous solution at 25°C (—, liquid crystalline phase) and at 1°C (- - -, coagel II phase). Ordinate scale has been normalized so that the intensities of corresponding bands are nearly the same in *A* and *B*.

(21). In the following sections, the state and orientation of the methylene chain in SDS and water will be examined mainly using the spectral data for the first black film of Fig. 3*A*, unless otherwise stated.

2. The CH stretching bands of SDS in first black films

Figure 4*A* shows two spectra in the CH stretching region recorded for different films. The reproducibility and noise level of spectra are apparent in this figure. Figure 4*B* reproduces spectra of 1.5 *M* aqueous solutions of SDS at 1 and 25°C, which are in the coagel II (hydrated crystalline) and liquid crystalline phases, respectively (22). By comparison of Fig. 4*A* and *B*, the methylene chain of SDS in the black film is easily identified as being in liquid crystalline state. This is rationalized by the following consideration. The occupied area per molecule in the SDS black film is thought to be about 0.52 nm^2/molecule (8, 23). This value is in good agreement with the reported value of 0.57 nm^2/molecule (24) for the SDS molecule in a liquid crystalline phase, and is much larger than the molecular cross section of 0.21 nm^2/molecule of a hydrated SDS crystal (25).

To investigate the orientation of the methylene chain of SDS,

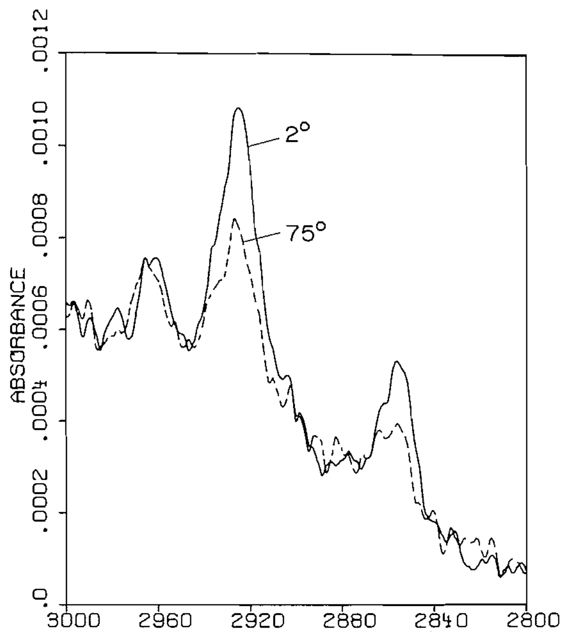

FIG. 5. Polarized infrared spectra in the CH stretching region of a first black film of SDS drawn from 0.06 *M* aqueous solution. Angles of incidence are 2° (—) and 75° (- - -) with electric vector parallel to the plane of incidence. Path lengths have been corrected for the oblique incidence.

the polarized infrared spectra of the film were recorded. First, it was ascertained by normal incidence of the polarized beam that there was no dichroism within the film surface. Then, the film was tilted around the center axis of the platinum frame, and the polarized beam with electric vector parallel to the plane of incidence was irradiated. To evaluate the angle of incidence, the infrared measurements were performed at various angles between −80° and +80°, and the angle 0° was obtained from the center of the symmetrical plot of various spectral parameters, such as peak wavenumber or intensity. This procedure made us read "normal" in the scale as 2°. The spectra at the angle of incidence of 2° and 75° are shown in Fig. 5. Here, the difference in path length has been corrected for the oblique incidence, by assuming the refractive index of SDS layer to be 1.4. Although the noise level is not small, the presence of the dichroism in the antisymmetric (2925 cm^{-1}) and symmetric (2854 cm^{-1}) CH_2 stretching bands is evident. The larger intensity in the 2° incidence reveals that the director of the methylene chains as an average tends to orient normal to the film surface. The dichroism for the asymmetric CH_3 stretching band at 2963 cm^{-1} does not seem to exist. This is reasonable if we consider that the methylene chain is in a liquid crystalline state.

3. Water bands in the first black film

To examine the orientation of water molecules in the film, the tilting method was also applied by using polarized infrared radiations with electric vector parallel to the plane of incidence. The result is given in Fig. 6. In this case, no correction has been made for the difference in path length. With increasing angle of incidence, the peak maximum shifts to higher wavenumbers. The peak intensity, on the other hand, first decreases and then increases. These results are not normally encountered for the well-resolved infrared band with a small absorptivity. Since the OH stretching band of water is believed to consist of many components (26, 27), the complexity in Fig. 6 seemed, at first, to be due to the presence of various dichroism depending on the components. However, for very intense bands as in this case, we have to be careful about distortions of band shapes due to reflection and interference effects at interfaces (28). Therefore, we tried to estimate these effects numerically. For thin layered films, Hansen has derived explicit formulas for the transmittance and reflectance (29). In this case, we consider a symmetric plane bounded system of five layers, that is, air/SDS/aqueous solution/SDS/air. For the *j*th layer, let us suppose that $\hat{n}_j$ is the complex refractive index, *i.e.*, $\hat{n}_j \equiv n_j + ik_j$, θ_j the

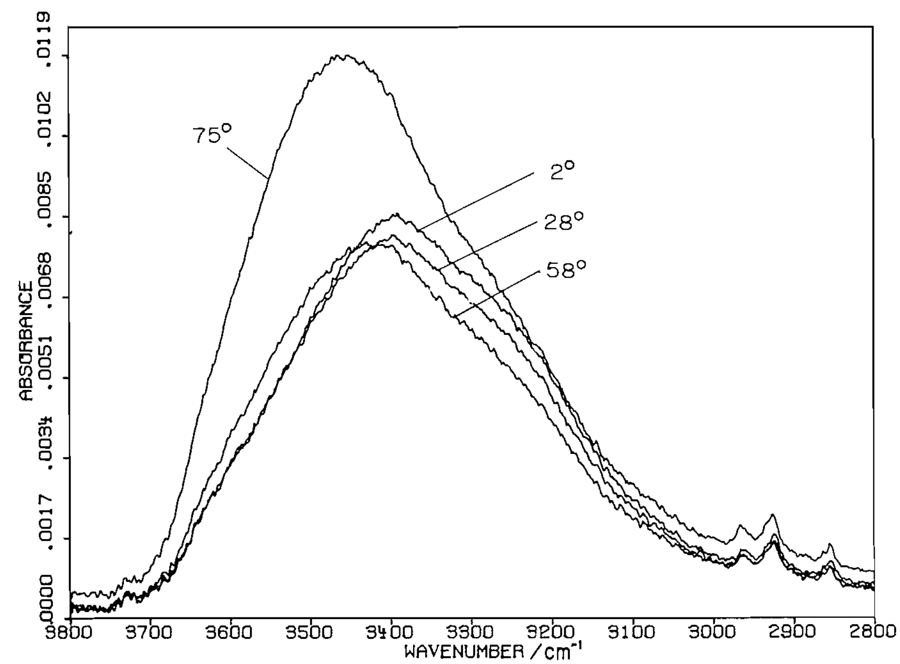

FIG. 6. Polarized infrared spectra of a first black film of SDS drawn from 0.06 *M* aqueous solution. The angles of incidence of polarized radiations with electric vector parallel to the plane of incidence are shown.

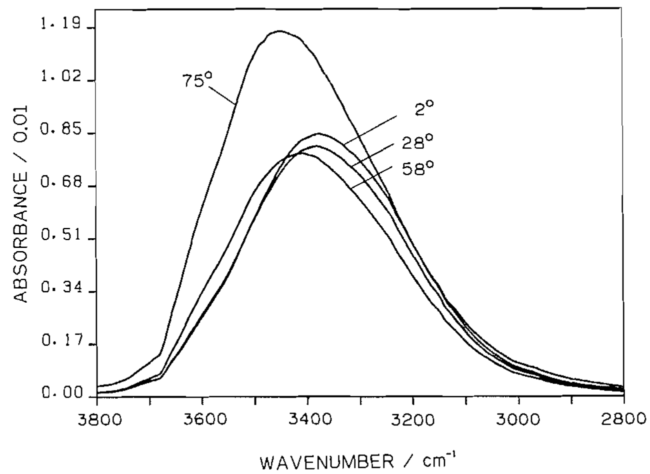

FIG. 7. Calculated absorbance curves in the OH stretching region of a first black film of SDS. The data correspond to the observed results shown in Fig. 6. In this calculation, $h_2 = h_4 = 1.1$ nm, $h_3 = 9.6$ nm, $\hat{n}_1 = \hat{n}_5 = 1$, $\hat{n}_2 = \hat{n}_4 = 1.4$, and $k(3400\ \text{cm}^{-1}) = 0.36$ are used.

angle of incidence or refraction, h_j the thickness, $q_j = \cos\theta_j/n_j$, ν the wavenumber of infrared radiation, and that $\beta_j = 2\pi\nu h_j\hat{n}_j \times \cos\theta_j$. If we make the usual assumption that the magnetic permeabilities of all the layers are unity, the transmittance of the system for the parallel polarization is expressed by (29)

$$[1]\quad T_p = \frac{Re(\cos\theta_5/\hat{n}_5)}{\cos\theta_1/n_1}\left|\frac{2q_1}{(m_{11}+m_{12})q_1+m_{21}+m_{22}q_5}\right|^2$$

where m_{kl} is the klth element of the matrix M characteristic of the total plane bounded system:

$$[2]\quad M = M_2M_3M_4$$

with

$$[3]\quad M_j = \begin{bmatrix} \cos\beta_j & -(i/q_j)\sin\beta_j \\ -iq_j\sin\beta_j & \cos\beta_j \end{bmatrix}$$

For the calculation, we assumed $\hat{n}_1 = \hat{n}_5 = 1$, $\hat{n}_2 = \hat{n}_4 = 1.4$, and $h_2 = h_4 = 1.1$ nm (estimated from the data in refs. 23 and 30). For the complex refractive index $\hat{n}_3(\nu)$ of water in the infrared region, we first adopted the data reported by Downing and Williams (31). However, it was not fully successful to reproduce the data in Fig. 6. The literature survey (32) shows that the values of the imaginary part k_3 (3400 cm^{-1}) of $\hat{n}_3$, *i.e.*, extinction coefficient of water at the 3400 cm^{-1} peak are widely distributed from 0.17 (33) to 0.92 (7), though the newly reported values converge into the range between 0.28 and 0.31 (20, 31, 34). Further, when ions are dissolved in water, the value is expected to change (35). Thus, in this calculation, we tried to calculate absorbance curves which give rise to the best fit to the experimental curves of Fig. 6, by changing both the $k_3(\nu)$ values of Downing and Williams by a constant factor and the thickness of the aqueous core, h_3. For the real part $n_3(\nu)$ of $\hat{n}_3$, we used the data of Downing and Williams (31). The final calculated results are demonstrated in Fig. 7. The experimental curves are surprisingly well reproduced for all angles of incidence examined. Thus, we have $h_3 = 9.6$ nm and k_3 (3400 cm^{-1}) = 0.36 as the converged values. The latter value means that the constant factor is 1.28. From the inspection of calculated data, the accuracy of these values is estimated to be better than a few percent. The change in the $\hat{n}_2$ value between 1.35 and 1.45 and that in the h_2 value between 0.85 (8) and 1.7 nm (24) had little effect on the calculated absorbances.

In this calculation, we used the optical parameters of unoriented bulk water. Thus it can be said that the water in the aqueous core between the two SDS monolayers does not show any specific orientation or structure formation.

4. *Second black films*

The second black film was produced by adding 0.35 M NaCl to the 0.01 M aqueous solution of SDS. The spectrum of the equilibrated second black film is illustrated in Fig. 8*A*, being

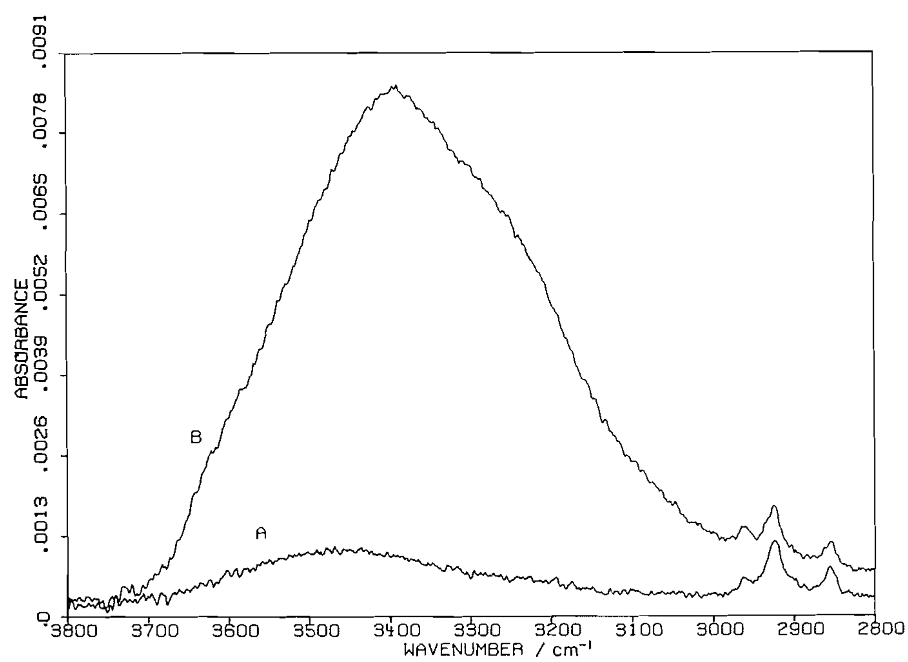

FIG. 8. Infrared spectra of a second black film (A) drawn from 0.01 M SDS solution + 0.35 M NaCl, compared with that of the first black film (B) drawn from 0.06 M SDS solution.

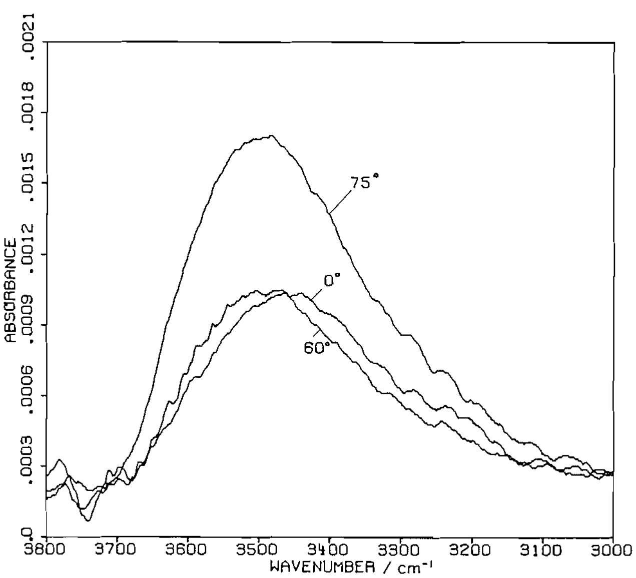

FIG. 9. Polarized infrared spectra of a second black film drawn from 0.01 M SDS solution + 0.35 M NaCl. The angles of incidence for polarized radiations with electric vector parallel to the plane of incidence are shown.

compared with that of the first black film from 0.06 M SDS solution (Fig. 8*B*). The intensity of the CH stretching bands in the second black film is almost the same as that of the first black film, suggesting that the thickness of the SDS layers are identical in both cases. However, the intensity of the water band in the second black film is about one-tenth of that of the first black film. This leads us to a conclusion that the thickness of the aqueous core is about 1 nm, considering that the absorptivities of both films are nearly the same (35). Adding this value to the SDS bilayer thickness of 2.2 nm (see above), we have the total film thickness of 3.2 nm. This is a little less than the reported value of 4.4 nm (18).

Furthermore, the peak wavenumber of the second black film is about 60 cm^{-1} higher than that of the first black film. Addition of 0.35 M NaCl to the bulk aqueous solution of SDS may result in a small wavenumber shift of a few cm^{-1} (35, 36). Thus, the large higher wavenumber shift of the second black film in Fig. 8*A* indicates that the aqueous core is in a highly ionic atomosphere. This is reasonable if we consider the presence of double layers of concentrated ions in the very thin aqueous core mentioned above.

The polarization measurements were also carried out for this second black film. The results are shown in Fig. 9 for three incident angles, 0°, 60°, and 75°. The trends of the wavenumber shift and intensity change are the same as in the case of the first black films shown in Fig. 6. Since the optical constants are thought to be different from those of pure water, we have not tried to reproduce the experimental absorbance curves in Fig. 9. However, it seems likely that there is no specific orientation or rigidified structure of water even in this thin second black film, as has been speculated by Lyklema *et al.* (8) who have characterized the SDS black films as "mobile" ones. A similarity between the bulk water and the water layers thicker than a few angstroms has been also pointed out by Clliford (37).

Orbital angular momentum eigenfunctions for many-particle systems

JOHN AVERY
Department of Physical Chemistry, H.C. Ørsted Institute, University of Copenhagen, DK-2100 Denmark

Received September 6, 1984

This paper is dedicated to Professor Camille Sandorfy on the occasion of his 65th birthday

JOHN AVERY. Can. J. Chem. **63**, 1719 (1985).

Methods are presented for constructing eigenfunctions of the total orbital angular momentum operator of a many-particle system without the use of the Clebsch–Gordan coefficients. One of the equations derived in this paper is analogous to Dirac's identity for total spin; and through this equation, a connection is established between eigenfunctions of L^2 and irreducible representations of the symmetric group S_n.

JOHN AVERY. Can. J. Chem. **63**, 1719 (1985).

On présente des méthodes qui permettent d'établir, sans faire appel aux coefficients de Clebsch–Gordan, les fonctions de eigen de l'opérateur total du moment angulaire de l'orbitale d'un système à plusieurs particules. L'une des équations ainsi obtenue dans ce travail est analogue à celle d'identité de Dirac relative au spin total; au moyen de cette équation, on a établi une corrélation entre les fonctions de eigen de L^2 et les représentations irréductibles du groupe de symétrie S_n.

[Traduit par le journal]

Introduction

In the quantum mechanical treatment of many-particle systems, one is often faced with the problem of constructing eigenfunctions of the total angular momentum operator

$$[1] \quad L^2 = \boldsymbol{L} \cdot \boldsymbol{L}$$

where

$$[2] \quad \boldsymbol{L} = \sum_{a=1}^{N} \boldsymbol{\ell}_a$$

and where

$$[3] \quad \begin{aligned} \ell_{ax} &= \frac{1}{i}\left(y_a \frac{\partial}{\partial z_a} - z_a \frac{\partial}{\partial y_a}\right) \\ \ell_{ay} &= \frac{1}{i}\left(z_a \frac{\partial}{\partial x_a} - x_a \frac{\partial}{\partial z_a}\right) \\ \ell_{az} &= \frac{1}{i}\left(x_a \frac{\partial}{\partial y_a} - y_a \frac{\partial}{\partial x_a}\right) \end{aligned}$$

Often the Clebsch–Gordan coefficients are used to construct eigenfunctions of L^2 and L_z. In this paper, we shall discuss an alternative method which avoids the use of Clebsch–Gordan coefficients.

An identity for L^2 analogous to Dirac's identity for S^2

From eqs. [1]–[3] it follows that

$$[4] \quad \begin{aligned} \boldsymbol{L}x_a &= (0, -iz_a, iy_a) \\ \boldsymbol{L}y_a &= (iz_a, 0, -ix_a) \\ \boldsymbol{L}z_a &= (-iy_a, ix_a, 0) \end{aligned}$$

so that

$$[5] \quad \begin{aligned} (\boldsymbol{L}x_a)\cdot(\boldsymbol{L}x_b) &= x_b x_a - (ab) \\ (\boldsymbol{L}y_a)\cdot(\boldsymbol{L}y_b) &= y_b y_a - (ab) \\ (\boldsymbol{L}z_a)\cdot(\boldsymbol{L}z_b) &= z_b z_a - (ab) \\ (\boldsymbol{L}x_a)\cdot(\boldsymbol{L}y_b) &= x_b y_a \\ (\boldsymbol{L}x_a)\cdot(\boldsymbol{L}z_b) &= x_b z_a \\ (\boldsymbol{L}y_a)\cdot(\boldsymbol{L}z_b) &= y_b z_a \qquad a, b = 1, 2, \ldots, N \end{aligned}$$

where, for the sake of brevity, we have introduced the notation

$$[6] \quad (ab) \equiv x_a x_b + y_a y_b + z_a z_b$$

Now let us suppose that L^2 acts on a product of the particle coordinates of the form

$$[7] \quad f = \underbrace{x_a x_b x_c \ldots y_d y_e y_g \ldots z_h z_i z_j \ldots}_{n \text{ factors}}$$

Since

$$[8] \quad L^2 f = \boldsymbol{L}\cdot(\boldsymbol{L}f) = \boldsymbol{L}\cdot[(\boldsymbol{L}x_a)x_b x_c \ldots + x_a(\boldsymbol{L}x_b)x_c \ldots + \ldots]$$

we have

$$[9] \quad L^2 f = \left[2n + 2\frac{(\boldsymbol{L}x_a)\cdot(\boldsymbol{L}x_b)}{x_a x_b} + 2\frac{(\boldsymbol{L}x_a)\cdot(\boldsymbol{L}x_c)}{x_a x_c} + \ldots \text{ (all possible pairs)}\right] f$$

Making use of eq. [5], we can rewrite [9] in the form

$$[10] \quad L^2 f = 2(n + Q - C) f$$

where Q is a sum of permutation operators

$$[11] \quad Q \equiv \underbrace{P_{ab} + P_{ac} + P_{bc} + \ldots}_{\frac{n(n-1)}{2} \text{ terms}}$$

and where C is a "contraction operator" defined by the relation

$$[12] \quad Cf \equiv \left[\frac{(ab)}{x_a x_b} + \ldots \text{ (all possible pairs of } x\text{'s)} + \frac{(de)}{y_d y_e} + \ldots \text{ (all possible pairs of } y\text{'s)} + \frac{(hi)}{z_h z_i} + \ldots \text{ (all possible pairs of } z\text{'s)}\right] f$$

It is understood that if C acts more than once on f, then the only pairs formed are between coordinates not already contracted. Thus, for example, if $f = x_a x_b x_c y_d y_e$, then

$$Cf = (ab)x_c y_d y_e + (ac)x_b y_d y_e + (bc)x_a y_d y_e + x_a x_b x_c (de)$$

[13] $$C^2 f = 2(de)\,[(ab)x_c + (ac)x_b + (bc)x_a]$$
$$C^3 f = 0$$

Equation [10] is analogous to Dirac's identity for the total spin operator. However, it should be noticed that the operator Q is a class-invariant of the symmetric group S_n, not of S_N, where n is the degree of the mononomial f, while N is the number of particles in the system (1–4).

Construction of symmetric eigenfunctions of L^2 and L_z with $M = 0$

We now let (5–8)

[14] $$F \equiv \underbrace{z_a z_b z_c z_d \ldots}_{n \text{ factors}}$$

Since F contains only z's, with no x's or y's, it is completely symmetric with respect to the interchanges P_{ab}, P_{ac}, ... etc. Therefore

[15] $$QF = \frac{n(n-1)}{2} F$$

and

[16] $$L^2 F = [n(n+1) - 2C]F$$

Furthermore, since

[17] $$L^2(ab)f = (ab)L^2 f$$

it follows that

[18] $$L^2 C^t F = [(n-2t)(n-2t+1) - 2C]C^t F$$

We would now like to show that, for $L = n, n-2, \ldots,$ the function

[19] $$F_L \equiv \frac{2L+1}{\left(\frac{n-L}{2}\right)!\,(n+L+1)!!} \times \sum_{s=0}^{[\frac{1}{2}L]} \frac{(-1)^s}{s!}(2L-2s-1)!!\,C^{s+(1/2)(n-L)} F$$

is an eigenfunction of L^2 corresponding to the eigenvalue $L(L+1)$. In other words, we would like to show that

[20] $$L^2 F_L = L(L+1)F_L \qquad L = n, n-2, n-4, \ldots$$

Letting L^2 act on the sum in eq. [19] and making use of [18], we obtain

$$L^2 \sum_{s=0}^{[\frac{1}{2}L]} \frac{(-1)^s}{s!}(2L-2s-1)!!\,C^{s+(1/2)(n-L)}F$$

[21] $$= \sum_{s=0}^{[\frac{1}{2}L]} \frac{(-1)^s}{s!}(2L-2s-1)!!\,[(L-2s)(L-2s+1) - 2C]C^{s+(1/2)(n-L)}F$$

$$= L(L+1)\sum_{s=0}^{[\frac{1}{2}L]} \frac{(-1)^s}{s!}(2L-2s-1)!!\,C^{s+(1/2)(n-L)}F$$

so that eq. [20] is established.

As an example, let us consider the case where $n = 2$. Then

[22] $$F = z_a z_b$$

and

[23] $$F_2 = F - \frac{1}{3}CF = z_a z_b - \frac{1}{3}(ab)$$
$$F_0 = \frac{1}{3}(ab) \qquad a, b = 1, 2, \ldots, N$$

It is easy to verify that F_2 is an eigenfunction of L^2 corresponding to the quantum number $L = 2$, while F_0 is an eigenfunction corresponding to $L = 0$; and this is true for all possible values of the particle indices a and b. If $a = b$, then F_2 has the angular dependence of a d-orbital, while if $a \neq b$, F_2 represents two p-orbitals coupled together.

As a second example, let us consider the case where $n = 3$, so that

[24] $$F = z_a z_b z_c$$

Then

[25] $$F_3 = F - \frac{1}{5}CF = z_a z_b z_c - \frac{1}{5}[(ab)z_c + (ac)z_b + (bc)z_a]$$
$$F_1 = \frac{1}{5}CF = \frac{1}{5}[(ab)z_c + (ac)z_b + (bc)z_a]$$

As in our previous example, no matter what values the particle indices take on, the functions F_L will still be eigenfunctions of L^2. If $a = b = c$, then F_3 corresponds to an f-orbital; if $a = b \neq c$, it corresponds to a d-orbital coupled to a p-orbital; and if $a \neq b$, $b \neq c$, and $c \neq a$, F_3 corresponds to three p-orbitals coupled together.

For $n = 4$, we have

[26] $$F_4 = F - \frac{1}{7}CF + \frac{1}{70}C^2F$$
$$F_2 = \frac{1}{7}CF - \frac{1}{21}C^2F$$
$$F_0 = \frac{1}{30}C^2F$$

Notice that

[27] $$F_0 + F_2 + F_4 = F$$

and in general,

[28] $$\sum_{L=0,2,\ldots}^{n} F_L = F$$

so that F_L corresponds to a projection of F onto that part of Hilbert space spanned by eigenfunctions of L^2 belonging to the quantum number L. Other examples, corresponding to higher values of n, are shown in Table 1.

Eigenfunctions of L^2 and L_z with $M = L$

The symmetric eigenfunctions of L^2 and L_z generated means of eq. [19] correspond to $M = 0$. Eigenfunctions corresponding to other values of M can of course be obtained from them by use of the raising and lowering operators

[29] $$L_\pm = L_x \pm iL_y$$

However, this procedure is somewhat laborious, and therefore it is interesting to see that eigenfunctions of L^2 with $M = L$ can be written down directly. To see this, we make use of the identity

TABLE 1. Totally symmetric eigenfunctions of L^2 and L_z with $M = 0$; $F \equiv z_a z_b z_c \ldots$, $a, b, c, \ldots = 1, 2, \ldots, N$; the "contraction operator" C is defined by eq. [12]

n	L	Eigenfunctions of L^2 and L_z
1	1	$F = z_a$
2	2	$F - \frac{1}{3}CF = z_a z_b - \frac{1}{3}(ab)$
	0	$\frac{1}{3}CF = \frac{1}{3}(ab)$
3	3	$F - \frac{1}{5}CF$
	0	$\frac{1}{5}CF$
4	4	$F - \frac{1}{7}CF + \frac{1}{70}C^2F$
	2	$\frac{1}{7}CF - \frac{1}{21}C^2F$
	0	$\frac{1}{30}C^2F$
5	5	$F - \frac{1}{9}CF + \frac{1}{126}C^2F$
	3	$\frac{1}{9}CF - \frac{1}{45}C^2F$
	1	$\frac{1}{70}C^2F$
6	6	$F - \frac{1}{11}CF + \frac{1}{198}C^2F - \frac{1}{4158}C^3F$
	4	$\frac{1}{11}CF - \frac{1}{77}C^2F + \frac{1}{770}C^3F$
	2	$\frac{1}{126}C^2F - \frac{1}{378}C^3F$
	0	$\frac{1}{630}C^3F$

[30] $L^2 = L_z(L_z + 1) + L_-L_+$

and we introduce the notation

[31] $a_+ \equiv x_a + iy_a$

Next we notice that

$$L_+a_+ = 0$$

[32] $$L_+a_+b_+ = 0$$

$$L_+a_+b_+c_+ = 0$$

etc. $\qquad a, b, c, \ldots = 1, 2, \ldots, N$

and that

$$L_za_+ = a_+$$

[33] $$L_za_+b_+ = 2a_+b_+$$

$$L_za_+b_+c_+ = 3a_+b_+c_+$$

etc. $\qquad a, b, c, \ldots = 1, 2, \ldots, N$

so that

TABLE 2. Eigenfunctions of L^2 and L_z with $M = L$; $a_+ \equiv x_a + iy_a$; (ab), $(a \times b)_+$, and $|abc|$ are defined respectively by eqs. [6], [31], and [38]; $a, b, c, \ldots = 1, 2, 3, \ldots, N$

n	L	
1	1	a_+
2	2	a_+b_+
	1	$(a \times b)_+$
	0	(ab)
3	3	$a_+b_+c_+$
	2	$(a \times b)_+c_+$
	1	$(ab)c_+$
	0	$\|abc\|$
4	4	$a_+b_+c_+d_+$
	3	$(a \times b)_+c_+d_+$
	2	$(a \times b)_+(c \times d)_+$
		$(ab)c_+d_+$
	1	$(ab)(c \times d)_+$
		$\|abc\|d_+$
	0	$(ab)(cd)$

[34]
$$L^2 \underbrace{a_+b_+c_+}_{n \text{ factors}} \ldots = n(n+1)a_+b_+c_+ \ldots$$

$$L_za_+b_+c_+ \ldots = na_+b_+c_+ \ldots$$

We then introduce the notation

[35] $(a \times b)_+ \equiv y_az_b - z_ay_b + i(z_ax_b - x_az_b)$

From [29], [2], and [3] it follows that

[36]
$$L_+(a \times b)_+ = 0$$

$$L_z(a \times b)_+ = (a \times b)_+$$

so that

[37]
$$[L^2 - n(n-1)]\underbrace{a_+b_+c_+ \ldots}_{n-2 \text{ factors}}(d \times e)_+ = 0$$

$$[L_z - (n-1)]a_+b_+c_+ \ldots (d \times e)_+ = 0$$

Finally we introduce the notation

[38] $|abc| \equiv \det \begin{vmatrix} x_a & y_a & z_a \\ x_b & y_b & z_b \\ x_c & y_c & z_c \end{vmatrix}$

and notice that

[39] $\mathbf{L}|abc| = 0$

so that

$$[40]\quad \begin{aligned} &[L^2 - (n-3)(n-2)]\,|abc|\underbrace{d_+e_+f_+\ldots}_{n-3\text{ factors}} = 0 \\ &[L_z - (n-3)]\,|abc|d_+e_+f_+\ldots = 0 \end{aligned}$$

Proceeding in this way, we can construct simultaneous eigenfunctions of L^2 and L_z corresponding to the quantum numbers L and $M = L$ as shown in Table 2.

If we compare Table 1 with Table 2, we notice immediately that the functions corresponding to odd values of $n - L$ are missing from Table 1. This is because the functions in Table 1 are required to be completely symmetric with respect to interchanges of the particle indices $a, b, c, \ldots$, while the functions corresponding to odd values of $n - L$ correspond to other irreducible representations of S_n. By allowing other symmetries, it is possible to use eq. [19] and Table 1 to generate eigenfunctions of L^2 and L_z with $M = 0$ also for odd values of $n - L$. For example, if we replace z_b in eq. [22] by $(b \times c)_z = x_b y_c - y_b x_c$, eqs. [22] and [23] take on the modified form

$$[41]\quad F' = z_a(x_b y_c - y_b x_c)$$

and

$$[42]\quad \begin{aligned} F_2' &= z_a(x_b y_c - y_b x_c) - \frac{1}{3}|abc| \\ F_0' &= \frac{1}{3}|abc| \end{aligned}$$

It is easy to verify that F_2' and F_0' are eigenfunctions of L^2 corresponding respectively to the quantum numbers $L = 2$ and $L = 0$.

Discussion

The fact that the functions in Tables 1 and 2 are eigenfunctions of L^2 and L_z regardless of the values taken on by the particle indices $a, b, c, \ldots$ can be understood as a consequence of the fact that the transformation properties of these functions under rotations of the system as a whole are independent of the particle indices. The method for constructing eigenfunctions of total orbital angular momentum discussed here is closely related to the method for generating hyperspherical harmonics by harmonic projection which we treated in our previous papers (5–7). It is also closely related to the irreducible tensor formalism, a discussion of which can be found, for example, in Hamermesh (9).

To see the relationship between the methods presented here and the usual methods for coupling angular momenta, we can compare the functions shown in eq. [23] with functions obtained using Clebsch–Gordan coefficients. Let us consider the case where $a \neq b$. Then

$$[43]\quad F_2 = z_a z_b - \frac{1}{3}(x_a x_b + y_a y_b + z_a z_b)$$

represents a d-orbital obtained by coupling two p-orbitals. If we instead used Clebsch–Gordan coefficients, we would find:

$$[44]\quad |L = 2, M = 0\rangle = \frac{1}{\sqrt{6}}|1, -1\rangle + \sqrt{\frac{2}{3}}|0, 0\rangle + \frac{1}{\sqrt{6}}|-1, 1\rangle$$

where

$$[45]\quad \begin{aligned} |1, -1\rangle &= -\frac{1}{2}(x_a + iy_a)(x_b - iy_b) \\ |0, 0\rangle &= z_a z_b \\ |-1, 1\rangle &= -\frac{1}{2}(x_a - iy_a)(x_b + iy_b) \end{aligned}$$

If we substitute [45] into [44] we obtain

$$[46]\quad |L = 2, M = 0\rangle = \frac{3}{\sqrt{6}}\left[z_a z_b - \frac{1}{3}(x_a x_b + y_a y_b + z_a z_b)\right]$$

which is proportional to the function shown in eq. [43].

When several angular momenta are coupled, there may be several different functions all of which correspond to the same values of L and M. These functions can be classified by Young operators, a situation which is analogous to the coupling of spins in the Yamanouchi–Kotani branching diagram. For this reason, the connection between angular momentum and the permutation group is an interesting one.

Rôle de la liaison hydrogène intra et intermoléculaire dans l'étude des propriétés spectroscopiques et photophysiques. Cas types: dérivés du carbazole

PIERRE D. HARVEY[1] ET GILLES DUROCHER[2]

Département de Chimie, Université de Montréal, C.P. 6210, Succ. A, Montréal (Qué.), Canada H3C 3V1

Reçu le 10 octobre 1984

Cet article est dédié au Professeur Camille Sandorfy à l'occasion de son 65^e^ anniversaire

PIERRE D. HARVEY et GILLES DUROCHER. Can. J. Chem. **63**, 1723 (1985).

Nous avons étudié les spectres d'absorption et de fluorescence de même que les rendements quantiques et les durées de vie de fluorescence des dérivés cyanurés et carboéthoxylés du carbazole en position 1 en phase gazeuse, dans les solutions fluides polaire et non-polaire de même que dans des matrices rigides à 77 K. Nous avons montré que le cyano-1 carbazole forme un dimère cyclique dans le méthyl-3 pentane avec une enthalpie de complexation de -39 kJ mol^{-1} et une entropie de complexation de -78 J mol^{-1} K^{-1}. Par ailleurs, aucun tautomère formé suite à l'excitation du dimère n'a pu être mis en évidence. Par ailleurs, la liaison hydrogène intramoléculaire prime chez le carboéthoxy-1 carbazole en phase gazeuse ou dissous dans les solvants non-polaires à l'état électronique fondamental de la molécule (système lié). Le rendement quantique de fluorescence de ce système lié à 23°C est par ailleurs très faible de sorte que seul le système libre émet à température ambiante. Par contre à 77 K en matrice rigide de 3MP, le système lié émet fortement en fluorescence. Cette liaison hydrogène intramoléculaire est par ailleurs rompue pour faire place à une liaison hydrogène intermoléculaire dans l'éthanol. Il en est ainsi pour le cyano-1 carbazole. Nous montrons que tous ces dérivés substitués en position 1 du carbazole forment des exciplexes lorsque dissous dans l'éthanol à 23°C. On explique la formation de ces exciplexes par le caractère transfert de charge élevé de l'état ^1L_b de ces molécules.

PIERRE D. HARVEY and GILLES DUROCHER. Can. J. Chem. **63**, 1723 (1985).

The absorption and fluorescence spectra along with the fluorescence quantum yields and lifetimes of the 1-cyano and 1-carboethoxy derivatives of carbazole in polar and non-polar fluids and in rigid solutions at 77 K have been investigated. The existence of the cyclic dimer has been confirmed for 1-cyanocarbazole in 3-methylpentane. The enthalpy and entropy of complexation are evaluated to be -39 kJ mol^{-1} and -78 J mol^{-1} K^{-1} respectively. No tautomeric species has been observed following excitation of the dimer. On the other hand, the intramolecular hydrogen bonding system always predominates in the gas phase and in non-polar solvents in the ground electronic state. This intramolecular hydrogen bonding has been shown to be broken in ethanol, where intermolecular hydrogen bonding to the solvent takes place. 1-Cyano carbazole follows the same behaviour in ethanol. All the 1-substituted derivatives of carbazole show exciplex fluorescence in ethanol and the formation of these exciplexes has been explained by the strong charge transfer character involved in the excited ^1L_b states of these molecules.

Introduction

Le Professeur Camille Sandorfy a tracé la voie depuis de nombreuses années à tous les chercheurs impliqués dans l'étude des effets de la liaison hydrogène dans les états électroniques fondamentaux des molécules en phase gazeuse (1) et en solutions (2). Nous avons voulu dans cet article, par quelques exemples choisis de dérivés substitués du carbazole, montrer comment la liaison hydrogène aussi bien intra qu'intermoléculaire influence les propriétés spectroscopiques et photophysiques de certaines molécules organiques.

La spectroscopie de même que la photophysique moléculaire des premiers états singulet et triplet excités du carbazole dans différents milieux ont fait l'objet de plusieurs études fondamentales au cours des années 1970 à 1980 (voir références dans l'article de G. E. Johnson (3)). Le carbazole est impliqué dans des autoassociations moléculaires (4) (dimères ou aggrégats) où encore il est lié par liaison hydrogène avec les solvants et cela dans son état électronique fondamental (5–7) ou dans ses états électroniques excités (8, 9). Par ailleurs contrairement à l'indole (10–13) ou au 3-H indole (14, 15) et à leurs dérivés, le carbazole en présence d'éthanol ou de solvants polaires ne forme pas de complexes excités (exciplexe) en solution fluide. Nous avons par ailleurs montré que le carbazole formait des exciplexes avec des molécules reconnus pour leur grande affinité électronique (les halocarbures aliphatiques) (16). Cependant, la constante de vitesse de second ordre pour la désactivation bimoléculaire s'est avérée plus faible pour le carbazole que pour l'indole et cela quel que soit l'halocarbure utilisé (17). Ce comportement s'explique par la théorie de Weller et Rehm qui tient compte de la différence d'énergie libre entre les états relaxés de la paire non-ionisée ($^1A_1 \ldots Q$) et de la paire d'ions ($^2A_0^+ \ldots {}^2Q^-$) (18).

Par ailleurs, outre les potentiels d'ionisation différents, les composés de l'indole possèdent une première bande électronique dans laquelle les transitions $^1L_b \leftarrow {}^1A$ et $^1L_a \leftarrow {}^1A$ sont très rapprochées en énergie ce qui confère à cette bande un caractère transfert de charge très important (à cause de l'intervention de l'état ^1L_a) qui est en fait absent dans la première transition ($^1L_b \leftarrow {}^1A$) du carbazole (19). Sachant que la substitution sur le noyau carbazole d'un groupement électroattracteur avait comme conséquence de réduire l'écart énergétique entre les transitions $^1L_b \leftarrow {}^1A$ et $^1L_a \leftarrow {}^1A$ du carbazole, nous avons procédé à la photosynthèse de plusieurs dérivés du carbazole substitués aux positions N, 1 et 3 du noyau (20) ainsi qu'à l'étude de la nature des différentes transitions électroniques chez ces mêmes composés (21–23). Les propriétés spectrales et photophysiques varient beaucoup d'un dérivé du carbazole à un autre. C'est ainsi qu'aucun transfert de charge intramoléculaire de torsion (TCIT) n'a pu être mis en évidence à l'état singulet excité dans le bichromophore du carbazole: le *N,N'*-di-carbazole (NNDC). La géométrie perpendiculaire du NNDC dans son état électronique fondamental est transformée en géométrie oblique dans l'état premier singulet relaxé sans intervention aucune de la polarité du solvant (24). D'autre part il a été

[1] Adresse actuelle: Département de Chimie, Université McGill, Montréal.

[2] Auteur à qui adresser la correspondance.

démontré récemment que les dérivés substitués aux positions de l'azote (N) et en position 3 du carbazole par des groupements électroattracteurs tels —CN et —COOEt sont très sensibles à la polarité du milieu. Les dérivés substitués en position 3 forment des exciplexes avec l'éthanol en solution fluide confirmant l'hypothèse de départ que plus l'écart énergétique entre les transitions $^1L_b\ (S_1) \leftarrow {}^1A$ et $^1L_a\ (S_2) \leftarrow {}^1A$ diminue plus la probabilité de formation d'exciplexes avec les solvants polaires augmente (25).

Les dérivés substitués en position 1 sont peut-être les plus intéressants à étudier en photophysique moléculaire puisque l'écart S_2-S_1 chez ces dérivés est approximativement identiques à celui du carbazole, et que d'autre part, d'autres possibilités d'interaction à l'état électronique fondamental s'offrent à ces molécules. En effet, la substitution d'un groupement carboethoxylé engendre une liaison hydrogène intramoléculaire (22). Par ailleurs, la substitution d'un groupement cyanuré provoque une dimérisation immédiate en solvant non-polaire, le dimère cyclique (double liaison hydrogène intermoléculaire) est stabilisé, comme nous l'avons confirmé récemment par une étude quantitative en infrarouge de transformée de Fourier (26). Il est aussi connu que d'autres dérivés du carbazole substitués en position 1 comme l'aza-1 carbazole (27) ainsi que l'aza-7 indole (28) se dimérisent à l'état électronique fondamental et que ce dimère lorsque photoexcité se tautomérise dans les solvants non-polaires produisant des fluorescences fortement déplacées vers le rouge suite à ces transferts de protons.

Le but de ce travail est donc de caractériser les diverses interactions intra et intermoléculaires de plusieurs dérivés substitués par des groupes électroattracteurs en position 1 du carbazole dans différents solvants et à diverses températures et cela dans leurs états électroniques fondamentaux et premiers singulets excités. Nous montrerons que ces divers types de liaison hydrogène affectent beaucoup les propriétés des états électroniques fondamentaux et excités de ces dérivés en plus de modifier en profondeur toute la dynamique des états excités de ces molécules.

Partie expérimentale

(a) *Produits*

Le carboethoxy-1 carbazole (1-COOEC) ainsi que le cyano-1 carbazole (1-CNC) ont été obtenus par photolyse du carbazole en présence de CCl_4 et ces produits ont été purifiés tel que décrit antérieurement (20). Le (carboethoxy)-1 éthyl-*N* carbazole (1-COOENEC) et le cyano-1 éthyl-*N* carbazole (1-CNNEC) ont été synthétisés par éthylation des dérivés N—H correspondant en utilisant la réaction catalytique de transfert de phase (29). Ces composés ont été purifiés par chromatographie sur colonne de gel de silice en utilisant un mélange d'éther de pétrole et d'éther éthylique (1:1) comme éluant. La pureté a été vérifiée par chromatographie sur couche mince et les produits ont été caractérisés par les spectroscopies de masse, ^{1}H rmn et infrarouge. Le méthyl-3 pentane (3MP) "pure grade" provenait de la compagnie Phillips Petroleum et il a été purifié tel que décrit antérieurement (16, 17). L'isopentane "pure grade" provenant de Phillips Petroleum et l'éther éthylique "analysed reagent" de la compagnie Baker ont été reflués sur H_2SO_4 concentré (4 mL/L) pendant 24 h et lavés plusieurs fois avec de l'eau bidistillé avant d'être distillé par fractionnement sur sodium. L'éthanol (EtOH) a été reflué sur H_2SO_4 (4 mL/L) pendant 24 h et distillé par fractionnement.

(b) *Instrumentation*

Les spectres d'absorption électronique ont été enregistré sur un spectrophotomètre Cary modèle 17. Une cellule métallique construite à nos ateliers, nous a permis d'enregistrer les spectres d'absorption aux diverses températures entre la température ambiante et celle de l'azote liquide (30). Les spectres de fluorescence ainsi que les spectres d'excitation corrigés de fluorescence ont été enregistrés à l'aide d'un spectrofluorimètre Spex Fluorolog modèle 1902 (14). Cet appareil est équipé d'un bain thermostaté fonctionnant entre 100 et −20°C. Aux températures inférieures, un montage à débit d'azote refroidi a été mis au point qui permet de stabiliser les températures à un degré près jusqu'à 77 K. Les spectres d'émission à l'état gazeux ont été obtenus à l'aide d'une cellule de quartz scellée sous un vide de 10^{-3} Torr (1 Torr = 133.3 Pa), puis placée dans un bain d'éthylène glycol chauffé à 160°C.

Les durées de vie de fluorescence ont été mesurées à l'aide d'un fluochronomètre construit dans nos laboratoires et qui utilise la technique de comptage de photon unique. Cet appareil de comptage comportant plusieurs modules de la compagnie Ortec Inc. a été décrit antérieurement (31). La méthode de convolution réitérative a été utilisée ainsi que la méthode statistique du χ^2 pour juger de la monoexponentialité des décroissances observées.

(c) *Procédure expérimentale*

Les solutions sans oxygène ont été obtenues par barbottage d'argon dans la solution. Le taux et le temps de barbottage ont été ajustés de façon à bien reproduire la durée de vie de fluorescence du carbazole obtenue par la méthode du gel–dégel. Les rendements quantiques de fluorescence ont été déterminés en utilisant le carbazole préalablement calibré par le diphényl-9,10 anthracène comme standard primaire (32). Les rendements quantiques de fluorescence ont tous été mesurés à des concentrations telles que l'autoabsorption ne puisse jouer aucun rôle. Les constantes théoriques de désactivation radiative ($k_F^{(t)}$) ont été calculées par l'équation de Birks et Dyson (33). Cette équation implique la connaissance de la variation de l'indice de réfraction du milieu en fonction de la longueur d'onde. Pour les solvants EtOH et 3MP à 23°C et pour l'EPA (éthanol, éther éthylique et isopentane 2:5:5) à 77 K, une expression pour la variation de l'indice de réfraction en fonction de la longueur d'onde a été décrite (24). Pour le 3MP à 77 K, la relation approximative suivante a été obtenue à partir des données de la littérature (34, 35):

$$n_{3MP}^{77\ K} \cong \left(2.2193 + \frac{7.450 \times 10^5}{\lambda^2}\right)^{1/2}$$

où λ est exprimée en angstrom (Å).

Les constantes radiatives (k_F) et non-radiatives (k_{nr}) de désactivation de la fluorescence ont été déterminées de façon usuelle par:

$$k_F = \phi_F/\tau_F$$

et

$$k_{nr} = (1 - \phi_F)/\tau_F$$

où ϕ_F et τ_F sont respectivement le rendement quantique et la durée de vie mesurée de la fluorescence de l'échantillon.

Résultats et discussion

I. *Cyano-1 carbazole: thermodynamique de formation du dimère à l'état électronique fondamental*

La figure 1 montre bien l'équilibre qui existe entre le monomère et une autre espèce lorsque l'on fait varier la température d'une solution 5×10^{-5} *M* (à 23°C) de 1-CNC dans le 3MP. Deux nouvelles bandes à 360 nm et à 342 nm apparaissent dans le spectre d'absorption et augmentent en intensité avec l'abaissement de la température alors que les bandes (0,0) et (0,1) de la première transition électronique $^1L_b \leftarrow {}^1A$ du 1-CNC respectivement situées à 347 et 333 nm diminuent avec l'abaissement de la température. Plusieurs points isobestiques apparaissent dans les spectres.

Un effet similaire sur le spectre est également observé lorsqu'à température fixe la concentration du 1-CNC est variée entre $3,3 \times 10^{-6}$ *M* et $2,3 \times 10^{-4}$ *M* dans le méthyl-3 pentane.

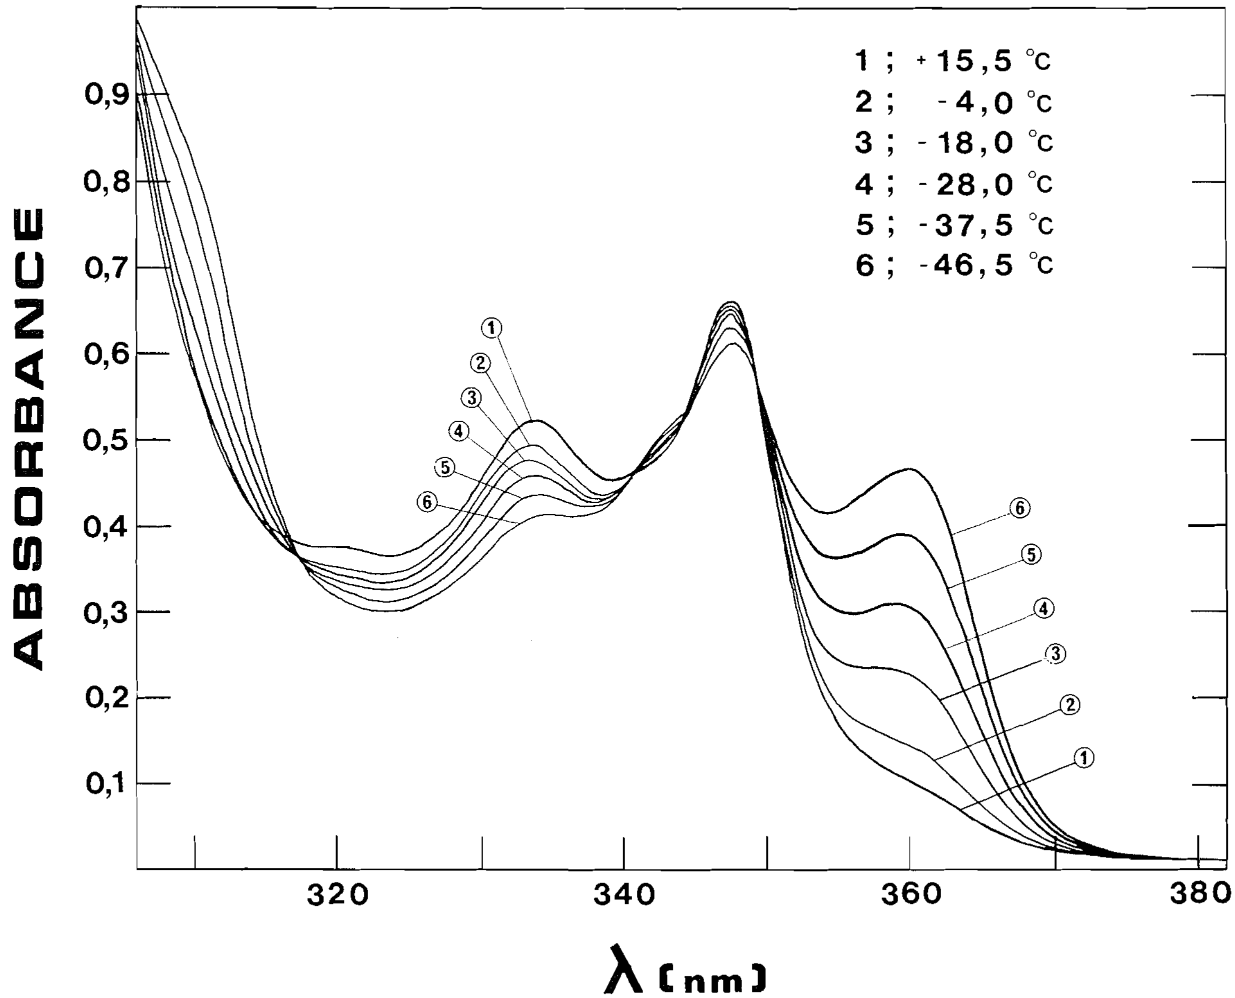

FIG. 1. Spectre d'absorption électronique du 1-CNC dans le 3MP à différentes températures. Concentration: $5{,}0 \times 10^{-5}$ M à 23°C.

Or nous avons montré récemment par spectroscopies ^{1}H rmn et infrarouge que le 1-CNC formait un dimère cyclique en solution dans le tétrachlorure de carbone (26).

Considérons un équilibre général entre n molécules de monomère (M) et un agrégat (P)

$$[1] \quad n\,\mathrm{M} \rightleftharpoons \mathrm{P}$$

La constante d'équilibre (K) à une température donnée est définie par:

$$[2] \quad K = \frac{[\mathrm{P}]}{[\mathrm{M}]^n} = \frac{[\mathrm{P}]}{(C_0 - n[\mathrm{P}])^n}$$

puisque la concentration totale C_0 qui est constante est toujours égale à $[\mathrm{M}] + n[\mathrm{P}]$. À condition qu'il n'y ait aucun recouvrement entre l'absorption de l'agrégat considéré et l'absorption du monomère à 360 nm, la concentration de l'agrégat peut être mesurée par son absorbance A:

$$[3] \quad [\mathrm{P}] = \frac{A}{\epsilon_{\mathrm{P}} l}$$

où ϵ_{P} devient le coefficient d'absorptivité molaire de l'agrégat considéré. Remplaçant [P] dans l'équation [2] par sa valeur en [3] on obtient la relation suivante:

$$[4] \quad \frac{C_0}{A} = \frac{n}{\epsilon_{\mathrm{P}}^{2/n} l^{2/n}} + \left(\frac{1}{\epsilon_{\mathrm{P}} l K}\right)^{1/n} \left(\frac{1}{A}\right)^{1-1/n}$$

Cette relation doit être linéaire pour la bonne valeur de n puisque C_0/A n'est pas une variable indépendante de $A^{(1/n-1)}$. Nous avons montré sur la fig. 2 qu'à toutes les températures utilisées dans cette étude, la variation de (C_0/A) en fonction de $(A)^{(1/n-1)}$ était linéaire lorsque $n = 2$ montrant clairement que l'agrégat considéré ici correspond à un dimère. Les résultats de la fig. 2 nous ont par la suite permis d'obtenir à chacune des températures la constante d'équilibre ainsi que le coefficient d'absorptivité molaire du dimère à 360 nm. La variation d'enthalpie et d'entropie de complexation a par la suite été calculée en utilisant l'équation de Van't Hoff (26). Ces résultats sont tous rassemblés au tableau 1. Les valeurs de ΔH et ΔS de complexation du 1-CNC dans le méthyl-3 pentane sont pratiquement identiques à celles obtenues dans le CCl_4 par infrarouge de transformée de Fourier compte-tenu des erreurs expérimentales inhérentes aux deux méthodes spectrales utilisées (26). Ceci implique donc que le dimère cyclique est également la structure la plus plausible dans les solvants hydrocarbonés étant donné la valeur très élevée obtenue pour le ΔH de complexation. On peut également souligner que l'ordre de grandeur des constantes d'équilibres obtenues se compare bien avec celui des constantes d'équilibre publiées pour les dimères cycliques de l'aza-1 carbazole (27) et de l'aza-7 indole (28) dans le même solvant.

Par ailleurs, le coefficient d'absorptivité molaire de la bande (0,0) du dimère semble augmenter régulièrement avec la dimi-

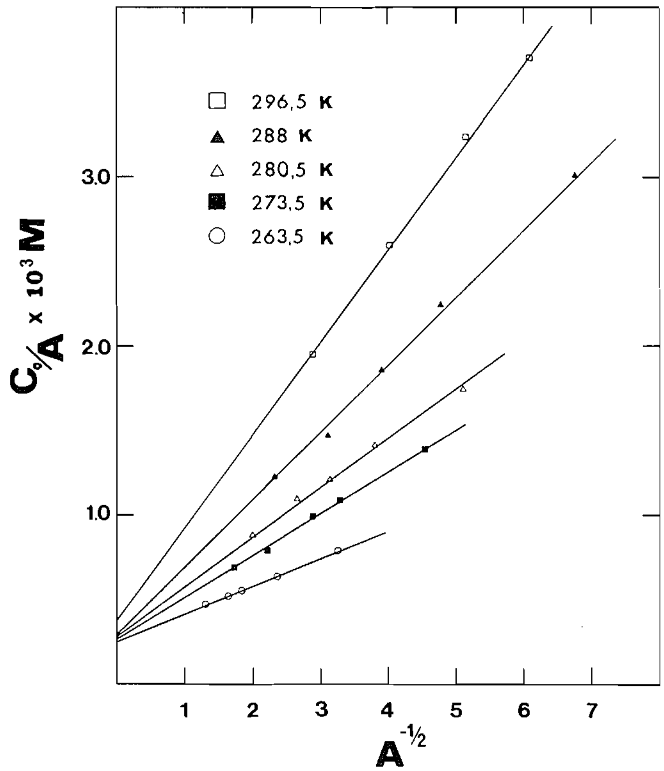

FIG. 2. Graphique de $[C_0]/A$ en fonction de $(A)^{-1/2}$ pour le système monomère–dimère (n = 2) du 1-CNC dans le 3MP où l'absorbance est mesurée à 360 nm et C_0 varient entre $6{,}0 \times 10^{-5}$ et $3{,}0 \times 10^{-4}$ M.

nution de la température du milieu comme le démontre la fig. 3. Ce coefficient atteint la valeur de 12×10^4 dm^2 mol^{-1} à 77 K toujours mesuré à 360 nm. Nous avons tracé sur la même figure la variation de la fréquence infrarouge du vibrateur NH lié dans ce même dimère en fonction de la température, données tirées d'un article récent (26). Il semble que plus la force de la liaison hydrogène augmente, plus grande est la probabilité de la première transition électronique dans le dimère cyclique du 1-CNC. Ceci va cependant à l'encontre d'un recouvrement entre les systèmes électronique-π des deux noyaux carbazoles par l'intermédiaire des atomes d'azote des deux groupements nitriles. En effet, si ce recouvrement existait, à cause de la symétrie C_{2h} du dimère, la première transition électronique serait permise en ordre zéro et la seconde interdite ce qui, suite à un calcul d'interaction de configurations, conduirait à prédire une diminution de l'intensité de cette première transition électronique comparativement à celle du monomère. Cette constatation ne favorise certainement pas le transfert des protons et la tautomérisation dans ce dimère (27, 28).

II. *Fluorescence du dimère du cyano-1 carbazole*

Sur la figure 4 apparaissent les spectres de fluorescence du 1-CNC dans le 3MP (c = $2{,}0 \times 10^{-5}$ M) à diverses températures. Le point isobestique à 368 nm montre bien qu'un équilibre existe entre le monomère et une autre entité. Le spectre de fluorescence du dimère pur est obtenu en matrice rigide de 3MP à 77 K et reproduit à la fig. 5. On peut voir la ressemblance qui existe entre le spectre de fluorescence du dimère à 77 K et le spectre 5 de la fig. 4. De plus une excellente image-miroir existe entre les spectres d'absorption et de fluorescence du dimère à 77 K. Peu importe la température de la

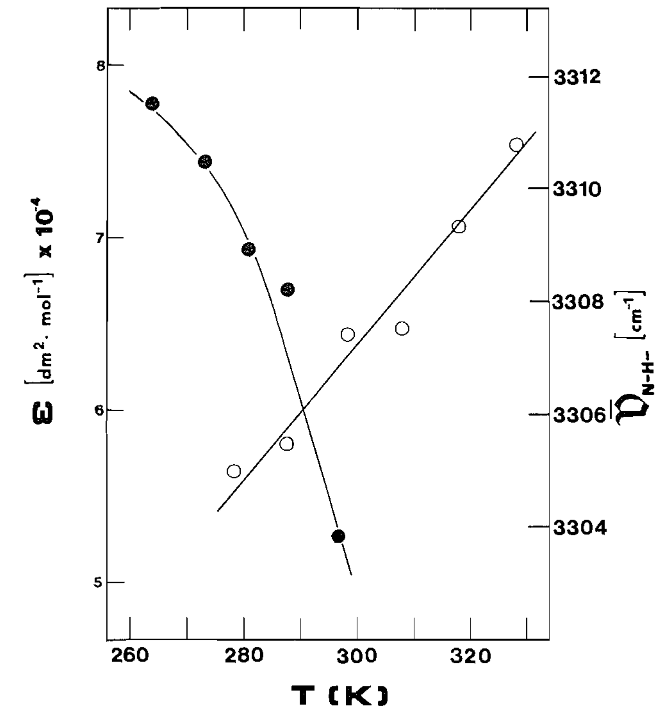

FIG. 3. Graphique du coefficient d'absorptivité molaire à 360 nm du dimère dans le 3MP (-•-•-•-) et de la fréquence de la vibration d'élongation du N—H associé du dimère dans le CCl_4 (o-o-o) en fonction de la température.

TABLEAU 1. Données spectrales et thermodynamiques de la formation du dimère du cyano-1 carbazole dans le méthyl-3 pentane mesurées à 360 nm

T (K)	$\epsilon_P \times 10^{-2}$ (dm^2 mol^{-1})	K (dm^3 mol^{-1})	ΔH^0 (kJ mol^{-1})	ΔS^0 (J mol^{-1} K^{-1})
296,5	525 ± 12	630 ± 20		
288,0	670 ± 26	910 ± 40		
280,5	693 ± 22	2050 ± 90	−39 ± 6	−78 ± 6
273,5	744 ± 23	2730 ± 120		
263,5	776 ± 22	4740 ± 130		

verses longueurs d'onde de fluorescence correspondent à une superposition des spectres d'absorption du monomère et du dimère. Une variation de la concentration du 1-CNC entre 1×10^{-6} M et 4×10^{-4} M n'a montré aucune différence dans les spectres de fluorescence et d'excitation de fluorescence enregistrés à 77 K dans le 3MP. Contrairement à l'aza-7 indole, aucun oligomère n'a pu être mis en évidence (28*c*). Par ailleurs, aucune phosphorescence n'a pu être détectée pour le dimère en matrice rigide de 3MP à 77 K. Il est en effet connu que les dimères de ce type n'émettent que très faiblement en phosphorescence (28*c*).

Aucun excimère ou tautomère n'a pu être détecté en fluorescence. Ceci montre que le tautomère ne peut se former à partir du dimère excité à cause d'une part, du peu de recouvrement entre les systèmes-π des deux chromophores du carbazole comme discuté antérieurement et en conséquence de la distance trop importante qui doit exister entre les protons et les atomes d'azote des groupements nitriles.

III. *Carboéthoxy-1 carbazole: liaison hydrogène intramoléculaire*

La géométrie du 1-COOEC favorise la formation d'une liai-

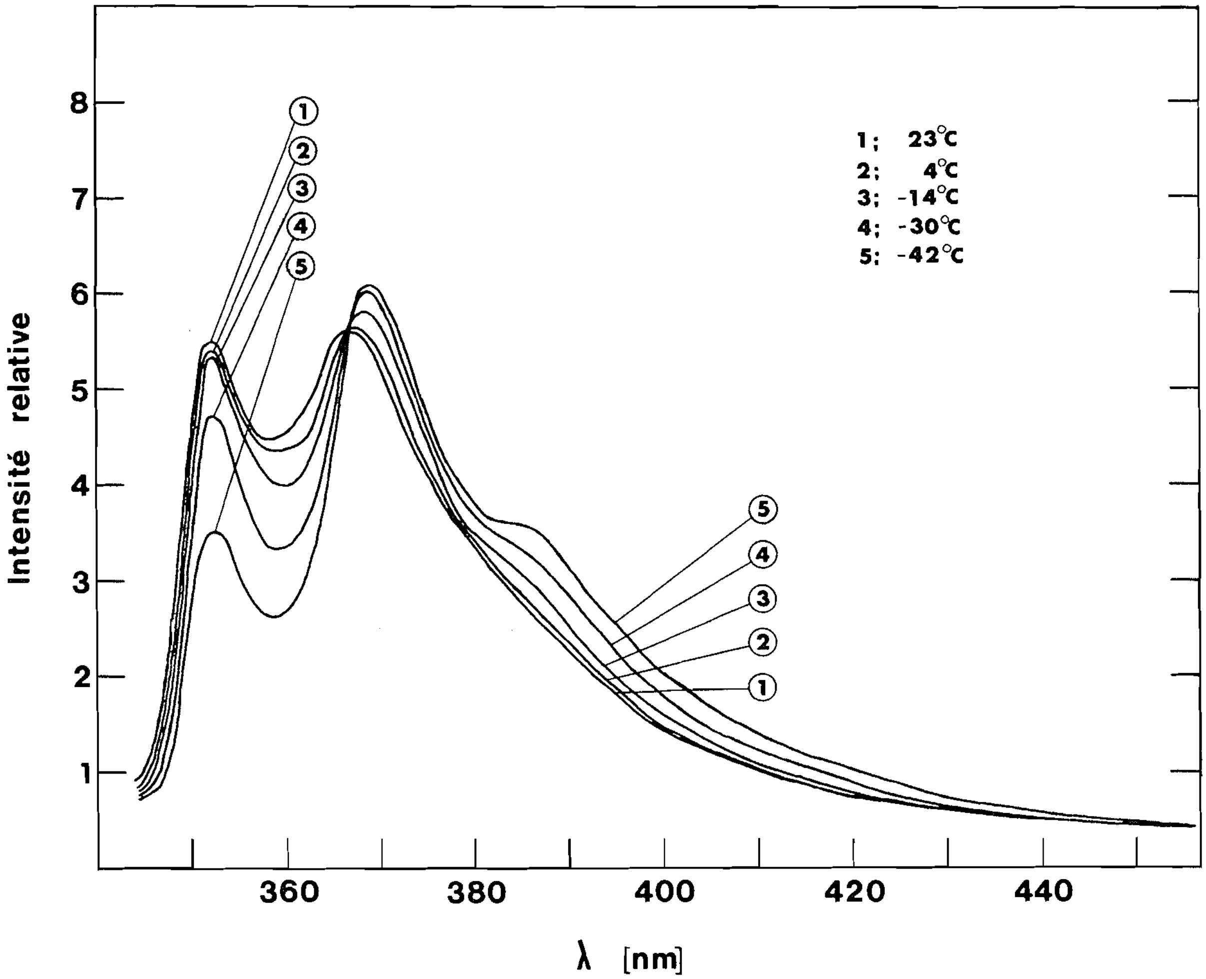

FIG. 4. Spectre de fluorescence du système monomère–dimère du 1-CNC dans le 3MP à différentes températures. Concentration: 2,0 × 10^{-5} *M* (23°C); λ (exc) = 340 nm.

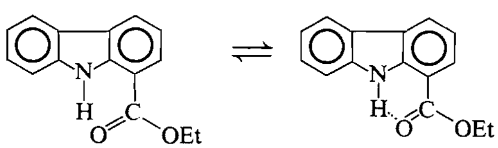
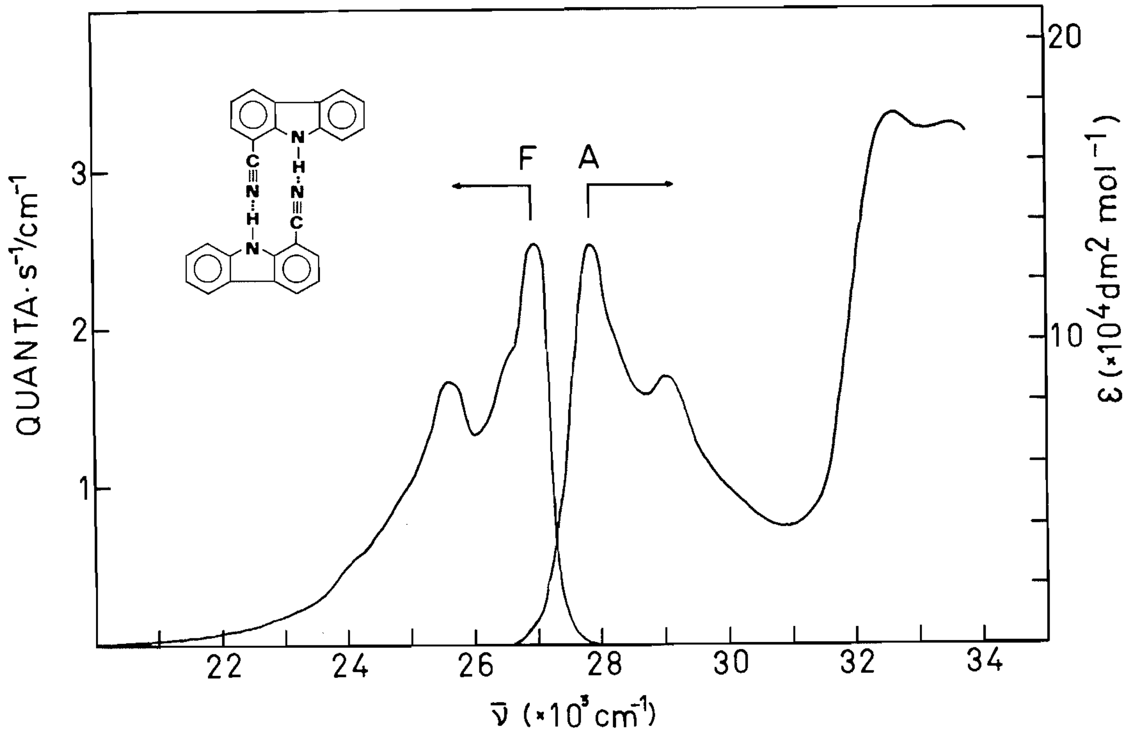
son hydrogène intramoléculaire entre le groupement NH et une paire électronique du groupement carbonyle:



Cependant, une telle interaction ne peut se produire que lorsque le lien C═O du groupement carboéthoxylé est dans le plan moléculaire. Nous avons montré récemment par infrarouge de transformée de Fourier qu'un équilibre existait entre une conformation planaire (système lié) et une autre non-planaire (système libre) (26). La constante d'équilibre obtenue entre les deux systèmes dans le tétrachlorure de carbone comme solvant est de 1,7 à 0°C et de 1,0 à 55°C montrant bien que l'équilibre se déplace que très lentement vers la forme libre en fonction de l'augmentation de la température.

Les spectres d'absorption électronique du 1-COOEC dans l'éthanol et le 3MP sont reproduits à la fig. 6. Les nombres d'onde de la transition ${}^1L_b \leftarrow {}^1A$ du 1-COOEC dans différents milieux sont donnés au tableau 2. Le 1-COOEC ainsi que le 1-CNC dans l'éthanol forment une liaison hydrogène intermoléculaire avec le solvant comme l'indique leurs nombres d'onde respectif de 27 860 et 28 090 cm^{-1}, ce qui correspond à un déplacement bathochrome d'environ 700 cm^{-1} pour le 1-CNC en passant du 3MP à l'éthanol, déplacement conventionnel pour ce type d'interaction dans le carbazole (22). Contrairement au 1-CNC dans le 3MP, le 1-COOEC dans le 3MP montre un spectre d'absorption quasi identique à celui dans l'éthanol à 23°C. Nous attribuons ce spectre surtout au conformère planaire liée de façon intramoléculaire. Dans le but de vérifier l'équilibre entre les conformères liée et libre, nous avons enregistré les spectres d'absorption du 1-COOEC dans l'hexadécane normal à plusieurs températures entre 23°C et 125°C et aucune modification visible n'est apparue dans le spectre d'absorption montrant par le fait même que dans les hydrocarbures aliphatiques l'équilibre est fortement déplacé vers la forme associée qui est surtout responsable de l'absorption. Même à l'état gazeux (160°C; 10^{-3} Torr) le système lié semble être la forme prédominante dans le spectre d'absorption électronique comme le démontre la fig. 7. La bande (0,0) de la première transition ${}^1L_b \leftarrow {}^1A$ apparaît à 28 200 cm^{-1} ce qui représente un déplacement hypsochrome par rapport au 3MP d'environ 400 cm^{-1}, valeur généralement obtenue entre un hydrocarbure aliphatique comme solvant et la phase gazeuse (voir données sur le carbazole (24, 36)).

Le spectre de fluorescence du 1-COOEC en phase gazeuse est reproduit sur la figure 7. Le spectre d'excitation corrigé de cette fluorescence se superpose relativement bien au spectre d'absorption ce qui indique que le système lié est à l'origine de l'espèce qui émet la fluorescence. Cependant, il est évident que



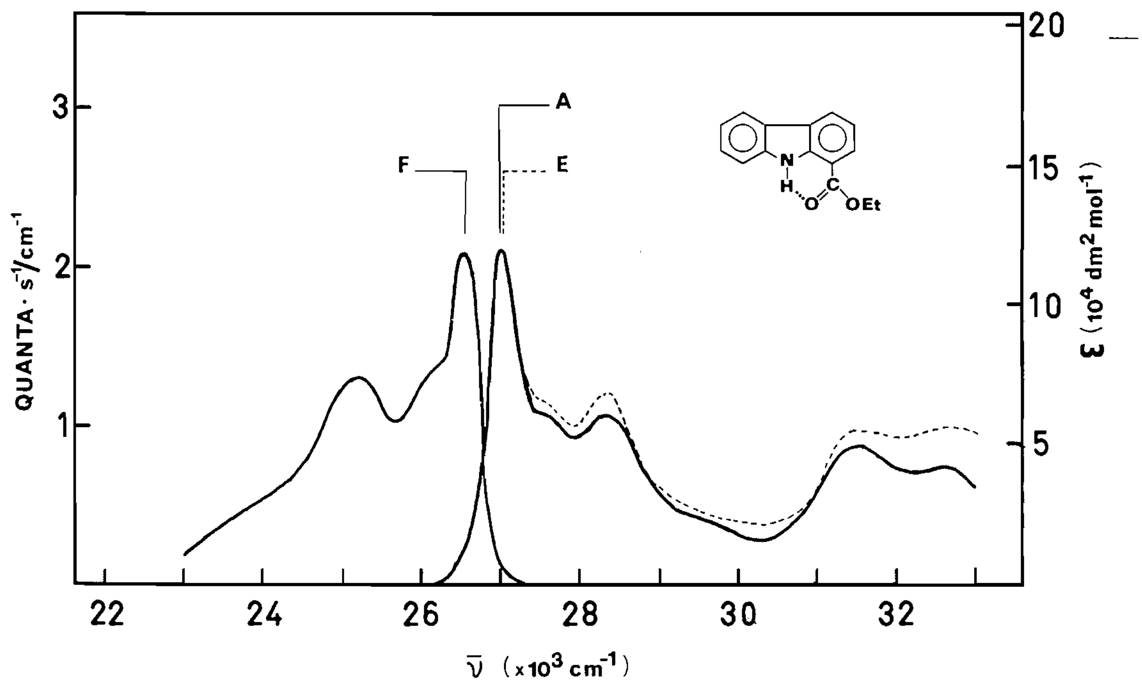


FIG. 5. Haut: spectre d'absorption et de fluorescence du dimère du 1-CNC dans le 3MP à 77 K. Concentration: (23°C) pour l'absorption: 2,0 $\times 10^{-5}$ *M*; pour le fluorescence: 3,0 $\times 10^{-6}$ *M*. Bas: spectres d'absorption, de fluorescence et d'excitation de la fluorescence du 1-COOEC dans le 3MP à 77 K.

l'image-miroir n'existe pas entre l'absorption et la fluorescence. De plus un déplacement Stokes de 2200 cm^{-1} existe entre les deux spectres. La largeur à la demi-hauteur du spectre de fluorescence est de 4000 cm^{-1}. Ce sont autant de caractéristiques qui semblent démontrer qu'une autre espèce que les systèmes lié ou libre est à l'origine de cette fluorescence en phase gazeuse à 160°C. Un transfert de proton à l'état excité de la forme associée et donc la formation d'une espèce tautomérique pourrait expliquer les caractéristiques observées. Une étude dynamique de la fluorescence picoseconde pourrait confirmer ou infirmer cette hypothèse.

Les spectres de fluorescence du cyano-1 carbazole protoné et *N*-éthylé de même que ceux du carboéthoxy carbazole protoné et *N*-éthylé dans le 3MP et dans l'éthanol sont présentés à la fig. 8 et les données spectroscopiques se retrouvent au tableau 2. Les spectres d'excitation de ces émissions correspondent tous

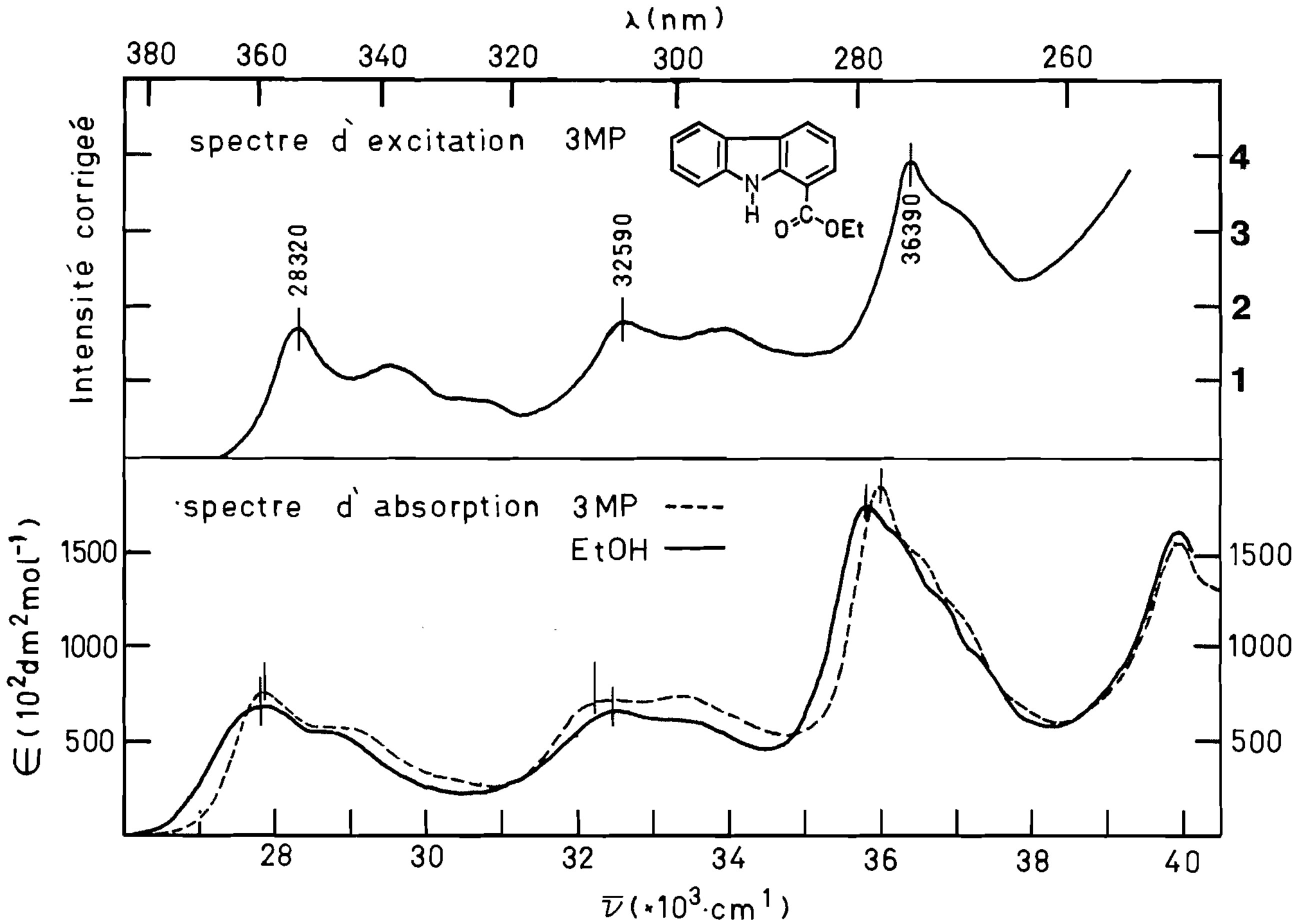

FIG. 6. Haut: spectre d'excitation de la fluorescence du 1-COOEC dans le 3MP à la température ambiante (peu importe la longueur d'onde de fluorescence observée). Bas: spectre d'absorption électronique du 1-COOEC dans le 3MP (---) et l'EtOH (—) à la température ambiante.

aux spectres d'absorption correspondant à la transition $^1L_b \leftarrow {}^1A$ de la molécule considérée sauf pour celui du 1-COOEC dans le 3MP que l'on peut voir sur la fig. 6. Un déplacement de 480 cm^{-1} vers le bleu est observé dans le spectre d'absorption dans le 3MP. Les bandes (0,0) des transitions $^1L_a \leftarrow {}^1A$ (32 590 cm^{-1}) et $^1B_b \leftarrow {}^1A$ (36 390 cm^{-1} (22)) subissent également un déplacement hypsochrome dans le spectre d'excitation de la fluorescence. D'autre part l'espèce responsable de l'émission ne peut être identique à celle qui absorbe puisque la bande (0,0) en absorption recouvre passablement la bande (0,0) de l'espèce émettrice et qu'il est connu pour les systèmes liés (EPA à 77 K dans le tableau 2) que les déplacements Stokes sont de l'ordre de 700 cm^{-1}. Nous attribuons donc la fluorescence observée à 23°C pour le 1-COOEC dans le 3MP au système libre.

Le système lié possède donc un rendement quantique pratiquement nul à la température ambiante. Cette attribution est aussi corroborée, en plus des deux points cités plus haut, par le fait que le rendement quantique apparent de cette émission est très faible (ϕ_F = 0,020; tableau 3). Puisque c'est le système lié qui est surtout responsable de l'absorption, ce rendement faible n'est donc pas le rendement réel du système libre. Cette attribution au système libre est de plus corroborée par le déplacement bathochrome de 1040 cm^{-1} observée pour la fluorescence dans le 3MP entre le 1-COOEC et le 1-COOENEC. Ce déplacement est identique à celui obtenu entre le carbazole et le *N*-éthyl carbazole dans le même solvant (17, 24, 26) pour lequel le groupement N—H du carbazole était libre. Il faut par surcroît noter que ce déplacement de 1040 cm^{-1} est en réalité plus élevé puisque la bande (0,0) du système libre subit un effet d'autoabsorption important à cause du recouvrement avec l'absorption du système lié. Le déplacement Stokes de 760 cm^{-1} dans le tableau 2 est assurément trop élevé pour le système libre à cause de cet effet.

Par abaissement de la température du 3MP, la fluorescence se déplace vers le rouge pour atteindre 26 560 cm^{-1} à 77 K. Son intensité augmente considérablement, le rendement quantique de fluorescence atteignant la valeur de 0,64 à 77 K. Par ailleurs, le spectre d'excitation de la fluorescence à 77 K se superpose parfaitement au spectre d'absorption du système lié à cette température comme le démontre la fig. 5. Ces résultats montrent clairement que la fluorescence observée en phase gazeuse ne peut provenir ni des systèmes lié ou libre. D'autre part, il semble que l'intensité de fluorescence du système lié soit très sensible à la température ou à la viscosité du milieu. A 77 K, cette fluorescence est également très sensible aux traces d'eau dans le 3MP produisant un élargissement du spectre, un déplacement vers le rouge, une diminution de l'intensité et une quasi extinction de la phosphorescence. Le spectre obtenu à la fig. 5 l'a été suite à des mesures extrêmes de protection du solvant contre l'eau atmosphérique.

IV. *Effet de l'éthanol sur les propriétés spectroscopiques des dérivés substitués en position 1 du carbazole*

Les spectres de quelques dérivés substitués du carbazole en position 1 dissous dans le 3MP et dans l'éthanol à 23°C sont rassemblés à la fig. 8. Une structure vibrationnelle bien déve-

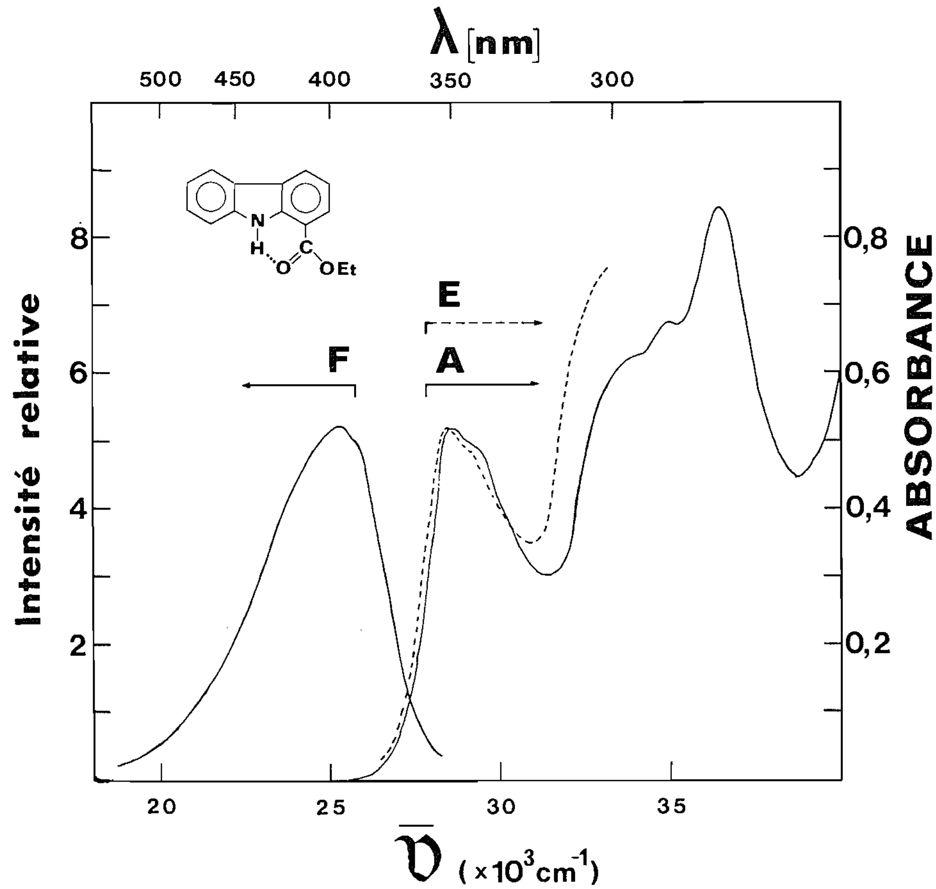

FIG. 7. Spectres d'absorption, de fluorescence et d'excitation de la fluorescence du 1-COOEC à l'état vapeur à 160°C et 10^{-3} Torr.

[d] Déplacement bathochrome de la bande (0,0) en fluorescence entre le 3MP et l'éthanol.

loppée existe dans les spectres où le 3MP sert de solvant. Par contre tous les spectres enregistrés pour les solutions d'éthanol à 23°C montrent une perte de structure fine vibrationnelle, une augmentation considérable de la largeur à la demi-hauteur, une augmentation du déplacement Stokes entre l'absorption et la fluorescence et une perte de l'image-miroir entre l'absorption et la fluorescence (voir tableau 3). Les spectres d'excitation de fluorescence correspondent bien aux spectres d'absorption cor-

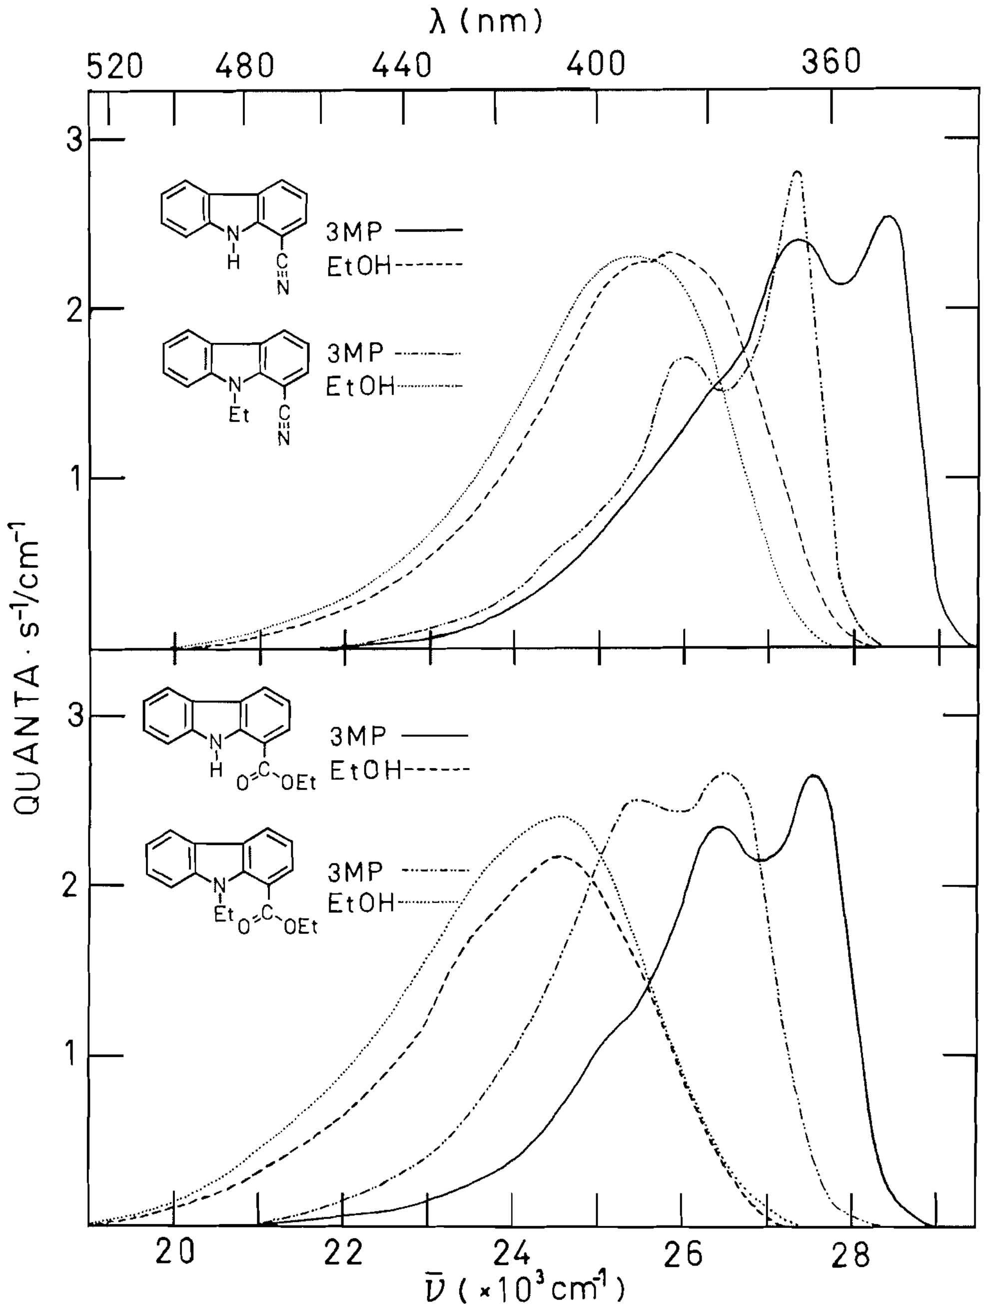

FIG. 8. Spectres de fluorescence du 1-CNC, 1-CNNEC, 1-COOEC et 1-COOENEC dissous dans le 3MP et l'éthanol à 23°C. Les concentrations étaient de 2,0 × 10^{-6} M pour le 1-CNC et de 1,0 × 10^{-5} M pour les autres dérivés étudiés.

respondant.

Le 1-CNC et le 1-COOEC forment avec l'éthanol un complexe par liaison hydrogène intermoléculaire à l'état électronique fondamental à 23°C et ce complexe existe également dans l'EPA comme le démontrent les valeurs de $\Delta\bar{\nu}_A$ dans le tableau 2. Rien de tel n'existe pour le 1-CNNEC et pour le 1-COOENEC puisque le groupement NH est remplacé par un groupement N—Et.

Une nouvelle espèce est donc responsable de la fluorescence de tous ces dérivés dans l'éthanol à 23°C. Le fait qu'un spectre bien structuré réapparaisse dans l'EPA ou l'éthanol à 77 K avec une largeur de bande de l'ordre de 2200 cm^{-1} ajouté aux autres caractéristiques déjà décrites enrichi l'hypothèse de l'exciplexe comme entité responsable de l'émission de fluorescence dans ces molécules dissoutes dans l'éthanol. Un exciplexe de stoïchiométrie 1 : 1 pourrait être responsable de la fluorescence du 1-CNNEC et du 1-COOENEC alors qu'un exciplexe de stoïchiométrie supérieure serait responsable de la fluorescence du 1-COOEC et 1-CNC dans l'éthanol puisque ces deux dernières molécules existent déjà sous forme complexée à l'état électronique fondamental (37). Une étude plus approfondie de chacune de ces molécules dans le 3MP avec ajout d'éthanol et d'eau est actuellement en cours de manière à définir la stoïchiométrie de ces exciplexes.

Par ailleurs, on sait que le carbazole et l'éthyl-*N* carbazole ne forment aucun exciplexe avec les alcools aliphatiques. Une explication possible pouvait être le fait que l'écart énergétique S_1-S_2 est relativement élevé (~4500 cm^{-1}) dans ces molécules alors que l'on sait que c'est la transition $^1L_a \leftarrow {}^1A$ chez les amines aromatiques qui confère le caractère transfert de charge

TABLEAU 3. Propriétés photophysiques de quelques dérivés substitués en position 1 du carbazole

[a] Ces rendements quantiques sont la moyenne de trois mesures individuelles qui se retrouvent toujours à l'intérieur d'une marge d'erreur de ± 0,02.

[b] Ces durées de vie proviennent de la moyenne de deux mesures expérimentales dont la marge d'erreur est de ± 0,25 ns. Ces décroissances sont toutes monoexponentielles.

nécessaire à la stabilisation de l'exciplexe (28*b*). Une étude récente des dérivés substitués en position 3 du carbazole semblait confirmer l'hypothèse de l'écart énergétique puisqu'il était réduit à 3000 cm^{-1} environ et que ces dérivés formaient des exciplexes avec l'éthanol (25). Cette hypothèse ne peut assurément pas expliquer la formation d'exciplexes entre les dérivés du carbazole substitués en position 1 et l'éthanol puisque les écarts S_1–S_2 pour l'ensemble des molécules étudiées varient entre 4350 cm^{-1} et 5040 cm^{-1} (22). La substitution d'un groupement électro-attracteur en position 1 du noyau doit donc être responsable du caractère transfert de charge nécessaire dans la fonction d'onde excitée ($^1L_b \leftarrow {}^1A$) pour permettre la stabilisation de l'exciplexe avec l'éthanol. Ceci est corroboré par le rapport des coefficients d'absorptivité molaire des bandes (0,0) des transitions $^1L_b \leftarrow {}^1A$ et $^1L_a \leftarrow {}^1A$ qui sont les suivants: 1-COOEC (1,1); 1-COOENEC (0,9); 1-CNC (0,6); 1-CNNEC (0,7) comparativement au carbazole (0,2) et à l'éthyl-*N* carbazole (0,2) (22). Chez les mêmes dérivés substitués en position de l'azote, ces rapports varient entre 0,3 et 0,4 (21) alors que chez les dérivés substitués en position 3, ils varient entre 0,2 et 0,4 (23). Nous croyons donc que l'écart énergétique ($^1L_b - {}^1L_a$) joue un rôle important dans la formation des exciplexes entre les dérivés substitués aux positions N et 3 du carbazole et l'éthanol, alors que c'est plutôt le caractère transfert de charge important de la transition $^1L_b \leftarrow {}^1A$ des dérivés substitués en position 1 du carbazole qui est responsable de la formation des exciplexes avec l'éthanol.

V. *Propriétés photophysiques de l'ensemble de ces systèmes*

Nous avons regroupé au tableau 3 l'ensemble des propriétés photophysiques des dérivés substitués en position 1 du carbazole. Nous remarquons un effet notable et du substituant et du milieu sur ces propriétés. Tout comme chez les dérivés substitués en position 3 (25) les dérivés cyanurés possèdent un rendement quantique de fluorescence plus élevé que celui des dérivés carboéthoxylés peu importe le milieu. Ceci peut être attribué à la rotation gênée du groupe carboéthoxylé comparativement au groupe cyanuré dans l'état S_1 relaxé puisque les durées de vie de fluorescence sont toujours plus élevées pour ces derniers dérivés dans le 3MP. Pour le 1-COOEC, le rendement quantique n'est pas significatif puisque l'absorption se fait par les deux systèmes libre et lié (mais surtout par ce dernier). Cependant, le système libre, seul responsable de l'émission possède une durée de vie de 6,2 ns, la plus faible valeur obtenue pour ces systèmes avec celle du 1-COOENEC dans le 3MP (5,0 ns) et ceci peut s'expliquer par la rotation gênée des groupements d'atomes en position 1 dans l'état premier singulet excité. La liaison hydrogène, qu'elle soit intramoléculaire (1-COOEC dans le 3MP à 77 K) ou intermoléculaire (1-COOEC dans l'EPA à 77 K), augmente la durée de vie des molécules à l'état S_1 d'environ 2 ns. Lorsque la rotation du groupement carboéthoxylé est complètement annihilée (1-COOEC dans le 3MP à 77 K) par la liaison hydrogène intramoléculaire, d'une part la probabilité radiative de transition $k_F^{(t)}$ ou k_F augmente considérablement (par un facteur 2 environ) par rapport à celle du carbazole (25) alors que la constante non-radiative n'augmente que très légèrement, ces deux facteurs conjugués sont responsables du rendement quantique relativement élevé du 1-COOEC dans le 3MP à 77 K.

Les paramètres photophysiques de tous ces dérivés dans l'éthanol à 23°C ne sont pas nécessairement significatifs sauf pour les durées de vie de fluorescence. Quant aux rendements quantiques, il se peut dans certains cas que la fluorescence observée soit un mélange d'exciplexe et de molécule non-complexée bien que les décroissances soient monoexponentielles peu importe la région du spectre de fluorescence observée. Une étude dynamique de la formation de ces exciplexes devrait être faite par ajout d'éthanol au 3MP pour mieux comprendre ces résultats globaux dans l'éthanol comme solvant. On remarque cependant que de façon très systématique, la durée de vie de fluorescence de toutes ces molécules dans l'éthanol est de 2 ns plus élevée que celle dans le 3MP. Enfin, le dimère du cyano-1 carbazole possède des propriétés photophysiques très semblables à celles du 1-COOEC liée de manière intramoléculaire en ce sens que dans ces deux structures rigides, la constante de désactivation non-radiative s'apparente à celle du carbazole et les probabilités de transitions radiatives sont beaucoup plus élevées.

Conclusion

Dans cet article, nous avons voulu montrer l'importance de la liaison hydrogène, qu'elle soit intermoléculaire ou intramoléculaire, sur la perturbation des propriétés spectroscopiques et photophysiques de certains dérivés substitués en position 1 du carbazole.

Le cyano-1 carbazole forme un dimère cyclique dans le 3MP avec une enthalpie et une entropie de complexation identiques à celles obtenues antérieurement pour la même molécule dans le tétrachlorure de carbone. Plus la force de la liaison hydrogène augmente dans le dimère, plus l'intensité de la première transition électronique du dimère augmente. Dû au peu de recouvrement des systèmes π des deux chromophores du carbazole, aucun tautomère n'a pu être détecté en fluorescence.

Le carboéthoxy-1 carbazole existe surtout sous forme liée de façon intramoléculaire dans les solvants non-polaires et en phase gazeuse dans son état électronique fondamental. Cette liaison hydrogène intramoléculaire est par ailleurs rompue pour faire place à une liaison hydrogène intermoléculaire dans l'éthanol. Le rendement quantique de fluorescence du système lié (intramoléculaire) est par ailleurs très faible en solution fluide de 3MP si bien qu'à température ambiante, seul le système libre émet. Ce phénomène a été confirmé par l'étude du spectre d'excitation de la fluorescence ainsi que par la valeur des durées de vie de fluorescence comparées. Par ailleurs, à 77 K en matrice rigide de 3MP, le système lié émet fortement comme le confirme le rendement quantique de 0,64. Le système libre du 1-COOEC possède une durée de vie de fluorescence plus courte que les systèmes liés de forme intermoléculaire ou intramoléculaire et ceci est surtout attribué à la rotation du groupement carboéthoxylé à l'état excité S_1. Par ailleurs, nous attribuons surtout à l'augmentation de la constante radiative (probabilité de transition $^1L_b \leftarrow {}^1A$), le fait que le rendement quantique de fluorescence du système lié dans le 3MP soit si élevé.

Nous avons également montré que tous les dérivés substitués du carbazole en position 1 forment des exciplexes avec l'éthanol. Les spectres d'excitation de la fluorescence de ces exciplexes démontrent que c'est la molécule libre qui est à l'origine de la formation des exciplexes pour le 1-CNNEC et le 1-COOENEC alors que ce sont les complexes 1-COOEC – EtOH et 1-CNC – EtOH (par liaison hydrogène intermoléculaire) qui sont à l'origine de la formation des exciplexes chez les molécules possédant un groupement NH. Par ailleurs, l'argument de l'écart énergétique réduit entre les états S_1 et S_2 invoqué pour expliquer la stabilisation des exciplexes entre les dérivés substitués du carbazole aux positions N et 3 et l'éthanol ne peut être utilisé pour les dérivés substitués en position 1 du noyau. Par contre, l'état ^1L_b de ces dérivés possède déjà un caractère transfert de charge important si l'on en juge par les rapports des coefficients d'absorptivité des deux premières transitions électroniques dans ces molécules.

Remerciements

Les auteurs remercient le Conseil de Recherches en sciences naturelles et en génie du Canada ainsi que le Ministère de l'Education du Québec pour leur assistance financière. Nous désirons aussi remercier le Dr. Bogumil Zelent de notre laboratoire pour les nombreuses discussions que nous avons eu concernant ce travail.

SCF MS Xα molecular orbital calculations are reported for the bis(η^6-benzene)- and bis(η^6-naphthalene)chromium(0) complexes. The bonding may be essentially discussed in terms of the covalent interactions between the metal 3*d* and ligand π and π^* orbitals. The different charges on chromium atom in the two systems are explained by the different balances between ligand-to-metal (bonding) and metal-to-ligand (back-bonding) electron donations. Some resemblances are found between the electronic structures of the two compounds and it is possible to correlate to a large extent the energy levels of their molecular orbitals. However, a shift towards lower values is predicted for the energy levels of the naphthalene complex, together with a large disruption of all the virtual π^* and $3d^*$ levels. This would undoubtedly favor nucleophilic attack followed by metal–ring or carbon–carbon bond cleavage, in agreement with the extreme lability of the coordinated arene rings observed in this complex.

JACQUES WEBER, E. PETER KUNDIG, ANNICK GOURSOT et EDOUARD PENIGAULT. Can. J. Chem. **63**, 1734 (1985).

On a effectué des calculs d'orbitales moléculaires MS Xα en champ autocohérent pour les complexes bis(η^6-benzène)- et bis(η^6-naphtalène)chrome(0). On peut decrire la liaison dans le complex presque essentiellement à l'aide des interactions covalentes entre les orbitales 3*d* du métal et les orbitales π et π^* du ligand. On explique les différentes charges sur l'atome de chrome dans les deux systèmes par des bilans differents entre la donation directe d'électrons ligand–métal et la rétro-donation métal–ligand. Toutefois, on prédit un déplacement vers des valeurs plus basses pour les niveaux énergétiques du complexe de naphtalène ainsi qu'un mélange important de tous les niveaux virtuels π^* et $3d^*$. Ceci devrait de toute évidence favoriser une attaque nucléophile, suivie d'une rupture de la liaison métal–cycle ou carbone–carbone, en accord avec la labilité extrême observée dans ces complexes pour les cycles aréniques coordonnés.

[Traduit par le journal]

Introduction

Whereas bis(η^6-benzene)chromium(0), **1**, has been known for thirty years (1), it is only recently that the preparation of bis(η^6-naphthalene)chromium(0), **2**, the parent compound with fused six-membered ring ligands, has been reported (2, 3).

One of the chief differences between **1** and **2** concerns the lability of the coordinated arene rings: whereas **1** is inert to arene displacement reactions, the naphthalene ligands of **2** are known to easily undergo substitution reactions. A similar situation exists in the $Cr(CO)_3$ complexes of the two arenes. The lability of the naphthalene—Cr bond is certainly at the origin of the catalytic properties of the naphthalene–$Cr(CO)_3$ complex (4, 5). This somewhat unexpected difference in reactivity between **1** and **2** may probably be related to differences in electronic structure and metal–ligand interactions in complexes with condensed aromatic ligands as compared with arene–metal complexes. It was therefore of interest to perform a comparative theoretical study of the electronic structure of **1** and **2** in an attempt to understand the different properties of these compounds. To this end, the multiple scattering (MS) Xα molecular orbital (MO) model was chosen since it has been previously shown to give reliable predictions of the electronic structure and related properties of organometallic compounds such as **1** (6) or several members of the metallocene series (7–11).

Intersphere	0.76608	—	0.76581	—

(12). For the geometry of $(\eta^6\text{-}C_6H_6)_2Cr$, the electron diffraction data of Haaland (13) are used, i.e., an eclipsed structure of D_{6h} symmetry with planar ligands, the bond lengths being C—C 1.423 Å, C—H 1.090 Å, and the vertical metal-to-ring distance 1.613 Å.

For the bisnaphthalene complex, a standard C_{2h} symmetry is assumed, with *anti*-oriented naphthalene rings. This is at variance with a recent X-ray crystal structure determination of **2** which concluded to *syn*-oriented ligands (14). However, most of the observations involving this compound being performed in vapor or liquid phase, the barrier to internal rotation is low enough to permit large amplitude torsional motion. In addition, the nature of ligand–metal interactions is very similar in both *anti*- and *syn*-forms. In order to make the comparison of electronic structures easier, the same metal-to-ring distance as for **1** (1.613 Å) has been chosen for **2**. Actually, this distance is only 0.05 Å smaller than the value deduced from the X-ray measurements performed for **2** (14). Similarly, a standard geometry has been adopted for the planar naphthalene rings, with C—C bond lengths and C—C—C bond angles assumed to be all equal to 1.395 Å and 120°, respectively. Actually, these data are the average values of the corresponding parameters obtained from the X-ray study of **2**. Finally, the C—H bond lengths of **2** have all been chosen as 1.085 Å.

Table 1 presents the MS Xα calculation parameters used. The values of atomic exchange parameters α are those optimized by Schwarz (15), except for hydrogen where we have chosen the spin-polarized value (16). A weighted average of the atomic values is chosen for the α value in interatomic, extramolecular (outer sphere), and intersphere regions.

Appropriate values for the radii of atomic spheres have been chosen according to the procedure previously described for the metallocenes (7, 9): the carbon and hydrogen touching sphere radii (i.e. of tangential atomic spheres) are first determined by the C—C and C—H bond distances, and then increased by 25%, leading thus to overlapping atomic spheres. The radius of chromium sphere is chosen to be tangent to the enlarged carbon sphere. Additional "empty" spheres are located in the center of all the phenyl rings. An externally tangent outer sphere is used in all the calculations. Partial waves up to $l = 2$ are included in the multiple scattering expansions in chromium sphere and extramolecular region, up to $l = 1$ in carbon and empty spheres, and for $l = 0$ in hydrogen spheres.

Results and discussion

The ground-state electronic structures of $(\eta^6\text{-}C_6H_6)_2Cr$ and $(\eta^6\text{-}C_{10}H_8)_2Cr$ are presented in Tables 2 and 3 and compared graphically in Fig. 1.

One should note that the results obtained for **1** differ slightly from those we have previously reported (6), since the radius of

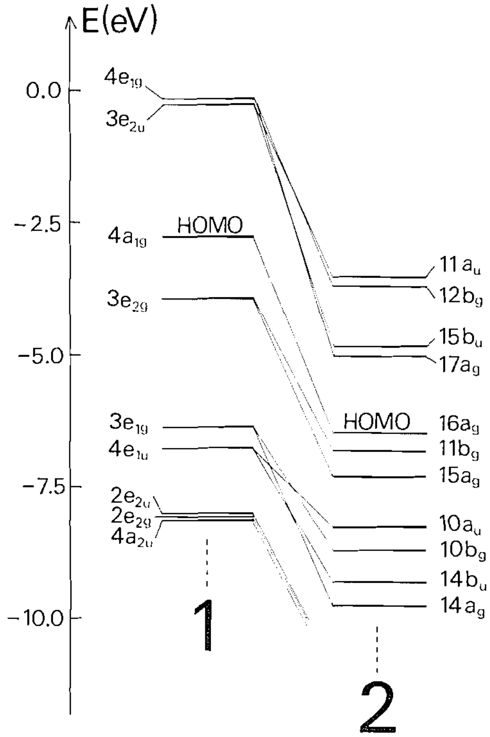

FIG. 1. Upper valence ground-state energy levels for compounds **1** and **2**.

metal sphere has been modified so as to be the same as that used for compound **2**, which actually leads to a more realistic value for this parameter.

The ground-state configuration of **1** is ${}^1A_{1g}\,(3e_{2g})^4\,(4a_{1g})^2$, the sequence of predominantly metal 3d orbitals being $3e_{2g}(3d\delta) \leq 4a_{1g}(3d\sigma) \leq 4e_{1g}(3d\pi)$,[2] in agreement with the general ligand field theory of such metal sandwich complexes (17).

It is seen from both Table 2 and Fig. 2 that these orbitals have different bonding characters: whereas the $3e_{2g}$ MO is strongly bonding through an in-phase combination of metal $3d\delta$ and ligand π orbitals, the $4a_{1g}$ MO, which is the highest occupied MO (HOMO), has a much larger metal character and it is essentially nonbonding. As to the virtual $4e_{1g}$ MO, it is strongly antibonding through an out-of-phase combination of metal $3d\pi$ and ligand π orbitals. It is seen from Table 2 that $4e_{1g}$ is not the lowest unoccupied MO (LUMO) of system **1**, as there is a pure ligand π^* orbital, namely $3e_{2u}$, which lies imme-

[2] According to pseudoaxial ligand field theory, the d-orbital set in D_{6h} symmetry is split into three irreducible representations: $a_{1g}(\sigma\text{: } d_{z^2})$, $e_{1g}(\pi\text{: } d_{xz}, d_{yz})$, $e_{2g}(\delta\text{: } d_{x^2-y^2}, d_{xy})$, where z is the sixfold rotational axis.

[a]For the sake of conciseness, all the C and H charge distributions, though arising from five non-equivalent atoms, have been summed up and are presented as single entries. The same procedure applies to empty sphere contributions.
[b]The notations *p*σ and *p*π refer to planar naphthalene rings (σ: $2p_x$ and $2p_y$; π: $2p_z$).

diately below it. This result is at variance with our previous calculation (6) which concluded to the opposite ordering for the $4e_{1g}$ and $3e_{2u}$ MOs, and therefore to a LUMO with predominant metal character. The result $3e_{2u} \leq 4e_{1g}$ is, however, that deduced for the anion $\mathbf{1}^-$ from both a detailed analysis of the esr spectrum and SCF MS Xα calculations (18). For the neutral system **1** this question is of minor importance since: (*i*) the energy difference between $3e_{2u}$ and $4e_{1g}$ is very small and (*ii*) there is no experimental evidence as to the nature of the LUMO level.

In the ground-state electronic structure of **1**, one finds at lower energies the ligand-based levels, which may be classified into pairs of π-type orbitals ($3e_{1g}$, $4e_{1u}$), σ-type ones ($2e_{2u}$, $2e_{2g}$) and again π-type ones ($4a_{2u}$ and $3a_{1g}$). Among them, $3e_{1g}$ has appreciable (16%) metal *d* character and, together with $3e_{2g}$, these levels are responsible for most of the metal–ligand bonding interactions in $(\eta^6\text{-}C_6H_6)_2Cr$. Let us turn now to **2** in order to see to which extent the electronic structure of this system resembles that of **1**.

It is immediately seen from Fig. 1 that despite a stabilizing

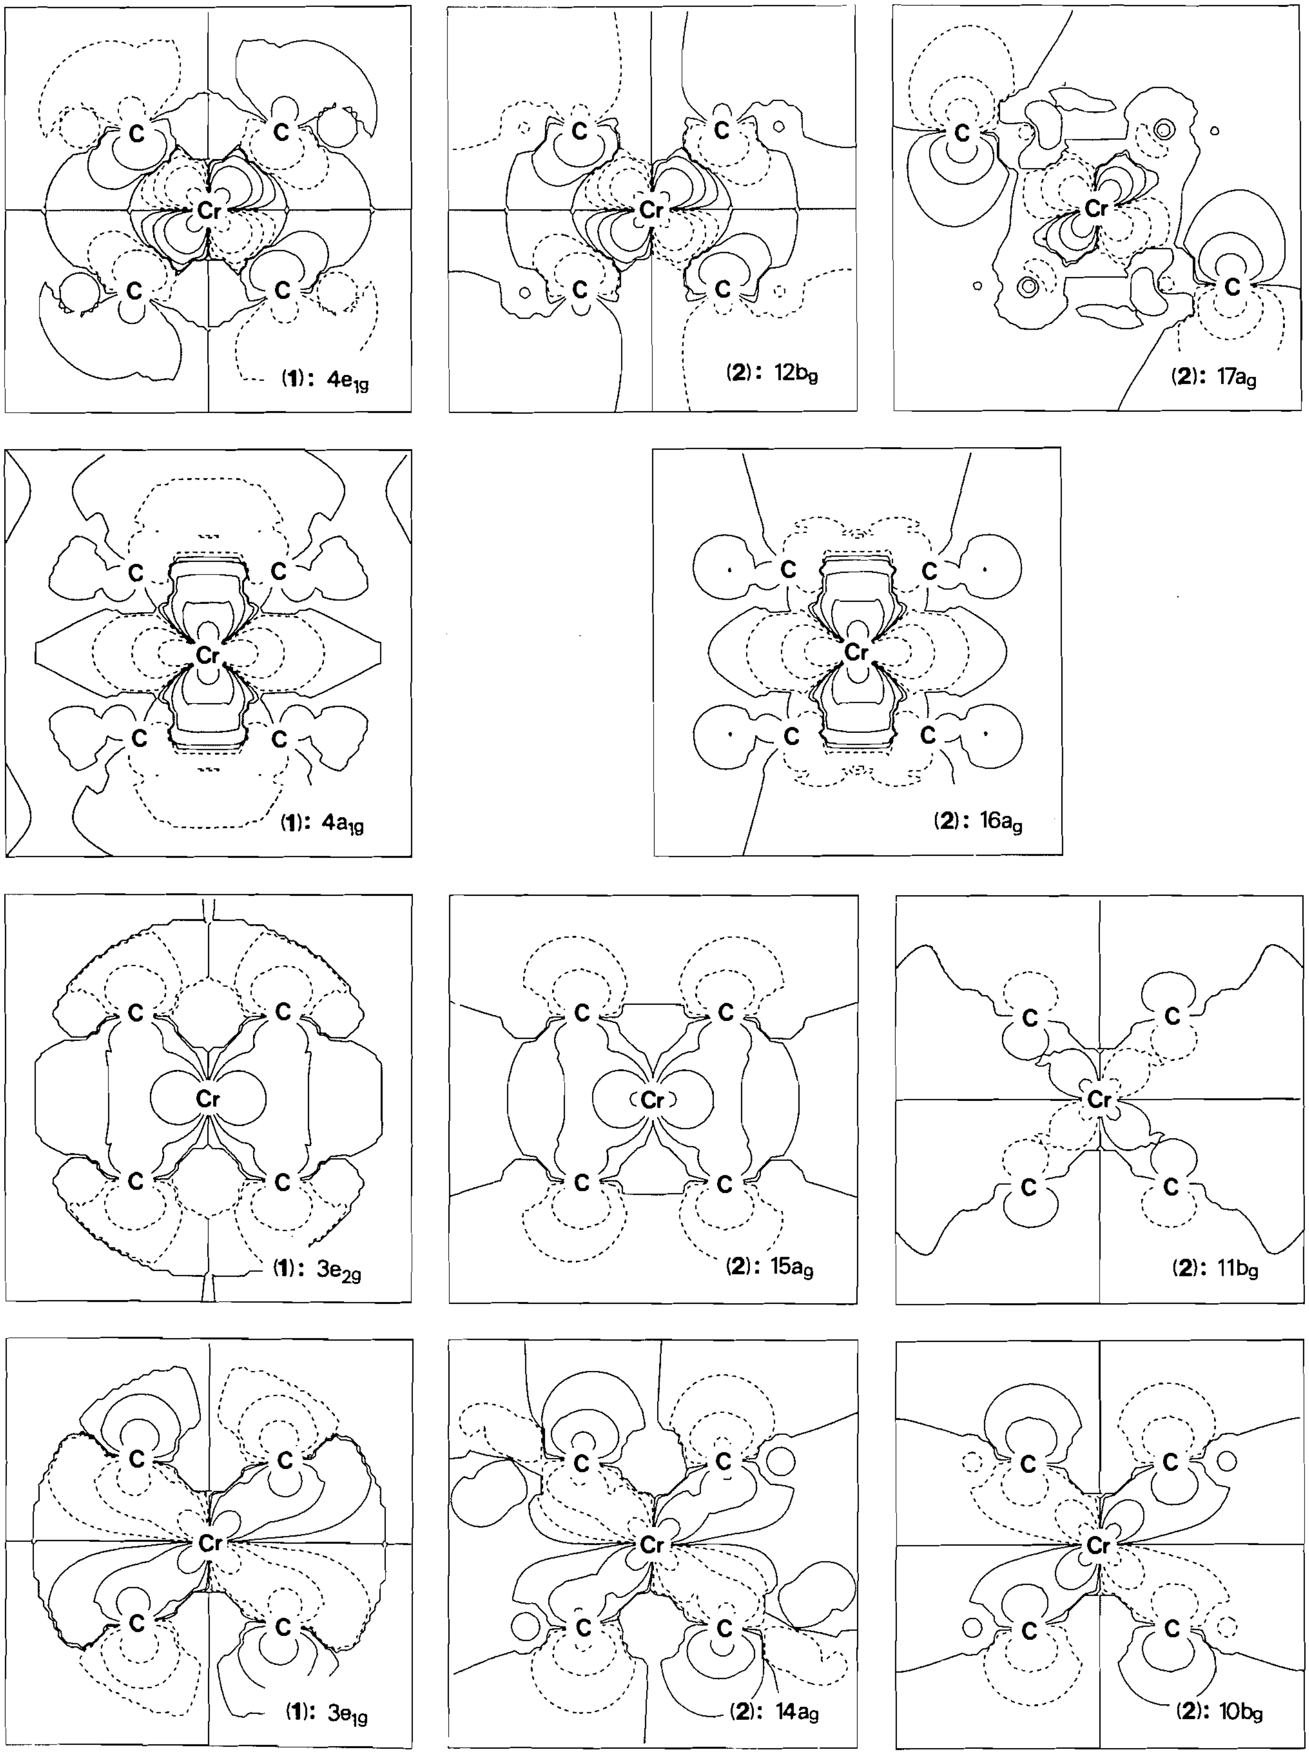

FIG. 2. Wave function contours of selected MOs of systems **1** and **2**. Except for the $17a_g$ level of **2**, which is plotted in a vertical plane containing the Cr and C_4 atoms, all the MOs are represented in the XOZ plane. Positive wave function contours are indicated by a solid line while negative contours are represented by a dashed line.

TABLE 4. Correlation table for D_{6h} to C_{2h} descent in symmetry

D_{6h}	C_{2h}
A_{1g}, A_{1u}	A_g, A_u
A_{2g}, A_{2u}	B_g, B_u
B_{1g}, B_{1u}	B_g, B_u
B_{2g}, B_{2u}	A_g, A_u
E_{1g}, E_{1u}	$A_g + B_g$, $A_u + B_u$
E_{2g}, E_{2u}	$A_g + B_g$, $A_u + B_u$

energy shift of 3–4 eV, the orbital pattern of **2** is to a large extent similar to that of **1**, the correlation for D_{6h} to C_{2h} descent in symmetry presented in Table 4 enabling a better comparison between the two systems.

The ground-state configuration of **2** is ^1A_g $(15a_g)^2$ $(11b_g)^2$ $(16a_g)^2$, with the sequence of predominantly metal 3d orbitals $15a_g(3d_{x^2-y^2}) \leq 11b_g(3d_{xy}) \leq 16a_g(3d_{z^2}) \leq 17a_g(3d_{yz}) \leq 12b_g(3d_{xz})$. This ordering is in perfect agreement with the result obtained for system **1**, since the $3e_{2g}(3d\delta)$ MO of **1** correlates with the $15a_g$ and $11b_g$ MOs of **2**, $4a_{1g}(3d\sigma)$ of **1** with $16a_g$ of **2** and $4e_{1g}(3d\pi)$ of **1** with $17a_g$ and $12b_g$ of **2**. The $16a_g$ MO of **2** is thus the HOMO and $17a_g$ the LUMO. However, the HOMO–LUMO energy gap is significantly smaller (by 1.07 eV) in **2** than in **1**. Inspection of Table 3 and Fig. 2 reveals a striking resemblance between $3e_{2g}$ (**1**) and $15a_g$ (**2**), $4a_{1g}$ (**1**) and $16a_g$ (**2**), $4e_{1g}$ (**1**) and $12b_g$ (**2**): $15a_g$, and to a lesser extent $11b_g$, are strongly bonding through in-phase combinations of 3$d\delta$ with ligand π orbitals and these two MOs play for system **2** the same role as $3e_{2g}$ for **1**, with a metal character larger by about 10%, however. The relative stability of $15a_g$ with respect to $11b_g$ is due to the different types of carbon atoms involved in metal–ligand bonding: in $15a_g$ the largest ligand contribution arises from the nearest C_2 atom whereas in $11b_g$ the farther C_4 and C_5 atoms contribute the most, which explains its slightly minor bonding character. Whereas the $16a_g$ HOMO of **2** has exactly the same nonbonding character as the $4a_{1g}$ HOMO of **1**, it is interesting to examine in detail the nature of the antibonding $17a_g$ and $12b_g$ MOs, which correlate with the $4e_{1g}$ level of system **1**. As a general result, we see that, the ligand π^* $15b_u$ and $11a_u$ MOs excepted, the low-lying virtual orbitals of **2** are considerably delocalized over the whole molecule and exhibit some antibonding character. Taking indeed the $17a_g$ and $12b_g$ MOs as examples, their metal character is only 27% and 48%, respectively, as compared with 73% in their $4e_{1g}$ counterpart in **1**. Moreover, the antibonding characters of these two MOs are very different as shown in Fig. 2: whereas $12b_g$ is metal–C_2 antibonding, $17a_g$ is mainly metal–(C_5,C_6) antibonding, with the result that $12b_g$ is much more antibonding than $17a_g$. This leads to a large destabilization of $12b_g$ with respect to $17a_g$ (1.29 eV), the energy difference between these MOs being much larger than that between the bonding MOs $15a_g$ and $11b_g$. When comparing systems **1** and **2**, and this point will be discussed in some detail further on, we may already point out that their different chemical properties are probably related to: (*i*) the important shift towards lower energies observed for all the MO levels of **2**; (*ii*) the significantly smaller HOMO-LUMO energy difference in **2**; and (*iii*) the larger delocalization of the LUMO and low-lying virtual levels of **2** over the whole compound.

At lower energies, i.e. below the predominantly metal 3d MOs, one finds the ligand-based levels which can be easily correlated with the corresponding levels of **1**: $14a_g$ and $10b_g$ correlate with $3e_{1g}$ as may be seen from Fig. 2, and their metal character is nearly the same as that of their congener in **1**. The $14b_u$ and $10a_u$ MOs are almost pure ligand π levels and correspond to $4e_{1u}$ in **1**, whereas $9a_u$ correlates with $4a_{2u}$. However, as there are 8 additional ligand π electrons and 28 additional ligand σ electrons in $(\eta^6\text{-}C_{10}H_8)_2Cr$ as compared with $(\eta^6\text{-}C_6H_6)_2Cr$, the orbital pattern of the former system is characterized by the presence of additional MOs. This is typically the case for $9b_g$ which has no counterpart in **1**. Finally, looking at the low-lying valence levels of **2**, it is seen that, as for system **1**, there is no clear-cut separation between predominantly π and σ ligand levels, but the highest σ levels intermingle with the lowest π orbitals. As for system **1**, the σ framework of ligands in **2** contributes very little to the bonding in the complex and most of the covalent metal–ligand interactions involve Cr 3d and ligand π orbitals.

Concerning the origin of the stabilizing shift in orbital energies between compounds **1** and **2**, one might conceivably attribute it to muffin-tin effects: due to the large intersphere volume in **2**, as compared with **1**, the volume averaging in this region tends to significantly delocalize the charge density over the whole molecule, which in turn leads to a stabilization of the levels. However, according to our experience and to some test calculations we have recently performed for the anion $\mathbf{1}^-$, this spurious effect is likely not to exceed 1–2 eV in our case, which suggests that on a qualitative basis the stabilization of the energy levels of **2** with respect to **1** is a real effect which is due to the different nature of the ligands in both complexes.

Table 5 presents the electronic configuration of the metal in the two complexes. The problem of charge partitioning has been solved by attributing both intersphere and outer sphere charges fully to the ligands. This procedure has been previously found to be adequate in the case of metallocenes (7, 9–11) as it leads to (*i*) a reasonable charge of the order of +0.5 on metal; (*ii*) a total metal 3d participation of nearly 100% in each pair of bonding–antibonding MOs of the same symmetry, which is a good criterion for the orthogonality of the wavefunctions. However, this scheme could be not very well suited to compound **2**, which exhibits a large intersphere volume, and we decided to use also for both compounds another charge partitioning procedure attributing to metal a large part of the interatomic charge. The results obtained using this alternative scheme do not change the main conclusions to be drawn from Table 5 and they will be summarized later on in this section. It is seen from Table 5 that 4s and 4p populations do not undergo great changes when going from system **1** to **2** and remain rather small, which indicates that the role of these orbitals in the bonding of the complexes is not important. However, substantial differences appear when comparing the populations of metal 3d orbitals: the partial populations of all the 3d components are larger in **2**, with the result that the total metal 3d population in **2** is larger by 0.62e than the corresponding value in **1**. A detailed analysis performed for all the occupied levels of the valence shell shows that: (*i*) the predominantly metal 3d MOs (i.e. $4a_{1g}$ and $3e_{2g}$ in **1**, and their counterparts in **2**) accommodate 0.36 additional 3d electrons in **2**, with respect to **1**; (*ii*) the ligand based MOs (i.e. all the occupied levels lying below $3e_{2g}$ in **1**, and their counterparts in **2**) contribute to the overall metal 3d population by 0.26 additional electrons in **2**, with respect to **1**. The increase in metal 3d population observed in **2** is therefore due to a larger metal 3d character exhibited by all the MOs of proper symmetry, the predominantly metal 3d levels con-

TABLE 5. Metal configuration in the complexes

	Electron population on chromium[a]									
			$3d^b$							
Complex	$4s$	$4p$	z^2	x^2-y^2	xy	xz	yz	Total	Metal charge
1	0.28	0.42	1.70	1.04	1.04	0.46	0.46	4.70	+0.60
2	0.28	0.44	1.76	1.20	1.36	0.54	0.46	5.32	−0.04

[a]The electron population of chromium atomic orbitals has been obtained by summing up over all the occupied MOs of the valence shell, with the intersphere, and outer sphere charge fully attributed to ligands.
[b]The x, y, and z axes are defined in structures **1** and **2**.

tributing the most. This leads ultimately to an almost neutral chromium atom in **2**, whereas the charge on this atom is +0.60 in **1**. Actually, starting from a Cr free atom configuration $3d^6$, the chromium charge of +0.60 in **1** (resp. −0.04 in **2**) results from: (*i*) a ligand-to-metal donation of 0.92e (resp. 1.00e) from the $2p\pi$ orbitals of ligand rings to metal $3d_{xz}$ and $3d_{yz}$ orbitals; (*ii*) a transfer of 0.70e (resp. 0.72e) from the $2p$ orbitals of the ligand rings to metal $4s$ and $4p$ orbitals; (*iii*) a back-bonding transfer of 2.22e (resp. 1.68e) from metal $3d_{z^2}$, $3d_{x^2-y^2}$, and $3d_{xy}$ orbitals to ligand $2p$ levels. We see thus that it is through the different balances between ligand-to-metal and metal-to-ligand donations that the effective charge on chromium is so different in both systems. As this feature is probably related to the different chemical properties of both systems, it is interesting to examine their ground-state electronic structures in more detail in order to seek an explanation for this difference in metal configurations.

As the formal oxidation state of metal in both systems is 0, one may reasonably expect that the calculations will lead to a small effective charge on metal atom. This means that both ligand-to-metal and metal-to-ligand donations should roughly compensate, which is the case for system **2**. When comparing the results obtained for systems **1** and **2**, we see that the total ligand-to-metal charge donation is smaller in **1** by 0.24e. This is undoubtedly due to the fact that the highest occupied MOs of π type lie at higher energies in naphthalene than in benzene, as exemplified by the first ionization energy of the two compounds: 8.15 eV for naphthalene (19) and 9.25 eV for benzene (20). This should lead for system **1** to a smaller admixture of metal $3d_{xz}$ and $3d_{yz}$ orbitals into the π MOs of ligands and, ultimately, to a smaller ligand-to-metal donation. The larger back-bonding metal-to-ligand donation in **1** as compared with **2** (0.40e) is slightly more difficult to explain. Indeed, according to the optical and uv absorption spectra of benzene and naphthalene (21), the energy gap between the π HOMO and the π^* LUMO is larger in benzene by approximately 1.0–1.5 eV, i.e. the same amount as the difference in ionization energies, which means that on an absolute scale and ignoring their interaction with the metal, the lowest virtual π^* levels of both systems should have roughly the same energy. According to this crude argument, they should thus mix equally with the metal $3d_{z^2}$, $3d_{x^2-y^2}$, and $3d_{xy}$ orbitals and lead to the same amount of back-bonding transfer, which is obviously not the case. Instead, we suggest that the solution to our problem has to be found in the D_{6h} to C_{2h} descent in symmetry when going from **1** to **2**: the virtual, predominantly ligand π^* MO of e_{2g} symmetry which is the main source of back-bonding in **1** through its significant metal $3d_{x^2-y^2}$, $3d_{xy}$ character, correlates in system **2** with a pair of MOs $a_g + b_g$. Because they are allowed to interact with several other low-lying virtual MOs of the same symmetry, these MOs are found in system **2** at much higher energies than their counterpart in **1**, which results in a significantly lower admixture of metal $3d_{x^2-y^2}$, $3d_{xy}$ orbitals, and therefore to a smaller back-bonding donation in **2**.

As there is no unique way to distribute the intersphere charge among the muffin-tin spheres, we decided to check the above conclusions by using another charge partition scheme. In view of the large difference in intersphere volumes in both compounds, one may indeed ask whether the attribution of the whole intersphere charge to the ligands is a realistic procedure and, consequently, whether the different charges on metal obtained for **1** and **2** are not an artifact of the calculation. As another, significantly different, charge partition scheme, we decided to use the alternative of distributing for each MO the interatomic charge among all atoms in the molecule proportionally to the amount of orbital charge (originating from this orbital) included in each sphere (6). This procedure leads to the following metal configurations: $3d^{5.66}\,4s^{0.34}\,4p^{0.52}$, i.e. $Cr^{-0.52}$ for **1**; $3d^{6.14}\,4s^{0.36}\,4p^{0.54}$, i.e. $Cr^{-1.04}$ for **2**. Though, as expected, the metal atom bears now a negative charge in both compounds, the same conclusions as before may be drawn: the $3d$ shell is significantly more populated in **2** than in **1** (+0.48e), which leads to a larger electronic charge on metal in **2**, the difference being −0.52e. In view of the drastic differences in the partition schemes used, one may expect that any other procedure would probably lead to metal populations and charges lying in between those obtained in our two calculations. Therefore, one may safely conclude that the differences in metal configurations obtained for the two compounds is a real trend which can be probably related to their different reactivity.

Finally, we would like to make a few comments on the possible correlation between the differences in reactivity exhibited by compounds **1** and **2** and the main features of their electronic structures. As we have pointed out above, all the valence levels of **2** undergo a negative energy shift with respect to **1**, with the result that the energy of the LUMO is lowered by almost 5 eV. Obviously, the system **2** presents an appreciable electrophilic character. Furthermore, the coordinated arene rings in **2** are almost neutral, whereas each of the arene rings in **1** bears a charge of −0.3, and the low-lying virtual orbitals of **2** show appreciable C_4—C_5 π antibonding character on the uncomplexed ring, as revealed by a detailed analysis of the distribution of charge of the $17a_g$ and $15b_u$ MOs. These features would favor reactions involving nucleophilic attack on the ligand rings, followed by cleavage of the C_4—C_5 bond, or on the metal, contributing thus to the remarkable lability of **2** towards naphthalene displacements by two-electron donor ligands (22).

Coming back to system **1**, the main difference is that it presents a significantly less electrophilic character because of its LUMO lying at a higher energy. It is therefore less reactive towards nucleophilic attack. However, to our knowledge, no reaction of nucleophilic addition to the arene rings in **1** or **2** has been reported.

Among the other electronic factors susceptible to shed some light on the reactivity of the compounds, the electron density on metal should not be underestimated since it is known to possibly affect arene reactivity in metal complexes (23). The substantial differences in metal charges between **1** and **2** (0.64e) indicates that the girdle of electron density around the Cr atom is larger in **2** than in **1**, resulting in different conditions for direct electrophilic and nucleophilic attacks at the metal and probably also at the ligand sites. Finally, both a large disruption of ligand π and π^* levels and a shift towards lower energies of all the valence levels have been recently found in a series of tetraperoxo metal complexes to be possible indicators as to an enhanced reactivity of the system (24). The present results suggest that this statement could also apply to organometallic complexes with arene or condensed arene ligands.

An analysis of atomic charges is presented for simple alkanes. Basically, Mulliken's scheme is followed, except for the partitioning of CH overlap populations. This achieves a relative ordering of atomic charges which is independent of the basis sets used in *ab initio* calculations. The absolute magnitude of atomic charges, however, is basis set dependent. Extensive geometry and scale factor optimizations yield the following results (in 10^{-3} e units) for the carbon net charge in ethane: 69.4 (STO-3G), 55.1 (STO-3G + CI), 42.8 (4-31G), and 37.8 (4-31G + CI). It appears that charge analyses converge toward the empirical result, 35.1×10^{-3} e, provided they are carried out after configuration interaction involving reasonably large optimized basis sets.

C. MIJOULE, J.-M. LECLERCQ, S. ODIOT et S. FLISZÁR. Can. J. Chem. **63**, 1741 (1985).

On rapporte une analyse des charges atomiques d'alcanes simples. On utilise principalement le schéma de Mulliken, excepté pour la répartition des recouvrements des populations de CH. Ceci permet d'établir un ordre relatif des charges atomiques qui est indépendant des ensembles de base utilisés dans les calculs *ab initio*. Toutefois, la valeur absolue des charges atomiques dépend de l'ensemble de base utilisé. A la suite d'optimisations importantes des géométries et des facteurs d'échelle, on a pu obtenir les résultats suivants (en unités 10^{-3} e) pour la charge nette du carbone de l'éthane: 69,4 (STO-3G), 55,1 (STO-3G + CI), 42,8 (4-31G) et 37,8 (4-31G + CI). Si les analyses sont effectuées après des interactions de configurations impliquant des ensembles de bases optimisés relativement étendus, les analyses convergent vers le résultat empirique de $35,1 \times 10^{-3}$ e.

Introduction

The concept of atomic charge is popular in chemistry. The quantity which is referred to in most cases is the net charge $q_k = Z_k - N(k)$, where Z_k is the nuclear charge of center k and $N(k)$ the number of electrons assigned to it. Numerous studies have dealt with the problem of charge partitioning, which are well reviewed (1): the disturbing fact is that charge results vary widely, depending on the methods involved in their calculation.

The question asked here is one concerning a realistic, physically meaningful partitioning which will not defeat itself in applications and comparisons involving experimental results. Though limited in scope (as we are primarily discussing saturated hydrocarbons), this work attempts to show what level of calculation fulfills the requirements for achieving this goal, a task involving some kind of experimental assessment of the theoretical results.

With this in mind, advantage is taken from earlier studies (2, 3) indicating that the individual bond energies of ground-state molecules are (to a good approximation) linearly dependent on the charges of the bond-forming atoms,[3] i.e.,

$$[1] \qquad \epsilon_{ij} = \epsilon_{ij}^0 + a_{ij}\Delta q_i + a_{ji}\Delta q_j$$

The sum of the ϵ_{ij}'s plus a small nonbonded contribution, $\Delta E_{\mathrm{nb}} = -E_{\mathrm{nb}}$, yields the atomization energy of the molecule in its hypothetical vibrationless state at 0 K,

$$[2] \qquad \Delta E_{\mathrm{a}}^* = \Sigma\epsilon_{ij}^0 + \Sigma_i\Sigma_j a_{ij}\Delta q_i - E_{\mathrm{nb}}^*$$

This expression, and comparison with experimental ΔE_{a}^* values, has the merit of permitting evaluations regarding the validity of calculated charges because, evidently, the use of "wrong" charges in eq. [2] leads to incorrect estimates of ΔE_{a}^* energies.

As concerns the charges, two basic aspects need to be considered, namely, (*i*) their *relative ordering* with respect to some arbitrarily selected reference and (*ii*) their *absolute magnitude*. Net charges deduced from Mulliken's analysis (4) do not satisfy eq. [2]. Indeed, when deduced from SCF (Hartree Fock) wave functions, this analysis yields charge results which are strongly basis set dependent (3, 5), both as regards their relative ordering and their magnitude.

The relative ordering, however, is easily acted upon with the use of a generalized Mulliken scheme (6), i.e., in conventional notation,

$$[3] \qquad N(k) = 2\sum_i\sum_r\left(c_{r_k i}^2 + \sum_{l \neq k} c_{r_k i}c_{s_l i}S_{r_k s_l}\lambda_{r_k s_l}\right)$$

where $\lambda_{r_k s_l}$ lifts the constraint of halving overlap populations between dissimilar atoms ($\lambda = 1$ in Mulliken's scheme). In terms of the difference between Mulliken charges and those given by eq. [3], it follows that

$$[4] \qquad q_k = q_k^{\mathrm{M}} + \sum_{l \neq k} p_{kl}$$

where charge normalization is ensured by the condition $p_{lk} = -p_{kl}$. For the saturated hydrocarbons under study, we approximate $\Sigma p_{\mathrm{CH}} = N_{\mathrm{CH}}p$ where p is the departure from the usual halving of the CH overlap population for one CH bond and N_{CH} is the number of hydrogen atoms bonded to a given carbon atom: eq. [4] simplifies to (6)

[3] That bond energies should depend on the charges of the bond-forming atoms comes as no surprise. Equation [1] features the effects due to changes in net atomic charges (Δq_i and Δq_j) with respect to the charges q_i^0 and q_j^0 of the same atom pair in a reference bond with energy ϵ_{ij}^0. The a_{ij} and a_{ji} parameters, which are deduced from theory (2, 3), measure the effect of unitary charge variations at atoms i (bonded to j) and j (bonded to i), respectively. These parameters can safely be treated as constants in the case of alkanes, namely, $a_{\mathrm{CC}} = -0.777$, $a_{\mathrm{CH}} = -0.394$, and $a_{\mathrm{HC}} = -1.007$ au (2, 3).

[5] $q_H = q_H^M - p$

[6] $q_C = q_C^M + N_{CH}p$

In this manner, with the use of an empirically determined p, we may well achieve a correct ordering of charges in a relative scale but not necessarily converge toward good absolute values: in fact, the latter turn out to be basis set dependent, which is precisely the point investigated here. This point matters because if all the charges (now supposed to be correctly ordered) were in error by a certain multiplying factor, so would be the $\Sigma_i\Sigma_j a_{ij}\Delta q_i$ term of eq. [2] calculated for each individual molecule, thus revealing the extent of the discrepancy between theoretical charges and those satisfying eq. [2].[4]

The present work concludes eventually that eqs. [5] and [6] are, indeed, satisfactory in conjunction with eq. [2] provided that charge analyses are carried out after configuration interaction involving sufficiently large optimized basis sets.

Relative ordering of net charges

This problem is most conveniently discussed with the aid of general formulas (2, 5, 6) expressing the net charges of selected alkanes in a relative scale. This scale is defined here with reference to the net charge of the ethane carbon atom, taken at 1 arbitrary charge unit. Multiplication of these relative charges by the "true" value (in charge units) of the ethane carbon atom, q_C^0, yields the corresponding results in charge units. The relative ordering is defined by n; q_C^0 determines the absolute magnitude. The important point is that Mulliken charges derived from any basis set satisfy these formulas[5] (2, 5, 6), with n and q_C^0 values differing from one basis set to another. Moreover, the general formulas of Table 1 apply equally well to results deduced from eqs. [5] and [6].

For a given basis set SCF calculation, Let n^M and q_C^{0M} represent the appropriate parameters corresponding to a Mulliken population analysis and let n and q_C^0 represent their counterparts for the more general solutions indicated in eqs. [5] and [6]. It has been shown (2, 6) that the following relationship holds:

[7] $$\frac{q_C^0}{n} = \frac{q_C^{0M}}{n^M}$$

Accordingly, the connection with eqs. [5] and [6] is established by

[8] $p = q_C^{0M}(n - n^M)/3n^M$

thus showing that the evaluation of the "true" n leads to p, and vice versa.

Let us examine an application involving STO-3G Mulliken charges corresponding to $q_C^{0M} = -20.96$ me ($= 10^{-3}$ electron units) and $n^M = 1.3325$ (Table 1). These charges enter eqs. [5] and [6] which, in turn, are introduced into eq. [2] with an undetermined multiplier intended to correct for a possible error in the absolute charge values used as input. A least-squares analysis involving experimental ΔE_a^*'s leads to $p = 30.3 \pm 0.3$ me (2). On the other hand, the same set of charges correlate with ^{13}C nmr shifts with $p = 30.12$ me (6): the corresponding n is -4.4122. The n value deduced from these analyses holds independently of the LCAO-MO method selected for calculating Mulliken charges because, evidently, the "physically true" relative ordering of charges is unique. Briefly, $n \approx -4.41$ satisfies energy calculations, eq. [2], correlations with ^{13}C nmr shifts, and ionization potentials of alkanes (7). This n value also follows from SCF-Xα-SW charge analyses (8) and, quite significantly, from Bader's virial partitioning method (9, 10). Moreover, this result is appealing because $n \simeq -4.41$ describes a situation in which all changes in electron populations occur "most reluctantly", thus keeping them as small as possible (2,6). On these grounds, it seems reasonable to consider that the problem regarding the "relative ordering" of charges is adequately taken care of for the alkane molecules under scrutiny.

TABLE 1. Net charges of selected atoms: general formulas and comparison with STO-3G results from Mulliken's analysis (5)

Molecule	Atom	Formula	Net charge (me) From formula[a]	Net charge (me) STO-3G
Methane	C	$4(n + 1)/3n$	−48.92	−48.92
Ethane	C	1	−20.96	−20.96
Propane	C_{prim}	$(3n + 0.55)/3n$	−23.84	−23.81
	C_{sec}	$(2n - 3.8)/3n$	5.95	5.94

[a]Calculated with $n = 1.3325$, $q_C^0 = -20.96$ me. For additional examples see ref. 5.

The real problem which now remains to be solved is that of the physically correct magnitude of net charges, i.e., that of the ethane carbon atom, q_C^0, which serves as reference. From regression analyses involving experimental ΔE_a^*'s one finds $q_C^0 \simeq 35.1$ me[4] (2). The disturbing circumstance is that present SCF charge analyses do not agree with this empirical result. For example, assuming now $n = -4.4122$ as a correct description of the relative ordering, eq. [7] predicts $q_C^0 = -4.4122 \times (-20.96)/1.3325 = 69.40$ me on the basis of fully optimized STO-3G calculations. Similarly, the q_C^0's corresponding to $7s3p|3s$ and 6-31G calculations are 60 and 58 me, respectively (3). Clearly, it is now time to examine results derived from improved wave functions.

Outline of calculations

SCF calculations, as well as the computation of the bielectronic integrals $\langle\phi_i\phi_j|\phi_k\phi_l\rangle$ used in the CI part, were carried out by means of the MONSTERGAUSS *ab initio* program (11). Molecular geometries and scale factor exponents were optimized with a split valence 4-31G basis, using the Davidson optimally conditioned minimization technique (12), until the gradient length

$$|g| = \left[\sum_{i=1}^{n} \frac{1}{n}(\partial E/\partial q_i)^2\right]^{1/2}$$

fell below 5×10^{-4} mdyn. Optimization results are indicated in Appendix I.

The configuration interaction following the optimized SCF calculation includes ~250 configurations, i.e., mono- ($k \rightarrow v$) and diexcited ($k, k \rightarrow v, v$; $k, k \rightarrow v, t$; $k, l \rightarrow v, v$; $k, l \rightarrow v, t$) states representing five excitation classes, where k and l refer

[4]Using the carbon net charge of ethane ($q_C^0 = 35.1$ me) as reference in the evaluation of the Δq_i's, $\Sigma_i\Sigma_j a_{ij}\Delta q_i$ is 20.82 for butane and 60.60 kcal mol^{-1} for cyclohexane (2, 3). If the assumed reference charge q_C^0 and, hence, all Δq_i's were in error by 10%, the resulting errors would be, in these examples, 2.08 and 6.06 kcal mol^{-1}, respectively. The validity of the estimated ethane C net charge (35.1 me) is best illustrated by the small average deviation, ~0.2 kcal mol^{-1}, between calculated and experimental ΔE_a^* energies, covering a body of ~150 molecules.

[5]This holds also true in semiempirical MO calculations, e.g., the extended Hückel method (2, 5).

TABLE 2. Mulliken net charges from 4-31G and 4-31G + CI calculations, compared with those deduced from the formulas indicated in Table 1

		Mulliken net charge (me)			
Molecule	Atom	4-31G	n = 39.45	4-31G + CI	n = 44.1
Methane	C	−523.2	−523.2	−515.7	−515.7
Ethane	C	−382.7	−382.7	−378.2	−378.2
Propane	C_{prim}	−384.0	−384.5	−380.8	−379.8
	C_{sec}	−244.9	−242.8	−243.4	−241.3

to fundamental closed shells, and v, t refer to virtual orbitals. Details regarding the calculation of the CI matrix using $\hat{S}^2$ eigenfunctions rather than single determinants are described elsewhere (13). The selection of monoexcited configurations, $\psi^{(i)}$, was made on the basis of $\Delta E = \langle\psi^{(i)}|H|\psi^{(i)}\rangle$ values and that of diexcited configurations also considered the value of the correlation at the second-order perturbation, $\Delta = -\langle\psi^{(i)}|H|\psi^{(0)}\rangle^2/(E_i - E_0)$.

As regards the charge analysis, we proceed as follows. For a wave function represented by a single determinant, $\psi = \psi^{(0)}$, the matrix element of the monoelectronic density operator $\hat{D}$, is defined as follows

$$[9] \quad D^{(0)}_{\mu\nu} = \langle\chi_\mu|\hat{D}|\chi_\nu\rangle = \sum_{i=1} n_i c_{i\mu} c_{i\nu}$$

where χ_μ and χ_ν are atomic basis functions, and $c_{i\mu}$, $c_{i\nu}$ are the expansion coefficients for χ_μ, χ_ν of the molecular orbital ψ_i. The occupation number of ψ_i is n_i (0, 1, 2), and the summation is over all molecular orbitals. Mulliken's population matrix elements are then

$$P^{(0)}_{\mu\nu} = D^{(0)}_{\mu\nu} S_{\mu\nu}$$

in which $S_{\mu\nu}$ is an element of the overlap matrix **S**. More generally, for a wave function developed over several determinants (a CI function), it is

$$\psi = \sum_{k=1} \alpha_k \psi^{(k)}$$

$$P_{\mu\nu} = D_{\mu\nu} S_{\mu\nu}$$

In this case, the density matrix element, $D_{\mu\nu}$, of the operator $\hat{D}$ must be redefined because $\hat{D}$ depends on the form of the wave function ψ. The overlap matrix **S**, however, remains unchanged because it depends only on the atomic basis functions χ. Finally, $D_{\mu\nu}$ is defined as follows

$$[10] \quad D_{\mu\nu} = \sum_{k=1} \sum_{l\neq 1} \alpha_k \alpha_l D^{kl}_{\mu\nu}$$

where $D^{kl}_{\mu\nu}$ is the matrix element associated with the determinants $\psi^{(k)}$ and $\psi^{(l)}$ of the density operator $\hat{D}$. For $k = l$, $D^{kl}_{\mu\nu}$ is simply as indicated in eq. [9]. For $k \neq l$, $D^{kl}_{\mu\nu}$ defines an element of a transition density matrix, $\mathbf{D}^{kl}$, constructed from determinants k and l (14). This $\mathbf{D}^{kl}$ matrix has nonzero elements only when $\psi^{(k)}$ and $\psi^{(l)}$ differ from one another by not more than one spin orbital. Equation [10] expresses the idea that the density matrix for a many-determinant wave function is simply a weighted sum of "transition density matrices" connecting all different pairs of determinants in the expansion. It is formulated as

$$D^{kl}_{\mu\nu} = a(c_{n\mu} c_{m\nu} + c_{n\nu} c_{m\mu})$$

when the determinants $\psi^{(k)}$ and $\psi^{(l)}$ differ from one another in their spin orbitals ψ_n and ψ_m; a is a coefficient given by Slater's rules.

Results

The charge results deduced from 4-31G and 4-31G + CI calculations are indicated in Table 2, together with their counterparts corresponding to the formulas given in Table 1. Geometry and scale factor optimizations were carried out automatically, with reference to the gradient of the total energy. For propane, a slight but non negligible oscillation in the charge values was noted toward the end of the optimization, particularly for the secondary carbon and hydrogen atoms. The latter results are thus not as accurate as those deduced for methane and ethane. A similar behavior was also observed earlier in STO-3G calculations of propane (15). Indeed, significantly more refined optimizations of the ζ's turned out to be necessary for the secondary C and H atoms (as compared with what is usually required) in order to ensure stabilization of the charge results for these atoms. In the present case, all ζ optimizations were uniformly carried out to the 4th significant figure. Additional optimization cycles were not performed for propane because, in spite of the minor uncertainties affecting its theoretical charges, the results are sufficiently clear to serve as an illustration for the general validity of the arguments leading to the formulas given in Table 1.

For comparison, we have also studied the effect of introducing configuration interaction at the level of optimized STO-3G calculations. The results are included in the following discussion.

Discussion

We now come to the main topic of this work, i.e., the value of the ethane carbon net atomic charge, q^0_C, corresponding to the assumed correct ordering defined by $n = -4.4122$. This value is easily deduced from eq. [7] using the Mulliken net charges of methane and ethane carbons for calculating n^M (see Table 1).

From the optimized STO-3G results ($n^M = 1.3325$ and $q^{0M}_C = -20.96$ me), it follows that $q^0_C = 69.40$ me. An optimized STO-3G calculation + CI gives $q^M_C = -46.37$ and -22.28 me for methane and ethane, respectively, leading to $n^M = 1.7828$ and $q^0_C = 55.1$ me, which is already significantly better than the value, 69.40 me, obtained without CI. At the 4.31G level ($n^M = 39.45$), it follows from eq. [7] that $q^0_C = 42.8$ me. The improvement over the STO-3G result is noticeable. Finally, applying now CI to the 4-31G calculations, it is found from $n^M = 44.1$ that $q^0_C = 37.8$ me.

It is clear that improvements in the basis set descriptions, and the final touch provided by CI, yield charge results for the ethane carbon atom converging toward its empirical counter-

part, 35.1 me, deduced with the help of the energy expression, eq. [2]. It is also clear that carbon atoms in saturated hydrocarbons are unmistakably slightly electron deficient (2, 3, 6) (a fact which is often forgotten or occasionally rediscovered in recent literature) and that the proposed value of 35.1 me for the ethane carbon presently represents the estimate which is best supported by theoretical and empirical arguments: this result is pivotal in numerous appplications of the energy expression, eq. [2], whose accuracy is abundantly illustrated by comparisons with experimental data (2).

Finally, it seems important to have gained knowledge about *realistic* atomic charges and the inclusion of correlation effects therein because of relevant implications in the interpretation of eqs. [1] and [2], namely, as regards correlations between tetrahedrally localized orbitals. The familiar approximate empirical bond additivity of thermochemistry could lead us to expect that the valence shell correlation energies of molecules like CH_4, C_2H_6, . . . would consist mainly of bond correlations. In contrast, the elegant analysis offered by Sinanoğlu and Skutnik (15) reveals that correlations between neighboring tetrahedral orbitals contribute about twice as much to the valence shell correlation energy of methane as the correlation within the four doubly occupied ("bonds") tetrahedral pairs. "Nonbonded interactions" are thus not negligible but may be an important part of the correlation energies of saturated molecules. (A more approximate semiempirical version of the theory for molecular correlation energies was also given and tested for π-electron systems (16).) While these studies analyze all-important theoretical aspects related to the origin of correlation energies, the present use of eqs. [1] and [2] involving charges obtained after configuration interaction implies that all contributions to correlation, including those due to nonbonded interactions, are already reflected in the Δq_i charges. Consequently, a specific correlation energy contribution arising from nonbonded terms is not part of the E_{nb} energy appearing in eq. [2]. Estimates of E_{nb}, using Del Re's approximation (17), reveal that (in the sense of eq. [2]) nonbonded Coulomb interactions are minor, indeed, about 0.02–0.05% of ΔE^*_a, whereas the true correlation energy, i.e., the difference between exact and Hartree–Fock energies, contains important contributions originating in terms other than those associated with chemical bonds.

TABLE 5. Calculated energies (au) from optimized bases

Method	Energy calculated for Methane	Ethane	Propane

The application of an extended version of the generalized Born formula including dielectric saturation effects, implemented within the SCF-CNDO/2 approximation, provides a complete set of data concerning the thermodynamics of solvation of some ammonium ions in water. The calculated free energies of solvation are in good agreement with experimental data. An estimation of the entropy and enthalpy of solvation is also given and satisfactory qualitative trends are obtained.

RENATO CONTRERAS et GILLES KLOPMAN. Can. J. Chem. **63**, 1746 (1985).

L'application d'une version étendue de la formule de Born généralisée incluant des effets de saturation diélectrique permet, dans le cadre de l'approximation SCF-CNDO/2, l'obtention des fonctions thermodynamiques de solvatation d'un nombre d'ions ammoniums dans l'eau. Les valeurs d'énergie libre de solvatation obtenues par cette méthode sont en bon accord avec l'expérience. Une estimation de l'entropie et de l'enthalpie de solvatation est faite et les résultats montrent une tendence qualitative satisfaisante.

1. Introduction

With the recently introduced ion cyclotron resonance technique, measurement of gas-phase basicities of amines combined with heats of hydration and heats of protonation of these compounds in water have provided, for the first time, reliable thermochemical data concerning solvation of a large number of ammonium ions (1). Thermodynamics of ion solvation within this series has been found to play a key role in the "anomalous order" of amine basicities in aqueous solutions (2–4). Up to now, quantum mechanical calculations of solvation energies, including a wide variety of molecules and molecular ions, have been performed following three different general approaches: (*a*) the well known supermolecule technique, suitable for the study of relatively small molecular system with a number of solvent molecules explicitly taken into account (5–7); (*b*) continuum models based mainly on the generalized Born formula (8–11), and (*c*) mixed continuum-supermolecule models (5, 12).

In the supermolecule approach, the solvation energy is calculated as the solute–solvent interaction energy, which corresponds essentially to an enthalpy of solvation (13). A complete thermodynamic picture of the solvation process may be achieved only, within this approach, by including Monte Carlo simulation techniques in order to account for the temperature averaging effects (14).

The second approach is based on the well-known Born equation (15), which gives the change in electrostatic free energy that takes place when a charge Q_0 is transferred from a conducting sphere of radius a, in vaccuum, to a sphere of equal radius in a polarizable medium characterized by its temperature-dependent bulk dielectric constant ϵ_B. It is written as

$$[1] \quad \Delta G_S(\epsilon_B) = -(1/2)\,(1 - 1/\epsilon_B)\,Q^2/a$$

Although in principle this model allows a complete thermodynamic picture of ion solvation (16, 17), it is well established that for monoatomic ions in water at 25°C, the values of the free energy, enthalpy, and entropy of solvation predicted by this model are too high (17, 18). The overestimation of these quantities is related mainly to two problems: (*a*) the increase in the crystallographic radii due to solvation and (*b*) the dielectric saturation in the vicinity of the solvated ions, reducing the effective dielectric constant of the medium.

Equation [1] has been generalized in order to allow the calculation of solvation energies (and other physico-chemical properties) in a wide variety of molecules and molecular ions within a quantum mechanical framework (8–11). In this approach, the solute–solvent interactions are treated within the framework of the reaction field (RF) theory and the solvation energies are expressed as a sum of Born-like terms, each one corresponding to the partially charged atomic centers of the solute molecule. For instance, within a CNDO/2 type approximation, we write:

$$[2] \quad \Delta E_S(\epsilon_B, P) = -(1/2)\,(1 - 1/\epsilon_B) \sum_A \sum_B Q_A(P)\,Q_B(P)\,\gamma_{AB}$$

which is the well-known Generalized Born Formula (GBF). It is expressed as a function of the net charges $Q_A(P)$ associated with the atomic A-center of the solute, the two electron Coulomb integrals γ_{AB}, representing the solute–solvent interaction, and the bulk dielectric constant of the solvent ϵ_B. Although some confusion concerning the physical meaning of this energy has been made in the literature (19, 20), it has been emphasized recently (21, 22) that the quantity ΔE_S represents the free energy variation of the solute–solvent system, maintained at a given temperature, when the polarized solute is transferred from the gas phase to the solvent.

As in the case of eq. [1], the application of the GBF yields free energies of solvation that are considerably overestimated when compared with experimental data. In a previous publication (18), we have discussed this problem in detail, and we have proposed an extension of the GBF, within the SCF-CNDO/2 approximation, in order to account for local dielectric effects (LRF model hereafter). This approach allows simulation, within a continuum framework, of the mixed continuum-supermolecule model of solvent effects where at least the first solvation layer is explicitly taken into account.

In this work, we present further development of this model that allows a complete thermodynamic picture of ion solvation to be obtained. As an illustration of the reliability of this extended formalism, calculations of thermodynamic functions of

solvation of a number of ammonium ions in water were performed.

2. Theory

(a) The modified GBF expression

The LRF theory is based upon the classical model proposed by Beveridge and Schnuelle (23). In this approach, a general expression was deduced for the free energy of a charge distribution imbedded in a spherical cavity $S(0,a)$, surrounded by a local concentric region of thickness R_S where a local dielectric value, $\epsilon_L < \epsilon_B$, was defined. This system is supposed to be immersed in the bulk solvent of dielectric constant ϵ_B. From this formalism, we have deduced the reaction field potential acting back on the charge distribution whose net charge is Q_0 (18). In the framework of the effective charge approximation, it is written as a function of the local and bulk dielectric constant as follows,

$$[3]\quad V_R(\epsilon_L, \epsilon_B) = -(1 - 1/\epsilon_L)Q_0/a - (1/\epsilon_L - 1/\epsilon_B)Q_0/(a + R_S)$$

which represents the reaction potential created by the polarization charges induced at the surfaces $S(0,a)$ and $S(0,a+R_S)$. These polarization charges are redefined here, without changing the results of the previous formulation (18), as:

$$[4]\quad Q_i^{\mathrm{pol}}(\epsilon_L, Q_0) = -(1 - 1/\epsilon_L)Q_0$$

and

$$[5]\quad Q_e^{\mathrm{pol}}(\epsilon_L, \epsilon_B, Q_0) = -(1/\epsilon_L - 1/\epsilon_B)Q_0$$

respectively. In this way, the reaction field potential may be conveniently divided into two contributions: one coming from the internal polarization charge distribution, Q_i^{pol}, induced in the local region, and the other coming from the external polarization charge distribution, Q_e^{pol}, induced in the bulk region. The solvation free energy $\Delta G_S(\epsilon_L, \epsilon_B)$ is then given by:

$$[6]\quad \Delta G_S(\epsilon_L, \epsilon_B) = (1/2)\, \Sigma_k Q_k[V_R^{\mathrm{i}}(\epsilon_L, a) + V_R^{\mathrm{e}}(\epsilon_L, \epsilon_B, a+R_S)]_k$$

Based on eq. [6], the modified GBF may be written as a function of the density matrix P as:

$$[7]\quad \Delta G_S(\epsilon_L, \epsilon_B, P) = (1/2) \sum_A Q_A(P)[V_R^{\mathrm{i}}(\epsilon_L, P) + V_R^{\mathrm{e}}(\epsilon_L, \epsilon_B, P)]_A$$
$$= -(1/2)(1 - 1/\epsilon_L) \sum_A \sum_B Q_A(P)Q_B(P)\gamma_{AB}^{\mathrm{i}}$$
$$-(1/2)(1/\epsilon_L - 1/\epsilon_B) \sum_A \sum_B Q_A(P)Q_B(P)\Gamma_{AB}^{\mathrm{e}}(R_S)$$

In this expression, γ_{AB}^{i} and $\Gamma_{AB}^{\mathrm{e}}(R_S)$ are the internal and external polarization charge–electron interaction integrals, respectively. Details about the calculation of these quantities are given in the next section of this paper.

(b) Estimation of the entropy of solvation

As was proposed recently (22), the total free energy of the solute–solvent system is obtained by adding to the total energy of the isolated solute, the electrostatic solvation energy $\Delta G_S(\epsilon_L, \epsilon_B, P)$ which corresponds to the free energy variation of the solute–solvent system, when the polarized solute is inserted isothermically into the solvent. This solvation term may be partitioned according to (21, 22):

$$[8]\quad \Delta G_S(\epsilon_L, \epsilon_B, P) = E_{s-\Sigma}(\epsilon_L, \epsilon_B, P) + E_\Sigma^{\mathrm{pol}}(\epsilon_L, \epsilon_B, P)$$

$$[9]\quad E_{s-\Sigma}(\epsilon_L, \epsilon_B, P) = -(1 - 1/\epsilon_L) \sum_A \sum_B Q_A(P)Q_B(P)\gamma_{AB}^{\mathrm{i}}$$
$$-(1/\epsilon_L - 1/\epsilon_B) \sum_A \sum_B Q_A(P)Q_B(P)\Gamma_{AB}^{\mathrm{e}}(R_S)$$

where $E_{s-\Sigma}(\epsilon_L, \epsilon_B, P)$ (eq. [9]), is the electrostatic solute–solvent interaction energy and $\Delta E_\Sigma^{\mathrm{pol}}(\epsilon_L, \epsilon_B, P)$ is the solvent polarization energy. This last term represents the orientational entropy change induced by the opposite effects of the orienting electric field arising from the ionic charge and the averaging temperature effects. These two quantities are related by the expression:

$$[10]\quad \Delta E_\Sigma^{\mathrm{pol}}(\epsilon_L, \epsilon_B, P) = -(1/2)E_{s-\Sigma}(\epsilon_L, \epsilon_B, P)$$

Within the RF model neglecting dielectric saturation, the solvent polarization is assumed to be entirely orientational and for a given temperature T, the following "incorrect" relation is then obtained:

$$[11]\quad T\Delta S_S(\epsilon_B, P) = \Delta E_\Sigma^{\mathrm{pol}}(\epsilon_B, P)$$
$$= (1/2)(1 - 1/\epsilon_B) \sum_A \sum_B Q_A(P)Q_B(P)\gamma_{AB}$$
$$= -\Delta G_S(\epsilon_B, P)$$

As a result, largely overestimated values of the term $-T\Delta S_S(\epsilon_L, \epsilon_B, P)$ are to be expected with this model.

The consideration of local dielectric effects allows a more realistic evaluation of the entropic contribution to ion solvation. Indeed, starting from eq. [7] and using eqs. [8] and [10], the solvent polarization energy may be expressed as:

$$[12]\quad \Delta E_\Sigma^{\mathrm{pol}}(\epsilon_L, \epsilon_B, P) = (1/2)(1 - 1/\epsilon_B) \sum_A \sum_B Q_A(P)Q_B(P)\gamma_{AB}^{\mathrm{i}}$$
$$+ (1/2)(1/\epsilon_L - 1/\epsilon_B) \sum_A \sum_B Q_A(P)Q_B(P)\Gamma_{AB}^{\mathrm{e}}(R_S)$$

The resulting eq. [12] is consistent with the classical theory of dielectric polarization. In fact, as was proposed by Marcus (24), the polarization of any dielectric medium may be regarded as consisting of electronic, atomic, and orientation contributions. Furthermore, if, as a first approximation, the atomic contribution is neglected, we may write the total polarization vector $\boldsymbol{P}_t(\boldsymbol{r})$ as:

$$[13]\quad \boldsymbol{P}_t(\boldsymbol{r}) = \boldsymbol{P}_{el}(\boldsymbol{r}) + \boldsymbol{P}_{or}(\boldsymbol{r})$$

where the first term in eq. [13] represents the electronic polarization associated with the electronic motion of the solvent molecules. It is interesting to note that, following a quite different procedure, the module of this electronic term has been found by Jortner (25) to be identical to our "internal polarization charge" defined in eq. [4]. In the same way, the module of the second term in eq. [13] representing the orientational polarization, is formally identical with our "external polarization charge" defined in eq. [5]. The temperature-dependent orientation polarization given by the second term of eq. [12] may be assimilated, in the framework of the LRF theory, to the orientational entropy change which, added to the solute–solvent interaction energy defined in eq. [9], gives the expression of the solvation free energy (eq. [7]).

Based on the above consideration we may write:

$$[14] \quad -T\Delta S_S(\epsilon_L, \epsilon_B, P) = (1/2)\,(1/\epsilon_L - 1/\epsilon_B) \sum_A \sum_B Q_A(P) Q_B(P) \Gamma_{AB}{}^{c}(R_S)$$

Finally, combining eqs. [7] and [14], the following expression for the enthalpy of solvation is obtained:

$$[15] \quad \Delta H_S(\epsilon_L, \epsilon_B, P) = -(1/2)\,(1 - 1/\epsilon_L) \sum_A \sum_B Q_A(P) Q_B(P) \gamma_{AB}{}^{i} - (1/\epsilon_L - 1/\epsilon_B) \sum_A \sum_B Q_A(P) Q_B(P) \Gamma_{AB}{}^{c}(R_S)$$

3. Results and discussion

The LRF model of solvent effects discussed in the previous section, was applied to the calculation of the thermodynamic functions of solvation of some ammonium ions in water. All bond angles were taken as 109.47. The following bond lengths were used: C—C = 1.53 Å , C—N = 1.47 Å, C—H = 1.09 Å, and N—H = 1.00 Å.

The internal polarization charge–electron interation integrals $\gamma_{AB}{}^{i}$ were calculated according to the parametrization suggested by Miertus and Kysel (19): that is, for AO's associated with the same atomic center as the polarization charge Q_A, $\gamma_{AA}{}^{i}$ is given by $1/r_A$, where r_A is the Pauling's Van der Waals radius of the particular atom (26). When the AO's and the internal polarization charges are associated with different atomic centers, A and B, the internal solute–solvent interaction integrals were calculated as:

$$[16] \quad \gamma_{AB}{}^{i} = 1/(R_{AB} + r_B)$$

where R_{AB} is the interatomic distance calculated, as in our previous work in terms of the $\gamma_{AB}{}^{i}$ integrals, as (18):

$$[17] \quad \Gamma_{AA}{}^{c}(R_S) = \gamma_{AA}{}^{i}/(1 + R_S\gamma_{AA}{}^{i})$$

and

$$[18] \quad \Gamma_{AB}{}^{c}(R_S) = 1/[R_{AB} + (1/2)(1/\Gamma_{AA}{}^{c}(R_S) + 1/\Gamma_{BB}{}^{c}(R_S)]$$

respectively.

The parameter R_S, measuring the extent of the local dielectric region, was taken as $R_S = n\, d_{H_2O}$ (n = 1,2), with d_{H_2O} equal to the diameter of a water molecule (i.e., 2.80 Å). Finally, as suggested in ref. 27 and based on previous calculations (18), we used the values ϵ_L = 5.0 and ϵ_B = 78.5.

The results of the calculations of free energies, enthalpies and entropies of solvation for a number of ammonium ions in water are shown in Table 1. Examination of the calculated free energies of solvation reveals a significant agreement with experimental data: within the primary ammonium ions series, alkylation of the NH_4^+ ion results in a decrease of ΔG_S in the order $NH_4^+ > MeNH_3^+ > EtNH_3^+ > n\text{-}PrNH_3^+ > n\text{-}BuNH_3^+$. With the only exception of Et_3NH^+, the same trend observed within the secondary and tertiary series are also satisfactorily accounted for by the LRF model. Methylation of the ion pyrrolidinium resulted in a decrease of ΔG_S of about 5.6 kcal/mol (for n = 1), compared with an experimental value of 6.6 kcal/mol.

TABLE 1. Thermodynamic functions of solvation of some selected ammonium ions in water[a]

Solute	Experimental[b] ΔG	ΔH	$-T\Delta S$	Calculated[c] ΔG	ΔH	$-T\Delta S$

[a] All values in kcal/mol.
[b] From ref. 1.
[c] First value corresponds to RS = 2.80 Å and the second one to RS = 5.60 Å.

It is interesting to notice that the best description of the ΔG_S values are obtained with n = 1, which corresponds to R_S = 2.80. This is approximately the value found by Laidler (28) and Conway (29) to be the critical distance from the ion where the dielectric saturation effects manifests itself. Furthermore, in a recent paper Kebarle *et al.* (30) concluded, from ion–solvent molecule equilibria studies, that relative solvation energies for ammonium ions can be obtained by considering the interaction of the ion and a few solvent molecules only. These results are consistent with our "one solvation layer" continuum model with n = 1. Recently, Kebarle's conclusions have been confirmed by *ab-initio* calculations reported by Ikuta (31).

Estimation of entropies of solvation using eq. [14] are also summarized in Table 1. For NH_4^+, a calculated value of 11.0 kcal/mol is obtained compared with an experimental value of 6.6 kcal/mol reported by Aue *et al.* (1). Although this property is not satisfactorily accounted for in quantitative terms, it may be seen that the general trends observed within the family of substituted ammonium ions is quite reasonable: within the primary amine series, alkylation of the ammonium ions results in an increase of the $-T\Delta S_S$ contribution in the order $MeNH_3^+ < EtNH_3^+ < n\text{-}PrNH_3^+ < n\text{-}BuNH_3^+$, in agreement with the observed data. In the same way, the variation of the entropy of solvation in the secondary amine series follows the order $Me_2NH_2^+ < Et_2NH_2^+$, $n\text{-}Pr_2NH_2^+ < n\text{-}Bu_2NH_2^+$, compared with the observed sequence $Me_2NH_2^+ < Et_2NH_2^+ < n\text{-}Pr_2NH_2^+ < n\text{-}Bu_2NH_2^+$. For the tertiary ammonium ions, although the order $Me_3NH^+ < Et_3NH^+$ is qualitatively reproduced (there is no experimental data available concerning $n\text{-}Pr_3NH^+$), the LRF model predicts a largely overestimated value of the entropy of solvation, and this, for both the Et_3NH^+ and $n\text{-}Pr_3NH^+$ ions. Finally, the decrease of $-T\Delta S_S$ by methylation of the pyrrolidinium ion is also qualitatively accounted for by the LRF model.

The overestimation of the entropy of solvation for the tertiary amine series could be related to the fact that the solvent–solvent polarization energy has been represented, within this model, by the interaction of hard spheres of radius $(r_A + R_S)$. As a result, two (or more) atoms in the molecule are close enough so that their cosphere overlap. In such a case, one would want some of the overlapping cosphere material to be displaced in a process in which the local dielectric material relaxes to the state of the normal bulk solvent (32). This effect which is expected to be even more pronounced when bulky substituents are incorporated into the molecule, is not accounted for in the present approach. Further developments of the present model, allowing for this steric hindrance effect to solvation to be included, is expected to improve the description of the entropy of solvation of sterically hindered molecular ions.

Finally, taking into account the correct trends predicted for the $-\Delta G_S$ contributions, it may be concluded that the somewhat irregular order of the enthalpy of solvation predicted by eq. [15] arises mainly from the overestimated $-T\Delta S_S$ contributions. This fact, as was discussed above, dramatically manifests itself in the tertiary ammonium ions.

Concluding remarks

The main conclusions that may be drawn from this work are the following: (*a*) The quantum mechanical extension of the Born formalism including dielectric saturation effects appears to work reasonably well, at least qualitatively, in accounting for the variations of the thermodynamic functions of solvation associated with changes in size of ions and substituent effects. This has been shown for ammonium ions and may hopefully be applied to other molecular systems as well. (*b*) Since the method necessarily involves a semi-empirical choice of ϵ_L and R_S, as well as a semi-empirical adjustment of the solute–solvent interaction integrals, we cannot consider the results obtained as quantitatively significant.

In spite of the above considerations, the present approach represents a considerable progress with respect to the current quantum mechanical approaches based on the Born formula. For the first time, to our knowledge, a complete thermodynamic picture of solvation for molecular ions has been obtained. This could be particularly useful in connection with the theoretical study of acid–base equilibria in solution involving a wide variety of systems.

Received August 22, 1984

This paper is dedicated to Professor Camille Sandorfy on the occasion of his 65th birthday

MARGARET ANN JAMES, T. STANLEY CAMERON, OSVALD KNOP, MURRAY NEUMAN, and MICHAEL FALK. Can. J. Chem. **63**, 1750 (1985).

A crystal structure determination has shown that the ethyl groups in the three isostructural ($P6_3mc$, Z = 2) triethylammonium halides, Et_3NHX (X = Cl, Br, I), at room temperature are orientationally disordered and the N—H···X groups are linear by symmetry. The unusual extent and complexity of the NH and ND stretching absorptions in the ir spectra of all three compounds between 10 and 293 K are discussed in terms of Fermi resonance interactions. The centroid ν(NH) and ν(ND) frequencies extracted from the spectra correlate with the $H_N \cdots X$ distances. It is shown that if Fermi resonance is the sole cause of the complexity of the stretching absorptions, then these centroids represent the ν(NH) and ν(ND) frequencies unperturbed by Fermi resonance. The centroid frequencies in the three halides are unusually low, pointing to strong N—H···X hydrogen bonding.

MARGARET ANN JAMES, T. STANLEY CAMERON, OSVALD KNOP, MURRAY NEUMAN et MICHAEL FALK. Can. J. Chem. **63**, 1750 (1985).

Une détermination de structure cristalline a permis de montrer que, à la température ambiante, les groupements éthyles des trois halogénures de triéthylammonium, Et_3NHX (X = Cl, Br, I), isostructuraux ($P6_3mc$, Z = 2) ne sont pas ordonnés du point du vue de l'orientation et que les groupements N—H···X ont une symétrie linéaire. Opérant à des températures allant de 10 à 293 K, on a mesuré les spectres infrarouges des trois composés qui présentent des absorptions d'élongation NH et ND dont l'importance et la complexité sont inhabituelles; on en discute en fonction d'interactions de résonance de Fermi. On peut établir une corrélation entre les fréquences centroïdes ν(NH) et ν(ND) que l'on peut extraire des spectres et les distances $H_N \cdots X$. On démontre que, si la résonance de Fermi est la seule cause de la complexité des absorptions d'élongation, ces centroïdes représentent les fréquences ν(NH) et ν(ND) qui ne sont pas perturbées par la résonance de Fermi. Les fréquences centroïdes des trois halogénures sont particulièrement basses et ce résultat suggère qu'il existe une liaison hydrogène N—H···X importante.

[Traduit par le journal]

The N—H···X bond in the three hexagonal Et_3NHX halides is known (1, 2) to be on a threefold axis and fairly short; in the chloride d(N···X) ~ 3.11 Å (2). The NH groups are all crystallographically equivalent and well separated (d(N···N) ~ 6 Å or longer). A single NH stretching absorption free from complications would thus be expected in the ir spectrum, and since the N—H···X bond is linear by symmetry, the three halides would seem to offer an excellent opportunity for correlating the N···X and H···X distances with the NH stretching frequency. However, the results of a number of ir studies of these compounds (3–7) are completely at variance with the expectation. The observed ν(NH) absorption is not a single peak but a complex multicomponent absorption extending over at least 400 cm^{-1} of the spectrum; the full extent and complexity of this absorption, and of the corresponding ν(ND) absorption in deuterated material, become evident at low temperatures (3, 6, 7). Similar observations have been made with other alkylammonium salts (8–14). While general explanations of this complexity have been advanced (4, 5, 8) (see below), the frequency–distance correlation was not pursued in any detail, both because of lack of accurate structural information on the three halides at the time and because of the uncertainty as to how to extract from each spectrum a single ν(NH) or ν(ND) frequency value to be used in such a correlation.

In the present investigation we have attempted to contribute toward a resolution of these problems in two ways. We have redetermined the crystal structure of the chloride and determined the structures of the bromide and iodide. We have also obtained high-quality ir spectra, between 10 and 293 K, of the undeuterated and partially deuterated halides, from which we have derived frequency centroids of the NH and ND stretching absorptions to be used in the frequency–distance correlation. It is shown that if Fermi resonance is the sole cause of the complexity of the stretching absorption, then on certain assumptions these centroids represent the ν(NH) and ν(ND) frequencies unperturbed by Fermi resonance.

Experimental

The title compounds were prepared by neutralizing Et_3N in aqueous solution with the appropriate aqueous HX. They were recrystallized from 50% EtOH. The crystal data of the three halides are listed in Table 1.

Space group

The lattice parameters are in reasonable agreement with those determined previously (1, 2). In each case there are two formula units in the hexagonal unit cell, which requires the N atoms to be situated in special positions but not at centres of symmetry, as the cation is not centrosymmetric. The systematic absence of $hkil$ reflections with $l = 2n + 1$ is consistent with the space groups $P31c \subset (P6_3mc, P\bar{6}2c, P\bar{3}1c) \subset P6_3/mmc$. Unless it is assumed from the outset that the cations are orientationally disordered, $P6_3/mmc$, $P\bar{6}2c$, and $P\bar{3}1c$ can be ruled out, as none of these contains twofold equipoints compatible in symmetry with the stereochemistry of the cation. In the two remain-

ing groups the N and X atoms would be situated on threefold axes, in $P6_3mc$ with site symmetry $3m$ and in $P31c$ with site symmetry 3. Since for structures containing atoms in general positions the equalities $|F(\bar{h}kl)| = |F(h\bar{k}l)|$ and $|F(hkl)| = |F(hk\bar{l})|$ hold in $P6_3mc$ but not in $P31c$, the space-group ambiguity can, in principle, be resolved by comparing the appropriate $|F_o|$ values. Under this scrutiny the space group $P6_3mc$ adopted by both Hendricks (1) and Genet (2) has been confirmed.

Structure determination

A CAD-4 four-circle diffractometer was used in the determination of the unit-cell dimensions and in the intensity collection. The intensities were reduced by routine procedures (15). Lorentz and polarization corrections were applied but not absorption or extinction corrections. The scattering factors for neutral atoms were taken from ref. 16. The structures were solved by Patterson and Fourier methods using the SHELX system (17). To ensure proper convergence, the C—H bond lengths were constrained in the refinement to 1.08 Å and the N—H to 1.03 Å in the chloride, 1.025 Å in the bromide, and 1.02 Å in the iodide. The CH_2 and CH_3 groups were refined as rigid bodies.

The positional parameters are listed in Table 2, the thermal parameters in Table 3,[2] structure factors in Tables 4–6,[2] and interatomic distances and bond angles in Table 7.

Infrared spectra

For the survey spectra, the finely ground sample powders were mulled in hydrocarbon or fluorocarbon oil and the mulls were held between CaF_2 windows. The spectra were recorded on a Perkin-Elmer model 180 grating spectrometer or a Bomem DA3.02 Fourier-transform ir spectrometer fitted with a closed-cycle He refrigerator (Displex model 202, Air Products and Chemicals Co.). For the more detailed study of the ND stretching band at isotopic dilution the salts were deposited as solid films on CaF_2 plates by forced evaporation of C_2H_5OH or 5:95 C_2H_5OD–C_2H_5OH solutions. The films were prepared in 0% D|5% D pairs matched in thickness. Their spectra at room temperature were recorded on the Bomem spectrometer and the spectral profiles of the ND absorptions were obtained by digital subtraction of the spectra of the matched pairs. The centres of gravity were determined by integrating the digital spectra.

Results and discussion

Crystal structures

To be compatible with the crystal data (Table 1), the N and X atoms must be located in equipoint $2(b)$ – $\frac{1}{3}, \frac{2}{3}, z$ etc. Hendricks (1) in 1928 placed both carbons of the C_2H_5 group in $6(c)$ – $x, \bar{x}, z$ etc., i.e. on the mirror plane. Genet (2) placed both carbons in the chloride in $12(d)$ – x, y, z etc., i.e. off the

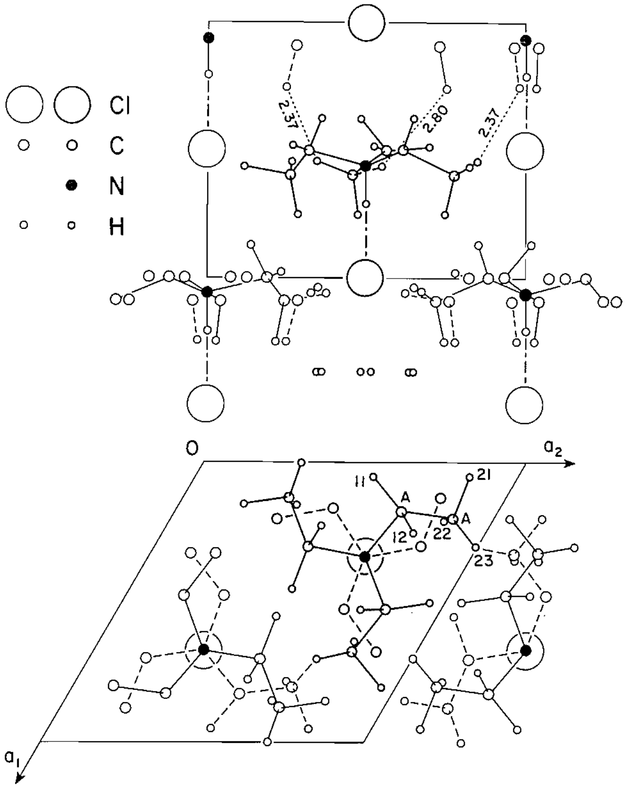

FIG. 1. $Et_3NH\underline{C}l$: projections of a portion of the structure on (0001) (*bottom*) and (10$\bar{1}$0) (*top*). The two possible orientations of a C_2H_5 group are distinguished by solid and broken lines, respectively. The N—H bonds are drawn as dash–dot lines, the shortest intermolecular $H_C \cdots H_C$ distances as dotted lines. The top projection shows the environment of a Et_3NHCl unit oriented as per Table 2.

mirror planes, which introduces twofold orientational disorder with respect to the mirrors; the final R was 0.10.

In our refinements both models were tried as well as a third model, with C(1) in 12(d) with half occupancy and C(2) in 6(c). The lowest R values (anisotropic temperature factors, hydrogens not yet included) for all three halides were obtained with C(1) and C(2) both disordered. This establishes that the three compounds are isostructural and the structure proposed for the chloride by Genet is correct. Inclusion of the H atoms lowered the R to 4.73% for the chloride, 3.01% for the bromide, and 5.04% for the iodide.

Unlike the structures of some alkylammonium salts (13), in which the "ionic" (i.e. —NH^+/anion containing) layers alternate with layers of the "fatty" alkyl residues, the Et_3NHX structures consist of identically populated staggered layers ‖(0001) stacked in an ABAB. . . sequence (Fig. 1). Each layer contains both the —NEt_3 groups (in a nearly flat conformation) and the X^- ions. The vertical separation of these layers, $c/2$, is almost equal to the N$\cdots$X distance; the N—H$\cdots$X bonds are parallel to c and thus perpendicular to the layers.

The Et groups, relative to the N—H bonds, are arranged indifferently in left-handed and right-handed Et_3NH units of C_3 symmetry. The structure may thus be regarded as a racemic crystal with a random distribution of the two chiralities. Genet (2) observed that, in the chloride, the minimum distances between atoms of neighbouring cations are too large for an effective interaction capable of giving rise to orientational ordering, at least at room temperature. Indeed, in Et_3NHCl the shortest intermolecular distance between two ethyl hydrogens is

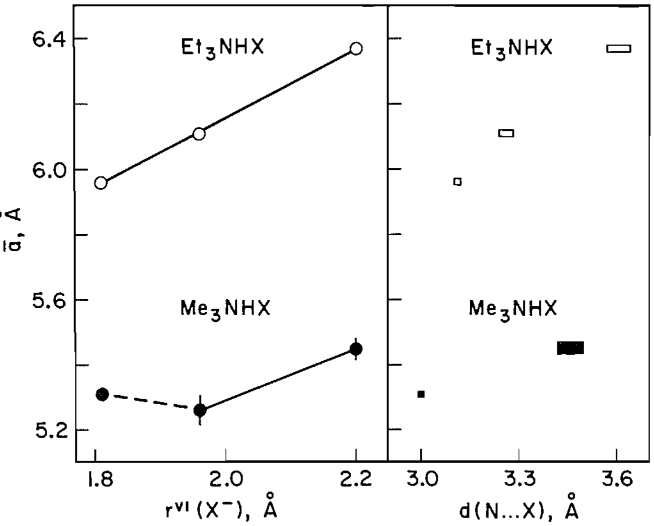

FIG. 2. Variation of the mean linear unit-cell dimension $\bar{a} = (V/Z)^{1/3}$ of Et_3NHX and Me_3NHX with the effective ionic radius of X^- (*left*) and d(N$\cdots$X) (*right*).

H(23A)$\cdots$H(22M) ~ 2.37 Å, followed by H(21C)$\cdots$H(22G) ~ 2.79 Å and H(21C)$\cdots$H(22K) ~ 2.96 Å; all the other $H_C \cdots H_C$ distances are greater than 3.5 Å.[3] In the bromide and iodide the corresponding distances are at least 2.7 Å. The structure thus has a considerable flexibility which increases from the chloride to the iodide. This is reflected in the esd's of the positional parameters (Table 2) and in the unusually large values of the thermal parameters in the iodide (Table 3[2]).

Comparison with Me_3NHX

Unlike the three Et_3NHX halides, the three Me_3NHX halides are not isostructural among themselves, even though they all have the same space-group symmetry, $P2_1/m$ (18–20), and they differ in important respects from the Et_3NHX in the organization of their structures. For Et_3NHX the variation of the mean linear unit-cell dimension $\bar{a} = (V/Z)^{1/3}$ with the effective ionic radius r^{vi} (X^-) (Fig. 2) is linear (r^2 = 0.999, σ = 0.009 Å), as would be expected for an isostructural salt series. In contrast, in the corresponding plot for Me_3NHX the points for X = Br and X = I define a straight line almost parallel to that for Et_3NHX, but the Cl point is significantly above this line. This is not unexpected: the structures of the chloride (19) and the iodide (20) are different, and while the structure of the bromide does not appear to have been determined, the unit-cell dimensions of that compound are similar to those of the iodide (18).

The d(N$\cdots$X) in Et_3NHX range from 3.11 to 3.60 Å (Table 7). These values are about 3% larger than the corresponding values for Me_3NHCl and Me_3NHI. The N$\cdots$Cl distance in Me_3NHCl is exceptionally small, about 10% smaller than the d(N$\cdots$Cl) in simple cubic NH_4Cl, so that in ref. 19 the structure of Me_3NHCl is regarded as consisting of neutral [$Me_3NH^+Cl^-$] ion pairs.

In the two trimethyl structures the N$\cdots$X (and by implication the N—H) vectors are arranged in parallel layers (Fig. 3), within which they are antiferro-ordered. The minimum perpendicular separation of these vectors is 4.3 Å in the chloride and ~4.5 Å in the iodide. In the polar Et_3NHX structures,

[3] Symmetry code: A, x, y, z; C, $y - x, 1 - x, z$; G, $1 - x, 1 - y, \frac{3}{2} + z$; K, $y, x, \frac{3}{2} + z$; M, $1 + x - y, 1 - y, \frac{3}{2} + z$.

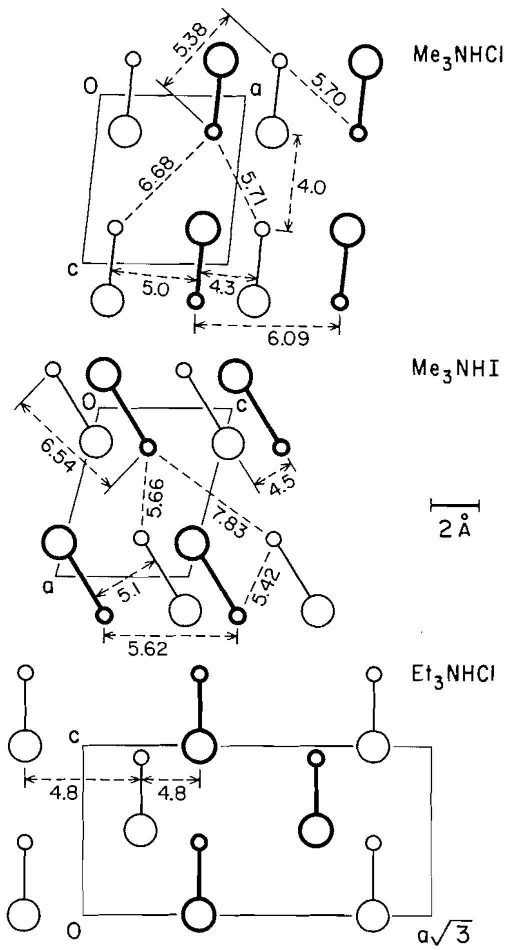

FIG. 3. Orientation and minimum perpendicular separation of the N—X vectors in the structures of Me_3NHCl, Me_3NHI, and Et_3NHCl. The large circles represent Cl or I, the small circles represent N.

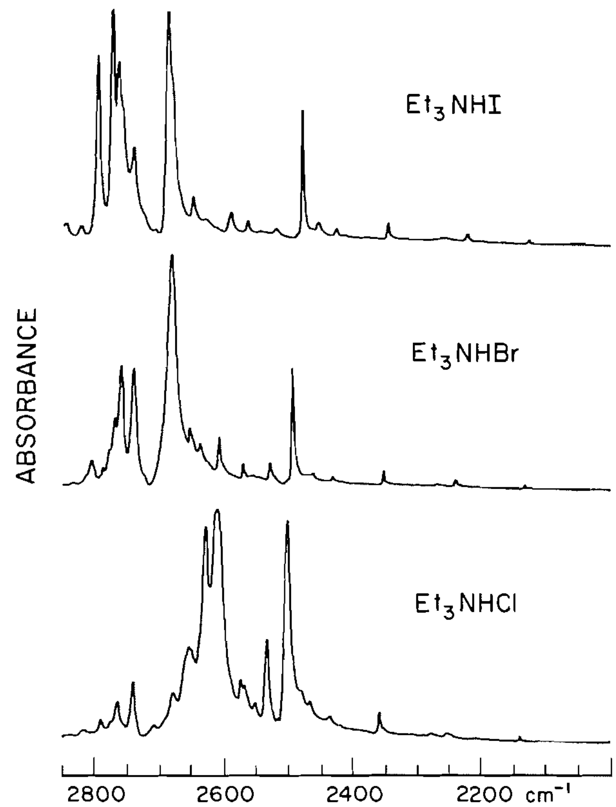

FIG. 4. NH stretching absorption in the ir spectrum of the three Et_3NHX halides at 10 K (0% D, fluorocarbon mulls). The absorbance was arbitrarily scaled to the same maximum peak height.

on the other hand, the packing is such that the N—H vectors are all *ferro*-ordered within staggered layers parallel to (0001); the minimum perpendicular separation of the threefold axes on which the N—H vectors are located is ≥4.8 Å, while the minimum $H_N \cdots H_N$ = N···N distance is ~6 Å or more. The considerably larger separation of the NH groups in Et_3NHX has important implications for vibrational coupling (see below).

Infrared spectra: previous studies

In the ir spectra of trialkylammonium halides, absorptions due to the NH and ND stretching fundamentals can extend over several hundreds of cm^{-1} and contain many sharp components. Sandorfy *et al.* (4, 5) and Lord and McDowell (3, 6, 7) made this observation with Et_3NHX, and Ebsworth and Sheppard (8) with Me_3NDI, some 25 years ago. The studies that have been published since, both on triethylammonium (10, 11, 14, 21, 22), trimethylammonium (9, 23–25), and higher trialkylammonium (21) halides bear witness to the continued interest in this phenomenon, and are not confined to the simple halides but include other alkylammonium salts as well (12, 13). The complex NH and ND stretching absorptions persist, with band sharpening and increased detail, down to liquid-helium temperature (3, 6) and are observed also in solution spectra of these salts (9–11, 14, 21, 22).

Sandorfy *et al.* (4, 5) interpreted the complexity of the NH stretching absorption in Et_3NHX in terms of combination bands involving mainly deformation vibrations, the ir intensity of which derives from electrical anharmonicities induced by the strong hydrogen bonds; Ebsworth and Sheppard (8) regarded the numerous strong absorption bands near the ND stretching fundamental of Me_3ND^+ as overtone and combination bands interacting with the ND stretching fundamental through Fermi resonance. That Fermi resonance perturbations are responsible for the complexity has been concluded also from the observation that the NH stretching absorption in the solution spectra of Et_3NH^+ salts is independent of the solvent (11, 14) and from the study of the ir spectra of the trimethylammonium–pyridine and triethylammonium–pyridine complex cations (9, 10). On this view the complexity of the NH and ND stretching absorptions in Et_3NHX arises from overtones and binary combinations of fundamental vibrations of the cations in the 1000–1500 cm^{-1} region, enhanced by extensive Fermi resonance with the NH or ND stretching fundamental.

Infrared spectra: present work

Such spectral changes as occur in the NH and ND stretching regions of the spectra of the three halides between 10 and 293 K are gradual and do not point to the existence of phase transitions in this temperature interval.

NH stretching absorption (Fig. 4). In undeuterated Et_3NHCl the complex absorption extends from above 2800 cm^{-1}, where it merges with the CH stretching fundamentals, to about 2100 cm^{-1}, where absorption peaks become sparse and gradually vanish into the background. The spectra agree very well with those recorded by McDowell (7) at the two temperatures studied, 80 and 300 K, except for the somewhat better resolution of our spectrometers.

*a, broadened and merged with other bands; vw, very weak; w, weak; m, medium; s, strong; vs, very strong; ~, broader peaks or shoulders, position uncertain by more than 1 cm^{-1}.

More than 20 absorption peaks are clearly resolved at 10 K; with increasing temperature they gradually broaden and coalesce. The NH stretching absorptions of the undeuterated bromide and iodide yield complex patterns of peaks similar to those of Et_3NHCl: sharp spectral features in the absorptions of the three compounds appear to correspond in relative intensity and temperature shift (Table 8). The positions of corresponding peaks tend to shift by a few cm^{-1} to lower wavenumbers going from the chloride to the iodide. The correspondence is most obvious in the low-frequency wing and disappears toward the band centre.

Assuming that the NH stretching absorption ends and the CH stretching absorption begins at 2850 cm^{-1}, the frequency centroids of the NH stretching absorption are computed as

Temperature	Frequency centroid (cm^{-1}) Cl	Br	I
10 K	2611(2)	2685(2)	2740(2)
293 K	2598(2)	2676(2)	2727(2)

Examination of the effect of N-deuteration indicates that in fact the NH absorption extends somewhat beyond 2850 cm^{-1} and allowance must be made for the NH/CH overlap, which increases from Cl to I. The true positions of the centroids are estimated to be ~5 cm^{-1} (Cl), ~10 cm^{-1} (Br), and ~30 cm^{-1} (I) higher than the respective above values.

Two trends are clearly demonstrated in spite of our uncertainty about the absolute positions of the NH centroids:

(*i*) The centroids shift to lower wavenumbers with increasing temperature. This agrees with the independent observation that most of the *individual* component peaks also shift in this direction (Table 8).

(*ii*) The centroid frequencies increase from Cl to I; the shifts are much larger than the experimental uncertainty.

ND stretching absorption (Figs. 5 and 6). As illustrated in Fig. 5 for the chloride, the ND absorption too extends over a wide range. The positions of the component peaks were found to be independent of the degree of deuteration. The ND spectra of the bromide and iodide resemble those of the chloride; their behaviour with temperature (Fig. 5) shows a close similarity to the NH spectra.

Unlike for $(C_2H_5)_3NH^+$, in $(C_2H_5)_3ND^+$ there is no interference from the CH stretching absorptions. The positions of the frequency centroids of the ND absorption can therefore be determined with considerable accuracy, as the subtraction procedure for the 0% D| 5% D matched spectra cancels, to a good approximation, all spectral features except those due to the ND stretching. At room temperature the centres of gravity were 2007(2) cm^{-1} for the chloride, 2062(2) cm^{-1} for the bromide, and 2135(2) cm^{-1} for the iodide. The above anion dependence of the NH centroids is thus confirmed beyond doubt.[4]

Infrared spectra: discussion

Vibrational coupling. The positions (and to a large extent the widths) of the component NH and ND stretching absorptions are independent of the degree of deuteration. This points to the absence of any appreciable dynamic coupling of vibrations of neighbouring NH or ND groups in the $Et_3N(H, D)X$ crystals. Such coupling thus does not contribute to the spectral complexity of the NH and ND stretching absorptions. A similar observation has been made with $(Et_3NH)_2SnCl_6$ (12) and $(Me_3NH)_2SnCl_6$ and $(Me_3NH)_2SnBr_6$ (13). However, evidence of vibrational coupling has been reported for Me_3NHCl (24).

The absence of vibrational coupling may be accounted for by the large separation of neighbouring NH groups in the crystal. In Me_3NHCl, where coupling appears to exist, the minimum N···N distance is 5.38 Å, and in Me_3NHI it is 5.42 Å. In comparison, in Et_3NHX it is at least ~6 Å, and in $(Me_3NH)_2SnCl_6$ (13) and $(Me_3NH)_2TeCl_6$ (26) it is >6.2 Å.

The configuration of the N—X vectors (the direction of which in Me_3NHX and Et_3NHX coincides more or less with that of the N—H vectors) may also be a factor. The nearest-neighbour N—X vectors in all three structures, Me_3NHCl, Me_3NHI, and Et_3NHX, are related by the operation of a two-fold screw axis. However, in the trimethyl compounds these vectors are in mirror planes perpendicular to the screw axis, whereas in Et_3NHX they are parallel to it (Fig. 3). The layers containing the N—X vectors are parallel to (001) in Me_3NHCl, to (100) in Me_3NHI, and to (0001) in Et_3NHX. The arrangement of the vectors in these layers is antiparallel in the trimethyl compounds, but in Et_3NHX the vectors are parallel and offset by the $c/2$ screw translation. In the triethyl compounds the N—X vectors are perpendicular to the layers, whereas they

[4]If this were desired, the NH/CH overlap problem in the NH centroid determination could be resolved by working from $(C_2D_5)_3NHX$ instead of $(C_2H_5)_3NHX$ spectra.

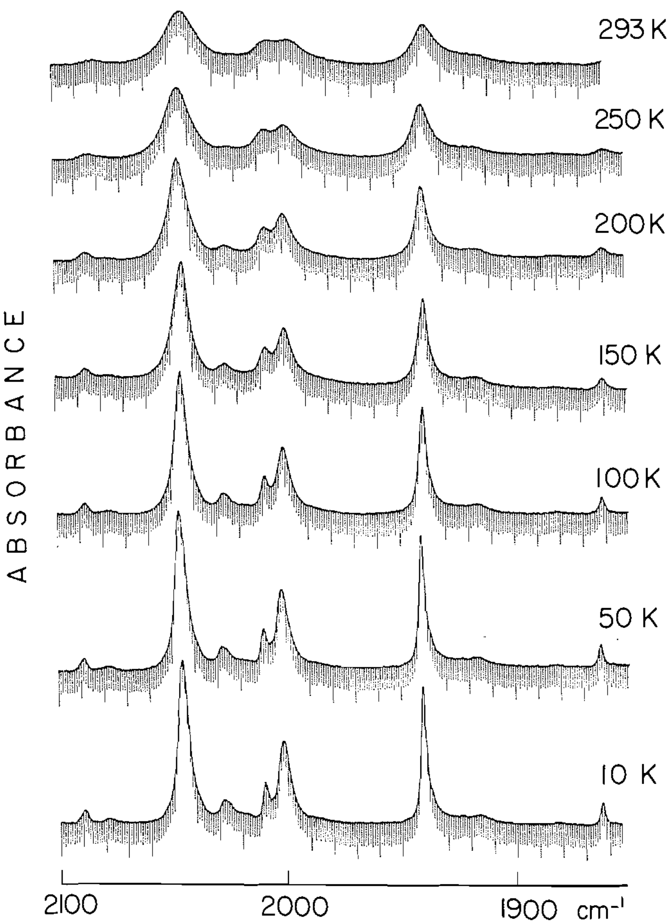

FIG. 5. The central part of the ND stretching absorption in the ir spectrum of Et_3NHCl (5% D) (fluorocarbon mull) at different temperatures.

are canted in the trimethyl compounds, ~85° relative to the layer in the chloride and ~60° in the iodide.

Frequency centroids. While the centres of gravity of the absorptions in the NH and ND stretching regions of Et_3NHX can be determined with considerable confidence, the question remains as to how the frequency values so obtained are related to the single frequencies that would be observed in the absence of spectral complications and thus measure, unambiguously, the relative strength of the hydrogen bonding in Et_3NHX.

The subtraction procedure using matched 0% D|5% D pairs practically eliminates spurious peaks, so that each peak in the ND stretching region of the difference spectrum (Fig. 6) can be considered as involving the ND stretching fundamental. The stretching absorptions are insensitive to the degree of deuteration, and the arbitrary choice of the cut-off limits of the integration interval cannot have a serious effect, as the peak intensities of the complex absorption fall off rapidly toward the limits of the interval. The centroid frequencies may thus be regarded as authentic spectral parameters of the three halides.

What do the centroids represent? The answer depends on what is taken to be the cause of the spectral complexity. If it is assumed, with the majority of authors (8, 9, 11–14, 24, 27), that the complex fine structure of the extensive stretching absorption results *entirely* from Fermi resonance and that the participating combination and overtone levels have no inherent intensity, then it can be shown (see Appendix) that the centroid frequency represents the ν(NH), or ν(ND), frequency *un-*

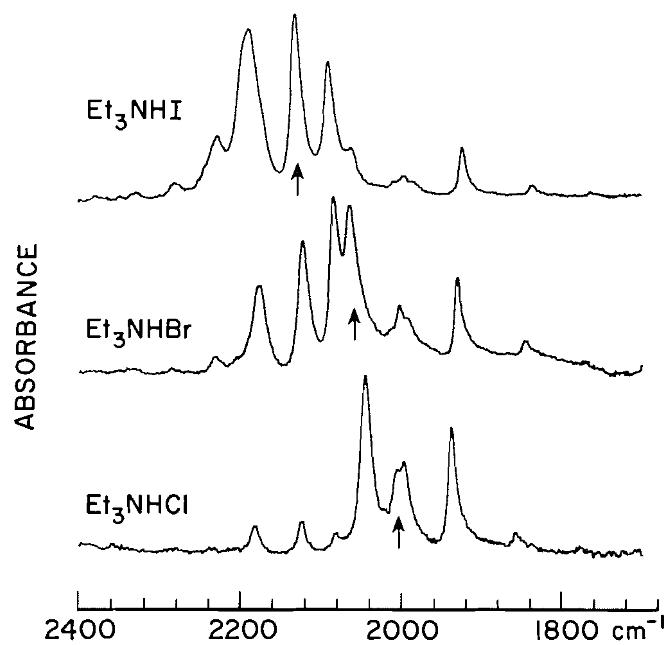

FIG. 6. Difference spectra of matched 0% D|5% D films of Et_3NHX at room temperature (solid films on CaF_2 plates). Absorbance scaled as in Fig. 4. Arrows represent centroids of the ND stretching absorptions.

perturbed by Fermi resonance and hence measures the relative strength of the N—H···X hydrogen bond in this isostructural series.

Sandorfy *et al.* (4, 5) consider Fermi resonance involving a single NH (or ND) fundamental as unlikely to give rise, alone, to an absorption as extensive as observed in the Et_3NHX spectra, although it may be operative close to the fundamental. However, the following observations support the view that Fermi resonance *is* the main cause of the complexity.

In the spectra of $(Me_3NH)_2SnX_6$ (X = Cl, Br) the fine structure of the absorption in the region of the NH and ND stretching fundamentals undergoes changes that may be described as temperature and anion tuning: when the fundamental moves away, as a result of change of temperature or change of the anion, from the nearby overtone and combination levels, the intensity of these levels decreases drastically (13). This is typical of Fermi resonance. In $(Me_3NH)_2SnX_6$ the hydrogen bonding is weak and the fine structure extends over only about 100 cm^{-1}. With increasing strength of the N—H···X bond the ir absorptions in the ν(NH) and ν(ND) regions become more intense and the extent of the fine structure increases (13). In Et_3NHX, where the hydrogen bonding is strong (see below), the fine structure extends over some 600 cm^{-1}. Temperature shifts are small compared with this wavenumber interval and temperature tuning is not appreciable, but anion shifts are large and anion tuning is clearly observed: as the centroid of the ν(NH) or ν(ND) absorption moves to higher frequencies in the series Cl—Br—I, the "corresponding" peaks in the low-frequency wing decrease in intensity, while those in the high-frequency wing increase in intensity (Figs. 4 and 6). These intensity changes are consistent with the participating overtone and combination levels borrowing much of their intensity from the fundamental by Fermi resonance, although it is not clear whether they also possess some inherent intensity independent of the resonance.

Hydrogen bonding and the frequency-distance correlation.

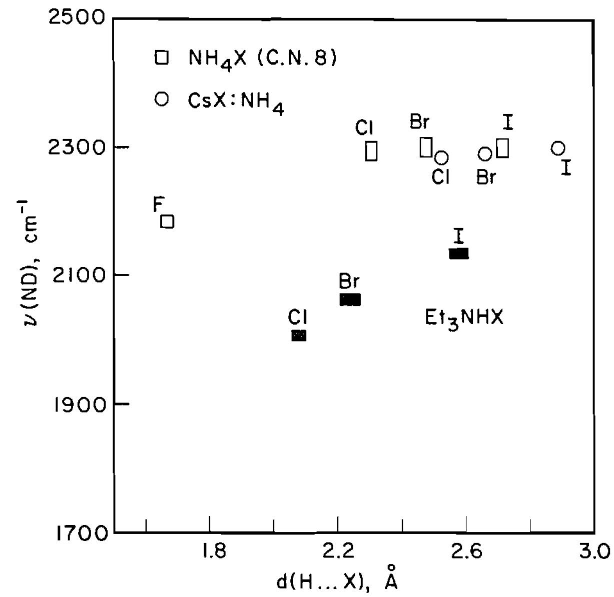

FIG. 7. Plot of the centroid frequency of the ND stretching absorption vs. $d(H\cdots X)$ in Et_3NHX at room temperature. NH_4X (X = F, Cl, Br, I) and $CsX:NH_4$ (X = Cl, Br, I) are included for comparison.

The quasi-normal distribution of intensity in the NH and ND stretching regions (Fig. 6) would seem to suggest that the effect of the perturbing factors will be the greatest near the unperturbed ν(NH) and ν(ND) frequencies. Hence whatever the real reasons for the complexity, the centroid cannot be far from the unperturbed frequency, and if Fermi resonance is *mainly* responsible, then the centroid is a sufficient approximation to the unperturbed ν(NH) and ν(ND).

The three points in the centroid frequency vs. $d(H\cdots X)$ plot (Fig. 7) lie on a curve of the expected curvature, viz. the frequency tends to level off with increasing $d(H\cdots X)$. Compared with the NH_4X halides and with NH_4^+ dispersed at low concentration in CsX matrices, the centroid ν(ND) frequencies are very low, in fact the lowest found for N—H···X (X = F, Cl, Br, I) to date. The centroid ν(ND) frequency in Et_3NHI is lower than the isotopically isolated ν(ND) frequency in NH_4F, which is the lowest such frequency in ammonium halides, simple or complex; the N—H···F bond in NH_4F is effectively linear and considered as strong. In contrast, in weakly deuterated $(Et_3NH)_2SnCl_6$ (12) the complex ν(ND) absorption centres at ~2320 cm^{-1}, and similar high values are observed in $(Et_3NH)PF_6$ and $(Et_3NH)BPh_4$ (unpublished results). An uncertainty of say 50 cm^{-1} in the Et_3NHX centroid ν(ND) frequency would not significantly affect the relative position of Et_3NHX in this set of compounds. It must be concluded that the N—H···X bonds in Et_3NHX are the strongest on record. If Et_3NHF isostructural with Et_3NHCl could be prepared, extrapolation in Fig. 7 would suggest that its unperturbed ν(ND) frequency would fall below 1900 cm^{-1}.

The absolute intensities of the ν(NH) absorptions could not be determined because of uncertain film thickness. However, the *ratios* of the integrated intensities of the NH and CH stretching absorptions in the 10 K spectra (computed on the not completely valid assumption that the 2850 cm^{-1} split corresponds to a clean separation of the two absorptions, see above) were found to increase from I to Cl. Since the intensity of the CH stretching absorption is not likely to change much from one halide to another, it is concluded that the NH absorption itself increases in this direction, consistent with the observed shifts to lower wavenumbers and with a strengthening of the hydrogen bond. The NH intensity changes from halide to halide are quite large and the trend is not affected by the uncertainties due to the NH/CH overlap.

Comparison of the NH absorptions of Et_3NHX in crystal and in solution

Odinokov *et al.* (28) in a recently published paper report the ir spectra of solutions of triethylammonium salts in $CHCl_3$.[5] These spectra, which presumably correspond to $Et_3NH^+|X^-$ ion pairs well separated by solvent molecules, invite comparison of the NH stretching fundamental in the solution spectra of the three halides (Fig. 1 and Table I of ref. 28) with that in the spectra of the corresponding crystals.

(*i*) The absorption in the NH stretching region in the solution spectra consists of broad and complex bands extending over the same spectral region as in the spectra of the corresponding crystals. This confirms that the absorbing entities in both cases are the same, viz. strongly hydrogen-bonded $Et_3NH^+|X^-$ ion pairs.

(*ii*) The component peaks in the solution spectra are broader and far less well resolved than in the crystal spectra. Such broadening is characteristic of the spectra of liquids compared with those of crystals.

(*iii*) The trends are the same for the solution spectra as for the crystal spectra: the centroids move to lower wavenumbers and relative intensities increase from I to Cl. This is consistent with the H···X bonds becoming stronger, in that order, in solution as well as in the crystal.

(*iv*) The NH stretching frequency centroids in the solution spectra are lower, relative to the crystal, by about 100 cm^{-1} for the chloride, ~75 cm^{-1} for the bromide, and ~40 cm^{-1} for the iodide. This implies that the hydrogen bonding in the $CHCl_3$ solution is considerably stronger. Presumably the ideal hydrogen-bonding situation is more nearly achieved in solution that in the crystal, where the dominant factor determining the shortest cation–anion distances (i.e. $N^+\cdots X^-$) is the electrostatic lattice energy rather than the hydrogen-bonding energy.

Acknowledgments

We thank Professor R. C. Lord for bringing to our attention his early results on Et_3NHX and for providing us with a copy of ref. 7. This work was supported by research grants from the Natural Sciences and Engineering Research Council of Canada to T.S.C. and O.K.

Appendix

Compensation for effect of Fermi resonance on observed vibrational frequencies

Often, as in the present work, it is useful to correct measured ir frequencies for the effects of Fermi resonance. In the following we prove a simple rule that is helpful for that purpose.

Fermi resonance causes important intensity transfers, as well as large frequency perturbations, among the transitions it affects. In the usual case, a single ir-active transition (commonly a fundamental) donates intensity, through the resonance interaction, to one or more nearby transitions (commonly overtones or combinations) that would otherwise be essentially forbidden. In this single-donor case the intensity transfer and the frequency perturbations turn out to be simply related, and it has been shown (29) how the unperturbed frequencies may be recovered from the observed frequencies and intensity ratio of a Fermi doublet. This rule has been expressed (13) in an especially convenient form: the observed centroid of the Fermi doublet coincides with the unperturbed frequency of the donor transition. *Ad hoc* extensions of the centroid rule to Fermi multiplets of order greater than two are found in numerous practical attempts (9–11, 27) to deduce an unperturbed donor frequency. To furnish a theoretical footing for these generalizations, we undertake to prove that, for a Fermi multiplet of *any* order, the centroid of the observed multiplet coincides with the unperturbed donor frequency. We retain the assumption of a single donor transition; indeed, the theorem fails otherwise.

According to "near-degenerate" perturbation theory (30) the perturbed wave functions and energy levels in an Nth-order resonance multiplet are governed (cf. ref. 31) by

$$[1] \qquad \begin{pmatrix} E_1^{(0)} & V_{12}\cdots V_{1N} \\ V_{21} & E_2^{(0)} \\ \cdot & \cdot \\ \cdot & \quad\cdot \\ \cdot & \qquad\cdot \\ V_{N1} & \qquad E_N^{(0)} \end{pmatrix} \begin{pmatrix} c_1^k \\ \cdot \\ \cdot \\ \cdot \\ \cdot \\ c_N^k \end{pmatrix} = E_k \begin{pmatrix} c_1^k \\ \cdot \\ \cdot \\ \cdot \\ \cdot \\ c_N^k \end{pmatrix}$$

$k = 1, \ldots, N$. Here $E_j^{(0)}$ is the energy of the jth unperturbed state $|j^{(0)}\rangle$; V_{ij} is the matrix element of the (anharmonic) perturbation V mixing $|i^{(0)}\rangle$ and $|j^{(0)}\rangle$; the eigenvalue E_k is the energy of the kth perturbed state $|k\rangle$; the c_i^k forming the kth eigencolumn represent the projections of $|k\rangle$ on the various $|i^{(0)}\rangle$, with the understanding that the c_i^k are normalized in the usual way so that

$$\sum_{i=1}^{N} c_i^{k*} c_i^k = 1$$

for each k. For brevity we rewrite eq. [1] as

$$[1'] \qquad \mathbf{H}\cdot\mathbf{c}^k = E_k\mathbf{c}^k$$

with the obvious definition of the variables. **H** is an Hermitian matrix if V is an Hermitian operator.

We suppose that $|m^{(0)}\rangle$ is the donor level. The matrix elements for the actual transitions may be written

$$\langle 0|\mathbf{p}|k\rangle = \sum_{i=1}^{N} c_i^k \langle 0|\mathbf{p}|i^{(0)}\rangle$$

where $\mathbf{p}$ is the dipole moment operator and $|0\rangle$ the ground state from which all the transitions are supposed to arise. Since it was assumed that, among the various transitions $0 \rightarrow i^{(0)}$ conceivable in the absence of resonance, only $0 \rightarrow m^{(0)}$ has intrinsic intensity, we have $\langle 0|\mathbf{p}|i^{(0)}\rangle = 0$ for $i \neq m$. Hence

$$\langle 0|\mathbf{p}|k\rangle = c_m^k \langle 0|\mathbf{p}|m^{(0)}\rangle$$

The observed intensities of the several $0 \rightarrow k$ are therefore, within a common multiple, just the respective values of $|c_m^k|^2$.

The centroid of the observed multiplet is given by the intensity-weighted average of the various transition energies $E_k - E_0$ from the ground state, namely

$$[2] \qquad \overline{\Delta E} = \sum_{k=1}^{N} |c_m^k|^2 (E_k - E_0) / \sum_{k=1}^{N} |c_m^k|^2$$

Since **H** is Hermitian it may be written in a "spectral representation" (32):

$$\mathbf{H} = \mathbf{U}\boldsymbol{\Lambda}\mathbf{U}^\dagger$$

where $\boldsymbol{\Lambda}$ is a diagonal matrix with the eigenvalues of **H** as diagonal elements, i.e. $\Lambda_{ij} = E_i\delta_{ij}$; **U** is the unitary matrix formed by the orthonormal eigencolumns of **H**, i.e. $U_{ij} = c_i^j$. Now

$$H_{ij} = \sum_k U_{ik}(\mathbf{\Lambda U}\dagger)_{kj} = \sum_k U_{ik} \sum_l \Lambda_{kl} U_{lj}\dagger$$
$$= \sum_k c_i^k \sum_l E_k \delta_{kl} c_j^{l*} = \sum_k E_k c_i^k c_j^{k*}$$

Since $H_{mm} = E_m^{(0)}$ by definition, it follows that

[3] $$E_m^{(0)} = \sum_k |c_m^k|^2 E_k$$

Further, since **U** is unitary, its rows as well as its columns are orthonormal:

$$(\mathbf{UU}\dagger)_{ij} = (\mathbf{UU}^{-1})_{ij} = \delta_{ij}$$

or $\sum_k c_i^k c_j^{k*} = \delta_{ij}$. For $i = j = m$ this gives

[4] $$\sum_k |c_m^k|^2 = 1$$

This incidentally shows that Fermi resonance preserves the original intrinsic intensity, merely redistributing it among the several $0 \rightarrow k$. Using eqs. [3] and [4] in eq. [2], we find $\overline{\Delta E} = E_m^{(0)} - E_0$. This establishes what we set out to prove, namely that the observed centroid of the multiplet coincides with the unperturbed frequency of $0 \rightarrow m^{(0)}$. A similar result has been derived previously (33) for Raman spectra perturbed by Fermi resonance.

Metal oxide coated p–n junction silicon electrodes for photoelectrochemical solar energy conversion

HIROSHI TSUBOMURA, YOSHIHIRO NAKATO, MASAHIRO HIRAMOTO, AND HIROYUKI YANO

Laboratory for Chemical Conversion of Solar Energy and Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka, 560 Japan

Received August 6, 1984

This paper is dedicated to Professor Camille Sandorfy on the occasion of his 65th birthday

HIROSHI TSUBOMURA, YOSHIHIRO NAKATO, MASAHIRO HIRAMOTO, and HIROYUKI YANO. Can. J. Chem. **63**, 1759 (1985).

Photoelectrochemical properties of p^+–n junction silicon electrodes, abbreviated as p^+n–Si, coated with thin oxide films of titanium, tungsten, or iron have been investigated in aqueous solutions of hydrogen iodide and iodine. The films were deposited by electron-beam evaporation of the metal oxide sinters. The photocurrent in a p^+n–Si electrode coated with TiO_2 increased dramatically when it was heated at temperatures higher than 500°C, though the O/Ti atomic ratio as determined by ESCA analysis was unchanged. The fill factor of the photovoltaic cell composed of this electrode, a platinum counter electrode and an aqueous solution of 7.6 *M* HI and 0.03 *M* I_2 was improved by coating with ruthenium or its oxide. The photovoltaic cell attained a high solar to electrical energy conversion efficiency of 9.3% (AM1), with an open circuit photovoltage of 0.58 V, a short circuit photocurrent of 26.6 mA cm^{-2} and a fill factor of 0.61. The photocurrent was stable for 350 h. For the cases of electrodes coated with a Fe_2O_3 or WO_3 film, high fill factors were obtained even without ruthenium coating. The effect of the nature of Si – metal oxide junctions, the donor density in the oxide, the relations between the flat band potential of the oxide and the redox potential of the solution, etc., on the conversion efficiency was discussed.

HIROSHI TSUBOMURA, YOSHIHIRO NAKATO, MASAHIRO HIRAMOTO et HIROYUKI YANO. Can. J. Chem. **63**, 1759 (1985).

Opérant dans des solutions aqueuses d'iodure d'hydrogène et d'iode, on a étudié les propriétés photoélectrochimiques d'électrodes de silicium, à jonction p^+–n représentées par p^+n–Si, recouvertes de minces couches d'oxydes de titane, de tungstène ou de fer. On a déposé les films en faisant appel à l'évaporation par faisceaux d'électrons de frittages d'oxydes de métaux. Le courant photoélectrique de l'électrode p^+n–Si sur laquelle on a déposé du TiO_2 augmente d'une façon dramatique lorsqu'on la chauffe à des températures supérieures à 500°C; on obtient ce résultat même si le rapport atomique de O/Ti, tel que déterminé par une analyse ESCA, demeure inchangé. Le facteur de remplissage de la cellule photovoltaïque composée de cette électrode, d'une contre-électrode de platine et d'une solution aqueuse 7,6 *M* en HI et 0,03 *M* en I_2 augmente si l'on y dépose du ruthénium ou son oxyde. On peut atteindre un haut degré (9,3% AM1) d'efficacité pour la conversion de l'énergie solaire en énergie électrique si l'on opère avec un photovoltage en circuit ouvert de 0,58 V, un photocourant de court circuit de 26,6 $mAcm^{-2}$ et un facteur de remplissage de 0,61. Le photocourant s'est avéré stable pour 350 h. Dans les cas des électrodes sur lesquelles on a déposé des films de Fe_2O_3 ou de WO_3, on a pu obtenir des facteurs de remplissage élevés sans même déposer du ruthénium. On discute de l'effet de la nature des jonctions Si – oxydes métalliques, de la densité des donneurs dans l'oxyde, des relations entre la bande de potentiel plane de l'oxyde et le potentiel redox de la solution, etc sur l'efficacité de la conversion.

[Traduit par le journal]

Introduction

Photoelectrochemical cells provided with semiconductor electrodes are the most promising tools for direct conversion of solar energy into chemical energy. For practical purposes, however, we must solve the problem of how to prevent the corrosion of semiconductor electrodes. We reported many years ago that semiconductor electrodes such as Si and GaP could be stabilized by coating with noble metals (1). The noble metal coating also displayed catalytic activity to enhance electrode reactions (2). Later, the stabilization effect by surface layers of noble metals (3, 4), metal oxides (5–15), metal silicides (16, 17), and organic materials (18–25) has been studied.

Recently, we reported that the decomposition of hydrogen iodide into hydrogen and iodine was achieved using a silicon single crystal electrode with a p^+–n junction inside (abbreviated as p^+n–Si) coated with platinum or its silicide, achieving an approximately 8% conversion efficiency and 4500 h stability (26–28). A similar efficiency has been obtained for hydrogen iodide decomposition using Pt-coated n^+p–Si electrodes (29).

Although these results are very encouraging, further improvements are desirable, because certain loss of the incident light energy is unavoidable by use of metal coatings. In this respect, we took up an approach to apply transparent metal oxide coatings. Although metal oxide coatings were studied by some workers, it appears that in many cases the mismatch in the electronic bands between the semiconductor and the oxide is troublesome. Bard and co-workers (6) studied the oxygen evolution reactions on Si, CdS, InP, etc., coated with TiO_2, and reported that the photocurrents arose only by the direct excitation of TiO_2. Tomkiewicz and Woodall (7) reported the similar results. Morisaki *et al.* (5) studied the oxygen evolving reaction on a pn–silicon electrode coated with TiO_2, and reported that the photocurrent was observed only when both Si and TiO_2 were simultaneously excited. Morisaki *et al.* (8, 9) and Nogami *et al.* (10) reported that the Si electrodes coated with iron oxide caused photocurrent by excitation of Si only. But the onset potential for it was close to that for the oxygen evolution on a platinum electrode. More recently, reports have been made for silicon electrodes with thin SiO_2 layers coated with conductive tin oxide or indium – tin oxide films (12–15), which gave fairly high photovoltages due to the MIS type junctions.

In this paper, we will report on the p^+n–Si electrodes coated with metal oxide films in aqueous solutions of hydrogen iodide and iodine. It has been found that these electrodes successfully undergo photoelectrolysis with the excitation of silicon.

Experimental

The p^+n–Si wafers prepared by ion implantation of boron on the (100) surface of n-type Si wafers were provided by Mitsubishi Electric Corp. The p-layer is ca. 0.9 μm thick, with a high boron concentration of 2×10^{20} cm^{-3}, and has a metallic conductivity.

The p^+n–Si wafers were etched in 46% hydrogen fluoride solutions for 2 min, promptly evacuated and metal oxide films were deposited on the p^+ surface by electron beam evaporation of sintered discs of TiO_2, or TiO_2 containing 6 wt.% Nb_2O_5, or pressed discs of iron oxide or tungsten oxide. The average thicknesses of the metal oxide films, monitored with a quartz vibrator, were from 3 to 20 nm, the deposition speed being 0.01, 0.05, and 0.003 nm s^{-1}, respectively, for TiO_2, WO_3, and Fe_2O_3. The temperature of the substrate, monitored with a chromel–alumel thermocouple, reached 80°C during the deposition. In some cases, the substrate was heated to a temperature of 350 to 450°C during the deposition. After the deposition, the wafers were in most cases heated at 400 to 600°C for 1 h under vacuum using a radiation heater, and were left in the vacuum till they cooled down to 100°C. Ruthenium oxide or ruthenium was attached either by electron beam evaporation of ruthenium dioxide, or by spraying a 2-propanol solution of ruthenium trichloride on the sample placed on a hot plate of 100°C, followed by heating under vacuum.

ESCA analysis (Electron Spectroscopy for Chemical Analysis) was performed using a Shimadzu ESCA 750 instrument. The surface atomic composition was determined from the area under the ESCA peaks, corrected for the ionization cross sections. The depth profiles of the atomic compositions were obtained by combining the ESCA analysis with 2 keV argon ion beam sputtering, the rate of sputter being estimated to be 0.04 nm s^{-1} for Si and 0.03 nm s^{-1} for TiO_2.

The electrodes were prepared by applying indium–gallium alloy on the back side of the wafer for ohmic contact. In some cases, the potentials of the p^+–Si surface and the TiO_2 layer were measured, by making ohmic contact with indium–gallium alloy for the former, and with a vacuum evaporated indium for the latter. A tungsten–halogen lamp or a Wacom solar simulater (AM1, 100 mW cm^{-2}) was used as the light source. The long term stability tests were carried out by cooling the electrochemical cells with circulating water. A saturated calomel electrode (SCE) was used as the reference electrode.

Results

Typical current density (j) – potential (U) curves for the p^+n–Si photoanodes coated with 20 nm thick TiO_2 in a solution of HI/I_2 are shown in Fig. 1. The TiO_2 film contains a small amount of Nb oxide. Only weak photocurrent flowed even under strongly positive potential region in the electrode coated with TiO_2 under 1×10^{-6} Torr (curve a), and the coated film peeled off partly during the measurement. When the TiO_2 coated electrode was heat-treated under 1.0×10^{-6} Torr at 500°C for 1 h, the photocurrent dramatically increased as shown by curve b. The onset potential also shifted extensively, to 0.45 V more negative than the redox potential of the I_3^-/I^- couple, $E(I_3^-/I^-)$. The heat treatment at 500 and 600°C was effective, but ineffective at 400°C. Curve c is for the case where TiO_2 was deposited under 1.0×10^{-6} Torr with the silicon substrate heated at 350°C, followed by the same heat treatment as for curve b. The onset potential of the photocurrent in this case was shifted more to the negative. When the electrode, prepared in the same way as for the case of curve a, was coated with ruthenium by applying a 2-propanol solution of $RuCl_3$ and heating at 500°C under 1.0×10^{-6} Torr for 1 h, the fill factor was further improved (curve d). The similar result was obtained when RuO_2 was electron beam evaporated.

The similar results as mentioned above were obtained for TiO_2 films without containing Nb oxide, though the fill factor was a little smaller. Little photocurrent was obtained for electrodes coated with TiO_2 thinner than 5 nm.

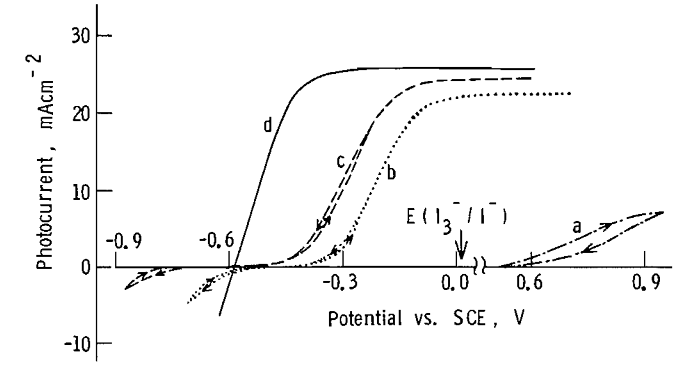

FIG. 1. Photocurrent (j) – potential (U) curves of TiO_2-coated p^+n–Si electrodes in a stirred solution of 7.6 M HI and 0.03 M I_2, illuminated with a Wacom solar simulator.

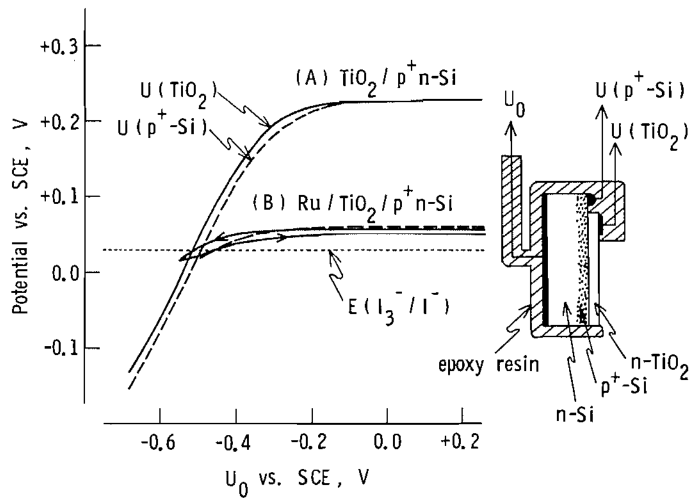

FIG. 2. Potential of the p^+–Si layer, $U(p^+{-}Si)$, and that of the TiO_2 film, $U(TiO_2)$, against the potential of the silicon electrode, U_0, controlled by a potentiostat in a stirred solution of 7.6 M HI and 0.05 M I_2. (A) is for a TiO_2-covered electrode and (B) is for a Ru-TiO_2-covered electrode. They are prepared in the same way as for the electrodes used for measurements of curves c and d in Fig. 1.

The result that the fill factor of the electrode coated with TiO_2 was greatly improved by a small amount of RuO_2 or Ru (Fig. 1, b and d) means that there is a high resistance at the interface between the TiO_2 film and the solution. The electrode coated with TiO_2 and RuO_2 (or Ru) gave a j–U curve nearly as good as that for a Pt coated p^+n–Si electrode (27). This implies that the p^+–Si layer and the TiO_2 film are in ohmic contact. These were confirmed by the measurements of the potential of the p^+–Si layer, that of the TiO_2 layer, and that of the electrode (Fig. 2). As shown in the figure, $U(TiO_2)$ and $U(p^+{-}Si)$ are close to each other at any of the U_0 value, irrespective of whether the electrode has Ru or not. The difference between $U(TiO_2)$ and $E(I_3^-/I^-)$ corresponds to an overvoltage at the working state of the electrode. It is very small (ca. 0.02 V) in the case where ruthenium is applied on the surface of the electrode. Without ruthenium, it increases with U_0 and reaches a constant value of 0.2 V, where the photocurrent becomes light intensity limited.

Figure 3 shows a result of ESCA analysis of a p^+n–Si surface covered with 20 nm TiO_2 and a small amount of RuO_2 and vacuum heated at 500°C for 1 h. The ratio of oxygen vs. titanium is a little higher than two in the region of the Ar^+ ion

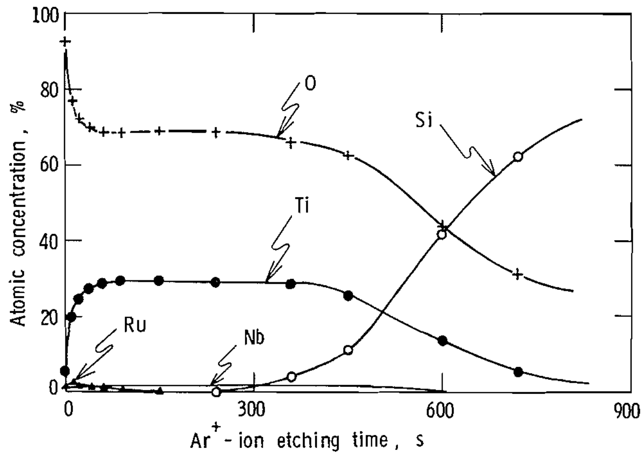

FIG. 3. Relative atomic concentrations as a function of Ar ion etching time, i.e., depth profile, of the $p^{+}n-Si$ surface covered with 20 nm TiO_2 and RuO_2, and heated at 500°C for 1 h under vacuum.

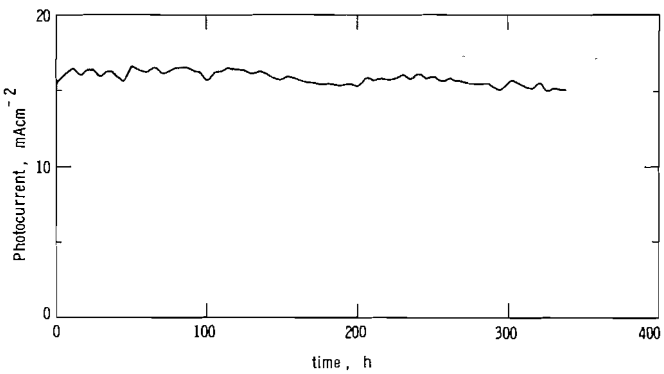

FIG. 4. A stability test for a $p^{+}n-Si$ electrode coated with TiO_2 and Ru, illuminated with a tungsten–halogen lamp. The small oscillatory change is probably due to light intensity fluctuation.

etching time from 60 to 400 s. This is considered to indicate that TiO_2 was formed by the electron beam evaporation of TiO_2, if the unavoidable oxygen contamination is taken into account. The atomic profile was almost unchanged by the heat treatment. In the case where $RuCl_3$ solution was applied and the wafer vacuum heated, the Ru concentration at the surface was almost equal to that of Ti and decreased toward the interior. The oxygen concentration at the surface was much lower than that expected from RuO_2 formed on TiO_2, suggesting that Ru is present almost in the form of metal in this case.

The best data were obtained from an electrode which was covered with a TiO_2 layer 20 nm thick treated with a $RuCl_3$ solution and heated at 500°C under 1.0×10^{-6} Torr for 1 h. The photocell composed of this electrode, a platinum counter-electrode and a solution of 7.6 *M* HI and 0.03 *M* I_2 showed an open circuit photovoltage of 0.58 V, a short-circuit photocurrent of 26.6 mA cm^{-2}, a fill factor of 0.61, and an energy conversion efficiency of 9.3% under AM1 radiation. This is nearly the same as the best value obtained by us with a platinum-covered $p^{+}n-Si$ electrode (27).

The long-term stability of the above cell was tested with the Si and Pt electrodes connected through a 200Ω resistance. This load resistance was used because it gave a potential difference of the maximum power point. The photocurrent, 16 mA cm^{-2}, was quite stable for 350 h (Fig. 4). The $j-U$ curve measured after the test agreed completely with that of the initial. The depth profile of the electrode did not change either.

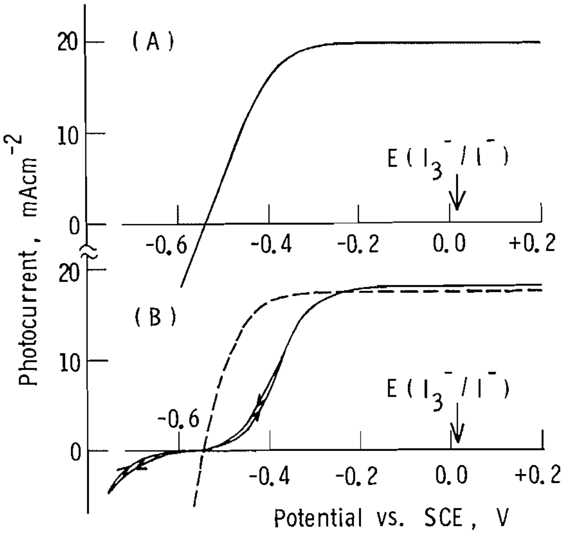

FIG. 5. Photocurrent–potential curves of $p^{+}n-Si$ electrodes under illumination with a Wacom solar simulator in a stirred solution of 7.6 *M* HI and 0.03 *M* I_2. (*A*) is for an electrode coated with iron oxide and (*B*) is for an electrode coated with tungsten oxide. For details see text.

In Fig. 5 are given the results for coatings of diiron trioxide and tungsten trioxide. The solid line in Fig. 5*A* shows the $j-U$ curve for an electrode on which iron oxide, 20 nm thick, was evaporated under 1.0×10^{-5} Torr and vacuum heated at 500°C under 1.0×10^{-6} Torr for 1 h. The solid lines in Fig. 5*B* are for the electrode on which 20 nm tungsten oxide was deposited under 1.0×10^{-4} Torr while the Si substrate was heated at 450°C, and heat-treated under 1.5×10^{-4} Torr at 450°C for 1 h. For these cases also, the heat treatment after the vacuum deposition was effective for obtaining good electrode characteristics. In the case of tungsten oxide, the fill factor was much improved when the electrode was kept under −5.0 V vs. SCE for 10 min in an HI/I_2 solution (broken lines in Fig. 5*B*). In both cases of iron and tungsten oxides, the onset potentials are deeply negative and the fill factors are pretty high, comparable to those for electrodes coated with TiO_2 and Ru (Fig. 1, curve *d*). It is worthwhile to note that high fill factors are obtained in these cases even without Ru coatings.

Discussion

As described in the previous section, the $p^{+}n-Si$ electrode coated with TiO_2 and not heat-treated causes weak photocurrent, and the TiO_2 film is liable to be removed. But the photocurrent is very much enhanced and the film becomes stable by heating under vacuum. Kaito *et al.* (30) reported on the basis of transmission electron microscopy that the TiO_2 film formed by deposition at room temperature was amorphous and it became crystalline by heating in air at 450 to 500°C for several hours. Their results seem to explain the stabilization in our case. In addition, as we heated the sample under vacuum, the film might have been reduced to some extent, yielding oxygen vacancies which make the film conductive, though this was not confirmed by our ESCA analysis because the change in the oxygen concentration was too small.

The overall process of the photoreactions in the electrode is explained by the energy diagram shown in Fig. 6. From the known band positions of TiO_2 and Si, the conduction band of the former is estimated to be considerably higher than the valence band of the latter. Therefore, when the two are in contact, an energy barrier should be formed at the interface.

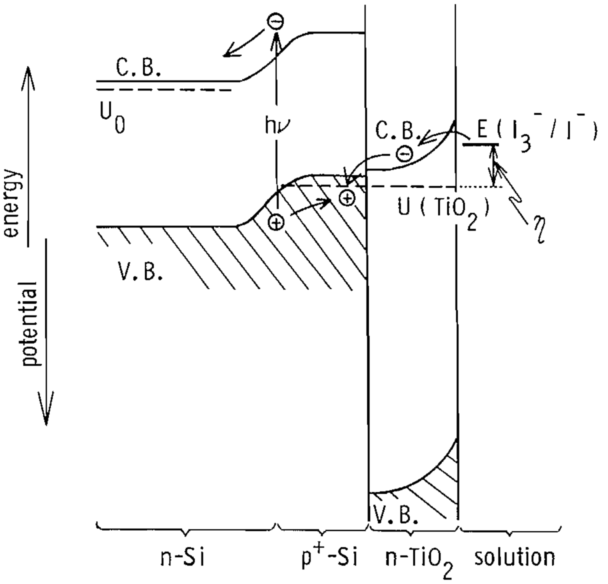

FIG. 6. An energy level diagram for the p^+n–Si electrode coated with TiO_2 in a HI/I_2 solution under illumination. η denotes the overpotential, C.B. the conduction band, and V.B. the valence band.

The results in Figs. 1 and 2 show, however, that the contact is ohmic. This can be explained by assuming that a reaction of the type, $TiO_2 + Si \rightarrow TiO_{2-x} + SiO_x$, occurs during the TiO_2 deposition and the heat treatment after that, forming interfacial TiO_2 having many O vacancies which warrants an ohmic contact between the TiO_2 film and the highly doped silicon. This assumption is supported by our ESCA analysis, which showed that a weak Si2*p* peak corresponding to Si oxide is present at the TiO_2–Si interface after the TiO_2 deposition, slightly growing by the heat treatment.

As the flat-band potential of *n*-TiO_2 is ca. 0.3 V more negative than the redox potential of the I_3^-/I^- couple, a Schottky barrier should be formed at the interface between TiO_2 and the solution, as shown in Fig. 6. Without RuO_2 or Ru, the fill factor of the j–U curve was small (Fig. 1), indicating that the electron transfer reaction from iodide in the solution to TiO_2 is slow, in harmony with the above supposition. The great decrease of the overpotential caused by applying RuO_2 or Ru can be explained by the disappearance of the barrier probably because the metallic RuO_2 or Ru makes ohmic contact with TiO_2. Another factor is that the Ru species works as a good catalyst for the electron transfer reaction.

It was reported in the previous section that a high fill factor was obtained for the case where Fe_2O_3 or WO_3 was coated. The flat band potentials of these oxides are either nearly the same as or more positive than the redox potential of the I_3^-/I^- couple, and hence no barrier should be formed at the interface between the oxides and the solution. In these cases an ohmic contact is expected to form, in agreement with the experimental results. That the short circuit photocurrents for these oxides were somewhat smaller than those for TiO_2 can be explained by assuming that these oxide films are more liable to be reduced and the reduced films absorb near-infrared part of the radiation. It was confirmed that these oxides absorb in the near-infrared region when they are reduced.

In conclusion, the silicon electrodes coated with metal oxides show high efficiencies and are promising for the chemical conversion of solar energy, in that they have high transparency and stability. It has been clarified in the present paper that the degree of crystallinity, that of reduction of the oxide, i.e., the donor density, and the relationship between the flat band potential of the oxide and the redox potential of the solution are the important factors in determining the performance of the photoelectrochemical cells.

This paper is dedicated to Professor Camille Sandorfy on the occasion of his 65th birthday

W. DANIEL EDWARDS, and MICHAEL C. ZERNER. Can. J. Chem. **63**, 1763 (1985).

A theoretical study is made of the electronic spectra of Mg(II), Zn(II), and Co(III) porphine and their π cations using the INDO/S-CI spectroscopic model. The calculated electronic spectra for the neutral compounds compare well with experiment. The two low-lying π cations, one of $^2A_{1u}$ and one of $^2A_{2u}$ symmetry are both examined for each of these systems. The $^2A_{1u}$ cations are calculated to lie lower in energy than the $^2A_{2u}$ cations by only 4 kcal/mol, consistent with the findings that both ions are found depending on substituents and solvent.

The visible region of the spectrum of the $^2A_{1u}$ species is predicted to consist of three separate bands decreasing in intensity with increasing energy, while that of the $^2A_{2u}$ species is calculated to consist of three allowed transitions of near equal intensity, in agreement with experimental findings. In general the Soret region of the $^2A_{1u}$ ions is dominated by one transition, while at least three strong bands are calculated in the Soret region for the $^2A_{2u}$ ions, again in reasonable accord with experiment. Charges, ionization energies, and spin densities are reported and discussed for all compounds.

W. DANIEL EDWARDS et MICHAEL C. ZERNER. Can. J. Chem. **63**, 1763 (1985).

Faisant appel au modèle spectroscopique INDO/S-IC, on a effectué une étude théorique des spectres électroniques des sels de Mg(II), de Zn(II) et de Co(III) des porphines et de leurs cations pi. Les spectres électroniques calculés pour les composés neutres se comparent bien avec les résultats expérimentaux. Pour chacun de ces systèmes, on a examiné les deux cations pi de faible valence: l'un de symétrie $^2A_{1u}$ et l'autre de symétrie $^2A_{2u}$. On a calculé que l'énergie des cations $^2A_{1u}$ est plus faible que celle des cations $^2A_{2u}$, que la différence entre les deux états n'est que 4 kcal/mol et que ceci est en accord avec le fait observé que les deux ions dépendent des substituants et du solvant.

On prédit que la région visible du spectre des espèces $^2A_{1u}$ consistera en trois bandes séparées dont l'intensité décroît lorsque l'énergie croît; par ailleurs, on calcule que le spectre des espèces $^2A_{2u}$ consistera en trois transitions permises d'intensités à peu près égale et ceci est en accord avec les faits expérimentaux. En général, une transition domine la région Soret des ions $^2A_{1u}$; par ailleurs, on calcule qu'il existera au moins trois bandes fortes dans la région Soret des ions $^2A_{2u}$ et encore une fois ces prédictions sont en accord avec les faits expérimentaux. Pour chacun des composés, on rapporte les charges, les énergies d'ionisation et les densités de spin pour tous les composés et on en discute.

I. Introduction

Based on the calculated electronic structure of magnesium porphine, we have proposed a possible mechanism for the initial photochemical event occurring in photosynthesis. This mechanism is outlined in Paper I (1). In a subsequent paper (2) we calculated the electronic structure of magnesium pheoporphine — a closer analogue of chlorophyll — and found qualitatively the same features.

However, independent of the exact nature of the initial photochemical event, all photosynthesis models predict the formation of reduced acceptor molecules and oxidized chlorophyll molecules. It is therefore clear that the nature of chlorophyll cations will play an important role in understanding photosynthesis. In this paper we present some preliminary work on the electronic structure of Co(III), Zn(II), and Mg(II) porphine, Fig. 1.

One of the earliest and most successful models for explaining the electronic spectra of metallo porphines is the 4-orbital model proposed by Gouterman (3). In this picture, only the two highest occupied and two lowest unoccupied orbitals are considered, Fig. 2. In D_{4h} symmetry, the Lowest Unoccupied Molecular Orbitals (LUMOs) are degenerate and of $e_g(\pi)$ symmetry. The Highest Occupied Molecular Orbitals (HOMOs) are of $a_{1u}(\pi)$ and $a_{2u}(\pi)$ symmetry, respectively. Since the a_{1u} and a_{2u} orbitals lie near in energy, electronic transitions from HOMOs to LUMOs would also lie very close in energy and would be expected to interact strongly. This configuration interaction would raise the energy of one transition and lower the energy of the other. The oscillator strengths for these two transitions should reinforce each other for the higher energy transition and cancel each other for the lower. This would give rise to a weakly allowed transition in the visible and an intense transition in the uv. This is the pattern seen in nearly all metalloporphyrins and is verified in nearly all calculations.

It is clear from this picture that there should be two low energy cations of metalloporphines, one of $^2A_{1u}$ symmetry and one of $^2A_{2u}$ symmetry. (In certain metalloporphine systems, removal of an electron from a transition metal d orbital is also low lying.) The nature of these π cations in chlorophyll and in many related systems has been widely studied and characterized through their optical spectra (4−11) and magnetic resonance spectra (5, 6, 11−19).

It is the purpose of this paper to examine the electronic properties of metalloporphine cations. The Co(III) system is included since two different, well-characterized spectra exist for the cation that correspond to the $^2A_{1u}$ and $^2A_{2u}$ π cations (21−23). Zn porphine is examined as a simple, relatively stable system (experimentally) with an obvious relationship to Mg porphine. Finally Mg porphine is examined. All of these systems have at least C_{4v} symmetry, and this high symmetry is used to aid in these calculations. Closer analogues of chlorophyll such as the Mg pheoporphine of our earlier studies (1, 2) are considerably more difficult to calculate accurately due to their lack of symmetry and will be considered in a subsequent

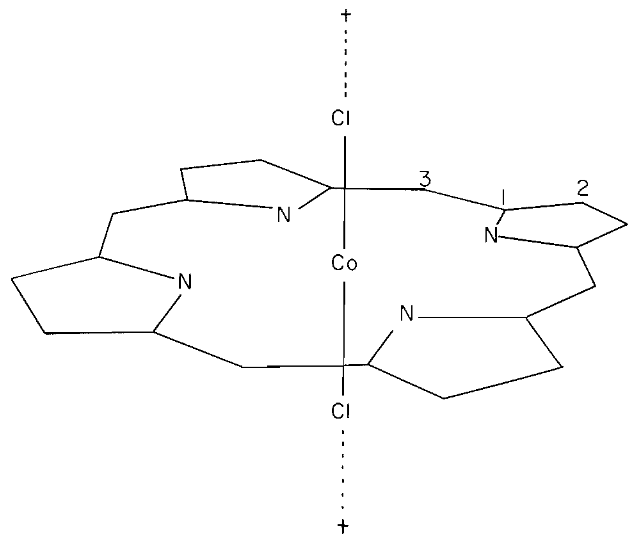

FIG. 1. The model and numbering for the compounds of this study. Shown is the $[Co(III)\ porphine]^{2+}$ π cation with 2 chlorine atoms 2.25 Å above and below the porphine plane and two positive point charges 2.25 Å from the chlorine atoms. For MgP and MgP^+ π cations the Mg is 0.40 Å above the porphin plane.

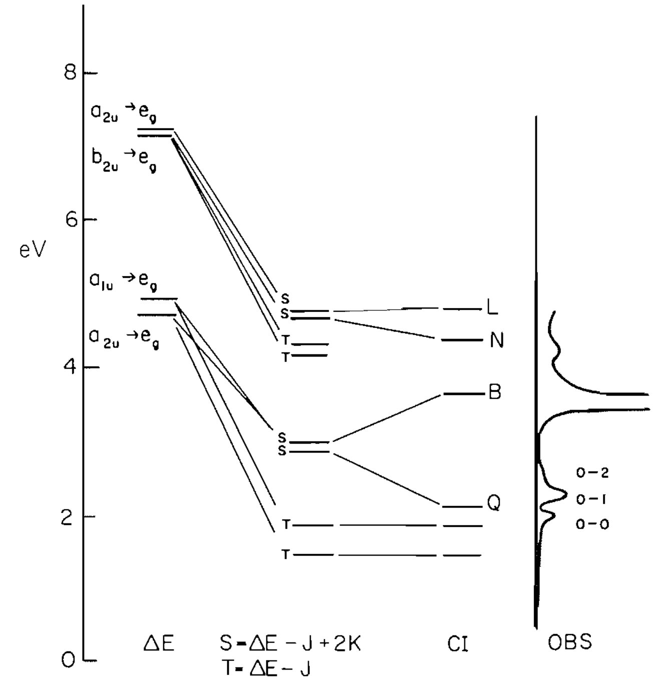

FIG. 2. The "four orbital model" consists of the configurational mixing of the two lowest singlet(s) states giving rise to the weakly allowed Q band and the strongly allowed B (Soret) band. As indicated in the synthesized spectrum, vibrational structure is often observed for the Q band.

work.

Previous calculations of the cation radicals of ethylchlorophyllide a and ethyl bacteriochlorophyllide a have been performed by Petke, Maggiora, Shipman, and Christoffersen (20) using an *ab initio* technique and, where appropriate, we will compare their results with those reported here. Earlier calculations of the Pariser–Parr–Pople π electron type were performed on "metal-like" porphine cations by Fajer, Borg, Forman, Dolphin, and Felton in which the potential importance of these π radical species in photosynthesis was stressed (24).

II. Methods

The calculations performed are of the INDO/S type, followed by configuration interaction (CI) (25, 26). The open shell systems are calculated using a restricted Hartree–Fock method (27), followed by a CI generated using Rumer diagram techniques (28, 29). Transition moments are calculated using the dipole length operator and keeping all one center terms.

The molecules of this study have either C_{2v} or D_{2h} Abelian subgroup symmetry, and this information is used to ease the CI calculation. After initial investigation with larger CI expansions, it was found that the calculated transitions in the visible and near uv region are reproduced with only about 400 configurations (100 for each of the four irreducible representations in C_{2v}) and about 200 for the open shell calculation. In both sets of calculations only single excitations are included in the CI. Higher excitations do affect the Soret region by depressing the calculated energies, bringing the predicted transitions in closer accord to that observed, but the general features of the Soret region are not changed. In these calculations, the higher energy transitions (N, L, M) do require the higher excitations in the CI for a good description of the transition energies and a more proper description of the states involved.

With these simplifications each of the closed shell calculations take about 18 min and each of the open shell calculations 90 min on the VAX 11/780 computer.

Geometries were based on symmetrized X-ray structures (30). For Co(III)P the Co—N bond length was set to 1.976 Å (31). For Zn(II)P the Zn—N bond length was fixed at 2.042 Å and both a planar structure (32) and a non-planar structure with the Zn atom placed 0.37 Å above the porphine plane (33, 34) were examined. For the Mg(II)P calculations the symmetrized structure with a Mg—N bond length of 2.092 Å was used (35); the Mg atom was placed 0.40 Å out of the porphine plane as suggested by the crystal structure of chlorophyll a (38).

III. Spectrum of closed shell metalloporphines

The electronic spectra of Zn(II), Mg(II), and Co(III) porphine have been calculated and are compared to experimental spectra in Tables 1, 2, and 3. It is clear from these tables that the Spectroscopic INDO method used is capable of accurately predicting transitions in the visible. For all three molecules, the lowest allowed transition is calculated within a few hundred wavenumbers of the experimentally observed band. Transitions which fall in the uv are not calculated as well and the average error for the Soret band is of the order of 5 000 cm^{-1}. In these calculations the four orbital model is an accurate description for these compounds since in the CI wavefunction, greater than 97% of the visible band and 91% of the Soret (B) band are constructed from these four excitations. The inclusion of higher excitations in the CI as mentioned in Section II has been shown to affect the Soret prediction (37–41) and is the principle reason for the high energy prediction of bands in the uv using the truncated CI of this study. These results are similar in accuracy to those we obtained in the study of Mg pheoporphine (2) where the energies and relative intensities of the Q_x and Q_y bands are accurately reproduced and the Soret band is calculated some 5000 cm^{-1} higher than their observed values.

Table 1 compares the calculated spectrum of both planar and non-planar Zn(II)P structures with those observed for Zn(II) octaethyl porphyrin (ZnOEP) (41). Very little difference is

[c]Only those transitions with calculated oscillator strengths are reported for transition above 31 300 cm^{-1}.

noted in the predicted Q or B bands. The porphine to Zn charge transfer bonds, designated $^1A_{1u}(\pi\rightarrow s)$ and $^1A_{2u}(\pi\rightarrow s)$ in D_{4h}, in contrast, are sensitive to this out-of-plane coordinate; these transitions decrease in energy with increasing Zn to porphine-plane distance (2). Above 35 000 cm^{-1} there are a great many transitions calculated and only the more intense are reported in the table. The N and L bands, both of ^1E_u symmetry, receive most of their intensity from a mixing between $b_{2u}(\pi)\rightarrow e_g(\pi^*)$ and $a_{2u}'(\pi)\rightarrow e_g(\pi^*)$, where the $a_{2u}'(\pi)$ is the second MO of that symmetry down in energy from the HOMO, see Fig. 1. As with the Soret band these states are also predicted to mix with double excitations not included here. The calculated energy is depressed to a value in better accord with experiment. The total oscillator strengths in the N and L region remain much the same after this mixing, but the intensity is spread over several near lying states. Of some interest is the $^1E_g(\sigma-\pi^*)$ excitation predicted at about 39 000 cm^{-1} in both calculations that arises from the promotion of an electron in an MO of $b_{1g}(\sigma)$ symmetry (71% nitrogen lone pair) to the LUMO $e_g(\pi^*)$. Although forbidden in the planar structure, in the non-planar structure, this excitation is of the same symmetry as the near-lying N and L (^1E) and picks up considerable intensity from them.

TABLE 4. The calculated spectra of the $^2A_{1u}$ and $^2A_{2u}$ Zn porphine cations, in 1 000 cm^{-1}; the $^1A_{1g}$ geometry of the neutral species is used for both cations

[a]Only states with calculated oscillators strength of greater than 0.01 are given if they lie above 15 000 cm^{-1}.
[b]From ref. 21, ZnTPP$^+$ClO$_4^-$: see also ref. 18.

Although INDO calculations have known deficiencies in the calculation of molecular geometries, a fully optimized calculation on Zn(II)P places the Zn atom 0.13 Å above the mean porphine plane and suggests a very flat potential around this minimum for Zn out-of-plane motion.

The calculated spectrum of Mg(II)P is reported in Table 2 and has much the same appearance as that of the non-planar Zn(II)P of Table 1. The $^1A_{1u}(a_{1u} \rightarrow \mathrm{M})$ is calculated to lie below the Soret band in the Mg complex, which may have significance in photosynthesis (2). We assign three separate allowed transitions to the N band region as suggested in Table 2 (but only two for the ZnP case, Table 1). The calculations of Christoffersen (39) find two states of ^1E symmetry with a very similar intensity pattern in this region.

In the Co(III) porphine calculation, the position of two Cl atoms 2.25 Å above and below the porphine plane, Fig. 1, determine the position of the $d_\pi \rightarrow d_{z^2}$ and $d_{xy} \rightarrow d_{z^2}$ Laporte transitions. The lowest of these is predicted at 12 400 cm^{-1}. The same is true of the two low-lying charge transfer excitations predicted at 14 400 cm^{-1} and 16 100 cm^{-1}. The position of the metal $d_{x^2-y^2}$ orbital, however, is less sensitive to those fifth and sixth position ligands, providing the metal atom remains in the mean plane of the four nitrogen atoms, and should be calculated reasonably well for an aqueous environment. The charge transfer excitations $^1B_{1u}(a_{1u}(\pi) \rightarrow d_{x^2-y^2})$ and $^1B_{2u}(a_{2u}(\pi) \rightarrow d_{x^2-y^2})$, however, have no intensity of their own and are calculated to lie near the intense Soret band. Similarly the $^1E_g(d_\pi \rightarrow d_{x^2-y^2})$ and $^1A_{2g}(d_{xy} \rightarrow d_{x^2-y^2})$ Laporte transitions are calculated to lie in a region of allowed $\pi-\pi^*$ transitions and therefore might not be observed.

IV. Spectrum of Zn porphine cations

The calculation of the spectrum of doublet ions is a more difficult task. For such molecules, an open shell ground state SCF calculation is performed and an open shell CI done on these states. Since there are two near-lying doublet states, both states must be calculated and comparable CI calculations done on each. The results for $^2A_{1u}$ and $^2A_{2u}$ Zn(II)P$^+$ are presented in Table 4 as are the results from experiment (21). Again a planar and a non-planar structure are reported. Due to the large number of calculated lines, it is difficult to decide on the basis of transition energies alone which species is experimentally found. However, by examining the oscillator strengths, it is possible to deduce that the experimentally observed spectrum comes from the $^2A_{2u}$ ground state. (Note that above 15 000 cm^{-1}, only those bands with non-zero oscillator strengths are reported.) This supports the conclusions reached by Browett and Stillman on the basis of MCD experiments (21) and Dolphin *et al.* on the basis of the uv and esr spectra (23).

It should be noted that these calculations predict the $^2A_{1u}$ state to be lower in energy, both at the SCF and at the CI level and both for the planar and non-planar structures. From the spectra of the Co(III) porphine cations discussed below, it is known that the two states must lie so close in energy that very weak perturbations and even solvent affects can reverse them.

V. The spectrum of cobalt (III) porphine cations

The electronic spectra of Co(III) porphine and Co(III) porphine cations have been experimentally measured (21–23) and are reproduced in Fig. 3 (43). Based on features in the spectrum and on the MCD results, it is concluded that the spectra of most metalloporphine cations arise from excitations from the $^2A_{2u}$ ground state. However, for the Co(III) OEP porphine cations, the ground state symmetry apparently depends on the nature of the counter ion. If the counter ions are perchlorate, the spectrum shows a typical $^2A_{2u}$ absorption spectrum. If the perchlorate ions are replaced by bromide ions, the spectrum changes dramatically and is best rationalized by assuming that the spectrum arises from an $^2A_{1u}$ ground state cation.

The results of our calculations on Co(III) porphine ions are presented in Table 5. For these calculations (as well as for the closed shell Co(III) porphine) the fifth and sixth position ligands were replaced by chloride ions at a distance of 2.25 Å. In order to maintain an appropriate charge on these chloride ions, positive point charges were also added at a distance of 2.25 Å from each of the chloride ions. These point charges also served to improve the self consistent field convergence properties of the calculations. The results in Table 5 are similar to those obtained for the Zn(II)P$^+$ cases. The $^2A_{1u}$ calculated spectrum shows a single strong peak at 15 000 cm^{-1} followed by a few weaker peaks at higher energy. The $^2A_{2u}$ calculated spectrum shows a series of peaks starting at 15 000 cm^{-1} and increasing in intensity through the visible. The experimental spectra show similar trends. The bromide shows a moderately strong peak at 15 000 cm^{-1}, followed by two weaker peaks at higher energy. These form a broad envelope of decreasing intensity. The perchlorate on the other hand shows a broad envelope of increasing intensity starting at 15 000 cm^{-1}. At higher energy, the bromide shows three intense peaks between 24 000 and 35 000 cm^{-1}, while the perchlorate shows one

TABLE 5. The calculated spectra of the $^2A_{1u}$ and $^2A_{2u}$ [Co(III) porphine]$^{2+}$ complex in 1 000 cm^{-1}; the neutral $^1A_{1g}$ geometry is assumed for both calculations; the oscillator strengths are given in parentheses

[a]From ref. 43.
[b]Only allowed bands above this value are given.

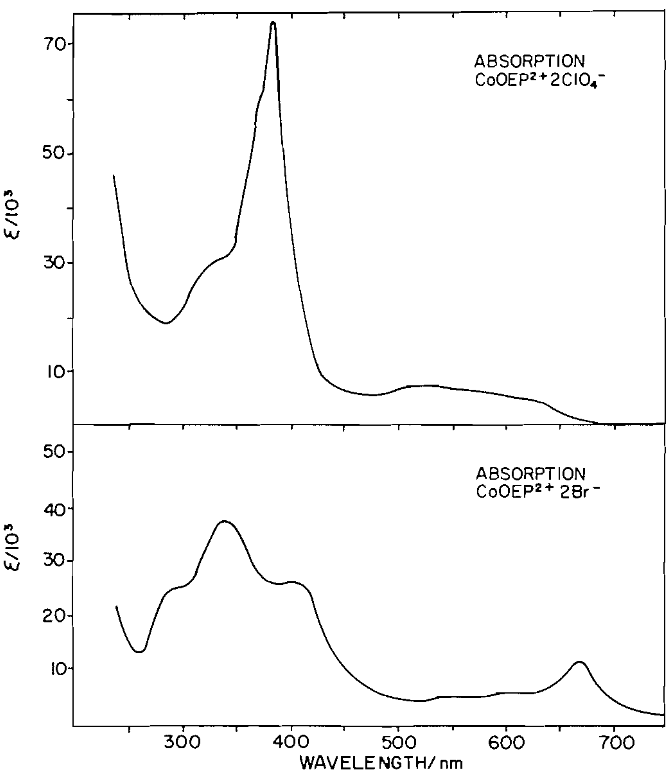

FIG. 3. The observed spectra of two Co(III)$^{2+}$ octaethylporphyin π cations, ref. 43. The only chemical difference is the counterion.

intense peak at 25 000 cm^{-1} and two weaker shoulders at higher energy. The calculated spectra reproduce these features. The $^2A_{1u}$ spectrum is calculated to have three intense peaks, but suggests the first of these is the most intense. Experimentally, the second peak appears most intense, but the experimental asymmetry of the first peak makes this uncertain. The transition energies for the Soret region bands are again calculated to be too high by approximately 6 000 cm^{-1}.

Figure 4 shows pictorially the molecular orbital energies that we obtain for $^1A_{1g}$ — Co(III)P$^+$, $^2A_{1u}$ — Co(III)P^{2+}, and $^2A_{2u}$ — Co(III)P^{2+}. There appears to be very little reorganization among the orbitals upon the loss of an electron from either an a_{1u} or a_{2u} orbital. These two MOs stay rather isolated from the next occupied MO of $e_g(\pi)$ symmetry and dominate the spectra of these species.

There is an apparent failure of the aufbau principal demonstrated here (and also for the Zn(II)P$^+$ and Mg(II)P$^+$ cases) for the $^2A_{2u}$ state, with a "hole" in the second highest occupied MO. Although relaxation in the SCF procedure is usually sufficient to reorder the orbital energies (especially among the highest lying occupied MOs when the orbitals involved contain no metal *d* character), this does not appear to be the case here. Since, however, the open shell orbital and the closed shell orbitals do not "see" quite the same (Fock) potential (27, 44, 45) and orbital energies approximate ionization potentials via Koopmans' approximation only for our closed shell operator (the open shell orbital energy needs a small exchange correction) we do not think there is any special significance in the observation of the single occupied a_{2u} MO "below" the doubly occupied a_{1u}. Promotion of an electron from the $a_{1u}(\pi)$ MO to the $a_{2u}(\pi)$ MO in the $^2A_{2u}$ state, Fig. 4, leads to the $^2A_{1u}$ state estimated to lie 1 400 cm^{-1} (0.17 eV) *below* the $^2A_{2u}$ references, Table 5. This difference in energy is less than the 5 800 cm^{-1} value (Table 5) calculated when starting from the $^2A_{1u}$ state and generating the orbital excitation $a_{2u}(\pi) \rightarrow a_{1u}(\pi)$. This difference reflects the energy advantage the self consistent field calculation affords the reference state and would disappear with a large enough CI.

Table 6 summarizes the nature of the excited states generated from the $^2A_{1u}$ and $^2A_{2u}$ cations of [Co(III)P]$^{2+}$, and they differ only in detail from the ZnP$^+$ and MgP$^+$ cases. In the neutral species the visible and near-uv spectrum (Q and B bands) are dominated by $a_{1u}(\pi) \rightarrow e_g(\pi^*)$ and $a_{2u}(\pi) \rightarrow e_g(\pi^*)$ transitions (Fig. 2). The positive ion spectra is much more complicated, the more intense bands involving not only those transitions, but also transitions from the doubly occupied πMOs to the singly occupied $a_{1u}(\pi)$ or $a_{2u}(\pi)$ orbitals (Fig. 4). Note also the Rydberg-like transitions calculated at 17 300 cm^{-1} for the $^2A_{1u}$ ion and 18 700 cm^{-1} for the $^2A_{2u}$ ion. The apparent similarity of the single intense peak in the Soret region calculated at 31 800 cm^{-1} for the $^2A_{2u}$ ion to that of the neutral species is misleading in the sense that the former has a considerable $e_g(\pi) \rightarrow a_{2u}(\pi)$ component.

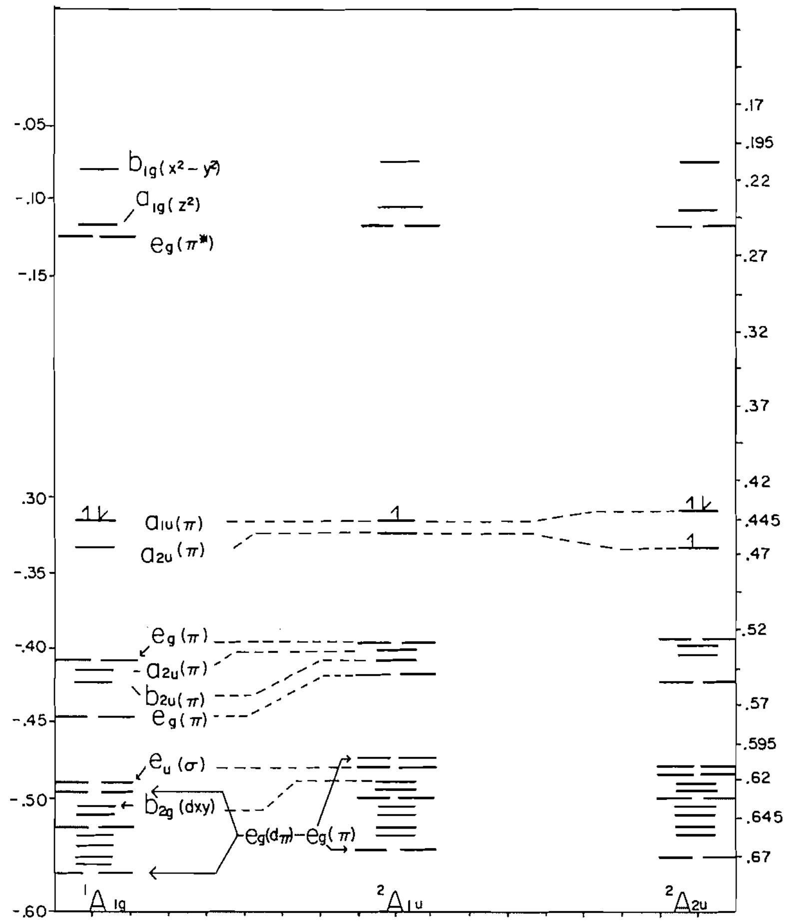

FIG. 4. The calculated molecular orbital energies of the $^2A_{1g}$ state of $[Co(III)P]^+Cl_2$ and the $^2A_{1u}$ and $^2A_{2u}$ states of $[Co(III)P]^{2+}Cl_2$, see Fig. 1.

VI. The spectrum of magnesium porphine cations

The calculated spectra of $^2A_{1u}$ and $^2A_{2u}$ $Mg(II)P^+$ are presented in Table 7, where they are compared with the experimental results on $Mg(II)OEP^+$ and $Mg(II)TPP^+$ (45). The geometry was optimized for the $^2A_{1u}$ state and compared with a similar optimization for the $^1A_{1g}$ state of Mg(II)P. The largest coordinate change was of the order of 0.006 Å, and the total energy lowering amounted to only 6.7 kJ/mol relative to the closed-shell optimized geometry. For a molecule of this size, this implies that the $^2A_{1u}$ geometry is nearly identical to the $^1A_{1g}$ geometry. A similar conclusion is deduced from the X-ray crystallographic study of the $Mg(II)TPP^+ClO_4^-$ cation by Barkigia, Spaulding, and Fajer (35).

$Mg(II)OEP^+$ is believed to be a $^2A_{1u}$ π cation. Three separate peaks are observed in the visible with decreasing intensity upon increasing transition energy, in good agreement with these calculated results. In contrast the spectrum of $Mg(II)TPP^+$ shows at least four less well-defined peaks in the visible. The apparent peak at 17 900 cm^{-1} may correspond to the Q_{10} peak of non-oxidized Mg(II)TPP. The position of the peak at 16 400 cm^{-1} may similarly be influenced by the weaker Q_{00} band of Mg(II)TPP. With these provisos, the calculated energies and their intensities are in excellent accord with the observed $Mg(II)TPP^+$ spectrum.

The $^2A_{1u}$ and $^2A_{2u}$ ions have predicted charge transfer excitations $^2A_{2g}$(TX) and $^2A_{1g}$(TX) calculated at 25 200 cm^{-1} and 25 500 cm^{-1}, respectively. The experimental spectra both show bands at about 22 000 cm^{-1} of the appropriate relative intensities to be assigned to these predicted transitions. States of this nature are not predicted to be present this low in energy in the $Zn(II)P^+$ spectra and, if the assignment of these bands could be verified, would provide a check of the relative position of the calculated charge transfer bands in these systems. These predictions require not only the correct positioning of the macrocycle π orbitals, but also of the Mg orbitals relative to these π orbitals. In the neutral Mg(II)P case, the charge transfer bands are predicted to lie under the Soret and no anomalous band is, in fact, seen. Confirmation of the assignment of the charge transfer assignment of the band observed at about 22 000 cm^{-1} makes the calculated position in the Mg(II)P case firmer and the possible importance of this state in photosynthesis more plausible (2).

The Soret region for $Mg(II)OEP^+$ has two intense peaks separated by about 1 100 cm^{-1}, in reasonable accord with the calculated values at 29 700 cm^{-1} and 30 700 cm^{-1}. Although these peaks are overlapping, the experiment indicates that the first of these should be more intense than the second, in contradiction to the calculated prediction. $Mg(II)TPP^+$ has one dominant peak at 24 400 cm^{-1} which we assign to the calculated ^1E_g state at 30 400 cm^{-1}. Another broad strong peak is observed at 26 700 cm^{-1}, which we assign to the ^1E_g state calculated at 33 400 cm^{-1}. The calculated spread of these two peaks of 3 000 cm^{-1} is in reasonable accord with that observed of 2 300 cm^{-1}. The Soret region of the $Co(III)OEP^{2+}$ $^2A_{1u}$ cation spectrum is characterized by three distinct peaks, Fig. 3, some 11 000 cm^{-1} from peak-to-peak. This region for the $MgOEP^+$ $^2A_{1u}$ cation spectrum is not as well resolved and perhaps contains four peaks, as suggested in Table 7. Assigned

[b] From ref. 46, in CH_2Cl_2.

to this region in the $Mg(II)OEP^+$ $^2A_{1u}$ case are four strong transitions.

In the above discussions we have used the traditional D_{4h} symmetry labels even though the non-planar cases possess only C_{4v} symmetry. This labelling seems appropriate except for the virtual molecular orbital localized to the Mg or Zn atom and which is responsible for the porphyrin to metal charge transfer bands. In the planar Zn(II)P cases, this orbital is a_{1g} with about 65% 4s character. In the non-planar Zn(II)P case, this orbital is a_1 with 56% 4s and 14% $4p_z$. In the non-planar Mg(II)P case this a_1 orbital is calculated to be even more p_z-like: 28% 3s and 54% $3p_z$. The association between D_{4h} and C_{4v} for the two low-lying π cations are $^2A_{2u} \leftrightarrow {}^2A_1$ and $^2A_{1u} \leftrightarrow {}^2A_2$.

VII. Ionization potentials

The calculated ionization potentials for all systems studied are summarized in Table 8. For comparison, ionization potentials for similar systems are reported at 6.25 to 6.80 eV (47) in very good agreement with the calculated values. For some systems a shoulder is reported about 0.13 eV higher in energy, which may correspond to the second ionization process (47). It is interesting to further note that the ionization potentials calculated for our model $Co(III)P^+$ are slightly lower than those of Zn(II)P and Mg(II)P, even though the former complex is locally positive. Experimentally Mn(II) *trans*-octaethylchlorin has an ionization potential about 0.27 eV less than that of free base octaethylchlorin (47). Non-planarity has very little effect on the calculated ionization potentials of ZnP.

VIII. Charge and spin densities

A summary of the charge and spin density obtained through a Mulliken population analysis is presented for $[Co(III)P]^+$ and its two low-lying cations in Table 9. Spin density results for Zn(II)P and Mg(II)P and their cations are given in Table 10.

C_1 total	7.968	7.997	7.982
Net charge	1+	2+	2+

The results for these three complexes are reasonably similar, except for the total charges on the metal atom, as noted in Table 9. The net charge on the Co atom is about +1.5 and is similar for all three states of the Co complex. The metal atoms in the $^2A_{2u}$ cases have the greatest net charges, the neutral $^1A_{1g}$ cases the least, in keeping with intuition that all the atoms in the molecule share in the loss of this electron. Since the a_{2u} MO has some metal p_z character, loss of an electron from this orbital removes more electrons from the central metal than loss of an electron from an a_{1u} MO with two nodes through the metal.

As noted in Tables 9 and 10, the $^2A_{1u}$ and $^2A_{2u}$ states have quite different spin densities, and these have been used traditionally to help characterize the nature of the ground states of these ions through EPR and ENDOR measurements (48). Most often for this purpose the hyperfine constants for protons are approximated through the McConnell relation (49)

$$a_{Hi} = Q\rho_i^\pi$$

where ρ_i^π is the π spin density on the neighboring atom, and Q is a constant characteristic of that neighbor. Table 10 contains a comparison of the spin densities obtained by Fujita, Hanson, Walker, and Fajer (18) using the interative extended Hückel (IEH) method for a $Zn(II)P^+$ pyridine complex. The spin densities obtained from both methods for the $^2A_{1u}$ state are very similar; those obtained for the $^2A_{2u}$ state are somewhat different. For the $^2A_{2u}$ state, the INDO/S method used here places far more unpaired spin density on the methine bridge carbon atom C_3 than it does on the chelating nitrogen atom.

Table 10 also contains spin densities obtained from Pariser–Parr–Pople (PPP) π electron calculations (24) for comparison. The $^2A_{1u}$ state results are again very similar to those we obtain here. The $^2A_{2u}$ results are essentially the same for the spin density on the nitrogen atom and for C_1 and C_2. The accumulated small differences are noted, however, on the methine bridge carbon, C_3, with the INDO/S results of this study nearly the average of the PPP and IEH results. The small negative spin density of the PPP computation for C_1 are the result of an analysis of a CI wave function. The INDO/S results reported in this study are from restricted calculations (all closed shell "electrons" are in spacially paired orbitals), and negative values cannot be obtained at the level of theory (Hartree–Fock) reported in this table.

For further comparison, Petke, Maggiora, Shipman, and Christoffersen (20) obtain a ground state of the ethyl chlorophyllide a and ethyl bacteriochlorophyllide a cations with an average spin density of 0.109 electrons on each of the 8 C_1 atoms (these atoms are not equivalent in the chlorophyll analogues calculated by Petke *et al.*), clearly corresponding to the $^2A_{1u}$ π cation of this study. Although not definitive, the experimental spin densities obtained through McConnell's relation (16) seem in reasonable accord (20). The calculations of Petke *et al.* also suggest a low-lying singlet state (~5 000 cm^{-1} for Et-chl-a$^+$ and ~7 000 cm^{-1} for Et-Bchl-a$^+$) with an average of 0.17 electrons on each of the four methine bridge C_3 atoms and 0.09 electrons on each of the chelating nitrogen atoms, corresponding to the $^2A_{2u}$ states of this study. The INDO/S calculations suggest a greater spin delocalization in the $^2A_{2u}$ state (0.017e on each of 8 C_2 atoms) than either the *ab initio* calculations of Petke, Maggiora, Shipman, and Christoffersen (20) or the extended Hückel calculations of Fujita *et al.* (18).

Before concluding this section, we note (Table 10) that in the $^2A_{2u}$ state there is a net spin density on the metal atom that is not present in the $^2A_{1u}$ ions, as expected from the model structure of the half-filled MO that gives rise to the symmetries of these states.

IX. Conclusions

We report here the calculated spectra of the $^2A_{1u}$ and $^2A_{2u}$ π cations of Mg(II), Zn(II), and Co(III) porphine, and the electron spin properties of these two near lying states.

The $^2A_{2u}$ spectrum is calculated to have three allowed bands in the visible region of near equal intensity and a Soret region of at least three allowed bands, but the intensity of this region is dominated by but one of them. This seems to be in accord with experimental observations. In contrast, the $^2A_{1u}$ spectrum is calculated to have again three allowed transitions in the visible but with decreasing intensity with increasing transition energy, again in agreement with experiment. The Soret region is calculated to be characterized by at least four allowed bands spread some 10 000 cm^{-1}. In the $Co(III)P^{2+}$ and $Zn(II)P^+$ cases, three bands well separated are calculated to carry the intensity. The $Co(III)TPP^{2+}$ experimental spectrum shows three well separated band peaks in the Soret region. We do not have access to experimental $Zn(II)P^+$ $^2A_{1u}$ spectra. In the $Mg(II)P^+$ $^2A_{1u}$ calculation, four transitions are calculated to carry the intensity. Experimentally four transitions can be dis-

TABLE 10. Mulliken π spin densities for the cations of ZnP^+ and MgP^+

	ZnP^+		MgP^+		MP^{+c}	
	$^2A_{2u}$	$^2A_{1u}$	$^2A_{2u}$	$^2A_{1u}$	$^2A_{2u}$	$^2A_{1u}$

[a]For ZnP^+ with a pyridine molecule in the fifth position. The values in parentheses have been symmetrized from ref. 18, and are obtained from an iterative extended Hückel calculation. The net spin density on the pyridine is 0.11 electrons.
[b]For this calculation the Mg atom is out of plane. Even so, very little spin density is found in the σ system except for a net 0.019 e in the Mg(3s).
[c]For "metal" porphine from Pariser–Parr–Pople π electron calculations, ref. 24.

TABLE 11. Net metal populations in the $^1A_{1g}$ stage of MgP, ZnP, and $[Co(III)P]^+$ and their $^2A_{2u}$ and $^2A_{1u}$ cations

Species	$^1A_{1g}$	$^2A_{2u}$	$^2A_{1u}$
MgP	+0.62	+0.73	+0.70
ZnP	+0.90	+0.94	+0.93
$[Co(III)P]^+$	+1.52	+1.54	+1.54

tinguished, but only the lower energy two are truly resolved.

The spin properties of the $^2A_{2u}$ and $^2A_{1u}$ π cations of these systems are dominated by the nodal structure of the corresponding molecular orbitals, are relatively insensitive to central atom displacement and remain very diagnostic of these two possible ground states.

Finally, our calculations suggest that at the optimized $^1A_{1g}$ geometry the $^2A_{1u}$ cation is lower in energy than the $^2A_{2u}$. This does not appear to be in accord with the more common situation for metal porphines, but is often observed, as discussed, for some $[Co(III)P]^{2+}$, ZnP^+, MgP^+, and RuP^+ complexes. Preliminary studies show that while geometry optimization of the doublet ions lowers their energy by only a few kcal/mol it is not sufficient to reverse the $^2A_{1u}$, $^2A_{2u}$, but only brings them closer in energy. The ground state observed for Et-chl-a$^+$ and Et-Bchl-a$^+$ (of considerably lower symmetry) probably also corresponds to the $^2A_{1u}$ states calculated here, and calculations on these more complex systems are currently underway.

This paper is dedicated to Professor Camille Sandorfy on the occasion of his 65th birthday

D. P. CRAIG and T. THIRUNAMACHANDRAN. Can. J. Chem. **63**, 1773 (1985).

The adiabatic approximation to vibronic interactions, and its relation to the crude adiabatic and other methods, need careful scrutiny when applied to processes where both participating states belong to the same electronic manifold. The processes include vibrational transitions by both electronic and magnetic mechanisms, and the property of vibrational circular dichroism in chiral systems. When moments and properties are calculated, general questions of dependence on the chosen origin of coordinates have to be resolved. These problems are examined.

D. P. CRAIG and T. THIRUNAMACHANDRAN. Can. J. Chem. **63**, 1773 (1985).

L'approximation adiabatique aux interactions vibroniques ainsi que sa relation à la méthode adiabatique grossière et autres ne doivent être appliquer qu'avec circonspection aux processus dans lesquels les deux états participants appartiennent au même niveau électronique. Ces processes comprennent les transitions vibrationnelles tant par des mécanismes électronique que magnétique ainsi que la propriété du dichroïsme circulaire vibrationnel dans des systèmes chiraux. Quand on calcule les moments et les propriétés, on doit résoudre les questions générales de la dépendance des coordonnées sur l'origine choisie. On examine ces problèmes.

[Traduit par le journal]

Introduction

In the early postwar years, when Camille Sandorfy was at the start of his career, the urgent problem in theoretical chemistry seemed to many of us to be how the principles of the theory of valency, enshrined for brevity in HLSP (Heitler–London–Slater–Pauling) and HMH (Hund–Mulliken–Hückel), were to be applied to complex aromatic molecules. In the years since new challenges have appeared. In a surprising number, not least in Professor Sandorfy's notable contributions to spectroscopy, interaction of nuclear and electronic motions is a central theme. His recent review (1) on vibrational spectra of hydrogen-bonded systems illustrates the point in transitions within the ground state manifold.

The present paper is on this interaction, which is germane also to theories of chemical kinetics and molecular dynamics. In the study of the coupling between electronic and nuclear motions the adiabatic approximation has been the basis of almost all work on vibronic interactions since its publication by Born and Oppenheimer (2). Very small molecules, H_2^+ and H_2, can be treated exactly (Kolos and Wolniewicz, ref. 3; Bishop and Cheung, ref. 4) and an interesting new approach has been suggested by Lathouwers and van Leuven (5) but for larger molecules no alternative method has been found suitable for general use.

The term adiabatic is used variously, and the adiabatic approximation applied at different levels. We begin by outlining the main models, and then apply them to infrared absorption and to rotational strength in chiral molecules. Finally, noting that results of calculations made in this approximation may be dependent on the choice of coordinate origin, we analyse the problem of origin-dependence, and give the conditions necessary for origin-independent results.

We have not given any discussion of the diabatic approximation (see e.g. Smith (6)), which is unlikely to be useful in the lower vibronic levels of the ground electronic state.

The adiabatic approximation

The Hamiltonian for a molecule can be partitioned as

$$[1] \quad H = T_N + T_e + U(q, Q)$$

where T_N and T_e are the nuclear and electronic kinetic energy operators and $U(q, Q)$ is the potential energy; q and Q are the electronic and nuclear coordinates. To solve the full Schrödinger equation [2]

$$[2] \quad H\Psi(q, Q) = E\Psi(q, Q)$$

we assume, in the adiabatic approximation, that the solutions of the electronic wave equation [3]

$$[3] \quad H_e\phi_n(q, Q) = E_n(Q)\phi_n(q, Q)$$

with

$$[4] \quad H_e = T_e + U(q, Q)$$

are known for sets of fixed values of Q, each set specifying a molecular configuration. With $\{\phi_n(q, Q)\}$ as a basis set, we expand the total wavefunction $\Psi(q, Q)$ according to [5] (7, 8),

$$[5] \quad \Psi(q, Q) = \sum_m \chi_m(Q)\phi_m(q, Q)$$

where the expansion coefficients are clearly functions of Q. Substituting in [2], multiplying both sides by $\bar{\phi}_n(q, Q)$, and integrating over the electronic coordinates, we get

$$[6] \quad \sum_m \int \bar{\phi}_n(q, Q)(T_N + H_e)\phi_m(q, Q)\mathrm{d}q\chi_m(Q) = E\sum_m \int \bar{\phi}_n(q, Q)\phi_m(q, Q)\mathrm{d}q\chi_m(Q)$$

so that, with [3], and the orthonormality of the electronic eigenfunctions $\{\phi_n(q, Q)\}$,

$$[7]\quad \left(T_N + E_n(Q)\right)\chi_n(Q) - \frac{\hbar^2}{2}\sum_m\left(\int\bar{\phi}_n(q, Q)\frac{\partial^2}{\partial Q^2}\phi_m(q, Q)\mathrm{d}q\right)\chi_m(Q) - \hbar^2\sum_m\int\left(\bar{\phi}_n(q, Q)\frac{\partial}{\partial Q}\phi_m(q, Q)\mathrm{d}q\right)\frac{\partial}{\partial Q}\chi_m(Q) = E\chi_n(Q)$$

Separating the diagonal terms from the sums and rearranging we find [8]

$$[8]\quad \left(T_N + E_n(Q) - \frac{\hbar^2}{2}\int\bar{\phi}_n(q, Q)\frac{\partial^2}{\partial Q^2}\phi_n(q, Q)\mathrm{d}q - E\right) \times \chi_n(Q) = \frac{\hbar^2}{2}\sum_{m\neq n}\left(\int\bar{\phi}_n(q, Q)\frac{\partial^2}{\partial Q^2}\phi_m(q, Q)\mathrm{d}q\right)\chi_m(Q) + \hbar^2\sum_{m\neq n}\left(\int\bar{\phi}_n(q, Q)\frac{\partial}{\partial Q}\phi_m(q, Q)\mathrm{d}q\right)\frac{\partial}{\partial Q}\chi_m(Q)$$

Equations [8] are a set of coupled differential equations with n taking different values according to [3]. The terms on the right hand side of [8] represent the coupling between the electronic functions through nuclear motion. If these terms are set equal to zero, the equations become uncoupled, giving [9]

$$[9]\quad \left(T_N + E_n(Q) - \frac{\hbar^2}{2}\int\bar{\phi}_n(q, Q)\frac{\partial^2}{\partial Q^2}\phi_n(q, Q)\mathrm{d}q - E\right) \times \chi_n(Q) = 0$$

which can be written as

$$[10]\quad (T_N + U_n(Q))\chi_{nv}(Q) = E_{nv}\chi_{nv}(Q)$$

where

$$[11]\quad U_n(Q) = E_n(Q) - \frac{\hbar^2}{2}\int\bar{\phi}_n(q, Q)\frac{\partial^2}{\partial Q^2}\phi_n(q, Q)\mathrm{d}q$$

In eq. [10], a further subscript v has been added to distinguish the different eigenvalues and eigenfunctions for a given n. The neglect of the terms on the right hand side of [8] is the basis of the *adiabatic approximation*. In adiabatic motion, electrons do not make transitions from one state to another. Instead, the electron distribution adapts itself by following the nuclear displacements. The potential energy $U_n(Q)$, given by [11], serves as the potential for nuclear motion in [10].

The adiabatic approximation may be distinguished from the original Born–Oppenheimer approximation (2) because the potential $U_n(Q)$ for the latter is simply $E_n(Q)$; that is, the expectation value of the nuclear kinetic energy over the electronic wavefunction $\phi_n(q, Q)$, given as the second term of [11], is neglected. This is a good approximation for many problems because of the small electron to nuclear mass ratio. In the Born–Oppenheimer approximation the potential is independent of the nuclear masses, and identical for different isotopes.

Higher order corrections can be made in the adiabatic model by including the coupling between different electronic functions, which was neglected in the derivation of the wave equation [10] for nuclear motion. Thus with the adiabatic products as basis functions, the off-diagonal elements of the total Hamiltonian are

$$[12]\quad \int\bar{\chi}_{n'v'}(Q)\bar{\phi}_{n'}(q, Q)H\phi_n(q, Q)\chi_{nv}(Q)\mathrm{d}q\mathrm{d}Q = -\frac{\hbar^2}{2}\int\bar{\chi}_{n'v'}(Q)\left(\int\bar{\phi}_{n'}(q, Q)\frac{\partial^2}{\partial Q^2}\phi_n(q, Q)\mathrm{d}q\right)\chi_{nv}(Q)\mathrm{d}Q - \hbar^2\int\bar{\chi}_{n'v'}(Q)\left(\int\bar{\phi}_{n'}(q, Q)\frac{\partial}{\partial Q}\phi_n(q, Q)\mathrm{d}q\right)\frac{\partial}{\partial Q}\chi_{nv}(Q)\mathrm{d}Q$$

The second term of [12] gives the coupling of electronic to nuclear motion caused by the nuclear momentum. It is usually larger than the first, which is often neglected. In the simplest case of the same vibrational force system in the coupled levels n and n', and unchanged molecular structure, the first term couples the states with the same vibrational quantum number. The second term couples states with $v' = v \pm 1$.

The crude adiabatic approximation

In the crude adiabatic model, the electronic factors $\phi_n^0 \equiv \phi_n(q, Q_0)$ are not functions of Q but apply to the equilibrium nuclear configuration for state n. The partitioning of the total Hamiltonian is now given by

$$[13]\quad H = T_N + T_e + U(q, Q_0) + U(q, Q) - U(q, Q_0) = T_N + H_e^0 + \Delta U$$

where

$$[14]\quad H_e^0 = T_e + U(q, Q_0)$$

and

$$[15]\quad \Delta U = U(q, Q) - U(q, Q_0)$$

The electronic eigenfunctions $\phi_n(q, Q_0)$ of H_e^0 are now used as the basis set for expanding the complete wavefunction $\Psi(q, Q)$:

$$[16]\quad (T_N + H_e^0 + \Delta U)\sum_m\chi_m(Q)\phi_m(q, Q_0) = E\sum_m\chi_m(Q)\phi_m(q, Q_0)$$

After multiplying both sides of [16] by $\bar{\phi}_n(q, Q_0)$, integrating over the electron coordinates, and rearranging

$$[17]\quad \left(T_N + E_n(Q_0) + \int\bar{\phi}_n(q, Q_0)\Delta U\phi_n(q, Q_0)\mathrm{d}q - E\right)\chi_n(Q) = -\sum_{m\neq n}\int\bar{\phi}_n(q, Q_0)\Delta U\phi_m(q, Q_0)\mathrm{d}q\chi_m(Q)$$

The crude adiabatic approximation involves setting the sum on the right hand side of [17] equal to zero. Thus the equation for nuclear motion is

$$[18]\quad \left(T_N + E_n(Q_0) + \int\bar{\phi}_n(q, Q_0)\Delta U\phi_n(q, Q_0)\mathrm{d}q\right)\chi_{nv}(Q) = E_{nv}\chi_{nv}(Q)$$

so that the potential for nuclear motion is

$$[19]\quad U_n(Q) = E_n(Q_0) + \int\bar{\phi}_n(q, Q_0)\Delta U\phi_n(q, Q_0)\mathrm{d}q = \int\bar{\phi}_n(q, Q_0)H_e\phi_n(q, Q_0)\mathrm{d}q$$

The vibrational wave functions found in the crude adiabatic method are not the same as in the adiabatic approximation, where they belong to the potential function [11].

Herzberg–Teller coupling and adiabatic motion

In the Herzberg–Teller model (12), the electronic wavefunctions are the same as those used in the crude adiabatic model. They are the eigenfunctions of H_e^0. With ΔU given by [15] as the perturbation, the electronic wavefunction for state n, correct to first order, is

$$[20] \quad \phi_n^{\mathrm{HT}}(q, Q) = \phi_n(q, Q_0) - \sum_{m \neq n} \frac{\int \bar{\phi}_m(q, Q_0)\Delta U \phi_n(q, Q_0)\mathrm{d}q}{E_m^0 - E_n^0} \phi_m(q, Q_0)$$

and the electronic energy is

$$[21] \quad E_n^{\mathrm{HT}}(Q) = E_n(Q_0) + \int \bar{\phi}_n(q, Q_0)\Delta U \phi_n(q, Q_0)\mathrm{d}q - \sum_{m \neq n} \frac{\left| \int \bar{\phi}_m(q, Q_0)\Delta U \phi_n(q, Q_0)\mathrm{d}q \right|^2}{E_m^0 - E_n^0}$$

Since $H_e = H_e^0 + \Delta U$, the wavefunction [20] can be regarded as the adiabatic electronic wavefunction, correct to first order in ΔU. It is of interest to note that if a product of the form $\phi_n^{\mathrm{HT}}(q, Q)\chi_{nv}^{\mathrm{HT}}(Q)$ is chosen to describe the vibronic state $|n,v\rangle$, then $\chi_{nv}(Q)$ satisfies eq. [22]

$$[22] \quad (T_{\mathrm{N}} + E_n^{\mathrm{HT}}(Q))\chi_{nv}^{\mathrm{HT}}(Q) = E_{nv}\chi_{nv}^{\mathrm{HT}}(Q)$$

where $E_n^{\mathrm{HT}}(Q)$ of eq. [21] serves as the potential for nuclear motion. In obtaining [22], the effect of T_{N} on $\phi_n^{\mathrm{HT}}(q, Q)$ has been ignored, as in the Born–Oppenheimer approximation. In contrast to the crude adiabatic potential [19] for nuclear motion, $E_n^{\mathrm{HT}}(Q)$ includes the second order contribution (third term of [21]). Hence $\phi_n^{\mathrm{HT}}(q, Q)\chi_{nv}^{\mathrm{HT}}(Q)$ may be considered to be a better approximation than $\phi_n(q, Q_0)\chi_{nv}(Q)$.

Off-diagonal terms in the adiabatic and crude adiabatic schemes

A useful insight into the relation of the two approximations comes from considering the Taylor expansion of the adiabatic electronic wave function $\phi_n(q, Q)$ in terms of crude adiabatic functions,

$$[23a] \quad \phi_n(q, Q) = \phi_n(q, Q_0) + (Q - Q_0)\left\{\frac{\partial}{\partial Q}\phi_n(q, Q)\right\}_0 + \ldots\ldots$$

$$[23b] \quad = \phi_n(q, Q_0) - (Q - Q_0)\sum_{m \neq n} \frac{\int \left\{\phi_m \frac{\partial U}{\partial Q}\phi_n\right\}_0 \mathrm{d}q}{E_m^0 - E_n^0} \phi_m(q, Q_0)$$

where the second form (9) follows using

$$[24] \quad \left(\frac{\partial}{\partial Q}\phi_0(q, Q)\right)_0 = -\sum_{m \neq 0} \frac{\left(\int \phi_m(q, Q)\frac{\partial U}{\partial Q}\phi_0(q, Q)\mathrm{d}q\right)_0}{E_m^0 - E_0^0} \phi_m(q, Q_0)$$

so that, up to the term linear in Q, the adiabatic vibronic wave function for the state $|n, v\rangle$ can be written as

$$[25] \quad |n, v\rangle = \phi_n^0\chi_{nv} + \sum_{m \neq n} \frac{\int \left\{\phi_m \frac{\partial U}{\partial Q}\phi_n\right\}_0 \mathrm{d}q}{E_m^0 - E_n^0} \phi_m^0 Q \chi_{nv}$$

showing that the adiabatic wave function already includes corrections of a type which in the crude adiabatic have to be brought in as off-diagonal terms by use of first-order pertubation theory. Also, terms [12] which are off-diagonal in the adiabatic method do not appear at all in the crude adiabatic method, in which coupling by nuclear motion is not taken account of.

In summary, the off-diagonal coupling between crude adiabatic vibronic states is included in zero-order adiabatic states. Off-diagonal matrix elements between the latter states are typically small.

Transitions within the ground state vibrational manifold

When the adiabatic approximation is applied to electric or magnetic transitions involving different electronic levels as in $\langle m, v'| \leftarrow \langle n, v|$, the nuclear part of the transition moment operator does not contribute. This is because adiabatic electronic wave functions belonging to different electronic energies are orthogonal for each set of values of the nuclear coordinates Q. However, infrared and vibrational Raman transitions, and transitions showing vibrational circular dichroism in chiral molecules, take place between different levels of the same (ground) electronic state. Both nuclear and electronic parts of the transition moment operator may contribute, and some interesting new problems have to dealt with.

Let us consider the transition $|0,1\rangle \leftarrow |0,0\rangle$ and suppose that only one mode is active and that the levels are non-degenerate. The wavefunctions can then be chosen to be real. With the adiabatic products $\phi_0(q, Q)\chi_{00}(Q)$ and $\phi_0(q, Q)\chi_{01}(Q)$ representing the molecular states, the electric and magnetic dipole transition moments are

$$[26] \quad \langle 1,0|\boldsymbol{\mu}|0,0\rangle = \int \chi_{01}(Q)\phi_0(q, Q)\boldsymbol{\mu}\phi_0(q, Q)\chi_{00}(Q)\mathrm{d}q\mathrm{d}Q$$

$$[27] \quad \langle 1,0|\boldsymbol{m}|0,0\rangle = \int \chi_{01}(Q)\phi_0(q, Q)\boldsymbol{m}\phi_0(q, Q)\chi_{00}(Q)\mathrm{d}q\mathrm{d}Q$$

where $\boldsymbol{\mu}$ and $\boldsymbol{m}$ are sums of nuclear and electronic terms. It is easily shown by integrating over electronic coordinates that the electronic contribution to the magnetic dipole transition moment is zero. For the electric dipole transition moment both electronic and nuclear terms contribute. The electric dipole moment operator is given by

$$[28] \quad \mu_i = -e \sum_{\alpha,\zeta} r_i(\alpha, \zeta) + e \sum_{\alpha} Z_\alpha R_i(\alpha)$$

where $Z_\alpha e$ is the charge on nucleus α and $\boldsymbol{R}(\alpha)$ is the position vector: $\boldsymbol{r}(\alpha, \zeta)$ is the position vector of electron ζ associated with nucleus α. In the case that the solutions to the electronic equation [3] are found in an all-electron *ab initio* framework the charges $Z_\alpha e$ are bare nuclear charges. In that case the large terms in the dipole moment [26] from the second term of [28] are at least partially cancelled by those from the first term, which is a sum over all electrons. In many calculations it is a good approximation to restrict the sum over electrons to valence electrons, and then the $Z_\alpha e$ must be treated as effective charges, with allowance for the screening by core electrons. In that case the reduced nuclear contribution to [26] is set against a matching reduction in the electronic contribution. Thus in different models that may be set up for calculating the adiabatic wave functions, defined by a range of Hamiltonians at different levels of approximation, there are different partitions of the electric moment. We note later the special importance of model dependence in the treatment of the magnetic moment.

In order to be able to use the electric moment operator [28] in [26], we need to express $R_i(\alpha)$ in terms of normal coordinates Q_k, and $r_i(\alpha, \zeta)$ in terms of relative coordinates $q_i(\alpha, \zeta)$. If $\boldsymbol{R}^0(\alpha)$ is the equilibrium position of nucleus α, then

$$[29] \quad R_i(\alpha) = R_i^0(\alpha) + M_\alpha^{-1/2} \sum_{k=1}^{3N-6} l_{ik}(\alpha) Q_k$$

where $k = 1, 2, \ldots, (3N-6)$, after elimination of translational and rotational degrees of freedom. The coefficients l_{ik} satisfy the orthonormality conditions

$$\sum_i l_{ki}(\alpha) l_{il}(\alpha) = \delta_{kl}$$

The coordinates $\boldsymbol{q}(\alpha, \zeta)$ are defined by [30]

$$[30] \quad \boldsymbol{q}(\alpha, \zeta) = \boldsymbol{r}(\alpha, \zeta) - \boldsymbol{R}^0(\alpha)$$

With the use of [29] in [26] the nuclear contribution to the electric dipole transition moment follows immediately. To calculate the electronic contribution, a convenient starting point is the expansion of the electronic wavefunction about the equilibrium position in the active normal coordinate as in [23a]. Using [23a] in [26] the leading term of $\boldsymbol{\mu}$ is found to be

$$[31] \quad 2\int \chi_{01}(Q)\phi_0(q, Q_0) Q \boldsymbol{\mu}^{\mathrm{elec}} \left(\frac{\partial}{\partial Q}\phi_0(q, Q)\right)_0 \chi_{00}(Q)\mathrm{d}q\mathrm{d}Q = 2\int \phi_0(q, Q_0)\boldsymbol{\mu}^{\mathrm{elec}} \left(\frac{\partial}{\partial Q}\phi_0(q, Q)\right)_0 \mathrm{d}q \int \chi_{01}(Q) Q \chi_{00}(Q)\mathrm{d}Q$$

The electronic integral depends on the ground state electronic wavefunction and its derivative evaluated at Q_0. This form of the integrand, depending solely on the ground state wave function and its Q derivative, may be convenient from a computational point of view. An alternative form (9) involving the electronic excited states can be obtained using [24]. The same result [31] can be obtained from the crude adiabatic approach. In this formalism, the wave function for the ground state $|0,0\rangle$, correct to first order, is

$$[32] \quad |0,0\rangle = \phi_0(q, Q_0)\chi_{00}(Q) - \sum_{mv} \int \frac{\chi_{mv}(Q)\phi_m(q, Q_0)\Delta U \phi_0(q, Q_0)\chi_{00}(Q)}{E_{mv} - E_{00}} \mathrm{d}q\mathrm{d}Q \times \phi_m(q, Q)\chi_{00}(Q)$$

A similar wavefunction holds for $|0,1\rangle$. The electric dipole transition moment is then found to be

$$[33] \quad -\sum_{mv} \int \chi_{01}(Q)\phi_0(q, Q_0)\boldsymbol{\mu}^{\mathrm{elec}}\phi_m(q, Q_0)\chi_{mv}(Q)\mathrm{d}q\mathrm{d}Q \times \frac{\int \chi_{mv}(Q)\phi_m(q, Q_0)\Delta U \phi_0(q, Q_0)\chi_{00}(Q)\mathrm{d}q\mathrm{d}Q}{E_{mv} - E_{00}}$$
$$- \sum_{mv} \frac{\int \chi_{01}(Q)\phi_0(q, Q_0)\Delta U \phi_m(q, Q_0)\chi_{mv}(Q)\mathrm{d}q\mathrm{d}Q}{E_{mv} - E_{01}} \times \int \chi_{mv}(Q)\,\phi_m(q, Q_0)\boldsymbol{\mu}^{\mathrm{elec}}\phi_0(q, Q_0)\mathrm{d}q\mathrm{d}Q$$

Expanding ΔU about Q_0 and retaining the leading terms, namely, $(Q - Q_0)\,(\partial U/\partial Q)_0$, expression [33] simplifies to

$$[34] \quad -2\sum_m \int \phi_0(q, Q_0)\boldsymbol{\mu}^{\mathrm{elec}}\phi_m(q, Q_0)\mathrm{d}q \times \frac{\int \phi_m(q, Q_0) Q (\partial U/\partial Q)_0 \phi_0(q, Q_0)\mathrm{d}q \int \chi_{01}(Q) Q \chi_{00}(Q)\mathrm{d}Q}{E_m^0 - E_0^0}$$

where the vibrational energy differences in the denominators have been neglected. Consequently, it has been possible to effect closure over the vibrational states associated with the intermediate state $\phi_m(q, Q_0)$. The use of the relationship [24] in [34] leads to the result [31] obtained from the adiabatic approach. It must be noted that, in making this identification, it has been tacitly assumed that the vibrational wavefunctions in the adiabatic and the crude adiabatic formalisms are essentially the same.

We now turn to the evaluation of the magnetic dipole transition moment. The electronic and nuclear parts of the magnetic dipole moment operator are given by

$$[35] \quad \boldsymbol{m} = \frac{e}{2m}\sum_{\alpha,\zeta}\{\boldsymbol{r}(\alpha, \zeta) \times \boldsymbol{p}(\alpha, \zeta)\} + \frac{e}{2}\sum_\alpha \frac{Z_\alpha}{M_\alpha}\{\boldsymbol{R}(\alpha) \times \tilde{\boldsymbol{P}}(\alpha)\}$$

where $\boldsymbol{p}$ and $\tilde{\boldsymbol{P}}$ are the electronic and nuclear momenta. The moments are taken about the centre of mass. In terms of $\boldsymbol{q}$ and $\boldsymbol{Q}$, we have for the ith component

$$[36] \quad m_i = -\frac{e}{2m}\sum_{\alpha,\zeta}\{\boldsymbol{R}^0(\alpha) \times \boldsymbol{p}(\alpha, \zeta)\}_i - \frac{e}{2m}\sum_{\alpha,\zeta}\{\boldsymbol{q}(\alpha, \zeta) \times \boldsymbol{p}(\alpha, \zeta)\}_i + \frac{e}{2}\sum_\alpha \frac{Z_\alpha}{M_\alpha}\{\boldsymbol{R}^0(\alpha) \times \tilde{\boldsymbol{P}}(\alpha)\}_i$$
$$+ \frac{e}{2}\epsilon_{ijl}\sum_\alpha \frac{Z_\alpha}{M_\alpha^{1/2}} \sum_{k=1}^{3N-6} l_{jk}(\alpha) Q_k \tilde{P}_l(\alpha)$$

In [36] the $\tilde{P}_l(\alpha)$ are not canonically conjugate to $Q_l(\alpha)$. They can be transformed according to

$$[37] \quad \tilde{P}_l(\alpha) = \sum M_\alpha^{1/2}\, l_{lk}(\alpha) P_k$$

where P_k are the canonical conjugates of Q_k. For the case where one mode only is active, the situation which we consider in this paper, the last term of [36] does not contribute. With zeroth-order adiabatic functions, the magnetic dipole transition is entirely made up of the nuclear contribution and is given by

$$[38]\quad \langle\chi_{01}(Q)|\langle\phi_0(q,Q)|m_i|\phi_0(q,Q)\rangle|\chi_{00}(Q)\rangle = \frac{e}{2}\epsilon_{ijl}\sum_\alpha M_\alpha^{-1/2}Z_\alpha R_j^0(\alpha)l_{lk}(\alpha)\int \chi_{01}(Q)P_k\chi_{00}(Q)\mathrm{d}Q$$

In contrast, as seen earlier, the electric dipole transition moment has both electronic and nuclear contributions with zeroth-order adiabatic functions.

Higher order contributions to transition moments

In the adiabatic model, the wavefunctions corrected to first order are obtained using the coupling [12]. For $|0,0\rangle$ we get

$$[39]\quad |0,0\rangle = \phi_0(q,Q)\chi_{00}(Q) + \hbar^2\sum_{mv}\int \chi_{mv}(Q)\int \phi_m(q,Q)\frac{\partial}{\partial Q}\phi_0(q,Q)\mathrm{d}q\frac{\partial}{\partial Q}\chi_{00}(Q)\mathrm{d}Q\phi_m(q,Q)\chi_{mv}(Q)$$
$$+\frac{\hbar^2}{2}\sum_{mv}\int \chi_{mv}(Q)\int \phi_m(q,Q)\frac{\partial^2}{\partial Q^2}\phi_0(q,Q)\mathrm{d}q\chi_{00}(Q)\mathrm{d}Q\phi_m(q,Q)\chi_{mv}(Q)$$

and a similar wavefunction for $|0,1\rangle$. With these wavefunctions, the corrections to the electric dipole transition moment are given by

$$[40]\quad \hbar^2\sum_{mv}\int \chi_{01}(Q)\boldsymbol{\mu}^{0m}(Q)\chi_{mv}(Q)\mathrm{d}Q\,\frac{\int\chi_{mv}(Q)\int \phi_m(q,Q)\frac{\partial}{\partial Q}\phi_0(q,Q)\mathrm{d}q\frac{\partial}{\partial Q}\chi_{00}(Q)\mathrm{d}Q}{E_{mv}-E_{00}}$$
$$+\hbar^2\sum_{mv}\int \chi_{00}(Q)\boldsymbol{\mu}^{0m}(Q)\chi_{mv}(Q)\mathrm{d}Q\,\frac{\int\chi_{mv}(Q)\int \phi_m(q,Q)\frac{\partial}{\partial Q}\phi_0(q,Q)\mathrm{d}q\frac{\partial}{\partial Q}\chi_{01}(Q)\mathrm{d}Q}{E_{mv}-E_{01}}$$
$$+\frac{\hbar^2}{2}\sum_{mv}\int \chi_{01}(Q)\boldsymbol{\mu}^{0m}(Q)\chi_{mv}(Q)\mathrm{d}Q\,\frac{\int\chi_{mv}(Q)\int \phi_m(q,Q)\frac{\partial^2}{\partial Q^2}\phi_0(q,Q)\mathrm{d}q\chi_{00}(Q)\mathrm{d}Q}{E_{mv}-E_{00}}$$
$$+\frac{\hbar^2}{2}\sum_{mv}\int \chi_{00}(Q)\boldsymbol{\mu}^{0m}(Q)\chi_{mv}(Q)\mathrm{d}Q\,\frac{\int\chi_{mv}(Q)\int \phi_m(q,Q)\frac{\partial^2}{\partial Q^2}\phi_0(q,Q)\mathrm{d}q\chi_{01}(Q)\mathrm{d}Q}{E_{mv}-E_{01}}$$

where

$$[41]\quad \boldsymbol{\mu}^{0m}(Q) = \int \phi_0(q,Q)\boldsymbol{\mu}^{\mathrm{elec}}\phi_m(q,Q)\mathrm{d}q$$

To find the leading contribution from the first two terms, we approximate the electronic integral

$$\int \phi_m(q,Q)\frac{\partial}{\partial Q}\phi_0(q,Q)\mathrm{d}q$$

by the value at Q_0, and also put $\boldsymbol{\mu}^{0m}(Q) = \boldsymbol{\mu}^{0m}(Q_0)$. We then get

$$[42]\quad \hbar^2\sum \boldsymbol{\mu}^{0m}(Q_0)\left(\int \phi_m(q,Q)\frac{\partial}{\partial Q}(q,Q)\mathrm{d}q\right)_0\left\{\frac{1}{E_{mv}-E_{00}}\int \chi_{01}(Q)\chi_{mv}(Q)\mathrm{d}Q\int \chi_{mv}(Q)\frac{\partial}{\partial Q}\chi_{00}(Q)\mathrm{d}Q\right.$$
$$\left.+\frac{1}{E_{mv}-E_{01}}\int \chi_{00}(Q)\chi_{mv}(Q)\mathrm{d}Q\int \chi_{mv}(Q)\frac{\partial}{\partial Q}\chi_{01}(Q)\mathrm{d}Q\right\}$$

If the vibrational energy differences in the denominators are neglected, then closure over the intermediate state vibrational wavefunctions may be effected to give

$$[43]\quad \hbar^2\sum \frac{\boldsymbol{\mu}^{0m}(Q_0)}{E_m^0-E_0^0}\left(\int \phi_m(q,Q)\frac{\partial}{\partial Q}\phi_0(q,Q)\mathrm{d}q\right)_0\left\{\int \chi_{01}(Q)\frac{\partial}{\partial Q}\chi_{00}(Q)\mathrm{d}Q + \int \chi_{00}(Q)\frac{\partial}{\partial Q}\chi_{01}(Q)\mathrm{d}Q\right\}$$

The vibrational integrals within the braces are equal and opposite, so that the correction to this order is zero. However, if the vibrational energy differences are retained then there is a small residual term from [42].

The contribution from the last two terms of [40] is found in a similar manner. It is given by

$$[44]\quad \hbar^2\sum \frac{\boldsymbol{\mu}^{0m}(Q_0)}{E_m^0-E_0^0}\left(\int \phi_m(q,Q)\frac{\partial^2}{\partial Q^2}\phi_0(q,Q)\mathrm{d}q\right)_0\int \chi_{01}(Q)\chi_{00}(Q)\mathrm{d}Q$$

which is zero because of the orthogonality of the vibrational wavefunctions.

The calculations for the magnetic dipole transition moment follow similar lines, with the important difference that $\boldsymbol{m}^{0m} = -\boldsymbol{m}^{m0}$. The leading contribution from the analogues of the first two terms of [40] is

$$[45]\quad -2\hbar^2 \sum \frac{m^{m0}(Q_0)}{E_m^0 - E_0^0}\left(\int \phi_m(q,Q)\frac{\partial}{\partial Q}\phi_0(q,Q)\mathrm{d}q\right)_0 \int \chi_{01}(Q)\frac{\partial}{\partial Q}\chi_{00}(Q)\mathrm{d}Q$$

The analogues of the last two terms are zero as in the electric dipole case because of the orthogonality of vibrational wavefunctions.

The question of model dependence is here of special importance. Different model Hamiltonians involve values of nuclear charge Z_α chosen to accord with assumptions about which electrons are to be treated as part of a nuclear core. The nuclear contribution to the magnetic transition moment [38] is proportional to the Z_α, and if the total moment is to be independent of model, there must be compensation by the electronic contribution. Since there is no electronic contribution in the same (zeroth) order, as in the electric moment, we look for compensation from the higher order terms [45]. It is essential to keep these perturbation corrections as small as possible, especially if only first order corrections are taken, and therefore essential to choose a model with the lowest realistic values of effective nuclear charge.

Circular dichroism can appear in vibrational transitions of optically active molecules. The total transition rate for such a transition $|0,1\rangle \leftarrow |0,0\rangle$ is

$$[46]\quad \Gamma^{(R/L)} = \frac{2\pi}{3\hbar}\left(\frac{n\hbar ck}{2\epsilon_0 V}\right)|\langle 1,0|\boldsymbol{\mu} \pm i\boldsymbol{m}|0,1\rangle|^2\rho$$

the plus and minus signs holding for right- and left-circularly polarized light, respectively. Circular dichroism is given by the difference in absorption rates:

$$[47]\quad \langle\Gamma^{(L)}_{01,00}\rangle - \langle\Gamma^{(R)}_{01,00}\rangle = \frac{2I}{3\hbar^2 c\epsilon_0}R^{01,00}$$

where I is energy density per unit frequency and

$$[48]\quad R^{01,00} = \langle 0,0|\boldsymbol{\mu}|0,1\rangle\cdot\langle 1,0|\boldsymbol{m}|0,0\rangle$$

Using the expressions for the electric and magnetic transition moments calculated in the previous sections, the expression for $R^{01,00}$ follows directly.

Origin-dependence of transition moments and rotatory strength

It is well known that the matrix elements of the electric dipole moment are origin-independent in neutral molecules. Writing the electric dipole moment operator as

$$[49]\quad \boldsymbol{\mu} = \sum_\alpha e_\alpha \boldsymbol{r}_\alpha$$

where the sum is over all the charged particles, and displacing the origin of the vectors $\boldsymbol{r}_\alpha$ by $\boldsymbol{\rho}$, we find the change in dipole moment, $\Delta\boldsymbol{\mu}$ to be

$$[50]\quad \Delta\boldsymbol{\mu} = -\boldsymbol{\rho}\sum e_\alpha$$

which vanishes if the net charge on the molecule is zero. Since the result applies to the dipole operator it holds for the matrix elements of the dipole moment in any basis, exact or approximate.

The matrix elements of the magnetic dipole moment are, however, origin-dependent, even in an exact basis. Writing the magnetic dipole moment operator as

$$[51]\quad \boldsymbol{m} = \frac{1}{2}\sum_\alpha\left(\frac{e_\alpha}{m_\alpha}\right)\boldsymbol{r}_\alpha \times \boldsymbol{p}_\alpha$$

the change caused in the matrix elements of $\boldsymbol{m}$ by an origin displacement by $\boldsymbol{\rho}$ is

$$[52]\quad \Delta\boldsymbol{m}^{n0} = -\frac{1}{2}\sum_\alpha\left(\frac{e_\alpha}{m_\alpha}\right)\boldsymbol{\rho}\times\boldsymbol{p}_\alpha^{n0}$$

If $|0\rangle$ and $|n\rangle$ are exact eigenstates of the molecular Hamiltonian, we can replace the matrix elements of $\boldsymbol{p}_\alpha$ by those of $\boldsymbol{r}_\alpha$,

$$[53]\quad \boldsymbol{p}_\alpha^{n0} = -\left(\frac{m_\alpha}{i\hbar}\right)E_{n0}\boldsymbol{r}_\alpha^{n0}$$

where E_{n0} is the transition energy. Substitution in [52] gives

$$[54]\quad \Delta\boldsymbol{m}^{n0} = \left(\frac{E_{n0}}{2i\hbar}\right)\sum_\alpha e_\alpha\boldsymbol{\rho}\times\boldsymbol{r}_\alpha^{n0} = \left(\frac{E_{n0}}{2i\hbar}\right)\boldsymbol{\rho}\times\boldsymbol{\mu}^{n0}$$

where $\boldsymbol{\mu}^{n0}$ is the matrix element of the electric dipole transition moment. Thus $\boldsymbol{m}$ is origin-dependent since [54] is not, in general, zero. However, if the electric dipole transition moment is zero, then [54] vanishes and the magnetic dipole transition moment is origin-independent. Similarly, the electric quadrupole transition moment, which is of the same order as the magnetic moment, can be shown to be origin-independent when the electric moment is zero.

We next show that matrix elements for circular dichroism are origin-independent in an exact basis, but not generally. The optical rotatory strength for a transition $n \leftarrow 0$ is given by [55].

$$[55]\quad R^{n0} = \mathrm{Im}\,\boldsymbol{\mu}^{0n}\cdot\boldsymbol{m}^{n0}$$

If the origin is displaced by $\boldsymbol{\rho}$ the change in the rotatory strength is given by [56], taking account of the origin-independence of $\boldsymbol{\mu}$

$$[56]\quad \Delta R^{n0} = \epsilon_{ijk}\mathrm{Im}\,\mu_i^{0n}\rho_j\sum_\alpha\left(\frac{e_\alpha}{2m_\alpha}\right)p_{k(\alpha)}^{n0}$$

where the states are eigenstates of the molecular Hamiltonian [1], we use the result [54] for the change in the magnetic moment and find for the change in the optical rotatory strength

$$[57]\quad \Delta R^{n0} = \left(\frac{E_{n0}}{2i\hbar}\right)\epsilon_{ijk}\mathrm{Im}(\mu_i^{0n}\rho_j\mu_k^{n0}) = 0$$

the zero coming from the symmetry of the dipole moment product to i, j interchange coupled with the antisymmetry of ϵ_{ijk}. Thus for exact eigenfunctions, the pseudoscalar rotatory strength R^{n0} is independent of choice of origin. However, if approximate wavefunctions are used to describe the states, then the relation [53] between $\boldsymbol{p}$ and $\boldsymbol{r}$ does not hold, and the calculated circular dichroism depends on the origin chosen.

For many calculations the origin is mostly conveniently chosen at the centre of mass. Translational motion is then uncoupled, and rotational averages of transition rates for randomly oriented molecules, calculated for this origin, can be compared with experimental values.

The minimal coupling Hamiltonian and origin dependence

The problem of origin-dependence in calculated quantities may be analysed within a broader frame, including the radiation field as well as the molecule. Origin-dependence is then a property of observables such as transition rate, instead of molecular properties such as multipole moments. In the minimal coupling formalism, the total Hamiltonian may be partitioned as

$$[58] \quad H = H_{\mathrm{mol}} + H_{\mathrm{rad}} + H_{\mathrm{int}}$$

where H_{mol} and H_{rad} are the molecule and radiation Hamiltonians and the radiation-molecule coupling H_{int}, correct to order e, is

$$[59] \quad H_{\mathrm{int}} = \sum_{\alpha} (e_\alpha/m_\alpha)\boldsymbol{p}_\alpha \cdot \boldsymbol{a}(\boldsymbol{q}_\alpha)$$

In [59] $\boldsymbol{p}_\alpha$ is the momentum of the αth particle with charge e_α, and $\boldsymbol{a}(\boldsymbol{q}_\alpha)$ is the vector potential at the particle position $\boldsymbol{q}_\alpha$. The matrix element for the transition $n \leftarrow 0$ is found, by the standard procedure (10, 11)

$$[60] \quad M_{n0} = (\hbar/2\epsilon_0 ckV)^{1/2} \sum_{\alpha} (e_\alpha/m_\alpha)\boldsymbol{e}\cdot\langle n|\boldsymbol{p}_\alpha \exp(i\boldsymbol{k}\cdot\boldsymbol{q}_\alpha)|0\rangle$$

where $\boldsymbol{k}$ is the wavevector of the incident photon resonant with the transition frequency,

$$[61] \quad \omega = ck = (E_n - E_0)/\hbar$$

and $\boldsymbol{e}$ is the photon polarization vector.

For many calculations it is sufficient to retain the leading term of [60] found by expanding the exponential term. Retention of this term only corresponds to treating the vector potential as uniform over the molecule; it is the electric dipole term and evidently origin-independent. However, for calculation of quantities such as the differential absorption rates, it is necessary to retain the following term containing the first derivative of the vector potential. This adds the electric quadrupole and the magnetic dipole terms in the multipolar formalism. The matrix element to this order is

$$[62] \quad M_{n0} = (\hbar/2\epsilon_0 ckV)^{1/2} \sum_{\alpha} (e_\alpha/m_\alpha)e_i\{p^{n0}_{i(\alpha)} + ik_j(p_{i(\alpha)}q_{j(\alpha)})^{n0}\}$$

From the Fermi rule, it follows that the absorption rate Γ is proportional to the modulus square of the matrix element, so that the correction to the pure electric dipole contribution is

$$[63] \quad \Delta\Gamma \propto \bar{e}_i e_j \bar{p}^{n0}_i (p_j q_k)^{n0} k_k - e_i \bar{e}_j p^{n0}_i \overline{(p_j q_k)}^{n0} k_k$$

In [63] the summation over the charges is implicit. The correction term arises from the interference between the pure electric dipole term and the electric quadrupole and the magnetic dipole terms. Suppose we displace the origin by $-\boldsymbol{\rho}$ so that $\boldsymbol{q} \rightarrow \boldsymbol{q} + \boldsymbol{\rho}$. Then the change ΔΓ is proportional to

$$[64] \quad \bar{e}_i e_j \bar{p}^{n0}_i p^{n0}_j \rho_k k_k - e_i \bar{e}_j p^{n0}_i \bar{p}^{n0}_j \rho_k k_k$$

which is clearly zero, as may be seen by interchanging the indices i and j in one of the terms. Thus the transition rate to this order is origin-independent and the result holds for any basis functions, exact or approximate.

A similar analysis within the multipolar framework leads to the result that observables such as absorption rates are, in general, origin-dependent if approximate wavefunctions are used for the calculations. With exact wavefunctions the rates are origin-independent. To illustrate the origin-dependence with approximate wavefunctions, we consider circular dichroism which is proportional to the rotational strength R^{n0} for a randomly oriented system. Recalling that

$$[65] \quad R^{n0} = \mathrm{Im}\, \boldsymbol{\mu}^{0n}\cdot\boldsymbol{m}^{n0} = \frac{e^2}{2m}\,\mathrm{Im}\,\langle 0|\boldsymbol{r}|n\rangle\cdot\langle n|\boldsymbol{r}\times\boldsymbol{p}|0\rangle$$

a change of origin by $\boldsymbol{\rho}$ gives rise to the additional term

$$[66] \quad \frac{e^2}{2m}\,\mathrm{Im}\,\langle 0|\boldsymbol{r}|n\rangle\cdot\langle n|\boldsymbol{\rho}\times\boldsymbol{p}|0\rangle$$

To keep the arguments simple, it is assumed that the wavefunction for the ground state is exact and that for the excited state is approximate. The excited state wavefunction can be expanded according to [67]

$$[67] \quad |\phi_n\rangle = \sum_m c_m|m\rangle$$

where $|m\rangle$ are the eigenfunctions of H_{mol}. Then the ρ-dependent term [66] becomes

$$[68] \quad \frac{e^2}{2m}\,\mathrm{Im} \sum_{m,m'} c_m c_{m'} \boldsymbol{r}^{0m}\cdot(\boldsymbol{\rho}\times\boldsymbol{p}^{m'0})$$

using the identity [53], the above term can be re-written as

$$[69] \quad \frac{e^2}{2\hbar}\boldsymbol{\rho}\cdot\sum_{m,m'} c_m c_{m'} E_{m'0}\boldsymbol{r}^{0m}\times\boldsymbol{r}^{m'0} = -\frac{e^2}{4\hbar}\boldsymbol{\rho}\cdot\sum_{m,m'} c_m c_{m'}(E_{m'0} - E_{m0})\boldsymbol{r}^{0m}\times\boldsymbol{r}^{m'0}$$

which is not necessarily zero, thus demonstrating the origin dependence of rotational strength calculated using approximate wavefunctions.

Adsorption of CO has been investigated on the surfaces of polycrystalline transition metals as well as alloys by employing electron energy loss spectroscopy (eels) and ultraviolet photoelectron spectroscopy (ups). CO adsorbs on polycrystalline transition metal surfaces with a multiplicity of sites, each being associated with a characteristic CO stretching frequency; the relative intensities vary with temperature as well as coverage. Whilst at low temperatures (80–120 K), low coordination sites are stabilized, the higher coordination sites are stabilized at higher temperatures (270–300 K). Adsorption on surfaces of polycrystalline alloys gives characteristic stretching frequencies due to the constituent metal sites. Alloying, however, causes a shift in the stretching frequencies, indicating the effect of the band structure on the nature of adsorption. The up spectra provide confirmatory evidence for the existence of separate metal sites in the alloys as well as for the high-temperature and low-temperature phases of adsorbed CO.

Faisant appel à la spectroscopie par perte d'énergie électronique (spee) et à la spectroscopie photoélectronique ultraviolette (spu), on a étudié l'adsorption du CO sur des surfaces de métaux de transition polycristallins ainsi que sur des alliages. Le CO s'adsorbe sur les surfaces polycristallines des métaux de transition avec une multiplicité de sites et chacun est associé à une fréquence d'élongation du CO qui est caractéristique; les intensités relatives varient avec la température ainsi qu'avec le niveau de couverture. Alors qu'à basse température (80–120 K) les sites de basse coordination sont stabilisés, les sites de coordination plus élevée sont stabilisés à des températures plus élevées (270–300 K). L'adsorption sur des surfaces d'alliages polycristallins fournit des fréquences d'élongation caractéristiques qui sont dues aux sites métalliques qui les constituent. La formation d'alliages provoque toutefois un déplacement dans les fréquences d'élongation et la SPU fournit des données qui confirment l'existence de sites métalliques séparés dans les alliages ainsi que la présence de phases de haute ainsi que de basse températures pour l'adsorption du CO.

Introduction

Adsorption of carbon monoxide on single crystal surfaces of transition metals has been investigated extensively by employing ultraviolet photoelectron spectroscopy (ups) and electron energy loss spectroscopy (eels) (1–5). We considered it most valuable to investigate the adsorption of CO on polycrystalline metal surfaces by employing eels and ups because of the similarity between polycrystalline surfaces and catalyst surfaces, and to compare the results with those obtained on single crystal surfaces. Since eels is especially sensitive to the geometry of the adsorption site, the study was expected to throw light on the available sites on polycrystalline surfaces. We have carried out studies on several transition metals including Mn, Fe, Co, Ni, Cu, Pd, Pt, and Ag in order to compare the reactivity of the metals with respect to CO. After having obtained the information on the multiplicity of sites on polycrystalline metal surfaces, we have examined the adsorption of CO on the surfaces of polycrystalline binary alloys of copper (Cu–Mn, Cu–Ni, and Cu–Pd) in order to compare the behaviour with that on pure metal surfaces. The study of adsorption on binary alloys is expected to be of relevance to the behaviour of bimetallic catalysts.

Band structure of alloys is a subject of great interest and has been investigated widely by employing photoelectron spectroscopy (6–8). These studies have shown that while the d-bands essentially behave as predicted by the coherent potential model, the s-bands mix and fall into a rigid band (9). The rigid band model has interesting consequences for the adsorption of molecules such as CO on alloy surfaces. Alloys composed of metals varying widely in their reactivities would be expected to show intermediate reactivities. The phenomenon of chemisorption can thus be a potential tool for understanding the electron states of alloys. It was our interest to explore whether the reactivities of alloy surfaces could be designed to lie in between those of the constituent metal surfaces, and also to determine in what way the alloy reactivity depends on the alloy composition.

Experimental

All electron spectroscopic measurements were performed on the ESCA III Mark 2 and VG ESCALAB - EELS spectrometers of V.G. Scientific Ltd., England. Both the spectrometers are fitted with sample preparation chambers and independent gas handling systems for carrying out adsorption studies. The spectrometers have been described elsewhere (10, 11).

Polycrystalline foils of metals and their alloys were mounted on special temperature-variable probes and cleaned by etching with argon ions. At no time was the temperature of the sample allowed to go beyond 500 K. The X-ray photoelectron signals of the various impurity levels were monitored using AlKα radiation ($h\nu$ = 1486.6 eV) to ensure sample purity.

High purity CO gas was introduced into the chamber using precision leak valves and exposures were measured in Langmuirs (L) (1 Langmuir = 10^6 Torr-s; 1 Torr = 133.3 Pa).

It is well known that the surface composition of alloys varies greatly from the bulk composition due to surface segregation on annealing at high temperatures. The sample temperature was therefore not allowed to go beyond 500 K. The metal core levels in the alloys were carefully

TABLE 1. Bulk and surface composition of the alloys[a]

Alloy	Nominal (bulk) composition atom percentage	Surface composition atom percentage
Cu–Pd	8.9 Pd	9 Pd
Cu–Pd	24.6 Pd	25 Pd
Cu–Pd	50 Pd	49 Pd
Cu–Mn	25 Mn	11.3 Mn
Cu–Ni	80 Ni	75 Ni
Cu–Ni	40 Ni	42 Ni

[a]Sample temperatures were generally below 500 K and no alloy was annealed at higher temperatures.

monitored in the XPS, throughout the experiment, to characterize the surface composition. The surface compositions were calculated by employing the method described in the literature (12, 13) and, in Table 1, we show the nominal (bulk) and surface compositions of the alloys studied by us. It was found that etching did not alter the surface composition significantly. Throughout the text, we have shown only the nominal compositions.

The loss peak arising from the CO stretching vibration was decomposed into component peaks, each having a line shape identical to the shape of the elastic peak, by using a least-squares fit. The component spectra were shifted with respect to one another until the best fit between the recorded spectrum and the constructed spectrum was obtained. We have found loss peaks as narrow as the elastic peaks on some metal surfaces, where invariably a single species is present. We have illustrated one such instance in Fig. 1.

A similar treatment of the peak arising from the metal–C stretching vibration could not be carried out, due to its close proximity to the elastic peak.

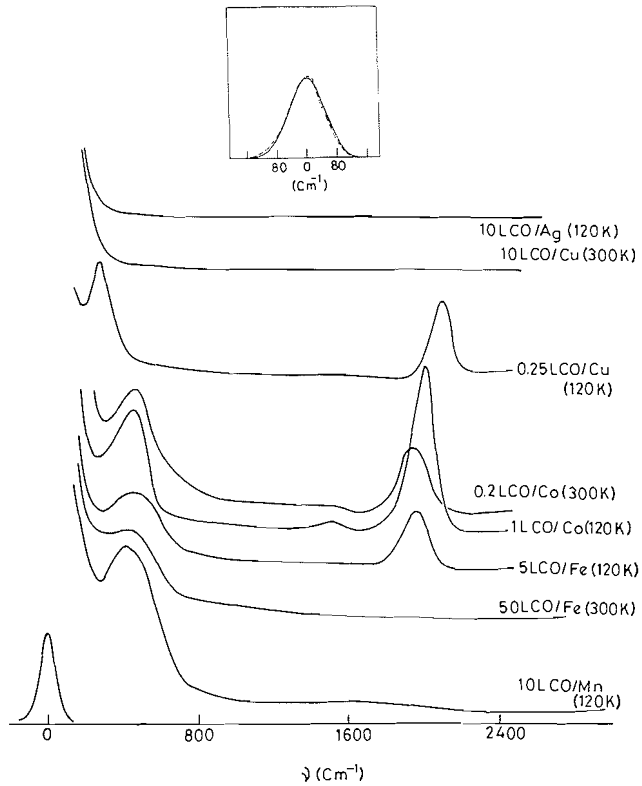

FIG. 1. Typical eel spectra of CO adsorbed on a series of first row transition metal surfaces. In the inset is shown a comparison of the elastic peak (full line) and the loss peak (dashed line) in the case of CO adsorbed on Cu (50 L) to illustrate that the two have an identical line shape.

Results and discussion

Adsorption of CO on polycrystalline metal surfaces by electron energy loss spectroscopy

Adsorption of CO on single crystal transition metal surfaces has been studied extensively and these results have been reviewed in the literature (14). The eels of chemisorbed CO shows two characteristic vibration frequencies due to the metal–carbon and the carbon–oxygen bond stretching modes. The appearance of the latter in eels suggests that the CO axis may be nearly perpendicular to the metal surface (15) as indeed established by LEED and other studies (16, 17).

CO binds to the metal site through its 5σ non-bonding orbital, while at the same time the metal back-donates substantial electron density into the 2π* level (18). This back-donation lowers the bond order in adsorbed CO, leading to a decreased stretching frequency. Depending on the strength of the metal–CO interaction, the CO stretching frequency lies in the ranges 1992–2110 cm^{-1}, 1850–1970 cm^{-1}, 1650–1850 cm^{-1}. Sheppard and Nguyen (19) have assigned these frequencies to CO in the linear, B_2 bridged, and B_4 bridged species. At step and kink sites, values of CO stretching frequencies as low as 1530 cm^{-1} are found (20). These values correspond well with those of the analogous transition metal complexes.

While the CO bond stretching frequency is known to vary with the change in the adsorption site, variation between the different single crystal surfaces is rather small for the same given site. Thus, while the B_2 bridged site and the linear on-top site show CO stretching frequencies of 1927 and 2064 cm^{-1} respectively on a Ni(100) surface (15), the B_2 bridged site on a Ni(111) surface shows a frequency of 1911 cm^{-1} (21). This shows that the effect of the surface structure of the adsorbent is secondary in nature. Similar conclusions have been derived by Broden *et al.* (23) in their systematic studies of the heats of adsorption of CO on transition metals.

In Fig. 1 we show typical eel spectra of CO adsorbed on a series of polycrystalline transition metal surfaces. The loss peaks are generally much broader than the elastic peaks in all cases, suggesting the existence of a multiplicity of adsorbed CO species on the polycrystalline metal surfaces. We have therefore decomposed the loss peak due to the CO stretch into several components in each case and the results of these analyses are summarized in Table 2. The loss peaks shift on increasing exposure, indicating the existence of strong lateral interactions in the adsorbate layer.

Polycrystalline Mn surfaces are extremely reactive to the adsorption of CO, on account of the very high enthalpy of formation of MnO and MnC (22). Accordingly, CO undergoes dissociative chemisorption on Mn at all temperatures ranging from 120–300 K and eel spectra show only a single loss peak in the low-energy range, corresponding to the Mn—O and Mn—C stretching frequencies.

Iron lies close to the border line (in the periodic table) separating metals which exhibit molecular adsorption of CO from those that exhibit dissociative adsorption (23). Consequently the behaviour of Fe is ambivalent and it adsorbs CO dissociatively at 300 K and molecularly at 120 K. In the low-temperature phase, the peak due to CO stretch is 60% broader than the elastic peak over the entire range of exposures, with a pronounced asymmetry on the lower-energy side. Decomposition of this peak into three distinct components yields the

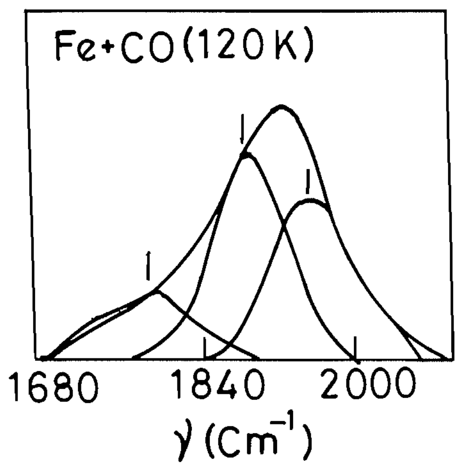

FIG. 2. CO stretching bands in eels of CO adsorbed on Fe along with the component peaks.

best fit between the recorded and the constructed spectra (Fig. 2); the three stretching frequencies at 1790, 1895, and 1967 cm^{-1} can be assigned to the B_4, B_2, and on-top linear species respectively. These frequencies progressively shift to 1846, 1935, and 2008 cm^{-1}, with increasing exposure (up to 60 L). These shifts could be due to adsorbate–adsorbate interaction. The nature of the species essentially remains unchanged. The 1895 cm^{-1} peak is about 47% in intensity over the whole range of exposures. The on-top linear species gains marginally in intensity at the expense of the B_4 species on increasing the exposure.

Cobalt exhibits molecular chemisorption of CO over the entire range of temperatures from 120–300 K. The nature of the species and their relative intensities, however, are different at 120 K and 300 K. At 120 K, we can discern three species with CO stretching frequencies at 1863, 1967, and 2040 cm^{-1}; the last of these, corresponding to the on-top linearly adsorbed species, grows rapidly with exposure to become the predominant species. At 300 K, the three peaks appear at 1822–1887, 1951, and 2016 cm^{-1}; with increasing exposure, the species at 1951 cm^{-1} grows in intensity at the expense of the species at 2016 cm^{-1}. The former is clearly due to the B_2 bridged CO while the latter is due to the linear on-top CO. While the on-top linear CO is the stable species at low temperatures (up to 120 K), the B_2 site appears to be the preferred site at 300 K.

CO adsorption on polycrystalline Ni shows characteristics identical to those on single crystal Ni surfaces (15). At low temperature (120 K), we see two stretching frequencies at 1927 and 2092 cm^{-1}, respectively, due to the B_2 bridged and linear on-top adsorption sites. In addition, a peak of low intensity is seen at 1790 cm^{-1}, which can be assigned to a CO bound to a higher coordination site. However, at 273 K, we do not see any CO stretch below 1800 cm^{-1}. At very low exposures (<1 L), we see two distinct peaks at 1887 and 2024 cm^{-1}. These two, however, merge at higher exposures to give a single broad peak with its maximum centred at 1967 cm^{-1}. This change has been attributed to a surface phase transition in adsorbed CO, in which a compression of the adsorbed layer lattice occurs (15).

Copper exhibits molecular chemisorption of CO at low temperatures (120–200 K) while at 300 K, even after prolonged exposure, no ad-layer pick-up is seen (Fig. 1). In the low-temperature phase, the peak due to the CO stretch is 20% broader than the elastic peak below 10 L exposure. The peak, however, gets progressively narrower and becomes as narrow as the elastic peak beyond 50 L; there is, however, no significant change in the peak position. We therefore sought to decompose the peaks at low exposures into two component peaks (see Fig. 3a); the decomposition yields two peaks at 2056 cm^{-1} and 2096 cm^{-1}, the intensity of the former progressively decreasing with increasing exposure. Clearly, at low exposures the presence of a large number of vacant sites permits the adsorption of CO in more than one geometry. On increasing the exposure, however, one of the species grows at the expense of the other (Fig. 3b).

CO adsorbs molecularly on Pd over the 120–300 K range forming a number of species. While the spectra at 300 K can be decomposed into three component peaks, spectra at 120 K show the existence of four peaks. The predominant peak at 300 K appears at 1935 cm^{-1}, having 50–60% of the total intensity, while the predominant peak at 120 K appears at 2000 cm^{-1}. The 1935 cm^{-1} peak is due to bridged B_2 CO, while the 2000 cm^{-1} peak is due to on-top linear CO. The low-temperature phase shows the existence of yet another weakly bound termi-

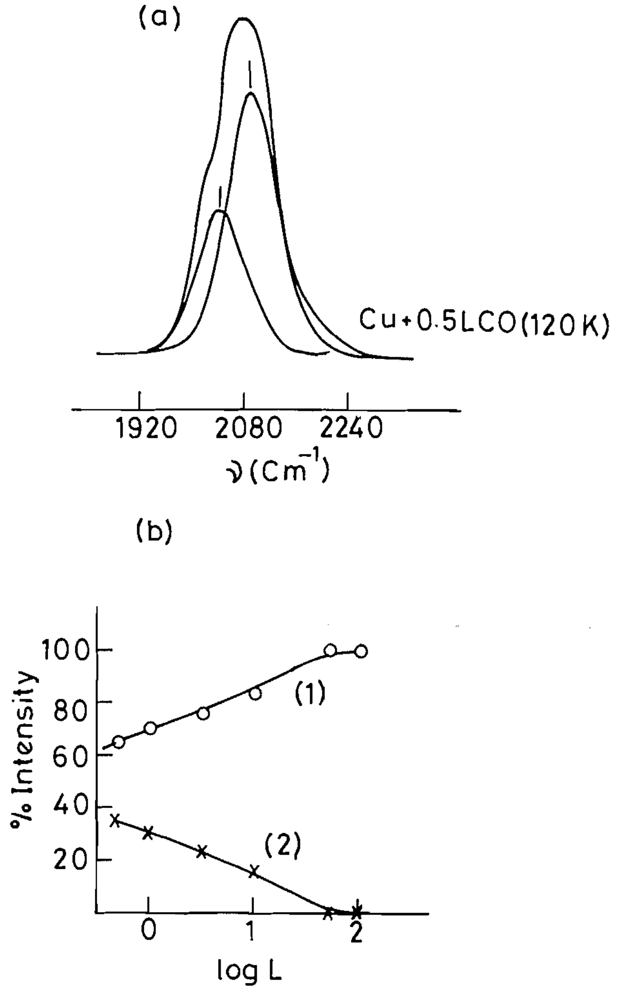

FIG. 3. (a) The eels of CO adsorbed on Cu showing the two-component peaks. (b) Variation of the intensity of the two-component peaks (expressed as a percentage of the total intensity) with exposure (in Langmuirs). Curve (1) is for the 2096 cm^{-1} peak and curve (2) is for the 2056 cm^{-1} peak.

nal CO at 2080 cm^{-1}, which is absent in the spectra recorded at 300 K. The predominant species in the 300 K spectra appears as the second most intense peak in the low-temperature spectra. The B_3 bridged CO at 1838 cm^{-1} appears with 11–25% intensity in the 300 K spectra, while at low temperature its intensity is ~10% of the total intensity. These observations indicate that at low temperatures the lower-coordination species are preferred, while at higher temperatures the higher-coordination species are preferred.

Pt also adsorbs CO molecularly at all temperatures from 120–300 K. At low exposures (<0.1 L at 300 K and <0.5 L at 150 K), we see a single sharp peak at 2064 cm^{-1}. On going to higher exposures, a second CO stretching peak at 1870 cm^{-1} appears. But the relative proportions of the two peaks remain unchanged on further exposure up to 1000 L. These two peaks can be readily assigned to the on-top linear (2064 cm^{-1}) and the B_2 bridge site (1871 cm^{-1}) adsorption respectively (Fig. 4). The proportion of the bridged site species is approximately 10% at 300 K and 16% at 150 K over a wide range of exposures.

Ag does not show any ad-layer pick-up, even on prolonged exposure to CO over the entire temperature range of 80–300 K. However, physisorption of CO seems to occur on Ag at temperatures below 50 K (24).

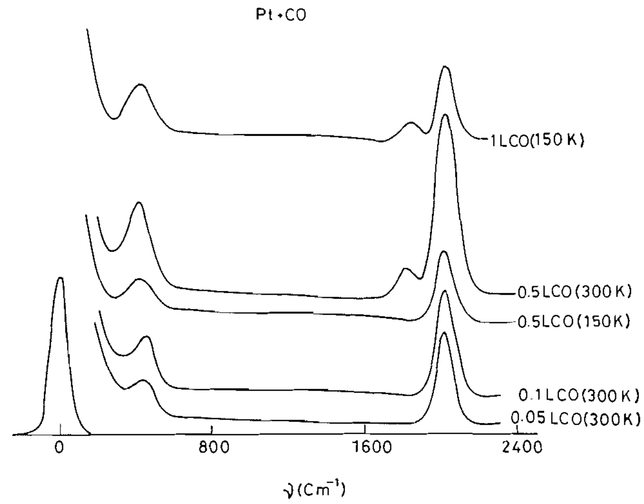

FIG. 4. The eel spectrum of CO adsorbed on polycrystalline Pt.

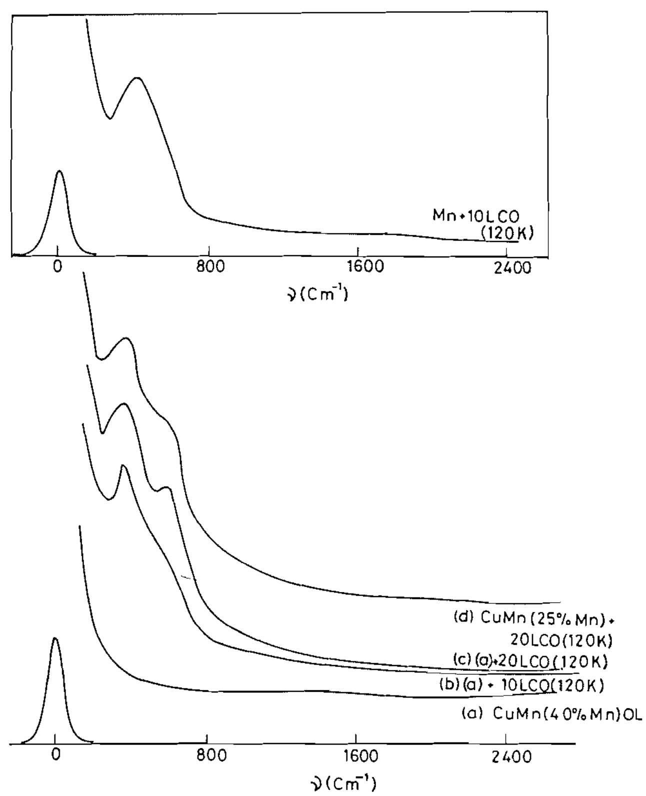

FIG. 5. The eel spectra of CO adsorbed on CuMn alloy surfaces. Inset shows the eel spectrum of CO adsorbed on polycrystalline Mn.

These studies of the adsorption of CO on polycrystalline metal surfaces suggest that the metal reactivity with respect to adsorption of CO varies in the order Mn ≈ Fe (300 K) > Fe (120 K) ≈ Co ≈ Ni ≈ Cu (120 K) > Cu (300 K) ≈ Ag. At one end we see dissociative chemisorption, while at the other end we see no chemisorption. We therefore thought it instructive to study the adsorption of CO on binary alloys of metals widely varying in their reactivities and also in the nature of adsorbed species they stabilize.

Adsorption of CO on polycrystalline alloy surfaces by electron energy loss spectroscopy

[a] Values in parentheses are peak positions observed at high exposures.

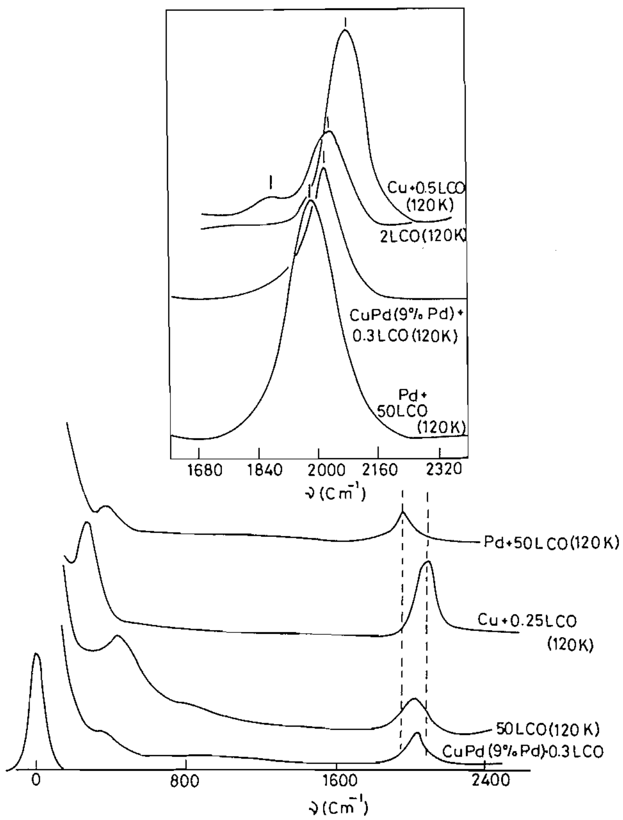

FIG. 6. The eel spectra of CO adsorbed on polycrystalline CuPd (9% Pd). Inset shows the peak due to the CO stretch. Vertical lines mark the peak positions.

25% Mn and 40% Mn are shown in Fig. 5. Two peaks at 371 cm^{-1} and 596 cm^{-1} can be seen and there are no peaks in the energy range 1700–2100 cm^{-1}. These two can be assigned to the metal–C and metal–O stretches of the mixed carbide–oxide layer arising from the dissociative chemisorption of CO on the alloy.

CO adsorbed on Cu–Ni alloys shows peaks at 1814, 1935, and 2088 cm^{-1} (Table 3), similar to those seen on Ni at low temperature (120 K). However, unlike those on pure Ni, the peaks do not merge at high exposures to give a single broad peak. It appears as though the Ni sites in Cu–Ni alloys are considerably different from those on pure Ni surface. Thus they exhibit features which are essentially those of Ni at low temperatures even at 273 K. It is, however, not clear if the Cu sites show adsorption at 273 K, for any such adsorption would lead to a peak at 2096 cm^{-1} (which cannot be explicitly resolved). The peak at 2088 cm^{-1}, however, has a much higher relative intensity in Cu–Ni alloys than in pure Ni, suggesting that the extra intensity could arise from the species adsorbed on the Cu sites of the alloy. We believe that the substantial changes found with the Cu–Ni alloys (compared to the parent metals) cannot be brought about by one of the metals merely acting as a spacer; this is particularly so in the Ni-rich alloys.

$Cu_{0.91}Pd_{0.09}$ does not show any ad-layer even after prolonged exposure to CO at 273 K. However, at lower temperatures (120 K), it shows a single peak at 2030 cm^{-1} at low exposures and two peaks at 1887 and 2056 cm^{-1} at higher exposures (Fig. 6). These two peaks can be attributed to CO stretching vibrations arising from the CO bonded to the Pd and the Cu sites respectively. As mentioned earlier, we observe two kinds of linearly adsorbed CO species on the surface of pure Cu, with stretching frequencies of 2056 and 2096 cm^{-1}. In $Cu_{0.91}Pd_{0.09}$ alloy, although the Cu and Pd sites remain distinct, it is the 2056 cm^{-1} species that is stabilized. This is indicative of a certain degree of mixing of the Cu and Pd bands on alloying. The Pd site shows a peak at 1887 cm^{-1}, which is different from those seen on pure Pd (Table 3).

In $Cu_{0.51}Pd_{0.49}$, low-temperature (120 K) adsorption gives rise to peaks at 1927 and 2096 cm^{-1}, probably due to CO adsorbed on Pd and Cu sites, respectively. At 273 K, there is a shift of the 2096 cm^{-1} peak to 2056 cm^{-1}, the latter corresponding to the peak found on Cu at low exposures (Fig. 7). It is noteworthy that on pure Cu there is no adsorption at 273 K.

Ultraviolet photoelectron spectra of CO adsorbed on polycrystalline metals and alloys

The up spectra of adsorbed CO generally consist of two peaks arising from the ($5\sigma + 1\pi$) and 4σ levels. This has been described in detail elsewhere (25). While CO adsorbed on Pd and Ni exhibits the characteristic two-peak spectrum in ups, CO adsorbed on Cu shows a complicated structure (Fig. 8) similar to that described by other workers (26). This distinct difference in the up spectra of CO adsorbed on Cu and other transition metals makes the study of CO adsorption on alloys feasible (Table 4).

The up spectrum of CO adsorbed on Cu–Mn alloys shows only one prominent peak at 6 eV below the Fermi level. Such a spectrum is characteristic of photoionization from the O(2p) level of atomic oxygen. This clearly shows that CO adsorbs dissociatively on the CuMn alloy surfaces (as also shown by eels); Cu–Mn alloys behave essentially like pure Mn, even in Cu-rich compositions.

The case of Cu–Pd alloys is more interesting. In Fig. 9 we show the up spectra of CO adsorbed on $Cu_{0.91}Pd_{0.09}$. At low exposures at 100 K we see the two-peak structure characteristic of CO adsorbed on Pd sites, although the peaks are substantially broader than on pure Pd (27). On increasing the exposure, the spectrum becomes more complicated, like that of Cu. This is understandable from the point of view of metal reactivity to

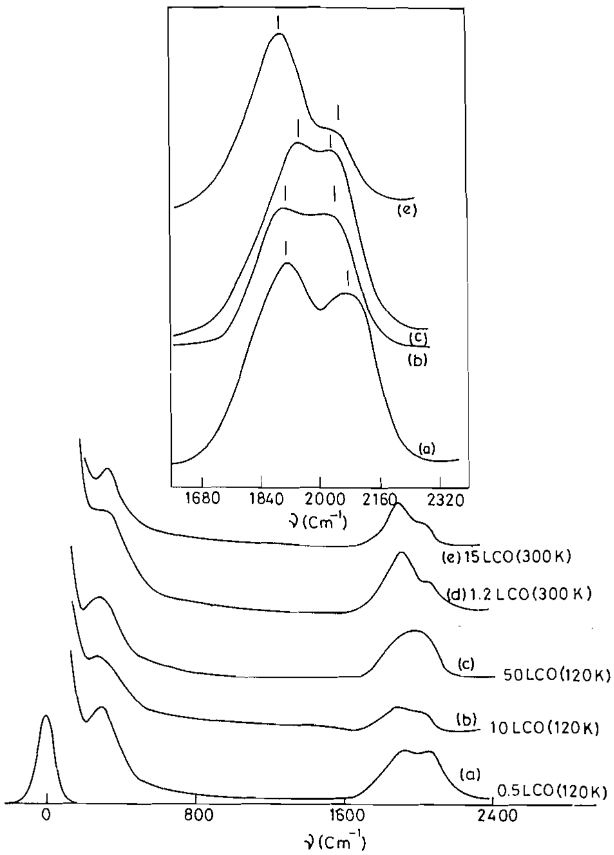

FIG. 7. The eel spectra of CO adsorbed on polycrystalline CuPd (49% Pd). Inset shows the peak due to CO stretch. Vertical lines mark the peak positions.

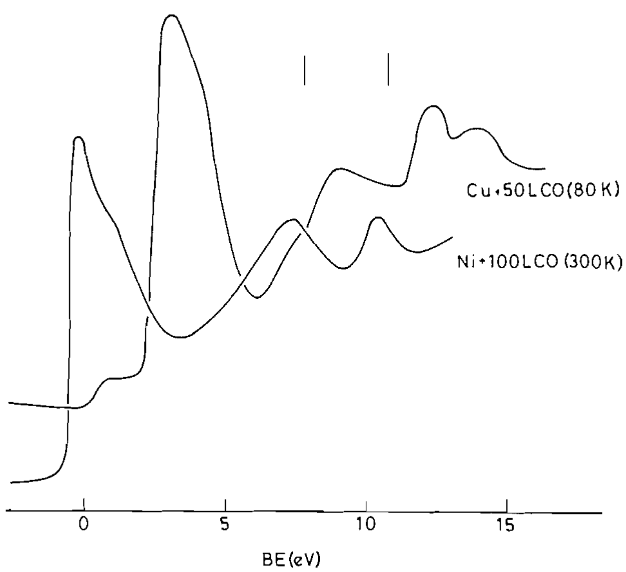

FIG. 8. Typical HeII spectra of CO adsorbed on polycrystalline Cu and Ni. Vertical lines in the figure mark the peak positions of CO adsorbed on polycrystalline Pd (ref. 27).

CO. Pd, being more reactive, gets covered first, the Cu sites being occupied only at higher exposures. On heating the alloy surface to 200 K, the spectral features revert to those found on the Pd surface. The high-temperature spectrum is much narrower and is shifted to lower energies. Such differences in the high-temperature and low-temperature phases have been observed earlier on $Cu_{0.08}Ni_{0.92}$ alloy (28) and can be attributed to adsorbate–adsorbate interactions. At 300 K, $Cu_{0.91}Pd_{0.09}$ does not show any CO pick-up, like Cu, while pure Pd metal adsorbs CO at room temperature.

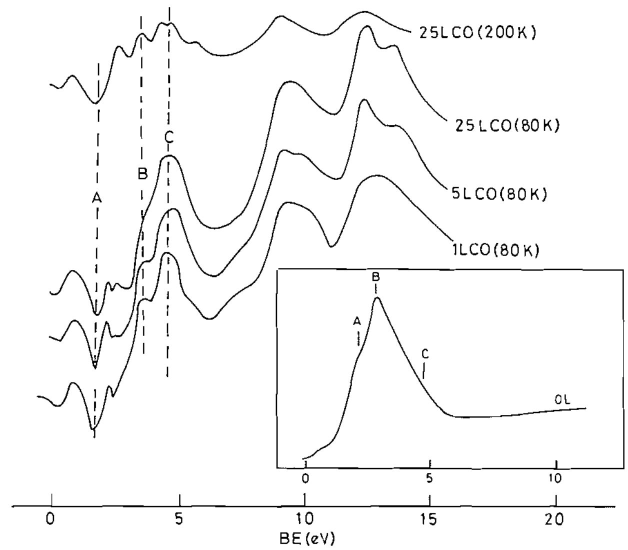

FIG. 9. Typical difference spectra for CO adsorbed on CuPd (9% Pd). For a description of the features marked A, B, and C, see the text.

[a]The features around 5 eV may be due to a level derived from the 5σ (CO) or a metal d $\pm$ $2\pi^*$ (CO) level.

The region of the spectrum in the energy range 0–5 eV is extremely interesting. The valence band of clean $Cu_{0.91}Pd_{0.09}$ alloy shows a new feature A, in addition to the s-band and d-band of pure Cu; the latter is marked B in Fig. 9. Feature A is clearly the contribution of Pd to the alloy valence band. On exposing the clean surface to CO, an additional feature marked C grows on the higher binding energy side of the alloy valence band. These peak shape changes are exemplified in the difference spectra shown in Fig. 9. The region A, where Pd contributes to the alloy valence band, clearly shows a depletion in electron density, while the region B clearly shows substantial remnant d-band electron density. The feature C appearing at ~4.8 eV is intense. We can conclude from these changes that the Pd sites are mainly responsible for electron transfer from the alloy to the adsorbed CO molecule. While it is possible that the feature C could be due to a 5σ-metal (d) derived level, we cannot preclude the possibility of its arising rom $\psi_{metal} \pm \psi_{2\pi^*(CO)}$ type of levels, which are expected to lie close to the Fermi level (29, 30). The nature of the spectrum remains essentially unchanged in the high-temperature phases of adsorbed

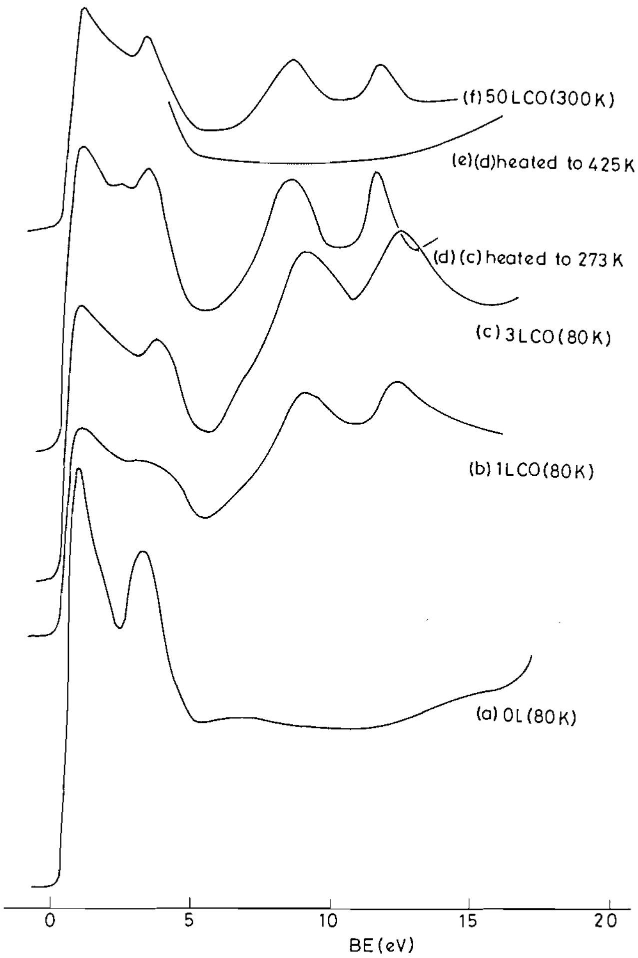

FIG. 10. Typical HeII spectra of CO adsorbed on polycrystalline CuNi (80% Ni) alloy.

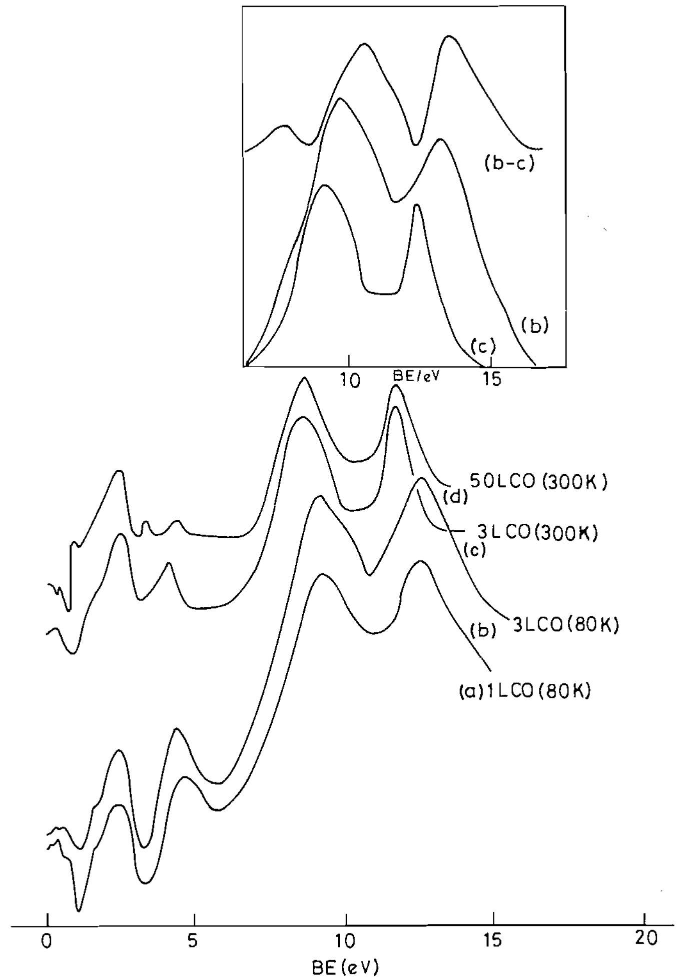

FIG. 11. Typical difference spectra for CO adsorbed on polycrystalline CuNi (80% Ni) alloy. Inset shows the spectra of low and high temperature phases of adsorbed CO.

CO, thus indicating that the nature of alloy–CO bonding also remains essentially unchanged.

In $Cu_{0.75}Pd_{0.25}$, adsorption characteristics of CO are identical to those seen in the case of pure Pd. There is, however, a small shift towards lower binding energy in the room temperature adsorbed phase compared to the low-temperature (80 K) adsorbed phase. The features in the 0–5 eV region remain similar to those observed in the case of $Cu_{0.91}Pd_{0.09}$ alloy.

$Cu_{0.60}Ni_{0.40}$ behaves similar to the $Cu_{0.91}Pd_{0.09}$ in that it shows a two-peak spectrum characteristic of CO adsorbed on the Ni sites at low exposures, while at higher exposures a complex spectrum similar to that found on Cu surface is seen. Warming the surface gives back the two-peak (Ni-like) spectrum, which is shifted to lower energies by nearly 1 eV.

$Cu_{0.20}Ni_{0.80}$ shows the two-peak spectrum characteristic of CO adsorbed on Ni at all exposures and over the entire 80–300 K range (see Fig. 10). There is, however, a 1-eV shift in the binding energies of the low- and high-temperature adsorbed phases, as in the case of the other alloys (see Fig. 11). The difference spectra with the Cu–Ni alloys show the existence of a third peak in the low-energy (0–5 eV) region similar to the one seen in the case of $Cu_{0.91}Pd_{0.09}$. The Ni d-band shows considerable depletion in electron density on adsorption of CO, showing thereby that Ni plays a role analogous to that of Pd in CuPd alloys.

Although eels shows the existence of several species in metals and alloys, ups seems to more clearly distinguish the different metal sites in alloys. The eels also provides information about the stereochemistry of the various adsorbed species.

Potentiel d'erreur et seconde quantification: application à la corrélation

ALEXANDRE LAFORGUE

Laboratoire de Mécanique Ondulatoire Appliquée, B.P. 347, Université de Reims, 51062 Reims Cedex, France

Reçu le 20 août 1984

Cet article est dédié au Professeur Camille Sandorfy à l'occasion de son 65[e] anniversaire

ALEXANDRE LAFORGUE. Can. J. Chem. **63**, 1788 (1985).

On soumet à un nouvel examen une méthode reposant sur le concept de potentiel d'erreur. La correction perturbative de l'erreur est analysée sur l'exemple de la corrélation. On peut substituer à un ensemble d'opérations dont le résultat ne peut être linéaire un opérateur de "perturbation corrective de l'erreur" indicé d'une configuration qui, lui, est linéaire dans tout l'espace des interactions. Sommant sur toutes les configurations, on parvient à un opérateur de correction linéarisée de l'erreur (Cle) indicé du rang de la correction et dont l'itération indéfinie réalise l'interaction de configuration complète, sans processus de diagonalisation. Une récurrence rapidement convergente permet la détermination de cet opérateur et son itération réalise un opérateur de corrélation adapté à toutes les configurations de la base. La seconde quantification permet de développer en polynomes de création–destruction tant la correction linéarisée de l'erreur que la corrélation globale. L'une et l'autre peuvent faire l'objet d'un développement en grappes. La matrice d'excitation apparait alors comme la somme d'une série de matrices calculables par perturbation.

ALEXANDRE LAFORGUE. Can. J. Chem. **63**, 1788 (1985).

We reexamine an error potential method. The so-called "perturbative error correction" is analysed on the pattern of the correlation problem. In the whole C.I. space the idea of a perturbation correction of each w.f., cannot lead to a linear operator. But a restriction of this process to the uncorrelated q-configurations only permits proposing a q-operator which is of linear form in the whole C.I. space. Summing over q we obtain a Cle$_r$ operator adapted to an r-repetitive method which performs the whole C.I. without diagonalization. On the other hand Cle$_r$ is determined by a rapidly convergent, recurrent process. Its r-times product has as a limit a correlation operator adapted to all the electronic configurations. Now, the second quantization formalism expands under a polynomial form both the cle$_r$ and the correlation operator. Both these operators can be expanded in clusters. Then the excitation matrix appears to be a sum of an infinite set of r-matrices which can be determined by an ordinary perturbation.

I. Introduction

I-1. *Historique*

J'ai rencontré Camille Sandorfy à Paris dès 1949 et il a guidé mes premiers pas dans les calculs de la chimie quantique. C'est pourquoi je voudrais consacrer cet article à un nouvel examen d'un sujet que j'ai développé à cette époque.

La théorie la plus séduisante était alors celle des chaînes organiques conjuguées (1) et des cycles aromatiques, où les approximations de Hückel en méthode des orbitales moléculaires donnent un accord étonnant avec l'expérience. Mais l'introduction des hétéroatomes étant un problème mal résolu, je tentais, comme beaucoup (2), de développer une extension cohérente (3–6). Dans notre cas, le concept d'approximations physiques successives corrigeant les contradictions du modèle (par exemple, modèration des moments polaires (7), ou, au contraire, apparition de moments polaires négligés en première approximation (8)) s'exprimait par l'emploi systèmatique de l'effet de charge (3), de l'effet de valence libre (4). Il conduisait à la recherche de l'erreur (9).

L'interaction de configuration (10–12) fournissait d'autre part un modèle intéressant de représentation de l'erreur (12–14). L'une des configurations en effet, largement dominante en général, peut être dite l'approximation non correllé et chacune des autres, si nombreuses soient-elles, n'est que l'une des composantes de l'erreur sur la fonction d'onde. Elle invite plus généralement encore à comparer toute approximation proposée à la solution rigoureuse (15).

I-2. *Potentiel d'erreur*

La notion introduite à cette fin est très simple et très générale (16–20). C'est le potentiel d'erreur que l'on doit ajouter au potentiel d'un système pour retrouver comme solution telle fonction approchée que l'on désire. Il est défini dans l'espace de configuration mais reçoit parfois une signification physique directe.

Ce potentiel permet soit l'analyse de l'erreur, soit sa correction (soit sur les structures, soit sur l'énergie) par des méthodes soit variationnelles soit perturbatives.

Une correction perturbative par le potentiel d'erreur attache à toute fonction d'onde une autre "meilleure", cette qualité étant précisée par le calcul de l'erreur à craindre sur les diverses grandeurs physiques. On est donc conduit à une correction indéfinie de l'erreur. Par exemple on résoud le problème de l'interaction de configuration, ce processus ayant pour effet de diagonaliser la matrice Hamiltonienne.

On imagine enfin des algorithmes élargissant le domaine de recherche au fur et à mesure que l'on progresse vers la solution optimale (21).

Les possibilités d'applications ne semblent pas limitées à un type étroit de problèmes. Le potentiel d'erreur intervient dans la compréhension des forces quantiques (20), dans la discussion de l'équation d'onde (21, 22), dans chacun des modes de construction des fonctions d'onde moléculaires.

Ainsi, les effets de charge et de valence libre étaient expliqués, les conséquences de l'interaction de configurations étaient interprétées, mais surtout on pouvait conclure qu'un problème essentiel de la chimie quantique était résolu: construire par des algorithmes répétitifs des fonctions d'onde s'approchant, autant qu'il est requis, de la solution exacte avec une incertitude calculable à l'avance sur une grandeur physique donnée.

I-3. *Discussion du potentiel d'erreur*

Or, trente ans plus tard, on constate que cette voie qui a pu séduire n'a pas été généralement suivie. Pourtant des formes particulières du potentiel d'erreur ont été retrouvées indépendamment par différents auteurs de 1960 à 1980: potentiel de fluctuation de Sinanoglu (23*a*); développements de Nesbet

(23b); méthodes d'interaction de configuration basées sur la théorie, telle M R D C I (23c) ou C I P S I (23d); théorie des paires d'electrons couplés de Cizek et Paldus (24a). D'autre part on assiste, dans la même période, au développement de la littérature sur le calcul d'erreur (voir par exemple la réf. 24b).

Enfin on peut citer, à l'actif de la théorie, des filiations avec les pseudo-potentiels (voir la réf. 24c), et plus généralement avec les Hamiltoniens effectifs, avec les techniques itératives de détermination des structures moléculaires, avec l'analyse d'une fonction d'onde en orbitales de recouvrement maximum (24d), sans parler de l'épistémologie de la chimie quantique.

Certes en 1954, le calcul électronique (sous une forme qui nous semble très archaïque) commençait tout juste à être mis en oeuvre en chimie quantique (3).

Mais je ne vois qu'une seule raison intrinsèque à la rareté d'utilisation de la théorie initiale: si nous envisageons, sous sa forme la plus directe, la perturbation corrigeant le potentiel d'erreur, *l'opérateur qui la représente globalement ne peut être linéaire*. Cette non-linéarité contrarie les formalismes mathématiques usuels, les habitudes de pensée, entraîne des difficultés pratiques.

I-4. *Objet de cet article*

Dans ce travail, nous essayons d'une part de surmonter cet obstacle, d'autre part de rattacher l'idée d'une correction perturbative de l'erreur au développement des méthodes de seconde quantification (24a, 25–27). Notre fil directeur sera la linéarisation de cet opérateur. Notre exemple privilégié sera celui de la corrélation.

On parvient d'abord à une formulation précise de cet opérateur implicite en se restreignant aux configurations pures, non correllées. Sommant sur ces configurations, on parviendra à un opérateur de "correction linéaire de l'erreur" (Cle). Une récurrence rapidement convergente détermine ces opérateurs.

Cet opérateur linéarisé s'exprime très directement dans les termes de la seconde quantification. Il en est de même du résultat d'une infinité d'itérations qui est un opérateur de corrélation adapté à toutes les configurations. L'un et l'autre pourront être développés en grappes (expanded in clusters). La matrice d'excitation apparaitra alors comme la somme d'une série de matrices attachées aux corrections successives. Ce nouvel accès aux méthodes de seconde quantification éclaire leur signification physique, semble permettre une nouvelle analyse de leurs résultats et de leurs extensions possibles, suggère une méthode alternative de calcul de la matrice d'excitation et donc des abaissements d'énergie.

II. Correction répétée du défaut de corrélation par perturbation

II-1. *Principe*

La chimie quantique construit fréquemment des fonctions non correllées. Il en résulte (17) un potentiel d'erreur. La correction perturbative de l'erreur représentée par ce potentiel, puis par les potentiels d'erreur successifs attachés aux fonctions de plus en plus correllées, constitue une méthode de correction indéfinie du défaut de corrélation.

Plus précisément, considérons un ensemble **U** d'orbitales moléculaires orthonormées l'ensemble $\{j\}$ des spinorbitales j correspondantes, l'ensemble $\{\phi\}$ des fonctions déterminants ϕ construites sur ces spinorbitales, l'ensemble des fonctions de configuration Γ construites sur ces déterminants et sous-tendant un espace $\mathscr{E}$. On peut indicer les Γ de $q = 0$ à $Q - 1$, selon les valeurs croissantes de l'intégrale

$$E_q = \langle \Gamma_q | \hat{H} | \Gamma_q \rangle$$

déduite de l'Hamiltonien $\hat{H}$. À chaque valeur de q correspond, souvent sans ambiguïté, un état propre $|\Lambda, q\rangle$ de $\hat{H}$ appartenant à une énergie propre W_q. La représentation $(\hat{H})$ de $\hat{H}$ dans $\mathscr{E}$ définit $|\Lambda^{\mathrm{IC}}, q\rangle$ et W_q^{IC} par interaction de configuration (IC) dite complète. La suite $|\Gamma, q\rangle$, E_q est l'approximation non correllée de la suite $|\Lambda^{\mathrm{IC}}, q\rangle$, W_q^{IC}, elle-même approximation de la suite $|\Lambda, q\rangle$, W_q. Il lui correspond la suite des potentiels d'erreur

$$[1] \qquad \mathscr{V}_q = (\Gamma, q)^{-1} (E_q - \hat{H}) (\Gamma, q)$$

(Nous ecrivons ici (Γ, q) parce qu'il s'agit de la forme analytique de la fonction et non du vecteur d'état.)

Nous avons proposé de représenter un opérateur de corrélation convenant à un état q par le produit d'une suite infinie de corrections approchées. Dans $\mathscr{E}$ ces divers opérateurs sont représentés par des matrices $(\hat{\mathbf{C}}_q)$ de telle sorte que

$$[2] \qquad |\Lambda^{\mathrm{IC}}, q\rangle = (\hat{\mathbf{C}}_q)\, |\Gamma, q\rangle$$

Ces corrections successives font intervenir une chaîne de fonctions approchées $|\psi, r\rangle$ depuis $|\Gamma, q\rangle$ jusqu'à $|\Lambda^{\mathrm{IC}}, q\rangle$:

$$[3] \qquad |\psi_0, q\rangle \equiv |\Gamma, q\rangle$$

$$[4] \qquad |\psi_\infty, q\rangle \equiv |\Lambda^{\mathrm{IC}}, q\rangle$$

Par définition la "correction perturbative de l'erreur, pour le niveau q approché", est *la perturbation par un potentiel* $-\mathscr{V}_q$ *– opposé du potentiel d'erreur*. Nous admettons ici que $|\psi_r, q\rangle$ ne peut être une moins bonne approximation que $|\psi_{r-1}, q\rangle$. Dans une discussion plus complète, on introduit un coefficient modulant ce potentiel (17), et on démontre la proposition précédente.

Le modèle d'un espace des interactions de configuration ainsi construit va nous servir dans les chapitres II et III, à développer la théorie selon des formules indépendantes de l'idée physique de corrélation. La corrélation proprement dite sera introduite au chapitre IV avec le formalisme de la seconde quantification.

II-2. *Réalisation de la perturbation corrective de l'erreur pour le niveau* q

Pour effectuer la correction perturbative, nous avons suggèré (17) d'utiliser formellement l'expression de Schrödinger en remplaçant la suite des états propres de $\hat{H} + \mathscr{V}_r$ par l'ensemble fini des $|\psi_r, q\rangle$ obtenus pour les divers niveaux q. Cette base est donc variable avec le rang r de l'itération.

Or la base obtenue par le perturbation seule, nécessairement tronquée à un ordre fini, n'est pas orthogonale. Nous pouvons soit adapter la formule des perturbations à une base oblique (17, Note 50, paragraphe XIII, 4), soit construire une base orthogonale $|\psi_r', q\rangle$ à partir d'une base oblique $|\theta_r, q\rangle$ selon un processus connu:

$$[5a] \qquad |\psi_r', q\rangle = |\theta_r, q\rangle + \sum_{r=0}^{q-1} \mu_p^{(r)}\, |\theta_r, p\rangle\, \langle \psi_r', p | \psi_r, q\rangle$$

$$[5b] \qquad p = 0, \ldots q - 1$$

Normalisons:

$$[6a] \qquad |\psi_r, q\rangle = \nu_r^q |\psi_r', q\rangle$$

$$[6b] \qquad (\nu_r^q)^2 \cdot \langle \psi_r', q | \psi_r', q\rangle = 1$$

Les Q equations [5] définissent les coefficients $\mu_p^q(r)$. La base construite $|\psi_r, q\rangle$ est la même pour l'étude de chaque niveau q, bien que ne contenant généralement pas $|\theta_r, q\rangle$ si $q \neq 0$.

On peut alors effectuer la perturbation par l'opposé du potentiel d'erreur sur $|\psi_r, q\rangle$:

$$[7a] \quad |\theta_{r+1}, q\rangle = |\psi_r, q\rangle + \sum_{p \neq q} \left[\rho_{pq}^{(r)} + \sum_{p \neq m \neq q} \rho_{pm}^{(r)} \rho_{mq}^{(r)} + \ldots \right] |\psi_r, p\rangle$$

$$[7b] \quad \delta_{r+1} E_q = \sum_{p \neq q} \rho_{pq}^{(r)} H_{pq}^{(r)} + \ldots.$$

$$[7c] \quad H_{pq}^{(r)} = \langle \psi_r, p|\hat{H}|\psi_r, q\rangle \quad \text{etc.} \ldots$$

$$\rho_{pq}^{0}(r) = \frac{H_{pq}^{(r)}}{H_{qq}^{(r)} - H_{pp}^{(r)}} \quad \text{etc.} \ldots$$

base orthogonale $\mathcal{A}$:

$$[8a] \quad \rho_{pq}^{(r)} = \rho_{pq}^{0}(r) \qquad \mu_p^q(r) \text{ selon } [5a,b]$$

base oblique $\mathcal{B}$:

$$[8b] \quad \mu_p^q(r) = 0 \qquad \rho_{pq}^{(r)} = \rho_{pq}^{0}(r) \left[1 - \frac{H_{pp}^{(r)}}{H_{pq}^{(r)}} \langle \psi_r, p|\psi_r, q\rangle \right]$$

Le potentiel d'erreur n'a ainsi servi que d'intermédiaire de calcul (17). On vérifie que dans le développement $\delta_r E_q$ de l'énergie de perturbation, la perturbation première est nulle.

Les vecteurs $|\psi_r, q\rangle$ constituent les approximations successives du vecteur $|\Lambda^{IC}, q\rangle$. Il résulte de la discussion (17, 19) que le processus [7a], [5] diminue l'erreur à craindre sur l'énergie. D'autre part il ne se ramène à l'opérateur identité que si

$$H_{pq}^{(r)} = 0 \quad \forall p$$

c'est-à-dire si l'on est parvenu à un vecteur propre de $\hat{H}$.

L'application de [7a], [6] aux divers niveaux résoud le problème de l'interaction de configuration complète en évitant la résolution des systèmes d'équations linéaires correspondantes mais avec l'obligation de redéfinir une base $\mathcal{A}$ ou $\mathcal{B}$ de $\mathcal{E}$ selon les équations [5], [6]... à chaque élévation de rang r.

Nous allons vérifier ces propriétés sur le modèle à deux niveaux et déterminer dans ce cas la vitesse de convergence.

II-3. *Modèle à deux niveaux*

Soit la matrice Hamiltonienne réelle

$$(\hat{H}) = \begin{pmatrix} E_0 & E_{01} \\ E_{01} & E_1 \end{pmatrix}$$

représentant $\hat{H}$ dans $\mathcal{E} = |\Gamma, 0\rangle \otimes |\Gamma, 1\rangle$. Ses valeurs propres sont

$$[9a] \quad \begin{aligned} W_0^{IC} &= \frac{E_0 + E_1}{2} - \frac{E_0 - E_1}{2 \cos \omega} \\ W_1^{IC} &= \frac{E_0 + E_1}{2} + \frac{E_0 - E_1}{2 \cos \omega} \end{aligned}$$

ses vecteurs propres sont

$$[9b] \quad \begin{aligned} |\Lambda^{IC}, 0\rangle &= \cos \omega\, |\Gamma, 0\rangle + \sin \omega\, |\Gamma, 1\rangle \\ |\Lambda^{IC}, 1\rangle &= \sin \omega\, |\Gamma, 0\rangle + \cos \omega\, |\Gamma, 1\rangle \end{aligned}$$

en posant

$$[9c] \quad \text{tg } 2\,\omega = \frac{2E_{10}}{E_1 - E_0} = 2\rho_{01}^{0}(0)$$

Retrouvons ces résultats par la correction indéfinie de potentiel d'erreur selon les formules [5], [6] et [7a,c]. Pour cela, utilisons le référentiel orthogonal mobile. L'itération de rang r s'écrit, après re-normalisation:

$$[10a] \quad |\psi_r, 0\rangle = \cos \gamma_r\, |\psi_r, 0\rangle + \sin \gamma_r\, |\psi_r, 1\rangle$$

$$[10b] \quad |\psi_r, 1\rangle = \sin \gamma_r\, |\psi_r, 0\rangle + \cos \gamma_r\, |\psi_r, 1\rangle$$

en posant

$$[10c] \quad \text{tg } \gamma_r = \rho_{01}^{0}(r)$$

On observe que [10a] est entièrement déterminé par la perturbation [7a] alors que [10b] est déterminé par l'orthogonalisation [6a,b]. On remarque la différence entre la formule [9c] qui détermine l'interaction de configuration et [10c] qui détermine la correction perturbative de l'erreur. À la première itération

$$[10d] \quad \text{tg } \gamma_0 = \tfrac{1}{2} \text{ tg } 2\omega$$

Lorsque l'erreur est petite,

$$\omega \simeq \frac{E_{10}}{E_1 - E_0} \simeq \gamma_0$$

la première correction conduit très près de l'interaction de configuration complète, l'erreur étant donnée par

$$[10e] \quad \gamma_0 - \omega = -\frac{1}{2} \left(\frac{E_{01}}{E_1 - E_0} \right)^3$$

Revenant au réferentiel fixe $|\Gamma, 0\rangle$, $|\Gamma, 1\rangle$.

$$[11a] \quad \begin{aligned} |\psi_r, 0\rangle &= |\Gamma, 0\rangle \cos \alpha_r + |\Gamma, 1\rangle \sin \alpha_r \\ |\psi_r, 1\rangle &= -|\Gamma, 0\rangle \sin \alpha_r + |\Gamma, 1\rangle \cos \alpha_r \end{aligned}$$

Nous avons (17, Note 51 du paragraphe XVI, 5) la relation de récurrence, équivalente à [10d] à la rotation près du réferentiel:

$$[11b] \quad \text{tg } (\alpha_r - \alpha_{r-1}) = \tfrac{1}{2} \text{ tg } 2(\omega - \alpha_{r-1})$$

La récurrence [11b] entraîne

$$[11c] \quad |\alpha_r - \alpha_{r-1}| \langle |\omega - \alpha_r|$$

et la suite α_r ne peut diverger.

Lorsque l'itération se poursuit

$$[11d] \quad \omega = \lim_{r \to \infty} \alpha_r = \sum_{r=0}^{\infty} \gamma_r$$

$$\lim_{r \to \infty} |\psi_r, 0\rangle = |\Lambda^{IC}, 0\rangle \qquad \lim_{r \to \infty} |\psi_r, 1\rangle = |\Lambda^{IC}, 1\rangle$$

Posant $\alpha_r - \omega = \epsilon_r$, on trouve par un développement limité de [11b], lorsque ϵ_r est suffisement petit (ou par usage du résultat [10e])

$$[11e] \quad \epsilon_r \simeq -\tfrac{1}{2} \epsilon_{r-1}^3$$

qui assure une convergence vers 0 par valeurs alternées. Plus précisément, cette convergence est analogue à celle de la suite

$$[11f] \quad \epsilon_r \approx (-1)^r \sqrt{2} \exp{(-3^r)} \text{ radian}$$

L'erreur correspondante sur l'énergie est:

$$\Delta E \simeq \epsilon_r^2 (E_0 + E_1)$$

À la quatrième itération

$\epsilon_r \approx 10^{-37}$ radian

$$\frac{\Delta E}{0{,}5\,(E_0 + E_1)} \approx 10^{-74}$$

Si nous désignons un opérateur de rotation dans le plan $\mathscr{C}$ par l'angle de rotation surmonté du symbole opérateur, les équations [10*a*,*b*], [11*a*] et [9*b*] s'écrivent encore pour $p = 1{,}2$

[12*a*] $|\psi_r, p\rangle = (\hat{\gamma}_r)\,|\psi_r, p\rangle$

[12*b*] $|\Gamma, p\rangle = (\hat{\alpha}_r)\,|\Gamma, p\rangle$

[12*c*] $|\Gamma, p\rangle = (\hat{\omega})\,|\Gamma, p\rangle$

Les angles γ_r, α_r, ω sont définis respectivement par [10*c*], [11*b*] et [9*c*] et vérifient [11*d*].

Nous allons généraliser les transformations [12*a*,*b*,*c*].

II-4. *Modèle à plusieurs niveaux*

Compte tenu de la discussion du paragraphe II-2 on peut dans les deux options représenter la perturbation par l'expression déduite de [7*a*], [7*c*]:

[12*d*] $$|\psi'_{r+1}, q\rangle = |\psi_r, q\rangle + \sum_{p \neq q} F_{pq}^{(r)}\,|\psi_r, p\rangle$$

normalisée selon [6*a*,*b*].

$\mathscr{A}$: Si le réferentiel mobile est orthogonalisé, selon [8*a*]

$$\rho_{pq}^{(r)} = \rho_{pq}^{0}(r)$$

$\mu_{p<q}^{q}(r)$ résulte de [5*a*,*b*] et on pose en outre

[13] $$\mu_{p>q}^{q}(r) = 0$$

$\mathscr{B}$: Si le réferentiel mobile n'est pas orthogonalisé, $\rho_{pq}^{(r)}$ résulte de [8*b*]; par construction

$$\mu_{pq}(r) \equiv 0$$

Dans les deux bases on peut écrire:

[14] $$F_{pq}^{(r)} = \mu_p^q(r) + \sum_m (\delta_{mq} + \mu_m^q(r)) \left[\rho_{pm} + \sum_{p \neq o \neq m} \rho_{po}^{(r)}\rho_{om}^{(r)} + \ldots\right]$$

δ_{mq} étant le symbole de Kronecker.

Passant du réferentiel mobile $|\psi_r, q\rangle$ au référentiel fixe $|\Gamma, q\rangle$,

[15*a*] $$|\psi_r, q\rangle = \sum_q x_q^m(r)\,|\Gamma, m\rangle$$

$F_{pq}^{(r)}$ étant défini par [14], $\rho_{pq}^{(r)}$ prend la valeur [8*a*] ou [8*b*], l'expression [7*c*] devenant

[15*b*] $$\rho_{pq}^{0}(r) = \frac{\sum_l \sum_m x_{pm}^{(r)} x_{ql}^{(r)} E_{lm}}{\sum_l \sum_m [x_q^l(r)\,x_q^m(r) - x_p^l(r)\,x_p^m(r)]E_{lm}}$$

et la correction [8*b*] s'écrivant

[15*c*] $$\rho_{pq}^{(r)} = \rho_{pq}^{0}(r) + \left(\sum_l \sum_m x_p^m x_q^l\right)\left(1 - \sum_l \sum_m x_p^m x_q^l E_{lm}\right)^{-1}$$

la matrice (E_{lm}) étant $(\hat{H})$ sur la base $|\Gamma, q\rangle$: $E_{lm} \equiv H_{lm}^{(o)}$.

Les coordonnées sont initialisées selon [3] par

[15*d*₁] $$x_q^m(o) = \delta_{qm}$$

La relation qui définit la normalisation [6*a*] est

[15*d*₂] $$x_q^m(r) = \nu_r^q\, x_q^{\prime m}(r)$$

La relation de récurrence est alors

[15*d*₃] $$x_q^m(r) = x_q^m(r-1) + \sum_{p \neq q} x_p^m(r-1)\,F_{pq}^{(r-1)}$$

ν_r^q étant défini par [6*b*]

[15*d*₄] $$(\nu_r^q)^2 \cdot \Sigma\,[x_q^{\prime m}(r)]^2 = 1$$

Si le processus est convergent,

[16*a*] $$\lim_{r \to \infty} x_q^m(r) = x_q^m(\mathrm{IC})$$

[16*b*] $$|\Lambda^{\mathrm{IC}}, q\rangle = \sum_m x_q^m(\mathrm{IC})\,|\Gamma, m\rangle$$

$$\nu_q^{\mathrm{IC}} = 1$$

Pour étudier la convergence, posons

$$\xi_q^m(r) = x_q^m(r) - x_q^m(\mathrm{IC}),$$

$$\xi_q^m(r) \to 0 \quad |r \to \infty, \forall\, q$$

La relation [15*d*] de récurrence devient [16*c*]:

[16*c*] $$\xi_q^m(r) - \xi_q^m(r-1) = \sum_{p \neq q} \xi_p^m(r-1)\,F_{pq}^{(r-1)}$$

où $F_{pq}^{(r-1)}$ est défini par [14*b*] avec l'expression [15*c*] qui devient pour $r \to \infty$:

$$\rho_{pq}^{0}(r) \simeq \frac{-\sum_l \sum_m [x_p^m(\mathrm{IC})\,\xi_q^l(r) + x_q^m(\mathrm{IC})\,\xi_p^l(r)]E_{lm}}{\sum_l \sum_m [x_q^l(\mathrm{IC})\,x_q^m(\mathrm{IC}) - x_p^l(\mathrm{IC})\,x_p^m(\mathrm{IC})]E_{lm}}$$

et [8*a*] ou [8*b*], alors

$$F_{pq}^{(r)} \sim \rho_{pq}^{(r)}$$

La discussion des signes montre, comme dans le cas des deux niveaux, une correction alternée de l'erreur. La relation [16*c*] s'écrit, en module:

$$|\xi_q^m(r)| + |\xi_q^m(r-1)| = \sum_{p \neq q} |\xi_p^m(r-1)|\,F_{pq}^{(r-1)}$$

Soit

$$\xi_{r-1} = \sup|\xi_q^m(r-1)|$$

$$E = \sup|E_{lm}|$$

$$W = \inf|W_q^{\mathrm{IC}} - W_p^{\mathrm{IC}}|$$

On trouve

$$\xi_r \gtrsim B\,\xi_{r-1}^2 \qquad B = \frac{2(Q-1)^2 E}{W}$$

Une suite majorante en module à partir d'un certain rang est

$$B^{-1}\exp(-2^r)$$

Puisque selon [11*f*] la convergence peut être plus rapide, disons que la convergence est analogue à celle d'une suite proportionnelle à

[16*d*] $$\exp(-K^r) \quad 2 \leq K \leq 3$$

II-5. *Discussion de la correction répètée*

Selon l'eq. [4], la suite des fonctions $|\psi_r, q\rangle$ converge vers la fonction propre $|\Lambda^{IC}, q\rangle$ et les énergies $H_{qq}^{(r)} = \langle\psi_r, q|\hat{H}|\psi_r, q\rangle$ convergent vers W_q^{IC}, valeur propre de la matrice $(\hat{H})$. En outre la formule [7*b*] donne en même temps que $|\psi_r,q\rangle$ une approximation de rang plus élevé de l'énergie. Les coordonnées $x_q^m(r)$ sont initialisées par [15d_1] et calculées par [15d_2] et [15d_3], le coefficient de normalisation ν_r^q etant déterminé par [15d_4]. On utilise pour celà les coefficients de perturbation $F_{pq}^{(r)}$ calculés selon [14] avec deux options. Dans l'option $\mathcal{B}$, non orthogonalisée, les μ_p^q sont nuls et les $\rho_{pq}^{(r)}$ calculés selon [15*b*] et [15*c*] à partir de la matrice (E_{lm}).

Cette technique est alternative de la diagonalisation purement mathématique de la matrice Hamiltonienne. Les intermédiaires de calcul ont un sens physique. Chaque approximation apporte la partie principale de l'erreur sur le résultat.

Mais elle n'est pas limitée à l'objectif d'une diagonalisation de matrice dans un espace donné. On peut se proposer la modification des spinorbitales *j* pour des arguments qui n'ont pas nécessairement le caractère d'un calcul variationnel. Nous avons discuté en particulier (17) de l'amélioration du potentiel d'erreur par des conditions locales. Cette modification des spinorbitales revient à considèrer un espace $\mathcal{E}$ mobile à l'intérieur d'un espace de Hilbert. On peut alterner les deux types de correction, donc utiliser à l'iteration *r* une matrice $(E_{lm}^{(r)})$ qui a été légèrement modifiée par rapport à $(E_{lm}^{(r-1)})$. Celà ne semble pas entraver la procédure indiquée ici.

III. Correction linearisée de l'erreur

III-1. *Correction de l'erreur par un operateur non linéaire*

Nous avons formulé la dite "correction perturbative de l'erreur pour le niveau *q*" selon [12*d*] pour les seules approximations successives du niveau *q* initié par la configuration pure $|\Gamma, q\rangle$.

Pour tenter d'effectuer cette correction pour d'autres vecteurs de $\mathcal{E}$ on pourrait se reporter à la définition, spécialement celle ($\mathcal{B}$), qui indique la perturbation par l'opposé du potentiel d'erreur, non suivie d'une orthogonalisation. Certains résultats semblent évidents (correction nulle pour les $|\Lambda^{IC}, q\rangle$).

Si l'on procède à une telle généralisation on constate que la correction nulle sur les $|\Lambda^{IC}, p\rangle$ définis par [9*b*] ne peut être mise sous la forme de la somme pondérée des corrections sur $|\Gamma, 0\rangle$ et sur $|\Gamma, 1\rangle$. L'opérateur ainsi généralisé ne serait pas linéaire.

Pour intéressante que soit cette idée, les formalismes disponibles ne se prêtent guère à en tirer les conséquences.

III-2. *Correction de l'erreur par un opérateur linéaire*

La correction que nous avons calculée au chapitre II s'exprime par la transformation [12*d*] éventuellement suivie de [6*a*]. Elle est donc effectuée par l'action de l'opérateur $|\psi_r^q, q\rangle\langle\psi_{r-1}, q|$ ou de l'opérateur $|\psi_r, q\rangle\langle\psi_{r-1}, q|$. Ces deux opérateurs sont définis dans $\mathcal{E}$ et linéaires. Ils sont physiquement équivalents, mais le premier est idempotent, c'est un opérateur de projection; le second conserve la norme. Nous consacrerons le chapitre III au second, le chapitre IV au premier.

La mise en oeuvre de cet opérateur pour le niveau *q* ne peut pas se séparer de la construction du référentiel mobile; nous sommes amenés à introduire un opérateur de "correction linéaire de l'erreur à l'ordre *r*" (cle_r)

$$[17] \quad \text{cle}_r = \sum_q |\psi_r, q\rangle\langle\psi_{r-1}, q|$$

L'expression [17] traduit l'évolution du référentiel mobile. Plus explicitement,

$$[18] \quad \text{cle}_r = \sum_q \nu_r^q |\psi_r, q\rangle\langle\psi_r, q| + \sum_q \sum_{p \neq q} \nu_r^q F_{pq}^{(r)} |\psi_r, p\rangle\langle\psi_r, q|$$

($F_{pq}^{(r)}$ étant défini par [14]). Tenant compte de [15*a*],

$$[19] \quad \text{cle}_r = \sum_p \sum_q \nu_r^q [\delta_{pq} + F_{pq}^{(r)}] \sum_l \sum_m x_p^m(r)\, x_l^q(r)\; |\Gamma, m\rangle\langle\Gamma, l|$$

L'itération de cet opérateur est représentée par l'equation

$$[20] \quad \text{cle}_r \cdot \text{cle}_{r+1} = \sum_q |\psi_{r+1}, q\rangle\, \langle\psi_{r-1}, q|$$

On obtient donc

$$[21] \quad \prod_{s=0}^{r} \text{cle}_s = \sum_q |\psi_s, q\rangle\, \langle\Gamma, q| = \sum_q \sum_m x_q^m(r)\, |\Gamma, m\rangle\, \langle\Gamma, q|$$

$x_q^m(r)$ dans [19], [21] et les équations suivantes, défini par [15*a*], se calcule selon [15$d_{1,2,3}$].

L'aboutissement du calcul est selon [16*a*]

$$[22] \quad \prod_{s=0}^{\infty} \text{cle}_s = \sum_q |\Lambda^{IC}, q\rangle\, \langle\Gamma, q| = \sum_q \sum_m x_q^m(\text{IC})\, |\Gamma, m\rangle\, \langle\Gamma, q|$$

$\prod_{s=0}^{\infty} \text{cle}_s$ est un opérateur de corrélation valable pour n'importe lequel des niveaux *q* et dont nous déclarons qu'il opère la corrélation dans l'espace $\mathcal{E}$: à un mélange de configurations pures, il fait correspondre le mélange statistique d'états de même pondération

$$\text{cle}_r \sum_q x_q\, |\Gamma, q\rangle = \sum_q x_q\, |\Lambda^{IC}, q\rangle$$

III-3. *Modèle à deux niveaux*

Dans l'exemple (paragraphe II-3) du modèle à deux niveaux, les opérateurs [18], [21] et [22] prennent tous la même forme, selon [12a, b, c]:

$$[23] \quad (\hat{\theta}) = \hat{I} \cos\theta + (|\Gamma, 1\rangle\, \langle\Gamma, 0| - |\Gamma, 0\rangle\, \langle\Gamma, 1|) \sin\theta$$

avec

$$[24] \quad \text{cle}_r = (\hat{\gamma}_r), \quad \prod_{s=0}^{\infty} \text{cle}_s = (\hat{\alpha}_r), \quad \prod_{s=0}^{\infty} \text{cle}_s = (\hat{\omega})$$

III-4. *Discussion de la correction linéaire*

En conclusion, les opérateurs cle_r, $\prod_{s=0}^{r} \text{cle}_s$, $\prod_{s=0}^{\infty} \text{cle}_s$ ne modifient pas la suite des calculs indiqués au paragraphe II-5. Leur intérêt est de parvenir à un opérateur de corrélation $\prod_{s=0}^{\infty} \text{cle}_s$ valable pour toute configuration, et de le construire sous forme d'un produit infini d'opérateurs partiels dont chacun cle_r corrige la partie principale de l'erreur et possède la signification très intuitive de perturbation corrective de l'erreur appliquée simultanément à l'ensemble du référentiel $|\psi_r, q\rangle$.

La forme générale des opérateurs de corrélation a par ailleurs été discutée. Pour que la condition [2] soit réalisée par

TABLEAU 1. Expression des opérateurs d'excitation B_p^q de H_3^+

	q			
p	0	1	2	3
0	$\hat{I}$	$\frac{1}{\sqrt{2}}(X_{\bar{u}}^+ X_{\bar{v}} + X_u^+ X_v)$	$X_{\bar{w}}^+ X_w^+ X_u X_{\bar{u}}$	$X_{\bar{u}} X_u X_v X_{\bar{v}}$
1	$\frac{1}{\sqrt{2}}(X_v^+ X_u + X_{\bar{v}}^+ X_{\bar{u}})$	$\hat{I}$	$\frac{1}{\sqrt{2}} X_{\bar{w}}^+ X_w^+ (X_u X_{\bar{v}} + X_v X_{\bar{u}})$	$\frac{1}{\sqrt{2}}(X_v^+ X_u + X_{\bar{v}}^+ X_{\bar{u}})$
2	$X_{\bar{u}}^+ X_u^+ X_w X_{\bar{w}}$	$\frac{1}{\sqrt{2}}(X_{\bar{v}}^+ X_u^+ + X_{\bar{u}}^+ X_v^+) X_w X_{\bar{w}}$	$\hat{I}$	$X_{\bar{v}} X_v X_w X_{\bar{w}}$
3	$X_{\bar{v}}^+ X_v^+ X_u X_{\bar{u}}$	$\frac{1}{\sqrt{2}}(X_v^+ X_u + X_{\bar{v}}^+ X_{\bar{u}})$	$X_{\bar{w}}^+ X_w^+ X_v X_{\bar{v}}$	$\hat{I}$

l'expression générale (réf. 25, éq. 2*a*)

$$\hat{C} = \Sigma\, c_{pg}\, |\Lambda^{\mathrm{IC}}, p\rangle \langle \Gamma, q|$$

il faut et il suffit que

$$c_{pq} = \delta_{pq}$$

L'expression [22] est donc bien la seule correllant selon [2] toutes les configurations $|\Gamma, q\rangle$.

Les opérateurs $\prod_{s=0}^{\infty} \mathrm{cle}_s$ sous forme matricielle ($\mathbf{x}_q^m$(IC)) seront utiles pour construire les opérateurs de décorrelation et par suite d'ionisation et d'attachement (25).

IV. Développement en grappes de la correction linearisée de l'erreur de corrélation

IV-1. *Utilisation des opérateurs de seconde quantification*

Les opérateurs de corrélation ont essentiellement été développés dans l'application des concepts de la seconde quantification à la chimie. Il y a donc lieu de comparer l'opérateur $\prod_{s=0}^{\infty} \mathrm{cle}_s$ aux opérateurs de corrélation auxquels conduit ce point de vue.

A. *Modèle à deux niveaux. Molécule H_2 en base minimale*

Les orbitales moléculaires de symètrie $1\sigma_g$ (respectivement $1\sigma_u$) étant désignées par i (resp. j), les deux configurations pures s'écrivent avec des notations évidentes:

$$|\Gamma, 0\rangle = |i\bar{i}| \quad |\Gamma, 1\rangle = |j\bar{j}\rangle$$

Appelons X (resp. X^+) les opérateurs de destruction (resp. création) indicés des spinorbitales. L'expression [23] s'écrit

$$[25a] \quad \hat{\theta} = \hat{I} \cos\theta + (X_j^+ X_{\bar{j}}^+ X_i X_{\bar{i}} - X_{\bar{i}}^+ X_i^+ X_j X_{\bar{j}}) \sin\theta$$

Sont de cette forme les opérateurs

$$[25b] \quad \mathrm{cle}_r = \hat{\gamma}_r \quad \prod_{s=0}^{r} = \hat{\alpha}_r \quad \prod_{s=0}^{\infty} \mathrm{cle}_s = \hat{\omega}_r$$

Ils admettent donc la relation générale

$$[25c] \quad \hat{\sigma} = \hat{\theta}_1 \cdot \hat{\theta}_2 \quad |\sigma = \theta_1 + \theta_2$$

Nous généraliserons cette relation au modèle à plusieurs niveaux par le concept de développement en grappes.

B. *Modèle à quatre niveaux. H_3^+ linéaire symètrique en base minimale*

Les orbitales moléculaires de symètrie $1\sigma_g$, $2\sigma_g$, $1\sigma_u$ désignées par u, v, w dépendent d'un paramètre (coefficient de l'orbitale atomique médiane dans u) dont les valeurs remarquables correspondent successivement aux orbitales de Hückel, orbitales de recouvrement maximum, orbitales naturelles, orbitales de pseudo-symètrie, orbitales de champ autocohérent (17, 21, 25, 28, 37). Les 4 configurations pures sont avec des notations évidentes (17, 25):

$$|\Gamma, 0\rangle = |u\bar{u}\rangle \quad |\Gamma, 1\rangle = \frac{1}{\sqrt{i}}(u\bar{v} + v\bar{u})$$

$$|\Gamma, 2\rangle = |w\bar{w}\rangle; \, |\Gamma, 3\rangle = |v\bar{v}\rangle$$

Les opérateurs d'excitation satisfaisant l'équation

$$[26a] \quad B_q^p\, |\Gamma, q\rangle = |\Gamma, p\rangle$$

sont indiqués par le tableau 1.

Voici (cf. la réf. 25) l'expression de ces mêmes opérateurs en fonction des ketbras de configuration: si

$$[26b] \quad p = q \quad \hat{B}_q^q = \hat{I} + \sum_{q=0}^{3} |\Gamma, q\rangle \langle \Gamma, q|$$

si

$$[26c] \quad p = 0,\, q = 1 \text{ ou } p = 1,\, q = 3$$

$$\hat{B} \uparrow\; = \hat{B}_0^1 = \hat{B}_1^3 = |\Gamma, 1\rangle \langle \Gamma, 0| + |\Gamma, 3\rangle \langle \Gamma, 1|$$

si

$$[26d] \quad p = 1,\, q = 0 \text{ ou } p = 3,\, q = 1$$

$$\hat{B} \downarrow\; = \hat{B}_1^0 = \hat{B}_3^1 = |\Gamma, 0\rangle \langle \Gamma, 1| + |\Gamma, 1\rangle \langle \Gamma, 3|$$

si non

$$[26e] \quad \hat{B}_p^q = |\Gamma, q\rangle \langle \Gamma, p|$$

Après avoir fait le calcul de l'interaction de configuration directement (31) ou indirectement selon [16*b*]

$$[26f] \quad |\Lambda^{\mathrm{IC}}, q\rangle = \sum_{p=0}^{3} x_q^p(\mathrm{IC})\, |\Gamma, p\rangle$$

on connait bien évidemment un opérateur de corrélation adapté à la configuration $|\Gamma, q\rangle$

$$[26g] \quad \hat{C}_q = \sum_{p=0}^{3} x_q^p(\mathrm{IC})\, B_p^q$$

Voici l'expression de cet opérateur en fonction linéaire des ketbras de configuration (compte tenu de [26*f*])

$$[26h] \quad \hat{C}_q = |\Lambda^{\mathrm{IC}}, q\rangle \langle \Gamma, q| + \sum_{p \neq q} x_p^r(\mathrm{IC})\, |\Gamma, p\rangle \langle \Gamma, p|$$

$$+ \delta_{q0}\, \delta_{p1}\, x_0^1(\mathrm{IC})\, |\Gamma, 3\rangle \langle \Gamma, 1| + \delta_{q1}\, \delta_{p3}\, x_1^3(\mathrm{IC})\, |\Gamma, 1\rangle \langle \Gamma, 0|$$

$$+ \delta_{q1}\, \delta_{p0}\, x_1^0(\mathrm{IC})\, |\Gamma, 1\rangle \langle \Gamma, 3| + \delta_{q3}\, \delta_{p1}\, x_3^1(\mathrm{IC})\, |\Gamma, 0\rangle \langle \Gamma, 1|$$

Cet opérateur est sensiblement différent de l'opérateur [22] adapté aux 4 configurations soit encore

$$[26i] \quad \prod_{s=0}^{\infty} \text{cle}_s = \sum_{q=0}^{3} |\Lambda_q^{\text{IC}}\rangle \langle \Gamma_q|$$

C. *Discussion de l'utilisation de l'algèbre de seconde quantification*

On peut donc se proposer de remplacer l'ensemble des $\hat{C}_q$ de configuration particulière par $\prod_{s=0}^{\infty}$ cle$_s$ valable pour toutes.

On peut d'autre part chercher à construire cet opérateur global de corrélation par multiplication des opérateurs de correction successifs. Cela nous a conduit dans le cas du modèle à deux niveaux (paragraphe IV-1A) à l'addition des angles γ_r successifs pour donner ω.

Or l'idée du développement en grappes (24*a*, 29, 37) est la recherche d'un polynome des excitations T tel que e^T soit l'opérateur de correlation. On pourrait donc se proposer de chercher un développement en grappe de même forme pour les opérateurs de correction de manière que le produit des opérateurs de correction soit exprimé par l'addition d'un polynome partiel d'excitation attaché à cette correction, de sorte que la matrice des excitations soit la somme de ces matrices successives attachées à la correction.

Toutefois l'opérateur cle$_s$ que nous avons défini [17] n'a pas une forme identifiable à un développement en série entière. Par exemple son terme inexcité est

$$[27] \quad \hat{K} = \sum_q \nu_r^q |\psi_{r-1}, q\rangle \langle \psi_{r-1}, q|$$

D. *Nouvelle forme de la correction linéarisée de l'erreur*

Si au contraire nous partons de l'opérateur idempotent défini au chapitre III-2, nous introduisons le nouvel opérateur Cle$_r$:

$$[28a] \quad \text{Cle}_r = \sum_q |\psi'_r, q\rangle \langle \psi_{r-1}, q|$$

Cet opérateur ne satisfait pas l'éq. [2]. Mais pour toute configuration $|\Gamma, p\rangle$ il existe un opérateur proportionnel à Cle$_r$ qui la satisfait

$$[28b] \quad \nu_r^p \, \text{Cle}_r = |\psi_r, p\rangle \langle \psi_{r-1}, p| + \sum_{q \neq p} \frac{\nu_r^q}{\nu_r^q} |\psi_r, q\rangle \langle \psi_{r-1}, q|$$

D'autre part cet opérateur est relié à celui étudié jusqu'à présent

$$[28c] \quad \text{cle}_r = \text{Cle}_r \cdot \hat{K}$$

Son développement fait apparaitre l'opérateur unité

$$[28d] \quad \text{Cle}_r = \hat{I} + \sum_q \sum_{p \neq q} F_{pq}^{(r)} |\psi_r, p\rangle \langle \psi_r, q|$$

$$[28e] \quad \text{Cle}_r = \hat{I} + \sum_q \sum_{p \neq q} F_{pq}^{(r)} x_q^m x_p^l |\Gamma, l\rangle \langle \Gamma, m|$$

Le résultat de deux opérations successives de correction sera

$$[29a] \quad \text{Cle}_r \cdot \text{Cle}_{r+1} = \sum_q \frac{1}{\nu_r^q} |\psi'_{r+1}, q\rangle \langle \psi_{r-1}, q|$$

On calculera donc de proche en proche

$$[29b] \quad \prod_{s=0}^{r} \text{Cle}_s = \sum_q \left(\prod_{s=0}^{r} \frac{1}{\nu_r^s}\right) |\psi_s, q\rangle \langle \Gamma, q|$$

$$[29c] \quad \prod_{s=0}^{\infty} \text{Cle}_s = \sum_q \left(\prod_{s=0}^{\infty} \frac{1}{\nu_r^s}\right) |\Lambda^{\text{IC}}, q\rangle \langle \Gamma, q|$$

$$[29d] \quad \prod_{s=0}^{\infty} \text{Cle}_s = \sum_q \left(\prod_{s=0}^{\infty} \frac{1}{\nu_r^s}\right) \sum_m x_q^m(\text{IC}) |\Gamma, m\rangle \langle \Gamma, q|$$

Pour calculer ces diverses expressions, la suite des matrices $(\mathbf{x}_q^m(r))$ et des coefficients de normalisation ν_r^q ainsi que leurs limites $((\mathbf{x}_q^m(\text{IC}))$ et 1) résultent des équations [15d_{1-4}] compte tenu de [14] et [15*b*, *c*] comme il a été indiqué au paragraphe II-5.

Voici l'exemple du modèle à 4 niveaux de H_3^+ linéaire, symétrique: selon le tableau 1, le polynome Cle$_r$ ordonné selon le nombre Z d'excitations se déduit de [28*e*]

$$[30] \quad \text{Cle}_r = \hat{I} + \text{Cle}_r^{[1]} + \text{Cle}_r^{[2]}$$

$$\text{Cle}_r^{[1]} = \sum_{q=0}^{3} \sum_{p \neq q} F_{pq}^{(r)} [(\delta_{m0}\, \delta_{l1}\, x_q^0(r)\, x_p^1(r) + \delta_{m1}\, \delta_{l3}\, x_q^1(r)\, x_p^3(r))\, \hat{B} \uparrow \; + (\delta_{m1}\, \delta_{l0}\, x_q^1(r)\, x_p^0(r) + \delta_{m3}\, \delta_{l1}\, x_q^3(r)\, x_p^1(r))\, \hat{B} \downarrow]$$

$$\text{Cle}_r^{[2]} = \sum_{q=0}^{3} \sum_{p \neq q} F_{pq}^{(r)} \sum\sum_{(m \neq l) \neq \begin{cases}(0,1)\\(1,3)\\(1,0)\\(3,1)\end{cases}} x_q^m(r)\, x_p^l(r)\, \hat{B}_m^l$$

les x étant donnés par solution des équations de récurrence.

Plus généralement chaque couple de configurations permet de définir un nombre d'excitations

$$[31a] \quad [p, q] = Z$$

On propose alors un développement, ordonné sur les couples *lm* et tronqué sur les couples *pq*.

$$[31b] \quad \text{Cle}_r = \hat{I} + \sum_Z \text{Cle}_r^{[Z]}$$

$$\text{Cle}_r\,[Z] = \sum\sum_{[P,Q] \leq Z} F_{pq}^{(r)} \sum\sum_{[m,l]=Z} \eta(m, l)\; x_q^m(r; Z)\, x_p^m(r; Z)\, \hat{B}_l^m$$

Les équations définissant $x_q^m(r; Z)$ sont déduites de [15$d_{1,3}$], la normalisation [15$d_{2,4}$] restant la même.

Les valeurs seront initialisées par

$$[32a] \quad x_q^m(0; Z \leq 2) = \delta_{qm}\; x_q^m(0; Z > 2) = x_q^m(\infty; Z - 1)$$

La relation de récurrence sera tronquée:

$$[32b] \quad x_q^{'m}(r; Z) = x_q^m(r - 1; Z) + \sum\sum_{[p,q] \leq Z} x_p^m(r - 1; Z)\, F_{pq}^{(r-1)}$$

IV-2. *Utilisation du développement en grappes*

Dans le cas général $\prod_{s=0}^{\infty}$ Cle$_s$ est un opérateur de corrélation pouvant en particulier prendre la forme [31*b*] d'un polynome de création–destruction. On peut donc le comparer aux opérateurs écrits dans les méthodes de seconde quantification (24*a*, 25, 27–34).

On sait que ces opérateurs sont "développés en grappes". Convenons d'utiliser ce terme chaque fois qu'un opérateur $\mathbb{O}$ résulte de l'exponentiation d'un polynôme T de création–destruction défini à partir de ses éléments matriciels $\langle \mathbf{t} \rangle$ selon les équations:

$$[33a] \quad \mathbb{O} = e^T = \sum_{k=0}^{\infty} \frac{1}{k!} T^k$$

$$[33b]\quad T = \sum_{z=0}^{N} T_z$$

$$[33c]\quad T_z = \sum \langle j_1'' \ldots j_3'' | t | j_1' \ldots j_3' \rangle X_{j_1''}^{+} \ldots X_{j_3''}^{+} X_{j_1'} \ldots X_{j_3'}$$

Nous pouvons développer en grappes, soit les opérateurs de corrélation, soit les opérateurs de correction linéarisée ordonnés,

$$[34]\quad \mathrm{Cle}_r = e^{G,r}$$

$$[35]\quad \prod_{s=0}^{\infty} \mathrm{Cle}_r = e^{T}$$

L'opérateur T généralise l'opérateur d'excitation dans la méthode de Cizek (24a, 25).

Les relations [34] et [35] entrainent:

$$[36]\quad T = \sum_{r=0}^{\infty} G, r$$

$$[37]\quad T_z = \sum_{r=0}^{\infty} G_z, r$$

D'autre part l'opérateur G, r peut être déterminé par l'éq. [34] en identifiant le développement de Cle_r ordonné en Z, avec un développement de la forme [33a,b,c] appliqué à G, r:

$$[38]\quad \begin{aligned} \mathrm{Cle}_r^{[1]} &= G_1, r \\ \mathrm{Cle}_r^{[2]} &= G_2, r + \frac{1}{2}(G_1, r)^2 \\ \mathrm{Cle}_r^{[3]} &= G_3, r + G_2, r \cdot G_1, r + \frac{1}{6}(G_1, r)^3 \\ \mathrm{Cle}_r^{[4]} &= G_4, r + G_3, r \cdot G_1, r + \frac{1}{2}(G_2, r)^2 \\ &\quad + \frac{1}{2} G_2, r \cdot (G_1, r)^2 + \frac{1}{24}(G_1, r)^4 \text{ etc.}\ldots \end{aligned}$$

$$[39]\quad \begin{aligned} G_1, r &= \mathrm{Cle}_r^{[1]} \\ G_2, r &= \mathrm{Cle}_r^{[2]} - \frac{1}{2}(\mathrm{Cle}_r^{[1]})^2 \\ G_3, r &= \mathrm{Cle}_r^{[3]} - \mathrm{Cle}_r^{[2]}\,\mathrm{Cle}_r^{[1]} + \frac{1}{3}(\mathrm{Cle}_r^{[1]})^3 \\ G_4, r &= \mathrm{Cle}_r^{[4]} - \mathrm{Cle}_r^{[3]}\,\mathrm{Cle}_r^{[1]} - \frac{1}{2}(\mathrm{Cle}_r^{[2]})^2 \\ &\quad + \mathrm{Cle}_r^{[2]}(\mathrm{Cle}_r^{[1]})^2 - \frac{3}{3}(\mathrm{Cle}_r^{[4]})^4 \end{aligned}$$

On en déduit selon [37], [39]

$$[40]\quad \begin{aligned} \langle j_1'' | t | j_1' \rangle &= \sum_{r=0}^{\infty} \langle j_1'' | g,r | j_1' \rangle = \sum_{r=0}^{\infty} \langle j_1'' | \mathrm{Cle}_r^{[1]} | j_1' \rangle \\ \langle j_1'' j_2'' | t | j_1' j_2' \rangle &= \sum_{r=0}^{\infty} \langle j_1'' j_2'' | g,r | j_1' j_2' \rangle \\ &= \sum_{r=0}^{\infty} \Big[\langle j_1'' j_2'' | \mathrm{Cle}_r^{[2]} | j_1' j_2' \rangle \\ &\quad - \frac{1}{2} \langle j_1'' | \mathrm{Cle}_r^{[1]} | j_1' \rangle \langle j_2'' | \mathrm{Cle}_r^{[1]} | j_2' \rangle \Big] \\ \langle j_1'' j_2'' j_3'' | t | j_1' j_2' j_3' \rangle &= \sum_{r=0}^{\infty} \langle j_1'' j_2'' j_3'' | g,r | j_1' j_2' j_3' \rangle \\ &= \sum_{r=0}^{\infty} [\langle j_1'' j_2'' j_3'' | \mathrm{Cle}_r^{[3]} | j_1' j_2' j_3' \rangle \\ &\quad - \langle j_1'' j_2'' | \mathrm{Cle}_r^{[2]} | j_1' j_2' \rangle \langle j_3'' | \mathrm{Cle}_r^{[1]} | j_3' \rangle \\ &\quad + \frac{1}{3} \langle j_1'' | \mathrm{Cle}_r^{[1]} | j_1' \rangle \langle j_2'' | \mathrm{Cle}_r^{[1]} | j_2' \rangle\, \mathrm{Cle}_r^{[1]} j_3' \rangle] \text{ etc.}\ldots \end{aligned}$$

Ce sont les éléments matriciels $\langle \mathbf{t} \rangle$ et $(\mathbf{g}, \mathbf{r})$ qui définissent les opérateurs T et G, r; ce sont les opérateurs $\mathrm{Cle}_r^{[Z]}$ qui définissent les élements $\langle \mathrm{Cle}_r^{[Z]} \rangle$.

Les équations [40] signifient que les éléments matriciels de G_Z, r forment des séries convergentes lorsque $r \rightarrow \infty$ dont la somme est l'élément matriciel, de même forme, de l'opérateur T. Le terme général de chacune de ces séries reçoit une expression utilisant les termes du développement ordonné de Cle_r.

IV-3. *Utilisation de l'Hamiltonien normal*

La forme "normale" de l'Hamiltonien est (24a, 31):

$$\hat{H} - \langle \Omega | \hat{H} | \Omega \rangle = \sum_{12} \langle 1 | \hat{f} | 2 \rangle \,\mathrm{N}\,[X_1^{+} X_2] + \frac{1}{2} \sum_{1234} \langle 12 | \hat{y} | 34 \rangle \,\mathrm{N}\,[X_1^{+} X_2^{+} X_3 X_4]$$

1,2,3,4 désignant les spinorbitales, N le produit normal, $\hat{f}$ contenant une partie de la répulsion interelectronique $\hat{y}$ selon une transformation citée en référence (méthode de Cizek).

On en déduit selon [7c] la matrice que l'on tronquera en fonction de Z

$$E_{[p,q] \leq Z} = \langle \Gamma_q | \hat{H} \hat{B}_p^q | \Gamma_q \rangle$$

le calcul des éléments matriciels de $\hat{H}\hat{B}_p^q$ renvoie à la méthode diagrammatique (23, 24, 31, 33). On déduit $\rho_{pq}^{(r)}[Z]$ selon [15b] et [15c], $F_{pq}^{(r)}[Z]$ selon [14]. Ils sont également tronqués en fonction de $[p, q] \leq Z$. Cle_r selon [28b] ordonné en création–destruction selon [31b], contient les $\hat{B}_l^m$ définis par [26a], les coordonnées $x_q^m(r; Z)$ solutions des équations [32a], [32b] et [15$d_{2,4}$]. La construction des $\mathrm{Cle}_r^{[Z]}$ de création–destruction permettra d'obtenir les $\langle y_Z, r \rangle$, d'où les $\langle T \rangle$.

Il faut souligner que l'expression [42] des éléments matriciels d'énergie d'excitation permet l'usage des diagrammes (24a) ou des tables qui les compilent (33). La différence essentielle avec la méthode utilisée jusqu'à présent est que la résolution de systèmes d'équations non linéaires à multiples inconnues disparait. On remarquera aussi que les concepts d'énergie asymètrique et de prénormalisation ne sont pas utilisés ici. Enfin on n'a pas particularisé la configuration fondamentale.

V. Conclusion

V-1. *Généralisations possibles*

Nous nous bornerons à signaler une perspective, la transcription des calculs indiqués sur les fonctions d'onde en calculs sur les matrices densités qui les traduisent, puis sur la généralisation de ces matrices en "diagrammes moléculaires" (35) précisés par les "opérateurs symètriques fondamentaux" (36). Mais surtout la théorie précédente n'est pas limitée au problème de la corrélation.

V-2. *Résultats acquis*

Parmi les diverses méthodes ouvertes par le concept de potentiel d'erreur, la plus facile à exprimer semble la correction perturbative de l'erreur par l'opposé de ce potentiel et sa correction indéfinie. Remarquant que les états à corriger sont un mélange d'états propres (ou vice versa) l'opérateur qui exprimerait cette correction dans tout l'espace des états ne pourrait être linéaire.

Mais d'autre part pour mettre en oeuvre une méthode de perturbation s'inspirant de la formulation de Schrödinger, il faut associer l'état erroné à un ensemble d'autres considérés comme conséquence d'une même erreur physique. Dès lors on ne peut corriger de cette erreur que les états de la base. Mais on peut construire, sur l'ensemble des corrections ainsi définies, un opérateur de correction, linéaire dans tout l'espace de la base

$$\sum_{\text{base}} |\text{corrigé}\rangle\langle\text{erroné}|$$

il peut être appliqué autant de fois qu'il sera requis. Il se ramène à l'opérateur identique à mesure que la correction devient négligeable, les états corrigés étant devenus les états propres. La discussion montre que la convergence est rapide, chaque correction correspondant à la partie principale de l'erreur restant à corriger.

L'espace des interactions de configuration à l'intérieur duquel ce processus est convergent pourrait être rendu mobile par rapport à l'espace des états, à chaque correction partielle, permettant ainsi d'explorer ce dernier à la recherche de l'état propre.

L'itération de l'opérateur de correction linéarisée du défaut de corrélation conduit à un opérateur de corrélation commun à toutes les configurations. De même que l'opérateur de corrélation, l'opérateur de correction linéarisé peut être écrit comme un polynôme de création–destruction. L'un et l'autre peuvent se développer en grappes, c'est-à-dire qu'on peut en déterminer un transformé par inversion de l'exponentielle. On considère ici le transformé de la correction linéarisée de l'erreur. Ses éléments matriciels successifs ont pour somme les éléments de la matrice d'excitation. Ils sont calculables par perturbation en utilisant l'Hamiltonien normal et l'analyse diagrammatique. On dispose ainsi d'un calcul d'erreur des methodes de seconde quantification qui doit permettre entre autres de discuter les extensions récemment proposées (31, 32) et apparemment aussi d'une méthode alternative pour la pratique.

This paper is dedicated to Professor Camille Sandorfy on the occasion of his 65th birthday

M. BÉNARD, W. G. LAIDLAW, and J. PALDUS. Can. J. Chem. **63**, 1797 (1985).

Crystallographic evidence indicates that the structure of the trisulfur trinitride anion, $S_3N_3^-$, is planar with equal SN bond lengths. Although the recent literature contains a number of molecular orbital calculations of D_{3h} symmetry there are also calculations which indicate inequivalent nitrogens, suggesting broken symmetry. The results of an investigation of Hartree–Fock instabilities of the *ab initio* molecular orbital description of this system are reported. The D_{3h} solution is indeed singlet stable but there are relatively close-lying C_{2v} broken-symmetry solutions. In the broken-symmetry solutions the π electron network encompasses only five centres; the sixth centre, essentially free of π charge, may be either a sulphur or a nitrogen, thus yielding two distinct broken-symmetry solutions.

M. BÉNARD, W. G. LAIDLAW et J. PALDUS. Can. J. Chem. **63**, 1797 (1985).

Les données cristallographiques indiquent que l'anion trinitrure de soufre, $S_3N_3^-$, a une structure plane avec des longueurs de liaisons SN qui sont égales. Quoique l'on retrouve dans la littérature récente un certain nombre de calculs d'orbitales moléculaires de symétrie D_{3h}, on y trouve également des calculs qui indiquent des azotes non équivalents et ceci suggère une rupture de la symétrie. On rapporte les résultats d'une étude des instabilités de Hartree–Fock pour la description ab initio de l'orbitale moléculaire de ce système. La solution D_{3h} est effectivement stable pour le singulet mais il y a des solutions de symétrie rompue C_{2v} qui y sont assez étroitement associées. Dans les solutions de symétrie rompue, le réseau d'électrons π entoure seulement cinq centres; le sixième centre qui est essentiellement dépourvue de charges π pourrait être soit le soufre soit l'azote et ceci conduit donc à deux solutions distinctes de symétrie rompue.

[Traduit par le journal]

I. Introduction

There has been considerable interest in unsaturated SN compounds as the recent reviews by Roesky (1), Chivers and Oakley (2), and Gleiter (3) attest. There are rings, cages, chains, cations, anions, and neutral species; many of these were made in the last 10 years. The particular focus of this work is the planar $S_3N_3^-$ anion first prepared by Bojes and Chivers in 1977 (4). The tetrabutylammonium salt yields stable yellow crystals which have been analyzed structurally by X-ray diffraction to yield the results depicted in Fig. 1. The bond lengths are 1.60 ± 0.02 Å and the system is planar to within 1°. A similar structure has been reported for this anion in $(Tl^+)_2$ $(S_3N_3^-)$ $(S_4N_5^-)$ (5). Consequently a reasonable representation of the molecular framework is a "hexagon" with bond lengths of 1.60 Å and internal angles of 120°, i.e., the symmetry point group of the nuclei is D_{3h}. The $S_3N_3^-$ anion has 34 valence electrons and, using a Hartree–Fock–Slater (HFS) single determinant wavefunction, Bojes *et al.* reported (6) that 10 of these were π electrons. Thus, the $S_3N_3^-$ anion is a π "electron-rich" system (7). The essential features of the eigenvalue manifold are given in Fig. 2 where it is to be noted that, in addition to the π "bonding orbitals", the degenerate antibonding π^* orbitals $2e''$ are also fully occupied. Bojes *et al.* (6) further characterized this anion in terms of bond orders and charge densities and all six SN bonds were found to be the same, all three nitrogens were equivalent, and all three sulphurs were equivalent.

[1] To whom all correspondence should be addressed.

Following the appearance of the first analysis of $S_3N_3^-$ (6), Bhattacharya and Turner reported CNDO/2 calculations (8) in which all three nitrogens were not equivalent, suggesting that $S_3N_3^-$ could be represented with a localized NSN π bond and a unique charged nitrogen. As such their calculation "broke symmetry" from D_{3h} to C_{2v}. The *ab initio* HFS calculations (7, 9) had, of course, shown no such tendency! Indeed a rather extensive investigation by Smith and co-workers (10) utilizing both a HFS scattered-wave procedure and the CNDO/2 method gave results indicating D_{3h} symmetry. Further a Hartree–Fock calculation by Nguyen and Ha (11), using an extended basis set, also gave a solution with D_{3h} symmetry. Other workers also reported only D_{3h} solutions to the SCF equations for a variety of calculational procedures (12). However, the question remained as to whether the Hartree–Fock results were stable to C_{2v} perturbations, i.e., under what circumstances was symmetry breaking possible.

The past two decades have seen considerable interest in symmetry breaking (cf. the reviews by Fukutome (13*a*) and by Löwdin *et al.* (13*b*)) and the problem has received steady attention since Löwdin formulated his "symmetry dilemma" (14) for the approximate variational wavefunctions in 1963. The response of the system to different variational parameters can provide a useful insight into the sources and mechanism of the Hartree–Fock instabilities. In earlier semiempirical work (15, 16) the ratio of the two- and one-electron interactions (i.e., the ratio γ_{ij}/β_{ij} of the Coulomb and resonance integrals of the Pariser–Parr–Pople π-electron Hamiltonian), representing the coupling constant for these models, was used to drive a given

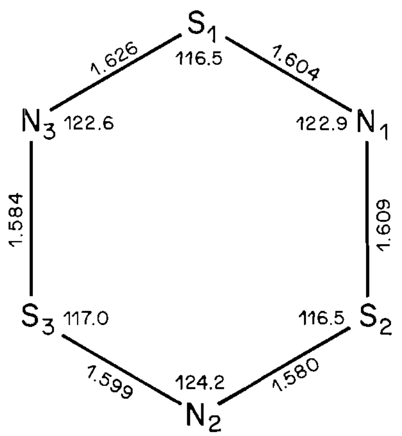

FIG. 1. Structure of the $S_3N_3^-$ anion (bond length in Å).

system to the instability, if present. Since the occurrence of broken-symmetry solutions is a direct consequence of the incorrect description of co-valent bond dissociation provided by the restricted Hartree–Fock method, the internuclear separation(s) can also serve in lieu of the coupling constant, particularly when one employs an *ab initio* Hamiltonian approach (17). Clearly, a large value of the coupling constant enhances the importance of the long range Coulomb interaction relative to the short range chemical forces which are responsible for the chemical bond formation. Such an enhancement will occur automatically in electron-rich or electron-crowded π-electron systems. Consequently, the 10π electron $S_3N_3^-$ anion seems to be a good candidate for the occurrence of the Hartree–Fock instability, at least for the coupling constants (i.e., the SN bond length) which are in the vicinity of their proper equilibrium values.

II. Broken symmetry

In order to establish notation we will review briefly some of the notions associated with symmetry breaking of self-consistent Hartree–Fock wave functions. In the Born–Openheimer approximation, the symmetry operators which leave the nuclear framework invariant commute with the exact Hamiltonian, so that solutions of the Schroedinger equation form a basis for the irreducible representations of the symmetry group, i.e., they are symmetry adapted. Thus,

[1] $H\Psi = E\Psi$ and $[H, R] = 0$ imply that $R\Psi = \lambda\Psi$

where R is a symmetry operator.

However, the Hartree–Fock operator, H_{SCF}, is defined in terms of the self-consistent field given by a density distribution of electrons. It is a non local opeator and in principle need not commute with the point group operators of the nuclear framework. In turn, the calculated Hartree–Fock wave function need not be an eigenfunction of the symmetry operators. As a result the Hartree–Fock wavefunction may exhibit "broken symmetry" — a lower symmetry than that of the nuclear framework. We should emphasize that this is not a Jahn–Teller symmetry distortion insofar as the HOMO-LUMO gap is nonzero; this is a symmetry breaking of the wavefunction, not of the nuclear framework.

To see how this symmetry breaking arises recall that the variational procedure ensures that the solution is a stationary point of the energy, i.e.,

[2] $\delta^{(1)}E = 0$

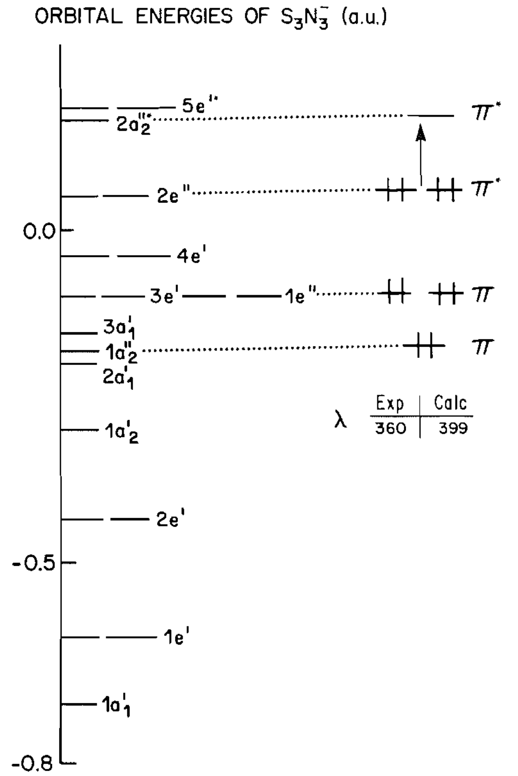

FIG. 2. Orbital energies of $S_3N_3^-$ (au).

where

[3] $E = \langle\Psi|H|\Psi\rangle/\langle\Psi|\Psi\rangle$

However, this stationary point can have complex character, as, for example, pointed out in Fig. 3, the stationary point can be a maximum or a saddle point with reference to a wider class of variations. In this figure we depict an energy surface as a function of bond length and symmetry type. Imagine that this is the SN bond length R in $S_3N_3^-$ and as the figure indicates the surface has a local minimum at R_a with respect to variations which break symmetry to C_{2v}. However, at R_b, a calculation in D_{3h} symmetry is in fact a saddle point and would break symmetry to a lower C_{2v} solution if permitted. The HF solution could break symmetry at the point R_b!

To determine whether a solution would break symmetry one needs to calculate δ^2E in the neighbourhood of the stationary point without imposing any symmetry restriction. If $\delta^2E > 0$ then the system is stable to the variation considered whereas if $\delta^2E < 0$ the system is unstable; hence we need only the sign of δ^2E.

The appropriate formulation of the problem dates back to the work of Thouless in 1961 (18) and a tractable method for spin-independent Hamiltonians was developed by Cizek and Paldus (15) in the late sixties.

One constructs a variational function, Ψ_{BS} for the potentially broken-symmetry solution using, as a basis, the symmetry-adapted solutions obtained at the stationary point of interest. It is worth pointing out that a combination of symmetry-adapted orbitals, belonging to two different irreducible representations, really does allow symmetry breaking. Consider the combination, depicted in Fig. 4, of two symmetry-adapted orbitals π and π^* of a homonuclear diatomic. The combinations $\pi' = \pi \pm \pi^*$ generate an orbital with density around one nucleus only; thus π' is certainly a broken-symmetry orbital. At the N-

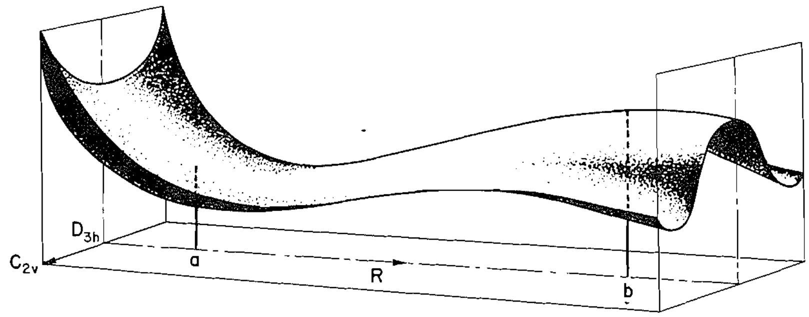

FIG. 3. A complex energy surface with potential for symmetry breaking.

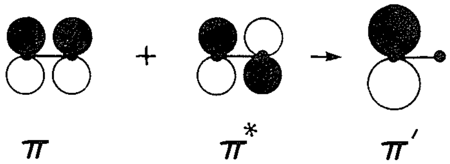

FIG. 4. Formation of a broken symmetry orbital.

electron level such an orbital implies that a general broken-symmetry wavefunction, Ψ_{BS}, can be expressed as a sum of the symmetry-adapted function, Ψ_{SA}, and the functions Ψ_1 and Ψ_2 generated by single and double excitations $\Psi_{SA}(i \to j)$ and $\Psi_{SA}\binom{i\to j}{k \to l}$. Thus

[5] $\Psi_{BS} = \Psi_{SA} + \Psi_1 + \Psi_2$

where

[6] $\Psi_1 = \Sigma d_{ij} \Psi_{SA}(i \to j)$

and

[7] $\Psi_2 = \Sigma d_{ij} d_{kl} \Psi_{SA}\binom{i\to j}{k \to l}$

The second variation, $\delta^2 E$, can be written as a quadratic form in d_{ij}

[8] $\delta^2 E = \Sigma\{d_{ij} d_{kl} A_{ijkl} + (1/2) d_{ij} d_{kl} B_{ijkl} + (1/2) d_{ij} d_{kl} \bar{B}_{ijkl}\}$

where the matrix elements A_{ijkl} and B_{ijkl} are defined by

[9] $A_{ijkl} = \langle i \to j | H - E_{SA} | k \to l \rangle$, $B_{ijkl} = \langle \binom{i\to j}{k \to l} | H - E_{SA} | \rangle$

where H is the Hamiltonian and E_{SA} is the energy of the symmetry-adapted solution at the stationary point of interest.

The sign of $\delta^2 E$ can be determined by calculating the eigenvalues λ_i of the characteristic matrix of the quadratic form given in eq. [8]. As shown by Cizek and Paldus (15) this problem can be broken into a number of subproblems depending on the constraints placed on the broken-symmetry solution. We require that the broken-symmetry solution be a singlet and write the singlet stability problem as

[10] $\begin{pmatrix} \mathbf{A} & \mathbf{B} \\ \bar{\mathbf{B}} & \bar{\mathbf{A}} \end{pmatrix} \begin{pmatrix} \mathbf{D} \\ \bar{\mathbf{D}} \end{pmatrix} = \lambda \begin{pmatrix} \mathbf{D} \\ \bar{\mathbf{D}} \end{pmatrix}$

where the elements of **A** and **B** are defined by eq. [9] and D_i are vectors giving the mixing coefficients d_{ij} corresponding to the broken-symmetry solution $\Psi_{BS,i}$. A positive value of λ_i indicates stability of the symmetry-adapted solution whereas a negative λ_i indicates the existence of a broken-symmetry solution of lower energy.

II. Calculations

For our stability calculations we have utilized a Hartree–Fock procedure with a minimal basis for the internal shells and a double ζ basis set for the valence shell. The basis sets used were those of Huzinaga (20); an 11.7 contracted to 5.3 for sulphur and a 9.5 contracted to 4.2 for nitrogen. The symmetry-adapted D_{3h} solution gave a minimum in energy at the SN bond length of 1.72 Å. The charges on sulphur and nitrogen were calculated to be $q_S = 0.6$ and $q_N = -0.9$ which are somewhat larger than expected but our orbital eigenvalue ordering is similar to that of Nguyen and Ha (11) and of Chivers *et al.* (7). Inclusion of a d orbital basis function (cf. Nguyen and Ha (11)) can lower the distance for minimum HF energy to 1.64 Å so that our basis could certainly be improved; however, for purposes of probing stability it should suffice. In fact, Hartree–Fock instability is induced by the large correlation effects associated with the dissociation of covalent bonds. These effects are not expected to be significantly basis-dependent. For instance, calculations carried out for the hexagonal H_6 model system (21) and for the allyl ion did not produce significant changes as the basis sets were extended. For our stability calculations we employed the "Asterix routine" (22) and we considered excitations involving orbitals between $2E'$ (cf. Fig. 2) and $11E'$ (a total of 41 MO's).

We have calculated the D_{3h} solution at a number of bond lengths R_{SN} from 1.6 to 2.4 Å. In each calculation, all bond lengths R_{SN} are the same, i.e., we consider a uniform expansion of all bonds and we always retain a D_{3h} nuclear framework. From the molecular orbitals in each case we generate the matrix elements A,B for the singlet stability problem outlined earlier. We then solved for the stability eigenvalues λ_i and eigenvectors D_i. If negative λ_i are found we solved the HF equations for the broken-symmetry solutions, using the D_i as a guide to construct the starting vector.

The dependence of the lowest stability eigenvalues, on the internuclear separation R_{SN}, is plotted in Fig. 5. All eigenvalues remain positive up to about 2.0 Å. Thus the symmetry-adapted D_{3h} solution remains stable to all singlet symmetry-breaking variations up to this point. In fact the first negative eigenvalue arises in a subproblem leading to C_{2v} symmetry breaking rather than a C_{3h} symmetry even though C_{3h} is the next lowest symmetry to the D_{3h} starting point. At about 2.0 Å one of the roots has crossed the zero axis, indicating that the stationary D_{3h} solution is no longer stable with reference to a C_{2v} broken-symmetry solution. The critical value of $R_{SN}^{crit} = 1.95$ Å is relatively close to the equilibrium bond distance of 1.60 Å — certainly much closer than is the critical value of $R_{CC}^{crit} \simeq 2.20$ Å in benzene (19) to the equilibrium bond distance of 1.4 Å, or of $R_{HH}^{crit} = 5.8$ Å to the equilibrium value of $R_{HH} = 1.92$ Å in H_6 (17).

In order to analyze the "driving force" for this instability we considered the stability of the π system separately, i.e., we

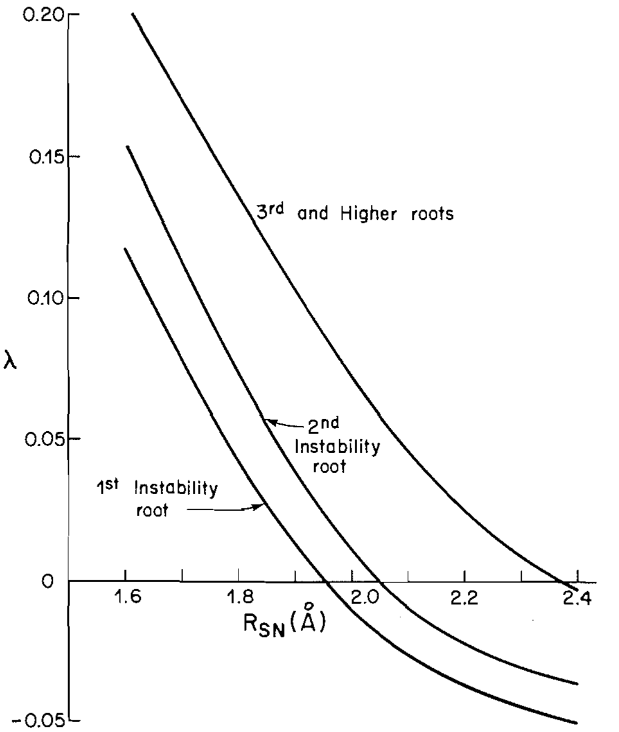

FIG. 5. Dependence of broken symmetry eigenvalues on internuclear distance R_{SN} in $S_3N_3^-$.

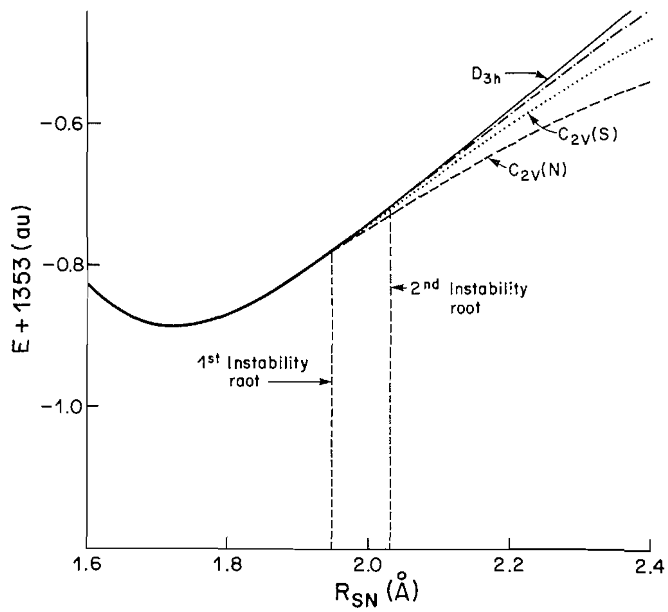

FIG. 6. Dependence of energy of symmetry adapted and broken symmetry HF solutions on internuclear distance R_{SN} in $S_3N_3^-$. Both the C_{2v}(N), - - -, and C_{2v}(S), ·····, solutions arise from the first instability root. The solution denoted by -·-·-· is of C_s symmetry and arises from the second instability root.

considered only excitations of π orbitals. In this case the eigenvalues of the stability problem are much higher, i.e., the system is more stable. For example at R_{SN} = 1.60 Å the stability eigenvalue was 0.28 but *with* $\sigma-\pi$ interaction it was less than half this at 0.12 so that σ-electron rearrangement helps to drive the stability eigenvalue towards its critical value of zero. Clearly both the σ and π interactions are responsible for the relative

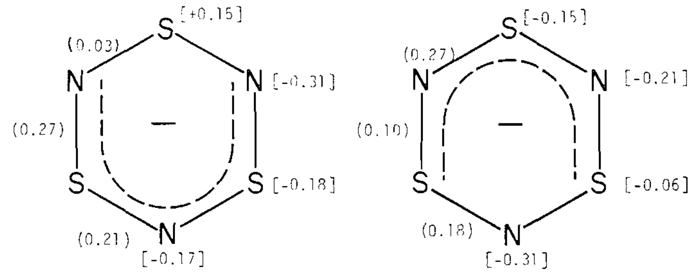

FIG. 7. Charges [ ] and bond overlap population ( ) in the C_{2v} broken symmetry HF solution at R_{SN} = 2.40 Å. (*a*) The C_{2v}(S) or sulphur π-hole solution; (*b*) the C_{2v}(N) or nitrogen π-hole solution.

ease of symmetry breaking here.

Perhaps more interesting is that the single C_{2v} root leads to two different broken-symmetry solutions. We find that both C_{2v} broken-symmetry solutions are 10π-electron systems and, as Fig. 6 shows, in the range 2.0 to 2.4 Å they are lower in energy than the D_{3h} symmetry-adapted solution, by as much as 35 and 70 kcal/mol at R_{SN} = 2.4 Å. The difference between the two C_{2v} solutions is intriguing also. Analysis of the orbital overlap populations given in Table 1, shows that in the lower of the C_{2v} broken-symmetry solutions, C_{2v}(N), the 10π-electrons are largely confined to the five atom SNSNS system and the unique nitrogen does not participate in the π system — it is an N π-hole as depicted in Fig. 7(*b*). The other C_{2v} solution, C_{2v}(S), has the 10π-electron system confined to the five atom NSNSN chain and the unique sulphur does not participate in the π system, it is an S π-hole as depicted in Fig. 7(*a*). Further the overlap populations (cf. Table 1) in the two are quite different. For example, at 2.40 Å the N π-hole system has a weak bond between the NSN and SNS fragments whereas the S π-hole has very weak bond (see Fig. 7) between the unique sulphur and the rest of the system.

III. Discussion

The appearance of C_{2v} as the lowest broken-symmetry solution for $S_3N_3^-$ is, at first glance, unexpected. One might have expected that the scheme would follow the D_{3h} subgroup chain, namely:

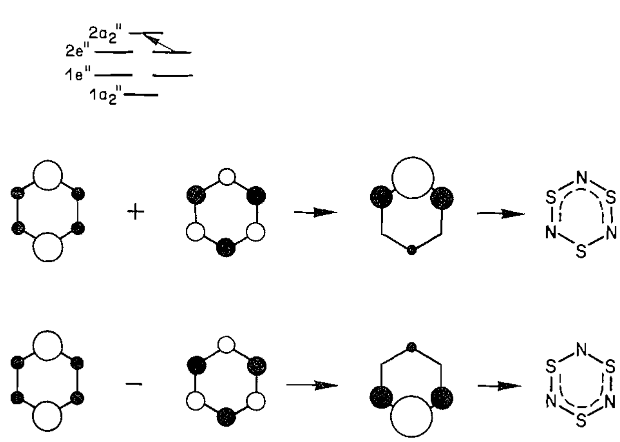

FIG. 8. Excitations generating C_{2v} symmetry.

D_{3h} (symmetry adapted with six equivalent SN bonds)
$\rightarrow C_{3h}$ (with 3 "double" and 3 "single" SN bonds)
$\rightarrow C_{2v}$ (with a unique nitrogen or sulphur)
$\rightarrow C_s$, etc.

For example, the symmetry-breaking route in cyclic polyenes, such as benzene, is first to the next lowest symmetry, i.e., for benzene the symmetry adapted D_{6h} breaks to D_{3h} (Kekulé structures). One can, however, explain this difference by recalling that $S_3N_3^-$ is a π "electron-rich" system where both $1e''$ and $2e''$ (cf. Fig. 2) are doubly occupied. Consequently the first low-lying available excitation is from $2e'' \rightarrow 2a_2''$. As Fig. 8 indicates mixing a $2e''$ orbital with $2a_2''$ leads to broken-symmetry orbitals of C_{2v} type. The mixing of $1e''$ and $2e''$ would, as Fig. 9 indicates, certainly result in C_{3h} type broken-symmetry solutions. However, since these orbitals are fully occupied in the 10π $S_3N_3^-$ system these excitations do not occur! This is of course not the case in the 6π system of benzene where they would be available and where, as mentioned above, one does indeed go to the nearest symmetry type, D_{3h}.

The lifting of the degeneracy for the C_{2v} problem is also different than the usual situation in cyclic polyenes where the plus and minus combination of symmetry-adapted orbitals remain degenerate. As the illustrations in Fig. 8 indicate, the excitation $2e_a'' \rightarrow 2a_2''$ giving either $2e_a'' + c2a_2''$ or $2e_a'' - c2a_2''$ yield different solutions due to the nonequivalence of the S and N sites and it is just these excitations which generate the broken-symmetry C_{2v}(N) and C_{2v}(S) solutions in $S_3N_3^-$. The $1e'' \rightarrow 2e''$ excitations yielding $1e'' \pm c2e''$ would, as Fig. 9 shows, remain degenerate and this is what one sees in benzene and what one would see in $S_3N_3^-$ except that they are not available for symmetry breaking.

The lower energy of the N π-hole broken-symmetry solution compared to the S π-hole can be explained by consideration of the σ and π electron system. An analysis of Table 1 and Fig. 7(*b*) would show that N_4 loses 1.8 π-electrons on going from D_{3h} to C_{2v}(N), (the π population changes from 1.9 to 0.1). However, the total charge on N_4 increases by 0.14 (i.e. -0.17 to -0.31) indicating a gain of about 1.9 σ electrons. Thus the σ electrons "move" in the opposite direction to the π electrons on breaking symmetry from D_{3h} to C_{2v}(N). A similar comparison of D_{3h} and C_{2v}(S) will show that the unique sulphur, S_1, loses about 1.2 π electrons but gains about 0.9 σ electrons so that here too the reorganization of σ and π electrons is in "opposite directions". It is well known (23) that the σ electronegativity of nitrogen is greater than that of sulphur; consequently nitrogen is better able to accept the rather massive σ charge required on the unique atom in the C_{2v} symmetry.

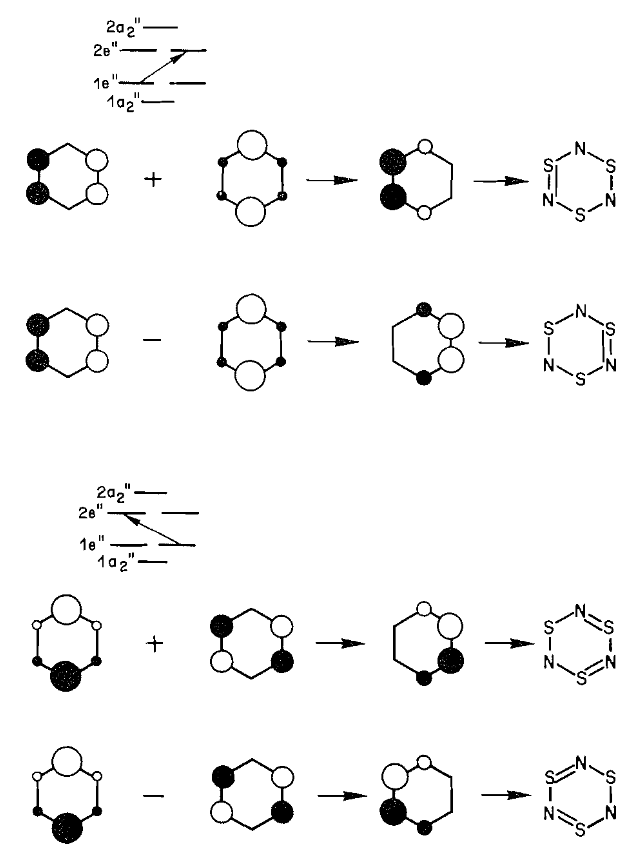

FIG. 9. Excitations generating C_{3h} symmetry.

Further investigation of the role of electronegativity differences in controlling HF instabilities is underway.

IV. Implications

The first and most obvious implication is that the Hartree–Fock D_{3h} solution is stable in the region of $R_{SN} = 1.6-1.8$ Å i.e., in the neighbourhood of the experimental bond length. This supports the contention of Smith and co-workers (10) and our own remarks (9) that the solution obtained by Bhattacharya and Turner (8) is spurious and is not a reflection of symmetry breaking. On a more positive note our investigations allow us to sketch the HF energy surface as in Fig. 10. As this figure shows the HF energy surface becomes more complex as the nuclear framework is uniformly stretched. At 2.0 Å the D_{3h} solution is unstable and at 2.4 Å there are three close-lying 10π electron systems indicating the inadequacy of the HF representation. However, broken-symmetry solutions can, in such a case, give an indication of the preferred distortions and or dissociations. In the lowest of the broken-symmetry solutions, the C_{2v} (N), one of the nitrogens does not even participate in the 10π system and the SN bond between the NSN and SNS fragments is markedly weaker. These are indeed the fragments which have been proposed (24) in the thermal degradation of this system as

[12] 
$\rightarrow S_2N^- + N_2S$

Hartree–Fock stability and symmetry breaking: oxygen doubly negative ion

JOSEF PALDUS AND JIŘÍ ČÍŽEK

Quantum Theory Group, Department of Applied Mathematics, and Department of Chemistry and (GWC)[2], Waterloo Campus, University of Waterloo, Waterloo, Ontario, Canada N2L 3G1

Received September 10, 1984

This paper is dedicated to Professor Camille Sandorfy on the occasion of his 65th birthday

JOSEF PALDUS and JIŘÍ ČÍŽEK. Can. J. Chem. **63**, 1803 (1985).

The Hartree–Fock stability problem, its relationship to the broken symmetry solutions, and the implications for a molecular nuclear framework distortion are briefly reviewed. The case where no nuclear framework distortion is possible is studied for the oxygen doubly negative ion, using an *ab initio* Slater-type orbital analytical approach, in order to illustrate other possible implications of the symmetry breaking in the independent particle models. It is shown that the existing pure singlet broken symmetry solutions for this ten electron ion, which were obtained earlier by *ad hoc* procedures, follows systematically and straightforwardly from the HF stability problem for the corresponding symmetry adapted solution which shows a strong singlet instability. The chemical and physical implications of this type of symmetry breaking are briefly discussed.

JOSEF PALDUS et JIŘÍ ČÍŽEK. Can. J. Chem. **63**, 1803 (1985).

On passe brièvement en revue le problème de la stabilité des solutions des équations de Hartree–Fock. On a mis en évidence le rôle des solutions de symétrie brisée et les implications par rapport à une distorsion du squelette nucléaire moléculaire. Dans le but d'illustrer d'autres implications possibles du bris de symétrie dans le modèle à particules indépendantes, on a utilisé une approche analytique *ab initio* avec des orbitales du type de Slater pour étudier l'ion doublement négatif de l'oxygène, un cas où il n'y a pas de possibilité de distorsion du squelette nucléaire. On démontre que, pour cet ion à dix électrons, les solutions de symétrie brisée correspondant à des singulets purs, qui ont été obtenues antérieurement par des procédures *ad hoc*, découlent systématiquement et d'une façon directe du problème de la stabilité HF. La solution correspondante adaptée pour la symétrie possède une instabilité forte du type singulet. On discute brièvement des implications chimiques et physiques de ce type de bris de symétrie.

[Traduit par le journal]

Introduction

About 15 years ago we introduced the concepts of singlet, non-singlet (triplet), and doublet stabilities (1, 2) for solutions to the restricted Hartree–Fock (RHF) equations, following the general stability criteria given by Thouless (3). This was just at the time when we had been privileged to establish personal contacts with Professor Camille Sandorfy, shortly after joining the University of Waterloo in 1968. Although we have been very fortunate to work at Waterloo, the time following our exodus from Czechoslovakia was rather difficult for us. Professor Sandorfy, who himself went through a similar ordeal earlier, took a deep interest in both our personal and professional problems, and we shall be forever grateful to him for his continued encouragement and friendship. We thus wish to dedicate this paper to him on the occasion of his 65th birthday as a small token of our respect and gratitude. We chose this topic both for personal reasons and also because the topic is still very much alive today as we shall explain.

It is well known that the exact wavefunction Ψ represents a simultaneous eigenstate of the (Born–Oppenheimer) Hamiltonian H of an atomic or molecular system, and all of its constants of motion (we assume for simplicity that Ψ is nondegenerate). In other words, the exact wavefunction is automatically symmetry-adapted with respect to all symmetry operations which leave H invariant. In contrast, for an approximate variational wavefunction Φ, the requirement of symmetry adaptation represents an additional constraint on the variational problem which can only raise the energy. Thus, one often finds a broken symmetry wavefunction Φ' to yield a lower energy than the symmetry-adapted one. This fact was first clearly stated by Löwdin and is known as the symmetry dilemma (4). A physical or chemical interpretation of the symmetry breaking is far from being straightforward: it may indeed imply a distortion of the molecular framework, or the chemical reaction to proceed in certain ways, but it can also be only a signal of the inadequacy of the given approximation. To give general global criteria for a variational wavefunction to correspond to the absolute minimum of the energy hypersurface is extremely difficult (cf. e.g. ref. 5). We thus restrict ourselves to the requirement that at least locally a given variational solution corresponds to a minimum on the energy hypersurface. Such a solution is referred to as *stable*, while in the opposite case, when the solution is *unstable*, we know that another solution with lower energy must exist. The mathematical formulation of the corresponding stability conditions is achieved in terms of the second variation, or in the usual finite dimensional case in terms of the corresponding Hessian. For the HF wavefunctions this was first done by Thouless (3) and for the Brueckner (maximum overlap) wavefunctions by Paldus, Čížek, and Keating (6).

The Hamiltonians encountered in the molecular electronic structure determination are generally spin-independent, so that both $\hat{S}_z$ and $\hat{S}^2$ operators represent an integral of motion. Using this fact we have formulated the multiplicity-preserving stability conditions. Thus, in the one-determinantal closed shell singlet case we distinguish the *singlet* and the *nonsinglet (triplet) stability conditions* (1): the former preserve the singlet character while the latter do not. Consequently, in case of instability, the former lead to pure singlet single-determinantal broken symmetry solutions (usually it is the space symmetry which gets broken) while the latter lead to the DODS (different orbitals for different spins)-type UHF (unrestricted Hartree–Fock) solutions. Similarly, we define *doublet* and *non-doublet instabilities* (2) in a simple open-shell case, etc. The stability is simply characterized by the vanishing index (the number of negative eigenvalues) of the pertinent Hessian. The eigenvector associated with the lowest negative eigenvalue, in case of an instability, can be shown to define the direction of the steepest descent on the energy hypersurface. (A similar interpretation can be made for higher eigenvalues and corresponding eigenvectors.) Following this direction one finds the wavefunction with lower energy which can be expected to be in the neighborhood of the corresponding broken-symmetry solution (similar to the "catchment regions" of Mezey (7)) and thus can conveniently be used as the starting approximation in iterating the HF equations. More general classification of the HF instabilities, in which not only the spin operators are considered but also the time-reversal (and spatial) symmetry, was given later by Fukutome (8). Stability conditions for RHF triplet states were also formulated (9). More recently, generalizations of projected HF schemes (10, 11), the formulations in terms of gap equations (12) as well as several other developments (13) have appeared. Presently, several excellent reviews are also available (10, 14, 15). We must also mention a close relationship of the HF stability criteria with other methodological developments, particularly with the RPA (random phase approximation) or TDHF (time-dependent Hartree–Fock) approaches (16, 17), and the polarization propagator and Green function approaches (18), but also with the MCSCF (multiconfiguration self-consistent-field) method (19) and the convergence problem for various SCF schemes (20), as well as with other approaches such as the generator coordinate method (21), complex molecular orbital approach (22), cluster expansion method (23), and sudden polarization (24).

For a large number of closed shell systems the symmetry-adapted RHF solutions are singlet-stable. However, for certain systems, particularly the so-called electron-rich systems, the symmetry-adapted RHF solution is singlet-unstable (the non-singlet instability is rather common and the UHF solutions for closed shell systems, which have a lower energy than the corresponding RHF solution, have been known (25) before the non-singlet stability conditions were formulated). Often the pertinent Hessian has more than one negative eigenvalue so that several broken symmetry solutions with lower than RHF energy can be found. The first systems for which the RHF ground state was found to be singlet unstable were cyclic polyene models C_NH_N, $N = 4\nu + 2$, $(\nu = 1, 2, \ldots)$ described by the semiempirical PPP (Pariser–Parr–Pople)-type Hamiltonians (1, 26). Later, a number of other π-systems have been examined and various instabilities found (27–29). Similar instabilities were also found at the *ab initio* level for the H_N systems, modelling a linear hydrogen metal (30), as well as for a number of other systems (31–37), even though the broken-symmetry solutions are often obtained without a prior examination of the character of the symmetry-adapted RHF solution (38–40). The singlet instabilities proved to be particularly important for transition metal complexes and systems containing multiple metal–metal bonds (34, 35, 41, 42), where one often finds the index of the pertinent Hessian, associated with the ground state symmetry-adapted RHF solution, to have very high values (~5). Thus, the stability conditions mentioned above have often been applied to various HF solutions (43–46), and broken-symmetry solutions are today known for many systems, both small and large, treated either at the *ab initio* or semiempirical levels (47).

When an instability of a given HF solution is found, it implies the existence of a broken symmetry solution with lower energy (1, 2), as schematically indicated in Fig. 1*a*. Though the converse does not hold, and a broken symmetry solution with lower energy can exist even when the RHF solution is stable (cf. Fig. 1*b*), no such case is actually known except for

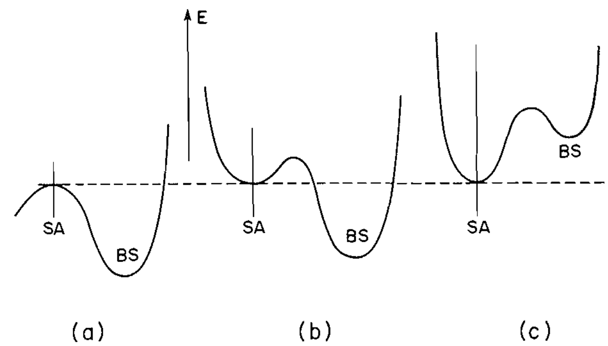

FIG. 1. A schematic representation of the variational energy hypersurface as a function of the variational parameters, indicating the basic possibilities for the relationship between the symmetry-adapted (SA) and broken-symmetry (BS) Hartree–Fock solutions.

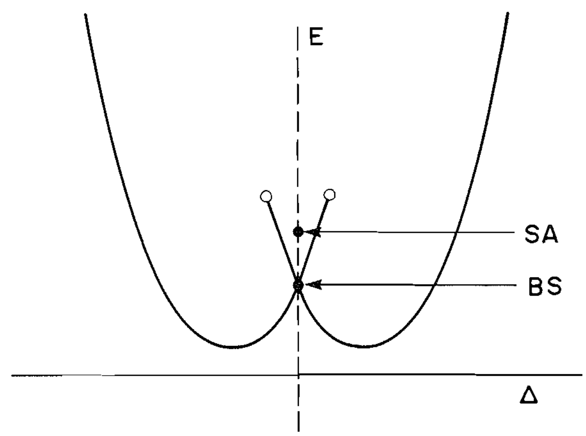

FIG. 2. A schematic representation of the HF potential energy surface as a function of the symmetry-breaking nuclear framework distortion (or vibrational coordinate) Δ. The symmetry adapted solution (SA) can only be obtained for the undistorted structure characterized by $\Delta = 0$. The broken symmetry (BS) solutions for $\Delta = 0$ are degenerate and each can be smoothly continued to $\Delta \neq 0$. The energy of each solution decreases when the nuclear framework is distorted as suggested by the charge density wave of the BS solution (in-phase distortion), both potential energy curves intersecting at the finite angle for undistorted ($\Delta = 0$) structure. When out of phase distortion is made, the energy rises but the solution usually disappears for larger distortions as indicated by open circles.

a simple one-electron model system studied by Katriel and Kventzel (48). The possible types of unstable (*a*) and stable (*b*, *c*) RHF solutions with related broken-symmetry solutions are schematically illustrated in Fig. 1. Clearly, the possibility represented by Fig. 1*b* cannot be *a priori* excluded. We must also stress that Fig. 1 depicts schematically the HF energy hypersurface as a function of variational parameters and *not* the potential energy surface of a given molecule. The latter may in fact possess a highly non-analytic character (as well as the former one, of course, see e.g. ref. 49) if the CDW (charge density wave) associated with the broken symmetry solution implies an actual distortion of the nuclear framework: designating by Δ the parameter (or vibrational coordinate) which characterizes this distortion (e.g., bond length alternation in long polyenes, asymmetric stretch in AB_2 type systems, etc.), the behavior of the potential energy surface as a function of Δ is schematically shown in Fig. 2 (30, 31, 50). (For a general bifurcation structure of the potential energy surface see the last entry in ref. 8.)

The problem of a possible physical significance of various broken symmetry solutions has often been addressed but there is still no simple and universal answer available. Undoubtedly, the instability is often only an indication of the inadequacy of the IPM (independent particle model) picture and of the necessity to use more sophisticated, multi-reference, approaches. This seems particularly to be the case for most small molecular species, although even here the instability can persist to the MC SCF or even CI (configuration interaction) levels (40), and can in fact imply a distorted geometry for certain states or, at least, the existence of vibrational modes with a very flat potential (39), as it does for large and extended systems (see below). A general argument for the possibility of broken symmetry solutions to describe physical phenomena, based on the ideas of Peierls and Yoccoz (51) and BCS theory of superconductivity (52), was extensively discussed by Fukutome (14). A very interesting link between the singlet instabilities (or near-instabilities) and the existence of negative force constant for a normal coordinate along which the pseudo Jahn–Teller distortion or the symmetry reduction may occur was recently established by Deguchi *et al.* (53). In the case of the energetically more efficient spin-symmetry breaking there is also significant evidence for possible chemical or physical implications, as was shown for example by Yamaguchi, Fueno, and collaborators (43, 54) in their classification of organic reaction mechanisms into the bi-radicaloid and non-radicaloid types. Finally, the symmetry breaking is of great importance for the electronic structure of extended systems, particularly for the organic polymers with conjugated double bonds. It is closely related with the so-called dimerization or Peierls' distortion found in linear chains (50, 55–57). These problems received a new impetus with the synthesis of polyacetylene films which show the most remarkable and promising electric, magnetic, optical, and other properties (58). Many important studies, both with semiempirical and *ab initio* Hamiltonians have been carried out in this direction (55–57, 59–66).

We can thus conclude that the existence of a singlet instability for closed shell ground states clearly indicates the need to investigate the studied system in higher approximation than the IPM. Even though the broken-symmetry solution, which inherently accounts for some part of the correlation error, will generally provide a better description of various properties than the RHF solution, great care must be exercised as far as actual distortion of the nuclear framework is concerned. Conversely, the instability may be present even when no space symmetry can be broken, say for the ABC-type triatomics and analogous polyatomic systems (e.g. CH_2CHO, CH_2CN etc.). In this case one can talk about the breaking of an *approximate symmetry* when the system is related with isoelectronic (AB_2 type) system. In a number of cases, however, there is no natural vibrational coordinate which can be related with the appearance of the instability, which thus must have other implications than the nuclear framework distortion. In such cases the instability is solely associated with the structure of the electronic cloud, as for example in the case of core-hole or valence-hole ionized diatomic species. Obviously, one should also have this possibility in mind even when considering polyatomic systems. The clearest form of this type of instability will be found in atomic systems, where no nuclear framework distortion is possible. We thus investigate such a case in this paper, considering the singlet instability of the oxygen doubly negative ion, O^{2-}, and the broken-symmetry solutions associated with it. One such broken-symmetry solution was found empirically by Prat (67). An exploitation of singlet instability conditions helped not only to recover this same solution, and to show that the situation characterized by Fig. 1*a* rather than Fig. 1*b* takes place, but also to find yet another pure singlet broken-symmetry solution with even lower energy (68). We shall also see what physical implications, if any, have the instabilities involving solely the electronic cloud.

Singlet and non-singlet stability conditions

We first briefly recall the explicit form of stability conditions for the closed shell systems. Consider the spin-independent Hamiltonian H,

$$[1] \quad H = Z + V = \sum_i z_i + \sum_{i<j} v_{ij}$$

and a single determinantal closed-shell RHF wavefunction Φ_0,

$$[2] \quad \Phi_0 = \det \|\phi_1\alpha\ \phi_1\beta\ \phi_2\alpha \ldots\ \phi_n\alpha\ \phi_n\beta\|,$$

where α and β are spin up and spin down functions, respectively, and ϕ_i ($i = 1, \ldots, n$) are occupied RHF MO's. Designating the virtual MO's by primed indices, ϕ_i', and labeling the monoexcitations $i \rightarrow j'$, arranged in some arbitrary but fixed order, by the single index u, $u \equiv u(i \rightarrow j')$, we can state the stability conditions as follows (1, 2). The HF solution [2] is singlet (x = s) or non-singlet (triplet) (x = t) stable, if the Hessian

$$[3] \quad \begin{vmatrix} \mathbf{A}^x & \mathbf{B}^x \\ \bar{\mathbf{B}}^x & \bar{\mathbf{A}}^x \end{vmatrix}$$

has only positive eigenvalues. The square matrices $\mathbf{A}^x$, $\mathbf{B}^x$ (x = s, t), whose rows and columns are labeled with all possible monoexcitations u, have the form

$$[4] \quad \begin{aligned} A^t_{uv} &\equiv \langle i \rightarrow j' | A^t | k \rightarrow l' \rangle \\ &= \epsilon_{j'}\delta_{j'l'} - \epsilon_i\delta_{ik} - \langle kj' | \hat{v} | il' \rangle \\ B^t_{uv} &= -\langle j'l' | \hat{v} | ki \rangle \\ A^s_{uv} &= A^t_{uv} + 2\langle kj' | \hat{v} | l'i \rangle \\ B^s_{uv} &= B^t_{uv} + 2\langle j'l' | \hat{v} | ik \rangle \end{aligned}$$

where ϵ_i designate HF canonical orbital energies, $\langle ij | \hat{v} | kl \rangle$ are the two-electron interaction matrix elements in the MO basis $\langle \phi_i\phi_j | \hat{v} | \phi_k\phi_l \rangle$, and $\bar{\mathbf{X}}$ designates the complex conjugate of $\mathbf{X}$.

When $\mathbf{A}^x$ and $\mathbf{B}^x$ (x = s, t) are real, we can further factorize the Hessian [3] and instead consider the matrices (1, 2)

$$[5] \quad (\mathbf{A}^x \pm \mathbf{B}^x)$$

The relationship between the eigenvectors of [3] and [5] is easily found (1, 2, 28). Finally, designating the eigenvector of [3] associated with the lowest eigenvalue λ_0 by $\boldsymbol{d} = \|d_{i\rightarrow j'}\|$, the trial wavefunction $\Phi(\kappa)$,

$$[6] \quad \Phi(\kappa) = \det \|\psi_1\alpha\ \psi_1\beta\ \psi_2\alpha \ldots \psi_n\alpha\ \psi_n\beta\|$$

with

$$[7] \quad \psi_i = \phi_i + \kappa \sum_{j'} d_{i\rightarrow j'}\phi_{j'}$$

gives the direction of the steepest descent ($\lambda_0 < 0$) or the slowest ascent ($\lambda_0 > 0$) on the mean-energy hypersurface, given by

$$[8] \quad E(\kappa) = \langle \Phi(\kappa) | \hat{H} | \Phi(\kappa) \rangle / \langle \Phi(\kappa) | \Phi(\kappa) \rangle$$

as a function of the mixing parameter κ. In other words, the eigenvector components $d_{i \rightarrow j'} \equiv d_u$ give the ratios in which the virtual orbitals must be admixed to the occupied orbitals in order to obtain a trial function corresponding to the direction of the steepest descent (slowest ascent) at the studied point represented by Φ_0 (1, 2, 28). We shall exploit this procedure to find the starting point for the usual SCF iterative method, which will converge to the broken-symmetry solution associated with a given negative root of the singlet stability problem.

Symmetry-adapted RHF solutions for O^{2-}

We shall use analytic HF solutions with the orbitals (i.e., "molecular" orbitals) expressed as linear combinations of Slater-type orbitals (STO's). The Hartree–Fock–Roothaan equations are then used to determine the linear coefficients in this expansion. We shall exploit two different bases in order to be able to discern the basis dependence of our considerations as much as possible. The first basis is taken from an early study of Clementi and McLean (69) and will be designated as the C-basis for short. The second basis, referred to as the H-basis, is that of Huzinaga and collaborators (70).

The HF problem for doubly negative ions has been often plagued with convergency problems, particularly when the usual SCF iterative procedure for solving of Hartree–Fock–Roothaan equations is employed (69, 71–73). These problems are further amplified in the numerical integration schemes (74), where it is generally impossible to obtain a converged HF solution (75).

We have encountered no difficulty in solving the pertinent Hartree–Fock–Roothaan SCF equations when we proceeded as follows. We have first increased the nuclear charge in order to obtain a neutral system and subsequently lowered the nuclear charge, in sufficiently small steps when necessary, always using the converged solution for higher nuclear charge as the initial approximation. In the studied case we started with the Ne atom ($Z = 10$), proceeding via F^- ($Z = 9$) and, after several steps, reaching O^{2-} ($Z = 8$). The converged solutions, given in Tables 1–3, are practically identical with those obtained earlier (70).

Stability calculation and broken-symmetry solutions

We have next applied the singlet and non-singlet stability conditions (see above) to the symmetry-adapted RHF solutions obtained for the O^{2-} ion. The Hessians [5] can be further factorized using the spatial symmetry of the problem and the relevant subproblems can be conveniently labeled by the change in the magnetic quantum number m. Rather than to restrict ourselves to the ion O^{2-}, it is instructive to follow a few

TABLE 3. Total HF energy (E), one- and two-particle HF energies (E_1 and E_2) and orbital energies ϵ_i (all in au's) for the symmetry-adapted and broken-symmetry HF solutions for the O^{2-} ion with both C and H STO bases (69, 70)

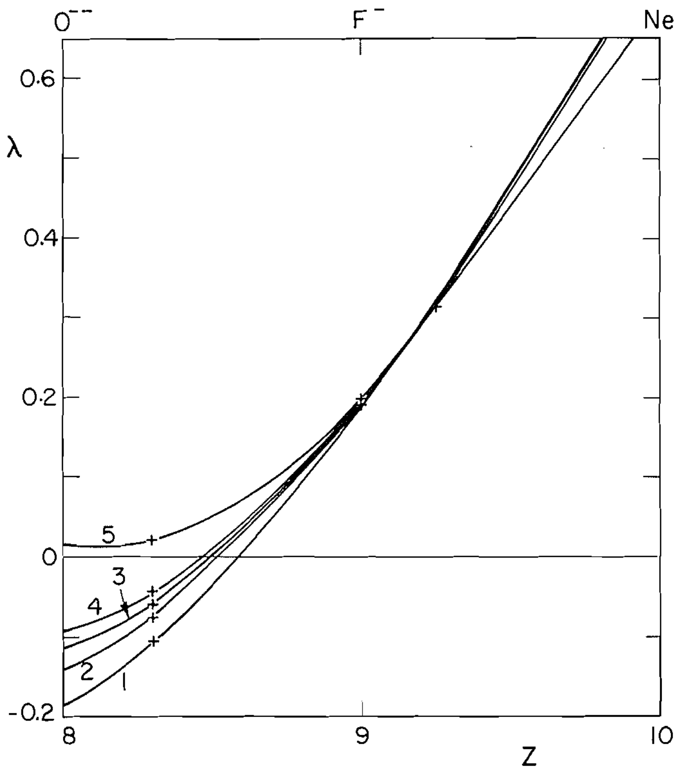

FIG. 3. The dependence of the first three triplet (*1–3*) and singlet (*3–5*) stability roots λ as a function of the nuclear charge Z for the 10-electron atomic system. The points Z = 8, 9, and 10 correspond to O^{2-}, F^-, and Ne atoms, respectively, as indicated at the top of the figure. Note that the third triplet stability root ($\mathbf{A}^t + \mathbf{B}^t$) is identical to the lowest singlet stability root ($\mathbf{A}^s + \mathbf{B}^s$), both represented by the curve *3*. The lowest singlet stability root (*3*) is triply degenerate and the second one (*4*) is quintuply degenerate.

lowest roots of the stability problem as a function of the nuclear charge Z, $8 \leq Z \leq 10$. While no negative roots are found for either the Ne or F^- cases, the three lowest triplet instability roots cross zero and become negative at about $Z \sim 8.6$. These are immediately followed by the two lowest singlet instability roots. In fact, the lowest singlet instability root, arising from the ($\mathbf{A}^s + \mathbf{B}^s$) subproblem, is identical to the third ($\mathbf{A}^t + \mathbf{B}^t$) root (see Fig. 3). The lowest singlet instability root is triply degenerate and occurs in the $\Delta m = 0$ and $\Delta m = \pm 1$ subproblems, while the second lowest root is quintuply degenerate, occurring in all Δm = 0, ±1, and ±2 subproblems. Consequently, we

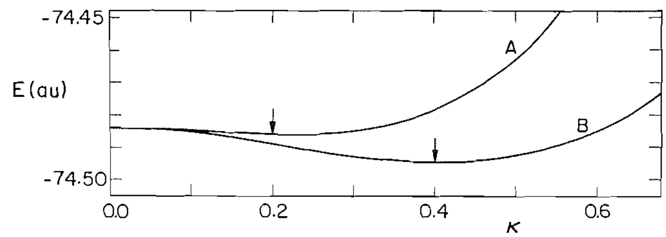

FIG. 4. Dependence of the mean energy value E (in au) on the mixing parameter κ, eqs. [6], [7], for O^{2-} with the C STO basis (69), for the singlet stability roots *3* and *4* of Fig. 3.

refer to these roots, and to the corresponding broken-symmetry solutions, as being of the P and D type, respectively.

In order to find the corresponding broken-symmetry solutions we first optimize the energy [8] as a function of the mixing parameter κ, eqs. [6], [7]. This energy mean-value dependence is shown in Figs. 4 and 5 for the cases of C and H bases, respectively. The Hartree–Fock solution corresponding to the minimum energy is then used as the starting point in solving iteratively the Hartree–Fock–Roothaan equations (without any constraints placed on the individual orbitals). The convergence is often rather slow and over 100 iterations may be required to achieve the desired accuracy. The resulting broken symmetry solutions of both P and D types are given in Tables 1–3.

The D-type solution, associated with the second lowest root of the stability problem, is identical to the solution found earlier by Prat (67). In this solution, the $m = +1$ and $m = -1$ $2p$ orbitals are still identical while the $m = 0$ $2p$ orbital is distinct. It is this unique orbital, whose orbital energy remains to be positive (note that all three (identical) $2p$ orbitals in the symmetry-adapted case have positive orbital energies).

The lowest root of the Hessian [3] yields another broken symmetry solution, which is referred to as the P-type solution (see Tables 1–3). In this case all three $2p$ orbitals are distinct, even though there is a great similarity between the $m = 0$ and $m = +1$ orbitals, while the $m = -1$ orbital, which has again positive orbital energy, is unique. Clearly, using the eigenvectors associated with other degenerate roots of the stability problem we could obtain analogous solutions characterized by other distribution of magnetic quantum numbers.

Discussion

We first briefly examine the character of obtained broken symmetry solutions. To get a better idea of the type and extent

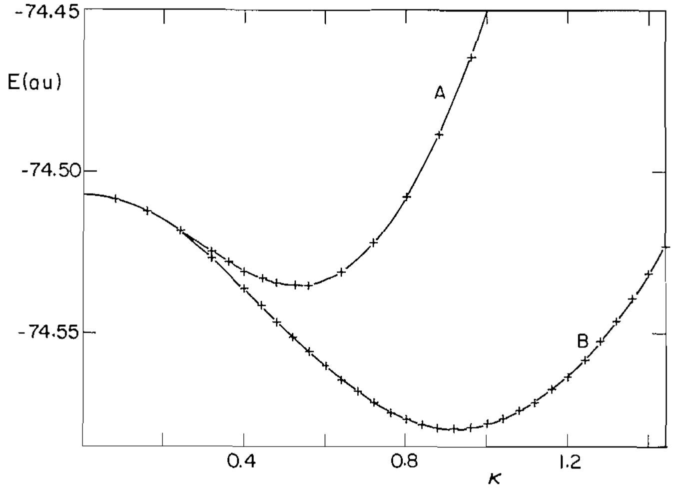

FIG. 5. Same as Fig. 4 for the H STO basis (70).

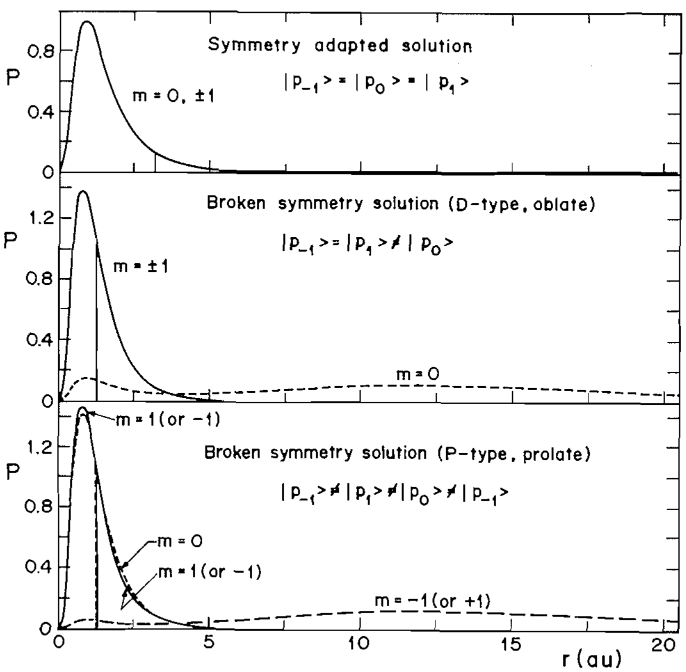

FIG. 6. The radial charge distribution P, eq. [10], as a function of the radial distance r (in au) for the symmetry-adapted and broken-symmetry solutions of the prolate and oblate types (see the text for details).

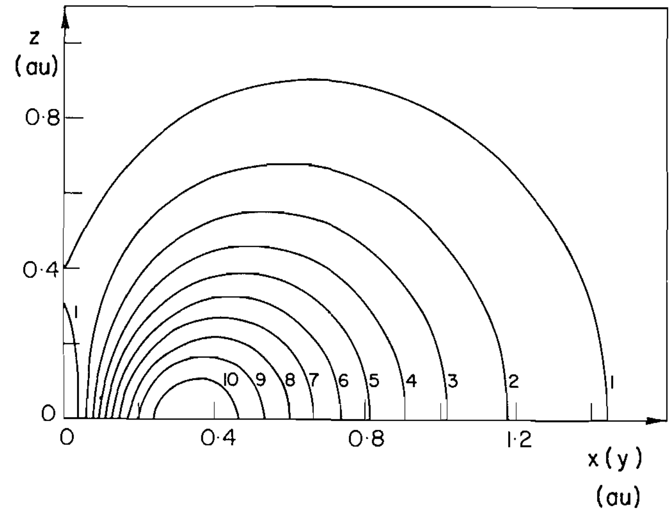

FIG. 7. Angular distribution of the electron density for the oblate D-type broken symmetry solution of the O^{2-} ion (with the H basis).

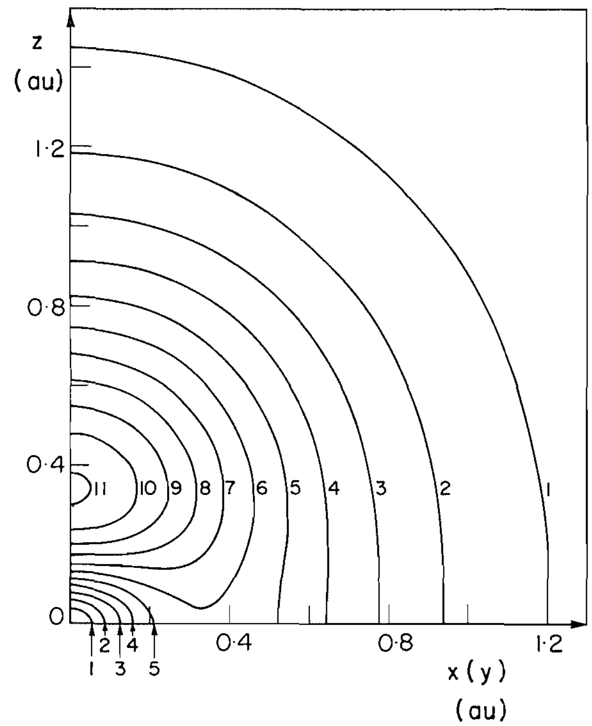

FIG. 8. Same as Fig. 7 for the prolate P-type broken-symmetry solution.

of the symmetry breaking involved, we first examine the radial density distribution for the p-orbitals in both symmetry-adapted and broken-symmetry cases (we present only the results obtained with the H basis, since the C basis results are very similar). Designating by $\gamma_m^{\mathrm{rad}}(r)$ the radial component of the one-density matrix $\gamma(1|1)$,

$$[9] \quad \gamma_m^{\mathrm{rad}}(r) = \frac{2}{\pi} \sum_{\mu,\nu} C_\mu^{(m)} C_\nu^{(m)} (\zeta_\mu \zeta_\nu)^{5/2} r^2 \exp\left[-(\zeta_\mu + \zeta_\nu) r\right]$$

where $C_\mu^{(m)}$ are pertinent expansion coefficients given in Table 2, we have plotted the radial charge distribution P,

$$[10] \quad P(r) = \frac{4\pi}{3} r^3 \gamma_m^{\mathrm{rad}}(r)$$

as a function of the radial distance r, in Fig. 6. We thus find that compared to the symmetry-adapted solution, two $2p$ orbitals for each broken symmetry solution contract while the third one becomes very diffuse. Depending on whether the diffuse orbital is associated with $m = 0$ or $m \neq 0$ $2p$ orbital, we get two distinct types of the symmetry breaking, the latter one being slightly more efficient in the energy lowering.

The angular distribution of the electron density for the two broken symmetry solutions is shown in Figs. 7 and 8. We see that the D-type broken-symmetry solution gives the electron distribution of the oblate-top type, while that of the lowest energy P-type solution can be characterized as being of the prolate-top type. In each case we see a clear tendency of electrons to "escape", and thus to lower the ionicity. Qualitatively, this escape would be expected to be more efficient energy-wise for the prolate-top deformation as is indeed the case (note,

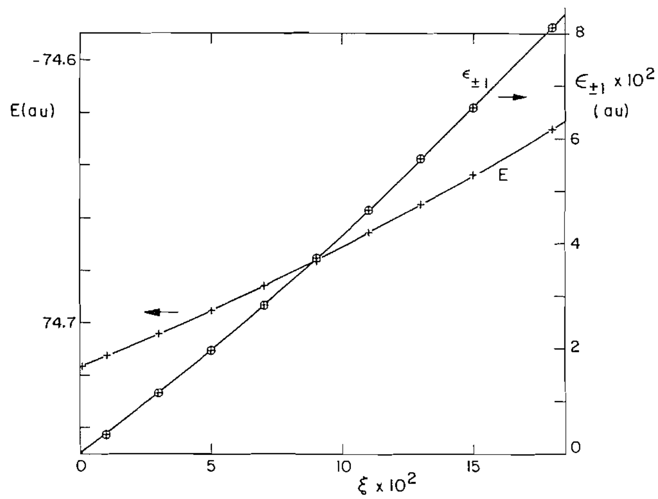

FIG. 9. Dependence of the total HF energy E (in au) and of the highest occupied HF orbital energy $\epsilon_{\pm}$ (in au) on the orbital exponent ζ of the most diffuse STO in the basis, for the lowest energy broken symmetry solution of O^{2-} and the H basis (70) (for which $\zeta = 0.1651966$).

however, that only the D-type solution possesses the exact rotational symmetry about the z axis). These broken symmetry solutions can thus be regarded as a clear indication of the physical instability of the O^{2-} ion, at least at the HF level of approximation. This is also the reason why no convergence was achieved with the numerical HF programs (74, 75), even when the nuclear charge was slowly decreased as explained above for the analytic-type solutions used here. While the F^- solution could be obtained without any difficulty, no converged solution was obtained for $Z < 8.5$, while the orbitals were showing a tendency to become plane waves (75). This tendency is clearly restricted by using a finite STO basis of the analytic approach, which confines the electrons to a more or less limited part of the space. A very similar effect could be achieved by placing the ion into a spherical cavity in an infinite dielectric medium.

In order to clearly demonstrate the tendency of electrons to "escape", we have performed a series of calculations with varying orbital exponents. In particular, varying the orbital exponent of the most diffuse orbital ($\zeta = 0.1651966$ in the H basis), we observe that the electron pair occupying this orbital has a tendency to ionize. As Fig. 9 shows, the total energy decreases with increasing diffuse character of the highest orbital, and its (positive) orbital energy gradually approaches zero as ζ does. We see already from Tables 2 and 3 that it is this most diffuse STO which is by far the highest lying orbital with positive energy in both broken-symmetry solutions. This is a clear indication that O^{2-} wants to rid itself of both excess electrons, since we are within the closed shell formalism. Should the spin-symmetry breaking be allowed, only one electron would leave leaving the stable O^- ion (68).

We thus see that in this particular case the space symmetry breaking, as implied by the singlet instability (triplet instability implying a similar result, see e.g. ref. 68) is indicative of the physical instability of the system considered. The broken symmetry solutions clearly show the tendency of the excess electrons to occupy free-electron, continuum states (73, 75). It would of course be interesting to study the HF solutions of the O^{2-} ion placed in the center of a spherical cavity in an infinite dielectric medium. In this way, the situation encountered in actual systems, be it a crystal lattice or a liquid, could be modelled. The dielectric surrounding would have a similar effect as the truncation of the AO basis, since it would represent a barrier for the electronic cloud, thus effectively stabilizing the symmetry-adapted O^{2-} solutions.

In concluding we would like to stress that the example studied in this paper amply illustrates the usefulness of the HF stability criteria, which are easy to apply, and which can provide useful information about the possible broken-symmetry solutions as well as to facilitate their systematic determination.

Received August 6, 1984

This paper is dedicated to Professor Camille Sandorfy on the occasion of his 65th birthday

S. HUZINAGA, M. KLOBUKOWSKI, and H. TATEWAKI. Can. J. Chem. **63**, 1812 (1985).

We have started to prepare a new family of high-quality Gaussian-type function basis sets capable of producing near Hartree–Fock atomic and molecular wave functions. A conspicuous feature of the family of basis sets is that many of the exponent parameters are shared among *s*-, *p*-, *d*-, and *f*-basis functions. In the present paper we report the first phase of the work covering atoms from Li to Ar, together with near Hartree–Fock calculations on N_2, CO, Na_2, and P_2 as the applications. A modified form of Raffenetti's contraction scheme is used.

S. HUZINAGA, M. KLOBUKOWSKI et H. TATEWAKI. Can. J. Chem. **63**, 1812 (1985).

Nous avons commencé à préparer une nouvelle famille d'ensembles de base, de haute qualité et du type de fonction gaussienne qui nous permettent de produire des fonctions d'onde moléculaires et atomiques qui se rapprochent de celles de Hartree–Fock. Une caractéristique évidente de cette famille d'ensembles de base réside dans le fait que plusieurs paramètres exponentiels sont répartis entre des fonctions de base *s*, *p*, *d* et *f*. Dans le présent travail, nous rapportons la première phase du travail couvrant les atomes allant du Li à l'argon ainsi que des calculs de Hartree–Fock sur le N_2, le CO, le Na_2 et le P_2, comme applications. On a utilisé une forme modifiée du schéma de contraction de Raffenetti.

[Traduit par le journal]

1. Introduction

The Hartree–Fock approximation gives the lowest energy of a many-electron system within the framework of independent electron (orbital) model. Remaining errors in the energy and other properties are attributed to electron correlation. This conceptual picture has attractive clarity. If we obtain the Hartree–Fock wave functions for a molecule and for the constituent atoms, we may talk about changes from atoms to molecules in the language of polarization, configurational change, electron transfer, etc.

Unfortunately, the majority of *ab initio* calculations of molecular electronic wave functions have been conducted using unsaturated Gaussian-type function (GTF) basis sets which do not produce near Hartree–Fock results. The economics of computation prevails; the clear-cut conceptual picture is blurred and the language of theoretical interpretation becomes ambiguous.

We are preparing a family of high-quality GTF basis sets capable of producing near Hartree–Fock atomic and molecular wave functions. In the present paper we report the first phase of the work covering atoms from Li to Ar, together with near Hartree–Fock calculations on N_2, CO, Na_2, and P_2 as the applications.

The basis set is termed as well-tempered (wohltemperierte). To illustrate the essential feature, the (16*s*13*p*8*d*) set for Kr is shown in Table 1. There are 16 distinct exponent parameters in the set. For the *s* functions all sixteen of them are used. For the *p* functions thirteen of them (numbered as 4, 5, 6, 7, . . . , 16) and for the *d* function eight of them (numbered as 7, 8, 9, . . . , 14) are used. These eight exponent parameters are shared among the *s*, *p*, and *d* functions.

2. Well-tempered GTF basis sets

The "even-tempered" basis set was proposed by Raffenetti and Ruedenberg (1) in 1973. A set of even-tempered atomic basis functions is defined by

$$[2.1] \quad N_l(\zeta_{lk}) \exp(-\zeta_{lk} r^p)\, r^n S_{lm}(\theta, \phi),\ k = 1, 2, \ldots, K_l$$

where $S_{lm}(\theta, \phi)$ are normalized real spherical harmonics, $p = 1$ for STF and $p = 2$ for GTF. $N_l(\zeta_{lk})$ are normalization factors for the radial functions. The name "even-tempered" comes from the constraint imposed on the choice of the exponent parameters

$$\{\zeta_{l_1}, \zeta_{l_2}, \ldots, \zeta_{lK_l}\}$$

$$[2.2] \quad \zeta_{lk} = \alpha_l \beta_l^{k-1},\ \alpha_l,\ \beta_l > 0,\ \beta_l \neq 1$$

$$k = 1, 2, \ldots, K_l$$

That is to say, they form a geometric sequence, α_l, $\alpha_l\beta_l$, $\alpha_l\beta_l^2$, ... There are only two parameters, α_l and β_l, to be optimized per group of atomic functions belonging to the same symmetry species. For example, for the ground states of *B* ($1s^22s^22p^1$, ^2P) through Ca ($1s^22s^22p^63s^23p^64s^2$, ^1S) only four parameters α_0, β_0, α_1, and β_1 are to be determined. For the first transition metal atoms there are six parameters α_0, β_0, α_1, β_1, α_2, and β_2 to be optimized.

Bardo and Ruedenberg (2) explored the possibility of using a common set of α and β for all *l*;

$$[2.3] \quad \zeta_k = \alpha\beta^{k-1},\ k = 1, 2, \ldots, K$$

Clementi and Corongiu (3) combined this restricted form of even-temperedness with the idea of the universal basis set (4) and managed to cover all the way from H to Sr by using the following two geometric sequences:

$$[\mathrm{I}] \quad \alpha = 0.016, \quad \beta = 3.0, \quad K = 20$$

$$[\mathrm{II}] \quad \alpha = 0.012, \quad \beta = 3.0, \quad K = 20$$

From the sequence [I], the small and the medium size sets were

developed. In the small set ($9s5p$) is chosen for Ne and ($18s11p5d$) for Sr. In the medium set ($10s6p$) for Ne and ($18s12p7d$) for Sr. From the sequence [II] the large set ($13s8p$) for Ne is constructed. For Sr the largest set is ($20s13p8d$) which gives -3131.4824 au as the ground state energy. The Hartree–Fock value is -3131.5379 au.

In 1982, apparently unaware of either Bardo-Ruedenberg's work or Clementi-Corongiu's, Kosugi (5) conceived a similar idea and started coding a molecular integral program based on the assumed availability of such basis sets that the GTF exponents are shared among *s, p, d*, and *f* functions. In response to Kosugi's request, we initiated a compilation of a new family of GTF basis sets, less ambitious than Clementi's and with different emphases.

In order to attain high accuracy with smaller basis size, the universal character is not sought and in place of the even-tempered formula [2.3] a generalized formula,

$$[2.4] \quad \zeta_k = \alpha\beta^{k-1}[1 + \gamma(k/K)^{\delta}], \quad k = 1, 2, \ldots, K$$

is used for generation of exponents which are then shared among radial functions with different l. Here α, β, γ, and δ are the four parameters to be optimized through the energy calculation of an individual atom. The generalized formula [2.4] shares with the even-tempered formula the ease of opti-

a) WT Energy values calculated using the well-tempered basis set.

b) HF Near Hartree-Fock energy values given by Clementi and Roetti. (Atomic Data and Nuclear Data Tables, 14, 177 (1974)).

mization. The (16s13p8d) set optimized through these four parameters gives −2752.0324 au as the ground state energy of Kr, while the largest (18s13p8d) set of Clementi and Corongiu gives −2752.0026 au. The $\{\zeta_k\}$ obtained through [2.4] were further individually optimized with the only constraint that they are still to be shared among s, p, and d radial functions. The resulting (16s13p8d) set is shown in Table 1 and it gives −2752.0403 au which is fairly close to the Hartree–Fock value −2752.0546 au.

On account of the parent well-tempered formula [2.4], the newly prepared basis sets may be called well-tempered because they are no longer "even-tempered" but still maintain averaged-out, well-spaced exponent values common for s, p, d, and f radial functions.

Table 2 shows the total and orbital energies of the ground states of Li through Ar obtained by our well-tempered basis sets. Their basis set parameters are given in Tables 3–18.

3. SCF calculations on N_2, CO, Na_2, and P_2

paper are of near Hartree–Fock quality for atoms as seen in Table 2. We have tested their effectiveness as basis sets for molecular calculations by performing carefully controlled SCF calculations on N_2, CO, Na_2, and P_2.

Raffenetti's general contraction scheme (6) is used throughout the work with a slight modification. Since we regard Raffenetti's contraction scheme as an integral part of our well-tempered basis sets, we shall explain the scheme using the (14*s*9*p*) set for N given in Table 7.

The minimal basis set obtained from the set by Raffenetti's scheme is composed of three distinct atomic radial functions,

$$[2.5] \quad s_1(r) = \sum_{k=1}^{14} a_{1s,k}\, g_s(\zeta_k; r)$$
$$s_2(r) = \sum_{k=1}^{14} a_{2s,k}\, g_s(\zeta_k; r)$$
$$p_1(r) = \sum_{k=6}^{14} a_{2p,k}\, g_p(\zeta_k; r)$$

where g_s and g_p are normalized radial functions,

$$[2.6] \quad g_s(\zeta; r) = N_s(\zeta) \exp(-\zeta r^2)$$
$$g_p(\zeta; r) = N_p(\zeta) r^1 \exp(-\zeta r^2)$$

and the expansion coefficients and the well-tempered exponents are given in Table 7. This minimal set may be denoted as (14, 14/9).

More flexible contracted basis sets can be generated by adding some primitive functions chosen from the original (14*s*9*p*) set to the above minimal set (14,14/9). For example, the following four functions,

$$[2.7] \quad s_3(r) = g_s(\zeta_{13}; r)$$
$$s_4(r) = g_s(\zeta_{14}; r)$$

may be added to the basis functions in [2.5] and the resulting contracted basis set may be denoted as (14,14,1,1/9,1,1). Both sets, (14,14/9) and (14,14,1,1/9,1,1), reproduce exactly the same total and orbital energies of the atom given in Table 2. There is no need of recalculating the atomic energies when a contracted basis set is generated from the original primitive ($14s9p$) set by Raffenetti's scheme.

It is possible to make Raffenetti's basis set less bulky while retaining the same accuracy and convenience. By combining the following three contracted basis functions,

$$[2.8]\qquad \begin{aligned} s_1'(r) &= \sum_{k=1}^{12} a_{1s,k}\, g_s(\zeta_k;\, r) \\ s_2'(r) &= \sum_{k=1}^{12} a_{2s,k}\, g_s(\zeta_k;\, r) \\ p_1'(r) &= \sum_{k=6}^{12} a_{2p,k}\, g_p(\zeta_k;\, r) \end{aligned}$$

with the four primitive functions in [2.7], we obtain a contracted basis set, (12,12,1,1/7,1,1). This modified contraction offers the same accuracy and flexibility as the original form (14,14,1,1/9,1,1) for atomic and molecular calculations.

3.1. N_2

We have performed a series of SCF calculations on N_2, first without, then with polarization functions. Table 19 shows the total energy and orbital energies at the internuclear distance of 2.068 au. The abbreviated designation of basis sets used in Table 19 corresponds to the one used in the previous section as follows,

(14,14/9)	[2/1]
(13,13,1/8,1)	[3/2]
(12,12,1,1/7,1,1)	[4/3]
(11,11,1,1,1/6,1,1,1)	[5/4]
(10,10,1,1,1,1/5,1,1,1,1)	[6/5]
.	.
.	.
.	.
.	.

The basis set denoted as [5/4/3*] in Table 19 is the (11,11,1,1,1/6,1,1,1) set supplemented by the following three primitve d radial functions

$$[2.9]\qquad \begin{aligned} d_1(r) &= g_d(\zeta_{11};\, r) \\ d_2(r) &= g_d(\zeta_{12};\, r) \\ d_3(r) &= g_d(\zeta_{13};\, r) \end{aligned}$$

where

$$[2.10]\qquad g_d(\zeta;\, r) = N_d(\zeta) r^2 \exp\,(-\zeta r^2)$$

and ζ_{11}, ζ_{12}, ζ_{13} are given in Table 7. The polarization functions used in [6/5/3*] and [7/6/3*] are the same as above. (In all calculations the 3s component of d orbitals is excluded.)

As is shown in Table 7, the 2s and 2p atomic orbitals are mainly composed of the four outermost primitive GTFs. Therefore the set [6/5] gives a limit of splitting of the valence shell. Proceeding from [2/1] to [14/9], we find that all the quantities listed in Table 19 change considerably from [2/1] to [4/3], but moderately from [4/3] to [6/5] and they are almost constant from [6/5] to [14/9]. The change in the total energies from [6/5] to [14/9] is only 0.00008 au ~ 0.05 kcal/mol. Contribution to the chemical bonding from the core electrons is negligibly small. The results of [5/4/3*], [6/5/3*], and [7/6/3*] show the importance of the polarization functions.

In this paragraph, the total energies and orbital energies given by the present work are compared with those of Cade, Sales, and Wahl (CSW) (7) who performed STF SCF calculations of N_2. Their basis set is basically composed of five s- and three p-type orbitals; they have, however, dropped one $p\sigma_u$ orbital and have employed eight σ_g, seven σ_u, and three π_u orbitals when the polarization functions are disregarded. The abbreviation for this set is (8 × 7 × 3) and the results are also shown in Table 19. The total energy by (8 × 7 × 3) at R = 2.068 au is between [3/2] and [4/3], although the atomic total energy given by them is slightly lower than the present one. The disregard of one of the $p\sigma_u$ orbitals results in the rather shallow total energy of (8 × 7 × 3). Adding the $3d\sigma_g$, $3d\sigma_g'$, $3d\sigma_g''$, $4f\sigma_g$, $3d\sigma_u$, $3d\pi_u'$, and $4f\pi_u$ to (8 × 7 × 3), they have constructed the set of (12 × 8 × 6). The total energy calculated is −108.9897 au which is only 0.0002 au lower than that by [6/5/3*]. The small difference between the two calculations may again be attributed to disregarding of one of the $2p\sigma_u$ orbitals. These days, only very rarely are the exponential parameters optimized in molecular calculations. In 1966 CSW performed careful exponent optimization which led to the substantial energy lowering of 0.0031 au (see the final row in Table 19).

The spectroscopic constants are summarized in Table 20. The sets [2/1] and [3/2] give the repulsive potential for the internuclear distance (r) ≤ 2.15 au, while others yield attractive ones. All the constants calculated with the full valence shell splitting set [6/5] are close to those of [14/9]. This is in

line with the cases of the total energies and orbital energies shown in Table 19. The spectroscopic constants given by the sets augmented with the polarization functions are quite similar to those of (12 × 8 × 6) except for $w_c\chi_c$ and D_c. In this work, the spectroscopic constants have been calculated with the third degree polynomials (8), which might be too crude to evaluate $w_c\chi_c$. The difference of ~0.08 eV in D_c arises from disregarding the *f* function in the present calculations.

3.2. CO

Total energies and orbital energies for CO calculated in this work are compared in Table 21 with those of McLean and Yoshimine (MY) (9) who employed five *s*-, four *p*-, one *d*-, and one *f*-type STFs. The values of the spectroscopic constants are collected in Table 22. The results of fully split valence shell set [6/5] in the two tables well simulate those of fully split set [14/9] as in the case of N_2, although the effect of splitting the orbital of the 1*s* core is larger than the case of N_2. The difference in the total energy and dissociation energy between [6/5] and [14/9] is ~0.36 kcal/mol, but it still remains in the acceptable error of 1 ~ 2 kcal/mol. The sets augmented with polarization functions give almost the same results as those of McLean and Yoshimine. The larger differences between the two calculations are in the total energies and dissociation energies (0.0024 au ~ 1.51 kcal/mol). The sum of the atomic total energies of carbon and oxygen by (5*s*4*p*) of STF is 0.0002 au lower than that by the present set and exponent optimization performed by MY brings extra energy lowering of 0.0005 au; the main reason for the difference between the two calculations rests in disregarding the *f*-type polarization functions in the present work.

Values of dipole moment as well as those of quadrupole moments at $R = 2.132$ au are presented in Table 23. They show the same tendency as the total energies, the orbital energies, and the spectroscopic constants.

The set [7/6/3*] gives the dipole moment of −0.104 au (C^+O^-) which has the opposite sign to that of experiment. Table 24 shows the dipole moment at different values of the internuclear distance. The moment calculated is parallel to that of Huo (10). It is to be noted that the sign of the moment changes around $R = 2.015$ au (C^-O^+), but according to the Mulliken population analysis (11) the molecule is still C^+O^-, indicating that the population analysis is not adequate to analyze the charge distribution of the CO molecule.

3.3. Na_2

Table 25 presents total energies and orbital energies obtained in the SCF calculations at R(Na—Na) = 6 au using the basis set from Table 11. Basis set [3/1] (16,16,16/9) is the minimal basis set corresponding to (16*s*9*p*) basis of the sodium atom in its ground state. The basis sets [4/1] and [5/1] have been obtained by consecutively releasing the primitives ζ_{16} and ζ_{15}.

[c] Reference 21.

The basis set [5/11*] has been obtained by adding one p-type GTF with ζ_{15} to improve the description of the p-space; similarly, the [5/12*] basis contains both ζ_{15} and ζ_{16} functions in the p-space. (Addition of these two functions is important due to the $3s$–$3p$ near-degeneracy.) Atomic calculations in the extended ($16s9p2p^*$) basis set give $E(^2P) - E(^2S) = 1.99$ eV, quite close to the experimental value of 2.10 eV (12). In the [6/22*] basis the s- and p-type GTFs with ζ_{13} are uncontracted to improve flexibility of the basis functions in the $2s$ and $2p$ regions. Finally, the [5/12*/3*] basis set is obtained by adding three sets of $3d$ GTFs with exponents ζ_{13}, ζ_{14}, and ζ_{15}.

The largest decrease of the total energy is obtained upon

inclusion of the first p-polarization function (0.004 au or 2.7 kcal/mol). Polarization of 2s and 2p AOs due to the chemical bonding seems to be negligible. The role of the d polarization functions seems to be negligible on the SCF level. However, they have been included in view of the later MCSCF calculations (*vide infra*).

Table 26 presents the potential curve parameters calculated with various basis sets and compared with other available all-electron SCF results. Again, addition of the polarization functions is required to secure convergence of the calculated properties. The Na_2 molecule is unbound with respect to the limit of two isolated Na(^2S) atoms. It seems that the bonding of 0.038 eV calculated by Martin and Davidson (14) at 5.82 au probably results from the basis set superposition error (cf. the review article by Tatewaki in ref. 15). Our [5/12*/3*] values of both D_e and R_e are very close to the results of Partridge *et al.* (13). It should be noted (Table 25) that their SCF total energy at the internuclear distance of 6 au is about 0.025 au above the [5/12*/3*] total energy.

For the sodium dimer we have also performed preliminary MC SCF calculations using the ALIS system of programs (16) to optimize a wave function which had the same structure as the N9XC function of Konowalow *et al.* (17). The calculations have been done using the [5/12*/3*] basis set at the internuclear distance of 6 au (close to the N9XC equilibrium distance). The MC SCF procedure gave in eight iterations the total energy of −323.742941 au (stable to $<10^{-6}$ au) which is only 0.06 kcal/mol above the value of −323.743039 au obtained by Konowalow *et al.* using a large STF basis set (17). (No f functions were included in either calculation.)

It is worth mentioning that calculation of integrals takes about 70% of the CPU time spent in the complete SCF calculation; this, however, is reduced to less than 10% of the CPU time needed for complete MCSCF calculation. (The ALIS sys-

3.4. P_2

Table 27 shows the behaviour of the total energy and the orbital energies of P_2 at the internuclear distance of 3.4974 au. For comparison, the corresponding values from a large STF calculation by Mulliken and Liu (18) are also given. Complete releasing of the valence GTFs (ζ_{14}, ζ_{15}, and ζ_{16}) is needed to obtain convergence of the total energy to $<10^{-3}$ au. Further releasing of ζ_{13} in [7/6] basis set lowers the total energy by only 0.0002 au. The [6/5] total energy is slightly lower (by about 0.0004 au or 0.26 kcal/mol) than the value obtained with the corresponding (no polarization functions) STF basis set (see row *a* in Table 27).

Inclusion of the *d* polarization functions brings about good agreement between the present orbital energies and the ones reported by Mulliken and Liu for STF basis with both *d* and *f* polarization functions. The relative ordering of the outer $1\pi_g$ and $3\sigma_u$ orbitals of the almost degenerate set derived from the atomic $2p$ orbitals would probably require releasing of more GTFs.

Convergence of the potential curve parameters is shown in Table 28. The [6/5] basis predicts that the P_2 molecule is unbound by 0.60 eV, quite close to the value of 0.66 eV obtained in STF calculations. Addition of the *d* polarization functions makes the P_2 molecule bound with respect to two isolated $P(^4S)$ atoms by 1.58 eV. Slightly larger bonding (1.71 eV) obtained by Mulliken and Liu is partly due to the presence of the *f* polarization functions in their basis set. Presence of the *d* polarization functions influences significantly the remaining parameters as well. The trends in the values as found using the STF basis set (without and with the polarization functions) are the same as found with the present GTF sets.

4. Concluding remarks

A quarter century ago, at the very beginning of the era of *ab initio* molecular calculations, the Chicago group produced the near Hartree–Fock wave functions for a number of basic diatomic molecules using STF basis sets. It is truly remarkable that they conducted such careful numerical studies with computer resources which were extremely limited by today's standard.

The present authors feel strongly that the use of GTF basis sets should have been administered as carefully and critically as the Chicago group did with the use of STF.

In the present paper we have shown that the high-quality well-tempered GTF basis sets can produce near Hartree–Fock wave functions for N_2, CO, Na_2, and P_2 *without* reoptimizing exponential parameters in molecules. These basis sets are expensive to use on currently available computers and programs because the number of primitive functions is large. However, the number of distinct exponent values of a well-tempered GTF basis set is far smaller than that of conventional GTF basis set of comparable quality.

This feature holds a great future potential for economizing the integral computations over the well-tempered GTF basis set especially when a molecular calculation involves the calculation of gradient of the energy expression. We anticipate that a properly designed algorithm which takes advantage of the shared exponent parameters among symmetry species and the program implementation on next-generation computers (large and small) will make high-quality molecular calculations fea-

sible for a variety of chemically interesting molecules.

Furthermore, in calculations which include electron correlation beyond the Hartree–Fock level the integral evaluation step takes only a minor part of the total computer time but the quality of the one-electron basis functions is of great importance. To quote I. Shavitt: "No amount of configuration interaction can remedy defects due to basis-set inadequacies in the underlying SCF calculation" (19).

Photoreluctant azoalkanes: 185-nm photolysis of *E*- and *Z*-diazacyclooct-2-ene

WALDEMAR ADAM[1] AND THOMAS OPPENLÄNDER[2]
Institut für Organische Chemie, Universität Würzburg, Am Hubland, D-8700 Würzburg, West Germany

Received July 30, 1984

This paper is dedicated to Professor Camille Sandorfy on the occasion of his 65th birthday

WALDEMAR ADAM and THOMAS OPPENLÄNDER. Can. J. Chem. **63**, 1829 (1985).

The 185-nm photolyses of *E*- and *Z*-1,2-diazacyclooct-1-enes (**1**) result mainly in denitrogenation, affording 1-hexene and cyclohexane in a 2:1 ratio. In comparison to the direct 350-nm photolyses the denitrogenation efficiencies are enhanced by 42- and 26-fold for the *E*- and *Z*-isomers, respectively. It is proposed that the photoisomerization (350 nm) takes place from the $S_1(n_-,\pi^*)$-state and the photodenitrogenation (185 nm) out of the S_2-state.

WALDEMAR ADAM et THOMAS OPPENLÄNDER. Can. J. Chem. **63**, 1829 (1985).

Les photolyses à 185 nm des diaza-1,2 cyclooctènes-*E* et -*Z* (**1**) provoquent principalement des déazotations qui conduisent à l'hexène-1 et au cyclohexane dans un rapport de 2/1. Par comparaison avec les photolyses directes à 350 nm, les efficacités des déazotations sont augmentées respectivement par des rapports de 42 et 26 pour les isomères -*E* et -*Z*. On suggère que la photoisomérisation (350 nm) se produit à partir de l'état $S_1(n_-,\pi^*)$ alors que la photodéazotation (185 nm) se produit à partir de l'état S_2.

[Traduit par le journal]

The importance of azoalkanes in the mechanistic studies of radicals and diradicals (1) and in synthetic applications (2) has been amply demonstrated over a number of decades. Through these studies, however, a group of azoalkanes, namely the structure types shown, have become recognized to be reluctant in eliminating molecular nitrogen on thermal as well as photochemical activation. Those in the fourth category include bridgehead-centered (3) and cyclopropyl (4) groups. Reasons for photoreluctance include deactivation of the n,π*-excited states via fluorescence, radiationless decay, intramolecular cyclization, hydrogen abstraction, phototautomerism and/or *cis–trans* isomerization (5). By means of photolysis in the gas phase or at elevated temperatures and introduction of radical-stabilizing substituents at the nitrogen-bearing carbons photoreluctance can be in part counteracted (6). More effective for this purpose is photolysis at 185 nm in solution, as demonstrated for all the structure types above but the 1,2-diazocyclooctene (3, 7).

For the latter, so far (8) only the direct and triplet-sensitized photolyses above 300 nm have been investigated, resulting in efficient *cis–trans* isomerization with merely <3% denitrogenation. It was, therefore, the purpose of this study to examine the 185-nm photochemistry of the reluctant *Z*- and *E*-1,2-diazacyclooct-1-enes (**1**) and compare it with the established behavior at long wavelengths (λ > 300 nm). While in the latter irradiations usually only n_-,π^*- excited states are involved (1), during excitation in the vacuum ultraviolet region (λ < 200 nm) higher excited states such as n_+,π^{*-}, π,π^{*-}, n_+,σ^{*-} and also molecular Rydberg states are feasible (Fig. 1) (9). In view of the distinct molecular symmetry of the *Z*- and *E*-isomers of **1**, the various possible excitations are of different probability and thus these isomers might show distinct photochemical behavior on 185-nm irradiation. For example, while for both isomers the π,π^{*-} transitions are allowed and thus intensive, for the *E*-isomer also the n_+,π^{*-} excitation and the $n_-,3p$-Rydberg transitions are symmetry-allowed, but for the *Z*-isomer additionally only the $n_-,3s$-Rydberg excitation (Fig. 1). Nevertheless, at least a greater efficiency of denitrogenation compared to *cis–trans* isomerization is expected (3, 7) at 185 nm compared to >300 nm for the azoalkane **1**. Herein we report the results of this study.

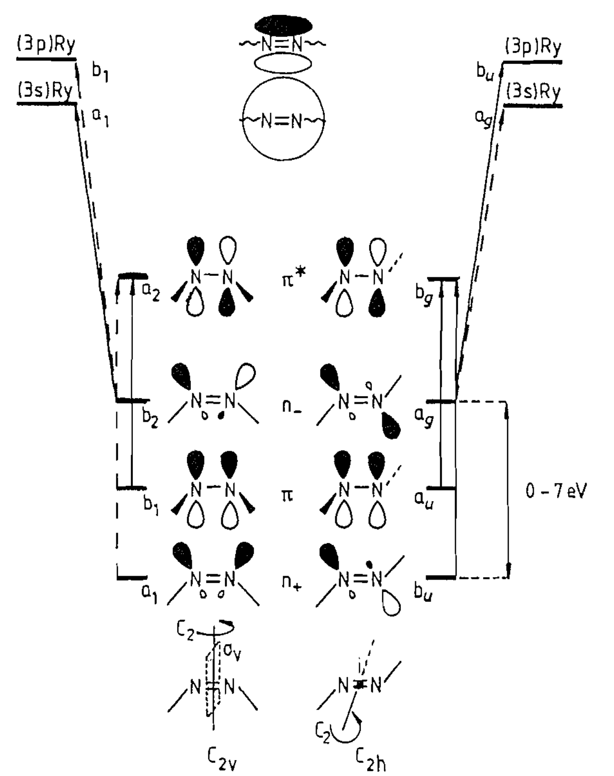

FIG. 1. Allowed (→) and forbidden (-→) electronic transitions for *cis*- and *trans*-azoalkanes.

Results

The synthesis of *Z*-**1** could be significantly improved (8) by employing the copper complex method (reaction [1]) for generating the azoalkane from its hydrazo derivative.

TABLE 1. Quantum yields for the 185-nm and the 350-nm photolyses of *Z*- and *E*-diazacyclooct-1-ene

				Photoproducts, ϕ_p[d]		
Substrate	Photolysis conditions[a]	ϕ_S[b]	ϕ_{iso}[c]			$\Sigma\phi_p + \phi_{iso}$
 [e,f]	350 nm, 25°C[g]	0.78	0.77	0.008	0.004	0.78
	185 nm, 25°C[h]	0.44	0.14	0.20	0.11	0.45
 [e,i]	350 nm, 25°C[g]	0.61	0.60	0.006	0.003	0.61
	185 nm, 25°C[h]	0.48	0.03	0.25	0.13	0.41

[a] All photolyses were performed in *n*-pentane.
[b] ϕ_S = quantum yield of consumption of azoalkanes *Z*-**1** and *E*-**1**, respectively.
[c] ϕ_{iso} = quantum yield of the formation of isomerized azoalkane.
[d] The experimental error corresponds to ca. 10–15% of the stated values.
[e] The benzophenone-sensitized photolyses ($\lambda > 300$ nm) led after 20 h irradiation to photostationary state of 55% *E*-**1** and 15% *Z*-**1**.
[f] [*Z*-**1**] = 0.0177 *M*.
[g] Aktinochrome R was used as actinometer (ref. 12).
[h] *cis–trans* isomerization of cyclooctene was used as actinometer (ref. 11).
[i] [*E*-**1**] = 0.0110 *M*.

[1] 
With the copper complex method (10) higher yields and stereoisomerically pure *Z*-**1** were obtained. Photoisomerization at 350 nm afforded the *E*-**1** isomer (reaction [1]). Both isomers are stable at room temperature (ca. 20–25°C), but quite photolabile even on exposure to daylight leading to photoisomerization.

Photolysis at 185 nm in *n*-pentane (cf. Experimental Section for details) led also to significant *cis–trans* isomerization, together with the denitrogenation products cyclohexane and 1-hexene. Concentration–time profiles of a typical 185-nm photolysis for each isomer are given in Fig. 2. During the first 20 min of photolysis the mass balance (Σ%) for both isomers was exceptionally high. The denitrogenation products cyclohexane and 1-hexene were, as expected, stable under the applied 185-nm photolysis conditions and were formed in a relative ratio of 2:1, as in the long wavelength ($\lambda > 300$ nm) irradiations.

The quantitative analyses were conducted by capillary gc using standardization plots and are summarized in Table 1. To assess the quantum yields for the 185-nm photolyses, the previously established (11) actinometry (*cis–trans* cyclooctene isomerization) was employed. For comparison the 350-nm photolyses were also performed. For this purpose the recently published (12) Aktinochrome R actinometer proved especially advantageous for the determination of the quantum yields in the long wavelength irradiations. The determination of quantum yields at 350 nm was based on the quantitative description of the *cis–trans* isomerization process (11) and corrected for back-reaction according to [2].

$$[2]\quad \frac{dy}{dt} = \frac{I_0 l}{VF}\left[\phi_{E\to Z}\epsilon_E(1-y) - \phi_{Z\to E}\epsilon_Z y\right]$$

where $y = [Z]/[Z]_0$, fraction of *Z*-isomer; I_0 = absolute light intensity, determined by using Aktinochrome R (248/334) (12); l = pathlength (cm); V = sample volume (l); $F = D/(1 - e^{-D})$ = fraction of incident light absorbed, in which the optical density $D = \ln I_0/I = C_0 l[\epsilon_E + (\epsilon_Z - \epsilon_E)y]$; $C_0 = [Z] + [E]$ = total concentration; ϵ = molar absorption coefficient at 350 nm (M^{-1} cm^{-1}); and ϕ_E = quantum yield of *E*-isomer formation and ϕ_Z = quantum yield of *Z*-isomer formation. Applying the steady-state conditions ($dy/dt = 0$, $t = \infty$) and integration of eq. [2] leads to eq. [3].

$$[3]\quad -f([Z]) = ([Z_0] + B[Z]_\infty)\ln A + B([Z] - [Z]_0) = mt + \text{constant}$$

where $A = ([Z] - [Z]_\infty)/([Z]_0 - [Z]_\infty)$, $B = (\epsilon_Z - \epsilon_E)/\epsilon_E$, $m = (I_0\phi_{E\to Z})/Vy_\infty$, and $\phi_{E\to Z} = my_\infty N_L/1000I_0$. The subscript indicates the photostationary state at infinite time and $N_L = 6.023 \times 10^{23}$ mol^{-1}.

To establish that $I_0 = I_{abs} = (3.66 \pm 0.14) \times 10^{16}$ quanta min^{-1} cm^{-3}, the photolysis of *Z*-**1** was performed at high concentrations ([*Z*-**1**] = 0.229 *M*) in the region of total absorption. Using the slope $m = (9.96 \pm 0.32) \times 10^{-5}$ *M* min^{-1} of the plot of $-f([Z])$ versus t and $y_\infty = 0.363$, the quantum yield of *Z*-isomer formation was determined to be $\phi_{E\to Z} = 0.60$. From eq. [4],

$$[4]\quad \phi_{Z\to E}\epsilon_Z[Z_\infty] = \phi_{E\to Z}\epsilon_E[E_\infty]$$

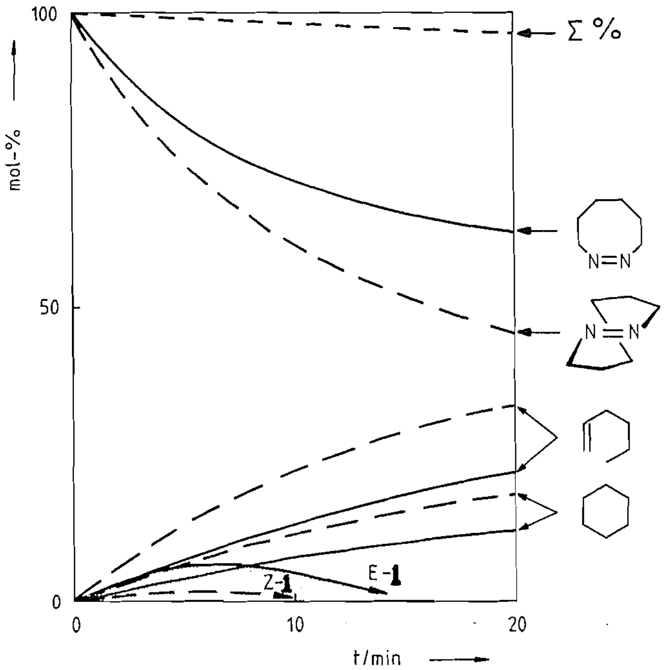

FIG. 2. Concentration–time profile of the 185-nm photolyses of Z- and E-1,2-diazacyclooct-1-ene in n-pentane.

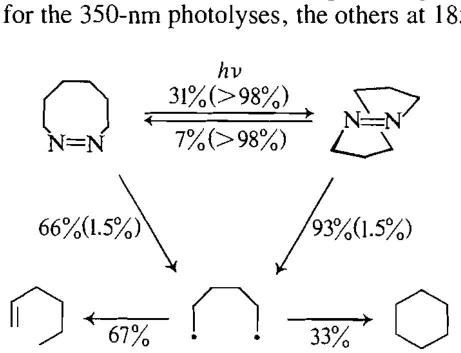
it was possible to calculate $\phi_{Z\to E} = 0.77$ with $\epsilon_Z^{350} = 44.6$, $\epsilon_E^{350} = 37.4$, $[Z]_\infty = 0.0831$ M, and $[E]_\infty = 0.128$ M.

The results in Table 1 reveal that on 350-nm irradiation the main photo-reaction by far is *cis–trans* isomerization ($\phi_{Z\to E} + \phi_{E\to Z} = 1.37$). However, at 185 nm this isomerization is substantially reduced ($\phi_{Z\to E} + \phi_{E\to E} = 0.17$) compared to denitrogenation ($\phi_{N_2} = 0.31$ and 0.38, respectively, for Z- and E-isomers). Thus, photodenitrogenation at 185 nm was ca. 26-fold more efficient than at 350 nm for the Z-isomer and ca. 42-fold for the E-isomer. Formation of the E-isomer was more efficient than of the Z-isomer at both wavelengths.

Discussion

The mechanistic interpretation of the photochemical results in Table 1 are presented in eq. [5]. The percentages in parentheses are for the 350-nm photolyses, the others at 185 nm. As

[5]



already stated, at the short wavelengths the main photoprocess is denitrogenation, while at the long wavelengths it is *cis–trans* isomerization. Furthermore, photodenitrogenation at 185 nm is considerably more efficient for the E-isomer, i.e. 93% versus 69%. Whether this enhanced photodenitrogenation of the E-isomer reflects the fact that for this isomer both the π,π^{*-} and n_+,π^{*-} excitations are symmetry-allowed (Fig. 1), is at this point difficult to know with certainty because the vacuum ultra-

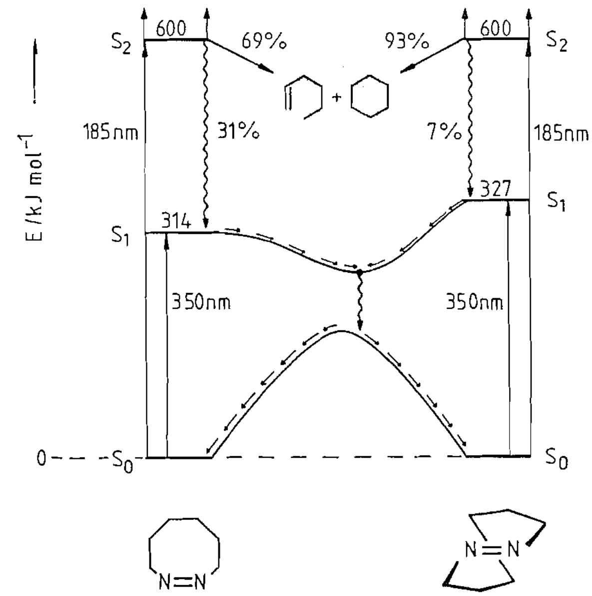


FIG. 3. Qualitative state diagram for the photolysis of E- and Z-1,2-diazacyclooct-2-ene.

violet spectroscopy of this system is still lacking. Besides, both isomers possess symmetry-allowed but distinct Rydberg transitions, namely $(n_-,3p)$Ry and $(n_-,3s)$Ry, respectively, for E-**1** and Z-**1**, so that a rigorous spectroscopic analysis would be complicated. Nevertheless, the greater efficiency of photodenitrogenation at 185 nm for the E-isomer is at least consistent with symmetry-allowed n_+,π^* excitation.

Irradiation at 350 nm leads to a photostationary state consisting of 60% E-isomer and 40% Z-isomer. This implies that for the potential energy surface that connects the S_1-states of the excited E- and Z-isomers, the energy minimum is displaced in favor of the E-isomer (Fig. 3). We postulate that *cis–trans* isomerization of the azoalkane **1** occurs from the $S_1(n_-,\pi^*)$-state, while the S_2-state is responsible for denitrogenation. The latter is reached on 185-nm excitation. Since radiationless deactivation ($S_2 \to S_1$) is expected to compete with denitrogenation, the observed *cis–trans* isomerization in the 185-nm photolyses can be rationalized by population of the $S_1(n_-,\pi^*)$-state via this pathway. However, a photostationary state in the 185-nm irradiations cannot be attained in view of competitive photodenitrogenation from the S_2-state. As already stated, at this point it is not possible to define the electronic configuration of the S_2-state that is generated in the 185-nm photolyses.

An additional point of photomechanistic interest is the fact that the sum of the quantum yields for *cis–trans* isomerization at 350 nm does not correspond to unity, i.e., $\phi_{Z\to E} + \phi_{E\to Z} = 1.37$. According to Hammond (13) this suggests that this photoisomerization does not involve a common intermediate. This feature supports the hypothesis made by Weiss and Warshel (14) concerning the dynamics of photoisomerization.

Experimental section

General aspects

All photolyses were performed in spectrograde n-pentane (11) under nitrogen atmosphere at room temperature (25°C). Before photolysis, the solutions were deoxygenated by bubbling through a slow stream of purified nitrogen. During photolysis the mixture was stirred effectively by means of a magnetic stirring bar.

Light sources and quantum yields

Photolyses above 300 nm were carried out on semi-preparative scale (150 mL) using a Rayonet Photochemical Reactor with the appropriate light sources (RPR-350-nm lamps) and a quartz tube. Quantum yields at this wavelength were determined on an optical bench, equipped with a xenon high pressure lamp (XBO-1600W, Osram) connected to a monochromator (Schoeffel Instrument GmbH, Kratos, f/36) using a quartz cuvette (QS, Hellma, 2.5 mL). For chemical actinometry the Aktinochrome R (248/334)-system (Amko company) was used, following the detailed literature procedure (12). The light intensity of the xenon lamp at 334 nm was determined by this method to be $I_0 = (3.66 \pm 0.14) \times 10^{16}$ quanta min^{-1} cm^{-3}.

Photolyses (185 nm) on preparative scale were carried out in a reaction vessel equipped with nitrogen inlet and a Suprasil tube, containing a low pressure mercury arc (HNS 10W/UoZ-Osram). During photolysis the 185-nm lamp was cooled by a slow stream of nitrogen. Quantitative 185-nm photolyses were performed by using a Suprasil cuvette (4 mL) with the nitrogen inlet placed directly in front of a sigmoidal low pressure mercury arc (15) (capillary lamp No. 4, Gräntzel Co., Karlsruhe). Photoreactivity at 254 nm (the main output of the 185-nm light sources) was established by selecting the 254-nm line (and higher wavelength) by means of a Vycor filter (M 235, Heraeus, Hanau).

Quantum yields at 185 nm were determined as described previously (11) using the *cis–trans* isomerization of cyclooctene as actinometer. The light intensity of the capillary lamp was $(6.56 \pm 0.19) \times 10^{17}$ quanta min^{-1} cm^{-3}.

Product analysis

All photoproducts were identified by ^{1}H-nmr (60 MHz) spectroscopy photolyzing 0.05 *M* solutions of the azoalkanes in C_6F_{14} directly in a quartz nmr tube at 185 nm or 350 nm. In addition the photoproducts were characterized by cgc coinjection with authentic samples on two different capillary columns (50 m × 0.8 mm Carbowax 20 M and 50 m × 0.8 mm Apiezon L). Quantitative product analyses were performed using a Carlo Erba Model 2900 capillary gas chromatograph (FID) and a 50 m × 0.8 mm glass capillary column with nitrogen carrier gas flow = 0.6 mL/min, column, injector, and detector temperatures of 30, 150, and 175°C, respectively. After 12 min, the column temperature was raised from 30°C up to 120°C (39°C/min). Calibration curves were constructed for the *Z*-**1** and *E*-**1** azoalkanes and for the denitrogenation products 1-hexene and cyclohexane affording calibration factors $f_i = 1.99 \pm 0.07$, $f_i = 1.75 \pm 0.02$, $f_i = 2.01 \pm 0.04$, and $f_i = 1.72 \pm 0.04$, respectively, against nonane as cgc standard.

Materials

Nonane (cgc standard), 1-hexene, and cyclohexane were commercially available in purities better than 99%.

(Z)-1,2-Diazacyclooct-1-ene. (**1**) (8*b*) was synthesized in 99% purity (cgc) by refluxing a solution of 0.50 g (1.9 mmol) 1,2-bis-(ethoxycarbonyl)-1,2-diazacyclooctane (8*b*) and 0.50 g (8.9 mmol) potassium hydroxide in 2 mL of isopropanol under nitrogen atmosphere for 5 h. After cooling the reaction mixture to room temperature (ca. 20°C), 10 mL of distilled water were added, and the solution was neutralized using concentrated HCl. Then 10 mL of a saturated copper(II) chloride solution were added and the reaction mixture was stirred for 6 h at ca. 20°C. The dark red precipitate was recovered by means of filtration and washed once with 10 mL of distilled water and with 10 mL of absolute ether. After drying over silica gel at 15 Torr, the copper complex was stirred with 5 mL of concentrated ammonia. Extraction of the blue solution with methylene chloride (4 × 10 mL) and washing the organic layer once with 10 mL saturated NaCl solution and with 10 mL distilled water yielded after drying over $MgSO_4$ a yellow solution. Evaporating the solvent in the dark at 0°C/18 Torr afforded a yellow oil which was distilled at 42°C/0.1 Torr to yield 0.20 g (91%) of a slight yellow oil. The infrared and ^{1}H-nmr (90 MHz) data were in agreement with published data (8). Ultraviolet (*n*-pentane): λ_{max} (ϵ) = 185 (2970), 254 (<5), 382 nm (158).

(E)-1,2-Diazacyclooct-1-ene. (**1**) was synthesized according to the known procedure (8) by photoisomerization of a 0.05 *M* solution of azoalkane *Z*-**1** in *n*-pentane at 350 nm. Isolation and purification of the *E*-isomer was achieved by preparative gc, using a Carlo Erba 4200 gas chromatograph equipped with glass column (1.5 m × 8 mm) packed with 10% Apiezon L on Chromosorb WHP (60/80 mesh) and a nitrogen carrier gas flow of 25 mL/min, column, injector, and detector temperatures of 80, 150, and 180°C, respectively. The azoalkane was obtained as a pale yellow oil in 99% purity (cgc). Infrared and ^{1}H-nmr (90 MHz) data were in agreement with the published data (8). Ultraviolet (*n*-pentane): λ_{max} (ϵ) = 185 (7880), 254 (<5), 366 nm (48).

254-nm corrections

Control experiments at 254 nm (and higher wavelength) were performed using the capillary lamp directly connected to a Vycor filter by photolyzing 0.01 *M* solutions of the azoalkanes at this wavelength and analyzing at distinct time intervals by means of cgc. The optical density of the Vycor filter at 254 nm was greater than 90%. The same experiment was repeated without Vycor filter under the same conditions and concentrations were corrected according to eq. [6].

$$[6] \quad [C]_{185} = [C]_{185+254} - [C]_{254}$$

Vacuum–ultraviolet photolysis (185 nm) of liquid 1,3-dioxan

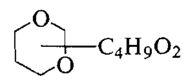
HEINZ-PETER SCHUCHMANN AND CLEMENS VON SONNTAG
Max-Planck-Institut für Strahlenchemie, Stiftstr. 34-36, D-4330 Mülheim a.d. Ruhr, W.-Germany

Received September 26, 1984

This paper is dedicated to Professor Camille Sandorfy on the occasion of his 65th birthday

HEINZ-PETER SCHUCHMANN and CLEMENS VON SONNTAG. Can. J. Chem. **63**, 1833 (1985).

1,3-Dioxan photolytic destruction at 185 nm occurs with a quantum yield of about 0.3 in the liquid phase. Of the 22 products determined, the major ones are *n*-propylformate (ϕ = 0.10), formaldehyde (0.075), 1,3-diox-4-en (0.06), hydrogen (0.05), ethylene (0.04), and 3-methoxypropionaldehyde (0.04). A number of the minor products are of the general type **B**,



B

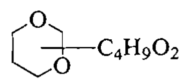
some of which bear a hydroxyl function at the end of the side chain. N_2O interacts with excited 1,3-dioxan, leading to the production of N_2.

Some experiments have been carried out in the vapour phase, the results of which indicate that considerable fragmentation of hot primary intermediates and products into low-molecular-weight products occurs. The nature of these products cannot be linked directly to the primary photolytic processes inferred from the liquid-phase studies.

Certain contrasts in the photolytic behaviour of 1,3-dioxan and 1,4-dioxan are discussed.

HEINZ-PETER SCHUCHMANN et CLEMENS VON SONNTAG. Can. J. Chem. **63**, 1833 (1985).

La destruction du dioxanne-1,3 lors de sa photolyse à 185 nm se produit avec un rendement quantique près de 0,3 dans la phase liquide. Parmi les 22 produits mesurés, le formiate de propyl (ϕ = 0,16), le formaldéhyde (0.075), le diox-1,3-ène-4 (0,06), l'hydrogène (0,05), l'éthylène (0,04) et le méthoxy-3-propionaldéhyde (0,04) sont les majeurs. Divers produits, mineurs, dont quelques-uns portent une fonction hydroxyl au bout de la chaîne latérale, revêtent la structure générale **B**.



B

Le N_2O interagit avec le dioxanne-1,3 excité, ce qui mène à la production de N_2.

Quelques expériences ont été faites en phase vapeur, dont les résultats indiquent une fragmentation considérable des intermédiaires et produits primaires, chauds. La nature des produits finaux ainsi formés ne peut pas être associée directement aux processus photolytiques primaires que l'on saurait reconnaître moyennant les études faites en phase liquide.

Certaines différences entre le dioxanne-1,3 et le dioxanne-1,4, en ce qui concerne leur comportement photolytique, sont discutées.

Introduction

Sandorfy (1) has shown that the first absorption band of saturated alcohols and ethers is due to an essentially $3s \leftarrow n$ transition. Its band maximum is around 185 nm where the low-pressure Hg arc has a strong emission line. Studies on the liquid-phase 185 nm photolysis of open-chain ethers have shown that the predominant process is the scission of a C—O linkage, a reaction the quantum yield of which can approach unity (2, 3). In cyclic ethers the same process also occurs, but the quantum yields are often considerably lower due to reclosure of the intermediate (singlet) diradical. A similar situation prevails in the series of open-chain acetals (4–6) and cyclic acetals (7, 8). Another member of this group is 1,3-dioxan, whose photochemistry was of special interest to us because it is an isomer of 1,4-dioxan whose photochemistry (9–13) and photophysics (13–15) have so far been receiving more attention.

Experimental

1,3-Dioxan was prepared from 1,3-propanediol and paraformaldehyde (16). The fractionated product showed a gas chromatographic purity of 99.97% by flame ionization detection.

Samples (2 mL) of the neat liquid contained in a suprasil cell (a photograph of the setup is shown and its use described in ref. 17) were deaerated by purging with argon for 30 min and irradiated with the unfiltered light of a low-pressure mercury lamp at a dose rate, determined by means of the Farkas actinometer (2), of 4.0×10^{17} quanta (185 nm) per min received by the sample. The 254 nm light is inactive in this system. 1,3-Dioxan begins to absorb near 200 nm. From its spectrum, measured on a Cary model 14 spectrophotometer, molar extinction coefficients of 9 and 0.6 M^{-1} cm^{-1} were calculated at 185 and 193 nm, respectively. (A small shoulder was observed at the onset of the absorption, near 220 nm, when the absorbance of the material was measured in a 1 cm cell.) Some samples containing N_2O at different concentrations were also photolyzed to investigate the influence of this additive. Since photoexcited 1,4-dioxan shows a fluorescence in the condensed phase (10, 13–15), it was decided to look for a similar fluorescence in liquid 1,3-dioxan also. This was done by exciting the compound with the 193 nm line of an ArF excimer laser (Spectra Physics).

The products except formaldehyde were analyzed by gc and identified by the use of reference material and/or their mass spectra obtained through gc–ms. Glass capillary columns were employed, the carrier gas being hydrogen. Non-derivatized, acetylated and benzoylated samples were analyzed on CW-20M, silylated ones on SE-30. Non-derivatized samples were also analyzed on PC-240 for better resolution of the more volatile products such as *n*-propanol, propyl formate, and 1,3-diox-4-en. Quantitative time-course studies were done only with non-derivatized samples. A levelling-off of the dose–yield curves of the products, in particular that of 1,3-diox-4-en, which is thought to have the highest extinction coefficient of all the products at 185 nm, was not observed even at maximum conversion which was of the order of 10^{-3}. Thus, photolysis of products is not expected to have been significant. The internal standard (18) was $C_{14}H_{30}$. The derivatized samples were prepared and analyzed in order to better recognize the nature of some of the photolysis products.

The following derivatizations were carried out: (*a*) treatment of irradiated 1,3-dioxan with bis(trimethylsilyl)trifluoroacetamide in order to trimethylsilylate those products that contain a hydroxyl function; (*b*) treatment of the photolysis products, after evaporation of the 1,3-dioxan, with acetic anhydride/sodium acetate to acetylate products with a hydroxyl function; (*c*) esterification with benzoic anhydride/sodium benzoate; and (*d*) hydrolysis of the photolysis products that contain an acetalic function, after evaporation of the remaining 1,3-dioxan, with hydrochloric acid at pH ~ 0.5 for two days at 60°C, neutralization and reduction of the hydrolysate with sodium borodeuteride overnight, removal of the boric acid after acidification by repeated evaporation with methanol, and trimethylsilylation of the evaporation residue.

The volatile products such as hydrogen, nitrogen (from N_2O-containing samples), ethylene, and carbon oxides were analyzed after purging them from the irradiated liquid with a carrier gas, to be collected into a flask for aliquots to be taken (ethylene), or to be swept directly into the gas chromatograph (hydrogen and nitrogen). Hydrogen and nitrogen were determined by thermal conductivity detection, ethylene, and carbon oxides (the latter after on-line catalytic reduction to methane) by flame ionisation detection. Formaldehyde was determined photometrically using acetylacetone/ ammonium acetate reagent (19). This procedure could be applied even though large amounts of 1,3-dioxan are present because 1,3-dioxan does not liberate formaldehyde under these conditions. For vapour phase photolysis experiments, liquid 1,3-dioxan was purged with argon, then kept at 10°C and the vapour transferred with a slow argon stream into a suprasil cell such as the above. After photolysis, the sample was expanded into a flask from which aliquots were taken and analyzed on an OV-225-coated capillary column, or alternatively on a column packed with activated alumina.

Results

In the photolysis of liquid 1,3-dioxan the major products are propyl formate, formaldehyde, ethylene, 3-methoxypropanal, 1,3-diox-4-en, and hydrogen. Furthermore, there is a considerable number of higher-molecular-weight products. Table 1 includes the most prominent ones. These are all formed in low yields, and structural determination has been carried only so far as to be able to identify their essential features. The yield of the products increased linearly with irradiation time, hence quantum yields could be calculated. They are based on $\phi(H_2) = 0.4$ for the Farkas actionometer (5 *M* ethanol in water) (2).

The determination of the low-molecular-weight products was straightforward since reference material was available, while the assignment of the products of higher molecular weight deserves some comment. In cases where reference material was not readily synthesized or mass spectra were not interpretable unambiguously, derivatives were prepared and their mass spectra recorded. Thus, the mass spectra obtained from derivatized samples suggest the presence of the compounds referred to in Table 2. Derivatives were generated by trimethylsilylation, acetylation, and benzoylation, as well as hydrolysis/reduction/trimethylsilylation. Beside the derivatives obtained by the latter procedure, listed in Table 3, there appears a number of lesser gc peaks at higher retention times whose mass spectra are suggestive of higher polyol trimethylsilyl ethers, among the precursors of which one might expect compounds such as **I–III**.

The derivative TMSO—CHD—CH_2—O—CH_2—CH_2—

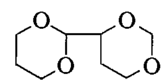
IV



V

CH_2—OTMS has not been seen, which seems to suggest that compound **IV** is not produced in the photolysis. There is also no hint of the deuterated derivative which would be formed on hydrolysis of compound **V** and reduction.

Some experiments have been carried out in the gas phase. Only gaseous products have been measured. They are listed in Table 4. Values are normalized to the ethylene yield since quantum yields have not been determined.

In our attempt to draw a comparison between 1,3-dioxan and 1,4-dioxan, we decided to look for fluorescence in 1,3-dioxan, and found an emission ($\lambda_{max} \approx 285$ nm) on laser excitation at 193 nm. Although the experiments did not permit an accurate measurement of the fluorescence lifetime, a rough estimate of $t_{1/2} = 20$ ns could be extracted by comparing the half-width of the signal to that of the laser pulse. This fluorescence is strongly quenched on saturation with O_2, but hardly if at all affected by N_2O (which is known to quench the fluorescence in 1,4-dioxan) even at saturation where $[N_2O] \approx 0.29$ *M*. Ausloos *et al.* (13) did not detect direct fluorescence upon radiolysis of 1,3-dioxan but found that methylnaphthalene was excited to fluoresce in that solvent. In view of these results we consider it not unlikely that the fluorescence seen in the present experiments could have been due to the intervention of an impurity whose signature might be the small shoulder which had been observed at the onset of the 1,3-dioxan absorption band. Moreover, in a further experiment, the intensity of this fluorescence was measured as a function of the excitation wavelength (using a Xenon lamp), and it was found that the intensity began to increase strongly as the excitation wavelength went below 250 nm, still far above the onset of absorption of the 1,3-dioxan proper.

Even though it does not quench the fluorescence, it is clear that in the 185 nm photolysis N_2O does indeed interact with an excited, 1,3-dioxan-derived species under formation of N_2. The nitrogen quantum yields obtained at different N_2O concentrations are given in Table 5 and are corrected for a contribution from the direct N_2O photolysis, assuming a quantum yield of

22	−	−	−

[a] − = none detected, + = one detected, ++ = both detected.
[b] Numbering as in Table 1.

unity for N_2 formation through the latter process, and bearing in mind that for N_2O, $\epsilon(185) = 36\ M^{-1}\ cm^{-1}$ (23). As to its influence on the formation of the other products, it is noteworthy that the quantum yield of formaldehyde is doubled to 0.15 and that of ethylene slightly lowered to 0.03 on saturation with N_2O. The effect regarding the remaining products (Table 1) appears to be small and has not been followed quantitatively.

Discussion

With $\epsilon(185\ nm) = 9\ M^{-1}\ cm^{-1}$, 1,3-dioxan is a liquid of a relatively low extinction coefficient, in line with other acetals (4, 5). Ethers tend to have a much higher extinction coefficient at this wavelength: cf. $\epsilon(185\ nm)$ (1,4-dioxan) = $2 \times 10^3\ M^{-1}$ cm^{-1}. Also, the ionisation potentials of acetals tend to be higher

TABLE 3. Compounds identified by gc–ms of 1,3-dioxan photolysis products (after hydrolysis, reduction with $NaBD_4$ and trimethylsilylation), and their probable precursors

0.029	0.03_9	0.03_0
0.0087	0.01_3	0.01_0

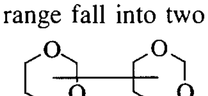
[a] N_2 quantum yields corrected for the nitrogen formed through direct photolysis of N_2O, assuming a quantum yield of unity for the latter process: $\phi_{N_2,\mathrm{corr}} = \phi_{N_2}(\epsilon_{\mathrm{diox}} \times [\mathrm{diox}] + \epsilon_{N_2O}[N_2O])/\epsilon_{\mathrm{diox}}[\mathrm{diox}] - \epsilon_{N_2O}[N_2O]/\epsilon_{\mathrm{diox}}[\mathrm{diox}]$.

than those of ethers: 10.15 eV for 1,3-dioxan vs. 9.47 eV for 1,4-dioxan (24). It has been shown (13) that 185 nm light does not lead to ionization in the neat liquid dioxans: for 1,4-dioxan the threshold is at about 7.6 eV (165 nm); for 1,3-dioxan it must be higher still as the gas phase ionization potential of the latter compound lies above that of the former.

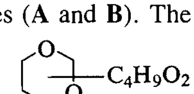
In order to rationalize the major products propyl formate, formaldehyde, ethylene, 3-methoxypropanal, 1,3-dioxen, and hydrogen (cf. Table 1), reactions [1]–[11] are postulated (Scheme 1). Based on the results of the photolysis of other cyclic acetals (8) one assumes that the scission of the C—O bonds as exemplified by reactions [2] and [4] will play a major role. The resulting diradicals may disproportionate (reactions [8], [8*a*], and [11]), thereby leading to products whose formation could also be envisioned through a rearrangement in the excited state (reactions [1] and [5]). A decision between these two types of processes cannot be made at present. Diradicals also undergo reclosure (reactions [−2] and [−4]). In the present system such processes cannot be monitored because they lead back to the starting material, but with suitably substituted cyclic acetals this type of reaction has been shown to occur (8). Although oxyl radicals are known to undergo β-fragmentation, reactions [9] and [10] are not likely to occur in the liquid phase because the excess energy remaining in the diradical after ring-opening (ca. 60 kcal mol^{-1}) is rapidly degraded at liquid densities, as has been inferred from results obtained on other cyclic systems (25), especially also from 1,4-dioxan (see below). It is in fact likely that the fragment products result from a breakdown of the molecule in the excited state (cf. ref. 25). Besides, there is formation of some hydrogen and 1,3-dioxen, either concomitantly as written (reaction [6]), or in reactions involving H atoms and other radicals with subsequent disproportionation of the resulting 1,3-dioxanyl radicals. That some 1,3-dioxen is formed in processes other than reaction [6] is suggested by the fact that its quantum yield is somewhat higher than that of hydrogen.

In the gas phase, fragmentation is more pronounced, and owing to a lack of easy deactivation a variety of secondary fragments arise (Table 5). We do not propose to explore the relationship between these fragments here. We do think that these phenomena in the gas phase are interesting in their own right, and that this liquid-phase study might serve as a starting point for such investigation.

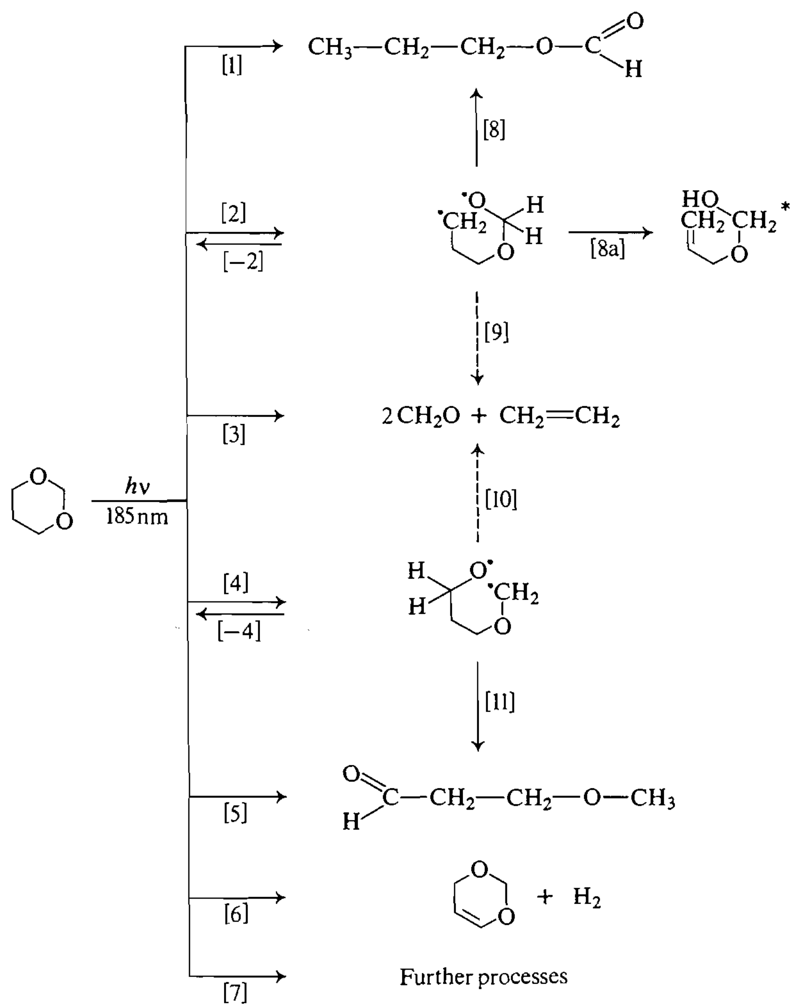
The ring-opened and fragmentation products found in the present system are reminiscent of those that occur in the photolysis of liquid 1,4-dioxan (10) (cf. Table 6), but in contrast to the latter, the photolysis of liquid 1,3-dioxan is further characterized by the formation of a relatively large number of products with their molecular weight in the dimer range (Table 1). Their combined quantum yield does not approach that of the products in the monomer range. The complete identification of these products proves to be elusive, and insofar as their nature is uncertain the photolysis mechanism remains tentative. However, the identification of these products is put on firmer ground by the additional information obtained through gc–ms analysis of their derivatives. It appears that the products in the dimer range fall into two categories (**A** and **B**). The products



A

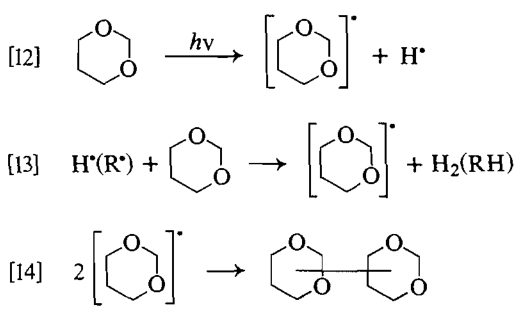


B



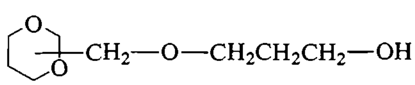
SCHEME 1. Asterisk denotes decomposition into allyl alcohol and formaldehyde under the conditions of analysis.

belonging to **A** might be formed via reactions [12]–[14]

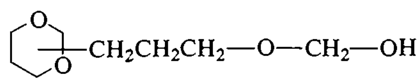


These products (dehydro-dimers) are relatively unimportant and present no interesting aspect compared to the 185 nm photolysis of other ethers carried out in the liquid phase (cf. ref. 3 and references therein).

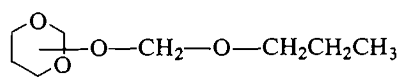
The products of category **B** may be distinguished further (**B**1, **B**2, **B**3, **B**4) whereby the experimental results (see tables) suggest that only those compounds that can be thought of formally as resulting from the insertion of an alkyl oxyl diradical into a 1,3-dioxan C—H bond should be considered.



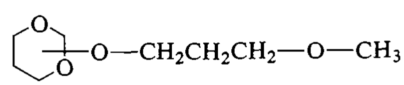
B1



B2



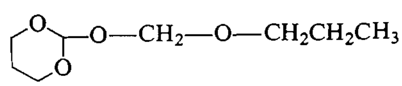
B3



B4

Compounds of category **B**1 are observed, namely **17** and **20**. Compounds of category **B**2, which are hemiacetals, should easily lose formaldehyde and yield products such as **15** and **18**.

The formation of *n*-propanol **7** and 3-hydroxypropylformate **13** hints at the existence of at least one class **B**3 compound, **VI**,



VI

which is presumed to be particularly sensitive towards adventitious moisture. It is not clear whether any compound of class **B**4 is formed.

TABLE 6. Comparison of the photolytic behaviour of deaerated neat liquid 1,3-dioxan and 1,4-dioxan when illuminated with 185 nm light in the liquid phase

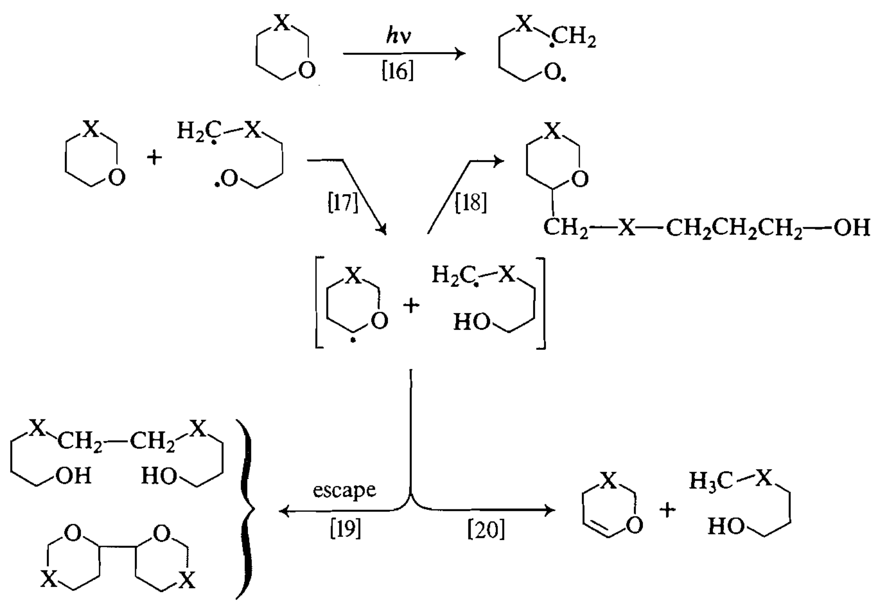
Further processes		~0.05		
Total		~0.3		~0.4



SCHEME 2

The formation of such dimers recalls analogous compounds from the photolysis of tetrahydropyran (26) and oxepan (27). Particularly in the case of tetrahydropyran, the quantum yield of that product was so high (0.21) compared to that of the escape products that it appeared necessary to postulate (26, 27) a reaction such as [15] ($X = CH_2$) rather than a reaction sequence (such as [16]–[18]; $X = CH_2$) involving a diradical; see Scheme 2.

[15] 
In the present case the situation seems less clearcut. The total dimer quantum yield is quite small, in absolute as well as in relative terms. The quantum yield of the dehydrodimers found, **16** and **19**, is not a lot smaller than that of the total dimers, and the glycol **22** is difficult to measure if present in only small amounts. Moreover, swift combination of the initial radical pair is favoured compared to the diffusion encounter pair case, since if the diradical is in the singlet state the ensuing radical pair would also be singlet, whereas an encounter pair would only have a 25% probability to be in this state. In fact, the product 3-methoxypropanol **11** might be most easily explained by a diradical mechanism ([16], [17], [20] X = O; see Scheme 2) where one must, however, assume that the radical pair is created by the hot alkyl oxyl diradical. Thermalized alkoxyl radicals are expected to react by hydrogen abstraction, in this and in similar systems, with a rate constant of between 10^5 and $10^6\ M^{-1}\ s^{-1}$, cf. ref. 28. On the other hand, self-termination of singlet diradicals is supposed to be fast, with rate constants ranging from 10^9 to $10^{12}\ s^{-1}$ (29–31). Bearing in mind that in the present case the available hydrogen donor concentration (the substrate itself) is about 10 M one realizes that self-termination must predominate for the thermalized diradical.

The comparison of the photobehaviour of 1,3-dioxan with that of 1,4-dioxan is phenomenological and therefore somewhat unsatisfying. It is felt that a deeper penetration necessitates the application of quantum-chemical calculations to their photochemistry. Simpler heterosystems such as methanol and methylamine are already being tackled with some success (32, 33). For the time being, such comparison reveals that fragmentation processes (see Table 6) occur about three times more readily in 1,4-dioxan; products ascribable to direct ring cleavage are formed on comparable scale. It has been suggested that the formation of small unsaturated product compounds, such as ethylene and formaldehyde in the photolysis of the dioxans, is due to the "unzipping" of initial diradical species (34). We prefer the concept of molecular fragmentation, avoiding the diradical intermediate in these processes. Arguments in favour of this supposition have been presented elsewhere (25). We consider the fact that the quantum yields of such fragmentation products contrast so strongly in the two dioxans (Table 6), culminating, in particular, in the absence of oxetane from 1,3-dioxan, also supportive of our concept. Dimer formation, not shown by 1,4-dioxan, results in a variety of products from 1,3-dioxan.

In 1,4-dioxan, fluorescence is observed at 250 nm (half-life about 2 ns (15)). Due to its large Stokes shift this fluorescence has been attributed to an eximer. This fluorescence is quenched by N_2O; and N_2, as well as oxygen atoms which insert into C—H bonds (10), are formed. N_2O also interferes with an excited state of 1,3-dioxan, thereby producing N_2. The yield of ethylene is also reduced, but that of formaldehyde is increased. This observation can be rationalized by the hypothesis that oxygen atoms insert into the C—H bonds at position 4. The resulting hemiacetal is expected to be unstable and to release formaldehyde under the conditions of the assay.

The data shown in Table 5 indicate that the N_2O-quenchable state might have a lifetime as short as 1 ns if one assumes that the reaction producing N_2 in competition against the unimolecular decay of the N_2O-quenchable state, has a second-order rate constant of 10^9 M^{-1} s^{-1}. This estimate drops to 0.1 ns if a rate constant of 10^{10} M^{-1} s^{-1} is assumed.

This paper is dedicated to Professor Camille Sandorfy on the occasion of his 65th birthday

JEAN CLAUDE MERLIN, EMRYS W. THOMAS, and GUISLAINE PETIT. Can. J. Chem. **63**, 1840 (1985).

Resonance Raman spectra and band assignments of some phenylhydrazonopropanedinitriles, including the 3-chloro and the 2-carboxy derivatives, in the 900–2300 cm^{-1} spectral range are presented and discussed. ^{15}N and ^{2}H isotopic shifts have been used to clarify the assignments, which have been made for both protonated and deprotonated forms of the compounds. The resonance Raman spectra of the protonated forms show strong coupling between NH deformation and hydrazone vibrations. This coupling is lost in the anionic forms, which are considered to have considerable carbanion character. By using the drastic changes between the resonance Raman spectra of protonated and deprotonated forms, the pK_a value of the 2-carboxy derivative has been determined.

JEAN CLAUDE MERLIN, EMRYS W. THOMAS et GUISLAINE PETIT. Can. J. Chem. **63**, 1840 (1985).

Les spectres Raman de résonance et l'attribution de leurs raies pour certains dérivés du phénylhydrazonopropanedinitrile comprenant les dérivés 3-chloro et 2-carboxy, dans la région spectrale 900–2300 cm^{-1} sont présentés et discutés. Les déplacements isotopiques obtenus en utilisant ^{15}N et ^{2}H ont permis de justifier l'attribution proposée à la fois pour les formes protonées et déprotonées des composés. Le spectre Raman de résonance de la forme protonée indique qu'un fort couplage existe entre la déformation du groupe NH et les vibrations du groupe hydrazone. Ce couplage disparaît dans la forme anionique qui présente alors une structure avec un caractère carbanion très marqué. Les profondes modifications observées dans les spectres Raman de résonance lors de la formation des formes protonées ou déprotonées ont permis de déterminer la valeur du pK_a du dérivé *méta*-carboxylé.

Introduction

Substituted phenylhydrazonopropanedinitriles (also known as carbonylcyanide phenylhydrazones) display a range of biological activities; they act as uncouplers of biological energy transducing systems (1), have bacteriostatic and fungistatic properties (2), and react rapidly with thiols in aqueous solution (3). In view of the usefulness of resonance Raman spectroscopy in studying biomolecular interactions at high dilution, we have obtained resonance Raman spectra of a number of the title compounds, including phenylhydrazonopropanedinitrile, 3-chloro-phenylhydrazonopropanedinitrile, and 2-carboxy-phenylhydrazonopropanedinitrile (abbreviated as PHPD, (3-Cl)-PHPD and (2-carboxy)-PHPD, respectively), together with selected ^{15}N and ^{2}H labelled analogues. The band assignments obtained lead to a clearer understanding of the protonic equilibria displayed by these compounds, and also provide a firm basis for resonance Raman studies on their interactions in biological systems.

Experimental

Preparation of compounds

All analogues were prepared by coupling the appropriate diazotized aromatic amine with malononitrile as described (4), and isolated by acidification of the reaction mixtures to pH 1, filtering, and washing with excess H_2O. Samples were then recrystallized from either chloroform or ethyl alcohol to constant melting point.

A ring deuterated analogue of PHPD, designated PHPD-d_5, was prepared using aniline-2,3,4,5,6-d_5 (Aldrich Chemical Co.).

A ^{15}N-labelled analogue of PHPD, incorporating ^{15}N in the nitrogen atom proximal to the aromatic ring, and designated PHPD-α ^{15}N, was prepared using aniline-^{15}N (95 atom%, BOC Limited, London, U.K.).

A ^{15}N-labelled analogue of (3-Cl)-PHPD, incorporating ^{15}N in the nitrogen atom proximal to the propanedinitrile group, and designated (3-Cl)-PHPD-β ^{15}N, were prepared by diazotization of 3-chloroaniline using $NaNO_2$-^{15}N (99 atom%, BOC Limited).

All compounds proved homogeneous by tlc, and had melting points agreeing with literature values (2). Mass spectral characterization of the ^{15}N-labelled analogues confirmed substitution by ^{15}N:PHPD; M^+ 170; PHPD-α ^{15}N:M^+ 171; (3-Cl)-PHPD:M^+ 204; (3-Cl)-PHPD-β ^{15}N:M^+ 205.

Spectral measurements

Resonance Raman spectra were obtained using a DILOR RT.30 spectrometer and an argon laser (Spectra Physics 164 AC) for excitation at 488 nm. Line frequencies were quoted to an accuracy of ±2 cm^{-1} by using plasma lines for calibration. Techniques and precautions used in the acquisition of resonance Raman spectra were fully described in previous publications (5, 6). The pK_a determination for (2-carboxy)-PHPD involved plotting the ratio of the intensities of the 1368 cm^{-1} and 1250 cm^{-1} lines (characteristic of the acid and basic forms of the molecule) against pH. When pH = pK_a, the corresponding intensity ratio equaled the Raman cross-section ratio for the two lines. This latter value was obtained from spectra measured at pH 5.7 and 12.0, using the 982 cm^{-1} line of Na_2SO_4 as an internal standard. Visible absorption spectra were recorded using a Pye-Unicam SP 1800 Spectrophotometer.

Results and discussion

In aqueous solution at pH 12, most of the compounds examined show intense ($\epsilon \simeq 2 \times 10^4 M^{-1} cm^{-1}$) absorption bands

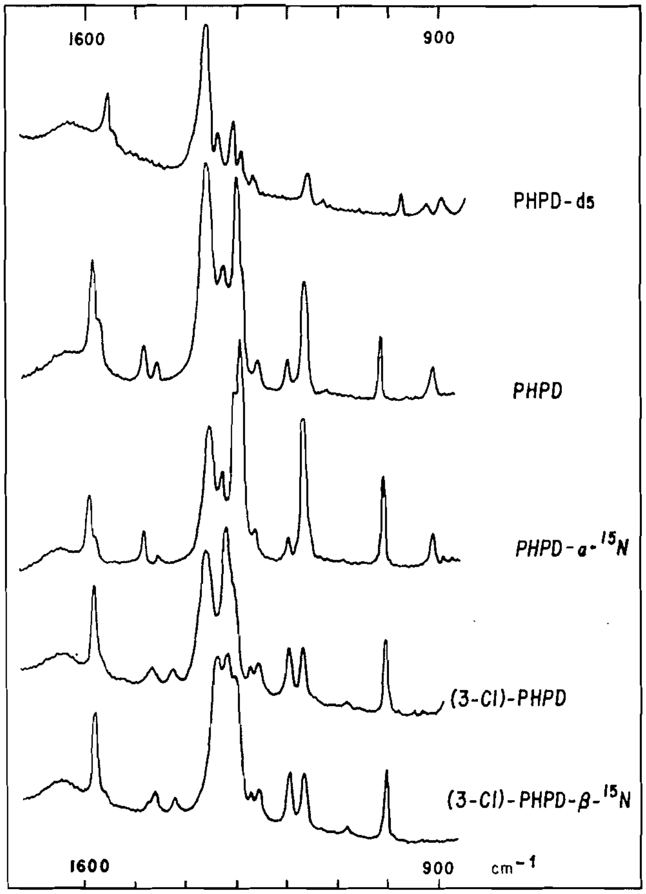

FIG. 1. Resonance Raman spectra of PHPD derivatives at alkaline pH (approximately 3×10^{-4} *M* in 0.01 *M* NaOH solution). Excitation wavelength at 488 nm (100 mW) and 6 cm^{-1} spectral slit width.

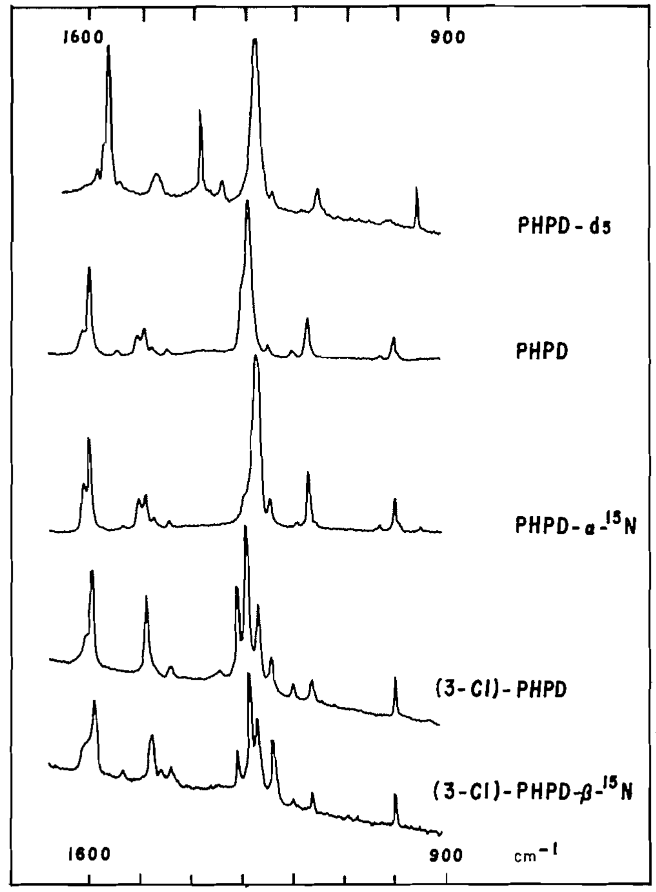

FIG. 2. Resonance Raman spectra of PHPD derivatives in the solid state. Excitation wavelength at 488 nm (50 mW) and 5 cm^{-1} spectral slit width.

at about 390 nm originating from the anionic form of the compound in question. Thus PHPD had λ_{max} 380 nm, $\epsilon = 1.97 \times 10^4\ M^{-1}\ cm^{-1}$; (3-Cl)-PHPD had λ_{max} 378 nm, $\epsilon = 2.37 \times 10^4\ M^{-1}\ cm^{-1}$; (2-carboxy)-PHPD had λ_{max} 376 nm, $\epsilon = 2.31 \times 10^4\ M^{-1}\ cm^{-1}$. In acidic media, protonated forms exist with bands near 360 nm: PHPD had λ_{max} 358 nm, $\epsilon = 1.77 \times 10^4\ M^{-1}\ cm^{-1}$; (3-Cl)-PHPD had λ_{max} 357 nm, $\epsilon = 2.10 \times 10^4\ M^{-1}\ cm^{-1}$; (2-carboxy)-PHPD had λ_{max} 365 nm, $\epsilon = 2.05 \times 10^4\ M^{-1}\ cm^{-1}$. Spectrophotometric titrations in all cases (data not shown) indicated participation of just two ionic species in the studied pH range, with the equilibrium described by pK_a value of $\simeq 6$ (7). (2-carboxy)-PHPD proved anomalous in this regard, displaying only a small (~ 10 nm) spectral shift on ionization with an approximate pK_a value of 9. Titration (results not shown) of (2-carboxy)-PHPD (in methanol/water, 2:1 v/v) clearly indicated two separate ionizations: one, governed by a pK_a values of about 3.75, is presumably due to the carboxyl group, while another ionization with $pK_a \sim 11$, is ascribed to the NH ionization (perturbed from the spectrophotometric pK_a due to the high methanol concentration in the titration medium).

With 488 nm excitation (in the pre-resonance region) good quality resonance-enhanced spectra were observed from low concentration solutions. Intense resonance Raman bands in the 900–1700 cm^{-1} spectral range were observed from basic solutions of all compounds (Fig. 1), with two additional lines in the 2200 cm^{-1} region (data not shown). These spectra originated from the anionic forms. Resonance Raman spectra of solid samples (Fig. 2) were typical of the neutral protonated forms; good quality spectra were not easy to obtain from acidic solutions due to poor solubility, but we included representative spectra obtained at pH 5.7 for comparison purposes (Fig. 3).

In the spectral range investigated, the following modes would be expected to be resonance Raman enhanced. (*1*) benzene ring modes: C—C stretching vibrations and C—H in-plane bending vibrations; (*2*) stretching modes of the ring substituents coupled with benzenoid ring modes; (*3*) hydrazonopropane group vibrations, strongly perturbed by protonation equilibria; and (*4*) nitrile function vibrations.

Tentative assignments for characteristic lines of the protonated and deprotonated forms are shown in Table 1, and merit discussion.

Deprotonated forms

(*i*) Two vibrations, involving a symmetric and antisymmetric stretching of the nitrile groups, are observable in the 2150–2200 cm^{-1} region.

(*ii*) Benzene ring vibrational modes, using standard assignments (10, 11), are easily distinguishable on the basis of spectral shifts observed on ring deuteration or substitution.

(*iii*) The Ph—N^- stretching, coupled with phenyl ring vibrations, and called "*e*" mode, should give an intense Raman band in the 1290–1370 cm^{-1} region (12, 13); this mode should be sensitive to both ring deuteration and α ^{15}N labelling. The 1303 cm^{-1} line in PHPD is accordingly assigned to the "*e*" (Ph—N^-) mode; it shifts to lower frequencies on α ^{15}N

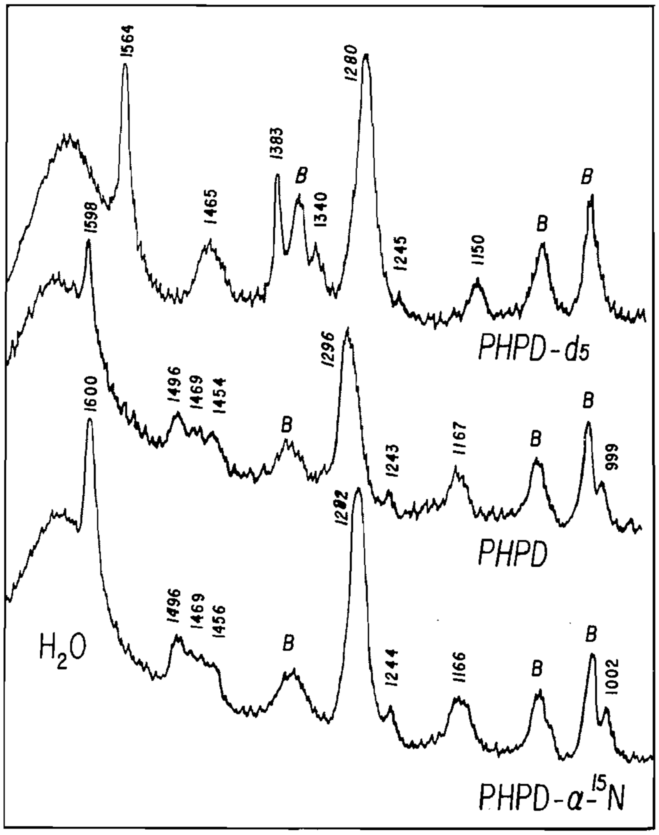

FIG. 3. Resonance Raman spectra of some PHPD derivatives in phosphate buffer solution (pH 5.7). The saturated solutions used are approximately 10^{-5} *M*. Excitation wavelength at 488 nm (350 mW) and 8 cm^{-1} spectral slit width. B indicates the buffer lines.

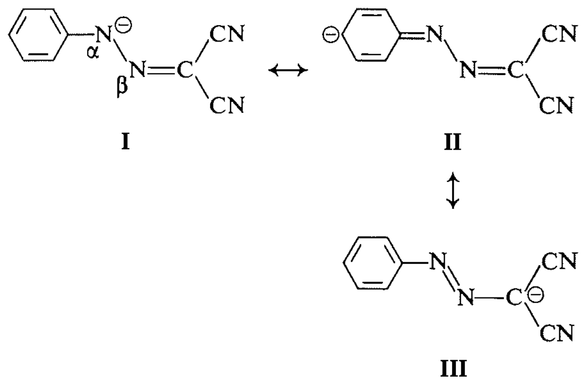
substitution, and disappears on ring deuteration.

The ring modes perturbed by deuteration are not strongly coupled to the Ph—N$^-$ stretching mode, and the wavenumber of the "*e*" (Ph—N$^-$) mode (now better described as a Ph—N$^-$ stretching) is expected to shift to higher values on ring deuteration. This shifted line in the PHPD-d_5 spectrum is presumably overlapped by other spectral features (perhaps the 1362 cm^{-1} line) which are not perturbed by ring deuteration.

(*iv*) The N—N stretching mode has been previously observed at 1202 cm^{-1} for diazoaminobenzene (11) and in the 1160–1200 cm^{-1} spectral range for other azobenzene derivatives in acid solution where hydrazone forms appear (6, 14, 15), so it is expected between 1150 and 1210 cm^{-1}. However, α and β ^{15}N labelling unambiguously assigns the 1363 cm^{-1} line in the PHPD spectrum as the N—N stretching; its relatively high frequency in this case would indicate a correspondingly high N—N bond order. If the anionic forms are described by three hybrid structures (Scheme 1) in which form **III** predominates, the relatively high stretching frequency can be rationalized.

(*v*) When comparing the resonance Raman spectra of (3-Cl)-PHPD and (3-Cl)-PHPD-β ^{15}N, no other frequency shifts distinct from that noted in (*iv*) are observed, and accordingly the C=N stretching mode cannot be assigned. If, however, as shown in Scheme 1, the bond orders and the force constants for the N⋯N and C⋯N bonds are of the same magnitude, a characteristic vibration for each bond would not be expected.

(*vi*) Two lines (1300 cm^{-1}; and 1250 cm^{-1} in PHPD spec-



SCHEME 1

trum), insensitive to ring deuteration and both α and β ^{15}N substitution, are assigned to symmetric and antisymmetric C—C stretching modes of the propanoid group.

Protonated forms

(*i*) Resonance Raman spectra of both solid samples and aqueous solutions at pH 5.7 are dominated by a strong band in the 1270–1300 cm^{-1} spectral range, assigned to the "*e*" (Ph—NH) mode. As this mode results from a coupling between a ring mode and the Ph—NH stretching, ^2H and α ^{15}N isotope shifts are of the same magnitude. The β ^{15}N shift of this band seen in the (3-Cl)-PHPD-β ^{15}N spectrum shows that this line is rather representative of an "*e*" (Ph—NH—N) mode; the force constants for the Ph—NH and N—N bonds should be of the same magnitude in this conjugated system.

(*ii*) The significant shift (19 cm^{-1}) of the above discussed line on ionization is explicable by participation of the N—H deformation mode: strong coupling between N—H bending and Ph—NH stretching can be invoked. A similar coupling perturbed by deuterium exchange of a N—H group in an analogous system has been previously observed (6).

(*iii*) Spectral shifts resulting from ring deuteration are different for the protonated and deprotonated forms. For protonated PHPD, deuterium substitution results in a shift of the "*e*" (Ph—NH—N) mode to lower frequency (1286 $cm^{-1} \rightarrow$ 1273 cm^{-1}). For the deprotonated form, the corresponding shift of the "*e*" (Ph—N$^-$) mode is to higher frequency (1303 $cm^{-1} \rightarrow$ 1362 cm^{-1}). Again, changes in coupling of "*e*" modes with N—H deformation mode explain these shifts. Analogous results have been previously obtained for phenylhydrazone functions developed when dimethylaminoazobenzene derivatives are examined in acid solution (15).

(*iv*) The symmetrical and antisymmetrical nitrile stretching modes are affected by the pH change. The increase in wavenumber (40 cm^{-1}) for the protonated forms is consistent with a decrease in conjugation within the protonated molecule (11) also manifested as a blue shift in the visible absorption band.

(*v*) Phenyl ring vibrational modes are easily assigned on the basis of deuterium shift, except for the 1400–1550 cm^{-1} spectral range where C=N stretching and N—H deformation modes must be considered (13). It is difficult to precisely locate the bands in this region, but the N—H deformation mode can be attributed to the weak 1543 cm^{-1} line in the PHPD spectrum, which shifts to 1532 cm^{-1} in the PHPD-α ^{15}N spectrum; these two lines are only observed for the solid state, probably being too weak to be seen in the solution spectra. The C=N stretching vibration can be located at lower wavenumbers (16); for both solution and solid state, the single line at 1465 cm^{-1},

The solution are approximately 3×10^{-4} *M*: (*a*) in phosphate buffer (pH 5.7), (*b*) in 0.01 *M* NaOH (pH 12.0). Insert: The titration curve obtained by non-linear least squares analysis and the structure of (2-carboxy)-PHPD at pH 5.7.

observed in the PHPD-d_5 spectrum, is assigned to this mode, being also consistent with the β ^{15}N shift observed in this region for (3-Cl)-PHPD-β ^{15}N.

*p*K$_a$ *value determination*

The dramatic differences in the resonance Raman spectra of the protonated and deprotonated forms, particularly for the "*e*" (Ph—NH) mode, allows a convenient assessment of pK_a values in those cases where spectrophotometric titration is not accurate (due to small spectral shifts). (2-carboxy)-PHPD is such a case; the relevant resonance Raman spectra shown in Fig. 4 are very similar to those of PHPD derivatives above discussed and indicate that the observed changes can be related to the deprotonation of the NH group. A fitted plot of the relative intensities of the two strong lines (I_{1368}/I_{1250}) vs. pH allows the pK_a determination. The relatively high pK_a value (9.2) is obviously a consequence of an intramolecular interaction between the carboxyl and NH groups (Fig. 4).

Conclusion

The resonance Raman data, together with the ^2H and ^{15}N isotope shifts, allow assignment of most of the observed bands, and also allow the protonated and deprotonated forms to be clearly distinguished. A strong line attributed to an "*e*" (Ph—NH—N) mode disappears at high pH due to ionization at N—H; the consequent increase in N—N bond order leads to a splitting whereby both "*e*" (Ph—N^-) and N—N stretching modes are observable in the spectra of the anionic form. This form is best defined by a resonance hybrid with strong carbanion character stabilized by the two electron-withdrawing nitrile groups. Such a structure explains well the chemical unreactivity of PHPD derivatives towards thiols at high pH (3) and also the instability of tetrahedral adducts of PHPD with thiols at high pH (3). The extensive charge delocalization within the anion is also relevant to its ability to diffuse across lipid bilayers, and thereby act as an uncoupling agent.

Received August 31, 1984

This paper is dedicated to Professor Camille Sandorfy on the occasion of his 65th birthday

PAUL J. KROPP, J. DEREK MASON, and GARDINER F. H. SMITH. Can. J. Chem. **63**, 1845 (1985).

The behavior of the three medium-sized cycloalkenes cyclooctene (**10**), cyclodecene (**17**), and cyclododecene (**21**) on direct irradiation in pentane and methanol solution has been studied. The results are summarized in Tables 1–3. Irradiation of medium-sized cycloalkenes is a convenient procedure for the preparation of bicyclic products (cf. **13**, **14**, **19**, **20**, and **23**) through transannular insertion reactions of carbene intermediates (cf. **11**, **18**, and **22**) thought to arise from rearrangement of the $^1[\pi,R(3s)]$ state via a 1,2-hydrogen shift. The formation of *trans*-decalin (**20**) is in contrast to the reported formation of the *cis* isomer on base-initiated decomposition of the corresponding tosylhydrazone. None of the three cycloalkenes **10**, **17**, or **21** underwent competing nucleophilic trapping of the $^1[\pi,R(3s)]$ state in methanol, in contrast with other alkenes previously studied. However, cyclododecene (**21**) afforded the methyl ether **25**, which apparently resulted from protonation of the $^1(\pi,\pi^*)$ state, and the epoxide **26**, which is thought to arise from electron transfer to oxygen by the $^1[\pi,R(3s)]$ state followed by protonation of the resulting superoxide ion and oxidation of unreacted cyclododecene (**21**).

PAUL J. KROPP, J. DEREK MASON et GARDINER F. H. SMITH. Can. J. Chem. **63**, 1845 (1985).

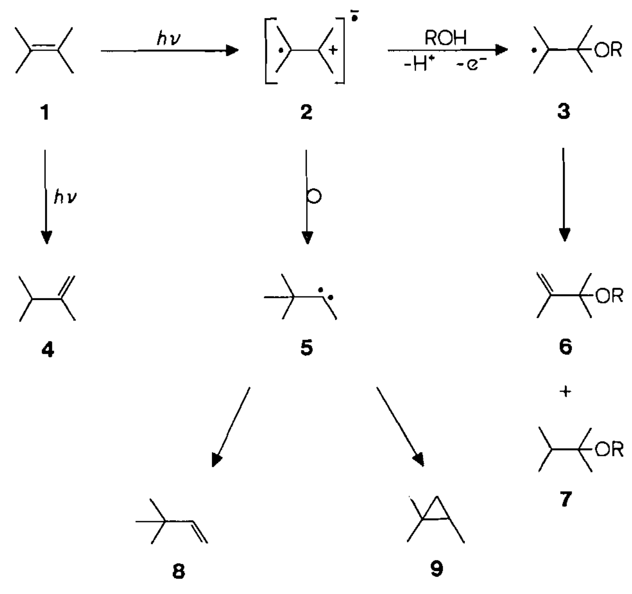
Opérant dans des solutions dans le pentane ainsi que dans le méthanol, on a étudié le comportement, vis-à-vis de l'irradiation directe, des trois cycloalkènes à cycles moyens suivants: cyclooctène (**10**), cyclodécène (**17**) et cyclododécène (**21**). On rapporte les résultats dans les tableaux 1–3. L'irradiation des cycloalkènes à cycles moyens est une méthode appropriée de préparer des produits bicycliques (comme **13**, **14**, **19**, **20** et **23**) par le biais de réactions intramoléculaires d'insertions transannulaires des carbènes intermédiaires (comme **11**, **18** et **22**) qui proviendraient d'une transposition de l'état $^1[\pi,R(3s)]$ via un déplacement-1,2 d'hydrogène. La formation de la décaline-*trans* (**20**) est en opposition avec le fait que des auteurs ont rapporté la formation de l'isomère *cis* lors de la décomposition, initée par les bases, de la tosylhydrazone correspondante. Par opposition avec les résultats obtenus avec les autres alkènes étudiés antérieurement, aucun des trois cycloalkènes **10**, **17** ou **21** ne subit de trappage nucléophile de l'état $^1[\pi,R(3s)]$ par le méthanol. Toutefois, le cyclododécène (**21**) conduit au méthyl éther **25**, qui proviendrait de la protonation de l'état $^1(\pi,\pi^*)$, ainsi qu'à l'époxyde **26** qui proviendrait dans une première étape d'un transfert électronique par l'état $^1[\pi,R(3s)]$ qui serait suivi d'une protonation de l'ion superoxyde qui en résulte et de l'oxydation du cyclododécène (**21**) qui n'a pas réagi.

[Traduit par le journal]

Introduction

Although theoretical and spectroscopic aspects of the Rydberg excited states of various organic chromophores have long been studied, little attention has been given to the chemical properties of these species.[3] This is particularly surprising in the case of a chromophore such as the carbon–carbon double bond, in which a Rydberg excited state is either the lowest lying or close in energy to the lowest lying singlet excited state.[4] As depicted in Scheme 1 for the case of 2,3-dimethyl-2-butene (**1**), studies in these laboratories directed toward elucidating the chemical properties of the $^1[\pi,R(3s)]$ state of alkenes have shown that irradiation of alkenes in hydroxylic media results in the formation of a mixture of saturated and unsaturated ethers (**6** and **7**), which appear to arise via nucleophilic trapping of the $^1[\pi,R(3s)]$ state (**2**) followed by disproportionation of the resulting alkoxy radical (**3**) (4).

In the absence of nucleophilic trapping the $^1[\pi,R(3s)]$ intermediate undergoes, instead, rearrangement via a carbene intermediate. Thus irradiation of **1** in non-hydroxylic media results in a mixture of the rearranged alkene **8** and the cyclopropane **9**, the expected 1,2- and 1,3-insertion products from the carbene intermediate **5** (5). These two reactions, nucleophilic trapping in hydroxylic media and rearrangement via a carbene intermediate in non-nucleophilic media, are apparently the first two observations of the chemical properties of the $^1[\pi,R(3s)]$ state. They have since been observed for a number of alkenes (for a review of the photobehavior of alkenes in solution see ref. 6).



SCHEME 1

These processes occur in competition with $E \rightleftharpoons Z$ isomerization of the alkene, which is not observable in the case of **1** and probably involves the π,π^* excited state (6), and with double bond migration, which gives rise to isomer **4** in the case

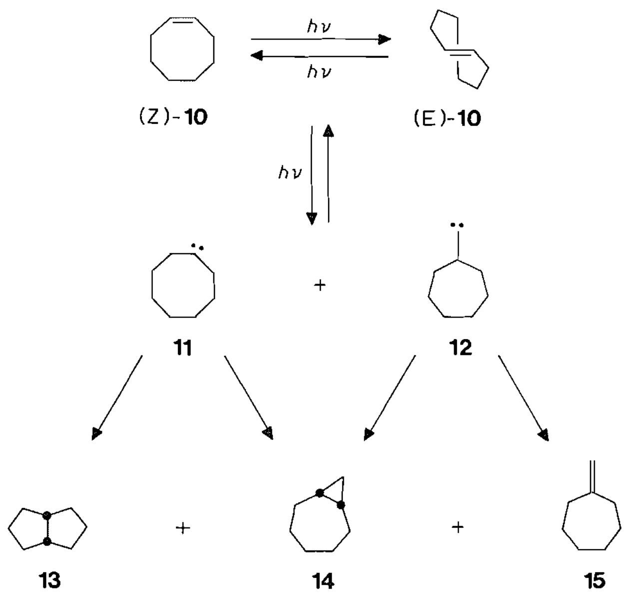
[1] For Part 8, see ref. 1.
[2] Author to whom correspondence may be addressed.
[3] Professor Sandorfy has been a leader in calling attention to the probable involvement of Rydberg intermediates in photochemical reactions. See, for example, ref. 2.
[4] For discussion of the excited states of alkenes see ref. 3.

of **1** and apparently involves yet a third excited intermediate (7, 8). In some cases reduction of the double bond is also observed, but it is not clear which excited state is involved in this process.

Photorearrangement of alkenes via carbene intermediates has the potential of useful synthetic applications but has the drawback of competing double bond migration. One way of eliminating the loss of material due to this competing isomerization is to incorporate the double bond in a cyclic environment such as that of cyclooctene (**10**), cyclodecene (**17**), or cyclododecene (**21**), in which double bond migration is an identity process. Such medium-sized cycloalkenes offer a further potential for synthetic interest arising from their propensity for undergoing transannular reactions. We report here the photobehavior of cycloalkenes **10**, **17**, and **21** induced by direct irradiation in solution.

Results

The results from irradiation of cycloalkenes **10**, **17**, and **21** are summarized in Tables 1–3, respectively. In addition to undergoing $E \rightleftharpoons Z$ isomerization, each alkene afforded one or more bicyclic products (**13**, **14**, **19**, **20**, and **23**).[5] The product



from cyclododecene (**21**) is assigned the novel bicyclo[7.3.0]-dodecane structure **23** on the basis of its ^{13}C nmr spectrum, as described in the experimental section, but the stereochemistry at the ring fusion is uncertain. Cyclooctene (**10**) afforded, in addition, the ring-contracted isomer **15**. In several cases acyclic cleavage products were observed: 1-octene (**16**) from **10** and 1-dodecene (**29**) and 1-dodecyne (**30**) from **21**. Since these products underwent competing destruction under the irradiation conditions, their yields decreased on extended irradiation. Cyclododecene (**21**) also afforded the reduction product **24**, the methyl ether **25**, and, in some runs, the oxide **26**. This latter product apparently arose from residual dissolved oxygen since its formation ceased after a short time.

Discussion

As predicted, irradiation of medium-sized cycloalkenes is a convenient method for preparing bicylic isomers. The products **13** and **14** from cyclooctene (**10**) are those expected for the carbene intermediate **11**, which is reported to undergo competing 1,5-, 1,3-, and 1,2-insertion when generated by base-initiated decomposition of the corresponding tosylhydrazone to afford a mixture of **13**, **14**, and cyclooctene (**10**) (10). In the present case any cyclooctene (**10**) formed would, of course, simply have been recycled. The accompanying formation of methylenecycloheptane (**15**) implies that the carbene intermediate **12**, which has previously been found to undergo competing 1,2- and 1,3-insertion to afford a mixture of **14** and **15** (11), is also formed. Thus the $^1[\pi,R(3s)]$ state of **10** apparently undergoes competing rearrangement via a 1,2-hydrogen shift to afford the carbene intermediate **11** and a 1,2-alkyl shift to afford **12**. By contrast, only products arising from the carbene intermediates **18** and **22**, formed via a 1,2-hydrogen shift, were observed for the larger-ring homologs **17** and **21**.

[5] Originally **14** and **15**, but not **13**, were reported as products from irradiation of cyclooctene (**10**) at 185 nm (9*a*). Since the initiation of our studies, **13** has also been reported (9*b*).

Generation of the C_{10} carbene intermediate **18** by base-initiated decomposition of the corresponding tosylhydrazone in aprotic media is reported to afford principally *cis*-bicyclo[5.3.0]decane (**19**), accompanied by (*Z*)- and (*E*)-cyclodecene (**17**) and *cis*-decalin (10). Medium-sized cyclic carbenes formed in this fashion generally afford *cis*-fused transannular cyclization products, presumably because they are formed in their singlet state and undergo concerted insertion into a transannular axial C—H bond (10). By contrast, irradiation of cyclodecene (**17**) afforded only the *trans* isomer **20**. This might suggest that the carbene intermediate **18** is formed photochemically in its triplet state, which undergoes a two-step insertion process via a radical intermediate that selectively closes to the thermodynamically more stable *trans* isomer **20**.[6] However, such a process should similarly afford the thermodynamically more stable *trans* isomer of **19**.[7] Perhaps the difference simply lies in the carbene intermediate being generated in a different geometry or with a different amount of residual energy from the two routes.

Generation of the C_{12} carbene intermediate **22** by base-initiated decomposition of the corresponding tosylhydrazone in aprotic media is reported to afford a mixture of (*Z*)- and (*E*)-cyclododecene (**21**) (14, 15) accompanied by a small amount of a bicyclic product, presumably **23**, which was formed in insufficient quantity to be characterized (15). In the present case any cyclododecene (**21**) arising from reversion of the carbene intermediate **22** would have been recycled, thus permitting substantially greater accumulation of the bicyclic product **23**. Quite surprisingly, irradiation of cyclododecene (**21**) in methanol afforded the two oxygen-containing products **25** and **26**.[8] When the irradiation was conducted in methanol-*d*, ether **25** was formed with substantial incorporation of deuterium, which was shown by ^{2}H nmr spectroscopy not to be located α to the methoxyl group. The incorporation of deuterium, along with the absence of any accompanying unsaturated ether, indicate that ether **25** does not arise via nucleophilic trapping of the ^{1}[π,R(3*s*)] state **27** in analogy with the formation of ethers **6** and **7** from alkene **1**. Indeed, it is noteworthy that none of the three cycloalkenes **10**, **17**, or **21** afforded products from nucleophilic trapping of the ^{1}[π,R(3*s*)] state. It has previously been found that disubstituted derivatives of ethene undergo nucleophilic trapping very inefficiently rela-

[6]For the relative stabilities of *cis*- and *trans*-decalin see ref. 12.
[7]The *trans* isomer of bicyclo[5.3.0]decane has been found to predominate at equilibrium, but only slightly; see ref. 13.

[8]Products having retention times corresponding to those of the C_{10} homologs of **25** and **26** were obtained on irradiation of cyclodecene (**17**), but in quantities insufficient for complete identification.

tive to rearrangement (6, 16). This behavior may be enhanced in medium-sized cycloalkene systems by steric encumbrance about the double bond, as previously observed with *tert*-butyl-substituted alkenes (1).

The lack of any detectable incorporation of deuterium in the α position also indicates that ether **25** does not arise via trapping of the carbene intermediate **22**. This is not surprising since alkyl carbenes generally undergo intramolecular insertion more rapidly than intermolecular trapping.

There remains a third alternative, which is consistent with the available data, that ether **25** arises via protonation of the $^1(\pi,\pi^*)$ state, which is thought to have dipolar character once it has relaxed to an orthogonal geometry (17). Protonation of this state does not normally occur because internal conversion to the ground state and relaxation to the *E* or *Z* isomer is generally more rapid than intermolecular trapping. However, an orthogonal species might have a lifetime longer than usual in the case of cyclododecene (**21**), simply because of the inability of this medium-ring system to relax to either the *E* or *Z* geometry without passing through large conformational barriers. Similar behavior was recently observed for *tert*-butyl-substituted alkenes (1).

The formation of oxides such as **26** on direct irradiation of alkenes has been observed previously (4), but no mechanism has been established. An attractive possibility involves initial reduction of oxygen to superoxide by electron transfer from the $^1[\pi,R(3s)]$ state (**27**) followed by attack on an unreacted molecule of cyclododecene (**21**). In methanol, protonation (18) and subsequent attack by the resulting hydroperoxy radical may be involved (19).

Conclusions

It is thus clear that irradiation of medium-sized cycloalkenes is a convenient method for the formation of bicyclic isomers. The photocyclization process is stereospecific and, in some cases, yields stereoisomers not afforded by the corresponding carbene intermediate when generated by conventional methods. The photochemical approach has the further advantage that competing reversion of the carbene intermediate to cycloalkene simply regenerates starting material, which is recycled. This is thus a useful illustration of the importance of Rydberg excited states in determining the photobehavior of an organic chromophore.

Experimental

General procedures

Infrared spectra were obtained in carbon tetrachloride solution with a Beckman 4250 spectrophotometer. Gas chromatographic analyses were performed on a Hewlett–Packard 5750 instrument with 10 ft × 0.125 in. stainless steel columns packed with either 20% (A) Carbowax 20M, (B) SF-96, or (C) β,β'-oxydipropionitrile on 60–80 mesh Chromosorb W. Preparative gas chromatographic separations were effected on a Varian Aerograph 90-P instrument with 10 ft × 0.25 in. stainless steel columns packed as described above. Melting points were determined on a Thomas–Hoover instrument and are uncorrected and uncalibrated. Nuclear magnetic resonance spectra were obtained in chloroform-*d* solution with a Varian XL-100 or Brucker WM-250 spectrometer. Isotopic compositions were calculated from mass spectra obtained on a VG Micromass 7070F spectrometer.

Irradiations

Irradiations were conducted under an atmosphere of nitrogen on 0.05 *M* solutions with the broad spectrum of a Hanovia 450-W medium-pressure mercury arc and either a water-cooled quartz immersion well or an Ace 7883 reflector and a quartz tube suspended in a water-cooled quartz immersion well. Before irradiation and after each aliquot was taken for analysis, nitrogen was bubbled through the solution for 10 min. After irradiation the solvent was removed by distillation through a Vigreux column.

*Irradiation of (*Z*)-cyclooctene ((*Z*)-**10**)*

A commercial specimen was redistilled at 45–46°C (17 Torr; 1 Torr = 133.3 Pa)) prior to use. From the irradiations described in Table 1 the following products were isolated by preparative gas chromatography.

cis-*Bicyclo[3.3.0]octane (**13**)* was isolated as a colorless liquid; ν_{max}: 2955, 2870, 1455 cm^{-1}; ^{1}H nmr δ: 2.6 (br m, 2, CH-1 and -5), 1.66 (m, 4), 1.5 (m, 2), 1.19 (m, 4) (lit. (20) ^{1}H nmr δ: 2.4, 1.7–1.1).

cis-*Bicyclo[5.1.0]octane (**14**)* was isolated as a colorless liquid; ^{1}H nmr δ: 2.11 (br m, 2, CH-1 and -7), 1.74 (br, 2), 1.32 (br q, 4), 0.02 (q, 1, axial cyclopropyl H) (lit. (21) ^{1}H nmr δ: −0.06 (1)).

*Methylenecycloheptane (**15**)* and *1-octene (**16**)* were isolated as colorless liquids having infrared and nmr spectra similar to those of commercial specimens.

*(*E*)- and (*Z*)-cyclodecene ((*E*)- and (*Z*)-**10**)*

A. *Preparation*

In a modification of the procedure of Brown and Ham (22), 2.83 g (18.1 mmol) of cyclodecanol in 25 mL of dry pyridine was added with cooling to a solution of 3.79 g (19.9 mmol) of *p*-toluenesulfonyl chloride in 25 mL of dry pyridine. The mixture was stirred until homogeneous, cooled for 24 h, diluted with 75 mL of distilled water, and extracted with 2 × 50 mL of diethyl ether. The ether extracts were combined, washed with 5 × 25 mL of cold 5% HCl and 2 × 30 mL each of saturated sodium bicarbonate and saturated sodium chloride solutions, and then dried over anhydrous sodium sulfate. The ether was partially removed by rotary evaporation, and the remaining ether was allowed to evaporate overnight. The resulting liquid was placed in a vacuum desiccator at room temperature for 48 h, then dissolved in pentane, extracted with 2 × 25 mL each of saturated sodium bicarbonate solution and saturated sodium chloride solution, and dried over anhydrous sodium sulfate. Evaporation of the pentane and distillation on a spinning band column gave 2.10 g (84% yield) of a 1:5 mixture of (*E*)- and (*Z*)-**17** as a colorless liquid; bp 52–53°C (13 Torr); ν_{max}: 3010, 2920, 2860, 2680, 1650, 1481, 1452 cm^{-1}; ^{1}H nmr δ: 5.37 (t, 2, CH=CH), 2.23 (m, 4, C=C—CH$_2$), 1.53 (s, 14)[9] (lit. (23) ν_{max}: 2915, 2680, 1456 cm^{-1}; ^{1}H nmr δ: 5.36 (2, CH=CH), 1.5 (14)).

B. *Irradiation*

From the irradiations described in Table 2 the following products were isolated by preparative gas chromatography.

cis-*Bicyclo[5.3.0]decane (**19**)* was isolated as a colorless liquid; ν_{max}: 2925, 2860, 1455 cm^{-1}; ^{1}H nmr δ: 1.98 (br m, 2, CH-1 and -7), 1.78 (br m, 4), 1.60 (br m, 4), 1.20 (m, 8); ^{13}C nmr δ: 43.5 (C-1 and -7), 35.8 (C-2 and -6), 33.0 (C-8 and -10), 31.7 (C-4), 29.7 (C-3 and -5), 26.4 (C-9) (lit. (24) ^{13}C nmr δ: 43.6, 35.9, 33.1, 31.8, 29.8, 26.1).

trans-*Decalin (**20**)* was isolated as a colorless liquid; ^{1}H nmr δ: 1.66 (br d, 4), 1.53 (br t, 4), 1.22 (br m, 4), 0.89 (br m, 6) (lit. (25) ^{1}H nmr δ: 1.66 (4), 1.53 (4), 1.23 (4), 0.93 (4), 0.84 (2)).

*Irradiation of (*E*)- and (*Z*)-cyclododecene ((*E*)- and (*Z*)-**21**)*

A commercial specimen which had an *E*/*Z* ratio of 1.5:1 was employed. From the irradiations described in Table 3 the following products were isolated.

*Bicyclo[7.3.0]dodecane (**23**)* was isolated as a colorless liquid; ν_{max}: 2920, 2866, 1441 cm^{-1}; ^{1}H nmr δ: 1.85 (br m, 2, CH-1 and -9), 1.45 (br m, 20); ^{13}C nmr δ: 43.2 (C-1 and -9), 34.4 (C-2 and -8), 28.9 (C-10 and -12), 27.9 (C-3 and -7), 26.2 (C-11), 25.3 (C-4 and -6), and 21.5 (C-5); mass spectrum, *m*/*e*: 166.1720 (calcd. for $C_{12}H_{22}$, 166.1721), 166 (41), 110 (28), 109 (35), 97 (31), 96 (88), 95 (57),

[9] Absorptions at δ 2.05 and 1.40 corresponding to (*E*)-**10** were also observed.

83 (43), 82 (100), 81 (72), 69 (40), 70 (46), 67 (90), 55 (77).

Cyclododecane (24) and methoxycyclododecane (25) were isolated as colorless liquids which exhibited spectral properties in agreement with those of specimens prepared independently as described below.

13-Oxabicyclo[10.1.0]tridecane (26) was isolated as a colorless liquid that was characterized by comparison of its spectral properties with those of a commercial specimen.

1-Dodecene (27) was isolated as a colorless liquid; ^{1}H nmr δ: 5.82 (m, 1, C=CH—C), 4.96 (br t, 2, C=CH_2), 2.05 (m, 2, C=CH_2), 1.28 (m, 16), 0.88 (t, 3, CH_3) (lit. (26) ^{1}H nmr δ: 5.75 (m, 1), 4.96 (br t, 2), 2.00 (m, 2), 1.3 (s, 16), 0.88 (t, 3)).

1-Dodecyne (28) was isolated as a colorless liquid; ν_{max}: 3335, 2130 cm^{-1}; ^{1}H nmr δ: 2.18 (t of d, J = 3.7 and 7.5, —CH_2—C≡C), 1.93 (t, 1, J = 3.7, —C≡CH), 1.28 (br s, 16, —CH_2—), 0.88 (t, 3, J = 7.5, —CH_3) (lit. (27) ν_{max}: 2120 cm^{-1}; ^{1}H nmr δ: 2.0–2.2 (m, CH_2—C≡C), 1.7 (t, —C≡CH), 0.9 (t, —CH_3)).

From the irradiation conducted in methanol-*d* the specimen of ether **25** which was isolated was found by mass spectral analysis to be 23% d_0, 70% d_1, 7% d_2; ^{2}H nmr δ: 1.58, 1.45. The specimen of bicyclo[7.3.0]dodecane (**23**) isolated showed no incorporation of deuterium.

Independent preparation of cyclododecane (24)

A solution of 260 mg of a commercial mixture of (E)- and (Z)-cyclododecene ((E)- and (Z)-**21**) in 30 mL of methanol was stirred with 21 mg of 10% palladium-on-charcoal under an atmosphere of hydrogen. Absorption ceased after the consumption of 1.1 molar equiv. of hydrogen. Removal of the catalyst by filtration and of the solvent by distillation afforded a colorless oil which crystallized slowly on standing; mp 58–60°C; ν_{max}: 1463, 1441, 1340, 714 cm^{-1}; ^{1}H nmr δ: 1.34 (s) (lit. (28) mp 61°C; lit. (29) ν_{max}: 1343 (s), 714 (s)).

Independent preparation of methoxycyclododecane (25)

A solution of 1.84 g (10.0 mmol) of cyclododecanol in 30 mL of ether was treated with 480 mg (20 mmol) of sodium hydride, and the resulting mixture was stirred under an atmosphere of nitrogen for 16 h. A solution of 7.10 g (50 mmol) of iodomethane in 30 mL of ether was then added and the reaction mixture was heated under reflux for 50 h. The excess sodium hydride was quenched by the careful addition of 5 mL of water and the resulting mixture was transferred to a separatory funnel. The ether layer was dried over 5 mL of saturated sodium chloride solution followed by anhydrous sodium sulfate and the solvent was removed by distillation through a Vigreux column. Gas chromatographic analysis of the residue revealed the formation of a single product in 69% yield and the continued presence of 30% of the starting alcohol. Isolation by preparative gas chromatography afforded ether **25** as a colorless liquid; ν_{max}: 1471, 1447, 1094 cm^{-1}; ^{1}H nmr δ: 3.33 (s, 4, CH-1 and —OCH_3), 1.35 (br s, 22) (lit. (30) ^{1}H nmr δ: 3.2 (?), 3.23).

Hydrogen bridges and electron transfer in biomolecules. Study of a possible mechanism on a model charge–recombination system

GIUSEPPE DEL RE, ANDREA PELUSO, AND CAMILLA MINICHINO
Cattedra di Chimica Teorica, Università di Napoli, Via Mezzocannone 4, I-80134 Napoli, Italy

Received August 16, 1984

This paper is dedicated to Professor Camille Sandorfy on the occasion of his 65th birthday

GIUSEPPE DEL RE, ANDREA PELUSO, and CAMILLA MINICHINO. Can. J. Chem. **63**, 1850 (1985).

It is suggested that internal electron transfer in biomolecules such as multiheme proteins can take place along H-bridge/peptide-link chains by a proton-relay process followed by radicalic return to the initial condition. The plausibility of such a process is assessed by (a) reference to published suggestions and evidence; (b) estimates of vibrational characteristics and of the free energies of the various states of a model system consisting of three H-bridges and one peptide group. It appears that the proposed mechanism is highly efficient and very fast, at least if the H-bonds formed by a peptide group evolve in a concerted manner.

GIUSEPPE DEL RE, ANDREA PELUSO et CAMILLA MINICHINO. Can. J. Chem. **63**, 1850 (1985).

On suggère que le transfert électronique interne dans des biomolécules, comme les protéines de multihème, peut se produire le long des chaînes ponts-H/liaisons-peptidiques par un processus de relais de protons qui serait suivi d'un retour radicalique à la condition initiale. On essaye de déterminer si un tel processus est plausible en faisant appel à (a) des références à des suggestions et à des données expérimentales publiées; (b) des évaluations des caractéristiques vibrationnelles et des énergies libres des divers états d'un système modèle comportant les trois ponts-H et un groupement peptidique. Il semble que le mécanisme proposé soit très efficace et très rapide, au moins si les liaisons H formées par un groupement peptidique évoluent d'une manière concertée.

1. "Assisted through-bond" ET mechanism

1a. When biomolecules containing several hemes participate in a redox process, intramolecular electron transfer (ET) between hemes is likely to be a feature of the overall phenomenon. The problem then arises of establishing the mechanism by which that interheme ET takes place (1). In general, the interheme distances and orbital overlaps have values such that direct electron jumps from one macrocycle to another require resonance conditions, even if they proceed through bridge molecules (1). Therefore, alternative mechanisms are worth investigating. In this paper an "assisted through-bond" ET mechanism is proposed and discussed. An example of molecules to which it applies are the multiheme cytochromes. In molecules of that class it is possible that internal ET takes place along a continuous H-bond/peptide-link chain, involving a few peptide links and possibly a water molecule, and connecting the imidazole rings of two hemes: although structural details are still unreliable, published work indicates that the chain in question could start with a bridge between an imidazole and the oxygen of a peptide link and terminate with the same type of H-bridge in the opposite order (2).

The ET mechanism to be associated with such a chain would consist in a proton-relay process followed by a radicalic rearrangement:

$$a:\quad e^- + \mathrm{A}\ldots\mathrm{H{-}B}\ldots\mathrm{H{-}C} \rightarrow \mathrm{A}^-\ldots\mathrm{H{-}B}\ldots\mathrm{H{-}C} \rightarrow \dot{\mathrm{A}}\mathrm{{-}H}\ldots\mathrm{B}^-\ldots\mathrm{H{-}C} \rightarrow \dot{\mathrm{A}}\mathrm{{-}H}\ldots\mathrm{B{-}H}\ldots\mathrm{C}^- \rightarrow \dot{\mathrm{A}}\mathrm{{-}H}\ldots\mathrm{B{-}H}\ldots\mathring{\mathrm{C}} + e^-$$

(I*a*)

where the dot denotes an electron and the small circle a hole; and

$$b:\quad \dot{\mathrm{A}}\mathrm{{-}H}\ldots\mathrm{B{-}H}\ldots\mathring{\mathrm{C}} \xrightarrow[\text{one or more steps}]{} \mathrm{A}\ldots\mathrm{H{-}B}\ldots\mathrm{H{-}C}$$

(I*b*)

In stage **I***b* actual ET takes place, because the hole on C attracts a proton *plus one electron*, and so on until the initial situation is restored.

1b. In order to assess the plausibility of mechanism **I**, two major questions must be answered. First: are such chains of H-bonds actually present in multiheme proteins? Second: is the proposed mechanism sufficiently fast and efficient?

The first question requires consideration of the specific protein structure (cf. section 2). In this paper we focus on the second question, by presenting a study of a model system which contains the most relevant features of a possible real system. A major drawback remains, in that highly reliable potential energy (PE) surfaces are difficult to obtain even for such a simplified system. Even *ab initio* computations, due to basis effects and correlation errors, do not yield uniformly reliable barrier heights and vibrational frequencies (3, 4). Fortunately, fair estimates of free-energy profiles are sufficient for our purposes: what may be very important is that temperature dependent effects should be taken into account.

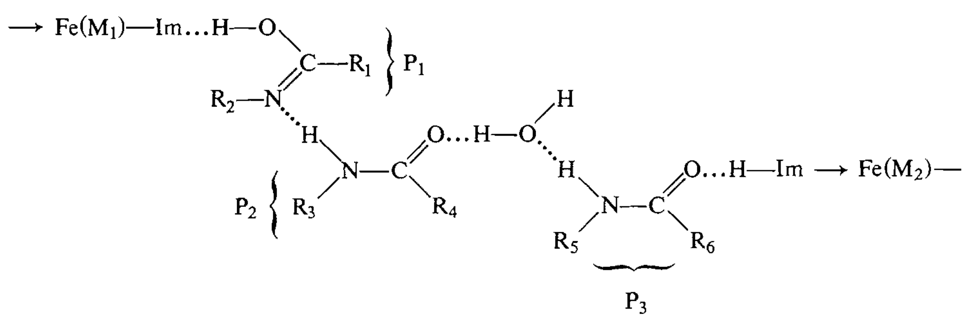
2. A specific example: heme–heme ET

2a. Consider, as a concrete example, the hemes of a multiheme cytochrome in their oxidized state. They may be represented by the abbreviated formulas

$$\mathrm{H{-}Im} \rightarrow \mathrm{Fe(M_1){-}Im}, \qquad \mathrm{H{-}Im} \rightarrow \mathrm{Fe(M_2){-}Im}$$

II

where Im stands for imidazolyl, M_1 and M_2 for the porphyrin macrocycles; the arrows denote dative N—Fe bonds, the dashes ordinary (covalent) N—Fe bonds resulting from substitution of a hydrogen atom by iron. Consider now the H-bond/peptide-bond chain:



III

Note: the *cis* and *trans* positions are not realistic

An electron-relay process of the type summarized by scheme **I** could take place (with M_1 acting as the electron acceptor and M_2 as the electron donor) along the chain of scheme **III** according to the following sequence of events.

A: An electron received by M_1 is transferred to the right-hand Im ligand, which becomes negative.

B: The resulting Im^- ring attracts the proton of the neighboring peptide group, P_1, which is initially in the enol form.

C: The negative charge now appearing on the end nitrogen of P_1 attracts the proton of P_2, which then goes over to the enol form.

D, E: Similar events take place at the water molecule and at P_3.

F: The second heme has now lost a proton, and has an imidazolate ion on its left-hand side. The negative charge is transferred to M_2, so that a hole is localized on Im.

G: M_2^- releases an electron to the external acceptor (or to another heme).

H: The electron-deficient left-hand imidazole of M_2 recalls the lost proton together with an electron.

I, J, K: The lost protons are taken back (with one electron) by P_3, the water molecule, P_2, and P_1 in succession. The left-hand heme thus loses the excess electron received at step A.

The whole mechanism just described is set "in motion", of course, when there are both a source of electrons acting on the left and an electron acceptor which creates the "driving force" on the right. If the latter were missing, reduction of the first heme would cause protons to shift so as to create a negatively charged deprotonated peptide group P_2^-; there would be no further motion because the high proton affinity of the OH^- makes the water molecule a very effective barrier.

2b. Aside from considerations specific to given protein structures, the following general questions must now be dealt with.

1. Is the oxidized-heme form **II** a reasonable assumption as compared with $[\text{H-Im—Fe(M)—Im-H}]^+$?

2. Is the assumption of a stable peptide bond in the enol form chemically plausible and consistent with available information?

3. Are the free-energy barriers involved in the charge-relay events A to G low enough?

The first point is easily disposed of, since the essential difference between the two cases is a normal covalent bond replacing a dative bond to iron, a proton being involved in any case in an H-bond connected to the imidazole, and one cannot see what should make that kind of bond less probable. In fact, the "deprotonated" oxidized form has been considered in several papers as a possible important feature of biological processes: "hydrogen bonding or actual deprotonation of imidazole ligands provides a means whereby the tertiary structure of the protein could moderate the reactivity or redox potential of the iron center" (5).

The second question requires a more detailed study. The enol form of the peptide bond is consistent with the rules of valency, but has never been observed. A theoretical study of the reaction formamide + water ⇄ formamidic acid + water suggests that the keto form has an energy ca. 60 kJ/mol lower than the enol form; the activation energy when a single water molecule plays the donor–acceptor role is ca. 100 kJ/mol. These results indicate that the energy changes involved in the keto–enol isomerization of the peptide bond are high enough to control the kinetics, but not so high that the process should be forbidden. Moreover, the above results apply to the gas phase; the presence of a special environment such as certainly exists close to a heme group may well bring about energy changes of the order of ca. 100 kJ/mol. The objection that peptide bonds permanently in the enol form would be detected by nmr does not apply to a typical protein of more than 100 aminoacid residues, since then only less than 4% of the peptide groups would be in the enol form.

As concerns energy barriers or, more generally, energy profiles, it might seem that, at least for simple models, straightforward *ab initio* calculations followed by evaluation of vibrational contributions is a safe procedure. Quite instructive papers (dealing, however, with energy differences between minima) have in fact been published according to this philosophy (6). Nevertheless, as has been mentioned, two orders of difficulties remain. First, without a fairly accurate study of the whole PE hypersurface the results lose much of their significance. Secondly, as has been extensively shown, in particular by Scheiner (7), the results for barriers are dramatically basis dependent. Scheiner has suggested that the 4.31 G basis should provide fairly reliable estimates, but he bases this conclusion on a few comparisons with $6.311\ G^{++}$ results corrected for correlation according to a special formula. Thus, for systems involving more than one hydrogen bond and a comparatively large number of atoms (as is the case with the model discussed below), a rigorous quantitative study of energy profiles is a

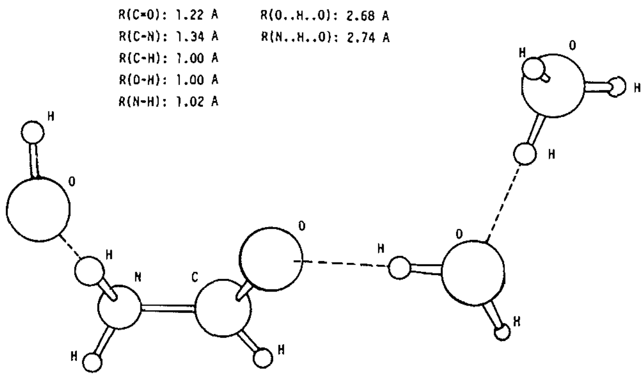


FIG. 1. Geometrical representation of model peptide residue.

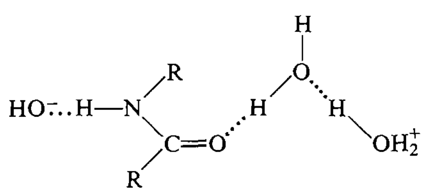
problem for the future. Less ambitious semiempirical calculations are certainly open to many reservations. In the present context they are the most reasonable choice because of the above considerations, because, as will be seen, they give acceptable results, and, most important, because all we really need is a semiquantitative description of the whole process under study. Moreover, as will be illustrated below, electronic calculations are in general just starting points for the evaluation of force constants, which require some kind of interpolation technique and the introduction of correction factors in all cases.

With the above premises, we intend to suggest that the answer to question 3 above is positive; indeed, we proceed to introduce our simplified model and to discuss the various aspects of the mechanism under study starting precisely with consideration of PE profiles.

3. The model system

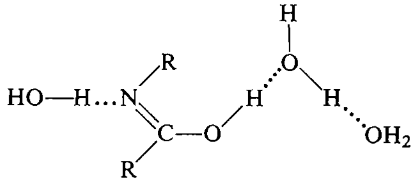
3a. A system which appears to us to incorporate the critical features of **III** is the triple-bridge system



$(R = H, CH_3)$

(**IV***a*)

which undergoes charge recombination by proton shifts from right to left. The two terminal ions simulate the left-hand heme + P_i system (after it has received an electron) and the right-hand heme, together with the virtual acceptor which creates the "driving force". Another feature characteristic of chain **III** is present, inasmuch as the recombined form contains a peptide group in the enol form:

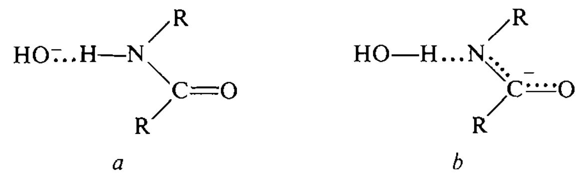


(**IV***b*)

As the model peptide unit we have chosen *N*-methylacetamide, in agreement with Del Bene (8), but for the geometry (cf. Fig. 1) we have used the standard data for a peptide residue (9). The valency angle for the C═O . . . H—O bridge has been taken to be 120°, in agreement with current estimates (10). For the H-bond distances we have taken 2.68 Å and 2.72 Å for O . . . O and N . . . O respectively.

Semiempirical (MNDO, ref. 15) computations yield the expected results for the Born–Oppenheimer (B.O.) potential energy profile along the H-bond line. No barrier is found for the end N . . . O and O . . . O bonds.

The absence of a barrier for the transition

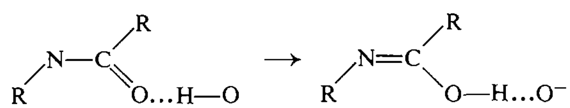


a *b*

(**V**)

may appear somewhat surprising, the more so as the B.O. energy difference between **V***a* and **V***b* of system **III** is predicted to be 249 kJ/mol (ca. 60 kcal/mol) in favor of **V***b*. In fact, neither STO 3G nor 4.31 G calculations predict a barrier at 2.8 Å (11, 12), and the greater stability of **V***b* is obviously related to the fact that the proton affinity of OH^- is particularly high (13).

The barrier to proton shift for the C═O . . . H—O bond is 82 kJ/mol in the right-to-left hand direction. This barrier includes electron rearrangement in the peptide group, because it corresponds to the process



a *b*

(**VI**)

System **IV** at stage **VI** is predicted to be less stable by only ca. 27 kJ/mol than the preceding stages; this is probably a result of the stabilization of OH^- by H_3O^+, viz., a consequence of the "driving force" produced by the terminal ions.

The absence of a barrier for the third bridge is in full agreement with the best *ab initio* results (14), which predict only ca. 11 kJ/mol at 2.75 Å for $H_3O_2^-$. This last step is characterized by the expected very large drop in energy, ca. 320 kJ/mol.

In short, the B.O. energies obtained by the MNDO (15) calculations are entirely reasonable and sufficient for our purposes. Their physical significance, however, is worth a more detailed discussion in connection with mechanism **I**.

What is somewhat puzzling is the physical meaning of having placed the two terminal ions so close to the central part of system **IV**. Had we selected distances 20% longer, at least the N . . . O bond would have shown a large B.O. barrier – as 4.31 G calculations go. Of course, a more complete study of **IV** as such should include consideration of this possibility, since one could imagine that the OH^- ion, for instance, slowly approaches the rest of the system, in which case the proton could be exchanged already at distances larger than 2.68 Å. (Although it may be noted that work by Brickmann (16), together with the results of ref. 7, predicts that the proton transfer times become exceedingly long already at 2.95 Å.)

Our problem here, however, is related to a given rigid structure, which relaxes very little upon reduction or oxidation (17). Therefore, it is correct to ignore relaxation and, especially, situations where the terminal ions are initially far from their "equilibrium" positions. Indeed, we have to think that at least the left-hand one is formed in place, as happens to Im in mechanism **III**.

Thus, we must accept as a possibility the absence of barriers at the terminal H-bonds. The question then arises: how will the process take place in time?

At first sight, one could expect that step **V** will take place upon formation of OH^-, followed by step **VI**, which must be preliminary to the last one. If this were so, we should think of a stepwise mechanism as most probable. However, this picture ignores the possibility that step **VI** may be immediately switched on as the removal of the NH proton from N begins. This is revealed in a PE surface by the fact that a path where the protons move concertedly (cf. below) involves a lower barrier (MNDO: 31 kJ/mol).

All this can be made somewhat more quantitative by consideration of thermodynamic characteristics of the process. As has been mentioned, the latter are the really significant quantities, not the Born–Oppenheimer potential energy in any degree of approximation.

4. Vibrational analysis

4a. As has been mentioned, the importance of vibrational contributions to physically significant quantities associated with the processes under consideration may be very large. This applies in particular to both terms of the free energy expression

$$[1] \quad \Delta G = \Delta H - T\,\Delta S$$

which must be estimated for the initial, activated, and final states of each reaction step. This can be done theoretically using the well-known rigid-rotator, harmonic-oscillator, and ideal-gas approximations, whereby eq. [1] can be cast into the form

$$[2] \quad \Delta G = \Delta E + \Delta G^{\mathrm{transl}} + \Delta G^{\mathrm{rot}} + \Delta G^{\mathrm{vib}} + \Delta E^{zp}$$

ΔE standing for the difference in interaction energies, ΔE^{zp} standing for the corresponding zero-point vibrational energy, and other symbols having the standard meanings (18). The terms corresponding to rotations and translations could be easily evaluated, if needed. In our case they play no role. On the other hand, evaluation of vibrational contributions is quite difficult, especially if an activated state is also to be studied. Theoretical estimates of vibrational frequencies are necessary because of the lack of experimental data for transition and activated states. Calculation of a complete force field is then necessary for the equilibrium states as well, lest inconsistencies be introduced.

For the reasons explained above, we have started from current semiempirical (MNDO) calculations, carried out for those equilibrium and activated states of the model system **IV** which correspond to (a) a stepwise mechanism where the protons move in succession along the H-bond lines; (b) a concerted mechanism where the protons also move along the H-bond lines, but cover simultaneously the same fraction of the distance between their initial and final positions. In agreement with the scope of this study, the part of the computations devoted to vibrations has been carried out by treating as hydrogens the methyl groups used for estimates of the PE profiles. This further simplification is justified because, whereas the methyl groups serve to fix the C—N and C=O equilibrium lengths at more realistic values, they have no important effect on the vibrational properties of H-bonds.

The errors of "theoretical" force constants arise mainly from the basis set choice and lack of correlation in *ab initio* calculations, and from the well-known drawbacks of the formulae in semiempirical calculations. Those errors can be eliminated to a large extent by transforming the Cartesian force constants to those associated with internal coordinates and applying suitable correction factors (19). Such correction factors can be determined from equilibrium states, where also experimental values are known. For activated states the assumption that the same correction factors apply is obviously a daring one, but there seems to be no other way out. Very important support for this assumption comes from the fact that with the correction factors obtained below the activated states do show one negative eigenvalue of the frequency matrix: this feature proves that the values used for the force constants are physically consistent. The six frequencies associated with rotations and translations are not exactly zero because (again to avoid not indispensable complications) we have not carried out a point-by-point optimization along the chosen reaction path.

4b. The most important results (Table 1) of force constant calculations can be summarized as follows. The force constants associated with the intermolecular NH . . . O and C—O—H . . . O stretching modes are both negative (−0.05 and −0.16 mdyn/Å, respectively), no barrier being predicted in these cases (4.31 G calculations confirm this for the NH . . . O bond (12)). The force constant of the CO bond appears to increase when the proton comes closer to the oxygen atom, while the CN force constant behaves normally. This surprising result may be due to the fact that we have not allowed for relaxation of the heavy nuclei during proton motion, but further *ad hoc* studies are perhaps necessary.

In agreement with experimental and theoretical results (26), our computations yield a comparatively high value of the force constant corresponding to the interaction between CN and CO stretching (2.2 mdyn/Å). This is in line with the expectation that the nitrogen lone pair is involved in the amide π-system.

The *intramolecular* stretching force constants of NH . . . O, CO . . . HO, and OH . . . O in the activated state for the concerted mechanism are all found to be ~1.9 mdyn/Å. The NH . . . O *intermolecular* force constant is negative (−0.33 mdyn/Å), while the other two are positive (CO . . . HO: 0.29 mdyn/Å; OH . . . O: 0.45 mdyn/Å). Of course, in the three activated states of the stepwise mechanism, the three intermolecular force constants are all negative.

4c. The corrected force constants have been used to compute the vibrational frequencies. The well-known **GF** method (20) has been used, the only variant being that, instead of computing the kinetic energy matrix **G** we have obtained the dynamical matrix by the expression

$$\mathbf{D} = \mathbf{M}^{-1/2}\,\tilde{\mathbf{B}}\mathbf{F}_{\mathrm{R}}\,\mathbf{B}\,\mathbf{M}^{-1/2}$$

where **M** is the (diagonal) matrix of the atomic masses, $\mathbf{F}_{\mathrm{R}}$ is the force constant matrix in the internal coordinates, and **B** is the matrix representing the transformation from the internal to the Cartesian coordinate system.

Table 1 contains the results, including mode assignments. The modes indicated correspond to the initial geometry. We have also tried to refer to the same geometry the modes of the activated and final states, so as to facilitate interpretation of frequency shifts. Of course, this means that the description given is not as detailed as it could be without this restriction.

The symbols used in the assignment of the intermolecular modes are in line with current literature (21). The inter-

molecular wagging and torsional modes, which depend very weakly on the position of the proton in the bridge, have not been included in the table.

Table 1 falls into two parts. The intermolecular modes range from 100 to 800 cm^{-1}. The intramolecular modes range from 1200 cm^{-1} to 3800 cm^{-1}. The intermolecular O—H..O modes at 252 and 405 cm^{-1} are in satisfactory agreement with the values found on the water dimer (272 and 483 cm^{-1} respectively) (22) by a much more sophisticated method.

In the range 1200–1800 cm^{-1} we have found the intramolecular modes of the amide system, as expected. The bending modes of the H_2O and H_3O^+ groups fall in the range 1800–2000 cm^{-1}, and are thus overestimated by ~300 cm^{-1} (22, 23, 25). The OH and NH stretching modes fall between 3000 and 3800 cm^{-1}. The predicted shifts for the intramolecular OH and NH stretching modes are of ca. 350 cm^{-1}, in agreement with the experimental value of ca. 300 cm^{-1} (24). Certain *ab initio* investigations (23) predict much lower intramolecular frequency shifts, e.g. 53 cm^{-1} for the stretching frequency of OH in an OH...O bridge.

We emphasize that, given the scope of our calculations, even refinements such as allowance for anharmonic corrections have

TABLE 2. Thermodynamic functions for concerted and stepwise mechanism at 300 K for recombination of system IVa

Parameters		States

been excluded. Suffice here to recall that they may be comparatively important in connection with intermolecular modes. Failure to take them into account might explain the grossly underestimated values obtained in *ab initio* calculations (22, 23). As concerns semiempirical calculations, we have not found examples of anharmonic corrections in the literature; it is possible that the predicted values would be further increased, and thus become overestimated.

4d. In the activated state, one vibrational degree of freedom becomes a dissociative one. For the concerted mechanism our calculations suggest that the major contribution to that dissociative mode comes from the CO . . . H . . . O stretching motion. There are still two frequencies (~300 and ~900 cm^{-1}) which correspond *grosso modo* to the proton motions along the O . . . H . . . O and N . . . H . . . O bridges, respectively.

In the stepwise mechanism the situation is more clearcut, and the dissociative mode appears to be exclusively the stretching one associated with the proton of the C=O . . . H—O bridge.

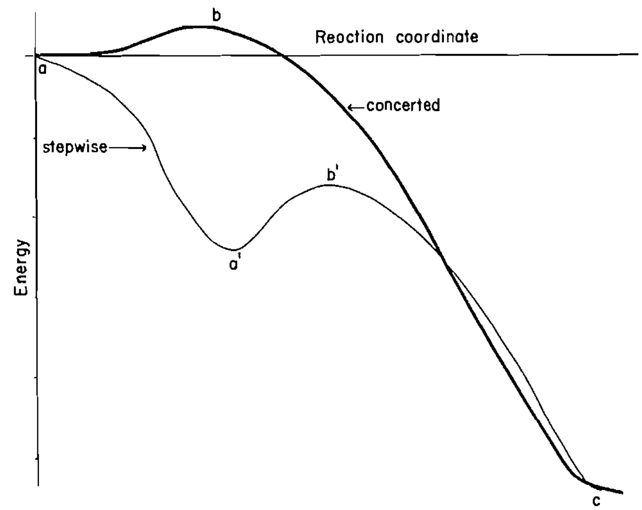

FIG. 2. Calculated energy profiles for proton motion in chain IV.

5. Discussion and conclusion

We are now in a position to go back to system **IV** and obtain some feeling for the thermodynamical quantities relevant to its evolution from **IV**a to **IV**b. Under the assumption that relaxation plays no decisive role, the relevant quantities have the values shown in Table 2. As expected, the concerted mechanism appears to be highly favored: the barrier is extremely low. Therefore the overall crossing time should be of the order of a vibration, i.e. very short as compared with diffusion times. The "yield" – which is the same in the stepwise mechanism, since it is measured by the equilibrium concentrations – is very large, due to the overall ΔG of more than 132 kcal/mol. Thus, at least in the concerted case, mechanism **I**a (with a "driving force" comparable to that of system **IV**) is physically plausible. It stands to reason that relaxation could only make it more efficient; at any rate, the estimated switching time is so short that, in fact, the assumption that relaxation is not important can be accepted.

The crucial question regarding the enol form of the peptide bond is also answered: the keto–enol transition is very easy if it is synchronous to the motions of all the H-bridge protons.

Of course, many points remain open. Here we shall only comment on one of them: the alternative between the concerted and the stepwise mechanisms.

The energy profiles obtained in our calculations are shown in Fig. 2, where the various states are labelled as in Table 2. Note first of all that the initial state *a* lies at the bottom of a well only in the profile associated with the concerted mechanism (thick line): this means that in a suitable multidimensional potential-energy map *a* would lie at a saddle point. This is not surprising if the system is assumed to originate from loss of a proton by the water molecule parent of the leftmost hydroxyl ion of **IV***a*, since then it is clear that formation of OH$^-$ corresponds to an energy maximum as far as the first H-bridge is concerned. Indeed, the preference for the concerted mechanism might be just a consequence of having adopted the point of view of transition state theory. According to that theory, the stepwise mechanism must be decomposed into three steps (a–a', a'–b', b'–c), and the rate-determining step a'–b' has the characteristics shown in Table 2. Now, this separation into three steps, each associated with a specific equilibrium, is not fully convincing in our case. The initial state is essentially a highly energetic transition state itself; therefore, it would appear more reasonable to treat the energy profile for the stepwise mechanism as if the first minimum at a' did not exist. In fact, the kinetic energy of the system after descent to a' cannot be ignored, at variance with what would happen if a were in turn at equilibrium with some previous stable species.

In short, if we assume that the minimum at a' is occupied by vibrationally highly excited molecules, whatever the temperature, just because of energy transfer from potential energy of a to vibrational energy of a', we have to assign to a' a vibrational contribution much larger than the zero-point one. Then the stepwise mechanism may become a greatly favored one. This conclusion may be important, because in large biomolecules the perturbations produced by the tertiary structure and the solvent could make a concerted mechanism more unlikely.

Acknowledgements

This paper is dedicated by Giuseppe Del Re to Camille Sandorfy as a token of friendship and scientific exchange extending over more than fifteen years. Support of the Italian CNR and Ministry of Education is acknowledged. Thanks are expressed to Dr. R. Haser (CRMCC, Marseille) for having pointed out the importance of the biochemical problem to which this paper refers and for many discussions and bibliographical indications.

This paper is dedicated to Professor Camille Sandorfy on the occasion of his 65th birthday

H. NAKATSUJI, J. USHIO, and T. YONEZAWA. Can. J. Chem. **63**, 1857 (1985).

The SAC (symmetry-adapted-cluster) and SAC-CI theories based on the cluster expansion of the wavefunction have been applied to the calculations of the potential energy curves of the ground, excited, and ionized states of the Li_2 molecule. The potential energy curves and the spectroscopic properties calculated agree well with the available experimental data and the previous theoretical results of Olson and Konowalow. For the $2^1\Sigma_g^+$ state, our calculation is the first and predicts a bound state whose minimum is at R_e = 6.8 bohr and 2.5 eV above the ground state. This state dissociates into ^2P and ^2S states of the Li atoms and has a hump which is higher than and outside of the hump of the $B^1\Pi_u$ state. The long-range behavior of the states which dissociate into ^2P and ^2S states of the Li atom is well predicted by the resonance interaction theory.

H. NAKATSUJI, J. USHIO et T. YONEZAWA. Can. J. Chem. **63**, 1857 (1985).

On a appliqué les théories SAC et SAC-CI, qui sont basées sur une expansion de l'agglomération de la fonction d'onde, au calcul des courbes d'énergie potentielle des états fondamental, excité et ionisé de la molécule Li_2. Les courbes d'énergie potentielle et les propriétés spectroscopiques calculées sont en bon accord avec les données expérimentales disponibles ainsi qu'avec les résultats théoriques antérieurs de Olson et Konowalow. Dans le cas de l'état $2^1\Sigma_g^+$, nos calculs correspondent à une première et ils prédisent un état lié dont le minimun se trouverait à R_e = 6,8 bohr et à 2,5 eV au-dessus de l'état fondamental. Cet état se dissocie dans les états ^2P et ^2S de l'atome de Li et il présente un maximum qui est plus élevé que et en dehors du maximum de l'état $B^1\Pi_u$. On peut facilement prédire le comportement à long terme des états qui se dissocient dans les états ^2P et ^2S de l'atome de Li en faisant appel à la théorie de l'interaction de résonance.

[Traduit par le journal]

Introduction

Accurate information on the potential energy hypersurfaces and the electronic structures of molecules, especially those of excited states, are very important for the study of chemical reactions and the dynamic behavior of molecules in excited states. Professor Sandorfy, who has developed various aspects of chemical spectroscopy (1, 2), has accumulated detailed knowledge on excited states, especially those of Rydberg type (3). These activities have, at the same time, increased the need for accurate theoretical data on electronic structures and potential energy hypersurfaces for excited-state molecules.

So far, a practical method of calculating accurate wavefunctions for molecules in excited states in a wide range of molecular configurations has been the CI method applied very carefully by experts. Buenker, Peyerimhoff, and their coworkers (4), for example, have been active in this field. The MC-SCF method has also been applied frequently, though the applicability is rather limited for higher excited states.

Cluster expansions of the wavefunction give another efficient way of calculating accurate correlated wavefunctions for the ground state and the various excited states of molecules (5, 6). We are currently using the Symmetry-Adapted Cluster (SAC) theory (7, 8) for calculations of the lowest closed-shell states, and the SAC-CI theory (8, 9) for calculations of the excited and ionized states generated therefrom. These theories have been successfully applied to the studies of molecular spectroscopy of valence and Rydberg excitations (10, 11) and ionizations of outer and inner valence electrons (11–13). The theory has also been applied to the study of the hyperfine splitting constants of doublet radicals in order to investigate the coupling of spin and electron correlations (14).

For the closed-shell ground state, Bartlett, Purvis, and coworkers (15–17) studied the applicability of the coupled-cluster theory (18) to the potential curves of N_2, Be + $H_2 \rightarrow BeH_2$, and the H_2O molecule with the elongated OH distance. They showed the superiority of the coupled-cluster theory in comparison with the CI theory including only single and double excitations from the Hartree–Fock configuration. Their conclusion applies also to the present SAC theory because of the similarity of the two methods. For molecules including multiple bonds, however, an ordinary single-reference coupled-cluster theory fails when the bond length is considerably elongated. There, the multi-reference version of the theory becomes necessary (19–21). Recently, we have developed multi-reference (MR) SAC theory (22). It is exact and unique without imposing completeness on the multi-reference space. It gives accurate descriptions of not only ordinary ground states but also quasi-degenerate states and excited states. This was confirmed from the calculations of the potential energy curves of the ground and excited states of the CO molecule (23).

In this paper, we consider applications of the SAC and SAC-CI theories to calculations of the potential energy curves of the Li_2 molecules in ground, excited, and ionized states. For the Li_2 molecule, the theory is capable of describing the proper dissociation of the ground and lower excited states.

The potential energy curves of the ground state and the lower excited states of Li_2 have been studied extensively by Olson and Konowalow (24) by the MC-SCF method. They studied all the states leading to the lower two separated atom limits, i.e., ^2S + ^2S and ^2S + ^2P, except for the $2^1\Sigma_g^+$ and $2^3\Sigma_u^+$ states. Kutzelnigg *et al.* (25) studied the potential curves of the ground and lowest $^3\Sigma_u^+$ states. Kahn *et al.* (26) studied the $B^1\Pi_u$ potential energy curve. Davies and Jones (27) and Takada *et al.* (28) calculated the lower potential curves by the quasi-degenerate many body perturbation method. Uzer and co-workers (29) analyzed the photodissociation of Li_2 based on the theoretical potential energy curve. Konowalow and Fish (30) recently studied the potential energy curve of the $3^1\Sigma_g^+$ state. We will calculate here the

[1] To whom all correspondence should be addressed.

potential energy curves and the spectroscopic constants of all the states which dissociate into the lower two separated atom limits, $^2S + ^2S$ and $^2P + ^2S$, except for the $2^3\Sigma_u^+$ state. This is the first paper which clarifies the bound nature and the existence of a hump in the $2^1\Sigma_g^+$ state.

For the cation of Li_2, Henderson *et al.* (31) reported the potential curves of low-lying states at the Hartree–Fock SCF level. Bottcher and Dalgarno (32) reported accurate model potential calculation. Müller and Jungen (33) reported extensive calculations of the potential energy curves. We will study the potential curve of the lowest $^2\Sigma_g^+$ state.

Method of selecting linked and unlinked operators

The method of calculations in the SAC and SAC-CI theories has already been described in detail (9, 11). The dimension of the matrices to be diagonalized is the same as the number of the linked operators. In the present application, the linked operator includes the identity operator and the single and double excitation operators from the closed-shell Hartree–Fock configurations. The triple and quadruple excitations are considered in the unlinked term. Even in this approximation, the number of linked operators easily becomes large even for moderate basis sets, so that we have adopted a systematic method of selection of linked operators (11). Further, since the calculation of the integrals for the unlinked terms is a time-consuming part, we have also adopted an appropriate method of selecting unlinked terms (11). However, in the calculations of the potential surface, an independent selection of operators for independent geometries may lead to a discontinuity of the potential curve and the properties. Therefore, we have adopted the following method of selections which we call the GSUM method.

An essential point of the GSUM method is to take the group sum of the operators (linked and unlinked) selected for all the representative points in the nuclear configuration space. We first select several representative points in the nuclear configuration space which cover the reaction under consideration. The Hartree–Fock MO's of each geometry are rearranged so as to have the same ordering as the MO's of the adjacent geometries. The linked and unlinked operators are selected for each geometry by the method described in ref. 11. We then take the group sum of these operators and the calculations are carried out at each geometry using the same set of this group sum of operators. This method is appropriate to study continuous changes in the potential energy curves and the properties along the change in nuclear configuration.

Calculational details

The molecular orbitals of Li_2 were calculated by the closed-shell Hartree–Fock–Roothaan method (34), using a slightly modified version of the HONDOG program (35). The HF MO's of the ground state were used as reference MO's for all the ground and excited states studied here. The basis set is $(9s5p)$ GTO's of Huzinaga (36) contracted to $(4s2p)$ set by Dunning (37) augmented with their derivative bases and one s-type GTO ($\zeta = 0.01$) as a Rydberg AO. This basis set consists of 74 CGTO's. The derivative bases, which are p and d GTO's for the s and p GTO's, respectively, are best suited for describing the polarization of the electron cloud in the course of the reaction as studied previously (38, 39). In the Appendix, we have shown some important effects of these derivative bases on the spectroscopic properties of the ground and lower excited states of Li_2.

TABLE 1. Dimensions of the linked operators in the SAC and SAC-CI calculations of Li_2

State	Space[a] symmetry	SE[b]	DE[b]	Total
Ground	s	77	234	312
Singlet excited	s	77	579	656
	a	76	562	638
Triplet excited	s	77	627	704
	a	76	707	783
Ionized	s	2	86	88
	a	1	77	78

[a] s and a denote symmetric and antisymmetric, respectively, with respect to the reflection plane perpendicular to the molecular axis.
[b] SE: single excitation, DE: double excitation.

The SAC and SAC-CI calculations were carried out with the program coded by Nakatsuji. As active MO's, we have taken the energetically lowest 54 MO's at the experimental internuclear distance and the corresponding MO's at any internuclear distances. The excitation operators were selected by the method described in ref. 11. The values of the thresholds λ_g and λ_e are 1×10^{-5} au. In the unlinked term, we have included all the double excitation operators whose coefficients are larger than 1×10^{-5} in the SDCI of the ground state. We selected five representative points at 4.0, 5.051, 6.5, 8.0, and 12.0 bohr in the internuclear distances. We have selected the excitation operators at the individual geometries and took the group sum of them by the GSUM method to cover all the reaction path. The dimension of the calculation after the GSUM method is shown in Table 1. They are relatively small by virtue of the cluster expansion theory. The ground state was calculated by the SAC theory and the excited and ionized states were calculated by the SAC-CI theory.

Results

The potential energy curves of the ground and lower excited states of Li_2 are displayed in Fig. 1. We have calculated all the singlet and triplet states of Li_2 which dissociate into the lowest two separated atom limits, $^2S + ^2S$ and $^2P + ^2S$, except for the $2^3\Sigma_u^+$ state. Figure 2 shows the potential energy curves for the lowest ionized states. Table 2 is a summary of the energies of these Li_2 system at various internuclear distances.

We show in Table 3 the spectroscopic constants of all the bound states of Li_2 studied here. The present theoretical values were calculated by the method of Dunham (40) from the potential curves displayed in Fig. 1. The experimental values were cited from Huber and Herzberg (41), Kusch and Hessel (42), and others (43, 44). In cases where the experimental values are not available, we have cited the theoretical values from Olson and Konowalow (24) for Li_2, and from Müller and Jungen (33) and Henderson *et al.* (31) for Li_2^+.

For the ground and lower excited states of Li_2, the general trends and the shapes of the potential energy curves shown in Fig. 1 are very similar to the results of the extensive MC-SCF calculations due to Olson and Konowalow (24). For the $2^1\Sigma_g^+$ state, the present result appears to be the first one reported. It shows an interesting potential curve which will be discussed in more detail later. The quality of the calculated potential curves is judged in detail by a comparison of the spectroscopic constants between theory and experiment (Table 3). For the $X^1\Sigma_g^+$, $A^1\Sigma_u^+$, and $B^1\Pi_u$ states, the adiabatic excitation energy T_e, equi-

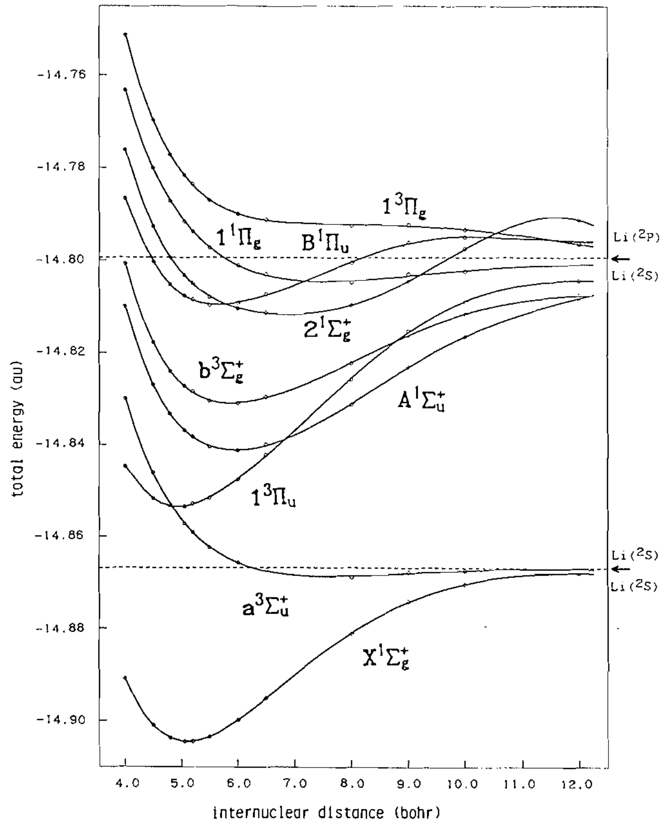

FIG. 1. Potential energy curves of the ground and lower excited states of Li_2.

librium length R_e, and the vibrational frequency ω_e show excellent agreement between theory and experiment. For other states where experimental values are not available, the present results show very good agreement with the results of Olson and Konowalow, except for the $a^3\Sigma_u^+$ state. This agreement is particularly excellent for the excitation energy, which is most reliable from the viewpoint of the data analysis.

The long range behavior of the potential energy curve of the state which dissociates into the ^2P and ^2S states of the Li atom is predicted from the resonance interaction theory for differently excited like atoms (45–47). Between the ^2P and ^2S states of Li atoms, the excitation energy is transferred in a resonant fashion and it gives rise to a first-order interaction which is written as

$$[1] \quad \Delta E = C_a/R^3 + \ldots$$

where the coefficient C_a depends on the specific state under consideration. From the sign of the coefficient C_a determined by Mulliken (47), we can predict the nature of the long-range interaction as follows.

$$[2] \quad \begin{array}{l} \text{Attractive: } {}^1\Sigma_u^+,\ {}^3\Sigma_g^+,\ {}^1\Pi_g,\ {}^3\Pi_u \\ \text{Repulsive: } {}^1\Sigma_g^+,\ {}^3\Sigma_u^+,\ {}^1\Pi_u,\ {}^3\Pi_g \end{array}$$

Here we assumed for the Σ states that the resonance interaction predominates the valence-type interaction.

Referring to Fig. 1, we see that all the states calculated here follow the prediction given in eq. [2]. The states $1^3\Pi_u$, $A^1\Sigma_u^+$, $b^3\Sigma_g^+$, and $1^1\Pi_g$ approach the dissociation limit from below, but the states $2^1\Sigma_g^+$, $B^1\Pi_u$, and $1^3\Pi_g$ approach it from above. Further, since the $2^1\Sigma_g^+$ and $B^1\Pi_u$ states have a minimum in the

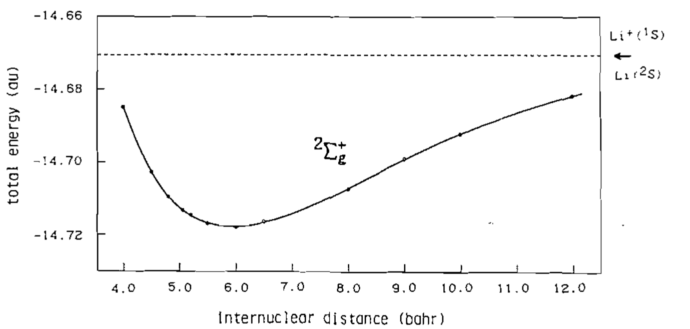

FIG. 2. Potential energy curves of the lowest ionized states.

shorter bond length region, the potential curves of these states should have a hump somewhere between the valence-type and resonance-type regions. For the $B^1\Pi_u$ state, the hump is at 10.1 bohr and for the $2^1\Sigma_g^+$ state it is at about 11.7 bohr. In Table 4 we have summarized the constants of these humps. Further from this consideration we expect that the shape of the hump is not symmetric with respect to the top position because the nature of the interaction is drastically different between shorter and longer regions. For the $1^3\Pi_g$ state our calculation didn't show any minimum. It is repulsive throughout.

We now discuss each state separately. The ground state, $X^1\Sigma_g^+$ was calculated by the SAC theory. It gives excellent results for the spectroscopic constants and shows a reasonable asymptotic behavior. In the calculation of the excited and ionized states, the electron correlation in this ground state was used as a starting point in the SAC-CI formalism (8, 9).

The $a^3\Sigma_u^+$ state is only very weakly bound, as pointed out by Kutzelnigg *et al.* (25). The calculated equilibrium length is longer than those of Olson and Konowalow. Our potential is more attractive than theirs. However, since the number of sampling points is not enough in the region near the potential minimum, we are not definitive on this conclusion.

The $1^3\Pi_u$ state was interesting due to its relation to the possibility of an alkali-dimer laser. Figure 1 shows that the $1^3\Pi_u$ state potential curve is crossed by the $a^3\Sigma_u^+$ potential curve at its repulsive limb. Therefore the present calculation supports the conclusion of Olson and Konowalow that the Li_2 laser is impossible (24).

The $B^1\Pi_u$ state is an interesting state which has a hump. It is attractive at shorter range because of the valence-type force but repulsive at long range because of the resonance force as shown by eq. [2]. This is the origin of the hump, which is therefore strongly unsymmetric with respect to the position of the hump maximum. From Table 4, the position of the hump maximum is at about 10.1 au. The hump height was calculated to be 981 cm^{-1}, which is closer to the experimental value of Velasco *et al.* (44). For the valence minimum, both the adiabatic excitation energy T_e and the equilibrium length R_e agree well with experiment (Table 3). The dissociation energy D_e is 2263 cm^{-1}, if it is relative to the dissociation limit. The value in parentheses, 3244 cm^{-1}, is measured relative to the hump maximum. The latter one is closer to the experimental value (43).

The $2^1\Sigma_g^+$ state is reported for the first time in this paper. It is a very interesting state which has a deeper valence-type minimum and higher hump than the $B^1\Pi_u$ state. The origin of the hump is the same as for the $B^1\Pi_u$ state. The maximum position and the height of the hump were analyzed to be 11.7 bohr and 1900 cm^{-1}, respectively, as shown in Table 4. However, since the number of calculated points near the hump is small, these values should be considered to be only semi-quantitative. Near the valence minimum the potential is rather deep but flat. The dissociation energy is 2794 cm^{-1}, if it is measured relative to the dissociation limit, but is about 5300 cm^{-1} relative to the maximum of the hump.

The $^3\Pi_g$ state is calculated to be repulsive throughout the internuclear distance but has a shoulder between 7.0 and 9.0 bohr as seen from Fig. 1. This feature also corresponds well to the result of Olson and Konowalow. Further, they suggested that an addition of the $\pi-\delta$ configurations to their calculations would lower the potential curve of this state at smaller internuclear distances to produce a local minimum. However, despite the inclusion of the $\pi-\delta$ configurations in our calculation, the present potential curve does not have any local minimum throughout the calculated range.

Lastly, we discuss the $^2\Sigma_g^+$ state of the Li_2 cation. The calculated potential curve is shown in Fig. 2 and the spectroscopic constants are given at the bottom of Table 3. Because of a loss of an electron from the bonding σ_g orbital, the equilibrium bond length is elongated by about 0.8 au. The potential also becomes flatter near the equilibrium length. However, since the ionization energy of the Li atom, (5.39 eV (48)) is larger than that of the $X^1\Sigma_g^+$ state of Li_2, (5.00 eV (41)), the dissociation energy of Li_2^+ is larger than that of Li_2.

Conclusion

The SAC and SAC-CI theories based on the cluster expansion of the wavefunction have been applied to studies of the potential energy curves of the ground, excited, and ionized states of the Li_2 molecule. The calculated potential energy curves and spectroscopic properties agree well with available experimental data and with the previous theoretical results of Olson and Konowalow (24). For the $2^1\Sigma_g^+$ state, the present result is the first calculation. It is an interesting state which has a deep valence minimum at 6.8 bohr and 2.5 eV above the ground state. It also has a hump of about 1900 cm^{-1} high at about 11.7 bohr. The long-range behavior of the potential curves of the states which dissociate into the $^2P + {}^2S$ states of the Li atom are well predicted from the first-order resonance interaction theory (45–47).

For the bond involved in the ground state of the Li_2 molecule, the SAC theory is shown to give an excellent potential curve up to the dissociation limit. The SAC-CI theory is essentially a multi-reference type theory (9) so that it gives a reasonable description of the excited and ionized states. Based on this research, the usefulness of the SAC and SAC-CI theory in the study of molecular excited states and molecular spectroscopy is extended.

TABLE 5. Comparison of the spectroscopic constants of the ground and lower excited states of Li_2 calculated with and without including the derivative bases

State	Source	T_e (eV)	R_e (au)	D_e (cm^{-1})	ω_e (cm^{-1})

Appendix

In Table 5 we have shown some spectroscopic properties of the ground and lower excited states of Li_2 calculated with and without including the derivative bases. Basis I is $(3s2p)$ set (49) and Basis II is the basis set used in the text which includes the derivative bases. From Table 5, it is seen that the results calculated with Basis II are consistently superior to those calculated with Basis I. This implies that the role of the derivative functions is important for the calculations of the potential curve.

The effects of selected gases upon ethanol: hydrogen bond breaking by O_2 and N_2

T. L. MATHERS, G. SCHOEFFLER, AND S. P. MCGLYNN
Chemistry Department, The Louisiana State University, Baton Rouge, LA 70803, USA

Received September 14, 1984

This paper is dedicated to Professor Camille Sandorfy on the occasion of his 65th birthday

T. L. MATHERS, G. SCHOEFFLER, and S. P. MCGLYNN. Can. J. Chem. **63**, 1864 (1985).

The temperature dependency of the phosphorescence properties of aromatic hydrocarbons in alcoholic glasses exhibits a number of phenomena that have not been described previously. Chief among these are the effects of added gases (O_2, N_2, C_2H_6, Ar), some of which produce major changes in the luminescence characteristics. These are discussed, and rationalized in terms of a model which presumes that O_2 and N_2 can disrupt the normal hydrogen bonding process between alcohol molecules.

T. L. MATHERS, G. SCHOEFFLER et S. P. MCGLYNN. Can. J. Chem. **63**, 1864 (1985).

L'effet de la température sur les propriétés de phosphorescence des hydrocarbures aromatiques dans des verres d'alcools présente un certain nombre de phénomènes inconnus jusqu'à maintenant. On peut souligner notamment l'effet des gaz ajoutés (O_2, N_2, C_2H_6, Ar) dont certains provoquent des changements importants au niveau des caractéristiques de la luminescence. On discute de ces changements et on les rationalise en fonction d'un modèle qui présume que le O_2 et le N_2 peuvent rompre les liaisons hydrogènes normales entre les molécules d'alcool.

[Traduit par le journal]

Introduction

The use of a luminescent probe to study a host system (i.e., crystal, glass, DNA, etc.) is well known (1). We have used this technique to study the effects of added gases on low-temperature ethanol matrices. Ethanol exhibits a well-known glass transition temperature and a well-defined crystalline form, and its properties are sensitively dependent (2−4) upon a strong hydrogen-bonding tendency that leads to dimers, trimers, and even polymeric chains at low temperatures. The present study indicates (5, 6) that certain nonpolar gases possess a heretofore unnoted quality, namely the ability to interfere with the hydrogen bonds in low-temperature ethanol matrices and, therefore, with the onsets of the glassy and crystalline phases.

In this work, the host was ethanol and the luminescent probe was phenanthrene. The two gases found to be especially effective in disrupting normal behavior of the ethanol matrix were oxygen and nitrogen. These gases, as well as all others, were individually added to a degassed ethanolic solution of phenanthrene which was then cooled to 77 K. In all cases, the onset of luminescence loss in both the glassy and crystalline regions of O_2-doped and N_2-doped ethanol initiated at significantly lower temperatures than normal. Conversely, the onset of the same luminescence losses in degassed ethanol occurred at higher temperatures than normal, normalcy in all instances being defined as the behavior of an ethanol system which had been equilibrated, prior to freezing, with ambient air at ~1 atm. Such large shifts were not observed upon the addition or removal of any other nonpolar gases.

The signal used to define normalcy or abnormalcy was the phosphorescence of the phenanthrene guest. The intent of the work was to address three questions: (*i*) why degassing produces such an unusual effect upon these systems; (*ii*) whether the well-known quenching ability of molecular oxygen can explain (*i*); and (*iii*) what is the nature of N_2-quenching? Other workers have studied similar systems (7, 8) and have assumed that the answer to question (*ii*) was "yes"; however, our work leads to different conclusions, the salient finding being that nitrogen affects both phases, glass and crystal, almost as much as does oxygen. Thus, the imputation that the quenching effect of O_2 is the pertinent (or dominant) characteristic is called into question.

The present work reveals certain difficulties in some prior interpretations (e.g. that of ref. 8 where certain suppositions may require alteration). The work of Lesikar (2−4), however, remains inviolate and relevant: Lesikar's study of binary alcoholic mixtures clearly delineates the effects of the hydrogen bonding of ethanol on its glass-formation temperature.

The relevance of this work to that of the Sandorfy school is tangential, yet pertinent. The Montreal investigations (9−12) have uncovered a relationship between the hydrogen bond breaking (HBB) ability of fluorocarbons and their anaesthetic potency. This connectedness, if it continues to be significant, will undoubtedly beget new advances in anaesthesiology. The relevance of the present work lies in the finding that oxygen and nitrogen also disrupt hydrogen bonds in ethanol and that this HBB ability manifests itself in readily demonstrable luminescence phenomena. Thus, in a most direct sense, we have shown, in conformity with Sandorfy, that rather subtle hydrogen bonding effects can produce major consequences. While it is not inappropriate to point out the anaesthetic-like properties (13, 14) of N_2 and the known toxicity of O_2, both at high pressures, it certainly is premature to associate these latter properties with the HBB abilities of N_2 and O_2. Such an extension of the Sandorfy correlation is not warranted by our findings. Nonetheless, it is proper to stress the *in vivo* ubiquity of hydrogen bonding of oxygen and of nitrogen and to suggest that their interplay will be of some biological importance (15).

Experimental

All sample tubes were equipped with vacuum stopcocks and could sustain pressures of approximately 2 atm. All samples were degassed by a minimum of 10 freeze−evacuate−thaw cycles, the maximum pressure in the evacuation stage being 1 mTorr.

The refrigeration apparatus consisted of a large-volume dewar, for better temperature stability, through which flowed chilled nitrogen vapors obtained by passing tank nitrogen through a copper coil immersed in liquid N_2. Since the rate of cooling is an important parameter in determining glass quality, average cooling rates of approximately 20 K/min were maintained down to the glass temperature of ethanol (~100 K), whereupon the rate was slowed to less than 5 K/min. These rates were sufficiently slow to produce uniform glasses and to minimize many of the effects noted by the French workers (8).

Temperature measurements were made by taping a copper−constantan thermocouple onto the outside of the sample tube. The flow of nitrogen refrigerant was adjusted until a stable temperature was

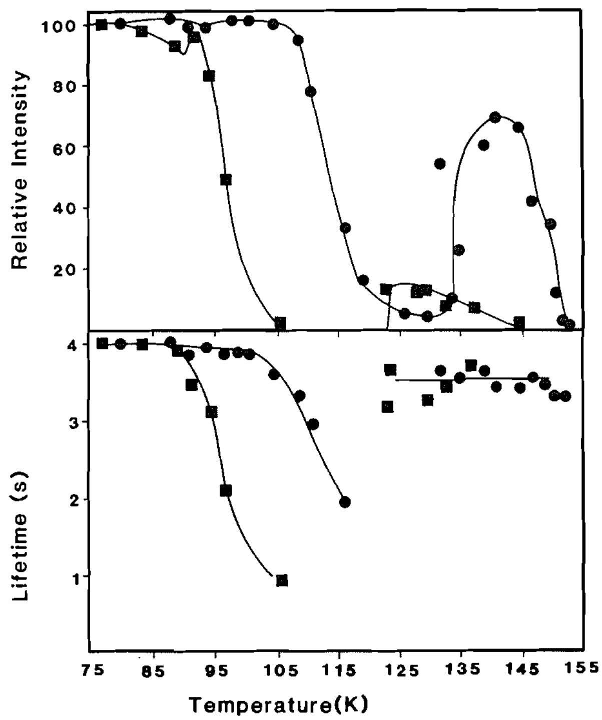

FIG. 1. Relative intensities and absolute lifetimes for the phosphorescence of phenanthrene in ethanol as a function of temperature: nondegassed sample (squares) and degassed sample (circles).

achieved and, after a wait of 5 min to permit thermal equilibration, observations proceeded. The average rate of warming during the course of a given set of measurements was approximately 1 K/min. The accuracy of the temperature measurement was ±2 K.

Most of the phosphorescence work was performed on an Amino-Keirs Spectrophosphorimeter with excitation at 285 nm and emission at 500 nm. Phosphorescent lifetimes were obtained by shuttering the excitation source and monitoring the emission decay on an electrometer–recorder system of 0.75 s inherent decay time. Polarization studies and fluorescence measurements were performed on an SLM Spectrofluorimeter (Model 4800).

Results and discussion

Glassy systems are notoriously difficult to control and their literature is beset with problems that originate in defects whose types and numbers are either irreproducible or reproducible only with utmost difficulty. Thus, one must exercise care in attempting to separate the real from the artifact, and one must be resigned to an almost endless repetition of experiment. By the same token, one must always remain wary of the urge to interpret. We believe we have satisfied both of these imperatives. We also believe that many of our results are novel and that they can be interpreted in a self-consistent way. However, we also admit that certain of our observations do not yield to any conclusive interpretation and that a great deal more work will be required in order to unravel their complexity. For that reason, and in order to stress the empirical nature of the work, a rather unorthodox mode of presentation is adopted in this paper. Six sets of data, each pointing up a new class of observation, have been chosen and each data set is discussed under the figure number that synopsizes that data set. Finally, parameters pertinent to all six data sets are collected in Table 1.

The temperature range of most figures, 75–160 K, covers two distinct ethanolic domains: (*i*) the glass domain which exhibits a normal transition range (3, 16) of 90–100 K and (*ii*) the crystal domain which consists of crystalline ethanol, possibly containing entrapped islets of phenanthrene, extending from 125 to 155 K with a maximum at some intermediate temperature.

Figure 1. The phosphorescence intensities and lifetimes of nondegassed and degassed samples are compared in Fig. 1. The onset of the low-temperature luminescence-loss for the non-degassed sample occurs in the region 90–100 K and corresponds well to the accepted values (3, 16) for the glass transition of ethanol. The primary observation is that the low-temperature onset in the degassed ethanol solution shifts upwards by +15 to +20 K. However, it is not clear at this point (i.e., from Fig. 1) whether this shift arises solely from diminution of oxygen quenching or from other unknown effects of air on the nature of the ethanol glass.

The crystalline ethanol region (i.e., the high-temperature luminescence domain) also shifts to higher temperatures upon degassing. Since the diffusion of quenchers such as O_2 is inhibited in the crystalline ethanol matrix, it is not possible to explain this luminescence behavior by invoking an oxygen diffusion and quenching mechanism. The lifetime data of Fig. 1 reinforce this surmise. In the low-temperature glassy domain, the phosphorescence lifetime curves are excellent mimics of the intensity curves whereas, in the high-temperature crystalline domain, this mimicry is absent. Indeed, apart from some scatter that might be associable with the coupling of phonon modes, the lifetimes in this latter domain remain essentially constant and independent of both temperature and the degassed/nondegassed character of the ethanol.

The interpretation is relatively straightforward:

(*i*) In the nondegassed sample, the quenching that occurs in the 95–115 K region is attributable, in part at least, to both oxygen and triplet–triplet annihilation. In the same region of the degassed sample, the quenching is attributable, in large part, to triplet–triplet annihilation, a supposition bolstered by the increase of delayed fluorescence observed (8) as

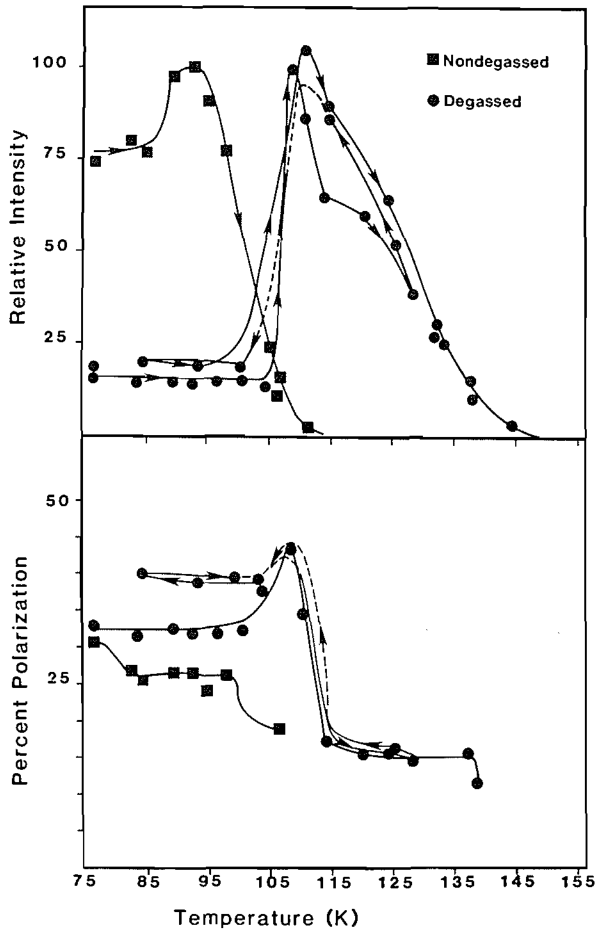

FIG. 2. Phosphorescence intensities and polarization for phenanthrene in ethanol: nondegassed samples (squares) and degassed sample (circles). The degassed sample was recooled and then rewarmed to check the reproducibility of results. The direction of the arrow indicates heating or cooling.

phosphorescence diminishes.

(*ii*) The intensity maximum observed in the region 125–155 K is associated with the formation of ethanol microcrystallites containing entrapped phenanthrene islets and their disappearance at higher temperatures. Indeed, the point of complete phosphorescence loss in the degassed sample (154 K) is quite consonant with the accepted melting point (17) of crystalline ethanol, namely 155 K. Thus, as the microcrystals grow, the intensity increases and, as they disappear, the intensity wanes. The lifetime, on the other hand, being characteristic of the crystal and independent of crystallite size or number remains unchanged throughout this region.

(*iii*) The absence of any effect of degassing on the lifetime in the crystalline region implies immobilization of O_2 in, or exclusion of O_2 from this environment. Thus, the shift of the intensity curves in the crystalline region is taken to imply an inhibition of crystal growth in the nondegassed sample, a supposition that will be discussed in some detail later.

Figure 2. A new set of phenomena is shown in Fig. 2. These phenomena occur at random in various sample preparations. In the present instance, they have been purposely maximized and made non-random by directing the excitation beam through the vicinity of the meniscus, where stresses and void concentrations are highest.

The low-temperature domain now splits into two subregions such that the constancy of intensity and polarization in the hard-glass, lower-temperature subregion is followed by a sudden increase of both the intensity and polarization in the soft-glass, higher temperature subregion. The onset of this sudden increase is clearly connected to the glass transition temperature and is, we believe, caused by the "annealing-out" of scattering centers such as cracks and inhomogeneities and the "filling-in" of voids both internal to the glassy matrix and at the interface between the matrix and the sample tube surface.

The absence of a crystalline region in Fig. 2 is noteworthy. The presence of a crystalline region is not always observed and its occurrence is in some way determined by the presence of appropriate seeding centers, whether in bulk or at the sample tube surface. In the present instance, both the ethanol and phenanthrene were highly-purified, fresh materials and it is probable that the absence of the crystalline region is associated with the purity and freshness of these materials.

Despite all of these oddities (i.e., the splitting of the glassy domain into two subregions and the absence of a crystalline phase), the +15 to +20 K differential of the quenching temperatures of the degassed and non-degassed samples is maintained, demonstrating the validity of this particular observation for samples that exhibit very different behavior.

Hysteresis of the degassed samples was also studied, one example being shown in Fig. 2, and was found to be surprisingly small. The reproducibility is taken to be indicative of a high degree of fidelity in reforming the meniscus region of the glass. The increase of polarization is taken to be supportive of an annealing mechanism that becomes operative prior to melting or hardening of the glass.

The point of Fig. 2 is to emphasize a behavior that, because of its lack of hysteresis, might be thought to be real but which, in reality, is almost certainly artifact. By the word "artifact" we mean, in this case, that the observed effect is a function of both sample preparation and the part of the glass that is sampled by the excitation beam.

Figure 3. The behavior of samples to which argon and ethane were added is shown in Fig. 3. In the low-temperature domain, the luminescence loss-mechanism for the degassed sample appears to lie ~4 K to higher temperatures. However, since this increment lies within the experimental error range, it is difficult to confirm it experimentally. Consequently, we assert that, within the limits of error, all three samples exhibit similar glass behavior.

The high temperature ranges for all three samples are also essentially identical. It seems that the crystal region, when observed, is fairly reproducible, the onset and the disappearance temperatures being especially so.

The salient point is that all three samples, apart from certain, presumedly-artifactual details, behave identically, at least within experimental error, in both the glassy and crystalline domains. We conclude that argon and ethane have little or no effect on the luminophore or the glass/crystallite characteristics.

We conclude from this behavior that, contrary to the effects of N_2 and O_2, both Ar and C_2H_6 produce only minor disruptive effects on the intermolecular H-bonding between the ethanol solvent molecules.

Figure 4. The results for several oxygenated samples are presented in Fig. 4. The O_2 "saturated" sample exhibits an extremely abrupt quenching in low-temperature domain, one whose onset lies well below the accepted glass transition temperature. In this same domain, the 500 Torr oxygen sample,

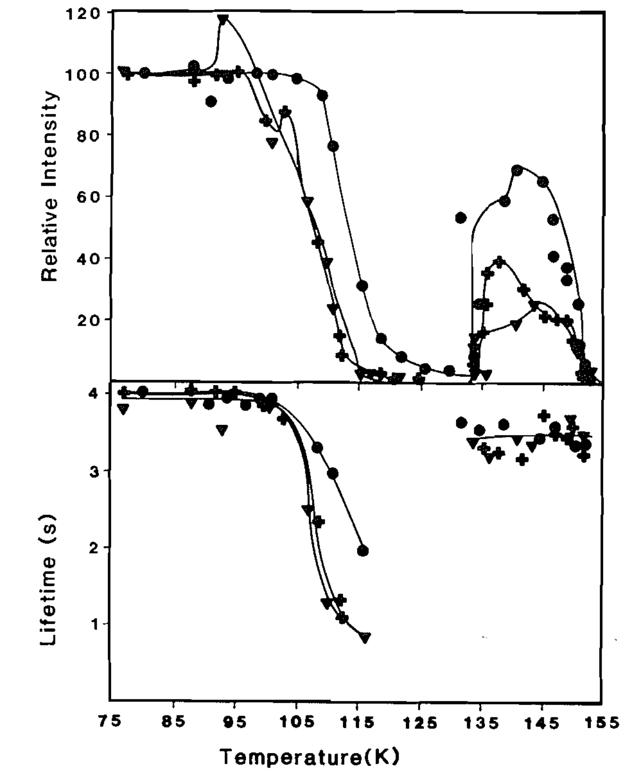

FIG. 3. Phosphorescence intensities and lifetimes for phenanthrene in ethanol: degassed samples (circles), degassed sample + 1000 Torr Ar (crosses) and degassed sample + 500 Torr ethane (triangles).

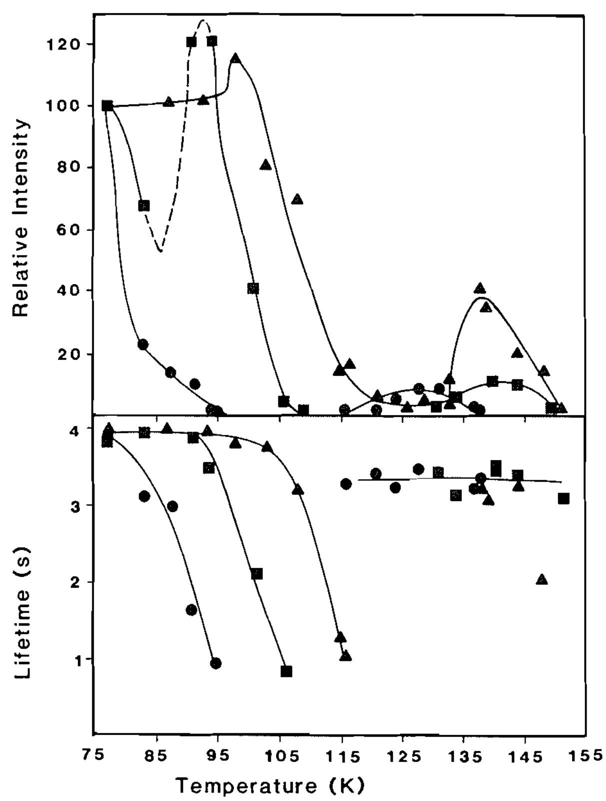

FIG. 4. Phosphorescence intensities and lifetimes for phenanthrene in ethanol: degassed sample + 500 mTorr O_2 (triangles), degassed sample + 500 Torr O_2 (squares), and O_2 "saturated" sample (circles). The O_2 "saturated" sample refers to a nondegassed solution which had been bubbled with pure O_2 until equilibrated at room temperature.

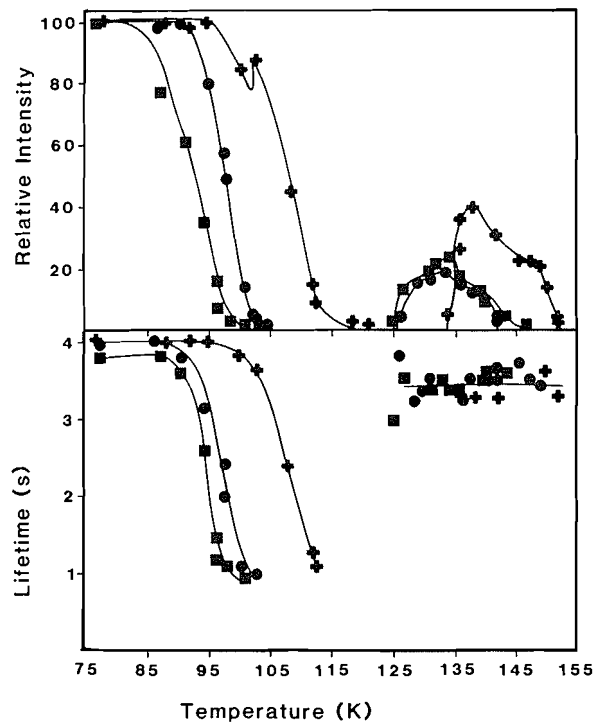

FIG. 5. Phosphorescence intensities and lifetimes of phenanthrene in ethanol: degassed sample + 1000 Torr Ar (crosses), degassed sample + 1000 Torr N_2 (circles), and N_2 "saturated" sample (squares).

apart from the presence of a strong Fig. 2-like characteristic, exhibits behavior intermediate between that of non-degassed and degassed samples. Finally, the 500 mTorr oxygen sample exhibits thermal characteristics which, within experimental error, are identical to those of the degassed sample. In the crystal domain, the O_2 "saturated" sample exhibits a 15 K decrement of onset, maximum, and disappearance relative to the degassed sample. Again, the 500 Torr sample exhibits intermediate behavior between the saturated and 500 mTorr specimens.

The interpretation of these data discords with current ideas (8). Firstly, in the O_2-saturated sample, quenching does occur at temperatures below the normally-accepted rigid glass point, suggesting that O_2 is mobile in ethanol glass even at temperatures below 80 K. Secondly, this sample also exhibits a shift of the crystal region to lower temperatures, suggesting both a decrease of the barrier to crystallite formation and a thermal destabilization of the crystalline region. It seems to us that the only reasonable interpretation of these data is that O_2 interferes with intermolecular H-bonding between the ethanol molecules.

Figure 5. Figure 5 shows two samples with nitrogen added and, for comparison, an Ar-added sample. In the low-temperature domain, both nitrogen samples exhibit large shifts relative to the argon sample. In the high-temperature domain, a remarkable similarity of the two nitrogen samples is evident and a consistent shift of -10 K relative to the Ar-added sample is observed. Thus, regardless of certain small peculiarities, there is no doubt that the addition of nitrogen produces significant differences relative to either Ar-added or degassed samples.

This figure demonstrates the distinctiveness of the N_2-effect relative to the null behavior of argon.

Figure 6. Finally, we investigated a glass-forming solvent,

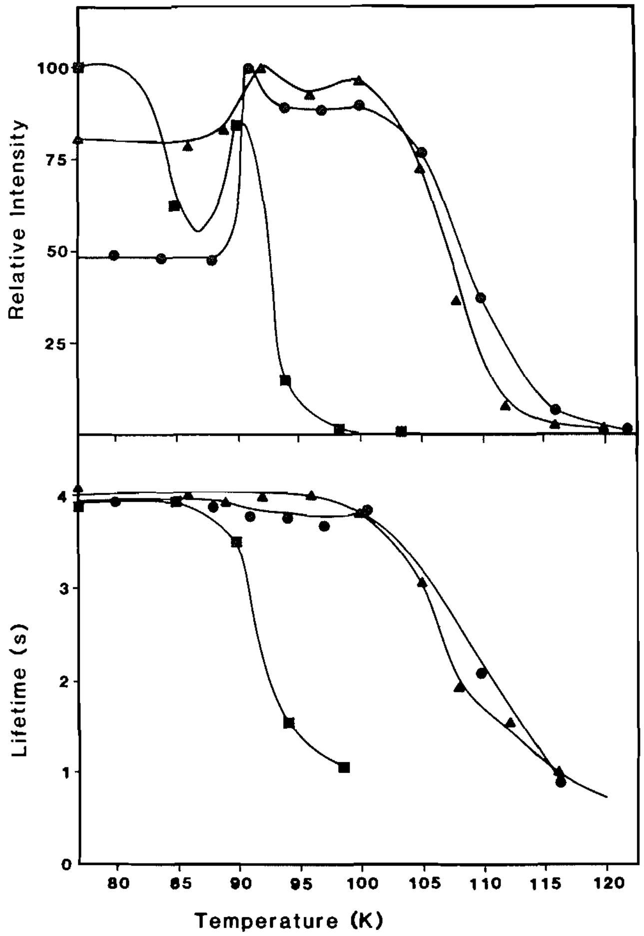

FIG. 6. Phosphorescence intensities and lifetimes for phenanthrene in 2,3-dimethylpentane: nondegassed sample (squares), degassed sample (circles), and degassed sample + 1026 Torr nitrogen (triangles).

2,3-dimethylpentane, that does not contain hydrogen bonds. Unfortunately, this solvent does not exhibit a crystal region. Regardless, we compare nondegassed, degassed, and degassed plus 1026 Torr N_2 samples in Fig. 6. The most interesting point is that the nitrogen-added and degassed samples are identical within experimental error. Furthermore, the point at which the sudden increase of intensity is observed (i.e., ~90 K) is the same within experimental error for all three samples.

We interpret these data in the following manner:

(*i*) Since the solvent does not hydrogen bond, the dissolved air and nitrogen gases are not expected to affect the glass transition point other than indirectly through dilution effects. Such effects, because of the low concentrations of the dissolved gases, are expected to be small.

(*ii*) The shift of the nondegassed sample relative to the nitrogen-added and the degassed samples is attributable to the dominance of oxygen quenching in the former sample and the imposed preference for T−T quenching in the latter samples.

(*iii*) The point of intensity increase (~90 K) in the glassy region is common to all three samples, suggesting an association between this point and the true glass transition temperature (reportedly (16) 80−85 K). As with the interpretation under the discussion of Fig. 2, we believe that this increase is associated with extensive miniscus formation and severe volume contraction exhibited by this solvent at its glass transition point. These effects, as well as the extensive strains, cracks and inhomogeneities that they impose are thought to be responsible for this behavior in the glass region.

Conclusion

The original question that motivated this work has been answered. The shift of the phosphorescence intensity or phosphorescence lifetime curves to higher temperatures caused by degassing is attributable to the removal of O_2 quenchers *and* to an elevation of both glass transition and crystal region temperatures. The importance of the latter mechanism is predicated upon the results obtained in the N_2-added systems as well as upon all data obtained for the crystalline regions. These results, in turn, are caused, we believe, by an interference of O_2 and N_2 with the dominant intermolecular interaction of ethanol, namely hydrogen bonding — oxygen being slightly more effective than nitrogen in this regard.

The characteristics observed here may prove useful for the general study of glasses. In particular, while we have demonstrated the incorrectness of the Martinez (8) assumption that these phenomena are predicated solely on oxygen quenching, there remains little doubt that the work of these authors (8) is an invaluable addition to the study of heating and cooling rates on glasses. Indeed, their results, in conjunction with ours, point to the probability of multiple "glass" points. That is, while one degree of freedom may dominate the transition of liquid to glass, the possibility that other degrees of freedom, ones frozen into non-equilibrium configurations by rapid cooling, may become extremely important may not be disregarded.

The only other glass-forming solvent investigated here (18), namely, isopropyl alcohol, exhibited little or no difference between degassed, nondegassed, and oxygen-saturated samples. This result may be understood in light of Lesikar's finding that hydrogen bonding is much more important in normal alcohols than in branched alcohols, at least insofar as the determination of glass transition temperatures is concerned.

The subsplitting of the glassy domain, attributed here to voids and other imperfections, requires elaboration. In particular, alternative techniques (e.g., DTA; molecular beam studies of complexes between H-bonding and HBB molecules; theoretical calculations of alcohol clusters (19) with a single added molecule of an HBB entity, etc.) could provide considerable elaboration of the theses presented in this work.

A broadband ν_3 sub-Doppler spectrum of HCN has been recorded in the range 3340–3280 cm^{-1} using a single frequency continuously scanable computer-controlled color center laser optothermal molecular beam spectrometer. Absolute frequencies for rovibrational transitions R(9) through P(9) have been determined to an accuracy $\leq$ 20 MHz or 2 parts in 10^7. An unconstrained five-parameter fit to this datum results in molecular constants: $B'' = 1.47822146(182)$, $D'' = 2.881(23) \times 10^{-6}$, $B' = 1.46779974(154)$, $D' = 2.863(18) \times 10^{-6}$, and $\nu_0 = 3311.47758(2)$ cm^{-1}, respectively.

Faisant appel à un spectromètre à faisceau moléculaire optothermique utilisant un laser dont le centre lumineux est contrôlé par ordinateur et dont les fréquences individuelles sont balayées d'une façon continue, on a enregistré le spectre sous-Doppler ν_3 à bande large de la molécule de HCN. On a déterminé les fréquences absolues des transitions rovibrationnelles de R(9) à P(9) avec une précision $\leq$ 20 MHz, soit 2 parties dans 10^7. Utilisant un ajustement sans contraintes à cinq paramètres de ces données, on a pu obtenir les constantes moléculaires suivantes: $B'' = 1{,}47822146(182)$, $D'' = 2{,}881(23) \times 10^{-6}$, $B' = 1{,}46779974(154)$, $D' = 2{,}863(18) \times 10^{-6}$ et $\nu_0 = 3311{,}47758(2)$ cm^{-1}.

Introduction

The rovibrational ν_3 spectrum of HCN is an important secondary frequency standard (1) in the 3 μm region and for this reason has been the subject of numerous rovibrational analyses using both classical and laser spectroscopic methods (2–4). Although high resolution spectra do exist for isolated transitions in this band (5, 6), most previous studies have, however, been carried out in the gas phase under situations in which Doppler and pressure broadening often result in transition overlap and consequently inaccuracies in frequency determination. Although very accurate ground and excited state microwave rotational spectra (7) are available for J $0 \rightarrow 1$; $1 \rightarrow 2$, $2 \rightarrow 3$, $00^0 0$ and J $0 \rightarrow 1$, $1 \rightarrow 2$, $2 \rightarrow 3$ and $3 \rightarrow 4$, $00^0 1$, states absolute rovibrational transition frequencies accurate to $\leq$ 30 MHz have not been determined for frequency calibration purposes.

The advent of broadly tunable single frequency color center laser optothermal molecular beam spectrometers (8) offer the opportunity of recording the broadband rovibrational spectrum of ν_3 HCN at sub-Doppler resolution in the cold collisionless situation of seeded molecular beams. In this paper, we report the broadband sub-Doppler spectrum of ν_3 HCN for rovibrational transitions R(9) through P(9). The absolute order and free spectral range of a highly stabilized Fabry-Perot etalon have been determined and used to calibrate the absolute frequencies of these transitions with an estimated accuracy of $\leq$ 20 MHz. Rotational constants B'', B'; distortional constants D'', D' and band origin frequency, ν_0, have also been determined from this data and are compared with the precisely determined parameters evaluated from other spectroscopic studies.

Experimental

Spectra have been recorded using a simple computer-controlled continuously tunable single frequency color center laser optothermal molecular beam spectrometer assembled in our laboratory (8). A schematic of the components necessary to control and monitor continuous single frequency scanning of the laser spectrometer are shown in Fig. 1. The system consists of a Kr^+ laser pumped Burleigh FCL-20 color center laser, diagnostic box, bolometric molecular beam detector (9), and a Micromation Z-64 microcomputer used to synchronously scan[1] the three tuning elements, (grating, 21.6 GHz internal etalon and folding mirror) of the color center laser necessary to provide broadband single frequency scanning of the spectrometer. For these experiments, 0.9 W of 6471 Å Kr^+ laser output was used to pump a RbCl:Li color center crystal producing 0.17–0.85 mW of continuously tunable single frequency laser output power from 3338–3284 cm^{-1} which could be tuned over segments of $\geq$ 30 cm^{-1} at a time. Although higher output power could have been obtained for continuous single frequency scans of shorter segments (approximately 2–3 cm^{-1}), it ultimately led to mode instability and was not used. 3 GHz and 150 MHz FSR etalons were used to calibrate the transition frequency separations. The spectrometer utilized a 50 μm cw stainless steel nozzle with a 250 μm skimmer at approximately 0.8 cm distance and a 1.7 K, 4 mm Ge:Ga bolometer (NEP 4.7×10^{-14} $W\sqrt{Hz^{-1}}$) at 60 cm. For the ν_3 HCN transitions, scans of 30 cm^{-1} took approximately 10 to 12 h which corresponded to the hold time in the helium Dewar of the bolometer. The sub-Doppler ν_3 spectrum was thus recorded in two segments with sufficient common transitions in each segment to ensure accurate frequency determination. Seeded mixtures of HCN/He varying from 1:15 to 0.5:100 were used with nozzle backing pressures of 0.4–7.7 atm. HCN was obtained from Fumico Inc., Amarillo, TX, and used without further purification. The laser output beam crossed the molecular beam orthogonally and was focussed by a CaF_2 F100 lens to produce FWHM linewidths of $\leq$ 5.8 MHz in ν_3 transitions of HCN (Fig. 2). The geometry of the spectrometer is expected to contribute $\leq$ 1.2 MHz of this linewidth. The remainder reflects transit time broadening but is primarily contributed by instabilities in the free running color center laser system. The incident infrared laser beam was modulated at 40 Hz, the bolometer signal amplified $\times$ 200 and then detected using a HR-8 lock-in amplifier. A Doppler-limited ν_3 HCN gas phase spectrum was simultaneously recorded to facilitate assignment and calibration of the spectrum.

Our current laser system has no Michaelson interferometer to enable accurate absolute frequency determination of any of the transitions to $\leq$ 30 MHz and no reference spectra exist within the continuous tuning

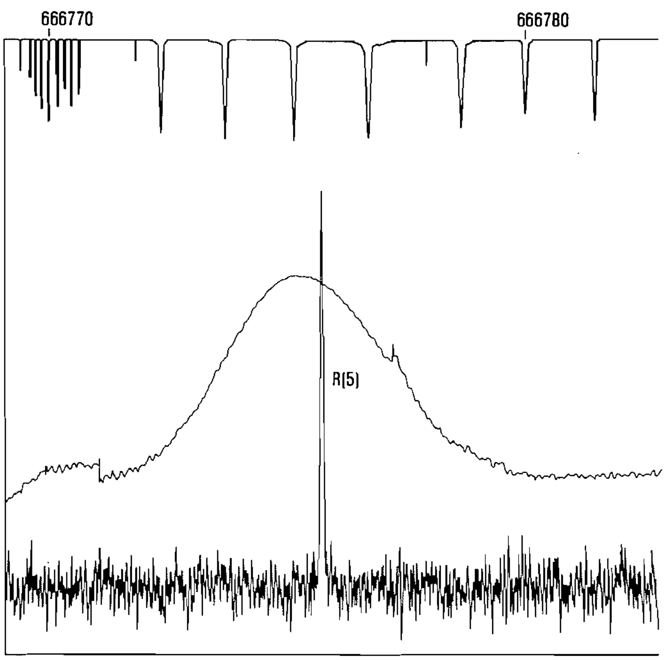

FIG. 2. A sub-Doppler spectrum of the R(5) ν_3 HCN transition. The 5.8 MHz sub-Doppler FWHM can be compared with a profile corresponding to the Doppler-limited transition. The etalon markers are separated by 149.666456(30) MHz; the glitch after every four etalon markers indicates the cavity reset. The etalon markers on the left of the spectrum have been compressed but are included to illustrate single mode scan over a larger range. The two spectra are not coincidental due to displaced recorder pen positions.

range of the spectrometer with that accuracy. The problem was overcome by calibrating the absolute order number of the 150 MHz confocal etalon and determining its free spectral range precisely using differences between rotational transition frequencies. The temperature of the etalon was stabilized to ±0.01°C using a Burleigh TC-10 temperature controller and the system evacuated with a small diffusion pump. The residual absolute pressure in the etalon was carefully monitored with a 220 BHS MKS Baratron gauge and the free spectral range (FSR) determined using the expression:

$$F = \frac{\Delta\nu n_a n_b}{(\Delta m + \Delta n_b m_a - \Delta n_a m_b)}$$

where

$$\frac{\nu_a}{F_a} = m_a = \frac{\nu_1 - \delta_1 F_1}{F_a}, \frac{\nu_b}{F_b} = m_b = \frac{\nu_2 + \delta_2 F_2}{F_b} \text{ and } F = \frac{c}{4n_{\text{vac}}d}$$

for a confocal etalon. $\Delta\nu$ is the frequency separation between specific rovibrational transitions determined from highly accurate microwave rotational transition frequencies; $n_a - n_b$, $\Delta n_a = (n_a - n_{\text{vac}})$, $\Delta n_b = (n_b - n_{\text{vac}})$ refer to refractive indices of dry air at etalon order numbers m_a and m_b occurring at frequencies ν_a, ν_b, respectively. The absolute order number of the etalon was readily determined from available rovibrational spectroscopic data (4) using the above expressions. Δm is the corresponding separation $\nu_1 - \nu_2$ of the transition pair and $\delta_1 = m_1 - m_a$, $\delta_2 = m_b - m_2$ in FSR's. A weighted average of transition separations was used to improve the estimated accuracy of the FSR permitting frequency determination to ≤ 20 MHz. Corrections were applied to take into account non-linearities in laser scanning and the effects of ^{14}N quadrupole coupling in HCN (6).

Results

The molecular beam sub-Doppler spectra of 19 P(J) and R(J) ν_3 HCN rovibrational transitions have been recorded in the frequency range 3340–3284 cm^{-1}. The observed linewidths are ≤ 5.8 MHz and we are able to determine absolute transition frequencies to within 20 MHz. A partial scan of the R(5) transition between absolute order numbers 666770 and 666780 in Fig. 1 corresponds to a FSR = 149.666456(30) MHz. The absolute transition frequencies for all measured transitions are given in Table 1. Also included in Table 2 are the results of a least-squares fit to the expression

$$\nu_m = \nu_0 + (B' + B'')m + (B' - B'' - D' + D'')m^2 - 2(D' + D'')m^3 - (D' - D'')m^4$$

where $m = -J$ for P branch lines and $J + 1$ for R branch lines. The data were not considered sufficiently accurate for inclusion of H′, H″ constants in the fit. The results of the unconstrained five parameter fit are given in Table 2 and can be compared with molecular constants evaluated in previous spectroscopic studies (4, 7). The standard deviation in the frequency fit is 1.56 × 10^{-5} cm^{-1} or 0.47 MHz for the 19 transitions considered and reflects the influence of a number of instrumental factors. The reset of the color center laser cavity and instabilities associated with the scanning of the free running laser are considered primary contributors. Molecular constants determined from this restricted data set compare favorably with the most accurate currently available (4, 7) (Table 2).

Conclusions

In this investigation we were extremely fortunate that very precise rotational spectra were available in both 00^00 and 00^01 states of HCN. This permitted us not only to determine the absolute order number of the confocal etalon but also enabled

us to calibrate its FSR and consequently rovibrational transition frequencies to ≤ 2 parts in 10^7 without utilizing a Michaelson interferometer or a frequency standard of corresponding accuracy. This method of determining absolute rovibrational transition frequencies will become increasingly feasible in other molecules as more rotational transitions are investigated in vibrationally excited states by microwave infrared double resonance techniques. This approach does, however, place stringent instrumental requirements on broadband laser tunability and can only produce absolute transition frequencies of intermediate accuracy for spectral calibration. It appears, however, that this is the first time that the ν_3 HCN rovibrational transition frequencies have been determined with an absolute accuracy of ≤ 20 MHz. These ν_3 HCN rovibrational transitions are very convenient secondary frequency standards for high resolution laser spectroscopy in the 3.0 μm region. We have recently used them to absolutely calibrate Doppler-limited and sub-Doppler transition frequencies in ν_1 $CH_3C{\equiv}CH$, ν_1 H—C≡CH, ν_2 HCN---HF, and ν_2 HCN---HCl.[1]

The γ-alkylation of cyclic β-ketoesters via their enamine derivatives

Denis Gravel[1] and Marc Labelle[2]

Département de Chimie, Université de Montréal, C.P. 6210, Montréal (Qué.), Canada H3C 3V1

Received August 16, 1984

This paper is dedicated to Professor Camille Sandorfy on the occasion of his 65th birthday

Denis Gravel and Marc Labelle. Can. J. Chem. **63**, 1874 (1985).

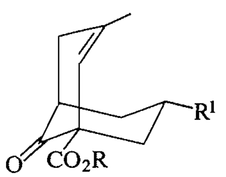
The γ-alkylation – functionalization of cyclic β-ketoesters via their enamine derivatives is discussed with particular emphasis on their preparation from β-ketoesters and their reaction with various electrophiles such as electrophilic olefins, halogenoïds, and allylic and benzylic halides. Although the amine ring size does not appear to affect reactivity to a great extent, the reaction is very sensitive to β-ketoester ring size, with six-membered rings giving the best results. In the latter case the alkylation–functionalization is general and specific to the γ-position and therefore provides an important complement to the dianion and related methodologies.

Denis Gravel et Marc Labelle. Can. J. Chem. **63**, 1874 (1985).

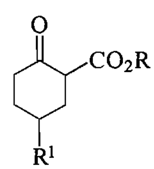
L'alkylation–fonctionnalisation en γ des β-cétoesters cycliques à partir de leurs dérivés énamines est discutée en regard de leur préparation à partir de β-cétoesters et leur réaction avec divers électrophiles tels que: les oléfines électrophiliques, les halogénoïdes et les halogénures allyliques et benzyliques. Quoique la grandeur de cycle de l'amine ne semble pas influencer la réactivité de façon importante, celle-ci est très sensible à la grandeur de cycle du β-cétoester où le cycle à six chaînons donne les meilleurs résultats. Dans ce dernier cas, la réaction d'alkylation–fonctionnalisation est générale et spécifique à la position-γ et donc constitue de toute évidence un complément important à la méthode des dianions et les autres méthodologies reliées.

Introduction

During the course of a synthetic investigation, we were confronted with the problem of gaining access to compounds of the 1-carbalkoxy-3-methyl-9-oxobicyclo[3.3.1]non-2-ene (**1**) type. One of the original plans envisaged called for the specific alkylation at the γ-position of a β-ketoester such as **2**, using methacrolein or an equivalent as the electrophile. From a



1



2

formal point of view, the problem reduces to finding ways of making the γ-position more reactive than the α-position. Examination of the literature revealed that this has been achieved in various ways and a number of methods of varying degrees of generality have become available.

The first such method which showed some generality is that of the dianions (1). This procedure has allowed chemospecific γ-alkylation with a number of different electrophiles such as: alkyl halides (2), α-chloroethers (3), esters (4), aldehydes and ketones (5), nitroolefins (6), and α,ω-dihaloalkanes (7). Further illustration of the efficiency of the method is provided in various multistep syntheses (8, 9) and an elegant solution (10) to the problem of regio-controlled access to the bicyclic alkene **1** with R = Me and R^1 = H, using a sulfur based equivalent of methacrolein (11) as alkylating agent. The same sequence was later applied in our own laboratory to test a selenium based equivalent of methacrolein which we developed (12) for this purpose.

An alternative method to that of the dianions was developed later and involves the reaction of the corresponding neutral bis-trimethylsilylenolethers (13, 14) or enamino trimethylsilylenolether (15) with various electrophiles such as: bromine, acid chlorides, aldehydes, ketones, acetals, α,β-unsaturated esters, and protected β-ketoaldehydes.

A third method of directing electrophilic reactions at the γ-position is based on the corresponding vinylogous carbamate anion which may be alkylated with various electrophiles (16, 17). The method, however, appears to be much less satisfactory with cyclic β-ketoesters (18), which are of prime importance in the present context.

Aside from the above methods of controlled γ-alkylation of β-ketoesters there are also other reported procedures which are of either limited applicability or which were isolated observations. These include the sequence: α-alkylation, retro-Dieckmann, Dieckmann cyclization to the γ-alkyl derivative (19), or many cases of α-functionalization followed by rearrangement to the γ-position. Some reactions which follow this pattern are: phenylselenenylation (20), bromination (21), dialkylaminomethylation (22), and phenylsulfoxyethylation (23). Finally, other cases of γ-functionalization have been observed and involve enamino derivatives of β-dicarbonyl compounds or equivalents thereof; these are the γ-trimethylenedithiolation of the vinylogous carbamate of ethyl acetoacetate (24) and many cases of enamine acylations that were found to yield the 1,3-diacyl derivative with reagents such as ethyl chloroformate (25), phenylisocyanate (26), phosgene (27), and methanesulfonyl chloride (28), which can be included in this category.

A last interesting case is that reported by Colonna *et al.* (29), who, while searching for a chemical method to evaluate the relative amounts of conjugated versus non-conjugated forms of various enamino derivatives of β-ketoesters at equilibrium, found important proportions of γ-functionalization using phenylisocyanate and diethyl azodicarboxylate, due to the displacement of the equilibrium as a result of the greater reactivity of the enamino form **3*a*** over the vinylogous carbamate form **3*b***.

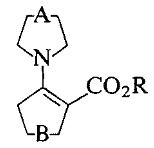
3*a*



3*b*

In conclusion, it appeared that although the dianion method had allowed the synthesis of models (10, 12) of compound **1**, neither this nor the other *direct alkylation* methods reviewed above were appropriate to the synthetic plan which involved the use of an intermediate sensitive to strong bases. Therefore, the problem at hand did not appear to have a ready solution and it seemed worthwhile to investigate the possibility of developing a *mild method* of γ-alkylation of β-ketoesters, based on the reported observations of γ-reactivity in their enamino derivatives (24–29).

Results and discussion

Preparation of the enamino derivatives of the cyclic β-ketoesters

The most frequently used method is the acylation of the enamine derivative of the chosen ketone. However, this procedure, although used throughout Colonna's work (29), was not retained for our experiments for various reasons: (*i*) widely varying yields (30), (*ii*) frequent formation of 1,3-diacylated products (25–28), and (*iii*) this method, starting from the enamine derivative at equilibrium, should not offer good prospects of regio-control in the case of 3-substituted ketone enamines.

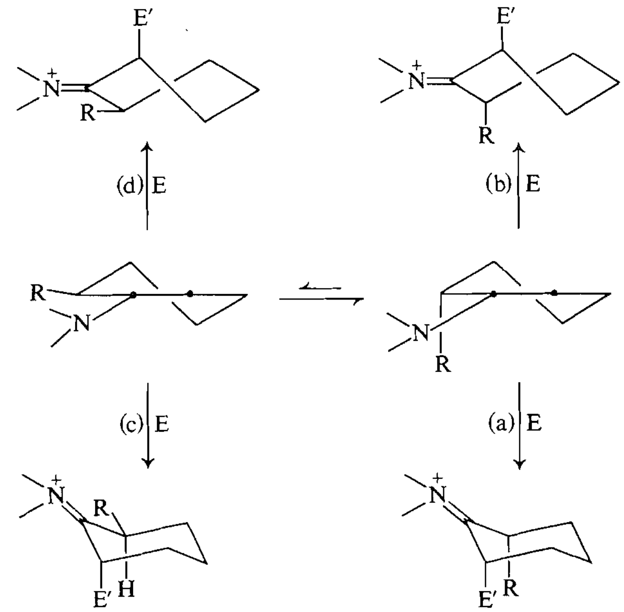
In the hope of having access to a more appropriate method to obtain these compounds we turned to the reverse sequence, which consists of first preparing the β-ketoester from the ketone and then generating the corresponding enamine derivative. Thus, the cyclic β-ketoesters (31) were treated under the usual enamination conditions (32) developed for cyclic ketones (33) and used generally for aliphatic β-ketoesters (34), but with some slight modification. Indeed, due to the extreme slowness of the reaction with our substrates, conditions had to be optimized for reaction temperature, amount of amine, and amount of *p*-toluenesulfonic acid using the piperidino enamine of 2-carbomethoxycyclohexanone as model (see Experimental).

γ-Alkylation – functionalization of enamine derivatives of cyclic β-ketoesters

Since it was well established following the definitive paper by Stork *et al.* (33) in 1963 that saturated alkyl halides do not give good yields in the alkylation of enamines, the present investigation was therefore restricted to some representative electrophilic olefins and allylic (and benzylic) halides which are efficient with enamines and offer the possibility of further functional elaboration; the same reason also applies to the bromination and phenylselenenylation reactions which were also examined in passing. Finally, acylation was not included in the study because a number of examples were already known in the literature through the acylation of enamine studies (25–29, *vide supra*).

The results obtained in the γ-alkylation – functionalization of enamine derivatives of cyclic β-ketoesters are presented in Table 1. It should also be noted that the amine used, i.e. piperidine or pyrrolidine, is adjusted to the electrophilic reagent based on known enamine reactivity (32).

The first and most important observation to be made upon



R = Me or COOEt
E = R′—X, E′ = R′
or E = $\diagup\!\!\diagdown$ Z, E′ = $\diagup\!\!\diagdown$ Z; Z
= electron withdrawing group, -M type.

SCHEME 1

inspection of Table 1 is that electrophiles react with enamine derivatives of *six-membered ring β-ketoesters to give only the γ-functionalized product* in fair to quite good yields (cf. entries 1 to 9), thus providing a *useful complement to the dianion and related methodologies* which require the use of strong bases. A second observation for the same entries, except 2 and 3, is that the contact times involved are generally long compared to the corresponding unsubstituted enamine alkylations. The reason here must be very similar to that which explains the relative slowness of reaction in the case of enamines of 2-methylcyclohexanone (38) (see Scheme 1). Indeed it is known (39, 40) that these, which exist under acid catalyzed equilibrium between the trisubstituted and the disfavored ($A^{1,3}$ strain) (41) tetrasubstituted forms, bear the methyl group in a quasi-axial position in the former in order to minimize $A^{1,2}$ strain (41); this then causes electrophilic reaction to take place at a reduced rate because of developing 1,3 diaxial interactions in an axial attack (a) or of increasing steric interactions due to the intermediacy of a twist-boat conformation in an equatorial attack (b).

On the other hand, axial attack (c) on the quasi-equatorial conformer should require a higher energy of activation than axial attack (a) on the quasi-axial conformer because of developing $A^{1,3}$ interactions.[3] Finally, there is evidence which indicates that equatorial attack (d) is also less favored on the quasi-equatorial conformer than on the quasi-axial one (42). In the case of reaction with electrophilic olefins, however (see Scheme 1), the reason for slowness of reaction is most probably (38) the involvement of the high energy intermediate (because of developing $A^{1,3}$ interactions) resulting from axial attack (c) on the enamine having a quasi-equatorial substituent, which in

[3] In the case of allyl halides, the reaction should proceed via N-alkylation followed by aza-Claisen rearrangement, and axial attack (a) for C—C bond formation should also be favored, see ref. 38, pp. 2018–2020.

TABLE 1. γ-Alkylation – functionalization of enamine derivatives of cyclic β-ketoesters

[a] Structures and regiochemistry follow mainly from spectroscopic data, see Experimental. Isolated after hydrolysis of the resulting vinylogous carbamate; it should be noted here that such hydrolyses are relatively difficult (35) compared to that of simple enamines and thus often require prolonged heating under acidic conditions.

[b] Low yield is due mostly to the difficulty in separating the product from the methacrolein polymer. The structure and regiochemistry of alkylation follow, aside from nmr analysis and fragmentation in mass spectrometry, from conversion to the known bicyclo[3.3.1] derivative **1**.

[c] The ir spectrum corresponds with that reported in the literature (21*a*) for the same compound obtained by an alternate route.

[d] The nmr spectrum observed is similar to that reported (20) for the carbomethoxy analog.

[e] The product is isolated as a mixture of stereoisomers and tautomers after hydrolysis and no attempt was made to convert it quantitatively to the bicyclic aldol.

[f] The electrophilic olefin is added in small portions throughout the reaction.

[g] Higher yields upon prolonged heating are probably due to N-alkylation of the amine followed by a thermal [3.3] sigmatropic shift of the chain to the γ-position in analogy to the case of simple enamines (36).

[h] Filtration of the benzyl bromide over basic alumina gives a reaction which is very slow to begin but gradually accelerates; this indicates the beneficial influence of a trace of acid in probably catalyzing the enamine – vinylogous carbamate equilibrium. This was supported by observing the positive influence of a trace of *p*-toluenesulfonic acid in a reaction mixture where the benzyl bromide was filtered over basic alumina.

[i] Obtained by integration of appropriate signals in the nmr spectrum of the hydrolyzed mixture because of difficulty of separation; the isolated yield was only 16%; see, however, entry 9.

[j] From the outset, the reaction gives a mixture of numerous products.

[k] Monitoring by vpc shows a simple chromatogram with disappearance of the starting material and appearance of a major product; hydrolysis, however, proved difficult (36 h, 10% HCl, 63°C) and yielded only 50% of the crude neutral fraction expected, from which only 27% of **17** and 2% of **18** were obtained. Attempts to prepare the piperidino enamine of the starting β-ketoester in order to examine its reactivity with methyl vinyl ketone failed.

[l] This reaction which, contrary to the cyclic analogs, gives α-alkylation was already reported in 1916 by Robinson (37) under slightly different conditions. Attempted reaction of the piperidino derivative of the same β-ketoester with methyl vinyl ketone gave a complex mixture of products.

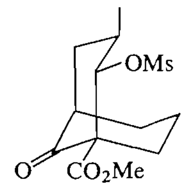
[m] This case, reported by Woodward *et al.* (24), to our knowledge represents the only example of the γ-functionalization of an enamine derivative of an aliphatic β-ketoester.

an efficient and stereoelectronically controlled intramolecular axial proton transfer would go to product; on the other hand, equatorial attack (d) on the same form or axial (a) or equatorial (b) attack on the form having a quasi-axial substituent would yield intermediate zwitterions which would most often revert to starting enamine because of the unavailability of an axial intramolecular proton for charge neutralization. Intermolecular proton transfer, although available, should not be efficient under the normal dilution conditions generally used.

A third observation which can be made upon inspection of Table 1 is that the enamine derivatives of five- and seven-membered ring β-ketoesters (entries 10, 11, 12) are not as uniformly reactive as their six-membered ring analogs. However, a trend favoring γ-reactivity is apparent in those cases and the selective development of specific reaction conditions might be necessary in each case. Finally, it appears that the enamine derivatives of aliphatic β-ketoesters (entries 13, 14) also do not form a uniformly reactive series, as γ and α selectivity are both apparent depending on the electrophile and conditions.

Preparation of 1-carbomethoxy-3-methyl-9-oxobicyclo-[3.3.1]non-2-ene (**1**, R = Me, R[1] = H)

Attempted tosylation of **4** (Table 1, entry 1) under standard conditions (43) for 15 days failed to give the desired product; mesylation (44), however, yielded up to a maximum of 40% of the corresponding mesylate **21**. This suggested that the pyridine used in the reaction was causing a displacement of the



21

aldol equilibrium to the open form, thus slowing down the mesylation reaction considerably and allowing side reactions to compete. The same reaction was then tried in acid medium using methanesulfonyl anhydride (45) but to no avail. Fortunately, however, we observed that the only way the acetate of ketol **4** could be prepared was by using pyridine in acetyl chloride, which are known ketene generating conditions (46). Also, we observed that the corresponding phenylcarbamate could easily be prepared from phenylisocyanate in acidic medium. These observations strongly suggested that the solution to the problem lay in using the corresponding sulfene as mesylating agent rather than methanesulfonyl chloride. Indeed, the reagent is linear, as are ketene and phenylisocyanate, as well as being very reactive. Therefore, by using a set of conditions inspired from the literature (47), we could obtain the desired mesylate **22** in the crystalline form and in a 70% yield. Various fruitless attempts were made to shorten the reaction time; for example, use of *N,N,N*-diethylmethyl methanesulfonyl ammonium ("Easy Mesyl"), recognized as a potent sulfene generator (48), failed to give the desired product (**21**) in good yield. It appears that use of these conditions with ketol **4** generates the sulfene too rapidly for uptake by the substrate, causing it to polymerize (49) and thus complicating isolation of the desired product (**21**).

The last step, i.e. the *cis* elimination, in the projected sequence was achieved in a 70% yield by heating the mesylate **21** in collidine (160°C) for 29 h. The 1-carbomethoxy-3-methyl-9-oxobicyclo[3.3.1]non-2-ene (**1**) thus obtained shows in the nmr a vinyl proton in the form of a broadened singlet at 5.38 ppm, a sharp singlet at 3.78 ppm for the carbomethoxy group, and a broadened singlet at 1.82 ppm for the allylic methyl protons. These values are in accord with those reported in the literature (10) as well as those observed in our own laboratory (12)[4] for the same compound prepared by two additional different methods.

Conclusion

Although the present study is based on a limited number of enamine derivatives, electrophiles, and reaction conditions, it nevertheless provides a good cross section of the possibilities of γ-alkylation(−functionalization) of enamine derivatives of cyclic β-ketoesters. Thus, the method is very good for the γ-alkylation or functionalization of β-ketoesters in the cyclohexane series but its prospects appear much more limited in the cyclopentane and cycloheptane series as well as the aliphatic series. The method is also applicable to substrates bearing base sensitive functionality, thus making it an important complement to the dianion and related methodologies which are usually not applicable in these cases.

From the point of view of electrophiles, electrophilic olefins provide the best results, as is usually the case with simple ketone enamines (32, 34, 38, 50); the generality of halogenation and phenylselenenylation, although assured in the six-membered ring series, remains to be tested in the other series.

Finally, this study has been first and foremost an exploration into the possibilities of the enamine reaction (32, 33, 38, 50) for the γ-alkylation (−functionalization) of β-ketoesters, with the aim of bringing out similarities and distinctions between β-ketoesters and simple ketones. As a result, a certain number of fundamental observations stand out from the preceding experiments. Thus, the chemoselectivity of alkylation in the six-membered ring series is noteworthy; the inertia of the vinylogous carbamate form (**3***b*) towards α-alkylation is most probably due to a weakness of conjugation or overlap of the amine lone pair with the double bond because of strong $A^{1,3}$ interactions. This is supported by the fact that aliphatic vinylogous carbamates, where the amine and carbalkoxy groups are *trans*, show good reactivity in the α-position at least with alkyl halides (see entry 13, Table 1). Also, the observed selectivity for monoalkylation is most important from a synthetic methodology point of view and is probably due to the fact that the monoalkylated or functionalized product exists solely (29) in the now more stable and less reactive vinylogous carbamate form.

A study of factors affecting the enamino versus the vinylogous carbamate forms in enamine derivatives of β-ketoesters has been carried out and is reported in the accompanying paper.

Experimental

Melting points were taken on a Büchi apparatus and are uncorrected. The ^{1}H nmr spectra were recorded, unless otherwise stated, in $CDCl_3$ using either a Bruker WH90 (90 MHz) or a Bruker WH400 (400 MHz). Chemical shifts (δ) are expressed in ppm with respect to tetramethylsilane (TMS) used as internal standard and multiplicities are expressed as "s" for singlet, "d" for doublet, "t" for triplet, "q" for quartet, "h" for heptuplet, and "m" for multiplet. Coupling constants are reported in Hz.

Infrared spectra were recorded on a Perkin Elmer, model 710B, apparatus either in $CDCl_3$, as pure liquid films, or in KBr pellets. High resolution mass spectra (EI) were taken on a AEI MS-902 apparatus and low resolution (EI or CI) were taken on a V.G. Micromass, model 12-12, apparatus. Homogeneity of all compounds prepared was ascertained by tlc or vpc, and ^{1}H nmr. In many cases, ^{13}C nmr spectra were recorded and are available in M. Labelle's Ph.D. thesis and partly in the following paper.

The vpc analyses were done under the following conditions; injection of 1 μL of solution in a Varian model 1200 chromatograph with a flame ionization detector. The column used was 3.5 m × 3 mm and packed with 3% OV-1 on 60–80 mesh Chromosorb W AW-DMCS and helium was used as carrier gas at a rate of 25 mL/min. Injector temperature was maintained at 230°C and the detector at 300°C. Finally, relative peak areas were taken as relative product composition and the results obtained were sufficiently accurate for the present purpose.

Thin-layer chromatography (tlc) was done on Merck Kieselgel 60

[4] Also, D. Gravel and D. Thoroval, unpublished results.

F_{254} using aluminium support and visualization was done by means of either uv light, iodine vapour, or sulfomolybdic mixture (51). Flash chromatography was done following the Still method (52) using Merck 40- to 63-μ mesh silica gel.

Purification of solvents and reagents used in this study was done according to the methods described below and is specified in the Experimental with the appropriate letter, (A) to (E). A: product distilled under inert atmosphere. B: product distilled over a sodium–potassium (1:1 w/w) liquid alloy and a little benzophenone under inert atmosphere. C: product distilled over calcium hydride under inert atmosphere. D: product filtered over basic alumina, activity I, under inert atmosphere. E: product distilled over calcium hydride under inert atmosphere and received in a flask containing (approx. 1% w/w) hydroquinone.

Preparation of enamine derivatives of β-ketoesters

General procedure

In a dry apparatus fitted with a Dean–Stark separator are introduced 1 equiv. of the β-ketoester (prepared by the slightly modified procedure of Ruest, Blouin, Deslongchamps (31)), 5 equiv. of the amine, and 0.05 equiv. of *p*-toluenesulfonic acid monohydrate. The mixture is then diluted with benzene, 20 mL per gram of β-ketoester, and the solution heated to reflux, using an oil bath at a temperature below 100°C since *higher temperatures often cause formation of the corresponding β-ketoamide*. The reaction is monitored by vpc and considered complete when the β-ketoester and β-ketoamide (formed on the column) peaks have disappeared and when the stoichiometric amount of water has been formed. Isolation of the product is carried out by evaporation at 45°C under 15 Torr (1 Torr = 133.3 Pa), by coevaporation with toluene at 45°C under 15 Torr, and by fractional distillation. The products may then be kept frozen under a pressure of approximately 25–50 psi of argon.

Methyl-2-(1-piperidinyl)-2 (and -1) -cyclohexenecarboxylate (**3***a* and **3***b*, A = CH_2, B = CH_2, R = Me)

The reaction was carried out according to the general procedure. Reagents: methyl-2-oxo-cyclohexanecarboxylate (31) (3.0 g, 19.2 mmol) and piperidine. The reaction was complete after about 3 days of light reflux. Distillation: yellowish liquid, 2.73 g (64%) (79–86% with lower bath temperature), bp 78–79°C/8.4 × 10^{-4} Torr; ir (film) ν_{max}: 1730, 1680, 1640, and 1550 cm^{-1}; ^1H nmr (90 MHz) δ: 4.89 (t, J = 4 Hz, 0.66H), 3.69 (s, 3H), and 3.33 (t broadened, 0.66H). Mass spectrum (CI, CH_4) m/e: 224 MH^+, 208 M − CH_3, 164 (100%) M − COOMe. *Exact Mass* calcd. for $C_{13}H_{21}NO_2$: 223.1572; found: 223.1569.

Ethyl-2-(1-piperidinyl)-2 (and -1) -cyclohexenecarboxylate (**3***a* and **3***b*, A = CH_2, B = CH_2, R = Et)

The reaction was carried out according to the general procedure. Reagents: ethyl-2-oxo-cyclohexanecarboxylate (31, 53) (10.0 g, 59 mmol) and piperidine. The reaction was complete after about 5 days of light reflux. Distillation: yellowish liquid, 9.68 g (70%), bp 73–86°C/3.6 × 10^{-4} Torr; ir ($CHCl_3$) ν_{max}: 1720, and 1630 cm^{-1}; ^1H nmr (90 MHz) δ: 4.88 (t, J = 5 Hz, 0.85H), 4.15 (q, J = 7 Hz, 2H), 3.30 (t broadened, 0.85H), and 1.26 (t, J = 7 Hz, 3H). Mass spectrum (EI, 70 eV) m/e: 237 $M^{+\cdot}$, 222 M − Me, 208 M − Et, 192 M − OEt, 164 (100%) M − COOEt. *Exact Mass* calcd. for $C_{14}H_{23}NO_2$: 237.1728; found: 237.1732. These data are in good accord with those reported (29, 54) for the same product.

Ethyl-2-(1-pyrrolidinyl)-2 (and -1) -cyclohexenecarboxylate (**3***a* and **3***b*, A = —, B = CH_2, R = Et)

The reaction was carried out according to the general procedure. Reagents: ethyl-2-oxo-cyclohexanecarboxylate (31, 53) (3.0 g, 17.7 mmol) and pyrrolidine. The reaction was complete after 4.5 h of light reflux. Distillation (Vigreux column): yellowish liquid, 2.04 g (52%). When the reaction was performed on a 6.0-g scale and omitting the Vigreux column for the distillation, the yield was raised to 85%, bp 84–90°C/3.4 × 10^{-4} Torr; ir (film) ν_{max}: 1730, 1670, and 1550 cm^{-1}; ^1H nmr (90 MHz) δ: 4.49 (t broadened, 0.12H), 4.12 (q, J = 7 Hz, 2H), 3.25 (t broadened, ~4H), 2.96 (t broadened, 0.12H), 4.12 (q, J = 7 Hz, 2H), 3.25 (t broadened, ~4H), 2.96 (t broadened, 0.48H), 2.41 (s, broad, ~4H), and 1.26 (t, J = 7 Hz, 3H). Mass spectrum (EI, 70 eV) m/e: 223 $M^{+\cdot}$, 208 (M − Me, 194 M − Et, 150 M − COOEt. *Exact Mass* calcd. for $C_{13}H_{21}NO_2$: 223.1572; found: 223.1576. These data are in good accord with those reported (29, 55) for the same product.

Ethyl-5-acetoxy-2-(1-pyrrolidinyl)-1-cyclohexenecarboxylate (**3***b*, A = —, B = CHOAc, R = Et)

The reaction was carried out according to the general procedure. Reagents: ethyl-5-acetoxy-2-oxo-cyclohexanecarboxylate (30) (2.12 g, 9.3 mmol) and pyrrolidine. The reaction was complete after 1.5 h of light reflux. Distillation: very viscous greenish liquid, 2.13 g (81%), bp 123–130°C/5.5 × 10^{-4} Torr; ir (film) ν_{max}: 1720, 1660, and 1550 cm^{-1}; ^1H nmr (90 MHz) δ: 4.96 (m, 1H), 4.11 (q, J = 7 Hz, 2H), 2.05 (s, 3H), and 1.25 (t, J = 7 Hz, 3H). Mass spectrum (CI, CH_4) m/e: 282 MH^+, 236 M − OEt, 221 M − CH_3COOH.

Ethyl-5-acetoxy-2-(1-piperidinyl)-2 (and -1) -cyclohexenecarboxylate (**3***a* and **3***b*, A = CH_2, B = CHOAc, R = Et)

The reaction was carried out according to the general procedure. Reagents: ethyl-5-acetoxy-2-oxo-cyclohexanecarboxylate (30) (4.0 g, 17.6 mmol) and piperidine. The reaction was complete after about 4 days of light reflux. Distillation: yellowish liquid, 2.6 g (50%), bp 105–136°C/3.2 × 10^{-4} Torr; ir (film) ν_{max}: 1730, 1680, 1640, and 1550 cm^{-1}; ^1H nmr (90 MHz) δ: 5.0 (m, 1.82H), 4.17 and 4.13 (2q, J = 7 Hz, 2H), 3.47 (t broadened, 0.82H), 2.04 and 2.03 (2s, 3H), and 1.26 (t, J = 7 Hz, 3H). Mass spectrum (EI, 70 eV) m/e: 295 $M^{+\cdot}$, 235 M − CH_3COOH, 162 (100%) M − CH_3COOH − COOEt.

Ethyl-2-(1-pyrrolidinyl)-1-cyclopentenecarboxylate (**3***b*, A = —, B = —, R = Et)

The reaction was carried out according to the general procedure. Reagents: ethyl-2-oxo-cyclopentanecarboxylate (31, 53) (2.76 g, 17.7 mmol) and pyrrolidine. The reaction was complete after 2 h of light reflux. Distillation: yellowish liquid, 2.08 g (57%); an experiment where the temperature of the oil bath did not exceed 98°C gave a 72% yield, bp 94–98°C/6.2 × 10^{-4} Torr; ir (film) ν_{max}: 1670 and 1560 cm^{-1}; ^1H nmr (90 MHz) δ: 4.11 (q, J = 7 Hz, 2H), 3.44 (t broadened, 4H), 2.62 and 2.61 (2t, J = 7 Hz, 4H), 1.86 and 1.74 (t, J = 7 Hz and q, J = 7 Hz, 6H), and 1.26 (t, J = 7 Hz, 3H). Mass spectrum (EI, 70 eV) m/e: 209 $M^{+\cdot}$, 180 M − Et, 164 M − OEt, 136 M − COOEt. These data are in accord with those reported in the literature (54) for the same product.

Ethyl-2-(1-piperidinyl)-1-cyclopentenecarboxylate (**3***b*, A = CH_2, B = —, R = Et)

The reaction was carried out according to the general procedure. Reagents: ethyl-2-oxo-cyclopentanecarboxylate (53) (2.76 g, 17.7 mmol) and piperidine. The reaction was complete after 16 h of light reflux. Distillation: yellowish liquid, 2.67 g (68%), bp 55–67°C/6.2 × 10^{-4} Torr; ir (film) ν_{max}: 1670 and 1560 cm^{-1}; ^1H nmr (90 MHz) δ: 4.12 (q, J = 7 Hz, 2H), 3.34 (s broadened, 4H), 2.63 and 2.56 (2t, J = 7 Hz, 4H), 1.83 (t, J = 7 Hz, 2H), 1.61 (s broadened, 6H), and 1.26 (t, J = 7 Hz, 3H). Mass spectrum (EI, 70 eV) m/e: 223 $M^{+\cdot}$, 194 M − Et, 178 M − OEt, 150 (100%) M − COOEt. *Exact Mass* calcd. for $C_{13}H_{21}NO_2$: 223.1572; found: 223.1525.

Ethyl-2-(1-pyrrolidinyl)-1-cycloheptenecarboxylate (**3***b*, A = —, B = $(CH_2)_2$, R = Et)

The reaction was carried out according to the general procedure. Reagents: ethyl-2-oxo-cycloheptanecarboxylate (31, 53) (3.0 g, 16.3 mmol) and pyrrolidine. The reaction was complete after 27 h of light reflux. Distillation: yellowish liquid, 3.14 g (81%), bp 88–98°C/5.5 × 10^{-4} Torr. At −15°C, this liquid solidifies to a white product which melts at 57–63°C; ir (film) ν_{max}: 1650 and 1530 cm^{-1}; ^1H nmr (90 MHz) δ: 4.11 (q, J = 7 Hz, 2H), 3.30 (t broadened, 4H), 2.6 (m, 4H), 1.85 (t broadened, 4H), 1.62 (m, 6H), and 1.25 (t, J = 7 Hz, 3H). Mass spectrum (CI, CH_4) m/e: 238 MH^+, 237 (100%) M^+, 222 M − CH_3, 208 M − Et, 192 M − OEt, 164 M − COOEt. *Exact Mass* calcd. for $C_{14}H_{23}NO_2$: 237.1728; found: 237.1700.

Ethyl-3-(1-pyrrolidinyl)-2-butanoate (**19**)

The reaction was carried out according to the general procedure. Reagents: ethyl-3-oxo-butanoate (6.5 g, 50 mmol) and pyrrolidine. The reaction was complete after 8 h of light reflux. Distillation: yellowish liquid, 6.83 g (75%), bp 105–110°C/1 × 10^{-3} Torr; ir (film) ν_{max}: 1670 and 1570 cm^{-1}; ^1H nmr (90 MHz) δ: 4.44 (s, 1H), 4.08 (q, J = 7 Hz, 2H), 3.29 (s broadened, 4H), 2.45 (s, 3H), 1.93 (m, 4H), and 1.24 (t, J = 7 Hz, 3H). *Exact Mass* calcd. for $C_{10}H_{17}NO_2$: 183.1259; found: 183.1239. These data are identical to those reported in the literature (33).

Methyl-2-hydroxy-3-methyl-bicyclo[3.3.1]nonan-9-one-1-carboxylate (**4**)

Under dry and inert atmosphere, a solution of enamino derivative **3**, A = CH_2, B = CH_2, R = Me (6.1 g, 27.3 mmol) in dioxane (B) (100 mL) was heated with an oil bath at 70°C and treated with freshly distilled methacrolein (E) (8.5 g, 121 mmol). After 9 days of heating, the solvent was evaporated under vacuum at 50°C and the residue stirred with 10% HCl (50 mL) during 90 min. Extraction with ether and treatment under the usual conditions gave a semi-solid which was distilled at 125°C/4 × 10^{-3} Torr in a Kugelrohr apparatus to yield a yellowish solid (2.94 g, 48%), mp 88–120°C. Recrystallization from CCl_4 gave a white solid, mp 122–123°C; ^1H nmr (90 MHz) δ: 3.98 (d, J = 10 Hz, 1H), 3.79 (s, 3H), and 1.09 (d, J = 6 Hz, 3H). *Exact Mass* calcd. for $C_{12}H_{18}O_4$: 226.1205; found: 226.1212.

Ethyl-3-bromo-2-oxo-cyclohexanecarboxylate (**5**)

Under dry and inert atmosphere, a solution (prepared at −20°C) of enamino derivative **3**, A = CH_2, B = CH_2, R = Et (500 mg, 2.11 mmol) in CH_2Cl_2 (A) (20 mL) was treated at −20°C with triethylamine (1.16 mL, 8.44 mmol) and the temperature lowered to −95°C. There was then added, over a 5-min period, a solution of bromine (338 mg, 2.11 mmol) in CH_2Cl_2 (10 mL). The yellow solution was maintained at −95°C for 2 h after which the reaction was quenched with 5% HCl (6 mL). The mixture was left overnight under strong stirring and the organic phase decanted, dried, and evaporated under vacuum (40°C) to give an oil (656 mg) which distilled at 95°C/6 × 10^{-4} Torr in a Kugelrohr apparatus to yield a colorless liquid (338 mg, 64%); ir ($CDCl_3$) ν_{max}: 1730, 1710, 1650, and 1610 cm^{-1}; ^1H nmr (90 MHz) δ: 12.10 (s, 0.6H), 4.69 (t, broadened, 0.6H), 4.55 (t, broadened, 0.4H), 4.24 (q, J = 7 Hz, 2H), 3.4 (m, 0.4H), and 1.31 and 1.29 (2t, J = 7 Hz, 3H). *Exact Mass* calcd. for $C_9H_{13}BrO_3$: 250.0028; found: 250.0039.

Ethyl-3-phenylselenenyl-2-oxo-cyclohexanecarboxylate (**6**)

Under dry and inert atmosphere a solution of enamino derivative **3**, A = CH_2, B = CH_2, R = Et (430 mg, 1.81 mmol) in THF (B) (10 mL) was cooled to about −110°C and treated, under stirring and over a 5-min period, with a solution of phenylselenenyl chloride (356 mg, 1.86 mmol) in THF (5 mL). The temperature was allowed to rise to −80°C (20 min) and the mixture quenched with water (8 mL) and ether (10 mL). Gradual warming of the mixture to room temperature (3 h) was then followed by the addition of 5% HCl (1 mL) to complete the hydrolysis during 12 h. The aqueous phase was decanted and extracted with ether (10 mL). Treatment of the organic phases in the usual manner gave a yellow oil (640 mg) which contained some diphenyldiselenide. Flash chromatography (ether–hexane, 3:97) purification of a small portion gave a colorless liquid, relatively unstable in air; ir (film) ν_{max}: 3025, 1730, 1700, 1640, and 1600 cm^{-1}; ^1H nmr (90 MHz) δ: 12.32 (s, ~1H), 7.65 and 7.29 (2m, 5H), 4.21 (q, J = 7 Hz, 2H), 4.10 (t, broadened, 1H), and 1.29 (t, J = 7 Hz, 3H). This spectrum corresponds very well with that of the methyl ester reported in the literature (20). Mass spectrum (EI, 70 eV) m/e: 226, 224, 222 and 220 M − CH_2CH_2 − COOEt, 168 M − PhSeH, 159, 157, 155 and 153 $PhSe^{+\cdot}$, 123 (100%) M − PhSeH − OEt.

Ethyl-2-hydroxy-bicyclo[3.3.1]nonan-9-one-1-carboxylate (**7**) *and ethyl-3-(3-oxo-propyl)-2-oxo-cyclohexanecarboxylate* (**8**)

Under dry and inert atmosphere, a solution of the enamino derivative **3**, A = CH_2, B = CH_2, R = Et (2.29 g, 9.6 mmol) and hydroquinone (100 mg) in dioxane (B) (50 mL) was heated to reflux (bath temp. 115°C) and treated with freshly distilled acrolein (E) (1.77 g, 28.8 mmol). The reaction was monitored by vpc and, after 3.5 h, an additional amount of acrolein (E) (0.88 g, 14.4 mmol) was added and the reflux prolonged for an additional 5.5 h. At the end of the reaction period, the excess acrolein was drawn away by a stream of argon during reflux. The dioxane was evaporated under vacuum (40°C) and the residue taken up in ether (50 mL). The organic phase was washed with 5% Na_2CO_3 (20 mL) and stirred vigorously with 5% HCl (10 mL) during 8.5 h at room temperature. The organic phase was decanted and the aqueous phase diluted with brine (10 mL) and extracted twice with ether (2 × 25 mL). The organic phases were treated in the usual way to yield an oil (1.58 g) which was distilled: bp 97–98°C/6 × 10^{-4} Torr to give a yellowish liquid (1.12 g, 51%) composed of a mixture of tautomers and isomers of the expected product; ir (film) ν_{max}: 3400, 2830, 1730, 1720, 1710, 1670, and 1630 cm^{-1}; ^1H nmr (90 MHz) δ: 12.44 (s, 0.17H), 9.77 (m, 0.5H), 4.5 (m, 0.5H), 4.25 and 4.21 (q, J = 7 Hz, 2H), 3.4 (m, 0.33H), 3.05 (s, broad, 0.5H) shifts with change in concentration, and 1.32, 1.30, 1.28 and 1.26 (4t, J = 7 Hz, 3H). Mass spectrum (EI, 70 eV) m/e: 208 M − H_2O, 180 M − H_2O − EtOH, 170 M − CH_2=CHCHO.

Ethyl-2-oxo-3-(3-oxo-butyl)-cyclohexanecarboxylate (**9**)

Under dry and inert atmosphere, a solution of the enamino derivative **3**, A = CH_2, B = CH_2, R = Et (320 mg, 1.36 mmol) in dioxane (B) (3 mL) was treated with freshly distilled methylvinylketone (E) (114 mg, 1.63 mmol) and the mixture heated to reflux on an oil bath at 120°C. The reaction was monitored by vpc and in the present case required the addition of further methylvinyl ketone (E) (20 mg, 0.33 mmol per addition) after 19, 43, and 54 h in order to bring the reaction to completion after 66 h. Evaporation of the solvent and unreacted methylvinylketone under vacuum at 45°C gave a residue which was taken up in $CHCl_3$ (10 mL) and the resulting solution stirred vigorously for 90 min with 10% HCl (4 mL). After separation, the aqueous phase was reextracted with $CHCl_3$ (15 mL) and the organic phases treated in the usual manner to yield a residue (320 mg) which was distilled in a Kugelrohr apparatus at 85°C under 3.3 × 10^{-4} Torr to give a slightly yellowish liquid (230 mg, 72%); ir (film) ν_{max}: 1730, 1710, 1630, and 1600 cm^{-1}; ^1H nmr (90 MHz) δ: 12.43 (s, 0.33H), exchangeable with D_2O, 4.21 (q, J = 7 Hz, 2H), 3.38 (m, 0.67 H), 2.16 and 2.13 (2s, 3H), and 1.30, 1.28, and 1.27 (3t, J = 7 Hz, 3H). Mass spectrum (EI, 70 eV) m/e: 222 M − H_2O, 195 M − OEt, 182 M − CH_3COCH_3, 168 M − $CH_3CH_2COCH_3$, 137 M − OEt − CH_3COCH_3.

Ethyl-3-(2-propenyl)-2-oxo-cyclohexanecarboxylate (**10**)

Under dry and inert atmosphere, a solution of the enamino derivative **3**, A = —, B = CH_2, R = Et (850 mg, 3.81 mmol) in dioxane (B) (10 mL) was heated to reflux in an oil bath at 125°C and treated with 3-bromopropene (1.40 g, 11.4 mmol). Monitoring by vpc showed that the reaction was complete after 11 h of reflux. The mixture was evaporated under vacuum (45°C), diluted with $CHCl_3$ (10 mL), and stirred vigorously with 5% HCl (5 mL) at 60°C; vpc monitoring showed the hydrolysis to be complete after 5 h. The organic phase was decanted and treated in the usual way to give a yellow oil (600 mg, 75%) of approximately 90% purity (vpc). A pure sample was prepared by flash chromatography (hexane–$CHCl_3$, 6:4); ir (film) ν_{max}: 3040, 1735, 1710, 1640, and 1600 cm^{-1}; ^1H nmr (90 MHz) δ: 12.44 (s, 0.55H), exchangeable with D_2O, 5.8 (m, broad, 1H), 5.10 and 4.97 (2m, 2H), 4.21 (q, J = 7 Hz, 2H), 3.6 (m, 0.45H), exchangeable with D_2O, K_2CO_3, 63°C, 15 min, and 1.30, 1.28, and 1.27 (3t, J = 7 Hz, 3H). Mass spectrum (EI, 70 eV) m/e: 210 $M^{+\cdot}$, 181 M − Et, 168 M − CH_2=$CHCH_3$, 164 M − CH_3CH_2OH, 137 M − COOEt. These data are in accord with those reported in the literature (2) for the corresponding methyl ester.

Ethyl-3-benzyl-2-oxo-cyclohexanecarboxylate (**11**)

Under dry and inert atmosphere, a solution of the enamino derivative **3**, A = —, B = CH_2, R = Et (530 mg, 2.37 mmol) in dioxane (B) (10 mL) was treated with benzyl bromide (721 mg, 4.22 mmol) and then heated to 95°C. Monitoring by vpc showed the disappearance of the enamino derivative after 97 h. The violet mixture was evaporated under vacuum (40°C) and the residue diluted with $CHCl_3$ (15 mL) and stirred under reflux with 10% HCl (5 mL). Hydrolysis was complete (vpc) after 2.25 h. The aqueous phase was decanted, extracted with $CHCl_3$ (15 mL), and the organic phases treated in the usual way to give a red oil. Distillation in a Kugelrohr apparatus at 110°C/5.8 × 10^{-4} Torr gave a colorless oil (385 mg, 64%); ir (film) ν_{max}: 3040, 1740, 1710, 1640, and 1610 cm^{-1}; ^1H nmr (90 MHz) δ: 12.54 (s, 0.4H), 7.22 and 7.18 (2s, 5H), 4.22 (q, J = 7 Hz, 2H), 3.30 (m, 1.6H), and 1.29 (t, J = 7 Hz, 3H). Mass spectrum (EI, 70 eV) m/e: 260 $M^{+\cdot}$, 242 M − H_2O, 214 M − CH_3CH_2OH, 187 M − COOEt, 169 M − CH_2Ph.

Ethyl-5-acetoxy-3-(2-propenyl)-2-oxo-cyclohexanecarboxylate (12)

Under dry and inert atmosphere, a solution of enamino derivative **3**, A = —, B = CHOAc, R = Et (420 mg, 1.5 mmol) and *p*-toluenesulfonic acid monohydrate (6 mg, 0.03 mmol) in dioxane (B) (10 mL) was heated to reflux on an oil bath at 115°C and treated with allyl bromide (C) (1.09 g, 90 mmol). Monitoring (vpc) showed the reaction to be complete after 48 h of reflux. The mixture was evaporated under vacuum (45°C), and the residue dissolved in $CHCl_3$ (10 mL). The resulting solution was stirred vigorously at 63°C with 5% HCl (7 mL). After 2 h, the aqueous layer was decanted and extracted with $CHCl_3$; the organic phases were treated in the usual manner to give an oil (301 mg) which was shown by nmr to contain 81% of alkylated product, giving thus a yield of 67% for the reaction. Due to the similar chromatographic properties of the alkylated and non-alkylated products, purification was done by medium pressure liquid chromatography (1 m × 1 cm column, ether–hexane 2:8) and, despite those efforts, yielded only 49 mg (16%) of the pure product; ir (film) ν_{max}: 3050, 1730, 1640, and 1600 cm^{-1}; ^1H nmr (90 MHz) δ: 12.53 and 12.49 (2s, 1H), 6.0–4.7 (m, 4H), 4.21 (q, J = 7 Hz, 2H), 2.06 and 2.05 (2s, 3H), and 1.30 (t, J = 7 Hz, 3H). Mass spectrum (CI, CH_4) m/e: 269 MH^+, 223 M − OEt, 209 (100%) M − $OCOCH_3$.

Ethyl-5-acetoxy-2-oxo-3-(3-oxo-butyl)-cyclohexanecarboxylate (13)

Under dry and inert atmosphere, a solution of enamino derivative **3**, A = CH_2, B = CHOAc, R = Et (1.0 g, 3.05 mmol) in dioxane (B) (10 mL) was heated to reflux on an oil bath at 115°C and then treated with methylvinylketone (E) (425 mg, 6.1 mmol). Monitoring by vpc showed that after 36 h of reflux the reaction appeared about complete. The solvent was evaporated under vacuum (45°C) and the residue taken up in $CHCl_3$ (15 mL); hydrolysis took place by stirring vigorously with 5% HCl (10 mL) for 10 h. The organic phase was decanted and treated in the usual manner to give a yellow oil (900 mg). Flash chromatography (ether–hexane, 1:1) gave a colorless oil (651 mg, 77%); ir (film) ν_{max}: 1735, 1710, 1650, and 1610 cm^{-1}; ^1H nmr (90 MHz) δ: 12.52 and 12.47 (2s, 1H), exchangeable with D_2O, 5.07 (m, broad, 1H), 4.21 (q, J = 7 Hz, 2H), 2.16 (s, 3H), 2.05 (s, 3H), and 1.30 (t, J = 7 Hz, 3H). Mass spectrum (EI, 70 eV) m/e: 280 M − H_2O, 238 M − CH_3COOH, 220 M − CH_3COOH − H_2O.

Ethyl-3-(2-propenyl)-2-oxo-cyclopentanecarboxylate (14) and ethyl-bis-1,3-(2-propenyl)-2-oxo-cyclopentanecarboxylate (15)

Under dry and inert atmosphere, a solution of enamino derivative **3**, A = —, B = —, R = Et (560 mg, 2.68 mmol) and *p*-toluenesulfonic acid monohydrate (25 mg, 0.13 mmol) in dioxane (B) (10 mL) was heated to reflux using an oil bath at 105°C and treated with allyl bromide (C) (3.24 g, 26.8 mmol). Monitoring (vpc) showed that the reaction ceased progressing after 5 days. The reaction mixture, evaporated under vacuum (45°C) and co-evaporated with toluene under the same conditions, was taken up in $CHCl_3$ (12 mL) and hydrolyzed by vigorous stirring with 10% HCl (3 mL) during 16 h. The aqueous phase was decanted and extracted twice with $CHCl_3$ (3 mL); the organic phases were treated in the usual manner to yield an oily residue (450 mg). Flash chromatography (ether–hexane, 1:9) gave the dialkylated product **15** as a yellowish oil (88 mg, 14%), the monoalkylated product **14** (70 mg, 13%), and some 2-carbethoxycyclopentanone (29 mg, 5%).

Compound 14: ir (film) ν_{max}: 3060, 1745, 1720, and 1630 cm^{-1}; ^1H nmr (90 MHz) δ: 5.7 (m, 1H), 5.1 (m, 2H), 4.70 and 4.16 (2 q, J = 7 Hz, 2H), and 1.28 and 1.25 (2t, J = 7 Hz, 3H). Mass spectrum (CI, CH_4) m/e: 197 MH^+, 168 M − $CH_2{=}CH_2$, 151 M − OEt, 150 M − CH_3CH_2OH.

Compound 15: ir (film) ν_{max}: 3060, 1745, 1715, and 1630 cm^{-1}; ^1H nmr (90 MHz) δ: 5.7 (m, 2H), 5.1 (m, 4H), 4.15 (q, J = 7 Hz, 2H), and 1.25 (t, J = 7 Hz, 3H). Mass spectrum (CI, CH_4) m/e: 237 (100%) MH^+, 208 M − $CH_2{=}CH_2$, 195 M − $CH_2CH{=}CH_2$, 191 M − OEt, 163 M − COOEt.

Ethyl-2-oxo-3-(3-oxo-butyl)cyclopentanecarboxylate (16)

Under dry and inert atmosphere, a solution of enamino derivative **3**, A = CH_2, B = —, R = Et (520 mg, 2.33 mmol) and *p*-toluenesulfonic acid monohydrate (4 mg, 0.02 mmol) in dioxane (B) (5 mL) was treated with methylvinylketone (E) (326 mg, 4.66 mmol) at room temperature. Monitoring by vpc showed the reaction to be complete after 30 h. Evaporation of the mixture under vacuum (40°C) and co-evaporation with toluene under the same conditions gave a residue which was taken up with $CHCl_3$ (10 mL) and stirred vigorously with 5% HCl (2 mL) for 18 h (vpc monitoring). The aqueous phase was decanted, extracted twice with $CHCl_3$ (4 mL), and the organic phases treated in the usual manner to give a residue which was separated by flash chromatography; elution with ether–hexane (20:80) gave in the first fractions 2-carbethoxycyclopentanone (72 mg); elution with ether–hexane (40:60) gave a yellowish liquid (300 mg, 60%) which is the monoalkylated product; ir (film) ν_{max}: 1740 and 1710 cm^{-1}; ^1H nmr (90 MHz) δ: 4.19 and 4.18 (2q, J = 7 Hz, 2H), 3.14 (m, 1H), 2.60 and 2.57 (2t, J = 7 Hz, 2H), 2.15 (s, 3H), and 1.28 (t, J = 7 Hz, 3H). Mass spectrum (EI, 70 eV) m/e: 208 M − H_2O, 181 M − OEt, 180 M − CH_3CH_2OH, 169 M − CH_2COCH_3, 156 M − $CH_2{=}CHCOCH_3$.

Ethyl-3-(2-propenyl)-2-oxo-cycloheptanecarboxylate (17) and ethyl-bis-1,3-(2-propenyl)-2-oxo-cycloheptanecarboxylate (18)

Under dry and inert atmosphere, a solution of enamino derivative **3**, A = —, B = $(CH_2)_2$, R = Et (480 mg, 2.02 mmol) and *p*-toluenesulfonic acid monohydrate (22 mg, 0.1 mmol) in dioxane (B) (10 mL) was heated to 100°C and treated with allyl bromide (C) (2.78 g, 20.2 mmol). Monitoring by vpc showed that the reaction ceased progressing after 19 h. Evaporation of the solvent under vacuum (40°C) led to a residue which was taken up in $CHCl_3$ (10 mL) and hydrolyzed by vigorously stirring at 63°C for 3 h with 10% HCl (3 mL). The aqueous phase was then decanted and reextracted with $CHCl_3$ (4 mL). The organic phases were treated in the usual manner to yield a brown liquid (246 mg). Flash chromatography (ether–hexane, 5:95) gave in the first fractions the dialkylated product **18** (9 mg, 2%) and in later fractions the monoalkylated product (**17**) (100 mg, 27%) as a mixture of 2 stereoisomers.

Compound 17: ir (film) ν_{max}: 3050, 1730, 1700, and 1630 cm^{-1}; ^1H nmr (90 MHz) δ: 5.7 (m, 1H), 5.0 (m, 2H), 4.19 and 4.15 (2q, J = 7 Hz, 2H), 3.52 (m, 1H), and 1.27 and 1.25 (2t, J = 7 Hz, 3H). Mass spectrum (CI, CH_4) m/e: 225 (100%) MH^+, 185 M − $CH_2CH{=}CH_2$, 179 M − OEt, 178 M − CH_3CH_2OH, 151 M − COOEt.

Compound 18: ir (film) ν_{max}: 3050, 1725, 1700, and 1630 cm^{-1}; ^1H nmr (90 MHz) δ: 5.7 (m, 2H), 5.1 (m, 4H), 4.21 (q, J = 7 Hz, 2H), and 1.28 (t, J = 7 Hz, 3H). Mass spectrum (CI, CH_4) m/e: 265 (100%) MH^+, 219 M − OEt.

Ethyl-2-acetyl-4-pentenoate (20)

Under dry and inert atmosphere, a solution of enamino derivative **19** (670 mg, 3.66 mmol) and *p*-toluenesulfonic acid monohydrate (26 mg, 0.18 mmol) in dioxane (B) (10 mL) was heated to 100°C and treated with allyl bromide (C) (3.3 g, 36.6 mmol). Monitoring by vpc showed the reaction to be complete after 17 h. The reaction mixture was evaporated under vacuum (40°C), the residue taken up in $CHCl_3$ (10 mL), and the solution stirred for 11 h with 5% HCl (vpc monitoring). The aqueous phase was decanted and extracted twice with $CHCl_3$ (4 mL); the organic phases were treated in the usual manner to yield a pale yellow liquid (560 mg, 90%) which showed only one peak by vpc; ir (film) ν_{max}: 3050, 1730, 1710, and 1630 cm^{-1}; ^1H nmr (90

MHz) δ: 5.7 (m, 1H), 5.11 (m, 2H), 4.20 (q, J = 7 Hz, 2H), 3.53 (t, J = 7 Hz, 1H), 2.60 (t, broadened, 2H), 2.24 (s, 3H), and 1.27 (t, J = 7 Hz, 3H). These data are in accord with those reported in the literature (56).

Methyl-2-methanesulfonyloxy-3-methyl-9-oxo-bicyclo[3.3.1]nonane-carboxylate (21)

Under dry and inert atmosphere, a solution of ketol ester **4** (20 mg, 88 μmol) in 400 μL of $CDCl_3$ (Merck) was treated with methanesulfonyl chloride (A) (41 mg, 350 μmol) and pyridine (C) (16 mg, 200 μmol) and progress of the reaction was monitored by nmr. After 5 days at room temperature, the reaction mixture was extracted with water (0.1 mL) and the aqueous phase reextracted with $CHCl_3$ (0.5 mL). The organic phases were combined and treated in the usual manner. The residue obtained was distilled in a Kugelrohr apparatus at 120°C/3.7 × 10^{-4} Torr to give a yellowish liquid (19 mg, 70%). In an alternate experiment, a crystalline product was obtained (mp 127–128°C ($CHCl_3$)) in a lower yield but showing the same spectroscopic characteristics as the former; ir ($CDCl_3$) ν_{max}: 1740, 1720, 1340, and 1170 cm^{-1}; ^1H nmr (90 MHz) δ: 5.25 (d, J = 10 Hz, 1H), 3.80 (s, 3H), 2.99 (s, 3H), and 1.19 (d, J = 6 Hz, 3H). Mass spectrum (CI, CH_4) m/e: 209 M − OSO_2CH_3, 208 M − CH_3SO_3H, 177 M − CH_3SO_3H − OCH_3, 149 M − CH_3SO_3H − $COOCH_3$.

Methyl-3-methyl-9-oxobicyclo[3.3.1]non-2-enecarboxylate (2)

Under inert atmosphere, a solution of ketomesylate **21** (266 mg, 0.87 mmol) in collidine (2 mL) was heated to 160°C for 29 h. The solution was cooled and the solvent evaporated at room temperature (0.5 Torr) to give a black residue. The latter was taken up in ether (3 mL) and 10% HCl (1 mL). The aqueous phase was decanted and extracted 3 times with ether (3 mL). The organic phases were treated in the usual manner to give a yellow oil (153 mg). Distillation in a Kugelrohr apparatus (75°C/4 × 10^{-4} Torr) gave a colorless liquid (129 mg, 71%); ir (film) ν_{max}: 1735 and 1710 cm^{-1}; ^1H nmr (400 MHz) δ: 5.38 (s, broadened, 1H), 3.78 (s, 3H), and 1.82 (s, 3H). Mass spectrum (CI, CH_4) m/e: 209 MH^+. *Exact Mass* calcd. for $C_{12}H_{16}O_3$: 208.1100; found: 208.1101. These data correspond to those reported in the literature (10, 12) for the same compound.

The conjugated–unconjugated tautomerism of β-ketoester enamines has been investigated. Enamines with different amine ring size, ketone ring size, and ester alkyl group have been prepared. Equilibrium ratios of the conjugated and unconjugated forms have been determined. A three-point rationalization is presented: (1) the relative instability of the conjugated form is due to a large steric interaction; (2) the ring size combination largely determines the equilibrium ratio because of energy differences between the resonance hybrid structures of the conjugated forms; (3) the ester alkyl group slightly affects the equilibrium ratio, through a difference in rotational freedom in the conjugated form. The degree of instability of double bonds exocyclic to 5-, and 6-, and 7-membered rings is discussed.

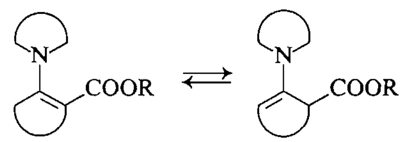
MARC LABELLE et DENIS GRAVEL. Can. J. Chem. **63**, 1884 (1985).

L'équilibre tautomérique des formes conjuguées et déconjuguées des énamines de β-cétoesters a été étudiée. Plusieurs énamines de diverses grandeurs de cycle à l'amine et au cétoester et divers groupes alkyles à l'ester ont été préparées. Les proportions de formes conjuguées et déconjuguées à l'équilibre sont rapportées. Les résultats sont expliqués à partir de trois effets: (1) l'instabilité relative des formes conjuguées est due à une importante interaction stérique; (2) les proportions des deux formes sont surtout controlées par la grandeur des cycles impliqués, en raison de différences d'énergie entre les structures hybrides de résonance; (3) la nature du groupe alkyle de l'ester influence le rapport des deux formes à cause d'une différence de liberté de rotation dans la forme conjuguée. Le degré d'instabilité des doubles liens exocycliques à des cycles à 5, 6 et 7 chaînons est discuté.

In the course of our study on the scope and limitations of β-ketoester enamines in organic synthesis (1), we became interested in investigating the factors which control the equilibrium between the conjugated and unconjugated forms in β-ketoester enamines (Scheme 1). An examination of the literature revealed that the presence, at equilibrium, of significant amounts of the unconjugated form is not a phenomenon limited to β-ketoester enamines (2–4) but has also been observed with β-ketoamide enamines (5–7), β-diketone enamines (4, 8, 9), β-ketosulfone enamines (10), and β-ketothioamide enamines (7). The presence of this equilibrium has also been frequently noted in the results of enamine acylations (3, 5, 8, 10, 11) which often give some 1,3-diacylated product, resulting from acylation of the unconjugated form of the monoacylated product.

The only systematic study dealing with the equilibrium between the conjugated and unconjugated forms in β-dicarbonyl enamines has been published by Colonna *et al.* (3). In this paper, the authors report the observed equilibrium proportions of conjugated and unconjugated forms for a number of β-dicarbonyl enamines, as well as the results of the reaction of these compounds with two electrophiles, namely phenylisocyanate and diethyl azodicarboxylate. A rationale for the equilibrium ratios, based on steric arguments (as in the case of 2-methylcyclohexanone enamines (12)), inductive and resonance effects, and differences in the conjugating ability of the amine moiety, is proposed by the authors (3).

In the present paper, we wish to report the results of a study focused on the case of β-ketoester enamines. The effect of both the ketone and the amine ring size, as well as that of the ester alkyl group have been examined. These new parameters should give a better characterization of the phenomenon and should allow a more accurate formulation of the factors responsible for the proportions of conjugated and unconjugated forms in β-ketoester enamines.



SCHEME 1

Synthesis of the enamine derivatives

The enamines were synthesized as previously described (1), using a β-ketoester,[3] 5 equivalents of the amine, and 0.05 equivalent of *p*-toluenesulfonic acid in gently refluxing benzene. The reactions are monitored by vpc, where disappearance of the β-ketoester and β-ketoamide[4] peaks, and appearance of the enamine peak could be observed. Interestingly, both the conjugated and unconjugated forms elute together in all the enamines studied, which indicates a rapid rate of equilibration between the two forms under the vpc conditions.

The enamine purification involves a distillation under high vacuum. In a few cases, the distillate solidified to a waxy solid on standing. This phenomenon was observed only with enamines where the conjugated form largely dominates the equilibrium. In order to confirm that the solid product is the conjugated form alone, the oily solid ethyl 2-(1-pyrrolidinyl) 1-(and 2-)cyclohexenecarboxylate (**1**), which is an 88 : 12 mixture of the conjugated and unconjugated forms at the equilibrium ($CDCl_3$, 23°C), was dissolved in hexane and cooled to −78°C to precipitate a white powder. This treatment, repeated once

[3] This approach to β-ketoester enamines required the preparation of several β-ketoesters as starting materials. For this purpose, a published preparation of methyl 2-oxocyclohexenecarboxylate (13) was used, which, with slight modifications, was extended into a fairly general method for generating β-ketoesters from cyclic ketones (see Experimental).

[4] The β-ketoamide is formed on the vpc column from the β-ketoester and the amine (see ref. 27).

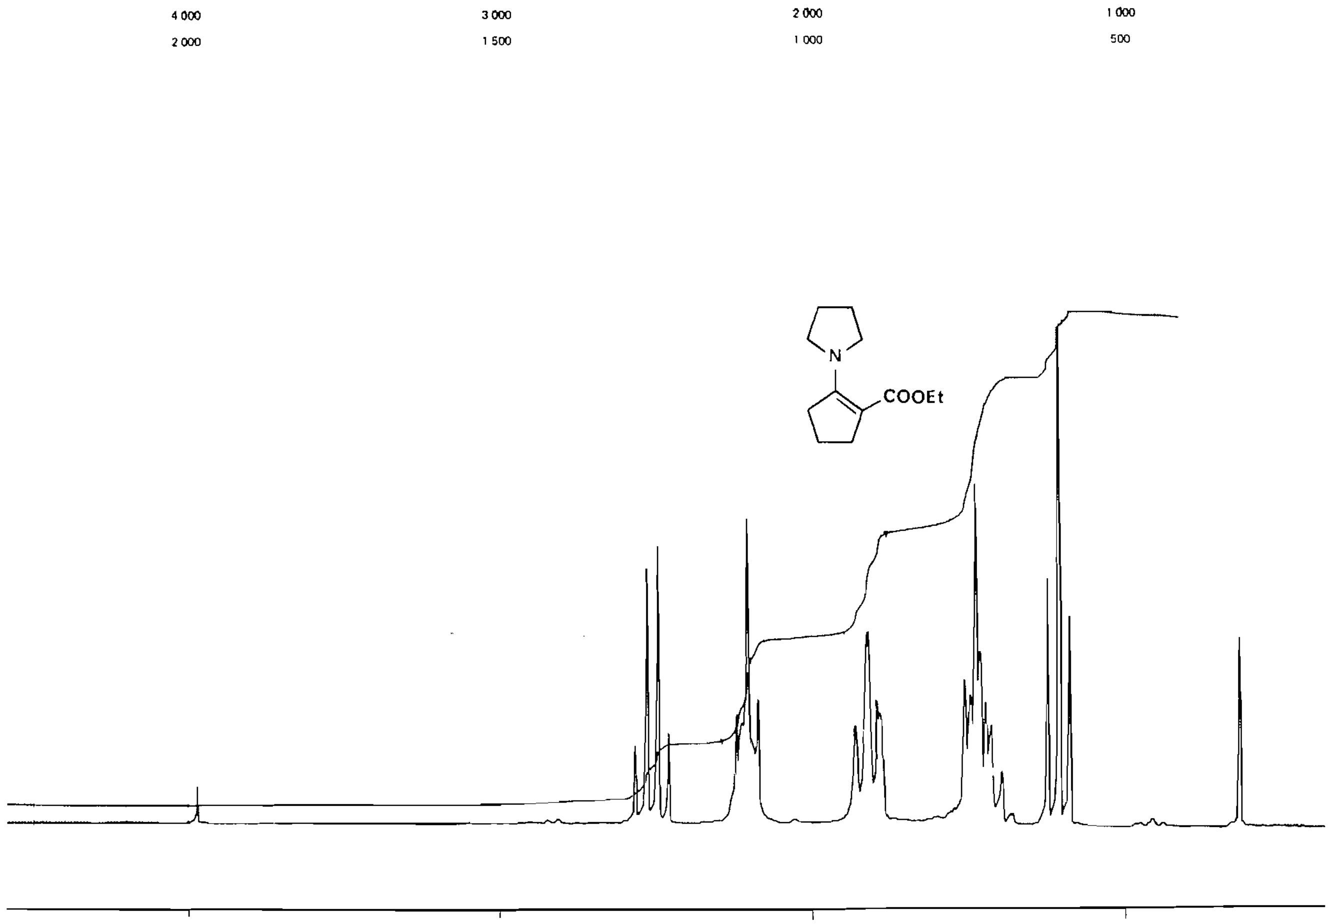

FIG. 1. ^{1}H nuclear magnetic resonance spectrum of compound **9**.

more, yielded a dry powder which, in a KBr emulsion at room temperature, showed only one set of ir bands, at 1670 and 1550 cm^{-1}, corresponding to vinylogous carbamate absorptions (14). This demonstrates that the solid form of the compound is indeed the vinylogous carbamate.

Interestingly, when this same powder was melted (40°C) between NaCl plates, the 1730 cm^{-1} enamine ir band appeared immediately, indicating that the compound had returned to the equilibrium mixture containing some unconjugated form. On cooling to room temperature, the compound did not solidify, and the ir spectrum was unchanged. This experiment shows that a rapid equilibration in the neat liquid phase is occurring for this particular enamine. As we shall see below, however, not all enamines equilibrate so rapidly at or around room temperature.

Results

The ratios of unconjugated to conjugated forms for the various enamines were determined by nmr. Typical spectra are shown in Figs. 1 and 2. The unconjugated form olefinic proton, when well separated (see Fig. 2), is a reliable source of quantitative information. However, in the case of the pyrrolidinoenamines ethyl and isopropyl 2-(1-pyrrolidinyl) 2- (and 1-)cyclohexenecarboxylate, **1** and **2**, this olefinic proton signal was masked by another band, and the desired unconjugated–conjugated ratio was obtained through the relative integration of the protons on the carbon attached to the nitrogen in the amine ring. This signal displays a considerable difference in chemical shift depending on whether the enamine double bond is conjugated to the ester or not.

Semi-quantitative support for the proton nmr derived ratios is obtained from the ^{13}C nmr and ir spectra. The carbon nmr shows several signals attributable to either the unconjugated or conjugated form. Their relative intensity, or the absence of one of the sets of signals, is an indication of the equilibrium ratio. The ir spectra provide the same kind of support to the proton nmr integration, especially through the relative intensity of the carbonyl band (unconjugated around 1730 cm^{-1}, conjugated around 1680 cm^{-1}) and the olefin band (unconjugated around 1640 cm^{-1}, conjugated around 1550 cm^{-1}).

A crucial aspect of these measurements is to make sure that the state of equilibrium has been reached when the ratio is measured. In some instances, especially for piperidinoenamines, the complete equilibration was rather slow. This was noticed when a careful fractional distillation of the enamine **3** was done, leading to a significant enrichment in the more volatile unconjugated form. In such cases, an nmr spectrum recorded 10 min after distillation has given ratios up to 92:8 in favor of the unconjugated form. The ratio of this solution, however, reached the equilibrium value of 75:25 within 3 days. This control of the equilibration has been performed on several other enamines but the equilibration of enamines with ring size combinations other than 6,6 appears to be much faster.

Table 1 represents the proportion of unconjugated form obtained for various enamines. Some of these compounds were already reported in the literature, as shown in Table 2. Part of the discrepancies observed may be due to different equi-

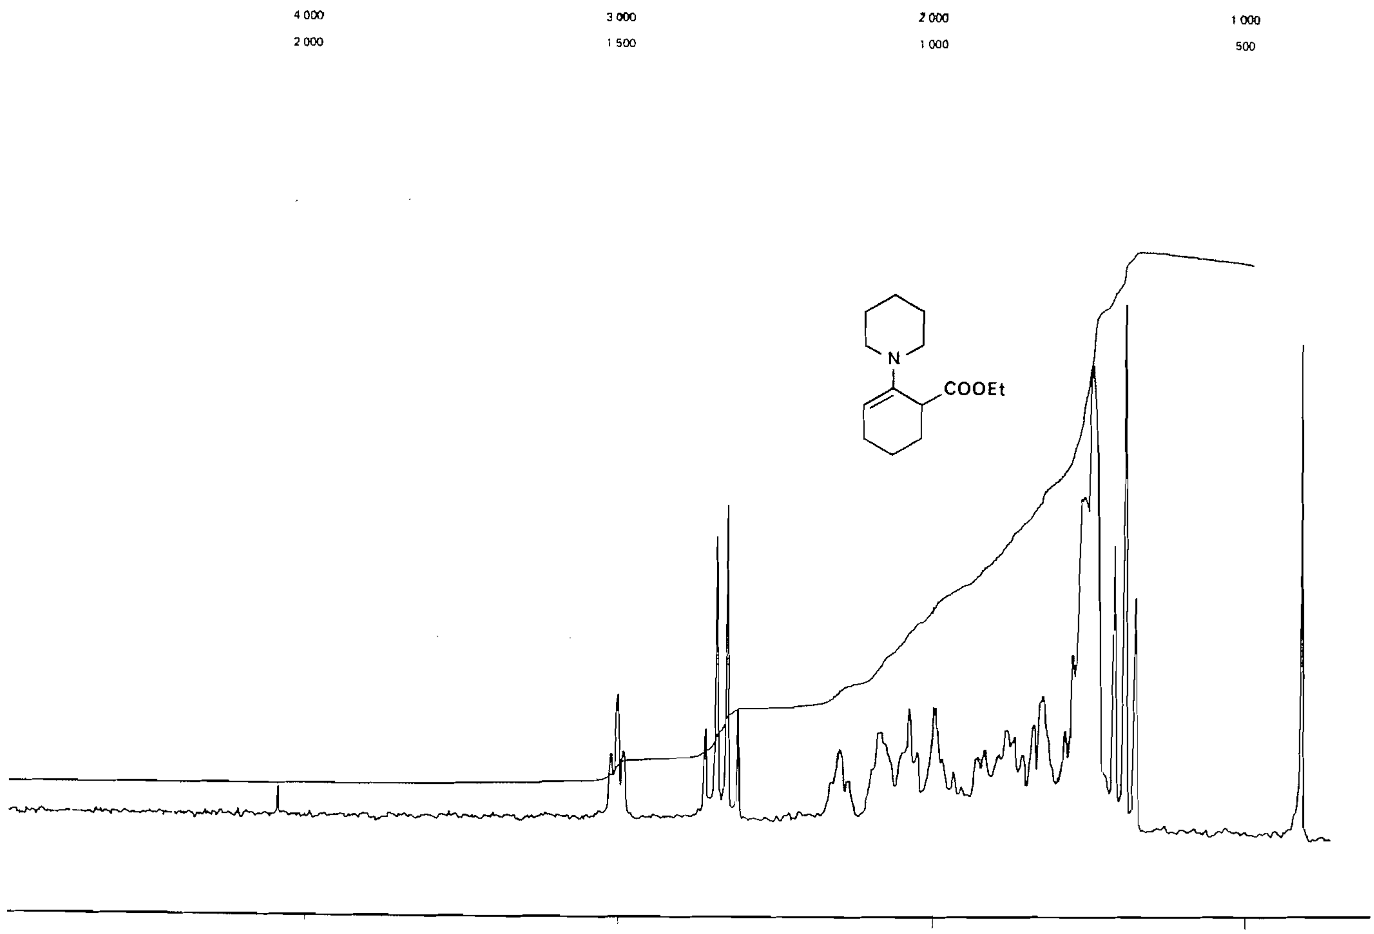

FIG. 2. [1]H nuclear magnetic resonance spectrum of compound **3**.

TABLE 1. Percentage of unconjugated form in β-ketoester enamines

libration conditions, since these conditions were not always specified in the literature.

In Table 1, one observes in the horizontal direction that the proportion of unconjugated form is smaller for a pyrrolidino-enamine than for a hexahydroazepino-enamine, which is smaller than that for a piperidino-enamine. The amine ring size therefore shows a 6 > 7 > 5 order for the tendency to unconjugation.

In the vertical direction, the effect of the β-ketoester ring size on the tendency towards unconjugation seems to be the same as that for the amine, the cyclopentanone showing less unconjugated form than the cyclohexanone, and the cycloheptanone being somewhere in between (only one example, however).

Within each ring size combination, the effect observed in varying the ester alkyl group is that a methyl ester shows less unconjugated form than the corresponding ethyl or isopropyl esters, which are about equal.

TABLE 2. β-Ketoester enamines reported in the literature

Enamine	% of unconjugated form (this work)	% of unconjugated form (literature)	Reference
1	12	0	25
		15	3
		30	2
3	75	73	3
		0[a]	25
8	5	10	3
9	<1	0	25
10	66	51	3

[a]The work reporting 0% of unconjugated form is based on ^{13}C nmr as only purity criterion, and the chemical shifts reported do not match ours.

TABLE 3. Time required for the formation of ethyl β-ketoester enamines (hours)

β-Ketoester ring	Amine ring 5	Amine ring 6	Amine ring 7
5	2	16	4
6	4.5	125	47
7	27	Very long[a]	Very long[a]

[a]Very slow reaction; only the competing β-ketoamide formation is observed.

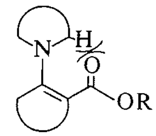
TABLE 4. Distance between O and H in the model and percentage of unconjugated form

Amine/β-ketoester ring sizes	O—H distance (Å)	% of unconjugated form
5/5	1.4	<1
5/6	1.4	12
6/5	0.4	<5
6/6	0.4	75

Discussion

In order to carry out a more systematic study of the effect of both ring sizes on the conjugated–unconjugated ratios, the preparation of all 9 possible ring size combinations using the most common 5-, 6-, and 7-membered rings was attempted. Unfortunately, the piperidino and hexahydroazepino enamines of ethyl 2-oxo cycloheptanecarboxylate (**16**) resisted all attempts of preparation by our method (1). Only starting material was recovered under normal conditions, and a higher reaction temperature resulted in the formation of β-ketoamide. Another method (15), using $TiCl_4$ as the dehydrating agent, also failed, although it has been used successfully for difficult cases with normal ketones. These results suggest that these two enamines probably cannot be prepared by a simple β-ketoester and amine dehydrative condensation, and that some more indirect route will be necessary.

This relative slowness of the 7-membered ring ketoesters to form the enamine is consistent with data from cycloheptanone enamines (16) as well as with the rest of our data. The time needed for the formation of the various enamines is shown in Table 3. As seen from the first column, the β-ketoester ring size affects the rate of reaction in the order 5 faster than 6, faster than 7. On the other hand, the first two rows show that the 5-membered ring amine gives faster reactions than the 7-membered ring analog, which is, this time, faster than the



SCHEME 2

E = CONHPh G = CH_3 ref. 5*b*

SCHEME 3

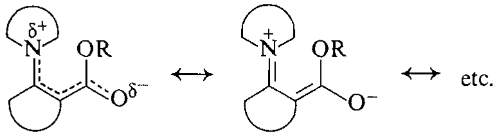
6-membered ring analog. From these trends, the two slowest reactions expected are precisely the two that did not work. The exact reason for this phenomenon is not known but one can safely speculate that it must be a combination of the difference in immonium ion energy and the rates of formation of the carbinolamines. Stork *et al.* (17) have observed that both steps are important in determining the rate of formation of simple ketone enamines, and our results clearly cannot be rationalized in terms of a single common rate-limiting step.

The equilibrium ratios of unconjugated and conjugated forms presented in Table 1 are rationalized by invoking three distinct factors.

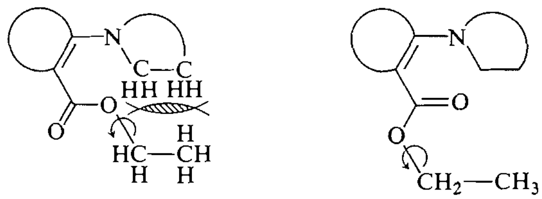
(1) The first factor, which explains the unexpected presence of the unconjugated form, is present in the conjugated form of all enamines. It is the high energy steric interaction ($A^{1,3}$ strain) that would be present in the planar form required for optimal conjugation. The energy forcing this molecule out of the perfect π-plane can be appreciated from Drieding models (Table 4), which show very large van der Waals interactions between the carbonyl O and the amine H's (Scheme 2). This strain forces at least one of the conjugating groups out of plane, making the resonance stabilization of the conjugated form so weak that its energy is of the same order of magnitude as that of the unconjugated form, thus making the relative abundances of the two forms about equal.

The steric, as opposed to electronic, nature of this interaction is supported by the very normal conjugation behavior of the closely related 6-alkyl systems (Scheme 3), which have a conjugating and a non-conjugating substituent in both α-positions of the enamine. In this case, where the enamine can experience steric hindrance in or out of conjugation, the conjugated form is the only one detected.

One could suggest that the magnitude of the steric interaction that would be encountered in the planar form could be related to the equilibrium ratio observed for the two forms. However, the O-to-H distances in Drieding models (Scheme 2, Table 4) and the unconjugated vs. conjugated form ratios do not correlate for all enamines, even when only the stereochemically well-defined 5- and 6-membered rings are considered. The problem arises when the 6/5 combination, expected to show mostly the unconjugated form from the short O-to-H distance in the model, actually exists in >95% in the conjugated form. The large equilibrium displacement from the expected "all



SCHEME 4



SCHEME 5

conjugated" situation brought about by steric interactions may still depend to a certain extent on the magnitude of that interaction. However, the strain is certainly avoided by an out-of-plane rotation of the amine ring[5] or of the carboxylate, and this type of strain relief is much less senstive to the exact size of the interacting groups, therefore contributing very little to the difference in energy among the various enamines.

(2) Since the first factor seems to affect all ring size combinations to a comparable extent, a second factor must be invoked to explain the differences observed upon ring size variation. It seems very plausible that the relative stability of the resonance hybrid (Scheme 4) is at the origin of the observed trends.[6] In fact, it is known (18) that the energy difference between exocyclic and endocyclic double bonds varies with the ring size. Thus, the number of double bonds exocyclic to unfavorable rings (6-membered, and 7-membered to a lesser extent) in the conjugated form (Scheme 4) could very well be related to the instability of that tautomer and therefore to its abundance at equilibrium. Table 5 illustrates this relationship. Assuming that an exocyclic double bond to a 7-membered ring is less stable than that to a 5-membered ring, but more than that to a 6-membered one, our results show an interesting correlation between the number of double bonds exocyclic to unfavorable rings and the position of the equilibrium between the two forms.

This order of exocyclic double bond "instability" with the 7-membered ring about halfway between the 5- and the 6-membered ones is not a very well established concept, and will be further discussed below.

(3) Finally, a third factor slightly alters the relative stabilities of the various alkyl esters. Our results indicate that the methyl esters have less tendency to unconjugation than the ethyl and isopropyl esters. The equivalence of the latter two alkyl groups suggests that the inductive effect of the alkyl group (3) cannot be the only cause of the greater instability of the ethyl and isopropyl conjugated forms. We therefore propose that the ethyl and isopropyl ester enamines, having the alkoxy chain one atom longer than the methyl ester, suffer a loss of rotational freedom (Scheme 5) in the electronically more stable *cis-s-trans* configuration (14) of the conjugated form, therefore slightly increasing the energy of that tautomer and thereby displacing the equilibrium towards the unconjugated form.

TABLE 5. Relation between the number of exocyclic double bonds and the percentage of unconjugated form in ethyl esters

Amine/β-ketoester ring sizes	% of unconjugated form	Number of exocyclic double bonds to various rings		
		5	7	6

Stability of double bonds exocyclic to 7-membered rings

The Brown generalization (18), despite early criticism, has been used successfully to explain many phenomena in organic chemistry. It specifies that exocyclic double bonds to 5-membered rings (5mr) are less unstable than double bonds to 6-membered rings (6mr). In the original paper, no mention of 7-membered rings (7mr) was made. Shortly thereafter, Brown and Ichikawa (19) published kinetic data of the borohydride reduction of many cycloalkanones, as well as kinetics for solvolysis of cycloalkyl chlorides and tosylates. The results, that 7mr and 5mr are solvolysed more rapidly or reduced more slowly than 6mr, were interpreted in terms of *I*-strain differences between the starting materials and the intermediates or the products. These results cannot, however, be considered as definitive concerning the position of 7mr relative to 6mr and 5mr in the relative exocyclic double bond instability, since other kinetic experiments have come to different conclusions. Thus, the exocyclic double bond instability order $6 \gg 7 > 5$ was obtained from the solvolysis of 1-alkyl cycloalkyl chlorides (20) and from the hydrolysis of lactams (21), whereas the oxygen exchange of cycloalkanones (22) gave an order of instability of $6 > 7 > 5$ in acid and $6 > 5 = 7$ in base.

Another way of evaluating the relative instability of the various exocyclic double bonds is based on measurements of the equilibrium ratio for compounds which can exist with a double bond exo- or endocyclic to the ring, as a function of the ring size. To our knowledge, there are two such cases reported in the literature, where the 7 mr are described. They are presented in eqs. [1] (ref. 23) and [2] (ref. 24).

[1] 
[2] 
In both cases, the exocyclic/endocyclic ratio follows the order $5 > 7 > 6$. This order of ratio is also the one given by our data, and we believe that it represents the relative tendency of the various rings to bear an exocyclic double bond. Since our

[5] Rotation about the N—C bond of the less hindered *trans* aliphatic vinylogous carbamates have $\Delta G^{\ddagger}$ of the order of 10–15 kcal/mol in refs. 14 and 26.

[6] The stability of the unconjugated forms should also be considered in determing the expected ratio of the two forms, but since the conjugation energy involved in the conjugated form is much larger, the energy difference can be assumed to be mostly dependent on the energy of the conjugated forms.

TABLE 6. ^{13}C nuclear magnetic resonance chemical shifts for β-ketoester enamines

[a]The carbon numbering system refers to Scheme 6. Chemical shifts labeled C are those attributed to the conjugated form, the ones labeled U belong to the unconjugated form.

data on 7mr consist mainly of hexahydroazepine enamines, however, it is not absolutely certain that a cyclopentanone–cyclohexanone–cycloheptanone enamine series would yield the same result. The only case we have seems, however, to indicate that, at least, no major change in the expected trend has occurred.

Conclusion

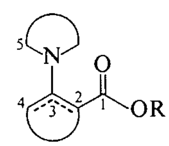
This study has shed some light on the somewhat unusual tendency towards unconjugation observed in certain β-ketoester enamines. Although the rationale of the phenomenon proposed by Colonna *et al.* (3) was basically correct, the present broader study has served to define more clearly the factors determining the proportions of the two tautomers of β-ketoester enamines at equilibrium. Three factors have been identified as influencing the position of this equilibrium. Firstly, all β-ketoester enamine conjugated forms suffer a large $A^{1,3}$ strain in their planar conformation, which reduces the conjugative stabilization and makes both tautomers of roughly equal energies. Secondly, the stabilization energy of the resonance hybrid has partial double bonds exocyclic to the rings, and the stability of exocyclic double bonds varies with the ring size. Finally, a hindered O-alkyl bond rotation in the conjugated form of esters larger than methyl slightly destabilizes them, thus increasing the amount of unconjugated form at the equilibrium.

Experimental

Melting points were recorded on a Büchi oil bath apparatus and are not corrected. Proton nmr spectra were recorded as $CDCl_3$ solutions from a Bruker WH90 or Bruker WP80, and ^{13}C nmr spectra were recorded on the Bruker WP80. A Perkin–Elmer 710B was used to obtain ir spectra. Low resolution mass spectra were recorded on a V.G. Micromass 12-12, and mass analyses were performed on an AEI MS-902 updated with a V.G. console and a V.G. System 2000 computer. A Varian model 1200 vapor phase chromatograph with a 3 mm × 3.5 m glass 3% OV-1/Chromosorb W AW-DMCS column and flame ionization detector was used for vpc analyses.

Synthesis of the starting β-ketoesters

Ethyl 2-oxo cyclopentanecarboxylate (**16**) is available from Aldrich. Methyl 2-oxo cyclohexanecarboxylate (**17**) was prepared in 92% yield as described by Ruest *et al.* (13). The other starting β-ketoesters were obtained following Ruest's procedure, but the ketone addition time and the reflux time were changed as described below.



SCHEME 6

Methyl 2-oxo cyclopentanecarboxylate (**18**) was obtained in 72% yield when the ketone was added over 60 min and the mixture refluxed for 30 min after the addition. Spectroscopic data match those reported in the literature (13).

Ethyl 2-oxo cyclohexanecarboxylate (**19**) was obtained in 88% yield. The ketone addition time was 75 min and the reflux time 30 min. Spectroscopic data are as described in the literature (26).

Isopropyl 2-oxo cyclohexanecarboxylate (**20**) was obtained in 78% yield. The ketone addition time was 210 min and the reflux time 90 min. Colorless liquid, bp 63–65°C under 0.55 Torr (1 Torr = 133.3 Pa); ir: 1730, 1710, 1640, 1600 cm^{-1}; nmr: 12.36 (s, 0.88H), 5.09 (septet, J = 6 Hz, 1H), 3.34 (t, 0.12H), 1.28 (d, J = 6 Hz, 6H); ms: 185, 143, 125.

Ethyl 2-oxo cycloheptanecarboxylate (**21**) was prepared in 90% yield with a ketone addition time of 60 min and a reflux time of 30 min. Spectroscopic data match those described in the literature (26).

Synthesis of the enamines

The following enamines were prepared as previously described (1): ethyl 2-(1-pyrrolidinyl) 1-cyclopentenecarboxylate (**9**), ethyl 2-(1-piperidinyl) 1-cyclopentenecarboxylate (**6**), ethyl 2-(1-pyrrolidinyl) 1-cyclohexenecarboxylate (**1**), ethyl 2-(1-piperidinyl) 1-cyclohexenecarboxylate (**3**), ethyl 2-(1-pyrrolidinyl) 1-cycloheptenecarboxylate (**15**), and methyl 2-(1-piperidinyl) 1- (and 2-)cyclohexenecarboxylate (**10**). The ^{13}C nmr data for the enamines are reported in Table 6, with the numbering system of Scheme 6.

Methyl 2-(1-pyrrolidinyl) 1-cyclopentenecarboxylate (**4**) was prepared by the method previously described (1), using 21 mmol of methyl 2-oxo cyclopentanecarboxylate (**18**) and pyrrolidine. A 1.85-g (45%) fraction distilled between 86 and 89°C under 3.3 × 10^{-4} Torr. On cooling to −15°C, this yellow oil solidified to a yellowish solid, mp 57–61°C (sealed tube); ir: 1670, 1560 cm^{-1}; nmr: 3.64 (s, 3H), 3.44 (t, 4H), 2.61 (t, J = 7 Hz, 4H); ms (EI): 195, 180, 164, 136.

Methyl 2-(1-piperidinyl) 1-cyclopentenecarboxylate (**5**) was prepared by the method previously described (1), using 19 mmol of methyl 2-oxo cyclopentanecarboxylate (**18**) and piperidine. A 2.21-g (56%) fraction of colorless liquid distilled between 76 and 80°C under 3.3 × 10^{-4} Torr; ir: 1660, 1550 cm^{-1}; nmr: 3.64 (s, 3H), 3.34 (s, 4H), 2.62 (t, J = 7 Hz) and 2.54 (t, J = 7 Hz, 4H), 1.74 (q, J = 7 Hz), and 1.61 (s, 8H); ms (EI): 209, 194, 178, 166, 150.

Ethyl 2-(1-hexahydroazepinyl) 1-cyclopentenecarboxylate (**7**) was prepared by the method previously described (1), using 17.7 mmol of ethyl 2-oxo cyclopentanecarboxylate (**16**) and hexahydroazepine. A 3.10-g (74%) fraction of yellowish liquid distilled between 101 and 110°C under 2×10^{-2} Torr; ir: 1728, 1675, 1560 cm^{-1}; nmr: 4.99 (t, <0.05H), 4.10 (q, J = 7 Hz, 2H), 3.48 (t, 4H), 2.63 (m, 4H), 1.74 (m, 6H), 1.57 (s, 4H), 1.26 (t, J = 7 Hz, 3H).

Methyl 2-(1-pyrrolidinyl) 1- (and 2-)cyclohexenecarboxylate (**8**) was prepared by the method previously described (1), using 19.2 mmol of methyl 2-oxo cyclohexanecarboxylate (**17**) and pyrrolidine. A 2.81-g (70%) fraction of colorless liquid distilled between 90 and 97°C under 8×10^{-4} Torr. On standing, this liquid solidified to a white solid, mp 69–79°C (sealed tube). ir: 1720, 1660, 1610, 1540 cm^{-1}; nmr: 4.50 (t, J = 3 Hz, 0.05H), 3.67 (s, 3H), 3.26 (t, 4H), 2.41 (t, 4H), 1.84 (m, 4H), 1.56 (m, 4H); ms (CI, CH_4): 210, 194, 178, 150. *Exact Mass* calcd.: 209.1415; found: 209.1401.

Isopropyl 2-(1-pyrrolidinyl) 1- (and 2-)cyclohexenecarboxylate (**2**) was prepared by the method previously described (1), using 16.3 mmol of isopropyl 2-oxo cyclohexanecarboxylate (**20**) and pyrrolidine. A 3.08-g (80%) fraction of colorless liquid distilled between 80 and 85°C under 9×10^{-4} Torr. On standing, this liquid solidified to a white solid, mp 51–57°C (sealed tube). ir: 1720, 1680, 1630, 1540 cm^{-1}; nmr:[7] 4.99 (septet, J = 6 Hz, 1H), 4.49 (t, J = 4 Hz, 0.17H), 3.24 (t, 3.3H), 2.96 (t, 0.7H), 2.40 (s, 4H), 1.23 (d, J = 6 Hz, 6H); ms (CI, CH_4): 238, 178, 150. *Exact Mass* calcd.: 237.1728; found: 237.1735.

Isopropyl 2-(1-piperidinyl) 1- (and 2-)cyclohexenecarboxylate (**11**) was prepared by the method previously described (1), using 16.3 mmol of isopropyl 2-oxo cyclohexanecarboxylate (**20**) and piperidine. A 2.68-g (72%) fraction of colorless liquid distilled between 75 and 77°C under 4.7×10^{-4} Torr; ir: 1720, 1640 cm^{-1}; nmr:[7] 5.02 (septet, J = 6 Hz, 1H), 4.88 (t, J = 4 Hz, 0.79H), 3.25 (t, 0.79H), 1.26 (d, J = 6 Hz), and 1.23 (d, J = 6 Hz, 6H); ms (CI, CH_4): 252, 192, 164. *Exact Mass* calcd.: 251.1848; found: 251.1885.

Methyl 2-(1-hexahydroazepinyl) 1- (and 2-)cyclohexenecarboxylate (**12**) was prepared by the method previously described (1), using 19.7 mmol of methyl 2-oxo cyclohexanecarboxylate (**17**) and hexahydroazepine. A 2.48-g (53%) fraction of colorless liquid distilled between 88 and 89°C under 8×10^{-4} Torr; ir: 1725, 1670, 1630, 1540 cm^{-1}; nmr:[7] 4.64 (t, J = 4 Hz, 0.32H), 3.70 (s) and 3.67 (s, 3H), 3.2 (m, 4H); ms (CI, CH_4): 238, 222, 206, 178. *Exact Mass* calcd.: 237.1728; found: 237.1711.

Ethyl 2-(1-hexahydroazepinyl) 1- (and 2-)cyclohexenecarboxylate (**13**) was prepared by the method previously described (1), using 17.7 mmol of ethyl 2-oxo cyclohexanecarboxylate (**19**) and hexahydroazepine. A 2.59-g (58%) fraction of yellowish liquid distilled between 76 and 80°C under 6×10^{-4} Torr; ir: 1720, 1660, 1620, 1540 cm^{-1}; nmr:[7] 4.63 (t, J = 4 Hz, 0.35H), 4.16 (q, J = 7 Hz) and 4.13 (q, J = 7 Hz, 2H), 3.17 (m, 4H), 1.26 (t, J = 7 Hz, 3H); ms (EI): 251, 236, 222, 207, 178. *Exact Mass* calcd.: 251.1885; found: 251.1908.

Isopropyl 2-(1-hexahydroazepinyl) 1- (and 2-)cyclohexenecarboxylate (**14**) was prepared by the method previously described (1), using 16.3 mmol of isopropyl 2-oxo cyclohexanecarboxylate (**20**) and hexahydroazepine. A 2.30-g (53%) fraction of yellowish liquid distilled between 82 and 90°C under 4.8×10^{-4} Torr; ir: 1720, 1670, 1630, 1550 cm^{-1}; nmr: 5.03 (septet, J = 6 Hz) and 4.99 (septet, J = 6 Hz, 1H), 4.63 (t, J = 4 Hz, 0.36H), 3.1 (m, 4.4H), 1.23 (d, J = 6 Hz, 6H); ms (CI, CH_4): 266, 206, 178. *Exact Mass* calcd.: 265.2041; found: 265.2046.

Proportions of enamine and vinylogous carbamate

The equilibrium proportions of unconjugated and conjugated forms in Table 1 were obtained from proton nmr spectra of $CDCl_3$ solutions at 23°C. The ir and ^{13}C nmr spectra used to secure the value obtained from this integration were also obtained from $CDCl_3$ at 23°C.

In order to make sure that the ratios observed are really representative of the equilibria under these conditions, random controls were performed in which an nmr tube containing the enamine solution under examination was sealed under vacuum and allowed to stand for several days at room temperature, in the dark. Under these conditions, constant ratios were obtained for all enamines tested. All equilibrations proved to be fast, except for that of alkyl 2-(1-piperidinyl) 1- (and 2-)cyclohexenecarboxylates **3**, **10**, and **11**, which were complete within 3 days.

[7] The conjugated–unconjugated ratio discrepancy between Table 1 and this spectrum is due to the fact that this sample was not allowed to equilibrate fully before recording the spectrum.

The photochemical reaction of purple membrane solubilized with Triton X-100 (T-BR) was investigated by low temperature spectrophotometry. The batho- and meta-intermediates of T-BR were observed to resemble bacteriorhodopsin in native purple membrane. Two photoproducts characteristic of the T-BR system were found, which were named the "490-nm complex" and the "380-nm complex". The 490-nm complex was in thermal equilibrium with T-BR in the dark. Cooling T-BR to low temperature favoured the 490-nm complex, which was photoinsensitive. On the other hand, the 380-nm complex was produced by warming the batho-intermediate and reverted to the original T-BR. The meta-intermediate of T-BR may possibly be in thermal equilibrium with the 380-nm complex. On the basis of the above results, the possible role of the membrane structure was discussed.

TATSUO IWASA, FUMIO TOKUNAGA et TÔRU YOSHIZAWA. Can. J. Chem. **63**, 1891 (1985).

Faisant appel à la spectrophotométrie à basse température, on a étudié la réaction photochimique de la membrane pourpre en solution dans le Triton X-100 (T-BR). Par example, on a observé les intermédiaires batho et méta du T-BR, comme la bactériorhodospine dans la membrane pourpre naturelle. On a trouvé deux produits photochimiques qui sont caractéristiques du système T-BR; on leur a donné les noms de "complexe 490 nm" et "complexe 380 nm". Dans l'obscurité, le complexe 490 nm est en équilibre thermique avec T-BR. Le refroidissement du T-BR favorise le complexe 490 nm qui est photosensible. Par ailleurs, le complexe 380 nm est obtenu en chauffant l'intermédiaire batho et il se retransforme en T-BR original. Il est possible que l'intermédiaire méta du T-BR soit en équilibre thermique avec le complexe 380 nm. À partir de ces résultats, on discute du rôle possible de la structure de la membrane.

Introduction

Bacteriorhodopsin (BR) is the sole protein in the purple membrane of *Halobacterium halobium* (1). Like animal rhodopsin, BR has a retinal as its chromophore which binds to the ϵ-amino group of lysine residue of the protein moiety through a Schiff base linkage (2, 3). The retinylidene chromophore of light-adapted BR (BR^L) is in an all-*trans* form. On absorption of light, BR^L (*trans*-bR) converts to several intermediates such as batho- (K), lumi- (L), and meta-*trans*-BR (M) and eventually reverts to the original pigment (4, 5). This photochemical cycle forms an electrochemical gradient of protons across the membrane (1).

According to an electron diffraction analysis, BR molecules form a trimer structure aligned in a hexagonal lattice with the lattice distance of about 62 Å (6). The retinylidene chromophores of BR in the trimer exhibit a typical circular dichroic (cd) band owing to an exciton coupling. The purple membrane solubilized with Triton X-100 (T-BR), however, displays no exciton cd band because of dissociation of the trimer structure, though it has a small positive cd band due to an intrinsic one (7, 8). This indicates that T-BR should be in monomeric form (9).

Now the question is whether or not such a lattice structure has any physiological meaning. To answer this question, we have tried to investigate the photoreaction of T-BR. Irradiation of T-BR produced photointermediates, similar to the batho- and meta-intermediates in purple membrane, but the meta-intermediate of T-BR was more stable than that in purple membrane. We also found two new molecular species named the "490-nm complex" and the "380-nm complex", which are characteristic of the T-BR system.

Materials and methods

The purple membrane was prepared from *Halobacterium halobium* R_1 by a slight modification (5) of the method described by Oesterhelt and Stoeckenius (10), and suspended in 10 m*M* phosphate buffer (pH 6.8). To solubilize the membrane, a Triton X-100 solution (10% v/v) was mixed with the membrane suspension to give a final concentration of 1% (v/v) (about 10^3 moles/mole BR). The mixture (16 μ*M* BR) was used for spectroscopic and cd measurements at room temperature. The cd spectra were measured with a recording spectropolarimeter (Jasco J-20). An optical cell containing the sample (10-mm light path; 1 OD) was placed close to the window of the detector to reduce the scattering of the measuring light.

For low temperature spectrophotometry, glycerol in a final concentration of 75% (v/v) was added to the mixture (160 μ*M* BR, 50−100 moles of Trixon X-100/mole BR) and a recording spectrophotometer (Hitachi 323, 320 or Shimadzu MPS 5000) was equipped with a cryostat described by Yoshizawa (11). The sample was placed in an optical cell composed of two quartz plates and a rubber ring (1- or 2-mm light path; 1 OD) under dim red light and incubated in the dark at least for 8 h to be fully dark-adapted. The temperature of the sample was monitored continuously with a copper vs. constantan thermocouple attached to the sample holder made of copper.

A 500-W xenon lamp (Ushio) was used as a light source for irradiation of the sample. The wavelength of the actinic light was selected by a combination of interference and (or) cut-off filters (Toshiba).

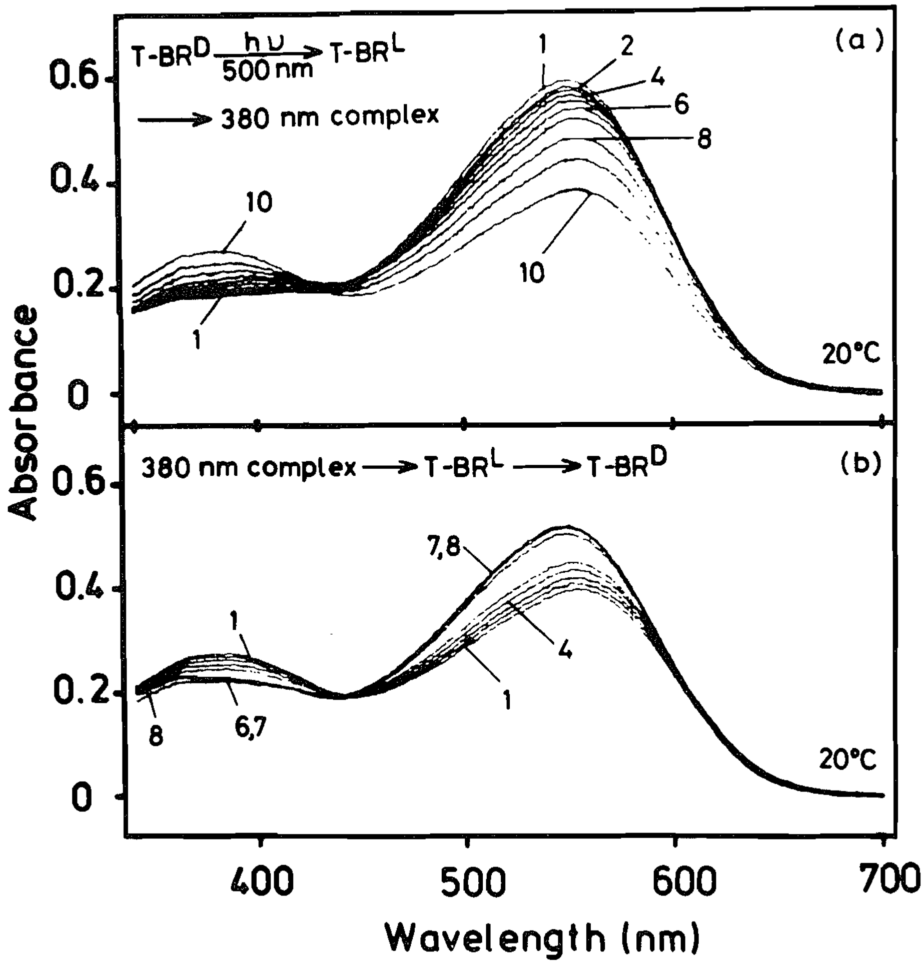

FIG. 1. (a) Photoreaction of T-BR^D at 20°C. Curve 1: T-BR^D (~10^3 moles of Triton X-100/mole BR). Curves 2–10: products of the successive irradiation of T-BR^D at 500 nm for 10, 10, 20, 40, 80, 160, 320, 640, and 1280 s, respectively. Curve 10 is a mixture of T-BR^L and the 380-nm complex. (b) Dark-reversion at 20°C. Curve 1: the mixture redrawn from curve 10 in (a). Curves 2–7: products of the successive dark incubation of the mixture. The spectra were measured at 5, 15, 40, 90, 585, and 955 min from the beginning of the dark incubation, respectively. Curve 8: a product of the dark incubation for more than 30 h.

The extraction of the chromophoric retinal from BR or T-BR was performed according to Tsuda *et al.*, (12). The sample (nearly 1 OD) was mixed with an equivolume of CH_2Cl_2 and the mixture was sonicated for a total of 5 min in an ice bath. After addition of 3 volumes of petroleum ether, 10–20 μL of the upper phase was injected to the hplc system (Jasco Tri-Rotar II with porous silica gel SS-05 column). All procedures were carried out at 0°C under dim red light and repeated 3 times.

Results

Photoreaction of dark-adapted T-BR and its thermal reversion; appearance of the "380-nm complex"

Upon addition of Triton X-100 to dark-adapted BR (BR^D, λ_{max}: 560 nm) the scattering of the measuring light decreased within 1 min, and the λ_{max} shifted to shorter wavelength (about 10 nm) within 7 min (data not shown), probably owing to some destruction of the membrane structure. The time course of these changes depends on the molecular ratio of Triton X-100 to BR molecules (13).

The dark-adapted T-BR (T-BR^D) thus obtained is shown in Fig. 1a as curve 1. An irradiation of T-BR^D with 500-nm light for 40 s at 20°C caused a bathochromic shift of the λ_{max} from 550 nm to 560 nm with a small decrease of absorbance at the λ_{max} (curves 2–4 in Fig. 1a). Since this spectral change can be regarded as that corresponding to the light-adaptation of the native BR, the product was designated as T-BR^L. Further irradiation with the same light caused a decrease of the absorbance around the λ_{max} and an increase in the wavelength region shorter than 440 nm, resulting in formation of a photoproduct having λ_{max} at 380 nm. Since the λ_{max} is located at a wavelength about 10 nm longer than that of free all-*trans* retinal, the chromophore seems to attach to the protein moiety. It is plausible that the chromophore may be located in the binding site, because the subsequent dark incubation slowly recovered the absorbance at 570 nm, with disappearance of the peak at 380 nm (Fig. 1b). Therefore, we designated the product as the "380-nm complex".

This slow "dark-reversion" is composed of two sequential reaction processes; one is the reversion from the 380-nm complex to T-BR^L and the other is the dark-adaptation of T-BR^L to T-BR^D. The reason is that the spectrum of the early stage in the spectral change (curve 3 – curve 1 in Fig. 1b) was similar in shape to that between the 380-nm complex and T-BR^L (curve 10 – curve 7 in Fig. 1a), indicating that the 380-nm complex reverted to T-BR^L. Also, the difference spectrum of the later stage (curve 7 – curve 4 in Fig. 1b) displayed a different shape from that of the early stage; the former showed the maximum in the shorter wavelength region and a smaller ratio of absorb-

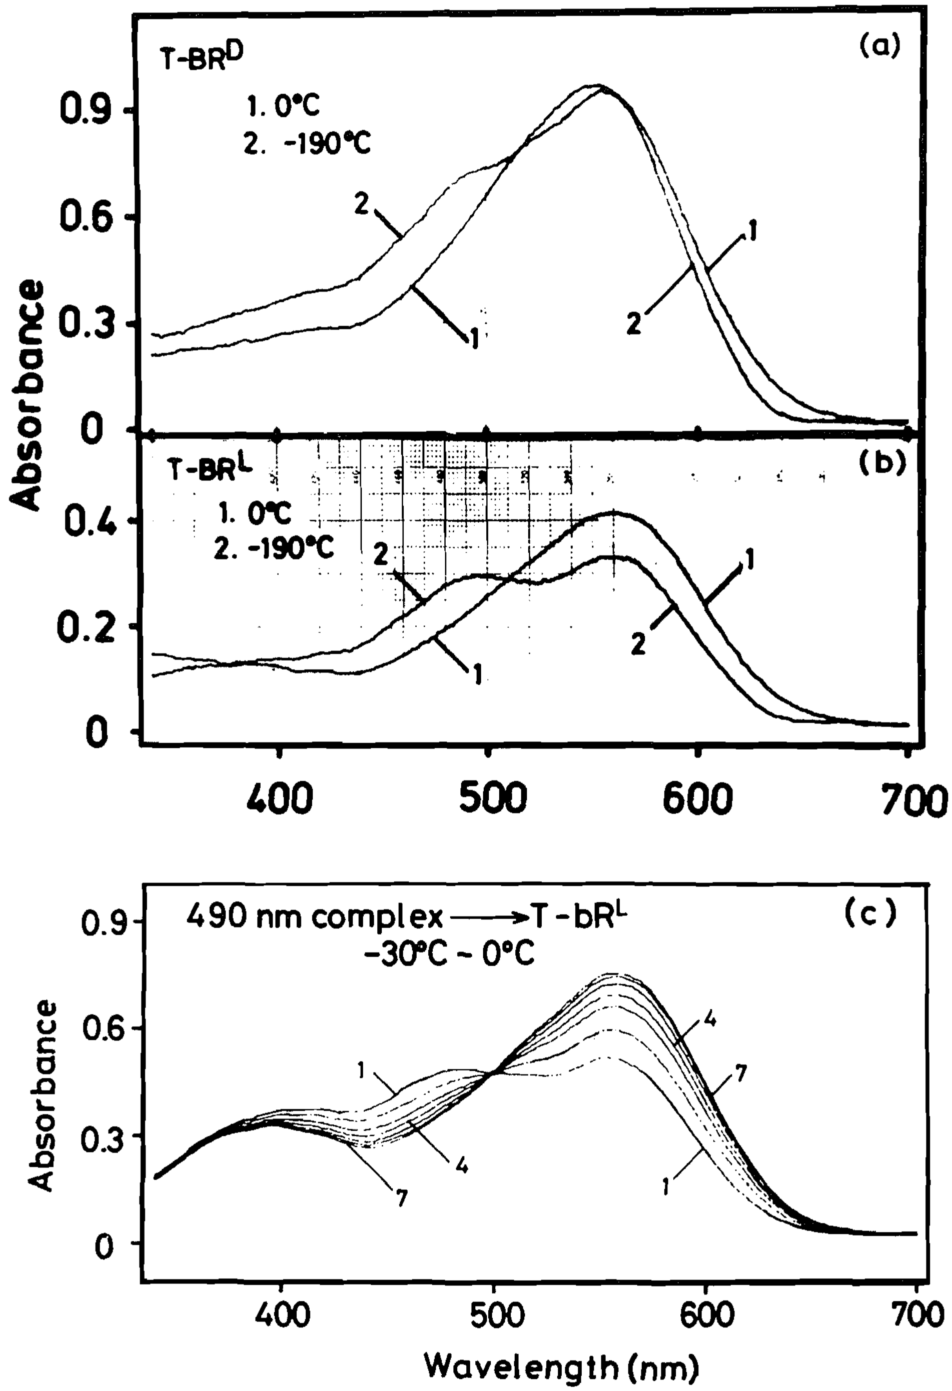

FIG. 2. Cooling effect on spectra of T-BR^D and T-BR^L. (a) T-BR^D (~10^3 moles of Triton X-100/mole BR). Curve 1: 0°C. Curve 2: −190°C. (b) T-BR^L (~10^3 moles of Triton X-100/mole BR). Curve 1: 0°C. Curve 2: −190°C. (c) Spectral change of T-BR^L on warming from −190°C to 0°C. Curves 1−7 were measured at −30, −25, −20, −15, −10, −5, and 0°C, respectively.

ance between the maximum and minimum than the latter. In addition, the semi-log plot of the absorbance change at 550 nm against the incubation time did not display a single exponential curve but, rather, the kinetics composed of two sequential thermal reactions, i.e. dark-reversion of the 380-nm complex to T-BR^L and dark-adaptation of T-BR^L to T-BR^D. The absorption spectrum of the final product of the dark-reversion (curve 8 in Fig. 1b) was smaller in absorbance than that of the initial one (curve 1 in Fig. 1a), presumably due to the destruction of the pigment during the slow dark-reversion.

Cooling effects on spectra of T-BR^D and T-BR^L; appearance of the "490-nm complex"

On cooling T-BR^D to −190°C, a shoulder around 490 nm appeared in the absorption spectrum (Fig. 2a). Upon warming to 0°C in the dark, the spectrum recovered its original shape. This spectral change was perfectly reversible. A similar experiment was performed on T-BR^L which had been prepared by irradiating T-BR^D with 500-nm light for 5 min at 0°C (Fig. 2b). It should be noted that the shoulder of T-BR^L at −190°C was more prominent than that of T-BR^D (Figs. 2a and b). On

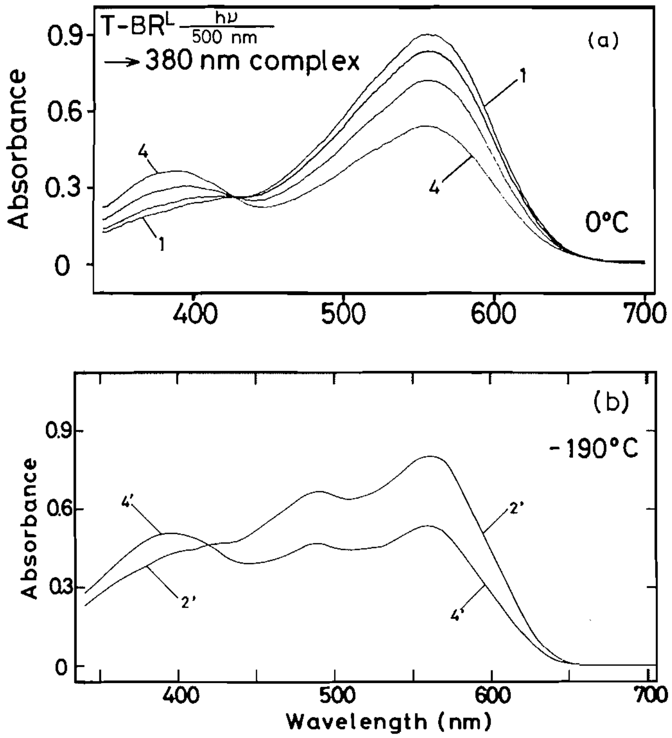

FIG. 3. Absorption spectra of mixtures composed of T-BR^L, 380-nm complex, and 490-nm complex. (a) Formation of the 380-nm complex by irradiation of T-BR^L ($\sim 10^3$ moles of Triton X-100/mole BR) (curve 1) with 500-nm light for 17, 40, and 70 min (curves 2−4), respectively. (b) Low temperature spectra of the products. Each product was cooled to −190°C and then spectra were measured. Curves 2′ and 4′ show low temperature spectra of the products designated as curves 2 and 4 in (a), respectively.

warming T-BR^L above −30°C, the absorbance at the shoulder decreased, with formation of an isosbestic point at 505 nm (Fig. 2c). This result indicates the presence of a thermal equilibrium between T-BR^L and a molecular species named the "490-nm complex"; low temperatures favoured the 490-nm complex. A similar spectral change was observed in warming T-BR^D from −190°C. The amount of 490-nm complex in the light-adapted sample was more than in dark-adapted one. The amount of 490-nm complex on cooling depends on the molar ratio of Triton X-100 to BR; the larger the ratio, the more 490-nm complex is formed.

A possibility that the 380-nm complex might convert to the 490-nm complex on cooling was excluded by the following experiment: T-BR^L was irradiated at 0°C for given periods in order to prepare the sample containing different amounts of 380-nm complex (Fig. 3a), and then their spectra were measured at −190°C. As shown in Fig. 3b, the absorption band characteristic of the 380-nm complex shifted to around 400 nm at −190°C. Thus it is clear that the 380-nm complex can not convert to the 490-nm complex on cooling.

Photoreactions at −190°C; formation of batho-intermediates

The photoreaction of T-BR was first examined by use of the sample shown in Figs. 2 and 3. The spectral changes of T-BR^L in the sample at −190°C were very small because of the large amount of 490-nm complex, which was photo-insensitive or less photosensitive (see below), present in the sample. In order to reduce the amount of 490-nm complex in the sample, a lesser amount of Triton X-100 was added to the purple membrane suspension (about 50 moles of Triton X-100/mole BR). As shown in Figs. 4 and 5, the amount of 490-nm complex in the sample was about 1/4 of that in Figs. 2 and 3. The shoulder around 520 nm seen in Figs. 4 and 5 was due to non-flatness of the baseline. It was confirmed that the shape of spectral change of photoreactions of T-BR at −190°C was independent of the molar ratio of Triton X-100 to BR, except for the amount of the spectral change.

Now the sample containing T-BR^D was irradiated at −190°C with light at 500 nm (curve 1 in Fig. 4a). The spectrum shifted to longer wavelengths. The absorbances in the range between 410 nm and 563 nm decreased and simultaneously those at longer wavelengths than 563 nm increased (curves 2−8 in Fig. 4a), indicating formation of a bathochromic intermediate (T-batho-BR^D). A prolonged irradiation yielded a photosteady-state mixture (curves 7 and 8 in Fig. 4a) designated as T-state^D. Then, another irradiation of T-state^D with red light at 718 nm, which was absorbed by mainly T-batho-BR^D, caused it to revert to T-BR^D (Fig. 4b). During the irradiation, the curve-intersection point of the spectra shifted from 585 nm to 550 nm (curves 1−10). On further irradiation with light of wavelengths longer than 640 nm (>640 nm), all the T-batho-BR^D reverted to the original T-BR^D (curve 11).

In the case of irradiation of BR^D in purple membrane at −190°C, two kinds of batho-intermediates, namely batho-*trans*-BR and batho-13-*cis*-BR, were formed (14), because BR^D in purple membrane is an equimolar mixture of *trans*-BR and 13-*cis*-BR (15, 16). The same was true in the T-BR^D system, because the hplc analysis of retinal isomers extracted from T-BR^D revealed that T-BR^D was a mixture of T-BR^t (51.3 ± 3%) and T-BR^{13} (48.7 ± 3%), though the spectral change did not display a clear distinction between the photoreaction due to *trans*-pigment (T-BR^t) and that due to 13-*cis*-pigment (T-BR^{13}).

In order to prepare T-BR^L, the T-BR^D (curve 11 in Fig. 4b) was warmed to 0°C and then irradiated with 500-nm light for 5 min. After cooling it to −190°C, the absorption spectrum was measured, which displayed λ_{max} at 568 nm and a shoulder due to the 490-nm complex (curve 1 in Fig. 5a). Irradiation of the preparation with 500-nm light caused a bathochromic shift with an isosbestic point at 584 nm (curves 2−7 in Fig. 5a), and finally reached a photosteady state, designated as T-state^L (curves 6 and 7 in Fig. 5a). Irradiation of T-state^L (curve 1 in Fig. 5b) with light at 718 nm caused a photoreversion to T-BR^L (curves 2−7 in Fig. 5b). For the complete reversion of the batho products, another irradiation with light of shorter wavelengths (>640 nm) was required. The spectrum of the final photoproduct of the irradiation (curve 8 in Fig. 5b) was in good agreement with the original T-BR^L (curve 1 in Fig. 5a). Thus, T-BR^L showed a photoreversible change at −190°C, like BR^L in purple membrane. The curve-intersection points among a series of spectra, however, shifted from 590 nm to 570 nm (Fig. 5b), suggesting that T-BR^L would be a mixture of T-BR^t and T-BR^{13}. In fact, the hplc analysis of retinal isomers extracted from T-BR^L demonstrated that the amount of 13-*cis* retinal (13.0 ± 2% of total amount) in T-BR^L was pretty large in comparison with that in BR^L (8.9 ± 2% of the total amount).

A question whether or not the 490-nm complex might be photosensitive was examined. The preparations containing the 490-nm complex ($\sim 10^3$ or ~ 50 moles of Triton X-100/mole BR) were irradiated at −190°C with various lights of wavelengths shorter than 500 nm. Their spectral changes due to the photoreactions were calculated, and were similar to

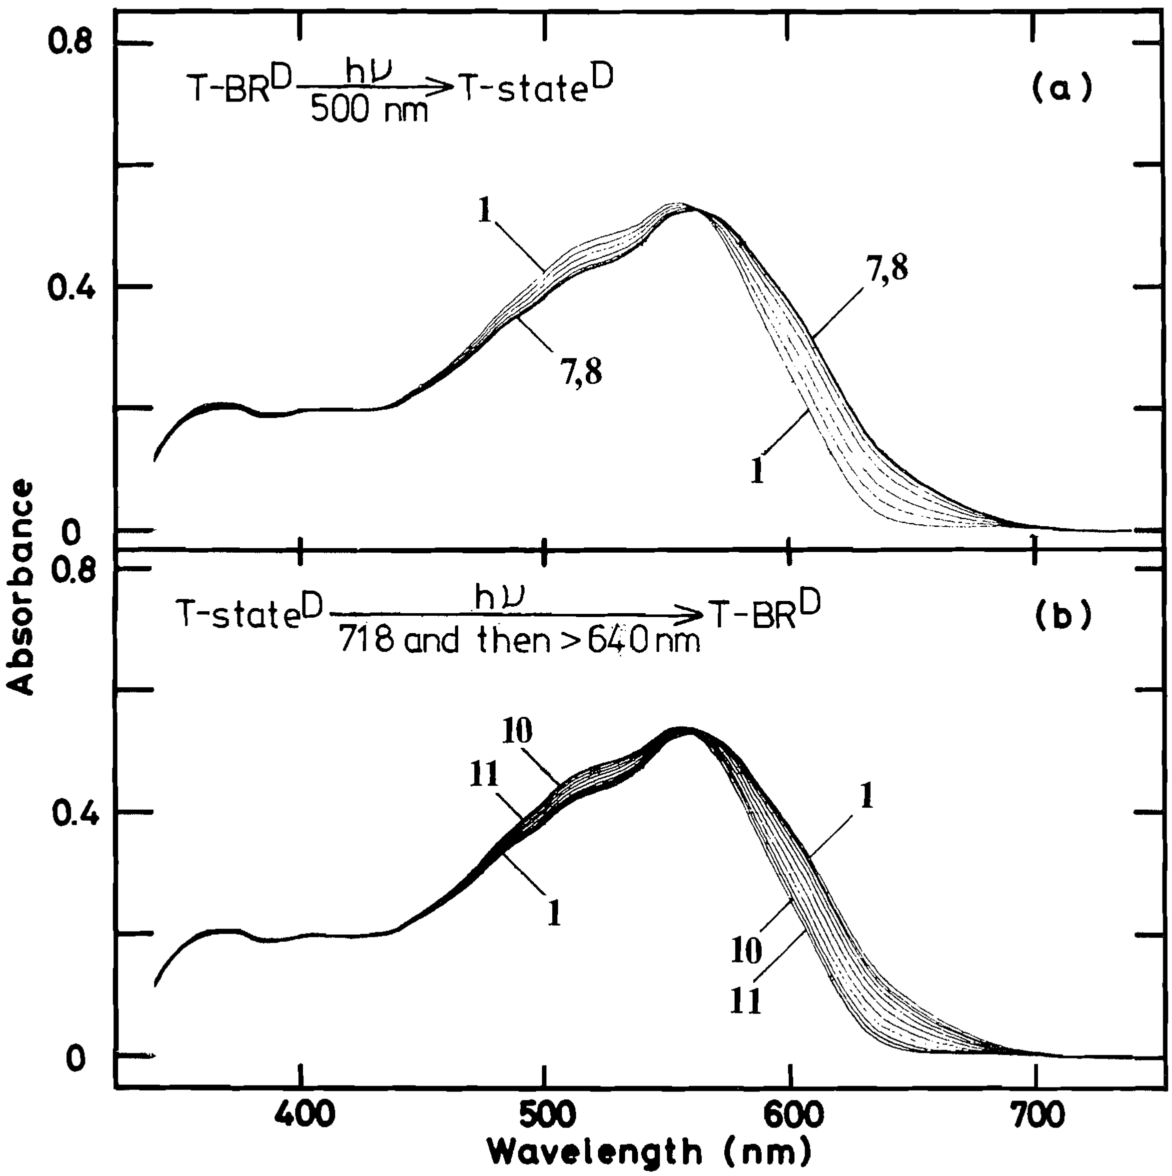

FIG. 4. Photoreaction of T-BR^D at −190°C. (a) Curve 1: T-BR^D (~50 moles of Triton X-100/mole BR) at −190°C. Curves 2−8: products of the successive irradiations of T-BR^D with 500-nm light for 5, 5, 10, 20, 40, 80, and 160 s, respectively. Curves 7 and 8 correspond to photosteady-state mixture designated as T-state^D. (b) Curve 1: T-state^D redrawn from curve 8 in (a). Curves 2−10: products of the successive irradiations of T-state^D with light at 718 nm for 10, 10, 20, 40, 80, 160, 320, 640, and 1280 s, respectively. Curve 11 was a product of further irradiation with red light (>640 nm) for 5 min, and in good agreement with curve 1 in (a).

those shown in Fig. 5. This fact indicates that the 490-nm complex at −190°C is photo-insensitive or has very low photosensitivity.

Photoreaction at −50°C; formation of the meta-intermediate

Irradiation of T-BR^L at −50°C with orange light (>580 nm) yielded a meta-like intermediate designated as T-meta-BR^i, which was stable at −50°C in the dark; a prolonged irradiation converted all the T-BR^L into T-meta-BR^i (curve 1 in Fig. 6a). The formation of T-meta-BR^i is composed of fast and slow phases. These results indicate that at −50°C the 490-nm complex slowly converted to T-BR^L in the dark. It should be noted that meta-BR^i (λ_{max}: 418 nm) in the purple membrane is not stable at −50°C under the same conditions (10 m*M* phosphate buffer, pH 6.8) (5).

The thermal conversion of T-meta-BR^i consisted of three elementary steps (Fig. 6). Warming from −50°C to −45°C decreased the absorbances around 410 nm and simultaneously increased those around 565 nm, forming an isosbestic point at 458 nm (curves 1−3 in Fig. 6a and circles in Fig. 6b). The difference spectrum between curves 3 and 1 is similar to that between meta-BR^i and BR^i (5) except for the fact that the wavelengths of the maximum and minimum in the difference spectrum and the isosbestic point are shorter by about 10 nm than those in the BR^i system. This shift is comparable to the shift of λ_{max} on addition of Triton X-100. Therefore, this spectral change should be regarded as a decay of T-meta-BR^i to T-BR^i.

On warming from −45°C to −35°C the absorbance around 380 nm decreased and that around 565 nm increased (curves 3−5 in Fig. 6a and triangles in Fig. 6b). The difference spectrum of this spectral change was similar in shape to that between the 380-nm complex and T-BR^L shown in Fig. 1b. In both spectra the isosbestic points were located at about 445 nm,

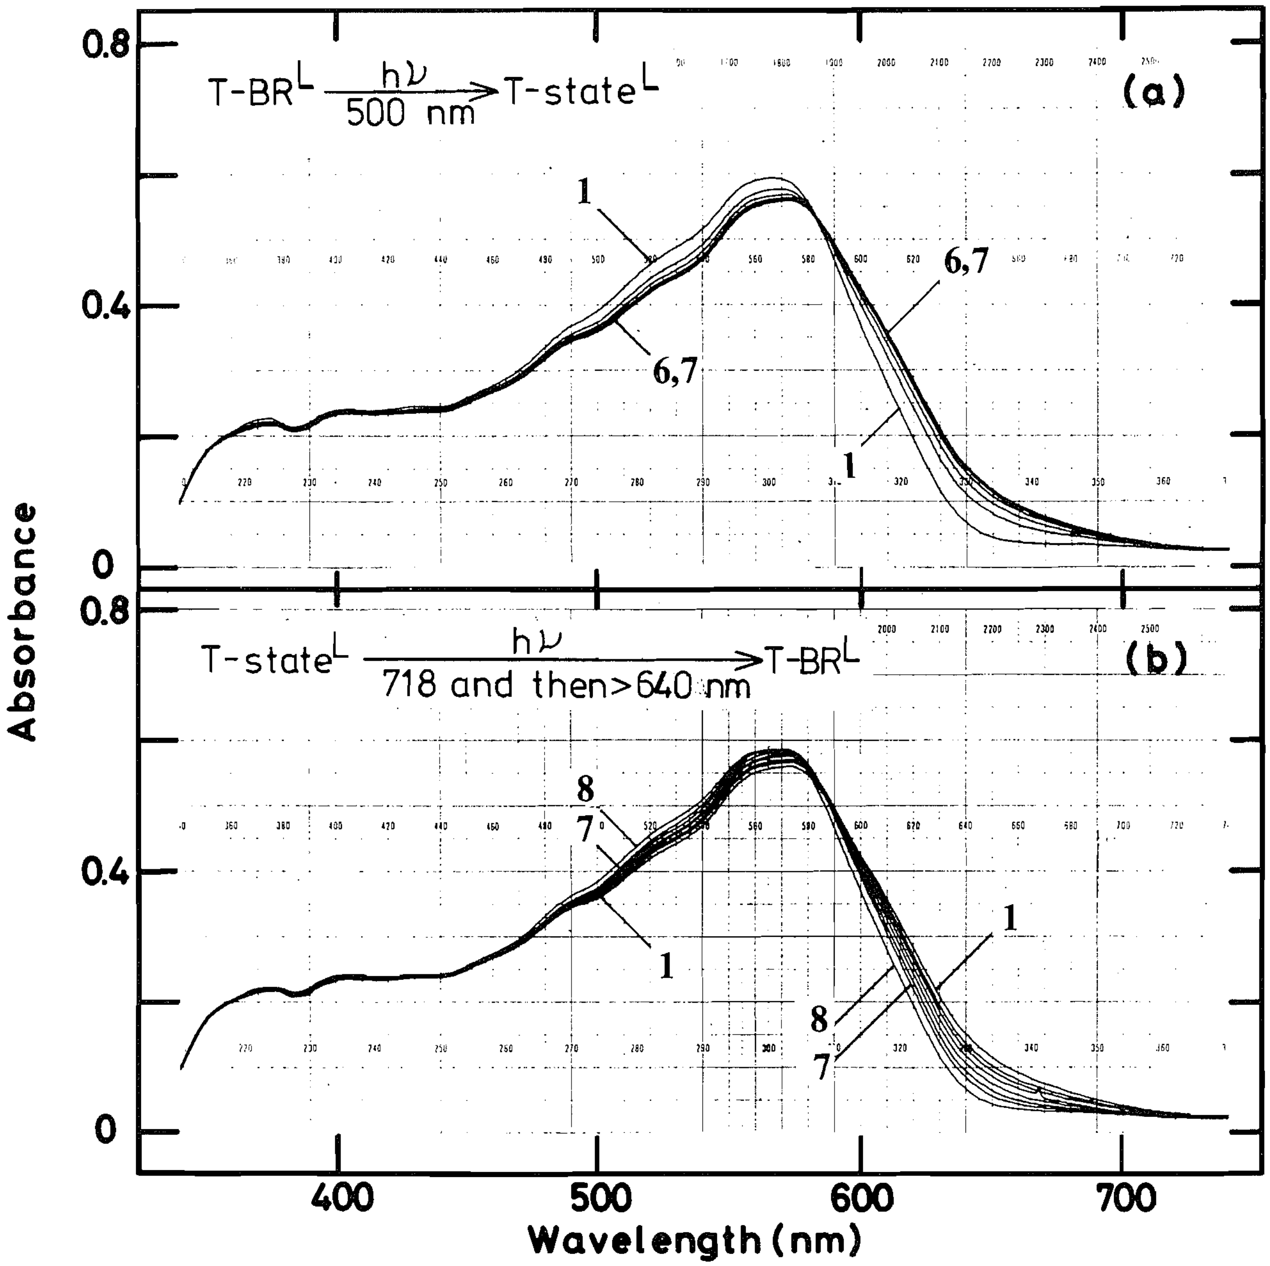

FIG. 5. The photoreaction of T-BR^L at −190°C. (a) Curve 1: T-BR^L (~50 moles of Triton X-100/mole BR) at −190°C. Curves 2−7: products of the successive irradiations of T-BR^L with 500-nm light for 10, 10, 15, 20, 40, and 80 s, respectively. Curves 6 and 7 represent a photosteady-state mixture designated as T-state^L. (b) Curve 1: T-state^L redrawn from curve 7 in (a). Curves 2−7: products of the successive irradiations of T-state^L (curve 1) with 718-nm light for 10, 10, 20, 40, 80, and 160 s, respectively. Curve 8: a product of the further irradiation with red light (>640 nm) for 5 min. Curve 8 is in good agreement with curve 1 in (a).

and the ratios in absorbance between the difference maximum and minimum were 0.37. These facts indicate that the spectral change may correspond to a conversion of the 380-nm complex to T-BR^L. It is not clear yet whether the 380-nm complex may be formed from T-meta-BR^l or from other earlier intermediates.

Above −25°C, the absorbance around 460 nm decreased and that around 565 nm increased (curves 7−12 in Fig. 6a and squares in Fig. 6b). This spectral change should be due to the decay of the 490-nm complex, because both the shape of the spectral change and the temperature range in which it was observed were in good agreement with those of the change of 490-nm complx to T-BR^L (Fig. 2c).

Discussion

We have described several properties of the T-BR system different from the BR system: the formation of the 490-nm and 380-nm complexes, and the stabilization of meta-intermediates. Needless to say, these differences can be attributed to the difference in the environment around the BR molecule. BR molecules in the purple membrane are in the lattice structure and form a "trimer" structure. The molecules in the trimer interact with each other as demonstrated in the energy transfer (17), the exciton cd band (7, 8), and the rate of dark-adaptation (18). According to the cd measurements, the solubilization of purple membrane with a detergent causes the lattice structure to dissociate, resulting in loss of the interaction among the mole-

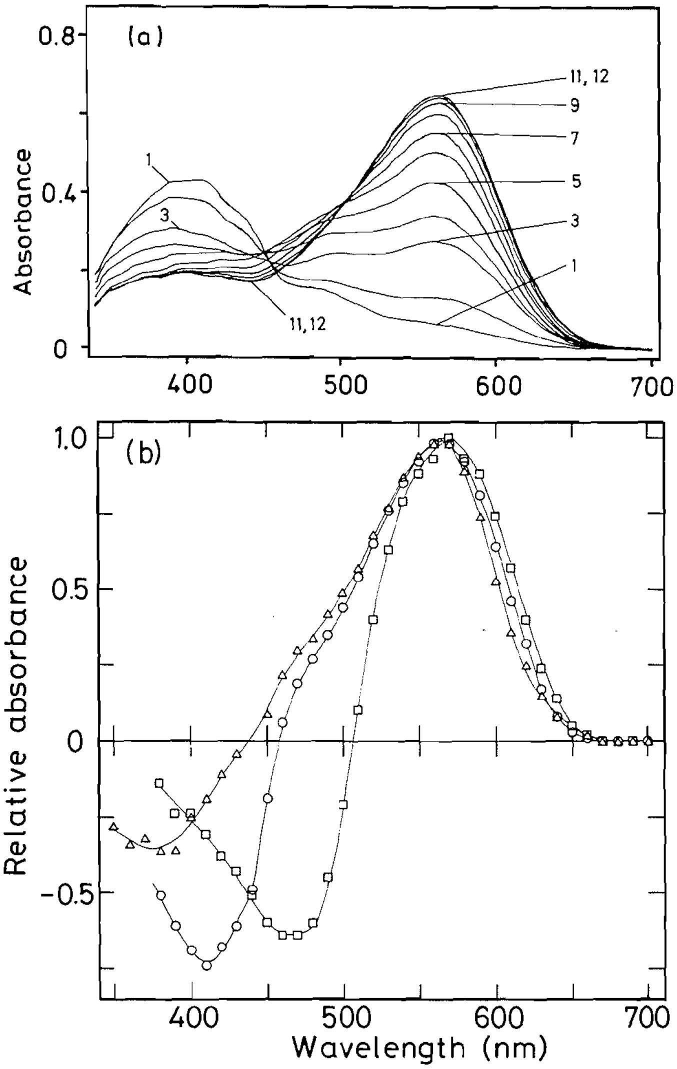

FIG. 6. (a) The thermal decay of T-meta-BR^t obtained by irradiation of T-BR^L at −50°C for 70 min with orange light (>580 nm). T-meta-BR^t was gradually warmed in the dark. The spectra were measured at −50, −48, −45°C (curves 1, 2, and 3) and then at intervals of 5°C (curves 4−12). (b) Circles (○—○): the difference spectrum between the spectra measured at −45 and −50°C (3 − 1). Triangles (▲—▲): the difference spectrum between −35 and −45°C (5 − 3). Squares (■—■): the difference spectrum between 0 and −25°C (12 − 7).

cules. An ultra-centrifugation experiment (9) showed that BR molecules in 2% Triton X-100 solution, probably in a micelle composed of Triton X-100 and several lipids, were in a monomeric form. Thus, the properties of T-BR different from the BR system mentioned above (see Fig. 7) should be attributed to some differences in lipid−protein, protein−protein, and detergent−protein interactions.

The 380-nm complex

The irradiation of T-BR brought an increase of absorbance at 380 nm (refs. 18, 19, and the present work). If the formation of the 380-nm complex was an indication of destruction of the Schiff base linkage between retinal and the ε-amino group of the lysine residue, the dark recovery would be a regeneration of T-BR from all-*trans* retinal and bacterioopsin. In order to test this possibility, all-*trans* retinal was mixed with bacterioopsin in 1% Triton X-100 solution. No pigment formation was observed. Thus, the 380-nm complex is a product formed not

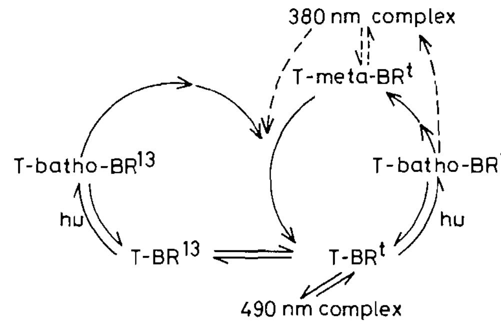

FIG. 7. A reaction cycle of T-BR. *Trans*-BR and 13-*cis*-BR in Triton X-100 solution, designated as T-BR^t and T-BR^{13}, respectively, formed batho-intermediates, i.e., T-batho-BR^t and T-batho-BR^{13}. The *meta*-intermediate was formed only from T-BR^t. Whether or not a lumi-like intermediate was formed has not yet been clarified, because the spectral complexity due to formation of the 490-nm complex. The 490-nm and 380-nm complexes are both characteristic of the T-BR photocycle.

by destruction of the Schiff base linkage, but by deprotonation of the Schiff base by some change of the microenvironment around the chromophore.

The 490-nm complex

The 490-nm complex was formed only by cooling to a temperature lower than 0°C. Its amount increased with decrease of temperature and reached a steady level at −40°C. The spectral change on cooling may possibly be due to change of pK value of a certain charged group or the phase transition of the glycerol−Triton−lipid micelle containing BR molecules.

We did not observe a molecular species similar to the 490-nm complex at 25°C in the pH range between 2.96 and 10.65. Below pH 4 a decrease of absorbance at λ_{max}, an increase at longer wavelengths (~650 nm), and an increase at shorter wavelengths (~360 nm) were observed. At pH higher than 9, a decrease of the absorbance at λ_{max} and an increase of that around 365 nm were observed. In the case of BR in purple membrane, an increase of absorbance around 470 nm can be observed in the pH region higher than 11, due to deprotonation of the Schiff base (20). However, such a molecular species having λ_{max} around 470 nm has never been observed in pH titration experiments of Triton-treated BR. According to Lozier *et al.* (21), BR in a phospholipid vesicle at pH 8.6 displays the λ_{max} at 480 nm. Such a blue shift of the λ_{max} has never been observed in any cell envelope vesicles. BR molecules in a phospholipid vesicle do not exhibit the exciton cd band, because BR molecules become monomeric in a phospholipid vesicle under these conditions. Because of similarities between the 480-nm absorbing species and the 490-nm complex, in conditions for their formation and their absorption maxima, it is indicated that both pigments may have a retinylidene chromophore in a similar microenvironment.

A few years ago, we reported the formation of a molecular species absorbing around 500 nm which was produced from acid-induced species with orange light irradiation (22). The isomeric form of the retinal extracted from this product was 9-*cis* retinal. When 9-*cis* retinal was mixed with bacterioopsin under neutral pH conditions, no formation of the pigment was observed, as reported by Oesterhelt and Schuhmann (23). It is not plausible that the 490-nm complex has 9-*cis* retinal as its chromophore. Further information about the structure of these molecular species would give some clue to explaining the coloration of BR.

Another noteworthy point is that the amount of the 490-nm complex formed from T-BR^{L} was larger than that from T-BR^{D} (Fig. 2). In the case of BR in the purple membrane, BR^{L} has only all-*trans* retinal as its chromophore but BR^{D} has both all-*trans* and 13-*cis* retinals in equimolar amount (15, 16). The present experiment showed that the ratios of 13-*cis* to all-*trans* retinals in T-BR^{L} and T-BR^{D} were 13.0 ± 2/87.0 ± 2 and 51.3 ± 3/48.7 ± 3, respectively. It should be noted that a part of T-BR^{L} has 13-*cis* retinal as its chromophore. The existence of 13-*cis* retinal in T-BR^{L} has already been reported by Casadio and Stoeckenius (18), but their result (38 ± 2% of the total amount) is much larger than ours. It is not yet clear why they are so different from each other. In any case, the species having all-*trans* retinal (T-BR^{t}) is more abundant in T-BR^{L} than in T-BR^{D}. Thus it may be safe to say that the 490-nm complex comes from T-BR^{t} rather than T-BR^{13}.

Stabilization of the meta-intermediate

The meta-intermediate was stabilized under several conditions: Oesterhelt and Hess (24) found that the 412-nm complex was easily formed by irradiating BR suspended in about 3.6 *M* NaCl solution saturated with ether, and mentioned that the ether could stabilize the 412-nm complex. Becher and Ebrey (25) reported that the high salt and high pH conditions (1 *M* NaCl, pH 10) could stabilize the meta-intermediate. Yoshida *et al.* (26) showed that guanidine hydrochloride prolonged the decay time of the meta-intermediate, and this effect depended on the concentration of guanidine hydrochloride. Even 8 *M* solution did not saturate this effect. Recently we investigated the photoreaction of tyrosine-iodinated BR at low temperature, and found meta-intermediates of tyrosine-iodinated BR stable at −65°C (27). As shown in the present paper and by Lam and Packer (28), the meta-intermediate also is more stable in Triton X-100 solution than under native conditions. The stabilization effects of guanidine hydrochloride, high salt − high pH conditions, and iodination of tyrosine on the meta-intermediate were probably due to change in the interaction between the retinylidene chromophore and charges on the bacterioopsin. This idea may be supported by the fact that the stabilization effect was also observed in replacement of guanidine hydrochloride by arginine hydrochloride. The effect resulting from ether or Triton X-100, however, was not explained clearly, because structural information about BR in both solutions is limited. The tertiary structure of the protein was changed with Triton X-100, as shown in the cd spectrum, and probably the secondary structure would be changed. These structural changes would result in charge replacement which might stabilize the meta-intermediate. Whether or not such an explanation can be applied to the effect needs further investigation, in order to obtain detailed information on the structure of the meta-intermediate and the protein moiety in such a micelle structure or organic solvent.

The investigation of solubilized BR revealed that the destruction of the lattice structure resulted in formation of by-products of the photoreaction cycle of BR, such as the 490-nm and 380-nm complexes; the former is probably formed from T-BR^{t}, and the latter slowly reverts to the original pigment. It seems probable that the lattice structure can stabilize the BR^{t} by preventing it from formation of by-products and can play a role in rapid rotation of the photoreaction cycle. Of course the possibility that the results mentioned above may be due to direct interaction between Triton X-100 molecule and BR rather than destruction of the lattice structure can not be excluded. Further investigation of the structure of BR in the micelle must be made. Such investigation may provide important information regarding structure and function of membrane proteins extracted with the aid of detergents.

It is shown that the concept of electron pairs may be introduced in conducting quasi-one-dimensional systems with electron delocalization such as $(CH)_x$ and the stacks of molecule-donors and acceptors of electrons TMTSF, TTT, TCNQ, etc. The introduction of pairing proves to be useful and electronic structure and electronic processes can be easily visualized. The two causative factors in the appearance of pairs in a many-electron system with repulsion are pointed out. The first one is the electron Fermi-statistics that does not allow a spatial region to be occupied by more than two electrons. The second one is the interaction of electrons with a soft lattice. The first of these factors is important at large and intermediate electron densities $\rho \gtrsim 1$, the second one dominates at $\rho \ll 1$. The kink-type excitation parameters in $(CH)_x$ are considered with a non-linear potential obtained in an electron-pair approach for the many-electron wave function of $(CH)_x$.

ALEXANDR S. DAVYDOV et IVAN I. UKRAINSKII. Can. J. Chem. **63**, 1899 (1985).

On démontre que le concept des paires d'électrons peut être introduit dans les systèmes conducteurs quasi-unidimensionnels avec une délocalisation électronique, comme $(CH)_x$, ou avec des empilements des molécules donneurs et accepteurs d'électrons, comme TMTSF, TTT, TCNQ, etc. L'introduction de pairages s'avère utile et les structures électroniques ainsi que les processus électroniques peuvent facilement être visualisés. On a mis en évidence les deux facteurs qui provoquent l'apparition de paires dans les systèmes à plusieurs électrons avec répulsion. Le premier est relié aux statistiques de Fermi de l'électron qui font qu'une région de l'espace ne peut être occupée par plus de deux électrons. Le deuxième est l'interaction des électrons avec un réseau douce. A des densités électroniques élevées ou moyennes, $\rho \gtrsim 1$, le premier de ces facteurs est important alors que le second domine lorsque $\rho \ll 1$. On considère les paramètres d'excitation du type "kink" dans les groupes $(CH)_x$ de concert avec un potentiel non-linéaire qui est obtenu dans une approche par paire d'électrons pour les fonctions d'onde à plusieurs électrons de $(CH)_x$.

[Traduit par le journal]

1. Introduction

The recent decade has witnessed considerable progress in the physics and physical chemistry of quasi-one-dimensional systems. The model of quasi-one-dimensional crystals that allows one to use the methods of solid-state theory seems to be the most suitable one for carrying out theoretical investigations of such systems. The most interesting for experimentalists and theorists are the properties inherent to quasi-one-dimensional crystals whose number of electrons per unit cell is odd. Therefore they have a metallic band structure. As examples of such quasi-one-dimensional systems we may cite the stacks of donor molecules or acceptor molecules in donor–acceptor molecular crystals, for example, crystals based on TCNQ, TTF, TTT molecules as well as their selenium and methyl derivatives, TMTTF, TST, etc.

Another class of quasi-one-dimensional systems with a metal-like structure of the one-particle spectrum is represented by polymer chain molecules with conjugate bonds such as sulphur nitride $(SN)_x$, polyacetylenes $(CH)_x$, and polydiacetylenes $({=}CR{-}C{\equiv}C{-}CR{=})_x$.

Of these polymers polyacetylenes $(CH)_x$ have assumed ever increasing importance. Owing to their electronic structure both polyacetylenes and molecular stacks in donor–acceptor crystals are many-particle systems where electron delocalization is important. This makes the correct description of these systems complicated, since it requires an account of delocalization and correlation of electrons and also their interaction with the lattice.

In molecules with saturated bonds the many-electron problem is easier to solve since all the electrons are pairwise localized in bonds and correlation is essential only in the electron pairs (1, 2).

Here we would like to show that the concept of electron pairs may also be introduced in quasi-one-dimensional systems with delocalization such as $(CH)_x$ and the stacks of donors and acceptors TMTSF, TTT etc. The electron pairs in this case are partially localized. However, the introduction of pairing proves to be useful and the electronic structure and electronic processes can be easily visualized.

We can point out two causative factors in the appearance of pairs in a many-electron system with repulsion. The first one is the electron Fermi-statistics that does not allow a spatial region to be occupied by more than two electrons. The second one is the interaction of electrons with a soft lattice. The first of these factors is important at large and average densities of electrons $\rho \lesssim 1$, the second one dominates at $\rho \ll 1$. For a quantitative description, we introduce the Hamiltonian of our quasi-one-dimensional system. Using second quantization we write the Hamiltonian as

$$[1.1] \quad \hat{H} = \hat{H}_{\text{el}} + \hat{H}_{\text{el-ph}} + \hat{H}_{\text{ph}}$$
$$= \sum_{m,\sigma} (-\beta)\left(\hat{C}^+_{m\sigma}\hat{C}_{m+1,\sigma} + \hat{C}^+_{m+1,\sigma}\hat{C}_{m\sigma}\right)$$
$$+ \frac{1}{2}\sum_{m,\sigma}\left(\gamma\hat{C}^+_{m\sigma}\hat{C}_{m\sigma}\hat{C}^+_{m,-\sigma}\hat{C}_{m,-\sigma}\right.$$
$$\left. + \sum_{\sigma'}\gamma_1\hat{C}^+_{m\sigma}\hat{C}_{m\sigma}\hat{C}^+_{m+1,\sigma'}\hat{C}_{m+1,\sigma'}\right)$$
$$+ \sum_{m,\sigma}\beta'\left(\hat{C}^+_{m\sigma}\hat{C}_{m+1,\sigma} + \hat{C}^+_{m+1,\sigma}\hat{C}_{m\sigma}\right)(x_{m+1} - x_m)$$
$$+ \frac{1}{2}\sum_{m}\left(K_0(x_m - x_{m+1})^2 + M\dot{x}^2_m\right)$$

[1]Revision received March 12, 1985.

where $\hat{C}^{+}_{m\sigma}$ is the operator for electron creation at point m with spin σ; β, β', γ, $\gamma_1 > 0$, M is the molecular mass, x_m is the displacement of the mth molecule from its equilibrium position.

In [1.1] the first term describes the resonance jump of an electron between the molecular chain centers, the second and the third terms deal with the interaction of electrons and the last two correspond to the molecular vibrations in the chain. A Hamiltonian of type [1.1] whose parameters have been properly chosen (3–5), describes well the properties of conjugate polymers and small molecules. It is also valid in studying donor–acceptor molecular crystals (6, 7).

In quantum chemistry the Pople Hamiltonian is widely used (3). The electron part of the expression [1.1] is just the cut Pople Hamiltonian. The important parameter for one-dimensional systems with the Hamiltonian [1.1] is the density of electrons:

[1.2] $$\rho = N_e/N$$

where N_e is the total number of electrons in the chain of $N \to \infty$ centers.

We consider two cases $\rho \approx 1$ and $\rho \ll 1$. The first case corresponds to such systems as $(CH)_x$, polyacetylene while the second corresponds to stack molecular chains with $\rho \ll 1$ (for example, crystal $(TMTSF)_2\ ClO_4$).

The case $\rho \ll 1$ is described in Section 2, and that of $\rho = 1$ in Section 3.

Notice that, in general, to the Hamiltonian [1.1] there corresponds the dispersion law of one-particle states. However, in the limit of small density $\rho \ll 1$, we can use the effective mass approximation, i.e., $\epsilon_k \sim k^2$.

2. Electron pairing and the mass of current carriers at $\rho \ll 1$

Let us consider small densities of the conduction electrons $\rho \ll 1$.

In this limit the Hamiltonian [1.1] can be replaced by its continuous analogue (see, for example, refs. 8–15).

We first examine one electron. The total Hamiltonian of the system as in [1.1] constitutes the sum of three terms, namely, the electron Hamiltonian, the phonon Hamiltonian, and the operator for their interaction:

[2.1] $$\hat{H} = \hat{H}_{el} + \hat{H}_{ph} + \hat{H}_{el-ph}$$

where

[2.2] $$\hat{H}_{el} = -\int \frac{dx}{a}\left[\frac{\hbar^2}{2m}\left(\frac{d\psi}{dx}\right)^2\right]$$

[2.3] $$\hat{H}_{ph} = \frac{M}{2}\int \frac{dx}{a}\left[\left(\frac{dR}{dt}\right)^2 + \left(\frac{dR}{dx}\right)^2 \frac{V_0^2}{a^2}\right]$$

[2.4] $$\hat{H}_{el\text{-}ph} = \chi \int \frac{dx}{a}\,|\psi|^2\,\frac{dR}{dx}$$

$R(x, t)$ is the phonon variable, a continuous analogue of points x_m displacements in [1.1], $\psi(x, t)$ is the normalized electron wave function

$$\int_{-\infty}^{\infty} dx\,|\psi(x, t)|^2 = 1$$

The equations of motion are in the form of (8–11)

[2.5]
$$\left[i\hbar\frac{d}{dt} + \frac{\hbar^2}{2m}\frac{d^2}{dx^2} + \chi\frac{dR}{dx}\right]\psi(x, t) = 0$$
$$\left[\frac{d^2}{dt^2} - V_0^2\frac{d^2}{dx^2}\right]\rho + \frac{a^2}{M}\chi|\psi(x, t)|^2 = 0$$
$$\rho(x, t) = dR(x, t)/dx$$

Let us introduce the wave variable

[2.6] $$\xi = x - Vt$$

and assume $\rho = \rho(\xi)$ (11) and

[2.7]
$$\psi(x, t) = \phi(\xi)\exp\{i(mVx - (\epsilon + mV^2/2)t]/\hbar\}$$
$$\rho(x, t) = \rho(\xi)$$

Then the system [2.5] reduces to a nonlinear Schrödinger equation for ϕ (8–11) which has the soliton-type solutions

[2.8] $$\phi(\xi) \sim 1/\cosh(\xi/l)$$

The soliton energy at sufficiently small velocities $V \ll V_0$ is always less than that of zone electrons by the value

[2.9] $$E_{sol} = g^2/4$$

where

$$g = ma^4\chi^2/[V_0^2 M(1 - V^2/V_0^2)\hbar]$$

The effective size of a soliton (in the constant lattice units a) l and its effective mass M_{sol} depend on the parameters m, M, V_0, χ, β, K_0 in [2.5] (8, 9, 11)

[2.10] $$l = 3K_0\beta/\chi^2 = 3K_0\hbar^2/(\chi^2 ma^2)$$

[2.11] $$M_{sol} = m_{el} + 4\chi^4 M/(27K_0^2 V_0^2\beta)$$

An account must be taken of the fact that there is an infinitely large number of electrons in our molecular chain, however, their density (see [1.2]) is small

$$\rho \ll 1$$

We choose the wave function of the many electron system as an antisymmetrized product of the functions of electron pairs (geminals)

[2.12] $$\Psi(1, 2, \ldots, 2M - 1, 2M) = \hat{A}\prod_{i=1}^{M} G_i(2i - 1, 2i)$$

where $\hat{A}$ is the antisymmetrization operator. Geminals have been introduced by Fock and his disciples in refs. 16 and 17.

In the simplest case each geminal in [2.12] can be chosen in the form of a Slater determinant corresponding to the singlet state of the pair

[2.13] $$G_i = \|\phi_i(x_{2i-1})\phi_i(x_{2i})\alpha(2i - 1)\beta(2i)\|$$

As it is seen from [2.13], the spatial functions (orbitals) of electrons of every pair coincide. The condition of orthonormalization

[2.14] $$\int dx\,\phi_i^*(x)\phi_j(x) = \delta_{ij}$$

is identical to that of a strong orthogonality of geminals G_i and G_j which greatly simplifies the calculations (18). The relation [2.14] can also be satisfied with good accuracy for the case of [2.8] type soliton states. Let

[2.15] $$\phi_n(x) = \cosh^{-1}[(\xi - nR_0)/l]$$

Then the relation is strictly satisfied if the distance between solitons $R_0 \gg l$, the soliton size, i.e. in the limit of small density

[2.16] $\rho = N_c/N = 2/R_0 \ll 1$

However, the expression [2.14] will be also fulfilled sufficiently accurately if $R_0 \gtrsim 4l$, i.e.

[2.17] $\rho = 2/R_0 \leqq 1/2l = \chi^2 Mma^2/(V_0^2\hbar^2)$

In this case the wave function [2.12] corresponds to a one-dimensional lattice with a period R_0.

A similar soliton lattice was first introduced in ref. 10. Our concept is most unique in that it allows electron–electron interaction and that our soliton lattice can move as a whole with velocity $V < V_0$, transferring the charge eN_c. Then the effective mass reads $N_c M_{sol}$ where M_{sol} corresponds to expression [2.11]. The binding energy of electron pairs in soliton states ϕ_n geminals G_n, exceeds the double value of the energy [2.9] since in the equation for ρ in [2.5] one should take into account the density of both electrons (19) which corresponds to the increase in the electron–phonon interaction constant χ by a factor of $\sqrt{2}$. In this case the binding energy increases by a factor of 4. In our opinion, this is just the effect of electron pairing through the lattice.

In order to determine the advantage attained by this pairing, we compare the energy gain $g^2/2$ with the repulsion of electrons in the pair $\tilde{K}$. To calculate $\tilde{K}$, we restrict ourselves to the consideration of the first term in the interaction operator in [1.1], i.e. the Hubbard approximation:

$$\hat{H}_{el-el} = \frac{1}{2}\sum_{m\sigma} \gamma \hat{C}^{+}_{m\sigma}\hat{C}_{m\sigma}\hat{C}^{+}_{m,-\sigma}\hat{C}_{m,-\sigma}$$

or within a continuum model

[2.18] $$H_{el-el} = \iint dx_1 dx_2\, |\psi_1(x_1)|^2|\psi_2(x_2)|^2\delta(x_1 - x_2)\cdot\gamma = \gamma\int dx\phi_1(x)^2\phi_2(x)^2 = \tilde{K}$$

Taking into account that for the pair

$$\phi_1(x) = \phi_2(x) = \cosh^{-1}(x/l)/\sqrt{2l}$$

we find

[2.19] $$K = \frac{\gamma}{4l^2}\int dx \cosh^{-4}(x/l) = \gamma/3l$$

So, the electron pairing is advantageous if

[2.20] $g^2/2 > \gamma/(3l)$

3. Electron pairs and the properties of carriers at $\rho = 1$

To describe the ground state of a cyclic chain of $N = 2M$ centers possessing $N_c = N$ electrons, we choose a variational function as (20)

[3.1] $$\psi_{VLG} = \prod_{m=1}^{M}(\cos\varphi \hat{f}^{+}_{m\uparrow}\hat{f}^{+}_{m\downarrow} + \sin\varphi \hat{\hat{f}}^{+}_{m\uparrow}\hat{\hat{f}}^{+}_{m\downarrow})|0\rangle$$

where the Fermi-operators $\hat{f}^{+}_{m\sigma}$ and $\hat{\hat{f}}^{+}_{m\sigma}$ correspond to the Wannier-type states

$$\hat{f}_{m\sigma} = \frac{1}{\sqrt{M}}\sum_{|k|<k_F} e^{-ikR_m}(\cos\theta_k\hat{a}_{k\sigma} + i\sin\theta_k\hat{a}_{\bar{k}\sigma})$$

[3.2] $$\hat{\hat{f}}_{m\sigma} = \frac{1}{\sqrt{M}}\sum_{|k|<k_F} e^{-ikR_m}(i\sin\theta_k\hat{a}_{k\sigma} + \cos\theta_k\hat{a}_{\bar{k}\sigma})$$

$$(\bar{k} = k + 2k_F, \qquad k_F = \pi/2a)$$

where k is the wave number, φ and θ_k are variational parameters and the operators $\hat{a}_{k\sigma}$ diagonalize the first term of the Hamiltonian [1.1] at $x_m = 0$,

[3.3] $$\hat{a}_{k\sigma} = N^{-1/2}\sum_n \hat{C}_{n\sigma}e^{ikn}$$

$$2\theta_k = 2k$$

[3.4] $R_m/a = 2m + \delta$

At $\varphi = 0$ and $\theta_k = 0$ the function [3.1] transforms into the Slater determinant (20)

[3.5] $$\psi_{VLG}(\varphi = 0, \theta_k = 0) = \prod_{|k|<k_F} a^{+}_{k\uparrow}a^{+}_{k\downarrow}|0\rangle$$

Hence, varying φ and θ_k we obtain the corrections to the energy.

The wave function [3.1] refers to the type of antisymmetrized product of strongly orthogonal geminals (APSG). The geminals or two electron functions have been introduced into the theory by V. A. Fock and his disciples (16, 17). The APSG approximation was proposed in ref. 18. One of the authors has introduced the approximation [3.1]–[3.4] to calculate correlation effects in quasi-one-dimensional systems (20–22). We call this approximation the varied localized geminals (VLG) approximation since the geminals

[3.6] $$\hat{G}^{+}_m = (\cos\varphi\hat{f}^{+}_{m\uparrow}\hat{f}^{+}_{m\downarrow} + \sin\varphi\hat{\hat{f}}^{+}_{m\uparrow}\hat{\hat{f}}^{+}_{m\downarrow})|0\rangle$$

are partially localized.

The VLG ground state [3.1] is doubly degenerate in the parameter δ when $x_m = 0$ in [1.1] (see ref. 20). When $\delta = +1/2$ and the value of λ in expression [3.4] tends to $+0.5$ the orbitals [3.2] become

$$f_{m\sigma} = (1/2)^{1/2}(C_{2m\sigma} + C_{2m+1,\sigma})$$

When $\delta = -1/2$ and $\lambda = -0.5$ we must replace the operator $C_{2m+1,\sigma}$ in this expression by $C_{2m-1,\sigma}$. So, the parameter δ determines the localization of orbitals [3.2]. At $\delta = 1/2$ they are localized on even C—C bonds and at $\delta = -1/2$ on the odd ones.

Thus, the functions $\psi_{VLG}(\delta = 0.5)$ and $\psi_{VLG}(\delta = -0.5)$ can be compared with the two resonant structures of polyacetylene ...—C=C—C=... and ...=C—C=C—...

When all the displacements of atoms in [1.1] $x_m = 0$, the VLG function has the form (22)

[3.7] $\psi_{VLG} = a\psi_{VLG}(+) + b\psi_{VLG}(-)$

and $|a| = |b|$, $\psi_{VLG}(\pm) = \psi_{VLG}(\delta = \pm 1/2)$.

If we introduce the periodic Peierls-type deformation

[3.8] $x_m = x\cos(Qma + \varphi_0)$

where $Q = 2k_F$ then the weight of one of the structures in [3.7] goes to zero, and the total energy takes the form

[3.9] $E_{VLG}(x) = (C_1x^2 + W^2)^{1/2}$

where

[3.10] $W = \langle\psi^{(+)}_{VLG}|\hat{H}|\psi^{(-)}_{VLG}\rangle \sim e^{-rN}$

$r > 0$ depends on the system parameters (21). From [3.9] it follows that for large systems ($N \rightarrow \infty$)

[3.11] $E_{VLG}(x) = (C_1)^{1/2}|x|$

Minimizing the total energy [1.1] in the adiabatic approximation $\dot{x}_m = 0$ we find the equilibrium amplitude of the Peierls deformation

$$[3.12] \quad x_0 = \sqrt{(C_1)}/K_0$$

where the two signs correspond to two resonant structures.

Attention should be called to the analogy with the above consideration of solitons at $\rho \ll 1$. Each pair of electrons occupies geminal [3.6] and is localized on one of the bonds. In addition, this bond is reduced by $2x_0$.

Besides purely qualitative analogy there is a formal one (see [2.5]), since the orbitals f_m satisfy the variational equation

$$\beta(f_{m+1} - f_{m-1}) - \tilde{K}|f_m|^2 f_m = \epsilon_m f_m$$

The ground state of the system is degenerate in the sign of the deformation amplitude [3.12]. The dependence of the potential energy on x is of a characteristic form with two minima. In such a system soliton excitations of a specific nature, kinks, are possible (23–25). These states can be described in the VLG method. To do this, the structure of the function [3.1] near a kink is changed as follows

$$[3.13] \quad \psi_{\mathrm{VLG}}^{(\mathrm{kink})} = \prod_{m<0} \tilde{G}_m^+(+) C_{0\sigma} \prod_{m>0} \tilde{G}_m^+(-)$$

The sign of the operators $\hat{G}_m$ [3.6] denotes their slight modification in order to satisfy the strong orthogonality condition. The modification affects, actually, the state with ± 1, ± 2 and reduces to changing

$$[3.14] \quad f_1 \rightarrow f_1 - (S_{11}/2)f_{-1} - S_{10}C_0$$

$$(S_{ij} = \langle f_i | f_j \rangle)$$

etc.

Qualitatively the properties of the soliton described by [3.13] at $\gamma > 0$ differ somewhat from those of the soliton in the approximation of noninteracting electrons (23–25): (*1*) the soliton is localized on 2–3 bonds with the parameters of the Hamiltonian [1.1] characteristic for $(CH)_x$ (6) $\beta = 2.5$ eV, $\beta' = 4$ eV/Å, $K_0 = 47$ eV/Å^2, $M = M_{CH}$; and (*2*) the energy of the electron transfer from the soliton level into the conduction band is inside the forbidden zone of polyacetylene.

The difference between our picture and the model of noninteracting electrons is that in our model the formation of neutral kinks is energetically advantageous compared with that of charged ones. This is supposed to be the unique fact able to explain the low conductivity of pure $(CH)_x$ films PA $\sigma < 10^{-9}$ (ohm cm)$^{-1}$ in the presence of paramagnetism χ_p.

In the model of noninteracting electrons the number of charged kinks should approximately coincide with that of neutral kinks.

Now some words about the mass of the kink-type soliton in $(CH)_x$. Up to now, there have been no rigorous calculations of this value in $(CH)_x$. Therefore we present the results of the model calculation. The model calculation of the kink dynamics consists in that a certain velocity V is given to a stationary kink without changing its form (23–25).

One may also consider a model elastic chain with energy

$$[3.15] \quad V = \sum_m \left[\frac{M}{2}\dot{y}_m^2 + K_1(y_m - y_{m+1})^2 + U(y_m)\right]$$

The potential $U(y)$ must have at least two minima. Using the expression [3.11] we obtain

$$[3.16] \quad U(y) = -A|y| + \tfrac{1}{2}K_0 y^2$$

The parameters A and K_0 in this expression are calculated in ref. 5 for $(CH)_x$: $A = 1.8$ eV/Å and $K_0 = 44$ eV/Å^2.

Within a continuous approach we can obtain from [3.15] and [3.16] the equation of motion

$$[3.17] \quad My_{tt} - K_1 a^2 y_{xx} + K_0 y - A \text{ sign }(y) = 0$$

This equation has a kink solution

$$[3.18] \quad y = y_0(1 - \exp(-\alpha|\xi|)) \text{ sign }(\xi)$$

where $y_0 = \pm A/K_0$ and

$$[3.19] \quad \xi = x - Vt, \qquad \alpha^2 = K_0/(2K_1a^2 - MV^2)$$

V is the kink velocity which should be less than $a\sqrt{2K_1/M} = V_0$.

Using eqs. [3.17]–[3.19] we can obtain the effective mass of kinks

$$[3.20] \quad M_{\mathrm{sol}} = M_{\mathrm{CH}}(y_0/a)^2(2K_0/K_1)^{1/2}$$

Since $K_1 \approx K_0$ (5) and the experimental estimates (26, 27) yield $2x_0 = 2y_0 = 0.035$Å, $a = 1.4$Å we find that $M_{\mathrm{sol}} \ll M_{\mathrm{CH}}$.

Note that using the sine-Gordon form of the potential [3.16]

$$U_{\mathrm{SG}}(y) = \tilde{A}\left(1 - \cos\frac{2\pi}{x_0}y\right)$$

we obtain nearly the same value of the kink mass

$$[3.21] \quad M_{\mathrm{sol}} = \frac{3}{2\pi}(K_0/K_1)^{1/2}(y_0/a)^2 M_{\mathrm{CH}}$$

Thus, solitons in $(CH)_x$ are rather mobile.

Infrared spectroscopy in the 1750–700 cm^{-1} region is used to characterize the right- and left-handed helices of poly(dG-dC)·poly(dG-dC) with sodium counterions. The use of polymers selectively deuterated on the C8 of guanines and methylated on the C5 of cytosines allows us to propose explanations for several spectroscopic modifications which occur under the $B \rightarrow Z$ transition. Similar substitutions on nucleosides and nucleotides are used so as to assign base absorptions in poly(dG-dC)·poly(dG-dC). A set of ir bands characteristic of DNA conformations, which can be used in studies of interactions with this polynucleotide and to identify the left handed Z conformation in more complex systems, is proposed.

J. A. TABOURY, J. LIQUIER, et E. TAILLANDIER. Can. J. Chem. **63**, 1904 (1985).

La spectroscopie infrarouge dans la région 1750–700 cm^{-1} permet de caractériser la forme droite et la forme gauche de la double hélice de poly(dG-dC)·poly(dG-dC). L'étude de dérivés du poly(dG-dC)·poly(dG-dC) deutériés sélectivement sur le C8 de la guanine ou méthylés sur le C5 de la cytosine permet d'expliquer différentes modifications du spectre de ce polynucléotide au cours de la transition $B \rightarrow Z$. Des modifications similaires sur des nucléotides ou nucléosides apportent également des informations pour l'attribution des bandes d'absorption des bases du poly(dG-dC)·poly(dG-dC). Nous proposons un ensemble de bandes d'absorption caractéristiques des conformations de l'ADN, qui pourra être utilisé pour l'étude d'interactions avec ce polynucléotide ou pour la mise en évidence de la conformation en double hélice gauche dans des systèmes plus complexes.

Introduction

The DNA molecule, which for a long time had been considered a rather rigid entity, is now known to be extremely flexible and capable of adopting a great variety of secondary structures. The study of purine–pyrimidine alternating copolymers has, moreover, shown that classical right-handed A and B helices can be turned into left-handed forms belonging to the so-called Z family. These novel structures were first characterized in the case of poly(dG-dC)·poly(dG-dC) by the modification of the uv absorbance spectrum and by the inversion of the cd (circular dichroism) signal (1). Their existence has been definitively proved by X-ray diffraction studies on d(C-G)$_3$ crystals (2). Nuclear magnetic resonance (nmr) (3, 4) and Raman spectroscopy (5–9) have also been used to investigate Z DNA. Thamann *et al.* (6) showed that the Raman spectrum of the Z DNA d(C-G)$_3$ crystal is essentially identical to the high salt solution spectrum of poly(dG-dC)·poly(dG-dC). Secondary structures of native or synthetic DNAs can be successfully studied by ir spectroscopy. A and B geometries and the $B \rightarrow A$ conformational transition of DNA, alone or in the presence of polypeptides, proteins, or drugs, in highly concentrated conditions (hydrated films), have been characterized and followed by this technique (10–12). The left-handed Z structure of poly(dG-dC)·poly(dG-dC) has also been investigated by ir spectroscopy (13–17), and we have previously shown that, in films, the reversible $B \rightarrow Z$ transition can be induced by varying the relative humidity (18). This conformational transition has been identified by correlating the ir and uv absorbance spectroscopy results obtained on the same films, in the same salt and hydration conditions. In this work we present a detailed study of the ir spectra of both B and Z conformations of poly(dG-dC)·poly(dG-dC) and two polynucleotides obtained by either selective deuteration of the C8 site of guanines or by methylation of the C5 site of cytosines. (The latter modification of cytosines is often encountered in native systems and may play an important role in transcription.) The simultaneous study of these three DNAs allows us to assign many of the absorption bands in the ir spectrum. This work was undertaken to identify the ir wavenumbers and intensities characteristic of the B and Z conformations of poly(dG-dC)·poly(dG-dC) in the vibrational region between 1750 and 700 cm^{-1}, both for deuterated and nondeuterated samples, for use as a basis for further studies of interactions of these synthetic polynucleotides with drugs, metal ions, and proteins.

Material and methods

All the ir spectra, which will be discussed below were obtained using DNA films. The counterion content and the water content were rigorously controlled as these two parameters are essential to stabilize a given secondary structure of the polynucleotide.

Poly(dG-dC)·poly(dG-dC) and poly(dG-dm^{5}C)·poly(dG-dm^{5}C) were obtained from P. L. Biochemicals, dissolved in 0.1 M NaCl pH 7, ethanol precipitated, washed so as to eliminate excess NaCl, deposited on the infrared plate (ZnSe), and gently dried so as to obtain homogeneous films. Known amounts of Na^+ (usually 1 Na^+ in excess per nucleotide) were added as a droplet allowed to diffuse in the film and then slowly dried. The films were then sealed in cells with controlled relative humidity (100–32% r.h.). The desired hydration was obtained by the introduction of small vessels containing saturated solutions of different salts. The exact amount of water contained in the film was determined directly on the ir spectrum by recording the water absorption bands around 3400 cm^{-1} and 700 cm^{-1}. The films were also exposed to saturated D_2O solutions of previously dehydrated salts. The corresponding spectra, which in the text will be referred to as "in D_2O", allow the infrared regions obscured by the intense H_2O absorptions (especially the 1650 cm^{-1} and 800 cm^{-1} regions) to be investigated. Selective deuteration of the C8 of guanines has been obtained by incubation of the poly(dG-dC)·poly(dG-dC) in 0.1 M NaCl D_2O at 80°C for 3 h.

The ir spectra were recorded with a Perkin Elmer 180 double-beam ratio recorder spectrophotometer coupled to a Hewlett–Packard 9825 A calculator. The stored data were treated in several ways: (1) the

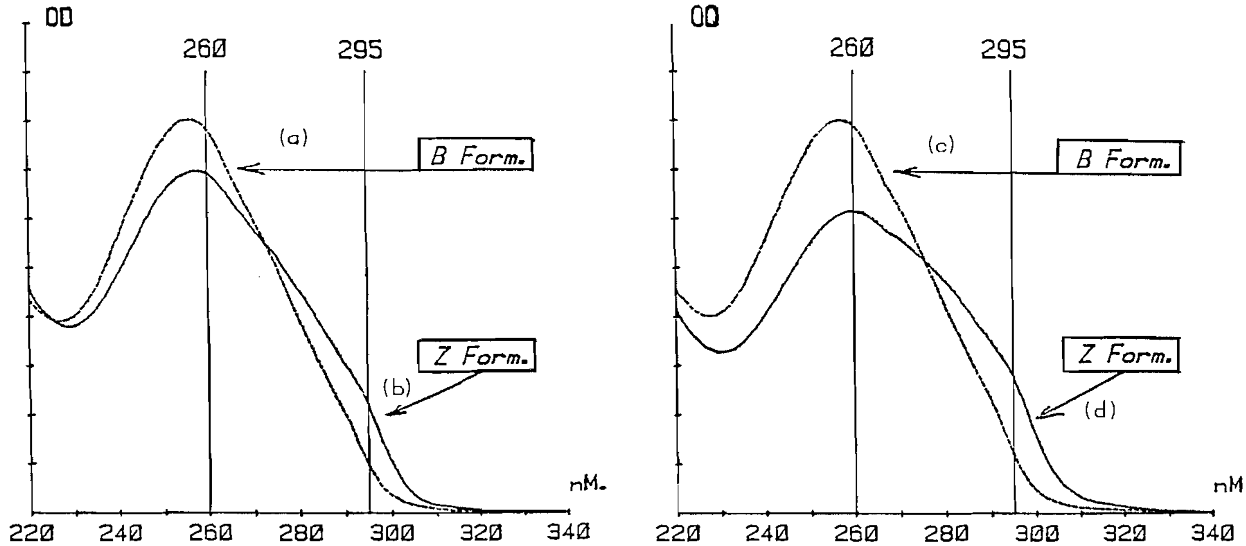

FIG. 1. Ultraviolet absorption spectra of poly(dG-dC)·poly(dG-dC)-Na^+. (a) Solution (0.1 *M* NaCl, 5 m*M* phosphate pH 7); (b) solution (4 *M* NaCl, 5 m*M* phosphate pH 7); (c) film 98% r.h. H_2O; (d) film 86% r.h. H_2O.

baseline was corrected using previously recorded spectra of the sample cells, so as to eliminate any possible difference between sample and reference cells; (2) the polynucleotide spectrum was corrected for the water contribution by subtracting a previously stored water spectrum; (3) the spectra were smoothed using 3 or 5 points and drawn using a Hewlett–Packard 7825 A digital plotter.

In the case of poly(dG-dC)·poly(dG-dC), we controlled the induction of the $B \rightarrow Z$ transition in the films by recording the corresponding uv absorption spectra. The uv absorption spectrum of a highly hydrated (98% r.h.) film (Fig. 1c) is the same as that of a low salt solution (0.1 *M* NaCl) (Fig. 1a) reflecting a *B*-type conformation. If the relative humidity is decreased to 86% r.h., a slight redshift and a weak hypochromicity of the 260-nm band are detected, along with an important hyperchromicity effect in the 295-nm region (Fig. 1d). This new spectrum is similar to that observed for the high salt solution (4 *M* NaCl) (Fig. 1b) and correlated with the *Z* conformation.

Results and discussion

The $B \rightarrow Z$ conformational transition of poly(dG-dC)·poly(dG-dC) is induced in films by a decrease of the hydration, as shown by the parallel study performed on the same samples in the same relative humidity conditions by ir and uv absorption spectroscopy. Above 93% r.h., poly(dG-dC)·poly(dG-dC) and poly(dD^{8}G-dC)·poly(dD^{8}G-dC) adopt a *B* conformation. Below 93% r.h., the secondary structure belongs to the *Z*-helical form. As regards the methylated polynucleotide, poly(dG-dm^{5}C)·poly(dG-dm^{5}C), it is well known that C5-methylation of cytosines greatly favours the *Z* conformation (19, 20). Therefore, in condensed phase, the ir spectrum of the *B* form is not obtained, even by exposing the film to 100% relative humidity. The *B* form spectrum of poly(dG-dC)·poly(dG-dC) and the *Z* form spectra of poly(dG-dC)·poly(dG-dC), poly(dD^{8}G-dC)·poly(dD^{8}G-dC), and poly(dG-dm^{5}C)·poly(dG- dm^{5}C) are presented in Fig. 2 between 1750 cm^{-1} and 700 cm^{-1}. The wavenumbers of the main absorptions as well as their assignments are summarized in Table 1. We shall discuss in detail the different spectral regions using expanded figures corresponding mainly to the deoxyribose vibrations coupled to the *G* or *C* motions and involving the C—N glycosidic linkage (Fig. 3) and to the phosphodiester chain and out-of-plane base vibrations (Fig. 4). Below 1550 cm^{-1}, many of the base absorptions of the polymer have been assigned by comparison with the spectra of 2′-deoxycytidine and 2′-deoxyguanosine-5′-phosphate (12, 21). Moreover, the effects of C5-methylation of cytosines and C8-deuteration of guanines on poly(dG-dC)·poly(dG-dC) spectra have been correlated with similar effects on cytidine and 5′-dGMP spectra respectively. Contributions of the two bases can be distinguished in the ir spectrum of the polymer. Thus the 1294 cm^{-1} and 1498 cm^{-1} bands of poly(dG-dC)·poly(dG-dC) are due to cytosine vibrations, while only a weak contribution of guanine is expected at 1482 cm^{-1}. Both bases are involved in the absorptions located at 1527 cm^{-1}, 1420–1409 cm^{-1}, and at 778 cm^{-1}.

1. *In-plane double bond stretching vibrations of bases*

In H_2O, after subtraction of the water contribution, the $B \rightarrow Z$ transition is detected by the shift of the 1710 cm^{-1} band (*B* form) to 1692 cm^{-1} (*Z* form) and by the presence of an absorption at 1630 cm^{-1} (Fig. 2*a*). The 1692 cm^{-1} band may be assigned to a guanine double-bond in-plane stretching vibration involving mainly the C6=O6 carbonyl group, as in the *Z* form spectrum of d(C-Br^{8}G-C-G-C-Br^{8}G), this band is split into two components located at 1697 cm^{-1} and 1680 cm^{-1}, reflecting the bromination effect on the initial and terminal guanines (22).

In D_2O, the two main absorptions of poly(dG-dC)·poly(dG-dC) are shifted from 1681–1649 cm^{-1} in the *B* form to 1666–1635 cm^{-1} in the *Z* form (Table 1). In the spectrum of the C5-methylated polymer in the *Z* form, these bands are found at higher wavenumbers, 1674–1643 cm^{-1}. Upon C5-methylation, a similar high wavenumber shift is also observed with 2′-deoxycytidine: the 1650 cm^{-1} band in the 2′-deoxycytidine spectrum is detected at 1666 cm^{-1} for the methylated nucleoside. This suggests that cytosine double-bond vibrations are involved in the two 1666–1635 cm^{-1} bands in the spectrum of poly(dG-dC)·poly(dG-dC) in heavy water. The in-plane double bond vibration region had also been studied by Raman spectroscopy. In the case of the unmethylated polymer, the $B \rightarrow Z$ transition is detected by shifts of the Raman lines from 1688 cm^{-1} and 1635 cm^{-1} to 1662 cm^{-1} and 1634 cm^{-1} (D_2O solutions) and from 1715 cm^{-1} to 1695 cm^{-1} (H_2O solutions) (8).

The 1750–1550 cm^{-1} spectral region is considered as being

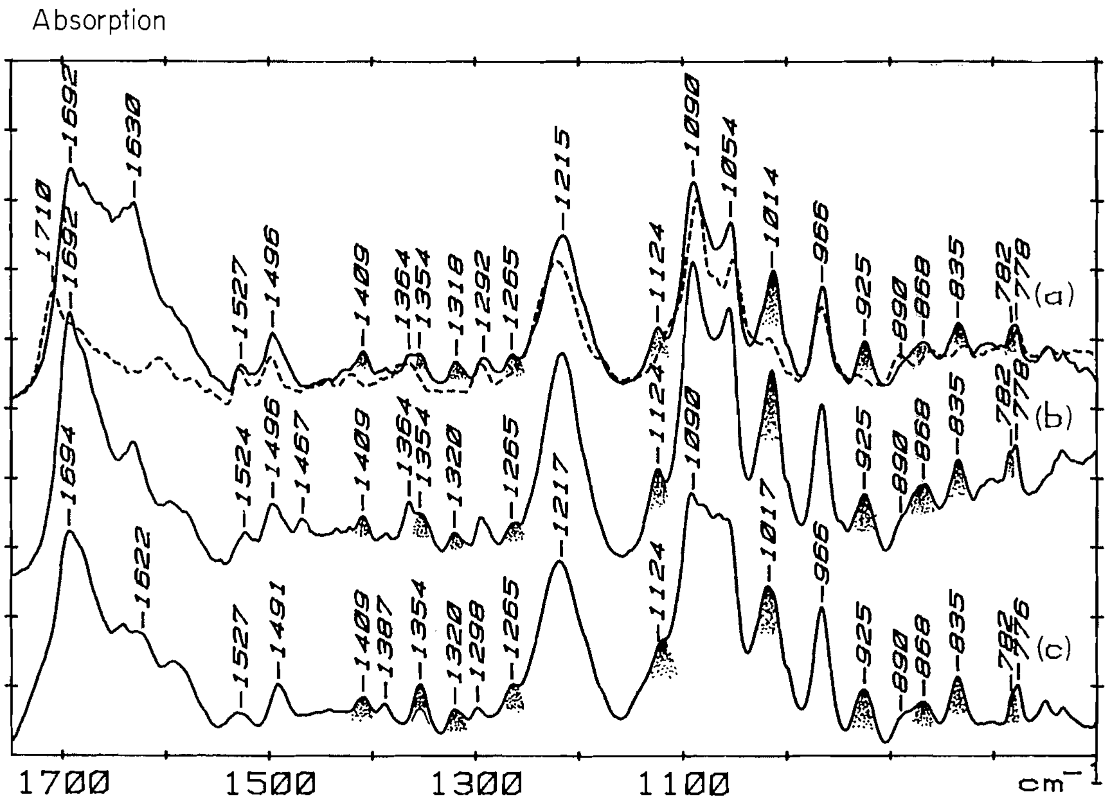

FIG. 2. Infrared absorption spectra of: (a) poly(dG-dC)·poly(dG-dC)-Na^+; —— *Z* form (86% r.h. H_2O); --- *B* form (98% r.h. H_2O). The ir spectrum of the water present in the film has been subtracted; (b) poly(dD^8G-dC)·poly(dD^8G-dC)-Na^+ at 86% r.h. (H_2O), *Z* form; (c) poly(dG-dm^5C)·poly(dG-dm^5C)-Na^+ at 86% r.h. (H_2O), *Z* form. The main bands assigned to the *Z* form have been shadowed.

sensitive to base pairing and to base stacking (23, 24). It has been shown by X-Ray diffraction that the *Z* form is a double helix structure with Watson–Crick base pairing. The *Z* configuration differs from the *B* one as cytosine bases are stacked on each other, while guanine bases are no longer stacked but in contact with the O1′-oxygen atoms of the adjacent deoxyribose residues (2). In polynucleotides, the existence of transition dipole coupling for C=O stretching vibrations was first pointed out by Tsuboi *et al.* (23). As the base pair stacking is changed under the $B \rightarrow Z$ transition, the dipole interaction is modified, as can be detected by shifts of the ir absorption bands.

2. *dG, dC, and C—N glycosidic linkage vibrations*

The spectral region between 1550 and 1250 cm^{-1} is useful to characterize the *B* and *Z* geometries of poly(dG-dC)·poly(dG-dC), as can be clearly observed in Fig. 3. The existence of the *Z* conformation of this polymer is reflected by the presence of two new absorptions at 1265 cm^{-1} and 1318 cm^{-1}, by shifts of the 1374–1364 cm^{-1} doublet to 1364–1354 cm^{-1}, and of the 1420 cm^{-1} band to 1409 cm^{-1}. Similar modifications are observed in the case of poly(dD^8G-dC)·poly(dD^8G-dC) upon the $B \rightarrow Z$ transition (Fig. 3c). The *Z* form spectrum of the methylated derivative (Fig. 3d) shows only one intense band at 1354 cm^{-1}, which may be interpreted as the sum of the shifted 1364 cm^{-1} band and of the 1354 cm^{-1} band. The low wavenumber shift of the 1364 cm^{-1} band is due to C5-methylation of cytosines as, in a similar way, the corresponding band at 1364 cm^{-1} in 2′-deoxycytidine is shifted to 1356 cm^{-1} upon C5-methylation (12). Therefore the 1364 cm^{-1} absorption in the ir spectrum of poly(dG-dC)·poly(dG-dC) reflects a vibrational mode of cytosine. The 1354 cm^{-1} band of *Z* form poly(dG-dC)·poly(dG-dC) may be assigned to a guanine vibration, as selective bromination of this base in the case of the d-(C-Br^8G-C-G-C-Br^8G) hexamer in the *Z* form reveals a low frequency shift of the 1354 cm^{-1} band to 1340 cm^{-1} (22). The dG residue which is in an *anti* conformation in the *B* form adopts a *syn* conformation in the *Z* form. This geometry modification may be reflected by the 1374–1354 cm^{-1} band shift in poly(dG-dC)·poly(dG-dC) and poly(dD^8G-dC)·poly(dD^8G-dC). This assignment is in agreement with the result of a theoretical calculation based on the GF-Wilson method performed on CpG and GpC sequences in *B* and *Z* geometries. The calculated results show that upon the $B \rightarrow Z$ transition, the important shifts from 1374 cm^{-1} to 1354 cm^{-1} (infrared bands) and from 685 cm^{-1} to 625 cm^{-1} (Raman lines) are essentially due to the *anti* → *syn* and C2′-*endo* → C3′-*endo* conformational modifications of the guanine residue and its associated sugar (16).

The band located at 1498 cm^{-1} in the *B* form poly(dG-dC)·poly(dG-dC) spectrum (1496 cm^{-1} in the *Z* form) (Fig. 3a, b) involves mainly cytosines with a weak contribution of guanines as previously mentioned. This can be deduced from the ir study of the methylation effect on cytosines: the shift of the 1496 cm^{-1} absorption (Fig. 3b) to 1491 cm^{-1} in the methylated polymer (Fig. 3d) is quite comparable to the displacement of the 1490 cm^{-1} band in 2′-deoxycytidine to 1485 cm^{-1} in 5-methylated 2′-deoxycytidine. The contribution of guanines to the absorption at 1498 cm^{-1} can be evidenced in the following way. Deuteration of the C8 site of 5′-dGMP shifts the 1482 cm^{-1} band to 1460 cm^{-1}. Similarly, selective deuteration of the C8 site of guanines in poly(dG-dC)·poly(dG-dC) shifts the

[b]Deoxyribose and phosphodiester backbone.

guanine band, hidden by the presence of the strong cytosine component at 1498 cm^{-1}, to 1467 cm^{-1} (Fig. 3c). The 1467 cm^{-1} band, which is well isolated and not modified by the $B \rightarrow Z$ transition, involves the motion of the N7 atom of guanines. Modifications of the intensity or shifts of this band will be extremely useful to evidence any interaction with this site of the polynucleotide (17).

3. *Phosphodiester chain and out-of-plane base vibrations*

The spectral region below 1030 cm^{-1} has been studied in D_2O so as to avoid the important water contribution. In Fig. 4 are presented the spectra of poly(dG-dC)·poly(dG-dC) (*B* and *Z* forms) and of poly(dG-dm^5C)·poly(dG-dm^5C) (*Z* form) recorded in D_2O.

Important modifications can be detected due to the $B \rightarrow Z$ transition. The intensity of the 893 cm^{-1} band is drastically decreased, whereas two absorptions at 925 cm^{-1} and 1014 cm^{-1} (1017 cm^{-1} for the methylated polynucleotide) are now observed. These bands can be associated with deoxyribose vibrations coupled to backbone vibrations, their strong hyperchromicity possibly reflecting the effect of the electronic polarization of the C—O—C deoxyribose atoms close to the guanine ring in the *Z* structure (2). The phosphodiester chain vibrations observed in D_2O at 828 cm^{-1} and 853 cm^{-1} in the *B*

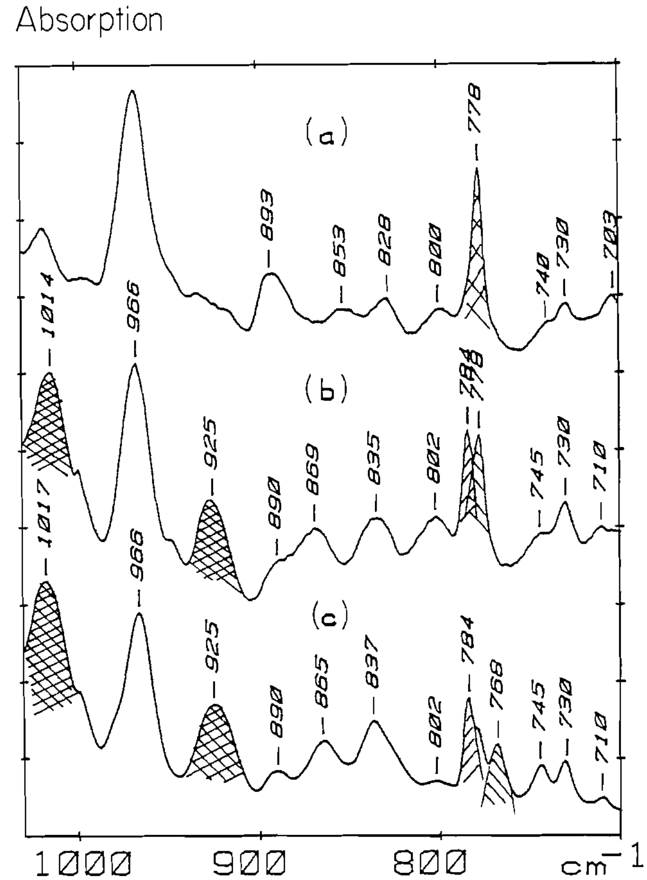

FIG. 4. Phosphodiester chain and out-of-plane base vibrations; (a) poly(dG-dC)·poly(dG-dC)-Na^+ B form (98% r.h. D_2O); (b) poly(dG-dC)·poly(dG-dC)-Na^+ Z form (86% r.h. D_2O); (c) poly(dG-dm^{5}C)·poly(dG-dm^{5}C)-Na^+ Z form (86% r.h. D_2O).

form are shifted to 835 cm^{-1} and 868 cm^{-1} in the Z form (837 cm^{-1} and 865 cm^{-1} for poly(dG-dm^{5}C)·poly(dG-dm^{5}C)). Finally, the sharp band at 778 cm^{-1} in the B form (Fig. 4a) is split into two components well separated in D_2O, at 784 cm^{-1} and 778 cm^{-1}, for Z form poly(dG-dC)·poly(dG-dC) (Fig. 4b). Methylation of cytosines in Z form poly(dG-dm^{5}C)·poly-(dG-dm^{5}C) induces a shift of the cytosine component from 778 cm^{-1} to 768 cm^{-1} (Fig. 4c) (776 cm^{-1} in H_2O, Fig. 2c). In a similar way bromination of the guanines shifts the absorption located at 784 cm^{-1} (22).

Thus in the poly(dG-dC)·poly(dG-dC) Z form spectrum the 784 cm^{-1} band is due to a guanine vibration while the 778 cm^{-1} band is due to a cytosine vibration. These two absorptions are assigned to out-of-plane ring vibrations, possibly coupled to the glycosidic torsion and carbonyl out-of-plane motions; as on the polarized ir spectra of oriented samples, these two absorptions remain parallelly polarized, whatever the DNA conformation (18). The corresponding transition dipole moments are thus oriented parallelly to the helix axis. The Raman spectrum in this region is also extremely sensitive to the $B \rightarrow Z$ conformational transition. The different Raman lines have been discussed either in terms of vibrations of the phosphate groups and of the cytosines (8) or in terms of base vibrations (7). The infrared spectrum presents two sharp bands at 784–778 cm^{-1} (bandwidth 8 cm^{-1}) assigned to base vibrations. However, deconvolution of this spectral region shows that a broad band located at 802 cm^{-1} (40 cm^{-1} bandwidth), probably due to a phosphate chain vibration mode, should be taken into account (12).

In summary, our study allows us to propose a set of characteristic features of the Z conformation spectrum of poly-(dG-dC)·poly(dG-dC) and to assign a number of absorptions by comparison with nucleosides, nucleotides, and modified polynucleotides (C8-deuteration of guanines and C5-methylation of cytosines): the $B \rightarrow Z$ transition is reflected by: (*i*) new or enhanced absorptions: 1630 cm^{-1}, 1318 cm^{-1}, 1265 cm^{-1}, 1124 cm^{-1}, 1014 cm^{-1}, 925 cm^{-1}; (*ii*) band shifts (in parentheses are wavenumbers of the corresponding absorptions in the B form): 1409 cm^{-1} (1420 cm^{-1}), 1354 cm^{-1} (1374 cm^{-1}). In H_2O: 1692 cm^{-1} (1710 cm^{-1}). In D_2O: 1666 cm^{-1} (1681 cm^{-1}), 1635 cm^{-1} (1649 cm^{-1}); (*iii*) band splitting: 784–778 cm^{-1} (778 cm^{-1}); (*iv*) decrease of the intensity of the absorption located at 893 cm^{-1}.

Besides, selective deuteration of C8 of guanines shifts the guanine contribution, overlapped by a cytosine band at 1496 cm^{-1}, to 1467 cm^{-1}, allowing evidence of interactions on the N7 site of the base.

These characteristic features of the ir spectrum of the Z conformation determined in the case of poly(dG-dC)·poly-(dG-dC) will be useful to help the detection of left-handed structures in other polynucleotides which have been theoretically predicted as able to adopt such conformations: regularly alternating purine–pyrimidine polymers such as poly(dA-dC)·poly(dG-dT) and poly(dA-dT)·poly(dA-dT). The absorptions which could therefore be used are those involving the deoxyribose phosphate backbone and, possibly, also bands common to the purine bases. In the high wavenumber range (double-bond stretching vibrations in the base plane), shifts to lower wavenumbers are expected, due to changes in base stacking during the $B \rightarrow Z$ transition. The displacement of the bands cannot be exactly predicted as it must depend both on nature of base and primary sequence of the alternating purine–pyrimidine DNA. The *anti* $\rightarrow$ *syn* transition of the purines should be reflected by a shift of the purine absorption coupled to the glycosyl linkage from 1374 cm^{-1} to 1354 cm^{-1}.

Below 1000 cm^{-1} native and synthetic DNA conformations may be distinguished by distinct sets of ir absorption bands. The right-handed geometries of the B family with a C2′-*endo anti* conformation of the nucleosides have been characterized by ir absorptions around 890 cm^{-1} and 835 cm^{-1}, whereas the right-handed A family helices with a C3′-*endo anti* conformation of nucleosides are detected by ir absorptions at about 890 cm^{-1}, 878 cm^{-1}, 860 cm^{-1}, and 805 cm^{-1} (11, 25). The left-handed helices with C2′-*endo anti* and C3′-*endo syn* alternating geometries may be identified, as in the case of poly(dG-dC)·poly(dG-dC), by ir bands occurring around 925 cm^{-1}, 868 cm^{-1}, 835 cm^{-1}, and 802 cm^{-1}.

Received August 16, 1984

This paper is dedicated to Professor Camille Sandorfy on the occasion of his 65th birthday

JOHN D. GODDARD. Can. J. Chem. **63**, 1910 (1985).

The structures of seven minima and five transition states of the S_0 and T_1 potential energy surfaces of thioformaldehyde have been located at the 3-21G* SCF level. Further calculations have been carried out to determine harmonic vibrational frequencies and to examine the effects of larger basis sets and of configuration interaction on energy differences. The molecular dissociation limit of H_2 and CS is thermodynamically accessible at the energy of the lowest n,π^* excited states and the singlet thiohydroxymethylenes lie only slightly too high. However, there are large barriers of ~85 to 90 kcal mol^{-1} to the molecular dissociation or to the 1,2-hydrogen shifts from thioformaldehyde to the thiohydroxymethylenes. The dissociation to H and HCS requires ~85.4 kcal mol^{-1} on the ground singlet and faces a barrier of several kcal mol^{-1} relative to products on the triplet surface. Any unimolecular photochemistry of thioformaldehyde is likely to require excitation to higher excited states than the lowest n,π^* states.

JOHN D. GODDARD. Can. J. Chem. **63**, 1910 (1985).

Les structures de sept minima et de cinq états de transition des surfaces d'énergie potentielle S_0 et T_1 du thioformaldéhyde ont été localisées au niveau autocohérent 3-21G*. On a effectué d'autres calculs pour déterminer les fréquences vibrationnelles harmoniques et pour examiner les effets d'ensembles de base plus larges et d'interactions de configuration sur les différences d'énergie. La limite de dissociation moléculaire en H_2 et CS est thermodynamiquement accessible au niveau d'énergie des états excités n,π^* les plus bas et les thiohydroxyméthylènes singulets sont situés à un niveau légèrement trop élevé. Toutefois, les barrières à la dissociation moléculaire ou aux transpositions-1,2 d'hydrogènes du thioformaldéhyde au thiohydroxyméthylènes sont très élevées, ~85 à 90 kcal mol^{-1}. La dissociation en H et HCS nécessite ~85.4 kcal mol^{-1} au niveau fondamental alors qu'au niveau de l'état triplet il existe une barrière de plusieurs kcal mol^{-1} par rapport aux produits. Toute photochimie unimoléculaire du thioformaldéhyde demandera probablement une excitation à des états excités supérieurs en énergie aux états n,π^* les plus bas.

Introduction

The spectroscopy and photophysics of the thioformaldehyde molecule, H_2CS, have recently been extensively studied by experimentalists and to a somewhat lesser degree by quantum chemists (1–9). Much of the work on the electronic and vibrational spectroscopies of thioformaldehyde in its ground and lowest-lying excited states has recently been reviewed (1). Spectroscopic studies aimed at determining the molecular constants of the $\tilde{a}\,^3A_2$ state have appeared (2) and are complemented to an extent by a DZ** SCF quantum chemical study (8). The photophysics of H_2CS in its lowest excited states has attracted recent attention (3–6) and there have been some speculations on the question of thioformaldehyde photochemistry (3, 5, 6). Some controversy exists as to whether thioformaldehyde may dissociate into the molecular products, H_2 + CS, on the S_0 surface reached by internal conversion from an initially excited $\tilde{A}(^1A_2)$ state (5, 6). Such a process is well known in the oxygen analogue, formaldehyde, (10) and has been examined in detail by computational studies (e.g. refs. 12, 13). Kawasaki *et al.* (5) raise the possibility of the nonradiative decay of H_2CS ($\tilde{A}\,^1A_2$) to H_2 and CS but this channel is dismissed by Bruno and Steer (6). The molecular products are probably thermodynamically accessible relative to the low-lying n,π^* states but there may be a large barrier to this dissociation (3, 6) if the formaldehyde molecule may serve as a guide (12, 13). The fact that the $^{3,1}n,\pi^*$ origins of thioformaldehyde are at 14 614 cm^{-1} or 41.8 kcal mol^{-1} and 16 395 cm^{-1} or 46.9 kcal mol^{-1}, as compared to 25 194 cm^{-1} or 72.0 kcal mol^{-1} and 28 188 cm^{-1} or 80.6 kcal mol^{-1} for formaldehyde (1), means that considerably less energy will be available for any unimolecular photochemical reactions of H_2CS after excitation into its lowest excited electronic states.

There has been a recent DZ** SCF and CI study (11) on the thioformyl radical, HCS, which is one probable product of any thioformaldehyde photochemistry. Most of the quantum chemical studies on H_2CS have focussed on the molecular structures and vibrational frequencies of the lowest triplet state (7, 8) or the vertical electronic excitation energies (9). There have been no quantum chemical studies on thioformaldehyde, investigating many features of the S_0 and T_1 potential energy surfaces, as there have been, for example, for formaldehyde (12, 13). In particular, the isomerization of thioformaldehyde to thiohydroxymethylenes may be thermodynamically feasible out of the lowest excited states (although the barrier height is unknown). In the case of formaldehyde, the hydroxymethylene isomer has received considerable attention from computationalists (e.g. refs. 12, 14, 15) and has been invoked in the interpretation of certain experiments (16).

The present study examines a number of minimum energy and transition state structures on the ground state, (S_0), and lowest triplet state, (T_1), surfaces of H_2CS. All geometries were optimized using SCF gradient methods and the 3-21G* basis set which includes 6-*d* type Gaussians on S. The natures of all stationary structures (i.e. minima, transition states) were verified by calculating the harmonic vibrational frequencies using analytic second derivatives. Higher level calculations both in terms of basis sets (6-31G*, 6-31G**) and electron correlation (3-21G* CISD) were carried out at the 3-21G* geometries. Potential energy surface features examined include: H_2CS (S_0 and T_1), *cis*- and *trans*-HCSH (thiohydroxymethylenes S_0), the transition state for the internal rotation interconverting the singlet thiohydroxymethylenes, the rearrangement barrier from H_2CS to *trans*-HCSH, the molecular dissociation limit of H_2 and CS and the transition state for this pathway, the radical dissociation products of H + HCS, triplet thiohydroxymethylene, the transition structure for triplet H_2CS rearranging to triplet HCSH, and the barrier for the dissociation of H_2CS (T_1) to H + HCS.

Computational methods

All computations were performed with the GAUSSIAN 82 program system (17). Geometries were optimized at the SCF level using analytic gradient methods and the 3-21G* basis set (18, 19). Note that the 3-21G* basis set includes a set of 6 *d*-type Gaussian functions only on S. Harmonic vibrational frequencies were calculated for all stationary point structures using analytic second derivatives (20) at the 3-21G* SCF level. Basis set extension effects on energy differences at the SCF level were examined at the 3-21G* geometries with single point 6-31G* (19, 21) and 6-31G** (21) computations. Recall that the 6-31G* basis involves sets of *d*-functions on C and S and that the 6-31G** augments the 6-31G* by adding *p*-functions on the hydrogens. Effects of electron correlation on energy differences were accounted for by singles and doubles configuration interaction (3-21G* CISD) relative to the SCF reference configuration with six frozen core MO (approximately the C $1s$ and S $1s2s$ $2p_x2p_y2p_z$ AO) excluded and all virtuals included. The effects of higher excitations were estimated by a size consistency correction (22). In the cases of the molecular (H_2 + CS) and radical (H + HCS) limits, computations were done in the "supermolecule approximation" with the fragments separated by a large distance. Changes in thermal energies were calculated as in GAUSSIAN 82 with a rigid rotator/harmonic oscillator model (e.g. ref. 19) but using the calculated 3-21G* SCF harmonic frequencies to determine zero point energy differences. Best estimates of energy differences were obtained by including the thermal corrections and assuming the additivity of polarization and correlation effects as has been shown to be approximately valid (23).

Results and discussion

The total energies as well as the energy differences relative to ground state thioformaldehyde at five levels of computation are presented in Table 1 for all twelve stationary points. Table 2 collects the 3-21G* SCF optimized geometries (r_e structures) for the seven minimum energy and five transition state structures. Table 3 displays the 3-21G* SCF harmonic vibrational frequencies in cm^{-1} along with these values scaled by 0.9 (see below) and the symmetry label where appropriate. Note that all transition state structures have exactly one imaginary frequency as required for a true transition state. Table 4 presents an analysis of the results in Tables 1 and 3 to yield the best estimates of this study for the thermochemical energy changes or barrier heights to reaction.

Energies

Comparisons of the calculated energy differences with experiment are in order where spectroscopic or thermochemical data exist. Spectroscopy places the T_1 origin in thioformaldehyde at 14 614 cm^{-1} or 41.8 kcal mol^{-1} (1), which is in quite good agreement with the computed value of 42.3 kcal mol^{-1} (3-21G* CISD + size consistency correction (SCC)) or the estimate of 40.9 kcal mol^{-1} (Table 4). The enthalpy difference between ground state H_2CS and the hydrogen molecule plus carbon monosulphide may be computed from thermochemical data (3, 24, 25) to be 31 ± 7.6 kcal mol^{-1} (a value of ~40 kcal mol^{-1} is used in Figs. 1 and 3 of refs. 3 and 6 respectively), which agrees reasonably well with the result of this study, 34.9 kcal mol^{-1}. As a partial test of the effects of using geometries optimized with correlated methods on the predicted energy differences, the H_2 + CS and H_2CS (S_0) structures were redetermined at the 3-21G* CISD level. At these CI geometries (and employing the thermal and basis set extension effects in Table 4), the energy change between ground state thioformaldehyde and the molecular dissociation limit is 36.5 kcal mol^{-1} and thus differs from the prediction at the SCF optimized geometries by only 1.6 kcal mol^{-1}. The enthalpy difference between S_0 thioformaldehyde and a hydrogen atom plus a thioformyl radical, HCS, is given as 90 ± 24 kcal mol^{-1} from experiment (3, 25, 26), with the large uncertainty due to the heat of formation of HCS of 63 ± 19 kcal mol^{-1} (26). The calculated value, in this work, of 85.4 kcal mol^{-1} for $H_2CS \rightarrow H + HCS$ is certainly reasonable.

As the 3-21G* basis set is relatively small, it is quite possible that the SCF energy differences are slightly too large due to basis set superposition errors (BSSE). However, as only the H_2CS minimum and the radical and molecular limits are of interest relative to experiment, it is unlikely that BSSE would be of very great significance on a scale of 34.9 or 85.4 kcal mol^{-1}, the computed dissociation energies. Corrections for such errors could become highly important in an accurate treatment of all regions of the potential surface, including very weak interactions.

For the other minimum energy species, the singlet and triplet thiohydroxymethylenes, no comparisons with experiment are possible. Some obvious and interesting comparisons with each other and with formaldehyde suggest themselves. Thiohydroxymethylene is a singlet stable carbene as is expected for a methylene with a hydrogen replaced by a somewhat electronegative substituent bearing lone pair electrons (27). The values in Table 4 place triplet HCSH ~9.1 kcal mol^{-1} higher in energy than singlet *trans*-HCSH. The comparable energy gap between *trans*-HCOH (S_0) and *gauche*-HCOH (T_1) has been computed to be ~25 kcal mol^{-1} (14). For the singlet thiohydroxymethylenes the *trans* isomer is slightly (2 kcal mol^{-1}) more stable than the *cis* form. In hydroxymethylene, HCOH, this difference is somewhat larger at 5.5 kcal mol^{-1} (12, 15). Relative to the oxygen analogues, there appears to be a "leveling effect" in the sulphur case with smaller energy gaps between the various thiohydroxymethylenes.

Two final comparisons of energy differences between minima, namely, H_2CS (S_0) vs. *trans*-HCSH (S_0) and H_2CS (T_1) vs. *gauche*-HCSH (T_1) should be made. *trans*-Thiohydroxymethylene singlet is predicted to be 52.3 kcal mol^{-1} higher in energy than ground state thioformaldehyde. In the case of H_2CO, the best calculated energy differences for the comparable quantity are in the range 52.6 to 55.4 kcal mol^{-1} (12, 15). *gauche*-Triplet thiohydroxymethylene lies ~19.2 kcal mol^{-1} above triplet thioformaldehyde while for the oxygen analogue this difference was calculated to be ~14 kcal mol^{-1} (14*b*). The relative energies of H_2CX and HCXH, singlet or triplet, are thus similar for X = O and S.

Certain qualitative features regarding the heights of reaction barriers should first be noted. Considerations of orbital or state correlation diagrams (28) suggest that the dissociation of H_2CS to H and HCS radicals on the S_0 surface should face no barrier beyond the reaction endothermicity. A barrier to the dissociation of triplet thioformaldehyde to the same radicals is predicted (28) and such a feature was approximately located in SCF computations on H_2CO (T_1) (29). A symmetry analysis of

the dissociation of formaldehyde to the molecular products, H_2 and CO, (e.g. ref. 30) suggests a high barrier and a transition state structure which may remain planar but is distorted from C_{2v} symmetry. Similar results may hold for thioformaldehyde. Consideration of the highest occupied molecular orbital (HOMO) in the case of the 1,2-hydrogen shift from singlet H_2CO to singlet *trans*-HCOH (31) suggests a large barrier to such a rearrangement as H_2CS (S_0) → *trans*-HCSH (S_0).

Turning to the computational results in Tables 1 and 4, the 3-21G* SCF barrier to the molecular dissociation is very large at 116.3 kcal mol^{-1}, relative to ground state thioformaldehyde. All the more elaborate calculations and the thermal correction act to decrease this barrier but it is still large at 87.1 kcal mol^{-1} for a best estimate. The energy requirement is some 46.2 kcal mol^{-1} above the calculated energy of the lowest excited n,π^* triplet state or ~40 kcal mol^{-1} above the experimental energy of the $^1n,\pi^*$ excited state. Relative to the molecular products of hydrogen molecule and carbon monosulphide the energy barrier is 52.2 kcal mol^{-1} as the reaction H_2CS (S_0) → H_2 + CS is overall endothermic by 34.9 kcal mol^{-1}. By way of comparison, the barrier in formaldehyde to dissociation to H_2 and CO is calculated to be 80.6 ± 3 kcal mol^{-1} (13*b*). There has been a detailed discussion regarding the adequacy of a single reference configuration for this transition state in H_2CO (13*b*). It is probable that for H_2CS a multi-reference CISD or MCSCF + CI calculation would predict a lower barrier by perhaps 5 to 10 kcal mol^{-1}. However, the barrier is certain to remain considerably greater than the energy available in the lowest n,π^* excited states of thioformaldehyde.

The barrier to the 1,2-hydrogen shift linking singlet thioformaldehyde to *trans*-thiohydroxymethylene is predicted to be 85.9 kcal mol^{-1} in Table 4. Thus, the reverse barrier from the *trans*-methylene to the aldehyde isomer is 33.6 kcal mol^{-1}. These barriers are quite reminiscent of those in formaldehyde whose analogous rearrangements require 84.4 to 85.9 and 29.0 to 30.0 kcal mol^{-1} (12, 15). Once again, the effects considered beyond the 3-21G* SCF calculation (barrier 104.4 kcal mol^{-1}) all lowered the energy for rearrangement. This energy requirement of 85.9 kcal mol^{-1} for the hydrogen shift is very similar to that for the molecular dissociation of 87.1 kcal mol^{-1} and to the dissociation energy to radicals on the S_0 surfaces at 85.4 kcal mol^{-1}.

The transition state for the triplet rearrangement from H_2CS to *gauche*-HCSH requires 46 kcal mol^{-1} relative to the aldehyde isomer. The reverse reaction faces a barrier of 26 kcal mol^{-1}. The analogous rearrangement of triplet formaldehyde has not been investigated. The 1,2-hydrogen shift from triplet vinylidene to triplet acetylene (32) has a large classical barrier of ~55 kcal mol^{-1} and proceeds through a decidedly nonplanar transition structure.

The energy required for the internal rotation from *trans*- to *cis*-thiohydroxymethylene is calculated to be 33.6 kcal mol^{-1} relative to *trans* or 31.6 kcal mol^{-1} relative to *cis*. Such a barrier is, of course, large for an internal rotation about a single bond. However, the CS bond acquires considerable double bond character through donation of the lone pairs on S into the formally vacant carbene C $p\pi$ type orbital (12). This favourable interaction is essentially lost at the transition state where the dihedral angle is nearly 90°. In formaldehyde the comparable barrier has been calculated to be ~29 kcal mol^{-1} (12, 15).

The dissociation of triplet state thioformaldehyde to the ground states of H and HCS has been calculated to have a thermodynamic energy requirement of 43.2 kcal mol^{-1}. However, as anticipated from symmetry arguments (28), there is an additional small barrier of ~5 kcal mol^{-1} relative to the dissociated radicals at infinite separation. The lowest triplet state of H_2CO also has a similar small hump in the potential for the cleavage to radicals of ~9 kcal mol^{-1} at the small basis set SCF level (29).

Structures

may be compared with experimental results. The 3-21G* SCF predictions for the structures of these species as well as for that of the thioformyl radical, HCS, may also be examined relative to earlier SCF calculations employing somewhat larger Gaussian basis sets. The experimental results for r_e(CS) and r_e(CH) in $\tilde{X}A_1$ H_2CS are 1.6110 Å and 1.0856 Å (33), in very reasonable agreement with the 3-21G* SCF predictions from Table 2 of 1.594 Å and 1.076 Å. The α_z(HCH) angle from the microwave spectrum is 116.2° (34) and is only 0.9° larger than the 3-21G* SCF value of 115.32°. The predicted CS bond length of 1.720 Å for $\tilde{a}\,^3A''$ thioformaldehyde is 0.037 Å longer than the experimental r_e value of 1.683 (8) Å (35). Difficulties in predicting an acceptable SCF bond length in the lowest triplet state of H_2CS have been discussed previously (7, 8). A similar problem may be noted in the SCF level CO bond length in the $^3n,\pi^*$ state of formaldehyde (36). The values of r_e(CH) = 1.072 Å and α_e (HCH) = 120.68° for the 3-21G* SCF geometry of T_1 thioformaldehyde are in reasonable agreement with experiment, 1.082 Å and 119.3° (35). Triplet H_2CS is not calculated to be pyramidal enough with the 3-21G* SCF method as the experimental out-of-plane angle is ~12° (35). However, motion out-of-plane in the n,π^* triplet state of thioformaldehyde is along an exceedingly soft potential with an inversion barrier estimated to be 4.1 cm^{-1} (35). Considerable sensitivity of the out-of-plane angle to basis set effects is understandable (7, 8). r_e(CS) in carbon monosulphide is calculated to be 1.523 Å (in a supermolecule along with H_2), which is slightly shorter than the experimental result of 1.534941 Å (37) and nearly identical to a DZ* SCF result (11). The hydrogen molecule bond length is predicted to be 0.735 Å whilst the experimental result is 0.74144 Å (37). The 3-21G* SCF clearly provides very reasonable representations relative to experiment of the molecular structures of a number of the species of interest in this study.

Although the 3-21G* SCF geometries appear reasonable and adequate for present purposes, the geometries of ground state thioformaldehyde and of the H_2 + CS system were reoptimized at the 3-21G* CISD level. The predicted CISD bond lengths

TABLE 3. 3-21G* SCF harmonic vibrational frequencies in cm^{-1}. Frequencies for the molecular and radical limits were calculated in the supermolecule approximation. Symmetry designations are in parentheses along with the value of the frequency scaled by 0.9 to allow for anharmonicity and the SCF approximation

in H_2 and CS (experimental values in parentheses) were: $r_e(HH) = 0.744$ Å (0.741 Å (37)) and $r_e(CS) = 1.543$ Å (1.535 Å (37)). In thioformaldehyde, the CISD parameters were $r_e(CS) = 1.614$ Å (1.611 Å (33)) and $r_e(CH) = 1.088$ Å (1.0856 Å (33)) and $\alpha_e(HCH) = 116.4°$ (116.2° (34)). The CISD bond lengths have all increased relative to the optimum SCF values and are now in better agreement with experimental results, although all are slightly (0.003 to 0.007 Å) too long. In light of recent studies on SO_2 and SO_3^{2-} (40), it is possible that a more appropriate choice of d-function exponent (in the 3-21G* basis) might yield yet shorter SCF bond lengths and thus even better agreement with experiment when correlation is included. However, such effects on CS bonds do not appear to be as large as those found in the case of the SO bonds (40).

The 3-21G* basis set with 6 d-functions on S only is a fairly compact basis set that may prove useful in studies of larger thioketones. Therefore, comparison of the 3-21G* SCF geometries with those from 6-31G* calculations where 6 d-functions are also included on carbon (19) is of value. The 6-31G* SCF r_e(CS) in carbon monosulphide is 1.520 Å (19) within 0.003 Å of the 3-21G* result in this work of 1.523 Å. For $\tilde{X}\,^1A_1$ H_2CS, the 6-31G* SCF geometry (19) is r_e(CS) = 1.597 Å, r_e(CH) = 1.078 Å, and α_e(HCH) = 115.5°, which is quite close to the 3-21G* SCF result of 1.594 Å, 1.076 Å, and 115.32°. In the case of the $\tilde{a}\,^3A_2$ state of thioformaldehyde, the 3-21G* SCF results of r_e(CS) = 1.720 Å and r(CH) = 1.072 Å compare favourably with the DZ** SCF values of 1.732 Å and 1.075 Å (7). The geometry for the ground state of the thioformyl radical is (in the supermolecule with H) r_e(CS) = 1.588 Å, r_e(CH) = 1.072 Å, and α_e(SHC) = 135.62° while the DZ** SCF parameters are 1.559 Å, 1.080 Å, and 134.8° (11). For those stationary point structures for which comparisons with experiment or earlier calculations or both are possible, the 3-21G* SCF geometries are quite adequate.

The other minimum energy structures, namely the *trans*- and *cis*-thiohydroxymethylene singlets and the *gauche*-thiohydroxymethylene triplet, should be compared one with another as well as with the hydroxymethylenes (12, 14, 15). The most noteworthy structural features of the singlet thiohydroxymethylenes are the relatively short CS bond lengths of 1.677 Å (*trans*) or 1.657 Å (*cis*). These short bond lengths are strong evidence of the partial double bond character created by the donation of the sulphur lone pair electrons into the formally vacant carbene carbon $p\pi$ orbital. Recall that a typical CS single bond distance in methanethiol is 1.819 Å, or 0.13 to 0.17 Å greater than the CS distances in the singlet thiohydroxymethylenes. The CS distances are 0.063 to 0.083 Å greater in the methylene isomer than for the double bond in ground state thioformaldehyde. The shorter CX distance in the *cis* rather than the *trans* form has also been noted in singlet HCOH (12, 14, 15). The CH distances in the thiohydroxymethylenes are 1.095 or 1.089 Å, which are longer than in H_2CS but fairly typical of CH lengths in singlet methylenes (e.g. in $^1A_1$ CH_2, r(CH), is 1.11 Å (38)). The r_e(SH) of 1.328 Å *trans* and 1.344 Å *cis* may be compared to the r_0 value of 1.328 Å in H_2S (38a). The SH bond distance in the *cis*-isomer is lengthened somewhat, presumably due to some steric crowding. The bond angles in the *trans*-isomer of SCH, 107.08°, and CSH, 99.90°, are ~5° and 8° larger than comparable angles in singlet CH_2 of 102.4° (38) and H_2S of 92.2° (38a). In the *cis* species, these angles open up considerably to α_e(SCH) = 114.26° and α_e(CSH) = 107.81°. A note of caution regarding the optimized geometries for the singlet thiohydroxymethylenes should be struck. It has often been seen (e.g. ref. 39) that an improved description of the electronic structures and geometries of species such as methylenes or silylenes is given by a two-configuration SCF calculation rather than the usual single-configuration SCF employed here. This point is currently under investigation for the singlet thiohydroxymethylenes.

Triplet thiohydroxymethylene adopts a *gauche* conformation with τ(HCSH) = 92.29° since, with the carbene C$p\pi$ orbital singly occupied, any donation of the S lone pair electron density into this orbital is inhibited. For a similar reason the CS distance in triplet-HCSH increases to 1.723 Å, a value markedly longer than in the singlet-thiohydroxymethylenes and very similar to the *calculated* distance in H_2CS (T_1). The r_e(SH) at 1.332 Å is similar to the value in *trans*-HCSH (S_0) or in H_2S (38). The r_e(CH) distance of 1.073 Å is close to the experimental value of 1.078 Å in $^3B_1$ methylene (38). The SCH angle of 130.46° is typical of a triplet carbene (e.g. $^3B_1$ CH_2 136° (38)) while the CSH angle of 98.79° is close to that in the *trans*-thiohydroxymethylene singlet.

The structures of the thioformaldehyde transition states may be referenced to the reactants and products of the process concerned, as well as to the calculations on formaldehyde (12, 13). The transition state structure for the internal rotation connecting the *trans*- and *cis*-HCSH singlet species occurs, as might be expected, at a dihedral angle close to 90° (89.00°) and with a significantly larger CS distance of 1.858 Å. The CH distance of 1.099 Å and the SH distance of 1.333 Å are close to their values in *trans*-HCSH. With the much longer CS distance the SCH angle closes down by ~2° relative to the *trans*-isomer to a value of 105.01° and the CSH angle decreases by ~9°, relative to *trans*, to 90.79°.

The transition state structures for the rearrangements of H_2CS (S_0) to *trans*-HCSH (S_0) and for H_2CS (T_1) to *gauche*-HCSH (T_1) make an interesting comparison. The hydrogen that is migrating is labelled H_r in Table 2. The singlet rearrangement proceeds through a planar transition state (τ(HCSH$_r$) = 180°), while in the triplet case this dihedral angle is 96.21°. The r(CS) of the singlet transition state is 1.693 Å, or 0.016 Å greater than the product value of 1.677 Å in *trans*-HCSH. The shifting hydrogen is 1.403 Å from the C it is leaving and 1.475 Å from the S to which it will become bonded in the singlet transition state. The SCH$_r$ angle is 55.96°. For the triplet hydrogen shift, the CS distance in the transition structure is only slightly longer than in triplet thioformaldehyde or thiohydroxymethylene. The hydrogen which migrates is 1.436 Å from C, 1.494 Å from S, and forms an SCH$_r$ angle of 55.30° in the triplet transition structure. The triplet transition state is thus slightly "looser" than the singlet one. The triplet torsional angle of 96.21° in the transition state will become 92.29° in the product, *gauche*-thiohydroxymethylene. For the structural features less directly involved in the rearrangement, in the singlet case r(CH) of 1.086 Å is nearly exactly midway between the distance in H_2CS (S_0) of 1.076 Å and that in *trans*-HCSH (S_0) of 1.095 Å. The SCH angle of 119.60° in the singlet transition state is ~2.7° less than in thioformaldehyde, but ~12.5° greater than in *trans*-HCSH. The triplet rearrangement transition structure has an SCH angle of 130.59°, which is essentially the final value in *gauche*-HCSH of 130.46°. The r_e(CH) of 1.072 Å in the triplet transition geometry is nearly equal to that in either the aldehyde or methylene triplet isomers.

The transition state for the dissociation to molecular products is reminiscent of the formaldehyde case (12, 13). It is planar but highly distorted with both hydrogens on the same side of the CS axis. One hydrogen (H_1 in Table 2) is at a very large distance from the carbon, namely 1.588 Å, while the other (H_2) is more modestly lengthened to $r_e(CH_2)$ = 1.156 Å. The H_1H_2 distance in the transition state structure is 1.036 Å, much greater than its calculated value in the final product H_2 of 0.735 Å. The CS distance in the molecular dissociation transition state is 1.565 Å, which is modestly greater than the calculated value in the product, carbon monosulphide, of 1.523 Å. On the basis of this transition state structure alone, strongly vibrationally excited H_2 but only modest vibrational excitation in CS could be predicted for the molecular dissociation products.

On the T_1 potential energy surface, the transition structure for the dissociation to radicals is noteworthy. The departing hydrogen atom is quite far removed from the thioformyl radical at the transition state with $r_e(CH_2) = 2.032$ Å. The dissociating H is nearly perpendicular to the HCS fragment as $\alpha_e(H_2CH_1) = 85.04°$ and $\alpha_e(SCH_2) = 105.02°$. In the thioformyl group, the H_1CS angle of 136.06° is less than 0.5° from its final calculated value of 135.62°. $r_e(CH_1)$ at 1.073 Å in the transition state is essentially equal to the value in the product HCS. $r_e(CS)$ equals 1.573 Å in the radical dissociation transition state, which is 0.015 Å shorter than in the product. A qualitatively similar transition state (particularly with regards to the near "perpendicularity" of the departing hydrogen atom) has been approximately located in the triplet radical dissociation of H_2CO (29).

Vibrational frequencies

The harmonic vibrational frequencies calculated at the 3-21G* SCF level and collected in Table 3 verify the nature (minimum, transition state) of the stationary point structures found in the geometry optimizations. For the minima, these frequencies may be scaled (in parentheses in Table 3) to allow both for anharmonic effects and the SCF approximation (e.g. ref. 41) and then compared with experimental results for H_2CS (S_0 and T_1), H_2, and CS. The scaled frequencies for the singlet and triplet thiohydroxymethylenes are first predictions of the vibrational spectra of these species. Inspection of the imaginary frequency for the different transition state structures provides additional information as to the nature of the reaction coordinate.

The optimum value of a scaling factor for calculated 3-21G* SCF harmonic frequencies is not known precisely but is likely to be ~0.90, on the basis of 3-21G SCF results on a number of molecules containing only first row atoms (41) and of DZ** SCF frequencies for $\tilde{X}\,^1A_1$ H_2CS and $^1\Sigma$ CS (8, 11). Using a scale factor of 0.90 to give the frequencies in brackets in Table 3 and the experimental frequencies of ground state H_2CS from ref. 1, the comparison is (scaled 3-21G* SCF/experiment): 3020/3024.6 b_2, 2947/2971 a_1, 1499/1457.3 a_1, 1071/1059.2 a_1, 1055/990.2 b_1, and 1001/991.0 b_2. The agreement is to within 65 cm^{-1} in the worst case and averages 28 cm^{-1} in magnitude. In the lowest triplet state, with experimental frequencies from refs. 1 and 2 or calculated and scaled DZ** SCF frequencies (8), if no experimental result is available after the slash the comparisons are (symmetry labels as in C_{2v}): 3092/3078 b_2, 2981/2962 a_1, 1368/1320 a_1, 810/861.6 a_1, 756/762.3 b_2, and 121/356 b_1. Except for the out-of-plane b_1 mode, which is at any rate poorly described in any harmonic approximation (8), the agreement is satisfactory. The 3-21G* scaled frequency for CS is 1277 cm^{-1} (in the supermolecule with H_2) which compares nicely with the experimental ω_e of 1285.08 cm^{-1} (37). The scaled frequency for the hydrogen molecule (21G description) is 4191 cm^{-1}, which is not in quite so good agreement with experiment (4401.21, ref. 37).

The predicted vibrational frequencies for the singlet and triplet thiohydroxymethylenes may aid in the identification of these species. In *trans*-HCSH (S_0), the modes which are predominantly the CH and SH stretches are at 2816 cm^{-1} and 2854 cm^{-1} respectively. The CH stretch shifts to slightly higher, 2867 cm^{-1}, and the SH stretch to slightly lower, 2455 cm^{-1}, frequency in the *cis*-isomer, nicely reflective of the CH and SH bond length changes (Table 2). The CH stretches may be compared to the best calculated values in the oxycarbenes of 3002 cm^{-1} and 2912 cm^{-1} (12). The SH stretches are at frequencies quite similar to that of the SH stretch in methanethiol of 2605 cm^{-1} (42). The out-of-plane modes (a'') in the thiohydroxymethylenes of 900 cm^{-1} *trans* or 876 cm^{-1} *cis* indicate clearly the stability of the planar forms. The modes which are largely CS stretches in the thiohydroxymethylenes have frequencies of 783 cm^{-1} (*trans*) or 752 cm^{-1} (*cis*), which are 27 to 30% less than the CS double bond stretch calculated for H_2CS (S_0) at 1071 cm^{-1} but greater than the observed CS single bond stretch in CH_3SH of 710 cm^{-1} (42).

The CH stretch in triplet thiohydroxymethylene is predicted at 3020 cm^{-1}, nearly 200 cm^{-1} higher than in the singlets. The SH stretch at 2584 cm^{-1} in the triplet is, however, quite similar to that in the singlets, especially the *cis*-isomer. The torsional mode for the triplet thiohydroxymethylene is fairly low at 325 cm^{-1} (although the harmonic approximation may not be a particularly good one for this mode). A mode dominated by the CS stretching is at 770 cm^{-1} in the triplet thiohydroxymethylene.

The imaginary frequency for the transition state structures corresponding to motion along the reaction coordinate at that point is of particular interest, but so also are the values of certain other frequencies relative to reactants or products. In the singlet rearrangement transition state from H_2CS (S_0) to *trans*-HCSH (S_0), the out-of-plane mode of 312 cm^{-1} verifies the planarity of the transition state but is considerably softer than the comparable vibrations in thioformaldehyde, 1055 cm^{-1}, or *trans*-thiohydroxymethylene, 900 cm^{-1}. The CH stretch, which is not involved in the shift, is at 2870 cm^{-1} or very nearly at the thiohydroxymethylene value of 2816 cm^{-1} and well below the CH stretches in thioformaldehyde at 3020 and 2947 cm^{-1}. The imaginary frequency of 2190i cm^{-1} is rather high as it involves principally motion of a hydrogen. The imaginary frequency for the 1,2-hydrogen shift transition state in the triplet case is 1841i cm^{-1}. The CH stretch for the hydrogen not rearranging is 3033 cm^{-1} and nearly equal to the value of 3020 cm^{-1} in *gauche*-HCSH. The mode at 613 cm^{-1} is chiefly the torsion and is ~160 cm^{-1} less than in the product thiohydroxymethylene.

The distorted transition state for the dissociation to molecular products is planar with an out-of-plane frequency (a'') of 868 cm^{-1}, only some 200 cm^{-1} less than the value in H_2CS (S_0). The mode which is principally a CS stretch occurs at 1032 cm^{-1} in this transition state, 1071 cm^{-1} in the reactant thioformaldehyde, and 1277 cm^{-1} in the product carbon monosulphide. The imaginary frequency of 1826i cm^{-1} is associated with the motions of the two hydrogens swinging across the CS axis and coming together in an incipient formation of the H_2 product.

The transition structure for the dissociation to radicals on the T_1 surface has an interesting pattern of vibrational frequencies. The CH stretch at 3012 cm^{-1} is within 10 cm^{-1} of its value in the thioformyl radical product, while the CS stretch at 1035 cm^{-1} and the bend at 805 cm^{-1} are slightly further from their values in HCS of 929 cm^{-1} and 852 cm^{-1}. The imaginary frequency of 766i cm^{-1} is almost totally involved with the $r(CH_2)$ distance, with a small component of the angular variables characterizing the near-dissociation hydrogen atom.

Concluding remarks

This fairly detailed examination of features on the S_0 and T_1

potential energy surfaces of thioformaldehyde has revealed many similarities to earlier results on the oxygen analogue, formaldehyde. Although still larger computations may change some of the energy differences of Table 4 by perhaps 5 kcal mol^{-1}, nevertheless much has been learned of the energetics of reaction of thioformaldehyde. Notably, the rearrangement barriers from singlet or triplet thioformaldehyde to the respective thiohydroxymethylenes, the internal rotation interconverting *trans*- and *cis*-HCSH (S_0), the molecular dissociation transition state, and the radical dissociations on either the S_0 or T_1 surfaces all require ~85 to 90 kcal mol^{-1} of energy relative to ground state H_2CS. Thus, with respect to the first excited n,π^* triplet state the excess energy requirement is ~40 to 45 kcal mol^{-1}. Clearly, if thioformaldehyde is to react photochemically and unimolecularly, involvement of higher excited electronic states (e.g. experimentally the origin of the S_2 state is at ~132 kcal mol^{-1} (3)) will be required.

As the calculations reported herein were nearing completion, Pope *et al.* published a communication (43) dealing with the rearrangement and fragmentation of H_2CS (S_0). The geometries determined at the triple-ζ plus C and S *d* function SCF level are similar to the comparable 3-21G* SCF structures in this work. Their triple-ζ plus two sets of *d* functions on C and S and *p* on H multireference CI yielded energy differences generally slightly smaller than the best estimates of Table 4. Their communication does *not* deal with *cis*-HCSH, the internal rotation transition state connecting *trans*- and *cis*-HCSH, or any of the triplet state species.

Acknowledgements

It is a pleasure to thank Professor Sandorfy for his assistance at several times during the author's graduate student days. The author's interest in thioformaldehyde was initiated through numerous discussions with Dr. D. J. Clouthier. Financial support of this work by the University of Guelph Research Board in the form of a start-up grant and by an operating grant from the Natural Sciences and Engineering Research Council of Canada is gratefully acknowledged.

This paper is dedicated to Professor Camille Sandorfy on the occasion of his 65th birthday

BRYAN R. HOLLEBONE, COOPER H. LANGFORD, and ARAMICE Y. S. MALKHASIAN. Can. J. Chem. **63**, 1918 (1985).

Magnetic circular dichroism spectra of several acidoamine cobalt(III) complexes are reported which reveal *B* terms for the spin allowed bands and *A* terms for the spin forbidden bands. It is shown that ligand field parameters derived from fitting of a full set of spin forbidden bands, including the quintet, gives Racah *B* and *C* electron repulsion parameters closer to those anticipated from theory than has been common using mainly the singlets and a single weak low energy absorption feature assigned to a triplet. The spectra indicate that the quintet which has figured in numerous photochemical speculations lies at relatively high energy. This conclusion is a consequence of both the recognition of an *A* term assignable to the quintet and the best fit ligand field parameters for all bands.

BRYAN R. HOLLEBONE, COOPER H. LANGFORD, et ARAMICE Y. S. MALKHASIAN. Can. J. Chem. **63**, 1918 (1985).

On a déterminé les spectres mcd de plusieurs complexes d'acidoamine de cobalt(III) qui mettent en évidence les termes *B* des bandes permises de spin et les termes *A* des bandes interdites de spin. On montre que les paramètres de champs de ligand que l'on peut obtenir en ajustant un ensemble complet de bandes interdites de spin, y compris le quintuplet, donne des paramètres de répulsion électronique du type Racah *B* et *C* qui se rapprochent d'avantage de ceux que l'on a généralement obtenus en faisant principalement appel aux singulets et à une caractéristique unique et faible d'absorption de basse énergie qui était attribuée à un triplet. Les spectres indiquent que l'énergie du quintuplet que l'on invoque dans plusieurs spéculations photochimiques se situe à un niveau relativement élevé. Cette conclusion résulte à la fois de la reconnaissance du terme *A* attribuable au quintuplet ainsi qu'à un meilleur ajustement des paramètres de champ du ligand pour toutes les bandes.

[Traduit par le journal]

Introduction

The assignment of the ligand field states and appropriate ligand field parameters to complexes of the d^6 Co(III) acido amine complexes is a classic problem in ligand field theory (1). Yet it remains incomplete in the sense that empirical information on the spin forbidden states is sparse.

This report concerns the gains in information which result from the use of magnetic circular dichroism (mcd) spectra. These are mainly a result of the very much greater relative intensities of the spin forbidden bands as compared to spin allowed bands in mcd (2). It proves possible to assign transitions to both of the triplet bands that are expected in octahedral d^6 complexes and as well to assign the position of the previously unreported quintet. These accomplishments in cobalt spectroscopy are not without precedent. In earlier work, it has proven possible to use mcd to resolve a spin forbidden ligand field band from under the tail of an allowed charge transfer transition (3) and to assign a doublet band which occurs between the two spin allowed bands in the spectrum of an octahedral d^3 Cr(III) complex (4).

The bands are interpreted in terms of octahedral local splittings. Reductions in symmetry are not large enough to be well defined. With some misgiving, we retain O_h labels, but this should be understood as a way of emphasizing the limit on resolution in these spectra!

It is perhaps useful to note that there is a current reason for renewed interest in this spectral problem. In the course of photochemical studies of chloroamine cobalt(III) complexes, we have found a complex pattern of wavelength dependence which requires consideration of intersystem crossing between singlet, triplet, and perhaps quintet excited states.

Experimental

The complexes were chloropentaminecobalt(III) chloride, *cis* and *trans* dichloro-bis(ethylenediamine)cobalt(III) chloride, and *cis* chloroisothiocyanatobis(ethylenediamine)cobalt(III) chloride. These were all prepared by well-established methods (5−8). Solutions were prepared by weighing into small beakers (to the nearest 0.01 mg) an amount of the solid salt about three to four times the quantity needed to prepare solutions for conventional absorption spectroscopy. A few milliliters of ultrapure water (Millipore system) were added and the beakers warmed gently until all the salt was dissolved. The mcd spectra were recorded immediately. Conventional absorption spectroscopy was carried out using a Perkin−Elmer 557.

The mcd spectra were recorded on a custom-built spectrometer using in sequence a xenon 150-W lamp, Cary 14 monochromator, Glan−Taylor polarizer, Hind's International Piezooptical polarizer, Walker Engineering 2.2 T electromagnet, and Hamamatsu 955 photomultiplier detector. The phototube DC current is kept constant by a feed-back circuit controlling a Hamamatsu power supply. The AC signal representing the 50-kHz mcd differential absorption is decoupled at the preamplifier mounted in the phototube socket, filtered, and amplified in a PAR Model 124 lock-in amplifier. The output is digitized by a 12-bit A/D converter linked to a Motorola Exorcisor II which automatically scans the spectrometer through the desired wavelength range under the desired signal-to-noise quality conditions. Baseline and spectrum data files are subsequently merged digitally and the resulting spectra plotted on a digital X−Y recorder.

The final aspect of the assignment of mcd spectra is the location of the zero, since the experiment is inherently single beam. This requires the choice of "lock" frequencies where the signal is taken to be zero. The locks in these spectra are set at the long wavelength end where absorption spectra show features have been exhausted. The other lock

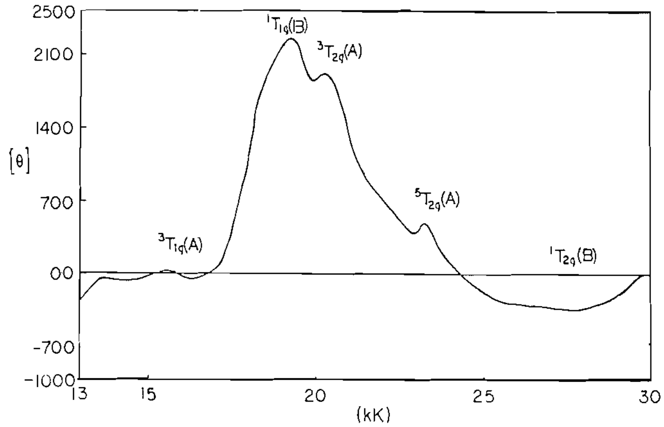

FIG. 1. The mcd spectrum of $Co(NH_3)_5Cl^{2+}$. Concentration 0.0521 *M*. Lock points at 13 kK and 24 kK.

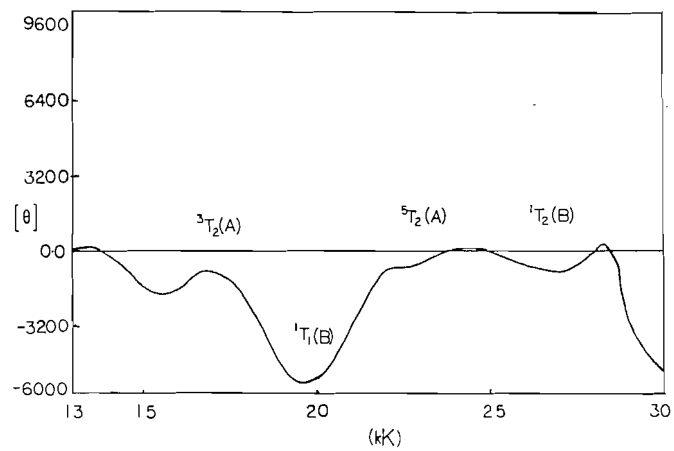

FIG. 2. The mcd spectrum of *trans*-$Coen_2Cl^+$. Concentration 0.0371 *M*. Lock points at 14 kK and 28 kK.

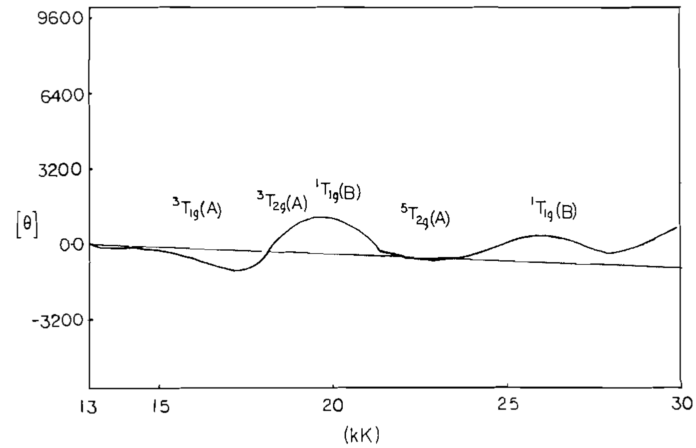

FIG. 3. The mcd spectrum of *cis*-$Coen_2Cl^+$. Concentration 0.0285 *M*. Lock points at 14 kK and 27 kK.

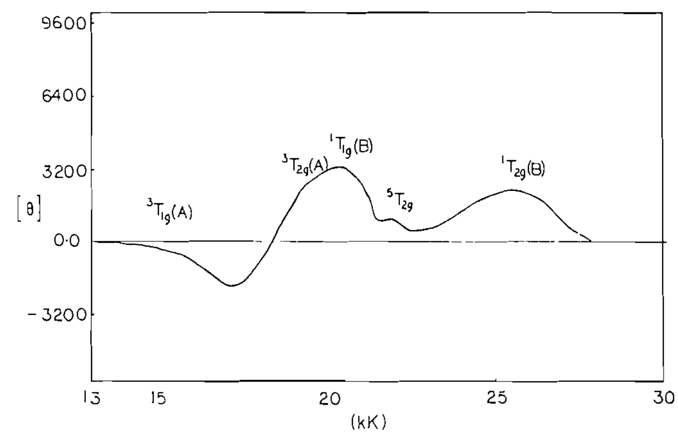

FIG. 4. The mcd spectrum of *cis*-$Coen_2(NCS)Cl^+$. Concentration 0.018 *M*. Lock points at 14 kK and 28 kK.

wavelength is set at the minimum point in the conventional absorption spectrum between the "*B*" terms associated with the singlets. This is a "debatable" choice and will involve some approximation in all cases. In consequence of the lack of a second lock point which is well defined, there will inevitably be some error in assignment of band centres. The sometimes poor agreement of "observed" with "calculated" values in Table 1 is in part a result. The essential correctness of the choice of lock points is indicated by the agreement of the peak frequencies of the *B* terms which are assigned to the singlets with the frequencies assigned to the same singlets in the ordinary absorption spectra.

Results

The four spectra are presented in Figs. 1 through 4 and Table 1. Assignments are indicated on the figures. The signal-to-noise ratio in these spectra is only slightly lower than the pen width indicates. Thus, the inflections indicating the presence of *A* terms are readily identified. However, this *qualitative* good resolution does not carry over into definition of band centres. The bands are broad, as expected, and it is difficult to identify peaks. The uncertainty in energies assigned is *rather large*! In addition to the lock point problems we call special attention to the width of the *B* terms. Precision in centre location is not much better than ± 1.0 kK. These spectra are to be compared with early mcd spectra reported by McCaffry, Stephens, and Schatz in 1967 (9). The error bars shown in ref. 9 indicated that, as expected, developments in signal recording and processing have allowed for much improved signal-to-noise in the current spectra. Thus, the spectra of ref. 9 do not reveal the *A* terms assigned in the figures. This lack of "resolution" also causes two problems. In the spectra of the *cis* dichloro ion, the "lock" point implied by the published spectrum (it is not explicitly stated) does not correspond to the minimum in the absorption spectrum. This leads to the assignment of two negative *B* terms which do not match peaks of the absorption spectrum. If the "lock" is placed at the minimum, the result is a single positive *B* term which does match the peak in the absorption spectrum. The negative features are revealed here to be a part of *A* terms. Similarly, there is a lock problem in the spectrum of the chloropentaamine complex shown in ref. 9. At the low energy end, the spectrum is brought to zero at too long a wavelength. The rough constancy of the spectrum from about 16.5 kK to 13 kK shows that the last "peak" shown in ref. 9 is an artifact. The modification of the point has the consequence of changing the first *B* term to a positive term. The resulting peaks agree with the absorption maxima from the conventional absorption spectra within the uncertainty.

Conventional absorption spectra determined with the present samples were in excellent agreement with earlier reports. These spectra are only summarized in the table, not plotted.

The treatment of the specta is conventional first order (10). All parameter assignments are derived using the mcd spectra as input data. Values of the Racah *B* parameters are derived from

the singlet–singlet splittings. Values of C are determined from the average of values from two singlet–triplet splittings using the B previously obtained. The octahedral splitting parameter is then fit. Only in the case of the *trans* dichloro complex where one triplet is missing was a general iteration used. Better agreement of calculated spectra could be obtained using general interation in all cases, but our purpose is to demonstrate the qualitative success of the fit with *minimal* adjustment. The spectral precision does not warrant quantitative interpretation of A, B, and C.

Discussion

In the figures, the mcd bands are assigned as either A or B terms. A terms arise (9) from a transition between a nondegenerate ground state and a degenerate excited state. Thus, it is expected that all of the singlet to triplet or quintet transitions in Co(III) ligand field spectra should correspond to A terms. B terms do not require a degeneracy. They involve the coupling of the states in the transition to all other states of the molecule in consequence of the perturbation produced by the magnetic field. It is therefore not surprising, and indeed consistent with results of ref. 9, that all singlet–singlet bands are B terms. In ref. 9, it was suggested that some of the splitting corresponding to the C_{4v}, C_{2v}, and D_{4h} symmetries of the mixed ligand complexes studied here could be resolved in mcd. Especially, two B terms are reported for the T_{1g} octahedral state of the *cis* dichloro ion. In point of fact, the resolution of these B terms exceeded the splittings that are seen in ordinary absorption spectra! This is not expected. The "derivative" shape of an A term or a C term can aid in spectral resolution of overlapping bands. However, there is no inherent reason why B terms of the same sign should show improved resolution. As was noted above, the resolution reported in ref. 9 appears to have been an artifact of poorer signal/noise and a slightly unfortunate choice of a lock point. We assign one band as B and a lower energy band as an A term. With this change, all singlets are poorly resolved and there is no basis for treatment of the spectra in an effective symmetry lower than octahedral. Therefore, we have attached O_h symmetry labels to all transitions as a reminder of this failure.

In octahedral symmetry, the strong field treatment of the state energies yields the energies of the transitions collected in Table 2 (10). Using these expressions for the energies, the octahedral ligand field splitting parameter, Δ, and the Racah electron repulsion parameters, B and C, are calculated and collected in Table 2. Table 1 shows the calculated spectra using these parameters.

The first point to note is that the A terms assigned to the lower triplets in these spectra are near the region of the spectrum where the well-characterized triplet of the hexaamine-cobalt(III) ion which has been extensively discussed recently by Wilson and Solomon (11) is found. However, the small peaks at about 10.5 kK which have been recorded several times for halopentaaminecobalt(III) ions are at much lower energy. Unfortunately, this region is not accessible to us. These low energy peaks have been assigned as ${}^3T_{1g}$ by several authors (10). This cannot be valid if the LF (ligand field) parameters calculated here are correct. That there is a problem is hinted by the fact that these bands appear at an energy more than 2 kK below the triplet of the hexaamine but *do not* vary with the ligand field strength of the halide ligand. If the triplets are lower, contribution by the halide to Δ would be the cause. Such a contribution has never been reported for the singlets (10), nor is it seen for singlets found in mcd. The origin of the 10.5-kK feature may be the overtone of an —NH_2 vibration which was identified at this energy by Wilson and Solomon from the comparison of Co and Cr amine complexes and by deuteration. (The other possibility is that the band is a "hot" band of the hypersensitive type since the singlet–triplet transition is associated with a $\Delta J = 2$ (12).)

An interesting specific feature of the —NCS complex is the reversal of the sign of the second B term compared to all the others. This may be a reminder of the charge transfer mixing into this band.

We now turn our attention to the parameters in Table 2. The values of the orbital splitting parameter, Δ, are slightly smaller than those reported earlier (10). They are similarly (10) insensitive to the ligand field strength of the halide. This may simply reflect low resolution. However, it does seem that insensitivity to reduced symmetry is typical for Co(III). The value of the mcd spectra is in the opportunity to observe spin forbidden bands. Earlier efforts to fit LF parameters to spin forbidden bands in acidoamine complexes (e.g. ref. 13) have produced rather odd values of the Racah parameters. The ratio C/B is expected to be 4 (10). Values calculated were nearer 8. This is now seen to be the consequence of the assignment of the lowest triplet at approximately 10.5 kK. With the triplet as seen here, the expected ratio is, in fact, obtained. Thus, although the mcd spectra may involve unusually weak bands for spin allowed transitions with consequent large error in the location of band centres, they appear to give us qualitatively correct LF spectra and parameters.

This leads to the point of photochemical significance (11, 14). The quintet appears to be located between the two singlet bands. This conclusion is established by two distinct arguments: first, and most directly, by the assignment of the A terms in this region; second, by the fitted position using the qualitatively correct LF parameters. The photochemical discussion has centered on the possibility that the quintet might be the lowest excited state. For this to be the case in the vertical excitation of absorption spectroscopy would require a value of the Racah parameter C much too large to match expectations from the simple theory which appears to be quite adequate.

REZSŐ GÁSPÁR and REZSŐ GÁSPÁR, JR. Can. J. Chem. **63**, 1922 (1985).

Gaussian nonlocal pseudopotentials are introduced for the simplification of the description of second row elements. Pseudopotential parameters for P, S, and Cl are presented. The pseudopotential method is applied to HCl, H_2S, and PH_3. Substantial reduction in the dimension of the orbital basis set is achieved. Results on total valence energies, binding energies, ionization potentials, force constants, equilibrium bond angles, bond lengths, and dipole moments are presented and compared to experiment as well as to the results of calculations with other methods.

Dans le but de simplifier la description des éléments de la deuxième rangée, on introduit des pseudopotentiels gaussiens qui ne sont pas localisés. On présente les paramètres de pseudopotentiel pour le P, le S et le Cl. On applique la méthode du pseudopotentiel au HCl, au H_2S et au PH_3. On réduit ainsi considérablement la dimension des ensembles de base des orbitales. On rapporte les résultats obtenus pour les énergies de valence totale, les énergies de fixation, les potentiels d'ionisation, les constantes de force, les angles d'équilibre des liaisons, les longueurs des liaisons et les moments dipolaires et on les compare avec les résultats expérimentaux ainsi qu'avec les résultats obtenus par calculs à l'aide d'autres méthodes.

[Traduit par le journal]

Introduction

A recently described pseudopotential method suitable for the treatment of molecules containing first row elements (Gáspár (1)) has been extended to second row elements and applied to molecular calculations. Pseudo- and model-potential approaches for second row elements of the periodic table have been published by Bonifacic and Huzinaga and by Topiol, Moskowitz, Melius, Newton, and Jafri (2). The perspective of the present method with respect to the general tendencies of the pseudopotential approach has been outlined in detail by Gáspár (1). The primary purpose of this article is to test the usefulness of the newly introduced pseudopotential parameters in molecular calculations. The molecules that have been investigated are HCl, H_2S, and PH_3.

The overall performance of the method in the molecular applications is satisfactory. Reasonable agreements have been obtained between bond lengths, bond angles, total valence energies, binding energies, and dipole moment values obtained by the pseudopotential calculations and by experiment. Results of calculations with other methods are also included for comparison.

The reduction in computing requirements is substantial for second row elements, for there is no reference in the present scheme to basis functions representing the core states. Basis sets and computing times are reduced substantially. Mini-, micro-, and even well equipped professional personal computers may be used to get results on molecules with second row elements. Due to the special parametrization of the pseudopotential, the core-valence electron correlation and relativistic effects are also taken into account implicitly by the present approach.

The computations have been performed by the program PSEUSMALLOBE, a modified version of Shillady's SMALLOBE (3).

All quantities in this paper are given in atomic units except when otherwise stated.

Method and basis set

For the pseudopotential treatment of second row elements the following form of the model pseudopotential has been chosen

$$[1]\quad V(r) = -\sum_{\alpha} \frac{Z^{\alpha} - N_c^{\alpha}}{r_{\alpha}} + \sum_{\alpha} \sum_{l=0}^{l_c+1} V_l(r_{\alpha})P_l$$

In formula [1] Z^{α} is the atomic number of the nucleus α at the position R_{α}, N_c^{α} is the number of electrons in the core α, and $Z^{\alpha} - N_c^{\alpha}$ is the reduced atomic number. P_l^{α} are the angular momentum projection operators with the center at R_{α}, and $r_{\alpha} = |r - R_{\alpha}|$. The radial factor in eq. [1] has been selected to be

$$[2]\quad V_l(r) = \sum_{i=1}^{m} A_l^i \exp(-a_l^i r^2)$$

The above form of the potential has been successfully employed in the pseudopotential description of first row elements (Gáspár (1)). For first row elements only one term in eq. [2] has been retained. For second row elements the summation has been extended, $m = 2$ has been selected for $l = 0$, and $m = 1$ for $l = 1$ and $l = 2$. In eq. [1] all terms with $l > l_c + 1$, where l_c is the greatest of the l quantum numbers of the core electrons, have been dropped, the corresponding ionic terms being hydrogenic to the desired accuracy.

For the determination of the pseudopotential parameters in eq. [2] a procedure, based on the numerical integration of the Schrödinger equation, has been described by Gáspár (1). Pseudopotential parameters for the Li isoelectronic series and extrapolation formulae of the A_0 and a_0 pseudopotential parameters have been published (Gáspár (1)). In the present calculations the extrapolation formulae of A_0 and a_0 have been used

TABLE 1. Parameters of the pseudopotential $V_l(r) = \sum_i A_l^i \exp(-a_l^i r^2)$ for $l = 0$ ($m = 2$); $l = 1$ and $l = 2$ ($m = 1$)[a]

Element	Reduced atomic no.	A_0^1	a_0^1	A_0^2	a_0^2

Cl	7	1.1	2.0	1.4	1.2	0.7	1.3

to determine the A_0^1 and a_0^1 pseudopotential parameters of second row elements. The rest of the A_l^i and a_l^i parameters have been determined by the numerical procedure referred to above, and their values are displayed in Table 1 for P, S, and Cl.

The form of the pseudopotential outlined above has been introduced into molecular calculations and the PSEUSMALLOBE procedure has been established (Gáspár (1)). Spherical Gaussian orbitals (SGO) and linear combinations of SGOs are employed by the PSEUSMALLOBE method and, depending on the values of the *Znl* parameters, contracted basis sets are generated for the description of the atomic orbitals. Individually positioned primitive Gaussians with radii ρ_i may also be included in the orbital basis set of the molecule under investigation. In the present calculations the representation of the *s* functions has been mainly solved by this latter option. Further details of the method are described by Shillady (3). In Table 2 values of the *Znl* parameters together with the radii of two primitive Gaussians, centered on the nuclei for the description of the *s* functions, may be found for P, S, and Cl. The primitive Gaussian generated through $Z4s$ is also included in the *s* function description. Throughout the molecular calculations presented in this paper the pseudopotential LCAO-MO-SCF procedure PSEUSMALLOBE with the parametrization represented by Tables 1 and 2 has been used.

Results and discussion

In Tables 3 and 4 results of pseudopotential LCAO-MO-SCF calculations using the proposed form of the pseudopotential with the numerical parameters of Table 1 are displayed for PH_3, H_2S, and HCl. For each molecule an orbital basis set, characteristic of the PSEUSMALLOBE procedure, has been generated according to the *Znl* parameters of Table 2.

At the beginning, a few calculations with preguessed basis sets were performed for orientation. Former calculations and experience on analogous molecules with heavier elements from

the first row of the periodic table have helped also substantially in the selection of the appropriate basis set. For H the standard basis set with $HZ1s = 1.2$ was used. It was observed also that the internuclear distances of the hydrides of P, S, and Cl are substantially larger than those of the corresponding molecules in the first row, and this made the basis set less sensitive to the central atom in the outer region.

Many basis sets have been suggested for the elements in the second row of the periodic table (Pietro *et al.* (5), Gordon *et al.* (6), Gianolio and Clementi (12), McLean and Chandler (13)). The most detailed study on basis sets of H_2S is given by Poirier *et al.* (14) and we select their Uniform Quality Basis Set UQ-5G $s \neq p$ for discussion. This basis set contains 15 spherical Gaussians for the description of *s* states partitioning into 11 Gaussians describing the $(1s)^2$ $(2s)^2$ core states and the inner part of the 3*s* valence state. For the outer part of 3*s* and for the virtual excited orbitals only 4 Gaussians are left. We use only 3 Gaussians for the description of the outer part of 3*s*. For the *p* states there are 3 × 10 Cartesian Gaussians, namely (7 and 3) × 3 for the inner and outer regions respectively, and we use 3 × 3 mimics for the *p* states in S. The pseudopotential is a one-electron operator and its effect on the computations with respect to time and storage is negligible. Its introduction permits a substantial reduction in the size of the orbital basis set and a great reduction in the number of two-electron integrals, together with a corresponding reduction in computer time and storage.

Calculated and experimental values of interatomic distances, bond angles, valence-only total energies, and electric dipole moments, belonging to the minimum-energy geometry of the molecules, are presented in the tables. Table 4 also contains dipole moment values for PH_3, H_2S, and HCl obtained by other calculational methods for comparison.

Tables 5 and 6 present a comparison of the calculated and experimental binding energy spectra of PH_3 and H_2S. For H_2S the results of single-zeta *ab initio* calculations using STOs, and calculations involving GTOs with the incorporation of diffuse low-exponent functions, are also available. In Table 5 the results of these calculations have also been included.

Recently the results of valence energy calculations involving the use of *ab initio* effective core potentials have been pub-

lished for HCl by Hay *et al.* (9). The results of the above calculations, -15.82516 and -15.66918, are compared to the valence-only total energy of HCl, -15.41042, provided by the pseudopotential approach of the present article. For HCl, ionization potential and force constant values have been derived from the results of the pseudopotential calculations. The calculated value of 0.48509 compares favourably with the experimental value of 0.46844 for the ionization potential of HCl (see Huber and Herzberg (10), p. 284). Similar good agreement has been found for the HCl force constant, the calculated value being 0.479 dyn/cm $\times$ 10^6 while the experimental value is 0.516 dyn/cm $\times$ 10^6. Unrestricted RHF calculations with different basis sets resulted in force constant values in the range of 0.470–0.614 dyn/cm $\times$ 10^6 (Sakai *et al.* (11)) and the model potential calculations of Sakai and Huzinaga (16) in the range of 0.497–0.563 dyn/cm $\times$ 10^6.

Temperature-induced cooperative conformational transitions in biopolymers may be examined in aqueous solution by the use of Fourier transform infrared spectroscopy. The transition is described in terms of a two-state model with a fractional population parameter (which describes the degree of transition at various values intermediate between the two limiting cases) that can be generated by a least-squares technique. This procedure allows for calculation of a conformational index without assuming a linear dependence of the infrared parameter on the extent of transition. Calculations based on the Zimm–Bragg theory of cooperative conformational transitions allow thermodynamic quantities to be derived using the conformational index in conjunction with calorimetric measurements.

The method is illustrated with data from the gel/liquid-crystalline phase transitions of binary phospholipid vesicles where the use of isotopic substitution allows the conformation of each component of the binary mixture to be independently monitored. The data suggest the coexistence of well-defined structural domains of phospholipid as well as the preferential clustering of one of the lipid components at the interface between the two phases.

R. A. DLUHY, D. MOFFATT, D. G. CAMERON, R. MENDELSOHN et H. H. MANTSCH. Can. J. Chem. **63**, 1925 (1985).

On peut étudier les transitions conformationnelles coopératives induites par la température des biopolymères en solution aqueuse en faisant appel à la spectroscopie infrarouge par transformation de Fourier. On peut décrire la transition en fonction d'un modèle à deux états avec un paramètre de population fractionnaire (qui décrit le degré de transition des diverses valeurs intermédiaires entre les deux cas limites) que l'on peut généré par la technique des moindres carrés. Ce procédé permet de calculer un indice conformationnel sans faire l'hypothèse qu'il existe une relation linéaire entre le paramètre infrarouge et le degré de transition. Des calculs basés sur la théorie de Zimm–Bragg des transitions conformationnelles coopératives permettent d'évaluer des quantités thermodynamiques à l'aide de l'indice conformationnel couplé à des mesures calorimétriques.

On illustre la méthode avec des données provenant de transitions de phases gel/liquide cristallin de vésicules de phospholipides binaires où l'utilisation de la substitution isotopique permet de déterminer d'une manière indépendante la conformation de chacun des composants du mélange binaire. Les données suggèrent qu'il y a une coexistence de domaines structuraux de phospholipides bien définis ainsi qu'une aggrégation préférentielle de l'un des lipides composants à l'interface entre les deux phases.

[Traduit par le journal]

Introduction

Recently, there have been numerous attempts to describe in detail the molecular events that occur during the cooperative conformational transitions of biopolymers. Such models generally rely on a statistical mechanical approach to characterize the phase transition. Thus, the contribution to the total energy of the molecule from various internal forces can be estimated (1–4).

An alternative approach to describing the individual, microscopic molecular events of a conformational phase transition is to consider the biopolymer on a macroscopic phenomenological level. In this approach, the phase transition is described as a simple order–disorder transition in which the two phases have considerably different thermodynamic parameters (5, 6).

Spectroscopic methods have had considerable success in elucidating the conformational behavior of biomolecules. Techniques such as nmr, esr, fluorescence, infrared and Raman spectroscopy have provided detailed information about the molecular events that occur within biomolecules during conformational transitions (7). Infrared spectroscopy, in particular, offers several advantages for the study of conformational transitions. Infrared spectra are sensitive to displacements of the dipole moment during vibrations which in turn depend upon changes in conformation and configuration of the bonds making up the normal mode of vibration (8). Identification of a group frequency characteristic of a certain aspect of molecular conformation allows the observation of changes in conformation as environmental conditions are varied without the use of perturbing probe molecules. The application of infrared techniques to the study of aqueous biophysical systems has been hindered mainly by the strong infrared absorptions of water. To this end, several techniques have been developed which partially overcome this handicap. Examples include solvent substitution (i.e., D_2O) and spectral data processing techniques (9, 10).

The current study describes the use of FT-IR spectroscopy to monitor cooperative conformational phase transitions of biopolymers. A simple two-state model is introduced in which

[1]NRCC No. 23642.

changes in a conformation-sensitive infrared spectral feature are related to a fractional conformation parameter. The use of a least-squares optimization procedure to generate this parameter removes the assumption that the observed infrared spectral changes are linear functions of the extent of the conformational transition. Such a refinement allows a more accurate calculation of the degree of transition at intermediate values. Finally, the use of the two-state model in conjunction with calorimetric measurements allows calculation of thermodynamic parameters based on the Zimm–Bragg theory of cooperative conformational transitions.

The method described here is illustrated using data from the temperature-induced gel/liquid-crystalline phase transition of binary phospholipid mixtures. The deuteration of one component of the mixture shifts its conformation-sensitive spectral features to a region of the spectrum free from interfering absorptions. Consequently, the conformation of each component of the binary mixture may be monitored separately throughout the conformational transition.

Materials and methods

Materials

DPPC and perdeuterated DMPC (DMPC-d_{54}) were purchased from Avanti Biochemicals (Birmingham, AL). Lipids were stored in chloroform under nitrogen at −40°C. Lipid concentrations were determined by phosphorous assay. Each lipid gave a single spot on TLC plates.

Sample preparation

Multilamellar lipid vesicles were prepared as follows: aliquots of the lipid chloroform solution containing the desired amounts of lipid (either pure or binary mixtures) were placed in a test tube and incubated at 50°C for 10 min. Solvent was removed with a stream of dry nitrogen followed by overnight evacuation. The lipid film was rehydrated in 50 m*M* Tris, pH 7.4 by vortexing. The lipid multilayers were heated above the phase transition and cooled to insure complete hydration and mixing. This cycle was repeated several times. The composition of the binary lipid vesicles was checked by gas chromatography of the methyl esters of the lipid acyl chains.

Fourier transform infrared spectroscopy

Samples were prepared for infrared analysis in 25 μm thick cells with CaF_2 windows. Spectra were recorded on a Digilab FTS-15 Fourier transform infrared spectrometer equipped with a HgCdTe detector. Two hundred and fifty interferograms, collected with an optical velocity of 1.26 cm s^{-1} and a maximum optical retardation of 0.25 cm, were coadded, apodized with a triangular function, and Fourier transformed with one level of zero filling to yield spectra with a resolution of 4 cm^{-1} and data encoded every 2 cm^{-1}.

Temperatures were controlled by a thermostatted EtOH–H_2O mixture flowing through a hollow cell mount and monitored by a copper–constantan thermocouple placed against the edge of the cell window (11). Frequencies were determined by computing the center of gravity of the C—H or C—D stretching bands from the topmost five data points; to remove baseline fluctuations due to the absorption of liquid water, all calculations were performed on derivative spectra (10). The use of special algorithms described elsewhere (12) permits the determination of the band maxima in a series of homologous infrared spectra with an uncertainty of less than 0.02 cm^{-1}.

Differential scanning calorimetry

Calorimetry measurements were made on a Micro-cal MC1 calorimeter. Sample volumes of 0.70 mL containing 1.4–2.0 mg of the appropriate lipid mixture were injected into the calorimeter sample cell with the same volume of H_2O used as a reference. Samples were scanned at ca. 24° h^{-1} starting at 4°C after a minimum of 2 h equilibration. Onset and completion data were determined as described. Duplicate runs of the same sample gave onset and completion temperatures reproducible to ±0.2°C. Independent samples gave data reproducible to 0.5°C. Excess heat capacity data were calibrated with a standard electronic pulse. Typically, the value of the enthalpy for a multilamellar suspension of DPPC was $\Delta H = 7.1 \pm 0.5$ kcal mol^{-1}.

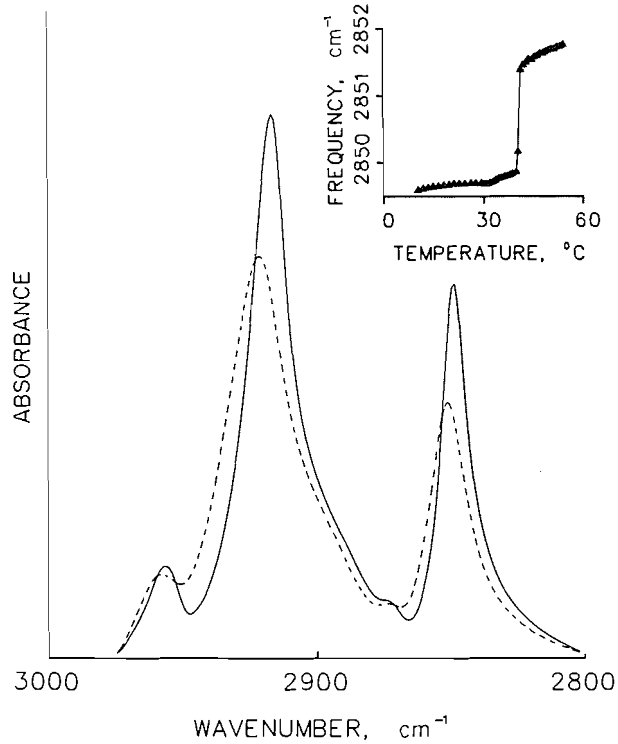

FIG. 1. Temperature dependence of the infrared spectra of 1,2-dipalmitoyl-*sn*-glycero-3-phosphocholine (DPPC) in the region of the C—H stretching bands. The upper spectrum (solid line) represents DPPC in the gel phase at 10°C. The lower spectrum (dashed line) represents DPPC in the liquid-crystalline phase at 50°C. *Inset*: The relationship between frequency and temperature for the CH_2 symmetric stretching band of DPPC.

Results

Part A. Generation of an infrared fractional conformational parameter

The procedure described here is developed for the case of a two-state transition where the molecule can exist only in the initial state, A, and the final state, B, with no thermodynamically stable intermediates present. Many biophysically relevant transitions have been described as cooperative two-state processes. Examples include: (*i*) helix–coil transitions in polypeptides (5, 13), (*ii*) double helix–coil transitions of nucleic acids (14), (*iii*) thermal denaturation of proteins (6), and (*iv*) phospholipid gel to liquid-crystalline phase transitions (15–17).

In the case of phospholipids, the infrared spectroscopic parameters used to identify phase changes include band frequency, bandwidth, peak height, and integrated intensity (18). Figure 1 illustrates the temperature dependence of the infrared spectra of the conformation-sensitive C—H stretching region for 1,2-dipalmitoyl-*sn*-glycero-3-phosphocholine (DPPC). The spectral features arise from the asymmetric and symmetric CH_3 stretching modes near 2956 and 2872 cm^{-1} (weak infrared bands), while the antisymmetric and symmetric CH_2 stretching modes (strong infrared bands) are observed at 2920 and 2850 cm^{-1} (19). An increase in temperature results in reductions of peak height and integrated intensity, an increase in bandwidth

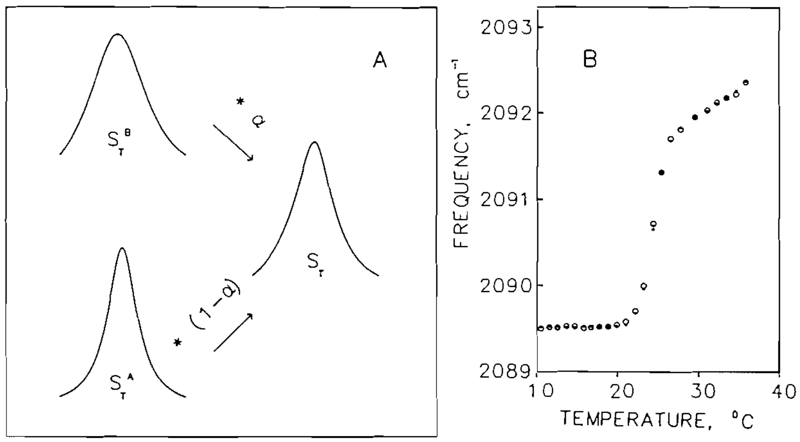

FIG. 2. Part *A*: Generation of a calculated spectrum S_T, from a linear combination of S_T^A and S_T^B. Part *B*: Temperature-dependence of the CD_2 frequency of experimental (open symbols) and calculated (closed symbols) spectra (S_T) of a binary lipid mixture.

and a shift in frequency to higher wavenumbers, with all the parameters showing discontinuities at the transition temperature. The temperature dependence of the band frequencies can be attributed on a molecular level to variations in the conformation of the mostly all-*trans* phospholipid acyl chains in the gel phase, with the introduction of *gauche* conformers at the characteristic phase transition temperature (20). As has been previously demonstrated (21) and illustrated in the inset in Fig. 1, the frequencies of the CH_2 stretching bands are sensitive indicators of the phospholipid gel to liquid-crystalline phase transition. The sensitivity of the C—H frequency to phase changes for various hydrocarbon systems has been attributed to changes in the interaction constants between adjacent CH_2 groups as the relative orientation of these groups changes with the introduction of *gauche* conformers (19).

A two-state transition model rests on the assumption that the initial and final states have measurably different thermodynamic properties (22). To unambiguously characterize these states via infrared spectroscopy, they must also have measurably different spectral characteristics. As seen above for the case of a phospholipid two-state phase transition, measurable changes occur in frequency, bandwidth and/or intensity. Computer simulations have shown that when two Lorentzian lineshapes with differing bandwidths and frequencies (corresponding to the bandshape of a pure initial and pure final state) are summed in varying proportions, the resulting changes in frequency and bandwidth are not linearly correlated with the proportion of either component (21, 23). This implies that changes in the commonly measured spectral parameters (e.g. frequency, bandwidth, etc.) are not linear indicators of the extent of transition due to the inherent spectral characteristics of overlapping band contours.

Efforts to quantitatively describe the extent of transition using observable experimental parameters generally have assumed the following relation between the degree of transition, α, and the observable parameter, r

$$\alpha = (r_A - r)/(r_A - r_B)$$

where r_A and r_B are the values of the experimental parameter in states A and B, respectively (24). The disadvantage of this method is that it assumes a linear dependence of r on α. Since this is not a reasonable assumption for a two-state cooperative transition characterized via infrared parameters (21), we have taken the following approach. For any two-state process, the infrared spectrum at a particular temperature, S_T, is a superposition of two bandshapes that correspond to the initial state A, S_T^A, and final state B, S_T^B. The proportion by which the two limiting-case bandshapes are added to generate the observed spectrum depends on α, the degree of transition. That is

$$[1] \quad S_T = (1 - \alpha)S_T^A + \alpha S_T^B$$

In order to generate bandshapes corresponding to the initial and final states at a particular temperature (i.e., S_T^A and S_T^B), the following procedure is employed. First, a conformation-sensitive vibrational feature is identified (e.g., the frequency of a C—H stretching band). Then, at each frequency, regression coefficients are generated by a linear least-squares fit of absorbance versus temperature. The resulting coefficients are used to calculate the pure component spectra S_T^A and S_T^B in the region of the transition. At any particular temperature within the two-phase region, S_T is estimated by a linear combination of S_T^A and S_T^B (Fig. 2*A*) and the value of α is calculated to minimize the squared residual between the band contour of S_T and the band contour of the experimental spectrum. Figure 2*B* compares the temperature dependence of the symmetric CD_2 stretching frequency of experimental versus calculated spectra (S_T) when the above procedure is applied to the infrared spectra of a binary mixture of DPPC : DMPC-d_{54}. The advantage of this procedure is that it removes the necessity for assuming a linear dependence of α on the experimental parameters and therefore gives a more accurate estimate of the degree of transition.

Part B. Description of the cooperative transition

In this section, the fractional degree of transition derived from the infrared measurements in the previous section is used in conjunction with the theory of cooperative transitions developed originally by Zimm and Bragg (13, 25) and widely applied to biomolecules (13–17). As the theory has been extensively discussed (26), only the results relevant to the present discussion will be described.

This type of approach to conformational transitions assumes that the initial and final states exist in discrete temperature-dependent clusters or domains that coexist in dynamic equilibrium during the cooperative transition (15). The thermodynamic properties of the transition can be characterized by two parameters, a cooperativity parameter, σ, and a partition function, s (26). Since the cooperativity parameter is related to the interfacial free energy between the two domains, it is also possible to describe the fraction of molecules at the interfacial region between the two domains (16).

If a transition of the form

$$A \rightleftharpoons B$$

is assumed and a degree of transition, α, defined as in Part A, then the apparent equilibrium constant for the transition is

$$K = \frac{\alpha}{1 - \alpha}$$

The temperature dependence of K is described by the van't Hoff equation:

$$\frac{\mathrm{d} \ln K}{\mathrm{d}T} = \frac{\Delta H_{\mathrm{vh}}}{RT^2} = \frac{1}{\alpha(1 - \alpha)} \frac{\mathrm{d}\alpha}{\mathrm{d}T}$$

At the transition midpoint (T_{m}), $\alpha = \frac{1}{2}$ and

$$[2] \quad \Delta H_{\mathrm{vh}} = 4RT_{\mathrm{m}}^{2} \left(\frac{\mathrm{d}\alpha}{\mathrm{d}T}\right)_{T_{\mathrm{m}}}$$

where ΔH_{vh} is the van't Hoff enthalpy which corresponds to the enthalpy of transition of the cooperative unit. If the $A \rightleftharpoons B$ interconversion is represented as an equilibrium with an equilibrium constant K, then a partition function, s, can be defined as

$$s = z_{\mathrm{b}}/z_{\mathrm{a}}$$

where z_a and z_b are the molecular partition functions for molecules in states A and B, respectively (26), and s is equal to the partition function for a unit in state B relative to state A. Also, thermodynamically,

$$[3] \quad s = \exp\,(\Delta G^{0}_{\mathrm{A \to B}}/RT)$$

where $\Delta G^{0}_{\mathrm{A \to B}}$ is the free energy change per molecule for the conversion of state A to state B. At the midpoint of the transition,

$$\Delta G^{0}_{\mathrm{A \to B}} = 0 \text{ and } s = 1$$

From the relationship between the calorimetric enthalpy and the van't Hoff enthalpy, a cooperativity parameter, σ, can be defined which essentially describes the steepness of the transition:

$$[4] \quad \sigma = (\Delta H_{\mathrm{cal}}/\Delta H_{\mathrm{vh}})^2$$

Also, σ is defined as the factor by which the partition function is diminished by the addition of a unit of B; $-RT \ln \sigma$ then corresponds to the interfacial free energy between the microscopic domains (16, 26). Therefore:

$$\sigma = \exp\,(\Delta G^{0}_{\mathrm{I \to B}}/RT)$$

and $\Delta G^{0}_{\mathrm{I \to B}}$ is defined as above.

The total molecular partition function can be described (26) as

$$Z = \sum_{n_b, n_a, n_i} (z_b^{n_b} z_a^{n_a} \sigma^{n_i})$$

where z_a, z_b, and σ are as defined, and n_a, n_b, and n_i correspond to the number of molecules in state A, B, and at the interface, respectively.

It has been shown (16, 26) that the mean fraction of molecules in state B can be expressed as

$$\theta = \frac{\langle n_b \rangle}{n} = \frac{1}{n} \frac{\partial \ln z}{\partial \ln s}$$

which reduces to

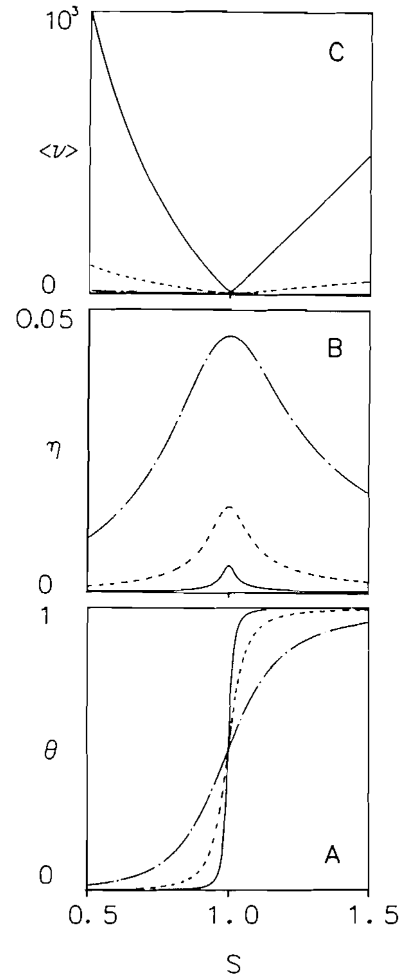

FIG. 3. Calculated values for the derived parameters of the Zimm–Bragg cooperative transition model. *A*: Fraction of molecules in the final phase (i.e., degree of transition). *B*: Fraction of molecules at the interfacial region between the phase boundaries. *C*: Mean size of the initial and final phases. All three parameters are plotted against the normalized temperature parameter, s, for three different values of the cooperativity parmeter σ, i.e., $\sigma = 10^{-4}$ (—), $\sigma = 10^{-3}$ (- - -) and σ 10^{-2} (-·-·-·-).

$$[5] \quad \theta = \frac{1}{2}\left[1 + \frac{s - 1}{\sqrt{(s-1)^2 + 4\sigma s}}\right]$$

Similarly, the mean fraction of molecules at the interfacial region between the two macroscopic domains, η, is expressed as

$$\eta = \frac{1}{n} \frac{\partial \ln z}{\partial \ln \sigma}$$

and, by substitution

$$[6] \quad \eta = \frac{2\sigma s}{(1+s)[(1-s)^2 + 4\sigma s]^{1/2} + (1-s)^2 + 4\sigma s}$$

The analytical expressions for θ and η thus depend upon σ, a cooperativity parameter, and s, a partition function. σ can be experimentally determined by use of eq. [4]. Equation [3] shows that s is dependent on the free energy difference between the two macroscopic states. To calculate s, it is known that at T_{m}, $\Delta G^{0}_{\mathrm{A \to B}} = 0$ and $s = 1$. For small deviations of s and T_{m}, a linear dependence of s with temperature is assumed (26) and a Taylor series expansion is performed about the midpoint T_{m}. Therefore,

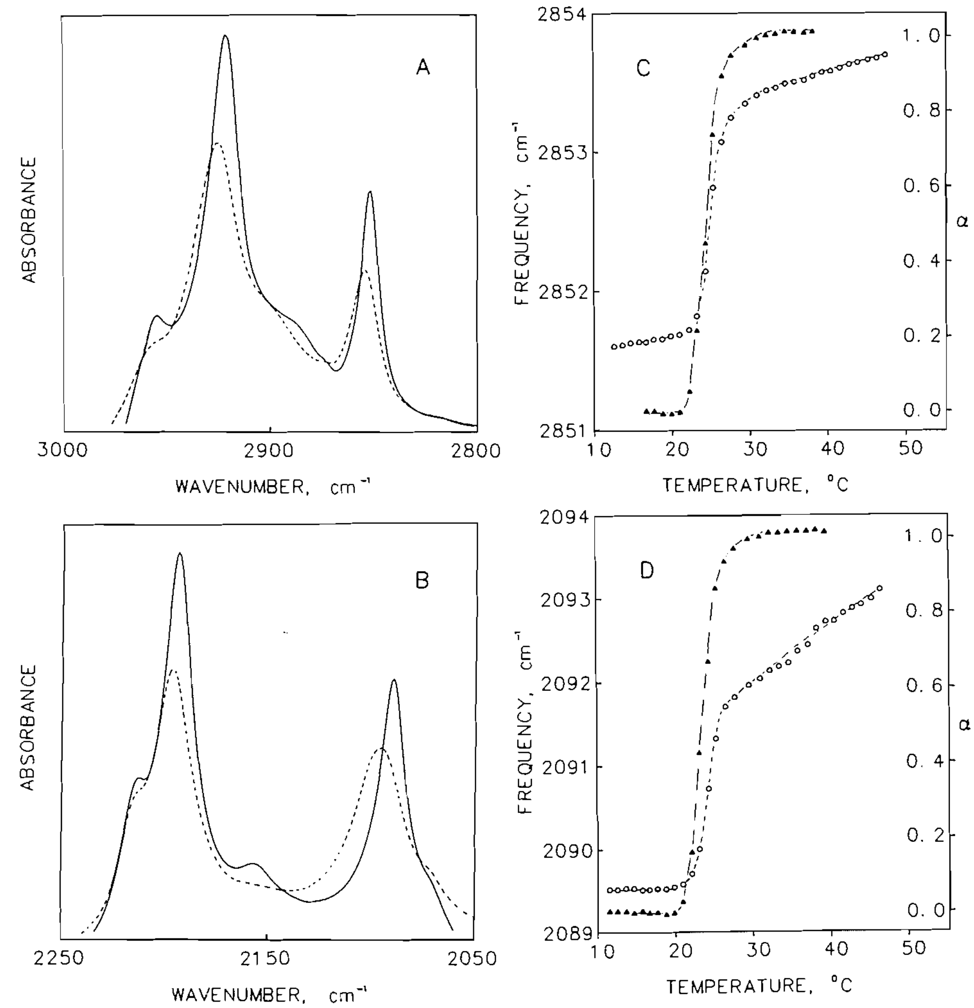

FIG. 4. *A*: Temperature dependence of the C—H stretching region in the infrared spectra of the DPPC component of a 75:25 binary mixture of DPPC:DMPC-d_{54}. *B*: The C—D stretching region of the DMPC-d_{54} component of the same binary mixture as in *A*. For the purposes of display, linear baselines extending from 3000 to 2800 cm^{-1} (in *A*) and 2300 to 2000 cm^{-1} (in *B*) have been subtracted. Solid lines indicate low temperature (15°C) spectra while dashed lines indicate high temperature (45°C) spectra. *C*: Temperature induced variation in the frequency of the CH_2 symmetric stretching band of DPPC (open symbols), along with the α values (closed symbols) calculated according to the procedure described in the text. *D*: Temperature induced variation in the frequency of the CD_2 symmetric stretching band of DMPC-d_{54} (open symbols) along with the calculated α values (closed symbols).

0.15:0.85	20.1	21.6	24.4	4.52	2.89×10^{-3}

[a]Onset, midpoint, and completion temperatures in °C.
[b]In kcal mol^{-1}.
[c]σ was calculated by (1) first calculating ΔH_{vh} by the equation $\Delta H_{vh} = 6.9 \times (T_m^2/\Delta T_{1/2})$ (38), (2) $\sigma = (\Delta H_{cal}/\Delta H_{vh})^2$.

$$[7] \quad s = \frac{\Delta H_{cal}}{R T_m^2}(T - T_m) + 1$$

where ΔH_{cal} equals the calorimetrically determined enthalpy change of the transition.

Given the mean fraction of molecules in state B and the mean fraction of molecules in the interfacial region (eqs. [5] and [6] above), it is possible to express the relative size of the regions of state A and state B as the mean number of molecules in that state per interfacial molecule (17). That is, for state B

$$[8] \quad \langle \nu_b \rangle = \frac{\theta}{\eta}$$

and for state A

$$[9] \quad \langle \nu_a \rangle = \frac{1 - \theta}{\eta}$$

In this fashion, the changes in the relative size of the two domains throughout the transition may be monitored.

Figure 3 illustrates the application of the above parameters for calculated transition curves and various quantities of the cooperativity parameter, σ. Plotting these parameters versus s in effect normalizes the transition temperature for the various parameters since at T_m, $s = 1$ (26). Figure 3*A* shows that for very non-cooperative transitions ($\sigma = 10^{-2}$) the fraction of molecules in state B increases very slowly and allows for the coexistence of the two phases over the transition range (Fig.

[b] σ was calculated by (1) first calculating ΔH_{vh} according to eq. [2], (2) assuming $\Delta H_{cal(1)} = \Delta H_{cal} \cdot X_1$, (3) $\sigma = (\Delta H_{cal(1)}/\Delta H_{vh})^2$.

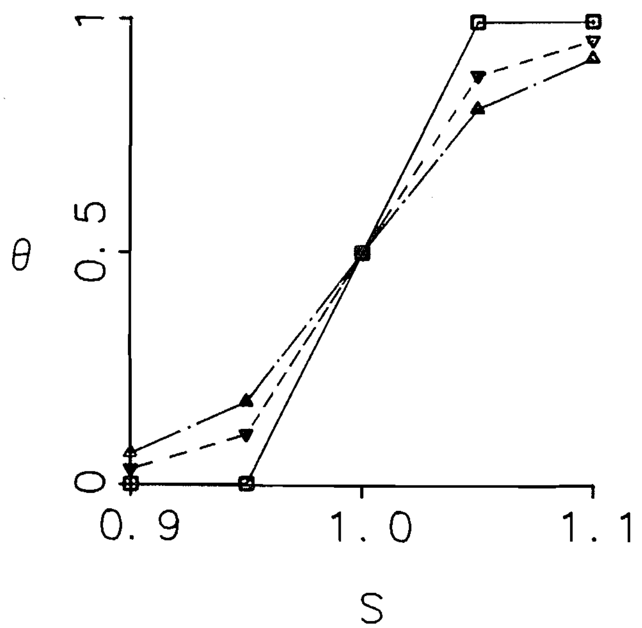

FIG. 5. Fraction of molecules in the fluid phase (i.e., degree of transition) plotted against the normalized transition temperature, s, for various mole fractions of DPPC in DPPC:DMPC-d_{54} binary mixtures. Mole fraction DPPC, 0.142 (—); 0.479 (- - -); and 0.808 (-·-·-·-).

3*C*). In addition, a low cooperativity transition has a high fraction of molecules at the phase boundaries between the two states (Fig. 3*B*).

Part C. Application of the model to phospholipid binary mixtures

The importance of the phospholipid phase transition to the structure and function of biological membranes has been extensively investigated in recent years (27); such processes as enzyme activity, active transport, and ion permeability have been shown to be dependent on the lipid phase state (28). In addition, in complex mixtures of lipids, the coexistence of laterally segregated domains of lipids differing in their physical structure may provide a particular chemical environment conducive to functional properties (29–31). Since the majority of biophysical membrane studies have focused on single lipid species, less information is available on the physical and chemical structure of binary lipid mixtures. Especially lacking is information concerning the cooperative nature of the transition for each component of the mixture and how that relates to the overall thermodynamic properties of the membrane.

Infrared spectroscopy offers certain advantages for the study of binary mixtures. In particular, if one component of the mixture is isotopically labelled in its conformation-sensitive region, the conformation of each component may be monitored simultaneously. Such an approach has been applied to phospholipids (32), where the synthetic incorporation of perdeuterated acyl chains allows the monitoring of the conformation-sensitive C—D stretching modes in a manner analogous to that of non-labelled acyl chains (Part A). In addition, for phospholipid mixtures, the C—D stretching modes of the deuterated chains occur in a spectral region free of interference from other lipid vibrational bands and are easily monitored (21). The data presented here illustrate the application of the two-state cooperative transition model described above to binary mixtures of 1,2-dipalmitoyl-*sn*-glycero-3-phosphocholine (DPPC) and acyl chain perdeuterated 1,2-dimyristoyl-*sn*-glycero-3-phosphocholine (DMPC-d_{54}). These phospholipids differ only by two carbons in the length of their acyl chains and have been shown to form nearly ideal mixtures (33). As a consequence of the perdeuteration of the DMPC acyl chains, the conformation of both components of the mixture may be monitored.

Figures 4*A* and 4*B* give the temperature dependence of the C—H and C—D stretching bands for a binary mixture of DPPC and DMPC-d_{54} (DPPC:DMPC-d_{54} mole ratio, 0.75:0.25). In the C—D stretching region (Fig. 4*A*), the CD_3 groups give rise to the weaker bands at 2212 (asymmetric stretch) and 2070 and 2156 cm^{-1} (symmetric stretch) while the strong bands at 2194 and 2089 cm^{-1} are the CD_2 antisymmetric and symmetric stretching bands, respectively (21, 34–37). The spectral assignments for the features in the C—H region of the non-deuterated acyl chain DPPC are given in Part A.

Figures 4*C* and 4*D* show the temperature-induced variation in the symmetric CD_2 and CH_2 frequencies for both components of the binary mixture. As expected for a binary system displaying miscibility (33), the frequency changes for the mixtures occur over a wider temperature interval than that of a pure lipid (compare Fig. 4 and Fig. 1). A further confirmation of a broadened transition in the binary mixtures comes from the calorimetric data for various mole ratios of DPPC and DMPC-d_{54} (Table 1).

Table 2 describes the six binary mixtures of DPPC and DMPC-d_{54} that were used in the spectroscopic experiments. For each mixture, temperature-induced changes in the frequency of the C—H or C—D stretching bands were documented as in Fig. 4. Then, in order to quantitate the degree of transition throughout the phase transition region for both components of the mixture, the melting profiles were analyzed according to eq. [1] and the procedure described in Part B.

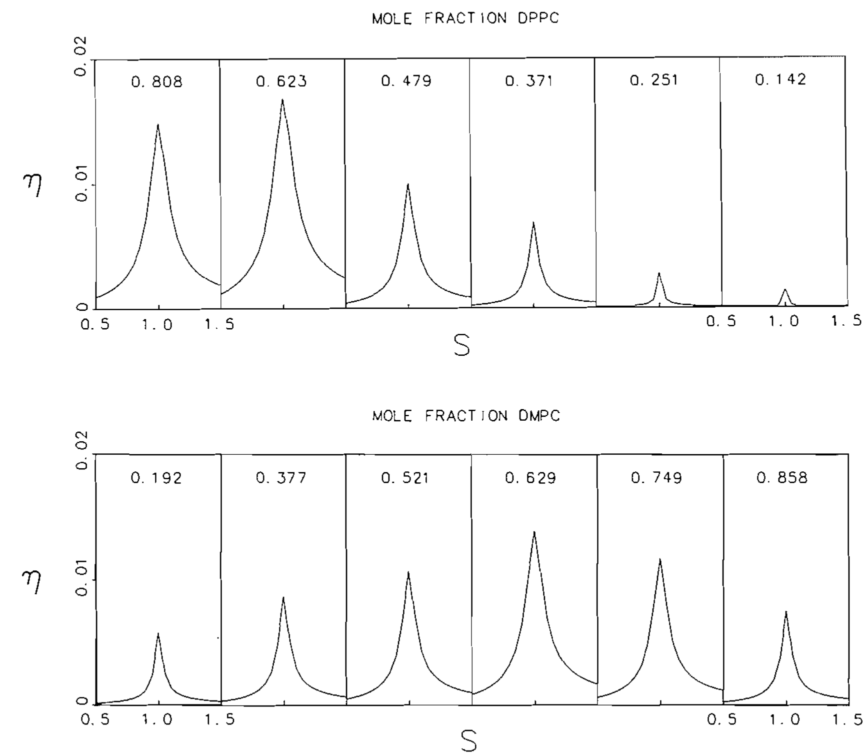

FIG. 6. Calculated values for the fraction of interfacial lipid, η, for each component of the six binary mixtures described in Table 2, plotted against the normalized transition temperature, s. η was calculated from eq. [6] and σ from eq. [4]; the values of σ are listed in Table 2.

Representative results for the DPPC component of three binary mixtures are shown in Fig. 5 and may be compared with the calculated curves of Fig. 3. The data in Fig. 5 indicate that at a low mole fraction (0.142), DPPC acts in a highly cooperative manner while a high mole fraction (0.808) has a much more broadened transition. Equimolar DPPC acts in an intermediate fashion. The diagrammatic results of Fig. 5 are summarized in Table 2 by the cooperativity parameter σ which was calculated using eq. [4]. Low mole fractions of DPPC result in the smallest values of σ and hence melt more cooperatively. The trend is to increasing values of σ with increasing mole fraction of DPPC. While not as great in magnitude, the same trend is observed for the σ values of the DMPC-d_{54} component.

The changes in the cooperative properties of the components of the binary lipid mixture with changes in their respective mole fractions has implications for the physical structure of the membrane. High cooperativity implies that one component has segregated into domains and that a lateral phase separation of the two components has occurred. Defects in crystal packing are likely to occur at the phase boundaries between the two domains and therefore, one of the components of the mixture might congregate specifically at the phase boundary.

Evidence for the specific clustering of one of the lipid components at the phase boundary between segregated domains is presented in Fig. 6. These curves were generated using eq. [6] and correspond to the mean fraction of molecules of each component at the interface between the two macroscopic domains. At equimolar values of DPPC and DMPC-d_{54} (0.521:0.479), both components are present at the interfacial regions in roughly equal amounts. Perturbing this equilibrium by increasing the mole fraction of one component causes the component in the minority to melt more cooperatively (compare the σ values in Table 2) implying the beginning of a lateral phase separation process. The molecules of the component in excess then begin to populate the interfacial regions to a greater extent (Fig. 6).

It should be emphasized that the process described above as lateral phase separation does not imply the existence of gel phase immiscibility in the two components. Calorimetric studies have shown DPPC and DMPC-d_{54} form nearly ideal mixtures (33). Rather, it suggests that ordered and fluid regions of lipid coexist in a dynamic equilibrium mediated by temperature and/or mole fraction.

Using eqs. [8] and [9] from Part B, it is possible to calculate the relative sizes of the gel and liquid crystalline domains compared to the amount of interfacial lipid for each component of the mixture. This is plotted in Fig. 7. The curves in Fig. 7 demonstrate that at low mole fraction, DPPC or DMPC-d_{54} tend to form clusters or domains, as suggested by Fig. 6. This tendency decreases at higher mole fractions, where the gel and liquid crystalline domains decrease in size relative to the amount of interfacial lipid, indicating a more monodisperse and homogeneous system, that coexists throughout the center of the transition.

Summary

The results from the previous sections have shown that monitoring a conformation-sensitive infrared band during a cooperative phase transition allows the calculation of a fractional conformation parameter that describes the degree of transition. The use of this parameter in conjunction with calorimetric measurements leads to calculations that describe the detailed thermodynamic behaviour of the system.

The application of this model to DPPC:DMPC-d_{54} phospholipid binary mixtures provides evidence for lateral phase separation and the coexistence of well-defined structural domains of phospholipid. In addition, the data suggest preferential clustering of one of the lipid components at the interface

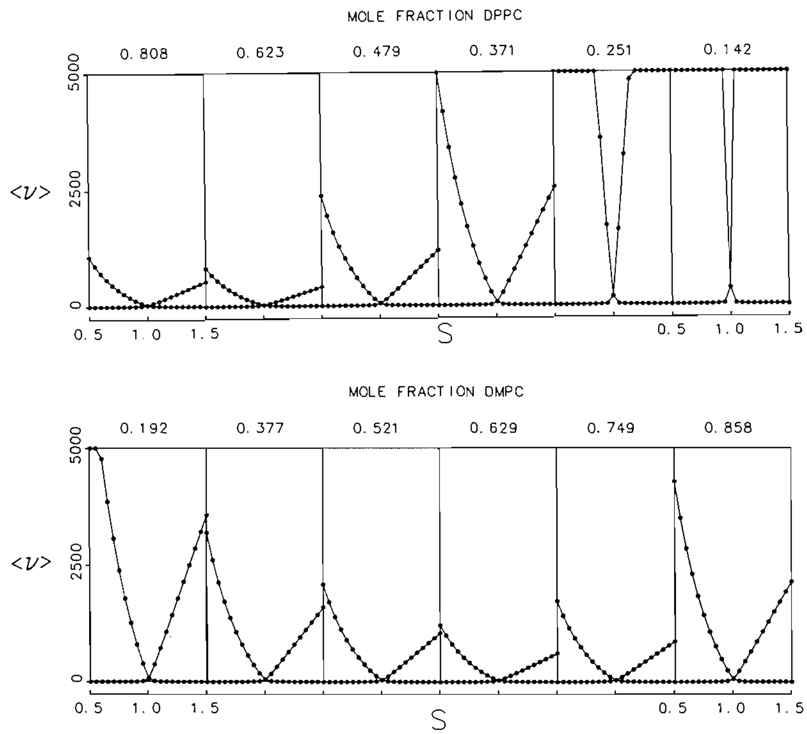

FIG. 7. Calculated values for the mean size of the gel and liquid crystalline domains for each component of the six binary mixtures described in Table 2, plotted against the normalized transition temperature, s. $\langle\nu_a\rangle$ (closed symbols) and $\langle\nu_b\rangle$ (open symbols), were calculated for each component using eq. [8] or [9], respectively. σ was calculated using eq. [4] and is listed in Table 2.

between the two phases. These results agree with recent experimental results which suggest that the compositional segregation of lipids at phase boundaries of binary lipid vesicles is responsible for permeability phenomena (29, 31).

A study of the molecular–cellular interface in visual photoreceptors by light scattering photometry

T. BORYS, S. DESHPANDE, R. JONES, AND E. W. ABRAHAMSON
Department of Chemistry and Biochemistry, University of Guelph, Guelph, Ont., Canada N1G 2W1

Received September 26, 1984

This paper is dedicated to Professor Camille Sandorfy on the occasion of his 65th birthday

T. BORYS, S. DESHPANDE, R. JONES, and E. W. ABRAHAMSON. Can. J. Chem. **63**, 1933 (1985).

The correlation of molecular events with structural changes within the cell requires a non-destructive relaxation technique that can be adapted to measure such cellular changes in a time range of milliseconds to minutes. Light scattering relaxation techniques have proved useful for such studies as they can often be measured simultaneously or in parallel with absorption or fluorescence spectral changes characterizing molecular or macromolecular processes. Such techniques are proving useful in the study of photobiological processes such as visual photoreception where specific cytological changes produced photochemically can be effected by alternate controlled perturbations such as osmotic shrinking or swelling of cell organelles and (or) whole cells. This paper illustrates how light scattering relaxation spectrophotometry can be applied to the correlation of molecular and cellular events in visual photoreceptors.

T. BORYS, S. DESHPANDE, R. JONES et E. W. ABRAHAMSON. Can. J. Chem. **63**, 1933 (1985).

Pour étudier des corrélations d'évènements se produisant au niveau moléculaire avec des changements de structure à l'intérieur de la ceullule, il faut disposer d'une technique de relaxation non destructive que l'on peut modifier pour mesurer de tels changements cellulaires à des temps allant des millisecondes à des minutes. Les techniques de relaxation de la lumière diffusée se révèlent pratiques dans de telles études puisqu'on peut souvent les mesurer soit simultanément soit en parallèle avec des changements dans les spectres d'absorption ou de fluorescence qui caractérisent les processus moléculaires ou macromoléculaires. De telles techniques se révèlent utiles dans l'étude des processus photobiologiques comme la photoréception visuelle au cours desquels des changements cytologiques spécifiques produits photochimiquement peuvent être affectés par des perturbations alternées et contrôlées, comme la contraction ou l'expansion osmotique d'organelles de cellules et/ou de cellules complètes. Cette communication démontre que l'on peut utiliser la spectrophotométrie de relaxation par dispersion de la lumière pour établir une corrélation entre des comportements moléculaires et cellulaires dans les photorécepteurs visuels.

Introduction

The interface of two organizational domains is a classic problem in the sciences and particularly in the biological sciences. Generally the study of such an interface presents problems which are not easily anticipated and only appreciated as the study progresses. The study of visual transduction, i.e. the process beginning with the absorption of a photon of light by a visual pigment molecule and terminating with a hyperpolarization of the rod and (or) cone cell, in vertebrate photoreceptors is such a process. Since the mid 1950's the photochemistry of the macromolecular visual pigment, rhodopsin, has been studied (1, 2) by the flash photolysis technique, and the details of the primary photochemical process and the subsequent rapid dark reactions are gradually emerging through the study of rapid absorption spectral changes. These rapid spectral changes which monitor molecular chromophoric and macromolecular changes in rhodopsin, however, give us no clue as to what is occurring at the cellular level. Electrophysiological studies can monitor the rapid electrical changes within the photoreceptor rod cell and show that the cell is rapidly "hyperpolarized" within milliseconds after the absorption of a photon by the visual pigment rhodopsin, but so far such studies have given only minor clues as to the sequence of processes that mediates light absorption and receptor potential generation. One looks for other cytological parameters such as size, shape, and electrical changes within the cell and its organelles, i.e. the pigment containing thylakoid disks, and the rod outer segment, to reveal the coupling details of the pigment molecule–cell interface.

For the study of the broad time range of intracellular changes, light-scattering techniques are coming into prominent use. In the present paper, by way of illustrating the potential of the method, we present an overview of the technique and a summary of the studies which our own laboratory has made to date using this technique to study "structural" changes in suspensions of vertebrate rod outer segments preceding and following their flash illumination with actinic light. One will note a formal resemblance of this technique of "light scattering photometry" to the conventional flash photolysis technique wherein rapid changes in absorption and (or) fluorescence spectra of molecules are studied.

Theory of light scattering

The light scattering properties of molecules and particles fall into three size domains: (*i*) Rayleigh scattering in which the molecule or particle is less than $\lambda/20$, where λ is the wavelength of the scattered light, (*ii*) Rayleigh–Gans–Debye scattering where the size of the particle is in the range $\lambda/20$ to $\lambda/2$, and (*iii*) Mie – van de Hulst scattering for particles with at least one dimension larger than $\lambda/2$. Einstein (3) and Debye (4) developed eq. [1] for application to particles of size less than $\lambda/20$ where I_θ is the intensity of light of wavelength scattered at angle θ and I_0 is the incident intensity of the unpolarized light. The parameters r, M, c, and N are, respectively, the distance between the scattering particle and the detector, the molecular weight of the particle, the concentration of particles, and Avagadro's number. The derivative $\mathrm{d}n/\mathrm{d}c$ is the differential increase in refractive index, n, with particle (solute) concentration. It is evident from eq. [1] that I_θ will depend on the size of the particle as measured by M, the concentration of the particles, c, and the refractive index, n (real part).

$$[1] \quad I_\theta = I_0 \frac{2\pi^2(\mathrm{d}n/\mathrm{d}c)^2 Mc(1+\cos^2\theta)}{N\lambda^4 r^4}$$

If the particle absorbs in addition to scattering radiation, this will have a pronounced effect on the scattering properties; the closer an absorption band is to the wavelength of the scattered light, the larger will be the refractive index n. Thus if a change in the light absorption of a particle occurs during a light scattering measurement there is a corresponding shift in the profile of the anomalous dispersion spectrum which markedly changes n and dn/dc. A hypsochromic (blue) shift in the absorption spectrum will produce a corresponding hypsochromic shift in the anomalous dispersion spectrum, resulting in a decrease in n and dn/dc at wavelengths bathochromic (red) to the absorption band.

Most solutions of macromolecules and small particles have at least one dimension which is larger than $\lambda/20$ and so fall in the Rayleigh–Gans region. This situation gives rise to the phenomenon of destructive interference of the scattered light arising from different regions of the particle. Complete destructive interference can set in when the particles approach $\lambda/2$ in size. The angular dependence $P(\theta)$ in this case is much more complex than the simple $(1 + \cos^2 \theta)$ of Rayleigh scattering and is given by eq. [2]:

$$[2] \quad P(\theta) = \frac{2}{W^2}(e^{-W} + W^{-1})$$

where $W = (4\pi/\lambda)(\sin^2 \theta/2) R_G$, where R_G is the radius of gyration of the particle, which varies markedly with shape. For example, in the case of a particle with a molecular weight of 5×10^5 g, R_G is calculated to be 45 Å for a sphere and 2500 Å for a rod 10 Å in diameter (5).

Hofmann *et al.* (6) have used the Rayleigh–Gans treatment to interpret their light scattering data from disk preparations. Our own studies of suspensions of rod outer segments (ROS) which, though not strictly homogeneous in size, are, for the most part, whole ROS with perforated membranes, fall in the Mie – van de Hulst scattering range (7, 8). For particle suspensions in this size range (length of rod $> \lambda/2$), I_0 is dependent on size, shape, and internal structure of the rod and becomes a complicated function of λ, θ, and $m = n_{\text{particle}}/n_{\text{medium}}$ (9).

Although the scattering and transmission of light by solutions or suspensions of biological particles are sensitive and convenient indicators of a variety of physiological processes, the complications described above have made it difficult to relate, theoretically, changes in light scattering intensity as a function of λ and θ to a particular physical or conformational change of (or within) the particle, e.g. a volume change (8). To identify the conformational change giving rise to any given change in the scattered light intensity therefore requires alternate experimental methods that clearly produce the same scattered light λ and θ intensity patterns.

Osmotically induced volume changes in rod-like bacteria have been made by Bateman (10). He has measured scattered light intensity changes I_0 at 90° but his results, when fitted to Mie theory, gave only partial agreement with van de Hulst's treatment, as the optical changes proved to be very sensitive to particle size and suspension concentration. The latter parameter is particularly important as "multiple particle" scattering can occur and the onset of this complicating situation is a function not only of particle concentration but also of the shape and volume of the containing vessel. Reliable, interpretable data require that "single particle" scattering conditions be maintained. A further complication arises if the particles are not "mono-dispersed", i.e. if they are not homogenous in size, shape, and internal structure. Thus meaningful light scattering measurements, from which interpretations of qualitative and quantitative structural changes in a particle can be made, depend on how carefully the conditions described above are met.

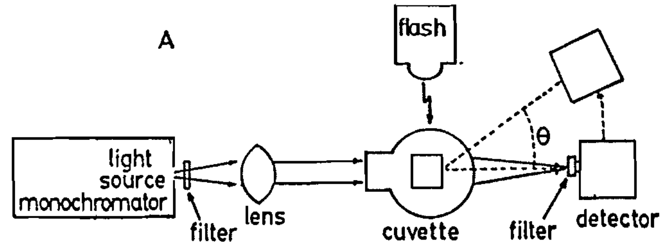

FIG. 1. Schematic representation of the light scattering apparatus.

Light scattering relaxation photometry

For the measurement of light scattering transients an apparatus similar to a conventional flash photolysis unit can be used. In fact, such a unit can be constructed so as to measure absorption and scattering changes simultaneously. Shown in Fig. 1 is a schematic of the unit we orginally used in our laboratory, which was designed to measure scattering changes only.

A commercial PRA xenon flash unit provided pulsed flashes of actinic light (450–550 nm) of controlled intensity and duration (50 μs). A tungsten lamp focused on the slit of a Bausch and Lomb monochromator (grating blased at 750 nm) served as a source of near infra-red radiation. The emergent parallel light was directed through a water (or occasionally air) thermostated cuvette containing an aqueous ROS suspension. The scattered light detector was an EG&G photodiode (UV 44B) mounted on an adjustable protractor which could be set at the desired angle.

A 1-cm square quartz cuvette with four transparent optically clear faces served as the light scattering cell. This was mounted in a spherical transparent water thermostat. An air thermostat, which used a Cambion model 801-2001-01 thermoelectric module for temperature regulation, was occasionally employed. The square cuvette limited the practical angular range of measurement from 0 to 30°. For larger angles a cylindrical cuvette was employed.

Measurements were routinely made at $\theta = 10°$ and at $\lambda = 810$ nm. Scattered light intensity voltage signals from the photodiode detector were passed through a preamplifier and compensated to zero voltage and then collected and displayed on a Nicolet Explorer III digital storage oscilloscope; the signals were stored on floppy disks for visual comparison or printing on an Omnigraph XY recorder.

Photoreceptor cell structure

There are two morphologically and functionally distinct regions in the vertebrate rod photoreceptor cell (Fig. 2): (*1*) the inner segment (RIS) containing organelles concerned with metabolic functions, such as the nucleus and the energy producing mitochondria, and (*2*) the outer segment (ROS), containing the visual pigment rhodopsin, which is connected to the RIS by a tubular ciliary process. The ROS consists of a stack of 500 to 2000 disks (depending on the species) enveloped by a plasma membrane (11). In bovine cells the ROS are quite small; they are 1 μm in diameter and up to 10 μm in length. The disks are flat saccules with a phospholipid bilayer membrane 60–70 Å thick enclosing an aqueous space (lumen) from 10 to 30 Å in depth (12). A cytoplasmic region of about 150 Å in thickness apparently containing a negatively charged gel-like polysaccharide matrix (13) separates the disks one from another. Recent electron microscopic evidence points to the existence of filamentary connections between adjacent disks[1] and there is

[1] M. L. Applebury, private communication.

the further suggestion that direct connections exist between the disk rims and the region exterior to the plasma membrane (14).

Rhodopsin and its photochemistry

Vertebrate rhodopsin is a hydrophobic glycoprotein with a molecular weight of about 39 000 daltons. Its amino acid sequence has recently been determined by two groups (15, 16). Hargrave (15) finds seven hydrophobic helical regions ranging from 21 to 28 amino acids which are oriented asymmetrically in serpentine transmembrane fashion in the disk membrane surface, the carboxyl terminal group at the cytoplasmic surface, and the amino terminus and carbohydrate moiety at the inner lumen surface. The retinylidene chromophore is attached to the ϵ-amino group of a lysine residue in the interior of the membrane on helix number 7. There are approximately 200 000 rhodopsin molecules in each bovine disk.

The 11-*cis* retinylidene chromophore is joined to the ϵ-amino group of lysine via a protonated Schiff base linkage (Fig. 3). Assuming the 7 helices are arranged in a cylindrical tertiary structure, the estimated diameter of the rhodopsin molecule is about 900 Å.

The absorption spectrum of rhodopsin (Fig. 3) has three characteristic regions: a principal long wavelength chromophoric band with a maximum in the vicinity of 500 nm, a weaker chromophoric (*cis*) band with a maximum near 350 nm, and a third apoprotein band whose maximum lies at 280 nm.

The absorption of a photon in the chromophoric regions of the spectrum of the rhodopsin molecule initiates a series of intermediate processes characterized by spectral changes occurring over several time ranges varying from picoseconds to minutes (Fig. 4). The times shown in Fig. 4 are the approximate transition times at 37°C. The initial very rapid primary

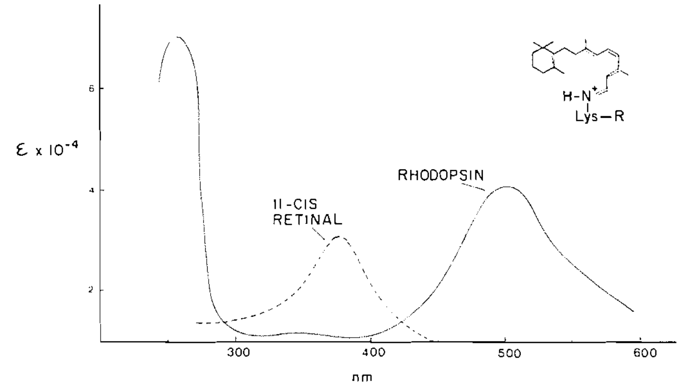

FIG. 3. The absorption spectrum of rhodopsin. The spectroscopy was carried out in 3% Ammonyx in 150 m*M* Pipes and 10 m*M* hydroxylamine.

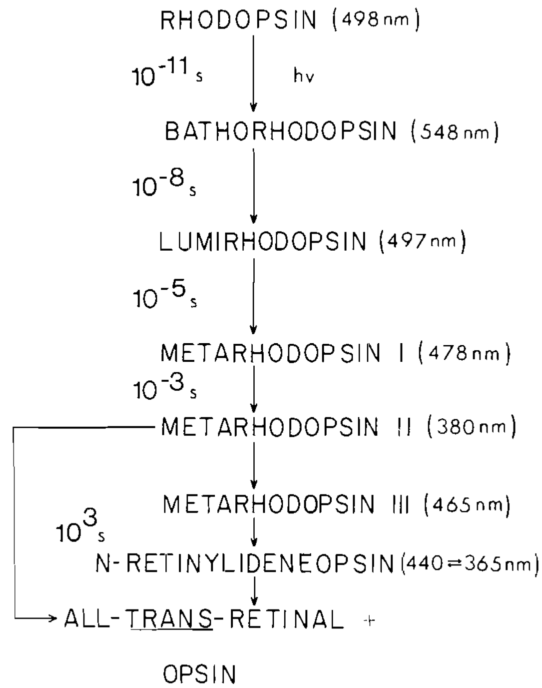

FIG. 4. The bleaching sequence of rhodopsin at 37°C.

photochemical process involves a partial photoisomerization of the chromophore to its all-*trans* isomeric form, possibly linked to a displacement of a hydrogen bond at the Schiff base nitrogen of the chromophore–protein linkage. Since visual transduction occurs in times of the order of 10 milliseconds, the latest process in the sequence shown in Fig. 4 that can be involved directly in this process is the metarhodopsin I → metarhodopsin II process. Significantly, this process is the first in the sequence that involves reaction with the environment, i.e. hydrogen ion uptake, and for this reason it is the process most likely to couple molecular with cellular domains.

The bulk of our studies have been performed on Bovine (heifer) rod outer segments (ROS). The eyes were excised within a few minutes of the animal's death and stored on ice in the dark. The retina were harvested and the ROS were prepared by a sucrose density gradient technique (17). Following this the ROS suspensions were passed through a syringe needle packed with glass wool. This operation served to perforate the plasma membrane as indicated by electron micrographs. The prepara-

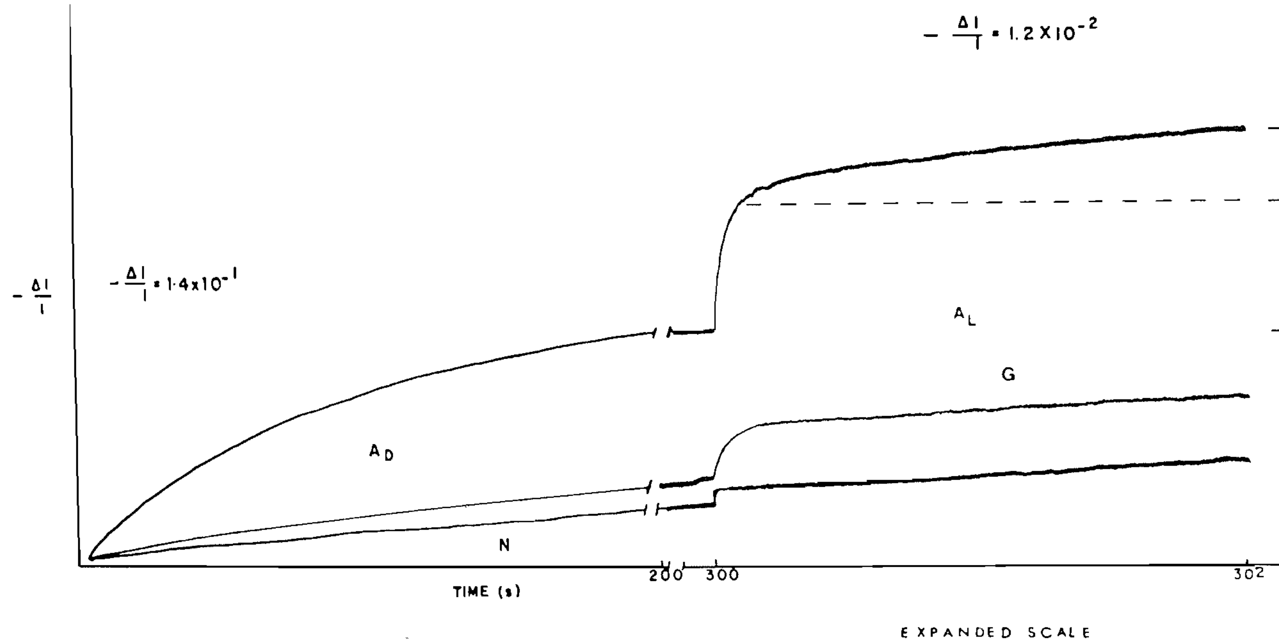

FIG. 5. The A, G, and N signals as observed from our scattering apparatus. Note the expanded scale at the point of actinic illumination.

tions were stored in plastic vials under liquid nitrogen until ready for use. This treatment had only a minimal effect on the scattering properties after several months of storage as compared to fresh preparations.

To ensure that measurements would be made in the single particle scattering range, the density of the ROS suspension was maintained at less than 2 μM rhodopsin. For the bulk of the studies flash intensities were such that less than 25% of the rhodopsin molecules were photobleached by a single flash.

A number of distinct types of light scattering signals were observed in ROS suspensions under a variety of conditions. The ones investigated in our laboratory are described below.

The N signal

The N signal (Fig. 5) describes the behavior of the relative scattered light intensity ($-\Delta I/I$) at a given λ and θ as a function of time. It is a simple "step" function in which a sudden increase in ($-\Delta I/I$) occurs contemporal with the light flash. It can be described as a summation of two processes: (*1*) internal, structural and electrical changes accompanying the metarhodopsin I $\rightarrow$ metarhodopsin II (MI/MII) process and (*2*) a hypsochromic shift of the anomalous dispersion spectral profile following the partial photobleaching of rhodopsin. These effects produce substantial changes in the refractive index n and dn/dc, which result in marked light scattering changes in the Mie scattering region.

The A signal

The A signal (Fig. 5) arises when Mg-ATP is added to a buffered suspension of ROS. It is unique in that it shows both a dark-A_D, and a light-stimulated component, A_L (18).

The dark A_D signal is produced when varying amounts of Mg-ATP are added to an ROS suspension buffered at pH = 7.3 with Tris-HCl. One observes a relative decrease in scattered light intensity ($-\Delta I/I$) which reaches near saturation at room temperature in approximately 10 min. This decrease, plotted as an increase in $-\Delta I/I$, accompanies an increase in inorganic phosphate (19), suggesting that ATP has been hydrolyzed via a Mg-ATPase contained in the disk membranes (18, 20). The fact that the A signal is insensitive to ouabain, and succinate dehydrogenase activity is negligible, indicates that the ATPase cannot be a Na^+/K^+ dependent arising from inner segment or mitochondrial contamination.

Summarizing our studies, we have found that the dark A_D light scattering signal has the following properties (17–20). (*i*) It is substantially inhibited by the non-hydrolyzable ATP analogue AMP-PNP at concentrations comparable to ATP. Furthermore, GMP-PNP has no effect on A_D. This suggests that the A_D signal arises from a process mediated by a disk membrane bound ATPase. Furthermore, the ATPase appears to have multi-subunits as indicated by the sigmoid character of a plot of the maximum $\Delta I/I$ amplitude versus ATP concentration.

(*ii*) Calcium and vanadate ions at concentrations 1/10 that of Mg^{2+} exhibited substantial inhibitory effects on the A_D.

(*iii*) The nucleotide cGMP when present at 1/10th the concentration of ATP shows a substantial enhancement of A_D.

(*iv*) The A_D signal is independent of the presence of "G" protein which has been identified as a disk associated GTPase; a low ionic strength extraction which removes "G" protein from the disks (4 mM Tris at 4°C) has no effect on A_D.

(*v*)The kinetics of A_D is essentially first order in the presence of excess Mg-ATP. Its activation energy, E_a, is estimated at 24 kcal/mol in the temperature range 15–37°C.

(*vi*) Comparison of the θ dependency of the A_D signal with that obtained from the controlled osmotic swelling of ROS suspension showed near identity of these patterns. It appears, therefore, that the A_D signal arises from the swelling of the disk matrix of the ROS.

(*vii*) The A_D signal is sensitive to the ROS particle concentration. In our apparatus, the single particle scattering range was between 0 and 2 μM rhodopsin. Most of our experiments were performed at concentrations of rhodopsin of 1 μM or less. There is essentially a linear increase in ($-\Delta I/I$) with rhodopsin concentration at constant flash intensity and at 10 $\pm$ 1° of scattering angle. Measurements performed on ROS suspensions having rhodopsin concentration greater than 2 μM showed erratic behavior; there was an actual decrease in the amplitude $-\Delta I/I$ versus particle concentration. The angular resolution is very important, particularly in the range 0–10°, as the variation of $-\Delta I/I$ versus θ varies sharply and shows biphasic behavior in this angular range.

The light stimulated A_L signal

If, after allowing the development of the dark A_D signal over a period of several minutes, the ROS suspension is flash illuminated with actinic light (500–550 nm) there is an instantaneous increase in the amplitude of $(-\Delta I/I)$ similiar to that occurring in the N signal, save that it is much larger in amplitude. The initial portion (50 ms) is termed A_{LF}. A_{LF} is followed by a much slower increase in amplitude over a period of several seconds. This slower portion of the signal is designated as A_{LS}.

Kinetically, the A_{LS} process, like A_D is first order but with a much faster rate than A_D which increases with the extent of photobleaching. At very low levels of photolysis the rate of A_{LS} approaches that of A_D.

A_{LS} in all its properties studied so far, save rate, duplicates those of A_D (17). λ and θ dependencies of A_L are the same as A_D. The rate of inorganic phosphate appearance is enhanced over that of A_D in the initial period following flash illumination consistent with the increased rate of A_{LS} over A_D (19). As in the case of A_D, A_{LS} is inhibited by calcium ions and enhanced by cGMP (17–20). Also similiar to A_D is the variation in scattering signal time profile of A_{LS} at particle densities greater than the single particle range.

The fast component of the A_L signal, A_{LF}, has much the same characteristics as that of the N signal with regard to λ and θ dependencies, suggesting that the structural and the electrical changes in the ROS were essentially those occurring as a direct consequence of the photolysis of rhodopsin to metarhodopsin II. The properties of A_D and A_{LS} can be logically interpreted as a "swelling" of the ROS disks in consequence of the ATPase mediated pumping of ions into the disk lumen. Our studies of the ions being pumped are described below.

Ion pumping accompanying the A signal

Cation pumping

In the dark, the disk membranes in the absence of nucleotides are impermeable to most anions (21). However, as a consequence of the ATPase activity one might expect cation pumping to accompany the A signal. In order to ascertain whether such cation pumping did in fact occur, the effects of various ionophores on the A_D and A_L signals were investigated. Proton ionophores were unique in their behavior; the powerful mitochondrial ATPase uncoupler, SF6847, at a concentration of 9 μM completely abolished the A_{LS} signal and substantially reduced A_D (17). Tributyl tin, an ionophore which exchanges OH^- and Cl^- across membranes, gave A signals identical to N signals when present at a concentration of 9 μM (17). Ionophores specific for cations other than protons did not show this behavior.

The most direct confirmation of proton pumping activity associated with the ATPase-induced A signal, A_D and A_{LS}, is shown by the following experiment. When the ROS suspension, after incubation with Mg-ATP for several minutes, was sonicated to rupture the disks, protons were released into the aqueous media as indicated by a decrease in pH. No such decrease in pH was observed on sonicating a control sample in which no Mg-ATP was added. Therefore, pumping of protons into the disk lumen appears to be the primary activity of the ATPase-driven A signal.

Anionic symport

Anion symport generally accompanies ATPase cation pumping to maintain electrical neutrality. Usually the symported

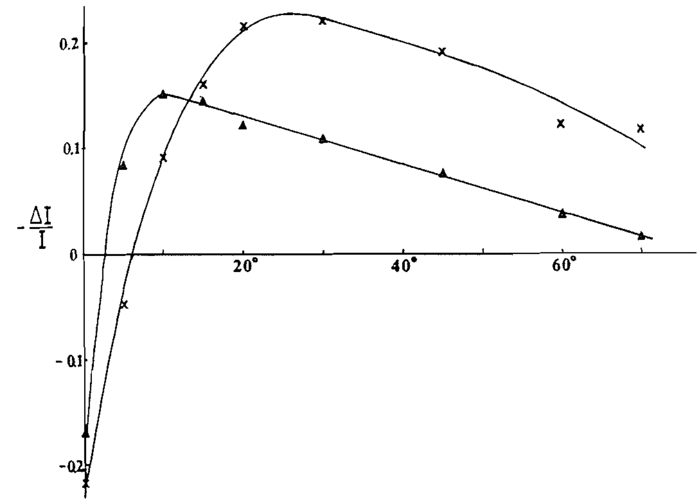

FIG. 6. Comparison of A_D and A_L versus the scattering angle. The (X) represents the A_L, and the (▲) represents the A_D.

anion is an impermeable one which requires a protein carrier closely coupled to the cation ATPase pump. A known blocking agent for such anion carriers is diisothiocyanostilbene sulfonic acid (DIDS). We found that DIDS substantially reduced the amplitude of the A signal. In the case of normally permeant anions such as SCN^-, no protein carrier is required and we observed that when this anion, SCN, was present, the rates of both A_D and A_{LS} were enhanced relative to their rates when Cl^- was present alone. Of the normally impermeant anions, Cl^- appears to be the most effective. Bicarbonate anion, although it can replace Cl^-, yields an A signal whose amplitude is considerably reduced over the Cl^-, suggesting a buffering action of bicarbonate ion within the disk lumen that alters the MI/MII ratio in favour of MI.

A physiological basis for the A signal

The A signal can also be observed in ROS preparations where the plasma membrane is intact. In such cases no exogenous Mg-ATP is needed to produce either A_D or A_L. Apparently, what happens in such cases is that endogenous Mg-ATP is present in the ROS and begins to act as soon as the frozen ROS preparation is brought to room temperature by the addition of the Tris buffer solution. Significantly, the A_D and A_L signals seen under these conditions are comparable to those observed in the presence of Cl^- ions rather than bicarbonate ions. These observations point to the A signal as having a physiological basis and that the active anion in the rods in this case is the Cl^-.

A molecular basis for the A signal

It is clear from Fig. 6 that both A_D and A_L can be interpreted as disk swelling processes. Furthermore, their first-order kinetics and the dependence of the rate constants on the concentration of ATP, together with the proton ionophore experiments, point to the principal molecular process involved as an ATPase mediated pumping of protons into the disk lumen. This suggests that the physiological role of the A_D and A_L signals is to insure protonation of rhodopsin in preparation for the metarhodopsin I $\rightarrow$ metarhodopsin II process, i.e. to maintain a high ratio of MII/MI according to eq. [3].

$$[3] \quad MI + H^+ \rightleftarrows MII$$

It is not possible from the kinetic studies made so far to determine the nature of the "saturation" of A_D or A_L; simple reversal of the pumping process and (or) mechanical limitations on the swelling could account for saturation.

We have mentioned that the A_L signal probably involves two processes: the hypsochromic shift in the anomalous dispersion spectrum and what can be interpreted as a rapid (20 ms) "shrinkage" of the disks. This shrinkage may possibly be accounted for by the rapid expulsion of cations from the disk lumen. The aforementioned proton ionophore experiments suggest that protons may be rapidly ejected from the lumen. But atomic absorption and specific ion electrode studies made in our laboratory indicate that Na and Ca ions are also ejected by light after dark incubation in the presence of ATP, suggesting that ATPases other than the proton ATPase are present in the disk (22). At the present time we have no data on the time course of the appearance of any of these cations.

The G signal

If one replaces exogenous Mg-ATP in a suspension of ROS with GTP along with a divalent cation (Mg^{2+}, Ca^{2+}, Mn^{2+}) one observes on flash illumination a scattering signal ($-\Delta I/I$) which increases with time, approaching near saturation in about 30 sec. This is termed the G signal. Unlike the A signal, there is no dark signal associated with the G signal comparable to A_D. Furthermore, the G signal is studied at levels of rhodopsin bleaching less than 10%, compared to levels approaching 25% usually used in the case of the A signal. There is no pronounced initial sharp amplitude increase in the G signal comparable to the N signal associated with A. Kuhn *et al.* (23) have studied the G signal under conditions of high multiple scattering concentrations and very low total levels of rhodopsin photobleaching (0.08%). At such high particle densities, the photobleaching will be highly inhomogenous and the scattering, as well as the photobleaching, should be limited to the outer layers of the suspension. Their scattering profiles are very much different than our G signals taken under conditions of single particle scattering (19).

In addition to those differences mentioned above, the G signal differs from the A signal in the following respects.

(*i*) The G signal is inhibited by the non-hydrolyzable analogue GMP-PNP but not by AMP-PNP. This is in contrast to the A signal, which is inhibited by AMP-PNP but not GMP-PNP. The two signals, A and G, therefore appear to be completely independent, the A signal arising from an ATPase activity and the G signal arising from a GTPase activity.

(*ii*) The G signal requires the presence of a multi-subunit "G protein" associated with a GTPase as shown by Kuhn *et al.* (23). The A signal, on the other hand, as mentioned previously is independent of the presence of the "G protein".

(*iii*) The G signal does not show Ca^{2+} ion inhibition as does the A signal.

(*iv*) cGMP, when present in concentrations less than that of the GTP, inhibits the G signal. The A signal is enhanced by the presence of cGMP in comparable concentration ratios.

(*v*) The G signal increases in amplitude with the extent of photobleaching, reaching saturation at about 10% photobleaching. The A signal does not show this saturation in amplitude.

A molecular basis for the G signal

The experimental evidence gathered in our laboratory indicates that the G signal is very complex; it cannot be interpreted in terms of simple molecular processes as is the case for the A signal. Differences in kinetic reaction order as well as thermal and pH dependency are observed in different temporal regions of the overall signal. In addition, changes in θ and λ dependencies which suggest different structural changes appear in different regions of the overall signal. GTP hydrolysis does not occur until the latter stage of the process, as is indicated by the inhibition of this portion by GMP-PNP. At the present time we offer a provisional molecular mechanism underlying this complex molecular–cellular process (Fig. 7) based on our own studies, which is similar although not identical to that presented by others (23).

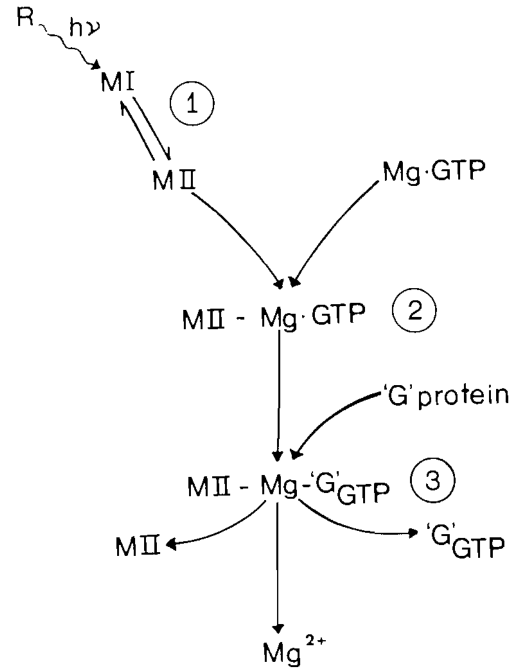

FIG. 7. A simple molecular mechanism for the G signal.

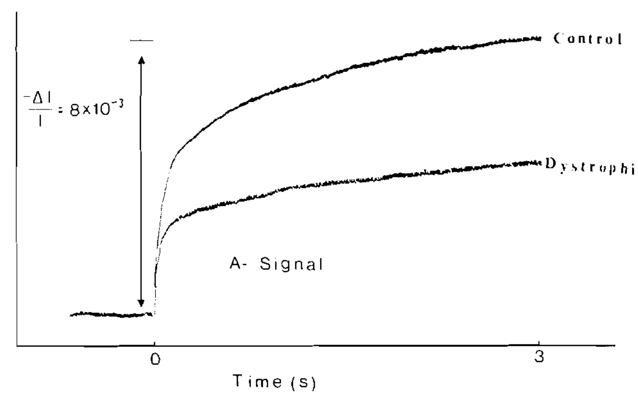

FIG. 8. A comparison of the A signals in control and dystrophic Royal College of Surgeons (RCS) rats.

The A and G signals in rat rod outer segments

The A and G scattering signals reflect complex physiological processes within the disk matrix in vertebrate ROS. They therefore serve to monitor key facets of the vertebrate visual photoreception process. With this thought in mind, we have been exploring the use of these signals in characterizing retinal dystrophies in laboratory animals. Our studies so far have focused on a colony of RCS (Royal College of Surgeons) rats which

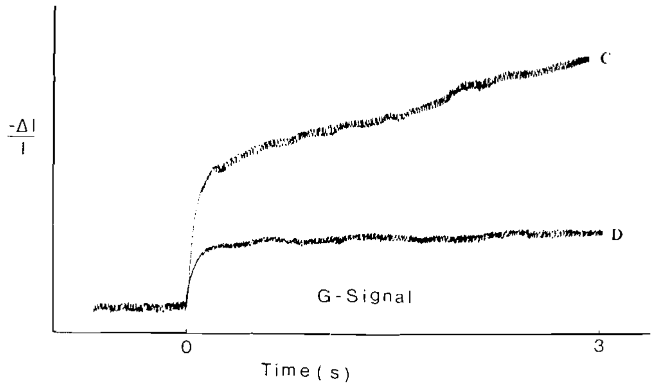

FIG. 9. A comparison of the G signals in control (C) and dystrophic (D) Royal College of Surgeons (RCS) rats.

have retinal dystrophy, mimicking in some respects the human disease retinitis pigmentosa. In our studies so far, we have found that A and G signals can be elicited from ROS preparations of both normal and dystrophic rats. In the dystrophic rat ROS, however, the progression of the disease is accompanied by the decrease in the amplitude of the A signal and the complete disappearance of the G signal (Figs. 8, 9). These processes are currently being studied in more detail (24).

Incoherent quasi-elastic neutron scattering experiments between 250–400 K and heat capacity measurements between 10–310 K have been performed on polycrystalline samples of NH_3SO_3. It is concluded that NH_3 groups undergo jumps of $2\pi/3$ and that the associated residence time is of 2×10^{-11} s at 300 K, while the activation energy is equal to 12 kJ mol^{-1}. These results are compared with those in the literature, in particular, we point out that the frequency derived from the Arrhenius relation is in fair agreement with the torsional frequency measured in Raman spectroscopy (247 cm^{-1}) while the activation energy is similar to that found by nmr. Finally the relative magnitude of potential barriers deriving from intra- and intermolecular interactions is estimated from potential calculation based on atom–atom potentials, the dominant terms are due to hydrogen bondings.

J. F. BOCQUET, K. CHHOR, G. LUCAZEAU et A. J. DIANOUX. Can. J. Chem. **63**, 1940 (1985).

Un échantillon polycristallin d'acide sulphamique, NH_3SO_3, a été étudié entre 250 et 450 K par diffusion quasi-élastique de neutrons. La courbe de capacité calorifique entre 10 et 310 K a également été obtenue. Les paramètres déterminant la dynamique des groupements NH_3 ont été déterminés: les protons effectuent des sauts de $2\pi/3$ avec des temps de résidence de 2×10^{-11} s à 300 K; l'énergie d'activation correspondante est égale à 12 kJ mol^{-1}. Ces résultats sont comparés avec ceux de la littérature; la fréquence d'attaque déduite de la relation d'Arrhénius est en bon accord avec la fréquence de torsion mesurée en Raman (247 cm^{-1}). L'énergie d'activation est très proche de celle trouvée en rmn. La barrière de potentiel s'opposant à la rotation des NH_3 a également été calculée à partir de potentiels atome–atome; les termes dominants sont dûs aux liaisons hydrogène.

I. Introduction

This work is a part of a general study about reorientational processes which take place in inorganic molecular crystals. We have systematically shown how the combination of neutron and Raman scattering and of heat capacity measurements can pinpoint the mechanism of reorientational motions which take place in molecular crystals such as metallocenes (1–3), arene metal carbonyls (4–8) or $NH_3(CH_2)_3NH_3MnCl_4$ (9,10) and to what extent they are responsible for phase transitions. The temperature dependence of the quasi-elastic neutron scattering function allows the determination of the activation energy which can generally be identified with the potential barrier hindering the reorientational motion, while the geometry of the motion can be derived from the Q dependence of the scattering function; for these reasons and because of the various resolutions available at ILL (Grenoble) the incoherent quasi-elastic neutron scattering (IQENS) can be considered the soundest technique of determining the parameters which characterize the hydrogen motions in a solid, specifically when several reorientational motions take place.

In this article, we shall first present and interpret our neutron results. We shall then discuss and compare our results with those of the literature: Raman (11, 12), nmr (13), particularly in terms of potential barriers originating from intra- and intermolecular interactions. Finally, we shall present some results of potential barrier calculations performed with the WMIN Busing's program (14) by using coulombian, Van der Waals, and hydrogen bonding atom–atom potentials.[2] A forthcoming paper, devoted to the discussion of the factors responsible for the Raman band broadening (reorientational motion, vibrational dephasing, anharmonicity) of the NH_3 torsion in sulphamic acid will be based on the conclusions of the present paper and on the neutron diffraction results recently recorded for ten temperatures between 4 and 300 K (15).

II. Experimental conditions

Sample

Sulphamic acid NH_3SO_3 was commercially obtained. The sample was purified by repeated recrystallizations from water–methanol mixture and dried in high vacuum. For heat capacity experiments, 13.99 g of the sample was used and loaded in the calorimetric vessel in which air was replaced with a few kPa of helium gas at 300 K. For IQENS experiments, powder samples were contained in circular thin-walled aluminum cans (5 cm in diameter). The thickness of the sample was adjusted to ensure a transmission of about 90%. Samples were examined by infrared analysis before and after experiments in order to check that no decomposition process had taken place.

Neutron scattering

Neutron experiments were performed at the Institut Laue-Langevin (I.L.L. Grenoble) with the time of flight (TOF) IN6 instrument. The angle between the sample plane and the incident neutron beam was taken equal to 135° for incident wavelength λ_0 = 5.1 Å and equal to 45° for λ_0 = 5.9 Å.

Ten temperatures ranging from 250 to 443 K were investigated. We used a heating and cooling loop device which operates between 77 and 700 K. However, due to a bad thermal contact between the sample holder and the loop, some of our measured temperatures may be in error by as much as 10 K. The average resolution for λ = 5.1 and 5.9 Å are 109 and 53 μeV, respectively, while the Q range investigated at 5.1 Å is between 0.25 and 2.21 Å^{-1}.

Angles that were contaminated by Bragg reflections were eliminated from the data. The spectra were corrected by standard ILL

[1]Unité Associée au C.N.R.S. N° 453.
[2]The computer program WMIN is capable of manipulating static and dynamic models of crystal or isolated molecules and calculating their energies from interatomic potential functions.

programs for detector efficiency, sample container efficiency, scattering absorption and self-shielding. All the TOF spectra were normalized to the elastic scattering from vanadium.

Calorimetric procedure

Heat capacity measurements were performed on an automatic adiabatic calorimeter from 10 to 310 K. Thermodynamic functions and C_p values will be reported in a separate paper.

The calorimeter and computer-operated adiabatic assembly is described elsewhere (16). Temperatures were determined by a germanium or a platinum thermometer in the ranges 10−30 K and 30−310 K, respectively.

The thermal analysis between 300−450 K was performed on a differential scanning calorimeter (M.C.B. Arion Grenoble, France) the heating and cooling rates were 0.5 K $\min^{-1}$ and the sample used was about 400 mg.

III. Structural data

The crystal structure is described by the *Pbca* space group with eight molecules per unit cell (Fig. 1*a*). The atomic positions have been reported at 300 K and 78 K from X-ray (17) and neutron (18) diffraction measurements. The intra- and intermolecular bond distances are reported on Fig. 1*b* and 1*c*, respectively. The three H atoms of a given NH_3 group are involved in three short NH---O hydrogen bonds and two long NH---O bonds. The atomic positions of ref. 18 were used in our potential calculations. The electron density has been determined from X—N maps (18). The S—N and S—O bonds have been found to be similar to bonds between first row atoms. The S—O double bond character has been deduced from its shortening (1.44 Å) with respect to the S—O single bond (1.69 Å). The net atomic charges reported in ref. 18 are given in Fig. 1*b*.

IV. Heat capacity results

Neither the heat capacity curve (Fig. 2) (10−310 K) nor the DTA curve (300−450 K) exhibit any anomaly which could indicate the presence of static disorder. In other words, the protons do not occupy distinguishable sites which could create an entropy increment: $\Delta S = R \ln N$ observable on the C_p curve. Thus, we can ignore the presence of subminima (for instance at $2\pi/6$) and safely assume that the approximate local threefold symmetry of a molecule as found by neutron diffraction (18) at 78 K is preserved at higher temperature. In this case we must consider that the potential function governing the NH_3 motion around the N—S bond has three deep minima which are essentially occupied between 10 and 310 K and that no drastic potential modification occurs in this temperature range.

V. Neutron scattering

V.1. Theoretical background

The neutron incoherent scattering law for a random motion of a uniaxial rotator in an *N*-fold cosine potential has been derived by Dianoux and Volino (19). They have shown that when the relative barrier height

$$\gamma = \frac{1}{2}\frac{V_0}{kT}$$

is large (in practice > 1.2) the scattering function $S(Q,\omega)$ can be written as in the case of instantaneous jumps between definite sites (20). In the present case, the experiments have been performed at about 300 K and we expect that the potential barrier is larger or equal to 12 kJ mol^{-1}, thus γ is larger or equal to 2.5 and the above condition is fulfilled.

The scattering law $S(Q,\omega)$ is obtained from the time Fourier transform of the intermediate scattering function $I_s(Q,t)$, for one mobile particule:

$$[1] \quad I_s(Q,t) = b_{\mathrm{inc}}^2 \iint g(\boldsymbol{r}_0)\, \mathrm{d}\boldsymbol{r}_0\, e^{iQ(r-r_0)}\, G_S(\boldsymbol{r}, \boldsymbol{r}_0, t)\, \mathrm{d}\boldsymbol{r}$$

in which $G_S(\boldsymbol{r}, \boldsymbol{r}_0, t)$ is the probability function to find the particle at $\boldsymbol{r}$ at time t if it was at $\boldsymbol{r}_0$ at time zero, with the probability distribution $g(\boldsymbol{r}_0)$ of initial position $\boldsymbol{r}_0$ as a weighting factor. In the rotational jump model the integral over initial positions ($\mathrm{d}\boldsymbol{r}_0$) is replaced by a summation over the three positions that a given proton can occupy; the integral over instantaneous positions is replaced by a summation over equilibrium positions of the proton. The G_S function writes $\sum_j \delta(\boldsymbol{r} - \boldsymbol{r}_{ij})P_j(t)$ in which $P_j(t)$ measures the time dependent

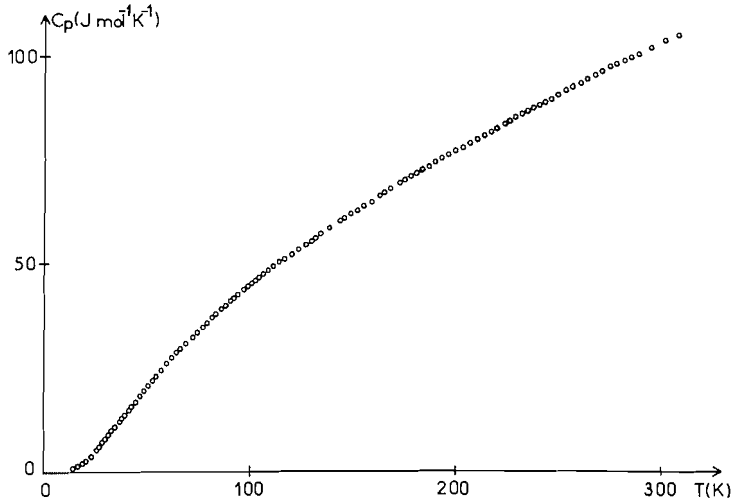

FIG. 2. Heat capacity curve of crystalline sulphamic acid.

probability of finding the proton at the site r_j if it was at r_i at $t = 0$, the jump distance r_{ij} being equal to $r_j - r_i$. Moreover, for NH_3SO_3 the three sites have an equal population and the jump rate from i to j is equal to that from j to i. Under these conditions, for an uniaxial rotation on a circle of radius R, and for a sample in a powdered form, the rotational scattering law takes the form:

$$[2] \quad s_{\text{inc}}^{\text{rot}}(Q,\omega) = A_0(Q)\delta(\omega) + \frac{1}{\pi}\sum_{l=1}^{N-1} A_l(Q)\, L\,(\tau_l^{-1})$$

where

$$[3] \quad A_l\,(Q) = \frac{1}{N}\sum_{j=1}^{N} j_0\,(2\,QR\,\sin\,(\pi j/N))\,\cos\,(2\pi lj/N)$$

l refers to the different jumps, j refers to the N-allowed sites. j_0 is the spherical Bessel function of the first kind of order zero ($j_0\,(x) = \sin x/x$) and $L(\tau_l^{-1})$ is the Lorentzian function,

$$[4] \quad L(\tau_l^{-1}) = \tau_l/(1 + \omega^2\tau_l^2)$$

in which τ_l^{-1} is the half-width at half-maximum (hwhm) and the characteristic times are given by

$$[5] \quad \tau_l = \tau_c/2\,\sin^2\,(\pi l/N)$$

where τ_c is the correlation time (residence time) between two successive jumps of a proton. It has been shown that the first broadened term in the summation over all the possible jumps gives the largest contribution and, therefore, the experimental hwhm of the quasi-elastic peak may be sometimes approximated by $1/\tau_1$; moreover in the limit $N \rightarrow \infty$, the jump probability $1/\tau_1$ can be identified with the rotational diffusion coefficient D_r. The term $A_0\,(Q)$ in eq. [2] represents the elastic incoherent structure factor (EISF): it is the fraction of the intensity due to mobile protons, that is contained in the purely elastic peak. The EISF is directly related to the geometry of the molecular motion. It is thus useful to measure the EISF as a function of Q and compare it with the calculated one for different models. In the present case a jump angle of $2\pi/3$ is the most probable for uniaxial rotational motion and we have considered that in the average each proton describes a circle of radius $R \simeq 0.97$ Å around the SN axis.

The quasi-elastic peak intensity increases with the $Q \cdot R$ product. Figure 3 shows this enhancement while conversely one observes the decrease of the pure elastic peak.

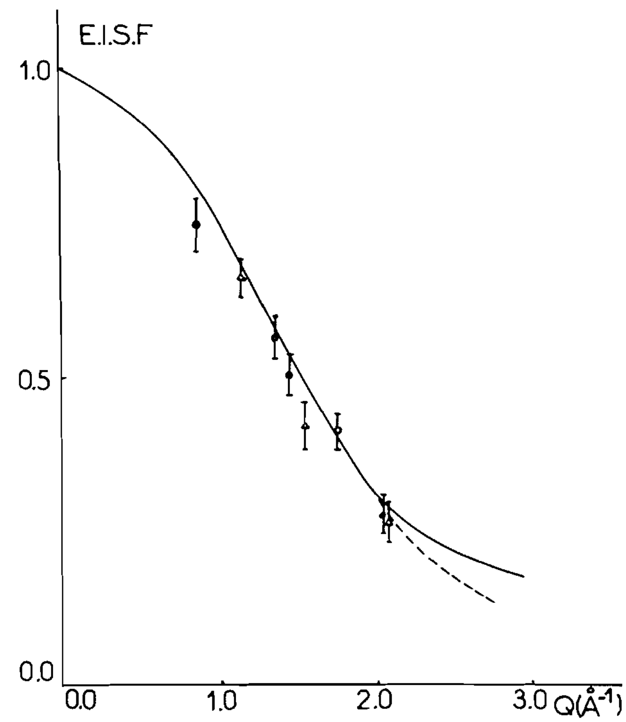

FIG. 3. Elastic incoherent structure factor: solid line, theoretical curve for the $2\pi/3$ jump model; dotted line, theoretical curve for the $2\pi/6$ jump model. Some experimental points ($I_{\text{elastic}}/I_{\text{total}}$) are reported: ●, 400 K, 5.1 Å; △, 333 K, 5.1 Å; ○, 403 K, 5.9 Å.

V.2. Results

Figures 4, 5 and 6 show some typical corrected spectra of NH_3SO_3 obtained on the time of flight IN6 spectrometer. The Q dependence of the relative fraction of elastic to the total elastic + quasi-elastic intensity (EISF) is represented and compared to the theoretical curves in Fig. 3. Figure 7 shows the variation of the mean residence time on a site against reciprocal temperature.

The EISF values reported in Fig. 3 have been extracted by fitting the corrected spectra in the 250–400 K temperature range to a single Lorentzian plus an elastic peak folded with the instrumental resolution. One cannot choose between the models corresponding to reorientational jumps of $2\pi/3$ or

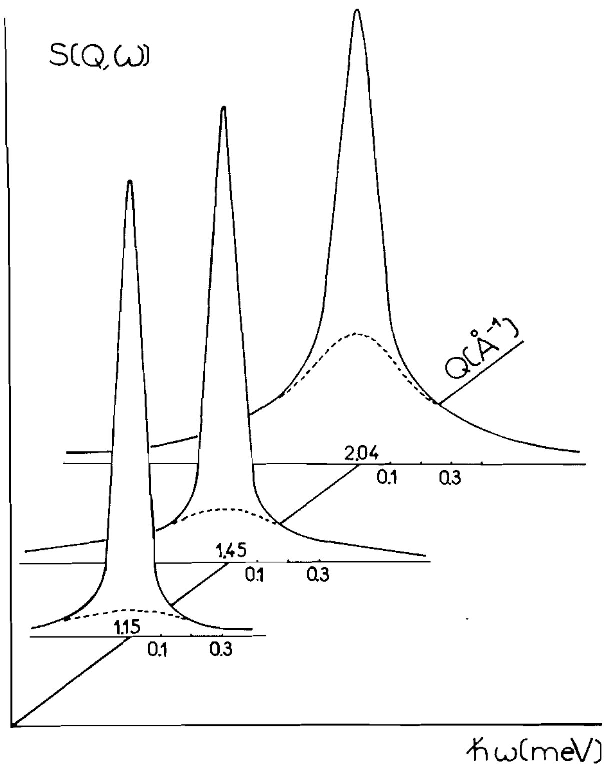

FIG. 4. Corrected quasi-elastic neutron scattering spectra for polycrystalline sample of NH_3SO_3 at 400 K for an incident wavelength $\lambda_0 = 5.1$ Å. The quasi-elastic contribution is represented by a dotted line in order to show its Q dependence.

$2\pi/6$. A broader Q range should be necessary, this would imply smaller incident wavelength. As a consequence the resolution would be smaller and the precision on the EISF determination would be very poor. Note that the $2\pi/6$ jump model almost corresponds to the diffusive case (21) in the observed Q range.

V.2.1. Determination of the residence times and of the activation energy

We have fitted the corrected spectra with those calculated by folding the scattering law for uniaxial rotational motions of protons with the instrumental resolutions for each angle.

The parameters used in the fitting procedure have been described elsewhere (4). Among these is τ_1^{-1}, which governs the width of the Lorentzian function appearing in the scattering function (see eq. [2]). In the case of $2\pi/3$ jump model there is a single τ_1 value and thus from eq. [5] the correlation time τ_c is found equal to $1.5\tau_1$. The two other parameters of importance are the radius of gyration R, which was fixed to 0.94 Å and the proportion of the non mobile protons p found to tend towards zero whatever the $2\pi/3$ or $2\pi/6$ jump model is introduced to fit the data. The fitting procedure has been performed on 10 angles simultaneously. The result of these fittings are reproduced in Table 1. This shows that at 406 K the fwhm ($2\tau_1^{-1}$) is two to four times larger than the experimental resolutions and therefore in such a favorable situation the dispersion of the points in Fig. 7 can only be explained by bad temperature measurements as indicated in the Experimental section.

The slope of the straight line (Fig. 7) representing the Arrhenius variation of τ_c as function of temperature gives a measure of the activation energy of the jump process, and is found equal to $E_a = 12 \pm 2$ kJ mol^{-1}.

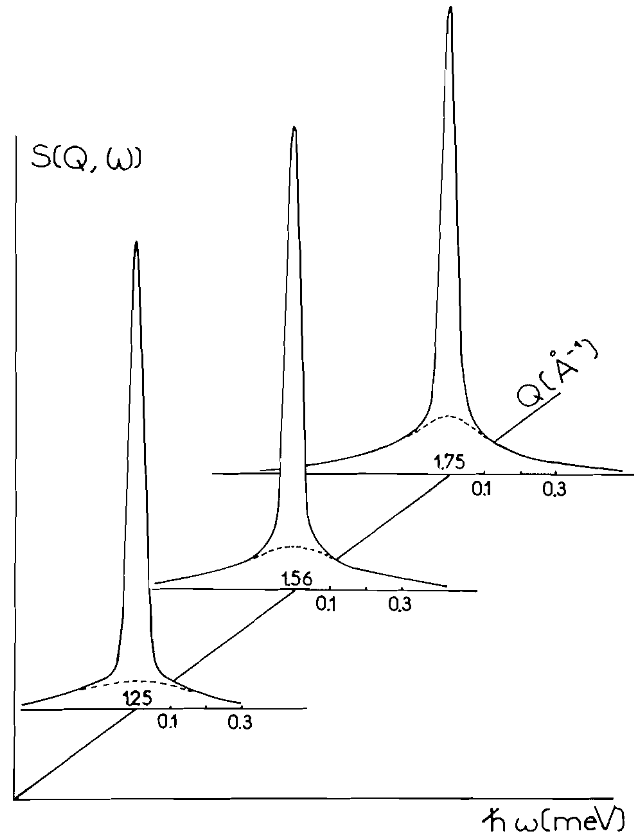

FIG. 5. Corrected quasi-elastic neutron scattering spectra of polycrystalline NH_3SO_3 at 400 K for an incident wavelength of 5.9 Å. The quasi-elastic contribution is represented by dotted line.

TABLE 1. Correlation times deduced from the different fits within the $2\pi/3$ jump model of NH_3 in sulphamic acid*

Configuration	Incident λ_c (Å)	T (K)	$1/\tau_1$ (μeV)	$\tau_c \times 10^{12}$ (s)

45°	5.9	323	104	9.48
		406	171	5.77

*$(\tau_1)^{-1}$ is a direct measure of the width of the Lorentzian function appearing in the quasi-elastic part of the spectra.

V.2.2. Conclusion relative to the neutron scattering experiments

The dynamics of the NH_3 groups is associated with $2\pi/3$ or $2\pi/6$ rotational jumps characterized by a residence time $\tau_c^{300\,K} = 2.1 \times 10^{-11}$ s at room temperature and an activation energy of 12 ± 2 kJ mol^{-1}.

VI. Discussion and comparison with literature results

– The Raman band observed at about 247 cm^{-1} at 300 K which shifts to 274 cm^{-1} at 30 K and which is characterized by an H/D isotopic ratio of 1.35 was assigned to an NH_3 torsional motion in which the SO_3 groups are weakly involved, the ratio

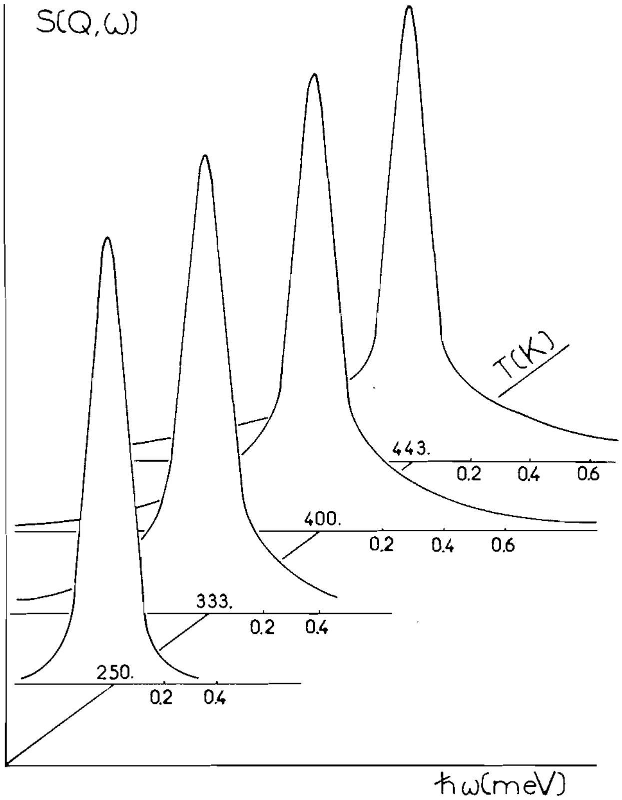

FIG. 6. Corrected quasi-elastic neutron scattering spectra of polycrystalline NH_3SO_3 for an incident wavelength of 5.1 Å at Q = 1.95 Å^{-1} for different temperatures.

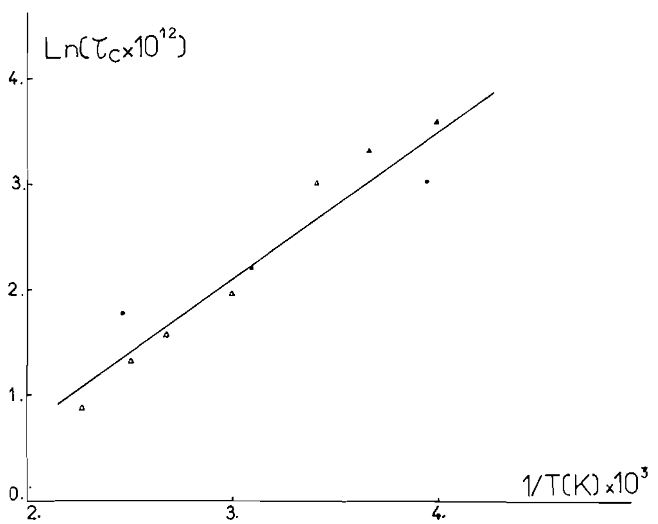

FIG. 7. Arrhenius plot of the mean residence time (τ_c) against reciprocal temperature; ●, 5.9 Å; △, 5.1 Å. The slope of the straight line gives an activation energy of 12 kJ mol^{-1}.

of square roots of reduced moment of inertia H/D (equal to 1.39, see Table V in ref. 11) being very near to the experimental frequency ratio. If the libration around S—N bond of the molecule as a whole was involved, the isotopic ratio would tend towards 1.02 (the corresponding libration band Ru was reported at about 90 cm^{-1}). Thus under these conditions where the SO_3 group libration amplitude is very small even at 300 K, a potential barrier V_3^0 of 14.6 kJ mol^{-1} at 300 K was derived through the assumption that the potential hindering the NH_3 rotation is of threefold order and that it can be written $V = (V_3^0/2)(1 - \cos 3\theta)$ where θ is the rotational coordinate of one proton. By subtracting the zero point energy, the rotational energy is equal to 11.9 kJ mol^{-1}. In the case where a sixfold potential V_6 is considered the barrier is four times lower. The perfect agreement of the V_3^0 barrier corrected from zero point energy with the neutron activation energy is thus in favor of the three-fold order as suggested by the heat capacity measurements.

Finally, the preexponential term of the Arrhenius relation can be derived from our neutron data; at 293 K it is equal to $\tau_c^0 = 1.55 \times 10^{-13}$ s, thus its inverse which represents the attempt frequency, $\nu_0 = 215$ cm^{-1}, is in fair agreement with the torsional frequency measured in Raman.

It is worthwhile to notice that the torsional motion in NH_3SO_3 in the above model is considered as an Einstein oscillator. Actually this is not a bad approximation. The coupling of this mode between the eight molecules in a unit cell gives rise to only four Raman frequencies spreading between 244 and 251 cm^{-1}. Moreover the density of states spectra deduced from inelastic neutron scattering (22) is sufficiently narrow (~30 cm^{-1}) to accept the above approximation. However, the dispersion of frequencies being smaller at $k = 0$ (~7 cm^{-1} for Raman modes) it appears preferable to consider correlated NH_3 in phase rotations for calculating potential barriers from atom–atom interactions (see last section). This remark allows us to account for a difference between the activation energy measured in neutron or nmr and the Raman potential barrier when the torsional mode is dispersive.

A second cause of discrepancy can also be due to the fact that the three-fold potential considered above is only an approximation. Strictly speaking, the NH_3 groups occupy general crystallographic positions and the general expression of the potential should be written:

$$V = \frac{V_1}{2}(1 - \cos\theta) + \frac{V_2}{2}(1 - \cos 2\theta) + \frac{V_3}{2}(1 - \cos 3\theta) + \text{---}.$$

The neglect of V_1 and V_2 terms is only based on qualitative local geometry considerations. In this respect Ratcliffe *et al.* (13) have underlined that the distribution of neighbouring oxygen atoms around NH_3 group is near a five-fold environment. If this were a perfect pentagon the first term to contribute would be $(V_{15}/2)(1 - \cos 15\,\theta)$, i.e., it would generate a quasi-free rotation at room temperature. Actually, the slight distortion is sufficient to avoid the cancellation of the V_3 terms. Ratcliffe *et al.*, assuming that the three-fold interaction potential between the three protons of one NH_3 group and a neighbouring oxygen atom is the same for the five oxygens and is equal to V_3'', have written that the total potential is

$$V = \frac{V_3''}{2}\left[5 - \sum_{i=1}^{5} \cos 3(\theta - \eta_i)\right]$$

where η_i are the angular positions of surrounding oxygens. The corresponding barrier height given by $V(\theta = 0) - V(\theta = 2\pi/6)$ is found equal to be 0.65 V_3''. If the η_i angles were multiples of $2\pi/5$ (instead of crystallographic values), this barrier would be zero, and it would be necessary to consider higher order terms such as V_{15}. One of the aims of the last section is thus to see to what extent similar conclusions can be obtained when the number of surrounding atoms is substantially increased. The second aim is to try to estimate the con-

[g]MnPDA: $NH_3(CH_2)_3NH_3MnCl_4$; ZPE: zero point energy $= \frac{1}{2} h\nu_0$; for IQENS, the attempt frequency in some cases (e.g., NH_3SO_3) compares well with vibrational frequency, however, it cannot be systematically identified with it (e.g. MnPDA). The activation energies deduced from nmr and IQENS are in a general agreement with the local barrier potential. In most cases these two quantities are in a close agreement.

tribution of intra- and intermolecular interactions to the total barrier or alternatively to analyse the relative weight of conformational isomerism and of matrix effects. In particular, if one assumes that the interaction potential between the NH_3 rotor with the three oxygens belonging to the same molecule is V_3' and that the intra term can be written $V = (3V_3'/2)(1 - \cos 3\theta)$, one finds a potential barrier equal to $3V_3'$. The relative magnitude of V_3' and V_3'' is difficult to estimate *a priori*, although Ratcliffe *et al.* consider that the total torsional barrier[3] can be decomposed as $V^0_{\rm intra} = 8.6$ kJ mol^{-1} and $V^0_{\rm inter} = 4.7$ kJ mol^{-1}, i.e. $V_3' = 7.2$ kJ mol^{-1} and $V_3'' = 2.9$ kJ mol^{-1}, in other terms, the intermolecular potential of the NH_3 group with surrounding atoms is larger than the intramolecular one.

Nuclear magnetic resonance spin lattice relaxation measurements in NH_3SO_3 (13) have been interpreted in terms of NH_3 reorientations. An activation energy E_a of 11.3 kJ mol^{-1} is reported while a preexponential factor $\tau_c^0 = 7.5 \times 10^{-11}$ s is given. Thus a nice agreement between the energetic parameters is found between neutron and nmr measurements. However, the preexponential factor when converted gives 400 cm^{-1}, i.e. a frequency far from the torsional one, and consequently the corresponding residence time at 300 K, $\tau_c = \tau_c^0 \exp(E_a/kT)$, is twice as large as that obtained in our neutron study. Because this correlation time is directly given by the fwhm of the quasielastic contribution we think that this value is more reliable. Table 2 illustrates this discussion; a comparison with NH_3 reorientation in $NH_3(CH_2)_3NH_3MnCl_4$ (10) is also given. In this last compound the NH_3 group is hydrogen bonded to only three chlorine atoms and as stated above, it is not surprising to find that the potential barrier is higher than for NH_3SO_3.

VII. Calculation of potential functions hindering the rotation of NH_3 group and NH_3SO_3 as a whole

The present calculation consists in computer simulating a postulated type of motion and evaluating the intermolecular interaction along the path of motion. Thus in the case of librational motion of NH_3 and SO_3 groups the pair wise interactions given by the expression

$$V(r) = V_c + V_{\rm vw} + V_R + V_{\rm HB}$$

[3]The intermolecular oxygen interactions are not taken into consideration due to the small amplitudes of SO_3 groups in the torsional mode.

which combines coulombian, Van der Waals, repulsion, and hydrogen bonding potentials, are added for each orientation of the groups of atoms and a curve referred to below as a torsional or librational potential is constructed. The WMIN Busing's program was used, as stated before it gives the advantage of considering correlated displacements and the main difference with similar approaches (e.g. Goldberg (23)) is that the neighbouring hydrogen atoms are not stationary. In other words, the potential curve reported in Fig. 8 corresponds to the relative variations of the potential energy when the eight NH_3 groups belonging to one unit cell are rotated in order to respect the cell symmetry and the NH_3 groups in neighbouring cells are rotated by the same angle that the congruent groups of the unit cell at the origin.

We are interested only in the relative variations of the torsional or librational potential energy and because no direct comparison with thermodynamic data such as lattice energy was possible (24), we have not attempted to adjust all the potential parameters by minimizing the energy, but we have only tried to adjust the most sensitive ones, in order to derive a potential curve compatible with the constraints listed below. The tests of convergence of Coulomb and Van der Waals energies in both direct and reciprocal spaces have shown that 7 Å and 0.4 Å^{-1} represent the corresponding limits for which no relative energy change larger than 10^{-4} was obtained. For 7 Å, 669 pair interactions were considered.

VII.1. Potentials used in the calculations

We have considered the same pair potentials for compounds in which NH---O (25), O---O, N---H, N---N, S---S interactions were reported (26) and which were fitted in a WMIN calculation without the addition of electrostatic terms such as those reported by Righini *et al.* for crystalline ammonia (27).

(*a*) For the coulombian interactions, the net charges deduced from X—N data (18) and reported in Fig. 1*b* were introduced in

$$V_c = -\frac{q_i q_{jj}}{r_{ij}}$$

(*b*) The Van der Waals attractive potential was written as

$$V_{\rm vw} = -\sum_{ij} \frac{C_{ij}}{r^6}$$

where the parameters C were taken from ref. 23. For S—H

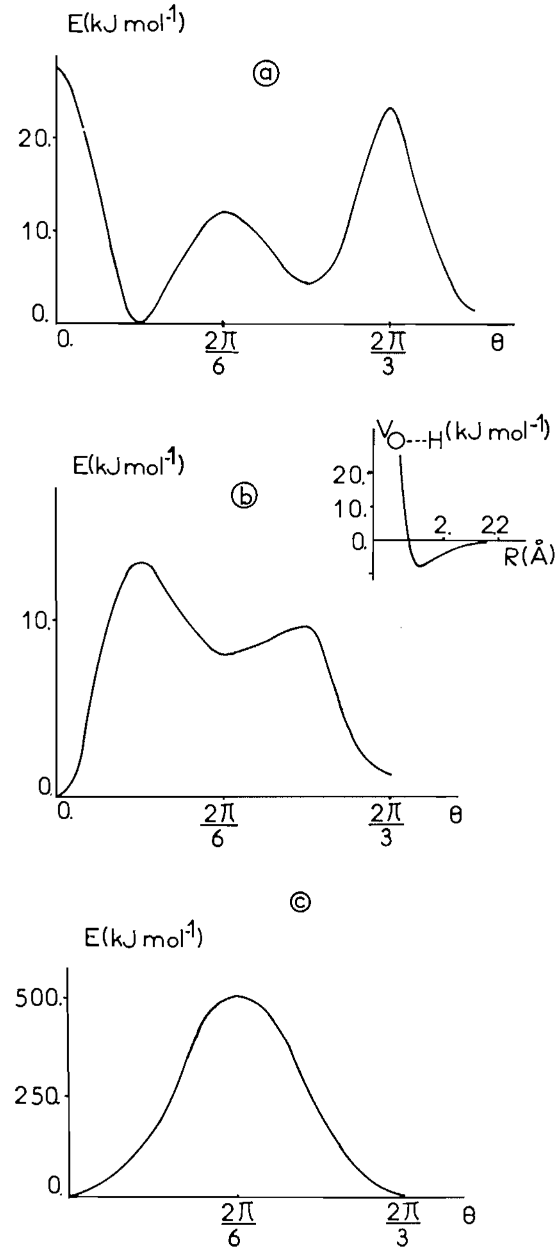

FIG. 8. Potential curves for the NH_3 rotation around the N—S axis in sulphamic acid. (*a*), calculated with coulombian interactions between net atomic charges and with Van der Waals and repulsion potentials; (*b*), calculated with the same parameters as in (*a*) plus a specific potential (represented on the right part) for the hydrogen bonds. Only the relative variations are reported; (*c*), potential curve for the rotation of the NH_3SO_3 molecule as a whole.

interactions we have considered the geometric average of SO and OH parameters.

(*c*) The repulsions were represented by the expression:

$$V_R = + \sum_{ij} \frac{a_{ij} \exp(-b_{ij} r_{ij})}{r_{ij}^d}$$

and the *a*, *b*, and *d* parameters were chosen in the same manner as *C* parameters.

(*d*) However, for hydrogen and oxygen atoms directly connected by a hydrogen bond, a specific Morse-like potential was introduced in such a way that it is zero for H---O distances larger than 2.2 Å and present a minimum at 1.92 Å (experimental average value). The depth of this minimum has been varied between 4 and 12.5 kJ mol^{-1}. The simple electrostatic H^+---O^- potential combined with a repulsive potential was not appropriate to generate a three fold order external potential (intermolecular) hindering the NH_3 rotation. In the literature, this difficulty has been overcome by using similar potentials (28). The Schroeder's model of a bent NH---O was not considered; the wide range of directions covered by the interatomic contacts giving an indirect account of the angle dependence. The expression given below gave satisfactory results; the repulsive part for $r < 1.85$ Å is not involved in the NH_3 rotation, the H---O contacts being all larger than this value.

$$V_{(r_{O\cdots H})} = D\left[1 - (1 - \exp(-\gamma(r - r_e))^2\right]$$

All H---O interactions are taken into account. This means that a given H can interact with several oxygens. However, the contributions of interactions for *r* larger than 2.5 Å are negligible and it is observed that for all configurations there are at maximum two H--O contacts for a given H which contribute to the energy.

(*e*) In order to examine the conformational isomerism of an isolated NH_3SO_3 molecule and to see at what extent the staggered conformation in the isolated molecule can be stabilized, we have also considered that the electrons of NH and SO bonds can interact with each other and with all the other charges. Their mutual interaction could be described by using a multipole expansion (28), but because of the lack of data on the local quadrupoles and octopoles of NH and SO bonds, the electrostatic interaction between two charge distributions were reduced to the Coulombian form given below:

$$V_{\alpha,\beta} = \sum_i \sum_j \frac{\alpha_i q_j}{r_{ij}} + \sum_j \sum_k \frac{\beta_k q_j}{r_{kj}} + \sum_i \sum_k \frac{\alpha_i \beta_k}{r_{ik}} + \sum_i \sum_{i'} \frac{\alpha_i \alpha_{i'}}{r_{ii'}}$$

The α_i and β_k parameters are for electronic charges of NH and SO bonds respectively, while q_j are for net atomic charges and r_{ij}, r_{kj}, r_{ik} are the inter-charge distances. The α, β parameters are introduced as formal charges located at the mid point of the NH and SO bonds. This potential was calculated for the isolated molecule and for the crystal. The polarization forces which are weaker than Van der Waals and electrostatic forces have been neglected, moreover, the induced dipole–dipole interactions being attractive, they cannot contribute to the stabilization of the staggered conformation, the existence of which is questioned here.

VII.2. Constraints

The different constraints that we introduced in our calculations are the following:

(*a*) The minima of the total potential function must be located at $\theta = 0$, $2\pi/3$, $4\pi/3$ where $\theta = 0$ corresponds to the crystallographic position of one proton. Subminima are allowed but their energy must be high enough for their occupation factor at 300 K is negligible.

(*b*) The maxima are also distant of $2\pi/3$ and the corresponding barrier is equal to 12 kJ mol^{-1}.

(*c*) The repulsive and attractive Van der Waals parameters for O---O, O---H, N---O, N---H interactions are fixed to the literature values derived for atoms involved in similar interactions. The other interactions are varied (the initial values are taken as geometric average).

(*d*) The coulombian charges on atoms are taken from X—N data (18).

(*e*) The potential barrier hindering the NH_3SO_3 rotation as a

whole must be much larger than that associated to the torsion; it is expected to be larger than 50 kJ mol^{-1}.[4]

VII.3. Results

Four stages have been developpped in our calculation:

(a) The net atomic charges and the set of parameters given in Table 3 are entered in the calculation and a sixfold potential function is obtained (Fig. 8a). The coulombian terms in the energy and thus its relative variations are the leading terms. The O---H Van der Waals attractions or repulsions terms inside a given molecule playing a negligible role because of the long interatomic distances ($d_{\mathrm{H}\cdots\mathrm{O}} > 2.67$ Å), thus the intermolecular potential is mainly coulombian. The interactions between bonded atoms are entered but do not contribute to the relative variations of the potential.

(b) In order to satisfy the constraint mentionned in (a), a specific potential for hydrogen bonds (see VII-1-d) is added to the above set of parameters and a three-fold potential function is obtained. Its depth can be varied by adjusting the D parameters. For $D = -8.4$ kJ mol^{-1} and $\gamma = 15.35$ the potential barrier is found equal to 13.4 kJ mol^{-1} Fig. 8b. The minimum at $2\pi/3$ is slightly higher than that at 0°, but their energy difference is sufficiently small for their occupation being equal above 200 K. The subminimum at $2\pi/6$ is much higher in agreement with the constraint (a).

(c) The coulombian interactions involving the NH and SO electronic charges were introduced.

Arbitrary values of bond charges α_{NH} and β_{NH} were used. Figure 9 represents the variation of the intramolecular electrostatic energy : for $\alpha = 0.1$, $\beta = 0.1$ and for $\alpha = 0.1$, $\beta = 1$ in both cases the staggered conformation is favored and the energy variation is less than 1.7 kJ mol^{-1}. This is due to the fact that the sums $\Sigma\, 1/r_{ij}$, $\Sigma\, 1/r_{kj}$, $\Sigma\, 1/r_{ik}$ do not vary appreciably

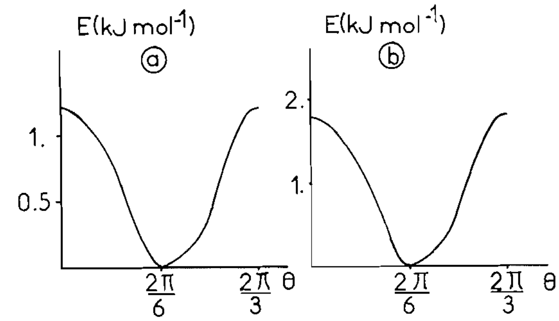

FIG. 9. Intramolecular potential curve for the torsion of NH_3 in an "isolated" molecule. The electrostatic interactions between net atomic charges q_i and charges α and β placed in the middle of the NH and SO bonds, respectively, are considered. (a), $\alpha = \beta = -0.1$; the total electrostatic energy varies between -1343.8 for $\theta = 0°$ and -1345 kJ mol^{-1} for $\theta = 60°$, i.e., $\Delta E = 1.2$; (b), $\alpha = -0.1$, $\beta = -1$; the total electrostatic energy varies between 1162.3 for $\theta = 0°$ and 1160.6 kJ mol^{-1} for $\theta = 60°$, i.e., $\Delta E = 1.7$ kJ mol^{-1}.

when NH_3 is rotated. One can conclude that the electrostatic interactions do not contribute significantly to the intramolecular torsional barrier. Moreover the overlap between S and O orbitals which could contribute to the torsional energy is expected weaker than in molecules such as ethane (the NH_3SO_3 molecule is not stable in the gas phase) and the intramolecular torsional potential barrier is likely much smaller than 4.2 kJ mol^{-1} and can be ignored.

(d) The NH_3SO_3 molecules were rotated as a whole. Figure 8c represents the variation of the energy calculated with the set of parameters of Table 3 plus the hydrogen-bond potential, the total potential function is of three-fold order the associated V_3 barrier is found equal to 500 kJ mol^{-1}, this value is mainly determined by the repulsive part of the hydrogen-bond potential, actually there are O---H distances of 1.78 Å for $\theta = 60°$, thus when varying the form of the potential we could decrease this barrier at a large extent. However, as already stated it must remain high enough for keeping the oxygen atoms fixed in the lattice and we think that the hydrogen-bond potential of Fig. 8b is not far from the actual situation.

VIII. Conclusions

The reorientation of the NH_3SO_3 molecules as a whole is strongly hindered by O---H and at a smaller extent by O---O repulsions; a potential barrier of 300 kJ mol^{-1} was derived.

The contributions of intermolecular H---H interactions to the relative variations of V' and V'' were found negligible and thus taking into account the correlated NH_3 motions does not change the potential results which could be obtained with a rigid lattice.

The staggered configuration is not generated by intramolecular interactions but rather by intermolecular O---H hydrogen bonding attractions.

The total potential function hindering the NH_3 reorientations has been derived, it presents minima separated by $2\pi/3$, the H---O interactions were chosen to give a potential barrier of 12 kJ mol^{-1}. The subminima found in the potential are not pronounced and can be considered as anharmonic contributions explaining the broadness of the Raman torsional band at 300 K. This point will be discussed in a forthcoming paper.

The coulombian and hydrogen bonding interactions dominate the relative potential variations and this can be related to the fact that the staggered form of NH_3SO_3 is only stabilized in

[4]The value 50 kJ mol^{-1} is obtained from the libration frequency observed at $R'_{\mathrm{u}} \simeq 80$ cm^{-1} (11). Assuming a threefold order sinusoidal potential, the relation:

$$V_3^0 = \frac{\nu^2 8\pi^2}{9h^2} I_{\mathrm{u}}$$

(where $I_{\mathrm{u}} = 97$ uma Å^2 is the inertia moment of the molecule around its long axis) gives a crude approximation of the barrier hindering the rotation of the molecule. This model considers that the bottom of the potential function can be osculated by a parabola. It is completely false for large angles for which strong repulsions can occur.

the crystal or solvents in which hydrogen bonds can be established (28).

Finally, this paper shows how the conjunction of heat capacity measurements, Raman and neutron scattering (29) delivers sufficiently sound experimental data which can be used as a basis before undertaking potential calculations. The calculations reported here are highly empirical, however they have the merit to show that the relative variations of the potential barrier are mainly determined by NH---O hydrogen bonds.

The photoabsorption of chlorodifluoroethenes in the vacuum ultraviolet

ECKART RÜHL, HANS-WERNER JOCHIMS, AND HELMUT BAUMGÄRTEL
Institut für Physikalische Chemie, Freie Universität Berlin, Takustr. 3, D-1000 Berlin 33

Received July 27, 1984

This paper is dedicated to Professor Camille Sandorfy on the occasion of his 65th birthday

ECKART RÜHL, HANS-WERNER JOCHIMS, and HELMUT BAUMGÄRTEL. Can. J. Chem. **63**, 1949 (1985).

The gas phase absorption spectra of 2-chloro-1,1-difluoroethene, *cis*- and *trans*-1-chloro-1,2-difluoroethene have been measured in the photon energy range from 6.5 to 25 eV. The $\pi \rightarrow \pi^*$ transition is assigned to bands centered around 7.17–7.20 eV for all three isomers. Four Rydberg series are observed in all the spectra, converging to the π ionization potential: two *np*-type Rydberg series, one *ns*, and one *nd* series are assigned. The convergence limits are: 9.84 eV (2-chloro-1,1-difluoroethene), 9.86 eV (*cis*-1-chloro-1,2-difluoroethene), and 9.85 eV (*trans*-1-chloro-1,2-difluoroethene). In the case of 2-chloro-1,1-difluoroethene four additional Rydberg series are found converging to the *n*Cl ionization potential. The convergence limit of these series is 12.15 eV.

Above 12 eV broad absorption bands dominate the spectra.

ECKART RÜHL, HANS-WERNER JOCHIMS et HELMUT BAUMGÄRTEL. Can. J. Chem. **63**, 1949 (1985).

Opérant à des énergies photoniques allant de 6,5 à 25 eV, on a mesuré les spectres d'absorption en phase gazeuse du chloro-2 difluoro-1,1 éthène et des chloro-1 difluoro-1,2 éthènes-*cis* et -*trans*. On attribue les bandes que l'on retrouve autour de 7,17 à 7,20 eV dans chacun de ces produits à la transition $\pi \rightarrow \pi^*$. Dans chacun des spectres, on a observé quatre séries de bandes de Rydberg; elles convergent vers le potentiel d'ionisation π: deux séries de bandes de Rydberg du type *np*, une série du type *ns* et une série du type *nd*. Les limites de convergence sont les suivantes: 9,84 eV (chloro-2 difluoro-1,1 éthène), 9,86 eV (chloro-1 difluoro-1,2 éthène-*cis*) et 9,85 eV (chloro-1 difluoro-1,2 éthène-*trans*).

Dans le cas dichloro-2 difluoro-1,1 éthène, on a trouvé quatre autres séries de bandes de Rydberg qui convergent vers le potentiel d'ionisation du *n*Cl. La limite de convergence de cette série est égale à 12,15 eV.

Au-dessus de 12 eV, les bandes d'absorption dominent le spectre.

[Traduit par le journal]

Introduction

The vacuum ultraviolet (vuv) absorption spectra of ethene and its halogen derivatives have long been of interest since a variety of excitations have been observed: e.g. Rydberg series, containing vibrational progressions, associated with the π-bond and halogen lone-pair excitations.

The vuv spectra of fluoroethenes, chloroethenes, and some chlorofluoroethenes have been studied between 6 eV and 12 eV (1). In particular, the influence of the substitution scheme on the vuv spectra was examined for dichloroethenes (1), difluoroethenes (2), and dibromoethenes (17). In these cases it was possible to apply the dipole selection rules to the observed electronic transitions. As the haloethenes studied in the present paper have C_s-symmetry no restrictions concerning dipole selection rules are expected (5).

Experimental

The experimental system consists of a 1 m normal incidence monochromator (McPherson 225) equipped with a single beam absorption cell behind the exit slit. Light detection was provided by a photomultiplier. Synchrotron radiation from the Berlin electron storage ring BESSY was used as a light source. In the 6.5 eV to 11 eV energy range the absorption cell was isolated from the monochromator by a lithium fluoride window, thus suppressing the higher order spectra and allowing exact pressure measurement by means of a capacitance manometer (Baratron 22). In the region above 9 eV the window was not used and the calibration of the absorption coefficient scale was provided by fitting the curves to the absolutely measured spectra in the overlapping region between 9 and 11 eV. This leads to an estimated overall uncertainty of about 15% in the absorption coefficient. All the spectra have been measured with about 0.1 nm wavelength resolution.

Syntheses

1,2-Difluoro-1,1,2-trichloroethane was prepared in 35% yield by reduction of 1,2-difluoro-1,1,2,2-tetrachloroethane with $LiAlH_4$ refluxing in absolute ether (18). The distilled product was dehalogenated with zinc dust in ethanol at 78°C yielding 75% of a mixture of *cis*- and *trans*-1-chloro-1,2-difluoroethene (15). The stereoisomers were separated by gas chromatography in two steps, in which the *trans* isomer was eluted first (11). (*1*) Preseparation: two columns packed with 15% squalane (length: 4 m each) at −6°C and 0°C, respectively; and (*2*) final separation: first column packed with KelF (length: 4 m) at 0°C, second column packed with 15% squalane (length: 4 m) at −10°C. After drying over Sicapent (Merck, Darmstadt) the *cis*- and *trans*-isomers were obtained in a purity exceeding 99.985%. The isomers were identified by means of their infrared spectra (11).

The 2-chloro-1,1-difluoroethene sample was purchased from PCR Inc., U.S.A. Gas chromatographic analysis showed no significant impurities.

Results and discussion

The spectra are presented in Figs. 1–7. Origins and vibrational excitations of Rydberg states are indicated by arrows. The corresponding numerical values are listed in Tables 1–4.

Many sharp bands appearing in the spectrum can be assigned according to the Rydberg formula:

$$[1] \quad E = \mathrm{IP}(n) - R/(n - \delta)^2$$

where E is the excitation energy of the observed transition, IP(n) is the corresponding ionization potential, δ is the quantum defect, and n is the principal quantum number. Several vibrational excitations have been observed which belong to Rydberg transitions with low principal quantum numbers. They have been assigned through comparison of vibrationally resolved photoelectron bands in 2-chloro-1,1-difluoroethene and with the aid of the fundamental vibrations (10, 11). Besides the sharp bands broader ones are observed and will be discussed below in connection with the Rydberg transitions belonging to higher ionization potentials. Reliable adiabatic ionization potentials are obtained from photoelectron spectra (PES) (*geminal* isomer (7)) or photoionization-mass-spectrometry (PIMS) (*vicinal* isomers (4)).

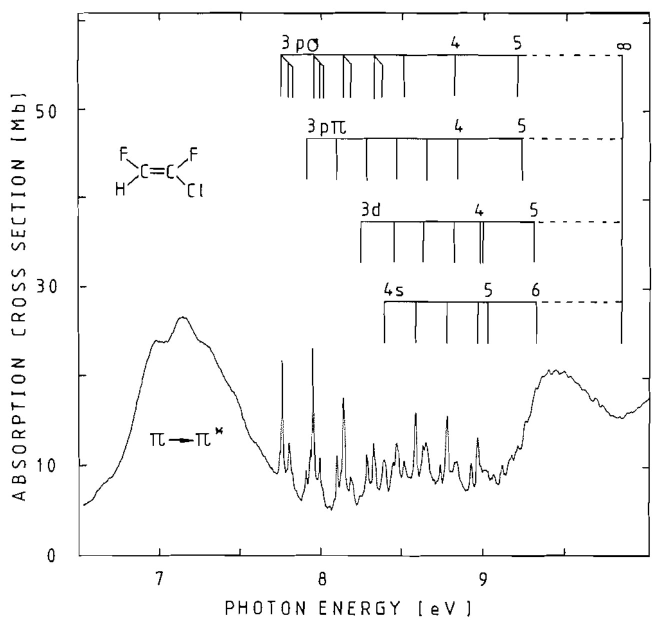

FIG. 2. Absorption spectrum of *cis*-1-chloro-1,2-difluoroethene in the energy range 6.5–10 eV.

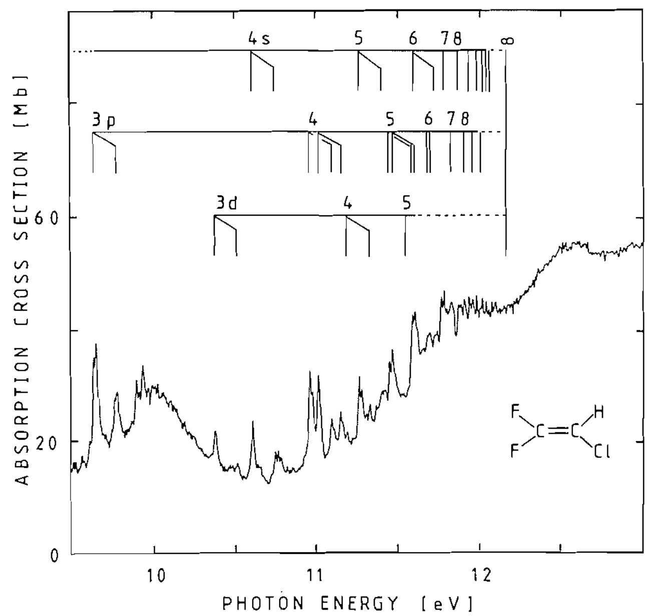

FIG. 4. Absorption spectrum of 2-chloro-1,1-difluoroethene in the energy range 9.5–13 eV.

1. The 6.5 – 10 eV region

A. 2-Chloro-1,1-difluoroethene

The first band which peaks at 7.17 eV is assigned to the $\pi \rightarrow \pi^*$ transition in agreement with the interpretation given by Scott and Russell (3). It shows the broad and intense structure typical for the $\pi \rightarrow \pi^*$ transition of all the haloethenes (1). Superimposed on this band are peaks resulting from vibrational excitations of the totally symmetric C=C stretching mode in the π^* state. The vibrational spacings (see Table 1) are significantly reduced compared to the ground state vibration (1745 cm^{-1}) (10). In the gas phase absorption spectrum in general no other valence transitions have been observed, but in fluoroethenes $\pi \rightarrow \sigma^*$ transitions have been identified by comparison with solid state and Kr matrix absorption spectra between 6.5 and 7.5 eV (6).

Four Rydberg series located in this energy region can be readily assigned to $\pi \rightarrow np$, nd, and ns transitions (Fig. 1). They all converge to 9.83 eV. Only the first members of each series reveal resolvable vibrational fine structure, with the exception of the $\pi \rightarrow nd$ transitions. Two p type Rydberg series (δ = 0.57 and δ = 0.44) can be clearly identified. In analogy to diatomic molecules the two p series may be related to $p\sigma$ and $p\pi$ subseries (13). The spectra of chloroethenes (1) and bromoethenes (16, 17) also show more than one electronic origin belonging to $\pi \rightarrow 3p$ Rydberg transitions. In fluoroethenes only one $\pi \rightarrow 3p$ transition is observed (1). Three fundamental vibrations belonging to the $\pi \rightarrow np$ transitions are observed (Table 1): (*i*) ν_2 = 1510–1560 cm^{-1} (C=C stretching, 1745

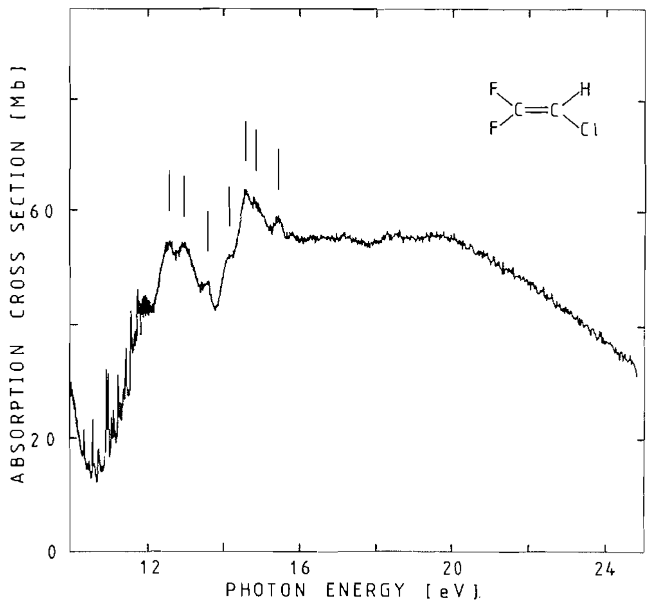

FIG. 5. Absorption spectrum of 2-chloro-1,1-difluoroethene in the energy range 10–25 eV.

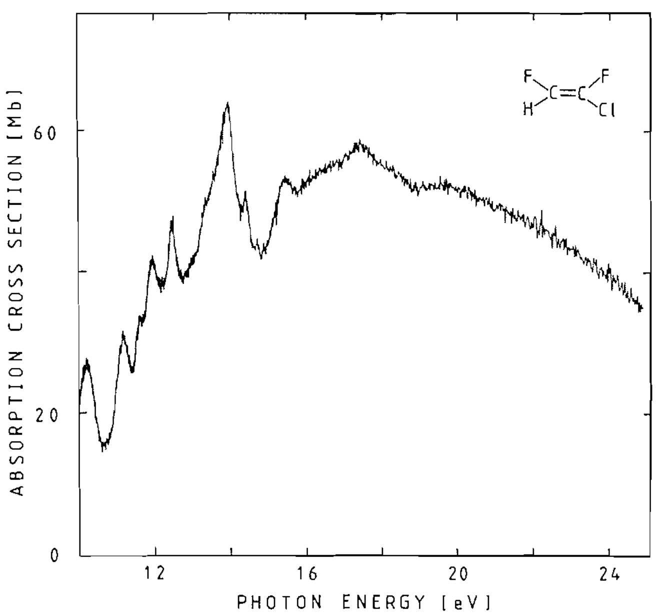

FIG. 6. Absorption spectrum of *cis*-1-chloro-1,2-difluoroethene in the energy range 10–25 eV.

$\mathrm{cm^{-1}}$ in the ground state), (*ii*) ν_6 = 815–860 $\mathrm{cm^{-1}}$ (C—Cl stretching, 845 $\mathrm{cm^{-1}}$ in the ground state), (*iii*) ν_8 = 420–460 $\mathrm{cm^{-1}}$ (C—Cl bending, 433 $\mathrm{cm^{-1}}$ in the ground state). The assignment of these vibrations is based on ir data (10); the description of the normal modes follows Craig *et al.* (11). Compared to the vibrations in the electronic ground state only the C—C stretching mode is red-shifted, which confirms the assignment of the Rydberg series. The vibrational spacings of the Rydberg transitions reported here correlate well with those of molecular ions observed in PES spectra, as was pointed out by Wittel *et al.* (9).

The $\pi \rightarrow nd$ Rydberg series begins with the weak $\pi \rightarrow 3d$ transition (δ = 0.08) at 8.225 eV (Table 1). A five membered progression in ν_2 belongs to the $\pi \rightarrow 3d$ Rydberg state. Vibrations are also observed in the $\pi \rightarrow 4d$ and $\pi \rightarrow 5d$ states.

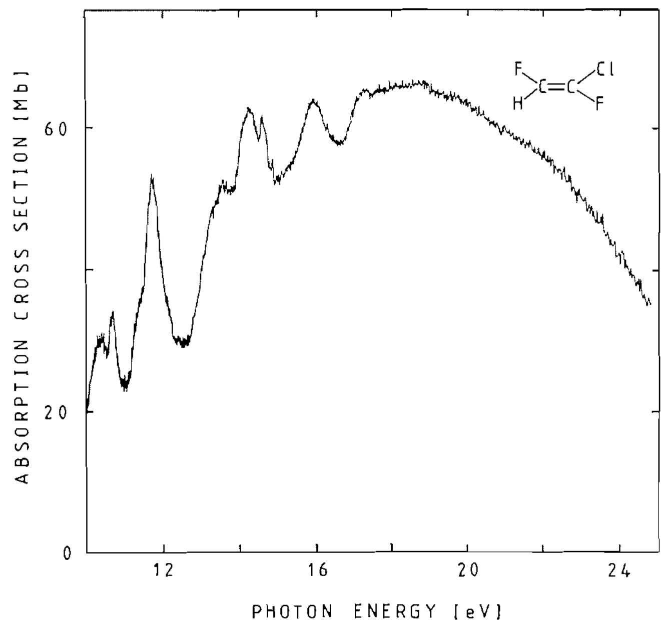

FIG. 7. Absorption spectrum of *trans*-1-chloro-1,2-difluoroethene in the energy range 10–25 eV.

The first member of the $\pi \rightarrow ns$ Rydberg series observed here is the $\pi \rightarrow 4s$ transition. Vibrational progressions in ν_2 belong to this transition are found. The $\pi \rightarrow 3s$ Rydberg state is not observed here, probably because of coupling with the π^* valence state.

There are two broad and intense pairs of structures at about 8.8 and 9.7 eV. The intense band at 8.8 eV was assigned to the $\pi \rightarrow 4s$ transition by Scott and Russell (3). Due to the high oscillator strength and the corresponding term value (27 600 $\mathrm{cm^{-1}}$) we believe this band has to be assigned instead to an excitation of the a' chlorine lone-pair electron. Therefore this transition is assigned to $n\mathrm{Cl} \rightarrow 3s$. The splitting of the absorption band is well correlated with that of the corresponding PES band. Following the arguments of Wittel and Bock (8) the PES band at 12.29 eV has to be interpreted as a vibrational excitation of the $\tilde{A}$-state of the molecular cation. A splitting of about 1100 $\mathrm{cm^{-1}}$ between these photoelectron peaks might be due to δ(C—H) excitation as observed in the PES spectrum of chloroethene (8). In 2-chloro-1,1-difluoroethene it cannot be decided whether the δ(C—H) vibration or the a(C—F) stretching causes this splitting (ground state vibrations: δ(C—H) = 1333 $\mathrm{cm^{-1}}$, a(C—F str.) = 1199 $\mathrm{cm^{-1}}$). Similarly the 9.7 eV absorption band also shows a splitting of 1100 $\mathrm{cm^{-1}}$ which results from vibrational excitation. The term value is 20 300 $\mathrm{cm^{-1}}$ which is typical for the so called D-bands (1). Therefore we assign this band to the $n\mathrm{Cl} \rightarrow 3p$ transition.

B. cis- *and* trans-*1-Chloro-1,2-difluoroethene*

Based on several similarities of the absorption spectra (Figs. 2, 3) a parallel treatment in interpretation is suggested.

In both isomers the $\pi \rightarrow \pi^*$ transition is located at nearly the same energy (Table 2). Compared to the geminal isomer no characteristic shift of this transition is observable. This indicates a negligible influence of substitution in contrast to the observation made in the case of difluoroethenes and dichloroethenes (1). Weak superimposed structures are assigned to the C=C— stretching mode of 1380–1480 $\mathrm{cm^{-1}}$, which may be compared with the molecular values of 1716 $\mathrm{cm^{-1}}$ (*cis*) and 1708 $\mathrm{cm^{-1}}$ (*trans*) (11), the decreased frequencies resulting

from the lowering of the C═C bond strength in the antibonding π^* state.

On the high energy side of the $\pi \rightarrow \pi^*$ band, two $\pi \rightarrow 3p$ Rydberg subseries can be discerned. However, the corresponding quantum defects are decreased with respect to the value for the geminal isomer, indicating a decreased perturbation of the π-system by the substituents. There are pronounced vibrational progressions ranging from 1450 to 1550 cm^{-1}. They are assigned to the symmetrical C═C stretching mode in analogy to the geminal isomer. In contrast to the $\pi \rightarrow \pi^*$ transition these stretching frequencies are less reduced in the Rydberg transitions, indicating a stronger C═C bond in the Rydberg state than in the antibonding π^* state. Weak vibrations of about 367−377 cm^{-1} (*cis*) and 364−417 cm^{-1} (*trans*) are observed. These intervals correspond to the C—Cl bending frequency in the Rydberg state. From ir spectra the ground state vibrations are 361 cm^{-1} (*cis*), 397 cm^{-1} (*trans*) (11). The C—Cl bending mode remains unchanged in both electronic states. Weak vibrations are found which correspond to the antisymmetric (C—F) bending mode: 490−492 cm^{-1} (*cis*), 565−584 cm^{-1} (*trans*). These vibrations also remain essentially unchanged (ground state: 480 cm^{-1} (*cis*), 578 cm^{-1} (*trans*), indicating that the excitation of the π electron does not seriously perturb the C—Cl and C—F bonds.

There are two weaker structures that are assigned to $\pi \rightarrow nd$ ($\delta = 0.1$) and $\pi \rightarrow ns$ ($\delta = 1.0$) transitions. Only the $\pi \rightarrow 3d$ and $\pi \rightarrow 4s$ transitions exhibit C═C stretching vibrations (1530−1550 cm^{-1}). Weaker vibrations are not revealed since several Rydberg transitions with vibrational excitations overlap in this energy region. Again, a $\pi \rightarrow 3s$ transition which is expected to be at 6.36 eV, is not observed. The ionization potentials obtained from series convergence are 9.86 eV (*cis*) and 9.85 eV (*trans*). These values agree well with those found by photoionization spectrometry (PI) (9.86 eV (*cis*), 9.84 eV (*trans*) (4).

Instead of the split band observed at 8.8 eV for 2-chloro-1,1-difluoroethene, a new band occurs centered around 9.4 eV (*cis*) and 9.5 eV (*trans*). As in the case of the *geminal* isomer these broad and structureless bands are assigned to nCl $\rightarrow 3s$ transitions. This predicts an $\tilde{A}$ photoelectron band which is blue-shifted relative to the PES band of the geminal isomer at 12.16 eV. The broad bands lying at 10.4 eV should be due to the nCl $\rightarrow 3p$ transition (D band) or a Rydberg transition belonging to a higher ionization potential. The band shapes suggest that the corresponding PES bands should be broad and structureless as well.

the second IP (Fig. 4). As the $\tilde{A}$ photoelectron band is sharp and split, the Rydberg transitions also exhibit these features. As in the 6.5–10 eV region, four Rydberg series are assigned (Table 3): two slightly separated *np* series (δ = 0.56 and δ = 0.63), one *ns* series (δ = 1.03–1.10), and only one weak *nd* series (δ = 0.23). All series start with a principal quantum number of three if one includes the strong absorption bands at 8.8 eV and 9.8 eV. This agrees well with generalized term value rules (1, 12). The typical vibrational excitation in this energy range is 1100 cm^{-1} to 1140 cm^{-1} which is assigned to the C—H bending or antisymmetric C—F stretching modes. The convergence limit of all Rydberg series coincides at 12.16 eV in excellent agreement with the value 12.15 eV obtained from the photoelectron spectrum (7).

The absorption spectrum at energies exceeding the second IP shows only flat and broad structures superimposed on an intense ionization continuum (Fig. 5). We cannot give a straightforward interpretation of these weak structures. Some of these may be assigned to D bands associated with higher chlorine ionization potentials (1). A similar interpretation is given by Sandorfy and co-workers for chlorofluoromethanes (14). Due to the rapid decrease of intensity only the first or second Rydberg members remain observable. A tentative interpretation of these structures using the Rydberg formula is given in Table 4.

Above 16 eV no significant structure is observed. Beyond 20 eV the absorption coefficient decreases continuously. This is commonly observed in photoabsorption spectra when the

ionization quantum efficiency approaches unity.

B. cis- *and* trans-*1-Chloro-1,2-difluoroethene*

Unlike the *geminal* isomer absorption spectrum, for the vicinal isomers there are no sharp structures that unambiguously correspond to Rydberg series (Figs. 6, 7). Obviously a geminal fluorine substitution distorts the non-bonding character of the a' chlorine lone-pair orbital.

The lack of PES data impedes a straightforward assignment of the absorption bands in this energy region. Comparison of photoionization mass spectra with vuv spectra may elucidate the influence of preionization as was pointed out by Momigny (4). Moreover, predissociation that leads to fragment ions is expected to correlate with the absorption bands found in the vuv spectra.

Conclusions

In this investigation on all the chlorodifluoroethenes a number of new Rydberg series and vibronic excitations have been assigned for the first time. The effect of substitution on electronic transitions has been discussed in connection with quantum defects and term value arguments. As there exist no experimental data for haloethenes in the energy range from 11 to 25 eV an assignment of these absorption bands remains somewhat tentative. Further theoretical studies and more experimental data may help to overcome this drawback.

Spherical box model and reduction of Coulomb interactions in the crystal field theory of $3d^n$ ions

ANDRÉ JULG AND ODETTE JULG
Laboratoire de Chimie Théorique, Université de Provence, Place Victor Hugo, 13331 Marseille 3, France

Received November 30, 1984

This paper is dedicated to Professor Camille Sandorfy on the occasion of his 65th birthday

ANDRÉ JULG and ODETTE JULG. Can. J. Chem. **63**, 1955 (1985).

With an accuracy of 0.1 eV, all the electron transitions in any $3d$ transition element and in the corresponding ions, isolated or inside a crystal, can be obtained with the Hartree–Fock model by using hydrogen d orbitals with suitable effective charges ζ. When the ion is embedded in a crystal, the value of ζ is generally weaker than that in the isolated state. For a given ion, the value of the reduction factor depends on the nature of the crystal. This phenomenon is explained by the boundaries imposed on the ion by the presence of the first neighboring ions (box effect). The application to some crystals (oxides and carbonates) corroborates this interpretation. An empirical relationship between the size of the ion and that of the cavity in which it is confined is proposed.

ANDRÉ JULG et ODETTE JULG. Can. J. Chem. **63**, 1955 (1985).

A la précision de 0.1 eV, toutes les énergies de transition des éléments de transition $3d$ et de leurs ions, à l'état isolé ou dans un cristal, peuvent être obtenues dans le cadre de Hartree–Fock en utilisant des orbitales hydrogénoïdes d de charge effective ζ convenable. La valeur de ζ pour un ion dans un cristal est en général plus petite que celle à l'état libre. Pour un ion donné, la valeur du facteur de réduction dépend de la nature du cristal. Le phénomène est expliqué par les limites imposées à l'ion par la présence des ions voisins (effet de boîte). L'application à divers cristaux (oxydes et carbonates) confirme cette interprétation. Une formule empirique est proposée pour calculer le facteur de réduction en fonction de la taille de l'ion et de celle de la cavité dans laquelle il est enfermé.

The interpretation of the spectra of atoms and ions, in the isolated state and inside a complex or a crystal, is often considered one of the greatest successes of quantum mechanics. In fact, the quantitative interpretation of these spectra necessitates the replacing of the exactly calculated values of the various terms which appear in the calculation of the transition energies, by values fitted to experiment (Slater–Condon integrals, Racah parameters) (1). Moreover, the Coulomb parameters corresponding to an ion in a complex or a crystal are, in general, weaker than those corresponding to the isolated state (1, 2). In order to explain this reduction, a partial covalency is often invoked (2, 3). Certain authors have also envisaged a modification in the form of the atomic orbitals (4, 5). We shall see that another factor, essentially geometric in origin, can also be invoked. Whatever that may be, it would be very helpful to the chemist (non specialist in sophisticated quantum calculations) to know the reduction factor directly. Indeed, the *a priori* knowledge of the absorption spectrum not only permits the identification of impurities inside the minerals, but also helps to lead the experimentalist in preparing inorganic compounds which possess well-determined optical properties (artificial gems (6), colored filters, and lasers).

Some results concerning atoms in the isolated state and within a crystal field

In order to simplify the discussion, we shall consider $3d^n$ ions only, the core-electrons being assumed to be completely localized around the nucleus. Since the reduction we propose to study brings modifications in energy for various levels much more important (ca. 100 times) than the splittings between the components of a given multiplet arising from the spin–orbit coupling, the latter will be neglected. The actual levels corresponding to a given ^{2S+1}X term (leaving J out of account) will be replaced by their center of gravity.

Using the Hartree–Fock model, the various states are described by linear combinations of Slater determinants, built up from the d-atomic orbitals. Their energies appear as follows

$$[1] \quad E = nI + \bar{C}$$

where I corresponds to the monoelectronic terms of the Hamiltonian (kinetic energy + core-attraction energy) and $\bar{C}$ is the total electron repulsion energy. The term I is the same for all d^n-states, so that it does not play any role in the d-transitions. The term $\bar{C}$ can be expressed as a linear function of the Coulomb and exchange integrals (in Slater's notation, F and G, respectively (7), or in SCF molecular methods (8), J and K). If we assume that all the d-orbitals possess the same radial function $f(r)$, these integrals can be expressed as linear functions of three of them, so that, in fact, $\bar{C}$ depends only on three parameters. For convenience, Racah proposed to replace the F and G Slater integrals by three linear combinations of these F and G: A, B, and C(9). In fact, the d-transition energies depend only on the B and C parameters, with the A parameters canceling out in the calculations.

The J and K, or F and G, or B and C parameters are calculable from the analytic expression for $f(r)$. Unfortunately, the exact expression for $f(r)$ is unknown. If we utilize hydrogenic functions with an effective charge ζ_m determined by the minimization of the ground state energy, or with charge ζ_{sl} given by Slater's rules (10) (both values are very close), the energies obtained for the transitions are too small (80% of the experimental values only), from which one concludes that the theoretical values have to be replaced by values fitted to experiment, without making the exact form of the orbitals precise. In the general case, two parameters (e.g. B and C) have to be determined. If we assume that $f(r)$ corresponds to a hydrogenic function, the ratio B/C is fixed (ca. 0.25), so that only one arbitrary parameter remains: B, for instance, or the single orbital Coulomb integral $J = \langle d^2|r^{-1}|d^2\rangle$ (the same for all the real d-orbitals). *A priori*, fitting by means of two parameters must lead to a better agreement with experiment than a one-parameter fit. In fact, if we are content with an accuracy of

TABLE 1. Values of J fitted to experiment (11) and values of the effective charge ζ, assuming the orbitals are hydrogenic ($J = 2.51\ \zeta$ eV)

M^{2+}	J (eV)	ζ	M^{3+}	J (eV)	ζ
Ni^{2+}	20.5	8.2

Cr^{2+}	16.0	6.4	Cr^{3+}	17.5	7.0
V^{2+}	14.4	5.8	V^{3+}	16.6	6.6
Ti^{2+}	13.4	5.3			

0.1 eV for all the energy levels of the transition elements and their ions, the use of one parameter (e.g. J) is sufficient. In Table 1, we have listed the smoothed values of J, and the values of ζ corresponding to the hydrogen d-orbitals, which are, of course, equivalent to Slater-type orbitals for the present case ($3d$).

The situation is the same when the atom is embedded inside a crystal. Within the same 0.1 eV accuracy, it is possible to reproduce the spectrum using, on the one hand, only one Coulomb parameter, J, and, on the other, parameters linked to the intensity and the symmetry of the crystal field. As an example, we show the case of the Ni^{2+} ion, in the isolated state, and inside a MgO matrix (Table 2).

The fact that it is possible to reproduce the spectra of an ion using the Hartree–Fock model, in the isolated state or inside a crystal, by means of a unique Coulomb parameter J, means that, with the accuracy of 0.1 eV for the energy, (i) explicit treatment of electron correlation can be neglected due to the parametric approach; and (ii) for the calculation of the Coulomb interaction, at least, it is possible to replace the actual orbitals by hydrogen-like functions with suitable effective charges.

With respect to the isolated state, the decrease in the Coulomb repulsion energy in a crystal can be interpreted as arising from a modification of the orbitals, which can be (formally at least) simulated by a simple ζ variation. We will completely neglect the question why, for the p-orbitals, Slater or optimum effective ζ's give larger J values than experiment (12, 13), whereas, for the d-orbitals, these same ζ's give smaller values. Our purpose, indeed, is only to study the difference in behavior of an ion in the isolated state and inside a crystal.

The reduction of the Coulomb interaction inside an ionic crystal

According to Table 2 concerning the Ni^{2+} ion in an MgO matrix, we see that it is necessary to reduce J by the factor $\lambda = 0.87$. In Table 3, the reader will find other examples for which we have calculated the reduction factor λ from experimental spectra published by various authors. Consequently, we find the same phenomenon as in the complex ions in solution. The interpretation of the spectra of these compounds, indeed, necessitates a reduction of Coulomb parameters (1, 20), adapted to the case under consideration.

In these ions, the reduction of the Coulomb interaction is usually explained by invoking a covalency effect (2, 3). Nevertheless, the question is far from being very clear, owing to the fact that in the molecular semiempirical π-methods — Parr–Pariser method (12) or the improved LCAO method (13) — the Coulomb parameters fitted to isolated atoms, lead to excellent values for the molecular transition energies. Given that, in this case, the bond-effect plays the main role, we are led to think that in crystals another factor must necessarily be introduced. As we have recalled in the Introduction, certain authors have envisaged a modification in the form of the atomic orbitals designed to take into account the boundary conditions assigned to the electron density by the surrounding ions.

The case of Cr^{3+} in MgO is very significant concerning the importance of the boundary conditions. The reduction indeed is greater than that for the other ions. The phenomenon is certainly connected with the small radius of Cr^{3+} (0.55 Å) which provokes a local relaxation of the lattice with a reduction of the R_{CrO} distance, whereas no relaxation appears for Ni^{2+} and Co^{2+} in MgO (3, 14), Ni^{2+} in NiO, and Mn^{2+} in MnO. We will come back to the case of Cr^{3+} in MgO later on. Moreover, in the planar π-systems, the electron density is essentially located above and below the plane of the molecule, i.e. within domains where no hindrance exists. All these remarks lead us to examine the eventual effect of the confinement of an atom inside a box.

The box effect

In order to study the problem in a detailed manner, we will consider the simple case of a helium atom located at the center of a spherical box of radius R. The case of a hydrogen atom (21) and that of various atoms belonging to the first row (31) in such a situation has been considered by many authors using various methods. The problem of the Coulomb repulsion does not seem to have been explicitly considered.

As for the case of ions in a crystal, we will remain within the Hartree–Fock framework. In order to simplify the calculations, we will consider the particular case for which the radius R is such that the product $R\zeta$ is equal to 2. The solution is then obvious.

$$\chi = \frac{\zeta^{3/2}}{\sqrt{32\pi}} (2 - r\zeta) \exp(-r\zeta/2) \qquad (0 < r \leq 2/\zeta)$$

The kinetic, nuclear repulsion, and Coulomb repulsion integrals are, respectively, equal to

$$\langle T \rangle = 1.410\zeta^2,\ \langle r^{-1} \rangle = 1.535\zeta \text{ and } \langle r_{\mu\nu}^{-1} \rangle = 1.046\zeta \text{ au}$$

If R is infinite (free atom), these integrals are respectively equal to $\zeta^2/2$, ζ, and $(5/8)\zeta$ au.

Inside the box, the energy of the atom is

$$E = 2.820\zeta^2 - 6.140\zeta + 1.046\zeta$$

The condition $\partial E/\partial \zeta = 0$ determines ζ (and consequently R), and the repulsion energy:

$$\zeta = 0.903; \qquad R = 2.215 \text{ au}; \qquad \bar{C} = 0.945 \text{ au}$$

If $R = \infty$, $\zeta = 1.698$ and $\bar{C} = 1.055$ au. Consequently within a box of a finite radius, the average electron repulsion is weaker than that for an isolated atom (the validity of this conclusion has been verified for various values of R). In the present case, where $R = 2.215$ au, $\lambda = 0.90$. More generally, for a He-like ion of a nuclear charge equal to Z, we have

$$\lambda = \frac{0.570Z - 0.195}{0.625Z - 0.195}$$

Practically, whatever Z may be, λ always remains very close to 0.9.

At first sight, this reduction can appear as surprising, given

TABLE 2. Absorption spectrum of Ni^{2+}, isolated and in MgO

(a) In the isolated state*

Transition	Exp. (13)	Calculated from ζ_m = 7.37,	J = 20.5 eV,	B = 1100, and C = 4120 cm^{-1}

Mn^{2+}	MnO (17)	0.86	0.80	2.22	0.86

that on the average the electrons are nearer to each other inside a box than in the free state. In fact, the decrease in the average distance enhances the mutual screening effects, so that ζ decreases.

This result can be applied qualitatively to our problem. We will remark, first, that if the sphere inside which the atom is confined, is uniformly charged, inside this sphere the potential is modified only by an additive constant, which does not change the result. Moreover, as a first approximation, we can approximate the field created by the atoms surrounding the central ion by that created by a continuous charge distribution.

Practically, we can say, of course, that the reduction of the Coulomb interaction arises from a modification in the radial function of the atomic orbitals, arising from boundary conditions. Nevertheless, the direction of the variation is not that which Sugano *et al.* have proposed (2). These authors, indeed, suggested that the radial functions are expanded towards the ligands. Our calculation can better be compared with attempts made by certain authors which take the presence of the neighboring atoms into account to evaluate the characteristics of the central ion. Kleiner, for instance, cuts the radial functions of the central atom at a certain distance from the nucleus (4). For his part, Watson, treating an Mn^{2+} ion surrounded by six point charges, obtains F and G terms slightly greater (by about 2%) than in the free ion (5).

Practical consequences

The previous calculation shows that, within the simple Hartree–Fock model, the confinement of an ion inside a crystal lattice provokes a reduction of the Coulomb interaction which can be simulated by a simple reduction of the effective nuclear charges ζ of the atomic orbitals. Independent of any eventual covalent effect, the box effect has to be taken into account.

In numerous cases, both of these effects can seem to be connected with each other, a large interionic distance corresponding to a weak bond-order, i.e. to a weak electron transfer from the anions to the cations. For instance, in cubic oxides (MgO, NiO, MnO): the net charges $Q \sim 1.6-1.8$ and $R_{MO} \sim 2.0 - 2.2$ Å, whereas in D_{3d} carbonates ($CaCO_3$, $FeCO_3$): $Q \sim 1.9$ and $R_{MO} \sim 3.2-3.5$ Å (22–23). In $MgCO_3$ and $MnCO_3$, however, Q is weaker (1.6 and 1.4 respectively) although $R > 3$ Å, so that the connection between the ionicity and the geometrical parameters is not obvious. In order to evaluate the relative contribution of both effects, we will consider various carbonates, pure or containing ionic impurities, namely: $CaCO_3$ with Fe^{2+}, Fe^{3+}, Ni^{2+}, $MgCO_3$ with Ni^{2+}, $FeCO_3$ and $MnCO_3$. This series corresponds to lattices in which the box effect should not interfere, owing to the large size of the cavity in which the chromophore ion is located. In other terms, $\lambda = 1$. In contrast, the degrees of covalency vary in a large range from 1.4 in $MnCO_3$ to 1.9 in $CaCO_3$.

In a first stage, we shall neglect any covalency effect, i.e. we will adopt the effective charges ζ which correspond to the isolated ions (Table 1).

Remark on the practical calculation of the crystal field potential

The calculation of the transition energies in a crystal requires not only the knowledge of the J integral corresponding to the

TABLE 4. Corrections to the orbital energies arising from the crystal field (net charges of crystal assumed equal to 2)*

*Color of crystals indicated in ref. 16.

central ion, but also that of the values of the crystal field parameters. Using a one-electron potential, these latter terms are easily calculable, on the one hand, from the analytical expression of the atomic orbitals, and, on the other, from the positions and the values of the charges which create the field. Although the charges carried by the first nearest-neighboring ions bring a contribution greater than 80% to the actual field (24), it is more advisable to utilize a multipole development. In this paper, we will utilize the method we have previously described (25).

Practically, the coefficients A_n of the multipoles P_n are obtained by writing that the potential $V = \Sigma A_n P_n$ is equal to the Madelung potential at the point where the chromophore ion is located, and that $V = 0$ for a certain number of points, determined by symmetry (e.g., in O_h symmetry: $a/2$, 0, 0; $a/2$, $a/2$, $a/2$; etc., a being the value of the distance between the nearest-neighboring ions). In order to obtain the coefficients of the N first multipoles, we must consider $(N - 1)$ points for which $V = 0$. It follows that the variation of the orbital energy e is equal to $\delta e = \Sigma A_n \langle d|P_n|d\rangle = \Sigma a_n \zeta^{-n}$. Table 4 gives the results corresponding to various crystals.

An important point is the following. According to the Slater rules (10), the electron transfer modifies the effective charges ζ. For instance, a transfer equal to 0.2 electron leads to a decrease of $0.2 \times 0.35 = 0.07$ which corresponds to a relative decrease in the transition energies of 1%, i.e. to 0.02−0.03 eV in the visible. Such a correction is much less than the accuracy (0.1 eV) of the model. For this reason, we will use the effective charges of the isolated ions to calculate the electronic Coulomb interactions. On the contrary, the electron transfers can play a non-negligible role in the evaluation of the crystal field. The electric potential, indeed, is proportional to the charges which create it. This effect has to be taken into account.

Results concerning O_h oxides and D_{3d} carbonates

In Table 4, we give the expressions of the terms arising from the crystal field, and in Table 5, the results corresponding to the spectra. When the spectrum is not determined experimentally, we indicate the color of the mineral.

Manifestly, the agreement with experiment is excellent. But the most remarkable point is that the spectra of carbonates can be interpreted from the effective charges ζ of the isolated ions ($\lambda = 1$) without introducing any covalent effect. The fact is all the more interesting since the degree of covalency varies in this series from 5 to 30%, whereas for oxides this degree varies from 15 to 20% only. In other terms, in the cases under consideration, the box effect does play a more important role than the covalency effect.

An empirical relationship between the reduction factor and the geometrical parameters

Independent of any theoretical consideration we can try to connect the reduction factor λ with the size of the cavity and the radius of the ion r. The following relationship

$$[2] \quad \lambda = 1 - 0.40 \left(\frac{r}{R_{MO} - 1.1}\right)^3 \qquad (r \text{ and } R_{MO} \text{ in Å})$$

leads to very satisfying results. The calculated values corresponding to oxides are listed in Table 3. For the carbonates, λ is practically equal to 1. Moreover, we have previously remarked that the reduction factor for Cr^{3+} in MgO is weaker (0.80) than the factors corresponding to the other cases (Table 3) and we have thought that the difference might arise from the small size of Cr^{3+} which would provoke a local relaxation. If we admit that Cr^{3+} is in contact with the oxygen ions ($R \sim 1.8$ Å), formula [2] gives $\lambda = 0.81$, i.e., a value very close to the actual value (0.80).

Another example which corroborates our interpretation is that of lizardite $(Mg, Ni)_3Si_2O_5(OH)_4$. In this mineral a certain proportion of Mg^{2+} ions is substituted by Ni^{2+} ions. The NiO distances are practically equal to 2.1 Å, i.e. to the value in an MgO matrix. The reduction factor is equal to 0.87−0.88, i.e. practically equal to that calculated for Ni^{2+} in MgO, even though lizardite presents a notable degree of covalency (30).

Investigations of the assignment of the 2190 cm^{-1} infrared band in polyfumaronitrile

KENNETH L. GALLAHER, DOROTHY LUKCO, AND JEANETTE G. GRASSELLI[1]

The Standard Oil Company (Ohio) Research and Development Center, 4440 Warrensville Center Road, Cleveland, OH 44128, U.S.A.

Received August 6, 1984

This paper is dedicated to Professor Camille Sandorfy on the occasion of his 65th birthday

KENNETH L. GALLAHER, DOROTHY LUKCO, and JEANETTE G. GRASSELLI. Can. J. Chem. **63**, 1960 (1985).

Polyfumaronitrile exhibits a band at 2190 cm^{-1} which has at various times been associated with a β-aminonitrile, an iminonitrile, or with C═N in an α-pyrrolenine ring. This band is of particular interest because it sometimes appears in degraded polyacrylonitrile and nitrile-containing resins. The previous conflicting assignments were made on the basis of ir, uv, ^{1}H nmr, and chemical results. This paper reports new infrared, esr, and solid-state carbon nmr results which indicate that the 2190 cm^{-1} band is most likely due to a β-aminonitrile functionality. The close spectral similarity with 3-amino crotonitrile is particularly noted. A mechanism is proposed which would explain the presence of such a nitrile in polyfumaronitrile.

KENNETH L. GALLAHER, DOROTHY LUKCO et JEANETTE G. GRASSELLI. Can. J. Chem. **63**, 1960 (1985).

Le spectre du polyfumaronitrile présente une bande à 2190 cm^{-1} qui a été attribué, par divers auteurs, soit à un β-aminonitrile, soit un iminonitrile ou à un C═N en α d'un cycle pyrrolénine. Cette bande présente un intérêt particulier à cause du fait qu'elle apparaît quelquefois dans les spectres de résines contenant des nitriles ou des polyacrylonitriles dégradés. Les attributions divergentes antérieures ont été faites sur la base de spectres ir, uv ou rmn du ^{1}H ainsi que sur des résultats chimiques. Dans le présent travail, on rapporte les résultats de nouvelles mesures en ir, en rpe et en rmn du ^{13}C à l'état solide; ces résultats indiquent que la bande à 2190 cm^{-1} est probablement due à un groupe β-aminonitrile. On note particulièrement la très grande ressemblance avec l'amino-3 crotonitrile. On propose un mécanisme qui pourrait expliquer la présence d'un tel nitrile dans le polyfumaronitrile.

[Traduit par le journal]

Introduction

Polyfumaronitrile (poly (*trans*-1,2-dicyanoethylene)), PFN, exhibits an absorbance at about 2190 cm^{-1} in its infrared spectrum. This band, which has at various times been associated with a β-aminonitrile, an iminonitrile, or with C═N in an α-pyrrolenine ring (Table 1), also sometimes appears in acrylonitrile-containing polymers as well as in degraded polyacrylonitrile. The most detailed study of PFN by Liepins *et al.* (1), using ir, uv, ^{1}H nmr, and a number of chemical tests, concluded that only the α-pyrrolenine structure was present and that a nitrile functionality was not present in the polymer.

Part of Liepins' argument was that 2190 cm^{-1} is low for a nitrile absorption and, indeed, Bellamy (2, 3) quotes the range in which nitriles absorb as between 2215 and 2260 cm^{-1}. However, there are a number of examples of nitrile-containing compounds which absorb considerably below 2200 cm^{-1} (4). This fact places some doubt on Liepins' interpretation, along with the fact that Liepins did not propose any alternative assignment except to state that the 2190 cm^{-1} band was "characteristic" of the structure he proposed. In order to better determine the true structure of polyfumaronitrile, further work was done using some new spectroscopic techniques such as carbon-13 nmr and carbon-13 solid-state nmr, which Liepins did not have readily available.

Experimental

Synthesis of the PFN was done according to Liepins' published method (1). Approximately 1 g of fumaronitrile was placed in a glass bottle with di-*tert*-butyl peroxide and reacted at 160°C in a metal bomb. It was determined that lower temperature and (or) shorter reaction time decreased molecular weight and increased solubility. Solubility was essential in order for any liquid phase nmr work to be done. But the reduced time and temperature also reduced the yield to as low as 1% in some cases. Residual fumaronitrile was removed by vacuum sublimation. This avoided the solvent contamination problems Liepins reported; however, it also reduced the yield of product since high speed gpc indicated that sublimation induced a nearly two-fold decrease in molecular weight and depolymerization back to the monomer in low molecular weight polymers. The polymer obtained ranged from a brown powder for lower molecular wieght material to a black shiny powder in the high molecular weight samples. Elemental analyses gave an empirical formula close to that of fumaronitrile with about 3% by weight oxygen. However, there was also as much as 10% "ash" which could either have been inorganic contaminants or graphite-type materials not fully consumed by the CHN analyzer.

All infrared spectra were obtained on a Nicolet 7199 FT-IR spectrometer. Sample spectra were obtained as KBr pellets. The KBr was not ground in order to minimize water contamination. The ^{1}H nmr spectra were obtained on a Varian EM-390 CW NMR with a Nicolet 1180 data system. Liquid ^{13}C nmr spectra were obtained on a Varian XL-100 with Nicolet multinuclear probe and data system. Solid state nmr spectra were obtained on a Nicolet S-100 instrument.

TABLE 1. Proposed assignment for 2190 cm^{-1} infrared band

$H_2N—\overset{\vert}{C}═\overset{\vert}{C}—C≡N$	β-Aminonitrile (enaminonitrile)
$HN═\overset{\vert}{C}—\overset{\vert}{C}H—C≡N$	Iminonitrile
	α-Pyrrolenine

Results and discussion

A. *Infrared*

The ir spectra contained a number of surprises. The high and low molecular weight polymers are clearly quite different (Fig. 1). The spectra show many differences in band intensities and

[1] Author to whom correspondence may be addressed.

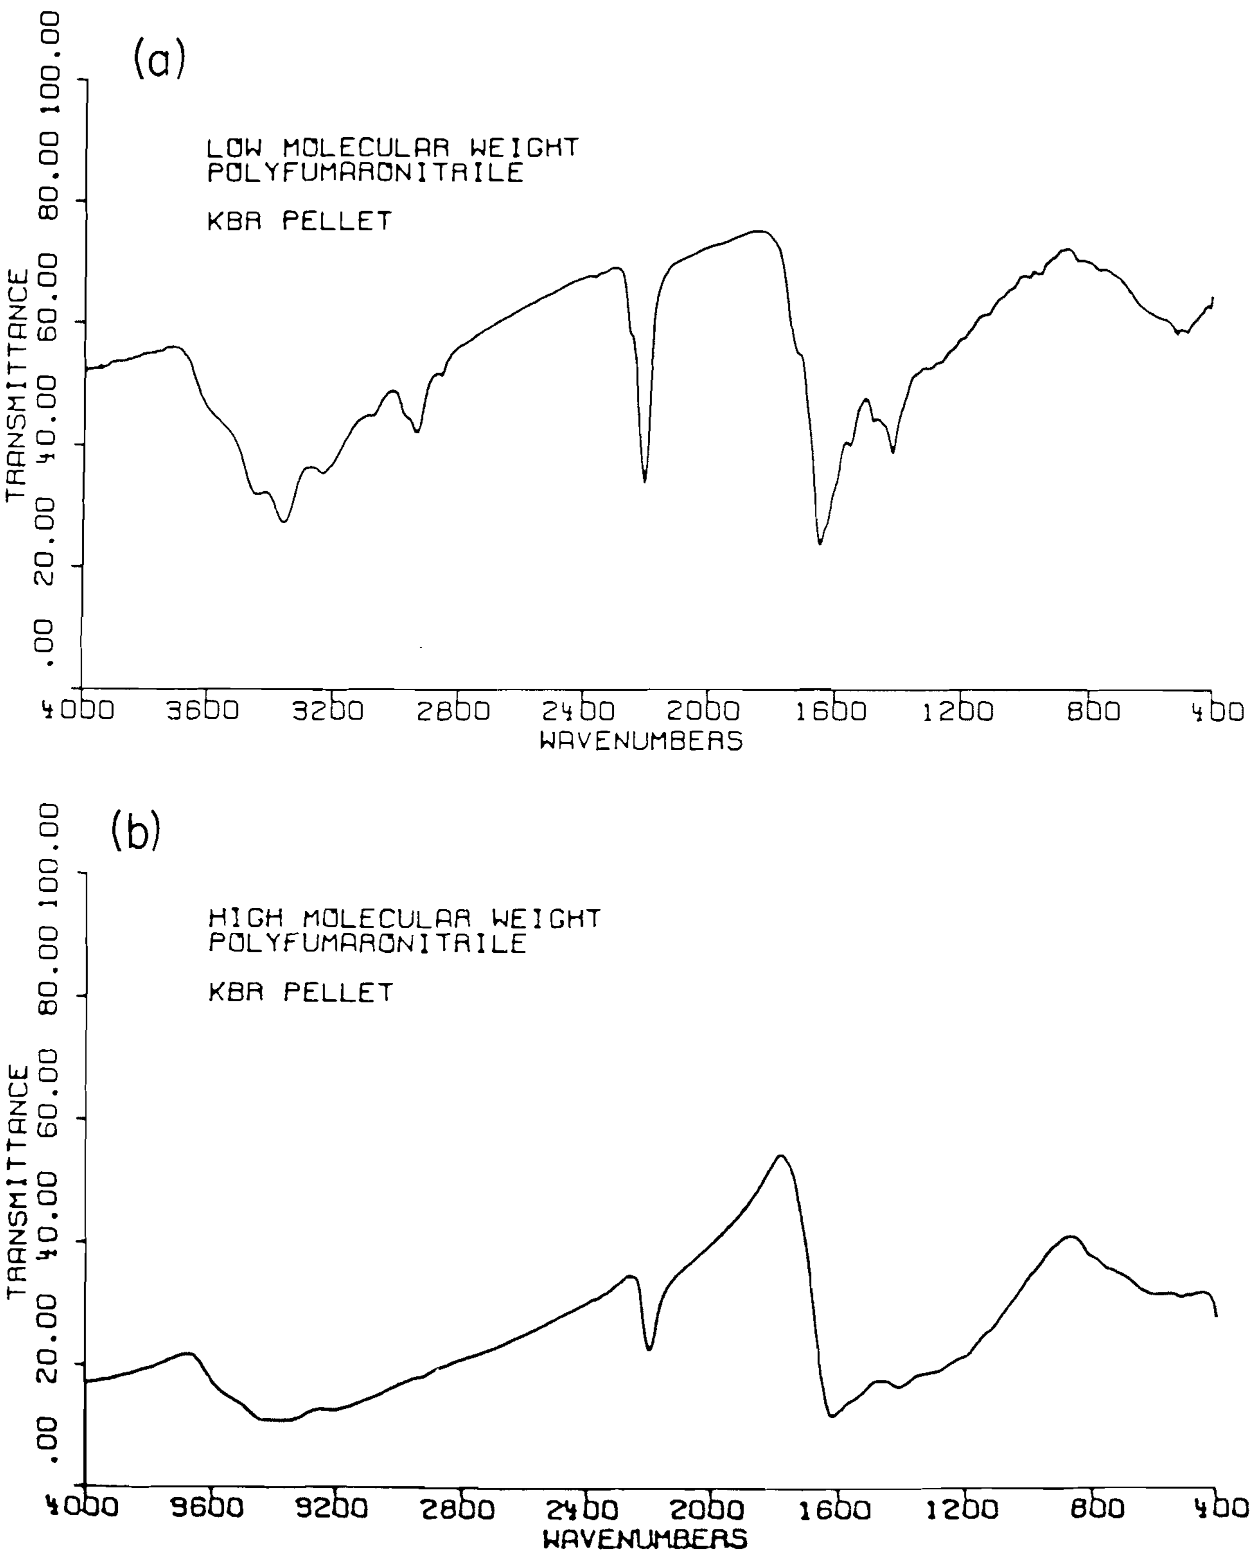

FIG. 1. Infrared spectra of polyfumaronitrile. (a) Low molecular weight; (b) High molecular weight.

position. The low molecular weight polymer in particular appears to contain primary amine. There are three fairly well resolved bands at 3442, 3359, and 3233 cm^{-1}, which are most likely due to N—H stretch. The strongest band in the spectrum has its maximum at 1648 cm^{-1} and could well be due to NH deformation in a primary amine. The sloping background between 900 and 500 cm^{-1} is also evidence for amine. This is, of course, completely contrary to the α-pyrrolenine structure, which contains only olefinic hydrogens. The high molecular weight polymer still shows absorption in the 3600–3000 region but it is less well resolved. The 1648 maximum has either disappeared or moved down to 1621 cm^{-1}. This shift could be due to increased conjugation, similar to that observed in azide- or aldehyde-substituted polyenes. Long chain polyenes all have a complex C═C absorption in the 1650–1600 cm^{-1} region with the strongest band always at 1650 cm^{-1}. However, when

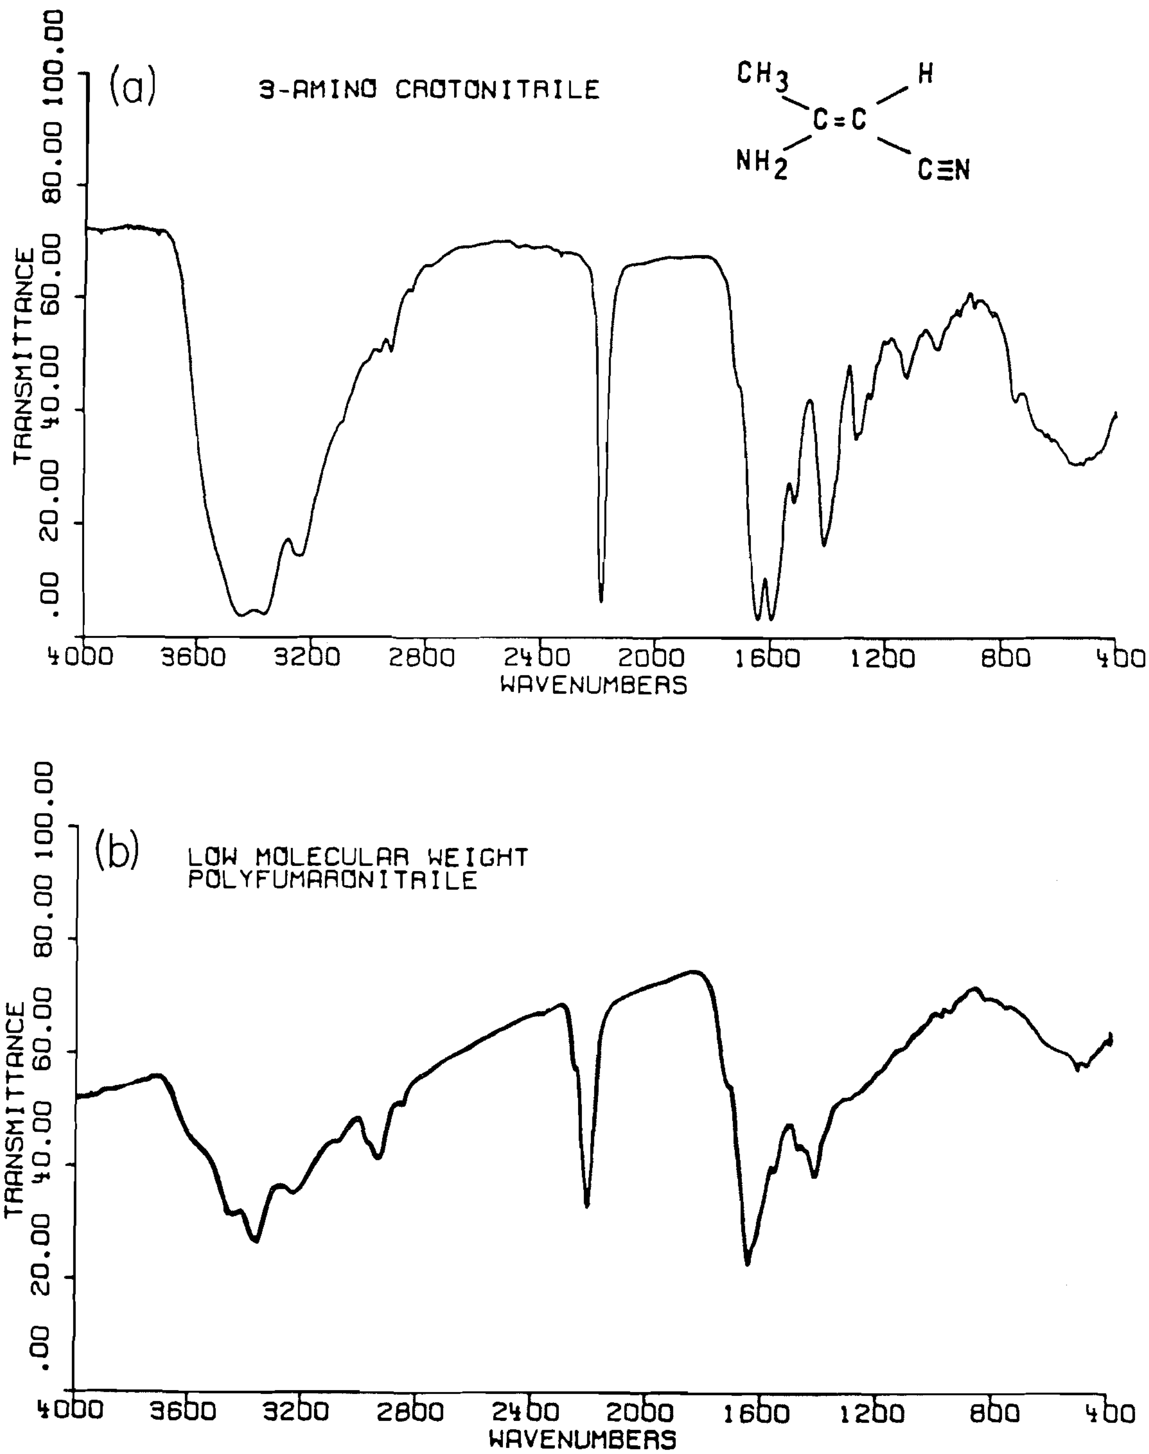

FIG. 2. (a) Infrared spectrum of 3-amino crotonitrile. (b) Infrared spectrum of low molecular weight polyfumaronitrile.

substituted with another kind of unsaturated functionality like an aldehyde or azide, the C═C vibration shifts to progressively lower frequency as the number of bonds in the conjugation increases (5). The "2190 cm^{-1}" band itself also moves. In the high molecular weight material the vibration is at 2195 cm^{-1}, while in the low molecular weight material it is at 2206 cm^{-1}.

Another piece of data which tends to support some of these interpretations is the ir spectrum of 3-amino crotonitrile (1-cyano 2-amino propylene) (Fig. 2). The overall resemblance to the low molecular weight PFN is striking. The N— H stretch bands are present, along with the 1650 cm^{-1} band and the weaker bands at 1415 and 1520 cm^{-1}. The nitrile peak position is 2185 cm^{-1}.

The spectral feature worthy of note in the low and high molecular weight polymers is the broadness of the 2190 cm^{-1} bands, which are nearly twice the width of the typically sharp nitrile vibration. There is also an upward sloping background in the high energy end of the ir spectra, especially in that of the high molecular weight polymer. Even extensively ground samples show this background, and so it is believed to be real, and not due to light scattering. A group of compounds which ex-

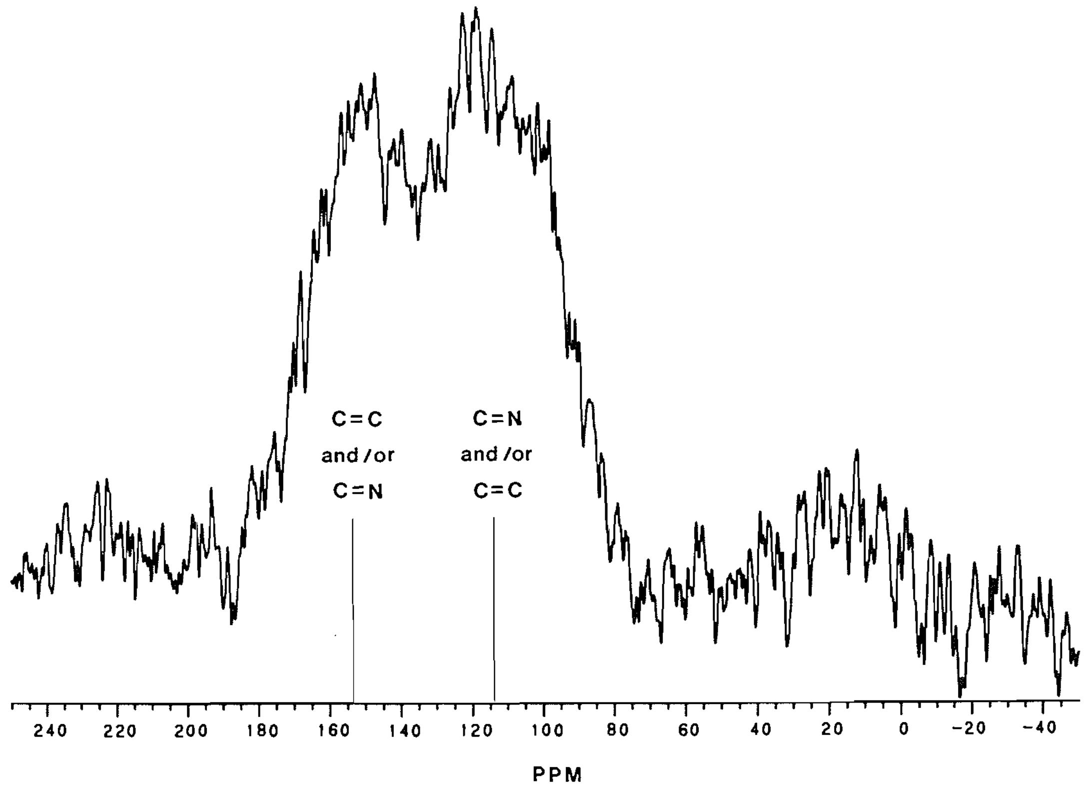

FIG. 3. Solid state ^{13}C nmr spectrum of high molecular weight polyfumaronitrile.

hibit similar spectral characteristics are 7,7,8,8-tetracyanoquinodimethane (TCNQ) and its salts (6). Most widely known for the high conductivity of its salts, TCNQ itself shows a narrow nitrile vibration at about 2220 cm^{-1}, while the corresponding band in the triethyl ammonium salt is considerably broadened and is between 2175 and 2198 cm^{-1}. Further, the salts show a broad near-ir band with a maximum at about 8000 cm^{-1} which is ascribed to electronic rather than vibrational absorption.

B. *^1H and ^{13}C nuclear magnetic resonance*

Efforts were also made to obtain good liquid nmr spectra. High molecular weight PFN is totally insoluble in a wide variety of solvents. Low molecular weight PFN appeared to dissolve in DMSO-d_6 to give a very dark, slightly viscous solution. However, the proton and carbon nmr spectra which were obtained were very weak and clearly not representative of the total material in the nmr tube. It is possible that the sample was not really as soluble as it appeared, or that free electrons might have seriously broadened the spectra.

The next step was to analyze the samples by esr (electron spin resonance), since if free electrons were present in large numbers they may well broaden an nmr spectrum; however, they will be observable by esr. There are a number of examples which suggest that the existence of free electrons in PFN is reasonable. For example, Rieger *et al.* (7) found that dissolving some polycyanocarbons in DMF was sufficient to produce anion radicals. Also tetracyanoethylene readily forms ion-radical salts with an esr spectrum that shows all of the 20 lines due to ^{13}C splitting as well as the nine lines expected from four equivalent nitrogens. Further, two nitrile bands are observed in these salts, one at 2210 and the other at 2180 cm^{-1}. Unlike TCNQ salts, these salts are not semiconductors. As one would expect, the high conductivity TCNQ salts do exhibit strong esr spectra.

Liepins himself reports that PFN has an esr spectrum and that its conductivity is in the semiconductor range. This implies extended conjugation in the polymer. However, no temperature study was done to determine if the polymer was truly a semiconductor. Liepins does not interpret this data, which makes the meaningfulness of his own (unpublished) ^1H nmr data questionable.

The esr spectra were obtained on both a low molecular weight PFN sample dissolved in DMSO-d_6 and also on a finely ground high molecular weight polymer. A large broad signal was obtained in both cases, indicating enough free electrons to possibly explain the lack of nmr signal if the unpaired electrons are widely diffused over the molecule. This is similar to what Liepins found. He apparently went to some lengths to observe coupling in the esr spectrum but, similar to our results, he found none.

C. *Solid state nuclear magnetic resonance*

In spite of the esr results, an attempt was made to obtain a solid state nmr spectrum. PFN is far from the ideal polymer to examine via solid state nmr. One can expect long relaxation times due to its rigid nature, and poor sensitivity because of the few hydrogens present, possibly none of which are on a carbon. There has also been discussion of broadening effects due to ^{14}N coupling. However, the spectrum shown in Fig. 3 was obtained for a high molecular weight PFN, although it required an unusually long (24 h) acquisition time.

In order to determine if this spectrum was reasonable, the proton and carbon nmr spectra of amino crotonitrile were closely examined. The ^1H nmr spectrum looks like a roughly 50:50 mixture of *cis* and *trans* compound (Fig. 4a). The ratio of the exchangeable protons to the olefin to the methyl is 2:1:3. There is no evidence for imine formation, although the strong upfield shift of the olefin certainly indicates a strong amine

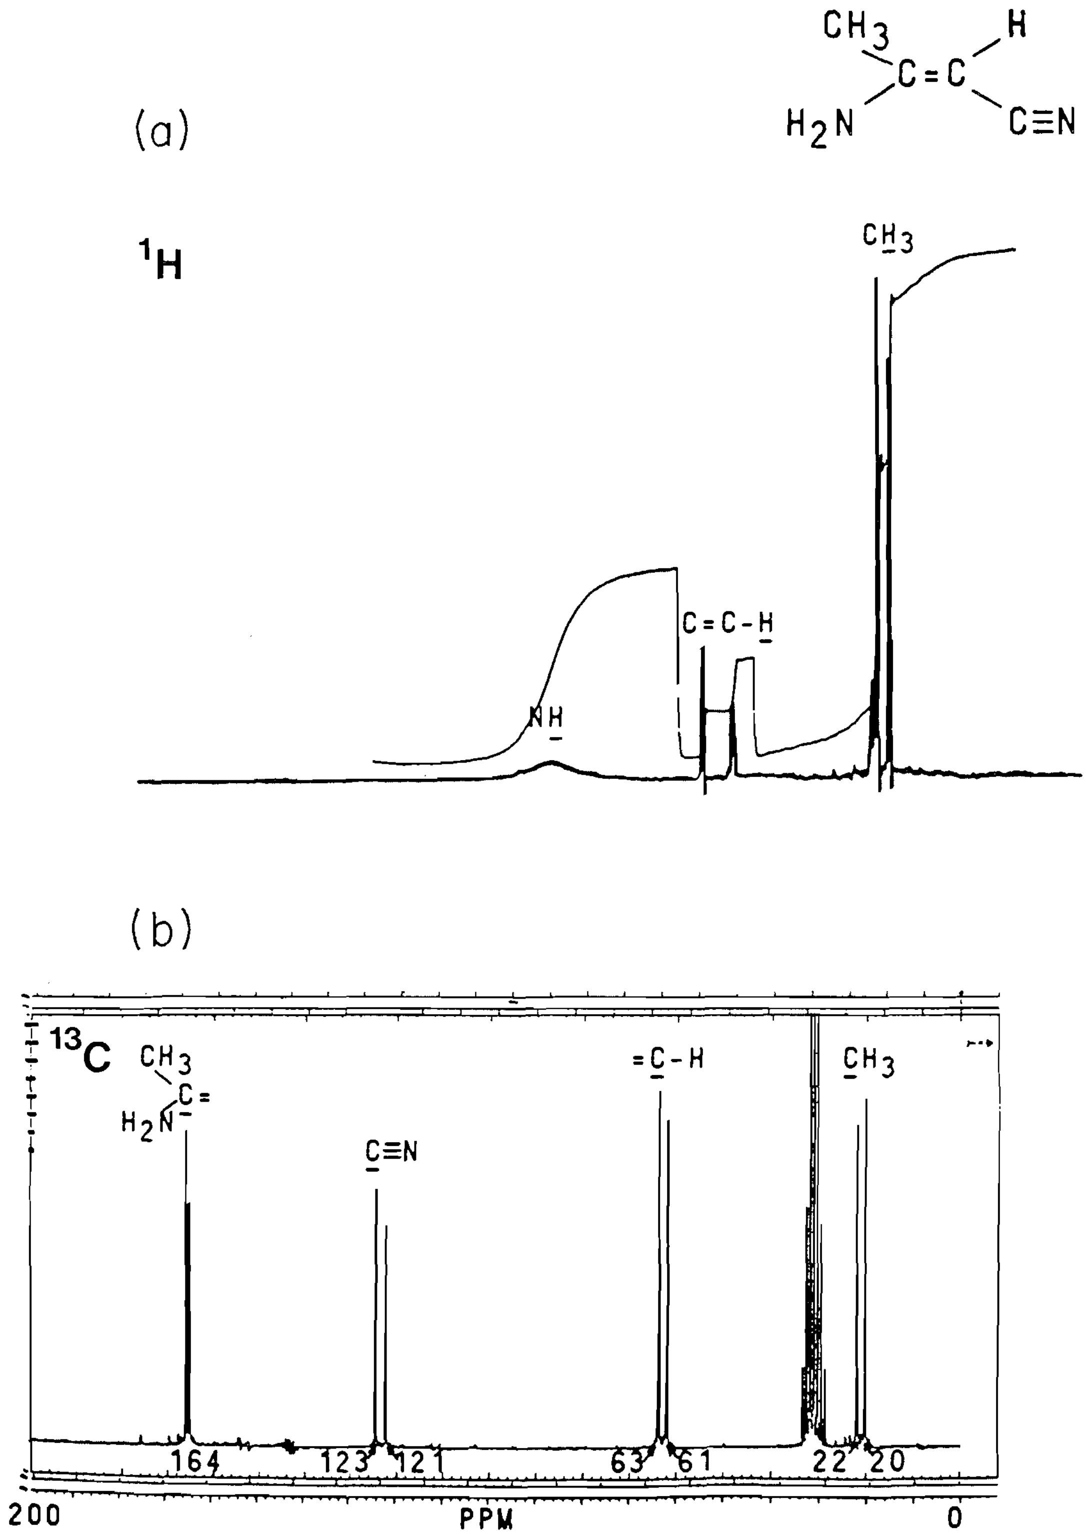

FIG. 4. Nuclear magnetic resonance spectra of 3-amino crotonitrile; (a) ^1H nmr; (b) ^{13}C nmr.

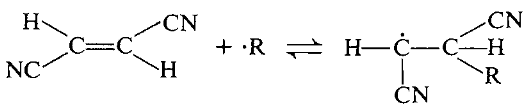
interaction. The higher field of the two olefin peaks no doubt corresponds to the isomer with the amino group *trans* to the olefinic hydrogen, both because one expects the *trans* interaction to be stronger and because the greater linewidth indicates coupling with the NH.

The ^{13}C spectrum can be interpreted similarly (Fig. 4b). The chemical shifts indicate a strong tendency towards the imine form, but no shift of hydrogen. The amine substituted carbon is pushed far downfield in the direction of the C=N bonded carbon, the nitrile and methyl carbons are in nearly normal positions, and the nitrile-substituted carbon is far upfield. Single frequency off-resonance decoupling experiments confirm no hydrogen transfer.

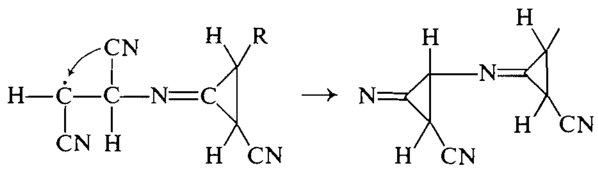
The PFN solid nmr resonance centered at 120 ppm could indeed be due in part to nitrile, while the resonance at 150 ppm could be due to olefin. There is little or no saturated carbon.

D. *Possible PFN mechanism*

How could a polyfumaronitrile that would contain enaminonitrile functionality form? The following mechanism has been postulated. In the initiation step, the fumaronitrile is attacked by a free radical, ·R (e.g. $\cdot CH_3$, $\cdot OC(CH_3)_3$):

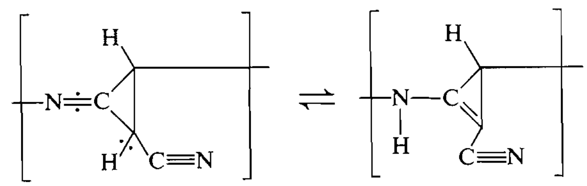


The ·N=C< then becomes the propagating radical, instead of ·R to give

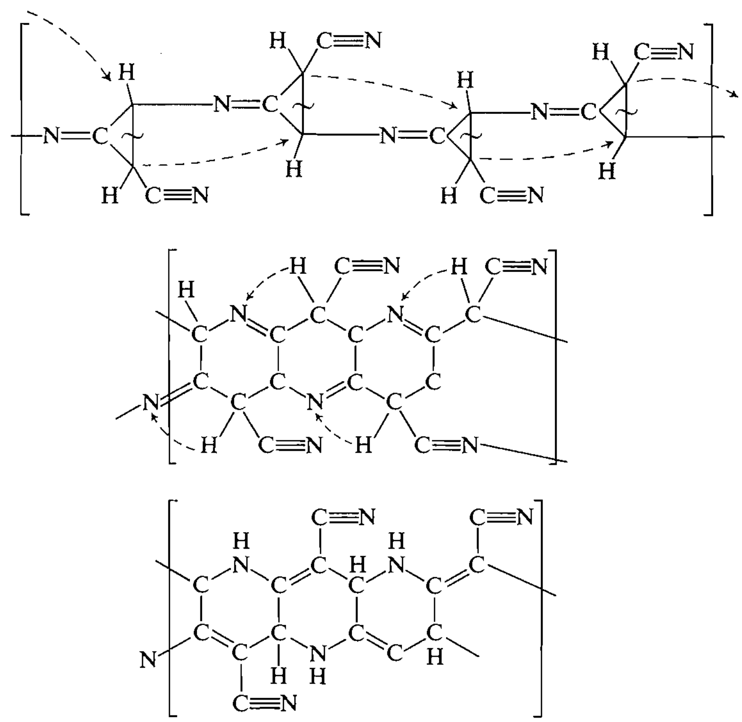


This intermediate could then rearrange to give more stable structures.

At low temperatures a simple proton shift could easily occur, so as to give a conjugated nitrile system:



At higher temperatures, ring cleavage will occur. The probable product would be the highly stable ladder structure with six-membered rings. Following the formation of this ladder structure, the same proton shift would occur to give a conjugated nitrile system.



What is the assignment of the 2190 cm^{-1} band in PFN? The resemblance of the low molecular weight PFN ir spectrum to that of amino crotonitrile is so strong that it is hard to assign the 2205 cm^{-1} band to anything but the nitrile absorption in an enaminonitrile. The comparison with the ^{1}H and ^{13}C spectra of amino crotonitrile further confirms that it is an enaminonitrile rather than an iminonitrile.

The 2195 cm^{-1} band is harder to assign. There still appears to be NH present, and it is easy to believe that more extended conjugation lowers the nitrile band 10 cm^{-1}. There are known nitrile compounds with even lower nitrile vibrations. Further, there is solid state nmr evidence for a structure much like that of amino crotonitrile in the high molecular weight (2195 cm^{-1}) material as well. However, the structure shown above cannot be completely correct since the solid's nmr shows so little aliphatic carbon. Further aromatization must be occurring.

Several possible structures for polyfumaronitrile have been proposed, some more reasonable than others. The α-pyrrolenine structure cannot be eliminated as being one component of the polymer. PFN is not a single homogeneous material. An initial structure is formed which is high in enaminonitrile functionality. As is observed in many other cyano polymers, increased reaction time results in further cyclization and (or) conjugation with loss or change of nitrile and NH.

The proposed structure must allow for extended conjugation and free electrons to explain the observed esr spectra and the high conductivity. A ladder structure like that of the ideal black Orlon with a polyene backbone might explain the high thermal stability and insolubility. The proposed reaction mechanism given above for the formation of polyfumaronitrile also supports a ladder-like structure composed of conjugated nitrile rings.

Acknowledgements

The authors would like to thank Dr. Dave Compton from The Standard Oil Co. for his ideas on the proposed reaction mechanism. They are also grateful to T. E. Hammond for helping them obtain a good solid state nmr spectrum.

The two-photon excitation spectrum of all-*trans*-N-retinylidene-*n*-butylamine (ATRSB) in EPA at 77 K is obtained over the wavelength region from 370 to 455 nm ($\lambda_{ex}/2$) using linearly polarized light. The two-photon excitation maximum is observed at ~422 nm ($\lambda_{ex}/2$) and is red shifted ~2800 cm^{-1} from the one-photon absorption maximum at ~377 nm. We assign the two-photon excitation spectrum to the "$^1A_g^{*-}$" $\leftarrow S_0$ transition which indicates that the "$^1A_g^{*-}$" $\pi\pi^*$ state lies below the "$^1B_u^{*+}$" $\pi\pi^*$ state in ATRSB. Comparisons of the one-photon absorption, two-photon excitation, and fluorescence spectra of ATRSB with the corresponding spectra of all-*trans*-retinal are presented. PPP-CISD calculations correctly predict the directions but not the magnitudes of the blue shifts of the $\pi\pi^*$ excited state transition energies in going from all-*trans*-retinal to ATRSB. We postulate that the "$^1A_g^{*-}$" $\pi\pi^*$ state is preferentially stabilized relative to both the ground state and the nearby "$^1B_u^{*+}$" state by hydrogen bonding to solvent molecules. Comparison of the spectra reported here with the two-photon spectra of rhodopsin provides further evidence that the chromophore in rhodopsin is protonated.

LIONEL P. MURRAY et ROBERT R. BIRGE. Can. J. Chem. **63**, 1967 (1985).

Faisant appel à de la lumière polarisée linéairement, opérant à des longueurs d'onde allant de 370 à 455 nm ($\lambda_{ex}/2$) et à une température de 77 K, on a mesuré le spectre d'excitation à deux photons de la *N*-rétinylidène *n*-butylamine complètement *trans* (ATRSB) dans l'EPA. L'absorption maximale pour l'excitation à deux photons se produit vers 422 nm ($\lambda_{ex}/2$) et est déplacée vers le rouge ~2800 cm^{-1} par comparaison avec l'absorption maximale à un photon qui est observée vers ~377 nm. On attribue le spectre d'excitation à deux photons à la transition "$^1A_g^{*-}$" $\leftarrow S_0$; ceci indique que, dans l'ATRSB, l'énergie de l'état "$^1A_g^{*-}$" $\pi\pi^*$ est plus faible que celle de l'état "$^1B_u^{*+}$" $\pi\pi^*$. On rapporte des comparaisons des spectres d'absorption à un photon, d'excitation à deux photons et de fluorescence de l'ATRSB avec les spectres correspondants du rétinal complètement *trans*. Des calculs PPP-CISD permettent de prédire correctement les directions, mais non les amplitudes, des déplacements vers le bleu des énergies de transition de l'état excité $\pi\pi^*$ lorsqu'on passe du rétinal complètement *trans* au ATRSB. Nous postulons que, par rapport tant à l'état fondamental qu'à l'état voisin "$^1B_u^{*+}$", l'état "$^1A_g^{*-}$" $\pi\pi^*$ est stabilisé d'une façon préférentielle par des liaisons hydrogènes avec des molécules de solvant. Une comparaison des spectres rapportés ici avec ceux des spectres à deux photons de la rhodopsine fournit des preuves supplémentaires que le chromophore de la rhodopsine est protoné.

[Traduit par le journal]

I. Introduction

The level ordering of the low-lying excited singlet states of the visual chromophores has been the subject of extensive theoretical and spectroscopic study (1–27).[2] It is now recognized that polyenes possess two low-lying excited singlet states, a strongly one-photon allowed excited state of $^1B_u^{*+}$ parentage and a canonically forbidden excited state of $^1A_g^{*-}$ parentage (1–7, 28–32). In long-chain linear polyenes, the forbidden $^1A_g^{*-}$ state is the lowest-lying excited state (1–7, 28–32). The presence of this lowest-lying forbidden state is responsible for many of the "anomalous" spectroscopic and photochemical properties that long-chain polyenes exhibit (1–7, 31). This level ordering, however, is not directly transferrable to the visual chromophores because the level ordering in these molecules is dependent upon molecular conformation, polarity, and solvent environment (1).

The location of the low-lying "forbidden" $^1A_g^{*-}$-like $\pi\pi^*$ state in the visual chromophores is now recognized to be of importance in defining the photochemical properties of these molecules (1, 2). This is particularly relevant in the case of rhodopsin where calculations indicate that the interaction of this state with a lowest-lying "$^1B_u^{*+}$" state may be directly responsible for producing a barrierless excited state potential energy surface for *cis–trans* isomerization (1, 6, 33). The extremely rapid formation of bathorhodopsin may therefore be a consequence of the photochemical lability of the "$^1A_g^{*-}$" state (1, 6). Excited state level ordering is also important in defining the photochemical properties of the visual chromophores in solution (1, 2, 18, 34, 35).

Previous two-photon investigations have shown that both all-*trans*-retinol (24) and all-*trans*-retinal (25) possess lowest lying $^1A_g^{*-}$-like states. More recent studies, however, indicate that this level-ordering may be reversed in the protonated Schiff bases and in the chromophore in rhodopsin (5). The present two-photon study of the *n*-butylamine Schiff base of all-*trans*-retinal was motivated by a desire to better understand how molecular and environmental perturbations influence the level ordering of these two states. A knowledge of the level ordering in the Schiff base of all-*trans*-retinal is important if we are to understand the electronic origin of the level ordering inversion observed for the chromophore in rhodopsin (5).

II. Experimental

All-*trans*-*N*-retinylidene-*n*-butylamine (ATRSB) was made by reacting all-*trans*-retinal (ATR) under nitrogen in freshly distilled *n*-butylamine in the presence of 3A molecular sieves at 0°C for 6 h following the procedures of Christensen *et al.* (12). The *n*-butylamine is added in molar excess (50:1) and then removed by rotary evaporation upon completion of the reaction.

Low temperature (77 K) absorption spectra were obtained using a Varian Cary 17D spectrophotometer using an optical Dewar assembly filled with liquid nitrogen. Uncorrected emission spectra were obtained using a Spex Fluorolog spectrofluorimeter also equipped with

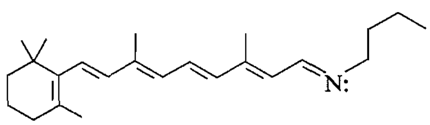
all-*trans*-Retinal (ATR)



all-*trans*-*N*-Retinylidene-*n*-butylamine (ATRSB)

an optical Dewar assembly. Fluorescence was monitored perpendicular to the excitation beam.

The two-photon excitation spectrum was obtained using the apparatus described in ref. 25. Laser excitation from a nitrogen-pumped dye laser was focussed using an 85 mm achromatic lens into a cylindrical quartz cell containing ATRSB (1×10^{-3} *M*) in degassed EPA (diethyl ether – isopentane – ethyl alcohol, 5:5:2 v/v) immersed in liquid nitrogen (77 K). The two-photon induced fluorescence of ATRSB was monitored perpendicular to the laser excitation beam through a Corning 4-65 glass filter in series with a 5 cm cell containing a nearly saturated (1.1 *M*) solution of $CuSO_4$ (see Fig. 19 of ref. 36). Although the transmission maximum of this filter combination ($\lambda_{max} \sim 490$ nm) is to the blue of the emission maximum of ATRSB ($\lambda_{max} \sim 570$ nm), this filter combination is effective in blocking scattered laser light in the wavelength range 650–950 nm. The use of an RCA 1P28 photomultiplier to detect the fluorescence further improves discrimination of the scattered laser light because this photomultiplier exhibits a very low quantum efficiency above 700 nm.

The two-photon character of the observed fluorescence signal was verified by determining the slope of the log (I_f) vs. log (I_r) at selected wavelengths using neutral density filters to attenuate the laser excitation beam (see ref. 36, pp. 165–167). At the two-photon excitation maximum ($\lambda_{ex} \cong 843$ nm) the slope was observed to be 1.85 ± 0.36.

III. Theoretical

Wave functions for the ground and excited electronic states of ATRSB were calculated using PPP-CISD molecular orbital procedures (15). The restricted π-electron PPP-CISD procedures included all 36 single and all 666 double excitations in the CI Hamiltonian. Repulsion integrals were calculated using the Ohno formula (37). Resonance integrals were calculated using the Roos and Skancke relationship (38). The semiempirical parameters listed in refs. 15 and 39 were adopted.

The two-photon properties of the excited states were calculated using the procedures described by Birge and Pierce (15). The basis set of intermediate states contained the ten lowest electronic states ($N = 10$ in eqs. 1, 2, 4–7 of ref. 15). Although the initial and final states should be formally included in the summation over intermediate states (see ref. 40), they were not included in the calculations reported here. We neglected these contributions because they are proportional to the changes in the dipole moment upon excitation. The PPP-CISD calculations do not include the entire retinyl framework and usually underestimate the dipole moments in both the ground and excited states. We believe that the accuracy of two-photon absorptivity calculations is decreased by the inclusion of the initial and final states when PPP-CISD calculations are used to generate the dipole moments.

IV. Results and discussion

The two-photon excitation spectrum of ATRSB in EPA (77 K) is compared to the one-photon absorption spectrum and the uncorrected fluorescence spectrum in the upper portion of Fig. 1. The two-photon excitation spectrum was obtained using linearly polarized laser excitation and is plotted as a function of (laser excitation wavelength)/2 to facilitate comparison with the one-photon absorption spectrum. Analogous spectra of all-*trans*-retinal in the same solvent environment at 77 K are shown in the lower portion of Fig. 1 for comparison.

(A) Analysis of one-photon and two-photon spectra

Both the one-photon absorption spectrum and the two-photon excitation spectrum are broad and unstructured, a spectroscopic property associated with severe inhomogeneous

[f]Ground and excited state dipole moments are for the π-system only and are predicted to underestimate the total molecular dipole moments.

broadening (27). This observation precludes accurate assignment of the system origins of the electronic states. The two-photon excitation maximum lies approximately 2800 cm^{-1} below the one-photon absorption maximum. We assign the two-photon excitation spectrum to the "$^1A_g{}^{*-}$" excited $\pi\pi^*$ state based on arguments analogous to those used to assign the two-photon spectrum of all-*trans*-retinal (25). Accordingly, ATRSB has a lowest-lying "$^1A_g{}^{*-}$" state. Our level ordering assignment agrees with that of Das *et al.* (17).

As noted by one of the referees of this paper, the two-photon excitation spectrum and the fluorescence spectrum display an anomalously large overlap in the region of the system origins. This prompted the referee to suggest the possibility that the fluorescence might originate from the higher energy $^1B_u{}^{*+}$-like excited state. The low symmetry of the molecule and the close proximity of the two low-lying excited states suggests that the vast majority of the emission is occurring from the lowest-lying $^1A_g{}^{*-}$-like state. The anomalous overlap is best explained as resulting from an inhomogeneous distribution of lowest-lying excited states involving varying degrees of hydrogen bonding between the solute and the solvent. In particular, we have noted that the shape of the fluorescence spectrum reversibly changes with temperature with the maximum shifting to lower energy with decreasing temperature. (An analogous study of the two-photon excitation spectrum was not possible, however, because the quantum yield of emission drops dramatically with increasing temperature preventing acquisition of a reliable two-photon excitation signal at temperatures above ~90 K.) The one-photon absorption spectrum does not show a large temperature effect suggesting that the one-photon absorbing state is not the state responsible for the emission spectrum. These observations coupled with the solvent effect studies described in ref. 17 suggest that the $^1A_g{}^{*-}$-like state is more energetically stabilized than the $^1B_u{}^{*+}$-like state by the hydrogen bonding solvent, a conclusion which is discussed in greater detail below.

A comparison of the observed and calculated one-photon and two-photon properties of the low-lying $\pi\pi^*$ excited states of all-*trans*-retinal and its Schiff base are presented in Table 1. The following observations can be made by reference to this table. Formation of the Schiff base linkage generates a blue shift in the Franck–Condon maxima of both the "$^1A_g{}^{*-}$" state and the "$^1B_u{}^{*+}$" state. The blue shift of the allowed state was predicted in earlier theoretical studies (see ref. 9). The present PPP-CISD calculations correctly predict the observed trends although the calculations significantly overestimate the observed blue shift in the "$^1A_g{}^{*-}$" state (see below). Accordingly, the observed increase in the separation of the two $\pi\pi^*$ low-lying states in going from retinal to its Schiff base is not accurately simulated in the PPP-CISD calculations. In particular, we observe an increase of approximately 400 cm^{-1} in the Franck–Condon separations, whereas the calculations predict that the Schiff base should actually have a smaller "$^1A_g{}^{*-}$"–"$^1B_u{}^{*+}$" separation. In analyzing this discrepancy, we must recognize that the calculations are for a molecule in a vacuum whereas our experimental observations are for polar molecules in a polar solvent environment. Given the small energy differences involved, a major portion of the discrepancy between experiment and theory may be due to solvent induced shifts rather than intrinsic electronic properties of the chromophore in vacuum. This possibility would appear to gain support from a casual inspection of the calculated dipole moments which are shown at the bottom of Table 1 for the ground and two lowest-lying $\pi\pi^*$ states. In particular, we note that the ground and excited state dipole moments of all-*trans*-retinal are larger than those of the corresponding states in the Schiff base.

Furthermore the change in dipole moments upon excitation, which will determine the magnitude of the solvent-induced red shift, are much larger in all-*trans*-retinal than in its Schiff base. The relative differences predicted by the PPP-CISD calculations agree with the experimental measurements of Corsetti and Kohler (41). These authors measured ground state dipole moments for ATR and ATRSB of 4.6 D and 2.1 D, respectively. The corresponding excited ("$^1B_u{}^{*+}$") state dipole moments were observed to fall in the ranges 7–10.3 D (ATR) and 4.7–6.4 D (ATRSB) (see Table VI of ref. 41). Accordingly, the PPP-CISD calculations appear to underestimate the dipole moments in both the ground and excited states, but correctly reproduce the observed trends in going from all-*trans*-retinal to its Schiff base. A closer examination of the calculated results, when analyzed in terms of the prevailing theories of electrostatic solvent shifts (see ref. 41 and references therein), suggest that the "$^1A_g{}^{*-}$" state in all-*trans*-retinal should be red-shifted by solvent polarity to a larger degree than the corresponding state in the Schiff base. Furthermore, analogous arguments can be used to predict that level separation should be enhanced in all-*trans*-retinal relative to its Schiff base based on electrostatic solvent shifts. (These arguments assume, of course, identical solvent environments.) We conclude that electrostatic solvent shifts do not explain the failure of the PPP-CISD calculations to accurately predict the observed increase in the level separation in going from all-*trans*-retinal to its Schiff base.

Dispersive solvent shift effects will also tend to increase the observed level separation in all-*trans*-retinal versus the Schiff base. This is due to the fact that the low-lying "$^1A_g{}^{*-}$" state has a larger calculated oscillator strength in all-*trans*-retinal than in its Schiff base (see Table 1). Accordingly the magnitude of the dispersive red shift for the "$^1A_g{}^{*-}$" state in all-*trans*-retinal will be greater than that for the corresponding state in the Schiff base and this will also enhance the level separation in all-*trans*-retinal relative to its Schiff base.

There are a number of possible explanations for the observed failure of the PPP-CISD calculations to properly reproduce the observed increase in the excited state level separation in going from ATR to ATRSB. We suggest the following as the most likely possibility based on an analysis of the data presented in Table I and inspection of the spectra shown in Fig. 1. We note first of all that the PPP-CISD calculations accurately reproduce the "$^1B_u{}^{*+}$" transition energies in going from all-*trans*-retinal to the Schiff base. In contrast the PPP-CISD calculations greatly overestimate the blue shift in the "$^1A_g{}^{*-}$" state. The solvent environment appears to be stabilizing the "$^1A_g{}^{*-}$" in the Schiff base by an anomalous amount. This observation is supported by the experimental work of Das and co-workers (17) who studied the all-*trans*-retinal Schiff base in both 3-methylpentane and EPA at 77 K. They noted that the emission maximum dramatically red-shifted in going from 3-methylpentane to EPA, whereas the absorption maximum red-shifted by a much smaller amount. A comparison of their results with our two-photon excitation data suggests that the Schiff base in EPA forms a hydrogen-bonded complex with the solvent and that this hydrogen-bonded complex is responsible for the anomalous red shift in both the "$^1A_g{}^{*-}$" excitation maximum as well as the fluorescence maximum. (Note that fluorescence originates from the "$^1A_g{}^{*-}$" state.) Analysis of Fig. 1 supports this conclusion in that the spectra of ATRSB are much broader than the spectra of ATR and suggest that the Schiff base in EPA is in a very inhomogeneous environment. We propose that the inhomogeneity, which induces an increased broadness in the absorption, excitation, and fluorescence spectra, is associated with hydrogen-bonding which tends to lower the energy of the excited state relative to the ground state. A range of species are therefore present in solution with varying degrees of hydrogen bonding and correspondingly different excitation energies.

The detailed calculations of Favrot *et al.* (20) and LeClercq and Sandorfy (42) demonstrate that hydrogen bonding to a Schiff base will red shift the absorption maximum of the "$^1B_u{}^{*+}$" state. Our experimental results suggest that the "$^1A_g{}^{*-}$" state experiences a similar but slightly larger red shift upon hydrogen-bonding. This experimental observation is indirectly supported by the PPP-CISD calculations which indicate that the "$^1A_g{}^{*-}$" state has a more negative nitrogen atom (−0.242) than the "$^1B_u{}^{*+}$" state (−0.233).

(B) Implications for the binding site of rhodopsin

Theoretical calculations suggest that protonation of the Schiff base will induce a level inversion and generate a lowest-lying "$^1B_u{}^{*+}$" state (1, 6, 15). Recent two-photon studies on the protonated Schiff base of all-*trans*-retinal support this conclusion (5) although it appears that the calculations overestimate the extent of the level reversal. A recent two-photon thermal lens study of rhodopsin indicates that the "$^1B_u{}^{*+}$" state lies approximately 2000 cm^{-1} below the "$^1A_g{}^{*-}$" state in the protein bound chromophore (5). The present work indicates that hydrogen-bonding tends to preferentially stabilize the "$^1A_g{}^{*-}$" state. If the chromophore in rhodopsin were a hydrogen-bonded Schiff base, rather than a protonated Schiff base, the "$^1A_g{}^{*-}$" state would lie below the "$^1B_u{}^{*+}$" state.

We are differentiating between two energetically possible situations. In one model, a neutral Schiff base chromophore is stabilized by hydrogen bonding to a residue with an "acidic" hydrogen near the Schiff base nitrogen atom. In the second model, a protonated Schiff base chromophore is stabilized by a negatively charged residue in the vicinity of the nitrogen atom. Based on these definitions, we can conclude from our present spectroscopic study that the chromophore in rhodopsin must be protonated.

Acknowledgments

This work was supported in part by grants to R.R.B. from the National Institutes of Health (EY-02202) and the National Science Foundation (CHE-7916336). R.R.B. thanks Professor C. Sandorfy for many interesting and helpful discussions on the nature of the binding site of rhodopsin and the effect of hydrogen bonding on the spectroscopic properties of Schiff bases.

Group theory of constrained reaction mechanisms

PAUL G. MEZEY

Department of Chemistry, University of Saskatchewan, Saskatoon, Sask., Canada S7N 0W0

Received July 30, 1984

This paper is dedicated to Professor Camille Sandorfy on the occasion of his 65th birthday

PAUL G. MEZEY. Can. J. Chem. **63**, 1972 (1985).

It is shown that the family of all possible reaction mechanisms on a given potential energy hypersurface, which reaction mechanisms are constrained by a *local stability criterion*, has an algebraic structure. The fundamental relations among all such "λ-constrained" reaction mechanisms are described in terms of a group, the one dimensional *homotopy group* $\pi_1(Y)$. In contrast with the *energy-dependent group* $\pi_1(F)$ of *fundamental reaction mechanisms*, proposed earlier for the *low energy domains F* of potential energy hypersurfaces, the new group $\pi_1(Y)$ is fully determined by the *distribution of catchment regions, representing chemical species* on the potential energy hypersurface.

PAUL G. MEZEY. Can. J. Chem. **63**, 1972 (1985).

On démontre que l'ensemble de tous les mécanismes de réaction possibles apparaissant sur une hypersurface donnée d'énergie potentielle et circonscris par un *critère de stabilité locale* est régi par une structure algébrique. Les relations fondamentales entre tous ces mécanismes de réaction "λ-circonscris" peut être décrit en fonction d'un groupe, le *groupe homotopie unidimensionnel* $\pi_1(Y)$. Par opposition avec le *groupe dépendant de l'énergie* $\pi_1(F)$ des mécanismes de réactions fondamentales, proposé antérieurement pour les *domaines de basse énergie F* des hypersurfaces d'énergie potentielle, le nouveau groupe $\pi_1(Y)$ est complètement déterminé par la *distribution des régions d'attachement, qui représente les espèces chimiques* sur l'hypersurface d'énergie potentielle.

[Traduit par le journal]

Introduction

Theoretical models, suitable for the description of entire families of molecules within a single mathematical framework, are powerful tools for the study of general trends and fundamental relations among chemical species (1, 2). The most fundamental relations often take the form of an algebraic structure. This has been the case in reaction topology, suitable for the quantum chemical description of all interconversion reactions of all chemical species composed from a given set of nuclei and a given number k of electrons, confined to a given potential energy hypersurface. (For recent reviews of reaction topology see refs. 3 and 4.) As it has been shown (5), by identifying quantum chemical reaction mechanisms with *classes* of homotopically equivalent reaction paths (that is, by equivalence classes of paths where within each class the reaction paths are continuously deformable into one another, *below* some energy limit A), the family of all fundamental reaction mechanisms on the potential surface form a *group*, the *fundamental group of reaction mechanisms* (5). Whereas this terminology is in part inherited from the homotopy theoretical concept of *fundamental group* (one dimensional homotopy group) of the relevant topological space (6), it also expresses the chemical significance of this algebraic structure. This group is indeed of fundamental role in the chemistry along the given potential energy hypersurface, as it describes the relations among all reaction mechanisms which are distinguishable at some energy bound A (5).

The fundamental group of reaction mechanisms has been defined in terms of a *level set F* of the nuclear configuration space M, i.e. in terms of a collection of nuclear configurations where the energy does not exceed some fixed value A (5). By a suitable choice of A the analysis can be restricted to the chemically most important *low energy regions* of the hypersurface, however, the method is general and the analysis is applicable for any choice of A. Such level sets reflect a global energy criterion (7), relevant to the *global stability* of various chemical species on the hypersurface. However, *local stability* is also of chemical importance, that may also serve as a basis for an analysis of reaction paths and reaction mechanisms. Local stability (8, 9), in turn, has been shown to be related to index λ of *catchment regions* $C(\lambda, i)$ of the potential energy hypersurface $E(K)$ (10). Catchment regions with higher λ indices, $\lambda \geq 2$, are of little direct importance in chemistry, however, chemical species represented by catchment regions of lower indices ($\lambda = 0$, and $\lambda = 1$) are of major importance: these are the stable molecules and transition structures. Hence, it is of some importance to study reaction paths and reaction mechanisms which are *constrained* to a collection of $C(\lambda, i)$ catchment regions of *small* λ *indices*.

In this study we shall describe the algebraic structure (a *group*) of λ-*constrained reaction mechanisms*, reflecting the local stability properties of various domains of the potential energy hypersurface. Pictorially, two reaction paths having common origin (beginning) and common extremity (end) will be regarded to belong to the same λ-*constrained reaction mechanism*, if they can be continuously deformed into each other *without* involving any highly unstable formal species, represented by a $C(\lambda, i)$ of high index λ. Reaction paths fulfilling this condition are chemically equivalent in the following sense: they both lead from a given reactant to a given product, through the same "passes" or "bottlenecks" of the hypersurface, as defined by a local stability condition. Otherwise, the difference between the two reaction paths will be regarded as essential, and the two paths to belong to two different λ-constrained reaction mechanism. The precise definition of λ-constrained reaction mechanisms as homotopy equivalence classes of reaction paths will simplify the problem to a remarkable extent. The direct analysis of all possible trajectories is an intractable problem, however, each homotopy class contains infinitely many reaction paths, hence using these *classes* as fundamental entities, formally the problem becomes infinitely simpler. It will be shown that the family of these constrained reaction mechanisms has an algebraic structure: a groupoid, containing a group. Some relations to the "reaction polyhedron", generated by a mapping to a compact manifold (11), and to the relevant homology and cohomology groups will be pointed out.

λ-constrained reaction mechanisms

First we shall recall some of the basic concepts of reaction topology (3, 4), necessary for the introduction of λ-constrained reaction mechanisms. For a given collection of N atomic nuclei the $3N - 6$ dimensional reduced nuclear configuration space M is the *quotient space* (space of equivalence classes) obtained from the $3N$ dimensional euclidean nuclear configuration space spanned by the mass-weighted cartesian coordinates of the N nuclei (4). This quotient space is defined with respect to the laboratory-frame equivalence of nuclear configurations related by rigid translation and rigid rotation. M is a metric space with a well-defined metric d (4). The energy expectation value functional $E(K)$, $K \in M$, with respect to some specified electronic state, defines an energy hypersurface E over M. With respect to any given E the catchment regions $\boldsymbol{C}(\lambda, i)$ of M are given as the collections of all those points K from where a formal steepest descent path leads to a common extremity $K(\lambda, i)$, that extremity is, typically, a critical point of E. Index λ is the number of negative canonical curvatures of E at $K(\lambda, i)$, i is an index of ordering. A catchment region $\boldsymbol{C}(\lambda, i)$ represents a stable molecular species if $\lambda = 0$, a transition structure if $\lambda = 1$, and an unstable, formal "species" if $\lambda \geq 2$, which latter formal "species" must also be considered for a complete partitioning of the nuclear configuration space M. The family of these catchment regions and their closures in the metric d serves as the defining subbase for the unique *reaction topology* T_C on M, associated with the given energy hypersurface E.

In practice it is often sufficient to consider, instead of the full space M, only a suitable connected subset $X \subset M$, e.g. when disregarding the internal motions of nuclei within a methyl group. Catchment regions defined within X lead to an analogous topologization of X, that topology is in fact the relative topology (10) on $X \subset M$, defined by T_C of M. Hence, we shall use the same notations, $\boldsymbol{C}(\lambda, i)$ and T_C within X with the understanding that only a subset $X \subset M$ is considered throughout this study. However, in the special case of $X = M$, the original topological space (M, T_C) is obtained.

In order to give a precise definition and to establish the relations between various λ-constrained reaction mechanisms, we consider the following subset of X:

$$[1] \quad Y = \bigcup_{\lambda' \leq \lambda \leq \lambda''} \boldsymbol{C}(\lambda, i)$$

Whereas the case of $\lambda' = 0$, $\lambda'' = 1$ is the most relevant to the usual pictorial interpretation of semiclassical nuclear rearrangements (restricting the analysis to formal stable molecular species and transition structures), other index choices within the general model [1] are also of certain theoretical interest (e.g., in boundary-network relations (12)), hence we shall consider the above general case throughout. The chemically most important choices for X, λ', and λ'' are those which lead to a *connected* set Y. If, however, Y is disconnected, then the following analysis is applicable for each maximum connected component Y_k of Y separately. In the following Y will denote the union defined by eq. [1], if it is connected, or one of the Y_k components, if the union is disconnected.

Our next task is to define λ-constrained *configuration-to-configuration* reaction mechanisms within set Y. Evidently, any reaction path, hence also any reaction mechanism within Y is, by definition, λ-constrained: $\lambda' \leq \lambda \leq \lambda''$. Each path p in Y is parametrized by the unit interval $I = [0, 1]$, points $p(0)$ and $p(1)$ being the *origin* and *extremity* of p, respectively. It is convenient to regard each p as a mapping from I to Y

$$[2] \quad p: I \rightarrow Y$$

We denote the family of *all* paths within Y by $\boldsymbol{p}(Y)$ or in short, by $\boldsymbol{p}$. Any two paths $p, p' \in \boldsymbol{p}$ are *homotopically equivalent*, $p \sim p'$, if $p(0) = p'(0)$, $p(1) = p'(1)$ (that is, their endpoints coincide) and if they are continuously deformable into each other within Y. Due to the definition of set Y, this is precisely the condition used in the introduction for the classification of reaction paths in terms of local stability, since for $\lambda' = 0$ and $\lambda'' = 1$ $p \sim p'$ implies that there is no highly unstable $\boldsymbol{C}(\lambda, i)$, $(\lambda \geq 2)$ formal species separating reaction paths p and p'. Hence the $p \sim p'$ homotopy equivalence does, indeed, reflect a well-defined *chemical equivalence* of reaction paths p and p'.

The following step is a straightforward application of homotopy theory to set $\boldsymbol{p}$ of Y, that nonetheless, leads to a remarkable simplification of the chemical problem. We denote the *class* of all paths of $\boldsymbol{p}$ which are *homotopically equivalent* to p by $[p]$. All of the following relations and results are independent of which actual path p from class $[p]$ is used to represent this class in the $[p]$ notation. *Each* class $[p]$ can then be regarded to represent a *λ-constrained reaction mechanism leading from configuration* $p(0)$ to *configuration* $p(1)$. These endpoints themselves can be regarded as "single point" paths (or, as constant mappings):

$$[3] \quad L^*(p) \in \boldsymbol{p}, \qquad L^*(p): I \rightarrow Y,\ L^*(p)\ (I) = p(0)$$

$$[4] \quad R^*(p) \in \boldsymbol{p}, \qquad R^*(p): I \rightarrow Y,\ R^*(p)\ (I) = p(1)$$

where the *left unit* $L^*(p)$ [*right unit* $R^*(p)$] of path p is itself a path in Y, hence an element of $\boldsymbol{p}$, which path maps the entire unit interval I onto the single point $p(0)$ [$p(1)$, respectively]. Interpreting these left and right units as some "degenerate" paths, rather than simply points, is essential in the following algebraic constructions.

The fundamental group of λ-constrained reaction mechanisms

The *product* pq of any two paths p, $q \in \boldsymbol{p}$, for which the condition

$$[5] \quad R^*(p) = L^*(q)$$

holds, is defined as the unique path obtained by *joining* q to p (continuing p by q). In particular,

$$[6] \quad L^*(pq) = L^*(p)$$

$$[7] \quad R^*(pq) = R^*(q)$$

This product exists if and only if [5] is fulfilled, hence product exists only for some ordered pairs of paths. The *inverse* p^{-1} of path p runs through the same points of Y as does p, but in reversed order, in particular,

$$[8] \quad L^*(p^{-1}) = R^*(p)$$

$$[9] \quad R^*(p^{-1}) = L^*(p)$$

Using the above algebraic concepts for individual reaction paths, similar algebraic concepts can be defined for their equivalence classes, that is, for reaction mechanisms. The *product* of *λ-constrained reaction mechanisms* $[p]$ and $[q]$ is defined as the λ-constrained reaction mechanism $[pq]$,

$$[10] \quad [p][q] = [pq]$$

that is, the homotopy class containing the product path pq, that product exists if and only if pq exists (condition [5]). The product $[p][p'][p'']$ is evidently associative, whenever it exists, since for the product of reaction paths $(pp')p'' \sim p(p'p'')$. Left unit $L([p])$ and right unit $R([p])$ of reaction mechanism $[p]$ are defined similarly:

[11] $L([p]) = [L^*(p)]$

[12] $R([p]) = [R^*(p)]$

that is, as the homotopy classes of all paths which are homotopically equivalent to (in fact, contractible to) single point paths $L^*(p)$ and $R^*(p)$, respectively. The *inverse* of λ-constrained reaction mechanisms $[p]$ is defined as

[13] $[p]^{-1} = [p^{-1}]$

Whereas the product pp^{-1} is *not* in general a unit element $L^*(p)$, the homotopy equivalence within $[pp^{-1}]$ ensures that the product $[p]\,[p]^{-1}$ is *necessarily* a unit element

[14] $[p]\,[p]^{-1} = L([p]) = R([p]^{-1})$

This is the very reason why reaction mechanisms (equivalence classes) have superior algebraic properties, as compared to individual reaction paths.

As follows from a general result of homotopy theory (6) the above listed properties guarantee that the family

[15] $\pi(Y) = \{[p]\}$

of *all λ-constrained reaction mechanism* has an *algebraic structure:* $\pi(Y)$ is a *groupoid*, that is, an associative algebraic structure with inverse and unit elements, but not in general with the closure property. Hence $\pi(Y)$ is not in general a group.

Groupoid $\pi(Y)$ of λ-constrained configuration-to-configuration reaction mechanisms $[p]$ is *much simpler* than the set of all possible reaction paths $\boldsymbol{p}$, since each $[p]$ is a collection of *infinitely many* paths $p \in \boldsymbol{p}$ which paths occur in *none of the other* λ-constrained mechanisms, $p \notin [q]$ if $[q] \neq [p]$. Hence in a formal sense $\pi(Y)$ is infinitely simpler than set $\boldsymbol{p}$ of all reaction paths within Y. Furthermore, $\boldsymbol{p}$ has no useful algebraic structure of its own, whereas $\pi(Y)$ is a groupoid with the "usual" relations between units and inverses.

By its construction, $\pi(Y)$ is the *fundamental groupoid* of the topological space (Y, d). Hence, as every fundamental groupoid, it contains an important subgroupoid that is also a group (6): the *fundamental group* $\pi_1(Y)$. In the following we shall consider a chemical interpretation of the fundamental group $\pi_1(Y)$.

Consider a special subset $\pi_1(Y, K_0)$ of $\pi(Y)$:

[16] $$\pi_1(Y, K_0) = \{[p]\colon [p]\in\pi(Y),\quad L([p]) = R([p]) = [p_0],\ p_0(I) = K_0\}$$

which is the family of all λ-constrained circular (or "loop") reaction mechanisms having their left and right units identical and common, which unit $[p_0]$ contains the unique constant path (single point path) p_0 at point $K_0 \in Y$.

$\pi_1(Y, K_0)$ is also a groupoid, a *subgroupoid* of $\pi(Y)$, but much more is true. Evidently, within $\pi_1(Y, K_0)$ all left and right units are identical to $[p_0]$, hence there exists a *unique unit element* in $\pi_1(Y, K_0)$. Furthermore, the product exists for any two λ-constrained reaction mechanisms from $\pi_1(Y, K_0)$, since condition [5] is necessarily valid for all choices. This implies, that besides a unique unit element, $\pi_1(Y, K_0)$ also has the *closure property* with respect to product defined by [10]. Associativity and unique inverse for each element have been inherited from groupoid $\pi(Y)$, hence $\pi_1(Y, K_0)$ is a *group*, the *fundamental group* of topological space (Y, d).

This group, henceforth referred to as the *fundamental group of λ-constrained reaction mechanisms*, is of particular interest to us. Since *any* λ-constrained reaction mechanism $[q] \in \pi(Y)$ can be extended to a "loop" mechanism (a circular chemical process) $[p] \in \pi_1(Y, K_0)$, therefore segments of mechanisms from group $\pi_1(Y, K_0)$ represent *all possible λ-constrained mechanisms within* Y. Consequently, group $\pi_1(Y, K_0)$ (or the family of groups $\pi_1(Y_k, K_k)$ of the maximum connected components Y_k of a disconnected set Y) expresses the interrelations among all λ-constrained reaction mechanisms within set $X \subset M$. Similarly to the group $\pi_1(F)$ of fundamental reaction mechanisms on a connected level set F (5), a typical group $\pi_1(Y, K_0)$ of a potential surface is a *finitely generated free group*, where the finite set of group generators, the *generator mechanisms* for Y, *are sufficient to generate any λ-constrained reaction mechanism* in X.

There is one apparent property of group $\pi_1(Y, K_0)$ that seems to be contrary to the underlying feature of Reaction Topology, of replacing *individual nuclear configurations* by *open sets* of configurations. Group $\pi_1(Y, K_0)$ implies a direct reference to an individual *point* $K_0 \in Y$. However, this apparent inconsistency is precisely that: only an apparent one, and can be removed easily. As follows from a general invariance property of fundamental groups (6), within any connected set Y, i.e., in any connected union of λ-constrained catchment regions $\boldsymbol{C}(\lambda, i)$, the fundamental group of λ-constrained reaction mechanisms, as an abstract group, is *invariant* to the choice of reference point $K_0 \in Y$. Hence, as far as the general relations between reaction mechanisms are concerned, the specification of K_0 is unnecessary. K_0 can be replaced by a reference to a given chemical species (catchment region) $\boldsymbol{C}(\lambda, i)$, $\lambda' \le \lambda \le \lambda''$. The actual group $\pi_1(Y, \boldsymbol{C}(\lambda, i))$ then formally refers to all circular λ-constrained reaction mechanisms passing through chemical species $\boldsymbol{C}(\lambda, i)$. In the extreme case, all reference to individual points and individual chemical species can be omitted, since the *abstract* fundamental group of λ-constrained reaction mechanisms, $\pi_1(Y)$ is *isomorphic* to any concrete group given as $\pi_1(Y, K_0)$, $K_0 \in Y$ or $\pi_1(Y, \boldsymbol{C}(\lambda, i))$, $\boldsymbol{C}(\lambda, i) \subset Y$. In fact, $\pi_1(Y)$ is a *topological invariant,* being the same for any union Y of catchment regions on the same or *even on two different potential energy hypersurfaces*, as long as the two sets Y and Y' are *topologically equivalent,* that is, if there exists a homeomorphism (one-to-one and onto mapping with a continuous inverse) between Y and Y'. Hence, fundamental groups are convenient devices for a classification of large families of seemingly unrelated potential surfaces, as these groups reflect the fundamental similarities between systems of reaction mechanisms, even if they involve very different molecular species, of different stoichiometries. In this context we note that a more detailed classification of families of potential energy hypersurfaces is possible by their mappings to compact manifolds (11), e.g. to hyperspheres or to more complicated manifolds. Since the energy hypersurface is then defined on the manifold, the catchment region partitioning on the manifold can be represented by an abstract polyhedron. For example, in the simple case of a two dimensional sphere the energy functional is analogous to the geographical concept of elevation above the sea level on the globe. The partitioning of the surface of the globe by the actual geographical watersheds and catchment regions is topologically equivalent to the polyhedron, with faces, edges and vertices corresponding to geographical catchment regions, mountain ridges and hilltops, respectively. Such abstract *"reaction polyhedra"* in the general, multidimensional case, are useful to establish relations between the numbers of various stable molecular species and interconversion processes (11). Whereas the fundamental groups $\pi_1(F)$ (5) and $\pi_1(Y)$ of the present study lead to an intuitively straightforward classification of various potential energy hypersurfaces, a more detailed classification is possible using multidimensional reaction polyhedra. As any polyhedra, reaction polyhedra obtained by compactification of nuclear configuration spaces (11), can be characterized in terms of *homology groups* and *cohomology groups* (6) of homology theory. These groups are topological (and also homotopical) invariants. Some of the topological invariants of simple homology groups have already been used for the estimation of the number of different chemical species on a hypersurface (ref. 11 and references therein). The reaction polyhedron model and the relative merits on the relevant homology groups and cohomology groups, as compared to the $\pi_1(F)$ and $\pi_1(Y)$ homotopy groups of ref. 5 and of the present study, will be discussed elsewhere in more detail (13).

The chemical significance of groups $\pi_1(Y)$ of reaction mechanism is illustrated by the following two problems: (*i*) knowing the existence of some reaction mechanisms within some domain X of a potential surface, how can one predict the existence of further reaction mechanisms? (*ii*) How to obtain a concise representation of all the relations among all reaction mechanisms controlled by a given potential energy hypersurface, that representation is suitable for applications in computer-based synthesis design?

The algebraic relations among elements of group $\pi_1(Y)$ provide a convenient test for problem (*i*). Unless the known reaction mechanisms already form a set of loop mechanisms of a *subgroup* of $\pi_1(Y)$, the extension of the known mechanisms to loops and subsequent generation of group products does lead to new reaction mechanisms.

The group $\pi_1(Y)$ over a given X domain (where X can be M, the full nuclear configuration space) represents all the essential relations among all reaction mechanisms. These relations may appear rather simple for two and three dimensional problems, where one may rely on simple visualization of "mountain passes" and "bottlenecks". However, no such visualization is possible for higher dimensional potential energy hypersurfaces, and one must rely on formal mathematical relations. With the rapid progress in supercomputer technology, computer-based synthesis design (relying on multidimensional potential surfaces) is expected to become feasible in the near future. The groups $\pi_1(Y)$ of reaction mechanisms serve as an algebraic framework for the quantum chemical analysis of large families of reaction mechanisms. This algebraic framework has the potential to aid the discovery of new reaction mechanisms and the development of computer-based molecular design.

Acknowledgments

I have been privileged to benefit from many interesting conversations with Professor Camille Sandorfy. I am very grateful for his interest and encouragement which have been a continuous source of stimulation.

This work has been supported by a research grant from the Natural Sciences and Engineering Research Council of Canada.

By means of carbon-13 nuclear magnetic resonance, carbonyl carbon ion-induced chemical shifts of the Gramicidin A channel are determined at 70°C and analyzed as a function of potassium ion concentration and as a function of thallium ion concentration. In both cases two binding processes are observed. The estimated binding constants for potassium ion binding are $28/M$ and $2.4/M$ for the tight (single ion occupancy) and weak (double ion occupancy) sites, respectively, and for thallium ion binding are of the order of $10^3/M$ for the tight site and approximately $70/M$ for the weak site. These studies, which utilize a 90% enriched carbonyl carbon within the binding site of the channel to monitor ion interaction, argue for the presence of two ions in the channel for conditions under which planar bilayer transport studies are commonly carried out.

D. W. URRY, T. L. TRAPANE, C. M. VENKATACHALAM et K. U. PRASAD. Can. J. Chem. **63**, 1976 (1985).

Utilisant la résonance magnétique nucléaire du ^{13}C et opérant à 70°C, on a déterminé l'effet d'induction ionique sur les déplacements chimiques des carbones de la fonction carbonyle du canal de la Gramicidine A et on les a analysé en fonction de la concentration en ion potassium et aussi en fonction de la concentration en ion thallium. Dans chacun de ces cas, on a observé deux processus de fixation. On a évalué les constantes de fixation du potassium qui sont respectivement $28/M$ et $2{,}4/M$ pour les sites compacts (comportant un seul ion) et pour les sites faibles (comportant deux ions); celles du thallium sont de l'ordre de $10^3/M$ pour le site compact et environ $70/M$ pour le site faible. Ces études, qui utilisent des carbones enrichis à 90% à l'intérieur du site d'association du canal pour repérer les interactions ioniques, suggèrent la présence de deux ions dans le canal pour les conditions dans lesquelles les études de transport de doubles couches sont généralement effectuées.

Introduction

It has been shown that heat incubation of Gramicidin A, HCO-L · Val^1-Gly^2-L · Ala^3-D · Leu^4-L · Ala^5-D · Val^6-L · Val^7-D · Val^8-L · Trp^9-D · Leu^{10}-L · Trp^{11}-D · Leu^{12}-L · Trp^{13}-D · Leu^{14}-L · Trp^{15}-$NHCH_2CH_2OH$ (1), with lysolecithin results in channel formation (2, 3). Sodium-23 (4, 5) and lithium-7 (6) nuclear magnetic resonance (nmr) and dielectric relaxation (7) studies have been carried out on this system to provide estimates of binding constants and rate constants, and these constants in the case of sodium ion have been shown to be capable of calculating single channel currents over wide ranges of ion activity and of applied potential when Eyring rate theory is utilized to introduce voltage dependence to the rate constants derived in the absence of an applied field (5, 8). It is useful, however, to have verification that the ion-nmr-derived binding constants are indeed due to ion binding within the channel and not due to interaction with lipid components.

As a series of Gramicidin A syntheses (in each of which a single carbonyl carbon has been 90% enriched) have been carried out to locate the ion binding sites within the channel (9), the ion-induced carbonyl carbon chemical shift of an enriched residue at a binding site may also be followed as a function of ion concentration to provide an estimate of binding constants. Such a study would be unequivocal with respect to ion interaction with the channel since a channel site is used for monitoring and as the magnitude of ion induced chemical shift indicates direct binding of ion with carbonyl oxygen.

In the present effort carbon-13 nmr of (1-^{13}C)Trp^{11}-Gramicidin A (GA) and (1-^{13}C) Trp^{13}-GA as a function of ion concentration is used to follow the binding of potassium ion and of thallium ion to the GA transmembrane channel. In both cases, and most dramatically and unambiguously with thallium ion, two binding processes are observed with binding constants which differ by more than an order of magnitude.

Experimental

Sample preparation and handling

The samples used to determine potassium and thallium ion binding by following the carbonyl carbon chemical shift were prepared from 1-^{13}C enriched Trp^{13}-GA and (1-^{13}C)Trp^{11}-GA which were synthesized and characterized in this laboratory (10). The conversion of (1-^{13}C)Trp^{11}-GA to the malonyl dimer was as previously described (5). Gramicidin channels were packaged into lysolecithin structures in ^2H_2O using the sonication and heat incubation procedure previously established (2). L-α-lysolecithin containing 75% palmitic and 25% stearic acids was purchased from Avanti Polar Lipids, Inc., Birmingham, AL. The purity of the lipid was confirmed by carbon-13 nmr and thin layer chromatography and was used without further purification. During sample preparation, the lipid to channel ratio was 30:1 and the ion concentration was 0.5 mM NaCl. This concentration of NaCl causes a negligible carbon-13 carbonyl chemical shift, but it is included to assess completion of channel formation as monitored by the sodium-23 chemical shift which is a sensitive indicator of channel concentration. After incubation, the samples were centrifuged to remove any peptide which had not been packaged into the lipid, and the supernatants were taken for the nmr studies. A small aliquot of each supernatant was lyophilized and resuspended in methanol in order to determine the concentration of channels associated with the lipid by observing the ultraviolet spectrum. Using an extinction coefficient in methanol of ϵ_{282} = 45 000 L/mol-cm for the Gramicidin dimer, channel concentrations in the 1-^{13}C enriched Gramicidin samples were found to be 2.9 mM for each of the samples used for the potassium ion and the thallium ion binding studies. Verification of the ion-interacting channel state was achieved by observing the circular dichroism spectrum and by determining the ion nmr chemical shift at 30°C. The CD spectra for both preparations are given in Fig. 1. For the (1-^{13}C)Trp^{13}-GA samples the chemical shift for 0.5 mM sodium ion in the presence of 2.9 mM channels was found to be −11.7 ppm (i.e. upfield) from the (10 mM NaCl in ^2H_2O) reference for the potassium ion titration and −12.2 ppm for the thallium ion binding study. These results indicate essentially complete channel formation (5, 8, 11). The potassium ion titrations were carried out by addition of dry

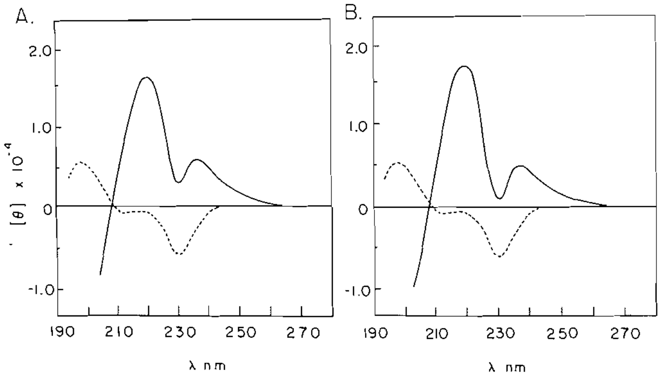

FIG. 1. Circular dichroism spectra in H_2O of 1-^{13}C enriched Trp^{13} Gramicidin A packaged into L-α-lysolecithin. These preparations were used for the potassium ion binding studies (*A*) and for the thallium ion binding studies (*B*). Both spectra indicate that the peptide has been properly incorporated as the channel state. When gramicidin has been completely packaged into the lipid in the proper ion-interacting conformation, a spectra, such as the one represented by the solid curve, is obtained. The dashed curves are due to a lysolecithin – Gramicidin A associated state which has insignificant interaction with cations. Conversion from the lipid-associated state to incorporation as the channel state is achieved by heating for 20 h at 70°C.

KCl (J. T. Baker Chemical Co., Phillipsburg, NJ, analytically certified ULTREX Lot 307081) to a fixed volume of sample in the nmr tube. Thallium acetate (Alfa Products, MA, Lot No. 031177) was added from a 200 m*M* stock solution up to 7 m*M* TlAc. Above this concentration the increments were greater and TlAc could be added dry.

Both heating of Gramicidin A with L-α-lysolecithin to form lipid bilayers (12, 13) and carbon-13 nmr observation of the enriched carbonyl carbon are carried out at 70°C. It is necessary, therefore, to be assured of sample stability during these extended periods of heating. Thin layer chromatography (tlc) using chloroform/methanol/water (65:25:4) and carbon-13 nmr were used to demonstrate the purity of the lipid after prolonged heating at 70°C. These methods, e.g., tlc, using chloroform/methanol/acetic acid (85:15:3), as well as circular dichroism, were utilized to demonstrate the absence of detectable Gramicidin A breakdown. In all, some nine samples have been successfully titrated at 70°C; a tenth effort using sodium ion was not successful due to growth of a thermophilic organism. Thallium ion, of course, is a toxic substance and care should be taken to avoid contact with the skin and to avoid inhalation of the dry powder.

Nuclear magnetic resonance

The (1-^{13}C)Trp^{13}-GA and the mal(1-^{13}C)Trp^{11}-GA carbonyl carbon chemical shifts were measured on a JEOL FX-100 nuclear magnetic resonance spectrometer equipped with a 10 mm multinuclear probe operating at 25 MHz under conditions of complete proton noise decoupling and internal deuterium lock. The spectra were accumulated at 70°C in order to facilitate observation of the broad signal of the enriched peptide carbonyl. Spectra of the lysolecithin packaged channel are given in Fig. 2 where the Trp^{13} carbonyl carbon is seen as the broad resonance just upfield from the sharp signal of the lysolecithin carbonyl carbon at 174 ppm.

When incorporated into lysolecithin–Gramicidin bilayers, the chemical shifts of the enriched Trp^{11} and Trp^{13} labels in the presence of negligible ion concentration (0.5 m*M* NaCl) at 70°C are 170.23 and 170.16 ppm, respectively, from external hexamethyldisiloxane. (In practice measurement is from the —$(CH_2)_n$— resonance of the fatty acid which is found to be 29.1 ppm from external hexamethyldisiloxane.) These values were obtained from the spectra of three different incorporations of the (1-^{13}C)Trp^{11}-Gramicidin and five incorporations with eight separate nmr samples of the (1-^{13}C)Trp^{13}-Gramicidin and are reported with a standard deviation of ±0.06 ppm. This provides a measure of the precision with which the enriched carbonyl

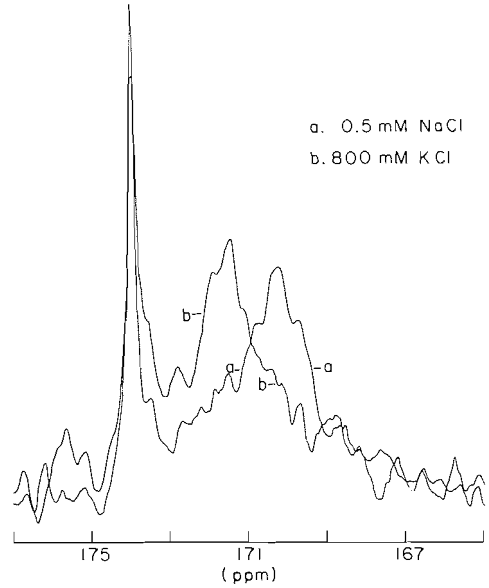

FIG. 2. Carbon-13 nuclear magnetic resonance spectra at 25 MHz and 70°C of the carbonyl region of lysolecithin packaged 1-^{13}C enriched Trp^{13} Gramicidin A. The broad upfield resonance is from the enriched peptide label and the sharp resonance at 174 ppm is from the lipid carbonyl. Two spectra are overlaid — one without (curve *a*) and one with (curve *b*) potassium ion present — showing the change in the chemical shift of the Trp^{13} carbonyl carbon upon addition of 800 m*M* KCl.

carbon chemical shift values may be determined in this system. Upon addition of ion, the change in chemical shift of the peptide carbonyl was determined by overlaying the lineshapes of the Trp^{13} or Trp^{11} signals in the presence of potassium or thallium ion with a reference spectrum taken without any potassium or thallium ion present. With this overlay the difference between the sharp lipid carbonyl signals (which did not exhibit a change in chemical shift upon addition of ion) becomes the ion-induced chemical shift.

Data analysis

From the dependence of the ^{13}C chemical shift on the KCl and TlAc concentrations, binding constants and the values of the chemical shifts due to site occupancy may be derived by fitting the titration curves according to the correct occupancy model. It has been demonstrated that there are two sites related by two-fold symmetry (refs. 9, 14 and see Discussion below). The method of analysis for studying ion nmr data has been already discussed in detail elsewhere (4–6, 8). Slight modification in procedure is required for analyzing the ^{13}C chemical shifts. The procedure is given for the two-site case. Taking δ_f to be the observed ^{13}C chemical shift in the absence of ion binding, δ_t to be the chemical shift when one ion is in the channel and exchanging rapidly between the two sites, and δ_w to be the chemical shift at the high ion concentration limit, i.e., the chemical shift when the second site is also occupied, the observed chemical shift, δ, will be given by

$$[1] \quad \delta = \frac{C_0}{C_T}\delta_f + \frac{C_1}{C_T}\delta_t + \frac{C_2}{C_T}\delta_w$$

where, C_0, C_1 and C_2 are, respectively, the concentrations of empty, singly occupied, and doubly occupied channel molecules. If only one site is occupied, the two carbons experience the same chemical shift due to rapid exchange (i.e. xo ⇄ ox). The concentration ratios appearing in this equation are dependent on the binding constants K_b^t and K_b^w (see eqs. A3, A4, A5, and A6 in ref. 4). Measuring only the *change* in the ^{13}C chemical shift on addition of ion gives a $\delta_f = 0$. Then, eq. [1] reduces to

$$[2] \quad \delta = \frac{C_1}{C_T}\delta_t + \frac{C_2}{C_T}\delta_w$$

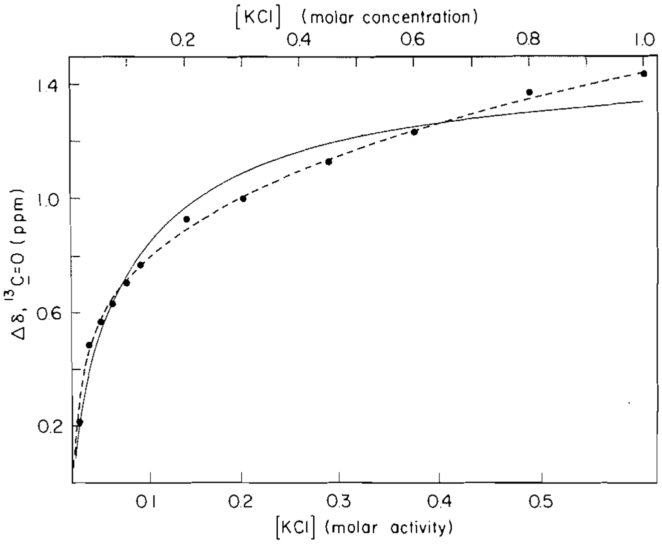

FIG. 3. Experimental data for the enriched carbonyl carbon chemical shift dependence on potassium ion concentration for the Trp[13] carbonyl carbon of the gramicidin channel. The dashed curve is calculated for a two site model which gives very good agreement to the observed shifts. The solid curve is the best fit which may be obtained assuming a single binding site in the channel which can be seen to correspond very poorly to the experimental data.

where C_T is the total channel concentration.

The activity coefficients were obtained for KCl at 70°C for the concentration range of 5 mM to 1 M by taking into account the experimental activities at 25°C for various concentrations (Table 12-2-2A of ref. 15), the temperature dependence of activity coefficient (eq. 12-4-3 of ref. 15) and the low concentration dependence (eq. 12-1-9 and Table 12-1-3A of ref. 15). The activity coefficients so obtained were found to be reproduced by the following equation:

$$[3] \quad \log (\text{activity coeff.}) = -\frac{0.57\sqrt{m}}{1 + 1.32\sqrt{m}} + 0.021\, m$$

where m is the molality.

The fitting procedure employed to obtain binding constants is as follows: the concentrations of the various species, such as ion-free channel, free ions, singly- and doubly-bound channel are dependent on the binding constants, K_b^t and K_b^w, and the total ion and channel concentrations. For the two-site model these dependences are given by eqs. A1 to A8 of ref. 4. An iterative procedure (4) is employed for solving these equations to obtain the complex concentrations from the binding constants and the total channel and ion concentrations. The curve fitting procedure consisted of adjusting the binding constants, K_b^t and K_b^w, and the chemical shifts, δ_t and δ_w of eq. [2], so as to minimize the sum of squares of differences between observed and calculated chemical shifts for various total ion concentrations. The binding constants were systematically varied in a step-wise manner; for a given pair of values of the binding constants, the chemical shifts, δ_t and δ_w, were optimized using a quasi-Newton algorithm to minimize the residual. This procedure was repeated for various values of K_b^t and K_b^w in a wide region in the K_b^t–K_b^w lattice until the lowest residual was obtained.

Results

Potassium ion binding

Non-linear least squares analysis of the observed variation of the ^{13}C chemical shift, δ, with KCl activity, using eq. [2], yielded the following values for the various constants: $K_b^t = 28/M$, $K_b^w = 2.4/M$, $\delta_t = 0.75$ ppm and $\delta_w = 2.48$ ppm. Figure 3 gives the experimental points and the theoretically calculated curve (dashed line). The agreement is very good.

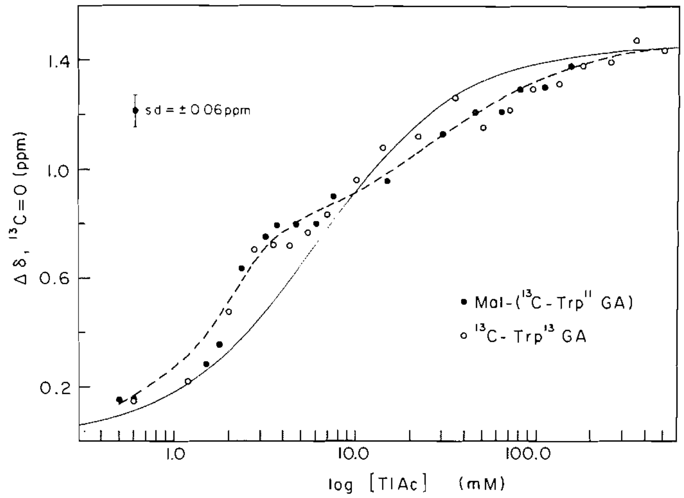

FIG. 4. Carbon-13 chemical shift dependence on thallium ion concentration for (1-^{13}C)Trp[11] mal-GA (●) and (1-^{13}C)Trp[13]-GA (○) carbonyl carbons of the gramicidin channel. The data are plotted as a function of log TlAc concentration so that the low concentration range and the two sigmoid curves — delineating the two channel binding sites — may be clearly seen. The standard deviation (sd) for determining chemical shift as discussed in the Experimental is given as a bar denoting ±0.06 ppm. The dashed curve represents a calculated fit to the data for a two site channel. The solid curve is that required for single site binding (K_b = 100/M) with a maximal chemical shift of about 1.5 ppm. For this curve to be reasonable the error near 3 mM TlAc would have to be as great as 0.3 ppm which is five times greater than the standard deviation for the measurements. The greater curvature of the experimental data at low ion concentration is considered in the Discussion.

That it is necessary to invoke multiple occupancy in the channel in order to successfully analyze these data, may best be demonstrated by a further fitting of the data assuming $K_b^w = 0$, i.e. by disallowing a second ion to bind a singly occupied channel. The best fit obtained holding $K_b^w = 0$, i.e. for single occupancy only, is shown in Fig. 3 as the solid curve. The optimum values for this fitting are $K_b^t = 6.6\ M^{-1}$ and $\delta_t = 1.51$ ppm. It is readily apparent that the agreement with experimental data is not satisfactory for a situation limited to single occupancy. The observed data, showing a steep rise at low ion concentration, i.e. up to 150 mM, and a slow increase continuing to 1000 mM, is inconsistent with a single occupancy model. This provides evidence for two binding sites in the channel with both of them being occupied to an appreciable fraction at high ion concentrations. The presence of two separate binding processes is even more apparent for thallium ion (see below).

Thallium ion binding

The thallium ion induced carbonyl carbon chemical shifts for (1-^{13}C)Trp[13]-GA and for mal(1-^{13}C)Trp[11]-GA are plotted in Fig. 4 as a function of log [TlAc]. The two sets of data are plotted together to show clearly the close similarity between data obtained on both GA and mal-GA and to show the extent of scatter within a given titration. Two sigmoid curves are clearly seen within the two sets of data and within the scatter for each. One sigmoid curve is centered between 1.5 mM and 2 mM TlAc and the second near 20 mM TlAc. While there is more scatter in these latter data, there could be a suggestion that the second binding process is slightly weaker for mal-GA than for GA as was found for sodium ion (5, 8). What is apparent when

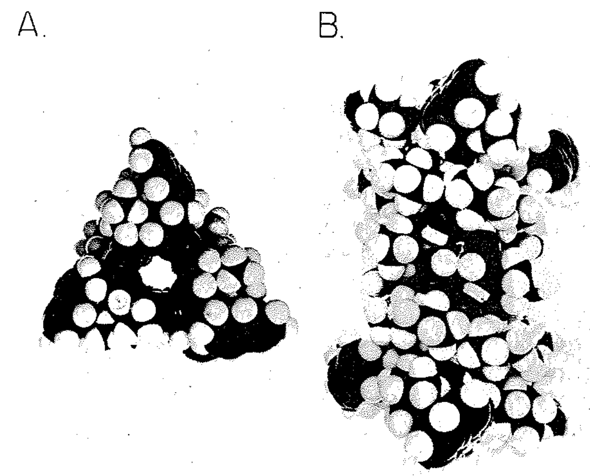

FIG. 5. Molecular structure of the Gramicidin A transmembrane channel. *A*. Space filling model in channel view showing peptide carbonyl oxygens of residues 15, 13, and 11 directed outward into solution. *B*. Channel side view showing two molecules associated head-to-head (formyl end to formyl end) with the formyl hydrogens in contact at center. Reproduced with permission from ref. 21.

WIRE MODEL AND ION BINDING SITES OF THE GRAMICIDIN A TRANSMEMBRANE CHANNEL

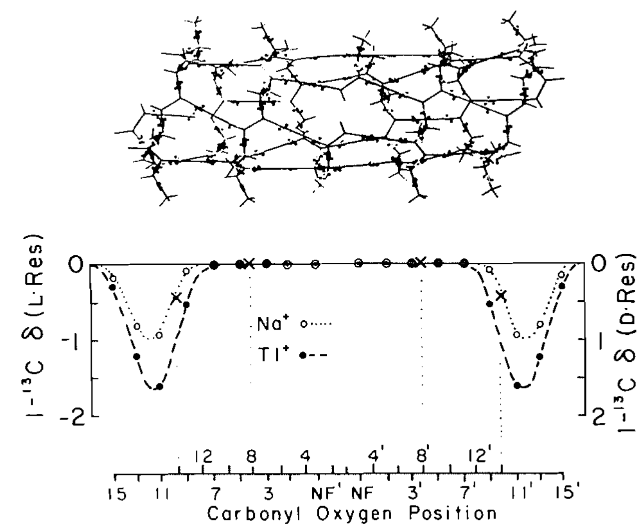

FIG. 6. Above: Wire model of the Gramicidin transmembrane channel displayed with the two formyl moieties at center as in Fig. 5*B*. Below: Plotted with respect to the carbonyls of the wire model above are the ion induced carbonyl carbon chemical shifts for thallium ion and for sodium ion. The observed chemical shift for Tl^+ is larger than for Na^+ because at the ion concentrations used there was greater occupancy for Tl^+ than Na^+. Plotted on the left hand ordinate are the downfield chemical shifts exhibited by the L·residue carbonyl carbons showing two well-defined and localized binding sites with two-fold symmetry. The chemical shifts due to the D·Val^8 and D·Leu^{14} residues (given as ×'s) are plotted on the right hand ordinate. The shift exhibited by the D·Leu^{14} residue but not by the D·Val^8 residue demonstrates that the structure is that of a left-handed helix. Reproduced with permission from ref. 3.

following the channel itself is that there are two binding processes, one with a binding constant of the order of $10^3/M$ or greater and a second which is weaker by an order of magnitude or more. The dashed curve in Fig. 4 was calculated using eq. [2] with $K_b^t = 5000/M$, $K_b^w = 70/M$, $\delta_t = 0.8$ ppm and $\delta_w = 1.4$ ppm. An intriguing feature of the data is the sharpness of curvature coming into the first sigmoid near 1 m*M* TlAc which cannot be fit even with a tight binding constant of $5000/M$. Additional experiments have been run to check this sharpness and indeed it is very reproducible. This feature is discussed below in terms of an ion induced disaggregation of channels giving rise to a positive cooperativity.

Discussion

While there have been a number of structural motifs suggested for the Gramicidin A channel (14–18), it is now well-established, both in planar bilayers (19) and in suspensions of channels (9, 20), that the structure is as proposed in 1971 (14) and as given in Fig. 5. This is a head-to-head (formyl end to formyl end) hydrogen bonded dimer of two left-handed, single stranded — $\beta_{3.3}^{6.3}$ — helices (21). Ion-induced carbonyl carbon chemical shifts observed in a set of single residue (1-^{13}C) enriched syntheses (10) are seen in Fig. 6. In the upper part of the figure is a wire model, including backbone atoms and β-carbons of the channel structure, and plotted below it are the ion-induced carbonyl carbon chemical shifts which demonstrate two ion binding sites related by a two-fold symmetry axis and separated by about 22 Å. This two-fold symmetry is responsible for the symmetric current/voltage curves exhibited by single channels (22) which requires that the free energy profile for ion movement through the channel be symmetric about the midpoint (3). Thus the activity of the malonyl dimer (14, 23) in which the formyl moiety is removed from each of two GA molecules and the two molecules are covalently bridged by the —CO—CH_2—CO— moiety in itself, is demonstration of the structure in Fig. 5. The issue is now one of ionic mechanism, and the already demonstrated location of ion binding sites is an important step in determining mechanism. As shown in this report, the ion-induced carbonyl carbon chemical shifts of a carbonyl at the binding site can also be used to estimate the magnitude of binding constants and to determine the conditions for single and double ion occupancy.

An estimate of the expected magnitude of carbonyl carbon chemical shift resulting from monovalent cation binding can be obtained from a carbon-13 nmr study of potassium ion binding to enniatin B (24). The crystal structure of the enniatin B–K^+ complex has been determined; the direct binding of carbonyls with K^+ has been demonstrated; and the relative orientation of K^+ and carbonyls is known (25). In analogy to Gramicidin A, enniatin B has an alternating L–D sequence; being a cyclic hexapeptide it has six residues in a cycle. This is analogous to the GA channel with 6.3 residues/turn. Accordingly monovalent cation binding would be very similar. The enniatin B–K^+ complex may be considered to be the cyclic conformational correlate of the cation containing Gramicidin A channel; and the chemical shifts exhibited by enniatin B carbonyls on binding K^+ of 1.5 to 2 ppm (24) can provide an estimate of the expected carbonyl carbon chemical shift on complete occupancy of a GA channel binding site. Since the magnitude of the observed carbonyl carbon chemical shift is proportional to the ion concentration and the resonance line width does not vary significantly through the titration, the sites are under conditions of rapid exchange. This being the case, one ion in the channel would be equivalent to half occupancy of the two structurally equivalent sites and the expected chemical shift for one ion in the channel would be 0.7 to 1 ppm. Two ions in the channel, one at each site, would be expected to result in a chemical shift of 1.5 to 2 ppm. As is apparent in the Results section (see Fig. 3 and the corresponding analysis), δ_t for potassium is 0.75 ppm. The chemical shift due to complete occupancy, δ_w, is 2.48 ppm, i.e. close to the maximum expected for the enniatin B–K^+ study (24). For the thallium ion binding study the two binding processes are easily resolved and the obvious break in the titration curve near 0.8 ppm on the chemical shift axis and 4 m*M* on the ion concentration axis defines completion of the titration for entry of the first ion in the channel. Above this concentration double occupancy is occurring. Thus it is clear that, at ion concentrations where single channel conductances are commonly measured in the planar bilayer studies, substantial double ion occupancy would be occurring at 70°C.

Since conductance studies are normally carried out at lower temperatures, it is useful to have some understanding as to the temperature dependence of the ion binding constants. This has been done by determining ion binding to the malonyl GA channel at 30°C, 45°C, 60°C, and 75°C by means of sodium-23 nmr longitudinal relaxation rate studies. Over this temperature range ΔH and ΔS are found to be quite small and the binding constant for the tight site (single ion occupancy) changes by less than a factor of three (Urry, Trapane, and Venkatachalam, to be published). It has also been found, using potassium-39 nmr longitudinal relaxation rate studies, that the binding constant for the weak site at 30°C is approximately $3.5/M$ which is essentially the same as obtained from analysis of the data in Fig. 3 (i.e. $2.4/M$). Thus it is not unreasonable to consider the data of Figs. 3 and 4 to be relevant to conductance by the Gramicidin transmembrane channel as measured by planar bilayer studies and to be similar to data obtained at 25 to 30°C.

Before considering estimates of binding constants from planar bilayer studies, it is useful to note an additional feature that is apparent in the Tl^+ titration of Fig. 4 when the tight binding constant is of the order of $10^3/M$. The sharpness of the curvature of the titration curve between 0.6 and 2 m*M* TlAc suggests a positive cooperativity, that is, a process whereby the binding constant increases with increasing concentration. Such an effect could result from an ion induced structural change from a low binding state to a higher binding state. It is relevant to note that the channels incorporated into lysolecithin bilayers, as described in the Experimental section, results in particles being seen in freeze fracture electron microscopy studies indicative of clusturing of channels, possibly up to a hexameric aggregate (26). Thus the early ion binding could be weak until sufficient binding occurs to result in disaggregation at which point the tight binding site is formed.

The working hypothesis is that ion binding is weak when the channel is aggregated, that initial ion binding causes disaggregation and that ion binding to the dispersed channel is stronger. Freeze fracture electron microscopy studies are underway to examine the incorporated state of the channel as a function of ion concentration. Preliminary results indicate an absence of observable aggregates when thallium ion concentration is 10% greater than the channel concentration (I. Pasquali-Ronchetti, L. Masotti, and D. W. Urry, unpublished data).

On the basis of the preceding several paragraphs, the binding constants obtained in this study may now be compared to previous studies of channels in suspensions and to studies involving fitting of conductances observed in planar bilayer studies. The estimates obtained here for the binding constants for potassium ion binding to the Gramicidin A channel are $28/M$ for the tight site (single ion occupancy) and $2.4/M$ for the weak site (double ion occupancy). These values may be compared with those obtained from conductance studies by Eisenman *et al.* (27) of $40/M$ and $1.5/M$ and by Urban *et al.* (28) of $410/M$ and $0.7/M$, respectively for the tight and weak sites. More recent values of Eisenman and Sandblom give $12/M$ for the tight site (29). The correspondence with the data of Eisenman *et al.* is quite satisfactory.

While for thallium ion the apparent positive cooperativity must yet be properly analyzed, it is reasonable to consider values of $\sim 1000/M$ for the tight site. For this site Veatch and Durkin (30) report values of 500 to $1000/M$ using equilibrium dialysis with dimyristoyl phosphatidylcholine vesicles, and Hinton *et al.* (31, 32) report a value of $900/M$ using the same system as studied here but following binding by thallium-205 nmr chemical shift. Values derived from planar bilayer conductance have ranged from $500/M$ to $3600/M$ due to studies of Eisenman *et al.* (29, 33) and $9000/M$ due to Hladky *et al.* (34). Part of this variation could be due to the need to consider properly the positive cooperativity apparent in Fig. 4.

This paper is dedicated to Professor Camille Sandorfy on the occasion of his 65th birthday

MARIO MORIN, ANIKO E. FOTI, and DENNIS R. SALAHUB. Can. J. Chem. **63**, 1982 (1985).

LCAO local density calculations for ozone yield a ground state geometry in good agreement with experiment (R = 1.27 Å vs. 1.278 Å (exp.), θ = 117.5° vs. 116.8° (exp.)). A second local minimum is found about 45 kcal/mol higher for a cyclic geometry (R = 1.44 Å, θ = 60°). For S_3 the calculations predict a bent ground state (R = 2.00 Å, θ = 116°) with the cyclic geometry (R = 2.125 Å, θ = 58°) about 15 kcal/mol higher.

MARIO MORIN, ANIKO E. FOTI et DENNIS R. SALAHUB. Can. J. Chem. **63**, 1982 (1985).

Des résultats de calculs du type LCAO densité locale sont en bon accord avec l'expérience pour la géométrie de l'état fondamental de l'ozone (R = 1.27 Å vs. 1.278 Å (exp.); θ = 117.5° vs. 116.8° (exp.)). Un deuxième minimum local pour une géométrie cyclique (R = 1.44 Å, θ = 60°) est prédit à une énergie plus élevée d'environ 45 kcal/mol. Pour S_3 les calculs prédisent une géométrie ouverte (R = 2.00 Å, θ = 116°) pour l'état fondamental avec la forme cyclique (R = 2.125 Å, θ = 58°) à peu près 15 kcal/mol plus haute.

Introduction

The ozone molecule has been the object of numerous experimental (1–6) and theoretical (7–13) studies. Because of its high biradical character (7, 9, 11, 12) it has become a classic example of a case where single determinantal Hartree–Fock theory is inadequate. In the usual wave function theory at least two determinants must be mixed to achieve a reasonable qualitative description. On the other hand, Xα (14–16) calculations, which should be viewed as approximate applications of density functional theory (17, 18), have yielded the correct singlet ground state and accurate values for the ionization potentials and many low-lying excitation energies (8, 13). These Xα calculations were performed with either the scattered-wave (16) or LCAO (Gaussian) (19, 20) version of the method and only the equilibrium geometry was considered. A direct optimization of the geometry was carried out by Laidlaw and Trsic (10) using the discrete variational (21, 22) Xα (Hartree–Fock–Slater) method. Their results were discouraging in that a closed geometry having a bond angle near 60° and involving six π electrons was predicted to lie lower in energy than the experimentally observed open form (θ = 117°) which involves four π electrons.

Ozone's third row congener thiozone is less well characterized. Although S_3 has been observed in sulfur vapour and liquid and its ionization potential is known (23) its structure has not been experimentally determined. Only a few electronic structure calculations have been performed for S_3. The Xα-SW method was applied (24) to the study of structural changes accompanying oxidation or reduction. Examination of the orbital energies and wave functions led to the suggestion that an open form with an angle of about 120° would be a reasonable choice for the ground state. Hartree–Fock calculations (25) using a double ζ basis set predict the closed form as the lowest energy conformer although the authors point out, by analogy with more accurate calculations for ozone, that correlation and polarization effects would likely reverse the order and place the open form lower. The DVM-Xα (HFS) calculations of Laidlaw and Trsic (10) also predict the closed form as the more stable conformer. However, as mentioned above, similar calculations for ozone yield erroneous results.

In this paper results of LCAO local density calculations for O_3 and S_3 are reported. The study was undertaken: (i) to determine whether the false energetic ordering of the closed and open forms of O_3 (and perhaps S_3) found in the DVM study (10) represents an intrinsic failure of local density functional theory or rather is due to inaccuracies in the particular method chosen to solve the local density equations; (ii) to complement our previous Xα-SW (8) and LCAO-Xα (13) studies of O_3 by optimizing the geometries of both open and closed forms; (iii) to complement our previous Xα-SW study of S_3 (24) with total energy results; (iv) to provide a further comparison (26–29) of Xα results with those obtained using a more accurate treatment of correlation in the underlying calculations on the homogeneous electron gas (30); and (v) to check for the possibility of broken-symmetry (antiferromagnetic) solutions (29) which might be suspected for the case of a singlet biradical.

Our calculations indicate that: (i) for both O_3 and S_3 the open form is more stable. This is in contrast to the published DVM results but agrees with a more recent study (31) using a transition state approach to the binding energy. The latter approach is thought to be more accurate; (ii) the calculated geometry of ozone is in good agreement with experiment; (iii) the rough geometry prediction for S_3 based on Xα-SW calculations (24) is borne out by the LCAO-Xα total energy results; (iv) Xα and VWN (30) potentials yield very similar results for S_3; and (v) the symmetry-adapted (C_{2v}) solutions are stable with respect to broken-symmetry (C_s) configurations of biradical (antiferromagnetic) character.

Computational details

The calculations were performed with the LCAO-Xα code of Dunlap *et al.* (20) slightly modified to permit the use of different approximations for the exchange-correlation potential and energy. Those employed here are Xα with the value of α taken from Schwarz's compilation (32) and the correlated potential of Vosko, Wilk, and Nusair (30). The latter represents an accurate interpolation–extrapolation of Monte-Carlo calculations (33) on the correlated homogeneous electron gas which are thought to be nearly exact. Hence, if the local density equations are solved to high accuracy using the VWN potential, any remaining errors should be ascribed to non-local effects.

The ($9s/5p$) orbital basis set for O was taken from Huzinaga

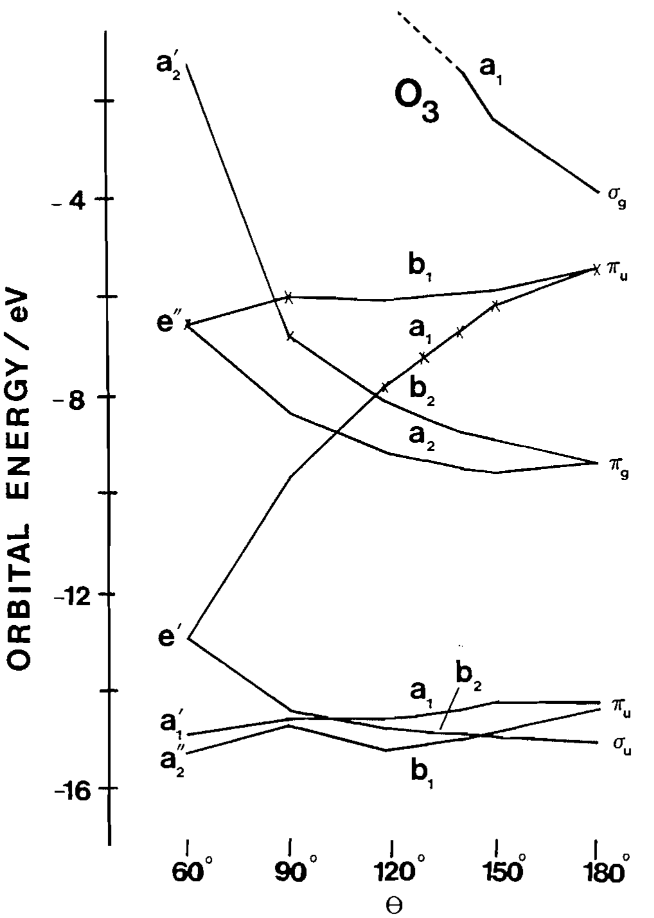

FIG. 1. LCAO-LD (VWN) Walsh Diagram (orbital energy vs. bond angle, θ) for R = 1.27 Å. The HOMO is marked by an ×. For θ = 90° double occupation of either the uppermost b_2 or b_1 level led to violation of Fermi statistics so the values shown are for single occupation of each of these levels. The slight lack of degeneracy for the lower π_u level at θ = 180° arises since the calculations were performed with C_{2v} symmetry constraints and the exchange fitting grid is not exactly cylindrically symmetric.

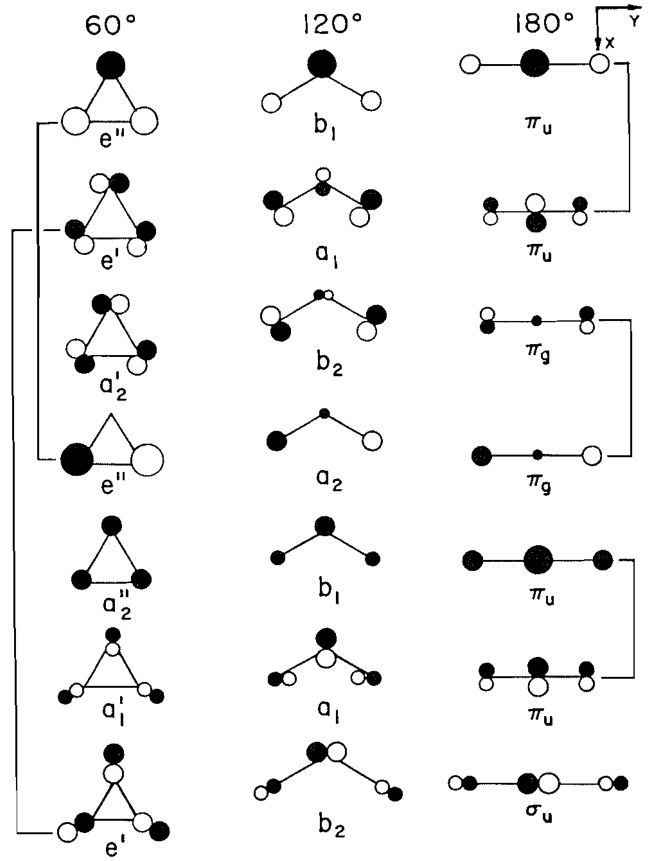

FIG. 2. Schematic diagram for the one-electron orbital wave functions of O_3 and S_3 for θ = 60, 120, and 180°. The orbitals are not shown in energetic order for the 60° column but rather are aligned with the C_{2v} orbital to which they correspond. The orbital energies may be found in Figs. 1 and 4. For degenerate orbitals both symmetry components of the orbital are given. The π orbitals are designated by circles. Black indicates positive and white negative values of wave function.

(34) and either augmented or not with a set of d functions of exponent 0.8. For S we have used the Veillard (35) ($12s/9p$) basis again either augmented or not with d polarization functions (exponent 0.8). Some tests were made for S with a slightly more diffuse d function (exponent 0.6). While this led to a slight lowering of the total energy (~6 kcal/mol for each point considered) the equilibrium geometry was negligibly affected. These basis sets, including the polarization functions, are very similar to those used by Huzinaga and Yoshimine (36) for calculations on SO_2. The significance of the d functions will be addressed later.

Auxiliary basis sets to fit the charge density and the exchange-correlation potential and energy were constructed as suggested by Dunlap *et al.* (20) including the use of bond-centered s functions (exponents 1.0 and 0.25). Tests for the cyclic form of ozone, in which zero, two or three bond-centered fitting functions were employed showed their effect to be negligible (<0.2 kcal/mol).

Results and discussion

Ozone

Two regions of the potential energy surface are of particular interest. The ground state equilibrium geometry has a bond length of 1.278 Å and an angle of 116.8° (1). The electronic configuration ($\ldots 1b_1^2\, 2b_2^2\, 3a_1^2\, 1a_2^2\, 3b_2^2\, 4a_1^2$) involves four π ($b_1$ and a_2) electrons. A second local minimum exists in the region of 60° and its configuration ($3a_1^2\, 1b_1^2\, 2b_2^2 4a_1^2\, 1a_2^2\, 2b_1^2$) has six π electrons. The rationale for the configuration change may be readily gleaned from the Walsh diagram shown in Fig. 1 and sketches of the MOs (Fig. 2). Briefly stated, if one starts with the equilateral form, then both the bonding (b_1 (a_2'' under D_{3h})) and antibonding (a_2 and b_1 (e'' under D_{3h})) π orbitals are occupied. The anti-bonding (b_2 (a_2' under D_{3h})) σ level is empty. Opening the angle stabilizes the σ level (relieving the 1–3 antibonding interaction) and destabilizes the b_1 component of the upper π level which is 1–3 bonding, leading to the configuration change. While this qualitative aspect of ozone's electronic structure seems straightforward enough, the question of the relative stabilities of the two forms is a quantitative one and rather delicate. It can serve as a stringent test of a quantum chemical method.

The salient results of our calculations using the VWN correlated potential are gathered in Table 1. We first note that with the polarized basis set agreement with the experimental geometry is excellent. The closed form is predicted to lie about 46 kcal/mol above the ground state. This may be compared with the value of 28 kcal/mol derived from the configuration interaction calculations of Hay and Dunning (9). After the

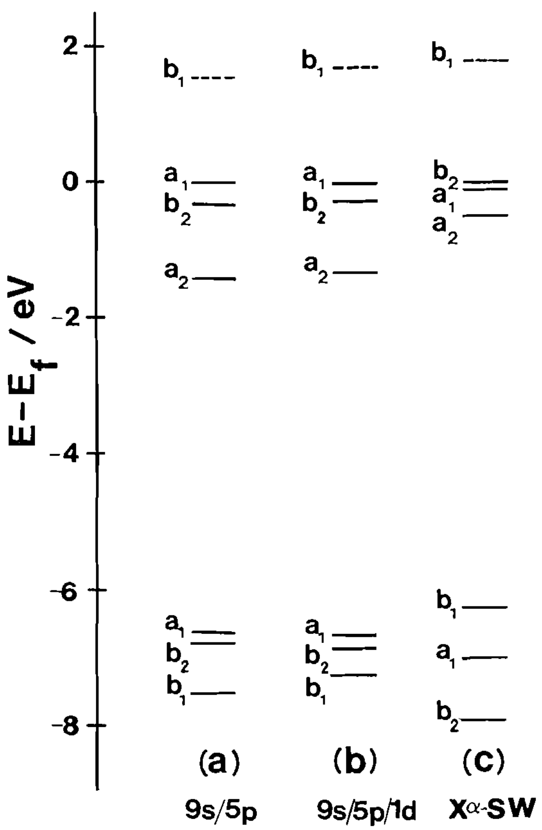

FIG. 3. Orbital energies for ozone relative to that of the HOMO (E_f) for: (a) the (9s/5p) basis, VWN potential, R = 1.27 Å, θ = 117.5°; (b) the (9s/5p/1d) basis, VWN potential, R = 1.27 Å, θ = 117.5°; (c) the Xα-SW results read from Fig. 1 of ref. 8. R = 1.278 Å, θ = 116.8°. The values of E_f are (a) −6.4 eV, (b) −6.1 eV, and (c) −8.1 eV.

original version of this paper was submitted, results were reported of an extensive CI study including ≈600 000 configurations by the Møller-Plesset barycenter method. Feng *et al.* (41) find the closed form 38 kcal/mol above the open form. In their transition state DVM calculations, Laidlaw and Trsic (31) find an open–closed separation of 21 kcal/mol, thus reversing their previous conclusion (10) about the energetic order of the two forms within the HFS(Xα) model. While the agreement between the two techniques (DVM and LCAO (Gaussian)) of solving the Xα equations is improved by the new calculations, there remains a discrepancy of about 25 kcal/mol. To our knowledge there is no experimental information on the energy position or the geometry of the closed form.

Consistent with the experience from *ab initio* calculations (9) we find that the (9s/5p) basis leads to significant errors in the bond lengths. The polarized basis yields shorter bonds by 0.08 Å and 0.06 Å for the open and closed geometries, respectively. The energy lowerings (including the effects of geometry relaxation) are nearly identical for the open and closed forms. Hence, the open–closed energy difference is correctly predicted by the *sp* basis even though the *sp* geometries are seriously in error. The effect of the *d* functions on the orbital energies at the equilibrium geometry is shown in Fig. 3. The HOMO's have been aligned, which involves a shift of 0.3 eV. Once this is done the positions of the levels with and without polarization functions agree to within 0.25 eV, an adequate precision for spectral assignments (13). However, for quantitative results, it is clear that the widely used (9s/5p) basis should be augmented with polarization functions.

We also show in Fig. 3 the orbital eigenvalues from Xα-SW calculations (8). Comparison of these results, which involve the muffin-tin approximation, with those of the LCAO method will serve to quantify the errors in the former. We note first, as has been previously pointed out (13) that the uppermost a_1 and b_2 levels are inverted, the LCAO results following the experimental order. However, since these levels lie very close to each other this should not be viewed as a serious condemnation of the SW results. In addition the a_2 π level is significantly more stable in the LCAO results. The same is true of the lower-lying b_1 π level, the differential shift being about 1 eV. The relative positions of the lower-lying a_1 and b_2 σ levels are also significantly different in the two methods. While the general features of the ozone electronic structure are reasonably given by the SW approach and the ionization potentials and several excitation energies involving the upper three occupied orbitals are of a useful accuracy (8), the comparison provided by Fig. 3 should make it clear that interpretations based on finer details of the SW results for a molecule such as this should be viewed with caution.

Thiozone

Not surprisingly the Walsh diagram for S_3 (Fig. 4) has a similar structure to that of O_3. There is some noticeable difference in the behaviour of the unoccupied a_1 level in the region near the linear geometry. For S_3 it proved impossible to satisfy the Fermi statistics for this geometry, the σ_g and π_u levels being nearly degenerate; whereas for O_3 the σ_g level is about 0.8 eV above π_u. Figure 4 is also quite similar to that previously generated by the Xα-SW method (Fig. 2 of ref. 24). Again the detailed behaviour of the unoccupied a_1 level differs between

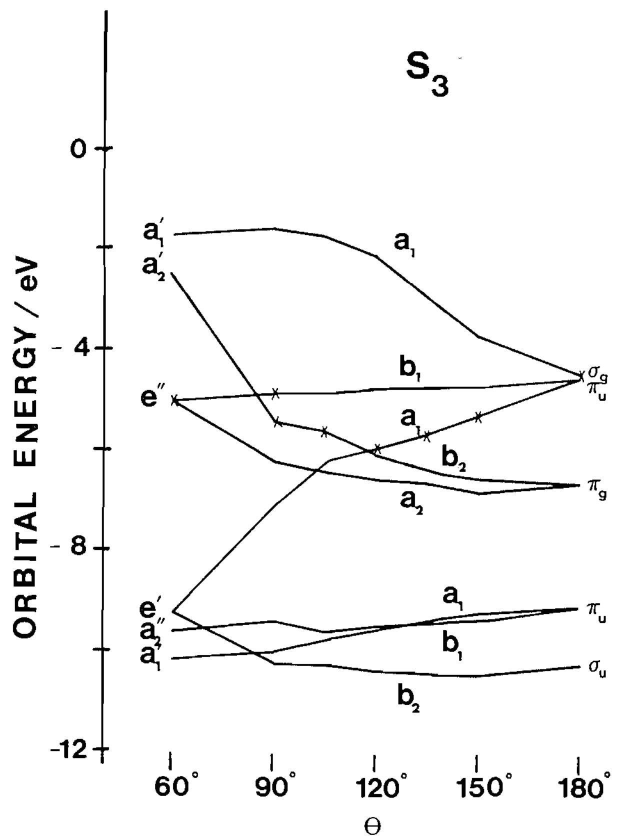

FIG. 4. LCAO-Xα Walsh diagram (orbital energy vs. bond angle, θ) for S_3 calculated for R = 1.99 Å. The HOMO is marked by an ×. For θ = 90° double occupation of either the uppermost b_2 or b_1 level led to violation of Fermi statistics so the values shown are for single occupation of each of these levels. For θ = 180° the Fermi statistics are not satisfied, π_u is empty — see text.

the two methods. This may be due to muffin-tin errors, the lack of d waves in the SW calculation and/or an inadequacy of the LCAO basis set for this higher-lying orbital. Since the orbital is empty for the physically interesting geometries we will not dwell on the matter.

The geometry and total energy results are summarized in Table 2. We first point out that the Xα and VWN potentials yield nearly identical geometries and energy differences. As was the case for ozone, the ground state of thiozone is found to be the open form, with a bond angle of 116°. The closed form lies about 15 kcal/mol higher. This may be compared with the value 17 kcal/mol from the very recent CI calculations of Feng *et al.* (41) and with the DVM transition state (31) value of 11 kcal/mol. Once again the d polarization functions have a large effect. They account for a shrinking of the bond length of about a tenth of an Ångstrom for all cases. The effect of polarization functions on the relative energies of the closed and open forms is considerably more marked for S_3 than was the case for O_3; the open–closed separation increases by about 5 kcal/mol when d functions are added to the basis.

The effect of the d functions and the choice of exchange-correlation potential on the orbital energies is shown in Fig. 5. After a uniform shift of 0.6 eV the (relative) Xα and VWN eigenvalues are practically identical. The differential shifts due to the d functions are again quite small, the largest being about 0.25 eV.

Comparison with the SW results follows similar lines as for ozone. The muffin-tin calculation correctly interprets the general features; however once again the π levels are destabilized relative to the LCAO results and there is a significant change in the spacing of the lower lying σ levels.

Symmetry breaking

Ab initio calculations (7, 9–12) have shown that ozone has a high biradical character. Within the Generalized Valence Bond (GVB) approach (7) this can be interpreted in terms of partially localized orbitals which result from strong "left–right" correlation. Proper space- and spin-symmetry adapted many electron wave functions are then constructed from these broken-symmetry orbitals. The simplest reasonable wave function consists of two determinants, the first having an up-spin π electron localized primarily on one terminal atom and a down-spin π electron localized on the other. The second determinant is the mirror image of the first. A somewhat analogous situation arises in the antiferromagnetic transition metal dimers (29) and here it has been found that localization of the Local Spin Density (LSD) orbitals is an important aspect of the calculations.

We have therefore examined the possibility of symmetry-breaking for O_3 and S_3. Spin-polarized calculations were started by arranging the exchange-correlation fitting coefficients to be fully polarized in an antiferromagnetic manner and imposing C_s symmetry constraints. For both molecules the

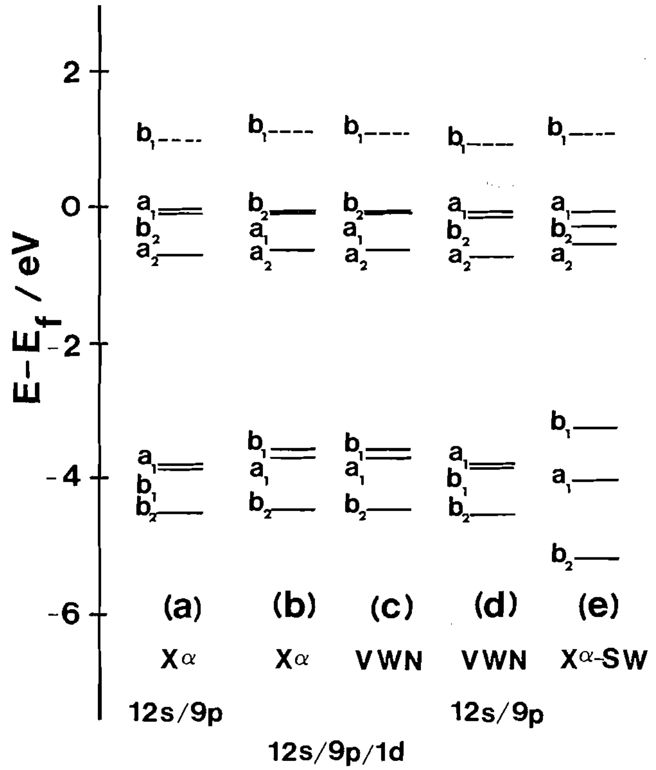

FIG. 5. Orbital energies for thiozone relative to that of the HOMO (E_F) for (*a*) the (12*s*/9*p*) basis, Xα potential, R = 2.11 Å, θ = 116°; (*b*) the (12*s*/9*p*/1*d*) basis, Xα potential, R = 1.99 Å, θ = 116°; (*c*) the (12*s*/9*p*/1*d*) basis, VWN potential, R = 2.11 Å, θ = 116°; (*d*) the (12*s*/9*p*) basis, VWN potential, R = 2.00 Å, θ = 116°; (*e*) the Xα-SW overlapping spheres results from ref. 24, R = 1.98 Å, θ = 120°. The values of E_f are (*a*) −6.0 eV, (*b*) −5.99 eV, (*c*) −6.60 eV, (*d*) −6.60 eV, (*e*) −6.60 eV.

calculations converged back to the fully symmetry-adapted (C_{2v}) situation. We also performed similar tests for bond angles increased to as much as 150° which should favour localization. In all cases fully delocalized orbitals resulted. The situation is somewhat analogous to that found for H_2 (37), Na_2 (38), or Cu_2 (39) where LSD calculations yield delocalized orbitals in the region of the equilibrium geometry. The orbital localization which is necessary for correct dissociation only occurs at much longer R. GVB orbitals for H_2 (40) are already partially localized at the equilibrium distance and the situation would undoubtedly be similar for Na_2 or Cu_2. In all of these cases the local density approach yields very satisfactory values of R_e and ω_e.[1]

Concluding remarks

Contrary to the impression which may have been created by ref. 10 the present results for ozone show that local density functional theory is capable of furnishing accurate geometrical information for molecules of this type. The ozone results also allow us to state with confidence that thiozone is bent with a bond angle of about 116° and an SS distance of about 2.00 Å.

Acknowledgements

We are grateful to Professor W. G. Laidlaw for several useful discussions and for communicating results prior to publication. Dr. N. A. Baykara's advice and help with the computations is most appreciated as is financial support from the Natural Sciences and Engineering Research Council of Canada and the Ministère de l'Education du Québec. Computing services were provided by the Centre de Calcul de l'Université de Montréal.

Ab initio studies on structures and proton affinities of fluoromethanols

F. GREIN

Department of Chemistry, University of New Brunswick, Fredericton, N.B., Canada E3B 6E2

Received August 13, 1984

This paper is dedicated to Professor Camille Sandorfy on the occasion of his 65th birthday

F. GREIN. Can. J. Chem. **63**, 1988 (1985).

Using gradient optimization techniques with 4-31G basis sets, the geometries of methanol, the three fluoromethanols, and their protonated species were optimized. Protonation on oxygen and fluorine was considered. The calculated proton affinities (PA) in kcal/mol are 181.0/178.1 for CH_2FOH, 162.3/162.6 for CHF_2OH, and 148.0/142.5 for CF_3OH, the first number for O- and the second for F-protonation.

F. GREIN. Can. J. Chem. **63**, 1988 (1985).

Utilisant des techniques d'optimisation des gradients avec des ensembles de base 4-31G, on a optimisé les géométries du méthanol, les trois fluorométhanols ainsi que celles de leurs espèces protonées. On a considéré la protonation de l'oxygène ainsi que celle du fluor. Les affinités pour le proton (AP), calculées en kcal/mol, sont de 181,0/178,1 pour le CH_2FOH, de 162,3/162,6 pour le CHF_2OH et de 148,0/142,5 pour le CF_3OH. Les premières valeurs correspondent aux fluorométhanols non protonés sur le O tandis que les secondes correspondent aux protonations sur le fluor.

[Traduit par le journal]

Introduction

α-Fluoro alcohols are difficult to synthesize due to elimination of HF. Trifluoromethanol CF_3OH has recently been prepared by Klöter and Seppelt (1) at low temperature. It has a boiling point of −20°C, and decomposes to CF_2O and HF at room temperature. The protonated form of H_2FCOH has been reported by Olah and Mateescu (2). The structure was identified by nmr. Attempts to isolate the free alcohol failed due to the loss of HF. Protonated difluoromethanol, $HF_2COH—H^+$, has been identified by Clair and McMahon (3). It is known that the proton affinity (PA) of HF_2COH is smaller than that of water (4).

Preparations to obtain all protonated fluoromethanols and to measure their proton affinities by ion cyclotron resonance (ICR) spectroscopy techniques are under way (4), and some more information should be available soon.

In aiding the experimental work, the equilibrium structures of the three fluoromethanols and their protonated species have been calculated by quantum chemical *ab initio* methods, and their proton affinities predicted from the energy differences of the optimized structures.

Methods

All geometry optimizations (SCF gradient methods) were performed using the 4-31G basis set and modified versions of the HONDO5 (5) and an IBM version (6*a*) of the GAUSSIAN80 (6*b*) computer programs. Usually, geometries were first optimized by the STO-3G basis set, providing the starting geometry for the (more expensive) 4-31G optimizations. All geometry parameters, both distances and angles, were allowed to vary, although in some cases one angle had to be fixed, as will be outlined. Protonation both on oxygen and fluorine was considered.

Results

Methanol

The proton affinity of methanol was calculated by Del Bene *et al.* (7) to be 194.9 kcal/mol (185.8 kcal/mol if zero-point energy differences and perturbation estimates of the correlation energy are included), using a 6-31G** basis set for both the parent and the protonated species. The most recent experimental value of the PA is 182.2 ± 2 kcal/mol obtained by ICR spectroscopy (8). Del Bene *et al.* found a large increase of the C—O bond length upon protonation (from 1.400 to 1.511 Å), indicating a possible dissociation to $H_2O + CH_3^+$.

Although there is no need to repeat the geometry optimization of CH_3OH and its protonated species by the 4-31G basis set, it was found to be useful for comparisons. The optimized geometries are shown in structures **I** and **II**, and given in Tables 1 and 2. The energies including PA are found in Table 4. Comparison with the experimental geometry of methanol (9) shows bond distance deviations up to 0.02 Å which are considered to be acceptable. Due to the inclusion of polarization functions, the optimized CO distance of Del Bene *et al.* is too short. On the other hand, the CO length increases upon protonation by about the same amount (from 1.430 to 1.542 Å in this work). Our calculated proton affinity is 200.0 kcal/mol, about 5 kcal/mol higher than the 6-31G** value obtained by Del Bene *et al.* Therefore, 4-31G calculations on the more difficult fluoromethanols are considered to be a reasonable compromise between accuracy obtained and effort made. Due to the emphasis placed in this paper on proton affinities, other theoretical treatments of methanol only will be ignored.

IV

Monofluoromethanol

For this molecule and the following members of the series, protonation on both oxygen and fluorine is possible, and it would be difficult from qualitative arguments to predict the preferred protonation site. Therefore, both types of protonation have been included in the calculations. The neutral species of

F_3COH	−411.09844	−411.33418	−411.32552	148.0	142.5

fluoromethanol is described by structure **I**, the O-protonated species by structure **II**, and the F-protonated species by structure **III**. In structure **III**, YZCOH is nearly planar, with CZ and OH in *cis* positions. The optimized geometries are given in Tables 1 to 3, and the energies in Table 4.

One would assume neutral monofluoromethanol to have structure **I**, with O—H *trans* to C—F (C_s symmetry). However, it was found that a geometry with the dihedral angle of O—H 60.2° relative to C—F, starting from a *cis*-conformation, or O—H in staggered position between C—F and C—H, leads to a lower energy (−213.61221 vs. −213.60192 hartree), with an energy difference of 6.5 kcal/mol. This indicates less repulsion with (the more distant) fluorine than with a methyl hydrogen. An explanation based on the anomeric effect will be given later. The geometry parameters given in Table 1 are for the F/H staggered conformation. Optimization for structure **I**, imposing C_s symmetry, leads to slightly different bond lengths (R_{CO} = 1.398 Å, R_{OH} = 0.951 Å, R_{CF} = 1.386 Å, R_{CH} = 1.077 Å).

For O-protonation (Table 2), the C—O distance increases by 0.16 Å, whereas the C—F distance decreases by 0.06 Å. The C—H and O—H distances remain nearly unchanged. The F-protonated molecule is characterized by the very large C—F bond length of 2.275 Å, indicating the formation of the molecular complex $HF\cdots H_2COH^+$. Indeed, as will be shown later, the geometry of the complex is very close to the geometries of the individual components. The C—O distance shortens by 0.14 Å.

The calculated proton affinities are 181.0 and 178.1 kcal, for the O- and F-protonated species, respectively. They are remarkably close together. Protonation on oxygen is preferred, in agreement with the analysis of protonated monofluoromethanol

TABLE 5. Optimized 4-31G geometries and energies of (planar) $YZCOH^+$ cations, structure **IV**; distances in Å, angles in deg, energy E in hartree, ΔE in kcal/mol[a, b]

	Distance						
$YZCOH^+$	C—O	O—H	C—Y	C—Z	∠C—O—H	E	ΔE
H_2COH^+	1.246	0.967	1.072	1.075	124.6	−113.98129	17.2
$FHCOH^+$	1.235	0.973	1.289	1.071	126.6	−212.70217	18.8
F_2COH^+	1.232	0.973	1.270	1.282	127.2	−311.40526	20.7

[a] ΔE is the stabilization energy of the molecular complex $HF\cdots YZCOH^+$.
[b] HF has a 4-31G optimized distance of 0.922 Å with an energy of −99.88728 hartree.

done by Olah and Mateescu (2). These authors found a triplet pmr spectrum for OH_2, consistent with structure **II**, but not with structure **III**.

Difluoromethanol

The optimized geometry for the neutral molecule is given in Table 1, and for the O- and F-protonated species in Tables 2 and 3.

Protonation on O leads to an increase in the C—O bond length by 0.17 Å. The difference to monofluoromethanol arises mainly from the shorter C—O bond in HF_2COH, which understandably decreases with increasing fluorine substitution. The C—F bond length decreases by 0.05 Å.

In the case of F-protonation, the proton could be attached to either one fluorine, or to two, being then located on the axis bisecting the FCF angle. Optimization leads to attachment to one fluorine, again resulting in a molecular complex consisting of HF and $HFCOH^+$ (structure **III**). This geometry is energetically more favourable than that of the proton interacting with two fluorines, who could not both separate from the remainder of the molecule. A similar observation was made in the case of the protonation of F_2CS (10), where a molecular complex of the form $HF\cdots FCS^+$ is preferred to a symmetric interaction of the proton with both fluorine atoms.

The calculated proton affinities (162.3 vs. 162.6 kcal/mol) give a slight preference to the F-protonation site. However, such small energy differences are beyond the accuracy expected from Hartree–Fock calculations, and the only important conclusion to be drawn is that the proton affinities are very similar. McMahon (4) found the PA of HF_2COH to be smaller than that of water. Our result obtained for HF_2COH is about 8 kcal/mol lower than the experimental PA of H_2O (170.3 ± 2 kcal/mol) (8).

Trifluoromethanol

The optimized geometry of the neutral molecule is compared in Table 1 with that of Olsen and Howell (11). The slight differences, combined with the lower energy obtained here (the energy of ref. 11 is −411.0982), suggest that Olsen and Howell forced the oxygen to lie on the C_3 symmetry axis defined by the symmetric CF_3 group. In our case, structure **I** is allowed to be "nonaxial", as can be seen in Table 1. For methanol and its trifluoro derivative the distances C—X, C—Y and the angles X—C—O and Y—C—O are allowed to be unequal.

The O-protonated F_3COH is again characterized by an increase in the CO (by 0.15 Å) and a decrease in the CF distance (by 0.03 Å). When allowing for F-protonation, the complex $HF\cdots F_2COH^+$ has the lowest energy, rather than a cation where H^+ interacts with two or even three negatively charged fluorines. The complex has a slightly smaller PA than the O-protonated molecule (142.5 vs. 148 kcal/mol); however, the two numbers are still quite close.

Molecular complexes

In Table 5, the stabilization energies ΔE of the complexes $HF\cdots YZCOH^+$ are given. These are the energy differences between the F-protonated fluoromethanols, Tables 3 and 4, and the separate HF plus $YZCOH^+$ fragments. Positive values of ΔE indicate that the complex is more stable than the separate parts, in agreement with the automatic geometry optimization which settles on a definite CF distance rather than leading to dissociation.

The geometry of HF and the three $YZCOH^+$ cations were optimized separately. All cations (structure **IV**) are planar. The geometry parameters are included in Table 5.

The stabilization energies range from 17.2 to 20.2 kcal/mol, similar to those of the $HF\cdots YCS^+$ systems of ref. 10 (17.2 kcal/mol for $HF\cdots HCS^+$ and 14.9 kcal/mol for $HF\cdots FCS^+$).

The geometries of the $YZCOH^+$ cations (Table 5) are close to the geometries of the cations in the complex (Table 3). Differences in bond distances are 0.005 Å or less.

Discussion

For the three fluorides of methanol, protonation on oxygen leads to very similar proton affinities as protonation on F. These values decrease with increasing fluorination, and range from 181.0 to 148 kcal/mol for the (usually slightly more stable) protonation on oxygen. According to the analysis done by Del Bene *et al.* (7), the calculated PA of methanol is reduced both by the zero-point energy correction and by differences in correlation energy. For methanol, the zero-point energy correction is 8.3 and the correlation correction 0.8 kcal/mol, for a total correction of 9.1 kcal/mol. Corrections with a similar trend would have to be expected for the fluoromethanols, although no quantitative values are available. One could argue that the correlation correction should be larger for F-protonation than for O-protonation, due to the larger changes in the C—F distances. Indeed, examples can be found in ref. 7 to support this argument. On the other hand, larger distance changes result in smaller zero-point energy corrections (see ref. 7 again for examples), which will partly or fully compensate for the increased correlation corrections. Therefore, in the absence of detailed correction energies for the molecules studied here, no general arguments can be applied to support higher corrections to the PA values in the case of F-protonation.

Protonation on F always leads to a molecular complex consisting of HF and $YZCOH^+$, having a long CF bond of 2.2 to 2.3 Å. The complex stabilization energies are typically 20 kcal/mol, and dissociation with the elimination of HF should be easily possible. In all O-protonated fluorides, the C—O distance increases by 0.15 to 0.17 Å.

The optimized geometries contain no surprises except for the structure of neutral monofluoromethanol. Here, the O—H hydrogen optimizes in a staggered position between C—F and

C—H, and not between the two C—H bonds of the methyl group as one would expect. Apparently, the nonsymmetrical structure has a lower repulsion between the O—H hydrogen and the CH_2F group, and the larger number of electrons on fluorine is compensated for by the larger CF distance. Actually, the structure obtained is another example of the anomeric effect (12). If one considers oxygen to be sp^3 hybridized, then one of the oxygen lone pairs is antiperiplanar (*trans*) to the polar C—F bond. This model results in a dihedral angle of 60° for the O—H group relative to C—F, in agreement with the calculations.

A brief check on the stability of neutral fluoromethanols with regard to decomposition into HF and formaldehyde or its fluorides showed that electronically the fluoromethanols are more stable than their dissociation products by 17 to 20 kcal/mol. The observed dissociation at normal temperatures should therefore be an entropy effect, in qualitative agreement with the synthesis of CF_3OH at low temperature, and its observed dissociation at higher temperatures (1).

Conclusion

The proton affinities of the fluoromethanols were predicted using quantum chemical Hartree–Fock methods with the 4-31G basis set. The geometries of the neutral, as well as O- and F-protonated species were optimized. From the energy differences, proton affinities, uncorrected for both zero-point vibrational energy and correlation energy, were obtained. The PA's decrease with increasing fluorine substitution. Protonation on oxygen is slightly preferred, although the difference in energy is never more than 5.5 kcal/mol. Protonation on fluorine leads to molecular complexes where HF has a large distance from the remaining cation. Since zero-point energy corrections would give a slight preference to the more loosely bound F-protonated species, F-protonation is expected to be in strong competition with O-protonation. For neutral monofluoromethanol, a conformation where the OH hydrogen is staggered between CF and CH has been found to have the lowest energy, in agreement with the concept of the anomeric effect.

Acknowledgements

I am grateful to Dr. T. B. McMahon for suggesting this topic, and for his continued interest. Thanks to Uday Sishta, Chris Grein, and Neilan Mehta for performing most of the calculations. Financial support by NSERC, and a generous grant of computer time by the University of New Brunswick, are gratefully acknowledged. I would also like to thank Dr. P. Deslongchamps for providing an explanation to the optimized structure of fluoromethanol via the anomeric effect.

Received November 22, 1984

This paper is dedicated to Professor Camille Sandorfy on the occasion of his 65th birthday

GÉZA BICZÓ. Can. J. Chem. **63**, 1992 (1985).

The history of Bloch's and Tamm's states is sketched. The present stage in the theory of the bounded infinite polymers and crystals and strange electronic states is outlined. To lay the foundations of the SCF LCAO bounded crystal orbital (BCO) method applicable for surface electronic problems, the direct recursion (transfer matrix) method (DRM) is formulated for perfect cyclic polymers and crystals. A simple combination of block-decomposition and matrix transpositions is applied to calculate $\mathbf{U}^{-1}$ directly from the blocks of $\mathbf{U}$, the similarity transformation bringing the recursion matrix $\mathbf{T}$ into its normal form. Several forms are given for the auxiliary and fundamental equation of the DRM. The crystal orbitals are derived by the DRM. Full matrix expression is presented for the resolvent (Green) matrix of perfect cyclic polymers, the unperturbed system in the SCF local-density approach of Ladik and Seel. The formulae of the charge-bond order matrix are derived both by the DRM and the indirect (Green matrix) recursion method (IRM).

GÉZA BICZÓ. Can. J. Chem. **63**, 1992 (1985).

On présente une revue de l'histoire des états de Bloch et de Tamm. On présente l'état actuel de la théorie relative aux polymères infinis qui sont liés et aux cristaux ainsi qu'aux états électroniques particuliers. Dans le but d'établir les bases de la méthode LCAO-SCF des orbitales cristallines liées (BCO) pour des polymères et des cristaux parfaits, on a développé une méthode de récurrence directe (matrice de transfert) (DRM) qui serait applicable aux problèmes de la structure électronique des surfaces. On utilise une combinaison simple de décompositions en blocs et de transpositions de matrices pour calculer $\mathbf{U}^{-1}$ directement à partir des blocs de $\mathbf{U}$; la transformation de similarité transforme la matrice de récurrence $\mathbf{T}$ en sa forme normale. On présente plusieurs formes pour les équations auxiliaire et fondamentale de la DRM. Utilisant la DRM, on a déduit les orbitales du cristal. On présente une expression pour la matrice complète de Green de polymères cycliques parfaits, le système non perturbé dans l'approche à densité locale en champ auto-cohérent de Ladik et Seel. Utilisant la DRM et la méthode de récurrence indirecte (matrice de Green) (IRM), on a déduit les formules de la matrice des charges et des ordres de liaison.

[Traduit par le journal]

1. Introduction

The purpose of this series is threefold: (*i*) To demonstrate the power of the *direct recursion* (transfer matrix) *method* (DRM) for the solution of various problems, *from bulk to strange electronic states*. (*ii*) To present a novel full matrix *self-consistent field linear combination of atomic orbitals bounded crystal orbital* (SCF LCAO BCO) formalism for bounded crystals in the infinite size limit. (*iii*) To point out possible experimental indications for the existence of *intermediate* (electronic) *states* (IS).

The important ideas and interrelationships are introduced below in six points. Namely, the history of Bloch's and Tamm's states (I, II), the present stage in the theory of bounded infinite crystals (III), the physical significance (IV), and the history (V) of the IS are recapitulated and finally a futuristic question is posed (VI).

(I) Forty five years elapsed between the discovery of *Floquet's theorem* in 1883 (1) and its application to the bulk electronic states of crystalline solids by *Bloch* (2) and another period of 39 years until its *general full matrix ab initio SCF LCAO CO* (Hartree-Fock-Roothaan-type (3)) *formulation* in 1967 for 3-dimensional *perfect infinite crystals* (4, 5), although a 2-dimensional (not *ab initio*) version was applied to graphite 8 years earlier (6). Note that even today, 17 years later, no similar formulation exists to include electronic correlation.

(II) Bloch's theorem was immediately applied to interpret the observed properties of solids. On the contrary, only the very recent advent of high vacuum science has led to the experimental verification of *Tamm's* theoretical prediction of 1932 (7) concerning the existence of *surface states in half-infinite* crystalline solids. This happened more than three decades later!

(III) The theory of half-infinite crystals is not yet at the 1967 stage of Bloch's theory. To proceed towards that *general full matrix ab initio SCF LCAO BCO* level, first its key term, the *charge-bond order matrix* was derived *for bounded polymers and solids in the infinite size limit* by DRM. The main results were published in ref. 8 and detailed in an unpublished preprint (Preprint TCG-1-77, CRIC HAS, Budapest, March, 1977, available by direct request). This formulation has completely described the *bulk state distortion* (BSD), *the dominating SCF effect*. It was given, however, only for simple (non-overlapping) energy band systems. The next paper (9), written with the same aim, presented an indirect (exact) perturbational method (IPM), a full matrix Koster-Slater-type (10) resolvent (Green's function) approach. The BSD, however, was not taken into account there. Nevertheless, the more advanced versions (11–13) of the SCF local-impurity formalism (14) developed for linear polymers already include the BSD and show how to generalize them for surface problems. (For further details concerning the other, more approximate but also SCF IPM calculations, see the references in refs. 11–14.)

(IV) The possible *physical significance* of the *third notable electronic state of the finite crystalline solids*, besides the well understood delocalized (bulk) and localized (surface, impurity, etc.) states, was studied only very recently (8, 15–20). This state is neither localized, as the surface states are, nor is it

[1]Permanent address.

uniformly delocalized, as for the bulk states. Therefore, it may be called an intermediate state, IS. The IS is a one-electron state of zero probability as compared to the other two, the bulk and the localized states, at least at first sight (15). It may appear under the fulfilment of special boundary conditions with one-electron energies lying at the centers of resonance (Van Hove singularities) and band edges (15, 16). The existence of a critical energy interval around the sharp energy of the IS was proved where any one-electron state becomes very similar to the central IS (17, 18). These almost IS (AIS) already have non-zero probability of appearance which is very advantageous with respect to their observability. All these were reviewed in a symposium paper (18), together with other considerations such as the effect of vibrations, possible host systems for IS, etc. The above statements are merely theoretical predictions.

(V) The history of the above third kind of solutions concerning its mathematical treatment was recently reviewed (21). At least two authors, however, are omitted in this review. Fairbairn (22) has mentioned the appearance of the above solutions. Unfortunately, he relegated the problem to a footnote, saying that it is simpler to consider the new kind of solution as a limiting case of the others than to treat it separately. Most correctly, Cottey has always treated separately the band edge states (BES) (23–26) which are special cases of the IS. He studied almost exclusively symmetrical models, when he refined the theory of the quantum size effect (QSE) (25*a*–*f*, 26*a*, *b*), solving the one-dimensional Schrödinger equation for a periodic potential terminated by two infinite abrupt potential barriers. The symmetrical models, however, can produce only bulk-like, uniformly delocalized states. Only a brief section is given on unsymmetric layers and their equation (25*d*). In a detailed paper (24), he has observed the linear variation in the amplitude of the BES leading to the intermediate character of the IS. He has also concluded that a BES cannot be a real physical state in an infinite or even in a semi-infinite crystal but only that of a finite one (25*a*).

Cottey's considerations (26*a*) strongly support the contention that certain observed structures in the tunnelling current through an oxide layer into a thin metal layer are due to the one-electron QSE levels. Naturally, some of the QSE levels may be IS or, rather, AIS. Thus they must be observable from the structure of the above tunnelling current curve, from certain well observable shoulders in the absorption spectrum, and from the characteristic structures appearing in photoelectric yield spectra. Experiments focused on the observation of the IS were proposed (19, 20).

(VI) Finally, with special attention to point (II) above, one can ask the poetic question. How many years will elapse until the acceptable experimental verification or complete rejection of the very recent theoretical predictions concerning the existence of strange electronic states, say, IS? This period is significantly lengthened by the sensitivity and other exceptional properties (15, 18) of these states. Our intention is to decrease the length of the period in question by presenting this paper.

2. Crystal orbitals by DRM

This section is devoted to introducing some technical details of the DRM. For this reason, the simplest full matrix problem, that of a perfect cyclic polymer is treated in the first neighbour's interaction approximation. Recurrence relations and boundary conditions (I), fundamental equation (II), auxiliary equations (III), a novel easy calculation of the inverse matrix in the similarity transformation (IV), spectral resolution (V), other forms of the fundamental equation (VI), and charge-bond order matrix (VII) are given.

(I) The transfer matrix approach was originally formulated for vibrational problems (27–32). Its use was later extended to the treatment of, e.g., LEED experiments (33–36), bulk and surface electronic structures (8, 15–20, 37–47), disordered systems (1–5, 48–50), structure factor calculations (51), and even random resistor networks (52). (See also the references in the papers quoted above.)

According to the nomenclature introduced by Grimley (53), the transfer matrix method is a DRM since it solves the matrix representation of the Schrödinger equation directly, utilizing the translational symmetry shown by the blocks of the Hamiltonian hypermatrix from a certain block on (41*a*, 44, 47). The indirect methods determine first the resolvent (or Green) matrix and then use it as a basis for all further calculations. The oldest class of indirect methods is the IPM already mentioned in point 1.III. The IPM is an exact perturbational method because of the absence of the series expansion. Its advantage is the easy calculation of the resolvent for the perfect bulk polymer as an unperturbed system (refs. 9–14, 53–58, and references therein). The indirect recursion methods (IRM) represents the newer class (58–65) and are the realizations of an old idea (66). They utilize the recurrence relations valid for the matrix blocks of the total resolvent describing the whole (possibly perturbed) system. The connection of the IRM and the DRM was already clarified (41*a*). In an actual ZnO (1010) surface calculation, a special DRM was faster than a Koster-Slater-type IPM (10) by about a factor of 11 (42*a*).

Using the LCAO method[2] and the nearest neighbour approximation one can characterize intra- and inter-cell interactions by the matrices $\mathbf{A} = \mathbf{F}_{11} - \lambda\mathbf{S}_{11}$ and $\mathbf{B} = \mathbf{F}_{12} - \lambda\mathbf{S}_{12}$ of, say, order n. They contain the block of form $\mathbf{F}_{jk}$ for the Fock matrix elements of the electronic Hamiltonian between the atomic basis functions, $\mathbf{S}_{jk}$ for the overlap integrals and λ is the one-electron energy. $\mathbf{F} = \{\mathbf{F}_{jk}\}$, the Fock hypermatrix of the whole perfect cyclic polymer reflects the symmetry of the system: $\mathbf{F}_{jj} = \mathbf{F}_{11}$ and $\mathbf{F}_{jj+1} = \mathbf{F}_{12}$ for $j = 1, 2, \ldots, N$ (when $j = N$, the value 1 must be used for index $j + 1$ instead of $N + 1$), if it consists of N monomers ("cells"). The same is valid for the overlap hypermatrix $\mathbf{S} = \{\mathbf{S}_{jk}\}$. The eigenvalue problem of the whole system has the usual form

$$[1] \quad \mathbf{F}c = \lambda\mathbf{S}c$$

which can be rewritten in a more convenient way as

$$[2] \quad (\mathbf{F} - \lambda\mathbf{S})c = \begin{bmatrix} \mathbf{A} & \mathbf{B} & & & & \mathbf{B}' \\ \mathbf{B}' & \mathbf{A} & \mathbf{B} & & & \\ & \mathbf{B}' & \cdot & & & \\ & & & \cdot & & \\ & & & \cdot & \mathbf{B} & \\ & & & \mathbf{B}' & \mathbf{A} & \mathbf{B} \\ \mathbf{B} & & & & \mathbf{B}' & \mathbf{A} \end{bmatrix} \begin{bmatrix} c_1 \\ c_2 \\ c_3 \\ \vdots \\ c_{N-1} \\ c_N \end{bmatrix}.$$

The prime means transposition and the blank spaces are zero blocks. The jth block row of [2] reads as

$$[3] \quad \mathbf{B}'c_{j-1} + \mathbf{A}c_j + \mathbf{B}c_{j+1} = 0$$

This equation is valid for all $j = 1, \ldots, N$, if the cyclic boundary condition

$$[4] \quad c_0 = c_N \quad \text{and} \quad c_{N+1} = c_1$$

[2] A special version of, but sometimes the LCAO method itself is called the tight binding method in solid state physics.

is introduced. One can decide before executing the next step on the use of either the older Schmidt-Hori-Asahi-type DRM (8, 27–32, 37–43, 45–46) or the newer inversion free DRM (IF DRM, 44, 47, 71). The former is applicable only when $\mathbf{B}$ is nonsingular and the latter for arbitrary $\mathbf{B}$. Restricting the treatment here to the former case, one can premultiply [3] by $\mathbf{B}^{-1}$:

$$c_{j+1} = (\mathbf{D}\ \mathbf{G})\begin{pmatrix} c_{j-1} \\ c_j \end{pmatrix}$$

where $\mathbf{D} = -\mathbf{B}^{-1}\mathbf{B}'$ and $\mathbf{G} = -\mathbf{B}^{-1}\mathbf{A}$. Completing this equation with the identity

$$c_j = (\mathbf{0}\ \mathbf{I})\begin{pmatrix} c_{j-1} \\ c_j \end{pmatrix}$$

and defining the recursion (transfer) matrix (27, 28)

$$[5]\quad \mathbf{T} = \begin{pmatrix} \mathbf{0} & \mathbf{I} \\ \mathbf{D} & \mathbf{G} \end{pmatrix}$$

and the column vector of two consecutive column vector blocks c_{j-1} and c_j from the hyper-columnvector c of eq. [1], [2]

$$x_j = \begin{pmatrix} c_{j-1} \\ c_j \end{pmatrix}$$

one can write [3] and [4] as

$$[6]\quad x_{j+1} = \mathbf{T}x_j$$

and

$$[7]\quad x_{N+1} = x_1$$

The recurrence relation [6] will have this form for perturbed and non-perfect polymers, too, only $\mathbf{T}$ will depend also on the index of the actual cell, $\mathbf{T} = \mathbf{T}_j$ must be written in [6]. The boundary condition [7] will have various forms for different problems.

(II) Contracting eq. [6], [7] by successive substitutions one obtains the *fundamental equation*

$$[8]\quad x_1 = \mathbf{T}^N x_1$$

This is its first form. It is a homogeneous linear equation for matrix $\mathbf{T}^N - \mathbf{I}$ which is a function of λ. It has non-trivial solutions at and only at the eigenvalues of the original generalized eigenvalue problem [1], where its determinant vanishes:

$$[9]\quad |\mathbf{T}^N - \mathbf{I}| = 0.$$

This characteristic equation is of order $2n$. For its evaluation, however, some auxiliary equations or the spectral resolution of $\mathbf{T}$ must be used because of the appearance of a high or even infinite power of $\mathbf{T}$.

(III) The spectral properties of the recursion matrix $\mathbf{T}$ play a very important role in the determination of the characteristic properties of the eigensolutions of [1]. For example, the appearance of Jordan blocks in the normal form of $\mathbf{T}$ are responsible for the creation of certain strange electronic states (8, 15–20, 41b). In perfectly periodic systems, however, these are not allowed states (24, 25a). At this point, therefore, one can accept Fairbairn's strategy restricting the treatment to the principal case when $\mathbf{T}$ is semisimple. In this case both the left and the right eigenvalue problems of $\mathbf{T}$ have complete systems of eigenvectors which can be used to form the non-singular matrices $\mathbf{U}$ and $\mathbf{Q}$. These eigenvalue problems, which are our auxiliary equations, have the compact form

$$[10]\quad \mathbf{UT} = \boldsymbol{\tau}\mathbf{U}$$

and

$$[11]\quad \mathbf{TQ} = \mathbf{Q}\boldsymbol{\tau}$$

where the diagonal matrix $\boldsymbol{\tau}$ contains the eigenvalues of $\mathbf{T}$ in the order of their absolute values (8). Namely, for

$$|\mu_1| \leqq |\mu_2| \leqq \ldots \leqq |\mu_n| \leqq |\nu_n| \leqq \ldots \leqq |\nu_2| \leqq |\nu_1|$$

the following relationship holds

$$[12]\quad \boldsymbol{\mu\nu} = \mathbf{I}, \qquad \boldsymbol{\tau} = \begin{pmatrix} \boldsymbol{\mu} & \mathbf{0} \\ \mathbf{0} & \boldsymbol{\nu} \end{pmatrix}$$

$$[13]\quad \mathbf{UQ} = \mathbf{I}, \quad \mathbf{U} = \begin{pmatrix} \mathbf{X} & \mathbf{Y} \\ \mathbf{W} & \mathbf{Z} \end{pmatrix}, \quad \text{and} \quad \mathbf{Q} = \begin{pmatrix} \mathbf{J} & \mathbf{K} \\ \mathbf{L} & \mathbf{M} \end{pmatrix}$$

Equation [12] is a direct consequence of the fact that $\mathbf{T}$ and $\mathbf{T}^{-1}$ (compare [5] and [34] on the left side of [10] and the right side of [11] eigenvalue equations of $\mathbf{T}$) have the same characteristic equation (8, 41a). It has already been shown (41a) that the $\mathbf{B}^{-1}$-free reduced forms of auxiliary equations [10], [11] are related to the fundamental equation of the Fromm-Koutecký IRM by a similarity transformation.

(IV) It is well known that a Hermitian matrix $\mathbf{H}$ can be diagonalized by a unitary matrix $\mathbf{U}$ as $\mathbf{UHU}^+ = \boldsymbol{\chi}$, where $\boldsymbol{\chi}$ is diagonal, $^+$ means adjoint and $\mathbf{U}^{-1} = \mathbf{U}^+$ can be determined simply by forming the adjoint. One might think, at first sight, that such a computationally advantageous procedure is impossible for $\mathbf{T}$, owing to its non-symmetrical structure. The more symmetrical form of the reduced auxiliary equations (41a), however suggests that a more or less similar procedure must exist for the blocks of $\mathbf{U}$ and $\mathbf{Q}$. It will be shown here that this is the case.

Let $\mathbf{YB}^{-1} = \mathbf{E}$ and $\mathbf{ZB}^{-1} = \mathbf{H}$. Then the upper block components of [10] lead to

$$[14]\quad -\mathbf{EB}' = \boldsymbol{\mu}\mathbf{X}$$

or, by [12], $\mathbf{X} = -\boldsymbol{\nu}\mathbf{EB}'$ and $\mathbf{X} - \mathbf{EA} = \boldsymbol{\mu}\mathbf{Y}$ or, by eliminating $\mathbf{X}$ through [14],

$$[15]\quad \mathbf{EB}' + \boldsymbol{\mu}\mathbf{EA} + \boldsymbol{\mu}^2\mathbf{EB} = \mathbf{0}$$

By analogy ($\mathbf{X}$, $\mathbf{Y}$, $\boldsymbol{\mu}$ correspond to $\mathbf{W}$, $\mathbf{Z}$, and $\boldsymbol{\nu}$),

$$[16]\quad \mathbf{W} = -\boldsymbol{\mu}\mathbf{HB}'$$

and

$$[17]\quad \mathbf{HB}' + \boldsymbol{\nu}\mathbf{HA} + \boldsymbol{\nu}^2\mathbf{HB} = \mathbf{0}$$

One can similarly split eq. [11]

$$[18]\quad \mathbf{L} = \mathbf{J}\boldsymbol{\mu}$$

$$[19]\quad \mathbf{B}'\mathbf{J} + \mathbf{AJ}\boldsymbol{\mu} + \mathbf{BJ}\boldsymbol{\mu}^2 = \mathbf{0}$$

$$[20]\quad \mathbf{M} = \mathbf{K}\boldsymbol{\nu}$$

and

$$[21]\quad \mathbf{B}'\mathbf{K} + \mathbf{AK}\boldsymbol{\nu} + \mathbf{BK}\boldsymbol{\nu}^2 = \mathbf{0}$$

Transposing, rearranging and postmultiplying [15] by $\boldsymbol{\nu}^2 = \boldsymbol{\mu}^{-2}$ (see [12]), one obtains the same equation [21] for $\mathbf{E}'$ as was obtained for $\mathbf{K}$ above. In the above assumed principal case (semi-simple $\mathbf{T}$), however, the eigenvectors of [10], [11] are determined up to a free constant factor. Thus

$$[22]\quad \mathbf{K} = \mathbf{E}'\boldsymbol{\gamma}$$

where $\boldsymbol{\gamma}$ is a diagonal matrix of order n containing half the free factors above. The rest of these factors are collected in the diagonal matrix $\boldsymbol{\delta}$ which appears in the analogous equation

$$[23] \quad \mathbf{J} = \mathbf{H}'\boldsymbol{\delta}$$

Substituting [14], [16], [18], [20], [22], [23] into [13], its two diagonal blocks determine $\boldsymbol{\gamma}$ and $\boldsymbol{\delta}$ as

$$[24] \quad \boldsymbol{\delta} = (\mathbf{EBH}'\boldsymbol{\mu} - \boldsymbol{\nu}\mathbf{EB}'\mathbf{H}')^{-1}$$

and

$$[25] \quad \boldsymbol{\gamma} = (\mathbf{HBE}'\boldsymbol{\nu} - \boldsymbol{\mu}\mathbf{HB}'\mathbf{E}')^{-1} = \boldsymbol{\gamma}' = -\boldsymbol{\delta}$$

The two off-diagonal blocks yield interesting non-trivial relations

$$[26] \quad \boldsymbol{\nu}\mathbf{EB}'\mathbf{E}' = \mathbf{EBE}'\boldsymbol{\nu} = (\mathbf{EB}'\mathbf{H}')'\boldsymbol{\nu}$$

and

$$[27] \quad \boldsymbol{\mu}\mathbf{HB}'\mathbf{H}' = \mathbf{HBH}'\boldsymbol{\mu} = (\mathbf{HB}'\mathbf{H}')'\boldsymbol{\mu}$$

which are very useful in the simplification of various formulae. Other useful relationships

$$[28] \quad \mathbf{H}'\boldsymbol{\delta\mu}\mathbf{E} - \mathbf{E}'\boldsymbol{\delta\nu}\mathbf{H} = \mathbf{B}^{-1}$$

and

$$[29] \quad \mathbf{H}'\boldsymbol{\delta}\mathbf{E} = \mathbf{E}'\boldsymbol{\delta}\mathbf{H} = (\mathbf{H}'\boldsymbol{\delta}\mathbf{E})'$$

are obtained from $\mathbf{QU} = \mathbf{I}$. (The other two expressions are merely the transposes of [28] and [29].)

Summarising,

$$[30] \quad \mathbf{U} = \begin{pmatrix} -\boldsymbol{\nu}\mathbf{EB}' & \mathbf{EB} \\ -\boldsymbol{\mu}\mathbf{HB}' & \mathbf{HB} \end{pmatrix}$$

and

$$[31] \quad \mathbf{Q} = \mathbf{U}^{-1} = \begin{pmatrix} \mathbf{H}'\boldsymbol{\delta} & -\mathbf{E}'\boldsymbol{\delta} \\ \mathbf{H}'\boldsymbol{\delta\mu} & -\mathbf{E}'\boldsymbol{\delta\nu} \end{pmatrix}$$

where $\boldsymbol{\delta}$ is given by [24], $\mathbf{E} = \mathbf{YB}^{-1}$ and $\mathbf{H} = \mathbf{ZB}^{-1}$.

(V) In accordance with [10]–[13], [30], [31],

$$[32] \quad \mathbf{T}^{j} = \mathbf{U}^{-1}\boldsymbol{\tau}^{j}\mathbf{U} = \begin{pmatrix} -\mathbf{V}_{j-1}\mathbf{B}' & \mathbf{V}_j\mathbf{B} \\ -\mathbf{V}_j\mathbf{B}' & \mathbf{V}_{j+1}\mathbf{B} \end{pmatrix}$$

is the spectral resolution, where

$$[33] \quad \mathbf{V}_j = \mathbf{H}'\boldsymbol{\delta\mu}^{j}\mathbf{E} - \mathbf{E}'\boldsymbol{\delta\nu}^{j}\mathbf{H}$$

It is evident from [29] and [28] that $\mathbf{V}_0 = \mathbf{0}$ and $\mathbf{V}_1 = \mathbf{B}^{-1}$. The first form (with $\boldsymbol{\tau}^j$) in [32] is the usual, and the second is a block-wise spectral resolution which reflects the reciprocal character of the problem. This reciprocity is a direct consequence of the physical structure of the system studied, namely, that the forward and backward propagation of the electronic states follow the same rules. The latter is easily demonstrated by a reversed numbering of the monomers (cells) and also by the simple inversion rule of the recursion matrix:

$$[34] \quad \mathbf{T}^{-1} = \begin{pmatrix} -\mathbf{B}'^{-1}\mathbf{A} & -\mathbf{B}'^{-1}\mathbf{B} \\ \mathbf{I} & \mathbf{0} \end{pmatrix}$$

The use of the block-wise spectral resolution is especially advantageous when a standard computer routine is available for the solution of the generalized eigenvalue problems of monic matrix polynomials (matrix pencils) (67) such as [15] and [17], since their order is only n and not $2n$ as for the original auxiliary equation [10].

The difference between these two methods of calculation is even more pronounced when farther than the first, say, the kth neighbour's interaction approximation is applied. Then further off-diagonal block positions are occupied in [2]; the jth upper and $(N-j)$th lower by $\mathbf{B}_j$, the jth lower and $(N-j)$th upper off-diagonal positions by $\mathbf{B}_{-j} = \mathbf{B}_j'$. Now, following Matsuda [29], [30], one can define the recursion matrix as

$$[35] \quad \mathbf{T} = \begin{bmatrix} \mathbf{0} & \mathbf{I} & \dots & \mathbf{0} & \mathbf{0} & \mathbf{0} & \dots & \mathbf{0} \\ & & & \dots & & & & \\ \mathbf{0} & \mathbf{0} & \dots & \mathbf{I} & \mathbf{0} & \mathbf{0} & \dots & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \dots & \mathbf{0} & \mathbf{I} & \mathbf{0} & \dots & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \dots & \mathbf{0} & \mathbf{0} & \mathbf{I} & \dots & \mathbf{0} \\ & & & \dots & & & & \\ \mathbf{0} & \mathbf{0} & \dots & \mathbf{0} & \mathbf{0} & \mathbf{0} & \dots & \mathbf{I} \\ \mathbf{D}_{-k} & \mathbf{D}_{1-k} & \dots & \mathbf{D}_{-1} & \mathbf{G}_k & \mathbf{D}_1 & \dots & \mathbf{D}_{k-1} \end{bmatrix}$$

where $\mathbf{G}_k = -\mathbf{B}_k^{-1}$ and $\mathbf{D}_j = -\mathbf{B}_k^{-1}\mathbf{B}_j$ $(j = -k, \dots, -1, 1, \dots, k-1)$. Its eigenvalue problem [10] is of order $2kn$. At the same time, the polynomial equation

$$[36] \quad \mathbf{EB}_k' + \dots + \boldsymbol{\mu}^{k-1}\mathbf{EB}_1' + \boldsymbol{\mu}^{k}\mathbf{EA} + \boldsymbol{\mu}^{k+1}\mathbf{EB}_1 + \dots + \boldsymbol{\mu}^{2k}\mathbf{EB}_k = \mathbf{0}$$

analogous to [15], still remains of order n. Note that [35] is just the first companion operator associated with [36] having an important role in the spectral analysis of matrix polynomials (68).

(VI) The second form of the fundamental equation is obtained by premultiplying [8] with $\mathbf{U}$ and using [10]:

$$[37] \quad (\boldsymbol{\tau}^N - \mathbf{I})\mathbf{Ux}_1 = \mathbf{0}.$$

Evidently, a non-trivial solution exists only when at least one eigenvalue of $\mathbf{T}$ is a complex root of unity:

$$[38] \quad \mu_m = \mu_m(q) = \exp(2\pi i q/N), \qquad 1 \leqq m \leqq n$$

Here μ_m and $\nu_m = \mu_m^{-1} = \exp[2\pi i(N-q)/N]$ have similar roles, but one can distinguish them by definition, requiring $0 \leqq q \leqq N/2$. The well-known double degeneracy of the Bloch states is striking now from [37] and [38] for $0 < q < N/2$, since then $\mu_m \neq \nu_m$ warrants two independently non-zero components in the column vector $\mathbf{Ux}_1$. This double degeneracy disappears when $q = 0$ or $N/2$, because $\mathbf{T}$ becomes defective and $\mu_m = \nu_m = +1$ or -1 introduce a Jordan block

$$[39] \quad \boldsymbol{\eta} = \begin{pmatrix} \epsilon & 1 \\ 0 & \epsilon \end{pmatrix} = \epsilon\mathbf{I} + \boldsymbol{\zeta}$$

where $\epsilon = \pm 1$ and $\boldsymbol{\zeta} = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}$. Here $\boldsymbol{\zeta}^2 = 0$, thus the expansion of $\boldsymbol{\eta}^N$ by the binomial theorem contains only two non-zero terms:

$$[40] \quad \boldsymbol{\eta}^N = \epsilon^N\mathbf{I} + \binom{N}{1}\epsilon^{N-1}\boldsymbol{\zeta} = \epsilon^N\begin{pmatrix} 1 & \epsilon N \\ 0 & 1 \end{pmatrix}$$

When such a block appears in [37] only one non-zero component can correspond to it in $\mathbf{Ux}_1$ and the other component must be zero just to exclude the appearance of coefficient N which would lead to an asymmetric IS violating the cyclic symmetry of the system. This is the mathematical mechanism which permits the occurrence of only bulk-like, uniformly distributed IS in the cyclic systems. A more detailed treatment of the defective case, together with the IF DRM, will be given elsewhere (71).

The derivation of the third, block decomposed form of the fundamental equation is very convenient from the block-wise spectral resolution, the second expression in [32], when bounded polymers or crystals are studied with free boundary conditions, as will be seen later. However, its application here would unnecessarily complicate the problem. At the same time, the usual spectral resolution given in the first expression of [32] yields again [37]. Its decomposition is trivial in the semisimple case:

$$[41] \quad (\boldsymbol{\mu}^N - \mathbf{I})\boldsymbol{d}_N = 0 \quad \text{and} \quad (\boldsymbol{\nu}^N - \mathbf{I})\boldsymbol{d}_1 = 0$$

or, premultiplying the latter by $-\boldsymbol{\mu}^N$,

$$[42] \quad (\boldsymbol{\mu}^N - \mathbf{I})\boldsymbol{d}_1 = 0$$

where $\boldsymbol{d}_N$ and $\boldsymbol{d}_1$ mean the upper and the lower component of $\mathbf{Ux}_1$. One fact must be observed here that one can always reformulate the blocks of the block-decomposed fundamental equation so that they contain only $\boldsymbol{\mu}$, i.e., only those eigenvalues of the recursion matrix which have absolute value not greater than 1. This was already shown for the auxiliary equation after eq. [21] and this possibility leads to the IF DRM (41*a*, 44, 47, 71).

(VII) The charge-bond order matrix will be derived by two different approaches: a DRM (*i*) and an IRM (*ii*).

(*i*) In point (VI) above, μ_m and ν_m were distinguished by definition. This will be important later when bounded systems will be studied. Here, for the cyclic system, it is simpler to treat them on the same footing permitting q to run from 1 to N when eq. [38] is used as is common in band theories. Thus one can get all the linearly independent solutions to [1], if only one non-zero component is kept in $\mathbf{Ux}_1$, say, $(\mathbf{Ux}_1)_m$ or $(\mathbf{Ux}_1)_{m+n}$. In the latter case $J(q)$ is also used for the K of eq. [21] and $\tau_m = \tau_m(q) = e^{i\kappa}$ $(\kappa = 2\pi q/N)$ for μ_m or ν_m. Now the less compact but most common eigenvalue equation form of [19] and [21] will be applied as one single equation

$$[43] \quad (\mathbf{B}' + \mathbf{A}\tau_m + \mathbf{B}\tau_m^2)\,\mathbf{J}_{*m}(q) = 0$$

where $\mathbf{J}_{*m}$ means the mth column vector of the n by n matrix $\mathbf{J}$. Multiplying [43] with τ_m^{-1}, using κ as the variable instead of q $(0 < \kappa \leqq 2\pi)$ and the definitions of $\mathbf{A}$ and $\mathbf{B}$ one obtains

$$[44] \quad (\mathbf{F}'_{12}e^{-i\kappa} + \mathbf{F}_{11} + \mathbf{F}_{12}e^{i\kappa})\,\mathbf{J}_{*m}(\kappa) = \lambda(\mathbf{S}'_{12}e^{-i\kappa} + \mathbf{S}_{11} + \mathbf{S}_{12}e^{i\kappa})\,\mathbf{J}_{*m}(\kappa)$$

This is just the well-known LCAO CO equation of finite or even infinite one-dimensional crystals if κ is regarded as continuous (4–6).

Now [6] and [32] yield

$$[45] \quad \mathbf{x}_{j+1} = \mathbf{T}^j\mathbf{x}_1 = \mathbf{Q}\boldsymbol{\tau}^j\mathbf{Ux}_1$$

and, with the above modified notations,

$$[46] \quad \boldsymbol{c}_j = \mathbf{J}_{*m}(\kappa)\,e^{ij\kappa}\,d$$

follows from the upper component of [45], d being the actual non-zero component of $\mathbf{Ux}_1$. It is convenient to use the normalized eigenvector block

$$[47] \quad \mathbf{C}_{*m}(\kappa) = |\mathbf{J}_{*m}(\kappa)|^{-1}\,\mathbf{J}_{*m}(\kappa)$$

where $||$ denotes the absolute value of the vector in question defined through the metric matrix

$$\mathbf{S} = \mathbf{S}'_{12}e^{-ik} + \mathbf{S}_{11} + \mathbf{S}_{12}e^{ik}$$

as $|\boldsymbol{v}| = (\boldsymbol{v} + \mathbf{S}\boldsymbol{v})^{1/2}$ where $\boldsymbol{v}$ is a column vector. If the hypereigenvector $\boldsymbol{c}$ is normalized to 1 and [47] is substituted into [46], then

$$[48] \quad c_j = \frac{1}{\sqrt{N}}\,\mathbf{C}_{*m}(\kappa)\,e^{ij\kappa}$$

In the simplest closed shell case, the charge-bond order matrix has the blocks

$$[49] \quad \mathbf{P}_{jk} = \frac{2}{N}\sum_{q=1}^{N} e^{2\pi i(j-k)q/N} \sum_{m}^{\text{occ.}} \mathbf{C}_{*m}(2\pi q/N)\mathbf{C}_{*m}(2\pi q/N)$$

for finite N and

$$[50] \quad \mathbf{P}_{jk} = \frac{1}{\pi}\int_0^{2\pi} e^{i(j-k)\kappa} \sum_{m}^{\text{occ.}} \mathbf{C}_{*m}(\kappa)\mathbf{C}^{+}_{*m}(\kappa)\,d\kappa$$

in the infinite size limit $(N \to \infty)$. Here "occ." on the summation means that just the labels m of the occupied bands have to be included.

(*ii*) The relation (69)

$$[51] \quad \mathbf{P}_{jk} = -\frac{2}{\pi}\int_{-\infty}^{\lambda_F} \operatorname{Im}[\mathbf{R}^0_{jk}(x)]\,dx$$

will be used here to derive the charge-bond order matrix. The factor two is due to the double occupancy which is assumed here. The abbreviation Im means imaginary part, λ_F is the Fermi level, the resolvent (Green) hypermatrix $\mathbf{R}$ is defined as

$$[52] \quad (z\mathbf{S} - \mathbf{F})\mathbf{R} = \mathbf{I}$$

it has the blocks $\mathbf{R}_{jk}(z)$ $(z = x + iy)$ of order n, and the superscript 0 indicates that first Im $[\mathbf{R}_{jk}(x + iy)]$ must be integrated for a positive y which afterwards approaches zero.

Generalizing the idea of McIntosh *et al.* (32) for the full matrix case, just the DRM will be applied here to determine $\mathbf{R}$ from [52]. This is the precise meaning that an IRM is used to calculate $\mathbf{P}$. Note that such an approach was already used to study the Green function method (G. Biczó, preprint TCG-1-77 quoted in point 1.III and ref. 39) and will be published in detail elsewhere (72).

Now

$$[53] \quad -\mathbf{B}'\mathbf{R}_{j-1k} - \mathbf{A}\mathbf{R}_{jk} - \mathbf{B}\mathbf{R}_{j+1k} = \delta_{jk}\mathbf{I}$$

is the block-decomposed form of [52] for $j, k = 1, \ldots, N$ if $j, k = 0$ or $N + 1$ corresponds to N or 1, respectively, and $\lambda = z = x + iy$ is substituted in the definition of $\mathbf{A}$ and $\mathbf{B}$. Comparing [52], [53] with [2], [3], one can observe two essential differences. First, that matrix blocks now occupy the places of the column vectors $\boldsymbol{c}_j$ of [3] and second that, contrary to [2], [52] represents a set of inhomogeneous linear matrix equations and not a homogeneous equation. Accordingly,

$$\mathbf{r}_{j+1} = \begin{pmatrix} \mathbf{R}_{jk} \\ \mathbf{R}_{j+1k} \end{pmatrix}$$

replaces $\mathbf{x}_{j+1}$ and the boundary condition is similar to [7]:

$$[54] \quad \mathbf{r}_{N+1} = \mathbf{r}_1$$

Naturally, [6] will be somewhat modified:

$$[55] \quad \mathbf{r}_{j+1} = \mathbf{T}\mathbf{r}_j + \delta_{jk}\mathbf{b} \qquad \text{with} \quad -\mathbf{b} = \begin{pmatrix} 0 \\ \mathbf{B}^{-1} \end{pmatrix}$$

The fundamental equation comes from [54] and [55]:

$$\mathbf{r}_{k+1} = \mathbf{T}\mathbf{r}_k + \mathbf{b} = \mathbf{T}^k\mathbf{r}_1 + \mathbf{b} = \mathbf{T}^k\mathbf{r}_{N+1} = \mathbf{T}^N\mathbf{r}_{k+1} + \mathbf{b}$$

or in a more explicit form

[56] $\mathbf{r}_{k+1} = (\mathbf{I} - \mathbf{T}^N)^{-1}\mathbf{b}$

This is valid independent of the actual value of k. For example, if $k = N$, then

[57] $\begin{pmatrix} \mathbf{R}_{jN} \\ \mathbf{R}_{j+1N} \end{pmatrix} = \mathbf{r}_{j+1} = \mathbf{T}^j\mathbf{r}_1 = \mathbf{T}^j\mathbf{r}_{N+1} = \mathbf{T}^j(\mathbf{I} - \mathbf{T}^N)^{-1}\mathbf{b}$

holds for $j = 1, \ldots, N-1$ giving all blocks of $\mathbf{R}$ either directly or by transposition and cyclic permutation of the blocks.

The second, block-decomposed form follows from equations [22]–[25], [32], [55]–[57]:

[58] $\mathbf{R}_{jN} = \mathbf{R}'_{Nj} = \mathbf{H}'\boldsymbol{\delta}\boldsymbol{\mu}^j(\boldsymbol{\mu}^N - \mathbf{I})^{-1}\mathbf{E} - \mathbf{E}'\boldsymbol{\delta}\boldsymbol{\nu}^j(\boldsymbol{\nu}^N - \mathbf{I})^{-1}\mathbf{H}$

being valid for $j = 0, \ldots, N$.

It is evident that outside the allowed continuous spectrum belonging to [1], $\mathbf{T}$ cannot have eigenvalues of absolute value 1. This is the case for real $\lambda = z = x$ by definition. Otherwise, supposing $\lambda = z = x + iy$ and $y \neq 0$, the existence of at least one such eigenvalue, say $e^{i\kappa}$, would warrant [44] to be a Hermitian generalized eigenvalue problem with a pure real spectrum for λ. This contradicts with the supposition $y \neq 0$.

As a consequence of the above fact and the very definition of eigenvalues μ_m, their absolute values are all less than 1. Thus, in the infinite size limit $N \to \infty$, $\boldsymbol{\mu}^N$ approaches $\mathbf{0}$ and [58] will be largely simplified:

[59] $\mathbf{R}_{jk} = \begin{cases} -\mathbf{E}'\boldsymbol{\delta}\boldsymbol{\mu}^{k-j}\mathbf{H} & \text{for } j \leqq k \\ -\mathbf{H}'\boldsymbol{\delta}\boldsymbol{\mu}^{j-k}\mathbf{E} & \text{for } k \leqq j \end{cases}$

where $\boldsymbol{\delta}$ is given by [24], $\mathbf{E}$ and $\mathbf{H}$ satisfy [15] and [17], while [29] warrants the equality of the two different expressions in [59] for the case of $j = k$.

Both the conceptual and computational advantages of the purely algebraic expression [59] are striking when it is compared with the usual integral expression (69)

[60] $[\mathbf{R}_{jk}(z)]_{pq} = \dfrac{1}{2\pi} \sum_{m=1}^{n} \int_{-\pi}^{\pi} \dfrac{\mathbf{C}_{pm}(\kappa)\mathbf{C}^*_{qm}(\kappa)}{z - \lambda_m(\kappa)} e^{i(j-k)\kappa}\, d\kappa$

which is evaluated by the use of the Dirac identity for $1/z$ and other relations for the delta functions, by integral transformations and the Kramers-Kronig relation, and by numerical integration techniques with a particular approach near the band edge singularities (12). Here the superscript * means complex conjugation, [44] and [47] define the eigenvectors $\mathbf{C}_{*m}(\kappa)$ and the eigenvalues $\lambda_m(\kappa)$ belonging to the mth band and to κ, the latter being proportional to the wave vector.

To point out the differences between [59] and [60] more markedly, one can pose an exercise; namely, to prove the equality

[61] $\dfrac{1}{2\pi} \int_{-\pi}^{\pi} \dfrac{e^{i\kappa(k-j)}}{z - a - 2b\cos\kappa}\, d\kappa = \dfrac{\mu^{|k-j|}}{b(\nu - \mu)}$

where $z = x + iy$, a and b are constants, k and j are nonnegative integers, $\mu = \text{minabs}[w \pm (w^2 - 1)^{1/2}] = \nu^{-1}$, $w = (z - a)/2b$ and minabs means that one has to choose one which is smaller in absolute value. The whole arsenal of the theory of complex functions must be applied to evaluate the left side of eq. [61], arriving finally at the compact algebraic expression of the right side, if we do not know the background of the problem. A numerical test of [61] would also be more tedious for the left than for the right side, because of the possibly singular integrand. At the same time, it is now evident that [61] is nothing but $\mathbf{G}_{jk}(z)$ of the simplest one-atomic chain ($\mathbf{F}_{11} = a$, $\mathbf{S}_{11} = 1$, $\mathbf{A} = a - \lambda$, $\mathbf{S}_{12} = 0$, and $\mathbf{B} = \mathbf{F}_{12} = b$) written in two different forms [60] and [59].

It has to be pointed out that one can work with expression [59] purely on the real axis of the complex energy plane. Instead of executing a limiting process $y \to +0$, one can calculate everything listed after eq. [59] just for the real values of $z = \lambda$, i.e., by substituting $y = 0$. Expression [59] so-obtained correctly displays the well-known characteristics of the resolvent, producing imaginary contributions inside the bands and singularities at the band edges and at the other Van Hove sites, and remaining purely real outside the bands (69). (Singularities caused usually by the discrete spectrum are naturally absent here in the cyclic problem.)

To be more explicit, expression [59] for $\mathbf{R}_{jk}$ will be decomposed as

[59a] $\mathbf{R}_{jk} = \sum_{m=1}^{n} \mathbf{R}^m_{jk} = \mathbf{R}^{\text{band}}_{jk} + \mathbf{R}^{\text{exp}}_{jk}$

where

[59b] $\mathbf{R}^m_{jk} = -\delta_{mm}\mu_m^{|k-j|}\,\mathbf{R}^m$

[59c] $\mathbf{R}^m = \begin{cases} (\mathbf{E}_{m*})'\mathbf{H}_{m*} & \text{for } j \leqq k \\ (\mathbf{H}_{m*})'\mathbf{E}_{m*} & \text{for } k < j \end{cases}$

[59d] $\mathbf{R}^{\text{band}}_{jk} = \sum_{m}^{|\mu_m|=1} \mathbf{R}^m_{jk}$

and

[59e] $\mathbf{R}^{\text{exp}}_{jk} = \sum_{m}^{|\mu_m|\neq 1} \mathbf{R}^m_{jk}$

Now

[24a] $\delta_{mm} = [\mathbf{E}_{m*}(\mathbf{B}\mu_m - \nu_m\mathbf{B}')(\mathbf{H}_{m*})']^{-1}$

follows from [24]. The decomposed forms

[15a] $\mathbf{E}_{m*}(\mathbf{B}'\nu_m + \mathbf{A} + \mathbf{B}\mu_m) = 0$

and

[17a] $\mathbf{H}_{m*}(\mathbf{B}'\mu_m + \mathbf{A} + \mathbf{B}\nu_m) = 0$

of eqs. [15] and [17] (for the derivation, compare them with [44]) have the common characteristic equation $|\mathbf{B}'t^{-1} + \mathbf{A} + \mathbf{B}t| = 0$. This is equivalent to the characteristic equation of [10] and [11]. Its reciprocal character was already mentioned after [13]. In addition, it is a real algebraic equation of order $2n$ for the variable t. This means that a real algebraic equation of order n determines $t + t^{-1} = x$. One can distinguish three cases when its solutions are classified.

(i) $|t| = 1$ if and only if x is a real number and $|x| \leqq 2$, defining by this way the allowed energy bands. Then $t^{-1} = t^*$, or, for an actual eigenvalue: $\nu_m = \mu^*_m$.

(ii) $|t| \neq 1$ and t is real if and only if x is real and $|x| > 2$. Here $|\mu_m| < 1$, $|\nu_m| > 1$ and both are real.

(iii) $|t| \neq 1$ and t is not real if and only if x is not real. In this case, however, due to the fundamental theorem of algebra, x^* is also a root of the above real algebraic equation of order n. Evidently, if just $\mu_m + \nu_m = x$, then $x^* = \mu_{m'} + \nu_{m'}$, $m' \neq m$, $\mu_{m'} = \mu^*_m$, and $\nu_{m'} = \nu^*_m$. The latter two cases lead to exponentially varying quantities outside the allowed bands.

In case (i), the complex conjugated form of [15a] is just equivalent to [17a], therefore $\mathbf{H}_{m*} = \mathbf{E}^*_{m*}$. Then [24$a$] yields

$$[24b] \quad \delta_{mm} = [\mathbf{E}_{m*}(\mathbf{B}\mu_m - \nu_m\mathbf{B}')(\mathbf{E}_{m*})^+]^{-1}$$

which is now purely imaginary, because $\mathbf{B}\mu_m - \nu_m\mathbf{B}'$ is antihermitian. Consequently, [59d] represents the complex contributions of the bands having non-zero imaginary part, where the specific form

$$[59f] \quad \mathbf{R}^m = \begin{cases} (\mathbf{H}_{m*})^+\mathbf{H}_{m*} & \text{for } j \leqq k \\ (\mathbf{E}_{m*})^+\mathbf{E}_{m*} & \text{for } k < j \end{cases}$$

of eq. [59c] is valid. Strikingly, $\mathbf{R}^m$ defined by [59f] has real diagonal elements. Thus the diagonal elements in [59d] are purely imaginary for $j = k$ and are complex otherwise.

In case (ii), both [15a] and [17a] give real solutions warranting the reality of the other quantities concerned here.

In case (iii), eqs. [15a] and [17a] written for index m' are equivalent to their complex conjugated forms stated for m. Therefore, $\mathbf{E}_{m'*} = \mathbf{E}_{m*}^*$, $\mathbf{H}_{m'*} = \mathbf{H}_{m*}^*$, etc., for all the other appearing quantities in [59b], [59c], and [59e]. In this way the sum of the pairs' contributions is always real.

Consequently, $\mathbf{R}_{jk}^{\text{exp}}$ of [59e] is purely real, too.

The second form of the charge-bond matrix mentioned above follows from [51], [59], and [59a]–[59f].

$$[62a] \quad \mathbf{P}_{jk} = (\mathbf{P}_{kj})' = -\frac{2}{\pi}\int_{-\infty}^{\lambda_F} \text{Im}\,(\mathbf{R}_{jk}^{\text{band}}|_{y=0})\,dx$$
$$= \frac{2}{\pi}\int_{-\infty}^{\lambda_F} \sum_{m}^{|\mu_m|=1} \text{Im}\,[\delta_{mm}\mu_m^{|k-j|}(\mathbf{E}_{m*})'\mathbf{E}_{m*}^*\,dx$$

where δ_{mm} is given by [24b], $\mu_m = e^{i\kappa_m}$ and $\mathbf{E}_{m*}^+ = \mathbf{J}_{*m}(\kappa_m)$ is just the solution of the LCAO CO eq. [44].

Note that in actual calculations one can always choose the more convenient one from the two dual forms [19] (or particularly [43]) and [44] of the auxiliary equation (41a).

Namely, [19] is a generalized polynomial eigenvalue problem (68) with eigenvalues μ_m (τ_m) for any fixed value of λ. The use of a standard routine to its solution is very advantageous if the size of the elementary cell (n) is large. Otherwise one can obtain its solutions with a standard eigenvalue routine from the original auxiliary equation [11], too. The latter is, however, a real but essentially asymmetrical eigenvalue problem. At the same time, it contains the complete information on both "band"- and "exp"-like solutions.

The other "dual" form [44] is a generalized Hermitian eigenvalue problem with eigenvalue λ for any fixed value of κ taken from the interval $(0, \pi)$. Whenever a band structure calculation is given, in fact, one has its solutions. To have the "exp"-like solutions, however, one has to use the original τ_m of [43] in [44] instead of $e^{i\kappa}$, when [44] becomes a genuinely asymmetrical (real or complex) generalized eigenvalue problem.

It is quite evident that the DRM has led to the simpler expression of the charge-bond order matrix [50], although [62] is already much simpler than the "pure IPM" expression would be from the combination of eqs. [51] and [60]. One can expect, therefore, significant simplifications in the calculation of several other physical quantities when the DRM, or at least the IRM is applied instead of the IPM.

It is interesting to note finally that eq. [44] is just one component for the block-diagonalized form of the starting eigenvalue problem [1]. Namely, reverting from $\kappa = 2\pi q/N$ to the original integer variable q, collecting the column vectors [47] for $m = 1, \ldots, n$ in matrix $\mathbf{C}(q)$ and defining the hypermatrices $\mathbf{C} = \{\boldsymbol{\delta}_{jq}\mathbf{C}(q)\}$ and $\boldsymbol{\Omega} = \{\boldsymbol{\Omega}_{pj}\}$ of order N with blocks $\mathbf{C}(q)$ and $\boldsymbol{\Omega}_{pj} = \mathbf{N}^{-1/2}\,\mathbf{I}\exp(2\pi ipj/N)$ of order n, the unitary matrix $\boldsymbol{\Omega}$ just block diagonalizes [1] and the unitary matrices $\mathbf{C}(q)$ diagonalize the blocks, as is well-known (4–6, 70): $\mathbf{C}^+\boldsymbol{\Omega}^+\mathbf{F}\boldsymbol{\Omega}\mathbf{C} = \mathbf{C}^+\boldsymbol{\Omega}^+\mathbf{S}\boldsymbol{\Omega}\mathbf{C}\boldsymbol{\Lambda}$ is the completely diagonal form, $\boldsymbol{\Omega}^+\mathbf{F}\boldsymbol{\Omega}$ and $\boldsymbol{\Omega}^+\mathbf{S}\boldsymbol{\Omega}$ are block diagonal, $\boldsymbol{\Lambda} = \{\delta_{pq}\Lambda(q)\}$ $(p, q = 1, \ldots, N)$ and $\Lambda(q) = \{\boldsymbol{\delta}_{km}\boldsymbol{\lambda}_m(q)\}(k, m = 1, \ldots, n)$. Here the DRM has led to both forms in one step. The block-diagonalization technique was learned from a special evaluation method of cyclic determinants in ref. 4 although the use of group theory is the most common.

3. Summary

More and more new problems arise when the simplest perfect infinite periodic models of polymers and crystals are complicated by boundaries and various other perturbations step by step. To make their description and understanding simpler, these problems were treated (and will be studied in the forthcoming papers) immediately at that step in which these first appear.

Deriving several forms for the fundamental and the auxiliary equations of the DRM, a simple combination of block-decomposition and transpositions was applied to calculate $\mathbf{U}^{-1}$ directly from the blocks of $\mathbf{U}$, the similarity transformation bringing the recursion matrix $\mathbf{T}$ into its normal form $\boldsymbol{\tau}$. Full-matrix expressions were given for the blocks of the resolvent (Green) matrix of perfect cyclic systems which can largely simplify the SCF local-impurity approach (11–14), where these blocks play a central role. Expressions for the charge-bond order matrix were derived both by the DRM and the IRM, providing a deeper insight into the relation of these methods.

Acknowledgements

The author would like to express his gratitude to Professor J. Ladik for his invitation to Germany and his hospitality, and stimulating discussions while the author was working there. It is a pleasure to thank Mr. M. Gies, Professor P. Otto, and Dr. M. Seel for their continuous kind help and fruitful discussions. Miss S. Patzak is also thanked for her kind assistance.

The infrared (3500 to 300 cm^{-1}) spectra of methylisothiocyanate, ethylisothiocyanate, isopropylisothiocyanate, and cyclopropylisothiocyanate isolated in argon and nitrogen matrices have been recorded. In general, the spectra were more complex in the nitrogen matrices and, for ethylisothiocyanate, nearly all of the fundamentals appeared as doublets in the nitrogen matrix but for the most part as single bands in the argon matrix. No evidence could be found for a second conformer for either ethylisothiocyanate or isopropylisothiocyanate. Even though cyclopropylisothiocyanate has been shown to exist as the *cis* and *trans* conformers at ambient temperature, little conclusive evidence could be found for two isomers in the infrared matrix material. The complex spectra observed in the NCS antisymmetric stretching region as well as in the 520 cm^{-1} region appear to arise in part from combinations involving the low-frequency large amplitude CNC bend or asymmetric torsion of these organoisothiocyanate molecules. It appears that the vibrational spectra of these molecules are not sensitive to the orientation of the NCS moiety.

J. R. DURIG, J. F. SULLIVAN, D. T. DURIG et STEPHEN CRADOCK. Can. J. Chem. **63**, 2000 (1985).

On a enregistré les spectres infrarouges (3500 à 300 cm^{-1}) des isothiocyanates de méthyle, d'éthyle, d'isopropyle et de cyclopropyle isolés dans des matrices d'argon et d'azote. D'une façon générale, les spectres enregistrés dans des matrices d'azote sont plus complexes que ceux enregistrés dans des matrices d'argon; dans le cas de l'isothiocyanate d'éthyle, pratiquement toutes les fondamentales se présentent sous forme de doublets dans la matrice d'azote alors qu'elles se présentent généralement sous forme de singulets dans la matrice d'argon. On n'a pas pu mettre en évidence l'existence d'un deuxième conformère dans les isothiocyanates d'éthyle ou d'isopropyle. Même s'il est connu que l'isothiocyanate de cyclopropyle existe sous les conformations *cis* et *trans* à la température ambiante, on n'a pas obtenu de données fermes relativement à la présence de ces deux conformères dans les matrices examinées par infrarouge. Le spectre complexe que l'on observe dans la région de vibration de valence antisymétrique du NCS ainsi que dans la région de 520 cm^{-1} semble résulter en partie de combinaisons impliquant soit la vibration de déformation angulaire du CNC de basse fréquence et de forte amplitude soit la vibration de torsion asymétrique de ces molécules d'organoisothiocyanates. Il semble que les spectres vibrationnels de ces molécules ne soient pas sensibles à l'orientation de la portion NCS.

[Traduit par le journal]

Introduction

We recently reported (1) the mid-infrared spectra of matrix isolated ethylisothiocyanate in a nitrogen matrix and observed that several of the fundamentals appeared as doublets. Since only one matrix material was utilized it was not possible to ascertain whether these doublets were due to two different matrix sites or whether the molecule was being trapped in two different conformations. The other vibrational data could be readily explained on the basis of a single conformer with C_s symmetry (*cis* conformer) with the isothiocyanate group eclipsing the methyl group. The major lines in the microwave spectrum could be explained (2) on the basis of this single conformer although there were additional microwave lines which were not assigned. The earlier conclusions (3) that ethylisothiocyanate exists as two conformers at low temperature was based on the assignment of two bands at 2199 and 2154 cm^{-1} in the infrared spectrum of the solid as the NCS antisymmetric stretches of the *gauche* and *trans* conformers. The most interesting spectral region is the 2080 to 2250 cm^{-1} region where unusual intensity changes and frequency shifts have been previously observed with changes in physical state or solvents. Although Kniseley *et al.* (3) agreed that a portion of the complexity in the spectral region is due to the overtone of the NCS symmetric stretch being in Fermi resonance with the antisymmetric mode, the fact that they observed four strong bands in the infrared spectrum of the solid led them (3) to conclude that two conformers are present in the solid state. In order to provide additional data for this spectral region, we recorded (4) the vibrational spectra of methylisothiocyanate and methyl-d_3-isothiocyanate where no conformers can exist and found three infrared bands in this spectral region of the solid. Additionally, unusual intensity changes were found in going from the gas or liquid to the solid state, but the frequency shifts or intensity changes could be readily explained on the basis that the lower frequency band in the Fermi doublet in the gas phase has a significantly larger amount of the antisymmetric NCS stretch whereas in the solid state the higher frequency band has a predominance of this fundamental (4). The third band was assigned as a combination band of the methyl deformation with the C_α—N stretch.

In order to provide additional spectral data on the NCS

[a] Abbreviations used: s, strong; m, medium; w, weak; v, very; sh, shoulder; and bd, broad.
[b] Data for the gas taken from ref. 4.
[c] We have kept the numbering of the fundamentals the same as in ref. 4 which is for a molecule with a quasi-linear heavy atom skeleton with C_{3v} symmetry although ν_6 through ν_{10} should be doublets for a molecule with C_s symmetry.

antisymmetric stretching mode, we have recorded the infrared spectra of some matrix isolated organoisothiocyanates. For the ethylisothiocyanate molecule, we were interested in whether the previously observed doubling of the fundamentals in the nitrogen matrix is due to the presence of conformers or to matrix site effects. Additionally, we have investigated the cyclopropylisothiocyanate molecule in order to determine if conformers can be identified from the vibrational data of the isothiocyanate molecules since we have found two conformers for this molecule at ambient temperature from a microwave study (5). However, from the previous vibrational study (6) of this molecule the authors assigned the observed spectra on the basis of a single conformer. The results of the study of the infrared spectra of matrix isolated methylisothiocyanate, ethylisothiocyanate, isopropylisothiocyanate, and cyclopropylisothiocyanate are reported herein.

Experimental

All the compounds were obtained from commercial sources and purified by low-temperature fractionation on a vacuum sublimation column. The infrared spectra of the samples isolated in either an Ar or N_2 matrix at ratios varying from 400:1 to 1000:1 were recorded with a Perkin-Elmer model 225 grating spectrophotometer between 3500 and 300 cm^{-1}. The matrix samples were prepared by the "pulsed-deposition" method on a CsI window held at ~10 K by an Air Products model CS-202 microrefrigerator. Samples were annealed to 30–35 K, but no significant changes in the spectra were noted except for the appearance of greater amounts of aggregated molecules.

Results

In order to ascertain the matrix effect on the normal modes of these organoisothiocyanates, we recorded the infrared spectra in both argon and nitrogen matrices. For the most part the argon matrices gave sharper bands and there certainly was less doubling of the fundamentals, except in the case of cyclopropylisothiocyanate. Therefore, for each molecule, we shall discuss the results obtained in the argon matrix and then compare them to those obtained in the nitrogen matrix.

Methylisothiocyanate

In Table 1, we have listed the frequencies for the normal modes of methylisothiocyanate which had previously been obtained (4) for the gas along with the observed frequencies in the two different matrices. For the most part there is reasonable agreement between the gas phase frequencies and those obtained in the matrix except for a few gas phase bands where it was difficult to ascertain the band centers because of the breadth of the bands. For example, the CH_3 antisymmetric stretch is found at 2998 cm^{-1} in the spectra of the matrices which is probably more nearly the band center in the gas phase rather than the lower frequency of 2983 cm^{-1} which was reported earlier (4). However, there was no indication that this band is split as it should be if the molecule has effective C_s symmetry at this low temperature. There are three other bands in this same general region at 2887, 2818, and 2791 which are as strong as the ν_6 fundamental but are obviously due to two combination bands and an overtone band. These same three bands were observed in the spectrum of the gas although $2\nu_7$ appears to have a lower frequency in the matrix, but it could well be due to the breadth of this band in the gas phase and the difficulty in choosing the band center.

There are a few differences between the gas phase frequencies and those obtained in the matrices which should be noted. In particular the ν_9 fundamental, the NCS bend, is broad in the gas with the maximum occurring at about 411 cm^{-1} and certainly not higher than 418 cm^{-1} but, in the argon matrix, this fundamental appears at 459 cm^{-1}, and at 451 cm^{-1} in the nitrogen matrix. This significant shift to higher frequency is attributed to the added constraints placed on the molecule by the matrix. The C_α—N stretch, ν_5, has a shift in the opposite direction where it is found at 676 cm^{-1} in the gas, as a doublet at 668 and 661 cm^{-1} in the argon matrix, and 652 cm^{-1} in the nitrogen matrix. The third fundamental which is significantly affected is the NCS antisymmetric stretch which shifts from 2089 cm^{-1} in the gas to a doublet at 2126 and 2118 cm^{-1} in the argon matrix but a single band at 2135 cm^{-1} in the nitrogen matrix. Overall, it appears that the nitrogen matrix has a greater effect on the fundamentals than the argon matrix. For example the CH_3 symmetric deformation, ν_3, appears as an intense doublet at 1422 and 1418 cm^{-1} in the nitrogen matrix whereas the same mode in the argon matrix appears at 1421 cm^{-1} with a possible shoulder at 1420 cm^{-1}. Although the CH_3 antisymmetric deformation, ν_7, appears as a sharp doublet at 1459 and 1452 cm^{-1} in the argon matrix (Fig. 1) the two corresponding bands at 1458 and 1453 cm^{-1} in the nitrogen matrix are very broad and each appears to contain at least two or possibly more bands. This is really the only mode which would be expected to be degenerate for a quasi-linear heavy atom skeleton that shows doubling in the spectrum of the matrix isolated material.

The most interesting spectral region is the 2100 cm^{-1} region where the NCS antisymmetric stretch, ν_2, appears. In the spectrum of the argon matrix this fundamental can readily be assigned to the doublet at 2126 and 2118 cm^{-1}, and to the single band at 2135 cm^{-1} in the nitrogen matrix. The overtone of the NCS symmetric stretch is significantly weaker than the ν_2 fundamental but again it appears as a doublet at 2217 and 2211 cm^{-1} in the argon matrix and as a single band at 2209 cm^{-1} in the nitrogen matrix. A third set of bands appear as doublets at 2256/2236 cm^{-1} in argon and 2242/2235 cm^{-1} in nitrogen which have been assigned as the combination of $\nu_2 + \nu_{10}$. These bands were not previously observed in either the infrared spectrum of the gas or solid. For further support of this assignment we annealed both matrices to 35 K and the bands became quite broad. This behavior is exactly what would be expected for the combination of $\nu_2 + \nu_{10}$. It should also be noted that with annealing the NCS bend, ν_9, shifted to lower frequency, i.e., ~435 cm^{-1}, and it became quite broad. The remaining fundamentals showed little change upon annealing except for the NCS antisymmetric stretch which developed a number of bands on the high frequency side where there had been a shoulder, but these bands are undoubtedly due to aggregate bands. The remaining band in this region is at 2085 cm^{-1} in the argon matrix and 2072 cm^{-1} in the nitrogen matrix. We believe this band is due to a combination of $\nu_3 + \nu_5$ which would be predicted to be about 12 cm^{-1} lower in the nitrogen matrix since ν_5 is 12 cm^{-1} lower in this matrix compared to the value in argon. The higher intensity of this band in the argon matrix may be due to greater Fermi resonance with ν_2 since it has a value closer to this fundamental in the argon matrix. With these assignments for the bands in this spectral region for the methylisothiocyanate molecule, we believe that we can provide a better explanation for the bands observed in this spectral region for the other simple organoisothiocyanate molecules.

Based on these studies in both the argon and nitrogen matrices, it should be noted that great care needs to be exercised in attempting to identify conformers from infrared matrix studies of organoisothiocyanate molecules. It appears that the argon matrix is better for this purpose but, even for this matrix, the ν_2, ν_5, and ν_7 fundamentals of methylisothiocyanate appeared as doublets with nearly equal intensities whereas only ν_7 should be split if the effective symmetry is C_s rather than C_{3v}.

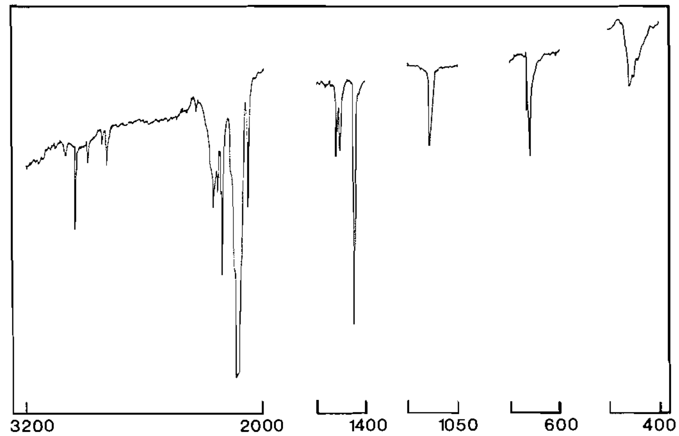

FIG. 1. Infrared spectrum of methylisothiocyanate isolated in an argon matrix. The indicated abscissa intervals below 1500 cm^{-1} are 100 cm^{-1}.

Ethylisothiocyanate

In the initial study (1) of matrix isolated ethylisothiocyanate, nitrogen was used as the host and practically all of the fundamentals were doublets and it was not possible to ascertain whether this doubling was due to matrix effects or the presence of a second conformer. Therefore we have recorded the infrared spectrum of this molecule in an argon matrix. There is a striking difference between the results for the two matrices for most of the fundamentals with the exception of the NCS antisymmetric stretch. In the nitrogen matrix most of the fundamentals appear as doublets whereas for the argon matrix most of the fundamentals are single bands. Therefore we have concluded that the doubling in the nitrogen matrix is due to matrix effects, i.e., the molecule is sitting on two different sites, or some other orientational effect relative to the matrix lattice is occurring. The absence of this doubling in argon is particularly noteworthy for the carbon–hydrogen bending modes.

For the most part there is reasonable agreement among the fundamental frequencies in the gas and the two matrices. Notable differences occur for the NCS bend(s), the NCS antisymmetric stretch, and the C—C stretch. The first two vibrations also showed significant differences in frequencies between the gas and matrices for the corresponding methyl compound. For example, the NCS bend in methylisothiocyanate is found at 411 cm^{-1} in the gas, but it is 40 cm^{-1} higher in the nitrogen matrix and 48 cm^{-1} higher in argon whereas for the ethyl compound these differences are 37 and 47 cm^{-1}, respectively. However, for the NCS antisymmetric stretch in methylisothiocyanate, the nitrogen matrix gives the highest frequency whereas for the ethyl compound it is the argon matrix. However, it should be noted that for the overtone of the symmetric NCS stretch as well as the two combination bands which appear in this region for CH_3NCS the highest frequencies appear in the argon matrix. One other similarity in this region should also be noted. In the argon matrix, both the overtone of the symmetric NCS stretch as well as the anti-

[b]Data for gas and nitrogen matrix taken from ref. 1; bands in parentheses are taken from the spectrum of the solid.

symmetric NCS stretch show doubling in the argon matrix whereas these bands are single bands in the nitrogen matrix for both ethyl- and methylisothiocyanate. In general the argon matrix leads to a more complex pattern in this spectral region.

Since the symmetric NCS stretch is at a lower frequency (1065 cm^{-1}) in ethylisothiocyanate than in the methyl compound (1106 cm^{-1}) the overtone is nearly coincident with the NCS antisymmetric stretch so that the Fermi resonance gives two bands in the 2100 cm^{-1} region of equal intensity and it is not possible to identify a particular band as the ν_4 fundamental. Additionally, the C_α—N stretch with the CH_3 or CH_2 deformations give combination frequencies in this same general region and it is probable that one of these combinations is also in Fermi resonance with the NCS antisymmetric stretch which gives rise to the other very strong band in this region. There are numerous combination bands, including those with the CNC bend or the asymmetric torsion with ν_4, which fall slightly higher in frequency than the NCS antisymmetric stretch which can explain the other weaker bands in this spectral region. The spectral assignments are summarized in Table 2.

The greater complexity in this spectral region compared to the methyl compound is apparently part of the reason why in the earlier studies it was concluded that two conformers exist in the solid state (3). Since the antisymmetric NCS stretch shifts to higher frequency by more than 100 cm^{-1} with solidification, the relative amounts of Fermi interaction with specific combinations or overtones vary with physical state. Additionally it should be noted that the symmetric NCS stretch shifts only slightly to lower frequency with solidification so that the overtone of this mode is expected to be at nearly the same frequency in the various physical states. This gives rise to significant alterations in intensity depending on the degree of Fermi resonance with the NCS antisymmetric stretch.

[b] Data for the gas taken from ref. 7; bands in parentheses are taken from the spectrum of the solid and the bands in brackets are from the Raman spectrum of the gas or solid.

tra of isopropylisothiocyanate and the microwave spectrum could be interpreted on the basis of a single conformer where the sum of the B and C rotational constants is consistent with the *skew* conformer with the NCS moiety eclipsing one of the methyl groups. Additionally, there was no evidence for a second conformer from the vibrational data. Similarly, for the spectrum of the matrix isolated material, there is no convincing evidence for the presence of a second conformer, since there is no consistent pattern of doubling in either the nitrogen or argon matrices. For example, the C_α—N stretch appears as a doublet in the argon matrix but a single band in the nitrogen matrix, whereas the CC_2 antisymmetric stretch appears as a doublet in the argon matrix but a single band in the nitrogen matrix. The CC_2 symmetric stretch shows no doubling in either spectrum.

The same complications observed in the NCS antisymmetric stretching region as observed for the methyl and ethyl compounds are also observed in the matrix isolated spectra of isopropylisothiocyanate. In these cases, ν_5 appears at 2065

[a] See Table 1 for an explanation for the abbreviations used.
[b] Data for the gas taken from ref. 6; bands in parentheses are from the solid. The CH_2 twist, ν_8, has not been observed or assigned.

cm^{-1} and shifts to 2087 cm^{-1} in argon and to 2122 cm^{-1} in the nitrogen matrix. However, for this molecule, one particular band appears to be stronger than the other ones and we have chosen it as the fundamental. Nevertheless, there are combination and overtone bands which also appear to be relatively strong in this spectral region.

There is a significant difference between the nitrogen and argon matrix spectra in the NCS bending region. For this molecule there does not appear to be any significant shift among the gas phase or matrix frequencies for this mode as was found for the methyl and ethyl compounds, but in the nitrogen matrix this mode appears as a doublet whereas in the argon matrix it is a single band but the combination band of this fundamental with the CNC bend is clearly observed in the argon matrix. We can not provide any reasonable explanation for these observations but it is quite evident that the different matrices have a profound effect on the frequency and number of bands for the motions associated with the NCS moiety for all of these organoisothiocyanate molecules.

The spectral data obtained from the matrices support, for the most part, the assignment previously given for isopropylisothiocyanate with the exception of two fundamentals. The matrix-isolated spectra indicate that one of the CH_3 antisymmetric deformations should be assigned at 1423 cm^{-1} and there is an indication that the 1271 cm^{-1} band could be assigned as a fundamental, possibly as one of the CH bending motions. However, this frequency fits that expected for $2\nu_{14}$ and we have tentatively assigned it as such. It should also be noted that the CC_2 deformation, which was previously observed only in the Raman spectrum, was not observed in the infrared matrix isolated spectra. The assignment is summarized in Table 3.

Cyclopropylisothiocyanate

We were particularly interested in the cyclopropylisothiocyanate molecule since in the initial investigation of the vibrational spectrum of this molecule the investigators (6) concluded that there is only one conformer present at ambient temperature but we (5) found both the *cis* and *trans* conformers present from a microwave study. Therefore we expected to find doublets for the CCN bends as well as the modes associated with the NCS moiety in the spectra of both matrices. An inspection of the data in Table 4 shows that most of these fundamentals are doublets in the spectrum of the argon matrix isolated material but in the nitrogen matrix many of these fundamentals appear as single bands, i.e., ν_{14}, ν_{15}, ν_{25}, and ν_{26}. Although many more of the fundamentals appear as doublets, particularly in the argon matrix, there really is no strong evidence for the presence of two conformers. The major difference in the spectrum of this molecule compared to the other three is the presence of two NCS bending modes and greater complexity in the NCS antisymmetric stretching region. It should also be noted that there appears to be little change in the frequencies of the NCS bends in the matrix material from those in the gas phase although it is much easier to obtain the band centers from the spectrum of the matrix compared to the broad nondescript bands found in the gas phase.

It is not possible to give very convincing assignments for the larger number of bands found in the NCS antisymmetric stretching region. Since the overtone of the NCS symmetric stretch falls at a lower frequency than in the methyl and ethyl compounds, it does not appear to be in Fermi resonance with the antisymmetric mode. It is possible that the band at 2162 cm^{-1} (argon matrix) is due to the combination of the NCS antisymmetric stretch with the asymmetric torsion. This portion of the spectrum appears to be very similar to that found in this region for the isopropylisothiocyanate molecule so that similar assignments should be appropriate for these two molecules. Thus, there is no reason to believe that the second strong band in this region is due to the second conformer.

We have made only two minor changes in the vibrational assignment (Table 4) from that previously proposed (6). The CH_2 twisting mode was not assigned earlier but it is very probable that this mode should be assigned to the 1081 cm^{-1} band and that the CH out-of-plane bend corresponds to the weak band observed at 970 cm^{-1} in the argon matrix. Finally, it should be noted that we followed the same assignment for the 520 cm^{-1} band as that given for the other isothiocyanate molecules where we believe this band arises from the combination of the NCS bend with the CNC bend. This particular band appears to be present in all of the organoisothiocyanate molecules where it is relatively strong in the gas but weak in the spectrum of the solid and usually not observed in the spectrum of the matrix isolated material.

Conclusions

The infrared spectra of the matrix isolated organoisothiocyanate molecules make it possible to obtain the band centers of the fundamentals, many of which are very broad and nondescript in the gas phase. The spectrum of the methylisothiocyanate molecule could be interpreted on the basis of a quasilinear molecule with effective C_{3v} symmetry. The previously reported (1) doubling of the fundamentals of ethylisothiocyanate in the nitrogen matrix is due to matrix effects and not due to the presence of a second conformer since comparable doubling was not found in the argon matrix. No evidence was found for a second conformer for isopropylisothiocyanate, and conclusive evidence for a second conformer of cyclopropylisothiocyanate could not be found even though this molecule has been found to exist at ambient temperature as the *cis* and *trans* conformers from a microwave study (5). Therefore it is concluded that the vibrational spectra of these molecules are not sensitive to the orientation of the NCS moiety and other techniques must be used to establish the presence of conformers in the organoisothiocyanate molecules. All these molecules give complex spectra in the NCS antisymmetric stretching region which is partly due to the overtone of the symmetric mode as well as possible combinations of the CNC bend or asymmetric torsion with this stretch. Certainly the large amplitude motions of the two low frequency fundamentals give rise to a complex band structure in the 570 cm^{-1} region which appears to be in combination with the NCS bend(s), and probably also contribute to the complex spectra in the NCS antisymmetric stretching region.

Adaptation of the Gelius intensity model in semiempirical HAM/3 molecular orbital calculations of valence photoelectron spectra excited by X-ray radiation

DELANO P. CHONG

Department of Chemistry, University of British Columbia, 2036 Main Mall, Vancouver, B.C., Canada V6T 1Y6

Received August 15, 1984

This paper is dedicated to Professor Camille Sandorfy on the occasion of his 65th birthday

DELANO P. CHONG. Can. J. Chem. **63**, 2007 (1985).

The Gelius intensity model has been adapted in the semiempirical HAM/3 method to calculate the valence ionization energies and intensities in XPS. Both semiempirical and *ab initio* Hartree–Fock–Slater atomic photoionization cross-sections can be used. Results presented for C_2H_2, C_2H_4, N_2, H_2O, CH_3OH, and CH_2F_2 demonstrate that the present method can facilitate the interpretation of experimental XPS.

DELANO P. CHONG. Can. J. Chem. **63**, 2007 (1985).

On a adapté le modèle d'intensité de Gélius dans la méthode semi-empirique HAM/3 pour calculer les énergies d'ionisation et les intensités de XPS. On peut utiliser aussi bien des sections droites de photoionisation atomique semi-empirique que les valeurs *ab initio* de Hartree–Fock–Slater. Les résultats rapportés pour les molécules de C_2H_2, C_2H_4, N_2, H_2O, CH_3OH et CH_2F_2 démontrent que la présente méthode peut faciliter l'interprétation de XPS expérimentaux.

[Traduit par le journal]

The Gelius intensity model

A model for calculating relative intensities in the valence region of X-ray photoelectron spectra (XPS) was presented by Gelius (1) over ten years ago. According to this model, the relative intensity for ionization from molecular orbital j is given by

$$[1] \quad I_j^{\mathrm{MO}} = \left[2 + \frac{\beta}{2}\right] \sum_A \sum_\lambda P_{A\lambda j}\, \alpha_{A\lambda}^{\mathrm{AO}}$$

where β is the asymmetry parameter, $P_{A\lambda j}$ is the gross atomic population on atom A from atomic orbital λ in molecular orbital j, and $\sigma_{A\lambda}^{\mathrm{AO}}$ is the relative photoionization cross-section of atomic orbital $A\lambda$. The asymmetry parameter was set to 2 except for π orbitals of linear molecules, in which case $\beta = -1$ was used. For MgKα radiation, Gelius gave values of $\sigma_{A\lambda}^{\mathrm{AO}}$ for the $2s$ and $2p$ orbitals of C, N, O, F, and Ne, and for the $3s$ and $3p$ orbitals of S and Ar. The model was successfully applied to the XPS of C_6H_6, C_4H_4O, C_4H_4S, CF_4, SF_6, C_3O_2, and N_2, despite the preliminary nature of the cross-section ratios.

Several changes have been made since then. A few relative cross-sections $\sigma_{A\lambda}^{\mathrm{AO}}$ were changed (2, 3). The asymmetry parameter was altered to $\beta = 0$ for π orbitals of linear molecules (3). Finally, $P_{A\lambda j}$ was taken to mean the net atomic population (3).

Adaptation of the Gelius model to the semiempirical HAM/3 method

The net atomic population is simply $C_{A\lambda j}^2$. In the semiempirical HAM/3 computer program (4), an additional set of orbital coefficients $\bar{C}_{A\lambda j}$ is available and is associated with the basis set of Löwdin orthogonalized atomic orbitals. The relative intensities obtained by using $C_{A\lambda j}^2$ and $\bar{C}_{A\lambda j}^2$ are similar and only the results from $\bar{C}_{A\lambda j}^2$ will be presented below.

In addition to the semiempirical relative cross-sections of the Gelius model (1–3), we have also incorporated the *ab initio* relative cross-sections for both MgKα (1253.6 eV) and AlKα (1486.6 eV) radiation of Nefedov *et al.* (5) based on the Hartree–Fock–Slater method. A complete list of $\sigma_{A\lambda}^{\mathrm{AO}}$ values used in this work is given in Table 1. The results from semiempirical and *ab initio* cross-sections are similar and only the relative intensities from *ab initio* cross-sections are presented in the figures.

Finally, since our version of the HAM/3 program (6) has been extended to include configuration-interaction (CI) calculations for valence-electron shake-up (VESU) satellite bands, the XPS intensities have likewise been extended. It was demonstrated (6) that the VESU results from HAM/3 can compete with those from two-particle-hole Tamm–Dancoff approximation (2ph-TDA) within the Green's function (GF) approach, especially when a truncated set of molecular orbitals and/or a limited set of atomic orbitals are used.

Results and discussion

The new version of the HAM/3 program was used to calculate the XPS of C_2H_2, C_2H_4, N_2, H_2O, CH_3OH, and CH_2F_2. These molecules were chosen partly because their gas-phase XPS are available and partly because HAM/3 can only handle molecules containing those five elements. The experimental equilibrium geometries for these molecules (7, 8) were used.

In Tables 2 to 7, we summarize the results of the computations. The vertical ionization potentials listed under PES and under VESU come from the runs excluding and including shake-up satellites, respectively. The column heading $\sigma = 1$ refers to the uniform in-phase non-interfering cross-section approximation, which was used previously (6) and corresponds to the so-called spectroscopic factor (9). Finally, the calculated results using *ab initio* atomic cross-sections are compared with the experimental spectra (10–14) in Figs. 1 to 5. In Figs. 2 to 5, contamination by the MgK$\alpha_{3,4}$ satellite line(s) is present as discussed by the experimental workers.

In Fig. 1, the calculated intensity of the shake-up band at 28 eV appears to be too low. However, the correct interpretation of the observed XPS of acetylene is still unclear. Neither CI (10) nor GF (14) calculations produce the experimental pattern around 27 eV. The latest synchrotron results (15) reconfirmed the difficulties of the interpretation, suggesting two different origins of the borrowed intensities for the VESU bands at 26.5 eV and 28 eV, as well as a new peak at 31.0 eV (all in agreement with the present results).

In Fig. 2, the VESU peak at 27 eV is given a new interpretation. The presence of two VESU states in this energy region of the XPS of ethylene is supported by GF results (16). These two cases show that the present HAM/3 approach is

moderately successful. It is in the next example that the shortcoming of our limited configurational space is more evident.

In Fig. 3, the weak peak at 32 eV is missing in the calculated spectrum because it is due to 2-particle-3-hole contributions (9), which are completely absent in our VESU configuration interaction as well as in 2ph-TDA GF calculations (17, 18). The interpretation of the peak at 27 eV in the XPS of N_2 is also quite complicated (9, 19). In fact, there are many significant VESU satellites in the inner valence region of N_2, as shown by the work of Nyholm *et al.* (20) and the present HAM/3 picture is undoubtedly an oversimplification.

In the next three cases, the present method works very well, providing grounds for its use.

method (21–23) but the relative intensities in those calculations are based on the $\sigma = 1$ model.

Finally, the HAM/3 results on CH_2F_2 are compared with the observed spectrum in Fig. 5. The outer-valence photoelectron spectrum of CH_2F_2 is well understood (24). The inner-valence region has been studied by the 2ph-TDA GF method (25) but the ionization energies and spectroscopic factors are inferior to the present results.

By relying heavily on Slater's screening concept, the semi-

empirical HAM/3 method simplifies the true situation by using a minimal basis set. The present version of the program also limits the configurational space for cationic CI to determinants with either one or three singly occupied molecular orbitals.

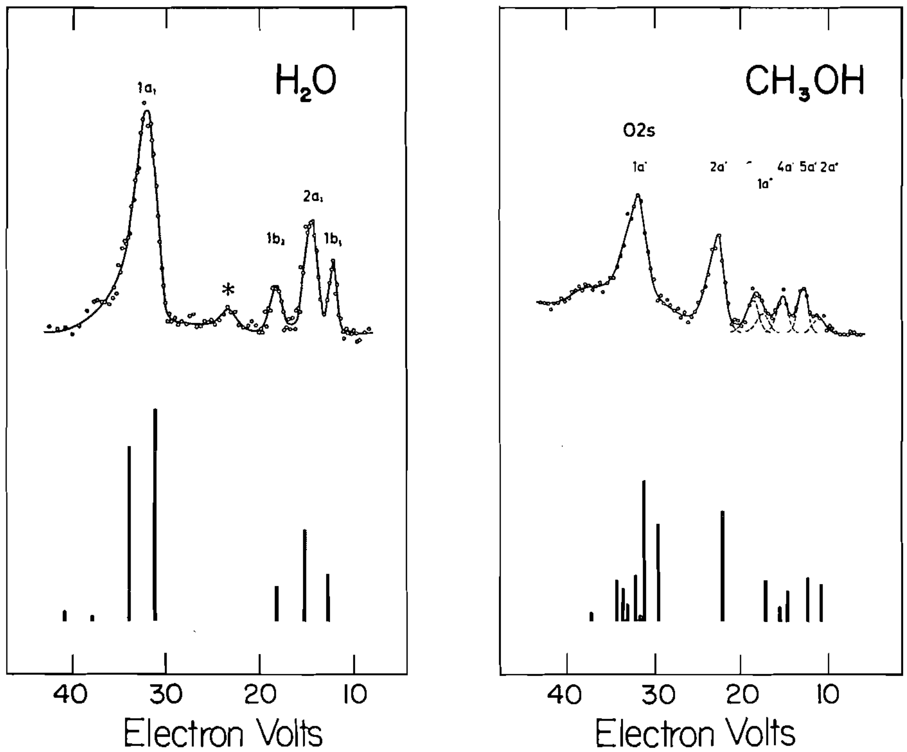

FIG. 4. Comparison of experimental (13) and calculated MgKα photoelectron spectra of H_2O and CH_3OH. The asterisk indicates contamination by MgK$\alpha_{3,4}$.

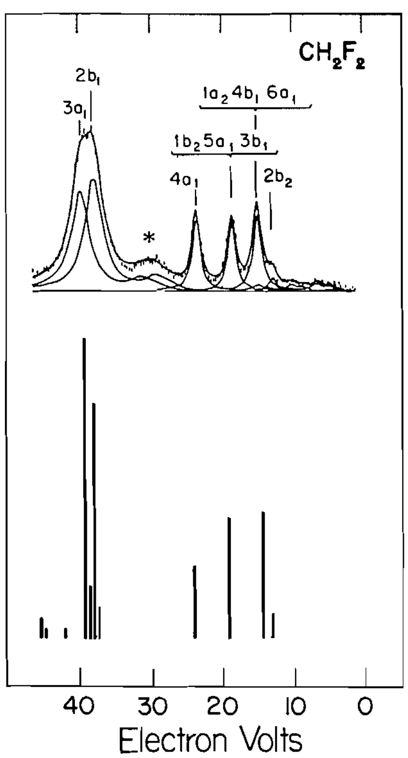

FIG. 5. Comparison of experimental (14) and calculated MgKα photoelectron spectrum of CH_2F_2. The asterisk indicates contamination by MgK$\alpha_{3,4}$.

Nevertheless, this version of the HAM/3 program performs remarkably well. The six molecules studied in this work required a total of 15 s of CPU time on an Amdahl V/8 computer.

In principle, the 2ph-TDA GF approach can be more reliable. In practice, however, severe truncation of the atomic orbital basis set and the molecular orbital space has led to considerable loss of accuracy. Moreover, most of the GF papers give spectroscopic factors rather than XPS intensities. Related to the present study is the work of Honjou *et al.* (26) who computed *ab initio* photoionization cross-sections with the plane-wave approximation, but their ionization energies tend to be less reliable because they use minimal Slater-type orbitals as basis set.

Other semiempirical approaches should be mentioned. Bigelow based his calculations on CNDO (27) and Schulz *et al.* (28) compared CNDO with MNDO and LNDO. In both cases, only the spectroscopic factors are obtained.

In summary, in spite of its simplicity, the present version of HAM/3 can provide useful calculated XPS to facilitate the interpretation of experimental spectra.

This paper is dedicated to Professor Camille Sandorfy on the occasion of his 65th birthday

G. MASSIG, M. STOCKBURGER, and TH. ALSHUTH. Can. J. Chem. **63**, 2012 (1985).

Resonance Raman (RR) spectra of the retinylidene Schiff's base (SB) chromophore of bacteriorhodopsin (BR) were obtained from purple membrane (PM) suspensions of *Halobacterium halobium* in three different equilibrium states: (1) the native state at neutral pH; (2) BR-605, the acidified membrane at pH 2; (3) BR-565(Cl^-) or BR-545 (F^-), at low pH and high ionic strength. In the native state the retinyl chromophore is stabilized by an ion-pair complex of the protonated SB group with a negative carboxylate counterion (A^-) of the protein, giving SBH^+---A^-. In the acidic form, BR-605, it is inferred from the RR spectra that the chromophore is immobilized. This is ascribed to a breakdown of the ionic interaction by protonation of A^-. In the two (3) forms the RR spectra show that the original structure of the chromophore in the native state is reestablished, which is attributed to the formation of SBH^+---Cl^-(F^-) complexes with the anions. It thus turns out from RR spectroscopic evidence that the retinyl chromophore in BR is largely governed by the SBH^+---A^- ion-pair formation, which is stabilized by surrounding water molecules.

G. MASSIG, M. STOCKBURGER et TH. ALSHUTH. Can. J. Chem. **63**, 2012 (1985).

On a obtenu les spectres de résonance Raman (RR) du chromophore de la bactériorhodopsine (BR) de la base de Schiff (BS) du rétinylidène, à partir de suspensions de la membrane pourpre (MP) du *Halobacterium halobium* dans trois états d'équilibre différents: (1) l'état naturel à pH neutre; (2) BR-605, la membrane acidifiée à un pH de 2; (3) BR-565 (Cl^-) ou BR-545 (F^-) à des pH faibles et à une force ionique élevée. À l'état naturel, le chromophore rétinyle est stabilisé par un complexe formé d'une paire d'ions du groupe BS protoné par l'ion carboxylate (A^-) de la protéine en donnant le BSH^+---A^-. Sur la base du spectre RR de la forme acidifiée, BR-605, on déduit que le chromophore est immobilisé. On attribue ceci à une rupture de l'interaction ionique par suite de la protonation de A^-. Dans les deux formes (3), le spectre RR indique que la structure originale du chromophore à l'état naturel est rétablie. On attribue ceci à la formation de complexes SBH^+---Cl^- (F^-) avec les anions. Il ressort donc des données spectroscopiques que le chromophore rétinyle de la BR dépend fortement de la formation de la paire d'ions SBH^+---A^- qui est stabilisée par les molécules d'eau environnantes.

[Traduit par le journal]

Introduction

Bacteriorhodopsin (BR) is a retinal-binding protein in the cell membrane of *Halobacterium halobium.* In the so-called purple membrane (PM) fraction it forms two-dimensional regular arrays and acts as a light-driven proton pump (1). This function is controlled by a chromophoric center which contains retinal bound to the protein via a Schiff's base (SB) linkage (for a review, see ref. 2). In the dark BR exists in a nearly 1 : 1 ratio of two forms with retinal in the all-*trans* (BR-570) and 13-*cis* (BR-548) configuration, respectively (Fig. 1) (3, 4). In the light the equilibrium is shifted towards the all-*trans* component, BR-570, the initial state of a light-induced cyclic process which induces BR's function as a proton pump (Fig. 2) (2).

The colour of a BR chromophore is largely determined by the state of protonation of the SB group. Thus protonation at the SB nitrogen induces a big red-shift (5, 6). As will be outlined below, the positive charge at the SB group interacts strongly with a negative counterion in the side group of an amino acid residue. The absorption maximum (λ_{max}) of a BR chromophore largely depends on the strength of this ionic interaction (5).

It was reported that λ_{max} of the light-adapted PM shifts from 570 to 605 nm when the pH value is decreased from 7 to 2. In more systematic titration experiments with hydrochloric acid it was found by Mowery *et al.* (7) that this transition to a new state, BR-605, can be described by a pK value of 2.9. When the pH value is decreased below 2 by addition of hydrochloric

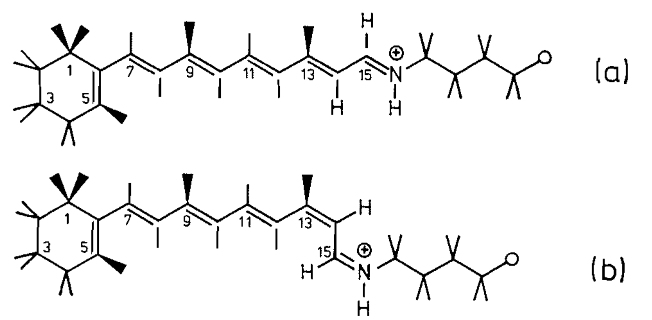

FIG. 1. In the BR chromophore retinal is bound to the ϵ-amino group of a lysine residue via a Schiff's base linkage; (a) native chromophore BR-570: all-*trans* retinal, 15-*anti* protonated SB group (21); (b) native chromophore BR-548: 13-*cis* retinal, 15-*syn* protonated SB group (21).

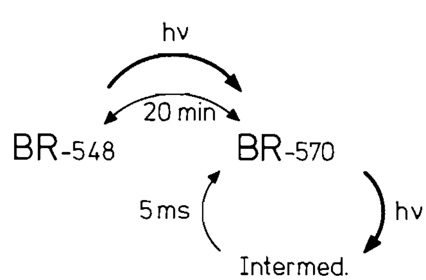

FIG. 2. Photoreactions of native bacteriorhodopsin. Light adaption shifts the equilibrium to BR-570, which runs through a photochemically induced cyclic process. The time constants refer to room temperature.

[1]Author to whom all correspondence should be addressed.

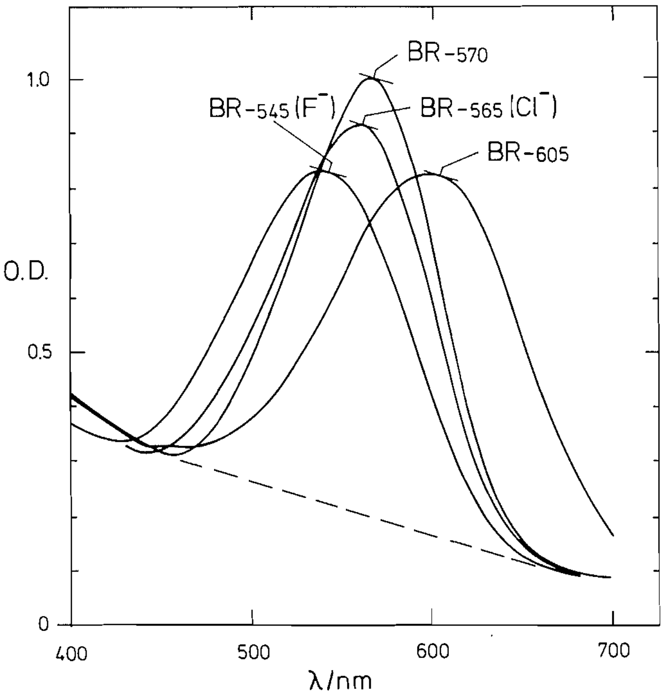

FIG. 3. Absorption spectra from purple membranes embedded in polyacrylamide gels. BR-570: neutral pH value. BR-605: equilibrated with HCl solution at pH 2. BR-565(Cl^-): equilibrated with HCl solution at pH 0. BR-545(F^-): equilibrated with solution of 0.67 *M* hydrofluoric acid and 0.33 *M* NaF, at pH 2.2. All absorption spectra refer to the same concentration of PM.

acid, a second equilibrium state with λ_{max} at 565 nm is established (Fig. 3). While the first transition to BR-605 obviously involves a proton transfer reaction, it could be demonstrated by Fischer and Oesterhelt (8) that the second transition is catalyzed by chloride or fluoride anions leading to final states with λ_{max}

$$[1]\quad \text{BR-570} \underset{\text{I}}{\overset{H^+}{\rightleftharpoons}} \text{BR-605} \underset{\text{II}}{\overset{Cl^-, F^-}{\rightleftharpoons}} \left\{ \begin{matrix} \text{BR-565}(Cl^-) \\ \text{BR-545}(F^-) \end{matrix} \right\}$$

at 565 and 545 nm, respectively (Fig. 3). Equilibrium constants of 1 $M[Cl^-]$ and 0.1 $M[F^-]$ were estimated for the anion-induced transitions (8).

The following view of the molecular mechanism of the reactions in eq. [1] was given by Fischer and Oesterhelt (8). In the parent chromophore, BR-570, the positively charged SB group interacts with a negative counterion giving SBH^+---A^-. When the environmental proton concentration is increased, A^- becomes protonated from the outside. The p*K* value of 2.9 for this reaction argues that A^- might be a carboxylate group of an aspartic or glutamic acid residue. Such a group presumably is located in close vicinity to the chromophore. This is supported by the observation that a carboxylate anion in the protein becomes protonated and deprotonated synchronously with intermediates of the photochemical cycle (9). Once the intrinsic anion is protonated, the original ion-pair interaction is interrupted giving (SBH^+, AH), which corresponds to the red-shifted species BR-605. When the ion strength is further increased, the role of the intrinsic anion can be taken over by extrinsically introduced anions like Cl^- or F^-, reestablishing ion-pair interaction of the form SBH^+---Cl^- (F^-) and shifting λ_{max} back to the blue.

In the present paper we have studied resonance Raman (RR) spectra of the acidified chromophore BR-605 and the two anion complexes BR-565(Cl^-) and BR-545(F^-). In an RR experiment the chromophoric site is selectively probed and one obtains from the vibrational spectra information on the configuration of the retinal chain or the state of protonation of the SB group. The analysis of the RR spectra therefore provides detailed information on the modified chromophoric species and consequently also on the structure of the native chromophore.

Experimental

In order to prevent aggregation of purple membranes arising at low pH values or at high ionic strength the PM patches were embedded into polyacrylamide gels. The gels were prepared as described in ref. 8 and PM was added to the gel at a concentration of 3×10^{-5} *M*. To adjust the pH value and (or) ionic strength and to exchange H_2O for D_2O the gel preparation was immersed in an aqueous reference solution and kept there several hours for equilibration. To record absorption spectra the gel was polymerized into a Plexiglass cuvette with apertures in the side walls to enable diffusional equilibration with the reference solution.

For resonance Raman measurements a demountable spinning cell of cylindrical shape made of Plexiglass was used (10). The cylinder had an inner diameter of 40 mm and a length of 5 mm. The cell was only half filled with liquid gel suspension and then rotated so that the liquid was pressed against the cylindrical wall. Rotation was continued until polymerization was complete, leaving behind a gel layer of a few millimeters in thickness. For equilibration with the reference solution the cell was demounted and the cylindrical wall with the gel layer was immersed in the solvent.

For excitation of Raman scattering the beam of a CW ion laser (argon or krypton) was aligned in the gel layer parallel to the cylindrical wall. The beam was focussed with a 200-mm lens into the middle of the cell, giving a focal diameter of 70 μm. The cell was rotated at a repetition rate of 50 s^{-1}. The conversion of a photolabile species is determined by the product $I_0 \Delta t$, where I_0 is the rate of the photoreaction which is proportional to the irradiation power and Δt is the transit time of a molecule across the focal area of the beam (11). This "photoconversion parameter" was kept below 0.2 for the native chromophore and for BR-605, which means that less than 10% of photoproducts are probed by the laser beam (11). For RR measurements with BR-565(Cl^-) and BR-545(F^-) this parameter was elevated by a factor of three, since up to this value no photointermediates were found.

Raman scattering was monitored perpendicular to the laser probe beam. The spectra were recorded by conventional equipment as described previously (12) using a spectral bandwidth of 3.7 cm^{-1}. The RR spectra of the unphotolyzed chromophores BR-570 and BR-548 were obtained from light- and dark-adapted PM in aqueous suspension as described previously (11–13). In all experiments the temperature was 25°C.

Purple membranes were isolated from *Halobacterium halobium* cells in the conventional way (14).

Results

At pH values between 5 and 7 the RR spectra obtained from gel-suspended PM were identical with the spectra from aqueous solution. In the following the solution spectra of the unphotolyzed species BR-570 and BR-548 will be taken as reference and therefore a brief account of the vibrational assignments will be given in advance. The characteristic bands of the terminal SB group can easily be inferred from a comparison of the spectra in H_2O and D_2O, since upon solvent exchange the proton at the nitrogen is replaced by a deuteron. From the spectra of BR-570 in Fig. 4, therefore, it follows that the band at 1641 cm^{-1} can be assigned to the C=N stretching motion of the $HC{=}NH^+$ group. This band shifts to 1624 cm^{-1} for the $HC{=}ND^+$ group. Similarly the bands at 1349 cm^{-1} in

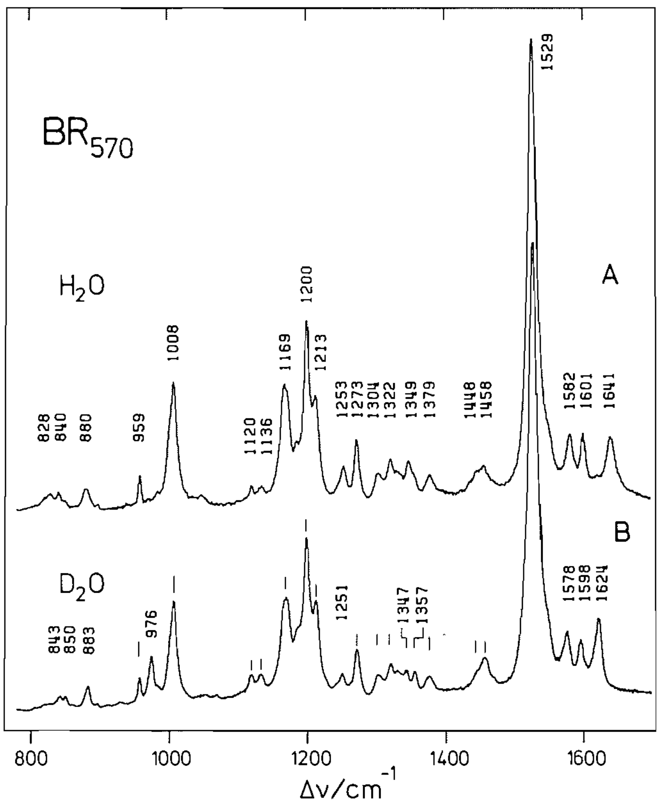

FIG. 4. Resonance Raman spectra of BR-570 from aqueous suspension of PM, excited at 514 nm.

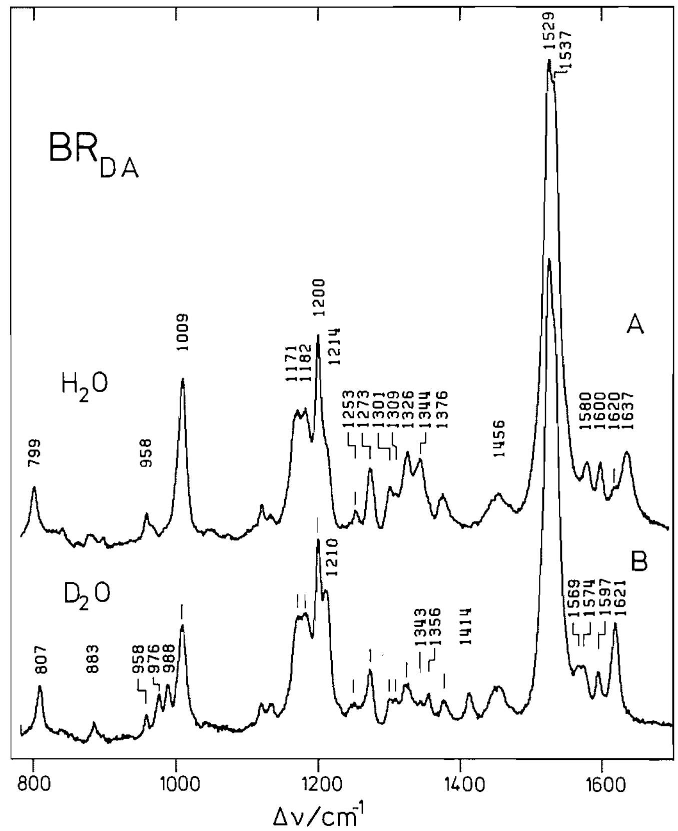

FIG. 5. Resonance Raman spectra from dark-adapted aqueous suspensions of PM, excited at 514 nm.

H_2O and at 976 cm^{-1} in D_2O can be assigned to a vibrational mode whose main component is the N—H or N—D in-plane bending motion. A qualitative assignment of the vibrational bands of the retinal moiety can be made on the basis of normal mode calculations of retinal (15–17). Thus the strongest band in the spectra at 1529 cm^{-1} refers to an "in-phase" stretching motion along the various C—C double bonds. The frequency of this "C═C stretch" varies as the inverse of λ_{max} of a chromophore and therefore is a measure of π-electron distribution along the retinal chain (11, 12, 18). The group of fairly strong bands between 1150 and 1220 cm^{-1} corresponds to vibrations which mainly involve a C—C single bond stretching component which, however, is strongly coupled with the C—H (N—H) in-plane (i.p.) bending motion. Such normal modes are fairly delocalized and therefore are sensitive to structural changes. The group of bands between 1150 and 1220 cm^{-1} thus constitutes a fingerprint for the configuration of the retinal moiety. Similarly the weaker bands between 1250 and 1400 cm^{-1}, which involve the C—H (N—H) in-plane bending motion as a principal component which is coupled to C—C single bond stretches, are also characteristic of the structure of retinal. C—H (N—H) out-of-plane modes lie between 800 and 1000 cm^{-1}. The appearance of intense RR bands in this region has been interpreted as a sign for considerable conformational distortion (13, 19, 20). In the spectra of BR-570 a few weak bands of this type are observed between 820 and 960 cm^{-1}. The fairly strong band at 1008 cm^{-1}, however, obtains its intensity mostly from the in-phase in-plane bending mode of the two methyl groups at the C(9) and C(13) position of the retinal chain (15).

The spectra of the dark-adapted PM in aqueous solution which consists of a 1:1 mixture of BR-570 and the 13-*cis* chromophore BR-548 are depicted in Fig. 5. The contribution of BR-548 is reflected by a number of new vibrational features. Thus a new C═C stretch appears at 1537 cm^{-1}, which corresponds to the shift of λ_{max} to 548 nm. In the fingerprint region a new band arises at 1182 cm^{-1} while in the H_2O spectrum intensity decreases at 1214 cm^{-1}. The fairly distinct feature at 800 cm^{-1} has been attributed to the C_{14}—H out-of-plane (o.p.) bending mode (16). The characteristic vibrations of the SB group can be inferred from isotope effects in Fig. 5. The rather strong band at 1344 cm^{-1} was assigned to a coupled i.p. bending mode of the two SB hydrogens from which the C_{15}—H component appears as a clear feature at 1414 cm^{-1} in the D_2O spectrum (13). The corresponding C_{15}—H o. p. bending mode was assigned to the 988 cm^{-1} band in the D_2O spectrum (13). It must be noted that the band at 1210 cm^{-1} in D_2O has been recently assigned to a C—C single bond stretch. In H_2O this is coupled to the N—H i. p. bend and therefore shifts down to 1160 cm^{-1} (20). It thus appears that the characteristic bands of the SB group are different for the two chromophores BR-570 and BR-548. This can be ascribed to the fact that the two SB hydrogens are in *anti* and *syn* position, respectively (Fig. 1) (21). A "pure" spectrum of BR-548 was obtained by subtracting the contribution of BR-570 (13).

The RR spectra obtained from a PM containing polyacrylamide gel at a pH value of 2 are shown in Fig. 6. Although the BR concentration was as low as 3×10^{-5} *M*, the resonantly enhanced scattering from the chromophore was about five times more intense than Raman scattering from the gel alone, whose contribution therefore could be easily subtracted. It is known that the chromophore established at pH 2, BR-605, is photolabile (22, 24). It also runs through a photochemical cycle

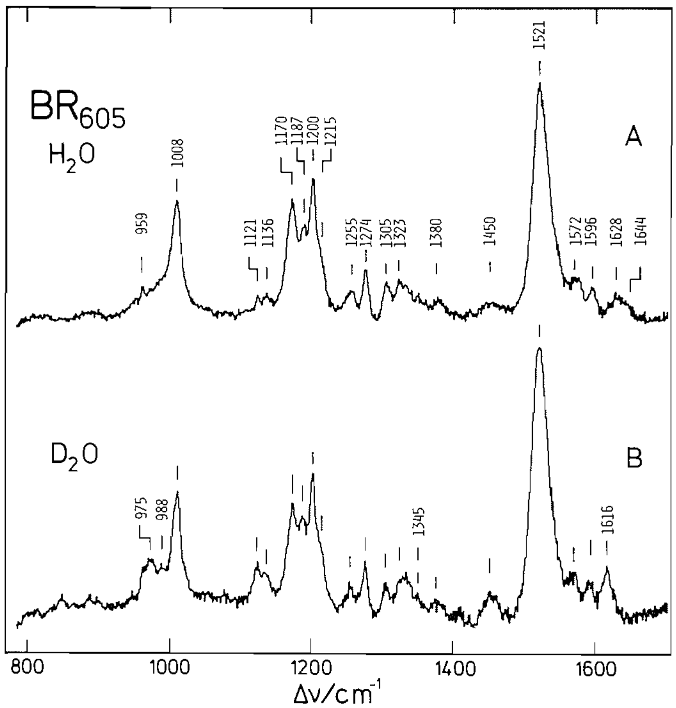

FIG. 6. Resonance Raman spectra of BR-605 excited at 568 nm. BR-605: PM in polyacrylamide gel equilibrated with HCl at pH 2.

with intermediates comparable to K-590 and L-550 of the native chromophore BR-570 (24). For the "L" intermediate a lifetime >700 μs is reported (24). In our RR experiments with a spinning cell it is estimated that less than 20% of photoproducts are formed during the transit of sample across the beam. However, since in the gel the BR molecules are in a fixed position, photointermediates or products whose lifetime is longer than the 20-ms cyclic period of the spinning cell might be accumulated. In the spectra of Fig. 6 the C=C stretch lies at 1521 cm^{-1}, which correlates with λ_{max} at 605 nm. This is strong evidence that in our RR experiment the unphotolyzed species BR-605 predominantly was probed. It is interesting to note that a second C=C stretch at 1533 cm^{-1} increases in intensity at the expense of the 1521 cm^{-1} line when the wavelengths of the Raman probe beam are tuned below 500 nm and therefore are out of resonance with BR-605. It may be that the 1533 cm^{-1} line belongs to the "L" intermediate of BR-605 whose RR scattering is resonantly enhanced in the blue-green region and therefore can be detected even at low concentration. Another possibility would be that the 1533 cm^{-1} line reflects the 9-*cis* photoproduct of BR-605, which also absorbs in the blue-green region (22, 23). Finally, it must be noted that after 10 min of irradiation under the conditions of our RR experiment a 3% bleaching of BR-605 and a concomitant decrease of its RR intensity are observed.

The spectra of BR-605 in Fig. 6 can now be compared with the spectra of the native membrane in Figs. 4 and 5. First of all, it can be concluded from isotopic shifts that the SB group in BR-605 is protonated. In the fingerprint region the intensity ratio of the two diagnostic bands at 1187 and 1215 cm^{-1} is similar to that in the dark-adapted membrane in H_2O suspension (Fig. 5A), suggesting that in BR-605 a mixture of all-*trans* and 13-*cis* retinal is established. This conclusion is in line with biochemical extraction experiments in which a nearly equal amount of the two isomers was found in the light- and dark-adapted state of the acidified membrane at pH 2 (7). On the other hand, the characteristic hydrogen bending modes of the SB group in the 13-*cis*/15-*syn* component of the dark-adapted membrane (799 and 1344 cm^{-1} in H_2O; 807, 988, and 1210 cm^{-1} in D_2O), giving rise to well-resolved vibrational features in the spectra of Fig. 5, cannot be identified in the spectra of BR-605. This implies that the SB group in the 13-*cis* component of BR-605 does not have the same structure as in the 13-*cis* component of the dark-adapted membrane. In this respect it is interesting to compare also other bands of the SB group of BR-605 with related bands of the dark-adapted membrane. Thus the band at 975 cm^{-1} in the spectrum of the acid membrane (Fig. 6B), which refers to the N—D i. p. bending mode of the all-*trans*/15-*anti* component, is much broader than the related band at 976 cm^{-1} in the spectra of the native membrane (Figs. 4B, 5B). This broadening obviously reflects an inhomogeneous structural distribution of the SB group. The C=N stretch in BR-605 is reflected by a fairly weak and broad feature at 1628 cm^{-1} (Fig. 6A) that in D_2O shifts to 1616 cm^{-1}. In the dark-adapted membrane this vibration gives rise to a much narrower band with higher peak intensity at 1637 cm^{-1}. Therefore the C=N stretch of BR-605 at 1628 cm^{-1} cannot be simply obtained by superposition of all-*trans*/15-*anti* and 13-*cis*/15-*syn* components as they occur in the native membrane, but rather reflects also a variety of different structures of the SB group.

Finally we consider the C=C stretch of the acidified membrane that peaks at 1621 cm^{-1} (Fig. 6). The width of this band is 27 cm^{-1} (FWHH) which is large compared with the width of the C=C stretch of the all-*trans* component in the native membrane, which is 15 cm^{-1} (Fig. 4). While in the spectra of the dark-adapted membrane the two components can be easily distinguished by two peaks at 1529 and 1537 cm^{-1}, only a single peak is observed in the spectra of BR-605. This is another clear indication that the BR-605 state is not a pure superposition of the two components of the native membrane.

On the basis of spectroscopic evidence the following picture is obtained. In the native membrane the chromophore is kept in a rather fixed position by interaction with the protein, giving rise to two stable components with all-*trans*/15-*anti* and 13-*cis*/15-*syn* configuration. In the acidified membrane at pH 2 the all-*trans* and 13-*cis* configuration of the retinal moiety is preserved while the fixed structure of the SB group is lost. In particular, the "15-*syn*" structure of this group as it is observed in the dark-adapted native membrane is no longer identified. It thus appears that in BR-605 the SB group obtains more structural mobility than in the native state.

Following the arguments of Fischer and Oesterhelt (8), the transition from BR-605 to a second equilibrium state is due to the increase of the ionic strength. In the present study RR spectra were obtained from two different samples. The first sample was equilibrated with 1 *M* HCl solution at a pH value of 0, the second sample with a solution of 0.67 *M* HF and 0.33 *M* NaF at a pH value of 2.2. The RR spectra in Fig. 7 from the two different samples are nearly identical, which implies that it is not the decrease in pH from 2 to 0 but the increase in ionic strength which is responsible for the transition II (eq. [1]). No indication was found for a long-lived photointermediate, so that the spectra in Fig. 7 represent the unphotolyzed species.

The spectra of the two species, BR-565(Cl^-) and BR-545(F^-), in Fig. 7 differ in many details from the spectrum of BR-605. Thus the C=C stretches at 1531 and 1536 cm^{-1} are narrow compared with BR-605. The C=NH stretch corre-

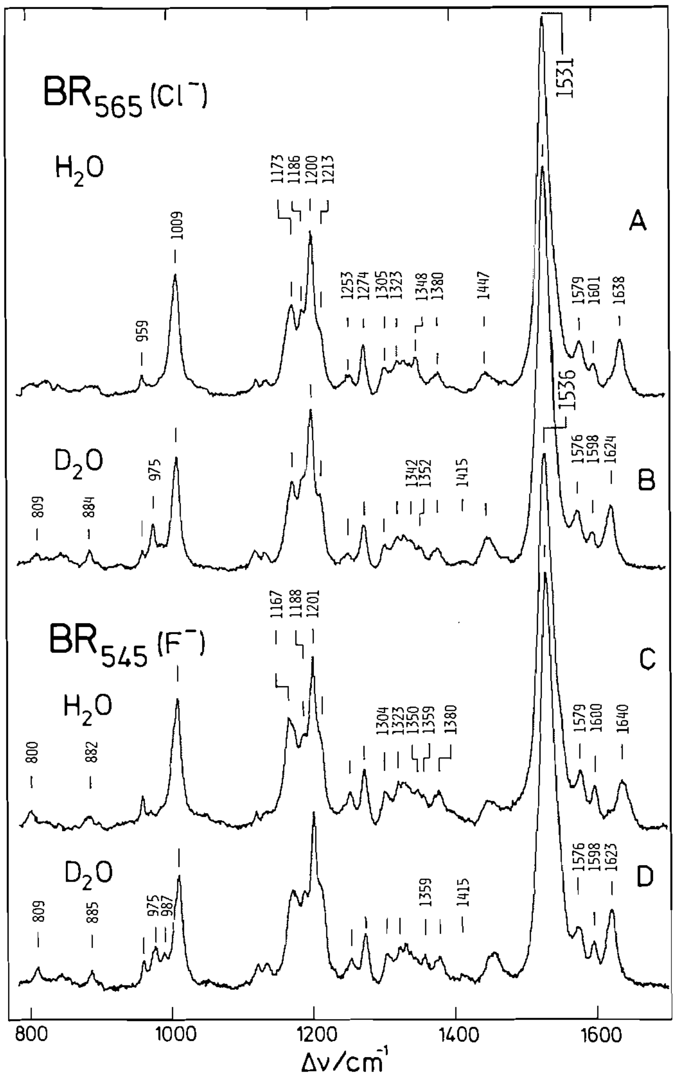

FIG. 7. Resonance Raman spectra from PM embedded in polyacrylamide gels, excited at 514 nm. BR-565(Cl^-): equilibrated with HCl solution at pH 0. BR-545(F^-): equilibrated with solution of 0.67 *M* HF and 0.33 *M* NaF at pH 2.2.

sponds now to bands at 1638 and 1640 cm^{-1}, which are narrower and higher in peak intensity than in the spectra of BR-605. Bands at 1348 and 1350 cm^{-1} can be clearly identified as N—H i. p. bending modes, which in D_2O move to 975 cm^{-1}. These bands correspond in all details to the SB group vibrations of the native chromophore BR-570. But, on the other hand, weak bands at 987, 1415, 800, and 809 cm^{-1} are found in Fig. 7, which correspond to SB group vibrations of BR-548. From spectroscopic evidence it is thus concluded that in BR-565(Cl^-) and BR-545(F^-) the all-*trans*/15-*anti* configuration dominates, while a minor fraction is in the 13-*cis*/15-*syn* form. On the basis of a 1:1 ratio of these two components in the spectra of the dark-adapted membrane (Fig. 5), a 85:15 ratio is estimated from the spectra of BR-545(F^-).

No evidence is obtained from absorption spectra at high ionic strength for a differentiation into light- and dark-adapted states as in the native chromophore (8). Obviously there is no preferential unidirectional phototransition which could establish a light-adapted state. The 85:15 ratio stated above therefore reflects the thermal equilibrium between the two components.

The spectra in Fig. 7 as a whole closely resemble the spectra of BR-570 in Fig. 4. This is in support of the above conclusion that at high ionic strength the all-*trans* (15-*anti*) component dominates. The similarity holds even for weak vibrational features like the two bands between 1570 and 1600 cm^{-1} in the C=C stretching region or the bands at 959 and 884 cm^{-1} in the o. p. bending region. This suggests that the structure of the relevant species is similar even with respect to conformational distortions of the retinal chain. It further appears that inhomogeneous broadening of the C=C and C=N stretching bands is much less pronounced in the spectra of Fig. 7 than was observed for BR-605. This suggests that in the states BR-565(Cl^-) and BR-545(F^-), at high ionic strength, the retinyl chromophore is immobilized in a similar way as in BR-570. It is important to note that analogous conclusions are suggested from circular dichroism studies (7).

Conclusions

It was proposed in a previous study that the interaction between the positively charged SB group and its negative counterion in native BR chromophores is stabilized by water molecules which are located in the immediate vicinity of the SB group (25). One important piece of evidence had been inferred from the fact that the width of the C=N stretch is narrowed when H_2O as a solvent is replaced by D_2O. This effect was ascribed to the strong interaction between the C=N stretch and the nearly degenerate bending mode of neighbouring H_2O molecules. This interaction contributes to the width of the C=N band at 1641 cm^{-1} in H_2O but vanishes for D_2O where the frequency match is no longer valid (see also Figs. 4 and 5).

From the spectra of Figs. 6 and 7 it is suggested that also at low pH and high ionic strength water molecules are closely attached to the SB group. Thus in the spectra of BR-605 the C=N stretch at 1616 cm^{-1} in D_2O is narrower and has a higher peak intensity than the corresponding band at 1628 cm^{-1} in H_2O. The same holds for the bands at 1640 and 1623 cm^{-1} in the spectra of BR-545(F^-). In the spectra of BR-565(Cl^-) this effect is less pronounced although a slight increase in peak intensity of the C=N stretch in D_2O (1624 cm^{-1}) is observed. For interpreting the results of the present study the influence of water molecules therefore has to be taken into account.

The most important phenomenon we observed is the formation of stable BR chromophores with the extrinsic anions Cl^- and F^- from the solution. It could be demonstrated that the structure of such complexes is very similar to that of the native species BR-570. It seems that the formation of BR-605 has to anticipate the formation of the Cl^-(F^-) complexes. In this respect a recent paper of Kimura *et al.* (26) is of interest, in which is demonstrated that BR-605 is also established by deionization of the membrane.

The fact that such different anions as the intrinsic carboxylate group and Cl^- or F^- from the solution form nearly identical chromophoric complexes can be better understood when water is considered as a common structural feature. It thus appears that the stability of SBH^+---A^- complexes is largely determined by the water molecules sitting between the ionic species. It is conceivable that a few water molecules in the electrostatic field of the two ions form microstructures which stabilize the ion-pair complex. Indeed, it could be concluded from RR spectra of dehydrated membranes that the influence of water is restricted to the terminal SB group and that the retinal chain is in a more hydrophobic environment (25).

In conclusion, the results of the present paper confirm that the terminal ion-pair complex is largely responsible for the structure and stability of the retinylidene chromophore in BR. This structure probably is important for BR's function as a light-driven proton pump.

Structures of Van der Waals complexes are predicted by a simple model based on electrostatic interaction between the monomers. Point multipoles are assigned to the atoms and embedded in hard spheres to represent short-range repulsions. Structures deduced for some 29 complexes are in agreement with experiment, and numerous predictions are made.

A. D. BUCKINGHAM et P. W. FOWLER. Can. J. Chem. **63**, 2018 (1985).

On peut prédire les structures des complexes de Van der Waals à l'aide d'un modèle simple qui est basé sur les interactions électrostatiques entre les monomères. On attribue des multipôles ponctuels aux atomes que l'on inclut dans des sphères rigides pour représenter les répulsions de faible portée. Les structures prévues pour 29 complexes sont en accord avec les données expérimentales.

[Traduit par le journal]

Introduction

In recent years Van der Waals complexes have been at the focus of much experimental and theoretical effort. The structures of many complexes, particularly those of the H-bonded type, have been determined by high-resolution spectroscopy (1–3). *Ab initio* calculations have been used to predict or confirm structures of small complexes with some success, e.g., refs. 4–6. Although quantitative details of a Van der Waals complex may result from sophisticated and expensive supermolecule calculations, there is a need for simpler theoretical approaches which enable us to understand the complex in terms of the properties of the monomers and the long-range forces between them (7).

Of the various components of the long-range interaction energy, the electrostatic contribution is known to be important in hydrogen bonding (4, 8, 9) and in particular in the angle dependence of the H bond potential energy (4, 9–11). This suggests that it should be possible to construct a simple physical model, involving electrostatic interactions and short-range repulsions, to predict equilibrium geometries of H-bonded complexes from the charge distributions of the isolated molecules. Such a model has been proposed (12) and is discussed further in the present paper.

Having reduced the problem from the supermolecule to the monomers, we can find the charge density of any particular monomer from accurate *ab initio* calculations of manageable size. In order to keep the model computationally simple the continuous charge densities are replaced by point multipoles.

2. The model

Each monomer charge distribution is described by sets of point multipoles — charges, dipoles, and quadrupoles — with values determined by *distributed multipole analysis* (= DMA) (13) of an *ab initio* wavefunction. The multipoles are located on the atoms and, in some cases, additionally at bond midpoints. They describe departures from local spherical symmetry in the molecular charge distribution and are often easily interpreted in terms of familiar concepts from valence theory. Thus a bonding pair or single lone pair can give rise to an atomic dipole, whereas the lone pairs on O in H_2O or H_2CO give an atomic quadrupole. An anisotropic bonding density such as the π cloud in C_2H_4 is represented by a quadrupole moment at the bond centre.

As well as satisfying chemical intuition, this multicentre representation of the charge distribution shows superior convergence behaviour to the one-centre molecular multipoles in calculations of the electrostatic potential around a molecule (13, 14). A DMA with a sensible choice of multipole sites is a compact summary of the information contained in the electronic wavefunction or in an electrostatic potential map in a form suitable for calculation of electrostatic interaction energies.

The wavefunctions we use have generally been calculated at the SCF level with large basis sets. Inclusion of electron correlation is known to affect multipole moments, e.g., typically decreasing the dipole moment by 5–10% (15) but is not expected to cause qualitative changes in our predicted structures. One example where correlation might be expected to be important, the CO molecule, has been examined at both SCF and Møller–Plesset levels. Although second-order Møller–Plesset correlation corrections reverse the small SCF dipole moment, the predicted structures of complexes containing CO at SCF and MP levels agree with each other and with experiment, as we show later in this paper.

The second important ingredient of the model is the way it treats the shapes of the monomer molecules. When two closed-shell molecules are sufficiently close that their charge clouds have appreciable overlap they experience a short-range repulsive force, which effectively defines the size and shape of each molecule. In our present molecule hard spheres are placed on the atomic centres to simulate this effect.

For heavy atoms the Van der Waals radii are taken from Pauling (16) without modification. CH_2 and CH_3 groups are treated as spheres of radius 2 Å. Pauling assigns a radius of 1.2 Å to H but, while useful for hydrocarbons, this is not appropriate for hydrogen-bonded complexes. A study of the

[1]Present address: Department of Theoretical Chemistry, University Chemical Laboratory, Lensfield Road, Cambridge CB2 1EW, U.K.

TABLE 1. An approximation for hydrogen bond lengths; the experimental distance $R(X...H—Y)$ between the X and Y atoms is compared with the sum of the heavy-atom Van der Waals radii $\sigma(X) + \sigma(Y)$ for a number of H-bonded complexes

Complex	$R(X...H—Y)$ (Å)	$\sigma(X) + \sigma(Y)$	Reference
$H_2CO...HF$	2.66	2.75	41
$H_2O...HF$	2.66	2.75	3
OC...HF	3.05	3.05	60
OC...HCN	3.67	3.40	63
HCN...HF	2.80	2.85	57

distances $R(X...H—Y)$ in hydrogen-bonded Van der Waals complexes shows that the X...Y distance is usually approximated to within 0.1 Å by assuming that the heavy-atom spheres are in contact,

$$R(X...H—Y) \simeq \sigma(X) + \sigma(Y)$$

and that the proton is inside the Van der Waals sphere of its Y partner. Some examples are given in Table 1. When Y is electronegative we expect that withdrawal of electron density from around H in the H—Y bond leads to a smaller effective Van der Waals radius for H. The small size of H, lacking an inner core of electrons, has been noted as a distinguishing feature of the hydrogen bond (7). It is perhaps significant that the only example in Table 1 where $R(X...H—Y)$ is greater than the sum of the Van der Waals radii is for Y = C, i.e., when Y is not very electronegative.

The equilibrium structure of a complex A...B is predicted by a constrained minimization of the electrostatic interaction of two assemblies of point multipoles (7). The total energy is a sum of pair terms,

$$U = \sum_{a \in A} \sum_{b \in B} U_{ab}$$

where

$$(4\pi\epsilon_0)U_{ab} = q^a q^b/R - R_\alpha(\mu^b_\alpha q^a - \mu^a_\alpha q^b)/R^3 + (3R_\alpha R_\beta - R^2\delta_{\alpha\beta})(q^a\theta^b_{\alpha\beta} + q^b\theta^a_{\alpha\beta} - 3\mu^a_\alpha\mu^b_\beta)/3R^5 + \ldots$$

$\boldsymbol{R}$ is the vector from site a in monomer A to site b in monomer B and q, μ, θ are site charge, dipole and quadrupole moments, respectively. The minimization is subject to the condition that no atoms are allowed to be closer than the sum of their hard-sphere radii,

$$R \geqslant \sigma(a) + \sigma(b) \text{ for all } a \in A,\ b \in B$$

One simple procedure is to place the monomers in contact and allow one molecule to roll over the other until a minimum in U is found. This is repeated for all possible contacts to find the global minimum in U.

3. Predictions of complex geometries

In a previous paper (12) we reported distributed multipoles for seven small molecules. Tables 2 and 3 give results for an extended list of eighteen molecules obtained at the SCF level using the HONDO/CADPAC program (17). In all cases the basis set was of at least double-zeta-plus-polarization quality. Bond-centre functions were added for F_2, N_2, Cl_2, CO, and SO_2. The total SCF energy and molecular moments are generally close to the Hartree–Fock limit. For instance, the SCF energy of SO_2 of $-547.21081E_h$ is the lowest so far achieved (cf. ref. 18).

In Table 2 the value of μ(H) in HCN is -0.288 au, correcting a misprint in (12). For C_2H_4 the hydrogen multipoles were moved to the nearest carbon to give the more manageable three-centre DMA shown in Table 3.

A large number of Van der Waals complexes may be constructed by taking any pair of monomers from this list and Table 4 lists the minimum energy structures predicted for a selection of them. Many of these complexes have been observed and, in all cases but one, where an experimental structure is known for a complex in Table 4, the model reproduces it qualitatively and often quantitatively. Thus the model distinguishes correctly between alternative H-bonded structures, e.g. finding that H_2O...HF is more stable than HF...H_2O, and HF...HCl than HCl...HF. It predicts details of the molecular shape, e.g., that $(HF)_2$ is bent whereas OC...HF is linear, and that H_3N...HX and H_3P...HX complexes have C_{3v} symmetry. In many cases the angles predicted for complexes of lower symmetry are in quantitative agreement with experiment. The angles for H_2CO...HF and H_2S...HF are striking examples of this.

TABLE 2. Monomer geometries and multipole moments (in au) for linear molecules; * is a bond midpoint; the origin is taken as the centre-of-mass of the commonest isotopomer; the DMA point multipoles are origin independent

Some of the results in Table 4 appeared in ref. 12. An error affecting H_2S complexes has been corrected, leading to small changes in the predicted angles for H_2S...HF and H_2S...HCl, but more importantly to a reversal of the relative stability of H_2S...HCN and HCN...H_2S. The H_2S...HX form is now predicted to be more stable for HX = HF, HCl, *and* HCN, in agreement with experimental results (19, 20). The structures of HX...H_2S and other secondary minima in the electrostatic energy surfaces are given in Table 5. Some of these less stable forms of Van der Waals complex have been observed when formed in inert gas matrices. For example, in an argon matrix at 12 K nonlinear HF...HCN is the preferred product but is converted to the more stable linear HCN...HF on warming above 20 K (21). Under similar conditions the antiparallel CH_3CN/HCN is formed but is converted on annealing to the C_{3v} CH_3CN...HCN (22).

The complexes SO_2...HX appear in both Tables 4 and 5 as HX may form a nearly linear H bond to O at two different angles, approximating to the directions of the two oxygen lone pairs, with HF and HCl preferring one direction, HCN the other. Although as mentioned above the DMA calculation on SO_2 is probably the best done so far, the details of the charge

distribution may not be well enough known to decide if the apparent switch in structure is significant. A supermolecule calculation on SO_2...HF using a much smaller basis (23) predicted a near-linear S—O...H—F arrangement, midway between our two structures.

Perhaps the most interesting of the secondary structures are the bridged complexes H_2CO/HCN and CH_3F/HCN. The HCN molecule can act as both H donor and H acceptor and is long enough to form two H-bonding interactions with other ambidentate molecules. The cyclic structures correspond to an antiparallel arrangement of dipoles but the angles for the H bonds depart from the usual linear HCN..H—X which may explain why the double interaction is not the primary stable structure.

The complexes between CH_3F and HX are found to have a minimum energy when X—H...F—C—H define a plane, HF and HCl preferring the staggered structure 7*a* and HCN the eclipsed 7*b*. In fact the energy varies very little as HX moves on a cone around C—F, e.g., CH_3F...HF has an energy of $U = -0.01064$ au in conformation 7*a* which increases to $U = -0.01058$ au in 7*b*. It is therefore likely that the complex will exhibit internal rotation of the HX subunit. Propyne...HF is an example of a Van der Waals molecule where internal rotational motion of HF has been studied (24).

Based on the available evidence, Table 4 strongly suggests that our model is successful in predicting the structures of hydrogen-bonded complexes. Some regularities emerge when the results for different complexes are compared. In hydrogen bonds Z—Y...H—X the direction of approach of the proton donor H—X varies with the nature of the proton acceptor Y. Thus when Y = N as in N_2, HCN, NH_3 the complex has axial symmetry but when Y is a halogen the Y...H—X atoms are approximately collinear and lie at an angle to the Z—Y symmetry axis. A rationalization of this behaviour has been proposed by Legon and Millen (3). Their rule for H-bonded geometries is that HX attaches along the line of a nonbonded pair on the Y atom or, in the absence of a lone pair, perpendicular to the π cloud in a π-bonded system. A simple hybridization picture suggests that the direction of attack would then be: axial for Z—N (*sp*), at 120° to the Z—O axis for O(sp^2) in H_2CO, at the tetrahedral angle for O(sp^3) in H_2O or F in HF. Deviations from these angles could be explained, in qualitative terms, by differential repulsion between lone and bonding pairs, using valence-shell-electron-pair repulsion (VSEPR) arguments.

The essence of the Legon–Millen rule is that a hydrogen bond forms to a region of high electron density in the proton acceptor. It is therefore a qualitative electrostatic model of H bonding. As our model incorporates a description of lone pair, σ and π bonding distributions through the point multipoles we obtain results which may be rationalized in the same way. Our model has the additional advantages that it predicts deviations from the idealized angles of the hybridization model, for instance that ∠COF in H_2CO..HF is 110° and not 120°, decides between alternative H-bonded structures, e.g. H_3N...HF vs. HF...H_3N, and has a wider application to non-H-bonded complexes.

Although most of the complexes in Table 4 contain a hydrogen bond, some molecules of other types are included. H_2CO...F_2 and complexes of F_2, Cl_2 and ClF with NH_3 have been studied by *ab initio* calculation (25) and found to have structures in line with the predictions of the electrostatic model. Decomposition of the SCF energy shows significant electrostatic and charge-transfer interaction energies in the equilibrium geometry (25) but the angular shape of the complex is largely determined by variation of the electrostatic component (10, 25). Halogen dimers and mixed dimers are predicted in Table 4 to have floppy "L" structures, consistent with the structure of solid Cl_2 (26) and molecular beam data (27). The very simplest electrostatic model, of a point quadrupole for each molecule, would predict a "T" structure for these dimers, but a representation of the spatial distribution of the lone pair density produces the "L" structure, **9** (10). In Kollman's (10) model this was achieved by a system of point charges, in ours by atomic quadrupoles.

A contrasting example is the CO_2 dimer. Once thought to have a polar "T" structure, there is experimental and theoretical evidence suggesting that it is nonpolar (28–30). Again two point molecular quadrupoles held at fixed distance apart favour a "T" shape but our model predicts the nonpolar skew parallel

structure, **10**, with ∠O=C...O ≃ 110°. The same structure was predicted by Barton, Chablo, and Howard (28) using a hard dumb-bell molecular shape *plus* central point quadrupoles. Thus in this case the key factor is the inclusion of molecular shape in the model rather than an improved description of the electron density.

Taken together, these examples show that both ingredients of the model (namely, electrostatics and size and shape) are needed for a successful description of noncovalent interactions. An accurate representation of the electron density and hence of the electrostatic potential in the region of space around a molecule may be constructed in a number of ways. Bentley (31) has derived atomic multipoles by fitting to total molecular multipoles. Kollman (11) and Brobjer and Murrell (32, 33) use arrays of point charges with magnitudes and positions mimicing bonding and lone pairs. The DMA method offers advantages in that it is completely *ab initio* and therefore capable of systematic improvement and is easily implemented in a standard SCF or CI package (13, 17). The hard-sphere model of molecular shape is extremely simple but appears adequate in most cases. A possible refinement would be to use a transferable empirical repulsive potential based on crystallographic data. An alternative approach uses experimental intermolecular separations (32, 33) but this cannot predict structures of complexes not yet observed in experiment.

Having shown the successes of our simple model, it is appropriate to enquire into its limitations. The DMA point multipoles were obtained in the SCF approximation. One case where the SCF multipoles might be unreliable is the CO molecule. In Table 6 we show the DMA for CO at SCF and second-order Møller−Plesset (i.e. uncorrelated and correlated) levels (34) and in Table 7 compare the predictions of both sets for the CO/HF and CO/HCl complexes. Inclusion of correlation changes the molecular dipole from 0.1007 au (C^+O^-) to 0.1681 au (C^-O^+), so significant changes occur in the DMA, leading to changes in the calculated electrostatic interaction energy. However, although correlation enhances the relative stability of OC...HX over CO...HX by factors of more than four, the qualitative prediction of which form is the more stable is the same at SCF and MP levels, and both agree with experiment. As CO might be considered as a "worst case" for the effect of correlation this is an encouraging result.

A second limitation is our use of the sum of Van der Waals radii to set the intermolecular distances in the calculation. If the experimental structure has a much shorter distance our model may be inappropriate (35). At first sight a shortened distance might be taken to imply a "chemical" rather than a physical electrostatic explanation of the binding. One example of interest is the complex between ClF and HF (35). From experiment this has the "anti-hydrogen-bonded" structure HF...ClF (36). If we apply our model using Van der Waals radii of $\sigma(\mathrm{Cl}) = 1.80$ Å and $\sigma(\mathrm{F}) = 1.35$ Å we find that the H-bonded structure with $\angle$ClFF = 108°, $\angle$FFH = 5° has $U = -0.00443$ au while the HF...ClF structure with $\angle$FClF = 172°, $\angle$ClFH = 125° has $U = -0.00243$ au. Similarly the H-bonded ClF...HCl is predicted to be more stable than FCl...ClH. However the Cl...F distance in HF...ClF is not 3.15 Å, which is the sum of the Van der Waals radii, but only 2.76 Å (36). When a smaller separation is used the electrostatic energy switches in favour of HF...ClF at a distance close to 2.75 Å. In large-basis supermolecule calculations (25) the electrostatic energy favours the experimental structure and is the factor which discriminates between the hydrogen-bonded and "anti-hydrogen-bonded" forms (9). Thus although the electrostatic energy still explains the bonding, the assumption of hard-sphere distances needs modification in this case. Similar arguments apply to HF...Cl_2, which is found from experiments to be "anti-hydrogen-bonded" (68) but is predicted to be H-bonded (Table 4) when the F...Cl distance is fixed at 3.15 Å).

We have shown that a very simple model incorporating electrostatic interactions and hard-sphere repulsions has considerable success in describing the structures of many Van der Waals complexes. The model also enables predictions of new structures to be made, and permits the evaluation of relative stabilities of tautomeric forms of a complex and of barrier heights for transitions between these tautomers. But representation of the repulsive potential by an infinite step function is a gross approximation which will be inadequate in some cases. The hard-sphere model does not permit the repulsive forces to moderate the binding energy. And in its present form the theory excludes the mutual distortion of the interacting molecules, and therefore lacks the (attractive) induction and dispersion contributions to the well-depth. The net effect of these approximations is usually to exaggerate the well-depth, particularly in the case of hydrogen-bonded complexes.

Refinements to the basic model will be explored in later work.

Received August 6, 1984

This paper is dedicated to Professor Camille Sandorfy on the occasion of his 65th birthday

N'SUAVI KOSSI N'SOUKPOÉ and ROGER M. LEBLANC. Can. J. Chem. **63**, 2026 (1985).

Triton X-100 purified rhodopsin has been incorporated into lipid bilayer membranes prepared by the combined lifting-and-touching method. The illumination of the membranes with white light and monochromatic light of λ = 498 nm resulted in a high selective increase of Ca^{2+} diffusion through the lipid bilayers compared to Na^+ and K^+. The stoichiometric ratios of photoinduced ion diffusion were found to be more than 888 Ca^{2+} Rh^{*-1} s^{-1} and 166 Na^+ Rh^{*-1} s^{-1} at 290 K using the white light, and 1 277 Ca^{2+} Rh^{*-1} s^{-1}, 96 K^+ Rh^{*-1} s^{-1}, and 50 Na^+ Rh^{*-1} s^{-1} at 276 K using the monochromatic light. It was inferred that Ca^{2+} is an excellent candidate as internal transmitter in the visual photo-transduction.

N'SUAVI KOSSI N'SOUKPOÉ et ROGER M. LEBLANC. Can. J. Chem. **63**, 2026 (1985).

On a incorporé de la rhodopsine purifiée au Triton X-100 dans des membranes de doubles couches de lipides préparées par la méthode combinant le soulèvement et le toucher. L'illumination des membranes par de la lumière blanche et de la lumière monochromatique de λ = 498 nm provoque une augmentation importante, si on la compare aux ions Na^+ et K^+, de la diffusion sélective du Ca^{2+} à travers les doubles couches de lipides. On a trouvé que les valeurs des rapports stoïchiométriques de diffusion ionique photoinduite sont égales à 888 Ca^{2+} Rh^{*-1} s^{-1} et 166 Na^+ Rh^{*-1} s^{-1}, à 290 K et sous l'influence de la lumière blanche, et 1277 Ca^{2+} Rh^{*-1} s^{-1}, 96 K^+ Rh^{*-1} s^{-1} et 50 Na^+ Rh^{*-1} s^{-1}, à 276 K et sous l'influence de la lumière monochromatique. On en déduit que le Ca^{2+} est un excellent candidat comme transmetteur interne dans la photo-transduction visuelle.

[Traduit par le journal]

Introduction

All the vertebrate photoreceptors share the ability to respond to light absorption by a change in ionic conductance of the plasma membrane.

If we consider the vertebrate rods, there exists a steady electric current in the darkness, the "dark current", which enters the outer segment, flows axially through the cytoplasm of the outer and inner segments, the nuclear and synapse regions, and returns to the outer segment via the intercellular space (1–4).

Membrane potential recordings (5–8) have revealed that light causes the plasma membrane to hyperpolarize from −40 mV to −60 mV. The "dark current" seems to be carried by Na^+ since the photo-response is suppressed by a complete removal of Na^+ from the external medium (9, 10) and the "dark current" is reduced in the presence of ouabain (3, 10). Most researchers agree that the effect of light, most likely, is to cause reduction of the sodium conductance (5, 9, 10, 11) by means of liberation of an internal transmitter which can block sodium channels present in the plasma membrane (10, 12, 13). The efficiency of light is so great that a single absorbed photon can transiently reduce a rod's "dark current" by about 3% (14). The very nature of the transmitter has not yet been clearly established. Experimental data are accumulating and there is a sounding indication that Ca^{2+} is the internal transmitter (15–24). But there also exists a possibility that *c*-GMP could be the internal transmitter (25–31). This point is not quite clear as yet. All that we know for sure is that (*i*) the presence of a transmitter is necessary for connecting the disc membrane (the site of excitation of the visual pigment) with the plasma membrane (the site of the electric response), disc and plasma membranes being structurally (32), osmotically (33), and electrically (14, 34) uncoupled and (*ii*) the transmitter should be released at a rate of $\sim 10^3$ molecules per excited pigment per second (35), may be less, $\sim 10^2$ (10).

In a previous paper (36) we have described an especial experimental procedure for preparing rhodopsin–lipid bilayer membranes by the monolayer technique. We have also presented the application of these lipid bilayers to the study of the ionic aspects of the visual process. Here, we are giving more details about the results obtained in relevance to the possible involvement of Ca^{2+} as an internal transmitter in the visual transduction.

Materials

Chemicals

Ethanol is purchased from Fisher Chem. Co., Montréal, Qué. Phosphatidylethanolamine (PE), phosphatidylcholine (PC), and phosphatidylserine (PS) extracted from bovine tissues are used as bought from Applied Sci. Lab., State College, PA, without further purification. Cholesterol is supplied by Sigma Co., St. Louis, MO. Fresh bovine eyes, obtained from a local slaughter-house, are dark-adapted for whole night at 277 K and the retinae dissected and kept frozen at 253 K until use. Water for the monolayer work is deionized and distilled through a quartz double distillation system (Brinkman Instruments Can. Ltd., Toronto, Ont.): the specific resistivity is greater than 18 MΩ cm and surface tension higher than 71 mN m^{-1} at 298 K.

Ion diffusion system

The ion diffusion measurements have been performed in a double compartment system (36) composed of two beakers connected together with Teflon joints, the contacts of which are sealed with O-rings and vacuum silicone grease. The whole device is carefully shielded against light with black tape except for the light-irradiation window (5 cm in diameter) on the side of compartment-I. The ionic activities are to be measured in compartment-II, using Orion ion specific electrodes (Fisher Sci. Co., Montréal, Qué.) connected with a pH meter (type PHM26, Radiometer, Copenhagen, Denmark), set as closer as possible to the membrane that will be placed between the two compartments. The capacity of compartment-I is 135 cm^3 and that of compartment-II is 75 cm^3.

Methods

Extraction and purification of rhodopsin

The rod outer segments (ROS) are isolated from the dark-adapted

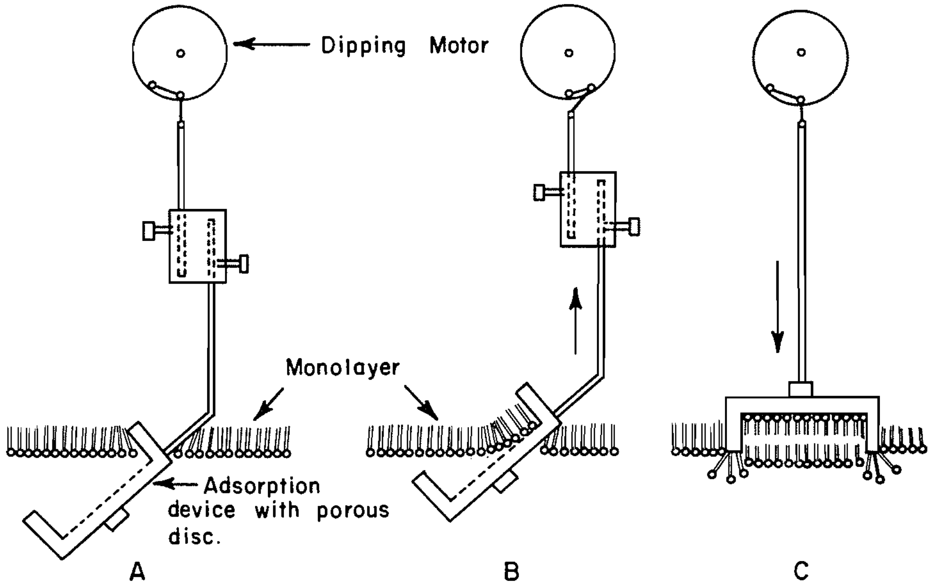

FIG. 1. Schematical representation of the combined lifting-and-touching method. (*A*): The adsorption device is immersed in the subphase (Tris-HCl, 2×10^{-3} mol dm^{-3}, pH: 7.2) while the rhodopsin-lipid monolayer is formed at the air–aqueous interface. (*B*): The adsorption of the first monolayer is shown during the lifting process. We see the hydrophilic adsorbing surface of the porous disc in broken line. (*C*): The touching process illustrates the formation of the bilayer (issued from ref. 36).

retinae using the sucrose gradient method described by Applebury *et al.* (37). The purified ROS are solubilized over a night by gentle agitation in 2% solution of Triton X-100 in Tris-HCl buffer (2×10^{-3} mol dm^{-3}, pH: 7.2). Rhodopsin solution is then centrifuged for 1 h at 40 000 g. The clear supernatant is adsorbed on top of an Ecteola cellulose column according to Osborne, Sardet, and Helenius (38). Purified rhodopsin is eluted with 2% solution of Triton X-100, Tris-HCl 2×10^{-3} mol dm^{-3}, NaCl 0.1 mol dm^{-3}, pH: 7.2. The purified rhodopsin solution is then diluted 1 : 1 with buffer and reconcentrated by the aid of an Immersible Molecular Separator Kit (Millipore, Mississauga, Ont.). This procedure repeated two or three times is aimed to remove a large amount of Triton X-100 from the rhodopsin solution. Then, the final removal of the detergent is effected by adsorption on bio-beads SM-2 using the inversion method as described by Holloway (39). Since rhodopsin is practically insoluble in water, it is important not to eliminate Triton X-100 over a certain critical point at which the pigment precipitates and most of the time gets denatured. The bio-beads treatment is accomplished stepwise in the sense that, after 1 h of continuous adsorption on bio-beads, the procedure is pursued at intervals of 2 min, measuring the elimination of the detergent by its absorption spectrum and simultaneously testing the surface pressure (Π) at the air-aqueous interface of a monolayer trough until the spreading of 100 μL of the rhodopsin solution does not show a significant initial surface pressure (i.e., $\Pi < 1$ mN m^{-1}). Usually, the solution is then centrifuged 30 min at 40 000 g to eliminate any small suspended particles in the solution.

Purified rhodopsin at air–aqueous interface

The "detergent-free" rhodopsin is spread at air-aqueous interface of a Langmuir type film balance (40), by means of the glass rod method described by Trurnit (41), the subphase being Tris-HCl 2×10^{-3} mol dm^{-3}, pH: 7.2. This spreading technique lessens the loss of material in the subphase. About 100 μL of rhodopsin solution 10^{-6}–10^{-5} mol dm^{-3} are used at a time. The concentration of rhodopsin is concurrently determined using the absorbance change ($\Delta A_{498\ \mathrm{nm}}$) before and after complete bleaching of the pigment, and by protein content measurement by Bio-Rad Protein Assay (Bio Rad Laboratories Canada, Ltd, Mississauga, Ont.).[1] The spread molecules are compressed uniformly and continuously at a speed of 17×10^6 Å^2 min^{-1} with a glass barrier moved by an electric compression motor provided with a rheostat for speed control. The limiting molecular area value has been used to evaluate rhodopsin cross section at the air-aqueous interface.

Preparation of the rhodopsin-containing lipid bilayers

The lipid bilayer membranes have been prepared by the combined lifting-and-touching method. An especially designed adsorption device has been used for this purpose. The device composed of a porous disc which was fixed to a Teflon block with a Teflon ring such as to expose one face of the porous disc to the preparation of the bilayer. The rhodopsin–lipid solutions used were prepared in 8% ethanol (v/v) according to their weight ratios in the native bovine rod outer segment disc membranes (42), i.e., 50.0% rhodopsin, 23.0% PE, 12.5% PC, 6.5% PS, and 8.0% cholesterol. The procedure for the preparation of the membrane is described by Kossi and Leblanc (36). Briefly, a porous disc made of triacetate cellulose, supported by a Teflon block (Fig. 1) was immersed in the subphase of a Langmuir trough which consisted of Tris buffer 2×10^{-3} mol dm^{-3}, pH: 7.2. The rhodopsin–lipid monolayer was spread at the air–aqueous interface and compressed at constant speed of 17×10^6 Å^2 min^{-1} to a pressure of 32 mN m^{-1}. The adsorption device was then lifted slowly and simultaneously compressing the monolayer to counterbalance the drop of the surface pressure due to the adsorption of a monolayer on the surface of the porous disc. After 5 min stabilization, the adsorption device was set parallel to the air–aqueous interfacial monolayer and allowed to come into contact with the monolayer horizontally. By raising the adsorption device, a second monolayer was adsorbed on the first one in a tail-to-tail fashion. Lipid bilayer membranes incorporated with rhodopsin prepared by this combined lifting-and-touching method have been used to study the photoinduced ion diffusion. Note that the membranes were prepared and transferred into the diffusion system under a dim red light. This technique makes it possible to obtain large membranes (14.82 cm^2).

Ionic permeability experiments

The artificial membrane supported by the porous disc was inserted in between a double compartment system which was sealed with vacuum silicone grease and filled with Tris-HCl (2×10^{-3} mol dm^{-3}, pH: 7.2). To measure the net photoinduced ion diffusion, the experiments have been performed in three irradiation conditions: (*i*) at 290 K by irradiating the membranes with an incandescent white light (300 W) placed at a distance of 60 cm away from the diffusion apparatus;

[1] Issued from Bio-Radiations, No. 25, September 1977, p. 4.

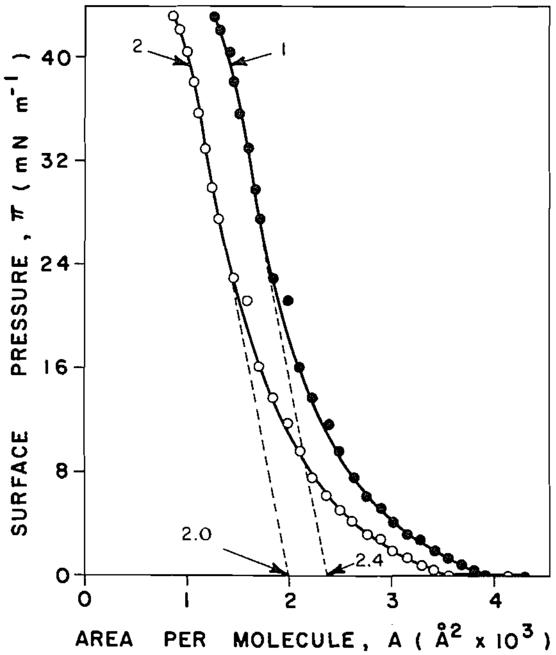

FIG. 2. Surface pressure–area isotherms of purified rhodopsin. The subphase is Tris-HCl buffer 2×10^{-3} mol dm^{-3}; pH: 7.2; T = 290 K. Curve 1 (●) is the isotherm obtained when using $\Delta A_{498\ nm}$ to calculate rhodopsin concentration. Curve 2 (○) is the isotherm obtained when using protein content values for rhodopsin concentration.

(*ii*) at 290 K by irradiating with the same light source filtered through a Corning colour filter (No. 2-61, Esco Products, Oak Ridge, NJ) the absorbance of which is 2 for $\lambda \leq 607$ nm; the purpose of using this safety light of $\lambda \geq 607$ nm is to test an eventual heating effect of the light source on the ion diffusion; and (*iii*) at 276 K by irradiating with a monochromatic light ($\lambda = 498 \pm 2$ nm) by means of a monochromator (Ser. No. 665 Am. ISA Inc., Metuchers, NJ). The light intensity was 2×10^{13} photons cm^{-2} s^{-1} as measured by a power meter (Model 21A, Optikon Ltd., Sci. Instr., Waterloo, Ont.). The membranes contained $3.5 \pm 0.1 \times 10^{13}$ rhodopsin molecules (23.6×10^{11} Rh cm^{-2}) as determined by the deposition ratios. The irradiation started 3 min after the ion under study was added to compartment-I, the ionic concentration of which was made 18.51×10^{-3} mol dm^{-3}. Both compartments were buffered with Tris-HCl 2×10^{-3} mol dm^{-3}, pH: 7.2. The illumination was kept on continuously through the measurements. The ionic activity resulting from photoinduced ion diffusion was measured in compartment-II using ion selective electrodes. A minimum of three measurements were run for each ion (i.e., Na^+, K^+, and Ca^{2+}) on three different membranes. The mean ion flux was plotted against time for the kinetic study of the ion diffusion induced by monochromatic beam (λ = 498 nm).

Results

Spectral properties of the purified rhodopsin

The Triton X-100 purification yielded 10^{-6}–10^{-5} mol dm^{-3} rhodopsin solutions as calculated from the absorbance difference at 498 nm before and after bleaching, using $\epsilon_{498\ nm}$ = 40 600 dm^3 mol^{-1} cm^{-1} (43). The spectral ratio $A_{278\ nm}/A_{498\ nm}$ was 2.0 ± 0.2, with 2 phospholipids per rhodopsin molecule as revealed by the phosphorus determination method developed by Fiske and Subbarow (44). The removal of the detergent proved very satisfactory as can be seen from the surface pressure-area isotherm (Π–A curves) of rhodopsin at air–aqueous interface (Fig. 2). This point will be elaborated in the following section.

Monolayer properties of the purified rhodopsin

When working with rhodopsin monolayer, it is of extreme importance to characterize the behaviour of this pigment at the air–water interface. The spreading of aqueous rhodopsin at air–water interface needs a special care in order to avoid loss of material in the subphase. The method developed by Trurnit (41) is suitable for rhodopsin solution nearly free from detergent. Indeed, we did not find any solubilization effect of rhodopsin in the subphase on the Π–A curves shown in Fig. 2. The Π–A curves rise monotonously as the molecules are gradually compressed. In Fig. 2, curve 1 is obtained by calculating rhodopsin concentration from the absorption data (i.e., $\Delta A_{498\ nm}$, $\epsilon_{498\ nm}$ = 40 600 dm^3 mol^{-1} cm^{-1}), and curve 2 was plotted using the protein content of rhodopsin solution. The extrapolation of the steep region of the Π–A curves to pressure zero gives the limiting molecular area which is 2 400 ± 120 Å^2 in the case of curve 1 and 2 000 ± 100 Å^2 for curve 2. Assuming that the cross section of rhodopsin at the air–aqueous interface is a circle as it seems to be by our own electron microscope observation (unpublished data) and from the literature (45, 46), and neglecting the contribution of the remaining Triton X-100 and phospholipids to the measured limiting area because of their small size compared to that of rhodopsin, the diameter would be 55.3 ± 1.3 Å and 50.4 ± 1.2 Å, respectively, when employing the former and latter limiting molecular areas. Values ranging between 40 Å and 80 Å have been obtained for rhodopsin diameter by Heller (46), Blasie *et al.* (45) and Darszon *et al.* (47). Many other works have been done on rhodopsin at air–aqueous interface (48–53) but the Π–A curve of rhodopsin appeared only in two papers: that of Hyono *et al.* (48) and that of Azuma and Takagi (49). The Π–A curve reported by Hyono *et al.* (48) was in arbitrary units, and accordingly, is useless for comparison. In Azuma and Takagi paper (49), the minimum extrapolated molecular area, obtained on pure water was found to be 4 000 Å^2 giving 71.3 Å for the diameter of rhodopsin; this work was performed with membrane fragments. Other works (54, 55) have shown that rhodopsin can be somewhat elongated.

Now, there is a significant difference between the limiting molecular areas when using the $\Delta A_{498\ nm}$ or the protein content determination methods to calculate the concentration of rhodopsin solutions. It makes clear that some bleaching of rhodopsin occurs during the numerous manipulations related to the purification of rhodopsin and to the removal of the detergent. This bleaching is possibly due to the elimination of the detergent since the use of Ecteola cellulose should have separated rhodopsin from contaminating opsin during the purification.

We can estimate rhodopsin activity in terms of spectral activity by the ratio of the two values for the limiting molecular areas (2 000/2 400) that gives 0.83. Therefore, any quantitative work involving the biological activity of rhodopsin should be based on its absorbance difference whereas size measurements are to be done on the basis of protein content analysis as far as monolayer work is concerned. The actual cross section of rhodopsin molecule should be equated to 2 000 Å^2 according to our determinations.

Photoinduced ion diffusion through the artificial membranes

From the light-effect experiments, it was observed as general features that, the white light and the monochromatic light of λ = 498 nm triggered the permeability of rhodopsin-containing lipid bilayers to ions, whereas light of $\lambda > 607$ nm, not absorbed by rhodopsin, had no detectable effect on the ion dif-

TABLE 1. Effect of light on the ion fluxes (ϕ) (number of ions per second)

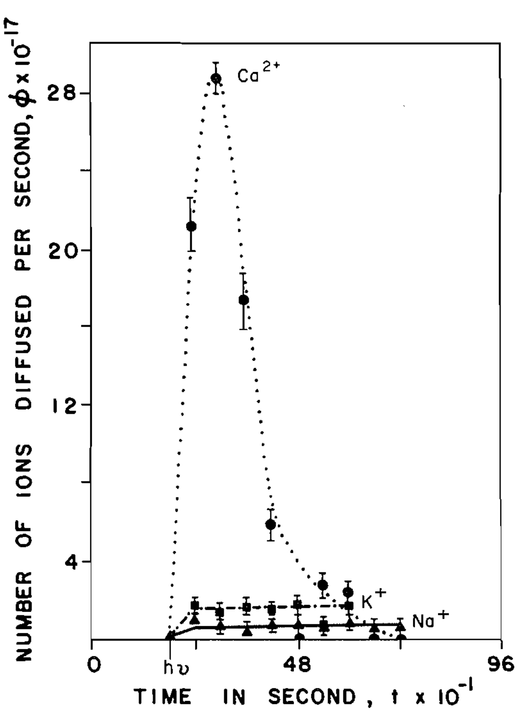

FIG. 3. Photoinduced ion diffusion curves using monochromatic light (λ = 498 nm) at 276 K for Na^+ flux (▲), K^+ flux (■), and Ca^{2+} flux (●).

fusion.

The mean ion fluxes are shown in Table 1; t measures the time (s) after the ion to be used was added to compartment-I. We can note that the variation of the fluxes with time is very irregular for Na^+ and Ca^{2+} ions with white light, and that only dark leakage of K^+ occurred in these conditions. The irregularity of the flux with the white light could simply be due to variations in the intensity of the incandescent lamp. The irradiation with monochromatic light (λ = 498 nm), most representative for bovine rhodopsin (λ_{max} = 498 nm), evoked a constant rate diffusion of Na^+ and K^+ as shown in Fig. 3. It could be also observed that Ca^{2+} flux curve clearly stands out from the others. It is concluded that the illumination of the membranes selectively increases the permeability to Ca^{2+} compared to Na^+ and K^+. The ion flux for Ca^{2+} (Fig. 3) presents an important jump at the beginning followed by an exponential decrease until electrochemical equilibrium is reached. The ion diffusion evoked by the 498 nm beam indicates that the excitation of rhodopsin is responsible for the effect observed.

The initial slopes of the diffusion curves (Fig. 3) can be used to calculate the stoichiometric ratios of the photoinduced ion diffusion. In our experiments, it was not possible to measure the exact number of rhodopsin molecules bleached during the irradiation because the porous disc is not transparent. To give an idea of the stoichiometry of the ion diffusion, we have assumed that most of rhodopsin molecules were bleached at the very beginning of the illumination. Based on this assumption, the white light induced ion diffusion rates were 166 Na^+ Rh^{*-1} s^{-1}, and 888 Ca^{2+} Rh^{*-1} s^{-1} at 290 K; at 276 K, the stoichiometric rates for the ion diffusion induced by the monochromatic light (λ = 498 nm) were found to be: 1 277 Ca^{2+} Rh^{*-1} s^{-1}, 96 K^+ Rh^{*-1} s^{-1} and 50 Na^+ Rh^{*-1} s^{-1}. The mean relative error is 10%. Since it is more likely that the number of molecules of rhodopsin effectively bleached is less than what has been assumed, the stoichiometric ratios reported here should be considered as minimum values.

To summarize, the results show that (i) light that does not excite rhodopsin ($\lambda \geq 607$ nm) has no effect on the lipid bilayer permeability; (ii) rhodopsin-exciting light (λ = 498 nm) causes the lipid bilayer permeability to increase for Na^+, K^+, and Ca^{2+} (except for K^+ at 290 K), with a marked selectivity for Ca^{2+}. This selectivity at 498 nm is 13:1 at 276 K for Ca^{2+} as compared with its nearest neighbour (i.e., K^+). The absorption of light energy by rhodopsin therefore does selectively evoke ion diffusion through the artificial membranes prepared by the combined lifting-and-touching method. Preliminary observations about ion diffusion through the porous disc alone do not show any apparent selectivity for the ions studied. Thus it clearly appears that the selectivity observed comes from rhodopsin present in the lipid bilayer.

Discussion

The conservation of the structural and physiological integrity, and the purification of extracted membrane proteins have long been a hard task. The common practice is not only to solubilize the membrane in a strong solvent such as detergents but also in a non-denaturing detergent so as to lessen the damage to the protein, which presents some problems. These problems are further complicated by the tension-interfering effect of detergents as far as monolayer work is concerned.

Thus, not only are we to choose a detergent which can highly purify the lipoprotein, rhodopsin, but also a detergent which would not affect much the structure and activity of rhodopsin, and above all, a detergent which can be removed easily to allow the air-aqueous interface experiments.

Many detergents have been used for these purposes such as digitonin (56–60), Emulphogene BC (61), cholic acid (62), and Triton X-100 (63, 64). We have chosen Triton X-100 for its removability and for the ease of following its removal by the absorbance decrease at 275 nm. The 17% loss of rhodopsin activity following the removal of Triton X-100, though not dramatic but significant, is unavoidable since we absolutely need a very low level of Triton X-100 in the rhodopsin solution for the monolayer work to be possible. However, the purity is good as indicated by $A_{278\ \mathrm{nm}}/A_{498\ \mathrm{nm}} = 2.0 \pm 0.2$ and by the $\Pi-A$ curves with a calculated diameter of 50.4 ± 1.2 Å in accordance with other results, e.g. 40–50 Å (45), 46 Å (46). Rhodopsin prepared in this way is stable for a few days to a week and should not be frozen in order to avoid precipitation. Note that our rhodopsin monolayer films contained traces of phospholipids (2 molecules of phospholipid per molecule of rhodopsin) and of Triton X-100. Accordingly, the calculated diameter which has been equated with that of rhodopsin represents a maximum value. However, the discrepancy from the true value should be negligible due to the small dimension of the contaminating molecules which are expected to act as space filler for rhodopsin molecules.

The results obtained from the light-effect experiments are quite encouraging. The bleaching of a single molecule of active rhodopsin is responsible for the diffusion of at least 50 Na^+, 96 K^+, and 1 277 Ca^{2+} ions per second at 276 K with 498 nm beam. This selective and amplified response could not but support the functional integrity of the pigment extracted. The lack of light-effect on K^+ diffusion at 290 K could be due to masking effect of K^+ diffusion induced by traces of all-*trans* retinal (50, 65, 66), which is not the case at 276 K since $t_{1/2}$ for the transition Metarhodopsin-I → Metarhodopsin-II is 160 min at 277 K (67). These results agree well with those obtained elsewhere on rhodopsin-containing vesicles: short light flashes promoted a steady release of Ca^{2+} from preloaded vesicles (23, 24), the diffusion of about 184 Na^+ per bleached rhodopsin and a greater stoichiometric ratio for Ca^{2+} (19). We have observed for the photoinduced ion diffusion, a latency of about 60 s. This latency should be considered as an apparent one mostly due to the delay time of the electrode response and to the distance to be run by the ions before reaching the electrodes.

Now, that light induces Ca^{2+} diffusion up to a rate of 1 277 ions per bleached rhodopsin per second is of great importance for the hypothesis that Ca^{2+} is the internal transmitter for the visual process. Cone (35) stated that the internal transmitter should have a stoichiometric release of 10^3 molecules per bleached rhodopsin per second. The high Ca^{2+} diffusion rate obtained here strongly suggests that Ca^{2+} is an excellent candidate for the internal transmitter. Thus, on the absorption of a photon, a single rhodopsin molecule among 10^6–10^9 in the vertebrate rod will form a unimolecular transmembrane channel (68) releasing over 10^3 Ca^{2+} per second that will diffuse to the plasma membrane where they will block sodium channels. The overall results will be a 3% reduction of the dark current (14). The Ca^{2+} will then be reconcentrated in the discs by means of a Ca^{2+} activated pump (69).

As such, the results obtained on artificial membranes are very suggestive for the Ca^{2+} hypothesis. The only disagreement is the varying and very low stoichiometry of Ca^{2+} photoinduced diffusion observed for isolated rod outer segments (15, 16, 21, 70, 71) and for isolated rod outer segment discs (20). Could this be due to the difficulties encountered in integral isolation (i.e., without loss of Ca^{2+} before the illumination) of these sub-cellular structures, or to some difference between the structural state of rhodopsin in these sub-cellular fractions and that in model systems? One thing is remarkable. Most of sub-cellular structures, if not all, show very small and slow photoinduced Ca^{2+} flux while model systems as this and others (19, 23, 24) present a steady and large Ca^{2+} flux evoked by illumination except one on rhodopsin-containing vesicles (72). If swelling of discs occurs during isolation as it is usually the case (73), one may question the physiological intactness of the isolated structures since disc membranes may be partially disrupted, probably releasing a great amount of their Ca^{2+} content. Isolation of rod outer segments might meet with the same problem too. On the other hand, rhodopsin in artificial membranes does respond to light by a large Ca^{2+} diffusion in accordance with the Ca^{2+} hypothesis, except for the delay time in some cases. Montal, Darszon, and Trissl (74) observed a latency of ca. 100 s which they attributed to the time required for different rhodopsin molecules to aggregate and form "multimolecular" channels for ion flux. This delay time will become shorter as rhodopsin molecules get more concentrated in the membranes. In our experiments, some 60 s delay was sometimes observed which is due, not only to the diffusion through the lipid bilayer, but much more to the distance separating the ion selective electrode from the bilayer. If one could record the ionic activity immediately on release of the cation from these artificial membranes, the latency would then shorten enough to be of physiological relevance.

If the role of rhodopsin on bleaching is to trigger the release of Ca^{2+}, then the visual pigment seems to work better in model systems than in sub-cellular ones: which looks strange. It appears necessary to find out what could be the cause of such a discrepancy. We are waiting for studies on the structural state of rhodopsin in our bilayer membranes to compare with that *in vivo*, and on the physiological intactness of the isolated structures used in calcium photoinduced diffusion experiments. The work done by George and Hagins (75) is noteworthy. They observed a large photoinduced Ca^{2+} release from isolated rod outer segment discs exceeding 10 000 ions in some trials in 90 s, in accordance with the Ca^{2+} hypothesis.

Conclusion

We have demonstrated the possibility to study the ionic aspects of the visual process on a new lipid bilayer model membrane obtained by the combined lifting-and-touching method. The effect of light resulted in a high increase of ion diffusion with a marked selectivity for Ca^{2+} relatively to Na^+ and K^+, suggesting that Ca^{2+} is the internal transmitter. We hope that these positive results obtained on artificial systems will encourage pursuing the work on living systems in order to confirm the Ca^{2+} hypothesis in the visual transduction process. Further work is required to elucidate the very mechanism of release of this transmitter.

Antibonding σ^* orbitals in molecular spectroscopy

M. B. ROBIN
AT&T Bell Laboratories, Murray Hill, NJ 07974, USA

Received August 1, 1984

This paper is dedicated to Professor Camille Sandorfy on the occasion of his 65th birthday

M. B. ROBIN. Can. J. Chem. **63**, 2032 (1985).

This paper discusses the role of σ^* antibonding valence MO's in the electronic spectra of large molecules. Using the term value and antishielding concepts, molecular absorption patterns terminating at σ^* MO's are systematized and rationalized; the frequencies of such excitations correlate with the ground-state bond strengths of the bonds giving rise to the σ^* MO's. In unsaturated systems, the $\pi \rightarrow \sigma^*$ and $np \rightarrow \sigma^*$ excitations can be distinguished on the basis of their term values. Confusion in the past regarding the existence of excitations to σ^* relates to the fact that σ^* MO's often can be totally mixed into the surrounding sea of Rydberg levels of the same symmetry, and for all practical purposes can cease to exist except as perturbations on the Rydberg levels. For nonpenetrating Rydberg manifolds there is little or no mixing with σ^* MO's of the same symmetry, setting the stage for the appearance of valence-shell excitations to σ^* in high-symmetry molecules which are analogous to the $d \rightarrow f$ inner-well giant resonances of atomic spectroscopy.

M. B. ROBIN. Can. J. Chem. **63**, 2032 (1985).

Dans ce travail, on discute du rôle des OM de valence antiliante σ^* dans les spectres électroniques des grosses molécules. Utilisant les concepts de valeur de terme et d'antiblindage, on systématise et on rationalise les types d'absorptions moléculaires qui se terminent au niveau des OM σ^*; il existe une corrélation entre les fréquences de telles excitations et les longueurs de liaisons dans l'état atomique fondamental qui donne lieu aux OM σ^*. Dans les systèmes non-saturés, on peut distinguer les excitations $\pi \rightarrow \sigma^*$ des excitations $np \rightarrow \sigma^*$ en se basant sur leurs valeurs de terme. La confusion qui a été observée dans le passé relativement à l'existence d'excitations vers les niveaux σ^* provient du fait que les OM σ^* peuvent souvent être complètement confondues avec les niveaux de Rydberg de même symétrie qui les entourent et, à toutes fins pratiques, elles cessent d'exister, excepté comme perturbations des niveaux de Rydberg. Pour les états non-pénétrants de Rydberg, il y peu ou pas du tout de mélange avec les OM σ^* de même symétrie et ceci permet, dans les molécules de haute symétrie, de noter l'apparition d'excitations des couches de valence vers les états σ^* qui sont semblables aux résonances géantes $d \rightarrow f$ de la spectroscopie atomique.

[Traduit par le journal]

I. Introduction

All molecules — from H_2 to DNA — have one aspect in common: a σ bond between two or more atoms, where "σ" expresses the local symmetry of the bonding orbital. In a molecular orbital description of the bonding, these σ bonding MO's unavoidably have valence-shell σ^* antibonding MO's associated with them, many of which are unoccupied in the ground state. Spectroscopic intuition suggests that transitions terminating at the various vacant σ^* MO's can be among the most intense electronic transitions in molecules, should appear in both the vapor-phase and condensed-phase spectra of all molecules regardless of size, polarity, geometry or degree of unsaturation, and will be intimately involved in every molecule's photochemistry. In this we include not only $\sigma \rightarrow \sigma^*$ excitations but those originating at π and np lone-pair orbitals as well.

Being an unavoidable component of every molecule's electronic spectrum, transitions to σ^* should have the highest priority for study by spectroscopists, photochemists, and theorists. Strange then that so very little is known about valence-shell transitions terminating at σ^* in molecules. In a spectroscopic literature replete with experimental and theoretical papers on $\pi \rightarrow \pi^*$ and Rydberg excitations, the transitions to σ^* orbitals are only indirectly mentioned, if at all. Indeed, there is a gaping hole in our understanding of molecular excited states which is both embarrassing to admit and tempting to jump into for the new insights it might yield. Chemists have hesitated to jump for two reasons: (*1*) those far from the field consider the situation obvious and so would not bother with it and (*2*) those close to the field consider it opaque and too difficult to deal with. As always, the truth lies somewhere in between, in this case, closer to point (*2*) than to point (*1*).

In this paper, I attempt to sketch the big picture for molecular excitations terminating at σ^* MO's. For this, an outline is constructed which uses the byproducts of many other studies, most often carried out for other reasons. Because we are interpreting very incomplete data, the approach used here is a qualitative one, aimed at better-defining the problems rather than rigorously solving them. Hopefully, others will pursue these qualitative ideas and test them more fully. The material discussed here is abstracted from a larger study (1), and the interested reader is referred to that work for more details. Since one of the few serious attempts at understanding the σ spectra of polyatomic molecules was that of Camille Sandorfy (2), and because a large volume of work on the problem has since come out of his laboratory, it is fitting that this paper is dedicated to him on his 65th birthday.

Our discussion centers upon a description of the spectral properties of the valence-shell excitations terminating at σ^* MO's called *A* bands. We focus first upon *A* bands, for the data are relatively copious here and trustworthy; much of what is learned from studying the *A* bands then is transferable to other transitions terminating at σ^*.

II. *A*-bands and term values

II.A. Definitions

The *A* bands of the alkyl halides are the best known molecular excitations involving σ^* MO's. The prototypical *A* band in the molecule R—$\ddot{X}$ is due to the excitation of an electron from the *np* lone-pair orbital on $\ddot{X}$ to the σ^*(R—X) antibonding MO involving the halogen and the radical bound to it, Fig. 1. Simply termed an *A* band in the past (3, 4), we now classify this excitation as an $A(np,\sigma^*)$ band. We further broaden the *A*-band definition by including as *A* bands the outer-shell valence ex-

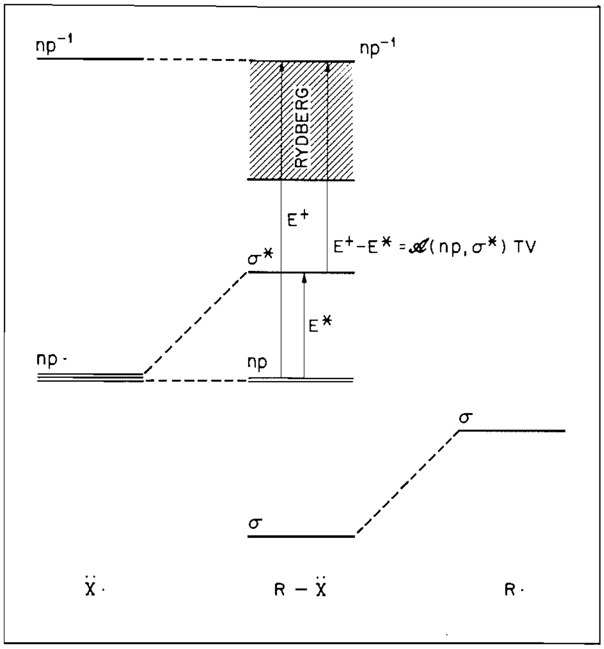

FIG. 1. Definition of the A-band term value in alkyl halides.

citations originating at nonbonding lone-pair orbitals in any system having such an orbital (e.g., trimethyl arsine, acetone, hexachlorobenzene, trimethylene sulfide, etc.). Inasmuch as all inner-shell orbitals in a spectroscopic sense are nonbonding and so also are lone pairs, all inner-shell valence transitions terminating at σ^* are hereby deemed to be A bands. In contrast to the A bands in which the originating orbital is essentially nonbonding and localized, the originating orbitals for $\pi \rightarrow \pi^*$ and $\sigma \rightarrow \sigma^*$ types of valence-shell bands are strongly bonding and delocalized; for these we maintain the time-honored $N \rightarrow V_n$ designation of Mulliken. See Section II.F for a discussion of A-band terminology in unsaturated systems.

Very early on, Mulliken (5) recognized the close similarity in nodal patterns between certain antibonding valence-shell orbitals and the lowest Rydberg orbitals of the same symmetry. Thus for example, the $a_1\sigma^*$ valence and $3sa_1$ Rydberg orbitals of methane both are totally symmetric with each having two radial nodes while in ethylene for example, the π^* valence and $3d_{xz}$ Rydberg orbitals each have two perpendicular nodal planes and no radial nodes. Though Mulliken's point of view has been that the differences between such look-alike pairs of Rydberg and valence-shell orbitals is only a semantic one, we consider configurations such as (ϕ_i, $3sa_1$) and (ϕ_i, $a_1\sigma^*$) to be distinct zero-order functions, with transitions imaginable to each separately or to their linear combinations if they are mixed. (See Section III.A for a short discussion on this point.) Pairs of terminating orbitals such as $a_1\sigma^*$ and $3sa_1$ are called "Rydberg/valence-shell conjugates" (1, 4). The $A(\phi_i, \sigma^*)$ levels of interest in this paper are the valence conjugates to either the (ϕ_i, ns), (ϕ_i, np), (ϕ_i, nd) or (ϕ_i, nf) Rydberg configurations of the system, depending upon the symmetry of a particular σ^*.

In attempting to gain some understanding of A-band spectra, we use an approach which has proved to be quite successful for identifying and correlating molecular Rydberg transitions: that of the molecular term value. In the case of Rydberg transitions, this approach is natural since the term value, $R/(n - \delta)^2$, appears prominently in the Rydberg formula describing the energetics of Rydberg series members. In this expression, R is the Rydberg constant, n is the principal quantum number of the Rydberg orbital, and δ in the quantum defect. Alternatively, being the difference between the ground-state ionization potential and the Rydberg excitation energy, the Rydberg term value can be interpreted as the Rydberg excited-state ionization potential. For a valence excited state (ϕ_i,σ^*), the term value has no meaning in the Rydberg sense since there is no convergent series of valence-shell states. However, the $A(\phi_i,\sigma^*)$ band term value as defined in Fig. 1 (the difference between the ϕ_i^{-1} ionization potential of energy E^+ and the $A(\phi_i,\sigma^*)$ band excitation energy E^*) does have meaning when viewed as the ionization potential of an electron in σ^* when promoted from ϕ_i. Thus we hope to learn something about σ^* orbitals by comparing their ionization potentials in groups of related (excited) molecules.

Data on A-band frequencies and term values in several classes of molecules are assembled in Tables 1, 2, and 3(1). Perusing this data, it is obvious that there is considerable regularity among the term values even though the transition is valence shell rather than Rydberg. In some cases the term-value trends parallel those of Rydberg excitations, while in others the trends are opposite. The A-band data in the tables lead to several conclusions, as discussed in the following sections.

II.B. Term-value trends and bond strengths

It is readily seen from Table 1 that the term values for the $A(np,\sigma^*)$ outer-shell transitions in the alkyl halides vary in a regular manner as one halide is replaced by another. For purposes of identifying such A bands in more complex systems, it is useful to note that the chloroalkane term values are in the 30 000 – 38 000 cm^{-1} range, with the bromo and iodoalkane term values some 3 000–6 000 cm^{-1} higher. In all cases, the A-band term value of a particular alkyl halide increases with increasing halogenation. Both this and the term-value increase in the Cl, Br, I monohalide series are counter to the trends observed for the conjugate (np,(n + 1)s) Rydberg excitations (4). These two trends of opposite sign cross between F and Cl, so that in the alkyl halides RCl, RBr, and RI the level ordering is A-band-below-conjugate-Rydberg, whereas in RF the ordering is conjugate-Rydberg-below-A-band. Other A-band term-value trends are discussed in Sections II.C and II.D.

As shown in Fig. 1, the interaction between the σ orbitals on R and X upon forming the R—X bond elevates σ^*, thereby reducing the $A(np,\sigma^*)$ term value. Since the σ^* level is raised more, the stronger the R—X bond, one expects the $A(np,\sigma^*)$ term values to vary *inversely* with the R—X bond strengths within a class of closely related molecules. Looking first at the methyl halides, Fig. 2, one notes the increasing (np,σ^*) term values in the series CH_3Cl, CH_3Br, and CH_3I, whereas the C—X bond strengths are decreasing in the same order. From this simple relationship we can extrapolate to a ($2p$,σ^*) term value of 26 800 cm^{-1} in CH_3F. Inasmuch as the ($2p$,$3s$) Rydberg term value is 33 000 cm^{-1} in CH_3F, it is now clear why A bands are not observed in the alkyl fluorides: the C—F bonds are so strong that σ^* lies within the thicket of Rydberg excitations. Again, there is a monotonic increase of the lowest (np,σ^*) term value as one goes from CH_3X to CX_4 for X = Cl, Br, and I, in inverse order of their C—X bond strengths.

A trend identical to that of the outer-shell term values is seen as well in the inner-shell ($1s_C$,σ^*) term values of the methyl halides, Fig. 2, with the ($1s_C$,σ^*) term value for a particular compound approximately 8 000 cm^{-1} larger than that for

(np,σ^*). The extrapolated $(1s_C,\sigma^*)$ term value for methyl fluoride is 36 500 cm^{-1}, a value which is very close to that for the $(1s_C,3s)$ inner-shell Rydberg state. Thus it is not surprise that these conjugate levels are found to be nearly degenerate in the inner-shell spectrum of CH_3F (1).

The influence of bond strength on the A-band frequencies also appears prominently in the spectra of the Group IV tetrachlorides MCl_4, Fig. 3, where $A(3p,\sigma^*)$ bands are readily observed in CCl_4, $GeCl_4$, and $SnCl_4$, but not in $SiCl_4$ (6). In this group, the M—Cl bond is especially strong in $SiCl_4$ (88 kcal/mol) compared to the others (*ca.* 72 kcal/mol), thereby elevating the $3p \rightarrow \sigma^*$ excitations of $SiCl_4$ among the Rydberg excitations where they are lost from view. At the opposite extreme, the Sn—Cl bond strength in $SnCl_4$ is only 68 kcal/mol, and its $A(3p,\sigma^*)$ bands are at the lowest frequencies observed for tetrachlorides.

Because the bond strength in BF_3 is very large (153 kcal/mol), the $A(1s_B,\sigma^*)$ term value is so far diminished as to become negative. That is, the $1s_B \rightarrow \sigma^*$ excitation in BF_3 is at higher frequency than the $1s_B^{-1}$ ionization potential (by 18 500 cm^{-1}), and consequently appears as a shape resonance (7). There is a strong possibility that the outer shell $A(2p_F,\sigma^*)$ band of BF_3 also will lie above the $2p_F^{-1}$ ionization limit. At the opposite extreme, in a molecule such as NF_3 (4) where the N—F bond strength is only 67 kcal/mol, the $A(2p_N,\sigma^*)$ term value is correspondingly elevated to 40 100 cm^{-1}, so that the A band precedes the Rydberg parade. In the $1s_N$ and $1s_F$ spectra of NF_3, the $(1s,\sigma^*)$ term values of the A bands increase to 52 000 cm^{-1}, as anticipated from the antishielding argument (Section II.D).

Whereas the term value of the $(np,(n+1)s)$ Rydberg configuration is understandable in terms of the core penetration of an essentially nonbonding $(n+1)s$ Rydberg orbital, in the case of the (np,σ^*) conjugate configuration the term value will strongly reflect the antibonding nature of the σ^* MO and therewith, the strength of the relevant σ bond.

II.C. Alkylation and fluorination effects on term values

The larger the R group in RX, the weaker the R—X bond. As in Section II.B above, this would tend to increase the (np,σ^*) term value. On the other hand, large R groups strongly stabilize the np^{-1} ionic state by hyperconjugation, thereby decreasing the (np,σ^*) term value. The latter factor is dominant. The effects of alkylation on the (np,σ^*) term value are seen most clearly in the iodides, Table 1. The $A(5p,\sigma^*)$ band falls consistently at 38 500 cm^{-1} in the alkyl iodides while the ionization potential decreases from 77 030 cm^{-1} in methyl iodide to 71 860 cm^{-1} in cyclohexyl iodide. As a result of this overwhelming stabilization of the cation by the hyperconjugative alkyl groups, the $(5p,\sigma^*)$ term value steadily drops from a value of 38 500 cm^{-1} in methyl iodide to 33 360 cm^{-1} in cyclohexyl iodide. In the alkyl chlorides, the same trend is evident, though with a smaller slope. The depressing effect of the alkyl group on A-band term values is evident as well in the inner-shell term values of HCl ($2p_{Cl}$, 47 500 cm^{-1}), CH_3Cl ($1s_C$, 40 000 cm^{-1}), and C_2H_5Cl ($1s_C$, 38 700 cm^{-1}). This trend parallels that for the corresponding conjugate Rydberg absorptions.

Fluorination of an alkyl halide acts in a direction opposite to that of alkylation, increasing the (np,σ^*) term values, as is also the case with the conjugate Rydberg excitations. The term-value effects of replacing hydrogen by fluorine on several valence excitations are summarized in Table 2. One sees that in the case of the halide A bands, fluorination shifts the outer-shell A band term value to higher frequencies by up to 12 000 cm^{-1}, but an average value is more like *ca.* 8 000 cm^{-1}. A similar positive increment applies to the inner-shell $(2p,\sigma^*)$ term values in the SiH_4/SiF_4 pair, the only one for which inner-shell data is available. A sampling of spectroscopic frequencies in highly fluorinated hypervalent species such as SF_6, XeF_6, etc., reveals A-band term values as large as 80 000 cm^{-1} for inner-shell transitions, consonant with the low M—F bond energies

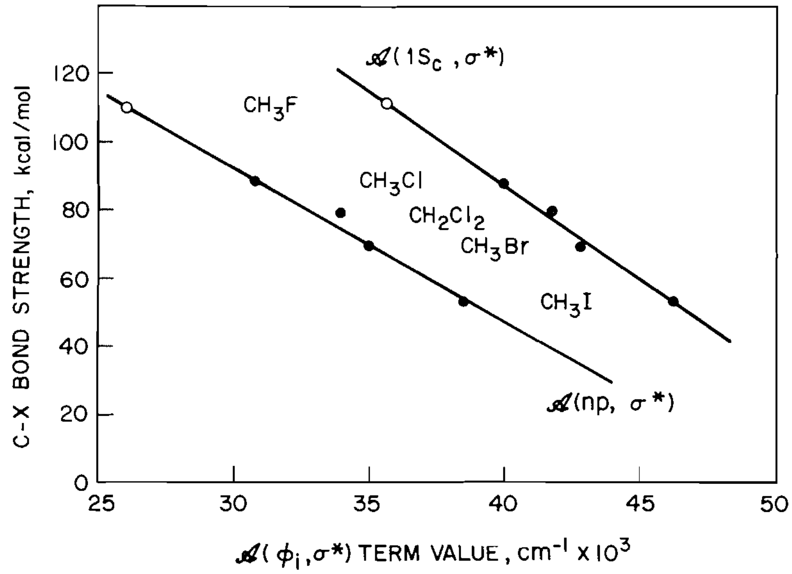

FIG. 2. Variation of the $A(np,\sigma^*)$ term values with C—X bond strength in the methyl halides.

TABLE 2. Fluorination effects on valence shell A-band term values (1)

Upper-state configuration	H compound	Term value, cm^{-1}	F compound	Term value, cm^{-1}
$(2p,\sigma^*)$	SiH_4	35 000	SiF_4	45 500
$^3(\pi,\pi^*)$	$H_2C{=}CH_2$	49 950	$F_2C{=}CF_2$	47 200
$^1(\pi,\pi^*)$	$H_2C{=}CH_2$	23 050	$F_2C{=}CF_2$	13 600
$^3(\pi,\pi^*)$	$H_2C{=}CHCl$	49 200	$F_2C{=}CFCl$	47 400
$^1(\pi,\pi^*)$	$H_2C{=}CHCl$	26 700	$F_2C{=}CFCl$	20 200
$(3p,\sigma^*)$	CH_3Cl	31 000	CF_2HCl	35 400
			CF_3Cl	39 500
$(3p,\sigma^*)$	CH_2Cl_2	35 900	CF_2Cl_2	43 100
$(3p,\sigma^*)$	$CHCl_3$	36 000	$CFCl_3$	40 400
$(3p,\sigma^*)$	C_2H_5Cl	30 000	CH_3CF_2Cl	36 900
			C_2F_5Cl	37 800
$(4p,\sigma^*)$	CH_3Br	34 000	CF_3Br	46 800
$(4p,\sigma^*)$	CH_2Br_2	40 000	CF_2Br_2	46 200
$(5p,\sigma^*)$	CH_3I	39 000	CF_3I	46 200
$(1s,\pi^*)$	$CH_3CH{=}CHCH_3$	46 000	$CF_3CF{=}CFCF_3$	54 800

in these molecules. It appears that the (np,σ^*) term-value decrease on alkylation of an alkyl halide is due largely to the alkyl group's effect on the np^{-1} ionization energy, whereas the increase of this term value on fluorination is due to the inductive lowering of the σ^* level.

II.D. Antishielding in the inner-shell spectra

The ionization energy (term value) in an $A(\phi_i,\sigma^*)$ configuration will depend not only upon the $\sigma-\sigma^*$ split as evidenced by the bond strength, but also upon the effective nuclear charges of the AO's in the σ^* MO. In the A-band upper state, the optical electron is electrostatically bound to the core due to the imperfect shielding of the nucleus by the valence electrons. The shielding of the σ^* orbital from the nucleus is more efficiently performed by the inner-shell electrons ($1s$) than the outer-shell electrons ($2s$ and $2p$) because the inner-shell orbitals are less easily penetrated by an electron in σ^*. Consequently, when the electronic configuration is changed from an outer-shell one such as $(2p,\sigma^*)$ to an inner-shell one such as $(1s,\sigma^*)$ the shielding of the σ^* orbital from the nucleus decreases and the term value rises. Looked at another way, the effective nuclear charge for a $2p$ orbital on C^+ in the outer-shell configuration $1s^22s^22p$ is 3.25 according to Slater's rules whereas for a $2p$ orbital in the $1s2s^22p^2$ inner-shell configuration, it is 3.75. This increased binding of the optical electron as the hole descends to a lower level we call "*antishielding*". The antishielding increment for inner-shell excitation over outer-shell excitation will be much larger for a σ^* MO than for a Rydberg orbital since σ^* MO's are more penetrating. Exchange effects also contribute somewhat to the larger term values of inner-shell A bands (8).

One sees in Table 3 that for excitation from the various halogen AO's into σ^*(C—X) of the halomethanes, the (ϕ_i,σ^*) term value indeed drops as the energy of ϕ_i descends, in accord with the antishielding concept. Moreover, a hole in $1s_C$ is about equivalent in antishielding to a hole in $2p_{Cl}$, but is much less antishielding than when ϕ_i is $2s_{Cl}$ or $1s_{Cl}$. For a given inner-shell originating orbital ϕ_i, there is also an increase of the (ϕ_i,σ^*) term value as the methane molecule is successively chlorinated, Table 3. This can be explained as due in part to a weakening of the C—Cl bond with chlorination and also to C—Cl/C—Cl interactions which split the σ^*(C—Cl) man-

ifold into several components, the lowest of which is progressively stabilized upon further chlorination. This stabilization is most evident in the valence temporary-negative-ion (TNI) resonances of the chloromethanes, in which a resonance measures the energy necessary to attach an electron to the molecule via the σ^* MO's (9). Thus between CH_3Cl and CCl_4 there is a monotonic decrease of the lowest valence TNI resonance frequency from 27 800 cm^{-1} to a figure which is actually just slightly negative. The antishielding enhancement of inner-shell term values is dramatically illustrated by the case of $SiCl_4$, where the $A(2p_{Si},\sigma^*)$ band is prominent as the lowest excitation, having a 51 000 cm^{-1} term value (4), in strong contrast to the $A(3p_{Cl},\sigma^*)$ band of the outer shell which is lost among the Rydberg bands and so must have a term value which is less than 25 000 cm^{-1}.

II.E. A *Bands in nonhalide systems*

All of the A-band trends quoted above are deduced from data on the alkyl halides. What now if the halogen and its lone pair in R—X are replaced by one of the groups —OH, —SCH$_3$, —NH$_2$, etc., so as to form alcohols, thioethers, amines, etc.? There is no choice but to follow the scheme of Fig. 1 and to consider $A(np,\sigma^*)$ and $A(1s,\sigma^*)$ bands in these substances as well. Though these systems are chemically different from the alkyl halides, one expects that their $A(np,\sigma^*)$ bands nonetheless will behave spectroscopically as described above, with the understanding however, that they will not necessarily lie below the Rydberg manifold. From this point of view, it is clear for example, that the weak transition in CF_3OF having a term value of 55 000 cm^{-1} with respect to the $2p_O^{-1}$ ionization potential (10) is an $A(2p_O,\sigma^*)$ band of extraordinarily large term value thanks to an O—F bond strength of only 43.5 kcal/mol . In H_2O_2, where the O—O bond strength is only 37 kcal/mol, a low-lying $A(2p_O,\sigma^*)$ band absorption likely is responsible for the observed dissociation into OH radicals with unit quantum yield at 2537 Å. However, given molecules having more normal bond strengths, one most often does not find $A(np,\sigma^*)$ bands in the outer-shell spectra of molecules bearing lone pairs on O, S, N, P, etc. For this, one must go to the X-ray spectra, thereby taking advantage of the inner-shell antishielding which increases the A-band term value (Section II.D). We defer discussion of the fate of outer-shell A bands in the nonhalides to Section III.B.

Since the antishielding effect operates more strongly on valence states than on Rydberg states, and more strongly in the inner-shell spectra than in the outer shell, $A(\phi_i,\sigma^*)$ bands are more often visible below their Rydberg conjugates in the inner-shell spectrum. The relative ease of spotting A bands in the inner-shell spectra is also promoted by the fact that outer-shell $A(np,\sigma^*)$ excitations for overlap reasons are among the weaker transitions in the outer-shell spectrum. Consequently such bands are visible only when their terms values are much larger than those of the similarly weak but far-more-numerous Rydberg bands in the same spectral region. On the other hand,

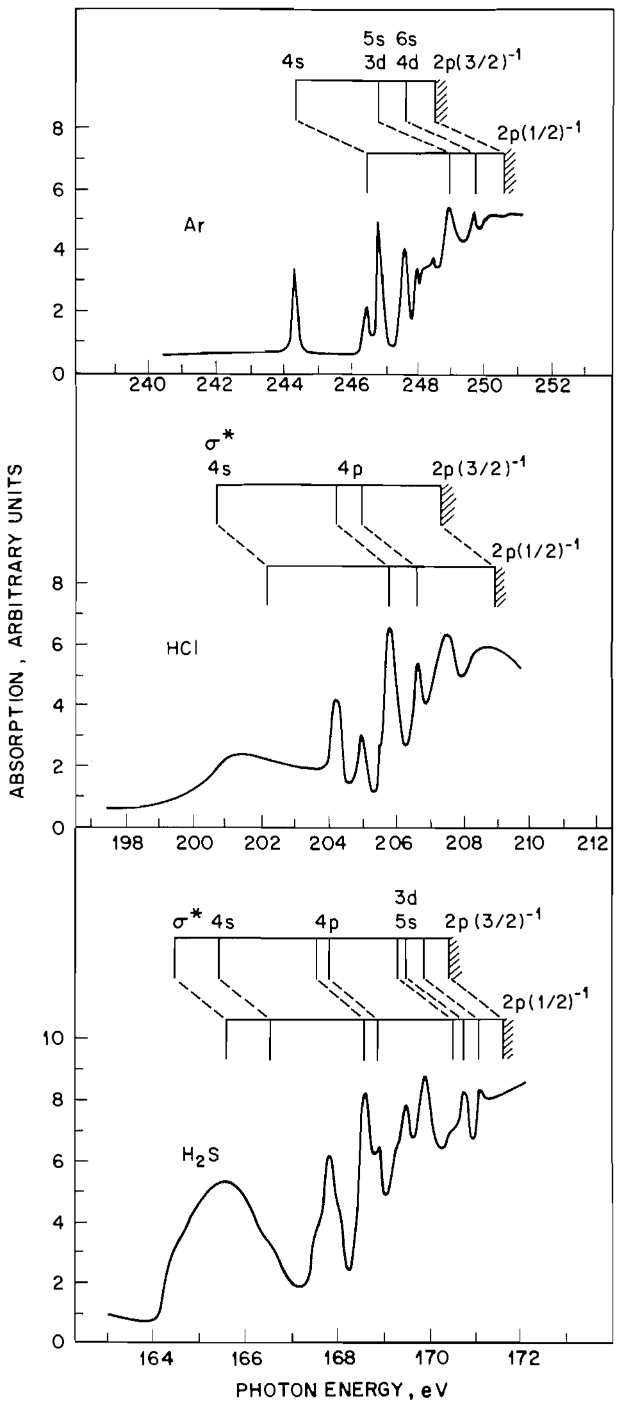

FIG. 4. Development of the $A(3p,\sigma^*)$ band in the isoelectronic series Ar, HCl, H_2S (redrawn from ref. 11).

$A(1s,\sigma^*)$ bands are among the most intense in the inner-shell spectrum, again for reasons of overlap between the originating and terminating orbitals.

It is easiest to see how σ* MO's influence molecular spectra by comparing the inner-shell spectra of several molecular hydrides with that of their isoelectronic united atom. Thus in Fig. 4, the $2p$ molecular spectra of HCl and H_2S are compared with that of Ar (see, for example, ref. 11), revealing a number of differences. Interpretation of these spectra requires an allowance for the $2p_{3/2}$–$2p_{1/2}$ spin–orbit splitting of the core in each case. First, we note that the very broad transitions about 50 000 cm^{-1} below the $2p^{-1}$ ionization limits in the molecular spectra do not appear in the spectrum of the isoelectronic atom, and hence must involve molecular σ* MO's, which is to say, these are $A(2p,\sigma^*)$ bands. Next, the sharp $2p \rightarrow 4s$ transition of the atom is barely detectable in the molecular spectra, suggesting appreciable mixing between the $(2p,a_1\sigma^*)$ and $(2p,4sa_1)$ conjugate configurations such that the former is intensified and the latter diminished. Finally, whereas the $2p \rightarrow 4p$ transition is absolutely forbidden in the atom, it is an allowed transition in the molecular case. Once beyond the transitions to $4p$, the Rydberg spectra of the Ar atom and its isoelectronic molecular hydrides are quite comparable, except for certain small core splittings in the latter. The $2p$ spectra of PH_3 and SiH_4 closely follow the pattern of molecular transitions described above for HCl and H_2S; however, the outer-shell transitions to σ* in PH_3 and SiH_4 do *not* precede the lowest Rydberg excitations, contrary to the ordering for HCl and H_2S in the outer-shell spectra.

II.F. A *band varieties in unsaturated systems*

When the group bearing the lone pair is bonded directly to an unsaturated center as in $H_2C{=}CHX$, the *A*-band possibilities are manifold. As in alkyl halides, there is an $A(np,\sigma^*)$ band present. However the $A(np,\sigma^*)$ band in unsaturated systems generally is not the lowest-frequency *A* band, for there generally are occupied π MO's above *np* in these compounds. In such a case, the lowest *A* band is $A(\pi,\sigma^*)$ in an obvious notation. $A(np,\sigma^*)$ and $A(\pi,\sigma^*)$ bands appear in the outer-shell spectrum with separations nearly equal to the difference of np^{-1} and π^{-1} ionization potentials, with each occupied π MO in the molecule responsible for a specific $A(\pi,\sigma^*)$ band. Two other transitions are possible here: $\pi \rightarrow \pi^*$ and $np \rightarrow \pi^*$. Since both of these are encompassed in the well-known V_n notation of $\pi \rightarrow \pi^*$ excitations, they have not been renamed to fit into the *A*-band scheme. The inner-shell spectra of such unsaturated systems will commence with $\phi_i \rightarrow \pi^*$ transitions, followed by $\phi_i \rightarrow \sigma^*$ and Rydberg excitations.

By way of example, note that the 43 500-cm^{-1} band of tetrachloroethylene must be valence shell as witnessed by its frequency and by its behavior in condensed phases (12), and involves either $3p\pi_{Cl}$ or $\pi(C{=}C)$ as originating MO's and either $\pi^*(C{=}C)$ or $\sigma^*(C{-}Cl)$ as terminating MO's. Since the $\pi(C{=}C)$ MO is above the uppermost $3p\pi_{Cl}$ MO by 17 000 cm^{-1} in tetrachloroethylene, one concludes that the lowest valence transition in tetrachloroethylene will originate at $\pi(C{=}C)$. Since the $\pi \rightarrow \pi^*$ assignment is preempted by the intense band at 47 600 cm^{-1}, we must assign the 43 500-cm^{-1} band of tetrachloroethylene as originating at $\pi(C{=}C)$ and terminating at $\sigma^*(C{-}Cl)$, i.e., it is an $A(\pi,\sigma^*)$ band analogous to those of the fluoroethylenes in the 55 000 – 57 000 cm^{-1} region. Another likely *A* band appears in tetrachloroethylene at 61 900 cm^{-1} as a sharp but unstructured feature. Dauber and Brith (8) observed this band clearly in the neat crystal and in a Kr matrix where it is shifted to the low-frequency side of the vapor-phase band, as is the $\pi \rightarrow \pi^*$ valence-shell band at 47 600 cm^{-1}. By contrast, the $\pi \rightarrow 4s$ Rydberg excitation between 50 000 and 57 000 cm^{-1} is high-frequency shifted in a Kr matrix, and does not appear at all in the spectrum of the neat crystal. Though it is clear from this that the 61 900-cm^{-1} band of tetrachloroethylene is a valence excitation, it can be assigned as either $3p_{Cl} \rightarrow \pi^*$ or $3p_{Cl} \rightarrow \sigma^*$. We note, however, that the $A(\pi,\sigma^*)$ and $A(np,\sigma^*)$ band term values of the haloethylenes are quite constant (28 000 ± 1 500 cm^{-1}), irrespective of the halogen's atomic number or the extent of halogenation (1). Assignment of the 61 900-cm^{-1} feature of tetrachloroethylene as an $A(np,\sigma^*)$ band results in a 30 000 cm^{-1} term value, just equal to that of the $A(\pi,\sigma^*)$ band. Looked at from the point of view of the ground state, the transitions to (π,σ^*) and to $(3p,\sigma^*)$ differ by exactly the difference between the π^{-1} and $3p^{-1}$ ionization potentials. The implication from such simple one-electron-like behavior of the A band energies is that such states are much better described at the Hartree–Fock level (along with $n \rightarrow \pi^*$ and Rydberg excitations) than are the singlet configurations (π,π^*) and (σ,σ^*).

II.G. A *bands in transition-metal complexes*

The arguments of previous sections also apply to the case where the central atom is a transition metal and the ligands again carry lone-pair electrons as in WF_6 or CrO_2Cl_2. For octahedral or tetrahedral symmetry, the virtual *nd* valence orbitals split into π^* and σ^* sets with π^* lower. The lowest transitions originating at *np* will be $np \rightarrow \pi^*$, but these will be followed by $A(np,\sigma^*)$ bands. For transitions terminating at π^*, the spectral splittings closely reflect those among the *np* orbitals as observed in the photoelectron spectrum (1), which is to say, the (np,π^*) term values are constant; similar splittings appear among the A band transitions to σ^*. The difference of (np,π^*) and (np,σ^*) term values relates closely to $10Dq$ in these compounds.

Note that in the case of WF_6 for example, the lowest *nd* orbitals ($n = 5$) of W are involved in bonding to the F atoms, and so are part of the virtual π^*/σ^* valence-orbital set, thereby making $(n + 1)d$ the lowest *d*-type Rydberg orbital. In SF_6 however, the lowest *nd* orbitals ($n = 3$) do not participate in the bonding of the ground state and so the $3d$ orbitals are part of the Rydberg manifold instead.

II.H. General factors influencing observation of A *bands*

In a practical sense, the largest difficulty with spectroscopy terminating at σ^* is that the spectral bands are continuous and so are both difficult to separate from other continua in the same region and do not allow for vibronic or rotational analysis. For the $A(np,\sigma^*)$ transitions, the excitation can be phrased in terms of valence-bond structures

$$\mathrm{R}\cdot\cdot\ddot{\mathrm{X}} \xrightarrow{h\nu} \mathrm{R}\cdot:\dot{\mathrm{X}}$$

which clearly show why the upper state is dissociative. In fact, there are no known $A(np,\sigma^*)$ band excitations which show any vibronic structure whatsoever. On the other hand, for $\sigma \rightarrow \sigma^*$ excitation the appropriate valence-bond structures are:

$$\mathrm{R}\cdot\cdot\ddot{\mathrm{X}} \xrightarrow{h\nu} \{\mathrm{R}:^-\ \ddot{\mathrm{X}}^+ \leftrightarrow \mathrm{R}^+:\ddot{\mathrm{X}}^-\}$$

the upper state of which is not necessarily dissociative considering the Coulomb attraction between the R and X fragments. Indeed, the $\sigma \rightarrow \sigma^*$ excitations of the hydrogen halides (13) are highly nonvertical but vibrationally structured!

In general, one can say that A bands involving σ^* can be observed in inner- and outer-shell spectra when the single bond of interest is weak (bond strength less than 85 kcal/mol) so that the A band falls below the Rydberg traffic, or is very strong (approximately 125 kcal/mol or more) so that it lies above the ionization limit. Most interesting is the intermediate situation appropriate to molecules such as CH_4, CF_4, H_2O, PF_3, and BCl_3 in which the transitions to σ^* fall among the Rydberg excitations originating at the same lone pair MO. The ramifications of this situation are discussed in the next Section.

III. Valence miscibility with the Rydberg sea

III.A. Reality and coexistence of valence/Rydberg conjugates

The question of the mixing of valence/Rydberg conjugate orbitals and the real or imagined existence of such conjugate pairs remains unsettled in the literature (14–17), however, it is our position that pairs of conjugate orbitals do coexist. In support of the simultaneous reality of conjugate Rydberg and valence-shell states, we first quote the numerous highly accurate calculations on a variety of molecules which predict their existence. Thus for example, in HF, Bettendorf *et al.* (18) calculate that the valence $A(2p\pi,\sigma^*)$ band will be centered at 84 040 cm^{-1} with the upper state being repulsive, whereas the conjugate Rydberg transition to $(2p\pi,3s)$ is predicted to fall at 105 400 cm^{-1} with a bound upper-state surface. These predicted transitions of HF are closely parallel to the $A(5p\pi,\sigma^*)$ and Rydberg $5p\pi \rightarrow 6s$ conjugate bands of methyl iodide, about which there is no question. Interestingly, X-α calculations on H_2S which do not employ the LCAO format at all nonetheless predict the separate existence of $(5a_1,\sigma^*)$ and $(5a_1,3p\sigma)$ conjugate excited states (19). Finally, we mention that the inner-shell spectra of several second-row hydrides (Fig. 4, for example) clearly and indisputably show that conjugate valence shell and Rydberg excitations are seen in the same spectrum. Note also that conjugate valence shell and Rydberg excitations are well-documented in atomic spectra (20). Of course, the observation of both $A(np,\sigma^*)$ valence-shell bands and $np \rightarrow (n + 1)s$ Rydberg bands in a huge number of alkyl halides (cf. Table 1, for example) is even better evidence for the simultaneous existence of conjugate upper states.

III.B. Conjugate mixing and its consequences

Having stated our point of view as regards the reality of distinct valence-shell and Rydberg conjugate states, we next consider the possibility of their mixing. Unfortunately, the most revealing calculations on this point involve π^* upper orbitals rather than σ^*, however we believe the phenomenon applies to both and so present a discussion of the former as illustrative of the latter. Buenker and Peyerimhoff (21, 22) explain that in ethylene the (π,π^*) valence state and the conjugate $(\pi,3d_{xz})$ Rydberg state are mixed so that each becomes an approximately 50:50 mixture. The higher component in which (π,π^*) and $(\pi,3d_{xz})$ are out-of-phase, in a sense is the valence conjugate of the $(\pi,4d_{xz})$ Rydberg level and again there is strong mixing between these. In this way, significant (π,π^*) valence character is dispersed throughout the entire (π,nd_{xz}) Rydberg manifold. In the above example, the lowest level retains sufficient (π,π^*) character after mixing to be labelled as such, however, this is not necessarily always the case. As a counterexample, the $(1b_1,a_1\sigma^*)$ valence configuration of water is calculated to be so thoroughly mixed into the $(1b_1,ns)$ levels of the Rydberg sea (23) that it no longer contributes enough to any one state to merit calling that state "$(1b_1,a_1\sigma^*)$". This extreme miscibility of the valence-shell level and its conjugate Rydberg manifold is most apparent in the outer-shell spectra of the first-row and second-row hydrides, excepting the hydrogen halides. Note too that the miscibility of σ^* valence orbitals with the conjugate Rydberg sea can be selective, for in H_2S, the $a_1\sigma^*$ MO is totally miscible (as in H_2O), whereas the $b_2\sigma^*$ MO is not.

It is a fascinating question as to when an interloping valence level will be totally dissolved in the Rydberg sea and when it is only dampened by it. It is our experience that the miscibility of a valence level with its conjugate Rydberg sea is governed by two factors: energy and symmetry. Looking at the spectra and calculations, it appears that the distinct transitions to such valence-shell levels still appear when they are energetically at the edges of the sea and so only get their feet wet, i.e., when the interlopers precede the Rydberg parade (as in the alkyl halides), and when they follow it as shape resonances (as in BF_3). In the intermediate region, valence levels find themselves in a high density of symmetry-compatible Rydberg levels and so might readily lose their valence identity through mixing. This is reasonable in light of the inherently small mixing element that exists between large-radius Rydberg and small-radius valence-shell wavefunctions, meaning that wavefunction mixing can be effective only when the levels are near-degenerate. Because the valence interloper will fall below the Rydberg parade when its term value is significantly larger than that of the lowest conjugate Rydberg level, weak σ bonds, fluorination of the molecule or exciting from inner-shell orbitals will promote the appearance of such *A* bands.

Symmetry is the second important factor in determining the miscibility of a valence level with the conjugate Rydberg sea. Note that the valence/Rydberg mixing occurs at the MO level, and so will depend upon the overlap of these orbitals. If a particular manifold of Rydberg orbitals has a very high angular momentum then the orbitals will not penetrate the core and so will have a greatly diminished tendency to mix with the conjugate antibonding valence MO. Generalizing, an antibonding valence MO of *s* symmetry will be most likely to dissolve in the conjugate *ns* Rydberg sea when dipped into it, whereas *p*-symmetry and *d*-symmetry antibonding valence MO's will be much less apt to dissolve in their less-penetrating Rydberg manifolds. Thus we have a natural explanation for why the $(1b_1,a_1\sigma^*)$ valence configuration of water dissolves completely in the conjugate $(1b_1,nsa_1)$ Rydberg manifold whereas the (π,π^*) valence configuration of ethylene does not dissolve completely in the conjugate $(\pi,3d_{xz})$ Rydberg manifold. An antibonding MO of *f* symmetry offers the extreme case, for the *nf* Rydberg orbitals are quite nonpenetrating and there will be very little tendency indeed for overlap and dissolution. However, the symmetry of the molecule also must be high if the *f*-type valence orbital is to retain totally its valence character, for only in high-symmetry systems will the more-penetrating *ns* and *np* Rydberg seas have symmetry representations different from that of one or more components of *nf*. Examples of these principles at work are discussed below (cf. Section III.D).

Yet another factor working in the same direction as symmetry is that of the width of the Rydberg sea. Since this is typically 35 000 cm^{-1} for the *ns* Rydberg manifold but only 6 400 cm^{-1} for *nf*, one sees that the near-degeneracy criterion for strong mixing will be easier to fulfill for σ^* levels of *s* symmetry than for σ^* levels of *f* symmetry.

Consideration of the two factors discussed above leads to the conclusion that complete miscibility of the valence level $(a\sigma^*)$ with the conjugate Rydberg sea occurs when a totally symmetric valence level falls within a sea which is both totally symmetric and penetrating (*nsa*). In this case, the σ^* level no longer is a distinct entity, but exists only as a perturbation of the conjugate Rydberg orbitals. If the valence level is either above or below the Rydberg manifold and/or has a symmetry such that its conjugate Rydberg levels are less penetrating, as with *np*, *nd*, or *nf* orbitals, then the mixing is correspondingly reduced and a distinct σ^* valence-shell level exists.

Experimental proof of the complete dissolution of a valence orbital in the Rydberg sea will be difficult, for it is not easy to ascertain if a distinct σ^* level still exists among the Rydberg levels, or if it exists above them as a shape resonance. Perhaps only a high-quality calculation can settle the question in any particular case. Note however that the valence/Rydberg nature of a nominally valence-shell configuration cannot be assessed correctly by calculation unless the basis set is rather complete in the conjugate Rydberg orbitals. This is in contrast to the approach often used of implementing the Rydberg basis only when concerned directly with calculating the higher Rydberg states.

Because the properties of Rydberg and valence-shell states are so different, mixing of these two types of configurations can produce profound effects. The consequences of Rydberg/valence shell mixing are best illustrated by calculations on the $^1(\pi,\pi^*)$ and $^1(\pi,3d_{xz})$ configurations of ethylene (22, 24). Again, these are presented as illustrative of what effects Rydberg/valence miscibility might have on transitions to σ^* orbitals. Calculations show that the mixing matrix element between Rydberg and valence-shell configurations generally is largest when the two configurations differ by a one-electron promotion, i.e., when they are conjugate. In the case of ethylene, mixing with the $^1(\pi,nd_{xz})$ manifold lowers the $^1(\pi,\pi^*)$ frequency by ca. 7 000 cm^{-1}, and results in a final V-state orbital which has 45–50% Rydberg character. For reasons of spatial overlap, the $\pi \rightarrow \pi^*$ valence excitation of ethylene is far more intense than the conjugate $\pi \rightarrow nd_{xz}$ Rydberg excitations, and consequently the calculated *f* value for the $\pi \rightarrow \pi^*$ excitation decreases from 0.485 to 0.293 upon admitting nd_{xz} orbitals into the calculation. Though the "missing" oscillator strength is donated to the Rydberg excitations, it is not very noticeable in any one of them since it is distributed among all of the $\pi \rightarrow nd_{xz}$ transitions. The importance of Rydberg/ valence-shell mixing on the *f* values in atoms also has been noted (20).

As expected, the values of $\langle x^2 \rangle$ for the out-of-plane *x* coordinate computed for valence shell and Rydberg MO's in planar molecules vary sharply depending upon orbital type. Thus for the π^* valence MO in the $^3(\pi,\pi^*)$ state of ethylene, $\langle x^2 \rangle$ is $3.88a_0^2$, while for $3d_{xz}$ in $^1(\pi,3d_{xz})$ it swells to $53.6a_0^2$; the π^* MO of mixed character in $^1(\pi,\pi^*)$ has the intermediate value $24.3a_0^2$. Another measure of spatial extent is offered by the Coulomb self-energy integral J_{jj} in the (ϕ_i,ϕ_j) configuration; the value of J_{jj} decreases with increasing ϕ_j orbital size, and in fact can be used as a criterion on which to base a Rydberg/ valence-shell assignment. One sees that valence-shell excitations terminating both at π^* and σ^* have computed upper orbital self-energies in the 70 000 – 95 000 cm^{-1} range whereas the Rydberg orbital self-energies occupy the 0 – 32 000 cm^{-1} range, depending upon their term values (1). Interestingly, the π^* self-energy of the $^1(\pi,\pi^*)$ valence-shell configuration after mixing, 32 500 cm^{-1}, is far below that normally assigned to valence-shell states, but at the top of the Rydberg range, a clear indication of its heavy Rydberg admixture. In contrast, the π^* self-energy for the $^1(1s,\pi^*)$ level of ethylene, 93 600 cm^{-1}, is solidly in the valence-shell camp, as appropriate for a purely valence configuration. With the exception of the $^1(\pi,\pi^*)$ level, the J_{jj} self-energies of (ϕ_i,ϕ_j) configurations of ethylene are very much independent of the open-shell orbital ϕ_i.

It is generally true that the Franck–Condon envelopes of the lowest Rydberg excitation in a molecule and the corresponding photoelectron band are identical (4). However, if a (ϕ_i,σ^*) valence level is strongly mixed with the (ϕ_i,ns) conjugate Rydberg levels such that they are dissociative and rapidly

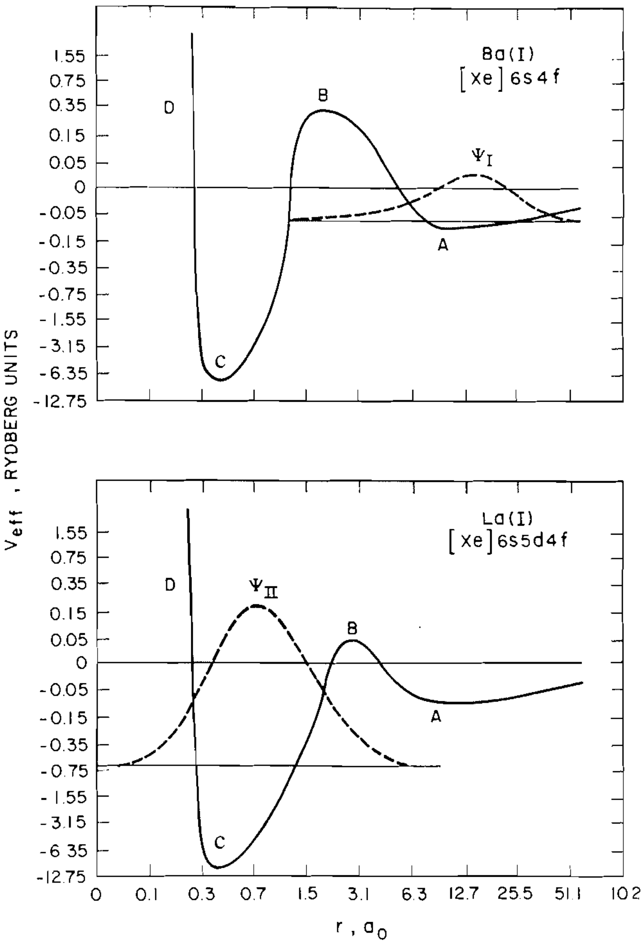

FIG. 5. Inner and outer wells and their wavefunctions.

deRydbergize with distance whereas the ϕ_i^{-1} ion is not so mixed, then the vibronic envelopes for the $\phi_i \rightarrow 3s$ and $\phi_i \rightarrow \infty$ transitions will be noticeably different. Thus, for example, the extreme differences of the $\phi_i \rightarrow 3s$ Rydberg and ϕ_i^{-1} photoelectron band profiles in H_2O, CH_4, H_2S, and HCOOH result from the strong mixing of their lowest Rydberg levels with their valence conjugates. On the other hand, such mixing is much weaker in NH_3 and effectively nonexistent in the alkyl chlorides, bromides, and iodides, for example.

If the $\phi_i \rightarrow a_1\sigma^*$ excitation is not observed below the Rydberg bands originating at ϕ_i, and does not mix with them as evidenced by the close similarity of the $\phi_i \rightarrow 3s$ and ϕ_i^{-1} band shapes, then it seems safe to conclude that $a_1\sigma^*$ is suspended in the ϕ_i^{-1} ionization continuum as a shape resonance. This argument does not hold for σ^* MO's which are less than totally symmetric, for these cases the conjugate Rydberg orbitals are only weakly penetrating and do not mix very well with σ^* regardless of their relative frequencies.

III.C. Conjugate unmixing

Provided the Rydberg/valence-shell mixing is not too extreme, it is possible to experimentally deperturb these levels. Thus any of the well-known external perturbations which are so effective in helping to distinguish valence-shell from Rydberg excitations (4) also are effective in removing the effects of Rydberg perturbations on valence-shell transitions. Interacting Rydberg and valence-shell levels also can be deperturbed by first producing an inner-shell hole which then shifts the offending Rydberg levels of the resulting ion far out of resonance with the valence-shell level of interest.

In addition to configurational mixing, it is now well documented that the mixing and unmixing of Rydberg and valence conjugates in molecules can be induced by changes of internuclear distance. Thus, for example, in each of the hydrides CH_4, C_2H_5, SiH_4, NH_3, PH_3, CH_3, and H_2O it has been computed that at the ground-state geometry, the first excited state of the same spin multiplicity is overwhelmingly Rydberg, as measured by any criterion. However, as either a hydrogen atom or a hydrogen molecule leaves the molecule, the Rydberg state in question rapidly evolves into a valence-shell state of the system, passing through all degrees of mixture on the way to total separation (deRydbergization). In this case, the increasing bond length leads to a decreasing $\sigma \rightarrow \sigma^*$ split. Consequently, the σ^* level quickly drops below the band of conjugate Rydberg levels, the mixing is turned off, and the eventual dissociation products have valence-shell configurations (17). It may also happen that at the ground-state equilibrium geometry, the σ^* valence MO is above the block of Rydberg levels so that $\phi_i \rightarrow \sigma^*$ is a shape resonance. In this case, as the relevant bond is lengthened, σ^* first comes into resonance with the Rydberg sea and assumes a strong Rydberg character before passing out the other side and becoming valence again at very large distances. These aspects of Rydberg/valence shell mixing are of extreme importance to a discussion of photochemistry in the vacuum ultraviolet, and the interested reader is referred to a number of papers in which the subject is explored in depth (17, 25–28). The rapidly changing Rydberg/valence-shell character of a potential surface raises a question of semantics for the photochemist who is concerned with its broadest reaches, however this is not as confounding for the spectroscopist who works closely in the vicinity of the ground-state R_e. Nonetheless, we must emphasize that even at R_e the mixing may be such that neither "valence" nor "Rydberg" designations are adequate.

III.D. Molecular giant resonances as manifestations of σ^* immiscibility

There is a fascinating development taking form in atomic spectroscopy which not only appears to have strong parallels in the area of molecular Rydberg/valence mixing, but impacts directly on the question of observing $\sigma \rightarrow \sigma^*$ valence shell excitations in saturated molecules. Consider the effective radial potential in an atom (V_{eff}) as consisting of a Coulombic term $(-1/r)$ and a centrifugal term $l(l+1)/r^2$ as plotted in Fig. 5 for the $4f$ orbital of lanthanum in the [Xe]$6s5d4f$ configuration. As Connerade explains (29, 30), in region A the Coulombic part of the potential is dominant, however as r decreases, the centrifugal effect acts to raise the potential, as in region B. Once into region B however, the electron then is able to penetrate the core more effectively, thereby experiencing a higher effective nuclear charge and so lowering the potential again, as in region C. Finally, at very short distances, region D, the $1/r^2$ dependence of the centrifugal potential overcomes the $-1/r$ dependence of the Coulombic potential and V_{eff} rises abruptly. The net result of these two competing potential terms in the case of atomic orbitals having $l \geqslant 2$ is a double-well effective potential. The hump in region II is called the centrifugal barrier, but in fairness it must be noted that it is due equally to the effect of penetration, and does not even appear in the hydrogen atom where penetration is not possible.

Figure 5 shows the double-well V_{eff} for $4f$ orbitals in the excited states of both the lanthanum and barium atoms, and as expected for neighboring atoms in the periodic table, the curves are semiquantitatively alike. What is most surprising to see is that the corresponding $4f$ wavefunctions are exceedingly different, with that in the [Xe]$6s4f$ configuration of Ba occupying the outer well and peaked at ca. $15a_0$, whereas that in the [Xe]$6s5d4f$ configuration of La occupies the inner well and is peaked at less than $1a_0$!! The $4f$ orbital in the Ba excited state is properly termed a Rydberg orbital due to its size and due to the fact that its energy is dictated largely by the $-1/r$ part of the potential. On the other hand, this is clearly not the case for the $4f$ orbital of La trapped in the inner well of region C, and so this is termed a "nonRydberg" orbital (29). Moreover, as is known for double-well potentials in general, even slight differences between the two well profiles are sufficient to shift the electron from one well to the other. Wavefunction collapse results from the transfer of the electron from the outer to the inner well. Only with very fine tuning is one able to get the wavefunction to occupy both wells simultaneously. Considerable theoretical and experimental work on atoms is now available to support the notion of large-l wavefunction collapse under relatively small perturbation.

In our attempt to apply this type of reasoning to molecules we first must discard the centrifugal potential because we wish to apply the double-well concept to states where l may equal zero or to low-symmetry molecules in which the angular momentum is quenched (31). In its place, we invoke a spatial modulation of the potential due to the spatially extended nature of the molecular core. In the molecular case, the repulsive hump comes not from the combination of centrifugal force and penetration, but from the orthogonality to the molecular bonds in the core. Depending upon the details of the potential, the lowest level may be strongly compressed (Ψ_I) or expanded (Ψ_{II}); after proper orthogonalization to the occupied core orbitals, these functions are seen to be antibonding valence-shell orbitals (σ^*, π^*, δ^*, etc., depending upon unspecified angular factors) and their Rydberg conjugates (*ns*, *np*π, *nd*δ, etc.), respectively. Arguing as in the atomic case, we expect that relatively small changes of potential will suffice to change drastically the nature of the lowest bound level, and in certain conditions can lead to a wavefunction which is a linear combination of Ψ_I and Ψ_{II}.

We have forced a parallel between the atomic and molecular potentials and then argued for analogous behavior in the two models largely because there are notable similarities in the experimental observations on Rydberg/nonRydberg spectra in atoms and on Rydberg/valence-shell mixing and ordering in molecules. Following the description of the atomic spectra given by Connerade (29) we note the following analogies:

(*i*) In atoms, the two states of the double-well potential are small radius (nonRydberg) and large radius (Rydberg). In molecules, the two states of the double-well potential are small radius (antibonding valence shell) and large radius (Rydberg).

(*ii*) As the effective potential for an atom is varied, the lowest level in the outer well may collapse into the inner well. As the M—H bond in a molecule is continuously lengthened, the lowest Rydberg level may be rapidly transformed (deRydbergized) into an antibonding valence level.

(*iii*) Atomic resonances to inner-well levels (*giant resonances*) are much more intense than transitions to outer-well levels (Rydberg excitations) for reasons of spatial overlap between the originating and terminating orbitals. Inner-shell molecular transitions to valence levels are much more intense than transitions to Rydberg levels for reasons of spatial overlap.

(*iv*) Atomic transitions to inner-well levels (giant resonances) appear in solids whereas those to outer-well Rydberg levels generally do not. This parallels exactly the behavior of valence-shell and Rydberg upper states in molecules.

(*v*) When the outer-well wavefunction in an atom collapses to the inner well, the next higher outer-well level moves down and then plays the role of the lowest outer-well level. Energetically, this lowest level can be close to the position of the lowest level before collapse, however, by its node count it is one higher. Thus there is a semantic problem as to whether the lowest outer-well function after collapse should be assigned principal quantum number n or $n + 1$. Exactly the same problem has been pointed out in regard the numbering of Rydberg levels when preceded by a conjugate valence level (cf. ref. 4, p. 26, for example).

(*vi*) In atoms, the inner-well levels may be below (bound levels) or above the relevant ionization limit (resonantly localized continuum levels). A similar situation holds for the valence states of molecules.

In view of the many similarities between the atomic and molecular cases, it is important to point out an essential difference as well. In the atomic case, a double-well effective potential is inappropriate for s or p symmetries because of their zero or small l values. In contrast, s and p electrons in molecules may move in a double-well effective potential with distinct inner-well and outer-well wavefunctions provided the inner-well wavefunction does not dissolve completely in the sea of outer-well functions.

Much of what we are saying here is either explicitly or implicitly contained in Dehmer's original discussion (32) of the double-well model for molecular excited states. What we want to emphasize is that the inner well is associated with antibonding valence MO's and that relatively small differences of the shape of the effective potential can make the lowest level appear as Rydberg, antibonding valence, or a mixture of these.

By way of example, let us now apply this to a molecular system. In certain hydrides (alkanes) of high symmetry, there can be an antibonding valence MO with symmetry conjugate *only* to one of the *nf* Rydberg orbitals, which orbitals in turn are notoriously poor at penetration. In these cases the inner-well antibonding MO (χ^*) will not be mixed with its conjugate Rydberg levels even if quasi-degenerate with them. In this case, the allowed electric-dipole excitations to the χ^* level must originate at an MO (χ) having a d orbital or g orbital nodal pattern, and will be very intense compared to the Rydberg transitions terminating at the conjugate *nf* Rydberg orbitals for reasons of spatial overlap. Additionally, such $\chi \rightarrow \chi^*(d \rightarrow f)$ molecular giant resonance will not be perturbed on going from the vapor to a condensed phase since the terminating level does not have an expanded wavefunction. We must point out how unusual this situation is, for virtually all discrete absorptions in alkanes have been assigned successfully as Rydberg transitions (1, 4).

Just such a giant resonance can be found in the D_{3h} molecule cyclopropane. The uppermost filled MO of cyclopropane has E' symmetry and a few of the lower $3e' \rightarrow ns$ and $3e' \rightarrow np$ Rydberg excitations have been identified in the 50 000 – 70 000 cm^{-1} region (33), Fig. 6. Following these, there is a broad and very intense feature centered at 82 000 cm^{-1} which has been calculated to be a valence shell $3e' \rightarrow 1a_2'$ excitation. We note here that the oscillator strength of 0.7 observed for this band is unusually high in the extreme for an alkane (the absorption

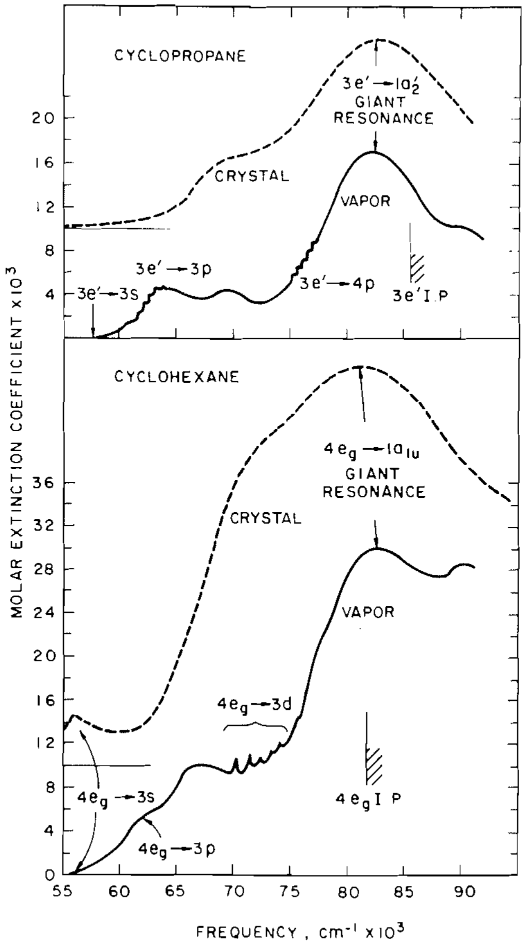

FIG. 6. The assignment of giant molecular resonances in the spectra of cyclopropane and cyclohexane (34).

cross section at the maximum is 68 Mb), and that spectra of thin films of cyclopropane, Fig. 6, show the band in question shifted slightly to 80 000 cm^{-1} but otherwise unperturbed. Finally, the χ^* MO of a_2' symmetry belongs to a representation which is unique to f orbitals in D_{3h}, whereas the $3e'$ MO has the symmetry of an atomic d orbital. Thus we see that the 82 000-cm^{-1} excitation of cyclopropane has the nodal properties of a $d \rightarrow f$ transition, however, since the a_2' terminating orbital is of the inner-well type the transition appears as a molecular giant resonance and is nonRydberg, *i.e.*, valence shell. It is amazing that the molecular analog of the $d \rightarrow f$ giant resonance of lanthanum at *ca.* 100 eV is to be found in cyclopropane at 10 eV! It also may be significant that both are found centered just at or above the ionization thresholds of the originating orbitals.

Arguing backward, the key features leading to a giant resonance in a polyatomic molecule are seen to be:

(*1*) The presence of an antibonding valence-shell orbital in the molecule which transforms like one of the components of the *nf* orbital manifold.

(*2*) Sufficiently high molecular symmetry so that the components of the *ns*, *np*, and *nd* Rydberg manifolds have symmetries different from that of the *f*-like antibonding valence-shell orbital and hence cannot mix with it.

(*3*) An originating valence MO of *d*-like atomic symmetry, thereby resulting in intense $d \rightarrow f$ dipole excitation.

Using the above criteria, we have searched for other $d \rightarrow f$ giant resonances in polyatomic molecules, and feel that others exist in cyclohexane (Fig. 6) and uranium hexafluoride (34).

III.E. Other cases of low-lying σ^* orbitals

We have established the idea that excitations to σ^* levels will lie below the Rydberg manifold and not be mixed with it provided the $\sigma \rightarrow \sigma^*$ split is not too large. This comes about not only when the M—X bond is inherently weak, but also when the molecule is severely strained. Thus a low-lying $\sigma \rightarrow \sigma^*$ excitation of strong valence character is expected in a molecule such as quadricyclane with its very long base bonds. There is no spectral data available as yet on systems such as this.

Yet another mechanism by which σ^* can be made relatively low-lying is by fluorinating a planar unsaturated system. In this case, the perfluoro effect (35) acts to dramatically lower the σ and σ^* manifolds with respect to π and π^*. This relative shift of *ca.* 2 eV between the centers of gravity of the π/π^* and σ/σ^* orbital sets is enough to bring $\pi \rightarrow \sigma^*$ out of the Rydberg woods and into the open. As examples, we note the prominent $\pi \rightarrow \sigma^*$ valence-shell bands in the spectra of the fluoroethylenes and in the fluorobenzenes (1, 36). Note however, that if the system is nonplanar, as in CH_3-containing olefins for example, both the π/π^* and σ/σ^* manifolds are depressed upon fluorination, with little or no depression of the $\pi \rightarrow \sigma^*$ interval.

A rare but well-documented example of a $\sigma \rightarrow \sigma^*$ excitation in a polyatomic molecule is the $3\sigma_g \rightarrow 3\sigma_u^*$ transition of acetylene at 107 500 cm^{-1}. In this case, the transition is just below the conjugate ($3\sigma_g$, *np*) Rydberg levels, and though it must be mixed somewhat with them, it has resisted total dissolution for reasons having to do both with frequency and symmetry. Less well-documented as $\sigma \rightarrow \sigma^*$ excitations are the intense transitions in the longer perfluoroalkanes (4); solid-film spectra of these systems would be most interesting. In π-electron systems, the fate of $\sigma \rightarrow \sigma^*$ excitations is especially cloudy inasmuch as there is strong mixing of (σ,σ^*) configurations with the highly polar (π,π^*) configurations, as discussed by Mulliken (37).

IV. Conclusions

Our overall study of excitations to σ^* lead us to a number of conclusions:

(*i*) Term values are of great use in correlating *A*-band transitions terminating at σ^*, even though these are valence excitations and the concept usually is reserved for Rydberg excitations.

(*ii*) The *A*-band term value is strongly dependent upon the strength of the σ bond appropriate to σ^*.

(*iii*) The *A*-band term values of the outer shell are enhanced in the inner-shell spectra by antishielding, *i.e.*, an enhanced effective nuclear charge for σ^* in the inner-shell spectra.

(*iv*) There is considerable evidence in favor of the simultaneous existence of both valence-shell states terminating at σ^* and their Rydberg conjugates.

(*v*) Contrary to expectations, *A* bands do not always appear in molecular spectra. Their appearance is strongly affected by the extent of valence/Rydberg miscibility, which in turn depends upon how closely the *A* band and Rydberg manifold match in frequency, and upon the ability of the Rydberg levels to overlap the valence level via penetration.

(*vi*) The $\sigma \rightarrow \sigma^*$ valence excitations are rare, but can appear as giant resonances in certain molecules of high symmetry.

(*vii*) Excitations of the sort $\pi \rightarrow \sigma^*$ in planar unsaturated systems are a regular feature in halogen-substituted systems. Heavy fluorination accentuates the prominence of $\pi \rightarrow \sigma^*$ excitations.

The relative energy of the closed and open forms of ozone and thiozone are calculated using the HFS DVM transition state method. For ozone the open form is lower by some 21 kcal/mol and for thiozone the open form is some 11 kcal/mol lower.

WILLIAM G. LAIDLAW et MILAN TRSIC. Can. J. Chem. **63**, 2044 (1985).

Utilisant la méthode de l'état de transition de HFS DVM, on a calculé les énergies relatives des formes ouvertes et fermées de l'ozone et de la thiozone. Les niveaux énergétiques des formes ouvertes de l'ozone et de la thiozone sont respectivement 21 kcal/mol et 11 kcal/mol plus faibles que ceux des formes fermées.

[Traduit par le journal]

Introduction

By the mid 1970's the Hartree Fock Slater (HFS) method had been applied, with considerable success, to the calculation of ionization energies, electron excitation energies, and other one-electron properties (1). In 1978 we explored the use of the HFS "total statistical energy" as a measure of the expectation value of the hamiltonian by calculating the single determinant statistical energy for various conformations of ozone and thiozone (2). We utilized a STO double ζ basis set (3) augmented with a $3d$ orbital on sulfur (exponent 1.71 (2)) and employed several calculational techniques such as diophantine numerical integration and a fitting procedure for the electron density which had been pioneered by Ziegler, Baerends, and co-workers (1*a*–*d*). We refer to this algorithm as the HFS DVM scheme and utilize an exchange coupling of $\alpha = 0.7$. The energy contributions which appeared sensitive to the numerical integration steps were calculated analytically following a method of Baerends and Ros (4). Our results indicated that the closed form (all three nuclei equidistant from one another) of both ozone and thiozone were lower in energy than the open form by some 40 kcal/mol. This result for ozone was certainly at variance with its known conformation (5). However, our results were comparable to rather good quality HF single determinant calculations which also predicted the closed form for these molecules (6). We concluded that the HFS statistical energy was at least as good a predictor as the Hartree Fock energy.

In the past half dozen years the evaluation of the energy in the Hartree Fock Slater context has received additional attention. The transition state method of Ziegler and co-workers (7) has shown great promise, especially for larger systems (8). Most recently the calculations of Morin, Foti, and Salahub (9) for the statistical energy of ozone and thiozone, using their HFS (LCAO-Xα and LCAO-Local Density (10)) procedures; renewed our interest in the problem. Consequently we have investigated the conformational energy of ozone and thiozone using, now, the transition state method (7).

The transition state method

The essence of the transition state method for bond energy is the *direct* calculation of the difference in energy of the molecule and the chosen reference fragments (usually atoms). In other words, one does *not* calculate separately the energy of molecule and the energy of its reference and then subtract the two. Rather one derives an expression for the energy difference and calculates this directly. The critical step in this procedure, for a molecule AB, is the introduction of the atomic (i.e. fragment) densities ρ_A and ρ_B, the molecular density $\rho_{\overline{AB}}$ and a transition state density

$$\rho_T = \frac{1}{2}(\rho_A + \rho_B + \rho_{\overline{AB}})$$

Since the statistical energy (the HFS representation of the expectation value of the hamiltonian H) is a functional of the density, the energy difference, $\Delta E = E_{AB} - (E_A + E_B)$, is a direct function of ρ_A, ρ_B, and $\rho_{\overline{AB}}$. Ziegler and Rauk (7) have shown that

$$[1] \quad \Delta E = -E_{cl} - \Delta E_{cx} - \sum_{ij} F_{ij}\Delta P_{ij}$$

where E_{cl} is the classical electronic energy of two distributions ρ_A and ρ_B and their associated nuclear repulsions, ΔE_{cx} is the difference between the HFS exchange interaction of $\rho_{\overline{AB}}$ and that of ρ_A and ρ_B and F_{ij} is a Taylor expansion around the transition state of matrix elements of the one-electron HFS hamiltonian operator h. The result given in eq. [1] is correct to third order in a Taylor expansion around the transition state density ρ_T.

Results

Using the same basis set and the same frozen core approximation as in our earlier work we calculated the bond energy ΔE of eq. [1] directly for both thiozone and ozone. Two electronic configurations $a_1^8a_2^2b_1^6b_2^2$ and $a_1^8a_2^2b_1^4b_2^4$ were considered and both the bond lengths and the bond angles were varied within C_{2v} symmetry to obtain the minimum bond energy ΔE (note, ΔE is negative). The result obtained for ozone showed that the minimum ΔE for the open form,

$$a_1^8a_2^2b_1^6b_2^2 \equiv 1a_1^2\ 1b_2^2\ 2a_1^2\ 2b_2^2\ 1b_1^2\ 3a_1^2\ 1a_2^2\ 3b_2^2\ 4a_1^2 \quad \text{(i.e., } 4\pi)$$

is obtained at a central angle of 120° and bond length 1.30 Å whereas the minimum ΔE for the closed form

$$a_1^8a_1^2b_1^4b_2^4 \equiv 1a_1^2(2a_1^2\ 1b_2^2)3a_1^2\ 1b_1^2(2b_2^2\ 4a_1^2)\ (1a_2^2\ 2b_1^2)(\text{i.e. } 6\pi)$$

was obtained for an equilateral form with a bond length of 1.45 Å. The open form is the lower by some 21 kcal/mol. The recent calculation by Morin *et al.* (9) using their versions of the HFS procedure favours the open form of ozone by some 45 kcal/mol whereas rather sophisticated CI treatments give the open form as lower by some 21 ± 5 kcal/mol (11*a*) or 28 kcal/mol (11*b*) or 38 kcal/mol (11*c*). The bond length 1.30 Å and bond angle 120° for the open form of ozone are to be compared to the experimental values in the range 1.28 Å for the bond lengths and 117° for the central angle (5). For thiozone a similar calculation for the minimum ΔE yields an open form,

$$a_1^8a_2^2b_1^6b_2^2 \equiv 1a_1^2\ 1b_2^2\ 2a_1^2\ 2b_2^2\ 1b_1^2\ 3a_1^2\ 1a_2^2\ 3b_2^2\ 4a_1^2$$

with a bond length of 1.95 Å and central angle of 120° whereas the closed form

$$a_1^8a_2^2b_1^4b_2^4 \equiv 1a_1^2(2a_1^2\ 1b_2^2)3a_1^2\ 1b_1^2(4a_1^2\ 2b_2^2)\ (2b_1^2\ 1a_2^2)$$

minimum has the equilateral form with a bond length of 2.06 Å. The open form of thiozone is lower than the closed form by some 11 kcal/mol which may be compared with 15 kcal/mol obtained by Morin *et al.* (9) and with the 17 kcal/mol results given in recent CI calculations (11*c*).

These results are in contrast to that reported in our earlier calculation (2) and are in contrast to the HF single determinant results, cf. ref. 6. However, they show the same preference for the open form given recently by Morin *et al.* (9) using their version of the HFS approach and of course are consistent with the known form for ozone (5) and with CI calculations for ozone (11*a*, 11*b*) and for thiozone (11*c*).

Discussion

The HFS SCF DVM scheme represents the molecular orbitals as an expansion in a chosen basis set (e.g. the Double ζ STOs) and develops the variational SCF problem in terms of the chosen basis set. However, for the sake of efficiency (a major consideration in the large molecules to which this procedure has been applied (8)) the density is always fitted by a least-squares procedure to a set of "fit functions". Further, the integrations required in the HFS SCF procedure are obtained numerically (diophantine point selection). We referred to this routine as the HFS DVM procedure.

It is relatively straightforward to increase the number of points in a numerical integration until stability is ensured and typically 1000 points per atom is sufficient for stability of one-electron properties. The generation of the best fit functions, although less direct, can be accomplished by using a family of STO *s, p,d*, etc. orbitals on each center with exponents chosen to span the space from diffuse to contracted. Again the precise choice does not materially affect one-electron properties. However, the numerical integration and fitting procedure do have serious implications for the calculation of the total energy of the system.

In 1978, Baerends and Ros (4) pointed out that the sensitivity to the number of points in the numerical integration can be overcome by evaluating all terms in the SCF energy except the exchange contribution by analytical rather than numerical integration. That is, the SCF electron density is fitted using the fit functions and inserted into the integrals contributing to the energy and these terms are then evaluated analytically. This reduces the sensitivity such that again about 1000 points per atom is sufficient for stability of the numerical integration. The sensitivity of the total statistical energy to the choice of fit functions can not so easily be removed since there is no straight forward criteria which can be applied, *a priori*, for all molecules. Consequently calculations of the total statistical energy by both Baerends and Ros (4) and by ourselves (2) were limited and all that appeared possible was that the results for total statistical energy using the HFS DVM algorithm were at least comparable to the Hartree Fock results.

However, the picture is much more positive using the transition state approach with the HFS DVM. We have already observed that certain terms in the total energy viz., the exchange term, ΔE_{ex}, were relatively insensitive to the numerical integration and fitting procedures. So also Ziegler and Rauk (7) found that the additional terms which are generated by the Taylor expansion in ΔE, i.e. the terms F_{ij}, in eq. [1], are relatively insensitive to the number of points in the numerical integration (in all cases tested 1000 points per atom achieved an accuracy to within 2 kcal per mol).[1]

The sensitivity to fit functions arises primarily through the term E_{el}. In the case of the transition state method, with atoms as fragments, E_{el} requires only atomic distributions. It is always easy to obtain optimum fit functions for atomic distributions (for the fit functions are generated automatically within the suite of programs and they are always *s*-type as befits a spherical distribution). The additional requirements that the molecular situation places on fit functions are not nearly as severe with the transition state calculation of ΔE as they were for the total statistical energy E. Nevertheless, we have augmented the standard fit set referred to above with fit functions including sets of *p* and *d* orbitals on each centre to generate an "extended molecular fit set". We have added yet more fit functions to our extended fit set and found no change in ΔE and we have *deleted* fit functions (e.g., *d*) and found some change (e.g., for thiozone deletion of *d* fit functions changed ΔE from −256 to −258 kcal/mol for the open form and from ΔE = −247 to −257 kcal/mol for the closed form for a change of about 4% in ΔE for the highly strained closed form where clearly the added flexibility of the expended fit set is necessary). We concluded that an extended set of fit functions are still essential and that our extended molecular fit set was approaching an optimal choice for thiozone.

This leaves choice of basis functions and the truncation procedure itself. Certainly the basis must be chosen with some care and perhaps the best criteria is comparison of experimental and calculated results. For diatomics the comparison of even just a DZ HFS basis vs. extended basis HF calculations as against experimental results is in favour of the HFS procedure and of course an extended basis HFS is normally an improvement (see Table 2 of ref. 7 for calculation results with DZ, and extended basis and comparison to HF and experimental results). In the calculations reported here the basis set is of DZ quality augmented by *d* functions.

Turning to the truncation procedure itself, perhaps the most telling point of the efficacy of the transition state method is

[1] See Table 1 of ref. 7 for calculations using 10^3, 10^4, 10^5 points for F_2. These results show that the term E_{el} is responsible for slow convergence and that the remaining terms in eq. [1] stabilize with, of the order of, 10^3 points. Our own tests, on thiozone with 1000, 2000, and 4000 points per atom gave values of ΔE of −247, −246, and −247 kcal/mol at R_{SS} = 2.1 Å for the closed form and −256, −255, and −256 kcal/mol at R_{SS} = 2.0 Å for the open form. This is a variation of ΔE of less than 2 kcal/mol.

comparison to experimental results for a variety of molecules. Rauk and Ziegler have shown in a number of cases, that the transition state method provides accurate representations of the bond energy when complete schemes, such as the HF, do not give the correct answer (see Table 2 of ref. 7 and also ref. 8). Indeed our calculation, giving the open form of ozone lower than the closed form by some 21 kcal/mol, compares favourably with the results of an extended CI calculation (11*a*). Consequently the truncation scheme appears to be satisfactory.

With these comments on numerical integration, fit functions, basis sets and truncation, in mind, we believe that eq. [1] is an appropriate representation of the bond energy, ΔE, in the HFS DVM scheme. That it is an adequate HFS probe of conformational energy is demonstrated by noting that it predicts that the open form is lower in energy than the closed for both thiozone and ozone — a result qualitatively similar to that of Salahub and co-workers (9) using their version of the HFS procedure.

Acknowledgements

The authors are pleased to acknowledge valuable conversations with Tom Ziegler and the use of programs developed by him and by the Amsterdam group of E. Baerends. We would also like to thank Dennis Salahub for stimulating us to repeat our work on S_3/O_3 and for his willingness to discuss, openly, his results prior to publication. Kim Wagstaff assisted with the calculations.

Raman investigations of collective vibrational motions in van der Waals liquids[1]

S. BRATOS AND G. TARJUS

Laboratoire de Physique Théorique des Liquides,[2] Université Pierre et Marie Curie, Paris, France

Received December 11, 1984

This paper is dedicated to Professor Camille Sandorfy on the occasion of his 65th birthday

S. BRATOS and G. TARJUS. Can. J. Chem. **63**, 2047 (1985).

Recent investigations of collective vibrational motions in pure van der Waals liquids and in their isotopic mixtures are reviewed. Experimental data are enumerated first. The theory is presented later, separately, for non-composite and composite bands of both isotropic and anisotropic Raman spectra. It is shown that isotropic Raman processes are partially coherent and contain information about collective vibrational motions in liquids. In turn, anisotropic Raman processes are incoherent in the zero-order description and their study is less important in the present context.

S. BRATOS et G. TARJUS. Can. J. Chem. **63**, 2047 (1985).

Les études récentes des mouvements vibrationnels collectifs dans des liquides de van der Waals purs et dans leurs mélanges isotopiques sont examinées. Les données expérimentales sont décrites d'abord. La théorie est présentée ensuite, séparément pour les bandes Raman composées et pour les bandes Raman non-composées, tant isotropes qu'anisotropes. On montre que les processus Raman isotropes sont partiellement cohérents et qu'ils contiennent des informations relatives aux mouvements vibrationnels collectifs dans les liquides. Par contre, les processus Raman anisotropes sont incohérents, dans la description d'ordre zéro au moins, et leur étude est moins importante dans le présent contexte.

[Traduit par le journal]

1. Introduction

Considerable interest has been manifested over the last decade in studying collective vibrational and rotational motions in liquids by Raman spectroscopy. The possibilities offered by this technique were not immediately recognized. In fact, the phases of molecular vibrations in dense fluids were considered in the early work to be randomly distributed, an assumption called the random phase assumption. A Raman process was thus believed to be intrinsically incoherent, incapable of giving any information about collective motions in liquids. However, recent investigations have shown that these processes may, in fact, be partially coherent. Raman spectroscopy was thus adopted, over the last few years, by scientists studying this problem. The purpose of the present paper is to review this subject, currently in rapid evolution. It will be shown that, although considerable progress has been made, the field still is far from maturity. For general reviews on vibrational spectroscopy of dense fluids see, e.g., refs. 1 and 2.

2. Experimental data

It is convenient to start this discussion by briefly presenting the basic experimental material submitted to a theoretical analysis in later sections. In the early work, collective vibrational effects were studied by diluting the liquid progressively in the usual "chemical" solvents (3–10). Unfortunately, diluting a liquid modifies the force law and the answer is rarely nonambiguous. All modern work thus employs the isotopic dilution technique, which is free of this complication (11–19). Progress has been accelerated by the existence of theories which influenced the proper choice of experiment. The main experimental data collected in this way are described below. They refer to pure liquids and to their isotopic solutions, if not stated otherwise.

The main characteristics of isotropic spectra are enumerated first. (*i*) Their bands are broader in pure liquids than in dilute solutions. This was shown quantitatively by Oehme and Klostermann (20) for the ν HBr and ν DBr bands in mixtures HBr/DBr and by Pinan-Lucarré (21) for the ν_2 band of CD_3I in mixtures CD_3I/CH_3I; see also ref. 22. (*ii*) The position of an isotropic Raman band is a linear function of concentration of the active species, whereas its half-width may exhibit a nonlinear concentration dependence. First discovered in "chemical" solvents by Bondarev and Mardaeva (23), Fujiyama *et al.* (24), Arndt and co-workers (25–27), Yarwood, Ackroyd *et al.* (28), and Scheibe (29), it was also reported by Kamoun and Mirone (30), Döge *et al.* (31), and Oehme and Klostermann (20) in the case of isotopic solutions. (*iii*) The half-width of an isotropic Raman band varies with temperature, but no simple rule seems to exist. The constant pressure and variable temperature experiment by Döge *et al.* (32) on the ν_1, ν_2, and ν_3 bands of liquids CH_3I showed that some bands narrow with increasing temperature, whereas some others broaden.

As far as the anisotropic spectra are concerned, they show a noticeably different behavior. (*i*) Little broadening of these bands takes place when going from dilute solutions to pure liquids. This observation due to Pinan-Luccaré and to Oehme and Klostermann was described in the papers cited earlier. (*ii*) The peak frequency of an anisotropic Raman band is much less concentration dependent than the peak frequency of the corresponding isotropic Raman band (20). (*iii*) The isotropic and anisotropic Raman bands do not coincide; this effect is called the "non-coincidence effect". First observed in pure liquids by Schwartz and Wang (33), it was studied in liquids and binary mixtures by Fini and Mirone (34), Perchard and Perchard (35), Korsunskii *et al.* (36), Mirone and Fini (37), and by Desbat and Huong (38); to our knowledge, it has not yet been examined in isotopic mixtures. The result from these data is that resonant interactions in pure liquids and isotopic mixtures affect differently the isotropic and anisotropic Raman spectra. For some reason, their action is quenched to a considerable extent in the latter case. One of the tasks with which the theory is confronted is to explain this difference.

[1]This paper was presented to the EMLG conference "Beyond the Monomolecular Approach" which took place in Nice, from September 3 to 8, 1984.

3. Theory. Non-composite Raman bands of pure liquids

(a) *Generalities*

Although the essential role of the resonant intermolecular coupling was correctly understood as early as 1960 (39), the theory of Raman bands of pure van der Waals liquids really started only thirteen years later. The first contribution was due to Döge, who proposed a crude picture of vibrational exciton transfer effects in Raman spectra (40). Later, Lynden-Bell showed how these effects are influenced by the symmetry of molecular vibrations (41). Analytical theories of band shapes appeared in 1977–1978, proposed nearly simultaneously by Wang (42), Wertheimer (43), and Oxtoby (1). They all concern the case of rapidly modulated isotropic Raman bands. Computer simulation techniques were introduced in this field in 1978 by Oxtoby *et al.* (44). Finally, the theory was extended in 1981 by Bratos and Tarjus (45); it applies to isotropic Raman spectra of arbitrary modulation speed and to anisotropic Raman spectra. These theories will be discussed in the present paper by taking the Bratos–Tarjus theory as a basis of discussion. In fact, this theory is general enough to encompass all previous work.

(b) *Method of calculation*

(1) The theory to be presented concerns a diatomic molecular liquid, the simplest prototype of molecular liquids. This choice is imposed by the need to eliminate, in a first analysis, such complicating features as harmonic and anharmonic coupling between various molecular vibrators, existence of different energy relaxation mechanisms, etc. A proper account of these effects seems beyond the scope of the majority of cases.

If an electromagnetic wave of frequency ω_0 is scattered from such a system, the isotropic and the anisotropic Raman differential cross-sections may be written

$$[1a]\quad \left[\frac{\partial^2\sigma}{\partial\omega\partial\Omega}\right]_{\text{iso}} = \frac{1}{2\pi} K_s^4 \int_{-\infty}^{+\infty} \mathrm{d}t\, e^{-i\omega t} \sum_{i,j} \langle a_{0i}^{(0)}(0)\, a_{0j}^{(0)}(t)\rangle$$

$$[1b]\quad \left[\frac{\partial^2\sigma}{\partial\omega\partial\Omega}\right]_{\text{ani}} = \frac{1}{2\pi} K_s^4 \int_{-\infty}^{+\infty} \mathrm{d}t\, e^{-i\omega t} \sum_{i,j} \langle a_{0i}^{(2)}(0)\, a_{0j}^{(2)}(t)\rangle$$

In these formulas, $a_{0i}^{(0)}$, $a_{0j}^{(0)}$, $a_{0i}^{(2)}$, $a_{0j}^{(2)}$ represent spherical components of the Raman polarizability tensors of various molecules. Moreover, ω is the difference between the frequencies of the scattered and incident light. Equations [1*a*, *b*] represent the basis of the subsequent discussion.

(2) The following model is used in this section. (*i*) The molecules are executing anharmonic vibrations described by internal vibrational coordinates $r = (r_1, r_2, \ldots, r_N)$. They are perturbed by a stochastic potential $V(r,t)$ expressing molecular interactions. The corresponding semi-classical Hamiltonian can be written:

$$[2]\quad H(r,t) = \left[\frac{1}{2}\sum_{i=1}^{N} p_i^2 + \frac{1}{2}\sum_{i=1}^{N} K r_i^2 + \frac{1}{6}\sum_{i=1}^{N} f r_i^3 + \ldots\right] + \left[\sum_{i=1}^{N} V_i(t) r_i + \frac{1}{2}\sum_{i,j=1}^{N} V_{ij}(t) r_i r_j + \frac{1}{6}\sum_{i,j,k=1}^{N} V_{ijk}(t) r_i r_j r_k + \ldots\right]$$

$V_i(t)$, $V_{ii}(t)$, $V_{iii}(t)$, etc. give rise to environmental fluctuations of vibrational frequency whereas $V_{ij}(t)$, $V_{ijk}(t)$, etc. describe the resonant intermolecular coupling. (*ii*) The molecules of the liquid are executing stochastic reorientations and translations. (*iii*) The correlation between vibrations and rotations, although present, is weak. (*iv*) There is no collision-induced scattering.

The validity of these assumptions merits discussion. The assumptions (*i*) and (*ii*) are of general use in the spectroscopy of liquids and are justified in the majority of cases of practical interest. The assumption (*iii*) is much more questionable. It was studied by Levesque *et al.* who employed molecular dynamics techniques (46) and by Tarjus and Bratos who used analytical methods (47). These investigations showed that the simple product approximation is surprisingly accurate and that the use of assumption (*iii*) is legitimate. Unfortunately, no definite statement can be made about assumption (*iv*). The error introduced by treating collision-induced processes separately is totally unknown.

(3) The central part of the present problem is to calculate the vibrations of a set of N-coupled vibrators evolving in a spatially and temporally disordered medium. Its counterpart in the ordered crystalline phase has been carefully examined by Born and Huang, Davidov, and many others. The basic equations are the Heisenberg equations of motion for the variables r_i. Then, (*i*) choosing a basic set composed of non-excited and mono-excited anharmonic vibrator wave functions, (*ii*) defining a frequency matrix where $\hbar\,\Omega_{st} = \langle s|V|t\rangle - \delta_{st}\langle 0|V|0\rangle$, (*iii*) suppressing in the Hamiltonian matrix all elements which connect vibrational states of different degree of excitation, and (*iv*) considering the basic equations [1*a*, *b*] of the theory, there results:

$$[3a]\quad G^{(0)}(t) = \sum_{ij} \langle a_{0i}^{(0)}(0)\, a_{0j}^{(0)}(t)\rangle = \frac{N\hbar}{2\mu\omega_0}\left(\frac{\partial\alpha}{\partial r}\right)_0^2 e^{i\omega_0 t} \sum_{ij} \left\langle \exp_0\left[i\int_0^t \mathrm{d}t_1\, \Omega(t_1)\right]\right\rangle_{ij}$$

$$\begin{aligned}[3b]\quad G^{(2)}(t) &= \sum_{ij} \langle a_{0i}^{(2)}(0)\, a_{0j}^{(2)}(t)\rangle \\ &= \frac{2}{15}\frac{N\hbar}{2\mu\omega_0}\left(\frac{\partial\beta}{\partial r}\right)_0^2 e^{i\omega_0 t} \sum_{ij}\Bigg[\langle D_{00}^{(2)}(\theta_i(0))\, D_{00}^{(2)}(\theta_j(t))\rangle \left\langle \exp_0\left[i\int_0^t \mathrm{d}t_1\, \Omega(t_1)\right]\right\rangle_{ij} \\ &\quad + i\int_0^t \mathrm{d}\tau \sum_{ijk} \langle\langle D_{00}^{(2)}(\theta_i(0))\, D_{00}^{(2)}(\theta_j(t))\rangle\, (\Omega_{jk}(\tau) - \langle\Omega_{jk}\rangle)\rangle \left\langle \exp_0\left[i\int_0^t \mathrm{d}t_1\, \Omega(t_1)\right]\right\rangle_{ki} + \ldots\Bigg] \\ &= G^{(20)}(t) + G^{(21)}(t) + \ldots\end{aligned}$$

In these equations $D_{st}^{(2)}(\theta)$ are elements of the Wigner rotation matrix $D^{(2)}(\theta)$, α is the mean Raman polarizability and β the Raman anisotropy of a diatomic molecule, whereas all other terms have their usual meaning. One notices that $G^{(2)}(t)$, contrary to $G^{(0)}(t)$, appears in the form of a series. Its leading term is the well-known product of rotational and vibrational functions, whereas the remaining terms provide a higher-order description of the rotation–vibration correlation effects. The assumption (*iii*) reduces the expansion of $G^{(2)}(t)$ to $G^{(20)}(t)$ and the subsequent theory is a zero-order theory. It should be emphasized, however, that the terms which couple rotations and vibrations are still present in the Hamiltonian and affect even this zero-order theory.

(4) The expressions [3*a*, *b*] contain ordered exponentials, objects which are difficult to handle. However, a considerable simplification is obtained by using symmetry arguments. In fact, a sample of pure liquid transforms into itself if two, three, or several molecules are permuted. The exact Hamiltonian of such a system is thus invariant under the operations of the full N-symmetric group; this is also true, mutatis mutandis, for the approximate Hamiltonian of eq. [2]. It then turns out that all ensemble-average matrices which enter into the calculation commute. They can always be diagonalized, whatever their order. The presence of this symmetry thus makes calculations practicable.

The theoretical method to be employed depends on the strength of molecular interactions. If they are weak, as for example in van der Waals liquids, the following procedure may be adopted. Vibrational correlation functions contained in eqs. [3*a*, *b*] are calculated by applying the cumulant expansion techniques (48, 49). Their use is particularly simple in the present case where all matrices commute after averaging. Thus generalized cumulants may be replaced by ordered cumulants and ordered exponentials by ordinary exponentials. In turn, rotational correlation functions involved in eq. [3*b*] are determined by supposing that the composite variable $A = (D^{(2)}_{00}(\theta_1), D^{(2)}_{00}(\theta_2), \ldots, D^{(2)}_{00}(\theta_N))$ obeys a simple Langevin equation with a constant $N \times N$ friction matrix. The following results are then found, valid for all modulation speeds:

$$[4a] \quad G^{(0)}(t) = \frac{N\hbar}{2\mu\omega_0}\left(\frac{\partial\alpha}{\partial r}\right)_0^2 e^{i\omega_0 t}\, e^{\lambda_1(t)}$$

$$[4b] \quad G^{(0)}_{\mathrm{S}}(t) = \frac{N\hbar}{2\mu\omega_0}\left(\frac{\partial\alpha}{\partial r}\right)_0^2 e^{i\omega_0 t}\, e^{\lambda_2(t)}$$

$$[4c] \quad G^{(0)}_{\mathrm{D}}(t) = \frac{N\hbar}{2\mu\omega_0}\left(\frac{\partial\alpha}{\partial r}\right)_0^2 e^{i\omega_0 t}\,(e^{\lambda_1(t)} - e^{\lambda_2(t)})$$

$$[4d] \quad G^{(20)}(t) = G^{(20)}_{\mathrm{S}}(t) = \frac{2}{15}\frac{N\hbar}{2\mu\omega_0}\left(\frac{\partial\beta}{\partial r}\right)_0^2 e^{i\omega_0 t}\, e^{\lambda_2(t) - \rho_2 t}$$

$$[4e] \quad G^{(20)}_{\mathrm{D}}(t) = 0$$

$$[4f] \quad \lambda_1(t) = i\int_0^t dt'\,[\langle\Omega_{11}(t')\rangle + N\langle\Omega_{12}(t')\rangle] + i^2\int_0^t dt'\int_0^{t'} dt''\,\{\langle\Delta\Omega_{11}(t')\Delta\Omega_{11}(t'')\rangle$$
$$+ N[\langle\Delta\Omega_{11}(t')\Delta\Omega_{12}(t'')\rangle + \langle\Delta\Omega_{12}(t')\Delta\Omega_{11}(t'')\rangle + \langle\Delta\Omega_{12}(t')\Delta\Omega_{12}(t'')\rangle] + N^2\langle\Delta\Omega_{12}(t')\Delta\Omega_{13}(t'')\rangle\} + \ldots$$

$$[4g] \quad \lambda_2(t) = i\int_0^t dt'\,\langle\Omega_{11}(t')\rangle + i^2\int_0^t dt'\int_0^{t'} dt''\,\{\langle\Delta\Omega_{11}(t')\Delta\Omega_{11}(t'')\rangle + N\langle\Delta\Omega_{12}(t')\Delta\Omega_{12}(t'')\rangle\} + \ldots$$

In these equations the subscripts S, D indicate the self- and distinct pair components, respectively, of $G^{(0)}(t)$, $G^{(20)}(t)$, $\Delta\Omega_{ij} = \Omega_{ij} - \langle\Omega_{ij}\rangle$, and ρ_2 is the $(N-1)$-fold degenerate root of the friction matrix. $\lambda_1(t)$ then represents the cumulant series describing collective vibrations in liquids and $\lambda_2(t)$ is its self-vibration analogue. All these equations are valid in the thermodynamic limit $N \to \infty$, $V \to \infty$, $N/V = \rho$, where ρ is a finite quantity.

If molecular interactions are strong enough, as for example in hydrogen bonded liquids, the convergence of the cumulant series is slow and may even become doubtful. Equations [4*a*–*g*] then break down and entirely different methods must be invented in order to carry out the averaging of ordered exponentials in eqs. [3*a*, *b*]. This problem, particularly acute in the presence of molecular associations, is currently under active investigation.[3]

(c) *Results and discussion*
