(1) Spectral properties of isotropic Raman spectra may be described either by the correlation function $G^{(0)}(t)$ or by its Fourier transform; compare with eqs. [4*a*], [4*b*], [4*c*], [4*f*], [4*g*]. The following conclusions, valid for a diatomic molecular liquid, may be reached theoretically. (*i*) The isotropic Raman process is a partially coherent process. This can be seen by noticing that, in eq. [4*c*], the distinct pair correlation function, $G^{(0)}_{\mathrm{D}}(t)$, is generally non-vanishing. This result is prior to the Bratos–Tarjus theory. Implicit in papers by Valiev (39), Tokuhiro and Rothschild (15), Rothschild (51), and Döge (40, 52), the coherence effect was treated explicitly in papers by Vincent-Geisse (53), Lynden-Bell (41, 54), Wang (42), Wertheimer (43, 55), and Oxtoby (1); see also the coherent exciton scattering approach due to Knapp (56). Its existence was confirmed by computer simulation studies due to Oxtoby and coworkers (44, 46). (*ii*) Distinct pair correlation functions give no contribution to the integrated intensity of an isotropic Raman band. This statement, due to Wang (42), can be proven by considering eq. [4*c*] and by noticing that the integrated intensity is proportional to $G^{(0)}(0)$. (*iii*) The temperature variation of an isotropic Raman band depends on that of $\lambda_1(t)$. More specifically, according to Wang, its half-width decreases with increasing temperature if the modulation is fast (42). All these predictions are in excellent agreement with experimental data enumerated in Section 2.

(2) Anisotropic Raman band profiles are described by eqs. [4*d*], [4*e*], [4*f*], and [4*g*]. The theory leads to the following conclusions. (*i*) In the zero-order approximation, an anisotropic Raman process is completely incoherent. This can be shown by noticing that the distinct pair correlation function, $G^{(20)}_{\mathrm{D}}(t)$, vanishes in this approximation. However, a small amount of coherence is reintroduced in higher order approximations (57). (*ii*) Only minor changes of the band shape are expected when going from a dilute isotopic solution to a pure liquid. In fact, not only does the distinct pair correlation function vanish, but also the self-contribution is virtually unaffected by dilution. This latter statement can be proven by assuming

[3] D. E. Logan, private communication.

the potential energy V of the system to be pair additive, $V = \sum_{i<j} v_{ij}$. Then

$$[5a] \quad \Omega_{ii} = \sum_{j \neq i} \omega_{ij}^{\mathrm{EF}} = \sum_{j \neq i} \frac{1}{2\mu\omega_0}\left[-\frac{f}{K}\left(\frac{\partial v_{ij}}{\partial r_i}\right)_0 + \left(\frac{\partial^2 v_{ij}}{\partial r_i^2}\right)_0\right]$$

$$[5b] \quad \Omega_{ij} = \omega_{ij}^{\mathrm{RT}} = \frac{1}{2\mu\omega_0}\left(\frac{\partial^2 v_{ij}}{\partial r_i \partial r_j}\right)_0$$

$$[6a] \quad \langle\Delta\Omega_{11}(t')\,\Delta\Omega_{11}(t'')\rangle = N\langle\Delta\omega_{12}^{\mathrm{EF}}(t')\,\Delta\omega_{12}^{\mathrm{EF}}(t'')\rangle + N^2\langle\Delta\omega_{12}^{\mathrm{EF}}(t')\,\Delta\omega_{13}^{\mathrm{EF}}(t'')\rangle$$

$$[6b] \quad N\langle\Delta\Omega_{12}(t')\,\Delta\Omega_{12}(t'')\rangle = N\langle\Delta\omega_{12}^{\mathrm{RT}}(t')\,\Delta\omega_{12}^{\mathrm{RT}}(t'')\rangle$$

where $\omega_{ij}^{\mathrm{EF}}$ describe the effect of environmental fluctuations of the transition frequency, whereas $\omega_{ij}^{\mathrm{RT}}$ take account of the resonant transfer of the vibrational energy. As for all diatomics, the anharmonicity of the diatomic vibrator makes $\omega_{ij}^{\mathrm{EF}}$s about an order of magnitude larger than $\omega_{ij}^{\mathrm{RT}}$s and, in addition, $\langle\Delta\Omega_{12}(t')\,\Delta\Omega_{12}(t'')\rangle$ is quadratic in $\omega_{ij}^{\mathrm{RT}}$s, the object [6*b*] is quite small as compared with the object [6*a*], which proves the statement (57). (*iii*) The isotropic and anisotropic Raman bands of liquids do not coincide. In the lowest order description, their first moments differ by $N\langle\Omega_{12}\rangle$. The exact expressions for those, and the second, spectral moments are available as well and are due to Wang and McHale (58) and McHale (59). (*iv*) The difference in the action of resonant coupling mechanisms in isotropic and anisotropic Raman spectra has its ultimate origin in the permutational symmetry of the liquid sample. For preliminary work on this problem, see the papers by Döge (40, 52) and Lynden-Bell (41). All these theoretical predictions are in an excellent agreement with the experimental data of Section 2. It is even astonishing that the zero-order theory can do so much.

(3) This section may be concluded by examining the possibility of an experimental determination of self- and distinct pair correlation functions. Two different procedures may be envisaged in the frame of the present theory. (*i*) In the first procedure the isotropic Raman spectrum is recorded for a pure liquid; its Fourier transform gives $G^{(0)}(t)$. Next, the isotropic and anisotropic Raman spectra of a dilute isotopic solution are measured. Applying standard VV–VH separation techniques and Fourier transforming the result gives the vibrational and rotational correlation functions of the active molecule in solution. The latter is equal to that of the pure liquid if rotational motions are not altered by the isotopic substitution. Finally, the anisotropic Raman spectrum of a pure liquid is experimentally determined and is Fourier transformed. Dividing by the rotational correlation function of the solution then gives $G_{\mathrm{S}}^{(0)}(t)$. (*ii*) In the second method, the isotropic Raman spectrum is recorded for a pure liquid and for a dilute isotopic solution. Then the Fourier inverted solution spectrum gives $G_{\mathrm{S}}^{(0)}(t)$ whereas the Fourier inverted liquid–solution difference spectrum gives $G_{\mathrm{D}}^{(0)}(t)$. The second procedure is much simpler, but relies on the identification of the vibrational correlation function of the dissolved molecule with the vibrational self-correlation function of the pure liquid. No assumption of this sort is required in the first procedure. At the present time, the practical use of either of these methods is handicapped by difficulties encountered in measuring weak Raman spectra of dilute solutions.

4. Theory. Non-composite Raman bands of isotopic mixtures

(a) *Generalities*

The study of this problem was initiated in 1973 by Bondarev and Mardaeva (23) and, later, by Fujiyama *et al.* (24) who proposed a simple model in which spectral effects in binary mixtures were interpreted in terms of concentration fluctuation of particles on a fictitious space lattice. More recently, in 1978, Knauss (60) and Wertheimer (61) examined the same problem in the framework of the Zwanzig–Mori theory of Brownian motion. Limited to the fast modulation regime, these theories emphasize the role of structure breaking in the usual solvents and its absence in isotopic solvents. Finally, in 1982, Knapp and Fischer (62) elaborated a kinetic model which accounts for both static and dynamic properties of the system and for concentration fluctuations around the reference molecule. All this work led to a partial analysis of Raman processes in binary mixtures. For reasons explained earlier in this paper, the subsequent discussion remains limited, basically, to the isotopic mixtures, and the usual "chemical" mixtures will be only briefly mentioned. Here again, the description is based on the Bratos–Tarjus theory (63) which encompasses, and generalizes, the results reached by previous authors.

(b) *Method of calculation*

The system under consideration contains N_{A} and N_{B} diatomic molecules of isotopic species A and B, respectively, $N_{\mathrm{A}} + N_{\mathrm{B}} = N$. Moreover, this mixture is such that there is no overlap of Raman bands of these isotopic species. This choice permits us to eliminate all complications due to the intra- or intermolecular energy relaxation, the anharmonic coupling of normal modes, etc. Equations [1*a*, *b*] still remain basic equations of the theory, as do the assumptions of the model described in Section 3b(2). However, they apply now to that one of the two isotopic species which is submitted to spectral examination. The potential energy $V(r, t)$ of an isotopic mixture is the same as that of a pure liquid; this is a consequence of the well-known Born–Oppenheimer theorem. Finally, the only difference is that the frequency matrix $\Omega(t)$ has the dimension $N_{\mathrm{A}} \times N_{\mathrm{A}}$ rather than $N \times N$, supposing the species A has been chosen for spectral investigation. The elements of this frequency matrix, both diagonal and non-diagonal, coincide with the corresponding elements of the frequency matrix of the pure liquid. Equations [4*a*–*h*] can then readily be modified to apply to isotopic mixtures. It is sufficient to replace N by $N_{\mathrm{A}} = c_{\mathrm{A}}N$, where c_{A} is the number density of the isotopic species A. The following results are easily obtainable in this way:

$$[7a] \quad G^{(0)}(c_{\mathrm{A}}, t) = c_{\mathrm{A}} \frac{N\hbar}{2\mu\omega_0}\left(\frac{\partial\alpha}{\partial r}\right)_0^2 e^{i\omega_0 t}\, e^{\lambda_1(c_{\mathrm{A}}, t)}$$

$$[7b] \quad G_{\mathrm{S}}^{(0)}(c_{\mathrm{A}}, t) = c_{\mathrm{A}} \frac{N\hbar}{2\mu\omega_0}\left(\frac{\partial\alpha}{\partial r}\right)_0^2 e^{i\omega_0 t}\, e^{\lambda_2(c_{\mathrm{A}}, t)}$$

$$[7c] \quad G_{\mathrm{D}}^{(0)}(c_{\mathrm{A}}, t) = c_{\mathrm{A}} \frac{N\hbar}{2\mu\omega_0}\left(\frac{\partial\alpha}{\partial r}\right)^2 e^{i\omega_0 t}\,(e^{\lambda_1(c_{\mathrm{A}}, t)} - e^{\lambda_2(c_{\mathrm{A}}, t)})$$

$$[7d] \quad G^{(20)}(c_{\mathrm{A}}, t) = G_{\mathrm{S}}^{(20)}(c_{\mathrm{A}}, t) = c_{\mathrm{A}} \frac{2}{15} \frac{N\hbar}{2\mu\omega_0}\left(\frac{\partial\beta}{\partial r}\right)_0^2 e^{i\omega_0 t}\, e^{\lambda_2(c_{\mathrm{A}}, t) - p_2 t}$$

$$[7e] \quad G_{\mathrm{D}}^{(20)}(c_{\mathrm{A}}, t) = 0$$

$$[7f]\quad \lambda_1(c_A,t) = i\int_0^t dt'\,\{[\langle\Omega_{11}(t')\rangle] + c_A[N\langle\Omega_{12}(t')\rangle]\} + i^2\int_0^t dt'\int_0^{t'} dt''\,\{[\langle\Delta\Omega_{11}(t')\,\Delta\Omega_{11}(t'')\rangle]$$
$$+ c_A[N\langle\Delta\Omega_{11}(t')\,\Delta\Omega_{12}(t'')\rangle + N\langle\Delta\Omega_{12}(t')\,\Delta\Omega_{11}(t'')\rangle + N\langle\Delta\Omega_{12}(t')\,\Delta\Omega_{12}(t'')\rangle] + c_A^2[N^2\langle\Delta\Omega_{12}(t')\,\Delta\Omega_{13}(t'')\rangle]\} + \ldots$$

$$[7g]\quad \lambda_2(c_A,t) = i\int_0^t dt'\,\{[\langle\Omega_{11}(t')\rangle]\} + i^2\int_0^t dt'\int_0^{t'} dt''\,\{[\langle\Delta\Omega_{11}(t')\,\Delta\Omega_{11}(t'')\rangle] + c_A[N\langle\Delta\Omega_{12}(t')\,\Delta\Omega_{12}(t'')\rangle]\} + \ldots$$

Similar equations are valid for the isotopic species B. It should be stressed that there is no hidden concentration dependence through the pair and three-body time-dependent distribution functions that are needed to calculate the correlation functions of eqs. [7*a*–*g*]. This is due to the absence of structure breaking in an isotopic dilution process.

(c) *Results and discussion*

The above zero-order theory of Raman processes in isotopic mixtures leads to the following results. (*i*) The peak frequency of an isotropic Raman band is a linear function of the concentration of the active species. This result, prior to the Bratos–Tarjus theory, is due to Wertheimer (61). On the other hand, the position of an anisotropic Raman band is independent of concentration. (*ii*) The variation of the half-width of an isotropic Raman band with concentration strongly depends on the speed of vibrational modulation. If it is fast, the half-width is a quadratic function of the concentration; if it is slow, it depends on the square root of this function. The former of these limits has already been discussed by Wertheimer (61) and Knauss (60), and the latter in the model due to Bondarev and Mardaeva (23) and Fujiyama *et al.* (24); see also Knapp and Fischer (62). (*iii*) The half-width of an anisotropic Raman band is a linear function of concentration if the vibrational modulation is fast and it depends on the square root of this function if it is slow. (*iv*) The c_A^2 term of $\lambda_1(c_A,t)$ and the c_A term of $\lambda_2(c_A,t)$ are expected to be small for all diatomics. The argument is the same as that of Section 3c(2). The half-width of an anisotropic Raman band is thus virtually independent of the concentration. These theoretical predictions conform to the data of Section 2.

The present discussion may be closed with some brief comments relative to non-isotopic mixtures. In this case, the fluctuation of the chemical composition of the first solvation shell of the reference molecule is the main source of the additional band broadening. Both $\lambda_1(c_A,t)$ and $\lambda_2(c_A,t)$ contain large c_A^2 dependent terms. Moreover, when the liquid is progressively diluted, the structure breaking occurs; the distribution functions may be strongly concentration dependent, particularly if the two species differ much in their dimensions and in their chemical properties. The models by Bondarev and Mardaeva (23), Fujiyama *et al.* (24), and Knapp and Fischer (62) describe this complicated situation in a rough manner. The only quantitative approach is due to Knauss (60), but its application remains difficult. Finally, the vibrational dephasing of Raman active ions in aqueous electrolyte solutions was studied by Kato (64).

5. Theory. Composite Raman bands of liquids and isotopic mixtures

(a) *Generalities*

The study of composite bands was initiated fifty years ago by analysing the structure of ν OH bands in hydrogen bonded liquids. Their properties were examined experimentally in several thousands of publications. Moreover, statistical theories of the band shape in dilute solutions were proposed as well; review papers are given in refs. 65 and 66. Contrasting with this situation is that relative to the composite Raman bands of pure van der Waals liquids and of their isotopic mixtures. The quantitative experimental work is virtually non-existent and only a few theories have been published. They are due to Wertheimer (61, 67, 68) and to McHale and Wang (69) who examined, between 1978 and 1980, three types of composite bands: hot bands corresponding to the transitions $0 \to \nu$ and $\nu' \to \nu' + \nu$ (67, 68), doublets produced by the Fermi resonance (69), and interacting fundamentals $0 \to \mu$ and $0 \to \nu$ of a given mode in isotopic mixtures (61). At the present time, the coverage of this field is fragmentary. The importance of these problems should by no means be underestimated: the majority of Raman bands of polyatomic molecules are overlapping composite bands.

(b) *Method of calculation*

The theories for this group are quantum mechanical in principle although, in practice, non-vibrational degrees of freedom are treated classically. The following model is used in these theories. (*i*) The Hamiltonian of a pure liquid is written $H = H_{KIN} + H_{POT} + H_{VIB}$ where H_{KIN} represents the translational and rotational kinetic energy of the fluid, H_{POT} describes molecular interactions, whereas H_{VIB} is the Hamiltonian of a system of non-interacting vibrators. The Hamiltonian of an isotopic binary mixture is written similarly, the indices J,K distinguishing its various components:

$$[8]\quad H = \sum_{J=1}^{2} H_{KIN}^{J} + \sum_{J,K=1}^{2} H_{POT}^{J,K} + \sum_{J=1}^{2} H_{VIB}^{J}$$

(*ii*) Thermal fluctuations of the bath are fast on the time scale of the experiment. (*iii*) Collision-induced contributions to the mean polarizability are neglected.

The assumptions (*i*) and (*iii*) above, as well as that postulating a classical thermal bath, were already examined in Section 3b(2) and do not need to be reexamined. On the contrary, assumption (*ii*) is new and limits the theory to rapidly modulated Raman processes. This restriction means that, in practice, only weakly interacting van der Waals liquids may be treated by the above theories. It should also be emphasized that, in polyatomic molecules, assigning a small set of transitions to a given composite band generally represents an approximation. It is in fact difficult to take into account all secondary energy and phase relaxation mechanisms contributing to the profile.

The calculation employs the Zwanzig–Mori theory of Brownian motion. The basic set of dynamical variables $a_i(t)$ is that of collective vibrational transition operators between the states to which the band is assigned. For example, in the problem of two overlapping fundamentals of an isotopic mixture, one has:

$$[9]\quad a_1 = (Nc_1)^{-1/2}\sum_j \sigma_{\mu 0}^{1j}; \quad a_2 = (Nc_2)^{-1/2}\sum_k \sigma_{\nu 0}^{2k}$$

In eqs. [9], $\sigma_{\mu 0}^{1j}$ is the transition operator for the $0 \rightarrow \mu$ transition of jth molecule of the species 1, $\sigma_{\nu 0}^{2k}$ that for the $0 \rightarrow \nu$ transition of kth molecule of the species 2, N the total number of molecules, and c_1, c_2 the concentrations of the two species. Furthermore, in refs. 61, 67, and 68 the frequency and the memory matrix were calculated by suppressing H_{POT} in the expressions for the density matrix and the projected propagator. Finally, simple models were employed in estimating the role of various band shaping exchange mechanisms.

(c) *Results and discussion*

The following results may be reached from these theories. As far as the $0 \rightarrow \nu$, $\nu' \rightarrow \nu + \nu'$ isotropic Raman bands are concerned (67, 68), the theory showed that the interaction between individual resonances originates essentially in intermolecular vibrational correlations. Moreover, various energy redistribution processes are spectrally active and may involve both low and high vibrational energy levels. The coupling mechanism produces a frequency shift, a broadening or narrowing, and an asymmetry of individual vibrational lines. It also leads to a redistribution of spectral intensity among various components. All these processes are thermally activated and vanish at low temperatures. Similar problems were investigated by Harris, Shelby and Cornelius (70, 71) and by Abbot and Oxtoby (50). However, the resonant interaction between molecules was not explicitly included in their calculations.

Intermolecular couplings were also introduced, in addition to intramolecular couplings, into the theory of the Fermi-resonance doublet (69). According to this theory, the spectral behavior is strongly concentration dependent. If the Fermi resonance is weak, the peaks of the coupled bands shift in opposite directions as the concentration is increased. If it is strong, the Fermi interaction parameter has a non-linear concentration dependence. This mechanism was also studied by Abbot and Oxtoby (50) in the case of dilute solutions.

Finally, it was found in isotropic Raman spectra of binary isotopic mixtures (61) that vibrational motions of different molecular species may be significantly coupled. This is due to the action of distinct vibrational correlations. The coupling, however, occurs only for weakly separated or overlapping bands. Moreover, the correlation time of vibrational self-coorelation functions turns out to be essentially independent of concentration. This result has its origin in the fact that the nearly resonant transfer between molecules of different types is almost as fast as the resonant transfer between molecules of the same species. A similar behavior of isolated isotropic Raman bands was discussed in Section 3c(2). It is probable that the majority of results cited here are of general validity, although the theories of this section are fast-modulation theories.

6. Conclusions

A first important conclusion of this review is that the random phase approximation can not be retained in its simple form. Intermolecular forces introduce a correlation between phases of individual vibrators and, in the absence of any complicating factor, distinct pair vibrational correlation functions survive. This is why isotropic Raman processes are partially coherent. However, though they are collective, rotational motions destroy these correlations if the rotation–vibration coupling is small enough. The coherence of anisotropic Raman processes, which can only be transmitted by this mechanism, thus remains small and resonance transfer effects are quenched correspondingly.

A second conclusion concerns the nature of collective processes accessible to a study by Raman spectroscopy. As shown earlier, isotropic Raman spectroscopy permits an analysis of a variety of dephasing and energy relaxation processes. The former can most conveniently be examined in the case of high frequency fundamentals where they alone are present. On the other hand, both phase and energy relaxation processes affect composite bands and cannot easily be disentangled from each other; the theory still remains fragmentary at this point. Resonance transfer and environmental fluctuation processes never act independently of each other; their interference in fact is usually the main source of the band broadening when going from dilute isotopic solutions to pure liquids. Using "chemical" solvents complicates the analysis to a considerable extent. Three new effects appear in this case: change of the force law, breaking of the liquid structure in the dilution process, and concentration fluctuations modifying the local chemical composition of the solution. From the other side, anisotropic Raman spectroscopy is not well adapted, by its nature, to the study of collective vibrational and rotational processes in liquids; it can be employed, however, to separate collective and monomolecular motions from one another. As a whole, the field is still far from maturity.

Finally, it is interesting to ask why spectacular spectroscopic features observed in quasi-elastic light scattering spectra, features such as the Rayleigh–Brillouin triplet or those resulting from the reorientation – shear wave coupling, have never been reported for non-elastic Raman spectra. The reasons for this non-observation are not known. However, the coherence of isotropic Raman spectra may not be sufficient to guarantee the existence of similar effects; this is still more true for the anisotropic Raman spectra. A further study of this problem certainly merits attention.

^{1}H and ^{13}C nmr study of exchange and isomerism in dimethylsulphoxide solutions of neutral methylmercury–xanthosine complexes

FRANÇOIS ALLAIRE, MICHEL SIMARD, AND ANDRÉ L. BEAUCHAMP[1]
Département de Chimie, Université de Montréal, C.P. 6210, Succ. A, Montréal (Qué.), Canada H3C 3V1

Received September 25, 1984

This paper is dedicated to Professor Camille Sandorfy on the occasion of his 65th birthday

FRANÇOIS ALLAIRE, MICHEL SIMARD, and ANDRÉ L. BEAUCHAMP. Can. J. Chem. **63**, 2054 (1985).

The xanthosine (H_2Xan) complexes $(CH_3Hg)(HXan)$ and $(CH_3Hg)_2(Xan)$ have been studied in $(CD_3)_2SO$ solution at room temperature by ^{1}H (90 MHz) and ^{13}C nmr (20.1 MHz) spectroscopy. For $(CH_3Hg)_2(Xan)$, where the N1-H and N3-H protons have been substituted by CH_3Hg^+ groups, individual ^{1}H and ^{13}C resonances from the unequivalent CH_3Hg^+ groups indicate that these cations do not exchange rapidly between the two sites. For solutions of $(CH_3Hg)(HXan)$, in which only one of the N—H protons has been substituted, both types of spectra show two sets of resonances for the purine unit as well as for the CH_3Hg^+ groups. This indicates that the 1:1 complex exists as two linkage isomers (N3—H, N1—Hg) and (N3—Hg, N1—H) in slow exchange. These two isomers are formed in equal amounts. When free xanthosine is added, the N3-mercurated complex exchanges rapidly with the free ligand, whereas the N1-mercurated complex does not exchange.

FRANÇOIS ALLAIRE, MICHEL SIMARD et ANDRÉ L. BEAUCHAMP. Can. J. Chem. **63**, 2054 (1985).

Les complexes $(CH_3Hg)(HXan)$ et $(CH_3Hg)_2(Xan)$ de la xanthosine (H_2Xan) ont été étudiés en solution dans $(CD_3)_2SO$ à température ambiante par rmn ^{1}H (90 MHz) et ^{13}C (20.1 MHz). Pour $(CH_3Hg)_2(Xan)$, composé dans lequel les protons N1-H et N3-H ont été substitués par des groupes CH_3Hg^+, les deux groupes CH_3Hg^+ non équivalents produisent des résonances ^{1}H et ^{13}C distinctes, ce qui indique que ces cations ne s'échangent pas rapidement entre les deux sites. Dans le cas des solutions de $(CH_3Hg)(HXan)$, où un seul proton N—H a été substitué, les deux sortes de spectres comportent deux séries de signaux tant pour le résidu purinique que pour les groupes CH_3Hg^+. Ceci montre que le complexe 1:1 existe sous forme de deux isomères de liaison (N3—H, N1—Hg) et (N3—Hg, N1—H) en échange lent. Ces deux isomères se forment en quantités égales. Si l'on ajoute de la xanthosine libre à la solution, on constate que le composé mercurié en N3 s'échange rapidement avec le ligand libre, tandis que le composé mercurié en N1 ne s'échange pas.

Introduction

Our laboratory has been examining the reactions of the CH_3Hg^+ cation with DNA constituents for several years. In a recent report (1), we described and structurally characterized a series of CH_3Hg^+ complexes of xanthine, a nucleobase related to guanine. That work was being extended to the analog nucleoside xanthosine (H_2Xan), **A**, when we became aware that a similar study was underway in another laboratory. The latter study by Buncel, Norris, and co-workers (2) has now been published. These authors have prepared a number of xanthosine compounds in which the CH_3Hg^+ cation has been shown to react by coordination of the N7 lone pair and by substitution of the N1-H and N3-H protons. These workers also obtained C8-methylmercurated derivatives. In our preliminary work on the CH_3Hg^+–xanthosine system, we had already isolated by slightly different methods the neutral $(CH_3Hg)(HXan)$ and $(CH_3Hg)_2(Xan)$ compounds and unusual peak splitting had been noted in the ^{1}H and ^{13}C nmr spectra of these compounds in $(CD_3)_2SO$. These observations have now been confirmed and they reveal interesting details pertaining to the exchange of the CH_3Hg^+ cation in these systems. These results are discussed in the present paper.

Experimental section

Xanthosine (Aldrich) and CH_3HgOH (Alfa, 1 *M* aqueous solution) were used without further purification. C, H, and N were analyzed by Schwarzkopf Laboratories, New York. The CH_3Hg^+ group was titrated potentiometrically with 0.05 *M* KCl (Ag/AgCl electrode) in an ethanol–water mixture, as described earlier (1, 3).

Nuclear magnetic resonance measurements

The ^{1}H nmr spectra were recorded with a Bruker WH-90 instrument and the ^{13}C spectra with a Bruker WH-80 instrument operating at 20.1 MHz, both at ambient probe temperature (28°C). Me_4Si was used as internal reference. In all cases, the compounds were dissolved in $(CD_3)_2SO$ (Merck, Sharp and Dohme, Canada). The solutions were prepared by dissolving ~150 mg of complex per mL.

Preparations

The methylmercury complexes were first reported by Buncel, Norris, and co-workers (2). They are prepared here by slightly different methods, yielding hydrated forms.

TABLE 1. ^1H nmr results for xanthosine and its CH_3Hg^+ complexes[a]

Complex	δ (ppm) N1-H	C8-H	$CH_3(Hg)$	$^2J(^1H—^{199}Hg)$[b]
H_2Xan (**A**)	10.94	7.91	—	—
$(CH_3Hg)(HXan)$ (N1, **C***a*)	—	7.80	0.78	196
$(CH_3Hg)(HXan)$ (N3, **C***b*)	10.77	7.88	0.82	220
$(CH_3Hg)_2(Xan)$ (**B**)	—	7.65	0.83	220 (N3)
			0.74	195 (N1)

[a] In $(CD_3)_2SO$, referenced to internal Me_4Si, 298 K, 90 MHz.
[b] ^2J coupling constant in Hz.

$(CH_3Hg)_2(Xan)\cdot H_2O$, ***B***. Xanthosine **A** (0.64 g, 2.0 mmol) was dissolved in a boiling mixture of 4.0 mL of 1 *M* CH_3HgOH and 60 mL of water. The hot solution was stirred for 1 h and allowed to cool. After 3 days, the solid was filtered, washed with ethanol, and dried at room temperature *in vacuo*. Yield: 1.26 g, 85%. The solid dried under these conditions is a monohydrate. *Anal.* calcd. for $C_{12}H_{18}Hg_2N_4O_7$: Hg 54.84, C 19.70, H 2.48, N 7.66; found: Hg 54.86, C 19.79, H 2.18, N 7.86. Substitution of both the N1-H and N3-H protons in this compound is evidenced from the shift of the whole carbonyl infrared absorption of xanthosine from ~1700 cm^{-1} to ~1635 cm^{-1}, as noted when the same two sites of xanthine are substituted (1).

$(CH_3Hg)(HXan)\cdot 2H_2O$, ***C***. Xanthosine **A** (0.64 g, 2.0 mmol) was dissolved in a boiling mixture of 2.0 mL of 1 *M* CH_3HgOH and 60 mL of water, and subsequently treated in the same way as above. Yield: 0.30 g, 28%. *Anal.* calcd. for $C_{11}H_{18}HgN_4O_8$: Hg 37.50; found: Hg 37.73. The ir spectrum shows carbonyl bands at ~1690 and ~1640 cm^{-1}, indicating that substitution has taken place at only one of the N—H sites, as found for an analogous substitution pattern in xanthine (1).

Results and discussion

Xanthosine (A)

The free nucleobase **A** contains two acidic protons attached to the pyrimidine ring. The N3-H proton dissociates first, with a pk_a values of 5.6, whereas the N1-H proton is less acidic (pk_a = 9.9) (4, 5).

The ^1H nmr data for xanthosine in $(CD_3)_2SO$ (Table 1 and Fig. 1*d*) are in good agreement with those previously reported (2). The C8-H proton produces a sharp resonance at 7.91 ppm. The spectrum also contains signals for the ribose protons, which will not be discussed here. At low field, a broad signal at 10.94 ppm, integrating for one proton, is due to N1-H (6). The N3-H proton should also give a resonance at still lower field, but it is not observed in this case. A similar situation was encountered for the N7-H proton of xanthine (pk_a = 7.7) (1), which was found to appear in the spectra of very dry $(CD_3)_2SO$, but to disappear when the amount of water in $(CD_3)_2SO$ increased, owing to exchange with the protons of water (6). The N3-H proton of xanthosine is more acidic and, therefore, probably more labile than the N7-H proton of xanthine, so that the absence of the N3-H resonance here is likely to result from fast exchange with water.

The ^{13}C spectrum of xanthosine (Table 2 and Fig. 2*d*) is in accord with the previous report (2).

*$(CH_3Hg)_2(Xan)$ (**B**)*

In this compound, two CH_3Hg^+ groups have substituted the N1-H and N3-H protons of xanthosine. Structure **B** is supported by the carbonyl stretching region of the ir infrared spectrum, which is similar to those observed for xanthine complexes in which both pyrimidine protons had been substituted (1).

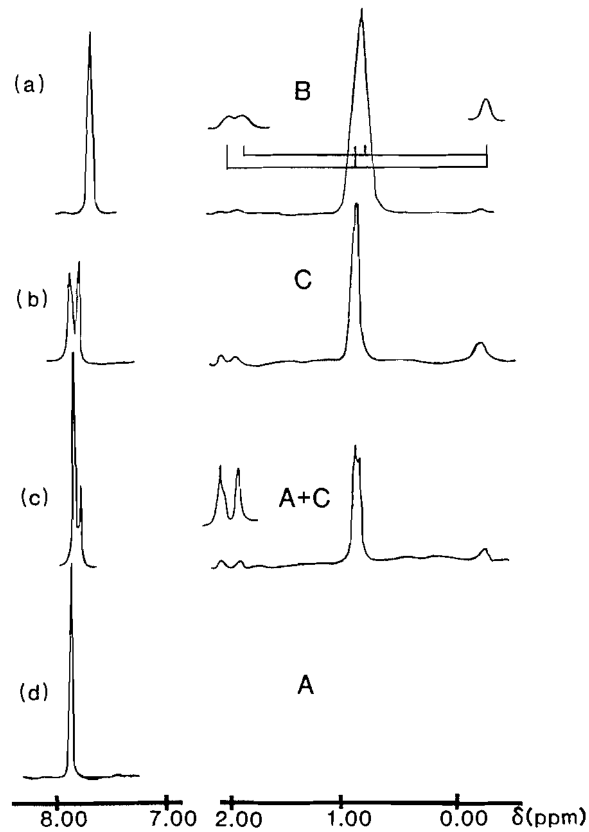

FIG. 1. C8-H (left) and CH_3Hg^+ (right) regions of the ^1H nmr spectra in $(CD_3)_2SO$ at room temperature. Chemical shifts referenced to Me_4Si. (*a*) $(CH_3Hg)_2(Xan)$ (**B**); (*b*) $(CH_3Hg)(HXan)$ (**C**); (*c*) 30:70 mixture of xanthosine (**A**) and $(CH_3Hg)(HXan)$ (**C**); and (*d*) xanthosine (**A**).

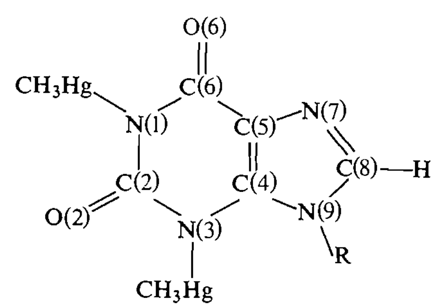

B

In agreement with this structure, the N1-H signal is absent from the ^1H spectrum of the complex. The C8-H signal has shifted upfield by 0.26 ppm compared to xanthosine (Fig. 1*a* and Table 1).

TABLE 2. ^{13}C nmr results for xanthosine and its CH_3Hg^+ complexes[a]

Complex	δ (ppm)										
	C2	C4	C5	C6	C8	CH_3(Hg)	C1′	C2′	C3′	C4′	C5′

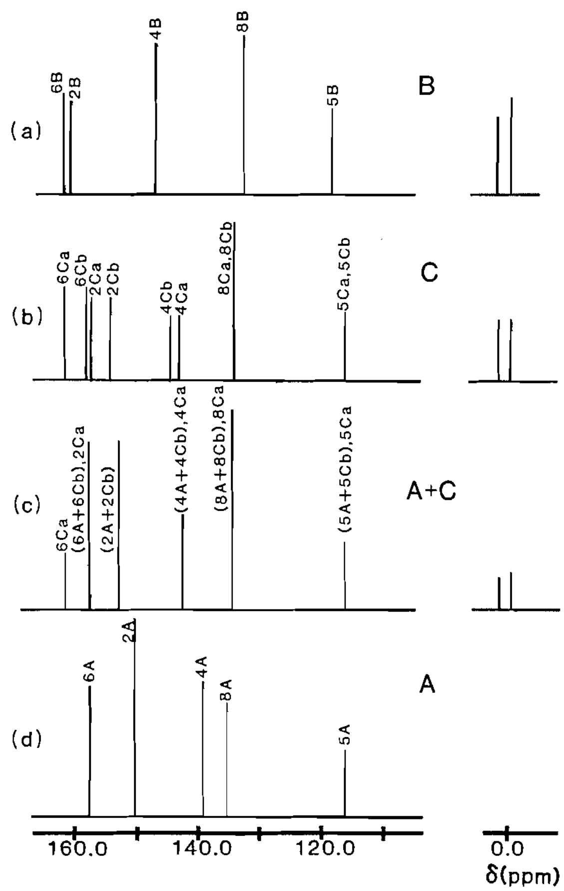

FIG. 2. Purine (left) and CH_3Hg^+ (right) regions of the ^{13}C nmr spectra in $(CD_3)_2SO$ at room temperature. Chemical shifts referenced to Me_4Si. (*a*) $(CH_3Hg)_2$(Xan) (**B**); (*b*) (CH_3Hg)(HXan) (**C**); (*c*) 30:70 mixture of xanthosine (**A**) and (CH_3Hg)(HXan) (**C**); and (*d*) xanthosine (**A**).

The most unusual feature of this spectrum is found in the high-field region, where the resonances for the CH_3Hg^+ groups appear (Fig. 1*a*). The methyl signal centered at 0.78 ppm is broader than usually found for similar systems (1, 8–12). The presence of two unresolved signals under this broad peak is indicated by the shape of the satellites due to coupling between the methyl protons and ^{199}Hg (17% abundance). Figure 1*a* clearly shows that the satellite at low field contains two equal components. This region can be interpreted in terms of a first resonance at 0.74 ppm with a ^2J(^{1}H—^{199}Hg) constant of 195 Hz, and a second component with the same intensity at 0.83 ppm with a ^2J constant of 220 Hz. This particular combination of chemical shifts and coupling constants produces two distinct peaks for the low-field satellites, but accidental coincidence of the components for the high-field satellites.

The presence of two distinct signals for N-bonded CH_3Hg^+ groups is unusual, since purine and pyrimidine complexes containing more than one type of CH_3Hg^+ groups commonly show only a single sharp resonance due to fast exchange of the CH_3Hg^+ groups between the various sites at room temperature (1, 7–12). The presence of two signals has been observed by Buncel, Norris, and co-workers (2, 8, 10–12) when N-bonded and C-bonded CH_3Hg^+ groups are simultaneously present, the latter being known to be non-labile. The presence of C-bonded groups in the present case can be ruled out, as this type of group should produce a resonance at higher field (~0.55 ppm) with a ^2J coupling constant of ~157 Hz (2, 8, 12). Therefore, in contrast by most similar systems, the two CH_3Hg^+ groups in the present compound do not exchange rapidly between the two coordination sites.

This interpretation is supported by the ^{13}C spectrum (Fig. 2*a* and Table 2), which also contains two resolved resonances at 1.3 and −0.7 ppm for the methyl carbons of CH_3Hg^+ groups in slow exchange. The remaining ^{13}C signals are in good agreement with those reported earlier (2), except for the weak C2 signal, which we have found to occur 2 ppm downfield from the reported value. The large downfield shifts of 9.9, 7.6, and 4.1 ppm on C2, C4, and C6, respectively, confirm the substitution of the N1-H and N3-H protons.

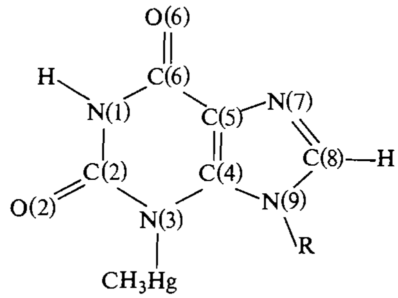
Rabenstein (13) examined CH_3HgL complexes with a series of ligands L by ^{1}H nmr spectroscopy and found that the ^2J coupling constant decreases linearly as a function of log *K* (where *K* is the formation constant of CH_3HgL). In fact, the "log *K*" term is used as a measure of the nucleophilic character of L with respect to the CH_3Hg^+ ion. Other workers (11, 14) have proposed a similar relation between ^2J and, this time, the pK_a value (where k_a is the ordinary dissociation constant of the ligand conjugated acid HL), which also measures the nucleophilic character of L, but with respect to H^+. The ^2J value was shown to decrease as the pk_a of the conjugated acid increased. This dependence of ^2J on the pk_a allows us to assign the signal at 0.74 ppm (^2J = 195 Hz) (Table 1) to the N1-bound CH_3Hg^+ group, whereas the other resonance at 0.83 ppm (^2J = 220 Hz) is due to the N3-bound group. In a second step, the ^{13}C signals for the CH_3Hg^+ groups can be assigned, since Buncel, Norris, and co-workers (2) have shown that the ^{13}C chemical shift increases as the ^2J constant decreases. Therefore, the ^{13}C signal at 1.3 ppm (Table 2) is assigned to the N1-bound CH_3Hg^+ group, while the −0.7 ppm resonance is due to the N3-bound group.

(CH_3Hg)(HXan) (C)

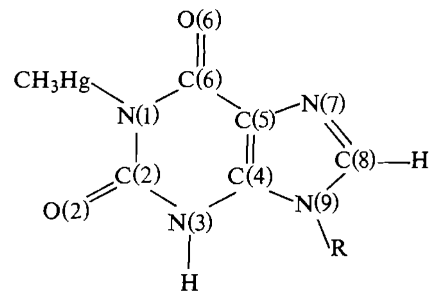
The high-field regions of the ^{1}H and ^{13}C nmr spectra (Figs.

1*b* and 2*b*, respectively) indicate that two types of slowly exchanging CH_3Hg^+ groups are again present. The ^{13}C spectrum exhibits two resolved signals. In some high-quality ^1H spectra, small splitting of the main signal at 0.81 ppm could be detected, but the presence of two unequivalent CH_3Hg^+ groups is evidenced mainly, as in the previous case, from the two components of the low-field satellite for $^1H-^{199}Hg$ coupling. The chemical shifts and coupling constants are close to those found for $(CH_3Hg)_2(Xan)$, indicating that the slowly exchanging CH_3Hg^+ groups are probably similar to those identified in **B**. However, the present system differs markedly from the previous case by the fact that the ligand signals provide evidence for two types of differently coordinated xanthosines in slow exchange. For instance, the C8-H resonance (Fig. 1*b*) exists as two discrete signals of roughly equal intensities at 7.80 and 7.88 ppm. The ^1H spectrum also includes a broad peak at 10.77 ppm (Table 1), whose integration corresponds to only one half of the combined integrations of both C8-H signals. This broad signal is very likely due to the N1-H proton in a species representing only one half of total xanthosine present. In the ^{13}C spectrum (Fig. 2*b*), the peaks for C5 and C8 at 116.2 and 134.1 ppm, respectively, are not split, but a total of six signals are found above 140 ppm, where only the ligand C2, C4, and C6 resonances are expected.

At first, it was believed that one set of signals could originate from $(CH_3Hg)_2(Xan)$ impurity. However, this assumption was ruled out, since the C8-H signal of **B** should occur at 7.65 ppm (Table 1). ^{13}C spectra of solutions of **C** containing added **B** led to the same conclusion.



C*b*



C*a*

Our results can be explained if the $(CH_3Hg)(HXan)$ complex exists as two linkage isomers, labelled **C***a* and **C***b*, corresponding to the two possible distributions of one H^+ and one CH_3Hg^+ ions on N1 and N3. The ^1H and ^{13}C resonances for the CH_3Hg^+ groups were interpreted by comparison with those deduced above for **B**. The broad signal at 10.77 ppm was assigned to the N1-H proton of **C***b*, whereas the analog N3-H resonance for **C***a* is believed to be absent from the spectrum, as for xanthosine, because of fast exchange with the protons of the water present in $(CD_3)_2SO$. The remaining ^1H signals and the ^{13}C resonances, except those of C8 and C5 which were unsplit, could not be unambiguously assigned at this stage. However, spectra of $(CH_3Hg)(HXan)$ in presence of uncomplexed xanthosine allowed us to remove this ambiguity because the two isomer exchange differently with free xanthosine.

Adding xanthosine **A** to a solution of **C** did not introduce a new set of ^{13}C peaks at the positions already observed in the spectrum of **A**. However, most of the purine resonances of **C** were displaced (Fig. 2*c*). Therefore, some exchange process involving free and complexed xanthosine must take place to produce signal averaging. Figure 2*c* corresponds to a 30:35:35 mixture of **A**, **C***a* and **C***b*. The signal observed at 152.9 ppm for the mixture results from averaging of the C2 resonances of xanthosine and one of the isomers of **C** in fast exchange. The fast-exchanging isomer will be identified as **C***b* later. The expected average chemical shift $(30 \times 150.4 + 35 \times 154.2)/65 = 152.4$ ppm) is in good agreement with the observed chemical shift. However, this exchange process cannot involve the other isomer, since the C6 resonance of **C** at 161.7 ppm is not displaced in the presence of free xanthosine, but simply loses intensity. This resonance is assigned to the non-exchanging isomer, to be later identified as **C***a*. The remaining signals above 130 ppm all contain overlapping peaks originating from **C***a* and the averaged signal for (**A** + **C***b*). For instance, the (**A** + **C***b*) signal for C6 expected to occur at 157.9 ppm and the C2 resonance of **C***a* at 157.2 ppm produce a broad signal at 157.9 ppm. Similarly, the (**A** + **C***b*) signals expected at 142.1 (C4) and 134.8 ppm (C8) are too close to the corresponding resonances of **C***a* (143.1 and 134.1 ppm, respectively) to give resolved peaks, and the mixture gives broad resonances centered at 142.7 and 134.7 ppm (Fig. 2*c*). As to the C5 signals, they occur at 116.2 ppm for the three species and they are not sensitive to exchange.

The ^1H spectrum (Fig. 1*c*) is consistent with the above interpretation. The C8-H peak at 7.80 ppm is assigned to **C***a*, since it occurs at the same position before and after the addition of free xanthosine. In the spectrum of the mixture, the 7.80 ppm peak is much weaker than the broad 7.88 ppm resonance due to (**A** + **C***b*).

The above discussion allowed us to distribute the ^1H and ^{13}C resonances observed in the spectrum of **C** (Figs. 1*b* and 2*b*) into two sets corresponding to a fast-exchanging isomer and a slow-exchanging isomer, respectively. However, the correspondence between each set and one isomer of **C** was not yet established. Final identification was based on the ^{13}C chemical shifts. It has been shown that substitution of an N—H proton by a CH_3Hg^+ ion in molecules of this type leads to large downfield shifts on both adjacent carbons (1, 8, 9). No clear conclusions could be drawn from the resonance of C2 (Table 2), which is adjacent to both N1 and N3. The C4 signal was affected almost to the same extent in both complexes and could not provide direct evidence. However, the C6 resonance of xanthosine was displaced downfield by 4.0 ppm for the non-exchanging isomer and remained essentially unmoved for the other. Therefore, the non-exchanging isomer must have C6 adjacent to the substituted N—H proton, and it is formally identified as **C***a*.

Concluding remarks

^{1}H and ^{13}C nmr spectroscopy shows that in contrast with most other systems containing more than one type of N-bonded CH_3Hg^+ ions, the neutral $(CH_3Hg)_2(Xan)$ compound gives rise to slow exchange of the CH_3Hg^+ groups on the nmr time scale at room temperature (90 MHz ^{1}H and 20.1 MHz ^{13}C). The $(CH_3Hg)(HXan)$ complex exists as two linkage isomers **C***a* and **C***b* because exchange of the CH_3Hg^+ groups between the N1 and N3 positions is also slow. However, the N3-Hg/N1-H isomer **C***b* exchanges rapidly with uncomplexed xanthosine, whereas the N1-Hg/N3-H isomer **C***a* does not. The greater lability of the N3-bound CH_3Hg^+ group is in good correlation with the fact mentioned earlier that the N3-H proton is more labile than the N1-H proton.

Another peculiar result revealed by this study is the constant values for the chemical shifts (both ^{1}H and ^{13}C) and ^{2}J coupling constants for CH_3Hg^+ groups bonded to a given site, no matter if the other site is occupied by another CH_3Hg^+ group or by a proton. For instance, the ^{1}H resonance of the N3-bound CH_3Hg^+ group occurs at 0.82 ppm with a ^{2}J coupling constant of 220 Hz for both **B** and **C***b*, in spite of the fact that the N1-H proton is present in **C***b* but substituted by another CH_3Hg^+ group in **B**. This suggests that at least in this system, the electronegativity difference between H and Hg does not lead to dramatic changes in electron distribution and basicity for the other coordination sites in the purine moiety.

Acknowledgments

We are grateful to E. Buncel and A. R. Norris for providing preprints of their work on the CH_3Hg^+ complexes with xanthosine (ref. 2) and other ligands. We wish to thank R. Mayer for his technical assistance in recording the nmr spectra. The financial support of the Natural Sciences and Engineering Research Council of Canada and the Ministère de l'Education du Québec is gratefully acknowledged.

This paper is dedicated to Professor Camille Sandorfy on the occasion of his 65th birthday

M. GUSSONI, C. CASTIGLIONI, and G. ZERBI. Can. J. Chem. **63**, 2059 (1985).

Static and dynamic electronic charges in cyclopropane are derived from infrared intensities using parametric methods already successfully tested on many other organic molecules. Rigorous and somewhat simpler methods are adopted and the results compared. It is shown that, because of the presence of strained CC bonds in the molecule, the electrical behaviour of the C—H groups approaches that of C—H bonds in $=CH_2$ groups. Comparison of data from cyclopropane and ethylene oxide is made.

M. GUSSONI, C. CASTIGLIONI et G. ZERBI. Can. J. Chem. **63**, 2059 (1985).

Utilisant des méthodes paramétriques que l'on a déjà vérifiées avec succès sur d'autres molécules organiques et se basant sur les intensités des bandes infrarouges, on a calculé les charges électroniques statiques ainsi que dynamiques du cyclopropane. Des méthodes rigoureuses et quelque peu plus simples ont été adaptées et l'on compare les résultats. On démontre que, à cause de la présence dans le cyclopropane de liaisons CC tendues, le comportement électrique des groupements C—H ressemble à celui des liaisons C—H des groupements $=CH_2$. On présente une comparaison des données relatives au cyclopropane et à l'oxyde d'éthylène.

[Traduit par le journal]

1. Introduction

The study of infrared intensities is a powerful tool to derive an *experimental distribution* (static and dynamic) of the electronic charge in molecules (1). The success of the use of infrared intensities in understanding the electrical behaviour of molecules heavily depends on the model adopted in the analysis of the experimental data. Of the various models proposed in the past few years the one based on the so-called electrooptical parameters (EOP) (2), seems to provide the most acceptable results. In the EOP model, the molecular dipole moment $\boldsymbol{M}$ is expressed as a sum of bond contributions, according to a valence representation:

$$\boldsymbol{M} = \Sigma_k \mu_k \boldsymbol{e}_k$$

Here μ_k is the bond dipole moment of the kth bond, whose direction is that of the unit vector $\boldsymbol{e}_k$.[1] Under this assumption it is possible to derive a set of electrooptical parameters such as the equilibrium dipole moments (μ_k^0) and their derivatives with respect to any internal or symmetry coordinate ($\partial\mu^k/\partial R_t$) from the intensities of the fundamental bands.[2]

From EOP it is also possible to derive, *unequivocally*, another set of parameters, even more meaningful, namely the equilibrium atomic charges (q_α^0) and charge fluxes ($\partial q_\alpha/\partial R_t$) (ECCF) (3). Due to their localization, EOP (and ECCF) are the parameters most suitable to be transferred from molecule to molecule and have been shown to be very useful in predicting spectra (4, 5). Moreover, it seems that they have a sound physical meaning (6) from the evidence so far collected; indeed they correlate with various experimental physical quantities independent of ir intensities (6) and allow the understanding of phenomena related to intra- and intermolecular electrical interactions (7–11).

Unfortunately, the derivation of EOP from ir intensities is not immediate: their derivation requires several intermediate steps (and assumptions) that sometimes undermine the reliability of the resulting parameters. The basic requirements to be fulfilled in order to derive "good" parameters are the following (5): (*i*) very accurate measurements of absolute intensities (A_i) must be carried out of all fundamental ir bands, and, possibly, of various isotopic derivatives; (*ii*) a reliable force field must be used; and (*iii*) safe procedures in the determination of the signs of $\partial\boldsymbol{M}/\partial Q_i$ ($A_i = |\partial\boldsymbol{M}/\partial Q_i|^2$) must be adopted, including the comparison of quantum mechanical calculations.

When the above requirements are satisfied *the* set $\partial M/\partial S_i$ (S_i = symmetry coordinate) is definitively determined. However, there is still another important weakness in the determination of EOP. In general, the number of EOP exceeds the number of experimental data. The problem is then to choose among the various sets, the set of EOP which is more likely to describe the characteristics of the molecular charge distribution. This difficulty can be overcome by the simultaneous analysis of the intensities of large classes of molecules: the parameters relative to the same atomic groups in similar or in different molecular environments must be compared and the "trends" suggested by EOP in relation to physical and chemical known properties must be analyzed.

Several sets of reliable EOP have been determined this way for several molecules. An extensive work has been carried out in the case of hydrocarbons with or without substituents (5–14). From these studies a detailed understanding of the electrical properties of C—H bonds at equilibrium and during vibration has been obtained. Some conclusions of general validity are as follows:

[1]The assumption that the bond dipole lies on the internuclear axis is the most naive, but it is necessary in order to avoid an arbitrary splitting of $\mu^k_{\mathrm{longitudinal}}$ and $\mu^k_{\mathrm{transverse}}$.

[2]R_t are vibrational coordinates such as bond stretching, angle deformation, or torsion about a bond. Linear combinations of R_t dictated by symmetry, are also used.

(*i*) All the hydrogens involved in C—H bonds are positive. This means that the carbon atom, when forming the bond, withdraws electrons from H. (See Appendix for a further discussion.)

(*ii*) q_H^0 is very sensitive to the state of hybridization of the adjacent carbon atom q_H^0 in ≡CH bonds is more positive than that in =CH_2 bonds; q_H^0 in =CH_2 bonds is more positive than that in >CH_2 and —CH_3 bonds; q_H^0 in hyperconjugated methyl groups (such as in propylene, propyne, acetone) have intermediate values.

(*iii*) The charge flux on the hydrogen, when the C—H bond stretches, is negative and practically the same ($\partial q^H/\partial r = -0.2$ e Å^{-1}) for all the H atoms bonded to carbons both in sp^2 and sp^3 hybridization.

(*iv*) In the presence of π electrons there are relevant charge fluxes with in-plane bending motions, one order of magnitude larger than those in unsaturated compounds. This fact has been shown to be relevant in the interpretation of the spectra of a number of molecules (8, 14).

Recently we have proposed simple rules for deriving directly some qualitative information on EOP from the intensity pattern of bands and not just from single isolated bands. It has been shown that in the case of H atoms bonded to C(sp^2) or C(sp^3) the sum of the C—H stretching intensities per C—H (ΣI^{str}/CH) increases when q_H^0 decreases, while the sum of bending intensities per C—H (ΣI^{def}/CH) decreases when q_H^0 decreases. This has been found and rationalized in a number of cases and is thoroughly discussed in refs. 9 and 14. These criteria have been very useful in the study of those cases where only "limited" intensity data were available, namely, when overlapped bands need to be measured, when a reliable force field is not available or when it is impossible to measure the *absolute intensities* of the bands. Recently, the use of the quantity $\Sigma I^{def}/\Sigma I^{str}$ has allowed the problem of lack of experimental data on absolute intensities to be bypassed and has provided good results in the study of complex molecules such as polyacetylene. Finally, $\Sigma I^{def}/\Sigma I^{str}$ seems to be a very sensitive indicator of the differences in the charge distribution in the various C—H bonds.

On these grounds we discuss in this paper the infrared intensities of cyclopropane (15) and derive a set of EOP. The objectives of this paper are (*i*) to clarify the influence of the presence of strained CC bonds on the charge distribution in the C—H bonds and (*ii*) to show the importance of the parallel use of qualitative information such as intensity ratios, together with the detailed analysis of EOP (see discussion above).

2. Cyclopropane

The infrared intensities of C_3H_6 and C_3D_6 have been accurately determined by Levin and Pearce (LP) (15). On the basis of the highly reliable force field of Duncan and Burns (16), using the isotopic invariance criterion and a comparison with quantum mechanical calculations for the choice of the signs of the $\partial M/\partial Q_i$, LP derive the experimental $\partial M/\partial S_i$ and the corresponding atomic polar tensor (APT) for cyclopropane. Our analysis is based both on the direct use of the experimental intensities and on the EOP that can be derived. Geometry, axes and definition of coordinates are the same as those reported in ref. 15.[3]

[3]Except for the (internal and symmetry) bending coordinates that we define in radians and not, as in ref. 15, in Å. r_{CH}^0 = 1.082 Å should be used for the conversion.

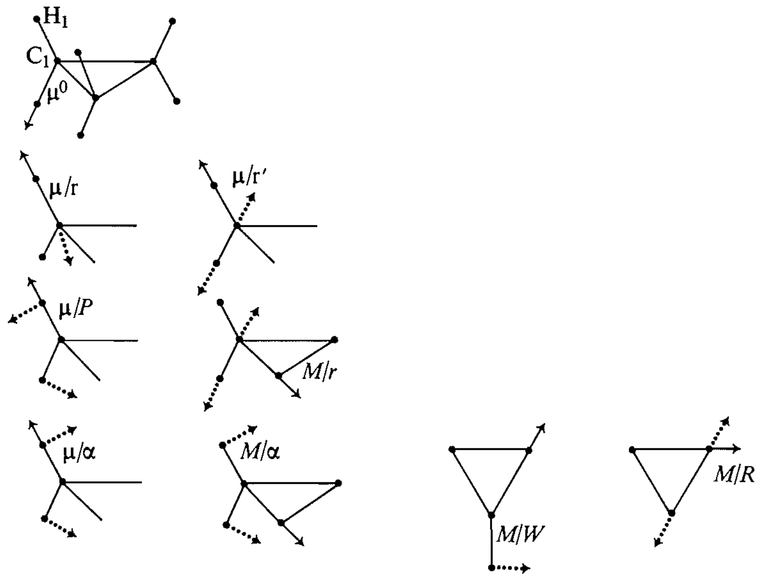
In Table 1, we have reported the observed (15) infrared intensities of C_3H_6. The first step is to compare infrared intensities of C_3H_6 with those of *n*-paraffins and those of ethylene since it turns out from quantum chemistry (17) that the orbitals of C_3H_6 possess intermediate properties. In Table 2 the sum of the CH stretching intensities per C—H bond (ΣI^{str}/CH) and the sum of CH bending intensities per C—H bond (ΣI^{def}/CH) of propane, cyclopropane, and ethylene are reported. It becomes apparent that the intensities of cyclopropane have an intermediate behaviour between propane and ethylene. Moreover, ΣI^{str}/CH suggests that the charge distribution of CH bonds in cyclopropane is more similar to that of ethylene; this agrees with other experimental data, such as isolated CH frequency and interatomic CH distance. The latter have been shown (18) to be very sensitive to the electrical nature of the bond. If we compare $\Sigma I^{str}/\Sigma I^{def}$ for cyclopropane, ethylene, and propane (see Table 2), we conclude that $q_H^0(C_2H_4) > q_H^0(C_3H_6) > q_H^0(C_3H_8)$ (see Introduction).

In Table 3 we report the expressions of $\partial M/\partial S_i$ of cyclopropane as a function of EOP. For a direct comparison, it is useful to introduce in these expressions the values of the electrooptical parameters of ethylene and of propane (see Table 4). In Table 5 the resulting $(\partial M/\partial S_i)^{calcd}$ and the corresponding infrared intensities A_i^{calcd} are reported and compared with the experimental values. It is apparent that $\partial M/\partial S_6$ predicted from propane is too large; therefore ΣA_{calcd}^{str} predicted from C_3H_8 is also too large. This indicates that the q_H^0 transferred from propane is too small (see Introduction). The same trend is suggested by the small values calculated for $\partial M/\partial S_{10}$ and for

TABLE 3. Analytical expressions for the $\partial M/\partial S_i$ of cyclopropane as a function of electrooptical parameters; see drawings for the definition of the parameters

$\partial M^z/\partial S_6$	$= \sqrt{6}\,(\partial\mu/\partial r - \partial\mu/\partial r')\sin(\alpha/2)$	$= -0.809$ D Å^{-1}
$\partial M^z/\partial S_7$	$= (2\sqrt{3})\sin(\alpha/2)\partial\mu/\partial P - 1.102\,\mu^0$	$= -0.094$ D
$\partial M^y/\partial S_8$	$= -\sqrt{3}\,(\partial\mu/\partial r + \partial\mu/\partial r')\cos(\alpha/2) + (3/2)\partial M/\partial r$	$= 0.731$ D Å^{-1}
$\partial M^y/\partial S_9$	$= -\sqrt{6}\cos(\alpha/2)\,\partial\mu/\partial\alpha - (3/2)\,\partial M/\partial\alpha + 0.663\,\mu^0$	$= 0.011$ D
$\partial M^y/\partial S_{10}$	$= -(\sqrt{3}/\sqrt{2})\,\partial M/\partial W - 2.180\,\mu^0$	$= -0.926$ D
$\partial M^y/\partial S_{11}$	$= \sqrt{2}\,\partial M/\partial R' - 0.248\,\mu^0/r^0$	$= -1.881$ D Å^{-1}



$\Sigma A^{\mathrm{def}}_{\mathrm{calcd}}$. Opposite characteristics are shown by the values calculated from ethylene; while the values of $(\partial M/\partial S_{\mathrm{str}})^{\mathrm{calcd}}$ are comparable with the experimental ones, as confirmed by the calculated values of stretching intensities, the $\Sigma A^{\mathrm{def}}_{\mathrm{calcd}}$ is very large, due to the large values assumed by $(\partial M/\partial S_{10})^{\mathrm{calcd}}$ and $(\partial M/\partial S_9)^{\mathrm{calcd}}$. The leading term in $\partial M/\partial S_{10}$ and $\partial M/\partial S_9$ is the C—H equilibrium dipole moment, that is $q^0_{\mathrm{H}} r^0_{\mathrm{CH}}$. In conclusion also a detailed transferring of EOP indicates that $q^0_{\mathrm{H}}(C_3H_8) < q^0_{\mathrm{H}}(C_3H_6) < q^0_{\mathrm{H}}(C_2H_4)$. From Table 5 one can observe that $\partial M/\partial S_{11}$ is heavily underestimated in both calculations: this indicates a large value of $\partial M^{\mathrm{CC}}/\partial R'$ in C_3H_6, suggesting the presence of a very mobile charge along the C—C bonds. It is also interesting to note that the values of the bending $\partial M/\partial S_i$ calculated from propane (i = 7, 9, 10) have the same order of magnitude. On the contrary, the corresponding experimental $\partial M/\partial S_i$ have very different values (compare $\partial M/\partial S_{10}$ with $\partial M/\partial S_7$, $\partial M/\partial S_9$). Experimental $\partial M/\partial S_i$ show similar behaviour as those calculated from ethylene. As the following will show, this behaviour can be ascribed to the presence of relevant charge fluxes on the hydrogens during bending motions, both in C_3H_6 and in C_2H_4.

We now proceed to derive a set of electrooptical parameters for C_3H_6. At this stage of the work some remarks on the determination of $\partial M/\partial S_i$ for cyclopropane are required. The positive sign chosen by LP for $\partial M/\partial S_7$ is anomalous when compared with the corresponding quantity in several other hydrocarbons: the sign of $\partial M/\partial S_i$ (S_i = bending coordinate) turns out to be the same as the sign of the deformation contribution. This also happens in C_3H_6 for all the bending $\partial M/\partial S_i$ determined by LP for the E species. We would therefore expect a negative sign for $\partial M/\partial S_7$. In the analysis of the problem we found that the L^{-1} matrix for the A species, used and published by LP, seems incorrect; the correct one is reported in Table 6. As it can be seen in Table 6, the use of the correct L^{-1} matrix modifies the results of the test of the isotopic invariance, indicating a preference, even if very slight, for the negative sign.

TABLE 4. Experimental electrooptical parameters of ethylene (13) and propane (12)

Parameter	Value: Ethylene	Value: Propane	Unit
μ^0	0.701	0.242	D
$\partial\mu/\partial r$	−0.506	−0.843	D Å^{-1}
$\partial\mu/\partial r'$	−0.067	−0.008	D Å^{-1}
$\partial M/\partial r$	—	—	D Å^{-1}
$\partial\mu/\partial P$	0.260	0.038	D rad^{-1}
$\partial\mu/\partial\alpha$	0.224	0.024	D rad^{-1}
$\partial M/\partial\alpha$	—	−0.026	D rad^{-1}
$\partial M/\partial W$	—	−0.167	D rad^{-1}
$\partial M/\partial R'$	—	−0.079	D Å^{-1}
q^0_{H}	0.134	0.045	e
$\partial q_{\mathrm{H}}/\partial r_{\mathrm{CH}}$	−0.220	−0.200	e Å^{-1}

Our analysis starts then from the $\partial M/\partial S_i$ derived by LP for the E species and from those derived for the A species with our sign choice. We work with nine unknown parameters (see Table 3), while there are only six experimental data. In general this problem is overcome by neglecting some parameters. Let us consider the bending $\partial M/\partial S_i$. As a first approximation let us retain only the terms containing μ^0. We thus have only one unknown in three equations, which turn out to be strongly incompatible ($\partial M/\partial S_7$ provides μ^0 = 0.112 D; $\partial M/\partial S_9$ provides μ^0 = 0.016 D, and $\partial M/\partial S_{10}$ provides μ^0 = 0.424 D).

TABLE 5. Comparison between the experimental $\partial M/\partial S_i$ and the infrared intensities A_i of cyclopropane and the same quantities calculated by transferring EOP from ethylene and propane; units are D Å^{-1} for $\partial M/\partial S_i$ (i = 6, 8, 11) and D for $\partial M/\partial S_i$ (i = 7, 9, 10); intensities are in darks

TABLE 6. Application of isotopic invariance criterion for the A species

$$\mathbf{L}^{-1}_{C_3H_6}\ (A\ \text{species}) = \begin{array}{c|cc} & S_6 & S_7 \\ Q_6 & 0.9476 & -0.0047 \\ Q_7 & 0.0713 & 0.8407 \end{array}$$

$\partial M^z/\partial Q_6 = \pm\ 0.846$ $\qquad \partial M^z/\partial Q_7 = \pm\ 0.109$

	C_3H_6		C_3D_6	
	(−+)	(−−)	(−−)	(−+)
$\partial M^z/\partial S_6$	−0.794	*−0.809*	−0.763	*−0.795*
$\partial M^z/\partial S_7$	0.096	*−0.087*	0.113	*−0.099*

This fact indicates that angular fluxes are relevant in cyclopropane, as already suggested by previous comparison with ethylene. However, we have five angular EOP (μ^0, $\partial\mu/\partial P$, $\partial\mu/\partial\alpha$, $\partial M^{CC}/\partial\alpha$, $\partial M^{CC}/\partial W$) and three experimental data ($\partial M/\partial S_7$, $\partial M/\partial S_9$, $\partial M/\partial S_{10}$). $\partial M/\partial S_{10}$ depends only on μ^0 and $\partial M^{CC}/\partial W$. The wagging motion ($W$) of cyclopropane is similar to the out-of-plane CH deformation in ethylene, which, for symmetry reasons, is independent of any charge flux parameter. It then seems reasonable to assume that $\partial M/\partial S_{10}$ (C_3H_6) is due to a pure deformation. With this assumption $\mu^0(C_3H_6)$ = 0.425 D and therefore $q_H^0(C_3H_6)$ = 0.082 e. It is important to verify whether the assumption $\partial M^{CC}/\partial W = 0$ is reasonable. In Table 7 we have compared the values of the equilibrium hydrogen charges of several hydrocarbons with $\Sigma A^{def}/\Sigma A^{str}$. It becomes apparent that q_H^0 and $\Sigma A^{def}/\Sigma A^{str}$ indicate the same trend; notice that also q_H^0 = 0.082 e of cyclopropane is perfectly in agreement with this trend.

In Table 8 we report EOP and ECCF derived using q_H^0 = 0.082 e. From $\partial M/\partial S_9$ we have derived two possible sets of charge fluxes with angular α deformation; the correct solution is, probably, intermediate. However, we notice that all the angular fluxes are relevant (compare with the values of ethylene and of propane in Table 4): this is a peculiar characteristic of systems containing π electrons (8). Moreover, $\partial M^{CC}/\partial R'$ is very high, as expected. As for the CH stretching $\partial M/\partial S_i$ (i = 6, 8), we have two experimental data and three parameters to be determined. We choose to set $\partial M^{CC}/\partial r_{CH}$ to 0, because the alternative solution $(\partial\mu^k/\partial r_j) = 0$ provides a too low value of $\partial\mu^k/\partial r_k$ (= −0.389 e Å^{-1}). This implies a charge flux $\partial q^H/\partial r_{CH}$ = −0.150 e Å^{-1}, which is low with respect to the standard value for hydrocarbons ($\partial q^H/\partial r_{CH}$ = −0.2 e Å^{-1}).

TABLE 7. Comparison of experimental equilibrium hydrogen charge and intensity ratios for several hydrocarbons, charges are in electrons

Compound	q_H^0	$\Sigma I^{def}/\Sigma I^{str}$
C_2H_6	0.05	0.14
CH_4	0.06	0.48
CH_3CHCH_2	0.07	0.53
C_3H_8	0.08	0.78
CH_3CCH	0.10	0.95
C_6H_6	0.12	1.83
C_2H_4	0.13	2.30
C_3H_4	0.15	3.48

In conclusion, the EOP derived for cyclopropane are in agreement with the general ideas obtained from direct analysis of the intensity data; they suggest that, in the presence of strained CC bonds, the C—H bonds behave almost as =CH_2 bonds.

3. Comparison with ethylene oxide

We feel that this work may add more confidence in the direct use of intensity data to detect some general electrical characteristics of the C—H bonds. Using the same criteria it might even be possible to have an idea of the electrical behaviour of C—H bonds in other cyclic compounds. In Table 9 we report the ratio $\Sigma I^{def}/\Sigma I^{str}$ for some cyclic hydrocarbons. It is apparent that only cyclopropane has $\Sigma I^{def}/\Sigma I^{str}$ very different from the typical values of n-alkanes (see also Table 7). Also from this view point we conclude that the behaviour of the infrared intensities of cyclopropane, very similar to that of ethylene, is due to the occurrence of strained CC bonds.

It might be even more interesting to extend these considerations to compounds with electron-withdrawing substituents. Let us compare the intensities of cyclopropane with those of ethylene oxide (23). We have already faced the same question comparing ethylene and formaldehyde. In formaldehyde the presence of the oxygen alters the charge distribution in the C—H bonds; $q_H^0(CH_2O)$ is less positive than $q_H^0(C_2H_4)$ due to the back-donation of electronic charge from the oxygen lone pairs. The effect (see Table 10) is a weakening of C—H bonds of CH_2O (see r^0_{CH}, ν^{is}_{CH}, k_{CH}) and an enhancement of the CH stretching intensities as a consequence of the decrease in q_H^0 (see Discussion). From Table 10 one derives the indication of back-donation from oxygen lone pairs also in the case of ethylene oxide. The CH stretching intensities per CH of C_2H_4O is twice as large as that of C_3H_6; bond length and CH force constant are respectively larger and smaller in ethylene oxide than in cyclopropane. Therefore, we expect $q_H^0(C_2H_4O)$ to be

TABLE 8. Electrooptical parameters and electronic charges and charge fluxes for cyclopropane (see drawings in Table 3)

$\partial M/\partial W$	= 0	D rad^{-1}		$\partial Q^{C}/\partial W$	= 0	e rad^{-1}
μ^0	= 0.425	D		$\overset{0}{q}_H$	= 0.082	e
$\partial\mu^k/\partial r_k$	= −0.595	D Å^{-1}		$\partial q^H/\partial r_{CH}$	= −0.190	e Å^{-1}
$\partial\mu^k/\partial r_j$	= −0.207	D Å^{-1}		$\partial q^H/\partial r'_{CH}$	= −0.040	e Å^{-1}
$\partial\mu/\partial\alpha$	= 0.210;	0 D rad^{-1}		$\partial q^H/\partial\alpha$	= 0.040;	0 e rad^{-1}
$\partial M/\partial\alpha$	= 0;	0.128 D rad^{-1}		$\partial Q^{C1}/\partial\alpha$	= 0;	−0.018 e rad^{-1}
$\partial\mu/\partial P$	= 0.127	D rad^{-1}		$\partial q^H/\partial P$	= 0.024	e rad^{-1}
$\partial M/\partial R'$	= −1.261	D Å^{-1}		$\partial Q^{C1}/\partial R'_{CC}$	= −0.175	e Å^{-1}

TABLE 9. Comparison of the intensity ratios $\Sigma I^{def}/\Sigma I^{str}$ for some cyclic hydrocarbons

	$\Sigma I^{def}/\Sigma I^{str}$	Source of data
[Ethylene	2.30]	Ref. 19
Cyclopropane	0.78	Ref. 15

Cyclopentane	0.06	Ref. 22
Cyclohexane	0.10	Ref. 22
[Ethane	0.14]	Ref. 23

less positive than $\overset{0}{q}_H$ (C_3H_6). Nevertheless, we still have a too-limited set of experimental data on cyclopropane and ethylene oxide to state safely that backdonation takes place in ethylene oxide. For instance, ν^{is}_{CH} has not been measured for C_2H_4O (ν^{is}_{CH} is *directly* derived from the ir spectra of selectively deuterated compounds and is *very sensitive* to electronic interactions such as backdonation (9, 18)). Therefore it is necessary to use microwave measurements of C—H bond lengths, which, unexpectedly, turn out to be less precise with respect to those determined by McKean from ν^{is}_{CH}. The CH force constant, k_{CH}, even if it measures the strength of the bond, is not a physical observable, but derives from a, perhaps arbitrary, parametrization of the vibrational frequencies. In conclusion, the study of back-donation in C_2H_4O requires a further determination of related physical quantities, in particular of ν^{is}_{CH}, and/or a detailed analysis of infrared intensities in terms of EOP.

On the other hand, we observe that, even if the increase of the CH stretching intensities of C_2H_4O is due to backdonation, still this effect is less pronounced than in the case of CH_2O. Two reasons, in principle, can be offered to rationalize such behaviour. In C_2H_4O there are *four* C—H bonds for one oxygen and all these bonds are equivalent with respect to the oxygen lone pairs; in CH_2O the hydrogens are only *two*. Moreover, it has been shown that back-donation is a *trans* effect, that is it involves only C—H bonds trans to lone pairs (this is the case of CH_3OH and of several polysacharides). In the case of ethylene oxide, no C—H are perfectly in a *trans* position with respect to lone pairs, a requirement certainly verified in the case of formaldehyde.

Appendix

The fact that all μ^0_{CH} are positive is unequivocal if the signs indicated for $\partial M/\partial S_i$ by isotopic invariance (*and* by "*ab initio*" calculations) for a large number of saturated and unsaturated hydrocarbons is assumed and if the hypothesis of alignment of the bond dipole moment with the internuclear axis is retained. Recently Wiberg (27), using the method of Bader, has pointed out that "*ab initio*" calculations do not confirm the validity of this approximation: they say that a component of the bond dipole perpendicular to the bond may exist. On this assumption, even a positive $\partial M/\partial S_{bend}$ may be split into a negative μ^0_{CH} and a positive flux of charge perpendicular to the bond. We are aware of this new line in the *interpretation* of the $\partial M/\partial S_i$ and we are grateful to the referee who has explicitly required a mention to this problem. Since Wiberg's approach so far has been applied only to a few molecules (ethylene, acetylene) with a somewhat arbitrary localization of the charges forming the bond dipoles, we believe that a larger number of molecules should be studied before introducing these concepts also in a phenomenological approach such as ours. In this case one should drop the assumption reported in the first paragraph of the Introduction and use also $\mu^k_{transverse}$. However, let us stress that the approach based on only $\mu^k_{longitudinal}$ has allowed us to explain successfully several inter- and intramolecular properties (5, 6, 10, 11).

Magnesium–nucleotide interaction. Synthesis, structure, ^{1}H, ^{13}C nuclear magnetic resonance and Fourier transform infrared studies of Mg-inosine-5′-monophosphate complexes

Received August 10, 1984

This paper is dedicated to Professor Camille Sandorfy on the occasion of his 65th birthday

H. A. TAJMIR-RIARI and T. THEOPHANIDES. Can. J. Chem. **63**, 2065 (1985).

The reaction of inosine-5′-monophosphate acid ($IMPH_2$) with hydrated magnesium chloride $MgCl_2 \cdot 6H_2O$ gives complexes of the type $Mg(IMP) \cdot 5H_2O$ and $Mg_2(IMP)_3 \cdot 15H_2O$. The FT-IR spectra of $Mg(IMP) \cdot 5H_2O$ in the region 1800–400 cm^{-1} showed marked similarities with that of the structurally characterized N_7-bound $Ni(IMP) \cdot 5H_2O$ and $Co(IMP) \cdot 5H_2O$ complexes, while $Mg_2(IMP)_3 \cdot 15H_2O$ exhibited distinct spectral similarities with the known $Cd_2(IMP)_3 \cdot 12H_2O$ and $Ca(IMP) \cdot 6.5H_2O$ compounds, where a direct metal–phosphate and metal–sugar binding as well as metal–N_7-coordination has been shown crystallographically. The Mg(II) ion in $Mg(IMP) \cdot 5H_2O$ is N_7-bound with an indirect metal–phosphate and metal–carbonyl interaction through a coordinated water molecule and in the $Mg_2(IMP)_3 \cdot 15H_2O$ compound it binds directly to the phosphate and to the sugar moiety as well as to the N_7-site of the purine ring system.

H. A. TAJMIR-RIARI et T. THEOPHANIDES. Can. J. Chem. **63**, 2065 (1985).

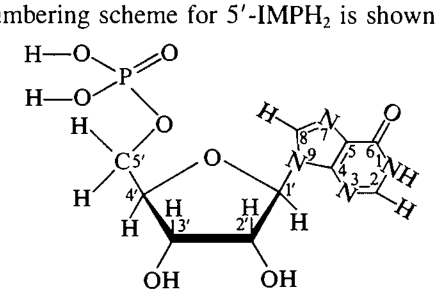
La réaction de l'acide inosinemonophosphate-5′ ($IMPH_2$) avec le chlorure de magnésium hydraté ($MgCl_2 \cdot 6H_2O$) conduit à la formation de complexes des types $Mg(IMP) \cdot 5H_2O$ et $Mg_2(IMP)_3 \cdot 15H_2O$. Le spectre IR par transformation de Fourier du complexe $Mg(IMP) \cdot 5H_2O$ dans la région de 1800 à 400 cm^{-1} présente des similitudes marquées avec ceux des complexes $Ni(IMP) \cdot 5H_2O$ et $Co(IMP) \cdot 5H_2O$ qui sont liés par le N_7 et qui ont été caractérisés du point de vue de la structure; par ailleurs le spectre du complexe $Mg_2(IMP)_3 \cdot 15H_2O$ présente des similarités spectrales distinctes avec les composés connus $Cd_2(IMP)_3 \cdot 12H_2O$ et $Ca(IMP) \cdot 6{,}5H_2O$ pour lesquels il a été démontré par cristallographie qu'il existe des liaisons directes métal–phosphate et métal–sucre ainsi qu'une coordination métal–N_7. L'ion Mg(II) du $Mg(IMP) \cdot 5H_2O$ est lié au N_7 par le biais d'une interaction indirecte métal–phosphate et métal–carbonyl impliquant une molécule d'eau coordonée; par ailleurs, dans le composé $Mg_2(IMP)_3 \cdot 15H_2O$, le Mg(II) se lie directement au phosphate ainsi qu'au sucre et au site N_7 du système cyclique de la purine.

[Traduit par le journal]

Introduction

There is little information on magnesium–IMP complexes. Our recent reports (1–5) showed that the Mg(II) ion behaves as a "soft" and "hard" acid by binding to the N_7-atom or to the phosphate oxygen atoms of guanosine-5′-monophosphate (GMP), deoxyguanosine-5′-monophosphate (dGMP), adenosine-5′-monophosphate (AMP), and xanthosine-5′-monophosphate (XMP) molecules under different chemical reaction conditions.

In the present work we describe the isolation and characterization of two Mg–IMP complexes synthesized at neutral pH values and we analyse the ^{1}H, ^{13}C nmr and Fourier Transform Infrared (FT-IR) spectra. Furthermore, having at our disposal unambiguous structural information on $Ni(IMP) \cdot 5H_2O$ (6), $Co(IMP) \cdot 5H_2O$ (6), $[Cu(IMP)]_n$ (7), $[Zn(IMP)]_n$ (8), $Cd_2(IMP)_3 \cdot 12H_2O$ (9), and $Ca(IMP) \cdot 6.5H_2O$ (10) we have examined the FT-IR spectra of these compounds hoping to detect characteristic features for the two structural types of Mg-complexes. In addition, we have established a correlation between spectral changes and coordination sites. The structure and the numbering scheme for 5′-$IMPH_2$ is shown below:



5′-$IMPH_2$

[1] To whom all correspondence should be addressed.

Experimental

Materials

The IMP acid and sodium salt were purchased from Sigma Chemical Company. D_2O (99.8%) and DMSO-d_6 (99.8%) were from Cambridge Isotope Laboratories. Hydrated magnesium chloride was from Baker Chemical Company. All the other chemicals were reagent grade and were used as supplied.

Preparation of magnesium complexes

A water solution of $MgCl_2 \cdot 6H_2O$ (1 mmol) was added to a solution of $IMPH_2$ (1 mmol) in H_2O. The pH of the solution was adjusted to 7.5 by addition of NaOH. An ethanolic solution was then used to precipitate the complex formed which was washed with alcohol several times and dried over $CaCl_2$. *Anal.* calcd. for $Mg(IMP) \cdot 5H_2O$: C 26.05, H 4.56, N 12.16, Mg 5.32; found: C 26.56, H 5.03, N 11.50, Mg, 5.15. In another attempt $MgCl_2 \cdot 6H_2O$ (2 mmol) in water was added to a solution of $IMPH_2$ (1 mmol) in H_2O and the pH was again adjusted to 7.5 with NaOH. The solution was left at room temperature for a week. Colourless crystals were separated, which were filtered off and washed with cold water and dried over $CaCl_2$. *Anal.* calcd. for $Mg_2(IMP)_3 \cdot 15H_2O$ (it should be noted that one of the IMP molecules is in the form of $IMPNa_2$): C 25.68, H 4.44, N 11.98, Mg 3.49; found: C 24.94, H 4.30, N 11.71, Mg 3.40. The two compounds are soluble in hot water and slightly soluble in hot DMSO, but are not soluble in other common organic solvents. The molar conductivities 120–200 $mol^{-1}\ \Omega^{-1}\ cm^2$ were obtained in H_2O solutions and are indicative of 2:2 electrolytes.

The structurally known complexes, $Ni(IMP) \cdot 5H_2O$, $Co(IMP) \cdot 5H_2O$, $[Cu(IMP)]_n$, $[Zn(IMP)]_n$, $Cd_2(IMP)_3 \cdot 12H_2O$, and $Ca(IMP) \cdot 6.5H_2O$ were prepared and recrystallized as reported (6–10).

^{1}H and ^{13}C nuclear magnetic resonance spectra

The spectra were recorded on a Bruker WP-80 spectrometer. Routine ^{1}H nmr spectra for analytical purposes were taken on a Varian EM 360–60 MHz. The solutions were D_2O and DMSO-d_6 containing Me_4Si or DDS as references (δ = 0.00 ppm).

[c] Structurally known compound; 5′-$IMPNa_2$ is not soluble in DMSO.

Fourier transform infrared spectra (FT-IR)

Infrared spectra were recorded on a DIGILAB FTS-15C/D Fourier transform infrared interferometer equipped with HgCdTe detector (Infrared Associates, New Brunswick, NJ), a beam splitter, and a Globar source. The spectra were obtained as KBr pellets with a resolution of 4 to 2 cm^{-1}.

X-ray powder diagrams

These were taken for comparative purposes by using a powder camera (Philips, Debye, Scherrer) with K_α-radiation and nickel filters.

Conductance measurements

The conductivity was measured with a Conductoscop E365B METROHM.

Elemental analysis

Mg(II) content was determined gravimetrically. C, H, and N were analysed at Schwarzkopf Microanalytical Laboratories (USA).

Results and discussion

Nuclear magnetic resonance spectra

The ^{13}C and ^{1}H nmr chemical shifts for 5′-$IMPH_2$ and some of its metal adducts in D_2O and DMSO solutions are given in Table 1. Unfortunately, the Na–, Mg–, and Ca–IMP compounds are not very soluble in DMSO to obtain their ^{13}C nmr spectra. The other structurally known divalent, Co–, Ni–, Cu–, Zn–, and Cd–IMP complexes (recrystallized from acidic solutions, pH = 4.5–3.8) are also not soluble in D_2O or DMSO for proton and carbon nmr spectra. We have therefore, compared the nmr spectra of only the soluble Mg–IMP compounds with the nmr spectra of the structurally characterized, Ca(IMP)·$6.5H_2O$ compound (Table 1). The nmr assignments shown here are in agreement with previously published reports (11, 12). Recently (5, 13, 14), ^{13}C and ^{1}H nmr spectroscopy was often used to characterize the nature of the interactions of alkaline-earth metals with nucleotides. The ^{13}C nmr results in D_2O (Table 1) showed that metalation (Na, Mg, and Ca) of 5′-$IMPH_2$ produces almost similar effects on the base and the sugar spectra. The largest chemical shifts observed (1 to 1.5 ppm) are for C_8, C_6, C_5, $C_{2'}$, $C_{3'}$, and $C_{4'}$ in the Na–, Mg–, and Ca–IMP compounds. On the other hand, X-ray structural analysis showed that $IMPH_2$ is N_7-protonated (15), while in $IMPNa_2$ (16) and IMPHNa (17) the Na^+ ions are coordinated to H_2O molecules and to the sugar hydroxyl groups. The N_7-site and the carbonyl group (C_6=O) are hydrogen bonded to coordinated water molecules. It has been also shown by X-ray crystal structure analysis (9) that the Ca(II) ion in Ca(IMP)·$6.5H_2O$ is directly bound to the N_7-atom of the purine ring and to the sugar hydroxyls, as well as, to water molecules.

The small chemical shifts observed for C_8, C_6, C_5, $C_{2'}$, $C_{3'}$, $C_{4'}$, and the marked nmr spectral similarities of $IMPNa_2$ (which is not N_7-coordinated in the solid state) with that of Mg(II)– and Ca–IMP complexes are indicative of coordination of these metal cations to water molecules in aqueous solution. The Ca–IMP is N7-bound in the solid state; however, in water solution the ^{13}C nmr spectra show that it is similar to $IMPNa_2$. The Ca—N7 bond must be dynamic and reversible. It is also interesting to note that the ^{1}H nmr results in D_2O did not show considerable changes for the H_8 chemical shift in the metal–IMP complexes (Table 1) and this is consistent with the ^{13}C nmr results.

The important feature of ^{1}H nmr results is the large downfield shift of the H_8 resonance when the spectra of the free acid ($IMPH_2$) are compared to those of the metalated species (Table 1). The proton downfield shift observed for H_8 in the free acid is mainly due to the protonation of the N_7-site of the purine ring. This is consistent with the presence of a zwitterionic form in the free acid both in solid state shown by crystallography (15) and in aqueous solution here. The results show a strong N_7-proton interaction in aqueous solution in contrast to the corresponding hydrated metal compounds. In DMSO solutions the H_8 resonance shows considerable downfield shift for the Mg(II)– and Ca(II)–IMP compounds compared to the free acid ($IMPH_2$). The large shift observed is consistent with a direct strong N_7–metal interaction for both Mg(II) and Ca(II) complexes (Table 1). The greater stability of the N_7–metal interaction in DMSO compared to the stability of the same species in aqueous solution (Table 1) is a solvent effect. In DMSO solution protonation of the N_7-site (ionization of the phosphate group) does not occur, while such protonation was easily observed in D_2O solutions (Table 1).

The N_1H chemical shift at 12.40 ppm did not show major changes in the nmr spectra of Mg(II)– and Ca(II)–IMP compounds (Table 1) which suggests that the N_1H group is not ionized and that it does not participate in metal–ligand bonding. More conclusive evidence regarding the nature of the metal–IMP interaction here is given from infrared spectroscopic studies discussed in the following section.

FT-IR spectra

Structurally known $Ni(IMP)\cdot 5H_2O$ and $Co(IMP)\cdot 5H_2O$ complexes showed (6) that Ni(II) and Co(II) are directly bound to the N_7-atom of the purine ring and coordinated to five H_2O molecules. The carbonyl and the phosphate groups are indirectly bound to the metal ions through coordinated water molecules by hydrogen bonding (5). On the other hand, X-ray structural analysis of the complexes, $[Zn(IMP)]_n$ (7) and $[Cu(IMP)]_n$ (8) showed that the Zn(II) and Cu(II) ions are directly linked to the oxygen atoms of the phosphate group and to the N_7-site of the ring system. In the corresponding, $Cd_2(IMP)_3\cdot 12H_2O$ (9) and $Ca(IMP)\cdot 6.5H_2O$ (10) metal complexes the metals exhibited direct metal–phosphate, metal–N_7, and metal–sugar ($O_{2'}H$ and $O_{3'}H$) binding. Furthermore, X-ray crystal structural studies on $IMPH_2$ (15) and its sodium salts ($IMPNa_2\cdot 7H_2O$ and $IMPHNa\cdot 6H_2O$) (16, 17) showed that the free acid exists in the zwitterionic form, protonated at N_7 and with a negative charge on a phosphate oxygen atom. In the disodium salt structure of IMP^{2-} the sodium ions are sugar and water coordinated (16, 17), whereas the N_7-site, the carbonyl group and the phosphate group are hydrogen bonded with water molecules (17). The FT-IR spectra of the above Cd, Ca, and Na, complexes have been recorded in the region 4000–400 cm^{-1} and compared with the corresponding Mg(II) compounds prepared in this work. The result of the spectroscopic analysis is described here.

In the region 3500 to 2500 cm^{-1} due to the presence of the strong hydrogen bonding network in the free nucleotide (15) and its metal-complexes (6–10) it is very difficult to draw conclusions on the nature of the metal–ligand bonding. The symmetric and asymmetric stretching vibrations of NH, OH, CH, and CH_2 groups of the free nucleotide occur in this region (18–20) and show no considerable changes upon nucleotide–metal complexation.

In the region 1800–400 cm^{-1} one finds drastic spectral changes in the spectra of the complexes, which are discussed below: (*a*) pyrimidine and purine ring vibrations, (*b*) phosphate vibrations, and (*c*) sugar vibrational frequencies.

(*a*) *Pyrimidine and purine ring vibrations.* A broad and strong absorption band at 1682 in the spectra of $IMPNa_2$ assigned to the $C_6{=}O$ stretching frequency (18–20) slightly shifted to higher frequencies in the spectra of Mg(II) and Ni(II) metal complexes except for Cd– and Ca–IMP compounds, where this band appeared at 1663 and 1674 cm^{-1}, respectively (Fig. 1 and Table 2). X-ray structural analysis of the known complexes showed that the carbonyl group was hydrogen bonded with outersphere coordinated water molecules ($M{-}OH_2\cdots O{=}C_6$). The small shift of the $C_6{=}O$ stretching frequency by $\Delta\bar{\nu}$ = 10–20 cm^{-1} is attributed to hydrogen bonded carbonyl or crystal packing effects. Similar spectral changes were observed in the spectra of the new Mg–IMP compounds synthesized here.

The medium intensity band at about 1640 cm^{-1} in all the spectra of N_7-bonded complexes which is not present in the spectrum of the sodium salt, most likely masked by the carbonyl band, could be assigned to the skeletal $C_6{=}C_5$ double bond stretching and to H_2O bending vibration (18–20). The NH bending vibration of the free base was observed at 1590 cm^{-1} and showed only slight changes in the spectra of the N_7-bonded complexes. In the spectrum of the $IMPH_2$ (acid) this band is not observable (Table 2). The absence of this band in the free acid spectrum (N_7-protonated) could be due to the strong and broad carbonyl absorption frequency which obscures the NH bending vibration or to the strong hydrogen bonding of the NH group in the crystal structure of the free acid (15) which could shift the NH bending towards higher frequencies and fall under the carbonyl band. The slight change of the NH bending in the spectral of Ca(II)– and Mg(II)–IMP compounds is consistent with the ^1H nmr chemical shifts of the N_1H group obtained in DMSO solution for the free acid (12.40 ppm), calcium (12.50 ppm) and magnesium (12.50 ppm) mononucleotide complexes (Table 1). It is worth noting that deprotonation of the NH group in inosine at a pH = 9–10 showed (21) disappearance of the NH stretching at 3300 cm^{-1} and the NH bending at 1590 cm^{-1}. The absorption bands at 1550 and 1519 cm^{-1} in the spectra of the free $IMPNa_2$ assigned to ring skeletal vibrations (18–20) showed a small shifting upon ligand metalation (Fig. 1 and Table 2). The shifts are mainly due to protonation or metalation of the N_7-site of the purine ring which perturbs the electronic distribution within the ring system and alters the ring skeletal frequencies.

The medium intensity band at 1481 cm^{-1} in the spectrum of $IMPNa_2$ shifted to lower frequencies at about 1475–1450 cm^{-1} upon nucleotide complexation. Since this absorption band was tentatively assigned (22) to the purine ring $N_7{-}C_8$ stretching and $C_8{-}H$ bending vibrations N_7-metalation or protonation perturbs these vibrations. The frequency changes observed ($\Delta\bar{\nu}$ = 5–30 cm^{-1}) are diagnostic of N_7-coordination of the imidazol ring to the metal, shown from crystallographic analysis (6–10). The N_7-binding of the Mg(II) ion was also demonstrated by proton nmr results obtained in DMSO solution. The chemical shifts of the H_8 of the purine ring in Mg–IMP compounds were similar to those of the corresponding N_7-coordinated, $Ca(IMP)\cdot 6.5H_2O$ compound (Table 1).

The bands centered at about 1370, 1360, 1350, 1250, 1238, and 1216 cm^{-1} in the free base spectrum assigned to the purine ring vibrational frequencies (20, 23) exhibited major intensity changes and shifting in the spectra of the N_7-coordinated complexes (Fig. 1 and Table 2). The assignment of the above bands to $N_7{-}C_5$, $N_7{-}C_8$, $N_9{-}C_8$, N_9—sugar stretchings and $C_8{-}H$ bending motion is in agreement with previous assignments (1–4). However, it seems that the N_7-electrophile bound perturbs the electron distribution in the ring system, where the vibrations are mostly localized and causes a distortion of the imidazol ring. These vibrations are also diagnostic of N_7-coordination.

The ring breathing mode at 692 cm^{-1} (20) in the spectrum of the sodium salt shifts to lower or higher frequencies depending on the nature of interaction, ie., metal–N_7, metal–phosphate, or metal–sugar interaction (Table 2). This band is sensitive to the nature of N_7-coordination and to the sugar conformational geometry (24).

(*b*) *The phosphate vibrations.* Recently we have reported (1) the vibrational frequencies of the PO_3^{2-} in mononucleotides. The infrared spectrum of 5′-$IMPNa_2$ shows five absorption bands in the region of 1100–400 cm^{-1} which are characteristic of the phosphate group (16, 19). The degenerate and symmetric stretchings of PO_3^{2-} are observed as sharp and strong absorption bands at 1090 and 977 cm^{-1}, respectively, while the P—O asymmetric stretching occurs at about 800–700 cm^{-1}. The

other two bands are observed at 530 and 470 cm^{-1} and are assigned to the PO_3^{2-} symmetric and degenerate deformation modes, respectively (1). The two bands at 1090 and 977 cm^{-1} show major modifications (shifting and splitting) upon direct metal–phosphate bonding. In the spectra of $[Cu(IMP)]_n$, $[Zn(IMP)]_n$, $Cd_2(IMP)_3\cdot 12H_2O$, and $Ca(IMP)\cdot 6.5H_2O$ complexes which by X-ray structural analysis (7–10) showed direct metal–phosphate binding, the bands at 1090 and 977 cm^{-1} exhibited shifting and splitting as well as major intensity changes (Fig. 1 and Table 2). The above bands did not show considerable changes in the spectra of $Ni(IMP)\cdot 5H_2O$ and $Co(IMP)\cdot 5H_2O$ complexes, where an indirect metal–phosphate interaction via two coordinated water molecules ($P—\bar{O} \cdots H_2O—M—OH_2 \cdots \bar{O}—P$) was shown by X-ray analysis (6) (Fig. 1 and Table 2). The phosphate vibrational frequencies in the spectra of $Mg_2(IMP)_3\cdot 15H_2O$ showed marked similarities with the spectra of the crystallographically studied Cd(II), Ca(II), Zn(II), and Cu–IMP complexes (Fig. 1 and Table 2). This is indicative of a direct Mg—phosphate binding for $Mg_2(IMP)_3\cdot 15H_2O$, whereas the spectrum of $Mg(IMP)\cdot 5H_2O$ exhibited distinct spectral similarities with the spectra of the corresponding Ni(II) and Co(II) compounds (Fig. 1) which contain an indirect metal—phosphate linkage through coordinated water molecules. Similar observations (1) were made for the PO_3^{2-} vibrational frequencies at 1090 and 977 cm^{-1} in the spectra of $Cu_3(GMP)_3\cdot 8H_2O$, where a direct Cu—phosphate binding as well as, N_7-coordination were reported from X-ray crystal analysis (25). On the other hand, no considerable changes were observed for these vibrational frequencies in the spectra (1) of $Ni(GMP)\cdot 5H_2O$ and $Co(GMP)\cdot 5H_2O$ complexes (26).

(*c*) *Sugar vibrational frequencies*. The symmetric and asymmetric stretching vibrations of the sugar OH, CH, and CH_2 groups in mononucleotides have been observed (18, 19, 27) in the region 3600–2700 cm^{-1} overlapping with the NH, NH_2 stretchings of the base moiety and the H_2O of the metal-hydrated water molecules. Other vibrational frequencies related to the ribose ring are also appearing as sharp and fine absorption bands in the region 1400–400 cm^{-1} which are also obscured by the strong and broad absorption bands of the phosphate group and the base moiety. The assignment of the absorption bands related to the sugar frequencies is a difficult task. Metalation of the phosphate group in mononucleotides was found to be helpful in assigning the phosphate vibrational frequencies (1–4). The sodium ions in both $IMPNa_2$ and IMPHNa (16, 17) are bound directly to $O_{2'}H$ and $O_{3'}H$ of the sugar hydroxyl groups and to four water molecules (no direct interaction with the phosphate group or the N_7-atom of the base moiety exists here). The Cd(II) and Ca(II) cations are directly bound to the $O_{2'}H$ and $O_{3'}H$ hydroxyl groups as well as to the N_7-site and the phosphate oxygen atoms in $Cd_2(IMP)_3\cdot 12H_2O$ and $Ca(IMP)\cdot 6.5H_2O$ complexes (9, 10). On comparison of the infrared spectra of the Na–, Cd–, and Ca–IMP compounds with the corresponding Ni and Co complexes they showed no metal–sugar interaction (6). One can see the presence of a strong absorption band at 1120 cm^{-1} in the spectrum of the sodium salt which is not present in the spectra of Ni– and Co–IMP compounds. This band splits into two strong components in the spectra of the Cd– and Ca–IMP compounds (Fig. 1). The shifting and splitting of this band in the spectra of Cd and Ca complexes is characteristic of sugar coordination and thus the band at 1120 cm^{-1} is assigned to the sugar C—O stretching frequency. It is interesting to note that the infrared spectra of $Mg_2(IMP)_3\cdot 15H_2O$ showed marked similarities with the corresponding Cd complex (shifting and splitting of the band at 1120 cm^{-1} to 1153 and 1111 cm^{-1}) indicating a direct Mg–sugar interaction, through the hydroxyl groups. On the other hand in the spectra of the $Mg(IMP)\cdot 5H_2O$ compound only the strong and broad absorption band of the PO_3^{2-} degenerate frequency was observed (Fig. 1) as in the case of the $Ni(IMP)\cdot 5H_2O$ which contains no metal–sugar interaction. Other sugar–phosphate bands (27) in the region 900–600 cm^{-1} also exhibited splitting and shifting as well as intensity changes (Fig. 1 and Table 2) depending upon the nature of metal–ligand bonding (N_7-, phosphate or sugar). These changes can be related to conformational changes in the sugar ring upon complexation (24). It should be added that the infrared spectra of $Co(IMP)\cdot 5H_2O$ was similar to that of $Ni(IMP)_5\cdot 5H_2O$ and that of $[Zn(IMP)]_n$ was similar to $[Cu(IMP)]_n$ also studied in this work.

The proposed coordination of the Mg(II) ion in $Mg(IMP)\cdot 5H_2O$ is similar to the well known $Ni(IMP)\cdot 5H_2O$ and $Co(IMP)\cdot 5H_2O$ complexes. The $Mg_2(IMP)_3\cdot 15H_2O$ compound is similar to crystallographically known $Cd_2(IMP)_3\cdot 12H_2O$. One Mg(II) ion binds to two N_7-atoms and to a phosphate oxygen atom as well as to H_2O molecules, whereas the second Mg(II) ion is linked directly to the $O_{2'}H$ and $O_{3'}H$ sugar hydroxyl groups and to the N_7-atom as well and to water molecules as in the case of Cd (9).

The reactions of $MgCl_2\cdot 6H_2O$ with $IMPH_2$ are summarized as follows:

$$MgCl_2\cdot 6H_2O + IMPH_2 \xrightarrow[pH\,=\,7.5]{NaOH} \begin{cases} \xrightarrow{2:3} Mg_2(IMP)_2(IMPNa_2)\cdot 15H_2O + 4NaCl \\ \xrightarrow{1:1} Mg(IMP)\cdot 5H_2O + 2NaCl \end{cases}$$

Summary

Correlation between X-ray structural information and infrared spectroscopic changes in the Ni–, Co–, Cu–, Zn–, Cd–, Ca– (N_7-coordinated) and Na–IMP (free from N_7-coordination) compounds investigated here allow assignment of the vibrational frequencies in IMP^{2-}. It is known that the purine ring vibrational frequencies are strongly coupled and that an individual assignment of each band is difficult to make. However, the unambiguous X-ray structural results of several N_7-metal coordinated compounds together with their spectra helped us to make the following findings:

(*1*) The N_7-metal bound IMP^{2-} anion shows considerable changes in the bands centered around 1480–1217 cm^{-1} which originate from the purine ring vibrational frequencies,

(*2*) The indirect metal–carbonyl interaction via a metal-coordinated water molecule only slightly shifts the carbonyl stretching frequency to lower frequencies,

(*3*) The direct coordination of the phosphate oxygen atoms

to the metal ion causes shifting and splitting of the phosphate bands at 1090 and 977 cm^{-1}, while the indirect metal–phosphate interaction through metal-coordinated water molecules does not perturb considerably the positions of these absorption bands,

(*4*) The absorption band at 1120 cm^{-1} in the spectrum of $IMPNa_2$ is definitely assigned to the sugar C—O stretching frequency, and

(*5*) The X-ray powder diagrams of the Mg–IMP complexes showed no isomorphic features with that of the corresponding Ca-compound. This is most likely due to the smaller coordination number (28) of the Mg(II) ion (C.N. = 6) in the above compound compared to the Ca(II) ion (C.N. = 8). On the other hand, there were marked similarities between the X-ray powder diagrams of $Mg_2(IMP)_3 \cdot 15H_2O$ with that of the $Cd_2(IMP)_3 \cdot 12H_2O$, indicating similar coordination environments in these metal complexes.

In this paper we report on the excited-state energetics of the two lowest-lying intravalence electronic excitations $S_0 \rightarrow S_1^x$ and $S_0 \rightarrow S_1^y$ of a large van der Waals complex, consisting of Ar bound to free-base porphine (H_2P). $H_2P \cdot Ar_n$ complexes were synthesized and interrogated by laser-induced fluorescence in seeded supersonic expansions of Ar and He/Ar. Diagnostic methods, which were based on the dependence of the intensity of the spectral features on the stagnation pressure and on spectroscopy in He(99%)/Ar(1%) mixtures, were utilized for the identification of the vibrationless electronic excitations of $H_2P \cdot Ar_1$. The spectroscopic data were supplemented by model calculations of the potential surface, which demonstrate that the single equilibrium configuration of $H_2P \cdot R_1$ (R = Ne, Ar, Kr, and Xe) corresponds to the R atom being located at the twofold symmetry axis perpendicular to the porphyrin ring. While the intense $S_0 \rightarrow S_1^y$ transition of $H_2P \cdot Ar_1$ exhibits a red, dispersive, microscopic solvent shift ($\delta\nu = -24$ cm^{-1}), the $S_0 \rightarrow S_1^x$ transition is characterized by a blue microscopic spectral shift ($\delta\nu = +8$ cm^{-1}), which provides a unique example for excited-state destabilization, originating from intramolecular configurational changes induced by van der Waals binding in a large complex.

UZI EVEN, JOSHUA JORTNER et ZIVA BERKOVITCH-YELLIN. Can. J. Chem. **63**, 2073 (1985).

On a déterminé les niveaux d'énergie de l'état excité des deux excitations électroniques intravalence ayant les plus bases énergies, soit $S_0 \rightarrow S_1^x$ et $S_0 \rightarrow S_1^y$, d'un vaste complexe de van der Waals qui comprend du Ar lié à de la porphine (H_2P) existant sous une forme libre. On a synthétisé les complexes $H_2P \cdot Ar_n$ et on les a examiné à l'aide de fluorescence induite par un laser dans des expansions supersoniques ensemencées de Ar et de He/Ar. Dans le but d'identifier les excitations électroniques sans vibrations de $H_2P \cdot Ar_1$, on a utilisé des méthodes d'évaluation qui sont basées sur la relation qui existe entre l'intensité des caractéristiques spectrales et la pression de stagnation ainsi que sur la spectroscopie dans des mélanges à 99% He/1% Ar. On a utilisé les données spectrales de concert avec des calculs modèles de la surface de potentiel qui démontrent que la seule configuration d'équilibre du $H_2P \cdot R_1$ (R = Ne, Ar, Kr et Xe) correspond à celle dans laquelle l'atome R se trouve au niveau de l'axe de symétrie binaire qui est perpendiculaire au noyau de la porphyrine. Alors que la transition intense $S_0 \rightarrow S_1^y$ du $H_2P \cdot Ar_1$ présente un déplacement microscopique dû au solvant qui soit dispersif et qui se déplace vers le rouge ($\delta\nu = -24$ cm^{-1}), la transition $S_0 \rightarrow S_1^x$ est caractérisée par un déplacement spectral microscopique vers le bleu ($\delta\nu = +8$ cm^{-1}); ces résultats correspondent à un exemple unique de déstabilisation de l'état excité provenant de changements configurationnels intramoléculaires qui sont induits par un couplage de van der Waals dans un vaste complexe.

[Traduit par le journal]

I. Introduction

We have recently explored the excited-state energetics and dynamics of large van der Waals (vdW) complexes ($M \cdot R_n$), consisting of rare-gas (R) atom(s) bound to a large aromatic hydrocarbon (M), which were synthesized and interrogated in supersonic expansions (1–4). The microscopic solvent shift (1), $\delta\nu$, for the electronic origin of the $S_0 \rightarrow S_1$ intravalence $\pi\pi^*$ transition of such vdW complexes originates from the following additive effects (1–4): (1) dispersive interactions, providing an extra stabilization of S_1 which results in a red spectral shift. These are exhibited for vdW complexes containing the heavy rare gases, e.g., Ne, Ar, Kr, and Xe; (2) short-range repulsive interactions which result in a blue spectral shift. This effect dominates the spectral shifts of $M \cdot He$ complexes for which the effects of dispersive interactions are minor.

The complexing of porphyrins and the elucidation of microscopic solvent effects on their excited-state energetics and dynamics is a subject of considerable physical, chemical, and biophysical interest. With this goal in mind, we have extended our studies of vdW complexes to investigate the electronic–vibrational excitations of complexes of porphyrins with molecular ligands (5) and with rare-gas atoms. Our studies of the electronic excitations of the complexes of porphyrins with molecular ligands (5) resulted in a wealth of information regarding microscopic spectral shifts. From the point of view of general methodology, the elucidation of the spectroscopy of porphyrin – rare-gas complexes will be of considerable interest. In this paper we report on the two lowest-lying electronic excitations of the $H_2P \cdot Ar$ complex, consisting of Ar bound to free-base porphine (H_2P). This system is of interest for several reasons. Firstly, from the spectroscopic point of view, H_2P is the most interesting porphyrin, so that spectroscopic studies of its vdW complexes are pertinent. Secondly, spectroscopy of large vdW complexes combined with theoretical simulations of their potential surfaces (2, 3) are expected to provide information pertaining to the structure of these complexes and bears on the question of the existence of chemical isomers of large vdW molecules (1–3). It will be interesting to extend the scope of previous studies for aromatic hydrocarbons to porphyrins. Thirdly, the energetics of the electronic excitations of porphyrin–R complexes will result in novel information on microscopic solvent spectral shifts.

II. Experimental

We have studied the laser-induced fluorescence (LIF) excitation spectra of H_2P and its Ar complexes in pulsed, seeded, supersonic expansions of He, Ar, and He + Ar mixtures, utilizing the techniques

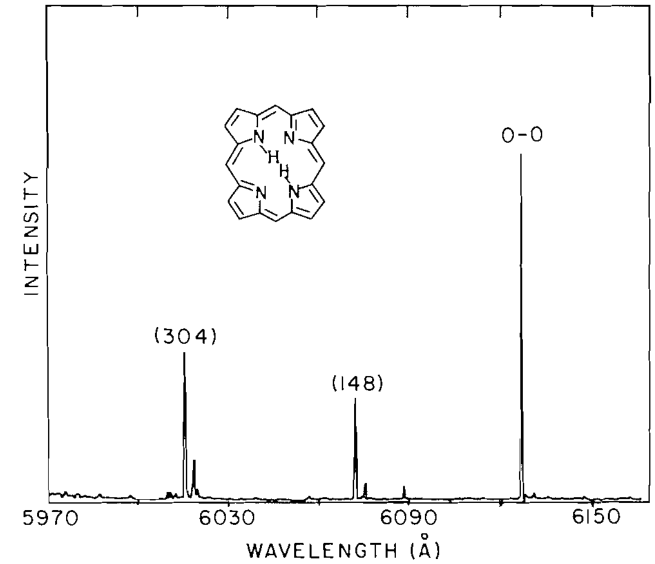

FIG. 1. The LIF spectrum in the region 5970–6160 Å of the H_2P molecule seeded in pulsed supersonic expansions of He. H_2P was heated in the nozzle chamber to 330°C, seeded in He at p = 2000 Torr, and expanded through the 0.06-cm nozzle. The exciting dye laser crossed the jet at 12 mm down the nozzle.

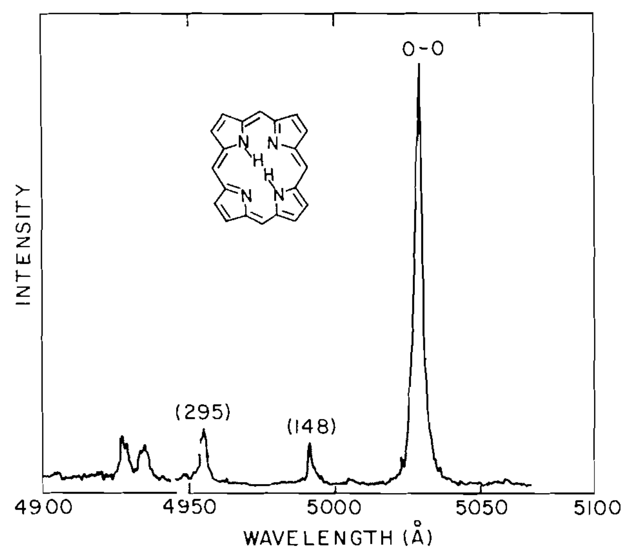

FIG. 2. The LIF spectrum in the region 4900–5100 Å of H_2P in pulsed supersonic expansions of He. Experimental conditions as in Fig. 1.

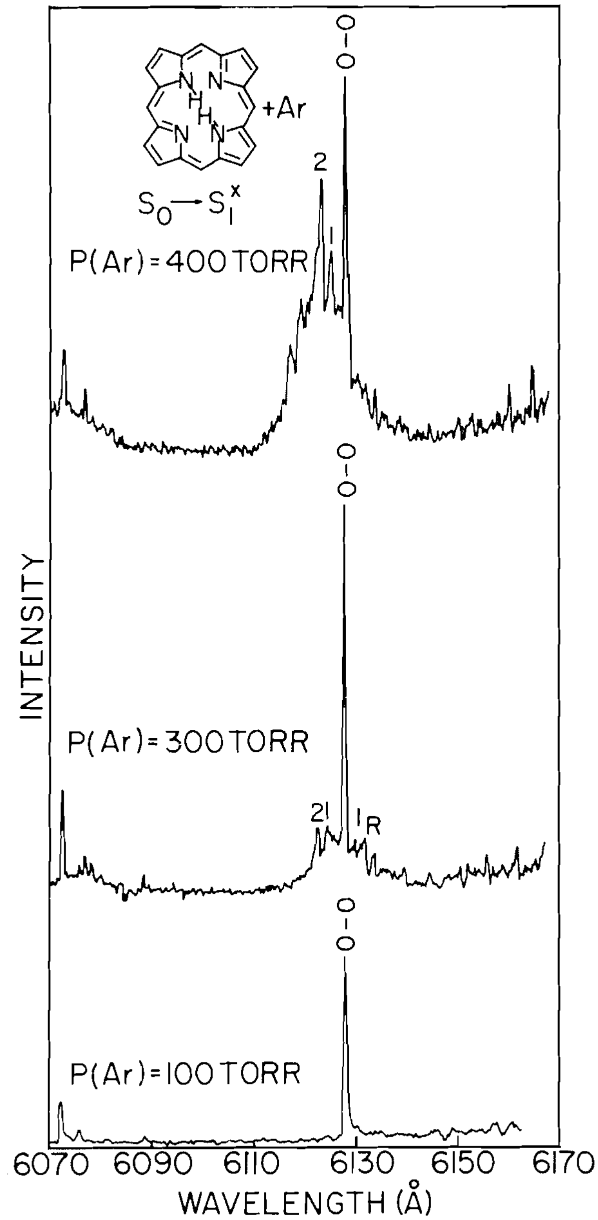

FIG. 3. The LIF spectra of H_2P in the range 6070–6170 Å in pulsed jets of Ar. The stagnation pressures of Ar are indicated on the spectra. All other experimental conditions as in Fig. 1. The $S_0 \rightarrow S_1^x$ electronic origin of the bare molecule is labelled 0–0. The spectral feature (1_R) corresponds to a hot band and the spectral features (1 and 2) attributed to the $S_0 \rightarrow S_1^x$ transition of $H_2P \cdot Ar_n$ (n = 1, 2) are marked.

previously described (6–8). A solid sample of H_2P (commercially obtained from Porphyrin Products, U.S.A.) was heated in the nozzle chamber to 330°C (vapor pressure 0.2 Torr (9); (1 Torr = 133.3 Pa). The H_2P molecule could effectively be cooled in supersonic expansions of Ar at the stagnation pressure p = 100–150 Torr and in He at p = 1500–2500 Torr, with the nozzle diameter being D = 600 μm. The LIF spectra obtained under these conditions correspond to the bare H_2P molecule, rather than to rare-gas – H_2P vdW complexes, as the spectra were identical in He and Ar. No spectroscopic evidence was obtained for the formation of He–H_2P vdW complexes under our experimental conditions. Ar–H_2P vdW complexes were synthesized in the following jets: (1) seeded expansions of Ar at p = 150–1500 Torr, and (2) seeded expansions of Ar + He mixtures containing 1–10% Ar expanded at p = 1500–2200 Torr. This preparation method results in the formation of $H_2P \cdot Ar_n$ vdW complexes with a low coordination number n, yielding preferably to complexes with n = 1. In addition, work on other large complexes (10) indicates that this preparation method allows for effective internal cooling of the vdW complex.

III. The $S_0 \rightarrow S_1^x$ transition of the $H_2P \cdot Ar_1$ complex

The lowering of the D_{4h} symmetry of the porphyrin ring by the H···H proton axis in H_2P results in the splitting of the Q band into two electronic transitions, ie., the $S_0 \rightarrow S_1^x$ transition (the Q_x band) and the $S_0 \rightarrow S_1^y$ transition (the Q_y band) (11). Figures 1 and 2 show portions of the LIF excitation spectrum of H_2P in the spectral ranges 5970–6140 Å and 4900–5050 Å, which exhibit the electronic origin of the $S_0 \rightarrow S_1^x$ transition (Fig. 1) at 16 320 cm^{-1} and the electronic origin of the $S_0 \rightarrow S_1^y$ transition (Fig. 2) located at 19 884 cm^{-1}, together with the lowest vibrational excitations in these two electronic states. Figure 3 shows the LIF spectrum of H_2P in Ar at p = 100–400

[c]See Fig. 3.
[d]Positive and negative values of $\delta\nu$ refer to blue and red spectral shifts, respectively.

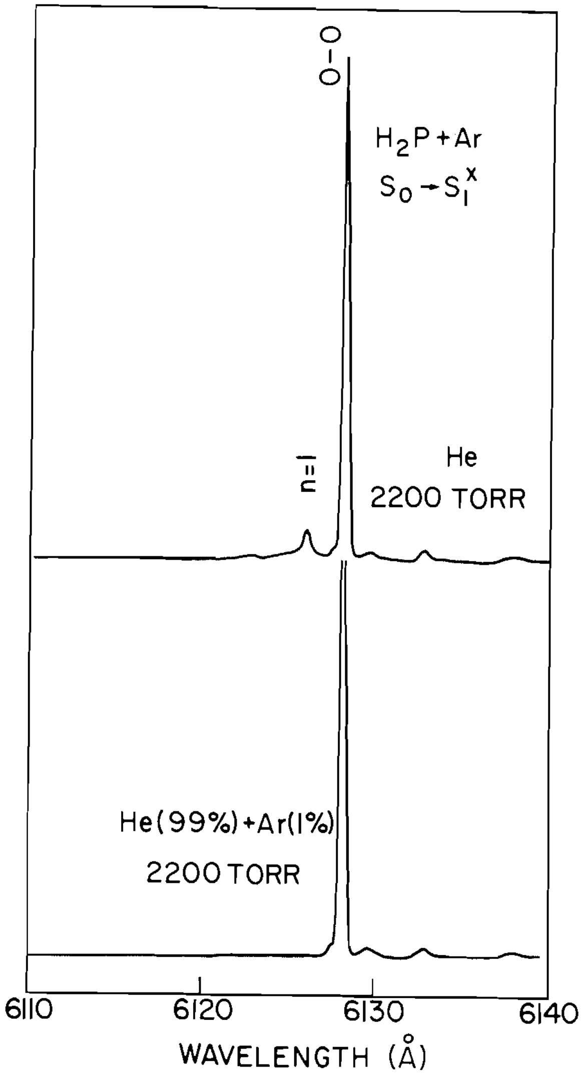

FIG. 4. The LIF spectrum of H_2P in pulsed jets of He (upper spectrum) and in a mixture of He (99%) + Ar (1%) (lower spectrum). The $S_0 \rightarrow S_1^x$ origin of $H_2P \cdot Ar_1$ is marked $n = 1$.

Torr over the range 6050–6170 Å. At p = 100 Torr only the electronic origin of the $S_0 \rightarrow S_1^x$ transition of the bare H_2P molecule is exhibited. With increasing stagnation pressure new spectral features are exhibited in Fig. 3, which involve the following two distinct types.

1. A low-energy absorption, which is red-shifted relative to the 0–0, whose relative intensity depends very weakly on the stagnation pressure (Table 1). Such low-energy absorption, which is almost devoid of any pronounced structure except a feature at $\delta\nu = -10.6$ cm^{-1}, is tentatively attributed to sequence bands and (or) hot bands of the complexes. This low-energy absorption becomes somewhat more pronounced at higher stagnation pressures of Ar due to local heating effects accompanying the formation of $H_2P \cdot Ar_n$ complexes.

2. Satellite bands appearing on the high-energy side of the electronic origin. These distinct spectral features (Fig. 3) are characterized by the following features: (*i*) their intensities depend strongly on the stagnation pressure; (*ii*) at higher pressures the spectral features at higher energies become more prominent. These properties are characteristic of vdW complexes. Accordingly, the high-energy satellite bands (Table 1) are attributed to the electronic origins of the $S_0 \rightarrow S_1^x$ transitions of $H_2P \cdot Ar_n$ vdW complexes, where the H_2P molecule within the complex is retained in its vibrationless state.

The spectroscopic data in Ar jets are insufficient to provide information concerning the composition of the $H_2P \cdot Ar_n$ vdW complexes. A conclusive spectroscopic identification of the spectral features of the $H_2P \cdot Ar_1$ complex was obtained from the spectra of H_2P seeded supersonic expansions of 99% He plus 1% Ar. From Fig. 4 it is evident that a new spectral feature at the high energy side of the electronic origin of the bare molecule is exhibited in the He + Ar mixture, which is absent in the bare molecule spectrum. As this new spectral feature appears in an He–Ar diluent of low Ar content (1%), it is attributed to the $H_2P \cdot Ar_1$ complex. As is apparent from Table 1, the energy of this spectral feature, corresponding to $H_2P \cdot Ar_1$ synthesized in an He + Ar mixture, coincides within experimental uncertainty with the energy of the lowest-lying excitation of the $H_2P \cdot Ar_n$ complexes of an unidentified composition observed in the pure Ar diluent. We also note in Fig. 4 the absence of any type 1 absorption on the low energy side of the bare molecule cooled in He + Ar. The absence of type 1 absorption in the He + Ar diluent provides some additional support to the assignment of this structureless low-energy absorption in Ar to sequence and (or) hot bands of $H_2P \cdot Ar_n$ complexes. The cooling accomplished in the He + Ar (1%) at p = 2200 Torr mixture is more efficient in precluding the appearance of these sequence and (or) hot bands.

On the basis of the identification of the spectral feature of the $H_2P \cdot Ar_1$ complex in He + Ar (1%) diluent, we can assign the excitation of this vdW complex in pure Ar (Fig. 3 and Table 1).

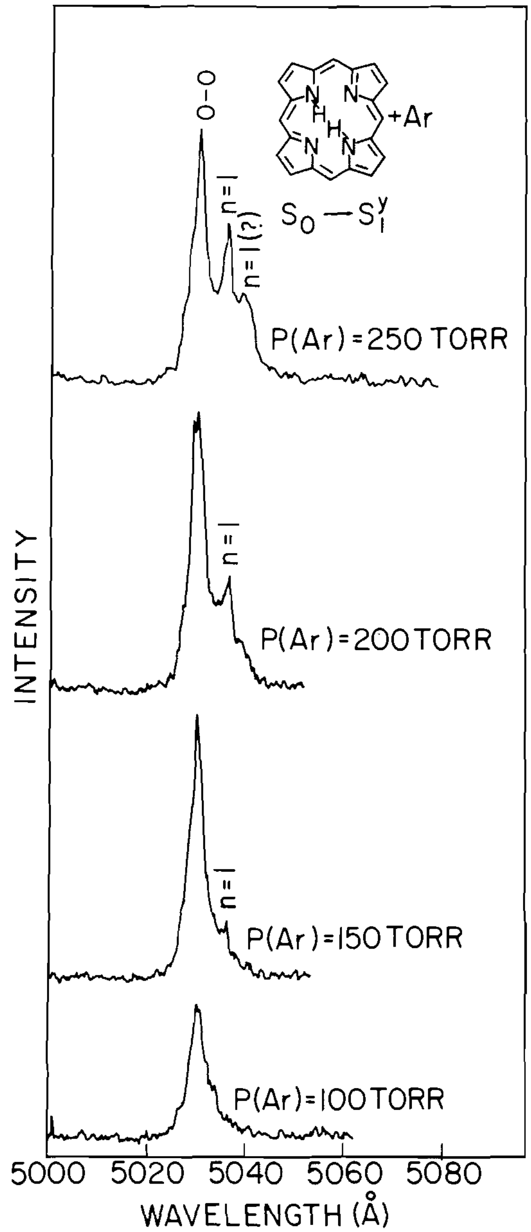

FIG. 5. The LIF spectrum of H_2P in the range 5000–5080 Å in pulsed jets of Ar. The Ar stagnation pressures are indicated on the spectra. The $S_0 \rightarrow S_1^y$ electronic origin of the bare molecule is labelled 0–0. $n = 1$ marks the spectral features attributed to the $S_0 \rightarrow S_1^y$ excitation of $H_2P \cdot Ar_1$.

The spectra of H_2P in Ar (Fig. 3) reveal additional satellite bands (Fig. 3 and Table 1) on the high energy side of the $H_2P \cdot Ar_1$ excitation, which are due to $H_2P \cdot Ar_n$ complexes with a higher $n > 1$, as yet unspecified, coordination number. A serious problem, which precludes the identification of the electronic origins of the $S_0 \rightarrow S_1^x$ transition of $H_2P \cdot Ar_n$ complexes ($n > 1$) in the Ar diluent, involves the excessive line broadening of their spectral features relative to the origin of the bare molecule (Fig. 3). This line broadening of the spectral features of the $S_0 \rightarrow S_1^x$ transition of $H_2P \cdot Ar_n$ complexes originates from: (*1*) rotational broadening effects, which are not expected to differ significantly from those of the bare molecule; (*2*) sequence and hot vibrational transitions involving the intermolecular low frequency vibrations of the Ar atoms(s) relative to the H_2P ring. The internal cooling of the intermolecular vibrational degrees of freedom of the complexes in the Ar diluent is insufficient to eliminate this thermal inhomogeneous broadening. It appears that the internal cooling in the He + Ar diluent (Fig. 4) is superior, providing a safe assignment of the electronic origin of $H_2P \cdot Ar_1$.

The identification of the spectral feature of the origin of the $S_0 \rightarrow S_1^x$ transition of $H_2P \cdot Ar_1$ (Table 1) leads to the following conclusions: (a) only a single spectral feature is exhibited; (b) the microscopic solvent shift of the electronic origin of the $S_0 \rightarrow S_1^x$ transition of H_2P in the $H_2P \cdot Ar_1$ complex relative to the bare molecule is $\delta\nu = +8 \pm 1$ cm^{-1} towards higher energies. Before alluding to the nature of this blue spectral shift, it is imperative to obtain supplementary information about the energetics of the electronic origin of the $S_0 \rightarrow S_1^y$ second electronic excitation of $H_2P \cdot Ar_1$.

IV. The $S_0 \rightarrow S_1^y$ transition of the $H_2P \cdot Ar_1$ and higher complexes

The electronic–vibrational excitations within the S_1^y manifold of bare H_2P exhibit appreciable line broadening due to intramolecular $S_1^y \rightarrow S_1^x$ electronic relaxation, the homogeneous linewidth of the electronic origin being $\delta = 11$ cm^{-1}, which corresponds to an intramolecular relaxation lifetime of 0.5 ps (8). This homogeneous relaxation line broadening is expected to be exhibited also for the $S_0 \rightarrow S_1^y$ transition of $H_2P \cdot Ar_n$ complexes and may mask the spectral features of these vdW molecules. Fortunately, we have found that the energetic separation between the electronic origin of the $S_0 \rightarrow S_1^y$ transition of bare H_2P and its complexes with Ar is sufficiently large relative to δ, so that well-characterized spectral features of the $S_0 \rightarrow S_1^y$ transition of $H_2P \cdot Ar_n$ complexes are amenable to observation and analysis.

In Figs. 5 and 6, we present the LIF spectra of H_2P in the vicinity of the electronic origin of the $S_0 \rightarrow S_1^y$ transition. These spectra of H_2P in Ar jets (Fig. 5) and in He + Ar jets (Fig. 6) clearly exhibit new spectral features on the low energy side of the electronic origin of the bare molecule, which are attributed to the vibrationless $S_0 \rightarrow S_1^y$ excitation of $H_2P \cdot Ar_n$ complexes. The intensities of these spectral features exhibit a strong dependence on the stagnation pressure, p, in Ar jets (Fig. 5) and on the partial pressure of Ar, p(Ar), in He + Ar jets. This pressure dependence enabled us to identify and characterize these well-resolved spectral features.

The two highest-energy spectral features corresponding to the $S_0 \rightarrow S_1^y$ vibrationless excitations of $H_2P \cdot Ar_n$ complexes are located at the energies -24 ± 1 cm^{-1} and -34 ± 1 cm^{-1} below the electronic origin of the bare molecule (Figs. 5 and 6 and Table 2). As is apparent from Fig. 7, the peak intensity, I, of the prominent spectral feature at -24 cm^{-1} relative to the peak intensity of the 0–0 transition of the bare molecule is given by the simple relations $I \propto p^2$ for pure Ar and $I \propto p$(Ar) for the He + Ar diluent. Accordingly, the -24-cm^{-1} feature, labelled as vdW(1), is attributed to the $H_2P \cdot Ar_1$ complex, which is formed by the three-body collision process

$$[1] \quad H_2P + Ar + Ar \rightarrow H_2P \cdot Ar_1 + Ar$$

in pure Ar, and

$$[2] \quad H_2P + Ar + He \rightarrow H_2P \cdot AR_1 + He$$

in He + Ar. The weaker spectral feature at -34 cm^{-1}, labelled as vdW(2), seems to exhibit qualitatively the same dependence on the stagnation pressure as vdW(1) (Fig. 7), and is tentatively also attributed to $H_2P \cdot Ar_1$ (Table 2). At high pressures of the

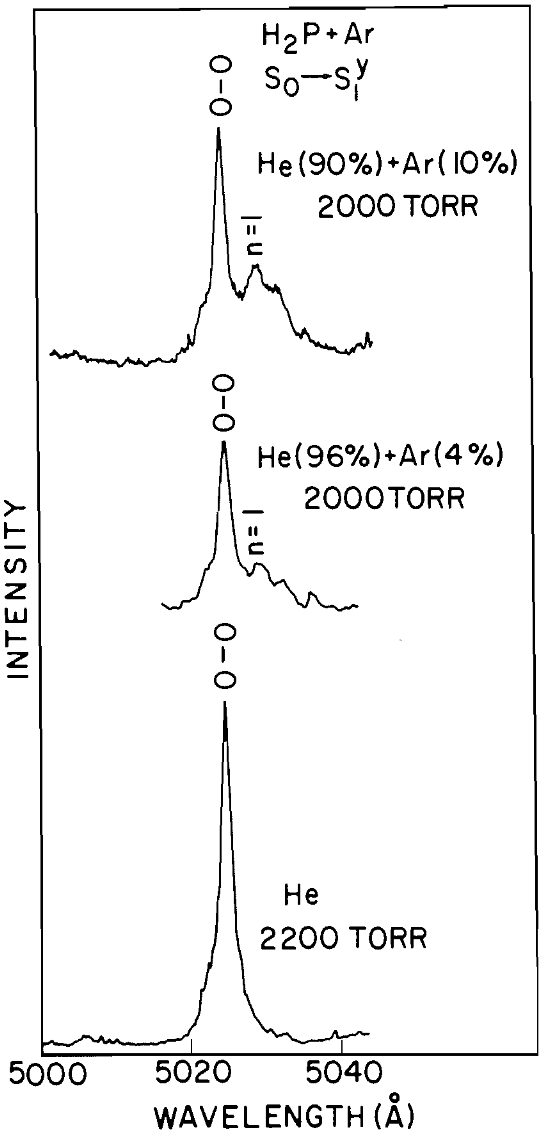

FIG. 6. The LIF spectra of H_2P in pulsed jets of He and of He/Ar mixtures at the compositions marked on the spectra. Labelling of the spectral features as in Fig. 5.

Ar diluent the lower energy features become more prominent (Fig. 8). At p = 300 Torr (Fig. 8) spectral structures due to excitations of individual $H_2P \cdot Ar_n$ complexes are well exhibited. On the basis of its order of appearance (1, 2), we tentatively attribute the spectral feature at -42 cm^{-1} below the electronic origin of bare H_2P to the $H_2P \cdot Ar_2$ complex. At higher pressures of Ar, p = 600–1200 Torr (Fig. 8), extensive complexing with Ar is exhibited, as is evident from the disappearance of the 0–0 excitation of the bare molecule. The spectra in this high p range are broad and structureless. The maximum of the broad band shifts gradually to lower energies with increasing p (Table 2). These spectra are attributed to large $H_2P \cdot Ar_n$ clusters with a high ($n > 2$) coordination number. The excessive line broadening originates from three causes: (*1*) inhomogeneous broadening originating from the overlap of spectral features of a variety of $H_2P \cdot Ar_n$ complexes with various coordination numbers; (*2*) homogeneous broadening due to phonon broadening effects of the absorption of $H_2P \cdot Ar_n$ molecules with a well-characterized structure and coordination number n; (*3*) homogeneous broadening due to intramolecular re-

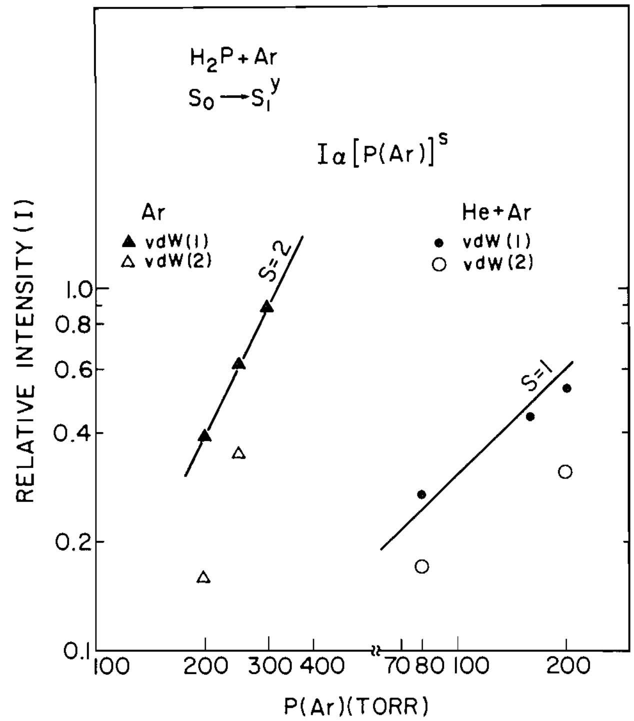

FIG. 7. The dependence of the peak intensities of the spectral features, which correspond to the $S_0 \rightarrow S_1^y$ electronic excitations of $H_2P \cdot Ar_n$ complexes on the stagnation pressure of Ar (in Ar jets) and on the partial stagnation pressure of Ar (in He + Ar) jets. The pressure dependence of both features (vdW(1)) and vdW(2)) is identical.

laxation of H_2P in the complex. At present we cannot distinguish between the intermolecular contributions (*1*) and (*2*) and the intramolecular contribution (*3*) in these large clusters.

V. Potential surfaces for H_2P – rare-gas complexes

The vibrationless $S_0 \rightarrow S_1^x$ transition of $H_2P\cdot Ar_1$ exhibits a single spectral feature, while the 0–0 $S_0 \rightarrow S_1^y$ transition of this molecule reveals two spectral features. On the basis of these spectroscopic data we were unable to infer whether the multiple spectrum of the vibrationless $S_0 \rightarrow S_1^y$ transition of $H_2P\cdot Ar_1$ originates from the presence of two nearly isoenergetic chemical isomers, whose spectra overlap in the case of the $S_0 \rightarrow S_1^x$ transition, or is due, rather, to other causes (2, 3). One approach towards the elucidation of the structure of large vdW molecules, which bears on the existence of chemical isomers, rests on model calculations of the ground state intermolecular potential surfaces.

We have constructed the potential surfaces for vdW complexes between H_2P and the rare-gas atoms R(Ne, Ar, Kr, and Xe). These model calculations, which rest on the procedure of

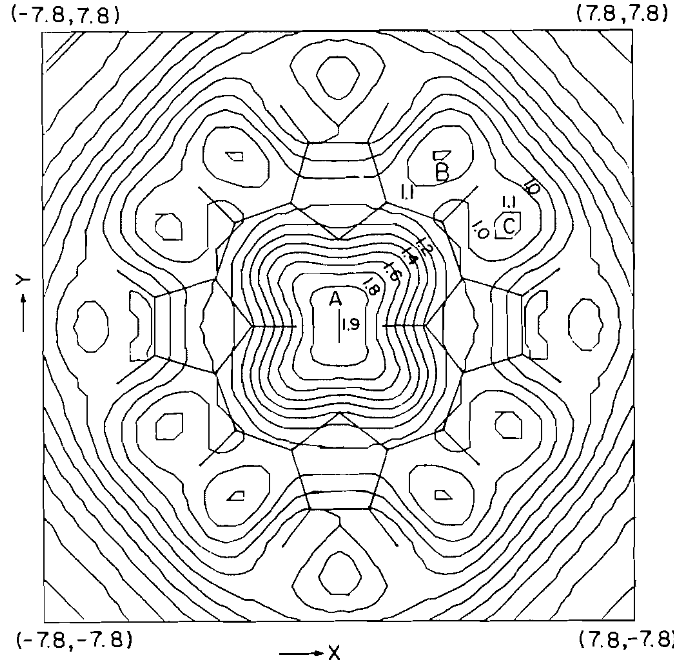

FIG. 9. Contour map for $H_2P\cdot Ar_1$ potential in the plane parallel to the porphyrin ring at a distance z = 3.2 Å from it. Distance points are given in Å units. Energies are given in kcal/mol. Points A, B, and C constitute the three points of minimum energy with point A being characterized by the lowest energy (see Table 4).

Jortner and co-workers (2, 3), provide information on the equilibrium configuration and ground-state binding energy of $H_2P\cdot R_1$ complexes and establish the energetic stability of chemical $H_2P\cdot R_1$ isomers with geometrically inequivalent sites for the R atom. The potential energy, V, for the nuclear motion of Ar in the $H_2P\cdot R_1$ complex was constructed as a superposition of pairwise atom–atom potentials between each of the C, N, and H atoms of H_2P and the R atom (3)

$$[3]\quad V(\{r_\beta\}) = \sum_\beta A_\beta\{-r_\beta^{-6} + [(r_\beta^0)^6/2]\, r_\beta^{-12}\}$$

where $r_\beta = |\boldsymbol{r} - \boldsymbol{r}_\beta|$ is the distance between the R atom located at the position $\boldsymbol{r}$, and the β-th atom of H_2P, which is located at $\boldsymbol{r}_\beta$. Three sets of potential parameters for A_β and r_β^0 were used:

Set 1: The R—C pair potential (PP) was taken from the heats of absorption of rare-gas atoms on graphite. The R—N PP was taken to be equal to the Ar—C PP. The Ar—H PPs were taken from our previous work (3).

Set 2: Using the Buckingham PP for H—H and C—C given by Mirsky (12) and the R—R potential (13), we have estimated the R—C and R—H PP using the combination rules (13). The N—R PP was taken to be equal to that of the C—R PP.

Set 3: The same as Set 1 for the C—R and the H—Ar PPs. The N—R potential was estimated from the N—N PP parameters of Hill (14).

The geometry of the H_2P ring was taken from crystallographic data. The two internal protons were assumed to be located in the porphyrin plane.

Figure 9 shows the potential surface of $H_2P\cdot Ar_1$ parallel to the H_2P xy plane at a distance of z = 3.2 Å from it, which was calculated by using Set 1 of the PPs. As is apparent from Fig. 9, three points of minimum energy are exhibited, which are labelled as A, B, and C. At this z = 3.2 Å distance, the points A, B, and C correspond to the absolute energy minima for the

TABLE 3. Test of potential parameters for $H_2P \cdot Ar_1$ by the calculation of the three points of minimum energy on the potential surface

	Set 1	Set 2	Set 3

z (Å)	3.2		

three-dimensional potential. Point A corresponds to the Ar atom located on the central twofold symmetry axis of the porphyrin ring, while points B and C are located between the pyrole rings and the *meso* C—H group. To assess the sensitivity of the energetic data for $H_2P \cdot Ar_1$ to the PPs, we present in Table 3 the energies and positions of the minimum energy points A, B, and C. It is apparent that the gross features of the potential surfaces, the energetic data, and the geometries for $H_2P \cdot Ar_1$ are similar for the three sets of the PPs. In view of the uncertainty in the assignment of PPs for the N—Ar (and N—R) interaction, we are somewhat reluctant to use Set 3, which considers explicitly this interaction. Accordingly, all subsequent calculations reported in the present paper were conducted by using Set 1.

From the calculations of the potential surfaces of $H_2P \cdot R_1$ complexes, the following conclusions emerge.

1. For all $H_2P \cdot R_1$ complexes there are three points of minimum energy on each side of the porphyrin ring (Fig. 9 and Table 4).

2. There is a single minimum point of lowest energy (point A) on each side of the ring.

3. The energies of the points B and C, which correspond to the two local minima (Fig. 9 and Table 4), are considerably higher than the energy of point A. The energy difference ΔE_{AB} between points A and B is ΔE_{AB} = 94 cm^{-1} for Ne, ΔE_{AB} = 241 cm^{-1} for Ar, ΔE_{AB} = 262 cm^{-1} for Kr, and ΔE_{AB} = 405 cm^{-1} for Xe, while the energy difference, ΔE_{AC}, between points A and C is ΔE_{AC} = 137 cm^{-1} for Ne, ΔE_{AC} = 273 cm^{-1} for Ar, ΔE_{AC} = 318 cm^{-1} for Kr, and ΔE_{AB} = 437 cm^{-1} for Xe.

4. The energy differences ΔE_{AB} and ΔE_{AC} considerably exceed the translational energies $kT_t \simeq$ 2–5 K (15) and the intramolecular vibrational energies $kT_V <$ 10–20 K (10), which prevail in the seeded supersonic expansions utilized in our experiments. Accordingly, we expect that only a single isomer of $H_2P \cdot R_1$ corresponding to the localization of the R atom around point A is energetically stable. No other isomers, i.e., conformers corresponding to vibrationally excited states, are expected to be accessible via thermal excitation.

5. The binding energies of the $H_2P \cdot R_1$ molecules are 310 cm^{-1} for $H_2P \cdot Ne_1$, 666 cm^{-1} for $H_2P \cdot Ar_1$, 796 cm^{-1} for $H_2P \cdot Kr_1$, and 990 cm^{-1} for $H_2P \cdot Xe_1$. Although the exact numerical values are only approximate, they indicate relatively large binding energies of an R atom to large aromatic hydrocarbons.

6. The equilibrium configuration of $H_2P \cdot R_1$ complexes corresponds to the R atom located at the twofold symmetry axis perpendicular to the porphyrin ring. The equilibrium distances are z = 2.9 Å for Ne, z = 3.2 Å for Ar, z = 3.3 Å for Kr, and z = 3.4 Å for Xe.

The only serious sin of omission inherent in these model calculations pertains to the role of the two internal H atoms, which were taken to be located in the porphyrin plane. In the bare H_2P molecule the two protons may be displaced out of the porphyrin plane. It is possible that the binding of an R atom to H_2P will modify the intramolecular equilibrium configuration of these two protons.

VI. Concluding remarks

Our spectroscopic studies provide quite extensive information on the $S_0 \rightarrow S_1{}^x$ and $S_0 \rightarrow S_1{}^y$ transitions of the $H_2P \cdot Ar_1$ complex with the porphyrin ring in the complex undergoing vibrationless electronic excitations. The information on microscopic spectral shifts induced by an Ar atom on the vibrationless excitations of H_2P pertains both to structural and energetic information. The facts are (*1*) a single spectral feature for the $S_0 \rightarrow S_1{}^x$ transition of $H_2P \cdot Ar_1$ was observed; (*2*) multiple spectra for the $S_0 \rightarrow S_1{}^y$ transition of $H_2P \cdot Ar_1$ were exhibited, revealing two spectral features; (*3*) the spectral features of the $S_0 \rightarrow S_1{}^x$ transition are blue shifted, being located at $\delta\nu = +8 \pm 1$ cm^{-1}; (*4*) the two spectral features of the $S_0 \rightarrow S_1{}^y$ transition of $H_2P \cdot Ar_1$ are red shifted relative to the 0–0 of the bare molecule, being located at $\delta\nu = -24 \pm 1$ cm^{-1} and at -35 ± 1 cm^{-1}. The main spectral feature is located at −24 cm^{-1}, while the −35-cm^{-1} feature is weaker, with a relative peak intensity of 25%. The observation of a single spectral feature for the $S_0 \rightarrow S_1{}^x$ transition provides (observation (*1*)) spectroscopic evidence for the existence of a single energetically stable structure of the $H_2P\cdot Ar_1$ complex. This conclusion is compatible with the results of our model calculations of the potential surface, which indicate the stability of the single configuration of this complex. Accordingly, we are reluctant to attribute the multiple spectrum consisting of two spectral features separated by 11 cm^{-1} for the $S_0 \rightarrow S_1^y$ transition (observation (*2*)) as originating from the excitation of two nearly isoenergetic isomers of $H_2P\cdot Ar_1$, because such a picture is incompatible with the results of the model calculation, as well as with observation (*1*). It should be borne in mind, however, that our model calculations disregarded the possibility of a configurational change of the H_2P induced by the binding of Ar, which may involve a displacement of the central H atoms. One may argue that the multiple spectrum of the Q_y band of $H_2P\cdot Ar_1$ originates from the contribution of two nearly isoenergetic isomers, where in both cases the Ar is located on the twofold axis of H_2P but differs in the configuration of the two protons. Obviously, observation (*1*) cannot easily be reconciled with such an assumption. The nature of the relatively weak satellite vdW(2) feature of the $S_0 \rightarrow S_1^y$ transition of $H_2P\cdot Ar_1$ requires further study.

The qualitative difference in the signs of the microscopic solvent shifts for the $S_0 \rightarrow S_1^x$ and $S_0 \rightarrow S_1^y$ transitions of $H_2P\cdot Ar_1$ (observations (*3*) and (*4*)) is of considerable interest. The spectral shift of the $S_0 \rightarrow S_1^y$ transition of the complex is $\delta\nu = -24\ cm^{-1}$. Such a red shift is characteristic of dispersive interactions, being ubiquitous in complexes of large organic molecules with heavy rare gases. The dispersive contribution to the spectral shift is expected to be determined by the polarizability α_R of R, and by the oscillator strength, f, for the corresponding electronic transition (4), i.e., $\delta\nu = -\alpha_R(a + bf)$, where a and b are constants. The $S_0 \rightarrow S_1^y$ transition of H_2P, which is characterized by a moderately large oscillator strength ($f \simeq 0.06$) (8, 11), is expected to exhibit an ordinary red spectral shift, being dominated by the dispersive contribution. On the other hand, the oscillator strength for the $S_0 \rightarrow S_1^x$ transition is low ($f \simeq 0.01$) (8, 11), and the contribution of the dispersive excited-state stabilization to the spectral shift for this transition in $H_2P\cdot Ar_1$ is expected to be small. The occurrence of a blue microscopic spectral shift $\delta\nu = +8\ cm^{-1}$ for the $S_0 \rightarrow S_1^x$ transition of $H_2P\cdot Ar_1$ clearly demonstrates that the microscopic solvent shift in this complex is not dominated by dispersive interactions. This blue spectral shift constitutes the first case of energetic destabilization of the excited state of a large vdW complex containing a heavy (Ar) R atom. The blue microscopic spectral shift for the $S_0 \rightarrow S_1^x$ origin of $H_2P\cdot Ar_1$ is attributed to configurational changes within the H_2P molecule induced by the binding of an Ar atom, which presumably involves a displacement of the central H atoms. The manifestation of this configurational change on the energetic destabilization of the electronically excited state is not masked by dispersive interactions, which are small in the present case. We were able to provide a unique example for a new contribution to a microscopic solvent spectral shift, which is due to intramolecular configurational changes induced by vdW binding in a large complex.

All the spectroscopic data for large vdW complexes reported to date pertain to intravalence electronic excitation of such systems. The extension of these studies for the interrogation of extravalence, Rydberg-type, electronic excitations of these large complexes will be of considerable interest. In this case, the major contribution to the microscopic spectral shift will originate from short-range excited-state repulsive interactions, unveiling novel features of solvent perturbations of excited-state energetics, nuclear dynamics, and intramolecular dynamics of extravalence molecular excitations. In this context, the search for Rydberg excitations of porphyrins and their vdW complexes will be of considerable intrinsic interest. It is expected that the novel spectroscopic methods in seeded supersonic jets will unveil the mystery of the Rydberg states of porphyrins, which constitute an important research area pioneered by Sandorfy and co-workers (16).

Azulenium cations. An experimental and theoretical study of the cations derived from hydrocarbon derivatives of azulene

J. W. LEWIS AND R. V. NAUMAN

Department of Chemistry, Louisiana State University, Baton Rouge, LA 70803, U.S.A.

Received August 6, 1984

This paper is dedicated to Professor Camille Sandorfy on the occasion of his 65th birthday

J. W. LEWIS and R. V. NAUMAN. Can. J. Chem. **63**, 2081 (1985).

The ambient temperature ultraviolet absorption and the 77 K luminescence spectra of a series of four hydrocarbon derivatives of azulene in sulfuric acid solution are presented and discussed in detail. CNDO/S calculations have been carried out and the calculational results are compared with the experimental results. The phosphorescences of these cationic species are reported for the first time. The present results suggest that an inversion in the order of electronic states is perhaps responsible for the normal emissions of the protonated species and the anomalous emissions of the parent molecules.

J. W. LEWIS et R. V. NAUMAN. Can. J. Chem. **63**, 2081 (1985).

Opérant en solution dans de l'acide sulfurique, on a mesuré les spectres d'absorption ultraviolette à la température ambiante et les spectres de luminescence à 77 K d'une série de 4 hydrocarbures dérivant de l'azulène; on en discute en détail. On a réalisé des calculs CNDO/S et on les a comparé avec les résultats expérimentaux. On rapporte pour le premier fois l'observation de phosphorescence de ces espèces cationiques. Les résultats actuels suggèrent qu'une inversion dans l'ordre des états électroniques est peut-être responsable des émissions normales des espèces protonées et des émissions anormales des molécules mères.

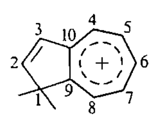
Introduction

The structure of azulene in strongly acidic medium has been studied for several years. Frey (1) in 1956 first attempted to use nuclear magnetic resonance (nmr) to determine the structure of the azulenium cation. Since that time several groups (2–9)



have, by means of nmr, established that the site of protonation is position one of the azulene nucleus (or, alternatively, position three of 1-substituted azulenes is protonated). These studies of the ground state structure show that the chemical shifts of protons two and three are only slightly altered by the protonation. On the other hand, those of the protons on the seven-membered ring are appreciably altered. The authors concluded that the electron deficiency is localized in the seven-membered ring and is shared almost equally throughout the ring. It is also generally established that only monoprotonation of all the hydrocarbon derivatives of azulene occurs. There is no firm evidence to support the existence of a doubly charged cation.

The azulenium cation has also been investigated theoretically and the electronic absorption spectrum was interpreted with the help of a "molecule in molecule" calculational model (10, 11). These calculations predict transitions at 352.1, 323.6, 259.1, 227.3, and 211.9 nm. These authors concluded that the lowest energy singlet–singlet transition has at least 60% charge-transfer character.

The luminescence of azulenium cations has not been systematically investigated previously. Heilbronner *et al.* (10, 12) have reported some fluorscence spectra in connection with studies of the ground and first excited singlet state pK values and of proton dissociation of the cations in the first excited singlet state. In addition, two other papers concerned with the emission of protonated azulenes have appeared (13, 14). The emissions reported in the literature (14) are normal $S_1 \rightarrow S_0$ fluorescences and they appear to be broad, structureless bands in the spectra recorded from room temperature solutions. There are no reports of the phosphorescence of the azulenium cations.

In the present work we present absorption and emission spectra of the cations of four hydrocarbon derivatives of azulene. We also present and discuss low temperature emission spectra of these cations and report for the first time phosphorescences of the cations. Finally, CNDO/S calculations have been carried out and the calculational results are compared with the experimental results. The calculational results appear to indicate that an inversion in the order of the two lowest energy unoccupied singlet orbitals of azulene is the most important result of protonation. The inversion in the order of these molecular orbitals is perhaps intimately related to the normal emissions of the protonated species and to the anomalous emissions of the parent species.

The CNDO/S program employed for these studies is a modified version of the modified CNDO method ((CNDO/S-CI), J. Del Bene and H. H. Jaffe, QCPE 174). This program has been modified in-house to accommodate 200 basic members and 99 atomic centers (as opposed to the 99 basic members and 31 atomic centers specified in the original version).

Experimental

The azulene and 4,6,8-trimethylazulene used in these studies are commercial products of Rutgerwerke A. G. and were prepared in 1959. The samples were subjected to three or more chromatographic separations (absorptive filtration), three crystallizations from purified hexane, and three to five vacuum sublimations. The samples treated in this manner gave no indication of the presence of naphthalene, a known photochemical product of azulene. 2-Phenylazulene was prepared by means of a modification of a literature procedure (15). 6-Phenylazulene was also prepared by means of a modification of a literature procedure (16, 17). These modifications are described in detail elsewhere (18). 2-Phenyl- and 6-phenylazulene were also subjected to the three different methods of purification employed above for azulene and were found to be spectroscopically homogeneous.

The absorption spectra were measured by means of a Cary 14 recording spectrophotometer. The emission spectra were recorded by

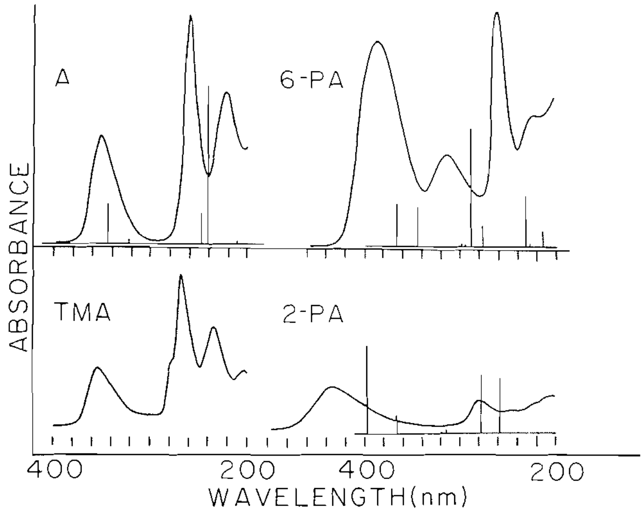


FIG. 1. Absorption spectra of the azulene derivatives in 60% H_2SO_4. The vertical lines represent the calculated transition energies (see text). The concentrations are: Azulene – 1.69×10^{-4} *M*, $\epsilon_{351\ \mathrm{nm}}$ (1.26×10^4), $\epsilon_{258\ \mathrm{nm}}$ (2.71×10^4), $\epsilon_{222\ \mathrm{nm}}$ (1.81×10^4); trimethylazulene – 1.41×10^{-4} *M*, $\epsilon_{353\ \mathrm{nm}}$ (1.50×10^4), $\epsilon_{267\ \mathrm{nm}}$ (3.83×10^4), $\epsilon_{234\ \mathrm{nm}}$ (2.52×10^4); 6-phenylazulene – 3.00×10^{-5} *M*, $\epsilon_{385\ \mathrm{nm}}$ (2.44×10^4), $\epsilon_{312\ \mathrm{nm}}$ (1.13×10^4), $\epsilon_{259\ \mathrm{nm}}$ (2.82×10^4); and 2-phenylazulene – 4.70×10^{-5} *M* $\epsilon_{438\ \mathrm{nm}}$ (3.23×10^3).

means of a home-built spectrometer system which is described elsewhere (19). A rotating dual blade phosphoroscope was installed on the spectrometer in order to obtain pure phosphorescence spectra. The reported emission spectra are not corrected for photomultiplier response, variation in the intensity of the exciting source, nor for the characteristics of the excitation and emission monochromators. Excitation was front surface for all the fluorescence measurements and was at 180 degrees to observation for all the phosphorescence measurements.

The analytical solutions of these azulene derivatives were prepared immediately prior to measurement in order to avoid some long-time chemical degradation which occurs in strongly acidic solution. The solvent in all cases consisted of 60 vol.% sulfuric acid. The solvent gave no emissions at the excitation wavelengths employed in this study. The solvent formed a partially transparent, cracked glass at 77 K.

Results

The absorption spectra recorded from ambient temperature solutions of azulene, 4,6,8-trimethylazulene (TMA), 2-phenylazulene (2-PA), and 6-phenylazulene (6-PA) in 60% sulfuric acid are reproduced in Fig. 1. The vertical lines shown in most of the spectra represent the position and relative oscillator strengths of the calculated transitions. The model chosen for the calculations is a somewhat restricted one in that the bond angles and bond distances used for the cations are identical to those of the unprotonated parent molecules. The only differences between the present model and that of the unprotonated parent molecules are rehybridization of the carbon atom at position one and delocalization of the positive charge.

The luminescence spectra recorded from solutions, maintained at 77 K, of the azulene derivatives in 60% sulfuric acid are reproduced in Fig. 2. It should be noted that the phosphorescences of the cations are much weaker than the fluorescences. The relative intensities of the two emissions are shown in the spectra of the azulenium cation. On the same scale as the fluorescence, the phosphorescence is seen as a slight bump in the baseline. (In alcoholic hydrochloric and hydrobromic acid solutions of azulene, the intensity of the phosphorescence increases appreciably.)

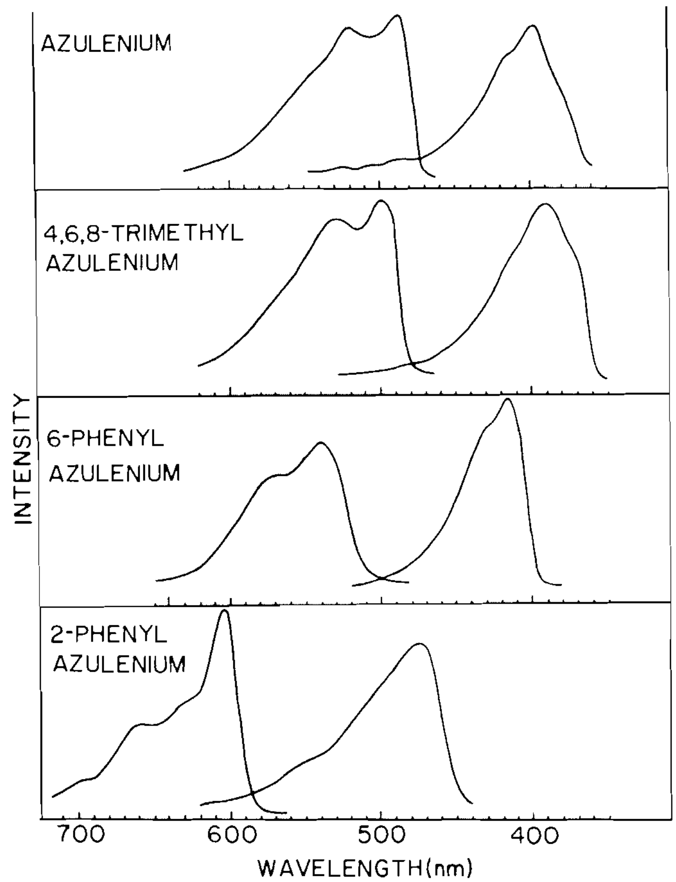

FIG. 2. Luminescence spectra of azulene derivatives in 60% H_2SO_4. The spectra are those from solutions in cracked glasses at 77 K. The concentration of each derivative is identical with that listed for the absorption spectrum. The phosphorescence appears on the left in each spectrum.

In Fig. 3 are shown the calculated transitions of three cations in the form of a transition correlation diagram. In this figure the dashed lines connect transitions of similar orbital character. In general, it can be seen that the theoretical transition energies are in excellent agreement with the experimental energies although the former are higher in every case.

Discussion

The model chosen for the CNDO/S calculations is, in some ways, a somewhat restricted one. The bond angles and bond distances of the protonated species are limited to those of the neutral parent molecules. The selected model should therefore by justified.

The azulene – azulenium cation equilibrium in solutions of various acid concentrations has been investigated by Long and Schulze (6–8) and by Challis and Long (9). In addition, Heilbronner *et al.* (11) have studied the proton dissociation of the azulenium cation in the first excited singlet state by means of flash photolytic techniques. These experiments demonstrated that one of the products produced by a flash is azulene in its ground state. A series of flashes leads to a distortion of the azulene – azulenium cation equilibrium which may be conveniently measured by monitoring the absorbance of the solution at some wavelength which corresponds to the position of the lowest energy absorption band of azulene. At higher

TABLE 1. Calculated transitions and oscillator strengths

Ion	Transition wavelength in nm (oscillator strength)					
Azulenium	345(0.141)	323(0.015)	248(0.112)	241(0.552)	213(0.105)	194(0.315)
6-Phenylazulenium	367(01.48)	345(0.135)	289(0.418)	277(0.074)	233(0.178)	227(0.199)
2-Phenylazulenium	399(0.315)	356(0.065)	270(0.213)	250(0.199)	228(0.237)	216(0.146)

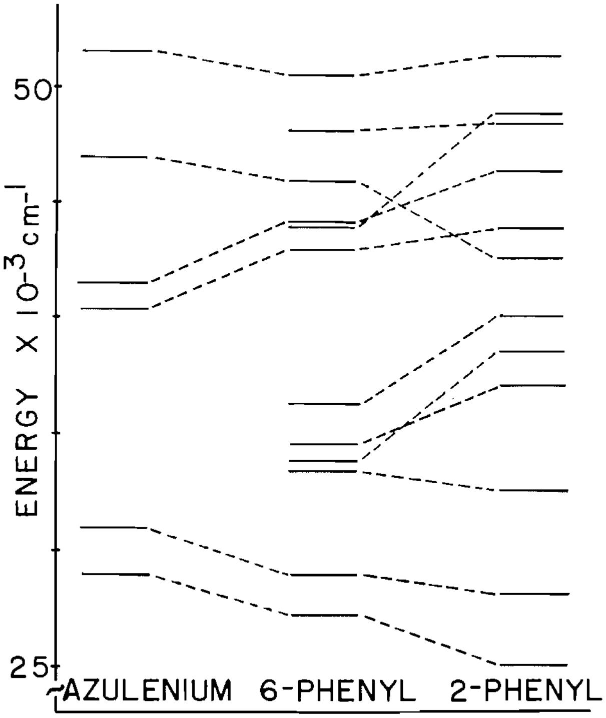

FIG. 3. Correlation diagram of the calculated transition energies of the azulenium, 6-phenylazulenium, and 2-phenylazulenium cations.

concentrations of acid, the reprotonation of azulene became too fast to measure with the equipment employed. The point, however, is that proton dissociation in the lowest energy excited state of the azulenium cation probably occurs even in very strongly acidic solutions, although the azulene molecule is not observed by means of conventional flash techniques. Since the neutral azulene molecule is produced from an excited azulenium cation by proton dissociation, it appears logical that the equilibrium geometry of the excited azulenium cation should be adequately represented by the ground state geometry of the azulene molecule. We realize, however, that this choice is not equally satisfactory for the ground state azulenium cation since the bond angles and bond distances, perhaps even the planarity, of the cation are probably relaxed upon protonation. On the other hand, the relaxed geometry of the ground state cation is not really satisfactory for the excited state cation so that a choice had to be made. The changes should have an effect only on the transition energies and not on the order of the transitions. The reasonable values of the calculated transitions and their close correspondence to the earlier values of Heilbronner *et al.* (10, 12) seem to justify the present choice of a model for the azulenium cations.

The general characteristics of the lowest energy absorption bands of all four of the hydrocarbon derivatives of azulene are very similar. The shapes of these bands in the various spectra are consistent with the presence of two electronic transitions in this wavelength region. The theoretical calculations also predict two transitions. The theoretical transitions and oscillator strengths are listed in Table 1. Comparison of these oscillator strengths for the pairs of transitions demonstrates that the higher energy transitions have the smaller oscillator strengths, thus the correct shape of the lowest energy absorption bands is also predicted by the restricted model. All these results are in excellent accord with the results of the earlier "molecule in molecule" calculations of Heilbronner *et al.* (10, 11). The pairing of transitions throughout the calculated spectrum appears to be a general phenomenon in all the azulene derivatives studied in this work. This effect was also predicted by the calculations of Heilbronner *et al.*

Although the spectra are not shown, there is a considerable difference between the locations of the wavelength maxima in the ambient temperature absorption and fluorescence excitation spectra of the azulenium and 2-phenylazulenium cations. The fluorescence excitation maximum of the first electronic transition of the azulenium cation shifts 940 cm^{-1} to lower energy relative to the maximum in the absorption spectrum and that of the 2-phenylazulenium cation shifts 825 cm^{-1} to lower energy. Ideally, of course, the fluorescence excitation maximum should be identical with the absorption maximum. Large shifts such as those listed here are normally indicative of substantial changes in geometry of the emitting species relative to that of the absorbing species. In view of our arguments given above, this latter result is entirely expected.

There is also a sizable blue shift of the fluorescence maxima of the cations as the temperature decreases. For example, the wavelength maximum of the ambient temperature azulenium fluorescence occurs at 428 nm, while that at 77 K occurs at 398 nm, which corresponds to an 1800 cm^{-1} blue shift. The shift of the fluorescence maximum of the 2-phenylazulenium cation is from 510 nm at room temperature to 475 nm at 77 K. This change corresponds to a 1450 cm^{-1} blue shift. In strongly acidic solution at room temperature azulene may be viewed as an ionic species that has a rather flexible structure and consequently gives rise to the structureless absorption and fluorescence spectra. At 77 K the structure is rigidly fixed by the solvent matrix. This rigidity is clearly demonstrated by the dramatic shift of the fluorescence to higher energy and by the increase in vibrational structure of the fluorescence.

It is found that the cations of the hydrocarbon derivatives of azulene fluoresce even more strongly at 77 K than they do at room temperature. The 77 K fluorescences have not been reported previously. Our room temperature fluorescence of azulene in 60% sulfuric acid agrees with that reported in the literature (14). The cations also exhibit phosphorescence at 77 K. Both these emissions originate from the lowest energy excited state of the appropriate multiplicity in contrast to the behavior of the parent molecules which fluoresce exclusively from the second excited singlet state (both $S_2 \rightarrow S_1$ and $S_2 \rightarrow S_0$ emissions are observed). These emissions that originate from the lowest excited singlet and triplet states would appear to suggest that the excited states of the cations are greatly different from the excited states of the parent molecules. However, an

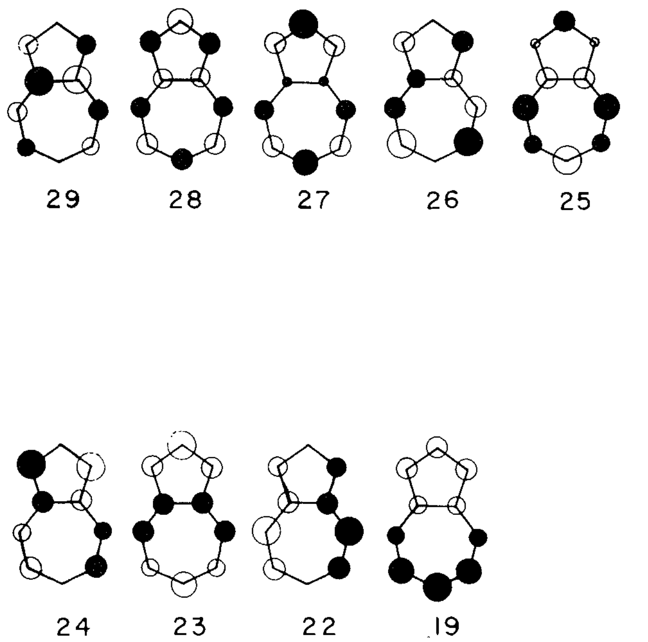

FIG. 4. The highest occupied (HOMO) and lowest unoccupied (LUMO) orbitals of azulene. Orbitals 19–24 are the HOMOs.

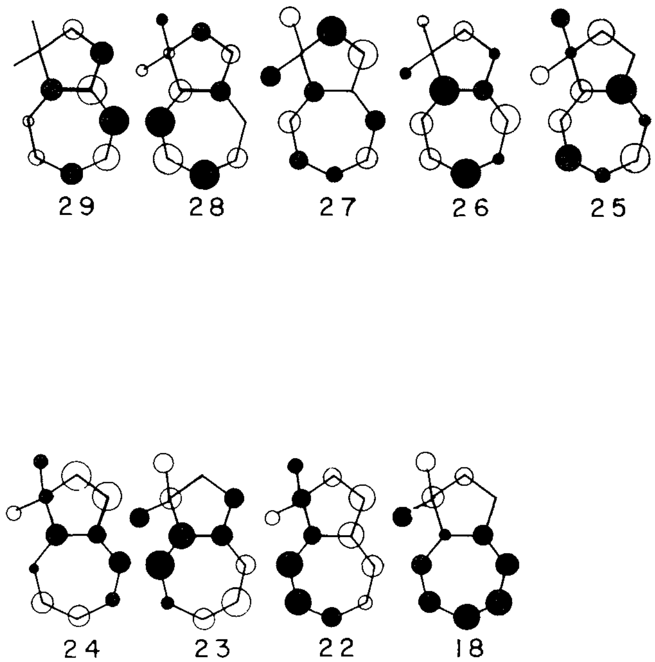

FIG. 5. The highest occupied (HOMO) and lowest unoccupied (LUMO) orbitals of the azulenium cation. Orbitals 18–24 are the HOMOs.

examination of the available information suggests that the excited singlet states of the cations and the parent molecules are somewhat similar, although the ordering of the states may be inverted. The present theoretical data indicate that a sufficient condition for normal Kasha's rule fluorescence is that the order of the two lowest energy unoccupied singlet states of azulene be reversed.

It is apparent that the association of an orbital transition, such as LUMO ← HOMO, with an electronic transition is a rather severe approximation. The incorporation of configuration interaction, such as is done in the CNDO/S procedure, somewhat lessens the severity of the approximation. The orbital representations obtained by the CNDO/S procedure are thus only an aid in the assignment of electronic transitions; however, within this degree of approximation the present calculations yield some interesting insights. Compare, for example, the orbital representations in Figs. 4 and 5. The orbitals labelled 25 and 26 represent the two lowest energy unoccupied orbitals of both the cation (Fig. 5) and the parent molecule (Fig. 4). The essential difference between the azulene orbital labelled 26 and the azulenium cation orbital labelled 25 is a small amount of electron density at positions 2 and 6 of the azulenium cation. Conversely, the azulene orbital labelled 25 is very similar to the azulenium cation orbital labelled 26. Thus, the present calculational results suggest that the order of the two lowest energy excited states of azulene is inverted upon protonation. If such is the case, then the emitting state of both species has the same orbital character and the inversion in the order of the states may explain the normal, Kasha's rule, emissions of the cations.

If one compares the absorption spectra of the azulenium ion with that of azulene (see Fig. 6), one finds that there is an amazing similarity between all the transitions, except that the first transition either does not appear in the spectrum of the azulenium ion or appears as a weak shoulder at about 320 nm in accord with the orbital inversion argument of the previous section. Very similar results are found in the spectra of all the hydrocarbon derivatives of azulene (18). This comparison suggests that the higher energy states of azulene may have geometries and charge distributions similar to those of the states of the azulenium ion and that only the first transition in azulene is unique.

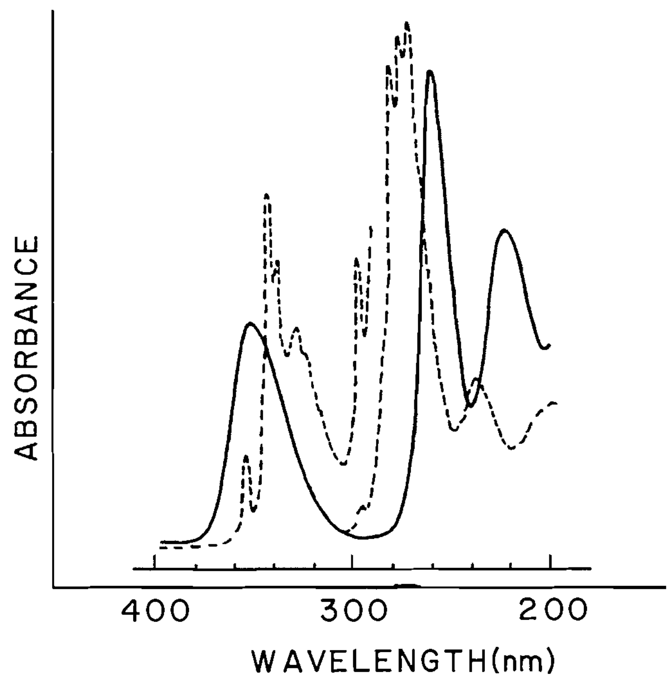

FIG. 6. Comparison of the absorption spectra of azulene (- - -) in 3-methylpentane solution (2.51×10^{-3} M and azulene (—) in 60% H_2SO_4 solution (1.69×10^{-4} M). The vertical scales for the two spectra are not the same.

In conclusion, it seems that the fluorescence emitting states of azulene and azulenium ion are very similar; perhaps the emission of azulene is not anomalous but it is the unusual first absorption that should be considered to be anomalous.

Although the photophysics of azulene has been reconsidered many times in the last twenty years, the similarity between the second excited singlet state of azulene and the first excited singlet state of the azulenium ion suggests that many phenomena should be reinvestigated; for example, is the first excited singlet state of azulene dissociative, predissociative, or an efficient sensitizer of a dissociative triplet state? Resonance Raman studies should lead to some clarification of these phenomena.

This paper is dedicated to Professor Camille Sandorfy on the occasion of his 65th birthday

D. J. GERSON and W. G. FATELEY. Can. J. Chem. **63**, 2086 (1985).

The far-infrared vibration–rotation spectra of the infrared-active internal rotation mode of dimethylether, dimethylamine, methylamine, and ethylamine have been recorded at several vapor pressures. The effect of pressure broadening on the $1 \leftarrow 0$ torsional transition has been experimentally determined. It was found that the Van Vleck – Weisskopf model gave the best fit to these experimental results. It was also found that pressure broadening of the $1 \leftarrow 0$ transition did not overlap the next transition in the series at sample vapor pressures less than 50 Torr.

D. J. GERSON et W. G. FATELEY. Can. J. Chem. **63**, 2086 (1985).

Opérant à plusieurs tensions de vapeur, on a déterminé les spectres de vibration–rotation dans le proche infrarouge du mode de rotation interne, actif dans l'infrarouge, du diméthyléther, de la diméthylamine, de la méthylamine ainsi que de l'éthylamine. On a déterminé expérimentalement l'effet d'élargissement dû à la pression sur la transition de torsion $1 \leftarrow 0$. On a aussi trouvé que, dans ces séries et à des tensions de vapeur inférieures à 50 Torr, l'élargissement dû à la pression de la transition $1 \leftarrow 0$ ne se superpose pas à la transition suivante.

Introduction

Recently, Durig and co-workers have presented a series of papers which have investigated the effect of top–top coupling on the observed vibration–rotation spectrum of molecules with two internal C_{3v} rotors (1). To obtain good spectra, these studies were performed using sample vapor pressures in excess of 100 Torr. At these pressures, significant amounts of vibrational fine structure is obscured by pressure broadening (2). Since the observable internal rotation torsional transitions are very narrow, the disappearance of bands due to pressure broadening could alter the vibrational assignment of the transitions and the subsequent potential function. Cooke and co-workers have shown that this occurs in dimethylether (3).

In an effort to determine the maximum vapor pressure of sample which maintains a well resolved vibration–rotation spectrum, the far-infrared spectra of dimethylether, dimethylamine, methylamine, and ethylamine were recorded at several sample vapor pressures. The resultant degradations in resolution with increased vapor pressure were compared to those expected from theory (4), and the results of these comparisons are reported herein.

Experimental

The samples of dimethylether, dimethylamine, methylamine, and ethylamine were purchased from Matheson, Inc. (East Rutherford, NJ). Samples were purified by low temperature fractional distillation and cold-trapping over 4A sieves prior to the acquisition of their spectra (5). The samples were then passed through activated molecular sieves at room temperature into the infrared vapor cell. Typical sample vapor pressures used in the analyses varied from 1 Torr to 750 Torr.

The spectra were obtained using an IBM Instruments IR/98 vacuum spectrometer equipped with mercury arc source, 500 lines/inch metal mesh beamsplitter and liquid helium cooled germanium bolometer operating below the lambda point. The samples were contained in a Wilks multipass gas cell equipped with polyethylene window lenses and vacuum fittings as supplied by IBM Instruments. The cell pathlength was fixed at 2.75 m for all spectra recorded for this study. The spectra were transformed from 512 coadded interferograms, boxcar apodized, to give an effective resolution of 0.022 cm^{-1}.

Calculations were performed using an IBM System 9001 computer system. Data analysis programs written in S9000 Pascal were used to analyze the experimental and theoretical data. The experimental data were transferred to the S9000 using standard RS232 protocol from the Aspect data system of the FTIR spectrometer.[2]

Results

The effect of increasing the sample vapor pressure on the resolution of the torsional fine structure of dimethyl ether is displayed graphically in Fig. 1. It can be seen that almost all of the observable fine structure disappears by 100 Torr of sample vapor pressure. Figure 2 shows this effect in the region of $10 \leftarrow 00$ transition.

The theoretical derivation of the Debye intensity for hard collisions between fixed dipoles has been given by Van Vleck and Weisskopf (4). In general, the net absorption coefficient, γ, is dependent upon the dipole moment of the transition, μ_{ij}, and the transition frequency, ν (eq. [1]).

where

$$[2] \quad |\mu_{ij}|^2 = \sum_M |u_x\langle JMJ'M'\rangle|^2 + |u_y\langle JMJ'M'\rangle|^2 + |u_z\langle JMJ'M'\rangle|^2$$

At low pressures, $\frac{1}{2}\pi\tau \ll \nu_0$, and the first term in eq. [1] predominates. If the observations are limited to the region near ν_0, eq. [1] reduces to:

$$\gamma = \frac{8\pi^2 Nf}{3ckT}\left|\mu_{ij}\right|^2 \nu^2\left[\frac{\Delta\nu}{(\nu-\nu_0)^2+(\Delta\nu)^2}\right]$$

provided $\Delta\nu \ll \nu_0$. Under these conditions, the integrated line intensity becomes

$$\gamma_I = \frac{8\pi^2 Nf}{3ckT}\left|\mu_{ij}\right|^2 \nu_0$$

and the halfwidth, $\Delta\nu$, is proportional to the sample pressure, $(1/2)\pi\tau$, for low pressures.

For the molecules examined in this study, the experimentally observed halfwidth, FWHH, and the integrated intensity, (the calculated values of the halfwidth and the relative error) are also presented in Table 1. As shown in Table 1, the differences between the calculated and observed values for the FWHH are

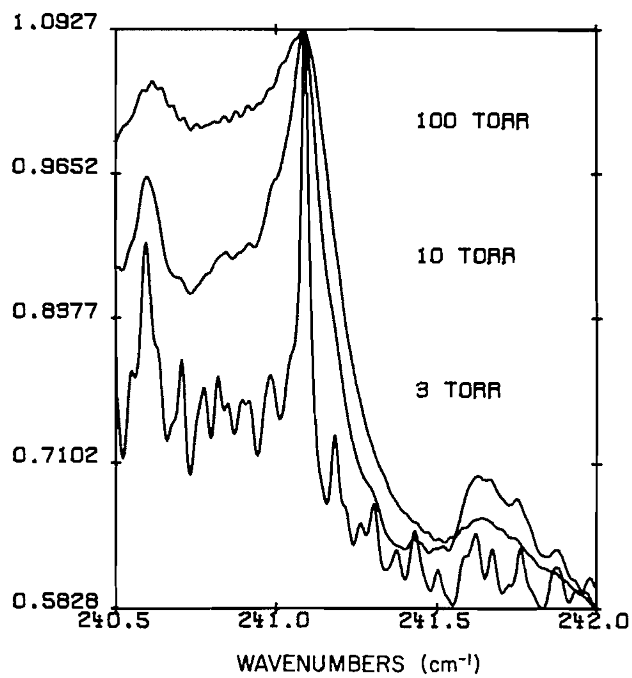

FIG. 2. Far-infrared spectrum of dimethyl ether in the region of the $1 0 \leftarrow 0 0$ transition. The same experimental conditions as in Fig. 1 are present here. The top spectrum is 100 Torr, middle spectrum is 10 Torr and the bottom spectrum is 3 Torr pressure of dimethylene.

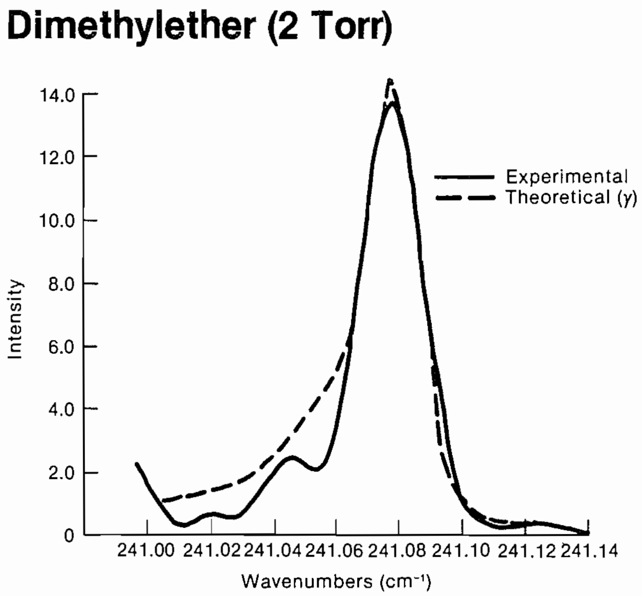

FIG. 3. Comparison of the experimental and theoretical band profile for the 10 ← 00 transition of dimethylether at 2 Torr.

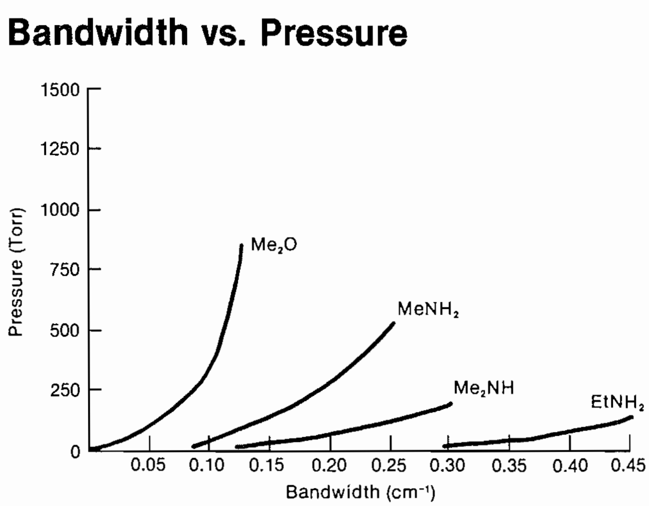

FIG. 4. Experimental pressure broadening effects for dimethylether, dimethylamine, methylamine, and ethylamine.

approximately the same as the resolution limit of the interferometer, 0.022 cm^{-1}.

Comparison of the theoretical (calculated) and experimental line shape, at low vapor pressure, for the 1 ← 0 transition of dimethylether is shown in Fig. 3. The good agreement between the experimentally observed band and the line shape calculated using eq. [4], is most probably indicative of the lack of observable intermolecular perturbations caused by the two internal rotors. At low vapor pressures, the halfwidth, $\Delta\nu$, is observed to follow a linear relationship with sample pressure. However, as shown in Fig. 4, at sample pressures greater than 100 Torr, this relationship does not hold.

[a]FWHH: frequency width at half height at 10 Torr.

Conclusion

The observed pressure broadening effects in dimethylether, dimethylamine, methylamine, and ethylamine have been found to follow the Van Vleck – Weisskopf model at pressures up to 750 Torr. No significant differences were found between the calculated and observed FWHH for the dimethyl-X compounds, indicating that the interaction between the two internal rotors has little effect on intermolecular events. The maximum vapor pressure found to give resolvable fine structure was 100 Torr for the two dimethyl rotor compounds. At pressures above 100 Torr, the 2 ← 1 transition was found to be obscurred by the pressure broadened 1 ← 0 transition. For methylamine and ethylamine, this was found to occur at pressures greater than 50 Torr.

Acknowledgments

The authors would like to thank Dr. J. M. Casper, IBM Instruments, for his assistance in obtaining the spectrum of dimethylether. The authors would also like to thank Dr. D. A. C. Compton, SOHIO Research, for his constructive comments during the course of this study.

One of the authors (W.G.F.) would like to acknowledge partial support for the study from an NSF grant CHE-8109570.

Reçu le 25 juillet 1984

BERNARD HANQUET, MICHEL FARNIER, ROGER GUILARD, CLAUDE LECOMTE et YVES DUSAUSOY. Can. J. Chem. **63**, 2089 (1985).

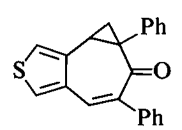
Opposées à l'éthanedithiol, les thiophéno[*c*] et [*b*]bishomotropones subissent un réarrangement original conduisant à un naphto[1,8-*bc*]thiophène et (ou) à un benzo[*b*]thiophène. La structure des produits obtenus est déterminée par marquage isotopique, examen comparatif des spectres de rmn protonique, et dans le cas du diphényl-5,6 naphto[1,8-*bc*]thiophène par analyse cristallographique. Un mécanisme réactionnel est proposé impliquant au stade déterminant un transfert électronique entre un nucléophile "doux" et un acide "dur".

BERNARD HANQUET, MICHEL FARNIER, ROGER GUILARD, CLAUDE LECOMTE, and YVES DUSAUSOY. Can. J. Chem. **63**, 2089 (1985).

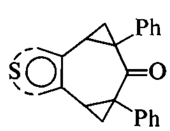
A non classical rearrangement is observed when thiopheno[*c*] and [*b*]bishomotropones react with ethanedithiol, leading to a naphtho[1,8-*bc*]thiophene and (or) a benzo[*b*]thiophene. The structure of the products is supported by deuterium labelling, ^{1}H nmr spectra, and X-ray analysis of 5,6-diphenyl naphtho[1,8-*bc*]thiophene. A mechanism is proposed which implies an electronic transfer between a "soft" nucleophile and a "hard" acid, in the key step.

Introduction

Dans un article antérieur nous avons décrit la réactivité singulière de la thiophénomonohomotropone **1** lorsqu'on l'oppose aux thiols (1). Nous avons montré en particulier qu'en présence d'éthanedithiol et d'acide paratoluènesulfonique (APTS), le dérivé homotroponique **1** subit un réarrangement original et conduit à un composé benzothiophénique porteur d'un groupement aldéhyde protégé par un reste dithiolanne. Le mécanisme de ce réarrangement implique entre autres la rupture d'une double liaison carbone–carbone résultant de l'action conjuguée de l'éthanedithiol – nucléophile "doux" – et du groupe carbonyle protoné – acide "dur".



1



2

Or lors de la synthèse des thiophénohomotropones (2) on observe parallèlement à la formation de monohomotropones **1** celle de bishomotropones **2**. Il nous est apparu intéressant d'étudier le comportement de ces derniers composés vis-à-vis de l'éthanedithiol pour préciser le rôle joué par la présence d'un second motif cyclopropanique et de vérifier si le réarrangement original observé dans le cas de dérivés thiophénomonohomotroponiques pouvait être étendu aux thiophénobishomotropones.

Nous décrivons dans le présent mémoire les résultats de cette étude et, sur la base des diverses données expérimentales et spectroscopiques, nous discutons le mécanisme rendant compte de la formation du produit de réarrangement obtenu.

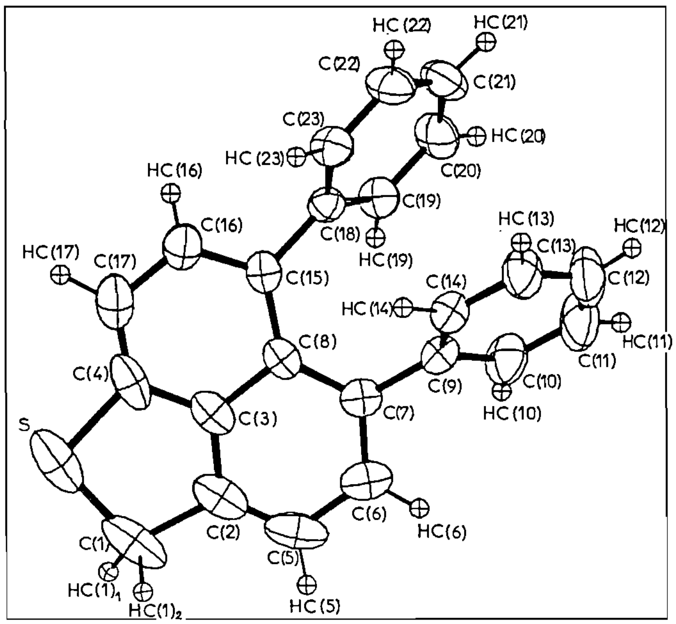

FIG. 1. Vue ORTEP de la structure cristalline de **3**.

Résultats

En opposant la thiophéno[*c*]bishomotropone **2***a* à l'éthanedithiol-1,2 en présence d'acide paratoluènesulfonique dans le toluène à reflux, on accède à un composé **3**. Les données du spectre de masse et l'analyse du spectre de rmn protonique n'apportent pas d'éléments décisifs pour la détermination de la structure. Nous avons alors été conduits à effectuer un examen radiocristallographique de **3**.

La conformation moléculaire est représentée par la fig. 1. Les distances et les angles de la molécule sont consignés dans le tableau 1. Les atomes constituant les trois cycles ortho-

plan 2			23,5°

condensés forment un plan; l'écart maximum d'un atome au plan moyen est de 0,07 Å. Dans le cycle à cinq chaînons, les liaisons communes aux deux cycles C(3)—C(4) et C(3)—C(2) sont de 1,417(6) et 1,391(6) Å. La liaison C(1)—C(2) est simple: 1,580(7) Å. Compte tenu de la valeur des écart-types et de l'agitation thermique la différence observée entre les deux liaisons S—C est tout juste significative. Dans les deux cycles à six chaînons orthocondensés la moyenne de la longueur est de 1,398(6) Å. Toutefois, on remarque une pseudosymétrie par rapport à C(3)—C(8): trois liaisons longues autour de C(8), deux liaisons courtes C(4)—C(17) et C(2)—C(5), deux liaisons équivalentes C(6)—C(7) et C(15)—C(16), deux autres très proches C(5)—C(6) et C(16)—C(17). Les atomes C(9) et C(18) des deux groupes phényles s'écartent de part et d'autre du plan moyen moléculaire de 0,27 Å et les liaisons C(15)—C(18) et C(7)—C(9) ne sont pas parallèles mais forment un angle de 16° (voir tableau 2). Ces deux écarts à la géométrie idéale correspondant à une hybridation sp^2 de C(7) et C(15), résultent de l'empêchement stérique entre les deux noyaux phényle. Ces derniers forment un angle de 23,5° et sont inclinés dans le même sens d'un angle de 55° par rapport aux trois cycles orthocondensés.

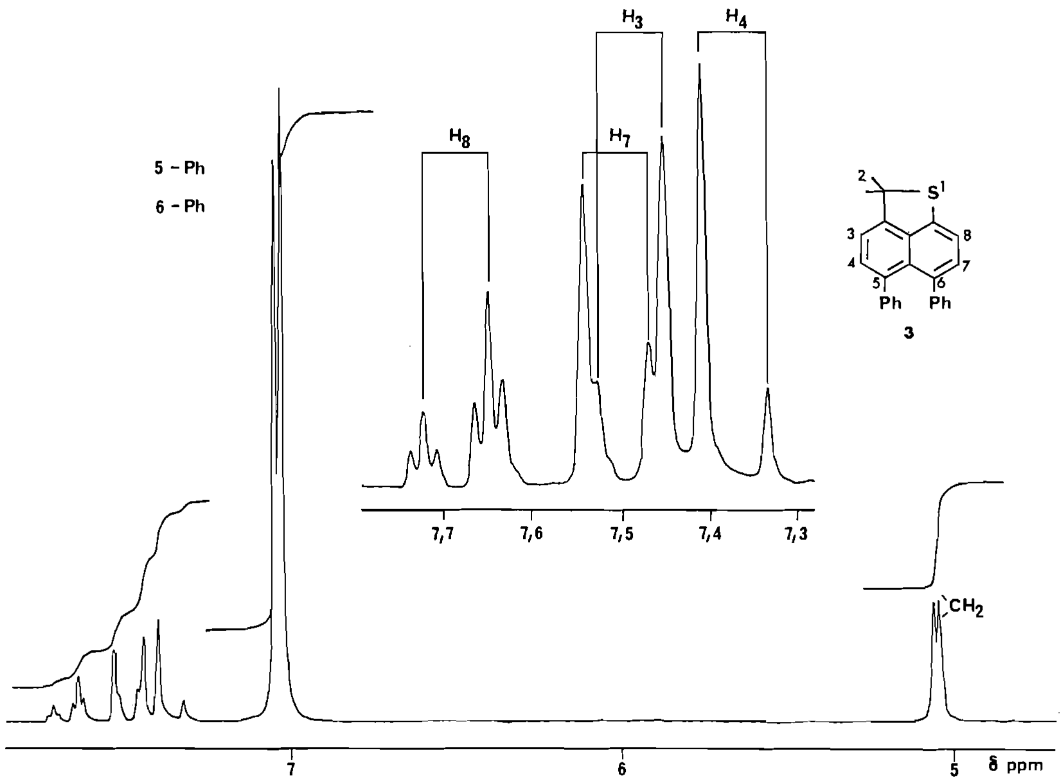

FIG. 2. Spectres rmn [1]H (100 MHz, $(CD_3)_2CO$) du naphto[1,8-*bc*]thiophène **3**.

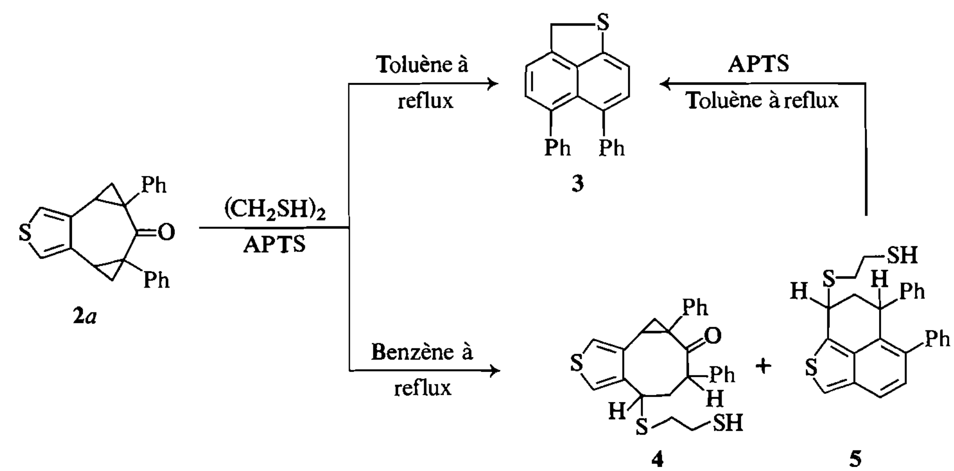

SCHÉMA 1

La structure de **3** étant établie, l'analyse de son spectre de rmn est alors très aisée (voir fig. 2).

Si la structure de ce naphto[1,8-*bc*]thiophène (3) **3** était établie sans ambiguïté, il convenait toutefois d'expliquer sa formation au départ de la thiophéno[*c*]bishomotropone et de proposer un mécanisme réactionnel rendant compte de cette transformation originale.

Étude expérimentale de la transformation des thiophénobishomotropones

Nous avons abordé l'étude du mécanisme conduisant à la formation du naphtothiophène **3** selon trois directions principales: (*i*) en étudiant l'influence des modalités opératoires sur l'évolution de la réaction; (*ii*) en mettant en oeuvre la thiophéno[*b*]bishomotropone **2***b* isomère de **2***a*; (*iii*) en procédant au départ d'analogues deutériés de **2**.

(a) *Influences de la température et du solvant*

Ces deux paramètres semblent jouer un rôle important: si on remplace le toluène par le benzène, on isole un mélange de deux produits **4** et **5** (proportions relatives 84 et 16%) différents du naphtothiophène **3** obtenu dans le toluène à reflux (voir schéma 1). La structure de **4** est déterminée par examen critique des ses données spectroscopiques. En infra-rouge on note la présence d'une bande d'intensité faible à 2570 cm^{-1} caractéristique d'un reste —SH et celle d'une vibration carbonyle à 1700 cm^{-1}. L'augmentation de la fréquence de ce vibrateur carbonyle par rapport à celle du composé de départ traduit la rupture d'un des cycles à trois chaînons, consécutive à l'addition d'une molécule d'éthanedithiol. Le spectre de masse conforte également cette hypothèse (voir partie expérimentale).

L'analyse du spectre de rmn protonique apparaît plus délicate. La partie la plus déblindée du spectre se présente sous la

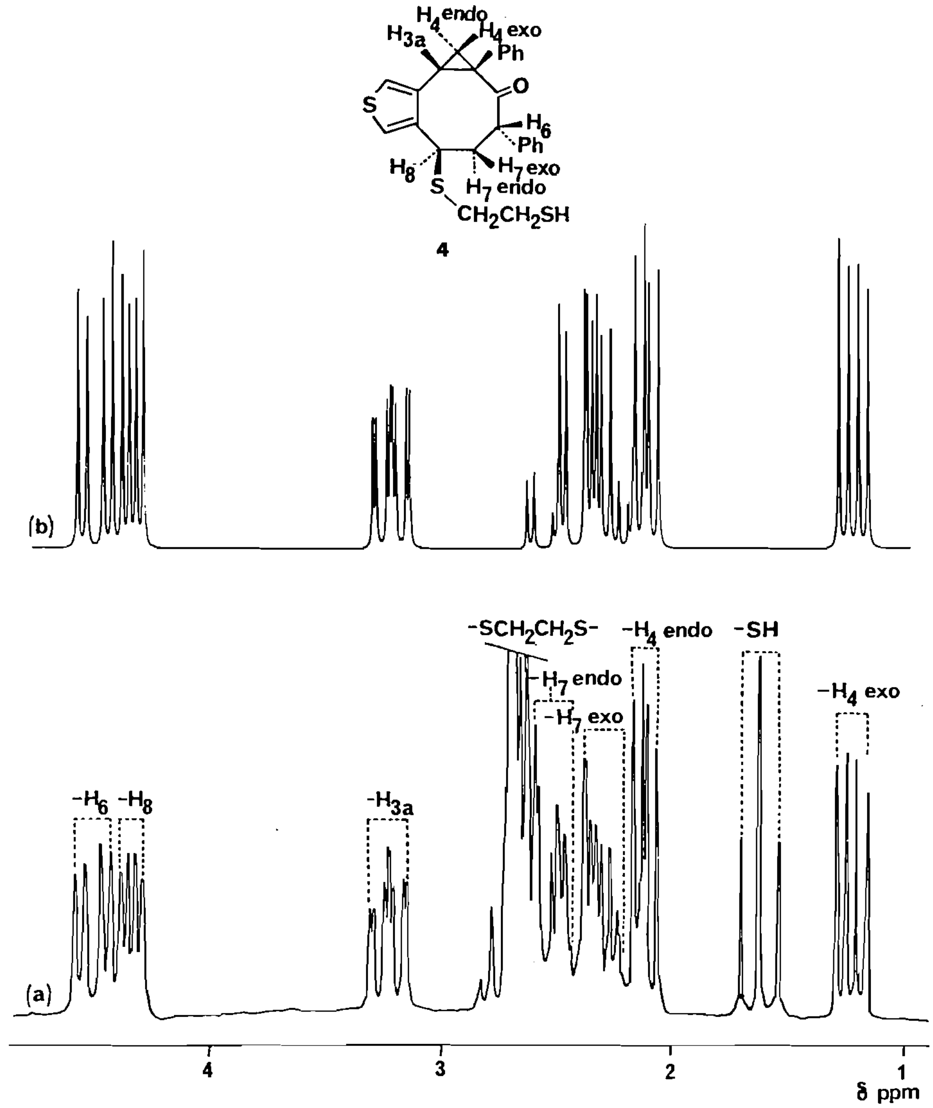

FIG. 3. (a) Spectre rmn ^1H expérimental du composé **4** (100 MHz, $CDCl_3$). (b) Spectre simulé (la partie —SCH_2CH_2SH a été volontairement omise).

forme d'un massif complexe (δ ~ 6,90–7,45 ppm) et correspond aux 12 protons des restes phényle et du noyau thiophénique. Dans le domaine 1,00 à 5,00 ppm (voir fig. 3a) apparaissent également les signaux de 12 protons: un système AMX correspond à un motif cyclopropanique, un massif complexe de 4 protons attribuable au reste —SCH_2CH_2S— et un unique proton —SH. Enfin les signaux relatifs aux quatre protons H_6, H_{7endo}, H_{7exo} et H_8 ont été analysés. Le spectre calculé coincide parfaitement avec le spectre expérimental (4) (voir fig. 3b). Il apparaît donc que **4** est l'adduit de Michael entre la thiophéno[*c*]homotropone et l'éthanedithiol-1,2. Une telle réaction est classique dans la série des cétones α,β-éthyléniques (5); dans notre cas le cycle à trois chaînons peut être assimilé à une double liaison.

Le composé **5** qui apparaît simultanément avec **4** présente certaines analogies spectroscopiques avec ce dernier: on observe une vibration —SH à 2562 cm^{-1} et l'absence de vibration associée à un reste carbonyle. Sur le spectre de masse de **5** le pic moléculaire diffère de 18 par rapport à celui de **4** par perte d'une molécule d'eau et on note la perte d'un reste $(CH_2SH)_2$. Le spectre de rmn (voir fig. 4) permet d'individualiser trois protons aromatiques: H_3 et H_4 couplés en *ortho* et H_2 qui présente un couplage à longue distance (^5J = 1,98 Hz) avec le proton résonant à 3,81 ppm. Pour ce dernier signal on note également deux autres couplages, comparables à ceux observés pour le proton H_8 de **4**. De même le massif à 4,39 ppm est attribuable à un proton —CHPh— (pour **4**, δ H_6 = 4,49 ppm). Pour le composé **5** aucun signal n'apparaît dans le domaine de résonance des protons cyclopropaniques alors que trois massifs (intensités respectives 4, 2 et 1) sont présents sur les spectres de **4** et de **5**. Ces signaux sont respectivement attribuables au motif —SCH_2CH_2S—, au méthylène "intracyclique" et enfin au proton —SH résonant à haut champ.

La structure proposée est celle d'un dihydronaphto[1,8-*bc*]-thiophène dont le squelette n'est pas sans rappeler celui de **3** obtenu dans le toluène à reflux.

Pour préciser l'influence du paramètre thermique sur l'évolution de la réaction nous avons tenté au départ de **4** d'accéder au naphtothiophène **3**. En chauffant **4** au reflux du toluène en présence d'APTS ce composé reste inaltéré, mais en revanche **5** conduit à **3** dans ces conditions de température et d'acidité.

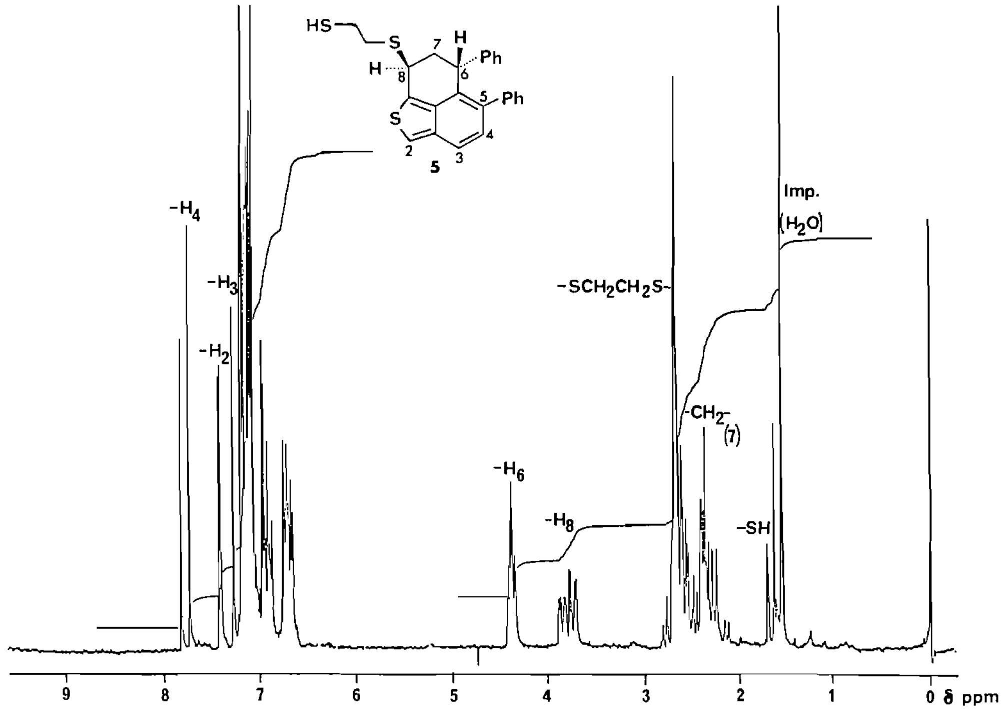

FIG. 4. Spectre rmn ^1H (100 MHz, $CDCl_3$) du composé **5**.

(b) *Synthèses au départ de la thiophéno[*b*]bishomotropone*

Comme nous l'avons indiqué plus haut il était intéressant de vérifier si une variation structurale opérée au niveau du substrat de départ pouvait conduire à des produits de réarrangement différents.

Après chauffage de la thiophéno[*b*]bishomotropone **2***b* isomère de **2***a* dans le toluène à reflux en présence d'APTS on isole le naphto[1,8-*bc*]thiophène **3** et un second produit **6** (proportions relatives: 4 et 96%; voir schéma 2).

L'analyse du spectre de masse de **6** suggère l'incorporation d'une molécule d'éthanedithiol ($M^+ = 418$), confirmée par la présence d'un fragment à 324 $[M - (CH_2SH)_2]^+$. Le spectre infra-rouge ne présente plus la vibration associée au carbonyle et l'absence de vibration —SH laisse supposer l'existence d'un aldéhyde ou d'une cétone protégée sous forme de dithiolanne. Cette hypothèse a été vérifiée en libérant le groupe aldéhyde par traitement de **6** à l'aide d'un sel mercurique (voir schéma 2). Le produit majoritaire **7** obtenu présente une bande intense à 1724 cm^{-1} caractéristique d'un aldéhyde aliphatique. De plus la désulfuration totale de **6** par le nickel de Raney permet d'accéder à **8** présentant en rmn protonique deux groupements éthyle. L'un de ces restes provient de la réduction du motif dithiolanne, l'autre de la chaîne carbonée du cycle thiophénique suggérant la présence d'un cycle benzo[*b*]thiophénique.

L'examen du spectre rmn de **6** permet de préciser la structure de ce composé: dans la partie située à haut champ on distingue 8 protons: un massif complexe de quatre protons (—SCH_2CH_2S—), un multiplet de deux protons (—CH_2—) et deux protons $H_{1'}$ et $H_{3'}$; dans la partie aromatique (voir fig. 5a) l'existence d'un motif α,β-thiophénique (respectivement H_2 et H_3) et d'un couplage orthobenzénique (H_4 et H_5) confirme le squelette benzo[*b*]thiophénique disubstitué.

L'examen attentif du signal à 7,60 ppm (voir fig. 5b) révèle l'existence de deux protons α-thiophéniques différents: le signal le plus intense (85%) est un doublet (J = 5,47 Hz) et correspond au proton H_2 de **6***a*. Sur l'autre signal (15%) apparaît un couplage supplémentaire de 0,53 Hz avec le proton H_6 de l'isomère **6***b*.

La structure de chacun des produits isolés lors des synthèses exposées plus haut étant connue, il convenait de préciser le mécanisme de réarrangement des thiophéno[*c*] et [*b*]bishomotropones; aussi avons-nous mis en oeuvre des analogues deutériés de ces différents substrats.

(c) *Synthèses au départ d'analogues deutériés de* **2**

Au départ de la thiophéno[*c*]bishomotropone D-3b,D-6a (**2***a'*) et en travaillant dans un milieu deutérié (APTS-OD, D_2O) on accède, dans le toluène à reflux, au dérivé **3'** (voir schéma 3). L'examen comparatif des spectres rmn de **3** et **3'** montre que les deux systèmes AB se simplifient en deux singulets élargis (couplage $^3J_{HD}$). On note également que le méthylène benzylique a subi, dans le milieu, une incorporation partielle de deutérium. Les atomes de deutérium initialement présents dans **2***a'* se retrouvent en position 3 et 8 du naphtothiophène **3'**: ce résultat sera mis à profit dans l'établissement du mécanisme de réarrangement.

Si la réaction est conduite dans le toluène en présence d'APTS non deutérié, on constate la perte totale des deux atomes de deutérium et on isole **3** et non **3'**. Cette donnée n'est pas en contradiction avec l'observation précédente si l'échange protonique avec le milieu réactionnel intervient lors d'un stade ultime du réarrangement. Toutefois, lors du chauffage de **3** dans le toluène en présence d'APTS-OD, D_2O, aucune incorporation de deutérium n'est constatée. L'échange H/D ne concerne donc pas le naphtothiophène lors d'un processus réversible.

En procédant au départ des mêmes réactifs on accède, dans le benzène à reflux, au dérivé **4'** analogue de **4**. Sur le spectre de rmn de l'adduit **4'** on note la conservation des deux atomes de deutérium dans les positions indiquées ainsi que l'incorporation partielle de deutérium au niveau du motif

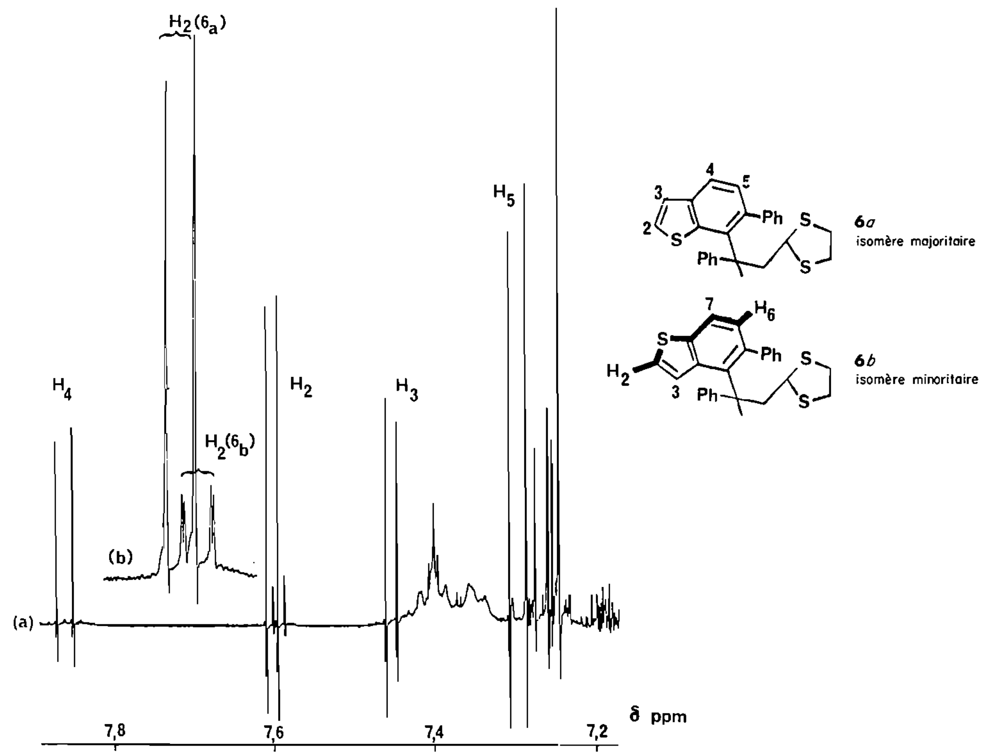

FIG. 5. Spectre rmn ¹H (400 MHz, $(CD_3)_2CO$) des composés **6*a*** et **6*b***.

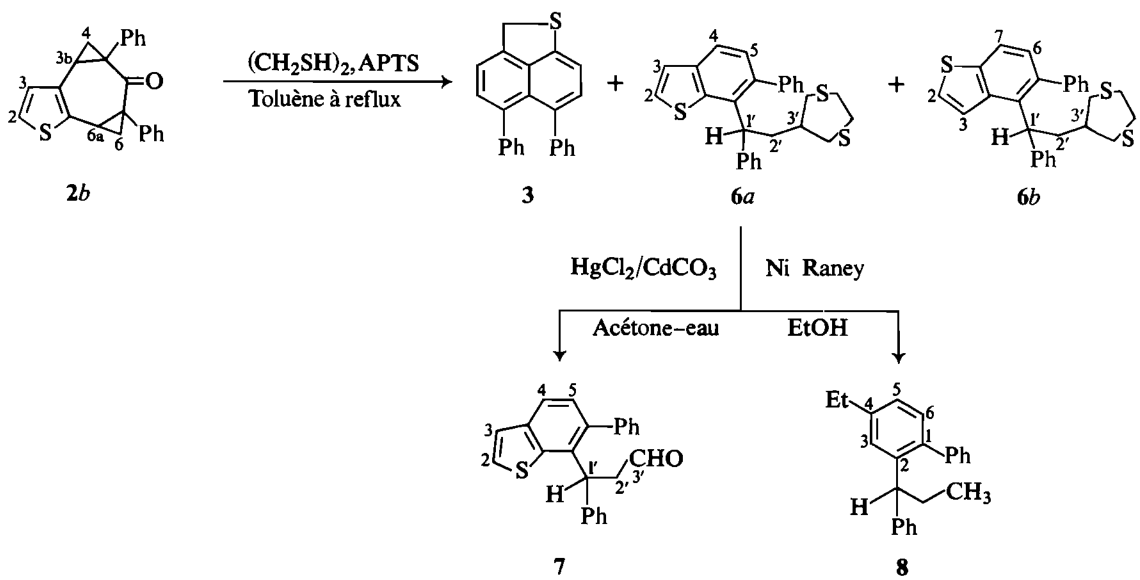

SCHÉMA 2

—CHPh— (voir schéma 3).

Nous avons également mis en oeuvre les composés **2*b*′** et **2*b*″** analogues monodeutériés de la thiophéno[*b*]bishomotropone **2*b*** (voir schéma 4).

Au départ de chacun de ces composés on isole le benzo[*b*]thiophène monodeutérié attendu (l'autre isomère n'apparaît qu'à l'état de traces) mais le naphtothiophène obtenu conjointement ne contient pas de deutéron. Les composés benzothiophéniques sont des intermédiaires monodeutériés, cependant, comme pour l'isomère [*c*], la thiophéno[*b*]bishomotropone subit, à un stade avancé du réarrangement, un échange isotopique D/H avec le milieu acide.

De l'ensemble de ces observations expérimentales, nous pensons pouvoir dégager trois points importants qui vont orienter notre analyse du mécanisme: (*i*) la thiophéno[*c*]bishomotropone livre – dans des conditions voisines – trois produits dont la formation résulte de processus successifs et compétitifs, mettant en jeu un ou deux groupes cyclopropaniques; (*ii*) la thiophéno[*b*]bishomotropone donne des produits ayant pour origine des réactions intéressant les deux sites cyclopropaniques de la molécule; (*iii*) l'analyse des résultats des réactions mettant en oeuvre des composés deutériés apporte des indications précieuses pour la formulation du mécanisme.

Mécanisme du réarrangement

À l'évidence la formation de l'adduit de Michael **4** intervient

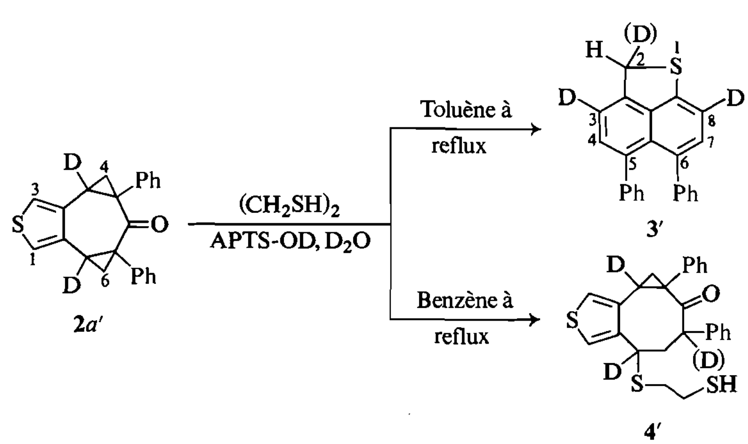

SCHÉMA 3

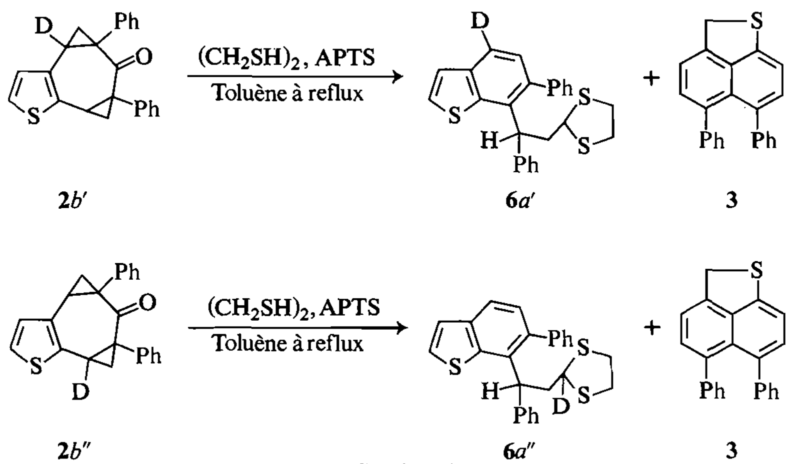

SCHÉMA 4

lors des premières étapes du réarrangement (voir schéma 5): après protonation de la bishomotropone et addition de l'éthane-dithiol, l'intermédiaire (a) subit une prototropie et l'énol protoné (b) s'équilibre en la cétone protonée (c). Après le départ d'un proton on obtient l'adduit **4**.

L'intermédiaire (c) peut évoluer différemment vers (d): l'atome de soufre peut attaquer l'atome de carbone 8 et le transfert du doublet de la liaison C_8—C_{8a} vers C_5 induit le retour du doublet du carbonyle. Cette migration transannulaire d'une liaison σ serait favorisée par l'attaque nucléophile du thiol et le caractère attracteur de l'ion oxonium. Une autre possibilité fait intervenir le cycle thiophénique qui agirait d'abord comme nucléophile. À titre d'exemple nous avons représenté sur le schéma 6 l'évolution de la thiophéno[*c*]bishomotropone dans cette hypothèse. Pour évaluer au départ de (d) le comportement spécifique de chacun des substrats lors des étapes ultérieures nous avons fait figurer les trois isomères sur le schéma 5: l'isomère thiophéno[*c*]bishomotroponique (voie A) se déshydrate avec ouverture simultanée du cycle à trois chaînons pour conduire à un benzo[*c*]thiophène non isolé. La cyclisation de ce dernier livre le naphto[1,8-*bc*]thiophène **3**; l'isomère thiophéno[*b*]bishomotroponique conduit selon la voie B au benzo[*b*]thiophène **6***b* qui se transforme *in situ* presque entièrement en naphto[1,8-*bc*]thiophène **3**; si l'attaque initiale a concerné l'autre motif cyclopropanique, la voie C conduit au benzo[*b*]thiophène **6***a* isomère du précédent qui ne peut se cycliser en naphto[1,8-*bc*]thiophène.

La différence de réactivité observée entre les deux séries isomères concerne essentiellement le passage (c) → (d). Lors de cette étape la rupture au niveau de l'hétérocycle intéresse le sommet β pour la voie A alors que cette rupture concerne le sommet α pour la voie C. La réactivité différente entre les positions α et β thiophéniques est bien connue; elle explique que la thiophéno[*b*]bishomotropone subit une attaque plus aisée sur un des deux sites cyclopropaniques, conduisant préférentiellement à **6***a*: la voie C est privilégiée par rapport à la voie B.

Il reste à préciser pourquoi la transformation conduite en milieu deutérié permet la conservation totale des deutérons, alors que ces derniers sont substitués lors de la dernière étape dans un milieu protique. Ce résultat est la conséquence d'un échange lors de la cyclisation conduisant à **3**. Un tel phénomène a déjà été observé par Cox *et al.* (6) lors de la cyclisation photochimique d'un thiobenzoylnaphtalène.

Conclusion

Le comportement des thiophéno[*c*] et [*b*]bishomotropones vis-à-vis de l'éthanedithiol en milieu acide apparaît très original. Le composé présentant un groupement carbonyle protégé n'apparaît jamais et suivant les conditions opératoires on obtient soit un adduit de Michael, soit un dérivé benzothiophénique, soit un naphtothiophène.

L'analyse du mécanisme de formation de ces dérivés a été rendue possible par la mise en oeuvre de substrats deutériés.

Ce réarrangement non classique fait apparaître – au stade déterminant – un transfert électronique concerté entre un nucléophile doux et un acide dur.

L'analyse comparative des spectres de rmn des produits et de

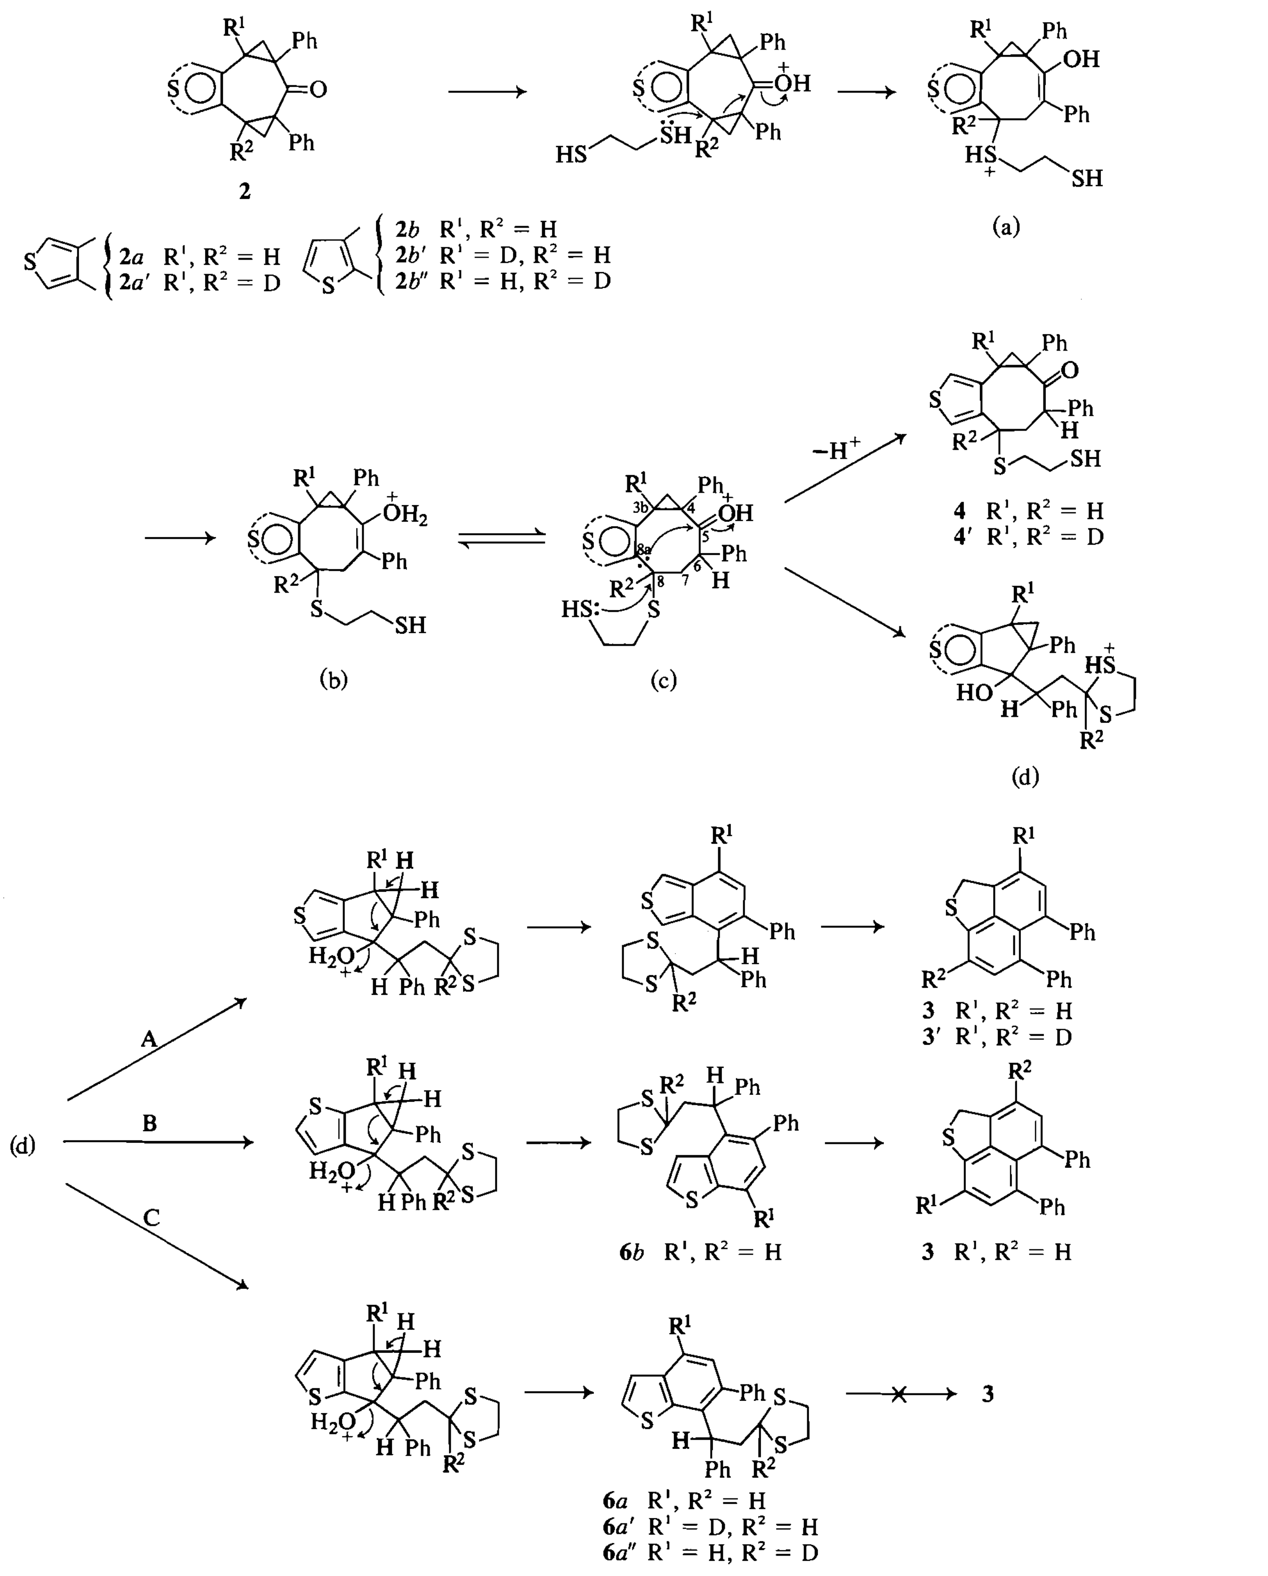

SCHÉMA 5

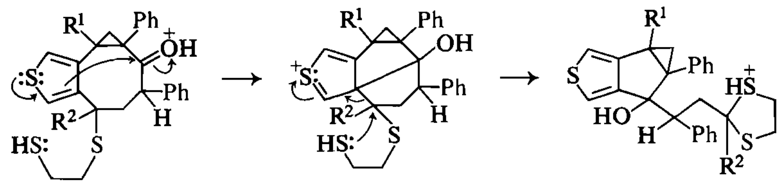
leurs analogues deutériés s'est révélée très précieuse et a permis de conforter de nombreuses étapes du mécanisme proposé.

Partie expérimentale

Les analyses élémentaires ont été effectuées par le Service Central d'Analyse du C.N.R.S. Les spectres de rmn ^{1}H ont été enregistrés à 100 MHz sur un appareil Jeol FX 100 et à 400 MHz sur un appareil Bruker WM 400. Un échantillon de 5 mg est – sauf indication contraire – dissous dans 0,2 cm^3 de $CDCl_3$. Les déplacements chimiques sont donnés en ppm par rapport à $SiMe_4$ et les constantes de couplage en Hz. Les multiplicités sont indiquées comme suit: s (singulet), d (doublet), t (triplet), q (quadruplet), m (multiplet). Les spectres infrarouge ont été relevés sur un appareil Perkin–Elmer 580 (2 mg de produit en suspension dans 200 mg de KBr). Les spectres de masse ont



(c) (d)

SCHÉMA 6

été obtenus par impact électronique (30–70 eV) à l'aide d'un appareil Finnigan 3300.

Thiophénotropones deutériées

*Diphényl-5,7 cyclohepta[*c*]thiophénone-6 (D-4, D-8)*

La préparation a été décrite dans un article antérieur (1).

*Diphényl-5,7 cyclohepta[*b*]thiophénone-6 (D-4) et diphényl-5,7 cyclohepta[*b*]thiophénone-6 (D-8)*

On procède comme dans le cas précédent respectivement au départ de diformyl-2,3 thiophène (CDO-3) ou (CDO-2). Rdts = 68 et 79%, F = 138 et 138°C.

Thiophénobishomotropones

trans *Diphényl-4a,5a tétrahydro-4,4a,6,6a 3b*H*,5a*H*-dicyclopropa[3,4:6,7]cyclohepta[1,2-*c*]thiophénone-5 (D-3b, D-6a),* **2**a′

On procède comme pour son analogue non deutérié (2), au départ de la thiophénotropone correspondante. Rdt = 62%, F = 208°C; rmn δ: 1,43 (d, H_{4exo} et H_{6exo}, J = 6,30 Hz), 2,10 (d, H_{4endo} et H_{6endo}, J = 6,30 Hz), 7,10–7,40 (m, 12H, arom.).

trans *Diphényl-4a,5a tétrahydro-4,4a,6,6a 3b*H*,5a*H*-dicyclopropa[3,4:6,7]cyclohepta[1,2-*b*]thiophénone-5,* **2**b

On procède comme pour l'isomère [*c*] (2). Rdt = 74%, F = 190°C; rmn δ: 1,44 (dd, H_{6exo}, J = 4,49 et 8,89 Hz), 1,49 (dd, H_{4exo}, J = 4,57 et 9,08 Hz), 2,06 (dd, H_{6endo}, J = 4,49 et 6,20 Hz), 2,22 (dd, H_{4endo}, J = 4,57 et 6,64 Hz), 2,73 (dd, H_{3b}, J = 6,64 et 9,08 Hz), 2,86 (dd, H_{6a}, J = 6,20 et 8,89 Hz), 6,92 (d, H_3, J = 5,13 Hz), 7,08 (d, H_2, J = 5,13 Hz), ~ 7,30 (m, 2-C_6H_5).

trans *Diphényl-4a,5a tétrahydro-4,4a,6,6a 3b*H*,5a*H*-dicyclopropa[3,4:6,7]cyclohepta[1,2-*b*]thiophénone-5 (D-3b),* **2**b′

On procède comme pour **2**b. Rdt = 59%, F = 189°C; rmn δ: 1,44 (dd, H_{6exo}, J = 5,08 et 8,91 Hz), 1,53 (d, H_{4exo}, J = 5,40 Hz), 2,05 (dd, H_{6endo}, J = 5,08 et 6,29 Hz), 2,22 (d, H_{4endo}, J = 5,40 Hz), 2,86 (dd, H_{6a}, J = 6,29 et 8,91 Hz), 6,91 (d, H_3, J = 5,19 Hz), 7,08 (d, H_2, J = 5,19 Hz), ~ 7,30 (m, 2-C_6H_5).

trans *Diphényl-4a,5a tétrahydro-4,4a,6,6a 3b*H*,5a*H*-dicyclopropa[3,4:6,7]cyclohepta[1,2-*b*]thiophénone-5 (D-6a),* **2**b″

On procède comme précédemment. Rdt = 62%, F = 184°C; rmn δ: 1,44 (d, H_{6exo}, J = 5,09 Hz), 1,48 (dd, H_{4exo}, J = 5,22 et 9,11 Hz), 2,07 (d, H_{6endo}, J = 5,09 Hz), 2,20 (dd, H_{4endo}, J = 5,22 et 6,64 Hz), 2,74 (dd, H_{3b}, J = 6,64 et 9,11 Hz), 6,91 (d, H_3, J = 5,19 Hz), 7,08 (d, H_2, J = 5,19 Hz), ~ 7,30 (m, 2-C_6H_5).

*Réactions de l'éthanedithiol et des thiophéno[*c*]bishomotropones*

*Diphényl-5,6 2*H*-naphto[1,8-*bc*]thiophène,* **3**

On porte à reflux pendant 18 h 1,71 g (5 mmol) de bishomotropone **2**a, 0,95 g (5 mmol) d'acide *p*-toluènesulfonique (APTS) et 1,26 cm^3 (15 mmol) d'éthanedithiol-1,2 dans 50 cm^3 de toluène anhydre. Le milieu se colore progressivement en lie-de-vin. Après refroidissement, on jette le mélange réactionnel sur 100 cm^3 de soude 2 *N*, extrait à l'éther, lave les phases organiques réunies à l'eau jusqu'à neutralité. Après séchage les solvants sont évaporés sous pression réduite et l'huile résiduelle est chromatographiée sur acide silicique (éluant: chlorure de méthylène/hexane 1:1). Les premières fractions d'élution – fortement colorées en rouge-violet – sont réunies et évaporées. Elles abandonnent 0,61 g (Rdt = 38%) du composé **3** par recristallisation dans l'éther diisopropylique; F = 171°C; ir (cm^{-1}): 3052, 3019, 1579, 1501, 1491, 1441, 1412, 1348, 1183, 1173, 1093, 1073, 1031, 896, 836, 820, 794, 758, 701; rmn δ (($(CD_3)_2CO$): 5,09 (d, —CH_2—, J = 1,47 Hz), 6,86 (s, —C_6H_5), 7,08 (s, —C_6H_5), 7,41 (d, H_4, J = 7,51 Hz), 7,50 (d, H_3, J = 7,51 Hz), 7,54 (d, H_7, J = 7,39 Hz), 7,71 (dt, H_8, J = 7,39 et 1,47 Hz); *m/e*: 324 (M), 323 (M − H), 247 (M − C_6H_5), 202 (247 − CHS). *Anal.* calc. pour $C_{23}H_{16}S$: C 85,14, H 4,97, S 9,88; trouvé: C 85,13, H 4,95, S 9,79.

*Diphényl-5,6 2*H*-naphto[1,8-*bc*]thiophène (D-3, D-8),* **3′**

La préparation de **3′** est identique à celle de **3** mais elle est conduite en présence d'APTS-OD préparé en dissolvant 0,19 g (1 mmol) d'APTS dans 50 cm^3 de toluène anhydre et 5 cm^3 d'eau lourde. Après 15 min d'échange à 50°C l'eau est entrainée sous forme d'azéotrope. L'opération d'échange isotopique est renouvelée trois fois. On ajoute ensuite 0,31 g (1 mmol) de la bishomotropone **2**a′ et 1 cm^3 d'éthanedithiol-1,2 (12 mmol). Après traitement, on isole 0,02 g de **3′**. Rdt = 7%, F = 170°C; ir (cm^{-1}): 3050, 3018, 1558, 1492, 1441, 1396, 1348, 1072, 904, 754, 700; rmn δ ($(CD_3)_2CO$): 5,08 (s élargi, —CH_2—), 7,05 (s, —C_6H_5), 7,07 (s, —C_6H_5), 7,41 (s, H_4), 7,54 (s, H_7); *m/e*: 326 (M), 249 (M − C_6H_5).

*Diphényl-4a,6 (éthanedithiolyl)-8 hexahydro-4,4a,5,6,7,8 3b*H*-cyclopropa[3,4]cycloocta[1,2-*c*]thiophénone-5,* **4** *et diphényl-5,6 (éthanedithiolyl)-8 dihydro-6,7 8*H*-naphto[1,8-*bc*]-thiophène,* **5**

Après 12 h de chauffage à reflux de 1,02 g (3 mmol) de **2**a, 0,57 g (3 mmol) d'APTS et de 1,26 cm^3 (15 mmol) d'éthanedithiol dans 30 cm^3 de benzène anhydre, on obtient un mélange de deux composés principaux, séparés par chromatographie sur acide silicique (chlorure de méthylène/hexane 1:2). Les premières fractions d'élution contiennent 0,05 g (Rdt = 4%, F = 90°C) de **5**, les dernières fractions abandonnent 0,28 g (Rdt = 21%, F = 128–134°C) de **4**. *Composé 4*: ir (cm^{-1}): 3096, 3086, 2568, 1702, 1492, 1060, 802, 698; rmn δ: 1,25 (dd, H_{4exo}, J = 4,11 et 8,30 Hz), 1,63 (t, —SH, J = 7,94 Hz), 2,12 (dd, H_{4endo}, J = 4,11 et 5,98 Hz), 2,28 (ddd, H_{7exo}, J = 3,22, 6,51 et 13,72 Hz), 2,48 (ddd, H_{7endo}, J = 2,68, 11,97 et 13,72 Hz), ~2,70 (m, —SCH_2CH_2S—), 3,22 (ddd, H_{3a}, J = 1,46, 5,98 et 8,30 Hz), 4,33 (dd, H_8, J = 2,68 et 6,51 Hz), 4,49 (dd, H_6, J = 3,22 et 11,97 Hz), 6,90–7,45 (m, 12H, arom.); *m/e*: 436 (M), 375 (M − CH_2CH_2SH), 342 (M − $(CH_2SH)_2$). *Anal.* calc. pour $C_{25}H_{24}OS_3$: C 68,76, H 5,54, O 3,66, S 22,03; trouvé: C 68,96, H 5,58, O 4,17, S 21,28. *Composé 5*: ir (cm^{-1}): 3058, 3026, 2562, 1493, 1449, 1439, 824, 778, 763, 700; rmn δ: 1,62 (t, —SH, J = 8,00 Hz), 2,35 (m, CH_2(7)), 2,65 (m, —SCH_2CH_2S—), 3,81 (ddd, H_8, J = 1,98, 4,39 et 6,37 Hz), 4,39 (t, H_6, J = 3,51 Hz), 6,70–7,20 (m, 10H, arom.), 7,29 (d, H_3, J = 8,57 Hz), 7,46 (d, H_2, J = 1,98 Hz), 7,83 (d, H_4, J = 8,57 Hz); *m/e*: 418 (M), 324 (M − $(CH_2SH)_2$), 247 (324 − C_6H_5).

*Diphényl-4a,6 (éthanedithiolyl)-8 hexahydro-4,4a,5,6,7,8 3b*H*-cyclopropa[3,4]cycloocta[1,2-*c*]thiophénone-5 (D-3a, D-6, D8)* **4′**

Après échange isotopique au départ de 0,19 g (1 mmol) d'APTS dans 50 cm^3 de benzène, on ajoute au milieu réactionnel 0,34 g (1 mmol) de **2**a′ et 1 cm^3 (12 mmol) d'éthanedithiol-1,2. Les quantités mises en jeu ne permettent d'isoler que 0,21 g de **4′** analogue deutérié de **4**. Rdt = 48%, F = 136–138°C; ir (cm^{-1}): 2940, 2910, 2560, 2300, 1696, 1498, 1492, 1037, 760, 698; rmn δ: 1,23 (d, H_{4exo}, J = 4,03 Hz), 1,62 (t, —SH, J = 7,69 Hz), 2,11 (d, H_{4endo}, J = 4,03 Hz), 2,25 (d, H_{7exo}, J = 13,79 Hz), 2,46 (d, H_{7endo}, J = 13,79 Hz), ~ 2,70 (m, —SCH_2CH_2S—), 6,90 – 7,45 (m, 12H, arom.). *Anal.* calc. pour $C_{25}H_{21}D_3OS_3$: C 68,32, O 3,64, S 21,84; trouvé: C 68,30, O 4,39, S 21,36.

*Réactions de l'éthanedithiol et des thiophéno[*b*]bishomotropones*

*Phényl-6 (phényl-1' dithiolannyl-3' n-propyl)-7 benzo[*c*]thiophène,* 6*a, phényl-5 (phényl-1' dithiolannyl-3' n-propyl)-4 benzo[*c*]thiophène* 6*b et 2*H*-naphto[1,8-*bc*]thiophène,* 3

Au départ de 1,71 g (5 mmol) de la bishomotropone **2***b*, de 0,95 g (5 mmol) d'APTS et de 2,0 cm^3 (25 mmol) d'éthanedithiol-1,2 dans 60 cm^3 de toluène à reflux pendant 12 h, on isole après traitement 0,02 g du composé **3** précédemment décrit (F = 171°C, Rdt ~2%) et 1,18 g du mélange **6***a* + **6***b* (F = 132°C, Rdt = 56%); ir (cm^{-1}): 3080, 3055, 3023, 1494, 1447, 1438, 820, 746, 720, 700; rmn δ (400 MHz, $(CD_3)_2CO$): 2,75 (m, —CH_2—), ~3,10 (m, —SCH_2CH_2S—), 4,13 (dd, $H_{3'}$, J = 5,74 et 8,42 Hz), 4,84 (dd, $H_{1'}$, J = 6,71 et 8,91 Hz), 7,00 – 7,40 (m, 10H, arom.), 7,30 (d, H_5, J = 8,11 Hz), 7,45 (d, H_3, J = 5,47 Hz), 7,59 (dd, H_2 (**6***b*), J = 0,53 et 5,47 Hz), 7,60 (d, H_2 (**6***a*), J = 5,47 Hz), 7,86 (d, H_4, J = 8,11 Hz); m/e: 418 (M), 324 (M − $(CH_2SH)_2$), 300 (M − $C_4H_8S_2$), 105 ($C_3H_5S_2$). *Anal.* calc. pour **6***a* + **6***b*, $C_{25}H_{22}S_3$: C 71,72, H 5,30, S 22,98; trouvé: C 71,86, H 5,45, S 22,92.

*Phényl-6 (phényl-1' dithiolannyl-3' n-propyl)-7 benzo[*b*]thiophène (D-4),* 6*a'*

On opère comme dans le cas précédent: au départ de 1,71 g (5 mmol) de **2***b'* on isole successivement 0,008 g de **3** (Rdt ~0,5%) et 0,46 g de **6***a'* (F = 132°C, Rdt = 22%); rmn δ: 2,75 (m, —CH_2—), ~3,00 (m, —SCH_2CH_2S—), 4,15 (dd, $H_{3'}$, J = 5,80 et 8,36 Hz), 4,83 (dd, $H_{1'}$, J = 6,74 et 8,70 Hz), 7,0–7,3 (m, 13H, arom.); m/e: 419 (M), 325 (M − $(CH_2SH)_2$), 301 (M − $C_4H_8S_2$), 105 ($C_3H_5S_2$). *Anal.* calc. pour $C_{25}H_{21}DS_3$: C 71,59, S 22,89; trouvé: C 72,02, S 22,82.

*Phényl-6 (phényl-1' dithiolannyl-3' n-propyl)-7 benzo[*b*]thiophène (D-3'),* 6*a''*

De même 1,71 g (5 mmol) de **2***b''* conduisent à 0,025 g de **3** (Rdt ~1,5%) et 1,11 g de **6***a''* (F = 132°C, Rdt = 53%). rmn δ: 2,75 (m, —CH_2—), ~3,00 (m, —SCH_2CH_2S—), 4,84 (dd, $H_{1'}$, J = 6,65 et 8,72 Hz), 7,0 – 7,3 (m, 13H, arom.), 7,75 (d, H_4, J = 8,06 Hz); m/e: 419 (M), 325 (M − $(CH_2SH)_2$), 301 (M − $C_4H_8S_2$), 106 ($C_3H_4DS_2$). *Anal.* calc. pour $C_{25}H_{21}DS_3$: C 71,59, S 22,89; trouvé: C 71,65, S 22,60.

Transformations au départ des composés 6*a et* 6*b*

*Phényl-6 (phényl-1' oxo-3' n-propyl)-7 benzo[*b*]thiophène,* 7

Suivant la procédure de Wolfrom (7), on agite à la température ambiante 0,42 g (1 mmol) du mélange des dithiolannes **6***a* + **6***b*, 8,00 g (30 mmol) de chlorure mercurique dans 60 cm^3 d'acétone et 10 cm^3 d'eau distillée. On ajoute ensuite, en quatre fractions, 8,00 g (46 mmol) de carbonate de cadmium toutes les deux heures. Après traitement le résidu obtenu est chromatographié sur acide silicique (chlorure de méthylène/hexane 1:1). La transformation n'est pas totale, elle permet d'isoler 0,03 g de l'aldéhyde majoritaire **7** (F = 133°C, Rdt = 10%); ir (cm^{-1}): 3094, 3054, 1724, 1450, 1087, 752, 720, 698; rmn δ: 3,18 (ddd, $H_{2'a}$, J = 1,96, 7,30 et 16,80 Hz), 3,48 (ddd, $H_{2'b}$, J = 2,42, 8,07 et 16,80 Hz), 5,24 (dd, $H_{1'}$, J = 7,30 et 8,07 Hz), 7,0 – 7,3 (m, 13H, arom.), 7,75 (d, H_4, J = 8,05 Hz), 9,55 (dd, —CHO, J = 1,96 et 2,42 Hz); m/e: 342 (M), 324 (M − H_2O), 298 (M − C_2H_4O). *Anal.* calc. pour $C_{23}H_{18}OS$: C 80,67, H 5,30, O 4,67, S 9,36; trouvé: C 81,17, H 5,18, O 5,08, S 8,81.

Phényl-1 éthyl-4 (phényl-1' n-propyl)-2 benzène, 8

On prépare le nickel de Raney au départ de 8 g d'alliage et de 30 cm^3 de lessive de soude à 30%. On agite magnétiquement 0,35 g (0,83 mmol) du mélange des dithiolannes **6***a* + **6***b* en présence du catalyseur, dans 40 cm^3 d'éthanol. Après 16 h de reflux on élimine le nickel et on évapore le solvant. Après chromatographie sur acide silicique (chlorure de méthylène/hexane 1:1), on isole un liquide (R_f ~ 0,3), Rdt = 80%; ir (cm^{-1}): 3058, 3025, 2963, 2931, 2872, 1600, 1494, 1482, 1451, 1009, 830, 763, 700; rmn δ: 0,70 (t, $CH_3(3')$, J = 7,40 Hz), 1,19 (t, $CH_3(2'')$, J = 7,60 Hz), 1,92 (quintuplet, $CH_2(2')$, J = 7,40 Hz), 2,60 (q, $CH_2(1'')$, J = 7,60 Hz), 3,86 (t, $CH(1')$, J = 7,40 Hz), 6,8 – 7,2 (m, 13H, arom.); m/e: 300 (M), 271 (M − C_2H_5), 193 (271 − C_6H_6). *Anal.* calc. pour $C_{23}H_{24}$: C 91,95, H 8,05; trouvé: C 90,83, H 8,02.

Monoclinique, a = 11,711(4), b = 9,707(6), c = 15,452(9) Å, β = 109,41(4)°, V = 1655,6 Å^3, Z = 4, D_c = 1,30, $F(000)$ = 680 e^-, CuK_α (λ = 1,54051 Å), groupe d'espace $P2_1/c$. Un cristal de dimensions 0,2 × 0,1 × 0,2 mm a été utilisé pour cette analyse. Les mesures ont été effectuées sur un diffractomètre automatique Nonius CAD4F avec un contrôle de dérive réalisé sur trois taches mesurées toutes les cent mesures. Les intensités de 3159 réflexions (1 < θ < 60°) ont été enregistrées selon la technique de balayage θ/2θ et 2118 d'entre elles ont été utilisées ($I > 2\sigma(I)$). La structure a été résolue par la méthode de détermination automatique des phases à l'aide du programme MULTAN (8). Elle a été affinée par une méthode de moindres carrés avec matrice complète (SHELX) (9). Les valeurs des facteurs de diffusion atomique sont celles de "International Tables for X-ray Crystallography". Les corrections d'extinction n'ont pas été effectuées et l'absorption a été négligée compte tenu de la taille du cristal (coefficient linéaire μ = 13 cm^{-1}). Dans l'affinement par moindres carrés la pondération w est maintenue égale à 1. La densité électronique différence observée sur la carte finale est de 0,45 e/Å^3. Les coordonnées des atomes d'hydrogène ont été déterminées à partir de section différence puis affinées avec un facteur d'agitation thermique isotrope bloqué égal à celui du carbone auquel il est attaché. Les valeurs des différentes coordonnées fractionnaires et le paramètre d'agitation thermique équivalent sont donnés dans le Tableau 3. Le facteur de reliabilité sans pondération est $R(F)$ = 0,059. Les amplitudes des facteurs de structure, les coordonnées fractionnaires des atomes d'hydrogène et les facteurs d'agitation thermique anisotropes des atomes lourds sont disponibles.[2]

Towards a complete account of diastereotopic hydrogen isotope exchange of carbon acids. III. Base-catalyzed exchange of sulfoxides. Evidence for exchange by inversion

NICK HENRY WERSTIUK AND SUJIT BANERJEE[1]
Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received July 16, 1984

NICK HENRY WERSTIUK and SUJIT BANERJEE. Can. J. Chem. **63**, 2100 (1985).

The rate constants for deuteroxide and hydroxide catalyzed H → D and D → H exchange of benzodihydrothiophene oxide (**1**a) and several of its deuterated analogs **1**b, **1**c, and **1**d at 30.00 ± 0.05°C are reported along with the rate constants for D → H exchange of deuterated benzyl methyl sulfoxides **2**b and **2**c. Application of the steady-state assumption to schemes involving equilibrating pyramidal anions yield equations which are used to fit experimentally determined $(k_f/k_s)^{H\rightarrow D}$ and $(k_f/k_s)^{D\rightarrow H}$ ratios. The analysis supports our view that exchange of the diastereotopic protons (deuterons) occurs by inversion. The inversion component contributes significantly to exchange of the "slow" proton (deuteron) of a diastereotopic pair and this accounts for the observation that $(k_f/k_s)^{D\rightarrow H} < (k_f/k_s)^{H\rightarrow D}$. This study establishes an upper limit of 6 kcal for the barrier to inversion of the carbanions derivable from **1** and **2**, if pyramidal anions are formed.

NICK HENRY WERSTIUK et SUJIT BANERJEE. Can. J. Chem. **63**, 2100 (1985).

Opérant à 30,00 ± 0,05°C et en présence de deutéroxyde et d'hydroxyde comme catalyseurs, on a mesuré les constantes de vitesse des réactions d'échange H → D et D → H, de l'oxyde de benzodihydrothiophène et de plusieurs de ses analogues deutérés (**1**b, **1**c et **1**d) ainsi que les constantes de vitesse des réactions d'échange D → H des benzylméthylesulfoxydes deutérés **2**b et **2**c. Si on applique l'hypothèse de l'état stationnaire aux processus impliquant un équilibre des anions pyramidaux, on obtient des équations que l'on peut utiliser pour établir une corrélation avec les rapports $(k_f/k_s)^{H\rightarrow D}$ et $(k_f/k_s)^{D\rightarrow H}$ obtenus expérimentalement. L'analyse est en accord avec notre hypothèse selon laquelle l'échange des protons (deutérons) diastéréotopes se fait par inversion. La composante de l'inversion contribue d'une façon importante à l'échange du proton (deutéron) "lent" d'une paire diastéréotope et ceci tient compte du fait que $(k_f/k_s)^{D\rightarrow H} < (k_f/k_s)^{H\rightarrow D}$. S'il se forme des anions pyramidaux, cette étude a permis d'établir à 6 kcal la limite supérieure pour la barrière d'inversion des carbanions provenant des composés **1** et **2**.

[Traduit par le journal]

Introduction

The stereochemistry of base-catalyzed hydrogen isotope exchange of carbon acids other than ketones has commanded considerable interest over the past two decades, and there have been documented numerous studies of the rates of "fast" and "slow" exchange of diastereotopic protons of sulfoxides (1−19, 33), sulfones (20−28), sulfonium salts (29−34), nitrosoamines (35−37), and other carbon acids (38, 39). Researchers were primarily interested in establishing the nature of the intermediate carbanions − planar or rapidly equilibrating − and the factors which control their stability.

By studying H → D and D → H exchange of bicyclo[2.2.1]-heptan-2-one we established that exchange of diastereotopic protons (deuterons) is quite complex − exchange of the "slow" proton (deuteron) by inversion is very important and is manifest in a $(k_f/k_s)^{D\rightarrow H}$ ratio which is considerably smaller than the $(k_f/k_s)^{H\rightarrow D}$ ratio (40). We assumed that a common enolate was generated by abstraction of a fast (*exo*) proton or slow (*endo*) proton and developed equations which related the observed rate ratios, $(k_f/k_s)^{H\rightarrow D}$ and $(k_f/k_s)^{D\rightarrow H}$, to the intrinsic selectivity, the primary and secondary kinetic isotope effects (KIEs) for deprotonation and protonation, and the solvent isotope effects (SIEs) (41).

In this paper we deal with more complex exchange schemes which include pyramidal diastereotopic carbanions as intermediates. We report the rate constants for H→D and D→H exchange of benzodihydrothiophene oxide (**1**a) and several of its deuterated analogs **1**b, **1**c, and **1**d, the rate constants for D → H exchange of benzyl methyl sulfoxide-d_2, and consider exchange data for labelled benzyl methyl sulfoxides published

by Fraser and Ng (18). It is clear, based on our analysis, that exchange of the slow proton of sulfoxides also occurs by inversion to a considerable extent.[2] We place an upper limit

[1]Present address: Safety and Environmental Protection Division, Brookhaven National Laboratory, Upton, New York 11973.

[2]For the purposes of simplicity our treatment ignores the fact that exchange of the fast proton must also occur by inversion to a very minor extent. This relates to $k_f^{H\rightarrow D}$ and $k_f^{D\rightarrow H}$ used in subsequent derivations. Also, when $k_f \gg k_s$, $k_{f_{obs}}^{H\rightarrow D} \simeq k_1 V_D$.

Results

The kinetics of H → D and D → H exchange of benzodihydrothiophene oxide (**1***a*) and its deuterated analogs **1***b*, **1***c*, and **1***d* were studied in NaOD−D_2O and NaOH−H_2O solutions, respectively, at 30.00 ± 0.05°C. D → H exchange studies of benzyl methyl sulfoxide-d_2 and benzyl methyl sulfoxide-d_1 were also undertaken. The sulfoxides were dissolved in the appropriate base solution; aliquots were withdrawn at suitable intervals, quenched by a buffer, and extracted with ether. Deuterium analyses were carried out mass spectrometrically at low voltage and the rate data were uncorrected for dilution due to exchange (42). The results for **1***a*, **1***b*, **1***c*, and **1***d* are given in Table 1 along with the $(k_f/k_s)^{H\to D}$ and $(k_f/k_s)^{D\to H}$ ratios, which are 59.2 ± 3.5 and 17.3 ± 2.3, respectively. Figures 1(A) and 1(B) show typical computer-generated plots, including the linear-least-square lines, for *trans* H → D exchange of **1***a* and D → H exchange of **1***b*. Figures 1(C) and 1(D) show the plots for *cis* H → D and D → H exchange of **1***c* and **1***d*, respectively. Our value of 59.2 ± 3.5 for $(k_f/k_s)^{H\to D}$ compares favourably with the value of 67 at 5°C reported by King and du Manoir, who established that the

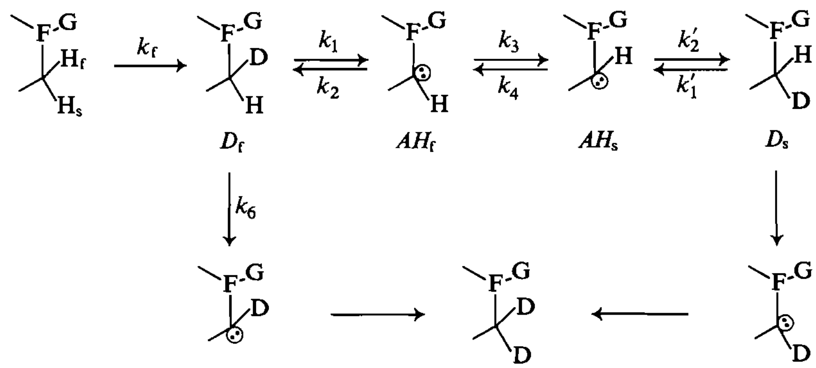


SCHEME 1

hydrogens *trans* to the oxygen of **1*a*** exchange faster than the *cis* hydrogens (15). Table 2 gives the data for exchange of **2*b*** and **2*c*** and $(k_f/k_s)^{D\to H}$ that is 10.8 ± 1.3. Figures 2(A) and 2(B) are typical computer-generated plots for exchange of **2*b*** and **2*c***, respectively. In **2** it is the pro-*R* hydrogen of *S* that exchanges faster than the pro-*S* hydrogen (7). The $(k_f/k_s)^{D\to H}$ ratios determined by ourselves and Fraser and Ng (9.9 ± 0.03) (18) compare very favourably.

Discussion and conclusions

Derivations of equations for H−D exchange

If Scheme 1 (F-G = functional group) is considered for H → D exchange of a carbon acid involving diastereotopic pyramidal anions as intermediates, then a steady-state treatment using AH_f, AH_s, and D_s as steady-state intermediates yields the expression given in eq. [1] for $k_s^{H\to D}$.[3] Rewriting eq. [1] with C given by eq. [2] yields eq. [3].

$$[1]\quad k_{s_{obs}}^{H\to S} \simeq k_6 + k_1\left\{1 - k_2\left[\frac{k_5(k_2' + k_4) + k_1'k_4}{k_2k_4(k_1' + k_5) + k_2'k_5(k_2 + k_3)}\right]\right\}$$

$$[2]\quad C = k_2'k_5 + k_4k_5 + k_1'k_4$$

$$[3]\quad k_{s_{obs}}^{H\to D} \simeq k_6 + k_1\left[1 - \frac{C}{C + \frac{k_3}{k_2}(k_2'k_5)}\right]$$

When k_3/k_2 is small − the barrier to inversion of AH_f is high − $k_{s_{obs}}^{H\to D} \simeq k_6$. However, if the barrier to inversion is low and k_3 is comparable to or larger than k_2, then I, given by eq. [4], corresponds basically to an inversion component of slow proton (deuteron) exchange and makes a substantial contribution to $k_{s_{obs}}^{H\to D}$ with the result that $k_{s_{obs}}^{H\to D} > k_6$. Clearly, under

$$[4]\quad I = k_1\left[1 - \frac{C}{C + \frac{k_3}{k_2}(k_2'k_5)}\right]$$

these circumstances, $(k_f/k_s)_{obs}^{H\to D}$ does not provide an accurate measure of the intrinsic selectivity. If S_D is the intrinsic selectivity in deuterated medium, V_D and L_D are the primary KIEs for "fast" and "slow" deprotonations, V_D' and L_D' are the primary KIEs for protonation, and v_D and l_D are the secondary KIEs, then the following relationships obtain:

$$S_D \simeq k_4k_2V_D'/k_3k_2'L_D' \simeq k_1V_Dk_1'L_D \simeq k_5v_D/k_6l_D,\qquad k_5 \simeq k_1V_D/v_D$$

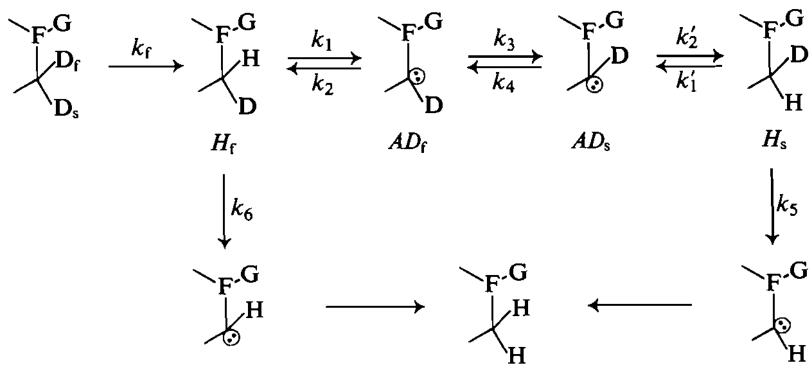
If two terms a_D and b_D defined as $a_D = k_3/k_2V_D'$ and $b_D = k_4/k_2'L_D'$ are used, then $b_D = a_DS_D$. Substitution of the appropriate terms into eq. [1], and simplification, yields eq. [5].

$$[5]\quad k_{s_{obs}}^{H\to D} \simeq k_6 + k_1\left[\frac{a_DS_DL_DV_D'}{S_D(b_DL_DL_D' + a_DV_D'L_D + L_D) + b_Dv_DL_D'}\right]$$

Since $k_6 \simeq k_5v_D/S_Dl_D \simeq k_1V_D/S_Dl_D$ and $k_f^{H\to D} \simeq k_1V_D$, eq. [5] yields eq. [6][2] that can be rewritten as eq. [7] since $b_D = a_DS_D$.

$$[6]\quad k_{s_{obs}}^{H\to D} \simeq k_{f_{obs}}^{H\to D}\left\{\frac{1}{S_Dl_D} + \frac{V_D'}{V_D}\left[\frac{a_DS_DL_D}{S_D(b_DL_DL_D' + a_DV_D'L_D + L_D + b_Dv_DL_D'}\right]\right\}$$

[3]As discussed in our preceding paper (41), it is likely that more complex alternatives, perhaps more quantitative analyses of the exchange of diastereotopic protons (deuterons, tritons), are possible. However, in our view, our analysis is a viable approach when $k_f \gg k_s$ and D_s and H_s can be considered as steady-state intermediates.



SCHEME 2

$$[7]\quad \left(\frac{k_f}{k_s}\right)_{obs}^{H\to D} \simeq \frac{l_D S_D\left(a_D L_D' S_D + a_D V_D' + \frac{a_D v_D L_D'}{L_D} + 1\right)}{a_D L_D' S_D + a_D V_D' + \frac{a_D v_D L_D'}{L_D} + \frac{a_D l_D S_D V_D'}{V_D} + 1}$$

If a_D is small ($k_3 \ll k_2$) or equal to 0 — the barrier to inversion is high or non-inverting anions are formed — then eq. [7] simplifies into eq. [8], exactly what would be expected if diastereomeric anions were formed and fast and slow exchange occurred only by retention.

$$[8]\quad \left(\frac{k_f}{k_s}\right)_{obs}^{H\to D} \simeq l_D S_D$$

In the case where a_D is large — the barrier to inversion is considerably smaller than the barrier to protonation — and $S_D > V_D > v_D$, eq. [9] obtains.

$$[9]\quad \left(\frac{k_f}{k_s}\right)_{obs}^{H\to D} \simeq \frac{l_D L_D' S_D}{L_D' + \frac{V_D'}{V_D} l_D}$$

That eq. [9] is exactly what is obtained in a simpler treatment when only a single intermediate is considered, i.e., ketones (40, 41), provides support for the validity of our analysis: the case where a_D is large ($k_3 \gg k_2$) is equivalent to the case where a single intermediate is generated. If the deprotonation and protonation KIEs are similar in magnitude — $V_D \simeq V_D' \simeq L_D \simeq L_D'$ — and set equal to i and the secondary KIEs are $\simeq 1$, eq. [9] simplifies to eq. [10].

$$[10]\quad \left(\frac{k_f}{k_s}\right)_{obs}^{H\to D} \simeq \frac{S_D i}{i+1}$$

Presently there is no information available on the relative magnitudes of the isotope effects although it is expected that the protonation KIEs should be equal to or less than the deprotonation KIEs. Limited data available for ketones (41) indicate that the protonation KIEs are equal to or less than the deprotonation KIEs.

Derivation of equations for D → H exchange

If Scheme 2 is considered for D → H exchange of a carbon acid where diastereotopic pyramidal carbanions are intermediates, then a steady-state treatment involving AD_f, AD_s, and H_s as steady-state intermediates yields expression [11] for $k_{s_{obs}}^{D\to H}$.

$$[11]\quad k_{s_{obs}}^{D\to H} \simeq k_6 + k_1\left\{1 - k_2\left[\frac{k_5(k_2' + k_4) + k_1'k_4}{k_2k_4(k_1' + k_5) + k_2'k_5(k_2 + k_3)}\right]\right\}$$

If C' is the collection of constants given by eq. [12], then eq. [11] can be rewritten as eq. [13].

$$[12]\quad C' = k_2'k_5 + k_4k_5 + k_1'k_4$$

$$[13]\quad k_{s_{obs}}^{D\to H} \simeq k_6 + k_1\left[1 - \frac{C'}{C' + \frac{k_3}{k_2}(k_2'k_5)}\right]$$

When the barrier to inversion of AD_f is high — k_3/k_2 is small — then $k_{obs}^{D\to H} \simeq k_6$. However, if the barrier to inversion is low and $k_3 \gg k_2$, then $k_{obs}^{D\to H} > k_6$. If S_H is the intrinsic selectivity, V_H and L_H are the primary KIEs for fast and slow deprotonation, respectively, in non-deuterated medium, v_H and l_H are the corresponding secondary KIEs, and, given that $S_H \simeq k_4k_2l_H/k_3k_2'v_H \simeq k_1v_H/k_1'l_H \simeq k_5V_H/k_6L_H$, $k_5 \simeq k_1v_H/V_H$, $a_H = k_3v_H/k_2$, $b_H = k_4l_H/k_2'$, and $b_H = a_HS_H$, eq. [14] obtains.

$$[14]\quad k_{obs}^{D\to H} \simeq k_6 + k_1\left(\frac{a_HS_Hl_H^2}{a_HS_HV_Hv_H + a_HS_H^2v_Hl_H + S_Hv_Hl_H^2 + a_HS_Hl_H^2}\right)$$

Since $S_H \simeq k_5V_H/k_6L_H$ and $k_5 \simeq k_1v_H/V_H$, eq. [14] can be rewritten as eq. [15].

$$[15]\quad k_{s_{obs}}^{D\to H} \simeq k_1\left[\frac{a_HV_Hv_H^2 + a_HS_Hv_H^2l_H + v_H^2l_H^2 + a_Hv_H^2l_H^2 + a_HS_HL_Hl_H^2}{S_HL_H(a_Hv_HV_H + a_HS_Hv_Hl_H + v_Hl_H^2 + a_Hl_H^2)}\right]$$

Since $k_1 \simeq k_f^{D\to H}V_H$, eq. [15] can be rewritten as eq. [16].[2]

$$[16]\quad \left(\frac{k_f}{k_s}\right)_{obs}^{D\to H} \simeq \frac{L_H}{V_H}\left[\frac{S_H(a_HV_Hv_H + a_HS_Hv_Hl_H + v_Hl_H^2 + a_Hl_H^2)}{a_HV_Hv_H^2 + a_HS_Hv_H^2l_H + v_H^2l_H^2 + a_Hv_H^2l_H^2 + a_HS_HL_Hl_H^2}\right]$$

TABLE 3. Hydrogen isotope exchange of benzyl methyl sulfoxide[a]

Substrate	Medium	k (M^{-1} min^{-1}) × 10^2 H	D	T
	NaOD–D_2O (0.04 M)	21.6±0.3		7.22±0.06
	NaOH–H_2O (0.04 M)		5.41±0.08	3.90±0.03
	NaOD–D_2O[b] (0.48 M)	0.942		0.330±0.004
	NaOH–H_2O (0.48 M)		0.545	0.392±0.004

[a]Taken from ref. 18.
[b]Exchange actually occurs on the D_f substituted species because $k_f = 21.6\ k_s$.

If the barrier to inversion of AD_f is high ($k_3 \ll k_2$ and a_H approaches 0) or exchange occurs only by retention, then eq. [16] reduces to eq. [17]. The result is exactly what would be expected for those cases. When a_H is large – the barrier to inversion is considerably smaller than the barrier to protonation – and S_H is larger than the KIEs, eq. [17] reduces to eq. [18]. If the deprotonation and protonation KIEs

$$[17]\quad \left(\frac{k_f}{k_s}\right)^{D\to H}_{obs} \simeq \frac{S_H L_H}{V_H \nu_H}$$

$$[18]\quad \left(\frac{k_f}{k_s}\right)^{D\to H}_{obs} \simeq \frac{S_H L_H \nu_H}{V_H(L_H l_H + \nu_H^2)}$$

are similar in magnitude and set equal to i and the secondary KIEs ≃ 1, eq. [18] further reduces to eq. [19].

$$[19]\quad \left(\frac{k_f}{k_s}\right)^{D\to H}_{obs} \simeq \frac{S_H}{i+1}$$

That eqs. [18] and [19] are identical to the equations for $(k_f/k_s)^{D\to H}_{obs}$ obtained previously, utilizing a scheme where a single intermediate (40, 41) is generated, i.e., from ketones, establishes the validity of our approach and the equations generated therefrom.

When a ratio of [10]/[19] is taken, eq. [20] results.

$$[20]\quad \frac{\left(\frac{k_f}{k_s}\right)^{H\to D}_{obs}}{\left(\frac{k_f}{k_s}\right)^{D\to H}_{obs}} \simeq \frac{\frac{S_D i_D}{i_D + 1}}{\frac{S_H}{i_H + 1}} \simeq \left(\frac{S_D i_D}{i_D + 1}\right)\left(\frac{i_H + 1}{S_H}\right)$$

Since $S_D = S_H$ and $i_D \simeq i_H$ are set equal to i, eq. [20] reduces to eq. [21].

$$[21]\quad \frac{\left(\frac{k_f}{k_s}\right)^{H\to D}_{obs}}{\left(\frac{k_f}{k_s}\right)^{D\to H}_{obs}} \simeq i$$

From the data in Table 1 the ratio given by eq. [21] for **1** is 3.41 ± 0.66, a reasonable value for i (*vide infra*). In Table 3 are listed data for hydrogen isotope exchange of benzyl methyl sulfoxide and its deuterated and tritiated analogs published by Fraser and Ng (18). The $(k_f/k_s)^{H\to D}$, $(k_f/k_s)^{D\to H}$, $(k_f/k_s)^{H\to T}$, and $(k_f/k_s)^{T\to H}$ ratios calculated from the data are 22.9 ± 0.7, 9.9 ± 0.03, 21.8 ± 0.2, and 10.0 ± 0.02, respectively. The H → D/D → H ratio for **2** is 2.31 ± 0.14. Since $(k_H/k_T)_f$ = 2.99, application of the Swain–Schaad relationship yields a value of 2.2 for $(k_H/k_D)_f$. Since $(k_H/k_D)_f \simeq i$, the correlation between the value of the ratio (i) given by eq. [21] and the experimentally obtained isotope effect for **2** is noteworthy and confirms the validity of our treatment.

Since eq. [22] holds for fast exchange of **2** in deuterated and non-deuterated medium ($SIE_f \simeq SIE_1$)

$$[22]\quad \frac{k_f^{H\to D}}{k_f^{D\to H}} = 3.99 \simeq V_H \nu_H\ SIE_f$$

and $V_H \simeq V_D = 2.2$, and ν_H the secondary KIE in non-deuterated medium should fall in the range of 1.1–1.2, SIE_f can range from 1.81–1.51, mid-range being around 1.6. The range evaluated for SIE_f is reasonable, based on the solvent isotope effects[4] that have been determined for a variety of carbon acids. The analysis also establishes that the secondary KIE for fast deprotonation (ν_D) is in the range expected for an $sp^3 \to$ "sp^2-like" process. A mid-range value of 1.15 will be used in subsequent discussions and calculations and it is assumed that $\nu_D \simeq l_D \simeq \nu_H \simeq l_H$. Since $k_f^{D\to H}$ is obtained from exchange of **1***b* that has two β-deuterons, assuming that the β-KIEs are cumulative, the H → D/D → H ratio for **1** is given by eq. [23].

[4]The SIEs for hydroxide-catalyzed reactions of nitroethane, 2-nitropropane, acetone, phenylacetylene, *tert*-butylmalononitrile, 9-fluoroenylmethane, and 1,4-dicyano-2-butene are 1.40, 1.35, 1.47, 1.33, 1.72, 1.49, and 1.38, respectively (43). Based on our analysis, values of 1.4 and 2.4 reported by Rauk *et al.* (44) for the secondary KIE and SIE, respectively, seem unusually high.

$$[23]\quad \frac{k_f^{H\to D}}{k_f^{D\to H}} = 6.6 \simeq V_H \nu_H (\nu_H^{\beta})^2 \mathrm{SIE_f}$$

Since ν_H^{β} should range between 1 and 1.1, V_H for **1** should fall in the range of 3.6–3.0 assuming that $\mathrm{SIE_f} \simeq 1.6$ (*vide supra*). The correlation between V_H evaluated using eq. [23] and *i* obtained from eq. [21] is significant and provides additional support for the validity of this treatment. There is a significant inversion component to the exchange of the slow proton (deuteron or triton) of a diastereotopic pair.

Derivation of equations for H → D exchange including solvent isotope effects

Although our analysis adequately accounts for the difference between the $(k_f/k_s)^{H\to D}$ and $(k_f/k_s)^{D\to H}$ ratios, it is necessary, in principle, to include solvent isotope effects for fast and slow exchange to obtain a more accurate measure of the intrinsic selectivity. It should be noted, however, that the effect on the rate ratio is minimal if $\mathrm{SIE_f} \simeq \mathrm{SIE_s}$, which is most likely in these cases because the fast–slow reactivities for **1** and **2** are not vastly different. Given the expressions for S_D developed for H → D exchange (*vide supra*) and since $\mathrm{SIE}'_1 \simeq \mathrm{SIE}_6$ and $\mathrm{SIE}_5 \simeq \mathrm{SIE}_1$, assuming that the SIEs for inversion of the diastereomeric anions are negligibly small, substitution of the appropriate terms for S_D, a_D, and b_D, which now include the SIEs,[5] into eq. [1] yields eq. [24]. If a_D is small – the barrier to inversion is high or two non-inverting anions are generated – then eq. [24] reduces to eq. [25],

$$[24]\quad \left(\frac{k_f}{k_s}\right)^{H\to D}_{obs} \simeq \frac{(l_D S_D)\left(a_D L'_D S_D \mathrm{SIE}_1^2 + \dfrac{a_D V'_D \mathrm{SIE}_1^2 \mathrm{SIE}'_2}{\mathrm{SIE}_2} + \mathrm{SIE}_1^2\mathrm{SIE}'_2 + \dfrac{a_D V_D L'_D \mathrm{SIE}_1 \mathrm{SIE}_6}{L_D}\right)}{a_D L'_D S_D \mathrm{SIE}_1\mathrm{SIE}_6 + \dfrac{a_D V'_D \mathrm{SIE}_1 \mathrm{SIE}'_2 \mathrm{SIE}_6}{\mathrm{SIE}_2} + \mathrm{SIE}_1\mathrm{SIE}'_2\mathrm{SIE}_6 + \dfrac{a_D \nu_D L'_D \mathrm{SIE}_6^2}{L_D} + \dfrac{a_D l_D V'_D S_D \mathrm{SIE}_1^2 \mathrm{SIE}'_2}{V_D \mathrm{SIE}_2}}$$

$$[25]\quad \left(\frac{k_f}{k_s}\right)^{H\to D}_{obs} \simeq \frac{l_D S_D \mathrm{SIE}_1}{\mathrm{SIE}_6}$$

exactly what would be expected for those cases. If a_D is large – the barrier to inversion is less than the barrier to protonation – and $S_D > V'_D$, L'_D, SIE_1, SIE_6, or ν_D, eq. [24] simplifies to eq. [26].

$$[26]\quad \left(\frac{k_f}{k_s}\right)^{H\to D}_{obs} \simeq \frac{l_D L'_D S_D \mathrm{SIE}_1}{\left[L'_D + \dfrac{\mathrm{SIE}_1}{\mathrm{SIE}_6}\dfrac{\mathrm{SIE}'_2}{\mathrm{SIE}_2}\left(\dfrac{l'_D V'_D}{V_D}\right)\right]\mathrm{SIE}_6}$$

From eqs. [18] and [26] we obtain eq. [27].

$$[27]\quad \left(\frac{k_s}{k_f}\right)^{H\to D}\left(\frac{k_f}{k_s}\right)^{D\to H} \simeq \frac{\left[L'_D + \left(\dfrac{\mathrm{SIE}_1\mathrm{SIE}'_2}{\mathrm{SIE}_6\mathrm{SIE}_2}\right)\left(\dfrac{l_D V'_D}{V_D}\right)\right]\mathrm{SIE}_6}{l_D L'_D S_D \mathrm{SIE}_1}\left[\frac{S_H L_H \nu_H}{V_H(L_H l_H + \nu_H^2)}\right]$$

Since $\mathrm{SIE}_1 \simeq \mathrm{SIE_f}$, on the assumption that $V_D \simeq V'_D \simeq L'_D \simeq L_H$, and l_D, ν_H, and $l_H \simeq 1$, and $\mathrm{SIE}_1 \simeq \mathrm{SIE}_6$, $\mathrm{SIE}_2 \simeq \mathrm{SIE}'_2$, eq. [27] can be transformed into eq. [28] using eq. [23]. Since $\mathrm{SIE}_1 \simeq \mathrm{SIE_f}$ was shown to be in the region of 1.6 (*vide supra*) and

$$[28]\quad \frac{k_s^{H\to D}}{k_s^{D\to H}} \simeq \nu_H(\nu_H^{\beta})^2\mathrm{SIE}_6$$

$\mathrm{SIE}_1 \simeq \mathrm{SIE}_6$, and since k_f and k_s are not vastly different, $k_s^{H\to D}/k_s^{D\to H}$, given by eq. [28], should be in the region of 1.8–2.2 if ν_H is set equal to 1.15 and ν_H^{β} lies between 1 and 1.1. The experimental values of the ratio for **1** and **2**, 1.94 ± 0.19 and 1.73, respectively, are in excellent agreement with the predicted value. If exchange of the slow proton (deuteron) occurs only by retention, then the $k_s^{H\to D}/k_s^{D\to H}$ ratio derived from eq. [29] – a ratio of eqs. [17] and [25] – would be expected to be considerably larger than the value predicted by our analysis. Given eq. [22], eq. [29] can be rearranged into

$$[29]\quad \frac{\left(\dfrac{k_f}{k_s}\right)^{H\to D}}{\left(\dfrac{k_f}{k_s}\right)^{D\to H}} \simeq \frac{\dfrac{l_D S_D \mathrm{SIE}_1}{\mathrm{SIE}_6}}{\dfrac{S_H L_H}{V_H \nu_H}}$$

eq. [30] ($S_H = S_D$). Using a value of 1.15 for l_D, 2.2 for V_H,

$$[30]\quad \frac{k_s^{H\to D}}{k_s^{D\to H}} \simeq \frac{L_H \mathrm{SIE}_6}{l_D}$$

and 1.6 for SIE_1, we calculate a ratio of 3.1 for **2** if exchange occurs only by retention. For **1**, since $V_H \simeq 3.3$, the ratio is predicted to be near 4.6.

By neglecting solvent isotope effects, using eqs. [8] and [17] for the cases where exchange occurs only by retention, and eqs. [7], [9], [16], and [18] for the cases where exchange by inversion is included, it is possible to evaluate the intrinsic selectivities and $(k_f/k_s)^{D\to H}$ ratios from the $(k_f/k_s)^{H\to D}_{obs}$ ratios. The experimental value for $(k_f/k_s)^{H\to D}$, the KIEs, and the inversion protonation parameters a_D and a_H were used to calculate S_R (selectivity calculated using eq. [8] assuming exchange with retention), S_I (selectivity calculated using eq. [7] including inversion), R_R ($(k_f/k_s)^{D\to H}$ calculating using eq. [17] assuming exchange with retention), and R_I ($(k_f/k_s)^{D\to H}$ calculated using eq. [16] assuming exchange by inversion). The data for **1**, using $(k_f/k_s)^{H\to D}_{obs} = 59.2$, are given in Table 4. As expected, S_R and R_R are invariant with a_D and a_H, and it is clear that the calculated $(k_f/k_s)^{D\to H}$ ratio ($R_I = 16.1$) corresponds closely to

[5] $S_D \simeq k_4 k_2 V'_D \mathrm{SIE}'_2 / k_3 k'_2 L'_D \mathrm{SIE}_2 \simeq k_1 V_D \mathrm{SIE}_6 / k'_1 L_D \mathrm{SIE}_1 \simeq k_5 \nu_D \mathrm{SIE}_6 / k_6 l_D \mathrm{SIE}_1$, $a_D = k_3 \mathrm{SIE}_2 / k_2 V'_D$ and $b_D = k_4 \mathrm{SIE}'_2 / k'_2 L'_D$ and $b_D = a_D S_D$.

TABLE 4. Calculated intrinsic selectivity and $(k_f/k_s)^{D\rightarrow H}$ for exchange of benzodehydrothiopene oxide

	Calculated selectivity		Calculated $(k_f/k_s)^{D\rightarrow H}$	
a_D	S_R[a]	S_I[a]	R_R[a,b]	R_I[a,b]
10^{-6}	51.5	51.5	44.8	44.7
10^{-5}	51.5	51.5	44.8	44.6
10^{-4}	51.5	51.8	44.8	42.9
10^{-3}	51.5	54.2	44.8	32.9
10^{-2}	51.5	63.4	44.8	19.2
10^{-1}	51.5	68.3	44.8	16.4
1	51.5	69.0	44.8	16.1
10	51.5	69.1	44.8	16.1
100	51.5	69.1	44.8	16.1
1000	51.5	69.1	44.8	16.1

[a]The constants used to evaluate the parameters were $(k_f/k_s)^{H\rightarrow D}$ (59.2), V_D, L_D, V'_D, L'_D, V_H, and L_H (all set at 3.3), ν_D, l_D, ν_H, and l_H (all sets at 1.15).
[b]It can be shown (*vide supra*) that $a_H = 3.8 \times a_D$ for **1** if $V_D \simeq 3.3$ and $\nu_H = 1.15$. A value of $3.8 \times a_D$ was used to evaluate R_R and R_I.

TABLE 5. Calculated intrinsic selectivities and rate ratios for D → H exchange of benzyl methyl sulfoxide

a_D	Calculated selectivity[a] S_I	Calculated $(k_f/k_s)^{D\rightarrow H}$[b,c] R_I
10^{-6}	19.9	17.3
10^{-5}	19.9	17.3
10^{-4}	20.0	17.2
10^{-3}	20.4	16.4
10^{-2}	23.4	13.2
10^{-1}	28.5	9.8
1	29.7	9.4
10	29.8	9.4
100	29.8	9.4
1000	29.8	9.4

[a]The other parameter S_R had the value 19.9.
[b]The other parameter R_R had the value 17.3.
[c]It can be shown (*vide supra*) that $a_H = 2.5 \times a_D$ for **2** when $V'_D = 2.2$ and $\nu_H = 1.15$. A value of $2.5 \times a_D$ was used for a_H in the calculation of R_I.

the observed value (17.3 ± 2.3) when inversion is included and $a_D \geq 0.1$. This is not the case if exchange is assumed to occur only with retention – $(k_f/k_s)^{D\rightarrow H}$ would have a much larger value of 44.8. Based on our analysis, the intrinsic selectivity is in the region of 68, 35% larger than the value of 51.5 calculated on the assumption that exchange occurs only with retention. An identical analysis carried out for **2** yielded the data listed in Table 5. As in the case of **1**, the calculated $(k_f/k_s)^{D\rightarrow H}$ ratio R_I (9.8–9.4) corresponds closely to the experimentally observed values of 10.8 ± 1.3 (this work) and 9.9 ± 0.03 (Fraser and Ng) when $a_D \geq 0.1$. The analysis establishes that the intrinsic selectivity for hydrogen isotope exchange of the diastereotopic protons of **2** is ≃29, approximately 45% larger than the value (19.9) which is obtained on the assumption that exchange occurs only with retention. That the calculated selectivity S_I and the $(k_f/k_s)^{D\rightarrow H}$ ratio R_I are not sensitive to the values for the protonation isotope effects V'_D and L'_D was established by using $V'_D = L'_D = 2.5$ and 3.8 for **2** and $V'_D = L'_D = 1.5$ and 3.0 for **1**. The differences in the calculated values were minimal. It is important to note that for both **1** and **2** S_I approaches S_{obs} and R_I approaches $(k_f/k_s)_{obs}^{D\rightarrow H}$ when $a_D \geq 0.1$. Consequently, when the barrier to inversion is comparable to the barrier to protonation, exchange of diastereotopic protons (deuterons) by inversion cannot be distinguished from a mechanism where a single intermediate is involved.

From the intrinsic selectivities for **1** (68) and **2** (29), the primary and secondary KIEs and the inversion–protonation parameters a_D and a_H, it is possible to calculate expected $(k_f/k_s)^{H\rightarrow D}$ and $(k_f/k_s)^{D\rightarrow H}$ ratios. Using eq. [1], a value of 3.3 for V_D, V'_D, L_D, and L'_D, a value of 1.15 for ν_D and l_D, we calculated $(k_f/k_s)^{H\rightarrow D}$ ratios for values of a_D which ranged from 10^{-6} to 10^3. A plot of the calculated values as a function of a_D given in Fig. 3(A) illustrates the variation of the observed rate ratio with a variation in the barrier to inversion. Similar calculations using eq. [16], values of 3.3 for V_H and L_H and 1.15 for ν_H and l_H, and a_H[6] that ranged from 3.8×10^{-6} to 3.8×10^3 were carried out to obtain $(k_f/k_s)^{D\rightarrow H}$. A plot is given in Fig. 3(B). Identical calculations were carried out for **2** using the appropriate parameters – $V_D = V'_D = L_D = L'_D = V_H = L_H = 2.2$, $\nu_D = l_D = l_H = 1.15$, a_D ranging from 10^{-6} to 10^{-3}, and a_H ranging from 2.5×10^{-6} to 2.5×10^3. Plots of the calculated $(k_f/k_s)^{H\rightarrow D}$ and $(k_f/k_s)^{D\rightarrow H}$ values versus a_D and a_H, respectively, are shown in Figs. 4(A) and (B). That the observed rate ratios plateau when $a_D(a_H)$ values are large and small is quite clear. The calculated values for $(k_f/k_s)^{H\rightarrow D}$ and $(k_f/k_s)^{D\rightarrow H}$ for **1** and **2** correspond closely to the observed values when $a_D(a_H) \geq 0.1$.

While it would be interesting to compare the rate ratios for H→D and D→H exchange of a carbon acid where diastereotopic anions with a high barrier to inversion ($a_D < 10^{-2}$) are generated, in practice it will be difficult to obtain such a substrate. Even 4-membered-ring sulfones have k_e/k_α values around 1. For example, thietane-1,1-dioxide **3** exhibits a k_e/k_α of 0.60–0.67 in $(CH_3)_3COD-(CH_3)_3COK$ (26) and 2-halogeno-3-morpholinothietane-1,1-dioxides of the type **4** exhibit k_e/k_α values around 1 in CD_3CN-D_2O (28).

Again, it is noteworthy that our analysis yields values of $(k_f/k_s)^{D\rightarrow H}$ for **1** and **2** that compare very well with the experimental values when the inversion–protonation parameter a_D is ≃ 0.1. This result is in accord with stereochemical studies of hydrogen isotope exchange of **5** (21) and **6** (14) where rates of exchange and racemization can be determined directly. For the $R-R$ and $R-S$ diastereomers of **5** the k_e/k_α ratios are 1.2 and 3.6, respectively, in $(CH_3)_3COK-(CH_3)_3COH$ at 60°C. For **6**, that is a particularly good model for **1** and **2**, $k_e/k_\alpha = 1.3$ in $NaOD-D_2O$ at 56°C. Since a k_e/k_α value of less than 2 signifies that inversion occurs more rapidly than reprotonation of the anion, the results establish the validity of our analysis and show that the stereochemical aspects of exchange of **1** and **2** are similar to **6**. From a_D it is possible to set an *upper limit* to the barrier of inversion of the diastereotopic anions, if they are intermediates. By using the Arrhenius equation and the fact that $k_{3(\mathrm{inv})}/k_{2(\mathrm{prot})} = a_D V'_D$, eqs. [31] and [32] obtain.

$$[31] \quad \ln a_D V'_D \simeq \ln \frac{A_{\mathrm{inv}}\, e^{\frac{-E_{\mathrm{inv}}}{RT}}}{A_{\mathrm{prot}}\, e^{\frac{-E_{\mathrm{prot}}}{RT}}}$$

[6]It can be shown that $a_H \simeq 3.8 \times a_D$ for **1** and $2.2 \times a_D$ for **2** (*vide supra*).

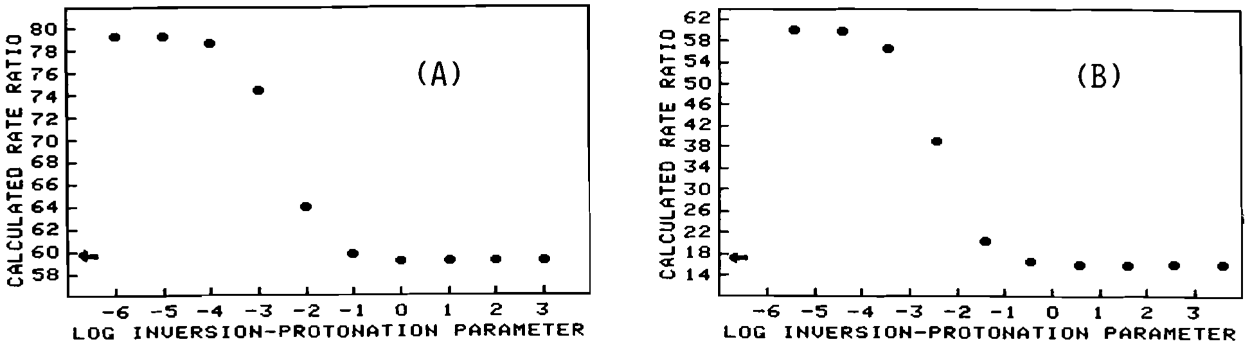


FIG. 3. (A) Plot of the calculated $(k_f/k_s)^{H\to D}$ ratio versus a_D for exchange of **1***a*. The bold-faced arrow indicates the experimentally determined value. (B) Plot of the calculated $(k_f/k_s)^{D\to H}$ ratio versus a_H for exchange of **1***b*. The bold-faced arrow indicates the experimentally determined value.

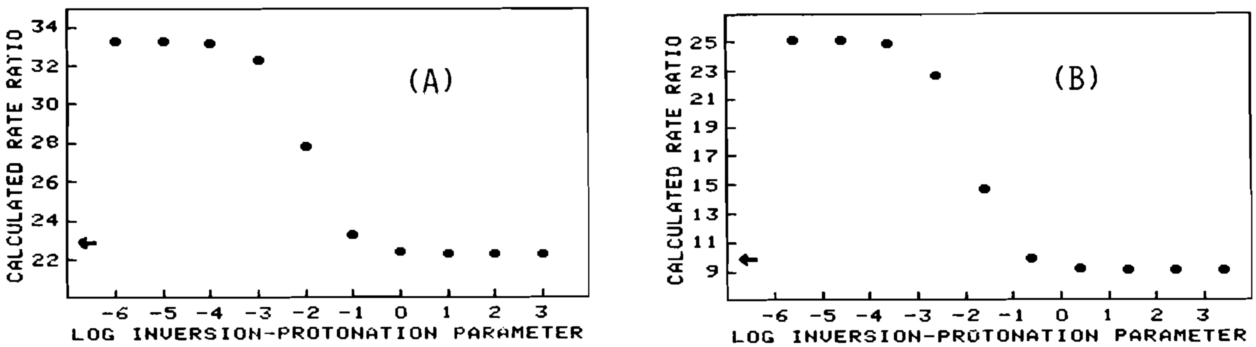

FIG. 4. (A) Plot of the calculated $(k_f/k_s)^{H\to D}$ ratio versus a_D for exchange of **2***a*. The bold-faced arrow indicates the experimentally determined value. (B) Plot of the calculated $(k_f/k_s)^{D\to H}$ ratio versus a_H for exchange of **2***b*. The bold-faced arrow indicates the experimentally determined value.

TABLE 6. Estimated inversion barriers for anions at 30°C

		Calculated inversion barrier (kcal)	
Protonation barrier (kcal)	k_{prot} (M^{-1} s^{-1})	1	2
3.0	2.1×10^9	4.8	5.0
4.0	4.1×10^8	5.8	6.0
5.0	7.8×10^7	6.8	7.0
6.0	1.5×10^7	7.8	8.0
7.0	2.9×10^6	8.8	9.0

$$[32] \quad E_{inv} \simeq RT\left(\ln A_{inv} - \ln A_{prot} + \frac{E_{prot}}{RT} - \ln a_D V'_D\right)$$

With $a_D = 0.1$, $V'_D = 3.3$ and 2.2 for **1** and **2**, respectively, $T = 303$, and estimates for E_{prot}, A_{inv} ($\sim 1 \times 10^{14}$) (45, 46), and A_{prot} ($\sim 3 \times 10^{11}$) (45, 46),[7] E_{inv} can be obtained (Table 6). If k_{prot} for the carbanions derived from **1** and **2** is $\geq 10^8$ (47) and if pyramidal diastereotopic anions are involved as intermediates in the exchange of **1** and **2**, then the inversion barriers must be ≤ 6 kcal. This is in keeping with current views on the barriers to inversion of carbanions (48).

It is clear from our analysis[8] that the diastereotopic hydrogens of **1** and **2** undergo exchange by inversion and that the inversion component contributes significantly to $k_s^{H\to D}$ and $k_s^{D\to H}$, yielding a $(k_f/k_s)^{D\to H}$ ratio that is substantially less than $(k_f/k_s)^{H\to D}$. Consequently, the Streitweiser–Swain method (49, 50) used to determine the extent of internal return for H → D(T) exchange of carbon acids should be applied with caution to cases where diastereotopic hydrogens, deuterons, or tritons are exchanged. This is so because k_s^H, k_s^D, and k_s^T used to obtain k_H/k_T and k_D/k_T can be significantly affected by the inversion component (*vide supra*), and the determination of the degree of internal return is particularly sensitive to the k_H/k_T and k_D/k_T values.

To illustrate the problem, consider the data (Table 3) for **2** accumulated by Fraser and Ng and used to establish that there is 3% and 12% internal return for exchange of the fast and slow protons, respectively. The only way we can reasonably account for the fact that $k_{T(s)}$ (0.392 ± 0.004) for exchange of **2**-H_f-T_s in NaOH–H_2O is greater than $k_{T(s)}$ (0.330 ± 0.004) for **2**-D_f-T_s in NaOD–D_2O is to invoke a larger component of inversion to exchange of **2**-H_f-T_s,[9] a reasonable consideration since $k_{H(f)}/$

[7]These are average values for the frequency factors for first-order and second-order processes.

[8]All derivations of equations have been deposited as Supplementary Material. Copies may be obtained, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada, K1A 0S2.

[9]Since SIE ≃ 1.6 and the secondary KIE ≃ 1.15, $k_{T(s)}$ for **2**-D_f-T_s should be 1.4 times larger than $k_{T(s)}$ for **2**-H_f-T_s. In the case of fast exchange of **2**, $k_{T(f)}$ for **2**-T_f-H_s in NaOD–D_2O is, as expected, approximately 1.6 × 1.15 times as fast as $k_{T(f)}$ for **2**-T_f-D_s in NaOH–H_2O).

$k_{D(f)} = 2.2$. The alternative is to assume that $SIE_s \simeq 1.0$, an unlikely situation because k_f and k_s are not vastly different. The transition states should not differ greatly and the degree of solvation of the base, the substrate, and the transition states should be comparable in each case.

Experimental

Preparation of substrates

Benzodihydrothiophene oxide (**1***a*) was prepared according to the method described by King and du Manior (15).

The tetradeuterated oxide **1***b* was prepared by exchange of **1***a* (1 g) in 0.1 *M* $NaOD-D_2O$ (25 mL) at 50°C for 1 h. The reaction mixture was extracted with ether (5 × 10 mL), the combined extracts were dried over $MgSO_4$, and the solvent was removed on the rotatory evaporator. Recrystallization of the residue from benzene–pentane gave **1***b* (0.8 g), mp 89–90°C. Mass spectral analysis showed that the d_4-species constituted 90.9% of the mixture.

Deuterated benzyl methyl sulfoxide **2***b* was prepared by treating **2***a* (0.25 g) in 1 *M* $NaOD-D_2O$ for 3 h at 70°C. The mixture was cooled and extracted with methylene chloride (4 × 2 mL). The combined extracts were dried over $MgSO_4$, the solvent was removed on the rotatory evaporator, and the residue was sublimed under aspirator vacuum to yield **2***b* (0.16 g), mp 52–53°C. Mass spectral analysis established that the d_2-species constituted 75.9% of the mixture.

Exchange kinetics

Benzodihydrothiophene oxide

To obtain the rate constant for *trans*-H → D (fast) exchange of **1***a*, **1***a* (5–10 mg) was dissolved in 1.5 mL of 0.0064 *M* $NaOH-H_2O$ that was equilibrated in a constant temperature bath maintained at 30.00 ± 0.05°C, and 5–7 aliquots (~0.1 mL) were removed at appropriate intervals and quenched in 1.5 mL of a dipotassium hydrogen phosphate buffer of pH 7.0 and ether (2 mL). The aliquots were extracted by repeatedly withdrawing and expelling the ether layer through the aqueous layer with a Pasteur pipette. The ether layer was dried, the solvent was evaporated, and the decrease in d_0-species was monitored mass spectrometrically at low voltage (12–15 eV). The peak intensities for each aliquot were obtained as an average of at least three scans.

To obtain the rate constant for *cis*-H → D (slow) exchange of **1***d*, **1***a* was exchanged as described above and the decrease of d_2-species was monitored mass spectrometrically by withdrawing aliquots after a 4-min interval.

The rate constant for *trans*-D → H (fast) exchange was obtained by exchanging **1***b* (3–5 mg) in 1.5 mL of 0.0233 *M* $NaOH-H_2O$ and the decrease in d_4-species with time was monitored mass spectrometrically in the usual manner.

To obtain the rate constant for *cis*-D → H (slow) exchange, **1***b* was exchanged in 0.0233 *M* $NaOH-H_2O$ as described above and the decrease of d_2-species with time was monitored mass spectrometrically after a 40-min interval.

Benzyl methyl sulfoxide

To obtain the rate constant for fast D → H exchange of dideuterated benzyl methyl sulfoxide **2***b*, **2***b* (10–15 mg) was dissolved in 1.5 mL of 0.6 *M* $NaOH-H_2O$ at 30.00 ± 0.05°C and aliquots were removed at appropriate periods, quenched with dipotassium hydrogen phosphate buffer (2 mL), and extracted with ether (2 mL). The decrease in d_2-species with time was monitored mass spectrometrically as described above.

The rate constant for slow D → H was obtained by exchanging **2***b*. Aliquots (5–6) were removed after an interval of ~100 min and the decrease in d_1-species with time was monitored mass spectrometrically as described above.

Fractionation of organic extracts of environmental water samples by low pressure column chromatography and high performance liquid chromatography techniques

R. A. MOORE AND F. W. KARASEK[1]
Department of Chemistry, University of Waterloo, Waterloo, Ont., Canada N2L 3G1

Received August 10, 1984

R. A. MOORE and F. W. KARASEK. Can. J. Chem. **63**, 2110 (1985).

Prefractionation procedures based on high performance liquid chromatography (hplc) and low pressure column chromatography (lpcc) were developed and applied to the separation of components in extracts of environmental samples. Effective fractionation was obtained using solvent systems based on hexane, carbon tetrachloride, dichloromethane, and ether for elution on lpcc Florisil and hplc silica columns. This facilitated the identification of over thirty compounds consisting mainly of aliphatic and polyaromatic hydrocarbons, phthalate esters, phenols, and pesticides in environmental samples extracted from water. Chromatographic background levels were minimized, and compounds whose chromatographic peaks were unresolved before fractionation were isolated into separate fractions. This afforded more highly reliable gc/ms identifications. Prefractionation also served to retard the rapid degradation of capillary columns which was caused by the injection of unfractionated samples.

R. A. MOORE et F. W. KARASEK. Can. J. Chem. **63**, 2110 (1985).

On a mis au point des méthodes de préfractionnement basées sur la chromatographie liquide à haute performance (clhp) et sur la chromatographie sur colonne à basse pression (ccbp) et on les a utilisées pour fractionner des extraits d'échantillons provenant de l'environnement. On a pu faire des séparations efficaces en utilisant des systèmes de solvants comportant de l'hexane, du tétrachlorure de carbone, du dichlorométhane et de l'éther comme éluants pour des colonnes de Florisile en ccbp et de silice en clhp. Ceci facilite l'identification de plus de trente composés constitués principalement d'hydrocarbures aliphatiques et polyaromatiques, de phtalates, de phénols et de pesticides dans des échantillons provenant de l'environnement et extraits de l'eau. On a minimisé les niveaux chromatographiques de base et on a obtenu des fractions séparées pour des composés dont les pics chromatographiques n'étaient pas résolus avant le fractionnement. Le préfractionnement permet également de retarder la dégradation rapide des colonnes capillaires qui est provoquée par l'injection d'échantillons non fractionnés.

Introduction

Organic extracts of water samples are often directly analyzed by gas chromatography (gc), and combined gas chromatography – mass spectrometry (gc/ms) techniques without prior sample clean-up. However, the analysis of complex water samples is greatly simplified through the application of some form of fractionation to separate compounds into similar groups prior to the final determinative step. This approach overcomes difficulties caused by overlapping chromatographic peaks of the complex mixture, which make quantitation inaccurate and lead to ambiguities in mass spectral identifications.

One of the earliest classification procedures employed for environmental water samples separated the complex ether extract of organic material, which had been previously concentrated onto carbon filters, into groups consisting of neutral, basic, acidic, amphoteric, and phenolic compounds (1, 2). This was accomplished through a series of solvent extractions under various conditions.

Rosen and Middleton (3) applied a fractionation procedure based on adsorption chromatography to the neutral extract of surface waters polluted by refinery wastes. The concentrated neutral fraction was adsorbed onto the top of a silica gel column which was sequentially eluted with isooctane, benzene, and a chloroform–methanol mixture. The isooctane fraction contained aliphatic hydrocarbons, aromatic hydrocarbons eluted in the benzene fraction, and the chloroform–methanol fraction contained oxygenated compounds. Shinohara *et al.* described a similar fractionation technique for the neutral organic fraction of extracts from tap-water samples (4). The silica gel column was eluted with isooctane, isooctane–benzene (1:1), benzene – ethyl acetate (1:1), and benzene–methanol (1:1). Aliphatic hydrocarbons were recovered in the isooctane fraction and aromatic compounds were present in the isooctane–benzene fraction. The other two fractions contained several oxygenated compounds.

Leenheer and Huffman developed a procedure called "dissolved organic carbon (DOC)" fractionation analysis, whereby organic solutes are concentrated and fractionated by non-ionic and ion-exchange resin adsorbents into hydrophobic-base, -acid, and -neutral fractions (5, 6). An anion-exchange resin prepared by chloromethylation of Amberlite XAD-4 resin was used by Richard and Fritz to isolate acidic organic material from other organics in aqueous solutions (7). Both hydrophilic and hydrophobic acids were recovered using this resin.

The applicability of high performance liquid chromatography (hplc) as an efficient means of separating organics in extracts of water samples into various polarity groups was demonstrated by Thruston (8). He employed μ-Porasil columns and gradient elution with hexane and chloroform to obtain three major fractions from tap-water samples. A first fraction contained polynuclear aromatic hydrocarbons, chlorinated hydrocarbons, and aliphatic hydrocarbons, the second fraction contained several oxygenated compounds, and the final fraction contained mainly phthalate esters.

During studies of trace organics in river water samples from Trinidad it was noted that direct analysis of concentrated extracts frequently resulted in complex chromatograms in which many peaks were only partly resolved and steeply rising baselines were evident (9). The lack of resolution often resulted in ambiguous spectral interpretations. Several of these extracts were also shown to cause rapid deterioration of the capillary columns used for chromatographic analysis. Prefractionation procedures based on low pressure column chromatography (lpcc) and hplc were developed in order to overcome these

difficulties. Effective fractionations were obtained using solvent systems based on hexane, carbon tetrachloride, dichloromethane, and ether for elution on lpcc Florisil columns and hplc silica columns. These fractionation procedures as applied to a standard mixture and to extracts of river water samples are the subject of this report.

Experimental

Solvents and standards

All solvents were "Distilled in Glass, UV grade" (Caledon Laboratories, Canada). Standard compounds used in the development of the fractionation procedure were obtained from U.S. Environmental Protection Agency Reference Standards Repository; Polyscience Corporation, U.S.A.; Chem. Service Inc. Pa; and Aldrich Chemical Company, Inc., Wisconsin, U.S.A. A standard test solution was prepared as described in a previous paper (10).

Low pressure column chromatographic fractionation

Florisil (60–100 mesh, Fisher Scientific Co., U.S.A.) and alumina (neutral, 80–100 mesh, Woelm Pharma, GmbH & Co., West Germany) adsorbents were heated at 300°C for 6 h prior to use. Glass columns (25 cm length id 1.0 cm), fitted with Teflon stopcocks, were dry packed with the adsorbents such that adsorbent columns of 9 cm length were obtained. Plugs of silanized glass wool which were pre-extracted with the eluting solvents were used at the top and bottom of the adsorbent columns. The column was pre-wet with the first eluting solvent prior to introduction of sample or standard to the top of the column with a Hamilton microsyringe. Fractionation was effected by the sequential addition of the required volume of each eluting solvent to the column, the solvent being allowed to percolate through the column under gravity flow. Fractions were collected in 250-mL glass round-bottom flasks and evaporated to 0.1 mL by rotary evaporation under vacuum followed by final volume reduction with a stream of high-purity nitrogen.

High performance liquid chromatographic fractionation

A Spectra-Physics SP-8000 high performance liquid chromatograph equipped with an SP-8400 uv–visible detector and SP-4100 integrator was used. The hplc column was a Spherisorb silica column (250 mm × 9.4 mm id, Terochem, Canada). A sample loop of 140 μL volume was employed for sample introduction into the hplc and a wavelength of 254 nm was used throughout for monitoring of the hplc effluent. The collected fractions were treated in the same manner as described for lpcc above, then subjected to gc and gc/ms analyses.

Gas chromatographic and mass spectral analyses

Quantitative gas chromatographic analyses were performed with a Hewlett–Packard (HP) 5880A gas chromatograph equipped with a level 4 integrator, a flame ionization detector, cool on-column injection system, and a widebore (0.32 mm × 30 m) DB-1701 fused silica capillary column (J & W Scientific Inc. Rancho Cardova, CA., U.S.A.). The gc conditions were: injection port 40°C; column temperature programmed from 40°C to 250°C at a rate of 4°C/min.; detector temperature 300°C; helium carrier gas flow rate measured at 40°C, 2 mL/min; injection volume 0.6 μL.

Capillary gc/ms analysis employing a Hewlett–Packard 5992A gc/ms calculator equipped with the same column was used to verify the identities of compounds corresponding to each gas chromatographic peak.

Results and discussion

Fractionation by low pressure column chromatography

In preliminary experiments, both alumina and Florisil were employed as adsorbents for lpcc fractionation of the test solution. However, use of alumina columns resulted in less effective overall fractionation and lower recovery of the more polar compounds compared to Florisil, for similar eluting conditions. It was therefore decided to restrict lpcc fractionation to Florisil adsorbent.

Use of hexane followed by carbon tetrachloride and ether for elution proved to be an effective method for fractionation of the test solution. Table 1 shows the results of fractionation employing this solvent sequence (50 mL of each solvent) and Florisil columns. Chromatograms of the three fractions are shown in Fig. 1.

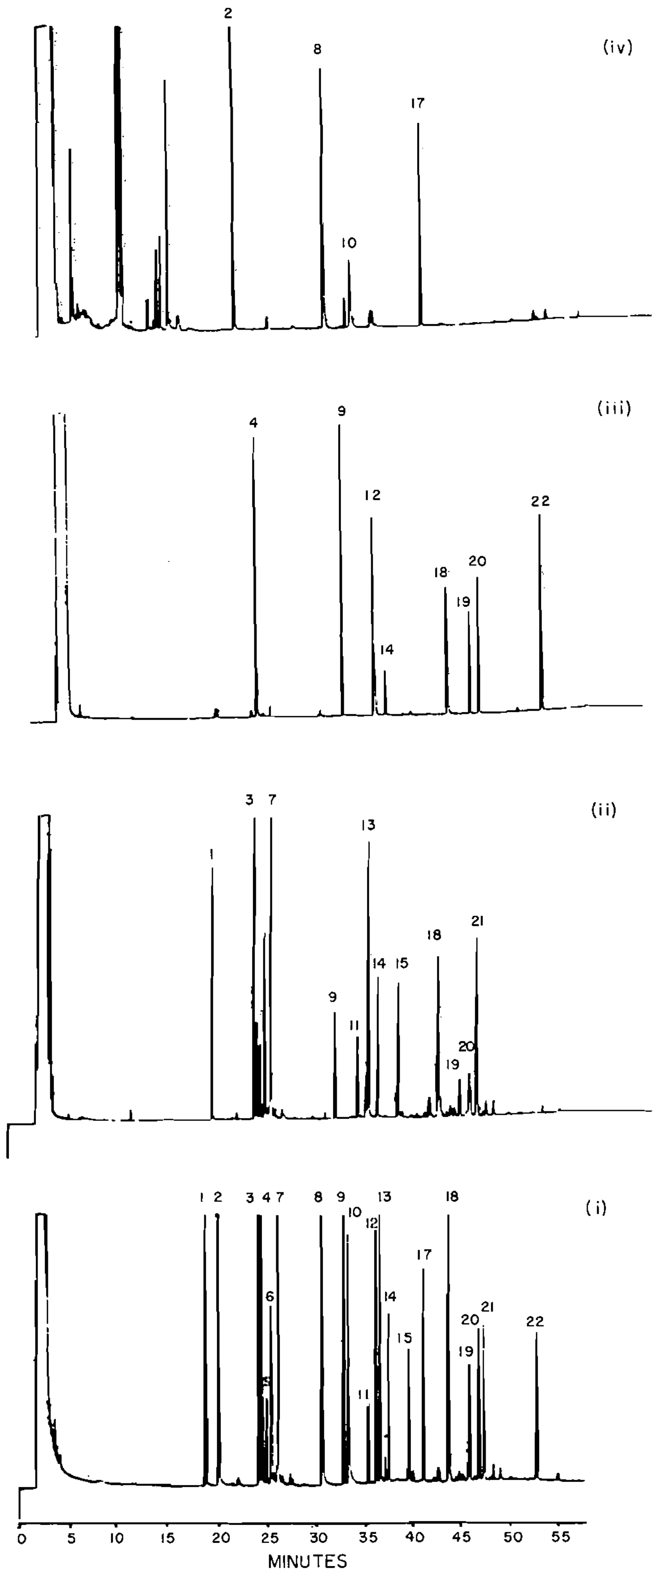

FIG. 1. Gas chromatograms of fractions obtained from lpcc separation of standard mixture. (i) Unfractionated solution. (ii) Hexane fraction. (iii) Carbon tetrachloride fraction. (iv) Ether fraction.

The phenols were confined exclusively to the ether fraction. The recovery of naphthol was, however, low (38%). The carbon tetrachloride fraction contained the major portion of endrin, dieldrin, benzyl benzoate, and the esters methyl tetradecanoate and methyl hendecanoate, and all of the methoxychlor appeared in this fraction. Fluoranthene was almost equally distributed between the hexane and carbon tetrachloride fractions. Aldrin, *o,p* DDT, α-BHC, dimethyl naphthalene, biphenyl, and n-hexyl benzene were confined to the hexane fraction; most of the phenanthrene (88%) and γ-BHC (79%) also appeared in this fraction.

Further optimization of the fractionation on Florisil required improvement in the low recovery of 1-naphthol. Increasing the volume of ether used for elution by a factor of three resulted in an improvement in the recovery of 1-naphthol from 38% to 64%, and a further increase to 79% was obtained on elution with 200 mL ether. Ether was replaced by acetone as the third eluting solvent but no compounds were recovered in the acetone. Attempts to use methanol as the third eluting solvent decreased the recovery of 1-naphthol as well as the other phenolic compounds. Severe peak distortion was also noted in the gc analysis of the methanol fraction. The system employing hexane, carbon tetrachloride, and ether was therefore adopted as our optimal low pressure chromatography fractionation procedure and applied to extracts of samples from Trinidad water systems.

Fractionation by high performance liquid chromatography

The eluting system of hexane – carbon tetrachloride – ether in a ternary gradient, which was effective for fractionation on Florisil, was investigated for the hplc fractionation of the test solution on a silica column. Use of ether as the third eluting solvent proved, however, to be unsuitable. Bubbles tended to form in the hplc system, thereby impairing the performance of the pump and impeding the flow of solvent. Further, no compounds were recovered in the ether fraction. Therefore, methylene chloride was substituted for ether as the third eluting solvent.

The gradient program illustrated in Fig. 2(i) yielded the recoveries shown in Table 2 for six collected fractions. With the exception of 1-naphthol, excellent recoveries were obtained for all compounds and the elution patterns of Table 2 indicated that a fractionation scheme based on this eluting system was feasible. It was apparent that combination of some fractions and modification of the solvent gradients could improve the overall efficiency of the hplc separation procedure. Therefore, the gradient program of Fig. 2(ii) was employed and three fractions collected at the times indicated. This scheme was very effective and yielded the results shown in Table 3. High reproducibility of fractionation was obtained and separation of compounds into fractions was very distinct, with little cross-contamination. Hexyl benzene, biphenyl, dimethyl naphthalane, phenanthrene, aldrin, fluoranthene, and *o,p* DDT were confined to the hexane fraction (fraction 1). The esters – benzyl benzoate, methyl hendecanocate, and methyl tetradecanoate, and methoxychlor, dieldrin, endrin, α-BHC, and γ-BHC eluted in fraction 2. α-BHC seemed to elute just at the beginning of fraction 2 with the result that a small increase in the volume of hexane (5 mL) causes it to elute in the first fraction. The phenolic compounds, *o*-ethyl phenol, phenyl phenol, and 1-naphthol together with dibutyl phthalate were eluted in fraction 3. The recovery of 1-naphthol increased from 36% to 57% as the volume of methylene chloride was increased from 75 mL (Table 2) to ≈150 mL (Table 3). Further increase in the methylene chloride to 200 mL improved the recovery of 1-naphthol to 81%.

Fractionation of extracts of environmental samples

The optimized lpcc and hplc fractionation schemes were

applied to the fractionation of organic extracts of water samples from Mausica River, Trinidad (9). Figure 3 shows chromatograms of the fractions of the hplc procedure. The chromatograms obtained for the lpcc fractionation were similar to those of hplc. The hexane fraction in both cases contained the alkanes. Most of the other constituents of the unfractionated samples occurred in the ether fraction of the lpcc method and in fraction 3 of the hplc technique. These included the phenols, phthalates, benzothiazole, 6-chloro-3,4-dimethylphenol n-methyl carbamate, 1-(3*H*)-isobenzofuranone, and 1,6-dimethyl 4-isopropyl naphthalene. The lpcc carbon tetrachloride fraction and hplc fraction 2 contained virtually no compounds except for a small amount of phenols which occurred in the lpcc carbon tetrachloride fraction.

[a] Peak number as shown in Fig. 3(iii); √ – present, but no estimate can be given.

Recoveries for some of the compounds in the various fractions are given in Table 4. These values are based on the integrated peak areas of the fractions compared with the corresponding peak areas of the unfractionated sample injected under the same conditions. The errors in these estimates for the peaks at retention times greater than 20 min (Fig. 3) are expected to be fairly high as a result of the low resolution of several peaks in this region of the chromatogram. The recoveries of several compounds in the ether fraction of the lpcc fractionation and fraction 3 of the hplc method were low. Increasing the volume of these eluents above the 50 mL volume which was used can be expected to result in improved recoveries.

Nonetheless, the fractionation schemes were effective in simplifying the sample extract and served to improve the reliability of mass spectral identifications. Compounds identified in extracts from the Mausica River are detailed in Table 4. Several of these compounds could not be identified from the mass spectra of the unfractionated samples because of peak overlap and high backgrounds. Their identification was facilitated by application of the fractionation procedures. Much of the unresolved "hump" evident in the chromatogram of the unfractionated sample was not seen in the chromatograms of the fractions (Fig. 3).

A further benefit of hplc and lpcc fractionation is the preservation of the chromatographic column. Figure 4 depicts the effect on the column performance of a single injection of the unfractionated sample. The lower trace represents a chromatogram of the test solution used in the earlier fractionation experiments, prior to the injection of the unfractionated sample. The

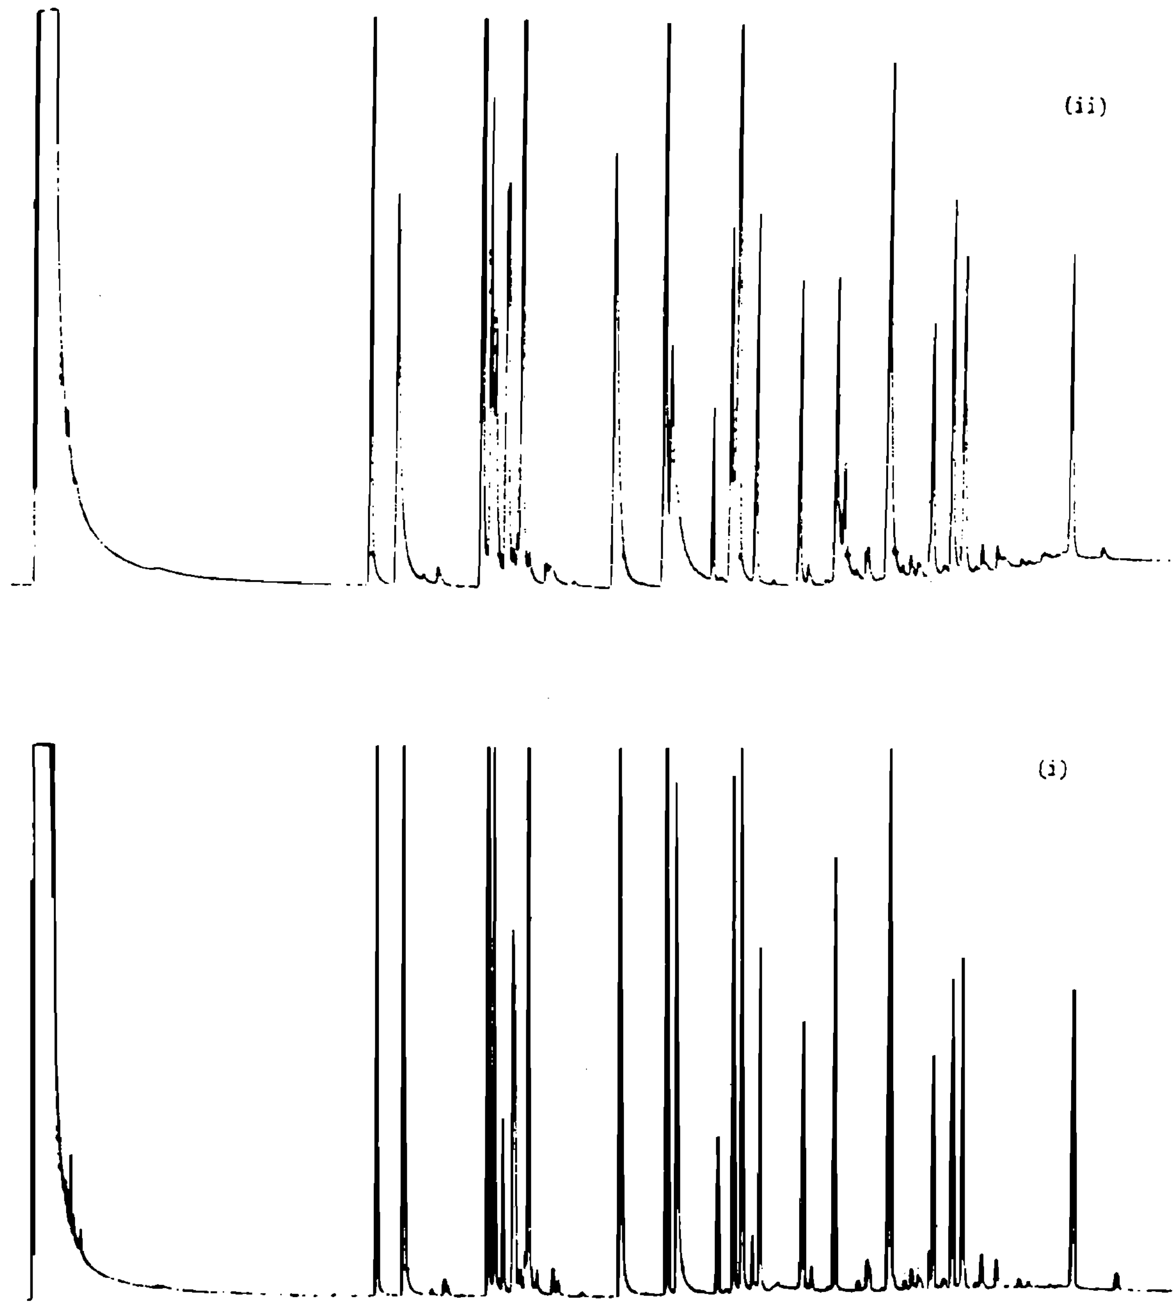

FIG. 4. Chromatograms illustrating the effect of unfractionated extracts of samples on column performance. (i) Standard mixture before injection of unfractionated extract. (ii) Standard mixture following one injection of unfractionated extract.

upper trace is the chromatogram obtained for the test solution injected immediately after the completion of the chromatographic run of the sample. The column efficiency is severely affected, as is evident from the broad tailing peaks. A portion of the front of the column had to be removed in order to restore the column performance to the original level. Column deterioriation was much slower when samples were subjected to fractionation prior to gc analysis.

Conclusion

The hplc and lpcc techniques were effectively used for fractionation of environmental water samples prior to gc and gc/ms analysis. This prefractionation afforded more highly reliable gc/ms identification of sample components and lessened degradation of the capillary columns. The hplc fractionation was faster and more highly reproducible than the lpcc technique. The effectiveness of methylene chloride for separation of the more polar components in the hplc method is advantageous compared to the lpcc method which required ether, since diethyl ether must be purified prior to being used. The lpcc method has the advantage of lower cost owing to the very simple apparatus that is required for its application.

Novel hydrogen bonding in crystalline tetra-n-butylammonium salts of catechol halides[1]

MASOOD A. KHAN, ARCHIBALD W. MCCULLOCH, AND A. GAVIN MCINNES

Atlantic Research Laboratory, National Research Council of Canada, 1411 Oxford Street, Halifax, N.S., Canada B3H 3Z1

Received August 28, 1984

MASOOD A. KHAN, ARCHIBALD W. MCCULLOCH, and A. GAVIN MCINNES. Can. J. Chem. **63**, 2119 (1985).

The crystal structures of $[N(n\text{-}C_4H_9)_4]$ [catechol...Cl] (**1**) and $[N(n\text{-}C_4H_9)_4]$ [catechol...Br] (**2**) have been determined by X-ray analysis which showed that the two structures are isomorphous, with the orthorhombic space group *Pbca*, $Z = 8$. The cell dimensions and final *R*-values are: (**1**) $a = 15.323(2)$, $b = 16.166(2)$, $c = 19.713(2)$ Å, $R = 0.048$ for 1361 observed reflections; (**2**) $a = 15.432(1)$, $b = 16.244(2)$, $c = 19.824(1)$ Å, $R = 0.041$ for 1958 observed reflections. The crystal structures consist of discrete tetra-n-butylammonium cations and catechol halide anions. Catechol forms two strong hydrogen bonds to a single halide ion giving a pattern of hydrogen bonding unique for such systems.

MASOOD A. KHAN, ARCHIBALD W. MCCULLOCH et A. GAVIN MCINNES. Can. J. Chem. **63**, 2119 (1985).

Faisant appel à la diffraction des rayons-X, on a déterminé les structures cristallines du $[N(n\text{-}C_4H_9)_4]$ [catéchol...Cl] (**1**) et du $[N(n\text{-}C_4H_9)_4]$ [catéchol...Br] (**2**) qui sont isomorphes, avec un groupe d'espace orthorhombique *Pbca* et $Z = 8$. Les dimensions de la maille et les valeurs finales de *R* sont: (**1**) a = 15,323(2), b = 16,166(2), c = 19,713(2) Å, R = 0,048 pour 1361 réflexions observées; (**2**) a = 15,432(1), b = 16,244(2), c = 19,824(1) Å, R = 0,041 pour 1958 réflexions observées. Les structures cristallines comportent des cations tétra-n-butylammonium ainsi que des anions halogénures de catéchol individuels. Le catéchol forme deux liaisons hydrogènes fortes avec un seul ion halogénure et ceci provoque la formation d'un type de liaisons hydrogènes qui est unique pour de tels systèmes.

[Traduit par le journal]

Introduction

During recent investigations of the use of the tetrabutylammonium salt of the silicon–catechol complex in silicon analysis we isolated a crystalline 2:1 complex of catechol and tetrabutylammonium hydroxide. A recent communication from this laboratory reported the synthesis and structural study of this and a series of other complexes of aromatic hydroxy compounds with ammonium salts and amines, and the existence of novel hydrogen-bonding networks in these compounds (1). We now report the preparation, characterization, and crystal structures of the tetra-n-butylammonium salts of catechol chloride **1** and catechol bromide **2**.

Experimental

The ^{1}H (80 MHz) and ^{13}C (20 MHz) nmr spectra were recorded in $CDCl_3$ on a Varian FT-80A spectrometer with internal ^{2}H lock to the solvent and a temperature of 35°C. Conditions for the ^{1}H spectra were SW 1000 Hz, AT 4.1 s (data accuracy ±0.1 Hz), FA 90°. The ^{13}C spectra were acquired with SW 4132 Hz, AT 0.99 or 1.982 s (data accuracy ±0.5 or ±0.3 Hz), FA 23° or 45°, ^{1}H irradiation at 80 Hz, (a) $\gamma H_2/2\pi \sim 4000$ Hz, modulation bandwidth 2000 Hz (broadband decoupling), (b) as for (a) but irradiating for 2.0 s between data acquisitions only to retain nOe (HR spectra). The infrared spectra were recorded on a BOMEM DA 3.02 FTIR spectrophotometer, the samples being in the form of fluorocarbon mulls sandwiched between KBr windows.

Preparation of complexes

1: A solution of tetra-n-butylammonium chloride (1.39 g) in water (15 mL) was added to a solution of 1,2-benzenediol (0.55 g) in water (10 mL). After a few minutes the aqueous mixture was extracted with CH_2Cl_2 (4 × 20 mL). Drying and evaporation followed by recrystallization from petroleum ether (bp 60–80°C)/ethyl acetate gave **1** as colorless prisms, mp 74–75°C; ν_{max}: most intense absorption at 3135 cm^{-1}; δ_H: 0.95 (12H, m), 1.40 (16H, m), 3.14 (8H, m), 6.76 (4H, centroid of AA'XX' m), 8.57 (2H, s); δ_C: 13.62 (qm), 19.57 (bt), 23.83 (bt), 58.46 (bt), 116.97 (dm, 157.7), 120.14 (dd, 160.4, 8.5), 145.16 (m).

TABLE 1. Summary of crystal data, intensity collections, and structural refinement for $C_{22}H_{42}ClNO_2$ (**1**) and $C_{22}H_{42}BrNO_2$ (**2**)

Crystallography

Crystals of **1** and **2** are orthorhombic, space group *Pbca* (from single-crystal photographs and diffractometry), $Z = 8$. Suitable specimens were mounted on glass fibers for data collection. The relative intensities of the independent reflections were measured with a Picker four-circle diffractometer, using Ni-filtered CuK_α radiation ($\lambda K\alpha_1$ = 1.54056 Å). The $\theta - 2\theta$ scan method was used, and individual reflection profiles were analysed as described by Grant and Gabe (2). The intensities of the three monitor reflections did not change significantly during data collection. The standard deviations were evaluated from the counting statistics, and only the reflections with $I_{net} > 2\sigma(I_{net})$ were used in the subsequent analysis. Absorption correction (Gaussian integration) was applied to the intensities.

The structures were solved by the heavy atom method and refined by block-diagonal least squares, minimizing $\Sigma w(F_o - kF_c)^2$ where $w = [\sigma^2(F_o) + 0.0003F_o^2]^{-1}$. Positional and thermal parameters (anisotropic thermal motion was assumed for all non-hydrogen atoms) were refined for all the atoms, except methylene and phenyl hydrogen atoms, which were included in the idealized position (C—H = 1.08 Å) and only an individual isotropic temperature factor was refined for them.

The computer programs used for calculation have been described by Larson and Gabe (3). The atomic scattering factors[2] were taken from International Tables, Vol. IV (ref. 4).

Crystal data and some details of refinement are given in Table 1, and atomic coordinates in Table 2. Bond lengths and angles are given in Table 3, and details of hydrogen-bond interactions in Table 4. Tables of structure factors, anisotropic thermal parameters, hydrogen atom coordinates are available as supplementary data.[3]

[2]Neutral scattering curves were used for Cl and Br.

[3]Complete set of data is available upon request, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1S 0A2.

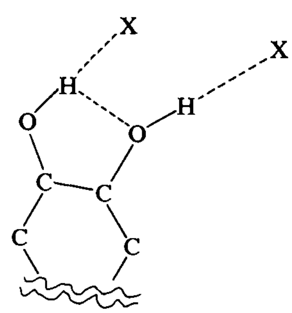
Results and discussion

The X-ray analysis of compounds **1** and **2** established that they are isomorphous and that the crystal structures consist of discrete tetra-n-butylammonium cations and catechol halide anions (Fig. 1). The structure of the tetra-n-butylammonium cation is normal and calls for no special comments (Table 3*b*).

The halide ion accepts two essentially linear hydrogen bonds from the same catechol (Fig. 1; Table 4). The O...Cl distances are at the lower end of the range of reported values (3.045(3)−3.317(2) Å (5)), while the O...Br distances are in the usual range (3.19(1)−3.22(1) Å (6, 7)). These distances are smaller than the corresponding sums of van der Waals radii (3.27 Å for **1**, 3.37 Å for **2** (8)); the differences are 0.24 and 0.26 Å for **1**, and 0.16 and 0.19 Å for **2**. These results indicate that hydrogen bonding is stronger in **1** than in **2**. This is substantiated by their ir spectra which are identical except in the region of the OH stretching modes. The OH stretching absorption band for **2** occurs at 3216 cm^{-1}, and that for **1** at 3135 cm^{-1}, 81 cm^{-1} lower.

The pattern of hydrogen bonding found in **1** and **2** appears to be unique for such systems. In a number of catecholamine halides (refs. 6, 9−11) the hydroxyl groups are hydrogen bonded to two different halogens, as in **3**. Moreover, in these



3

compounds, as in native catechol (12), and in the tetraethylammonium salt (1), one hydrogen atom lies outside the sector bounded by the C—O vectors, while the other lies inside, often forming an intramolecular bond (see, **3**). The pattern of hydrogen bonding in **1** and **2**, in which the halide ion accepts two bonds from the same catechol, requires that both hydrogen atoms lie inside the sector (Fig. 1) with unusually short non-bonded distances of 2.10(6) Å for **1** and 2.09(7) Å for **2**. Crystal packing may be the determining factor for such an unusual hydrogen-bond configuration, since it would otherwise be unstable, because of the repulsion of the similarly charged hydrogen atoms (13). This repulsion causes the oxygen atoms to be farther apart than they would otherwise be, with an increase of the C(1)—C(2)—O(2) and C(2)—C(1)—O(1) angles (Fig. 1; 122.2(4) to 123.9(4)°), and a decrease of the C(3)—C(2)—O(2) and C(6)—C(1)—O(1) angles (116.8(4) to 118.5(4)°) from the ideal value of 120°.

Our studies of hydrogen bonding in these complexes are continuing. If indeed crystal packing forces dictate the unusual pattern observed in **1** and **2**, substitution of a smaller cation may result in restoration of the more usual hydrogen-bonding network. We are also studying the nature of hydrogen bonding of **1** and **2** in solution.

The reaction of 3-methyltricarballylic acid with acetic anhydride: three products of acylative decarboxylation[1]

GEORGE M. STRUNZ, GESSIE BRISARD,[2] AND PIERRE GIGUÈRE
Maritimes Forest Research Centre, Canadian Forestry Service, P.O. Box 4000, Fredericton, N.B., Canada E3B 5P7

Received September 20, 1984

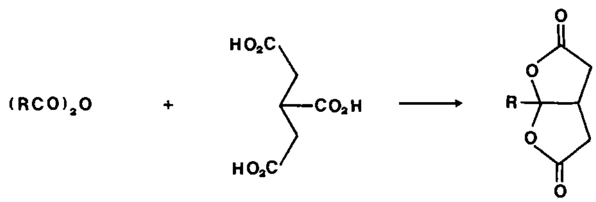
GEORGE M. STRUNZ, GESSIE BRISARD, and PIERRE GIGUÈRE. Can. J. Chem. **63**, 2123 (1985).

Three products, 2-acetonyl-2-methylsuccinic anhydride (**5**), 2,7-dioxa-1,5-dimethylbicyclo[3.2.1]octane-3,6-dione (**6**), and 3-acetonyl-3,5-dimethyl-2(3*H*) furanone (**7**) were identified from the base-catalysed reaction of 3-methyltricarballylic acid with acetic anhydride. These compounds arise as a result of acylative decarboxylation of 3-methyltricarballylic acid.

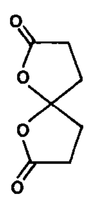
GEORGE M. STRUNZ, GESSIE BRISARD et PIERRE GIGUÈRE. Can. J. Chem. **63**, 2123 (1985).

On a identifié trois produits de la réaction de l'acide tricarballylique-3-méthyle avec l'anhydride acétique sous catalyse basique: l'anhydride succinique acétonyl-2 méthyl-2 (**5**), le bicyclo[3.2.1] octane dioxa-2,7 dicéto-3,6 diméthyl-1,5 (**6**), et le 2(3*H*) furanone acétonyl-3 dimethyl-3,5 (**7**). Ces composés résultent de la décarboxylation acylative de l'acide tricarballylique-3-méthyle.

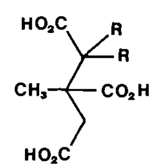
In 1901, Rudolph Fittig reported that reaction of the sodium salt of tricarballylic acid with acid anhydrides afforded bislactones of structure **1** (1). We have been interested in the potential of these compounds (and of the spiro bislactone **2**) as precursors for the synthesis of 1,4-diketones, hence of substituted cyclopentenones (2, 3).



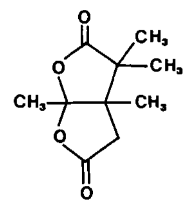
1



2



3



4

In contemplating the mechanism by which the bislactones **1** are formed, Fittig (1) recognized that acylation of tricarballylic acid (or a derivative) at C-3 would afford a β-ketoacid which could readily undergo decarboxylation to a ketodicarboxylic acid capable of cyclization to **1**. To test whether this was indeed the course of the transformation, he selected a tricarballylic acid derivative, camphoronic acid **3** (R = CH_3), which could not undergo direct acylation at C-3 prior to decarboxylation, and subjected its salt similarly to reaction wih acetic anhydride. The isolation in low yield of a crystalline product, which he considered to be the bislactone **4**, led Fittig to propose that the reaction proceeded instead by extrusion of carbon dioxide from a mixed anhydride, involving the carboxyl group at C-3 (Fig. 1). The first mechanism, which can be formulated in several essentially equivalent ways (e.g., Scheme 1 (R = H)[3,4]; cf. ref. 4) appears to provide a more plausible pathway to the bislactones (1), notwithstanding its inability to account for the formation of **4** from camphoronic acid. We report herein our parallel studies on the reaction of the related, simpler and more readily available[5] 3-methyltricarballylic acid **3** (R = H) with acetic anhydride. The results suggest an alternative interpretation of Fittig's observations in the camphoronic acid experiment.

In his pioneering studies, Fittig obtained optimum results when he treated the sodium salt of tricarballylic acid with 1.5 equivalents of anhydride (1). Later workers found that enhanced yields of the bislactones were obtained when the free acid was used with a larger excess of anhydride (5), particularly in the presence of powdered soft glass or employing a reaction vessel which was previously washed with a strongly alkaline detergent (6). Our own studies demonstrated that pyridine can be an effective catalyst for the process (2).

When 3-methyltricarballylic acid **3** (R = H) was heated under reflux with an excess of acetic anhydride in the presence of a catalytic amount of pyridine, evolution of carbon dioxide was sluggish. A more expeditious reaction occurred when 4-dimethylaminopyridine (7) was employed as catalyst. The attendant, initially vigorous, evolution of carbon dioxide moderated with time, and was quite slow after 4.5 h, when the reaction was terminated by removal of volatile material under reduced pressure. After charcoal treatment, the crude residue solidified, and afforded a pure product, A, by crystallization from ethyl acetate. Flash chromatography (8) of the mother liquor augmented the yield of A (total 42%), and gave two additional (incompletely resolved) products, designated B and C in order of increasing chromatographic mobility. Product B could be isolated by crystallization of material from the appropriate chromatographic fractions, while the minor component C required further chromatographic purification.

[1] Presented in part at the CAN–AM Chemical Congress, Montreal, June 6, 1984.

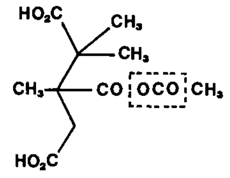

FIG. 1

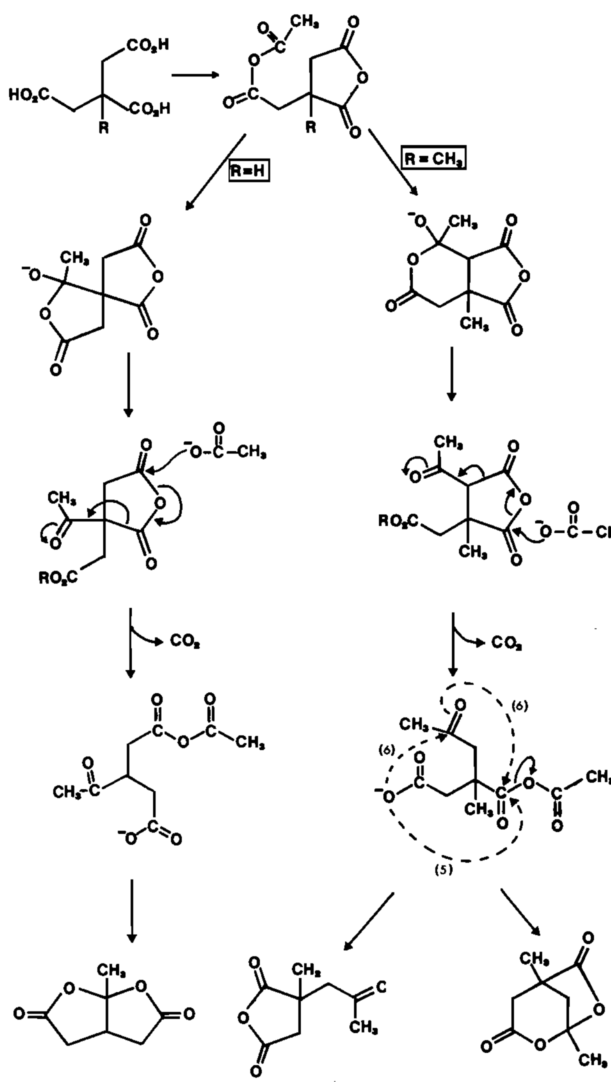

1 5 6

SCHEME 1

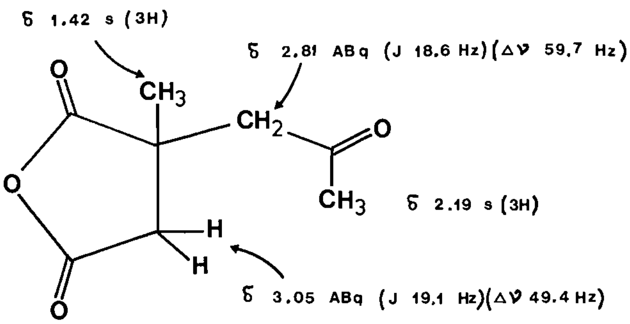

FIG. 2

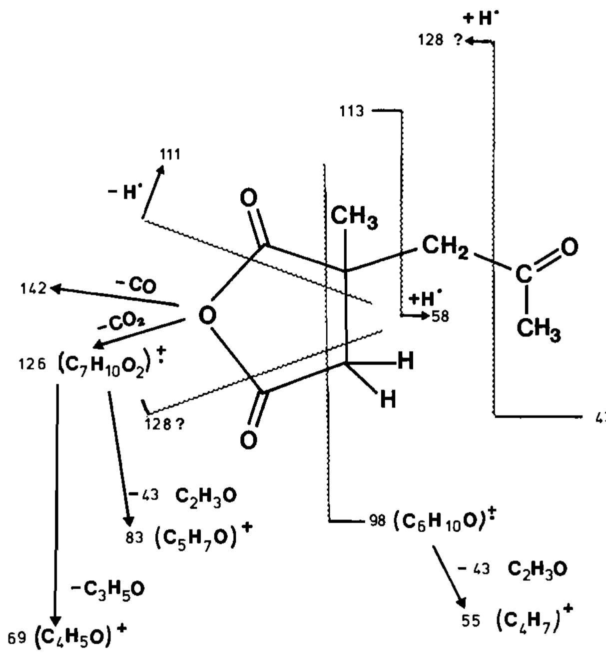

FIG. 3

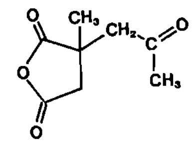
The most abundant and least mobile product A, $C_8H_{10}O_4$, was readily identified as 2-acetonyl-2-methylsuccinic anhydride, **5**, by analysis of its spectra. Thus, the infrared spectrum ($CHCl_3$) demonstrates the presence of a five-membered cyclic anhydride by bands at 1864 and 1787 cm^{-1} (9) and the ketone is manifested as a peak at 1718 cm^{-1}.

Signals in the 200-MHz ^{1}Hmr spectrum and their assignments are indicated in Fig. 2. Mass spectral fragmentations are proposed in Fig. 3 (sequence not implied).

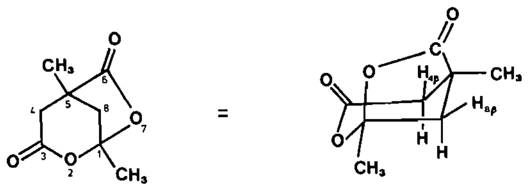
A mechanism involving acylation at C-2 of a suitable derivative of 3-methyltricarballylic acid could account for the formation of **5** (cf. Scheme 1 (R = CH_3)).[3,4]

The crystalline product B (obtained in 7.4% yield) is isomeric and interconvertible with the anhydride A (**5**), *vide infra*. Spectroscopic and chemical evidence indicates that it possesses the bridged bislactone structure **6**. Infrared bands associated with the bislactone system are found at 1812, 1792, and 1760 cm^{-1}. The 200-MHz ^{1}Hmr spectrum shows three-proton singlets at δ 1.38 and 1.81, corresponding to the hydrogens of the two methyl groups. The spectrum is also characterized by AB patterns centred at δ 2.30 ($|J_{AB}|$ 12.5 Hz; $\Delta\nu_{AB}$ 16.3 Hz) and δ 2.82 ($|J_{AB}|$ 19.0 Hz; $\Delta\nu_{AB}$ 45.7 Hz) attributable to the pairs of geminal hydrogens on the two methylene carbons. A structurally diagnostic feature of the spectrum is the long-range "*W*-coupling" (10) (1.9 Hz) exhibited by the lower field proton of each pair (H-4β and H-8β). The mass spectrum of B (*m/e* 170 ($M^{+\cdot}$); 98 (M − CO_2 and CO)$^{+\cdot}$ base peak) appears to be fully consistent with structure **6**. Such a structure may be derived from the same type of intermediate as **5** (cf. Scheme 1). Furthermore, acid-catalysed dehydration of the ketodiacid obtained by hydrolysis of either anhydride **5** or bislactone **6** produced a mixture of **5** and **6**, confirming the structural relationship between these compounds and providing additional support for formulation **6**.

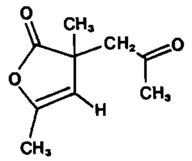
The third product C, $C_9H_{12}O_3$ (~1% yield) was readily identified as **7** by spectroscopic analysis. Thus, the enol lactone and ketone functionality are manifested in the infrared spectrum by



5



6



7

bands at 1793 and 1721 cm^{-1}, respectively (9). In the 200-MHz ^{1}Hmr spectrum, the hydrogens of the angular methyl group and methyl ketone give rise to singlets at δ 1.29 and 2.11, respectively. The vinylic methyl group is represented by a three-proton doublet at δ 2.00, displaying coupling (J 1.5 Hz) with the vinyl hydrogen at δ 5.16 (q, J 1.5 Hz). The geminal methylene protons α to the ketone appear as an AB quartet at δ 2.83 ($|J_{AB}|$ 17.9 Hz; $\Delta\nu$ = 21.5 Hz). The mass spectrum (m/e 168 ($M^{+\cdot}$); 111 ($M - C_3H_5O)^+$; 83 ($M - C_3H_5O$ and $CO)^+$ base peak) is in accord with the assigned structure.

The formation of C (**7**), may be rationalized in terms of a double acylation–decarboxylation process leading to 4-carboxy-4-methyl-heptane-2,6-dione or an acid anhydride thereof, which cyclizes to the enol lactone product.

Although the substrate and conditions examined in the present study differ from those investigated by Fittig, we note that homologues of **5** and **6**, bearing *gem*-dimethyl groups at the appropriate position, (C-3 and C-4, respectively) could in principle be formed by similar acylative decarboxylation of camphoronic acid. Such compounds are isomeric with the putative bislactone **4**, and the three structures could not readily have been distinguished on the basis of the data and methodology available to Fittig.

Experimental

Melting points were determined on a hot-stage apparatus and are uncorrected. Infrared spectra were recorded on a Beckman Acculab 2 spectrophotometer. Nuclear magnetic resonance spectra were run on a Varian XL-200 instrument. Mass spectra were obtained with an Hitachi Perkin Elmer RMU-6D mass spectrometer. High resolution mass spectra were provided by Mr. A. I. Budd, University of Alberta. Microanalyses were performed by Spang Microanalytical laboratory, Eagle Harbor, MI.

Reaction of 3-methyltricarballylic acid with acetic anhydride

To freshly distilled acetic anhydride (20 mL) containing 4-dimethylaminopyridine (200 mg, 1.64 mmol) was added 3-methyltricarballylic acid (1.95 g, 10.26 mmol). The solution was heated under reflux, and CO_2 evolution was periodically monitored by the precipitation of carbonate from a solution of barium hydroxide. The initially fairly vigorous evolution of CO_2 moderated with time, and was quite slow after 4.5 h, when the reaction was terminated by distillation of the volatile material under reduced pressure (water pump; bath temperature ambient to 95°C). (In some runs, the mixture was allowed to cool and set aside for several hours before distillation.) The dark brown residue was dissolved in ethyl acetate and treated with activated charcoal. After removal of the charcoal by filtration, evaporation of the solvent *in vacuo* yielded an orange-colored residue. Crystallization from ethyl acetate afforded almost colorless crystals of A, contaminated by a small amount of a second product. Compound A (**5**) was rendered colorless and pure by recrystallization from ethyl acetate, dimorphic crystals, mp 112–117°C and 149–151°C; ir ($CHCl_3$), inter alia: 1864, 1787, 1718 and 1010 cm^{-1}; nmr ($CDCl_3$, 200 MHz), see Fig. 2; mass spectrum (inter alia), m/e (relative intensity) (ion): 170.0577 (7) $(C_8H_{10}O_4)^{+\cdot}$ ($M^{+\cdot}$), 142.0632 (11) $(C_7H_{10}O_3)^{+\cdot}$, 128.0484 (24) $(C_6H_8O_3)^{+\cdot}$, 126.0680 (9) $(C_7H_{10}O_2)^{+\cdot}$, 124.0524 (12) $(C_7H_8O_2)^{+\cdot}$, 113.0245 (26) $(C_5H_5O_3)^+$, 111.0453 (44) $(C_6H_7O_2)^+$, 98.0733 (100) $(C_6H_{10}O)^{+\cdot}$, 83.0510 (56) $(C_5H_7O)^+$, 82.0434 (33) $(C_5H_6O)^{+\cdot}$, 69.0344 (9) $(C_4H_5O)^+$, 58.0448 (15) $C_3H_6O)^{+\cdot}$, 55.0572 (34) $(C_4H_7)^+$. *Anal.* calcd. for $C_8H_{10}O_4$: C 56.46, H 5.92; found: C 56.88, H 6.08.

The yield of A was augmented to a total of 738 mg (42%) by additional material obtained from flash chromotography (8) of the mother liquor. The eluent was chloroform – ethyl acetate in a stepwise gradient from 95:5 to 88:12.

Earlier fractions from the chromatography contained components B (**6**) and C (**7**) which were not completely resolved. Fractions richest in component B were combined and evaporated to dryness *in vacuo*. Crystallization from cyclohexane–toluene yielded 130 mg (7.4%) of bislactone B (**6**), mp 101–103°C. A sample recrystallized from toluene had mp 102–104°C; ir (KBr): 3000, 2965, 2945, 2925, 2885, 1812 (s), 1792, 1760 (s), 1455, 1412, 1390, 1350, 1322, 1290, 1265, 1172, 1142, 1122, 1077, 1034, 986, 974, 925, 902, 894, 800, and 735 cm^{-1}; nmr ($CDCl_3$, 200 MHz), see text; mass spectrum (inter alia), m/e (relative intensity) (ion): 171.0662 (0.65) $(C_8H_{11}O_4)^+$ (MH^+), 170.0563 (0.24) $(C_8H_{10}O_4)^{+\cdot}$ ($M^{+\cdot}$), 126.0682 (75) $(C_7H_{10}O_2)^{+\cdot}$, 111.0446 (5) $(C_6H_7O_2)^+$, 100.0524 (8) $(C_5H_8O_2)^{+\cdot}$, 98.0732 (100) $(C_6H_{10}O)^{+\cdot}$, 83.0499 (54) $(C_5H_7O)^+$, 69.0343 (13) $(C_4H_5O)^+$, 55.0566 (23) $(C_4H_7)^+$. *Anal.* calcd. for $C_8H_{10}O_4$: C 56.46, H 5.92; found: C 56.54, H 5.96.

Mother liquors from crystallization of B were combined with the chromatographic fractions containing C, and the resulting mixture was chromatographed on a column of Lichroprep Si 60 (Merck), eluting with hexane – ethyl acetate (7:3) under a pressure of 0.2 kg cm^{-2}, flow rate 2 mL min^{-1}. The olefin C (**7**) was obtained in about 1% yield as a pale yellow oil which set on standing to a soft white solid. The product resisted further purification attempts by recrystallization or preparative layer chromatography and the persistence of some minor contaminants could be detected in the mass and nmr spectra, as well as by gc: ir ($CHCl_3$), inter alia: 1793, 1721 cm^{-1}; nmr ($CDCl_3$, 200 MHz), see text; mass spectrum, m/e (relative intensity) (ion), inter alia: 208.0733 (2.4) ($C_{11}H_{12}O_4$ – contaminant), 194.0573 (1.4) ($C_{10}H_{10}O_4$ – contaminant), 168.0784 (6.9) $(C_9H_{12}O_3)^{+\cdot}$ ($M^{+\cdot}$), 153.0550 (2) $(C_8H_9O_3)^+$, 125.0604 (33) $(C_7H_9O_2)^+$, 124.0890 (32) $(C_8H_{12}O)^{+\cdot}$, 111.0444 (36) $(C_6H_7O_2)^+$, 109.0654 (19) $(C_7H_9O)^+$, 98.0730 (22) $(C_6H_{10}O)^{+\cdot}$, 97.0653 (16) $(C_6H_9O)^+$, 83.0498 (100) $(C_5H_7O)^+$.

*Interconversion of bislactone **6** and anhydride **5***

The bislactone **6** (65.0 mg, 0.38 mmol) was suspended in distilled water (20 mL) and the system was gradually brought to reflux temperature. At about 50°C all solid material had dissolved, and test paper indicated a pH of approximately 5, which dropped to about 3 as the temperature increased. The solution was heated under reflux for 3 h, after which it was evaporated to dryness under reduced pressure. To the resulting crude ketodiacid was added toluene (30 mL) and p-toluenesulfonic acid (3.0 mg), and the solution was heated under reflux with a Dean–Stark water separator for 3 h. Preparative layer chromatography of the product afforded 26 mg of the anhydride **5**, identified by comparison with an authentic sample, and 12 mg of regenerated bislactone **6**. Similar results were obtained with the ketodiacid obtained from hydrolysis of the anhydride **5**.

Mahmooda G. Ahmed and William E. Jones. Can. J. Chem. **63**, 2127 (1985).

The absolute rate constants for the addition of H atoms to C_2H_3F, 1,1-$C_2H_2F_2$, C_2HF_3, C_2H_3Cl, 1,1-$C_2H_2Cl_2$, C_2HCl_3, and C_2H_3Br have been determined at 298 ± 2 K over the pressure range 0.70−1.35 Torr. For each of the compounds, the rate constants are found to undergo a modest increase with pressure. At 1.00 Torr the values determined for the rate constants are: C_2H_3F, (8.86 ± 1.12) × 10^{-14}; 1,1-$C_2H_2F_2$, (8.16 ± 0.66) × 10^{-14}; C_2HF_3, (6.21 ± 0.53) × 10^{-14}; C_2H_3Cl, (27.0 ± 0.5) × 10^{-14}; 1,1-$C_2H_2Cl_2$, (59.6 ± 3.4) × 10^{-14}; C_2HCl_3, (10.4 ± 0.8) × 10^{-14}; C_2H_3Br, (27.8 ± 2.5) × 10^{-14}; in units of cm^3 $molecule^{-1}$ s^{-1}.

Mahmooda G. Ahmed et William E. Jones. Can. J. Chem. **63**, 2127 (1985).

Opérant à 298 ± 2 K et à des pressions allant de 0,70 à 1,35 Torr, on a déterminé les constantes absolues des vitesses d'additions d'atomes de H aux C_2H_3F, $C_2H_2F_2$-1,1, C_2HF_3, C_2H_3Cl, $C_2H_2Cl_2$-1,1, C_2HCl_3 et C_2H_3Br. Pour chacun des composés, on a trouvé que les constantes de vitesse augmentent légèrement avec une augmentation de la pression. A 1,00 Torr, les valeurs déterminées pour les constantes de vitesse sont les suivantes: C_2H_3F, (8,86 ± 1,12) × 10^{-14}; $C_2H_2F_2$-1,1, (8,16 ± 0,66) × 10^{-14}; C_2HF_3, (6,21 ± 0,53) × 10^{-14}; C_2H_3Cl, (27,0 ± 0,5) × 10^{-14}; $C_2H_2Cl_2$-1,1, (59,6 ± 3,4) × 10^{-14}; C_2HCl_3, (10,4 ± 0,8) × 10^{-14}; C_2H_3Br, (27,8 ± 2,5) × 10^{-14}; les unités étant cm^3 $molécule^{-1}$ s^{-1}.

[Traduit par le journal]

Introduction

While much work has been published on the reactions of hydrogen atoms with ethylene (1, 2), there have been few reports on the kinetics of the reactions of hydrogen atoms with halo-substituted ethylenes.

Teng and Jones (3, 4) have discussed in detail the mechanisms for the reactions of H atoms with fluoro-ethylene and 1,1-difluoro-ethylene. From an analysis of the products formed in a normal fast flow system and using computer simulation, they calculated rate constants for each of the steps in the mechanisms of these reactions. The absolute rate constants for the addition of H atoms to ethylene and fluorinated ethylenes have been reported by Sugawara *et al.* (5). They observed a decrease in the value of the absolute rate constant as the substitution by fluorine increased. A similar trend was observed by Kilcoyne and Jennings (6), in their study of the relative rates of the addition of hydrogen atoms to fluorinated ethylenes. However, work by Penzhorn and Sandoval (7) did not indicate the same regular increase in relative rates from ethylene to tetrafluoro-ethylene.

To date, there have been two studies reported on the reaction of atomic hydrogen with chloro-substituted ethylenes. Rennert and Wijnen (8), from their study of the reaction with vinyl chloride suggested that the abstraction of a chlorine from the vinyl chloride was faster than the addition of an hydrogen atom to the vinyl chloride. Tanner and Jamieson (9), by trapping products formed in a flow system, determined independent rate constants for the formation of HCl and hydrocarbons (C_2H_4 and C_2H_6).

In the present study, the absolute rate constants for the addition of hydrogen atoms to chloro-ethylene, 1,1-dichloro-ethylene, and trichloro-ethylene have been measured using a fast flow vacuum system coupled to a mass spectrometer. In addition, the reaction of H atoms with vinyl fluoride, 1,1-difluoro-ethylene, and trifluoro-ethylene have been measured and are reported for comparison with previous measurements and with the chloro compounds. The absolute rate constant for the addition of H atoms to vinyl bromide has also been measured and is reported for the first time. Each of the rates have been measured for at least three pressures and a definite dependence on pressure is indicated.

Experimental

The reactions were studied in a typical fast flow vacuum system coupled to a mass spectrometer. A portion of the reaction mixture passed directly into the mass spectrometer ionization chamber through a line of sight double pinhole system. Details of the flow system, the pinhole region, the mass spectrometer, and the data acquisition system are described elsewhere (10).

Hydrogen atoms were produced by passing a mixture of molecular hydrogen and helium through a 2450-MHz electrodeless discharge sustained by a 100-W Kiva MPG-2 generator. Typical flow conditions were: He, 3 × 10^{-4} mol s^{-1}; H_2, 1.8 × 10^{-5} mol s^{-1}. The reaction tube was coated with ortho-phosphoric acid, in order to minimize heterogeneous wall recombination.

The concentration of hydrogen atoms was measured by NO_2 titration. An excess of NO_2 at a known pressure was introduced to the stream of H atoms. The decay of NO_2^+ (m/z = 46) was then followed with time as the flow of NO_2 was allowed to decrease. The end point was determined as the flow of NO_2 at which the NO_2^+ signal became constant or was essentially zero. A typical titration curve is shown in Fig. 1. The flow rate of H atoms was determined from the flow rate of NO_2 at the end point on the assumption that $[H]/[NO_2]$ = 1:1.5 (11). The usual correction for the NO_2/N_2O_4 equilibrium was applied to the calculation of the flow rate of NO_2.

The concentration of H atoms was also determined directly from the extent of H_2 conversion to H by monitoring the change in the molecular H_2 peak height when the microwave discharge was on and off. The maximum deviation between the direct measurement and the titration method was approximately 8%. The change in the concentration of hydrogen atoms along the reaction tube was found to be less than 3% as calculated by the titration method at different reactant inlet jets.

Helium and molecular hydrogen were obtained from Linde. Vinyl fluoride, vinyl chloride, vinyl bromide, and NO_2 were obtained from Matheson of Canada Ltd. All condensable gases were purified by bulb-to-bulb distillation, until no impurity could be detected mass spectrometrically. NO_2 was treated with molecular oxygen and

[1]Present address: Department of Chemistry, Jahangirnagar University, Savar Dhaka, Bangladesh.

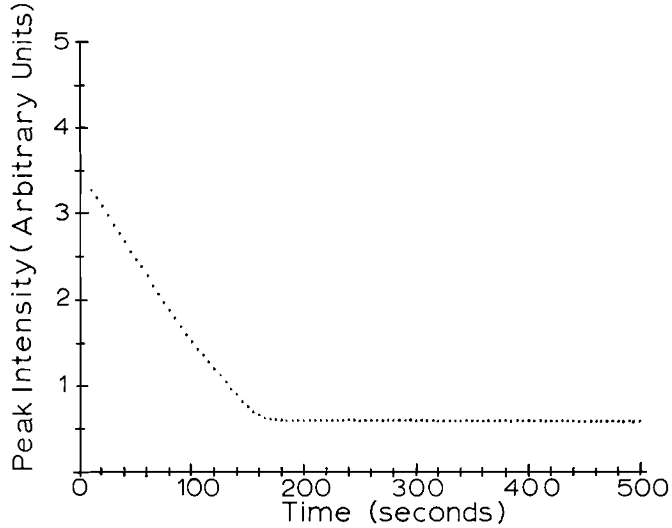

FIG. 1. A typical titration curve for the determination of the concentration of atomic hydrogen with NO_2. The curve indicates the decay of NO_2^+ as the flow of NO_2 is decreased regularly with time.

purified by trap-to-trap distillation *in vacuo*.

Since the present experiments required very low concentrations of halo-ethylene, about 1% of the H atom concentration, a mixture of 1% halo-ethylene in helium was prepared and admitted through the reactant inlet at a flow rate which provided the required concentration of halo-ethylene. This procedure also prevented back diffusion of H atoms into the reactant inlet which might have occurred if very low flow rates of halo-ethylene had been added directly.

Room temperature, 298 ± 2 K, was used for all experiments. The heat generated in the experiment was considered to be negligible since the halo-ethylene concentration was small relative to the amount of gas flowing in the tube. The reaction pressure was measured by a mercury McLeod gauge. The axial pressure gradient in the reactor was less than 2% of the total pressure. The pressure in the mass spectrometer was approximately 2×10^{-5} Torr (1 Torr = 133.3 Pa). The ionization voltage was maintained at 50 eV. The reaction time was calculated from the distance between the point of mixing of the reactants and the glass pinhole, on the assumption that the reaction stopped when the pressure dropped to approximately 5×10^{-5} Torr at this point. Under the experimental conditions used, a plug flow condition could be assumed and the time was calculated as $t = d/v$, where v is the linear flow velocity of reactant gases, and d is the distance from the reactant jet to the glass pinhole. The halo-ethylene molecular ion peak was monitored as the halo-ethylene was admitted to the stream of H atoms through each reactant inlet. From these measurements the variation of the concentration of the halo-ethylene with reaction time was obtained.

Results

A simplified scheme for the bimolecular reaction between hydrogen atoms and halo-ethylenes, RX, may be represented as

$$\mathrm{H} + \mathrm{RX} \rightarrow \text{products}$$

On the assumption that the H atom concentration is constant, the integrated rate expression for this reaction is given by

$$\ln\,[\mathrm{RX}]_t = -k[\mathrm{H}]t + \ln\,[\mathrm{RX}]_0$$

where k is the apparent bimolecular rate constant, and $[\mathrm{RX}]_t$ and $[\mathrm{RX}]_0$ are the concentrations of halo-ethylene at time t and 0, respectively. Under pseudo-first-order conditions, i.e., $[\mathrm{H}] \gg [\mathrm{RX}]$, the integrated equation becomes;

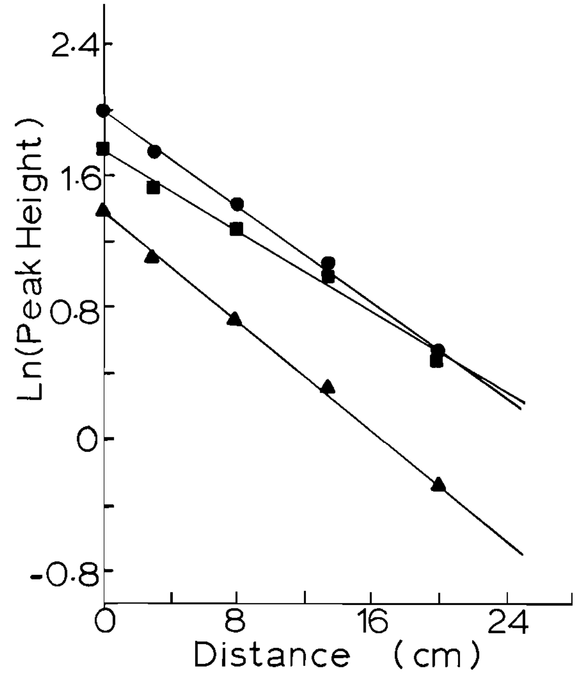

FIG. 2. A sample plot showing the variation of ln (peak height) of the halo-ethylene molecular ion peak with distance of the inlet from the sampling pinhole. (Vinyl chloride is the sample halo-ethylene.) ■ 1.35 Torr $F_H = 7.35 \times 10^{-6}$ mol s^{-1}; $k = 2.87 \times 10^{-13}$ cm^3 molecule^{-1} s^{-1}. ● 1.00 Torr $F_H = 6.88 \times 10^{-6}$ mol s^{-1}; $k = 2.63 \times 10^{-13}$ cm^3 molecule^{-1} s^{-1}. ▲ 0.70 Torr $F_H = 7.54 \times 10^{-6}$ mol s^{-1}; $k = 2.14 \times 10^{-13}$ cm^3 molecule^{-1} s^{-1}.

$$\ln\,[\mathrm{RX}]_t = -k_{\mathrm{obs}}t + \ln\,[\mathrm{RX}]_0$$

where k_{obs} is the pseudo-first-order rate constant. It is assumed in this equation that the rate constant k_{obs} is independent of the mode of loss of H atoms and that halo-ethylene is lost only through its reaction with H atoms and is not consumed or regenerated in subsequent reactions. These assumptions have been verified for all the halo-ethylenes used. The concentration of halo-ethylene was varied threefold and the rate constant was found to be independent of the initial concentration of the halo-ethylene. Analysis of the products also showed that the halo-ethylene was not consumed in secondary reactions.

A plot of $-\ln\,[\mathrm{RX}]$ vs. time t gives the pseudo-first-order rate constant k_{obs}. The value of k is then calculated using the value of [H].

The variation with distance (equivalent to reaction time) of ln (peak height) of the molecular ion of the halo-ethylene was monitored using computer assisted data acquisition. A sample plot for vinyl chloride is shown in Fig. 2. After conversion of the distance axis to time, the slope of the line provides the pseudo-first-order rate constant. From the concentration of the H atoms, the apparent bimolecular rate constant k is determined.

The values for the bimolecular rate constant for each of the reactants C_2H_3Cl, $C_2H_2Cl_2$, C_2HCl_3, C_2H_3F, $C_2H_2F_2$, C_2HF_3, and C_2H_3Br are given in Table 1.

Discussion

A comparison of the products resulting from the reaction of hydrogen atoms with the various halo-ethylenes indicated that a general mechanism analogous to that for the reaction of H atoms with ethylene (3, 4) may be applicable to the H atom –

TABLE 1. Apparent bimolecular rate constants for the addition of hydrogen atoms (temperature 298 ± 2 K)

Pressure (Torr)	Reactant (k in units of cm^3 $molecule^{-1}$ s^{-1} $\times 10^{14}$)						
	$C_2H_3F^a$	$1,1\text{-}C_2H_2F_2^b$	$C_2HF_3^b$	$C_2H_3Cl^a$	$1,1\text{-}C_2H_2Cl_2^b$	$C_2HCl_3^c$	$C_2H_3Br^a$
0.70±0.05	7.64±0.78	7.32±0.29	5.17±0.35	21.2±1.6	47.3±3.1	9.2±0.8	24.6±1.4
1.00±0.05	8.86±1.12	8.16±0.66	6.21±0.53	27.0±0.5	59.6±3.4	10.4±0.8	27.8±2.5
1.30±0.05	10.80±0.90	10.47±0.41	7.30±0.46	30.3±3.9	63.8±3.5	11.9±1.6	38.3±1.8

NOTE: For C_2Cl_4 an upper limit for k at 1.30 Torr was found to be 1.3×10^{-14} cm^3 $molecule^{-1}$ s^{-1}.
[a]Twenty determinations at each pressure.
[b]Ten determinations at each pressure.
[c]Five determinations at each pressure.

halo-ethylene reaction as follows:

$$[1]\quad H + RX \xrightarrow{k_1} RHX^*$$

$$[2]\quad RHX^* \xrightarrow{k_2} RX + H$$

$$[3]\quad RHX^* + M \xrightarrow{k_3} RHX + M$$

$$[4]\quad H + RHX \rightarrow RH_2X \rightarrow RH + HX \quad (k_4)$$

where RX is the halo-ethylene molecule with X as F, Cl, or Br and M is a third body. The addition of an H atom to RX produces a vibrationally excited RHX* radical which can decompose to H and RX, or to be stabilized through collision as in eq. [3]. The stabilized radical can react with an H atom as in eq. [4] to produce an excited molecule which will decompose to produce RH and HX.

Applying the steady state treatment to the above mechanism, the rate of disappearance of RX may be shown to be:

$$-d[RX]/dt = (k_1 [H] [RX] \times k_3[M])/(k_2 + k_3[M])$$

which gives the apparent bimolecular rate constant k as:

$$k = (k_1 \times k_3[M])/(k_2 + k_3[M])$$

If $k_2 = 0$ or if $k_2 \ll k_3[M]$, k is equal to k_1 at any pressure. If neither of these conditions exists, the value of k will increase with pressure.

The experimental values of k for the addition of H atoms to C_2H_3F, $1,1\text{-}C_2H_2F_2$, C_2HF_3, C_2H_3Cl, $1,1\text{-}C_2H_2Cl_2$, C_2HCl_3, and C_2H_3Br presented in Table 1 show a modest increase with increasing pressure over the limited pressure range 0.7−1.35 Torr used in this work.

The value of the rate constant for the addition of H atoms to C_2H_3F at a pressure of 1.00 Torr is $8.82 \pm 1.12 \times 10^{-14}$ cm^3 $molecule^{-1}$ s^{-1}, which is in reasonable agreement with the value 4.53×10^{-14} determined by Teng and Jones (3). Sugawara *et al.* (5) obtained a value of 5.2×10^{-13} cm^3 $molecule^{-1}$ s^{-1} at a pressure greater than 180 Torr. From the steady state treatment it can be seen that a plot of k^{-1} against P^{-1} or $[M]^{-1}$ should be linear. An extrapolation of this plot to 180 Torr gives a value of approximately 2×10^{-13} which, at about half the value of Sugawara *et al.*, is quite satisfactory agreement considering the length of the extrapolation.

Successive substitution of F atoms for H atoms in ethylene has been found to decrease the rate constant for the addition of H atoms to the resulting fluoro-ethylene (4−6). A similar trend has been observed in the present study, as may be seen in Table 1.

The only value available for the rate constant for the addition of H atoms to C_2H_3Cl is 6.90×10^{-14} cm^3 $molecule^{-1}$ s^{-1} as given by Rennert and Wijnen (8), which is somewhat smaller than the value calculated in the present work.

To our knowledge, there is no previous report in the literature which gives the rate constant for the reaction of H atoms with C_2H_3Br.

The values of the rate constants given in Table 1 for C_2H_3F, C_2H_3Cl, and C_2H_3Br tend to increase from C_2H_3F to C_2H_3Br. A similar trend in reactivity has been observed for the reaction of O atoms with these same molecules (12−15). This has been explained by considering two opposing influences created by the substituted halogen atom on the reactivity of the olefin. These influences can be attributed to the strong negative inductive effect ($-I$) due to the electronegativity of the halogen, and the positive inductive effect ($+I$) as a result of the repulsion of π electrons present in the p orbitals of the halogen atom and the mesomeric ($+M$) effect, as distinguished by Clark *et al.* (16). When an F atom is substituted in C_2H_4, a deactivation of the double bond occurs due to the combined effects described above, and the reaction of H atoms with C_2H_3F becomes slower than that for the reaction with the C_2H_4 molecule.

The donation of the unshared electrons from the substituted halogen to the double bond increases along the series H < F < Cl < Br while the electronegativities of the atoms decrease along the series F > Cl > Br > H. These combined effects cause a change in the reactivity when F is substituted for Cl or Br. A change in the reactivity is also observed with an increase in the number of substituents (4−6). The rate constants presented in Table 1 indicate that as fluorine substitution increases the rate constants decrease. For chlorine substitution, an increase in the rate constants occurs between C_2H_3Cl and $1,1\text{-}C_2H_2Cl_2$, but substitution of a third Cl atom decreases the rate constant. Preliminary results indicate that further substitution by a Cl atom further decreases the rate constant.

Received October 5, 1984

WILLIAM J. LEIGH, DEBBIE T. FRENDO, and PAUL J. KLAWUNN. Can. J. Chem. **63**, 2131 (1985).

The effect of cholesteric liquid crystalline solvents on the energetics of rotational thermal *cis–trans* isomerization of olefins has been examined. Rate constants have been obtained over a 70-degree temperature range for isomerization of *trans*-1,2-di-(4-cyanophenyl)-1,2-diphenylethylene in two isotropic solvents and three cholesteric liquid crystals and the Arrhenius parameters determined. The rates of isomerization are found to be consistently slower in the liquid crystalline phases compared to the isotropic solvents. The Arrhenius parameters for isomerization of the olefin in the isotropic solvents (E_a = 34.8 ± 0.3 kcal/mol; $\Delta S^{\neq}$ = −1.5 ± 0.5 e.u.) compare favourably with reported values for its isomerization in benzene solution. In the cholesteric phases, E_a is consistently 1–1.5 kcal/mol higher and $\Delta S^{\neq}$ slightly more positive than the corresponding values for the isotropic solvents. The results are tentatively rationalized in terms of disruption of liquid crystalline order as the olefin twists from its pseudo-planar, ground state geometry through the globular, twisted transition state. The magnitude of this effect is proposed to depend on both the difference in steric bulk of the ground and transition states and the "tightness" of the solvation shell seen by the isomerizing molecule. It is believed that in the present case the observed effects are somewhat truncated as a result of rather poor solvation of the bulky olefin in the liquid crystalline phases.

WILLIAM J. LEIGH, DEBBIE T. FRENDO et PAUL J. KLAWUNN. Can. J. Chem. **63**, 2131 (1985).

On a étudié l'effet des solvants cholestériques cristaux-liquides sur les niveaux énergétiques de l'isomérisation *cis–trans* thermique de rotation des oléfines. Opérant sur une plage de température de 70 degrés, on a obtenu les constantes de vitesse d'isomérisation du di-(cyano-4 phényl)-1,2 diphényl-1,2 éthylène dans deux solvants isotropes ainsi que dans trois cristaux liquides cholestériques et on a aussi déterminé les paramètres d'Arrhénius. On a trouvé que les vitesses d'isomérisation sont systématiquement plus lentes dans les phases de cristaux liquides que dans les solvants isotropes. Les paramètres d'Arrhénius pour l'isomérisation de l'oléfine dans les solvants isotropes (E_a = 34,8 ± 0,3 kcal/mol; $\Delta S^{\neq}$ = −1,5 ± 0,5 u.e.) se comparent favorablement avec les valeurs rapportées antérieurement pour son isomérisation en solution dans le benzène. Dans les phases cholestériques, les valeurs de E_a sont systématiquement de 1 à 1,5 kcal/mol plus élevées et la valeur du $\Delta S^{\neq}$ est légèrement plus positive que les valeurs correspondantes pour les solvants isotropes. D'une façon préliminaire, on rationalise les résultats en fonction d'une dislocation de l'ordre du liquide cristallin alors que l'oléfine se déplace de la géométrie pseudo-planaire de son état fondamental vers l'état de transition globulaire qui a subi une torsion. On croit que l'amplitude de cet effet dépend à la fois de la différence entre les encombrements des états fondamental et de transition et de la nature compacte du noyau de solvatation ressenti par la molécule qui s'isomérise. Dans le cas présent, on croit que les effets observés sont un peu tronqués à cause de la mauvaise solvatation de l'oléfine encombrée dans les phases liquides cristallines.

[Traduit par le journal]

Introduction

The use of thermotropic liquid crystals as solvents for thermal and photochemical reactions has been the subject of numerous reports in recent years (1–13). Most commonly, these investigations have examined the effects of these materials on unimolecular processes which involve some degree of distortion of an oriented solute's molecular framework. Examples include the Claisen rearrangement in nematic solvents (1), intramolecular excimer formation in cholesterics (2), and the Norrish Type II reaction in cholesteric and smectic solvents (3). The common thread in each of these examples is that the reaction or process in question involves cyclization of an oriented, rod-like solute; if this results in disruption of liquid crystalline order, then some effect on the rate of the process is generally observed.

Increasing attention is being focussed on the effects of liquid crystalline solvents on the dynamics of bimolecular reactions (4–8), and Samori and co-workers have noted that the largest effects on reactivity are to be expected for reactions whose energetics are dominated by entropy factors (8), that is, in reactions which are subject to rather severe orientational constraints in the transition state. The systems which have been investigated to date have used liquid crystals to control the mutual orientations of the reactive solutes, the idea being that reaction efficiency should be greater when the reactive moieties are held in the optimum mutual orientation for interaction. Examples include the photodimerizations of acenapthylene (6) and tetraphenylbutatriene (4), pyrene excimer and exciplex formation (7), and sulfonate ester rearrangements (8).

Several years ago, Nerbonne and Weiss reported an investigation of the effects of cholesteric liquid crystalline solvents on the energetics of the thermal *cis–trans* isomerization of azobenzene (9*a*), in an attempt to elucidate the mechanism of this process, whether via bond rotation or nitrogen inversion. The transition states for these two mechanisms differ considerably in their shapes, and thus might be expected to be solvated somewhat differently in a liquid crystal. It was suggested that isomerization by bond rotation should be impeded in a liquid crystalline solvent as a result of the disruptive effects of the bulky, globular transition state on solvent order. Isomerization by nitrogen inversion, on the other hand, should not be affected by liquid crystalline solvents, since passage through this transition state involves a change in solute geometry which is more compatible with the macroscopic solvent "structure". This idea that transition states of different steric shape might be solvated somewhat differently in a liquid crystalline solvent is

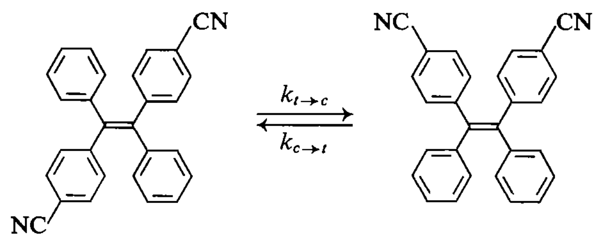
	0.5	172–174	227–228

[a] In °C, corrected; measured by thermal microscopy.
[b] Solid to cholesteric transition.
[c] Cholesteric to isotropic transition.

directly analogous to the known behaviour of liquid crystals with respect to the differences in their ability to solvate planar or rod-like solutes and non-planar or globular ones (14). The result that both the activation energy and entropy for the isomerization of azobenzene were significantly more positive in a cholesteric liquid crystal compared to isotropic solvents was taken as evidence for the bond rotation mechanism for this isomerization (9*a*). Since that time, a number of studies have provided rather convincing evidence in favour of the bond inversion mechanism (15). Otruba and Weiss have recently reported a correction to their earlier report (9*b*). They have found that the energetics of the thermal *cis–trans* isomerization of azobenzene and a series of substituted derivatives are in fact *not at all affected* by liquid crystalline solvents; they conclude that azobenzene must therefore isomerize via the more widely accepted (15) nitrogen inversion mechanism.

The proposal that a liquid crystalline solvent might be able to distinguish between rotational and inversion transition states in the azobenzene isomerization, while seemingly viable, remains unproven. No reliable indication exists of the potential magnitude of the effect on the energetics of rotational *cis–trans* isomerization of olefins by liquid crystalline solvents. A report of a two-fold enhancement in the rate of thermal *cis–trans* isomerization of *cis*-stilbene in a nematic solvent relative to that in isotropic media (16) must be viewed as suspect, since at the temperature examined (156°C), the isomerization rates are grossly incompatible with the known activation parameters for the uncatalysed thermal isomerization of this olefin (17).

We wish to report the results of our study of the kinetics of the thermal *cis–trans* isomerization of 1,2-di-(4-cyanophenyl)-1,2-diphenylethylene (**1**) in cholesteric liquid crystalline



1

and isotropic solvents. Our results suggest that cholesteric liquid crystals are indeed capable of affecting the energetics of rotational *cis–trans* isomerization, although the observed effect is small and it is difficult to derive definitive conclusions with regard to its origins. The magnitude of the effect which is observed in this system can be explained as being the result of several factors, all of which derive from the manner in which this solute is solvated in the liquid crystalline environment.

Results

Transition temperatures for the liquid crystalline materials used in this study were measured by thermal microscopy for both the pure materials and the doped mixtures used in the kinetic studies. These are collected in Table 1. The **1**-doped samples were prepared by evaporation of methylene chloride solutions of **1** and the aromatic esters under vacuum to ensure intimate mixing of the two components. While the substantial effects on both the K → Ch and Ch → I transition temperatures indicate that the olefin is, presumably, soluble in each of the mesophases employed, this was further corroborated by simple monitoring of the dissolution of a small crystal of *trans*-**1** in the cholesteric phase of each of these materials by thermal microscopy. In each case, dissolution appeared to be complete within ca. 5 min at a temperature ca. 10°C above that of the K → Ch transition.

The rates of isomerization of *trans*-**1** were measured over the temperature range 170–245°C as the rates of approach to equilibrium, according to published procedures (18). The data were analysed according to eq. [1], in which X_0^T, X_t^T, and X_e^T are the mole fractions of the *trans*-isomer initially, at time *t*, and at

$$[1] \quad \ln (X_t^T - X_e^T) = \ln (X_0^T - X_e^T) - kt$$

equilibrium, respectively, and *k* represents the sum of the rate constants for the forward and reverse reactions. Equilibrium compositions were established from both directions in order to ensure complete equilibration. At a given temperature, the equilibrium composition for **1** did not vary significantly as a function of solvent. Rate and equilibrium data for the thermal isomerization of **1** as 0.5 or 1.0 wt.% solutions in cholesteryl benzoate (CB), 3β-cholestanyl 4-toluate (CT), cholesteryl 4-chlorobenzoate (CCB), cholesteryl 6-methoxy-2-naphthoate (CMN), and n-decyl 4-anisoate (DA) are collected in Table 2. The quoted errors in the rate constants have been estimated as the standard deviations, obtained from weighted linear least-squares analyses of the data according to eq. [1]. Representative plots are shown in Fig. 1 for the isomerization of *trans*-**1** in the cholesteric phase of CCB and the isotropic phase of CB at 200°C.

Kinetic runs using DA and CMN as solvents were performed simultaneously at each temperature; thus, differences in the rate constants at each temperature are more meaningful for these two solvents than for the other three. The runs using CB, CT, and CCB as solvents were done separately, and the temperature varied by ±1° from run to run. While the temperatures

recorded in Table 2 do not reveal these minor differences, they were in fact incorporated in the Arrhenius plots and calculations discussed below.

A sample of DA was heated at 230°C for 35 h and examined by ^{1}Hmr spectroscopy in order to ensure that solvent decomposition does not occur to any significant extent at these temperatures during the times required for the kinetic analyses. *p*-Anisic acid could not be detected in the nmr spectrum of DA after being subjected to this treatment.

[a]Measured by thermal microscopy.

Mesophase stability over the time periods necessary for the kinetic analyses was verified for each of the liquid crystals employed, by visual inspection of **1**-doped samples in a thermal microscope held at 240°C (220°C for CT) for 3 h.

The rates of isomerization of *trans*-**1** in CMN at 210°C were measured using samples containing 0.2, 0.5, 1.0, and 2.0 wt.% **1**. These data are collected in Table 3, along with the measured transition temperatures for each of the mixtures.

Arrhenius plots for our data are shown in Figs. 2 and 3. Least-squares analysis of each yielded the Arrhenius parameters collected in Table 4. The insert in Fig. 3 shows a plot which illustrates the dependence of the ratio of the rate constants in isotropic DA and cholesteric CMN on inverse temperature; such a plot gives a better indication of the differences in the Arrhenius parameters obtained, along with the estimated errors in these differences. Least-squares analysis of this plot

TABLE 4. Arrhenius parameters for the thermal *cis–trans* isomerization of **1** in cholesteric and isotropic media[a]

Solvent	Phase	E_a[b]	ln A[c]	$\Delta S^{\neq}$ (200°)[d]
CB	Isotropic	35.0 ± 0.6	28.56 ± 0.64	−1.4 ± 0.6

yields the differences in the Arrhenius parameters for isomerization of **1** in the two solvents: $\Delta E_a = 2.5 \pm 1.2$ kcal/mol and $\Delta(\Delta S^{\neq}) = 2 \pm 2$ e.u. ($R^2 = -0.83$).

Discussion

Liquid crystals are ordered fluids, with properties intermediate between those of an isotropic liquid and a crystalline solid, and are characterized according to the degree and type of orientational and translational ordering of their constituent molecules (19*a*).[3] The primary requirement met by all thermotropic liquid crystals (with the exception of discotics) is that the molecular shape of the component molecules be rod-like (19). The order in nematic liquid crystals is purely orientational; the constituent molecules are, on the average, oriented with their long molecular axes parallel to one another. Unlike the more highly ordered smectic types, there is no translational ordering in nematics, and hence these are the most fluid type of liquid crystalline phase.

Cholesteric phases are formed by optically active molecules (such as cholesteryl esters) or by nematics doped with an optically active solute (20). The structure of cholesterics is best described as "twisted nematic"; that is, the ordering is nematic, with a gradual twist in the orientational alignment (characterized by the director, *n*) as one proceeds through the bulk of the sample (21). This gradual twist in the director describes a helix, the period of which typically proceeds over a few thousand angstroms, and this imparts a macroscopic chirality to the liquid crystal. Cholesterics are widely described as being layered, consisting of a series of nematic "sheets" which are stacked such that the director twists slightly upon proceeding from layer to layer (2, 20*b*). While this description of cholesterics perhaps aids in the visualization of the nature of their optical activity, it must be emphasized that it is *only* an approximation (21), insofar as crystallographic studies do not substantiate the presence of discrete layers in these materials.[4]

Solubilization of solutes in liquid crystals occurs so as to incorporate the solute with a minimal amount of disruption of the surrounding crystalline lattice, and appears to be governed primarily by steric factors (14, 19).[5] A solute whose molecular shape is similar to that of the solvent molecules is more effectively solubilized and creates less disruption of liquid crystalline order than one which is grossly dissimilar in structure (14).[5] If the solute undergoes some unimolecular reaction which involves a change in shape as it proceeds through the transition state, then some effect on the energetics of the reaction is expected as a result of the necessary disruption of the ordered solvation shell. The magnitude of this effect will depend on how tightly the solute (in its ground state geometry) is solubilized in the liquid crystal, as well as the degree of distortion which the molecule must undergo (and hence the extent of disruption it imposes on solvent order) in order to reach the transition state.

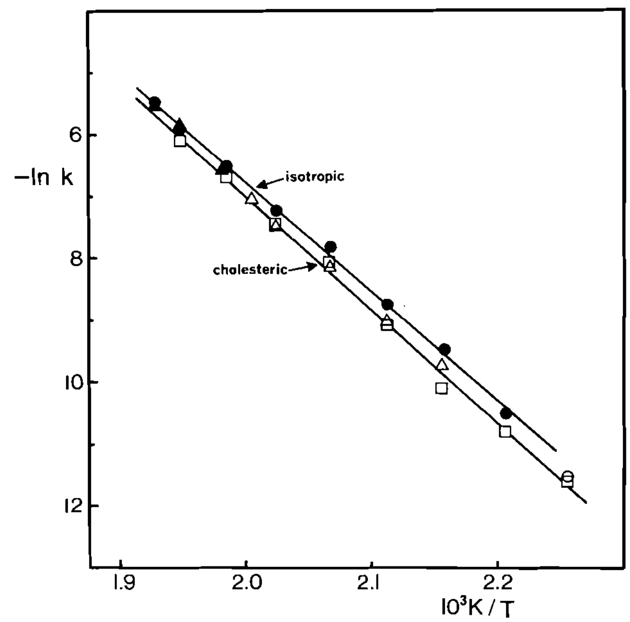

FIG. 2. Arrhenius plots for the thermal *cis–trans* isomerization of **1** in the isotropic and cholesteric phases of CB (chol. ○; isot. ●), CT (chol. △; isot. ▲), and CCB (chol. □). The lines drawn represent those obtained from least-squares analysis of the two sets of the *combined* data.

A number of examples of the effects of liquid crystalline order on the energetics of unimolecular reactions have been reported (1–3, 9–13), and it is clear that the effects on reactivity are greatest when the solute is well oriented in the liquid crystal (12). For rod-like reactants, the solvation shell is reasonably tight, and reaction involves "dragging" portions of the solute's framework out of their solvent-induced orientations. Reactivity is affected as a result of the solvent's ability to orient

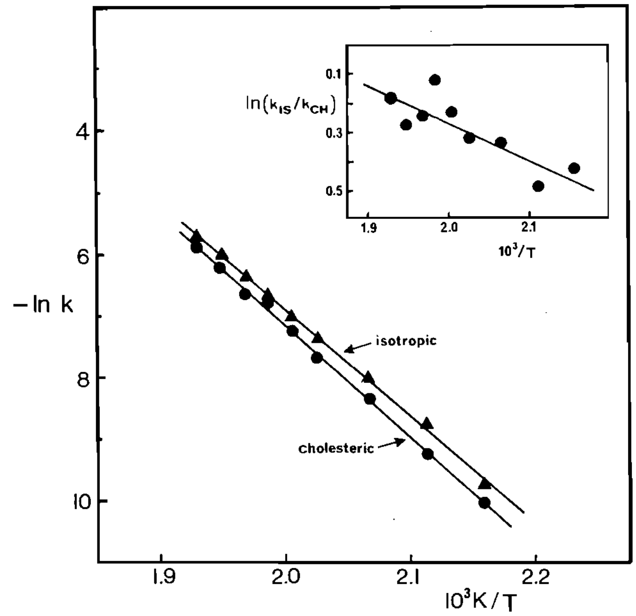

FIG. 3. Arrhenius plots for the thermal *cis–trans* isomerization of **1** in isotropic DA (▲) and cholesteric CMN (●). Insert: Arrhenius-type plot using the ratios of the rate constants in CMN and DA (k_{CH}/k_{IS}).

the solute and inhibit molecular motions which deviate from that orientation. Tetraphenylethylene is disc-like in shape, and therefore is expected to be oriented in a cholesteric phase with its molecular plane parallel to the long molecular axes of the surrounding solvent molecules (23). As a result of its disc-like shape, it will not be as tightly solvated in a cholesteric phase as would be a rod-like solute. Nevertheless, twisting about the double bond in the course of *cis–trans* isomerization does involve rather substantial changes in molecular shape, and this should result in disruption of whatever solvent order exists in, or surrounding, the primary solvation shell.

There is a slight variation in the rate of isomerization of **1** as a function of solvent for the two isotropic solvents examined, n-decyl anisoate (DA) and cholesteryl benzoate (CB) (see Table 2), the rates being consistently slower in the former at each of the temperatures examined. The origin of this solvent effect, if it is real, is not clear. It is not the result of differences in solvent polarity, since the rates in the more polar DA correlate better with those in benzene (calculated from the published Arrhenius parameters). It is possible that the somewhat faster rates in CB are the result of catalysis by trace impurities, although the rate of isomerization of **1** at 220°C did not vary using a more rigorously purified sample of that solvent.

It is important to note that the rates of isomerization of **1** in isotropic CB agree rather well with those in isotropic cholestanyl toluate (CT) (>225°C). Furthermore, the rates of isomerization in the cholesteric phases of CT (<225°C) and CB (170°C) are identical to those in cholesteric CCB at the same temperatures. Thus, the rate data for isomerization of **1** in CB, CT, and CCB, at least, appear to be internally consistent.

It is well known that the density and viscosity of a liquid crystalline phase vary significantly over the temperature range at which it exists; hence for a particular liquid crystal, the mesophase will be more "rigid" the closer it is to its K → Ch transition temperature (i.e., the lower its solvent reduced temperature, T/T_I, where T_I represents the mesophase → isotropic transition temperature).[6] Furthermore, mesogens of similar structure tend to show the same dependencies on reduced temperature with respect to these properties and other properties related to them (24). We wondered if the magnitude of the effect of cholesteric order on the rate of isomerization of **1** would depend on the "rigidity" of the liquid crystalline phase, and the three cholesterics used in the present study were chosen with this in mind. Thus, CT (chol. 172–228°C (25)), CCB (chol. 169–248°C (26)), and CMN (chol. 182–290°C (27)) were chosen so as to provide cholesteric phases which are at the upper end, in the middle, and at the lower end of their mesophase temperature ranges, respectively, over the temperature range at which our rate measurements were carried out. While the significantly slower rates of isomerization in CMN may indicate that there is in fact some dependence of rate on mesophase rigidity, this interpretation must be viewed with caution. Firstly, if it is correct, then a significant difference is expected in the rates of isomerization of **1** in CB and CCB at 170°C (these two are at the extreme high and low ends of their mesophase ranges, respectively, at this temperature). This is clearly not the case. We note that the differences in the rates in CMN relative to CT and CCB are of a similar magnitude to those observed for the isotropic solvents DA and CB. Thus, it appears likely that the same sort of solvent effect responsible for the difference in the rates of isomerization of **1** in DA and CB is operating in the cholesteric phases as well. For the purposes of discussion, it seems prudent to restrict comparison of the data in CMN to those in DA, and consider the CB/CT/CCB rate data as a separate set.

The data in Table 2 demonstrate that at every temperature, the rate of thermal *cis–trans* isomerization of **1** is significantly (and reproducibly) slower in the cholesteric solvents than in the corresponding model isotropic solvents throughout the temperature range examined, by 10–35%. Clearly, rotation about the carbon–carbon double bond in this olefin is inhibited in the ordered liquid crystalline phases relative to isotropic media.

The Arrhenius plots in Fig. 2 demonstrate more clearly the relationship between the measured rates of isomerization of **1** in CB, CT, and CCB. The lines drawn in Fig. 2 represent those obtained from least-squares analysis of the *combined* data for these three solvents. Analysis of the data for the isotropic solvents yields E_a = 34.8 ± 0.3 kcal/mol and $\Delta S^{\neq}$ (200°) = −1.5 ± 0.5 e.u., in excellent agreement with the parameters reported previously for isomerization of this olefin in benzene solution (18). Similar analysis of the data for the cholesteric phases of CB, CT, and CCB yields E_a = 36.0 ± 0.2 kcal/mol and $\Delta S^{\neq}$ (200°) = −0.5 ± 0.6 e.u. The correlation coefficients for the two analyses were better than 0.999 in both cases. Figure 3 shows the Arrhenius plots for DA and CMN, and the calculated Arrhenius parameters for these solvents are collected in Table 4.

While these plots clearly demonstrate that there is *some* difference between the energetics of *cis–trans* isomerization in the cholesteric and isotropic solvents, it is difficult to get a clear idea of the origin of this effect (whether enthalpic, entropic, or both) from the calculated Arrhenius parameters, considering the magnitude of the errors. The differences in $\Delta S^{\neq}$ certainly cannot be considered to be significant. An Arrhenius-type plot using the ratios of the rate constants in cholesteric CMN and isotropic DA, shown as an insert in Fig. 3, gives a somewhat more sensitive indication of the significance of the differences

[6] Reference 19*b*, chapt. 8, and references cited therein.

in the Arrhenius parameters. Keeping in mind that the errors in the calculated rate ratios are much larger than those in the rate constants themselves, the trend in the plot is clearly consistent with a slightly higher activation energy for isomerization of **1** in the cholesteric phase relative to the isotropic solvent.

It is tempting to ascribe the slightly higher activation energy for thermal isomerization of **1** in the cholesteric phases to the effects of liquid crystalline order on the transition state for *cis–trans* isomerization. If the change in shape from the "plate-like" ground state geometry of **1** to the globular 90°-twisted transition state is accompanied by some disruption of local solvent order, then increases in both the energy and entropy of activation for the process relative to their values in isotropic solvents are expected. Considering the sizeable difference in the shapes of the "planar" and twisted geometries of **1**, the magnitude of the observed effect in the present case is, however, clearly not large. The reason for this can be rationalized on the basis of how effectively **1** is expected to be solvated in the cholesteric phases examined.

Crystallographic data show that tetraphenylethylene is a rather bulky molecule in its ground state geometry. The phenyl groups are situated in a propeller-like arrangement, and the double bond is twisted by ca. 8° (28). As the data in Table 1 show, incorporation of as little as 0.5 wt.% (ca. 0.015 *M*) *trans*-**1** has a fairly substantial effect on the Ch → I transition temperatures of each of the cholesterics employed in the present study. Thus, the presence of **1** in even low concentrations disrupts cholesteric order to a significant extent, with the result that **1** is rather poorly solvated in these liquid crystals. Indeed, while the bulk mixtures remain liquid crystalline even at olefin concentrations up to 2%, it is possible that local disruption of solvent order is so severe that the effective solvation of individual solute molecules is almost isotropic. Further support for this idea derives from the lack of variation in the rate of isomerization of **1** as a function of either its concentration (Table 3) in the cholesteric phases or the rigidity of the mesophase.[7] Thus, as **1** isomerizes, any further disruption of solvent order is of a secondary nature, and the isomerization is inhibited to only a small extent.

Intimately related to this explanation is the possibility that the observed differences are the result of viscosity effects. Liquid crystals are highly viscous fluids in the bulk, and on a microscopic level their viscosity is highly anisotropic (19). The hindered rotation about the double bond in **1** in the cholesteric phases might then be attributed to viscous drag effects. However, to the extent that overcoming this viscous drag must involve disruption of solvent order, such a distinction seems superfluous. There is, nonetheless, another possible explanation for the observed effect, which is based on solvent viscosity arguments. It is reasonable to expect that the viscosity in an isotropic "microdroplet" which is surrounded by an ordered environment might be considerably higher than that in the bulk isotropic phase. The primary solvation shell of **1** in a cholesteric liquid crystal might then be viewed as a highly viscous, isotropic solvent, and it is this high effective viscosity which inhibits the isomerization, *not* the necessity of disrupting solvent order beyond the primary solvation shell. In order to account for the observed rate effects, the effective viscosity in the isotropic microdomains containing the solute must then be several orders of magnitude larger than that in the bulk isotropic phase, since the Arrhenius parameters for isomerization of **1** in the isotropic phase of cholesteryl benzoate are the same as those reported for that in benzene solution, and the bulk viscosities of these two solvents differ by at least two orders of magnitude at 180°C (29).

The "twisted nematic" description of the macroscopic order in cholesterics, insofar as it implies overall nematic order with no discrete solvent layering (30), leads to the expectation that **1** is oriented in the liquid crystal with its molecular plane held (on the average) parallel to the long molecular axes of the surrounding solvent molecules (23). The same orientation is expected in nematic and smectic liquid crystals. According to this picture, one would then expect that *any* liquid crystalline phase should produce an effect on the energetics of thermal isomerization of **1**, with the magnitude of the effect correlating with the degree of mesophase order. Thus, it would be predicted that nematic phases should produce an effect similar to that of cholesterics on the Arrhenius parameters for isomerization of **1**, while the effect of smectic phases might be somewhat greater owing to their higher degree of order and rigidity. The reported effect of a nematic solvent on the rate of isomerization of *cis*-stilbene (16) is consistent with this idea. Unfortunately, it is difficult to test this hypothesis with the present system, owing to the unavailability of nematic and smectic solvents in the temperature range required to observe the isomerization of **1**. These ideas clearly deserve systematic investigation.[8]

Despite our uncertainties with respect to the precise nature of the effect of cholesteric solvation on the energetics of *cis–trans* isomerization of **1**, the fact that an effect is observed at all indicates that cholesteric liquid crystals are indeed capable of inhibiting processes which involve a substantial change in molecular shape in the transition state, even for solutes which are not particularly well solvated in the liquid crystal. In the case of azobenzene, which is incorporated much more effectively in these media (32), it is probable that rotational *cis–trans* isomerization, if it occurred, could in fact be detected in cholesteric liquid crystalline solvents. We believe that the result that the energetics of isomerization of azobenzene are unaffected in cholesteric liquid crystals relative to their magnitude in isotropic solvents (9*b*) indicates that the bond inversion mechanism is indeed the operative mechanism for *cis–trans* isomerization of this molecule. However, it is difficult to predict what magnitude of an effect would obtain for bond rotation in this system, if it did occur. While azobenzene is solubilized more effectively than **1** in a liquid crystal (allowing potentially more disruption of solvent order in the course of bond rotation), the change in its shape as it approaches the rotational transition state is much less substantial.

Our observation that cholesteric liquid crystalline solvents are able to affect the dynamics of a solute's unimolecular reaction involving formation of a globular transition state from a relatively poorly solvated, disc-like ground state may illustrate the potential of these media towards controlling chemical reactivity in a useful manner. For example, it may be possible to use liquid crystals to exert stereochemical control on bimolecular reactions which normally yield some variety of products through transition states of grossly different shape, as a result of differences in liquid crystalline transition state solvation. Work in this area is currently in progress and will be reported in the near future.

[7] We thank one of the referees for pointing this out.

[8] While this paper was being reviewed, a report appeared describing substantial inhibition of bond rotation in 4-(dimethylamino)pyrimidine in a nematic solvent (see ref. 31).

Experimental

Melting points and transition temperatures were measured on a Reichert micro-hot stage microscope with polarizing lenses and are corrected. The [1]Hmr spectra were recorded in deuteriochloroform solution on a Varian EM390 nmr spectrometer. A Jumo-MS D.B.P. mercury thermoregulator, a Fisher Model 32 transistor relay, and an insulated silicon oil (Dow Corning 710) bath were used for temperature control in the kinetic studies. Temperatures were recorded with a Leeds & Northrup Model 8692 temperature potentiometer and a copper–constantan thermocouple, or a Cole–Parmer Model 8110-10 Type K thermocouple thermometer, and did not vary by more than 0.4°C during any particular run. Temperatures are considered accurate to ±1.0°C.

Analyses of mixtures of *cis*- and *trans*-**1** were performed using a Gilson isocratic hplc (high performance liquid chromatography) system, consisting of a Model 302 pump, Model 802B manometric module, Holochrome variable wavelength detector, a Rheodyne Model 7125 loop injection valve, and a Varian Model A-6 strip chart recorder, in conjunction with a 25 × 0.46 cm Merck Hibar Si60 (10 μ) analytical column. Dichloromethane was used as eluant, with a flow rate of 1.0 mL/min, and an analytical wavelength of 300 nm was used for all analyses. Preparative lc (liquid chromatography) was performed using the same system, in conjunction with 24 × 1.1 cm or 31 × 2.5 cm Merck Lobar Si60 (40–63 μ) glass columns. The detector was interfaced to a Unitron microcomputer via an Adalab data acquisition/control card (Interactive Microware, Inc.), after amplification of the 10-mV signal with an Adaamp analog amplifier. Chromatogram acquisition, analysis, and storage were performed using the Chromatochart (Interactive Microware, Inc.) software. Apparent mole fractions of the *trans* isomer so obtained were then converted to true mole fractions with a working curve, constructed with eleven standard solutions of accurately weighed mixtures of pure *cis*- and *trans*-**1**.

n-Decanol was used as received from BDH Chemicals, Ltd. Cholesterol (BDH) was recrystallized once from 95% ethanol. 3β-Cholestanol (Aldrich) was recrystallized once from 95% ethanol. Cholesteryl benzoate (Aldrich) was recrystallized twice from n-pentanol (33), and finally from ligroin/ethanol. A more highly purified sample was prepared by column chromatography (silica gel; hexanes) followed by one further recrystallization from ligroin/ethanol. Dichloromethane was Caledon HPLC grade and used as received. Hexanes (Caledon reagent grade) was distilled before use.

4-Anisoyl chloride, 4-toluoyl chloride, 4-chlorobenzoyl chloride, and 6-methoxy-2-naphthoyl chloride were prepared by refluxing the corresponding carboxylic acid in thionyl chloride for 2–8 h, followed by removal of excess thionyl chloride by vacuum distillation. The acid chlorides were used without further purification. 6-Methoxy-2-naphthoic acid was synthesized according to published procedures (34), and was recrystallized thrice from 95% ethanol (mp 197–198°C (lit. (34) mp 202°C)).

n-Decyl anisoate (DA) was prepared by refluxing n-decanol (16 g, 0.1 mol) and 4-anisoyl chloride (17 g, 0.1 mol) in freshly distilled *N,N*-dimethylaniline (60 mL) for 3 h (27). After cooling, the reaction mixture was poured onto crushed ice, and extracted with ether (5 × 50 mL). The combined ether extracts were washed with 5% aqueous hydrochloric acid (7 × 30 mL), 10% aqueous sodium hydroxide (5 × 30 mL), and water (5 × 30 mL). Drying over anhydrous magnesium sulfate, followed by evaporation of solvent, afforded a brown oil which was chromatographed on silica gel, using hexanes as the eluant, to yield a yellow oil which subsequently crystallized. Two recrystallizations from methanol afforded colourless crystals (7.5 g, 0.026 mol, 26%) of n-decyl anisoate (mp 28–29°C; bp 155–156°C (0.01 Torr; 1 Torr = 133.3 Pa)), assigned on the basis of its [1]Hmr and infrared spectra.

Cholesteryl 6-methoxy-2-naphthoate (CMN) was prepared in similar fashion, and was obtained in 21% yield after four recrystallizations from chloroform/ethanol (1:1). The product was further purified by preparative lc, using hexanes as the eluant, followed by one further recrystallization from chloroform/ethanol, yielding colourless crystals. Transition temperatures are listed in Table 1 (lit. (27): K → Ch, 183°C; Ch → I, 302.5°C). Better yields (>80%) were obtained using pyridine as solvent in the preparation, according to the procedure outlined below for CCB and CT.

Cholesteryl 4-chlorobenzoate (CCB) and cholestanyl 4-toluate (CT) were prepared by heating mixtures of cholesterol and 3β-cholestanol, respectively, with the appropriate acid chloride in pyridine for 12 h at 50–60°C. The reaction mixtures were quenched with water, extracted with dichloromethane, and the organic extracts were washed successively with 5% aqueous HCl, 10% aqueous sodium hydroxide, and water (five times each). The solutions were dried over anhydrous magnesium sulfate and the solvent was evaporated. The resulting solids were then chromatographed on silica gel using hexanes as eluant. CCB was further purified by recrystallization from ethanol, n-pentanol, and again from ethanol to yield colourless crystals (22%), the transition temperatures for which are listed in Table 1 (lit. (26): K → Ch, 165°C; Ch → I, 240°C). CT was further purified by recrystallization from n-pentanol, preparative lc (hexanes as eluant), and final recrystallization from chloroform/ethanol (1:2), to yield colourless crystals (18%). The transition temperatures are listed in Table 1 (lit. (25): K → Ch, 172°C; Ch → I, 225°C).

The stability of these materials towards thermolysis at the temperatures employed in the kinetic studies was examined by heating a sample of DA in a sealed tube at 230°C for 35 h. The [1]Hmr spectrum of the contents of the tube had not changed perceptibly from that recorded before this treatment.

The *cis*- and *trans*-**1** were prepared according to the published procedure (18). The crude yellow solid obtained from the preparation was chromatographed on a silica gel column, eluting with hexane/benzene (1:9). The mixture of olefins obtained as the first fraction from this column was then separated by semi-preparative lc, using dichloromethane as eluant. The first component collected was recrystallized from chloroform/ethanol, affording *trans*-**1** as slightly yellow needles (mp 204–206°C (lit. (18) mp 203–204°C)). The second component collected was recrystallized as well from chloroform/ethanol to yield slightly yellow needles of *cis*-**1** (mp 247–249°C (lit. (18) mp 247–249°C)). The hplc analyses of the two indicated them to be >99% isomerically pure in each case.

Solutions of *cis*- and *trans*-**1** for the kinetic measurements were prepared by adding an appropriate aliquot of a 0.1 *M* solution of the olefin in benzene to 0.6-g portions of each of the esters, dissolving the mixtures in dichloromethane, evaporating the solvent on the rotary evaporator, and finally pumping on the mixtures under high vacuum for 3 h to remove final traces of volatile solvents. Portions (5–7 mg) were placed in 7-mm Pyrex tubes (soaked in 10% sodium hydroxide (2 h), rinsed four times with distilled water, and finally oven-dried), the tubes were evacuated on a vacuum line to ca. 10^{-5} Torr, cooled in liquid nitrogen, and sealed.

Eight or nine tubes containing the *trans*-isomer, and one containing the *cis*, were then placed simultaneously in the preset insulated kinetic bath. In runs carried out above 210°C, the tubes were prewarmed briefly (ca. 1 min) in another oil bath set at 150°C before placing them in the kinetic bath, in order to prevent drastic temperature fluctuation. The temperature of the kinetic bath did not vary by more than 1° during the addition of the sample tubes, and recovered to its original value within 1.5 min. Samples were removed after suitable time intervals, quenched in an ice-bath, opened, and the contents were dissolved in benzene or dichloromethane and analysed by hplc. In all cases, the esteric solvents eluted well before the isomeric olefins, and their presence in such large quantities was shown to have no effect on the relative peak areas of *cis*- and *trans*-**1** by injection of standard mixtures. In no case did the hplc traces of the heated mixtures change during the course of a run, other than in the relative amounts of the isomeric olefins. Several of the unheated sealed tubes were used to check the initial composition of the samples to ensure that no accidental heating had occurred during the sealing process. The *cis* sample and one of the *trans* samples were heated for extended periods of time to evaluate the equilibrium composition in each solvent at each temperature examined. The equilibrium constants recorded in Table 2 are the average of all determinations at a given temperature.

Rate constants ($k_{c \to t} + k_{t \to c}$) were determined by weighted linear least-squares analyses of the mole fraction vs. time data according to eq. [1], and are collected in Table 2. Arrhenius parameters were determined by linear least-squares analyses of the rate data according to the Arrhenius equation, and are collected in Table 4.

Synthetic study on *N*-hydroxyaspartic acid

T. KOLASA[1]

Department of Organic Chemistry, Technical University of Gdansk, 80-952 Gdansk, Poland

Received August 10, 1984

T. KOLASA. Can. J. Chem. **63**, 2139 (1985).

The synthesis of *N*-acyl derivatives of *N*-hydroxyaspartic acid was achieved by use of *N*-benzyloxyaspartic acid esters as starting material. The preparation of *N*-benzyloxyaspartic acid is described.

T. KOLASA. Can. J. Chem. **63**, 2139 (1985).

Utilisant des esters de l'acide *N*-benzoyloxyaspartique comme produit de départ, on a réussi la synthèse de dérivés *N*-acylés de l'acide *N*-hydroxyaspartique. On décrit la préparation de l'acide *N*-benzyloxyaspartique.

[Traduit par le journal]

Introduction

The naturally occurring hydroxamic acids are *N*-acyl derivatives of *N*-hydroxyamino acids. Although free *N*-hydroxyamino acids have not been found in living cells, these compounds have been isolated from the parent hydroxamic acids after hydrolysis.

In this manner, the most frequently isolated *N*-hydroxyamino acids are ω-*N*-hydroxyamino acids, such as ε-*N*-hydroxylysine and δ-*N*-hydroxyornithine (1). The α-*N*-hydroxyamino acids appear very rarely, and until now the presence of only a few α-*N*-hydroxyamino acids in nature has been confirmed. These include *N*-hydroxyglycine in hadacidin (2), α-*N*-hydroxytyrosine and α-*N*-hydroxyalanine in mycelianamide (3), α-*N*-hydroxyisoleucine in aspergillic acid (4), α-*N*-hydroxyleucine in pulcherrimin (5), and *N*-hydroxyaspartic acid in peptide hydroxamates isolated from cultures of *Corynebacterium kutscheri* (6) and *Mycobacterium avium* (7).

Several experimental approaches to the synthesis of α-*N*-hydroxyamino acids have been developed (8–11). While most α-*N*-hydroxyamino acids, including many naturally occurring derivatives have been prepared, *N*-hydroxyaspartic acid has not been synthesized previously.

Emery (12) showed that enzyme extracts from *Bacillus cadaveris* or *Proteus vulgaris* synthesize *N*-hydroxyaspartic acid from fumaric acid and hydroxylamine. Unfortunately, in spite of unquestionable confirmation of the appearance of that amino acid, an extensive effort to isolate and purify it was unsuccessful. Similarly, attempted chemical syntheses of *N*-hydroxyaspartic acid by the reaction of bromosuccinic acid with hydroxylamine and the reaction of hydroxylamine with fumaric acid were unsuccessful. Furthermore, efforts to synthesize *N*-hydroxyaspartic acid acyl derivatives have not been successful. In addition, the attempted isolation of *N*-hydroxyaspartic acid through acidic hydrolysis of the naturally occurring dipeptide, L-α-asparaginyl-L-α-(*N*-hydroxy)asparagine, was also unsuccessful (7).

The problems described above, plus the unique structure of the peptide hydroxamates isolated by McCullough and Merkal (6, 7) prompted our synthetic studies.

Results and discussion

This work describes the synthesis of *N*-hydroxyaspartic acid derivatives through an application of the benzyl group for protection of the hydroxylamine moiety.

The synthesis of α-*N*-benzyloxyamino acids (10) and their application to the synthesis of *N*-acyl-α-*N*-hydroxyamino acids (13) and α-*N*-hydroxypeptides (14) has been described earlier. Thus, treatment of bromosuccinic acid with *O*-benzylhydroxylamine was anticipated to provide *N*-benzyloxyaspartic acid. Unfortunately, instead of the desired material, two other products were isolated. First, compound A, mp 160–161°C, precipitated from aqueous solution at pH 4, while the second compound B, mp 110–112°C, separated at pH 3. Compound A was the main product of the reaction.

The nmr spectra of both compounds were identical and the elementary analyses indicated the same formulas. A comparison of the ir spectra of both products indicated that compound A is characterized by two carbonyl absorption bands at 1710 and 1670 cm^{-1}, while compound B has only one carbonyl absorption band at 1715 cm^{-1}. Furthermore, the hydrogenolysis of compound A gave a hydroxamic acid (positive $FeCl_3$ test), while a product of the hydrogenolysis of compound B appeared to have an *N*-hydroxyamine group (positive $AgNO_3$ test).

Structural assignment of the compounds based on elemental analysis, ir and ^{1}H nmr spectroscopy, as well as chemical properties, showed that compound A is a β-*N*-benzyloxyamide of malic acid and compound B is *N*-benzyloxyaspartic acid. Hence the reaction of bromosuccinic acid with *O*-benzylhydroxylamine can be represented by Scheme 1.

The literature (15, 16) describes many examples of formation of the β-hydroxyacid amides during the reaction of β-bromoacids with ammonia and suggests that they are formed from intermediate β-lactones. Recently, the β-lactones of malic acid were used in the process of synthesis of the β-lactam ring (17, 18). It has also been shown that the β-lactone of *N*-protected threonine reacts very smoothly with *O*-benzylhydroxylamine to provide the *N*-benzyloxyamide (19).

These results suggested that protection of the carbonyl groups was necessary. Indeed, the reaction of bromosuccinic acid esters with *O*-benzylhydroxylamine gave the desired products, *N*-benzyloxyaspartic acid esters, with good yields. Thus, the dimethyl, diethyl, and di-*tert*-butyl esters of *N*-benzyloxyaspartic acid were obtained from bromosuccinic acid as well as *O*-tosyl malic acid diesters. In addition, the free *N*-benzyloxyaspartic acid is a stable compound and can be easily prepared from the di-*tert*-butyl esters. The *N*-hydroxyaspartic acid, obtained from *N*-benzyloxyaspartic acid by hydrogenolysis, is very unstable. Efforts to isolate and purify it were unsuccessful, as were the attempts of Emery (12). Unlike the unstable free *N*-hydroxyaspartic acid, the di-*tert*-butyl ester is

[1]Present address: Department of Chemistry, University of Notre Dame, Notre Dame, Indiana 46556, U.S.A.

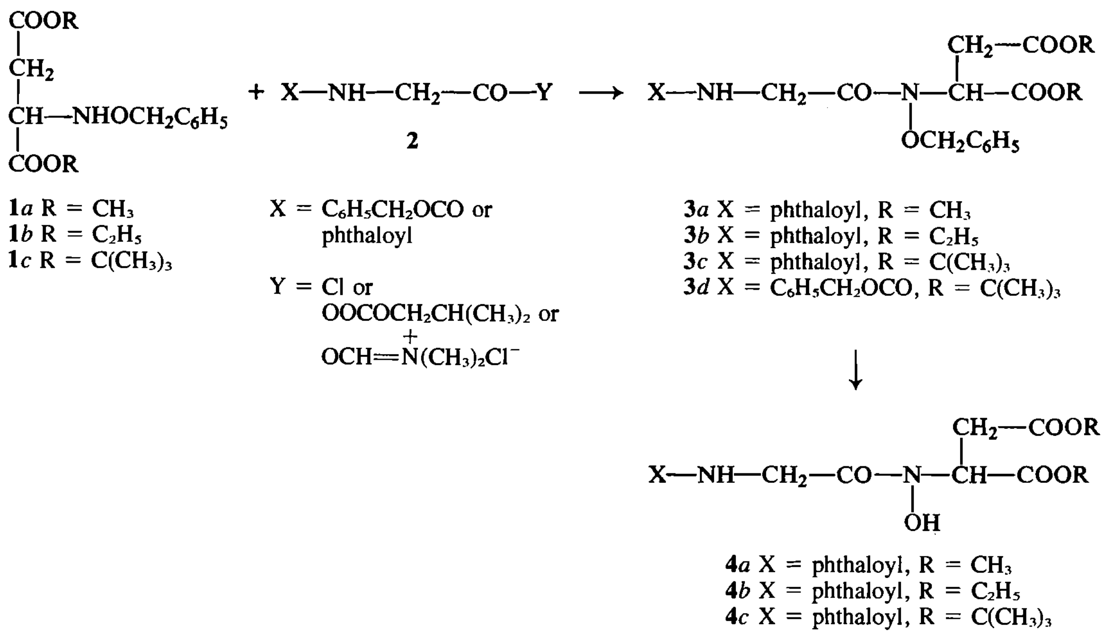
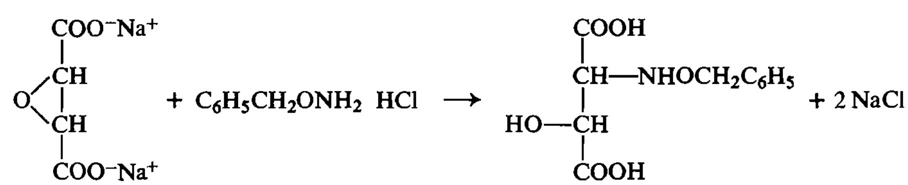


SCHEME 2



SCHEME 3

stable and can be stored at room temperature.

According to Emery (12), the synthesis of *N*-hydroxyaspartic acid *N*-acyl derivatives through acylation of free *N*-hydroxyaspartic acid did not give the desired products. Therefore, direct use of *N*-benzyloxyaspartic acid diesters as the starting materials seemed to be more attractive. Based on the above considerations, the *N*-formyl and *N*-acetyl-*N*-hydroxyaspartic acid diesters were synthesized earlier (13). Described here are the syntheses of the *N*-hydroxypeptides (Scheme 2).

As has been shown earlier (14), the preparation of *N*-benzyloxypeptides with *N*-terminal glycine proceeds with good yields, but with other *N*-terminal amino acids the yields are very low. Therefore, a new method was utilized for the synthesis of *N*-benzyloxyamides (20). Use of iminochlorides as activating agents of the carboxyl groups afforded the *N*-benzyloxypeptides in good yields. The *N*-benzyloxypeptides can be readily converted to the corresponding *N*-hydroxypeptides by hydrogenation.

Additionally, *threo*-β-hydroxy-*N*-benzyloxyaspartic acid has been synthesized by the reaction of *cis*-epoxysuccinic acid with *O*-benzylhydroxylamine (Scheme 3). Initially, the direct preparation of β-hydroxy-*N*-hydroxyaspartic acid was attempted by reaction of hydroxylamine hydrochloride with the disodium salt of *cis*-epoxysuccinic acid. Unfortunately, although many products were found, none was the desired one, probably because of decomposition. Also, the attempted isolation of the product of hydrogenolysis of β-hydroxy-*N*-benzyloxyaspartic acid was unsuccessful.

Experimental

All melting points are uncorrected. The nmr spectra were obtained with a Tesla BS 487 spectrometer 80 MHz. The L- and D-bromosuccinic acids were prepared from the corresponding aspartic acids according to the procedure of Testa *et al.* (21).

β-N-Benzyloxyamide of malic acid

To a solution of bromosuccinic acid (19.7 g, 0.1 mol) in ethanol (100 mL) was added *O*-benzylhydroxylamine (61.5 g, 0.5 mol). The reaction mixture was kept at room temperature for 10 days and then concentrated *in vacuo*. The residue was dissolved in ethyl ether and washed several times with 10% $NaHCO_3$. The water solution was acidified with 2 *N* HCl to pH 4, to precipitate 19.1 g of compound A (80%), mp 160–161°C (EtOH); ^{1}H nmr (in DMSO-d_6) δ: 2.5 (2H, d, J = 7 Hz, —CH_2—), 4.2 (1H, m, —CHO—), 4.82 (2H, s, —CH_2O—), 7.38 (5H, s, aromatic). *Anal.* calcd. for $C_{11}H_{13}NO_5$: C 55.23, H 5.44; N 5.86%; found: C 55.57, H 5.09, N 6.07%. Further acidification to pH 3 gave a compound B (1.2 g, 5%), mp 110–112°C; ^{1}H nmr (in DMSO-d_6) δ: 2.66 (2H, dd, J = 7 Hz, 3 Hz, —CH_2—), 4.0 (1H, t, J = 7 Hz, —CHN—), 4.72 (2H, s, —CH_2O—), 7.38 (5H, s, aromatic). *Anal.* calcd. for $C_{11}H_{13}NO_5$: C 55.23, H 5.44, N 5.86%; found: C 54.89, H 5.24, N 5.66%.

*N-Benzyloxyaspartic acid esters **1**a, **1**b, and **1**c*

To a solution of bromosuccinic acid (or *O*-tosyl malic acid) esters (0.1 mol) in 100 mL of ethanol was added *O*-benzylhydroxylamine (0.3 mol). The reaction was kept at room temperature for 10 days. Then the solution was concentrated *in vacuo*, dissolved in ethyl ether, and washed with 2 *N* HCl (or 5% citric acid in the case of *tert*-butyl esters) and water. The organic layer was dried ($MgSO_4$) and concentrated *in vacuo*. The oily residue was treated with an ethereal solution of HCl (in the case of *tert*-butyl esters, silica gel column chromatography with benzene as eluent was used); after cooling, the hydrochlorides were filtered off and crystallized from EtOH–Et_2O. The yields and properties are given below.

N-Benzyloxy-D-aspartic acid dimethyl ester was prepared from L-bromosuccinic acid dimethyl ester in 87% yield, $[\alpha]_D^{20}$ +2.0 (*c* 7, CH_3OH); mp (hydrochloride) 115–116°C; ^{1}H nmr (in DMSO-d_6) δ: 3.1 (2H, d, J = 7 Hz, —CH_2—), 3.72 (3H, s, —OCH_3), 3.85 (3H, s, —OCH_3), 4.58 (1H, t, J = 7 Hz, —CHN—), 5.12 (2H, s, —CH_2O—), 7.5 (5H, s, aromatic), 10.05 (2H, broad s, NH_2^+). *Anal.* calcd. for $C_{13}H_{18}NO_5Cl$: C 51.40, H 5.92, N 4.61%; found: C 51.12, H 6.07, N 4.89%.

This compound has also been synthesized from *O*-tosyl-L-malic acid dimethyl ester in 80% yield, $[\alpha]_D^{20}$ +2.3 (*c* 7, CH_3OH); mp (hydrochloride) 113–115°C. *Anal.* calcd. for $C_{13}H_{18}NO_5Cl$: N 4.61; found: N 4.65%.

N-Benzyloxy-L-aspartic acid dimethyl ester was synthesized from D-bromosuccinic acid dimethyl ester in 93% yield, $[\alpha]_D^{25}$ = −2.7 (*c* 7, CH_3OH); mp (hydrochloride) 116–117°C; ^{1}H nmr (in DMSO-d_6) δ: 3.05 (2H, d, J = 7 Hz, —CH_2—), 3.7 (3H, s, —OCH_3), 3.8 (3H, s, —OCH_3), 4.5 (1H, t, J = 7 Hz, —CHN—), 5.03 (2H, s, —CH_2O—), 7.43 (5H, s, aromatic), 11.23 (2H, broad s, NH_2^+). *Anal.* calcd. for $C_{13}H_{18}NO_5Cl$: N 4.61%; found: N 4.72%.

N-Benzyloxy-DL-aspartic acid dimethyl ester was prepared from *O*-tosyl-DL-malic acid dimethyl ester in 82% yield, mp (hydrochloride) 108–110°C; ^{1}H nmr (in TFA) δ: 3.1 (2H, m, —CH_2—), 3.42 (3H, s, —OCH_3), 3.6 (3H, s, —OCH_3), 4.8 (1H, m, —CHN—), 5.2 (2H, s, —CH_2O—), 7.3 (5H, s, aromatic). *Anal.* calcd. for $C_{13}H_{18}NO_5Cl$: N 4.61%; found: N 4.44%.

N-Benzyloxy-DL-aspartic acid diethyl ester was synthesized from *O*-tosyl-DL-malic acid diethyl ester in 78% yield, mp (hydrochloride) 98–100°C; ^{1}H nmr (in DMSO-d_6) δ: 1.3 (6H, q, J = 7 Hz, 2 × —CH_3), 3.08 (2H, d, J = 7 Hz, —CH_2—), 4.24 (4H, dt, J = 7 Hz, 2 × —OCH_2—), 4.53 (1H, m, —CHN—), 5.13 (2H, s, benzylic), 7.5 (5H, s, aromatic), 11.0 (2H, broad s, NH_2^+). *Anal.* calcd. for $C_{15}H_{22}NO_5Cl$: C 54.29, H 6.64, N 4.22%; found: C 53.98, H 6.39, N 4.46%.

This compound was also prepared from DL-bromosuccinic acid diethyl ester in 88% yield, mp (hydrochloride) 103–105°C; ^{1}H nmr (in $CDCl_3$) δ: 1.0 (6H, q, J = 7 Hz, 2 × —CH_3), 3.0 (2H, m, —CH_2—), 3.95 (4H, dt, J = 7 Hz, 2 × —OCH_2—), 4.52 (1H, m, —CHN—), 5.18 (2H, s, benzylic), 7.13 (5H, s, aromatic), 8.85 (2H, broad s, NH_2^+). *Anal.* calcd. for $C_{15}H_{22}NO_5Cl$: N 4.22%; found: N 4.48%.

*N-Benzyloxy-D-aspartic acid di-*tert*-butyl ester* was obtained from L-bromosuccinic acid di-*tert*-butyl ester in 74% yield, mp (hydrochloride) 73–75°C; $[\alpha]_D^{20}$ +6.0 (*c* 6, CH_2Cl_2); ^{1}H nmr (in $CDCl_3$) δ: 1.3 (9H, s, —$C(CH_3)_3$), 1.36 (9H, s, —$C(CH_3)_3$), 2.4 (2H, dd, J = 7 Hz, 4 Hz, —CH_2—), 3.75 (1H, q, J = 7 Hz, —CHN—), 5.05 (2H, s, —CH_2O—), 6.08 (1H, d, J = 7 Hz, —NH—) 7.17 (5H, s, aromatic). *Anal.* calcd. for $C_{19}H_{29}NO_5$: C 64.96, H 8.26, N 3.99%; found: C 64.68, H 8.40, N 4.20%.

*N-Benzyloxy-L-aspartic acid di-*tert*-butyl ester* was synthesized from D-bromosuccinic acid di-*tert*-butyl ester in 72% yield, mp (hydrochloride) 78–80°C; $[\alpha]_D^{20}$ −5.6 (*c* 6, CH_2Cl_2); ^{1}H nmr (in $CDCl_3$) δ: 1.3 (18H, s, 2 × —$C(CH_3)_3$), 2.4 (2H, dd, J = 7 Hz, 4 Hz, —CH_2—), 3.72 (1H, q, J = 7 Hz, —CHN—), 5.0 (2H, s, —CH_2O—), 6.05 (1H, d, J = 7 Hz, —NH—), 7.25 (5H, s, aromatic). *Anal.* calcd. for $C_{19}H_{29}NO_5$: N 3.99%; found: N 4.07%.

*N-Benzyloxy-DL-aspartic acid di-*tert*-butyl ester* was prepared from DL-bromosuccinic acid in 63% yield, mp (hydrochloride) 69–71°C; ^{1}H nmr (in $CDCl_3$) δ: 1.42 (18H, s, 2 × —$C(CH_3)_3$), 2.66 (2H, dd, J = 7 Hz, 3 Hz, —CH_2—), 4.0 (1H, t, J = 7 Hz, —CHN—), 5.34 (2H, s, —CH_2O—), 7.0 (1H, broad s, —NH—), 7.65 (5H, s, aromatic). *Anal.* calcd. for $C_{19}H_{29}NO_5$: N 3.99%; found: N 4.39%.

N-Benzyloxy-D-aspartic acid

To *N*-benzyloxy-D-aspartic acid di-*tert*-butyl ester (3.51 g, 10 mmol) was added 4 mL of trifluoroacetic acid and after 30 min the reaction mixture was concentrated *in vacuo*. To the residue, 10 mL of water was added and the solution was cooled in an ice bath. The solution was then filtered, and washed with cold water to give the product (2.1 g, 90%), mp 120–121°C (EtOH–H_2O); $[\alpha]_D^{25}$ +6.3 (*c* 6, MeOH); ^{1}H nmr (in DMSO-d_6) δ: 2.68 (2H, dd, J = 7 Hz, 4 Hz, —CH_2—), 3.97 (1H, t, J = 7 Hz, —CHN—), 4.7 (2H, s, —CH_2O—), 7.4 (5H, s, aromatic). *Anal.* calcd. for $C_{11}H_{13}NO_5$: N 5.86%; found: N 5.82%.

*N-Hydroxy-DL-aspartic acid di-*tert*-butyl ester*

To a solution of *N*-benzyloxy-DL-aspartic acid di-*tert*-butyl ester (1.76 g, 5 mmol) in ethanol (10 mL) was added 10% Pd/C (50 mg) and hydrogen was passed through the solution for 1 h. Then the filtered solution was evaporated to dryness, redissolved in chloroform, and purified on a silica gel column, using $CHCl_3$–MeOH (9:1) as eluent to give an oily product (2.07 g, 83%); ^{1}H nmr (in $CDCl_3$) δ: 1.3 (9H, s, —$C(CH_3)_3$), 1.33 (9H, s, —$C(CH_3)_3$), 2.58 (2H, d, J = 7 Hz, —CH_2—), 3.75 (1H, t, J = 7 Hz, —CHN—). *Anal.* calcd. for $C_{12}H_{23}NO_5$: N 5.37%; found: N 5.62%.

N-Carbobenzoxy-N-benzyloxy-DL-aspartic acid

To a solution of *N*-benzyloxy-DL-aspartic acid di-*tert*-butyl ester (3.51 g, 10 mmol) in CH_2Cl_2 (20 mL) was added solid $NaHCO_3$ (1.26 g, 15 mmol) and 11 mmol of carbobenzoxy chloride. The reaction mixture was stirred at room temperature overnight, and then was washed with water, dried ($MgSO_4$), and concentrated *in vacuo*. Then 3 mL of trifluoroacetic acid was added and after 30 min the solvent was evaporated to dryness. The residue was dissolved in ethyl ether and washed with 10% $NaHCO_3$. The water solution was acidified to pH 4 and the precipitated product filtered off to provide a white powder (2 g, 54%), mp 123–125°C (EtOAc – petroleum ether 30–60°C); ^{1}H nmr (in DMSO-d_6) δ: 3.0 (2H, dd, J = 7 Hz, 4 Hz, —CH_2—), 4.82 (1H, t, J = 7 Hz, —CHN—), 4.97 (2H, s, —CH_2O—), 5.3 (2H, s, —CH_2O—), 7.35 (5H, s, aromatic), 7.44 (5H, s, aromatic). *Anal.* calcd. for $C_{19}H_{19}NO_7$: N 3.75%; found: N 3.99%.

threo-β-Hydroxy-N-benzyloxy-DL-aspartic acid was obtained in 60% yield, according to the known procedure for preparation of β-hydroxyaspartic acid (22, 23), mp 150–152°C; ^{1}H nmr (in TFA) δ: 5.3 (2H, s, —CH—CH—), 5.4 (2H, s, —CH_2O—), 7.6 (5H, s, aromatic). *Anal.* calcd. for $C_{11}H_{13}NO_6$: N 5.49%; found: N 5.40%.

N-*Phthaloylglycyl*-N-*benzyloxyaspartic acid esters* **3**a, **3**b, **3**c were synthesized according to the standard procedures already used for the preparation of *N*-benzyloxypeptides (14).

N-*Phthaloylglycyl*-N-*benzyloxy*-D-*aspartic acid dimethyl ester* was prepared by the acid chloride method in 66% yield, mp 58–59°C (EtOAc – pet. ether 30–60°C), $[\alpha]_D^{20}$ −6.0 (*c* 6, $CHCl_3$); ^{1}H nmr (in $CDCl_3$) δ: 2.83 (2H, t, *J* = 7 Hz, —CH_2—), 3.45 (3H, s, —OCH_3), 3.53 (3H, s, —OCH_3), 4.38 (2H, s, —CH_2N—), 4.9 (2H, s, —CH_2O—), 5.05 (1H, t, *J* = 7 Hz, —CHN—), 7.1 (5H, s, aromatic), 7.5 (4H, m, aromatic). *Anal.* calcd. for $C_{23}H_{22}N_2O_8$: C 60.79, H 4.84, N 6.17%; found: C 61.02, H 4.98, N 6.50%.

N-*Phthaloylglycyl*-N-*benzyloxy*-DL-*aspartic acid diethyl ester* was synthesized as an oily compound in 85% yield by the acid chloride method and in 78% yield by the mixed anhydride method; ^{1}H nmr (in $CDCl_3$) δ: 1.05 (6H, dt, *J* = 7 Hz, 3 Hz, 2 × —CH_3), 2.87 (2H, t, *J* = 7 Hz, —CH_2—), 4.0 (4H, dq, *J* = 7 Hz, 3 Hz, 2 × —CH_2O—), 4.35 (2H, s, —CH_2N—), 4.9 (2H, s, benzylic), 5.0 (1H, t, *J* = 7 Hz, —CHN—), 7.2 (5H, s, aromatic), 7.5 (4H, s, aromatic). *Anal.* calcd. for $C_{25}H_{26}N_2O_8$: C 62.24, H 5.39, N 5.81%; found: C 62.03, H 5.13, N 5.84%.

N-*Phthaloylglycyl*-N-*benzyloxy*-DL-*aspartic acid di*-tert-*butyl ester* was obtained by the acid chloride method in 63% yield, mp 72–73°C (EtOAc – pet. ether 30–60°C); ^{1}H nmr (in $CDCl_3$) δ: 1.32 (18H, s, 2 × —$C(CH_3)_3$), 2.78 (2H, t, *J* = 7 Hz, —CH_2—), 4.38 (2H, s, —CH_2N—), 4.92 (3H, s + m, —CH_2O—, —CHN—), 7.3 (5H, s, aromatic), 7.58 (4H, m, aromatic). *Anal.* calcd. for $C_{29}H_{34}N_2O_8$: C 64.68, H 6.32, N 5.20%; found: C 64.33, H 6.58, N 5.40%.

N-*Phthaloylglycyl*-N-*benzyloxy*-D-*aspartic acid di*-tert-*butyl ester* was prepared by the acid chloride method in 65% yield, mp 69–70°C (EtOAc – pet. ether 30–60°C), $[\alpha]_D^{20}$ +11.0 (*c* 4, acetone); ^{1}H nmr (in $CDCl_3$) δ: 1.3 (18H, s, 2 × —$C(CH_3)_3$), 2.73 (1H, d, *J* = 7 Hz, 1/2 × —CH_2—), 2.9 (1H, d, *J* = 7 Hz, 1/2 × —CH_2—), 4.37 (2H, s, —CH_2N—), 4.97 (3H, s + m, —CH_2O—, —CHN—), 7.27 (5H, s, aromatic), 7.6 (4H, m, aromatic). *Anal.* calcd. for $C_{29}H_{34}N_2O_8$: N 5.20%; found: N 5.37%.

N-*Carbobenzoxyglycyl*-N-*benzyloxy*-DL-*aspartic acid di*-tert-*butyl ester* **1**d was synthesized by the mixed anhydride method as an oily compound in 76% yield; ^{1}H nmr (in $CDCl_3$) δ: 1.27 (18H, s, 2 × —$C(CH_3)_3$), 2.7 (1H, d, *J* = 7 Hz, 1/2 × —CH_2—), 2.85 (1H, d, *J* = 7 Hz, 1/2 × —CH_2—), 4.0 (2H, m, —CH_2N—), 4.8 (2H, s, —CH_2O—), 4.95 (2H, s, —CH_2O—), 5.2 (2H, m, —CHN—), 7.17 (5H, s, aromatic), 7.22 (5H, s, aromatic). *Anal.* calcd. for $C_{29}H_{38}N_2O_8$: C 64.20, H 7.01, N 5.16%; found: C 63.93, H 7.23, N 5.26%.

This compound was also prepared by the iminochloride method (20) in 82% yield. *Anal.* calcd. for $C_{29}H_{38}N_2O_8$: C 64.20, H 7.01, N 5.16%; found: C 64.01, H 7.12, N 5.13%.

N-*Phthaloylglycyl*-N-*hydroxyaspartic acid esters* **4**a, **4**b, **4**c were synthesized by hydrogenation of *N*-benzyloxypeptides according to an earlier described procedure (14).

N-*Phthaloylglycyl*-N-*hydroxy*-D-*aspartic acid dimethyl ester* was obtained in 97% yield, mp 172–173°C (EtOAc – pet. ether 30–60°C), $[\alpha]_D^{20}$ −9.0 (*c* 4, acetone–DMF 4:1); ^{1}H nmr (in $CDCl_3$ + a few drops of TFA) δ: 3.05 (2H, d, *J* = 7 Hz, —CH_2—), 3.6 (3H, s, —OCH_3), 3.67 (3H, s, —OCH_3), 4.75 (2H, s, —CH_2N—), 5.5 (1H, t, *J* = 7 Hz, —CHN—), 7.65 (4H, m, aromatic). *Anal.* calcd. for $C_{16}H_{16}N_2O_8$: N 7.69%; found: N 7.94%.

N-*Phthaloylglycyl*-N-*hydroxy*-DL-*aspartic acid diethyl ester* was prepared in 82% yield, mp 108–109°C (EtOAc – pet. ether 30–60°C); ^{1}H nmr (in $CDCl_3$) δ: 1.12 (6H, dt, *J* = 7 Hz, 3 Hz, 2 × —CH_3), 2.85 (2H, d, *J* = 7 Hz, —CH_2—), 4.05 (4H, dq, *J* = 7 Hz, 3 Hz, 2 × —CH_2O—), 4.65 (2H, s, —CH_2N—), 5.3 (1H, t, *J* = 7 Hz, —CHN—), 7.68 (4H, m, aromatic). *Anal.* calcd. for $C_{18}H_{20}N_2O_8$: N 7.18%; found: N 6.91%.

N-*Phthaloylglycyl*-N-*hydroxy*-DL-*aspartic acid di*-tert-*butyl ester* was isolated in 90% yield, mp 167–168°C (EtOAc – pet. ether 30–60°C); ^{1}H nmr (in DMSO-d_6) δ: 1.3 (18H, s, 2 × —$C(CH_3)_3$), 2.95 (2H, d, *J* = 7 Hz, —CH_2—), 4.8 (2H, s, —CH_2N—), 5.25 (1H, t, *J* = 7 Hz, —CHN—), 7.62 (4H, m, aromatic). *Anal.* calcd. for $C_{28}H_{28}N_2O_8$: N 6.25%; found: N 6.13%.

Glycyl-N-*hydroxy*-DL-*aspartic acid* was obtained from *N*-carbobenzoxyglycyl-*N*-benzyloxy-DL-aspartic acid di-*tert*-butyl ester as described earlier (14) (by removing *tert*-butyl groups with trifluoroacetic acid, followed by simultaneous hydrogenation of the carbobenzoxy and benzyl groups) in 72% yield; mp 164–167°C dec. (H_2O–EtOH); ^{1}H nmr (in D_2O) δ: 2.97 (2H, d, *J* = 7 Hz, —CH_2—), 4.1 (2H, s, —CH_2N—), 5.2 (1H, t, *J* = 7 Hz, —CHN—). *Anal.* calcd. for $C_6H_{10}N_2O_6$: N 13.59%; found: 13.33%.

N-*Formyl*-N-*hydroxy*-L-*alanyl*-N-*hydroxy*-L-*aspartic acid dimethyl ester*

To a solution of absolute DMF (9.2 mL, 0.12 mol) in dry CH_2Cl_2 (50 mL) was added dropwise at −10 to −5°C freshly distilled oxalyl chloride (4 mL, 0.048 mol). After 15 min, the *N*-formyl-*N*-benzyloxy-L-alanine (6.6 g, 30 mmol) was added. The reaction mixture was stirred for 30 min at −15 to −5°C and then *N*-benzyloxy-L-aspartic acid dimethyl ester hydrochloride (9.1 g, 30 mmol) in pyridine (22 mL, 0.25 mol) was added. After 2 h at −5 to 0°C and 2 h at room temperature water was added and the methylene chloride solution was separated. The organic layer was washed with water, dried ($MgSO_4$), and concentrated *in vacuo*. The oily residue was dissolved in MeOH, 10% Pd/C (100 mg) was added, and hydrogen was passed through the solution for 2 h. After filtration and removing methanol under reduced pressure, the product was purified on a silica gel column using $CHCl_3$–MeOH (8:1) as the eluent to yield an oily product (4.5 g, 52%); ^{1}H nmr (in $CDCl_3$) δ: 1.25 (3H, m, —CH_3), 2.84 (2H, d, *J* = 7 Hz, —CH_2—), 3.46 (6H, s, 2 × —OCH_3), 4.4 (1H, m, —CHN—), 4.9 (1H, t, *J* = 7 Hz, —CHN—), 7.93 (0.5H, s, 1/2 × H—C=O), 8.1 (0.5H, s, 1/2 × H—C=O). *Anal.* calcd. for $C_{10}H_{16}N_2O_8$: N 9.59; found: N 9.40%.

Low temperature ^{13}C nuclear magnetic resonance spectroscopy has been employed to obtain the chemical shifts and to examine the conformational equilibria of the four chlorohydrins and bromohydrins of 3-methoxycyclohexene. The corresponding acetates and the unsubstituted halohydrins have also been examined. The observed chemical shifts were compared with those calculated from additivity considerations. Limitations of this approach are discussed. Relative peak area measurements have been used to obtain conformational free energies in favourable cases.

G. W. BUCHANAN, J. W. BOVENKAMP, A. RODRIGUE, R. A. B. BANNARD et R. Y. MOIR. Can. J. Chem. **63**, 2143 (1985).

On a fait appel à résonance magnétique nucléaire du ^{13}C pour déterminer les déplacements chimiques et pour évaluer l'équilibre conformationnel de quatre chlorohydrines et bromohydrines du méthoxy-3 cyclohexène. On a aussi examiné les spectres des acétates correspondants ainsi que ceux des halohydrines qui ne sont pas substituées. On a comparé les déplacements chimiques observés avec ceux calculés à l'aide de considérations d'additivité. On discute des limitations de cette approche. Dans des cas favorables, on a utilisé des mesures d'intensités relatives des pics pour obtenir les énergies libres conformationnelles.

Introduction

The compounds shown in Fig. 1 have been the subject of several previous investigations (1, 2). The most recent work (1) involved a study of the kinetics of formation of the *cis*- and *trans*-3-methoxycyclohexane epoxides from the halohydrins **3**, **8**, **5**, and **10** and **2**, **7**, **4**, and **9**, respectively, as well as the kinetics of scission of these epoxides by hydrogen chloride. Earlier studies were concerned with elaboration of the regio- and stereochemistry of the latter reactions, by the separation and characterization of isomeric chlorohydrins **2**–**5** and isomeric bromohydrins **7**–**10**. Structural proofs for these compounds relied very heavily on the use of the splitting pattern of the methine protons in the proton magnetic resonance spectra of the corresponding acetates **12**–**15** and **17**–**20** (3–5).

In this paper, a low-temperature ^{13}C nmr study of the four *trans*-chlorohydrins (**2**–**5**) and the four *trans*-bromohydrins (**7**–**10**) derived from 3-methoxycyclohexene is described. Results for the unsubstituted halohydrins (**1** and **6**), as well as those for the corresponding acetates (**11**–**20**), are also reported. Predicted ^{13}C chemical shifts calculated from additivity considerations derived from monosubstituted cyclohexanes are compared with the observed chemical shifts. The equilibrium constants, from which the conformational free energy differences were calculated, were obtained from the relative peak area measurements of the resonances of individual conformers at 178 K.

Results and discussion

The structures and numbering schemes for the twenty compounds studied are depicted in Fig. 1. Tables 1–4 contain the ^{13}C nmr chemical shifts observed at room temperature as well as those for individual conformations A and B, obtained at 178 K. Parenthesized values denote ambiguous assignments, while A and B describe the less and more stable conformations, respectively. For the all *trans*-substituted compounds **2**, **7**, **12**, **17**, **5**, **10**, **15**, and **20**, only conformer B could be detected. We estimate our detection limit as 1%.

(a) *Resonance assignments*

A variety of techniques were used for ^{13}C signal assignments. Resonances for CH_3, CH_2, CH, and quaternary carbons were distinguished by single frequency off-resonance ^1H decoupling or APT (6) experiments. Distinction between CH carbons bonded to OMe, OH, and OAc was made via selective ^1H decoupling, since the methine proton resonances are well separated, and have characteristic chemical shifts (7). For compounds such as **1**, the assignment of room temperature methylene carbon resonances was made unambiguously via two-dimensional, double quantum coherence spectra, i.e. 2D-INADEQUATE experiments (8).

In order to aid assignments of pairs of resonances due to conformational isomers, detailed studies of the spectra near the coalescence temperatures (typically 200–233 K) were carried out. Extensive use was made of the fact that the larger the chemical shift difference between an exchanging pair of resonances, the higher will be the observed coalescence temperature.

(b) *Chemical shifts*

A model compound approach can be successfully used to predict the resonance positions for *unsubstituted* ring carbons

to within $\pm$1.0 ppm, on the average, of those observed for both major and minor conformations. Available ^{13}C data (9–11) for individual conformers of monosubstituted cyclohexanes (Table 5) were employed along with additivity considerations to give the calculated ring carbon chemical shifts shown in Table 6. If one regards substitution of a group X as depicted below, one

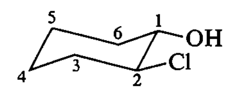
can then employ the known substituent induced shifts for α_{ax}, α_{eq}, β_{ax}, β_{eq}, γ_{ax}, γ_{eq}, δ_{ax}, and δ_{eq} sites, for X = Cl, Br, OAc, OH, and OMe (9–11).

The additivity approach is illustrated below for the C-3 and C-4 sites of the major conformation of **1**, starting with a shift



1B

of 27.7 ppm for cyclohexane itself. Thus, for C-3, one predicts $\delta_C = 27.7 + \beta_{eq}(Cl) + \gamma_{eq}(OH)$; i.e. $\delta_C = 27.7 + 10.5 - 2.7 = 35.5$. The observed shift is 35.75, in excellent agreement with that predicted. Similarly for C-4 one predicts $\delta_C = 27.7 + \gamma_{eq}(Cl) + \delta_{eq}(OH) = 27.7 - 0.6 - 2.0 = 25.1$, in good agreement with the observed chemical shift of 25.81 ppm.

For substituted ring carbons, one cannot reliably employ such a pairwise additivity approach. Table 7 illustrates the differences between calculated and observed ^{13}C shieldings for a typical series **4**, **9**, **14**, and **19**, depicted in Fig. 1. Clearly the agreement between calculated and observed shifts for a particular carbon depends on the stereochemistry. This is most dramatically apparent at C-2, the halogenated carbon.

The additivity approach fails to take into account the γ–*gauche* interactions between the vicinal substituents, which are expected to lead to observed shifts which are upfield from those predicted (i.e. positive differences in Table 7). There is ample literature precedent for this observation (12, 13). Also, the additivity approach assumes that the addition of a polar group to cyclohexane would cause the same chemical shift effect as the addition of a polar group to a cyclohexane ring in which the ring carbons are subjected to the inductive effect of existing substituents. Note that although the values in Table 7 are generally positive, some negative values are also present.

Recently, Schneider *et al.* (14) have studied a series of vicinally substituted dihalocyclohexanes. In agreement with our findings, they observe differences of up to ca. 9 ppm between the observed ^{13}C shifts, and those calculated from pairwise additivity for the halogenated carbons. They interpret

their results in terms of a linear electric field theory (15) for ^{13}C shieldings, in which enhanced electron flow to the carbon bearing the substituent of highest polarizability is predicted. The calculations of Schneider *et al.* (14), however, lead to the conclusion that carbons bearing the substituents of highest polarizability are in fact *deshielded*, rather than shielded, as one might expect on the basis of intuitive electron density arguments.

Applying such an approach to our compounds, one would then suggest that the halogenated carbons should show the lowest positive values in Table 7, since halogens are more polarizable than oxygen. In the conformers "B" of Table 7, this is indeed true, i.e. C-2 shows the lowest +'ve difference.

In the "A" conformers of Table 7, however, just the opposite result is found, with the halogenated carbon showing the largest positive deviation between calculated and observed ^{13}C shifts.

It is evident that several factors must be contributing to the observed ^{13}C shifts in these 1,2,3-trisubstituted cyclohexanes. It would be valuable to examine 1,3-disubstituted cyclohexanes in the future, to delineate the role of 1,3 interactions to the observed shifts.

In addition to ring carbon chemical shift differences between conformational isomers, the methoxyl carbon resonances show consistent stereochemical dependence. For the series of materials **3**, **8**, **13**, and **18** the "A" isomers (below) all have equatorial

4,9,14,19A **B**

It is interesting to note that for methoxycyclohexane itself (9) the axial and equatorial OCH_3 groups were found to have identical chemical shifts (δ_C = 55.05) at 180 K in CF_2Cl_2 solvent.

Separate carbonyl carbon resonances for *O*-acetyl groups for both conformations were observed for compounds **11**, **13**, **14**, **18**, and **19**. For compounds bearing methoxyl groups, the carbonyl carbon of the axial OAc is shielded relative to its equatorial counterpart. In **11**, however, the carbonyl carbon of the equatorial OAc group is more shielded, by 1.13 ppm. For acetoxycyclohexane itself at 180 K, no chemical shift difference between conformers was detected (9).

In the case of the CH_3 groups of the OAc moieties, we were unable to detect separate resonances for axial and equatorial substituents, in accord with previous observations for acetoxycyclohexane (9).

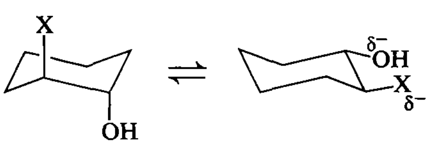
(c) *Conformational free energies*

The equilibrium constants collected in Table 8 were calculated from relative peak area measurements of resonances for individual conformers. Values for $-\Delta G^0$, the conformational free energy difference, were subsequently calculated using the equation $-\Delta G^0 = RT \ln K$. Error limits in $-\Delta G^0$ were obtained from the standard deviations in the equilibrium constants derived from individual resonances.

Initially, in discussing the $-\Delta G^0$ data, it is important to note that relatively concentrated solutions (0.8 *M* in CD_2Cl_2) are necessary for this work. As a result, materials in which there can be intermolecular association (such as alcohols) will tend to show a larger preference for the equatorial OH conformation (especially for alcohols without significant γ−*gauche* interactions) than would be the case at lower solute concentrations. This is due to the higher spatial accessibility of an equatorial OH relative to its axial counterpart for intermolecular hydrogen bonding.

The low temperature ^{13}C results for cyclohexanol itself illustrate this point. To date, we have not been able to detect ^{13}C resonances for the axial conformer (under the conditions used for the other compounds in this study), presumably due to the above-mentioned dimerization effects which stabilize the equatorial conformation. Since our limit of detection is ca. 1%, we estimate K for cyclohexanol itself to exceed 99 under the present experimental conditions. Schneider and Hoppen (9) also were not able to detect the axial conformer in CF_2Cl_2, although Subbotin and Sergeyev (11) succeeded in detecting it in CS_2 solution.

It is interesting for both *trans* halohydrins **1** and **6**, that the minor diaxial conformers *can* be detected by ^{13}C nmr at low temperature. The increased preference for the "A" conformations, bearing two axial substituents, may be due to destabilization of the "B" conformers resulting from dipole−dipole repulsion between the neighbouring polar groups. Such



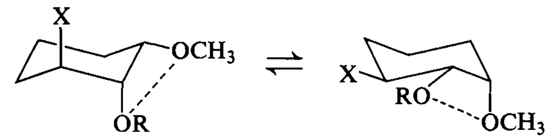
1, 6, A **B**

dipolar effects are well known in *trans*-1,2-dibromocyclohexane and lead to a preference for the diaxial form in CCl_4 and benzene solution (16). Also, the spatial accessibility of the equatorial OH and thus its capability to take part in intermolecular hydrogen bonding is probably reduced by the γ−*gauche* interaction with the chlorine substituent.

For the corresponding acetates **11** and **16**, the equilibria are further biased towards the diaxial conformer (reductions of 0.43 kcal/mol in $-\Delta G^0$ for both comparisons). Since the conformational free energies of OH and OAc are expected to be close (17), the main reason for this is presumed to be that intermolecular hydrogen bonding stabilizes the diequatorial conformers of the alcohols but not those of the acetates.

For the second series of molecules depicted in Fig. 1, i.e. **2**, **7**, **12**, and **17**, no spectra of the minor conformations were obtainable.

Introduction of a methoxyl group *cis* to the OR function,



3, 8, 13, 18 A **B**

as in the series **3**, **8**, **13**, and **18** (Fig. 1 and Table 8), considerably enhances the amount of conformer A present in the equilibrium. Since the γ−*gauche* interaction (depicted above) between an equatorial methoxyl and an axial OR is expected to be essentially the same as that between an axial methoxyl and an equatorial OH, the conformational free energy difference between pairs of conformers (e.g., $-\Delta G^0$ for **1** minus $-\Delta G^0$ for **3**) is expected to be approximately 0.75 kcal/mol (9) on the introduction of the methoxyl group in **3**, **8**, **13**, and **18**. (The same argument holds for **4**, **9**, **14**, and **19** where the methoxyl is introduced *cis* to the halogen.) The other interactions involving halogen and OR with each other and with the remainder of the ring are expected to cancel when the $-\Delta G^0$ values of corresponding compounds in Table 7 with and without methoxyl are subtracted.

For the alcohols **3** and **8**, as compared to **1** and **6** respectively, the $-\Delta G^0$ values decrease by 0.90 and 1.03 kcal/mol. These larger than expected differences in $-\Delta G^0$ values require comment. A possible interpretation might involve intramolecular hydrogen bonding between the methoxyl and the *cis* hydroxyl. However, even larger differences in $-\Delta G^0$ values are found when **4** and **9** are compared with **1** and **6** and in these comparisons hydrogen bonding differences are unlikely to be significant (*vide infra*). For the acetates **13** and **18**, as compared to **11** and **16**, respectively, the $-\Delta G^0$ values decrease by 0.43 and 0.52 kcal/mol. These are smaller than the 0.75 kcal/mol decrease expected.

The equilibria of **4**, **9**, **14**, and **19** exhibit more conformer A than any of the other compounds shown in Fig. 1. In these cases, the methoxyl is introduced *cis* to the halogen and again the approximate difference in $-\Delta G^0$ values from the corresponding compounds without the methoxyl group (**1**, **6**, **11**, and **16**) should be about 0.75 kcal/mol. The actual differences are 1.06, 1.21, 0.61, and 0.94 kcal/mol respectively. Again, it is the chloro- and bromohydrins which have the largest differences in $-\Delta G^0$ values. As pointed out above, the addition of a methoxyl *cis* to the halogen should not interfere with the hydrogen bonding characteristics of the halohydrins.

Finally, it is interesting to note that the bromoacetate **19** has significantly more conformer A than the chloroacetate **14**, whereas in the other two pairs of acetates (i.e. **11** vs. **16** and **13** vs. **18**) it is the chloroacetate which has relatively more A conformer present.

To summarize, it is evident that ^{13}C nmr represents an interesting addition to available techniques for examining stereochemical properties of these molecules. It is also clear, however, that further efforts in this field will be necessary in order to delineate more properly the influences of hydrogen bonding and dipolar effects on the observed ^{13}C chemical shifts and conformational equilibria.

To these ends, other series of appropriately 1,2 and 1,3-disubstituted cyclohexanes are under examination.

Experimental

(a) *Spectra*

The ^{13}C spectra were obtained at 50.3 MHz using a Varian XL-200 spectrometer. Sample concentrations were 0.8 *M* in CD_2Cl_2 solutions contained in 10-mm od tubes. Routinely, spectra were obtained with complete ^1H noise decoupling. Normal conditions were as follows: sweep width = 10 000 Hz, number of data points = 32 000, pulse width = 7.0 μs (45°), acquisition time = 1.6 s, and repetition rate = 1.0 s. The number of accumulations for the low temperature spectra was typically 2000.

The equilibrium constants were calculated from relative peak area measurements, which were made electronically. No significant difference in *K* values resulted from spectra obtained with the above conditions as opposed to those recorded under suppressed $^1H-^{13}C$ nuclear Overhauser effect conditions.

The 2D INADEQUATE spectra (8) were obtained using the CCC2D pulse sequence of the XL-200 software. For **1** the sweep width in each domain was 3741 Hz. A 560 × 256 data point matrix was used, transforming 1024 and 512 points respectively.

(b) *Materials*

The compounds **1**−**20**, which were available (1−5) from previous studies, were redistilled or recrystallized before use. Purities were determined by gas−liquid chromatography (Perkin-Elmer model Sigma 1B, equipped with a thermal conductivity detector (250°C) and dedicated computer with built-in recorder; column: 10-ft glass (2-mm id) packed with 10% UCW-98 on Gas-Chrom. Q 80/100 mesh; flow rate of carrier gas (He) was 20 mL/min; oven temperature was 150°C). The purities were determined as: 99.9% (**1**, **3**, **10**, **12**, **15**, and **20**), 99.8% (**2** and **7**), 99.7% (**6**, **8**, and **17**), 99.6% (**5**, **11**, and **16**), 99.2% (**14**), 99.1% (**13**), 98.6% (**18**), 98.3% (**19**), and 97.8% (**4** and **9**). See ref. 18 for a detailed analysis of the glc retention time behaviour of these compounds.

Carbohydrate Research Institute and Department of Chemistry, Queen's University, Kingston, Ont., Canada K7L 3N6
Received October 20, 1983[1]

WALTER A. SZAREK, B. MARIO PINTO, and MASAHARU IWAKAWA. Can. J. Chem. **63**, 2149 (1985).

The synthesis of a variety of nucleoside analogs involving modifications in the carbohydrate ring is described. In particular, 6-substituted purin-9-yl derivatives of 1-oxa-4-thiacyclohexane and 1,4-dioxacyclohexane have been synthesized. A number of 6-chloropurin-9-yl derivatives of substituted 1-oxa-4-thiacyclohexane have also been derived from the parent compounds by way of a Pummerer rearrangement. A route to nucleoside analogs of 1-oxa-4-thiacyclohexane from naturally occurring nucleosides is illustrated for the case of inosine. A route to nucleoside analogs in which the carbohydrate moiety is replaced by an acyclic moiety bearing α,β-unsaturated esters is also illustrated for the case of uridine. The results of biological screening of these analogs and others previously synthesized in our program against leukemia L-1210 cells in vitro are presented; some of these compounds showed marginal antitumor activity. The screening results of selected compounds against the human HeLa cell line in vitro are also presented; none of the compounds that were tested showed significant inhibitory activity of cell growth.

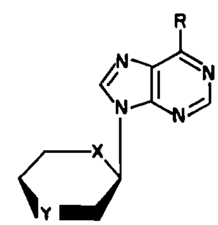
WALTER A. SZAREK, B. MARIO PINTO et MASAHARU IWAKAWA. Can. J. Chem. **63**, 2149 (1985).

On décrit une synthèse de divers analogues des nucléosides qui fait appel à des modifications du cycle du sucre. On a ainsi synthétisé des dérivés purinyl-9 substitués en position 6 de l'oxa-1 thia-4 cyclohexane et du dioxa-1,4 cyclohexane. Une transformation de Pummerer sur des composés apparentés permet d'obtenir des dérivés chloro-6 purinyl-9 de l'oxa-1 thia-4 cyclohexane substitué. Utilisant l'inosine comme exemple, on illustre une voie d'accès aux analogues oxa-1 thio-4 cyclohexanes des nucléosides en faisant appel à des nucléosides réactionnels comme produits de départ. Utilisant l'uridine comme exemple, on propose une méthode d'obtenir des analogues de nucléosides dans lesquels on a remplacé l'unité d'hydrate de carbone par une unité acyclique comportant une unité d'esters α,β insaturés. On présente les résultats obtenus lors d'une évaluation biologique in vitro de ces analogues et d'autres synthétisés antérieurement au cours de notre programme contre les cellules L-1210 de la leucémie. Quelques uns de ces composés présentent une activité anti-tumorale faible. On présente également les résultats obtenus lors d'évaluations in vitro de composés choisis pour leur activité contre la lignée de cellules HeLa humaines. Les composés étudiés ne montrent aucune activité inhibitrice significative sur la croissance des cellules.

[Traduit par le journal]

Introduction

In recent years an active area of research in this laboratory has been the synthesis of nucleoside analogs involving modifications in the carbohydrate ring. As part of this program, the synthesis of nucleoside analogs containing more than one heteroatom in the "carbohydrate" ring has been undertaken. The stimulus for this aspect of nucleoside chemistry was provided by the reported biological activity of the adduct of periodate-oxidized adenosine with isonicotinic acid hydrazide (1) and the interesting biological properties exhibited by ribonucleoside dialdehydes themselves (2). The latter compounds exist in solution as several hydrated species, one of which possesses a 1,4-dioxacyclohexane structure (3). Thus far, reports (4) from this laboratory have described the synthesis of 6-substituted purin-9-yl derivatives of 1-oxa-4-thiacyclohexane, 1,4-dithiacyclohexane, 1,4-dioxacyclohexane, 1-oxa-4-azacyclohexane, and 1-thia-4-azacyclohexane (**1–10**), and of some corresponding pyrimidine derivatives. In addition, the synthesis of nucleoside analogs in which the sugar moiety is replaced by thiazolidine derivatives (**11**, **12**) has also been reported (5). Since that time, McCormick and McElhinney have reported (6) the synthesis of nucleoside analogs of 6-substituted purinyl derivatives in which the carbohydrate moiety is replaced by substituted 1-thia-4-azacyclohexane derivatives and Dvonch and Alburn (7) have reported the synthesis and antileukemic activity of nucleoside analogs derived from the reaction of ethanol or methanol with periodate-oxidized inosine, adenosine, or cytidine. The latter compounds possess 1,4-dioxane structures. Furthermore, periodate-oxidized 5′-deoxyinosine has recently



1 X = O, Y = S, R = Cl
2 X = O, Y = S, R = NH_2
3 X = O, Y = S, R = SH
4 X = S, Y = O, R = Cl
5 X = Y = S, R = Cl
6 X = Y = S, R = NH_2
7 X = Y = S, R = SH
8 X = Y = O, R = Cl
9 X = O, Y = N-Bz, R = Cl
10 X = S, Y = N-Bz, R = Cl
13 X = S, Y = O, R = NH_2
14 X = S, Y = O, R = SH
15 X = Y = O, R = NH_2
16 X = Y = O, R = SH

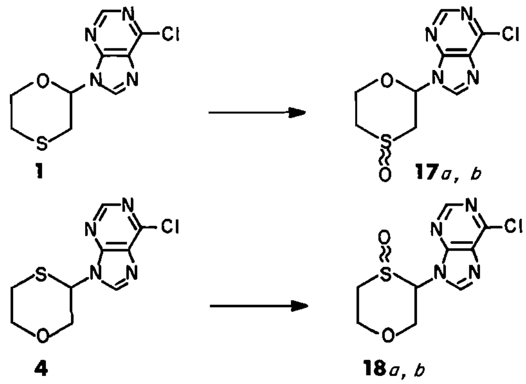


SCHEME 1

been reported (8) to be a more potent antitumor agent than inosine dialdehyde.

As a further extension, we now report the synthesis of 9-(1-oxa-4-thiacyclohexan-3-yl)adenine (**13**) and 9-(1-oxa-4-thiacyclohexan-3-yl)-9*H*-purine-6(1*H*)-thione (**14**) from **4** and of 9-(1,4-dioxacyclohexan-2-yl)adenine (**15**) and 9-(1,4-dioxacyclohexan-2-yl)-9*H*-purine-6(1*H*)-thione (**16**) from **8**. In addition, a number of 6-chloropurin-9-yl derivatives of substituted 1-oxa-4-thiacyclohexane have been synthesized from **1** and **4** in order to evaluate the effects of substituents, if any, on the biological activity of these compounds. Furthermore, a general route to nucleoside analogs of 1-oxa-4-thiacyclohexane from naturally occurring nucleosides is illustrated for the case of inosine; this approach is patterned after the work of Foster and co-workers (9) on the conversion of suitably protected glycopyranosides into derivatives of 2-hydroxy-1-oxa-4-thiacyclohexane.

Since inosine dialdehyde has been shown (10) to contain two aldehyde groups which can cross-link protein molecules, the synthesis of nucleoside analogs bearing functionality that is capable of reacting in similar fashion with functional groups in proteins is also of interest. A route to novel nucleoside analogs bearing such functionality is illustrated, therefore, for the case of uridine.

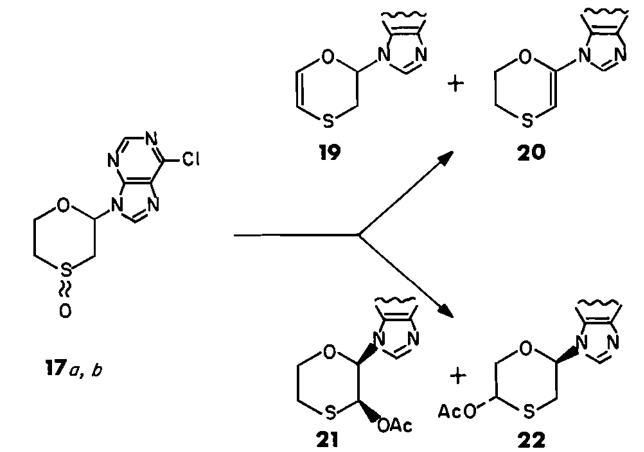
We also now report the results of biological screening of some of the nucleoside analogs synthesized in our program.

Results and discussion

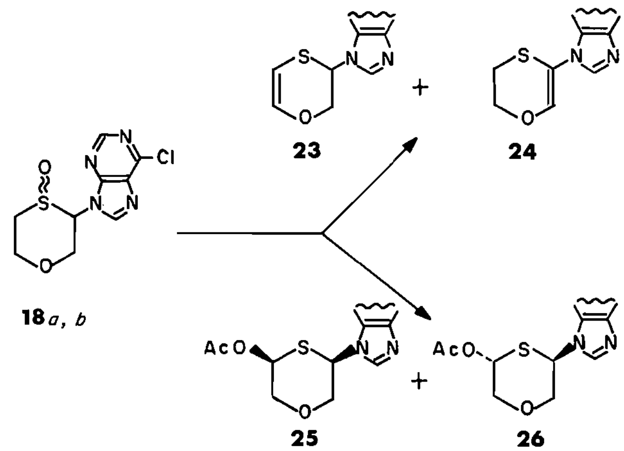
(a) *Synthesis*

Treatment of **4** with methanolic ammonia gave crystalline 9-(1-oxa-4-thiacyclohexan-3-yl)adenine (**13**) in 83% yield whereas the use of methanolic potassium hydrosulfide afforded crystalline 9-(1-oxa-4-thiacyclohexan-3-yl)-9*H*-purine-6(1*H*)-thione (**14**) in 87% yield. Similarly, compound **8** was converted into crystalline 9-(1,4-dioxacyclohexan-2-yl)adenine (**15**) in 81% yield and into crystalline 9-(1,4-dioxacyclohexan-2-yl)-9*H*-purine-6(1*H*)-thione (**16**) in 92% yield. Compounds **13**, **14** and **15**, **16** exhibited conformational behaviour that was similar to that observed (11) for the parent, 6-chloro derivatives, **4** and **8**, respectively.

6-Chloro-9-(1-oxa-4-thiacyclohexan-2-yl)-9*H*-purine (**1**) was converted into a mixture of isomeric sulfoxides (**17***a*, **17***b*) by oxidation with sodium metaperiodate according to the method of Leonard and Johnson (12) (Scheme 1). The ^{1}H nmr spectrum indicated the presence of two isomeric sulfoxides in a ratio of 3.2:1, as estimated by integration of the corresponding signals for H-2′. Recrystallization from ethanol resulted in



SCHEME 2

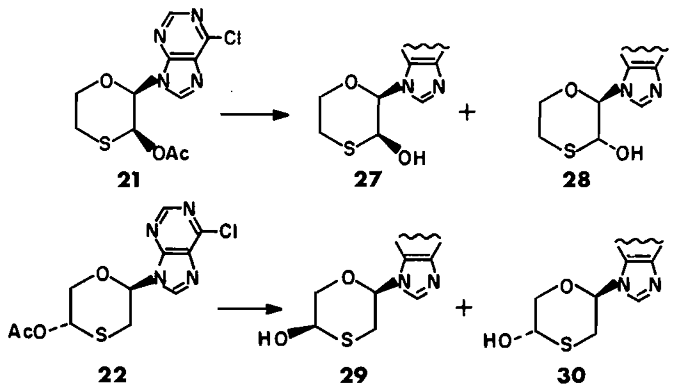


SCHEME 3

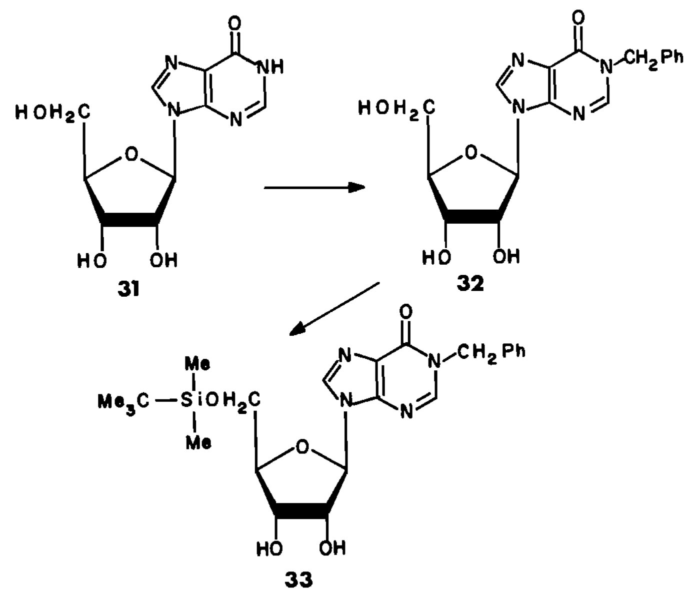
a mixture that was highly enriched in the major isomer (**17***a*). The major and minor isomers were assigned the *trans* and *cis* stereochemistry, respectively, on the basis of their nmr spectra. The detailed examination of the configurations and conformations of these derivatives and others reported below will be described in a subsequent paper (13).

Oxidation of 6-chloro-9-(1-oxa-4-thiacyclohexan-3-yl)-9*H*-purine (**4**) with sodium metaperiodate afforded a mixture of the isomeric sulfoxides **18***a* and **18***b* in a ratio of 1.2:1, as indicated by its ^{1}H nmr spectrum (Scheme 1). Recrystallization from ethanol–hexane afforded white prisms which were shown by ^{1}H nmr spectroscopy to consist predominantly of the major isomer (**18***a*); thus, the unambiguous assignment of signals to the two isomers **18***a* and **18***b* could be made in the ^{1}H nmr and ^{13}C nmr spectra of the isomeric mixture of sulfoxides. Compound **18***a* was assigned the *cis* stereochemistry and **18***b* was assigned the *trans* stereochemistry (13).

Treatment of a mixture of the isomeric sulfoxides **17** with an excess of acetic anhydride in benzene containing a trace of *p*-toluenesulfonic acid monohydrate at 60–70°C afforded a mixture of four components, two of which were identified as being acetoxy derivatives and two of which were identified as being the products of elimination reactions (see Scheme 2). The structures of the olefins were readily established by nmr spectroscopy and the compounds were identified as being 6-chloro-9-(1-oxa-4-thiacyclohex-5-en-2-yl)-9*H*-purine (**19**)



SCHEME 4



SCHEME 5

and 6-chloro-9-(1-oxa-4-thiacyclohex-2-en-2-yl)-9*H*-purine (**20**). The constitution and stereochemistry of the acetoxy derivatives were also established by nmr spectroscopy (13). Compound **21** was identified as being *cis*-6-chloro-9-(3-acetoxy-1-oxa-4-thiacyclohexan-2-yl)-9*H*-purine and compound **22** was identified as being *trans*-6-chloro-9-(5-acetoxy-1-oxa-4-thiacyclohexan-2-yl)-9*H*-purine (13). The *cis*-3′-acetoxy derivative (**21**), the *trans*-5′-acetoxy derivative (**22**), the 2′,3′-olefin (**20**), and the 5′,6′-olefin (**19**) were obtained from the Pummerer reaction of **17** in a ratio of 12:2:2.4:1, respectively.

Treatment of a mixture of isomeric sulfoxides **18** with an excess of acetic anhydride in benzene containing a trace of *p*-toluenesulfonic acid monohydrate at 60–70°C afforded a solid which was revealed by tlc, after multiple development of the plate, to consist of four components (see Scheme 3). The individual components were isolated after tedious preparative thin-layer chromatography in which the plate was subjected to multiple development. The two faster-moving components were readily identified by means of ^{1}H nmr spectroscopy as being the unsaturated compounds, namely 6-chloro-9-(1-oxa-4-thiacyclohex-5-en-3-yl)-9*H*-purine (**23**), and 6-chloro-9-(1-oxa-4-thiacyclohex-2-en-3-yl)-9*H*-purine (**24**) (see Scheme 3). The two slower-moving components were isolated as crystalline solids and were identified as being the *cis*- and *trans*-5′-acetoxy derivatives by nmr spectroscopy (13).

Treatment of the acetate **21** with sodium borohydride in methanol afforded a solid which was identified as being a mixture of *cis*- and *trans*-6-chloro-9-(3-hydroxy-1-oxa-4-thiacyclohexan-2-yl)-9*H*-purine, **27** and **28**, respectively (see Scheme 4).

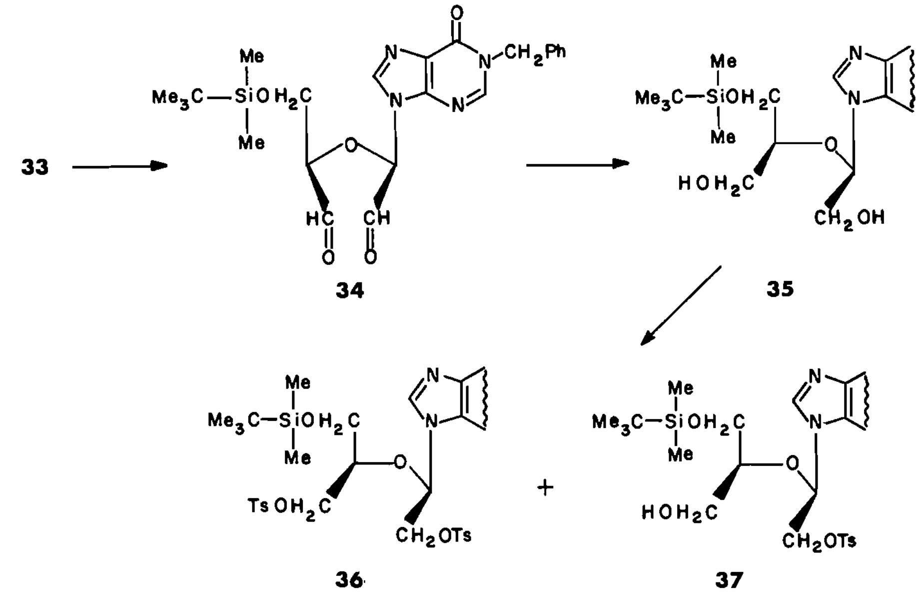
Treatment of the regioisomeric acetate **22** with sodium borohydride in methanol afforded a solid which was identified as being a mixture of *cis*- and *trans*-6-chloro-9-(5-hydroxy-1-oxa-4-thiacyclohexan-2-yl)-9*H*-purine, **29** and **30**, respectively (see Scheme 4).

Treatment of a mixture of *cis*- and *trans*-6-chloro-9-(5-acetoxy-1-oxa-4-thiacyclohexan-3-yl)-9*H*-purine (**25**, **26**) with sodium borohydride did not furnish the expected hydroxy derivatives. Thin-layer chromatography indicated the absence of uv-active components other than that at the origin. Presumably, the products decompose with loss of 6-chloropurine.

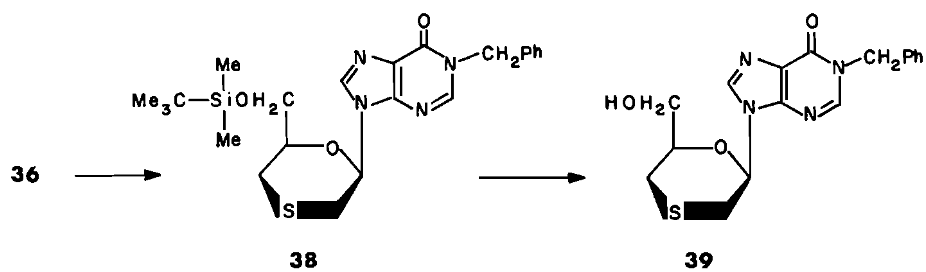
Thus far, the synthesis of nucleoside analogs from noncarbohydrate precursors has been described. The method has consisted, therefore, of the appropriate functionalization of the saturated heterocycle and the subsequent coupling of this product with an appropriate nucleoside base. Modifications of the nucleoside base and of the saturated heterocyclic moiety itself have then been effected. It would be advantageous, however, to have a route to compounds of this type which would circumvent the coupling step. In particular, a synthesis which employed naturally occurring nucleosides as starting materials would be particularly useful. An entry into nucleoside analogs of 1-oxa-4-thiacyclohexanes starting from naturally occurring nucleosides is described below. The method is illustrated for the case of inosine as the starting nucleoside. A merit of using this starting material is that the hypoxanthine moiety can be readily modified to give 6-chloro, 6-amino, or 6-thiono derivatives (see, for example, ref. 14).

Treatment of inosine (**31**) with benzyl chloride and sodium hydrogen carbonate in *N*,*N*-dimethylformamide, by modification of the method of Shaw (15), afforded 1-benzylinosine (**32**) as a white crystalline solid. Protection of *N*-1 was considered necessary in order to obviate its participation in subsequent reactions. For example, it is known (16) that attempted iodination of 2′,3′-*O*-isopropylideneinosine using methyltriphenoxyphosphonium iodide gives 2′,3′-*O*-isopropylidene-3,5′-cycloinosine as the major product. Moreover, Holmes and Robins (17) have shown that 5′-*O*-*p*-tolylsulfonyl-2′,3′-*O*-isopropylideneinosine is also converted into the cyclonucleoside in refluxing dioxane, and Hampton *et al.* (18) have shown that cyclonucleoside formation accompanies bimolecular displacement reactions at C-5′ of the *p*-tolylsulfonyl derivative. Compound **32** was then treated with 1.1 equivalents of *tert*-butyldimethylsilyl chloride in dry *N*,*N*-dimethylformamide containing imidazole (19, 20) to give crystalline 1-benzyl-5′-*O*-*tert*-butyldimethylsilylinosine (**33**) (see Scheme 5). The selectivity of this reagent for reaction at the 5′-position of ribonucleosides is well documented (19).

Oxidation of **33** with sodium metaperiodate in a mixture of ethanol and water followed by borohydride reduction of the resulting "dialdehyde" **34** afforded the diol **35** (see Scheme 6). The functionalization of the diol **35** proved to be much more difficult than had been anticipated. Thus, treatment of **35** with an excess of *p*-toluenesulfonyl chloride in pyridine for an extended time period afforded a mixture of the ditosylate **36** and the monotosylate **37** in low yield (Scheme 6) but yielded mostly unreacted starting material. Other attempts to convert the hy-



SCHEME 6



SCHEME 7

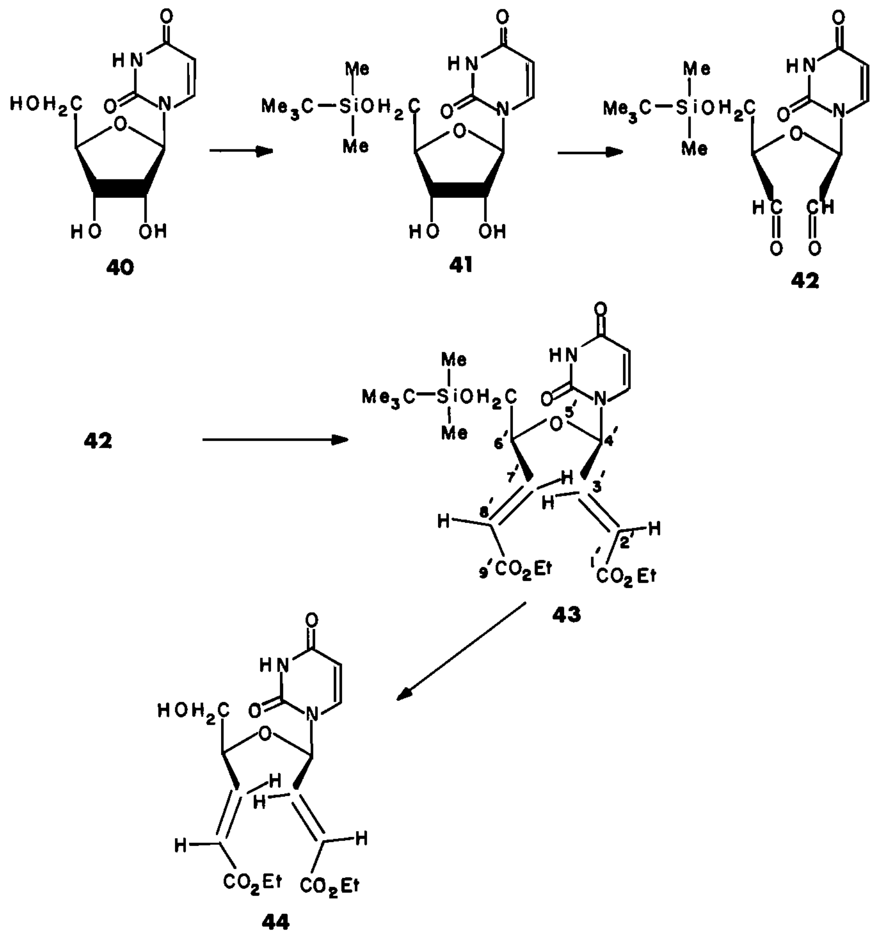
droxyl functions into suitable leaving groups did not offer a significant improvement of yield. For instance, attempts to form the dimesylate using methanesulfonyl chloride in pyridine afforded mostly starting material, even with prolonged reaction times at room temperature. Attempts to synthesize the corresponding dichloride with thionyl chloride or the corresponding dibromide using carbon tetrabromide and triphenylphosphine (21) were also unsuccessful and yielded mostly unreacted starting material. Attempted conversion of the hydroxyl functions into trifluoromethanesulfonic esters using triflic anhydride in a mixture of pyridine and methylene chloride (22) gave a product distribution similar to that observed in the reaction with *p*-toluenesulfonyl chloride. It is noteworthy that Dailey and Fuchs (23) have recently reported a similar problematic situation involving the conversion of the hydroxyl group of a "neopentyl" alcohol into a suitable leaving group. Some of the methods described above were also applied in this system, although without much success.

Treatment of the ditosylate **36** with sodium sulfide in refluxing ethanol afforded, after chromatography, a small amount of a white foam that was identified as being the desired 1-oxa-4-thiacyclohexane derivative **38** by means of nmr spectroscopy. Compound **38** is assigned the conformation in which both the purine moiety and the silyloxymethyl function adopt equatorial orientations since the signal for H-2′ in the ^{1}H nmr spectrum appears as a doublet of doublets having a value for $|J_{2',3'} + J_{2',3''}|$ of 13 Hz, a value that is typical for an axial proton coupled to the axial and equatorial protons of a vicinal methylene group, and since the sequence of reactions is expected to proceed with retention of configuration at C-1′ and C-4′ of inosine (**31**). The apparently low yield of **38** was accounted for by isolation of a second, more polar component that was identified as being the alcohol **39** resulting from desilylation of **38**. Compound **39** was also obtained as a white foam from the silyl ether **38** by treatment with tetra-*n*-butylammonium fluoride in tetrahydrofuran (20) (Scheme 7). The structure of **39** was unambiguously established by complete assignment of its ^{1}H nmr spectrum recorded in chloroform-*d* at 220 MHz (13).

The sequence of reactions outlined above could, presumably, be extended to other naturally occurring nucleosides to furnish both purine and pyrimidine derivatives of 1,4-oxathiane.

In view of the promising antitumor activity exhibited (2*d*, 24) by inosine dialdehyde and in view of its ability to cross-link proteins (10), it was felt that the synthesis of nucleoside analogs bearing functionality that could react in a similar fashion with certain functional groups in proteins would also be of interest. A synthetic scheme employing naturally occurring nucleosides as substrates would be particularly desirable. A general route to such nucleoside analogs is illustrated below for the case of uridine as the starting material. The route is analogous to that employed by Ireson *et al.* (25) in the synthesis of diolefins from methyl 4,6-*O*-benzylidene-α-D-glucopyranoside.

Treatment of uridine (**40**) with *tert*-butyldimethylsilyl chloride and imidazole in *N*,*N*-dimethylformamide (19, 20) af-



SCHEME 8

forded solid 5′-*O*-*tert*-butyldimethylsilyluridine (**41**) (Scheme 8). Periodate oxidation of **41** yielded the "dialdehyde" **42** which was used without further purification. Treatment of **42** with the Wittig reagent, carbethoxymethylenetriphenylphosphorane, in *N*,*N*-dimethylformamide at 95°C for 3 h (Scheme 8) afforded a syrup that was purified by high performance liquid chromatography. Compound **43** was obtained as white needles from ether–hexane. It was identified as being the (2*E*,7*E*), (4*R*,6*S*) isomer (13).

Treatment of **43** with tetra-*n*-butylammonium fluoride in tetrahydrofuran (20) afforded the alcohol **44** as a white foam. Its ^{1}H nmr spectrum recorded at 60 MHz in chloroform-*d* was similar to that of the silyl ether **43**; chemical shift assignments were made, therefore, by analogy with those (13) in the spectrum of **43**.

The α,β-unsaturated esters in compound **44** should be capable of functioning as alkylating agents since they should readily undergo conjugate addition with different nucleophiles (see ref. 25).

The route outlined above should be applicable to other suitably protected, naturally occurring nucleosides. Furthermore, this type of analog offers entry into a variety of nucleoside analogs of substituted 1-oxa-4-thiacyclohexanes and 1-oxa-4-azacyclohexanes via double conjugate addition of sodium sulfide or ammonia, respectively, as exemplified by the work of Ireson *et al.* (25).

(b) *Biological activity*

The inhibitory effects of the nucleoside analogs synthesized in this program on the growth of various mammalian tumor cell lines in vitro and on bacterial cells were investigated. The biological activity against the murine L-1210 tumor cell line, the human HeLa cell line, and the bacterial strains was evaluated by Dr. A. Bloch and co-workers of the Department of Experimental Therapeutics, Grace Cancer Drug Center at the Ros-well Park Memorial Institute. The protocol, methodology, and testing conditions have been previously reported (26–28).

The inhibitory effects that these agents exerted on the in vitro growth of murine L-1210 tumor cells are shown in Table 1. The activities of 6-chloro-9-(tetrahydropyran-2-yl)-9*H*-purine (**45**), 2′-azido-2′-deoxyarabinosylcytosine (**46**), and 2′-amino-2′-deoxyarabinosylcytosine (**47**) in the same test system are also documented for the purposes of comparison. Compounds **46** and **47** were synthesized by Bloch and co-workers (29) and have been screened under conditions identical to those used for the nucleoside analogs synthesized in this program. Compound **45** was prepared by the method of Robins *et al.* (30); this compound has been reported (31) to show significant antitumor activity.

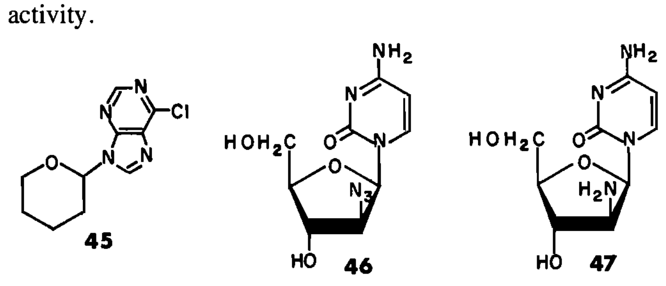


TABLE 1. Inhibitory effects of nucleoside analogs on the growth of murine leukemia L-1210 cells in vitro[a]

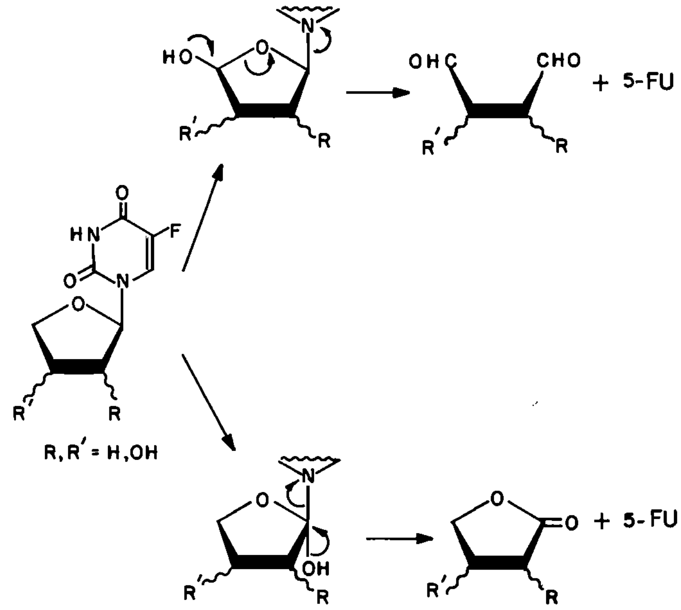
6-Chloropurine	$>10^{-4}$

[a] The culture conditions used have been published in ref. 28.
[b] Average value from multiple tests.
[c] Compound was insufficiently soluble in 10% dimethylsulfoxide in water to be tested.
[d] Prepared by the method of Robins *et al.* (30).
[e] Value from ref. 31.
[f] Values from ref. 29.

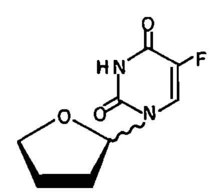
As shown in Table 1, the nucleoside analogs inhibit the growth of leukemia L-1210 cells in vitro at concentrations ranging from $1 \times 10^{-6}\,M$ to $> 10^{-4}\,M$. In comparison, the tetrahydropyran-2-yl derivative **45** exerts its effect at a concentration of $8 \times 10^{-6}\,M$ for 50% inhibition of growth, and 2′-azido- and 2′-amino-2′-deoxyarabinosylcytosine exert a similar effect at concentrations of $6 \times 10^{-7}\,M$ and $4 \times 10^{-6}\,M$, respectively. Comparison of the anti-proliferative activities of the 6-substituted purin-9-yl derivatives of unsubstituted 1,4-oxathiane, 1,4-dioxane, and 1,4-dithiane indicates that, in general, the 6-chloropurinyl derivatives inhibit cell proliferation more than their 6-amino and 6-thio analogs. In addition, the 6-amino derivatives, with the exception of the dithiane derivative **6**, show inhibitory effects at concentrations greater than $10^{-4}\,M$ and are considered, therefore, to be inactive. Since 6-chloropurine itself has been reported to show significant antitumor activity (14*b*) and 6-mercaptopurine is used for the treatment of acute leukemia (32), and in view of the fact that the 6-amino derivatives are inactive, it is conceivable that the activity of the 6-chloro and the 6-thio derivatives is mediated



SCHEME 9

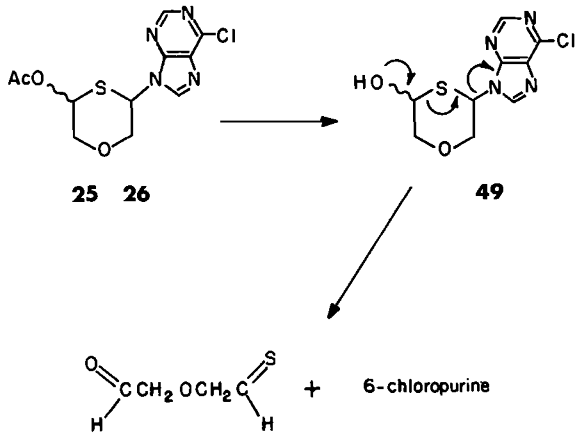
via release of the purine base. The proposed mode of action would then require metabolic activation of the nucleoside analogs to give the free bases which could either inhibit utilization of free purines or, alternatively, could be incorporated into aberrant nucleotides which could then inhibit a number of vital metabolic reactions. Within this context the nucleoside analogs could be considered to be functioning as prodrugs. However, the mechanisms by which the compounds bring about cell death are not clear, and it is also possible that the intact nucleoside analogs act as inhibitors of metabolic functions. There is ample evidence in the literature in support of both modes of action of related nucleoside analogs.

For example, the ribonucleosides containing 6-mercaptopurine, 6-thioguanine, and 5-fluorouracil exert effects similar to the free bases, mainly as a result of extensive cleavage of the nucleosides to the bases (33). The bases then undergo metabolic activation through phosphorylation and subsequent incorporation into nucleotides. However, the depot forms of the aberrant bases are sometimes advantageous in that they can provide for longer survival times (34) or can result in reduced toxicity (35) relative to the free bases. The point is further illustrated by the biological activities (36, 37) of 5-fluorouracil (5-FU) and (*R*,*S*)-1-(tetrahydrofuran-2-yl)-5-fluorouracil (ftorafur or FT) (**48**). Ftorafur has shown significant antitumor



48

activity with a spectrum of activity similar to that of 5-FU, but it is less toxic than 5-FU (36). Lin *et al.* (37) have also reported that 3′- and 4′-hydroxyftorafur (hydroxylated FT metabolites that have also been isolated from patients' urine after FT administration (38)) exert inhibitory effects on HeLa cell growth equal to that of FT. These workers have suggested that the



SCHEME 10

metabolic conversion of FT into 5-FU may involve hydroxylation and, in particular, hydroxylation at C-2′ or C-5′, which leads to the liberation of 5-fluorouracil, as indicated in Scheme 9. The possibility that formation of such hemiacetals or hemiketals can lead to the liberation of the base moiety is supported by one of the results presented in the preceding section. Thus, the attempted reduction of the acetoxy compounds (**25** and **26**) resulted in the liberation of 6-chloropurine. One could envisage the loss of the purine base from the hemiacetal **49** as proceeding by a mechanism analogous to that proposed by Lin *et al.* (37) (see Scheme 10).

In contrast, there is evidence that certain nucleoside analogs might exert their effects by mechanisms other than those involving the loss of the aberrant bases. For instance, 9-methyl-6-thioguanine and 9-(*n*-butyl)-6-thioguanine are active against tumor cell lines that are resistant to 6-thioguanine (39*a*, *b*). Moreover, it has been shown that 9-(*n*-butyl)-6-thioguanine is neither dealkylated nor incorporated into nucleic acid in the mouse, and that the compound may exert its effect by interference of utilization of preformed adenine for DNA synthesis (39*b*, *c*). In addition, a number of 9-alkyl derivatives of 6-thiopurine are reported to be active against 6-thiopurine-resistant tumor cell lines (40). These results suggest that the inhibitory activity of the 9-alkyl-6-substituted purines is not mediated by release of the free bases; alternatively, these compounds may act upon enzymes which have been deleted in the resistant strains (41). Similarly, 6-thio-9-(β-D-erythrofuranosyl)purine has been reported (42) to retain its activity against a strain of *S. faecium* that was resistant to the effects of 6-thiopurine or 6-thioinosine, an observation that provides evidence for a mode of action not involving liberation of 6-thiopurine.

Table 1 also shows that the concentration of 6-chloropurine required for 50% inhibition of cell growth is greater than 10^{-4} *M*. It would appear, therefore, that the saturated heterocyclic moieties in the nucleoside analogs do make a significant contribution to the activity of certain derivatives. This is particularly evident in the case of 9-(1,4-dithian-2-yl)adenine (**6**) which shows an ID_{50} of 9×10^{-5} *M*. The latter result is reminiscent of the reported activity of 9-(tetrahydrofuran-2-yl)-adenine against Adenocarcinoma 755 (43).

Interestingly, the 6-chloropurin-9-yl derivative of 4-benzoyl-1-oxa-4-azacyclohexane (**9**) inhibits cell proliferation at a concentration of 5×10^{-5} *M* whereas the corresponding 4-benzoyl-1-thia-4-azacyclohexane analog (**10**) is inactive.

The introduction of acetoxy or hydroxy substituents into the 1,4-oxathiane ring of the nucleoside analogs does not appear to affect the biological activity appreciably; the molar concentrations required for 50% inhibition of growth range from 1×10^{-5} to 3×10^{-5}. Moreover, the presence of an acetoxy group in place of a hydroxy group does not lead to any marked difference in activity of the corresponding nucleoside analogs. It is interesting to note that the acylation of nucleosides has sometimes led to an improvement of their therapeutic effectiveness (for a discussion, see ref. 44). The improvement may be attributed to the increased stabilization of the acylated compounds towards metabolic degradation as well as to their increased lipophilicity.

TABLE 2. Inhibitory effects of nucleoside analogs on the growth of human HeLa tumor cells in vitro[a]

Compound	Molar concentration for 50% inhibition of growth[b]
4	$>10^{-4}$ (40% inhibition at 10^{-4} *M*)
8	$>10^{-4}$ (35% inhibition at 10^{-4} *M*)
18	$>10^{-4}$
21	$>10^{-4}$ (30% inhibition at 10^{-4} *M*)
22	$>10^{-4}$ (40% inhibition at 10^{-4} *M*)
24	$>10^{-4}$
25, 26	$>10^{-4}$
27, 28	$>10^{-4}$
29, 30	$>10^{-4}$
46	2×10^{-7}[c]
47	3×10^{-5}[c]

[a] The culture conditions used have been published in ref. 28.
[b] Average value from multiple tests.
[c] Values from ref. 29.

The introduction of unsaturation into the 1,4-oxathiane ring provides an interesting result. Thus, 6-chloro-9-(1-oxa-4-thiacyclohex-2-en-3-yl)-9*H*-purine (**24**) inhibits the growth of leukemia L-1210 cells in vitro at a concentration of 6×10^{-6} *M* whereas the regioisomer, namely 6-chloro-9-(1-oxa-4-thiacyclohex-2-en-2-yl)-9*H*-purine (**20**), is inactive.

Oxidation of the 1,4-oxathiane moiety to give the sulfoxides furnishes nucleoside analogs which show inhibitory activity that is comparable to that of the parent compound. The result is only available for **18** since the regioisomer **17** was insufficiently soluble in 10% dimethylsulfoxide in water to be tested.

The acyclic, uracil-base nucleoside analog **44** shows an ID_{50} of 3×10^{-5} *M*.

The substituted thiazolidine derivative **12** containing 6-chloropurine inhibits the growth of L-1210 cells at a concentration of 8×10^{-5} *M* whereas the derivative **11** containing 6-benzamidopurine is inactive.

The encouraging activity exhibited by various of the nucleoside analogs against leukemia L-1210 cells in vitro prompted the screening of selected compounds in the human HeLa tumor cell line in vitro. As indicated in Table 2, none of the nucleoside analogs synthesized in this program that were tested showed significant inhibitory activity of the cell growth of HeLa cells in vitro although these compounds displayed activity in the leukemia L-1210 test system. In comparison, 2′-azido-2′-deoxyarabinosylcytosine (**46**) and 2′-amino-2′-deoxyarabinosylcytosine (**47**) inhibit the growth of HeLa cells in vitro at concentrations of 2×10^{-7} *M* and 3×10^{-5} *M*, respectively.

Various nucleoside analogs synthesized in this program were also subjected to screening against several bacterial strains, namely *Streptococcus faecium*, *E. coli* K-12, and *E. coli* B. However, none of the compounds tested showed significant activity in these bacterial systems.

Experimental

Melting points were determined with a Fisher–Johns apparatus and are uncorrected. Mass spectra were recorded on a CEC 21-104 mass spectrometer under electron-impact conditions at 70 eV ionizing voltage. Proton magnetic resonance (^{1}H nmr) spectra were recorded on a Bruker HX-60 or Varian HR-220 spectrometer. Carbon-13 magnetic resonance (^{13}C nmr) spectra were recorded on a Bruker HX-60 spectrometer equipped with a FT60M Fourier transform accessory at 15.09 MHz. Chemical shifts are given in ppm downfield from tetramethylsilane (TMS). Ultraviolet (uv) spectra were measured on a Unicam SP 800.

Analytical thin-layer chromatography (tlc) was performed on pre-coated glass plates with Merck silica gel 60F-254 as the adsorbent (layer thickness 0.25 mm). The developed plates were air-dried and exposed to uv light and (or) sprayed with a solution of cerium sulfate (1%) and molybdic acid (1.5%) in 10% aqueous sulfuric acid, and heated at 150°C. Preparative thin-layer chromatography was performed on pre-coated glass plates with Merck silica gel 60F-254 as the adsorbent (layer thickness 2 mm). Column chromatography was performed on Brinkman silica gel (70–235 mesh, E. Merck). High performance liquid chromatography was performed on a Waters Associates Prep/LC System 500. The chromatographic solvents (v/v) employed in this work are as follows: (A) benzene – ethyl acetate, 1:1; (B) 2:1; (C) *n*-propanol – ethyl acetate – water, 3:1:1; (D) ethyl acetate – ethanol, 20:1; (E) toluene – ethyl acetate, 1:1; (F) 1:2; (G) benzene – ethyl acetate, 3:1; (H) ethyl acetate.

Solvents were evaporated under reduced pressure and below 40°C.

*6-Chloro-9-(1-oxa-4-thiacyclohexan-3-yl)-9*H*-purine (4)*

The title compound was prepared from 3-hydroxy-1-oxa-4-thiacyclohexane by treatment with diethyl azodicarboxylate, methyldiphenylphosphine, and 6-chloropurine, by the method of Szarek *et al.* (4*c*, 5, 45, 46).[2]

9-(1-Oxa-4-thiacyclohexan-3-yl)adenine (13)

A solution of 6-chloro-9-(1-oxa-4-thiacyclohexan-3-yl)-9*H*-purine (**4**) (0.25 g, 0.97 mmol) in methanolic ammonia (10 mL, 10%) was heated at 90°C in a sealed glass tube for 4 h. The mixture was cooled to room temperature and then to 0°C. The crystals were removed by filtration and were identified as being 9-(1-oxa-4-thiacyclohexan-3-yl)adenine (**13**) (0.192 g, 83%), mp 199–202°C; uv λ_{max} (ethanol): 260 nm (ϵ 7,912), 229.5 (ϵ 1,846); λ_{max} (ethanol containing a trace of acid, pH 2): 260 nm (ϵ 7,912), 233 nm (ϵ 3,516); λ_{max} (ethanol containing a trace of sodium hydroxide, pH 10): 260 nm (ϵ 8,352), 232 nm (ϵ 2,593); ^{1}H nmr data (60 MHz, DMSO-d_6) δ: 2.62 (1H, d of m, J = 14 Hz, H-5′e), 3.08 (1H, m, H-5′a), 3.64–4.70 (4H, m's, 2H-2″s, 2H-6″s), 5.53 (1H, t, $|J_{3',2'} + J_{3',2''}|$ = 6.1 Hz, H-3′), 7.29 (2H, br s, NH_2), 8.17, 8.48 (2H, s's, H-2, H-8). *Anal.* calcd. for $C_9H_{11}N_5OS$: C 45.56, H 4.67, N 29.52, S 13.51; found: C 45.57, H 4.81, N 29.39, S 13.33.

*9-(1-Oxa-4-thiacyclohexan-3-yl)-9*H*-purine-6(1*H*)-thione (14)*

To a solution of 6-chloro-9-(1-oxa-4-thiacyclohexan-3-yl)-9*H*-purine (**4**) (0.31 g, 1.21 mmol) in methanol (7 mL) was added 2 mL of methanolic potassium hydrosulfide (prepared by saturating a solution of potassium hydroxide (0.3 g) in methanol (3 mL) with hydrogen sulfide at 0°C), and the mixture was heated at reflux temperature for 20 min. The mixture was cooled to room temperature and then to 0°C. The crystals were collected, and washed with cold methanol and water. The crystals were dried under vacuum over phosphorus pentoxide and were identified as being 9-(1-oxa-4-thiacyclohexan-3-yl)-9*H*-purine-6(1*H*)-thione (**14**) (0.267 g, 87%), mp 215°C (discoloring), 257°C (dec.); ^{1}H nmr data (60 MHz, DMSO-d_6) δ: 2.58 (1H, d of m, J = 14 Hz, H-5′e), 3.10 (1H, m, H-5′a), 3.5–4.25 (2H, m's, 2H-6″s), 4.15 (1H, d of d, J = 2.7, 12.4 Hz, H-2′e), 4.47 (1H, d of d, J = 2.9, 12.4 Hz, H-2′a), 5.5 (1H, t, $|J_{3',2'} + J_{3',2''}|$ = 6.0 Hz, H-3′), 8.24, 8.59 (2H, s's, H-2, H-8). *Anal.* calcd. for $C_9H_{10}N_4OS_2$: C 42.50, H 3.96, N 22.03, S 25.14; found: C 42.64, H 4.11, N 21.85, S 24.99.

9-(1,4-Dioxacyclohexan-2-yl)adenine (15)

A solution of 6-chloro-9-(1,4-dioxacyclohexan-2-yl)-9*H*-purine (**8**) (0.25 g, 1.04 mmol), prepared by the method of Szarek *et al.* (4*b*), in methanolic ammonia (10 mL, 10%) was heated at 90°C in a sealed glass tube for 4 h. The mixture was cooled to room temperature and then to 0°C. The crystals were obtained by filtration and were identified as being 9-(1,4-dioxacyclohexan-2-yl)adenine (**15**) (0.186 g, 81%), mp 185–186°C; uv λ_{max} (ethanol): 259.5 nm (ϵ 14 136), 226 nm (ϵ 1,571); λ_{max} (ethanol containing a trace of hydrochloric acid, pH 2): 259.5 nm (ϵ 14 136), 230 nm (ϵ 3,246); λ_{max} (ethanol containing a trace of sodium hydroxide, pH 10): 260 nm (ϵ 14 450), 232 nm (ϵ 4,293); ^{1}H nmr data (60 MHz, DMSO-d_6) δ: 3.80 (4H, m, 2H-5″s, 2H-6″s), 3.83–4.5 (2H, m's, 2H-3″s), 5.82 (1H, d of d, J = 3.4, 6.8 Hz, $|J_{2',3'} + J_{2',3''}|$ = 10.2 Hz, H-2′), 7.30 (2H, br s, NH_2), 8.17, 8.35 (2H, s's, H-2, H-8). *Anal.* calcd. for $C_9H_{11}N_5O_2$: C 48.86, H 5.01, N 31.66; found: C 49.20, H 5.24, N 31.38.

*9-(1,4-Dioxacyclohexan-2-yl)-9*H*-purine-6(1*H*)-thione (16)*

To a solution of 6-chloro-9-(1,4-dioxacyclohexan-2-yl)-9*H*-purine (**8**) (0.31 g, 1.29 mmol) in methanol (6 mL) was added 1.5 mL of methanolic potassium hydrosulfide (prepared by saturating a solution of potassium hydroxide (0.3 g) in methanol (3 mL) with hydrogen sulfide at 0°C), and the mixture was heated at reflux temperature for 20 min. The mixture was cooled and the crystals were collected, and washed with cold methanol and water. The crystals were dried under vacuum over phosphorus pentoxide and were identified as being 9-(1,4-dioxacyclohexan-2-yl)-9*H*-purine-6(1*H*)-thione (**16**) (0.285 g, 92%), mp 240°C (dec.); ^{1}H nmr data (60 MHz, DMSO-d_6) δ: 3.80 (4H, m, 2H-5″s, 2H-6″s), 3.83–4.42 (2H, m's, 2H-3″s), 5.83 (1H, d of d, J = 3.9, 6.1 Hz, $|J_{2',3'} + J_{2',3''}|$ = 9.8 Hz, H-2′), 8.23, 8.49 (2H, s's, H-2, H-8). *Anal.* calcd. for $C_9H_{10}N_4O_2S$: C 45.37, H 4.23, N 23.51, S 13.46; found: C 45.32, H 4.24, N 23.43, S 13.37.

Cis- *and* trans-*6-chloro-9-(1-oxa-4-oxo-4-thiacyclohexan-2-yl)-9*H*-purine (17*a*, 17*b*)*

A solution of 6-chloro-9-(1-oxa-4-thiacyclohexan-2-yl)-9*H*-purine (**1**) (0.896 g, 3.49 mmol), prepared by the method of Szarek *et al.* (4*b*), in methanol (50 mL) was added dropwise over a period of 0.5 h to a solution of sodium metaperiodate (0.822 g, 3.84 mmol) in water (40 mL) at 0°C. The mixture was stirred at 0°C for 8 h and then filtered. The methanol was evaporated, and the resulting aqueous solution was continuously extracted with chloroform (200 mL) for 4 h. The extracts were dried over anhydrous sodium sulfate, and concentrated to give a solid (0.926 g, 97%). Thin-layer chromatography (Solvent A) indicated the absence of starting material (R_f 0.56) and the presence of a component at the origin. The ^{1}H nmr spectrum indicated the presence of two isomeric sulfoxides in a ratio of 3.2:1. Recrystallization from ethanol afforded white crystals which were shown by ^{1}H nmr spectroscopy to consist of a mixture that was enriched in the major isomer **17***a*, mp 173–185°C (dec.). Compound **17***a* was identified as being *trans*-6-chloro-9-(1-oxa-4-oxo-4-thiacyclohexan-2-yl)-9*H*-purine; ^{1}H nmr data (60 MHz, DMSO-d_6) δ: 2.83–5.0 (6H, m's, 2H-3″s, 2H-5″s, 2H-6″s), 6.53 (1H, d of d, J = 2.1, 10.6 Hz, $|J_{2',3'} + J_{2',3''}|$ = 12.7 Hz, H-2′), 8.83, 8.93 (2H, s's, H-2, H-8). Compound **17***b* was identified as being *cis*-6-chloro-9-(4-oxo-1-oxa-4-thiacyclohexan-2-yl)-9*H*-purine; ^{1}H nmr data (60 MHz, DMSO-d_6) δ: 2.83–5.0 (6H, m's, 2H-3″s, 2H-5″s, 2H-6″s), 6.15 (1H, d of d, $|J_{2',3'} + J_{2',3''}|$ = 8.3 Hz, H-2′), 8.83, 9.07 (2H, s's, H-2, H-8). *Anal.* calcd. for $C_9H_9N_4O_2SCl$: C 39.64, H 3.33, N 20.54, S 11.76; found: C 39.45, H 3.59, N 20.38, S 11.64.

Cis- *and* trans-*6-chloro-9-(1-oxa-4-oxo-4-thiacyclohexan-3-yl)-9*H*-purine (18*a*, 18*b*)*

A solution of 6-chloro-9-(1-oxa-4-thiacyclohexan-3-yl)-9*H*-purine

[2] Also, M. C. Depew and W. A. Szarek, unpublished results.

(**4**) (0.295 g, 1.15 mmol), prepared from 3-hydroxy-1-oxa-4-thiacyclohexane by treatment with diethyl azodicarboxylate, methyldiphenylphosphine, and 6-chloropurine, by the method of Szarek *et al.* (4*c*, 5, 45, 46), in methanol (20 mL) was added to a solution of sodium metaperiodate (0.258 g, 1.21 mmol) in water (20 mL) at 0°C dropwise over a period of 10 min. The mixture was stirred at 0°C for 12 h and then at room temperature for 12 h. Thin-layer chromatography (Solvent A) indicated the presence of starting material (R_f 0.43). Sodium metaperiodate (0.16 g) was added and the mixture was stirred for 24 h; tlc still showed the presence of a small amount of starting material. Sodium metaperiodate (0.025 g) was added and stirring was continued for an additional 24 h; tlc (Solvent A) indicated the absence of starting material and the presence of a component having an R_f value of 0.14. The mixture was concentrated to remove methanol and was then subjected to continuous extraction with chloroform (200 mL) for 12 h. The extracts were dried over anhydrous magnesium sulfate, and concentrated to give a solid (0.29 g, 93%). The ^{1}H nmr spectrum indicated the presence of two isomeric sulfoxides in a ratio of 1.2:1. Recrystallization from ethanol–hexane afforded white prisms which were shown by ^{1}H nmr spectroscopy to consist predominantly of the major isomer (**18*a***), mp 197–204°C (dec.). Compound **18*a*** was identified as being *cis*-6-chloro-9-(1-oxa-4-oxo-4-thiacyclohexan-3-yl)-9*H*-purine; ^{1}H nmr data (100 MHz, DMSO-d_6) δ: 3.10 (1H, d of t, J = 14 Hz, $W_{1/2} \simeq 8$ Hz, H-5′e), 3.41 (1H, d of d, $J \simeq 14$, 4.2 Hz, H-5′a), 3.8–4.2 (3H, m's, H-2′e, H-6′a, H-6′e), 4.71 (1H, d of d, J = 12.4, 10 Hz, H-2′a), 5.99 (1H, d of d, J = 10.1, 4.0 Hz, $|J_{3',2'} + J_{3',2''}|$ = 14.1 Hz, H-3′), 8.70, 8.83 (2H, s's, H-2, H-8); ^{13}C nmr data (DMSO-d_6) δ: 44.85 (C-5), 57.40 (C-6), 60.77 (C-2), 62.06 (C-3), 130.3, 145.0, 151.8 (purine). Compound **18*b*** was identified as being *trans*-6-chloro-9-(1-oxa-4-oxo-4-thiacyclohexan-3-yl)-9*H*-purine; ^{1}H nmr data (60 MHz, DMSO-d_6) δ: 2.83–5.1 (6H, m's, 2H-2′′s, 2H-5′′s, 2H-6′′s), 5.58 (1H, d of d, $|J_{3',2'} + J_{3',2''}|$ = 10.5 Hz, H-3′), 8.87 (2H, s, H-2, H-8); ^{13}C nmr data (DMSO-d_6) δ: 47.44 (C-5), 61.29 (C-6), 64.07 (C-2), 68.02 (C-3), 130.7, 145.9, 149.5, 151.8 (purine). *Anal.* calcd. for $C_9H_9N_4O_2SCl$: C 39.64, H 3.33, N 20.54, S 11.76; found: C 39.32, H 3.33, N 20.36, S 11.58.

Pummerer reaction with cis- *and* trans-*6-chloro-9-(1-oxa-4-oxo-4-thiacyclohexan-2-yl)-9*H*-purine (17*a, *17*b)

A suspension of a mixture of sulfoxides (**17*a***, **17*b***) (1.58 g, 5.87 mmol) in acetic anhydride (40 mL) and benzene (100 mL), containing *p*-toluenesulfonic acid (10 mg), was heated at 60–70°C for 48 h. As the reaction proceeded, a clear solution was obtained. The mixture was cooled and was stirred with sodium hydrogen carbonate solution (150 mL) for 2 h. The layers were separated and the organic layer was washed with sodium hydrogen carbonate solution (75 mL) and then with water (75 mL), and dried over magnesium sulfate. Evaporation of the solvent afforded a solid which was revealed by tlc (Solvent B) to consist of four components having R_f values of 0.43, 0.37, 0.31, and 0.22. The mixture was chromatographed on silica gel using Solvent B as eluant. The component having an R_f value of 0.43 was obtained as a syrup and was identified as being 6-chloro-9-(1-oxa-4-thiacyclohex-5-en-2-yl)-9*H*-purine (**19**) (0.05 g, 3.3%); ^{1}H nmr data (60 MHz, $CDCl_3$) δ: 3.43 (2H, m, 2H-3′′s), 5.42 (1H, br d, J = 6.3 Hz, $W_{1/2}$ = 2.5 Hz, H-5′), 6.70 (1H, t, $|J_{2',3'} + J_{2',3''}|$ = 8.5 Hz, H-2′), 6.76 (1H, d, J = 6.3 Hz, H-6′), 8.36, 8.77 (2H, s's, H-2, H-8). The component having an R_f value of 0.37 was isolated as a solid and was recrystallized from ethanol to give white crystals (0.113 g, 8%), mp 113–135°C; it was identified as being 6-chloro-9-(1-oxa-4-thiacyclohex-2-en-2-yl)-9*H*-purine (**20**); ^{1}H nmr data (100 MHz $CDCl_3$) δ: 3.18 (2H, m, 2H-5′′s), 4.67 (2H, m, 2H-6′′s), 6.37 (1H, s, H-3′), 8.34, 8.77 (2H, s's, H-2, H-8); ^{13}C nmr data ($CDCl_3$) δ: 25.05 (C-5′), 67.69 (C-6′), 88.40 (C-3′), (C-2′ masked by $CDCl_3$), 132.0, 141.86, 152.41 (purine). *Anal.* calcd. for $C_9H_7N_4OSCl$: C 42.44, H 2.77, N 22.00, S 12.59; found: C 42.28, H 2.74, N 21.89, S 12.63.

The component having an R_f value of 0.31 was obtained as a white solid from ethanol–hexane (0.727 g, 39%), mp 157–158°C, and was identified as being *cis*-6-chloro-9-(3-acetoxy-1-oxa-4-thiacyclohexan-2-yl)-9*H*-purine (**21**); ^{1}H nmr data (100 MHz, $CDCl_3$) δ: 2.01 (3H, s, Me), 3.02 (2H, m, 2H-5′′s), 4.15 (2H, m, 2H-6′′s), 6.13 (1H, d, $J_{2',3'}$ = 5.6 Hz, H-2′ or H-3′), 6.29 (1H, d, $J_{2',3'}$ = 5.6 Hz, H-3′ or H-2′), 8.62, 8.75 (2H, s's, H-2, H-8); ^{13}C nmr data ($CDCl_3$) δ: 20.58 (Me), 25.69 (C-5′), 65.88 (C-6′), 68.47 (C-3′), 81.35 (C-2′), 143.3, 152.34 (purine), 168.5 (CO). *Anal.* calcd. for $C_{11}H_{11}N_4O_3SCl$: C 41.98, H 3.52, N 17.80, S 10.19; found: C 41.96, H 3.69, N 17.94, S 10.08.

The component having an R_f value of 0.22 was isolated as a solid and was recrystallized from ethanol to give white crystals (0.118 g, 64%), mp 147–148°C; it was identified as being *trans*-6-chloro-9-(5-acetoxy-1-oxa-4-thiacyclohexan-2-yl)-9*H*-purine (**22**); ^{1}H nmr data (100 MHz, $CDCl_3$) δ: 2.20 (3H, s, Me), 3.46 (1H, d of d, J = 14.5, 4.5 Hz, H-3′), 3.72 (1H, d of d, J = 14.5, 3.9 Hz, H-3″), 4.03 (1H, d of d, J = 13.1, 4 Hz, H-6′), 4.22 (1H, d of d, J = 13.1, 2.75 Hz, H-6″), 5.79 (1H, t, $|J_{5',6'} + J_{5',6''}|$ = 6.75 Hz, J = 2.75–3.25 Hz, H-5′), 6.36 (1H, t, $|J_{2',3'} + J_{2',3''}|$ = 8.25 Hz, J = 4 Hz, H-2′), 8.72 (2H, s, H-2, H-8); ^{13}C nmr data ($CDCl_3$) δ: 20.97 (Me), 25.89 (C-3′), 65.23 (C-6′), 67.37 (C-5′), 77.72 (C-2′), 131.57, 143.67, 152.21 (purine), 169.36 (CO). *Anal.* calcd. for $C_{11}H_{11}N_4O_3SCl$: C 41.98, H 3.52, N 17.80, S 10.19; found: C 41.63, H 3.51, N 17.68, S 10.01.

Pummerer reaction with cis- *and* trans-*6-chloro-9-(1-oxa-4-oxo-4-thiacyclohexan-3-yl)-9*H*-purine (18*a, *18*b)

An isomeric mixture of sulfoxides (**18*a***, **18*b***) (0.65 g, 2.38 mmol) in acetic anhydride (60 mL) and benzene (40 mL), containing *p*-toluenesulfonic acid (33 mg), was heated at 60–70°C for 40 h. The mixture was diluted with benzene (50 mL) and aqueous sodium hydrogen carbonate solution (50 mL) was added. The mixture was stirred for 2 h. The organic layer was separated, washed with water (50 mL), and was dried over anhydrous sodium sulfate. Evaporation of the solvent afforded a solid which was revealed by tlc (Solvent B) to consist of four components having R_f values of 0.65, 0.57, 0.48, and 0.41 after the plate had been developed three times. The aqueous layer was subjected to continuous extraction with chloroform for 12 h. The extracts were concentrated to give a solid which was identified as being unreacted starting material (**18*a***, **18*b***) (0.166 g). The crude mixture from above was applied to preparative thin-layer plates and the plates were developed five times using Solvent B as eluant. The component having an R_f value of 0.65 was isolated as a syrup and was identified as being 6-chloro-9-(1-oxa-4-thiacyclohex-5-en-3-yl)-9*H*-purine (**23**) (0.004 g, 1%); ^{1}H nmr data (60 MHz, $CDCl_3$) δ: 4.39 (1H, d of d, J = 12, 2 Hz, H-2′), 4.72 (1H, d of d, J = 12, 3 Hz, H-2″), 5.46 (1H, d of d, $J_{5',6'}$ = 7 Hz, $J_{5',3'}$ = 2 Hz, H-5′), 6.23 (1H, m, $|J_{3',2'} + J_{3',2''}|$ = 4.5 Hz, H-3′), 6.87 (1H, d, $J_{6',5'}$ = 7 Hz, H-6′), 8.47, 8.79 (2H, s's, H-2, H-8). The component having an R_f value of 0.57 was isolated as a solid and was recrystallized from ethanol to give white needles (0.062 g, 13.7%), mp 143–144°C; it was identified as being 6-chloro-9-(1-oxa-4-thiacyclohex-2-en-3-yl)-9*H*-purine (**24**); ^{1}H nmr data (60 MHz, $CDCl_3$) δ: 3.27 (2H, m, 2H-5′′s), 4.47 (2H, m, 2H-6′′s), 7.13 (1H, s, H-2′), 8.18, 8.82 (2H, s's, H-2, H-8). *Anal.* calcd. for $C_9H_7N_4OSCl$: C 42.44, H 2.77, N 22.00, S 12.59; found: C 42.38, H 2.83, N 21.77, S 12.37.

The component having an R_f value of 0.48 was isolated as a solid and was recrystallized from ethanol as white prisms (0.025 g, 4.5%), mp 160–164°C (dec.); it was identified as being *cis*-6-chloro-9-(5-acetoxy-1-oxa-4-thiacyclohexan-3-yl)-9*H*-purine (**25**); ^{1}H nmr data (100 MHz, $CDCl_3$) δ: 2.08 (3H, s, Me), 3.85–4.80 (4H, m's, 2H-2′′s, 2H-6′′s), 5.75 (2H, m, $W_{1/2}$ = 8 Hz, H-3′, H-5′), 8.74, 9.06 (2H, s's, H-2, H-8). The component having an R_f value of 0.41 was isolated as a solid and was recrystallized from ethanol to give white prisms (0.05 g, 9%), mp 144–145°C; it was identified as being *trans*-6-chloro-9-(5-acetoxy-1-oxa-4-thiacyclohexan-3-yl)-9*H*-purine (**26**); ^{1}H nmr data (100 MHz, $CDCl_3$) δ: 2.24 (3H, s, Me), 3.85–4.60 (4H, m, 2H-2′′s, 2H-6′′s), 5.97 (1H, t, $|J_{3',2'} + J_{3',2''}|$ = 4.5 Hz, H-3′), 6.19 (1H, d of d, J = 4.2, 8.4 Hz, $|J_{5',6'} + J_{5',6''}|$ = 12.6 Hz, H-5′), 8.36, 8.77 (2H, s's, H-2, H-8); ^{13}C nmr data ($CDCl_3$) δ: 20.97 (Me), 49.18 (C-3′), 70.15, 70.73, 71.12 (C-2′, C-5′, C-6′), 131.57, 143.48, 152.34 (purine), 168.5 (CO). *Anal.* calcd. for $C_{11}H_{11}N_4O_3SCl$: C 41.98, H 3.52, N 17.80, S 10.19; found (for a mixture of **25** and **26**): C 41.77, H 3.43, N 17.78, S 10.24.

Cis- *and* trans-*6-chloro-9-(3-hydroxy-1-oxa-4-thiacyclohexan-2-yl)-9*H-*purine (27, 28)*

Sodium borohydride (0.02 g, 0.53 mmol) was added to an ice-cooled solution of the acetate **21** (0.167 g, 0.53 mmol) in dry methanol (40 mL). The mixture was warmed to room temperature and was stirred for 12 h. The mixture was neutralized with moist Amberlite IRC 50 (H), the resin was removed by filtration, and the solution was concentrated to give a solid. Thin-layer chromatography (Solvent A) revealed the absence of starting material (R_f 0.53) and the presence of a component having an R_f value of 0.44. Preparative thin-layer chromatography using Solvent A as eluant afforded a white solid which was identified as being a mixture of *cis*- and *trans*-6-chloro-9-(3-hydroxy-1-oxa-4-thiacyclohexan-2-yl)-9*H*-purine (**27**, **28**) (0.097 g, 67%), mp 135–137°C; ir (KBr): 3410, 3200 (br OH), 1590, 1560, 1480 (purine ring) cm^{-1}; ^{1}H nmr data (60 MHz, $CDCl_3$ with D_2O, 300 K) *cis*-isomer **27**, δ: 2.33 (1H, d of t, H-5′e), 3.40 (1H, d of q, J = 14, 11, 4.8 Hz, H-5″a), 3.85–4.7 (2H, m's, 2H-6′′s), 4.98 (1H, br s, H-3′), 6.28 (1H, d, $J_{2',3'}$ = 1.2 Hz, H-2′), 8.60, 8.66 (2H, s's, H-2, H-8); *trans*-isomer **28**, δ: 5.34 (1H, d, $J_{2',3'}$ = 8 Hz, H-2′ or H-3′), 5.87 (1H, $J_{2',3'}$ = 8 Hz, H-3′ or H-2′); ratio of **27**:**28** = 3.25:1; (60 MHz, DMSO-d_6 with D_2O, 300 K), *cis*-isomer **27**, δ: 4.95 (1H, br s, H-3′), 6.23 (1H, br s, H-2′), 8.66, 8.80 (2H, s's, H-2, H-8); *trans*-isomer **28**, δ: 5.49 (1H, d, $J_{2',3'}$ = 8.3 Hz, H-2′ or H-3′), 5.83 (1H, d, $J_{2',3'}$ = 8.3 Hz, H-3′ or H-2′), 8.83, 8.92 (2H, s's, H-2, H-8); ratio of **27**:**28** = 1.3:1; 60 MHz, DMSO-d_6 with D_2O, 340 K), *cis*-isomer **27**, δ: 4.95 (1H, br s, H-3′), 6.23 (1H, d, $J_{2',3'}$ = 1.5 Hz, H-2′), 8.65, 8.78 (2H, s's, H-2, H-8); *trans*-isomer **28**, δ: 5.49, 5.83 (2H, d's, $J_{2',3'}$ = 8.3 Hz, H-2′, H-3′), 8.81, 8.85 (2H, s's, H-2, H-8). Ratio of **27**:**28** = 2.6:1. The ^{13}C nmr data (DMSO-d_6) **27**, δ: 20.77 (C-5′), 67.50 (C-3′), 70.86 (C-6′), 83.74 (C-2′), 145.09, 145.87, 151.76 (purine); **28**, δ: 28.60 (C-5′), 69.38 (C-3′), 69.76 (C-6′), 86.33 (C-2′); ratio of **27**:**28** 1:1; (DMSO-d_6 + $CDCl_3$), **27**, δ: 21.41 (C-5′), 68.29 (C-3′), 71.27 (C-6′), 83.88 (C-2′), 144.35, 145.0, 151.53, 151.85 (purine); **28**, δ: 28.97 (C-5′), 69.91 (C-3′), 70.43 (C-6′), 86.66 (C-2′); ratio of **27**:**28** ≃ 2:1. *Anal.* calcd. for $C_9H_9O_2SCl$: C 39.64, H 3.33, N 20.54, S 11.76; found: C 39.77, H 3.44, N 19.68, S 11.83.

Cis- *and* trans-*6-chloro-9-(5-hydroxy-1-oxa-4-thiacyclohexan-2-yl)-9*H-*purine (29, 30)*

Sodium borohydride (0.015 g, 0.39 mmol) was added to an ice-cooled solution of the acetate **22** (0.122 g, 0.39 mmol) in dry methanol (30 mL). The mixture was warmed to room temperature and was stirred for 15 h. The mixture was neutralized with moist Amberlite IRC 50 (H), filtered, and the solvent was evaporated to give a syrup. Thin-layer chromatography (Solvent B) indicated the absence of starting material (R_f 0.25) and the presence of another component having an R_f value of 0.08. Preparative thin-layer chromatography using Solvent A as eluant afforded a white solid which was identified as being a mixture of *cis*- and *trans*-6-chloro-9-(5-hydroxy-1-oxa-4-thiacyclohexan-2-yl)-9*H*-purine (**29**, **30**) (0.53 g, 50%), mp 164–166°C (dec.); ir (KBr): 3370, 3290 (br, OH), 1598, 1560, 1488 (purine ring) cm^{-1}; ^{1}H nmr data (60 MHz, $CDCl_3$, 300 K), *cis*-isomer **29** only, δ: 2.83 (1H, d of d, J = 13, 2.2 Hz, H-3′e), 3.25–4.6 (3H, m's, H-3″a, 2H-6′′s), 4.85 (1H, m, $|J_{5',6'} + J_{5',6''}|$ = 5 Hz, H-5′), 6.13 (1H, d of d, J = 10.5, 2.2 Hz, $|J_{2',3'} + J_{2',3''}|$ = 12.7 Hz, H-2′), 8.50, 8.76 (2H, s's, H-2, H-8); (60 MHz, DMSO-d_6 with D_2O, ~300 K), *cis*-isomer **29**, δ: 2.89 (1H, d of d, J = 13, 2 Hz, H-3′e), 3.5–4.4 (3H, m's, H-3″a, 2H-6′′s), 4.77 (1H, m, $|J_{5',6'} + J_{5',6''}|$ = 4.5 Hz, H-5′), 6.09 (1H, d of d, J = 10.8, 2.2 Hz, $|J_{2',3'} + J_{2',3''}|$ = 13.0 Hz, H-2′), 8.83, 8.92 (2H, s's, H-2, H-8); *trans*- isomer **30**, δ: 4.97 (1H, d of d, J = 7.5, 3.2 Hz, $|J_{5',6'} + J_{5',6''}|$ = 10.7 Hz, H-5′), 6.18 (1H, m, $|J_{2',3'} + J_{2',3''}|$ ≃ 9 Hz, partially obscured by H-2′ of **29**, H-2′); ratio of **29**:**30** = 2.7:1; (DMSO-d_6 with D_2O, 340 K), *cis*-isomer **29**, δ: 4.77 (1H, m, $|J_{5',6'} + J_{5',6''}|$ = 5.2 Hz, H-5′), 6.10 (1H, d of d, J = 10.2, 2.2 Hz, $|J_{2',3'} + J_{2',3''}|$ = 12.4 Hz, H-2′), 8.80, 8.83 (2H, s's, H-2, H-8); *trans*-isomer **30**, δ: 5.0 (1H, d of d, J = 7.3, 3.2 Hz, $|J_{5',6'} + J_{5',6''}|$ = 10.5 Hz, H-5′), ~6.2 (1H, m, H-2′); ratio of **29**:**30** = 2.2:1; (DMSO-d_6 with D_2O, 400 K), *cis*-isomer **29**, δ: 4.77 (1H, m $|J_{5',6'} + J_{5',6''}|$ = 5.2 Hz, H-5′), 6.10 (1H, d of d, J = 2.4, 10.2 Hz, $|J_{2',3'} + J_{2',3''}|$ = 12.7 Hz, H-2′), 8.74 (2H, s, H-2, H-8); *trans*-isomer **30**, δ: 5.02 (1H, d of d, J = 3.9, 7.3 Hz, $|J_{5',6'} + J_{5',6''}|$ = 11.2 Hz, H-5′), ~6.2 (1H, d of d, $|J_{2',3'} + J_{2',3''}|$ = 7–8 Hz, partially obscured by H-2′ of **29**, H-2′); ratio of **29**:**30** = 2.7:1; ^{13}C nmr data (DMSO-d_6) **29**, δ: 24.53 (C-3′), 66.01 (C-5′), 72.20 (C-6′), 81.48 (C-2′), 130.86, 145.16, 151.76 (purine); **30**, δ: 28.41 (C-3′), 68.22 (C-5′), 72.61 (C-6′), 80.44 (C-2′). *Anal.* calcd. for $C_9H_9N_4SO_2Cl$: C 39.64, H 3.33, N 20.54, S 11.76; found: C 39.53, H 3.45, N 20.35, S 11.81.

Attempted reduction of cis- *and* trans-*6-chloro-9-(5-acetoxy-1-oxa-4-thiacyclohexan-3-yl)-9*H-*purine (25, 26)*

Sodium borohydride (0.011 g, 0.3 mmol) was added to an ice-cooled solution of a mixture of the acetates **25** and **26** (0.09 g, 0.29 mmol) in dry methanol (25 mL). The mixture was warmed to room temperature and was stirred for 12 h. Thin-layer chromatography (Solvent A) indicated that the main uv-active component was present at the origin. The mixture was neutralized with Rexyn 102 (H), the resin was removed by filtration, and the solvent was evaporated to give a syrup; tlc indicated the absence of a uv-active component other than that at the origin (6-chloropurine).

1-Benzylinosine (32)

Inosine (**31**) (8.36 g, 0.031 mol) was dissolved with heating in *N*,*N*-dimethylformamide (240 mL). Sodium hydrogen carbonate (8.4 g, 0.1 mol) and benzyl chloride (8.5 mL, 0.074 mol) were added and the mixture was heated at 90°C for 6 h. The solvent was removed under reduced pressure to give a solid. Water (250 mL) was added to the residue and, after trituration, was removed under reduced pressure. The process was repeated. The residue was triturated with warm water (150 mL) and the remaining solid was collected (10.2 g, 85%), mp 215–220°C. Thin-layer chromatography (Solvent C) indicated the presence of one component having an R_f value of 0.71. Recrystallization from 95% ethanol afforded white crystals which were identified as being 1-benzylinosine (**32**), mp 221–222°C; lit. (15) mp 219–222°C; ^{1}H nmr data (60 MHz, DMSO-d_6) δ: 3.45 (br peak, OH), 3.74 (2H, m, H-5′, H-5″), 3.85–4.38 (2H, m's, H-3′, H-4′), 4.57 (1H, m, H-2′), 5.2 (br peak, OH), 5.23 (2H, s, CH_2Ph), 5.91 (1H, d, J = 5 Hz, H-1′), 7.35 (5H, s, Ph), 8.40, 8.66 (two 1H s's, H-2, H-8).

*1-Benzyl-5′-*O-tert-*butyldimethylsilylinosine (33)*

To a mixture of 1-benzylinosine (**32**) (5.85 g, 0.015 mol) and imidazole (2.15 g, 0.031 mol) in amine-free, dry *N*,*N*-dimethylformamide (250 mL) was added *tert*-butyldimethylsilyl chloride (2.72 g, 0.018 mol) with stirring. The mixture was let stand at room temperature for 12 h, after which the solvent was removed under reduced pressure. The residue was triturated with water (125 mL) and the water was carefully decanted. The process was repeated. The gummy residue was treated with ethanol (40 mL) and the remaining solid was collected. This was identified as being unreacted material (**32**) (0.46 g). The filtrate was concentrated to give a solid (6.98 g, 98%). Thin-layer chromatography (Solvent C) indicated the absence of starting material and the presence of a faster-moving component. Compound **33** was obtained from methanol as white needles, mp 204.5–206.5°C. ^{1}H nmr data (60 MHz, DMSO-d_6) δ: 0.05 (6H, s, 2-Me), 0.87 (9H, s, *t*-Bu), 3.7–4.33 (m's, H-3′, H-4′, OH), 4.5 (1H, m, H-2′), 5.24 (2H, s, CH_2Ph), 5.62 (1H, d, J = 5.8 Hz, OH), 5.90 (1H, d, J = 4.6 Hz, H-1′), 7.31 (5H, s, Ph), 8.27, 8.61 (two 1H s's, H-2, H-8). *Anal.* calcd. for $C_{23}H_{32}N_4O_5Si$: C 58.45, H 6.83, N 11.86; found: C 58.63, H 6.88, N 11.99.

*1-Benzyl-6-oxo-9-[(1*R*,3*R*)-1,3-bis(*p*-tolylsulfonyloxymethyl)-4-*tert*-butyldimethylsilyloxy-2-oxabutyl]-9*H*-purine (36)*

To a solution of 1-benzyl-5′-*O*-*tert*-butyldimethylsilylinosine (**33**) (3.0 g, 6.35 mmol) in ethanol (250 mL) at 0°C was added a solution of sodium metaperiodate (1.63 g, 7.62 mmol) in water (60 mL) with stirring. The mixture was warmed to room temperature and stirring was continued for 24 h. Barium chloride solution (10%) was added to precipitate iodate and periodate ions. The mixture was cooled and the salts were removed by filtration. The filtrate was concentrated to afford a solid which was dissolved in methanol (60 mL) and water (30 mL). The solution was cooled to 0°C and sodium borohydride (0.722 g, 19.1 mmol) was added in portions; the flask was protected from light. The mixture was gradually warmed to room temperature and stirring was continued for 12 h. The mixture was brought to pH 8 by addition of wet Amberlite IRC 50 (H). The resin was removed by filtration and the filtrate was concentrated. The residue was repeatedly concentrated from methanol to remove boric acid, and the resulting white foam was dried under vacuum. Thin-layer chromatography (Solvent D) indicated the presence of one component having an R_f value of 0.22. The foam was dissolved in pyridine and the solution was cooled to 0°C. *p*-Toluenesulfonyl chloride (4.0 g, 0.02 mol) was added in portions. The mixture was gradually warmed to room temperature and was stirred for 72 h. The mixture was poured into ice and was then extracted with methylene chloride (3 × 100 mL). The extracts were washed with sodium hydrogen carbonate solution (100 mL) and water (100 mL), and dried over anhydrous magnesium sulfate. Evaporation of the solvent afforded a foam. Thin-layer chromatography (Solvent A) indicated the presence of two major components having R_f values of 0.45 and 0.34 as well as a large amount of unreacted diol **35**. The foam was chromatographed on silica gel using Solvent E as eluant initially and then Solvent F as eluant. The component having an R_f value of 0.45 was obtained as a foam and was identified as being the ditosylate **36** (0.82 g, 17%); ^{1}H nmr data ($CDCl_3$, 60 MHz) δ: 0.02 (6H, s, $SiMe_2$), 0.87 (9H, s, *t*-Bu), 2.55, 2.60 (two 3 H s's, 2-Me), 3.08–4.83 (7H, m's, 2-CH_2OTs, CH_2OSi, H-3′), 5.37 (2H, s, CH_2Ph), 6.12 (1H, t, J = 5.2 Hz, H-1′), 7.42 (5H, s, Ph), 7.33, 7.73 (two 1H d's, J = 8 Hz, Ar), 7.42, 7.90 (two 1H d's, J = 8 Hz, Ar), 7.90, 8.15 (two 1H s's, H-2, H-8). *Anal.* calcd. for $C_{37}H_{46}N_4O_9S_2Si$: C 56.75, H 5.92, N 7.16, S 8.19; found: C 56.88, H 6.04, N 7.66, S 7.95.

The component having an R_f value of 0.34 was obtained as a syrup and was identified as being the monotosylate **37** (0.125 g, 3%); ^{1}H nmr data ($CDCl_3$, 60 MHz) δ: 0.1 (6H, s, $SiMe_2$), 0.84 (9H, s, *t*-Bu), 2.48 (3H, s, Me), 3.34–4.05 (5H, m's, CH_2OSi, CH_2OH, H-3′), 4.52 (2H, d, J = 5.8 Hz, CH_2OTs), 5.27 (2H, "s", CH_2Ph), 6.24 (1H, t, J = 5.8 Hz, H-1′), 7.26, 7.67 (two 1H d's, J = 8 Hz, Ar), 7.38 (5H, s, Ph), 7.92, 8.01 (two 1H s's, H-2, H-8).

*1-Benzyl-6-oxo-9-[(2*R*,6*R*)-6-*tert*-butyldimethylsilyloxymethyl-1-oxa-4-thiacyclohexan-2-yl]-9*H*-purine (38)*

To a refluxing solution of the ditosylate **36** (0.578 g, 0.74 mmol) in 95% ethanol (100 mL) was added a solution of sodium sulfide (0.087 g, 1.11 mmol) (freshly recrystallized from ethanol) in hot 95% ethanol (60 mL) dropwise over a period of 1 h. After 5 h tlc (Solvent A) indicated the presence of starting material as well as a slower-moving component having an R_f value of 0.39. Sodium sulfide (0.060 g) was added and refluxing was continued. After 12 h tlc (Solvent A) still showed the presence of starting material. An additional amount of sodium sulfide (0.030 g) was added and refluxing was continued for 24 h. Thin-layer chromatography indicated that the major component present was that having an R_f value of 0.39. Dry Ice was added to neutralize the mixture and the ethanol was evaporated. The residue was partitioned between methylene chloride and sodium hydrogen carbonate (150 mL/100 mL). The methylene chloride layer was dried over anhydrous sodium sulfate, and concentrated to give a syrup which was chromatographed on silica gel using Solvent E as eluant. The component having an R_f value of 0.39 was obtained as a white foam and was identified as being compound **38** (0.031 g, 9%); ^{1}H nmr data ($CDCl_3$, 60 MHz) δ: 0.02 (6H, s, 2-Me), 0.87 (9H, s, *t*-Bu), 2.47–3.17 (4H, m's, H-3′, H-3″, H-5′, H-5″), 3.17–4.2 (3H, m's, H-6′, CH_2OSi), 5.18 (2H, "s", CH_2Ph), 5.80 (1H, d of d, $J_{2',3'e}$ = 3 Hz, $J_{2',3''a}$ = 10 Hz, H-2′), 7.23 (5H, s, Ph), 7.79, 7.90 (two 1H s's, H-2, H-8); ^{13}C nmr data (in $CDCl_3$) δ: 5.37 (Me), 25.80 (*t*-Bu), 27.87 (C-5′), 31.17 (C-3′), 49.22 (CH_2OSi), 65.32 (CH_2Ph), 81.36 (C-6′), 82.39 (C-2′), 128.05, 128.96, 135.88, 137.17, 147.07, 156.38 (Ar), 204.3 (CO). *Anal.* calcd. for $C_{23}H_{32}N_4O_3SSi$: C 58.44, H 6.83, N 11.85, S 6.78; found: C 58.79, H 7.22, N 10.84, S 6.67. Mol. Wt. calcd. for $C_{23}H_{32}N_4O_3SSi$: 472.7; found: *m/e* 415 ($M^{+\cdot}$ − *t*-Bu), 358 ($M^{+\cdot}$ − *t*-BuMe$_2$Si).

After compound **38** was isolated, the column was eluted with Solvent D to yield a component having an R_f value of 0.25 (Solvent D). This component was obtained as a white foam and was identified as being the alcohol **39** resulting from desilylation of **38** (0.39, 49%).

*1-Benzyl-6-oxo-9-[(2*R*,6*R*)-6-hydroxymethyl-1-oxa-4-thiacyclohexan-2-yl]-9*H*-purine (39)*

The silyl ether **38** (0.038 g, 0.8 mmol) was treated with tetra-*n*-butylammonium fluoride (2 mL, 1.3 *N* in tetrahydrofuran) for 12 h. Thin-layer chromatography (Solvent D) indicated the absence of starting material and the presence of a more polar component having an R_f value of 0.25. The solvent was evaporated and the residue was partitioned between methylene chloride and water (20 mL/10 mL). The organic layer was dried over anhydrous sodium sulfate, and concentrated to afford a syrup. Preparative thin-layer chromatography using Solvent D as eluant yielded compound **39** as a white foam (0.026 g, 90%); ^{1}H nmr data ($CDCl_3$, 220 MHz) δ: 2.39 (1H, br d, J_{gem} = 14 Hz, $W_{1/2}$ = 5 Hz, H-5′e), 2.72 (1H, br d, J_{gem} = 13–15 Hz, $W_{1/2}$ = 5 Hz, H-3′e), 2.76 (1H, d of d, J_{gem} = 14 Hz, $J_{5''a,6'}$ = 11 Hz, H-5″a), 3.17 (1H, d of d, J_{gem} = 13 Hz, $J_{3''a,2'}$ = 11 Hz, H-3′a), 3.67 (2H, m, CH_2OH), 4.15 (1H, octet, H-6′), 5.23 (2H ABq, $J \simeq$ 14 Hz, CH_2Ph), 5.90 (1H, d of d, $J_{2',3'e}$ = 1.8 Hz, $J_{2',3''a}$ = 10.8 Hz, $|J_{2',3'} + J_{2',3''}|$ = 12.6 Hz, H-2′), 7.39 (5H, s, Ph), 7.99, 8.08 (two 1H s's, H-2, H-8).

*5′-O-*tert*-Butyldimethylsilyluridine (41)*

To a solution of uridine (**40**) (0.5 g, 2.05 mmol) and imidazole (0.31 g, 4.51 mmol) in amine-free, dry *N,N*-dimethylformamide (40 mL) at room temperature was added *tert*-butyldimethylsilyl chloride (0.34 g, 2.25 mmol). The mixture was stirred for 1 h. The solvent was evaporated under reduced pressure and water was added to the residue. The solid that formed was collected and washed with water. Compound **41** was obtained as a white solid from methanol–water (0.7 g, 95%), mp 85–88°C; ^{1}H nmr data (DMSO-d_6, 60 MHz) δ: 0.08 (6H, s, 2-Me), 0.91 (9H, s, *t*-Bu), 3.3–4.47 (6H, m, H-2′, H-3′, H-4′, H-5′, H-5″, OH), 5.59 (1H, d, J = 8.4 Hz, H-6), 5.81 (1H, d, J = 4 Hz, H-1′), 7.84 (1H, d, J = 8.4 Hz, H-5), 11.42 (1H, br peak, NH).

*5′-O-*tert*-Butyldimethylsilyluridine "dialdehyde" (42)*

To a stirred solution of *tert*-butyldimethylsilyluridine (**41**) (1.0 g, 2.79 mmol) in methanol (60 mL) at 0°C was added sodium metaperiodate (0.72 g, 3.35 mmol) in water (30 mL). The mixture was gradually warmed to room temperature and was stirred for 12 h. The solution was concentrated to a volume of 40 mL. Ethanol (100 mL) was added and the mixture was stirred for 15 min. The salts were removed by filtration and the filtrate was concentrated to afford a solid.

*1-[(2*E*,7*E*),(4*R*,6*S*)-Diethyl 6-*tert*-butyldimethylsilyloxymethyl-5-oxanona-2,7-dienoate-4-yl]uracil (43)*

A solution of the "dialdehyde" **42** (0.55 g, 1.53 mmol) and carbethoxymethylenetriphenylphosphorane (1.6 g, 4.59 mmol) in *N,N*-dimethylformamide (50 mL) was heated at 95°C for 3 h. The solvent was removed under reduced pressure to yield a syrup. Thin-layer chromatography (Solvent B) indicated the presence of one major component having an R_f value of 0.38. High performance liquid chromatography using Solvent G as eluant afforded a white solid (0.51 g, 67%). Recrystallization from ether–hexane yielded compound **43** as white needles, mp 105.5–106.5°C; ^{1}H nmr data ($CDCl_3$, 220 MHz) δ: 0.045 (6H, s, 2-Me), 0.86 (9H, s, *t*-Bu), 1.32, 1.33 (two 3H t's, 2-Me), 3.66 (2H, AB pattern, CH_2OSi), 4.24, 4.26 (two 2H q's, 2-CH_2CH_3), ~4.21 (1H, m, (obscured by CH_2CH_3 signals), H-6′), 5.81 (1H, d of d, $J_{6,5}$ = 8 Hz, $^4J_{6,4'}$ = 2 Hz, H-6), 6.11 (1H, d of d, $J_{8',7'}$ = 16 Hz, $^4J_{8',6'}$ = 1.1 Hz, H-8′), 6.31 (1H, d of d, $J_{7',8'}$ = 15.7 Hz, $J_{7',6'}$ = 2 Hz, H-7′), 6.39 (1H, d of d, $J_{4',3'}$ = 3.9 Hz, $^4J_{4',6}$ = 2 Hz, H-4′), 6.77 (1H, d of d, $J_{2',3'}$ = 15.7 Hz, $^4J_{2',4'}$ = 1.1 Hz, H-2′), 6.79 (1H, d of d, $J_{3',2'}$ = 15.8 Hz, $J_{3',4'}$ = 3.9 Hz, H-3′), 7.35 (1H, d, $J_{5,6}$ = 8 Hz, H-5), 9.46 (1H, br s, NH). *Anal.* calcd. for $C_{23}H_{36}N_2O_8Si$: C 55.62, H 7.31, N 5.64; found: C 55.56, H 7.51, N 5.41.

*1-[(2E,7E),(4R,6S)-Diethyl 6-hydroxymethyl-5-oxanona-2,7-dieneoate-4-yl]uracil (**44**)*

The silyl ether **43** (0.183 g, 0.37 mmol) was treated with tetra-*n*-butylammonium fluoride (1.5 mL, 1.3 *N* in tetrahydrofuran) for 2 h. Thin-layer chromatography (Solvent H) indicated the presence of one component having an R_f value of 0.34. The solvent was evaporated and the residue was partitioned between methylene chloride and water (20 mL/10 mL). The organic layer was dried over anhydrous magnesium sulfate, and concentrated to afford a syrup. Chromatography on silica gel using Solvent H as eluant gave a white foam which was identified as being compound **44** (0.13 g, 92%); ^{1}H nmr data ($CDCl_3$, 60 MHz) δ: 1.30, 1.32 (two 3H t's, 2-Me), 3.68 (2H, m, CH_2OH), 4.17, 4.23 (two 2H q's, 2-CH_2CH_3), ~4.2 (1H, m (partially obscured by CH_2 signals), H-6′), 5.73 (1H, d, J = 8 Hz, H-6), 6.1 (1H, d, J = 16 Hz, H-8′), 6.3 (1H, d, J = 16 Hz, H-7′), 6.38 (1H, d, $J \simeq 4$ Hz, H-4′), 6.78 (1H, d, $J \simeq 16$ Hz, H-2′), 6.83 (1H, br d, J = 16 Hz, H-3′), 7.42 (1H, d, J = 8 Hz, H-5), 10.62 (1H, br s, NH). *Anal.* calcd. for $C_{17}H_{22}O_8N_2$: C 53.40, H 5.80, N 7.33; found: C 53.38, H 6.30, N 6.93.

Acknowledgements

The authors are grateful to Dr. A. Bloch of Roswell Park Memorial Institute for performing the biological screening of the nucleoside analogs. Financial assistance from NSERC Canada in the form of grants (to W.A.S.) and a scholarship (to B.M.P.) is gratefully acknowledged. The authors also wish to thank Queen's University for financial support.

Nucleoside analogs involving modifications in the carbohydrate ring: nuclear magnetic resonance spectroscopic studies

WALTER A. SZAREK, B. MARIO PINTO, AND MASAHARU IWAKAWA
Carbohydrate Research Institute and Department of Chemistry, Queen's University, Kingston, Ont., Canada K7L 3N6

Received October 20, 1983[1]

WALTER A. SZAREK, B. MARIO PINTO, and MASAHARU IWAKAWA. Can. J. Chem. **63**, 2162 (1985).

The concomitant use of ^{1}H nmr and ^{13}C nmr spectroscopy as a probe of structure, stereochemistry, and conformation of several nucleoside analogs derived from 1-oxa-4-thiacyclohexane is described. The ^{1}H nmr spectroscopic properties of an acyclic nucleoside analog derived from uridine are also described.

WALTER A. SZAREK, B. MARIO PINTO et MASAHARU IWAKAWA. Can. J. Chem. **63**, 2162 (1985).

On décrit l'utilisation concomitante de la spectroscopie rmn du ^{1}H et du ^{13}C comme méthode pour déterminer la structure, la stéréochimie et la conformation de plusieurs analogues nucléosides dérivant de l'oxa-1 thia-4 cyclohexane. On décrit aussi les propriétés spectroscopiques, en rmn du ^{1}H, d'un analogue acyclique nucléoside dérivé d'une uridine.

[Traduit par le journal]

Introduction

In recent years an active area of research in this laboratory has been the synthesis (1) and conformational analysis (2) of nucleoside analogs involving modifications in the carbohydrate ring. As part of this program we have recently reported (3) the synthesis and biological activity of the nucleoside analogs **1**–**12**. In this paper we describe their nuclear magnetic resonance spectroscopic properties. The concomitant use of ^{1}H nmr and ^{13}C nmr spectroscopy has proved invaluable in the proof of structure and in the investigation of stereochemistry and conformation of these compounds.

Results and discussion

The isomeric sulfoxides **1***a*, **1***b* were obtained by oxidation of 6-chloro-9-(1-oxa-4-thiacyclohexan-2-yl)-9*H*-purine (**13**) with sodium metaperiodate (3). The ^{1}H nmr spectrum indicated the presence of two isomeric sulfoxides in a ratio of 3.2:1, as estimated by integration of the corresponding signals for H-2′. Recrystallization from ethanol resulted in a mixture that was highly enriched in the major isomer (**1***a*). The H-2′ signal in the spectrum of **1***a* appeared as a doublet of doublets ($|J_{2',3'} + J_{2',3''}|$ = 12.7 Hz) at δ 6.53 whereas that for **1***b* appeared at δ 6.15 as a doublet of doublets ($|J_{2',3'} + J_{2',3''}|$ = 8.3 Hz). The assignment of stereochemistry and conformation in **1***a* and **1***b* was made on the basis of the signs and magnitudes of the sulfoxidation chemical-shift increments ($\Delta\delta_{H\text{-}i} = \delta_{H\text{-}i}^{S-O} - \delta_{H\text{-}i}^{S}$) of H-2′ signals in the ^{1}H nmr spectra of the two isomers. Examination of the spectra of **13** and **1***a* shows that the H-2′ signal in the spectrum of **1***a* is shifted downfield by 0.5 ppm relative to the corresponding signal in the spectrum of the sulfide **13**. This deshielding has been ascribed to electric-field effects and (or) the acetylene-like anisotropy of the S=O bond, and is consistent with a *syn*-axial relationship of H-2′ to the sulfinyl group (4–7). This assignment is supported by the observed value for $|J_{2',3'} + J_{2',3''}|$ which suggests a preponderance of the conformation in which the purine moiety is equatorially oriented. Compound **1***a* is identified, therefore, as being *trans*-6-chloro-9-(1-oxa-4-oxo-4-thiacyclohexan-2-yl)-9*H*-purine (see Fig. 1). In contrast, the H-2′ signal in the spectrum of **1***b* is shifted downfield by only 0.12 ppm relative to the corresponding signal in the spectrum of **13**, and is consistent with the assignment of the *cis*-stereochemistry to this compound. The value obtained for $|J_{2',3'} + J_{2',3''}|$ is also indicative of a preponderance of the conformer in which both the sulfinyl group and the purine moiety adopt the axial orientation (see Fig. 1). The strong preference for the axial orientation of the sulfinyl group in related sulfoxides is well documented (2*a*, 2*b*, 4–8). Compound **1***b* is identified, therefore, as being *cis*-6-chloro-9-(1-

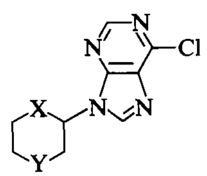
oxa-4-oxo-4-thiacyclohexan-2-yl)-9*H*-purine. Unfortunately, the sulfoxides **1** were insufficiently soluble to permit the recording of their ^{13}C nmr spectra.



13 X = O, Y = S
14 X = S, Y = O

Oxidation of 6-chloro-9-(1-oxa-4-thiacyclohexan-3-yl)-9*H*-purine (**14**) with sodium metaperiodate (3) afforded a mixture of the isomeric sulfoxides **2a** and **2b** in a ratio of 1.2:1, as indicated by its ^1H nmr spectrum. Recrystallization from ethanol–hexane afforded white prisms which were shown by ^1H nmr spectroscopy to consist of predominantly the major isomer (**2a**); this permitted the unambiguous assignment of signals to the two isomers **2a** and **2b** in the ^1H nmr and ^{13}C nmr spectra of the isomeric mixture of sulfoxides. The H-3′ signal in the spectrum of **2a** appeared as a doublet of doublets ($|J_{3',2'} + J_{3',2''}| = 14.1$ Hz) at δ 5.99 whereas the corresponding signal in the spectrum of **2b** appeared as a doublet of doublets ($|J_{3',2'} + J_{3',2''}| = 10.5$ Hz) at δ 5.58. The observed value of $|J_{3',2'} + J_{3',2''}|$ in the spectrum of **2a** is most certainly indicative of a conformation in which the purine moiety is almost exclusively equatorially oriented whereas that observed for **2b** suggests a preponderance of a conformation in which the purine moiety is equatorial, although not nearly to the extent as is present in **2a**. It is noteworthy that the H-3′ signal in the ^1H nmr spectrum of **2a** is shifted downfield by 0.42 ppm relative to the corresponding signal in the spectrum of the parent sulfide (**14**) whereas the H-3′ signal in the spectrum of **2b** appears at virtually the same chemical shift as that in the spectrum of **14**. Examination of the ^{13}C nmr spectrum of **2a** indicates that C-2′ and C-6′ are shielded by ~10 ppm and C-3′ and C-5′ are deshielded by 12.7 ppm and 20.7 ppm, respectively, relative to the corresponding carbons in the parent sulfide **14** (see Table 1). The magnitude of the shielding of the β-carbons in six-membered, cyclic sulfoxides relative to those in the corresponding sulfides is associated with an axial disposition of the sulfinyl oxygen in the sulfoxides (**2a**, **2b**, 7–9). The ^{13}C nmr data for **2a** are consistent, therefore, with the preponderance of a conformation in which the sulfinyl group is axially disposed, and compound **2a** is identified as being *cis*-6-chloro-9-(1-oxa-4-oxo-4-thiacyclohexan-3-yl)-9*H*-purine (see Fig. 2). Consequently, compound **2b** is assigned the *trans* stereochemistry. Examination of the ^{13}C nmr spectrum of **2b** shows that C-2′ and C-6′ are shielded by ~7 ppm and C-3′ and C-5′ are deshielded by 18.6 ppm and 23.3 ppm, respectively, relative to the corresponding carbons in **14** (Table 1). The lesser shielding of C-2′ and C-6′ in **2b** as compared to that in **2a** (relative to C-2′ and C-6′ in **14**) can be taken as evidence for a lesser proportion of the conformation in which the sulfinyl group is axial in the former case. It should be noted that the equatorial disposition of the sulfinyl group in six-membered, cyclic sulfoxides also results in shielding of the β-carbons relative to those in the parent sulfides, although the magnitude of the shielding is considerably smaller than that observed in the corresponding systems having axially-disposed sulfinyl groups (7–9). It is not clear whether this is yet another example of shielding as a result of a γ-*anti* substituent effect (10, 11). Additional information about the conformational behaviour of **2b** may be obtained by comparison of the chemical-shift differences of the signals for

FIG. 3. Possible configurational and conformational isomers of 6-chloro-9-(3-acetoxy-1-oxa-4-thiacyclohexan-2-yl)-9*H*-purine (**3***a* and **3***b*, **15***a* and **15***b*), 6-chloro-9-(5-acetoxy-1-oxa-4-thiacyclohexan-2-yl)-9*H*-purine (**4***a* and **4***b*, **16***a* and **16***b*), 6-chloro-9-(5-acetoxy-1-oxa-4-thiacyclohexan-3-yl)-9*H*-purine (**5***a* and **5***b*, **6***a* and **6***b*), 6-chloro-9-(3-hydroxy-1-oxa-4-thiacyclohexan-2-yl)-9*H*-purine (**7***a* and **7***b*, **8***a* and **8***b*), and 6-chloro-9-(5-hydroxy-1-oxa-4-thiacyclohexan-2-yl)-9*H*-purine (**9***a* and **9***b*, **10***a* and **10***b*).

the β-carbons in the isomeric sulfoxides, **2***a* and **2***b*, with the corresponding differences in appropriate isomeric sulfoxides. Thus, for example, $\Delta\delta_{C\text{-}6'}$ is 3.9 ppm for **2***a* and **2***b* whereas the corresponding chemical-shift difference for the C-2 or C-6 signals in the spectra of axial and equatorial 1,4-oxathiane 4-oxides is 7.02 ppm (8), and the chemical-shift difference for the C-2 signals in the spectra of *trans*-hexahydro-1,4-benzoxathiane 4-oxides is 5.96 ppm (7). This evidence suggests that *trans*-6-chloro-9-(1-oxa-4-oxo-4-thiacyclohexan-3-yl)-9*H*-purine (**2***b*) exists as a mixture of conformers which contains a significant amount of the conformer in which the sulfinyl moiety is axially oriented (see Fig. 2). It is possible to estimate approximately the extent of this equilibrium provided that values of $|J_{2',3'} + J_{2'',3'}|$ in conformationally-locked systems are available. Using approximate values for $|J_{2',3'} + J_{2'',3'}|$ for the two conformations in which the purine moiety is either axial or equatorial (2*c*), one estimates that **2***b* exists in the conformation in which the purine moiety and sulfinyl group are both equatorial to the extent of 63%. The slight equatorial preference of the purine moiety in **2***b* and the almost exclusive equatorial orientation of the purine moiety in **2***a* contrast with the conformational behaviour of the parent sulfide (**14**). The latter compound exhibits a marked preference for the conformation in which the purine moiety is axial (89%) (2*c*).

The acetoxy derivatives **3** and **4** were obtained from the Pummerer reaction of the isomeric sulfoxides **1** (3); their constitution and stereochemistry were established as follows. The ^{1}H nmr spectrum of the major product of the reaction, **3**, showed the presence of two mutually-coupled doublets at δ 6.13 and δ 6.29 (J = 5.6 Hz), a result that is consistent with the presence of the acetoxy group at the 3′-position. The value of $J_{2',3'}$ further suggests that compound **3** is unlikely to exist to a great extent in a conformation in which H-2′ and H-3′ are *trans*-diaxially disposed (see **15***a* and **15***b* in Fig. 3). The possible configurational and conformational isomers for **3** are shown in Fig. 3. Examination of the ^{13}C nmr spectral data (Table 2) for **3** permitted the assignment of stereochemistry and preferred conformation. The chemical-shift assignments were facilitated by consideration of the substitutent effects on the ^{13}C chemical shifts in related compounds (2) and by means of gated-decoupling experiments. One would anticipate that a preferred conformation in which the acetoxy group was axially oriented would be manifested in a shielding of C-5′ by virtue of a γ-*gauche* interaction (2, 12). The data presented in Table 2 indicate that the signal for C-5′ in the spectrum of **3** appears at virtually the same chemical shift as the corresponding signal in the spectrum of **13**. This result is, therefore, inconsistent with the preference for a conformation in which the acetoxy group is axially disposed. Furthermore, the signal for C-6′ in the spectrum of **3** is shifted upfield by 4.32 ppm relative to the corresponding signal in the spectrum of **13**. This may be attributed to a γ-*gauche* interaction between the purine moiety and C-6′ (2, 12) in **3**. In contrast, the signal for C-6′ in the spectrum of **13** (which has been shown (2) to exist preponderantly in the conformation in which the purine moiety is equatorial) is shifted downfield by 1.7 ppm relative to C-2 and C-6 in 1,4-oxathiane. Compound **3** is assigned, therefore, a preponderant conformation in which the acetoxy group is equatorial and the purine moiety is axial (see **3***a*), and is identified as being *cis*-6-chloro-9-(3-acetoxy-1-oxa-4-thiacyclohexan-2-yl)-9*H*-purine. It is noteworthy that the conformational preference of the purine moiety in **3** contrasts with that observed for **13** in which the purine moiety is predominantly equatorial (2), and the conformational preference of the acetoxy group contrasts with previous examples of the anomeric effect in sulfur heterocycles (13–15). However, the preference for a *gauche* arrangement of atoms within the 1,2-disubstituted ethane-type fragment is maintained.

4	77.72	67.37	25.89	65.23

[a] In ppm downfield from internal TMS in chloroform-*d*.

The structure of the second acetoxy derivative **4** was deduced in an analogous manner to that described above. The ^{1}H nmr spectrum of **4** showed the presence of two ABX systems, a result that is consistent only with the presence of the acetoxy group at the 5′-position. The possible configurational and conformational isomers for a 5′-acetoxy derivative are shown in Fig. 3. Examination of the ^{1}H nmr spectrum of **4** indicated that the signals for the methine protons appeared as triplets at δ 5.69 ($|J_{AX} + J_{BX}|$ = 6.75 Hz) and δ 6.36 ($|J_{AX} + J_{BX}|$ = 8.25 Hz). Since the signals for the methylene protons are readily assigned to H-3′, H-3″ and H-6′, H-6″, the signals at δ 5.79 and δ 6.36 are assigned to H-5′ and H-2′, respectively, on the basis of the difference in coupling constants between these protons and the corresponding methylene protons. Furthermore, examination of the AB portions of both ABX patterns indicates that all of the coupling constants to H-5′ or H-2′ are small (2.75–4.5 Hz). This suggests a preponderance of a conformation in which both methine protons are equatorially oriented (see **4***a* in Fig. 3); the conclusion is supported by the values of $|J_{2',3'} + J_{2',3''}| = 8.25$ Hz and $|J_{5',6'} + J_{5',6''}| = 6.75$ Hz (2*c*). Compound **4** is assigned, therefore, a preferred conformation in which both the acetoxy group and the purine moiety are axially disposed, and is identified as being *trans*-6-chloro-9-(5-acetoxy-1-oxa-4-thiacyclohexan-2-yl)-9*H*-purine. The assignment is further corroborated by the ^{13}C nmr data for **4** which are presented in Table 2; the chemical shift assignments were made as previously described. Thus, the signals for C-3′ and C-6′ in the spectrum of **4** are shifted upfield by 5.2 ppm and 5.0 ppm, respectively, relative to the corresponding signals in the spectrum of **13**. This result is consistent with the axial orientation of both the acetoxy group and the purine moiety, a situation which should be manifested in a shielding of C-3′ and C-6′, respectively, by virtue of the γ-*gauche* interactions (2, 12). The axial preference of the purine moiety in **4** contrasts with that observed for **13** in which the purine moiety adopts an equatorial orientation in the preferred conformation, but the axial preference of the acetoxy group is consistent with expectations based on knowledge of the anomeric effect in sulfur heterocycles (13–15).

The structures of the acetoxy derivatives **5** and **6**, obtained from the isomeric sulfoxides **2** (3), were deduced as follows. The possible configurational and conformational isomers are shown in Fig. 3. Examination of the ^{1}H nmr spectrum of the less polar (tlc) of the two acetoxy derivatives indicated that the signals for H-3′ and H-5′ overlapped to give a narrow multiplet at δ 5.75 whose width at half-height was 7 Hz. The value of $W_{1/2}$ is indicative of a preponderance of a conformation in which both H-3′ and H-5′ are equatorially oriented. This component is assigned, therefore, the *cis*-stereochemistry (see **5***b* in Fig. 3) and is identified as being *cis*-6-chloro-9-(5-acetoxy-1-oxa-4-thiacyclohexan-3-yl)-9*H*-purine (**5**). The more polar of the two acetoxy compounds is assigned, consequently, the *trans*-stereochemistry. The signal for H-3′ in the ^{1}H nmr spectrum of this component appears at δ 5.79 as a triplet whose width at half-height ($|J_{3',2'} + J_{3',2''}|$) is 4.5 Hz whereas the signal for H-5′ appears at δ 6.19 as a doublet of doublets ($|J_{5',6'} + J_{5',6''}| = 12.6$ Hz). The values of $|J_{AX} + J_{BX}|$ are indicative of a preponderance of a conformation in which the acetoxy group is equatorial and the purine moiety is axial (see **6***b* in Fig. 3) and are consistent, therefore, with the assignment of the *trans*-stereochemistry to this compound. The assignment is further corroborated by the ^{13}C nmr data for this compound. The ^{13}C nmr spectrum shows a signal at δ 49.18 and three signals at δ 71.12, 70.73, and 70.15 for the saturated-ring carbons. The signal at δ 49.18 is assigned to C-3′ by analogy with the chemical shift of C-3′ (δ 49.4) in the spectrum of **14** (2) but the latter group of signals could not be assigned to the respective carbons with certainty. However, it is obvious that the signal for C-2′ appears at virtually the same chemical shift as does the corresponding signal (δ 71.1) in the spectrum of **14**. This is consistent with a preponderant conformation in which the acetoxy group is equatorial since an axial orientation of the 5′-acetoxy substituent would be expected to be manifested in an upfield shift of the C-2′ signal by virtue of the γ-*gauche* effect (2, 12). The more polar of the two acetoxy compounds is identified, therefore, as being *trans*-6-chloro-9-(5-acetoxy-1-oxa-4-thiacyclohexan-3-yl)-9*H*-purine (**6***b*). It is noteworthy that the purine moiety adopts an axial orientation in the preponderant conformations of both **5** and **6**, a preference that is also manifested in the predominant conformation of the parent compound **14**.

Treatment of the acetate **3** with sodium borohydride (3) afforded a mixture of *cis*- and *trans*-6-chloro-9-(3-hydroxy-1-oxa-4-thiacyclohexan-2-yl)-9*H*-purine, **7** and **8**, respectively. The possible configurational and conformational isomers for the 3′-hydroxy derivative are shown in Fig. 3. The elucidation of stereochemistry and preferred conformations of **7** and **8** was effected in the following manner. Examination of the ^{1}H nmr spectrum that was obtained in chloroform-*d* containing a trace of deuterium oxide, at 300 K, revealed the presence of two sets of signals corresponding to the methine hydrogens in **7** and **8**, one set being of greater intensity than the other (3.25:1). The signals attributable to the major isomer appeared as a broadened singlet at δ 4.98 and a doublet at δ 6.28 ($J = 1.2$ Hz) whereas the corresponding signals for the minor isomer appeared as two mutually-coupled doublets at δ 5.34 and δ 5.87 with a coupling constant of 8 Hz. The value of 8 Hz obtained for $|J_{2',3'}|$ in the minor isomer is indicative of a preponderant conformation in which H-2′ and H-3′ are *trans*-diaxially disposed (see **8***b* in Fig. 3). The minor isomer is identified, therefore, as being *trans*-6-chloro-9-(3-hydroxy-1-oxa-4-thiacyclohexan-2-yl)-9*H*-purine (**8**). The major isomer must be, therefore, *cis*-6-chloro-9-(3-hydroxy-1-oxa-4-thiacyclohexan-2-yl)-9*H*-purine (**7**) (the magnitude of $|J_{2',3'}|$ in this isomer is unusually small for J_{ae} coupling). When the ^{1}H nmr spectrum of the mixture of alcohols was obtained in dimethylsulfoxide-d_6 instead of chloroform-*d*, at 300 K, the ratio of the two isomers **7**:**8** was observed to change to a value of 1.3:1, thereby suggesting that equilibration of the two isomers was taking place by way of the intermediate aldehyde. Moreover, the spectrum of the mixture that was obtained in dimethylsulfoxide-d_6 at 340 K indicated the presence of **7** and **8** in a ratio of 2.6:1.

TABLE 3. Carbon-13 chemical-shift data[a] for saturated-ring carbons in 6-chloropurin-9-yl derivatives of hydroxy-substituted 1-oxa-4-thiacyclohexanes

	Carbon			
Compound	C-2′	C-3′	C-5′	C-6′

[a]In ppm downfield from internal TMS in dimethylsulfoxide-d_6.

The carbon-13 nmr data for the saturated-ring carbons in **7** and **8** are presented in Table 3. The ^{13}C nmr spectrum, obtained in dimethylsulfoxide-d_6 at 300 K, showed the presence of two sets of peaks in a ratio of ~1:1. Chemical-shift assignments were facilitated by obtaining the spectrum in a mixture of chloroform-*d* and dimethylsulfoxide-d_6 in which the ratio of **7**:**8** was found to be 2:1. (The compounds were insufficiently soluble in chloroform-*d* alone to permit the recording of the ^{13}C spectrum in this solvent.) The chemical-shift assignments were confirmed by means of gated-decoupling experiments. Inspection of the ^{13}C nmr data for **7** (Table 3) and **13** (Table 2) indicates that the signal for C-5′ in the spectrum of **7** is shifted upfield by 5.1 ppm relative to the corresponding signal in the spectrum of **13**. This is consistent with a preponderant conformation in which the hydroxyl group is axial (see **7***b* in Fig. 3) since a shielding of C-5′ in **7***b* as compared to C-5′ in **13**, by virtue of the γ-*gauche* effect, would then be predicted. The nearly identical chemical shifts of the C-6′ signals in the spectra of **7** and **13** also suggest that the purine moiety is equatorial

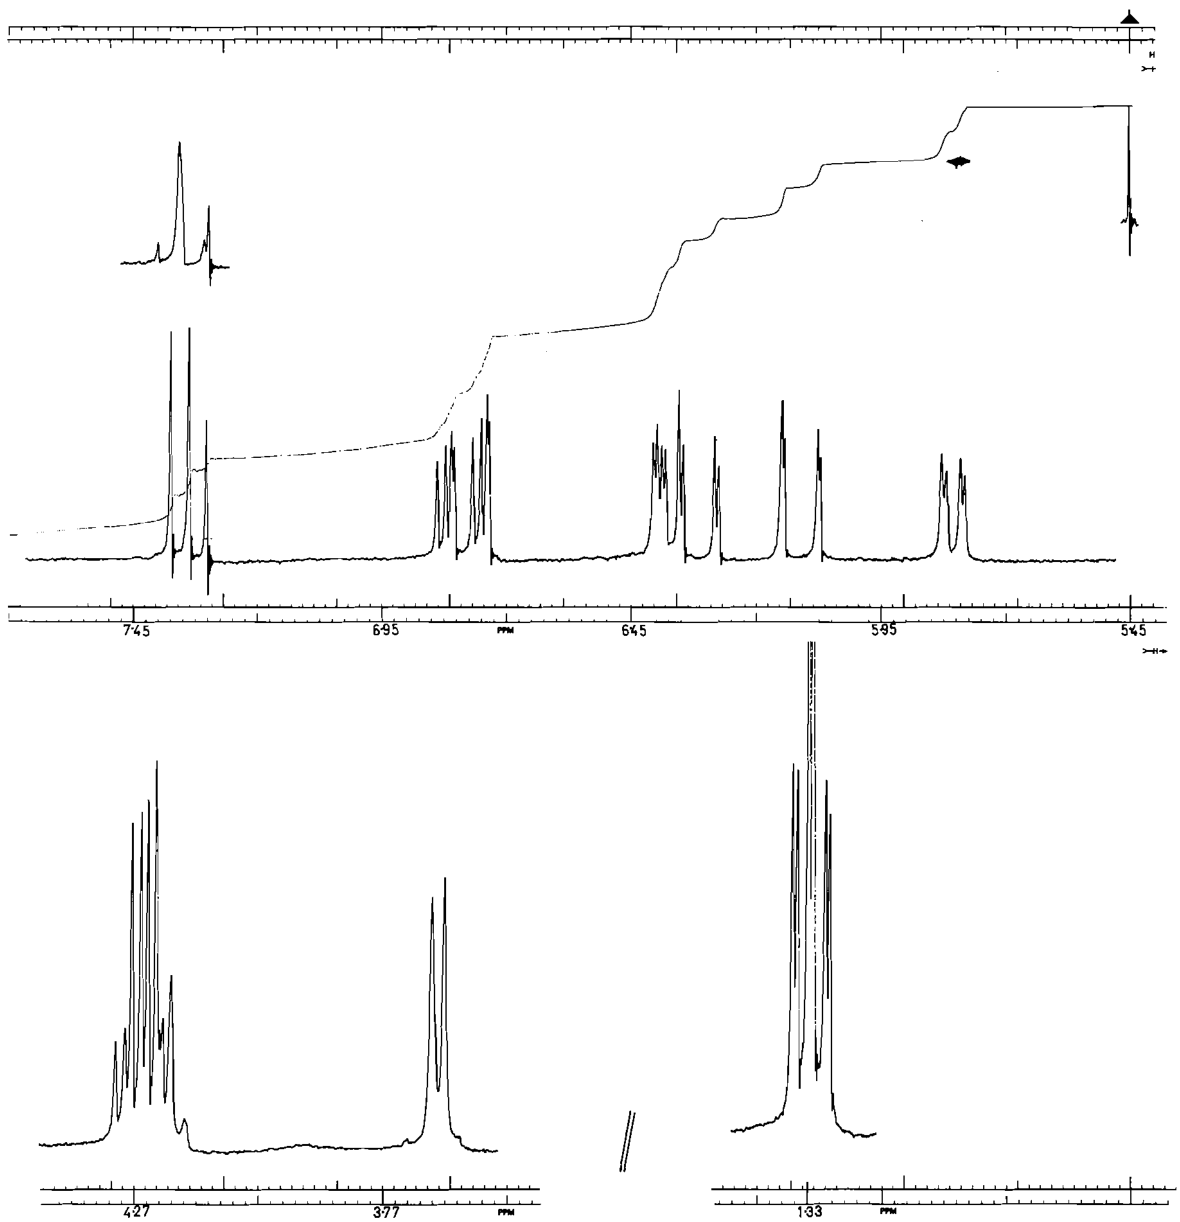

FIG. 4. The ^{1}H nmr spectrum of **12** recorded at 220 MHz in chloroform-*d*.

in the preferred conformation. The ^{13}C nmr data, therefore, support the earlier assignment of *cis*-stereochemistry in the major isomer. Similarly, the ^{13}C nmr data for **8** are also consistent with the assignment of a predominant conformation in which both the hydroxyl group and the purine moiety are equatorially oriented. For instance, the signal for C-6′ in the spectrum of **8** appears at virtually the same chemical shift as the corresponding signal in the spectrum of **13**, thereby suggesting an equatorial orientation of the purine moiety in the preferred conformation. It should be noted, however, that C-5′ in **8** is deshielded by 2.7 ppm relative to C-5′ in **13**. This result remains an anomaly in view of what is known about the γ-*anti* substituent effect in related systems (11, 16). Of particular relevance is the fact that C-5 in 2-methyl-1,4-dioxane-*2a,3e*-diol (in which the 3-OH group is *anti* to C-5) is shielded by 1.8 ppm relative to C-2 in 1,4-dioxane (16).

It is interesting to note that the *cis*-isomer **7** is preferred over the *trans*-isomer **8**. It is possible that this preference is brought about by the manifestation of the reverse anomeric effect which favours the equatorial orientation of the purine moiety, the anomeric effect which favours the axial orientation of the hydroxyl group, and an attractive *gauche* effect within the 1,2-disubstituted ethane-type fragment. Since all three conformational effects (2*b*, *c*) act in such a manner as to stabilize **7***b*, it would be the preferred conformation. However, by use of similar arguments it would also have been predicted that the corresponding acetoxy derivative **3** would exist preferentially in a conformation in which the purine moiety was equatorial and the acetoxy group was axial. As described earlier, exactly the opposite conformational behaviour was observed for **3**. The conformational preference of the *trans*-3′-hydroxy derivative **8** reflects the strong preference of the purine moiety to adopt an equatorial orientation, a preference that overrides the anomeric effect at the hemiacetal centre.

Treatment of the regioisomeric acetate **4** with sodium borohydride (3) afforded a mixture of *cis*- and *trans*-6-chloro-9-(5-

hydroxy-1-oxa-4-thiacyclohexan-2-yl)-9*H*-purine, **9** and **10**, respectively. The possible configurational and conformational isomers for the 5′-hydroxy derivative are shown in Fig. 3. Examination of the [1]H nmr spectrum of the mixture that was obtained in chloroform-*d* at 300 K indicated the presence of only one isomer. Thus, the signal for H-5′ appeared as a poorly resolved multiplet at δ 4.85 ($|J_{5',6'} + J_{5',6''}|$ = 5 Hz) and the signal for H-2′ appeared as a doublet of doublets at δ 6.13 ($|J_{2',3'} + J_{2',3''}|$ = 12.7 Hz). The values of $|J_{AX} + J_{BX}|$ are consistent with the predominance of a conformation in which the purine moiety is equatorial and the hydroxyl group is axial (see **9***b* in Fig. 3). Once again, the conformational preference is consistent with that which would be predicted on the basis of the reverse anomeric effect and the anomeric effect. This isomer is identified, therefore, as being *cis*-6-chloro-9-(5-hydroxy-1-oxa-4-thiacyclohexan-2-yl)-9*H*-purine (**9**). In contrast, the [1]H nmr spectrum of the mixture in dimethylsulfoxide-d_6 containing deuterium oxide, at 300 K, indicated the presence of two isomers, **9** and **10**, in a ratio of 2.7:1. The signal for H-5′ in the minor isomer **10** appeared as a doublet of doublets at δ 4.97 ($|J_{5',6'} + J_{5',6''}|$ = 10.7 Hz) and the signal for H-2′ appeared as a multiplet at 6.18 that was partially obscured by the signal for H-2′ of the *cis*-isomer **9**. The value for $|J_{2',3'} + J_{2',3''}|$ was estimated, consequently, as being approximately 9 Hz. The values of $|J_{AX} + J_{BX}|$ suggest that there is a predominance of the conformation in which both the purine moiety and the hydroxyl group are equatorial (see **10***b* in Fig. 3), although there is a significant contribution to the conformational equilibrium from the alternate conformation **10***a*. Thus, in the case of **10**, the reverse anomeric effect and anomeric effect oppose one another in exerting their influence on the conformational preference. Compound **10** is identified, therefore, as being *trans*-6-chloro-9-(5-hydroxy-1-oxa-4-thiacyclohexan-2-yl)-9*H*-purine. The [1]H nmr spectra in dimethylsulfoxide-d_6 at higher temperatures showed slight changes in the ratio of *cis*- and *trans*-isomers as well as slight changes in the positions of the conformational equilibria of the two isomers.

The carbon-13 nmr data for the isomeric hydroxy derivatives **9**, **10** are presented in Table 3. Comparison of the [13]C nmr data for **9** and for **13** (Table 2) indicates that the C-3′ in **9** experiences a shielding of 6.6 ppm relative to C-3′ in the parent compound **13**. The shielding is attributable to a γ-*gauche* interaction and is consistent, therefore, with the previous assignment of the hydroxyl group being in the axial orientation in the preferred conformation of **9**. The assignment of the conformational behaviour of the *trans*-isomer **10** on the basis of [1]H nmr spectroscopic evidence is further supported by the [13]C nmr data for **10**. For instance, the signal for C-3′ in the spectrum of **10** is shifted upfield by 2.7 ppm relative to the corresponding signal in the spectrum of **13**. The magnitude of the shielding can be attributed to the operation of the γ-*anti* substituent effect of the hydroxyl group in conformation **10***b* (11, 16). For example, examination of the [13]C nmr data for methyl-substituted derivatives of 1,4-dioxacyclohexane-2,3-diols (16) indicates that the γ-*anti* substituent effect of hydroxyl, acting across the ring oxygen atom, is shielding by 1.8 ppm. Should conformation **10***a* exist to an appreciable extent in the conformational equilibrium, there would result also a shielding of C-3′ in **10** relative to that in **13** by virtue of the γ-*gauche* effect. Thus, the overall effect of having a conformational equilibrium which is biased in favour of **10***b* but which contains an appreciable amount of **10***a* should be manifested in a slight shielding of C-3′ in **10** relative to C-3′ in **13**. The shielding of C-6′ in **10** relative to C-6′ in **9** can also be taken as evidence for the presence of a significant amount of **10***a* in the conformational equilibrium, given that **9** exists almost exclusively in conformation **9***b* and assuming that the magnitudes of the γ-*anti* substituent effects in **9***b* and **10***b* are approximately equal.

Since the parent nucleoside analogs **13** and **14** that were used for the elaboration of the substituted compounds, as discussed in the preceding section, were racemic mixtures, it follows that the compounds derived from **13** and **14** will also be mixtures of enantiomers. In the preceding discussion, only one enantiomeric form for each of **1**–**10** has been shown; however, these structures should be viewed as enantiomeric pairs of compounds. It should be noted also that chair conformations have been assumed to be the most stable conformations of the 6-chloropurin-9-yl derivatives described in the preceding sections, although it is recognized that bond-angle and torsional-angle distortion will undoubtedly be present in these compounds and will result, consequently, in some distortion of the six-membered ring.

It is clear from the preceding section that the concomitant use of [1]H nmr and [13]C nmr spectroscopy provides an extremely useful tool for the investigation of stereochemistry and conformation in substituted 1,4-diheterocyclohexanes. In particular, it should be noted that substituent effects on [13]C shieldings in substituted diheterocyclohexanes are at least qualitatively the same as in substituted cyclohexanes, as indicated also by the work of Ayras (16) on substituted 1,4-dioxanes. The use of the γ-*gauche* and γ-*anti* substituent effects as probes of stereochemistry and conformation is especially noteworthy.

The structure of compound **11** was unambiguously assigned by complete assignment of its [1]H nmr spectrum recorded in chloroform-*d* at 220 MHz (3). The values of $|J_{2',3'} + J_{2',3''}|$ (12.6 Hz) and $J_{5'a,6'}$ (11 Hz) leave no doubt that compound **11** exists in a conformation in which both the purine moiety and the hydroxymethyl function adopt equatorial orientations. The (2′*R*,6′*R*) stereochemistry is consistent with retention of configuration at these centres in the course of the reactions (3).

The partial [1]H nmr spectrum of **12** recorded at 220 MHz in chloroform-*d* is shown in Fig. 4. Chemical-shift assignments were readily made by first-order analysis of the spectrum and by matching of signals attributable to mutually-coupled protons; the assignments have been documented previously (3). An interesting feature of the spectrum is the appearance of the H-6 signal of the uracil moiety as a doublet of doublets. There is no doubt about the assignment since decoupling of this signal resulted in collapse of the low field doublet appearing at δ 7.35; the latter signal is assigned to H-5 of the uracil moiety. The coupling of 2 Hz in the signal for H-6 is attributed, therefore, to long-range four-bond coupling interactions between H-4′ and H-6; the signal for H-4′ at δ 6.39 also shows a coupling of 2 Hz. Long-range four-bond coupling interactions between H-8′ and H-6′ ($^4J_{8',6'}$ = 1.1 Hz) and between H-2′ and H-4′ ($^4J_{2',4'}$ = 1.1 Hz) are also observed. The [1]H nmr spectrum further indicates that $J_{2',3'}$ and $J_{7',8'}$ are about 16 Hz; this value is typical for coupling of olefinic protons having an *anti* relationship to one another (17). Compound **12** is identified, therefore, as being the (2*E*,7*E*), (4*R*,6*S*) isomer.

Experimental

All compounds were prepared as described previously (3). Proton magnetic resonance ([1]H nmr) spectra were recorded on a Bruker HX-60 or Varian HR-220 spectrometer. Carbon-13 magnetic resonance ([13]C nmr) spectra were recorded on a Bruker HX-60 spectrometer equipped with a FT60M Fourier transform accessory at 15.09 MHz. Chemical shifts are given in ppm downfield from tetramethylsilane (TMS). The complete nmr spectral data have been previously documented (3).

An X-ray crystallographic analysis of *N*-benzoyl-DL-alanine ethyl dithioester demonstrates that it takes up a *B*-type conformation comparable to that found for *N*-acylglycine dithioesters in the crystalline state. *B*-conformations are characterized by small N—C—C—S(thiol) torsional angles resulting from an N···S(thiol) interaction. In the present case the N—C—C—S torsional angle is −23° and the N···S distance 2.830 Å. A Raman spectroscopic study of a single crystal and a resonance Raman (RR) spectroscopic study of powdered *N*-benzoyl-DL-alanine ethyl dithioester establish the RR signature for the compound in its *B*-form. The RR spectra of the dithioester in CCl_4 and H_2O/CH_3CN, aided by $^{13}C{=}S$ substitution, provide information on the RR signatures of *B, A,* and C_5 type conformers in solution. The *A* and C_5 signatures for the *N*-acylalanine dithioester resemble closely those for an *N*-acylglycine dithioester but the *B* signature is perturbed markedly compared to that of a glycine analog.

R. H. ANGUS, P. R. CAREY, H. LEE, A. C. STORER, and K. I. VARUGHESE. Can. J. Chem. **63**, 2169 (1985).

Une analyse des données cristallographiques obtenues par diffraction des rayons-X sur le dithioester éthylique de la *N*-benzoyl DL-alanine démontre que ce composé existe sous une conformation du type *B* comparable à celle, trouvée à l'état cristallin, des dithioesters de la *N*-acylglycine. Les conformations de type *B* sont caractérisées par de petits angles de torsion N—C—C—S(thiol) qui proviennent d'une interaction N···S(thiol). Dans le cas présent, l'angle de torsion N—C—C—S est égal à −23° et la distance N···S est égale à 2,830 Å. Une étude par spectroscopie Raman sur un cristal unique et une étude par spectroscopie Raman de résonance (RR) sur le dithioester éthylique de la *N*-benzoyl DL-alanine en poudre ont permis d'établir la signature RR du composé sous sa forme *B*. Les spectres RR du dithioester, dans le CCl_4 ainsi que dans un mélange H_2O/CH_3CN, couplés à des substitutions $^{13}C{=}S$ ont permis d'obtenir de l'information sur les signatures RR des conformères des types *B, A* et C_5 en solution. Les signatures des conformations *A* et C_5 du dithioester de la *N*-acylalanine ressemblent beaucoup à celles d'un dithioester de la *N*-acylglycine; toutefois la signature de la conformation *B* diffère passablement de celle de l'analogue de la glycine.

[Traduit par le journal]

Introduction

By reacting thionoesters, of the form $RC({=}O)NHCH_2C({=}S)OCH_3$, with cysteine proteinases such as papain it is possible to generate transient acyl–enzyme intermediates $RC({=}O)NHCH_2({=}S)S$-papain, where the substrate is linked to the enzyme by the thiol sulfur of cysteine 25. These intermediates have an intense electronic absorption band near 315 nm due to the dithioester chromophore that affords the opportunity of obtaining the resonance Raman (RR) spectrum of the dithioester group and the adjacent bonds (1). Thus, we are able to observe the vibrational spectrum of the group undergoing transformation in the active site and, by combining RR and other techniques, arrive at a detailed description of conformational events during enzymolysis.

Interpretation of the RR spectra of the enzyme–substrate intermediates has been greatly facilitated by joint Raman X-ray crystallographic studies on model compounds of the type $RC({=}O)NHCH_2C({=}S)SC_2H_5$, which have led to a set of precise spectra–structure correlations (2,3). It has also been necessary to undertake an analysis of the conformational properties of these dithioesters in solution by Raman, RR, and FTIR spectroscopy (4). Taking the crystallographic and spectroscopic results together, the findings are that in non-hydrogen bonding solvents such as CCl_4 the glycine-based dithioesters exist in a major populational state known as C_5 in which the N—H forms a hydrogen bond to the thiono sulfur and the resultant five-membered ring is essentially planar (Fig. 1). There is a minor population of a state known as conformer *B* in CCl_4 and this is the predominant form in H-bonding solvents such as H_2O. The *B*-form is also shown in Fig. 1 and has the N atom *cis* to the thiol sulfur as a consequence of a N···S interaction. This form is essentially unique to dithio- and thiolesters (5) and is of importance for the dithioacyl enzymes since it is the sole conformational state in native $RC({=}O)NHCH_2C({=}S)S$-papains (6) and other plant cysteine proteinases (7). Returning to the model compounds, there is another conformational state found in hydrogen bonding solvents. This is the *A*-form shown in Fig. 1; it is converted to the C_5 conformer by a 90° rotation about the NH—CH_2 bond, and the N—H group participates in H-bonding to solvent rather than bonding intramolecularly to the thiono sulfur (2,4).

To date, our studies have dealt with substrates and their corresponding model compounds based on glycine derivatives. Glycine is atypical among the amino acids in having a fairly unhindered conformational space (8). Moreover, it has been known for some time from kinetic studies that the reactivity of papain towards substrates based on other amino acid derivatives may vary markedly (9). Thus, it is of obvious importance to explore the conformational properties of non-glycine dithioesters both as model compounds and as enzyme–substrate intermediates. In the present work we show that *N*-benzoyl-DL-alanine ethyl dithioester takes up a conformation in the crystalline state resembling very closely the *B*-conformation that has such importance for glycine dithioesters. In addition, we establish RR spectra – structure correlations for the alanine dithioester.

Experimental

Materials

The D and L mixtures of $PhC({=}O)NHCH(CH_3)C({=}S)SC_2H_5$ and $PhC({=}O)NHCH(CH_3)^{13}C({=}S)SC_2H_5$ were prepared from their re-

[1]NRCC No. 24211.

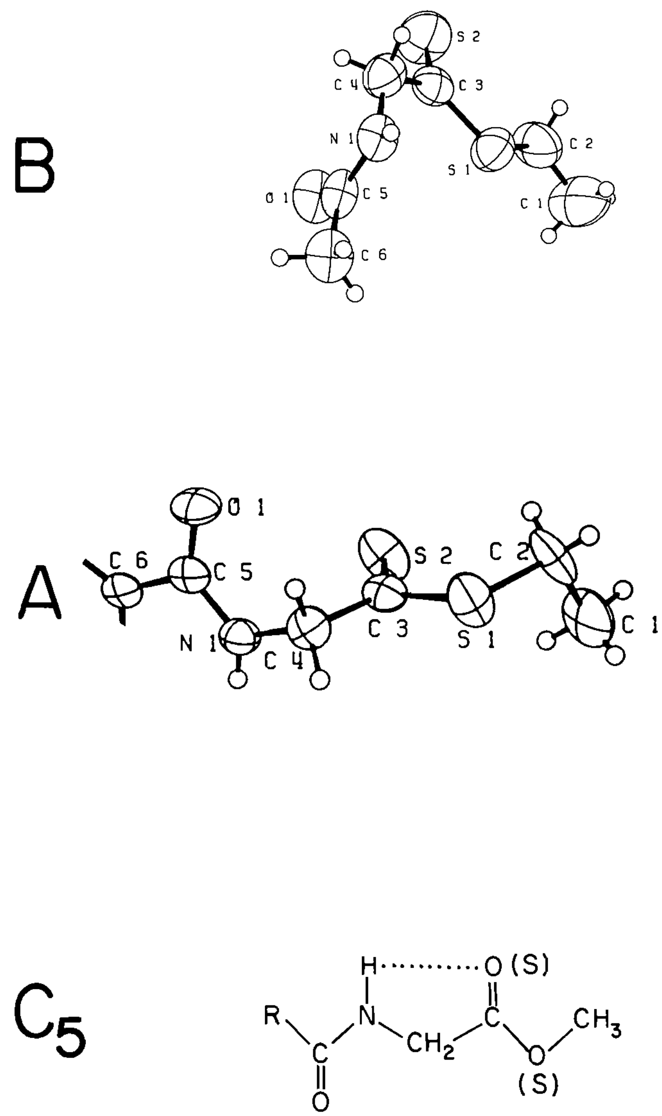

FIG. 1. The three types of conformations taken up by glycine-based dithio esters.

spective nitriles as described by Storer *et al.* (10). The *N*-benzoyl α-aminopropionitriles were obtained by modifying the synthesis of DL-alanine (11). For the unlabelled derivative, acetaldehyde (0.1 equiv.) was reacted with a mixture of ammonium chloride and an ice cold solution of sodium cyanide. (For the [^{13}C] substituted nitrile, sodium [^{13}C] cyanide (99 at.%, Merck, Sharp and Dohme, Canada) was used and the preparation was scaled down five-fold.) The mixture was brought to room temperature and stirred for 4 h. The light yellow mixture was placed in an Erlenmeyer flask, cooled, and titrated with 5 *N* NaOH to pH 10−11. Benzoyl chloride (0.1 equiv.), dissolved in ether (10% solution), was added dropwise while the pH of the mixture was maintained at 10−11. After addition was complete, the mixture was stirred for 30 min at 0°C, then for 1 h at room temperature, while the ether was removed by a stream of air. The nitrile separated out as a slightly yellow solid, which was collected by filtration, washed with cold water, and dried.

The nitrile (1.74 g, 0.01 mol) was added to a 250-mL round bottom flask with 50 mL CH_2Cl_2 and ethanethiol (1.86 g, 0.03 mol) then cooled to 0°C. Dry HCl (gas) was bubbled through this mixture for 20 min. The thioimido ester hydrochloride was precipitated by addition of anhydrous ether. The gummy solid adhered to the sides of the flask so the ethereal solution was decanted and the solid was dried under vacuum in a desiccator, as these salts are extremely hygroscopic.

Pyridine (15 mL), cooled to 0°C and saturated with H_2S (gas), was added to the flask containing the precipitated thioimido ester, then H_2S (gas) was passed through the cooled (0°C), deep yellow solution for no more than 15 min after which the solution was allowed to stand stoppered for 5 min. The cooled solution was then treated with 2 *N* HCl to neutralize the pyridine and produce a pH of approximately 1. The oily mixture was extracted with ether, then the ethereal solution was washed with 1 *N* HCl, H_2O, saturated NaCl solution, then dried over Na_2SO_4. The solution was then filtered and the ether removed by rotary evaporation. The dithioester was purified by passage down a silica gel column using ether/acetonitrile 9:1. The purity of the sample was checked by nmr and elemental analysis. The yield was 0.127 g (5% of theoretical yield based on nitrile), for the unlabelled material.

Crystal data

$C_{12}H_{15}ONS_2$ fw = 253.38
Orthorhombic, $Pca2_1$, a = 9.522 (2), b = 6.587 (1), c = 21.025 (4) Å, z = 4, ρ_c = 1.278 g cm^{-3}, λ (Mo K_α) = 0.7107 Å, μ (Mo K_α) = 3.75 cm^{-1}.

Yellow crystals of *N*-benzoyl-DL-alanine ethyl dithioester were obtained by diffusing hexane into a solution of the compound in ether. The data were measured at room temperature on an Enraf−Nonius CAD-4 diffractometer using a crystal of dimensions 0.70 × 0.40 × 0.15 mm with Zr-filtered Mo K_α radiation. The unit cell dimensions were determined using 22 well-centered reflections in the 2θ range 26−38°. The intensity data were measured to a 2θ limit of 60° by the ω/θ scan mode (Δω = 0.80 + 0.25 tan θ°) with a prescan speed of 3 1/3° per minute and the final scan with a time limit of 60 s. An empirical ϕ absorption correction was applied making use of measurements on two reflections with χ ≃ 90°. A total of 1969 unique reflections were measured of which 1641 had intensities greater than $2\sigma(I)$.

The structure was solved using the computer program MULTAN 80 (12) and refined using a block diagonal least-squares procedure. Weights for individual reflections were assigned from counting statistics. All the hydrogen atoms were located from the difference electron density map and were refined assigning isotropic thermal parameters, while non-hydrogen atoms were refined anisotropically. The scattering factors were taken from "International Tables" (13). All the 1969 unique reflections measured were used in the refinement, the final $R(\Sigma|\Delta F|/\Sigma|F_o|)$ = 0.052, $R(\Sigma w|\Delta F|/\Sigma w|F_o|)$ = 0.046, and the final electron density map was essentially featureless. The shift to σ ratios in the last cycle were all less than 0.1 and $S[\Sigma w\Delta F^2/(m-n)]^{\frac{1}{2}}$ = 1.05

Spectral data

The 647.1-nm excited Raman spectrum of a single crystal of *N*-benzoyl-DL-alanine ethyl dithioester was obtained using a Jarrell−Ash 25-400 spectrometer-based system (14); approximately 50 mW of laser power and a spectral slit of 8 cm^{-1} were used. The 324-nm excited RR spectra of *N*-benzoyl-DL-alanine ethyl dithioester in a powdered form were obtained using a multichannel system described recently (15). The solid material was used to coat the inside of a spinning quartz nmr tube and examined in the backscattering geometry. The RR spectra of *N*-benzoyl-DL-alanine ethyl dithioester in solution were obtained from 1−2 mL of solution contained in a quartz cuvette. The solution was stirred by a small Teflon-coated magnetic stirrer to obviate problems associated with photodecomposition or photo-isomerization (15), and examined in the normal 90° excitation-observation geometry. The RR spectra were obtained using approximately 70 mW of 324-nm Kr^+ excitation and a spectral slit of 12 cm^{-1}.

Results and discussion

The crystal structure of N-*benzoyl-*DL-*alanine ethyl dithioester*

Both the D and L forms of the dithioester occur in the crystal but since the cysteine proteinases exhibit a specificity for the L form of amino acid substrates the discussion will be concerned

[a]The fractional coordinates are multiplied by 10^3.

primarily with the L enantiomer. In the crystal structure the L and D forms are symmetry related. The positional parameters, the torsion angles, etc. reported in this paper are for the L form. The positional and thermal parameters of non-hydrogen atoms and hydrogen atoms in the *N*-benzoyl-L-alanine ethyl dithioester are shown in Tables 1*a* and 1*b*,[3] respectively, and its structure is depicted in Fig. 2. Some relevant torsional angles are given in Table 2 and bond distances and bond angles are given in Fig. 3.

An important finding is that the *N*-benzoyl-DL-alanine ethyl dithioester assumes a *B*-type conformation. The characteristics of a *B* conformer are a small N—C—C—S(thiol) torsional angle resulting from an N···S interaction, and nearly orthogonal amide and ester planes. The N—C(4)—C(3)—S(1) (ψ') and C(6)—N—C(4)—C(3) (ϕ') torsional angles are −23.0° and −84.0°, respectively, and the N···S distance is 2.830 Å.

[3]Tables of observed and calculated structure factors and anisotropic temperature factors are available at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

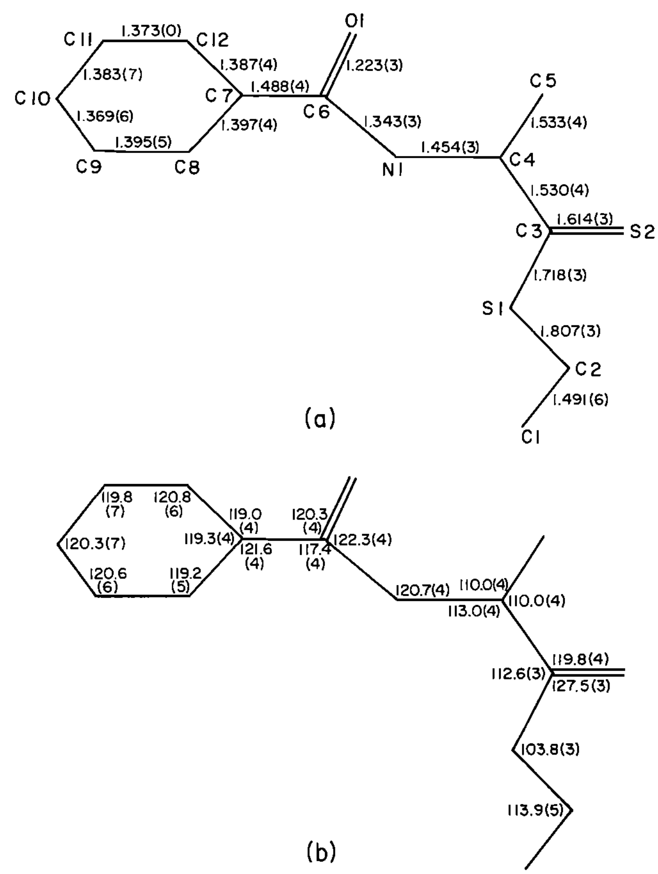

FIG. 3. (*a*) Bond lengths and (*b*) angles for *N*-benzoyl-L-alanine ethyl dithioester.

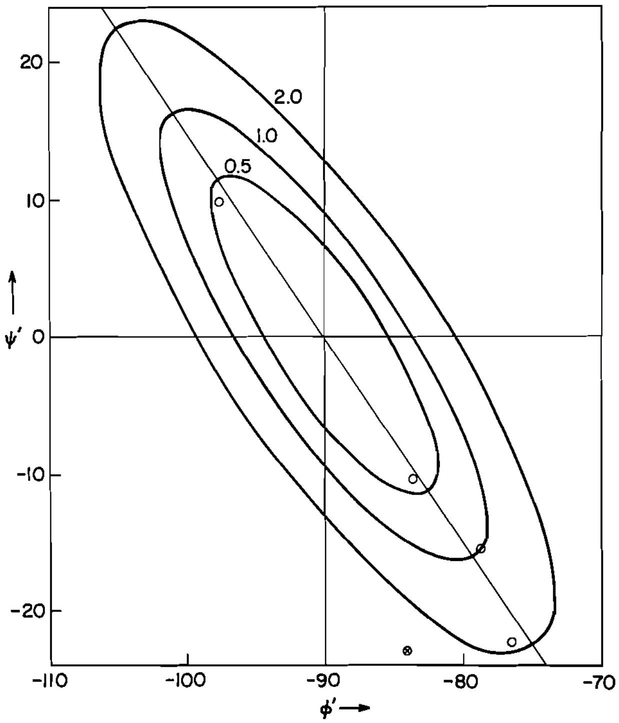

FIG. 4. The θ plot. The contours represent Δθ (deviations from θ minimum = 20.1°) of 0.5°, 1.0°, and 2.0°. The open circles represent the ψ',ϕ' values for four glycine dithioesters. The ψ',ϕ point for *N*-benzoyl-L-alanine ethyl dithioester is marked as ⊗.

B-type conformations are a favored conformational state of dithio- and thiol-esters of glycine but are essentially absent for glycine dioxygen esters (5). The pertinent structural parameters for *N*-benzoyl-DL-alanine ethyl dithioester are compared to those for various glycine dithio- and thiol-esters in Table 3. It is seen that the ψ', ϕ' angles, the N···S distance, and the bond lengths around the dithioester chromophore fall within, or close to, the range delineated for glycine dithioesters. Therefore, alanine dithioesters (and in all likelihood alanine thiolesters) can take up a *B*-type conformation very similar to that found for glycine based dithioesters and thiolesters. This finding is significant in view of the fact that substitution at the α carbon atom greatly restricts the conformational space available to dipeptides and depsipeptides (8).

In a recent publication (3) it was shown that the ϕ', ψ' angles of four glycine dithioesters are correlated, a plot of ϕ' vs. ψ' for the four dithioesters lying close to a straight line. These results demonstrated that there is a strongly preferred line of approach of the nitrogen to the thiol sulfur atom, which is retained over a fairly wide range of values for ϕ' and ψ'. The correlation is illustrated in Fig. 4 which also plots the contours for θ, which is defined as the angle between the N···S direction and the normal to the amide plane at the nitrogen atom (3). On purely geometrical grounds it can be shown that the smallest value of θ possible is about 20.1°, and Fig. 4 demonstrates that the glycine dithioester points all lie close to the θ minimum. For the present structure the ϕ', ψ' point lies slightly off the line defined by the glycine dithioester conformations (Fig. 4). However, the deviation from θ_{min} is less than 3° and clearly the line of approach of N to S (thiol) is very similar in the present alanine case to that found for the glycine dithioesters. This small deviation is most probably due to the steric effect of introducing the β CH_3 group in the alanine case. Further evidence for a strong N···S interaction is found in the N···S distance of 2.830 Å (Table 3). This is the shortest N···S distance found to date, in this class of compound, and should be compared to the sum of the van der Waals radii of 3.35 Å (16).

For *N*-benzoyl-DL-alanine ethyl dithioester the benzene ring is tilted by about 35° from the plane of the carbonyl. The C(1)—C(2) bond is essentially *gauche* with respect to the C(3)—S(1) bond; the torsional angle C(1)—C(2)—S(1)—C(3) is −84.8°. Values close to +80°, −80°, and 180° have been found for this angle in dithio- and thiol-esters and are probably selected by crystal packing forces. The bonds meeting at C(3) and at C(6) are planar and thus there is no evidence for pyramidalization at either atom. As is normal for molecules containing the peptide linkage, there is an intermolecular N—H···O hydrogen bond. The N—H distance is 0.77(3) Å, the N···O distance 2.941(3) Å, and the N—H···O angle 161(5)°.

Resonance Raman signatures for N-*benzoyl*-DL-*alanine ethyl dithioester in its* B *and non-B conformations*

The RR signature for *N*-benzoyl-DL-alanine ethyl dithioester in its *B* form can be obtained by comparing the Raman spectrum of a single crystal of the compound (Fig. 5) with the RR spectrum of the powdered material (Fig. 6). Under the experimental conditions employed in this work, the Raman, or RR, spectrum of the D form is identical to the spectrum of the L form. Thus, the spectral data for the DL mixture may be correlated immediately to the structure of the L form given emphasis here. The Raman spectrum was obtained from the same crystal used for X-ray crystallographic analysis and the conformationally sensitive bands in the RR spectrum at 1091, 683, and 566 cm^{-1} in all likelihood correspond to the bands seen in the Raman spectrum at 1086, 680, and 562 cm^{-1}. The correspondence between the Raman spectrum of the single crystal and the RR spectrum of the powdered material is supported by the results for the $PhC(=O)NHCHCH_3{}^{13}C(=S)SC_2H_5$ compound. The RR results (Fig. 6) indicate that the 1091 cm^{-1} band is a composite feature, the most intense part of which shifts to 1063 cm^{-1}. Similarly the feature at 1086 cm^{-1} in the single crystal spectrum (Fig. 5) is probably made up of more than one band and its major contributor shifts to 1066 cm^{-1} upon $^{13}C{=}S$ substitution (data not shown). The band near 682 cm^{-1} is unshifted in both the Raman and RR spectra upon $^{13}C{=}S$ substitution and the band near 504 cm^{-1} shifts to lower frequency by 4−5 cm^{-1} in both cases. Since the single crystal is known to be in the *B*-form, the correspondence between the Raman and RR spectra establishes that the powdered material is also in the *B* form and that the RR *B*-signature of *N*-benzoyl-DL-alanine ethyl dithioester is that seen in Fig. 6.

The relationship between RR spectral signature and conformations is fairly well understood for glycine-based dithioesters (1−4). This class of molecules in the *B*-form has an intense RR band near 1130 cm^{-1}, designated Band II (10), which has major contributions from $\nu_{C=S}$ and ν_{C-C} (from the C—C(=S) linkage) motions. For the alanine derivative, the 28 cm^{-1} shift seen in the 1091 cm^{-1} band upon $^{13}C{=}S$ substitution (Fig. 6) makes it probable that the 1091 cm^{-1} feature corresponds to Band II for this molecule. The 1169 cm^{-1} feature (Fig. 6) is probably analogous to the highly delocalized mode seen in this region in glycine derivatives (3). RR features are also seen near 1040 and 685 cm^{-1} for both glycine and alanine dithioesters (Figs. 5 and 6, and ref. 3) and it is likely

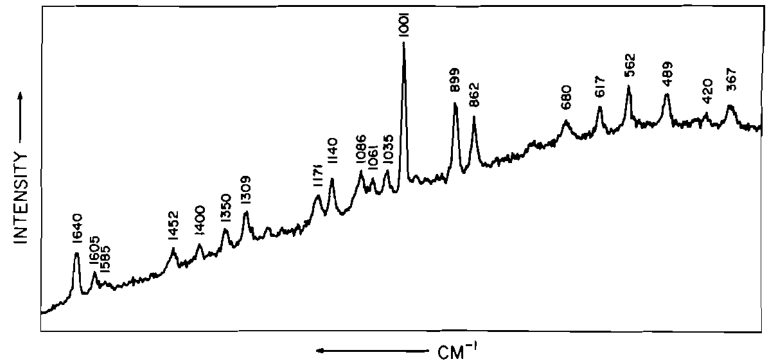

FIG. 5. The 654.1-nm excited Raman spectrum of a single crystal of *N*-benzoyl-DL-alanine ethyl dithioester.

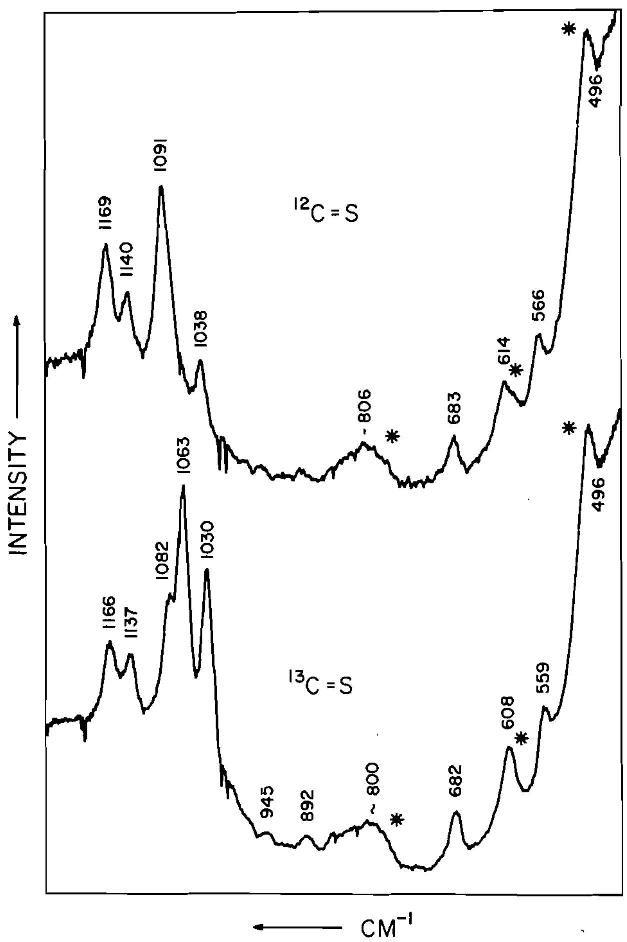

FIG. 6. Resonance Raman spectra of powdered *N*-benzoyl-DL-alanine ethyl dithioester. The quartz of the sample tube makes a contribution in the regions marked with an asterisk.

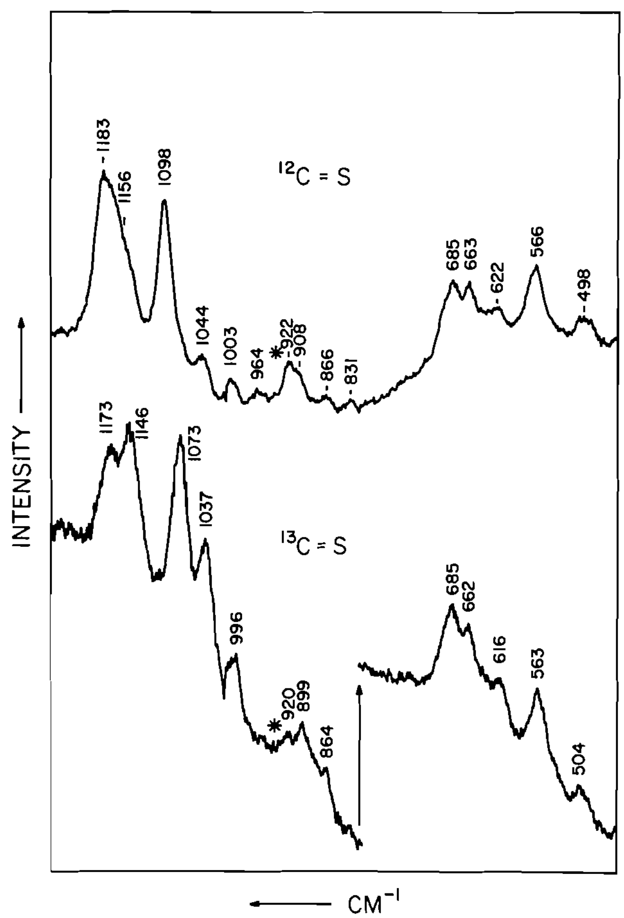

FIG. 7. Resonance Raman spectra (324-nm excitation) of ~2 × 10^{-4} *M* *N*-benzoyl-DL-alanine ethyl dithioester in CH_3CN/H_2O (1:200 v/v). The feature marked with an asterisk is due to CH_3CN.

that the latter band has a major contribution from ν_{S-C} (from the S—CH_2 bond) in both cases. The RR peak near 565 cm^{-1} (Figs. 5, 6) probably corresponds to the conformationally sensitive mode seen near 600 cm^{-1} for glycine dithioesters (4), neither feature being very sensitive to $^{13}C{=}S$ substitution. Thus, both the conformationally sensitive features, one in the 1100 and the other in the 600 cm^{-1} region, appear at approximately 30 cm^{-1} lower in the alanine case. Since the crystallographic results indicate that bond lengths are very similar in the glycine and alanine derivatives, it is unlikely that the frequency differences are due to a change in bond order. Rather, it is likely that the lowering of the frequencies is brought about by the change in the potential energy distribution as a consequence of the insertion of the methyl group at the α carbon. In this regard, it is noteworthy that the most intense features in the RR spectra of ethyl dithiotrimethyl acetate occur at atypically low frequencies for a dialkyl dithioester, namely at 1108 and 573 cm^{-1} (17).

Figure 7 demonstrates that the *B*-signature, and thus the conformation, is similar in H_2O/CH_3CN solution to that in the solid phase. The conformationally sensitive *B*-markers occur at 1098 and 566 cm^{-1} in CH_3CN/H_2O, close to the 1091 and 566 cm^{-1} values found for the solid. Moreover, the 25 cm^{-1} shift

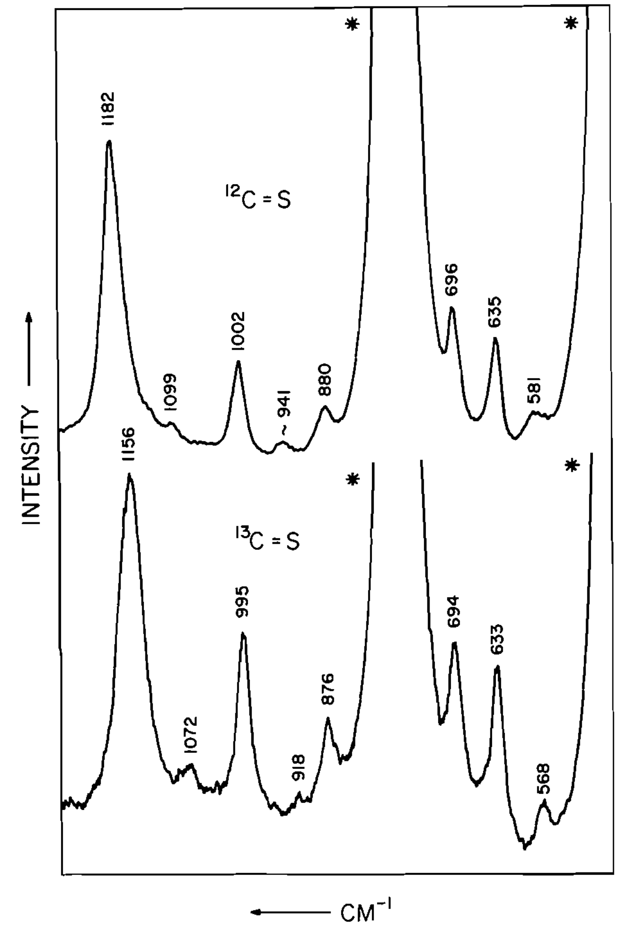

FIG. 8. Resonance Raman spectra (324-nm excitation) of ~8 × 10^{-4} *M* *N*-benzoyl-DL-alanine ethyl dithioester in CCl_4. Features marked with an asterisk are due to CCl_4.

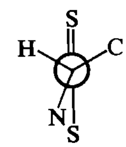
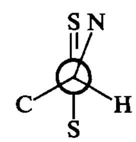
in the 1098 cm^{-1} feature and the 3 cm^{-1} shifts in the 563 cm^{-1} feature upon $^{13}C{=}S$ substitution (Fig. 7) mimic closely the behaviour of the solid material. Additionally, there are several bands seen in the solution RR spectra which are not present in the spectrum of the solid. In particular, the intense band in the 1175 cm^{-1} region and the less intense feature occurring at 663 cm^{-1} are characteristic *A* conformer markers in the case of glycine-based dithioesters. Although the band profile in the 1175 cm^{-1} region is complex due to the overlap of *A* and *B* conformer bands, it is probable that the "centre of gravity" of the composite feature moves to lower wavenumbers upon $^{13}C{=}S$ substitution due to a substantial shift in the "*A* peak" near 1180 cm^{-1}. (There is further evidence for this in the RR spectrum of *N*(β-phenylpropionyl)alanine ethyl dithioester, unpublished work, this laboratory.) For glycine based dithioesters the predominant species in non-hydrogen bonding solvents such as CCl_4 is the C_5 conformer (Fig. 1). The RR spectra of *N*-benzoyl-DL-alanine ethyl dithioester and its $^{13}C{=}S$ analog in CCl_4 (Fig. 8) are very similar to those of a glycine dithioester in a C_5 type conformer. The 1182 and 635 cm^{-1} features are C_5 conformer markers and the similarity of *A* and C_5 marker bands in the 1175 cm^{-1} region adds weight to the argument for assigning a band near 1175 cm^{-1} in the spectra from H_2O/CH_3CN solution to an *A* conformer. The band near 1000 cm^{-1} seen in Fig. 8 is not present in the spectra of glycine derivatives in CCl_4 and it is suggested that it has some ν_{C-C} character from the C_α—CH_3 bond.

It follows from the above discussion that vibrational coupling involving the C_α—CH_3 group modifies the RR signature of the *B* conformer, but not the C_5 (and probably not the A) form. Thus, considering a Newman projection along C4—C3 the potential energy distribution is modified for



conformer *B*

but not for



conformer C_5

One outcome of the present work will be that the characteristic signatures for C_5 (and *A*) and *B* type conformers of the alanine dithioester established here can be used in future investigations of acyl-papains in which the alanine moiety is bound to cysteine-25 in papain's active site.

Structure and nuclear magnetic resonance spectra of 6-bromo-3,3′,4′,5,7-penta-O-methylcatechin

F. W. B. EINSTEIN,[1] E. KIEHLMANN,[1] AND E. K. WOLOWIDNYK
Department of Chemistry, Simon Fraser University, Burnaby, B.C., Canada V5A 1S6

Received September 12, 1984

F. W. B. EINSTEIN, E. KIEHLMANN, and E. K. WOLOWIDNYK. Can. J. Chem. **63**, 2176 (1985).

The title compound has been synthesized by selective debromination of 6,8-dibromocatechin and indirect methylation of the resulting 6-bromocatechin via its pentaacetate. The structure of $C_{20}H_{23}BrO_6$ has been determined by X-ray crystallography. The compound crystallizes in the space group $P1$ with $a = 9.589(3)$ Å, $b = 11.576(3)$ Å, $c = 11.326(3)$ Å, $\alpha = 118.80(3)°$, $\beta = 93.23(3)°$, $\gamma = 111.44(3)°$, $\rho_c = 1.481$ g cm^{-3}, and $Z = 2$. Intensities were measured for 2584 independent reflections ($2\theta < 45°$) of which 2213 were observed ($I > 3.0\sigma(I)$) and used in subsequent refinement (final R values were $R = 0.0268$ and $R_w = 0.0344$). Crystallographic and pmr data confirm the position of the bromine atom at C-6, the *trans*-diaxial arrangement of H-2/H-3 and the quasi-equatorial orientation of the 3,4-dimethoxyphenyl group (ring B). The two heterocyclic ring conformations are consistent with the expected flexibility of the molecule.

F. W. B. EINSTEIN, E. KIEHLMANN et E. K. WOLOWIDNYK. Can. J. Chem. **63**, 2176 (1985).

On a synthétisé le composé mentionné dans le titre par une débromation de la dibromo-6,8 catéchine et par une méthylation indirecte de la bromo-6 catéchine qui en résulte, via son pentaacétate. On a déterminé la structure du composé $C_{20}H_{23}BrO_6$ par diffraction des rayons x. Le composé cristallise dans le groupe d'espace $P1$, avec $a = 9{,}589(3)$ Å, $b = 11{,}576(3)$ Å, $c = 11{,}326(3)$ Å, $\alpha = 118{,}80(3)°$, $\beta = 93{,}23(3)°$, $\gamma = 111{,}44(3)°$, $\rho_c = 1{,}481$ g cm^{-3} et $Z = 2$. On a mesuré les intensités pour 2584 réflexions indépendantes ($2\theta < 45°$) desquelles 2213 ont été observées ($I > 3\sigma(I)$) et utilisées pour l'affinement jusqu'à des valeurs finales de $R = 0{,}0268$ et $R_w = 0{,}0344$. Les données cristallographiques et de rmn du ^{1}H confirment la position de l'atome de brome en C-6, l'arrangement *trans*-diaxial des H-2/H-3 et l'orientation quasi-équatoriale du groupement diméthoxy-3,4 phényle (cycle B). Les conformations des deux hétérocycles sont en accord avec la flexibilité attendue de la molécule.

Introduction

The regiochemistry of electrophilic substitution of the phloroglucinol ring (ring A) of flavan-3,5,7-triols continues to attract attention in view of its importance in determining the structure and conformations of condensed tannins. The first halogenations of catechin derivatives were reported by Liebermann and Tauchert (1) who obtained monochloro- and monobromocatechin pentaacetates from catechin pentaacetate and molecular halogen in glacial acetic acid, and by Kostanecki and co-workers (2) and Freudenberg and co-workers (3) who halogenated methylated catechins by the same procedure. Weinges and co-workers (4) claimed in 1968 that electrophilic substitution occurs preferentially at C-8; however, the techniques of structure determination available at that time did not permit a clear distinction between two regio-isomeric monosubstitution products. It was not until 1977 that the configuration of 8-bromo-tetra-O-methylcatechin was proven by X-ray structure analysis (5), the pmr parameters of a series of chemically correlated 8-substituted catechins were recorded and the first 6-bromo derivative was synthesized by partial debromination of the corresponding 6,8-dibromo compound (6), as shown in route *a* of reaction [1]

*B_{eq} is the arithmetic mean of the principal axes of the thermal ellipsoid.

In this reaction, lithiation was postulated to occur regioselectively at the sterically less hindered C-8 position, based on the measured pmr parameters of **1**, though Weinges, in a related study (7), had claimed lithiation at C-6 of 6,8-dibromopenta-*O*-methylcatechin under comparable conditions (reaction [1], route *b*). To resolve this discrepancy, rule out epimerization as competing reaction and to obtain an authentic sample of a 6-substituted catechin for chemical and spectral correlation, we decided to prepare 6-bromopenta-*O*-methylcatechin by a new route and determine its structure by X-ray diffraction.

Discussion

6-Bromocatechin was synthesized by regioselective debromination of 6,8-dibromocatechin as described in the literature (10). Although direct pentamethylation with methyl iodide and silver oxide (11) is possible, we chose Freudenberg's acetylation–methylation sequence (12) in order to compare the pmr parameters of the resulting intermediates with published literature values. In the event, we found reasonable agreement for 6-bromocatechin pentaacetate and excellent agreement of the chemical shifts and coupling constants reported for 6-bromotetra-*O*-methylcatechin (13). Since the latter compound has been previously prepared under much milder reaction conditions, i.e., methylation of 6-bromocatechin with diazomethane (13) and catalytic hydrogenolysis of the corresponding 3-*O*-benzyl ether (6*b*), our results demonstrate that epimerization is not a significant side reaction in the conversion of 6-bromocatechin pentaacetate to 6-bromo-tetra-*O*-methylcatechin with dimethyl sulfate and strong base. This procedure may, therefore, be used to derivatize flavanoids which give low yields and/or mixtures of partially methylated products with diazomethane or dimethyl sulfate/potassium carbonate. 6-Bromo-3′,4′,5(or 7)-tri-*O*-methyl-7(or 5)-*O*-acetylcatechin was identified as byproduct.

While the major product of partial debromination of 3-*O*-benzyl-6,8-dibromo-3′,4′,5,7-tetra-*O*-methylcatechin with *n*-butyl lithium, followed by protonation of the lithiated intermediate (reaction [1], route *a*) and chromatographic purification (6), is indeed 3-*O*-benzyl-6-bromo-3′,4′,5,7-tetra-*O*-methylcatechin as evidenced by the identity (melting point, pmr) of its hydrogenolysis product with the 6-bromotetra-*O*-methylcatechin prepared independently by the afore-mentioned route, the 8-bromo isomer is also formed but retained longer on the chromatography column. Thus, the isolation of 6-deutero-8-bromopenta-*O*-methylcatechin (**2**) from the partial lithiation and deuteration of 6,8-dibromopenta-*O*-methylcatechin (reaction [1], route *b*) by Weinges *et al.* (7) appears to be simply a consequence of its lower solubility in ethanol (relative to the 6-bromo isomer). It may, therefore, be concluded that the 6- and 8-position of alkylated 6,8-dibromocatechins do not differ significantly in their reactivity toward *n*-butyl lithium. Our finding that catechin pentaacetate undergoes predominantly 6-bromination provides further proof that steric accessibility (favoring C-8 over C-6) is not the only factor determining the orientation in substitution reactions of ring A of catechin derivatives.

Methylation of the 3-hydroxy group was achieved by Purdie's method (11), thus completing the synthesis of this new compound (reaction [2]).

Detailed analysis of the pmr spectrum (in $CDCl_3$) of 6-bromopenta-*O*-methylcatechin (**3**), including computer simulation, permitted for the first time the assignment of all resonances to specific protons with the exception of the two methoxy peaks of ring B. The heterocyclic ring protons absorb at 4.892 (H-2), 3.689 (H-3), 3.051 (H-4 equatorial) and 2.770 (H-4 axial) ppm, with coupling constants of 7.2 (J_{23}), 5.0 (J_{34e}), 7.7 (J_{34a}), and 16.3 Hz (J_{44}). The large values for J_{23} and J_{34a} are indicative of *trans*-diaxial arrangements in a half-chair conformation. Decoupling experiments showed that H-2 is long-range coupled to H-4a (J = 0.4 Hz) and H-6′ (J = 0.6 Hz), and that both H-4a and H-4e are weakly coupled to H-8 (line broadening). The aromatic protons of ring B resonate at 6.895 (H-2′), 6.876 (H-5′), and 6.941 ppm (H-6′), with coupling constants of 2.0 ($J_{2'6'}$) and 8.2 Hz ($J_{5'6'}$); the line widths of the H-2′ and H-5′ signals indicate weak *para* coupling. Irradiation of H-8 (δ 6.379 ppm) leads to NOE enhancement of the singlet at 3.828 ppm which can, therefore, be assigned to the methoxy group at C-7 (14). Line shape analysis reveals that of the five methoxy peaks only three are broadened due to long-range spin coupling to the respective *ortho*-hydrogens (J approx. 0.2 Hz) thus permitting their assignment to MeO-7 (3.828 ppm) and MeO-3′,4′ (3.887 and 3.875 ppm) and the assignment of the singlets at 3.817 and 3.251 ppm to MeO-5 and MeO-3, respectively.

The unit cell contains two molecules which differ in the conformation of the heterocyclic ring.[2] While C-2 is above and C-3 below the plane of ring A in both molecules, the heavy atoms attached at these two positions (C-11 at C-2 and O at C-3) are located above this plane in molecule B ("sofa") and below in molecule A ("half-chair"), indicating a high degree of conformational flexibility (see Tables 4 and 5) (Fig. 1). The dihedral angles measured for the "sofa" conformation are very close to the values reported in the literature (5) for 8-bromo-tetra-*O*-methylcatechin. The O/C-2/C-3/C-4 dihedral angle of 60° shows the *trans*-diaxial arrangement of H-2 and H-3 and the quasi-equatorial position of ring B in both molecules.

[2]The complete set of data can be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

Experimental

Mass spectra were recorded on an HP-5985 quadrupole instrument, nmr spectra on a Bruker spectrometer (400 MHz); chemical shifts (in $CDCl_3$) are reported in ppm downfield from TMS.

6-Bromocatechin was prepared as described in the literature (10) and acetylated with acetic anhydride and pyridine (13). The pentaacetate (290 mg), mp 146–149°C (lit. (13) 149–151°C) was dissolved in methanol (1.5 mL) and methylated with dimethyl sulphate (0.70 mL) and 50% aqueous KOH (added dropwise over a 1-h period) according to Freudenberg's procedure (12). The usual workup gave a mixture (133 mg) containing 6-bromotetra-*O*-methylcatechin (**1**) as major product, with melting point (126–128°C) and pmr spectrum of a purified sample identical to the values reported in the literature (6, 13), and 6-bromo-3′,4′,5(or 7)-tri-*O*-methyl-7(or 5)-*O*-acetylcatechin as minor product, identified by its pmr parameters: δ 6.980/6.936/6.894 (3H, dd/d/d, J = 2.0 and 8.2 Hz, H-2′/5′/6′), 6.454 (s, H-8), 4.653 (d, J = 8.6 Hz, H-2), 4.06 (m, H-3), 3.887/3.821 (s, 9H, 3 × OMe), 2.97/2.62 (m, 2H, H-4), and 2.360 (s, 3H, OAc).

Exhaustive methylation (11) of the mixture (42 mg) in DMF (0.40 mL) with silver oxide (50 mg) and methyl iodide (0.16 mL, added in four portions over a period of six days) gave the title compound in 93%

Structure determination

Crystal data fw = 439.14

$C_{20}H_{23}BrO_6$

Triclinic $P1$, a = 9.589(3) Å, b = 11.576(3) Å, c = 11.326(3) Å, α = 118.80(3)°, β = 93.23(3)°, γ = 111.44(3)°, V = 982.8 Å^3, ρ_c = 1.481 g cm^{-3}, Z = 2, μ = 20.998 cm^{-1}, γ (MoKα_1) = 0.70930 Å, F(000) = 451.94.

A colourless rectangular shaped crystal (0.28 × 0.22 × 0.40 mm) was mounted on a Nonius CAD4F diffractometer with a graphite monochromator. Cell dimensions were determined using 25 independent reflections (2θ = 17−31°). The take-off angle was 2.9° and a symmetrical θ−2θ scan of (1.3 + 0.692 tan θ)° was used. Intensity data were collected in the 2θ ≤ 45° region at a variable speed (minimum 2°θ min^{-1}). The intensities of two standards were measured every 100 reflections and they were used to scale the data (±3.5%). Amongst 2584 independent reflections, 2213 were observed ($I > 3.0\sigma(I)$), and the structure analysis is based on them. Analytical absorption corrections were applied by the method of Tompa (τ = 0.524−0.659) (8*a*).

Conventional Patterson and Fourier methods were used to solve the structure. Refinement by full-matrix least-squares proceeded slowly. The chirality of the molecule was confirmed prior to inclusion of the hydrogen atoms and anisotropic refinement of the lighter atoms. Several cycles of refinement, not including anomalous scattering, were followed by two independent refinements (for each band), the difference in results being R = 0.0617, R_w = 0.0685 and GOF = 9.53 for the correct (indicated) model and R = 0.0629, R_w = 0.0703 and GOF = 9.78 for the alternative. $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$, $R_w = [\Sigma_w(|F_o| - |F_c|)^2/\Sigma_w|F_o|^2]^{1/2}$, and GOF $= (\Sigma_w(|F_o| - |F_c|)^2/(N_{obs} - N_{var}))^{1/2}$. Hydrogen atoms were mostly located from electron density difference maps and in all cases recalculated with a C—H distance of 0.95 Å. The temperature factors assigned were 7.11 Å^2 for methyl hydrogen atoms and 4.74 Å^2 for the remainder.

Final full-matrix least-squares refinement was carried out for all non-hydrogen atoms (anisotropic temperature factors). The final agreement was R = 0.0268 and R_w = 0.034 and GOF = 1.48 for 484 variables. A weighting scheme of the form $w = 1/(\sigma^2(F_o) + kF_o^2)$ was applied (where k = 0.0004) and did not show any systematic trends as a function of $|F_o|$, sin θ/λ or h, k, l. The final difference map had, as its only major feature, six peaks and troughs (max. 0.38(5), −0.22(5) e/Å^3) around the bromine atoms.

The atomic scattering factors, including anomalous scattering, were taken from ref. 9. The computer programs used are those from ref. 8. Final coordinates are listed in Table 1, and interatomic distances and angles are listed in Tables 2 and 3.

A vanadium-51 nuclear magnetic resonance investigation of vanadate oxyanions in a lyotropic liquid crystalline bilayer system

ALAN S. TRACEY[1] AND KEITH RADLEY

Department of Chemistry, Simon Fraser University, Burnaby, B.C., Canada V5A 1S6

Received August 7, 1984

ALAN S. TRACEY and KEITH RADLEY. Can. J. Chem. **63**, 2181 (1985).

The vanadate ion VO_4H^{2-} and two of its polymeric forms contained in mixed lyotropic mesophase prepared from potassium dodecanoate/*n*-alkyltrimethylammonium bromide in water have been investigated by ^{51}V nuclear magnetic resonance spectroscopy. The results indicate that the tetrahedral ion interacts with the micellar surface through the hydrating water associated with this ion. The ion undergoes strong interactions with the carboxylate headgroup of the dodecanoate as well as with the headgroup of the alkyltrimethylammonium detergent, which of course is of opposite charge. The other two species investigated have previously been assigned by various workers to $V_2O_7^{4-}$ and its cyclic dimer $V_4O_{12}^{4-}$. The results obtained here are not consistent with those assignments but rather with more symmetrical compounds such as the tetrahedral uncharged molecule V_4O_{10} and a higher analogue of this, respectively. The nmr spectra from these latter species show that they undergo, at best, extremely weak interactions with the cationic surface but strong interactions with an anionic one. The behaviour of the quadrupole splittings observed is consistent with specific interactions to the carboxylate moiety. The observation of an induced chemical shift separation between vanadium resonances from the same highly symmetric species confirms that binding of this compound is very strong.

ALAN S. TRACEY et KEITH RADLEY. Can. J. Chem. **63**, 2181 (1985).

Faisant appel à la rmn du ^{51}V, on a étudié l'ion vanadate VO_4H^{2-} et deux de ses formes polymériques contenus dans une mésophase lyotrope préparée à partir de dodecanoate de potassium/bromure de *n*-alkyltriméthylammonium dans de l'eau. Les résultats indiquent que l'ion tétraédrique interagit avec la surface micellaire par le biais de l'eau hydratante qui est associée avec cet ion. L'ion subit de fortes interactions du groupe carboxylate du dodécanoate de même que du groupe alkyltriméthylammonium du détergent qui est de charge opposée. Pour les deux autres espèces étudiées, divers auteurs leurs avaient antérieurement attribué les structures suivantes: $V_2O_7^{4-}$ et son dimère cyclique $V_4O_{12}^{4-}$. Les résultats obtenus dans notre travail ne sont pas en accord avec ces attributions; ils favorisent plutôt des structures plus symétriques comme celles d'une molécule tétraédrique ne portant pas de charge, V_4O_{10}, ainsi que celle d'un de ses analogues supérieurs. Les spectres rmn de ces espèces montrent que, dans les meilleures conditions, ils ne subissent que de faibles interactions avec la surface cationique alors qu'ils subissent de fortes interactions avec la surface anionique. Le comportement observé pour les couplages quadrupolaires est en accord avec les interactions spécifiques de la portion carboxylate. La présence d'une séparation induite par le déplacement chimique, entre les diverses résonances du vanadium des mêmes espèces hautement symétriques, confirme que la coordination de ce composé est très forte.

Introduction

The oxyanions of vanadium (V) display a complex chemistry in aqueous solution, forming an extensive array of anionic forms varying from the monomeric VO_4^{3-} to the polymeric decavanadate $V_{10}O_{28}^{6-}$. These ions have been investigated by ^{51}V nuclear magnetic resonance (nmr) spectroscopic techniques and structures have been assigned to most of the observed resonances (1−6).

Vanadate oxyanions are of great importance to the life processes of biological systems, vanadium apparently being an essential nutrient which appears to have its major effect on the action of enzymes (7). However, its function is not well understood.

In view of both the intrinsic interest in vanadate anions themselves and of their importance in living systems, it was decided to investigate the behaviour of these ions in the liquid crystalline bilayer system prepared from potassium dodecanoate/*n*-alkyltrimethylammonium bromide combined in various proportions in D_2O. This system is particularly useful since the charge on the bilayer surface can be varied as desired. Details of ion binding interactions not otherwise readily available can be obtained via the nuclear quadrupole splitting (8, 9).

Vanadium-51 is a spin 7/2 nucleus and therefore has an electric nuclear quadrupole moment. As a consequence of the quadrupole moment, ^{51}V provides nmr spectra characterized by a chemical shift and a quadrupole splitting when contained in an anisotropic solvent. The quadrupole splitting, $\Delta\nu$, is dependent on the partial alignment of the quadrupolar nucleus with respect to the applied magnetic field of the nmr spectrometer, so that eq. [1] is obtained, where Q_v is the quadrupole coupling constant for ^{51}V in the chemical species of interest and

$$[1] \quad \Delta\nu = \frac{Q_v}{2I(2I-1)}(3S'_{zz} + \eta(S'_{xx} - S'_{yy}))$$

I is the nuclear spin (10). η is a measure of the asymmetry in Q_v and this term is not important for the highly symmetrical species investigated here. The various S'_{ii} are order parameters describing the partial alignment of the molecular fixed electric field gradients, which alignment gives rise to the quadrupole splitting. The S'_{ii} can be written in terms of a molecular based coordinate system but this transformation is not necessary for this study.

Quadrupole splittings from molecular or ionic species with tetrahedral or higher symmetry can only arise by distorting the highly symmetric shape to lower symmetry. Specific interactions (11, 12) including those resulting from ion binding (11) can cause distortions, therefore giving rise to such splittings. If the molecule being investigated has symmetry lower than tetrahedral, the forces within the liquid crystal will impose a partial alignment and quadrupole splittings will be obtained. The imposition of alignment may be taken to represent the fact that the three spatial coordinate axes are not equivalent. The

liquid crystalline materials used here have a unique axis, the optic axis.

At the vanadate concentration and pH of the solutions investigated here three species are observable. The two major components correspond in chemical shift to those ions assigned to VO_4H^{2-} and $V_2O_7^{4-}$ while the minor component corresponds to $V_4O_{12}^{4-}$ (3–5). VO_4H^{2-} is the monoprotonated derivative of the tetrahedral ion VO_4^{3-} while $V_2O_7^{4-}$ and $V_4O_{12}^{4-}$ are the dimer and tetramer of this ion, the vanadium atoms being linked through oxygen.

Experimental

The liquid crystalline materials used in this study have been described elsewhere and the procedure used here differs little from that previously reported (8, 9, 13). The compositions for the various mesophases studied are given in Table 1. ^{51}V and ^{17}O nmr spectra were obtained at 30°C from a 400-MHz broadband nmr spectrometer operating unlocked in the FT mode at ambient temperature.

The assignment of ^{51}V resonances in the liquid crystal spectra was carried out by comparison of those spectra to spectra from aqueous solutions of varying composition and pH. The relevant spectra were distinguished only by minor differences from those given in ref. 4. No significant chemical shift differences between isotropic and anisotropic spectra were observed.

Spectra were also obtained from solutions similar to those of the bottom entry of Table 1, except that decanol was not included in the preparation so that the solution was isotropic. The two major ^{51}V signals were studied as a function of vanadate concentration.

A solution similar to the top entry of Table 1 was prepared using ^{17}O enriched H_2O (15 at.% ^{17}O) but with no decanol, so that the solution was isotropic. Several ^{51}V and ^{17}O spectra were obtained and carefully integrated. The requisite quantity of decanol was then added to the sample so as to form the nematic material. Further ^{17}O and a ^{51}V spectrum were obtained. ^{17}O assignments were taken from ref. 4.

Vanadium chemical shifts are reported relative to $VOCl_3$ prepared as an external reference, while oxygen shifts are relative to the ^{17}O of the water.

Results and discussion

The results of this study are summarized in Table 1. Figure 1 shows the various vanadium spectra obtained on proceeding through the series of mesophases starting with 100% anionic amphiphile (potassium dodecanoate) to 100% cationic amphiphile (tetradecyltrimethylammonium bromide). There are various puzzling features of these spectra which must be explained.

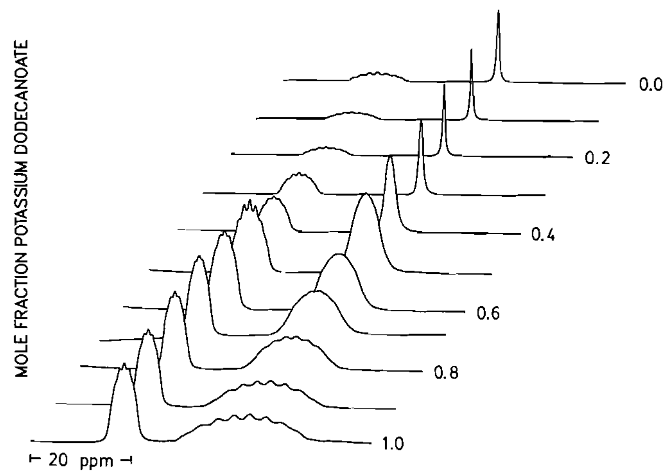

FIG. 1. The ^{51}V nmr spectra obtained from the vanadate species as the mole fraction, X, of anionic detergent in total detergent was varied from $X = 0$ to $X = 1$.

Turning first to the quadrupole splittings for Na^+ and D_2O contained in the various samples (Table 1), it is observed that the values are typical for these materials (8, 9, 13). Some minor problems were encountered with the formation of 50 and 60 mol% phases, as seen in Fig. 1, but this is not important here. It is important to note that quadrupole splittings of up to several kHz were induced in the nominally spherical hydrated sodium ion by interactions with the anisotropic solvent.

From Fig. 1 it is observed that one vanadate species provides quadrupole splittings throughout the range of compositions. From its chemical shift, −537.5 ppm, and from dilution and pH studies in aqueous solution this resonance is assigned to VO_4H^{2-}, which is in agreement with the detailed work of other groups (2–6). The magnitude of the quadrupole splittings is

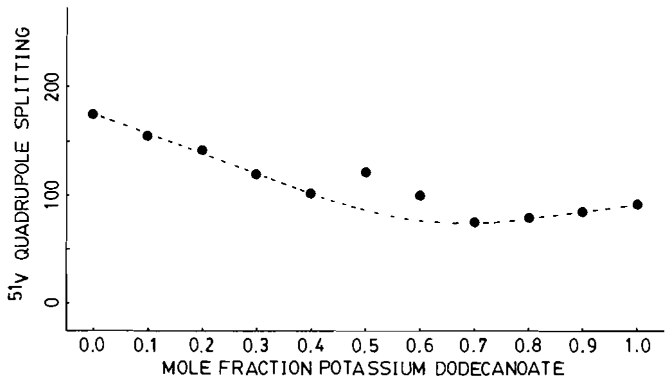

FIG. 2. The variation in the ^{51}V quadrupole splitting from the VO_4H^{2-} ion throughout the range of compositions of mesophases employed in this study. The dashed line has no theoretical significance.

small, as expected from a vanadium nucleus in a tetrahedral environment. In fact the magnitude of the splitting is consistent with an ion that is very close to perfectly tetrahedral, which indicates that the proton of this ion, VO_4H^{2-}, is probably only associated with the ion through the waters of hydration, so that tetrahedral symmetry is not lost.

Figure 2 shows the variation of quadrupole splitting from the VO_4H^{2-} ion as the charge on the micellar surface is varied from fully positive, $X = 0$, to fully negative, $X = 1.0$. The jog in the figure at $X = 0.5$ and $X = 0.6$ is associated with mesophase formation problems, probably a result of the alkaline conditions employed. On proceeding from the anionic mesophase $X = 1$ to $X = 0.7$ there is a gradual decrease in the quadrupole splitting. A minimum is reached between $X = 0.5$ and 0.6, at which point the splitting begins to increase, reaching a maximum at $X = 0$, the cationic mesophase. The magnitude of the maximum change in quadrupole splittings, about a factor of two, is not indicative of major changes in the mechanism of binding to the interface. The presence of a minimum in the curve may indicate that this ion, although carrying a negative charge, undergoes positive interactions with both the cationic and the anionic surfaces, although three-site binding cannot be ruled out. It has previously been found that the negatively charged aluminum ion, $Al(OH)_4^-$, interacts strongly in a positive manner with carboxylate groups (8). It was suggested in that case that binding to the carboxylates occurred through the hydrating water. A similar mechanism may be operative here.

On turning to Fig. 1 it is clear that the second resonance investigated here, which occurs at −552.1 ppm, shows a much different behaviour from that of the vanadate ion. This resonance corresponds to that which has been assigned to the $V_2O_7^{4-}$ ion. Because of the low symmetry of such an ion the forces of the anisotropic solvent should easily align it to give quadrupole splittings, particularly in the cationic mesophase. ^{51}V quadrupole splittings not only are not observed in that mesophase but the measured linewidths are not significantly different from those in normal aqueous medium, being about 60 Hz in either case. Furthermore, quadrupole splittings, as evidenced by increasing linewidth, for this species arise only when a signitficant proportion (≈40%) of cationic amphiphile has been replaced by the anionic material. Since quadrupole splittings were not resolved in the majority of the spectra, Fig. 3 shows the total linewidth of this resonance as a function of the mole fraction of potassium dodecanoate. The spectral width when corrected for the linewidth of a single transition,

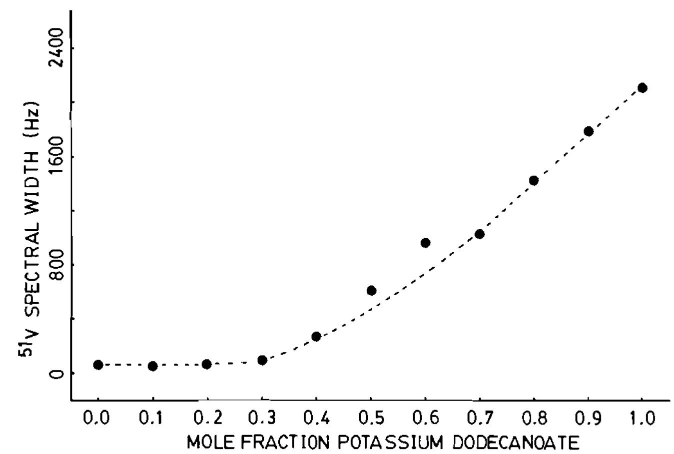

FIG. 3. The spectral width variation of the ^{51}V resonance from the second component observed in this study. No theoretical significance should be attached to the dashed line.

then divided by six, is a reasonable approximation to the quadrupole splitting, as is easily verified from Table 1.

It is possible to provide rational arguments, based on structure and orientation, to explain the absence of ^{51}V quadrupole splittings from this ion. Such arguments cannot simultaneously account for the absence of dipolar couplings between the two vanadium nuclei. In addition the ^{17}O spectrum from an ^{17}O-enriched sample showed no quadrupole splitting from the oxygens of this ion. It can only be that the ion is not being aligned by the anisotropic forces of the cationic solvent. It is extremely difficult to rationalize this conclusion in terms of the $V_2O_7^{4-}$ ion. Some information concerning this species is provided by comparing oxygen and vanadium spectra of an isotropic solution prepared according to the composition of the top entry of Table 1, but without the decanol. From several independent vanadium spectra, a ratio of intensities for the −537 and −562-ppm resonances of 1:0.82 ± 0.02 was obtained. The corresponding ratio in the oxygen spectrum was 1:0.54 ± 0.02, where the errors represent the maximum deviation from the mean. From these values and assuming that VO_4H^{2-} is the correct structural assignment for the −537 and 574.5-ppm resonances of the vanadium and oxygen spectra, respectively, a ratio of 2:5.3 ± 0.2 for V to O is obtained. This provides the possible formulae $n(V_2O_5)$ and $n(V_4O_{11})$. Interestingly enough, if it is assumed that the species presumed to be VO_4 is actually VO_6, then a ratio of vanadium to oxygen for the second species of 1:4.0 ± 0.2 is obtained. The oxygen signal of this second compound occurs at 696.8 ppm. Two other signals are observed which occur at 407 and 713 ppm. The former has previously been assigned to the bridging oxygen of $V_2O_7^{4-}$, the latter has not previously been reported. It is not clear that either are associated with the much more intense 696.8-ppm resonance. The 713-ppm ^{17}O resonance may be associated with the low intensity ^{51}V signal not yet discussed.

The third ^{51}V species investigated in this study, occurring at −573.1 ppm but not seen in Fig. 1 because of its low concentration, also shows no quadrupole splittings in the $X = 0$ to $X = 0.3$ range of the nematic solutions. This latter species has been tentatively identified as the cyclic tetramer $V_4O_{12}^{4-}$ (4). Again, the absence of partial alignment is difficult to accept. There are various lines of evidence which point to the high symmetry of the species giving rise to the −562.1-ppm ^{51}V resonance. They include the ^{51}V linewidth of about 60 Hz, which is comparable to that of the −537.5 ppm (VO_4H^{2-}) resonance. Narrow linewidths derive from inefficient quadrupole relaxation, a consequence of high symmetry. The most compelling evidence for high symmetry is the fact that there is no alignment of this compound in the cationic liquid crystalline solution. No compound of other than tetrahedral or higher symmetry has been observed not to align in a liquid crystalline medium and even such highly symmetrical species almost invariably give rise to quadrupole or dipole splittings because of distortion forces. In this vanadium case, we have not one but two species which are not aligned yet have been assigned structures not compatible with that finding. It is therefore proposed that the second species being observed is V_4O_{10}, the tetrahedral uncharged dimer of $V_2O_7^{4-}$, while the third species is a higher analogue. V_4O_{10} will have vanadium at the vertices of a tetrahedron with linkages occurring through oxygen. Like other tetrahedral species, quadrupole splittings can only be observed if the molecule is distorted from its high symmetry by interactions with the solvent.

Irrespective of identity, it is clear that this compound undergoes extremely weak if not repulsive interactions with the positively charged surface and only begins interacting with the interface when about 40% of the amphiphilic headgroups in the interface are carboxylates. There follows an approximately linear increase in quadrupole splitting with dodecanoate concentration, which indicates that specific interactions between the carboxylate groups of potassium dodecanoate and this vanadate species occur. An important aspect of the signal is the apparent lack of resolution until high concentrations of carboxylate are employed, at which point not seven but eight transitions occurring in pairs of equal intensity were obtained. This behaviour can be seen, although not clearly, in Fig. 1. Such a spectrum can only be ascribed to two superimposed, equally intense spectra chemically shifted from each other by about one quadrupole splitting. Spectra simulation served to confirm this conclusion. Heating the sample until it became isotropic (337 K) caused collapse of the spectrum to a single transition. Furthermore, preparation of samples similar to the bottom entry of Table 1 for which the composition was unchanged, except for the absence of decanol (thus providing an isotropic solution), also provided a single transition for this species. From this it is apparent that collapse of this spectrum to a single transition results from the loss of an induced shift because of the change to isotropic medium. Liquid crystals can induce chemical shifts because the shift is a tensor quantity and, like quadrupole splittings, is orientation dependent (14, 15).

It is clear from these results that this species interacts very strongly with the carboxylate headgroups of the bilayer interface. The binding is sufficient to slow exchange enough to see signals from two types of vanadium nuclei in the same molecule via an induced chemical shift. These nuclei would be identical if the molecule was not bound. This accounts for the broadness of the transitions in the intermediate regions of Fig. 1, where exchange occurs at a rate comparable to chemical shift.

Dilution studies were carried out for preparations in which decanol was not included. While the other components were kept at constant proportions the vanadate concentration was decreased by factors of 2 to a total change of 64. The relative proportions of the two components were obtained from the nmr spectra. Comparison of these proportions with those calculated from a simple equilibrium expression indicated the presence of an equilibrium of the type $3V_1 \leftrightarrows 2V_2$, where V_1 corresponds to vanadium resonance 1 and V_2 to resonance 2. These results apparently rule out an equilibrium of the type $4VO_4 \leftrightarrows V_4O_{10}$ and may indicate that resonance 1, ascribed to VO_4H^{2-}, has been incorrectly described.

The results of this dilution study are ambiguous, the situation no doubt being complicated by the presence of potassium dodecanoate. Considerably more work is required for this vanadate system, particularly in an aqueous system free from the complicating influence of detergents and electrolytes. The species assigned here and by others as VO_4H^{2-} must be unequivocally identified. Independent evidence for the structure of V_4O_{10} is also required since the results here, although indicating a highly symmetric species, do not specify the number of vanadium nuclei in that compound. Work aimed at providing an unambiguous identification of these and the various other vanadium resonances observed in aqueous solution is in progress.

Received September 19, 1984

A. LACHAPELLE and M. ST-JACQUES. Can. J. Chem. **63**, 2185 (1985).

The conformational properties of 8,11-dimethyl-5,6-benzo-2-oxo-1,3,2-dioxathiepin (**5**) and of 4,4-dimethyl-5,6-benzo-2-oxo-1,3,2-dioxathiepin (**6**) have been investigated using ^{1}H and ^{13}C dnmr as well as ir spectroscopy. Analysis of low temperature nmr spectra (down to −148°C) and of S═O stretching vibrations in room temperature ir spectra indicates that the most stable conformations detected for solutions in CHF_2Cl/CD_2Cl_2 (80:20) are TB (83%) and C-a (17%) for **5** and only the TB **7** for **6**. Substituent effects of methyl groups at the *peri* and the benzylic positions on the conformational properties of the seven-membered sulfites are discussed.

A. LACHAPELLE et M. ST-JACQUES. Can. J. Chem. **63**, 2185 (1985).

Les propriétés conformationnnelles de la diméthyl-8,11-benzo-5,6-oxo-2-dioxathiépine-1,3,2 (**5**) et de la diméthyl-4,4-benzo-5,6-oxo-2-dioxathiépine-1,3,2 (**6**) ont été étudiées à l'aide de la spectroscopie rmn dynamique ^{1}H et ^{13}C, ainsi que de la spectroscopie ir. L'analyse des spectres de la rmn à basse température (jusqu'à −148°C) et des fréquences de vibration d'élongation du lien S═O à température de la pièce indique que les conformations les plus stables en solution dans un mélange CHF_2Cl/CD_2Cl_2 (80:20) sont TB (83%) et C-a (17%) pour le composé **5** et seulement la forme TB **7** pour le composé **6**. Les effets de groupements méthyles en position *péri* ou benzylique sur les propriétés conformationnelles des sulfites à sept chaînons sont discutés.

Introduction

The conformational properties of six-membered cyclic sulfites have been thoroughly studied during the last two decades (1–8), while those of seven-membered and larger ring homologs were scarcely investigated (9–15). Recently, St-Jacques and co-workers (15) showed that enlargement from six to seven-membered ring, resulting from the replacement of the 5 methylene unit in 2-oxo-1,3,2-dioxathiane (**1**) by a benzo group, led to a change from the single C-a form, observed for **1**, to a 1:1 mixture (C-a ⇌ TB) for **2**, in CHF_2Cl, at −100°C. Further investigations (16) of methyl derivatives of **2**, using room temperature ir as well as low temperature ^{1}H and ^{13}C nmr methods, indicated that the presence of a methyl group, at the 4 position, *cis* to the S═O double bond (**3**), shifted the equilibrium toward the TB form (96% TB-*c*-Me_e and 4% TB-*c*-Me_a[2] in CHF_2Cl, at −80°C) because of severe 1,3-diaxial interactions in the C-a form. In contrast, a methyl group *trans* to the S═O double bond, at the same 4 position (**4**), unexpectedly shifted the equilibrium toward the C-a form (82% C-a and 18% TB-*t*-Me_e[2] in CHF_2Cl, at −80°C).

4 $R^1 = CH_3, R^2 = R^3 = H$ (*trans*)
5 $R^1 = R^2 = H, R^3 = CH_3$
6 $R^1 = R^2 = CH_3, R^3 = H$

These results, together with our general interest in the conformational properties of seven-membered rings, led us to investigate the conformational properties of 8,11-dimethyl-5,6-benzo-1,3,2-dioxathiepin (**5**) and of 4,4-dimethyl-5,6-benzo-1,3,2-dioxathiepin (**6**), which combine some of the structural characteristics of both compounds **3** and **4**. The additional data obtained shed some light into the nature of the interactions of methyl groups situated near the junction of the seven-membered and the aromatic rings.

TABLE 1. Infrared spectral data for the S═O stretching band of compounds **2**, **5**, and **6** in CS_2 and in CH_3CN

Compound	Solvent	(S═O) stretching band (cm^{-1})	Relative integration (%)
2	CS_2[a]	1223(S); 1184(S)[b]	46:54
	CH_3CN[a]	1210(S); 1179(S)	55:45
5	CS_2	1222(S); 1184(M)	70:30
	CH_3CN	1213(S); 1182(M)	81:19
6	CS_2	1217(S)	~100
	CH_3CN	1208(S)	~100

[a] The data for this compound were taken from ref. 16.
[b] The letters S and M refer to strong and medium intensities respectively.

Results

Infrared spectra

The ir spectra of 0.05 *M* solutions of compounds **5** and **6** were recorded both in CS_2 and in CH_3CN; they showed characteristic stretching vibrations for the S═O bond in the 1175–1230 cm^{-1} region, as reported in Table 1. Compound **5** showed two bands of unequal intensity in both solvents, a strong band at 1222 cm^{-1} and a weaker band at 1184 cm^{-1} in CS_2 in the ratio 70:30, while in CH_3CN the relative proportions of the strong band at 1213 cm^{-1} and of the weaker band at 1182 cm^{-1} are 81:19. Compound **6**, on the other hand, showed only a single strong band at 1217 cm^{-1} in CS_2; it shifted to 1208 cm^{-1} in CH_3CN.

Nuclear magnetic resonance spectra

High field ^{1}H (400 MHz) and ^{13}C (100 MHz) nmr spectra of compounds **5** and **6** were taken at different temperatures be-

[1] Author to whom correspondence should be addressed.
[2] The letters "*c*" and "*t*" refer to the *cis* and *trans* relations between the methyl group and the S═O double bond, while the letters "a" and "e", placed as subscript after Me, refer to the equatorial and axial orientations of the methyl groups in the various conformations.

TABLE 2. Carbon-13 chemical shifts and dynamic data for compounds **5** and **6** at high and low temperatures[a]

[a] The spectra were recorded at 400 MHz in CHF_2Cl (80%)/CD_2Cl_2 (20%) with internal TMS.
[b] The first row of chemical shifts corresponds to the less intense set of signals.
[c] The presence of broad peaks does not allow determination of the coupling constants.

tween −15 and −140°C. Tables 2 and 3 summarize the pertinent parameters.

Compound **5** revealed two spectral modifications in both ^1H and ^{13}C spectra recorded in a CHF_2Cl/CD_2Cl_2 solvent mixture (80:20) at low temperatures, as shown in Fig. 1. The ^{13}C spectrum at −20°C shows five well-resolved signals (chemical shifts are given in Table 2), most of which were assigned from a consideration of methyl substituent effects on the parameters of the parent compound **2** (16). All carbon signals broaden at lower temperatures and give at −80°C two sets of signals in the ratio 83:17 (the letter "b" identifies the set of taller signals while the letter "c" refers to the set of weaker signals). The free activation energy for the underlying process is estimated at 9.5 ± 0.3 kcal/mol (40 ± 1 kJ/mol) at −58°C, using standard equations (17) and a transmission coefficient of 1.

At −125°C, all the minor "c" signals remain sharp, while appreciable broadening occurs for one of the major "b" quaternary carbons signals (134.54 ppm at −80°C) as well as for the major "b" benzylic carbon signal (61.87 ppm). This last signal, when recorded at 20 MHz down to −148°C, splits into two lines of equal intensities, as shown in the inset of Fig. 1. A free activation energy of 6.5 ± 0.3 kcal/mol (27 ± 1 kJ/mol) at −125°C was estimated for that second process, using a method similar to that for the higher energy process.

The ^1H spectrum of compound **5** at −10°C, on the right hand side of Fig. 1, reveals a low-field averaged AX pattern (H-4 and H-7 methylene protons) and a high-field singlet (methyl protons) whose parameters are given in Table 3. The AX pattern undergoes two major modifications at lower temperatures. First, a process transforms the four methylene lines into eight lines at −85°C consisting of a minor AX pattern, labelled "c", and a major AB pattern labelled "b". The left side of that AB pattern further broadens at lower temperatures to give, at −140°C, two broadened peaks at 5.9 and 5.1 ppm, as illustrated by the splitting diagram. The signal at 5.1 ppm is partially obscured from overlap with the right half of the AB pattern observed at −85°C and which has only broadened at −140°C. A free activation energy of 6.3 ± 0.3 kcal/mol (26 ± 1 kJ/mol) was estimated for that last process at −130°C.

In contrast, the ^1H methyl signal undergoes only one spectral change at lower temperatures, whereby the singlet at −20°C splits into two lines (also labelled "b" and "c") of unequal

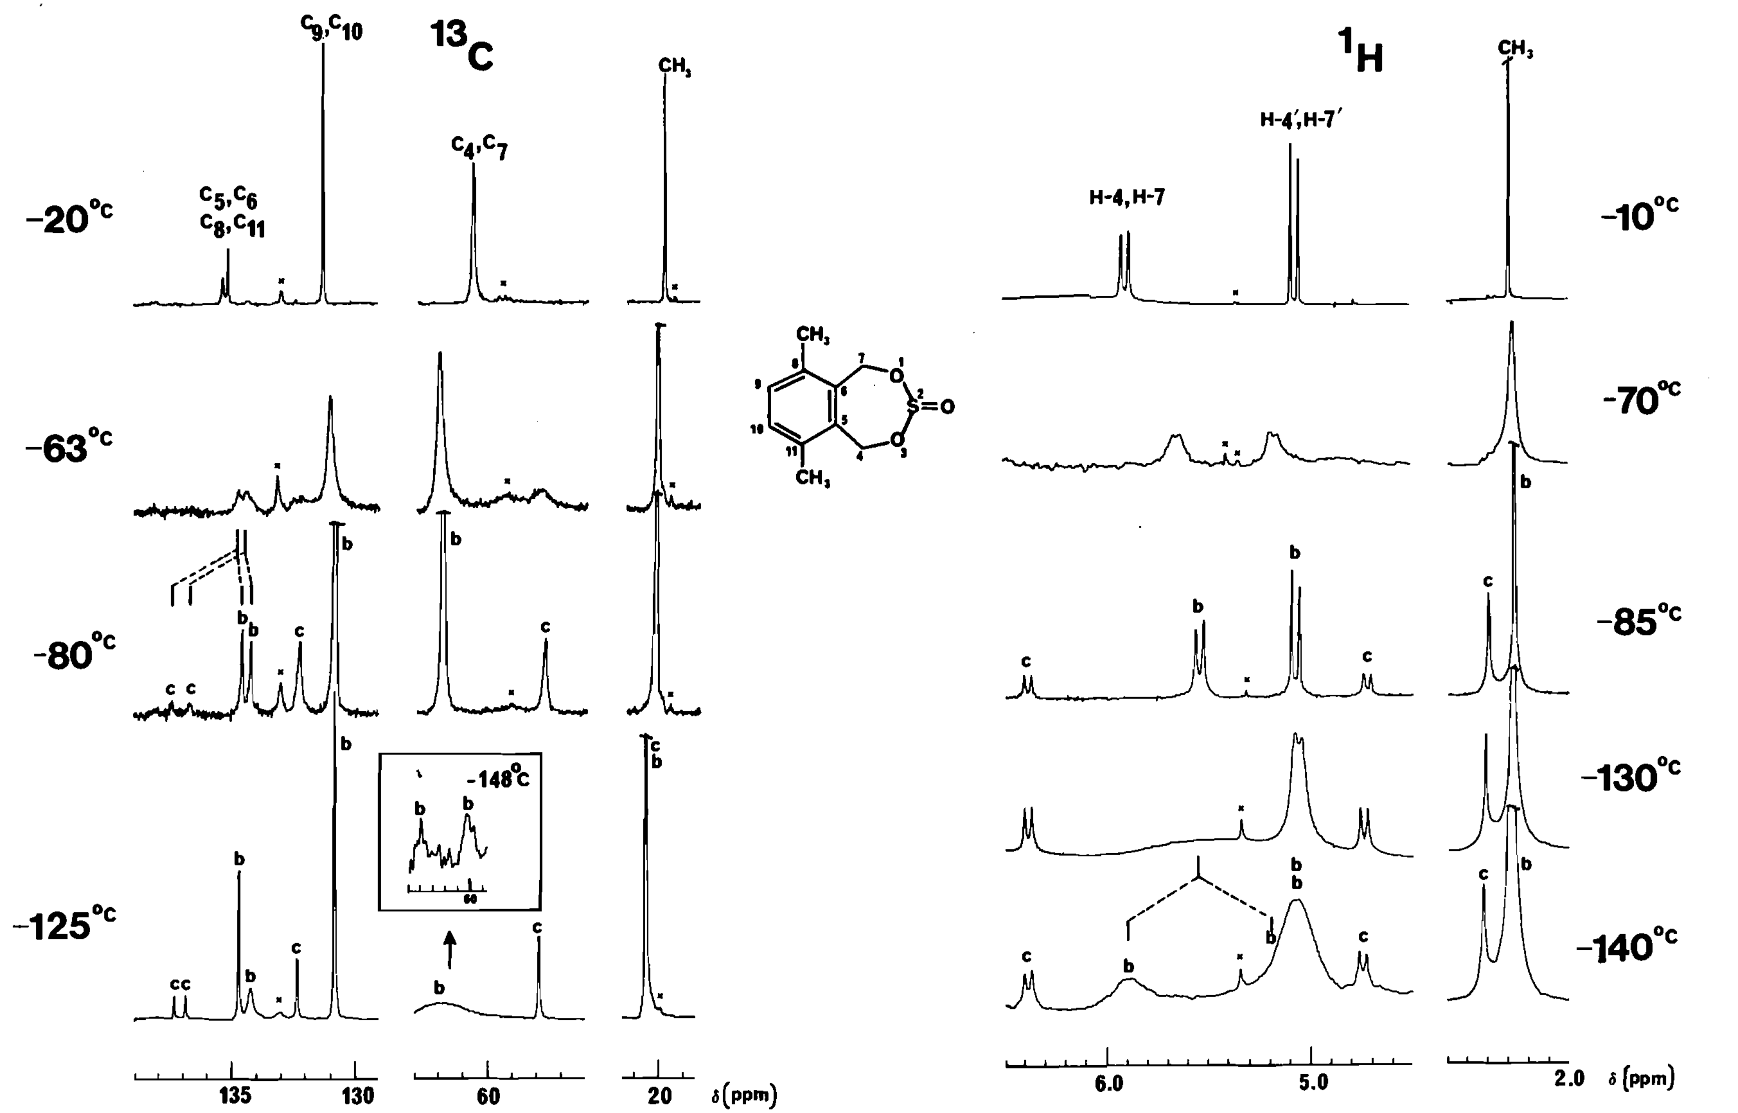

FIG. 1. Partial 100.6-MHz ^{13}C (left-hand side) and 400.1-MHz ^{1}H (right-hand side) nmr spectra of **5** in CHF_2Cl/CD_2Cl_2 (80:20) at several temperatures. The meaning of the letters b and c is given in the text. Small impurity signals are denoted by X. The origin of the signals in the inset on the bottom left-hand side is discussed in the text.

intensities at −85°C. A free activation energy of 9.8 ± 0.3 kcal/mol (41 ± 1 kJ/mol) was estimated for the underlying process at −70°C. Further lowering of the temperature down to −140°C only broadens these two unequal lines.

By comparison, compound **6** showed no spectral modification down to −125°C, for both ^{1}H and ^{13}C spectra taken in a CHF_2Cl/CD_2Cl_2 solvent mixture (80:20). The ^{13}C spectrum at −10°C reveals ten signals which were readily identified using the same procedure as for compound **5**. Table 2 contains the pertinent ^{13}C chemical shift parameters. The ^{1}H spectrum of **6** at −15°C shows a low-field AX pattern (H-7 methylene protons) and two high-field singlets (methyl protons). All signals broadened at low temperature, but no ^{1}H spectral splitting was observed down to −125°C. Table 3 contains the pertinent ^{1}H parameters.

Discussion

Ring conformation from infrared spectra

Extensive infrared investigations of six-membered cyclic sulfites revealed that specific frequency domains, associated with the S=O stretching vibration, are characteristic of each of the three possible spatial arrangements for the sulfite moiety (axial, isoclinal, or equatorial) (1). This relation holds only when molecular association effects are negligible, as for concentrations of 0.05 *M* or less. These frequency domains later proved to be equally applicable to seven-membered cyclic sulfites (11, 15) for which the straightforward observation of the S=O stretching bands in the 1150–1300 cm^{-1} region constitutes a direct probe for the conformational disposition of the sulfite moiety. This information then permits unambiguous identification of chair (C) or twist-boat (TB) ring geometries.

The ir spectra of **5**, for example, reveal two bands in both CS_2 and CH_3CN, as summarized in Table 1. The most intense band (1222 cm^{-1} in CS_2), is characteristic of an isoclinally oriented sulfite moiety (TB form) while the less intense band at 1184 cm^{-1}, in the same solvent, is characteristic of an axially oriented sulfite moiety (C-a or B-a form). Previous results for **2** (15) indicate that the B-a form is not likely to exist in such a system. The induced solvent shifts of 9 cm^{-1} (major band) and of 2 cm^{-1} (minor band) on going from CS_2 to CH_3CN follow trends similar to those observed in six-membered rings (1) for TB and C-a forms respectively. Finally, the increase in the population of the major band (TB) in a more polar solvent (CH_3CN) confirms the above conformational assignments because TB is more polar than C-a (15).

The presence of only one band at 1217 cm^{-1} in the ir spectrum of **6**, in CS_2, and the induced solvent shift of 9 cm^{-1} on going from CS_2 to CH_3CN identifies the TB form as the only detectable conformation for this compound. It is, however, important to point out that the geminal methyl groups of compound **6** can be located at two different benzylic positions in the TB conformation, that is, either *anti* (**7**) or *syn* (**8**) to the S=O double bond. Although ir methods fail to distinguish between these two possibilities, ^{1}H and ^{13}C nmr techniques provide parameters capable of probing the difference between **7** and **8** and thereby complement the conformational information deduced from the ir spectra.

Conformational features from nmr spectra

Proton and carbon-13 nmr parameters have been used extensively to define the orientation of the sulfite moiety as well as the spatial arrangement of nearby substituents. Data for each nucleus derive their utility from different characteristics of the sulfite function, which affect nearby nuclei.

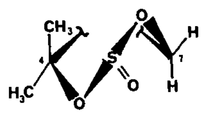
Proton nmr, for example, can help differentiate between axial, isoclinal, and equatorial orientations of the S=O double bond through anisotropy effects on adjacent methylene protons. The effect decreases with a change of the S=O position from axial to equatorial in the chair form of six-membered cyclic sulfites (6). The chemical shift difference between geminal protons γ to the S=O double bond can therefore act as a useful conformational probe. By comparison, ^{13}C nmr parameters, especially through the γ effect (which represents the shift produced by the S=O bond on the γ carbon), can be utilized to deduce stereochemical relationships and thereby discriminate between various orientations of the S=O bond in the different conformations possible.

The averaged ^{1}H and ^{13}C spectra (Fig. 1) of **5** at −10°C have changed, at intermediate temperatures (−80°C for ^{1}H and −85°C for ^{13}C), into two sets of signals of unequal intensities. The minor set (labelled "c") remains unchanged down to −148°C; this observation is consistent with a rigid conformation possessing a plane of symmetry, most probably the chair form. Moreover, the large ^{1}H chemical shift difference ($\Delta\delta$ = 1.67 ppm) observed at −85°C between the two geminal benzylic protons (H-4 or H-7) of that minor C form indicates a large S=O anisotropy effect. Furthermore, the chair geometry explains the highly shielded C-4,7 carbon-13 signals (57.71 ppm at −80°C) relative to 76.25 ppm for the same carbons in 5,6-benzo-1,3-dioxepin (18). This large upfield shift (18.54 ppm) cannot be accounted for solely by the γ effect of the *peri* methyl groups as indicated by the fact that a similar γ effect in 1-methylnaphthalene is only 3.7 ppm (19). Such a high degree of shielding must also involve a *gauche* effect relative to the S=O band. These combined arguments, together with the symmetrical nature of the conformation, support the conclusion that C-a is the minor conformation of **5**, as was deduced from ir data.

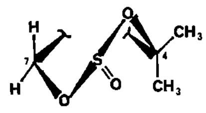
The major sets of signals, labelled "b" both in the ^{1}H spectrum at −85°C and in the ^{13}C spectrum at −80°C, undergo additional changes as the temperature is lowered. The low-field half of the ^{1}H "b" pattern broadens extensively, splits, and gives, at −140°C, two distinct but broadened "b" peaks as illustrated by the splitting diagram. These two peaks, together with the high-field signal labelled "bb" which has only broadened at −140°C, indicate that the underlying conformation has at least three (and very likely four) chemically non-equivalent benzylic protons. This result suggests that the major conformation of **5** lacks a plane of symmetry, and is therefore a TB form. This conclusion is confirmed by the observation at −148°C of two chemically non-equivalent benzylic carbon-13 signals for the major conformation (Fig. 1, inset), again characteristic of the TB form.

Symmetry arguments, however, cannot be used for compound **6** because all conformations possible are inherently devoid of symmetry. Proton and carbon-13 nmr data can, however, be used to distinguish between the two possible TB forms, namely **7** or **8**.

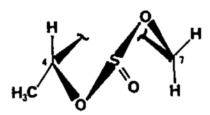
The absence of change noted for the ^{1}H and ^{13}C spectra of **6** down to −125°C can be explained in one of the two following ways: either only one TB form (**7** or **8**) exists very predominantly or, alternatively, compound **6** exists as a mixture of **7** and **8** still undergoing rapid pseudorotation at −125°C. Close examination of results for related compounds helps resolve this ambiguity. First, St-Jacques and co-workers (16) have found that the C-7 signals for the TB forms of *cis*-4-methyl-5,6-



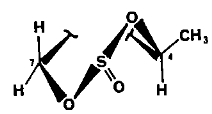
7



8



9



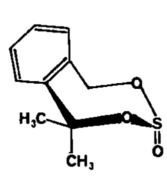
10

benzo-1,3,2-dioxathiepin (**9**) and of *trans*-4-methyl-5,6-benzo-1,3,2-dioxathiepin (**10**) have distinct chemical shifts at −125°C (63.91 and 67.19 ppm respectively). Next, the examination of structures **7**, **8**, **9**, and **10** indicates that the **7**–**9** pair and the **8**–**10** pair differ only by the addition of an axial methyl group at C-4 to **9** and **10**. Molecular models show that these axial methyl groups are quite remote from C-7, so that the C-7 chemical shifts obtained for **9** and **10** could be used as probes for the geometry of the TB form of **6** (**7** or **8**). The observation that the chemical shift of the C-7 signal of **6**, (64.30 ppm at −125°C) lies fairly close to the C-7 chemical shift of **9** (63.91 ppm at −125°C) (16) therefore points to the TB form **7**.

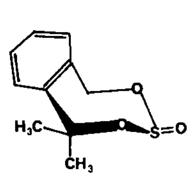
The above suggestion is further corroborated by the proton spectrum of **6** at −125°C, which reveals a chemical shift difference of 1.63 ppm for the two H-7 methylene protons. Corresponding values (15) for the benzylic protons of the TB form of **2** show that striking differences exist between the chemical shift difference of the CH_2 group *syn* ($\Delta\delta$ = 1.2 ppm) and *anti* ($\Delta\delta$ = 0.3 ppm) to the S═O bond, as a consequence of a stronger anisotropy effect for the *syn* CH_2 group. Therefore, the value ($\Delta\delta$ = 1.63 ppm) obtained for the geminal H-7 protons of **6** not only points to **7** as the preferred TB form for compound **6**, but also suggests the existence of some distortion around the *syn* C-7 carbon, which would lead to a stronger anisotropy effect in **7** than in **2**, and also in **9**, for which $\Delta\delta$ = 1.33 ppm (16).

Characteristics of methyl interactions

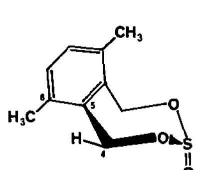
Although the results thus far presented for compounds **5** and **6** indicate a similar shift towards the TB form (relative to the 50:50 C-a/TB conformational equilibrium of compound **2** (15)), the methyl interactions governing those conformational preferences differ significantly for the two compounds on hand.



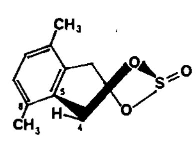
11



12



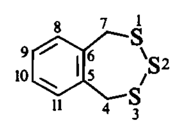
13



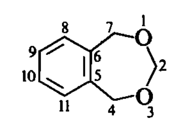
14

For example, compound **6** can exist as four possible conformers: two TB forms (**7** and **8**), a C-a form (**11**) and a C-e form (**12**). Among them, the C-a form **11** and the TB form **8** exhibit severe steric interactions between the axial methyl group (pseudoaxial in **8**) and the S═O bond. The C-e form **12**, on the other hand, is destabilized by an unfavorable electronic arrangement of the sulfite function (15) and by a 1,5 steric interaction between the axial methyl group and the axial H-7 proton. These unfavorable interactions in **8**, **11**, and **12** therefore explain the fact that the TB form **7** is found to be most stable for compound **6**.

In contrast, compound **5** exhibits particular methyl hydrogen interactions involving the two rings of the molecule. Molecular models show that the introduction of methyl groups at positions 8 and 11 of the parent compound **2** creates strong interactions between those methyl groups and one of the adjacent benzylic protons. Furthermore, examination of the C(4)—C(5)—C(8) plane of the same models indicates that the angle between the *peri*-methyl group and the equatorial H-4 proton is smaller in the C-a form (**13**) than in the TB form (**14**). This should result in a significantly stronger steric CH_3–H-4_e interaction in the C-a form than in the TB form. Consequently, the changes in the ^{13}C data whereby the γ' methyl effect on C(4) (or C(7)) is greater for the C-a form (−4.72 ppm) than for the TB form (−2.59 ppm) are compatible with the above.



15



16

Similar increases in TB population were also noted upon introduction of methyl groups at the *peri* positions of other closely related systems (20),[3] namely 5,6-benzo-1,2,3-trithiacycloheptene (**15**) and 5,6-benzo-1,3-dioxepin (**16**). The above arguments suggest that these molecules should also exhibit stronger *peri* interactions in the C-a form.

Finally, it is informative to analyse the conformational effect associated with a "reverse" *peri* interaction, involving an equatorial benzylic methyl group and a *peri* aromatic proton. Compound **4**, for example, provides such a case. Even though ^{13}C parameters (16) suggest that the interaction between the methyl group and the *peri* aromatic proton is stronger in the C-a form that in the TB form, compound **4** unexpectedly favours the C-a form. The nature of the CH_3---H interaction is either not simple or solely operative in **4** so that the concept of "reversibility" is not applicable in such circumstances.

Experimental

Melting points are uncorrected and were determined using a Buchi melting point apparatus. High resolution spectra at 70 eV were recorded using a modified MS-9 spectrometer. Flash chromatography was performed on 230–400 mesh silica gel under standard conditions described by Still and co-workers (21). Anhydrous ether was taken directly from a freshly opened sealed can (Fisher), while thionyl chloride was distilled from quinoline, and triethylamine from calcium oxide.

The ir spectra of compounds **5** and **6** were taken as 0.05 *M* solutions in CS_2 and in CH_3CN, using a 0.05-mm KBr cell (nominal value), and were recorded on a Digilab FTS-15C/D Fourier transform infrared spectrometer, equipped with a wide-range photoconductive mercury

[3] Also, R. St-Amour and M. St-Jacques, unpublished results.

cadmium telluride detector, a KBr beam splitter, and a Lobar source. The instrument was purged with nitrogen before use. Typically, 200 interferograms of 2096 points each, recorded with a maximum optical retardation of 0.50 cm^{-1} and an optical velocity of 1.2 cm^{-1}, were co-added, apodized with a triangular function, and Fourier transformed with 8 levels of zero filling, resulting in a spectral resolution of 2 cm^{-1}. The base line was corrected using multiple linear least-square functions. Integrations were performed using a PEAKAREA program (Digilab), which leads to approximate values in the case of partially overlapping peaks.

Routine ^1H nmr spectra were taken on a Bruker WH-90 spectrometer: solutions were typically 10% (w/v) in $CDCl_3$ containing Me_4Si as reference. The following abbreviations will be used to describe the peaks: s = singlet, m = multiplet, br = broad. Routine ^{13}C nmr spectra were taken on a Bruker WP-80 spectrometer; solutions were typically 15% (w/v) in $CDCl_3$ containing Me_4Si as reference.

The variable temperature ^1H nmr spectra at 400 MHz and ^{13}C nmr spectra at 100.62 MHz were obtained using a Bruker WH-400 spectrometer equipped with a variable temperature unit B-VT-1000. Calibration using a thermocouple inside a solvent-containing nmr tube indicates that the low temperatures reported are exact within 2°C.

The ^1H spectra were recorded as solutions in chlorodifluoromethane (10 mg in 0.55 mL of solution) containing Me_4Si and about 15–20% of CD_2Cl_2 (for locking purposes), in standard 5-mm tubes which had been degassed and sealed. The following parameters were used: flip angle: 60–65°; SW = 4000 Hz; pulse delay = none; data size 4K; acquistion time = 0.512 s. The ^{13}C spectra were recorded with proton noise decoupling for solutions in chlorodifluoromethane (150 mg in 2.2 mL of solution) containing Me_4Si and about 15–20% of CD_2Cl_2, as locking agent, in standard 10-mm tubes which were degassed and sealed. The following instrumental parameters were used: flip angle = 65–70°; SW = 17 000 – 22 000 Hz; data size = 16K; acquisition time = 0.323–0.482 s; pulse delay = none.

The rate constants were determined at the coalescence temperature using the equation $k = \pi\Delta\nu\sqrt{2}$ for singlet to doublet splitting in ^1H (methyl signal of **5**) and ^{13}C nmr spectra (the equation provides an acceptable estimate for lines of unequal intensity (22)). The free energy barriers were calculated from standard equations (17) using a transmission coefficient of 1.

2,5-Dimethylphthalic anhydride

This compound was prepared by a Diels–Alder reaction between 2,5-dimethylfuran (Aldrich) and maleic anhydride, followed by dehydration with concentrated sulfuric acid, as described by Newman and Lord (23). The white solid was characterized by its melting point (139–142°C), which was identical with that published, and by its ^1H nmr (90 MHz, $CDCl_3$) spectrum: δ 2.67 (s, 6H), 7.53 (s, 2H).

*2,5-Dimethyl-(*o*)-benzenedimethanol*

To a mixture of 2.5 g $LiAlH_4$ in 30 mL of boiling anhydrous THF was added dropwise, under argon, a solution of 7.0 g of 2,5-dimethylphthalic anhydride in 70 mL of anhydrous THF. The resultant solution was refluxed during 48 h and then cooled to room temperature. The excess hydride was decomposed cautiously with 5 mL of 10% H_2SO_4 and filtered through sintered glass. The filtrate was then evaporated, giving 3.8 g (58% yield) of a white solid, which was characterized by its melting point (69–70°C), identical with that published (24), and by its ^1H nmr (90 MHz, $CDCl_3$) spectrum: δ 2.37 (s, 6H), 3.25 (br, 2H, exchangeable with D_2O), 4.71 (s, 4H), 7.05 (s, 2H).

8,11-Dimethyl-5,6-benzo-2-oxo-1,3,2-dioxathiepin (5)

To a mixture of 1.5 g of 2,5-dimethyl-(*o*)-benzenedimethanol, and 2.8 mL of triethylamine (2 equiv.) in 20 mL of anhydrous ether, at 0°C, was added dropwise, under argon, a solution of 0.72 mL (1 equiv.) of thionyl chloride in 20 mL of anhydrous ether. A white precipitate (triethylammonium chloride) appeared at the beginning of the addition and became more abundant as the reaction proceeded. After the addition was completed, the solution was stirred an additional 1.5 h, warmed to room temperature, then filtered on a Büchner funnel and evaporated, giving an oil which was triturated in hexane: 1.0 g (52% yield) of a white powder was thus obtained. This crude material was purified by flash chromatography on silica gel, using CH_2Cl_2 as eluent, giving, in the media fraction, analytically pure white crystals (mp 48°C). The ^1H and ^{13}C nmr spectra (Tables 2 and 3), as well as the high resolution mass spectrum confirm its identity. *Mol. Wt.* calcd. for **5**, $C_{10}H_{12}O_3S$: 212.0507; found (mass spectrum at 70 eV): 212.0510.

*α,α-Dimethyl-*o*-xylene α,α'-diol*

This compound was prepared from phthalide (Aldrich) by a procedure similar to the one of Goldschmidt and Zoebelein (25) in 58% yield. Analytically pure material was obtained by distillation under reduced pressure (100°C/0.3 Torr; 1 Torr = 133.3 Pa), giving an oil which crystallized on standing (mp 62–63°C); ^1H nmr (90 MHz, $CDCl_3$): δ 1.59 (s, 6H), 4.71 (s, 4H), two of which are exchangeable with D_2O, 7.22 (m, 4H, aromatic protons).

4,4-Dimethyl-5,6-benzo-2-oxo-1,3,2-dioxathiepin (6)

To a mixture of 1.5 g of α,α-dimethyl-*o*-xylene α,α'-diol, and 6.3 mL (5 equiv.) of triethylamine in 25 mL of anhydrous ether, at 0°C, was added dropwise a solution of 0.7 mL (1 equiv.) of thionyl chloride in 25 mL of anhydrous ether. The solution was then allowed to warm at room temperature, and stirred during 96 h. Filtration of the salts followed by evaporation under reduced pressure yielded 1.42 g (74% yield) of a yellow oil. Flash column chromatography on 40–63 μm silica gel (Merck no. 9385) using dichloromethane as solvent gave, in the middle fractions, pure **6** as a white powder (mp 48°C). Its identity was later confirmed by its ^1H and ^{13}C nmr spectra (Tables 2 and 3) as well as by its high resolution mass spectrum. *Mol. Wt.* calcd. for **6**, $C_{10}H_{12}O_3S$: 212.0507; found (mass spectrum at 70 eV): 212.0500.

Photocyclization of 2-vinylbiphenyls: stereochemistry of the triplet state cyclization

RENÉ LAPOUYADE, CLAUDE MANIGAND, AND AZIZ NOURMAMODE

Laboratoire Associé au CNRS N° 348 et Ecole Nationale Supérieure de Chimie et de Physique de Bordeaux, Université de Bordeaux 1, 33405 Talence Cédex, France

Received July 19, 1984

This paper is dedicated to Professor Paul de Mayo on the occasion of his 60th birthday

RENÉ LAPOUYADE, CLAUDE MANIGAND, and AZIZ NOURMAMODE. Can. J. Chem. **63**, 2192 (1985).

The photochemistry of five- to eight-membered ring containing 2-cycloalkenyl biphenyls was examined under direct and sensitized irradiation. From the singlet excited state only *trans* 9,10-cycloalkyl-9,10-dihydrophenanthrenes were obtained. From the triplet state the *trans* isomer was exclusively formed from 2-cyclopentenyl and 2-cyclohexenyl biphenyls while the *cis* isomer also appeared with 2-cycloheptenyl and 2-cyclooctenyl biphenyls. We propose that the *cis* isomers resulted from the cyclization of the perpendicular triplet of cycloheptenyl biphenyl and from the perpendicular and *trans* triplet of cyclooctenyl biphenyl. Whereas the photocyclization of 2-vinylbiphenyls was regarded as a singlet-state reaction, the quantum yields of reaction of 2-cycloalkenyl biphenyls, from both singlet and triplet states, were high ($\Phi_S = 0.20–0.26$; $\Phi_T = 0.15–0.46$).

RENÉ LAPOUYADE, CLAUDE MANIGAND et AZIZ NOURMAMODE. Can. J. Chem. **63**, 2192 (1985).

On a étudié, par irradiation directe et sensibilisée, la photoréactivité de quatre cycloalcényl-2 biphényles où le groupe cycloalcène varie du cyclopentène au cyclooctène. Par l'état excité singulet, il ne se forme que les cycloalkyl-9,10 dihydro-9,10 phénanthrènes *trans*. Par l'état triplet, l'isomère *trans* est obtenu seul dans le cas des cyclopenténуl-2 et cyclohexényl-2 biphényles, alors que l'isomère *cis* apparaît avec les cycloheptényl-2 et cyclooctényl-2 biphényles. Les isomères *cis* sont attribués à la cyclisation des cycloalcènes perpendiculaires et du cyclooctényl *trans* à l'état triplet. Alors que la cyclisation des vinyl-2 biphényles était considérée comme une réaction de l'état singulet, les rendements quantiques de réaction sont élevés, aussi bien par le triplet que par le singulet ($\Phi_S = 0{,}20–0{,}26$; $\Phi_T = 0{,}15–0{,}46$).

Introduction

Mechanistic interpretations of the complicated photochemistry of conjugated hexatrienes have been discussed recently (1). The number of reactive pathways was dramatically reduced by incorporating two consecutive double bonds in benzene rings; namely, with 2-vinylbiphenyls only *cis–trans* photo-izomerization and -cyclization were observed. With *Z*(*E*)-1-biphenyl-2-yl-1-phenylpropene **1** we reported (2) a stereoselective singlet cyclization, as anticipated for a concerted conrotatory [6π] electrocyclic ring closure, and a nonstereoselective triplet cyclization which was no less expected, since in order to be concerted a triplet electrocyclic reaction either would have to produce a triplet product or possess a mechanism for efficient intersystem crossing to the ground state of the product (3). We interpreted the unchanged stereochemistry of the triplet cyclization, whatever the isomer irradiated by a cyclization through a common intermediate, as possibly a perpendicular triplet state.

But it has now been established that a fast equilibrium between the planar and perpendicular triplet states occurs with stilbene, and naphthyl- and biphenyl-substituted olefines (4–6), so that the identical stereochemistry of triplet cyclization of **1***E* and **1***Z* could also be explained by a cyclization from planar triplets **1***E* and **1***Z* in equilibrium.

With a view to determining at which point along the excited singlet and triplet surfaces the new bond is made, we have now measured the efficiency and determined the stereochemistry of cyclization of a series of 2-vinylbiphenyls where the double bond is inserted in five- to eight-membered rings whose effect on the geometry of the triplet state we have previously discussed for α-naphthyl (6) and β-naphthyl (7) ethylene derivatives.

Results

I. *Synthesis of photochemical reactants*

Compound **1** was prepared from 2-benzoylbiphenyl by a Wittig reaction with the "instant ylide" ethyltriphenylphosphonium bromide – sodium amide, developed by Schlosser and Schaub (8): the two isomers (9) were formed in equal amounts and separated by flash chromatography (10). 1-(2-Biphenyl)-cycloalkenes (**2–5**) (11) were obtained by reaction of 2-lithiobiphenyl with appropriate cycloalkanones and dehydration of the resulting alcohols with thionyl chloride in pyridine (12) (Scheme 1). Only the cyclopentyl derivative was not satisfactorily dehydrated by this method, and P_2O_5 in CCl_4 was used. When an acidic dehydrating agent was employed, the desired products were contaminated with the corresponding spirocycloalkane fluorenes (13). We verified that compounds **2–5** were quantitatively cyclized to spirocycloalkane fluorenes by refluxing a benzene solution with a catalytic amount of *p*-toluenesulfonic acid (Scheme 1).

II. *Photolysis of* **2–5** *and identification of the photoproducts*

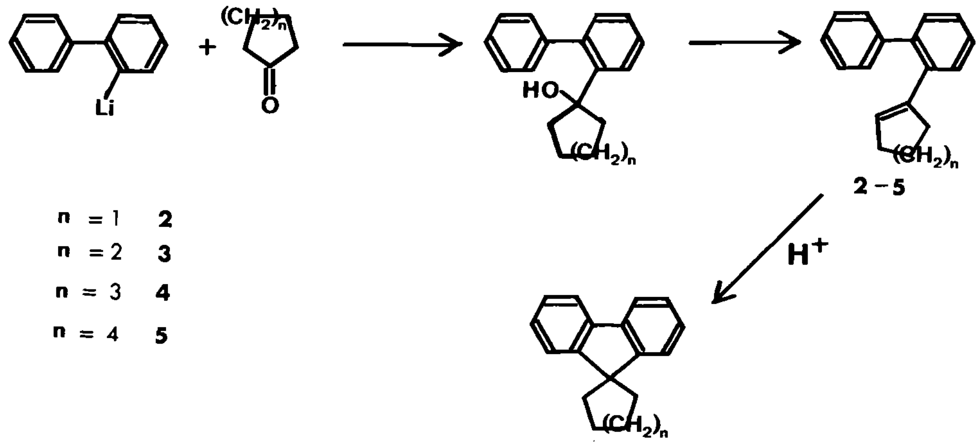
1. *Direct irradiation*

Under preparative conditions the direct irradiation (313 nm) of degassed cyclohexane solutions of **2** and **3** (5×10^{-3} *M*) afforded only one isomer of the corresponding 9,10-cycloalkyl-9,10-dihydrophenanthrenes. Irradiation of argon degassed solutions of **4** and **5** gave the two isomers in a ratio of 86:14 for **4** and 80:20 for **5**. But by adding piperylene (10^{-3} *M*) the previously minor isomer disappeared completely for **4** while 5% remained with the irradiation of **5**. The ratio of the photoproducts was not altered by an extended irradiation.

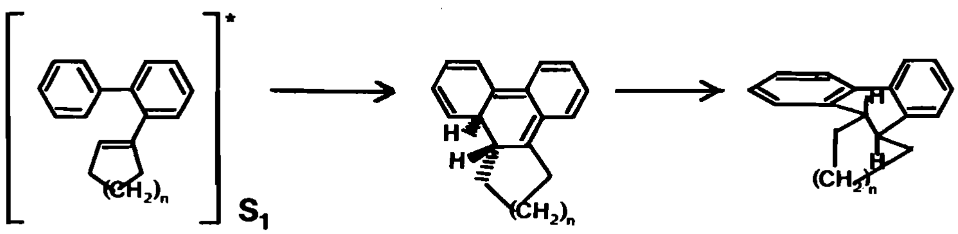
2. *Isomerization of the photoproducts and assignment of their configuration*

We assigned a *trans* configuration to the single isomers obtained by direct irradiations of **2–5** for the following reasons:

(*a*) A conrotatory ring closure followed by a suprafacial [1,5] sigmatropic hydrogen shift is the accepted mechanism of the singlet cyclization of 2-vinylbiphenyls. It has accounted for the stereoselectivity observed by several authors (2, 14) (Scheme 2).



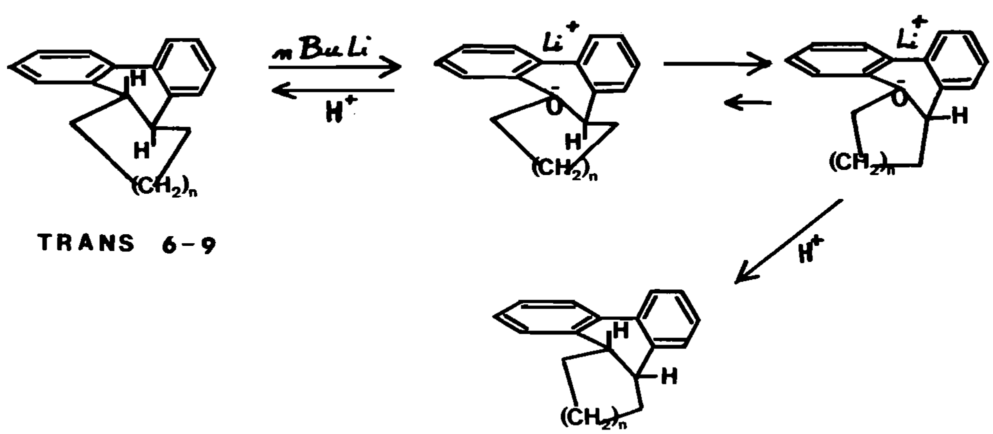
SCHEME 1. Synthesis of 1-(2-biphenyl)-cycloalkenes.



2 – 5 TRANS 6 – 9

SCHEME 2. Singlet cyclization of 1-(2-biphenyl)-cycloalkenes.

(b) We have isomerized the photoproducts via the carbanion generated with nBuli in diethyl ether with six equivalents of HMPA. Rabideau and Harvey (15) had already observed a 100% *cis* stereoselectivity for the protonation from the pseudo-axial direction of 9,10-dialkyl-9-lithio-9,10-dihydrophenanthrenes, while the vicinal alkyl group assumed the relatively unhindered axial position. We thought that with a fully HMPA solvated cation the axial protonation of the planar carbanion might be favoured (16–19), while the large solvated cation, maintained in the vicinity of the anion by the low polarity of the solvent, could add to the perihydrogen interaction to favour an axial position for the vicinal cycloalkyl substitution and, as a consequence, the *cis* isomer would result (Scheme 3). In fact, the photoisomers were all converted to the other isomers, which became predominant. Since the reaction mixture is not equilibrating, the observed ratios of isomers do not reflect the relative thermodynamic stability but, rather, the stereochemistry of kinetic protonation of the unstable carbanions.



CIS 6 – 9

Reactants	Products (%)
trans **6**	*trans* **6** (25), *cis* **6** (75)
trans **7**	*trans* **7** (36.5), *cis* **7** (63.5)
trans **8**	*trans* **8** (7), *cis* **8** (93)
trans **9**	*trans* **9** (13), *cis* **9** (87)

SCHEME 3. *trans–cis* Isomerization of 9,10-cycloalkyl-9,10-dihydrophenanthrenes with nBuli in ether–HMPA.

(c) Since direct irradiation of **2–5** gave only one isomer of **6–9** but base isomerization afforded the other isomer we were able to compare the properties of configurational isomers for each couple. The nmr analysis of the benzylic hydrogen signals of 9,10-dihydrophenanthrenes has proved useful for configurational and conformational studies (18, 20) but extension to compounds **6–9** was not straightforward, since if one could assume that the *cis* isomers (Scheme 3) were rapidly interconverting and averaging the axial and equatorial benzylic hydrogens, after inspection of molecular models it appeared that the *trans* isomers could only present the saturated ring bisequatorially fused to the 9,10 bond (Scheme 3), whereas Harvey showed that *trans*-9,10-dialkyl-9,10-dihydrophenanthrenes preferred the diaxial conformation. Furthermore, axial and equatorial hydrogens cannot be distinguished on the basis of chemical shift alone and coupling constants are not easily available for these structurally (*cis*) or dynamically (*trans*) symmetrically substituted 9,10-dihydrophenanthrenes. Nevertheless we observed a complete homogeneity from **6** to **9** for the chemical shift of benzylic hydrogens: the photoproducts (*trans* isomers, axial hydrogens) are shielded relative to their isomers (*cis* isomers, axial and equatorial hydrogens) (see Experimental).

The photoproducts are eluted after their isomers on silica gel, and have a longer retention time on gas chromatography with a column of 3% OV1 on Chromosorb W-HP.

Dehydrogenation of dihydroaromatic hydrocarbons over 10% Pd/C in refluxing diglyme has already been observed to be slower for the isomer where the substituents interfere with adsorption on the catalyst surface (21). In this regard we expected a faster dehydrogenation for the *cis* isomer, where one face presents the two hydrogens accessible to the catalyst. In fact, after 2 h of reflux an equivalent mixture of *cis*- and *trans*-**7** has been transformed to triphenylene and unaffected *trans*-**7**.

3. *Sensitized cyclization*

In contrast to direct irradiations, xanthone (2×10^{-3} *M*) sensitized irradiations of nitrogen degassed benzenic solutions of **2–5** (2.25×10^{-3} *M*) led to a different stereochemistry of cyclization, depending on the size of the cycloalkene ring: with cyclopentene (**2**) and cyclohexene (**3**) only one isomer was formed, which was identical with the one obtained by direct irradiation, consequently the *trans*-isomer; with cycloheptene (**4**) the *trans* isomer was predominant (65%) but the *cis* was also formed (35%); and with cyclooctene, at the beginning of the irradiation (see quantum yields) the ratio *cis*/*trans* was 54:46, while further irradiation increased the *cis* proportion, which reached 85:15 when the cyclization was complete.

We also observed a reduced proportion of *cis*-**8** when the irradiated acetonitrile solution of **4** was saturated with air or oxygen: *trans*/*cis* = 65:35 (nitrogen saturated), 67:33 (air saturated), 73:27 (oxygen saturated) when the conversion was approximately 20%.

As for direct excitation, prolonged irradiations did not change the ratio of the photoproduct isomers.

4. *Quantum yields of direct and sensitized photocyclizations*

Quantum yields (Tables 1 and 2) were determined using an optical bench with a 2-kW xenon lamp and a Jobin–Yvon HL monochromator. Aberchrome 540 ($\phi = 0.20$) (22) was used to measure the intensity of the incident light at 315 nm (direct irradiations) and 340 nm (sensitized irradiations). The concentrations of **2–5** were such that more than 98% of the incident light was absorbed (direct irradiations, concentration = 5×10^{-2} *M*) or complete triplet quenching of the sensitizer occurred (sensitized reactions, concentration = 5×10^{-2} *M*). After irradiation, the degree of reaction and the amount of photoproducts were determined by vapor phase chromatography using a 25-m fused silica capillary column packed with CP Sil 8 CB. The internal standard was *m*- or *p*-terphenyl. The conversions never exceeded 2%.

TABLE 1. Quantum yields for direct irradiations

		Quantum yields of photoproducts		
Compounds	Additive	*trans*	*cis*	*trans* + *cis*
2	—	0.31	—	0.31
2	Piperylene	0.20	—	0.20
3	—	0.36	—	0.36
3	Piperylene	0.20	—	0.20
4	—	0.26	—	0.26
4	Piperylene	0.24	—	0.24
5	—	0.21	0.02	0.23
5	Piperylene	0.19	0.01	0.20

λ_{excit} = 315 nm; solvent: acetonitrile; **2–5** conc. = 5×10^{-2} *M*; nitrogen degassed.

TABLE 2. Quantum yields for xanthone sensitized cyclizations

	Quantum yields of photoproducts		
Compounds	*trans*	*cis*	*trans* + *cis*
2	0.46	—	0.46
3	0.37	—	0.37
4	0.19	0.11	0.30
5	0.07	0.08	0.15

λ_{excit} = 340 nm; solvent: acetonitrile; **2–5** conc. 5×10^{-2} *M*; xanthone conc. = 4×10^{-4} *M*, degassing with four freeze–thaw cycles.

Interpretative discussion

Singlet cyclization

The stereochemistry of the singlet cyclization of 2-vinylbiphenyls was well accounted for by a concerted conrotatory ring closure followed by a suprafacial 1,5 hydrogen shift (2, 14, 23–25). From 2-cycloalkenylbiphenyls **2–4**, which are only stable in the *cis* configuration in the ground state, the exclusive formation of the *trans* photoproducts, as also the relatively constant quantum yields, denote a cyclization from the *cis* isomer without a concurrent isomerization in the excited state. The *cis* photoproduct (~5%) obtained with **5** could arise from a small amount of *trans*-**5** already present before irradiation. We shall not discuss further the singlet cyclization of these compounds since we have now observed a biexponential decay of their fluorescence, so that the principle of nonequilibration of excited rotamers (26) (NEER) should apply and the quantum yield of reaction should be highly dependent on the reactive conformer proportion.

Triplet cyclization

We have not yet been able to differentiate the triplet state conformers but if the NEER principle is maintained during the triplet lifetime, as we have shown in the β-naphthalene series (7), we might emphasize the high efficiency of the sensitized reactions, since the quantum yield of cyclization of the reactive conformer would be still higher than the measured quantum yield. As for the singlet cyclization, it is possible that differential population of the conformers contributes to the observed quantum yield trends, but in the triplet state the appearance of *cis* photoproduct is indicative of an initial photoisomerization; therefore we will discuss the relation between the size of the cycloalkene and the efficiency and the stereochemistry of the cyclization. Biphenyl has an intermediate triplet energy (65–66 kcal mol^{-1}), between fluorene (68 kcal mol^{-1}) and naphthalene (61 kcal mol^{-1}) (27). Thus at room temperature, we could anticipate a fast interconversion between planar and perpendicular conformations of the triplet state for 2-vinylbiphenyls, as directly observed by Tokumaru and co-workers with unreactive 4-vinylbiphenyls (5). For 2-cycloalkenyl biphenyls the relative populations of planar and perpendicular triplets might be in the order of those described for 1-cycloalkenyl naphthalenes (6), with perhaps an increase in the percentage of the perpendicular triplets as a result of the higher triplet energy of biphenyl vs. naphthalene. Thus one may expect an exclusively planar triplet for **2** and **3** and a fast equilibrium between planar and perpendicular triplet for **4**. With **5** a *trans* triplet can also be expected. The observed increase in efficiency of the cyclization, with the hindering of isomerization from **5** to **2**, is consistent with an efficient cyclization from a planar triplet in competition with a decay from twisted configurations with the latter becoming faster with increasing size of the cycloalkene. The stereochemistry of the reaction of **2** and **3** is the same as that observed from the singlet state; a concerted mechanism and consequently perhaps adiabatic cyclization from a planar *cis* triplet can be inferred.

The formation of the *cis* photoproducts from **4** can only be explained by a cyclization from the perpendicular triplet state since a *trans* triplet state is not expected on energetic grounds (6), and a *trans* ground state, if it cyclized thermally, would give the *trans* photoproduct by disrotatory cyclization.

With **5** the *cis* photoproduct can also result from the cyclization of the perpendicular triplet but the increase of the *cis* proportion with conversion indicates the participation of a concerted cyclization following excitation of the *trans* ground state.

Depending on the size of the cycloalkenes, we have found products resulting from the cyclization of three different triplet conformations: (*i*) with smaller cycloalkenes, **2** and **3**, an efficient cyclization occurs from the planar *cis* triplet state; (*ii*) with the cycloheptenyl derivative **4**, the perpendicular triplet state is attainable and can explain the appearance of the *cis* photoproduct; the *trans* photoproduct could result from the cyclization of the planar *cis* and the perpendicular triplet conformers; (*iii*) the stereochemistry of cyclization of the cyclooctenyl derivative **5** is accounted for by the participation of the three triplet conformers (*cis*, perpendicular, and *trans*).

For unstrained acyclic 2-vinylbiphenyls, we can foresee a fast equilibrium between the three conformers of the triplet state consistent with the unchanged stereochemistry of cyclization, whatever the isomer irradiated (2), but the discovery of the more reactive conformers must await further investigations.

Experimental

The ^1H nmr spectra were recorded on either Hitachi–Perkin–Elmer R 24 B (60 MHz) or Brücker WH 90 (90 MHz) Instruments. Chemical shifts were given in δ (ppm) relative to tetramethylsilane (TMS) as the internal reference. Mass spectra were taken on a VG Micromass 16 F. The ^{13}C nmr spectra were obtained on a Brüker WP 60 (15.08 MHz) spectrometer equipped with a Nicolet BNC 12 calculator (4K programme, 8K acquisition) using 10–15% (w/v) solutions in chloroform-*d* containing 0.5% TMS. The individual carbon shieldings were measured from noise-decoupled spectra. nBuli from Aldrich was used as received. Diethyl ether was dried over sodium and stored under nitrogen over 4 Å molecular sieves. Hexamethylphosphoric triamide (HMPT) was distilled over calcium hydride and stored over 4 Å molecular sieves. All reactions were stirred magnetically and carried out under an atmosphere of nitrogen in flame dried glassware.

1-(2-Biphenyl)-cycloalcenes

1-(2-Biphenyl)-cyclopentene, **2**, and 1-(2-biphenyl)-cyclohexene, **3**, were known (11); we prepared these compounds according to the procedure described for **4**.

1-(2-Biphenyl)-cycloheptene, 4

To 2-biphenyllithium, prepared from 2-bromobiphenyl (1.11 g, 5×10^{-2} mol) in ether (50 mL) and a 1.5 *M* solution of n-butyllithium (5 mL) was added slowly at 0°C a solution of cycloheptanone (0.84 g, 7.5×10^{-2} mol) in ether (20 mL). The mixture was stirred for 1 h at room temperature, refluxed for 3 h, hydrolyzed with cold aqueous 10% ammonium chloride (50 mL), and extracted with ether (2 × 20 mL). The residue from evaporation of the dried (magnesium sulfate) ethereal extracts was chromatographed on a silica gel column. Petroleum ether elution gave 110 mg of biphenyl and diethylether elution gave 950 mg of an oil. This oil was dissolved in 30 mL of dry pyridine, chilled to −5°C, and 3 mL of thionylchloride was added. The mixture was allowed to stand at 10°C for 4 h, and then poured into ice water. The oily mixture was extracted with 100 mL of ether, the extract was washed with saturated saline solution, and dried and evaporated under reduced pressure. Chromatography on a silica gel column and elution with petroleum ether of the residue gave 760 mg (64%) of 1-(2-biphenyl)-cycloheptene in oil; nmr (CCl_4): 1–2.4 (m, 10H), 5.8 (t, 1H, *J* = 6.8 Hz), 7.1–7.5 (m, 9H). *Anal.* calcd. for $C_{19}H_{20}$: C 91.93, H 8.06; found: C 91.66, H 7.89.

1-(2-Biphenyl)-cyclooctene, 5

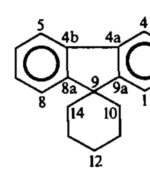
According to the procedure given for **4**, we obtained 820 mg (65%) of **5** (oil); nmr (CCL_4): 1.1–2.47 (m, 12H), 5.7 (t, 1H, *J* = 7.8 Hz), 7.03–7.48 (m, 9H). *Anal.* calcd. for $C_{20}H_{22}$: C 91.6, H 8.41; found: C 91.48, H 8.28.

Spiro[cycloalkane-9,9 fluorenes]

All 1-(2-biphenyl)-cycloalkenes gave quantitatively the corresponding spiro[cycloalkane-9,9 fluorenes] when treated as described for the cyclohexenyl derivative.

Spiro[cyclohexane-9,9 fluorene]

1-(2-Biphenyl)-cyclohexene, **3** (234 mg), was refluxed in benzene (1 h) with a catalytic amount of paratoluene sulfonic acid. Thin-layer chromatography on silica gel developed with light petroleum ether showed only one spot in uv light with a slightly shorter R_f than **3**. Chromatography on a silica gel column gave 198 mg (84%) of spiro[cyclohexane-9,9 fluorene] (13) which was recrystallized from 95% ethanol to afford white crystals, mp 82–83°C; ^1H nmr (CCl_4): 0.8–2.16 (m, 10H), 7.16–7.87 (m, 8H); ^{13}C nmr ($CDCl_3$): 153.036 ($C_{4a,b}$), 139.525 ($C_{8a,9a}$), 126.682 ($C_{2,3,6,7}$), 124.248 ($C_{1,8}$), 119.622 ($C_{4,5}$), 50.116 (C_9), 35.509 ($C_{10,14}$), 25.466 (C_{12}), 22.545 ($C_{11,13}$); mass spectra *m/e* (calcd. for $C_{18}H_{18}$: 234): 235 (12.8, M + 1), 234 (68, M), 191 (41, M − ($CH_2{=}CH_2$ + $^{\bullet}CH_3$), 178 (100, M − $2CH_2{=}CH_2$, phenanthrene).



General procedure for preparative irradiations

Preparative irradiations were carried out in a Rayonet RPR-100 reactor at 300 nm with a quartz tube for direct irradiations, or at 350 nm in a Pyrex vessel for sensitized reactions with xanthone. In direct photolysis, solutions of 1-(2-biphenyl)-cycloalkenes (5×10^{-3} *M*) in cyclohexane (100 mL) were purged with argon for 30 min and irradiated 4 h. Sensitized reactions were conducted in degassed benzene solution (100 mL) with 2.25×10^{-3} *M* of reactant and 2×10^{-3} *M* of xanthone; after 4 h of irradiation, all the reactants had been cyclized and the relative amounts of the photoproduct isomers were estimated by comparing the integrations of the corresponding peaks in glc.

trans-*9,10-Cyclopentyl-9,10-dihydrophenanthrene* t-***6***

Direct and sensitized irradiation gave only one isomer (glc). The solutions were evaporated and chromatographed on a silica gel column. Elution with petroleum ether, followed by recrystallization from methanol, afforded 86% (direct) and 88% (sensitized) of *trans*-9,10-cyclopentyl-9,10-dihydrophenanthrene as white needles, mp 155°C; ^{1}H nmr (CCl_4): 1.3–2.5 (m, 6H), 2.62 (m, 2H), 7–7.5 (m, 6H), 7.5–7.96 (m, 2H); mass spectra, *m/e* (calcd. for $C_{17}H_{16}$: 220): 221 (18.7, M + 1), 220 (100, M), 192 (70.9, M − $CH_2{=}CH_2$), 191 (97.9, M − CH_3 − CH_2), 178 (40.5, phenanthrene). *Anal.* calcd. for $C_{17}H_{16}$: C 92.73, H 7.27, found: C 92.19, H 7.26.

trans-*9,10-Cyclohexyl-9,10-dihydrophenanthrene t-7*

Direct and sensitized irradiations gave only the *trans* isomer (glc). Chromatography from a silica gel column, with petroleum ether as eluent, afforded 82% (direct) and 85% (sensitized) of *trans*-9,10-cyclohexyl-9,10-dihydrophenanthrene. Recrystallization from methanol gave white crystals, mp 90°C; ^{1}H nmr (CCl_4): 1.2–2.2 (m, 8H), 2.4 (m, 2H), 7–7.3 (m, 6H), 7.4–7.8 (m, 2H); mass spectra, *m/e* (calcd. for $C_{18}H_{18}$: 234): 235 (31.1, M + 1), 234 (100, M), 192 (52.4), 191 (96.2), 178 (29). *Anal.* calcd. for $C_{18}H_{18}$: C 92.31, H 7.69; found: C 91.96, H 7.93.

trans-*9,10-Cycloheptyl-9,10-dihydrophenanthrene,* t-***8***

Direct irradiation of **4** in a standard solution as described above, but containing also 10^{-3} *M* of piperylene, gave only *trans*-9,10-cycloheptyl-9,10-dihydrophenanthrene (glc) as an oil (78%); ^{1}H nmr (CCl_4): 1.6–2.5 (m, 10H), 2.53 (m, 2H), 7.1–7.5 (m, 6H), 7.6–7.9 (m, 2H); mass spectra, *m/e* (calcd. for $C_{19}H_{20}$: 248): 249 (13.6, M + 1), 248 (65.4, M), 192 (49), 191 (100), 178 (42.4). *Anal.* calcd. for $C_{19}H_{20}$: C 91.93, H 8.06; found: C 91.68, H 8.01.

trans-*9,10-Cyclooctyl-9,10-dihydrophenanthrene,* t-***9***

Direct irradiation of **5** in the standard solution containing 10^{-3} *M* piperylene gave a mixture of *trans* (95%) and *cis* (5%) **9** (glc). Chromatography on silica gel impregnated with 10% caffeine gave first a mixture of *trans* and *cis* **9** and then pure *trans*-**9**, mp 104°C; ^{1}H nmr (CCl_4): 1.4–2.5 (m, 12H), 2.88 (m, 2H), 7–7.5 (m, 6H), 7.5–7.9 (m, 2H); mass spectra, *m/e* (calcd. for $C_{20}H_{22}$: 262): 263 (16.6, M + 1), 262 (76, M), 192 (60.1), 191 (100), 178 (47). *Anal.* calcd. for $C_{20}H_{22}$: C 91.6, H 8.41; found: 91.48, H 8.26.

Base isomerization of trans-*9,10-cycloalkyl-9,10-dihydrophenanthrenes, **6–9***

By treating, at 0°C and under nitrogen, a solution of 5 mmol of *trans*-9,10-cycloalkyl-9,10-dihydrophenanthrene in 80 mL of diethyl ether and 6.4 mL (60 mmol) of HMPT with 10 mmol of nBuli in hexane for 4 h we obtained, after hydrolysis with methanol, a mixture of *trans* and *cis* **6–9** where the *cis* isomer is always dominant (see table, Scheme 3). The *cis* isomers have always a shorter retention time and the relative amounts are estimated from the corresponding areas in glc. Chromatography on silica gel impregnated with 10% caffeine, with petroleum ether as eluent, gave pure cis **6–9**. The *cis* isomers have the same mass spectra as the *trans* isomers.

cis-*9,10-Cyclopentyl-9,10-dihydrophenanthrene, c-**6***, mp 72°C; nmr (CCl_4): 1.3–2.5 (m, 6H), 3.23 (m, 2H), 7.1–7.4 (m, 6H), 7.5–7.94 (m, 2H). *Anal.* calcd. for $C_{17}H_{16}$: C 92.73, H 7.27; found: C 92.49, H 7.16.

cis-*9,10-Cyclohexyl-9,10-dihydrophenanthrene,* c-*7*, oil; nmr (CCl_4): 1.3–2.2 (m, 8H), 3.07 (m, 2H), 7.1–7.4 (m, 6H), 7.5–7.94 (m, 2). *Anal.* calcd. for $C_{18}H_{18}$: C 92.31, H 7.69; found: C 92.08, H 7.57.

cis-*9,10-Cycloheptyl-9,10-dihydrophenanthrene,* c-***8***, oil; nmr (CCl_4): 1.4–2.4 (m, 10H), 3.11 (m, 2H), 7.1–7.5 (m, 6H), 7.5–7.9 (m, 2H). *Anal.* calcd. for $C_{19}H_{20}$: C 91.63, H 8.06; found: C 91.60, H 7.89.

cis-*9,10-Cyclooctyl-9,10-dihydrophenanthrene,* c-***9***, oil, nmr (CCl_4): 1.4–2.5 (m, 12H), 3.15 (m, 2H), 7–7.5 (m, 6H), 7.5–7.9 (m, 2H). *Anal.* calcd. for $C_{20}H_{22}$: C 91.6, H 8.41; found: C 91.59, H 8.48.

Dehydrogenation of cis- *and* trans-*9,10-cyclohexyl-9,10-dihydrophenanthrene*

An equimolar mixture of *cis* and *trans*-9,10-cyclohexyl-9,10-dihydrophenanthrene (214 mg) dissolved in diglyme (50 mL) containing 20 mg of 10% Pd/C were refluxed under nitrogen. After 2 h a glc control showed that approximately half of the *cis* isomer had been dehydrogenated to tetrahydrotriphenylene and triphenylene while the *trans* isomer was unchanged. After refluxing overnight, the solvent was removed under vacuum and the residue chromatographed on a silica gel column. Elution with petroleum ether gave 82 mg of *t*-**7** and 108 mg of triphenylene.

Model bromamides were photolysed to investigate the reactivity of intramolecular C-5 hydrogen abstraction (from the nitrogen atom) of the corresponding amidyl radicals and of the cyclization of the resulting C-bromides. The observed results are discussed in terms of stereoelectronic as well as energetic considerations. In the former C-5 hydrogen abstraction, the reactivity difference between semi-rigid *trans* and *cis*-oriented reaction centers is only slightly in favor of the latter; the small difference is interpreted as due to the planar ground state Π amidyl radical structure with a low N—CO twisting barrier (4–5 kcal/mol). This interpretation is supported by the efficient C-5 hydrogen abstraction in *N*-bromo-*N*-alkyltoluamides, since a rigid planar amidyl radical does not allow the methyl C—H bond to colinearly approach the Π orbital. In marked contrast, there are large reactivity differences in the cyclization of C-bromides derived from these intramolecular H—Br exchanges; these arise from the requirement of colinearity of the approaching and departing bonds. Thus this requires the coplanar orientation of the C—CH_3 and C—CO bonds and this is the source of the reactivity differences.

YUAN L. CHOW, THOMAS W. MOJELSKY, LEON J. MAGDZINSKI et M. TICHÝ. Can. J. Chem. **63**, 2197 (1985).

On a effectué la photolyse de bromamides modèles dans le but d'étudier la réactivité, vis-à-vis de l'enlèvement intramoléculaire de l'hydrogène en C-5 (par rapport à l'atome d'azote), des radicaux amidyles correspondants ainsi que la cyclisation des C-bromures qui en résultent. On discute des résultats observés en fonction de considérations tant stéréoélectroniques qu'énergétiques. Dans le cas de l'enlèvement des hydrogènes en position C-5, la différence de réactivité entre les centres réactionnels semi-régides orientés en *cis* ou en *trans* ne favorise que légèrement les premiers; on peut interpréter la différence minime en supposant que l'état fondamental planaire Π de la structure radicalaire amidyle comporte une barrière à la rotation N—CO qui est faible (environ 4 à 5 kcal/mol). Cette interprétation est en accord avec le fait que l'enlèvement des hydrogènes en position C-5 des *N*-bromo *N*-alkyltoluamides est une réaction efficace et que ce résultat est dû à l'existence d'un radical amidyle planaire rigide qui ne permet pas à la liaison C—H du méthyle de s'approcher colinéairement de l'orbitale Π. Par opposition, il existe de grandes différences dans la réactivité des cyclisations des C-bromures qui dérivent de ces échanges H—Br intramoléculaires; ces différences proviennent du fait qu'il doit y avoir une colinéarité entre les liens qui approchent et ceux qui partent. Ceci requiert donc une orientation coplanaire des liaisons C—CH_3 et C—CO et ceci est la source des différences dans les réactivités.

[Traduit par le journal]

Amidyl radicals, RCON̈R′ (for reviews, see ref. 1), may have the Σ or Π electronic configurations as shown in **A** and **B**, assuming a sp^2 hybridization of the nitrogen atom. An N—CO bond twisted structure from **B** (Π configuration) is shown in **D**. If *sp* hybridization of the nitrogen atom is assumed, three non-bonded electrons are located in two *p*-orbitals as in **C**, which structurally resembles the Σ configuration.

D

About 15 years ago, we (2) showed that amidyl radicals do not react from the O-centered radical, but rather from the N-centered radical, and that amidyl radicals preferentially abstract the C-5 hydrogen (from the N-center) from the alkyl side chain rather than from the acyl side chain (3–5). On the basis of the Π electronic configuration of amidyl radicals indicated by esr (electron spin resonance) (6) and ^{13}C CIDNP (7) evidence we have proposed, after extensive model analyses, that amidyl radicals can twist around the N—CO bond with a small energy barrier (8) which causes the observed preference in intramolecular H-abstraction from the alkyl side chain. Later, using stereochemical considerations to explain the intramolecular additions of amidyl radicals to olefinic (9) and aryl groups (10, 11), others proposed the Σ (or Π) electronic configuration for the reactive state of amidyl radicals, which is generally the ground state unless special conditions prevail. While theoretical calculations on this question have been inconclusive (12, 13), detailed esr studies by Ingold's group (14–16) have finally confirmed that simple amidyl radicals have the Π radical ground state, which has either a planar or a twisted N—CO conformation with a low energy barrier (14). The latter had previously been generally neglected in considering the stereochemical implications of amidyl radical additions (9–11). As it is now possible to present a definite discussion, we deem it worthwhile to publish these old results describing intramolecular H-abstraction reactivities involving acyl chains as related to the amidyl radical configurations.

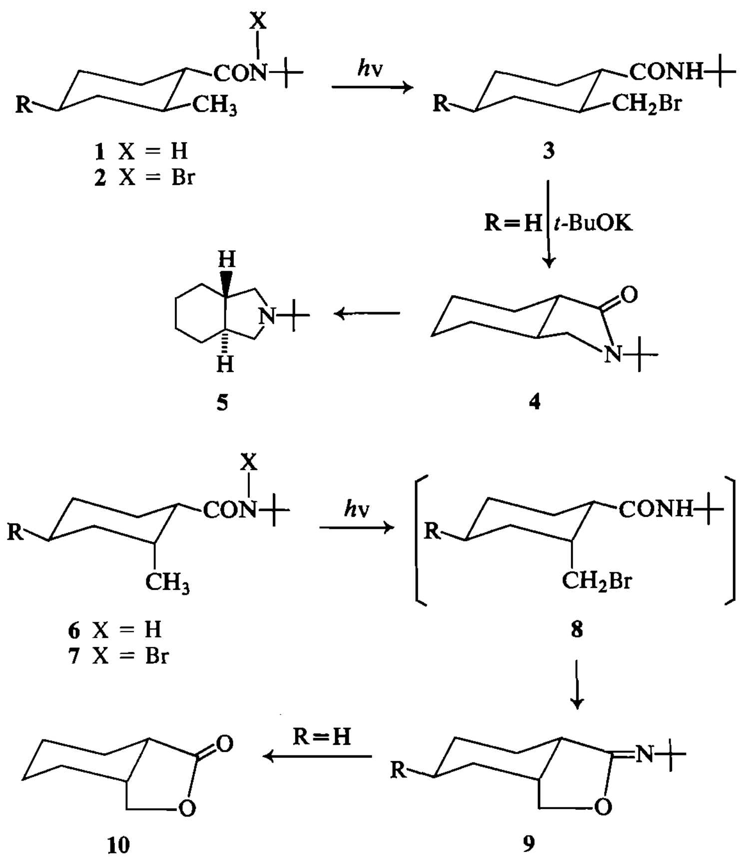
Results

The plan of this investigation was to generate the amidyl radicals by photolysis of *N*-bromamides **2**, **7**, and **14** and to examine the facility of intramolecular H-abstraction by product pattern analysis. Each amidyl radical should undergo intramolecular H-abstraction preferentially from the CH_3 group located at the C-5 position in the acyl side chains. Their efficiencies are expected to be controlled by the geometry of the methyl and carboxamide groups attached on rigid or semi-rigid ring systems.

The *N-tert*-butyl carboxamides **1***a* and **6***a* of *trans*- and *cis*-2-methylcyclohexane carboxylic acids were brominated with *tert*-butylhypobromite and the bromamides **2***a* and **7***a* were photolyzed in benzene by a procedure similar to that described before (8). In contrast to the excellent yields of bromide **3***a* from *trans*-bromamide **2***a*, the irradiation of *cis*-bromamide **7***a* gave more than 14 compounds; among them were amide **6***a* (33%) and iminolactones **9***a*, **11**, and **12**. These iminolactones were not isolated in pure states, but lactone **10** was obtained after vigorous hydrolysis of a mixture of iminolactones. The



Series *a* R = H; series *b* R = *t*-Bu

C-bromide **3***a* did not cyclize on heating but did so under the effect of hot *t*-BuOK to give lactam **4***a*, which was reduced to give pyrrolidin derivative **5***a*; this proved the lactam formation instead of the iminolactone formation which has been shown to be facile in acyclic bromamide photolysis (4, 8). The formation of iminolactones **11** and **12** and the complexity of the product pattern indicate that the *cis*-1,2-disubstituted cyclohexane ring must have a substantial population of the alternate chair conformation in which the *t*-BuN(X)CO group takes the axial conformation,[2] allowing H-abstraction from the C(3)-axial and C(5)-axial hydrogen to occur (see Discussion).

The use of 4-*tert*-butyl group substituted semi-rigid carboxamides **1***b* and **6***b* prevented the ring inversion to occur and gave cleaner results; in these models the cyclohexane ring is anchored on one side but the opposite side is flexible enough to do flattening and puckering. Photolysis of bromamide **2***b* gave a stable C-bromide **3** in about 90% yield, with small amounts of **1***b* and three by-products. Photolysis of *cis*-bromamide **7***b* gave more than 92% of the hydrobromide of iminolactone **9**, obviously formed from the primary photoproduct C-bromide **8***b*, and gave the free base **9** on neutralization. The structures of both **3***b* and **9***b* were decided by the fact that the nmr signals of the methyl groups in the starting bromamides were replaced by CH_2 signals with magnetically nonequivalent protons at the expected chemical shifts.

Either bromamides **14***a* or **14***b*, derived from *N*-methyl- or *N-tert*-butyltoluamides, were photolyzed in benzene or benzene containing 10% cyclohexane to give essentially quantitative yields of iminolactones **16***a* and **16***b* via the intermediacy of unisolated C-bromides **15***a* and **15***b*. In the presence or absence of a bromine atom and bromine scavenger, the product patterns were not affected, indicating that intramolecular hydrogen abstraction by the amidyl radicals from the *ortho*-methyl group is extremely efficient and operates cleanly.

[2] Using *cis*-ethyl-4-methylcyclohexane carboxylate as an approximate model, the population of the conformational isomer corresponding to **6***a* (or **7***a*) is 28% (17).

TABLE 1. Competitive inter- and intramolecular hydrogen abstraction by the amido radicals **17** and **18**

Solvent: % (v/v) cyclohexane in benzene	% Recovered amides (% of products)[a]	
	trans-**1***b* (% **3***b*)[a]	*cis*-**6***b* (% **9***b*)[a]
100	96 (≈2.5)	91 (≈8)
26.7	37 (63)	22 (77)
12.0	32 (68)	17 (83)
8.3	28 (72)	13 (87)
0.0	<5 (≈90)[b]	0 (>92)[b]

[a]The yields of the products were taken as (100% − % of recovered amides) and were also checked against their vpc peaks. These are shown in the brackets.
[b]The % yields of the products were determined from the isolation and confirmed by vpc analysis.

The competitive inter- versus intra-molecular H-abstraction of the amidyl radicals **17** and **18** (R = *tert*-butyl) generated from *cis*- and *trans*-bromamides **2***b* and **7***b* was investigated in solvent mixtures of cyclohexane–benzene. With increasing amounts of cyclohexane, intermolecular H-abstraction increased to afford more parent amides **1***b* and **6***b* in competition with the formation of **3***b* and **8***b* (i.e., **9***b*, see Table 1). The extent of the formation of these products should vary depending on the energetics (or the geometry) of the transition states in H-abstraction. In addition, the extent of the former, **1***b* and **6***b*, also depends on the concentrations of cyclohexane. Since quantitative gc analysis of **3***b* and **9***b* was frustrated by the broad and unsymmetrical peaks, the % yields of the parent amides **1***b* and **6***b* were analysed against an internal standard.

phthalide

Series *a* R = CH_3; series *b* R = $(CH_3)_3C$—

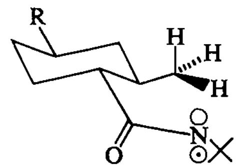
The photolysis conditions were kept constant except for solvent variations, and the starting bromamides were examined with ir to make sure no starting amides were left unbrominated. The lack of the starting materials prevented us from getting more points, but each point was repeated twice to give average values. Because of many steps taken in working up to give gc analytical samples, estimations of degree of accuracy were not easy. But the trend of decreases could be easily discerned.

Discussion

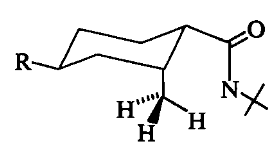
While intramolecular H-abstraction from the C-5 hydrogen of the acyl side chain in acyclic flexible amidyl radicals is relatively ineffective (3, 4, 8), the model amidyl radicals **17** and **18** generated from **1** and **6** in the present case undergo such H-abstraction very efficiently, at least in benzene, a poor H-atom donating solvent. This efficiency no doubt arises from the fact that the reacting carboxamide and methyl groups are held in a semi-rigid framework and that β-elimination, which has been shown to occur more readily than this type of intramolecular H-abstraction (3, 8), is blocked. Similar intramolecular H-abstraction in the aromatic amidyl radicals **20** generated from **13** is more efficient since even where the β-elimination is not blocked (with —$\dot{N}$—CH_3 from **13***a*) and intermolecular H-abstraction is possible, the intramolecular H-abstraction has prevailed over other possibilities. That functionalization at the methyl group of toluamide does not arise from a bromine atom chain reaction is demonstrated by the lack of effects on the pattern of the reaction in the presence of a bromine atom (or Br_2) scavenger, *tert*-butylethylene.

Table 1 shows the comparison of the efficiency of the intramolecular H-abstraction in *trans*- and *cis*-amidyl radicals **17***b* and **18***b* (k_t and k_c) using the independent competitions against intermolecular H-abstraction from cyclohexane (k_i[cyclohexane]) as the standard. This comparison is based on the assumption that intermolecular H-abstractions from cyclohexane by **17***b* and **18***b* occur with approximately the same rate constant, as both *N*-*tert*-butyl carboxamide groups have approximately, but not exactly, the same environment. This assumption is reasonable since the steric effects of the *N*-*tert*-butyl group exert such overwhelming influences on intermolecular H-abstraction that those of others become insignificant. While the difference in the intramolecular H-abstractions in **17***b* and **18***b* are small, **18***b* with the *cis*-configuration does so more efficiently, as shown by the two trends in Table 1. The smallness of the observed difference is a critical phenomenon which requires discussion.

The intramolecular H-transfers between an alkoxy (18–21) or aminium (22) radical and a C-5 hydrogen bond are generally evaluated with the O···C (or N^+···C) distance in an appropriate conformation. Owing to the definite structure assumed, and



17



18

19

accepted, in amidyl radicals, the orientation of the interacting orbital containing the unpaired electron and the C—H bond has to be considered in various probable conformations. Studies of Dreiding models have indicated that should amidyl radicals react in the Σ configuration, the observed small reactivity difference could be interpreted readily: in either *trans*-**17***b* or *cis*-**18***b*, the carboxamide and methyl groups could rotate to orient the sp^2-orbital and a C—H bond in a N···C distance of

2.5–2.6 Å with near colinear orientation without imposing much strain on the cyclohexane ring. Undoubtedly, similar considerations in the intramolecular addition reaction had led other groups to come to the conclusion that amidyl radicals might have the reactive state Σ configuration (9). This would be reasonable if the esr results were not known (14), since in the Π-configuration such close proximity and colinearity of the interacting centers could not be achieved. Model studies of the more rigid aromatic amidyl radical **20** shows these features more clearly; the Π radical has no chance for intramolecular H-transfer. But, *this argument is faulty in assuming that the* Π *configuration is planar and rigid, or planar and having an energy barrier of twisting higher than the activation energy of intramolecular H-abstraction.*

Electron spin resonance evidence from Ingold's group leaves no doubt that amidyl radicals, RCOṄR′, have the Π ground state configuration (14). If twisting of the N—CO bond with a low energy barrier (8, 14) is accepted for the Π-radicals, it is readily seen that the intramolecular H-transfer in models **17** and **18** occurs without perceivable efficiency difference between the *cis*- and *trans*-configurations. Dreiding models show the interacting orbitals can be near colinear, with the N···C distance about 2.5 Å, by twisting the N—CO bond for both. Early esr work also established that the delocalization of the unpaired electron to a CO or electron-withdrawing group in various radicals is minimal (6, 23); thus a low energy barrier (of N—CO twisting) and, also, the lack of the O-radical behavior for amidyl radicals are supported. Experimental activation energies (16) may be used to estimate the N—CO twisting energy barrier. We have proposed that the overwhelming preference (by a factor of at least 100) for abstraction of an acyl C-5 hydrogen over an alkyl C-5 hydrogen in an intramolecular competition arises primarily from the requirement to twist the N—CO out of the plane (8); this assumption has led us to estimate the energy barrier of twisting to be 3–4 kcal/mol. The difference of activation energies (16) in the two types of intramolecular H-abstractions is 1.4 kcal/mol, probably the lower limit of the twisting barrier; the necessity for this barrier to be lower than the activation energy of acyl C-5 hydrogen abstraction (9.1 kcal/mol) (16) can place the upper limit of this barrier at this figure. Thus, 4–5 kcal/mol for the N—CO twisting barrier is reasonable and surprisingly low in comparison to the N—CO twisting barrier of amides, determined to be ≈16–22 kcal/mol by variable temperature nmr studies (24).[3]

We now consider the *slightly* more efficient intramolecular C-5 hydrogen abstraction in *cis*-**18** than in *trans*-**17**. The transition state of the intramolecular H-abstraction can be facilitated by moving the C—CH_3 and C—CO bonds in the e,e-orientation in *trans*-**17***b* and those in the e,a-orientation in *cis*-**18***b* closer from the normal dihedral angles of 65° and 55°, respectively.[3] This motion is possible in *cis*-**18***b* since it causes flattening of the cyclohexane ring, but it is prohibited in *trans*-**17***b* since the motion causes the puckering of the ring (25). Thus, the smallness in the efficiency difference between two series of experiments (Table 1) indicates that coplanarity (21, 22) of these two bonds is not important; otherwise the difference will be substantial, as shown in the ring closure of C-bromides **3***b* and **8***b* discussed below.

[3]In the transition state of radical H-abstraction from a C-5 hydrogen, coplanarity requirements are also considered (see refs. 19 and 23).

The great efficiency difference in the ring closure of **3***b* and **8***b* to the iminolactones is a nice contrast to the intramolecular H-abstraction discussed above. For the iminolactone formation, the C=O has to approach the rear end of the C—Br bond in the transition state in which the colinearity of the interacting orbitals is the best geometry, minimizing the energy requirement. Similar Dreiding model studies show that such transition states require bringing the C—CO and C—CH_2Br bond close to coplanar orientation, which means the puckering of the cyclohexane ring in **3***b* (compare **17***b*). As this motion requires a large energy expenditure, the corresponding iminolactone is not formed even under forced conditions. Similar coplanarity requirements in **8***b* mean the flattening of the cyclohexane ring (compare **18***b*), which demands a relatively small energy expenditure (<10 kcal/mol), thus the facile formation of iminolactone **9***b* from **8***b* (25). For the unisolated aromatic C-bromide **15** from **14**, the cyclization is even more facile since the two relevant bonds are already held in coplanar orientation; the ring closure is spontaneous.

Though iminolactones **11** and **12** have not been isolated, their formation on irradiation of **7***a* is certain. From the consideration of conformation free energies, the alternative conformation to **6***a* and **7***a* should exist to a certain extent (17) and should generate amidyl radical **19** which undergoes intramolecular H-abstraction from the C(3)- and C(5)-axial hydrogens as discussed above. In the present H-abstraction, since the C—H bonds are semi-rigid, the requirement of the N—CO twisting in the Π amidyl radical is more obvious than ever. It should be noted that the cyclohexane ring inversion **18***a* ⇄ **19** is quite likely much slower than intramolecular H-abstraction from energetic considerations. The activation energies of the latter have been shown to be 9.1 kcal/mol in acyclic amidyl radicals (16) and, in the present case, probably <9.0 kcal/mol because of semi-rigid model **6***a*. In contrast, the activation energies for the former are generally ≈10 kcal/mol (25) and in **18***a* ⇄ **19** it should be higher than this value because of the eclipsing of 1,2-disubstituents in the transition state.

The small difference in intramolecular H-abstraction between *trans*-**17***b* and *cis*-**18***b* is surprising and has been explained by the Π amidyl radical configuration having a low energy barrier for twisting around the N—CO bond; undoubtedly, the esr results (14–16) provide us some confidence in arriving at this conclusion. However, another explanation is possible, though more speculative in nature. For this, we assume that Π and Σ radical configurations (i.e., **B** and **A**) as the ground and lowest excited state electronic configurations of amidyl radicals, and that the energy split between the two states is fairly small, say < 9.1 kcal/mol, in other words, much less than the activation energy for intramolecular H-abstraction from acyl chains (16). Under such a circumstance, intramolecular H-abstraction from acyl chains must involve the transition of the Π radical configuration **B** to the Σ radical configuration **A**. As such, no significant stereoelectronic control of the intramolecular H-abstraction can be observed with the model amidyl radicals used in the present study.

While the model systems adapted in the present study are inadequate to give us a finite solution, they have led us to recognize immensely intricate electronic configurations of amidyl radicals in their static and dynamic (reactive) states. The challenge led us to extend considerations to other reactive radicals with possibilities of delocalization, such as carboxyl and nitrogen dioxide radicals.

Experimental

The conditions and equipment are the same as those given in ref. 8. The samples of *trans*-4-*tert*-butyl-*trans*-2-methylcyclohexanecarboxylic acid and its *cis* isomer were obtained from the synthetic scheme published previously (26). The carboxylic acids were treated with $SOCl_2$ followed by *tert*-butylamine to afford the *N-tert*-butylcarboxamides **1***b* and **6***b*.

Photolysis of trans-*bromamide* **2**b

To a 25-mL aluminum foil-protected Erlenmeyer flask was added the *t*-BuOBr solution (5 mL) and **1***b* (0.148 g), which were stirred for 2 h at 0°C. After 2 h reaction, an aliquot was tested by ir spectroscopy for the absence of the 1500 cm^{-1} peak. The resulting crude solid was dissolved in anhydrous benzene (120 mL) placed a Pyrex photocell kept at 20°C. A 200-W medium pressure Hanovia lamp was used as the irradiation source. The photolysis was carried out for 45 min but the reaction was essentially complete in 30 min, as shown by KI–AcOH tests. The benzene solution was concentrated to give a solid residue (0.220 g); ir: 3430 (m), 3300 (m), 1665, 1505 (m) cm^{-1}; nmr: 5.7 (b, 1H), 4.5 (bs, 2H), 1.4 (s), 0.9 (s) ppm. Vapor phase chromatography (vpc) showed that the product had one major peak (90%) and four small peaks, of which one was the amide **1***b*.

A portion (0.180 g) of this photoproduct was subjected to preparative tlc on silica gel plates with 2% CH_3OH in $CHCl_3$ as the eluting solvent. The appropriate portion of the plates was scraped off and the silica gel was extracted with 15 mL CH_3OH for 1 h. The material recovered from the CH_3OH solution was taken up in $CHCl_3$ (2 mL) and was filtered through a short column containing neutral alumina (2 g) and further eluted with $CHCl_3$ (100 mL). Evaporation of $CHCl_3$ left a solid (0.130 g) which was recrystallized from acetone/petroleum ether (1:9) to give white crystals of **3***b*, mp 134–135°C; ir: 3430 (m), 1665, 1505 (m) cm^{-1}; ms *m/e*: 333 (M^+, 27), 331 (M^+, 27), 318 (18), 316 (18), 276 (64), 274 (59), 252 (100). *Anal.* calcd. for $C_{16}H_{30}NOBr$: C 57.84, H 9.10, N 4.22; found: C 57.78, H 9.04, N 4.25.

Compound **3***b* (30 mg) was refluxed in 20 mL benzene for 2 h. No change was observed in the ir spectrum of the residue.

Photolysis of cis-*bromamide* **7**b

The *N*-bromamide was prepared from **6***b* (0.147 g) and *t*-BuOBr in the usual manner to give **7***b* as a yellow solid (0.232 g). This material was dissolved in anhydrous benzene (120 mL) and photolyzed in the usual manner for 45 min. The photolysate was evaporated to give the solid HBr salt of **9***b* (0.233 g); ir: 3350 (m), 2950, 2860, 2750, 2670 (m), 1675, 1510 (w) cm^{-1}; nmr: 7.0 (bs, 1H), 4.7 (m, 1H), 3.9 (m, 1H), 2.7 (m, 1H), 1.55 (s), 0.9 (s) ppm. Irradiation at ca. 1.7 ppm changed the 4.7 and 3.9 ppm signals to an unsymmetrical AB quartet (J = 17 Hz).

The photoproducts (0.160 g) were taken up in 25 mL saturated Na_2CO_3 solution which was extracted with $CHCl_3$ (3 × 10 mL). The combined organic extracts were worked up to give, upon evaporation, a solid (0.076 g), which on gc showed one major peak (>92%) and three minor peaks, none of which corresponded to the starting amide **6***b*. The solid was subjected to preparative tlc on silica gel with 2% $CH_3OH - CHCl_3$ as eluent. After the usual extraction process, it gave a solid residue (0.06 g) which was recrystallized from $CHCl_3$/acetone (3:1) mixture to yield **9***b*, mp 92–93°C; ir: 1700, 1505, 1235, 1010 cm^{-1}; ms *m/e*: 251 (M^+, 10), 237 (54), 236 (100), 194 (15), 180 (11), 84 (47). *Anal.* calcd. for $C_{16}H_{29}NO$: C 76.44, H 11.63, N 5.57; found: C 76.71, H 11.65, N 5.39.

Quantitative analysis of cis- *and* trans-*bromamide photolyses*

Amide **1***b* or **6***b* (50.0 mg) and the *tert*-butylhypobromite solution (4 mL) were reacted as described before. After 2 h reaction time, a sample was taken for ir spectrum examination. Once the absence of absorption at 1500 cm^{-1} had been confirmed, the solution was concentrated at 0°C to a constant weight of residue while taking precautions to avoid exposure to light. The solid was then dissolved in the solvent mixture (120 mL) and was photolyzed under the conditions previously described.

For the photolysate obtained from amide **1***b*, 0.2 mL of the internal standard (*N-tert*-butyltoluamide 9.7 mg/5.0 mL $CHCl_3$) and sufficient photolysate were mixed to make exactly 5.0 mL solution, which was then concentrated on the rotary evaporator (15°C water bath temperature) until all the solvent was removed. Then 0.25 mL $CHCl_3$ was added and the resulting solution was analyzed by vpc (15% DEGS column at 180°C). The ratio of the area for amide **1***b* to internal standard was calculated and, with the assistance of a previously prepared calibration curve, the quantity of **1***b* in the solution was determined.

The photolysate obtained from amide **6***b* was treated with Na_2CO_3 solution. After drying, 5.0 mL of the photolysate was withdrawn and concentrated on the rotary evaporator (water bath at 15°C). To the residue was added 0.25 mL 2-phenylpropanone internal standard solution (concentration 0.268 mg/mL). The solution was analysed by vpc as above.

Photolysis of trans-*bromamide* **2**a

Sodium and isoamyl alcohol reduction of *o*-toluic acid according to the published method (27) gave *trans*-2-methylcyclohexanecarboxylic acid, mp 41–43°C; anilide mp 147–148°C (lit. (27) mp 148°C). The *N-tert*-butylamide **19** was recrystallized from aqueous ethanol; mp 159–160°C; ir (CCl_4): 3455, 1670, 1510 cm^{-1}; nmr: 0.87 (d, J = 5 Hz, 3H), 1.27 (s, 9H) ppm. *Anal.* calcd. for $C_{12}H_{23}NO$: C 73.04, H 11.75, N 7.10; found: C 72.96, H 11.55, N 7.23.

The usual bromination of **1***a* with *t*-BuOBr afforded bromamide **2***a*; ir (CCl_4): 1664, 1450 cm^{-1}; nmr: 0.93 (d, J = 6 Hz, 3H), 1.45 (s, 9H). This bromamide (870 mg) in benzene (30 mL) was photolyzed for 30 min, and the photolysate was evaporated under vacuum. The residue was chromatographed on silicic acid to give amide **1***a* (33 mg) and impure C-bromo compound **3***a* (662 mg); ir: 3440, 1640, 1510 cm^{-1}; nmr: 3.41 (bd, 2H); ms *m/e*: 377, 375, 260, 262, 220, 222, 203, 205, 196, 140, 95. Heating of the latter fraction in benzene caused darkening of the solution and gave **3***a* on work-up.

The residue obtained from photolysis of **2***a* (652 mg) was refluxed with *t*-BuOK (230 mg) in *t*-BuOH (6 mL) for 2 h. The product was analyzed by vpc showing **4** (66%, RT 7 min), **1***a* (16%, RT 4.8 min), and some unreacted **3***a*. Silicic acid chromatography of the product gave lactam **4** (196 mg); ir: 1690, 1400, 1365 cm^{-1}; nmr: 1.37 (s, 9H), 3.39 (dd, J = 9 and 5.5 Hz, 1H), 2.98 (dd, J = 9 and 2 Hz, 1H) ppm; ms *m/e*: 195 (M^+, 16), 180 (100), 178 (55), 152 (53), 58 (19).

The lactam **4** was reduced with LAH to pyrrolidine **5** which gave a picrate, mp 155–157°C. *Anal.* calcd. for $C_{18}H_{26}N_4O_7$: C 52.68, H 6.39, N 13.65; found: C 52.83, H 6.44, N 13.58.

Photolysis of cis-*bromamide* **7**a

Hydrogenation of *o*-toluic acid in the presence of PtO_2 in acetic acid followed by fractional distillation (28) gave a fraction boiling at 106–108°C/0.5 Torr (1 Torr = 133.3 Pa). The methyl ester of the fraction was analyzed by vpc showing the presence of 95% of *cis*-2-methylcyclohexanecarboxylic acid and 5% of the *trans* isomer. The corresponding amide had mp 151–152°C (lit. (28) mp 151–153°C); ir: 3360, 3180, 1660, 1620; nmr: 0.91 (d, J = 6 Hz, 3H), 2.57 (m, $W_{1/2}$ = 15 Hz, 1H) ppm. The corresponding anilide had mp 119–122°C (lit. (28) mp 68°C); ir: 3325, 1655, 1600, 1520. *N-tert*-butylamide **6***a* was recrystallized from a pet. ether – benzene mixture giving white crystals, mp 111–112°C; ir: 3320, 1645, 1550 cm^{-1}; nmr: 0.92 (d, J = 7 Hz, 3H), 1.38 (s, 9H) ppm. *Anal.* calcd. for $C_{12}H_{23}NO$: C 73.04, H 11.75, N 7.10; found: C 73.01, H 11.68, N 7.28.

Amide **6***a* (0.5 g) was brominated and photolyzed as described above. The crude product showed more than 10 spots on tlc analysis. The crude product was separated by silicic acid chromatograph to give fractions 1 (228 mg), 2 (192 mg), and 3 (50 mg). Fraction 1 contained the parent amide **6***a* (33% overall estimated from peak areas) and several minor components as shown by vpc. Fraction 2 was rechromatographed to give an amorphous solid; ir: 1705, 1460, 1310, 1140; nmr: 4.67 (t, J = 4), 4.35 ($W_{1/2}$ = 7 Hz), 3.25 ($W_{1/2}$ = 7 Hz), 2.33 ($W_{1/2}$ = 8 Hz), 0.97 (d, J = 6.5 Hz), 1.02 (d, J = 6.5 Hz) ppm.

This amorphous solid was assumed to be a mixture of iminolactones **11** and **12**. On attempted recrystallization from a benzene–ethanol mixture, the ir and nmr of the recovered solid exhibited patterns similar to those of fraction 3, which was believed to be an isomeric mixture of hydrolysis products of **11** and **12**. Another portion obtained from this chromatography exhibited the nmr signal at 4.1 (dd, J = 9 and 3.5 Hz) and 4.0 (J = 9 and 2 Hz) ppm due to **9***a*.

A combined fraction 2 (626 mg) was hydrolyzed in hot 4 N HCl solution for 20 h. The product was separated into an acidic fraction (126 mg) and a neutral fraction (310 mg). The acidic fraction was chromatographed on silicic acid to afford lactone **10** (66 mg); ir: 2875, 1780, 1140, 950 cm^{-1}; nmr: 4.09 (dd, J = 9 and 4 Hz, 1H), 3.80 (dd, J = 9 and 1 Hz, 1H) ppm. An authentic lactone **10** was synthesized from LAH reduction of *cis*-1,2-cyclohexanedicarboxylic acid and showed identical ir and nmr spectra with those obtained from the photolysis sample.

Photolysis of N-*bromo*-N-*methyltoluamide* *14*a

The toluamide **13***a* (0.23 g) and *t*-BuOBr (6 mL) were reacted to give a bromamide **14***a* (0.37 g) which was taken up in benzene (120 mL) and irradiated as above at 20°C for 1 h. The photolysate was evaporated to afford a residue (0.31 g) which was recrystallized three times from $CHCl_3$–acetone (1:3) to give the hydrobromide of iminolactone **16***a*, mp 205–206°C; ir: 3460 (m), 2700 (m), 1700; nmr (D_2O): 7.9 (4H, m), 6.0 (2H, s), 3.4 (3H, s) ppm. *Anal.* calcd. for $C_9H_{10}NOBr$: C 47.39, H 4.42, N 6.14; found: C 47.47, H 4.51, N 6.25.

The residue from the mother liquor was treated with saturated Na_2CO_3 solution (20 mL) and extracted with CH_2Cl_2. Work-up of the extracts gave iminolactone **16***a* (0.113 g); ir: 1700 cm^{-1}; nmr: 7.5 (4H, m), 5.3 (2H, s), 3.18 (3H, s) ppm; ms m/e (%): 148 (M^+, 16), 147 (100), 146 (84), 118 (77). The solid in pet. ether was chromatographed on neutral alumina to give, as the only solid, phthalide, mp 69–71°C (lit. (29) mp 72–73°C); ir and nmr spectra were identical with those of another sample.

In a separate experiment, bromamide **14***a* (0.32 g) was photolyzed in 5% cyclohexane – benzene (120 mL) containing 3 drops of *tert*-butylethylene. The crude product before or after basification, or after chromatography, did not yield the starting amide **13***a*.

Photolysis of N-*bromo*-N-tert-*butyltoluamide* *14*b

The parent amide, **13***b*, (0.22 g) was treated with *t*-BuOBr (6 mL) to give *N*-bromamide **14***b* (0.33 g) which was photolyzed as above for 1 h at 20°C and evaporated to give a residue (0.25 g). Part of this (0.13 g) was recrystallized from acetone–$CHCl_3$ (3:1) to give the hydrobromide of iminolactone **16***b*, mp 110–111°C; ir: 1675 cm^{-1}; nmr: 7.8 (4H, m), 5.9 (2H, s), 1.75 (9H, s) ppm. The residue (0.12 g) was treated with saturated Na_2CO_3 solution (10 mL) and extracted with CH_2Cl_2 to give iminolactone **16***b* (0.07 g); ir: 1700, 1650 cm^{-1}; nmr: 7.8 (4H, m), 5.25 (2H, s), 1.4 (9H, s); ms m/e (%): 189 (M^+, 12), 174 (100), 134 (71).

Attempts to reduce iminolactone **16***b* with an excess of LAH gave only **16***b*. Iminolactone **16***b* (0.05 g) in 20% H_2SO_4 was refluxed for 3 h. The solution was extracted with $CHCl_3$. The extracts were evaporated to give phthalide (0.03 g), mp 72–73°C (29), as the only peak shown in gc analysis.

In a separate experiment, bromamide **14***b* (0.22 g) was photolyzed in 5% cyclohexane – benzene containing 3 drops of *tert*-butylethylene. The photolysate was neutralized, extracted, and worked up to give iminolactone **16***b* without contamination.

Chemistry of amidyl radicals: intramolecular reactivities of alkenyl amidyl radicals

YUAN L. CHOW[1] AND RICHARD A. PERRY[2]

Department of Chemistry, Simon Fraser University, Burnaby, B.C., Canada V5A 1S6

Received August 10, 1984

YUAN L. CHOW and RICHARD A. PERRY. Can. J. Chem. **63**, 2203 (1985).

Amidyl radicals possessing $\Delta^{4,5}$, $\Delta^{5,6}$, and $\Delta^{6,7}$ double bonds were generated from the photodecomposition of nitrosamides and chloramides and the products were identified. Dichotomies of amidyl radical reactivities were discovered and compared with published kinetic rate constants. In complete reversal to intermolecular reactivities, intramolecularly the alkenyl amidyl radicals preferentially add to the double bonds rather than abstract a C-5 hydrogen even if it is allylic. In intramolecular competition, amidyl radicals add to an acyl side chain double bond more efficiently than to an alkyl one; this is just the opposite to intramolecular H-abstraction of amidyl radicals. Taken together with the published results, it is established that, in intramolecular attacks of double bonds, amidyl radicals selectively undergo the *propia*-addition to generate an *exo*-cyclic radical rather than the *longa*-addition to an *endo*-cyclic radical: this rule should replace the old one that amidyl radicals preferentially cyclize to form five-membered rings if choices are available.

YUAN L. CHOW et RICHARD A. PERRY. Can. J. Chem. **63**, 2203 (1985).

On a généré des radicaux amidyles possédant des doubles liaisons $\Delta^{4,5}$, $\Delta^{5,6}$ et $\Delta^{6,7}$ en faisant appel à la photodécomposition de nitrosamides et de chloramides et on a identifié les produits obtenus. On a découvert les dichotomies des réactivités des radicaux amidyles et on les a comparé avec les constantes de vitesses cinétiques publiées antérieurement. En opposition complète avec les réactivités intermoléculaires, les radicaux amidyles alkényles s'additionnent préférentiellement d'une façon intramoléculaire sur les doubles liaisons plutôt que d'enlever un hydrogène en C-5, même s'il est allylique. Dans une compétition intramoléculaire, les radicaux amidyles s'additionnent plus facilement à une double liaison d'une chaîne latérale acyle qu'à une chaîne alkyle; ce résultat est justement l'opposé de ce qui se produit lors d'un enlèvement intramoléculaire de H des radicaux amidyles. Si l'on prend ces résultats avec ceux qui ont été publiés antérieurement, on peut établir que, lors d'attaques intramoléculaires sur des doubles liaisons, les radicaux amidyles subissent sélectivement une addition *propia* conduisant à un radical cyclique *exo* plutôt qu'une addition *longa* conduisant à un radical cyclique *endo*: cette règle devrait remplacer la règle antérieure selon laquelle les radicaux amidyles se cyclisent préférentiellement pour former des cycles à cinq chaînons, s'ils en ont le choix.

[Traduit par le journal]

Chemistry of amidyl radicals has attracted much attention in the last two decades (1–11) and been reviewed (1–4). The major interest has been the electronic configuration from which amidyl radicals (RCOṄR) (12–20) react with substrates and its relation to amidyl radical reactivities. Fifteen years ago, we found that *N*-alkylamidyl radicals interact with an olefin (e.g., 1,3-pentadiene and cyclohexene) by exclusive allylic hydrogen abstraction but no addition (21, 22);[3] this preference was totally reversed in intramolecular reactivity, e.g., addition to the C(5)-atom of the olefinic bond prevailed over H-abstraction from the C(5)-allylic hydrogen (24). These observations have led us to an extensive investigation of the intramolecular reactivity of amidyl radicals (25). In the meantime, while arguments on the Σ and Π amidyl radical configurations continued inconclusively, several works (14–18) on intramolecular reactivities, in particular cyclizations of alkenyl amidyl radicals, were published and interpreted in favor of Σ and (or) Π electronic configurations as the reactive state. Theoretical calculations (19, 20) on the $\Sigma-\Pi$ structure of amidyl radicals have not been able to give a definitive answer (19). Recently, Ingold's group (26–29) has extended the esr observations reported earlier by Danen and Gellert (12), and proven convincingly that amidyl radicals (RCOṄR) possess Π structure in their ground state; they have also determined many valuable rate constants of amidyl radical reactions by kinetic esr spectroscopy (27, 29). The availability of these finite parameters allows us to discuss our old results more intelligently. We wish to publish this work now.

Results

The general plan was to generate amidyl radicals carrying a $\Delta^{4,5}$, $\Delta^{5,6}$, or $\Delta^{6,7}$ (from the N center) olefinic bond either in N-alkyl or N-acyl chains and investigate competing intramolecular H-abstraction from the C(5)-hydrogens and additions to the double bonds. It should be noted that intramolecularly, amidyl radicals preferentially abstract the C-5 hydrogens on the alkyl side chain of the N-center rather than those from the acyl side chain (9, 14), and do so from the nitrogen center but not from the amide oxygen center (14, 15).

The required amides **1***a*–**6***a* were prepared by the usual reactions and the details of their preparation have been described in the thesis submitted by one of the authors (25). Nitrosamides **1***b*–**6***b* were prepared by nitrosation with either $NaNO_2$ in $AcOH-Ac_2O$ or N_2O_4 in CH_2Cl_2 and the crude products were utilized in photolysis without purification since nitrosamides are generally sensitive to heat and light (9, 30). By either method, one of the side reactions was the addition of N_2O_4 or N_2O_3 to the double bond. While this addition was slower than the nitrosamide formations in general, some of these nitrosamides were contaminated with a small amount of the addition products (see Table 1). In the preparation of **4***b* and **6***b* the contaminants amounted to as much as 15% and were clearly observable in the nmr and ir spectra. Therefore, all these nitrosamide samples were closely monitored with ir and nmr spectra before photolysis and the light source was filtered with $NaNO_2$ – sodium naphthalate filter solution to cut off the energy <400 nm in order to avoid excitation of nitro or nitrite

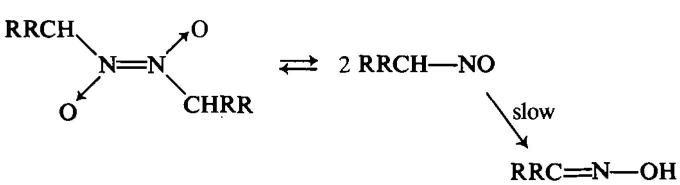
groups. The filter system allows us to selectively excite the $n \rightarrow \pi^*$ transition band of nitrosamides and gives cleaner product formation, as demonstrated in earlier studies (30). The preparation of nitrosamides **1***b*–**6***b* and chloramides **1***c* and **6***c* was described in the thesis (25). Their physical data are given in Table 1.

Photolysis of nitrosamides under nitrogen generally gives the C-nitroso compounds as the primary photoproducts that are in equilibrium with their dimer and also tautomerize to the corresponding *syn*- and *anti*-oximes[4] with a slower rate. Depending on the photolysis conditions, the C-nitroso dimer absorption in the 300-nm region can be observed and the dimers can be isolated if the photolysates are worked up quickly (9). In general, the photolysates were kept at room temperature for a long time to allow their tautomerization to oximes as shown below. The structures and stereochemistry of *syn*- and *anti*-oximes were determined from chemical shifts and coupling patterns of the neighboring protons (e.g., N—CH_3, N—CH, etc.) and characteristic ir absorptions; the correlations were well established from our previous work (31).



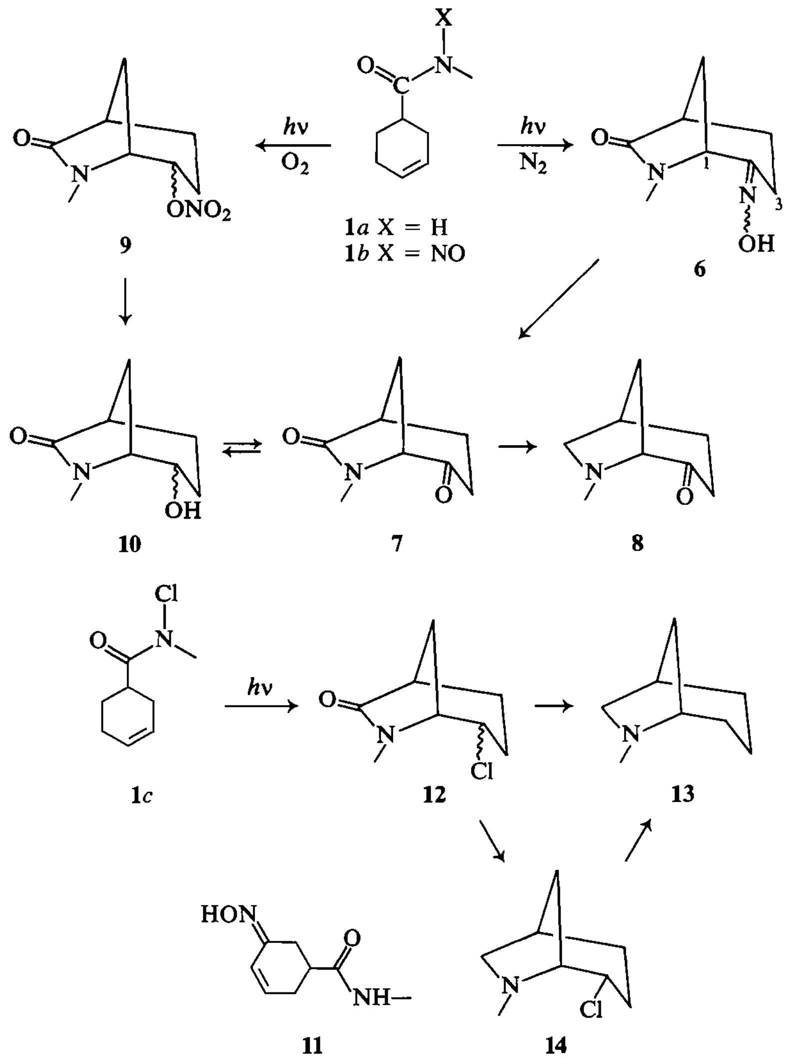
Photolysis of **1***b* in benzene under nitrogen gave *anti*- and *syn*-oximes **6** (2:1 ratio, up to 68%), ketolactam **7** (18%), and a mixture of *syn*- and *anti*-enone oximes **11** (6%); about 4% of nitratolactam **9** was also detected. The crude product contained the corresponding C-nitroso dimer and could be hydrolysed by sodium bisulfite to give ketolactam **7** in 56% yield. As *syn*-**6** was slowly isomerized to *anti*-**6** on standing, a sample of *syn*-oxime was obtained as a mixture with *anti*-**6**. Their configurations were clearly indicated by the N−CH and N−CH_3 protons at 3.90 and 2.82 ppm for *anti*-**6** as compared to those at 4.65 and 2.89 ppm for *syn*-**6**. The ketolactam **7** was reduced with $NaBH_4$ to *endo*- and *exo*-hydroxylactams **10**, and with LAH followed by Jones' oxidation to aminoketone **8**, the structure of which was established previously (32). Enone oxime **11** could not be separated to its *syn* and *anti* isomers, but showed ir absorptions at 1670 and 1550 cm^{-1} for a secondary amide and the chemical shifts of the olefinic protons at 6.3 and 5.8 ppm regions assignable to such conjugated oximes (33).

Photolysis of **1***b* under oxygen, other conditions being the same, was straightforward, giving the *exo*- and *endo*-isomeric pair of nitratolactams **9** (51%) and that of hydroxylactams **10** in addition to nitrolactams as the minor products, in agreement with the oxidative photoreaction of nitrosamides shown previously (30). The nitrolactams were obtained in only small amounts and could not be isolated. The structures of **9** and **10** were related to ketolactam **7** and aminoketone **8** by a series of hydrolysis, reduction, and oxidation as described in the Experimental. The *endo*- and *exo*-nitratolactams **9** showed the expected ir bands at 1690, 1630, 1280, and 860 cm^{-1} and similar ms fragmentation patterns; the *endo* and *exo* configurations were confirmed by the proton signals of CH—ONO_2; the former gave a double doublet at 5.1 ppm (J = 9 and 7 Hz) for the axial H and the latter a narrow signal at 5.26 ppm ($W_{1/2}$ = 9 Hz) for the equatorial H.

Photolysis of chloramide **1***c* was also investigated under nitrogen to give *endo*- and *exo*-chlorolactams **12** (33 and 39% isolated yields), both of which showed well-defined nmr spectra and the same ms pattern; the former showed an axial proton (for CHCl) at 4.25 ppm (ddd with J = 9, 7 and 1 Hz) and the latter an equatorial proton at 4.32 (dd, with J = 6 and 3 Hz). Chlorolactams **12** were easily reduced to chloroamines **14**, but only *endo*-**14** could be isolated. The *exo*-**14** was unstable and reduced by LAH much more rapidly (than *endo*-**14**) to the known amine **13** (34), due to the efficient participation of the amine in displacing the chloride; the intermediate, aziridinium ion, was obviously reduced to give the azabicyclic[3.2.1] system as in **13**.

Photolysis of nitrosamide **2***b* under nitrogen gave *syn*-β-lactam oxime **15** (44%) and the corresponding keto-β-lactam (7%); a β-lactam was indicated by the ir peak at 1725 cm^{-1}. By decoupling experiments, the low-field doublet (C(1)−H) and triplet (C(6)−H) were shown to be coupled to each other with J = 5 Hz, in analogy to nmr data of a *cis*-fused lactam ring system (35). This, together with the fact that the C(1)−H is shown not to be coupled to other high-field protons, virtually eliminates the alternate structure **16** as the product. The assignment of the *syn* orientation was based on the low chemical shift of C(1)−H at 4.05 ppm and relatively high chemical shift of C(3)-equatorial hydrogen at 2.6 ppm in accordance with the

[4]Following the previous definition (30), the *syn*-oxime is the one possessing the oximino OH on the side of the lactam ring and the *anti*-oxime is the one possessing that on the opposite side.



previous correlation (31). The keto-β-lactam was not isolated in the pure state.

Successful use of $BrCCl_3$ as a radical trapping agent (32) led us to photolyze nitrosamide 3*b* in $BrCCl_3$ whereby single *exo*-bromolactam **17** was isolated in 89% yield. In the process, CCl_3NO was also formed, as shown by the uv absorption (32) at 580 nm. The nmr spectrum became well separated on addition of $Eu(fod)_3$; decoupling experiments on this spectrum (see Experimental) clarified the coupling patterns of the protons. The coupling constants of $J_{1,5}$ = 8 Hz and $J_{1,8}$ = 1.5 Hz are in good agreement with other azabicyclo[3.3.0] derivatives (36) and confirm the *exo*-bromo orientation in **17**. LAH reduction of **17** to the known amine **18** completed the proof of the structure (37).

The preparation of nitrosamide 4*b* was accompanied by N_2O_4 addition to the double bond. The best sample contained a small amount of the starting amide 4*a* and some N_2O_4 adducts (ca. 10%); this material was used in the photolysis under nitrogen. The crude product was a complex mixture but gave *anti*-oxime **19** (25%) and a fraction tentatively assigned to enone oxime **21** (≈7%) after extensive chromatography. The *anti*-oxime **19** was the only *tertiary* amide obtained, showing a low amide CO stretching frequency at 1605 cm^{-1} and the OH signal at 10 ppm. The nmr triplet at 3.85 ppm indicated a more symmetrical skeleton of the [3.3.1] system than the [4.2.1] system. This chemical shift, together with the multiplet at 3.25 ppm for the equatorial C(7)−H, indicated the *anti*-oxime configuration. The ketolactam was reduced with LAH and oxidized by Jones' reagent to give aminoketone **22**.[5] All other fractions were secondary amides (ca. 1640, 1550 cm^{-1}) that did not show typical olefinic proton signals, except for one which exhibited ir absorptions at 1635 and 1550 cm^{-1}, and olefinic proton signals for an enone oxime (33) at the 6.2 and 6.8 ppm regions. This compound could be the oxime **21**. Various difficulties prevented us from continuing the work.

Photolysis of 5*b* under nitrogen gave *syn*- and *anti*-oximino-amides **23** (49%) and ketoamide **24** (14%). The C-nitroso dimer was also detected during irradiation (λ_{max} 295 nm) and tautomerized slowly to the oximes. In spite of extensive search for enone oximes, only the starting amide 5*a* (8%) was obtained from the crude product. The *syn*-oxime **23** was not isolated in the pure state but as a mixture with *anti*-**23**. This mixture was hydrolysed to ketoamide **24** as the only product. The oximes *anti*-**23** and *syn*-**23** exhibited the expected nmr signals (31) for the C(1)−H at 4.39 ppm (dd, J = 5.5 and 1 Hz) and 5.40 ppm (broad d, J = 5.5), respectively.

Nitrosation of acetamide 6*a* was contaminated with ca. 10% of the N_2O_4 addition products as the best sample ever obtained.

[5]It should be mentioned that aminium radicals preferentially add to a double bond, either in intermolecular or intramolecular reactions (38).

This sample decomposed slowly in benzene in the dark. Photolysis of this sample showed no formation of C-nitroso compound, and the crude product gave **6***a* (37%) and 4-acetoxycyclohexene (9%) in addition to many minor products. The preparation and photolysis of *N*-chloramide **6***c* were even more complicated, giving at least 14 compounds in the 5−10% yield range after photolysis. As in neither photolysis was a bicyclic acetamide detected, the work was not pursued further.

Discussion

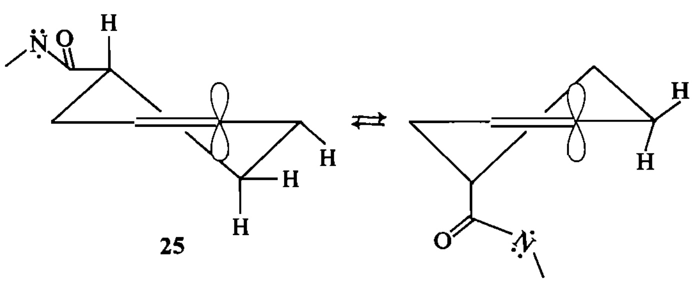
Three general conclusions can be drawn from the intramolecular reactions presented here and published in the literature (17, 18). First of all, in contrast to the intermolecular reactivities reported before (21−23), intramolecular addition of amidyl radicals preferentially occurs to suitably located double bonds (e.g. $\Delta^{3,4}$, $\Delta^{4,5}$, and $\Delta^{5,6}$ from nitrogen) either in acyl or alkyl side chains to form 4, 5, and 6-membered rings, rather than to abstract C-5 hydrogens, even if these hydrogens are allylic. Secondly, the attack on these double bonds always occurs specifically in the *propia*-mode (i.e. attack at the nearest end of the double bond) to generate *exo*-cyclic C-radicals rather than in the *longa*-mode (i.e. attack at the further removed end of the double bond).[6] It is now established that for amidyl

[6]The new term *propia−longa* addition is derived from the Latin adjectives *propius* (near) and *longus* (far) to describe the point of attack during the course of reactions. This term is preferred over that of the *exo−endo* cyclization (refs. 29 and 39) since conceptually the latter can give alternative pathways and cause ambiguity in the formation of polycyclic systems.

radicals *propia*-cyclization takes precedence over ring size considerations: e.g., $\Delta^{4,5}$, $\Delta^{5,6}$, and $\Delta^{6,7}$-alkenyl amidyl radicals cyclize to give four, five, and six-membered rings, respectively. Similar preference for *propia*-addition has been reported for the kinetically controlled cyclization of alkenyl C-radicals (39). Thirdly, the *propia*-cyclization of amidyl radicals involving the acyl chain occurs more efficiently than that involving an alkyl chain; this is in sharp contrast to the pattern of the intramolecular H-abstraction reactivity of amidyl radicals (14).

These conclusions can be expanded for individual cases with reference to kinetic data reported for intramolecular reactions of amidyl radicals (27, 29). As these kinetic data were obtained with open chain amidyl models, comparisons with them have to take into account semi-flexible cyclic alkenyl groups in the amidyl models used in these studies.

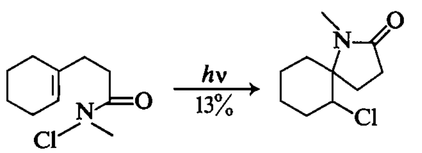
The activation energy for intramolecular H-abstraction is 6–9 kcal/mol ranging from C-5 allylic to C-5 methyl hydrogen, and that for the *propia*-cyclic addition 5–8 kcal/mol in the addition to C-5 and C-6 olefinic carbons (29); it is expected that corresponding reactions in intermolecular modes will require even higher activation energies, as their rate constants of H-abstraction by amidyl radicals suggest ($\approx 10^4\ M^{-1}\ s^{-1}$) (21, 29). As some cyclohexene derivatives are shown to have the activation energy of inversion (e.g. **25** ⇄ **26**) of 5–6 kcal/mol (40), the cyclohexene ring inversion can be faster than any



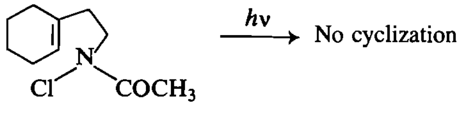
25 **26**

inter- and intramolecular reactions. As such, the requirement for the axial orientation of the amidyl radical side chain as in **26** would not be expected to be the rate limiting factor in the intramolecular reactions.

The second conclusion is best illustrated by cycloaddition of **2*b***, where a strained β-lactam is formed without a trace of a γ-lactam, and is also shown in the *N*-chloramide cyclizations of **27** and **28** reported by Kuehne and Horne (18). The cyclization in **28** to a four-membered ring obviously requires so high an activation energy that intermolecular reactions supersede the overall pattern; unfortunately, H-abstraction from C-5 allylic hydrogen was not carefully investigated. With two distinct exceptions involving bicyclo[3.3.1]non-6-en-3-yl amidyl radical systems, chromous chloride promoted cyclization of *N*-chloramides mostly follows this rule (41), indicating that chromous ions may have not changed the behavior of amidyl radicals by coordination.

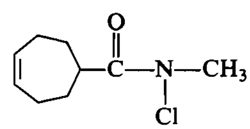


27

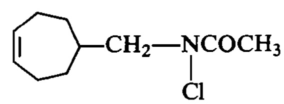


28

The first conclusion is amply substantiated by **1*b***, **1*c***, and **5*b*** in this paper and other chloramides reported by others (17, 18): intramolecular addition to the C-5 olefinic carbon always occurs preferentially over H-abstraction from the C-5 allylic hydrogen. The published kinetic data on open chain amidyl radical reactions (29) show that the ratio of rate constants for the former addition to the latter H-abstraction is ≥2 in the competition involving acyl chains. A similar ratio for the competition involving alkyl chains is estimated[7] to be $5 \times 10^4/1 \times 10^7 = 1/200$, which is dramatically different from the nil H-abstraction observed in **5*b*** and similar *N*-chloramide decompositions (17, 18). The kinetic data (29) also indicate the rate constant ratio of addition to the C-6 of a $\Delta^{6,7}$ olefinic bond to H-abstraction from a C-5 allylic hydrogen to be $1 \times 10^6/5 \times 10^6 = 1/5$, when involving acyl chain reactions. The observed results from the decompositions of **4*b*** and *N*-chloramide **29** are just the reverse, e.g., the addition to form the six-membered ring occurs preferentially over H-abstraction from the allylic C-5 hydrogens in acyl chain reactions (though less efficiently than $\Delta^{5,6}$ cyclization in **1*b*** and **1*c***). There is a curious lack of H-abstraction from the C-5 allylic hydrogens located on the alkyl side of amidyl radicals generated from *N*-chloramide **30**, even when the addition to the $\Delta^{6,7}$ double bond does not occur (17).



29



30

The third conclusion is demonstrated by the better yields of the cyclization products from **1*b*** and **1*c*** in comparison to the poorer yield of those from **5*b***. This is more dramatically demonstrated in the benzoyl peroxide initiated decomposition of three series of *N*-chloramides (e.g. **29** vs. **30**) previously reported (17), and is also supported by kinetic data (29). It is noteworthy that amidyl radical intramolecular H-abstraction from C-5 hydrogen is far more (at least 100 times) efficient with those hydrogens in an alkyl chain than those in an acyl chain (14), just the reverse of the observed intramolecular addition reactivity.

While the diverse reactivity differences described above should be intrinsically related to the Σ–Π radical structures of amidyl radicals, it is difficult to provide convincing explanations for all cases. As suggested by Waegel, Lessard, and co-workers (17), the Σ configuration of the amidyl radical could provide some rationale, *albeit* weak, for the observed geometry of the cyclizations. The esr results of the Π-configuration with twisting of the N—CO bond open up

[7]The rate constant of intramolecular hydrogen abstraction by amidyl radicals from C-5 allylic —CH_2— in alkyl side chains is estimated from ref. 29 as follows. The rate ratio of abstraction from C-5 methyl hydrogens in alkyl side chains to those in acyl side chains is calculated to be 2.5. The multiplication of this ratio with the rate constant of intramolecular hydrogen abstraction from C-5 allylic (CH_2) hydrogen in an acyl side chain ($5 \times 10^6\ M^{-1}\ s^{-1}$) is taken as the corresponding rate constant involving an alkyl side chain.

wide possibilities for interpretation and they indicate that the model amides used in this and other investigations (17) are utterly powerless to correlate the reactivities with electronic configurations. Nevertheless, one suggestion can be made to rationalize the amidyl radical intramolecular reactivities, i.e., preference in addition over H-abstraction and that for acyl over alkyl side chains. It is envisaged that the amide carbonyl, being scarcely conjugated (42), may have some attractive interaction with a suitably located double bond to facilitate intramolecular addition of the nitrogen radical center. The CO group in **5** and **30** apparently has difficulties in assuming a favored conformation for such interactions; this may arise from the small barrier required for the N—CO bond twisting as proposed before (14).

The observed reactivity discrepancy between esr kinetic results (28, 29) and the results from product analysis (*vide supra*) could arise from the fact that the rate constants are determined for individual model compounds and their comparisons are intermolecular, i.e., between two different compounds. In this study, the comparisons involve intramolecular competitions in which conditions are the same for addition and abstraction reactivities. Indeed, in the kinetic studies by esr signal decays, Ingold's group (28, 29) has concluded that intramolecular reactions of amidyl radicals are very sensitive to steric factors that may still be significant over surprisingly large distances. If so, comparisons of amidyl radical reactivities even by intramolecular competitions within a molecular framework, such as in **1**, **4**, or **5**, may also be subject to subtle remote steric effects. Therefore, even if these results from product analysis are experimentally meaningful, their interpretations are beyond our present understanding. In short, the flexible and semi-flexible models utilized so far in this paper and others (17, 18), although synthetically useful, are not adequate to elucidate the details of the transition state in amidyl radical reactions and are likewise powerless to probe the electronic configurations of amidyl radicals.

Experimental

Unless otherwise specified, nmr spectra were recorded with a Varian A56/60 spectrometer in $CDCl_3$ using TMS as the internal standard. Infrared spectra were recorded as Nujol mulls or neat liquids with a Perkin Elmer model 457 grating spectrophotometer, uv spectra with a Unicam SP800 spectrometer, and mass spectra with a Hitachi–Perkin–Elmer RMU-6E instrument at 80 eV. Melting points were recorded with a Fisher Johns hot stage apparatus and were uncorrected. Microanalyses were performed by Mr. M. K. Yang, Department of Biological Sciences, Simon Fraser University.

Preparation of nitrosamides and chloramides

The required amides **1***a*–**6***a* were prepared by the usual methods and described in the thesis (25). Nitrosation of amides followed published methods (9, 32, 38) using $NaNO_2$ in $AcOH-Ac_2O$ or N_2O_4 in CH_2Cl_2. In certain cases, the addition of N_2O_4 to the alkenyl bonds also occurred to give nitrosamides contaminated by such by-products. The nitrosamides **1***b*–**6***b* obtained from the preparation were examined with ir and nmr spectroscopy to see the extent of the addition to double bond. These crude nitrosamide specimens were characterized by spectroscopic data (Table 1) and were used without purification.

N-Chloramides were prepared by standard procedure using sodium hypochlorite (or Purfex bleach) (5, 14) and the spectroscopic data are given in Table 1. The crude products were used for photolysis without purification.

Photolysis of alkenyl nitrosamides

A nitrosamide (1–15 mmol) in redistilled benzene (230 mL) was irradiated with a Hanovia medium pressure Hg lamp through a $NaNO_2$ – sodium naphthalate filter solution (<400-nm cut-off) (30) while the solution was purged with dry nitrogen and cooled externally with an ice bath. At intervals, samples were taken to examine decreases of the absorption at the 405-nm region; in some cases, the intense absorption of the dimer of the C-nitroso compounds at λ_{max} 290 nm appeared. In all cases, a small sample was set in a dark place at the same temperature as the dark reaction; no decrease of the uv absorption was observed. When the 405-nm absorption disappeared (1–4 h), the photolysates were evaporated and crude products were chromatographed or treated further accordingly.

1. N-*Nitroso*-N-*methyl-3-cylcohexene-1-carboxamide* (**1***b*)

(a) *Under nitrogen*

Nitrosamide **1***b* prepared from **19** (2.2 g) in benzene (230 mL) was photolyzed to give a crude product which contained a C-nitroso dimer (ir 1220 cm^{-1}, λ_{max} 295 nm, and an nmr singlet at 2.91 ppm). On standing, the dimer disappeared. Recrystallization from $EtOH-H_2O$ gave a solid (730 mg) which was recrystallized to give *anti*-oxime **6**, mp 203–205°C; ir (KBr): 3300 (b), 3100 (m), 1670, 1230, 950, 920 cm^{-1}; nmr (pyridine-d_5): 4.09 (1H, dd, J = 5.5 and 1 Hz), 3.6–3.3 (1H, m), 2.74 (3H, 8), 2.52 (1H, m), 2.2–1.6 (5H, m) ppm; ms (130°C), m/e (%): 168(M^+, 14), 152(14), 151(100), 123(14), 110(37), 98(26), 94(14), 42(40). *Exact Mass* calcd. for $C_8H_{12}N_2O_2$: 168.0898; found (ms): 168.0882. *Anal.* calcd. for $C_8H_{12}N_2O_2$: C 57.14, H 7.14, N 16.67; found: C 57.27, H 7.17, N 16.60. Decoupling experiments showed that neither signal at 4.08 and 2.52 ppm was coupled to the equatorial C(3)–H at 3.5 ppm.

In a separate experiment, the crude residue obtained from photolysis of nitrosamide **1***b* (amide **1***a*, 2 g, as the starting material) was heated in 50% EtOH (60 mL) with sodium bisulfite (35 g). The solution was made basic (pH 9), and was extracted with CH_2Cl_2 and chromatographed on alumina to give the first fraction, which was distilled at 84–85°C/5 Torr (1 Torr = 133.3 Pa) to give ketolactam **7** (1.23 g); ir (CCl_4): 1735 (sh), 1715, 1645, 1400 cm^{-1}; nmr: 3.70 (1H, dd, J = 5 and 2 Hz), 2.86 (3H, s), 2.8–1.85 (7H, m) ppm; ms (30°C), m/e (%): 153(M^+, 64), 137(11), 125 (44), 110(22), 109(17), 97(100), 96(44), 80(28), 79(22), 69(67), 68(42), 42(92). *Exact Mass* calcd. for $C_8H_{11}NO_2$: 153.0789; found (ms): 153.0744. The ketolactam **7** (1.03 g) in ether (150 mL) was refluxed with LAH (2 g, 0.05 mol) for 48 h. The ether extracts were carefully distilled with a Vigreux column to afford the corresponding volatile alcohols (32). The alcohol mixture (150 mg) was oxidized with a Jones' reagent for 20 min to give, after work-up, aminoketone **8** (90 mg); the ir, nmr, and mass spectra were identical with those of the authentic sample (32). Ketolactam **7** was reduced by $NaBH_4$ to give a mixture of *exo*- and *endo*-hydroxylactam **10** (*vide infra*).

A crude residue (2.4 g) from another photolysis was chromatographed on basic alumina (120 g) in the CH_2Cl_2-MeOH solvent system. Ketolactam **7** (510 mg) contaminated by a small amount of nitratolactams **9** was eluted with CH_2Cl_2. The second fraction (80 mg) was a mixture of *syn*- and *anti*-oxime **11**; ir: 3400 (b), 1670 (s), 1550 (m), 1400, 1070 (m), 1050 (m); nmr: ≈6.3 (1H, m), 5.75 (1H, m), 3.8–3.3 (2H, m), 2.79 (3H, s); ms (30°C), m/e (%): 168(M^+, 67), 137(90), 109(27), 96(67), 80(87), 79(100), 55(33), 42(47). The third fraction (430 mg) was a complex mixture containing the C-nitroso dimer, **6**, and **11**. The fourth fraction eluted with 2–3% MeOH – CH_2Cl_2 was *anti*-oxime **6** (310 mg). The following fractions (810 mg) were mixtures of *syn*-oxime **6** (4.65 and 2.89 ppm) and *anti*-oxime **6** (3.90 and 2.82 ppm). A mixture of the oximes **6** (120 mg) was treated with sodium bisulfite in ethanol to afford ketolactam **7** (105 mg).

(b) *Under oxygen*

Crude nitrosamide **1***b* prepared from 1.2 g amide **1***a* was irradiated in benzene (230 mL) as above except that oxygen, instead of nitrogen, was bubbled through the solution. No uv absorption of the C-nitroso dimer at 295 nm was observed. The photolysate was evaporated and the crude oil chromatographed on neutral silica (65 g) eluted with 0.5% MeOH – CH_2Cl_2 to afford a mixture (970 mg) of *endo*- and *exo*-nitratolactam **9** (2:1 ratio) contaminated with **1***a* (8%): nmr singlets at 2.95, 2.92, and 2.81 ppm. The second fraction (200 mg) was a mixture of *exo*- and *endo*-hydroxylactams **10**; ir: 3400 (b), 1670, 1070 cm^{-1}; nmr: 4.3 (m), 3.9 (m), 2.86 (s), 2.83 (s) ppm. The last fraction (500 mg) was mainly **10** contaminated by nitro compounds, as shown by ir absorptions at 1680, 1550; *m/e* at 184; and nmr multiplet at 4.7 ppm. A portion of this fraction (90 mg) was oxidized with Jones' reagent and chromatographed to give ketolactam **7**, but nitrolactam could not be isolated. The first fraction was chromatographed again to afford two nitratolactams:

Exo-**9**; ir: 1690, 1630, 1280, 860 cm^{-1}; nmr: 5.26 (1H, m, $W_{1/2}$ = 9 Hz), 3.82 (H, m), 2.92 (3H, s), 3.0−1.5 (8H, m) ppm; ms (80°C), *m/e*(%): 200(M^+, 1), 168(4), 154(52), 138(19), 126(17), 110(89), 98(81), 81(22), 69(33), 55(33), 42(100).

Endo-**9** has the same ir pattern as *exo*-**9**; nmr: 5.10 (1H, dd, *J* = 9 and 7 Hz), 3.85 (1H, bd, *J* = 6), 2.95 (3H, s), 2.8−1.4 (8H, m) ppm; ms (75°C), *m/e*(%): 154(58), 138(17), 126(17), 110(100), 98(89), 83(17), 81(17), 69(33), 55(28), 42(100); ms(70°C), *m/e*(%): 200(M^+, 1), 154(63).

Hydrolysis of a mixture of *exo*- and *endo*-**9** with dilute NaOH in $EtOH-H_2O$ (0.1 *N*) gave a mixture of *exo*- and *endo*-**10** which was oxidized by Jones' reagent to ketolactam **7**. A mixture of *exo*- and *endo*-**9** was reduced by LAH in ether for 48 h, followed by oxidation with Jones' reagent to give aminoketone **8**.

N-Nitroso-N-methyl-2-cyclohexene-1-carboxamide (**2***a*)

The crude nitrosamide (obtained from 450 mg of **2***a* without purification) was photolyzed as above under nitrogen to give a residue (450 mg) which was recrystallized from benzene twice to give *syn*-oxime **15** (150 mg), mp 145−150°C (dec.); ir (KBr): 3200 (b), 3080 (m), 1725 (s), 1650 (m), 1440, 935 cm^{-1}; nmr: 8.7 (OH), 4.02 (1H, d, *J* = 5 Hz), 3.55 (1H, t, *J* = 5 Hz), 2.82 (3H, s), 2.8−1.3 (6H, m) ppm; ms (100°C), *m/e*(%): 169(M^+ + 1, 7), 168(M^+, 4), 151(5), 140(5), 112(36), 111(100), 110(27), 94(48), 67(39), 66(63), 42(36); ms (30°C), *m/e*(%): 169(M^+ + 1, 2), 168(M^+, 9). *Exact Mass* calcd. for $C_8H_{12}N_2O_2$: 168.0899; found (ms): 168.0856. *Anal.* calcd. for $C_8H_{12}N_2O_2$: C 57.13, H 7.19, N 16.66; found: C 56.94, H 7.36, N 16.86.

The mother liquor was chromatographed on neutral alumina eluted with 0−0.5% $CH_3OH-CH_2Cl_2$ to give the first fraction (100 mg) containing **2***a* and the ketolactam of **15** (ir 1745 cm^{-1}, and nmr 3.6 (m) and 1.90 (s) ppm). Elution with 5−20% MeOH − CH_2Cl_2 gave *syn*-oxime **15** (90 mg). Hydrolysis of **15** with sodium bisulfite gave a complex mixture.

N-Nitroso-N-methyl-(2-cyclopenten-1-yl)acetamide (**3***b*)

Crude nitrosamide **3***b* (640 mg) in $BrCCl_3$ (230 mL) was photolyzed under nitrogen in the usual manner. The distilled solvent showed a uv absorption at 580 nm due to CCl_3NO. The residue was chromatographed to give **3***a* and *exo*-bromolactam **17** (730 mg) which was distilled; ir: 1685 (s), 1400 (s), 1255 (s), 600 (m); nmr: 4.2 (2H, m), 2.92 (3H, s), 3.15−1.8 (6H, m), 1.5 (1H, m) ppm: gc−ms *m/e*(%): 219(M^+, 37), 217(37), 138(10), 110(100), 96(25), 82(16), 68(23), 42(29). *Exact Mass* calcd. for $C_8H_{12}NOBr$: 217.0103; found (ms): 217.0054. LAH reduction of **17** gave the amine **18**; the picrate from ethanol, mp 204−207°C (dec.) (lit. (37) mp 207°C).

Exo-bromolactam **17** (20 mg) and Eu(fod) (3 mg) in $CDCl_3$ exhibited a well-separated spectrum shown in the thesis (25). Irradiation of C(5)−H (4.6 ppm) collapsed C(1)−H (6.25 ppm) to singlet and the *endo*- and *exo*-C(4)−H (7.1 and 8.15 ppm) to an AB quartet (*J* = 18.5 Hz); the C(6)−H (3.15 and 3.75 ppm) coupling patterns were also changed. Irradiation of the *endo*-C(4)−H changed the *exo*-C(4)−H to a doublet (10 Hz) and C(5)−H to doublet of quartet (*J* = 8.9 and 3 Hz). Irradiation of *exo*-C(7)−H (3.0 ppm) changed *endo*-C(8)−H (6.05 ppm) to a double doublet (*J* = 3.5 and 1.5 Hz).

N-Nitroso-N-methyl-(3-cyclohexen-1-yl)acetamide (**4***b*)

A crude nitrosamide **4***b* contained by-products (ca. 15%) arising from the addition of N_2O_4 to the double bond, as shown by the nmr and ir spectra. This nitrosamide (1.39 g) in benzene was photolyzed as shown above. The crude product was chromatographed on neutral alumina to afford a mixture of unidentified secondary amides containing no double bond (290 mg) as the first fraction. The second fraction eluted with 1% MeOH − CH_2Cl_2 was recrystallized from acetone to give *anti*-oxime **19** (250 mg), mp 165−167°C (dec.); ir (CCl_4): 3200 (b), 3100 (b), 1605, 930 cm^{-1}; nmr: 10.0 (OH), 3.85 (1H, t, *J* = 3 Hz), 3.25 (1H, m), 2.88 (3H, s), 2.85−1.2 (9H, m); ms (110°C), *m/e*(%): 182(M^+, 10), 165(60), 150(40), 123(35), 110(35), 108(50), 95(10), 73(100), 58(35). *Anal.* calcd. for $C_9H_{14}N_2O_2$: C 59.32, H 7.74, N 15.37; found: C 59.50, H 7.80, N 15.27. The remaining fractions showed ir bands at 1640 and 1550 cm^{-1} and only one nmr signal in the 6.0−5.0 ppm region. This fraction (75 mg) was contaminated by other components and showed ir peaks at 3300 (b), 1635, 1550, 985, 970 cm^{-1}; nmr: ≈6.8 (m), 6.2 (m), 2.78 (d, on addition of D_2O collapsed to singlet); ms (180°C), *m/e*(%): 182(5), 165(32), 151(21), 134(21), 124(32), 106(100), 91(86), 79(36), 77(36), 73(79), 58(68), 45(36). It decomposed to a complex mixture on attempted bulb-to-bulb distillation at ≈100°C.

The *anti*-oxime **19** (80 mg) was treated with sodium bisulfite in aqueous ethanol to give ketolactam **20**; ir: 1720, 1625, 1395 cm^{-1}; ms (65°C), *m/e*(%): 167(M^+, 34), 139(20), 123(51), 110(100), 82(24), 73(17), 68(20), 59(37), 57(29), 42(37). Ketolactam (50 mg) was reduced in ether with LAH (150 mg) and the residue was oxidized with Jones' reagent to give the known (38) aminoketone **22** (28 mg): the picrate mp 205−210°C; an identical ir spectrum with that of an authentic sample (38).

N-Nitroso-N-(3-cyclohexen-1-ylmethyl)acetamide (**5***b*)

Crude nitrosamide (1.25 g) in benzene was irradiated for 1.75 h under normal conditions to show a C-nitroso dimer uv absorption at ca. 300 nm. The crude product was chromatographed on basic alumina. The parent amide **5***a* and ketoamide **24** were eluted as mixtures with 0.5−1% MeOH − CH_2Cl_2: this was rechromatographed to give **1***a* (75 mg) and **24** (200 mg) which was distilled at 1 Torr; ir: 1725 (s), 1630 (s); nmr: 4.14 (d, *J* = 6 Hz), 3.65 (d, *J* = 3 Hz), 6.57 (bs, $W_{1/2}$ = 5 Hz); ms (100°C), *m/e*(%): 167(M^+, 28), 139(25), 126(50), 110(50), 68(100), 43(56). The remaining fractions (580 mg) were mixtures of *anti*- and *syn*-oxime **23** (4:1 ratio). The *anti*-oxime **23** was recrystallized from acetone, mp 160−163°C (dec.); ir (KBr): 3300 (b), 1615 (s), 1460, 1420, 955, 940 cm^{-1}; nmr: 9.5 (OH), 4.39 (1H, bd, *J* = 5.5 Hz), 3.51 (1H, m), 2.55 (1H, m), 2.07 (3H, s), 2.4−1.4 (6H, m); ms (90°C), *m/e*(%): 182(M^+, 25), 165(8), 123(100), 85(40), 83(52), 80(17), 68(17), 59(33), 43(54). *Exact Mass* calcd. for $C_9H_{14}N_2O_2$: 182.1055; found (ms): 182.1009. *Anal.* calcd. for $C_9H_{14}N_2O_2$: C 59.32, H 7.74, N 15.37; found: C 59.18, H 7.80, N 15.40. Rechromatography of the residue gave a fraction containing *syn*-oxime **23** as the major component (ca. 80%) and showed an nmr doublet at 5.40 (*J* = 5.5 Hz).

A mixture of *syn*- and *anti*-oxime **23** in 6 *N* HCl (20 mL) was heated on a water bath for 5 h. The crude products were chromatographed to give ketoamide **24** (60 mg) and the starting oximes (25 mg).

Photolysis of N-chloro-N-methyl-3-cyclohexene-1-carboxamide (**1***c*)

N-Chloramide **1***c* (1.2 g) in benzene (250 mL) was photolyzed through a Vycor filter under nitrogen for 4 h. The crude product showed an nmr singlet at 3.05 (*endo*-**12**), 2.88 (*exo*-**12**), and 2.81 (for **1***a*) in a ratio of 41:53:6 and three gc peaks at 5.7, 5.0, and 3.5 min (for **1***a*) in a ratio of 44:49:7. The crude product (1.4 g) was chromatographed on silicic acid (50 g) eluted with 0−3% MeOH − CH_2Cl_2 to give an oil which was distilled at 5 Torr to give *exo*-chlorolactam **12** (700 mg); ir: 1690, 1450, 815 cm^{-1}; nmr: 4.32 (1H, dd, *J* = 6.0 and 3.0 Hz), 3.70 (1H, t, *J* = 4 Hz), 2.88 (3H, s), 2.5 (1H, bm, $W_{1/2}$ = 7 Hz), 2.45−1.5 (6H, m) ppm; ms (100°C), *m/e*(%): 175(M^+, 23), 173(M^+, 67), 138(68), 110(100), 96(64), 83(22), 68(30), 53(29), 42(42). *Exact Mass* calcd. for $C_8H_{12}NO^{35}Cl$: 173.0607; found (ms): 173.0602. The fractions eluted with 3% MeOH − CH_2Cl_2 (700 mg) contained *endo*-chlorolactam **12** and **1***a* and were rechromatographed to give *endo*-**12**; ir: 1690, 1450, 765, 750 cm^{-1}; nmr: 4.25 (1H, ddd, *J* = 9, 7, and 1 Hz), 3.86 (1H, dd, *J* = 5.5 and 1 Hz), 3.05 (3H, s), 2.5−1.5 (7H, m) ppm; ms showed the same pattern as that of *exo*-**12**.

An ether solution of *exo*-**12** (100 mg) and LAH (0.8 g) in ether was set aside for 5 days. The crude oil obtained was treated with picric acid in benzene; the precipitate was recrystallized from EtOH to afford the picrate of bicyclic amine **13**, mp 255°C (dec.) (lit. (34) mp 250°C). *Anal.* calcd. for $C_{14}H_{18}N_4O_7$: C 47.46, H 5.08, N 15.82; found: C 47.69, H 5.12, N 15.59.

A crude product (1.2 g) containing *exo*-**12**, *endo*-**12**, and **1***a* in a ratio of 48:42:10 in ether was stirred with LAH (3 g) and aliquots were removed at intervals for work-up and examined with gc. In 10 h, the above three peaks disappeared and were replaced by peaks at 1.7 (**13**), 1.8 (methyl-3-cyclohexenylmethylamine), and 3.5 (*endo*-chloramine **14**) min. After this, the peak of **13** gradually increased at the expense of the peak of *endo*-**14**. In 30 h, the latter disappeared to give only the former peak. LAH reduction of a crude product was stopped at 10 h, and the reaction was worked up to give a crude product that was chromatographed to give *endo*-chloramine **14** (360 mg); ir: 1450, 780 cm^{-1}; nmr: 3.2 (h, ddd, J = 9, 7 and 1.5 Hz), 2.96 (2H, m), 2.52 (3H, s), 2.45 (1H, b, $W_{1/2}$ = 5), 2.7−1.2 (7H, m) ppm; ms (100°C), m/e(%): 161(M^+, 12), 159(M^+, 32), 124(22), 96(32), 82(100), 67(16), 55(18), 42(50). The ir and nmr spectra were superimposable with an authentic sample (42). Further elution afforded amine **12** and *N*-(3-cyclohexenyl)methylmethylamine.

When *exo*-chlorolactam **12** (180 mg) was reduced with LAH (1 g) for 5 h in ether, it gave **13** and what appeared to be the *exo*-chloramine **14** as a 1:3 mixture; ir: 1450, 760 cm^{-1}; nmr: 4.3 (2H, m), 2.8 (1H, m), 2.43 (3H, s), 2.5−1.1 ppm (8H, m) ppm. This compound decomposed on standing at room temperature.

Shielding anisotropy in tin compounds: spectroscopic studies of alkyltin cations in strong acid solutions

THOMAS BIRCHALL[1] AND VEERAGATHY MANIVANNAN

Received May 4, 1984[2]

THOMAS BIRCHALL and VEERAGATHY MANIVANNAN. Can. J. Chem. **63**, 2211 (1985).

We have observed that the ^{119}Sn nmr spectra of dialkyltin cationic species in highly acidic solutions are strongly field dependent. Relaxation time measurements at three different magnetic fields have established that the dominant spin-lattice relaxation mechanism for these species at high magnetic field is shielding anisotropy. A comparison of T_1^{-1} and T_2^{-1} values indicates that at room temperature a rapid chemical exchange process is occurring. In the case of the $(CH_3)_2Sn(SO_3F)_2-HSO_3F$ system variable temperature ^{119}Sn nmr reveals the presence of three tin species which are involved in this exchange process.

THOMAS BIRCHALL et VEERAGATHY MANIVANNAN. Can. J. Chem. **63**, 2211 (1985).

On a observé que les spectres rmn du ^{119}Sn d'espèces cationiques dialkylétain, en solutions dans des milieux fortement acides, dépendent beaucoup du champ. Des mesures de temps de relaxation à trois champs magnétiques différents ont permis d'établir que, pour ces espèces soumises à un champ magnétique élevé, le mécanisme principal de relaxation spin-réseau est l'anisotropie de blindage. Une comparaison des valeurs de T_1^{-1} et T_2^{-1} indique que, à température ambiante, il se produit un processus rapide d'échange chimique. Dans le cas du système $(CH_3)_2Sn(SO_3F)_2-HSO_3F$, la rmn du ^{119}Sn à température variable permet de révéler la présence de trois espèces d'étain qui sont impliquées dans ce processus d'échange.

Introduction

A number of dimethyl- and trimethyl-tin derivatives of substituted sulphuric acids have been isolated as solids and characterized by Mössbauer and vibrational spectroscopy (1, 2). In one case, dimethyltin(IV) fluorosulphate, an X-ray crystal structure has been reported (3). The nature of these species in solution prior to crystallization has been studied by ^{1}H nmr and frozen solution ^{119}Sn Mössbauer spectroscopy and the structures in solution inferred from this data (4). This present study was initially aimed at measuring one-bond spin–spin coupling constants, $^1J_{^{119}Sn-^{13}C}$, in order to correlate these values with the Mössbauer data for these species. In so doing we observed that the ^{119}Sn nmr signal line width increased dramatically with the field of the instrument used to make the measurements. This led us to carry out relaxation time measurements at three different magnetic fields. There have been relatively few reports of relaxation time measurements on the ^{119}Sn nucleus and most of these studies have been made on relatively small and nearly symmetrical molecules (5, 6*a*). In these latter cases the dominant relaxation mechanisms are dipolar, spin-rotation, and scalar relaxation. Recently Blunden *et al.* (6*b*) have measured ^{119}Sn spin lattice relaxation times, and nuclear Overhauser enhancement (nOe) factors, for some organotin compounds. Although their T_1 and η values for $Bu_2Sn(OAc)_2$ were found to be field dependent, they attributed this to an exchange process. Here we present data which shows that for the $[(CH_3)_2Sn]^{2+}$ species shielding anisotropy (SA) is the dominant relaxation mechanism in ^{119}Sn nmr at high magnetic field. The complete dominance of the SA mechanism has been observed for several heavy nuclei such as ^{195}Pt (7), ^{199}Hg (8), ^{205}Tl (9), and ^{207}Pb (10), particularly in cases where there is a large asymmetry at the nucleus of interest. Also we have been able to observe, by variable temperature ^{119}Sn nmr, the presence of three tin species in solution that are involved in an exchange process.

Experimental

Dimethyl- and trimethyl-tin species in sulphuric acid were prepared following the published procedure (4). The diethyltin species in sulphuric acid was prepared by the dissolution of diethyltin dichloride in 100% H_2SO_4 at room temperature (RT). The triethyltin species in fluorosulphuric acid was prepared by the reaction of tetraethyltin in HSO_3F at -30°C. The dibutyltin species was obtained by reacting $(n-C_4H_9)_6Sn_2$ with 100% H_2SO_4 at room temperature.

Tin-119 nmr spectra were recorded at operating frequencies of 33.56, 93.27, and 149.21 MHz on Bruker WH-90, WM-250, and WH-400 instruments respectively. Samples were contained in 10-mm (od) round bottomed tubes without a lock substance on the WM-250 and WH-400 instruments. For spectra recorded on the WH-90, samples were contained in an 8-mm (od) round bottomed tube which was placed concentrically into a 10-mm outer tube containing D_2O as the lock substance. Chemical shifts were measured relative to an external reference of neat $(CH_3)_4Sn$.

All spin-lattice relaxation times were measured using the inversion recovery technique and calculated using a three-parameter fitting procedure (11). The lengths of the 90° pulses used were 36 μs (WH-90), 28 μs (WM-250), and 29 μs (WH-400). The operating temperatures were 24°C and 22°C for the WM-250 and WH-400, respectively except for the variable temperature work. The estimated errors in T_1 measurements are less than 10%. The nOe measurements were obtained on the WH-90 by the gated decoupling technique with a minimum delay of 10 T_1. All samples were degassed by bubbling dry nitrogen through the sample.

Results and discussion

Dialkyltin sulphates have been produced by the solvolysis of R_4Sn, R_3SnX, or R_2SnX_2 with sulphuric or substituted sulphuric acids (1). The compounds isolated from these solutions have been examined by a variety of spectroscopic methods, and it was concluded that the tin environment was distorted octahedral with four equatorial oxygens, from sulphate groups, and *trans* axial alkyl groups completing the coordination (1, 2). This has been confirmed for $(CH_3)_2Sn(SO_3F)_2$ (3). Frozen solution ^{119}Sn Mössbauer data and ^{1}H nmr spectroscopy, of solutions of these species in strong acids, suggested that this

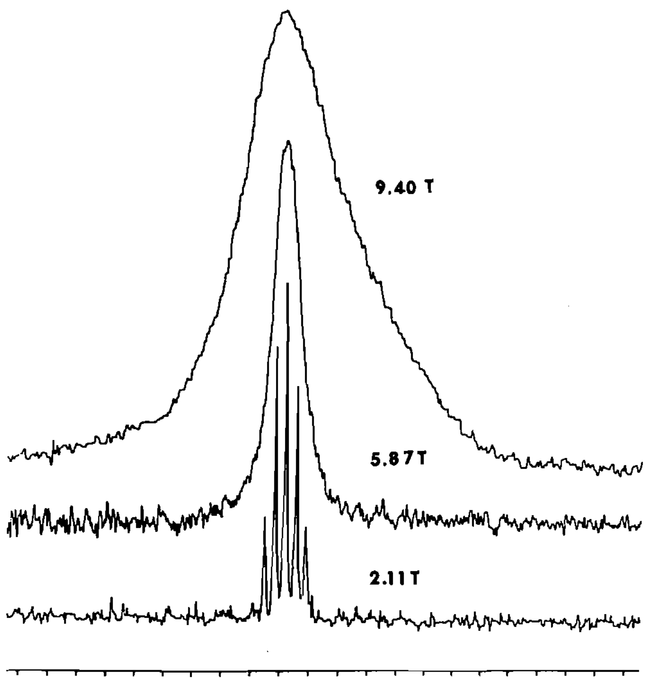

FIG. 1. ^{119}Sn nmr spectra of 0.8 M^{-1} $[(CH_3)_2Sn][SO_4]$ in 100% H_2SO_4 at field strengths of 2.11 T, 5.87 T, and 9.40 T.

geometry was preserved in solution (4). Since Mössbauer isomer shifts (δ) measure the s electron density at the tin nucleus, the participation of s electrons in the tin–ligand bonds will be reflected in a change in these isomer shifts (8). In the nmr experiment one might expect the $^{119}Sn-^{13}C$ coupling constant to be sensitive to the s character of the tin–carbon bond, if the Fermi contact term is the dominant contributor. Therefore there should be a relationship between δ and $^1J_{^{119}Sn-^{13}C}$. With this in mind we set out to measure $^1J_{^{119}Sn-^{13}C}$ for a series of alkyltin species in an attempt to correlate these values with ^{119}Sn Mössbauer data. Tin-119 nmr spectra of the sulphuric acid solutions, recorded at 33.56 MHz (2.114 T), showed the expected multiplet patterns due to coupling with the protons from the alkyl groups, though the individual lines were broad (Fig. 1). It was not, however, possible to observe the ^{13}C satellite peaks in the hydrogen decoupled spectrum, and $^1J_{^{119}Sn-^{13}C}$ values were subsequently obtained from the ^{13}C spectra. In an attempt to obtain better spectra, ^{119}Sn nmr data were recorded at higher magnetic fields (5.872 T and 9.40 T). This had the effect of broadening the ^{119}Sn lines so that the spin–spin coupling of the protons to the tin nucleus was obscured, Fig. 1. It became obvious that an accurate measure of both T_1 and T_2, the spin-lattice and spin–spin relaxation times, would be necessary before a satisfactory explanation of these spectra could be obtained.

There are several possible mechanisms which contribute to spin-lattice relaxation, namely (*i*) dipole–dipole, $T_{1(DD)}^{-1}$; (*ii*) spin-rotation, $T_{1(SR)}^{-1}$; (*iii*) scalar relaxation $T_{1(SC)}^{-1}$; and (*iv*) shielding anisotropy $T_{1(SA)}^{-1}$ (12). Of these, the spin-rotation mechanism is likely to be a minor contributor because of the large size of these solvated tin cations. Scalar relaxation usually occurs through a modulation of the scalar coupling via interaction with a nucleus having a short relaxation time, usually a quadrupolar nucleus. This leaves dipole–dipole and SA as the main line-broadening mechanisms, eq. [1], and these have been measured and tabulated in Table 1. From these data it is clear that T_1 for all three species is field dependent and de-

$$[1]\quad T_1^{-1} = T_{1(DD)}^{-1} + T_{1(SA)}^{-1}$$

creases with increasing field strength. It is interesting to note that at 2.114 T the relaxation time of the methyl species is much longer than for either the ethyl or butyl species, but as the field strength increases the difference decreases, until at 9.40 T the ethyl and butyl have longer relaxation times than the methyl species.

In order to obtain an estimate of $T_{1(DD)}^{-1}$, nOe measurements were made. The nOe is defined as the ratio of the double resonance intensity to the single resonance intensity and, since ^{119}Sn has a negative magnetogyric ratio, this results in a diminution of this nOe ratio (12). The nOe operates by cross relaxation between the two spin systems and the main contributor is from dipole–dipole coupling, except when there can be scalar coupling modulated by chemical exchange. Since, in these systems, the alkyl groups are not directly involved in any exchange process, scalar coupling can be eliminated.

Figure 2 shows plots of T_1^{-1} versus ν_0^2 for the dimethyl and diethyl species in 100% H_2SO_4: the T_1^{-1} values, at zero field (ν_0

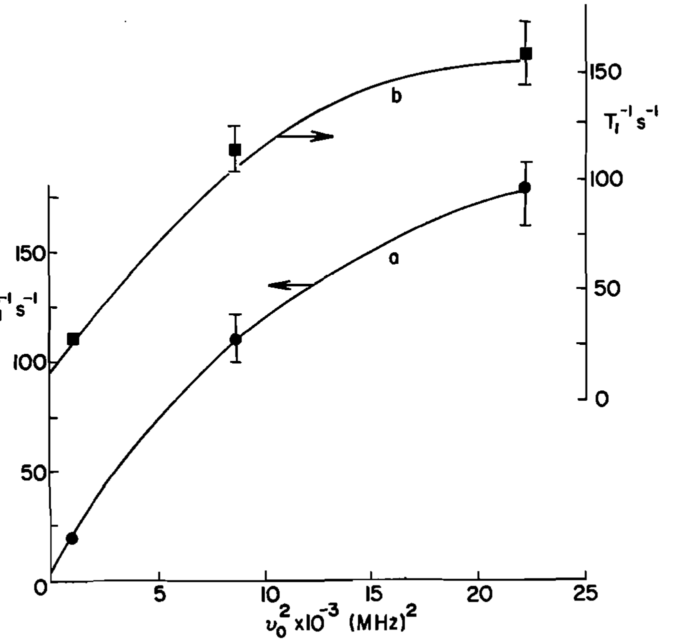

FIG. 2. Plots of T_1^{-1} versus ν_0^2 for: (a) $[(CH_3)_2Sn][SO_4]$ (L.H.S.) ● and (b) $[(C_2H_5)_2Sn][SO_4]$ (R.H.S.) ⊞ in 100% H_2SO_4.

= 0) are obtained by extrapolation. When B_0 approaches zero field strength, the effect of SA is negligible and the main contributors to the relaxation can only be dipolar, since the spin rotation mechanism can be neglected because of the large size of the solvated cation. Therefore, for the dimethyltin species at zero field, $T_1^{-1} = T_{1(DD)}^{-1} = 3.3\ s^{-1}$ and the corresponding value for the diethyltin species is $15.0\ s^{-1}$. Under extreme narrowing conditions, the relaxation rate of spin I, due to intramolecular dipole–dipole interactions with spin S, $T_{1(DD)}^{-1}$ (intra) is independent of frequency and is given by eq. [2] (12).

$$[2] \quad T_{1(DD)}^{-1}\ (\text{intra}) = \frac{\mu_0^2\gamma_I^2\gamma_S^2 h^2 s(s+1)}{12\pi^2 \sum_i r_{IS_i}^6}\tau_c$$

where μ_0 is the permeability of a vacuum, h is Planck's constant, r_{IS_i} is the internuclear distance between nucleus of spin I and S_i, and τ_c is the molecular tumbling correlation time.

Using eq. [2], and the above values for $T_{1(DD)}^{-1}$, τ_c is estimated to be 3.0×10^{-9} s and 1.3×10^{-8} s for the dimethyltin and diethyltin species respectively. With these τ_c values the magnitudes of $(\omega_0\tau_c)^2$, at three different fields 2.114 T, 5.872 T and 9.401 T, were found to be $(CH_3)_2Sn^{2+}$: 0.40, 3.09, 7.91; $(C_2H_5)_2Sn^{2+}$: 7.50, 58.04, 148.50, respectively. From these values it is clear that these systems deviate from the extreme narrowing condition even at 2.114 T, and the general equation must be used to calculate $T_{1(DD)}^{-1}$.

Werbelow (13) has established an expression for the frequency dependence of the nOe effect for coupled nuclei with gyromagnetic ratios of opposite sign. Using the equation given in this reference (13), η_{max} can be calculated using the estimated τ_c for the dimethyltin and diethyltin species at 2.114 T. From the experimentally measured nOe factors at 2.114 T, $T_{1(DD)}^{-1}$ was calculated using eq. [3]

$$[3] \quad \text{nOe} = 1 + \eta, \quad \eta = \eta_{max}\frac{T_1}{T_{1(DD)}}$$

The $T_{1(DD)}^{-1}$ values at zero field are different from those at 2.114 T. This difference is expected since these systems are outside the extreme narrowing condition.

The increased dipolar contribution in the diethyl species compared to the dimethyl may be attributed to its lower mobility, longer τ_c, and to the contribution from the additional protons. For the di-n-butyl case, we believe that its effective solvated size may not be very different from that of the diethyl species in these solutions and the increased number of protons in the former case will have little additional effect due to the r^{-6} dependence. Spin-lattice relaxation time and nOe measurements, made for the dimethyltin species in D_2SO_4 solution, were found to be the same as in H_2SO_4, indicating that intermolecular dipole–dipole relaxation is not significant in this system.

At 9.40 T we were unable to detect a nOe effect, indicating that the SA mechanism is the dominant one at high magnetic fields, whereas at lower fields dipolar mechanisms play a significant role for these species. Therefore it is reasonable to assume, at 5.872 T and 9.40 T, that the measured T_1^{-1} is equal to $T_{1(SA)}^{-1}$. Note the large increase in SA contribution as the field is increased from 2.114 T through 5.872 T to 9.40 T.

To our knowledge this is the first documented case of SA for the ^{119}Sn nucleus, though the effect has been noted for ^{195}Pt (7), ^{199}Hg (8), ^{205}Tl (9), and ^{207}Pb (10). In these latter cases the molecules studied are quite asymmetric and it is under these situations that nmr spectra obtained at high magnetic fields will be broadened due to SA. For the dialkyltin species the effect is dramatic (Fig. 1) and no useful spin–spin coupling information could be obtained by recording spectra at high fields. However, this broadening is augmented considerably by chemical exchange processes, which are discussed in the next section. That these molecules are very asymmetric at the tin nucleus has been demonstrated by ^{119}Sn Mössbauer measurements, which show very large quadrupole splittings (4). When the molecules are less asymmetric the broadening at high field is less serious and, for the triethyltin species in fluorosulphuric acid at 5.872 T, some spin–spin coupling can be resolved. Mössbauer measurements show that the trialkyltin compounds have a smaller quadrupole splitting than the corresponding (*trans*) dialkyltin molecules (4).

The SA contribution to T_1 is given by eq. [4]

$$[4] \quad \frac{1}{T_1}(\text{SA}) = \frac{1}{15}(\gamma_I B_0)^2(\Delta\sigma)^2\left[\frac{(2\tau_c)}{1+\omega_0^2\tau_c^2}\right]$$

where $\Delta\sigma$ is the shielding anisotropy. Using the above value for τ_c and the ^{119}Sn T_1 measured at 9.40 T, for the $(CH_3)_2Sn^{2+}$ and diethyl species, one arrives at values of 2005 ppm and 4478 ppm respectively for $\Delta\sigma$. These values are not unreasonable considering the large range for ^{119}Sn chemical shifts. They may be compared with the values obtained for other cases, e.g. $(CH_3)_2Hg$ $\Delta\sigma = 6100$ ppm (8). However, care should be taken in considering the magnitude of this value since the rotational correlation time may not be the same as that which modulates the SA. This estimate is further clouded by the fact that the tin is involved in a chemical exchange process (see below). For some cobalt systems it has been suggested that this correlation time is associated with the lifetime of hydrogen bonded second sphere complexes (14), and there is no doubt that hydrogen bonding will be extensive in our systems, between the coordinated sulphate groups and the solvent.

From the simple theory of the SA effect under extreme narrowing conditions one would have expected a linear plot of $T_{1(SA)}^{-1}$ versus ν_0 (2). However, our experimental data do not

follow a straight line (Fig. 2) because, for the systems studied here, the conditions for extreme narrowing do not apply at the higher magnetic field.

Chemical exchange

The measured line widths of the ^{119}Sn signals in 100% H_2SO_4 varied considerably with applied magnetic field (Table 1). These measured widths at half height are inversely proportional to the spin–spin relaxation times T_2 ($\Delta W_{1/2} = 1/\pi T_2$) so that it is possible to estimate T_2^{-1} after allowance has been made for $^2J_{^{119}\text{Sn}-\text{C}-^1\text{H}}$. Even though there are large errors associated with these estimates, it is apparent that T_2^{-1} is much larger than T_1^{-1} in all cases. There are three possible sources for these differences, namely (*i*) scalar relaxation, which is not possible here for the reasons given above; (*ii*) SA, which would lead to differences between T_1^{-1} and T_2^{-1}. Since these systems are outside the extreme narrowing condition, $T_{2(\text{SA})}^{-1}$ is estimated using the general equation (12). This leads to values of 73.1 s^{-1}, 434.8 s^{-1}, and 1021.0 s^{-1} for the dimethyltin species at 2.114 T, 5.872 T, and 9.40 T respectively. The differences observed between T_1^{-1} and T_2^{-1} are much greater than can be accounted for by the SA contribution. This leaves (*iii*) chemical exchange broadening as the source of the difference between T_1 and T_2.

Tin-119 nmr spectra for the dimethyltin and diethyltin species in 100% H_2SO_4 were recorded at three different magnetic fields and at two or three different concentrations. Spectra for the dibutyltin species were obtained at 9.40 T at two concentrations. The line widths and chemical shifts are recorded in Table 2. It is apparent that, in addition to the increased line broadening with field, there is also a marked increase in line width with increasing dilution, with the exception of the dibutyltin case where no significant change was observed. These changes with dilution support the idea that chemical exchange is occurring and that the rate of exchange is dependent upon the nature of the alkyl group. As the size of the alkyl group increases, the width at half height of the ^{119}Sn resonance decreases. Since there is only one tin signal observed in these solutions, these line width changes suggest that the rate of exchange is faster for the butyl than for the ethyl derivative and that the dimethyltin species is involved in the slowest exchange process.

Solutions in 100% sulphuric acid are not very suitable for variable temperature nmr studies, since these solutions freeze at ~10°C, but fluorosulphuric acid solutions can be studied down to ~−90°C. A solution of the dimethyltin species in fluorosulphuric acid was examined at 5.872 T and a single broadened resonance was observed δ = −106 ppm (Table 3). On cooling to −70°C a new tin resonance appeared at ~8.2 ppm, which increased in intensity on further cooling. By −80°C a third broad resonance was clearly visible at ~5 ppm. During this cooling the intensity of the high field signal decreased as the signals at lower field increased in intensity (Fig. 3). Cooling to −90°C produced no further changes and the sample was frozen below this temperature. These observations clearly confirm that an exchange process (or processes) is involved in these solutions. At 9.40 T the spectra are very similar, except that at −90°C the high field signal has now disappeared and only two broad signals remain. From these observations it is apparent that there are at least three distinct dimethyltin species present. For a solution of the diethyltin species in HSO_3F only one broad ^{119}Sn resonance was ever observed, even at −80°C. This is consistent with the earlier

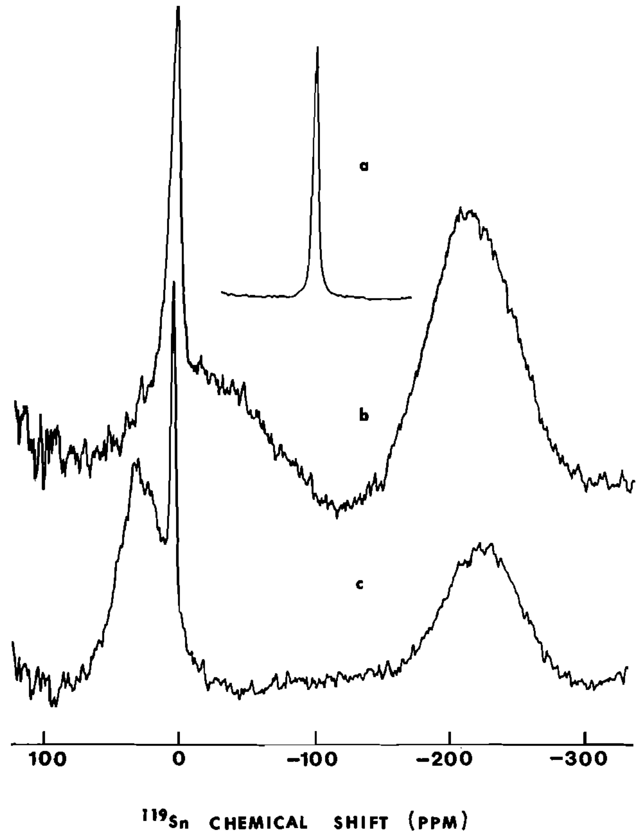

FIG. 3. ^{119}Sn nmr spectra of a 1.16 M^{-1} solution of $[(CH_3)_2Sn]\cdot[SO_3F]$ in HSO_3F at (a) 24°C, (b) −75°C, and (c) −90°C at a magnetic field strength of 5.87 T.

discussion, and confirms that the exchange process is faster for the diethyl- than for the dimethyltin case.

The concentration and temperature dependence of $^1J_{^{13}\text{C}-^{119}\text{Sn}}$ was found by recording ^{13}C nmr spectra (see Table 3). A small increase of ~15 Hz is noted over the temperature range studied. Under these conditions the ^{119}Sn spectra indicate the presence of three tin species, but at the ^{13}C resonance frequency these three species are not resolvable and only an average $^1J_{^{117,119}\text{Sn}-^{13}\text{C}}$ is measurable. Since this increase in the spin–spin coupling is only ~2.5% we conclude that the exchanging tin species have very similar geometries. Changes in the tin environment produce substantial changes in $^1J_{^{117,119}\text{Sn}-^{13}\text{C}}$. For example $(CH_3)_4Sn$ has $^1J_{^{119}\text{Sn}-^{13}\text{C}} = 335$ Hz, five-coordinate tin has a coupling of ~400 Hz, while for six-coordinate tin the value is often in excess of 600 Hz. These trends are in qualitative agreement with an increasing *s* character to the C—Sn bonds, i.e. from sp^3 in R_4Sn, through sp^2 in $[R_3Sn]^+$, to sp in $[R_2Sn]^{2+}$ in the solvated cationic species. The $^2J_{^{119}\text{Sn}-\text{C}-^1\text{H}}$ couplings follow the same trend. For the ethyl derivative it is interesting to note that $^3J_{^{119}\text{Sn}-\text{C}-\text{C}-^1\text{H}}$ is much larger in magnitude than $^2J_{^{119}\text{Sn}-\text{C}-^1\text{H}}$ though these probably have opposite signs (15). The ^{119}Sn chemical shifts and $^1J_{^{119}\text{Sn}-^{13}\text{C}}$ coupling constants found for the trialkyl- and dialkyltin species in strong acids are consistent with the idea that these species are strongly solvated and have trigonal bipyramidal and *trans* octahedral geometries respectively in solution (4). Dimethyltin(IV) fluorosulphate in the solid state has been shown to have an octahedral geometry with *trans* CH_3 groups (3). It had been concluded earlier (4) that this *trans* octahedral geometry was preserved in solution.

Since the ^{119}Sn nmr shows that more than one tin species is present in the low temperature HSO_3F solutions, we decided to reexamine the frozen solutions by more careful Mössbauer measurements. A two-line spectrum was observed, but the two lines do not have the same intensity or width. Many reasons exist for such spectra but, in view of the nmr evidence, we conclude that these spectra arise from overlapping quadrupole split doublets. However, we were only able to fit two doublets to the absorption envelopes (δ_1, 1.94 mm s^{-1}; Δ_1, 5.51 mm s^{-1}; δ_2, 1.73 mm s^{-1}; Δ_2, 5.08 mm s^{-1}, where δ is the Mössbauer isomer shift, relative to $CaSnO_3$, and Δ is the quadrupole splitting parameter). The sets of parameters indicate that the two tin environments are very similar to that found for $(CH_3)_2Sn(SO_3F)_2$ in the solid state (3). These two overlapping spectra must arise from the two tin species which dominate the low temperature ^{119}Sn nmr spectrum shown in Fig. 3. Presumably the tin species, giving rise to the highest field nmr resonance at more elevated temperatures, is no longer present in the frozen Mössbauer samples.

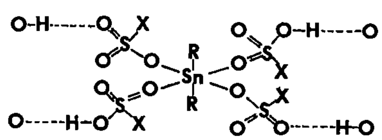
Clearly there are at least three different tin species present in these strong acid solutions that are involved in equilibria which, on the nmr time scale, average the tin environments. Aubke and co-workers (2) have shown that dimethyltin sulphonates, in the parent acid, are not completely ionized according to eq. [5] even in dilute solution. Both nmr and Mössbauer evidence indicate that the tin species in these solu-

$$[5]\quad (CH_3)_2SnSO_4 + H_2SO_4 \rightleftarrows \underset{\mathbf{I}}{[(CH_3)_2Sn]^{2+}} + [2HSO_4]^-$$

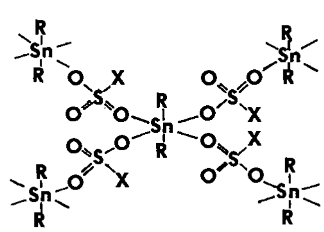
tions are six coordinate, and eq. [5] should perhaps be rewritten as eq. [6]

$$[6]\quad \underset{\mathbf{II}}{(CH_3)_2Sn(HSO_4)_2(H_2SO_4)_2} + 2H_2SO_4 \rightleftarrows \underset{\mathbf{III}}{[(CH_3)_2Sn(H_2SO_4)_4]^{2+}} + 2[HSO_4]^-$$

with the equilibrium lying heavily to the left. Since proton transfer processes are extremely fast it is unlikely that cooling, even to −90°C, will result in resolvable signals for **II** and **III**, but the equilibrium would be displaced towards **II** and account for the shift of the ^{119}Sn nmr signal to higher magnetic field, **II** being more shielded than **III**. This would also be consistent with the observation that the tin-119 nmr line widths become broader on dilution.



IV



V

At low temperature, species less shielded than **II** are present and since the $^1J_{^{117,119}Sn-^{13}C}$ values change only marginally, the difference in shielding must come from a redistribution of electron density from the sulphonate ligands. We believe that **II** is an isolated species linked to other units or solvent by hydrogen bonding and that each $[SO_3X]^-$ or HSO_3X ligand is monodentate. At lower temperatures these weak hydrogen bonded interactions must be converted to stronger linkages via sulphonate bridges, and result in the deshielding observed. We suggest that the peak in the ^{119}Sn nmr spectrum at ~4 ppm arises from a polymeric species **IV** while that at lowest field, ~29 ppm, has the polymeric units of **IV** cross linked to give **V**, which is the structure observed in the solid state for $(CH_3)_2Sn(SO_3F)_2$ (3). The two ^{119}Sn Mössbauer doublets observed in the frozen solution of $(CH_3)_2Sn(SO_3F)_2$ in HSO_3F we attribute to species **IV** and **V**.

$^5J(CH_3,SH)$ as a negative proximate or as a positive $\sigma-\pi$ coupling in 2-methylthiophenol derivatives

TED SCHAEFER, JAMES PEELING,[1] RUDY SEBASTIAN, AND JAMES D. BALEJA
Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received November 5, 1984

TED SCHAEFER, JAMES PEELING, RUDY SEBASTIAN, and JAMES D. BALEJA. Can. J. Chem. **63**, 2217 (1985).

Analyses of the ^1H nmr spectra of 6-chloro-2-methylthiophenol and of 4-*tert*-butyl-2-methylthiophenol in CCl_4 solution, together with double irradiation experiments, show that $^5J(CH_5,SH)$ in the former compound is -0.66 Hz and is $+0.47$ Hz in the latter. In the chloro compound, the sulfhydryl group spends relatively little time in out-of-plane conformations at 300 K. The negative coupling is a consequence of a through-space or proximate coupling mechanism. In the other compound, the sulfhydryl group samples many out-of-plane conformations but relatively few in which the S—H bond lies near the methyl group. Therefore $^5J(CH_3,SH)$ is now dominated by a $\sigma-\pi$ electron mechanism and is positive. Probably by coincidence, $^4J(H,SH)$ in this compound is equal in magnitude but opposite in sign to $^5J(CH_3,SH)$.

TED SCHAEFER, JAMES PEELING, RUDY SEBASTIAN et JAMES D. BALEJA. Can. J. Chem. **63**, 2217 (1985).

L'analyse des spectres rmn du ^1H du chloro-6 méthyl-2 thiophénol et du *tert*-butyl-4 méthyl-2 thiophénol, en solutions dans du CCl_4 et faite de concert avec des expériences de double irradiation, permet de montrer que la valeur de $^5J(CH_5,SH)$ dans le premier composé est égale à $-0,66$ Hz alors qu'elle est égale à $+0,47$ dans le dernier composé. À 300 K, le groupement sulfhydryle du composé chloré n'est pratiquement jamais dans le conformation hors-plan. La constante de couplage négative serait une conséquence d'une mécanisme de couplage à travers l'espace ou par proximité. Dans l'autre composé, le groupement sulfhydryle pourrait occuper plusieurs conformations hors-plan; toutefois, il en existe relativement peu dans lesquelles la liaison S—H se situerait près du groupement méthyle. Donc, le couplage $^5J(CH_3,SH)$ est dominé par un mécanisme électronique $\sigma-\pi$ et il est positif. Probablement dû à une coïncidence, la valeur de $^4J(H,SH)$ dans ce composé est d'amplitude égale mais de signe opposé à la valeur de $^5J(CH_3,SH)$.

Introduction

The long-range spin–spin coupling constants, $^nJ(H,SH)$, between the sulfhydryl and ring protons in thiophenol and various of its derivatives are moderately well understood as conformational indicators (1–6). $^6J(H,SH)$, involving the *para* proton, depends on $\sin^2\theta$, where θ is the angle by which the S—H bond twists out of the benzene plane, and is therefore a so-called $\sigma-\pi$ coupling. $^5J(H,SH)$ is a composite of $\sigma-\pi$, depending on $\sin^2\theta$, and σ, proportional to $\sin^2(\theta/2)$, interactions among nuclear and electronic angular momenta. Such couplings can be employed in the derivation of expectation values of the angular functions which, in turn, can be related to the internal barrier to rotation about the C—S bond. The assumption that $^4J(H,SH)$ is also predominantly a $\sigma-\pi$ coupling allows a reasonable description of the change in internal barrier caused by electronic perturbations from the *para* substituent in a number of thiophenol derivatives (3, 5).

One test for a predominant $\sigma-\pi$ mechanism relies on the "methyl group replacement" technique (7), in which a ring hydrogen is replaced by a methyl group. The test implies, for example, that $^6J(H,CH_3) = -^7J(CH_3,CH_3) = -0.62$ Hz in toluene and *p*-xylene if a $\sigma-\pi$ mechanism accounts for ^6J. This equality is borne out by experiment (8, 9). However, the corresponding relationship does not hold for *o*-xylene (8, 9) in which $^5J(CH_3,CH_3)$ is $+0.45(2)$ Hz (9), whereas $^4J(H,CH_3)$ is $-0.75(3)$ Hz in toluene (10). Of course, it might appear that the $\sigma-\pi$ component of $^4J(H,CH_3)$ is -0.45 Hz. This appearance is very likely misleading, primarily because of the likelihood of a "through-space" or proximate coupling component in $^5J(CH_3,CH_3)$. A proximate mechanism implies spin polarization transmitted via interactions between electron orbitals in proximate bonds or even between orbitals centered on the coupled nuclei (11). Therefore, $^5J(CH_3,CH_3)$ may measure a composite of $\sigma-\pi$ and proximate mechanisms. Judging from a proximate coupling like $^5J(H,CH_3)$ in anisole (12–14), the proximate component of $^5J(CH_3,CH_3)$ in *o*-xylene may well be negative, implying a rather larger $\sigma-\pi$ component of $^4J(H,CH_3)$ than would be deduced from an uncritical use of the methyl replacement procedure. Computations of $^5J(CH_3,CH_3)$ support (15) the existence of a proximate component but, probably because of the local threefold symmetry of each methyl group and the concomitant averaging over so many couplings (three protons in each group), experimental proof of its existence has not been forthcoming.

If one of the methyl groups is replaced by a sulfhydryl group and if the latter can be held at various orientations with respect to the methyl moiety (preferred θ values), then the existence of a $\sigma-\pi$ component in $^5J(CH_3,SH)$, having a maximum at $\theta = 90°$, *and* of a proximate component, with a maximum magnitude (perhaps of opposite sign to the $\sigma-\pi$ component) when the S—H bond lies near the methyl group, may be demonstrable. In this paper we show that $^5J(SH,CH_3)$ is negative in 6-chloro-2-methylthiophenol, **1**, and is positive in 2-methyl-4-*tert*-butylthiophenol, **2**.

[a]For a 2.5 mol% solution in CCl_4, containing some cyclohexane-d_{12} and at 300 K.
[b]For a 3.0 mol% solution in CCl_4, containing some tetramethylsilane and at 305 K.
[c]The shifts are given in Hz at 300.135 MHz relative to internal TMS for **1** and at 100.001 MHz (centerband) for **2**.
[d]For **1** the numbers in parentheses are probable errors while for **2** they are standard deviations.

Experimental

6-Chloro-2-methylthiophenol, **1**, from Fairfield Chem. Co. was prepared as a 2.5 mol% solution in CCl_4, which also contained 0.6 mol% cyclohexane-d_{12}. A 3.0 mol% solution of 2-methyl-4-*tert*-butylthiophenol, **2**, from Aldrich, in CCl_4 contained some tetramethylsilane. These samples were transferred to 5-mm od nmr tubes, which were degassed by numerous freeze–pump–thaw cycles and were then flame-sealed.

The ^{1}H nmr spectrum of **2** was calibrated by a procedure previously described (16) on an HA100 spectrometer at a probe temperature of 305 K. Because the existence of small, unresolvable couplings between the protons of the *tert*-butyl group and the ring protons led to increased linewidths for the peaks of H-3 and H-5, the calibration procedure was performed during irradiation of the *tert*-butyl proton peak at δ 1.268. The calibration gave peak frequencies with standard deviations of ≤0.02 Hz.

The ^{1}H nmr spectrum of **1** was obtained on an AM300 spectrometer at a probe temperature of 300 K. Typically, 8 scans were acquired using quadrature detection. In order to obtain a digital resolution of 0.01 Hz/point, narrow sweepwidths, say 300 Hz, and acquisition times of 27.3 s were used.

The signs of $^{5}J(CH_3,SH)$ in **1** and **2** were obtained by weak double irradiation methods. For **1** it proved most convenient to record the CH_3 peaks while perturbing selected peaks in the H-3 multiplet. Among other sign ratios so determined, it was shown that $^{5}J(H,SH)/{}^{5}J(CH_3,SH) < 0$. $^{5}J(H,SH)$ is positive (2). For **2**, irradiation of selected peaks in the CH_3 multiplet led to perturbations of certain peaks in the H-6 region, which showed that $^{4}J(H,SH)/{}^{5}J(CH_3,SH) < 0$. $^{4}J(H,SH)$ is negative (2). The positive sign of $^{5}J(CH_3,SH)$ was confirmed by experiments in which $^{4}J(H,SH)$ and $^{5}J(H,SH)$ had their signs determined relative to those of the long-range couplings between the methyl and ring protons. The latter are known (17).

STO 3G MO computations (18) were performed with the geometry optimization algorithm of the program MONSTERGAUSS (19). INDO MO FPT (20, 21) calculations of coupling constants assumed the STO 3G MO geometries.

Results and discussion

Spectral analysis

Because almost all the expected peaks in the ^{1}H nmr spectrum of **1** at 300 MHz were resolved, the analysis with the program PANIC (part of the software on the AM300) was straightforward. The spectral parameters are given in Table 1. Figure 1 displays the ^{1}H nmr spectrum of the sulfhydryl proton, illustrating resolution of the smallest proton–proton coupling in **1**.

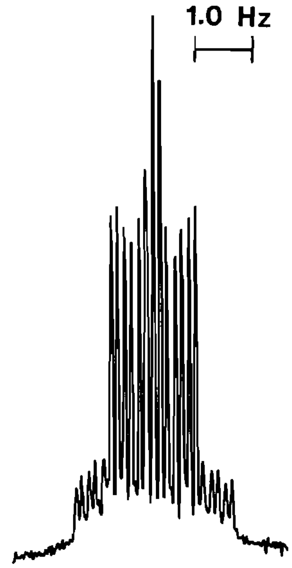

FIG. 1. The ^{1}H nmr spectrum of the sulfhydryl proton at 300.135 MHz and 300 K for a 2.5 mol% solution of 6-chloro-2-methylthiophenol in CCl_4 solution. The smallest splitting has a magnitude of 0.097(2) Hz and represents the coupling between the sulfhydryl proton and H-4, six bonds away.

The ^{1}H nmr spectrum of **2** was analyzed with the program LAME (22, 23), having been calibrated in the cw mode at 100 MHz while irradiating the transitions of the *tert*-butyl protons. The ring protons are fairly tightly coupled, leading to somewhat lower precision in the spectral parameters in Table 1 than for **1**, which displayed an essentially first-order spectrum at 300 MHz.

Both analyses assumed signs of coupling constants consistent with the double resonance experiments described above.

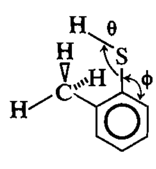
$^{5}J(CH_3SH)$ in 6-chloro-2-methylthiophenol, 1

If $^{6}J(H,SH)$ were zero, then a discussion in terms of planar conformations **1***a* and **1***c* would be adequate. In fact, $^{6}J(H,SH)$ vanishes or is very small in 2,6-dichlorothiophenol (3), in which intramolecular hydrogen bonding may help to stabilize the planar conformation, and is -0.97 Hz in 2-hydroxythiophenol (4), where the S—H bond is held in a plane nearly perpendicular to the molecular plane by a stereospecific O—H...S hydrogen bond involving the 3*p* lone-pair on sulfur. These data are consistent with a $\sigma-\pi$ mechanism for ^{6}J(H,SH), obeying $-0.97 \langle \sin^2 \theta \rangle$, angular brackets indicating an average over all the populated hindered rotor states of the S—H group. Then the observed ^{6}J(H,SH) of -0.097 Hz in **1** implies $\langle \sin^2 \theta \rangle$ as 0.10. If the barrier to rotation about the C—S bond in **1** were twofold, then its magnitude would be about 16 kJ/mol (5, 24) and a discussion in terms of a **1***a* $\rightleftarrows$ **1***c* equilibrium would be adequate at 300 K, V_2 being much larger than *kT*.

Of course, a substantial V_1 component exists, as indicated by the relative magnitudes of ^{5}J(H,SH) in **1**. In terms of the two-site equilibrium, one may write (3) $\Delta G_{300} = -RT \ln K = -RT \ln (0.531/0.247) = -1.9$ kJ/mol, favoring **1***a* ($K = 2.1_5$). A proper treatment would involve computations of the change in $\langle \sin^2 \theta \rangle$ caused by the presence of V_1, yielding a correction to V_2. However, because V_2 is nearly an order of magnitude larger than V_1, the perturbation would be small, as would the correction to V_1 caused by a finite $\langle \sin^2 \theta \rangle$.

Because (4) ^{4}J(H,SH) is near -1.1 Hz at $\theta = 90°$, it follows that as a $\sigma-\pi$ coupling its value would be about -0.11 Hz in the hypothetical molecule containing no methyl group but otherwise obeying the approximate potential function derived from ^{6}J(H,SH) and ^{5}J(H,SH). Hence ^{5}J(CH_3,SH) would be about $+0.11$ Hz if it were measuring the $\sigma-\pi$ component of ^{4}J(H,SH). The actual value of ^{5}J(CH_3,SH) is $-0.65(1)$ Hz in **1**.

The most likely source of this large negative coupling is the proximate coupling mechanism. The following approach was taken to the computation of the proximate interaction. The optimized geometry of 2-methylthiophenol, **3**, obtained from



3

STO 3G MO computations, was used to calculate ^{5}J(CH_3,SH) by the INDO MO FPT approach. For $\theta = 98.0°$ and $\phi = 114.9°$, the computations gave ^{5}J(CH_3,SH) as -1.28 Hz. An increase of 2° in ϕ resulted in a calculated coupling of -1.73 Hz whereas a decrease of 2° in θ yielded -1.52 Hz. For the planar *trans* form of 2-methylthiophenol, the optimized geometry yielded ^{5}J(CH_3,SH) as 0.21 Hz. In **1**, the latter conformation is about 68% abundant. Therefore, a naive approach yields ^{5}J(CH_3,SH) as $0.68\ (0.21) + 0.32\ (-1.28)$ or -0.28 Hz. Of course, the *ortho* chlorine substituent will very likely cause a somewhat more compressed geometry of the SH and CH_3 groups in **1***c* than in 2-methylthiophenol, leading to a larger magnitude of the coupling. Furthermore, the coupling **1** contains some nonplanar populations, **1***b*. It seem bootless to compute further in an attempt to match the computed coupling in **1** to its observed value of -0.65 Hz, but it is also eminently reasonable that this sizeable negative number is indeed the consequence of a proximate mechanism. The discussion now turns to the coupling in **2**, in which the large populations of conformers containing out-of-plane SH groups should entail a dominant $\sigma-\pi$ mechanism and hence a positive sign.

*^{5}J(CH_3,SH) in 2-methyl-4-*tert*-butylthiophenol, 2*

To within experimental error, ^{4}J(H,SH) and ^{5}J(CH_3,SH) are equal and opposite in sign, as expected if ^{4}J(H,SH) is a $\sigma-\pi$ coupling and ^{5}J(CH_3,SH) is now also a $\sigma-\pi$ coupling, in contrast to the situation in **1**. In **2**, nonplanar SH conformations are predominant, in contrast to **1**, and $\langle \sin^2 \theta \rangle$ is 0.43 because ^{4}J(H,SH) is -1.1 Hz at $\theta = 90°$ (4, 5). Consequently, it is a poor approximation to employ ^{5}J(H,SH) in the estimation of an equilibrium between planar conformations, as was done for **1** above. For nonplanar conformations, ^{5}J(H,SH) has a significant $\sigma-\pi$ component (5), varying as $\sin^2 \theta$, while the σ component varies as $\sin^2 (\theta/2)$. Hence ^{5}J(H-5,SH) may be appreciable in **2** (it is 0.29 Hz compared to 0.42 Hz for ^{5}J(H-3,SH)) without the necessity for a significant population of type **1***c*.

The STO 3G MO computations on 2-methylthiophenol, when corrected for the fact that they overestimate the twofold barrier in thiophenol by about 10 kJ/mol (4), imply that the SH group spends only 10% of its time in conformations characterized by $120° < \theta < 180°$. Consequently, the negative proximate component of ^{5}J(CH_3,SH) will be small.

On the other hand, the conformation with $\theta = 0°$ is of lowest energy and the computed coupling at this angle is 0.21 Hz (see previous section). Therefore it is difficult to disentangle the components of ^{5}J(CH_3,SH) in **2** and its observed equality in magnitude with ^{4}J(H,SH) must be regarded as a coincidence. Nevertheless, the large magnitude of the coupling strongly suggests a major $\sigma-\pi$ component and is compatible with the large out-of-plane excursions of the SH bond predicted by the MO results.

Branched-chain sugars in asymmetric synthesis. Total synthesis of marine antibiotic (−)-malyngolide

PAK-TSUN HO[1] AND SIMMIE WONG

Guelph–Waterloo Centre for Graduate Work in Chemistry, University of Waterloo, Waterloo, Ont., Canada N2L 3G1

Received October 25, 1984

PAK-TSUN HO and SIMMIE WONG. Can. J. Chem. **63**, 2221 (1985).

Marine antibiotic (−)-malyngolide has been stereospecifically synthesized in about 25% overall yield from 2,3-*O*-isopropylidene-D-apiose, easily prepared from D-mannose.

PAK-TSUN HO et SIMMIE WONG. Can. J. Chem. **63**, 2221 (1985).

Utilisant comme produit de départ l'*O*-isopropylidène-2,3-D-apiose que l'on peut facilement préparer à partir du D-mannose, on a réalisé une synthèse stéréospécifique (rendement global de 25%) de l'antibiotique marin, (−)-malyngolide.

[Traduit par le journal]

Marine antibiotic (−)-malyngolide **1**, which was isolated in 1979 by Moore and co-workers (1) from a variety of the alga *Lyngbya majuscula*, exhibits significant activity against *Mycobacterium smegmatis* and *Streptococcus pyogenes* (2). A number of syntheses of malyngolide have been recently recorded (3), since its structure determination was reported (1).

In connection with our interest in the use of branched-chain sugars as chiral synthons for the asymmetric synthesis of natural products (4), we consider that the configuration at C-5 of (−)-malyngolide is derived from a C-3-hydroxymethyl branched-chain sugar as illustrated by the analysis in Scheme 1. Thus, bond disconnection at C-2 and C-3 of (−)-malyngolide generates a D-apiose derivative. Our synthesis started with D-mannose and converged to 2-*C*-(hydroxymethyl)-2,3-*O*-isopropylidene-D-mannofuranose **2**, which has been prepared by a one-step methodology developed in our laboratory (5). Transformation of **2** to 2,3-*O*-isopropylidene-D-apiose **3** has been accomplished in a simple one-pot operation in excellent yield (6).

SCHEME 1

Reaction of compound **3** with tosyl chloride (1 equiv.) in dichloromethane in the presence of pyridine at 5°C gave the crystalline tosylate **4** in quantitative yield, mp 104°C. Treatment of compound **4** with *p*-toluenesulfonic acid (20% by weight) in anhydrous methanol at refluxing temperature for $2\frac{1}{2}$ days, followed by addition of methanolic potassium hydroxide to pH 10 at ice temperature, led to the formation of the epoxide **5** in 80% yield after chromatographic purification. The proton nuclear magnetic resonance spectrum of the substance fully corroborated the structural assignment (see experimental section).

The stage was set for the attachment of the hydrocarbon side chain by a cuprous iodide catalyzed Grignard reaction. Reaction of the epoxide **5** with octylmagnesium bromide (2.5 equiv.) in the presence of 10% cuprous iodide in tetrahydrofuran at −40°C afforded quantitatively the tertiary alcohol **6**. The use of tetrahydrofuran as the solvent for this reaction is essential. Any other solvent, such as diethyl ether or DME, used for this reaction gave either extremely low yield or no formation of the desired product.

Completion of the synthesis of the marine antibiotic required removal of the hydroxyl function at the C-2 carbon of compound **6**. Conversion of the diol **6** to compound **7** was accomplished in 89% overall yield by standard procedures, acetylation of the secondary alcohol (acetic anhydride, pyridine, room temperature), formation of the methylthiomethyl ether (acetic anhydride, dimethyl sulfoxide, room temperature), and generation of the secondary alcohol by mild alkali hydrolysis. Thiocarbonylation of compound **7** with thiocarbonyl diimidazole in tetrahydrofuran at 60°C afforded the thiocarbonate **8**. When this material was allowed to react with excess of tri-n-butyltin hydride (2 equiv.) in benzene in the presence of a catalytic amount of radical initiator α,α′-azobisisobutyronitrile at refluxing temperature, the deoxygenated product **9** was smoothly formed in 82% yield (7). Exposure of compound **9** to acidic conditions (in aqueous hydrochloric acid, acetone) resulted in the isolation of the desired furanose derivative **10** in 75% yield after purification.

Further elaboration of the cyclic hemiacetal **10** was accomplished in the following way. Wittig reaction of **10** with carbethoxyethylidene triphenylphosphorane (2 equiv.) in acetonitrile at 50°C yielded presumably the *trans* isomer **11** as the sole product in 72% yield. Its proton nuclear magnetic resonance spectrum shows a broad triplet (J = 10 Hz) at δ 6.97, a doublet (J = 10 Hz) at δ 2.40, and a broad singlet at δ 1.87. These values are in agreement with the assigned structure. The unsaturated ester was hydrogenated in quantitative yield to a diastereoisomeric mixture of the esters **12** in a ratio of 1:1 based on steric reasoning and its proton nuclear magnetic resonance spectrum and these two isomers were not separated at this stage. The corresponding acids **13** were obtained quantitatively by reaction of compunds **12** with potassium hydroxide in aqueous methanol at room temperature. Finally, the acids **13**, on treatment with either dicyclohexylcarbodiimide and

pyridine in benzene at room temperature (8), or dipyridyl disulfide and triphenylphosphine in benzene at room temperature (9), were converted in 90% yield to the epimeric lactones **14** and **1**, easily separable by chromatography on silica gel (5% acetone in hexane and dichloromethane). The proton nuclear magnetic resonance spectrum of the lactone **1** exhibits a pair of doublets (J = 12 Hz) at δ 3.7 and δ 3.47 ppm for the isolated hydroxymethyl and is completely identical with the spectrum reported for the naturally occurring (−)-malyngolide, $[\alpha]_D$ −12.8° (c 0.8, chloroform) (lit. (1) $[\alpha]_D$ −13° (c 2, chloroform)). Compound **14**, which is (+)-epimalyngolide, shows a broad singlet at δ 3.61 ppm for the methylene of the isolated primary alcohol in its proton nuclear magnetic resonance spectrum and exhibits a specific rotation of $[\alpha]_D$ +17.6° (c 1.1, chloroform) (lit. (3) $[\alpha]_D$ +17°). The epimalyngolide, on treatment with potassium *tert*-butoxide in dimethylsulfoxide (3), has been easily epimerized to the natural (−)-malyngolide. Thus, the synthesis of (−)-malyngolide was stereospecific.

Experimental

General

Melting points were determined on a Reichert hot stage apparatus and are uncorrected. Optical rotations were determined by a Karl–Zeiss model LEP 370740 polarimeter at 546 and 578 nm at room temperature. Infrared spectra were recorded on a Beckmann model IR-10 spectrometer using chloroform as solvent. Proton nuclear magnetic resonance (^{1}H nmr) spectra were measured with Bruker spectrometers, models WP-80 or WH-400, using deuteriochloroform with tetramethylsilane as internal standard unless otherwise specified. Thin layer and preparative layer chromatography were done using silica gel containing fluorescent indicator (G_{254}).

Tosylation of 2,3-O-isopropylidene-D-apiose 3

To a stirred solution of compound **3** (13.7 g, 7.2 mmol) and anhydrous pyridine (27 mL, 21.6 mmol) in anhydrous dichloromethane (150 mL) at 5°C, tosyl chloride (14.8 g, 7.8 mmol) was added. The mixture was left overnight at the same temperature, after which time the mixture was diluted with diethyl ether (300 mL). A standard work-up gave the crystalline tosylate **4** in quantitative yield, mp 104°C; $[\alpha]_D$ −43° (c 2.0, chloroform); ir (chloroform): 3500 (hydroxyl) cm^{-1}; ^{1}H nmr δ: 7.81 and 7.35 (2d, 4H, aromatic protons), 5.34 (s, 1H, C-1 proton), 4.30 (s, 1H, C-2 proton), 4.22 (s, 2H, C-4 protons), 3.93 (s, 2H, C-3′ protons), 2.44 (s, 3H, methyl), 1.3 and 1.40 (2s, 6H, 2 methyls). *Anal.* calcd. for $C_{15}H_{20}O_7S$: C 52.31, H 5.86; found: C 52.26, H 5.92.

Preparation of the epoxide 5

A solution of compound **4** (17.3 g, 50.3 mmol) and *p*-toluenesulfonic acid (3.4 g, 20% by weight) in anhydrous methanol (500 mL) was refluxed for 2½ days. The reaction mixture was then cooled to 0°C and methanolic potassium hydroxide was added until the solution became pH 10. The mixture was stirred at room temperature for 2 h, after which time it was carefully neutralized with *p*-toluenesulfonic acid. Removal of the white precipitates and evaporation of the solvent gave a residue. Flash chromatography of the crude product on silica gel using 10% diethyl ether in chloroform as solvent afforded the epoxide **5** (5.88 g, 80%) as a homogeneous syrup, $[\alpha]_D$ −95° (c 1.13, chloroform); ir (chloroform): 3500 (hydroxyl) cm^{-1}; ^{1}H nmr δ: 4.97 (s, 1H, C-1 proton), 4.06 (q, 2H, J = 13 Hz, C-4 protons), 3.94 (s, 1H, C-2 proton), 3.41 (s, 3H, methoxyl), 3.06 (dd, 2H, J = 8 Hz, epoxide). *Anal.* calcd. for $C_6H_{10}O_4$: C 49.31, H 6.89; found: C 49.36, H 6.87.

Preparation of compound 6

Cuprous iodide (0.1 g, 0.51 mmol) was added to the well-stirred Grignard reagent prepared from octyl bromide (0.99 g, 5.14 mmol) and magnesium metal (0.13 g, 5.15 mmol) in 20 mL of dry tetrahydrofuran at −40°C under argon. The mixture was stirred at the same temperature for 2 h and the solution of compound **5** (0.3 g, 2.05 mmol) in 10 mL of tetrahydrofuran was added dropwise over a period of 30 min. The resulting yellow solution was warmed up to room temperature and stirred for 15 min. Saturated aqueous ammonium chloride and ether were added successively and the layers were separated. The aqueous layer was extracted with ether and the combined extracts were washed with saturated aqueous ammonium chloride and dried over anhydrous magnesium sulfate. Removal of the solvent provided an oil which was purified by flash chromatography on silica gel to give the desired product **6** in quantitative yield; $[\alpha]_D$ −74° (c 1.18, chloroform); ir (chloroform): 3500 (hydroxyl) cm^{-1}; ^{1}H nmr δ: 4.85 (s, 1H, C-1 proton), 3.95 (s, 1H, C-2 proton), 3.85 (s, 2H, C-4 proton), 1.25 (m, 16H, methylene protons), 0.88 (t, 3H, methyl). *Anal.* calcd. for $C_{14}H_{28}O_4$: C 64.58, H 10.84; found: C 64.59, H 10.82.

Preparation of the hydroxyl methylthiomethyl ether 7

Acetylation of compound **6** (1.12 g, 4.55 mmol) under standard conditions gave the hydroxyl acetate in quantitative yield; ^{1}H nmr δ: 4.90 (s, 2H, C-1 and C-2 protons), 3.86 (s, 2H, C-4 protons), 3.37

(s, 3H, methoxyl), 2.13 (s, 3H, acetate), 1.25 (m, 16H, methylene protons), 0.88 (t, 3H, methyl).

The hydroxyl acetate was mixed with dimethyl sulfoxide (5 mL) and acetic anhydride (5 mL). The mixture was stirred at room temperature for 3 days, after which time removal of the solvents under vacuum gave an oily material. This material was dissolved in 10% aqueous methanol (5 mL), followed by the addition of potassium carbonate (0.25 g). The solution was stirred at room temperature for 5 h and 10 mL of water was added. The reaction mixture was extracted with ether (3 × 4.0 mL) and the combined extracts were washed with brine water, dried over anhydrous magnesium sulfate, and concentrated to a syrup. Chromatography of the crude product **7** on silica gel yielded a pure product **7** (1.23 g, 89%); $[\alpha]_D$ −57° (*c* 1.3, chloroform); ir (chloroform): 3500 (hydroxyl) cm^{-1}; ^{1}H nmr δ: 4.84 (broad s, 1H, C-1 proton), 4.64 (s, 2H, —O—CH$_2$—S—), 3.96 (dd, 2H, *J* = 16 Hz, C-4 protons), 3.85 (br s, 1H, C-2 proton), 3.37 (s, 3H, methoxyl), 2.17 (s, 3H, methyl), 1.25 (m, 16H, methylene protons), 0.88 (t, 3H, methyl). *Anal.* calcd. for $C_{16}H_{32}O_4S$: C 59.94, H 10.10; found: C 59.90, H 10.18.

*Thiocarbonylation of compound **7** to compound **8***

Compound **7** (1.07 g, 3.5 mmol) and 1,1′-thiocarbonyl diimidazole (0.75 g, 7 mmol) were dissolved in 20 mL of anhydrous tetrahydrofuran. The solution was heated under reflux for 1 h, after which time removal of the solvent gave a yellow residue. Flash chromatography of the yellow material on silica gel using 5% diethyl ether in dichloromethane as solvent yielded compound **8** (1.27 g, 87%) as a homogeneous syrup, $[\alpha]_D$ −24° (*c* 1.8, chloroform); ^{1}H nmr δ: 7.33 (br s, 1H, imidazole proton), 7.10 (br s, 1H, imidazole proton), 5.73 (s, 1H, C-2 protons), 5.10 (s, 1H, C-1 proton), 4.58 (s, 2H, —O—CH$_2$—S—), 4.15 (dd, 2H, *J* = 16 Hz, C-4 protons), 3.37 (s, 3H, methoxyl), 2.17 (s, 3H, methyl), 1.25 (m, 16H, methylene protons), 0.88 (t, 3H, methyl). *Anal.* calcd. for $C_{20}H_{34}O_4S_2N_2$: C 55.79, H 7.97; found: C 55.68, H 7.92.

*Deoxygenation of compound **8** to compound **9***

To a hot (80°C) stirred solution of tri-*n*-butyltin hydride (0.25 mL, 1.02 mmol) and a catalytic amount of α,α′-azobisisobutyronitrile in anhydrous benzene (5 mL) under an atmosphere of argon was added dropwise a solution of the thiocarbonate **8** (0.282 g, 0.68 mmol) in 20 mL of anhydrous benzene. The solution was stirred under reflux for additional $\frac{1}{2}$ h and concentrated under vacuum to an oily material. The crude product was purified by flash chromatography on silica gel using 5% ethyl acetate in hexane as eluant to afford the desired product **9** (0.181 g, 82%) as a homogeneous syrup; $[\alpha]_D$ −56.5° (*c* 1.2, chloroform); ^{1}H nmr δ: 5.07 (m, 1H, C-1 proton), 4.47 (s, 2H, —O—CH$_2$—S—), 3.86 (dd, 2H, *J* = 14 Hz, C-4 protons), 3.37 (s, 3H, methoxyl), 2.17 (s, 3H, methyl), 1.87 (m, 2H, C-2 protons), 1.25 (m, 16H, methylene protons), 0.88 (t, 3H, methyl). *Anal.* calcd. for $C_{16}H_{32}O_3S$: C 63.12, H 10.60; found: C 63.11, H 10.63.

*Hydrolysis of compound **9** to furanose derivative **10***

A solution of compound **9** (0.2 g, 0.69 mmol) in 5 mL of 1 *N* aqueous hydrochloric acid and 8 mL of acetone was stirred at 70°C for $2\frac{1}{2}$ h. The reaction mixture was neutralized with aqueous sodium bicarbonate to pH 7. Removal of the solvent gave a residue which was extracted with dichloromethane. The combined extracts were dried over anhydrous magnesium sulfate and concentrated to a syrup. Chromatography of the syrup on silica gel using 3% methanol, 27% ether, and 70% dichloromethane as eluant yielded the desired product **10** as a homogeneous syrup (0.113 g, 75%); $[\alpha]_D$ +21° (*c* 1.0, chloroform); ir (chloroform): 3550−3480 (hydroxyl) cm^{-1}; ^{1}H nmr δ: 5.43 (br t, 1H, C-1 proton), 3.82 (dd, 2H, *J* = 18 Hz, C-4 protons), 2.00 (br m, 2H, C-2 protons), 1.25 (m, 16H, methylene protons), 0.88 (br t, 3H, methyl). *Anal.* calcd. for $C_{13}H_{26}O_3$: C 67.79, H 11.38; found: C 67.73, H 11.29.

*Preparation of the hydroxyl unsaturated ester **11***

A solution of compound **10** (87 mg, 0.38 mmol) and carboethoxyethylidene triphenylphosphorane (274 mg, 0.76 mmol) in 5 mL of anhydrous acetonitrile was stirred at 50°C under argon for $2\frac{1}{2}$ h. After removal of the solvent, flash chromatography of the crude product on silica gel using 10% acetone in chloroform as eluant afforded the pure unsaturated ester **11** (85 mg, 72%) as a homogeneous syrup; $[\alpha]_D$ −2.5° (*c* 1.0, chloroform); ir (chloroform): 3500−3300 (hydroxyl), 1720 (unsaturated ester) cm^{-1}; ^{1}H nmr δ: 6.97 (br t, 1H, *J* = 10 Hz, vinyl proton), 4.27 (dd, 2H, *J* = 8 Hz, —CH$_2$—O—CO—), 3.53 (s, 2H, hydroxymethylene), 2.40 (d, 2H, *J* = 10 Hz, allylic protons), 1.87 (br s, 3H, methyl), 1.25 (m, 16H, methylene protons), 0.88 (t, 3H, methyl). *Anal.* calcd. for $C_{18}H_{34}O_4$: C 68.74, H 10.91; found: C 68.72, H 10.93.

*Hydrogenation of compound **11** to the saturated esters **12***

A solution of compound **11** (76 mg, 0.24 mmol) in 6 mL of ethanol in the presence of 10% palladium on activated carbon (10 mg) was hydrogenated at atmospheric pressure for 3 h. Removal of the catalyst and solvent yielded a pair of the diastereoisomeric esters **12** in quantitative yield; ir (chloroform): 3500−3300 (hydroxyl), 1731 (ester) cm^{-1}; ^{1}H nmr δ: 4.13 (q, 2H, *J* = 8 Hz, —CH$_2$—O—CO—), 3.40 (br s, 2H, hydroxymethylene), 1.25 (m, 19H, methylene and methyl), 0.88 (t, 3H, methyl). *Anal.* calcd. for $C_{18}H_{36}O_4$: C 68.31, H 11.47; found: C 68.39, H 11.44.

*Formation of the hydroxyl carboxylic acid **13***

The ester **12** (68 mg, 0.22 mmol) was hydrolyzed in 50% aqueous methanol (5 mL) with potassium hydroxide (0.3 g) at room temperature for 3 h. The solution was then acidified to pH 3 with aqueous hydrochloric acid and extracted with dichloromethane (3 × 10 mL). The combined extracts were dried over anhydrous magnesium sulfate and removal of the solvent afforded the desired product **13** in quantitative yield; ir (chloroform): 3500−2500 and 1710 (carboxylic acid) cm^{-1}; ^{1}H nmr δ: 3.47 (br s, 2H, hydroxymethylene), 1.25 (m, 23 H, methylene and methyl), 0.88 (t, 3H, methyl). *Anal.* calcd. for $C_{16}H_{32}O_4$: C 66.61, H 11.20; found: C 66.58, H 11.12.

*Preparation of (−)-malyngolide **1** and (+)-epimalyngolide **14***

(a) A solution of compound **13** (56 mg, 0.20 mmol), triphenylphosphine (79 mg, 0.3 mmol), and 2,2′-dipyridyldisulfide (66 mg, 0.3 mmol) in benzene (3 mL) was stirred at room temperature for 3 h. Removal of the solvent gave the epimeric lactones (ratio 1:1), which were separated with preparative tlc on silica gel using 5% acetone in hexane and dichloromethane (50:50) as solvent to yield (−)-malyngolide **1** and its epimeric lactone **14** (52 mg, 90%).

(b) When a solution of compound **13** (56 mg, 0.20 mmol), dicyclohexylcarbodiimide (62 mg, 0.3 mmol), and pyridine (32 mg, 0.4 mmol) in 3 mL of anhydrous benzene was stirred at room temperature overnight, a similar result was obtained.

(−)-Malyngolide exhibited infrared and ^{1}H nmr spectra identical with those of the natural product; $[\alpha]_D$ −12.8° (*c* 0.8, chloroform); ir (chloroform): 3500−3400 (hydroxyl), 1731 (lactone) cm^{-1}; ^{1}H nmr δ: 3.71 and 3.47 (2d, 2H, *J* = 12 Hz, hydroxymethylene), 2.41 (m, 1H, —*CH*—CO—), 2.20−1.45 (m, 4H, methylene protons), 1.25 (m, 19H, methylene and methyl), 0.88 (t, 3H, methyl). *Anal.* calcd. for $C_{16}H_{30}O_3$: C 71.07, H 11.18; found: C 71.01, H 11.26. (+)-Epimalyngolide: $[\alpha]_D$ +17.5° (*c* 1.1, chloroform); ir (chloroform): 3500−3400 (hydroxyl), 1731 (lactone) cm^{-1}; ^{1}H nmr δ: 3.60 (s, 2H, hydroxymethylene), 2.45 (m, 1H, —*CH*—CO—), 2.10−1.45 (m, 4H, methylene protons), 1.25 (m, 19H, methylene and methyl), 0.86 (t, 3H, methyl). *Anal.* calcd. for $C_{16}H_{30}O_3$: C 71.07, H 11.18; found: C 70.98, H 11.09.

Acknowledgments

We thank the Natural Sciences and Engineering Research Council of Canada for financial support of this work, and Dr. P. Sinay for sending us various spectra of synthetic and natural malyngolide for comparison.

A nuclear magnetic resonance study of the equilibria and kinetics of the reaction of penicillamine with cystine and related disulfides

YVON THERIAULT AND DALLAS L. RABENSTEIN[1]

Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received October 29, 1984

YVON THERIAULT and DALLAS L. RABENSTEIN. Can. J. Chem. **63**, 2225 (1985).

The thiol/disulfide exchange reactions of penicillamine (PSH) with cystine and several related disulfides (RSSR) have been studied by ^{1}H nmr. The reactions take place in two steps:

$$PSH + RSSR \rightleftarrows PSSR + RSH$$
$$PSH + PSSR \rightleftarrows PSSP + RSH$$

The equilibria and kinetics of the reactions of PSH with cystine were characterized over the pH range 5–8, while the reactions with the disulfides of cysteamine, homocysteine, 2-mercaptoethanol, mercaptoacetic acid, 3-mercaptopropionic acid, and mercaptosuccinic acid were studied at neutral pH. From the pH dependence of the rate of the reaction of PSH with cystine, the reactive species are identified as penicillamine with its amino group protonated and its thiol group deprotonated and cystine and penicillamine–cysteine mixed disulfide with their amino groups protonated. For all the disulfides studied, the extent to which the first reaction occurs is within a factor of 2–3 of that predicted by a random distribution, while the extent to which the second reaction occurs is considerably less than for a random distribution. This is attributed to steric effects due to the two methyl groups next to the sulfur of penicillamine.

YVON THERIAULT et DALLAS L. RABENSTEIN. Can. J. Chem. **63**, 2225 (1985).

Faisant appel à la rmn du ^{1}H, on a étudié les réactions d'échange thiol/disulfure de la pénicillamine (PSH) avec la cystéine et plusieurs disulfures (RSSR). Les réactions se produisent en deux étapes

$$PSH + RSSR \rightleftarrows PSSR + RSH$$
$$PSH + PSSR \rightleftarrows PSSP + RSH$$

On a caractérisé les équilibres et les cinétiques des réactions de la PSH avec la cystéine dans un intervalle de pH allant de 5 à 8 tandis qu'on a étudié les réactions avec les disulfures de la cystéamine, de l'homocystéine, du mercapto-2 éthanol, de l'acide mercaptoacétique, de l'acide mercapto-3 propionique et de l'acide mercaptosuccinique à des pH neutres. L'effet du pH sur la vitesse de réaction de la PSH avec la cystéine a permis d'identifier, comme espèces réactives, la pénicillamine avec son groupe amino protoné et son groupe thiol déprotoné ainsi que le disulfure mixte pénicillamine–cystéine avec leur groupe amino protoné. Pour tous les disulfures étudiés, une comparaison des taux de réactions observés avec les taux prévus en se basant sur une distribution au hasard indique que dans le cas de la première réaction le facteur est égal à 2–3 alors que pour la deuxième réaction, le taux est beaucoup plus faible que celui prévu sur cette base. On attribue ceci aux effets stériques des deux groupes méthyles présents au voisinage du soufre de la pénicillamine.

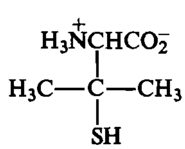
Introduction

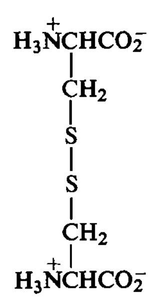
Penicillamine (PSH, **1**), is widely used in medicine (1, 2) for the treatment of cystinuria (3), Wilson's disease (4), heavy metal poisoning (5, 6), and rheumatoid arthritis (7–10). In the treatment of cystinuria, the mechanism of action is the reaction of penicillamine with relatively insoluble cystine[2] (CSSC, **2**) to form penicillamine–cysteine mixed disulfide (PSSC, **3**).



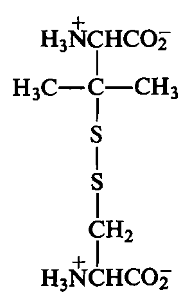
1

Because PSSC is somewhat more soluble than CSSC, treatment with penicillamine results in decreased formation of cystine stones in the kidneys of cystinuric patients (1, 3).

Penicillamine reacts with CSSC to form PSSC by the thiol/disulfide exchange reaction:



2



3

[1] $PSH + CSSC \rightleftarrows PSSC + CSH$

A second thiol/disulfide exchange can also take place, yielding the symmetrical disulfide PSSP.

[2] $PSH + PSSC \rightleftarrows PSSP + CSH$

These thiol/disulfide exchange reactions are important not only because they form the basis for the treatment of cystinuria with penicillamine, but also because they represent a major pathway by which penicillamine is metabolized in all patients who are given penicillamine (10).

In this paper, we report the results of a detailed study of the reaction of PSH with cystine and several related disul-

[1]Author to whom correspondence may be addressed at the Department of Chemistry, University of California–Riverside, Riverside, CA 92521, U.S.A.

[2]CSSC has a solubility of 2.8×10^{-4} *M* at pH 6.95 and 25°C (11).

fides. Equilibrium and kinetic data were obtained by ^1H nuclear magnetic resonance (nmr) spectroscopy over a wide pH range. Resolved resonances were obtained for the various penicillamine-containing species, making it possible to characterize separately the two steps in the thiol/disulfide exchange. From the pH dependence of the equilibrium and kinetic data, the reactive species are identified and pH independent equilibrium and rate constants are evaluated.

Experimental

D-Penicillamine and cysteine were obtained from Sigma Chemical Co. D-Penicillamine disulfide, 2-hydroxyethyldisulfide, cystamine, and cysteamine were obtained from Aldrich Chemical Co. Cystine and homocystine were from ICN Pharmaceuticals, and homocysteine was from Nutritional Biochemical Corp. For most experiments, the thiols and disulfides were used as received. In several experiments, solutions of penicillamine were electrolyzed over a Hg pool electrode (12) to reduce traces (<1%) of penicillamine disulfide.

The pH measurements were made at 25°C with a Fisher Accumet pH meter equipped with a standard glass electrode and a fiber-tipped, saturated calomel reference electrode, or a microcombination electrode. The ^1H nmr spectra were measured at 200 MHz and 25°C on a Bruker WH-200 nmr spectrometer operating in the pulse/Fourier transform mode. All nmr spectra were measured on aqueous solutions. To avoid the dynamic range problem, the water resonance was reduced in intensity by saturating it with a decoupler pulse applied at the water resonance frequency for 2 s prior to the observation pulse. The spectrometer was run in the unlocked mode. The ^1H chemical shifts were measured relative to the methyl resonance of *tert*-butanol (TBA) which was added to the solutions at a concentration of 0.001–0.01 *M*, depending on the thiol and disulfide concentrations. Chemical shifts are reported relative to the methyl resonance of sodium-2,2-dimethyl-2-silapentane-5-sulfonate (DSS). So that quantitative information could be obtained from resonance intensities, the repetition time was at least 5 times the longest T_1 of the methyl resonances of interest. T_1 values were measured by the inversion–recovery method.

Solutions were prepared in water which had been purified by distilling it twice and then passing it through a Barnstead D8902 Ultrapure mixed-bed ion exchange resin. KCl (1 *M*) and EDTA (0.003 *M*) were added for ionic strength control and to complex traces of heavy metals which would catalyze the air oxidation of thiols (13). The solvent mixture was deoxygenated by bubbling with argon or nitrogen before addition of thiol to minimize oxidation by dissolved oxygen. Inert gas was blown over the solution during adjustment of pH, and nmr tubes were flushed with gas before transfer of an aliquot of solution to the tube. For solutions which required more than several hours to come to equilibrium, the solution was degassed by taking it, in an nmr tube, through at least three freeze–pump–thaw cycles on a vacuum line. The nmr tube was then sealed while still on the vacuum line.

Results

Reaction of penicillamine with cystine

In Fig. 1 are shown ^1H nmr spectra of PSH (A), CSSC (B), CSH (D), and PSSP (E), and of a solution prepared from PSH and CSSC (C). The ^1H nmr spectrum of PSH consists of a singlet at 3.29 ppm from the methine proton on C_α, and two singlets at 1.27 and 1.55 ppm from the two methyl groups. The two methyl groups give two separate resonances due to the asymmetric carbon at C_α. The resonance at 1.2397 ppm in spectrum A is from TBA. The same assignment applies to the resonances in the spectrum of PSSP. The spectrum of CSH consists of an ABX pattern. The AB part is centered at 2.8 ppm and is from the two nonequivalent methylene protons on C_β, while the X part from the methine proton on C_α is centered at 3.50 ppm. The spectrum for CSSC also consists of an ABX pattern, and the assignment is the same.

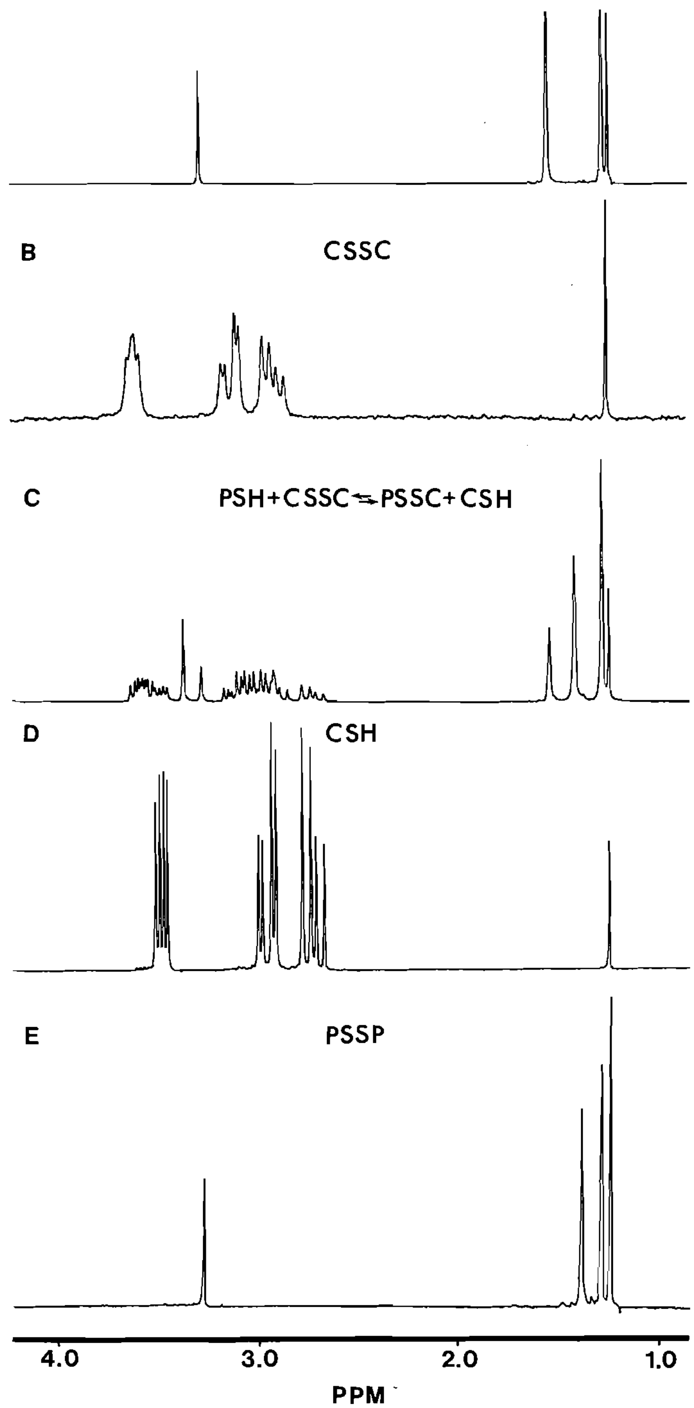


FIG. 1. The 200-MHz ^1H nmr spectra of (A) 0.20 *M* PSH, (B) 0.18 *M* CSSC, (C) a solution which contained initially 0.10 *M* PSH and 0.090 *M* CSSC, (D) 0.45 *M* CSH, and (E) 0.010 *M* PSSP at 23°C. All solutions were in D_2O and contained *tert*-butanol. pH = 10.0.

In spectrum C, there are resonances in addition to those from PSH and CSSC. These are assigned to PSSC and CSH, the products of the thiol/disulfide exchange reaction between PSH and CSSC. Under these solution conditions, there is negligible reaction of PSSC with PSH to form PSSP. There is considerable overlap of the resonances in the ABX patterns of CSH, CSSC, and PSSC. However, the singlet methine and methyl

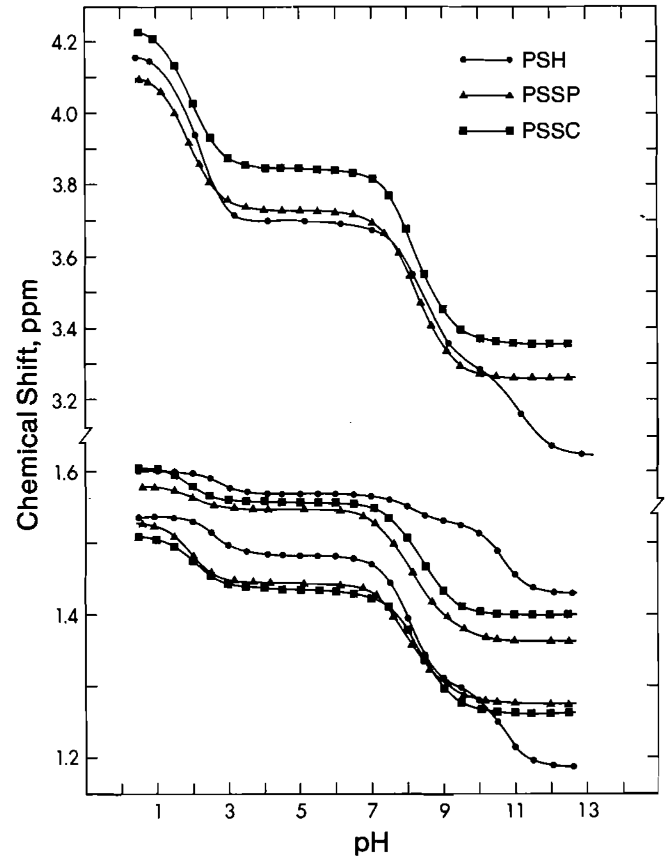

FIG. 2. Chemical shifts of the methine (top) and methyl (bottom) protons of PSH, PSSP, and the PSH part of PSSC as a function of pH.

resonances of PSH, PSSP, and PSSC are resolved over a wide pH range, as shown by the chemical shift data plotted in Fig. 2. The equilibria and kinetics of the thiol/disulfide exchange reactions were characterized using the methine and methyl resonances.

The reaction of PSH with CSSC takes place in two steps:

$$[3]\quad PSH_t + CSSC_t \underset{k_{2c}}{\overset{k_{1c}}{\rightleftarrows}} PSSC_t + CSH_t$$

$$[4]\quad PSH_t + PSSC_t \underset{k_{4c}}{\overset{k_{3c}}{\rightleftarrows}} PSSP_t + CSH_t$$

where PSH_t, $PSSC_t$, etc. represent the total concentrations of the various protonated forms of PSH, PSSC, etc., at a particular pH, and $k_{1c}-k_{4c}$ are conditional rate constants, i.e. rate constants for the thiol/disulfide exchange reactions for those conditions. The two stepwise reactions are described by the conditional equilibrium constants, K_{1c} and K_{2c}, which are defined as:

$$[5]\quad K_{1c} = \frac{[PSSC_t][CSH_t]}{[PSH_t][CSSC_t]}$$

$$[6]\quad K_{2c} = \frac{[PSSP_t][CSH_t]}{[PSH_t][PSSC_t]}$$

The conditional equilibrium constants were determined over a wide range of solution pH from the intensities of the methyl resonances in solutions prepared from PSH and CSSC. First, the concentrations of PSH, PSSC, and PSSP, if present, were calculated from the initial PSH concentration and the relative areas of the methyl resonances, and then the concentrations of

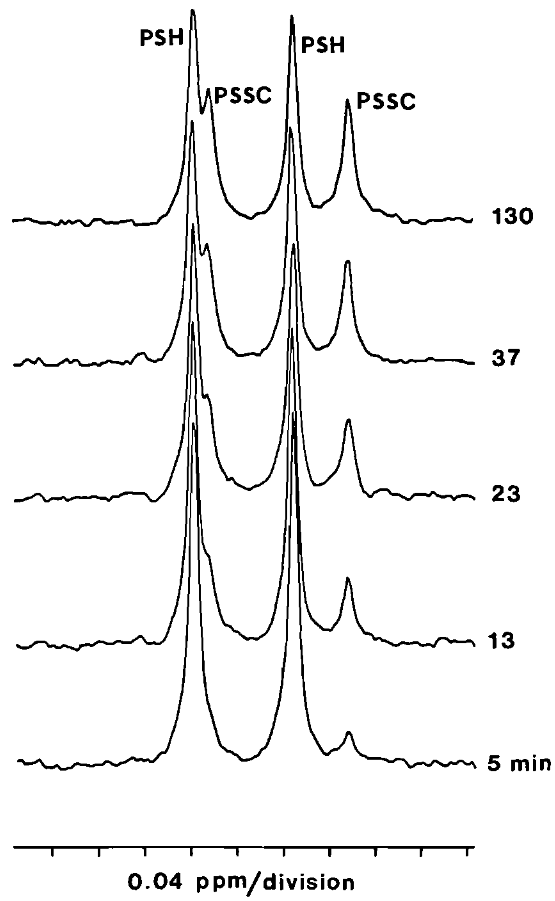

FIG. 3. The 200-MHz ^{1}H nmr spectra of the methyl groups in a solution which contained initially 0.00504 M PSH and 0.00297 M CSSC as a function of time. 1 M KCl, 0.003 M EDTA. pH = 5.94, 24°C.

CSH and CSSC were obtained by difference. To minimize air oxidation of thiol, the solutions were contained in nmr tubes which were degassed and sealed under vacuum. Spectra were obtained for each solution at intervals of 2–3 days until there were no further changes in resonance intensities. The concentrations of PSH and CSSC used and the conditional equilibrium constants obtained are given in Table 1. The conditional equilibrium constants for the reaction of PSH with CSSC at pH 7.4 and 37°C have also been estimated by Eldjarn and Hambraeus (15) using radioactive isotope tracer methods. They estimated K_{1c} to be 0.13 and K_{2c} to be ~0.01, both of which differ

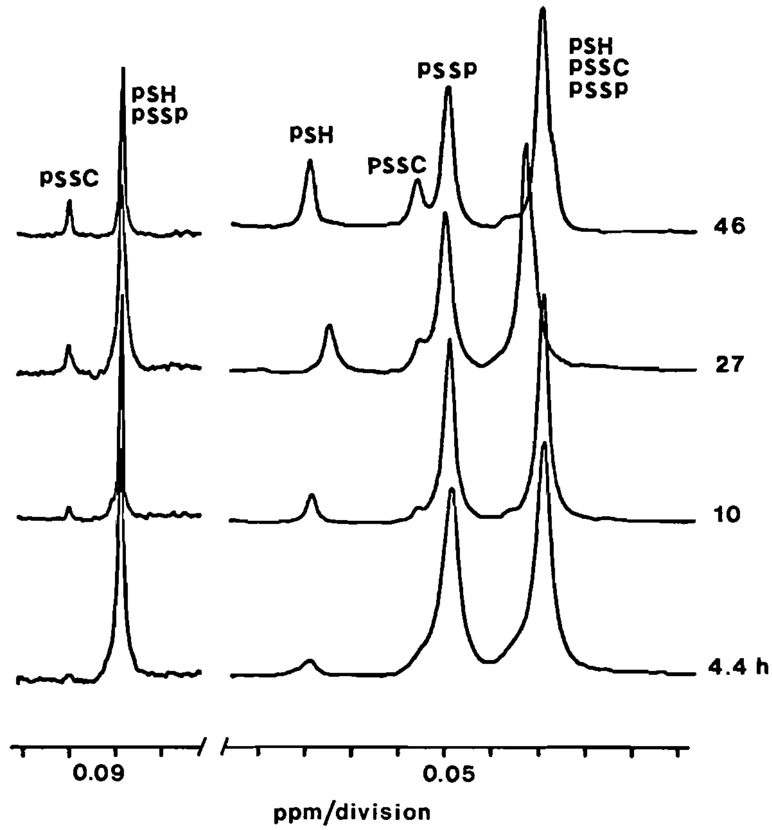

FIG. 4. The 200-MHz ^{1}H nmr spectra of the methine (left) and methyl (right) protons of PSH, PSSP, and PSSC in a solution which contained initially 0.102 M CSH and 0.100 M PSSP. The reaction was run at pH = 12.44, aliquots were quenched by lowering the pH to ~0.5, and then the pH was raised to ~9 when nmr spectra were run so that resolved resonances would be obtained for the various species. The pH was not identical for each nmr sample.

considerably from the values determined in the present work. The large differences may result from their experimental method which used radioactively-labelled cystine. Products of the reaction of PSH with labelled CSSC were separated by electrophoresis and then CSSC, PSSC, and CSH were determined by measuring the radioactivity. However, there was uncertainty in the results because CSSC and PSSC migrated together, and also the concentration of PSSP, which our work shows to be very small, had to be calculated by taking the difference between larger numbers of similar magnitude.

Spectra measured as a function of time in the equilibrium study indicate that the reaction of PSH with CSSC (eq. [3]) is much faster than the subsequent reaction of PSH with PSSC (eq. [4]). Thus, the kinetics of the two reactions were characterized separately. Figure 3 shows spectra obtained in a typical kinetics experiment. Rate constant k_{1c} was obtained by fitting time course data of this type by nonlinear least-squares calculations (14) to eq. [7], which is the integrated form of the rate expression for a second order, reversible reaction.

$$[7] \quad X = \frac{A_0B_0X_e\left(1 - \exp\left(\frac{k_{1c}t}{A}\right)\right)}{X_e(A_0 + B_0) - A_0B_0\left(1 + \exp\left(\frac{k_{1c}t}{A}\right)\right)}$$

where

$$[8] \quad A = \frac{X_e}{2A_0B_0 - X_e(A_0 + B_0)}$$

X and X_e are the concentrations of PSSC at time t and at equilibrium, and A_0 and B_0 are the initial concentrations of PSH and CSSC. k_{1c} and X_e were both treated as unknowns in the nonlinear least-squares calculations. The experimental conditions and the values obtained for k_{1c} from kinetic data covering the pH range 5–8 are given in Table 2.

The rate of the reaction of CSH with PSSP is slow, and to bring it onto a time scale convenient for study a combination of high pH (pH 10–12) and high reactant concentrations was used. Typical time course data are shown in Fig. 4. The concentration of PSSC was obtained from the methine resonances while the concentration of PSH was obtained from the methyl resonances. The values obtained by the initial slope method for k_{4c} from time course data of this type are (pH, k_{4c}): 10.39, 0.0052 M^{-1} min^{-1}; 10.73, 0.0037 M^{-1} min^{-1}; 11.95, 0.0033

Reaction of penicillamine with other disulfides

The conditional equilibrium constants K_{1c} and K_{2c} and the conditional rate constant k_{1c} were measured for the reaction of PSH with the disulfides of cysteamine (CySSCy), homocysteine (HSSH), 2-mercaptoethanol (ESSE), mercaptoacetic acid (MSSM), 3-mercaptopropionic acid (PrSSPr), and mercaptosuccinic acid (SuSSSu) at pH values in the pH range 7–8. The equilibrium data were obtained from solutions which were degassed in the nmr tube by the freeze–pump–thaw method and then the nmr tube was sealed. Spectra were measured at various times up to 200 h after mixing to ensure that the two thiol/disulfide exchange reactions had come to equilibrium. The conditional equilibrium constants at pH 7.4 calculated from the intensities of the methyl resonances by the methods described in the previous section are given in Table 3.

Conditional rate constant k_{1c} was also determined for these thiols by fitting the concentrations of the mixed disulfides, RSSP, as determined from the relative intensities of the methyl resonances for PSH and RSSP as a function of time, to eq. [7]. The reaction of PSH with RSSP is much slower than its reaction with RSSR, and the collection of kinetic data was stopped before detectable PSSP had formed. The k_{1c} values, and the values calculated for k_{2c} from k_{1c} and K_{1c}, at pH 7.4, are also given in Table 3.

Discussion

Thiol/disulfide exchange reactions proceed via the thiolate anion (11, 15–23). For PSH, there are two thiolate anion species possible: PS^-, in which the thiol group is deprotonated and the ammonium group protonated, and PS^{2-}, in which both groups are deprotonated. Both are present at low concentrations over the pH range 5–8; however, the dependence of their concentrations on pH is different. The logarithms of the fractional concentrations (α) of these two species, as calculated from pK_A values for PSH (24), are plotted as a function of pH over the pH range 5–8 in Fig. 5. The slope of the log α_{PS^-} vs. pH plot is one, over the pH range 5–7, while that of the log $\alpha_{PS^{2-}}$ vs. pH plot is two. Also plotted in Fig. 5 is log k_{1c} for the reaction of PSH with cystine (Table 2) vs. pH. The parallel dependence of log k_{1c} and log α_{PS^-} on pH indicates PS^- to be the reactive species.

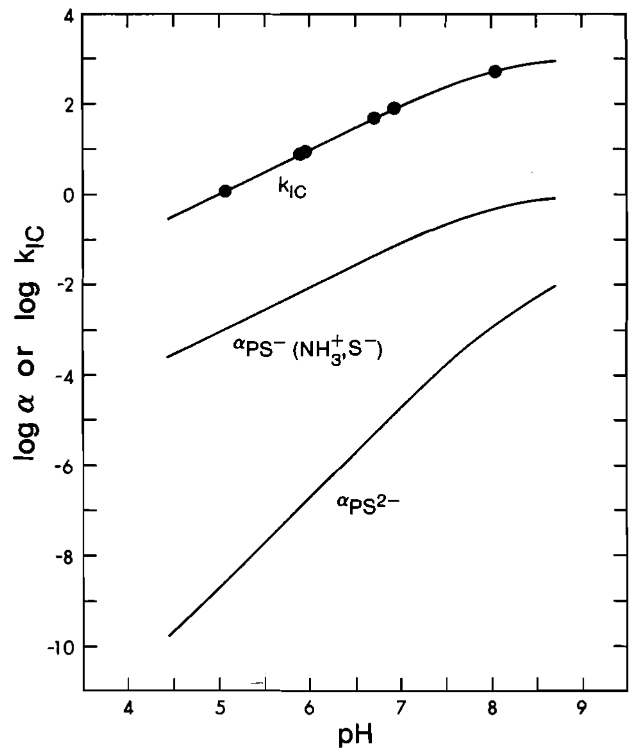

FIG. 5. The logarithm of the fractional concentration, α, of penicillamine in the amino-protonated, thiol-deprotonated (PS^-) and amino-deprotonated, thiol-deprotonated (PS^{2-}) forms and of the conditional rate constant k_{1c} for the reaction of PSH with CSSC as a function of pH. The solid curve through the experimental points is the theoretical curve predicted by a single pH-independent rate constant. See text for details.

The pH-independent rate constant for the reaction of PS^- with cystine is related to k_{1c} by eq. [9].

$$[9] \quad k_{1c} = k_1 \left(\frac{k_{a12} a_H}{a_H^2 + a_H K_{A2} + K_{A2} K_{A3}} \right)$$

where K_{A2} and K_{A3} are acid dissociation constants for PSH and a_H is activity of hydrogen as calculated directly from the pH meter reading. k_{a12} is the microscopic acid dissociation constant for the deprotonation of the thiol group of the PSH species in which both the amino and thiol groups are protonated (24). A value of 1090 ± 53 M^{-1} min^{-1} was obtained for k_1 by a nonlinear least-squares fit (14) of the data in Table 2 to eq. [9]. The straight line through the experimental data in Fig. 5 is the theoretical curve predicted by this value for k_1.

There is also the possibility that the rate constant depends on the protonation state of CSSC. However, the excellent agreement between the experimental data in Fig. 5 and the theoretical curve predicted by a single rate constant, k_1, indicates that either there is no dependence of k_{1c} on the protonation state of CSSC over the pH range 5–8 or the fractional concentration of the reactive CSSC species is constant over this pH range. The fractional concentration of the carboxylate-deprotonated, amino-protonated form, $CSSC^{\circ}$, varies from 1 to 0.4 over this pH range, while that of the species having only one amino group protonated, $CSSC^-$, varies from 0.001 to 0.6. The good fit of the experimental data in Fig. 5 to a single rate constant suggests that the rate constants for the reaction of PS^- with $CSSC^{\circ}$ and $CSSC^-$ are similar.

Assuming the reactive PSH species in the other thiol/disulfide exchange reactions to also be PS^-, pH-independent rate constants can be calculated using eq. [9]. The results are: CySSCy, k_1 = 800 ± 230 M^{-1} min^{-1}; ESSE, k_1 = 63.3 ± 3.0 M^{-1} min^{-1}; MSSM, k_1 = 230 ± 27 M^{-1} min^{-1}; PrSSPr, k_1 = 92 ± 6 M^{-1} min^{-1}; SuSSSu, k_1 = 0.95 ± 0.05 M^{-1} min^{-1}.

The equilibrium constants in Tables 1 and 3 are pH-dependent conditional equilibrium constants in terms of all the species present at the particular pH values. pH-independent equilibrium constants, K_1 and K_2, for the PSH–cystine thiol/disulfide exchange reactions in terms of the reactive species, eq. [10]–[13],

[10] $PS^- + CSSC^{\circ} \rightleftarrows PSSC^{\circ} + CS^-$

[11] $PS^- + PSSC^{\circ} \rightleftarrows PSSP^{\circ} + CS^-$

[12] $$K_1 = \frac{[PSSC^{\circ}][CS^-]}{[PS^-][CSSC^{\circ}]}$$

[13] $$K_2 = \frac{[PSSP^{\circ}][CS^-]}{[PSSC^{\circ}][PS^-]}$$

are related to the values for K_{1c} and K_{2c} by eqs. [14] and [15].

[14] $$K_1 = K_{1c}\frac{\alpha_1\alpha_2}{\alpha_3\alpha_4}$$

[15] $$K_2 = K_{2c}\frac{\alpha_2\alpha_5}{\alpha_1\alpha_3}$$

where α_1 is the fraction of $PSSC_t$ that is in the form $PSSC^{\circ}$, α_2 and α_3 the fractions of CSH_t and PSH_t that are in the amino-protonated, thiol-deprotonated forms, and α_4 and α_5 the fractions of $CSSC_t$ and $PSSP_t$, respectively, that are in the $CSSC^{\circ}$ and $PSSP^{\circ}$ forms. α_1–α_5 were calculated from the acid dissociation constants of the different species (25). Values of 5.36 ± 0.42 and 0.0198 ± 0.0028 were obtained for K_1 and K_2 by fitting the K_{1c} and K_{2c} values in Table 1 to eqs. [14] and [15]. pH-independent equilibrium constants for the reactions written in terms of all the reactants and products in their fully deprotonated forms can also be calculated from the results in Table 1. The values obtained are 12.0 ± 1.5 and 0.099 ± 0.012 for the first and second reactions, respectively.

The pH-independent equilibrium constants for the reactions written in terms of the reactive species cannot be calculated from the conditional equilibrium constants in Table 3 for the other disulfides studied because the acid dissociation constants of the various mixed disulfides are not known.

The equilibrium constant for the overall reaction of PSH with CSSC, K_3, is calculated to be 0.106 using the relation

[16] $2PS^- + CSSC^{\circ} \rightleftarrows PSSP^{\circ} + 2CS^-$

$K_3 = K_1K_2$. If the equilibrium positions in the two stepwise reactions were governed by random distribution, K_1 and K_2 would be 2 and 0.5, respectively, and K_3 would be 1. The values obtained for the analogous thiol/disulfide exchange reactions involving penicillamine and glutathione disulfide are K_1 = 0.56 ± 0.02, K_2 = 0.0143 ± 0.0014, and $K_3 = 8.0 \times 10^{-3}$ (23). For both systems, K_1 differs from the random distribution value of 2 by a factor of 2–3, although in opposite directions, whereas K_2 and K_3 are considerably less than the random distribution values. In contrast, K_1 = 1.27, K_2 = 0.27, and K_3 = 0.34 for the analogous thiol/disulfide exchange reactions involving cysteine and glutathione disulfide (20). These results, along with the values for K_{2c} in Table 3, indicate that PSH has considerably less tendency to react with its mixed disulfides to form the symmetrical disulfide PSSP than predicted by random distribution. As compared to cysteine, this is presumably due to steric effects from the replacement of the two hydrogens on the β carbon of cysteine by the two methyl groups of PSH. Similar steric effects have been reported previously for thiol/disulfide exchange reactions involving a series of alkyl thiols and disulfides (26), a series of substituted 2-aminoethane thiols and 4,4′-dithiobis(benzene sulfonate) (19) and glutathione reacting with a series of mercaptoalkane–cysteine mixed disulfides (27).

The values listed in Table 3 for the conditional equilibrium constant K_{1c} for the reaction of PSH with the eight disulfides are quite similar, as are the eight values for K_{2c}. However, the values for the conditional rate constant k_{1c} cover a wide range, with that for mercaptosuccinic acid disulfide a factor of approximately 1000 less than those for cystine and cysteamine disulfide. It is not possible to identify the factors which govern the rates of reaction from these results, although they do suggest that the total charge on the disulfide is important; mercaptosuccinic acid disulfide has a charge of −4 at pH 7.4, whereas the disulfides for which k_{1c} is in the intermediate range have total charges of −2 or 0 at this pH, and cystine and cysteamine disulfide have total charges of 0 and +2, respectively. Since the pH is the same, the reactive penicillamine species in each reaction is presumably the same, with a charge of −1.

The values in Table 3 for the overall equilibrium constant K_{3c} are related to the differences between the formal electrode potential $E^{\circ\prime}$ for the various RSSR/RSH redox couples and that of the PSSP/PSH couple according to eq. [17].

[17] $$\Delta E^{\circ\prime} = E^{\circ\prime}_{RSSR/RSH} - E^{\circ\prime}_{PSSP/PSH} = \frac{RT}{nF}\ln K_{3c}$$

Listed in Table 3 are the differences, $\Delta E^{\circ\prime}$, calculated from the values determined for K_{3c}. The values for $\Delta E^{\circ\prime}$ are all negative, indicating that the thiol forms of all seven molecules have slightly greater reducing power at physiological pH than does PSH. The small values for K_{2c} indicate that the smaller overall reducing power of PSH is due to its much smaller tendency to form its symmetrical disulfide. The values for $\Delta E^{\circ\prime}$ for the seven thiols are similar, indicating that they have similar reducing strength at physiological pH. However, for this to be the case, their intrinsic reducing strengths must increase in the order 3-mercaptopropionic acid > mercaptosuccinic acid > mercaptoethanol > glutathione > cysteamine ~ cysteine, i.e. the order in which the thiol pK_A values decrease (24), since the thiolate species is the active form in the reduction of disulfide by thiol.

Received October 12, 1984

FAROUK S. EL-FERALY, STEVE F. CHEATHAM, and JAMES D. MCCHESNEY. Can. J. Chem. **63**, 2232 (1985).

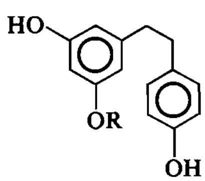
Two synthetic approaches to cannithrene 1 (**1**) have been explored. One-pot annelation of 6,8-dimethoxytetralone by first forming a β-keto sulfoxide, then addition of methyl vinyl ketone, gave, unexpectedly, after elimination of the sulfoxide, the naphthol (**10**). The successful route to cannithrene 1 (**1**) involved regiospecific demethylation of 6,8-dimethoxytetralone, then its conversion to enone **16**. Pyridinium bromide perbromide provided the necessary aromatization to give cannithrene 1 (**1**) after deprotection by hydrogenolysis. The ^{13}C nmr assignments of **1** were made.

FAROUK S. EL-FERALY, STEVE F. CHEATHAM et JAMES D. MCCHESNEY. Can. J. Chem. **63**, 2232 (1985).

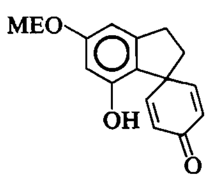
On a évalué deux approches différentes pour la synthèse du cannithrène 1 (**1**). D'une façon surprenante, l'annellation dans un seul récipient de la diméthoxy-6,8 tétralone impliquant en premier lieu la formation d'un β-cétosulfoxyde, puis l'addition de méthylvinylcétone ne conduit, après l'élimination du sulfoxyde, qu'au naphtol **10**. La façon d'obtenir le cannithrène 1 (**1**) implique une déméthylation régiospécifique de la diméthoxy-6,8 tétralone, puis sa conversion en énone **16**. Après une déprotection par hydrogénolyse, l'aromatisation conduisant au cannithrène 1 (**1**) se fait sous l'influence du perbromure du bromure de pyridinium. On a fait les attributions des carbones du composé **1** dans le spectre rmn du ^{13}C.

[Traduit par le journal]

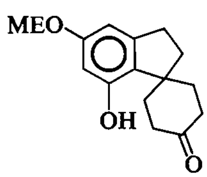
Cannabis sativa (marihuana) contains a group of dihydrostilbenes (1−3) like dihydroreserveratrole (**2**) and its monomethyl ether **3** which seem to be important precursors to various other stilbenoid derivatives. Thus, biogenetic phenol−phenol coupling could lead to cannabispiradienone (**4**) and cannabispiran (**5**) and its dehydro analog **6** and also could possibly lead



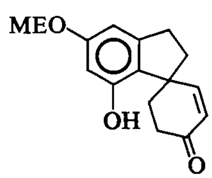
2, R = H
3, R = ME



4



5



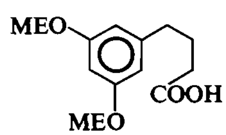
6

biogenetically to cannithrene 1 (**1**), another cannabis constituent. Indeed, Crombie *et al.* (4) have shown that heating **4** above its melting point caused the dienone−phenol rearrangement to give cannithrene 1 (**1**).

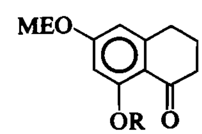
Cannithrene 1 (**1**) was obtained in only 4 mg per kg yield from *Cannabis*. Because of its structural similarity to the orchid phytoalexins (5), a study of its antimicrobial (especially its antifungal) properties was deemed important. This necessitated the development of an unambiguous synthetic route to this compound. Furthermore, a readily available supply of **1** was expected to make it possible to evaluate it biologically for many of the pharmacologic effects of marihuana.[2]

The synthetic plan for cannithrene 1 (**1**) depended upon first synthesizing 6,8-dimethoxytetralone (**7**), followed by addition of the mono oxygenated aromatic ring by a Robinson-type annelation. Thus, commercially available 3,5-dimethoxycinnamic acid was catalytically hydrogenated to its dihydro derivative, which was converted to the acid chloride by treatment with oxalyl chloride. Arndt−Eistert homologation of the acid chloride furnished the methyl ester which was hydrolyzed to the free acid **8**, then cyclized to 6,8-dimethoxytetralone (**7**) using polyphosphoric acid.[3]

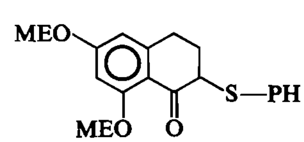
The most appropriate conditions for the annelation of **7** appeared to be the one-pot annelation conditions reported by Boger *et al.* (6). This annelation sequence involved first forming the β-keto phenyl sulfene **9** by sulfenylating the lithium enolate of **7** with diphenyldisulfide. The product **9** was



8



7, R = CH_3
12, R = H



9

oxidized to the sulfoxide with sodium periodate and then reacted immediately with methyl vinyl ketone in the presence of sodium methoxide. Unfortunately, the isolated phenolic product turned out to be the naphthol **10** and not cannithrene 1 (**1**). The structure of **10** was established, based on its spec-

[1]Author to whom correspondence may be addressed.

[2]The results of screening cannithrene 1 (**1**) for antimicrobial and antiglaucoma activities will be reported elsewhere.

[3]Direct rearrangement of the diazo ketone to the free acid was possible using silver oxide in aqueous dioxane, but the yield was lower than the overall yield obtained by rearrangement in methanol and subsequent hydrolysis of the resulting ester.

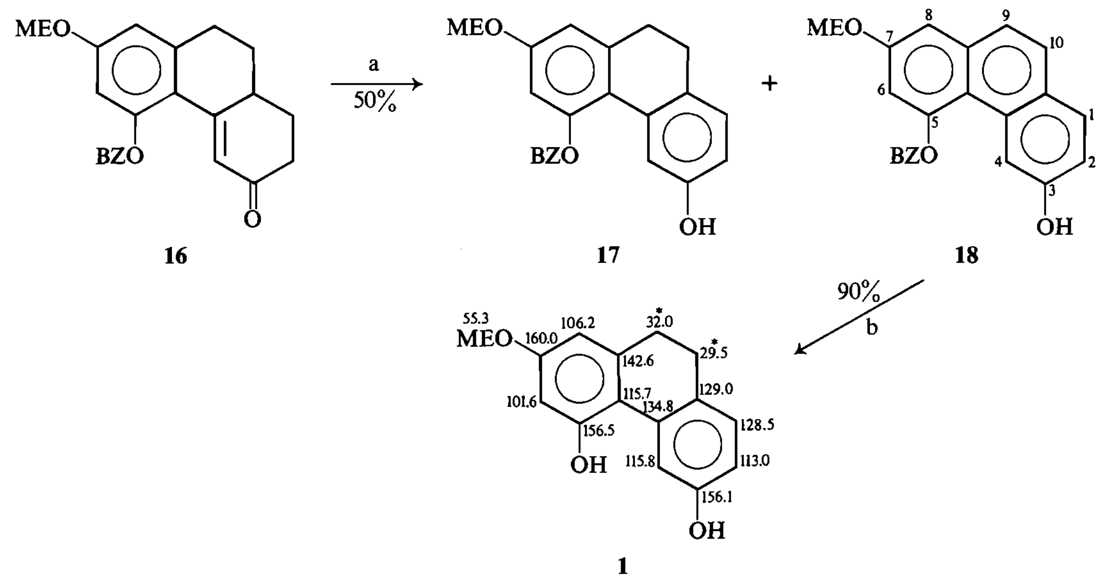
SCHEME 2

troscopic properties (see Experimental) including its ^{13}C nmr signals (see structure **10** in Scheme 1). The unexpected formation of **10** may be rationalized by a consideration of the reaction conditions and the mechanism proposed by Boger *et al.* (6) for the annelation reaction. For a dihydrophenanthrene to be formed, aldolization should precede the sulfoxide elimination. Apparently the reverse took place and this led to the formation of the naphthol **10**. The driving force for the facile elimination of the sulfoxide group in **11** is probably the formation of the aromatic system (Scheme 1).

The successful synthetic approach to cannithrene 1 (**1**) depended on, first, regiospecific demethylation of 6,8-dimethoxytetralone (**7**) to 8-hydroxy-6-methoxytetralone (**12**) using boron trichloride in methylene chloride. The ir spectrum of the product **12**, when compared to that of the starting material **7**, showed that the carbonyl peak had shifted approximately 30 cm^{-1}, from 1654 cm^{-1} in **7** to 1623 cm^{-1} in **11**, which is consistent with the formation of an intramolecular hydrogen bond. Protection of the hydroxyl group in **12** by benzylation, and formylation using ethyl formate and excess sodium methoxide, provided the intermediate **13**. Crude **13** was treated with methyl vinyl ketone to give the alkylated product **14** quantitatively. Smooth cyclization of **14** was accomplished after considerable experimentation by first briefly treating **14** with sodium ethoxide to give **15**, and usually a small amount of **16**, followed by treatment of the mixture with sodium hydride to furnish **16** (Scheme 2).

The aromatization of **16** to a dihydrophenanthrene proved to be a formidable task. Treatment with 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ), chloranil (tetrachloro-1,4-benzoquinone), or Pd/C did not yield the desired product. Treatment with pyridinium bromide perbromide (7), on the



a: Pyridinium bromide perbromide; b: 10% Pd/C (90%)

SCHEME 3

other hand, gave a mixture of benzyl cannithrene 1 (**17**) and the corresponding phenanthrene **18** as based on ^{1}H nmr analysis of the mixture. Hydrogenation of this mixture using 10% palladium on carbon as catalyst gave a single product identical with cannithrene 1 (**1**), based on spectral comparisons.

The previously unreported ^{13}C nmr assignments for cannithrene 1 (**1**) are listed in Scheme 3. The ^{13}C nmr assignments were made by inspecting the coupled spectrum. Cannithrene 1 (**1**) exhibited three oxygenated aromatic signals at δ 160.0, 156.5, and 156.1. The signal at δ 160.0 appeared as a quartet (J = 2.0 Hz) in the coupled spectrum because of three-bond coupling to the methoxy protons. This confirmed that the signal at δ 160.0 was due to C-7. The signal at δ 156.5 appeared as a singlet (no three-bond coupling) and was assigned to C-5, leaving the signal at δ 156.1 (partially masked by the signal at δ 156.5) to be assigned to C-3. Of the aromatic singlets in the off-resonance spectrum, carbon-8a has no three-bond couplings and is the singlet at δ 142.6. Carbon-4a occurred as a doublet (J = 6.8 Hz) in the coupled spectrum at δ 139.4 due to three-bond coupling to H-1. The signal at δ 129.0 is a triplet (J = 6.8 Hz) in the coupled spectrum and was unambiguously assigned to C-10a due to three-bond coupling to both H-2 and H-4. The final aromatic singlet occurred at δ 115.7 and appeared as a multiplet in the coupled spectrum and was assigned to C-4b. Most of the aromatic doublets in the off-resonance spectrum could also be assigned by inspection of the coupled spectrum. The signal at δ 128.5 was a doublet (J = 156 Hz) with no further three-bond couplings and was assigned to C-1. The other two off-resonance doublets which could be assigned based on the coupled data were the signals at δ 106.2 and 101.6, ascribed to C-8 and C-6, respectively. This assignment was consistent with the former signal being a doublet (J = 158 Hz) with unresolved three-bond coupling (to H-6 and C-9 protons), while the latter was only three-bond coupled to H-8 and appeared as a sharp double doublet (J = 158, 4.9 Hz). The assignments of C-8 and C-6 were also consistent with their chemical shift values, as the more shielded of the two (C-6) is *ortho* to two oxygen functions, while the other (C-8) is *ortho* to only one oxygen function. The signals at δ 115.8 and 113.0 could not be assigned on the basis of the coupled data and assignments were made by selective proton decoupling. Irradiation at δ 7.94 (H-4) caused the carbon signal at δ 115.8 to collapse to a singlet, whereas the signal at δ 113.0 remained a doublet. Likewise, irradiation at δ 6.58 caused the signal at δ 113.0 to collapse, while the signal at δ 115.8 remained a doublet. This confirmed the assignment of C-2 to the signal at δ 113.0 and C-4 to the signal at δ 115.8.

In addition to the above signals, the methoxy carbon was found to resonate at δ 55.3, and the two methylene triplets, which could not be distinguished, resonated at δ 32.0 and 29.4.

Experimental

Melting points (mp, °C) were determined on a Thomas–Hoover melting point apparatus and are uncorrected. The ir spectra (cm^{-1}) were obtained on a Perkin–Elmer 281B spectrophotometer and measured in a KBr disk or as 10% solution in $CHCl_3$. The ^{1}H nmr spectra were recorded on JEOL C-60 HL, Varian EM-390, and JEOL JNM-FX 60 spectrometers using tetramethylsilane (TMS) as internal standard; chemical shifts were reported in δ (ppm) units. The ^{13}C nmr spectra were taken on a JEOL JNM-FX 60 (15.03 MHz) and the chemical shifts are also reported in δ (ppm) units. Coupled spectra were recorded using gated decoupling with 16K data points (decoupler off during data aquisition) and integrations recorded with decoupler on during data aquisitions and long pulse delays. Mass spectral data were obtained on a Finnigan 3200 spectrometer with an INCOS data system.

4-(3,5-Dimethoxyphenyl)butyric acid (8) and its methyl ester

The acid chloride of 3-(3,5-dimethoxyphenyl) propionic acid (8) was prepared by dissolving the acid (5 g, 22.3 mmol) in 50 mL of benzene containing four drops of DMF, followed by the addition of 10 mL of oxalyl chloride (54.15 mmol). The mixture was stirred at room temperature for 0.5 h. Removal of the benzene left the crude acid chloride which was dissolved in 25 mL of ether and added to 250 mL of an ethereal solution of diazomethane (excess). Evaporation of the ether left the diazoketone as a reddish oil which was dissolved in MeOH (400 mL) and stirred for 3 h at 60°C with freshly prepared Ag_2O, prepared by adding 10 mL of 25% aqueous KOH to 2.5 g of $AgNO_3$ in 10 mL of H_2O. Filtration and evaporation of the MeOH phase left a black oil that was dissolved in $CHCl_3$ and filtered over a short column of SiO_2. Evaporation of $CHCl_3$ left 4.93 (87%) of the methyl ester of **8** as a pale yellow oil; ir ($CHCl_3$): 1730, 1600; ^{1}H nmr ($CDCl_3$): 1.97 (m, 2H), 2.34 (t, 2H, J = 7.0 Hz), 2.60 (t, 2H, J = 7.0 Hz), 3.67 (s, 3H), 3.77 (s, 6H), 6.33 (s, 3H); ^{13}C nmr ($CDCl_3$): 173.8 (s), 161.1 (s), 143.9 (s), 106.8 (d), 98.4 (d), 55.2 (q), 51.3 (q), 35.4 (t), 33.4 (t), 26.3 (t); ms: M^+ at m/z 238 (28%). *Anal.* calcd. for $C_{13}H_{18}O_4$ (238): C 65.53, H 7.61; found: C 65.66, H 7.89.

The same reaction was tried following a general literature (9) procedure starting with 0.5 g of the above acid chloride, but the rearrangement of the acid chloride was carried out in aqueous dioxane and the product crystallized from ether–hexane to give colorless needles of **8** (290 mg, 55%), mp 64–65°C; ir ($CHCl_3$): 3300–2400, 1708, 1593; ^{1}H nmr ($CDCl_3$): 1.98 (m, 2H), 2.37 (t, 2H, J = 7.0 Hz), 2.62 (t, 2H, J = 7.0 Hz), 3.76 (s, 6H), 6.34 (s, 3H), 9.77 (br s, exchangeable); ^{13}C nmr ($CDCl_3$): 179.2 (s), 161.0 (s), 143.7 (s), 106.8 (d), 98.3 (d), 55.2 (q), 35.3 (t), 33.3 (t), 26.1 (t); ms: M^+ m/z 224 (34%). *Anal.* calcd. for $C_{12}H_{16}O_4$ (224): C 64.27, H 7.19; found: C 64.50, H 7.37.

The same acid was obtained by stirring for 3 h under N_2 a solution of the ester obtained above (4.8 g) in MeOH (50 mL) to which was added a solution of KOH (5 g) in 15 mL of H_2O. Removal of the MeOH and $CHCl_3$ extraction of the acidified residue gave 4.33 g (96%) of this acid.

6,8-Dimethoxytetralone (7)

The acid **8** (3.76 g) was added with stirring to polyphosphoric acid (60 g) heated to 100–110°C and stirring continued for 4 h. Work-up by addition of ice and $CHCl_3$ extraction furnished a product that was subjected to flash chromatography (10) using acetone–CH_2Cl_2 (1:9) as solvent to give 3.0 g (87%) of 6,8-dimethoxytetralone (**7**), crystallizing as yellow plates from ether–hexane, mp 64–65°C (lit. (11) mp 65°C); ir ($CHCl_3$): 2920, 1654, 1592; ^{1}H nmr ($CDCl_3$): 1.71 (m, 2H), 2.56 (t, 2H, J = 6.5 Hz), 2.88 (t, 2H, J = 6.5 Hz), 3.83 (s, 3H), 3.87 (s, 3H), 6.33 (s, 2H); ^{13}C nmr ($CDCl_3$): 195.3 (s), 163.9 (s), 162.6 (s), 149.1 (s), 116.5 (s), 104.9 (d), 97.3 (d), 55.9 (q), 55.3 (q), 40.8 (t), 31.5 (t), 22.9 (t); ms: M^+ m/z 206 (60%).

Sulfenylation of 6,8-dimethoxytetralone (7) to 9

Diisopropylamine (0.25 mL) was added to a flame dried flask under N_2 in a Dry Ice – acetone bath. Dry THF (1 mL) was added, followed by 1.2 mL of 1.6 *M* *n*-butyllithium in cyclohexane. This mixture was stirred for 0.25 h, then 200 mg of 6,8-dimethoxytetralone (**7**) in 1 mL of THF was added. Stirring was continued for 1 h, then a solution of 425 mg of diphenyldisulfide in 1 mL of THF was added. Stirring was continued for 2 h in a Dry Ice – CCl_4 bath and for 1 h at room temperature. After normal work-up and flash chromatography (10) of the crude product using acetone–$CHCl_3$ (1:9) as solvent, 237 mg (78%) of **9** were obtained as an oil, homogenous on tlc (one spot, R_f 0.52 on SiO_2 plates using 10% acetone in $CHCl_3$ as solvent); ir ($CHCl_3$): 3000, 1660; ^{1}H nmr ($CDCl_3$): 2.0–3.43 (m, 4H), 3.82 (s, 3H), 3.86 (s, 3H), 4.03 (dd, 1H, J = 7.5, 4.0 Hz), 6.30 (2H, J = 1.0 Hz), and the 5 aromatic protons from 7.2 to 7.6; ^{13}C nmr ($CDCl_3$): 191.5 (s), 164.3 (s), 163.4 (s), 147.6 (s), 134.4 (s), 132.3 (d), 128.9 (d), 127.3 (d), 115.4 (s), 104.8 (d), 97.7 (d), 56.0 (q), 55.4 (q), 29.1 (t), 28.3 (t); ms: M^+ m/z 314 (5%). *Anal.* calcd. for $C_{18}H_{18}O_3$ (314): C 68.77, H 8.39, S 10.20; found: C 68.60, H 8.59, S 10.49.

Attempted annelation of 9; isolation of 10

The sulfenylated ketone **9** (265 mg) was dissolved in MeOH (4 mL) and chilled in an ice bath. Sodium periodate (174 mg) in a minimum amount of H_2O was added. After 22.5 h, when the reaction went to completion, the mixture was filtered and MeOH was evaporated, leaving 300 mg of a residue which was dissolved in 10 mL of THF–MeOH (1:1), and 0.04 mL of a 25% $NaOCH_3$ solution in MeOH was added. Methyl vinyl ketone (0.1 mL) was added to the mixture which was chilled to 0°C for 24 h. Excess $NaOCH_3$ solution was added (0.25 mL) and stirring continued for 31 h. The usual work-up and extraction of the product with $CHCl_3$ furnished 286 mg of a dark oil that was chromatographed over 50 g of SiO_2 using 1% acetone in $CHCl_3$ as solvent to give 48 mg (23%) of **10**, as an oil that was homogeneous on tlc; ir ($CHCl_3$): 3400, 1708, 1630, 1590; ^{1}H nmr ($CDCl_3$): 2.10 (s, 3H), 2.90 (m, 4H), 3.88 (s, 3H), 4.01 (s, 3H), 6.47 (d, 1H, J = 2.5 Hz), 6.70 (d, 1H, J = 2.5 Hz), 7.10 (d, 1H, J = 8.0 Hz), 7.23 (d, 1H, J = 8.0 Hz), 9.30 (s, 1H, exchangeable); ^{13}C nmr ($CDCl_3$): see structure **10**; ms: M^+ m/z 274 (40%). *Mol. Wt.* calcd. for $C_{16}H_{18}O_4$: 274.1205; found: 274.1207.

8-Hydroxy-6-methoxytetralone

6,8-Dimethoxytetralone (**7**) (2.0 g) was dissolved in 20 mL CH_2Cl_2 under N_2 and the solution was cooled to −78°C. BCl_3 (30 mL of a 1 *M* solution in CH_2Cl_2) was added dropwise to the solution. The Dry Ice – acetone bath was then removed, and the solution stirred 0.5 h while returning to room temperature. Work-up and extraction with ethyl acetate provided 1.44 g (77%) of 8-hydroxy-6-methoxytetralone, which crystallized from ether–hexane to give the analytical sample, mp 68–69°C; ir ($CHCl_3$): 3250–3020, 1623; ^{1}H nmr ($CDCl_3$): 2.02 (m, 2H), 2.61 (t, 2H, J = 6.0 Hz), 2.84 (t, 2H, J = 6.0 Hz), 3.79 (s, 3H), 6.24 (s, 2H), 12.83 (s, 1H exchangeable); ^{13}C nmr ($CDCl_3$): 202.9 (s), 165.8 (s), 165.6 (s), 147.2 (s), 111.6 (s), 106.6 (d), 98.8 (d), 55.4 (q), 38.5 (t), 29.8 (t), 22.9 (t); ms: M^+ m/z 192 (80%). *Anal.* calcd. for $C_{11}H_{12}O_3$: C 70.58, H 5.92; found: C 70.34, H 5.76.

8-Benzyloxy-6-methoxytetralone

The hydroxy tetralone obtained above (1.6 g) was benzylated by refluxing for 24 h in acetone solution (150 mL) in the presence of K_2CO_3 (12.9 g) and benzylbromide (3.20 g). Work-up and chromatography of the product on SiO_2 using $CHCl_3$ as solvent provided 2.23 g (95%) of the benzyloxy derivative as an oil; ir ($CHCl_3$): 1663, 1595; ^{1}H nmr ($CDCl_3$): 2.00 (m, 2H), 2.59 (t, 2H, J = 7.0 Hz), 2.87 (t, 2H, J = 7.0 Hz), 3.76 (s, 3H), 5.12 (s, 2H), 6.29 (d, 1H, J = 2.0 Hz), 6.33 (d, 1H, J = 2.0 Hz), 7.20–7.70 (m, 5H); ^{13}C nmr ($CDCl_3$): 195.4 (s), 163.8 (s), 161.6 (s), 149.1 (s), 137.0 (s), 128.5 (d), 127.6 (d), 126.8 (d), 117.2 (s), 105.5 (d), 99.3 (d), 70.7 (t), 55.3 (q), 40.9 (t), 31.6 (t), 22.9 (t); ms: M^+ m/z 282 (14%). *Anal.* calcd. for $C_{18}H_{18}O_3$: C 76.57, H 6.43; found: C 76.39, H 6.76.

Hydroxymethylation of 8-benzyloxy-6-methoxytetralone to 13

A solution of 8-benzyloxy-5-methoxytetralone (2.58 g) in ethyl formate (5 mL) was stirred overnight with a mixture of solid $NaOCH_3$ (2.5 g) and dried ethyl formate (20 mL). Acidification and chloroform extraction gave 2.89 g (100%) of **13**, which crystallized from MeOH to afford slightly yellow clusters, mp 96–99°C; ir ($CHCl_3$): 2370, 1630, 1595; ^{1}H nmr ($CDCl_3$): 2.42 (t, 2H, J = 7.0 Hz), 2.82 (t, 2H, J = 7.0 Hz), 3.80 (s, 3H), 5.20 (s, 2H), 6.34 (d, 1H, J = 2.5 Hz), 6.43 (d, 1H, J = 2.5 Hz), 7.24–7.76 (m, 5H), 8.10 (bs, 1H), 14.6 (bs, exchangeable); ^{13}C nmr ($CDCl_3$): 185.7 (s), 172.2 (d), 163.8 (s), 146.8 (s), 136.5 (s), 128.6 (d), 127.9 (d), 126.9 (d), 105.8 (d), 99.3 (d), 70.8 (t), 55.4 (q), 31.1 (t), 23.1 (t); ms: M^+ m/z 310 (1%). *Mol. Wt.* calcd. for $C_{19}H_{18}O_4$: 310.1205; found: 310.1200.

Alkylation of 13 to 14

The crude ketone **13** (1.2 g) was dissolved in benzene (12 mL) and stirred for 7 days with methyl vinyl ketone (0.5 mL) and 0.3 mL of triethylamine. The usual work-up using benzene gave 1.5 g (100%) of adduct **14** that proved to be unstable; ir ($CHCl_3$): 1710, 1648; ^{1}H nmr ($CDCl_3$): 1.68–2.57 (m, 7H), 2.07 (s, 3H), 3.77 (s, 3H), 5.16 (s, 2H), 6.26 (d, 1H, J = 2.5 Hz), 6.38 (d, 1H, J = 2.5 Hz), 7.25–7.67 (m, 5H), 9.71 (s, 1H); ^{13}C nmr ($CDCl_3$): 207.0 (s), 201.7 (d), 193.7 (s) due to the 3 carbonyl groups. The material was used in the next step without further purification.

Cyclization of 14 to 16 using NaOEt–NaH

To a solution of 980 mg of crude **14** in absolute EtOH (20 mL) cooled in an ice bath was added 180 mg NaOEt in 20 mL of absolute EtOH. After stirring for 3 h, 0.3 mL of CH_3COOH was added and EtOH removed. The usual work-up and chromatography of the crude product on SiO_2 using 20% ethyl acetate in benzene produced: (a) **16** (41 mg) as colorless needles, mp 94–95°C; ir ($CHCl_3$): 1634, 1592, 1570; ^{1}H nmr ($CDCl_3$): 1.33–2.97 (m, 9H), 3.70 (s, 3H), 5.10 (s, 2H), 6.28 (d, 1H, J = 2.5 Hz), 6.38 (d, 1H, J = 2.5 Hz), 7.37 (bs, 5H); ^{13}C nmr ($CDCl_3$): 200.6 (s), 161.2 (s), 160.3 (s), 155.4 (s), 143.9 (s), 136.4 (s), 128.6 (d), 128.0 (d), 127.1 (d), 125.6 (d), 115.6 (s), 106.2 (d), 99.2 (d), 70.9 (d), 55.2 (q), 37.8 (d), 37.3 (t), 31.4 (t), 30.5 (t), 30.3 (t); ms: M^+ m/z 334 (1%). *Anal.* calcd. for $C_{22}H_{22}O_3$: C 79.02, H 6.63; found: C 79.30, H 6.60. (b) **15** (615 mg), crystallized from MeOH, mp 93–94°C; ir ($CHCl_3$): 1704, 1658, 1593; ^1H nmr ($CDCl_3$): 1.58–2.64 (m, 7H), 2.24 (s, 3H), 2.97 (dd, 2H, J = 7.2, 4.8 Hz), 3.78 (s, 3H), 5.14 (s, 2H), 6.24 (d, 1H, J = 3.0 Hz), 6.69 (d, 1H, J = 3.0 Hz), 7.24–7.71 (m, 5H); ^{13}C nmr ($CDCl_3$): 208.8 (s), 197.6 (s), 163.5 (s), 161.4 (s), 148.3 (s), 136.9 (s), 128.6 (d), 127.6 (d), 126.8 (d), 116.8 (s), 105.1 (d), 99.2 (d), 70.5 (t), 55.3 (q), 48.0 (d), 41.5 (t), 30.0 (t), 29.8 (q), 28.7 (t), 24.7 (t); ms: M^+ m/z 352 (3%). *Anal.* calcd. for $C_{22}H_{24}O_4$: C 74.98, H 6.86; found: C 75.02, H 6.76.

In all later runs the mixture was not separated but directly treated with NaH as follows. The mixture (3.8 g) was dissolved in THF (50 mL) and added to 240 mg of NaH in 50 mL of THF. After stirring for 24 h, the usual work-up and flash chromatography of the product gave 3.15 g of **16** (60%), identical to the material obtained above.

Cannithrene 1 (1)[4]

The enone **16** (1.0 g) was dissolved in acetic acid (300 mL) and pyridinium bromide perbromide (1.19 g) was added slowly with vigorous stirring for 10 min. The mixture was allowed to stand for 0.5 h, then evaporated. The usual work-up produced 0.94 g of a red oil that was flash chromatographed on SiO_2 using 4% ethyl acetate in benzene to give back 0.19 g of **16** and 0.48 g (50%) of a mixture of **17** and the corresponding phenanthrene **18**. Without further purification, this mixture was dissolved in 40 mL EtOH and hydrogenated in the presence of 70 mg of 10% Pd/C. After 16 h, tlc revealed the presence of a single compound, R_f 0.24 on SiO_2 plate using 20% ethyl acetate in benzene as solvent. The usual work-up provided 0.35 g (100%) of a chromatographically homogeneous light tan oil that crystallized reluctantly from ether–hexane to give 0.27 g (38% from **16**) of cannithrene 1 (**1**) as colorless needles, mp 175–180°C with darkening (lit. (3) mp 189°C with darkening). The ^1H nmr (CD_3COCD_3) spectrum of synthetic cannithrene 1 (**1**) was identical to that of the natural material, showing signals at δ 2.67 (s, 4H), 3.75 (s, 3H), 6.38 (d, 1H, J = 2.5 Hz), 6.47 (d, 1H, J = 2.5 Hz), 6.62 (dd, 1H, J = 8.0, 2.5 Hz), 7.04 (d, 1H, J = 8.0 Hz), 8.0 (d, 1H, J = 2.5 Hz), 8.72 (s, 1H exchangeable); ir ($CHCl_3$): 3320, 1600 cm^{-1}; the ^{13}C nmr assignments are shown in Scheme 3; ms: M at m/z 242 (100%). *Anal.* calcd. for $C_{15}H_{14}O_3$: C 74.36, H 5.82; found: C 74.31, H 6.03.

[4]Conditions for the aromatization of **16** were worked out using as a model compound the analog 9,10,10a-3(2*H*)-tetrahydrophenanthrene, synthesized from commercially available α-tetralone. Pyridinium bromide perbromide dehydrogenated it to 3-hydroxydihydrophenanthrene in 75% yield with a 14% yield of the analogous 2-bromo derivative.

Hydride transfer reactions. A kinetic study of oxidation of 10-methyl-9-phenylacridan by some π acceptors and a one-electron oxidant

ALLAN K. COLTER, A. GREGG PARSONS, AND KAREN FOOHEY
Guelph–Waterloo Centre for Graduate Work in Chemistry, Department of Chemistry and Biochemistry, University of Guleph, Guelph, Ont., Canada N1G 2W1

Received November 2, 1984

ALLAN K. COLTER, A. GREGG PARSONS, and KAREN FOOHEY. Can. J. Chem. **63**, 2237 (1985).

The kinetics of oxidation of 10-methyl-9-phenylacridan (**1**(H)) and 9-deuterio-10-methyl-9-phenylacridan (**1**(D)) to 10-methyl-9-phenylacridinium ion (**3**) by eight oxidants have been investigated. The oxidants included the π-acceptors 1,4-benzoquinone (BQ), 7,7,8,8-tetracyanoquinodimethane (TCNQ), *p*-bromanil (BA), *p*-chloranil (CA), tetracyanoethylene (TCNE), 2,3-dicyano-1,4-benzoquinone (DCBQ) and 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ) in acetonitrile (AN), BQ in 50:50 (v/v) AN–water, and the one-electron oxidant tris(2,2′-bipyridyl)cobalt(III), $Co(bipy)_3^{3+}$, in AN. The seven π acceptors cover a 10^9-fold range of reactivity from BQ to DDQ and the deuterium kinetic isotope effect varies from 11.9 (BQ in AN) to 5.8 (DDQ). For π acceptors (BQ, TCNQ, CA, TCNE, and DCBQ) previously investigated with 10-methylacridan (NMA), **1**(H) is less reactive than NMA by factors ranging from 9.1 (BQ) to 1.7×10^2 (TCNE). The isotope effects and relative reactivities for the π acceptor oxidations are most simply explained by a one-step hydride transfer mechanism.

ALLAN K. COLTER, A. GREGG PARSONS et KAREN FOOHEY. Can. J. Chem. **63**, 2237 (1985).

On a étudié les cinétiques d'oxydation, sous l'influence de huit oxydants, du méthyl-10 phényl-9 acridane (**1**(H)) et du deutéro-9 méthyl-10 phényl-9 acridane (**1**(D)) en ion méthyl-10 phényl-9 acridinium (**3**). Les oxydants comprennent des accepteurs π comme la benzoquinone-1,4 (BQ), le tétracyano-7,7,8,8 quinodiméthane (TCNQ), le *p*-bromanil (BA), le *p*-chloranil (CA), le tétracyanoéthylène (TCNE), la dicyano-2,3 benzoquinone-1,4 (DCBQ) et la dichloro-2,3 dicyano-5,6 benzoquinone-1,4 (DDQ) dans l'acétonitrile (AN), la BQ dans un mélange 50:50 (v/v) de AN–eau ainsi que par un oxydant à un électron, le tris(bipyridyl-2,2′) cobalt(III), $Co(bipy)_3^{3+}$, dans du AN. Les sept accepteurs π couvrent un domaine de réactivité de l'ordre de 10^3 allant de la BQ à la DDQ; l'effet isotopique cinétique varie de 11,9 (BQ dans AN) à 5,8 (DDQ). Pour les accepteurs π (BQ, TCNQ, CA, TCNE et DCBQ) étudiés antérieurement avec le méthyl-10 acridane (NMA), le composé **1**(H) est moins réactif que le NMA par des facteurs allant de 9,1 (BQ) à $1{,}7 \times 10^2$ (TCNE). La plus simple explication des effets isotopiques et des réactivités relatives lors d'oxydations par des accepteurs π fait appel à un mécanisme de transfert d'hydrure en une étape.

Introduction

The detailed mechanisms of hydride transfer reactions of nicotinamide coenzyme models, particularly the possibility of stepwise mechanisms initiated by a single electron transfer (SET), continue to attract considerable attention (refs. 1, 2 and references cited). In earlier papers in this series (1, 3, 4) we have examined substituent, solvent, and kinetic isotope effects in oxidation of 10-alkylacridans with a number of quinone and dicyanomethylene π acceptors. The general characteristics of these oxidations remain remarkably similar in spite of rate variations of greater than 10^8-fold. Most of these results are most economically accommodated by a one-step hydride transfer mechanism, eq. [1], although the responses of the rate to changes in structure or solvent expected for eq. [1] and for a three-step e^-, H^+, e^- mechanism in which the proton transfer is rate-determining, eq. [2], are very similar.

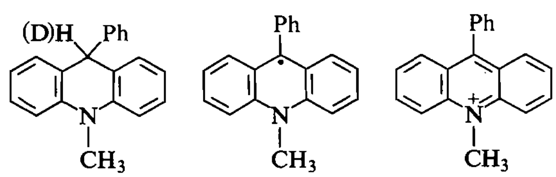
$$[1]\quad DH + A \xrightarrow{\sim H^{-}} D^+ + AH^-$$

$$[2]\quad DH + A \underset{}{\overset{\sim e^-}{\rightleftharpoons}} DH^{+\cdot}\, A^{-\cdot} \underset{\text{slow}}{\xrightarrow{\sim H^+}} D\cdot\, AH\cdot \underset{\text{fast}}{\xrightarrow{\sim e^-}} D^+ + AH^-$$

(DH = hydride donor, A = π acceptor oxidant)

While the radical cation – radical anion intermediate, $DH^{+\cdot}\, A^{-\cdot}$, of eq. [2] can be excluded on energetic grounds for *p*-chloranil (CA) and quinones of lower reduction potential (4), a SET-initiated stepwise mechanism such as eq. [2] should become increasingly feasible with increasing acceptor reduction potential (2, 4, 5).

As part of an effort aimed at defining the range of mechanisms possible for hydride transfers from dihydropyridines and related compounds to π acceptors we have investigated the oxidation of 10-methyl-9-phenylacridan (**1**) by a series of π acceptors and a one-electron oxidant. This study was prompted



1, DH **2**, D· **3**, D^+

by the following considerations: A 9-phenyl group might be expected to favor a stepwise mechanism by steric inhibition of direct hydride transfer relative to electron transfer and by stabilization of the intermediate 9-phenyl-9-acridanyl radical (D·, **2**). This radical is long-lived, and has been produced by uv irradiation of methanolic solutions of 10-methyl-9-phenylacridinium chloride (6). The fact that **1** has a single 9-H greatly simplifies measurement of the primary kinetic deuterium isotope effect.

Results

The oxidants investigated in this work included 5 benzoquinones (**4–8**), two cyanomethylene acceptors (**9** and **10**), and the one-electron oxidant tris(2,2′-bipyridyl)cobalt(III), $Co(bipy)_3^{3+}$. BA was included to compare two different benzoquinones (BA and CA) of nearly identical oxidizing strength but different steric requirements. The lower reactivity of **1**

10, TCNE

compared to 10-methylacridan (NMA) made it possible to extend the kinetic measurements to DDQ. The other six oxidants have been investigated earlier with NMA (3, 7).

The reactions of **1** with the oxidants included in this study are identical to the corresponding reactions of NMA (1, 3, 7, 8). Quantitative oxidation of **1** to **3** was confirmed by uv–visible spectral examination of kinetic solutions for all oxidants except TCNQ, where the spectrum of **3** is masked by that of the radical ion $TCNQ^{\cdot-}$, produced in equimolar quantities to the **1** consumed. The oxidation product, **3**, was also isolated in greater than 90% yields as the perchlorate or chloride salt using DDQ oxidant. As discussed earlier (1, 3, 4), the reduction product of the π acceptors, as well as the overall stoichiometry, depends on the extent to which the rapid reaction of the product of hydride transfer, AH^-, with unreacted acceptor ($2AH^- + A \rightleftharpoons AH_2 + 2A^{\cdot-}$) occurs. This reaction occurs to a slight extent with CA and BA, and essentially completely with DCBQ and DDQ.

The kinetic results for reaction of **1**(H) and **1**(D) with the eight oxidants in acetonitrile (AN) and with BQ in 50:50 v/v AN–water are summarized in Table 1. Rate measurements with all oxidants except BA and $Co(bipy)_3^{3+}$ were carried out under pseudo first-order conditions using a 30-fold or greater excess of oxidant. With BA and $Co(bipy)_3^{3+}$, lower molar ratios of oxidant to **1** were used and the data analyzed using the appropriate second-order rate equation. A first-order dependence on both acridan and oxidant concentrations is well established by this and earlier work (1, 3, 4) for the π acceptors.

With $Co(bipy)_3^{3+}$ a second-order rate law was again observed under the conditions investigated. The results of our studies of oxidation of NMA by $Co(bipy)_3^{3+}$ are consistent with a mechanism involving rate-determining SET with subsequent or concurrent loss of H^+. This mechanism (1), which is analogous to that suggested by Bruice and co-workers (9) for oxidation of dihydropyridine analogs with $Fe(CN)_6^{3-}$, allows, in principle, for retardation of the rate by $Co(bipy)_3^{2+}$ produced in the reaction. At $(2–4) \times 10^{-5}\ M$ **1**, however, no measurable deviation from second-order behavior was observed. Added $Co(bipy)_3^{2+}$ at concentrations of $2 \times 10^{-4}\ M$ or higher does produce measurable decreases in rate but the interpretation of these effects is complicated by a negative salt effect. Consequently, we were unable to obtain a reliable estimate of the ratio of the rate constants for the proton-transfer and reverse electron-transfer steps, or of the deuterium isotope effect for the proton-transfer step (9).

At the beginning of this investigation we planned to examine the symmetrical hydride transfer between **1** and **3** (to regenerate **1** and **3**) for evidence for a stepwise mechanism, using esr spectroscopy to detect any D· and nmr spectroscopy to detect any H/D exchange at the 9-position in AN–D_2O solvent. However, using **1** with a $^{14}CH_3$ label and a procedure similar to that of Powell and Bruice (2), we found the hydride transfer from **1** to **3** to be too slow (at least 10^3 times slower than that between NMA and 10-methylacridinium ion (2)) to make such experiments practical.

Discussion

The primary deuterium kinetic isotope effects (kie's) (Table 1) are remarkably similar to those observed for oxidation of NMA with the same π acceptors (3). Where there are significant differences, the kie is marginally greater for **1** (viz., 10.4 ± 0.7 vs. 7.7 ± 0.4 with CA, 5.9 ± 0.3 vs. 4.8 ± 0.3 with TCNE, 8.0 ± 1.1 vs. 5.4 ± 0.4 with DCBQ). Furthermore the trends are identical, the kie decreasing from AN to AN–water with BQ and with increasing oxidizing strength within a series of structurally-related oxidants. Any differences in the steric requirements of BA and CA are not great enough to have a measurable effect on the kie.

An earlier analysis (4) led to the conclusion that the radical cation – radical anion pair intermediate, $DH^{+\cdot}\ A^{-\cdot}$, of a SET-initiated mechanism is energetically inaccessible in oxidation with BQ or CA ($E^0 = -0.51$ V and 0.01 V, respectively). These arguments lead to the same conclusion for **1**, whose one-electron oxidation potential should be slightly greater than that of NMA (below). The same analysis was used earlier by Verhoeven and co-workers (5) to exclude SET-initiated mechanisms in oxidation of *N*-benzyl-1,4-dihydronicotinamide (BNAH) by CA in AN. More recently Miller and co-workers (14) have investigated the kinetics of oxidation of NADH by a series of ferrocinium cation one-electron oxidants in aqueous 1-propanol. Their results enable them to estimate E^0 for one-electron oxidation of NADH in aqueous solution, and from it the rate constant for formation of the $DH^{+\cdot}\ A^{-\cdot}$ intermediate in oxidation of NADH by BQ. The calculated rate constant was 4×10^4 times smaller than the experimental rate constant, leading to the conclusion that oxidation of NADH by BQ in water cannot occur by a SET-initiated pathway.

Although a SET-initiated mechanism cannot be excluded by the same arguments for DCBQ ($E^0 = 0.30$ V), the relative reactivities of 2- and 3-methoxy-*N*-methoxyacridans (1) and of NMA and 10,10′-dimethyl-9,9′-biacridanyl (7) strongly indicate a synchronous mechanism for this acceptor as well. The kie in reaction of **1** with DDQ ($E^0 = 0.50$ V) remains large and is not out of line with that expected from the kie's of the less reactive benzoquinones. Consequently, although the extent of C—H bond breaking, C—O bond making, and degree of charge transfer (1) must change in a regular way from BQ to DDQ, the kie's for the benzoquinones are most simply accommodated by a mechanism in which electron and proton transfer are strongly coupled, that is, essentially a one-step hydride transfer.

It is interesting to compare the kie's observed in this work with those reported in two recent related studies. Kreevoy and co-workers (15) have reported primary kie's of 5.71 and 5.45, respectively, in oxidation of 9,9′-dideuterio-NMA by *N*-methyl- and *N*-(4-trifluoromethylbenzyl)-3-cyanoquinolinium ions in 4:1 2-propanol – water at 25°C. The measured equilibrium constants for the two oxidations are 0.70 and 28, respectively, and therefore these kie's would be expected to be close to the theoretical maximum. Interestingly, several of the kie's observed in oxidation of **1** and NMA (3) by uncharged π acceptors in AN are considerably larger. Further work is required to determine the reasons for these differences.

In a second related study Tanaka and co-workers (16) measured kie's in oxidation of BNAH with a series of benzoquinones ranging in reactivity from trimethyl-1,4-benzoquinone ($E^0 = -0.75$ V, $k_H/k_D = 5.61$) to DDQ ($E^0 = 0.51$ V, $k_H/k_D = 1.5$) in AN at 25°C. A bell-shaped dependence of the kie on E^0 was observed, with a maximum at BQ ($E^0 = -0.50$ V, $k_H/k_D = 6.2$). The results were interpreted in terms of a proton transfer within the ion pair intermediate, $BNAH^{+\cdot}A^{-\cdot}$, and the maximum kie for BQ taken to mean that the pK_a's of $BNAH^{+\cdot}$ and $BQH\cdot$ are approximately equal, i.e. that ΔG^0 for the proton transfer step is approximately zero. Aside from the prohibitively high energy expected for the $BNAH^{+\cdot}BQ^{-\cdot}$ intermediate (5) there is another problem with this explanation. The pK_a of the semiquinone radical $BQH\cdot$ is around 4.0 ± 0.1 in water (17, 18) while that of $BNAH^{+\cdot}$ has been estimated as −4 in AN (19) and as −3.5 in water (14). Clearly, $BNAH^{+\cdot}$ is close to 10^7 times as acidic as $BQH\cdot$ in water and the difference will surely be much greater in AN because $BQ^{-\cdot}$ is more strongly solvated by hydrogen bonding in water than $BNA\cdot$ (20). It is clear, therefore, that the proton transfer within a $BNAH^{+\cdot}A^{-\cdot}$ intermediate would be highly exoergic for BQ, and likely for all of the quinones investigated.

In contrast to the π acceptor results, the kie in the e^-, H^+, e^- oxidation by $Co(bipy)_3^{3+}$ indicates only minor C—H bond weakening in the transition state for the rate-determining electron transfer step. For this particular system we have not been successful in determining the kie for the proton transfer step, as has recently been accomplished for several similar $Fe(CN)_6^{3-}$ oxidations (9). Further efforts along these lines are planned.

The reactivities of **1** relative to NMA (Table 1) reflect a more complex combination of effects. NMA is more rapidly oxidized than **1** with all oxidants studied, relative reactivities varying from 9.1 to 1.7×10^2. A hydride transfer transition state is expected to be much more sensitive to the steric requirements of a C-9 substituent than an electron transfer transition state. In apparent contradiction to this expectation, the relative reactivities of NMA and **1** are nearly identical for CA and $Co(bipy)_3^{3+}$, which are known to react by one-step hydride transfer and stepwise e^-, H^+, e^- mechanisms, respectively. In attempting to understand these relative reactivities it is useful to first consider the expected electronic effect of the 9-phenyl substituent in relation to transition state structure.

The pK_{R^+} values of *N*-methylacridinium ion (NMA^+) and **3** (25°C, ionic strength 0.1) (eq. [3]) are, respectively, 10.03 and 11.01 (21). The 9-phenyl substituent therefore increases the stability of the acridinium ion oxidation product relative to the acridan, and, if the transition state resembles the acridinium ion, the electronic effect of the 9-phenyl should result in a rate

[3] 
increase. A linear relationship between log k (oxidation) and pK_{R^+} was demonstrated in oxidation of a series of N-(substituted benzyl)acridans by BQ, TCNQ, CA, TCNE, and DCBQ (4). Using these relationships and the pK_{R^+} values for NMA^+ and **3**, the electronic effect of a 9-phenyl substituent should make **1** more reactive than NMA by factors of about 2.3 (BQ, AN), 3.9 (BQ, 50:50 AN–H_2O), 6.3 (TCNQ), 4.9 (CA), and 5.0 (DCBQ). In agreement with expectation, NMA^+ reacts 31 times as fast as **3** as a hydride *acceptor* with 1-benzyl-1,4-dihydronicotinamide (AN, 20°C) (22), though this difference is undoubtedly partly steric in origin.

In contrast, the anodic peak potential for (essentially reversible) one-electron oxidation of 9,9-diphenyl-NMA in AN occurs at 0.13 V higher potential than that of 9,9-dimethyl-NMA (23). From the σ_I values of H, CH_3, and phenyl (0.00, −0.04, and 0.10, respectively (ref. 20, p. 98)), we estimate that replacement of a single 9-H by phenyl should result in an increase in the one-electron oxidation potential of ca. (0.13/2)

$\times (0.10/0.14) = 4.6 \times 10^{-2}$ V. If the full influence on ΔG^0 for electrochemical oxidation is felt in $\Delta G^{\ddagger}$ for oxidation by $Co(bipy)_3^{3+}$, the electronic effect of the 9-phenyl substituent would lead to a rate decrease of ca. 6-fold.

For the benzoquinones the rate ratios (NMA vs. **1**) are approximately constant (within a factor of about 2). Given the other evidence for a one-step mechanism for these oxidations (above), these ratios are believed to reflect a combination of electronic rate enhancement and steric retardation by the 9-phenyl substituent. The estimates of electronic rate enhancements (above) lead to estimates of steric retardation factors of $9.1 \times 2.3 = 21$ (BQ), 98 (CA), and 65 (DCBQ). The reactivities of NMA relative to **1** toward TCNQ and TCNE are larger, leading by the same procedure to estimates of steric retardation factors of ca. 4.2×10^2 (TCNQ) and 5.6×10^2 (TCNE). The larger steric effects with the dicyanomethylene acceptors may be a result of greater steric requirements of a dicyanomethylene carbon vs. a carbonyl oxygen. The observed rate ratio with $Co(bipy)_3^{3+}$ reflects both electronic and steric retardation so that the steric retardation factor is estimated to be around $24/6 = 4$. More systematic investigations of steric effects in hydride transfer reactions and their use in defining the mechanism are in progress.

Experimental

Melting points were measured in open capillary tubes and are uncorrected. Proton nmr spectra were measured using a Varian EM-360 spectrometer. Chemical shifts are reported in δ units, with tetramethylsilane as internal standard. Ultraviolet–visible spectra were obtained using a Cary 118C spectrophotometer and mass spectra with a VG 7070G spectrometer. Elemental microanalyses were performed by Guelph Chemical Laboratories, Guelph, Ontario.

Reagents and solvents

BQ, TCNQ, CA, TCNE, DCBQ, and $Co(bipy)_3(ClO_4)_3 \cdot 3H_2O$ were obtained and purified as described earlier (1, 3). BA was prepared from hydroquinone following Torrey and Hunter (24) and purified by crystallization from benzene, mp 304–305°C (lit. (25) mp 300°C). DDQ (Aldrich) was purified by crystallization from benzene followed by drying under vacuum, mp 215–217°C (lit. (26) mp 215–217°C).

10-Methyl-9-phenylacridan (**1**(H)) was obtained, along with variable amounts of 10,10′-dimethyl-9,9′-biacridanyl by reaction of *N*-methylacridinium iodide (3) with phenylmagnesium bromide in anhydrous ether (27) and purified by recrystallizing twice from ethanol, mp 104–106°C (lit. (27) mp 104°C); nmr ($CDCl_3$) δ: 3.3 (s, 3H, N-CH_3), 5.10 (s, 1H, 9-H), 6.67–7.32 (m, 13H, aromatic). Mass spectrum (*m/e*): 271 (M^+), 194 (M^+ − phenyl). *Anal.* calcd. for $C_{20}H_{17}N$: C 88.52, H 6.31, N 5.16; found: 88.54, H 6.25, N 5.30.

9-Deuterio-10-methyl-9-phenylacridan (**1**(D)) was obtained by reduction of 10-methyl-9-phenylacridinium perchlorate with sodium borodeuteride (min. 98 at.% D) as described earlier for reduction of *N*-methylacridinium perchlorate (3) and purified by recrystallizing 3 times from absolute ethanol, mp 107–108°C. The yield of purified product was 37%. Its nmr spectrum indicated about 5% H at the 9 position. 10-Methyl-9-phenylacridinium perchlorate was obtained in yields over 90% by oxidation of **1** with DDQ in ether solution as described earlier for oxidation of NMA (3).

Kinetic measurements

Kinetics of oxidation were measured spectrophotometrically using methods and instrumentation described earlier (1, 3). The progress of the reaction was followed at the 10-methyl-9-phenylacridinium ion maximum at 361 nm (22) for all oxidants except TCNQ, where the formation of $TCNQ^{\cdot -}$ was followed at 680 or 740 nm. Measurements were carried out under pseudo first-order conditions using a 30-fold or greater excess of oxidant over acridan with all oxidants except BA and $Co(bipy)_3^{3+}$, where lower ratios (Table 1) were used and the data analyzed using the appropriate second-order rate equation (1). $Co(bipy)_3^{3+}$ rates were run under N_2 atmosphere after degassing.

BENITO ALCAIDE, CARMEN L. MARDOMINGO, RAFAEL PÉREZ-OSSORIO, JOAQUÍN PLUMET, ROGER PHAN-TAN-LUU et MICHELLE SARGENT. Can. J. Chem. **63**, 2241 (1985).

À partir du rapport *RR,SS*/*RS,SR* des 2-aminoéthanols isomères obtenus par réduction de 24 α-iminocétones ($LiAlH_4$) les auteurs ont étudié l'influence des substituants sur la stéréochimie de la réaction en postulant un modèle mathématique à 7 coefficients. Les valeurs de ces coefficients calculées par regression multilinéaire sont d'accord avec le mécanisme de réduction postulé précédemment et mettent en évidence quelques conclusions additionnelles. L'application des méthodes modernes de construction de matrices d'expériences permet d'en choisir 10 d'un ensemble de 24 expériences et montre que ce sous-ensemble permet d'extraire des informations de la même qualité.

BENITO ALCAIDE, CARMEN L. MARDOMINGO, RAFAEL PÉREZ-OSSORIO, JOAQUÍN PLUMET, ROGER PHAN-TAN-LUU, and MICHELLE SARGENT. Can. J. Chem. **63**, 2241 (1985).

Using the isomeric ratio of *RR,SS* to *RS,SR* of a series of 2-aminoethanols obtained by the $LiAlH_4$ reduction of 24 α-iminoketones we propose a mathematical model with 7 coefficients for the effect of substituent on the stereochemical course of the reaction. The values of these coefficients obtained by multilinear regression analysis are in agreement with the previously proposed mechanism for reduction but allow for some additional conclusions. The use of modern methods for the construction of experimental matrices allows us to choose 10 from a total of 24 experiments and shows that information of the same quality can be obtained from this subset.

Introduction

La réduction des α-iminocétones par l'action de l'hydrure de lithium-aluminium (HAL) conduit à la formation de mélanges de 2-aminoéthanols stéréoisomères (1, 2).

L'étude du cours du processus permet d'établir que la stéréochimie de la réaction est le résultat d'une compétition entre deux chemins réactionnels formulés dans la fig. 1. Le chemin **a** est le résultat de l'attaque préalable du groupement carbonyle conduisant à l'isomère *RR,SS*, et le chemin **b**, issu de l'attaque préalable du groupement imino conduisant à l'isomère *RS,SR*. Cette simplification fondée sur les données expérimentales dans le cas des α-iminocétones dérivées des systèmes benzyliques[2] et raisonnablement étendue aux autres α-iminocétones[3] a été expliqué précédemment à l'aide des modèles stéréochimiques qui rendent compte du résultat du processus (2).

L'objectif de ce travail est de déduire une équation multiparamétrique, en utilisant les données expérimentales disponibles et qui nous permettra d'établir quantitativement l'influence de la modification structurelle des α-iminocétones sur la stéréochimie de la réduction. Dans ce but, nous avons fait varier les substituants R^1 et R^2 (Ph ou Me, fig. 1), et R^3 par le changement de la nature et de la position (*m* ou *p*) du substituant aromatique X. Pour caractériser ce substituant, nous avons choisi deux paramètres électroniques qui décrivent les effets inductif et de résonance que nous voulons considérer. Finalement nous effectuerons une critique méthodologique "a posteriori" de la démarche suivie dans le traitement du problème.

Modèle mathématique

Notre modèle mathématique est une équation dont la réponse étudiée est le pourcentage du stéréoisomère *RR,SS*, et qui comprend quatre termes du premier degré, traduisant l'effet global des variables étudiées et deux termes d'intéraction qui tiennent compte de la possibilité de que l'effet de la nature du substituant R^3 n'est pas indépendant de la nature du substituant R^2. L'effet global de R^3 est décrit par les paramètres σ_0^R et σ_I (5).

Le modèle peut donc s'écrire:

$$[1] \quad Y = (\%RR,SS) = a_0 + a_1(R^1) + a_2(R^2) + a_3(\sigma_0^R \text{ de X}) + a_4(\sigma_I \text{ de X}) + a_{23}(R^2)(\sigma_0^R \text{ de X}) + a_{24}(R^2)(\sigma_I \text{ de X})$$

Nous avons réuni l'ensemble de 24 molécules dont on a étudié la réduction avec HAL/Et_2O dans le tableau 1, ainsi que les valeurs des variables correspondantes et la réponse expérimentale obtenue. Pour éviter le danger d'une interprétation du modèle exprimé avec des variables naturelles, nous utilisons pour le facteur R^3 des variables codées (6) qui sont obtenues à partir de la transformation:

$$[2] \quad \text{variable codée} = (\text{variable naturelle} - \text{centre})/\text{pas}$$

Pour chaque variable, le centre choisi est la valeur médiane et le pas de variation est tel que la variable codée est comprise entre +1 et −1. Le tableau 2 résume les valeurs du centre et

22	Me	Me	pIC_6H_4	−0,12	0,39	32,1
23	Me	Me	$pMeOC_6H_4$	−0,41	0,26	28,1
24	Me	Me	$pMe_2NC_6H_4$	−0,52	0,05	23,7

pas choisies pour chaque variable.

L'équation [1] peut alors s'écrire:

$$[3] \quad Y = b_0 + b_1x_1 + b_2x_2 + b_3x_3 + b_4x_4 + b_{23}x_2x_3 + b_{24}x_2x_4$$

Nous donnons dans le tableau 3 la matrice d'expériences exprimée en variables codées.

Les valeurs trouvées pour les facteurs d'inflation[4] étant satisfaisantes (tableau 4), nous pouvons calculer par la méthode des moindres carrés des estimations valables des coefficients du modèle:

$$[4] \quad Y = 55{,}7 - 1{,}1x_1 + 27{,}9x_2 - 6{,}9x_3 - 1{,}5x_4 - 11{,}6x_2x_3 - 3{,}2x_2x_4 \quad (R_A^2 = 0{,}96)^5$$

Interprétation

Nous pouvons constater la faible influence de la variable x_1 ($b_1 = -1{,}1$). Les autres coefficients b_2, b_3 et b_4, respectivement égaux à +27,9, −6,5 et −1,5 ne peuvent être interprétés seuls, les effets des variables x_2, x_3 et x_4 n'étant pas indépendants par hypothèse (intéractions x_2x_3 et x_2x_4). D'autre part, la haute valeur du coefficient b_{23} (−11,6) et la petite valeur (−3,2) de b_{24} sont significatives. L'intéraction la plus importante, b_{23}, correspond aux variables (R^2): (σ_0^R de X) ce qui signifie que les effets des substituants en position 3 sur la réponse étudiée ne sont pas additifs, c'est-à-dire, l'influence de σ_0^R de X sur %*RR*,*SS* n'est pas la même suivant la nature de R^2 (Me ou Ph). Ceci peut être visualisé facilement en représentant la réponse *Y* en fonction de σ_0^R de X (fig. 2).

Nous en déduisons que l'influence de σ_0^R de X sur la stéréochimie de la réaction est beaucoup plus importante dans le cas

de monoimines dérivées du benzyl (expériences 1–10, correspondant à la présence d'un groupement phényl en position 2) que dans le cas où R^2 est un groupement méthyl, expériences 11–24 pour lesquelles l'influence de σ_0^R est pratiquement nulle.

Conclusion du point de vue chimique

L'étude de la réaction de réduction réalisée sur l'ensemble de 24 α-iminocétones et celle du modèle confirment le schéma réactionnel proposé (fig. 1) et mettent en évidence le changement de mécanisme en passant des composés avec R^2 = Ph aux composés avec R^2 = Me.

Pour les molécules 1–10, le chemin de réaction **a** est choisi de préférence au chemin **b**: les caractéristiques électroniques du groupement phényl en position 2 provoquent un "durcissement" du groupement carbonyle (chemin **a**) et donc l'augmentation du pourcentage de l'isomère *RR,SS* (voir fig. 1). Ceci implique que la cétone n'est pas conjugée au groupe imino, ce qui a été confirmé pour ces composés par analyse au rayons-X (8) et rmn du carbone-13 (9).

Dans le premier groupe de molécules l'influence de la nature électronique de R^3 est confirmée (2). Plus le substituant R^3 est électrodonneur plus la conjugaison augmente, c'est-à-dire, plus grande est la planarité entre groupements aromatique R^3 et imino. Par conséquent il y a une augmentation du pourcentage de l'isomère *RR,SS*.

Par contre cette influence est nulle pour le deuxième sous-ensemble d'iminocétones (11–24, R^2 = Me). Nous constatons que la substitution d'un méthyl par un phényl en position 1, et le caractère inductif du substituant R^3 n'ont pas d'influence sur la stéreochimie de la réduction de ce genre de composés.

Présentation d'une strategie optimale

Les données que nous avons utilisées dans la première partie de cette étude ont été obtenues sans suivre une strategie bien définie, le problème se précisant au fur et à mesure de l'avancement du travail.

Nous allons illustrer l'application de la Méthodologie de la Récherche Expérimentale (10) à notre problème en supposant qu'aucune expérience n'a été faite. Nous avons à notre disposition 24 molécules candidates.

1. Cet ensemble de molécules contient-il assez d'information?

Les valeurs des coefficients d'inflation permettent de dire que cet ensemble est bien structuré et que les informations obtenues sont de bonne qualité. Rappelons que les facteurs d'inflation peuvent être calculés avant d'avoir effectué des expériences.

2. Peut-on réduire le nombre d'expériences sans affecter sensiblement la qualité des informations fournies?

Nous avons extrait de l'ensemble de 24 points candidats le meilleur sous-ensemble permettant d'étudier le modèle postulé. Le critère choisi est le critère d'optimalité-D (maximisation du déterminant de la matrice d'information normée $|\mathbf{M}|$). Pour différentes valeurs de N (N = nombre de molécules) nous avons calculé la matrice d'expériences optimale-D. Dans la fig. 3, nous montrons la variation de $|\mathbf{M}|$ en fonction de N. On peut constater l'existence d'un maximum pour N = 10. La matrice d'expériences correspondente comporte les molécules données dans le tableau 5. La valeur du déterminant normé décroit régulièrement de N = 10 à N = 24 (fig. 3). Les valeurs des facteurs d'inflation sont satisfaisantes pour la matrice d'expériences optimale-D (tableau 4).

Nous avons calculé les coefficients du modèle (éq. [3]) par la méthode des moindres carrés en utilisant le sous-ensemble des 10 molécules. Les valeurs de ces coefficients ne diffèrent

pas significativement de celles que nous avons calculées plus haut avec la totalité de molécules (tableau 6).

Dans le tableau 7, nous avons réuni les valeurs expérimentales (*%RR,SS*) et les valeurs de la réponse calculées à partir des modèles à 24 et à 10 expériences. L'accord entre ces valeurs est satisfaisant.

Matrice d'expériences robuste

La structure de la matrice d'expériences optimale n'est valable que pour le modèle formulé. Si nous changeons de modèle, il est évident que la matrice d'expériences sera modifiée, les informations nécessaires n'étant pas les mêmes.

Dans une deuxième démarche, nous envisageons le cas où nous ne faisons aucune hypothèse sur le modèle. Nous avons utilisé une démarche analoge à celle de Kennard et Stone (11) qui propose une répartition uniforme de points dans le domaine expérimental. La procédure originale est insuffisante à certain niveau: elle ne donne que l'ordre d'apparition des points mais ne permet pas de mettre en évidence des arrangements de points constituants des structures optimales que nous appelons "stables". Nous avons utilisé un algorithme modifié mettant en évidence ces structures. Ceci nous permet de selectionner un sous-ensemble de points qui nous donne suffisamment d'information pour envisager une interpolation ultérieure. La meilleure distribution de points donnant une structure stable est celle donnée dans le tableau 8.

Les deux matrices obtenues comportent de nombreux points communs. Notons la proximité topologique des points 19 et 20.

Étude cinétique de l'ouverture thermique de la liaison C—C d'aziridines et d'époxydes dipôles-1,3 potentiels: I. Méthode d'étude expérimentale

AÏCHA DERDOUR ET FERNAND TEXIER

Laboratoire de synthèse organique, ONRS 75B/033, Institut de Chimie, Université d'Oran, Es-Sénia, Algérie

Reçu le 25 septembre 1984

AÏCHA DERDOUR et FERNAND TEXIER. Can. J. Chem. **63**, 2245 (1985).

Les cyano-2 aziridines **1**, les alcoxy carbonyl-2 aziridines **2**, les aroyl-2 aziridines **3** et les dicyano-2,2 aryl-3 oxiranes **4** s'ouvrent thermiquement entre les deux carbones pour donner respectivement un ylure d'azométhine et un ylure de carbonyle. La réaction de ces ylures d'azométhine avec l'ACDM (acétylène dicarboxylate de méthyle) conduit à une pyrroline-3 qui évolue, selon les substituants, en pyrroline-2 ou en pyrrole. L'addition des ylures de carbonyle donne des dihydrofuranes. Le traitement cinétique de l'addition de ces hétérocycles **1** à **4** à l'ACDM permet la détermination de la constante de vitesse d'ouverture de la liaison C—C (k_1). La réaction est suivie à l'aide de l'ir dans le cas des aziridines **1** et de la hplc dans tous les autres cas. La constante expérimentale de vitesse (k_{ex}) est toujours d'ordre 1 par rapport à l'hétérocycle. Dans le cas des *N*-cyclohexyl cyano-2 alkyl-3 aziridines et de la *N*-cyclohexyl carbométhoxy-2 phényl-3 aziridine, k_{ex} dépend de la concentration en ACDM, ce qui implique que la cycloaddition de l'ylure d'azométhine et sa refermeture en aziridine ont des vitesses comparables. Dans les autres cas, k_{ex} est indépendante de la concentration en ACDM, ce qui correspond à une lente transformation de l'hétérocycle en dipôle-1,3 suivie d'une cycloaddition rapide, $k_{ex} \simeq k_1$.

AÏCHA DERDOUR and FERNAND TEXIER. Can. J. Chem. **63**, 2245 (1985).

The thermolysis of the 2-cyanoaziridines (**1**), 2-alkoxycarbonylaziridines (**2**), 2-arylaziridines (**3**), and 2,2-dicyano-3-aryloxiranes (**4**) leads to a rupture of the carbon–carbon bond yielding an azomethine ylide and the ylide of a carbonyl. The reaction of these ylides of azomethine with methyl acetylene dicarboxylate (MADC) leads to the formation of a 3-pyroline, which is transformed, according to the substituants, to a 2-pyrroline or to pyrrole. The addition of the ylides of carbonyl leads to the formation of dihydrofurans. Through the kinetic treatment of the addition of these heterocyclic compounds (**1** to **4**) to MADC, it is possible to determine the rate constants for the opening of the C—C bond (k_1). In the case of the aziridines **1**, the rates have been determined by ir while hplc has been used in the other cases. Relative to the heterocyclic compounds, the order of the experimental rate constants (k_{ex}) is always equal to one. In the cases of the *N*-cyclohexyl-2-cyano-3-alkylaziridines and of the *N*-cyclohexyl-2-carbomethoxy-3-phenylaziridine, k_{ex} varies with the concentration of MADC and this implies that the rate constants for the cycloaddition of the ylide of azomethine and its reclosing to give aziridine are similar. In the other cases, k_{ex} is independent of the concentration of MADC and this implies that the heterocyclic compounds are slowly transformed into 1,3-dipoles, followed by a rapid cycloaddition, $k_{ex} \simeq k_1$.

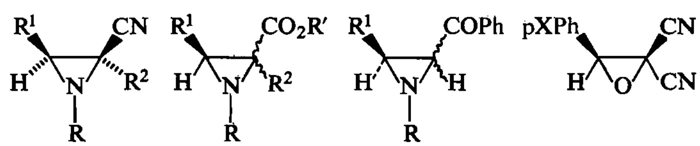
[Journal translation]

Introduction

Les aziridines et époxydes convenablement substitués s'ouvrent thermiquement entre les deux carbones (1, 2). Les dipôles-1,3 ainsi formés ne sont pas isolés, mais ils peuvent être additionnés à différents dipolarophiles permettant ainsi la synthèse d'hétérocycles à cinq chaînons variés (schéma 1).

Malgré la diversité des réactions de cycloaddition d'ylures d'azométhine et d'ylures de carbonyle obtenus par thermolyse du petit cycle à trois chaînons correspondant, l'étude cinétique de ces réactions n'a été que partiellement abordée (3, 4) et le but recherché par ces auteurs n'était pas l'étude des facteurs qui favorisent l'ouverture électrocyclique.

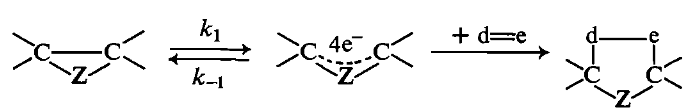
La stéréochimie de l'ouverture de ces petits cycles en dipôles-1,3 est bien expliquée par les règles de Woodward et Hoffmann (5). Par contre, les facteurs qui favorisent ces réactions ne semblent pas avoir été clairement dégagés malgré quelques tentatives faites par Epiotis (6) et Carpenter (7); récemment, l'un d'entre nous a tenté d'interpréter la réactivité péricyclique des cycles à trois chaînons à l'aide de la méthode des relaxations (8). C'est pourquoi, nous nous sommes proposés d'étudier la vitesse d'ouverture des aziridines **1**, **2** et **3** substituées respectivement en 2 par un nitrile, un ester ou une cétone, et des époxydes **4** substitués en 2 par deux nitriles; en effet, selon la littérature, l'ouverture péricyclique des aziridines et époxydes est facilitée par des substituants électro-attracteurs sur les carbones (1, 2, 8):



1 **2** **3** **4**

1. Position du problème

Les ylures d'azométhine ainsi que les ylures de carbonyle obtenus par ouverture thermique des hétérocycles à trois chaînons correspondants sont des intermédiaires réactionnels qui ne sont mis en évidence que par leurs produits de cycloaddition. L'équilibre aziridine ⇄ ylure d'azométhine est considérablement déplacé vers l'aziridine (9), de telle sorte que les ylures d'azométhine ne sont pas détectables par les méthodes spectroscopiques usuelles. Cependant, il peut être démontré, grâce à des études cinétiques, que l'addition d'une aziridine, ou

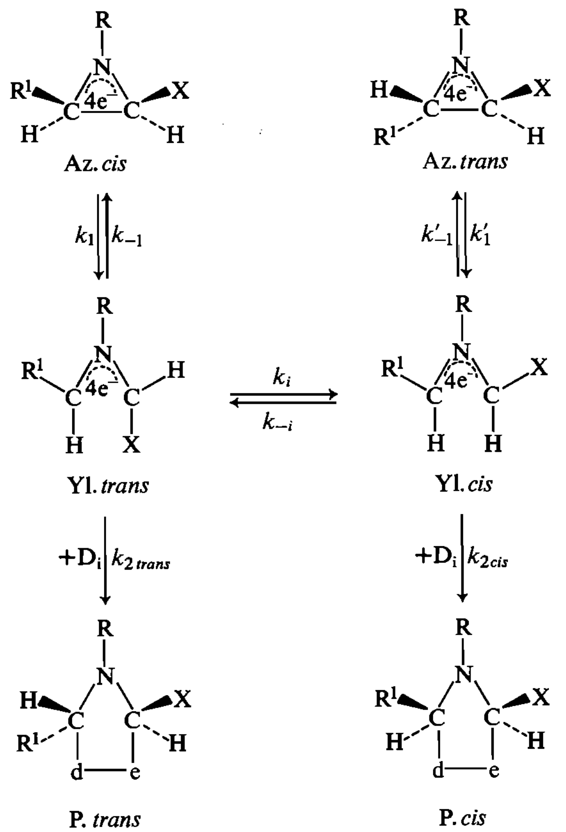


[Z = N—R: ylure d'azométhine
Z = O: ylure de carbonyle]

SCHÉMA 1

d'un époxyde, à un dipolarophile est précédée de la formation réversible d'un intermédiaire d'énergie élevée (3, 9, 10). C'est la raison pour laquelle nous avons étudié la cinétique de l'addition des aziridines **1** à **3** et des époxydes **4** à l'acétylène dicarboxylate de méthyle (ACDM) afin de déterminer les constantes de vitesse correspondant à l'ouverture thermique de la liaison C—C.

D'une manière générale, l'addition d'une aziridine ylure d'azométhine potentiel à un dipolarophile peut être schématisée comme suit (schéma 2):



k_1, k'_1: constantes cinétiques d'ouverture des aziridines
k_{-1} k'_{-1}: constantes cinétiques de refermeture des ylures
k_{2trans}, k_{2cis}: constantes cinétiques de la cycloaddition
k_i, k_{-i}: constantes d'isomérisation
P_{cis}, P_{trans}: produits d'addition
D_i = dipolarophile (d═e)
Az: aziridine
Yl: ylure d'azométhine

SCHÉMA 2

Si l'on considère une aziridine *cis*, son ouverture conrotatoire,[1] dont la constante de vitesse est k_1, conduit à l'ylure d'azométhine *trans*. En l'absence de dipolarophile, l'ylure *trans* peut s'isomériser en ylure *cis*; ce dernier peut se cycliser en aziridine *trans*. Ce phénomène explique l'isomérisation thermique des aziridines ylures d'azométhine potentiels (10–12). En présence d'un dipolarophile si la cycloaddition est rapide par rapport à l'isomérisation, c'est-à-dire lorsque $k_2\,[D_i] \gg k_i$, l'isomérisation de l'ylure peut être ignorée. C'est la raison pour laquelle nous avons utilisé l'ACDM qui est l'un des meilleurs dipolarophiles vis-à-vis des ylures d'azométhine et de carbonyle. Dans ces conditions l'ouverture thermique des aziridines peut se mettre sous la forme:

$$\mathrm{Az} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \mathrm{Yl} + \mathrm{D_i} \xrightarrow{k_2} \mathrm{P}$$

Az: aziridine; Yl: ylure d'azométhine; D_i: dipolarophile; P: produit d'addition.

La vitesse de la réaction s'exprime de la manière suivante:

$$[1]\quad v = +\frac{dP}{dt} = k_2\,[\mathrm{Yl}]\,[\mathrm{D_i}]$$

En appliquant le principe de l'état stationnaire au réactif intermédiaire (ylure), on obtient l'éq. [2]

$$[2]\quad v = +\frac{dP}{dt} = \frac{k_1 k_2 [\mathrm{Az}][\mathrm{D_i}]}{k_{-1} + k_2[\mathrm{D_i}]}$$

Cette expression de la vitesse peut s'écrire:

$$[3]\quad v = +\frac{dP}{dt} = k_{ex}\,[\mathrm{Az}]$$

avec

$$k_{ex} = \frac{k_1 k_2 [\mathrm{D_i}]}{k_{-1} + k_2[\mathrm{D_i}]}$$

ou

$$k_{ex} = k_1 - \frac{k_{-1}}{k_2}\cdot\frac{k_{ex}}{[\mathrm{D_i}]}$$

La constante expérimentale de vitesse correspond à une réaction du pseudo ordre 1 et varie avec la concentration en ACDM. La courbe représentant $k_{ex} = f(k_{ex}/[D_i])$ est une droite de pente k_{-1}/k_2 et d'ordonnée à l'origine k_1, la constante cinétique d'ouverture de l'aziridine.

L'expression de la vitesse peut encore être simplifiée lorsque $k_{-1} \ll k_2[D_i]$, c'est-à-dire dans le cas où la vitesse de refermeture de l'ylure en aziridine est faible devant la vitesse de cycloaddition.

La vitesse s'exprime alors par:

$$[4]\quad v = k_1\,[\mathrm{Az}]$$

Dans ce cas, la constante cinétique de la réaction n'est autre que la constante d'ouverture k_1 de l'aziridine. Celle-ci est alors indépendante de la concentration en dipolarophile.

2. Méthode d'étude

La détermination des constantes d'ouverture (k_1) des hétérocycles **1** à **4** se résume donc à suivre la vitesse de disparition de l'aziridine ou de l'époxyde lors de sa réaction avec l'ACDM et d'appliquer, selon le cas, l'éq. [3] ou [4]. La cinétique d'ouverture des cyano-2 aziridines **1** a été suivie à l'aide de l'ir (infrarouge), dans les autres cas, nous avons utilisé la chromatographie en phase liquide (cpl).

2.1. Utilisation de l'infra-rouge

L'addition des ylures d'azométhine **5** résultant de l'ouverture thermique des cyano-2 aziridines **1**, à l'ACDM, conduit à des pyrroles **7** qui proviennent de l'élimination spontanée de HCN à partir du produit de cycloaddition **6**, une pyrroline-3 (12) (schéma 3).

Après avoir vérifié que les aziridines **1** suivent la loi de Lambert–Beer, nous avons suivi la disparition de **1** en me-

[1] L'ouverture conrotatoire peut se faire a priori de deux manières différentes conduisant à deux isomères conformationnels de l'ylure d'azométhine (10, 13).

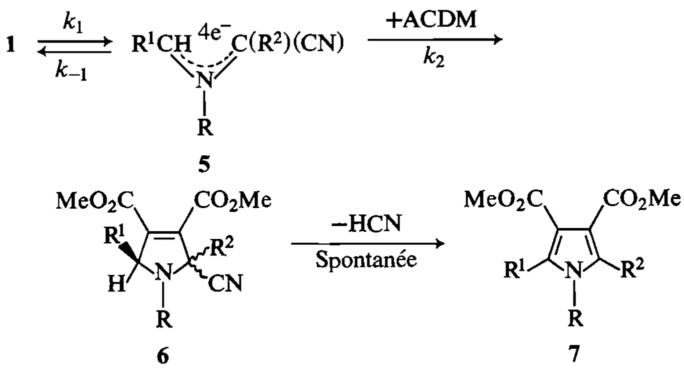


SCHÉMA 3

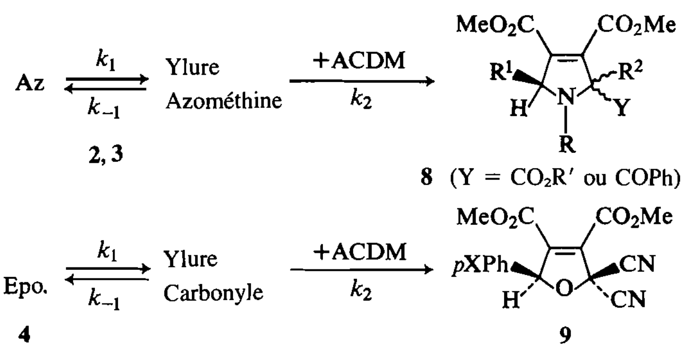

SCHÉMA 4

surant la transmission de la bande d'absorption $\nu C{\equiv}N$ vers 2240 cm^{-1}; HCN absorbe à 2095 cm^{-1} et il n'y a pas de chevauchement des bandes de l'aziridine et des produits formés. La constante expérimentale de vitesse k_{ex} est déterminée graphiquement, après avoir fait pour chaque pointe un minimum de trois mesures de la transmission. La précision de la mesure de la transmission étant de 1% (voir la partie expérimentale pour l'appareillage), k_1 est déterminée avec une précision de l'ordre de 10% après calcul de régression linéaire. Malgré l'importance relative de l'erreur commise sur k_1 (ceci étant dû à la méthode utilisée), les valeurs obtenues avec les aziridines diversement substituées sont suffisamment différentes pour qu'elles puissent être discutées.

2.2. Utilisation de la chromatographie en phase liquide

L'addition des aziridines **2** et **3** et des époxydes **4** conduit respectivement à des pyrrolines-3 **8** (1, 11, 15), qui parfois sont isomérisées en pyrrolines-2, et à des dihydrofuranes **9** (16) (schéma 4).

Une étude ir et uv (ultraviolet) s'est avérée impossible à cause des chevauchements des bandes d'absorption des produits initiaux et des produits formés, c'est pourquoi nous avons suivi la vitesse de disparition des composés **2**, **3** et **4** en les dosant tout au long de la réaction à l'aide de la cpl. Les constantes expérimentales de vitesse sont obtenues avec un pourcentage d'erreur inférieur à 5%.

Nous avons vérifié que les constantes de vitesse ainsi obtenues sont tout à fait comparables à celles obtenues par ir, comme le montre l'exemple de l'aziridine **1***a*; les valeurs obtenues sont pratiquement les mêmes, compte tenu des pourcentages d'erreur inhérents à chaque méthode.

3. Résultats et discussion

Les différents époxydes et aziridines dipôles-1,3 potentiels

k_1 (cpl) $28{,}8 \times 10^{-5}$ s^{-1}

étudiés au cours de ce travail sont répertoriés dans les tableaux 1 et 1 bis; ils sont préparés en utilisant des méthodes connues et décrites dans la littérature.

Toutes les aziridines **1** utilisées au cours de ce travail n'ont pas été étudiées précédemment, c'est pourquoi, avant l'étude cinétique, nous avons vérifié que l'addition à l'ACDM conduit dans chaque cas à un pyrrole **7** (14) selon la réaction décrite par Merah et Texier (12).

La réactivité des époxydes **4** vis-à-vis de l'ACDM a été étudiée par Robert *et al.* (16); toutefois, celle de l'époxyde **4***d* (X = NO_2) est si faible que le produit d'addition n'avait pas été isolé. Nous avons vérifié que la réaction conduit bien au dihydrofurane correspondant **9***d* (X = NO_2) que nous avons isolé et purifié. Les caractéristiques des nouveaux pyrroles **7** et du

composé **9**d sont rassemblées dans la partie expérimentale.

Pour toutes les aziridines **1** et **3**, l'isomérisation de l'ylure d'azométhine peut être négligée (k_2/[D_i] >> k_i). Les époxydes **4** portent deux substituants identiques sur le carbone 2 et le problème d'isomérisation ne se pose pas.

Lorsque R et R^1 sont des alkyles (composés **1**h à j), la constante expérimentale de vitesse k_{ex} dépend de la concentration en ACDM (tableau 2) et la constante k_1 est déterminée graphiquement en résolvant l'éq. [3]. Ces résultats montrent que dans ces cas, la cycloaddition de l'ylure d'azométhine et sa refermeture en aziridine ont des vitesses comparables.

Lorsque R ou R^1 est un aryle, la constante expérimentale de vitesse k_{ex} est pratiquement indépendante de la concentration en ACDM, comme le montrent les résultats rassemblés dans les tableaux 3 et 4. Ceci correspond au fait que $k_{-1} \ll k_2$[ACDM]; dans ces conditions, $k_{ex} = k_1$, la constante d'ouverture de l'hétérocycle. Ces résultats impliquent une lente transformation de l'hétérocycle en dipôle-1,3 suivie d'une cycloaddition rapide.

Les aziridines **2** (Y = CO_2R') ont un comportement particulier. La vitesse d'isomérisation des composés **2**a et **2**b est du même ordre de grandeur que la vitesse d'addition de l'ylure d'azométhine à l'ACDM et de ce fait, elle ne peut être négligée.

TABLEAU 4. Influence de la concentration en ACDM sur k_{ex} (cas des époxydes **4**a à **4**d; T = 121,5 ± 0.1°C, solvant: CCl_4)

	T (°C)			
	60	82,5	105	121,5
$k_I \times 10^4$ (s^{-1})	0,7	1,9	10,1	43,1
$k_{-I} \times 10^4$ (s^{-1})	0,8	1,8	9,8	39,9
$K = k_I/k_{-I}$	0,98	1,07	1,03	1,08
$k_1 \times 10^4$ (s^{-1})	2,9	8,2	34,1	100,0

[a] K: constante de vitesse globale d'isomérisation; k_I et k_{-I} constantes directe et inverse d'isomérisation.

gée. À titre d'exemple, nous avons rassemblé dans le tableau 5 les constantes de vitesse globale d'isomérisation de l'aziridine **2**b *cis*. La constante k_1 doit donc être déterminée en cinétique initiale à partir de l'équation:

$$V_0 = \frac{d[P trans]}{dt} = k_2[Yl \cdot trans]\,[ACDM]$$

De plus, la constante k_{ex} (déterminée en vitesse initiale) de l'aziridine **2**a (R = C_6H_{11}) dépend de la concentration en ACDM, k_1 est obtenue en traçant la courbe $k_{ex} = f(k_{ex}/$[ACDM]). Dans le cas des composés **2**b et **2**c, l'éq. [6] est applicable, $k_{ex} \simeq k_1$. Avec l'aziridine **2**c nous avons observé un phénomène particulier, la cycloaddition est réversible[2] et l'addition de l'aziridine à l'ACDM est équilibrée, ce qui explique que, dans les conditions de synthèse, le rendement en pyrroline-3 est toujours médiocre (23). La constante de vitesse doit donc être déterminée également en vitesse initiale; les différentes constantes de vitesse ainsi obtenues sont rassemblées dans le tableau 6.

Une partie des effets de substituant a été discutée dans deux courtes communications (24). Une discussion détaillée est effectuée dans l'article suivant, à partir des paramètres d'activation déterminés après avoir mesuré la constante d'ouverture k_1 à différentes températures.

Partie expérimentale

Les aziridines **1**a, **1**j, **1**k, **2** et **3** et les époxydes **4** sont connus. Ils sont préparés selon le mode opératoire décrit dans la référence correspondante du tableau 1.

Les aziridines **1**b à **1**i sont obtenues en appliquant la méthode de Cromwell, selon le mode opératoire décrit par Merah et Texier pour

[2] La réversibilité de la cycloaddition dipôlaire-1,3 a été observée avec divers dipôles-1,3 (26) parmi lesquels les ylures d'azométhine, mais à notre connaissance, aucune rationalisation de ces résultats n'a été tentée.

TABLEAU 6. Influence de la concentration en ACDM sur k_{ex} (cas des aziridines esters **2***a* à **2***c*; T = 121,5 ± 0,1°C, solvant: toluène)

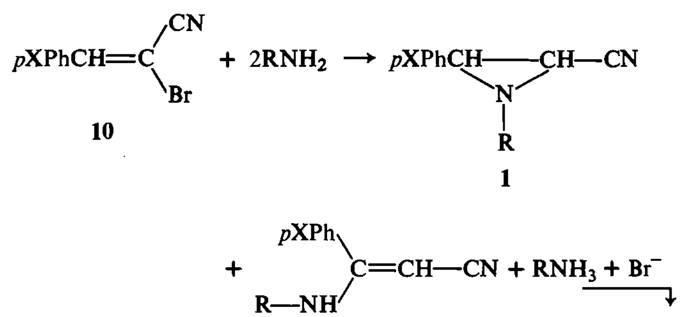
la synthèse de l'aziridine **1***a* (12).

Deux équivalents de cyclohexylamine (R = C_6H_{11}) sont ajoutés goutte à goutte aux oléfines α-bromées **10**, en solution dans le benzène ou l'éther lorsque R[1] est un aroyle (soit 0,1 mol de cyclohexylamine dans 100 mL de solvant), dans l'acétonitrile lorsque R[1] est un alkyle. La température est maintenue entre 5 et 10°C. Le mélange est alors abandonné à la température ambiante, dans l'obscurité. L'état d'avancement de la réaction est suivi par pesée du bromhydrate qui précipite. Finalement, le solvant est évaporé et le résidu est recristallisé dans l'éthanol à 95%. L'aziridine **1***b* a été purifiée par chromatographie sur colonne d'alumine (80 g/1 g d'huile) avec éther/éther de pétrole 50:50 comme éluant.

La synthèse des cyano-2 aziridines pour lesquelles R[1] est un substituant aromatique s'accompagne toujours de la formation d'énamines **11** isomères (12). Dans tous les cas, l'aziridine précipite en premier, et par recristallisation fractionnée dans l'éthanol à 95°C, on obtient parfois l'énamine qui précipite à partir du 3ème jet de cristallisation. Le pourcentage relatif aziridine/énamine, déterminé par analyse rmn (résonance magnétique nucléaire) du produit brut réactionnel, est donné dans le tableau 7, mais nous n'avons pas cherché à isoler et purifier l'énamine **11** dans tous les cas.



10 **1** **11**

Toutes les aziridines **1** ainsi obtenues pour lesquelles R[1] est un substituant aryle ont la configuration *cis* (R[1] par rapport à CN). Les caractéristiques physiques des aziridines ainsi que les rendements en produits isolés sont rassemblés dans le tableau 8, les résultats des analyses centésimales figurent au tableau 9.

Synthèse des pyrroles 7

L'aziridine **1** (1 g) et l'ACDM en quantité stoechiométrique sont portés à l'ébullition dans 30 cm^3 de toluène anhydre, pendant 24 h. Le

solvant est distillé et le résidu dissous dans le minimum de méthanol. Par refroidissement, le produit d'addition cristallise; il est essoré, lavé puis séché. Les caractéristiques des pyrroles ainsi que les rendements sont consignés dans le tableau 10; leurs analyses centésimales sont rassemblées dans le tableau 11.

Synthèse du dihydrofurane 9d *(X = NO_2)*

L'époxyde **4***d* (1 g) est additionné à 0,66 g d'ACDM dans 30 cm^3 de xylène anhydre. La solution est portée à reflux pendant 30 h. Après distillation du solvant, le résidu est dissous dans le minimum de méthanol chaud. Par refroidissement, le dihydrofurane **9***d* précipite.

Après recristallisation dans le méthanol, il fond à 124–125°C; ir: 1744 et 1758 cm^{-1} (νC═O ester), 2250 (νC≡N); rmn ($CDCl_3$): 3,85 et 4,05 (s, méthyles ester), 6,95 (H, s). *Anal.* calc. pour $C_{16}H_{11}N_3O_7$: C 53,78, N 11,77, O 31,37; tr.: C 53,50, N 11,70, O 31,48.

Solvants et ACDM

Les solvants utilisés pour les études cinétiques sont purifiés selon les méthodes décrites dans la littérature (25) et utilisés fraîchement distillés.

L'ACDM est un produit commercial Fluka purissimum.

Méthodes d'analyse

L'infra-rouge

L'appareil utilisé est un spectrophotomètre Perkin–Elmer 457 à double faisceau. La longueur d'onde est celle de la bande d'absorption du nitrile, vers 2240 cm^{-1}.

Après avoir vérifié que les aziridines **1** suivent la loi de Lambert–Beer, une courbe d'étalonnage est établie pour chaque cas.

La solution est préparée par dissolution de l'aziridine dans 9 cm^3 de solvant contenant l'ACDM à la concentration de 8×10^{-4} mol L^{-1}. La concentration initiale en aziridine est mesurée par ir, elle est déduite de la courbe d'étalonnage, elle est choisie de façon à obtenir une densité optique initiale D_0 voisine de 0,75. Suivant l'aziridine, la concentration varie de 0,2 à $0,4 \times 10^{-4}$ mol L^{-1}. Cette solution est partagée en 10 fractions qui sont placées dans des tubes en verre de 2 cm^3. Ces derniers sont scellés et placés au temps $t = 0$ dans un bain thermostaté. Les tubes, prélevés au cours du temps sont refroidis immédiatement dans l'azote liquide et dosés par ir.[3]

Nous avons vérifié pour chaque aziridine qu'elle ne se dégrade pas au cours du temps à la température de l'expérience. Pour celà, l'aziridine est placée dans un tube témoin, sans ACDM, dans les mêmes conditions de T (°C), concentration et solvant. Le dosage ir permet de s'assurer que la dégradation est négligeable aux températures utilisées.

Détermination expérimentale de k_{ex}

La vitesse globale de la réaction d'ouverture est d'ordre 1 par rapport à la concentration en aziridine, elle s'exprime à l'aide de l'éq. [3]

$$[3] \quad v = \frac{dx}{dt} = k_{ex}[\mathrm{Az}]$$

À l'instant $t = 0$, $[\mathrm{Az}] = [\mathrm{Az}]_0$ et l'expression peut s'écrire:

$$[5] \quad \frac{dx}{[\mathrm{Az}]_0 - x} = k_{ex}\, dt$$

et

$$\log [\mathrm{Az}]_0 - \log ([\mathrm{Az}]_0 - x) = k_{ex}\, t$$

En appliquant la loi de Beer–Lambert, nous pouvons écrire:

$$[6] \quad \log D = \log \epsilon\, l + \log [\mathrm{Az}]$$

D étant la densité optique, ϵ le coefficient d'extinction, et l la largeur de la cuve. À $t = 0$:

$$[7] \quad \log D_0 = \log \epsilon\, l + \log [\mathrm{Az}]_0$$

En comparant les équations [5] et [7], on en déduit l'éq. [8].

$$[8] \quad \log D_0 - \log D = k_{ex}t$$

La constante expérimentale de vitesse est déterminée graphiquement à partir de la pente de la droite $-\log D = f(t)$; elle est précisée par un calcul de régression linéaire. Dans tous les cas, le coefficient de correlation est de l'ordre de 0,999.

[3] L'ouverture des aziridines **1** en ylures d'azométhine est négligeable à la température ambiante, l'addition à l'ACDM ne se produit que lorsque la solution est mise dans le bain thermostaté. Aussi, après refroidissement, la solution peut être conservée au froid plusieurs heures avant d'effectuer le dosage ir.

TABLEAU 13. Détermination des constantes globales d'équilibre de l'addition de **2***c* à l'ACDM à différentes températures

$$2c + \mathrm{ACDM} \underset{K_{-1}}{\overset{K_1}{\rightleftharpoons}} \text{pyrroline-3}$$

T (°C):	60	78,5	105	121,2	138,5
$K = \dfrac{K_1}{K_{-1}}$:	1,20	1,24	1,25	1,48	1,54

Méthode chromatographique

L'appareil utilisé est un Waters 440, ayant un système de détection uv à 254 nm. Les références des colonnes utilisées, de longueur 30 cm, ainsi que les éluants sont donnés dans le tableau 12.

Le facteur de sensibilité de l'appareil est donné par la relation [9], il est déterminé pour chaque produit.

$$[9] \quad f_p = \frac{A_p}{A_i} \cdot \frac{m_i}{m_p}$$

m_p: masse du composé p (g), m_i: masse de l'étalon interne, A_p: surface de pic du composé, A_i: surface de pic de l'étalon interne. Connaissant différentes masses m_i, m_p et leurs surfaces correspondantes, on en déduit f_p.

La quantité d'aziridine (tableau 12) pesée exactement est dissoute dans 5 cm^3 de solution, 0,5 cm^3 est utilisé comme référence et dans le reste de la solution, on ajoute en excés (10:1) la quantité d'ACDM. Cette solution est répartie dans 10 tubes en verre qui sont scellés et plongés à $t = 0$ dans un bain thermostaté à la température désirée.

Les tubes sont prélevés à différents temps et refroidis dans l'azote liquide. Ensuite ils sont dosés après y avoir ajouté une quantité bien déterminée d'étalon interne.

Notre choix s'est porté sur le méthacrylate de dodécyle qui a un volume de rétention très différent des produits réactionnels. Nous avons préféré ajouter l'étalon interne après réaction pour éviter de fausser l'effet du solvant. Mais il est vrai que les erreurs engendrées par cette manière d'opérer ne sont pas négligeables, et nous avons comparé la précision des mesures à celle obtenue par un dosage statistique (injection d'une même quantité de solution à plusieurs reprises) en mesurant directement la surface du pic. Il s'est avéré, après calcul de régression linéaire, que la précision des mesures par ces deux méthodes était comparable.

Cas particulier: L'addition de l'ACDM à l'aziridine **2***c* est réversible et équilibrée. Dans le tableau 13 nous avons rassemblé les constantes d'équilibre à différentes températures. La variaiton de $-\log [\mathrm{Az}] = f(t)$ permet d'obtenir k_1 en prenant la tangente à l'origine de la courbe représentative. La variation de $\log [\mathrm{Az}]_e/[\mathrm{Az}_e - \mathrm{Az}] = f(t)$ permet de calculer k_{-1}, qui correspond à la constante de vitesse de cycloréversion.

Six-bond ^{1}H,^{1}H and ^{1}H,^{19}F spin coupling constants as indicators of geometry in aniline and *p*-fluoroaniline

TED SCHAEFER AND GLENN H. PENNER
Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received November 16, 1984

TED SCHAEFER and GLENN H. PENNER. Can. J. Chem. **63**, 2253 (1985).

The long-range coupling constants between amino protons and the ring proton or fluorine nucleus in the *para* position of aniline and *p*-fluoroaniline imply that, in benzene solution, the geometry at the amino group is very similar in the two compounds. The ratio of the two coupling constants is consistent with potential functions for inversion at nitrogen derived from far infrared data, but inconsistent with microwave spectra which indicate that the angle defining the intersection of the amino and benzene planes differs by 9° in these two compounds.

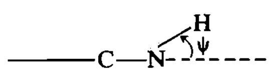
TED SCHAEFER et GLENN H. PENNER. Can. J. Chem. **63**, 2253 (1985).

Les constantes à longue distance entre les protons du groupe amino et les protons du cycle ou les noyaux de fluor en position *para* de l'aniline et de la *p*-fluoroaniline impliquent que, en solution dans le benzène, la géométrie du groupe amino de chacun de ces deux composés est très semblable. Le rapport entre les deux constantes de couplage est en accord avec les fonctions de potentiel pour l'inversion au niveau de l'azote que l'on peut dériver à partir de données obtenues par des spectres dans l'infrarouge lointain; toutefois le rapport n'est pas en accord avec les spectres de microondes qui indiquent que l'angle défini par l'intersection entre le plan du groupe amino et celui du benzène diffère de 9° dans ces deux composés.

[Traduit par le journal]

Introduction

The nonplanarity of aniline, **1**, is well established (1–6). Considered as a derivative of pyramidal ammonia, this nonplanarity is entirely reasonable and can be defined by the angle in **1***a*, measuring the intersection between the HNH and benzene planes. The corresponding angle in ammonia itself is



1*a*

53.8°, corresponding to the equilibrium configuration (7). Conjugation of the lone pair on nitrogen with the π electron system of the aromatic nucleus leads to a decrease of ψ relative to its value in ammonia. A rather full substitution structure for aniline in the gas phase yields ψ as 37.5 ± 2°, the error indicating the difficulty with which the amino hydrogen atoms are determined from microwave spectroscopy (4). Ultraviolet absorption (2) and fluorescence (3) spectra of aniline imply 47° and 42°, respectively, for ψ, and the spectra for aniline in argon matrices suggest a lowering of ψ. Far infrared gas spectra of aniline (5) are used to deduce a ψ of 42.2°, together with a potential for the inversion at nitrogen. The barrier to inversion of 6.3 kJ/mol agrees very well with that obtained from another study of the far infrared spectrum (6).

The presence of a substituent in the *para* position should alter the extent of conjugation across the C—N bond in aniline and therefore should cause a change in ψ. Fluorine is a π electron donor. Consequently, in *p*-fluoroaniline, **2**, ψ should be larger than in aniline and, indeed, the microwave spectra of this compound (8) and its NHD isotopic derivative are interpreted to mean that ψ is 46.4°. This corresponds to a change of 9° relative to aniline and, at first sight, appears rather large. The far infrared spectrum (5) yields ψ as 42.7°; in the same work that gave 42.2° for aniline. By way of comparison, the microwave spectra of six isotopic species of *p*-chloroaniline imply ψ as 42.5° (9). A study of *p*-bromoaniline partly oriented in a nematic solvent suggests that ψ is 40.2° and that it is 33.4° for *p*-nitroaniline (10). STO 3G MO calculations indicate very small differences in ψ for aniline and *p*-fluoroaniline (11). Our own optimized geometries yield ψ near 52° for **1** and **2**. It is well known that rather larger basis sets are needed if a correct geometry is to be calculated at nitrogen in ammonia and its derivatives (12, 13).

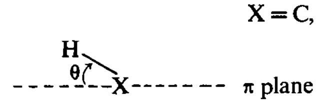
MINDO computations indicate that ψ increases by 3° in the presence of a *p*-fluoro substituent (14). A correlation of $^1J(^1\mathrm{H},^{15}\mathrm{N})$ values and the N—H stretching frequencies places *p*-fluoroaniline well on the regression line (15). However, when its microwave geometry is used to calculate the bond order of the N—H bond, *p*-fluoroaniline deviates significantly from the correlation between the bond order and $^1J(^1\mathrm{H},^{15}\mathrm{N})$. This result is reasonable because $^1J(^1\mathrm{H},^{15}\mathrm{N})$ is -78.6 ± 0.2 Hz for aniline in chloroform solution (16) and -78.9 Hz in benzene solution (17), and changes very little, to -77.8 ± 0.2 Hz (16) for *p*-fluoroaniline in chloroform solution, the same value we measure in benzene solution. $^1J(^1\mathrm{H},^{15}\mathrm{N})$ is linearly related to the hybridization at nitrogen (18), % *s* character = $-0.43\ ^1J(^1\mathrm{H},^{15}\mathrm{N}) - 6$, so that the couplings imply only a small change in geometry at nitrogen in **1** and **2**.

Long-range couplings and amino group geometry

Because of the disagreement among the various approaches to the determination of ψ and because the geometry may well be different in solution and the vapor phase, it appears useful to examine other molecular properties which depend on the geometry of the molecule. One such property is the long-range coupling interaction between nuclei, transmitted by the intervening electrons.

For example, in toluene the coupling over six formal bonds between methyl protons and the ring proton in the *para* position, $^6J^{\mathrm{H,H}}$, is -0.62 Hz (19). It can be written (20) as $^6J^{\mathrm{H,H}} = {}^6J_{90}^{\mathrm{H,H}} \langle \sin^2 \theta \rangle$, where $^6J_{90}$ is the value at $\theta = 90°$ in **3** and $\langle \sin^2 \theta \rangle$ is the expectation value of $\sin^2 \theta$. This quantity can be

X = C, N, etc.



3

calculated, classically or quantum mechanically (21), if the potential function for the internal rotation about the exocyclic C—C bond is known. Alternatively, if ${}^6J_{90}^{\mathrm{H,H}}$ is known and ${}^6J^{\mathrm{H,H}}$ is measured, then $\langle \sin^2 \theta \rangle$ can be used to find the internal barrier. In toluene the latter is only 0.058 kJ/mol, $\langle \sin^2 \theta \rangle$ becomes 0.5 at ambient temperatures, and ${}^6J_{90}$ is therefore -1.24 Hz.

In *p*-fluorotoluene, ${}^6J^{\mathrm{H,F}}$ is 1.15 Hz (22, 23). Because ${}^6J^{\mathrm{H,H}}$ and ${}^6J^{\mathrm{H,F}}$ are examples of $\sigma-\pi$ couplings (23), they can be expressed as ${}^6J^{\mathrm{H,H}} \propto Q_{\mathrm{CCH}}^{\mathrm{H}} Q_{\mathrm{CH}}^{\mathrm{H}}$ and ${}^6J^{\mathrm{H,F}} \propto Q_{\mathrm{CCH}}^{\mathrm{H}} Q_{\mathrm{CF}}^{\mathrm{F}}$. In these expressions, $Q_{\mathrm{CH}}^{\mathrm{H}}$ represents the hyperfine coupling parameter (spin polarization) determining the magnitude of the interaction between an electron spin in the π system and the proton in the C—H bond, $Q_{\mathrm{CF}}^{\mathrm{F}}$ is the analogous quantity for a C—F bond, and $Q_{\mathrm{CCH}}^{\mathrm{H}}$ represents the β-interaction for the CH bond in the sidechain with the π electrons. It is the latter quantity which introduces the θ dependence of ${}^6J$. For toluene and *p*-fluorotoluene, then, ${}^6J^{\mathrm{H,H}}/J^{\mathrm{H,F}} = -0.62/1.15 = -0.539 \propto Q_{\mathrm{CH}}/Q_{\mathrm{CF}}$. A similar result should hold for **1** and **2**. A study of radicals containing aniline and *p*-fluoroaniline adducts suggests $Q_{\mathrm{CF}}^{\mathrm{F}} \sim -2Q_{\mathrm{CH}}^{\mathrm{H}}$ (24). In **1** in benzene-d_6 solution (17), ${}^6J^{\mathrm{H,H}}$ is $-0.137(3)$ Hz while ${}^6J^{\mathrm{H,F}}$ for **2** in benzene-d_6 solution is $+0.26(2)$ Hz; both numbers are measured at 305 K. Their ratio is -0.523, a hint that perhaps the ground state geometry is very similar for the two molecules in benzene solution.

A more quantitative approach goes as follows. The angle ψ is related to the angle θ to a good approximation by $\tan \theta = \mathrm{ctn}(\phi/2) \sin \psi$ in which φ is the HNH bond angle (12). Now, because the barrier to rotation about the C—N bond in **1** and **2** is near 21 kJ/mol (5), the dependence of $\langle \sin^2 \theta \rangle$ on torsion about this bond is very small at 305 K (21). Accordingly, we calculate $\langle \sin^2 \theta \rangle$ for the available potential functions given by Larsen *et al.* (5). These are $V(\psi)$ (kJ mol^{-1}) $= 138.8(1 - \cos \psi) \times 46.8(1 - \cos 2\psi)$ for aniline and $148.8(1 - \cos \psi) - 50.6(1 - \cos 2\psi)$ for *p*-fluoroaniline. These functions are evaluated at intervals of 5° and a classical averaging procedure yields $\langle \sin^2 \theta \rangle$ as 0.148_4 and 0.154_1 for **1** and **2**, respectively, at 350 K. The value of θ is derived for a given ψ from the above formula and φ is estimated from a fit of values of φ and ψ known at ψ = 0, 38, 46, and 53.8°. The fit is $\phi = 120.6 - 4.44 \times 10^{-3} \psi^2$ and is sufficiently accurate for our purposes.

The ratio of the $\langle \sin^2 \theta \rangle$ values is 0.963 and implicitly assumes values of ψ of 42.2° and 42.7° at the minimum of the potentials above. Again, the corresponding ratio involving ${}^6J^{\mathrm{H,H}}$ and ${}^6J^{\mathrm{H,F}}$ is $({}^6J^{\mathrm{H,H}}/J^{\mathrm{H,F}})\,({}^6J_{90}^{\mathrm{H,F}}/{}^6J_{90}^{\mathrm{H,H}}) = (-0.137/0.264)(2.30/-1.24) = 0.963$. Here ${}^6J_{90}^{\mathrm{H,F}}/{}^6J_{90}^{\mathrm{H,H}}$ is equivalent to $Q_{\mathrm{CH}}^{\mathrm{H}}/Q_{\mathrm{CF}}^{\mathrm{H}}$ and is derived from toluene, as discussed above.

The good agreement is emphasized by the following comparison. If it were assumed that the equilibrium ψ values of 42.2° and 42.7° for **1** and **2** defined rigid molecules, then $\sin^2 \theta$ would be 0.166_5 and 0.170_5. These numbers are about 10% larger than the more precise $\langle \sin^2 \theta \rangle$ values found from the averaging procedure. If the ψ values for **1** and **2** differed by 9° in solution, then (using 38° and 46°) an estimated corrected ratio of $\langle \sin^2 \theta \rangle$ values for the two molecules would be 0.664 and not 0.963.

Now, the present arguments are not meant to imply that ψ is nearly 42° for both molecules in solution, *only* that ψ must have very similar values in solution. A full substitution structure for *p*-fluoroaniline in the gas phase would be of interest.

A check on the $\sigma-\pi$ nature of ${}^6J^{\mathrm{H,H}}$ and ${}^6J^{\mathrm{H,F}}$, which should vanish at θ = 0°, is available from the unobservable ${}^6J^{\mathrm{H,H}}$ in 2,6-dibromoaniline (25), the ±0.08 ± 0.02 Hz for ${}^6J^{\mathrm{H,F}}$ in 2,4,6-trifluoroaniline (see below), and the unobservable ${}^6J^{\mathrm{H,F}}$ in 2,6-dibromo-4-fluoroaniline. The *ortho* substituents cause a flattening of the pyramid at nitrogen, as indicated by ${}^1J({}^1\mathrm{H},{}^{15}\mathrm{N})$, probably because of intramolecular hydrogen bonding. The difference of 1 Hz in the ${}^1J({}^1\mathrm{H},{}^{15}\mathrm{N})$ in the two molecules can be accommodated by a difference of 0.4 in the % *s* character at nitrogen (18), corresponding to a change of 0.6° in the HNH bond angle, which, in the vicinity of 40°, translates into a change of 1.5° in ψ. That is, ${}^1J({}^1\mathrm{H},{}^{15}\mathrm{N})$ is consistent with only a slightly larger value of ψ in *p*-fluoroaniline. The far infrared spectra in the gas phase imply a difference of 0.5° in ψ. Both these values are consistent with ${}^6J^{\mathrm{H,H}}$ and ${}^6J^{\mathrm{H,F}}$.

Also consistent with similar ψ values in the two compounds are the ${}^5J^{\mathrm{H,H}}$ of 0.296(3) and 0.300(2) Hz in aniline and *p*-fluoroaniline. It is very likely that ${}^5J^{\mathrm{H,H}}$ can be written as $A\langle \sin^2 \theta \rangle + B\langle \sin^2 \theta/2 \rangle$, just as for toluene (26) and thiophenol (27). Consequently a difference of 9° in ψ should yield rather different ${}^5J^{\mathrm{H,H}}$ numbers because θ changes by 4° for such a change in ψ. Near ψ = 40°, the ratio of the $\langle \sin^2 \theta \rangle$ values would be 0.76 and a significant difference in ${}^5J^{\mathrm{H,H}}$ would be expected. Similar remarks hold for the ${}^4J^{\mathrm{H,H}}$ values of $-0.189(3)$ and $-0.209(2)$ Hz for **1** and **2**, although the θ dependence of ${}^4J^{\mathrm{H,H}}$ is somewhat more ambiguous.

Finally, it may be noted that our INDO MO FPT computations of ${}^6J^{\mathrm{H,H}}$ in **1** and of ${}^6J^{\mathrm{H,F}}$ in **2** yield a $\sin^2 \theta$ dependence and that ${}^6J_{90}^{\mathrm{H,H}}$ is -1.08 ± 0.10 Hz for a statistical fit and ${}^6J_{90}^{\mathrm{H,F}}$ is 1.68 ± 0.05 Hz. The $\langle \sin^2 \theta \rangle$ value of 0.148_4 obtained for **1** from the potential functions above implies a ${}^6J_{90}^{\mathrm{H,H}}$ of -1.08 Hz. For **2** $\langle \sin^2 \theta \rangle$ was found as 0.154_1 above and suggests a ${}^6J_{90}^{\mathrm{H,F}}$ of 0.262/0.154 or 1.70 Hz, probably in accidental agreement with the INDO result because INDO MO FPT calculations underestimate ${}^6J_{90}^{\mathrm{H,F}}$ in *p*-fluorotoluene (20).

Conclusions

The long-range nuclear spin–spin coupling constants for aniline and *p*-fluoroaniline in benzene-d_6 solution imply very similar amino group geometries in the two molecules. This result is consistent with the interpretation of the far infrared spectra of these molecules in the gas phase and, in quantitative detail, with the potential functions for inversion derived from the infrared data. Apparently, intermolecular association or perturbations in solution do not significantly alter the geometry nor the inversion rates, perhaps because the nuclear (proton) motions involved in the inversion can proceed with minimal changes in the effective volume of the molecules.

However, the microwave spectrum of *p*-fluoroaniline suggests rather a large change in the geometry at nitrogen relative to aniline. If a full substitution structure were to bear out this suggestion, then the agreement between nmr and infrared data above would presumably be coincidental.

Experimental

p-Fluoroaniline, **2**, 2,4,6-trifluoroaniline, **4**, and 2,4-difluoroaniline came from Aldrich Chemical Co. Bromination of the latter compounds yielded 2-bromo-4,6-difluoroaniline, **5**. Solutions (5 mol%) of **2**, **4**, and **5** were prepared in benzene-d_6 solution. Intermolecular amino proton exchange was retarded as described previously (17). Samples contained a drop of tetramethylsilane and were transferred to 5-mm od nmr tubes. The samples were degassed by the freeze–pump–thaw procedure and were flame sealed.

The ^{1}H and ^{19}F nmr spectra were recorded with a Bruker WH-90-DS at a probe temperature of 305 K and in a manner recently described in detail (28). The sign of ${}^6J^{\mathrm{H,F}}$ in **2** was determined by weak ${}^{19}\mathrm{F}\{{}^1\mathrm{H}\}$ irradiation experiments (29) which showed that ${}^6J^{\mathrm{H,F}}/{}^5J^{\mathrm{H,NH}} > 0$.

TABLE 1. The ^{1}H and ^{19}F spectral parameters for a 5 mol% solution of *p*-fluoroaniline, **2**, in benzene-d_6 at 305 K

Parameter	Value	Parameter	Value
ν_{amino}	300.0	$^{4}J^{H,NH}$	−0.209(2)
$\nu_2 = \nu_6$	546.569(1)[a]	$^{5}J_{25}$	0.357(1)
$\nu_3 = \nu_5$	603.656(1)[a]	$^{5}J^{H,NH}$	0.300(2)
$^{3}J_{23}$	8.743(2)[b]	$^{6}J^{F,NH}$	0.262(2)
$^{3}J_{34}$	8.523(2)	Transitions calcd.	256
$^{4}J_{24}$	4.474(2)	Transitions assigned	189
$^{4}J_{26}$	2.990(2)	Largest difference	0.028
$^{4}J_{35}$	2.987(2)	Root mean square error	0.010

[a]In Hz at 90.023 MHz relative to internal TMS. The ^{19}F spectrum was recorded at 84.700 MHz.
[b]The numbers in parentheses are the standard deviations from the NUMARIT analysis. No amino proton transitions were assigned, of course.

$^{5}J^{H,NH}$ is positive (30). For **4**, decoupling experiments and linewidth simulations demonstrated that $^{6}J^{H,F} = \pm 0.08 \pm 0.01$ Hz. For **5** no broadening of the F-4 spectrum due to $^{6}J^{H,F}$ could be detected and $^{6}J^{H,F}$ must be less than 0.05 Hz in magnitude.

The ^{1}H and ^{19}F nmr spectra of **2**, **4**, and **5** were analyzed with the computer programs LAME (31, 32) and NUMARIT (33). Table 1 gives the spectral data for **2** and shows the precision obtained in the analyses. Amino proton transitions were not assigned in any of the analyses because the ^{1}H nmr spectra of these protons are broad bands caused by intermediate rates of spin-lattice relaxation of the quadrupolar ^{14}N nucleus.

The conformational behaviour of 2-fluoro and of 2,6-difluoroacetophenone implied by proximate spin–spin coupling constants and MO calculations

TED SCHAEFER, GLENN H. PENNER, TIMOTHY A. WILDMAN, AND JAMES PEELING[1]

Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received December 12, 1984

TED SCHAEFER, GLENN H. PENNER, TIMOTHY A. WILDMAN, and JAMES PEELING. Can. J. Chem. **63**, 2256 (1985).

The temperature dependence of ${}^5J_o^{\mathrm{F,CH_3}} \equiv {}^5J$, the nuclear spin–spin coupling constant over five formal bonds between the methyl protons and the ^{19}F nucleus in 2-fluoroacetophenone and 2,6-difluoroacetophenone, is modelled on the assumption that ${}^5J$ is a proximate coupling and that the STO 3G MO potential functions describe the population distributions of the rotamers defined by rotation about the exocyclic sp^2–sp^2 carbon–carbon bond. It is assumed that ${}^5J$ has a $\cos^4\theta$ dependence between 0 and 90°, where θ is the angle by which the acetyl group twists out of the plane of the benzene plane. The potential function is obtained from extensive geometry optimization procedures for a range of θ values. At 305 K, nonplanar conformations are substantially populated in 2-fluoroacetophenone, according to this model, which is also consistent with the idea that the 2,6-difluoro derivative has a markedly nonplanar ground state. The model reproduces the large ${}^5J$ in the monofluoro relative to the difluoro compound, as well as the much larger temperature dependence in the former.

TED SCHAEFER, GLENN H. PENNER, TIMOTHY A. WILDMAN et JAMES PEELING. Can. J. Chem. **63**, 2256 (1985).

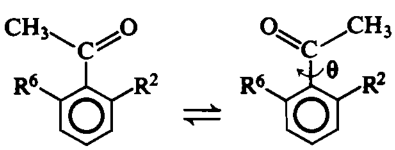
On explique l'effet de la température sur les constantes de couplage nucléaire ${}^5J_o^{\mathrm{F,CH_3}} \equiv {}^5J$, à travers 5 liaisons formelles entre les protons du méthyle et le noyau de ^{19}F de la fluoro-2 acétophénone et de la difluoro-2,6 acétophénone, en se basant sur l'hypothèse que ${}^5J$ est un couplage dû à un effet de proximité et que les fonctions de potentiel des orbitales moléculaires STO 3G décrivent bien les distributions de population des rotamères définis par la rotation autour de la liaison exocyclique carbone–carbone sp^2–sp^2. On suppose que, entre 0 et 90°, il existe une relation entre ${}^5J$ et le $\cos^4\theta$, où θ est l'angle formé par le plan du groupe acétyle et le plan du benzène. On obtient la fonction de potentiel à partir de méthodes étendues d'optimisation de la géométrie pour une large échelle de valeurs de θ. À 305 K, ce modèle suggère que les proportions de fluoro-acétophénone qui existent dans des conformations qui ne sont pas planes sont assez importantes; ceci est également en accord avec l'idée que l'état fondamental du dérivé difluoro-2,6 est nettement non planaire. Le modèle reproduit l'importante valeur de ${}^5J$ du composé monofluoré par rapport au composé difluoré ainsi que l'effet beaucoup plus grand de la température dans le cas du composé monofluoré.

[Traduit par le journal]

Introduction

The conformational preference of the acetyl group in 2-fluoroacetophenone, **2**, has been discussed extensively (1–7). For the parent compound, **1**, an adequate discussion has been done in terms of a **1***a* ⇌ **1***b* equilibrium (8–11) at ambient or lower temperatures. The barrier to rotation about the

1 $R^2 = R^6 = H$
2 $R^2 = F$, $R^6 = H$
3 $R^2 = R^6 = F$



θ = 180° — *a*; θ = 0° — *b*

Csp^2—Csp^2 exocyclic bond is estimated as 13 kJ/mol from torsional frequencies in the vapor (12) and as 22.4 kJ/mol from dynamic nmr experiments in solution (13). For **2**, various techniques purport to find preferences ranging from all *a* (1), through markedly nonplanar froms (5*a*, *b*) intermediate between *a* and *b*, to a possibly all *b* (3, 7). A recent paper (7) reviews the previous work and, on the basis of dipole moment and Kerr constant measurements in CCl_4 solution, concludes that *b* is present to the extent of 95 ± 5% at 298 K and that the angle of twist, θ, about the exocyclic Csp^2—Csp^2 bond is 10 ± 10°. This conclusion assumes the same out-of-plane angles in *a* and *b*.

For 2,6-difluoroacetophenone, an estimate of 40° for θ is based on ^{19}F nmr chemical shifts (5*a*), but is predicated on a value of 33 to 40° for θ in 4-fluoroacetophenone. The latter value is intuitively doubtful in that the π electron donating fluorine substituent should increase the double bond character of the exocyclic C—C bond. Now, one of the most striking properties of the ^{1}H nmr spectrum of **2** is the large magnitude of the formally five-bond coupling, ${}^5J_o^{\mathrm{F,CH_3}}$, between the methyl protons and the *ortho* ^{19}F nucleus. It is reported as 4.80 Hz at 305 K in $CDCl_3$, C_6D_6, and $C_6D_5CD_3$ solutions, and as 4.20 Hz in DMSO at 305 K (14). In $C_6D_5CD_3$ solution, ${}^5J_o^{\mathrm{F,CH_3}}$ is 6.50 Hz at 203 K and 4.20 Hz at 383 K (15). It is also reported as 6.2 Hz at 210 K and 4.1 Hz at 423 K, but it is unclear in what solvent these couplings were obtained (4). In a 30 mol% solution in $(CH_3)_2C{=}O$, ${}^5J_o^{\mathrm{F,CH_3}}$ is 4.72 Hz (2) at about 300 K.

${}^5J_o^{\mathrm{F,CH_3}} \equiv {}^5J$ in **2** is assumed (14) to be a "through-space" or proximate coupling. Such couplings are remarkably sensitive to the distance between the bonds carrying the coupled nuclei (16, 17) and hence ${}^5J$ is taken as evidence for a preponderance of *b* in the *a*/*b* equilibrium (2, 4, 15). It is also suggested (15) that the observed ${}^5J$ is a measure of this equilibrium, although ${}^5J_a$ and ${}^5J_b$ are as yet unknown.

One difficulty with the application of such an assumption is the distance sensitivity of proximate coupling mechanisms. Thus, a thorough theoretical study (18) of the proximate coupling, ${}^5J_o^{\mathrm{H,CH_3}}$, in anisole and its comparison with experiment (18, 19) shows that its magnitude drops rapidly as the methyl group twists out of the benzene plane. When the angle of twist about the Csp^2—O bond reaches about 60°, ${}^5J_o^{\mathrm{H,CH_3}}$ is very nearly zero. If ${}^5J_o^{\mathrm{F,CH_3}}$ behaves in a similar manner, then a simple *a*/*b* equilibrium no longer suffices as a model because values of θ other than zero, as in *b*, and 180°, as in *a*, must surely be represented at temperatures above absolute zero.

[1] Present address, University of Petroleum and Minerals, Saudi Arabia.

In this paper, certain assumptions about the θ dependence of ^5J together with MO calculations of $V(\theta)$, the potential function for the conformation of the acetyl group, are combined with the observed temperature dependence of ^5J, to show that a simple a/b equilibrium is an inadequate description for **2**. True, b is the low-energy form for **2**, but many other conformers corresponding to various θ values are appreciably populated at temperatures between 180 and 423 K. For **3**, similar considerations also provide an estimate of θ for the preferred nonplanar conformation of the acetyl moiety.

Experimental

Unlabelled and methyl-^{13}C-enriched 2-fluoroacetophenone were obtained by addition (20) of 2-fluorobenzaldehyde (Aldrich) to ethereal methyl magnesium iodide to yield 1-(2-fluorophenyl) ethanol. A solution of the crude alcohol in CH_2Cl_2 was added to a mixture of pyridinium chlorochromate (21) in CH_2Cl_2, and the crude product of 2-fluoroacetophenone, **2**, was chromatographed on silica gel plates with hexanes containing a small amount of ether. The product contained some residual 2-fluorobenzaldehyde, but was used without further purification, spectral analysis proceeding without difficulties. The 2,6-difluoroacetophenone, **3**, came from Maybridge and the 2,3,4,5,6-pentafluoroacetophenone from Fairfield. Methyl iodide (95% ^{13}C) was obtained from Stohler.

Solutions for nmr analysis were prepared by weight in acetone-d_6, were transferred to 5-mm od nmr tubes by filtering through cotton wool, and were degassed by eight freeze–pump–thaw cycles before the tubes were flame sealed.

The ^{1}H nmr spectrum of a 4.9 mol% solution of 2-fluoroacetophenone-α-^{13}C was calibrated at a probe temperature of 305 K on an HA100 nmr spectrometer by a procedure whose details have been described (22). The ^{1}H nmr spectrum of a 5.3 mol% solution of 2-fluoroacetophenone was accumulated on a pulsed Bruker WH90 instrument at 305 K, again by methods previously described (22).

Weak double irradiation experiments (23) on the enriched **2**, in which the ^{1}H nmr peaks of the methyl protons were perturbed while observing the ^{19}F nmr spectrum, demonstrated that $^1J(^1\text{H},^{13}\text{C})/^4J(^{13}\text{C},^{19}\text{F}) > 0$. Since $^1J(^1\text{H},^{13}\text{C})$ is positive (24), so is $^4J(^{13}\text{C},^{19}\text{F})$. A second set of experiments involved the observation of the methyl ^{13}C nmr spectrum while the transitions of the methyl ^{1}H nmr spectrum were weakly perturbed. It followed that $^4J(^{13}\text{C},^{19}\text{F})/^5J(^1\text{H},^{19}\text{F})$ was positive. Consequently the proximate coupling $^5J(^1\text{H},^{19}\text{F}) = {}^5J_o^{\text{F,CH}_3} \equiv {}^5J$ is positive.

The ^{1}H spectrum of a 3 mol% solution of 2,6-difluoroacetophenone, **3**, was accumulated at 90 MHz and at a probe temperature of 305 K. The ^{19}F nmr spectrum was also recorded.

Variable temperature experiments employed the Bruker B-ST100/700 temperature controller and the digital resolution was about 0.05 Hz/real point. Samples were equilibriated for at least 15 min at each temperature. The temperature control unit was calibrated with a copper–constantan thermocouple immersed in CH_2Cl_2 between 170 and 305 K.

STO 3G MO computations (25) utilized an Amdahl 470/V8 system with the program MONSTERGAUSS (26). INDO MO FPT calculations (27) of spin–spin coupling constants were also performed using the program FINDO,[2] a version (28) of CNINDO/74 (29) containing numerous options including the modification of Fock matrix elements.

Results and discussion

Spectral analyses

The ^{1}H nmr spectra of **2** at 90 and 100 MHz were both analyzed with the computer program LAME (30, 31). As many as 873 transitions were assigned in these analyses, the standard deviations in the spectral parameters all being below 0.005 Hz.

260	4.97	1.63	192	5.88	1.76$_5$
250	5.09	1.65	182	5.99	—
240	5.21	1.66			

^{a} Accurate to at least 1 K.
^{b} For a 4.9 mol% solution in acetone-d_6.
^{c} For a 3 mol% solution in acetone-d_6.
^{d} These numbers are reproduced by the equation ^5J (Hz) = $8.15_2 - 0.012_1\,T$ (r = 0.9971).
^{e} These numbers are reproduced by ^5J (Hz) = $2.11_1 - 1.83_9 \times 10^{-3}\,T$ (r = 0.9971).
^{f} For a 4.7 mol% solution of pentafluoroacetophenone in acetone-d_6, ^5J is 1.887, 1.861, 1.823, and 1.777 Hz at 280, 290, 305, 315, and 325 K, respectively. These numbers are reproduced by ^5J (Hz) = $2.57_1 - 2.44_7 \times 10^{-3}\,T$ (r = 0.9996).

These parameters are not reproduced here because previous values are available (4). However, ^5J was +4.48(2) Hz for the enriched sample and 4.510(1) Hz for the unenriched. The former gave $^1J(^1\text{H},^{13}\text{C})$ as 128.246(2) Hz, while $^5J(\text{H-5},^{13}\text{C})$ and $^4J(\text{H-6},^{13}\text{C})$ were ± 0.399(2) and ±0.105(2) Hz, respectively, and of the same sign, as determined by $^1\text{H}\{^1\text{H}\}$ experiments.

The ^{1}H and ^{19}F nmr spectra of **3** were analyzed, assigning a total of 474 transitions. Only $^5J_p^{\text{H,F}}$ differed by more than 0.1 Hz from a previous analysis (32), the present value being −1.183(2) Hz. For the 3 mol% solution in acetone-d_6, the ^{19}F chemical shift is 50.15 ppm to low field of internal C_6F_6 at 305 K.

The analyses confirm that the identification of ^5J with the observed splitting of the methyl ^{1}H nmr peaks in **2** and **3** is valid and therefore that the measured temperature dependence of ^5J from splittings is reliable.

The temperature dependence of $^5\text{J} \equiv {}^5\text{J}_o^{\text{F,CH}_3}$

Table 1 presents ^5J as a function of temperature for **2** and **3**. The coupling increases as the temperature decreases, as anticipated for a proximate coupling if the drop in temperature entails a decreased average distance between the methyl group and the C—F bond. The simplest approach to the data for **2** assumes a two-site equilibrium, say a/b, with a temperature independent energy difference between a and b. A good fit[3] of ^5J to K^{-1} is found, with a rms deviation of 0.01_1 Hz for 13 points between 182 and 305 K. The model yields a value of $3.1_4 \pm 0.2_6$ kJ/mol for the energetic preference of conformer b, an intuitively reasonable value. However, it also gives ^5J as $7.4_9 \pm 0.2_2$ Hz for b and $-5.8_2 \pm 0.3_4$ Hz for a (90% confidence level). This latter number is most likely absurd and emphasizes the inadequacy of the model. Accordingly it is rejected, even though the energy difference obtained from it happens to agree with the *ab initio* MO calculations below. Furthermore, a two-

[i] For the other two C—H bonds.

site model for **3** is hardly sensible, yet ^5J in **3** also depends on temperature.

An n*-site model*

A rigorous description of the variation of ^5J with temperature demands a knowledge of the potential energy surface for the movement of the acetyl group relative to the benzene ring considered as a frame (including rotational and vibrational motion of the methyl group), of how this surface changes with temperature in the presence of solvent molecules, and of how ^5J depends on this potential surface. Here we take a simple approach designed to reproduce semiquantitatively, first, the large magnitude of ^5J in **2** relative to **3** and, second, the larger absolute changes in ^5J in **2** caused by temperature changes.

Evidence that ^5J is a proximate coupling can be adduced via INDO MO FPT computations as follows, in spite of the well-known failures (33–36) of this technique for certain proximate H,F couplings. In Table 2 such computations of ^5J are found. As expected from calculations of couplings with a large proximate component in other molecules, such as 2-fluorotoluene (35) and 2-methylbenzoylfluoride (34), ^5J is calculated as either very small or as large and negative when the methyl group lies near the C—F bond, that is, for small θ values. Using Barfield's procedure (37), in which certain off-diagonal matrix elements in the Fock matrices are held at zero throughout the iterative cycles, one may attempt to identify the source of the qualitative discrepancy between theory and experiment. For example, in Table 2 the third column represents the couplings computed when no spin state information is allowed to be transmitted *directly* between orbitals centered on fluorine and those centered on the atoms of the methyl group. Up to a point, these numbers yield the couplings transmitted via the intervening bonds. In the fourth column, all elements between the orbitals on fluorine and the methyl carbon are forced to vanish. The large negative ^5J numbers for small θ imply that it is H,F interactions which are incorrectly given by theory. Indeed, in the last column of Table 2 large positive ^5J numbers appear when the Fock matrix elements involving fluorine and methyl hydrogen orbitals are absent. Furthermore, ^5J drops rapidly from 5.84 Hz at θ = 0° to 0.45 Hz at θ = 60°, qualitatively as expected for a proximate coupling.

The results are reminiscent of those obtained in a detailed study of $^5J_o^{H,CH_3}$ in anisole (18), in which the observed negative and proximate coupling is quantitatively reproduced by the INDO MO FPT approach. $^5J_o^{H,CH_3}$, as calculated, very closely approximates a $\cos^4\theta$ function.

The assumption is now made that ^5J in **2** also follows $\cos^4\theta$ as in $^5J = {}^5J_o \cos^4\theta$ (defined for $0 \le \theta \le 90°$), where ^5J_o is that at θ = 0. The ^5J values at θ = 0 in Table 2 are not reliable in view of the above discussion. A more reliable ^5J_o must be sought in experiment. For **2** in Table 1, ^5J is given as $8.15_2 - 0.012_1\ T$ (r = 0.997). This empirical linear dependence on temperature is assumed to give ^5J_o as 8.15_2 Hz.

A potential function for the rotation of the acetyl group in **2** was obtained via the geometry optimization routine in the program MONSTERGAUSS. Bond lengths and bond angles were optimized as θ changed in steps of 15° between 0 and 180° with the proviso, however, that the benzene core remain a hexagon. The calculated energies can be fitted to give $V(\theta)$ (kJ) = $(3.0 \pm 0.2)\sin^2(\theta/2) + (9.9 \pm 0.3)\sin^2\theta - (1.4 \pm 0.3)\sin^2(2\theta)$ at the 95% confidence interval. In other words, *b* is more stable than *a* by 3.0 kJ/mol, rather close to the 3.1 kJ/mol predicted by the inadequate 2-site model above. It is clear, however, that $V(\theta)$ implies substantial populations of nonplanar forms at the temperatures given in Table 1, although conformer *b* is confirmed as that of lowest energy.

A simple calculation of ^5J at a given temperature proceeds by weighting each ^5J at a given θ with the population implied by $V(\theta)$ and the appropriate Boltzmann factor. In Table 3 the results of this procedure applied to **2** are given at three temperatures. At 305 K, ^5J is calculated as 4.88 Hz, the observed value being 4.51 Hz. At 240 K, the calculated and measured values are 5.37 and 5.21 Hz, respectively, while at 182 K they are 6.08 and 5.99 Hz. The agreement between the model and experiment improves at the lower temperatures. The improvement is *not* to be taken as proof that the model is correct at lower temperatures. An adjustment of $V(\theta)$, no doubt itself a function of temperature in solution, and (or) of ^5J_o could be made so as to produce a better match between observed and model-derived ^5J values at the 13 temperatures in Table 1. Such adjustments were abjured because even an exact fit would not *prove* the $\cos^4\theta$ dependence of ^5J nor its ^5J_o value, nor, for that matter, the exactness of $V(\theta)$.

That $V(\theta)$ is dependent on solvent is indicated by the solvent dependence of ^5J, described above. Using the $V(\theta)$ above and ^5J (θ = 0) as 8.15_2 Hz, the calculated ^5J at 203, 305, and 383 K becomes 5.79, 4.88, and 4.23 Hz, respectively. The observed values in toluene solution are 6.50, 4.80, and 4.20 Hz at these temperatures (15). In this solvent the calculated and observed couplings agree better at higher temperatures, in contrast to the acetone solution above. At 305 K, ^5J is 4.80 Hz in $CDCl_3$, toluene, and benzene solutions (14).

^{a}For $\theta = 0$ the molecule has all heavy atoms in a plane.

^{b}The energy at $\theta = 30°$ is $-572.622{,}066$ hartrees.

^{c}Calculated as explained in Table 3.

^{d}Calculated as in Table 3 with $^5J_o = 8.15_2$ Hz.

^{e}The minimum energy occurs at 39° for the fitted equation in the text, but note the small difference in the calculated energies at $\theta = 30$ and 45°. The equation in the text yields the energy at 39° as 0.3 ± 0.3 kJ/mol lower than at 30°.

^{f}Note that the sum of the ^5J values must be divided by two to make a comparison with the observed ^5J.

Another test of the model may be had in the temperature dependence of ^5J in 2,6-difluoroacetophenone, **3**. The STO 3G optimized energies yield $V(\theta)$ (kJ) $= 1.8 + (3.0 \pm 0.2) \sin^2 \theta - (3.4 \pm 0.2) \sin^2 (2\theta)$ at the 95% confidence level. Clearly, the (flat) minimum in energy occurs in the vicinity of 39°, a distinctly nonplanar conformation. Table 4 gives the actual calculated energies as a function of θ as well as the calculations of ^5J by the procedure used for **2**. At 305 K the calculated and observed values are 1.90 and 1.56 Hz, respectively; they are 1.93 and 1.77 Hz at 192 K. The important point is that the model predicts small ^5J values, relative to **2**, and also a much smaller temperature dependence of ^5J than in **2**; both predictions are correct.

The observed temperature dependence of ^5J in Table 1 for **3** is empirically given by $^5J = 2.11_1 - 1.83_9 \times 10^{-3}\, T$ ($r = 0.997_1$). The value of 2.11 Hz is reproduced by the $\cos^4 \theta$ dependence at $\theta = 44.5°$, yielding 2.81 Hz at 40° and 1.39 Hz at 50°. The computed $V(\theta)$ is flat in this region, differing by only 0.1 kJ/mol between $\theta = 30$ and 45°. The model is consistent with the idea that **3** is a nonplanar molecule and that the preferred value of θ lies in the vicinity of 45°.

Although $V(\theta)$ was not calculated for pentafluoroacetophenone, its ^5J values between 280 and 325 K (Table 1) are given by ^5J (Hz) $= 2.57_1 - 2.44_7 \times 10^{-3}\, T$ ($r = 0.999_6$), implying that its nonplanarity is not quite as pronounced as for **3**. The empirical ^5J dependence on θ implies θ as 41° when ^5J is 2.57 Hz. The *para* fluorine substituent should act to increase the conjugation of the acetyl group with the π system of the ring, thereby decreasing the expectation value of θ (13), but the *meta* substituents *may* act in the opposite direction.

The vapor pressure of 2-fluoroacetophenone at ambient temperatures is very small because its normal boiling point lies near 473 K. Nevertheless, an ^{1}H nmr gas phase spectrum was obtained on a Bruker AM300 spectrometer from a sample containing some gaseous TMS and sufficient SF_6 to give a total gas pressure of 2500 to 3000 Torr (1 Torr = 133.3 Pa). The presence of the SF_6 increased T_2 (38) sufficiently to produce a linewidth at half height of 1.1 Hz for the TMS peak. Under these conditions, the linewidth of the methyl proton resonance was 2.5 Hz. Naturally, the intrinsic linewidth of the methyl proton resonance need not be the same as the TMS resonance, and may well be larger. Nevertheless, an upper limit of not more than 1.5 Hz for $^5J(F,CH_3)$ is indicated by these results.

It follows from the present coupling model that the molecule is no longer planar in its conformation of lowest energy. A rough estimate is that the angle of twist, θ, for the acetyl group lies in the vicinity of 50°. In that event, the conjugational energy of the acetyl group with the π system of the benzene nucleus is reduced by about 50%. Indeed, our measurements indicate that the shift range of the ring protons is about 0.2 ppm, as compared to 0.6 ppm in acetone-d_6 solution.

Furthermore, the available data for acetophenone indicate an internal barrier of 13 kJ/mol in the gas phase (39) and 22.4 kJ/mol in solution (40). Then, perhaps, the present gas phase data for 2-fluoroacetophenone become less puzzling. Indeed, speculations about solvent-assisted charge separation are tempting and suggest a number of measurements on other molecules.

The coordinating properties of a variety of unsymmetrical uninegative tridentate chelating "pyrazolylgallate" ligands have been studied using the tricarbonyl moieties "$M(CO)_3$", where M = Mn or Re, as acceptor species. A series of monomeric, pseudo octahedral complexes has been characterized and a *fac* mode of coordination established for the tridentate gallate ligands from ^1H nmr, ir measurements, and X-ray structure determinations. Nitrosylation of a selection of the rhenium tricarbonyl compounds has yielded a number of cationic rhenium mononitrosyl dicarbonyl species. The reactivity of these cations towards reducing agents has been investigated.

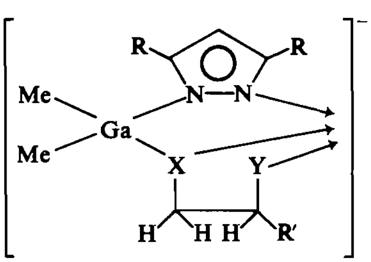
Brenda M. Louie, Steven J. Rettig, Alan Storr et James Trotter. Can. J. Chem. **63**, 2261 (1985).

On a étudié les propriétées coordinantes d'une variété de ligands chélatants, tridentates, univalents et non-symétriques du type "pyrazolylgallate" en utilisant des unités tricarbonyles "$M(CO)_3$", dans lesquelles M = Mn ou Re, comme accepteurs. On a caractérisé une série de complexes monomères, pseudooctaédriques et, faisant appel à des mesures ir et rmn du ^1H ainsi que des déterminations de structures par diffraction des rayons X, on a établi que le mode de coordination est *fac*. La nitrosylation de composés rhénium tricarbonyles choisis conduit à un certain nombre d'espèces cationiques rhénium mononitrosyle dicarbonyles. On a étudié la réactivité de ces cations avec des agents de réductions.

[Traduit par le journal]

Introduction

In our continuing investigations of anionic tridentate chelating pyrazolylgallate ligands a number of new rhenium and manganese carbonyl derivatives have been prepared using a variety of three atom donor ligands of the general formula:



1

X = O or S; Y = NMe_2 or NH_2; R′ = H; R = H or Me
X = O; Y = SEt or SPh; R′ = H; R = Me
X = O; Y = NH_2; R′ = Me or Et; R = Me

This report introduces the ligands where X = S, and the ligands incorporating the chiral amino alcohols (R′ = Me or Et), for the first time. In addition to the complexes bearing the ligands **1**, the complex $[MeGa(N_2C_3H_3)_3]Re(CO)_3$ has been prepared and characterized. The configuration of the tridentate ligands in the complexes has been determined from infrared and ^1H nmr measurements, and the reactivity of a selection of the Re tricarbonyl compounds towards nitrosylation and subsequent reduction procedures has been probed. Definitive X-ray structural results are presented for four representative compounds.

Experimental

Starting materials

Air-sensitive materials were handled in oxygen-free dry nitrogen. Tetrahydrofuran (THF) and benzene were dried by refluxing over sodium/benzophenone and molten potassium, respectively. Methylene chloride and acetonitrile were each dried over P_2O_5 prior to distillation. All distilled solvents were stored under dry nitrogen following distillation. $Mn(CO)_5Br$ (1) and $[Re(CO)_4Cl]_2$ (2) were prepared from the corresponding $[M(CO)_5]_2$ compounds (M = Mn or Re) (Strem) by standard routes. L-2-amino-1-propanol (Aldrich), *d*-2-amino-1-butanol (Aldrich), *l*-2-amino-1-butanol (Aldrich), nitryl hexafluorophosphate (Alpha), and nitrosyl tetrafluoroborate were used as supplied. Nitrosyl hexafluorophosphate (Alpha) was dried *in vacuo* over P_2O_5 before use. Iodosobenzene (ICN) was used as supplied. Lithium triethylborohydride and potassium tri-*sec*-butylborohydride were purchased as 1 *M* solutions in THF (Aldrich) and used as supplied.

Ligand synthesis

All the ligands **1** were prepared as standard solutions in THF. The ligands involving (X = O; Y = NH_2; R′ = Me or Et) and (X = S; Y = NH_2 or NMe_2) were prepared by refluxing $Na^+[Me_3Ga(N_2C_3H_3)]^-$ or $Na^+[Me_3Ga(N_2C_5H_7)]^-$ with the appropriate chiral amino alcohol or amino thiol in THF until cessation of methane evolution. The resulting ligand solution was then made up to standard volume and aliquots used in subsequent reactions. The remaining ligands **1** and the ligand $Na^+[MeGa(N_2C_3H_3)_3]^-$ were prepared as described earlier (3–6).

Preparation of manganese and rhenium tricarbonyl complexes

The general method employed for the preparation of the complexes **1–16** listed in Table 1, together with analytical and ir data, and the complex **17** $[MeGa(N_2C_3H_3)_3]Re(CO)_3$ (*Anal.* calcd. for $[MeGa(N_2C_3H_3)_3]Re(CO)_3$: C 28.06, H 2.16, N 15.11; found: C 27.95, H 2.13, N 14.90. ν_{CO} 2028, 1918 cm^{-1} (cyclohexane). ^1H nmr (C_6D_6), τ = 10.04s (Ga—Me), 4.20t (pz-H^4), 3.09d (pz-H^5), 2.22d (pz-H^3) (τ values refer to $\tau_{C_6H_6}$ = 2.84 ppm, pz = pyrazolyl, $N_2C_3H_3$, J_{HCCH} = ~2 Hz for pz protons), was to react one or two molar equivalents of the appropriate ligand with ~0.5 g of $Mn(CO)_5Br$ or $[Re(CO)_4Cl]_2$, respectively, dissolved in ~75 mL THF. The mixture was refluxed overnight and the THF subsequently removed *in vacuo*. The solid remaining was then extracted with ~20 mL benzene and the mixture filtered. Slow evaporation of the benzene from the filtrate resulted in either well-formed crystalline products or amorphous solids in ~55–80% yields. The latter were either recrystallized from benzene/CH_2Cl_2 mixtures or dried by pumping *in vacuo* at ~50°C. ^1H nmr data for the complexes are collected in Tables 2 and 3.

Nitrosylation of selected rhenium tricarbonyl complexes

In general a slight excess of NO_2PF_6 dissolved in CH_2Cl_2/acetonitrile was added dropwise to ~0.3 g of $LRe(CO)_3$ {L = $[MeGa(N_2C_3H_3)_3]$, $[Me_2Ga(N_2C_3H_3)(OCH_2CH_2NMe_2)]$, or [Me$_2$Ga-

$(N_2C_5H_7)(OCH_2CH_2NMe_2)]\}$ dissolved in ~50 mL CH_2Cl_2. The addition caused rapid evolution of CO and a change of the solution from colorless to brown. After stirring the reaction mixture for 5 min ~200 mL of anhydrous Et_2O was added resulting in the immediate precipitation of a dark orange–brown solid. The solvents were decanted off and the solid dried for ~12 h *in vacuo* at ~50°C. When L = $[MeGa(N_2C_3H_3)_3]$ the very air-sensitive nitrosylated product formed in 20% yield. For the remaining two tridentate ligands yields varied between 30 and 70%.

$NOPF_6$ and $NOBF_4$ could also be used as nitrosylating agents but longer reaction times of ~8 h were necessary. Physical data for the rhenium nitrosyl cations prepared, as well as for the starting tricarbonyl complexes in the same solvents, are tabulated in Table 4.

Spectra

Mass spectra were recorded on either a Varian MAT CH4B (Mn complexes) or AES MS 50 (Kratos) (Re complexes) spectrometer operating at 70 eV. Representative data for three of the complexes together with typical assignments are tabulated in Table 5. Infrared spectra were recorded on a Perkin-Elmer 598 spectrometer. ^{1}H nmr spectra were obtained on either a Varian XL-100 or Bruker WP80 instrument using FT techniques.

X-ray crystallographic analyses of *$[Me_2Ga(N_2C_5H_7)(OCH_2CH_2NMe_2)]Re(CO)_3$, 8, $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2SPh)]Re(CO)_3$, 13, $[Me_2Ga(N_2C_5H_7)(OCH_2C(H)EtNH_2)]Re(CO)_3$, 16, and $[MeGa(N_2C_3H_3)_3]Re(CO)_3$, 17*

Crystallographic data are presented in Table 6. Unit-cell parameters were refined by least-squares on 2 sin θ/λ values for 25 reflections with 2θ = 40–50° measured with Mo-K_{α_1} radiation. The intensities of three standard reflections, measured every hour throughout the data collections, showed only small random fluctuations in each case. The data were processed[1] and corrected for absorption using the Gaussian integration method (7, 8) for compounds **8**, **16**, and **17** (224, 208, and 216 integration points, respectively) and the analytical method (7, 9) for compound **13**.

The structure of **13** is isomorphous with that of the manganese analog (10), the refinement initiated with the coordinates of non-hydrogen atoms determined for $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2SPh)]$-$Mn(CO)_3$ (10). The three remaining structures were solved by conventional heavy-atom methods, the Re and Ga coordinates being determined from the Patterson functions and those of the remaining non-hydrogen atoms from subsequent difference maps. In the case of **17**, the non-centrosymmetric space group $Pn2_1a$ was indicated by *E*-statistics and by the Patterson function. In each case the non-hydrogen atoms were refined (full-matrix) with anisotropic thermal parameters. For **8**, **13**, and **17** the hydrogen atoms were included as fixed contributors in idealized positions (based on observed positions with C(sp^2)—H = 0.97 and C(sp^3)—H = 0.98 Å). The scattering factors of ref. 11 were used for the non-hydrogen atoms and those of ref. 12 for hydrogen atoms. Anomalous scattering corrections (13) were applied for Re, Ga, and S atoms. The absolute configuration of **16** is determined by that known for the chiral starting material. In the case of **17** attempts to determine the polarity by parallel refinement were unsuccessful.

The final positional and equivalent isotropic thermal parameters for non-hydrogen atoms appear in Table 7. Bond lengths, bond angles, and intra-annular torsion angles are given in Tables 8–10, respectively. Calculated hydrogen parameters, anisotropic thermal parameters, and complete listings of torsion angles (Tables 11–13) have been placed in the Depository for Unpublished Data[2] along with measured and calculated structure factor amplitudes for the four compounds.

Results and discussion

Analysis of mass spectral, ir, and ^{1}H nmr data for the complexes listed in Table 1 and also for the compound $[MeGa(N_2C_3H_3)_3]Re(CO)_3$ points to the monomeric octahedral structures for the whole series of compounds studied. Unlike the $[MeGa(N_2C_3H_3)_3]^-$ ligand (5) and the related pyrazolylborate ligands, $[RB(N_2C_3H_3)_3]$ (R = H, alkyl, aryl) (14–16), which coordinate exclusively in a *fac* conformation due to

[1]The computer programs used include locally written programs for data processing and locally modified versions of the following: ORFLS, full-matrix least-squares, and ORFFE, function and errors, by W. R. Busing, K. O. Martin and H. A. Levy; Patterson and Fourier syntheses, by A. Zalkin; ORTEP II, illustrations, by C. K. Johnson.

geometric constraints, the unsymmetric ligands **1** can potentially coordinate in either a *fac* or *mer* configuration (4, 17). However, in each of the complexes described in this paper, the transition metal is coordinated entirely by a *fac* arrangement of **1**. This arrangement of the ligating atoms is evident from both the ir and the ^1H nmr results and has been confirmed by crystal structure determinations for complexes **8**, **13**, **16**, and **17** (see below).

[$Me_2Ga(N_2C_3HR_2)(XCH_2CH_2NR''_2)$]$M(CO)_3$ (R, R″ = H or Me; X = O or S; M = Re) or (R, R″ = H or Me; X = S; M = Mn)

Three strong bands in the ν_{CO} region (see Table 1) for each of the complexes **1–16** indicate that the pyrazolylgallate tridentate ligand occupies three facial positions in the octahedral structures, with the three CO groups occupying the remaining set of facial positions. A *mer* arrangement for the unsymmetrical pyrazolylgallate ligand in these complexes would lead to two weak ν_{CO} bands and one strong ν_{CO} band in the ir of the complexes (18). The ^1H nmr spectra for the complexes (Table 2) also supports the *fac* conformation for the chelating ligands in the complexes with two sharp Ga—Me signals observed in each case. A *mer* arrangement would make the two Ga—Me groups equivalent and hence just one signal would be observed in this region of the spectrum. The X-ray crystal structure of the complex where R = R″ = Me, X = O, and M = Re is shown in Fig. 1.

Mass spectral data obtained for the complexes (Table 5) reveal interesting behavioural differences between the Re and Mn derivatives. Although the fragmentation patterns appear very similar for the three complexes the relative intensities of the signals differ sharply. Thus while the strongest signal is assignable to the P − Me^+ ion (P = parent) for the Re compounds, this signal is of much lower intensity for the valence

*U_{eq} = (1/3) trace U_{diag}.

isoelectronic Mn compound, which displays as its most intense signal that arising from the P − 3CO$^+$ ion. This difference in behaviour reflects stronger M—CO bonds for the Re complexes when compared to the Mn species. In support of this conjecture an examination of the ν_{CO} stretching frequencies for the compounds (Table 1) reveals repeatedly lower ν_{CO} values for the Re complexes than the corresponding Mn compounds. This can only result from stronger back bonding to the carbonyl ligands in the Re species, which leads to stronger "Re—CO" bonds.

Three general points can be made from a comparison of the complexes **1**−**12** and the four related Mn compounds where X = O; R, R″ = H or Me (19). Firstly, complexes where M = Re are air-stable while the corresponding complexes where M = Mn tend to be air-sensitive. Secondly, complexes where X = O show greater air stability than the corresponding

complexes where X = S. In addition, the presence of an alkyl group at the R and R″ positions of the tridentate ligand also resulted in some stabilization of the complexes, an effect observed in other compounds incorporating this type of ligand (19, 20).

$[Me_2Ga(N_2C_5H_7)(OCH_2CH_2SR''')]Re(CO)_3$ (R‴ = Et or Ph)

The complexation of the tridentate "SR‴" ligands to various transition metal moieties has been detailed previously (6, 10). These ligands reacted readily with $[Re(CO)_4Cl]_2$ forming colorless crystalline tricarbonyl complexes (Tables 1 and 2). The mass spectra of both the "S—Et" and "S—Ph" species were dominated, like the Re complexes discussed above, by the signal attributable to the $P - Me^+$ ion (100%). The highest m/e signals recorded corresponded to the parent ions (P^+, 20%), with weak signals (<3%) assignable to successive loss of CO from both the P^+ and $P - Me^+$ ions being recorded. The X-ray crystal structure of the complex where R‴ = Ph is shown in Fig. 2.

$[Me_2Ga(N_2C_5H_7)(OCH_2C(H)R'NH_2)]Re(CO)_3$ (R′ = Me or Et)

A chiral carbon centre was incorporated into the unsymmetric pyrazolylgallate ligand by reacting the appropriate chiral amino alcohols with $Na^+[Me_3Ga(N_2C_5H_7)]^-$. The resulting ligands reacted readily with $[Re(CO)_4Cl]_2$ to form air-stable, crystalline, monomeric products. The resulting tricarbonyl complexes may be formed as two possible diastereoisomers (see Fig. 3). These have been designated "*cis*' when the R′ group is on the same side of the transition metal as the "pyrazolyl" group and "*trans*" when the R′ group is on the opposite side. The ^1H data for these complexes are tabulated in Table 3. The assignment of the aminoalcohol protons was established by double resonance experiments. From steric arguments the "*trans*" isomer is favored over the "*cis*" isomer and indeed a crystal structure determination (R′ = Et) has confirmed this arrangement in the solid state (Fig. 4). The ^1H nmr results suggest a mixture of isomers to be present in solution with the ratio varying with the solvent. Thus, dissolving the sample used for the X-ray crystal structure determination in C_6D_6, resulted in two sets of signals in the ratio of ~3:1. In d_6-acetone the ratio was ~10:1. It is conjectured that the predominant isomer in solution is the *trans* isomer and that interconversion between this isomer and the *cis* form may result from initial breaking of the Re—N bond to give a five coordinate intermediate followed by inversion about the oxygen atom, and reforming of the Re—N bond. A relatively weak "M—N" bond (M = transition metal) has been suggested in several other related complexes containing unsymmetric pyrazolylgallate ligands, complexes which also exhibit fluxional behaviour in solution (6, 20–22).

$[MeGa(N_2C_3H_3)_3]Re(CO)_3$

This tricarbonyl complex containing the symmetric methyl tris(1-pyrazolyl) gallate ligand crystallized as large colorless cubic crystals from benzene. The facial coordination of the gallate ligand and the three CO groups was evident from the ν_{CO} vibrations which consisted of two bands in the predicted intensity pattern for such an octahedral complex (18). An X-ray crystal structure determination has confirmed this arrangement in the solid state (Fig. 5). The mass spectrum of the complex displayed a prominent signal due to the parent ion, P^+ (50%), with other strong signals due to the ions $P - Me^+$ (92%), $P - CO^+$ (27%), $P - 2CO^+$ (24%), $P - 3CO^+$ (100%), $P - Me - 3CO^+$ (9%), and Ga^+ (30%).

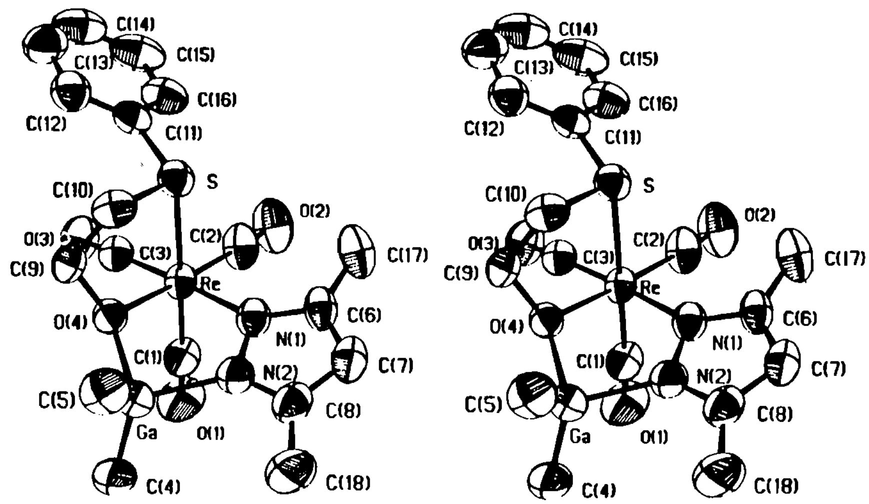

FIG. 2. Stereoscopic view of the $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2SPh)]Re(CO)_3$ molecule. 50% probability thermal ellipsoids are shown for the non-hydrogen atoms.

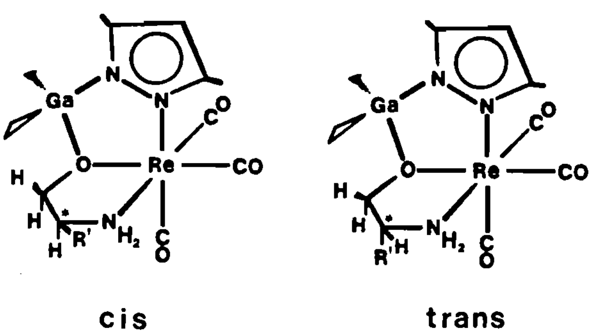

FIG. 3. Diastereoisomers formed in octahedral complexes incorporating facial tridentate pyrazolyl gallate ligands derived from chiral amino alcohols.

Reactivity of selected $LRe(CO)_3$ complexes {L = $[MeGa(N_2C_3H_3)_3]$ or $[Me_2Ga(N_2C_3HR_2)(OCH_2CH_2NMe_2)]$ (R = H or Me)}

(a) Nitrosylation

The reactions of the selected $LRe(CO)_3$ complexes with NO_2PF_6, $NOPF_6$, or $NOBF_4$ resulted in air-sensitive orange–brown powders of the corresponding nitrosyl cations $LRe(CO)_2(NO)^+$ in variable yields. These cations differ from their air-stable cyclopentadienyl analogs, $(\eta^5\text{-}C_5H_5)Re(CO)_2(NO)^+$, which can be prepared in near quantitative yields by similar reaction procedures (23, 24).

The $LRe(CO)_2(NO)^+$ cations were shown to be fluxional in d_6-acetone solution by variable temperature ^{1}H nmr experiments. When L = $[MeGa(N_2C_3H_3)_3]$ two different types of pyrazolyl rings should be evident in a ratio of 2:1 for a rigid species as observed for the isoelectronic complexes $[MeGa(N_2C_3H_3)_3]M(CO)_2(NO)$ (where M = Mo or W) (5). However, the ^{1}H nmr spectrum of $[MeGa(N_2C_3H_3)_3]Re(CO)_2(NO)^+$ displayed only one set of pyrazolyl resonances in d_6-acetone at room temperature. These resonances showed considerable broadening at lower temperatures (Fig. 6) but no clear splitting of the signals was observed. The room temperature spectrum can be explained by a rapid rotation of the tridentate ligand about the Re...Ga axis or alternatively by a rapid ligand rearrangement occurring via a 5-coordinate intermediate in which the chelating ligand coordinates in a bidentate fashion. A similar mechanism has been proposed recently to account for the solution behaviour of $[B(N_2C_3H_3)_4]Rh$(diene), (where diene = duroquinone, 1,5-cyclooctadiene or norbornadiene) (25).

The nitrosylation of $LRe(CO)_3$ when L is an unsymmetrical ligand can occur theoretically at any one of the three possible sites A, B, C in Fig. 7. For any rigid isomer produced, the ^{1}H nmr spectrum should display two equally intense Ga—Me singlets, giving a maximum of six Ga—Me singlets if all three isomers are formed. The actual room temperature ^{1}H nmr spectra of the two complexes $LRe(CO)_2(NO)^+$ {L = $[Me_2Ga(N_2C_3HR_2)(OCH_2CH_2NMe_2)]$ where R = H or Me} both display but one Ga—Me singlet, which, although broadened at −70°C, could not be resolved into separate signals. The room temperature spectra can be explained by the presence of a fluxional species in solution which interconverts via a 5-coordinate intermediate as shown in Fig. 8. Thus in the 5-coordinate intermediate the Ga—Me groups become equivalent, producing one signal in the ^{1}H nmr spectra. This explanation presumes that the nitrosylation has occurred solely at position C (Fig. 7) since substitution at the A or B positions would leave the Ga—Me groups inequivalent even in the proposed 5-coordinate intermediate unless a concomitant scrambling of the nitrosyl and carbonyl groups was also occurring.

(b) Attempted hydride reduction of a coordinated carbonyl ligand

Recently the ability of the $(\eta^5\text{-}C_5H_5)Re(CO)_2(NO)^+$ cation to be converted into unusually stable complexes having coordinated organic functional groups has been recognized (23, 24, 26, 27). Thus the hydride reduction of the cation results in a series of relatively stable neutral complexes (23), i.e.

$$L'Re{-}CO^+ \rightarrow L'Re{-}CHO \rightarrow L'Re{-}CH_2OH \rightarrow L'Re{-}CH_3$$
$$[L' = (\eta^5\text{-}C_5H_5)(CO)(NO)]$$

It has been suggested earlier that hydride reduced metal carbonyl species should become more stabilized by increasing the electron density on the transition metal centre in the precursor species (24, 27). It is well known that pyrazolylgallate ligands have a greater propensity to fulfill this function than the cyclopentadienyl ligand in metal carbonyl species (5, 19), as reflected in lower ν_{CO} stretching frequencies for the former complexes. Thus it was anticipated that the $LRe(CO)_2(NO)^+$ cations produced in this study might well undergo ready conversion to stable, neutral organo rhenium derivatives. How-

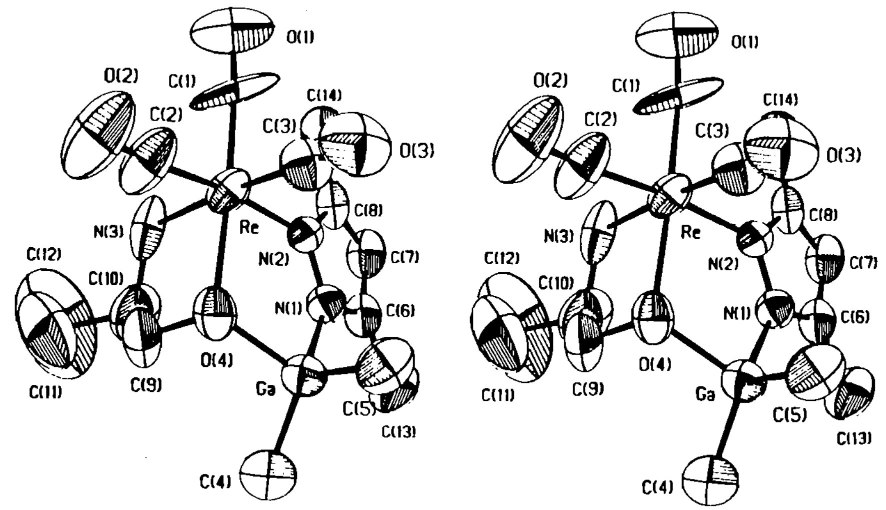

FIG. 4. Stereoscopic view of the $[Me_2Ga(N_2C_5H_7)(OCH_2C(H)EtNH_2]Re(CO)_3$ molecule. 50% probability thermal ellipsoids are shown for the non-hydrogen atoms.

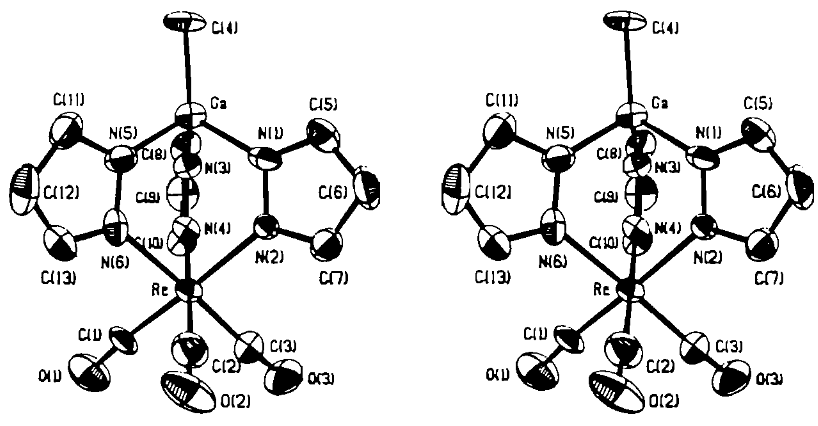

FIG. 5. Stereoscopic view of the $[MeGa(N_2C_3H_3)_3]Re(CO)_3$ molecule. 50% probability thermal ellipsoids are shown for the non-hydrogen atoms.

ever, despite repeated attempts with a variety of reducing agents (e.g., $LiEt_3BH$, K(*sec*-Bu)$_3$BH) at −78°C to room temperature no organo rhenium species was identified. Indeed ir and ^{1}H nmr measurements did not indicate the presence of either a reduced coordinated carbonyl ligand or a rhenium hydride species. It appeared instead that the pyrazolylgallate ligands themselves were unstable under the reaction conditions.

(c) Attempted substitution of a carbonyl with a tertiary phosphine

(η^5-C_5H_5)Re(CO)$_2$(PPh$_3$) can be prepared by the uv irradiation of (η^5-C_5H_5)Re(CO)$_3$ and PPh$_3$ in THF (28). The substituted nitrosyl cations (η^5-C_5H_5)Mn(CO)(NO)(L″)$^+$ and (η^5-C_5H_5)Re(CO)(NO)(L″)$^+$ (where L″ = a neutral two-electron donor ligand) have been prepared by refluxing (η^5-C_5H_5)M(CO)$_2$(NO)$^+$ (M = Mn or Re), and L″ in the presence of Et_3N/acetone (29) or iodosobenzene/MeCN (24), respectively. In contrast to these results it was found that the carbonyl ligands in both the LRe(CO)$_3$ and LRe(CO)$_2$(NO)$^+$ complexes were inert with respect to substitution with $PR_3^†$ ($R^†$ = Ph, OPh or OMe). This observed non-lability of the coordinated carbonyl groups may result from the superior electron-donating strength of pyrazolylgallate ligands compared to the cyclopentadienyl ligand (5, 19).

*Crystal structures of **8**, **13**, **16**, and **17***

In each of the four molecules the tridentate gallate ligand is facially coordinated, the geometry about the rhenium atom being irregular octahedral. Deviations from "ideal" geometry are smallest for **17** in which no five-membered chelate rings are formed. The average D—Re—D (D = N, O or S), OC—Re—CO, *cis*- and *trans*-D—Re—CO angles are 82.9, 86.4, 95.3 and 175.7° for **8**; 81.7, 88.6, 94.8 and 174.8° for **13**; 80.7, 88.4, 95.3 and 174.7° for **16**; 88.2, 88.9, 91.5 and 177.8° for **17**. All bond distances involving Re lie within the normal ranges. The Re—O and Re—N(pz) distances in **8**, **13**, and **16** are equal within experimental error, the mean values (with rms deviations from the mean in parentheses) being 2.154(3) and 2.184(5) Å, respectively. The mean Re—N(pz) distance of 2.165(7) Å in **17**, involving unsubstituted pyrazolyl groups, is marginally (2σ) shorter. The mean Re—CO distance of 1.94(2) Å in **17** is ~2σ longer than the corresponding values of 1.905(6), 1.910(4), and 1.87(1) Å in **8**, **13**, and **16**, respectively. The Re—S distance in **13** is 2.509(1) Å and, as expected, the "Re—NMe$_2$" distance of 2.300(7) Å in **8** is longer than the "Re—NH$_2$" distance of 2.254(11) Å in **16**. With the exception of parameters involving the poorly defined (and possibly disordered) ethyl side chain in **16**, bond lengths and angles in all four structures are as expected.

Pyrazolyl and phenyl rings are all planar within experimental error ($\chi^2 = 0.2-4.3$). The five-membered chelate rings in **8**, **13**, and **16** are all significantly non-planar and have either envelope or irregular puckered conformations (see Table 10). The three six-membered chelate rings in **17** have slightly irregular boat conformations. The non-bonded Re···Ga separations are 3.459(1), 3.4780(6), 3.459(1), and 3.592(3) Å, respectively, for **8**, **13**, **16**, and **17**.

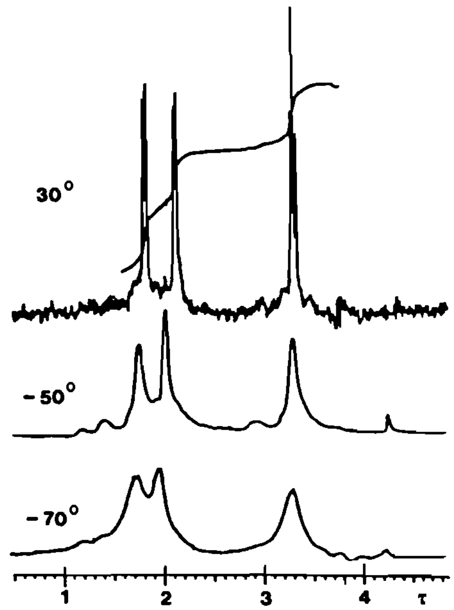

FIG. 6. Variable temperature 80 MHz ^1H nmr spectra of $[MeGa(N_2C_3H_3)_3]Re(CO)_2(NO)^+$ in d_6-acetone (pyrazolyl protons only).

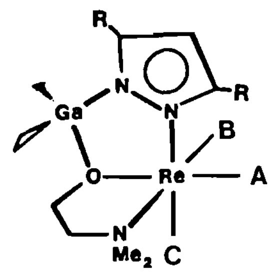

FIG. 7. Three possible sites (A, B, C) for carbonyl substitution in $LRe(CO)_3$ complexes (L = unsymmetrical tridentate ligand).

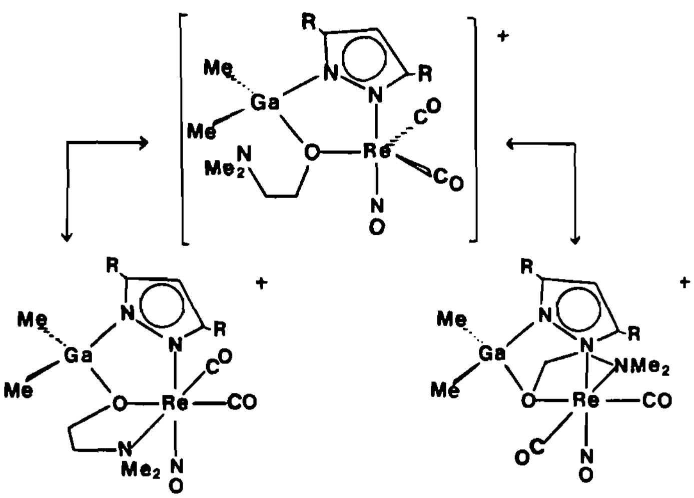

FIG. 8. Proposed fluxional behaviour of nitrosyl cations in solution at room temperature.

The structure of **8** consists of discrete molecules, all intermolecular distances being greater than the sum of van der Waals radii. In **13** and **17** there are possible weak intermolecular interactions: C(10)—H(10a)···S($1-x, 2-y, 1-z$) (H···S = 3.00, C···S = 3.905(6) Å, C—H···S = 153°) in **13**;

C(4)—H(4b)···O(1) ($1 - x, y - 1/2, -z$), C(10)—H(10)···O(2) ($x, y, z - 1$), and C(11)—H(11)···O(2) ($1 - x, y - 1/2, 1 - z$) (H···O = 2.57, 2.58, 2.50, C···O = 3.50(3), 3.43(3), 3.41(3) Å, C—H···O = 158, 147, 154°) in **17**. Molecules of **16** are each linked to two others by inferred N—H···O(carbonyl) hydrogen bonds: N(3)···O(2) ($1/2 + x, 3/2 - y, 1 - z$) = 3.07(2) Å and N(3)···O(2) ($1 + x, y, z$) = 3.20(2) Å.

Summary

The reactions between a variety of tridentate pyrazolylgallate anionic ligands and $[Re(CO)_4Cl]_2$ or $Mn(CO)_5Br$ have been described. In all compounds isolated the chelating ligand was found to coordinate in a facial manner. The reactivity of selected pyrazolylgallate rhenium species has also been probed. Presently we are investigating a series of rhodium complexes in which the unsymmetric tridentate ligands are meridionally coordinated in both four and five-coordinate species.

Received August 13, 1984

CLEMENT LAU, JACK PASSMORE, E. KEITH RICHARDSON, TOM K. WHIDDEN, and PETER S. WHITE. Can. J. Chem. **63**, 2273 (1985).

The reaction of $(C_2F_5)_2Te$ and XeF_2 in a slurry of SO_2ClF yielded $(C_2F_5)_2TeF_2$ essentially quantitatively. Chlorine and $(C_2F_5)_2Te$ gave $(C_2F_5)_2TeCl_2$. Both $(C_2F_5)_2TeF_2$ and $(C_2F_5)_2TeCl_2$ were assigned a trigonal bipyramidal geometry, on the basis of their ^{19}F nmr and vibrational spectra, with the lone pair and C_2F_5 groups in equatorial, and the halogens in the axial positions. Perfluoroethyl tellurium trifluoride was prepared essentially quantitatively by the reaction of $C_2F_5TeTeC_2F_5$ and XeF_2 in liquid SO_2F_2. The generally inert SO_2ClF was found to react with $C_2F_5TeTeC_2F_5$ to give $C_2F_5TeCl_xF_{3-x}$ and sulphur dioxide. The structure of $C_2F_5TeF_3$ was determined by X-ray diffraction. The crystals are tetragonal with a = 10.129(4), c = 25.561(6) Å, and Z = 16. The structure was refined in space group $I4_1/a$ to a conventional R factor of 0.051 for 901 observed reflections with $I \geq 3\sigma(I)$. Each tellurium atom is surrounded by two terminal fluorine atoms and two bridging fluorine atoms and a C_2F_5 group in an axial position around the apex of a distorted square pyramid. The square-pyramidal units are linked by symmetrical *cis* bridging atoms into endless chains with bridging angles of 180° and 177°. The geometry of the $(C_2F_5TeF_4)$ group is consistent with steric activity of the non-bonded electron pair. The ^{19}F nmr and Raman spectra of $C_2F_5TeF_3$ were recorded and the Raman spectrum assigned. *trans*-$C_2F_5TeClF_4$ was prepared by the reaction of $C_2F_5TeTeC_2F_5$, and an excess of ClF. The *trans* octahedral geometry of $C_2F_5TeClF_4$ was unambiguously assigned from its ^{19}F nmr and vibrational spectra. A mixture of *trans*-$(C_2F_5)_2TeF_4$ and *trans*-$C_2F_5TeClF_4$ was obtained from the reaction of $(C_2F_5)_2Te$ and an excess of ClF. *Trans* geometry of $(C_2F_5)_2TeF_4$ was unambiguously assigned from its ^{19}F nmr spectrum.

CLEMENT LAU, JACK PASSMORE, E. KEITH RICHARDSON, TOM K. WHIDDEN et PETER S. WHITE.Can. J. Chem. **63**, 2273 (1985).

La réaction du $(C_2F_5)_2Te$ et du XeF_2 dans une pâte de SO_2ClF donne du $(C_2F_5)_2TeF_2$ avec un rendement essentiellement quantitatif. Le chlore et le $(C_2F_5)_2Te$ donnent du $(C_2F_5)_2TeCl_2$. En se basant sur leurs spectres de rmn du ^{19}F et sur leurs spectres vibrationnels, on attribue une géométrie pyramidale trigonales aux composés $(C_2F_5)_2TeF_2$ et $(C_2F_5)_2TeCl_2$; le doublet libre et les groupes C_2F_5 seraient en position équatoriale, alors que les halogènes seraient en position axiale. On a préparé le trifluorure du perfluroéthyle de tellure avec un rendement essentiellement quantitatif en faisant réagir le $C_2F_5TeTeC_2F_5$ avec le XeF_2 dans du SO_2F_2 liquide. On a trouvé que le SO_2ClF, généralement inerte, réagit avec le $C_2F_5TeTeF_5$ pour donner du $C_2F_5TeCl_xF_{3-x}$ et du bioxyde de soufre. On a déterminé la structure du $C_2F_5TeF_3$ par diffraction de rayons X. Les cristaux sont tétragonaux, avec a = 10,129(4), c = 25,561(6) Å et Z = 16. On a affiné la structure dans le groupe d'espace $I4_1/a$ jusqu'à un facteur conventionnel R de 0,051 pour 901 réflexions observées avec $I \geq 3\sigma(I)$. Chaque atome de tellure est entouré par deux atomes terminaux de fluor, deux atomes de fluor en position de pont et un groupe C_2F_5 en position axiale autour du sommet d'une pyramide carrée déformé. Les unités pyramides carrées sont liées par des atomes *cis* symétriques en position de pont dans des chaînes sans fin avec des angles de liaison de 180° et de 177°. La géométrie du groupe $C_2F_5TeF_4$ est en accord avec une activité stérique de la paire d'électrons non liés. On a enregistré les spectres de rmn du ^{19}F et les spectres Raman du $C_2F_5TeF_3$ et on a attribué les pics du spectre Raman. On a préparé le $C_2F_5TeClF_4$-*trans* par réaction du $C_2F_5TeTeC_2F_5$ avec un excès de ClF. On lui a attribué sans équivoque une géométrie octaédrique en se basant sur son spectre de rmn du ^{19}F et sur son spectre vibrationnel. On a obtenu un mélange de $(C_2F_5)_2TeF_4$ *trans* et de $C_2F_5TeClF_4$ *trans* en faisant réagir le $(C_2F_5)_2Te$ avec un excès de ClF. Les spectres de rmn du ^{19}F et Raman ont permis d'attribuer sans équivoque une géométrie *trans* au $(C_2F_5)_2TeF_4$.

[Traduit par le journal]

Introduction

In the course of our investigations of the chemistry of homopolyatomic cations of sulphur, selenium, and tellurium (1–4), we found that $(C_2F_5)_2Te_n$ (n = 1, 2) could be prepared in reasonable yields by the reaction of $Te_4(AsF_6)_2$ and C_2F_4. The only report of a perfluoroalkyl of tellurium prior to this work was $(CF_3)_2Te_2$ (5), prepared in small amounts by the reaction of CF_3 radicals with a tellurium film. Perfluoroalkyl derivatives of sulphur and selenium tetrafluorides and hexafluorides had been readily prepared in good yield by the oxidations of $(C_2F_5)_2Se_n$ (n = 1, 2) (6), and R_fS_n (n = 1, 2) (R_f various perfluoroalkyls) (7, 8) with chlorine monofluoride. Perfluoroalkyl derivatives of tellurium tetrafluoride and hexafluoride were unknown and therefore $(C_2F_5)_2Te_n$ (n = 1, 2) were reacted with the fluorinating agents chlorine monofluoride and xenon difluoride, leading to compounds listed in the title. A preliminary report of this work has been published (9) and a full account is given below. *trans*-$C_2F_5TeClF_4$ and *trans*-$(C_2F_5)_2TeF_4$ are the only known organic derivatives of TeF_6. The related *cis*- and *trans*-$(MeO)TeClF_4$ have been prepared (10). Since our preliminary report was published, $(CF_3)_2Te_n$ (n = 1, 2) have been prepared by a variety of routes (11–14). Bis(perfluoromethyl) telluride has been oxidised to $(CF_3)_2TeF_2$ (15), $(CF_3)_2TeX_2$ (X = Cl, Br (12, 16) and CF_3TeX_3 (X = Cl, Br (17)).

Diorganotellurium(IV) dihalides of the type R_2TeX_2 (X = F, Cl, Br), e.g. $(C_6H_5)_2TeX_2$ (X = F, Cl, Br), $(CH_3)_2TeCl_2$, $(C_{12}H_8O)_2TeCl_2$ are established as having simple molecular structures with some tellurium–halogen intermolecular association (18, 19). The structure of the difluoride appears to show the least secondary interactions, and it is therefore not surprising that the structures of $(C_2F_5)_2TeF_2$ (below) and $(CF_3)_2TeF_2$ (15) are readily assigned in V.S.E.P.R. terms (20) as having AX_2Y_2E geometries on the basis of their vibrational spectra and ^{19}F nmr spectroscopy, with two fluorine

atoms occupying axial positions of the trigonal bipyramid. The organo tellurium trichlorides, $RTeCl_3$ (R = C_6H_5, OC_6H_4, $ClCH_2CH_3$) have chlorine bridged polymeric structures (18), tellurium tetrafluoride (21) is an associated *cis*-bridged polymer and the properties of $C_2F_5TeF_3$ suggested it was also polymeric. The structure of $C_2F_5TeF_3$ was not unambiguously deduced from its vibrational spectrum, or ^{19}F nmr. We therefore determined the single crystal X-ray structure of this compound and the results are reported below. As far as we are aware, this is the first report of an X-ray structural determination of a perfluoro-organic derivative of TeF_4, and the first report of a structure of an organic derivative of the type $RTeF_3$.

Experimental

Apparatus and techniques have been described (4, 6). $(C_2F_5)_2Te_n$ n = 1, 2, were prepared according to ref. 4, and their purity established by vpc and mass spectra. The ditelluride decomposes into the monotelluride and elemental tellurium on exposure to light, therefore $(C_2F_5)_2Te_2$ was stored in the dark at −78°C and experiments involving

this compound carried out in the dark. XeF_2 was prepared photochemically (22). The SO_2F_2, SO_2ClF, and CCl_3F were stored over 3 Å molecular sieves prior to use. Reactions were carried out in glass vessels connected to a metal vacuum line via a 1KS4 stainless steel Whitey valve. Volumes of vessels containing XeF_2 as a reagent were such that the final pressure was less than 4 atm. Xenon was sometimes removed prior to the addition of the final aliquots of telluride. Caution must be exercised in all these reactions to prevent overheating and subsequent explosions.

Preparation of $(C_2F_5)_2TeF_2$

In a typical reaction $(C_2F_5)_2Te$ (2.67 g, 7.30 mmol) was condensed onto a slurry of XeF_2 (1.13 g, 6.67 mmol) and SO_2ClF (1.60 g) in six aliquots. The mixture was kept at −45°C for 1 h prior to the addition of the next aliquot. After complete addition of $Te(C_2F_5)_2$ the mixture was allowed to warm slowly from −45°C to room temperature over a period of 12 h. The materials, volatile at −95°C (0.75 g), −22°C (1.85 g), and room temperature (0.30 g), were mixtures of Xe, SO_2ClF, and C_2F_6; C_2F_6, C_2F_5Cl, $(C_2F_5)_2Te$, $(C_2F_5)_2TeF_2$, and SO_2F_2; and $(C_2F_5)_2TeF_2$ with traces of $(C_2F_5)_2Te$, respectively. The remaining product 2.56 g (6.34 mmol assuming $(C_2F_5)_2TeF_2$) was a white highly crystalline solid, mp 57°C, shown to be pure by ^{19}F nmr spectroscopy. The vibrational spectrum is given in Table 1, and the ^{19}F nmr spectral results summarised in Table 2. Sizable single translucent crystals were obtained in low yield in a similar reaction with CH_3CN replacing SO_2ClF as solvent.

Preparation of $(C_2F_5)_2TeCl_2$

Chlorine (0.251 g, 3.54 mmol) was condensed on $Te(C_2F_5)_2$ (0.941 g, 2.57 mmol) in six aliquots. The vessel was held at −78°C for 15 min, and then warmed to room temperature prior to the addition of the next aliquot. A crystalline white solid (1.07 g, 2.45 mmol assuming $(C_2F_5)_2TeCl_2$), and a yellow volatile liquid (0.085 g), C_2F_5Cl and Cl_2 were obtained. Sublimation of the solid *in vacuo* at 40°C led to a highly crystalline product. The solid had a small vapour pressure at room temperature and a melting point of 45°C. *Anal.* calcd. for $(C_2F_5)_2TeCl_2$: C 11.00, F 43.53, Te 29.23, Cl 16.14; found: C 11.24, F 43.85, Te 28.82, Cl 16.01. The Raman spectrum is

given in Table 3, and the ^{19}F nmr spectral results are summarised in Table 2.

Preparation of $C_2F_5TeF_3$

In a typical experiment, $(C_2F_5)_2Te_2$ (0.784 g, 1.59 mmol) was condensed in two aliquots onto a slurry of XeF_2 (0.730 g, 4.31 mmol) and SO_2F_2 (5.53 g) in a Monel vessel (vol. ca. 50 mL) and held at −45°C after the addition of each aliquot, and finally allowed to slowly warm to room temperature over a period of 12 h. The volatiles (5.86 g) contained SO_2F_2, Xe, unreacted $(C_2F_5)_2Te_2$, and traces of C_2F_6. The remaining solid (0.65 g) (2.14 mmol assuming $C_2F_5TeF_3$) was identified as $C_2F_5TeF_3$ by its Raman and ^{19}F nmr spectra and melting point.

In another experiment $(C_2F_5)_2Te_2$ (1.07 g, 2.16 mmol) was condensed into a slurry of XeF_2 (1.06 g, or 6.26 mmol) and SO_2ClF (1.54 g) in a glass vessel in three aliquots and treated as described above. The volatiles (2.43 g) contained Xe, SO_2ClF, and traces of SO_2 and C_2F_6. The white microcrystalline solid 1.23 g (4.05 mmol assuming $C_2F_5TeF_3$) was identified as such by ^{19}F nmr and Raman spectroscopy. A saturated solution of $C_2F_5TeF_3$ in SO_2 when left for 2 h yielding rectangular crystals. The solution was decanted into a separate vessel and traces of solvent removed by evacuation. Some of these white translucent crystals were mounted in Pyrex capillaries in a Vacuum Atmosphere Dry-Box and flame sealed. A suitable single crystal was then chosen for the X-ray diffraction studies. *Anal.* calcd. for $C_2F_5TeF_3$; C 7.90, F 50.06, Te 42.03; found (bulk material): C 7.66, F 49.68, Te 42.42. The Raman spectrum is listed in Table 4 and ^{19}F nmr spectrum in Table 2. The mp of the single crystals (142−143°C), ir, and Raman spectra, and ^{19}F nmr of the crystals in SO_2 solution were identical to those of the bulk material produced in both reactions (SO_2F_2 and SO_2ClF as dilutents for XeF_2).

Reaction of SO_2ClF and $(C_2F_5)_2Te_2$

Sulphuryl chlorofluoride (1.71 g, 14.45 mmol) was condensed onto $(C_2F_5)_2Te_2$ (0.191 g, 0.38 mmol) in a glass vessel giving a red−brown solution. After 1 h, small amounts of white precipitate were observed, and after 12 h, a clear solution over a white solid. The volatile material was SO_2 and SO_2ClF (ir, ^{19}F nmr) and the white solid (0.252 g) was $C_2F_5TeCl_xF_{3-x}$ (ir, Raman, ^{19}F nmr and mp). The experiment was repeated under conditions identical to those of the synthesis of $C_2F_5TeF_3$ using SO_2ClF as a diluent for XeF_2. Ninety percent of the $(C_2F_5)_2Te_2$ was recovered from the reaction, 10% had reacted to give traces of SO_2 (ir, Raman) and $(C_2F_5)TeCl_xF_{x-3}$.

Preparation of trans-$C_2F_5TeClF_4$

(*a*) By the reaction of $(C_2F_5)_2Te_2$ with an excess of ClF. In a typical experiment ClF (0.95 g, 17.5 mmol) was reacted with $(C_2F_5)_2Te_2$ (0.67 g, 1.36 mmol) in eight aliquots in a Kel-F vessel of ca. 20 mL volume. The mixture was held at −78°C for about 10 min and then the vessel warmed in order to let any solid materials on the sides of the vessel, or on the top of the reactants, melt prior to the addition of the next aliquot. A white solid was formed when the ratio of ClF:$(C_2F_5)_2Te_2$ was about 6:1. The solid remained on further additions of ClF aliquots. The solid gradually disappeared, and the product became a yellow liquid, on standing at room temperature for 3 h. The volatile material at −78°C contained Cl_2, C_2F_6, C_2F_5Cl, $TeClF_5$, *trans*-$C_2F_5TeClF_5$, and ClF. The involatile fraction melted to a clear liquid (0.95 g) at room temperature, consisting of *trans*-$C_2F_5TeClF_4$ and small amounts of $TeClF_5$ and C_2F_5Cl. Pure *trans*-$C_2F_5TeClF_4$ was obtained from the least volatile fraction of this mixture. *Anal.* calcd. for $C_2F_5TeClF_4$: C 6.70, F 47.7, Te 35.64, Cl 9.90; found: C 6.53, F 45.98, Te 35.07, Cl 10.07. The clear colourless liquid has a vapour pressure of ca. 70 Torr at room temperature. At −78°C it is a gel-like solid. It was stable in a Kel-F vessel at room temperature over several months. The ir and Raman spectra are listed in Table 5, and ^{19}F nmr spectral data given in Table 2.

It is noted that in order for a good yield of *trans*-$C_2F_5TeClF_4$, ClF must be added in small aliquots and the temperature raised slowly. Reaction with addition of a large amount of ClF and held at room temperature was extremely exothermic. In a reaction of $(C_2F_5)_2Te_2$ (1.39 g, 2.82 mmol) and ClF (1.46 g, 26.8 mmol) were condensed into a Monel vessel held at room temperature overnight. The vessel bomb initially becomes hot to the touch and the products were identified as C_2F_6 and TeF_6 (1.75 g) (ir) and a solid mixture of $TeCl_4$ and TeF_4 (ca. 1.1 g) (Raman).

(*b*) By the reaction of $C_2F_5TeCl_xF_{3-x}$ ($1 > x > 0$) with ClF. Chlorine monofluoride (0.26 g, 4.8 mmol) was added in one aliquot onto $C_2F_5TeCl_3F_{3-x}$ (0.34 g). The solid gradually disappeared on standing at room temperature giving a yellow liquid after 4 h. The materials volatile at −78°C, contained C_2F_4, CF_4, C_2F_5Cl, $TeClF_5$ (ir, ^{19}F nmr), and probably Cl_2. The material volatile at room temperature

contained mainly *trans*-$C_2F_5TeClF_4$, traces of $TeClF_5$ and some unidentified material as indicated by the ^{19}F nmr spectrum.

Preparation of a mixture of trans-$C_2F_5TeClF_4$ *and* trans-$(C_2F_5)_2TeF_4$

In typical reaction, ClF (0.59 g 10.8 mmol) was reacted in eight aliquots with $(C_2F_5)_2Te$ (0.76 g, 2.08 mmol) in a Kel-F vessel. On addition of each aliquot the mixture was held at −78°C for a few minutes and then briefly allowed to warm to room temperature to enable the solid product to melt. Finally the vessel was left standing for 1 h at room temperature. The volatile material at −78°C contained C_2F_6, C_2F_5Cl, $FClO_2$ (impurity in the ClF), and small amounts of $TeClF_5$ and *trans*-$C_2F_5TeClF_5$ (ir) and probably chlorine. The material volatile at room temperature (0.90 g) contained a 2:1 mixture of *trans*-$C_2F_5TeClF_5$ and *trans*-$(C_2F_5)_2TeF_4$ and traces of C_2F_5Cl and $TeClF_5$. The ^{19}F nmr data for *trans*-$(C_2F_5)_2TeF_4$ is given in Table 2. In other similar reactions, the ratios of *trans*-$C_2F_5TeClF_4$ and *trans*-$(C_2F_5)_2TeF_4$ varied, and small amounts of other unidentified species were also detected by ^{19}F nmr.

Reactions of trans-$C_2F_5TeClF_4$ *with ClF*

Chlorine monofluoride (0.08 g, 1.4 mmol) was reacted with *trans*-$C_2F_5TeClF_4$ (0.40 g, 1.1 mmol) in a Monel vessel at 90°C overnight. The products were *trans*-$C_2F_5TeClF_4$, a small amount of $TeClF_5$ (ir, ^{19}F nmr) and an unidentified material. Chlorine monofluoride and $C_2F_5TeClF_5$ did not appear to react at room temperature.

X-ray crystal structure of $C_2F_5TeF_3$

Preliminary precession photographs showed the space group to be $I4_1/a$ (hkl, $h + k + l = 2n$; $hk0$, $h = 2n$ and $k = 2n$; hhl, $l = 2n$; $00l$, $l = 4n$). The crystal was mounted on a Picker FACS-I diffractometer equipped with graphite monochromated MoKα radiation. Cell data and an orientation matrix were obtained from a least squares fit to the coordinates of 15 Friedel pairs of centered reflections in the range $30 \leq 2\theta \leq 40°$. Intensity data were collected using an $\omega-2\theta$ scan, for $2\theta \leq 55°$. The background intensity was estimated by standing counts of 1/10 of the scan time at each end of the scan; if the reflection was considered significant ($I > 2\sigma(I)$) the scan profile was

TABLE 6. Fractional atomic coordinates (esd's in parentheses)

analysed to provide a better estimate of the background. The relevant crystallographic data are:

$C_2F_5TeF_3$ fw = 303.6

Tetragonal, space group $I4_1/a$, a = 10.129(4), c = 25.561(6) Å, V = 2622(3) Å^3, Z = 16, $F(000)$ = 2032, D_{calcd} = 3.076 Mg m^{-3}, crystal size 0.26 × 0.25 × 0.14 mm, μ(MoKα) = 4.82 mm^{-1}, λ(MoKα) = 0.71069 Å. Number of unique reflections measured = 1516, number observed ($I \geqq 3\sigma(I)$) reflections = 901 (59%).

The structure was solved using the MULTAN (23) direct methods program, correction for absorption (transmission factors 0.30−0.48) and initial refinement was performed using Larson and Gabe's program (24) for the PDP8/A computer. Final full-matrix least-squares refinement was performed on a Wicat Systems computer using SHELX-76 (25). Scattering factors were taken from the International tables for X-ray crystallography (26) and were corrected for anomalous dispersion. The final agreement factors were $R = \Sigma|\Delta F|/\Sigma|F|$ = 0.051 and $R_w = \Sigma w^{1/2}|\Delta F|/\Sigma w^{1/2}|F|$ = 0.056 with weights based on counter statistics. A difference synthesis showed no unexpected features and had a maximum electron density of 1.18 $e^-/Å^3$ at a position 0.7 Å from the tellurium. The final atomic coordinates are given in Table 6.[1]

Results and discussion

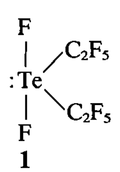
Preparation and characterisation of $(C_2F_5)_2TeF_2$ and $(C_2F_5)_2TeCl_2$

Careful addition of $(C_2F_5)_2Te$ in small aliquots to XeF_2 in a slurry of SO_2ClF according to eq. [1] led to $(C_2F_5)_2TeF_2$ in essentially quantitative yield.

[1] $(C_2F_5)_2Te + XeF_2 \xrightarrow[\text{low temp}]{SO_2ClF} (C_2F_5)_2TeF_2 + Xe$

Single crystals of $(C_2F_5)_2TeF_2$ had a melting point of 57°C. In our preliminary communication we had reported $(C_2F_5)_2TeF_2$ to be a liquid (9). This material was in fact a mixture of $(C_2F_5)_2TeF_2$, $(C_2F_5)_2TeClF$, and $(C_2F_5)_2TeCl_2$. We note that the melting point of $(CF_3)_2TeF_2$ is reported to be 185–195°C (15), higher than that (130°C (27)) of TeF_4.

The ^{19}F nmr spectrum of $(C_2F_5)_2TeF_2$ (Table 2) is consistent with the presence of two equivalent fluorine atoms and two equivalent C_2F_5 groups. The spectrum is first order and indicative of free rotation of the C_2F_5 groups about the tellurium atom, in contrast to the ^{19}F nmr spectrum of $(C_2F_5)_2SeF_2$ which is more complicated and may suggest restricted rotation of C_2F_5 about the selenium–carbon bond (7). The vibration spectrum of liquid and solid $(C_2F_5)_2TeF_2$ (Table 1) showed peaks attributable to C_2F_5 that were similar to $(C_2F_5)_2SeF_2$ (6), in addition peaks at ca. 520 and 500 cm^{-1} (see Table 1) that are reasonably assigned to asymmetric and symmetric axial F—Te—F stretches by comparison with monomeric TeF_4 in a solid N_2 matrix (axial F—Te—F asym. 587, sym. 572) (28). The vibrational spectrum of $(CF_3)_2TeF_2$ (15) had peaks (ir 485, Raman 493, 542) in a similar region that are likely similar tellurium–fluorine stretching frequencies. The structure of $(C_2F_5)_2TeF_2$ may therefore reasonably be assigned as **1** with the two fluorine atoms in the axial positions. Bis(perfluoroethyl) tellurium difluoride has a sufficient vapour pressure at room temperature to allow an infrared spectrum to be recorded (Table 1). Thus, its physical properties, ^{19}F nmr and vibrational spectrum, indicate that $(C_2F_5)_2TeF_2$ has the molecular structure (**1**), although some weak intermolecular association cannot be ruled out.



1

Bis(perfluoroethyl) tellurium dichloride was prepared essentially quantitatively by the careful addition of chlorine to $(C_2F_5)_2Te$, and was purified by sublimation. It was characterised by chemical analyses and ^{19}F nmr (Table 2). The strong peak in the Raman spectrum at 284 cm^{-1} is indicative of a Cl—Te—Cl axial symmetric stretch, by comparison with the vibrational spectrum of $(CH_3)_2TeCl_2$ (27) and $(CF_3)_2TeCl_2$ (16).

[1]Tables of anisotropic thermal parameters, and observed and calculated structure factors are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

Attempts to prepare $(C_2F_5)_2TeF_2$ by the reaction of $(C_2F_5)_2Te$ and chlorine monofluoride under a variety of conditions, led to mixtures of $(C_2F_5)_2TeF_2$, $(C_2F_5)_2TeClF$, $(C_2F_5)_2TeCl_2$, $C_2F_5TeCl_xF_{3-x}$, C_2F_5Cl, $TeClF_5$, and *trans*-$C_2F_5TeClF_4$.

The reaction of $(CF_3)_2Te$ and chlorine monofluoride (15) in a diluent at −78°C led to a mixture of $(CF_3)_2TeCl_xF_{2-x}$ ($x = 0, 1, 2$). Our reaction of $(C_2F_5)_2Te$ and chlorine monofluoride was carried out under less mild conditions, i.e., in a neat reaction, with some cleavage of tellurium–carbon bonds and oxidation of tellurium to Te(VI).

We note that the analogous reactions of $(C_2F_5)_2Se$ and $(C_2F_5Se)_2$ and chlorine monofluoride at room temperature were much less exothermic than the tellurium reactions, and led quantitatively to $(C_2F_5)_2SeF_2$ and $C_2F_5SeF_3$, respectively. At 80°C $(C_2F_5)_2SeF_2$ and $C_2F_5SeF_3$ reacted with chlorine monofluoride giving *trans*-$C_2F_5SeClF_4$ in good yield (6).

Preparation and characterisation of $C_2F_5TeF_3$

Perfluoroethyl tellurium trifluoride was prepared essentially quantitatively by the careful addition of $(C_2F_5)_2Te_2$ to XeF_2 in a slurry of SO_2F_2 according to reaction [2].

[2] $(C_2F_5)_2Te_2 + 3XeF_2 \xrightarrow[-45°C]{SO_2F_2} 2C_2F_5TeF_3 + Xe$

A similar experiment, but using SO_2ClF as a slurry for XeF_2, led to some SO_2 in the product. A blank reaction of SO_2ClF and $(C_2F_5)_2Te_2$ led to reaction of 10% of the ditelluride with formation of a $C_2F_5Cl_xF_{3-x}$ mixture according to reaction [3].

[3] $(C_2F_5)_2Te_2 + 3SO_2ClF \rightarrow 3SO_2 + 2C_2F_5TeCl_xF_{3-x}$ (average $x \approx 1.5$)

SO_2ClF is generally chemically very inert and is used as an unreactive solvent. However it has been used to convert $R_3P{=}X$ (R = alkyl or alkoxy, X = S) to fluorinated organophosphorus compounds (29). The $C_2F_5TeF_3$ produced in the presence of SO_2ClF appeared to be identical to that with SO_2F_2. It is therefore likely that reaction [2] was faster than reaction [3]. It is possible that reaction [3] proceeds via the TeC_2F_5 radical in equilibrium with $(C_2F_5)_2Te_2$ or by the direct reaction of SO_2ClF and $(C_2F_5)_2Te_2$.

The melting point of $C_2F_5TeF_3$ is 142–143°C. The material we previously reported as $C_2F_5TeF_3$ (mp ca. 95°C (9)) was in fact $C_2F_5TeF_xCl_{3-x}$. The ^{19}F nmr of $C_2F_5TeF_3$ in SO_2 solution (Table 2) showed the presence of C_2F_5 and Te—F, but no coupling was observed presumably due to exchange. The Raman spectrum of solid $C_2F_5TeF_3$ (Table 3) shows peaks attributable to C_2F_5, and tellurium–fluorine stretches (632(s), 594 m(br)), that are similar to those assigned to the equatorial tellurium–fluorine stretches (621 msh, 603 ms, 572 ms) in TeF_4 (28). This is consistent with the X-ray structure of $C_2F_5TeF_3$ (see below).

Attempts to prepare pure $C_2F_5TeF_3$ by the reaction of $(C_2F_5)_2Te_x$ $x = 1, 2$ and ClF under a variety of conditions, lead to $C_2F_5TeCl_3F_{3-x}$, C_2F_5Cl, and *trans*-$C_2F_5TeClF_4$.

The preparation and characterisation of trans-$C_2F_5TeClF_4$ *and* trans-$(C_2F_5)_2TeF_4$

The colourless liquid *trans*-$C_2F_5TeClF_4$ is prepared by the careful addition of ClF in a number of small aliquots at low temperature to $(C_2F_5)_2Te_2$ in ca. 90% yield according to reaction [4]

[4] $(C_2F_5)_2Te_2 + 8ClF \rightarrow 2C_2F_5TeClF_4 + 3Cl_2$

It can also be prepared from $C_2F_5TeCl_xF_{3-x}$ presumably accord-

ing to reactions [5] and [6].

[5] $C_2F_5TeClF_2 + ClF \rightarrow C_2F_5TeF_3 + Cl_2$

[6] $C_2F_5TeF_3 + ClF \rightarrow C_2F_5TeClF_4$

The minor products C_2F_5Cl and $TeClF_5$ are also observed. *trans*-$C_2F_5TeClF_4$ and ClF do not react at room temperature. Chlorine monofluoride does react with TeF_4 and $TeCl_4$ at room temperature to yield $TeClF_5$ (31). It is possible that $TeClF_5$ and C_2F_5Cl are formed by reactions of chlorine with perfluoroethyl tellurium species, e.g., according to reactions [7]–[9].

[7] $C_2F_5TeF_3 + Cl_2 \rightarrow C_2F_5Cl$ + "$TeClF_3$"

[8] "$TeClF_3$" $+ ClF \rightarrow Cl_2 + TeF_4$

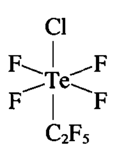
[9] $TeF_4 + ClF \rightarrow TeClF_5$

The analogous reactions of chlorine with CF_3TeCl_3 has been reported (17) to proceed according to reaction [10].

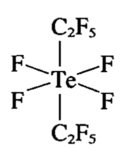
[10] $CF_3TeCl_3 + Cl_2 \rightarrow TeCl_4 + CClF_3$

The octahedral *trans*-$C_2F_5TeClF_4$ symmetry **2** is readily assigned by means of ^{19}F nmr (Table 2) and from vibration spectra (Table 5). A comparison, and assignment, of the $ClTeF_4$ vibrational frequencies in *trans*-$C_2F_5TeClF_4$, $TeClF_5$, and *trans*-$CH_3OTeClF_4$ have been given in ref. 10.

A careful reaction at low temperature of $(C_2F_5)_2Te$ and chlorine monofluoride in a 1:5 mole ratio led to a 2:1 ratio of *trans*-$C_2F_5TeClF_4$ (**2**),



2



3

and *trans*-$(C_2F_5)_2TeF_4$ (**3**). The products were unambiguously identified by their ^{19}F nmr spectra (Table 2), although pure *trans*-$(C_2F_5)_2TeF_4$ was not isolated.

Crystal structure of $C_2F_5TeF_3$

The crystal packing of $C_2F_5TeF_3$ is illustrated in Fig. 1, and the coordination of atoms around tellurium are shown in Fig. 2. Bond distances and angles are given in Tables 7 and 8,

respectively. Solid $C_2F_5TeF_3$, like TeF_4 (21), has a *cis*-fluorine bridged polymeric structure, but unlike TeF_4, the structure consists of mutually perpendicular polymeric chains (see Fig. 1). Each tellurium, in VSEPR terms (20), has an AX_4YE geometry (X = F, Y = C_2F_5, E, lone pair), see Figs. 2 and 3. The four fluorine atoms are planar within ±0.13 Å, and the lone pair is *trans* to the C_2F_5 group. Consistently, the four fluorine atoms are bent back from the lone pair, with the tellurium atom 0.26 Å above the plane of the four fluorine atoms. The geometries of the atoms around tellurium in $C_2F_5TeF_3$ and TeF_4 are similar, with the C_2F_5 group of $C_2F_5TeF_3$, in the position of the axial fluorine atom in TeF_4, and are compared in Fig. 3. The tellurium atoms in $C_2F_5TeF_3$ are linked by two essentially linear (see Table 8 and Fig. 2) *cis*-fluorine bridges, giving the chains a square wave shape (Fig. 1). The fluorine bridges in TeF_4 are neither linear (TeFTe 159(2.5)° (21)), nor symmetrical (TeF (bridging) 2.08(3), 2.26(3) Å). Thus, $C_2F_5TeF_3$ is more nearly polymeric, and TeF_4 more nearly a strong interacting molecular solid. Consistently, the melting point of $C_2F_5TeF_3$ (142–143°C) is higher than that of TeF_4 (130°C). The C_2F_5 groups and lone pairs in adjacent $C_2F_5TeF_4$ groups, and axial fluorine atoms and lone pairs in TeF_4, are *trans* to one another. Chains are linked by a weak tellurium fluorine interaction (Te—F3′, 3.168(9) Å, sum of van der Waals radii (Pauling) 3.55 Å) illustrated in Fig. 2. Chains in TeF_4, are linked by two stronger contacts (2.94(3), 3.01(3) Å), reflecting the greater partial positive charge on the tellurium atom, in tellurium tetrafluoride. The geometries of various related $RTeX_3$ (X =

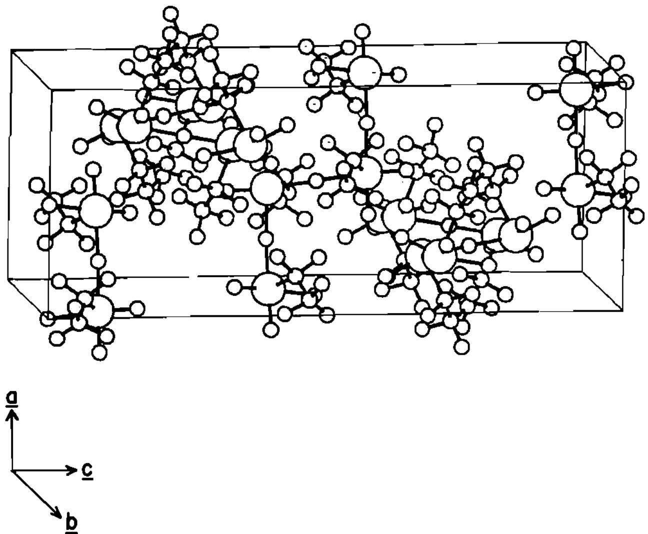

FIG. 1. Crystal packing in $C_2F_5TeF_3$.

TABLE 9. Selected tellurium–carbon distances

Compound/species	Te—C (Å)	Reference
$C_2F_5TeF_3$	2.20(2)	This work
$Te(CH_3)_3^+$ in $Te(CH_3)_3BPh_4$	2.14(1) (mean)	33
$(CH_3)_2TeI_4$	2.14(1) (mean)	34
$(CH_3)_2TeCl_2$	2.09(3) (mean)	35
α-$(CH_3)_2TeI_2$	2.12(3) (mean)	34
$ClC_2H_4TeCl_3$	2.16(1)	36

Cl(18), Br(30), I(31)) have been determined, and discussed.

The average equatorial tellurium–fluorine terminal and bridging bonds in TeF_4 (1.90(2), 2.17(3) Å) and $C_2F_5TeF_3$ (1.872(7), 2.193(5) Å) are similar in length. The average FTeF angles within the equatorial TeF_4 base, are also similar in TeF_4 (88.8(2.4)° and $C_2F_5TeF_4$ 89.0(6)°). If the lone pair in $C_2F_5TeF_3$ were perfectly opposite the C_2F_5 group, then the angles within the TeF_4 base would be determined solely by the strengths of the tellurium fluorine bonds, and in the order F2TeF3 > F3TeF1 ≈ F2TeF4 > F4TeF1. This is not the case, and presumably the lone pair is displaced towards F4 and F1, reflecting a contribution of the valence bond structures $C_2F_5TeF2F3^+F4^-$ and $C_2F_5TeF2F3^+F1^-$, to the overall bonding in the polymer. The average C1TeF (basal) angle of 83.2(6)° is similar to the average F (axial) TeF (basal) (82.0(2.3)°) angle in TeF_4. Both are less than 90° consistent with the presence of a lone pair opposite the axial ligand. C1TeF (bridging) angles are, as anticipated by VSEPR (20) theory, smaller than C1TeF (terminal) angles. The two terminal fluorine bond distances, and, the two bridging bond distances are essentially equal, therefore it would be expected that C1TeF2 would equal C1TeF3, and C1TeF4 equal C1TeF1. However, this is not the case (see Fig. 3).

The tellurium carbon bond distance (2.20(2) Å) is likely longer than that reported for other tellurium carbon bond distances (see Table 9, and refs. 18, 30–32). Oberhammer (36) has examined the effect of substitution of methyl by perfluoromethyl in $O(CH_3)_2$, $S(CH_3)_2$, $N(CH_3)_3$, and $P(CH_3)_3$, and concluded that lengthening occurs when the central atom has an electronegativity less than 2.5 (Pauling scale). Tellurium has an electronegativity on the Pauling scale of 2.34, and length-

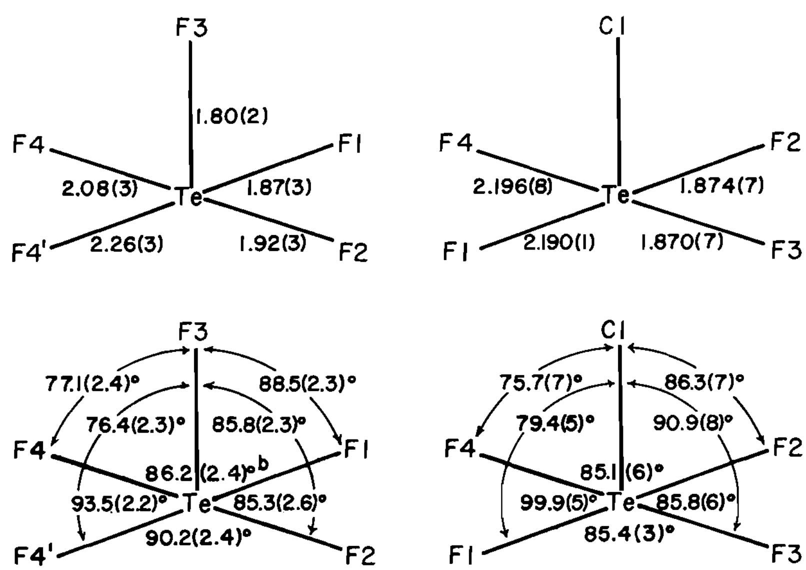

FIG. 3. A comparison of the geometries about tellurium in TeF_4 and $C_2F_5TeF_3$. Bond distances in Å.

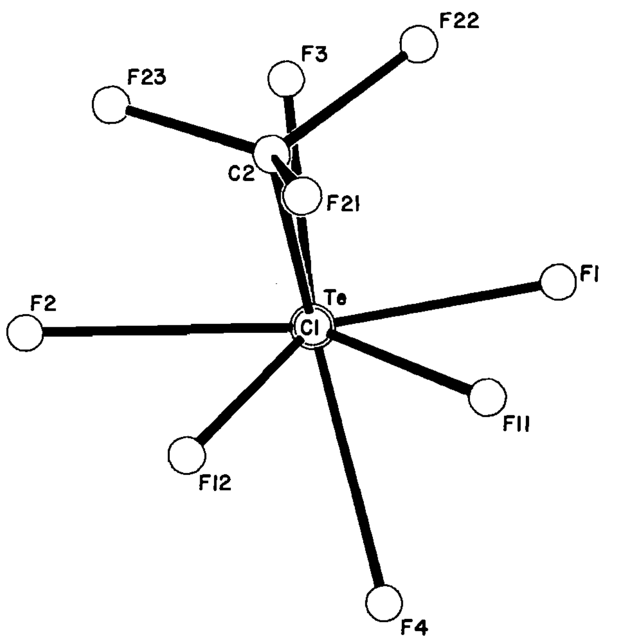

FIG. 4. View of the $C_2F_5TeF_3$ moiety projected along the Cl—Te bond.

ening is therefore expected.

Figure 4 shows a view of the $C_2F_5TeF_3$ moiety as projected along the C1—Te bond. The fluorine atoms of the C_2F_5 group and those of the basal TeF_4 are staggered relative to one another. The two fluorine atoms of the CF_2 groups have contacts to tellurium (2.93(9), 2.98(1), that are considerably less than the sum of the corresponding van der Waals radii (3.55 Å), and likely represent very weakly bonding interactions. The high standard deviations, and high thermal parameters of the atoms of the C_2F_5 group do not allow a detailed comparison with related molecules (e.g. C_2F_5I (37), *trans*-$PtClC_2F_5(PMePh_2)_2$ (38)). The TeC1C2 angle (123(2)°), which is substantially larger than the expected tetrahedral angle of 109° (28), is similar to that observed in a variety of related compounds (ref. 38 and references quoted therein) including C_2H_5 derivatives of transition metals, and it has been suggested that the opening of the MC1C2 angle may be caused by ligand–ligand interaction and/or molecular packing forces.

2-Isopropoxy-1,4-naphthoquinone has been used as a photoredox reagent in non-silver imaging process. The present study showed that the photoreactions of this quinone are very sensitive to solvent due to the competing intramolecular hydrogen abstraction from the isopropoxy group. The presence of cobalt acetylacetonate often modifies the reactions which leads to a very high quantum efficiency of producing the radical intermediates. The ether oxygen in the 2-substituent provides a further coordinating site for organometallic compounds and the quinone behaves as a 1,2-quinone when interacting with metals.

M. Catherine Depew, B. B. Adeleke, Allison Rutter et J. K. S. Wan. Can. J. Chem. **63,** 2281 (1985).

On a utilisé l'isopropoxy-2 naphtoquinone-1,4 comme agent photoréducteur dans un processus de formation d'image n'impliquant pas l'argent. Notre étude a démontré que les photoréactions de cette quinone sont très sensibles à la nature du solvant et ce fait est dû à une réaction compétitive d'enlèvement intramoléculaire d'hydrogène du groupe isopropoxyle. La présence d'acétylacétonate de cobalt modifie souvent les réactions et ceci conduit à une efficacité quantique très élevée pour la production d'intermédiaires radicalaires. L'oxygène de l'éther du substituant en position 2 fournit un nouveau site de coordination pour les composés organométalliques et la quinone se comporte comme une quinone-1,2 lorsqu'elle interagit avec les métaux.

[Traduit par le journal]

Introduction

The photochemistry of quinones has long been a subject of many studies. Much of the chemical information has been utilized when we initiated quinones as model systems for CIDEP (chemically induced dynamic electron polarization) and CIDNP (chemically induced dynamic nuclear polarization) studies (1). As well, quinones have been extensively explored as reagents to interact with metal ions and organometallics (2, 3). In recent years the use of some substituted quinones as photoredox agents in non-silver imaging processes has led to the development of a novel high gain photothermographic imaging process by the Eastman Kodak Company (4, 5). In this paper we report some of esr and CIDEP results of the photoredox reactions of 2-isopropoxy-1,4-naphthoquinone and the subsequent interactions with cobalt compounds and other organometallics. The photochemical reactions of this quinone are strongly solvent dependent; the presence of the Co(III)–acetylacetonate often modifies the esr observations of the quinone radical intermediates by secondary redox reactions. With the 2-isopropoxy substituent, the 1,4-quinone behaves efficiently as a 1,2-quinone in which the ether oxygen serves as an additional coordinating site with a number of organometallic compounds, including the manganese and rhenium carbonyls. The results will shed some light on the extremely high quantum efficiency of this quinone in the photothermographic imaging process.

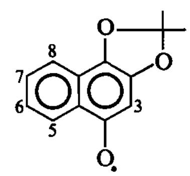
Experimental

2-Isopropoxy-1,4-naphthoquinone (INQ) and 3-chloro-2-isopropoxy-1,4-naphthoquinone (CINQ) were gifts from Dr. Thap Dominh of the Eastman Kodak Company. Cobalt salts and many of the organometallics used were supplied by Aldrich Chemicals. Organic solvents were purified by appropriate methods before use. Sample solutions were all deoxygenated by purging with nitrogen gas immediately before use. In cw experiments samples were irradiated with a super pressure mercury lamp with Pyrex optics directly within the microwave cavity of an X-band esr spectrophotometer with a 100 kHz field modulation. Microwave frequency was monitored by a Hewlett Packard 5432 frequency counter and the magnetic field was measured by a Bruker nmr oscillator calibrated against DPPH. In CIDEP experiments the transient spin-polarised radicals were produced by laser photolysis using a Molectron 1 MW nitrogen laser and dc detection. The CIDEP apparatus and the method of estimating T_1 from the experimental data were described previously in detail (6).

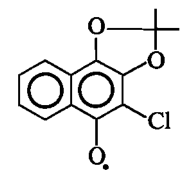
Results and discussion

1. Photolysis of INQ and CINQ in benzene solution

The photolysis of INQ in benzene solution at room temperature produced a well resolved esr spectrum of a radical intermediate which can be assigned to the following structure (**I**):



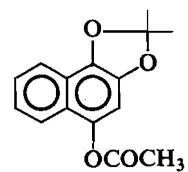
I



II

The photolysis of CINQ led to the observation of radical **II**. The assignments of both radicals **I** and **II** are given in Table 1.

It is obvious that both radicals are necessarily the result of some secondary photochemical reactions. In benzene solution the only primary photochemical reactions of INQ and CINQ are the intramolecular hydrogen abstraction from the 2-isopropoxy group. Similar photochemical reactions of 2-substituted quinones have been well characterized (7–9). The photolysis of INQ in acetic anhydride led to the formation of the rearranged product **III** (10):



III

Thus it is reasonable that radical **I** is formed as shown in the following scheme:

TABLE 1. The esr parameters of INQ radicals generated in the photolysis of INQ in various solvents at 23°C

Radical	Solvent	g-factor	Proton hyperfine coupling constants* (G)
 (I)	Benzene	2.0041±0.0002	a_3 = 4.90; a_6 = a_8 = 2.94; a_5 = a_7 = 0.98
 (II)	Benzene	2.0034	a_6 = a_8 = 2.78; a_5 = a_7 = 0.76
 (VIII)	EPA	2.0044	$a_H^{(O—CH—)}$ = 2.37; a_{OH} = a_6 = a_8 = 1.22; a_3 = a_7 = 0.30

*Refer to diagrams in text for proton positions.

[1] INQ + $h\nu$ $\xrightarrow{\text{benzene}}$ ^{3}(INQ)*

[2] 
IV

[3] ^{3}(INQ)* + **IV** ⟶ Radical $\dot{\text{I}}$* + INQH$^{\bullet}$

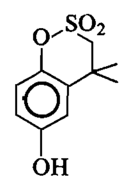
where ^{3}(INQ)* indicates a spin-polarized triplet. Photolysis of CINQ would be expected to result in the formation of radical **II** in an analogous fashion. This reaction scheme is further supported by two sets of experiments. In the first set, the addition of some di-*t*-butylperoxide to the photolysed INQ benzene solution greatly enhanced the esr intensity of radical **I**, due to the efficient reaction

[4] R$\dot{\text{O}}$ + **IV** → $\dot{\textbf{I}}$ + ROH

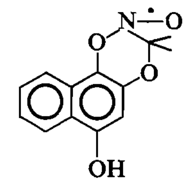
In the second set of experiments, flash laser photolysis was employed in the CIDEP mode of detection. When a fresh benzene solution of INQ was flash photolysed, no radicals could be observed. However, when the solution was pre-irradiated for 3 min and then subjected to laser flash photolysis, radical **I** was immediately detected in a totally emissive mode. The polarization was strong at room temperature and can be accounted for by the triplet mechanism associated with intersystem crossing and subsequent reaction of the spin-polarized triplet in reactions [1] and [3]. The T_1 of radical **I** in benzene solution at room temperature was estimated at 2.8 μs.

Similar polarization of radical **II** was observed when CINQ in benzene was photolysed. As expected the T_1 of radical **II** is similar to that of radical **I**.

The rearrangement in reaction [2] presumably involves a biradical intermediate as proposed by Farid (8). In the photoreaction of *t*-butyl-*p*-benzoquinone, Farid (8) has used sulfur dioxide to trap the biradical which led to the formation of sultone (**V**) as the major product. In the photolysis of some cyclic ketones believed to involve a biradical as an intermediate, Scaiano (11) has successfully trapped such biradicals with nitric oxide to yield a relatively persistent nitroxide radical. In our experiments, when a benzene solution of INQ saturated with nitric oxide was photolysed, the formation of radical **I** was quenched and in its place a nitroxide radical was observed. The new nitroxide radical had the following spectral parameters: g = 2.0064; a_N = 11.6 G. Consistent with Farid's (8) observation, we have *tentatively* assigned the nitroxide radical to the structure **VI**. Prolonged irradiation further led to the



V



VI

observation of an additional triplet with a larger splitting of 29.9 G which is characteristic of an iminoxy type of radical. The identity of this second radical remains uncertain. However, identical experiments performed with 1,4-naphthoquinone did not yield any nitroxide radicals; this result is not unexpected since no biradical intermediates would have been involved.

2. The effect of addition of Co(III) acetylacetonate

Radicals **I** and **II** generated during the photolysis at room temperature disappeared immediately upon termination of irradiation. When Co(III) acetylacetonate was added to the benzene solution of INQ and photolysed, the esr spectrum of the radical could be observed hours after the light was turned off. In a typical experiment, the photolysis of a benzene solution containing CINQ, Co(III) acetylacetonate greatly enhanced the steady state esr signal intensity of radical **II**. A complementary examination of the photolyzed solution by uv–visible spectrometry showed a new absorption band at 490 nm. The experimental results can be explained by the following cycle, similar to that proposed by DoMinh (4) in his photothermographic imaging process:

[5] 
The new absorption band at 490 nm can be associated with the Co(II) complex with the protonated CINQ which further undergoes a redox reaction to yield Co(III) and the product **VII** to complete the cycle. Experimentally, the initial effect on the magnitude of radical enhancement was found to depend upon the concentration of Co(III) added. The cycle can continue in the dark to "maintain" the concentration of radicals for esr observation many hours after the termination of irradiation. In effect, the quantum yield of the radical formation was greatly magnified.

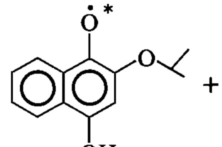
3. Photolysis of INQ in an EPA solution

A mixed solvent system containing ether, isopentane, and ethanol (EPA, 2:2:5 by volume) was used in the low temperature photolysis of INQ because of its good optical quality in the glassy state. The purpose of the experiment, carried out at 77 K, was to trap the biradical intermediate of the INQ for direct esr observation. The experiment was not successful, as neither the $M_s = 2$ nor the $M = 1$ transitions could be detected.

However, when INQ was photolysed in EPA solution at room temperature, a well-resolved esr spectrum was observed. The spectrum cannot be ascribed to the same radical **I** formed in benzene. Furthermore, the spectrum exhibited total emission immediately upon laser flash photolysis. This observation indicates that the radical is a primary polarized intermediate resulting directly from the reaction of a spin-polarized INQ triplet with the solvents. The esr parameters of this radical (given in Table 1) can be assigned to the semiquinone radical **VIII** with polarization being accounted for by the following mechanism:

[1] $\text{INQ} + h\nu \xrightarrow{\text{ISC}} {}^3(\text{INQ})^*$

[6] ${}^3(\text{INQ})^* + \text{RH (EPA solvent)} \longrightarrow$



$+ \text{R}^{\bullet *}$

VIII

Under the experimental conditions, the counter radical R$_*$ was not observed. It is therefore not known which component of the EPA system reacted with the INQ triplet. However, abstraction of a hydrogen atom from ethers by quinone triplets has been observed in other systems (12).

Because of the strong polarization observed in radical **VIII**, it follows that reaction [6] must have taken place faster than the spin lattice relaxation time of the polarized INQ triplet, which in liquid solution is normally in the order of 10^{-9} s. Furthermore, since radical **I** was not observed simultaneously during the cw photolysis of INQ in EPA solvent, it appears that reaction [6] competes favorably with the intramolecular hydrogen abstraction, in reaction [2].

The photolysis of INQ was also carried out at room temperature in a number of different solvents, which can react directly with the excited triplet INQ. In THF solvent, the predominant radical intermediate was the radical anion of INQ, which also exhibited strong polarization in the emissive mode. In 2-propanol solvent, the abstraction reaction was not expected to be as fast and only a weak esr signal of the radical **VIII** was observed in cw photolysis. The CIDEP data showed that the radical **VIII** in alcoholic solvents possessed a longer spin lattice relaxation time (3.5 μs) compared to that of radical **I** in benzene (2.8 μs). This difference, however, is not due to the structural variations between the two radicals. Rather, the difference is mainly due to the different nature of the solvents with the alcoholic solvents being capable of forming hydrogen bonds with the radical **VIII**.

4. Organometallic radical adducts of INQ and CINQ

Photolysis of a number of organometallic compounds in benzene in the presence of either INQ or CINQ led to the formation of corresponding radical–quinone adducts. It is well known that for 1,2-quinones the two carbonyl oxygens both participate in the coordination. Although INQ and CINQ are

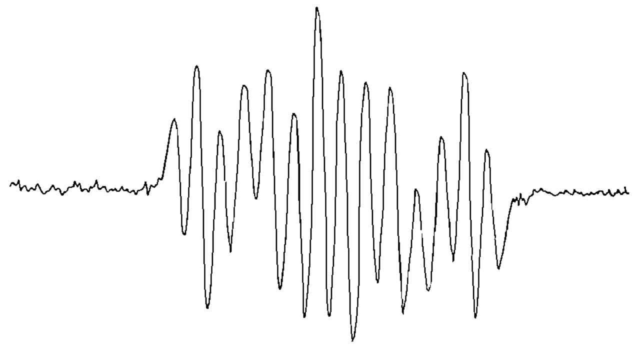


FIG. 1. Electron spin resonance spectrum obtained during cw photolysis of INQ in benzene at 23°C. CIDEP experiments showed that all hyperfine lines in the spectrum were in the emissive mode.

TABLE 2. Electron spin resonance parameters of some metal carbonyl radical adducts of INQ and CINQ in benzene at 23°C

Metal carbonyl	Organic moiety	g-factor	Metal hyperfine couplings (G)
$Re(CO)_4$, 1:1	INQ	2.0032	$a_{Re} = 15.69$
	CINQ	2.0035	$a_{Re} = 15.71$
	1,2-Naphthoquinone	2.0030	$a_{Re} = 24.2$
$Re(CO)_4$, 1:2	INQ	2.0025	$a_{Re} = 19.10$
	CINQ	2.0035	$a_{Re} = 20.19$
$Mn(CO)_4$	INQ	2.0030	$a_{Mn} = 4.75$
	CINQ	2.0030	$a_{Mn} = 6.05$
$C_5H_5V(CO)_2$	INQ	1.9750	$a_V = 82.5$
	CINQ	1.9684	$a_V = 85.8$
$C_5H_5Mo(CO)_2$	INQ	1.9666	$a_{Mo} = 35.2$
	CINQ	1.9678	$a_{Mo} = 37.8$

1,4-quinones they possess a 2-isopropoxy substituent. The results indicate that the 2-ether oxygen participates efficiently in the coordination and both INQ and CINQ thus both behave as 1,2-quinones towards the formation and stabilization of organometallic radical adducts. However, a significantly different behavior was observed between 1,2-naphthoquinone and INQ when they reacted with $Re(CO)_5$. Our previous studies (13, 14) of rhenium carbonyl – quinone (or diketone) radical adducts showed that only 1:1 adducts were observed. In only one case, when 1,10-phenanthroline was used, was a 1:2 radical complex formed. In the present system using INQ, both the 1:1 *and* the 1:2 radical complexes were simultaneously formed and observed during the photolysis. The relative intensities of the two radical complexes followed the relative concentrations of the two reagents, INQ and $Re(CO)_{10}$. It is therefore rather simple to assign the two spectra to the respective radical complexes. Although relatively persistent compared to the other INQ–organometallic adducts formed in this study, these rhenium–INQ radical adducts were still not sufficiently long-lived for isolation and further characterization. The spectral parameters for these and several other organometallic radical adducts are given in Table 2.

Laser flash photolysis experiments were also carried out in these systems where the organometallic radical adducts were formed. No CIDEP was observed in any of the radical adducts.

Acknowledgments

We are grateful to Dr. T. DoMinh of the Eastman Kodak Company for his assistance and enlightening discussion. This research is supported by the Natural Sciences and Engineering Research Council of Canada. Some of the preliminary experiments were performed by Mr. Liu Zhongli.

Mechanism of the oxidation of triphenyl derivatives of P, As, and Sb by peroxodiphosphate

C. SRINIVASAN AND K. PITCHUMANI
School of Chemistry, Madurai Kamaraj University, Madurai – 625 021, India

Received August 30, 1984

C. SRINIVASAN and K. PITCHUMANI. Can. J. Chem. **63**, 2285 (1985).

Rate coefficients have been determined for the oxidation of Ph_3M (M = P, As, Sb) by potassium peroxodiphosphate. The reaction is found to follow second-order kinetics, first order in each in the oxidant and Ph_3M. $[H^+]$ has a pronounced accelerating effect on the reaction rate. An interesting dependence of the active species on the nature of the substrate has been observed. The reaction rate is influenced by changing the ionic strength of the medium. Acrylonitrile has no effect on the rate of oxidation. On the basis of the kinetic evidence, a general mechanism involving a biomolecular nucleophilic displacement of the substrate on the peroxo ion has been proposed. The relative rate order is found to be $Ph_3P > Ph_3Sb > Ph_3As$ and an explanation has been offered for the transposition of Ph_3Sb and Ph_3As.

C. SRINIVASAN et K. PITCHUMANI. Can. J. Chem. **63**, 2285 (1985).

On a déterminé les coefficients de vitesse pour les réactions d'oxydation des Ph_3M (M = P, As, Sb) par le peroxodiphosphate de potassium. On a trouvé que la cinétique de la réaction est du deuxième ordre, soit du premier ordre dans chacun des réactifs (oxydant et Ph_3M). La concentration en H^+ provoque une accélération importante de la vitesse. On a observé une relation intéressante entre les espèces actives et la nature du substrat. La réaction est influencée par des changements dans la force ionique du milieu réactionnel. L'acrylonitrile n'a pas d'effet sur la vitesse de la réaction. Si on se base sur les données cinétiques, on peut proposer une mécanisme général impliquant une substitution nucléophile bimoléculaire du substrat sur l'ion peroxo. On a trouvé que les vitesses relatives de réaction sont $Ph_3P > Ph_3Sb > Ph_3As$ et on offre une explication pour la transposition du Ph_3Sb et du Ph_3As.

[Traduit par le journal]

Introduction

The reactions of organic peroxides with triphenyl derivatives of Group V elements have been the subject of several investigations (1–3). They depend on the nature of both the peroxide and of the element. Though there are some kinetic studies on the oxidation of Ph_3M (M = P, As, Sb) by organic peroxides, notably by Hiatt *et al.* (4, 5), more investigations with inorganic peroxo compounds are desirable. Recently we have reported on the kinetics and mechanism of peroxodisulfate (PS) oxidation of Ph_3M in acetonitrile–water mixture (7), and on the substituent effect in the PS oxidation of triphenylarsines (8). The present paper summarizes the results of our kinetic studies of the oxidation of triphenyl derivatives of P, As, and Sb by potassium peroxodiphosphate (PP).

Experimental

Materials

Triphenylphosphine (Riedel, Prosynth) and triphenylarsine (Fluka, Purum) were recrystallized from ethanol. Triphenylstibine was prepared by the Grignard addition of phenyl magnesium bromide to antimony trichloride (9) and recrystallized from ethanol. Tetrapotassium peroxodiphosphate (FMC corporation) was used after repeated recrystallization from methanol–water mixture. A commercial sample of acetonitrile was purified by standard procedure. All the other chemicals used were of AnalaR grade.

Kinetics

Rate coefficients have been determined for the oxidation of Ph_3M (M = P, As, Sb) in 60% acetonitrile – 40% water (v/v) mixture at constant ionic strength (maintained by the addition of sodium perchlorate) and at constant $[H^+]$ under pseudo first-order conditions with a large excess of the oxidant concentration. The reaction was followed by estimating the unreacted triphenylphosphine (TPP) or triphenylarsine (TPA) by an iodometric method (10, 11). In the case of triphenylstibine (TPS), since it does not undergo instantaneous reaction with iodine, a spectrophotometric method was adopted. Rates were determined by monitoring the disappearance of the uv absorption characteristic of TPS (λ_{max} = 255 nm) using a Perkin–Elmer model 402 uv–visible spectrophotometer provided with thermostated silica cells. The alkalinity of PP was always taken into account in the calculation of $[H^+]$. Reactions were generally followed to >60% completions; reproducible results giving good first-order plots (correlation coefficient $r > 0.995$) were obtained for reactions run in duplicate or triplicate. Rate constants were calculated by the least-squares technique using a Micro 2200 computer (Hindustan Computers Ltd.,). The precision of k values is given in terms of 95% confidence limit, calculated with "Student t".

Product studies

The reaction mixture was monitored by tlc (silica gel). The product of the reaction was found to be the respective oxide in the case of TPP and TPA oxidations. Oxidations of TPS gave only a crystalline antimony product that does not melt even after heating to 280°C and liberates free iodine from potassium iodide in glacial acetic acid. This is consistent with the characteristics of a polymeric material (oxide) produced by the oxidation of TPS by hydrogen peroxide (12) and not the monomeric triphenylstibine oxide prepared by McEwen *et al.* (13). In the reaction of TPS with *tert*-butylhydroperoxide, a polymeric product is also obtained (6, 14).

The product studies were also confirmed by the uv absorption characteristics of the respective oxides (15), as the products gave peaks similar to those obtained for authentic samples of the respective oxides.

Results and discussion

Rate coefficients for different concentrations of PP and Ph_3M at constant ionic strength and $[H^+]$ are presented in Table 1. Plots of log $[Ph_3M]$ versus time yield good straight lines, from the slopes of which k_1 are calculated (Fig. 1). The linearity of the rate profiles indicates that the reaction is first order in substrate. From the double logarithmic plots of the initial rate versus initial concentrations of PP, the order with respect to PP has also been evaluated and is found to be unity in all the three cases.

TPP: slope = 0.99 ± 0.02, $r = 0.999$, $s = 0.002$
TPA: slope = 1.01 ± 0.08, $r = 0.999$, $s = 0.01$
TPS: slope = 1.06 ± 0.17, $r = 0.996$, $s = 0.02$

§I = 0.36 M; $[H^+]$ = 0.01 M; t = 40°C.
‖I = 0.1 M; $[H^+]$ = 0.006 M; t = 35°C.

In each substrate the plot of k_1 versus [PP] gives a good straight line passing through the origin (TPP: r = 0.999, TPA: r = 0.999, TPS: r = 0.993) showing the second-order nature of the reaction, which is also confirmed by the constancy of second-order rate constants obtained from the pseudo first-order rate constants as $k_2 = k_1/[PP]$ (Table 1).

Hydrogen ion dependence and active species

The rate of oxidation of Ph_3M by PP increases significantly with increase in $[H^+]$ at constant ionic strength. The results are presented in Table 2.

A plot of log k_1 against log $[H^+]$ gave a good straight line with a slope of 0.94 ± 0.03 (r = 0.999, s = 0.003) (Fig. 2) showing the near first-order dependence in $[H^+]$ in the oxidation of TPP. It is also confirmed from the constant values of the third-order rate constants (k_3). A plot of k_1 against $[H^+]$ is linear (r = 0.999) with an intercept indicating the presence of uncatalysed oxidation (Fig. 3).

In the oxidation of TPA, a second-order dependence in $[H^+]$ was observed when the log k_1 values are plotted against the log $[H^+]$ values (slope = 1.99 ± 0.03, r = 0.999, s = 0.01) (Fig. 2). Further, an excellent correlation is found to exist between k_1 and $[H^+]^2$ (r = 0.999) and the linear plot passes

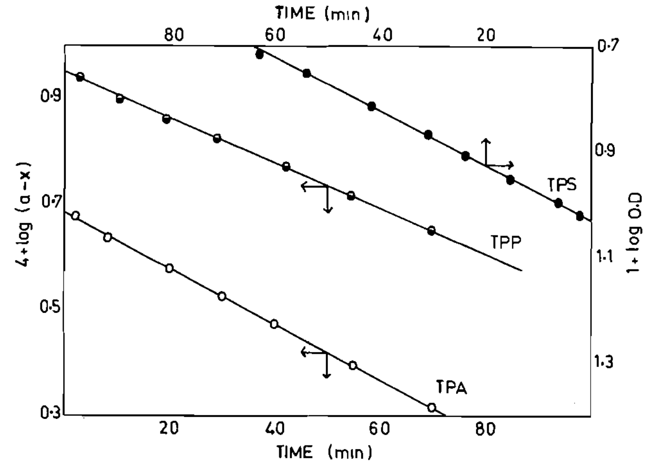

FIG. 1. Pseudo first-order plot for the oxidation of Ph_3M by PP. TPP: Plot of log $(a-x)$ versus time. [PP] = 0.03 M, [TPP] = 0.001 M, I = 0.36 M, t = 40°C. TPA: Plot of log $(a-x)$ versus time. [PP] = 0.0075 M, [TPA] = 0.0005 M, I = 0.2 M, $[H^+]$ = 0.02 M, t = 40°C. TPS: Plot of log O.D. versus time. [PP] = 0.003 M, [TPS] = 0.0001 M, I = 0.1 M, $[H^+]$ = 0.006 M, t = 35°C.

through the origin (Fig. 3). The constant values of $k_1/[H^+]^2$ (Table 2) also indicate the second-order dependence on $[H^+]$.

In the oxidation of TPS, a slope of 1.03 ± 0.09 (r = 0.998, s = 0.02) is obtained from the log–log plot of rate constants and $[H^+]$ (Fig. 2). Constant values of third-order rate constants are obtained, thus confirming the first-order dependence in $[H^+]$ (Table 2). Further, a good straight line (r = 0.998) passing almost through the origin is obtained (Fig. 3), showing that the reaction is completely acid dependent.

Active species

Peroxodiphosphate anion is tetranegative and is extensively protonated in acid medium. Hence, the various species[1] which are likely to be present are $P_2O_8^{4-}$, $HP_2O_8^{3-}$, $H_2P_2O_8^{2-}$, $H_3P_2O_8^-$, and $H_4P_2O_8$, and their relative concentration as a function of pH has been discussed by Crutchfield (16). In the present study, the pH has been maintained in the range 1–3, in which the three species, viz., $H_2P_2O_8^{2-}$, $H_3P_2O_8^-$, and $H_4P_2O_8$ may be present (16, 17) in solution. Hence the total concentration of PP is given by eq. [1]:

$$[1]\quad [PP]_T = [H_2P_2O_8^{2-}] + [H_3P_2O_8^-] + [H_4P_2O_8]$$

If all the three species are considered to contribute to the rate with respect to PP, the rate expression for the disappearance of PP can be represented (16–19) by eq. [2].

$$[2]\quad -\frac{d[PP]}{dt} = k_1'[H_2P_2O_8^{2-}] + k_2'[H_3P_2O_8^-] + k_3'[H_4P_2O_8]$$
$$= [PP]_T\frac{(k_1' + k_2'K_1[H^+] + k_3'K_1K_2[H^+]^2)}{1 + K_1[H^+] + K_1K_2[H^+]^2}$$

where k_1', k_2', and k_3' are the rate constants for the disappearance of $H_2P_2O_8^{2-}$, $H_3P_2O_8^-$, and $H_4P_2O_8$ respectively, and K_1 and K_2 represent the equilibrium constants for the protonation of $H_2P_2O_8^{2-}$ and $H_3P_2O_8^-$ respectively.

It is possible (18) to simplify the rate expression into eq. [3] by neglecting the second and third terms in the denominator in comparison to unity (17–19). Hence

[1] It is presumed that the same trend of pK_a values will be maintained in acetonitrile – water mixture as in water.

TABLE 2. Effect of $[H^+]$ on the oxidation of Ph_3M

Rate constants	$[H^+]$ (10^3 mol/L)

*General reaction conditions: $[PP]_0 = 0.01$ M and $[Ph_3M] = 0.001$ M in 60% acetonitrile – 40% water (v/v) mixture at 40°C at $I = 0.2$ M.
†$[PP]_0 = 0.03$ M, [TPS] = 0.0001 M at $I = 0.1$ M in 60% acetonitrile – 40% water (v/v) mixture at 35°C.

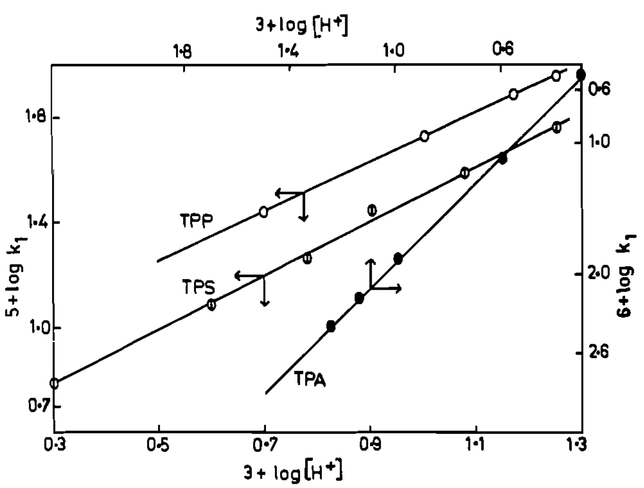

FIG. 2. Order plot for $[H^+]$. TPP: slope = 0.94 ± 0.03; r = 0.999; s = 0.003. TPA: slope = 1.99 ± 0.03; r = 0.999; s = 0.01. TPS: slope = 1.03 ± 0.09; r = 0.998; s = 0.02.

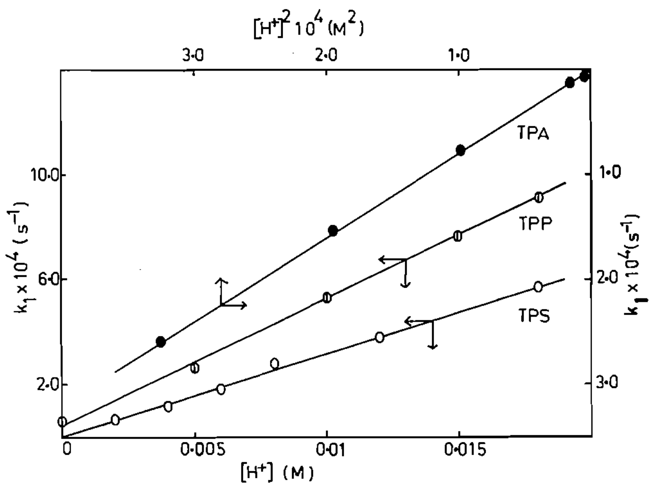

FIG. 3. Variation of k_1 with $[H^+]$ or $[H^+]^2$. TPP: r = 0.999. TPA: r = 0.999. TPS: r = 0.998.

$$[3] \quad -\frac{d[PP]}{dt} = [PP]_T\,(k_1' + k_2'K_1[H^+] + k_3'K_1K_2[H^+]^2)$$
$$= [PP]_T\, k_1 \text{ at constant } [H^+]$$

where k_1 is the pseudo first-order rate constant.

An interesting feature has been noticed here, viz., the active species in each case depends on the nature of the substrate. The nature of the active species of PP may be arrived at on the basis of the dependence of the reaction rate on $[H^+]$ and also from the plots of k_1 versus $[H^+]$ or $[H^+]^2$. The plot of k_1 versus $[H^+]$ (Fig. 3) gives a straight line with a finite intercept and eq. [3] indicates that $H_2P_2O_8^{2-}$ and $H_3P_2O_8^-$ are the active species in the oxidation of TPP. Similar analysis with Fig. 3 and eq. [3] indicates that $H_4P_2O_8$ is the active species in the oxidation of TPA. However, in the oxidation of TPS, as the least-squares analysis gives an intercept of 1.35×10^{-6} for the plot of k_1 versus $[H^+]$, the major active species will be $H_3P_2O_8^-$ with a minor contribution from $H_2P_2O_8^{2-}$.

An analysis of the dependence on $[H^+]$ and the nature of the active species of PP involved in the oxidation reveals the relative rates of oxidation[2] are TPP > TPS > TPA. An explanation for this anomalous behaviour is offered (*vide infra*).

Effect of ionic strength

In the case of TPP, there is no appreciable effect on the rate when the ionic strength is varied, while in the case of TPA and TPS the logarithm of the rate constants decreases linearly with an increase in the ionic strength of the medium (Fig. 4). The overall effect of ionic strength would be determined by eqs. [4]–[6] (*vide infra*). Steps [4] and [5] in the mechanism predict a decrease in rate with increasing ionic strength while the second-order rate constant of the rate-limiting step [6] may not be very sensitive to the change in the ionic strength since it involves a neutral species.

In the case of TPP, $H_2P_2O_8^{2-}$ is the main oxidizing species. Hence the protonation equilibria [4] and [5] do not play any role, thereby rendering the reaction insensitive to ionic strength variation. In TPA and TPS oxidations, $H_4P_2O_8$ and $H_3P_2O_8^-$

[2] We have studied the rates of oxidation of Ph_3M under identical conditions (Table 3) and the results also reveal that the relative rates of oxidation follows the same order TPP > TPS > TPA.

TABLE 3. Effect of temperature on the rate* of oxidation and activation parameters

t°C	k_2 (10^3 L mol^{-1} s^{-1}) TPP	TPA	TPS
20	20.2 ± 1.8		
25	39.4 ± 3.3	9.00 ± 0.58	19.0 ± 0.50

35		20.8 ± 1.2	64.0 ± 1.9
$\Delta H^{\neq}$† (kJ mol^{-1})	92.4 ± 10.9	61.3 ± 6.54	90.1 ± 5.20
$\Delta S^{\neq}$† (J deg^{-1} mol^{-1})	38.1 ± 37.9	−78.6 ± 22.3	24.4 ± 17.7

*$[PP]_0 = 0.003$ M; $[Ph_3M]_0 = 0.0001$ M; $[H^+] = 0.006$ M; $I = 0.1$ M in 60% acetonitrile – 40% water (v/v) mixture.

†The precision of $\Delta H^{\neq}$ and $\Delta S^{\neq}$ values was calculated using the method of Petersen *et al.* (26).

respectively (formed by the protonation equilibrium steps [4] and [5]) are the active species of PP involved in the oxidation. Here the protonation constants K_1 and K_2 may decrease with increasing ionic strength, setting the same trend for the combined constants $k_2'K_1$ and $k_3'K_1K_2$ (18, 19).

The rate constants for the oxidation of Ph_3M (M = P, As, Sb) are unaffected by the presence of acrylonitrile (AN), indicating that the oxidations of Ph_3M do not involve any free radical intermediates. Since AN was found to undergo polymerization in the presence of TPP (20), an indirect method has been resorted to in order to study the effect of AN on the oxidation of TPP by PP. A blank run without PP and another with PP, TPP, and AN were carried out. Using the rate expression

$$-\frac{dx}{dt} = k[\mathrm{TPP}][\mathrm{PP}] + k_3'[\mathrm{TPP}][\mathrm{AN}]$$

the rate constant k was calculated. This compares well with the second-order rate constant obtained in the absence of AN under identical conditions. Hence it is concluded that the effect of AN on the oxidation of TPP by PP is negligible and a free-radical mechanism is ruled out.

The dependence of rate constants on temperature at constant $[H^+]$ and ionic strength was measured at three temperatures (Table 3). The activation parameters are calculated and are listed.

Mechanism and rate law

On the basis of the foregoing kinetic evidence, a general polar mechanism may be envisaged for all the triphenyl derivatives of Group V elements:

$$[4] \quad H_2P_2O_8^{2-} + H^+ \rightleftharpoons H_3P_2O_8^-$$

$$[5] \quad H_3P_2O_8^- + H^+ \rightleftharpoons H_4P_2O_8$$

$$[6] \quad Ph_3\ddot{M} + H_{4-n}P_2O_8^{n-} \xrightarrow[\text{slow and rate-determining}]{k'} \text{Intermediate} \xrightarrow[\text{fast}]{H_2O} \text{Products}$$

where n = 0, 1, or 2. For example, when n = 2,

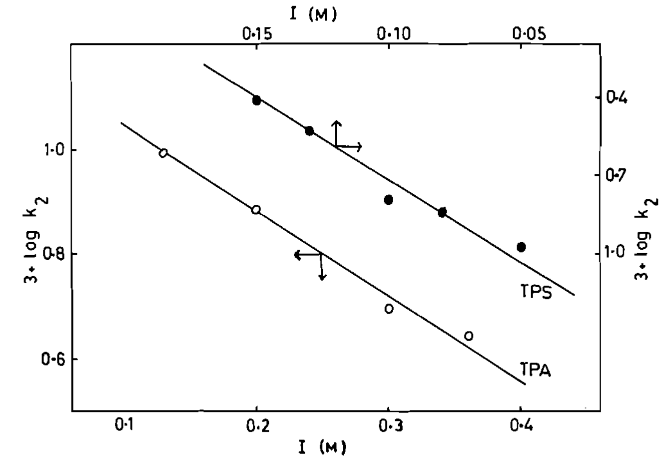

FIG. 4. Influence of ionic strength on PP oxidation of Ph_3M. TPA: r = 0.993. TPS: r = 0.978.

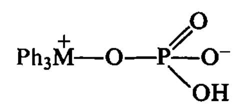
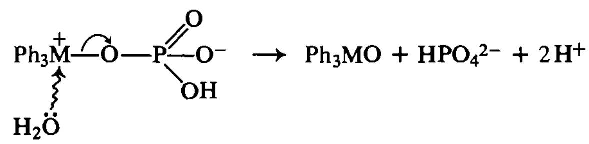
$$[7] \quad Ph_3\ddot{M} + H_2P_2O_8^{2-} \xrightarrow[\text{slow and rate-determining}]{k'}$$

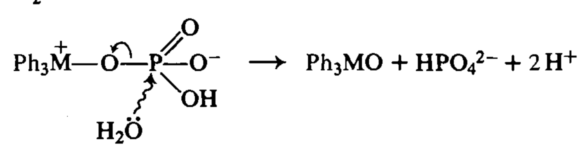


I

[8]



[9]



The proposed mechanism involves a bimolecular nucleophilic displacement of the substrate on the peroxide molecule in the rate-determining step [7], resulting in the formation of intermediate **I**, which then may decompose to give the oxide by the attack of water as indicated in step [8] or [9]. The question regarding the origin of the oxide oxygen, whether from solvent water or from PP, has not been solved. In a recent study (21) of the PS oxidation of TPP where the product triphenylphosphine oxide was analysed by using the ^{18}O isotope effect in ^{31}P nmr spectroscopy, it has been shown that the oxygen originates from PS.

The proposed mechanism accounts for (*i*) the second-order nature of the reaction at constant $[H^+]$ and ionic strength, (*ii*) the dependence of rate on the variation of $[H^+]$, and (*iii*) the lack of influence of acrylonitrile on the rate of oxidation. The rate law can be written as

$$[10] \quad -\frac{d[Ph_3M]}{dt} = -\frac{d[PP]}{dt} = k_2\,[Ph_3M][PP]_T$$

at constant $[H^+]$. The stoichiometry of the reaction was found to be 1 : 1 and the stoichiometric equation can be represented as

$$[11] \quad Ph_3M + H_{4-n}P_2O_8^{n-} \rightarrow Ph_3MO + 2H_{3-n}PO_4^{n-} + nH^+$$

The stoichiometric studies also confirm the proposed mechanism of the oxidation studies.

Relative reactivities

The observed order of reactivity (Table 3), TPP > TPS > TPA, is interesting because of the transposition of TPA and TPS. In the reactions of *tert*-butylhydroperoxide with Ph_3M (5, 14) and also in the PS oxidation (7) the same order of reactivity has been observed. Hiatt *et al.* (14) attribute this order to two conflicting trends, availability of *d* orbitals for π-bonding with peroxide oxygen and the Group V element-to-oxygen bond strength. The reactivity order in PS oxidation (7) has also been attributed to the above two conflicting trends.

The simultaneous considerations of the shift of electron density from the phenyl group towards the P, As, and Sb atoms via their *d* orbitals (which increases with the atomic number of M in Ph_3M) (22, 23) and the strength of the M-to-oxygen bond (the P—O bond is strong and both the As—O and Sb—O bonds are weak) (24) will account for the trend of the reactivity pattern observed in the PP oxidation. The reactivity is also in agreement with the charge density on the heteroatom in Ph_3M (25). We have determined the activation parameters under identical conditions (Table 3). The same trend of $\Delta H^{\neq}$ and $\Delta S^{\neq}$ values with TPP and TPS may be due to the involvement of the same active species in these oxidations. The repulsion between the negatively charged oxygen atom of the active species (see mechanism) and the π-electrons of the phenyl rings in the transition state may presumably be the cause of the positive entropy of activation. The absence of such a repulsion in the reaction of TPA with $H_4P_2O_8$ leads to a negative entropy of activation.

Physical changes in $BaSO_4$ caused by K^+ and Fe^{3+} ions

L. V. HALEY, T. A. MATTIOLI, AND D. R. WILES
Chemistry Department, Carleton University, Ottawa, Ont., Canada K1S 5B6

Received October 10, 1984

L. V. HALEY, T. A. MATTIOLI, and D. R. WILES. Can. J. Chem. **63**, 2290 (1985).

The effects of coprecipitated K^+ and Fe^{3+} ions on the nature of freshly precipitated $BaSO_4$ were studied. The presence of K^+ in the precipitate is seen to have a pronounced effect on crystal habit and increases the specific surface area of the crystals. Micro-Raman measurements show a progressive shift in the SO_4^{2-} ν_1 band for precipitates doped with potassium. This shift is seen to be a linear approach toward the ν_1 frequency of K_2SO_4. X-ray diffraction studies indicate no marked changes in cell parameters but do reveal changes in relative intensities in the diffraction patterns of potassium-doped precipitates. In the concentration ranges studied, ferric ions show no marked changes in any of the above properties. The changes are interpreted as being due to the formation of solid solution of potassium with barium sulphate, while iron is adsorbed onto the crystal surfaces. This is seen as a novel use of micro-Raman spectroscopy in the study of doped crystals.

L. V. HALEY, T. A. MATTIOLI et D. R. WILES. Can. J. Chem. **63**, 2290 (1985).

On a étudié les effets des ions K^+ et Fe^{3+} coprécipités sur la nature du $BaSO_4$ fraîchement précipité. La présence de K^+ dans le précipité semble provoquer un effet important sur les habitudes des cristaux et semble augmenter la surface spécifique des cristaux. Des mesures de micro-Raman permettent de mettre en évidence un déplacement progressif de la bande ν_1 des SO_4^{2-} dans les précipités dopés au potassium. On croit que ce déplacement présente une approche linéaire avec la fréquence ν_1 du K_2SO_4. Des études par diffraction des rayons-X n'indiquent pas de changements importants dans les paramètres de la cellule; on note toutefois des changements dans les intensités relatives des patrons de diffraction des précipités dopés au potassium. A l'intérieur des limites de concentration étudiées, les ions ferriques ne semblent pas provoquer des changements importants dans les propriétés mentionnées plus haut. On interprète les changements en fonction d'une formation de solutions solides de potassium avec le sulfate de baryum alors que le fer serait adsorbé sur les surfaces cristallines. On croit que ceci est une nouvelle méthode d'utiliser la spectroscopie micro-Raman pour étudier des cristaux dopés.

[Traduit par le journal]

Introduction

Recent studies on the use of $BaSO_4$ as a carrier in ^{230}Th determination have shown that $BaSO_4$ is an effective carrier for traces of thorium (1), but only if a sufficient quantity of potassium is present in the precipitation solution. Preliminary studies have shown (2) that both surface area and surface activity were affected by the presence of K^+ in the crystals themselves. The effect of ferric ions on the carrying of thorium with $BaSO_4$ was shown (1) to be one of suppression but up until now the properties of iron-doped $BaSO_4$ have not been studied in order to account for this interference. The present study applies Raman spectroscopy in a novel fashion, as well as electron microscopy and X-ray diffraction, to assist in discovering the nature of the influences of K^+ and Fe^{3+}.

It is known that K^+ ions and Fe^{3+} (and Fe^{2+}) ions coprecipitate with barium sulphate (3, 4). If this is so, then clearly the nature of the resultant precipitate will be altered as it will possess physical and chemical properties different from those of the pure precipitate. For instance, it is generally accepted that the coprecipitation of K^+ with barium sulphate is probably due to mixed crystal formation (3) while the Fe^{3+} coprecipitates with barium sulphate via adsorption processes (4). The possibility that potassium forms mixed crystals with barium sulphate was also recognized by Walton and Walden (5) using precision X-ray diffraction techniques and also by Ambe and Lieser (6) who were studying the coprecipitation of K^+ and Th^{4+} with $BaSO_4$.

With these different coprecipitation mechanisms, the effects of each cation upon certain properties of barium sulphate are not expected to be similar or occur to the same extent. For instance, a cation which is actually incorporated into the crystal lattice is expected to change the properties of the resulting precipitate markedly since its incorporation will cause structural changes in the crystal. The same cannot be said for impurities which are merely adsorbed or occluded in the crystal since they should not affect the fundamental structure of lattice.

The present study attempts to show that the analytical and other effects of potassium in $BaSO_4$ are symptoms of a more fundamental change in the crystal lattice. The formation of mixed crystals of K^+ with $BaSO_4$ results in changes in the precipitate's crystal habit, surface area, X-ray diffraction patterns, and Raman spectral properties. The coprecipitation of Fe^{3+} ions with $BaSO_4$ results in very small, if any, observable changes in the above mentioned properties. This is consistent with an adsorption or occlusion mechanism. The results of studies on other properties such as isotopic exchange behaviour (7) and K^+ and Fe^{3+} coprecipitation behaviour (8) are consistent with those presented here but are discussed elsewhere.

During the course of this study, we have investigated the effects of a solid solute on the Raman spectrum of a solid. This novel application of micro-Raman spectroscopy shows promise of being widely applicable to the study of coprecipitation phenomena.

Experimental

Materials

All reagents used were of the highest available purity and were used without further purification. Barium sulphate crystals were prepared by the addition of 50 mg Ba^{2+} and 2.0 mL of 9 *M* H_2SO_4 to a stirred 100 mL solution 0.1 *M* in HNO_3, and held constant at 25.0°C. The crystals were filtered on a 0.45 μm membrane (Gelman DM-450) and washed with 0.1 *M* HNO_3 and with distilled water. Potassium and ferric ion was added as needed to the solution prior to the addition of H_2SO_4. The concentrations of potassium and iron in the crystals were determined by direct analysis (7).

Raman spectroscopy

The spectroscopic studies were done on small samples mounted on a microscope slide under the 4880.0 Å beam of an argon ion laser. The beam was focussed through a Zeiss–Winkel microscope down to a

FIG. 1. Electron micrographs (× 3000) of $BaSO_4$ crystals freshly precipitated from 0.1 *M* HNO_3 plus (*a*) nothing, (*b*) K^+ 5×10^{-3} *M*, (*c*) Fe^{3+} 5×10^{-3} *M*, (*d*) K^+ and Fe^{3+}, both 5×10^{-3} *M*.

diameter of about 1 μm. This gave the opportunity to scan various regions of small crystals which, though not essential to the present work, enabled us to examine several portions of the crystals to check for inhomogeneities. The technique is more fully described elsewhere (9, 10).

The ν_1 band of SO_4^{2-} was selected for this study because of its prominence and because it was found to display an obvious dependence on potassium concentration. Quantitative determination of the spectral parameters was done using a Hewlett-Packard 9111A graphics digit tablet connected to a Hewlett-Packard 9836 minicomputer.

Results and discussion

Crystal habit

It is well known that the conditions of precipitation of an ionic solid greatly affect the appearance or habit of the crystals formed. Particularly, it is known (11) that the presence of foreign ions influences crystal habit. It has been pointed out by Walton (12) that foreign ions which are known to form mixed crystals with the precipitate being formed caused definite changes in habit modification and that, in general, ions which are only adsorbed onto the crystal surface do not cause major changes in habit.

Scanning electron micrographs show quite clearly that potassium ions have a pronounced effect upon the morphology of $BaSO_4$ crystals (2). This has been confirmed in the present work. Fig. 1*a* shows a representative electron micrograph of

*Sample descriptions: 1, $BaSO_4$ — 10 mg of Ba^{2+} in 100 mL 0.1 *M* HNO_3 precipitated with 2 mL of 9 *M* H_2SO_4; 2, same as 1 except p[K^+] = 1.5; 3, same as 1 except p[K^+] = 0.0; 4, same as 1 except p[Fe^{3+}] = 2.3; 5, same as 1 except p[Fe^{3+}] = 1.5; 6, same as 1 except p[Fe^{3+}] = 0.0; 7, N.B.S. standard: $BaCO_3$ treated with H_2SO_4; excess H_2SO_4 was fumed off and the sample was annealed overnight at 690°C.

barium sulphate crystals precipitated from 0.1 *M* HNO_3 solution (10 mg Ba^{2+} per 100 mL of solution). The crystal habit is the same as that reported by Fischer and Rheinehammer (11) for the precipitation conditions used. The effect of potassium ions at $pK^+ = 2.3$ is seen in Fig. 1*b* to increase lateral growth from the main axis of the crystal. It also appears that dendritic growth is increased as well as particle size and, perhaps, specific surface area.

The effect of ferric ions is not as pronounced as those of potassium. The electron micrograph in Fig. 1*c* shows $BaSO_4$ crystals precipitated in the presence of ferric ions. Here the Fe(III) concentrations were comparable to those of potassium ions in the solution from which the crystals in Fig. 1*b* were formed. The precipitate formed in the presence of ferric ions (p[Fe^{3+}] = 3.0 in solution) closely resembles the precipitate formed in the absence of K^+ and Fe^{3+} ions, and in fact, are almost indistinguishable. It is interesting to note that at the same concentration of potassium ions (i.e. p[K^+] = 3.0 in solution) Burk and Wiles (2) were still able to observe changes in the crystal habit.

As a note of further interest, the effects of the ferric ions on morphology may be examined in a different manner. When both K^+ and Fe^{3+} are present in solution, the crystal of the resulting precipitate (Fig. 1*d*) is changed in the manner consistent with potassium ions (Fig. 1*b*), although it is seen that the change in crystal habit due to potassium ions is not as pronounced when ferric ions are also present in solution.

Surface area measurement

As we previously mentioned, the potassium-doped $BaSO_4$ crystals appeared on visual inspection of the photomicrographs to possess a greater specific area than did the undoped crystals. To confirm this visual observation, the surface area of various $BaSO_4$ preparations were measured. The results are given below:

Sample	Surface area (m^2 g^{-1})
$BaSO_4$ (no added K^+ or Fe^{3+})	1.9±0.2
$BaSO_4$ (p[K^+] = 1.6)	3.6±0.1
$BaSO_4$ (p[Fe^{3+}] = 2.0)	1.8±0.2

The values in the parentheses indicate the cation concentration in the precipitation solution. Measurements were made using the Micrometrics Model 2200 High Speed Surface Analyser employing the BET method. Purified N_2 gas was used

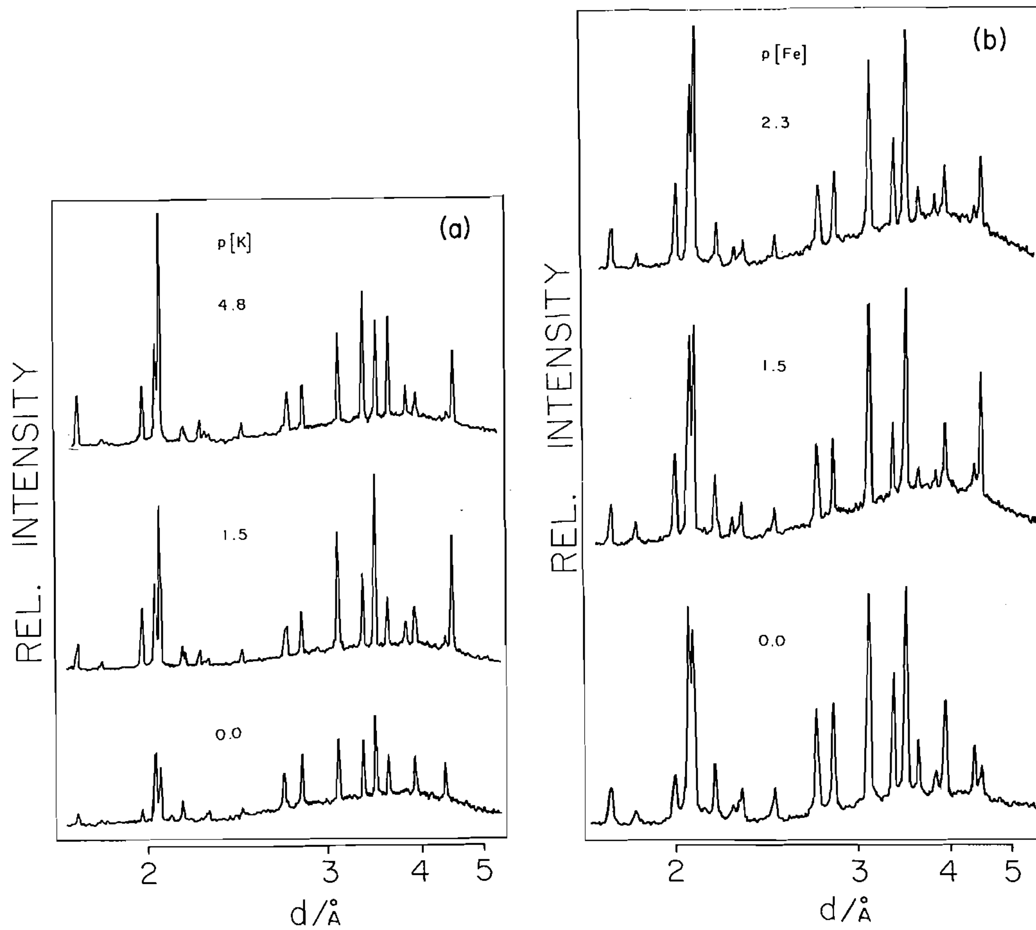

FIG. 2. (*a*) X-ray diffract ion patterns for K^+-doped $BaSO_4$. The values of p[K^+] in the precipitating solutions and given in the Figure. (*b*) X-ray diffraction patterns for the Fe^{3+}-doped $BaSO_4$. The values of p[Fe^{3+}] in the precipitating solutions are given in the figure.

as the adsorbent.

The above data clearly show that the presence of potassium results in a precipitate with greater surface area, while the presence of ferric ions is seen to have only a negligible effect on the surface area.

X-ray diffraction study

The X-ray diffraction patterns obtained for various barium sulphate precipitates containing potassium and ferric ions showed no lines other than those of barium sulphate. This corroborates observations made by Ambe and Lieser (6). Table 1 lists the observed lattice parameters and unit cell volumes of various barium sulphate precipitates.

Since K^+ ions have nearly the same ionic radii as barium ions, 1.33 Å and 1.34 Å, respectively, one would expect the lattice parameters of the potassium-doped barium sulphate to remain essentially the same if the simplistic replacement of one K^+ for one Ba^{2+} is assumed. For ferric ion, however, the ionic radius is considerably smaller than that of barium (0.64 Å for Fe^{3+} as compared to 1.34 Å for Ba^{2+}). Thus, if Fe^{3+} ions were becoming incorporated into the $BaSO_4$ lattice, one would expect changes in the lattice parameters.

It is clear from Table 1 that no trend is shown in the lattice parameters for the iron-doped precipitates. Any variation is within the expected uncertainty limits. While no conclusion can be drawn with any confidence, the results are again consistent with the anticipated effects of potassium ions being in the lattice, but not iron.

The respective diffraction patterns are given for visual comparison in Fig. 2. Although new lines were not observed, changes in their relative intensities are quite evident for those precipitates containing potassium (Fig. 2*a*). The iron-doped precipitates, on the other hand, gave patterns whose relative intensities did not show marked changes (Fig. 2*b*). To prove that the changes in relative intensities were not due to sample preparation, two separate samples were prepared and each sample was rotated 90° within the diffractometer. These precautions did not change the relative intensities of the pattern lines, verifying that the observed effect was not an artifact introduced through the sample preparation.

Structure factors were calculated for those planes which, according to Fig. 2*a*, seemed to show significant changes in intensity. These structure factors did not reveal any structural regularity and thus failed to indicate preference of certain planes for potassium substitution. The intensity changes were therefore interpreted as being due to changes in crystal habit. This interpretation is supported by the electron micrographs which were discussed above. The virtual absence of fluctuations in line intensities of the iron-doped precipitates is also consistent with this interpretation. Isotopic-exchange data (2, 7) indicate that the number of Ba^{2+} exchange sites in K^+-doped $BaSO_4$ is greater than can be explained by the increase in surface area which suggests crystallographic faces which are rich in Ba^{2+} sites are being exposed to greater degrees.

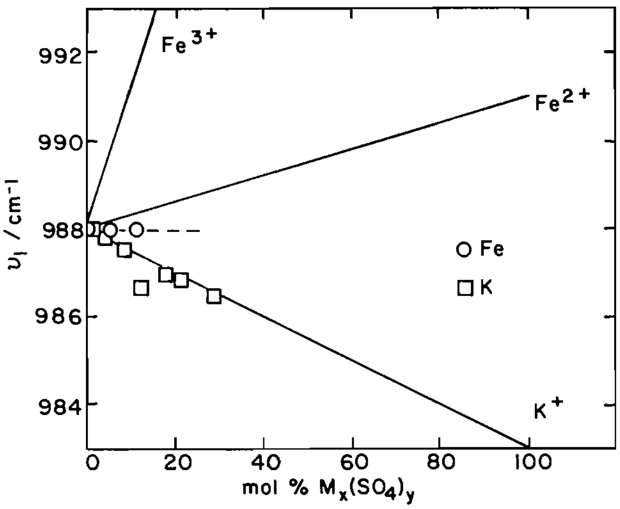

FIG. 3. Raman frequencies of the SO_4^{2-} ν_1 lines in $BaSO_4$ crystals as a function of mole percent K^+ and Fe^{3+}. See the text for a brief discussion of the anomalous point.

Micro-Raman spectroscopy study

Line frequencies in the Raman spectrum of an ion such as SO_4^{2-} will be sensitive to the electrostatic environment in the lattice which, in turn, will depend on the extent of randomly spaced substitute cations. While a mixture of $BaSO_4$ and K_2SO_4 crystals will give the two superimposed spectra, the spectrum of a true solid solution of K_2SO_4 in $BaSO_4$ should show the effect of a weighted average lattice. One can envisage various types of behaviour of the line frequency as a function of concentration. Most simply is the direct linear relationship as in this study. More likely, especially if the ionic sizes are less closely similar, will be a positive or negative deviation from the straight line. Furthermore, one can expect discontinuous behaviour when the limit of solid solubility has been exceeded with probable strong deviations just before and after the discontinuity. Finally, one can expect no change in the Raman frequencies in cases where the impurity remains in a phase distinct from the major lattice.

The observed Raman spectra for potassium-doped $BaSO_4$ crystals showed a marked shift in the frequency of the ν_1 vibrational mode of the SO_4^{2-} ion. The shift appeared to be essentially a linear function of the concentration of potassium present in the crystals for the concentration ranges studied. The results for the iron-doped $BaSO_4$ crystals were quite different, in that the ν_1 band frequency was essentially unaffected by the presence of Fe^{3+} in the precipitate.

These frequency data are plotted in Fig. 3. In this figure, three hypothetical straight lines are given which join the SO_4^{2-} ν_1 frequencies of pure $BaSO_4$ with those in pure K_2SO_4, $FeSO_4.H_2O$ and $Fe_2(SO_4)_3.H_2O$, respectively. It is evident from this diagram that the relationship is convincingly linear for the $BaSO_4-K_2SO_4$ system. The $Ba(Fe)SO_4$ data, on the other hand, show no distinct change of frequency and are not at all close to the $BaSO_4-FeSO_4$ line or to the $BaSO_4-Fe_2(SO_4)_3$ line. It is clear, therefore, that the two dopant ions interact differently with the lattice, in agreement with conclusions drawn from other experiments as described above. Potassium seems to be present in the lattice as a direct replacement for Ba^{2+} while Fe^{3+} is not. The only conjecture which can be made about the iron is that it may be adsorbed on the surface, or perhaps occluded as a separate impurity phase.

We wish to draw attention to the one point in Fig. 3 whose value puts it well below the straight line. That particular sample showed anomalous behaviour in several ways and tempted us to look for a sharp discontinuity at this composition. Since the data on both sides are directly on the proper straight line, it may rather be that the analytical data are in error. For the present we can only speculate as to whether the point as it is shown is real or not.

If the effect described here is general, and it is found that mixed crystals produced by coprecipitation always display a Raman spectrum whose line frequencies are simple functions of the mole fraction of impurity cations, then a new method will be available to investigate the nature of coprecipitated ions. This will be of considerable interest in analytical chemistry, radiochemistry, preparative inorganic chemistry, mineralogy, and in other areas of solid state chemistry. We expect to publish further reports on this subject in the near future.

Summary

Precipitates of barium sulphate containing potassium show changes in properties such as morphology and specific surface area whereas those containing iron do not, at least to the same extent, under the conditions used.

Raman data show structural changes in potassium-doped $BaSO_4$ which X-ray diffraction data could not. The progressive shift in the ν_1 frequency of the SO_4^{2-} ion suggests that mixed crystal formation is occurring. The invariance of the ν_1 frequency for iron-doped precipitates indicates that iron is present in such a manner which does not detectably affect the SO_4^{2-} environment and that solid solution is not occurring. It is suggested that this provides a new tool for the study of doped or contaminated crystals.

The state of the iron impurities is less certain than that of potassium. It can be said, however, that iron is present in such a manner as not to alter the SO_4^{2-} environment in the lattice which excludes the possibility of mixed crystal formation or incorporation into the $BaSO_4$ lattice. We conclude that the iron is adsorbed or occluded within the crystals.

PETER DE WIT, HANS CERFONTAIN, and ALFRED FISCHER. Can. J. Chem. **63**, 2294 (1985).

The mono- and di-sulfonation of the 1,8-alkano- and 1,8:4,5-dialkano-naphthalenes **1–5** with SO_3 in dioxane and nitromethane as solvent have been studied and the results compared with those of 1,8-di- (**6**) and 1,4,5,8-tetramethylnaphthalene (**7**). The most reactive position of 1,8-ethano- (**1**), 1,8-propano-naphthalene (**2**), and **6** is the 4-position. Sulfonation adjacent to the 1,8-ethano bridge can be effected with SO_3 in dioxane as reagent, whereas sulfonation *ortho* to the longer alkano bridges requires the more reactive reagent SO_3 in nitromethane. Disulfonation of the 1,8:4,5-dialkanonaphthalenes **3–5** leads to the predominant formation of the "noncrossed" (i.e. the 2,7-) disulfonic acid due to the substituent effect of the 2-sulfonic acid group. The isomer distribution data for the sulfonation of the arenes and their monosulfonic acids show that the steric hindrance increases in the order ethano $\ll$ propano $\leq$ butano and propano $<$ *peri* dimethyl.

PETER DE WIT, HANS CERFONTAIN et ALFRED FISCHER. Can. J. Chem. **63**, 2294 (1985).

Opérant dans le dioxanne et dans le nitrométhane comme solvants, on a étudié les mono- et di-sulfonations des alkano-1,8 et dialkano-1,8:4,5 naphtalènes (**1–5**) par le SO_3; on compare les résultats avec ceux obtenus antérieurement avec les diméthyl-1,8 et tétraméthyl-1,4,5,8 naphtalènes (**6** et **7**). La position la plus réactive des éthano-1,8 (**1**), propano-1,8 (**2**) et diméthyl-1,8 (**6**) naphtalènes est la position 4. On peut effectuer une sulfonation sur la position adjacente du pont éthano-1,8 si l'on opère avec du SO_3 dans le dioxanne; toutefois, pour effectuer des sulfonations en *ortho* des ponts alkano plus longs on doit utiliser du SO_3 dans le nitrométhane qui est un réactif plus énergique. La disulfonation des dialkano-1,8:4,5 naphtalènes **3–5** conduit à la formation préférentielle de l'acide disulfonique "non croisé" (comme le -2,7) à cause de l'effet de substituant du groupement acide sulfonique-2. Les données sur la distribution des isomères pour la sulfonation des arènes et de leurs acides monosulfoniques montre que l'empêchement stérique augmente dans l'ordre suivant: éthano $\ll$ propano $\leq$ butano et propano $<$ *péri*-diméthyle.

[Traduit par le journal]

On disulfonation of 1,4-di-, 1,5-di-, 1,4,5-tri-, and 1,4,5,8-tetramethylnaphthalene there is a strong preference for the formation of the "noncrossed" 2,7-disulfonic acid over the "crossed" 2,6-disulfonic acid (2, 3). This was explained in terms of a larger degree of destabilization of the σ-complex for the sulfonation of the 6- than of the 7-position of the 2-sulfonic acid, due to the strong electron-withdrawing effect of the sulfo group (3, 4). In order to obtain more information on the factors governing the formation of the "crossed" and "noncrossed" disulfonic acids, we have extended our studies on the sulfonation of polymethylnaphthalenes (2, 3) to a series of alkanonaphthalenes, viz. acenaphthene (**1**), perinaphthane (**2**), 1,2,3,6,7,8-hexahydropyrene (**3**), 5,6,7,8-tetrahydrocyclohepta-acenaphthene (**4**), and 1,2,3,4,7,8,9,10-octahydrodicyclohepta[*de,ij*]naphthalene (**5**).[3]

Results

The hydrocarbons **1–5** have been sulfonated with SO_3 in $[^2H_8]$dioxane and (or) $[^2H_3]$nitromethane or nitromethane. The resulting sulfo products were assigned on the basis of the ^1H nmr data listed in Table 1. The sulfonic acid product compositions for the various sulfonations are collected in Table 2, together with those of 1,8-dimethylnaphthalene (**6**) (2) for comparison. The very predominant formation of the 2,7-disulfonic acid with **4** and **5** was further substantiated by 250-MHz ^{13}C nmr spectroscopy of the isolated dipotassium salts. The disulfonate of **5** showed ten signals (viz. at 139.9, 139.3, 139.1, 137.5, 137.0, 125.4, 33.5, 29.6, 25.7, and 25.0 ppm), whereas the 2,6-isomer would exhibit only nine signals. Similarly the disulfonate of **4** exhibits nine signals (viz. at 145.8, 143.1, 141.9, 136.3, 135.8, 127.7, 34.4, 33.1, and 28.8), illustrating the formation of a "non-crossed" disulfonate (the "crossed" isomer would exhibit sixteen signals). In view of steric hindrance (see later), the sulfonation will be very much slower adjacent to the seven- than to the five-membered ring,

[a] A–D stand for SO_3 in $[^2H_8]$dioxane, SO_3 in nitromethane, SO_3 in $[^2H_3]$nitromethane, and trimethylsilyl chlorosulfate (5), respectively.
[b] P, Q, and R stand for homogeneous, heterogeneous due to the limited substrate solubility, and heterogenous due to precipitation of sulfonic acid products.
[c] The first number gives the position(s) of the sulfo substituent(s) and the one in parentheses the relative yield in %.
[d] See ref. 2.

rendering the formation of the 3,6-disulfonate as alternative for the assigned 2,7-isomer highly improbable.

The substrates **3** and **5** did *not* react with SO_3 in dioxane at 25°C over a period of 27 h.

The isomer distributions of the disulfonic acids on sulfonation of the various arenemonosulfonic acids, estimated from the product composition of Table 2, are collected in Table 3, together with reported data for 1,8-dimethylnaphthalene-4-sulfonic acid and 1,4,5,8-tetramethylnaphthalene-2-sulfonic acid.

Discussion

Arenemonosulfonation

The partial rate factor ratio f_2/f_4 for the sulfonation of acenaphthene (**1**) with SO_3 in dioxane as reagent is 0.25 and with trimethylsilyl chlorosulfate 0.14 (Table 2). These values are comparable to the value obtained with chlorosulfuric acid in nitrobenzene at 0°C (~0.3, based on 75% of isolated 4-sulfonic acid) (refs. 6–8), but are significantly smaller than that obtained using 95% H_2SO_4 as reagent at 25°C (2.1) (ref. 8).[4] The large dependence of the f_2/f_4 ratio on the nature of the reagent was also observed for the bromination of **1**, the degree of 2-substitution varying from 3.2 to 32.4% (ref. 11). The higher reactivity of the 4- as compared with the 2-position was also observed in protiodetritiation, f_2/f_4 being 0.37 (refs. 12–14),

[4] For toluene, f_2/f_4 is also much greater for 95.8% H_2SO_4 as reagent (1.69) (ref. 9) than for SO_3 in nitromethane (0.13) (ref. 10).

TABLE 3. Isomer distribution of the disulfonic acids formed by sulfonation of the sulfonic acids of **1**–**6**[a]

Substrate	Sulfonation isomer distribution (%)[b]	
1-2-SO_3H	2,4(46)	2,5(54)
1-4-SO_3H	2,4(42)	4,7 = 2,5(58)
2-4-SO_3H	2,4(27)	2,5(73)
3-2-SO_3H	2,6(11)	2,7(89)
4-2-SO_3H	2,6(<2)	2,7(>98)
5-2-SO_3H	2,6(13)	2,7(87)
6-4-SO_3H[c]	2,4(20)	4,7 = 2,5(80)
7-2-SO_3H[d]	2,6(5)	2,7(95)

for which reaction there is no evidence whatsoever of any steric hindrance (15), and was further observed in the nitration with nitric acid and in acetic anhydride (16) and the chlorination with chlorine in carbon tetrachloride – acetic acid (17). The f_2/f_4 ratios are rather similar for the chlorination (17) of **1**, **2**, and **6**, as are the f_2/f_4 ratios for the bromination of these three substrates (11).

The absence of sulfonation of the 2-position with **2** and **6** is ascribed to steric hindrance,[5] the C(1a)—C(1)—C(2) angle of **1** and **6** being 132.8 and 116.2° respectively (11), whereas that of **2** is in between these two extremes (12).

The argument of steric hindrance also explains the observation that SO_3 in *dioxane* leads to 2-substitution – i.e. adjacent to the alkano bridge – only with **1** and **4**, both of which contain an 1,8-ethano bridge. In fact, **3** and **5** are unreactive towards SO_3 in dioxane, and **2** gives only 4-substitution. Sulfonation adjacent to the 1,8-propano and 1,8-butano bridges is inhibited due to steric hindrance, but can be effected using the more reactive SO_3 in *nitromethane*.

Reaction of **1** with 1.0 equiv. of SO_3 in dioxane yields only monosulfonic acids, but by using 1.0 equiv. of the more reactive SO_3 in nitromethane a substantial amount of disulfonic acids (19%) is obtained. The yield of disulfonic acids is far more pronounced in the (heterogeneous) sulfonation of **3** with 1.0 equiv. of SO_3 in nitromethane (43%). The formation of disulfonic acids under conditions of monosulfonation was observed before with some polymethylnaphthalenes (3), polymethylphenanthrenes (19), pyrene and perylene (20), using SO_3 in nitromethane, and for azulene and 1,3-di-*tert*-butylazulene with SO_3 in dioxane as reagent (21). It may be explained in terms of the mixing-disguised competitive, consecutive reaction model advanced by Rys (22), as discussed before (19–21). The higher yield of disulfonation of **3** may be explained in part by assuming that the rate of sulfonation of the monosulfonic acid is higher than the rate of dissolving of the substrate.

Arenesulfonic acid sulfonation

With the monosulfonic acids of **1**, **2**, and **6**, the very substantial degree of sulfonation of the ring containing the original sulfo substituent is remarkable in view of the strong deactivating effect of the primary sulfonic acid substituent, which is only partially of conjugative origin (23). In fact, with the two naphthalenesulfonic acids, the sulfonation in the ring containing the primary sulfo group is at best very low.[6] Apparently the selectivity of the sulfonation is reduced as a result of the activating 1,8-alkano and 1,8-dimethyl substituents. The content of the 2,4-disulfonic acid product decreases in the substrate order **1**-4-SO_3H > **2**-4-SO_3H > **6**-4-SO_3H. This order reflects the enhanced steric restrictions for sulfonating the 2-position (see before), as the f_2/f_4 ratio for protiodetritiation of the parent hydrocarbons – which reaction is devoid of steric hindrance (15) – exhibits a different order, viz. **6** > **1** ≃ **2** (ref. 12).

The disulfonation of the symmetrically substituted 1,8:4,5-dialkanonaphthalenes **3** and **5** leads very predominantly to the "non-crossed" disulfonic acids, the 2,6- to 2,7-disulfonic acid ratio being 0.12 and 0.15, respectively. The preference for the "noncrossed" disulfonic acid may be explained in terms of the higher energy content of the σ-complex for the 7- as compared with the 6-substitution, due to the larger degree of destabilization by the initial sulfonic acid substituent of which the sulfur is electropositive toward the surrounding oxygens, as discussed at length elsewhere (4).

The f_6/f_7 ratios are somewhat greater for the 2-sulfonic acids of **3** (0.12) and **5** (0.15) than for that of 1,4,5,8-tetramethylnaphthalene (**7**) (0.08) (ref. 3). The lower ratio for the latter sulfonic acid is ascribed to a relative increase in the rate of 7-substitution, as will now be discussed. The steric hindrance for sulfodeprotonation of the 2-position of the alkylated naphthalenes is greater for **7** than for **3** and **5** (see before). Accordingly, the steric strain in the 2-sulfonic acid of **7** is greater than in those of **3** and **5**. To accommodate (part of) the *ortho* and *peri* strain in the 2-sulfonic acid, C(1a) will be bent out of the plane of the naphthalene skeleton in the opposite direction to the adjacent 2-SO_3H and C(8a).[7] The steric hindrance for sulfonation of the 7-position will thus be more reduced for the 2-sulfonic acid of **7** than for those of **3** and **5**, leading to a higher f_6/f_7 ratio for **7**-2-SO_3H, as observed.

The f_6/f_7 ratio is very much smaller for the 2-sulfonic acid of **4** (<0.02) than for that of **5** (0.15), due to the lesser steric hindrance for sulfonating the 7-position – i.e. adjacent to the five-membered ring – of the former sulfonic acid.

We have indicated before, for the sulfonation of polymethylnaphthalenes with SO_3, that the alternative for the direct sulfodeprotonation, viz. initial *ipso*-attack, followed by a 1,2-sulfo shift, can not be excluded (2, 3). Again in this study there is no evidence in favour of this additional sulfonation route, but it is of interest that Fischer and Leonard observed *ipso*-attack in the nitration of **3** and **4** with nitric acid in acetic anhydride (27).

Experimental

Materials

Acenaphthene was Puriss grade (Rütgerswerke, FRG), **2** (28) and **4** (29) were prepared by known procedures, **3** was obtained as a gift, and the synthesis of **5** was described before (30).

[5]The steric requirements for substitution increase in the order hydrogen exchange << chlorination < nitration < bromination < sulfonation (15, 18).

[6]Sulfonation of naphthalene-1-sulfonic acid in 98.5% H_2SO_4 at 25°C does not yield any detectable amount of 1,3-disulfonic acid, whereas the 2-sulfonic acid yields only 4% of that isomer (24). Sulfonation of naphthalene with 1.0 equiv. of SO_3 in nitromethane yields ≃90% 1- and ≃10% 2-sulfonic acid and, with 4.0 equiv. of SO_3, 48% 1,6-, 25% 1,5-, and 5% 1,7-disulfonic acid with, as additional products, the 1,3-, 2,6-, and 2,7-disulfonic acids and (possibly some) 1,3,6- and 1,3,7-trisulfonic acids (P. de Wit and H. Cerfontain, unpublished results).

[7]The methyls of octamethylnaphthalene (25) and the methyl and sulfonate groups of dipotasisum mesitylenedisulfonate (26) are displaced alternately above and below the mean molecular plane.

Sulfonations

The procedures of the sulfonation with SO_3, the working up of the reaction mixture, and the product analyses were performed as described previously (21, 31). The sulfonation of acenaphthene with trimethylsilyl chlorosulfate (Fluka) was carried out following the standard procedure (5).

Interaction of strong acids with a conjugated imine

MARTINE BISSONNETTE, HOA LE THANH, AND DANIEL VOCELLE[1]
Département de chimie, Université du Québec à Montréal (Qué.), Canada H3C 3P8

Received July 13, 1984

MARTINE BISSONNETTE, HOA LE THANH, and DANIEL VOCELLE. Can. J. Chem. **63**, 2298 (1985).

The state of protonation of a Schiff base, *trans-trans*-heptadienylidene *tert*-butylamine (HBA) was evaluated by uv and ^{1}H nmr spectroscopies. Using three strong acids, HCl, HBr, HI and by taking spectra at low temperatures, it was found that in a non-polar solvent like chloroform (or $CDCl_3$), no proton exchange occurred between the iminium ion and the halide anion. In contrast, CD_3OH induced a leveling effect and some proton transfer occurred between the iminium ion and the solvent for the HBr and HI salts. No proton exchange was present for the HBA:HCl salt. The interaction of trichloroacetic acid with HBA was also studied: full proton exchange occurred between the iminium ion and CD_3OH. In $CDCl_3$, proton transfer was also present between the iminium ion and the carboxylate anion. These facts are discussed in relation with the controversy surrounding the true state of protonation of rhodopsin.

MARTINE BISSONNETTE, HOA LE THANH et DANIEL VOCELLE. Can. J. Chem. **63**, 2298 (1985).

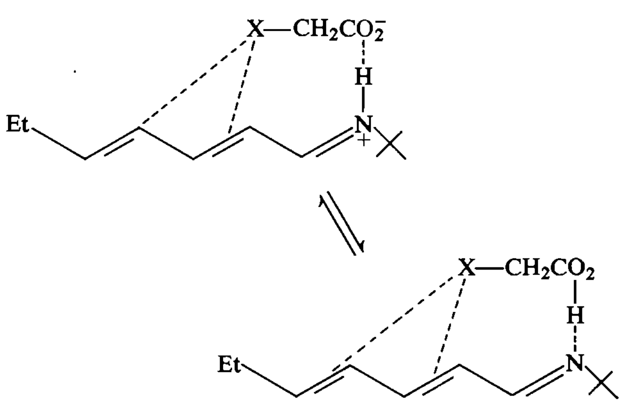
La protonation d'une base de Schiff, la *trans-trans*-heptadiénylidène *tert*-butylamine (HBA) a été étudiée par les spectroscopies ultraviolette et de résonance magnétique nucléaire. Par l'emploi de trois acides forts, HCl, HBr, HI et par l'obtention de spectres à basses températures, il est démontré qu'aucun échange de proton entre l'ion iminium et l'anion halogénure se produit lorsque le solvant est le chloroforme. Par contre, lorsque CD_3OH est utilisé comme solvant, un début d'échange protonique entre le solvant et l'ion iminium peut être noté. Toutefois, pour HCl, aucun échange a pu être observé. Finalement, lorsque l'acide trichloroacétique a été utilisé en conjonction avec HBA, la présence d'un transfert complet de proton a pu être observé entre l'ion iminium et CD_3OH. Dans le $CDCl_3$, un échange de proton est également présent mais cette fois-ci, entre l'ion iminium et l'anion carboxylate. Ces observations sont discutées en relation avec le problème concernant l'état de protonation de la rhodopsine.

Introduction

In the photoconversion of rhodopsin to bathorhodopsin the question of the protonation of the retinal Schiff base is still problematic (1). The most accepted model concerning the structure of rhodopsin's chromophore is the external point charge theory proposed by Nakanishi (2).

Recently, we have developed our own model of rhodopsin consisting of a dienylidene Schiff base (e.g. RCH=CH—CH=CH—CH=N—R′) and substituted acetic acids (XCH_2CO_2H). When studied by uv and ^{1}H nmr spectroscopies, this simple model indicated, among other things, that an equilibrium such as the one shown in reaction [1] was possible for certain carboxylic acids in a non-polar solvent like chloroform.

[1]



Was this equilibrium possible because of the presence of the X group of acetic acid (similar to the point charge proposed by Nakanishi) or could it exist without it? Since acetic acid or propionic acid cannot protonate a Schiff base like *trans-trans*-2,4-heptadienylidene *tert*-butylamine (HBA) (3), we thought using strong mineral acids like HCl, HBr, and HI which could fully protonate the azomethine without the help of an external point charge. Two solvents were used: chloroform (or $CDCl_3$) for a non-polar solvent and methanol (or CD_3OH) for a more polar one.

Experimental

Blatz and co-workers (4) have previously studied the interactions of these acids with N-retinylidene *n*-butylamine (NRBA) in the same two solvents. They concluded from their studies in $CHCl_3$ that the λ_{max} of NRBA depended on the distance between the protonated Schiff base nitrogen and the counter-ion. In methanol, there was a leveling effect which meant that all data in that solvent were identical. It became interesting, then, to use our model with the same acids and to study the nmr spectra and in particular, the behavior of H_7 (see Table 1 for the numbering of the hydrogens in HBA), the aldimine hydrogen —C*H*=N—, when the Schiff base is fully protonated. For an unprotonated HBA, H_7 appears as a doublet because of the

$$\begin{array}{c} \ \ \ H \\ \ \ \ | \\ —CH=C—C=N— \\ \ \ | \\ \ \ H \end{array}$$

system; for a protonated HBA, H_7 should become a doublet of doublets (5). The splitting of H_7 is then related to the state of protonation of the Schiff base and as such should give precious information on this vital problem in the chemistry of visual pigments (1).

Materials and methods

Preparation and purification of *trans-trans*-2,4-heptadienylidene *tert*-butylamine (HBA) have been described before (3). Preparation of the salts was easy: it consisted in the bubbling gazeous HCl, HBr, and HI, respectively, into an ether solution of HBA. The salt was filtered, washed with ether, and dried *in vacuo*. Gazeous HBr and HI were prepared according to classical methods (6). Solutions of the salts in chloroform or in methanol are somewhat unstable to oxygen, light and especially water. Fresh solutions are mandatory and special precautions must be taken such as working in an anhydrous atmosphere (dry box). Concentrations were always in the same range: 10^{-4} *M* for uv studies and 10^{-2} *M* for nmr. Chloroform was first percolated in a

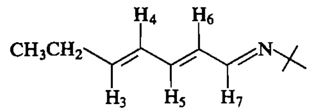
TABLE 1. Chemical shifts of H_3 to H_7 of HBA and its salts in $CDCl_3$ and CD_3OH; values of the deshielding due to the acids used are in parentheses



Solvent	Compounds	H_7	H_6	H_5	H_4	H_3
	HBA	8.04	6.32	6.85	6.33	6.16
CD_3OH	HBA/HCl	8.68(0.64)	6.69(0.37)	7.73(0.88)	6.62(0.29)	6.79(0.63)
	HBA/HBr	8.72(0.68)	6.69(0.37)	7.77(0.92)	6.69(0.29)	6.80(0.64)
	HBA/HI	8.67(0.63)	6.62(0.30)	7.74(0.89)	6.63(0.30)	6.80(0.64)
	HBA/TCA	8.64(0.60)	6.66(0.34)	7.69(0.84)	6.60(0.27)	6.77(0.61)
	HBA	7.87	6.26	6.57	6.18	5.95
$CDCl_3$	HBA/HCl	8.19(0.32)	7.26(1.00)	7.35(0.78)	6.37(0.19)	6.49(0.54)
	HBA/HBr	8.15(0.28)	7.38(1.12)	7.38(0.81)	6.44(0.26)	6.55(0.60)
	HBA/HI	8.41(0.54)	7.36(1.10)	7.61(1.24)	6.46(0.28)	6.69(0.74)
	HBA/TCA	7.97(0.10)	6.94(0.68)	7.19(0.62)	6.35(0.17)	6.44(0.49)

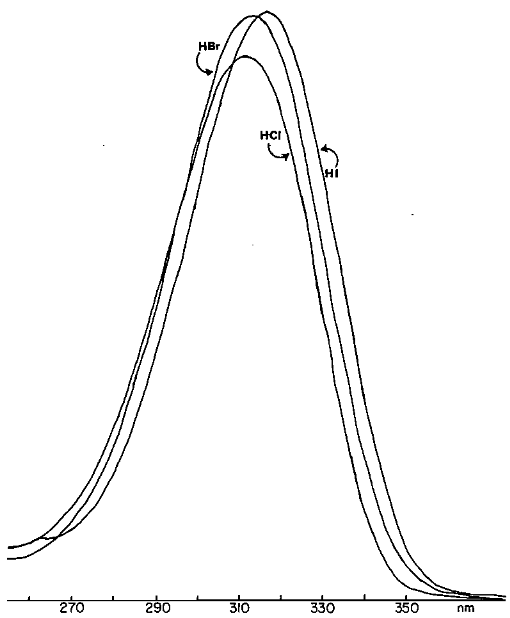


FIG. 1. Ultraviolet spectra of the hydrochloride, hydrobromide, and hydroiodide salts of HBA in chloroform.

basic alumina column and then dried over 4A molecular sieves. With this procedure, chloroform is perfectly dried and free from ethanol. The purity of this solvent was checked by gas chromatography (Varian instrument, model 3700 equipped with an 8 foot OV-101 column). Since it is extremely difficult to have completely dry methanol, CD_3OH obtained from Merck, Sharp and Dohme, was used in both uv and nmr studies.

Ultraviolet studies were made on a Cary 17 instrument while ^1H nmr spectra were recorded on a Bruker WH 400/DS (400 MHz) instrument. Assignments of chemical shifts to proper ethylenic hydrogens were done using double resonance technique.

Results and discussion

The electronic spectra of the HBA salts are simple: they consist of a single band with absorption maxima ranging from 306 to 317 nm depending on the counter-ion and the solvent used. Figure 1 shows the spectra of HBA with HCl, HBr, and HI in chloroform.

These results indicate full protonation and are in agreement with those obtained by Blatz (4) which noted the same order in the red shift of NRBA salts: iodide having a bigger shift than bromide than chloride. In methanol (CD_3OH), NRBA salts gave uv spectra consisting of a single band with λ_{max} at 306, 307, and 306 nm for the iodide, bromide, and chloride anions, respectively. This last result indicates a leveling effect by methanol. The same effect has been noted previously by Blatz (4) and also by us (3).

The nmr spectra are far more interesting. Figure 2 *a* and *b* show the 400 MHz nmr spectra of HBA and of its hydrochloride salt in $CDCl_3$ while Table 1 gives the chemical shifts of all ethylenic hydrogens (H_3 to H_7) of HBA salts in $CDCl_3$ and CD_3OH. The data for equimolar concentrations of trichloroacetic acid and HBA are also given for reasons which will be discussed later on.

It will be noted by looking at Fig. 2 *a* and *b* that the acids are inducing a pronounced deshielding especially on H_5 and H_6 in $CDCl_3$ and H_6 in CD_3OH. Nuclear magnetic resonance techniques are thus very revealing of the interactions of an acid on the hydrogens of a Schiff base. From Table 1, it is readily noticeable that a leveling effect is present in CD_3OH since the chemical shifts are all very similar, thus confirming the uv spectral data. On the basis of this effect and following Blatz's (4) explanations, it follows that the protonated azomethine is separated from the anion (Cl^-, Br^-, I^-) by at least one molecule of CD_3OH. Solvation of protonated HBA means that there must exist a rapid exchange between the hydrogens of the solvent and the acidic proton (5) as in reaction [2] and H_7 should appear as a doublet.

$$[2] \quad R{-}CH{=}CH{-}CH{=}\overset{H^*}{\underset{\oplus}{N}}{-}C(CH_3)_3 + CD_3OH \rightleftharpoons RCH{=}CH{-}CH{=}\overset{H}{\underset{\oplus}{N}}{-}C(CH_3)_3 + CD_3OH^*$$

Figure 3*a* shows the splitting of H_7, in CD_3OH, for the three salts and for the TCA:HBA system.

The hydrochloride salt of HBA indicates a doublet of doublets for H_7 while for the hydrobromide and hydroiodide, it

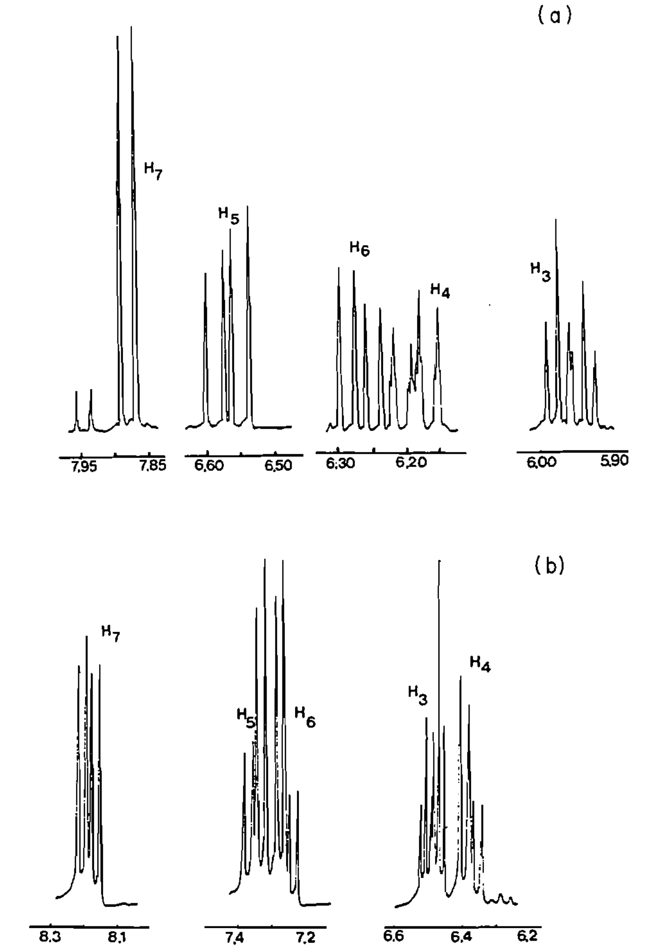

FIG. 2. ^{1}H nmr (400 MHz) spectra of (*a*) HBA in $CDCl_3$ and (*b*) HBA·HCl salt in $CDCl_3$.

is a poorly resolved multiplet. By comparison, TCA produces a well-defined doublet for H_7 and yet it has the same chemical shift (Table 1) and the same uv spectral data (for a 1:1 ratio of HBA and TCA, uv spectrum indicates one single band with a λ_{max} = 307 nm) as with the mineral acids.

To understand more fully the significance of these results, the hydroiodide solution and the TCA:HBA system were studied by nmr at different temperatures. Figure 4 *a* and *b* shows the results.

By lowering the temperature, H_7 for the HI:HBA system becomes a doublet of doublets at a temperature of 5°C while for TCA:HBA, it must reach −30°C. A doublet of doublets signifies that a proton is located on the nitrogen of the azomethine while a doublet means that a rapid exchange is present. At room temperature then, the hydroiodide and hydrobromide are exchanging protons with the solvent while the hydrochloride is not. With TCA, the exchange is more complete (faster) than with the hydroiodide and a well-defined doublet is obtained. From these results and explanations and remembering that all acids (including HCl) induce almost identical deshielding on the hydrogens of HBA, it must be inferred that in methanol: (*a*) with HCl, a tight-ion pair must exist between the chloride anion and the *solvated* cation so that proton exchange is minimal; (*b*) with HBr and HI, the ion pair is more loosely held together and some proton exchange is present; and (*c*) with TCA, there is no ion pair and both the anion and cation are fully solvated and proton exchange occurs readily.

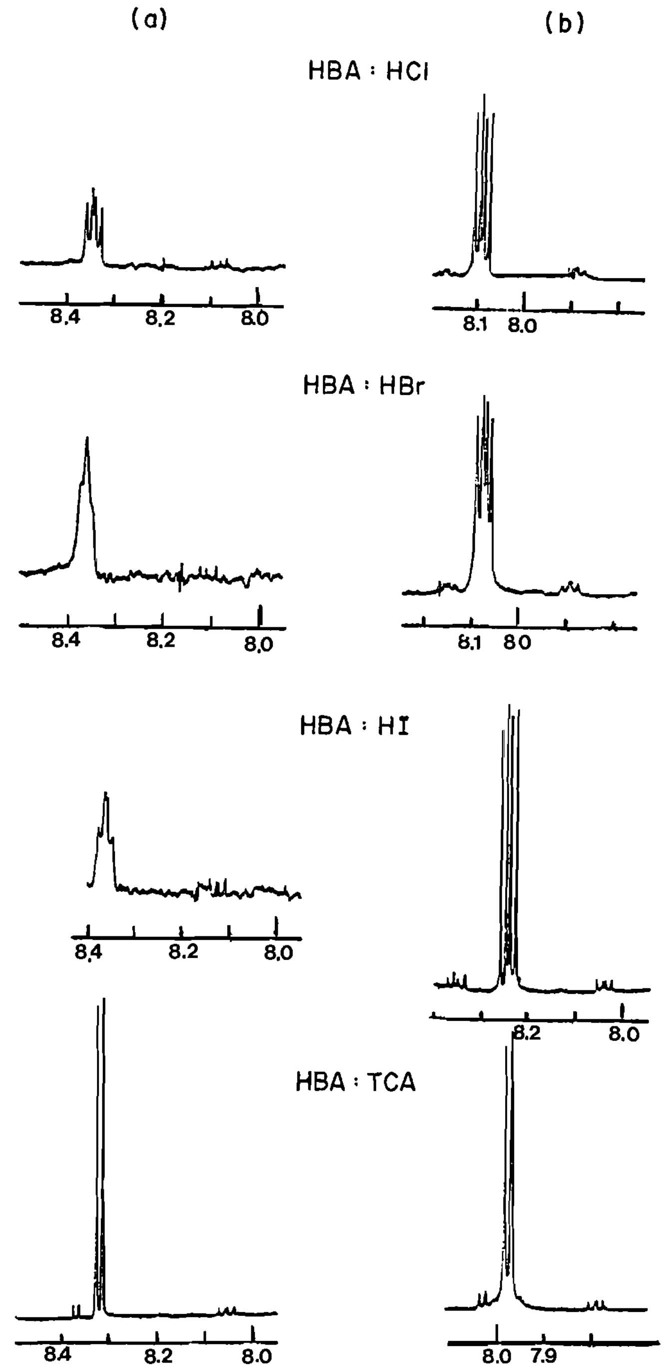

FIG. 3. Spin–spin couplings of H_7 for HBA salts: (*a*) in CD_3OH and (*b*) in $CDCl_3$.

In deuterated chloroform, the solvent being non-polar and having a low dielectric constant, ion pairs must be expected. Table 1 shows that the chemical shifts are different and thus, no leveling effects seems to exist. Acids cause a pronounced deshielding on H_6 and this deshielding vary according to the size of the anion as anticipated (4). Figure 3*b* shows the splitting of H_7 in $CDCl_3$. The three strong acids protonate fully the Schiff base and the acidic proton sits on the nitrogen without proton exchange, so that a doublet of doublets is the results. However, TCA is protonating fully HBA as shown by the uv spectrum (one band only with a λ_{max} = 310 nm) and yet H_7 appears as a doublet. This can be explained by invoking an equilibrium between unprotonated and protonated HBA (see

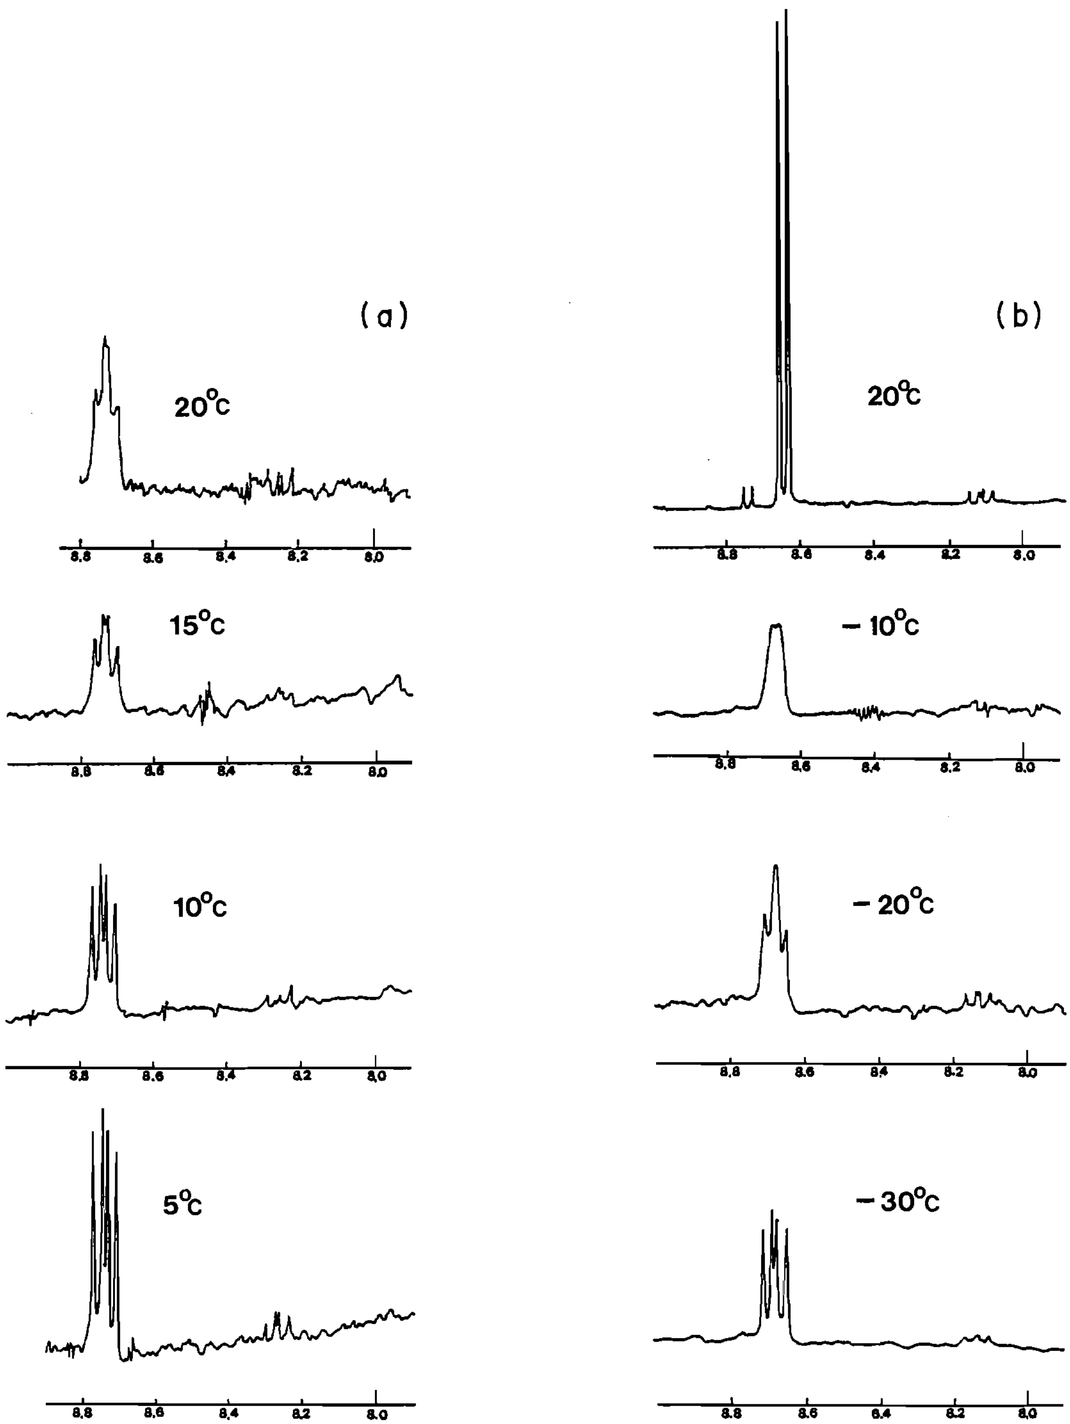

FIG. 4. Spin–spin couplings of H_7 for (*a*) HBA:HI, (*b*) TCA:HBA at different temperatures in CD_3OH.

reaction [1]). Nuclear magnetic resonance spectra in $CDCl_3$ at different temperatures show the same pattern as before in CD_3OH (Fig. 4). At −25°C, a doublet of doublets is obtained. In our previous work with halogenated carboxylic acids (3), similar conclusions were drawn. In deuterated chloroform, acids like the mono-, di-, and tri-halogenated acetic acids induced a pronounced deshielding on H_5 and H_6 while H_7 always appeared as a doublet. By increasing the proportion of acid toward the imine, a doublet of doublets was obtained for H_7. This result is analogous to the one reported here by lowering the temperature of the TCA–imine system and it confirms the fact that in chloroform, the acidic proton is wandering between the carboxylate anion and the Schiff base. Surprisingly enough, uv spectroscopy is insensitive to the proton transfer.

In conclusion, this study shows that the acidic proton on a protonated Schiff base is very labile and moves constantly between the imine group and the solvating species (if the medium is polar) or the counter-ion if it is a carboxylate anion and the milieu is non-polar. Extrapolation of our results to rhodopsin is too risky to be done since it was shown, quite recently, by two-proton spectroscopic measurements (ref. 7*a*, for a comment of one of the referees, see ref. 7*b*) that the degree of protonation did vary according to the existing milieu. This fact seems also verified by ^{13}C nmr studies done on samples of bacteriorhodopsin whose preparations were different (8). This being the case, it is nevertheless interesting to note the great lability of the acidic proton in our model and the effect of lowering the temperature which freezes the proton exchange and permits the acidic proton to be located solely on the Schiff base nitrogen.

Acknowledgements

The authors are most grateful to Professor Camille Sandorfy for helpful discussions and to the Laboratoire Régional de RMN à haut champ (Dr Phan Viet Minh Tan) of University of Montreal for all the 400 MHz nmr spectra. We acknowledge the financial help of the National Research Council of Canada (grant A0943) and of the Université du Québec à Montréal. We owe many thanks also to Ms. Danielle Sabourin for typing this manuscript.

A Raman spectroscopic study of the equilibria in aqueous solutions of Hg(II) chloride

PATRICE B. BENTHAM, CYNTHIA G. ROMAK, AND HERBERT F. SHURVELL[1]
Department of Chemistry, Queen's University, Kingston, Ont., Canada K7L 3N6

Received September 25, 1984

PATRICE B. BENTHAM, CYNTHIA G. ROMAK, and HERBERT F. SHURVELL. Can. J. Chem. **63**, 2303 (1985).

The techniques of factor analysis (principal component analysis) and band contour resolution have been applied to Raman spectra obtained from seven aqueous solutions of $HgCl_2$ with various amounts of HCl added to increase the chloride to mercury ratio. The digitized spectra of the Hg—Cl stretching region (200−380 cm^{-1}) were subjected to baseline fitting and removal, and normalization using the ν_2 band of ClO_4^- (380−530 cm^{-1}) as an internal intensity standard. Factor analysis indicated the presence of three scattering components in the Hg—Cl stretching band envelope. Band resolution gave the positions of peaks assigned to $HgCl_2$, $HgCl_3^-$, and $HgCl_4^{2-}$ at 320, 290, and 269 cm^{-1}, respectively. Approximate values for equilibrium constants for the equilibria present in the system have been calculated from the resolved band areas.

PATRICE B. BENTHAM, CYNTHIA G. ROMAK et HERBERT F. SHURVELL. Can. J. Chem. **63**, 2303 (1985).

On a appliqué les techniques d'analyse factorielle (analyse du composant principal) et de résolution du coutour de la bande aux spectres Raman obtenus à partir de sept solutions aqueuses de $HgCl_2$ dans lesquelles on a ajouté diverses quantités de HCl dans le but d'augmenter le rapport chlorure/mercure. On a soumis les spectres digitalisés de la région d'élongation Hg—Cl (200−380 cm^{-1}) à un ajustement et une élimination de la ligne de base, puis à une normalisation faisant appel à la bande ν_2 du ClO_4^- (380−530 cm^{-1}) comme standard interne. Dans l'enveloppe de la bande d'élongation Hg—Cl, l'analyse factorielle suggère la présence de trois composantes qui diffusent. À l'aide de la résolution des bandes, on a pu attribuer les bandes à 320, 290 et 269 cm^{-1} respectivement aux entités $HgCl_2$, $HgCl_3^-$ et $HgCl_4^{2-}$. En se basant sur les bandes résolues, on a déterminer les valeurs approximatives des constantes d'équilibre pour l'équilibre présent dans le système.

[Traduit par le journal]

Introduction

Factor analysis (or principal component analysis) and band contour resolution techniques have been useful in the infrared studies of various equilibria in CCl_4 solutions (1, 2). The method was later adapted for Raman studies, and successfully used in the investigation of aqueous In(III) chloride solutions (3) and aqueous Zn(II) chloride solutions (4). A review of the procedure with applications has been published (5). As a further extension of the method, it was decided to examine the Raman spectra of aqueous Hg(II) chloride solutions with chloride added to vary the Cl^- to Hg ratio.

Aqueous mercury(II) chloride solutions have been the subject of numerous investigations (6−19). It is generally agreed that the main aquated species present in aqueous solutions of mercury(II) chloride with concentrations of free chloride in the range 10^{-3} to 1 *M*, are $HgCl_2$, $HgCl_3^-$, and $HgCl_4^{2-}$. There is some disagreement in the literature over the assignment of the Hg—Cl stretching frequencies of the various complexes. The reported wavenumbers are compared in Tables 1, 2, and 3.

Detailed resolution of the Hg—Cl stretching band in aqueous mercury(II) chloride solutions using modern computing methods has not been attempted previously and it was felt that such a study would provide useful information on this system.

In the present study, we have recorded digitally the Hg—Cl stretching band of solutions with various *R* (chloride : mercury) ratios. By means of factor analysis and band resolution techniques, it has been possible to identify the complexed species, obtain wavenumbers for the symmetric Hg—Cl stretching modes of these species, and obtain approximate values for the equilibrium constants of the following reactions:

[1] $HgCl_2 + Cl^- \rightleftharpoons HgCl_3^-$

[2] $HgCl_3^- + Cl^- \rightleftharpoons HgCl_4^{2-}$

[3] $HgCl_2 + 2Cl^- \rightleftharpoons HgCl_4^{2-}$

[1]To whom all correspondence should be addressed.

Experimental

Reagent grade mercuric chloride (Pfaltz and Bauer) was used to prepare a near-saturated aqueous stock solution. This was filtered to remove suspended particles and solutions containing 0.172 *M* $HgCl_2$, 1.59 *M* $HClO_4$, and varying concentrations of HCl were prepared. Details of the seven solutions used are given in Table 4.

Raman spectra of the seven solutions were recorded at 22 ± 1°C using a Jarrell-Ash 25-100 double Czerny-Turner monochromator, a RCA 30032-02 photomultiplier tube together with photon counting electronics. Raman spectra were excited by the 514.5 nm line of a Spectra-Physics Model 171 Ion laser. Laser powers between 200 and 500 mW at the sample were used. The sample was contained in a 5 mm × 5 mm × 50 mm silica cell. Two regions were scanned during the course of the study: 200 cm^{-1} to 380 cm^{-1} (the Hg—Cl stretching region) and 380 cm^{-1} to 500 cm^{-1} (the ν_2 region of the ClO_4^- ion used as an internal intensity standard). Duplicate spectra were recorded. Any spectra showing intensity variations greater than 1% between consecutive scans were rejected. The spectra were calibrated using emission lines from a neon lamp and the wavenumbers reported from

the present work in Tables 1, 2, and 3 are believed to be accurate to within ± 1 cm^{-1}.

Computing methods

(i) Digitization

All spectra were digitized by computer. The output from the photon counting system was interfaced to a PDP11 computer. Spectra recorded in this manner were permanently stored on floppy disks as well as being transferred to the IBM 4341 computer for further processing.

(ii) Baseline removal

Duplicate spectra were averaged. A plot of a typical raw spectrum obtained in this study is shown in Fig. 1. Removal of the baseline was accomplished using a revised version of the program BSLINE (20). Three types of baseline fits were used, either an exponential baseline was fitted across the entire spectrum, or the spectrum was arbitrarily divided at 380 cm^{-1} and a linear baseline fitted to the reference peak, while an exponential-quadratic baseline was fitted to the band envelope. These three types of fits are illustrated in Figs. 1, 2 and 3*a*, respectively. The fitted baselines were subtracted from the raw spectra to give the baseline removed spectra. An example is shown in Fig. 3*b*.

(iii) Treatment of spectra

The seven baseline removed spectra were subjected to factor analysis (principal component analysis) using the program CHISQ (5). Band resolution was accomplished using a version of the program PC116 originally written by Jones *et al.* (21), but modified here for fitting Raman bands. Details of the modifications are available from the authors on request. Areas of the component bands were determined and used to calculate the equilibrium constants.

Results and discussions

(i) Factor analysis

Factor analysis (principal component analysis) (1, 5) has been applied to the Raman band envelope in the Hg—Cl stretching region of the seven solutions of 0.172 M $HgCl_2$ with added HCl, listed in Table 4. The analysis indicates that there are three scattering components contributing to the band envelope.

TABLE 4. Composition of the seven samples[a]

Solution number	Added [Cl^-] from HCl (M)	Total [Cl^-] (M)	R ([Cl^-]:[Hg^{2+}])
1	0.0	0.344	2.0
2	0.113	0.454	2.66
3	0.170	0.514	2.99
4	0.227	0.571	3.32
5	0.214	0.628	3.65
6	0.340	0.665	3.86
7	0.454	0.798	4.64

[a]Each solution was 0.17 M in $HgCl_2$ and 1.59 M in $HClO_4$. Total volume of each solution was 10.0 mL.

6	1272	2	0	0	38.5	176.0
7	1274	0	0	0	0	0

In principal component analysis, the matrix $\mathbf{Q} = \mathbf{I}^T\mathbf{I}$, where $\mathbf{I}$ is the Raman intensity matrix and $\mathbf{I}^T$, its transpose, is formed. The number of scattering components is taken to be the number of non-zero eigenvalues of $\mathbf{Q}$. Due to experimental and computational errors, statistical tests must be employed to determine which eigenvalues are really non-zero.

One criterion is the square root of variance test. The number of scattering components is taken as the number of eigenvalues greater than the square root of their variance. The results of this criterion are shown in Table 5, where it is seen that the first three eigenvalues are larger than their variance.

Two further criteria are the regeneration of the intensity matrix using the minimum number of eigenvectors and the estimation of χ^2_m. When m equals the number of components, χ^2_m should have a value near the expectation value (22) which, in the present case, is given by $(N_W - m)(N_S - m)$ (23), where

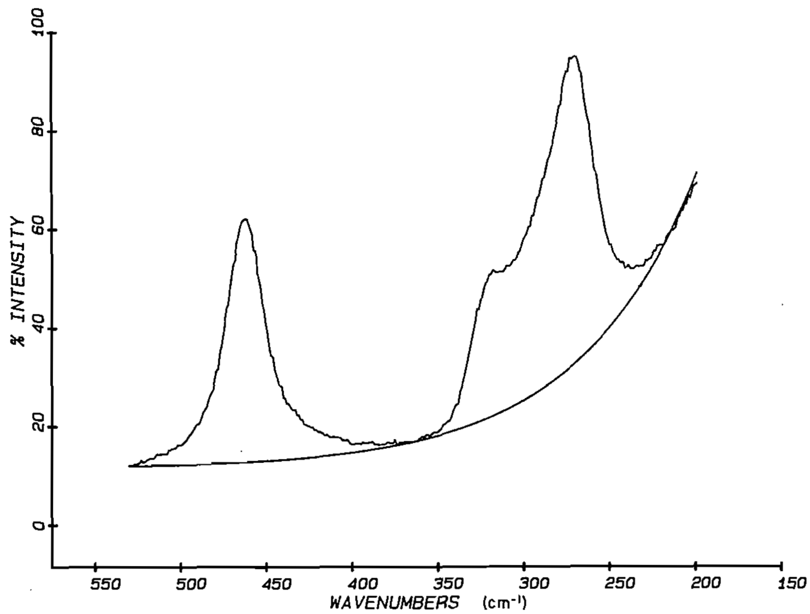

FIG. 1. The raw spectrum from sample 6 (R = 3.86) with a fitted exponential baseline.

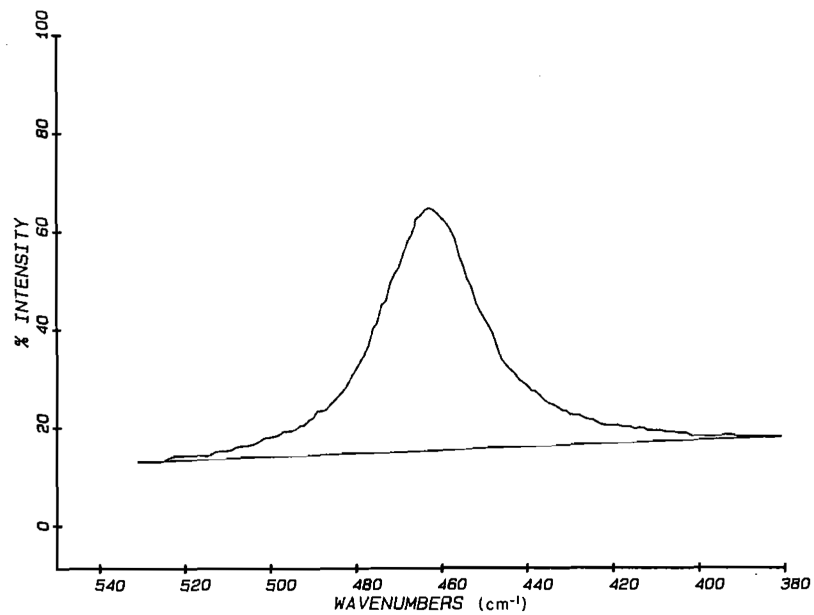

FIG. 2. A linear baseline fitted to the reference band (ν_2 of ClO_4^-) from sample 1.

N_W is the number of digitized points in the spectrum and N_S the number of solutions. The results of these two criteria are given in Table 6.

It can be seen that three eigenvectors are needed to regenerate the intensity matrix with 1272 out of 1274 points within three standard deviations of the experimental values. The χ^2 test also indicates three components, since the calculated χ_2^2 for two components is greater than the expectation value, while χ_3^2 is comparable to the expectation value.

Band resolution

Band resolution of the seven spectra was carried out. The results for solution 3 (R = 2.99) and solution 7 (R = 4.64) are shown in Figs. 4 and 5. It was found that the three bands required by the factor analysis were centered at 320 cm^{-1}, 290 cm^{-1}, and 269 cm^{-1}. The band at 320 cm^{-1}, which predominates at low chloride to mercury ratios was assigned to $HgCl_2$. The band at 269 cm^{-1} which predominates at high R values was assigned to $HgCl_4^{2-}$. The middle band, centered at 290 cm^{-1}, was assigned to $HgCl_3^-$.

Calculation of equilibrium constants

The equilibrium constants for the reactions $HgCl_2 + Cl^- \rightleftharpoons HgCl_3^-$, $HgCl_3^- + Cl^- \rightleftharpoons HgCl_4^{2-}$, and $HgCl_2 + 2Cl^- \rightleftharpoons HgCl_4^{2-}$ may be calculated from the following equations:

$$[4] \quad K_3 = \frac{[HgCl_3^-]}{[HgCl_2][Cl^-]}$$

$$[5] \quad K_4 = \frac{[HgCl_4^{2-}]}{[HgCl_3^-][Cl^-]}$$

$$[6] \quad K_3K_4 = \frac{[HgCl_4^{2-}]}{[HgCl_2][Cl^-]^2}$$

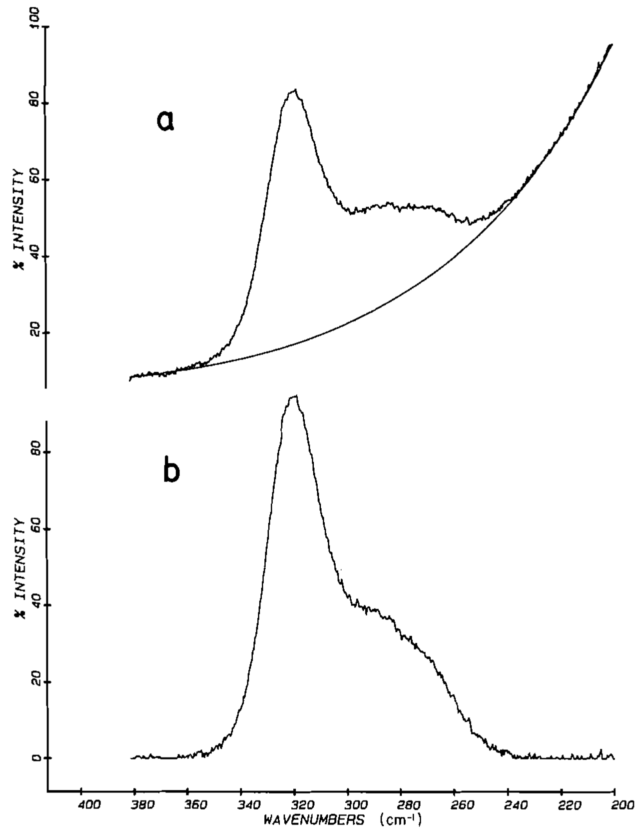

FIG. 3. The Hg—Cl stretching band from sample 2 (R = 2.66): (a) with a fitted exponential-quadratic baseline, (b) the baseline-removed band.

where the square brackets represent the concentrations of the respective species. Concentrations (C_i) may be related to resolved band areas (A_i) by the relationship:

$$[7] \quad A_i = J_iC_i$$

where J_i is a molar scattering coefficient. An approximate

TABLE 7. Results of band fitting and Cl^- ion-selective electrode measurements

Solution	Area (320 band)	Area (290 band)	Area (269 band)	$[Cl^-]$ (M)
2	498.31	313.90	113.93	0.007
3	449.85	327.95	242.13	0.004
4	674.57	469.79	532.98	0.046
5	489.84	553.84	859.51	0.064
6	321.00	562.09	963.66	0.072
7	167.62	435.62	1079.06	0.121

calculation of equilibrium constants can be made if it is assumed that the molar scattering coefficients (J_i) for the symmetric stretching bands of $HgCl_2$, $HgCl_3^-$, and $HgCl_4^{2-}$ are equal. In this case, we replace the concentrations in eqs. [4], [5], and [6] by resolved normalized band areas. The concentration of the free Cl^- ion was measured independently using a Cl^- ion-selective electrode. Table 7 lists the areas of the various bands as well as the free Cl^- ion concentration, as measured by the ion-selective electrode for each solution. All activity coefficients were assumed to be unity in this work.

Table 8 compares the values of $\log_{10} K$ for the various stepwise equilibria present in the Hg(II)/Cl^- system studied in this work with those obtained by other workers. Sillen and Ciavatta used electrochemical techniques, while Marcus employed a solvent (benzene) distribution method. The values determined here, for the equilibrium constants (eqs. [4], [5], and [6]) listed in Table 8, are somewhat higher than the literature values. However, our values would be a little lower and hence closer to the literature values if we were to make the assumption that the molar scattering coefficients (J_i) are in the ratio 2:3:4 rather than 1:1:1. This is not an unreasonable assumption, since the J_i could increase with increasing number of HgCl bonds.

Conclusions

Principal component analysis and Raman band contour resolution has shown that three scattering species are present in

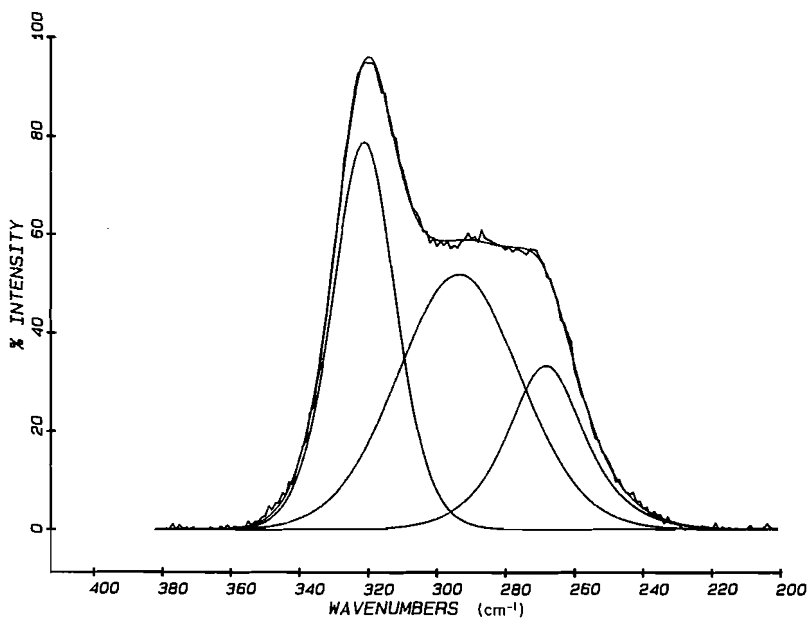

FIG. 4. The fitted Hg—Cl stretching band envelope for sample 3 (R = 2.99).

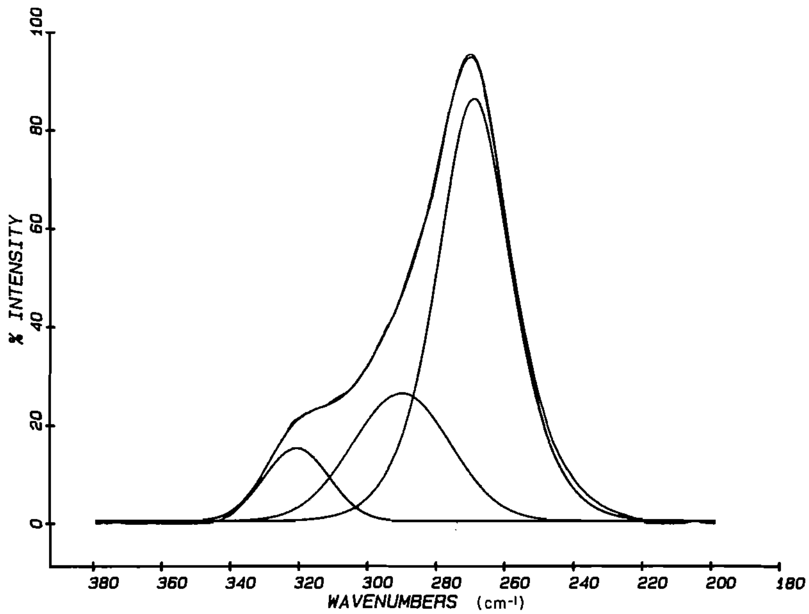

FIG. 5. The fitted Hg—Cl stretching band envelope for sample 7 (R = 4.64).

TABLE 8. Values of $\log_{10} K$ for various stepwise equilibria in Hg^{2+} system with added Cl^-

Reaction	Constant	Sillén (6) (25°C)	Marcus (8) (25°C)	Ciavatta (9) (25°C)	This work (22 ± 1°C)
$Hg^{2+} + Cl^- = HgCl^+$	$\log K_1$	6.73±0.018	—	6.72±0.02	—
$HgCl^+ + Cl^- = HgCl_2$	$\log K_2$	—	6.30±0.02	—	—
$HgCl_2 + Cl^- = HgCl_3^-$	$\log K_3$	0.85±0.15	0.95±0.03	1.00±0.01	1.29±0.25
$HgCl_3 + Cl^- = HgCl_4^{2-}$	$\log K_4$	—	—	—	1.36±0.25
$HgCl_2 + 2Cl^- = HgCl_4^{2-}$	$\log K_3K_4$	0.85±0.05	2.00±0.05	1.97±0.025	2.65±0.50

solutions of $HgCl_2$ containing added chloride ion. It is concluded that the three species are $HgCl_2$, $HgCl_3^-$, and $HgCl_4^{2-}$. The totally symmetric stretching frequencies of these species are 320 cm^{-1}, 290 cm^{-1}, and 269 cm^{-1}, respectively.

A value of 1.29 ± 0.25 was obtained for $\log_{10} K_3$, 1.36 ± 0.25 for $\log_{10} K_4$, and 2.65 ± 0.50 for $\log_{10} K_3K_4$. These values are somewhat higher than literature values. The discrepancies are most probably due to the assumptions that the molar scattering coefficients of the symmetric stretching modes of the three species were equal and that all activity coefficients were unity. The different techniques employed and different concentration ranges studied also may have contributed to the differences between our values and previous values for the equilibrium constants.

A comparison of the electron impact and fast atom bombardment mass spectra of some group IV organometallic halides

JACK M. MILLER AND ADRIAN FULCHER

Department of Chemistry, Brock University, St. Catharines, Ont., Canada L2S 3A1

Received October 15, 1984

JACK M. MILLER and ADRIAN FULCHER. Can. J. Chem. **63**, 2308 (1985).

The positive ion fast atom bombardment (FAB) mass spectra of a series of group IV organometallic halides, $(phenyl)_3MCl$ (M = Ge, Sn, Pb), $(phenyl)_3PbX$ (X = Cl, Br, I) and $Sn(phenyl)_nCl_{4-n}$ are reported in a sulfolane matrix, and compared to their corresponding EI spectra. The use of other matrix liquids such as glycerol thioglycerol, diamylphenol, 18-crown-6/tetraglyme, and *p*-nitrophenyloctylether are discussed. Disappointingly FAB, like EI, does not produce significant parent ions for group IV organometallics. The FAB and EI spectra are remarkably similar with one major exception. In EI, the loss of a phenyl is preferred over the loss of a halide, while in FAB the reverse is the case, strongly suggesting that the primary ionization occurs in the condensed phase.

JACK M. MILLER et ADRIAN FULCHER. Can. J. Chem. **63**, 2308 (1985).

Opérant dans des matrices de sulfolane, on a déterminé les spectres de masse, par bombardement avec des atomes rapides d'ions positifs, d'une série d'halogénures de composés organométalliques du groupe IV, soit les $(phényl)_3MCl$ (M = Ge, Sn, Pb), les $(phényl)_3PbX$ (X = Cl, Br, I) et les $SN(phényl)_nCl_{4-n}$; on compare les spectres obtenus grâce à cette technique avec ceux obtenus par IE. On discute aussi de l'utilisation d'autres liquides matriciels comme le glycérol, le thioglycérol, le diamylphénol, l'éther 18-couronne-6/tétraglyme et l'éther *p*-nitrophénoxyoctane. Les spectres obtenus à l'aide de cette technique moderne sont désappointants puisque les quantités d'ions parents qui sont obtenues sont aussi faibles que celles obtenues sous IE et que les deux séries de spectres sont très semblables, à une exception près. Dans les spectres sous IE, la perte du phényle se fait plus facilement que celle de l'halogénure alors que c'est l'inverse dans les spectres par bombardement avec des atomes rapides; ceci suggère fortement que l'ionisation primaire se produit dans la phase condensée.

Introduction

While the use of fast atom bombardment (FAB) mass spectrometry by organic and biochemists grew rapidly immediately after the discovery of the technique, inorganic and organometallic chemists have been slower to apply this important new soft ionization technique — even though at first glance the method should solve many problems associated with thermally labile, unstable, or relatively involatile organometallics. One of the drawbacks is that, unlike polar biochemical species which have an excellent chance of yielding good FAB spectra in a glycerol or thioglycerol matrix, organometallics, with a wide range of polarities, reactivities, Lewis acidities, and susceptibility to hydrolysis do not automatically yield a molecular or quasi-molecular ion on the first try in FAB with the most common and easily used matrix liquids. In addition, just as applications of EI mass spectrometry to organometallics lagged behind application to organics because it was difficult for organometallic chemists to gain access to instruments and because there are more complex rules for understanding the spectra, application of FAB to organometallics is also being delayed for the same reasons. The new very high mass (10 000 Daltons and higher) mass spectrometers now becoming available, have for the most part been installed in labs with a biomedical orientation and have been less accessible to the inorganic chemist.

However, inorganic, organometallic, and coordination chemical applications of FAB are now multiplying (1, 2). Although papers have been published on transition metal organometallics also containing group IV elements (3, 4), no details of a systematic FAB study on simple group IV organometallics have been reported in the primary literature (5). We present such a study here. The EI spectra of many of these compounds have previously been reported by Glockling and co-workers (6, 7) or obtained by us as part of an earlier EI study of some HMPA adducts (8, 9), but with one exception, they are repeated here so that we have comparisons on the same samples run in EI and FAB on the same instrument with the same geometry and under the same experimental conditions.

Experimental

Samples used were commercially available organometallics (Alfa). They were used without further purification if the melting points corresponded with those in the literature and if the mass spectra were free of obvious impurity peaks. The matrix liquids, sulfolane, diamylphenol, thioglycerol, 18-crown-6, tetraglyme (Aldrich), glycerol (BDH), and *p*-nitrophenyloctylether (Fluka) were used without further purification.

Mass spectra were obtained on a Kratos (AEI) MS30 mass spectrometer, interfaced to a Kratos DS55 data system. EI spectra were obtained from beam 2 of the MS30 with a source temperature of 180°C, samples being evaporated from a direct insertion probe heated just enough to maintain adequate sample pressure. A 4 kV accelerating voltage was used at resolution 1000, with a 300 μA regulated trap current. The FAB source was a Kratos retrofit to beam 1 of the MS30, involving the addition of fast pumping for the source, an Ion Tech Fast Atom Gun in place of the normal direct insertion lock, and a modified source endplate with a rear entry lock for the FAB probe. Argon, or preferably xenon, was used as the bombarding gas with atom gun energies of 6−8 kV and a gun current of approximately 1 mA, and a source pressure with bombarding gas flowing and evaporating matrix liquid of $1-2 \times 10^{-5}$ Torr. Samples dissolved in the matrix liquid were placed on the 2 mm diameter beveled stainless steel probe tips. The source was operated at room temperature, with the same resolution and accelerating voltage as for the EI spectra. The data system was calibrated with PFK (perfluorokerosine) for the EI spectra with real time, time to mass conversion. For FAB, perfluoroheptatriazine was used for the calibration, and data were acquired as time files and converted to mass off line, since we were not certain of having a lock mass. The matrix background could be subtracted by the data system, leaving the spectrum of the organometallic. At low masses in particular, the matrix subtraction did not always completely remove the matrix peaks, a result of the variation of the matrix spectrum with concentration. The data presented are for metal-containing ions only, normalized to 100%. Ion intensities are summed over all isotopic contributions.

*Sulf = sulfolane, the FAB matrix liquid.

For the bulk of the study in sulfolane matrix, the matrix solutions were saturated with the organometallic. For the comparison of the various matrix liquids, samples were prepared with 100 mg of organometallic dissolved in 100 μL of matrix liquid.

Results and discussion

a. Comparisons of EI mass spectra with FAB mass spectra in sulfolane

In the first series of EI/FAB comparisons, Table 1 shows the differences occurring when the group IV metal is changed from lead, to tin, and then to germanium, for their respective triphenylmetalchloride derivatives. Two things stand out immediately. FAB mass spectra of these group IV organometallics show no molecular ions, quasi-molecular ions, or molecular ions coordinated to a molecule of the matrix liquid, and thus appear to be somewhat of a disappointment to those who hoped for a soft ionization technique which would readily provide a molecular ion for species such as the group IV organometallics which have notoriously weak, or absent parent ions. Only the EI spectra of the tin and germanium derivatives showed weak molecular ions. The FAB spectrum in the germanium case showed a digermanium species, presumably as a result of ion/molecule reactions occurring immediately on sputtering in the region near the matrix surface where the concentration of ions and molecules is quite high.

Two obvious differences are quickly apparent on comparison of these FAB and EI data. First there is the presence in FAB of ions involving a molecule (or even two molecules) of matrix liquid coordinated to an ion fragment, which is itself observed in both EI and FAB, the unsolvated fragment always being of greater intensity than the solvated one. The second striking difference is the relatively low abundance of organometallic ions containing the chloride, or metal chloride ions for that matter, in FAB compared to EI. Basically it appears that in FAB mass spectra of these derivatives, chloride is lost in preference to a phenyl group, whereas in EI the phenyl is lost preferentially. This might suggest that there is a pre-equilibrium or pre-ionization step in solution. Examples of pre-ionization could include protonation, i.e. a pseudo chemical ionization. A R_3MXH^+ ion thus formed could readily lose HX. Alternately, a molecule of matrix liquid could displace a halide ion giving R_3MMat^+. Under these circumstances, with energy supplied to the solution by the bombarding atoms, a cation can be formed directly by chloride loss from the parent molecule. A chloride ion might be more readily lost in solution (with a polar matrix molecule being available to solvate it) than would a phenyl anion or radical. Phenyl loss would still require a subsequent ionization step for the remaining organometallic radical species. In EI, however, in the gas phase ionization process, there is simple competition between the strength of the metal carbon and metal halogen bonds without any possibility of solvation entering the picture.

This relative halide/phenyl loss is most apparent for the triphenyl−metal ions vs. diphenyl − metal-chloride ions, where, for each metal, the FAB abundances of the former ions are virtually interchangeable with the EI intensities of the latter. The metal chloride ions themselves are also greatly reduced in FAB, to the extent of being absent for germanium. The simple phenyl M ion is reasonably consistent between EI and FAB and for each metal. The bare metal ions themselves are only observed for lead and tin, the FAB/EI ratio being reversed for the two metals. Germanium ions are absent. Another ion of interest is that due to the loss of a benzene molecule from the triphenyl germanium and tin ions. This species, appearing one mass unit below the expected mass of the essentially absent diphenyl−metal species, is observed in the EI spectrum of the tin and germanium derivatives; it being much stronger in the latter, which also shows this species as an abundant ion in its FAB spectrum.

A similar comparison on changing the halide from chloride to bromide to iodide is shown in Table 2 for the triphenyllead halides. Again we do not see parent ions in either EI or FAB, and again some preference for loss of halide is observed in FAB in comparison to the EI loss of phenyl, though this difference is less for the bromide than for the chloride. In the case of the iodide, this behavior is not apparent for the organometallic species, but still prevails for the simple lead iodide. For much of the data, the chlorides and bromides behave very much alike. With the exception of the species corresponding to tri-coordinate lead, the trends observed in the EI spectra are

reflected in the FAB data. Formation of free lead cations is twice as probable in the EI spectra as in the FAB, and is not dependent on the halide.

As a potential analytical technique for this series of compounds, there is nothing to choose between the two ionization techniques. Essentially all important ions seen by one technique are seen by the other, with the exception of the coordination of matrix molecules. As the matrix is known, these are easily predictable.

When we look at a series in which the number of phenyls on tin is varied from four down to one, we observe the data shown in Table 3. The EI spectra all show parent ions, with intensities increasing as the chloride content rises, all of them quite weak except for the trichloride. In the latter case the FAB spectrum as well shows a parent molecular ion, though only two thirds the intensity of that observed in the EI spectrum. In the case of the trihalide, the generalization made above about loss of halide for the FAB spectrum in comparison with the EI spectrum breaks down to some extent, tin trichloride species in FAB being more abundant than in EI, but so too are the diphenyltin chloride containing ions. Interestingly, though FAB usually seems to lead to the loss of a halide in preference to a phenyl, the presence of three chlorides leads to the observation of a molecular ion. It is also interesting to note that it is a true molecular ion, not a quasi-molecular ion that is observed in the FAB spectrum.

FAB spectra show more metal-containing ions than the corresponding EI spectra except for the case of the tetraphenyl derivative. This difference is usually due to the presence of ions solvated by the matrix sulfolane.

b. Comparisons of various matrix liquids

In Table 4 we show the effect of changing the matrix liquid on the FAB spectra of triphenyl tin chloride. Since the concentration was kept approximately constant for the comparison of the various matrix liquids, the sulfolane data are repeated, once as the saturated solution, and once as a slightly more dilute sample. There is some variation, rather more than might be expected on repeat runs of an EI spectra, but there are no significant inversions of ion intensities. All the spectra in the matrix comparison were run on the same day with identical instrument settings, source and atom gun conditions, and with the same operator. The EI data are presented in the first column for comparison purposes. There is really no single matrix liquid which gives a FAB spectrum most closely resembling the EI spectrum, though the glycerol spectrum is clearly the farthest from the EI.

The data are presented with the matrix liquids in approximately decreasing order of polarity, with the three having acidic protons being presented first. Of these thioclycerol gave the triphenyltin cation as the base peak, i.e. not just the most intense metal-containing ion, but the most intense ion in the whole spectrum, i.e. including matrix peaks, and one to two orders of magnitude greater than that observed for diamylphenol or glycerol itself. The thioglycerol had few simple matrix ions in the spectrum, but did have some unidentified high mass species. Of the non-protic matrix liquids, only the sulfolane gave the triphenyltin cation as the base peak, with both the nitrophenyloctylether and crown ethers having low mass matrix fragments as the base peaks. Thioglycerine and sulfolane give remarkably similar spectra. As one moves across the table, with the exception of "Dap", the triphenyltin cation relative abundance decreases, and the diphenyltinchloride ion increases, though only for NPOE does the intensity invert, with the halide being more intense. In this sense, perhaps the NPOE matrix most closely resembles the EI data.

Though the sulfolane spectrum gave the triphenyltin ion as the overall base peak, in absolute intensity (counts of the digitizer) terms, it was more intense in both the thioglycerol and crown matrices. In terms of apearance, the NPOE (only 5th in R_3Sn^+ intensity) and Crown (2nd) gave spectra more readily interpretable at a glance than did either sulfolane (3rd) or thioglycerol (1st in absolute intensity). However, these factors do not appear to seriously affect the actual ion intensities, the consistency rather than the differences between the matrix liquids being the more remarkable. There are differences due to solvation, and ionic equilibria, but on the whole they are less than the differences between the EI and FAB data.

c. *Other systems*

Though for the halide systems, glycerol was the worst matrix investigated, we show in Table 5 that for a non-halogenated tin, glycerol is an adequate matrix for organometallics. The EI (10) and FAB spectra are compared for the triphenyltin derivatives of pentafluorophenol and pentafluorothiophenol. If we compare the metal-containing species in both cases, the EI and FAB data are remarkably similar.

In Table 6 we compare the effect of changing the organic group from phenyl to benzyl in the R_2SnCl_2 system using a sulfolane matrix. The benzyl group appears to redistribute in the matrix under FAB conditions much more so than does a phenyl group. Loss of halide is also much more prevalent in the benzyl case. These data suggest that a study of organic exchange reactions by FAB may well be feasible if the ligands are sufficiently labile.

In conclusion, FAB appears to be a useful way to study group IV organometallics. It is, in fact, somewhat worse than EI mass spectrometry, in observing a molecular ion of the species of interest, a notoriously difficult problem for compounds of this type. However, the fragmentation appears to be similar to, though not exactly the same as, that observed in EI spectra. Thus FAB can be used for identification of known species or investigation of unknowns, especially systems not likely to be volatile or thermally stable in conventional EI inlet systems. Certainly FAB is complementary to EI data. The matrix liquids have some effect on the spectrum, but basically, if a spectrum is obtainable, the data are interpretable. Protic matrix liquids do not cause particularly serious problems with halides that are potentially hydrolytically unstable.

Reactions of amines with β-(phenylseleninyl)vinyl sulfones derived from the selenosulfonation of acetylenes. Formation of enamine sulfones[1]

THOMAS G. BACK,[2] SCOTT COLLINS,[3] AND KWOK-WAI LAW
Department of Chemistry, University of Calgary, Calgary, Alta., Canada T2N 1N4

Received October 3, 1984

THOMAS G. BACK, SCOTT COLLINS, and KWOK-WAI LAW. Can. J. Chem. **63**, 2313 (1985).

β-(Phenylseleno)vinyl sulfones **2** were prepared from the selenosulfonation of acetylenes and were oxidized to the corresponding selenoxides **3**. These were treated *in situ* with morpholine (**4**) or pyrrolidine (**5**) to afford the corresponding enamine sulfones **6** and, in those cases where **3** were derived from terminal acetylenes, their selenenylated analogues **7**. The formation of the latter was enhanced by adding benzeneselenenyl chloride to the reaction mixture, and suppressed by the presence of selenenic acid scavengers such as enamine **10** or ethyl vinyl ether. In several instances the enamine sulfones were hydrolyzed to β-keto sulfones prior to work-up. A mechanistic rationale for the formation of **6** and **7** is presented. Selenoxide **3***f* behaved anomalously when treated with pyrrolidine and underwent isomerization to an allyl selenoxide, followed by [2,3] sigmatropic rearrangement to produce allyl alcohol **18**. Selenoxide **3***f* was reduced by *N*,*N*-dimethylhydrazine to the selenide **2***f*.

THOMAS G. BACK, SCOTT COLLINS et KWOK-WAI LAW. Can. J. Chem. **63**, 2313 (1985).

La sélénosulfonation des acétylènes a fourni les β-(phénylséléno)sulfones **2** qui ont été oxydés en sélénoxydes **3**. Le traitement de ces derniers composés *in situ* avec la morpholine (**4**) ou la pyrrolidine (**5**) a donné les énamines sulfones **6** et, dans les cas où les sélénoxydes **3** ont été dérivés des acétylènes monosubstitués, les analogues séléniés **7**. Les rendements de **7** ont été augmentés par l'addition du chlorure benzènesélénénique au mélange de la réaction et diminués par la présence des agents de trappement de l'acide benzènesélénénique, comme l'éther éthylique vinylique ou l'énamine **10**. Dans quelques cas, les énamines sulfones **6** ont été hydrolysées en sulfones β-cétoniques avant l'isolation. Une explication mécanique pour la formation de **6** et **7** est présentée. Le comportement du sélénoxyde **3***f* en présence de la pyrrolidine était anomal. Une isomérisation en sélénoxyde allylique, suivie par un réarrangement [2,3] sigmatropique, a produit l'alcool allylique **18**. Le même sélénoxyde **3***f* a été réduit par la *N*,*N*-diméthylhydrazine en séléniure **2***f*.

Introduction

The free-radical additions of selenosulfonates to olefins (1−3), allenes (4), diazomethane (5), and acetylenes (6−8) have recently been reported. In particular, the selenosulfonation of acetylenes with Se-phenyl *p*-tolueneselenosulfonate (**1**) provides an efficient route to β-(phenylseleno)vinyl sulfones **2**, which can in turn be oxidized to the corresponding selenoxides **3** (6−8) (eq. [1]). As part of our studies of selenosulfonation and its synthetic applications, we have been interested in the reactions of **2** and **3** with nucleophiles. For instance, selenides **2** undergo substitution with alkyl selenocuprates (9) (eq. [2]), and selenoxides **3** react with alcohols via Michael addition (6) to form enol ethers or ketals (eq. [3]).

[1] 
[2] 
[3] 
The present work is concerned with the extension of these studies to the reactions of selenoxides **3** with amines such as morpholine (**4**), pyrrolidine (**5**), and several related nucleophiles. By analogy with eqs. [2] and [3], the expected products are enamine sulfones **6** (eq. [4]). These compounds are, with some exceptions (10), unavailable from the condensation of amines with β-keto sulfones, as the latter undergo facile base-catalyzed C—C bond cleavage (11). Alternatively, the formation of enamine sulfones has been previously noted from the addition of amines to acetylenic sulfones (12−14), and from their reactions with 2-chlorovinyl (15) or 2,2-dichloroethyl sulfones (16). We now report that the aminolysis of selenoxides **3** provides enamine sulfones **6**, their selenenylated products **7**, or the corresponding β-keto sulfones, depending upon the substrate and conditions.

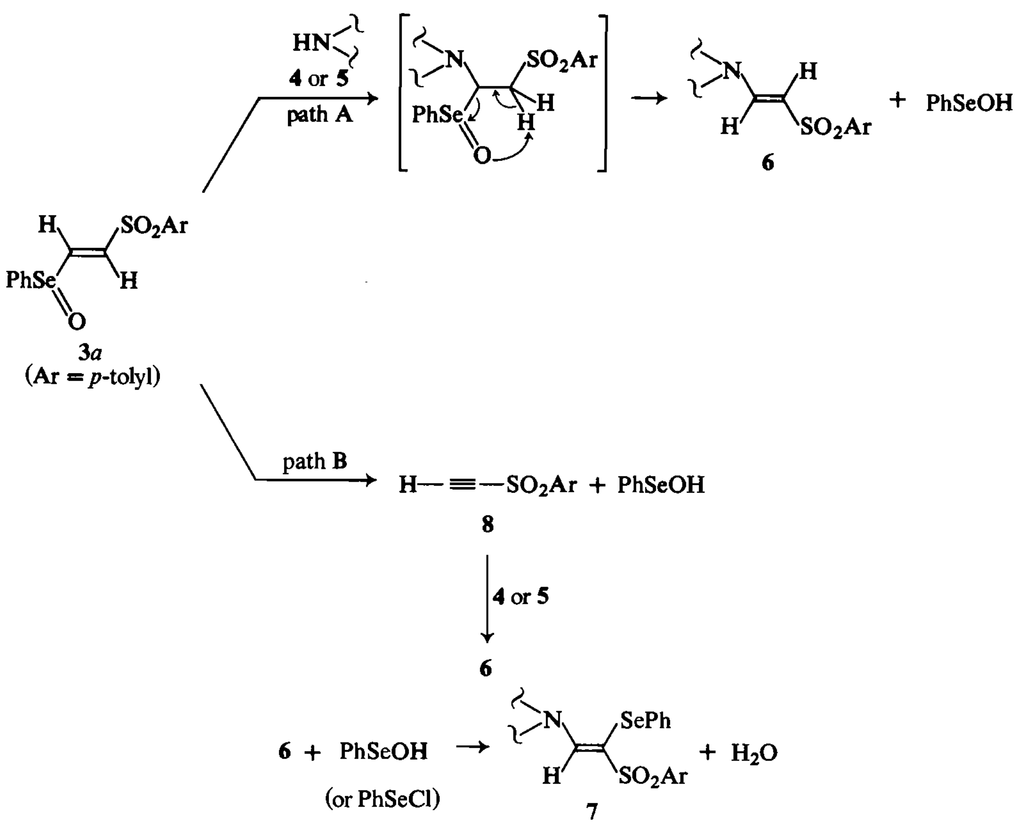
[a]All experiments were conducted at room temperature. Method A: THF solvent. Method B: (*i*) THF solvent, (*ii*) excess PhSeCl added. Method C: THF solvent in presence of excess ethyl vinyl ether. Method D: (*i*) Et_2O solvent; (*ii*) H_3O^+.
[b]Isolated yields reported.
[c]Isolated as the β-keto sulfone.
[d]Product **18** (eq. [5]) was isolated in 70% yield.

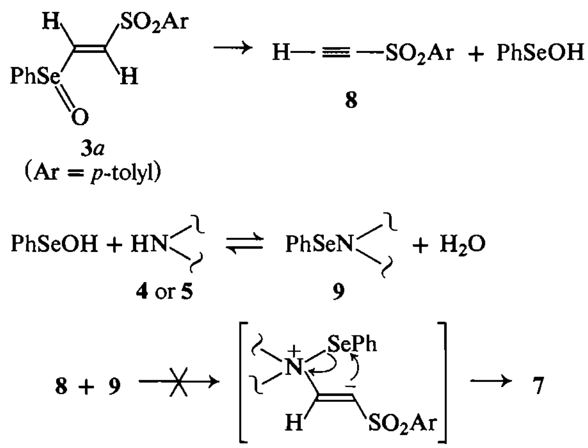
Results and discussion

The results of the reactions of selenoxides **3***a*–**3***f* with morpholine (**4**) and pyrrolidine (**5**) are summarized in Table 1. Selenoxide **3***a* reacted rapidly with morpholine to afford **6** and **7** (R = R′ = H) as the minor and major products, respectively (entry 1). Only the selenenylated product **7** was obtained when the reaction mixture was further treated with benzeneselenenyl chloride (PhSeCl), or when pyrrolidine was employed instead of morpholine (entries 2 and 3). A plausible mechanism for these transformations is shown in path A of Scheme 1, in which **3***a* undergoes Michael addition of the amine to the vinyl sulfone moiety (17), followed by selenoxide elimination (18) to



3 PhSeOH ⇌ PhSeSePh + $PhSeO_2H$ + H_2O

SCHEME 1

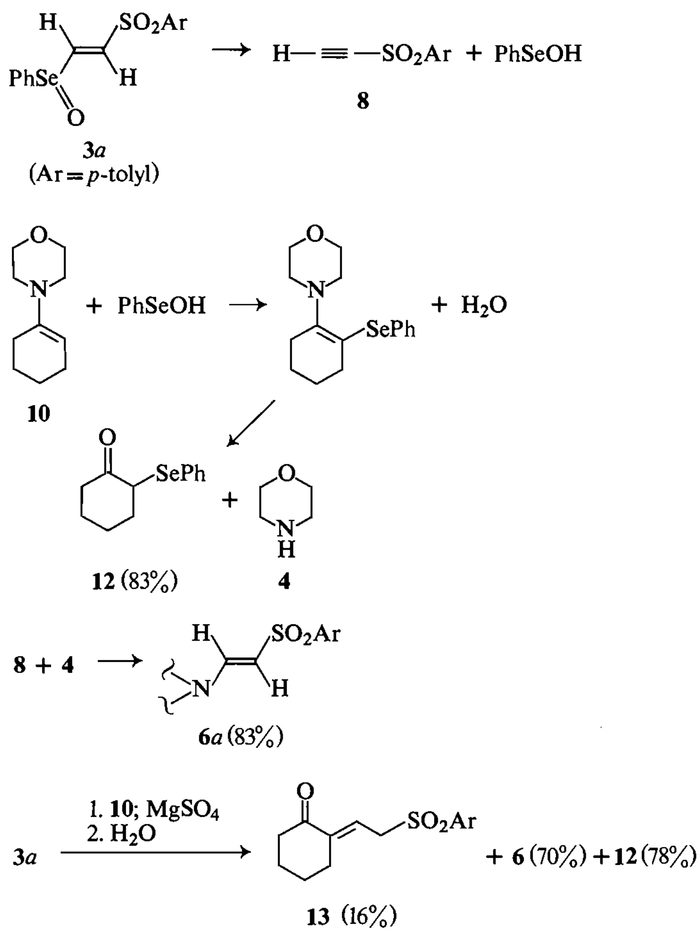


SCHEME 2

afford **6** and benzeneselenenic acid (PhSeOH). Selenoxides such as 3*a*, where R′ = H, are known to eliminate particularly rapidly under base-catalyzed conditions (6). It is therefore possible that in such systems elimination precedes Michael addition (path B) and involves intermediate acetylenic sulfones **8**, which are known to produce enamine sulfones in the presence of amines (12−14). Clearly the latter mode of reaction is precluded for those selenoxides in Table 1 where R′ ≠ H, as the absence of a vinylic hydrogen atom prevents elimination from becoming the initial step. The by-product selenenic acid (19) or a related electrophile such as the corresponding anhydride PhSeOSePh (20) can then react with the enamine sulfone to afford the selenenylated product **7**. Similar reactions of other enamines with selenenic electrophiles have been previously reported (21) and provide a precedent for this step. Any selenenic acid not consumed by the transformation of **6** to **7** disproportionates to benzeneseleninic acid and diphenyl diselenide (19), with the latter observed as a minor by-product. The addition of an excess of a selenenylating agent such as PhSeCl after the initial reaction effects the complete conversion of **6** to **7** (entry 2).

An alternative mechanism for the formation of **7** must also be considered. The selenenic acid which is produced together with the acetylenic sulfone **8** during the fragmentation of selenoxide 3*a* is expected to react with the amine to generate selenenamide **9** (22) (Scheme 2). The further reaction of this species with **8** would then afford the selenenylated product **7** via a sequential Michael addition and intramolecular selenenylation, analogous to the reactions of selenenamides with enones (22) and dimethyl acetylenedicarboxylate (23) previously reported by Reich *et al.* However, when the reaction in entry 1 was carefully monitored by ^{1}H nmr spectroscopy, it became evident that the enamine sulfone **6** is formed first and that the selenenylated product **7** arises subsequently at its expense. This observation is more consistent with Scheme 1, where **6** is the direct precursor of **7**, than with Scheme 2 where the formation of **6** and **7** proceeds independently.

The reaction of selenoxide 3*a* with excess 1-(*N*-morpholino)cyclohexene (**10**) was also investigated. Previous workers had demonstrated the additions of several enamines to vinyl sulfones (24), and the analogous process was expected to produce the corresponding γ-sulfonyl enone **13** in the present instance. Instead, however, the principal products were the enamine sulfone **6** and 2-phenylselenocyclohexanone **12**, each formed in 83% yield based on 3*a* (Scheme 3 and entry 4,



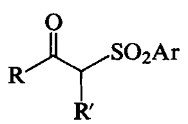
SCHEME 3

Table 1). This suggests that enamine **10** reacts not with selenoxide 3*a*, but rather with the benzeneselenenic acid produced during the fragmentation of 3*a* to the acetylenic sulfone **8**. Hydrolysis of the resulting intermediate **11** *in situ* then affords the α-seleno ketone **12**, and simultaneously liberates morpholine which adds to **8** in the usual manner to provide **6**. When the reaction was repeated under anhydrous conditions in the presence of magnesium sulfate to remove liberated water, it proceeded more slowly and the γ-sulfonyl enone **13** was obtained in a low yield of 16%; however, the previous products **6** and **12** continued to dominate. Thus, although the reactions of selenoxides **3** with enamines do not appear promising as a practical route to enones such as **13**, the present example did furnish the originally sought enamine sulfone **6**. Other attempts to efficiently convert 3*a* to **6** by blocking the subsequent selenenylation step through the *in situ* removal of the benzeneselenenic acid with a large excess of amine (25), or by its further oxidation to the corresponding seleninic acid (25), proved unsuccessful.

Entries 5 and 6 in Table 1 further illustrate the effect of a selenenic acid scavenger. The reaction of selenoxide 3*b* with morpholine (**4**) in THF produced the selenenylated enamine **7** as the only isolable product. However, when the reaction was repeated in the presence of a large excess of ethyl vinyl ether, the enamine sulfone **6** was obtained in excellent yield. It therefore appears that the nucleophilic enol ether, like enamine **10** in entry 4, is an effective trapping agent for the selenenic acid and prevents the further selenenylation of the enamine sulfone **6**.

The stereochemistry of addition of amines to acetylenic sulfones has been studied in detail by Truce *et al.* (12) and Stirling and co-workers (13, 14). When secondary amines (except aziridine) are employed, the product enamine sulfones are formed by *cis* addition to afford exclusively products with the *E*-configuration. It has been demonstrated that *Z*-products are formed kinetically, but isomerize readily to their *E*-counterparts, which are favoured because of the opposing dipoles and absence of nonbonded interactions between the amino and sulfone groups (14). The additions of secondary amines **4** and **5** to selenoxides **3** in Table 1 also proceed in a highly stereoselective manner, producing in each case only one geometric isomer of the corresponding enamine sulfone **6**. The configuration of the product **6** obtained from selenoxide **3***a* and morpholine is unequivocally established as *E* on the basis of the large vinylic coupling constant of 13 Hz. Unambiguous evidence for the configurational assignment of the other enamine sulfones in Table 1 is lacking as a result of the unavailability of both isomers for comparison. However, on the basis of the previous arguments, it is reasonable to assume that they too are the *E*-isomers. The selenenylated products **7** were also formed in a highly stereoselective manner and similar lines of reasoning suggest that they might possess the *Z*-configuration, where the amino group and sulfone moiety are once again *trans*-oriented. Such conclusions are tentative, however, in the absence of more concrete evidence.

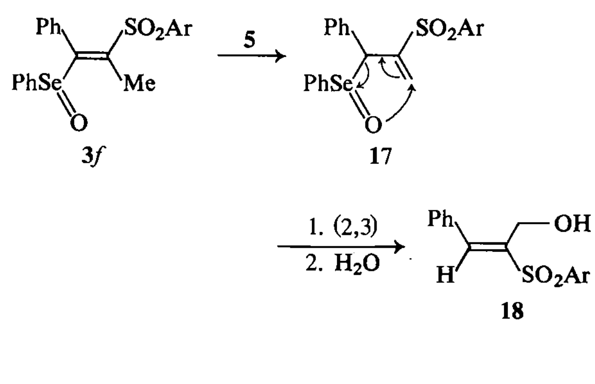
Selenoxide **3***c* reacted with pyrrolidine to produce the expected mixture of the corresponding products **6** and **7** (entry 8, Table 1). The presence of the former compound was clearly evident from a vinylic signal at δ 4.8 in the ^{1}H nmr spectrum of the reaction mixture. However, the products could not be separated by crystallization and underwent partial hydrolysis to the corresponding β-keto sulfones **14** and **15** upon flash, column, or preparative thin-layer chromatography on either silica gel or alumina. Consequently the hydrolysis was deliberately allowed to proceed to completion and Table 1 lists the yields of the resulting β-keto sulfones. The crude enamine sulfone from selenoxide **3***d* (entry 9) also proved difficult to purify and so was similarly converted to β-keto sulfone **16** prior to isolation.



14 R = *n*-C_8H_{17}; R′ = H
15 R = *n*-C_8H_{17}; R′ = SePH
16 R = *n*-Bu = R′

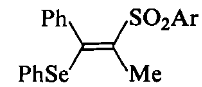
An anomalous, though not entirely surprising result occurred when selenoxide **3***f* was treated with pyrrolidine (entry 11, Table 1). Base-catalyzed isomerization of **3***f* to the corresponding allylic selenoxide **17**, followed by [2,3] sigmatropic rearrangement, afforded the allylic alcohol **18** (eq. [5]). The same product has been previously observed (7) when **3***f* was allowed to react with KOH and 18-crown-6.

[5]



The reaction of selenoxide **3***f* with *N*,*N*-dimethylhydrazine was also investigated. Instead of addition, a redox process occurred which resulted in the formation of the corresponding selenide in nearly quantitative yield (eq. [6]). Several other oxidations of nitrogenous compounds with selenoxides are known (26).

[6] $3f + Me_2NNH_2 \longrightarrow$



2*f*

These experiments indicate that acetylenes can in many instances be efficiently converted to enamine sulfones **6** by the sequence of selenosulfonation, oxidation, and aminolysis. When terminal acetylenes are employed as precursors, selenenylated enamines **7** generally dominate unless steps are taken to trap the electrophilic by-product, benzeneselenenic acid, as it is formed.

Experimental

Melting points were obtained on an A. H. Thomas hot-stage apparatus and are uncorrected. The ir spectra were recorded on a Perkin–Elmer 467 spectrometer. The nmr spectra were obtained on a Hitachi Perkin–Elmer R24B or a Varian XL-200 spectrometer. All nmr spectra were run in $CDCl_3$ solution and are reported in ppm downfield from tetramethylsilane. Mass spectra were recorded on a Varian MAT CH5 or a Kratos MS 80 instrument. Preparative tlc was performed on Analtech 20 × 20 cm glass plates coated with silica gel GF (1000 μm) unless otherwise noted. Ether and THF solvents were dried over $LiAlH_4$; morpholine and pyrrolidine were distilled when discolouration was apparent and were stored over KOH or molecular sieves. All other reagents, unless otherwise noted, were purchased from commercial sources and used without further purification.

Preparation of selenides 2

Selenides **2***a*–**2***d* and **2***f* were prepared from the selenosulfonation of the corresponding acetylenes as described previously (6, 7). Selenide **2***c*, formerly reported as an oil (6), was crystallized from hexane, mp 38–40°C.

Selenide 2e

Dimethyl acetylenedicarboxylate (1.42 g, 10 mmol) and Se-phenyl *p*-tolueneselenosulfonate **1** (27) (1.56 g, 5 mmol) were refluxed 48 h in 15 mL of benzene. Several portions (ca. 5 mg each) of azobis(isobutyronitrile) were added during this time. The product was evaporated *in vacuo* and crystallized from chloroform–hexane to afford 1.59 g (70%) of **2***e*, mp 172–173.5°C; ir (Nujol): 1730, 1689, 1595, 1307, 1160 cm^{-1}; nmr: 7.8–7.0 (complex 9H), 3.60 (s, 3H), 3.08 (s, 3H), 2.28 (s, 3H); mass spectrum, *m/e* (relative intensity, %): 454 (M^+, ^{80}Se, 22), 452 (M^+, ^{78}Se, 12). *Anal.* calcd. for $C_{19}H_{18}O_6SSe$: C 50.33, H 4.00, S 7.06; found: C 50.26, H 3.98, S 6.95.

Preparation of selenoxides 3a–3f

Selenoxides **3***a*–**3***f* were prepared on a scale of 0.5–1.0 mmol *in situ* just prior to use by treating the corresponding selenides **2***a*–**2***f* with a small excess (10–20%) of *m*-chloroperbenzoic acid (MCPBA) in THF or ether; tlc analysis after ca. 10 min indicated complete consumption of the selenide. In some cases the by-product *m*-chlorobenzoic acid was removed prior to use by washing the solution with aqueous K_2CO_3.

Reactions of selenoxides 3 with amines (See Table 1)

Selenoxide 3a with morpholine (4) (entry 1 and 2)

(a) Selenoxide **3***a* (0.50 mmol) and morpholine (104 mg, 1.20 mmol) were stirred for 1 h in 10 mL of THF. The solution was diluted with ether, washed with aqueous NaCl, dried over anhydrous $MgSO_4$, and concentrated *in vacuo*. Preparative tlc in 5% methanol–benzene provided 37 mg (28%) of *E*-1-(*N*-morpholino)-2-(*p*-toluenesulfonyl)-

ethene (**6**, R = R′ = H), R_f 0.42; mp 131–132°C (from dichloromethane–hexane) (lit. (15) mp 136°C); ir (KBr): 1610, 1317, 1302, 1293, 1270, 1130 cm^{-1}; nmr: 7.60 (d, J = 8 Hz, 2H), 7.10 (two superimposed d, J = 8, 13 Hz, total 3H), 4.92 (d, J = 13 Hz, 1H), 3.57 (m, 4H), 3.04 (m, 4H), 2.28 (s, 3H); mass spectrum, *m/e* (relative intensity, %): 267 (M^+, 23). A more mobile band afforded 104 mg (50%) of 2-(*N*-morpholino)-1-(phenylseleno)-1-(*p*-toluenesulfonyl)ethene (**7**, R = H), R_f 0.58; mp 160–162°C (from dichloromethane–hexane); ir (KBr): 1590, 1279, 1140 cm^{-1}; nmr: 7.91 (s, 1H), 7.58 (d, J = 8 Hz, 2H), 7.1–6.8 (complex, 7H), 3.7–3.2 (complex, 8H), 2.18 (s, 3H); mass spectrum, *m/e* (relative intensity, %): 423 (M^+, ^{80}Se, 47), 421 (M^+, ^{78}Se, 24), 268 ($M^+ - SO_2Ar$, ^{80}Se, 100). *Anal.* calcd. for $C_{19}H_{21}NO_3SSe$: C 54.03, H 5.01, N 3.32, S 7.59; found: C 54.11, H 4.99, N 3.08, S 7.34.

(b) The above procedure was repeated, except that 2.6 equivalents of PhSeCl were added to the reaction mixture prior to work-up. The product **7** (R = H) was isolated as before in 86% yield.

(c) Selenoxide **3***a* (42 mg, 0.12 mmol) and 22 mg (0.25 mmol) of morpholine were allowed to react in 1 mL of $CDCl_3$ while the reaction was monitored by ^{1}H nmr spectroscopy. After 5 min at room temperature the ratio of the signal at δ 4.92 (vinylic H of **6**) to that at δ 7.91 (vinylic H of **7**) was 4:1. It gradually decreased to 0.36:1 after 18 h.

Selenoxide 3a *with pyrrolidine (5) (entry 3)*

The reaction was performed as in entry 1. Preparative tlc in 5% methanol–benzene afforded 79% of 1-(phenylseleno)-2-(*N*-pyrrolidino)-1-(*p*-toluenesulfonyl)ethene (**7**, R = H), R_f 0.66; mp 180–182°C (from dichloromethane–hexane); ir (KBr): 1601, 1281, 1140 cm^{-1}; nmr: 8.19 (s, 1H), 7.62 (d, J = 8 Hz, 2H), 7.2–6.8 (complex, 7H), 3.7–3.4 (m, 4H), 2.19 (s, 3H), 1.9–1.6 (m, 4H); mass spectrum, *m/e* (relative intensity, %): 407 (M^+, ^{80}Se, 31), 405 (M^+, ^{78}Se, 18), 252 ($M^+ - SO_2Ar$, ^{80}Se, 100). *Anal.* calcd. for $C_{19}H_{21}NO_2SSe$: C 56.15, H 5.21, N 3.45, S 7.89; found: C 56.36, H 5.21, N 3.11, S 7.71.

Selenoxide 3a *with enamine* **10** *(entry 4)*

(a) The reaction was performed as in entry 1. Preparative tlc in 2% methanol–benzene provided 83% of 2-(phenylseleno)cyclohexanone (**12**) (28), identified by its ir, nmr, and mass spectra, and 83% of the enamine sulfone **6**, identical to the product of entry 1.

(b) The above reaction was repeated in oven-dried apparatus under dry N_2 in the presence of 0.5 g of anhydrous $MgSO_4$. It was necessary to reflux the solution for 1 h in order to effect the complete consumption of selenoxide **3***a*. Work-up as in entry 1 afforded **12** (78%), **6** (70%), and a band of intermediate mobility which provided 16% of the γ-sulfonyl enone **13**, mp 95–98°C; ir ($CHCl_3$): 1690, 1618, 1595, 1325, 1150 cm^{-1}; nmr: 7.72 (d, J = 8 Hz, 2H), 7.34 (d, J = 8 Hz, 2H), 6.32 (tt, J = 8.2, 2.1 Hz, 1H), 3.90 (d, J = 8.2 Hz, 2H), 2.5–2.0 (s at δ 2.42 superimposed on m, total 7H), 2.0–1.5 (complex, 4H); mass spectrum, *m/e* (relative intensity, %): 278 (M^+, 2), 123 ($M^+ - ArSO_2$, 100). *Anal.* calcd. for $C_{15}H_{18}O_3S$: C 64.72, H 6.52; found: C 64.33, H 6.67.

Selenoxide 3b *with morpholine (4) (entry 5 and 6)*

(a) The reaction was performed as in entry 1. Preparative tlc in 40% ethyl acetate – hexane provided 75% of 1-(*N*-morpholino)-1-phenyl-2-(phenylseleno)-2-(*p*-toluenesulfonyl)ethene **7** (R = Ph) as a yellow gum, R_f 0.45; ir (Nujol): 1597, 1578, 1300, 1285, 1268, 1136, 1120 cm^{-1}; nmr: 7.9–6.9 (complex, 14H), 3.7–2.7 (complex, 8H), 2.36 (s, 3H); mass spectrum, *m/e* (relative intensity, %): 499 (M^+, ^{80}Se, 26), 497 (M^+, ^{78}Se, 14), 344 ($M^+ - SO_2Ar$, ^{80}Se, 100). *Exact Mass*, high resolution mass spectrum, calcd. for $C_{25}H_{25}NO_3SSe$: 499.0720; found: 499.0748.

(b) Selenoxide **3***b* (255 mg, 0.60 mmol) and morpholine (0.2 mL, 2.28 mmol) were stirred 26 h in 5 mL of THF and 3 mL of ethyl vinyl ether. Volatile material was then removed *in vacuo* and preparative tlc on alumina GF with 50% ethyl acetate – hexane afforded 1-(*N*-morpholino)-1-phenyl-2-(*p*-toluenesulfonyl)ethene **6** (R = Ph), R_f 0.50, mp 121–122.5°C (from dichloromethane–hexane); ir (Nujol): 1594, 1310, 1135 cm^{-1}; nmr: 7.2–6.6 (complex, 9H), 5.28 (s, 1H), 3.36 (crude t, 4H), 2.71 (crude t, 4H), 2.11 (s, 3H); mass spectrum, *m/e* (relative intensity, %): 343 (M^+, 10), 188 ($M^+ - SO_2Ar$, 100). *Anal.* calcd. for $C_{19}H_{21}NO_3S$: C 66.45, H 6.16, N 4.08, S 9.33; found: C 66.45, H 6.29, N 3.96, S 9.59.

Selenoxide 3b *with pyrrolidine (5) (entry 7)*

The reaction was performed as in entry 6. The reaction mixture was concentrated and crystallized from dichloromethane–hexane to afford 76% of 1-phenyl-1-(*N*-pyrrolidino)-2-(*p*-toluenesulfonyl)ethene **6** (R = Ph), mp 192–193°C (lit. (29) mp 192–194°C); ir (Nujol): 1598, 1288, 1138 cm^{-1}; nmr: 7.3–6.7 (complex, 9H), 5.06 (s, 1H), 2.85 (m, 4H), 2.20 (s, 3H), 1.70 (m, 4H); mass spectrum, *m/e* (relative intensity, %): 327 (M^+, 15), 172 ($M^+ - SO_2Ar$, 100).

Selenoxide 3c *with pyrrolidine (5) (entry 8)*

The selenoxide (0.50 mmol) and pyrrolidine (0.5 mL, 6.0 mmol) were stirred 5 h in 5 mL of ether. The solution was evaporated *in vacuo* and the nmr spectrum of the residue revealed the presence of the enamine sulfone **6** (R = n-C_8H_{17}, R′ = H) by the presence of a prominent signal at δ 4.80 (vinylic H). The product was dissolved in 5 mL of THF and 2 mL of 3 *N* HCl were added. After 1 h, the mixture was diluted with ether, washed with water, then with aqueous K_2CO_3, dried over anhydrous $MgSO_4$, and evaporated to dryness. Preparative tlc in 20% ethyl acetate – hexane afforded 83 mg (54%) of β-keto sulfone **14**, R_f 0.37, identical to an authentic sample (6) (mp, ir, nmr, mass spectrum). A more mobile band furnished 83 mg (36%) of the α-phenylseleno derivative **15** as a pale yellow oil, R_f 0.50; ir (film): 1702, 1599, 1580, 1307, 1155 cm^{-1}; nmr: 7.9–7.1 (complex, 9H), 4.78 (s, 1H), 2.75 (t, J = 7 Hz, 2H), 2.45 (s, 3H), 1.8–1.1 (complex, 12H), 0.88 (t, J = 5 Hz, 3H), (signals from an unidentified impurity were observed at δ 5.45 and 5.20); mass spectrum, *m/e* (relative intensity, %): 466 (M^+, ^{80}Se, 7), 464 (M^+, ^{78}Se, 6), 91 ($C_7H_7^+$, 100). *Exact Mass*, high resolution mass spectrum, calcd. for $C_{23}H_{30}O_3SSe$: 466.10805; found: 466.1082.

Selenoxide 3d *with pyrrolidine (5) (entry 9)*

The reaction and hydrolysis were performed as in entry 8. Preparative tlc with dichloromethane afforded 83% of β-keto sulfone **16** as a pale yellow oil, R_f 0.77; bp (bulb-to-bulb) 120°C at 0.05 Torr (1 Torr = 133.3 Pa); ir (film): 1720, 1600, 1306, 1150 cm^{-1}; nmr: 7.60 (d, J = 8 Hz, 2H), 7.25 (d, J = 8 Hz, 2H), 4.03 (t, J = 7 Hz, 1H), 2.62 (t, J = 6 Hz, 2H), 2.42 (s, 3H), 2.1–0.7 (complex, 16 H); mass spectrum, *m/e* (relative intensity, %): 310 (M^+, 0.2), 85 ($nBu\overset{+}{C}{=}O$, 100). *Anal.* calcd. for $C_{17}H_{26}O_3S$: C 65.77, H 8.44, S 10.31; found: C 65.39, H 8.41, S 10.40.

Selenoxide 3e *with pyrrolidine (5) (entry 10)*

The reaction was performed as in entry 1. Flash chromatography over 20 g of alumina (elution with dichloromethane) provided 72% of dimethyl 2-(*N*-pyrrolidino)-3-(*p*-toluenesulfonyl)fumarate **6** (R = R′ = CO_2Me), mp 148–149°C (from chloroform–hexane); ir (Nujol): 1738, 1680, 1600, 1316, 1147 cm^{-1}; nmr: 7.82 (d, J = 8 Hz, 2H), 7.25 (d, J = 8 Hz, 2H), 3.98 (s, 3H), 3.55 (s, 3H), 3.42 (m, 4H), 2.40 (s, 3H), 1.96 (m, 4H); mass spectrum, *m/e* (relative intensity, %): 367 (M^+, 2), 85 (71), 83 (100). *Anal.* calcd. for $C_{17}H_{21}NO_6S$: C 55.57, H 5.76, N 3.81, S 8.73; found: C 55.82, H 5.83, N 3.90, S 8.62.

Selenoxide 3f *with pyrrolidine (5) (entry 11)*

The reaction was performed as in entry 1. Preparative tlc in 5% methanol–benzene afforded 70% of alcohol **18**, R_f 0.53, identical to an authentic sample (7) (mp, ir, nmr). A more polar band furnished 8% of the starting selenoxide.

Reaction of selenoxide 3f *with* N,N-*dimethylhydrazine*

Selenoxide **3***f* (0.50 mmol) and *N*,*N*-dimethylhydrazine (0.5 mL, 6.6 mmol) were allowed to stand for 3 days in 5 mL of THF. The solution was then diluted with ether, washed once with aqueous NaCl and 3 times with aqueous K_2CO_3. It was dried over anhydrous $MgSO_4$, evaporated to dryness, and recrystallized from ether–hexane to afford 205 mg (96%) of selenide **2***f*, identical in all respects with the original starting material.

Multicomponent diffusion of aqueous sodium carbonate and aqueous sodium bicarbonate

DEREK G. LEAIST[1] AND ROBERT A. NOULTY
Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received September 18, 1984

DEREK G. LEAIST, and ROBERT A. NOULTY. Can. J. Chem. **63**, 2319 (1985).

Diffusion coefficients of Na_2CO_3 + H_2O and $NaHCO_3$ + H_2O have been measured by a conductimetric technique at 25°C. Above 0.1 mol L^{-1}, diffusion of aqueous Na_2CO_3 is typical of a simple binary electrolyte. At lower concentrations a significant proportion of the Na_2CO_3 component diffuses as $NaHCO_3$ and NaOH produced by hydrolysis: $Na_2CO_3 + H_2O \rightleftarrows NaHCO_3 + NaOH$. Because OH^- is more mobile than $HCO_3{}^-$, binary Na_2CO_3 + H_2O solutions undergoing diffusion separate spontaneously into two ternary solutions: Na_2CO_3 + NaOH + H_2O ahead of the diffusion boundary and Na_2CO_3 + $NaHCO_3$ + H_2O left behind the boundary. A procedure is developed for measuring multicomponent diffusion coefficients of hydrolyzing salts. Results for Na_2CO_3 are in satisfactory agreement with predicted ternary values. As a consequence of the disproportionation reaction: $2NaHCO_3 \rightleftarrows CO_2 + Na_2CO_3 + H_2O$, diffusion of aqueous $NaHCO_3$ is formally a ternary process. However, because reactants and products have similar mobilities and because only about 1% of the salt disporportionates, diffusion of aqueous $NaHCO_3$ is effectively binary.

DEREK G. LEAIST et ROBERT A. NOULTY. Can. J. Chem. **63**, 2319 (1985).

Utilisant une technique de conductimétrie à 25°C, on a mesuré les coefficients de diffusion du Na_2CO_3 + H_2O et du $NaHCO_3$ + H_2O. Au-dessus d'une concentration de 0,1 mol/L, la diffusion du Na_2CO_3 aqueux est typique d'un électrolyte binaire simple. À une concentration plus faible, une proportion notable de Na_2CO_3 diffuse sous la forme de $NaHCO_3$ et de NaOH produits par l'hydrolyse $Na_2CO_3 + H_2O \rightleftarrows NaHCO_3 + NaOH$. Puisque l'ion OH^- est plus labile que l'ion $HCO_3{}^-$, les solutions binaires de Na_2CO_3 + H_2O subissent une diffusion et se séparent spontanément en deux solutions ternaires, Na_2CO_3 + NaOH + H_2O en avant de la frontière de diffusion et Na_2CO_3 + $NaHCO_3$ + H_2O en arrière de cette frontière. On a mis au point une méthode de mesure des coefficients de diffusion dans des systèmes à plusieurs composants de sels subissant une hydrolyse. Les résultats obtenus avec le Na_2CO_3 s'accordent de façon satisfaisante avec les valeurs ternaires prévues. La réaction de dismutation $2NaHCO_3 \rightleftarrows CO_2 + Na_2CO_3 + H_2O$ implique que la diffusion du $NaHCO_3$ aqueux est formellement un processus ternaire. Cependant, en raison du fait que les réactifs et les produits ont des mobilités analogues et en raison du fait que seulement 1% du sel se dismute, la diffusion du $NaHCO_3$ aqueux est effectivement un processus binaire.

[Traduit par le journal]

1. Introduction

Aqueous solutions containing carbonate and bicarbonate salts are of biological, geological, and practical interest. Diffusion data for these electrolytes are thus essential in order to understand the transport properties of many important systems. Nevertheless, reliable diffusivities for carbonates or bicarbonates have not been published (1*a*, 2, 3).

This study was undertaken to determine accurate diffusion coefficients of Na_2CO_3 + H_2O and $NaHCO_3$ + H_2O. The sodium salts were chosen because of their general importance. Recently, activity coefficients for these systems were reported over wide ranges of composition (4, 5). With activity data, a more detailed interpretation of diffusion is possible.

Like many other important electrolytes, dilute carbonates are extensively hydrolyzed (5)

$$[\mathrm{I}]\quad CO_3^{2-} + H_2O \rightleftarrows HCO_3^- + OH^-$$
$$K_h(25°C) = 2.15 \times 10^{-4}\ \mathrm{mol\ L^{-1}}$$

Hydroxide is several times more mobile than bicarbonate. Therefore, when Na_2CO_3 diffuses in water, the total flow of NaOH should exceed the equimolar flows of $NaHCO_3$ and NaOH that are transported as the hydrolyzed portion of the Na_2CO_3 component. These considerations have led to speculation that isothermal diffusion in "binary" Na_2CO_3 + H_2O solutions is actually a multicomponent process described by a flow of partially hydrolyzed Na_2CO_3 together with a coupled flow of NaOH (6). Diffusion of Na_2CO_3 + H_2O would then be governed by ternary equations

$$[1]\quad -J_1 = D_{11}\nabla c_1 + D_{12}\nabla c_2$$

$$[2]\quad -J_2 = D_{21}\nabla c_1 + D_{22}\nabla c_2$$

rather than simpler binary expressions such as $-J = D\nabla c$ used previously (1*a*).

This paper presents an experimental procedure for measuring multicomponent diffusion coefficients of hydrolyzing salts. Results for aqueous sodium carbonate are used to establish by experiment whether or not diffusion of a hydrolyzing salt is a ternary process.

The effects of the disproportionation reaction (5)

$$[\mathrm{II}]\quad 2HCO_3^- \rightleftarrows CO_2 + CO_3^{2-} + H_2O$$
$$K(25°C) = 1.04 \times 10^{-4}$$

on diffusion of aqueous sodium bicarbonate are also discussed.

2. Experimental

Diffusion coefficients were measured at 25°C using a simplified version of Harned's conductimetric procedure (7). Initial concentrations were formed by injecting 0.1–0.4 mL of electrolyte solution into the bottom of a solution-filled channel (12.70 mm diameter, 45.63 ± 0.02 mm height). Diffusion was followed for 5–6 days by monitoring changes in electrical conductance at levels one-sixth of the distance from the top and bottom of the channel. Details of the equipment and procedure have been described (7–9).

The conductimetric technique was chosen so that measurements could be made at low concentrations where hydrolysis of Na_2CO_3 is extensive. Until very recently this technique was unreliable for studies of alkaline solutions because of errors caused by adsorption of OH^- (10) or leaching (11) of glass diffusion cells (7) during the long experiments. To avoid these problems, the cells used in this work were

[a]Calculated with $a = 4 \times 10^{-10}$ m for the mean distance of closest approach of the ions.

constructed from high density polyethylene and fitted with very small (1 mm diameter) platinum electrodes (8, 9).

Binary diffusion coefficients

Conductances were measured five or six times per day. By pairing each reading with the corresponding reading taken on the following day, 18–24 values of the binary diffusion coefficient were calculated for each experiment using the difference relation (7, 9, 12, 13)

$$[3] \quad D = -\frac{A^2}{\pi^2} \frac{\Delta \ln (rK_B - K_T)}{\Delta t}$$

in which A is the length of the diffusion channel, $r = k_B/k_T$ is the ratio of cell constants of the bottom (B) and top (T) electrode pairs, and K_B and K_T denote conductances measured at time t.

For each $NaHCO_3$ experiment and for each Na_2CO_3 experiment above 0.1 mol L^{-1}, the standard deviation of the D values calculated from eq. [3] was 0.1–0.2%. The absence of a discernible trend in D over 5-6 days indicated that the measured diffusion coefficients corresponded to binary differential values at the final cell composition (12, 13).

Ternary diffusion

On the other hand, values of D computed from eg. [3] for dilute Na_2CO_3 solutions drifted downward by several percent over the duration of each experiment. The trend was most pronounced at 0.005 mol L^{-1}, the lowest concentration studied. This behavior was consistent with anticipated ternary diffusion (6): the apparent rate of diffusion of dilute Na_2CO_3 was initially high as NaOH produced by hydrolysis diffused rapidly along the column, while diffusion of slower Na_2CO_3 dominated the later stages of the experiment. Accordingly, diffusion of dilute Na_2CO_3 solutions was also analyzed as ternary diffusion of $Na_2CO_3(c_1)$ + NaOH$(c_2 = 0)$ + H_2O mixtures.

In order to measure ternary diffusion of this system it was necessary to run experiments with the initial gradient in the NaOH component (7, 9) for average cell compositions Na_2CO_3 + H_2O free of added NaOH. This was accomplished by introducing Na_2CO_3 + NaOH solutions into the bottom of diffusion channels filled with Na_2CO_3 + $NaHCO_3$ solutions. The concentrations were adjusted to that the amount of added NaOH component introduced into the cell at the start of the experiment was identical to the amount of added $NaHCO_3$ component initially in the cell above the injected layer. As the two solutions interdiffused, the neutralization reaction $NaHCO_3$ + NaOH $\rightleftarrows$ $2Na_2CO_3$ ensured that the final solution in the cell had binary composition Na_2CO_3 + H_2O. At 0.0500 mol L^{-1} Na_2CO_3, for example, 0.250 mL of solution containing 0.0100 mol L^{-1} Na_2CO_3 and 0.924 mol L^{-1} NaOH was injected into a cell filled with 5.53 mL of solution containing 0.0100 mol L^{-1} Na_2CO_3 and 0.0418 mol L^{-1} $NaHCO_3$; after diffusion, the final composition of solution in the cell was 0.050 mol L^{-1} Na_2CO_3.

At the same final cell composition, experiments were also run with the initial gradient in the Na_2CO_3 component. The conductance decay curves for the Na_2CO_3-gradient and the NaOH-gradient experiments were analyzed for ternary diffusion by an eigenvalue procedure. Details of this procedure have been reported (9). Each ternary experiment was run in triplicate.

Reagents

Na_2CO_3 and $NaHCO_3$ were A.C.S. reagent grade. Solutions of the salts were freshly prepared by weight prior to each run. Solutions of sodium hydroxide were prepared by dilution of highly pure saturated solutions. Winkler analyses indicated that the purified product contained negligible carbonate (<0.05% Na_2CO_3 based on total alkali). Hydroxide solutions were stored in polyethylene containers that were protected from atmospheric carbon dioxide. Concentrations of NaOH were determined by titration of potassium hydrogen phthalate.

3. Results and discussion

Aqueous sodium bicarbonate

The mean diffusion coefficients determined for this system are given in Table 1. Although the precision of D values from each run was 0.1 to 0.2% uncertainties in both the cell constant ratio and the length of the diffusion channel limited the reproducibility from run to run to ±0.5%.

At low ionic strengths the concentration-dependence of the diffusion coefficient of a strong 1:1 electrolyte is described by the Onsager–Fuoss equation (14, 15)

$$[4] \quad D(c) = (D^0 + \Delta_1 + \Delta_2)(1 + c \, d \ln y_{\pm}/dc)$$

where $y_{\pm}$ is the mean ionic activity coefficient on the molar concentration scale and D^0 is the limiting diffusion coefficient calculated from limiting ionic conductances and Nernst's expression

$$[5] \quad D^0 = \frac{RT}{F^2} \frac{\nu_+ + \nu_-}{\nu_+ z_+} \frac{\lambda_+^0 \lambda_-^0}{\lambda_+^0 + \lambda_-^0}$$

Allowance is made for the effects of ion–ion interactions using first and second order electrophoretic corrections calculated from (15)

$$[6] \quad \Delta_1 = -\frac{kT}{6\pi\eta} \frac{(z_+ t_-^0 + z_- t_+^0)^2}{|z_+ z_-|} \frac{\kappa}{1 + \kappa a}$$

$$[7] \quad \Delta_2 = -\frac{e^2}{12\pi\eta\epsilon} \frac{(z_+^2 t_-^0 + z_-^2 t_+^0)^2}{|z_+ z_-|} \left(\frac{\kappa e^{\kappa a}}{1 + \kappa a}\right)^2 \times \left[0.5772 + \ln (2\kappa a) + \sum_{n=1}^{\infty} \frac{(-2\kappa a)^n}{n(n!)}\right]$$

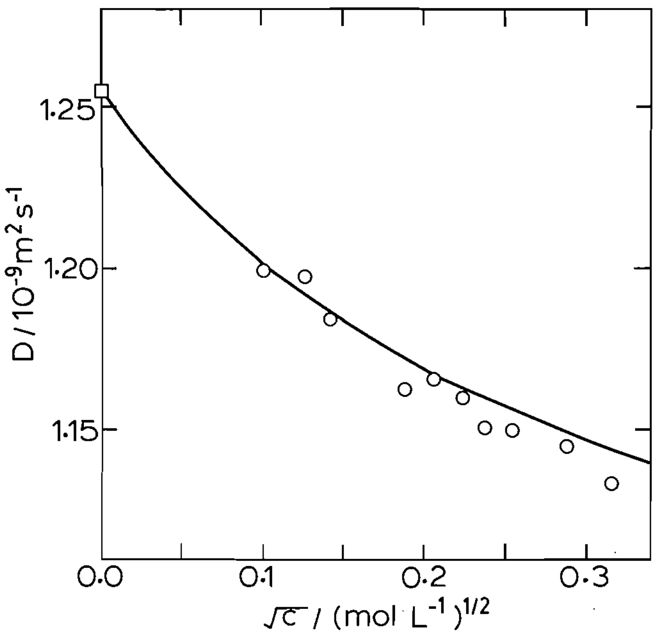

FIG. 1. Comparison of observed and predicted diffusion coefficients of aqueous $NaHCO_3$ solutions at 25°C.

in which

$$[8] \quad \kappa^2 = \frac{4\pi Ne^2}{1000\epsilon kT}(\nu_+ z_+^2 + \nu_- z_-^2)c$$

The remaining symbols appearing in eqs. [4]–[6] follow accepted electrochemical usage (15).

From the limiting ionic conductances (16*a*, 17–19) $\lambda_+^0(Na^+) = 0.005010$ and $\lambda_-^0(HCO_3^-) = 0.00445$ m² S equiv.$^{-1}$ we obtain $D^0 = 1.255 \times 10^{-9}$ m² s^{-1} for the limiting diffusion coefficient of aqueous sodium bicarbonate at 25°C and infinite dilution. The thermodynamic term $c\,d\ln y_\pm/dc$ was evaluated using activity coefficients derived by Pitzer and Peiper (4) from electrochemical-cell data. The reported molal activity coefficients ($\gamma_\pm$) were converted to molar activity coefficients required here using published densities (1*b*) and the relation (16*b*)

$$[9] \quad y_\pm = (md_0/c)\gamma_\pm$$

where m is the molality and d_0 is the density of pure water. Calculated values of the thermodynamic term are listed in Table 1.

In Table 1 observed diffusion coefficients for $NaHCO_3$ are compared with values predicted by eq. [4]. As shown in Fig. 1, agreement is especially good below 0.02 mol L^{-1}. In this region predictions made by the Onsager–Fuoss equation for 1:1 salts are generally reliable. At higher concentrations the observed diffusion coefficients are about 0.5% lower than the predicted curve. However, the discrepancy is small.

Vinograd and McBain (2) have used a porous diaphragm cell technique to measure diffusion of aqueous $NaHCO_3$. For 0.1 mol L^{-1} $NaHCO_3$ diffusing into pure water at 25°C, they report the integral diffusion coefficient 1.22×10^{-9} m² s^{-1}. The present conductimetric results over this range are consistent with an integral coefficient of about $1.16\ 10^{-9}$ m² s^{-1}, a value 5% lower. However, the diaphragm cell measurements were made before reliable procedures for calibration or stirring had been developed (20, 21). Also, diaphragm cell measurements on dilute solutions generally lead to high values of D (3). The conductimetric results are probably more reliable.

[a]Apparent values.

In addition to Na^+ and HCO_3^-, aqueous solutions of sodium bicarbonate contain small amounts of CO_3^{2-} and CO_2 produced by disproportionation (reaction [II]). The conditions of electroneutrality and local chemical equilibrium place two restrictions on fluxes of the four solute species. Nevertheless, two solute fluxes are independent. Therefore, strictly speaking, isothermal diffusion in aqueous solutions of sodium bicarbonate is a ternary process. In practice though, only about 1% ($\sim K^{1/2}$) of the salt disproportionates (5). Furthermore, reactants and products have similar diffusivities (16*a*, 17–19, 22, 23): $D(Na^+) = 1.33 \times 10^{-9}$, $D(HCO_3^-) = 1.18 \times 10^{-9}$, $D(CO_3^{2-}) = 0.92 \times 10^{-9}$, and $D(CO_2) = \sim 1.9 \times 10^{-9}$ m² s^{-1}. For these two reasons disproportionation is not expected to have significant effects on diffusion of sodium bicarbonate. The excellent agreement between observed diffusion coefficients and predicted binary values supports the idea that diffusion in aqueous sodium bicarbonate solutions is effectively a binary process.

Aqueous sodium carbonate

Diffusion coefficients were measured for Na_2CO_3 solutions over the range 0.005–0.5 mol L^{-1}. The results are listed in Table 2. Values for the degree of hydrolysis of the salt (5)

$$[10] \quad \beta = \frac{[OH^-]}{[CO_3^{2-}] + [OH^-]}$$

are also tabulated. D drops steadily with concentration. This behavior has been observed for aqueous Na_2SO_4 and other strong electrolytes of the 2:1 or 1:2 category (3).

In order to determine the effects of hydrolysis on the diffusional properties of the salt, it is informative to compare the measured diffusion coefficients with values predicted under the assumption of hydrolysis-free conditions. In the absence of hydrolysis or ion association, the diffusion coefficient of a dilute, unsymmetrical electrolyte is given by the expression (15)

$$[11] \quad D = (D^0 + \Delta_1)(1 + c\,d\ln y_\pm/dc)$$

(Following Stokes (15), the second order electrophoretic term, Δ_2, has been omitted for reasons of self-consistency.) Upon substitution into eq. [5] of $\lambda_-^0(CO_3^{2-}) = 0.00693$ m² s^{-1} equiv.$^{-1}$ (16*a*, 23) and the value of $\lambda_+^0(Na^+)$ quoted previously, we obtain $D^0 = 1.162 \times 10^{-9}$ m² s^{-1} for the limiting diffusion coefficient of a hypothetical solution of unhydrolyzed Na_2CO_3 at 25°C.

Goldberg (24) has derived activity coefficients of aqueous

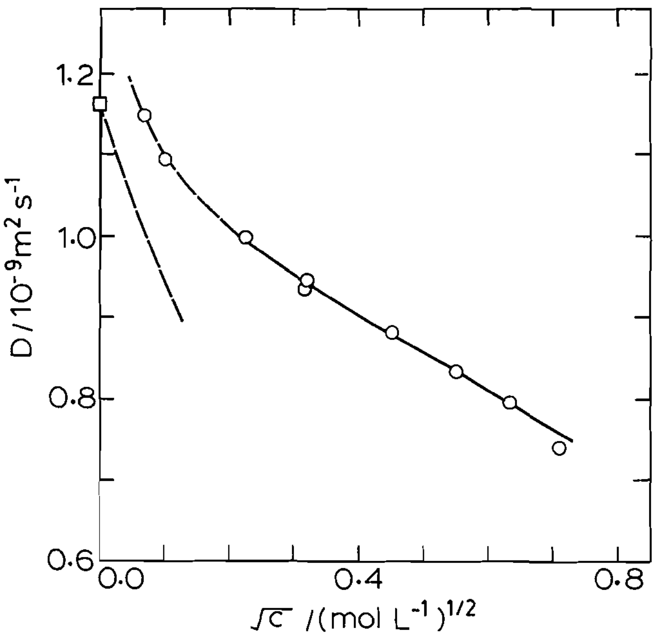

FIG. 2. Diffusion coefficients of aqueous Na_2CO_3 solutions at 25°C. Upper curve: observed values. Lower curve: predicted by eq. [11] for hydrolysis-free salt.

Na_2CO_3 from isopiestic measurements. Since hydrolysis was omitted from the analysis, diffusion coefficients of hydrolysis-free Na_2CO_3 can be estimated by evaluating the thermodynamic term in eq. [11] using Goldberg's activity data. The results of the calculations are given by the lower curve in Fig. 2.

It is evident from Fig. 2 that measured values of D are larger than anticipated for the unhydrolyzed salt. Although data above 0.1 mol L^{-1} appear to extrapolate to a limiting value close to 1.16×10^{-9} m^2 s^{-1}, results obtained below this limit curve sharply upward. In this region hydrolysis produces a significant proportion of highly mobile hydroxide ion ($D = 5.28 \times 10^{-9}$ m^2 s^{-1}).

Precise binary diffusion coefficients could not be determined at concentrations below 0.1 mol L^{-1}. For those solutions, D computed from eq. [3] was not a well-defined diffusion coefficient, but rather a time-dependent apparent binary diffusion coefficient of the mixed electrolyte Na_2CO_3 + $NaHCO_3$ + NaOH. Although the apparent molar conductance of dilute Na_2CO_3 can be interpreted by the relation (10)

$$[12] \quad \Lambda_a = (1 - \beta)\Lambda(Na_2CO_3) + \beta\Lambda(NaHCO_3) + \beta\Lambda(NaOH)$$

no simple additive rule exists to interpret the apparent diffusion coefficient of the partially hydrolyzed salt (6).

Diffusion of aqueous Na_2CO_3 produces fluxes of four solute species: Na^+, CO_3^{2-}, HCO_3^-, and OH^-. After electroneutrality and local chemical equilibrium of the hydrolysis reaction are taken into account, two solute flows must be specified to give a precise description of isothermal diffusion in aqueous solutions of the salt. We will analyze the diffusional properties of the system in terms of the molar flux J_1 of the partially hydrolyzed Na_2CO_3 component and molar flux J_2 of the NaOH component (6). (Note that J_2 is the flux of NaOH in excess of NaOH transported with $NaHCO_3$ as the hydrolyzed fraction of the Na_2CO_3 component, not the total NaOH flux.) The ternary

[a]Units: c_i in mol L^{-1}, D_{ik} in 10^{-9} m^2 s^{-1}.

diffusion coefficients of the components are defined by eqs. [1] and [2]. Cross-coefficient D_{21} measures the flux of the NaOH component produced per unit gradient in concentration of the Na_2CO_3 component.

Ternary diffusion coefficients were measured at three compositions: 0.005, 0.01, and 0.05 mol L^{-1} Na_2CO_3. The results of the experiments are summarized in Table 3. Although D_{21} is zero within experimental error at 0.05 mol L^{-1} Na_2CO_3, the highest concentration studied, positive values of D_{21} observed at lower concentrations confirm that diffusion of dilute Na_2CO_3 generates concurrent transport of NaOH.

At 0.005 mol L^{-1} Na_2CO_3 the magnitude of D_{21} is about one-fifth that of D_{11}, the main diffusion coefficient of the Na_2CO_3 component. This means that the initial gradient in Na_2CO_3 produces a simultaneous flow of NaOH that is one-fifth as large as the flow of Na_2CO_3 even though the solution is free of added NaOH. Because the conductance of NaOH is large, the experimental procedure used in the present study is well-suited to the task of measuring the coupled flow of NaOH. The measurements demonstrate conclusively the ternary nature of diffusion in dilute Na_2CO_3 solutions.

The observed values of D_{22}, the main diffusion coefficient of the NaOH in aqueous Na_2CO_3, range from $3.0-3.7 \times 10^{-9}$ m^2 s^{-1}. At equivalent ionic strengths the binary diffusion coefficient of NaOH + H_2O solutions is significantly lower: $1.9-2.0 \times 10^{-9}$ m^2 s^{-1} (25, 26). In binary solutions, however, OH^- is constrained by electroneutrality to diffuse at the same rate as less-mobile Na^+. This restriction does not apply to diffusion of NaOH in aqueous Na_2CO_3 since OH^- is able to diffuse more rapidly than Na^+ while still maintaining electroneutrality by generating coupled flows of CO_3^{2-} and HCO_3^- in the opposite direction. In this instance the electric field set up by diffusion of NaOH which slows down highly mobile OH^- also drives countertransport of CO_3^{2-} and HCO_3^-. Cross-coefficient D_{12} which determines the coupled flow of the Na_2CO_3 component produced per unit gradient in NaOH is thus large and negative.

A procedure has been developed for predicting multicomponent diffusion coefficients of hydrolyzing salts (6). First, knowledge of the concentrations and diffusion coefficients of the various solute species is used to estimate Onsager transport coefficients defined by the flow equations

$$[13] \quad -J_i = \sum_k L_{ik} \nabla \mu_k$$

Diffusion coefficients of the components are then estimated from the relation

$$[14] \quad D_{ik} = \sum_m L_{im}\partial\mu_m/\partial c_k$$

Table 4 lists calculated values of L_{ik} and $\partial\mu_m/\partial c_k$. The latter were derived from activity coefficients reported by Peiper and Pitzer (5). (Hydrolysis was included in their analysis.)

Observed and predicted ternary diffusion coefficients of dilute Na_2CO_3 solutions are compared in Table 3. Since it is difficult to make accurate predictions of transport coefficients for unsymmetric mixtures (15, 27) (especially for systems such as the one under discussion in which the ions have widely different mobilities (28)), agreement can be considered satisfactory. The agreement lends support to the correctness of the measured ternary diffusion coefficients.

Bearing in mind that diffusion is usually regarded as a mixing process, it is noteworthy that diffusion causes binary $Na_2CO_3 + H_2O$ solutions to spontaneously separate into two ternary solutions: $Na_2CO_3 + NaOH + H_2O$ ahead of the diffusion boundary and $Na_2CO_3 + NaHCO_3 + H_2O$ remaining behind the boundary. Although ternary diffusion of Na_2CO_3 is important only for relatively dilute solutions, strongly hydrolyzing electrolytes such as phosphates and salts of transition metals should display ternary behavior at much higher concentrations.

Studies of infrared multiphoton dissociation rates of protonated aliphatic alcohol dimers

ALEXANDER BALDWIN YOUNG,[1] RAYMOND EVANS MARCH,[2] AND RICHARD JAMES HUGHES
Department of Chemistry, Trent University, Peterborough, Ont., Canada K9J 7B8

Received October 24, 1984

ALEXANDER BALDWIN YOUNG, RAYMOND EVANS MARCH, and RICHARD JAMES HUGHES. Can. J. Chem. **63**, 2324 (1985).

The rates of photodissociation induced by absorption of infrared radiation of protonated dimers of 2-propanol and its deuterated analogues are reported. Protonated alcohol dimer ions created in a quadrupole ion store (QUISTOR) were irradiated in isolation and as a function of parent gas pressure and added collision gas (N_2). The relative weights and nature of ionic photoproducts were determined by mass spectrometry. The effect upon photolysis of collisions both prior to and during irradiation were examined. Photodissociation rates were defined by σ_D, which is the measured photodissociation rate constant normalized to the laser intensity. Nascent dimer ions which can possess up to 130 kJ mol^{-1} internal energy dissociated readily with σ_D of 15.8×10^{-21} cm^2 extrapolated to collision-free conditions. Photodissociation products from nascent dimer ions were produced via two major reaction channels. As the number of collisions suffered by the nascent dimer ion prior to irradiation was increased, the value of σ_D diminished and a single reaction channel became more prevalent. After some 270 collisions the ions appear to be collisionally relaxed prior to photolysis. The value of σ_D of 13.1×10^{-21} cm^2 extrapolated to collision-free conditions was obtained. The products from photodissociation of relaxed ions were obtained from a single reaction channel. An increase in σ_D values obtained with added nitrogen collision gas indicated a blockage or "bottleneck" in multiphoton absorption which is attributed to rotational population depletion. Three deuterated analogues of 2-propanol showed similar behaviour to that of 2-propanol with the exception that deuteron-bound dimers formed from 2-propanol (OD) and perdeutero-2-propanol failed to show rotational population depletion. The apparent lack of a "bottleneck" in multiphoton absorption by deuteron bound dimers is attributed to the diminished spacings between rotational levels of these species compared with the rotational level spacings for proton-bound dimers. Proton-bound ethanol dimers were selected for the examination of temperature effects upon photodissociation rates. While values for σ_D, extrapolated to collision-free conditions, of 15.6×10^{-21} cm^2 at 321 K (in agreement with the 2-propanol results obtained solely at this temperature) and 8.55×10^{-21} cm^2 at 293 K were obtained, the precise interpretation of such a marked temperature effect is not immediately obvious.

ALEXANDER BALDWIN YOUNG, RAYMOND EVANS MARCH et RICHARD JAMES HUGHES. Can. J. Chem. **63**, 2324 (1985).

On a mesuré les vitesses de photodissociations, induites par adsorption de radiation infrarouge, de dimères protonés du propanol-2 et de ses analogues deutérés. Opérant d'une manière isolée ainsi qu'en fonction de la pression du gaz parent et du gaz additionné (N_2), on a irradié des ions dimères d'alcool protoné créés dans un piège d'ions quadrupolaires. Faisant appel à la spectroscopie de masse, on a déterminé les masses relatives ainsi que la nature des photoproduits ioniques. On a évalué l'effet sur la photolyse de collisions qui précèdent l'irradiation ou qui lui sont concurrentes. On a défini les vitesses de photodissociations par σ_D qui est la constante de vitesse de photodissociation mesurée normalisée pour l'intensité du laser. Les ions dimères naissants, qui peuvent posséder jusqu'à 130 kJ mol^{-1} d'énergie interne, se dissocient facilement avec un σ_D de $15{,}8 \times 10^{-21}$ cm^2 si l'on extrapole aux conditions ou il n'y a pas de collisions. Les produits de photodissociations des ions dimères naissants proviennent de deux voies réactionnelles principales. Lorsqu'on augmente le nombre des collisions auxquelles sont soumis les ions dimères naissants avant l'irradiation, la valeur de σ_D diminue et une voie réactionnelle devient alors plus prévalente. Après environ 270 collisions, les ions semblent avoir atteint un état de relaxation complète avant la photolyse. On a obtenu une valeur de σ_D de $13{,}1 \times 10^{-21}$ cm^2 par extrapolation à des conditions où il n'y a pas de collisions. Les produits de photodissociations des ions dans un état de relaxation complète ont été obtenus pour une seule voie réactionnelle. Par addition azote, il se produit une augmentation des valeurs de σ_D provenant de collisions avec le gaz et indiquant un bloquage ou un "étranglement" dans l'absorption multiphoton qui est attribué à une diminution de la population rotationnelle. Trois analogues deutérés du propanol-2 présentent des comportements similaires à celui du propanol-2, à l'exception du fait que les dimères liés par un deutérium et formés à partir du propanol-2 (OD) et du perdeutéropropanol-2 ne présentent pas de diminution de la population rotationnelle. On attribue ce manque apparent d'"étranglement" dans l'absorption multiphoton par des dimères liés par des deutérium à des diminutions dans les écarts entre les niveaux rotationnels de ces espèces comparées avec les écarts entre les niveaux rotationnels dans les dimères liés par des protons. On a choisi les dimères d'éthanol liés par des protons pour examiner l'effet de la température sur les vitesses de photodissociations. Les valeurs de σ_D, extrapolées à des conditions où il n'y a pas de collisions, sont de $15{,}6 \times 10^{-21}$ cm^2 à 321 K (en accord avec les valeurs obtenues avec le propanol-2 à cette température) et de $8{,}55 \times 10^{-21}$ cm^2 à 293 K; l'interprétation précise d'un tel effet marqué de la température n'est pas immédiatement évident.

[Traduit par le journal]

Introduction

Single species photochemistry of a molecule or ion cannot be ascertained unambiguously unless the mean time between collisions is greater than that required for excitation and unimolecular decomposition. Likewise, single species chemistry induced by multiphoton absorption can only be ascertained unambiguously when the overall rate of photoexcitation and unimolecular dissociation exceeds that of a known collision rate. A novel dimension is added when the ion of interest is generated *in situ* through exoergic ion/molecule reactions, wherein the nascent ion can contain some 130 kJ mol^{-1} of internal energy as prevails for the protonated dimers of aliphatic alcohols (1). Previous studies employing slow Infrared Multiphoton Dissociation (IRMPD) as a probe of activation energy hierarchies in the gas phase photolysis of proton-bound

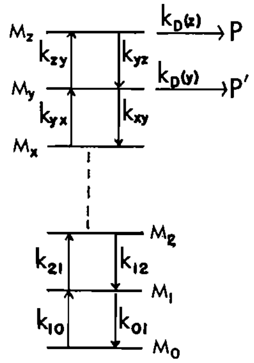

FIG. 1. Master equation approach to IRMPD.

dimers have been carried out with each of 2-propanol (2–5), ethanol (6), and I-butanol (7). It has been shown that the relative weights of reaction pathways followed by an ion excited through the absorption of several photons change with the number of collisions suffered by the nascent ion prior to irradiation. We have set out to explore the effects of collisional deactivation prior to and during irradiation through variation of parent molecule pressure, added collision gas pressure and relaxation time.

A simple physical model (8) for Infrared Multiphoton Dissociation (IRMPD) is depicted in Fig. 1, wherein the rates of population of excited levels of the specie, M, compete with the rates of depopulation. For levels with internal energy in excess of the unimolecular dissociation threshold ($E_{int} \geqslant yh\nu$) depopulation can also occur via product formation with rate constant $k_d(y)$. The difficulty in applying this treatment to experimental data from IRMPD lies in the lack of knowledge of the individual rate constants required to solve the master equation. In IRMPD the dissociation yield is measured as a function of fluence at a specified pressure and wavelength (pulsed CO_2 laser) or as a function of irradiation time at a specified pressure, wavelength and intensity (CW CO_2 laser).

It has been demonstrated (9, 10) that absorption involving only incoherent, single photon transitions between vibrational levels leads to an overall rate of dissociation which can be adequately described by a unimolecular rate law. Large polyatomic species exhibit such absorption processes due to the proximity of the quasi-continuum region of vibrational states to the ground vibrational state at ambient temperature. In these species the rate of photon absorption is much slower than the rate of intramolecular v → v transfer and the internal energy distribution can be described as ergodic, or characterized by a mean vibrational temperature (8, 9). At internal energy levels above the threshold for dissociation, the relative magnitudes of the overall rate of excitation and the rate of unimolecular dissociation affect the extent of further photon absorption of a species prior to dissociation. Quack (11) examined the case where the rate of excitation ≪ rate of dissociation and developed the equation:

$$[1] \quad k_{uni}^{ss} = \frac{-\mathrm{d}\ln(1 - F_D)}{\mathrm{d}(It)}$$

where k_{uni}^{ss} is the steady state, unimolecular dissociation rate constant; F_D is the fraction of molecules or ions decomposed by the laser; I is the measured laser intensity, and t is the duration of irradiation. Equation [1] predicts that a plot of $-\ln(1 - F_D)$ vs. fluence ($I \times t$) should produce a straight line of slope k_{uni}^{ss}; deviations from linearity are regarded by Quack as evidence that a steady state condition does not exist. In the experiments to be described, the CW CO_2 laser intensity is constant; the extent of IRMPD of the protonated alcohol dimer is measured as a function of irradiation time. In these experiments, a plot of $-\ln(1 - F_D)$ vs. time produces a straight line of slope k_{uni}^{ss}. The rate constant may also be expressed (8, 9, 12, 13) as:

$$[2] \quad k_{uni}^{ss} = \sigma_D \Phi$$

where Φ is the photon flux and σ_D is a phenomenologically defined photon absorption cross-section. The photon flux is calculated:

$$[3] \quad \Phi = \frac{I\lambda}{hc}$$

where λ is the wavelength of the laser, h is Planck's constant, and c is the speed of light. The σ_D values are thus proportional to the unimolecular rate constant, k_{uni}^{ss}, normalized to the laser intensities employed.

Experimental

Although the apparatus has been described in detail previously (2–4) some modifications have been made.

In the experiments described, a square wave generator (Heathkit) was employed to drive a mechanical chopper (PAR 222), typically with a 1:1 wheel and phase-locked to the input signal. The output signal from the chopper triggers the creation pulse (Hewlett-Packard 214A; typically +60 V/100 μs) which was applied to a gate biased at −100 V to bar filament electrons (−70 V) from the trap. The creation pulse was used to trigger a linear gate/scan delay generator combination (Ortec Brookdeal 9415 and 9425A), and the output pulse from the scan delay generator triggered an extraction pulse (Hewlett-Packard 214B; typically −40 V/5 μs) concomitantly with the detection pulse. The scan delay generator was operated via an ISAAC/APPLE IIe interface and the signal intensity of the ion of interest signal averaged and displayed on an XY recorder.

In the experiments described the signal intensity of the protonated alcohol dimer was monitored with concomitant resonance ejection (14, 15) (QRE) of the protonated parent alcohol. Four sweeps were averaged from 50 to 100 ms with and without the laser (944 cm^{-1}). Laser power was measured both before and after the experiment (Optical Engineering, Laser Power Probe). Pressures were measured via a capacitance manometer (MKS Baratron).

In those experiments which examined the extent of laser-wrought dissociation of the protonated dimer in the presence of added buffer gas (N_2), a heated inlet system connected to a 6 L glass bulb with a septum attachment was employed. Buffer gas quantities were measured by an aneroid pressure gauge (Matheson); alcohol volumes were measured via syringe and the corresponding pressure increment recorded. The bulb temperature was maintained at a temperature identical to that of the heated sidearm inlet system (50°C) used for pure alcohol introduction. In these ethanol experiments labelled "cold", the sidearm and tank were maintained at ambient temperature (~20°C). All other experiments were performed with a heated tank (48°C).

The laser power within the QUISTOR was measured via a calibrated homemade thermocouple. Reported photodissociation cross-sections were corrected for laser intensity losses due to the NaCl entrance window and the 3.0 mm aperture in the ring electrode of the QUISTOR.

Results and discussion

Protonated alcohols are formed in the gas phase via proton transfers between primary ionic fragments and the neutral alcohol. In the 2-propanol system, α-cleavage of the molecular ion produces protonated ethanal:

$$[4] \quad (CH_3)_2CHOH^{+\cdot} \rightarrow CH_3CHOH^+ + \cdot CH_3$$

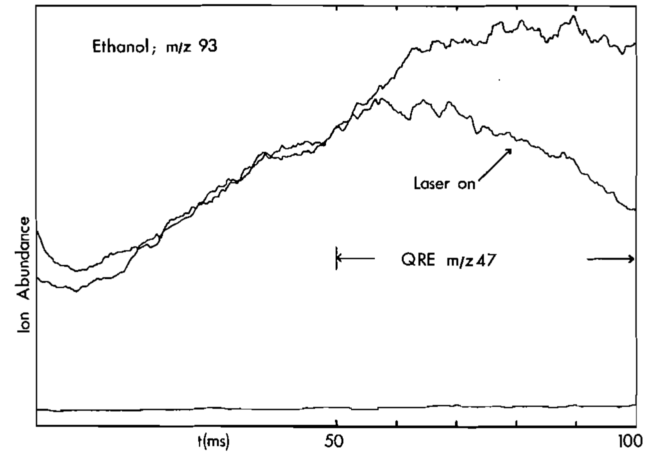

FIG. 2. Single ion monitoring trace of the protonated dimer of ethanol (m/z 93) with concomitant resonance ejection of the precursor protonated alcohol (m/z 47). Two experiments are depicted: laser on refers to 50 ms of laser irradiation at 944 cm^{-1}; in the other trace the laser is blocked.

which transfers a proton to the neutral alcohol (16):

[5] $CH_3CHOH^+ + (CH_3)_2CHOH \rightarrow CH_3CHO + (CH_3)_2CHOH_2^+$ (m/z 61)

The protonated parent alcohol reacts with another neutral alcohol, forming an excited proton-bound dimer, which may then be collisionally or radiatively relaxed:

[6] $[(CH_3)_2CHOH]_2H^{+*} \xrightarrow[{[M]}]{-h\nu} [(CH_3)_2CHOH]_2H^+$

Three reaction channels are available to the relaxed dimer:

[7] $[(CH_3)_2CHOH]_2H^+ \rightarrow (CH_3)_2CHOH_2^+ + (CH_3)_2CHOH$
m/z 61

[8] $[(CH_3)_2CHOH]_2H^+ \rightarrow (CH_3)_2CHOH_2^+ \cdot H_2O + C_3H_6$
m/z 79

[9] $[(CH_3)_2CHOH]_2H^+ \rightarrow [(CH_3)_2CH]_2OH^+ + H_2O$
m/z 103

No activation energy in excess of reaction endothermicity is expected for reaction [7]; the reported ΔH of -130 kJ mol^{-1} (1) corresponds to the absorption of 12 photons of wavelength 10.6 μm. The enthalpies of reactions [8] and [9] may be calculated from thermodynamic data (17), and are 92 kJ mol^{-1} and 79 kJ mol^{-1}, respectively. The corresponding activation energies are unknown.

The analogous reactions leading to dimer formation in deuterated 2-propanols resulted in a proton-bound dimer for 2-d_1-2-propanol and deuteron-bound dimers for 2-propanol (OD) and perdeutero-2-propanol. The proton-bound dimer derived from ethanol exhibited solely the reactions analogous to [7] and [9] upon photolysis.

Ethanol

A typical experiment is shown in Fig. 2; the resulting plot of $-\ln(1 - F_D)$ vs. time is depicted in Fig. 3. Least-squares linear regression analysis is used to calculate the slope of the best fit straight line through the data (k_{uni}^{ss}). The calibrated laser (944 cm^{-1}) intensity within the QUISTOR (beam diameter of 3 mm) is employed to calculate the phenomenologically defined photodissociation cross section, σ_D. In Table 1, values of σ_D versus pressure and collision rate are listed for a series of hot (48°C) and cold (20°C) tank experiments.

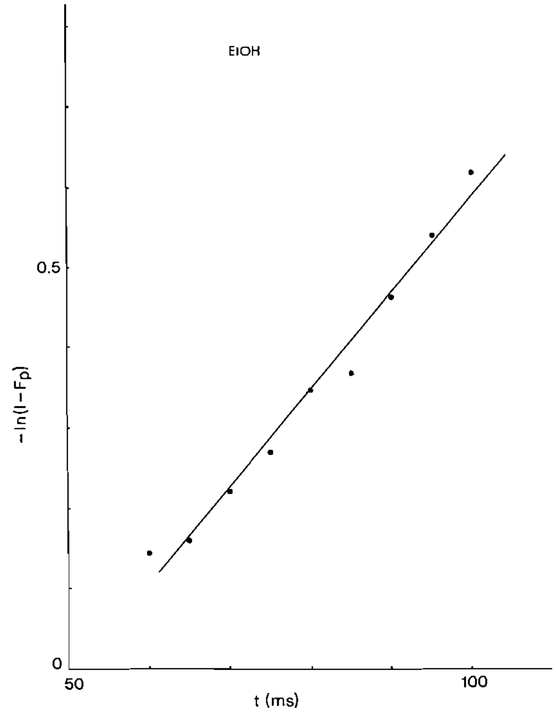

FIG. 3. Plot of $-\ln(1 - F_D)$ vs. time of the experimental data of Fig. 2.

	1.3×10^{-3}	0.66	3.3	6.8	0.967
	2.7×10^{-3}	1.32	6.6	6.0	0.933

The collision rate and number of collisions prior to photolysis are calculated using Dehmelt velocities and a cross-section of 1 nm^2. The actual velocities of the trapped ions in the QUISTOR are not known precisely, however a Dehmelt potential well calculation (18) indicates that initial, collision-free ion velocities are approximately five times those derived thermally. A more recent study (8) showed that approximately 80 collisions were required to remove $\leq$ 100 kJ mol^{-1} of excess internal energy by resonant v ← v transfer which suggests that the thermal collision rate and number of collisions should be increased by at least a factor of 2 in light of the relaxation studies on the protonated dimer of 2-propanol (*vide infra*).

In Fig. 4, it can be seen that σ_D for the ethanol protonated dimer decreases with increasing collision rate. Furthermore, at low collision rates, the rate of σ_D increase is greater than for the cold experiments.

The results are difficult to rationalize as calculations of the thermal energy contribution to the internal energy of the

proton-bound dimer show ~9 kJ mol^{-1} average vibrational energy is contributed at 293 K and ~12 kJ mol^{-1} at 321 K. The latter amount is the equivalent of the absorption of one photon at 944 cm^{-1}; however, this is insufficient to place the dimer in the quasi-continuum prior to photolysis. Calculations performed using the well-known Whitten–Rabinovitch approximation (19, 20) and the frequencies for ethanol (21) with frequencies for the proton bridge derived from the study of Bowers and co-workers (22) predict that the density of vibrational states corresponding to the absorption of 1 photon is 5.0×10^{-1} states/cm^{-1}. Using the assumption of Beauchamp and co-workers (13) that the quasi-continuum is not attained until the density of vibrational states $\gtrsim 10^3$ states/cm^{-1} due to the narrow line width of the CW CO_2 laser, this condition is fulfilled for the proton bound dimer of ethanol only after the absorption of four 944 cm^{-1} photons whereupon the density of vibrational states is 2.1×10^3 states/cm^{-1}. Anharmonicity in the vibrational mode (944 cm^{-1}) may be more easily overcome when only 3 photons are required to populate the quasi-continuum (23) by absorption initially via the P branch of the mode. The subsequent 2 photons may be absorbed in the Q and R branches, respectively; however, due to the small internal energy difference between the dimers at the two temperatures, this possibility seems tenuous.

Best fit straight lines through the data points give σ_D values in the absence of collisions when extrapolated, yielding values of 15.6×10^{-21} cm^2 and 8.55×10^{-21} cm^2 for the "hot" and "cold" proton-bound ethanol dimers, respectively.

2-Propanol

Three sets of experiments, all performed at 321 K, are reported. The first two sets comprised 50 ms of dark period followed by 50 ms of laser irradiation (944 cm^{-1}); one series examining protonated dimers formed in a pure alcohol system, the other protonated dimers formed in a 1:1 mixture of alcohol and nitrogen. The third series of experiments employed a dark period of 160 ms followed by 40 ms of laser irradiation. The protonated dimers were formed in an alcohol only system. In Table 2 measured σ_D values are reported. The data in Table 2 are plotted as σ_D vs. collisions prior to photolysis and σ_D vs.

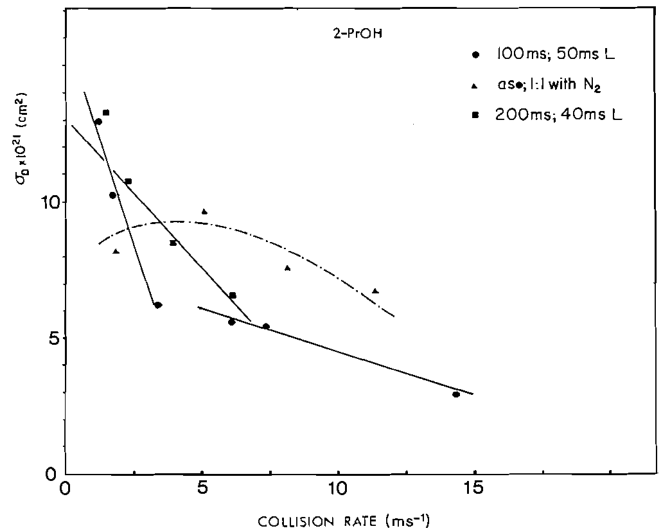

FIG. 6. Plot of σ_D vs. collision rate for IRMPD of $(2\text{-PrOH})_2H^+$.

collision rate in Figs. 5 and 6, respectively. The data obtained from the alcohol : N_2 (1 : 1) experiments are plotted as a function of Dehmelt collision rates (corrected for molecular flow) of the dimer and the neutral alcohol only.

In Fig. 5, the data for the 100 ms experiments employing the alcohol only exhibit a linear dependence of σ_D with the number of collisions prior to photolysis, albeit divided into two regions. At few collisions of the dimer before laser irradiation, the data extrapolate to a collision-free σ_D value of 15.8×10^{-21} cm²; here, the dimer population has suffered too few collisions prior to the photolysis to be fully relaxed. The steep decrease in σ_D with the number of collisions in this region is attributed to an increase in the number of photons required to effect dissociation in competition with increasing collisional deactivation (Fig. 6).

At more than about 250 collisions (*vide infra*), the dimer is fully relaxed and the path of lowest E_a is followed exclusively. The decrease in σ_D is attributed to collisional deactivation during photolysis (Fig. 6). The data in this region extrapolate to a collision-free σ_D of 8.0×10^{-21} cm².

Three of the data points from the 200 ms experiments were also fitted to a straight line and extrapolated to a collision-free σ_D value of 13.1×10^{-21} cm². Photodissociation product analysis revealed the protonated diisopropyl ether as the dominant (~95%) product from three experiments. A small amount (~5%) of protonated alcohol was also produced — presumably via photolysis of the hot protonated ether (4, 24). The lowest E_a pathway only is accessed by the laser in these experiments (24), and the proton-bound dimer ions are fully collisionally relaxed at the onset of irradiation. Although product analysis was not performed for the data point corresponding to $\sigma_D = 13.3 \times 10^{-21}$ cm², previous work (4) showed that 250 to 300 collisions prior to photolysis were required to relax fully the dimer as shown in Fig. 7. From the data in Table 2, the requisite number of collisions have not occurred for the latter dimer, hence it was not included in the calculation of the best fit straight line. The fully relaxed data from the 200 ms experiments are obtained at lower collision rates than those from the 100 ms experiments (Fig. 6); the data from the former are expected to extrapolate to a higher collision-free σ_D value. The roughly parallel nature of the decrease of σ_D with the increase in the number of collisions is due to the fact that at identical

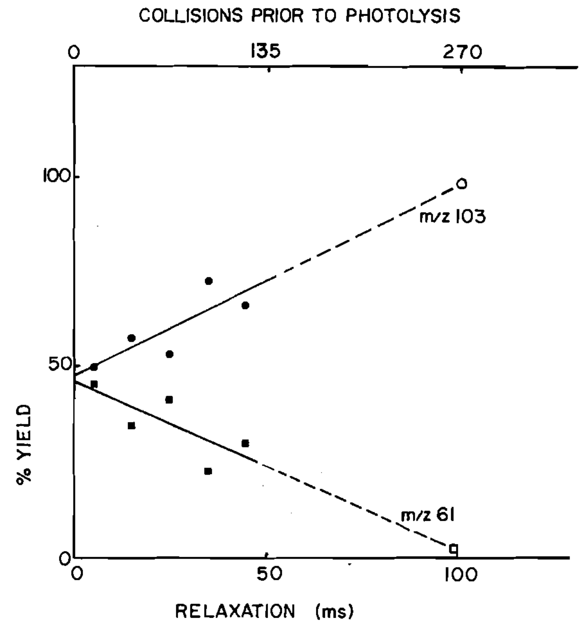

FIG. 7. Plot of IRMPD product % yield vs. relaxation time prior to photolysis of the proton-bound dimer of 2-propanol. M/z 103 is the protonated diisopropyl ether product; m/z 61 is the protonated parent alcohol. The data are extrapolated, assuming a linear fit to the yields observed in an ICR cell (24) at differing relaxation times and numbers of collisions than those employed in this study. The ICR cell yields are depicted as open symbols and are attributed to photolysis of fully relaxed dimer ions.

numbers of collisions prior to photolysis, the fully relaxed dimers from the 100 ms experiments have experienced a three-fold increase in the collision rate during photolysis. The decrease in σ_D with increasing numbers of collisions in both cases is due to an increase in collisional deactivation during photolysis, while displacement of the 200 ms results from those at 100 ms reflects the greater collision rate during photolysis of the latter resulting in a correspondingly reduced total energy increment supplied by the laser.

The data obtained from photodissociation of dimers formed in a 1 : 1 mixture of 2-propanol and nitrogen are plotted as σ_D vs. the number of collisions of the dimer with the neutral alcohol only. If nitrogen has no effect upon the photodissociation of the protonated dimers, then the data points obtained experimentally should mimic the behaviour of those obtained from the 100 ms experiments utilizing solely 2-propanol. The data are characterized by a decreased σ_D value at low numbers of collisions and enhanced σ_D values at higher collision values.

Similar behaviour has been previously reported (25–27). The enhancement has been attributed to collisional repopulation of rotational levels depleted by laser-pumping effected by collisions with the buffer gas. The data indicate that the bottleneck occurs at a low level of internal excitation of the dimer i.e. after the dimer has experienced a large number of collisions prior to photolysis.

In Fig. 6, the effect upon σ_D of the collision rate during photolysis is examined. The data obtained in the 100 ms experiments using 2-propanol only are fitted to two straight lines according to the rationale outlined previously. The steep portion of the slope corresponds to proton-bound dimers with low collision rates during photolysis and excess ($\leqslant$ 131 kJ mol⁻¹) (1) internal energy. The rapid decrease of σ_D with increasing

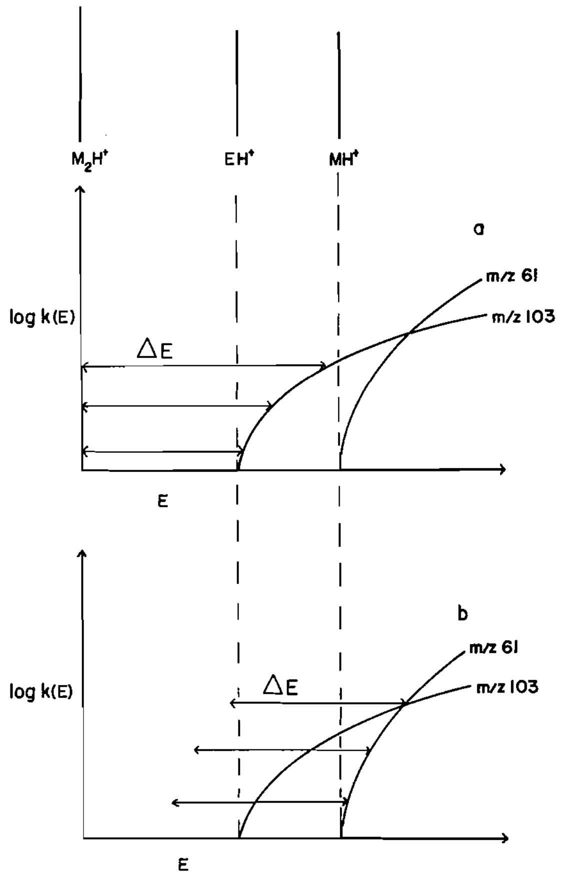

FIG. 8. Plot of log $k(E)$ vs. internal energy for the two reaction pathways of $(2\text{-PrOH})_2H^+$ upon photolysis. The symbols used are defined as follows: M_2H^+, protonated dimer; MH^+ protonated alcohol (m/z 61); EH^+, protonated ether (m/z 103); ΔE, total energy supplied by the laser.

collision rates is due to both collisional deactivation during and diminished internal energy at the onset of photolysis. At higher ($\geqslant 5$ ms^{-1}) collision rates, the decrease in σ_D is less pronounced. This is attributed to a fully relaxed dimer population at the onset of irradiation; thus laser-pumping starts at the same level of internal excitation. Furthermore, as the lowest E_a pathway only is accessed, the sole variable in the data is that of collisional deactivation which is proportional to the collision rate.

For the 200 ms results, only those experiments which produced the lowest E_a pathway exclusively were used to calculate a best fit straight line (*vide supra*). The data indicate a greater decline of σ_D with collision rates ($\leqslant 5$ ms^{-1}) than the data derived from fully relaxed dimers in the 100 ms experiments at higher collision rates (>5 ms^{-1}). Complete relaxation of the protonated dimers at the onset of irradiation in the two sets of experiments is supported by the similarity in σ_D values (within the limits of experimental error) at identical collision rates of 6 ms^{-1}, despite a threefold difference in the number of collisions prior to photolysis (Fig. 5).

In Fig. 8, the variation of log $k(E)$ is plotted as a function of internal energy, E (28, 29). The curves as drawn are of a qualitative nature and the corresponding energy spacings in the proton-bound dimer are depicted above. Case (a) corresponds to the fully relaxed situation wherein the collision rate during photolysis affects the overall energy increment (ΔE) supplied by the laser. Case (b) depicts a constant total energy increment;

TABLE 3. Calculated dissociation rates for the reaction pathway of lowest E_a of the proton-bound dimer of 2-propanol

n	m	s	ω (s^{-1})	k (s^{-1})
9	9	69	2.83×10^{13}	176
10	9	69	2.83×10^{13}	1.5×10^{3}
10	10	69	2.83×10^{13}	22.5
11	10	69	2.83×10^{13}	216
11	11	69	2.83×10^{13}	3.2
12	11	69	2.83×10^{13}	33.1
12	12	69	2.83×10^{13}	4.8×10^{-1}

however, laser-pumping starts at differing levels of internal energy of the dimer above ground state.

The collision-free σ_D value derived for fully relaxed 2-propanol dimers and leading to the protonated ether product solely is 13.1×10^{-21} cm^2. This value corresponds to a unimolecular dissociation rate constant of 29 s^{-1} calculated from eq. [2]; this rate constant may then be expressed using the Kassel form of RRKM theory (20) as:

$$[10] \quad \text{Rate} = \omega \frac{n!(n - m + s - 1)!}{(n - m)!(n + s - 1)!}$$

where n is the total number of photons absorbed by the ion, m is the number of photons required for reaction, s is the number of vibrational degrees of freedom of the ion, and ω is the laser photon frequency. For the proton-bound 2-propanol dimer, s is equal to 69, and when k_{diss} is assumed to be much greater than the overall rate of multiphoton excitation, n is equal to m. The photon employed corresponds to a frequency of 2.83×10^{13} s^{-1}. In Table 3, calculated values for the rate constant are given, along with the values of n, s, m, and ω used for the calculation.

Comparison of the calculated rate constants in Table 3 with the experimental value of 29 s^{-1} suggests an E_a for the dehydration reaction:

$$[11] \quad (2\text{-PrOH})_2H^+ + mh\nu \rightarrow 2\text{-}Pr_2OH^+ + H_2O$$

of 10 or 11 photons, of energy 11.3 kJ mol^{-1}. The E_a thus lies in the range 113 to 124 kJ mol^{-1}. In comparison, Bowers *et al.* (22) calculated an activation energy for the reaction:

$$[12] \quad (MeOH)_2H^+ \rightarrow Me_2OH^+ + H_2O$$

of 105 kJ mol^{-1}.

Deuterated 2-propanols

The observed increase in σ_D in the dimer derived from 2-propanol with added N_2 has been attributed to collisional repopulation of rotational levels which are resonant with the laser photon employed. As previously noted (25–27) such behaviour has been observed in other molecules upon ir laser photolysis. When a depletion of rotational levels which are resonant with the laser leads to a bottleneck in the IRMPD process, then the rotational level spacings should have an effect upon the magnitude of the bottleneck. Substitution of deuterium for hydrogen reduces the rotational level spacing, thus the effect of added N_2 upon σ_D values obtained from the IRMPD of various deuterated 2-propanols was investigated. In the experiments with a mixture of alcohol and nitrogen, the collision rates pertain only to collisions between the neutral alcohol and the protonated dimer. If nitrogen has no effect upon σ_D, then the data should mimic that obtained from the alcohol-only experiments.

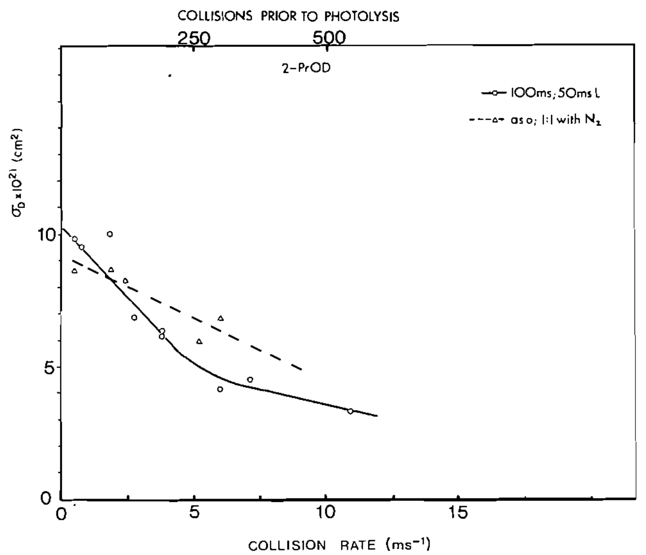

FIG. 9. Plot of σ_D vs. collision rate and number of collisions prior to photolysis for the protonated dimer of 2-propanol (OD), 2-PrOD.

2-Propanol (OD)

In Fig. 9, the results from two sets of experiments are shown as σ_D vs. collision rate. The data from the added N_2 experiments are plotted as a function of collisions of the dimer with the neutral alcohol only.

In the alcohol-only system, the decline in σ_D at low ($\leqslant 5$ ms^{-1}) collision rates is due to both the decrease in internal energy content of the dimer prior to and the increase in collisional deactivation during photolysis. At collision rates $\geqslant 5$ ms^{-1}, the dimers have experienced the requisite number of collisions for complete relaxation prior to irradiation and the gentler decline of σ_D with the increased collision rate results from collisional deactivation during photolysis. The collision-free σ_D value is 10.25×10^{-21} cm^2.

The σ_D values obtained in the alcohol and nitrogen experiments (1:1) show a small enhancement at collision rates $\geqslant 5$ ms^{-1}. At a collision rate of 5 ms^{-1}, the deuteronated dimers have suffered an average of 250 resonant collisions prior to photolysis. Evidence from the 2-propanol system suggests that these dimers are fully relaxed prior to irradiation. The alcohol/N_2 experiments indicate a smaller bottleneck than in the 2-propanol system which occurs at or near the ground state of the dimer.

2-d$_1$-2-Propanol

Three sets of experiments were performed and the results are plotted as σ_D vs. collision rate in Fig. 10. Despite fewer data points, the observed decrease of σ_D with increasing collision rate in the alcohol-only system is qualitatively similar to that observed in the previous alcohol dimers. The collision-free σ_D value is 16.1×10^{-21} cm^2.

The 1:1 mixture of alcohol and nitrogen exhibits a large increase in σ_D indicating a blockage of IRMPD in the protonated alcohol dimer. The bottleneck appears to occur at or near the ground state of the dimer.

The 1:4 mixture of alcohol and nitrogen shows essentially no enhancement of σ_D. As the data correspond to only 70 and 140 resonant collisions with the neutral alcohol, the dimers have excess internal energy and are being pumped from a level above the bottleneck.

No allowance for collisional deactivation of the dimers by non-resonant processes involving N_2 has been made. Such an allowance would shift the data points to higher collision rates.

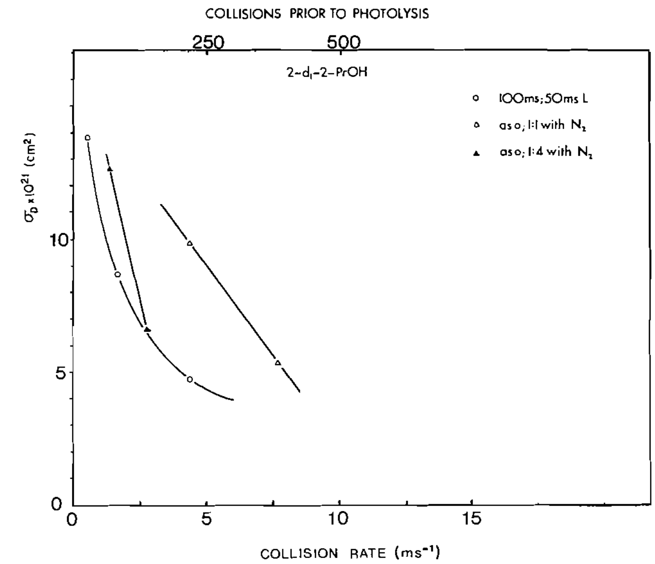

FIG. 10. Plot of σ_D vs. collision rate and number of collisions prior to photolysis for the protonated dimer of 2-d_1-2-propanol.

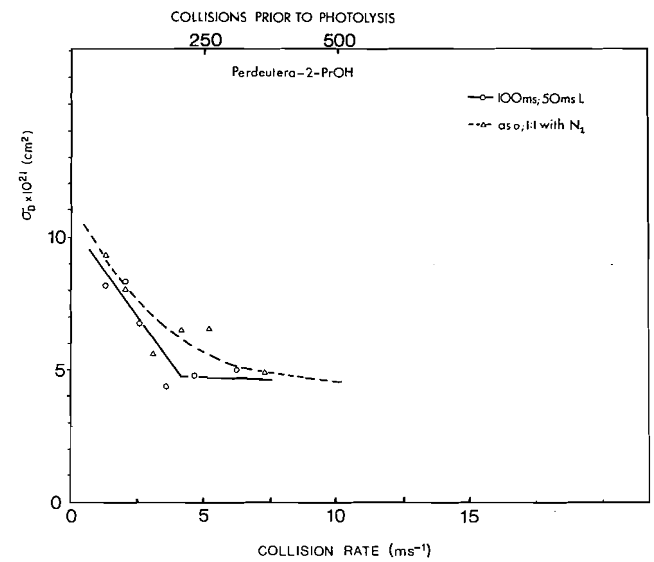

FIG. 11. Plot of σ_D vs. collision rate and number of collisions prior to photolysis for the protonated dimer of perdeutero-2-propanol.

Perdeutero-2-propanol

The results of two sets of experiments are shown in Fig. 11. Proton-bound dimers produced in the alcohol-only system exhibit the usual initial steep decrease of σ_D at low collision rates and a very gentle decrease of σ_D at higher collision rates. The collision-free σ_D is 10.5×10^{-21} cm^2.

Dimers produced in a 1:1 mixture of alcohol and nitrogen show a small increase in σ_D at collision rates = 5 ms^{-1}. Such behaviour indicates a small bottleneck in the IRMPD process occurring at or near the ground state of the deuteronated dimer.

Conclusion

Based on the results of the IRMPD studies, the four 2-propanols may be divided into two groups: those with proton-bound dimers and those with deuteron-bound dimers. The latter group exhibit both smaller collision-free σ_D values and smaller increases in σ_D when nitrogen is added to the system.

The lower collision-free σ_D value is attributed to a decrease in the rate constants for both the dehydration and scission reactions due to deuterium substitution in an active vibrational mode for product formation (30).

The smaller increase in σ_D of the deuteron-bound dimers when nitrogen is added is presumably due to a decrease in the spacing of rotational levels by deuterium substitution in the mode being pumped by the laser. The most probable identity of the vibrational mode initially pumped by the laser is the OH in plane bend at ~1385 to 1250 cm^{-1} in primary and secondary aliphatic alcohols (31). This mode shifts by a factor of approximately $(\sqrt{2})^{-1}$ upon the substitution of D for H in perdeutero and 2-propanol (OD); such a "red" shift moves the OD in plane bend into resonance with the laser operating at 944 cm^{-1}, and the smaller rotational spacings provide less of an impediment to IRMPD via anharmonic energy mismatching.

In the IRMPD of the protonated dimer of 2-propanol RRKM calculations employing the simple quantum Kassel equation suggested an activation energy of 113 to 124 kJ mol^{-1} for the reaction pathway leading to the production of protonated diisopropyl ether.

^{1}H spin-lattice relaxation rates and nuclear Overhauser effect difference spectra have been measured (at 400 MHz) for six dimers derived from methyl-substituted 7-hydroxyindenes. Used in combination, these measurements identify the relaxation pathways available to all of the protons in the molecules. Analysis of these pathways has permitted assignment of all chemical shifts, and identification of the relative stereochemistry at all chiral centres.

WALTER J. CHAZIN, LAWRENCE D. COLEBROOK, BRIAN R. DAVIS, I. ROSS N. MCCORMICK et STEPHEN J. JOHNSON. Can. J. Chem. **63**, 2332 (1985).

On a mesuré les vitesses de relaxation spin-réseau du ^{1}H et les différences d'effet Overhauser nucléaire dans les spectres, à 400 MHz, de six dimères obtenus à partir d'hydroxy-7 indènes substitués par des groupes méthyles. Si on les combine, ces mesures permettent d'identifier les diverses voies de relaxation de tous les protons de ces molécules. Une analyse de ces diverses voies de relaxation a permis d'attribuer tous les déplacements chimiques et d'identifier les stéréochimies relatives de tous les centres chiraux.

[Traduit par le journal]

Introduction

The analysis of ^{1}H nuclear magnetic resonance spin-lattice relaxation parameters, which can be conveniently and efficiently measured using a modern pulse Fourier transform nmr spectrometer, can provide a significant amount of information about the structure and stereochemistry of organic molecules (1–3). In this report, we describe the solution structure determination of a series of methyl-substituted 7-hydroxyindene dimers, **1–6**, by nmr analysis of their ^{1}H relaxation pathways.

	11b	R^{1}	R^{2}	R^{3}
1	β	H	H	H
2	α	H	H	H
3	β	CH_3	CH_3	H
4	β	CH_3	H	CH_3
5	α	CH_3	H	CH_3
6	α	CH_3	CH_3	H

8

One of these compounds, **5**, was originally obtained as a mixture with its C-11 epimer, together with the expected tertiary alcohol, on the treatment of 3,4-dimethyl-7-hydroxyindan-1-one with methylmagnesium iodide. The structure of **5** was initially assigned (4) on the basis of its 60-MHz ^{1}H nmr spectrum, and was confirmed by an X-ray diffraction study of its 8-bromo derivative (5). Subsequent investigation resulted in the synthesis and isolation of the remaining compounds (6). In general, the dimers were prepared by treatment of the relevant indene (**7** or **8**) in chloroform with 0.5% trifluoroacetic acid. Of the tetramethyl dimers, **1** and **2**, prepared from **7**, **1** was the kinetic product, and **2** the thermodynamic product of the dimerization reaction. Compounds **1** and **2** were readily separated by chromatography. The hexamethyl dimers, **3–6**, prepared from **8**, were obtained as the kinetic product, **3**, and the successive isomerization products, **4**, **5**, and **6**, on longer acid treatment. Fractional crystallization was employed to separate **4** from **3**, and **6** from **5**.

Preliminary stereochemical assignments were made largely on the basis of the ^{13}C nmr spectra, by considering the effects of adding methyl groups, e.g. γ–*gauche* and δ–synaxial effects. The ^{13}C chemical shift assignments were made by comparison between the two series (tetra- and hexamethyl), by experiments in which the 1-methyl of the hydroxyindene was enriched in ^{13}C, and by the analysis of spectra of some mixed dimers in which an n-butyl group was substituted for the 6a-methyl group. These assignments were in complete agreement with the X-ray crystallographic analysis of the 8-bromo derivative of **5**, and have been verified by the present study. Details of these related studies will be published elsewhere (7).

The dimeric nature of these compounds creates difficulties in the application of standard ^{1}H nmr techniques to their unambiguous structure determination. In particular, the assignment of ^{1}H chemical shifts to corresponding protons in each half of the dimer is difficult because of only very slight differences in shielding. High field ^{1}H spectra (Fig. 1) were neces-

FIG. 1. The 400-MHz ^{1}H nmr spectrum of **3**, 0.1 *M* in $CDCl_3$.

sary to provide sufficient chemical shift dispersion to resolve all of the signals, while relaxation pathway analysis was critical for chemical shift assignment, and for the determination of stereochemistry at the chiral centres. Complete analysis of the spectral parameters of all proton signals, including differentiation of all methylene signals, and identification of the stereochemistry at all (three or five) chiral centres, has been achieved. The solution structure and stereochemistry of **5**, as determined by nmr techniques, was completely consistent with the X-ray crystallographic structure determination of the bromo derivative (5).

Relaxation pathway analysis

Proton spin-lattice relaxation in molecules of m.wt. < 1000 d, in 0.1 *M* solution in a non-viscous perdeuterated solvent, occurs predominantly by intramolecular dipolar interactions with other protons. The dipolar relaxation rate (R_{1d}) of a proton depends on the numbers of other protons in the molecule, and their distances, according to eq. [1]:

$$[1] \quad R_{1d_j} = K\left[\gamma 4 \sum_i (1/r_{ij})^6 \tau_{c_{ij}}\right] \qquad (i \neq j)$$

K is a constant, γ is the magnetogyric ratio for the proton, r_{ij} is the distance between protons i and j, and $\tau_{c_{ij}}$ is the rotational correlation time for the ij interproton vector. The τ_c term in eq. [1] contains contributions associated with segmental motion, e.g. of methyl groups, in addition to the effects of tumbling of the molecule as a whole. When a molecule tumbles isotropically, the values of τ_c are all equivalent, and a very simple relationship exists between R_1 values for any two protons:

$$[2] \quad \frac{R_{1_j}}{R_{1_k}} = \frac{\sum_i (1/r_{ij})^6 \qquad (i \neq j)}{\sum_i (1/r_{ik})^6 \qquad (i \neq k)}$$

A related parameter is the nuclear Overhauser effect (nOe) enhancement (8), which is a measure of the efficiency of the dipolar interaction between two specific nuclei. Relative nOe enhancements may be predicted in a similar manner, by calculating the contribution of each $(1/r_{ij})^6$ term to the overall sum.

The inverse sixth power dependence on internuclear distance implies that relaxation contributions are significant only for the nearest neighbors of a particular proton. In consequence, R_1 values and nOe enhancement factors are extremely sensitive to local structure and stereochemistry. Due to the unique location of each proton in the molecule, there is a unique set of relaxation pathways which characterize each proton. The various relaxation pathways to and from a particular proton can be found through the use of nOe and R_1 measurements, thereby establishing its identity.

In a relaxation pathway analysis of a complex molecule, some form of modelling is required to aid in interpretation of the data. The simple model employed uses interproton distances measured from Dreiding molecular models of possible molecular structures, and the assumption that molecular tumbling is isotropic. The latter is a reasonable approximation for these molecules at the semi-quantitative level of the analysis. This approach had worked well for some strychnos alkaloids (3). Due to the difficulties in accurately predicting the relaxation contributions from the numerous methyl groups in these molecules, calculations could only be used as a qualitative guide to the interpretation of the data.

Prediction of nOe enhancements provided guidance in the selection of key nOe experiments necessary to assign stereochemistry and corroborate chemical shift assignments. The qualitative outcome of such experiments could, in all cases, be adequately interpreted by inspection of molecular models. The small differences in chemical shifts of corresponding resonances in each half of the dimer required that subsaturating

power levels (soft experiments) be used in the nOe experiments in order to achieve adequate selectivity. This restriction prohibited quantitative comparisons between calculated and experimental nOe enhancements, and hence the measurement of interproton distances.

Results and discussion

The strategy adopted in this study was to first carry out non-selective ^1H spin-lattice relaxation measurements, then to use selected nOe difference (nOed) (9–11)[3] measurements to identify specific relaxation pathways.

Relaxation measurements provide a fast, efficient aid to the assignment of proton chemical shifts, since the R_1 value of a particular proton is strongly dependent on its environment. The relatively isolated, and hence slowly relaxing, OH and aromatic protons have the lowest R_1 values (0.3–0.4 and 0.3–0.5 s^{-1}, respectively). The other methine protons relax more efficiently since they have a larger number of near neighbors (R_1 values of 0.7–1.0 s^{-1}). Due to their close proximity, the methylene protons relax each other very efficiently, and have higher R_1 values (1.1–2.0 s^{-1}). Under most circumstances, methyl group relaxation is also dominated by dipolar effects. Since the methyl group protons are close to each other, they relax so efficiently that they experience little dipolar relaxation from other protons in the molecule. Interpretation of methyl group R_1 values can, therefore, be based on analysis of motional effects. This implies that, for any particular molecule, differences in methyl R_1 values can be attributed to different rates of methyl rotation. The aryl methyl groups, which are relatively free to rotate about the C—CH_3 bond axis, have R_1 values of 0.7–1.0 s^{-1}. In contrast, the alkyl methyl groups, whose rotation is evidently more restricted in these compounds, relax more efficiently, with R_1 values of 1.3–2.1 s^{-1}.

Stereochemical determinations

Differentiation of methine from methylene protons at C-1, C-2, C-11, and C-11a was easily made by consideration of ^1H R_1 values (Table 1), since methylene protons in these compounds generally relax about twice as fast as the methine protons. Tentative assignments were made by consideration of chemical shifts and coupling constants, assisted by spin-decoupling experiments. The stereochemistry at positions 1, 2, 11, 11a, and 11b was then determined relative to that of the methyl group at position 6a (designated as being located on the upper (β) face of the molecules (5)), by relaxation pathway analysis. In all cases, H-11a was on the same (β) side of the molecule as CH_3-6aβ, as evidenced by the substantial nOe enhancements between the two (Figs. 2 and 3, Tables 2 and 3). In a similar manner, the relative stereochemistry at position 11b could be determined from the magnitudes of nuclear Overhauser effects between CH_3-11b and H-11aβ. A large nOe established the ring fusion as *cis* (compounds **1**, **3**, and **4**, Fig. 2); a small nOe, determined under similar conditions, established the ring fusion as *trans* (compounds **2**, **5**, and **6**, Fig. 3). The proton or methyl group in the β-position at C-11 was clearly distinguished from the α-position substituent by significant nOe enhancements to and from both H-11aβ and CH_3-6aβ. For all hexamethyl dimers, the 11-methyl group was identified as having β-stereochemistry.

The assignments at C-1 and C-2 were carried out in a similar manner, but required more careful consideration of the relaxation data and close inspection of molecular models. For the compounds which have *trans*-geometry of rings B and D (**2**, **5**,

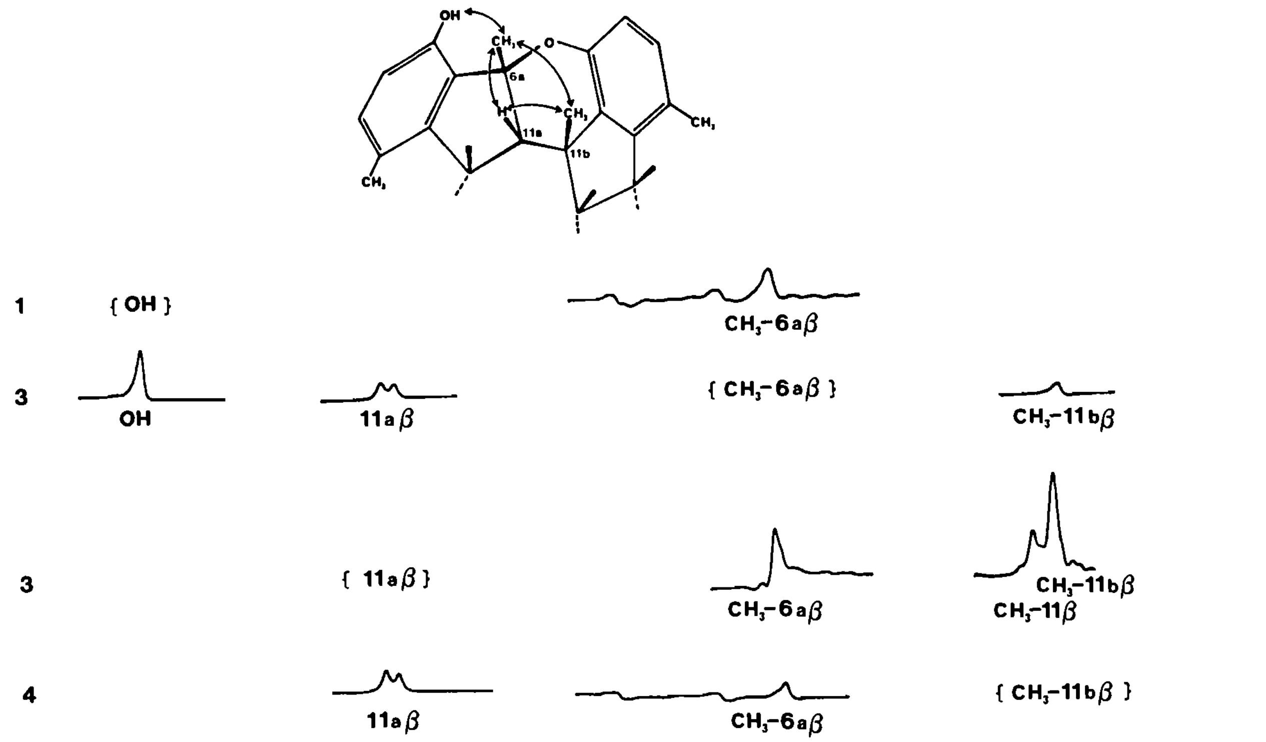

FIG. 2. Relaxation pathways (arrows), and partial nOed spectra used to determine ring fusion in *cis*-fused compounds. Transitions irradiated are indicated {}.

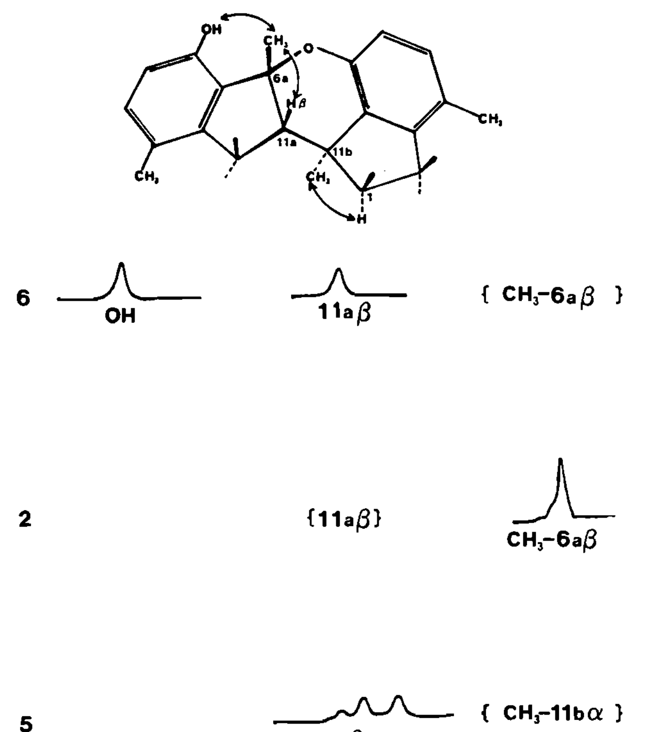

FIG. 3. Relaxation pathways (arrows), and partial nOed spectra used to determine ring fusion in *trans*-fused compounds. Transitions irradiated are indicated {}.

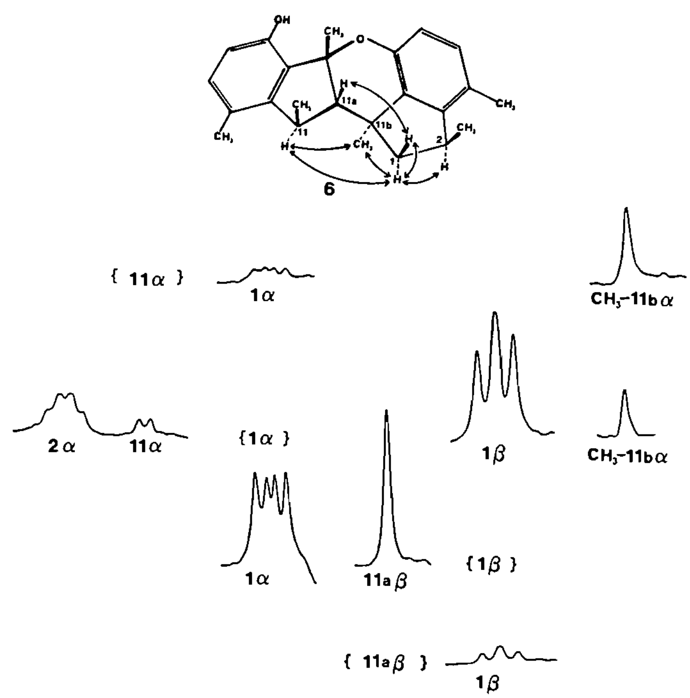

FIG. 4. Relaxation pathways (arrows), and partial nOed spectra used to determine C-1 and C-2 stereochemistry in a *trans*-fused compound, **6**. Transitions irradiated are indicated {}.

and **6**), the relaxation pathway between CH_3-11bα and the C-1 proton on the same side of the molecule serves to distinguish between the two C-1 protons (see Fig. 4). The relative magnitudes of the nOe enhancement to and from the C-1 substituents and the previously assigned C-11 substituents corroborate these assignments. The assignments at C-2 were then made by relaying the stereochemical assignments at C-1 through the relative magnitudes of the nOe enhancements (large values for adjacent substituents on the same face of the molecule, Fig. 4).

For compounds with *cis*-geometry of rings B and D (**1**, **3**,

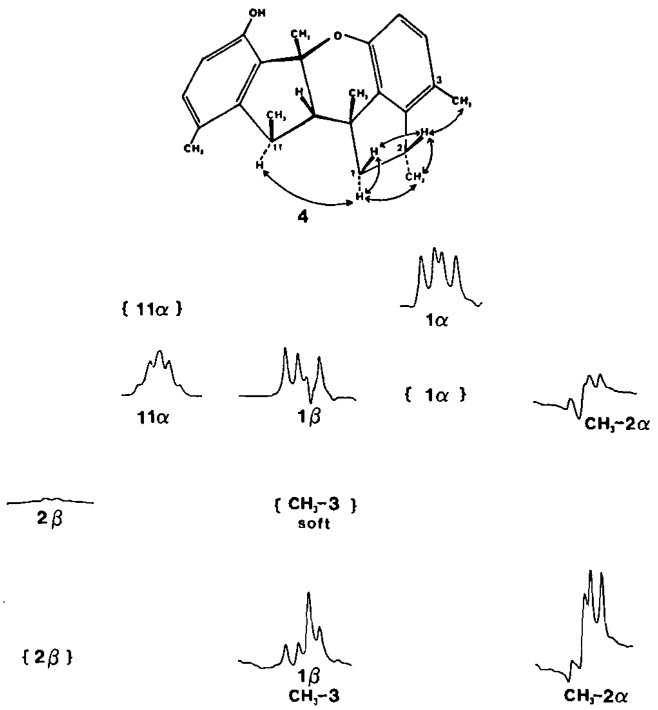

FIG. 5. Relaxation pathways (arrows), and partial nOed spectra used to determine C-1 and C-2 stereochemistry in a *cis*-fused compound, **4**. Transitions irradiated are indicated {}.

and **4**), the relaxation pathway between CH_3-11bβ and the C-1 protons (Fig. 5) clearly differentiates between the two protons. In these molecules, there is also a significant nOe between the substituents in the α-positions of C-1 and C-11, verifying the assignment and reflecting the folded geometry of the molecules. The assignments at C-2 were again made by relaying the stereochemistry established at C-1, through the magnitudes of the nOe enhancements.

Assignments in aromatic rings

The signals (400 MHz) arising from ring A protons could be distinguished from the corresponding ring E signals by a combination of chemical shift arguments, double resonance, and, in particular, by relaxation pathway analysis. The hydroxyl proton signals were readily identified as the slowly relaxing singlets at 6.1–6.8 ppm. H-8 may be distinguished from H-9, and H-4 from H-5 on the basis of the greater shielding effect in the *ortho* position from the oxygen substituents (OH-7 and OR-5a), and by the higher relaxation rates of the 4 and 9 protons resulting from significant contributions from the adjacent 3 and 10 methyl groups.

A definitive distinction between the ring A and ring E aromatic signals was established by identification, through nOed experiments, of consecutive relaxation pathways originating on the previously assigned C-2 and C-11 protons. Saturation of the H-11α resonance gave an enhancement of CH_3-10, while irradiation of the H-2α and (or) H-2β transitions gave an enhancement of CH_3-3 (Fig. 6). Since the chemical shifts of the two methyl resonances were very different ($\Delta\delta = 0.2$ ppm), these nOe enhancements gave the methyl assignments unambiguously. The H-4 and H-9 resonances could then be assigned from the nOe enhancements observed upon irradiation of CH_3-3 and CH_3-10, respectively (Fig. 6). The completion of the aromatic proton relaxation sequences to the 8 and 5 protons:

$$CH_3\text{-}3 \leftrightarrow \text{H-4} \leftrightarrow \text{H-5} \qquad CH_3\text{-}10 \leftrightarrow \text{H-9} \leftrightarrow \text{H-8}$$

was trivial, so chemical shifts of all aromatic resonances were assigned.

With this information, the structural analysis was complete, and the full set of assignments of the nmr parameters could be made. These were refined by computer simulation when necessary, and are listed in Table 4. The stereochemistry of all six compounds was consistent with the coupling constants measured directly, or obtained using computer simulation.

Conclusion

By utilizing the relaxation pathway analysis technique outlined in the Introduction, it was possible to assign all the signals in the ^{1}H nmr spectrum of the six 7-hydroxyindene dimers, including the diastereotopic methylene protons. In addition, by careful analysis of nOe enhancements with the aid of molecular models, it was possible to determine ring fusion, and to assign the stereochemistry at all three or five chiral centres. This report demonstrates the power of the relaxation pathway technique for the analysis of the solution structure of organic molecules, even in situations where detailed quantitative analysis is not possible.

Experimental

Solutions for nmr studies were made 0.1 *M* in $CDCl_3$, without degassing, since this has been shown to be unnecessary for qualitative studies of this type (2). Spectra (eight transients) were acquired into 32K (standard spectra and R_1 measurements) or 16K (nOed spectra) data blocks over a spectral range of 3800 Hz on a Bruker WH-400 spectrometer (Montreal Regional High Field NMR Laboratory). All spectra were acquired at ambient temperature (292 K). Spectral simulations were carried out on a Hewlett–Packard 1000 computer, using a modified LAOCOON III (12) program.

R_1 values were measured using the standard inversion–recovery pulse sequence (13). The 180° pulse-width was checked at the beginning of each experiment. R_1 data within the initial slope region (14)

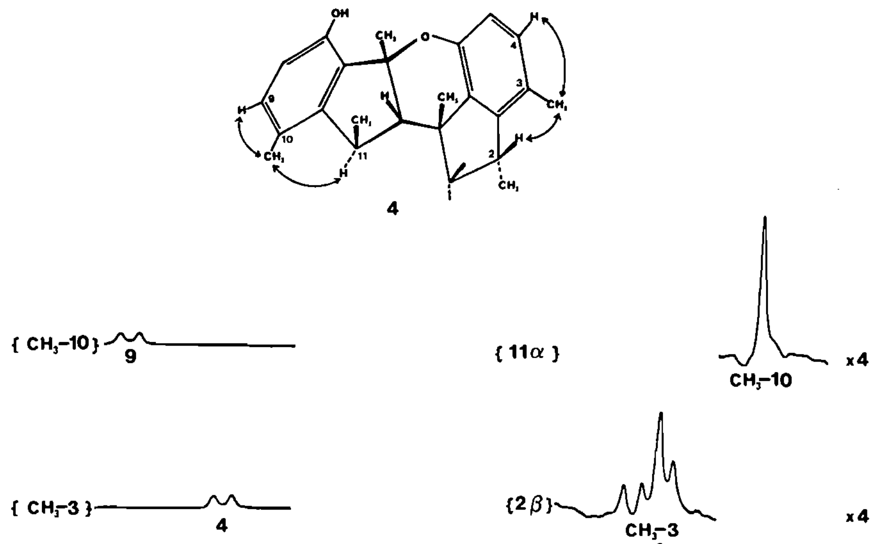

FIG. 6. Relaxation pathways (arrows), and partial nOed spectra used to distinguish between aromatic ring signals in **4**. Transitions irradiated are indicated {}.

were calculated by two-parameter, non-linear regressional analysis on the HP-1000 computer. The absolute accuracy of R_1 measurements is typically ±10% but, within a single experiment, the relative R_1 values can be determined to a precision of better than ±5%.

Theoretical R_1 values and nOe enhancements were calculated for the model described by eq. [2], using the HP-1000 computer.

The nOe enhancements were measured by the sensitive difference method using a modification, which has been described previously (3), of the procedure reported by Hall and Sanders (9). A full $5 \times T_1$ preparation period was allowed before each scan, although it is now firmly established that the use of a $1-3 \times T_1$ preparation period is more efficient when carrying out qualitative studies (11). In several of the nOe difference experiments, the use of subsaturating power levels (soft experiments) was not sufficient to ensure selectivity. In these cases, additional experiments were carried out to determine the influence of decoupler power and decoupler frequency offset on observed nOe enhancements, thereby verifying the origin of the enhancements. Although the nOed technique has been shown to be sensitive down to the order of a few tenths of a percent (11), in those instances when irradiation selectivity was a problem, only relatively large enhancements (>1%) were considered to be sufficiently reliable.

Mass spectra were recorded at 12 or 70 eV. Peak positions (m/e) are followed by relative abundances in parentheses.

Synthetic procedures

*(6aβ,11aβ,11bβ)-1,2,6a,11,11a,11b-Hexahydro-3,6a,10,11b-tetramethyldiindeno[7,1-*bc*:2′,1′-*e*]pyran-7-ol (1)*

A solution of trifluoroacetic acid in chloroform (5% v/v, 0.02 mL) was added to indenol **7** (100 mg) in chloroform (0.5 mL) at room temperature. After 90 min the mixture was worked up to give the crude product (100 mg) which was purified by preparative thin-layer chromatography (ptlc) to give the dimer **1** (60 mg), mp 130–130.5°C (from n-pentane); m/e (12 eV): 320 (6, M$^+$), 160 (34), 159 (100). *Anal.* calcd. for $C_{22}H_{24}O_2$: C 82.5, H 7.6; found: C 82.4, H 7.7.

*(6aβ,11aβ,11bα)-1,2,6a,11,11a,11b-Hexahydro-3,6a,10,11b-tetramethyldiindeno[7,1-*bc*:2′,1′-*e*]pyran-7-ol (2)*

Trifluoroacetic acid (0.025 mL) was added to the indenol **7** (100 mg) in chloroform (0.5 mL) at room temperature. After 30 min the mixture was diluted with ether and worked up to give crude product (100 mg). Chromatography and recrystallization gave the dimer **2** (60 mg), mp 157–158°C (from n-hexane); m/e (12 eV): 320 (3, M$^+$), 160 (53), 159 (100). *Anal.* calcd. for $C_{22}H_{24}O_2$: C 82.5, H 7.6; found: C 82.6, H 7.5.

*(2β,6aβ,11β,11aβ,11bβ)-1,2,6a,11,11a,11b-Hexahydro-2,3,6a,10,11,11b-hexamethyldiindeno[7,1-*bc*:2′,1′-*e*]pyran-7-ol (3)*

A solution of trifluoroacetic acid in carbon tetrachloride (5% v/v, 0.1 mL) was added to indene **8** (0.30 g) in chloroform (2.5 mL). After 35 min the solution was diluted with ether (25 mL), shaken with 5% sodium bicarbonate solution (20 mL), and worked up to give the crude product (0.30 g). Purification by ptlc gave the main component (0.20 g) which was recrystallized from n-hexane to give dimer **3** (0.17 g, 57%), mp 155–157°C; m/e (12 eV): 348 (4, M$^+$), 174 (100); (70 eV): 348 (2, M$^+$), 175 (50), 174 (72), 159 (100). *Anal.* calcd. for $C_{24}H_{28}O_2$: C 82.72, H 8.10; found: C 82.97, H 8.36. The residue from the crystallization (approximately 0.03 g) was a 2:1 mixture of dimer **3** and the C-2 epimer, dimer **4**.

*(2α,6aβ,11β,11aβ,11bβ)-1,2,6a,11,11a,11b-Hexahydro-2,3,6a,10,11,11b-hexamethyldiindeno[7,1-*bc*:2′,1′-*e*]pyran-7-ol (4)*

The indene **8** (250 mg) in chloroform (1 mL) was mixed with trifluoroacetic acid (0.01 mL) in chloroform (1 mL) at room temperature. After 1 h, work-up gave a product mixture (250 mg) which was separated by ptlc to give a fraction containing dimer **5** (60 mg) and a lower R_f fraction consisting of a 1:1 mixture of dimers **3** and **4** (150 mg). Recrystallization of this mixture from n-pentane gave crystals enriched in dimer **3**. Successive fractional recrystallizations were performed, and when the concentration of dimer **4** in the residue exceeded 65%, this dimer became concentrated in the crystals and eventually dimer **4** was obtained pure, mp 131–132.5°C; m/e (12 eV): 348 (12, M$^+$), 174 (100). *Anal.* calcd. for $C_{24}H_{28}O_2$: C 82.72, H 8.10; found: C 82.89, H 8.16.

*(2α,6aβ,11β,11aβ,11bα)-1,2,6a,11,11a,11b-Hexahydro-2,3,6a,10,11,11b-hexamethyldiindeno[7,1-*bc*:2′,1′-*e*]pyran-7-ol (5)*

Trifluoroacetic acid (0.025 mL) was added to the indene **8** (75 mg) in chloroform (0.5 mL). Work-up of the reaction mixture after 30 min and separation by ptlc gave the main component (40 mg, 54%), a 10:1 mixture of dimer **5** and the C-2 epimer, dimer **6**. Recrystallization gave pure dimer **5**, mp 167–169°C (from n-hexane); m/e (12 eV): 348 (5, M$^+$), 175 (30), 174 (100); (70 eV): 348 (3, M$^+$), 175 (100), 174 (80), 159 (43). *Anal.* calcd. for $C_{24}H_{28}O_2$: C 82.72, H 8.10; found: C 82.56, H 8.02.

*(2β,6aβ,11β,11aβ,11bα)-1,2,6a,11,11a,11b-Hexahydro-2,3,6a,10,11,11b-hexamethyldiindeno[7,1-*bc*:2′,1′-*e*]pyran-7-ol (6)*

Trifluoroacetic acid (0.2 mL) was added to the dimer **5** (0.50 g) in chloroform (5 mL) and the dark red solution was heated under reflux for 2 h. Work-up and ptlc gave a 1:1 mixture of dimers **5** and **6** (0.30

g) and a 1 : 1 mixture of dimers **3** and **4** (0.04 g). The mixture of dimers **5** and **6** (0.30 g) in methanol (20 mL) was mixed with trifluoroacetic acid (1 mL) and the solution was heated under reflux for 30 min. Work-up and ptlc gave a 1:7 mixture of dimers **5** and **6** (90 mg). Recrystallization gave pure dimer **6**, mp 173–174°C; *m/e* (12 eV): 348 (14, M^+), 175 (68), 174 (100), 159 (20); (70 eV): 348 (7.5, M^+), 175 (100), 174 (55), 159 (47). *Anal.* calcd. for $C_{24}H_{28}O_2$: C 82.72, H 8.10; found: C 83.10, H 8.41.

A laser interferometric study of sessile drop shape and contact angle

R. N. O'BRIEN AND PAUL SAVILLE
Department of Chemistry, University of Victoria, Victoria, B.C., Canada V8W 2Y2

Received March 26, 1985

R. N. O'BRIEN and PAUL SAVILLE. Can. J. Chem. **63**, 2339 (1985).

Small contact angles, such as water on glass, have been shown to be measurable interferometrically using fringes of equal thickness after the fashion of Newton's rings. The measured angle for the water on glass system was 0.049 ± 0.006 degrees of arc.

R. N. O'BRIEN et PAUL SAVILLE. Can. J. Chem. **63**, 2339 (1985).

On montre qu'on peut faire appel à l'interférométrie pour mesurer les petits angles de contact, tel celui de l'eau avec le verre, en utilisant des franges d'égale épaisseur à la manière des anneaux de Newton. L'angle de contact de l'eau avec le verre est de 0,049 ± 0,006.

[Traduit par le journal]

The contact angle of pure water on clean smooth glass has been the subject of investigation by many methods and over many years (1, 2). Contact angles are important for many reasons, not the least of which are those related to adhesion and biological aspects.

Probably the contact angle of water (on a variety of substrates) has been most often studied and especially on glass and siliceous materials generally (3, 4). For this reason it was decided to attempt to obtain the profile of a sessile drop on glass by interferometric means. A first trial was made using holographic interferometry. The interferogram was measurable but of poor quality. The technique was difficult and time consuming, and the measurements made from them were not totally convincing. A simpler method using fringes of equal thickness after the fashion of Newton's rings (Fig. 1(*a*)) where instead of a thin lens convex side down there was a "thin" drop of water convex side up. All of the other optical arrangements in Fig. 1 produced Fresnel fringes as well as true interference fringes but the Fresnel fringes are of so much greater definition (contrast between constructive and destructive interference) that the true interference fringe system was unusable. Figure 2 is an example of such a combined system produced by the optical system in Fig. 1(*b*). Fresnel fringes should have a bright spot in the centre and the fringes should be at r (the radius) = $\sqrt{1}$, $\sqrt{2}$, $\sqrt{3}$ etc. (5). Figure 2 clearly does not show this type of periodicity and this will be the subject of further research.

A series of interferograms made using the optical arrangement in Fig. 1(*a*) is shown in Fig. 3. These interferograms were taken with a 35 mm camera. The whole sequence was also recorded with a color video-recorder/camera and the monitor then photographed for measuring and reproduction. The interferograms were taken with a guard ring to avoid stray air currents and unsymmetrical evaporation (which was observed) and at room temperature (22°C ± 0.5). The parallel straight fringes interrupted by the drop's fringes are the result of the non-parallel sides of the glass flat.

A series of 12 drops were measured from opposite sides, that is the distance between fringes was measured. Each successive fringe from the edge of the drop (which could be unambiguously located) was located and the results averaged. The glass was float glass, expected to be 1/4 λ flat over 3 mm cleaned with Sparkleen laboratory detergent. The water was NANOpure water.

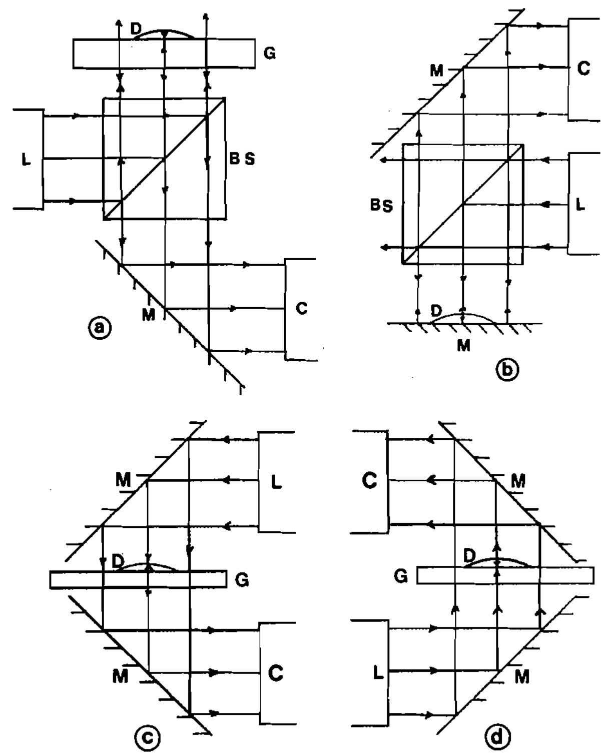

FIG. 1. Schematic diagrams of four candidate optical arrangements for interferometric determination of drop contours; (*a*) and (*b*) results are shown in Figs. 2 and 3, (*c*) and (*d*) produced similar results to (*b*). The parts are labelled L for laser (He Ne gas laser nominal 5 mW), C for camera (35 mm or video), M for first surface mirror, D for drop, and G for glass flat.

The measured contact angle was 0.049 ± 0.006 deg of arc. This agrees reasonably well with Irons (3) and Stepanov *et al.* (4) and with the general consensus that the contact angle is very small. There are even those (6) who say the angle is a "non-angle". The textbook approach is that the angle is zero or so close to it that any measurement is suspect as likely to be within the uncertainty of measurement with previously available methods. To the best of our knowledge this is the first measurement where the value is not obscured by the uncertainty of measurement.

Further work is planned in which specially prepared glass

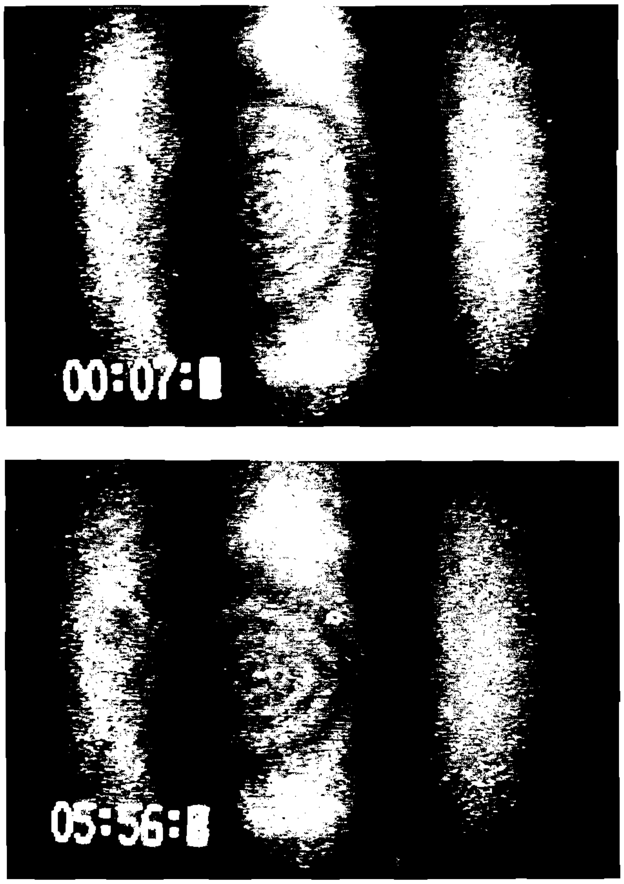

FIG. 2. Two interferograms photographed from the video monitor at the times shown after drop deposit from a drawn capillary. Note these are 5 fringes in the top frame and 4 in. in the bottom, or the drop depth has decreased by $\lambda/2$ or 316.4 nm approximately.

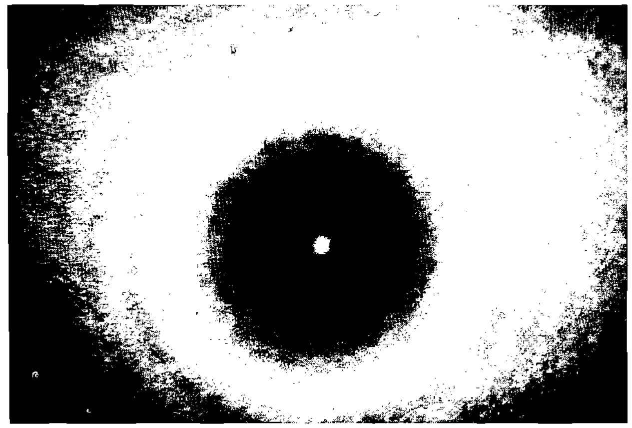

FIG. 3. An interferogram made using the optical arrangement in Fig. 1(*b*) containing a bright Fresnel diffraction pattern obscuring the fringes of equal thickness shown in Fig. 2.

flats with a minimum surface roughness will be used. Specially purified water will be tested with controlled amounts of various solutes and an attempt to add to a drop as well as to allow it to evaporate to measure advancing and retreating drop edges.

Radical ions in photochemistry. 16. The photosensitized (electron transfer) carbon–carbon bond-cleavage reaction of radical cations

AKIO OKAMOTO[1] AND DONALD R. ARNOLD[2]
Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received January 14, 1985

AKIO OKAMOTO and DONALD R. ARNOLD. Can. J. Chem. **63**, 2340 (1985).

The photosensitized (electron transfer) carbon–carbon bond cleavage of 1,1,2,2-tetraphenylethane (**1***b*), 2-(4-methoxyphenyl)-1,1-diphenyl-2-methylpropane (**1***c*), 1,1,2-triphenyl-2-methylpropane (**1***d*), and 2-(4-trifluoromethylphenyl)-1,1-diphenyl-2-methylpropane (**1***e*) has been studied with 1,4-dicyanobenzene (**2**) serving as the electron-accepting sensitizer. The oxidation potential of **1***b–e* have been measured by cyclic voltammetry. Estimation of the free-energy associated with the electron transfer between these donors (**1***b–e*) and the first excited singlet state of **2**, using the Weller equation, indicates the process is favorable in every case. There is, in every case, a one-to-one correspondence of products derived from reaction of the carbocation fragment and from the carbanion derived from the initially formed radical fragment. The efficiency of the reaction of **1***b*, which gives a good yield of diphenylmethane (**3**) and methyl diphenylmethyl ether, has been studied as a function of temperature. The observed activation energy (7.2 kcal mol^{-1}) is equated to the bond dissociation energy of the central bond of the radical cation ($1b^{+\cdot}$). The ratio of products from the unsymmetric compounds is dependent upon the redox potentials of the fragment radicals and carbocations.

Utilisant le dicyano-1,4 benzène (**2**) comme sensibilisateur accepteur d'électrons, on a étudié la réaction photosensibilisée (transfert d'électrons) de clivage de la liaison carbone–carbone du tétraphényl-1,1,2,2 éthane (**1***b*), du (méthoxy-4 phényl)-2 diphényl-1,1 méthyl-2 propane (**1***d*) et du (trifluorométhyl-4 phényl)-2 diphényl-1,1 méthyl-2 propane (**1***e*). On a mesuré les potentiels d'oxydo-réduction des composés (**1***b–e*) par voltamétrie cyclique. L'évaluation, à l'aide de l'équation de Weller, de l'énergie libre associée au transfert d'électron entre ces donneurs **1***b–e* et le premier état singulet excité indique que dans tous les cas le processus est favorisé. Dans chaque cas, il y a une correspondance du type 1 à 1 des produits provenant d'une part de la réaction de la portion carbocationique et d'autre part du carbanion issu du fragment radicalaire qui se forme initialement. On a étudié, en fonction de la température, l'efficacité de la réaction du composé (**1***b*) qui donne avec un bon rendement du diphénylméthane (**3**) et du méthoxydiphénylméthane. La valeur de l'énergie d'activation (7,2 kcal mol^{-1}) est égale à l'énergie de dissociation de la liaison centrale du cation radicalaire **1***b*$^{+\cdot}$. Le rapport des produits provenant des composés asymétriques dépend des potentiels rédox respectifs des fragments radicalaire et carbocationique.

[Traduit par le journal]

Cleavage of radical cations to the fragments, radical and carbocation, is an important general reaction, not only in the gas phase where it accounts for most of the fragments in a mass spectrum, but also in solution (1–4). Our interest in this area stems from the observed cleavage of the radical cation of methyl 2,2-diphenylethyl ether (**1***a*) generated by photosensitization (electron transfer) using electron-accepting sensitizers, e.g., 1,4-dicyanobenzene (**2**) (reaction [1]). The good yield of diphenylmethane and the acetal of formaldehyde were

$$[1]\quad \underset{\mathbf{1}a}{(C_6H_5)_2CHCH_2OCH_3} \xrightarrow[CH_3CN/CH_3OH]{h\nu\,(\text{sens. }(\mathbf{2}))} \underset{\mathbf{3}}{(C_6H_5)_2CH_2} + \underset{\mathbf{4}}{CH_3OCH_2OCH_3}$$

accounted for by Scheme 1, involving the diphenylmethyl radical (R$^\cdot$) and the α-oxycarbocation fragments (R$'$ = CH_2OCH_3) (1). We have now extended this study to a series of compounds which have in common the diphenylmethyl fragment (reaction [2]). The results, which are summarized in Table 1, indicate:

$$[a]\quad \text{Sens. (A)} \xrightarrow{h\nu} A^*$$

$$[b]\quad A^* + R\text{—}R' \rightarrow A^{-\cdot} + R\text{—}R'^{+\cdot}$$

$$[c]\quad R\text{—}R'^{+\cdot} \rightarrow R^\cdot + R'^+$$

$$[d]\quad R^\cdot + R'^+ \rightleftarrows R^+ + R'^\cdot$$

$$[e]\quad R'^+ + Nu^- \rightarrow R'\text{—}Nu$$

$$[f]\quad R^\cdot + A^{-\cdot} \rightarrow R^- + A$$

$$[g]\quad R^- + H^+ \rightarrow R\text{—}H$$

SCHEME 1

(*1*) there is a one-to-one correspondence between product derived from the carbocation and that derived from the anion via the radical; (*2*) cleavage of the radical cation can be a thermally activated process; and, (*3*) the product ratio is dependent upon the relative redox potential of the fragment radical and carbocation.

$$[2]\quad \underset{\mathbf{1}}{(C_6H_5)_2CH\text{—}R'} \xrightarrow[CH_3CN/CH_3OH]{h\nu\ (\mathbf{2})\ \ 18\,\text{h at }10^\circ\text{C}\,(80^\circ\text{C})} \begin{array}{l}(C_6H_5)_2CH_2 + R'\text{—}OCH_3\\ (C_6H_5)_2CH\text{—}OCH_3 + R'\text{—}H\end{array}$$

b: R$'$ = $CH(C_6H_5)_2$
c: R$'$ = $C(CH_3)_2C_6H_4$-4-OCH_3
d: R$'$ = $C(CH_3)_2C_6H_5$
e: R$'$ = $C(CH_3)_2C_6H_4$-4-CF_3

In this series, **1***b* represents the standard; this molecule is symmetric so only two fragments can be formed (Scheme 1, step *c*). Although **1***b* is not cleaved upon irradiation at 10°C, reaction does produce diphenylmethane and methyl diphenylmethyl ether in essentially quantitative yield at 33% conversion after irradiation for 18 h at 80°C.[3] Plotting the relative efficiency of this reaction as a function of temperature, between 50–80°C, we derived an activation energy of 7.2 kcal/mol (r = 0.989) for the rate-determining step. We suggest that this represents a minimum value, close to the bond dissociation energy for the central carbon–carbon bond in the radical cation of **1***b*.

NOTE ADDED IN PROOF: The kinetic analysis used to estimate the activation energy requires several assumptions (that the temperature dependence reflects a variation in the rate of the cleavage process, that the maximum quantum yield is one, and that the actual quantum yield is low). A more thorough analysis is in progress.

Using the oxidation potentails of **1***a–e*, listed in Table 2, in the Weller equation (5), gives an indication that electron transfer between these donors and the first excited singlet state of **2** as the acceptor is favorable in every case. The results also suggest that changing the singly occupied molecular orbital from the diphenylmethyl moiety in **1***d* and **1***e* to the methoxy-substituted ring in **1***c* has no effect.

[3] There is no reaction at 80°C without irradiation or upon irradiation without the photosensitizer.

The photosensitized (electron transfer) irradiation of **1***b* in *oxygenated* acetonitrile at ca. 40°C gives benzophenone (2*a*). The mechanism of this reaction may be more complex than simply reaction of the diphenylmethyl radical with some oxygen species.

Flash photolysis studies (temperature unspecified) involving the radical cation of **1***b* indicate formation of a transient with an intense absorption band at 330 nm which was attributed to the diphenylmethyl radical (2*b*). The radical formed by deprotonation of the radical cation should, however, have a similar absorption spectrum.

TABLE 1. The photosensitized bond-cleavage reaction of $(C_6H_5)_2CH—R'$[a]

	Conversion%		Product ratio[b]						
Product	10°C	80°C	$(C_6H_5)_2CH_2$	:	CH_3OR'	:	$(C_6H_5)_2CHOCH_3$	:	HR'
1*b*	0	30	1		—		1		—
1*c*	90	100	1		1		0		0
1*d*	40	65	1		1		Trace		Trace
1*e*	40	50	1		1		1		1

[a]All irradiations were carried out on nitrogen-purged CH_3CN/CH_3OH (3/1) solutions of $(C_6H_5)_2CH—R'$ (0.2 *M*) and (**2**) (0.05 *M*) in Pyrex tubes using a 450-W medium-pressure mercury vapor lamp (Hanovia) through Pyrex glass filters for 18 h. Extent of reaction and the product ratio were determined by ^1H nmr and are accurate to 5%. Essentially all the starting material consumed was accounted for by the products listed.

[b]The efficiency of the cleavage is temperature dependent but the ratio of products is not.

TABLE 2. Oxidation potentials measured by cyclic voltammetry[a]

Compound	$E_{1/2}$/V vs. sce
1*a*	2.15[b]
1*b*	2.01 ± 0.05
1*c*	1.5 ± 0.1
1*d*	1.97 ± 0.05
1*e*	2.1 ± 0.1
$HCH(C_6H_5)_2$	2.15 ± 0.05
$HC(CH_3)_2C_6H_4$-4-OCH_3	1.57 ± 0.05
$HC(CH_3)_2C_6H_5$	2.31 ± 0.05
$HC(CH_3)_2C_6H_4$-4-CF_3	2.7 ± 0.1

[a]In acetonitrile containing 0.1 *M* tetraethylammonium perchlorate. The anodic process is irreversible; this accounts for $E_{1/2}$ being taken as 0.03 V cathodic from the anodic peak position.

[b]Reference 1.

While the oxidation potentials of the intermediate radicals are not known, it seems likely that the substituent effect on the carbocation (6) is greater than that on the radical (7); the oxidation potentials for the intermediate cumyl radicals should therefore increase in the order *para*-methoxy < unsubstituted < *para*-trifluoromethyl (8). We see (Table 1) that the product ratios depend upon the difference in the oxidation potentials of the two fragment radicals. If electron transfer rapidly equilibrated the radicals and carbocations (Scheme 1, step *d*) so that the product ratio would depend upon the relative rate of reaction of the two possible carbocations with the nucleophile, the less stable carbocation would react more rapidly (9); such is obviously not the case.

We will investigate further the kinetics of the photosensitized (electron transfer) bond-cleavage reaction and also attempt to measure the oxidation potentials of the intermediate radicals to compare with the product ratios.

GEORGES GUIHÉNEUF, CHRISTIAN BÉNARD, ABDELJALIL LACHKAR et MARYVONNE LUÇON. Can. J. Chem. **63**, 2343 (1985).

Les spectres infrarouges des α-aminoacétates d'éthyle présentent trois bandes dans la région ν_{CO}. Les effets de solvant ont montré qu'il ne s'agit pas de résonance de Fermi. Ces spectres ont été interprétés à partir d'un modèle qui tient compte des interactions entre le doublet des électrons non liés de l'azote et le groupe carbonyle. On prévoit l'existence d'équilibres entre les conformères résultant de l'orientation variable du doublet de l'azote par rapport au groupe CO. Ce modèle a permis l'interprétation des absorptions ν_{CO} des acétates d'éthyle substitués en α par les groupes méthoxy et éthoxy.

GEORGES GUIHÉNEUF, CHRISTIAN BÉNARD, ABDELJALIL LACHKAR, and MARYVONNE LUÇON. Can. J. Chem. **63**, 2343 (1985).

Infrared spectra of ethyl α-aminoacetates show three bands in the carbonyl region. Solvent effects show that this is not due to Fermi resonance. These spectra can be interpreted using a model that considers the interactions between the nitrogen lone pair and the carbonyl group. The existence of an equilibrium between the conformers caused by the different orientations of the nitrogen lone pair with respect to the carbonyl group can be forecast. This model enables the interpretation of the carbonyl absorptions of the α-substituted (methoxy and ethoxy) ethyl acetates.

[Journal translation]

Les spectres infrarouges des composés carbonylés α-halogénés présentent un dédoublement de la band ν_{CO}. Ce phénomène, également observé avec les α-aminocétones (1, 2), α-méthoxy et α-méthylthiocétones (3, 4), a été interprété à partir de l'existence de deux conformations énergétiquement favorisées, résultant de la rotation du groupe CH_2X par rapport à la liaison $C_{(carbonyle)}$— C_α (1–13).

Nous avons constaté l'apparition de trois bandes dans le domaine d'absorption ν_{CO} de cinq α-aminoacétates d'éthyle. L'analyse des effets de solvant sur ces spectres nous a permis de mettre en évidence un équilibre conformationnel et de proposer un modèle d'interaction applicable à d'autres types de substituants.

Résultats

Les spectres infrarouges des cinq α-aminoacétates d'éthyle suivants: α-*N*,*N* diméthylamino (**1**), α-*N*,*N* diéthylamino (**2**), α-pipéridino (**3**), α-morpholino (**4**), et α-pyrrolidino (**5**) ont été enregistrés en solution dans divers solvants entre 1900 et 1650 cm^{-1}. Quelques enregistrements sont reproduits sur les figures 1 et 2.

En raison de la proximité des trois pics d'absorption, il est préférable de procéder à une décomposition de la bande complexe. Cette séparation a été réalisée en utilisant la procédure proposée par Pitha et Jones (14); le profil des bandes correspond au produit d'une fonction de Cauchy par une fonction de Gauss. On obtient ainsi les valeurs des maxima d'absorption de chaque bande et les intensités relatives (caractérisées par l'absorption au maximum de chacune d'elles), réunies dans le tableau 1. Pour comparaison, les fréquences ν_{CO} de l'acétate d'éthyle, du propionate d'éthyle, des α-fluoro, α-chloro et α-iodo acétates d'éthyle, déterminées dans les mêmes conditions, sont rassemblées dans le tableau 2.

La précision des positions et des intensités des bandes séparées varie avec l'importance de leur recouvrement. L'accord entre les absorptions expérimentales et calculées est caractérisé par l'écart moyen et par l'écart maximum entre ces deux grandeurs. L'écart moyen est compris entre 3×10^{-3} et 10^{-3} unité de densité optique; l'écart maximum est toujours inférieur à

[b]Après séparation des deux bandes.

2×10^{-2} unité de densité optique. Le spectre expérimental est donc reproduit avec une bonne précision. Nous avons vérifié que le choix des paramètres initiaux, nécessaires au calcul, n'influait pas sur les résultats. Les tests effectués ont montré que les positions des maxima d'absorption sont reproductibles à mieux que 0,5 cm^{-1} près et que l'écart sur les intensités est inférieur à 10%.

Bien que des décompositions totalement indépendantes conduisent à des positions de maxima d'absorption très voisines pour les cinq composés, il n'est pas exclu qu'une décomposition puisse accidentellement introduire une erreur supérieure à la limite de 0,5 cm^{-1}. C'est pourquoi un résultat n'est jamais exploité isolément. Seules les variations progressives sont prises en considération.

Pour les cinq α-aminoacétates d'éthyle nous avons retenu la présence de trois bandes, même si, parfois, il était possible, au vu des spectres, de se limiter à deux. Les calculs dans cette hypothèse donnent les résultats suivants: la position de la bande

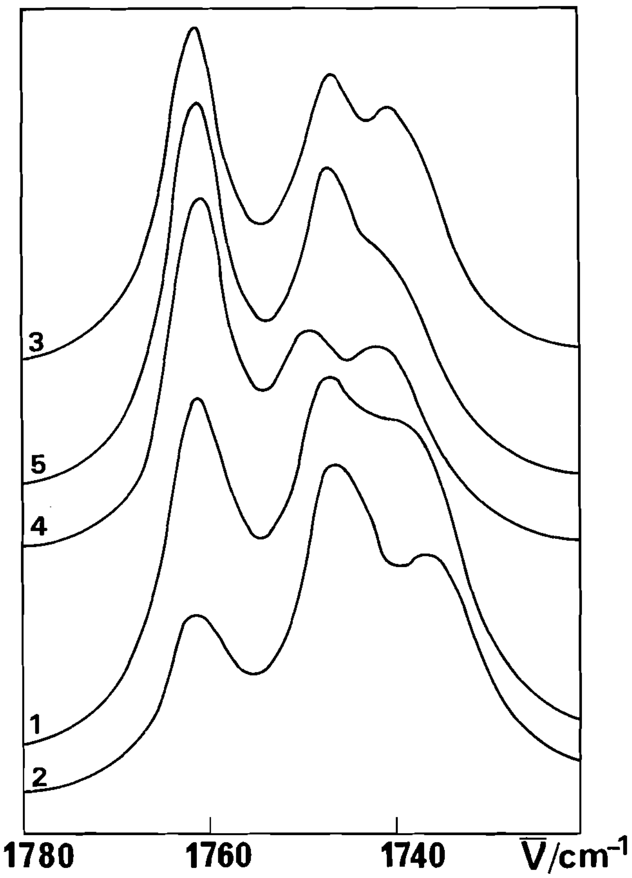

FIG. 2. Spectres des α-*N,N* diméthylamino (**1**), α-*N,N* diéthylamino (**2**), α-pipéridino (**3**), α-morpholino (**4**), α-pyrrolidino (**5**) acétates d'éthyle, en solution dans le cyclohexane.

de plus haute fréquence n'est pas modifiée mais la largeur à mi-hauteur de la deuxième bande est supérieure aux largeurs habituellement observées et son maximum après décomposition est plus proche de la première bande que le maximum apparent alors que l'on doit toujours obtenir l'inverse. Le passage à trois bandes permet d'éliminer ces anomalies.

Discussion

Dans un solvant donné, les intensités relatives des absorptions varient d'un composé à l'autre; mais dans les solvants apolaires (hydrocarbures et CCl_4) les maxima d'absorption des cinq composés se retrouvent pratiquement aux mêmes fréquences.

Nous désignerons par ν_A la bande de plus haute fréquence, par ν_B celle de fréquence intermédiaire et par ν_C la bande dont la fréquence est la plus basse. En solution dans l'heptane, par exemple, la bande ν_A est proche, pour les cinq composés, de 1763 cm^{-1}; ν_B est voisine de 1748 cm^{-1}; la dernière, ν_C, se situe vers 1740 cm^{-1}, à l'exception de **2** pour lequel la valeur est légèrement inférieure.

Cette homogénéité ne peut être fortuite et nous conduit à une première remarque: *le même phénomène doit être à l'origine de l'apparition des trois bandes pour les cinq produits étudiés.*

En solution dans l'acétonitrile, l'accord entre les positions des bandes ν_B et ν_C est moins bon. Dans ce cas, les interactions soluté–solvant sont fortes. La structure des substituants, en particulier leur encombrement, peut modifier sensiblement ces interactions et, en conséquence, les fréquences ν_B et ν_C.

Pour tous les solvants, les solutions utilisées sont très diluées et les intensités relatives des bandes sont indépendantes des concentrations. Nous pouvons donc exclure l'éventualité d'associations intermoléculaires. Trois hypothèses peuvent alors être formulées pour expliquer cette multiplicité: (a) une double résonance de Fermi entre la transition ν_{CO} et deux transitions interdites (15–17); (b) un équilibre conformationnel entre deux formes, associé à une résonance de Fermi affectant la transition ν_{CO} d'un seul des conformères; (c) un équilibre faisant intervenir trois conformations.

TABLEAU 3. Coefficients de corrélation des relations entre les fréquences ν_{CO} dans les différents solvants: α-*N,N* diméthylamino (**1**), α-*N,N* diéthylamino (**2**), α-pipéridino (**3**), α-morpholino (**4**), α-pyrrolidino (**5**) acétates d'éthyle

Corrélation de:	1	2	3	4	5
ν_B avec ν_A	0,987	0,999	0,97	0,994	0,988
ν_C avec ν_A	0,995	0,998	0,99	0,985	0,96
ν_A avec $\nu_{CH_3COOC_2H_5}$	0,965	0,99	0,987	0,99	0,987

1. *Hypothèses faisant intervenir une résonance de Fermi*

Les fréquences ν_{CO} d'un composé quelconque, en solution dans une série de solvants, sont linéairement reliées aux fréquences ν_{CO} d'un produit de référence, en solution dans les mêmes solvants (18–20). Une résonance de Fermi entraîne, pour l'une des bandes, des déviations systématiques à la relation linéaire et, en général, l'absence totale de relation pour les autres (16, 17, 21). Il n'existe pas de relation entre les fréquences des bandes du composé considéré.

En prenant l'acétate d'éthyle pour référence, chaque bande suit une relation satisfaisante et pour chaque composé les fréquences des bandes sont liées entre elles (tableau 3).

Ces résultats vont donc à l'encontre de l'hypothèse d'une résonance de Fermi.

L'analyse qualitative des variations des intensités relatives des bandes avec le solvant va dans le même sens: dans le cas d'une résonance de Fermi, la bande qui comporte la plus forte contribution de la transition fondamentale est la plus intense. L'origine de la multiplicité étant la même pour tous les produits, cette absorption, dans un solvant donné, devrait s'identifier à une même bande: ν_A, ν_B ou ν_C. Or la bande la plus intense est tantôt ν_A, tantôt ν_B et parfois ν_C. Ces observations sont incompatibles avec l'hypothèse d'une résonance de Fermi simple ou double. Il faut donc attribuer l'origine de la multiplicité ν_{CO} à un équilibre entre trois conformères.

2. *Hypothèse d'un équilibre conformationnel*

Les équilibres habituellement retenus dans le cas des molécules XCH_2COR sont les suivants[3] (fig. 3):

Les conformations où la liaison C—X, ou une liaison C—H, éclipse la liaison C═O sont plus stables que les conformations décalées (22–24): si, à l'état gazeux, la forme *anti* est prépondérante pour le chloroacétaldéhyde (25) et la fluoroacétone (26), seules les conformations *gauche* et *syn* apparaissent lorsque les molécules XCH_2COR (X = halogène) sont en solution (3–13, 25).

L'effet du substituant NR_2, en fonction de son orientation, peut être analysé uniquement à partir des interactions orbitalaires, spatiales ou à travers les liaisons, et de l'hyperconjugaison du NR_2 avec le système π du carbonyle. Il est possible

[3]Nous avons préféré les appellations *syn* et *anti* à *s-cis* et *s-trans*, souvent utilisées.

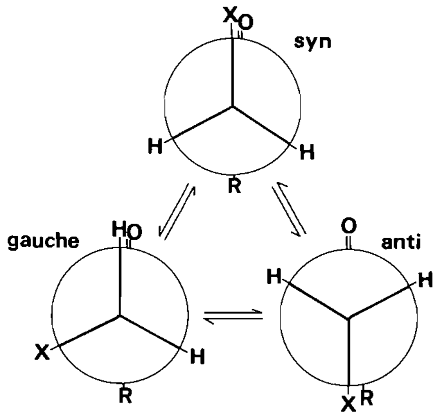

FIG. 3. Conformations privilégiées des composés XCH_2COR.

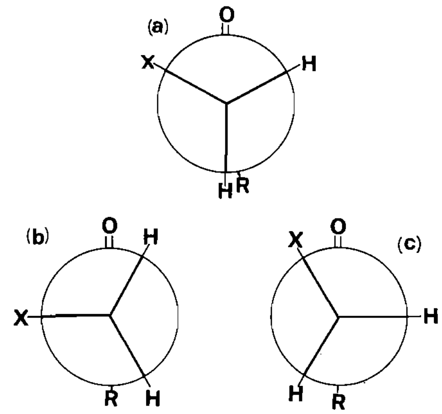

FIG. 4. Conformations décalées des composés XCH_2COR.

d'expliquer ainsi les déplacements de la transition $n - \pi$ des α-aminocétones (24). Les différences d'énergie entre les conformères, dans l'état fondamental, sont faibles et jusqu'à présent on a préféré se référer aux effets inductifs et interactions dipolaires et d'hyperconjugaison pour interpréter les variations de la fréquence ν_{CO}. Il faut remarquer que, qualitativement, les conclusions ne dépendent pas du modèle choisi.

Récemment, l'importance de l'hyperconjugaison de X avec le système π du carbonyle a été soulignée, dans le cas des cétones XCH_2COCH_3 (3). Ainsi, la variation de la fréquence ν_{CO} de 1720 cm^{-1} à 1717 cm^{-1} et à 1713 cm^{-1} dans la série X = CH_3, NMe_2, I a été attribuée, pour l'essentiel, à l'hyperconjugaison. Il ne semble pas nécessaire de prendre cet effet en considération dans la série $XCH_2COOC_2H_5$. Pour les trois mêmes substituants, on relève les valeurs suivantes: 1739,5; 1734,5 et 1739,5 cm^{-1}. La comparaison des deux séries montre que le rôle de l'hyperconjugaison est très certainement secondaire dans les acétates d'éthyle α-substitués.

L'interaction dipolaire entre les groupes CO et CX est donc le facteur primordial; elle varie avec l'orientation relative des deux dipôles et provoque le dédoublement de la bande ν_{CO}. Cet effet est maximum pour le conformère *syn*: la bande ν_{CO} de cette forme doit être située à une fréquence supérieure à celle de l'ester non substitué. Par ailleurs, la proportion de ce conformère doit augmenter avec la polarité du solvant (6, 13). Au contraire, l'interaction est faible dans la conformation *gauche* et la fréquence ν_{CO} doit être pratiquement celle de la molécule non substituée.

Ces remarques pourraient nous permettre de procéder aux corrélations suivantes: ν_A et *syn*, ν_B et *gauche*, ν_C et *anti*; mais les attributions de la bande ν_B à la forme *gauche* et de la bande ν_C à la forme *anti* sont en contradiction avec les effets de solvant. La forme *gauche* étant plus polaire que la forme *anti*, l'intensité relative de la bande correspondante (ν_B) devrait croître avec la polarité du solvant. L'inverse est observé. La considération de formes décalées parfois proposées (fig. 4) ne saurait apporter une solution satisfaisante puisqu'elles impliquent des fréquences ν_{CO} supérieures ou égales à celle de la forme *gauche*. L'hyperconjugaison maximum pour B pourrait provoquer un abaissement de la fréquence ν_{CO}, mais nous avons montré précédemment que cet effet est négligeable.

Devant l'insuffisance de ces modèles, nous proposons l'introduction d'un nouveau facteur: l'orientation du doublet d'électrons non liés de l'azote par rapport au carbonyle. Le dipôle du groupe C—X résulte de la combinaison du dipôle de la liaison C—X et du dipôle dû aux électrons non liés de X.

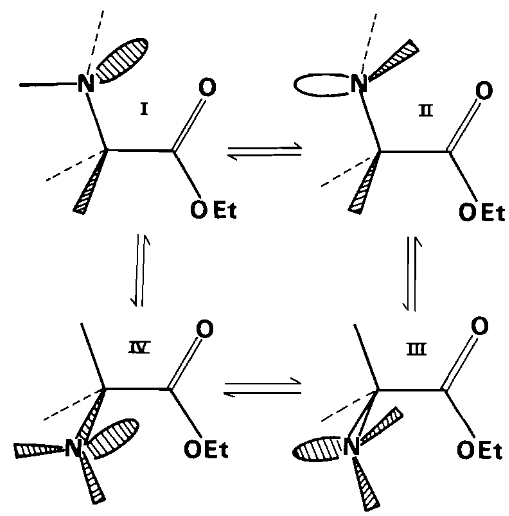

FIG. 5. Conformations des amino acétates d'éthyle.

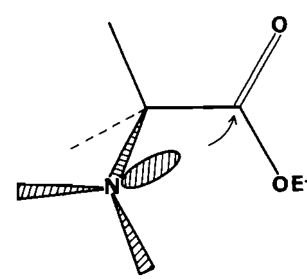

FIG. 6. Effet transannulaire dans les composés carbonylés α-aminés.

Lorsque X est un halogène, ce dipôle est dirigé selon l'axe de la liaison C—X. Ce n'est plus le cas pour X = NR_2; de plus, le dipôle formé par la liaison C—N est faible; en effet, la différence d'électronégativité entre l'atome d'azote et le carbone substitué est diminuée par le groupe CO attracteur. Le moment dipolaire du group C—NR_2 est donc essentiellement lié à l'orientation du doublet non liant de l'azote. Si, à partir des conformations *syn* et *gauche*, on envisage les diverses orientations[4] du groupe NR_2 par rapport à la liaison C—N, on

[4]Ces orientations peuvent être obtenues par rotation du groupe amino autour de la liaison C—N ou par inversion de l'azote; nos conclusions ne s'en trouvent pas modifiées.

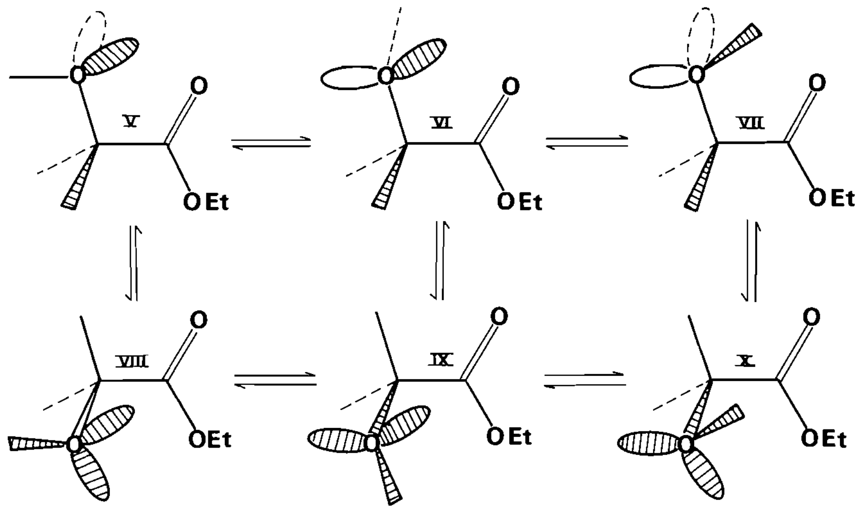

FIG. 7. Conformations des composés **6** : $CH_3OCH_2COOC_2H_5$ et **7** : $C_2H_5OCH_2COOC_2H_5$.

aboutit aux équilibres suivants (fig. 5) entre les quatre conformères I à IV: Nous avons retenu des conformations décalées pour le groupe CH_2NH_2 par analogie avec les résultats obtenus avec les amines (27), les α-aminocétones et les α-aminoaldéhydes (24).

3. *Test de validité du modèle*

Deux facteurs doivent être pris en considération: la direction relative des dipôles et leur distance (28). Le dipôle C—N étant négligeable, l'interaction est maximale pour le conformère I: en effet, l'angle dièdre entre le doublet et la liaison C=O est nul et la distance entre les deux groupes est minimale. Ce conformère est celui qui possède le moment dipolaire global le plus grand. Nous prévoyons que la fréquence ν_{CO} de I sera la plus élevée et qu'en passant d'un solvant apolaire à un solvant polaire la proportion de ce conformère augmentera, entraînant un accroissement de l'intensité relative de la bande correspondante.

Le doublet non liant de l'azote, dans la conformation II est dirigé quasi-perpendiculairement au groupe CO et la distance est plus grande que dans I. On n'attend pas d'interaction pour cette forme. Le moment dipolaire de II sera plus faible que celui de I. Le même raisonnement s'applique à III, la distance entre les dipôles étant encore plus importante. Nous ne pouvons pas espérer distinguer ces deux conformations. Les fréquences ν_{CO} de II et III doivent être confondues et semblables à celle de l'acétate d'éthyle. Par ailleurs, l'intensité relative de cette bande doit diminuer avec la polarité du solvant. Enfin, l'interaction dipolaire sera faible dans la forme IV, mais ce conformère présente la particularité d'autoriser un effet transannulaire (29) (fig. 6), déjà envisagé pour les α-morpholino et pipéridinoacétophénone (2) et prévu dans le modèle des interactions orbitalaires spatiales (24). Il en résulte un abaissement de la bande ν_{CO} correspondante par rapport à celle de l'acétate d'éthyle et la polarité attendue doit être supérieure à celle de II ou III.

Sur la base de ce modèle nous pouvons donc attendre trois bandes ν_{CO} distinctes:

La première, due aux conformations II et III, sera située à la même fréquence que celle de l'acétate d'éthyle.

La seconde, située à une fréquence supérieure, correspondra à la conformation I.

La troisième, de plus basse fréquence, sera attribuée à IV.

L'intensité relative de la bande intermédiaire devra diminuer lorsque la polarité du solvant augmentera. Les intensités des bandes extrêmes devront varier dans une faible proportion, celle de plus haute fréquence étant probablement favorisée par les solvants les plus polaires.

La confrontation de nos résultats expérimentaux avec ces prévisions montre une bonne concordance et justifie l'utilisation de ce modèle. La bande ν_A peut être attribuée à la conformation I, la band ν_B aux conformations II et IV, et la bande ν_C à la conformation III. L'évolution des intensités relatives de ces bandes en fonction du solvant confirme ces attributions: quel que soit le substrat, on note un accroissement des bandes ν_A et ν_C par rapport à ν_B lorsque la polarité du solvant augmente. Dans certains cas la bande ν_B est pratiquement absente. On note aussi que ν_A augmente légèrement plus que ν_C.

4. *Extension aux substituants méthoxy et éthoxy*

Le modèle que nous proposons doit pouvoir s'appliquer à d'autres types de substituants, en particulier aux groupes $—OCH_3$ ou $—OC_2H_5$. Les conformations à envisager doivent tenir compte de l'existence de deux doublets non liés sur l'atome d'oxygène (fig. 7).

Le moment dipolaire du conformère V est particulièrement élevé et, compte tenu des résultats obtenus pour les composés **1** et **2**, il est peu vraisemblable que la bande correspondante apparaisse, même dans les solvants les plus polaires. Les conformations VI et VII sont de ce point de vue équivalentes, de même que VIII et IX, avec une possibilité d'un effet transannulaire. Il n'existe pas de conformère analogue à II, c'est-à-dire *syn*, sans interaction dipolaire. Enfin, dans le conformère X il existe une contrainte assez forte entre les groupes CH_3 ou C_2H_5 et l'oxygène de l'ester: cette forme est vraisemblablement défavorisée.

En conséquence, nous prévoyons deux bandes principales pour les α-méthoxy (**6**) et α-éthoxy (**7**) acétates d'éthyle. La première est due aux conformères VI et VII: en négligeant le dipôle de liaison C—O et l'effet du doublet perpendiculaire au groupe C=O, nous attendons cette bande à la même position que la bande ν_A des α-aminoacétates d'éthyle. La seconde doit être située à une fréquence inférieure à celle de la molécule non substituée. Toutefois le caractère donneur de l'oxygène est moins marqué que celui de l'azote et l'effet transannulaire doit être moindre. L'abaissement de fréquence sera moins impor-

TABLEAU 4. Fréquences (cm^{-1}) et intensitiés relatives[a] des absorptions ν_{CO} des composés **6** et **7**[c]

		Solvants							
Composés	Paramètres	FC.75[b]	C_5H_{12}	C_7H_{16}	C_6H_{12}	C_2Cl_4	CCl_4	CS_2	CH_3CN

tant que pour les substituants amino. Par ailleurs l'influence des solvants doit être comparable à celle que nous observons pour les bandes ν_A et ν_C des dérivés aminés.

Les résultats expérimentaux pour **6** et **7** sont conformes à cette attente et apportent une confirmation satisfaisante au modèle retenu (tableau 4).

Partie expérimentale

Tous les produits sont commerciaux, à l'exception de **3**, **4** et **5** qui ont été préparés par les méthodes habituelles. Ils ont été purifiés immédiatement avant usage (30).

Les deux spectrophotomètres utilisés pour l'enregistrement des spectres ont été étalonnés, dans la gamme 1600–1800 cm^{-1} par rapport au spectre de la vapeur d'eau. Les écarts sont inférieurs à 0,2 cm^{-1} pour le spectrophotomètre Beckman IR 9 et 0,5 cm^{-1} pour le Perkin–Elmer 683. Les reproductibilités des nombres d'ondes sont respectivement de 0,1 et 0,2 cm^{-1}.

Les spectres sont enregistrés en double faisceau, le solvant étant placé en référence. Les concentrations des produits dans les solutions varient de 2×10^{-2} à 5×10^{-3} mol L^{-1}. Les épaisseurs des cellules, équipées de fenêtres KBr ou NaCl, sont comprises entre 0,25 et 1 mm. Les conditions de concentration et d'épaisseur de cellule sont déterminées par la solubilité du produit et la transparence du solvant dans le domaine spectral étudié.

Des cellules à épaisseur variable (0–6 mm) ont été utilisées pour l'étude de l'effet des concentrations (10^{-1} à 10^{-3} mol L^{-1}) sur l'absorption ν_{CO}.

The mechanism of the oxidative deamination and decarboxylation of serine and threonine by periodate in acid medium

ROSA PASCUAL[1] AND MIGUEL A. HERRÁEZ
Departamento de Química Física, Facultad de Química, Universidad de Salamanca, Salamanca, España

Received July 12, 1984[2]

ROSA PASCUAL and MIGUEL A. HERRÁEZ. Can. J. Chem. **63**, 2349 (1985).

The kinetics of oxidation of serine and threonine by periodate have been investigated in acid medium at 10°C. The reaction rate is first order in both periodate and amino acid, and the overall reaction follows second-order kinetics. The rates decrease with increase in $[H^+]$. A catalytic effect of the buffers was not observed in the oxidation process. An analysis of the dependence of the rate on $[H^+]$ reveals that the reactive species under the experimental conditions are periodate monoanion and dianion and the dipolar form of the amino acid. The mechanism proposed and the derived rate law are consistent with the observed kinetics. The rate constants predicted using the derived rate law are in agreement with the observed rate constants, thus justifying this rate law and hence the proposed mechanistic scheme.

ROSA PASCUAL et MIGUEL A. HERRÁEZ. Can. J. Chem. **63**, 2349 (1985).

Opérant à 10°C et dans un milieu acide, on a étudié la cinétique de l'oxydation de la sérine et de la thréonine par le periodate. La réaction est du premier ordre tant en periodate qu'en acide aminé et l'ensemble de la réaction est du deuxième ordre. Les vitesses diminuent avec une augmentation de l'acidité. On n'a pas observé d'effet catalytique des tampons sur les processus d'oxydation. Une analyse de la relation entre les vitesses de réaction et la concentration en H^+ révèle que les espèces réactives dans ces conditions expérimentales sont les monoanion et dianion du periodate et la forme dipolaire de l'acide aminé. Le mécanisme proposé ainsi que l'équation de vitesse qui en dérive sont en accord avec les cinétiques observées. Les constantes de vitesse que l'on peut prévoir en se basant sur l'équation de vitesse que l'on a obtenu sont en accord avec les constantes de vitesses observées et ces résultats justifient cette équation de vitesse et donc le schéma mécanistique proposé.

[Traduit par le journal]

Introduction

It is known that periodate is used for identifying compounds which have hydroxyl, carbonyl, or amino groups on adjacent carbon atoms, and it is a clean and relatively selective reagent for their oxidative carbon–carbon cleavage. The literature on the kinetics of the periodic acid oxidation of glycols (1, 2) is quite extensive but the kinetics of the periodate oxidation of amino alcohols (3), dicarbonyl compounds (4), and amino acids (5), however, has received much less attention. Although the oxidative capacity of this reagent has been widely utilized for the quantitative determination of serine and threonine, no kinetic investigation has been attempted in order to understand the mechanistic aspects of these reactions. It has been reported (6–8) that the reaction between periodate and serine or threonine follows the scheme:

$$CH_2(OH)\text{—}CH(NH_2)\text{—}CO_2H + 2IO_4H \rightarrow CH_2O + H\text{—}CO_2H + NH_3 + CO_2 + 2IO_3H$$

$$CH_3\text{—}CH(OH)\text{—}CH(NH_2)\text{—}CO_2H + 2IO_4H \rightarrow CH_3\text{—}CHO + H\text{—}CO_2H + NH_3 + CO_2 + 2IO_3H$$

Because serine and threonine contain groups toward which periodate is highly specific and because of the various possibilities for reaction between the different species of both periodate and amino acid that can exist in aqueous solution, it seemed that an investigation of the oxidation of β-hydroxy-α-amino acids would be of interest.

Experimental

Materials

All the chemicals were obtained from Merck, and all were of analytical grade. Doubly distilled water from alkaline permanganate was used to prepare all solutions. In each series of experiments the initial pH was maintained constant throughout each reaction by use of acetate or chloroacetate buffers. The ionic strength of the system was kept at a constant value (0.20 *M*) by the addition of sodium perchlorate. Standard stock solutions of amino acids were prepared by dissolving accurately weighed amino acid in buffer solution. Sodium periodate solution was prepared in water and titrated (9) with sodium arsenite.

Kinetic method

Reaction rates were measured by following the decrease of periodate concentration with time. The iodometric determination method of unreacted periodate in a measured aliquot of the reaction mixture at different intervals of time was found unsatisfactory. Therefore a spectrophotometric procedure was utilized and the reactions were followed by measuring the absorbance of the unreacted periodate from time to time at 310 nm, using a Pye–Unicam SP600 UV instrument. Although the absorption maximum of periodate (10) is at 222 nm, this wavelength was not of practical use because of interfering absorption by other compounds in the reaction mixture. The molar absorptivities at 310 nm were obtained at all pHs used in the experiments. Reactions were followed to ca. 80–90% conversion of the initial periodate concentration. In all cases 2–3 runs were carried out.

Stoichiometry

Varying ratios of periodate to amino acid, keeping [periodate] > [amino acid] in all buffers, were allowed to stand until the completion of the reaction. Estimation of residual oxidant showed that 2 moles of periodate are consumed per mole of amino acid. Formaldehyde was detected among the reaction products of serine (11). Since glyoxylic acid has been detected as an intermediate during the periodic acid oxidation of serine and threonine (12), the stoichiometry of the periodate–glyoxylic reaction was determined through the same procedure[3] and it was found to be 1 : 1. Carbon dioxide and formic acid were detected (13) in the reaction mixture. It was observed that no visible polymerization occurs in the presence of acrylonitrile during the course of reactions. Thus, the presence of free-radical intermediates is unlikely.

Results

The kinetics of oxidation of serine and threonine by periodate was investigated at several initial concentrations of the reactants in acid media at pH 2.1−5.0.

At constant pH with the amino acid in excess, plots of log [periodate]$_0$/[periodate] vs. time were linear, indicating that the reactions are first-order in periodate concentration [Per]. The pseudo first-order rate constants, k'_ψ, are given in Table 1. This was also confirmed by varying the periodate concentration, which did not show any change in the pseudo first-order rate constants (Table 1). The values of k'_ψ increase with amino acid concentration. Plots of log k'_ψ vs. log [amino acid]$_0$ are linear (Fig. 1) with a slope of unity in both cases, thus indicating a first-order dependence on the amino acid concentration [AA]. Under these conditions the constancy of the second-order rate constants, k''_ψ, was checked. Plots of k'_ψ against the amino acid concentration were linear with intercepts close to zero, and their slopes gave the second-order rate constants for oxidation of the amino acids. It was observed that pH changes have a marked effect on the rates of oxidation of the amino acids. The rate increases with increase in pH of the system. The plot of the observed rate constants as a function of pH is shown in Fig. 2. In this pH range the rate is unaffected by general acids or bases. This was verified by showing that the rate of oxidation of amino acids in chloroacetate or acetate buffers at constant pH, is independent of the buffer concentration (Table 2).

Discussion

Aliphatic amino acids in water are known (14) to exist almost entirely in the dipolar ionic form. The equilibrium involved in acidic media is:

$$[1]\quad \underset{AA^{\pm}}{R{-}CH(NH_3^+){-}CO_2^-} + H^+ \overset{K_a}{\rightleftharpoons} \underset{AA^+}{R{-}CH(NH_3^+){-}CO_2H}$$

In acid aqueous periodate solutions, equilibria:

$$[2]\quad H_5IO_6 \overset{K_1}{\rightleftharpoons} H_4IO_6^- + H^+$$

$$[3]\quad H_4IO_6^- \overset{K_D}{\rightleftharpoons} IO_4^- + 2H_2O$$

$$[4]\quad H_4IO_6^- \overset{K_2}{\rightleftharpoons} H_3IO_6^{2-} + H^+$$

have been detected (10) and the several equilibrium constants determined.

The results suggest that the oxidation of serine and threonine by periodic acid involves multisteps. The first-order dependence of the rate on amino acid and periodate concentration, suggests the interaction between the effective species of the reactants in the rate-limiting step.

[a]$[Per] = 8.00 \times 10^{-3}\ M$; $[AA] = 4.00 \times 10^{-2}\ M$; $I = 0.20\ M$; temperature = 10°C.

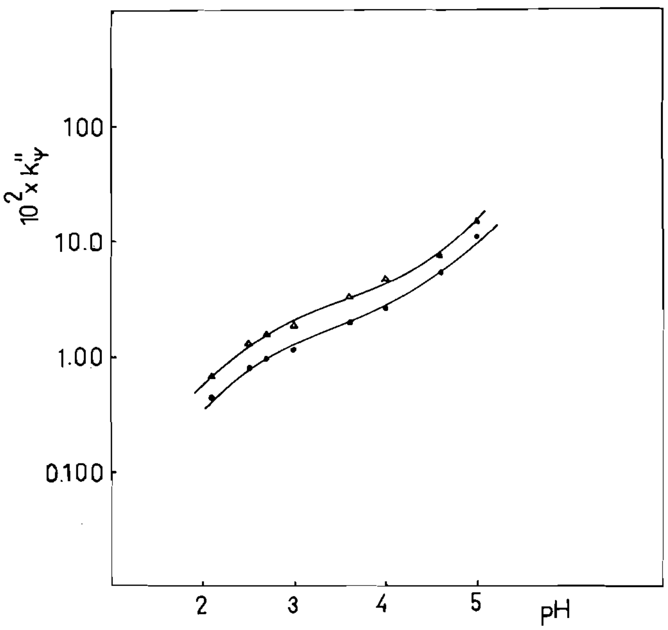

FIG. 2. Dependence of second-order rate constants on pH; ● serine; △ threonine. $[Per] = 8.00 \times 10^{-3}\ M$; $[AA] = 4.00 \times 10^{-2}\ M$; $I = 0.20\ M$; temperature = 10°C.

For the purpose of the kinetic treatment, the following scheme can be proposed:

$$[5]\quad AA + Per \underset{k_-}{\overset{k}{\rightleftharpoons}} C_1$$

$$[6]\quad C_1 \xrightarrow{k_1} Gly + aldehyde + NH_3 + IO_3H$$

$$[7]\quad Gly + Per \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} C_2$$

$$[8]\quad C_2 \xrightarrow{k_3} CO_2 + H—CO_2H + IO_3H$$

(Per represents the totality of periodic acid and its anions.) We assume that the amino acid and periodate can reversibly form a complex (C_1) which decomposes giving the intermediate glyoxylic acid (Gly), the aldehyde (formaldehyde or acetaldehyde from serine and threonine respectively), ammonia, and iodate. Glyoxylic acid has been detected as an intermediate during the periodic acid oxidation of serine and threonine (12), and it has been reported (15) that the reaction between glyoxylic acid and periodate leads to a cyclic intermediate which undergoes disproportionation to give the products.

The observation of overall second-order kinetics under all conditions tested can be interpreted as an indication that there is not accumulation of a periodate − amino acid complex. We accept that the concentrations of C_1, Gly, and C_2 are low and that we can apply the steady-state approximation to them. In

addition, if C_1 decomposes to products so rapidly that the rate of reaction is formation of C_1; i.e., $k_1 \gg k_-$, the kinetics expression for the reaction is:

$$[9]\quad -\frac{d[Per]}{dt} = k[AA][Per]$$

In order to understand the process by which periodate oxidizes serine and threonine, it is necessary to know what species of periodate are active in these reactions. The observation that the rate of oxidation increases with decrease in pK_a value of amino acid led us to consider the dipolar ionic form of the substrate as its reactive species. The pH−rate profiles for the reactions (Fig. 2), together with the pK values of Table 3, suggest that, around pH 5, the decline in rate constant as we get to higher acidities must be due to the periodate dianion, which declines in significance in that region. In the lower pH range the oxidation of substrate must be brought about by the periodate monoanion, and the rate of this reaction should be lower than the rate of reaction of periodate dianion. Then, moving further to lower pH, the second steep decline in rate constant around pH 2 can only be due to the beginning of the decline in the zwitterions of the substrates.

In analyzing the variation of reaction rate with pH, we consider that the effective reactants are the monoanion ($H_4IO_6^-$ + IO_4^-) and dianion ($H_3IO_6^{2-}$) of periodate and the dipolar ionic form of the amino acid. Thus, for the overall rate equation, we can write:

$$[10]\quad k''_\psi[Per][AA] = [k^-(Per^-) + k^{2-}(Per^{2-})][AA^\pm]$$

where (Per^-) and (Per^{2-}) represent the various periodate species for the charges represented, and k^- and k^{2-} the rate constants for reaction between dipolar amino acid and periodate monoanion and dianion respectively.

In formulating eq. [10], we assume that the rate of reaction between the undissociated periodic acid (Per^0) and dipolar ami-

no acid is negligible. Our kinetic treatment does not distinguish between the hydrated ($H_4IO_6^-$) and dehydrated (IO_4^-) forms of the periodate monoanion. The total concentration of periodate [Per] and amino acid [AA] over the acid range:

$$[11]\quad [Per] = [Per^0] + [Per^-] + [Per^{2-}]$$

$$[12]\quad [AA] = [AA^\pm] + [AA^+]$$

From the dissociation equilibria [1]–[4] and eqs. [11] and [12], eq. [9] becomes:

$$[13]\quad -\frac{d[Per]}{dt} = k''_\psi[AA][Per]$$

where:

$$[14]\quad k''_\psi = \frac{k^-K_1[H^+] + k^{2-}K_1K_2}{[H^+]^2 + K_1[H^+] + K_1K_2}\cdot\frac{K_a}{K_a + [H^+]}$$

In order to calculate the values of k^- and k^{2-} in eq. [14], we will consider the various pH regions separately. In treating the results we use values of K_1 and K_2, the apparent first and second dissociation constants of periodic acid (Table 3) expressed in terms of concentrations. They were determined for the ionic strength 0.20 M and 10°C from existing results (10).

At pH 2.1–3.0, we can ignore reactions of the periodate dianion (Per^{2-}) and eq. [14] reduces to:

$$[15]\quad k''_\psi = \frac{k^-K_1K_a}{[H^+]^2 + [H^+](K_1 + K_a) + K_1K_a}$$

Using the values of k''_ψ from Table 5 for pH ≤ 3.0 and eq. [15] in the form:

$$[16]\quad k''_\psi \cdot f_a(H^+) = k^-K_1K_a$$

where:

$$[17]\quad f_a(H^+) = [H^+]^2 + [H^+](K_1 + K_a) + K_1K_a$$

we obtain the value of $10^2 k^- = 1.52$ and $2.27\ L\ mol^{-1}\ s^{-1}$ for serine and threonine respectively. The constancy of $k''_\psi \cdot f_a[H^+]$ supports the assumption of negligible reaction between the amino acid and undissociated periodic acid in this pH range.

At pH 3.6–5.0 we consider all the amino acid to be in the dipolar ionic form, and eq. [14] becomes:

$$[18]\quad k''_\psi = \frac{k^-K_1[H^+] + k^{2-}K_1K_2}{[H^+]^2 + K_1[H^+] + K_1K_2}$$

or:

$$[19]\quad k''_\psi \cdot f_b(H^+) = k^-K_1[H^+] + k^{2-}K_1K_2$$

where:

$$[20]\quad f_b(H^+) = [H^+]^2 + K_1[H^+] + K_1K_2$$

The function $k''_\psi \cdot f_b(H^+)$ plotted against $[H^+]$ gives a straight line. From the slope and the intercept of the line, values of the individual rate constants for the oxidation of amino acids were found to be: $k^- = 1.68 \times 10^{-2}\ L\ mol^{-1}\ s^{-1}$ and $k^{2-} = 2.04 \times 10^2\ L\ mol^{-1}\ s^{-1}$ for serine and $k^- = 2.73 \times 10^{-2}\ L\ mol^{-1}\ s^{-1}$ and $k^{2-} = 2.52 \times 10^2\ L\ mol^{-1}\ s^{-1}$ for threonine.

To check the validity of eq. [14], we used it to calculate the rate constants as $[H^+]$ varies. The rate constants were evaluated from the constants in Table 4, values of $f_b(H^+)$, and corrections made for the concentration of amino acid in the dipolar form. The values of $f_b(H^+)$, and calculated values of k''_ψ are shown in Table 5, along with the experimentally observed values of k''_ψ.

In the treatment given, it has been assumed that the reaction could be represented by a summation of bimolecular reactions, each involving one molecule of periodate in one of its stages of ionization and one molecule of amino acid in the dipolar form. The data have been fitted with this assumption to within the experimental error. As calculations show, the periodate dianion is more reactive than the monoanion. A similar result has been observed (4) in the oxidation of 1,2-dioxo compounds by periodate, where an increase of the reaction rate with increase in the charge of the periodate species was shown.

Our kinetic analysis includes an attack of periodate on amino acid to form a complex. We have found no evidence for the formation of a kinetically detectable concentration of complex in the oxidation of amino acids by periodate. However, this does not rule out the possibility that substrate–periodate complexes are intermediates in oxidation if their formation, rather than their decomposition to products, is rate controlling.

Synthèse d'aryl nitronorbornènes par cycloaddition de Diels–Alder entre les aryl-nitroéthylènes et le cyclopentadiène. Justification de la stéréochimie et de la réactivité relative observées par la méthode CNDO/II. Obtention d'aryl aminonorbornènes

JEAN BOURGUIGNON, GILLES LE NARD ET GUY QUEGUINER[1]

Laboratoire de Chimie Organique Hétérocyclique, Institut National Supérieur de Chimie Industrielle de Rouen, 76130 – Mont Saint Aignan, France

Reçu le 23 mai 1984[2]

JEAN BOURGUIGNON, GILLES LE NARD et GUY QUEGUINER. Can. J. Chem. **63**, 2354 (1985).

Les synthèses d'un certain nombre d'aryl-2 nitroéthylènes (nitrostyrènes) ont été optimisées. Les nitrostyrènes ont été opposés au cyclopentadiène dans des cycloadditions de type Diels–Alder, et les aryl-3 nitro-2 norbornènes obtenus ont été réduits en aryl-3 amino-2 norbornènes. Ces composés sont susceptibles de posséder une activité dopaminergique. La stéréochimie des adduits obtenus dans les réactions de Diels–Alder a été déterminée par rmn de ^1H. Ce résultat et la réactivité relative des nitrostyrènes vis-à-vis du cyclopentadiène ont été confirmés par des calculs théoriques basés sur la méthode CNDO/II.

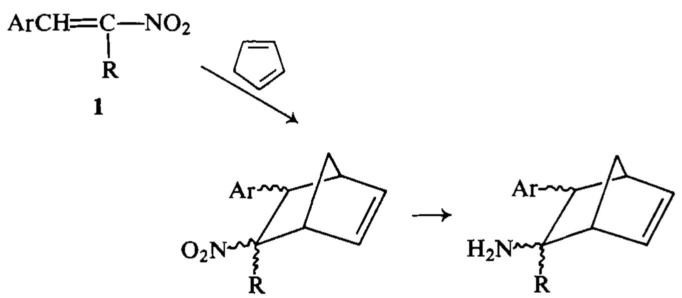
JEAN BOURGUIGNON, GILLES LE NARD, and GUY QUEGUINER. Can. J. Chem. **63**, 2354 (1985).

Syntheses of numerous 2-aryl nitroethylenes (nitrostyrenes) have been optimized. The nitrostyrenes have been reacted with cyclopentadiene in Diels–Alder cycloadditions and the 3-aryl 2-nitronorbornenes obtained have been reduced into 3-aryl 2-aminonorbornenes. These compounds are potentially dopaminergic molecules. The stereochemistry of the adducts obtained in the Diels–Alder reaction has been determined by ^1H nmr. The stereochemistry and the relative reactivity of the nitrostyrenes versus cyclopentadiene have been confirmed by theoretical calculations based on the CNDO/II method.

Les aryl-2 nitroéthylènes **1** ou nitrostyrènes sont facilement préparés par action de nitroalcanes sur des aldéhydes aromatiques. Les produits ainsi obtenus, opposés au cyclopentadiène dans les réactions de type Diels–Alder, conduisent à des aryl-3 nitro-2 bicyclo[2,2,1]heptènes-5 ou aryl-3 nitro-2 norbornènes **2**. La réduction du groupe nitro de ces composés fournit les amines correspondantes **3** qui possèdent l'enchaînement Ar—C—C—N susceptible de leur conférer une activité antiparkinsonienne (1).[3]

$$ArCHO + \underset{\displaystyle R}{\underset{|}{C}}H_2—NO_2 \longrightarrow ARCH(OH)—CH(R)—NO_2 \xrightarrow{-H_2O}$$

(R = H ou CH_3)



1 **2** **3**

Le premier β-nitrostyrène a été préparé en 1884 par deshydratation du nitroalcool résultant de la condensation du benzaldéhyde et du nitrométhane (2). Depuis, cette réaction a été effectuée dans des conditions très variées: utilisation de catalyseurs basiques divers pour réaliser la condensation, deshydratation dans des conditions très différentes les unes des autres, etc. . . . (3). Les rendements sont parfois faibles ou les procédés quelquefois difficiles à mettre en oeuvre: nous avons simplifié et amélioré les méthodes permettant de préparer les aryl-2 nitroéthylènes que nous souhaitions obtenir.

La réaction de Diels–Alder conduisant aux aryl nitronorbornènes **2** est une réaction stéréospécifique. Au départ d'un nitrostyrène de configuration donnée, elle peut donner plusieurs isomères selon la position des substituants par rapport au système bicyclique ponté: une étude spectroscopique nous a permis de préciser la structure des produits obtenus.

Nous avons par ailleurs constaté expérimentalement une réactivité très différente des nitrostyrènes vis-à-vis du cyclopentadiène. Ceci nous a incité à effectuer une étude théorique (utilisant la méthode CNDO/II). Cette étude montre une excellente corrélation entre les calculs et les résultats observés. De plus, la théorie permet aussi de justifier la stéréochimie de la réaction.

Enfin la réduction des nitronorbornènes **2** en aryl amino norbornènes **3** a été réalisée par l'intermédiaire de $LiAlH_4$ qui laisse intacte la double liaison du norbornène.

I. Synthèse des aryl-2 nitroéthylènes, aryl nitro et aryl amino norbornènes

1. *Aryl-2 nitroéthylènes 1*

$$ArCHO + CH_3NO_2 \longrightarrow \underset{\textbf{1}}{ArCH{=}CH—NO_2} + H_2O$$

Au départ du nitrométhane les aryl-2 nitroéthylènes (ou nitrostyrènes) ont été obtenus par l'une des trois méthodes suivantes: passage par un intermédiaire nitronate transformé "*in situ*" en nitrostyrène (méthode A (4)); formation d'une imine et obtention de la double liaison en milieu tamponné (méthode B (5a, 5b)); mise en oeuvre de méthodes particulières pour les aldéhydes pyridiniques (méthode C (voir partie expérimentale)).

Les rendements obtenus par l'une ou l'autre méthode sont en général supérieurs à ceux donnés dans la littérature. En série pyridinique nous avons considérablement amélioré les méthodes décrites: la réaction a lieu en quelques heures au lieu de plusieurs jours (6). Les produits obtenus sont rassemblés dans

[3]Les amines seront testées au laboratoire du Professeur Costentin de la Faculté de Pharmacie de Rouen.

le tableau 1.[4]

À partir du nitroéthane, nous avons préparé des β-méthyl β-nitrostyrènes (ou aryl-3 nitro-2 propènes-2) par une méthode très voisine de la méthode B (voir partie expérimentale).

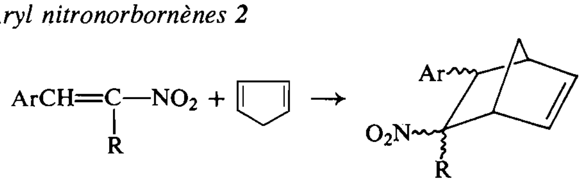
$$ArCHO + CH_3CH_2NO_2 \longrightarrow ArCH{=}C(CH_3){-}NO_2$$

Ar = phényle-1: **1***o*; thiényle-2: **1***p*

Le manque de réactivité de ces composés lors des cycloadditions de Diels–Alder ne nous a pas incité à préparer d'autres composés de ce type.

Les nitrostyrènes obtenus sont facilement identifiés en spectroscopie ir et rmn de ^{1}H. On observe en effet un couplage de 14 Hz entre les protons éthyléniques caractéristique de la configuration *E*. Par ailleurs, l'attribution au proton éthylénique voisin du cycle aromatique du déplacement chimique le plus élevé a été faite: (*i*) par comparaison avec le déplacement chimique du proton en α du cycle des β-méthyl β-nitrostyrènes $Ar{-}C(H){=}C(CH_3){-}NO_2$; (*ii*) par application de la formule de Pascual (7*a*, *b*) δ (C=C—H) = 5,28 + ΣZ_i qui permet de prévoir les déplacements chimiques du proton éthylénique selon la configuration de la double liaison (ΣZ_i étant la somme des incréments des divers groupements voisins du proton étudié).

2. *Aryl nitronorbornènes 2*



2

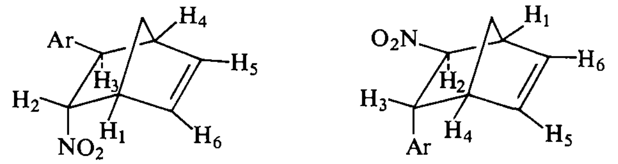
Les conditions expérimentales mises en jeu pour réaliser la cycloaddition sont de deux types: Catégorie A: réaction à température ambiante; Catégorie B: réaction vers 110 à 120°C. Certains composés n'ont pas réagi, nous les avons rangé dans la catégorie C.

Remarque: La réaction de Diels–Alder est une réaction réversible (retro Diels–Alder) lorsqu'on élève la température. Ceci nous a posé des problèmes pour purifier certains adduits par distillation (voir partie expérimentale).

Lors de la cycloaddition, la configuration *s-trans* de la partie de l'adduit correspondante au nitrostyrène peut donner deux structures différentes selon que le groupe nitro par exemple est en position "*endo*" ou "*exo*" par rapport au système bicyclique ponté.

Noland *et al.* (10) ont effectué une étude détaillée des spectres de rmn de ^{1}H des deux isomères *endo* et *exo* dans le cas du nitro-2 phényl-3 bicyclo[2,2,1]heptène-5 **2***a*. Ils n'ont pas attribué tous les signaux observés mais il apparaît cependant que le signal du proton H_2 permet de repérer sans ambiguïté les deux isomères: dans le composé "*endo*", il se présente sous la forme d'un triplet possédant un déplacement chimique de 4,18 ppm alors que dans l'isomère "*exo*" il se présente sous forme d'un quadruplet à 4,41 ppm.

L'examen de la courbe d'intégration du produit obtenu directement à partir du milieu réactionnel brut de réaction nous a permis de préciser les pourcentages des deux isomères obtenus (Tableau 1).



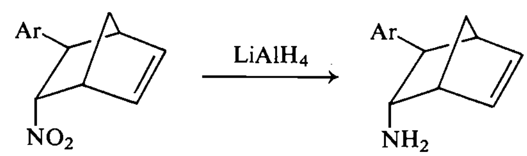
Remarque: Nous avons utilisé deux solvants différents, le toluène et l'acide acétique. Nous n'avons pas trouvé de différence entre les pourcentages des deux isomères *endo* et *exo*.

On remarque que l'on obtient de manière prépondérante l'isomère nitro "*endo*". Généralement après purification l'isomère minoritaire est éliminé. Jusqu'à présent on expliquait cette prépondérance de l'isomère nitro "*endo*" par le fait que le groupement nitro est plus petit que le groupement phényle (11). Nous verrons plus loin que l'on peut confirmer ce résultat par le calcul.

3. *Aryl aminonorbornènes 3*

La réduction du groupement nitro des aryl nitronorbornènes donne lieu à des molécules possédant l'enchaînement Ar—C—C—NH_2. Les composés possédant cet enchaînement, en particulier sous la forme "*s-trans*", sont connus pour posséder fréquemment des activités dopaminergiques et notamment antiparkinsonienne. Citons, par exemple, les plus connues de ces molécules: la dopamine, l'apomorphine, ...

Nous avons effectué la réduction du groupe nitro en utilisant $LiAlH_4$. La réaction ne pose guère de problèmes.



2 **3**

Les réductions ont été effectuées dans l'éther éthylique ou dans le tétrahydrofuranne (THF) suivant la solubilité des réactifs nitrés (Tableau 1).

L'hydrolyse du mélange réactionnel a été effectuée selon la séquence suivante: eau, puis soude, puis eau. L'hydroxyde d'aluminium est ainsi filtré facilement et la solution est évaporée laissant un produit purifiable soit par distillation, soit par chromatographie sur colonne.

Tous les produits obtenus présentent en spectroscopie infrarouge une bande intense à environ 3400 cm^{-1} correspondant à la vibration du groupe NH_2. En spectroscopie de résonance magnétique nucléaire du proton, on note le glissement d'environ 1,5 ppm vers les champs forts du proton H_2 par rapport au déplacement chimique du même proton dans le composé nitré initial (adjacent au nitro, puis après réduction à l'amino).

II. Étude de la réactivité et de la stéréospécifité lors de la réaction de Diels–Alder par la méthode CNDO/II

1. *Introduction*

La réaction de Diels–Alder est une cycloaddition qui fait intervenir un diène et un diénophile. L'étude des mécanismes de cette réaction a été fortement influencée par les règles de Woodward–Hoffmann (8). La réaction se passe en général sous contrôle orbitalaire frontalier: la plus haute orbitale occupée (H.O.) de l'un des réactifs interagit en général avec la plus basse vacante (B.V.) de l'autre réactif. Dans certains cas les

[4] Les produits préparés sont repérés par une lettre indiquée en indice après le numéro du composé. Cette lettre est utilisée pour désigner le groupe Ar et sert à identifier les divers composés **1**, **2** et **3**.

deux H.O. et B.V. de chacun des deux composés peuvent interagir si le diène et le diénophile ont des orbitales frontières de niveau d'énergie voisins (9).

La cycloaddition fait intervenir les carbones 1 et 4 du diène et les carbones 1 et 2 du diénophile (voir schéma 1). L'équation simplifiée ci-dessous exprime les interactions orbitalaires:

$$\Delta E = \frac{(C_{1\,\mathrm{H.O.}} \cdot C_{1\,\mathrm{B.V.}}\ \beta_{1.1} + C_{4\,\mathrm{H.O.}} \cdot C_{2\,\mathrm{B.V.}}\ \beta_{4.2})^2}{E_{\mathrm{H.O.\ (diène)}} - E_{\mathrm{B.V.\ (diénophile)}}} + \frac{(C_{1\,\mathrm{B.V.}} \cdot C_{1\,\mathrm{H.O.}}\ \beta_{1.1} + C_{2\,\mathrm{H.O.}} \cdot C_{4\,\mathrm{B.V.}}\ \beta'_{2.4})^2}{E_{\mathrm{H.O.\ (diénophile)}} - E_{\mathrm{B.V.\ (diène)}}}$$

$C_{1\,\mathrm{H.O.}}$: coefficient de l'orbitale atomique du carbone 1 dans l'orbitale H.O. et $\beta_{1.1}$: intégrale de résonance.

Lorsqu'on étudie le comportement d'un diène unique vis-à-vis d'une série homogène de diénophiles on peut alors simplifier encore ΔE jusqu'à l'expression ci-dessous (9):

(a) (b)

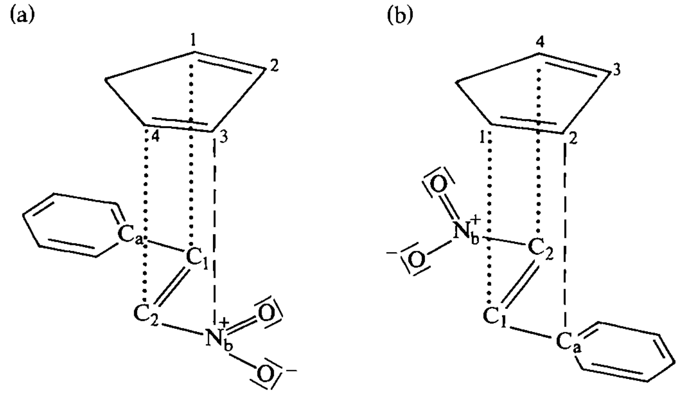

SCHÉMA 1

$$\Delta E = k - \frac{1}{E_{\mathrm{H.O.}} - E_{\mathrm{B.V.}}}$$

La réaction de Diels–Alder que nous étudions est probablement du type dit "normal". Ce diénophile comprend un groupe électroattracteur (le groupe nitro) et un cycle aromatique qui étend la conjugaison. Le niveau énergétique des orbitales vacantes doit donc être normalement considérablement abaissé. C'est ce que nous nous proposons de montrer par le calcul.

La connaissance du terme $E_{\mathrm{H.O.}} - E_{\mathrm{B.V.}}$ doit donc nous permettre en plus de comparer la réactivité de divers nitrostyrènes vis-à-vis du cyclopentadiène.

En ce qui concerne l'aspect stérique de la réaction, on sait que dans le cas des diènes cycliques le composé obtenu est majoritairement le composé "*endo*". On justifie ce résultat en examinant les interactions secondaires qui peuvent se produire à côté des interactions primaires responsables de la cycloaddition. Dans le cas de la réaction étudiée ici, ces interactions secondaires peuvent concerner soit l'azote N_b du groupe nitro soit le carbone C_a du cycle aromatique du nitrostyrène.

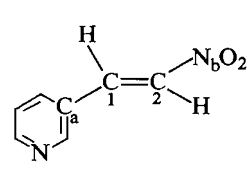
Le terme représentant cette interaction secondaire se trouve cette fois au numérateur de l'équation développée initiale. L'énergie de perturbation sera d'autant plus importante que le coefficient orbitalaire de l'atome considéré du diénophile (C_a ou N_b) sera plus élevé.

Pour évaluer ces différents termes nous permettant de répondre aux questions posées concernant la réactivité des divers nitrostyrènes et la stéréochimie de la réaction, nous avons effectué les calculs par la méthode CNDO/II: dans le cas d'une famille homogène, cette méthode fournit d'excellents éléments de comparaison (12).

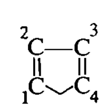
On peut négliger le rôle du solvant car c'est une réaction concertée (13).

2. *Résultats*

À partir des données géométriques fournies par la littérature (14) le calcul donne par exemple les résultats suivants dans le cas du composé **1***m* et du cyclopentadiène.



1*m*



$E_{\mathrm{H.O.}} = -12{,}76$ eV $\quad E_{\mathrm{H.O.}} = 12{,}35$ eV
$E_{\mathrm{B.V.}} = 0{,}5$ eV $\quad E_{\mathrm{B.V.}} = 3{,}05$ eV

Coefficients des orbitales frontières:

B.V.: $C_a = 0{,}2172$ $C_1 = 0{,}4828$
$C_2 = -0{,}3673$ $N_b = -0{,}3702$
H.O.: $C_a = 0{,}0199$ $C_1 = -0{,}0145$
$C_2 = -0{,}0189$ $N_b = 0{,}0087$

H.O.: $C_1 = -0{,}5778$ $C_2 = -0{,}4078$
$C_3 = 0{,}4078$ $C_4 = 0{,}5778$

3. *Discussion*

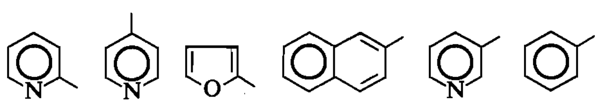
La différence $E_{H.O.} - E_{B.V.}$ la plus faible en valeur absolue est obtenue en faisant intervenir (comme prévu) la B.V. du nitrostyrène et la H.O. du cyclopentadiène: 12,85 eV contre 15,81 eV dans l'autre cas. On confirme ainsi que l'on a affaire à une réaction de Diels–Alder "normale" (9).

Par ailleurs, on observe que le coefficient orbitalaire de l'azote N_b dans le B.V. du diénophile est plus élevé que celui du carbone C_a. L'interaction secondaire attractive avec le carbone C_2 (ou C_3) du cyclopentadiène sera donc plus forte si on considère l'azote N_b et il est donc normal que l'on obtienne préférentiellement l'isomère "*endo*" nitro.

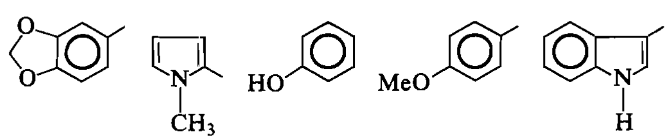
Remarque: Ce résultat est confirmé par l'examen des coefficients de l'azote N_b et du carbone C_a dans l'orbitale H.O. du diénophile: dans ce cas on observe que le coefficient du carbone C_a est plus élevé en valeur absolue que celui de l'azote N_b. L'interaction secondaire repulsive est donc plus forte si on considère le carbone C_a ce qui défavorise l'obtention de l'isomère "*endo*" aryl (15).

Nous donnons dans le tableau 2, la valeur $E_{H.O.} - E_{B.V.}$ calculée pour tous les nitrostyrènes ainsi que les valeurs absolues des coefficients orbitalaires de l'azote N_b et du carbone C_a dans les orbitales B.V. et H.O. du diénophile.

Les valeurs de $E_{H.O.} - E_{B.V.}$ permettent de déduire l'échelle de réactivité suivante:



1*l* **1***n* **1***e* **1***b* **1***m* **1***a*



1*i* **1***j* **1***g* **1***h* **1***k*

Cette séquence permet de justifier les observations expérimentales concernant les conditions dans lesquelles les divers nitrostyrènes pouvaient réagir avec le cyclopentadiène.

On peut en effet remarquer que les composés **1***a*, **1***b*, **1***e*, **1***l*, **1***m* et **1***n* qui réagissent à température ordinaire sont ceux pour lesquels $E_{H.O.} - E_{B.V.} < 12{,}91$ (catégorie A).

Les nitrostyrènes **1***g*, **1***h* et **1***i* qui réagissent à 110–120°C sont ceux pour lesquels $12{,}91 < E_{H.O.} - E_{B.V.} < 13{,}07$ (catégorie B).

Les nitrostyrènes **1***j* et **1***k* n'ont pas réagi dans les conditions utilisées. Pour **1***j* cela peut sembler anormal ($E_{H.O.} - E_{B.V.} = 13{,}01$) mais pour **1***k* cela paraît tout à fait justifié ($E_{H.O.} - E_{B.V.} = 13{,}39$).

On peut donc dire que mis à part le composé **1***j* on constate qu'il existe une très bonne corrélation entre les valeurs calculées et les résultats expérimentaux.

Nous avons pu vérifier la validité de la méthode en l'appliquant au dérivé *N*-acétylé du composé **1***k* qui réagit avec le cyclopentadiène uniquement à température élevée comme l'ont montré Royer et Beugelmans-Verrier (16). Le calcul de $E_{H.O.} - E_{B.V.}$ donne une valeur de 13,06 eV ce qui place bien ce composé dans la catégorie B.

Enfin dans le cas du β-méthyl β-nitrostyrène **1***o* le calcul de $E_{H.O.} - E_{B.V.}$ montre que l'on obtient sensiblement la même valeur lorsqu'on fait intervenir les orbitales H.O. et B.V. du diène ou du diénophile (12,90 et 13,01 eV respectivement). La réaction est alors "à demande neutre en électrons" et elle est plus difficile à réaliser (9). Ceci explique que nous n'ayons pas obtenu d'adduit avec le cyclopentadiène.

Partie expérimentale

Les points de fusion ont été déterminés sur un banc de Kofler et n'ont pas été corrigés.

Les spectres ir ont été enregistrés soit avec un spectrographe Perkin–Elmer 237 soit avec un spectrographe Beckman IR 4250: les solides sont dispersés dans du KBr sous forme de pastilles et les liquides sont insérés dans des fenêtres de NaCl sous forme de film.

Les spectres de rmn de ^1H ont été enregistrés sur un appareil Varian A60 ou Varian T60. La double irradiation a été effectuée sur un appareil Bruker WH 90D par Mme Chapelle du Service Commun de l'Université de Rouen que nous remercions à cette occasion.

Les microanalyses ont été réalisées sur un appareil Technicon. Dans les tableaux récapitulatifs, les produits pour lesquels la formule brute est donnée ont fourni des résultats corrects à l'analyse.

A. *Synthèse des nitrostyrènes*

I. *Méthode A: méthode à froid*

Dans un tricol muni d'une agitation et d'un thermomètre, on introduit 200 mL de méthanol, 61 g (1 mol) de CH_3NO_2 et 2 mL d'une solution de soude 10,5 *M*. On ajoute ensuite goutte à goutte à l'aide d'une ampoule de coulée, 1 mol d'aldéhyde en maintenant la température inférieure ou égale à 10°C. On abaisse alors la température du mélange à 5°C, puis on introduit goutte à goutte 98 mL de soude 10,5 *M* en maintenant la température inférieure à 15°C. Il se forme alors un précipité de plus en plus épais (un ajout de méthanol peut être nécessaire pour rendre le milieu plus fluide).

Après 30 min d'agitation, on introduit 350 mL d'un mélange eau–glace qui fait passer la pâte en solution. Celle-ci est alors ajoutée goutte à goutte à 100 mL d'acide chlorhydrique concentré et 150 mL d'eau. Il se forme un précipité qui est filtré, puis lavé à l'eau jusqu'à disparition de l'acidité. On recristallise dans l'éthanol.

II. *Méthode B: méthode à chaud*

Dans un ballon de 250 mL, on introduit 24,4 g (0,4 mol) de nitrométhane, 0,4 mol d'aldéhyde, 50 mL d'isopropanol puis 2,8 g de benzylamine et 2,4 g d'acide acétique glacial. Le mélange est porté 1 h à reflux. Il y a apparition d'un précipité que l'on filtre et qui est recristallisé dans l'éthanol. Dans le cas du *N*-méthyl formyl-2 pyrrole et du formyl-3 indole, le mode opératoire a été modifié comme suit: À 200 mL de nitrométhane sont ajoutés 0,1 mol d'aldéhyde et 4 g d'acétate d'ammonium. Le mélange est alors porté, sous agitation, à la température de reflux pendant une demi-heure, puis refroidi. Le nitrostyrène est alors filtré, puis recristallisé dans l'éthanol absolu.

III. *Méthode C: méthodes particulières*

1. *Synthèse de la (nitro-2 éthényl)-3 pyridine* **1**m

Dans un tricol muni d'une agitation, on introduit successivement 25 mL d'éthanol absolu, 8,6 g (0,14 mol) de nitrométhane, 0,2 g de chlorhydrate de méthylamine et 0,04 g de carbonate de sodium

TABLEAU 2. $E_{H.O.} - E_{B.V.}$ et valeurs absolues des coefficients orbitalaires de l'azote N_b et du carbone C_a dans la B.V. et la H.O. du diénophile

anhydre. On ajoute alors à cette solution vigoureusement agitée 15 g (0,14 mol) de formyl-3 pyridine. Trois jours plus tard, le mélange refroidi est filtré. Le solide jaune est alors lavé avec de l'éther sulfurique puis séché dans un dessiccateur. On obtient ainsi 11,6 g de (nitro-2 éthényl)-3 pyridine **1***m*. F = 141°C. Rendement = 55%; cristaux jaunes.

2. *Synthèse de la (nitro-2 éthényl)-2 pyridine 1*l

(*a*) Dans un ballon contenant 180 mL de nitrométhane refroidi par un bain de glace, on ajoute 53,8 g (0,5 mol) de formyl-2 pyridine. Le mélange est agité vigoureusement, et l'on ajoute 2,7 g de carbonate de potassium. On laisse réagir 15 h à 0°C puis l'on ajoute 200 à 300 mL d'éthanol absolu. On fait alors passer dans la solution un courant d'acide chlorhydrique sec, provoquant la précipitation du chlorhydrate de (nitro-2 éthanol-1)-2 pyridine qui est filtré et séché sous vide. F = 138°C. Rendement = 85%.

(*b*) À une solution de 50 mL d'anhydride acétique contenant 20,4 g (0,1 mol) de chlorhydrate de (nitro-2 éthanol-1)-2 pyridine, on ajoute 16,4 g (0,2 mol) d'acétate de sodium. Le mélange est agité et placé dans un bain de glace pendant 24 h. Il est ensuite versé dans 300 mL d'eau glacée et extrait au chloroforme. Les phases organiques rassemblées sont lavées avec une solution saturée en hydrogénocarbonate de sodium, puis avec de l'eau. Elles sont ensuite séchées sur sulfate de magnésium et évaporées sous vide à température ambiante. Le solide ainsi recueilli est dissous dans du tétrachlorure de carbone et la solution est filtrée deux fois sur charbon actif, puis évaporée à sec laissant 8,5 g d'un solide jaune: la (nitro-2 éthényl)-2 pyridine **1***l*. F = 73°C. Rendement = 57%; rendement global = 48%.

3. *Synthèse de la (nitro-2 éthényl)-4 pyridine 1*n

(*a*) À une solution de 100 mL de nitrométhane contenant 30 g (0,28 mol) de formyl-4 pyridine fraîchement distillée, on ajoute 1,5 g de carbonate de potassium en agitant fortement. La température monte à environ 35°C et le mélange est alors placé 30 min dans un bain de glace tout en maintenant l'agitation. Le solide blanc formé est alors extrait dans du méthanol, plus filtré. La solution recueillie est évaporée à sec à température ambiante laissant 41 g d'un solide blanc: la (nitro-2 éthanol-1)-4 pyridine. F = 95°C. Rendement = 90%.

(*b*) À 10 g (0,06 mol) de (nitro-2 éthanol-1)-4 pyridine en suspension dans 50 mL d'anhydride acétique sont ajoutés 9,8 g (0,12 mol) d'acétate de sodium. Le mélange est agité fortement sur bain de glace pendant quelques heures, puis versé dans 250 mL d'eau glacée. La solution obtenue est extraite au chloroforme, les phases organiques rassemblées sont lavées à l'eau, séchées sur sulfate de magnésium et

évaporée sous vide à température ambiante, laissant 6,84 g de cristaux bruns. Rendement = 76,5%; rendement global = 69%.

IV. *Synthèses des* β*-méthyl* β*-nitrostyrènes*

Dans un ballon de 250 mL on introduit 30 g (0,4 mol) de nitroéthane, 0,4 mol d'aldéhyde, 50 mL d'isopropanol, puis 1,9 g de n-butylamine et 2,4 g d'acide acétique glacial. Le mélange est porté à reflux pendant une nuit, puis refroidi. Le solide formé est filtré, lavé à l'éthanol puis recristallisé dans du méthanol.

Les caractéristiques des nitrostyrènes préparés sont indiquées dans le tableau 3.

B. *Synthèse des aryl-3 nitro-2 bicyclo*[2,2,*1*]*heptènes-5 ou arylnitronorbornènes*

Remarque: dans un souci de cohérence et de simplicité nous avons systématiquement placé le cycle avant le nitro dans l'appellation des arylnitronorbornènes sans tenir compte de l'ordre alphabétique.

Les nitrostyrènes peuvent être classés en trois catégories:

I. *Catégorie A*

Dans un erlen muni d'une agitation magnétique, on verse successivement 100 mL de toluène, 0,1 mol de nitrostyrène et 0,1 mol de cyclopentadiène fraîchement distillé. Le flacon est bouché hermétiquement et le mélange agité est laissé réagir pendant un temps variant de une journée à trois jours suivant le nitrostyrène de départ. Le toluène est alors éliminé sous vide et le résidu est purifiée par l'une des trois méthodes suivantes dans le but d'obtenir les arylnitronorbornènes purs:

méthode 1 : distillation sous vide
méthode 2 : chromatographie sur colonne
méthode 3 : filtration

II. *Catégorie B*

Dans un tricol muni d'une agitation et d'un réfrigérant, on verse 100 mL de toluène ou d'acide acétique, 0,1 mol de nitrostyrène et 0,1 mol de cyclopentadiène fraîchement préparé. Le mélange est porté à ébullition pendant environ 20 h. Le solvant est alors évaporé et la solution obtenue est traitée par distillation ou chromatographie sur colonne d'alumine.

verse 500 mL d'éther éthylique (ou de tétrahydrofuranne). L'ensemble est placé dans un bain de glace et l'on introduit 5,7 g (0,15 mol) d'hydrure d'aluminium en poudre.

On fait alors couler goutte à goutte, à l'aide d'une ampoule à brome, 0,1 mol de nitrostyrène dissous dans 100 mL de solvant. La température est maintenue inférieure à 30°C. On laisse alors réagir 30 min supplémentaires, puis on introduit successivement, avec précaution, 5,7 mL d'eau, 5,7 mL de soude à 15% et 17,1 mL d'eau. La solution est alors filtrée, séchée sur sulfate de magnésium et évaporée sous vide. Le produit obtenu est alors purifié soit par distillation (méthode 1) soit par chromatographie sur colonne d'alumine (méthode 2).

Remerciements

Il nous est agréable de remercier le Dr. André Loupy pour les discussions fructueuses que nous avons eues avec lui. Nous remercions également la Société Chimique de la Grande Paroisse pour l'aide financière nous permettant de réaliser ce travail et qui nous a approvisionné en nitroalcanes.

Some reactions of 1-methyl-1,2-dihydropyridines with organic azides. Synthesis and reactions of 1,2,5,6-tetrahydropyridylidene-2-cyan(sulfon)amides and piperidylidene-2-cyan(sulfon)amides

THEODORE A. ONDRUS, PURUSHOTTAM R. PEDNEKAR, AND EDWARD E. KNAUS[1]

Received August 7, 1984

THEODORE A. ONDRUS, PURUSHOTTAM R. PEDNEKAR, and EDWARD E. KNAUS. Can. J. Chem. **63**, 2362 (1985).

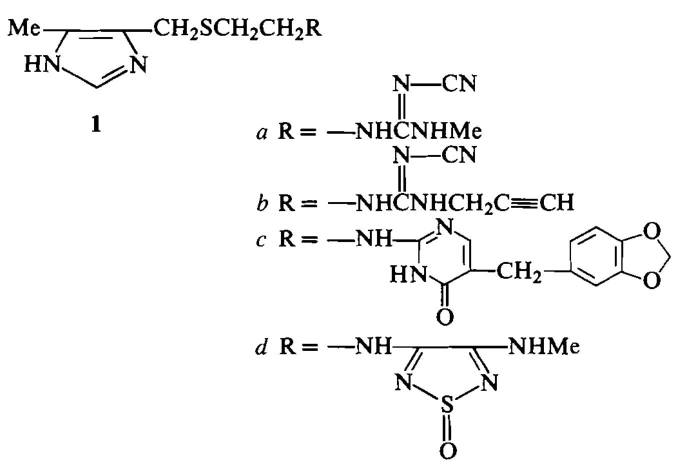
The regiospecific 1,3-dipolar cycloaddition reaction of 1,2-dihydropyridines **2** with organic azides **3** affords 2,7-diazabicyclo[4.1.0]hept-4-enes **4**. Treatment of **4***a* with neutral aluminum oxide opened the aziridine ring to afford the 1,2,5,6-tetrahydropyridylidene-2-cyanamide **5**. Catalytic hydrogenation of **4** and **5** using palladium-on-charcoal and hydrogen yielded the 1-methyl-2-piperidylidenes **6**. Oxidation of 1-methyl-1,2,5,6-tetrahydropyridylidene-2-cyanamide (**5**) with alkaline hydrogen peroxide yielded the oxirane **7** arising from epoxidation of the 3,4-olefenic bond, whereas oxidation of the bicyclic aziridine **4***a* with *m*-chloroperbenzoic acid resulted in epoxidation of the 4,5-olefenic bond and opening of the aziridine ring to give the oxirane 3-methyl-3-aza-7-oxabicyclo[4.1.0]heptylidene-4-cyanamide (**10**). Base-catalyzed abstraction of the C-3 proton of 1-methyl-2-piperidylidenes **6** yielded the 3-lithio analogs which, after bromination, were converted to the target compounds **18** upon condensation with 4-[(2-aminoethyl)thiomethyl]-5-methylimidazole.

THEODORE A. ONDRUS, PURUSHOTTAM R. PEDNEKAR et EDWARD E. KNAUS. Can. J. Chem. **63**, 2362 (1985).

La réaction de cycloaddition dipolaire-1,3 régiospécifique des dihydro-1,2 pyridines **2** avec les azotures organiques **3** conduit aux diaza-2,7 bicyclo[4.1.0]heptènes-4 **4**. L'alumine neutre provoque l'ouverture du cycle de l'aziridine du composé **4***a* et conduit au tétrahydro-1,2,5,6 pyridylidènecyanamide-2 **5**. L'hydrogénation catalytique des composés **4** et **5** en présence de palladium déposé sur du charbon permet d'accéder aux méthyl-1 pipéridylènes-2 **6**. L'oxydation du méthyl-1 tétrahydro-1,2,5,6 pyridylènecyanamide-2 **5** par de l'eau oxygénée en milieu alcalin conduit à l'oxirane **7** qui provient de l'époxydation de la liaison oléfinique en positions 3 et 4 tandis que l'oxydation de l'aziridine bicyclique **4***a* par l'acide *m*-chloroperbenzoïque conduit à l'époxydation de la liaison oléfinique en positions 4 et 5 et l'ouverture du cycle de l'aziridine donne l'oxirane méthyl-3 aza-3 oxa-7 bicyclo[4.1.0]heptylidènecyanamide-2 (**10**). L'enlèvement d'un proton en C-3 des méthyl-1 pipérylidènes-2 **6**, catalysé par une base, fournit les analogues lithiés-3 qui, après bromation et condensation sur le [(amino-2 éthyl)thiométhyl]-4 méthyl-5 imidazole, conduisent aux composés **18** attendus.

[Traduit par le journal]

The discovery of histamine H_2-receptor antagonists led to the development of cimetidine (**1***a*), which is used widely as a clinically effective inhibitor of gastric acid secretion in the treatment of duodenal ulcers and related conditions (1, 2). More recently, the development of etintidine (**1***b*) (3), oxmetidine (**1***c*) (4), and the 3,4-diamino-1,2,5-thiadiazole 1-oxide analog (**1***d*) (5) has demonstrated the potential for an increase in potency relative to cimetidine while still maintaining high H_2-receptor specificity.



In an earlier study, we showed that the regiospecific 1,3-dipolar cycloaddition reaction of 2-substituted-1,2-dihydropyridines with azides afforded diazabicyclo[4.1.0]hept-4-enes in quantitative yield (6). It was therefore of interest to investigate the 1,3-dipolar cycloaddition reaction of 1-methyl-1,2-dihydropyridines **2** with selected organic azides **3** as a method for the synthesis of 2-methyl-2,7-diazabicyclo[4.1.0]-hept-4-enes **4** for elaboration to 1-methyl-1,2,5,6-tetrahydropyridylidene-2-cyanamide **5** and 1-methyl-2-piperidylidenes **6***a*–*d*. The piperidylidenes **5** and **6***a* bear some structural similarity to the cyanoguanidine (*a*, *b*), isocytosine (*c*), and aminothiazole (*d*) R-moieties of **1**. It was therefore of interest to prepare compounds of general structure **1** utilizing **5** and **6** as potential heterocyclic pharmacophores of *a*–*d*. We now describe some chemical studies directed toward the utilization of **5** and **6** as novel heterocyclic pharmacophores for the synthesis of new heterocycles with potential H_2-receptor antagonistic activity.

Reaction of 1-methyl-1,2-dihydropyridines **2** with organic azides **3** proceeded rapidly at 0°C with evolution of nitrogen to yield 2-methyl-2,7-diazabicyclo[4.1.0]hept-4-enes (**4**) in good yield (see Scheme 1). Treatment of **4***a* with neutral aluminum oxide (Brockman Activity 1) in methylene chloride at 25°C afforded **5** (82%). Hydrogenation of either 1-methyl-1,2,5,6-tetrahydropyridylidene-2-cyanamide (**5**) or 2-methyl-2,7-diazabicyclo[4.1.0]hept-2-enes (**4***a*–*d*) using 10% palladium-on-charcoal and hydrogen gas at 35 psi (1 psi = 6.9 kPa) afforded the respective 1-methyl-2-piperidylidenes **6***a*–*d* in quantitative yield.

Treatment of **5** with alkaline hydrogen peroxide afforded the bicyclic oxirane 3-methyl-3-aza-7-oxabicyclo[4.1.0]heptylidene-2-cyanamide (**7**) in 99% yield. In contrast, reaction of **5** with *m*-chloroperbenzoic acid in methylene chloride gave only a trace yield of **7** along with unreacted **5**. Reaction of **7** with

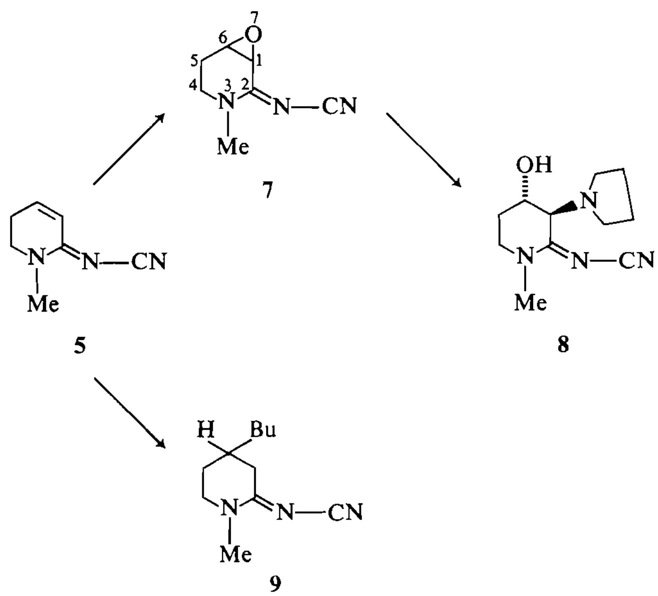
SCHEME 1



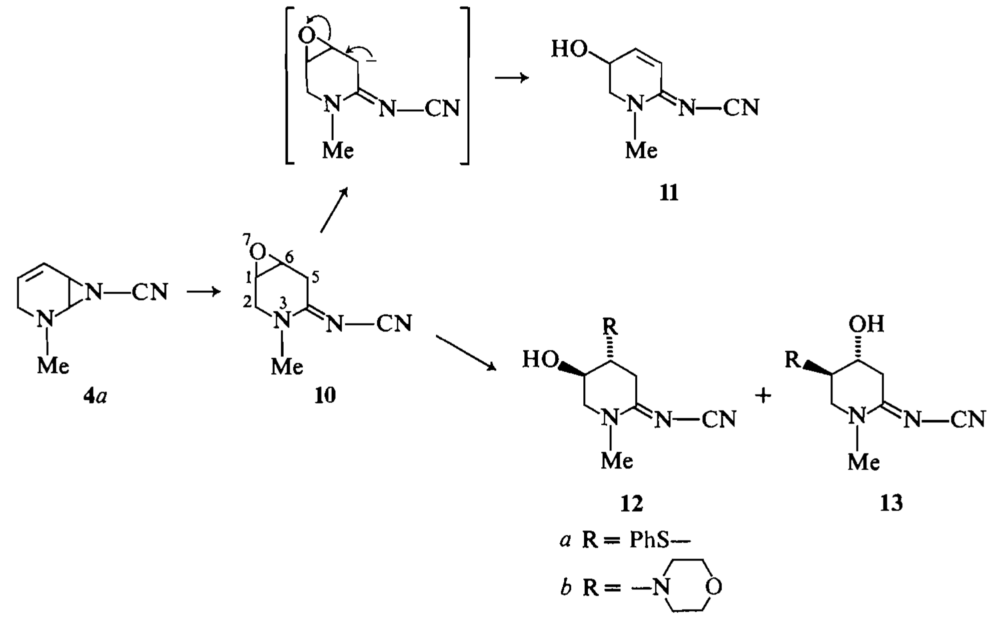
SCHEME 2

pyrrolidine as solvent and nucleophile yielded the expected *trans*-aminoalcohol **8** in 95% yield due to regiospecific nucleophilic attack at the more electropositive C-1 position. The *trans*-aminoalcohol **8** exhibited a $J_{3,4}$ coupling constant of 3.75 Hz, which is consistent with either a $J_{3,4}$ eq−eq or ax−eq coupling (7). On this basis, it was expected that **7** would serve as a useful intermediate for incorporation of the 5-methylimidazol-4-ylmethylthioethylamino moiety into the C-1 position of **7**. However, reaction of **7** with the less reactive 4-[(2-aminoethyl)thiomethyl]-5-methylimidazole in tetrahydrofuran at reflux temperature did not occur and **7** was recovered unchanged. The Michael reaction of n-butyllithium with **5** yielded **9** (89%) (see Scheme 2).

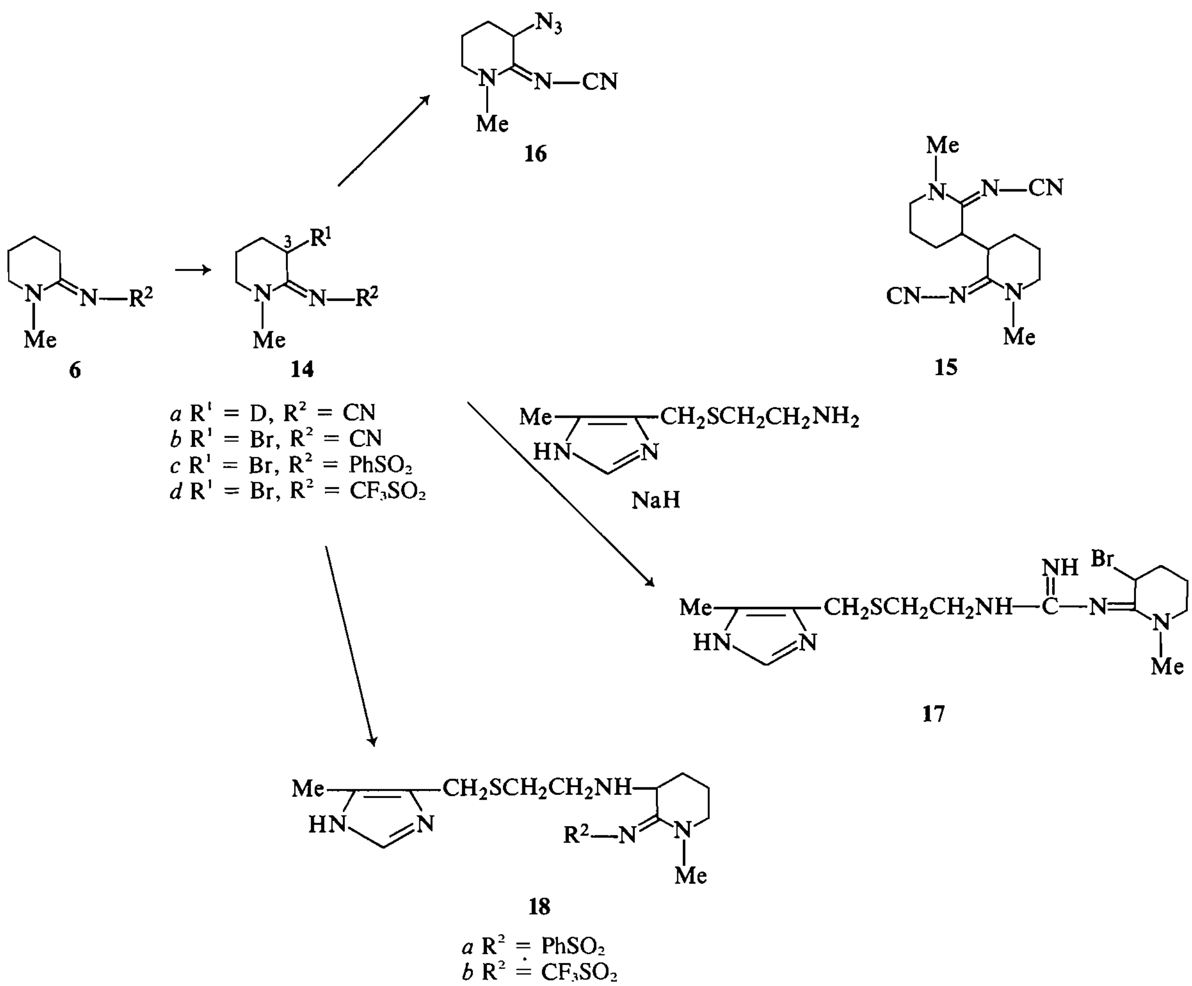
Oxidation of **4***a* with *meta*-chloroperbenzoic acid yielded the bicyclic oxirane **10** (93%) (see Scheme 3). The allylic alcohol **11** (98%) was obtained when a solution of **10** in methanol containing suspended neutral aluminum oxide was stirred at 25°C for 18 h. This reaction represents an alternative procedure to effect the oxirane-to-allylic alcohol transformation (8). The C-4 cyanamide substitutent of **10** exerts an influence in this transformation, presumably by increasing the acidity of the C-5 methylene protons, since treatment of the bicyclic oxirane **7** with neutral aluminum oxide in methylene chloride gave a complex mixture of at least five products. Reaction of **10** with sodium thiophenolate gave **12***a* and **13***a* in a ratio of 1 : 1. When the more nucleophilic sodium thiophenolate is used, **12** may be formed by either a Michael addition to **11** or by nucleophilic attack at the C-6 position of **10**. Compound **13** is formed by nucleophilic attack at the C-1 position of **10**. A similar reaction of **10** with morpholine in tetrahydrofuran at 25°C afforded a mixture of **12***b* and **13***b* (88%) which could not be separated by tlc. The bicyclic oxirane **10** is much more reactive to morpholine than is the bicyclic oxirane **7**, since **7** did not react in refluxing tetrahydrofuran.

It was expected that the C-3 position of 1-methyl-2-piperidylidenes **6** would be an active methylene. Incorporation of a suitable C-3 substituent would provide the required intermediates for condensation with 4-[(2-aminoethyl)thiomethyl]-5-methylimidazole to prepare the target compounds. Thus, reaction of **6***a* with n-butyllithium and quenching with deuterium oxide yielded **14***a*, having a C-3 deuterium substituent (see Scheme 4). Addition of the 3-lithio derivative of **6***a*, obtained from the reaction of **6***a* with n-butyllithium, to a solution of *N*-bromosuccinimide at −77°C yielded the 3-bromo derivative **14***b* (71%) together with the dimeric product **15** (22%). A similar reaction using molecular bromine afforded **14***b* (67%) and **15** (12%). The temperature and mode of addition influence the product ratios since addition of *N*-bromosuccinimide to the 3-lithio analog of **6***a* at 0°C gave **14***b* (15%) and **15** (79%). The 3-bromo derivatives **14***c* (91%) and **14***d* (90%) were prepared from **6***c* and **6***d* respectively, using *N*-bromosuccinimide. The dimeric product **15** likely arises from the subsequent reaction of **14***b* with 1-methyl-3-lithiopiperidylidene-2-cyanamide.

The preparation of 1-methyl-3-aminopiperidylidene-2-cyanamide (**14**, R^1 = NH_2, R^2 = CN) was investigated, since the 3-amino substituent would be amenable to condensation with a variety of 5-methylimidazol-4-ylmethylthioethyl agents having a good leaving substituent at the terminal position of the ethyl chain. Several attempts to prepare **14** (R^1 = NH_2, R^2 = CN) by reaction of the corresponding 3-lithio derivative with chloroamine, methoxylamine, or hydroxylamine-*O*-sulfonic acid were unsuccessful. On the other hand, reaction of the 3-bromo derivative **14***b* with sodium azide afforded the 3-azido analog **16** (100%). The reduction of the 3-azido substituent of **16** using lithium aluminum hydride or 10% palladium-on-charcoal and



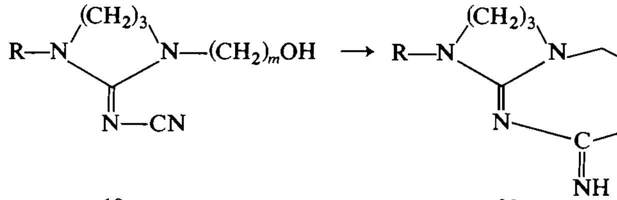
SCHEME 3



SCHEME 4

H_2 gas at 35 psi proceeded rapidly to afford a complex mixture of products from which the desired 3-amino product could not be isolated.

The reaction of the 3-bromo derivative **14***b* with 4-[(2-aminoethyl)thiomethyl]-5-methylimidazole dihydrobromide and excess sodium hydride was investigated, since nucleophilic displacement of the 3-bromo substituent of **14***b* would provide the target compound in one step. When this reaction was performed, a product which exhibited spectral and microanalytical data consistent with structure **17** (90%) was obtained. The ir spectrum of **17** did not show an absorption due to nitrile stretching but it did exhibit two C=N absorptions at 1595 and 1645 cm^{-1}, indicating that the cyano moiety had participated in the reaction. Kosasayama *et al.* have reported that the bicyclic compound **20** may be formed by intramolecular addition of the hydroxy substituent to the cyanamide moiety of **19** (9). The 3-bromopiperidylidenes **14***c* (R^1 = $PhSO_2$) and **14***d* (R^2 = CF_3SO_2) were therefore prepared in order that the undesired reaction involving the cyano group of **14***b* could be precluded.



19 20

Condensation of **14***c* and **14***d* with 4-[(2-aminoethyl)thiomethyl]-5-methylimidazole in ethanol at reflux afforded the target compounds **18***a* (43%) and **18***b* (36%) respectively.

The benzenesulfonyl analog **18***a* was evaluated as an antagonist of the positive chronotropic action of histamine in the isolated guinea pig right atrium, which is a standard assay for histamine H_2-receptor antagonists, and was found to be inactive at a concentration of 3×10^{-4} molar.

Experimental

Melting points were determined with a Büchi capillary apparatus and are uncorrected. Infrared spectra (potassium bromide unless otherwise noted) were taken on a Unicam SP 1000 or Nicolet 5DX FT spectrometer. Nuclear magnetic resonance spectra were determined for solutions in deuterochloroform, unless otherwise stated, with a Bruker AM 300, WH 200, or Varian EM 360A spectrometer and these exact mass measurements are in some instances used in lieu of elemental analysis. All of the products described gave rise to a single spot on tlc, using a solvent system less polar and more polar than the specific solvent system described for purification of the reaction mixture. No residue remained after combustion of the products purified by chromatographic procedures. Mass spectra were measured on an AEI MS-50 mass spectrometer. Preparative high pressure liquid chromatography was performed using a Water's Prep LC/System 500 A using Prep Pak-500 silica cartridges. 1,2-Dihydropyridines **2***a*,*b* were prepared according to the procedure of Fowler (10). The azides **3***b*,*c* were prepared from the reaction of the respective sulfonyl chloride with five equivalents sodium azide in acetonitrile. **Warning: Cyanogen azide is a hazardous material**. It should be handled only in solution. Concentration to pure material will result in violent detonation by heat or shock (11).

*2-Methyl-7-cyano-2,7-diazabicyclo[4.1.0]hept-4-ene (4*a*)*

A solution of 1-methyl-1,2-dihydropyridine (**2***a*, 6.18 g, 65 mmol) in 100 mL of dry ether was added slowly with stirring to a solution of cyanogen azide (65 mmol), prepared from cyanogen bromide (6.89 g, 65 mmol) and sodium azide (22.1 g, 0.325 mol), as reported previously (6), in 150 mL of acetonitrile under a nitrogen atmosphere at 0°C. The reaction mixture was allowed to warm to 25°C during 15 min. Removal of the solvent *in vacuo* gave a solid which was redissolved in 200 mL of methylene chloride. This solution was washed with water (2 × 75 mL) and the water washes were extracted with 75 mL of methylene chloride. The combined organic extracts were dried ($MgSO_4$) and the solvent removed *in vacuo* to give a pale brown solid which on recrystallization from ether–methanol (4:1 v/v) afforded **4***a* (7.11 g, 81%); mp 118°C; ir: 1560 (C=C), 2160 (CN) cm^{-1}; ^1H nmr δ: 3.18 (s, 3H, Me), 3.41 (m, 2H, H-1, H-6), 4.06 (m, 2H, H-3), 5.83 (m, 2H, H-4, H-5). *Exact Mass* calcd. for $C_7H_9N_3$: 135.0796; found (high resolution ms): 135.0796.

*2,5-Dimethyl-7-cyano-2,7-diazabicyclo[4.1.0]hept-4-ene (4*b*)*

Reaction of **2***b* (9.69 g, 65 mmol) with cyanogen azide (5.1 g, 75 mmol), using the procedure outlined for the preparation of **4***a*, gave **4***b*, yield (76%); mp 117°C; ir: 2175 (CN) cm^{-1}; ^1H nmr δ: 1.8 (s, 3H, C(5)-Me), 3.17 (s, 3H, N-Me), 3.3 (m, 2H, H-1, H-6), 4.01 (m, 2H, H-3), 5.52 (m, 1H, H-4). *Exact Mass* calcd. for $C_8H_{11}N_3$: 149.0953; found (high resolution ms): 149.0951.

*2-Methyl-7-benzenesulfonyl-2,7-diazabicyclo[4.1.0]hept-4-ene (4*c*)*

A solution of **2***a* (20 mmol) in 100 mL of ether was added to a solution of **3***b* (20 mmol) in 5 mL of ether and the reaction was completed as outlined for the preparation of **4***a*, to give a red viscous product (5.4 g). The product was purified by preparative tlc, using eleven 200 × 200 mm silica gel G plates, 1.0 mm in thickness, with benzene – ethyl acetate (1:1 v/v) as development solvent. Extraction of the band having R_f 0.45 yielded **4***c* (2.58 g, 51%); mp 78°C; ir: 1570 (C=C) cm^{-1}; ^1H nmr δ: 3.08 (s, 3H, Me), 3.6 (m, 2H, H-1, H-6), 3.95 (m, 2H, H-3), 5.7 (m, 2H, H-4, H-5), 7.5 (m, 3H, *meta* and *para* phenyl hydrogens), 8.0 (m, 2H, *ortho* phenyl hydrogens). *Exact Mass* calcd. for $C_{12}H_{14}N_2O_2S$: 250.0756; found (high resolution ms): 250.0766.

*2-Methyl-7-trifluoromethanesulfonyl-2,7-diazabicyclo[4.1.0]hept-4-ene (4*d*)*

Reaction of **2***a* (20 mmol) with **3***c* (30 mmol), using the procedure outlined for the preparation of **4***a*, gave a red viscous oil (3.35 g) which was purified by preparative tlc using twelve 200 × 200 mm silica gel G plates, 0.75 mm in thickness, with benzene – ethyl acetate (1:1 v/v) as development solvent. Extraction of the band having R_f 0.6 yielded **4***d* (2.0 g, 41%); mp 70°C; ir: 1605 (C=C) cm^{-1}; ^1H nmr δ: 3.25 (s, 3H, Me), 3.66 (m, 2H, H-1, H-6), 4.17 (m, 2H, H-3), 5.86 (m, 2H, H-4, H-5). *Exact Mass* calcd. for $C_7H_9N_2O_2SF_3$: 242.0337; found (high resolution ms): 242.0332.

1-Methyl-1,2,5,6-tetrahydropyridylidene-2-cyanamide (5)

A mixture of **4***a* (2.0 g, 14.8 mmol) and neutral aluminum oxide (10 g, Brockman Activity 1) suspended in 50 mL of methylene chloride was stirred for 24 h at 25°C. The alumina was filtered and washed with 200 mL of ethyl acetate. Removal of the solvent from the combined organic extracts *in vacuo* afforded a white solid (1.6 g) which was shown by ^1H nmr to consist of 82% **5** and 18% **4***a* as determined from the integrals of H-4 and H-5 at 5.83 δ for **4***a* and of H-3 and H-4 at 6.63 δ for **5**. A pure sample of **5** was obtained by preparative hplc (1.55 g reaction mixture) using ethyl acetate – methylene chloride (1:9 v/v) as eluant at a flow rate of 250 mL min^{-1}. Collection of the first 1500 mL eluant gave **5** (0.531 g); mp 66°C; ir: 2150 (CN), 1555 (C=N) cm^{-1}; ^1H nmr δ: 2.53 (m, 2H, H-5), 3.13 (s, 3H, Me), 3.57 (m, 2H, H-6), 6.63 (m, 2H, H-3, H-4). *Exact Mass* calcd. for $C_7H_9N_3$: 135.0797; found (high resolution ms): 135.0797. Collection of the 1500 to 2500-mL eluant gave 0.848 g of a mixture of **5** and **4***a* in a ratio of 4.55:1, as determined by ^1H nmr integrals. The 2500 to 3500-mL fraction gave 0.145 g of a mixture of **5** and **4***a* in a ratio of 1.6:1, as determined by ^1H nmr integrals.

*1-Methylpiperidylidene-2-cyanamide (6*a*)*

Method A

Hydrogenation of **5** (0.0675 g, 0.5 mmol) in 75 mL of methanol using 30 mg of 10% palladium-on-charcoal and hydrogen gas at 35 psi for 4 h at 25°C, followed by filtration and removal of the solvent *in vacuo*, afforded **6***a* (68.5 mg, 100%); mp 98°C; ir: 2160 (CN) and 1590 (C=N) cm^{-1}; ^1H nmr δ: 1.9 (m, 4H, H-4, H-5), 2.82 (m, 2H, H-3), 3.13 (s, 3H, Me), 3.47 (m, 2H, H-6). *Exact Mass* calcd. for $C_7H_{11}N_3$: 137.0952; found (high resolution ms): 137.0952.

A similar hydrogenation of the mixture **4***a* and **5**, obtained by treatment of **4***a* with neutral aluminum oxide as described above, also yielded **6***a* in quantitative yield.

Method B

Hydrogenation of **4***a* (0.135 g, 1 mmol) in 25 mL of methanol using

50 mg of 10% palladium-on-charcoal and hydrogen gas at 35 psi for 4 h at 25°C, as described in Method A above, also afforded **6***a* (0.137 g, 100%).

*1,4-Dimethylpiperidylidene-2-cyanamide (***6**b*)*

Reduction of **4***b* (2.23 g, 15 mmol) in 50 mL of methanol using 400 mg of 10% palladium-on-charcoal and hydrogen gas at 35 psi for 24 h, as described in Method A, gave **6***b* (2.26 g, 100%) as a white solid; mp 94°C; ir: 2180 (CN) and 1598 (C=N) cm^{-1}; ^{1}H nmr δ: 1.04 (d, J = 5 Hz, 3H, C(4)-Me), 1.2–2.15 (m, 3H, H-4, H-5), 2.35 (m, 1H, H-3), 2.9 (m, 1H, H-3), 3.05 (s, 3H, N-Me), 3.44 (m, 2H, H-6). *Exact Mass* calcd. for $C_8H_{11}N_3$: 151.1109; found (high resolution ms): 151.1107.

*1-Methylpiperidylidene-2-benzenesulfonamide (***6**c*)*

The reduction of **4***c* (76 mg, 0.304 mmol) in 25 mL of methanol using 50 mg of 10% palladium-on-charcoal and hydrogen gas at 35 psi for 3 h at 25°C, as outlined in Method A, yielded **6***c* (77 mg, 100%) as a white solid; mp 104°C; ir: 1580 (C=N) cm^{-1}; ^{1}H nmr δ: 1.6–1.89 (m, 4H, H-4, H-5), 2.89–3.2 (m, 5H, H-3, Me), 3.2–3.5 (m, 2H, H-6), 7.48 (m, 3H, *meta* and *para* phenyl hydrogens), 7.96 (m, 2H, *ortho* phenyl hydrogens). *Anal.* calcd. for $C_{12}H_{16}N_2O_2S$: C 57.12, H 6.39, N 11.10; found: C 56.80, H 6.57, N 11.14. *Exact Mass* calcd. for $C_{12}H_{16}N_2O_2S$: 250.0767; found (high resolution ms): 250.0766.

*1-Methylpiperidylidene-2-trifluoromethylsulfonamide (***6**d*)*

Hydrogenation of **4***d* (0.3 g, 1.24 mmol) in 50 mL of methanol using 100 mg of 10% palladium-on-charcoal and hydrogen gas at 35 psi for 3 h, as described in Method A, afforded **6***d* (0.303 g, 100%) as a colorless oil; mp ≃ 20°C; ir: 1600 (C=N) cm^{-1}; ^{1}H nmr δ: 1.82 (m, 4H, H-4, H-5), 3.0 (m, 2H, H-3), 3.12 (s, 3H, Me), 3.5 (m, 2H, H-6). *Exact Mass* calcd. for $C_7H_{11}N_2O_2SF_3$: 244.0493; found (high resolution ms): 244.0493.

3-Methyl-3-aza-7-oxabicyclo[4.1.0]heptylidene-2-cyanamide (7)

Hydrogen peroxide (1.3 mL of 30%, 11.6 mmol) was added slowly with stirring to a solution of **5** (1.05 g, 7.7 mmol) in 50 mL of methanol at 0°C. A solution of sodium hydroxide (3.85 mL of 1 *M*, 3.85 mmol) was added slowly with stirring and the reaction mixture was stirred for 15 min at 0°C prior to pouring onto 100 mL of ice water. The mixture was neutralized (38.5 mL of 0.1 *N* hydrochloric acid), extracted with methylene chloride (3 × 100 mL), the extract dried ($MgSO_4$), and the solvent removed *in vacuo* to afford **7** as a white solid (1.14 g, 99%); mp 111°C; ir: 2200 (CN) and 1595 (C=N) cm^{-1}; ^{1}H nmr δ: 1.85–2.75 (complex m, 2H, H-5), 3.13 (s, 3H, Me), 3.0–3.75 (complex m, 2H, H-4), 3.82 (m, 1H, H-6), 4.22 (d, $J_{1,6}$ = 4 Hz, 1H, H-1). *Exact Mass* calcd. for $C_7H_9N_3O$: 151.0746; found (high resolution ms): 151.0747.

trans-*1-Methyl-3-(1-pyrrolidinyl)-4-hydroxypiperidylidene-2-cyanamide (8)*

A solution of **7** (0.151 g, 1 mmol) in 50 mL of pyrrolidine was heated at reflux for 20 h and the solvent was removed *in vacuo* to yield a yellow semi-solid. The reaction product was purified on four 200 × 200 mm silica gel G plates, 1.0 mm in thickness, with methylene chloride – methanol (19:1 v/v) as development solvent. Extraction of the fraction having R_f 0.49 yielded **8** (0.193 g, 95%); mp 105°C; ir: 3305 (OH), 2210 (CN), and 1598 (C=N) cm^{-1}; ^{1}H nmr δ: 1.75 (m, 4H, H-3 and H-4 of pyrrolidine ring), 2.0–2.6 (m, 2H, H-5), 2.6–3.0 (m, 4H, H-2 and H-5 of pyrrolidine ring), 3.1 (s, 3H, Me), 3.51 (m, 2H, H-6), 3.88 (d, $J_{3,4}$ = 3.75 Hz, 1H, H-3), 4.3 (m, 1H, H-4, coupled to C(4)-OH), 4.53 (br s, 1H, OH, exchanges with deuterium oxide). *Exact Mass* calcd. for $C_{11}H_{18}N_4O$: 222.1480; found (high resolution ms): 222.1479.

1-Methyl-4-n-butylpiperidylidene-2-cyanamide (9)

A solution of **5** (0.162 g, 1 mmol) in 10 mL of dry tetrahydrofuran was added slowly with stirring to a solution of n-butyllithium (1 mmol) in 25 mL of dry tetrahydrofuran under a nitrogen atmosphere at −77°C. The reaction mixture was allowed to warm to 25°C during 20 min and then 50 mL of water was added. Extraction with methylene chloride (2 × 50 mL), drying the organic extract ($MgSO_4$), and removal of the solvent *in vacuo* afforded an orange oil. Preparative silica gel G tlc on four 200 mm × 200 mm plates, 1.0 mm in thickness, was performed using methylene chloride – methanol (19:1 v/v) as development solvent. Extraction of the band having R_f 0.81 yielded **9** as a colorless oil (0.145 g, 89%); ir (film): 2185 (CN) and 1598 (C=N) cm^{-1}; ^{1}H nmr δ: 0.9 (t, J = 7 Hz, 3H, —$(CH_2)_3$*CH_3*), 1.32 (m, 6H, —*$(CH_2)_3$*CH_3), 1.5–2.2 (m, 3H, H-4, H-5), 2.37 (m, 1H, H-3), 3.1 (s, 3H, N-Me), 2.85–3.2 (m, 1H, H-3), 3.43 (m, 2H, H-6). *Exact Mass* calcd. for $C_{11}H_{19}N_3$: 193.1579; found (high resolution ms): 193.1580.

3-Methyl-3-aza-7-oxabicyclo[4.1.0]heptylidene-4-cyanamide (10)

The bicyclic compound **4***a* (0.54 g, 4 mmol) was added to a suspension of *meta*-chloroperbenzoic acid (2.43 g of 85%, 12 mmol) in 75 mL of methylene chloride at 25°C with stirring. The reaction mixture was heated at reflux for 72 h and, after cooling, the stoppered vessel and contents were placed in the freezer for 2 h. The reaction mixture was filtered to remove the acids present (1.21 g). The filtrate was evaporated *in vacuo* to give a pale yellow solid, which was partitioned between 75 mL of ether and 75 mL of water. The aqueous fraction was extracted with a further 75 mL of ether and the combined ether extracts were washed with water. Removal of the water from the aqueous fraction *in vacuo* (<40°C) afforded a yellow product, which was dissolved in methylene chloride (5 mL) and the solvent removed *in vacuo* to yield **10** as a pale yellow solid (0.559 g, 93%); mp 106°C; ir: 2180 (CN) and 1603 (C=N) cm^{-1}; ^{1}H nmr δ: 3.02 (m, J_{5gem} = 20 Hz, 1H, H-5), 3.07 (s, 3H, N-Me), 3.5 (m, 2H, H-1, H-6), 3.63 (m, J_{5gem} = 20 Hz, 1H, H-5′), 3.78 (m, J_{2gem} = 15 Hz, 1H, H-2), 3.88 (m, J_{2gem} = 15 Hz, 1H, H-2′). *Exact Mass* calcd. for $C_7H_9N_3O$: 151.0746; found (high resolution ms): 151.0742.

1-Methyl-5-hydroxy-1,2,5,6-tetrahydropyridylidene-2-cyanamide (11)

A solution of **10** (0.151 g, 1 mmol) in 5 mL of methanol was added to a suspension of neutral aluminum oxide (5 g, Brockman Activity 1) in 25 mL of methanol with stirring. The mixture was stirred for 18 h at 25°C, filtered, and the solvent removed *in vacuo* to yield a white solid. Dissolution in 10 mL of methylene chloride, filtration, and removal of the solvent *in vacuo* afforded **11** as a pale yellow solid (0.148 g, 98%); mp 141°C; ir: 3340 (OH), 2090 (CN), 1655 (C=C), and 1585 (C=N) cm^{-1}; ^{1}H nmr (DMSO-d_6) δ: 3.03 (s, 3H, Me), 3.51 (m, 2H, H-6), 4.32 (d, $J_{5,OH}$ = 6 Hz of d, $J_{5,6}$ = 5 Hz of d, $J_{4,5}$ = 4.5 Hz, 1H, H-5), 5.59 (d, $J_{5,OH}$ = 6 Hz, 1H, OH, exchanges with deuterium oxide), 6.42 (d, $J_{3,4}$ = 10 Hz, 1H, H-3), 6.8 (d, $J_{3,4}$ = 10 Hz of d, $J_{4,5}$ = 4.5 Hz, 1H, H-4). *Exact Mass* calcd. for $C_7H_9N_3O$: 151.0746; found (high resolution ms): 151.0743.

trans-*1-Methyl-4-phenylthio-5-hydroxypiperidylidene-2-cyanamide (***12**a*) and* trans-*1-methyl-4-hydroxy-5-phenylthiopiperidylidene-2-cyanamide (***13**a*)*

A solution of **10** (0.151 g, 1 mmol) in 2 mL of dry tetrahydrofuran was added slowly with stirring to a suspension of sodium thiophenolate (1.1 mmol) in 25 mL of tetrahydrofuran at −77°C under a nitrogen atmosphere. After 30 min, the reaction mixture was allowed to warm to 25°C during 30 min, at which time all material dissolved. The reaction mixture was acidified (11 mL of 0.1 *N* HCl) and the solvent removed *in vacuo* to yield a semi-solid. Extraction with 5 mL of methylene chloride, filtration, and removal of the solvent *in vacuo* afforded a solid, which was purified by preparative silica gel G tlc on three 200 × 200 mm plates, 1.0 mm in thickness, with ether–methanol (10:1 v/v) as development solvent. Extraction of the band having R_f 0.41 yielded **12***a* (0.159 g, 49%); mp 135°C; ir: 3345 (OH), 2195 (CN), and 1615 (C=N) cm^{-1}; ^{1}H nmr (DMSO-d_6) δ: 2.96 (s, 3H, N-Me), 2.4–4.08 (complex m, 5H, H-3, H-5, H-6), 4.12 (m, 1H, H-4), 5.72 (m, 1H, OH, exchanges with deuterium oxide), 7.4 (m, 5H, Ph). *Anal.* calcd. for $C_{13}H_{15}N_3OS$: C 59.75, H 5.78, N 16.08; found: C 59.35, H 5.65, N 16.14. Extraction of the fraction having R_f 0.58 afforded **13***a* (0.168 g, 51%); mp 98°C; ir: 3430 (OH), 2180 (CN), and 1603 (C=N) cm^{-1}; ^{1}H nmr δ: 3.03 (s, 3H, N-Me), 2.58–3.32 (m, 2H, H-3), 3.32–3.82 (m, 3H, H-5, H-6), 3.97 (m, 1H, H-4), 4.8 (br s, 1H, OH, exchanges with deuterium oxide), 7.38

(m, 5H, Ph). *Anal.* calcd. for $C_{11}H_{15}N_3OS$: C 59.75, H 5.78, N 16.08; found: C 59.73, H 5.63, N 16.17.

trans-1-Methyl-4-(4-morpholino)-5-hydroxypiperidylidene-2-cyanamide (12b) and trans-1-methyl-4-hydroxy-5-(4-morpholino)piperidylidene-2-cyanamide (13b)

Morpholine (0.18 mL, 2 mmol) was added to a solution of **10** (0.151 g, 1 mmol) in 50 mL of dry tetrahydrofuran with stirring. The reaction was allowed to proceed for 25 h at 25°C. Removal of the solvent *in vacuo* gave an oily brown solid, which was subjected to preparative silica gel G tlc on four 200 × 200 mm plates, 1.0 mm in thickness, with methylene chloride – methanol (15:1 v/v) as development solvent. Extraction of the band having R_f 0.25 gave a mixture of **12*b*** and **13*b*** (0.21 g, 88%); mp 135–139°C; ir: 3380 (OH), 2095 (CN), and 1601 (C=N) cm^{-1}; ^{1}H nmr (300 MHz) δ: 2.63 (m, morpholino H-3, H-5), 3.08 and 3.10 (two singlets, 3:1 ratio, 3H, N-Me), 3.73 (m, 4H, morpholino H-2, H-6), 3.97 (br s, 1H, OH, exchanges with deuterium oxide), 3.15–4.37 (complex m, 5H, H-3, H-4, H-5, H-6). The ^{13}Cmr spectrum ($CDCl_3$) exhibited dual resonances at 26.74 and 28.81 (3:1 ratio), 48.7 and 50.4 (3:1 ratio), 54.43 and 55.2 (1:3 ratio), and 66.89 and 67.13 (1:3 ratio), which indicates the product was a mixture of **12*b*** and **13*b***. *Exact Mass* calcd. for $C_{11}H_{18}N_4O_2$: 238.1429; found (high resolution ms): 238.1427.

1-Methyl-3-deuteriopiperidylidene-2-cyanamide (14a)

n-Butyllithium (2 mmol) in hexane (0.82 mL) was added dropwise to a suspension of **6*a*** (0.274 g, 2 mmol) in 50 mL of dry tetrahydrofuran at −77°C under a nitrogen atmosphere with stirring. The resulting solution was maintained at −77°C for 10 min prior to warming to 0°C during 10 min and addition of deuterium oxide (0.4 mL, 20 mmol). The reaction mixture was allowed to warm to 25°C and 50 mL of water was added. Extraction with methylene chloride (3 × 50 mL), drying ($MgSO_4$), and removal of the solvent *in vacuo* yielded **14*a*** (0.257 g, 93%); ^{1}H nmr δ: 1.87 (m, 4H, H-4, H-5), 2.82 (m, 1H, H-3), 3.10 (s, 3H, Me), 3.42 (m, 2H, H-6).

1-Methyl-3-bromopiperidylidene-2-cyanamide (14b) and 3,3′-bis(1-methylpiperidylidene-2-cyanamide (15)

Method A

n-Butyllithium (2 mmol) in hexane (0.83 mL) was added to a suspension of **6*a*** (0.274 g, 2 mmol) in 50 mL of dry tetrahydrofuran at −77°C under a nitrogen atmosphere with stirring and the reaction was allowed to proceed for 10 min. *N*-Bromosuccinimide (0.356 g, 2 mmol) was dissolved in 50 mL of dry tetrahydrofuran under a nitrogen atmosphere and the solution was cooled to −77°C. The former solution of the organolithium reagent was added slowly during 20 min, with stirring at −77°C, to the *N*-bromosuccinimide solution. The reaction was allowed to warm to 25°C and 50 mL of water was added. Extraction with methylene chloride (2 × 75 mL), washing the organic extract with 50 mL of water, drying the organic extract ($MgSO_4$), and removal of the solvent *in vacuo* afforded a pale yellow solid. The products were purified by preparative silica gel G tlc using four 200 × 200 mm plates, 1.0 mm in thickness, with methylene chloride – methanol (15:1 v/v) as development solvent. Extraction of the band having R_f 0.68 with 50 mL of methanol afforded **14*b*** (0.231 g, 71%); mp 116–118°C; ir: 2160 (CN) and 1600 (C=N) cm^{-1}; ^{1}H nmr δ: 1.7–2.45 (m, 4H, H-4, H-5), 3.12 (s, 3H, Me), 3.56 (m, 2H, H-6), 5.11 (m, 1H, H-3, collapses to a singlet upon irradiation of H-4 and H-5 at 2.2 δ). *Exact Mass* calcd. for $C_7H_{10}N_3{}^{79}Br$: 215.0058; found (high resolution ms): 215.0055. Extraction of the band having R_f 0.54 gave **15** (0.045 g, 22%); mp 219°C (dec.); ir: 2170 (CN) and 1605 (C=N) cm^{-1}; ^{1}H nmr δ: 1.7–2.7 (m, 8H, H-4, H-5, H-4′, H-5′), 3.1 (s, 6H, Me), 3.15–4.05 (m, 6H, H-3, H-3′, H-6, H-6′). *Exact Mass* calcd. for $C_{14}H_{20}N_6$: 272.1749; found (high resolution ms): 272.1751.

Method B

A solution of the organolithium reagent (2 mmol) in 50 mL of tetrahydrofuran was added slowly to a solution of bromine (0.512 mL, 10 mmol) in 25 mL of dry tetrahydrofuran at −77°C under nitrogen with stirring, as described in Method A. The reaction was allowed to proceed at −77°C for 15 min prior to warming to 25°C. The reaction was completed according to Method A. The orange oil obtained was dissolved in 100 mL of methylene chloride, washed with water (2 × 100 mL), and the solvent from the organic fraction was removed *in vacuo* to give an orange semi-solid. Purification, as outlined in Method A, using methylene chloride – absolute ethanol (15:1 v/v) was performed. Extraction of the band having R_f 0.55 gave **14*b*** (0.125 g, 67%) and R_f 0.3 yielded **15** (0.014 g, 12%), which exhibited the same physical and spectral properties as **14*b*** and **15** obtained by Method A.

1-Methyl-3-bromopiperidylidene-2-benzenesulfonamide (14c)

Addition of the organolithium reagent, prepared by reaction of **6*c*** (2 mmol) with n-butyllithium (2 mmol), to a solution of *N*-bromosuccinimide (2 mmol) and completion of the reaction as outlined in Method A for the preparation of **14*b*** gave a yellow semi-solid. Preparative silica gel G tlc was effected on ten 200 × 200 mm plates, 0.75 mm in thickness, with methylene chloride – methanol (19:1 v/v) as development solvent. Extraction of the band having R_f 0.83 afforded **14*c*** (0.491 g, 91%); mp 94–96°C; ir: 1580 (C=N) cm^{-1}; ^{1}H nmr δ: 1.6–2.7 (m, 4H, H-4, H-5), 2.95 (s, 3H, Me), 3.5 (m, 2H, H-6), 6.05 (m, 1H, H-3), 7.46 (m, 3H, *meta* and *para* phenyl hydrogens), 7.95 (m, 2H, *ortho* phenyl hydrogens). *Exact Mass* calcd. for $C_{12}H_{15}N_2O_2SBr$: 330.0064; found (high resolution ms): 330.0025.

1-Methyl-3-bromopiperidylidene-2-trifluoromethanesulfonamide (14d)

Addition of the organolithium reagent, prepared by reaction of **6*d*** (2 mmol) with n-butyllithium (2 mmol) to a solution of *N*-bromosuccinimide (2 mmol) in dry tetrahydrofuran (50 mL) and completion of the reaction as outlined in Method A for the preparation of **14*b*** gave a yellow oil. Silica gel flash chromatography using ethyl acetate – petroleum oil (1:1 v/v) as eluant afforded **14*d*** (0.581 g, 90%); mp 134°C; ir: 1605 (C=N) cm^{-1}; ^{1}H nmr δ: 2.2 (m, 2H, H-4, H-5), 3.12 (s, 3H, N-Me), 3.6 (m, 2H, H-6), 5.75 (m, 1H, H-3). *Exact Mass* calcd. for $C_7H_{10}N_2O_2SBrF_3$: 321.9605; found (high resolution ms): 321.9606.

1-Methyl-3-azidopiperidylidene-2-cyanamide (16)

Sodium azide (0.326 g, 5 mmol) was added to a solution of **14*b*** (0.216 g, 1 mmol) in 50 mL of dry acetonitrile and the reaction was allowed to proceed for 20 h at 25°C with stirring. The fine solid was filtered and the solvent removed *in vacuo* to yield a yellow oil containing a white suspended solid. This was extracted with 5 mL of methylene chloride, filtered, and the solvent removed *in vacuo* to give **16** as a yellow oil that solidified (0.178 g, 100%); mp 62°C; ir (neat): 2190 (CN), 2115 (N_3), and 1605 (C=N) cm^{-1}; ^{1}H nmr δ: 2.03 (m, 4H, H-4, H-5), 3.1 (s, 3H, Me), 3.48 (m, 2H, H-6), 4.81 (m, 1H, H-3). *Exact Mass* calcd. for $C_7H_{10}N_6$: 178.0967; found (high resolution ms): 178.0969.

N-[2-(1-Methyl-3-bromo-2-piperidylidene)]-N′-[2-[(5-methylimidazol-4-yl)methylthio]ethyl]guanidine (17)

Sodium hydride (0.24 g, 5 mmol) was added to a solution of 4-[(2-aminoethyl)thiomethyl]-5-methylimidazole dihydrobromide (12) (0.832 g, 2.5 mmol) in 100 mL of dry tetrahydrofuran with stirring and the reaction mixture was heated at reflux for 2 h. After cooling to 25°C a solution of **14*b*** (0.54 g, 2.5 mmol) in 100 mL of dry tetrahydrofuran was added and the reaction was heated at reflux for 24 h. Removal of the solvent *in vacuo* yielded 1.6 g of crude material, which was purified by preparative silica gel G tlc. Chromatography was performed using eighteen plates 200 × 200 mm, 1.0 mm in thickness, with methylene chloride – methanol (3:1 v/v) as development solvent. Extraction of the fraction having R_f 0.56–0.61 afforded **17** (0.87 g, 90%); mp 248°C (dec.); ir: 3120 and 3240 (NH), 1645, and 1595 (C=N) cm^{-1}; ^{1}H nmr (DMSO-d_6) δ: 1.4 (m, 1H, H-4), 1.9 (m, 2H, H-5), 2.16 (s, 3H, ≻—Me), 2.46 (m, 1H, H-4′), 2.72 (m, 2H, SCH_2CH_2N), 3.12 (s, 3H, N-Me), 3.48 (m, 2H, H-6), 2.56 (m, 1H, S*CH*(H′)CH_2N), 3.74 (s, 2H, ≻—CH_2—S), 3.83 (m, 1H, S*CH*′(H)CH_2N), 4.7 (d, $J_{3,4}$ = 11 Hz of d, $J_{3,4'}$ = 6.5 Hz, 1H, H-3), 7.48 (s, 1H, H-2 of imidazole), 8.95 and 9.7 (br s, 2H, NH, exchange with deuterium oxide). These assignments were confirmed by double resonance studies. *Anal.* calcd. for $C_{14}H_{23}N_6SBr$: C 43.4, H 6.0, N 21.7, S 8.3, Br 20.6; found: C 43.22, H 5.89, N 21.63, S 8.38, Br 20.64.

*1-Methyl-3-[(5-methylimidazol-4-yl)methylthioethylamino)]-piperidylidene-2-benzensulfonamide (18*a*)*

Potassium carbonate (20 mL of a 25% v/v solution) was added with stirring to a solution of 4-[(2-aminoethyl)thiomethyl]-5-methylimidazole dihydrobromide (5.0 g, 15 mmol) in 25 mL of water. The solvent was removed *in vacuo* at 45°C and the residue was extracted with 50 mL of isopropanol. Filtration and removal of the solvent *in vacuo* gave a white solid (4.1 g), which was purified by silica gel flash chromatography with isopropanol−methanol (4:1 v/v) as eluant to give pure 4-[(2-aminoethyl)thiomethyl]-5-methylimidazole. A solution of the latter (0.171 g, 1 mmol) in 20 mL of ethanol was added to a solution of **14***c* (0.331 g, 1 mmol) in 35 mL of ethanol and the reaction mixture was heated at reflux for 24 h with stirring. Removal of the solvent *in vacuo* gave a brown oil, which was purified by silica gel flash chromatography with ethyl acetate − methanol (1:1 v/v) as eluant to afford **18***a* (0.179 g, 43%); ^{1}H nmr (DMSO-d_6) δ: 1.61 and 1.82 (m, 2H each, H-4, H-5 of piperidine), 2.1 (s, 3H, imidazole C-5 *Me*), 2.44 (m, 2H, SCH_2CH_2NH), 2.66 (m, 2H, SCH_2CH_2NH), 2.96 (s, 3H, N-*Me*), 3.47 (m, 2H, H-6 of piperidine), 3.62 (s, 2H, ≻—CH_2—S—), 4.23 (m, 1H, H-3 of piperidine), 7.38 (s, 1H, H-2 of imidazole), 7.53 (m, 3H, *meta* and *para* phenyl hydrogens), 7.82 (d, 2H, *ortho* phenyl hydrogens), 8.78 (m, 1H, imidazole NH, exchanges with deuterium oxide). *Exact Mass* calcd. for $C_{19}H_{27}N_5O_2S_2$: 421.1644; found (high resolution ms): 421.1641. *Anal.* calcd. for $C_{19}H_{27}N_5O_2S_2.H_2Cl_6Pt$: C 27.44, H 3.49, N 8.42; found: C 28.22, H 3.49, N 8.46.

*1-Methyl-3-[(5-methylimidazol-4-ylmethylthioethylamino)]-piperidylidene-2-trifluoromethanesulfonamide (18*b*)*

A solution of 4-[(2-aminoethyl)thiomethyl]-5-methylimidazole (0.171 g, 1 mmol) in 20 mL of absolute ethanol, prepared as described in the synthesis of **18***a*, was added to a solution of **14***d* (0.323 g, 1 mmol) in 35 mL of absolute ethanol with stirring and then the reaction mixture was heated at reflux for 24 h. Removal of the solvent *in vacuo* gave a brown oil. Purification by flash silica gel column chromatography with ethyl acetate − methanol (1:1 v/v) as eluant afforded **18***b* (0.149 g, 36%); ^{1}H nmr (DMSO-d_6) δ: 1.92 (m, 4H, H-4, H-5 of piperidine), 2.23 (s, 3H, ≻—CH_3), 2.73 (m, 2H, SCH_2CH_2NH), 2.84 (m, 2H, SCH_2CH_2NH), 3.18 (s, 3H, N*Me*), 3.5 (m, 2H, H-6), 3.78 (s, 2H, ≻—CH_2—S), 4.08 (m, 1H, H-3 of piperidine), 5.8 (m, 2H, NH, exchanges with deuterium oxide), 7.63 (s, 1H, H-2 of imidazole). *Exact Mass* calcd. for $C_{14}H_{22}N_5O_2S_2F_3$: 413.1167; found (high resolution ms): 413.1223. Compound **17***b* was quite unstable, as it decomposed slowly upon standing under nitrogen at freezer temperature.

A spectroelectrochemical study of the technetium(IV)/technetium(III) couple in bicarbonate solutions[1]

JEAN PAQUETTE AND WARWICK E. LAWRENCE

Research Chemistry Branch, Atomic Energy of Canada Limited, Whiteshell Nuclear Research Establishment, Pinawa, Man., Canada R0E 1L0

Received November 5, 1984

JEAN PAQUETTE and WARWICK E. LAWRENCE. Can. J. Chem. **63**, 2369 (1985).

Spectroelectrochemistry at an optically transparent electrode, in conjunction with controlled potential coulometry, has been used to study the Tc(IV)/Tc(III) redox couple in aqueous bicarbonate solutions. The complexation provided by bicarbonate/carbonate ions was found to stabilize both Tc(IV) and Tc(III). The uv–visible absorption spectra for technetium(III) and technetium(IV) carbonate complexes are described. The redox potential for the Tc(IV)/Tc(III) couple, as well as the number of electrons, the number of carbonate groups, and the number of hydroxyl groups exchanged during the redox process in bicarbonate media are reported.

JEAN PAQUETTE et WARWICK E. LAWRENCE. Can. J. Chem. **63**, 2369 (1985).

Nous avons utilisé des mesures spectroélectrochimiques, ainsi que la coulométrie à potentiel controlé, pour étudier le couple oxydo-réducteur Tc(IV)/Tc(III) en milieu aqueux contenant des ions bicarbonates. On a trouvé que la complexation par les ions carbonates stabilise le Tc(IV) et le Tc(III). Les spectres d'absorbtion uv–visible du technétium(III) et (IV) sont décrits. Le potentiel oxido-réducteur du couple Tc(IV)/Tc(III), ainsi que le nombre d'électrons, le nombre d'ions carbonates et le nombre d'ions hydroxyles échangés lors de la réduction en milieu bicarbonate sont rapportés.

Introduction

Despite the wide use of ^{99m}Tc in nuclear medicine, the aqueous chemistry of technetium remains poorly understood, particularly in its lower oxidation states. In the past few years, the need for reliable chemical data for compounds and complexes of this element has increased, as attempts are made to assess the probable behaviour of encapsulated high-level radioactive wastes, in contact with groundwater in deep underground disposal vaults. Such facilities would contain relatively large quantities of the long-lived isotope ^{99}Tc.

Deep groundwater systems are often reducing. Although there are reports in the literature of the existence of complexes of reduced technetium with simple inorganic ions such as fluoride, chloride, sulphate, and phosphate (1), there is no report of the occurrence of complexes between reduced technetium and the geochemically important carbonate/bicarbonate ions. As part of a broader radioactive waste management program (2), we have examined the chemistry of technetium in its low oxidation states in bicarbonate media using spectroelectrochemical techniques. Spectral and electrochemical information on the various oxidation states of technetium in these media is critical to both the qualitative and quantitative understanding of its behaviour in geological environments being considered for nuclear waste disposal.

Experimental

Electrodes

An optically transparent electrode was made from 10 pore-per-inch reticulated vitreous carbon (RVC), obtained from Normar Industries, Anaheim, California. RVC is a glassy carbon material with a porous three-dimensional structure and good electrochemical properties. It has a free void volume of over 95% and a surface area of about 60 cm^2/cm^3. Due to the weak light absorption of the solutions used in this study, a 1-cm thick slice was used instead of the more typical 1–2 mm thickness. The RVC was fitted into a square 1-cm spectrophotometric quartz cell (Helma 100-QS). Electrical contact was made by means of a platinum wire attached to the electrode with conducting glue. The reference electrode was a miniature Ag/AgCl flexible electrode (−0.044 V vs. SCE) from Microelectrodes Inc., modified by replacing the ceramic junction with a Vycor plug. The counter-electrode was a platinum mesh enclosed in Teflon tubing, and separated from the solution by a Vycor plug. The resistance between the reference and the working electrode was about 3 kΩ. The cell had provisions for gas purging. All potentials will be quoted versus the SCE.

Apparatus

Electrochemical measurements were performed with an EG&G Princeton Applied Research Model 173/179 potentiostat/coulometer coupled to a Hewlett–Packard Model 7100B recorder. The pH measurements were made with an Orion Model 701A ionalyzer and a Microelectrodes Inc. microcombination pH electrode. Spectra were recorded in digital form, using a Hewlett–Packard Model 8450A double-beam diode array uv–visible spectrophotometer.

Reagents

The ^{99}Tc was obtained from New England Nuclear as a 0.33 mol dm^{-3} NH_4TcO_4 solution. The ammonium pertechnetate was converted to the potassium salt, which was purified by recrystallization from water, according to the procedure described by Boyd (3). A 0.1 mol dm^{-3} stock solution was then prepared and used in all experiments. Other stock solutions were made from standard ACS-grade reagents, and distilled, deionized water, without further purification. The CO_2 and Ar gases, from Canadian Liquid Air, were passed through a solid catalyst (Oxy-trap, Alltech Associates) to remove oxygen, and then through a water saturator.

Procedure

The ionic strength was maintained constant at 1.0 mol dm^{-3}, using sodium trifluoromethanesulfonate; the more customary sodium perchlorate and sodium nitrate salts were found to reoxidize reduced technetium. The solutions were purged with a CO_2–Ar mixture. The partial pressure of CO_2 needed to maintain a given $[H^+]$ and total carbonate concentration can be calculated from

$$[1] \quad pCO_2 = \frac{[H^+]C_T}{K_1 K_H}$$

which is valid for $[H^+]$ between 10^{-7} and 10^{-9} mol dm^{-3}. Here K_H is the Henry's law constant for CO_2 solubility, K_1 is the first acidity constant for carbonic acid, and C_T is the total carbonate concentration. The two constants depend on the ionic strength and on the medium used. Since their values are not known accurately for a CF_3SO_3Na

[1]Issued as AECL-8529.

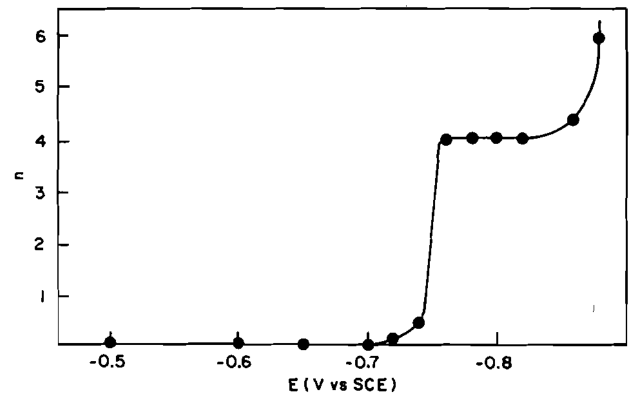

FIG. 1. Number of electrons transferred as a function of the applied potential, for a 1.2×10^{-4} mol dm^{-3} TcO_4^- solution in 0.5 mol dm^{-3} HCO_3^- medium, pH 8, at a RVC electrode.

medium, the following approach was used. A solution containing a mixture of $NaHCO_3$ and CF_3SO_3Na at an initial pH of 8 was equilibrated at a fixed partial pressure of CO_2 for 72 h. The hydrogen-ion concentration was then measured and the total carbonate concentration was obtained by titration with CF_3SO_3H, allowing the determination of K_1K_H, using eq. [1]. This value of K_1K_H was then used to calculate the required pCO_2 for various $[HCO_3^-]$ and $[H^+]$ values.

The optically transparent cell, with all electrodes in place, was fitted in the light path of the spectrophotometer and purged with the appropriate mixture of Ar and CO_2. An identical cell was placed on the reference side of the instrument, and the baseline recorded. Typically, 2 cm^3 of carefully purged HCO_3^-/TcO_4^- solution was transferred to the sample cell. The reference cell was similarly filled with a bicarbonate solution at the same concentration. Reducing potentials were applied to the sample cell, and the current, as well as the spectrum of the solution in the region between 200 and 800 nm, were monitored as a function of time and applied potential. Forty spectra were obtained and averaged at each potential.

Results and discussion

The three-dimensional structure of RVC permits a large electrode surface/solution volume ratio, and thus complete electrolysis of an electroactive species can be accomplished in a short time. Due to its open pore structure, RVC is optically transparent, with an essentially constant transmittance throughout the entire uv–visible spectral region. These properties make RVC a very useful material for *in situ* spectral monitoring of electrochemical reactions, and for the study of a variety of oxidation–reduction systems (4).

With solutions initially 1.2×10^{-4} mol dm^{-3} in TcO_4^- and 0.5 mol dm^{-3} in HCO_3^- (pH adjusted to 8.00), no significant current was observed at the RVC electrode for applied potentials above −0.62 V. At potentials below −0.70 V, the solution rapidly turned pink and then pale blue, indicating a chemical transformation. The number of electrons (n) transferred during the reduction was measured coulometrically as a function of the electrode potential. The results are shown in Fig. 1. The curve of n against applied potential displays a plateau from −0.76 to −0.82 V, corresponding to a transfer of 4.1 electrons. At more reducing potentials, n increases rapidly due to catalytic hydrogen evolution.

The reduced solution was found to be very sensitive to air oxidation, turning rapidly from blue to pink upon brief exposure to air. The same behaviour was observed on applying −0.4 V to the electrode. The number of electrons exchanged during the reoxidation was 0.9. The pink solution could be

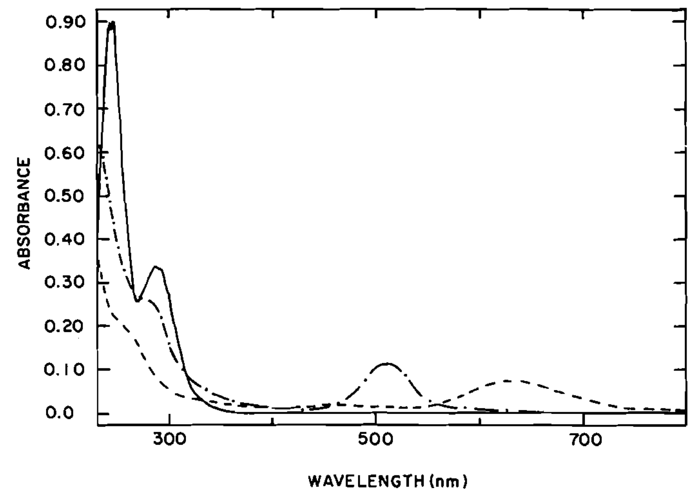

FIG. 2. Ultraviolet–visible absorption spectra for TcO_4^- (full line), Tc(IV), Tc(III) (dashed line), all at 1.2×10^{-4} mol dm^{-3} in 0.5 mol dm^{-3} HCO_3^- medium, pH 8.

rereduced at a potential of −0.75 V, with a color change to blue and an n value of 1.1.

Similar behaviour was observed at a mercury electrode. This behaviour is consistent with TcO_4^- being reduced to Tc(III) at RVC and mercury electrodes in bicarbonate media. This agrees with previous observations for a mercury electrode in various phosphate, EDTA, and DTPA solutions near neutral pH (5).

Reduction of pertechnetate at a pH of 8, in the absence of bicarbonate ions, results in precipitation of $TcO_2 \cdot 2H_2O$. Technetium(III), obtained by reduction at a pH value of one, disproportionates if the pH is raised above a value of three. Thus, soluble reduced species obtained in bicarbonate media are very likely bicarbonate/carbonate complexes of reduced technetium.

The uv–visible absorption spectra for the reduced bicarbonate species are shown in Fig. 2, together with the spectrum for TcO_4^-. The fine-structured charge transfer bands at 240 nm and 290 nm, characteristic of TcO_4^-, are replaced by intense bands with maxima below 230 nm. Both reduced species show a shoulder at 280 nm, which is more obvious for Tc(IV). The reduced species also display weaker bands in the visible, which are responsible for the color of the solutions. These are located at 512 nm for Tc(IV) and at 470 nm and 630 nm for Tc(III).

The bands in the uv region of the spectrum have high intensities and most likely belong to charge-transfer transitions. The bands in the visible region have extinction coefficients of about 800 dm^3 mol^{-1} cm^{-1}, which is too high a value for a d–d transition in a complex having a high degree of symmetry, such as octahedral or tetrahedral. If these bands were due to intrasubshell d–d transitions, then the complexes should possess a low symmetry, i.e. no center of inversion, or a distorted square planar symmetry.

The kinetics of reduction of TcO_4^- to Tc(III) in 0.5 mol dm^{-3} HCO_3^-, at a pH value of 8, have been followed *in situ* by applying a potential of −0.76 V to the RVC electrode and recording the spectra between 210 and 800 nm as a function of time. The matrix multicomponent analysis routine resident in the HP-8450A spectrophotometer was then used, together with the spectra for TcO_4^-, Tc(III), and Tc(IV), to calculate the concentration of the three species as a function of time. The results are shown in Fig. 3.

Since the RVC electrode does not have a well-defined geom-

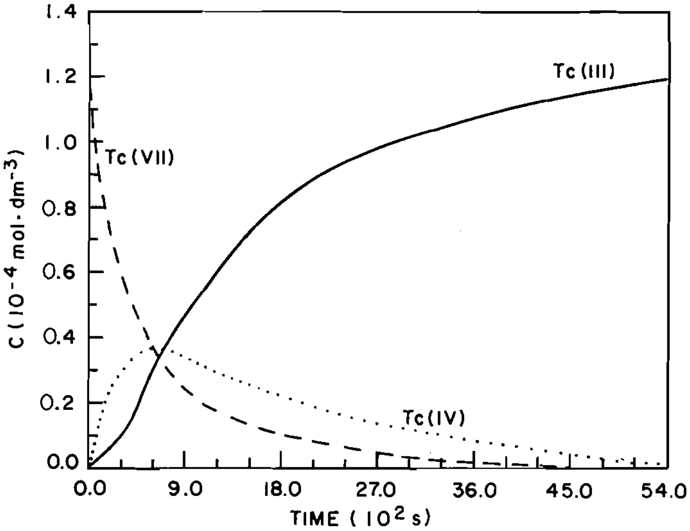

FIG. 3. Kinetics of reduction of TcO_4^- at a RVC electrode in 0.5 mol dm^{-3} HCO_3^- medium, pH 8.

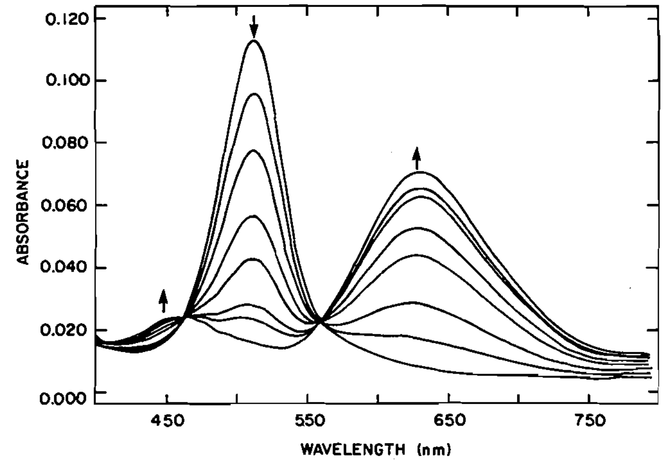

FIG. 4. Visible spectra obtained by successive application of a series of potentials from −0.5 V down to −0.78 V to a 1.2×10^{-4} mol dm^{-3} Tc(IV) solution at a pH of 8, in 0.5 mol dm^{-3} HCO_3^- medium. Arrows indicate the directions the peaks moved with decreasing potential.

etry, a quantitative calculation of the kinetic parameters was not attempted. However, some qualitative conclusions can be drawn. The concentration of TcO_4^- decreases with time, whereas the concentration of Tc(III) increases. The concentration of Tc(IV) goes through a maximum. This is typical of an A → B → C mechanism. The reduction of TcO_4^- appears to be diffusion controlled, i.e. a plot of the concentration of TcO_4^- against the square root of time is linear, for times up to 10 min. Figure 3 confirms the visual observation of the color changes during the reduction process (colorless to pink to blue) and indicates that the rate of reduction of Tc(IV) to Tc(III) is faster than the overall rate of reduction of TcO_4^- to Tc(IV). No spectral change was observed on mixing TcO_4^- with Tc(III), ruling out a reaction between them as a source of Tc(IV).

Figure 4 shows spectra obtained by successive application of a series of potentials, from −0.5 V down to −0.78 V, to a 1.2×10^{-4} mol dm^{-3} Tc(IV) solution at a pH value of 8, in 0.5 mol dm^{-3} bicarbonate medium. About 20 min were required at each potential to obtain a stable spectrum. The absorbance at 512 nm decreased, while that at 630 nm increased, with decreasing potential. Well-defined isobestic points could be observed at 470 and 560 nm. The spectra were found to be linearly dependent. That is, for the function

$$[2] \quad \delta = (1 - b)A_{\lambda,E_1} + bA_{\lambda,E_2} - A_{\lambda,E_3}$$

where A_{λ,E_i} are absorbances at fixed wavelength λ and potential E_i, there exists a value of b, for each possible combination of three spectra, that makes δ equal to zero, within experimental error, at all wavelengths except the isobestic points. In other words, any one spectrum at a particular potential is a linear combination of any two other spectra at two different potentials. This, together with the presence of isobestic points, is an indication that only two interrelated light-absorbing species are present (6), and that no significant loss of materials is occurring through precipitation or plating on the electrode.

The above behaviour implies a reversible or quasi-reversible electrochemical system, in which case the Nernst equation can be written as (7)

$$[3] \quad E = E^{0'} + \frac{0.059}{n} \log \frac{A_2 - A_1}{A_3 - A_2}$$

In eq. [3], E is the applied potential, $E^{0'}$ is the formal reduction potential, n is the number of electrons exchanged, A_1 is the absorbance for the reduced form, A_3 is the absorbance for the oxidized form, and A_2 is the absorbance for the mixture of reduced and oxidized forms. A plot of the applied potential, E, against $\log \frac{A_2 - A_1}{A_3 - A_2}$ should be a straight line with a slope of $0.059/n$ and an intercept of $E^{0'}$. Figure 5 shows plots of E versus $\log \frac{A_2 - A_1}{A_3 - A_2}$ obtained by starting with a potential at which only the oxidized form (Tc(IV)) was present, and then decreasing the potential stepwise to generate the reduced form. The plots are linear as expected from eq. [3]. The slopes correspond to an n value of 0.9 ± 0.1, as expected from the coulometric measurements, and the intercept is −0.625 V.

At constant pH and bicarbonate concentration, the redox equilibrium can be written as

$$[4] \quad \sum_{m=1}^{M} j\mathrm{Tc}_i(\mathrm{IV}) + \sum_{m=1}^{M} jie^- \rightleftharpoons \sum_{n=1}^{N} k\mathrm{Tc}_l(\mathrm{III})$$

and the electrochemical potential as

$$[5] \quad E = E^{0'} + 0.059 \log \frac{\prod_{m=1}^{M} [\mathrm{Tc}_i(\mathrm{IV})]^j}{\prod_{n=1}^{N} [\mathrm{Tc}_l(\mathrm{III})]^k}$$

where i, j, k, and l are stoichiometric coefficients, and m and n are the number of Tc(IV) and Tc(III) species present. The experimentally accessible variable is the absorbance of the solutions, given by

$$[6] \quad A_{(\mathrm{T},\lambda)} = \sum_{m=1}^{M} \epsilon_{m,\lambda}\mathrm{Tc}_i(\mathrm{IV}) + \sum_{n=1}^{N} \epsilon_{n,\lambda}\mathrm{Tc}_l(\mathrm{III})$$

where $A_{(\mathrm{T},\lambda)}$ is the total absorbance at wavelength λ, and $\epsilon_{m,\lambda}$ and $\epsilon_{n,\lambda}$ are the extinction coefficients for species m and n at wavelength λ. The fact that a plot using eq. [3] gives a straight line with a reasonable intercept and with the expected slope of 0.059 is a good indication that only one oxidized and one reduced species are present in the system, and that both of these species are mononuclear. This conclusion is consistent with the

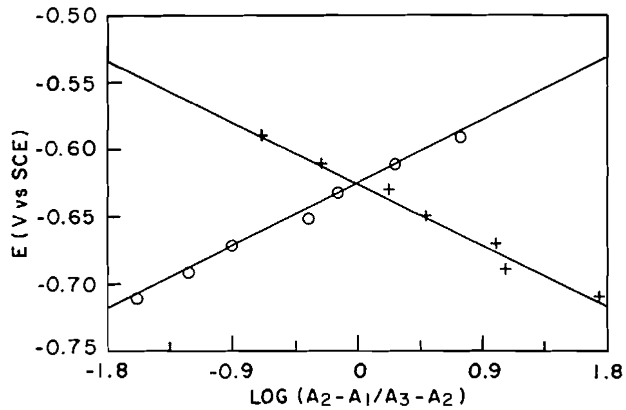

FIG. 5. Plots of applied potential against log [Tc(IV)]/[Tc(III)] for the spectra in Fig. 4. Data obtained at: + = 512 nm; ○ = 630 nm.

presence of isobestic points. The existence of only two mononuclear species was further demonstrated by increasing the initial Tc concentration from 1.2×10^{-4} mol dm^{-3} to 3.5×10^{-4} mol dm^{-3} and repeating the step reduction at the same pH and bicarbonate concentration. The same values for n and $E^{0'}$ were obtained at the higher concentration. Also, the isobestic points remained at the same wavelengths. Furthermore, the initial Tc(IV) and the final Tc(III) absorbances were equal, within experimental error, to 2.9 times the low concentration absorbance, over the 210 to 800-nm wavelength range.

For variable pH and carbonate concentration, the redox equilibrium is then given by

$$[7] \quad \mathrm{Tc(OH)}_p(\mathrm{CO_3})_q^{4-p-2q} + r\mathrm{CO_3^{-2}} + m\mathrm{H_2O} + 1e^- \rightleftharpoons \mathrm{Tc(OH)}_{p+m}(\mathrm{CO_3})_{q+r}^{3-(p+m)-2(q+r)} + m\mathrm{H^+}$$

The complexes could also be written as $\mathrm{Tc(OH)}_x(\mathrm{CO_2})_y$. By using a spectroelectrochemical method only, one cannot, from a mathematical viewpoint, distinguish between the two entities. We have chosen to use the first notation for convenience. The electrochemical potential can be rewritten as

$$[8] \quad E = E^0 + 0.059 \log \frac{[\mathrm{Tc(OH)}_p(\mathrm{CO_3})_q][\mathrm{CO_3}]^r}{[\mathrm{Tc(OH)}_{p+m}(\mathrm{CO_3})_{q+r}][\mathrm{H^+}]^m}$$

or

$$[9] \quad E = E^{0'} + 0.059 \log \frac{[\mathrm{Tc(IV)}]}{[\mathrm{Tc(III)}]}$$

where:

$$[10] \quad E^{0'} = E^0 + 0.059(r \log [\mathrm{CO_3^{-2}}] + m\,\mathrm{pH})$$

A plot of $E^{0'}$ as a function of log [$\mathrm{CO_3^{-2}}$], at constant pH, should have a slope of $0.059r$. Similarly, a plot of $E^{0'}$ as a function of pH, at constant [$\mathrm{CO_3^{-2}}$], should have a slope of $0.059m$. Combining the results from the two plots allows the calculation of E^0. The value of $E^{0'}$ was found to be independent of the bicarbonate concentration, at a constant pH of 8 and a constant ionic strength of 1 mol dm^{-3}. Hence, r is equal to zero, i.e. the two species contain the same number of carbonate ions per molecule. The slope of $E^{0'}$ against pH at constant bicarbonate concentration is 0.0585, giving a value of 0.99 for m. Hence, the Tc(III) bicarbonate species contains one more hydroxyl group than the Tc(IV) species. In that case, combining eqs. [6] and [8] gives

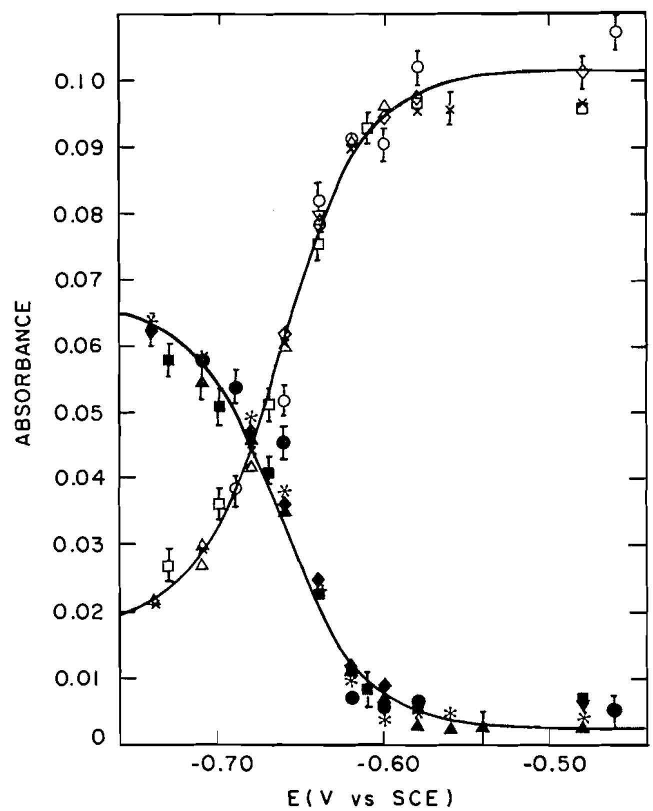

FIG. 6. Absorbance vs. applied potential at a pH value of 8. The curves have been calculated with $E^0 = -1.131$ V in eq. [11]. Open symbols are data obtained at 512 nm. Closed symbols are data obtained at 630 nm. Bicarbonate concentrations: □, 0.5 mol dm^{-3}; ▽, 0.625 mol dm^{-3}; *, ◇, 0.8 mol dm^{-3}; ○, △, 1.0 mol dm^{-3}.

$$[11] \quad A_{(\mathrm{T},\lambda)} = \frac{[\mathrm{Tc}]\epsilon_{\mathrm{IV},\lambda} \cdot 10^{E-E^0-0.059\mathrm{pH}} + [\mathrm{Tc}]\epsilon_{\mathrm{III},\lambda}}{1 + 10^{E-E^0-0.059\mathrm{pH}}}$$

where [Tc] is the total technetium concentration, $\epsilon_{\mathrm{IV},\lambda}$ is the extinction coefficient for the Tc(IV) species at wavelength λ, and $\epsilon_{\mathrm{III},\lambda}$ is the extinction coefficient for the Tc(III) species at wavelength λ.

The experimental data, plotted in Fig. 6 as absorbance vs. applied potential, fall, within experimental error, on single curves, confirming the validity of the model. A non-linear, least-squares-fitting routine was used to calculate E^0 and the extinction coefficients, giving: $E^0 = -1.131$ V; $\epsilon_{\mathrm{IV},512} = 680$; $\epsilon_{\mathrm{III},512} = 120$; $\epsilon_{\mathrm{IV},630} = 14$; and $\epsilon_{\mathrm{III},630} = 430$.

Using the above determined potential, it can be calculated that, in carbonated groundwater with a pH of 8 and a redox potential of −0.300 V (a reasonable value, if the redox potential is controlled by the Fe(III)/Fe(II) mineral equilibria), the ratio [Tc(III)]/[Tc(IV)] would be equal to 10^{-6}. Thus, soluble Tc(III) carbonate species are not expected to be important in the transport of technetium in groundwater.

The charge sign of the Tc(IV) carbonate complex was determined using a simple electromigration technique. An H-shaped cell with three compartments separated by glass frits was used. The two outer compartments were fitted with platinum electrodes and filled with bicarbonate solution. The central compartment contained a Tc(IV) bicarbonate solution. A potential of 15 V was applied between the two platinum electrodes, and the two outer compartments were analyzed for Tc by liquid scintillation counting. Tests with $\mathrm{TcO_4^-}$ showed that, in the absence of an applied potential, natural migration is insignificant over a period of 24 h, but that TcO_4^- migrates rapidly to the anode side when a potential of 15 V is applied. In all cases, the Tc(IV) carbonate complex migrated to the anode; no migration to the cathode occurred. Thus, the Tc(IV) complex is negatively charged. This was confirmed using ion-exchange resins. Technetium(IV) was quickly removed from bicarbonate solutions by an anion-exchange resin (DOWEX 1X8), but not by a cation-exchange resin (AG-50W-X8). Thus, $p + 2q$ in eq. [7] and following is greater than four. Unfortunately, the sign of the Tc(III) complex could not be measured reliably due to its rapid oxidation to Tc(IV).

Conclusions

Spectroelectrochemical techniques have been found useful for elucidation of the behaviour of reduced technetium in bicarbonate solutions. The existence of a reversible, or quasi-reversible, Tc(IV)/Tc(III) couple in these media was demonstrated. The redox potential for the couple and also the number of carbonate and hydroxyl ions exchanged during the reduction were determined. The redox equilibrium is

$$[12] \quad Tc(OH)_p(CO_3)_q^{4-p-2q} + H_2O + 1e^- \rightleftharpoons Tc(OH)_{p+1}(CO_3)_q^{3-(p+1)-2q} + H^+$$

where $p + 2q$ is greater than four. It appears that soluble Tc(IV) carbonate species would be more important than Tc(III) carbonate species in the transport of technetium in groundwater. Experiments to determine the stoichiometry and the stability of the complexes are underway.

It is shown that there will be strong orienting effects in the collision of two radicals which will invalidate attempts to calculate disproportionation–recombination ratios by simple geometric arguments.

L. K. COHEN et H. O. PRITCHARD. Can. J. Chem. 63, 2374 (1985).
On démontre qu'il existe des effets directifs importants dans la collision de deux radicaux et que ces effets rendent invalides tous les essais de calculer les rapports de disproportionation–recombinaison par des arguments géométriques simples.
[Traduit par le journal]

It is possible to take two extreme views of the disproportionation process which occurs between a pair of alkyl radicals, e.g.

$$CH_3 + CF_2H \rightarrow CH_4 + CF_2$$

At one extreme, one can consider that the methyl radical abstracts a hydrogen atom from the difluoromethyl radical (1); at the other extreme, that the products are the "dissociated" species in a chemical activation process, with the recombined product ($C_2H_4F_2$ in this case) being the "stabilised" fraction of the initial flux (2). It is the purpose of this note to throw some light on the mechanisms of these processes by performing trajectory calculations for the approach of two bodies under the influence of a strongly directional attractive potential, such as is characteristic of a *p*-orbital in an aliphatic free radical. We find that in such collisions, provided that the radicals are not rotating too strongly, there is a propensity for them to orient themselves so that they are "facing" each other. Thus, rather like a pair of dancers, they remain facing each other during the whole of the intimate encounter, regaining independent rotational motion only after they have receded beyond a critical value of the interparticle separation; however (to continue with the dancing analogy), collisions in which one radical "turns its back" on the other are not entirely excluded. These observations complicate attempts, such as those of Benson recently (3), to calculate disproportionation–recombination ratios by simple geometric arguments based on the spatial characteristics of the radicals.

We are faced with a multitude of possible disproportionation reactions (4) and so, for our first examination of this problem, we restrict ourselves to a carefully chosen model of the collision between two methyl radicals which retains, we believe, sufficient physical reality to enable the salient physical effects to be discerned; extension to real reactive systems is then only a matter of detail and of computational complexity.

The model and the potential

The dominant interactions are the bonding attraction between the two radical centres, and the non-bonded repulsions between the valence-saturated atoms in the system. For the attractive potential we chose, simulating ethane, a Morse curve

$$[1a] \quad V_-(r) = D_e\{\exp[-2a(r - r_e)] - 2\exp[-a(r - r_e)]\}$$

with $D_e = 88.6$ kcal mol^{-1}, $r_e = 1.54$ Å, and $a = 1.885$ Å^{-1}, derived from $D_0 = 87.2$ kcal mol^{-1} and a vibration frequency of 995 cm^{-1} (5, 6).

The repulsive potential was chosen in such a way that there was little or no repulsion beyond interparticle distances (r_i) of 5 Å, but a strong repulsion occurred for $r_i \leq 2$ Å: the simple form

$$[1b] \quad V_+(r_i) = 0.25\, D_e\{\exp[-a(r_i - r_e)]\}$$

gave rise to an empirical potential which was qualitatively satisfactory.

In order to test our conjecture that most, if not all, of the initial rotational angular momentum is converted into overall angular momentum during closest approach, it is not necessary to perform a full three-dimensional calculation with two radicals: the physical picture remains the same if one of the radicals is replaced by an atom and, further, there is no loss of physical insight if the motion is confined to two dimensions. Figure 1 shows the final mechanical system used in these model calculations: one methyl radical is splayed out flat with a mass of 12 amu at the centre, and three masses each of 1 amu located at $l = 1.1$ Å away, disposed at $i\pi/2$ ($i = 1, 2, 3$) with respect to the centreline of the nascent C—C bond, and it is considered to be rigid; the other methyl radical is replaced by a structureless mass of 15 amu. The total potential is then

$$[1] \quad V(r, \psi) = V_-(r) + \sum_i V_+(r_i)$$

where

$$r_i = [r^2 + l^2 + 2rl \sin(\psi + i\pi/2)]^{1/2}$$

and in which ψ, the angle of alignment, is the difference of the two inertial angular coordinates $\phi-\theta$; some sections of $V(r, \psi)$ are shown in Fig. 2 for three different values of the distance between the bonding centres. In the repulsive region, there are two minima which actually become weakly attractive at some distances: we regard this as reasonable, since the tetrahedral methyl group will exert strong replusions along the lines of the C—H bonds, but in the angles between each pair the repulsions will be weaker, and in the basin lying symmetrically between the three C—H bonds; also, the real potential becomes weakly attrractive in some non-bonding orientations, corresponding to the existence of Van der Waals forces. If our model did not exhibit these secondary minima in directions away from the bonding axis, then every collision would be oriented;[1] an oriented collision is defined as one in which the closest approach occurs for values of $-\pi/2 < \psi < \pi/2$ i.e. in the sector containing the normal C—C bond direction.

[1] Except at very high rotational rates, c.f. discussion of Fig. 5.

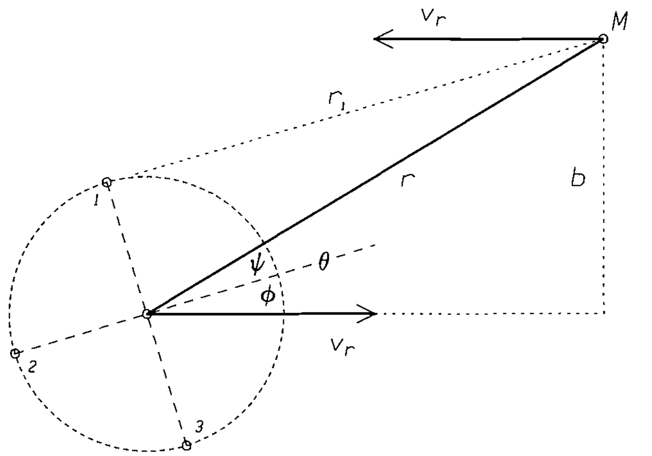

FIG. 1. Definition of the model collision system. The left-hand (distributed) particle consists of four mass points, one of 12 amu at the centre and three, each of 1 amu, held rigidly at a distance of 1.1 Å with a $\pi/2$ separation between them; the right-hand particle M is a point mass of 15 amu. Particle M interacts with the distributed particle via an attractive potential with the 12 amu mass point (eq. [1*a*]) and a repulsive potential with each of the 1 amu mass points (eq. [1*b*]). An additional simplification of the algorithm was achieved by considering that the mass of the three light particles was uniformly distributed on the circumference of a circle of radius 1.1 Å leaving only their force centres at the positions shown; this causes the centre of mass of the distributed particle to coincide with the position of the heavy mass point.

The equations of motion

In the centre-of-mass coordinates, the Hamiltonian is

$$[2] \quad H = \frac{p^2}{2\mu} + \frac{s(s+1)\hbar^2}{2I} + V(r, \psi)$$

where p is the linear momentum, μ is the reduced mass of the system, s is the rotational quantum number of the methyl radical, I is its moment of inertia, and $V(r, \psi)$ is as already defined. The canonical coordinate pairs for the system are (r, p) and (ϕ, j) where

$$[3] \quad p' = -\frac{\partial H}{\partial r}, \; r' = \frac{\partial H}{\partial p}, \; j' = -\frac{\partial H}{\partial \phi}, \; \phi' = \frac{\partial H}{\partial j}$$

with the primes denoting differentiation with respect to time. The use of the Hamiltonian $H_s = s(s+1)\hbar^2/2I$ for the angular component of the motion leads, with $s = I\phi'/\hbar$, to

$$H_s = (1/2)\frac{\partial H_s}{\partial j}\left(\frac{I\partial H_s}{\partial j} + \hbar\right)$$

which does not have a simple solution; however, by making the usual classical approximation (7) that $H_s = s^2\hbar^2/2I$, then

$$H_s = (1/2)\, I\left(\frac{\partial H_s}{\partial j}\right)^2$$

which integrates readily to $j^2/2I$, and so $j = s$ and $\phi' = j'/I$. With this simplification, all the derivatives in [3] can be evaluated analytically from [1] and [2] and the integration becomes straightforward.

Integration and selection of trajectories

The integration was performed by using a third-order Runge–Kutta method in combination with a 5-point Adams–Moulton predictor–corrector procedure. Conservation of energy was required to within 6×10^{-3} kcal mol^{-1}, which leads to the requirement of step lengths in the range 4×10^{-16} to 3×10^{-14} s; the total angular momentum, i.e.

$$\boldsymbol{J} = \boldsymbol{L} + \boldsymbol{S} = \boldsymbol{r} \times \boldsymbol{p} + \boldsymbol{\phi}'I$$

was conserved to within $10^{-4}\hbar$, always.

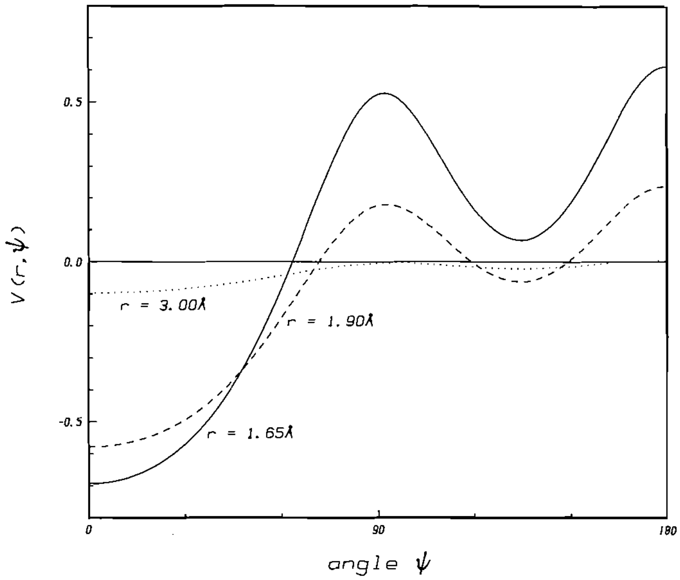

FIG. 2. Three sections through the potential surface, eq. [1], at r = 1.65, 1.9, and 3.0 Å; notice that for all angles $-\pi/2 < \psi < \pi/2$, the torque is such as to pull the system towards $\psi = 0$ where the potential is a minimum. The scale of the vertical axis is $1.0 \equiv D_e$.

Initial trajectories were chosen to sample the important regions of phase space for the recombination of two methyl radicals at 300 K, and some 2000 trajectories were examined; only integral values of s were used in the starting conditions. Figure 3 shows two typical trajectories, one in which the expected orientation occurs, and one in which it does not; the incoming segment of each trajectory is shown as a solid line, the departure path after encounter is shown broken and the dotted lines separate regions of ψ corresponding to alignment or non-alignment, as we have defined it. A qualitative time scale is shown on each trajectory, each marker denoting the time at which completed *free* rotations would have occurred in the absence of any fields; thus, the straight line sections of these graphs correspond to free rotation of the radical. It can be seen that the rotation is essentially free until a distance of between 5 and 6 Å is reached. The interaction begins to take effect at this separation and the particles are pulled towards each other; those which make their closest approach in the bond direction generally reach a turning point of within 1.2–1.3 Å of each other (depending of course upon the initial relative energy), but those which make their closest approach in a non-bonding direction do not often approach closer than 1.95 Å. There is no requirement in this calculation that the final rotational motion shall be quantised, but it is clear that these two trajectories are essentially elastic.

Since we spent most of our effort in probing the dividing lines between the aligned and the non-aligned collisions, we encountered a significant number of unusual trajectories, two of which are shown in Fig. 4: partial trapping occurs in one of these two trajectories, and it is much more inelastic, with an interconversion of translational and rotational energy taking

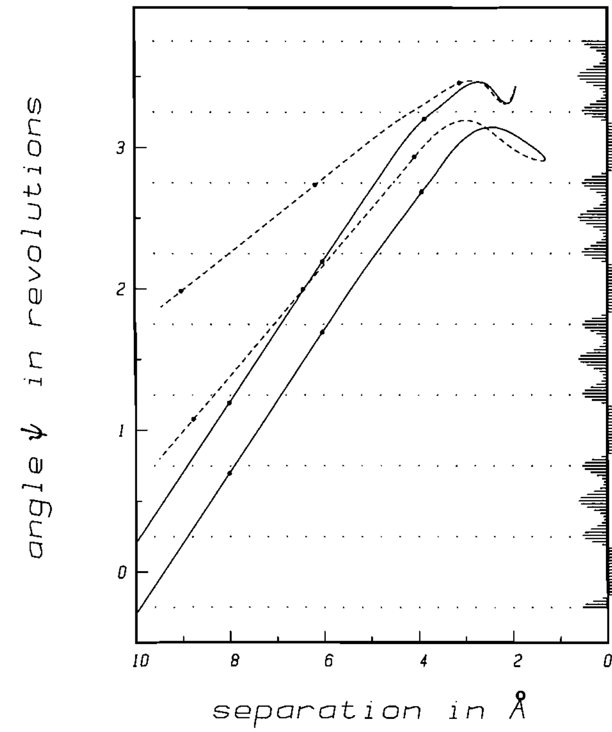

FIG. 3. A pair of typical trajectories: approach is represented by solid lines and departure by dashed lines; markers on the trajectories represent the time scale, the space between each marker representing the time taken for one *free* revolution of the distributed particle, given its initial angular momentum. The right-hand ordinate shows a schematic representation of the potential, with repulsion to the left and attraction to the right, and the regions in which the torque pulls towards $\psi = 0$ or $\pi/2 < \psi < 3\pi/2$ are separated by dotted lines. The initial conditions for all trajectories are: velocity $v_0 = \bar{v}$ (the average relative velocity for particles of mass 15 amu at 300 K); angular momentum for distributed particle = 9 $\hbar$.

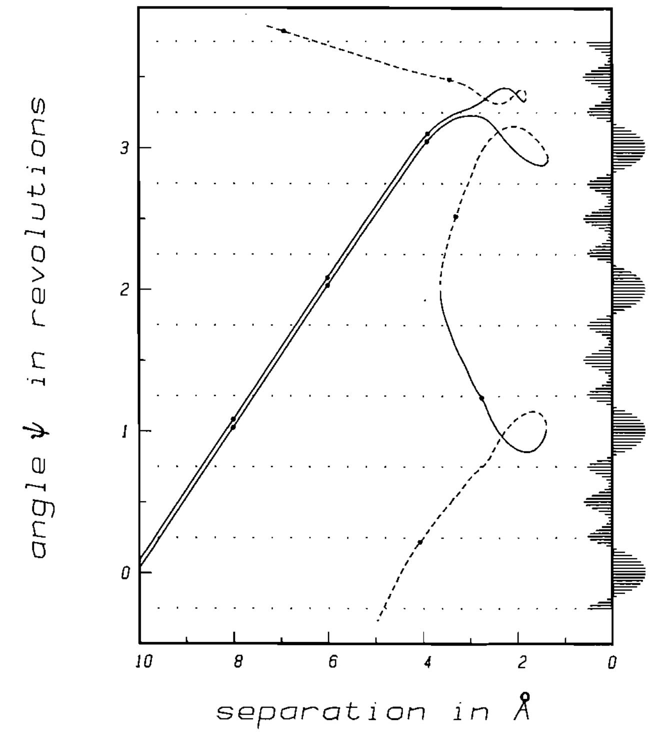

FIG. 4. A pair of atypical trajectories: see legend to Fig. 3 for further details.

place; the other is a double collision.[2]

Figure 5 shows, for a fixed initial approach velocity equal to be average value for 300 K, the fraction of non-aligned collisions as a function of the initial rotational quantum number s of the radical, in the interesting range of values of s. For the rotationless radical, $s = 0$, the probabilities of alignment and non-alignment are equal because the potential has maxima at $\psi = \pm\pi/2$. On the other hand, for exceedingly large values of s, usually $s > 50$, no collisions lead to close encounters because the radical is rotating so quickly that the attractive part of the potential does not have time to draw the particles significantly closer together before the next repulsive impulse occurs. In the important region, however (most probable value of $s \approx 3$), significant preference for oriented collisions appears, in the sense that about 70% of the collisions occur in the bonding direction and about 30% in the non-bonding direction. Results are similar at other approach velocities, with the exception of very low ones ($v_0 \leq \bar{v}/4$) where the graph exhibits considerable structure. Table 1 shows for each initial approach velocity, v_0, the mean fraction of repulsive collisions, obtained from diagrams analogous to Fig. 5 by integrating over the normal distribution of rotational quantum numbers of 300 K in this system; although the details of these curves differ somewhat with v_0, the fraction of repulsive collisions remains remarkably constant. Thus, when averaged over the appropriate Boltzmann distri-

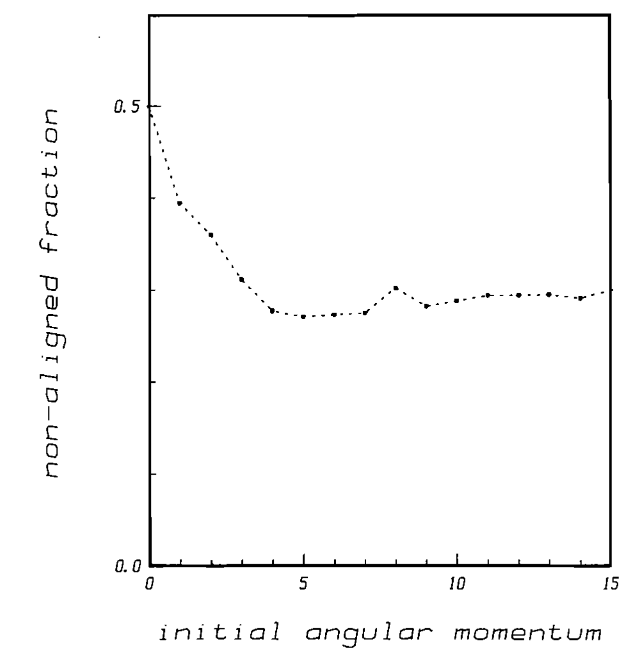

FIG. 5. Plot of the fraction of non-aligned collisions for initial approach velocity $\bar{v}$, as a function of initial angular momentum in the distributed particle. The physically interesting range at 300 K is $0 \leq s < 10$; note that as $s \rightarrow \infty$, the curve will tend to a limiting value of unity, as explained in the text. All points on this graph are determined to better than ± 0.001.

[2] Trajectories which were even more complex than this were found, but we do not reproduce them here; one, for example was initially similar to the non-aligned trajectory in Fig. 4, but on outward path, at a separation of about 4.5 Å, it was turned completely around and entered the alignment region again, approaching to within 1.3 Å before receding finally.

TABLE 1. Fraction of non-aligned collisions as a function of initial approach velocity*

v_0	Fraction
$\bar{v}/4$	0.218
$\bar{v}/2$	0.274
$\bar{v}/\sqrt{2}$	0.296
$\bar{v}$	0.320
$1.31\,\bar{v}$	0.323
$1.61\,\bar{v}$	0.369
$2.06\,\bar{v}$	0.393

* $\bar{v}$ is the average approach velocity for a pair of masses of 15 amu at 300 K, and the fraction is averaged over the rotational distribution for that temperature.

bution of approach fluxes, we find that oriented collisions are favoured in the ratio of 2.17 to 1, whereas the phase-space theory of Benson (3) would distribute the collisions equally between oriented and non-oriented. Notice that the insensitivity of the rotationally averaged alignment ratio to the initial approach velocity (in conjunction with the broad nature of the minimum found in Fig. 5 and others like it) means that the overall alignment ratio will change very little with temperature, which is a reasonable result.

Conclusions

Arguments concerning the ratio of disproportionation to recombination in alkyl radical systems cannot be based solely upon geometric considerations, since there is a strong propensity for colliding radicals to orient themselves in the bonding configuration. We have chosen a very simple model as an illustration of this point. More realistic calculations would take into consideration the three-dimensional quality of the real problem, and should allow for the fact that the radicals may deform under the influence of neighbouring particles. This is especially so in the case of methyl radicals: we have chosen to mimic the behaviour as though the methyl radical were fixed rigidly in its tetrahedral configuration (so that our conclusions would apply more generally to most radical systems), but the methyl radical is free to invert itself; our model is too simple to deal with this problem, for it would lead to the conclusion that *every* collision would be oriented at reasonable values of v_0 and s (the only exception being at very high rotational rates, as already explained in the preceding paragraph).

Unfortunately, at the present level of oversimplification, these calculations do not permit us to eliminate either of the two models of disproportionation mentioned in the Introduction: if approaches in the non-bonding directions are allowed, then abstraction is possible, but if deformation were to be so easy as to preclude such approaches, then elimination would be the only permissible mechanism.

The effects of substituents in the *meta* and *para* positions of the benzyl radical on the α-hydrogen hyperfine coupling constants (hfc's) are discussed. The electron spin resonance (esr) spectra of the *para*-methyl, ethyl, isopropyl, and *tert*-butyl substituted benzyl and cumyl radicals are analysed. Hyperconjugation involving the C—C bond is 40–60% as effective as C—H hyperconjugation for delocalizing spin density. This conclusion is supported by INDO molecular orbital calculations. Similar analysis of the ^{13}Cmr spectra of the *para*-alkyl substituted cumyl carbocations provides evidence that C—C hyperconjugation is 75–90% as effective as C—H hyperconjugation for delocalizing charge density.

DANIAL D. M. WAYNER et DONALD R. ARNOLD. Can. J. Chem. **63**, 2378 (1985).

On discute des effets des substituants en positions *méta* et *para* des radicaux benzyles sur les constantes de couplage hyperfin (chf) des hydrogènes en α. On a analysé les spectres de résonance paramagnétique électronique (rpe) des radicaux cumyles et benzyles substitués en position *para* par des groupements méthyle, éthyle, isopropyle ou *tert*-butyle. L'efficacité de l'hyperconjugaison impliquant la liaison C—C n'est que 40–60% de celle de l'hyperconjugaison C—H pour relocaliser la densité de spin. Cette conclusion est en accord avec des calculs d'orbitales moléculaires INDO. Une analyse similaire des spectres rmn du ^{13}C de carbocations cumyles substitués en position *para* par des substituants alkyles suggère que l'efficacité de l'hyperconjugaison C—C est environ 75–90% de celle de l'hyperconjugaison C—H pour délocaliser la densité de charge.

Introduction

The variation in carbocation stability as a function of the degree of branching of an adjacent alkyl group has received considerable attention over a period extending back more than fifty years, to the original proposal of hyperconjugation (1). The problem, of course, is assessing the relative importance of steric and electronic effects from relative rate data (2). In addition, both C—H and C—C hyperconjugation are possible and sorting out the relative contributions of each of these effects has created some controversy (3–5).

In comparison, little is known about the effect of variation in alkyl branching on the stability of an adjacent radical centre. This may be a result of the justifiable realization that the effect of adjacent alkyl branching on the rate of most free radical reactions will be small, too small, perhaps, to be accurately measured by kinetic methods. For example, the variation in activation energy for decomposition of the symmetric azoalkanes from azo-2-methyl-2-propane to azo-2-*tert*-butyl-2-propane is too small to be critically analysed in view of the rather large experimental error (6).

The study of *para*-substituted benzyl and cumyl radicals avoids many of the difficulties, such as steric and anchimeric effects, associated with systems which have the substituent directly bonded to the reaction centre. The α-H hyperfine coupling (α-hfc) in substituted benzyl radicals has been used to define a substituent parameter (eq. [1], Table 1) which reflects the effect of the substituent on the spin density at the benzylic position (7). It is generally believed that the extent of spin delocalization away from the benzylic position should be reflected in decreased reactivity (i.e. increased stability). This reasoning has now been applied to determine the effect of branching of a *para*-alkyl substituent on the delocalization of spin density in benzyl and cumyl radicals. These results are then compared to the effect of *para*-alkyl substituents on the charge density of the cumyl carbocation.

$$[1] \quad (\sigma_\alpha^\bullet)_X = 1 - \alpha\text{-hfc}_X/\alpha\text{-hfc}_H$$

Results

The observed hyperfine coupling constants (hfc's) for several alkyl substituted benzyl and cumyl radicals are shown in Table 2. The radicals were generated by hydrogen atom abstraction from the corresponding toluene or by bromine atom abstraction from the corresponding benzylic bromide. The hfc's were estimated by initial measurement of the line positions from the signal averager and refined by computer simulation (8).

The observed ^{13}Cmr chemical shifts of the *para*-alkyl substituted cumyl carbocations are shown in Table 3. The ions were generated from the cumyl chlorides in a mixture of SbF_5/FSO_3H/SO_2ClF at −40°C as outlined by Kelly and Brown (9).

Discussion

There are some general features of the $\sigma_\alpha^\bullet$ scale which give valuable insight into the mode of interaction of substituents with the benzylic radical center.

Most of the *para* substituents delocalize spin density more effectively than the unsubstituted radical ($\sigma_\alpha^\bullet > 0$). These substituents fall into two classes. Those with non-bonding lone pairs can interact by donating an electron (Fig. 1a). In this case, the substituent is a β-spin donor. Unsaturated substituents, on the other hand, can interact by accepting an electron (Fig. 1b). In this case, the substituent is an α-spin acceptor. The orbital interactions can be represented using simple perturbation molecular orbital theory. For the β-spin donors, the orbital interactions are two-orbital, three-electron interactions and lead to a net one-electron stabilization (10). For the α-spin acceptors, the orbital interactions are three-electron, three-orbital interactions and lead to a net two-electron stabilization (10).

From this simple treatment, some qualitative predictions can be made. For the β-spin donors, the stabilization energy will depend on the energy of the lone pair. As the energy of the lone pair decreases, the ionization potential increases, and the contribution of the valence bond structure in Fig. 1a will decrease. This rationale leads to the prediction that the order of increasing spin delocalization should be —F < —Cl < —OR < —SR, which is the order observed.

Similarly, as the energy of the π (or σ)-orbital of the α-acceptors decreases, spin delocalization in the benzyl radical also should decrease. This, again, leads to the correct qualitative prediction that, for these substituents, spin delocalization should increase in the order —CF$_3$ < —CH$_3$ < —CN < —COR. The *para*-CF$_3$ and *para*-CH$_3$ substituents are considered to be α-acceptors since interaction with filled σ-orbitals is possible. In this case, the stabilizing effect of course will be much smaller since the energy separation between these orbitals is much greater (11).

This approach assumes that hydrogen as a substituent has no stabilizing effect. As a result, the relative stabilization of the benzyl radical by a *para* substituent can be predicted, but it is

FIG. 1. Substituent interactions in benzyl radicals; (a) β-spin donating substituent; (b) β-spin accepting substituent.

impossible to predict *a priori* where hydrogen will fit in the series. Furthermore, it is not possible to rank the relative effect of the β-spin donors against the α-spin acceptors.

So far, only effects on the π-system have been considered; effects on unpaired electron delocalization through the σ-framework have been ignored. Since the *meta* substituents do not interact directly with the benzylic carbon through the π-system, these substituted radicals can be used to assess the effect of substitution on delocalization in the σ-framework.

Most of the *meta* substituents delocalize spin density less effectively than the unsubstituted benzyl radical ($\sigma_\alpha^\bullet < 0$). This can be explained in terms of an inductive effect. Correlation of the α-H hfc's with σ_m, in fact, gives a straight line with a slope of 0.6 having a correlation coefficient (r) of 0.927 with the ten available points (Fig. 2). The correlation of the *meta*-substituted derivatives with σ_m also was noted by Creary from his study of the rearrangement of 2-aryl-3,3-dimethylmethylenecyclopropanes (12). This correlation can be related to the electrophilic nature of the radical.

The decreased delocalization by inductive withdrawal of electrons must not be unique to the *meta* substituents. The three *para* substituents which lead to decreased delocalization (relative to the unsubstituted radical) are all inductively withdrawing substituents; the σ values for *para*-CF$_3$, *para*-F, and *para*-OCOCH$_3$ are 0.53, 0.15, and 0.31 respectively (13). Certainly, in the case of *para*-F and *para*-CF$_3$, delocalization involving the π-system is expected to be small (14).

The decrease in spin delocalization as substituents become more electron withdrawing in nature should not come as a complete surprise. The electrophilic nature of the benzylic radical is well known (15) and, while this has often been considered to be a transition state polar effect (16), it is not unreasonable that the benzyl radical should be intrinsically electron deficient.

The mechanism by which the inductive withdrawal of electron density can lead to a decrease in spin delocalization is not so easily visualized. There is an excess of β-charge density at the *meta* position in the benzyl radical. Inductive withdrawal of

[a]The ratio of the experimental hfc to the calculated hfc is in parentheses.
[b]These hfc's depends on the preferred conformation of the C—H bond with respect to the aryl ring.

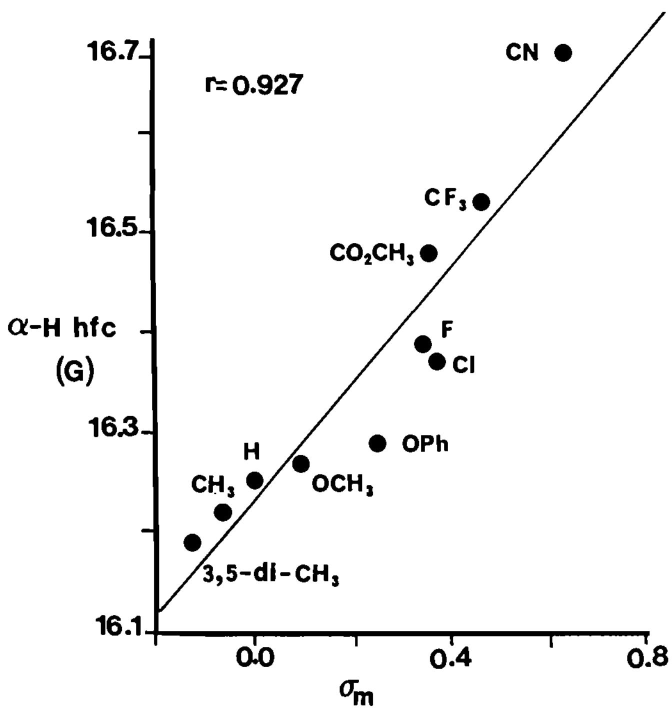

FIG. 2. Plot of α-H hfc versus σ_m for the *meta*-substituted benzyl radicals.

an excess of β-charge density by a substituent can lead to a net donation of β-charge density by the benzylic carbon into the ring. In this case, the apparent decrease in spin delocalization would be because of a net withdrawal of β-charge density from the benzylic position. For inductively donating substituents such as *meta*-CH_3, the apparent increase in spin delocalization could then be the result of a net increase in β-charge density at the benzylic carbon.

It should be noted that while this explanation accommodates the observed "*meta* effect", it cannot be used to rationalize the effect of the three *para* substituents with negative $\sigma_\alpha^\bullet$ values. If, however, the McConnell relationship applies to the entire series of benzyl radicals, the usefulness of the $\sigma_\alpha^\bullet$ scale as a reactivity parameter is not diminished, since relative reactivity will be proportional to the α-spin density (in the absence of transition state polar effects).

The calculated (INDO) hfc's for several *meta*- and *para*-substituted benzyl radicals are shown in Table 4. The ratio of the experimental hfc to the calculated hfc is approximately constant for most of the radicals. It is clear, however, that the spin distribution in the benzyl radical is not adequately reproduced for quantitative evaluation of the effects. The general trends are reproduced, but the *meta* effect is underestimated and the decreased delocalization in the *para*-fluorobenzyl radical is not predicted.

One of the difficulties with the molecular orbital approach is that complete geometry optimization of each structure is not feasible. The inductive withdrawal of electron density from the σ-framework may have the effect of lengthening the bond between the benzylic carbon and the aryl ring. This of course would lead to a decreased orbital overlap between the carbons and, consequently, a larger α-H hfc. It has been found, using *ab initio* calculations (STO-3G), that small variations in this carbon−carbon bond length have a negligible effect on the electronic *energy* of the benzyl radical, but a large effect on the *spin density* on the benzylic carbon.[3] Therefore, there is a possibility that the inductive withdrawal of electron density will result in *increased* localization of α-spin density at the benzylic position either by decreasing the overlap between the interacting centres or by increasing the energy separation between the interacting systems. In other words, the electron-withdrawing groups will lower the energy of the aromatic π-system (i.e. increase the ionization potential), which, from

[3]A. M. de P. Nicholas and D. R. Arnold, Unpublished results.

simple PMO theory, results in a decreased interaction between the benzylic carbon and the aromatic system (11). This alternative explanation should be general for both *meta* and *para* substitution.

Other MO calculations by Gey *et al.* also using model geometries, failed to adequately reproduce the experimentally determined spin distribution or substituent effect (17). Inclusion of configuration interaction improved the agreement with experimental results only slightly.

While there have been numerous studies of esr spectra of alkyl radicals (5, 18), most of these studies have been directed towards the investigation of conformational preferences, which are influenced by both steric and hyperconjugative interactions. While some studies have specifically addressed the question of the effect of substitution at the β-carbon on spin delocalization (19), the effect of branching at the α-carbon of an alkyl substituent on spin delocalization in benzylic radicals is not known. This understanding is important since many free radical reactions involve this type of intermediate, and since comparison of the effect of alkyl substituents on the spin density at the benzylic carbon in the radicals to the effect on charge density (as measured by ^{13}Cmr) at the benzylic carbon in the carbocations can be made.

The order of decreasing spin delocalization by a *para*-alkyl substituent in benzyl and cumyl radicals is methyl > ethyl > isopropyl > *tert*-butyl, in accord with the Baker–Nathan order of stabilization (Table 2). Similar results have been reported for the alkyl substituted cyclopentadienyl radicals (19).

The substituent effects on the β-H hfc in the cumyl radicals (20) are only just outside the quoted experimental uncertainty (±0.03 G) for the entire range (*para*-methyl to *para-tert*-butyl). It is, therefore, difficult to draw firm conclusions from the differences between, for example, *para*-methyl and *para*-ethyl or *para*-ethyl and *para*-isopropyl. The range of α-H hfc for the benzyl radicals is larger (0.12 G) but, even here, comparisons between adjacent members in the series is difficult. It is clear, however, that the difference (>0.1 G) between *para*-methyl and *para-tert*-butyl in both radicals is real.

It is tempting to attribute all of this effect to a difference in hyperconjugative interactions with a C—C bond relative to a C—H bond. This, certainly, will not be the case since, as we have discussed above, there must be some inductive interactions. The inductive effects, however, will be comparatively small. For example, the increased delocalization, relative to the unsubstituted benzyl radical, by a *meta*-methyl substituent is only 0.03 G. If the plot of α-hfc versus σ_m for the *meta*-substituted derivatives is extrapolated, the predicted α-hfc for the *meta-tert*-butylbenzyl radical is only 0.05 G less than for the unsubstituted benzyl radical. Therefore, the ratio of α-hfc (*tert*-butyl)/α-hfc (methyl) will slightly overestimate the relative effectiveness of C—C versus C—H hyperconjugation. By taking the difference between the *para*- and the *meta*-substituted derivatives, the ratio of these differences is approximately 40%, compared to 60% obtained when correction for the inductive effect is not included. A similar upper limit is predicted for the cumyl radicals.

It is also possible to assess the relative importance of C—C and C—H hyperconjugation in benzyl radicals from the INDO calculations. The calculated spin densities on the carbon atoms of the *tert*-butyl group in the *para-tert*-butylbenzyl radical and on the hydrogens of the methyl group in the *para*-methylbenzyl radical are shown in Table 5. The contribution from spin polarization is estimated from the spin density at a dihedral angle of

TABLE 5. Hyperconjugative interactions of C—H and C—C bonds from INDO calculations

[b]Carbons of the *tert*-butyl group in the 4-*tert*-butylbenzyl radical.
[c]Calculated by subtracting the spin density from the spin polarization mechanism (θ = 0) from the spin density on the atom. The ratio of the difference is an estimate of the relative contribution of hyperconjugation.

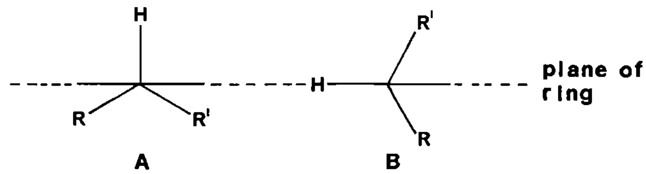

FIG. 3. Conformational preferences of *para*-alkyl substituents. (a) θ = 90° (b) θ = 0°.

0° (measured as the angle between the C—X bond and the plane of the ring), since there will be no contribution from hyperconjugation in this conformation. The results in Table 5 lead to the prediction that C—C hyperconjugation is about 65% as effective as C—H hyperconjugation. This compares favourably with the ratio estimated from the esr data.

Hyperfine coupling to the hydrogens of the alkyl substituents can give information about the conformational preference of the substituent. While the barrier to rotation of the alkyl groups is probably small, there will be preferred conformations which balance the steric interactions between the β-methyl groups and the *meta* ring hydrogens against the favourable hyperconjugative interactions (21). The magnitude of the β-hfc (of the benzylic hydrogens on the alkyl group) follows a $\sin^2 \theta$ relationship (22), where θ is the angle between the C—H bond and the plane of the ring. Two conformations are generally considered (Fig. 3). If an average angle of 45° for the *para*-methyl substituent is used, an approximate equation for the β-hfc can be determined (eq. [2]) for the cumyl radicals.

[2] $\beta\text{-hfc} \simeq 11.6 \sin^2 \theta$

From this equation an average angle (θ) of 30° is estimated for the *para*-ethyl group (at −40°C). This implies that conformation A is preferred for this substituent. For the *para*-isopropyl group, an average angle (θ) of 27° is calculated. The *para*-isopropyl benzyl radical shows a small but positive temperature coefficient (β-H hfc is 2.35 G at −40°C and 2.25 G at −60°C), which implies that, for the isopropyl group, conformation B is preferred (i.e. θ_{ave} decreases as the temperature decreases).

A comparison of the alkyl substituted cumyl radicals to the carbocations is now possible. Recently, Brown *et al.* have published the ^{13}Cmr spectra of several *para*-alkyl substituted cumyl carbocations, including -methyl, -ethyl, -isopropyl, and -*tert*-butyl (23). It was found that, in contrast to gas phase studies (4, 5) in solution, the stabilization by alkyl substituents follows the Baker–Nathan order. The differences between the gas phase and solution studies were attributed to a greater inductive contribution to the stabilization of the carbocation in the gas phase.

TABLE 6. ^{13}C-SCS of aryl ring carbons in 4-alkyl cumyl carbocations and monoalkylbenzenes[a]

[a]Data for monoalkylbenzenes taken from ref. 24. For clarity the aryl carbons are numbered such that the substituent is bound to C_4.

The ^{13}Cmr spectra of the *para*-methyl, *para*-ethyl, *para*-isopropyl, and *para-tert*-butyl cumyl carbocations had also been measured in this laboratory. The observed chemical shifts are similar to those reported by Brown *et al.* (Table 3). However, our measurements were performed at −40°C, the same temperature used in the esr study. While we agree with the conclusions drawn by Brown and his co-workers, i.e., the Baker−Nathan order of stabilization is followed for the cumyl carbocations, there are other features of the ^{13}Cmr spectra which are noteworthy.

If the chemical shifts of the *meta*-methyl and *meta-tert*-butyl groups are interpolated from the plot of δ^{13}C versus σ^+, treatment similar to that used above for the radical indicates that C—C hyperconjugation is 75−90% as effective as C—H hyperconjugation. This compares very well with the 80% estimated by Brown *et al.* in their previous study of the solvolysis of cumyl chlorides (3).

Although the upfield shift of the C^+ chemical shift indicates that the cumyl carbon is becoming more shielded from *para-tert*-butyl to *para*-methyl, the effects on the ring carbon chemical shifts in some cases are in the opposite direction. The ^{13}C-SCS (substituent chemical shift) for the ring carbons of the cumyl carbocations and the monosubstituted alkyl benzenes (24), relative to the respective unsubstituted derivatives, are shown in Table 6. The differences between the two sets of numbers reveal an interesting trend. For C_1 and $C_{2,6}$ the differences indicate that there is no substituent effect on the carbocation beyond that expected by substitution of an alkyl group alone. On the other hand, $C_{3,5}$ shows an increasing effect while C_4 shows a decreasing effect. Furthermore, the difference in ^{13}C-SCS at C_4 is between 8 and 10 ppm, with methyl causing the greatest downfield shift and the other alkyl groups causing progressively smaller downfield shifts. These effects are another indication that C—H hyperconjugation is more effective than C—C hyperconjugation; in fact, this appears to be an even more sensitive probe than the chemical shift at C^+.

As the ^{13}C-SCS at C_4 decreases from methyl to *tert*-butyl, the chemical shifts of the alkyl carbons shift downfield. This also indicates that hyperconjugation to hydrogen is more effective than to carbon, since increasing the number of β-methyl groups results in less charge delocalization from C'_α, thus causing a downfield shift. The increased charge at C'_α would certainly be transmitted to C'_β.

Conclusions

The substituent effects on benzyl radical hfc's can be rationalized by simple perturbation molecular orbital theory. The interactions in the *para*-position will be predominantly either two-orbital, three-electron interactions, if the substituent has a lone pair of electrons; or three-orbital, three-electron interactions, if the substituent is unsaturated. With substitution in the *meta* position, the α-H hfc's correlate positively with σ_{meta}, indicating that the benzyl radical is intrinsically electrophilic.

The esr spectra of the *para*-alkyl substituted cumyl radicals indicate that the Baker-Nathan order of stabilization is followed. It is suggested that C—C hyperconjugation is from 40−60% as effective as C—H hyperconjugation for delocalizing spin density.

From the ^{13}Cmr spectra of the *para*-alkyl substituted cumyl carbocations, it is found that the Baker−Nathan order of stability is followed and that C—C hyperconjugation is 75−90% as effective as C—H.

Experimental

General information

The esr spectra were recorded on a Varian Associates E 109 B electron paramagnetic resonance spectrometer equipped with a liquid nitrogen variable temperature accessory. All spectra were recorded with the aid of the Nicolet 1170 signal averager. Typically, sixteen spectra were averaged (2 min per spectrum). Coupling constants were measured directly from the oscilloscope and refined by computer simulation (8) using the IBM-PC. All spectra were reproducible within the experimental uncertainty. The estimated uncertainty of ±0.03 G is the limit of resolution of the recording device used to plot the experimental spectra and the simulations. The ^{1}Hmr spectra were recorded on a Varian T-60 spectrometer and are reported in parts per million downfield from TMS. The ^{13}Cmr spectra of the cumyl cations were referenced with respect to external acetone-d_6, which has a chemical shift of 207.1 ppm downfield from TMS at −40°C. All ^{13}Cmr spectra were measured with the Atlantic Region Magnetic Resonance Centre Nicolet 360-MHz nmr spectrometer.

Di-*tert*-butyl peroxide (DTBP) and triethylsilane were obtained from Pfaltz and Bauer Inc. and were used without further purification. Hexamethylditin was obtained from Alpha Products and used without further purification. *para*-Methoxyacetophenone (PMA) was obtained from Aldrich Chemical Company Inc. and was recrystallized twice from 95% ethanol prior to use. Chlorobenzene (J. T. Baker Chemicals Inc.) was stirred over concentrated sulphuric acid, washed successively with water, saturated sodium bicarbonate, and water, dried over anhydrous magnesium sulphate, and distilled through a Vigreux column.

Preparation of benzyl bromides

The method of Grice and Owen (25) was used for the conversion of substituted benzyl alcohols to the bromides. Typically, the benzyl alcohol (0.02 mol) was dissolved in benzene (100 mL). Hydrogen bromide gas was passed through the solution for 1 h or until the solution was saturated. The reactants were heated to reflux and the water which formed was removed via a Dean−Stark trap. The solution was then dried over anhydrous magnesium sulphate, filtered, and the solvent removed at reduced pressure. The bromide was then purified by sublimation. Preparation and purification of the cumyl bromides have been described previously (7, 10).

para-*Ethylbenzylbromide*

The crude product was purified by vacuum distillation (88°C at 1 Torr; 1 Torr = 133.3 Pa) to give a 70% yield of the bromide (26); ^{1}Hmr ($CDCl_3$): 7.18 (m, 4H), 3.80 (s, 2H), 2.65 (q, 2H), 1.23 (t, 3H).

para-*(2-Propyl)benzylbromide*

The product was purified by vacuum distillation (62°C at 0.02 Torr) to give a 73% yield of the bromide (27); ^{1}Hmr ($CDCl_3$): 7.17 (m, 4H), 4.38 (s, 2H), 2.87 (m, 1H), 1.22 (d, 6H).

Electron spin resonance experiments

Toluenes

A static solution of DTBP (0.5 mL) and the toluene (100 mg) with PMA (45 mg) was irradiated in the esr spectrometer cavity using a filtered (methanol in a quartz tube) 1-kW Xe−Hg high-pressure lamp. Temperatures were controlled between 20°C and −60°C (depending on the solubility), with the majority of the samples examined at −40°C. All samples were purged with nitrogen for 5 min prior to irradiation.

Benzylbromides

Two methods were used to generate the benzyl radicals from the bromides. In method 1, a static solution of DTBP (0.2 mL), triethylsilane (0.2 mL), and the bromide (50−100 mg), diluted if necessary with chlorobenzene, was purged with nitrogen and irradiated as described above in the esr spectrometer cavity. In method 2, a solution of the bromide (50−100 mg) in *tert*-butylbenzene or chlorobenzene was continuously purged while hexamethylditin (0.1 mL) was injected via the nitrogen purge tube. It was necessary to have a glass wool plug in the purge tube to filter the hexamethylditin. This solution was irradiated as described above. The use of chlorobenzene allowed cooling of the sample to temperatures as low as −20°C without precipitation of the hexamethylditin.

Reçu le 12 septembre 1984

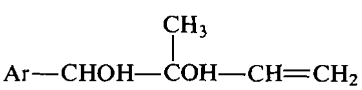
JOSYANE GHARBI-BENAROUS, MARTHA S. MORALES-RIOS et GILBERT DANA. Can. J. Chem. **63**, 2384 (1985).

À partir de dérivés dihydro-2,3 furanniques, on prépare successivement les bromhydrines et les bromobutyrolactones correspondantes. Une méthode d'équilibration de ces dernières par solvolyse dans le DMF est décrite. Les divers stéréoisomères sont séparés et étudiés à l'état pur. Une réaction d'élimination catalysée par les bases faibles (LiBr) conduit au buténolide correspondant avec un excellent rendement lorsque la lactone comporte un substituant en Cβ. La réaction se produit quelle que soit la configuration de l'isomère de départ. Une application de la réaction est décrite avec la synthèse stéréosélective du γ-diol du titre avec un rendement total supérieur à 85%.

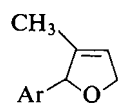
JOSYANE GHARBI-BENAROUS, MARTHA S. MORALES-RIOS, and GILBERT DANA. Can. J. Chem. **63**, 2384 (1985).

Starting from 2,3-dihydrofuranic compounds, we prepare the corresponding α-bromohydrines and α-bromo-butyrolactones. A solvolytic method of equilibration of these bromolactones in DMF is described. All the stereoisomers are separated and studied. With a Cβ substituent, the elimination promoted by a weak base (LiBr) gives the Δ^2 butenolide in good yield, whatever the starting isomer configuration may be. An application is given with the stereoselective synthesis of a trisubstitued ethylenic γ-diol with a *Z* configuration.

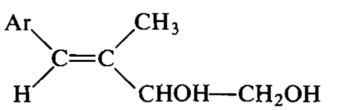
Au cours de nos études concernant la déshydratation des α-diols éthyléniques, nous avons montré que les diols du type **1** peuvent conduire de façon quasi-exclusive (1) à des composés dihydro-2,5 furanniques **2**. Récemment, nous avons mis en évidence l'existence d'un intermédiaire réactionnel, l'α-diol éthylénique **3** de configuration *E*, isomère de **1** (2) dont la formation semble nécessiter le passage par un γ-diol insaturé, de type **4**,*Z* ou **4**,*E*.



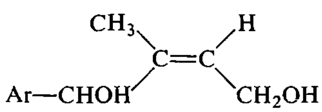
1



2



3,*E*



4,*Z*

Suivant sa configuration, ce diol **4** pourrait être un précurseur direct de **2** (isomère *Z*) ou un précurseur de **3** qui évolue ensuite en **2** (2). Dans le présent mémoire nous décrivons une synthèse sélective et aisée du méthyl-2 phényl-1 butène-2 diol-1,4 (**4**, Ar = C_6H_5) de configuration *Z*.

Cette synthèse consiste principalement à préparer, à partir des deux dérivés dihydro-2,3 furanniques **5** et **6** (3, 4), le buténolide **7** (schéma 1): on forme d'abord les bromhydrines correspondant aux dérivés dihydrofuranniques **5** et **6**; par oxydation ces bromhydrines donnent accès à des butyrolactones α-bromées dont la débromhydratation en Δ^2-buténolide s'est avérée facile. La réduction de ce buténolide en diol **4** de configuration *Z*, a été réalisée par action de $LiAlH_4$.

Nous discuterons la stéréochimie des différentes étapes de façon à montrer comment, partant du mélange des deux dérivés dihydrofuranniques **5** et **6** et obtenant successivement un mélange de 8 bromhydrines et de 4 bromolactones, nous avons pu préparer dans de bonnes conditions le buténolide **7** et, donc de façon rapide, efficace et stéréosélective, le diol **4**,*Z*.

SCHÉMA 1

1. Préparation des bromhydrines

Le *N*-bromosuccinimide (NBS), en solution dans le diméthyl-sulfoxyde (DMSO) anhydre (5) réagit habituellement sur les oléfines pour former des dérivés dibromés. En présence d'humidité, le DMSO intervenant comme réactif (6) en même temps que solvant, conduit généralement par addition *anti* aux bromhydrines correspondantes, de façon stéréosélective (6, 7).

Avec les dérivés dihydrofuranniques **5** et **6**, le NBS en solution dans le DMSO humide conduit au mélange des *cis* et *trans* bromhydrines (schémas 2 et 3).

L'ion bromonium intermédiaire est en effet en équilibre avec un carbocation fortement stabilisé par les doublets libres de l'oxygène. La stéréochimie de la réaction rappelle tout à fait celle observée lors de l'étude d'autres additions électrophiles sur des éthers d'énols, linéaires (8) ou cycliques (9, 10). Comme pour les cas analogues de l'addition du chlore ou du brome (9, 11), l'entrée initiale du réactif électrophile se fait de façon largement prépondérante par la face α, opposée au noyau benzénique (~90%). Finalement chacun des composés dihydrofuranniques **5** et **6** conduit à un mélange où prédominent deux bromhydrines épimères (**8***a et* **8***b* pour **5** et **10***a* et **10***b* pour **6**, schéma 3).

La réaction est effectuée à température ambiante sur le composé dihydrofurannique **5** pur (4) ou sur des mélanges **5** et **6** (3) diversement enrichis en **6** (50 à 70%). Les bilans sont établis par rmn du proton à 80 MHz sur les produits bruts de la réaction; les spectres de certains isomères purs ont été repris à 250 MHz (tableau 1).

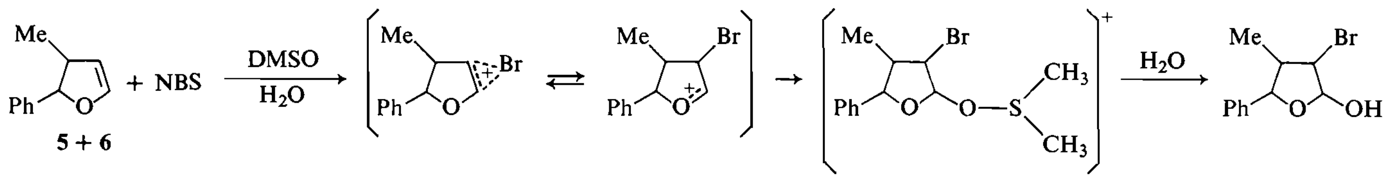

SCHÉMA 2

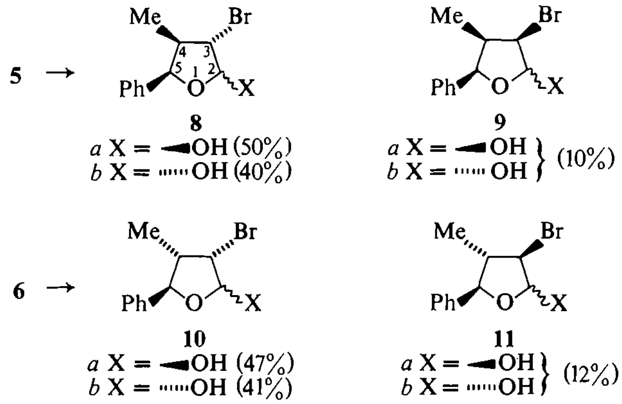

N.B.: Nous désignerons par α les substituants sur la face opposée au phényle et par β les substituants sur la même face que le phényle: *a*, X = OHβ; *b*, X = OHα

SCHÉMA 3

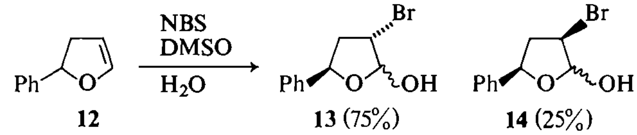

SCHÉMA 4

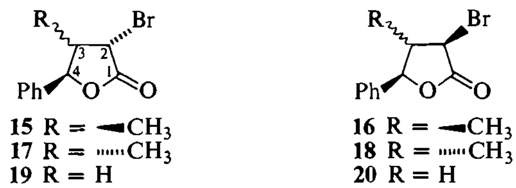

SCHÉMA 5

Par cristallisation (éther de pétrole), on isole aisément la bromhydrine **10***a* (F = 132°C). Les différents isomères peuvent être séparés par chromatographie en couche mince (ccm) sur silice, après acétylation. Les spectres rmn de chaque bromhydrine et de son acétate sont discernables principalement par le déplacement chimique du proton H2, plus déblindé de 0.7 à 1 ppm dans les acétates (tableau 1).

L'attribution des structures des différentes bromhydrines est effectuée d'une part grâce à l'analyse des couplages observés en rmn du proton (9, 12) et d'autre part grâce à l'étude des lactones préparées pour l'étape suivante de la synthèse. Nous verrons que cette oxydation supprime le centre asymétrique hémiacétalique sans altérer la configuration du carbone voisin, porteur du brome; l'analyse du mélange de lactones obtenues (schéma 5) indique donc directement l'importance relative des attaques électrophiles par la face opposée au phényle (face α) ou du côté du phényle (face β), pour chacun des composés dihydrofuranniques **5** ou **6**. Il apparaît que 10% environ d'entrée de l'électrophile Br^+ se fait par la face β du dihydrofuranne, quelle que soit l'orientation du méthyle en 3. Il peut paraître surprenant que la présence du méthyle sur l'une ou l'autre face du cycle dihydrofurannique intervienne aussi peu au cours de l'étape d'approche du réactif électrophile.

Il nous a alors paru intéressant d'examiner le cas du dérivé dihydrofurannique **12**, non méthylé en 3. On obtient de nouveau un mélange de 4 bromhydrines (schéma 4) puis de deux lactones (schéma 5) plus facilement analysable par rmn. On note alors que la lactone résultant de l'approche de l'électrophile par la face la plus encombrée **20** représente 25% du mélange. Apparemment, le méthyle en 3 intervient de façon complexe dans le problème de l'approche des réactifs, modifiant par un effet conformationnel, l'orientation du phényle.

II. Préparation des lactones bromées

Après extraction à l'éther, le mélange brut des bromhydrines est oxydé à l'aide du réactif de Jones (13). On obtient avec un rendement de 96 à 98% par rapport aux dérivés dihydrofuranniques **5** et **6** de départ, un mélange de lactones bromées séparables par ccm. La composition du mélange reflète à la fois celle des dihydrofurannes **5** et **6** de départ et, pour chacun, le pourcentage d'attaque électrophile par l'une ou l'autre face du cycle dihydrofurannique. Nous avons pu en effet montrer que les bromhydrines **8** à **11** donnent respectivement les lactones **15** à **18**.

Au cours de l'étape suivante de la synthèse (débromhydratation des lactones), nous avons mis en évidence une méthode simple d'équilibration de ces bromolactones par épimérisation du brome en α du carbonyle. Cette réaction permet d'accéder aux isomères **16** et **18** en quantité notable et de connaître la composition des mélanges à l'équilibre (**16**/**15** = 23:77 et **18**/**17** = 56:44). Nous avons pu alors vérifier que l'oxydation par le réactif de Jones de bromhydrines pures ou diversement enrichies donne bien les lactones correspondantes et que ces lactones, hors d'équilibre, n'évoluent pas dans le milieu réactionnel.

Les structures de ces lactones sont établies par rmn du proton (interprétation des déplacements chimiques et des couplages) (tableau 2).

Un certain nombre d'analyses cristallographiques de γ-lactones (14) a montré que l'hétérocycle adopte une conformation enveloppe dans laquelle le carbonyle, l'oxygène hétérocyclique ainsi que les deux carbones voisins (C2 et C4) sont coplanaires. Si la même situation prévaut dans notre cas, les lactones **15** à **18**, en solution, doivent se trouver dans un état d'équilibre conformationnel entre deux formes enveloppes non équivalentes.

L'étude des constantes de couplage vicinal J(H2H3) et J(H3H4) en rmn du proton, l'étude du déplacement chimique de l'hydrogène H4 et du méthyle 3 permettent, en même temps que la confirmation de structure des différentes lactones bromées, le choix éventuel des conformations privilégiées.

Lorsque le méthyle est *cis* par rapport au phényle, son déplacement chimique est de l'ordre de 0,7 à 0,8 ppm alors que pour les isomères *trans*, le méthyle apparaît au dessus de 1 ppm. Ceci est sans doute lié, comme dans le cas des dérivés

TABLEAU 1. Spectres rmn (^{1}H) des bromhydrines tétrahydrofuranniques méthylées en 4 et de leurs dérivés acétylés (spectres effectués à 250 MHz en solution dans $CDCl_3$, TMS interne, δ en ppm, J en Hz)

dihydro (15) et tétrahydrofuranniques (16) analogues, à l'anisotropie du phényle dont la rotation est gênée par la proximité des substituants en 3. Pour la même raison, l'hydrogène H4 est simultanément déplacé en sens inverse (tableau 2). On peut alors noter que dans cette série de lactones bromées le couplage J(H3H4) *cis* est plus petit que J(H3H4) *trans* indépendamment de l'orientation du brome, ce qui résulte probablement d'une abondance relativement grande des conformations **17*a*** et **18*a*** (fig. 1) comportant deux hydrogènes H3 et H4 *trans* diaxiaux.

En ce qui concerne le couplage J(H2H3), une grande valeur (11,5 Hz pour **18**) peut être associée à une orientation diaxiale des deux hydrogènes *trans* alors qu'une petite valeur (3,5 Hz pour **15**) peut être associée à leur orientation biéquatoriale (fig. 1). Les valeurs de couplages *cis* (de type équatorial–axial) sont intermédiaires (tableau 2). Il est donc probable que la lactone **15** se trouve dans la conformation **15*a*** prédominante dans laquelle le phényle équatorial, en raison de son encombrement stérique et le brome axial, en raison des effets dipolaires (17) sont le plus à l'aise; le méthyle doit alors s'accommoder d'une orientation axiale. De même, la lactone **18** doit être dans la conformation **18*a*** prédominante avec phényle et méthyle équatoriaux, le brome devant alors s'accommoder d'une orientation pseudo-équatoriale. Pour les deux autres lactones, la rmn ne permet pas de choisir une conformation prépondérante. On peut néanmoins penser que la lactone **17** se trouve dans sa conformation **17*a*** de façon probablement exclusive, ayant à la fois les substituants volumineux phényle et méthyle, équatoriaux (J(H3H4) grand) et le substituant polaire brome, en α du carbonyle, axial. Dans le cas de la lactone **16**, il est probable que les deux conformations participent à l'équilibre.

Il résulte de cette analyse que l'on doit s'attendre à ce que la lactone **17** et dans une moindre mesure, **16** (grâce à sa conformation **16*b***) soient les isomères les plus aptes à subir l'élimination E2.

III. Obtention du buténolide 7

Il était alors important de trouver des conditions équilibrantes de débromhydratation, de façon que les isomères **15** et **18** ne soient pas perdus pour la synthèse.

Les sels de lithium (LiCl, LiBr. . .) employés comme nucléophiles dans des solvants polaires aprotiques permettent d'accéder à des doubles liaisons conjuguées à des groupes attracteurs par un mécanisme d'élimination bimoléculaire (18).

Or il est connu que certains solvants aprotiques sont capables d'épimériser une bromocétone en milieu non énolisant (17) et que le DMF est le meilleur solvant pour les solvolyses en milieu aprotique (18*b*, 18*c*).

Nous avons donc soumis le mélange des bromolactones précédentes, en solution dans le DMF anhydre, à l'action de LiBr et obtenu le Δ^2 buténolide correspondant **7**, facilement identifiable par ses propriétés spectroscopiques (ir, rmn) (19). Le procédé est rapide et efficace puisque le buténolide est obtenu avec un rendement de 95% en 1 h à 120°C, indépendamment de la configuration de la bromolactone de départ. Le produit brut de la réaction d'oxydation par le réactif de Jones peut donc être utilisé sans inconvénients.

Il était alors intéressant d'examiner le comportement de chacun des isomères des bromolactones (séparés par ccm) dans le même milieu (solution dans le DMF), à 60 ou 70°C, en présence ou en l'absence de LiBr.

En l'absence de LiBr, on observe que les deux couples de lactones (**15**, **16** d'une part et **17**, **18** d'autre part) ont des réactivités nettement différentes. L'équilibre **15** ⇄ **16** s'établit

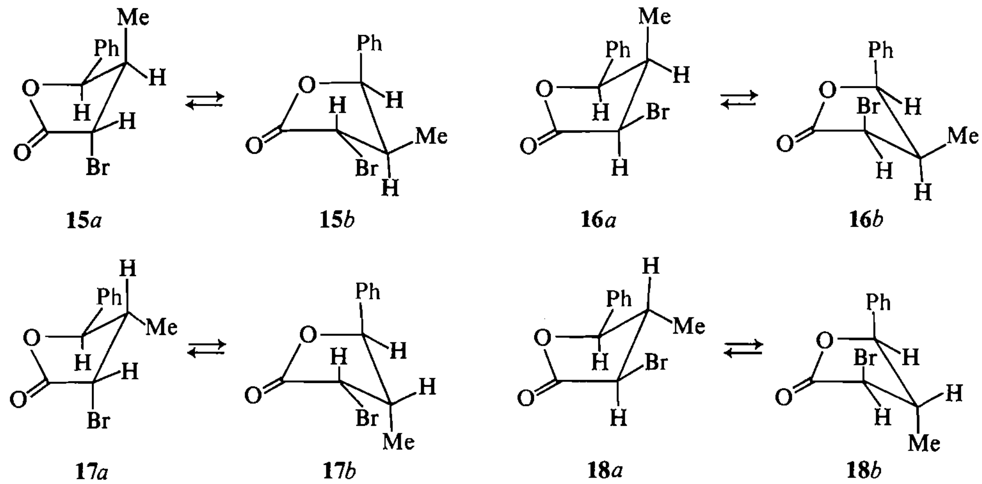

FIG. 1

plus lentement et il faut attendre environ 5 jours à 60°C pour atteindre une composition voisine de l'équilibre: **15**/**16** = 80:20 à partir de **15** ou **15**/**16** = 74:26 à partir de **16**. Au contraire l'équilibre **17** ⇄ **18** est atteint en moins de 12 h à 60°C: **17**/**18** = 42:58 à partir de **18** et **17**/**18** = 45:55 à partir de **17**. Cette équilibration dans le DMF peut en fait s'accompagner d'une lente élimination en buténolide **7**. On observe que cette nouvelle réaction est plus rapide pour les lactones **15** et **16** que pour **17** et **18**. C'est ainsi qu'à 70°C, en 1 jour, **15** et **16** ont donné 44% de buténolide alors que **17** et **18** n'en ont donnée que 6%.

En présence de LiBr, on observe les mêmes réactions d'équilibration et d'élimination; la réactivité relative des différents isomères reste la même qu'en l'absence de LiBr, avec toutefois des vitesses fortement accrues par la présence du catalyseur. Ainsi, avec une solution environ 0,15 molaire de LiBr dans le DMF, à 70°C en 1 h, les isomères **15** ou **16** ont donné 35% de buténolide alors que **17** ou **18** n'en ont donné que 8%, les lactones résiduelles étant dans un rapport **15**/**16** = 70:30 dans le premier cas et **17**/**18** = 60:40 dans le deuxième cas, à partir de chacun des quatre isomères purs.

On peut donc penser que dans le DMF pur, seules les réactions de solvolyse ont lieu, alors qu'en présence des ions Br^- apparaît la possibilité supplémentaire des réactions bimoléculaires S_N2 et E2.

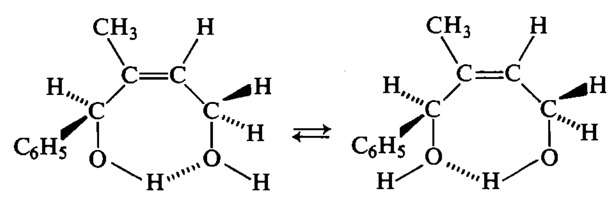
Une étude plus détaillée sur le mécanisme de l'élimination et de l'isomérisation des bromolactones sera présentée dans un prochain mémoire. Nous y décrirons notamment les difficultés rencontrées dans le cas des lactones non méthylées **19** et **20**.

En conclusion, pour ce qui concerne la préparation du Δ^2-buténolide **7**, nous avons pu en réaliser une synthèse intéressante en trois étapes simples et quantitatives, ne nécessitant pas la purification ou la séparation des produits intermédiaires. On sait tout l'intérêt que suscite ce type de molécules en raison de l'abondance des buténolides parmi les substances naturelles (20) ou la variété de leur propriétés physiologiques (21). Un certain nombre d'halolactones (22) présentent également un grand intérêt au point de vue synthèse. Nous avons, quant à nous, utilisé le buténolide **7** pour préparer le γ-diol **4**, de configuration Z.

IV. Préparation du γ-diol 4,Z (Ar = C_6H_5)

Par analogie avec la réduction d'autres γ-lactones (23) la réduction du buténolide **7** par $LiAlH_4$ en suspension dans l'éther nous a fourni de façon tout à fait sélective le γ-diol insaturé **4** de configuration *Z*, avec un rendement de 90%. Le diol est purifié par cristallisation dans le mélange benzène – éther de pétrole (10:90) (*F* = 75°C) et caractérisé par ses propriétés spectroscopiques. Son isomère *E* (*F* = 122–125°C) a été récemment isolé et décrit (24).

Le diol de configuration *Z* obtenu se distingue aisément de son stéréoisomère *E* par le fait que les deux protons du groupe CH_2OH terminal ne sont pas magnétiquement équivalents en rmn. Le centre asymétrique étant séparé du CH_2 par la double liaison, on assiste à un phénomène de diastéréotopie lointain qui tient sans doute à la possibilité d'une liaison hydrogène forte.



Cette structure ne peut évidemment pas exister pour l'isomère *E* (24). Le spectre ir, effectué en solution 5 × 10^{-3} molaire dans CCl_4 montre une raie fine à 3625 cm^{-1} et une bande large à 3460 cm^{-1}, l'aspect du spectre étant tout à fait analogue à celui des γ-diols saturés déjà décrits (25).

En spectrographie de masse, on note également des différences spectaculaires dans les spectres de fragmentations des isomères Z et E. Alors que l'isomère E est décrit (24) comme ne présentant pas de pic à $m/e = M - 18$, nous trouvons pour l'isomère Z que ce fragment donne le pic de base (m/e = 160:100%). D'autres pics intenses (159, 145, 116, 115, 105) n'existent pas pour l'isomère E et nous avons montré par filiation (défocalisation de métastables) qu'ils proviennent du fragment $M - 18$.

Partie expérimentale

Ce travail a été effectué à l'aide du matériel de spectroscopie et du Laboratoire de Microanalyse du Centre de Spectrochimie de Paris-Centre.

Les spectres rmn ^{1}H et ^{13}C ont été effectués sur spectrographe Bruker WP-80 et WP 250, en solution dans $CDCl_3$. Les déplacements chimiques sont exprimés en δ par rapport au tétraméthylsilane utilisé comme référence interne. Les constantes de couplage sont exprimées en hertz.

Les spectres de masse ont été réalisés avec le spectromètre Kratos MS50, les pourcentages des différents ions étant exprimés en % d'abondance relative. Les spectres ir sont faits en film liquide à l'état pur, ou en pastille KBr sur un spectrographe Perkin–Elmer modèle 357. Les points de fusion ont été déterminés sur le bloc Kofler.

Préparation des bromhydrines

À une solution refroidie à 10°C de 1 g (6,2 mmol) du mélange environ 1:1 des dérivés dihydrofuranniques **5** + **6** (3) dans 5 mL de DMSO additionné de 223 mg d'eau (2 équivalents), on ajoute sous atmosphère d'azote et sous agitation énergique, en une fois, 2,2 g de NBS. Au bout de 2 à 3 min, la solution s'échauffe légèrement et devient progressivement jaune puis orange. L'agitation est maintenue 10 à 15 min. On ajoute alors une douzaine de mL d'eau bicarbonatée. La solution s'éclaircit. On l'extrait à l'éther. Après séchage et évaporation de l'éther, le produit obtenu (1,57 g; rendement 98%) sera utilisé pour l'oxydation en lactone.

Le rendement est analogue à partir du dérivé dihydrofurannique *cis* **6** pur (4).

Hydroxy-2β bromo-3α méthyl-4α phényl-5β tétrahydrofuranne (**10***a*), F = 132°C

On dissout dans 5 mL d'éther, 850 mg de bromhydrines obtenues à partir du mélange **5** + **6**. Par addition progressive d'éther de pétrole, on obtient un précipité que l'on filtre (280 mg) et recristallise dans le même solvant: c'est l'isomère **10***a* (F = 132°C); ir: les bromhydrines présentent toujours une bande caractéristique ν_{OH} = 3400 cm^{-1} intense; rmn ^{1}H: tableau 1; ^{13}C: 12,4 (Me), 103,2 (C2), 60,5 (C3), 43,8 (C4), 87,3 (C5), 128,3 (C_p), 127,1 et 128,5 ($C_{m,o}$); masse m/e: 256 et 258 ($M^{+\cdot}$: 2%), 177 (29%), 77 (48%), 71 (100%). *Anal.* calc. pour $C_{11}H_{13}O_2Br$: C 51,36, H 5,09, Br 31,10; tr.: C 50,92, H 5,19, Br 30,79%.

Préparation des acétates des bromhydrines

On dissout 200 mg des bromhydrines dans le mélange anhydride acétique – pyridine (2 mL: 1 mL). Après 12 h à température ambiante, on hydrolyse et on extrait à l'éther. Les acétates ont été purifiés par ccm (éther/éther de pétrole 20:80). L'isomère **10***c* (X = OAcβ) cristallise (éther de pétrole/éther, F = 93°C).

Acetoxy-2β bromo-3α méthyl-4α phényl-5β tétrahydrofuranne (**10***c*), F = 93°C; ir (cm^{-1}): 1750 ($\nu_{C=O}$), 1270 (ν_{C-O}); rmn ^{1}H: tableau 1; masse m/e: 239 et 241 (7%: $M^{+\cdot} - 61$), 131 (88%), 91 (35%), 71 (55%), 43 (100%). *Anal.* calc. pour $C_{13}H_{15}O_3Br$: C 52,18, H 5,05, Br 26,70; tr.: C 52,12, H 5,12, Br 26,56%.

Les bromhydrines dérivées de **12** sont préparées de la même façon et avec des rendements analogues.

Hydroxy-2β bromo-3α phényl-5β tétrahydrofuranne (**13***a*), F = 80°C; rmn ^{1}H: 5,65 (H2α), 4,32 (H3β), 2,62 (H4α), 2,58 (H4β), 5,45 (H5α), 7,35 (H(Ph)), J(H2H3) = 0; J(H3H4α) = 0,5; J(H3H4β) = 4,25; J(H4αH4β) = −14,2; J(H5H4α) = 5,9; J(H5H4β) = 10,1. *Anal.* calc. pour $C_{10}H_{11}O_2Br$: C 49,38, H 4,53, Br 32,92; tr.: C 49,48, H 4,85, Br 32,62%.

Acetoxy-2β bromo-3α phényl-5β tétrahydrofuranne (**13***c*)

Cet ester est obtenu à partir de la bromhydrine cristallisée précédente; rmn ^{1}H: 6,5 (H2), 4,42 (H3), 2,65 (H4α), 2,55 (H4β), 5,55 (H5), 7,2 (H(Ph)), 2,08 (H(OAc)); J(H2H3) = 0,6; J(H3H4α) = 0,4; J(H3H4β) = 4,25; J(H4αH4β) = −14,4; J(H5H4α) = 5,8; J(H5H4β) = 10,2. *Anal.* calc. pour $C_{12}H_{13}O_3Br$: C 50,53, H 4,56, Br 28,07; tr.: C 50,21, H 4,69, Br 27,75%.

Préparation des bromo-lactones

Le mélange des bromhydrines (1,57 g) obtenu sous forme d'une huile claire à partir de **5** + **6** est dissous dans 30 mL d'acétone, puis refroidi à 0°C. On ajoute alors goutte à goutte, sous agitation, le réactif de Jones (13) (solution de 10,3 g CrO_3 dans 30 mL d'eau à laquelle on additionne dans la glace 8,7 mL H_2SO_4, d = 1,839) jusqu'à coloration rouge persistante. On laisse agiter 10 min puis on ajoute le minimum d'isopropanol pour revenir à la coloration verte. L'acétone est évaporée et le résidu solide, repris dans l'eau est extrait à l'éther. La solution éthérée est neutralisée (solution de bicarbonate), lavée, séchée et évaporée. Le produit huileux obtenu (1,56 g) apparaît par rmn et par ccm comme un mélange très propre de quatre lactones bien discernables (rendement 97% par rapport à **5** + **6**). Il est utilisable directement pour préparer le buténolide **7**.

Le mélange obtenu comporte deux isomères largement prédominants **15** (dérivé de **5**) et **17** (dérivé de **6**) et cristallise spontanément pour donner l'isomère **15** solide (F = 92°C).

Par isomérisation dans le DMF, on peut obtenir les deux autres lactones **16** et **18** purifiables par ccm sur silice (éther – éther de pétrole 30:70).

La formule exacte des différentes bromolactones a été confirmée par la mesure de la masse exacte de l'ion moléculaire en spectrographie de masse; ir: le spectre ir montre bien la disparition de la bande hydroxyle et la présence d'une bande double attribuable au groupe carbonyle d'une lactone α halogénée (26): 1770–1790 cm^{-1}; rmn: tableau 2.

De la même façon, le dérivé dihydrofurannique **12** conduit au mélange des deux bromolactones **19** et **20** séparables par ccm. L'isomère **19** cristallise après purification. À partir de 500 mg de **12**, on obtient 770 mg de lactones dont on extrait environ 550 mg de cristaux (F = 79°C).

Préparation du méthyl-3 phényl-4 $\Delta^{2(3)}$-butyrolactone (**7**)

Une solution de 1 g de LiBr dans 8 mL de DMF a été ajoutée à la solution de 1,56 g des bromo-lactones précédentes dans 35 mL de DMF. La solution est agitée pendant 1 h dans un bain d'huile à 120°C, sous atmosphère d'argon. Puis le mélange réactionnel est dilué avec 5 mL d'eau. Le buténolide extrait à l'éther (1,03 g) est pur. Après ccm (éther de pétrole – éther éthylique 50:50), il reste liquide (rendement final 95% par rapport au mélange **5** + **6** de départ); ir: 1760, 1645 cm^{-1}; rmn ^{1}H: 1,80 (m, 3H), 5,57 (m, 1H), 5,77 (m, 1H); J(H2H4) ≃ 0,6 Hz mesuré par découplage du méthyle. *Anal.* calc. pour $C_{11}H_{10}O_2$: C 75,86, H 5,74; tr.: C 75,77, H 5,86%.

Le même buténolide a été obtenu à partir de **6** pur: à partir de 500 mg de dérivé dihydrofurannique **6** de départ, on obtient 518 mg de buténolide **7**.

Préparation du phényl-1 méthyl-2 butène-2 diol-1,4 (**4**) (isomère Z)

Une solution de 100 mg de buténolide **7** dans l'éther anhydre est ajoutée lentement à 20 mg d'hydrure de lithium et d'aluminium en suspension dans 8 mL d'éther anhydre à 0°C. On chauffe 2–3 h à reflux sous agitation puis on hydrolyse. L'extraction à l'éther donne 98 mg du γ-diol **4** que l'on recristallise dans le mélange benzène – éther de pétrole (F = 75°C, rendement: 90% par rapport au mélange **5** + **6** de départ). Le même rendement a été obtenu sur une préparation de 4 g; ir (KBr): 1600 ($\nu_{C=C}$); 3360 (ν_{OH}). Le spectre en solution diluée dans CCl_4 a été discuté plus haut; rmn ^{1}H (à 250 MHz, $CDCl_3$): 1,60 (H(Me), s), 3,0 (H(OH), bande large), 4,18 et 4,41 (H4 et H4′), 5,61 (H3), 5,68 (H1, s), 7,30 (H(Ph)). Les protons H3, H4′ forment un système AMX, à 250 MHz, avec J(H4H4′) = 12 Hz, J(H4H3) = 6 Hz et 8 Hz; masse m/e: 178 ($M^{+\cdot}$: 1%), 160 (100%), 147 (14%), 145

(75%), 131 (47%), 129 (46%), 117 (32%), 115 (28%), 107 (41%), 105 (85%), 91 (40%); spectre de masse de l'isomère *E* (24): 178 (3%), 147 (18%), 131 (11%), 107 (24%), 105 (100%), 79 (28%), 77 (26%), 69 (11%), 51 (11%). *Anal.* calc. pour $C_{11}H_{14}O_2$: C 74,12, H 7,91; tr.: C 74,10, H 7,89%.

ipso Nitration. XXVI.[1] Nitration of 1,2-dimethyl-4-nitrobenzene. Formation and reactions of adducts[2]

ALFRED FISCHER,[3] GEORGE N. HENDERSON, AND LOKANATHAN M. IYER
Department of Chemistry, University of Victoria, Victoria, B.C., Canada V8W 2Y2

Received November 16, 1984

ALFRED FISCHER, GEORGE N. HENDERSON, and LOKANATHAN M. IYER. Can. J. Chem. **63**, 2390 (1985).

Nitration of 1,2-dimethyl-4-nitrobenzene in a mixture of acetic anhydride and trifluoroacetic anhydride gives the diastereoisomers of 4,5-dimethyl-2,4-dinitrocyclohexa-2,5-dienyl acetate (50%), in addition to the 1,2-dimethyldinitrobenzenes. In moderate and more strongly acid conditions the adduct gives 4-nitro-, 3,4-dinitro-, and 3,5-dinitro-*o*-xylene. In neutral and weakly acid solutions 4-nitro- and 3,5-dinitro-*o*-xylene are formed by a radical and a sigmatropic pathway. The adduct reacts facilely with nucleophiles by allylic substitution to give a 5,6-dimethyl-6-nitrocyclohexa-2,4-dienyl derivative which, in many instances, undergoes a second allylic substitution to a new 4,5-dimethyl-2,4-dinitrocyclohexa-2,5-dienyl derivative. Depending on the nature of the introduced substituent, these 2,4- and 2,5-dienyl products may eliminate nitrous acid, under the reaction conditions, to give the corresponding aromatic compound. The dienyl acetates undergo acid-catalysed transesterification to the corresponding dienols.

ALFRED FISCHER, GEORGE N. HENDERSON et LOKANATHAN M. IYER. Can. J. Chem. **63**, 2390 (1985).

La nitration du diméthyl-1,2 nitro-4 benzène dans un mélange d'anhydride acétique et d'anhydride trifluoroacétique conduit, en plus des diméthyl-1,2 dinitrobenzènes, à la formation des diastéréoisomères de l'acétate du diméthyl-4,5 dinitro-2,4 cyclohexadiène-2,5 yle (50%). Dans des milieux modérément et plus fortement acides, l'adduit conduit aux nitro-4, dinitro-3,4 et dinitro-3,5 *o*-xylènes. Dans des milieux neutre ou légèrement acide, les nitro-4 et dinitro-3,5 *o*-xylènes se forment par un mécanisme radicalaire suivi d'une transposition sigmatropique. Par substitution allylique, l'adduit réagit facilement avec les nucléophiles et il conduit à un dérivé diméthyl-5,6 nitro-*o* cyclohexadiène-2,4 yle qui, dans plusieurs cas, subit une deuxième substitution allylique pour conduire à un nouveau dérivé diméthyl-4,5 dinitro-2,4 cyclohexadiène-2,5 yle. Dépendant de la nature des substituants introduits, ces produits diène-2,4 (ou −2,5) yles peuvent éliminer de l'acide nitreux dans les conditions de la réaction afin de conduire à la formation du composé aromatique correspondant. Les acétates de diènyles subissent des transestérifications acido-catalysées conduisant aux diénols correspondants.

[Traduit par le journal]

Nitration at a substituted position, *ipso* nitration (3), is competitive with nitration at an unsubstituted position in many aromatic compounds. The resulting *ipso*-nitrocyclohexadienyl cation is captured as a relatively stable acetate ester in acetic anhydride and can be isolated. In previous work the adduct from 3,4-dimethybenzonitrile has been obtained (4). The nitro group has directing and deactivating effects similar to those of the cyano group and it was anticipated that nitration of 1,2-dimethyl-4-nitrobenzene (4-nitro-*o*-xylene) would occur at the 2 position, *ipso* to methyl, to form an adduct.

Results and discussion

4-Nitro-*o*-xylene did not react at all when it was treated with nitric acid (5 mol ratio) in acetic anhydride (10 mol ratio) at 0°C for 48 h. Substituent constant data indicate that the nitro group is more electron withdrawing than the cyano group and this accounts for the reduced reactivity of the nitroxylene compared with the cyanoxylene. Addition of trifluoroacetic anhydride increased the reactivity of the nitrating mixture and the 4-nitro-*o*-xylene was then readily nitrated to form 3,4-dinitro- (16%), 4,5-dinitro- (12%), and 3,5-dinitro-*o*-xylene (22%), and the diastereoisomers of 4,5-dimethyl-2,4-dinitrocyclohexa-2,5-dienyl acetate (**1***am*) (40% and 10%). The reaction products were isolated by chromatography on silica and recrystallization of appropriate fractions.

Trifluoroacetic anhydride is a very effective catalyst for the nitration reaction and makes possible the nitration of deactivated substrates. 4-Nitro-*o*-xylene does not react at all in its absence, and the less deactivated 3,4-dimethylbenzonitrile, which reacts with nitric acid in acetic anhydride to the extent of 60% in 24 h, reacts to the extent of 85% in 1 h when trifluoroacetic anhydride is added.[4] In acetic anhydride nitric acid is converted into acetyl nitrate and this is accompanied by the formation of acetic acid. The trifluoroacetic anhydride would convert the acetic acid into the mixed anhydride and release trifluoroacetic acid. Since the nitration reaction is subject to acid catalysis (5), replacing the weaker acetic acid by the stronger trifluoroacetic acid would increase the rate of the reaction. Alternatively, trifluoroacetyl nitrate might be formed which would transfer nitronium ion more rapidly to the substrate and (or) exist in equilibrium with a higher concentration of nitronium ions, which react with the substrate.

Infrared, nuclear magnetic resonance, and elemental analytical data confirmed the presence of the substituents and functionalities depicted in structure **1***am*. The ultraviolet absorption maxima (*E*-**1***am* 225 nm; *Z*-**1***am* 227 nm) demonstrated that the

TABLE 1. Relative gradients (gradient 1-$OCOCH_3$ = 1.00) of proton chemical shifts for diene adducts from the addition of Eu([$^2H_9$]fod)$_3$

Compound	1-H	3-H	4-CH_3/4-H	5-CH_3	6-H/CH_3
E*-1*am	1.62	0.24	0.16	0.03	0.70
Z*-1*am	1.57	0.28	0.09	0.06	0.69
12*m*	1.73	0.34	0.22	0.16	0.50

adducts are non-conjugated cyclohexadienes. Conjugated cyclohexadienes absorb above 250 nm (6). There are three possible locations for the double bonds in a non-conjugated cyclohexadiene derived from 4-nitro-*o*-xylene, the structures for which may be described, using the enumeration of the nitroxylene, as 1,4-, 2,5-, and 3,6-dienes. The 2,5-diene would have adjacent vinylic protons (5-H and 6-H) and these would exhibit a 10-Hz coupling which was not observed in either diene isomer. In the 1,4-diene the methyl groups would have similar magnetic environments in that each is attached to a vinylic carbon of the 1,2 double bond and each vinylic carbon is also attached to a tetrahedral carbon bearing a single hydrogen. Both methyl groups would be expected to be similarly coupled. However, only one methyl group in each isomer was split. Furthermore, the low-field proton, the 5-H in the 1,4-diene (attached to the other end of the 4,5 double bond to which the nitro group is attached), should exhibit a three-bond allylic coupling to the adjacent proton ($J \geqslant 2.6$ Hz (7)). However, in both isomers the low-field proton appeared as a singlet. Thus only the 3,6-diene arrangement of the double bonds, that shown in structure **1***am*, accounts for the ^{1}H nmr. Furthermore, only the 3,6-diene structure is in accord with the ^{13}C nmr spectra which exhibited absorptions at 61.4 and 88.9 ppm (*E*), and 60.9 and 87.7 ppm (*Z*) for the two diastereomers. These are characteristic absorptions for saturated carbon atoms. In the gated spectra the higher-field absorptions (61.4 and 60.9 ppm) were split into doublets (J = 155 Hz), indicating that in each isomer one of the atoms attached to the higher-field carbon is hydrogen, while the lower-field absorptions remained as singlets, indicating that there is no hydrogen atom attached to the lower-field saturated carbon atom. The 1,2-diene structure has one hydrogen on both saturated carbon atoms, while in the 2,5-diene neither carbon has an attached hdyrogen. Although the structure, in which the positions of the nitro and acetate are interchanged from those depicted in **1***am*, would also account for the ^{1}H nmr spectra, it would not account for the ^{13}C nmr spectra, which showed that the higher-field carbon atom, and therefore the one with acetate rather than nitro attached, is the one also attached to the hydrogen. This structure can also be rejected on the grounds that, being a secondary nitro compound, it would eliminate acetic acid exceedingly readily on treatment with base and, even if formed, would not have survived the work-up process.

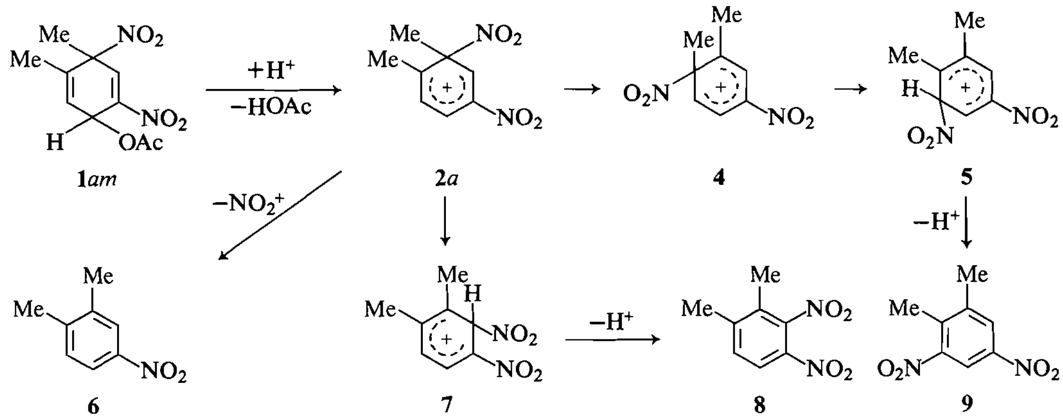
The stereochemistry of the diastereoisomers was assigned on the basis of shift reagent effects. Addition of *tris*-(1,1,1,2,2,3,3-heptafluoro-7,7-[$^2H_6$]dimethyl-4,6-[$^2H_3$]octanedionato)europium(III) shifted the peaks of all protons to lower fields (Table 1). In both isomers the magnitude of the downfield shift followed the sequence 1-H > $OCOCH_3$ > 6-H > 3-H > 4-CH_3 > 5-CH_3 in accord with the expectation that the magnitude of the shift is a function of the inverse of the distance between the europium ion, attached to the acetate function, and the proton in question, and supporting the structural assignment discussed above. The shift of the 4-CH_3 protons in the major isomer (mp 95°C, eluted first) was markedly greater than that of the same protons in the minor isomer (mp 115°C, eluted second), and thus the *E* configuration (OAc *cis* to 4-CH_3) was assigned to the former and the *Z* configuration (OAc *trans* to 4-CH_3) to the latter.

Addition of nitronium ion to the 2 position of the substrate nitroxylene is the dominant nitration process. This is in accord with expectation since the nitro group is *meta* directing and, in *o*-xylene itself, *ipso* addition predominates over attack at an unsubstituted position (8). Thus, that *ipso* position which is *meta* to the nitro group is expected, and found, to be the most reactive site in 4-nitro-*o*-xylene. Calculations based on the assumed additivity of substituent effects, and using the relative partial rate factors for the nitration of toluene in acetic anhydride (9), and the isomer distribution for nitration of nitrobenzene in mixed acid (10), give the following relative extents of attack (parenthesized) at the indicated nuclear positions of 4-nitro-*o*-xylene: 1 (3), 2 (64), 3 (2), 4 (0), 5 (2), 6 (29). The observed order 2 > 6 > 3 ≈ 5 follows that calculated, but the 3 and 5 positions are much more reactive than predicted. Part of the difference between observation and calculation may lie in the fact that data for the isomer distribution for nitration of nitrobenzene in acetic anhydride is not available and data for mixed acid are used instead. However, it also appears that substituent effects in nitration are additive to only a rough approximation, at best (11, 12).

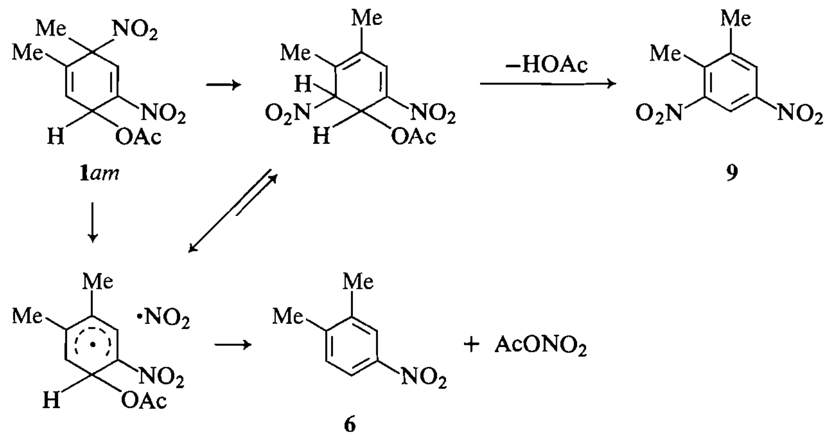
Reactions of diene 1am *with acids*

Previous studies of *ipso*-nitrocyclohexadienyl acetates have shown that the dominant reactions involve, in the initial step, either the acid-catalysed loss of acetate to (re)generate the *ipso*-nitrocyclohexadienyl cation, or the solvolysis of the nitro group, which departs as nitrite, to generate an acetoxycyclohexadienyl cation (13–16). Although the loss of nitrite is also reported to be acid-catalysed (16, 17), it is less sensitive to such catalysis than is the loss of acetate. Thus, strongly acidic conditions favour the formation of the nitrocyclohexadienyl cation, while weakly acidic, or neutral, ionizing conditions favour the formation of the acetoxycyclohexadienyl cation. The competitive balance between these two reaction pathways should be markedly affected by other substituents present in the cyclohexadiene ring. The presence of an electron-withdrawing substituent at the position *meta* to the *ipso*-nitro position results in the formation of the nitrocyclohexadienyl cation being competitive with the formation of the acetoxycyclohexadienyl cation down to lower acidity levels. The relevant cations in the case of **1***am* are **2***a* and **3***a*. Cation **3***a* is destabilized to a much greater extent by the presence of the substituent nitro group (attached to a formally positively charged centre in **3***a*) than cation **2***a* (in which the nitro goup is not attached to one of the formally positively charged centres). Similarly, the transition state leading to **3***a* is more destabilized than that leading to **2***a*. Thus the competitive balance between the two initial cation-forming reactions that exists when X = H is altered, when X = NO_2, in favour of the formation of **2***a*. In fact, cation **3***a* is so destabilized by the presence of the substituent nitro group that even at the lowest acidity levels it was not formed (none of its deprotonation product 2-nitro-4,5-dimethylphenyl acetate was detected) as other reactions intervened (*vide infra*).

Reaction of **1***am* with boron trifluoride-etherate or with trifluoroacetic acid gave the nitroxylene **6** (75%) plus the dinitroxylenes **8** and **9** (Table 2). These products arise from cation **2***a* by loss of nitronium ion, and by a sequence of 1,2 nitro shifts followed by deprotonation, respectively (Scheme 1). Myhre



SCHEME 1

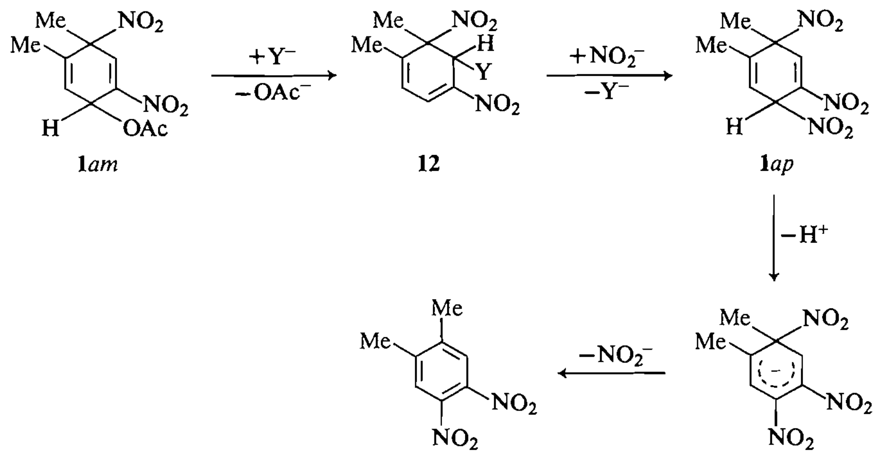


SCHEME 2

has shown that in the *ipso*-nitro cation from *o*-xylene 2*b* (2*a* and 4 are the 5-nitro and 4-nitro derivatives, respectively, of this cation) migration of the nitro group to the adjacent substituted position is fifty times faster than migration to the adjacent unsubstituted position (18). If the migration of the nitro group between the *ipso* positions of 2*a* and 4 is similarly favoured over migration to the *ortho* positions, then 2*a* and 4 should be quasi-equilibrated. At equilibrium 2*a* should be favoured because of the electronic effect of the substituent nitro group. On the other hand, the conversion of 2*a* to 7 should be inhibited by the substituent nitro group, whereas the conversion of 4 to 5 should be favoured. Thus 4, at a lower concentration, will rearrange with a higher rate constant to 5, whereas 2*a*, at a higher concentration, will rearrange with a smaller rate constant to 7. The combined effect results in the rates of formation of 5 and 7 being comparable, and thus similar amounts of 8 and 9 were obtained. Confirmation that an intermediate nitrocyclohexadienyl cation was involved in these reactions with acids was provided by repeating the reaction with boron trifluoride-etherate in the presence of mesitylene. The mesitylene captured cation 2*a* almost quantitatively to form the biphenyl **10** (19). The effect of the substituent in determining the reaction product of reactions carried out at a fixed acidity is nicely illustrated by reactions in trifluoroacetic acid. Whereas diene 1*am* gives the (di)nitroxylenes by loss of acetic acid, dienes 1*cm*, 1*dm*, and 1*em* give the aryl acetate by loss of nitrous acid (4, 20).

Reaction of 1*am* with hydrogen bromide in ether (which was not investigated in detail by glc) gave 4-nitro-*o*-xylene as the major product. In trifluoromethanesulfonic acid all three dinitro-*o*-xylenes were formed, in addition to a reduced amount of 4-nitro-*o*-xylene. An initial reaction would lead to **6**, **8**, and **9**, as in Scheme 1. In the strong acid, renitration of **6** can occur by the nitric acid liberated. If it is assumed that **6**, **8**, and **9** are initially formed in the same ratio as the average ratio of the trifluoroacetic and boron trifluoride catalysed reactions (75%, 14%, 11%) and that 44 of the 75% of **6** is renitrated to the dinitroxylenes **8**, **9**, and **11** in the same ratio that these are formed on nitration of **6** in trifluoroacetic anhydride – acetic anhydride (32:44:24), then the calculated product distribution of **6**:**8**:**9**:**11** is 31:28:30:11. The similarity to the observed ratio of 31:25:31:13 supports the proposed interpretation.

Diene 1*am* was stable to acetic acid at ambient temperature but rearomatized on heating to give **6** and **9** in nearly equal amounts. The same two products were obtained, although in a different ratio, when 1*am* was heated in toluene or pyrolyzed in the inlet of a gas chromatograph. These thermolytic reactions appear to share a common pathway. The 3,5-dinitroxylene **9** is obtained by a formal 1,3 shift of the nitro group. Such 1,3 shifts have also been observed in the rearomatization of diene adducts from dimethylbenzonitriles (4). We have shown that the adduct from 3,4-dimethylbenzonitrile (1*cm*) rearranges via a sigmatropic 1,3 nitro shift to a 2-cyano-6-nitrocyclohexa-2,4-dienyl acetate which readily eliminates acetic acid to form the 5-nitrobenzonitrile (21). The same mechanism, which also provides for the possibility of a minor contribution to the rearrangement reaction from a radical process, and which accounts for the formation of **6** and **9**, is applied to 1*am* in Scheme 2. In the presence of hydroquinone the reaction of 1*am* in acetic acid gave more **6** (68%) and less **9** (32%). Hydroquinone would act as a radical scavenger and the result suggests that a portion



11

SCHEME 3

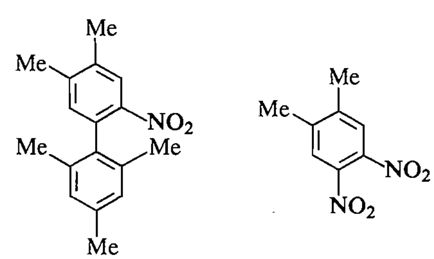
of the rearrangement reaction involves the radical pathway. In earlier work we suggested that such 1,3 nitro shifts occur in the *ipso*-nitro cation (4). Formal 1,3 nitro shifts do occur in the cation, as illustrated by the formation of **9** from **1***am* (Scheme 1), but these are a combination of successive 1,2 shifts and are accompanied, where possible, by the formation of the 1,2 shift product. No 3,4-dinitroxylene **8** (the 1,2 shift product) was obtained in the thermolytic reactions of **1***am* and, likewise, no 3,4-dimethyl-2-nitrobenzonitrile was obtained on the thermolysis of **1***cm*, which gave 3,4-dimethylbenzonitrile, 3,4-dimethyl-5-nitrobenzonitrile, and a trace amount of 2-cyano-3,4-dimethylphenyl acetate. It is now clear that the conditions used for the thermolytic reactions are too weakly acidic for the formation of the nitrocyclohexadienyl cation at a sufficient concentration for it to be the source of the aromatization products.

Reaction of **1***am* with 5% sulfuric acid in methanol resulted in transesterification and the formation of the *ipso*-nitrodienol **1***ao*. Because of the deactivating effect of the nitro substituent the normal $A_{AL}1$ cleavage to form **2***a*, which would give the dienyl methyl ether **1***an* and (or) **12***n*, is not competitive with $A_{AC}2$ reaction leading to the dienol. The stereochemistry at the AL chiral centre is preserved in the $A_{AC}2$ reaction and thus we were able to assign the configuration of the diastereoisomeric dienols **1***ao*: *E*-**1***am* gives *E*-**1***ao* and *Z*-**1***am* gives *Z*-**1***ao*.

Mention was made above of the effect of acidity on the competition between the formation of the ions **2***a* and **3***a* and that it appears that **3***a* is not formed even under the most favourable conditions (low acidity, ionizing solvent). Thus solvolysis of **1***am* in aqueous methanol gave **6** as the major product and no 4,5-dimethyl-2-nitrophenyl acetate (the deprotonation product of **3***a*) was obtained. As the acidity is reduced and formation of **2***a* becomes slower, **1***am* reacts by the radical and sigmatropic pathways, shown in Scheme 2, and by allylic substitution (*vide infra*). With less powerful electron-withdrawing groups than nitro, formation of the acetoxycyclohexadienyl cation **3** is more favoured and the product from this (the 2-X-3,4-dimethylphenyl acetate) begins to appear at low acidities. Thus a small amount of 2-cyano-3,4-dimethylphenyl acetate was present in the products of thermolysis of **1***cm* and, as the acidity was increased and conditions made more favourable for ionic reactions, the amount of the aryl acetate increased, becoming the major product in trifluoroacetic acid. Of course, in strongly acidic conditions the product of acetate loss and nitro migration, the dimethylbenzonitrile, should be favoured, although reaction of **1***cm* under these conditions was not investigated. The acyl-dienes **1***dm* and **1***em* gave the 2-acyl-4,5-dimethylphenyl acetate on rearomatization in neutral and weakly acid solution (i.e. on heating under reflux in toluene, acetic acid, or on standing in acetic acid (20)). No products were detected from a sigmatropic and (or) radical process, as illustrated in Scheme 2. The acyl groups are less electron-withdrawing than cyano (σ_{p-NO_2} = 0.78, σ_{p-CN} = 0.66, σ_{p-Ac} = 0.50 (22)) and the cations **3***d* and **3***e* should be more stable than **3***c*. At high acidities (boron trifluoride-etherate, 78% sufuric acid, 50% sufuric acid in acetic acid) these adducts rearomatized via cations **2***d* or **2***e* to form the 3,4-dimethylphenyl ketone and its 2-nitro and 5-nitro derivatives.

Reactions with nucleophiles

Diene **1***am* is unusual among nitronium acetate adducts in that it reacts with nucleophiles. The first such reaction was observed when we attempted to acetylate dienol **1***ao* using the acetic anhydride – pyridine reagent conventionally employed for the acetylation of hydroxyl groups (23), whence 1,2-dimethyl-4,5-dinitrobenzene (**11**) was obtained. The dienol itself was stable to pyridine, indicating that acetylation preceded aromatization, and this was confirmed by reacting the dienyl acetate **1***am* with neat pyridine to give **11** in close to quantitative yield. The reaction of **1***am* with pyridine provides a useful synthetic route to **11**.



10 **11**

The mechanism shown in Scheme 3 involving consecutive S_N2' processes accounts for the apparent 1,4 migration of the nitro group (2). In the first step a general nucleophile adds at the 3 position of **1***am*, allylic to the acetate group which simultaneously departs as an anion. In the second step the general nucleophile is itself substituted at the new allylic position by the nitrite anion. For each substitution the normally unreactive (towards nucleophiles) vinyl carbon is activated by conjugation

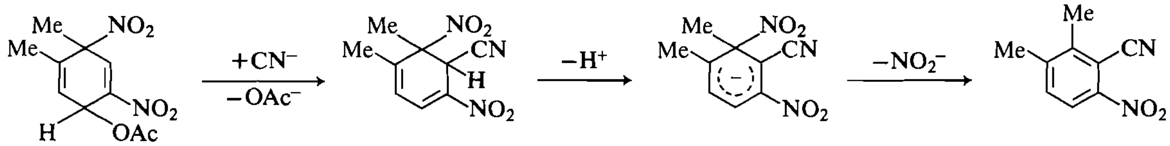
of the double bond with the (non-migrating) vinylic nitro group. The proton α to the new nitro group in diene **1***ap* is acidic and is readily removed by base to form an anion which, in turn, rapidly loses the *ipso* nitro group as a nitrite anion (which is thus regenerated) to give **11**. The small amount of nitrite anion required to initiate the reaction could be formed by elimination of the elements of nitrous acid from **1***am* by the base. Support for the proposed mechanism is provided by the observation and isolation of the intermediate conjugated diene **12***m* and its further reaction to give **11**. It was possible to observe **12***m* as an intermediate in the reaction of **1***am* with 2,6-dimethylpyridine which reacts at ca. one-fifth of the rate of the reaction with pyridine. Thus reaction of **1***am* in chloroform with 2,6-dimethylpyridine gave, over 2 h at 0°C, unreacted **1***am* (67%) together with **12***m* (17%) and **11** (15%), whereas reaction with neat 2,6-dimethylpyridine gave **11** (94%) in 15



1*am* 12*q* 13 14

SCHEME 4

min. A more detailed nmr investigation of the reaction of dienol 1*ao* with acetic anhydride and pyridine at 0°C showed that acetylation to 1*am* was complete within 6 min and was accompanied by partial isomerization to give **12***m*. Formation of **11** then occurred and it was substantially complete in 1 h, during which time the intermediate formation of **12***m* was quite apparent. When 2,6-dimethylpyridine was used as the catalyst, both the acetylation and the aromatization reactions were much slower. After 24 h only 3% of **11** had been formed and the major compounds present were dienes **1***am* and **12***m*.

Generally, reaction of **1***am* with nucleophiles (Table 2) gave yields of **11** ranging from significant to substantial and indicating that nitrite anion is a very competitive nucleophile towards **12**. Thus, reaction of **1***am* in acetonitrile with hydroxide, *tert*-butoxide, phenoxide, acetate, thiocyanate, and halide ions, all gave high yields of **11**. Most notably in the reaction carried out with potassium bromide for a shorter reaction time, but also in some of the other reactions, the intermediate formation of **12***m* was apparent, supporting the mechanism outlined in Scheme 3. Thiophenoxide was an effective competitor for intermediate **12***m* in acetonitrile. Reaction of **1***am* with sodium thiophenoxide gave 4,5-dimethyl-2-nitrophenyl phenyl sulfide (99%). *tert*-Butylamine on reaction with **1***am* in chloroform gave a 19% yield of a compound tentatively identified as *N*-tert-butyl-4,5-dimethyl-2-nitroaniline, and presumably formed by attack of the amine on **12***m*, although **11** was the major product (60%). Since acetate appears to play the role of the nucleophile in the first substitution step of many of the above reactions, it is possible that this step may involve an internal concerted 1,3 migration of the ester acetate function, instigated by the addition of a nucleophile to the carbonyl carbon and thus converting the carbonyl oxygen into the more nucleophilic alkoxide. When cyanide ion was used as the nucleophile some **11** was formed, but 2,3-dimethyl-6-nitrobenzonitrile (**14**) was the major product (Scheme 4). We assume that in this case the cyanide ion successfully competes with acetate for the 3 position of **1***am*, giving **12***q*. The hydrogen atom α to the cyanide group in **12***q* is acidic and should be readily lost to give the corresponding anion **13** which would rearomatize by loss of nitrite. Cyanide is a poorer leaving group than acetate and this is another factor which would inhibit the allylic substitution of nitrite for cyanide in **12***q*, which would lead to **11**.

Acetate is liberated in the formation of **11** from **1***am* (Scheme 3) and is thus available in solution as a potential nucleophile. A striking feature of the competition between acetate and nitrite as nucleophiles is that, whereas acetate is the more effective nucleophile towards **1***am* (no intermediate **12***p* was detected, not even when **1***am* was reacted with potassium nitrite), nitrite is much more effective as a nucleophile towards **12***m*, as shown by the fact that reaction of **1***am* with potassium acetate in acetonitrile gave only **11**. Diene **12***p*, if formed, might be expected to rearomatize rapidly to **8**, but yields of this product in the nucleophilic reactions were at most very small and it is likely that these small amounts were formed by some other pathway. The 3 position in **1***am*, which is susceptible to nucleophilic attack, is flanked by methyl and nitro substituents at the quaternary centre, on one side, and by a nitro group attached to the sp^2 carbon on the other. These would hinder the approach of the bulky nitrite ion (with nitrogen acting as the nucleophilic centre). Even if this ion did add to give **12***p* it is possible that the latter would undergo rapid allylic substitution, rather than deprotonation to an anion and rearomatization to **8**, since this rearomatization process would require the newly introduced nitro group to move into the plane of the ring with increased steric interaction with the flanking groups. In contrast to nitrite, the linear (and therefore less subject to hindrance) cyanide ion readily attacked the 3 position of **1***am*, and the resulting **12***q* was readily deprotonated.

In reactions carried out in methanol there was more effective competition with nitrite for the intermediate **12**. The major product (~50%) in the reactions with potassium bromide, fluoride, and iodide was 4,5-dimethyl-2,4-dinitrocylohexa-2,5-dienyl methyl ether (**1***an*). It seems likely that the reactivity of nitrite as a nucleophile is reduced in methanol by hydrogen bonding or protonation, which allows methoxide ion or methanol to compete for the intermediate **12***m* with the small amount of available nitrite. In accordance with this suggestion, the reactions with potassium halides in methanol were much slower than reactions with potassium halides in acetonitrile. Again in these reactions the formation of **12***m* as an intermediate was apparent in the nmr spectra. Reaction of **1***am* with potassium nitrite in methanol did give **11** quantitatively, as did the reaction with potassium thiocyanate. Reaction of **1***am* with sodium methoxide in methanol at 0°C gave **12***n* in less than 5 min.

Reaction of **1***am* with potassium bromide in acetic anhydride proved to be an effective means of preparing **12***m*. In this solvent the further reaction of **12***m* with nitrite was suppressed, presumably by protonation or acetylation of the latter, and the reaction stopped at the intermediate stage. Reactions in which the conjugated diene **12***m* and its analogue **12***n* were used as substrates gave products in accord with the mechanisms outlined above (Table 3). Reaction of **12***m* with sodium methoxide in methanol gave the allylic substitution product **1***an* (77%) and **12***n* (23%). Presumably **12***n* is formed from **1***an* by a second allylic substitution. Reaction of potassium cyanide in methanol with **12***m* gave 4,5-dimethyl-2-nitrobenzonitrile and a small amount of **11**. Here the cyanide ion is able to compete effectively with nitrite (or methoxide) in the allylic substitution and the resulting **1***aq*, like **1***ap*, readily aromatizes by base-catalysed elimination of nitrous acid (cf. Scheme 3). Reaction of **12***n* with pyridine in chloroform, and with potassium iodide in acetonitrile, gave **11**. Reaction with potassium nitrite in methanol also gave **11** but, surprisingly, a substantial yield of **6** as well. Reaction with potassium cyanide in acetonitrile gave 4,5-dimethyl-2-nitrobenzonitrile and a further reaction product, 4,5-dimethyl-1,2-benzenedicarbonitrile.

Reaction of the cyanodiene **1***cm* (4) with potassium cyanide in acetonitrile gave 2-cyano-4,5-dimethylphenyl acetate (**15**)

TABLE 3. Yields of products from reactions of **1***ao*, **12***n*, and **12***m* (mol%)

SCHEME 5

and its corresponding phenol **16** (Scheme 5). Evidently the 1,4 elimination of nitrous acid is preferred over the allylic substitution that occurs in **1***am*, most likely because the cyano group is less activating than nitro towards the Michael addition. Elimination to **15** also occurred, over two weeks, on reaction with sodium nitrite in methanol at 20°C. No reaction occurred between **1***cm* and pyridine in chloroform, at 20°C, over 1 week.

Other reactions

Reaction of dienol **1***ao* with sulfuric acid in acetic anhydride gave mainly **6**, together with **8** and **9**. Presumably cation **2***a* is formed as an intermediate, either directly, by acid-catalysed loss of hydroxyl, or by acetylation of **1***ao* to **1***am* followed by protonation and loss of acetic acid. Each of the diastereoisomers of **1***ao* was stereospecifically methylated with methyl iodide and silver oxide to its corresponding methyl ether. Since the stereochemistry of the dienols **1***ao* was established by the stereospecific transesterification of the acetates **1***am* (*vide supra*), the stereochemistry of the ethers was able to be determined: *E*-**1***ao* gives *E*-**1***an* and *Z*-**1***ao* gives *Z*-**1***an*.

5,6-Dimethyl-2,6-dinitrocyclohexa-2,4-dienyl methyl ether (**12***n*) reacted over 7 days with boron trifluoride-etherate, at 20°C, to give **6** and 2,3-dimethyl-6-nitro anisole. Methoxide is a poorer leaving group than acetate and the loss of nitrite from **12***n*, leading to the anisole, is competitive with loss of methoxide to form **2***a* and thence **6**. Pyrolysis of **12***n* gave mainly **6**.

5,6-Dimethyl-2,6-dinitrocyclohexa-2,4-dienyl acetate (**12***m*) underwent transesterification to the corresponding dienol (**12***o*) on treatment with sulfuric acid in methanol.

Experimental

The ir spectra, calibrated with polystyrene, were recorded as Nujol mulls or as potassium bromide discs, for solids, and as thin films between sodium chloride plates for oils, using a Pye–Unicam SP1000 or a Perkin–Elmer 283 spectrometer. The ^{1}H nmr spectra were recorded on Perkin–Elmer R32 (90 MHz) and Perkin–Elmer R12A (60 MHz) instruments. Spectra were routinely recorded in [^{2}H]chloroform, with tetramethylsilane as an internal standard. The ^{13}C nmr spectra were obtained in [^{2}H]chloroform, with tetramethylsilane as an internal reference, on a Nicolet TT14 (15.1 MHz) spectrometer. The uv spectra were recorded on a Cary-17 spectrometer, with methanol as solvent. Mass spectra were recorded on a Hitachi Perkin–Elmer RMU7 spectrometer at 70 eV. The glc analyses were performed on a Varian Aerograph 2400, using a 1.3 m × 3 mm column of 3% SE-30 on Chromosorb P at 180°C. A Finnegan 3300 system was used for combined gas chromatography and mass spectrometry of mixtures. A Waters Associates Prep LC/System 500 was employed for liquid chromatography.

1,2-Dimethyl-4-nitrobenzene was from Aldrich. Acetic anhydride was certified ACS, Fisher, and trifluoroacetic anhydride was Aldrich Gold Label (99+%). Nitric acid (300 cm^3, fuming, Fisher) was purified by distilling at 1 Torr (1 Torr = 133.3 Pa) from urea (10 g, reagent, Fisher) and sulfuric acid (500 cm^3) and stored at −25°C. Solvents used for chromatography including pentane (reagent, Fisher), anhydrous ether (reagent, Amachem), and benzene (reagent, Amachem) were further purified by drying over sodium followed by distillation and storage over molecular sieves. Non-deuterated solvents employed for spectroscopy were certified ACS, spectranalyzed (Fisher), and deuterated solvents were obtained from Merck, Sharp and Dohme. Silica gel (60–200 mesh) was Davison commercial grade H and neutral alumina (Camag, Activity I), deactivated with 3% of distilled water, was used.

In order to optimize the reaction conditions to obtain the maximum extent of diene formation on nitration, a series of reactions was carried out on a small scale (1 mmol of substrate). The reaction mixture was prepared at −78°C, the temperature then raised to 0°C, and aliquots were withdrawn at regular intervals. The ^{1}H nmr spectra of these samples were determined at −20°C. Each sample was then added to ether and neutralized with aqueous sodium bicarbonate. The ether extract was washed and dried ($MgSO_4$), the ether evaporated, and the ^{1}H nmr spectrum of the residue determined in [^{2}H]chloroform.

Small scale (nmr tube) reactions of the dienes were worked up by transferring the contents of the tube to a flask (25 cm^3), rinsing with ether, and neutralizing (where necessary) at low temperature with ammonia (for acidic reagents) or hydrochloric acid (for basic reagents). After washing with water the ether extract was dried and the ether evaporated, at 15°C, on a rotary evaporator. The product mixture was analysed by ^{1}H nmr and by glc–ms. Some reactions were only examined by ^{1}H nmr and this is indicated in the text.

*Nitration of 4-nitro-*o*-xylene*

Nitric acid (32 g, 0.51 mol) at −20°C was added cautiously and in small portions, with stirring, to a mixture of acetic anhydride (80 g) and trifluoroacetic anhydride (100 g) at −78°C.[5] The temperature of the mixture was raised to 0°C for 5 min to ensure complete reaction, and then lowered to −78°C. This nitrating mixture was added dropwise, over 10 min, to a solution of 4-nitro-*o*-xylene (**6**) (15 g, 0.1 mol) in acetic anhydride (20 g) at −78°C. The reaction temperature was then raised to 0°C and maintained for 2 h with stirring. At the end of this period, the reaction mixture was poured into a beaker containing ice (800 g) and ether (800 cm^3). Sodium bicarbonate was added to the stirred mixture until the latter was mildly alkaline (pH 8). The ether was separated and the aqueous phase extracted with ether. The combined extract was washed with water (2 × 600 cm^3), dried ($MgSO_4$), and evaporated at 15°C. Integration of the ^{1}H nmr spectrum of the crude reaction product showed that the diene adducts constituted ca. 50% of the total mixture.

The product was chromatographed on silica gel, at −40°C, using pentane–ether mixtures as eluent. Fractions eluted with up to 40% ether in pentane gave 1,2-dimethyl-3,5-dinitrobenzene (**9**) as the principal product, mp 75°C (lit. (24) mp 77°C); ir (KBr): 1520 and 1348 (NO_2) cm^{-1}; ^{1}H nmr (90 MHz, $CDCl_3$) δ: 2.46 (s, 3, 1-CH_3), 2.51 (s, 3, 2-CH_3), 8.18 (d, 1, 6-*H*), 8.35 (d, 1, 4-*H*) ppm, J_{46} = 2 Hz; ms (70 eV) *m/e* (relative intensity): 196 (40, *M*), 180 (15), 179 (100, *M* − OH), 133 (27), 132 (13), 104 (26), 103 (36), 91 (24), 78 (19), 77 (34), metastable peak at 163.5 corresponding to 196 → 179.

The 45% and 50% ether–pentane fractions gave a mixture containing 1,2-dimethyl-4,5-dinitrobenzene (**11**) (ca. 20%) and diene adducts (ca. 80%), which, on recrystallization from ether at −20°C, gave the *E* diastereomer of 4,5-dimethyl-2,4-dinitrocyclohexa-2,5-dienyl acetate (*E*-**1***am*), mp 95°C; uv (CH_3OH): 225 (775), 194 nm (1540 m^2 mol^{-1}); ir (Nujol): 1238 and 1742 ($OCOCH_3$), 1560 (NO_2) cm^{-1}; ^{1}H nmr (90 MHz, $CDCl_3$) δ: 1.88 (t, 3, 5-CH_3), 1.95 (s, 3, 4-CH_3), 2.06 (s, 3, $OCOCH_3$), 5.98 (m, 1, 6-*H*), 6.46 (m, 1, 1-*H*), 7.44 (s, 1, 3-*H*) ppm, J_{16} = 4, $J_{6,5\text{-Me}}$ = 1.5, $J_{1,5\text{-Me}}$ = 1.3 Hz. On a 300 Hz expanded spectrum, the peak due to 5-CH_3 appeared as a triplet (overlapping doublets) and the peak due to 1-H appeared as a multiplet. Irradiation of the methyl resonance at δ 1.88 collapsed the peaks at δ 5.98 and δ 6.46 ppm to two doublets. Irradiation at either δ 5.98 or δ 6.46 resulted in the collapse of 5-CH_3 to a doublet; ^{13}C nmr ($CDCl_3$) δ_C: 17.4 (5-CH_3), 20.6 ($OCOCH_3$), 23.4 (4-CH_3), 61.4 (*C*-1), 88.9 (*C*-4), 124.3 (*C*-6), 133.6 (*C*-3), 134.8 (*C*-5), 148.3 (*C*-2), 169.5 ($OCOCH_3$) ppm. *Anal.* calcd. for $C_{10}H_{12}N_2O_6$: C 46.88, H 4.72, N 10.93; found: C 47.02, H 4.70, N 10.82.

The mother liquor from these fractions was subjected to another recrystallization to give **11**, which was further recrystallized from ethanol and then had mp 118°C (lit. (24) mp 118°C); ir (KBr): 1528, 1548, 1378, and 1338 cm^{-1}; ^{1}H nmr (90 MHz, $CDCl_3$) δ: 2.37 (s, 6, 1-CH_3 and 2-CH_3), 7.63 (s, 2, 3-*H* and 6-*H*); ms (70 eV) *m/e* (relative intensity): 197 (12), 196 (100, *M*), 180 (20), 150 (14, *M* − NO_2), 108 (48), 103 (24), 92 (14), 91 (79), 80 (24), 79 (26), 78 (21), 77 (45).

The 55% ether–pentane column fraction gave a mixture of **11**, 1,2-dimethyl-3,4-dinitrobenzene (**8**), and the diene adducts in the ratio 1:4:5. This fraction was recrystallized from ether at −20°C to give the *Z*-diastereomer of **1***am*, mp 115°C (dec.); uv (CH_3OH): 227 (830), 195 nm (1620 m^2 mol^{-1}); ir (Nujol): 1240 and 1750 ($OCOCH_3$), 1560 (NO_2) cm^{-1}; ^{1}H nmr (90 MHz, $CDCl_3$) δ: 1.86 (br s, 6, 4-CH_3 and 5-CH_3), 2.04 (s, 3, $OCOCH_3$), 5.96 (m, 1, 6-*H*), 6.34 (d, 1, 1-*H*), 7.34 (s, 1, 3-*H*), J_{16} = 4 Hz, $J_{6,5\text{-Me}}$ = 1.5 Hz. Expansion of the spectrum and double resonance studies as described from *E*-**1***am* enabled the coupling constants to be determined; ^{13}C nmr ($CDCl_3$) δ_C: 17.4 (5-CH_3), 20.6 ($OCOCH_3$), 24.1 (4-CH_3), 60.9 (*C*-1), 87.7 (*C*-4), 124.3 (*C*-6), 132.8 (*C*-3), 133.9 (*C*-5), 148.4 (*C*-2), 169.8 ($OCOCH_3$). *Anal* calcd. for $C_{10}H_{12}N_2O_6$: C 46.88, H 4.72, N 10.93; found: C 46.70, H 4.72, N 10.65.

Further elution with 60% ether–pentane, followed by recrystallization of the residue from the eluate from carbon tetrachloride, gave **8**, which was further recrystallized from ethanol and then had mp 82°C (lit. (24) mp 82°C); ir (KBr): 1352 and 1540 (NO_2) cm^{-1}; ^{1}H nmr (90 MHz, $CDCl_3$) δ: 2.22 (s, 3, 1-CH_3), 2.41 (s, 3, 2-CH_3), 7.41 (d, 1, 5-*H*), 7.92 (d, 1, 6-*H*), J_{56} = 8.5 Hz; ms (70 eV) *m/e* (relative intensity): 196 (57, M), 180 (16), 179 (100, *M* − OH), 148 (13), 150 (96, *M* − NO_2), 105 (11), 104 (14), 103 (23), 92 (13), 91 (63), 79 (12), 78 (27), metastable peak at 163.5 corresponding to 196 → 179.

The separation of the diene adducts from each other and from the aromatic compounds was greatly improved using benzene as eluent at 5–10°C. The diene adducts were readily separated on the Waters liquid chromatograph.

Reactions of dienes **1**am, **12**m, *and* **12**n *with acids*

Boron trifluoride-etherate

Boron trifluoride-etherate solution (300 mm^3), at −78°C, was added to diene **1***am* (100 mg) in an nmr tube, also at −78°C. The temperature was raised to 0°C, whereupon the diene dissolved and reacted within 5 min. After work-up the products were identified as **6** (78%, *m/e* 151, *M*), **9** (8%, *m/e* 196, *M*), and **8** (14%, *m/e* 196, *M*). Diene **12***n* was treated similarly with boron trifluoride-etherate. No reaction occurred over 72 h. The mixture was worked up after 20 days at 20°C to give **6** (58%, *m/e* 151, *M*) and 2,3-dimethyl-6-nitroanisole (42%; *m/e* 181, *M*); ^{1}H nmr (90 MHz, $CDCl_3$) δ: 2.22 (s, 3, 2-CH_3), 2.29 (s, 3, 3-CH_3), 3.82 (s, 3, OCH_3), 6.95 (d, 1, 4-*H*), 7.54 (d, 1, 5-*H*), J_{45} = 9 Hz.

Boron trifluoride-etherate and mesitylene

Cold BF_3-etherate solution (250 mm^3) was added to a solution of the diene **1***am* (100 mg, 0.39 mmol) and mesitylene (250 mg, 2.1 mmol) in methylene chloride (250 mm^3) at −78°C. The solution was allowed to warm to 20°C and left to stand for 1 h. After work-up, the composition of the product was **6** (1%; *m/e* 151) and 2-nitro-2′,4,4′,5,6′-pentamethylbiphenyl (99%, *m/e* 269.143 (M_r($^{12}C_{17}{}^1H_{19}{}^{14}N^{16}O_2$) = 269.143); ^{1}H nmr (90 MHz, $CDCl_3$) δ: 1.88 (s, 6, 2′-CH_3 and 6′-CH_3), 2.25 (s, 6, 4-CH_3 and 4′-CH_3), 2.28 (s, 3, 5-CH_3), 6.81 (s, 2, 3′-*H* and 5′-*H*), 6.90 (s, 1, 6-*H*), 7.73 (s, 1, 3-*H*) ppm.

[5]**Caution**: the nitrating mixture of nitric acid in acetic anhydride and trifluoroacetic anhydride must be prepared carefully since it can spontaneously react violently.

Trifluoroacetic acid

Cold trifluoroacetic acid (450 mm^3) was added to diene **1***am* (64 mg) in an nmr tube at −78°C. No reaction occurred over 1 h after raising the temperature to 0°C. At 20°C partial rearomatization occurred over 4 h. The reaction mixture was left at 20°C for 18 h and then worked up to give a mixture of **6** (72%, *m/e* 151, *M*), **9** (13%, *m/e*, 196, *M*), and **8** (15%, *m/e* 196, *M*).

5% Sulfuric acid in methanol

Cold 5% sulfuric acid in methanol (25 cm^3) was added to diene *E*-**1***am* (600 mg), at 0°C. The mixture was allowed to warm to 20°C and the solution stirred for 18 h. The product was transferred with ether (25 cm^3) to a two-necked flask and neutralized with liquid ammonia at −78°C. The solution was filtered and the solvent removed from the filtrate at 0°C. The product was dissolved in ether (50 cm^3) and washed with water (2 × 25 cm^3). The ether extract was dried over anhydrous magnesium sulfate, filtered, and the solvent removed at 0°C to give *E*-4,5-dimethyl-2,4-dinitrocyclohexa-2,5-dien-1-ol (*E*-**1***ao*); ir (film): 3400 and 1050 (OH), 1555 (NO_2) cm^{-1}; ^1H nmr (90 MHz, $CDCl_3$) δ: 1.84 (d, 3, 5-CH_3), 1.89 (s, 3, 4-CH_3), 3.42 (s, 1, *OH*), 5.25 (d, 1, 1-*H*), 5.94 (m, 1, 6-*H*), 7.19 (s, 1, 3-*H*) ppm, J_{16} = 4, $J_{6,5\text{-Me}}$ = 1.40 Hz; ^{13}C nmr ($CDCl_3$) δ_C: 17.5 (5-CH_3), 23.5 (4-CH_3), 60.3 (*C*-1), 89.1 (*C*-4), 127.5 (*C*-6), 131.2 (*C*-3), 132.8 (*C*-5), 151.6 (*C*-2) ppm.

Under similar conditions, acetate *Z*-**1***am* gave dienol *Z*-**1***ao*; ir (film): 3420 and 1053 (OH), 1550 (NO_2) cm^{-1}; ^1H nmr (90 MHz, $CDCl_3$) δ: 1.82 (s, 6, 4-CH_3 and 5-CH_3), 3.42 (s, 1, *OH*), 5.18 (d, 1, 1-*H*), 6.00 (m, 1, 6-*H*), 7.17 (s, 1, 3-*H*) ppm, J_{16} = 4, $J_{6,5\text{-Me}}$ = 1.40 Hz; ^{13}C nmr ($CDCl_3$) δ_C: 17.4 (5-CH_3), 23.9 (4-CH_3), 60.2 (*C*-1), 88.3 (*C*-4), 127.6 (*C*-6), 130.4 (*C*-3), 132.5 (*C*-5), 151.6 (C-2) ppm.

The same reaction on diene **12***m* gave 5,6-dimethyl-2,6-dinitrocyclohexa-2,4-dien-1-ol (**12***o*); ^1H nmr (90 MHz, $CDCl_3$) δ: 1.85 (s, 3, 6-CH_3), 2.06 (d, 1, 5-CH_3), 3.80 (s, 1, *OH*), 5.43 (s, 1, 1-*H*), 6.26 (dd, 1, 3-*H*), 7.30 (d, 1, 4-*H*) ppm. A small amount (ca. 10%) of aromatic products was also formed. The dienol **12***o* was not very stable, and on vacuum drying decomposed extensively with evolution of brown fumes. It also decomposed when an attempt was made to methylate it with methyl iodide and silver oxide.

Trifluoromethanesulfonic acid

Cold trifluoromethanesulfonic acid (300 mm^3) was added to the diene **1***am* (90 mg) in an nmr tube at −78°C and the temperature was then raised to −20°C. The diene had decomposed completely in 5 min (^1H nmr). After work-up, the product composition was **6** (31%, *m/e* 151, *M*), **9** (31%, *m/e* 196, *M*), **8** (25%, *m/e* 196, *M*), and **11** (13%, *m/e* 196, *M*).

Hydrogen bromide in ether

Cold ether (500 mm^3), saturated with hydrogen bromide, was added to the diene **1***am* (64 mg) at −78°C. The temperature was raised to 0°C and, after 90 min, the ^1H nmr spectrum indicated partial rearomatization. After 18 h at 0°C, followed by work-up, **6** (95%) and **11** (5%) were obtained (^1H nmr only).

Acetic acid

Acetic acid (450 mm^3) was added to the diene **1***am* (70 mg) at 20°C. The ^1H nmr of the reaction mixture was unchanged after 30 days at 20°C. The solution was heated for 15 min at 100°C when brown fumes were evolved and after which the ^1H nmr indicated that the rearomatization was complete. After work-up the product composition was **6** (49%, *m/e* 151, *M*) and **9** (51%, *m/e* 196, *M*).

A solution of 10% (v/v) acetic anhydride in acetic acid (320 mm^3) was heated to 100°C for 10 min, cooled to 20°C, and diene **1***am* (50 mg) added. The solution was heated to 100°C for 10 min after which time ^1H nmr indicated complete rearomatization. After work-up, a mixture of **6** (44%, *m/e* 151, *M*) and **9** (56%, *m/e* 196, *M*) was obtained.

A solution of the diene **1***am* (64 mg, 0.25 mmol) and hydroquinone (28 mg, 0.25 mmol) in acetic acid (400 mm^3) was heated for 20 min at 100°C. After work-up, the product composition was **6** (68%, *m/e* 151, *M*) and **9** (32%, *m/e* 196, *M*).

Reaction of dienes **1**am, *with nucleophiles*

Pyridine and 2,6-dimethylpyridine

Cold [$^2H_5$]pyridine (315 mm^3) was added to the diene **1***am* (70 mg) in an nmr tube at −78°C. The solution turned orange-red. The temperature of the mixture was raised to 0°C and ^1H nmr, after 2 min, indicated complete rearomatization. After work-up, the product composition was **6** (3%, *m/e* 151, *M*), **8** (5%, *m/e* 196, *M*), and **11** (92%, *m/e* 196, *M*). With 2,6-dimethylpyridine rearomatization was complete after 15 min and **6** (2%, *m/e* 151, *M*), **8** (4%, *m/e* 196, *M*), and **11** (94%, *m/e* 196, *M*) were obtained.

The reaction was also carried out by adding [$^2H_5$]pyridine (21 mm^3) to a solution of the diene **1***am* (64 mg) in [^2H]chloroform (290 mm^3) at −60°C. The temperature was raised to 0°C (in 10° intervals) and the progress of the reaction monitored by ^1H nmr for 2 h. The conversion of the diene to **11** proceeded smoothly; time(min), % dienes, % arene: 30, 63, 37; 60, 43, 57; 120, 36, 64. The reaction mixture was worked up after 18 h at 0°C and the product composition was then **6** (2%, *m/e* 151, *M*), **8** (3%, *m/e* 196, *M*), and **11** (95%, *m/e* 196, *M*). Reaction of diene **12***n* with pyridine in chloroform for 48 h likewise gave **11** (~100%).

Cold 2,6-dimethylpyridine (58 mm^3) was added to a solution of diene **1***am* (64 mg) in [^2H]chloroform (290 mm^3) at −60°C. The temperature of the mixture was raised to 0°C and maintained for 2 h at this temperature. After work-up, the product composition was shown (^1H nmr) to be **11** (15%), diene **1***am* (67%), and 5,6-dimethyl-2,6-dinitrocyclohexa-2,4-dienyl acetate (**12***m*) (17%).

tert-*Butylamine*

Cold *tert*-butylamine (26 mm^3) was added to a solution of **1***am* in [^2H]chloroform. The reaction mixture was worked up after 18 h at 0°C. The product composition was **6** (4%, *m/e* 151, *M*), **9** (7%, *m/e* 196, *M*), **8** (10%, *m/e* 196, *M*), **11** (60%, *m/e* 196, *M*), and a compound tentatively identified as *N*-*tert*-butyl-4,5-dimethyl-2-nitroaniline (19%, ^1H nmr δ 1.48 ppm ($C(CH_3)_3$), *m/e* 222, *M*).

Sodium methoxide in methanol

Sodium methoxide (42 mg, 0.78 mmol) was added to a solution of the diene *E*-**1***am* (100 mg, 0.39 mmol) in methanol (350 mm^3) at −78°C. The mixture went orange-red. The temperature of the mixture was raised to 0°C for 2 h to ensure complete reaction. After work-up, the product was identified by ^1H nmr as one diastereomer of 5,6-dimethyl-2,6-dinitrocyclohexa-2,4-dienyl methyl ether (**12***n*). The reaction was repeated under similar conditions on the diastereoisomer *Z*-**1***am*, whereupon the same diastereomer of **12***n* was obtained.

Ether **12***n* was made using the crude nitration product of **6** (4 g, containing ca. 50% diene adducts). After reaction with sodium methoxide and work-up, the product was separated by hplc (Waters) using benzene as solvent. The first fraction contained mainly a mixture of aromatic compounds, present in the nitration product. The second fraction, after recrystallization from ether at −20°C, gave **12***n*, mp 69°C; uv (CH_3OH) 328 (595), 203 nm (950 m^2 mol^{-1}); ir (Nujol): 1555 (NO_2), 1090 (C—O—C) cm^{-1}; ^1H nmr (90 MHz, $CDCl_3$) δ: 1.88 (s, 3, 6-CH_3), 2.19 (d, 3, 5-CH_3), 3.55 (s, 3, OCH_3), 5.12 (s, 1, 1-*H*), 6.25 (dd, 1, 4-*H*), 7.38 (d, 1, 3-*H*) ppm, J_{34} = 6, $J_{4,5\text{-Me}}$ = 1.5 Hz. Irradiation of the 5-CH_3 (d) resonance resulted in the collapse of the 4-H (dd) resonance to a doublet. Irradiation of the 3-H (d) resonance resulted in the collapse of the 4-H (dd) resonance to a different doublet; ^{13}C nmr ($CDCl_3$) δ_C: 19.6 (6-CH_3), 20.0 (5-CH_3), 60.5 (OCH_3), 75.1 (*C*-1), 91.6 (*C*-6), 123.4 (*C*-4), 129.6 (*C*-3), 142.8 (*C*-5), 146.0 (*C*-2). *Anal.* calcd. for $C_9H_{12}N_2O_5$: C 47.37, H 5.30, N 12.27; found: C 47.55, H 5.24, N 12.14.

Acetate **12***m* was reacted similarly with sodium methoxide in methanol and gave, after work-up (^1H nmr), one diastereomer of ether **12***n* (23%) and both diastereomers of ether **1***an* (77%). The ratio of the diastereomers *E*-**1***an*/*Z*-**1***an* was 9:1, by integration of the methoxy peaks.

Sodium thiophenoxide

Sodium thiophenoxide (50 mg, 0.38 mmol) was added to a solution of diene **1***am* (64 mg, 0.25 mmol) in acetonitrile (400 mm^3) at −40°C and the temperature was raised to 0°C. After 5 min, ^{1}H nmr indicated that the diene had rearomatized. After work-up, the product composition was **6** (1%, *m/e* 151, *M*) and 4,5-dimethyl-2-nitrophenyl phenyl sulfide (99%). On recrystallization from ether, pale-yellow cubic crystals of the sulfide were obtained, mp 79°C; ^{1}H nmr (90 MHz, $CDCl_3$) δ: 2.07 (s, 3, 4-CH_3), 2.21 (s, 3, 5-CH_3), 6.60 (s, 1, 6-*H*), 7.45 (m, 5, C_6H_5), 7.96 (s, 1, 3-*H*) ppm; ms (70 eV) *m/e* (relative intensity): 259.057 (36, M_r ($C_{14}H_{13}NO_2S$) = 259.067), 199 (16), 198 (55), 196 (45), 195 (100), 182 (20), 181 (95), 166 (15).

Potassium nitrite

[$^2H_4$]Methanol (315 mm^3) was added to a mixture of the diene **1*am*** (70 mg, 0.27 mmol), potassium nitrite (35 mg, 0.42 mmol), and 18-crown-6 (35 mg, 0.41 mmol) at −78°C in an nmr tube. The ^{1}H nmr of the solution after 5 min at 0°C indicated complete rearomatization. The product, after work-up, was **11** (100%, *m/e* 196, *M*).

The reaction with potassium nitrite was carried out on the diene **12*n*** under similar conditions. The reaction mixture was left for 15 days at ambient temperature and worked up to give **6** (44%, *m/e* 151, *M*) and **11** (56%, *m/e* 196, *M*).

Potassium cyanide

Cold [$^2H_4$]methanol (315 mm^3) was added to a mixture of the diene **1*am*** (64 mg, 0.25 mmol), potassium cyanide (25 mg, 0.38 mmol), and 18-crown-6 (99 mg, 0.38 mmol) at −78°C. The mixture was warmed to 0°C for 30 min. After work-up, the products were 2,3-dimethyl-6-nitrobenzonitrile (**14**, 94%, ^{1}H nmr (90 MHz, $CDCl_3$) δ: 2.45 (s, 3, 2-CH_3), 2.60 (s, 3, 3-CH_3), 7.54 (d, 1, 4-*H*), 8.04 (d, 1, 5-*H*) ppm, J_{45} = 8.6 Hz; *m/e* 176, *M*) and **11** (6%, *m/e* 196, *M*). When the reaction was carried in acetonitrile the product ratio after work-up (^{1}H nmr) was **14**/**11** = 70:30, and in 50% (v/v) pyridine–methanol the ratio was 58:42.

Diene **12*m*** was reacted with potassium cyanide in methanol and gave 4,5-dimethyl-2-nitrobenzonitrile (87%, *m/e* 176, *M*) and **11** (13% *m/e* 196, *M*).

Diene **12*n*** on reaction with potassium cyanide in acetonitrile gave 4,5-dimethyl-2-nitrobenzonitrile (70%, ir (Nujol): 2235 (CN), 1525 and 1350 (NO_2) cm^{-1}; ^{1}H nmr (90 MHz, $CDCl_3$) δ: 2.40 (s, 3, CH_3), 2.43 (s, 3, CH_3), 7.59 (s, 1, 2-*H*), 8.05 (s, 1, 5-*H*) ppm; *m/e* 176, *M*) and 4,5-dimethyl-1,2-benzenedicarbonitrile (30%, ^{1}H nmr (90 MHz, $CDCl_3$) δ: 2.37 (s, 6, 4, CH_3 and 5-CH_3), 7.51 (s, 2, 3-*H* and 6-*H*) ppm; *m/e* 156.068 (M_r ($^{12}C_{10}{}^1H_8{}^{14}N_2$) = 156.064)).

Potassium halides

Cold methanol (400 mm^3) was added to a mixture of diene **1*am*** (64 mg, 0.25 mmol), 18-crown-6 (99 mg, 0.38 mmol), and potassium iodide (62 mg, 0.38 mmol) at −78°C. The temperature was raised to 0°C. After 1 h ^{1}H nmr showed that no reaction had occurred. The mixture was warmed to 20°C for 48 h. After work-up, ^{1}H nmr showed the products to be **11** (58%) and 4,5-dimethyl-2,4-dinitrocyclohexa-2,5-dienyl [$^2H_3$]methyl ether (**1*an***, 42%), identified by comparison of its spectrum with that of an authentic sample.

The reaction was repeated under similar conditions with potassium bromide and the mixture worked up after 78 h at 20°C to give (^{1}H nmr) **1*an*** (45%), **11** (22%), and **12*m*** (33%). The last compound was identified by comparison of its spectrum with that of an authentic sample.

With potassium chloride, and the mixture worked up after 7 days at 20°C, **1*am*** gave (^{1}H nmr) **11** as the only product.

With potassium fluoride, the product composition (^{1}H nmr) after 20 h at 0°C was **11** (28%), **1*an*** (57%), **12*m*** (15%).

[$^2H_3$]Acetonitrile (400 mm^3) was added to a mixture of potassium fluoride (22 mg, 0.38 mmol) and 18-crown-6 (99 mg, 0.38 mmol). The mixture was warmed to 50°C and the solution cooled to 0°C. Diene **1*am*** (64 mg, 0.25 mmol) was added and the reaction worked up after 20 min at 0°C to give (^{1}H nmr) **11** (ca. 100%).

With potassium bromide for 18 h at 0°C the products were **11** (95%, *m/e* 196, *M*), **8** (3%, *m/e* 196, *M*), and **9** (2%, *m/e* 196, *M*). Reaction for 5 h at 0°C gave (^{1}H nmr) **11** (32%) and **12*m*** (68%). The product mixture from this reaction on treatment with potassium iodide (62 mg, 0.38 mmol) and 18-crown-6 (99 mg, 0.38 mmol) in acetonitrile (400 mm^3) for 18 h at 0°C gave (^{1}H nmr) **11** as the main product.

With potassium iodide for 1 h at 0°C the products were (^{1}H nmr) **11** (77%) and **12*m*** (23%). The product mixture from this reaction, on further treatment with potassium iodide (62 mg, 0.38 mmol) and 18-crown-6 (99 mg, 0.38 mmol) in methanol (400 mm^3) for 18 h at 0°C, gave (^{1}H nmr) **11**. Reaction of diene **12*n*** with potassium iodide in acetonitrile for 18 h at 20°C gave (^{1}H nmr) **11**.

Cold 50% (v/v) acetic anhydride in acetonitrile (700 mm^3) was added to a mixture of potassium bromide (45 mg, 0.38 mmol) and 18-crown-6 (99 mg, 0.38 mmol) in an nmr tube. The mixture was warmed to 50°C, cooled to 0°C, and diene **1*am*** (64 mg, 0.25 mmol) added. The reaction mixture was worked up after 18 h at 0°C to give, by ^{1}H nmr, **11** (3%), diene **1*am*** (22%), and **12*m*** (75%).

In neat acetic anhydride (400 mm^3) containing potassium bromide, diene **1*am*** gave, after 18 h, a mixture of one diastereomer of **12*m*** (75%) and **1*am*** (25%).

The reaction with potassium bromide in acetic anhydride was carried out on the crude nitration product of **6** (containing ca. 50% dienes). The reaction product was worked up after 48 h at 0°C and separated by hplc using benzene as solvent. The first fraction contained mainly the aromatic compounds which were present in the original nitration product. The second fraction, after recrystallization from ether at −20°C, gave one diastereomer of **12*m***, mp 99°C; uv (CH_3OH): 325 (1145), 195 nm (1380 m^2 mol^{-1}); ir (Nujol): 1753 and 1210 ($OCOCH_3$), 1555 (NO_2) cm^{-1}; ^{1}H nmr (90 MHz, $CDCl_3$) δ: 1.78 (s, 3, 6-CH_3), 2.08 (s, 3, OCOCH_3), 2.12 (d, 3, 5-CH_3), 6.35 (dd, 1, 4-*H*), 6.93 (s, 1, 1-*H*), 7.48 (d, 1, 3-*H*) ppm, J_{34} = 7, $J_{4,5\,Me}$ = 1.5 Hz. Irradiation of the 4-H (dd) resonance resulted in the collapse of the 5-CH_3(d) resonance to a singlet and the 3-H (d) resonance to a singlet; ^{13}C nmr ($CDCl_3$) δ_C: 19.3 (6-*C*H_3), 19.8 (5-*C*H_3), 20.4 (OCO*C*H_3), 65.5 (*C*-1), 90.9 (*C*-6), 123.4 (*C*-4), 130.6 (*C*-3), 130.9 (*C*-5), 142.2 (*C*-2), 169.0 (O*C*OCH$_3$) ppm. *Anal.* calcd. for $C_{10}H_{12}N_2O_6$: C 46.88, H 4.72, N 10.93; found: C 46.80, H 4.79, N 10.82.

Other nucleophiles

The reaction of **1*am*** with potassium hydroxide, potassium *tert*-butoxide, sodium phenoxide, potassium acetate, and potassium thiocyanate, in acetonitrile, and with potassium nitrite and potassium thiocyanate in methanol, gave **11** as the major or sole product (Table 2).

Thermolysis

A solution of diene **1*am*** (64 mg) in toluene (10 cm^3) was heated under reflux for 1 h. The solvent was then removed from the yellow solution under reduced pressure. The product composition was **6** (78%, *m/e* 151, *M*) and **9** (22%, *m/e* 196, *M*). A similar result was obtained when a 1% solution of the diene **1*am*** in acetone was injected into the inlet (270°C) of a gas chromatograph.

A 1% solution of diene **12*n*** in acetone was injected into the inlet of a gas chromatograph (260°C). The products (glc–ms) were **6** (98%, *m/e* 151, *M*) and 2,3-dimethyl-6-nitroanisole (2%, *m/e* 181, *M*).

80% Methanol–water

A cold solution of 80% (v/v) methanol–water (350 mm^3) was added to the diene **1*am*** (64 mg) and the resulting mixture was left in an ultrasonic bath at ambient temperature until dissolution was complete (72 h). The ^{1}H nmr of the product indicated complete rearomatization of the diene to give **6** (82%, *m/e* 181, *M*) and **11** (18%, *m/e* 196, *M*).

*Reactions of 4,5-dimethyl-2,4-dinitrocyclohexa-2,5-dien-1-ol (***1ao***)*

Sulfuric acid in acetic anhydride

Cold 2% (v/v) sulfuric acid in acetic anhydride (250 cm^3) was added to a solution of diene **1*ao*** (90 mg), in acetic anhydride (250 mm^3) at 0°C. The temperature was raised to 35°C. After 18 h 5% rearomatization had occurred. Sulfuric acid (10 mm^3) was added to the solution at 0°C and the temperature raised to 35°C. Rearomatization was complete in 2 min and the product composition after work-up was (by ^{1}H nmr) **6** (82%), **9** (11%), and **8** (7%).

$[^2H_5]$Pyridine and acetic anhydride

Cold $[^2H_5]$pyridine (300 mm^3) was added to the diene **1***ao* (90 mg) at −78°C. The solution was warmed to 0°C and ^{1}H nmr, after 18 h, showed that no reaction had occurred. Cold acetic anhydride (450 mm^3) was added. The mixture immediately turned dark brown and ^{1}H nmr showed that no diene remained. Work-up gave (by ^{1}H nmr) **11** (~100%).

Cold $[^2H_5]$pyridine (40 mm^3, 0.5 mmol) was added to a solution of the diene **1***ao* (70 mg, 0.33 mmol) in acetic anhydride (300 mm^3) at −40°C. The temperature was raised to 0°C and the ^{1}H nmr recorded. The acetylation of **1***ao* to **1***am* was complete within 6 min, although partial isomerization to **12***m* (ca. 5%) was also observed. After 18 h at 0°C **11** was obtained on work-up (^{1}H nmr).

When 2,6-dimethylpyridine was used instead of pyridine, 50% of **1***ao* was acetylated after 150 min. Work-up after 18 h at 0°C gave (^{1}H nmr) **11** (3%), **1***am* (40%), and **12***m* (57%).

Methyl iodide and moist silver oxide

Moist silver oxide was freshly prepared as follows. Aqueous sodium hydroxide (10 cm^3, 0.05 mol) was added to a solution of silver nitrate (3.38 g) in distilled water (5 cm^3). The precipitate of silver oxide was filtered under suction and washed with distilled water (5 × 20 cm^3) to remove excess alkali.

A mixture of silver oxide (1.90 g), methyl iodide (7 cm^3), potassium hydroxide (0.01 g), and the diene *E*-**1***ao* (0.52 g) was stirred for 5 h at 20°C. The mixture was then filtered and the residue washed with ether (5 × 60 cm^3). The ether extract was dried ($MgSO_4$) and the ether and excess methyl iodide evaporated at 15°C. The product, after vacuum drying, was found to be one diastereomer of 4,5-dimethyl-2,4-dinitrocyclohexa-2,5-dienyl methyl ether (*E*-**1***an*); ^{1}H nmr (90 MHz, $CDCl_3$) δ: 1.86 (d, 3, 5-CH_3), 1.89 (s, 3, 4-CH_3), 3.35 (s, 3, OCH_3), 4.99 (d, 1, 1-*H*), 6.04 (m, 1, 6-*H*), 7.18 (s, 1, 3-*H*) ppm, $J_{16} = 4$, $J_{6,5\text{-}CH_3} = 1.35$ Hz; ^{13}C nmr ($CDCl_3$) δ_C: 17.6 (5-CH_3), 23.3 (4-CH_3), 56.8 (OCH_3), 68.0 (*C*-1), 88.9 (*C*-4), 125.5 (*C*-6), 131.6 (*C*-3), 133.6 (*C*-5), 150.4 (*C*-2) ppm.

The reaction was repeated on diene *Z*-**1***ao* to give *Z*-**1***an*; ^{1}H nmr (90 MHz, $CDCl_3$) δ: 1.86 (s, 6, 5-CH_3 and 4-CH_3), 3.30 (s, 3, OCH_3), 4.99 (d, 1, 1-*H*), 5.96 (m, 1, 6-*H*), 7.15 (s, 1, 3-*H*) ppm, $J_{16} = 4$ Hz; ^{13}C nmr ($CDCl_3$) δ_C: 18.7 (5-CH_3), 23.9 (4-CH_3), 54.9 (OCH_3), 67.1 (*C*-1), 88.1 (*C*-4), 125.9 (*C*-6), 131.4 (*C*-3), 133.7 (*C*-5), 150.3 (*C*-2) ppm.

Shift reagent studies

Eu(fod)$_3$ was added in small increments (5–10 mg) to a solution of the diene (35–50 mg) in $[^2H]$chloroform at 0°C. The weight of the reagent added and the ^{1}H nmr spectrum (tetramethylsilane reference) were determined after each addition. The volume increase resulting on addition of the reagent was ignored.

Surface photochemistry: silica gel as a medium for photochemical cycloaddition of enones to allene[1]

VINOD DAVE, RAJEEV FARWAHA, PAUL DE MAYO,[2] AND J. B. STOTHERS[2]
Photochemistry Unit, Department of Chemistry, The University of Western Ontario, London, Ont., Canada N6A 5B7

Received October 19, 1984

VINOD DAVE, RAJEEV FARWAHA, PAUL DE MAYO, and J. B. STOTHERS. Can. J. Chem. **63**, 2401 (1985).

The photocycloaddition of allene to the steroidal enone **1***a*, normally occurring from the (less hindered) α side, has been directed in part to the (more hindered) β side by adsorption on the surface of silica gel. For a series of cyclic enone–allene photocycloadditions it is shown that the normally favored formation of the β,γ-regioisomeric adduct in homogeneous systems can be shifted to favor the γ,δ adduct on a silica gel surface.

VINOD DAVE, RAJEEV FARWAHA, PAUL DE MAYO et J. B. STOTHERS. Can. J. Chem. **63**, 2401 (1985).

La photocycloaddition de l'allène sur l'énone stéroïdale (**1***a*), qui se produit normalement par la face α (la moins empêchée) peut être amenée à se produire en partie par la face β (la plus empêchée) par adsorption sur une surface de gel de silice. On a montré, pour une série de photocycloadditions cycliques énone–allène, que la formation de l'adduit régioisomère-β,γ, qui est normalement favorisée dans les systèmes homogènes, peut être déplacée en faveur de l'adduit γ,δ si l'on opère sur une surface de gel de silice.

[Traduit par le journal]

Introduction

Photochemical cycloaddition between an alkene and an α,β-unsaturated cyclic ketone has proved to be a very useful tool for the synthesis of alicyclic compounds (1). Its application has been limited, however, by the lack of regio- and stereoselectivity in the reaction.

It has been known for some time that if the two faces of the double bond in the enone are stereochemically non-equivalent the major product generally arises by reaction of the olefin from the less hindered side of the enone (ref. 2, see, however, ref. 4). Recently it has been shown that such photocycloadditions can be induced on dry silica gel (3) using steroidal enones as substrates. With these compounds the α face is less hindered than the β face and thus this face is preferentially adsorbed on the gel, rendering the β face relatively more prone to attack by the olefin.

Some years ago, Wiesner and co-workers (4) proposed that the stereochemistry of the enone photocycloaddition could be predicted from the conformational posture of the enone excited state. It was postulated that the configuration of the photoadduct is controlled by a species which is trigonal in the α- and pyramidal in the β-position. This species was assumed to select the more stable configuration and thus to determine the configuration of the adduct: this resultant stereochemistry might or might not derive from the steric ease of approach of the olefin. According to the proposal, the α carbon is slightly positive in comparison to the β carbon in the transition state and an overlap of the β orbital with the terminal position of allene would be required for bond formation. Since allene addition always results in the formation of a *cis*-fused adduct, one cannot, from the stereochemistry, discuss whether α or β bond formation occurred first (1*a*, 5). The question of whether the biradical intermediate is formed by initial bond formation at C_α or C_β is not well resolved, although there is evidence that the initial bond formation can be at C_α or C_β, depending upon the structure of enone and alkene involved (ref. 6; see also refs. 1*a* and 1*d*). Several exceptions to the Wiesner proposal have recently appeared (7).[3]

As a test for his predictive guide Wiesner carried out the photocycloaddition of allene to **1** and **2** at −78°C. It was expected (4*c*) that **1** should undergo reaction on the α face, and it indeed did so, giving **3***a* (together with **4**). On the other hand, **2** was predicted to react from the β face, but the reaction could be inhibited by steric hindrance: in fact, the reaction was found to be very sluggish.

Such substances as **1** and **2** seemed of interest to test the efficiency of adsorption on silica gel for directing cycloaddition. Specifically, we were interested to know if such adsorption for **1** could lead to the formation of the hindered β adduct. This, as reported below, was found to be the case. In addition, a regioselective difference in the mode of addition to allene was observed between heterogeneous and homogeneous systems, and for this reason the study was extended to include several other enones.

Results and discussion

The photocycloaddition of 3β-acetoxy-$\Delta^{8,9}$-cholesten-7-one (**1**) and allene adsorbed on silica gel was carried out using a 450-W medium-pressure mercury lamp. The irradiation product was chromatographed to give the previously reported rearrangement product **4** and α adduct **3***a* (4*c*) in 10% and 20% yields, respectively. In addition to these known adducts, a mixture of three isomeric cycloadducts was also obtained in 70% yield. The complex mixture was not well resolved on tlc and was therefore converted to the corresponding alcohols by hydrolysis with methanolic KOH. There was obtained a new adduct as a crystalline solid[4] and a 1 : 1 mixture of alcohols identified below as **5** and **6**. This mixture was separated by flash chromatography, giving a solid and a liquid adduct. That one photoproduct, **6**, was an allene adduct followed from the mass spectrum (*m*/*e* 440); ^{1}Hmr (δ 4.49, $C{=}CH_2$) and ^{13}Cmr (δ_C: 106.3, $={CH_2}$). The head-to-head regiochemistry was re-

6

vealed by its medium intensity uv maximum at 290 nm (ε 96), characteristic of a β,γ-unsaturated ketone (8). The photocycloadduct **5** was also an allene adduct, as judged from the mass spectrum (*m/e* 440); the ^{1}Hmr (δ 5.17 brs, 1H and 4.93 m, 1H, —C=CH_2) and ^{13}Cmr (δ_C: 110.7 =CH_2). Cycloadduct **5** showed a very weak uv absorption maximum at 290 nm (ε 39), characteristic of an unperturbed carbonyl group, indicating it to be an γ,δ-unsaturated ketone. The stereochemistry of addition in **5** and **6** became apparent from their ^{13}Cmr spectra upon comparison with that for **3***b*. In addition to the signals for the side-chain carbons in each, there were several similarities in the spectra of **3***b* and **5** but very few for **3***b* and **6**. For **3***b* and **5** the signals for five methylene, two methine, and a quaternary centre differ by less than 0.1 ppm in the two spectra while the angular methyl, another methylene, and quaternary signals fall within 0.2 ppm (see Experimental). Thus, 12 of the 17 signals for the skeletal carbons are remarkably similar. In contrast, only a single methylene absorption for compound **6** is found within 0.1 ppm of any of those for compounds **3***b* and **5**; the quaternary centres differ by 3–8 ppm, the methines by 3–10 ppm, and the angular methyls by 1–2 ppm. On the basis of the ^{13}Cmr data, combined with the above mentioned uv absorption, it is concluded that **5** is the regioisomeric α-adduct with γ,δ-unsaturation and **6** is the β-adduct of the β,γ-unsaturated ketone.

It has been suggested that an overlap of the β orbital of the α,β-unsaturated ketone with the terminal allene carbon is required for the formation of a β,γ allene cycloadduct (4). Furthermore, it is known that ethyl, methyl, and isopropyl radicals add exclusively to the terminal carbon of allene (9). By analogy with this radical-like transition state, and *assuming that attack at the terminal position of allene is unaffected by adsorption on silica gel*, the formation of the γ,δ regioisomeric adduct **5** can be explained by assuming that initial bond formation occurs at the α carbon of the steroidal α,β-unsaturated ketone.

The photocycloaddition of 3β-acetoxy-$\Delta^{8,9}$-cholesten-11-one (**2**) and allene in methylene chloride was carried out using the reported procedure (4*c*). Thin-layer chromatography of the crude product showed the presence of mainly unreacted starting unsaturated ketone, together with a minor compound (<5%) less polar than **2**, as previously reported. Repeating this reaction on silica gel did not reveal any noticeable change.

The use of silica gel has thus induced photocycloaddition to the β face of the 8:9 double bond and, more importantly, in reasonable amount; β photoadduct **6** represents about one-third of the allene adducts formed. In addition to the exceptions reported for homogeneous systems, it appears that the proposed stereochemical rule (4) should also be applied to heterogeneous systems with caution.

The formation of the head-to-tail adduct **5** on silica gel in the photocycloaddition of steroidal enone **1** to allene encouraged us to examine the photocycloaddition reactions of some simple cyclic enones to allene under heterogeneous conditions to determine the limits and utility of the reaction. The compounds chosen for photocycloaddition were cyclohexenone (disubstituted olefin), isophorone (trisubstituted), and four bicyclic

ketones **11**, **13**, **15**, **17** (tetrasubstituted). Their photocycloaddition reactions with allene were carried out in solution (CH_2Cl_2) and on dry silica gel. Except for the isophorone–allene cycloadduct mixture, which could be resolved on tlc, no other adduct mixtures could be resolved by glc or tlc to permit the determination of the ratio of the two regioisomeric adducts: the head-to-head (H/H)/head-to-tail (H/T) ratios in these mixtures were determined by integration of suitable signals in the ^{13}Cmr spectrum. The most reliable signal for this integration was the *sp*^{2} carbon (=CH_2) in each of the two adducts.

It is clear from the literature (1*d*) that the major product formed by photocycloaddition of allene to simple cyclopentenones and cyclohexenones *in solution* is the head-to-head adduct with a *cis* ring junction. Using this as a guide, the carbon spectra of the six unsaturated ketone–allene photocycloaddition products were examined. For the total reaction products from *solution irradiations* the spectra showed the presence of two peaks, one of high and the other of low intensity, in the region δ 104–109 ppm. These were assigned to the =CH_2 signals of the major β,γ-unsaturated ketone and the minor γ,δ-unsaturated ketone, respectively (see Table 1). These two peaks were carefully integrated to give the ratio of β,γ (head-to-head) and γ,δ (head-to-tail) adducts from the unsaturated ketones (**7**, **9**, **11**, **13**, **15**, and **17**) by solution irradiation (Table 2). The same two peaks were also integrated for the product mixtures derived from ketone–allene irradiation on dry *silica gel*. The ratios obtained are listed in Table 2.

The photocycloaddition of allene to isophorone **9** in methylene chloride and on silica gel gave two cycloadducts (**10***a* and **10***b*). Their regiochemistry was easily ascertained from their ^{1}Hmr spectra since the vinyl protons appeared as a multiplet at ~δ 5.0 in **10***a* and as two triplets at δ 4.82 and δ 4.71 in the case of **10***b*. The β,γ adduct (**10***a*) showed a low-field proton signal at δ 3.2, attributed to the methine proton at C-2: an indication of head-to-head (H/H) regiochemistry. In contrast, for **10***b* no low-field signal was detected near 3.0 ppm, which indicated head-to-tail (H/T) regiochemistry. Additional confirmation of this assignment was obtained from the ^{13}Cmr spectra of the two isomeric adducts. The assignment was made by comparisons with the data for similar analogues (Table 1).

The photocycloaddition of enones (**7**, **9**, **11**, **13**, **15**, and **17**) to allene in methylene chloride gave (H/H) regioisomers as major photoadducts with the (H/T) regioisomers present in small amounts, as shown by ^{13}Cmr. In contrast, irradiation of these enones and allene on silica produced a pronounced shift towards H/T adduct formation. The formation of the H/T product indicates a preference for reaction of the α position of the enone with the terminal allene position, or reaction at the β position of the enone with the central position of the allene. Presumably the change is caused by changes in electron distribution induced by adsorption onto the silica gel surface, but no evidence is presently available to distinguish between these possibilities. In any event the ability to change the adduct composition may be of synthetic utility.

TABLE 2. Conditions and the results of the photocycloaddition of enones to allene

Enone	System[a]	Product	Regioisomer (%)[b] H/H	H/T

[a] A, methylene chloride solution; B, dry silica gel.
[b] Analysed by ^{13}Cmr (see text), estimated precision ±5%.
[c] Relative ratio of isolated adducts.

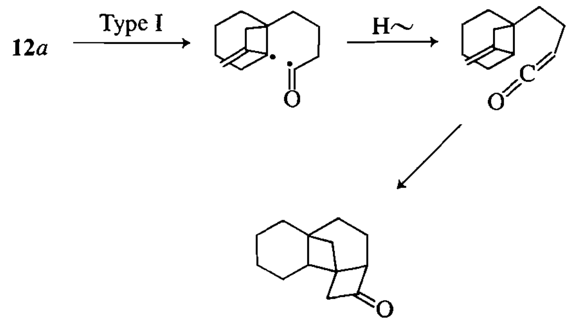
In the photocycloaddition of bicyclo[4.4.0]dec-1(6)-en-one (**11**) on silica gel there was obtained, in addition to the expected adducts **12***a* and **12***b*, ~5% of a minor compound with the molecular formula $C_{13}H_{18}O$, i.e., isomeric with **12***a* and **12***b*. It appeared to contain a four-membered ring ketone since it exhibited carbonyl absorption at 1760 cm^{-1}. The ^{13}Cmr spectrum showed signals for a carbonyl carbon, two methine carbons, two quaternary carbons, and eight methylene carbons. The ^{1}Hmr spectrum contained a one-proton doublet at δ 2.7 ppm (J = 8 Hz, 1H) and a two-proton multiplet at δ 2.67–3.0 ppm (J_{AB} = 18 Hz, J_{AX} = ~2.5 Hz). To determine the origin of this product, a mixture of photocycloadducts **12***a* and **12***b* was irradiated on silica gel. The irradiation mixture was found to contain major amounts of the starting adducts **12***a* and **12***b* with 5–10% of the cyclobutanone. Thus, this compound is an over-irradiation product of **12***a* or **12***b*. Formation of this novel rearrangement product from **12***a* or **12***b* can be readily rationalized (see Scheme 1) and the structure arrived at is compatible with all the available data (but is not rigorously required by them).

Type I cleavage of **12***a*, followed by an intramolecular hydrogen transfer gives a ketene intermediate, which can subsequently undergo an allowed thermal ($2\pi_s + 2\pi_a$) cycloaddition to give the cycloadduct **12***c*. An equivalent structure can be written derived from **12***b*. Close analogy with this thermal intramolecular cycloaddition has been reported (10), see Scheme 2.

Experimental

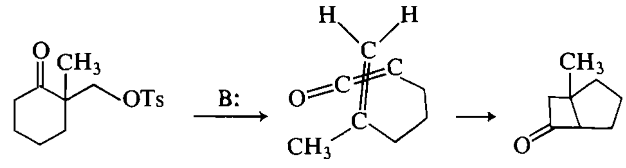
Apparatus

Ultraviolet spectra were recorded on a Varian Cary 219 spectrophotometer. The ^{1}Hmr spectra were recorded on a Varian XL-100 (100 MHz) or an XL-200 (200 MHz). The latter instrument was used



12c

SCHEME 1



SCHEME 2

to record the ^{13}C spectra (50.3 MHz), and comparison of the fully decoupled spectra with those obtained with either the APT (11) or INEPT (12) sequence served to identify the methyl, methylene, methine, and quaternary signals. Chemical shifts are reported in parts per million (ppm) on the δ scale relative to $(CH_3)_4Si$ as internal standard. The proportions of H/H and H/T isomers in the product mixtures from irradiations of **7**, **9**, **11**,**13**,**15**, and **17** were obtained from the relative integrated intensities of the *exo*-methylene carbon signals. Measurements from spectra obtained for the same sample with 20° and 30° pulses showed good agreement (±2%); thus, the precision of the ratios is judged to be ±5%. Infrared spectra were recorded with a Beckman–Acculab 4 spectrophotometer. Mass spectra were obtained on a Varian MAT 311A system at 70 eV (direct inlet). Melting points were measured on a Reichert hot-stage apparatus and are uncorrected.

Materials

Methylene chloride was dried over CaH_2, Spectral grade methanol was used. Thin-layer chromatography (tlc) was on Kiesel gel DF-5 (Camag) plates and flash chromatography (FC) columns were prepared as described (13). Merck silica gel 60 (E. M. Merck, 35–70 mesh) was used in all irradiation experiments. The following compounds were prepared by known methods and gave satisfactory physical and spectral data: 3β-acetoxy-$\Delta^{8,9}$-cholesten-7-one (**1**) (14), 3β-acetoxy-$\Delta^{8,9}$-cholesten-11-one (**2**) (15), bicyclo[4.4.0]dec-1(6)-en-one (**11**) (16), bicyclo[0.3.3]-Δ^7-octen-1-one **13** (16), 4,5,6,7-tetrahydroindan-1-one (**15**) (16), and Δ^8-hydrindenone (**17**) (16). Allene (Canadian Liquid Air) was used as supplied.

Procedure for sample preparation and irradiation on dry silica

A preweighed sample of silica gel (~6 g) was introduced into a Pyrex tube equipped with a side arm in apparatus described elsewhere (17), and to it was added a sample of steroidal enone **1** (~0.45 mmol). The silica gel was dried at 200°C (3 h; 0.3 Torr) (1 Torr = 133.3 Pa). The silica gel was then allowed to cool to room temperature under vacuum, the enone was dropped onto the gel, and dry methylene chloride (30 mL) was condensed on to the gel by cooling the Pyrex cylinder containing the silica gel to −78°C. The slurry was shaken well in order to dissolve the enone and the methylene chloride was removed by distillation back to the original container. The silica gel was further dried in vacuum for 6 h. In the case of liquid enones **7**, **9**, **11**, **13**, **15**, and **17**, a preweighed sample (~1.0 mmol) was condensed into the Pyrex cylinder containing silica gel cooled to −78°C. The allene gas was introduced at 1 Torr (133.3 Pa) pressure into the Pyrex cylinder, containing gel and an enone, of total capacity ~43 mL at 0°C. The Pyrex cylinder was then sealed and rotated on its long axis in front of a 450-W medium-pressure Hg lamp. Irradiation times varied considerably depending upon the substrate and conversion required.

Sample analysis

The silica gel was extracted with ether and with methanol. The adduct products, except in the case of **1** and **2**, were analysed by ^{13}Cmr using the sp^2 carbon atoms (=CH_2) as probes.

Solution irradiations

A solution of enone (~0.05 *M*) in methylene chloride was irradiated while a continuous stream of allene was bubbled through the solution.

Photocycloaddition of 3β-acetoxy-$\Delta^{8,9}$-cholesten-7-one (1) to allene

Irradiation of **1** (200 mg, 0.45 mmol) and allene on 6 g of silica gave 190 mg of yellow oil which was purified by ptlc (6:4 (v/v) hexane–ether, 7 developments). The band at R_f 0.81 gave 12.3 mg of colourless solid. One recrystallization from ether–methanol gave 7.6 mg of **4**: mp 175.5–177°C (lit. (4*c*) mp 177–178°C). The band at R_f 0.74 gave 23 mg of reported (4*c*) α adduct **3*a***, mp 116–118°C (lit. (4*c*) mp 119.5–120.5°C); derived hydroxy ketone **3*b*** ^{13}Cmr ($CDCl_3$) δ_C: 22.8, 22.6, 19.1, 15.8, 12.2 (5 × CH_3), 45.3, 39.5, 38.1, 37.3, 36.1, 34.7, 30.9, 30.3, 27.6, 25.4, 23.8, 20.3 (12 × CH_2), 70.3, 55.4, 55.4, 36.0, 33.9, 28.0 (6 × CH), 60.3, 47.9, 40.3, 38.5 (4 × quat. C), 103.1 (*CH*$_2$=C—), 151.2 (CH_2=*C*—), 211.9 (C=O).

The band at R_f 0.65 gave 87 mg of colorless oil (a mixture of three adducts). This material was hydrolyzed with methanolic KOH at room temperature for 1 h. The usual work-up gave an oily solid. To this was added ether and the supernatant liquid was pipetted out leaving 21.3 mg of an unidentified adduct[4] as a colourless crystalline solid, mp 183–185°C; ir ($CHCl_3$) ν_{max}: 3400–3500, 1710 cm^{-1}; ^{1}Hmr δ: 3.52 (m, 1H); ^{13}Cmr ($CDCl_3$) δ_C: 22.8, 22.6, 19.5, 19.1, 11.7 (5 × CH_3), 49.54, 48.04, 42.5, 41.8, 39.5, 38.1, 36.1, 35.1, 32.1, 26.7, 23.8, 22.1, 19.6 (13 × CH_2), 68.3, 57.9, 55.8, 44.3, 35.7, 28.0 (6 × CH), 56.7, 56.6, 49.0, 43.1, 42.5 (5 × quat. C), 215.7 (C=O). *Exact Mass* calcd. for $C_{30}H_{48}O_2$: 440.3654; found: 440.3651. The ether soluble material (56 mg) was purified by ptlc (64:36 hexane–EtOAc, 4 developments). The band at R_f 0.51 gave 36 mg of a mixture of alcohols **5** and **6** as a colourless viscous oil. The band at R_f 0.44 gave 9.8 mg of the same unidentified cycloadduct.[4]

The acetate of the above hydroxyketone[4] was made in the usual way, giving the acetoxyketone derivative as colourless granules, mp 105–108°C (from CH_3OH); ir ($CHCl_3$) ν_{max}: 1710 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 2.04 (s, 3H), 4.67 (m, 1H). *Exact Mass* calcd. for $C_{32}H_{50}O_2$: 482.3759; found: 482.3759.

The above acetoxyketone (33 mg, 0.07 mmol) was reduced with 60 mg (1.5 mmol) of lithium aluminium hydride in 10 mL of ether. The usual work-up gave 28 mg of diol as an oily solid. This oily solid was purified by ptlc (76:24 hexane–EtOAc, 3 developments). The band at R_f 0.53 gave 20 mg of colourless diol, mp 154°C (dec. from Et_2O – petroleum ether); ir ($CHCl_3$) ν_{max}: 3600, 3400 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 4.08–4.1 (d, J = 6 Hz, 1H), 3.46–3.6 (m, 2H); ^{13}Cmr ($CDCl_3$) δ_C: 23.1, 22.8, 20.2, 19.4, 13.0 (5 × CH_3), 54.1, 45.8, 44.1, 43.9, 40.3, 39.0, 36.8, 36.5, 33.2, 30.6, 24.5, 23.7, 21.7 (13 × CH_2), 72.5, 68.4, 61.4, 57.5, 45.3, 36.7, 28.7 (7 × CH), 54.6, 51.8, 47.6, 47.1, 42.8 (5 × quat. C). *Exact Mass* calcd. for $C_{30}H_{50}O_2$: 442.3811; found: 442.3798.

A ~50:50 mixture of alcohols (53 mg) **5** and **6** was purified using flash column chromatography on SiO_2 (Et_2O – petroleum ether, 70:30) to give 10 mg of **6** (mp 143–146°C; ir ($CHCl_3$) ν_{max}: 3600–3400, 1705 cm^{-1}; uv (CH_3OH) λ_{max}: 290 nm (ε 96 M^{-1} cm^{-1}); ^{1}Hmr ($CDCl_3$) δ: 4.49 (brs, 2H), 3.37 (m, 1H); ^{13}Cmr ($CDCl_3$) δ_C: 22.8, 22.6, 18.8, 13.4, 11.4 (5 × CH_3), 43.0, 39.5, 38.4, 37.6, 36.2, 36.17, 31.3, 29.6, 28.5, 27.3, 25.5, 23.7 (12 × CH_2), 66.6, 54.8, 52.7, 46.2, 35.6, 28.0 (6 × CH), 54.8, 53.6, 48.6, 45.6 (4 × quat. C), 106.3 (*CH*$_2$=C—), 152.4 (CH_2=*C*—), 210.5 (C=O). *Exact Mass* calcd. for $C_{30}H_{48}O_2$: 440.3654; found: 440.3652), together with 36 mg of mixed isomers, and 8 mg of **5** as a colourless viscous oil; ir ($CHCl_3$) ν_{max}: 3400–3600, 1690 cm^{-1}; uv (CH_3OH) λ_{max}: 290 nm (ε 38.5 M^{-1} cm^{-1}); $[\alpha]^{25}$ ($CHCl_3$) −23.1°; ^{1}Hmr ($CDCl_3$) δ: 5.17 (brs, 1H), 4.93 (m, 1H), 3.04 (m, 1H); ^{13}Cmr ($CDCl_3$) δ_C: 22.8, 22.6, 19.0, 15.5, 12.5 (5 × CH_3), 44.7, 44.2, 39.5, 38.4, 37.3, 36.1, 30.9, 30.4, 27.6, 24.8, 23,7, 20.2 (12 × CH_2), 70.2, 57.4, 55.5, 36.3, 35.9, 28.0 (6 × CH), 62,3, 50.5, 40.7, 38.7 (4 × quat. C), 110.7 (*CH_2*=C—), 150.2 (CH_2=*C*—), 213.4 (C=O). *Exact Mass* calcd. for $C_{30}H_{48}O_2$: 440.3654; found: 440.3661.

Irradiation of 3β-acetoxy-$\Delta^{8,9}$-cholesten-11-one (2) and allene on silica gel

Irradiation of 3 mg of **2** and allene on 300 mg of silica gel was performed as described previously. The tlc of the crude silica irradiation product was found to be identical with the irradiation of **2** in methylene chloride at room temperature.

Irradiation of isophorone (9) and allene on silica gel

Irradiation of **9** (150 mg, 1.08 mmol) and allene on 6 g of silica gave 170 mg of oil. Chromatography of the crude irradiation product by ptlc (eluent: benzene, 4 developments) gave 78 mg of **10***a* as a colourless oil; ^{1}Hmr ($CDCl_3$) δ: 5.0–4.9 (m, 2H), 3.3–3.1 (brs, 1H), 1.3 (s, 3H), 1.12 (s, 3H), 0.85 (s, 3H); ^{13}Cmr ($CDCl_3$) δ_C: 30.9, 30.3, 27.7 (3 × CH_3), 59.7 (quat. C), 108.2 (*CH_2*=C—), 142.3 (CH_2=*C*—), 209.9 (C=O). *Exact Mass* calcd. for $C_{12}H_{18}O$: 178.1357; found: 178.1362; and 55 mg of **10***b* as a colorless oil: ^{1}Hmr ($CDCl_3$) δ: 4.90–4.78 (t, J = 2 Hz, 1H), 4.78–4.62 (t, J = 2 Hz, 1H), 1.4 (s, 3H), 1.0 (s, 6H); ^{13}Cmr ($CDCl_3$) δ_C: 30.4, 29.45, 29.3 (3 × CH_3), 47.6 (quat. C), 103.5 (*CH_2*=C—), 156.1 (CH_2=*C*—), 214.2 (C=O). *Exact Mass* calcd. for $C_{12}H_{18}O$: 178.1357; found: 178.1357.

Irradiation of bicyclo[4.4.0]dec-1(6)-en-one (11) and allene on silica gel

Irradiation of **11** (150 mg, 0.79 mmol) and allene on 5 g of silica gave 140 mg of crude oil. Chromatography of the crude oil gave 60 mg of a mixture of photocycloadducts **12***a* and **12***b*; the ^{13}Cmr data are collected in Table 2. *Exact Mass* calcd. for $C_{13}H_{18}O$: 190.1357; found: 190.1362. Also obtained was 7 mg of **12***c* as a colourless oil. A total of 33.5 mg of this material was collected from several reactions and purified by ptlc (hexane – ethyl acetate, 96:4, 3 developments) to give 20 mg of rearrangement product **12***c* as an oil; ir ($CHCl_3$) ν_{max}: 1760 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 3.44 (d, J = 8 Hz, 1H) 3.0–2.67 (m, J_{AB} = 18 Hz, J_{AX} = ~2.5 Hz); ^{13}Cmr δ_C: 48.8, 37.6, 30.5, 29.6, 27.7, 25.0, 22.4, 21.6 (8 × CH_2), 69.6, 32.0 (2 × CH), 51.0, 45.9 (2 × quat. C), 212.6 (C=O). *Exact Mass* calcd. for $C_{13}H_{18}O$: 190.1357; found: 190.1355; oxime mp 72–82°C. *Exact Mass* calcd. for $C_{13}H_{19}ON$: 205.1466; found: 205.1469.

Irradiation of **11** and allene in methylene chloride was performed as described previously and no rearrangement product **12***c* was detected.

Photocycloaddition of 7, 9, 11, 13, 15, and 17 to allene

The photocycloaddition of the enones **7**, **9**, **11**, **13**, **15**, and **17** in methylene chloride and on silica gel was performed as previously described and products analysed by ^{13}Cmr (see Tables 1 and 2). The molecular formulae were confirmed by mass spectrometry, results for which are as follows. Mixture of **8***a* and **8***b*: *Exact Mass* calcd. for $C_9H_{12}O$: 136.0888; found 136.0893; **10***a* and **10***b*: *Exact Mass* calcd. for $C_{12}H_{18}O$: 178.1357; found 178.1362; **12***a* and **12***b*: *Exact Mass* calcd. for $C_{13}H_{18}O$: 190.1357; found 190.1362; **14***a* and **14***b*: *Exact Mass* calcd. for $C_{11}H_{14}O$: 162.1044; found 162.1040; **16***a* and **16***b*: *Exact Mass* calcd. for $C_{12}H_{16}O$: 176.1201; found 176.1201; **18***a* and **18***b*: *Exact Mass* calcd. for $C_{12}H_{16}O$: 176.1201; found 176.1200.

Novel sterols from the finger sponge *Haliclona oculata*

JOHN A. FINDLAY AND ASHOK D. PATIL
Chemistry Department, University of New Brunswick, Fredericton, N.B., Canada E3B 6E2

Received May 29, 1984[1]

JOHN A. FINDLAY and ASHOK D. PATIL. Can. J. Chem. **63**, 2406 (1985).

From the finger sponge, *Haliclona oculata* (Linnaeus), six new polar sterols have been isolated and their structures determined by chemical and spectroscopic means. These are 3β-hydroxy-cholesta-5,25-dien-24-one (**2**), 3β-hydroxy-24-methylene-5-cholesten-7-one (**6**), 24-methylene-5-cholesten-3β,7β-diol (**9**), 24-methylcholesta-5,22-dien-3β,7β-diol (**11**), 24-methylene-5-cholesten-3β,7α-diol (**12**), and 5β,6-epoxy-24-methylene-cholestan-3β-ol (**16**). Also shown to be present are the known monohydroxysterols (22*E*,24*S*)-24-methylcholesta-5,22-dien-3β-ol (**1**), (22*Z*)-24-norcholesta-5,22-dien-3β-ol, 24-methylene-5-cholesten-3β-ol, 24-isoethylidene-5-cholesten-3β-ol, (22*E*)-24-norcholesta-5,22-dien-3β-ol and (23*E*)-cholesta-5,23-dien-3β,25-diol. The structure **14** is tentatively proposed for a novel C_{24} sterol and **8** is suggested for the structure of a compound accompanying **6**.

JOHN A. FINDLAY et ASHOK D. PATIL. Can. J. Chem. **63**, 2406 (1985).

On a isolé six nouveaux stérols polaires de l'éponge *Haliclona oculata* (Linnaeus) et on a déterminé leurs structures par des méthodes chimiques et spectroscopiques. Il s'agit de l'hydroxy-3β cholestadiène-5,25 one-24 (**2**), de l'hydroxy-3β méthylène-24 cholestène-5 one-7 (**6**), du méthylène-24 cholestène-5 diol-3β,7β (**9**), du méthyl-24 cholestadiène-5,22 diol-3β,7β (**11**), du méthylène-24 cholestène-5 diol-3β,7α (**12**) et de l'époxy-5β,6 méthylène-24 cholestanol-3β (**16**). On a aussi montré que les monohydroxystérols connus (22*E*,24*S*) méthyl-24 cholestadiène-5,22 ol-3β (**1**), (22*Z*) nor-24 cholestadiène-5,22 ol-3β, méthylène-24 cholestène-5 ol-3β, isoéthylidène-24 cholestène-5 ol-3β, (22*E*) nor-24 cholestadiène-5,22 ol-3β et (23*E*) cholestadiène-5,23 diol-3β,25 sont aussi présents. Sur une base préliminaire, on a attribué la structure **14** à un nouveau stérol en C_{24} et la structure **8** à un composé accompagnant le composé **6**.

[Traduit par le journal]

Chemical studies on sponges have shown that they often are a source of novel sterols of biogenetic interest (1, 2). As part of a continuing study of marine natural products from Bay of Fundy organisms, we have examined the sterols of the abundant finger sponge *Haliclona oculata* (Linnaeus) and now report our findings.

Thin-layer chromatography (tlc) of fractions from silica gel column chromatography of a methanol extract of *H. oculata* showed the presence of substantial amounts of compounds more polar than the monohydroxylated sterol fraction. The five major monohydroxylated sterols were separated and identified by comparison of their spectral characteristics with literature data. The major sterol (85%) of this fraction proved to be (22*E*,24*S*)-24-methylcholesta-5,22-dien-3β-ol (22-dehydrocampesterol), **1** (3, 4), while other components were identified as (22*Z*)-24-norcholesta-5,22-dien-3β-ol (4) (1.5%), 24-methylene-5-cholesten-3β-ol (5) (2.4%), 24-isoethylidene-5-cholesten-3β-ol (isofucosterol) (4) (2.9%), and (22*E*)-24-norcholesta-5,22-dien-3β-ol (4) (0.8%).

Purification of the more polar sterols was achieved by a combination of column chromatography, preparative tlc, and high pressure liquid chromatography (hplc) on silica gel and reverse phase systems. In some cases it was necessary to separate mixtures after acetylation. In this manner we have succeeded in isolating and characterizing the six new sterols **2**, **6**, **9**, **11**, **12**, and **16**, plus the previously reported diene diol **4** (6).

The novel ketone **2** was purified as its acetate **3** whose ir spectrum ($CHCl_3$) displays strong bands at 1730 and 1670 cm^{-1} attributed to the ester and α,β-unsaturated ketone, respectively. The uv spectrum showing λ_{max} (C_2H_5OH) 223 (ε 11 440) allows placement of the enone in the sidechain. The mass spectrum of **2** shows a molecular ion *m/e* 398 ($C_{27}H_{42}O_2$) and the base peak, *m/e* 271, is attributed to loss of the sidechain plus two hydrogens. An abundant ion *m/e* 314 results from

[a] As determined by DEPT analysis.
[b] Assignments after Wright *et al.* (3).
[c, d, e] Assignments may be interchanged.

cleavage of the C22—C23 bond, together with a hydrogen transfer. Both of these fragments are typical of sterols possessing a cholesterol nucleus plus a double bond in the sidechain (7, 8). Confirmation of the assigned structure is available from the 200-MHz ^1H nmr spectrum, which shows signals consistent with the cholesterol nucleus plus additional methyl signals at δ 0.95 (d, J = 6 Hz) and δ 1.95 (s) assigned to the $21CH_3$ and $27CH_3$, respectively. The vinylic protons at C26 appear as singlets at δ 5.78 and δ 5.98 ppm.

The diene diol **4** displays in its mass spectrum a molecular ion m/e 400 ($C_{27}H_{44}O_2$) plus a series of fragments m/e 271, 255, and 213 consistent with its nuclear and sidechain features (7, 8). Other prominent ions m/e 382 (M − H_2O), 385 (M − CH_3), 367 (M − H_2O − CH_3), 349 (M − $2H_2O$ − CH_3) support the functionality and composition of **4**. The ^1H nmr spectrum displays a sharp singlet at δ 1.34 (6H) assigned to the terminal methyls, while the secondary methyl is seen at δ 0.92 ppm (J = 6.5 Hz). Irradiation of the allylic region (~ δ 2.0) caused the sidechain vinylic proton multiplet to collapse to an AB quartet (J_{AB} = 15.5 Hz), while the multiplicity of the $21CH_3$ was unchanged and the 3CH signal was transformed to a less complex multiplet. Thus the placement of all functional groups and the Δ^{23} geometry are established. Diene diol **4** on acetylation provided the monoacetate **5** whose infrared spectrum featured a band at 3600 cm^{-1} (tertiary OH). Comparison of the ^{13}C nmr spectrum of **4** with that of the known (3) 22-dehydrocampesterol **1** (see Table 1) provides detailed corroboration of the structure and stereochemistry of **4**, which was previously isolated from marine sources, characterized as its acetate, and designated trans-liagosterol (6).

A major component of the polar sterol fraction proved to be the novel dienone **6**, which was inseparable from a minor isomer tentatively assigned structure **8**, in view of the presence of a multiplet at δ 5.25 similar in pattern to the $\Delta^{22,23}$ proton signals in **1**. The enone feature was inferred from the infrared ($CHCl_3$) spectral features (1655 and 1640 cm^{-1}) and its ultraviolet spectrum (λ_{max} (C_2H_5OH) 238.5 (ε 15 600)). The mass spectrum exhibits a strong molecular ion m/e 412 ($C_{28}H_{44}O_2$), while an abundant ion m/e 269 results from dehydration plus loss of the sidechain from C20. An ion m/e 310 is accounted for by McLafferty rearrangement of a dehydrated species. The ^1H nmr spectrum displays singlets at δ 4.65, 4.76, and 5.64 ppm, assigned to the C24 methylene protons and the C6H, respectively, while other signals confirm the presence of two tertiary and three secondary methyls in field positions in accord with expectation (9). Distortionless enhancement bipolarization transfer (DEPT) analysis of the ^{13}C nmr spectrum of the acetate **7** of alcohol **6** shows that twenty-four of the thirty carbon atoms bear protons and, of these, eight are primary, ten are secondary, and six are tertiary. Table 1 provides assignments for the ^{13}C signals and a detailed corroboration for structures **6** and **7**. The chemical shift assignments are in close agreement with the corresponding assignments for the nuclear carbon atoms of 3β-acetoxy-cholest-5-en-7-one (12).

Hydrolysis of acetate **7** with 5% ethanolic KOH furnished the trienone **13**, which shows infrared absorption bands at

1650, 1620, and 1590 cm^{-1} and λ_{max} (C_2H_5OH) 280.5 (ϵ 15 560) in its ultraviolet spectrum, establishing the conjugated dienone features. The mass spectrum, predictably, shows prominent ions at *m/e* 269 and 310 (*vide supra*) while the ^1H nmr spectrum features a singlet at δ 5.63 (C6H) and multiplets at δ 6.08–6.28 (2H) assigned to the C3 and C4 hydrogens. The spectroscopic data are consistent with those for cholesta-3,5-dien-7-one (10) and other sterols possessing the same dienone system (11). A multiplet at δ 5.26 (0.3 H) similar in pattern to the $\Delta^{22,23}$ signal in the ^1H nmr spectrum of **1** suggests the presence (~15%) of compound **8**.

The novel diol **9** was characterized as its diacetate **10**. The mass spectrum of **9** displays a molecular ion *m/e* 414 ($C_{28}H_{46}O_2$). A prominent ion at *m/e* 253 is ascribed to a 3,5,7-triene fragment derived by loss of two molecules of water plus the sidechain, thus placing both hydroxyls in the nucleus. The relationship of functional groups in the nucleus was demonstrated by ^1H nmr experiments. Irradiation of C3H at δ 3.56 removed a coupling to the allylic hydrogen signals at δ 2.32, while irradiation at δ 1.38 (C8H) changed the C7H doublet at δ 3.84 (J = 8 Hz) to a broad singlet, thus supporting the assignment of an α configuration to the C7H. Other ^1H nmr signals are consistent with the indicated sidechain and nucleus stereochemistry. The ^{13}C nmr spectrum and DEPT analysis confirmed the number and substitution of carbon atoms in alcohol **9**, and chemical shift assignments based on comparative data for the related compound **1**, with the same skeletal ring junction stereochemistry, are given in Table 1.

The spectral characteristics of diene diol **12** are very similar to those of its C7 epimer **9**, except for the ^1H nmr signals for C6H and C7H, which appear as a doublet at δ 5.62 (J = 6 Hz) and a broad singlet at δ 3.80 ($W_{1/2}$ = 11 Hz), respectively.

The diol **11** showed a molecular ion *m/e* 416 ($C_{28}H_{48}O_2$) and a fragmentation pattern consistent with its assigned structure. The ^1H nmr spectrum displayed signals for C3H, C6H, and C8H, virtually identical with those of **9**, while the $28CH_3$ gave rise to a doublet at δ 0.88 ppm, as does the corresponding $28CH_3$ in the known compound **1** (3, 4).

The most remarkable of the polar sterols isolated from *H. oculata*, albeit in trace amounts, has the composition $C_{24}H_{38}O_2$ and features only three methyl groups, two being tertiary and giving rise to ^1H nmr signals at δ 0.68 and δ 0.96, while the third shows as a doublet at δ 0.96 (J = 6.5 Hz). These values are typical for C18, C19, and C21 methyls of the cholesterol nucleus. The absence of additional methyls, together with the elemental composition, led us to assign structure **14** to this compound on a tentative basis. The compound was converted into a monoacetate **15** whose infrared showed the presence of hydroxyl absorption.

The mass spectrum of epoxide **16** showed a molecular ion *m/e* 412 in confirmation of the composition $C_{28}H_{46}O_2$ deduced by analysis of ^{13}C nmr data (Table 1). The ion *m/e* 287, due to loss of sidechain with transfer of 2 hydrogens, and the characteristic ion at *m/e* 330, formed as a result of McLafferty rearrangement, confirm the presence of an additional oxygen in the nucleus. This is incorporated as a 5β,6-epoxide in view of ^1H nmr, which displays a broad singlet at δ 3.06 assigned to C6H and a multiplet δ 3.74 due to the C3H. The latter is found at lower field than usual due to its proximity to the epoxide. Other ^1H nmr features were consistent with the assigned structure, and the good correlation of ^{13}C nmr chemical shifts with related compounds in Table 1 provides compelling evidence in favour of structure **16**. Location of the epoxide at the 4,5-position was excluded by double irradiation experiments, and assignment of configuration is based on comparison of ^{13}C nmr chemical shift data with that of other 5β,6-epoxides (13).[2]

Experimental

General

Low resolution mass spectra were recorded with an Hitachi Perkin–Elmer RMU 6D mass spectrometer and high resolution mass spectra on an AEI-MS 50 instrument using homogeneous samples as determined by hplc and ^1H nmr. The ^1H and ^{13}C nmr spectra were recorded in $CDCl_3$ solution on a Varian XL200 instrument.

The hplc was carried out on a Waters system employing 440 absorbance and R401 refractive index detectors and using a μ-Porasil column (30 cm × 3.9 mm). Analytical and preparative tlc was performed with precoated silica gel G (Kieselgel 60, F-254) and reverse phase ($KC_{18}F$) plates. Infrared spectra were recorded on a Perkin–Elmer 598 spectrophotometer. Ultraviolet spectra were recorded on a Beckman 25 instrument and optical rotations were measured in chloroform solution using a Perkin–Elmer 241 polarimeter.

Extractions and separations

The sponge *Haliclona oculata* (Linnaeus) (3.5 kg wet weight) was collected in Passamaquoddy Bay, New Brunswick, Canada, in early spring 1982. The organisms were chopped, partially freeze-dried, and extracted in a Soxhlet with methanol. The methanolic extract (45 g), after evaporation, was chromatographed on a silica gel column (400 g, 70–200 mesh) using methanol/chloroform (1:5). Early fractions containing lipids and fats were discarded. Later fractions containing sterols and polar sterols were combined (4.5 g) and rechromatographed on a silica gel G column prepared in hexane. The free sterol fraction (1.62 g) eluted with hexane/ethyl acetate (7:3) was crystallized from methanol and acetylated with acetic anhydride/pyridine at room temperature. The steryl acetate mixture thus obtained was separated on a column of $AgNO_3$-impregnated silica gel using hexane and hexane/benzene (1:1). The individual acetates were hydrolysed with 5% ethanolic KOH to provide five known sterols which were identified by comparison of their spectral characteristics with literature data. These were: (22*E*,24*S*)-24-methylcholesta-5,22-dien-3β-ol, **1** (22-dehydrocampesterol) (85%); (22*Z*)-24-norcholesta-5,22-dien-3β-ol (1.5%); 24-methylene-5-cholesten-3β-ol (2.4%); 24-isoethylidene-5-cholesten-3β-ol (2.9%) and (22*E*)-24-norcholesta-5,22-dien-3β-ol (0.8%).

Further elution of the silica gel G column using increasing percentages of methanol in chloroform furnished several fractions which were monitored by tlc (silica gel and reverse phase). Final purifications were effected using ptlc and hplc and, in some cases, via acetates.

Compound **14** (6 mg) was eluted with methanol/chloroform (3:97) followed by **2** (23 mg), whose acetate was purified by ptlc (R_f 0.35 on silica gel using ethyl acetate/hexane, 1:10) and hplc (silica gel using ethyl acetate/chloroform, 3:97) to give pure 3β-acetoxy-cholesta-5,22-dien-24-one, **3** (26 mg) which was hydrolysed with 5% ethanolic KOH to give pure **2** (19 mg).

Other fractions also eluted with methanol/chloroform (3:97), after purification by ptlc (R_f 0.45 on silica gel using ether/hexane, 4:6), afforded 24-methylene-5-cholesten-3β-ol (47 mg).

Fractions eluted with methanol/chloroform (4:96) (53 mg), after purification via ptlc (R_f 0.50, on silica gel, methanol/chloroform, 5:95) gave pure (23*E*)-cholesta-5,23-dien-3β,25-diol, **4** (31 mg). Compound **16**, eluted immediately following **4**, was purified in similar manner.

Elution with methanol/chloroform (6:94) provided a fraction (169 mg) which after double purification by ptlc (R_f 0.43 on silica gel methanol/chloroform (9:91) and R_f 0.74 on reverse phase with ethyl acetate/ether (4:6)) afforded 3β-hydroxy-24-methylene-5-cholesten-7-one, **6** (119 mg), together with traces of the minor isomer **8**. Further

[2] The authors are grateful to a referee for drawing attention to this paper.

elution with this solvent gave a fraction (79 mg) which was acetylated and purified by ptlc (silica gel with acetone/benzene, 1:9) and hydrolysed with 5% ethanolic KOH to give a mixture of **9** (28 mg) and **11** (35 mg), separated by ptlc (reverse phase with ethyl acetate/ether, 3:7). The last fraction (37 mg) was purified on reverse phase ptlc (ethyl acetate/ether, 1:1) to provide compound **12** (29 mg) in crystalline form.

(S)-2,2,5,5-Tetramethylthiazolidine-4-carboxylic acid: a compound which exists in the amino acid rather than the zwitterion form

HELEN ELAINE HOWARD-LOCK,[1] COLIN JAMES LYNE LOCK, AND PHILIP STUART SMALLEY
Institute for Materials Research, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received November 7, 1984

HELEN ELAINE HOWARD-LOCK, COLIN JAMES LYNE LOCK, and PHILIP STUART SMALLEY. Can. J. Chem. **63**, 2411 (1985).

The X-ray crystal structure of (S)-2,2,5,5-tetramethylthiazolidine-4-carboxylic acid, **1**, has been determined. Crystals are monoclinic, $P2_1$, with cell dimensions a = 11.351(4) b = 8.303(2), c = 11.969(3) Å, β = 116.69(2)°, and Z = 4. The structure was solved by standard methods and refined to R_1 = 0.0774, R_2 = 0.0670 for 2388 independent reflections. Compound **1** exists in the amino-acid form as shown by two distinctly different C—O bond lengths, 1.209 and 1.309 Å, typical of the COOH group, and by the positions of the hydrogen atoms. The amino-acid form of **1** found in the solid also exists in solution as shown by infrared and Raman spectra. The mass spectra, and ^{1}H and ^{13}C nmr spectra are reported, as well as detailed infrared and Raman spectra for the title compound and several deuterated species.

HELEN ELAINE HOWARD-LOCK, COLIN JAMES LYNE LOCK et PHILIP STUART SMALLEY. Can. J. Chem. **63**, 2411 (1985).

Faisant appel à la diffraction des rayons-X, on a déterminé la structure cristalline de l'acide (S)-tétraméthyl-2,2,5,5 thiazolidinecarboxylique-4, **1**. Les cristaux sont monocliniques, groupe d'espace $P2_1$, avec a = 11,351(4), b = 8,303(2), c = 11,969(3) Å, β = 116,69(2)° et Z = 4. On a résolu la structure par des méthodes directes et on l'a affinée jusqu'à des valeurs de R_1 = 0,0774 et R_2 = 0,0670 pour 2388 réflexions indépendantes. Le composé **1** existe sous la forme de l'acide aminé représenté; ceci est démontré par deux longueurs bien distinctes pour les liaisons C—O, 1,209 et 1,309 Å, qui sont typiques du groupe COOH ainsi que par les positions des atomes d'hydrogènes. La forme acide aminé de **1** que l'on trouve dans la forme solide se retrouverait aussi en solution si l'on se base sur les spectres infrarouge et Raman. On rapporte aussi les spectres de masse, les spectres rmn du ^{1}H et du ^{13}C ainsi que les spectres infrarouge et Raman détaillés du composé mentionné dans le titre ainsi que de plusieurs de ses dérivés deutérés.

Introduction

D-Penicillamine has been used increasingly in the treatment of many diseases, of which Wilson's disease (1), rheumatoid arthritis (2), and cystinuria (3) are the best-known of several diseases (4). We have been investigating its use in rheumatoid arthritis, and establishing the spectroscopic properties and structures of its reaction products. The modes of therapeutic action and adverse side effects of the drug are based on three types of biochemical reactions: (i) the ability to form thiazolidine rings with compounds containing carbonyl groups such as ketones and aldehydes, (ii) the oxidation of the sulfhydryl group with the consequent formation of disulfide links, and (iii) the ability to chelate metals. It is reaction (i), formation of thiazolidine rings, which is the basis for the suggested use of D-penicillamine as an alcohol detoxicant (5), and for treatment of scleroderma, morphea, keloid formation, and of vitreous and scleral scarring of the eye. Interference with collagen synthesis may be responsible for reported cases of hyperextensibility of young children treated with D-penicillamine, and for a similar reason D-penicillamine has been suggested as a possible teratogen (4). Formation of thiazolidine rings is also the probable mode of action of D-penicillamine as a vitamin B6 antagonist (4, 6).

We have, therefore, been investigating (S)-2,2,5,5-tetramethylthiazolidine-4-carboxylic acid, which we first isolated when attempting to prepare crystals of D-penicillamine. Our interest was aroused because vibrational spectra suggested that the solid contained the amino-acid form rather than the zwitterion form, and that the amino-acid form existed in significant amounts in aqueous solution.

Amino acids generally exist in the zwitterion form, at least in aqueous solution. This is because the pK_a of the —COOH group is typically 2.0 and the pK_a of the —NH_3^+ group is ~10.0. Under these circumstances only about 0.01% of the compound exists as the amino-acid form in solution. We decided to investigate the problem further, particularly since the presence of the amino-acid form was not detected either in the solid state or in solution for the parent thiazolidine-4-carboxylic acid (7, 8).[2]

Experimental

(S)-2,2,5,5-tetramethylthiazolidine-4-carboxylic acid, 1

D-(−)-Penicillamine of reagent grade was supplied by Sigma Chemical Co., St. Louis, Missouri. To a saturated water solution of D-penicillamine (1.5 g, in 15 mL) was added 40 mL acetone. The mixture was evaporated under nitrogen to near dryness and filtered. The white solid (**I**) was recrystallized from acetone, and air dried. Yield 88%, mp (in air) 172–174°C (dec). The same procedure was repeated with acetone-d_6 to produce (S)-2,2-bis(trideuteromethyl)-5,5-dimethylthiazolidine-4-carboxylic acid (**2**). Compounds (**1**) and (**2**) were recrystallized from D_2O and acetone to produce (S)-3-deutero-2,2,5,5-tetramethylthiazolidine-4-carboxylic acid (-OD), **3**, and (S)-3-deutero-2,2-bis(trideuteromethyl)-5,5-dimethylthiazolidine-4-carboxylic acid (-OD), **4**. Crystals of **1** suitable for X-ray studies were slowly precipitated from an aqueous solution by vapour diffusion of acetone. The pKs of the —COOH and =NH groups were measured by titration of an aqueous solution of **1** against 0.1 N NaOH. The pHs were measured with a Corning Model 130 pH meter which was standardized with Corning potassium hydrogen phthalate buffer (pH = 4.00), BDH pH 7.00 buffer, and Fisher potassium carbonate/potassium borate/potassium hydroxide buffer (pH 10.00). The pKs of **1** were 2.8 (—CO_2H) and 5.5 (—NH—).

[2]There is ambiguity in this paper about whether the structure of the (R) or (S) form was determined. There are statements "crystal structure for L-thiazolidine-4-carboxylic acid" and "values reported for L-thiazolidine-4-carboxylic acid" as compared to "the crystal structure of (S)-thiazolidine-4-carboxylic acid was determined" and the configuration shown is S. As correctly shown by Loscalzo *et al.*, the configuration of L-thiazolidine-4-carboxylic acid is R.

TABLE 1. Crystal data for 2,2,5,5-tetramethylthiazolidine-4-carboxylic acid, $C_8H_{15}NO_2S$

Parameter	Value
Formula weight	189.27
Crystal size (mm)	Plate 0.17 × 0.30 × 0.37
Space group	$P2_1$ (No. 4)
Systematic absences	O*k*O, $k = 2n + 1$
Unit cell	$a = 11.351(4)$, $b = 8.303(2)$, $c = 11.969(3)$ Å, $\beta = 116.69\ (2)°$; $V = 1007.9(5)$ Å^3, $Z = 4$
ρ (calcd.)	1.24 g cm^{-3}
ρ (obs.)	1.26(1) g cm^{-3}
Linear absorption coefficient	2.40 cm^{-1}
Max 2θ	45°
Reflections measured	$h, \pm k, \pm l$
Standrd reflections (esd)	−4 −2 −1 (0.013) −4 −2 −3 (0.014)
Temperature	22°C
Number of independent reflections	2555
Number of reflections ($I > 0$)	2388
Number of variables last cycle	157
Final R_1, $(R_2)^a$	0.0774 (0.0670)
Highest peak, location	0.6 eÅ^{-3}, 0.34, 0.08, 0.68
Lowest valley, location	0.4 eÅ^{-3}, 0.06, 0.02, −0.04
Weighting, $w = (\sigma^2 + (0.03\ F_0)^2)^{-1}$; error in an observation of unit weight	0.8672

$^aR_1 = \Sigma\|F_o| - |F_c\|/\Sigma|F_o|$; $R_2 = \{\Sigma w(|F_o| - |F_c|)^2/\Sigma_w F_o^2\}^{1/2}$.

Spectral measurements

Solutions for nmr studies were prepared in D_2O and concentrations were about 100 mg (solid) mL^{-1} of solvent. External TMS was used as the reference. Proton nmr spectra were recorded on a Varian T60 spectrometer and ^{13}C nmr spectra were recorded on a Bruker WP-80 spectrometer operating at 20.115 MHz. Mass spectra were obtained with a VG Micromass 7070F mass spectrometer with use of direct probe introduction and an ion source temperature of 200−220°C, electron potential of 70 eV, and an ionizing current of 100 A.

Infrared spectra were recorded on both Nicolet 7199 FT-IR and Perkin−Elmer Model 283 spectrophotometers. The samples were ground with KBr at a concentration of approx. 1% by weight and then pressed into pellets. To confirm that certain peaks were real, and not manifestations of the pelleting procedure, the spectra of certain samples were also run in Nujol and again in hexachlorobutadiene. For D_2O solution spectra, AgCl windows were used. Spectra were calibrated with polystyrene. For the region 500−100 cm^{-1}, the samples were prepared as Nujol mulls on polyethylene plates. Raman spectra were excited by means of the $\lambda = 5145$ Å radiation from a Spectra-Physics Model 164-02 argon ion laser and recorded on a Spex 14018 double monochromator. Solid samples were contained in glass melting point tubes, and solutions in nmr tubes. The spectrometer was calibrated regularly against an indene standard and had previously been calibrated with a neon lamp; the wavelength readout scale was found not to change (±1−2 cm^{-1}).

Collection of the X-ray diffraction data

A plate-like single crystal was sealed in a Lindemann capillary for the X-ray studies. Precession photographs showed that the crystals of **1** were monoclinic. Unit cell parameters were obtained from least-squares fit of χ, φ, and 2θ for 15 reflections in the range 19.1° < 2θ < 31.8° measured on a Nicolet P3 diffractometer having graphite-monochromated MoKα radiation (λ = 0.70926 Å at 22°C). Crystal data and other numbers related to data collection are summarized in Table 1. The density of the crystals was measured by flotation in a benzene−bromoform mixture. Intensities were also measured with use of the Nicolet P3 diffractometer and a coupled θ (crystal) − 2θ (counter) scan. The methods of selection of scan rates and initial data treatment have been described (9, 10). Corrections were made for Lorentz polarization effects but not for absorption. This will make a maximum error in F_o of 1.0%.

Solution of the structure

The sulfur atom was found from a three-dimensional Patterson synthesis and all other atoms were found from electron density difference maps. Hydrogen atoms were given temperature factors of about twice those of the atoms to which they were attached, but were not refined at this stage. Temperature factors for sulfur and oxygen atoms and adjacent carbon atoms were made anisotropic. The significance of the additional parameters was tested at each stage (11). Refinement, which minimized $\Sigma w(|F_o| - |F_c|)^2$, was continued until the maximum shift/error was 0.1. At this point, in addition to variation of all parameters for non-hydrogen atoms, x, y, z for hydrogen atoms were varied for one cycle to give a rough estimate of the hydrogen atom errors. Refinement was terminated after one further cycle with variation of only the parameters for non-hydrogen atoms. No corrections were needed for secondary extinction. Scattering curves were taken from Cromer and Waber (12) and anomalous dispersion corrections were taken from Cromer (13) and applied to the curves for S, N, O, and C. The atom parameters are listed in Table 2.[3,4]

[3]Tables of anisotropic temperature factors, H atom positions, dihedral and torsional angles, moduli of F_o and F_c, and mass spectral fragmentation patterns of **1** and **2** are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S7.

[4]All calculations were carried out on a CYBER 170/730 computer. Programs from the XRAY 76 package (14). The structure was solved by means of SHELX (15). The internally written programs CUDLS (Stephens, J.S.) and SYMFOU (Rutherford, J.S.) were used for final full-matrix least-squares and difference syntheses. The least-squares planes calculations used NRC-22 (16) and diagrams were prepared with use of ORTEP-II (17).

Discussion

There are two independent molecules in the unit cell, but they are very similar. One molecule is illustrated in Fig. 1, and selected interatomic distances and angles are given in Table 3. The surprising feature is that **1** has the amino-acid form rather than the zwitterion form. The carboxylate hydrogen atoms were clearly located and the presence of the hydroxyl group is reflected in the differences in the C═O (1.183(8), 1.206(7) Å) and C—OH (1.331(8), 1.307(7) Å) bond lengths. This is in contrast to thiazolidine-4-carboxylic acid, where the zwitterion is found in the solid state (7, 8). The hydrogen atoms were not detected in this case but the zwitterion form was confirmed by the near equivalence of the C—O bond lengths (1.240(8), 1.248(8) Å). It appeared that the amino-acid form of **1** might be caused by the steric hindrance of the methyl groups, but models show that it would be possible to coordinate an extra hydrogen atom at N. Further, there is strong hydrogen bonding between the carboxylic acid of one molecule and the nitrogen atom of another. The zwitterion form would be obtained if this hydrogen atom moved only 0.6 Å from the oxygen atom towards the nitrogen atom. The question arises as to whether the observed molecular structure is an artifact of the solid state or whether significant amounts of the amino-acid form exist in solution. Vibrational spectroscopy (see below) shows that small but significant amounts of **1** are present in solution. This should be reflected in the p*K*'s of the —CO_2H and —NH_2^+— sites. The fact that the p*K* of the —NH_2^+— group in the thiazolidine-4-carboxylic acid was shifted to 6.24 from the value of 10 usually found in amino acids was interpreted in terms of strain preventing the necessary sp^3 hybridization at nitrogen (18). Even greater strain is present in **1**, and this may cause the lower —NH_2^+— p*K* of 5.5. At the same time the extra methyl groups in **1** (compared to thiazolidine-4-carboxylic acid) have the normal inductive effect on the carboxylic acid function and raise its p*K* from 1.63 in thiazolidine-4-carboxylic acid to 2.8 in **1**. From these p*K* values we calculate that for thiazolidine-4-carboxylic acid, in aqueous solution, about 0.5% is present as the amino-acid form. This is a much greater amount than is present in most amino acids, but it is still undetectable by vibrational spectroscopy. As can be seen in Fig. 2a, there is no detectable carboxylic acid peak at ~1700−

[a,b]The atom is related to those given in Table 2 by the transformation, a, $1 - x, y - 1/2, -z$; *b*, $1 - x, 1/2 + y, 1 - z$.

[c]The second column of numbers after each bond length or angle relates to the molecule of which the atoms are designated by a prime in Table 2.

1730 cm^{-1} but the ν_a and ν_s CO_2^- peaks of the carboxylate group are clearly visible at 1638 and 1400 cm^{-1}. For **1**, however, about 5% should be present as the amino acid in aqueous solution, which is detectable by infrared (D_2O solution) spectroscopy, as shown by the weak band at 1700 cm^{-1}, Fig. 2b. Using these p*K* values, we calculate that the free energy of amino acid to zwitterion transition for thiazolidine-4-carboxylic acid is about −3.2 kcal mol^{-1}, whereas for **1** it is only −1.8 kcal mol^{-1}. This energy difference in the two forms of **1** is considerably smaller than the lattice energies, particularly in a structure in which strong hydrogen bonding is present, and we assume that the lattice energy of the amino-acid form is greater for **1**, allowing isolation of the crystalline product.

Most bond lengths and angles within the two molecules of **1** are normal. The C—S distances (mean 1.850, range 1.827(7)−1.869(6) Å) are larger than those found in (*R*)-thiazolidine-4-carboxylic acid (mean 1.799 Å) and the C—S—C angles are also larger (95.4(3), 94.5(3) vs. 89.4(4)°) (7). These differences are apparently caused by the steric requirements of the methyl groups. Similar differences in other D-penicillamine vs. L-cysteine derivatives have been noted previously. The presence of the methyl groups also affects the conformation of the thiazolidine ring. In thiazolidine-4-carboxylic acid the conformation of the ring was an envelope with the S atom 0.843 Å out of the best CNCC plane (7). In **1** the conformation is less regular and the ring flatter, but it can best be pictured as a plane defined by C(5a)SC(2)) with N (0.382(4) Å) and C(4) (0.269(5) Å) asymmetrically twisted out of the plane on opposite sides of the plane (corresponding distances for the prime molecule: N′ (0.346(4) Å), C(4′) (0.296(5) Å). Alternatively it can be considered, less satisfactorily, as an envelope with the nitrogen atom 0.563(4) Å out of the plane formed by C(2)SC(5)C(4). This is a consequence of the steric effects of the methyl groups. Figure 3 illustrates important dihedral angles in the structure. As can be seen, the two independent molecules have almost identical conformations. Very often in amino acids and particularly in derivatives of cysteine, the O(1)C(1)C(4)N-equivalent torsion angles are very small. The angles for **1** of 26.4(7) and 23.7(6)° are considerably larger than normal. Large angles have been observed previously in penicillamine (19) and its derivatives (20, 21) and have been explained in terms of non-bonding steric interactions. Similar interactions of the carboxylate group and the 5-methyl groups appear to be present here.

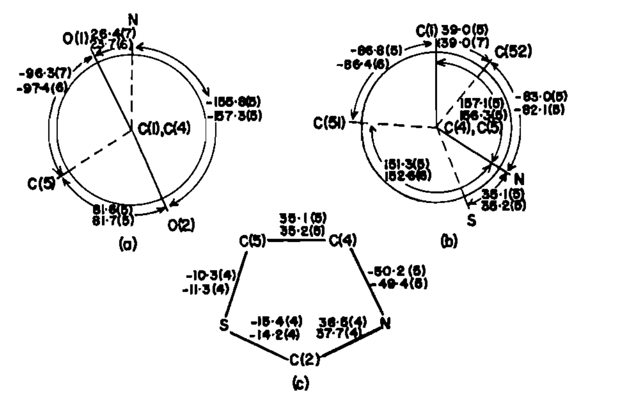

FIG. 3. Torsional angles in **1**. In (a) and (b) torsion angles are about the C(1), C(4) and C(4), C(5) bonds respectively. In (c) the torsion angles are for the two adjacent bonds about the bond to which the figures are affixed. In any pair of values, the upper refers to molecule one and the lower to molecule two (prime).

The packing in the unit cell is shown in Fig. 4. The chains of molecules up the 2_1 axes at $x = 1/2$ and $z = 0,1/2$ comprise the dominant feature of the structure. The molecules are held together by the strong hydrogen bond between the carboxylic acid group of one molecule and the amine group of the next. A question arises as to why there are two molecules in the asymmetric unit. An examination of the layers at $z = 0,1/2$ shows that the ring parts of the molecule are almost identical, except that the NH group is interchanged with the CH group. The difference lies in the COOH groups. At $x = 0$ they are arranged so that the hydrogen bonding network spirals down the 2_1 axis whereas at $x = 1/2$ the hydrogen bonding network spirals up the 2_1 axis. The CH—NH interchange, noted above, means that N—H points at the carboxyl group of an adjacent molecule whereas N′—H′ points at the sulfur atom of an adjacent molecule. In neither case is there any hydrogen bonding present, however. All other interactions are weak van der Waals forces. In the *a* direction the oxygen atoms interact with the methyl groups and in the *c* direction, the interactions are between sulfur atoms and methyl groups.

The title compound **1** is a secondary α-amino acid that is a five-membered heterocyclic molecule having no symmetry elements. There is very little published work relating to the vibrational spectra of thiazolidine-4-carboxylic acids. Some isolated C—S bond frequencies are listed by Freeman (22) for various cyclic sulfides. A study of the vibrational spectra of thiazolidine and ND thiazolidine has been reported, followed by a similar study of three monomethyl thiazolidines substituted at the C(2), C(4), and C(5) positions (23). These studies did not include work on the 4-carboxylic acids. The infrared spectra of some chelates of thiazolidine acids, including the spectra of free ligands 2-methyl-, 2,2-dimethyl-, 2,2,5,5-tetramethyl-, and 2-benzyl-thiazolidine-4-carboxylic acid have been reported for the range 4000−400 cm^{-1} (24). Our spectra of these ligands cover a greater cm^{-1} range, and they differ in many details. A detailed study of the spectra of D(−)-penicillamine and its deuterated derivatives, in solid and solution, both acid and zwitterion forms, has been reported recently (19).

The vibrational spectra and assignments for compounds **1**−**4** are shown in Table 4. The mode descriptions should be considered approximate since force constant analyses usually show considerable coupling of vibrations, particularly in the middle frequency region (800−1600 cm^{-1}). The spectra show many similarities to those for D-penicillamine and its deuterated derivatives, the main differences being (*i*) absence of ν S—H and δ S—H bands; (*ii*) replacement of bands of the NH_3^+ group by those of the NH group, and (*iii*) the presence of the three unique ring deformations δ CSC, δ CNC, and δ NCS, which are not present in D-penicillamine.

The assignment of ν N—H is unambiguous with a sharp, single band at 3262−3265 cm^{-1} in **1** and **2**. In **3** and **4** a band is observed at 2420 cm^{-1}. The isotopic shift ratio is 1.35, which is close to average for ν N—H/ν N—D ratios.

Strong, broad bands in the infrared spectrum at 2500 and 1930 cm^{-1}, which are little affected by deuterium substitution, are typical of fairly strong O—H···N bonding. These bands appear only in the infrared, and not in the Raman spectra. They are present in all samples, whether prepared as KBr discs or Nujol or hexachlorobutadiene mulls (and thus are not spurious bands from moisture in KBr).

The strong infrared bands at 1724, 1330, and 1190−1215 cm^{-1} are assigned as ν C=O, δ OH, and ν C—O respectively (see Fig. 2c). These assignments are consistent with the findings of the X-ray work indicating that **1** exists in the solid in the strongly hydrogen-bonded acid form. Deuterium exchange seems to weaken this hydrogen bonding, however, with a new band appearing at 1612 cm^{-1} (infrared); such a band in D-penicillamine was asigned to ν_a CO_2^-, and would only occur for the zwitterionic species.

The ring stretching modes can be described only very roughly as 2 ν C—S, 2 ν C—N, and ν C—C, with asymmetric stretches being more intense in the infrared, and symmetric (e.g., "ring-breathing") more intense in the Raman spectra.

We assign the strong Raman band at 580 cm^{-1} (**1**) to ν C—S; this band shows a downward shift in **2** to 537 cm^{-1}, apparently a mass effect of the CD_3 group, the isotopic ratio being 1.07. These bands also show a splitting which is attributed to Fermi resonance with the overtone of δ CCS at 294 cm^{-1} in **1**, 270 cm^{-1} in **2**. The medium intensity band at 506 cm^{-1} is assigned to the asymmetric ν C—S. These assignments are unusual and deserve discussion. Two major effects may be expected to affect the ν (C—S) frequencies. Ring strain may be expected to affect the C—S bond lengths, the C—S—C angle, and hence the C—S stretching vibrational frequency. Secondly, the C—S stretching frequency may be reduced by steric hindrance; substitution of hydrogen atoms adjacent to a C—S—C system reduces C—S stretches from 672−720 cm^{-1} (Raman, highly polarized, $\rho = 0.05-0.15$) in tetrahydrothiophene and thiazolidine to 582 cm^{-1} in di(*tert*-butyl)sulfide, 513 cm^{-1} in hexamethyl-*S*-trithiane(trithioacetone), and 547 cm^{-1} in 5-thia-10,11-diazadispiro[3.1.3.2.]undecane (22). In **1** the two effects are not independent. The substitution of the C(5) and C(2) centres with bulky methyl groups affects the conformation of the molecule **1**, in a way that seems to be a combination of the following effects: (1) the C—S bonds are lengthened as compared with both thiazolidine and D-penicillamine; (2) the C—S—C angle is increased compared to unsubstituted thiazolidine; (3) the C(2) and C(5) atoms rotate in opposite directions to minimize the C—S—C angle, for which 90° is the preferred equilibrium value.

Both the substitution and the long C—S bonds suggest that ν (C—S) should be lower than the normal range in cyclic sulfides (670−720 cm^{-1}) (22). The observed wave numbers are lower for one band but not as low as one would expect. Thus one (C—S) in **1** is higher than in D-penicillamine (580 vs. 548 cm^{-1}), close to the value for di(*tert*-butyl)sulfide. We assume the lowering effects are partially balanced by excess ring strain in **1**. The assignment of the second C—S band to 506 cm^{-1} is as expected for tetra-substituted carbons flanking the S. The assignment is supported by a weak side band of position and intensity expected for ^{34}S, which occurs on both the 506 and 473 cm^{-1} bands.

The assigned ring deformations are δ CNC at 376 cm^{-1}, δ NCS at 294 cm^{-1}, and δ CSC at 188 cm^{-1}. The deformations involving the S atom are all intense in the Raman spectrum, and all show an isotopic shift (adjacent CD_3 groups) of 1.06 to 1.07. The strong Raman band at 294 cm^{-1}, **1**; 270 cm^{-1}, **2** is not observed in unsubstituted thiazolidine-4-carboxylic acid and is therefore assigned as a δ NCS, deformation of the N—$C(CH_3)_2$—S moiety. This assignment is supported by the larger isotopic shift ratio of 1.09 for **2**.

The other assignments of bands for the methyl groups are straightforward and very similar to those for D-penicillamine. The isotopic shifts show the usual value: for the stretches they are in the range 1.33−1.40; for the deformations δ_a and δ_s they are 1.38 and 1.35, and for the rocks, ~1.2. An isotopic shift of 1.085 occurs for coupled vibrations of the C—CH_3 and C—CD_3 moieties.

The mass spectra of **1** and **2** are shown in Fig. 5. Under electron impact conditions the title compound shows a signifi-

[a]Infrared notations: bands in cm^{-1}, intensities relative to strongest band = 100, half width at half maximum in cm^{-1}; s = strong, m = medium, w = weak, v = very, sh = shoulder, br = broad, shp = sharp.
[b]Raman intensities relative to the strongest Raman band with arbitrary intensity 100.
[c]Assigned notations: ν = stretching frequency, a = antisymmetric, s = symmetric, δ = deformation, r = rock, γ = out-of-plane deformation; FR = Fermi resonance; ρ = isotopic shift ratio. $^+$, $^{++}$ show which overtone bands contribute to FR.
[d]Measured from sample in D_2O solution.

cant molecular ion peak (M) at $m/z = 189$, $I = 39\%$ ($m/z = 195$, $I = 23\%$, **2**). Loss of a methyl group is shown by an $M - 15$ peak ($m/z = 174$, $I = 21\%$). That this loss is solely from C(2), and not from C(5), is confirmed by the spectrum of **2** (Fig. 5b), where only an $M - 18$ peak (loss of CD_3) at $m/z = 177$ (14%) is observed and not an $M - 15$.

Ring fragmentation patterns for thiazolidines have been studied previously and it has been found that the dominant

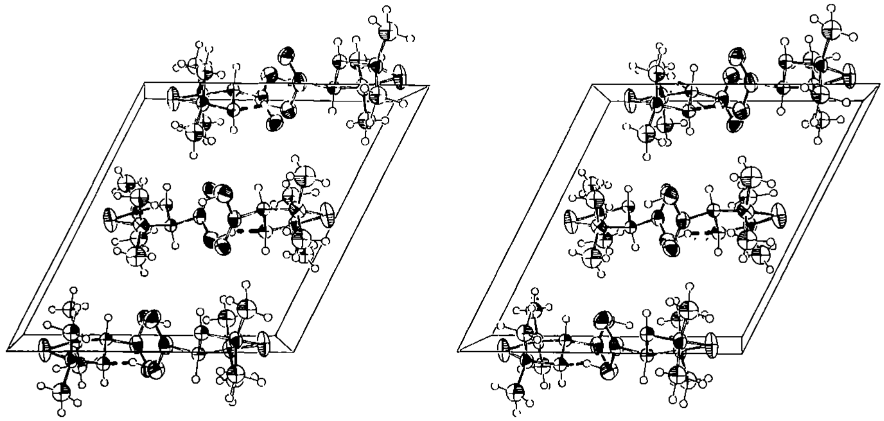

FIG. 4. The packing within the unit cell. a and c^* are parallel to the bottom and side of the page respectively and the view is down b. Hydrogen bonds are shown as dotted lines.

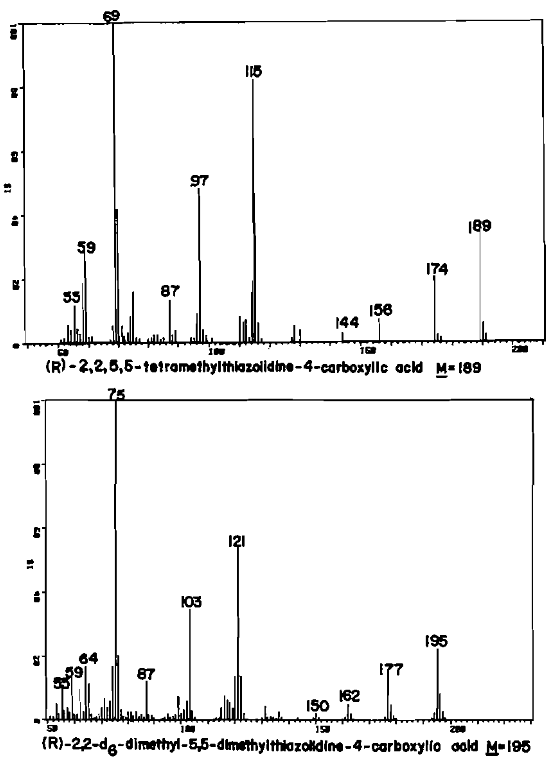

FIG. 5. The mass spectra of (S)-2,2,5,5-tetramethylthiazolidine-4-carboxylic acid and (S)-2,2-d_6-dimethyl-5,5-dimethylthiazolidine-4-carboxylic acid.

fragmentation patterns are 1,4- and 2,5-ring cleavages, with the 1,4-cleavage preferred (25). The spectrum of **1** alone does not allow differentiation between the two cleavages, but the spectrum of **2**, the deuterated analogue, shows that the 1,4-ring cleavage is highly favoured. There is a pattern of three relatively intense peaks (m/z = 115, 97, 69 in **1**; 121, 103, 75 in **2**) which arises from this 1,4-cleavage. Loss of $(CH_3)_2$ C=S leads to the intense $M - 74$ peaks at m/z = 115, **1** and 121, **2**. In **2**, there is very little loss of $(CD_3)_2$ C=S ($M - 80$, m/z = 115, 4%), which arises from 2,5-cleavage. Further fragmentation of the ions $(CX_3)C{=}\overset{+}{N}H{-}\dot{C}H\cdot CO_2H$ (X = H, m/z = 115, **1**; X = D, m/z = 121, **2**) derived from the 1,4-cleavage appears to be a two-step process, with loss of water giving $(CX_3)_2C{=}\overset{+}{N}{=}CH{-}\dot{C}{\equiv}O$ (m/z = 97, 48%, **1**; m/z = 103, 49%, **2**) followed by loss of CO to give $(CX_3)_2\dot{C}{-}\overset{+}{N}{\equiv}CH$ (m/z = 69, 100%, **1**; m/z = 75, 100%, **2**).

In both **1** and **2** the $M - 74$ peak is accompanied by an $M - 75$ peak (m/z = 114, 16% **1**; m/z = 120, 14%, **2**). Hydrogen transfer to give the $(CX_3)_2\dot{C}SH$ fragment of mass 75 comes mainly from either NH or CO_2H, since very little D transfer is apparent (m/z = 119, I = 4%) in **2**.

A 1,2-cleavage (loss of $(CX_3)_2C$, mass 42 or 48) must also occur, giving rise to a very unstable ion. No peaks were observed at m/z = 147 ($M - 42$, **1**; $M - 48$, **2**), but fragments giving peaks at m/z = 87 ($CH_3{-}\underset{\underset{S}{\|}}{C}{-}CH{=}\overset{+}{N}H$) and 55 ($CH_2{=}CH{-}CH{-}\overset{+}{N}H$) (further loss of S) for both **1** and **2** can be derived from this cleavage. Two other fragmentation patterns observed for both **1** and **2** are explained by the loss of COOH from the molecular ion ($M - 45$ peak at m/z = 144, 3%, **1**; 150, 3%, **2**) and the loss of SH ($M - 33$ peak at m/z = 156, 8%, **1**; 162, 5%, **2**).

Other peaks in the spectra can be assigned tentatively as subsequent fragmentation of the ions at m/z = 115, 121; for example, loss of COOH, gives m/z = 70, 42%, **1**; 76, 20%, **2**. The remaining significant peaks at m/z = 59 ($CH_2{=}\overset{+}{C}{-}SH$) **1** and **2** and 58, **1**, 64, **2** ($(CH_3)_2C{=}\overset{+}{N}H_2$, $(CD_3)_2C{=}\overset{+}{N}H_2$) are presumably derived from further decomposition of one of the 1,4 fragments. The various fragments suggested in the above discussion have the requisite masses and are reasonable, although other arrangements are possible.

The ^1H and ^{13}C nmr spectra for **1** and **2** and the assignments are given in Table 5. The four methyl peaks in the ^1H spectrum of **1** are resolved into two pairs (at C(2) and C(5)) by deuteration of the C(2) methyl groups. The assignment of the two peaks attached to C(5) is based on an assumed analogy to penicillin. Cooper and co-workers (26) have employed nOe experiments to study thiazolidine ring conformations in penicillin derivatives in solution and have found that the pro R methyl protons are always to high field of the pro S methyl protons. On this basis we assign the highest field resonance of **1** to the C(52), pro R, methyl group and the next highest to the C(51), pro S, methyl group. The only assignment left uncertain is the identity of the peaks arising from the methyl groups attached to C(2). In DMSO-d_6, all resonances are shifted to low field, but by unequal amounts, so that the peaks for both C(21) and C(22) methyl groups overlap.

The ^{13}C nmr spectrum of **1** also showed overlap. The normal

proton decoupled spectrum consisted of seven lines for the eight carbon atoms. The resonance at 73.46 ppm was much more intense than the others, so we assumed it was two peaks overlapping. Comparison with benzoylpenicillin showed that C(2) and C(4) of the thiazolidine ring are very close in chemical shift. Since C(2) is a quaternary carbon atom and C(4) is a tertiary carbon atom, it was possible to assign these peaks by an off-resonance experiment. The overlap of C(2) and C(4) peaks also occurred in the spectrum of **2**. The two deuterated methyl groups induce a small upfield isotope shift of (6×0.25) ppm (27) but the resulting resonance of 74.68 ppm is still close enough to overlap the non-deuterated C(2) resonance at 73.46 ppm.

The ^{13}C methyl groups were again assigned by deuteration and comparison with penicillin spectra. The overall effect of deuteration is to greatly reduce the peak intensity of the deuterated carbon atoms because of decreased nOe enhancement, increased relaxation time, and dispersal of the intensity into multiplets caused by coupling between ^{13}C and ^{2}H. The results show that the resonances from the C(5) methyl groups are upfield from those on C(2), and this is presumably caused by the γ-shielding effect of the CO_2H on the C(5) methyls (27).

Synthesis and protonation studies of a *meso*-unsubstituted surfactant porphyrin

MICHEL RINGUET AND JACQUES GAGNON

Département de chimie–biologie, Université du Québec à Trois-Rivières, C.P. 500, Trois-Rivières (Qué.), Canada G9A 5H7

Received September 5, 1984

MICHEL RINGUET and JACQUES GAGNON. Can. J. Chem. **63**, 2420 (1985).

A *meso*-unsubstituted surfactant porphyrin has been synthesized. Spectroscopic studies show that intermolecular protonation occurs between the side-chain carboxyl groups and the inner nitrogen atoms of the porphyrin, leading to the formation of a porphyrin dication. In 5×10^{-5} *M* chloroform solution, 27% of the porphyrin molecules are in the dicationic form and they are self-associated with some remaining molecules in the free base form.

MICHEL RINGUET et JACQUES GAGNON. Can. J. Chem. **63**, 2420 (1985).

On a réalisé la synthèse d'une porphyrine tensio-active qui n'est pas substituée en position *meso*. Des études spectroscopiques démontrent que la protonation intermoléculaire se produit entre les groupements carboxyliques des chaînes latérales et les atomes d'azote du coeur de la porphyrine; ceci conduit à la formation d'un dication porphyrine. En solution à 5×10^{-5} *M* dans du chloroforme, 27% des molécules de porphyrine existent sous la forme de dications et elles sont auto-associées avec quelques-unes des molécules qui restent sous la forme de bases libres.

[Traduit par le journal]

Introduction

The potential catalytic importance of porphyrins incorporated into synthetic organized molecular systems has stimulated considerable interest in the syntheses of surfactant porphyrins (1–4). These products are usually obtained by alkylation of a functionalized *meso*-tetraarylporphyrin (1–7), or esterification of natural carboxyporphyrins (8).

As part of our work on the development of a synthetic model which would mimic the primary events of green plant photosynthesis (9), the synthesis of a *meso*-unsubstituted carboxyporphyrin seemed more pertinent. This substrate would show an *etio*-type absorption spectrum, similar to the ones observed for most natural porphyrins (10), and would have the ionizable functional group needed for further studies in organized media. Hence we wish to report here the synthesis and a spectroscopic study of the protonation of a new type of surface-active porphyrin, dioctadecyldeuteroporphyrin II, **1**. Our data are consistent with an intermolecular exchange of protons between the side-chain carboxyl group of a porphyrin molecule and the inner nitrogen atom of another porphyrin ring. The nature and the extent of protonation were determined.

Results and discussion

Synthesis

The porphyrin **1** is synthesized by formation and *in situ* coupling of the properly substituted 5-methyl-5′-carboxydipyrromethene, a method first reported by Chang (11).

A modification of the procedure of Clezy *et al.* (12) for the lead tetraacetate oxidation of pyrrole **3** gives the 5-formylpyrrole **4**. The long-chain substituted pyrrole **6** is prepared by acylation of pyrrole **5** with stearoyl chloride in the presence of stannic chloride. Diborane reduction of **6** affords the surfactant pyrrole **7** which is transbenzylated to give pyrrole **8**. The overall yield from pyrrole **5** to **8** is 48%. Hydrogenolysis of pyrroles **4** and **8** gives the carboxypyrroles **9** and **10** respectively, which are mixed in equimolar quantities in hot formic acid and treated with hydrobromic acid to afford the crude dipyrromethene. Self-coupling of the latter in hot formic acid in the presence of excess bromine leads to a mixture of the dicarboxyporphyrin **1**, its diester **2**, and the monoacid monoester. The mixture is then esterified to give porphyrin **2** in 8% yield from pyrrole **10**. This relatively low yield is due to the well-known lack of reactivity of long-chain substrates. Repeating the series with hexyl- rather than octadecyl-pyrrole led to a 25% yield in the last step. Hydrolysis of **2** in a mixture of water and tetrahydrofuran gives **1**.

Spectrophotometric studies

Absorption spectra of porphyrins **1** and **2** in protophylic solvents such as THF are *etio*-type (10) and follow the Beer–Lambert law over the range of concentration studied (10^{-6} to 10^{-4} *M*). In protophobic solvents, such as chloroform

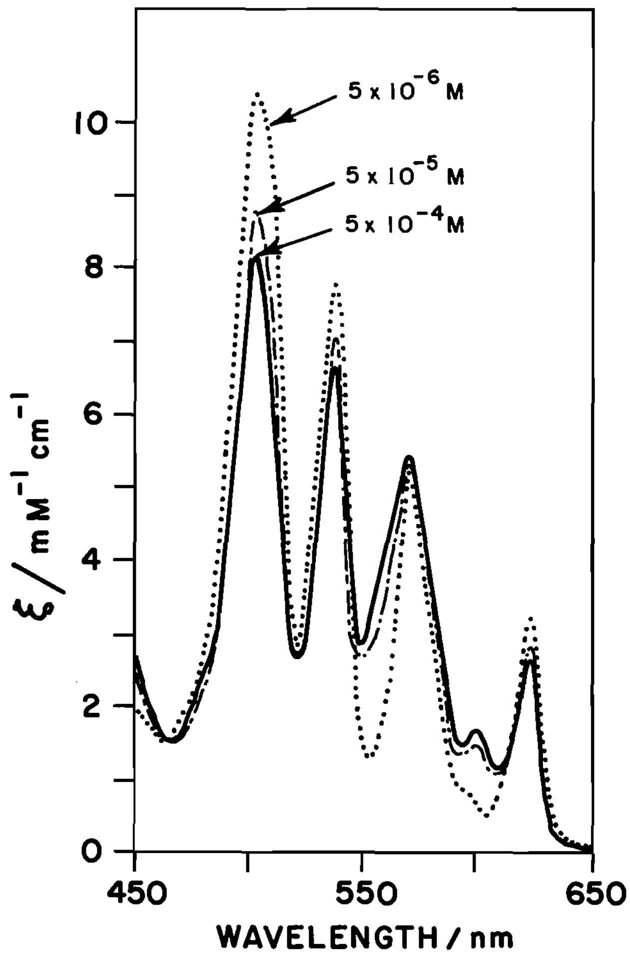

FIG. 1. Concentration dependence of the absorption spectrum of compound **1** in $CHCl_3$.

and xylene, the diester porphyrin **2** still acts in accordance with the Beer–Lambert law but the dicarboxyporphyrin **1** does not. The four maxima observed for chloroform solutions of porphyrin **1** show a concentration dependence, and a new maximum at 595 nm appears as the concentration is increased (Fig. 1).

Two different types of fluorescence spectrum are obtained by exciting a 3×10^{-5} *M* solution of compound **1** in chloroform. Excitation at 400, 485, 535, or 620 nm produces a four-band spectrum with maxima at 624, 656, 674, and 690 nm. This spectrum is similar to the ones obtained by exciting at any wavelength the 10^{-4} to 10^{-6} *M* chloroform solutions of porphyrin **2** and the 10^{-6} *M* chloroform solution of porphyrin **1**. The 10^{-4} to 10^{-6} *M* solutions of porphyrins **1** and **2** in THF give the same type of spectrum. These spectra are typical of free base porphyrins (13). The other type of spectrum has maxima at 604, 624, 664, and 690 nm and is obtained when the 3×10^{-5} *M* chloroform solution of compound **1** is excited at 420, 558, or 598 nm. These results suggest that there are two species in this solution, i.e. the free base and the protonated porphyrin, as will be shown later. This protonation is not due to HCl contamination in the chloroform since, if this was so, the protonation would also occur in the 10^{-6} *M* chloroform solution of porphyrin **1** and in the chloroform solution of porphyrin **2**. In addition, the aggregation of a carboxyporphyrin has been reported to give intermolecular protonation (4). A spectrophotometric titration from 450 to 650 nm was done with

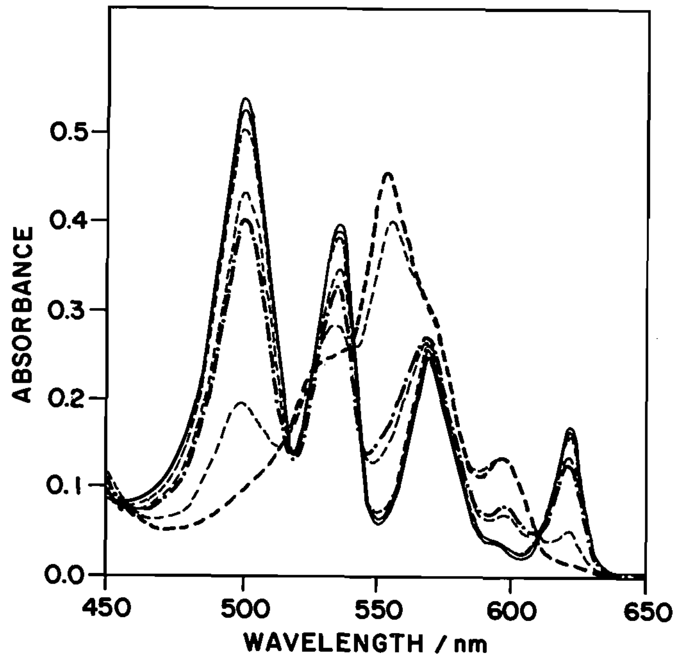

FIG. 2. Absorption spectra of a 5×10^{-5} *M* solution of compound **1** in chloroform (-··-), when titrated with triethylamine (—), and with acetic acid (......).

triethylamine (TEA) and glacial acetic acid (GAA) to identify the protonated species. Mixtures of 0.01–0.1% TEA in chloroform show the free base porphyrin spectrum, as expected. The spectrum of compound **1** was independent of solvent composition for mixtures of 0.1–10% GAA in chloroform and was also identical to the free base spectrum. At high (up to 100%) GAA concentrations, the spectra are characteristic of the porphyrin monocation, as usually found in GAA (14), with maxima at 530, 558, and 598 nm (Fig. 2). At 30% GAA in chloroform, the spectrum of compound **1** is quite similar to the one obtained with the chloroform solution.

However, the difference spectra of the chloroform solution of compound **1** relative to a solution of the free base form of the same porphyrin show the two-band spectrum typical of the dication (10). The same difference spectra for the 30% GAA in chloroform solution clearly show the three-band spectrum of the porphyrin monocation (Fig. 3). Therefore the protonated porphyrin species in the chloroform solution, a dication, is different than the monocation found in the 30% GAA in chloroform solution.

Spectrophotometric titrations with trifluoroacetic acid (TFAA) led to the formation of the dication. They were done with chloroform solutions of compound **1** to determine the percentage of dication in the solutions. These series of spectra are isosbestically related (Fig. 4). Using the method of Grigg *et al.* (14) the ratios (c_P/c_B) of the respective concentrations of the protonated and free base forms of compound **1** in chloroform were determined by eq. [1]:

$$[1] \quad (c_P/c_B) = (A - A_B)/(A_P - A)$$

where A, A_B, and A_P are the absorbance, at a particular wavelength, of a fixed concentration of the porphyrin in chloroform, in 0.1% TEA in chloroform (i.e. free base), and in 1% TFAA in chloroform (i.e. dication) respectively. The ratios were obtained for five wavelengths corresponding to the absorption maxima of either the free base (500, 530, and 622 nm) or the

TABLE 1. Extent of protonation of compound **1** in 5×10^{-5} *M* solutions

	Absorbance			
λ (nm)	1% TFAA–$CHCl_3$	0.1% TEA–$CHCl_3$	$CHCl_3$	(c_P/c_B)
500	0.059	0.539	0.403	0.39 ± 0.03
530	0.131	0.336	0.280	0.38 ± 0.06
555	0.564	0.070	0.196	0.36 ± 0.03
595	0.224	0.028	0.083	0.39 ± 0.07

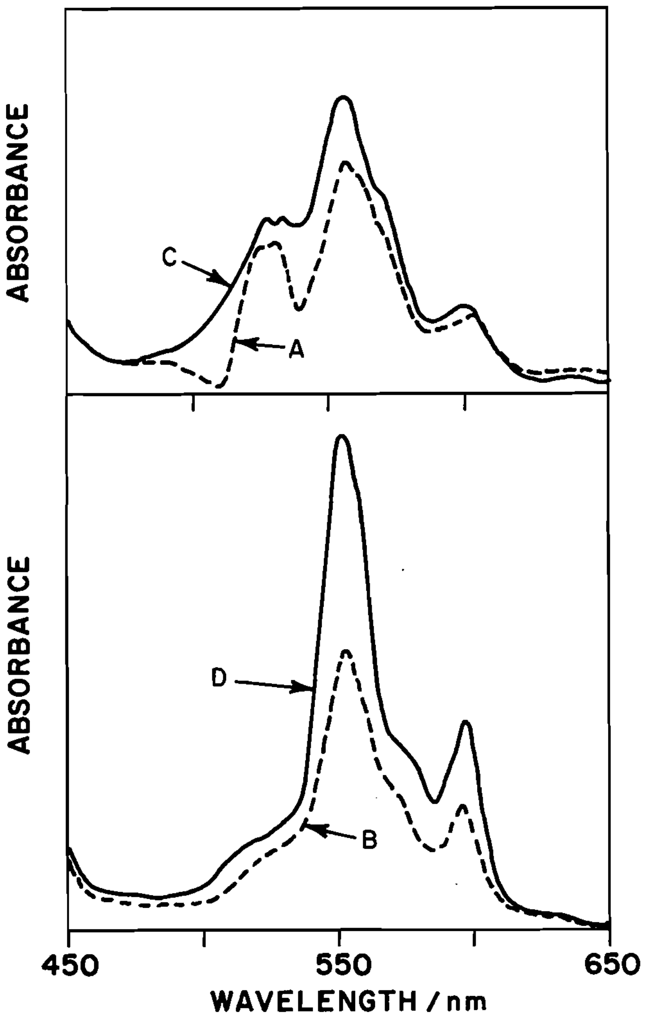

FIG. 3. Difference spectra, against free base porphyrin **1** for 5×10^{-5} *M* solutions of porphyrin **1** in 30% GAA in $CHCl_3$ (A), and in $CHCl_3$ (B). Absorption spectra of porphyrin **1** monocation (C) and dication (D).

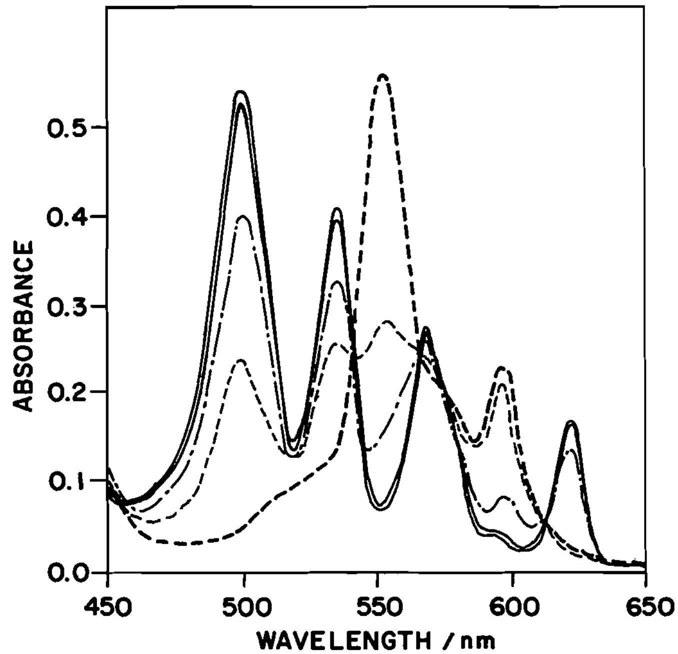

FIG. 4. Absorption spectra of a 5×10^{-5} *M* solution of compound **1** in chloroform (-·-), when titrated with triethylamine (—), and with trifluoroacetic acid (......).

dication (555 and 595 nm). Table 1 shows that 27 ± 3% of the porphyrin is in the dication form in the 5×10^{-5} *M* solution. Uniformity of the calculated ratios definitely supports the above conclusion that this chloroform solution contains an equilibrium mixture of the free base and the dication. If the same calculation is made with the monocation as the protonated reference species the ratios are sporadic. The ratios were also determined for 5×10^{-4} *M* and 5×10^{-6} *M* solutions in chloroform, which resulted in 29% and 0% dication respectively.

Molecular models show that intramolecular protonation of the inner nitrogen atoms by the side-chain carboxyl groups is not possible. So, according to our results, an aggregation phenomenon which occurs at concentrations over 5×10^{-5} *M* in chloroform leads to intermolecular protonation, the aggregates being held as ion pairs. When acetic acid is added in low concentration to the solution, the porphyrin aggregates are broken and only the free base form is observed. Neither was protonation detected in other protophylic solvents. It is noteworthy that protophobic solvents favor the ionic form while polar solvents (methanol, 10% GAA in chloroform) do not. This is in agreement with Menger's observation of a large rate enhancement for proton exchange of benzyl alcohol when catalysed by amines in benzene solvent as compared to DMSO (15). Thus, in polar solvents, the solvation of the carboxyl group by the polar solvent keeps this group from forming a hydrogen bond with the amino group which would hence lead to the ion pair.

The proximity of the porphyrin rings in the aggregates allows for the formation of the porphyrin dication, which is thermodynamically favored over the monocation but is not usually found in weak carboxylic acid solutions (10). Additional evidence of aggregation is given by vapor phase osomometry. This method gives an average molecular weight of 1313 ± 53 for porphyrin **1** in chloroform (10^{-3} *M*) as compared to a monomer molecular weight of 1016 determined by mass spectrometry. These data suggest a 1:2 dimer/monomer ratio at high porphyrin concentrations in chloroform. Assuming that the dimer is made of a dicationic porphyrin aggregated with a free base porphyrin, then this 1:2 ratio would be consistent with the approximate 1:3 dication/free base ratio found by absorption spectroscopy.

It is also noticeable that the spectrum of the chloroform solution, in which compound **1** exists as an equilibrium mixture of the free base and the dication, is isosbestically related to the set of spectra observed for the free base – monocation equilibrium. In this specific case one cannot rely on the isosbestic set of spectra to affirm that only two species are present in the mixture. Work is in progress to study this aggregation phenomenon in organized media. Preliminary results on surface pressure and surface potential of porphyrin **1** at the air–water interface show the surface properties of a surfactant.

Experimental

Instruments and method

The normal conditions and instruments for the spectra quoted in the experimental section are: uv, tetrahydrofuran solutions (ϵ_{mM} in parentheses), Cary 17D or Perkin Elmer 553; ir, Perkin Elmer 1430 or 597; nmr solutions with internal TMS standard, Varian EM 360L. Elemental analyses and vapor phase osmometry were by Schwarzkopf, New York, mass spectrometry by Université de Montréal. The solvents used in the titration study were Spectrograde and freshly distilled. Stock solutions of the porphyrin in chloroform were prepared and diluted by volume with the required solvent mixture. Only the visible region of the spectrum was retained for this study. Difference spectra were obtained by placing in the reference beam of the spectrophotometer a solution of compound **1** in its free base form (1% TEA in chloroform) at the concentration required to cancel the 500-nm band.

Benzyl 5-formyl-4-(2′-methoxycarbonylethyl)-3-methylpyrrole-2-carboxylate 4

The dimethylpyrrole **3** was prepared following essentially the procedure of Johnson *et al.* (16), yield 61%, mp 99–101°C (lit. (16) mp 99–101°C). *Anal.* calcd. for $C_{18}H_{21}NO_4$: C 68.55, H 6.71, N 4.35; found: C 68.56, H 6.69, N 4.44. Pyrrole **3** was then treated with lead tetraacetate according to Clezy *et al.* (12). Filtration over Celite of the reaction mixture before work-up led to a product which crystallized on standing. Recrystallization from ether/hexane 1:1 gave pyrrole **4**, yield 65%, mp 80–81°C (lit. (16) mp 78–79°C). *Anal.* calcd. for $C_{18}H_{19}NO_5$: C 65.64, H 5.81, N 4.25; found: C 65.57, H 5.88, N 4.05.

Ethyl 3,5-dimethyl-4-(1′-oxooctadecyl)pyrrole-2-carboxylate 6

The pyrrole **5** was prepared following the procedure of Kleinspehn (17), yield 59%, mp 124–125°C (lit. (17) mp 124–125.5°C). To pyrrole **5** (10.0 g, 60 mmol) in dry benzene (10 mL) under nitrogen was added stearoyl chloride (22.5 mL, 66 mmol). The flask contents were cooled to, and maintained at, 0°C while stannic chloride (10.5 mL, 90 mmol) was added drop by drop. The mixture was stirred for 2 h, 10% hydrochloric acid (40 mL) was added, and stirring was continued for 15 min. Chloroform extraction and recrystallization from acetone gave the pyrrole **6** (20.4 g, 47 mmol, 78%), mp 94–95°C; ν_{KBr}: 3280, 2910, 2840, 1655, 1645, 1265; δ (CCl_4): 0.85 (bt, 3H, H-18′), 1.25 (m, 30H, H-3′ to 17′), 1.30 (t, 3H, J = 7 Hz, —OCH_2CH_3), 2.50 (s, 6H, 2 × —CH_3), 2.62 (t, 2H, J = 7 Hz, H-2′), 4.23 (q, 2H, J = 7 Hz, —OCH_2—), 9.80 (bs, 1H, NH). *Anal.* calcd. for $C_{27}H_{47}NO_3$: C 74.78, H 10.92, N 3.23; found: C 74.91, H 10.75, N 3.25.

Ethyl 3,5-dimethyl-4-octadecylpyrrole-2-carboxylate 7

Pyrrole **6** (5 g, 11.5 mmol) was added to a 1 *M* solution of borane in tetrahydrofuran (60 mL, 60 mmol). The mixture was stirred under nitrogen for 12 h. Methanol was slowly added until gas formation ceased. The mixture was evaporated to dryness, methanol (60 mL) was added, and the flask contents were refluxed for 5 min. Evaporation and recrystallization from hexanes gave pyrrole **7** (4.8 g, 11.4 mmol, 99%), mp 93.5–94°C; ν_{KBr}: 3300, 2910, 2860, 1655, 1265; δ (CCl_4): 0.90 (bt, 3H, H-18′), 1.25 (m, 32H, H-2′ to 17′), 1.30 (t, 3H, J = 7 Hz, —OCH_2CH_3), 2.20 (s, 6H, 2 × —CH_3), 2.25 (bt, 2H, H-1′), 4.25 (q, 2H, J = 7 Hz, —OCH_2—), 9.00 (bs, 1H, NH). *Anal.* calcd. for $C_{27}H_{49}NO_2$: C 77.27, H 11.77, N 3.34; found: C 77.13, H 11.93, N 3.18.

Benzyl 3,5-dimethyl-4-octadecylpyrrole-2-carboxylate 8

To pyrrole **7** (5.0 g, 12 mmol) in benzyl alcohol (16 mL) was added sodium (65 mg, 3 mmol) and the mixture was heated to 80°C under reduced pressure (10 mm Hg, 1.3 kPa) for 4 h. The solvent was removed under reduced pressure. An ethanol solution of the residue was washed with water, dried, and evaporated. Recrystallization from methanol gave pyrrole **8** (3.5 g, 7.2 mmol, 61%), mp 105–106°C; ν_{KBr}: 3280, 3030, 2910, 2840, 1660, 1610, 1265; δ (CCl_4): 0.85 (bt, 3H, H-18′), 1.25 (m, 32H, H-2′ to 17′), 2.20 (s, 6H, 2 × —CH_3), 2.30 (bt, 2H, H-1′), 5.20 (s, 2H, —OCH_2—), 7.30 (s, 5H, —C_6H_5), 9.00 (bs, 1H, NH). *Anal.* calcd. for $C_{32}H_{51}NO_2$: C 79.78, H 10.67, N 2.91; found: 80.09, H 10.18, N 2.70.

Dioctadecyldeuteroporphyrin II dimethyl ester 2

The pyrrole **4** (2.9 g, 8.8 mmol) was hydrogenated at 162 kPa (1.6 atm) for 30 min in tetrahydrofuran (50 mL) containing triethylamine (0.05 mL) and 5% Pd on activated charcoal (100 mg). The mixture was filtrated over Celite and the Celite was washed with methanol (20 mL) and acetonitrile (40 mL).

The pyrrole **8** (4.3 g, 8.7 mmol) was hydrogenated as described above, with similar work-up. The two resulting solutions were mixed together and evaporated at 25°C. The residue was taken up in hot formic acid (75 mL). The mixture was stirred vigorously and 31% hydrobromic acid in glacial acetic acid (4.5 mL) was added. The mixture was refluxed for 1 h and the temperature was lowered to 25°C, bromine (1.1 mL) was added, and the reflux was continued for 2 h. The solvent was evaporated by heating under an air stream. Methanol (50 mL) containing 5% sulfuric acid was added and the mixture was stirred for 12 h. Methanol (40 mL) was evaporated from the mixture and chloroform extraction gave a dark oil which was chromatographed over silica gel. Recrystallization from chloroform/methanol 1:20 of the red fraction gave porphyrin **2** (720 mg, 0.7 mmol, 8%), mp 91–92°C; λ_{max}: 398 (120), 498 (9.8), 530 (6.2), 568 (5.7), 595 (0.8), 622 (3.8); ν_{KBr}: 3300, 2950, 2800, 1730, 1550, 1165; δ ($CDCl_3$): −4.30 (bs, 2H, NH), 0.70 (m, 6H, H-18′), 1.08 (m, 60H, H-3′ to 17′), 2.15 (bt, 4H, H-2′), 3.28 (bt, 4H, —CH_2CO—), 3.30 (s, 12H, C-CH_3), 3.45 (s, 6H, —OCH_3), 3.67 (bt, 4H, C(2)-CH_2, C(6)-CH_2), 4.01 (bt, 4H, C(4)-CH_2, C(8)-CH_2), 9.55, 9.65 (s's, 4H, *meso* protons). *Anal.* calcd. for $C_{68}H_{106}N_4O_4$: C 78.26, H 10.24, N 5.37; found: C 77.95, H 9.95, N 5.66.

Dioctadecyldeuteroporphyrin II 1

Porphyrin **2** (104 mg, 0.1 mmol) was added to a mixture of tetrahydrofuran (10 mL) and 6 *N* hydrochloric acid (10 mL). The mixture was stirred in the dark for 48 h. Brine (100 mL) was added and extraction with tetrahydrofuran gave a residue which was purified by preparative tlc on cellulose plates to give **1** (79 mg, 0.078 mmol, 78%), mp 90–91°C; λ_{max}: 398 (140), 498 (11.0), 535 (7.7), 567 (5.4), 595 (0.7), 623 (4.8); ν_{KBr}: 3300, 3100, 2950, 2920, 2800, 1715; δ ($CDCl_3$): −3.10 (bs, ≅2H, NH), 0.70 (m, 6H, H-18′), 1.08 (m, 60H, H-3′ to 17′), 2.15 (bt, 4H, H-2′), 3.30 (bt, 4H, —CH_2CO—), 3.32 (s, 12H, C-CH_3), 3.67 (bt, 4H, C(2)-CH_2, C(6)-CH_2), 4.00 (bt, 4H, C(4)-CH_2, C(8)-CH_2), 9.60 (bs, 4H, *meso* protons); m/e (FAB, crown ether): 1016. *Anal.* calcd. for $C_{66}H_{102}N_4O_4$: C 78.06, H 10.12, N 5.52; found: C 77.69, H 9.86, N 5.89.

Acknowledgements

We would like to thank Professor C. K. Chang for invaluable advice on porphyrin synthesis and Dr Surat Hotchandani for his help in the spectroscopic studies. We also thank the Natural Sciences and Engineering Research Council of Canada and the Université du Québec à Trois-Rivières for their financial support.

Synthesis and nuclear magnetic resonance spectra of platinum compounds with thiourea derivatives

F. D. ROCHON, J. BARIYANGA, AND P. C. KONG

Département de chimie, Université du Québec à Montréal, C.P. 8888, Succ. A, Montréal (Qué.), Canada H3C 3P8

Received August 2, 1984

F. D. ROCHON, J. BARIYANGA, and P. C. KONG. Can. J. Chem. **63**, 2425 (1985).

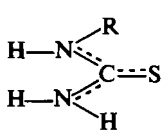
Compounds of the type *trans*-$[PtL_2T_2]Cl_2$ where L = NH_3, methylamine, dimethylamine, pyridine, and 2-aminopyrimidine and T = *N*-methylthiourea and *N,N'*-dimethylthiourea and where L = NH_3 and T = *N,N,N',N'*-tetramethylthiourea have been synthesized. The ^{1}H nmr spectra have shown that the thiourea derivatives are bonded to platinum by the sulfur atom. The methyl protons of *N*-methylthiourea and one methyl group protons of *N,N'*-dimethylthiourea in the complexes, where L is aromatic, showed resonance at higher field after coordination to the metal. This was explained by an intramolecular interaction between the methyl group and the aromatic ring. The nmr spectra of the $[PtT_4]Cl_2$ compounds were also measured.

F. D. ROCHON, J. BARIYANGA et P. C. KONG. Can. J. Chem. **63**, 2425 (1985).

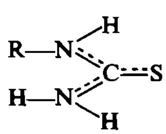
Les complexes de type *trans*-$[PtL_2T_2]Cl_2$ où L = NH_3, méthylamine, diméthylamine, pyridine et amino-2 pyrimidine et T = *N*-méthylthiourée, et *N,N'*-diméthylthiourée ainsi que L = NH_3 et T = *N,N,N',N'*-tétraméthylthiourée ont été synthétisés. Les spectres de résonance magnétique nucléaire ^{1}H ont montré que les dérivés de la thiourée étaient liés au platine par l'atome de soufre. Les protons de *N*-méthylthiourée et d'un groupement méthyle de *N,N'*-diméthylthiourée dans les complexes où L est aromatique, ont montré un blindage lorsque ces ligands étaient coordinés au métal. Ce blindage a été expliqué par une association intramoléculaire entre le groupement méthyle de T et le noyau aromatique. Les spectres rmn des trois composés $[PtT_4]Cl_2$ ont également été mesurés.

Introduction

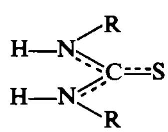
Infrared studies of thiourea (tu) and its N-alkyl derivatives (T) have been reported (1, 2). The interpretation of the spectra is not easy since many absorption bands result from a mixture of vibrations. The C—N bond of thiourea and its derivatives has an appreciable double bond character. Therefore thiourea derivatives can have different conformations where the thioamide hydrogen atom and the thiocarbonyl bond are *cis* or *trans*. For *N*-alkylthiourea, there are two isomers, *trans* and *cis*, whereas for *N,N'*-dialkylthiourea, there are three isomers, *trans*−*trans*, *cis*−*cis*, and *cis*−*trans*.



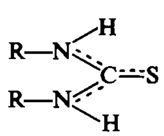
trans



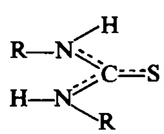
cis



trans−*trans*



cis−*cis*



cis−*trans*

Lane *et al.* (3) studied the infrared spectra of several thiourea derivatives in the solid state. He found that *N,N'*-dimethylthiourea and *N,N'*-diethylthiourea were *trans*−*trans* isomers. *N,N'*-di-*t*-butylthiourea showed both structures *cis* and *trans*. But the authors were not able to determine whether it was the *cis*−*trans* isomer or a mixture of the *cis*−*cis* and *trans*−*trans* compounds. Methylthiourea was identified as the *trans* isomer.

Several infrared studies of $[Pt(tu)_4]Cl_2$ (4−7) have shown that thiourea was bonded to platinum through its S atom. A band between 205 and 298 cm^{-1} was assigned to the stretching Pt—S vibration. Belluco *et al.* (8) studied the infrared spectra of several platinum complexes with thiourea derivatives $[PtT_4]Cl_2$ where T = *N,N'*-dimethylthiourea (DMT), methylthiourea (MT), and tetramethylthiourea (TMT). They observe a decrease of the frequency of ν(N—H) and therefore suggested that the coordination site was N. They also assigned a new band around 350 cm^{-1} to the vibration ν(Pt—N). A year later, Gosavi *et al.* (9) showed that TMT was coordinated to platinum through its sulfur atom.

The structures of thiourea and some of its derivatives were determined. The C—N and C—S bond distances are shown on Table 1. The average C—N distance is 1.33 Å and the average C—S distance is 1.70 Å. The four atoms SCNN are in the same plane. These results confirm the double bond character of the C—N bond and show that the order of the C—S bond is less than two. The rotation around the C—N bond is partly hindered, resulting in the formation of the isomers discussed above.

The crystal structure of several metallic complexes have shown that the binding site of thiourea and its derivatives was the sulfur atom. The C—S and C—N bond distances are shown on Table 1. The average C—N distance is 1.31 Å while the average C—S distance is 1.73 Å. The C—N bond distances seem slightly shorter (0.02 Å) than in the free ligand while the C—S bond is longer (0.03 Å). These differences are relatively small but they seem significant. Therefore upon coordination, the bond order of S—C is reduced while that of C—N is slightly increased.

Very few platinum compounds of thiourea derivatives (T) have been reported. We have now synthesized several complexes of the type *trans*-$[PtL_2T_2]Cl_2$ (where L = nitrogen ligand) and $[PtT_4]Cl_2$. We have measured the infrared spectra of these compounds in the solid state, and the nmr spectra in D_2O. These results are reported below.

Experimental

trans-$[PtL_2Cl_2]$

The compounds *trans*-$[PtL_2Cl_2]$ where L = NH_3, methylamine (MA), dimethylamine (DMA), and pyridine (Py) were synthesized by the method described by Kauffman (22, 23). The compound with L = 2-aminopyrimidine (AP) was prepared by the method described by Kong and Rochon (24).

trans-$[PtL_2T_2]Cl_2$

The compound *trans*-$[Pt(NH_3)_2(MT)_2]Cl_2$ where MT = *N*-methyl-

*ET = ethylthiourea.

thiourea was prepared by the following method. *trans*-$[Pt(NH_3)_2Cl_2]$ (1 mm) was suspended in 5 mL of water. An aqueous solution of MT (4 mm in 5 mL H_2O) was added. The mixture was stirred at room temperature and after 30 min became clear. The yellow solution was filtered and evaporated to dryness under vacuum. The residue was washed with acetone and dried under vacuum for 12 h. Yield: 77%. Dec. 187−204°C. IR: 3310br, 1630s, 1550s, 970s cm^{-1}.

trans-$[Pt(NH_3)_2(DMT)_2]Cl_2$ was prepared as follows. *trans*-$[Pt(NH_3)_2Cl_2]$ (1 mm) was dissolved in 15 mL of DMF and filtered. DMT (2 mm) was added to the solution and stirred for 2 days at room temperature. The solution was kept in a refrigerator at night. More DMT (2 mm) was then added and stirred. Two hours later the precipitate was filtered and dissolved in water. The solution was filtered and evaporated to dryness under vacuum. The residue was washed with ether and dried under vacuum overnight. Yield: 50%. Dec. 195−215°C. IR: 3409m, 3325s, 3200br, 1585s, 1500s, 1275m cm^{-1}.

trans-$[Pt(NH_3)_2(TMT)_2]Cl_2$ was prepared by the following method. *trans*-$[Pt(NH_3)_2Cl_2]$ (1 mm) was dissolved in 15 mL DMF and filtered. TMT (4 mm) was added and the mixture was stirred for 24 h. Ether (20 mL) was then added and the precipitate was filtered and washed with ether. The compound was then dissolved in water and the solution was filtered and evaporated to dryness under vacuum. The residue was washed with ether and dried under vacuum overnight. Yield: 30%. Dec. 190−204°C. IR: 3250br, 3120br, 1550s, 1095s cm^{-1}.

The compounds *trans*-$[PtL_2T_2]Cl_2$ where L = MA, DMA, and Py and T = MT and DMT were prepared as follows. The compound *trans*-$[PtL_2Cl_2]$ (1 mm) was dissolved in 10 mL of DMF and filtered. An excess of T (3 mm) was added and the solution stirred until a pale yellow precipitate was obtained. After filtration, the precipitate was washed with ether and dissolved in water. The solution was filtered and evaporated to dryness under vacuum. The yellow residue was washed with ether and dried under vacuum for 12 h.

trans-$[Pt(MA)_2(MT)_2]Cl_2$: Yield: 50%. Dec. 138−160°C. IR: 3340s, 3320s, 3185br, 1665w, 1644s, 1556s, 973w cm^{-1}.
trans-$[Pt(MA)_2(DMT)_2]Cl_2$: Yield: 50%. Dec. 165−195°C. IR: 3244sh, 3170br, 3100br, 1595s, 1576s, 1495s, 1285m, 1256m cm^{-1}.
trans-$[Pt(DMA)_2(MT)_2]Cl_2$: Yield: 75%. Dec. 170−202°C. IR: 3334s, 3242s, 3200sh, 3127s, 1605s, 966m cm^{-1}.
trans-$[Pt(DMA)_2(DMT)_2]Cl_2$: Yield: 60%. Dec. 190−235°C. IR: 3195s, 3110s, 1578s, 1490s, 1283m cm^{-1}.
trans-$[Pt(Py)_2(MT)_2]Cl_2$: Yield: 60%. Dec. 190−195°C. IR: 3260br, 3170br, 1621s, 1603sh, 1556s, 958m cm^{-1}.
trans-$[Pt(Py)_2(DMT)_2]Cl_2$: Yield: 50%. Dec. 203−215°C. IR: 3120br, 1603sh, 1570s, 1270s cm^{-1}.

Complexes of the type *trans*-$[Pt(AP)_2T_2]Cl_2$ were synthesized according to the method described by Kong and Rochon (24). *trans*-$[Pt(AP)_2(MT)_2]Cl_2$: Yield, 70%. Dec. 200−208°C. IR: 3300br, 3160br, 1610s, 1580m, 1554s, 971m, 961m cm^{-1}. *trans*-$[Pt(AP)_2(DMT)_2]Cl_2$: Yield: 40%. Dec. 224−240°C. IR: 3320s, 3120br, 1615s, 1570s, 1550s, 1490s, 1270s cm^{-1}.

$[PtT_4]Cl_2$

The complexes where T = MT and DMT were prepared by the method described by Kukushkin *et al.* (25) and Kurnakov (26). Yields: 60%. mp $[Pt(MT)_4]Cl_2$: 160°C, $[Pt(DMT)_4]Cl_2$: 200°C.

$[Pt(TMT)_4]Cl_2$ was prepared as follows. K_2PtCl_4 (1 mm) was dissolved in 10 mL of water containing 3 drops of concentrated HCl. An ethanol solution of TMT (0.55 g in 5 mL ethanol) was added and stirred for 40 min. The solution was then filtered and the yellow solution was evaporated to dryness under vacuum. The residue was washed with ether and redissolved in ethanol. After filtration, the solution was evaporated to dryness under vacuum. The compound was dried at 80°C under vacuum for 12 h. Yield: 80%. Dec. 290−300°C.

The infrared spectra were measured as Nujol mulls on a P.E. 621 spectrometer. A 60 MHz Varian EM 360C was used to record the ^1H nmr spectra. The spectra were measured at 30°C in D_2O (~0.2 *M*) and a very small quantity of DSS was used as internal standard.

Discussion

The reaction between complexes of the type *trans*-$[PtL_2Cl_2]$ where L = NH_3, MA, DMA, Py, and AP and thiourea derivatives, MT, DMT, and TMT was studied. The reaction was as follows:

$$trans\text{-}[PtL_2Cl_2] + 2T \xrightarrow[\text{or DMF}]{H_2O} trans\text{-}[PtL_2T_2]Cl_2$$

trans-$[Pt(NH_3)_2(MT)_2]Cl_2$ was synthesized in water while all other complexes were synthesized in DMF. It was not possible to isolate complexes *trans*-$[PtL_2(TMT)_2]Cl_2$ for L = MA, DMA, Py, and AP probably because of steric hindrance reasons.

Compounds $[PtT_4]Cl_2$ where T = MT, DMT, and TMT were also prepared.

The results of the elemental analyses of all the compounds are shown on Table 2.

The infrared spectra of the compounds *trans*-$[PtL_2T_2]Cl_2$ were measured. The most important bands are shown in the Experimental section. Since most of the infrared bands of the thiourea derivatives are caused by combination vibrations and since there are also numerous amine bands, it was not possible to assign the vibrations observed in the infrared spectra of the compounds. Infrared spectroscopy is not an adequate method to identify the nature of the metal−ligand bond in this type of compounds. It was not possible to differentiate the —NH and —NH_2 vibrations of the T ligands from those of the amines (L). Therefore the binding site of the thiourea derivatives could not be determined by this method. Most compounds showed some weak bands between 230 and 300 cm^{-1} which might be assigned to ν(Pt—S), but the T ligands also showed some weak absorption in this region.

*Calculated values in the first rows.

Nuclear magnetic resonance spectroscopy was found much more useful. The nmr spectra of the ligands and complexes where L = NH_3, MA, and DMA are shown on Table 3. All the methyl protons are shifted towards lower field upon coordination, the amine being more affected than T. The methyl protons in the amine couple with ^{195}Pt with a coupling constant of about 40 Hz. The splitting of the DMA peaks in all the complexes is caused by steric hindrance of four bulky groups, which prevents the free rotation around the Pt—N and Pt—S bonds. Therefore the environment around the two methyl groups in bonded DMA is different. For the same reasons, the DMT signals are split into two peaks in all the complexes. There is no coupling between ^{195}Pt and the methyl protons of T. Therefore the binding site of T is not the N atom, but the S atom.

The nmr spectral data of the complexes containing aromatic amines (Py and AP) are shown in Table 3. In the pyridine complexes, the $H_{2,6}$ values are shifted to a lower field by 0.7 ppm, the $H_{3,5}$ values by 0.3 ppm, and the H_4 values by 0.45 ppm. If we consider only the distances between the protons and the bonded pair of electrons on N, the sequence of deshielding should be $H_{2,6} > H_{3,5} > H_4$. But upon coordination, there is a rearrangement of the molecular orbitals and the *ortho* and *para* positions are more affected than the meta position (27). A coupling constant of 36 Hz was observed between ^{195}Pt and $H_{2,6}$.

For 2-aminopyrimidine, H_6 was most affected by the coordination to platinum, being shifted to a lower field by 0.6 ppm.

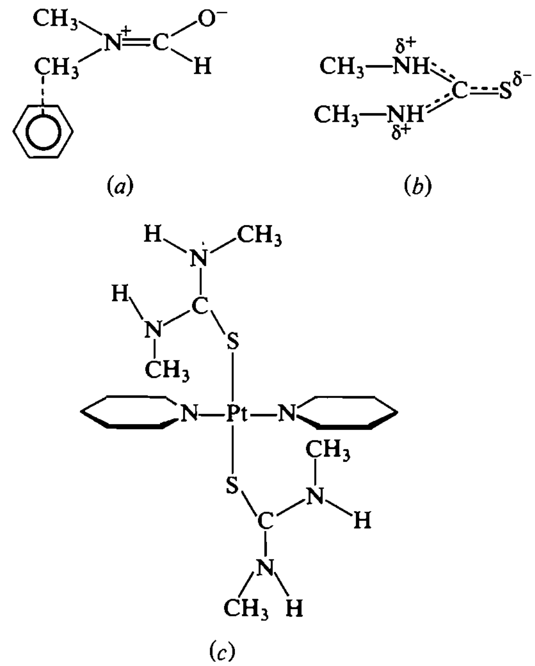

FIG. 1. (*a*) Interaction between DMF and benzene as suggested in ref. 28; (*b*) partial charges in DMT; (*c*) suggested structure for *trans*-[Pt(Py)$_2$(DMT)$_2$]$^{2+}$.

The shifts of H_5 and H_4 were 0.25 and 0.2 ppm, respectively. H_6 is coupled with ^{195}Pt (coupling constant of 36 Hz) showing that the binding site of AP is N_1. This is in agreement with the results obtained from the study of *trans*-[Pt(AP)$_2$(tu)$_2$]Cl_2 where AP was bonded to Pt through N_1 (24).

The protons of MT and of one methyl group of DMT are shifted to a higher field upon coordination to platinum. The shifts vary from 0.20 to 0.48 ppm. This observed shielding can be explained assuming the methyl group of MT and one methyl group of DMT are in the close environment of the aromatic ring of the amine. For steric reasons, the rotations around the Pt—S and Pt—N bonded are hindered and the methyl protons of T would be influenced by the π electrons of Py or AP.

A similar observation was made by Hatton and Richards (28) in a nmr study of DMF in benzene or phenol. When DMF was diluted in these solvents, the signals of the methyl protons were shifted to higher fields. This shift was explained on the base on some interaction (Fig. 1*a*) between the methyl groups of DMF and the solvent (benzene or phenol). In a similar manner, the methyl groups of MT and DMT of the platinum complexes can interact with the aromatic ring of Py and AP. Infrared and X-ray diffraction structures have confirmed the double bond character of the C—N bond, while the order of the C—S bond was considerably reduced. Therefore there is some partial charge on the T ligand, similarly to DMF (Fig. 1*b*). Therefore a close interaction between T and Py or AP would be favored because of the positive partial charge on the N atom. The structures of the compounds *trans*-[PtL_2T_2]Cl_2 where L = Py and AP and T = MT and DMT are suggested to be as on Fig. 1*c*. In this hypothesis, MT would have the *trans* conformation, while DMT could be either *trans*—*trans* or *trans*—*cis*.

The nmr spectra of the complexes were measured at different concentration in D_2O in order to confirm that these interactions were not intermolecular. There was no concentration effect on the positions of the methyl protons of MT and DMT. There-

fore, the interactions between the methyl groups of T and the aromatic ring are of intramolecular nature.

The nmr spectrum of *trans*-$[Pt(Py)_2(DMT)_2]Cl_2$ was measured at temperatures from 22 to 80°C. Because of the small solubility of the complex, it was not possible to record the spectrum at lower temperature. All the peaks were shifted to lower fields as the temperature increased (Table 4). The two —CH_3 peaks of DMT became wider, but remained distinct.

More work is needed to confirm our hypothesis on the structures of *trans*-$[PtL_2T_2]Cl_2$ where L = Py and AP. We intend to synthesize compounds with T containing some aromatic rings, for example diphenylthiourea. We would be interested to know if the methyl groups of L could be affected by the close environment of an aromatic ring. This work is presently being done, but compounds with diphenylthiourea seem difficult to synthesize.

The nmr spectra of the $[PtT_4]Cl_2$ compounds were also measured (Table 5). All the peaks are shifted to lower field upon coordination. The shift seemed to increase with the number of C atoms (0.02, 0.05, and 0.21 ppm). All the peaks are singlets, even for the TMT complex indicating that the environment of all the methyl groups is identical.

TABLE 5. Nuclear magnetic resonance spectra of T and $[PtT_4]Cl_2$

T	δ (ppm)
MT	2.90
$[Pt(MT)_4]Cl_2$	2.92
DMT	2.90
$[Pt(DMT)_4]Cl_2$	2.95
TMT	3.05
$[Pt(TMT)_4]Cl$	3.26

ALAN P. ARNOLD, ALLAN J. CANTY, R. STEPHEN REID, and DALLAS L. RABENSTEIN. Can. J. Chem. **63**, 2430 (1985).

Complexation of methylmercury, $CH_3Hg(II)$, by 2,3-dimercaptosuccinic acid (DMSA), 2,3-dimercaptopropanesulfonate (DMPS, Unithiol), dithioerythritol (DTE), and 2,3-dimercaptopropanol (British AntiLewisite, BAL) has been studied by ^1H nuclear magnetic resonance spectroscopy and by potentiometric titration. In the nmr study, the equilibrium constants for displacement of mercaptoacetate from its $CH_3Hg(II)$ complex by the dithiols were determined over a wide pH range, from mercaptoacetate chemical shift data. Similar competition reactions between the dithiols and mercaptoethanol were used in the potentiometric study. Using previously determined $CH_3Hg(II)$ formation constants for the competing ligands, equilibrium constants for the formation of mono- and bis-$CH_3Hg(II)$ complexes with the dithiols have been determined. The formation constants for the mono-$CH_3Hg(II)$ complexes with the vicinal dithiols BAL and DMPS are significantly higher than expected by consideration of the basicity of the sulfhydryl donors, in comparison with those for DMSA, non-vicinal DTE, and monothiols. We interpret this to indicate chelation of $CH_3Hg(II)$ by BAL and DMPS but not by DMSA. The conditional formation constants at physiological pH are discussed with reference to the effectiveness of BAL, DMPS, and DMSA as antidotes for methylmercury poisoning. In particular, the constants obtained indicate that, for dithiol antidotes at concentrations greater than that of methylmercury(II), methylmercury(II) complexes formed at physiological pH are of 1:1 stoichiometry. For BAL, a substantial proportion of the complex will be in the neutral form, in contrast to DMPS and DMSA which form anionic species only.

ALAN P. ARNOLD, ALLAN J. CANTY, R. STEPHEN REID et DALLAS L. RABENSTEIN. Can. J. Chem. **63**, 2430 (1985).

Faisant appel à la rmn du ^1H et à des titrages potentiométriques, on a étudié la complexation du méthylmercure, $CH_3Hg(II)$, par les composés suivantes: l'acide dimercaptosuccinique (ADMS), le dimercapto-2,3 propanesulfonate (DMPS, Unithiol), le dithioérythritol (DTE) et le dimercapto-2,3 propanol (British AntiLewisite, BAL). A partir des données de déplacement chimique du mercaptoacetate en rmn du ^1H, on a déterminé, sur un large intervalle de pH, les constantes d'équilibre des réactions de déplacement, par les dithiols, du mercaptoacétate de son complexe de $CH_3Hg(II)$. On a également utilisé des réactions de compétitions du même type entre des dithiols et le mercaptoéthanol, lors de l'étude potentiométrique. Faisant appel à des constantes de formation du $CH_3Hg(II)$ qui ont été déterminées antérieurement pour les ligands entrant en compétition, on a déterminé les constantes d'équilibre de formation des complexes mono- et bis-CH_3Hg avec les dithiols. Si on les compare avec les constantes de l'ADMS, du DTE (qui sont des dithiols qui ne sont pas vicinaux) ou avec celles des monothiols, les constantes de formation des complexes de mono-$CH_3Hg(II)$ avec les dithiols vicinaux BAL et DMPS sont nettement plus élevées que celles prévues en tenant compte de la basicité des sulfhydryles donneurs. Pour interpréter ces résultats, nous suggérons la présence d'une chélation du $CH_3Hg(II)$ par le BAL et le DMPS qui n'existerait pas dans le cas de l'ADMS. On discute des constantes de formation conditionnelles, à pH physiologique, en fonction d'une utilisation possible du BAL, de l'ADMS et du DMPS comme antidotes dans les empoisonnements par le méthylmercure. En particulier, les constantes obtenues indiquent que, pour des antidotes du type dithiols agissant à des concentrations supérieures à celles de méthylmercure(II), les complexes de méthylmercure formés à des pH physiologiques sont du type 1:1. Dans le cas du BAL, une proportion importante du complexe existe sous la forme neutre, contrairement au DMPS et à l'ADMS qui forment uniquement des espèces anioniques.

[Traduit par le journal]

Introduction

Methylmercury, $CH_3Hg(II)$, forms very stable complexes with monothiols (1, 2), with the result that $CH_3Hg(II)$ is thought to be essentially all thiol-bound in biological systems. For example, in human erythrocytes, $CH_3Hg(II)$ is bound almost entirely to glutathione (ca. 51%) and hemoglobin (ca. 49%) (3, 4). Complexation therapy, using monothiols such as D-penicillamine (5) or *N*-acetyl-D,L-penicillamine (5), is one of several techniques used for treatment of $CH_3Hg(II)$ poisoning; however dithiols, such as 2,3-dimercaptosuccinic acid (DMSA) (6) and 2,3-dimercaptopropanesulfonate (DMPS, Unithiol) (7) are more effective antidotes. The non-sulfonated analog of DMPS, 2,3-dimercaptopropanol (British Anti-Lewisite, BAL), is contraindicated as an antidote for $CH_3Hg(II)$ poisoning because it causes rapid redistribution of the metal into the brain (8).

Although the term "chelation therapy" is often used for such treatment, there has been no evidence that $CH_3Hg(II)$ binds simultaneously to adjacent sulfhydryl sites of these vicinal dithiols, although similar binding is found in the solid state in the 2:1 $CH_3Hg(II)$ complex of sterically rigid toluene-3,4-dithiol (9).

We have measured the equilibrium constants for the binding of $CH_3Hg(II)$ by the vicinal dithiols BAL, DMPS, and DMSA and by non-vicinal dithioerythritol (DTE) by ^1H nmr and potentiometric titration methods. The results provide evidence that BAL and DMPS do indeed chelate $CH_3Hg(II)$ in solution, whereas DMSA and DTE do not.

Experimental

Chemicals

Methylmercuric iodide (Alfa Products, Morton Thiokol Inc.) was converted to stock solutions of methylmercuric hydroxide for use in ^1H nmr (1) and potentiometric titration (2) experiments. The stock solutions were standardized as described previously. Mercaptoacetic acid, 2,3-dimercaptopropanol (Aldrich), and 2-mercaptoethanol (Koch-Light) were fractionally distilled under reduced nitrogen pressure. *Meso*-2,3-dimercaptosuccinic acid (Sigma Chemical Co.), 2,3-dimercaptopropanesulfonic acid, sodium salt (Aldrich and Heyl and Co., Chem.-Pharm. Fabrik, Berlin), and dithioerythritol (Aldrich) were used as received. All thiols were stored under inert atmosphere below −4°C.

pH measurements

For the ^1H nmr study, all pH measurements were made at 25 ± 1°C with an Orion Model 701 meter equipped with either a standard glass electrode – porous ceramic junction reference electrode pair, or a microcombination electrode, in solutions containing 0.3 M KNO_3 (1). For the equilibrium potentiometric titrations, pH measurements were made at 25 ± 0.02°C with an Orion Model 701A meter equipped with a Philips glass electrode (GAT130) and glass sleeve double-junction calomel reference electrode (R44/2-SD/1) in solutions containing 0.1 M KNO_3 (2).

^1H nuclear magnetic resonance measurements

Proton nmr spectra were recorded on a Varian A60D spectrometer at a probe temperature of 25 ± 1°C with a sweep rate of 0.1 Hz/s. Chemical shifts were measured relative to either the central resonance of the triplet of tetramethylammonium ion or the singlet for 1,4-dioxane. Chemical shifts are reported relative to the methyl resonance of sodium 2,2-dimethyl-2-silapentane-5-sulfonate (DSS).

Results

Acid dissociation constants for the dithiols were determined potentiometrically in the ionic strength medium appropriate for subsequent determination of $CH_3Hg(II)$ formation constants by ^1H nmr (1) or potentiometric titration (2). Particular care was taken to preclude carbonate contamination of the titrant base, and to use values of pK_w determined under our experimental conditions. Both of these parameters significantly affect pK_a values which are determined from data above pH 10. Acid dissociation constants determined for the dithiols are listed in Table 1.

^1H nmr determination of formation constants

Formation constants for the $CH_3Hg(II)$ complexes of DMSA and DTE were determined from the exchange-averaged chemical shift of the mercaptoacetic acid (MAA) resonance in solutions containing MAA, $CH_3Hg(II)$, and the dithiol. The procedure was similar to that used to determine formation constants for monothiol–$CH_3Hg(II)$ complexes (1). Chemical shift titration data are shown in Fig. 1 for (A) a solution containing only MAA, (B) a solution containing the $CH_3Hg(II)$–MAA complex, and (C) a solution containing equimolar concentrations of MAA, $CH_3Hg(II)$, and DMSA. Curve C lies between curves A and B, indicating displacement of some of the complexed MAA by DMSA and fast exchange of MAA between its free and complexed forms. The exchange-averaged chemical shift of MAA yields directly P_f, the proportion of uncomplexed MAA (1), from which the formation constant $K_{fH,}$ defined by eq. [1],

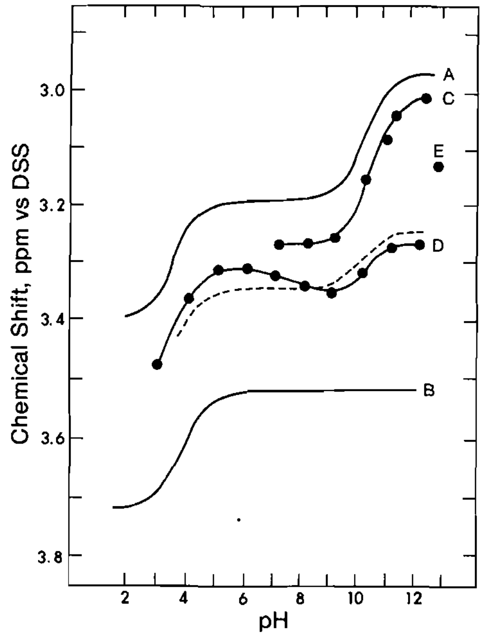

FIG. 1. pH dependence of the chemical shift of the exchange-averaged MAA resonance in solutions containing (*A*) 0.10 *M* MAA, (*B*) 0.10 *M* MAA and 0.10 *M* $CH_3Hg(II)$, (*C*) as in (*B*) plus 1 mole equivalent of DMSA, (*D*) as in (*B*) plus 0.5 mole equivalent of DMPS (—•—•— experimental and --- calculated using formation constants determined by potentiometry), and (*E*) MAA:$CH_3Hg(II)$:DTE of 2:1:1.

$$[1] \quad CH_3Hg^+ + {}^-S\,SH \rightleftarrows CH_3HgS\,SH$$

$$k_{fH} = \frac{[CH_3HgS\,SH]}{[CH_3Hg^+][{}^-S\,SH]}$$

can be calculated with eq. [2][2,3]

$$[2] \quad k_{fH}^2\,(C_M - (1 - P_f)C_{MAA} - 2C_{Dithiol})K_{dp}k_3[M]^2/[H]^2 + k_{fH}(C_M - (1 - P_f)C_{MAA} - C_{Dithiol})[M](1 + k_3/[H]) + (C_M - (1 - P_f)C_{MAA})(1 + [H]/K_3 + K_4/[H]) = 0$$

where C_M, C_{MAA}, and $C_{Dithiol}$ are the total concentrations of $CH_3Hg(II)$, MAA, and dithiol, and [M] is the concentration of free CH_3Hg^+. $[M] = (1 - P_f)/(P_f\,\alpha_{MAA}K_{fMAA})$ where K_{fMAA} is the formation constant of the $CH_3Hg(II)$−MAA complex and $\alpha = K_{aMAA}/([H] + K_{aMAA})$; K_{aMAA} is the acid dissociation constant for the thiol group of MAA (1). The equilibrium constants k_3 and K_{dp} are defined by eqs. [3] and [4].[2]

$$[3] \quad CH_3HgS\,SH \rightleftarrows CH_3HgS\,S^- + H^+$$

$$k_3 = \frac{[CH_3HgS\,S^-][H^+]}{[CH_3HgS\,SH]}$$

$$[4] \quad CH_3HgS\,S^- + CH_3HgS\,SH \rightleftarrows CH_3HgS\,SHgCH_3 + HS\,S^-$$

$$K_{dp} = \frac{[CH_3HgS\,SHgCH_3][HS\,S^-]}{[CH_3HgS\,S^-][CH_3HgS\,SH]}$$

[2] HS SH, $^-$S SH, and $^-$S S$^-$ represent dithiol, singly deprotonated dithiol, and doubly deprotonated dithiol, respectively. $CH_3HgS\,SH$ and $CH_3HgS\,S^-$ represent the 1:1 $CH_3Hg(II)$ complexes with singly and doubly deprotonated dithiol and $CH_3HgS\,SHgCH_3$ the 2:1 complex with doubly deprotonated dithiol.

[3] Lower case *k*'s are used to represent microscopic (site specific) acid-dissociation and complex formation constants.

TABLE 2. Formation constants for methylmercury(II)−dithiol complexes

Ligand	Formation constant	log (formation constant)
$^-O_2CCH(S^-)$—$CH(S^-)CO_2^-$	K_{f1}	18.4 ± 0.2^a
	K_{f2}	16.9 ± 0.2^a
	$k_{f1}^{\,b}$	18.1 ± 0.2
	$k_{f2}^{\,b}$	17.2 ± 0.2
$^-O_2CCH(S^-)$—$CH(SH)CO_2^-$	$k_{fH}^{\,b}$	17.16 ± 0.05^a
$CH_2(S^-)CH(S^-)CH_2OH$	K_{f1}	19.56 ± 0.09^c
	K_{f2}	10.46 ± 0.10^c
$CH_2(S^-)CH(SH)CH_2OH$ + $CH_2(SH)CH(S^-)CH_2OH$	K_{fH}	16.54^c
$CH_2(S^-)CH(S^-)CH_2SO_3^-$	K_{f1}	21.01 ± 0.08^c
	K_{f2}	10.26 ± 0.008^c
$CH_2(S^-)CH(SH)CH_2SO_3^-$ + $CH_2(SH)CH(S^-)CH_2SO_3^-$	K_{fH}	17.19^c
$CH_2(S^-)CHOHCHOHCH_2(S^-)$	K_{f1}	17.0 ± 0.2^a
	$k_{f1}^{\,b}$	16.7 ± 0.2
$CH_2(S^-)CHOHCHOHCH_2(SH)$	$k_{fH}^{\,b}$	16.6 ± 0.2^a

[a] Determined by nmr; 25°C, 0.3 *M* KNO_3. Uncertainties are the standard error of the estimate obtained from KINET fits.
[b] Microscopic constant as defined in Fig. 5.
[c] Determined by potentiometric titration; 25°C, 0.1 *M* KNO_3. Uncertainties are one standard deviation obtained from MINIQUAD fits.

The constants k_3 and K_{dp} were determined by titrating an equimolar mixture of $CH_3Hg(II)$ and DMSA at high pH with acid, until incipient precipitation (pH 4). A nonlinear least-squares fit of the titration data, using the rigorously weighted algorithm in KINET (10), to the algebraic model obtained from the equilibrium and mass balance equations, gave the values $pk_3 = 9.86 \pm 0.06$ and $K_{dp} = 0.6 \pm 0.2$ for DMSA. The titration data could not be fitted to a simple model involving only protonated and deprotonated 1:1 complex (eq. [3]) because the uncomplexed sulfhydryl group of the 1:1 complex still has a very high affinity for $CH_3Hg(II)$ so that, even at 1:1 $CH_3Hg(II)$:dithiol ratios, a significant amount of 2:1 complex is present.

Direct substitution of the P_f values obtained from the chemical shift titration data into eq. [2] and using these values for k_3 and K_{dp} yielded a value of log $k_{fH} = 17.16 \pm 0.05$. The formation constants calculated for the deprotonated 1:1 complex and the 2:1 complex (eqs. [5] and [6])[2]

$$[5] \quad CH_3Hg^+ + {}^-S\,S^- \rightleftarrows CH_3HgS\,S^-$$

$$K_{f1} = \frac{[CH_3HgS\,S^-]}{[CH_3Hg^+][S\,S^-]}$$

$$[6] \quad CH_3Hg^+ + CH_3HgS\,S^- \rightleftarrows CH_3HgS\,SHgCH_3$$

$$K_{f2} = \frac{[CH_3HgS\,SHgCH_3]}{[CH_3Hg^+][CH_3HgS\,S^-]}$$

using these values are listed in Table 2.

For DTE, precipitate formation in the presence of $CH_3Hg(II)$ precluded the measurement of a chemical shift titration

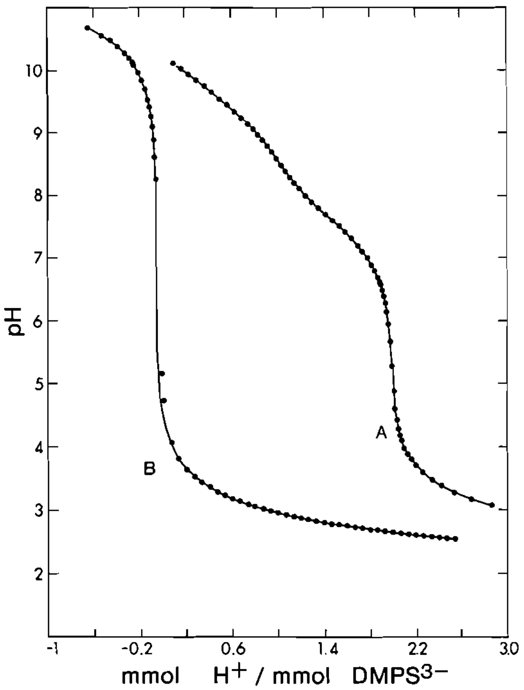

FIG. 2. Potentiometric titration curves for the $CH_3Hg(II)$-DMPS system. (A) with and (B) without ME competition. The fitted curves are calculated using the constants in Tables 1 and 2. (A) 1.186×10^{-3} M $CH_3Hg(II)$, 1.134×10^{-3} M DMPS, 3.799×10^{-3} M H^+ (total titratable), 1.178×10^{-3} M ME, (B) 2.563×10^{-3} M $CH_3Hg(II)$, 1.250×10^{-3} M DMPS, 3.168×10^{-3} M H^+ (total titratable).

curve. However, replicate measurements on a 2:1:1 MAA:$CH_3Hg(II)$:DTE solution at pH 12.2 gave a value for log k_{fH} of 16.6. The value used for k_3 in this calculation (Table 1) was calculated from pH data for the titration of an equimolar solution of DTE and $CH_3Hg(II)$ from high pH to pH 9, using a value of 0.6 for K_{dp}.

Curve D in Fig. 1 is chemical shift titration data for MAA in a solution containing MAA, $CH_3Hg(II)$, and DMPS. The intermediate chemical shift again indicates displacement of MAA by the dithiol, but because DMPS is not symmetrical, it was not possible to derive an algebraic model such as that for DMSA. However, since the MAA shift lies closer to that of $CH_3Hg(II)$−MAA, it can be concluded that the conditional formation constant, defined by eq. [7],

$$[7] \quad K_{fC} = \frac{[CH_3Hg(II) \text{ complexed by dithiol}]}{[\text{uncomplexed } CH_3Hg(II)][\text{uncomplexed dithiol SH}]}$$

is less, under these conditions, than that for the $CH_3Hg(II)$−DMSA system.

Potentiometric determination of formation constants

Formation constants for the $CH_3Hg(II)$ complexes of DMPS and BAL were determined by potentiometric titration. It has been demonstrated previously (2) that protons cannot compete effectively with $CH_3Hg(II)$ in the presence of monothiols, necessitating the use of a competitive ligand such as iodide, in order to use the potentiometric titration method. In this work, 2-mercaptoethanol (ME) was used to compete with the dithiols for $CH_3Hg(II)$. The $CH_3Hg(II)$ complex of ME has been characterized previously (log K_f = 16.13 (2), 16.12 (11)), and has no acid−base behavior, which keeps the number of species in the competition complexation model to a minimum. Representative titration data for the $CH_3Hg(II)$−DMPS system are shown in Fig. 2. Equilibrium constants were obtained from titration data using a version of MINIQUAD (12) by procedures described previously (2).

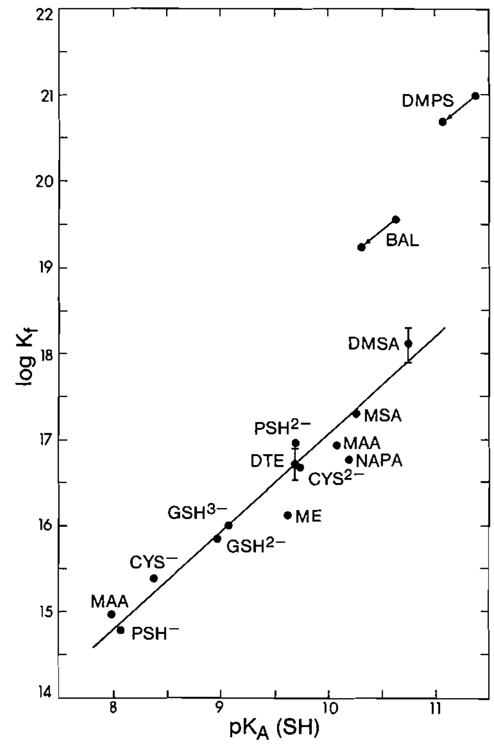

FIG. 3. Correlation between the microscopic log K_f of $CH_3Hg(II)$−thiol complexes and the microscopic pK_A of the thiol groups. ME, MAA, BAL, DMPS, DMSA, and DTE are defined in the text. O-MAA is O-methylmercaptoacetate, PSH^-, CYS^-, and GSH^{2-} the amino-protonated, thiol-deprotonated and PSH^{2-}, CYS^{2-}, and GSH^{3-} the completely deprotonated forms of penicillamine, cysteine, and glutathione, respectively, NAPA is N-acetylpenicillamine and MSA is mercaptosuccinic acid. Data for the monothiols are from [1], [2], and [4].

Potentiometric titration curves for mixtures containing equimolar amounts of BAL or DMPS and $CH_3Hg(II)$ and ME could be fitted very well to a simple model involving only protonated and deprotonated 1:1 $CH_3Hg(II)$−dithiol complexes along with the complex of ME. The values obtained for K_{fH}, K_3, and K_{f1}, eqs. [1], [3], and [5], are listed in Tables 1 and 2.

The formation constants for the 2:1 complexes of BAL and DMPS, eq. [6], were obtained from titration data of 2:1 $CH_3Hg(II)$:dithiol mixtures in the absence of ME. Under these conditions, the first sulfhydryl group is always complexed and, because of the lower affinity of the second sulfhydryl group for $CH_3Hg(II)$, the proton can compete effectively with $CH_3Hg(II)$ for this binding site. It is convenient to consider the 1:1 complex as a ligand in the presence of $CH_3Hg(II)$. The values obtained for K_{f2} for the BAL and DMPS systems are listed in Table 2.

The equilibrium constants obtained potentiometrically for the $CH_3Hg(II)$−DMPS complexes have been used to predict the chemical shift titration curve for MAA in the mixture used in the nmr study of the $CH_3Hg(II)$−DMPS system. The experimental and predicted curves are shown in Fig. 1, and the similarity between the two indicates good agreement between the nmr and potentiometric methods, considering the differences in experimental conditions.

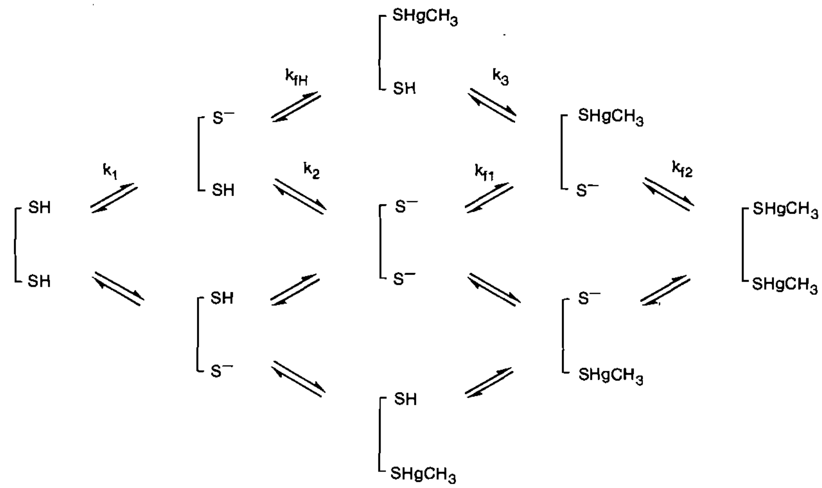

FIG. 4. Microscopic acid–base and complexation equilibria for the thiol groups of DMSA and DTE in solutions containing $CH_3Hg(II)$.

Attempts were made to determine formation constants for the $CH_3Hg(II)$–DMSA complexes by potentiometry. However, even in equimolar $CH_3Hg(II)$: dithiol solutions containing an excess of ME, significant amounts of 2 : 1 $CH_3Hg(II)$: dithiol complex are present because of the high affinity of the second sulfhydryl of DMSA for $CH_3Hg(II)$. It was not possible to refine the equilibrium constants in this system with MINIQUAD because they are too highly correlated. However, titration curves calculated with equilibrium constants obtained from the nmr study gave a good fit to the experimental pH titration curves.

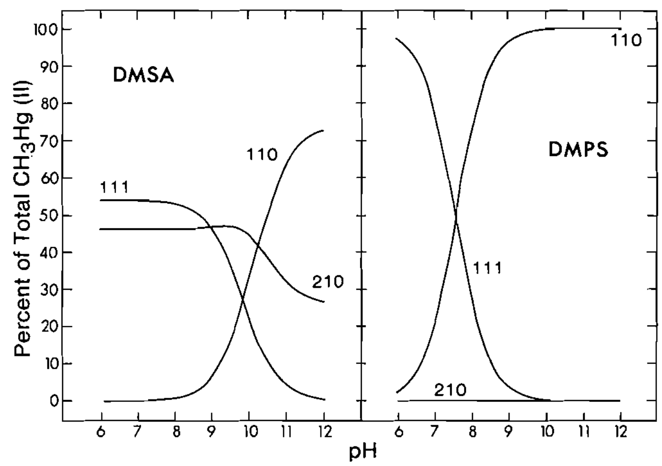

FIG. 5. Percent of total $CH_3Hg(II)$ in the various complexed forms, $M_mL_lH_h$ where m, l, and h are given by three numbers by each curve, as a function of pH in solutions containing 0.001 M $CH_3Hg(II)$ and 0.001 M dithiol. Calculated using the constants in Tables 1 and 2.

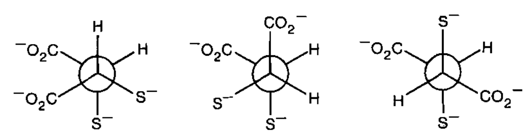
Discussion

The results in Tables 1 and 2 provide evidence for chelation in the sulfhydryl-deprotonated 1 : 1 $CH_3Hg(II)$ complexes of BAL and DMPS but not in those of DMSA and DTE. Chelation is indicated by the formation constants of the 1 : 1 deprotonated complexes, K_{f1}, which are significantly higher for the DMPS and BAL complexes than for the DMSA and DTE complexes. Figure 3 shows the relationship between the microscopic formation constant, k_{f1}, and the microscopic sulfhydryl acid dissociation constant for the $CH_3Hg(II)$ complexes of a series of monothiols (1, 2, 4) and the symmetrical dithiols DMSA and DTE. The microscopic acid dissociation and formation constants for DMSA and DTE are defined in Fig. 4, and for DMSA are related to the macroscopic constants by $k_1 = K_3/2$, $k_2 = 2K_4$, $k_{f1} = K_{f1}/2$, and $k_{f2} = 2K_{f2}$. While it was not possible to obtain the analogous microscopic constants for unsymmetrical BAL and DMPS, limits can be determined from the macroscopic constants and these are plotted in Fig. 3.

The monothiols and DMSA and DTE show the expected (1, 13) linear correlation between log K_f of their $CH_3Hg(II)$ complex and the pK_A of the coordinating group. However, it is apparent that the $CH_3Hg(II)$ complexes of BAL and DMPS are considerably more stable than would be expected by consideration of the basicity of the donor sulfur alone. We interpret this to be evidence for chelation of $CH_3Hg(II)$ in the deprotonated 1 : 1 complexes of BAL and DMPS. Chelation is also consistent with the lower sulfhydryl basicity in the deprotonated 1 : 1 complexes compared with once-protonated uncomplexed dithiol; for the protonated BAL and DMPS complexes pK_3 is significantly less than pK_1 for the doubly protonated dithiols whereas for the protonated DMSA and DTE complexes pK_3 is slightly larger. Proton displacement followed by chelation lowers pK_3 for the BAL and DMPS complexes. Alcock, Lampe, and Moore (9) have shown that $CH_3Hg(II)$ is chelated by sterically rigid vicinal dithiols in the solid state.

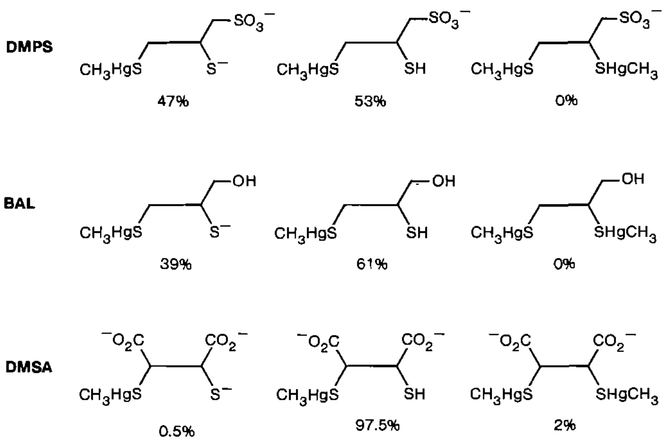
It seems reasonable to suggest that chelation is not present in the 1 : 1 complex of DMSA, despite the vicinal sulfhydryl groups, because of the resultant unfavorable proximity of the two deprotonated carboxylate groups which would result in this case.



In this complex, the two sulfhydryl groups act more independently than is the case for the analogous complexes of BAL and DMPS. This is indicated by the stepwise formation constant, log K_{f2}, which for the addition of the second $CH_3Hg(II)$ cation to DMSA is 16.9 but is reduced to 10.46 and 10.26 in the BAL and DMPS complexes by chelation in the 1 : 1 complexes.

The large differences in the relative magnitudes of K_{f1}, K_{f2}, and K_{fH} for the DMSA, BAL, and DMPS complexes result in quite different distributions of $CH_3Hg(II)$ among the possible complexes, as illustrated by the species distribution diagrams in Fig. 5 for the DMSA and DMPS complexes. For the DMSA system, a large fraction of the $CH_3Hg(II)$ is present as the 2:1 complex whereas, for the DMPS system, the 2:1 complex represents <0.1% for the conditions in Fig. 5.

Since BAL, DMPS, and DMSA have all been used as antidotes for various forms of heavy-metal poisoning, it is appropriate to consider the nature of the $CH_3Hg(II)$–dithiol species expected to be present under physiological conditions. Using the equilibrium constants determined in this study, and a [dithiol]:[$CH_3Hg(II)$] ratio of 20:1, the following complexed dithiol species are expected at pH 7.4:



Mono-$CH_3Hg(II)$ species dominate for all the dithiols. For BAL and DMPS, about half of the complexed dithiol has a deprotonated sulfhydryl, while for DMSA, the analogous site is almost completely protonated. For DMSA and DMPS, all the major species are negatively charged. This is consistent with observed removal of $CH_3Hg(II)$ via the kidney by these dithiols (6, 7, 14). It is also known that these dithiols do not cross the red blood cell membrane, but do rapidly mobilize intracellular $CH_3Hg(II)$ (15 and footnote 4). Both are effective antidotes for $CH_3Hg(II)$ poisoning (6, 7, 15).

On the other hand, a large fraction of $CH_3Hg(II)$ complexed BAL is in the form of a neutral species under these conditions. Consistent with the expected lipophilic character of neutral BAL complexes, 1-octanol/water partition coefficients, $[CH_3Hg(II)]_{octanol}/[CH_3Hg(II)]_{water}$ for [dithiol]:[$CH_3Hg(II)$] ratios of 1:1 at pH 6.9, are ca. 10^4 greater for BAL than for DMSA and DMPS (16). Although this dithiol is an effective antidote for many other metals, including inorganic Hg(II), it redistributes $CH_3Hg(II)$ across the blood-brain barrier into the brain, and is contraindicated in cases of $CH_3Hg(II)$ toxicity.

The effectiveness of DMSA and DMPS as antidotes for $CH_3Hg(II)$ toxicity when administered orally with food, as judged by the removal of $CH_3Hg(II)$ from the brain and blood of mice, is DMSA > DMPS (14). Although factors other than formation constants are expected to be important in the effectiveness of antidotes, e.g. metabolism of antidotes and their $CH_3Hg(II)$ complexes, and the solubility properties of complexes discussed above, it is appropriate to consider possible effects of the constants determined in this study.

Since $CH_3Hg(II)$–thiol binding is extremely labile (3, 13, 17), it is likely that $CH_3Hg(II)$ in biological systems is distributed among the various intra- and extra-cellular and membrane bound sulfhydryl groups and those of antidote molecules according to an equilibrium model. If so, the relative effectiveness of DMSA and DMPS as antidotes may be related to the conditional formation constants, defined by eq. [7], of their $CH_3Hg(II)$ complexes and those of endogenous thiols at physiological pH. The dependence of the conditional formation constants of the DMSA and DMPS complexes on dithiol: $CH_3Hg(II)$ ratio is shown in Fig. 6, together with log K_{fc} for the $CH_3Hg(II)$ complexes of glutathione (GSH). Glutathione is the most abundant nonprotein thiol in biological systems (18), and has been identified as $CH_3Hg(II)$ binding site in red blood cells (3, 19) and liver cytosol (20), and 30% of rat cerebral soluble $CH_3Hg(II)$ is in a GSH complex (21). The curves illustrate the complexity of the situation, since at high dithiol:$CH_3Hg(II)$ ratios such as those expected under antidotal conditions, log K_{fc}(DMPS) > log K_{fc}(DMSA) > log K_{fc}(GSH) but at low ratios the order is altered to log K_{fc}(DMSA) > log K_{fc}(GSH) > log K_{fc}(DMPS). At low dithiol:$CH_3Hg(II)$ ratios, ^1H nmr studies of the removal of $CH_3Hg(II)$ from hemolyzed human erythrocytes (22) indicate that DMSA competes more effectively with intracellular thiols for $CH_3Hg(II)$ than DMPS.

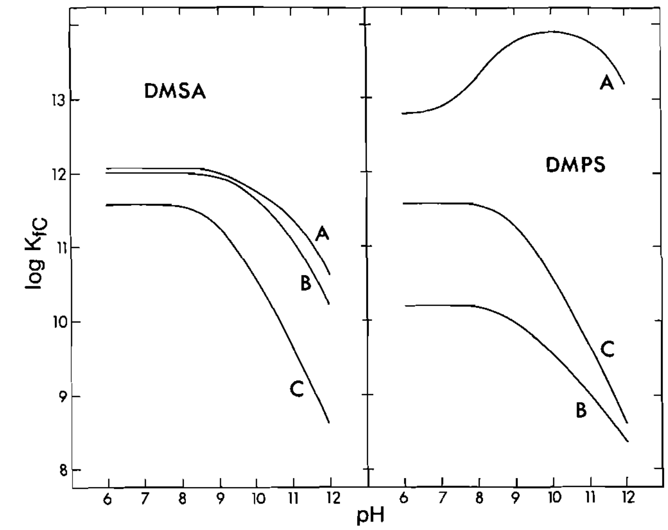


FIG. 6. pH and concentration dependence of the conditional formation constants for the $CH_3Hg(II)$–dithiol complexes and pH dependence of the conditional formation constant for the $CH_3Hg(II)$–GSH complex (*A*) 0.001 *M* $CH_3Hg(II)$, 0.01 *M* dithiol, (*B*) 0.001 *M* $CH_3Hg(II)$, 0.001 *M* dithiol. (*A*) and (*B*) were calculated with constants in Tables 1 and 2, the GSH curve (*C*) was calculated with constants in [4].

Received November 9, 1984

R. G. BARRADAS, D. A. RENNIE, and T. J. VANDERNOOT. Can. J. Chem. **63**, 2437 (1985).

Linear potential sweeps and potentiostatic pulse perturbations have been employed to investigate the influence of the expander ammonium lignosulphonate, on the anodic formation of $PbSO_4$ on lead amalgam electrodes in sulphuric acid solutions at 24°C. It was found that the expander strongly adsorbs onto the clean amalgam surface thus affecting the formation of the $PbSO_4$ film. The expander increased the charge necessary for passivation, inhibited the cathodic reduction of the film, and produced a more porous film. Evidence is given for the presence of an optimum concentration of expander. Some speculations concerning the mode of action of the expander onto the amalgam surface are presented.

R. G. BARRADAS, D. A. RENNIE et T. J. VANDERNOOT. Can. J. Chem. **63**, 2437 (1985).

Opérant à 24°C et dans des solutions d'acide sulfurique, on a utilisé des balayages linéaires de potentiel ainsi que des perturbations potentiostatiques pulsées pour étudier l'influence du lignosulfate d'ammonium sur la formation anodique du $PbSO_4$ sur des électrodes d'amalgame de plomb. On a trouvé que l'expanseur s'adsorbe fortement sur la surface propre d'amalgame et que ceci affecte la formation du film de $PbSO_4$. L'expanseur augmente la charge nécessaire à la passivation, inhibe la réduction cathodique du film et provoque la production d'un film plus poreux. On présente des données suggérant la présence d'une concentration optimale d'expanseur. On présente aussi quelques spéculations sur le mode d'action de l'expanseur sur la surface d'amalgame.

Introduction

Much of the previous work in the literature relating to the formation of $PbSO_4$ in sulphuric acid in the presence of expanders has dealt with solid lead electrodes. During the discharge process, the expander affects the $PbSO_4$ film formed making it more porous (1–3). The $PbSO_4$ crystals were more loosely attached and they extended further from the electrode surface (1). The size of the $PbSO_4$ crystals was also reduced due to the adsorption of the expander onto the growing $PbSO_4$ crystal (3). It was also found that the expander increased the amount of charge required for passivation (3–5). The expander inhibited the cathodic reduction of the $PbSO_4$ film (3, 4, 6, 7).

Amalgam electrodes are advantageous in that they give reproducible smooth fresh surfaces which are free from surface defects and have accurately known areas. Amalgam electrodes have been employed in studies of $PbSO_4$ formation (6, 8) with and without battery expander. In the present article, the effect of the organic additive, ammonium lignosulphonate, as an expander on the formation of $PbSO_4$ on a lead amalgam electrode in sulphuric acid solutions was investigated at 24°C. An extensive set of results from sweep and step perturbations are presented for various concentrations of expander. Double layer capacitance measurements have been used to show the adsorption of the expander onto the amalgam surface. As well, the capacitance and resistance of completed $PbSO_4$ films formed in the presence of the expander have been used to make inferences concerning the film structure.

Experimental

A lead amalgam of 1.26% by weight of lead was prepared by dissolving lead beads (99.999%, Cominco of Canada Ltd.) in ultrapure mercury (99.9998% Alfa Inorganics). One millilitre of a very dilute solution of perchloric acid was kept over the amalgam to maintain it free of organic contaminants prior to use.

All solutions were prepared with ARISTAR sulphuric acid and triply distilled water. Separate deoxygenated solutions of 0.0, 0.72, 7.89, 17.45, and 76.60 ppm of ammonium lignosulphonate (Lignosol C-16, Lignosol Chemicals Ltd., Quebec) in 1.30 molal sulphuric acid were prepared. The concentrations (in ppm) are with respect to the weight of the 1.30 molal sulphuric acid solution. The composition of ammonium lignosulphonate may be found in ref. 9. The solutions were deaerated for 15 min prior to the commencement of the experiment with purified nitrogen and deaeration was continued throughout the experiment. All experiments were carried out at 24°C.

The cell body and lid were cylindrical and machined from Teflon. A hole in the bottom of the cell allowed a syringe to be inserted into the cell body. The cell body and lid were cleaned using a solution of potassium hydroxide, rinsed with thrice distilled water, and then left to soak in concentrated sulphuric acid. Prior to use, they were thoroughly rinsed again with triply distilled water followed by further cleaning in a nitrogen plasma whereby the free nitrogen radicals attack any existing organic contaminants on the surface of the cell.

The reference electrode was a Hg/Hg_2SO_4 electrode in the same acidic solution and all potentials are quoted with respect to it. A Luggin capillary was used to minimize uncompensated solution resistance.

The counter electrode was a cylindrical Pt gauze that completely surrounded the working amalgam electrode.

The needle from a glass capillary syringe (Hamilton gas tight, 50 μL) was removed and the end pulled to a very fine tip whose inner diameter was 331 μm. The working electrode consisted of a small amalgam drop that was extruded on the upturned tip. Prior to an experiment, the tip was thoroughly cleaned in potassium hydroxide, dilute nitric acid, followed by a thorough rinse in triply distilled water, and further cleansing in a nitrogen plasma. After cleaning the tip, it was rendered hydrophobic to avoid solution creepage into the tip by soaking in a solution of dimethyldichlorosilane in CCl_4. The plunger of the syringe was controlled by a micrometer (Moore and Wright, Sheffield, England) which was securely attached to the body of the syringe. The Teflon tip on the plunger of the syringe was cut away to expose the tip of the stainless steel plunger. This allowed electrical contact to be made with the amalgam electrode. Each drop was maintained at −1100 mV before a linear potential sweep or potential step was carried out.

The potentiostat was a Stonehart BC 1200 used in conjunction with a PAR model 175 programmer. An HP model 3310B function generator was used to supply a 3.98 mV rms sinusoidal signal to the

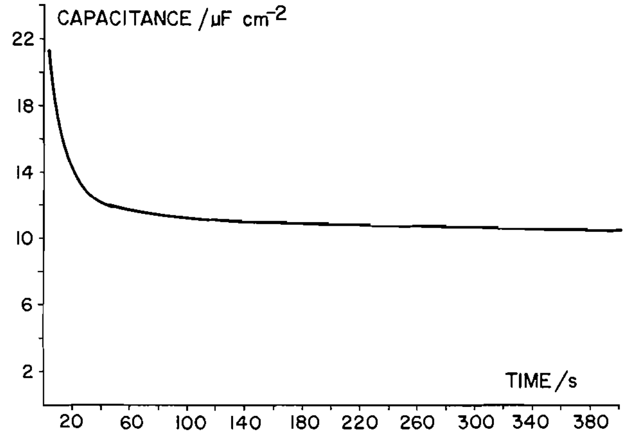

FIG. 1. A plot of the double layer capacitance as a function of time for a fresh amalgam drop in 17.45 ppm of expander. The capacitance was measured at −1100 mV vs. Hg/Hg_2SO_4.

electrode and the in-phase and out-of-phase components of admittance were measured using a PAR model 128A Lockin Amplifier. The current transients in response to potential sweeps or steps were recorded on a Nicolet 3091 digital oscilloscope and then plotted on an HP model 7047A x-y plotter. A Harrick model PDC-3XG plasma cleaner was used for cleaning.

The size of the amalgam drop was accurately determined from a calibration curve of the double layer capacitance of the drop as a function of drop size. When the drop was dislodged, the amalgam would break off inside the capillary of the tip. A new drop was slowly extruded and the capacitance recorded as a function of micrometer travel. The capacitance was relatively constant while the amalgam was still inside the capillary, and increased sharply as the drop began to form on the tip. The point when the capacitance changed sharply was taken to be the capacitance of a hemisphere of amalgam which could subsequently be employed to obtain the area of a spherical sessile drop. A calibration curve was obtained for each solution used. Fresh amalgam drops were used for each individual measurement and were all of the same approximate area (4.5×10^{-3} cm^2) in order to give a consistent geometry of the drop and capillary tip. The sessile drops were assumed to be sections of a sphere.

The expander was found to adsorb onto the electrode surface causing a change in the double layer capacitance of the drop. It was therefore necessary to wait a sufficient period of time to let the expander adsorb onto the electrode surface to its equilibrium value before the transients were obtained. This occurred when the double layer capacitance became constant. For 0.72 ppm the amount of adsorption was so small, and so slow that it was essentially equivalent to no expander being present. Therefore, for 0.0 and 0.72 ppm the transients were recorded immediately after extrusion of a drop. The higher concentrations of expander had appreciable amounts of adsorption which occurred fairly quickly. For these solutions the drops were maintained at −1100 mV until adsorption was complete.

The uncompensated resistance, Ru, was measured by applying a 50 kHz sinusoidal voltage input (3.98 mV rms) to the drop and recording the in-phase current using the lockin amplifier. The uncompensated resistance included the resistance of the Hg in the syringe. The value of Ru was checked independently by observing at what value of ohmic compensation the potentiostat began oscillating. Any overcompensation would have been obvious had it been present.

Results and discussion

(a) Adsorption of expander

The double layer capacitance of a drop was measured as a function of time at −1100 mV to determine what effect the addition of the expander had on the amalgam electrode. Figure 1 illustrates that the double layer capacitance decreases with time in a solution containing 17.45 ppm of expander. A decrease in the double layer capacitance with time in the presence of an expander has been reported previously (4, 7). It has been suggested (4, 7, 10) that the decrease in the double layer capacitance is due to the presence of an adsorbed layer of the expander on the electrode surface. At higher concentrations of expander, the double layer capacitance decreases much more quickly indicating that the rate at which the expander adsorbed onto the electrode was increased. In 1.30 molal sulphuric acid with no expander, the double layer capacitance was constant with time, and in 0.72 ppm there was a very slow decrease in the double layer capacitance. The final double layer capacitance decreased from 17 μF cm^{-2} for 0.0 ppm to 8 μF cm^{-2} for 76.60 ppm of expander. It has been suggested (4, 5, 10) that the expander forms thick multilayers on the surface of the electrode with increasing concentration, and our observations are consistent with multilayer adsorption of the expander onto the amalgam surface.

(b) Potential step dependence

The geometric models for 2D and 3D nucleation and growth of anodic films that have been developed (11, 12) treat the growth kinetics in terms of two growth rates and the nucleation rate. The growth rates involved are the lateral growth rate, k_1, representing the crystal growth parallel to the plane surface of the electrode, and the vertical growth rate, k_2, describing the growth perpendicular to the electrode surface.

The potential dependence of the kinetics of nucleation and growth of the $PbSO_4$ film on the amalgam electrode in the presence of the expander has been investigated by potential steps. The equation describing the current response due to the nucleation and growth of a 3D deposit is (12)

$$[1] \quad i = nFk_2[1 - \exp(-\pi M^2k_1^2At^3/3\rho^2)] \times \exp\left[\frac{-\pi M^2k_1^2At^3}{3\rho^2}\right]$$

where i is the current, n is the number of electrons, F is Faraday's constant, k_2 is the vertical growth rate, M is the molecular weight, k_1 is the lateral growth rate, A is the nucleation rate, t is the time, and ρ is the density of the deposit. Experimental transients can be analyzed to give values for the parameters k_2 and k_1^2A from the current maximum in the transient, i_m, and the time to the current maximum, t_m. For 3D nucleation and growth the equations for i_m and t_m are, (12)

$$[2] \quad i_m = nFk_2/4$$

$$[3] \quad t_m = \left[\frac{3\rho^2 \ln 2}{\pi M^2k_1^2A}\right]^{1/3}$$

There have been some discussions concerning the validity of certain aspects of the 3D model (13) but this article will not deal with this question.

A sample transient where the potential was stepped from −1100 to −874 mV in 7.89 ppm solution is given in Fig. 2. The falling currents before the maximum are due to lead dissolution and plots of i versus $t^{-1/2}$ are linear. The shape of the transient is characteristic for that of 3D nucleation and growth electrocrystallisation processes since the charges passed are too large for 2D monolayer formation. As the concentration of the expander was increased, the transient broadened and the tail became longer as demonstrated in the reduced variable plot of Fig. 3. The trend observed for the various concentrations of expander in Fig. 3 was also observed in the formation of thick layers of $PbCl_2$ on a lead amalgam (9). The trend may result

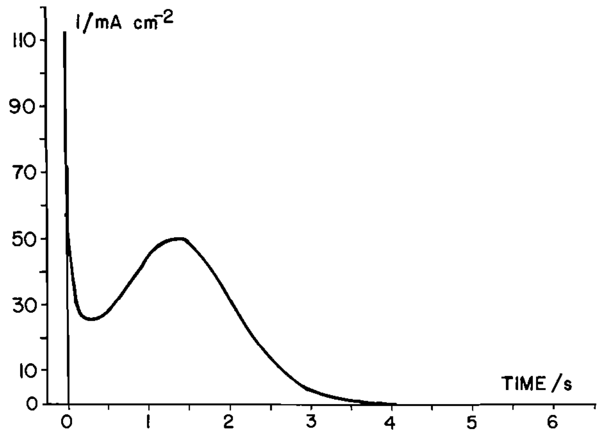

FIG. 2. A sample potential step transient where the potential was stepped from −1100 to −874 mV in 7.89 ppm of expander. Note the large initial lead dissolution current before the onset of electrocrystallisation.

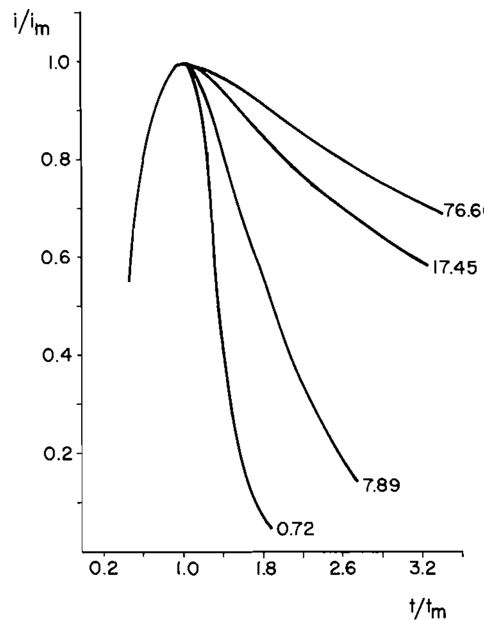

FIG. 3. Potentiostatic current−time transients plotted in nondimensional form. The numbers at the end of the curves are the expander concentrations in ppm. The curve for 0.0 ppm is not shown because it was essentially the same as that for 0.72 ppm. A single curve for the rising portion of the transients was drawn rather than the separate curves for each concentration since these portions of the transients were all very close to one another.

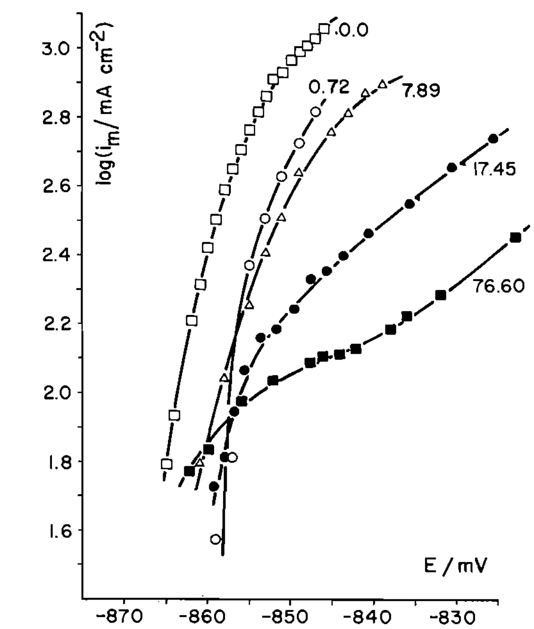

FIG. 4. A semilog plot of the maximum current, i_m, as a function of potential, E, for the potentiostatic transients. The numbers beside the curves represent the expander concentrations.

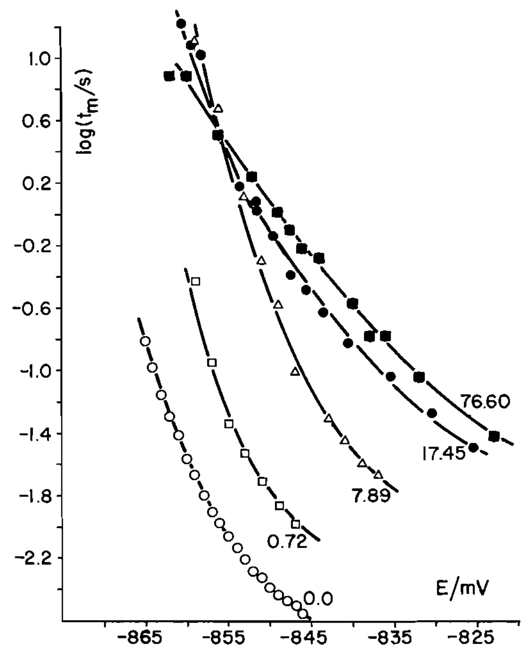

FIG. 5. A semilog plot of t_m as a function of potential, E, for the potentiostatic transients. The numbers beside the curves represent the expander concentrations.

from changes in the nucleation rate, or the lateral growth rate, or both. However, at times greater than t_m, the nucleation in terms of centres that could grow to an appreciable size is effectively over. Therefore, beyond t_m the growth of the already existing centres predominates. Since the shape of the rising portions of the curves before t_m are essentially the same for all concentrations of expander, the nucleation rate is probably unaltered by the expander. But, the tails of the transients are vastly different which suggests that the lateral growth rate must be affected by the expander.

The semilog plot of the maximum current, i_m, as a function of potential, E, is given in Fig. 4. From eq. [2] it can be seen that i_m is a function of the vertical growth rate. At low overpotentials there is not a large change in the i_m values with different concentrations of expander. However, the effect is more severe at higher overpotentials and concentrations of expander. This suggests that the expander does have some effect on the vertical growth rate and its dependence on potential at higher overpotentials and concentrations of expander.

Equation [3] shows that the time at which the maximum current occurs, t_m, is inversely proportional to the square of the lateral growth rate times the nucleation rate. Figure 5 illustrates that for a given potential, for example, −845 mV, the expander

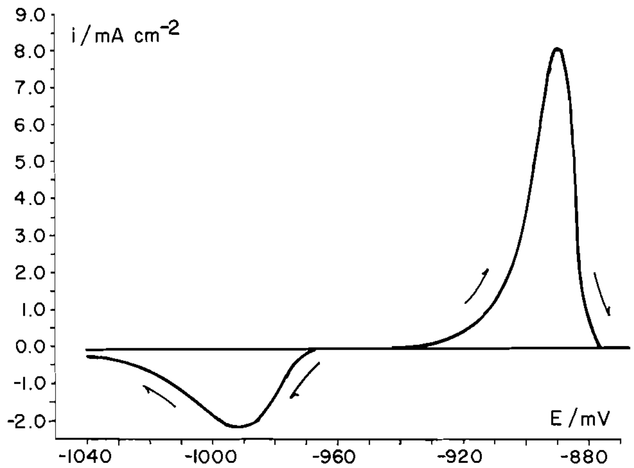

FIG. 6. A linear potential sweep at 20 mV s^{-1} in 1.30 molal H_2SO_4 with no expander added. The potential was swept anodically from −1100 to −850 mV, reversed and swept cathodically back to −1100 mV. Only the potential range from −1040 to −870 mV has been shown in the diagram.

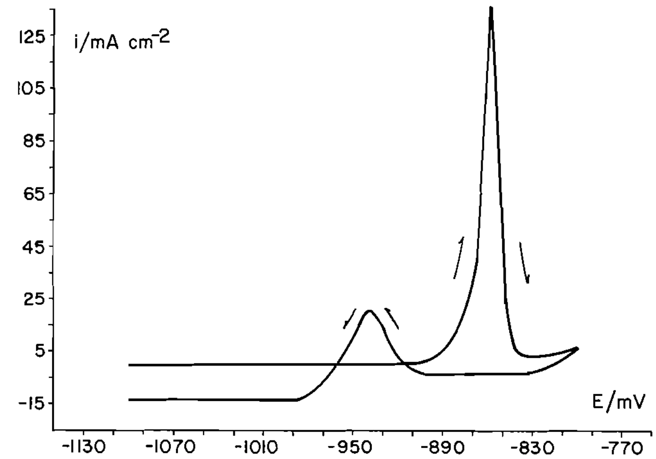

FIG. 7. A linear potential sweep at 20 mV s^{-1} in 7.89 ppm of expander. The potential was swept anodically from −1100 to −800 mV, reversed and swept cathodically to −1700 mV, again reversed and swept anodically to −1100 mV. Only the potential range from −800 to −1100 mV is shown. The current on the axes as indicated is the anodic current. The current on the reverse sweep has been expanded by a factor of 10. Note the small reduction current that is independent of potential, and the small anodic peak on the reverse sweep.

has a greater dependence on t_m than on i_m, thus affecting the lateral growth rate of the $PbSO_4$ film and/or the nucleation rate. A 1 decade change in i_m corresponds to a 1 decade change in k_2, whereas a 1 decade change in t_m corresponds to a 3 decade change in k_1^2A as indicated by eqs. [2] and [3]. Since the expander is adsorbed onto the amalgam surface it could inhibit the nucleation rate by allowing less free surface to be available for $PbSO_4$ seed nuclei. The lateral growth rate could be decreased if the expander is adsorbed onto kink sites where incorporation of $PbSO_4$ molecules occurs. It would not take a large amount of expander to block these kink sites. This is consistent with Sharpe's results (14) where it was reported that the adsorption of expander onto $PbSO_4$ was much less favourable than onto the metallic lead surface. It should be pointed out that Sharpe observed the effects on $PbSO_4$ powder and not on a growing film of $PbSO_4$ but the results are still applicable. It would be harder to prove that the expander affects the lateral growth rate than the nucleation rate since very little expander would be involved in the adsorption. It is important to point out that the relative changes of k_1 and k_2 may vary depending on the electrode substrate. The lateral growth rate k_1 should be different on the solid lead compared to the amalgam, but k_2 should be the same for both systems.

In both Figs. 4 and 5 the slopes for the curves for the lower concentrations of expander are very steep indicating electrocrystallisation. This high potential dependence of i_m and t_m at low overpotentials has been observed for both 2D and 3D systems (13).

On the basis of our results, it is not possible to conclude exactly which kinetic parameters are affected and to what degree. The general effect of the expander was to lower i_m and increase t_m which means the electrode is slower to passivate. However, the charges passed are higher, therefore, more Pb^{2+} ions must be diffusing away towards the solution side of the interphase.

(c) Linear potential sweep dependence

Figure 6 depicts a linear potential sweep at 20 mV s^{-1} in 1.30 molal sulphuric acid with no expander added. The potential was swept anodically from −1100 to −850 mV, reversed and swept cathodically back to −1100 mV. The sweep shows the presence of an anodic peak in the region of −940 to −820 mV resulting from the formation of a $PbSO_4$ film, and a cathodic peak resulting from the reduction of the film. The potential region of film formation is consistent with earlier results on solid electrodes (15−20). The equilibrium potential of the sulphated amalgam electrode in 1.30 molal sulphuric acid was calculated to be −970 mV vs. Hg_2SO_4. As seen from Fig. 6, the reduction of the $PbSO_4$ film begins at −970 mV, but a larger overpotential is necessary for the $PbSO_4$ film formation to begin.

This sweep can be compared to a similar sweep done at 20 mV s^{-1} in 7.89 ppm of expander as shown in Fig. 7. The current scale on the reverse sweep has been expanded by a factor of 10. The significant differences are the larger anodic peak current which has been shifted anodically, the presence of a small anodic peak on the reverse sweep, and the small reduction current that is independent of potential out to the region of hydrogen evolution. The absence of a reduction peak has been previously reported (3, 4, 7). It is possible that the presence of the adsorbed expander on the bare portions of the electrode inhibits the cathodic reduction of Pb^{2+} ions.

The following explanation is offered as a possible reason for the small anodic peak on the reverse sweep. A preliminary experiment investigating the double layer charging on a mercury drop in the presence of expander indicates some sort of desorption or re-orientation of the absorbed expander film in the same potential region as the small anodic peak. If desorption or re-orientation is occurring, then it is possible that bare portions of the electrode are being generated allowing for further oxidation of lead.

The linear potential sweeps in pure sulphuric acid often exhibited a sharp transition or "kink" separating the regions of lead dissolution and nucleation and growth. The lead dissolution region showed a rising curve which broke sharply at the onset of nucleation and growth. The kink was not evident on the transients from any of the solutions containing the expander.

If the potential is swept anodically from −1100 to −800 mV

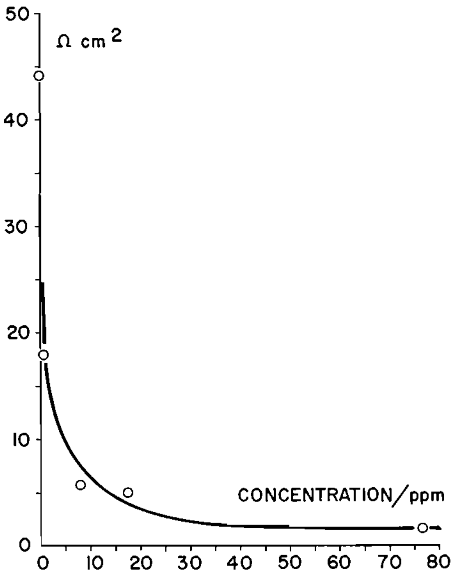

FIG. 8. The resistance of the $PbSO_4$ film measured at −800 mV as a function of expander concentration. The resistance has been multiplied by the area of the drop. The average drop area was 4.47×10^{-3} cm^2.

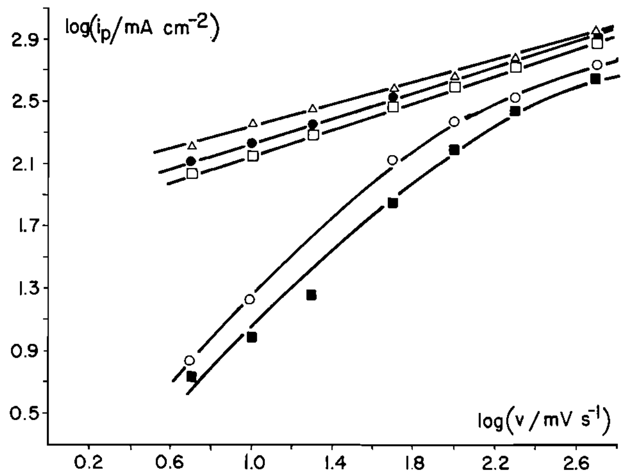

FIG. 9. A log−lot plot of the anodic peak current, i_p, as a function of sweep rate, v, for the various concentrations of expander. The symbols are ■ for 0.0 ppm, ○ for 0.72 ppm, □ for 76.60 ppm, ● for 17.45 ppm, and △ for 7.89 ppm.

to form a film of $PbSO_4$ and kept at −800 mV, the capacitance and resistance of the film can be measured. An increase in the concentration of the expander caused a small change from 0.82 to 1.99 $\mu F\ cm^{-2}$ in the capacitance of the film but a larger change in the resistance of the film occurs as shown in Fig. 8. The resistances as shown in the figure have been mutiplied by the area of the drop which is equivalent to the product of the intrinsic resistivity and the thickness of the layer. The decrease in the resistance of the film with an increase in the concentration of the expander may be due to the formation of a more porous film. An increase in the porosity of the film with the addition of expanders has been previously reported (1−3, 21, 22) and was attributed to the change in the lead sulphate crystal structure. The porosity of the film will increase if there are empty spaces or voids in the deposit. If the growth of the deposit is not complete enough for the electrode surface to be completely covered, then voids will form in the deposit. This

incomplete growth will result if the lateral growth rate is inhibited in some way.

The Tafel plots obtained from low current regions prior to onset of $PbSO_4$ nucleation and growth sweeps at 10 mV s^{-1} for 0.0 and 17.45 ppm of expander added gave linear relationships in which the slopes were 27.37 and 30.26 mV dec^{-1}, respectively. These slopes are very close to that expected (29.58 mV dec^{-1}) for a reversible 2 electron transfer reaction. In sulphuric acid solutions slopes of this magnitude have been previously reported (8, 16, 23).

The log−log dependence of the anodic peak current, i_p, as a function of sweep rate, v, is shown in Fig. 9. The slopes of the curves for 7.89, 17.45, and 76.60 ppm are less than one half. The reaction is diffusion-controlled for these concentrations as indicated by linear i_p versus the square root of the sweep rate plots. However, the plots had positive intercepts which was due to the contribution of spherical diffusion at low sweep rates. For 0.0 and 0.72 ppm the steep slopes in Fig. 9 indicates that the process is not controlled by diffusion but electrocrystallization.

An interesting feature to note is the fact that the curves for 17.45 and 76.60 ppm lie below that of 7.89 ppm. This suggests the existence of an optimum concentration of expander as reported by Mahato (5) who found 20 ppm as the optimum concentration and beyond that the expander exhibited an inhibitory effect. Pierson *et al.* (21) also mentioned that a small amount of an organic material will produce an expander effect and an excess adversely affects the functioning of the electrode.

A further effect of the expander was to increase the amount of charge required for passivation as the concentration of the expander increased as previously reported (3, 4, 6). Figure 10 depicts the increase in charge for sweep rates of 10 and 20 mV s^{-1} as a function of expander concentration. The charge required for passivation is larger but the rate of growth of the $PbSO_4$ film has decreased as expander concentration is increased. Therefore, there will be more Pb^{2+} ions diffusing into solution which increases the charge. Fewer Pb^{2+} ions will be

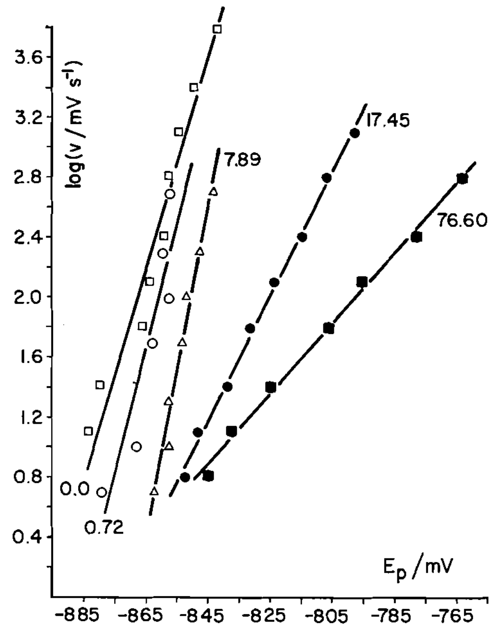

FIG. 11. A semilog plot of sweep rate, v, as a function of peak potential, E_p. The numbers beside each line represents the expander concentration in ppm. The steepness of the slopes of the curves at low concentrations of expander are characteristic of an electrocrystallisation process.

incorporated into the $PbSO_4$ film, thereby reducing the charge efficiency into the film. The expander may also help to stabilize the Pb^{2+} ions by forming complexes with the ions in solution. The inhibitory effect of the expander is evident as shown by the decrease in the curves toward 76.60 ppm. Mahato (5) observed a decrease of 37% in the charge passed when the concentration of expander was increased from 20 to 40 ppm. He attributed the charge inhibition to the multilayer surface adsorption of the expander and/or the expander's orientation on the electrode surface.

Figure 11 shows a semilog plot of the peak potential, E_p as a function of sweep rate, v. An increase in the expander concentration produces an anodic shift in the peak potential as demonstrated previously by Archdale and Harrison (6). The slopes for 0.0 and 7.89 ppm are very steep which is characteristic of rate control by electrocrystallisation. The slope of 42.37 mV dec^{-1} for 76.60 ppm is greater than 30 mV dec^{-1} that would have been expected for a 2 electron diffusion controlled process. This larger slope represents further evidence of the inhibitory effect of the expander, Archdale and Harrison have also observed a slope in the order of 30–40 mV dec^{-1} (6).
