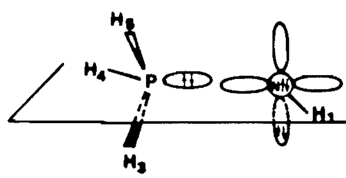
l'approche de la paire libre de la phosphine n_P étant réalisée dans la direction de l'orbitale vacante du nitrène, avec les deux paires libres de cette entité dans le plan orthogonal.



La délocalisation de la paire du phosphore vers l'orbitale vacante du nitrène assure la liaison P—N en σ. Cette liaison apparaît polarisée $P^+—N^-$, compte tenu du fort pouvoir attracteur de l'azote. On remarque toutefois un phénomène de rétrodonation selon l'axe P—N, qui aboutit à un peuplement de 0,13 e de l'orbitale d du phosphore dirigée selon cet axe.

Parallèlement, des transferts interviennent des deux paires de l'atome d'azote, que nous définissons par n_N^π (paire perpendiculaire au plan H_4PNH_1) et n_N^σ (paire dans le plan H_4PNH_1), vers les orbitales d de symétrie adaptée du phosphore, conduisant à des populations respectives de 0,17 et de 0,25 sur ces orbitales. Nous observons de plus en π une délocalisation par hyperconjugaison de la paire n_N^π vers les liaisons P—H.

Ces interactions $n_N \rightarrow d_P$ apparaissent au niveau des deux dernières orbitales occupées de l'iminophosphane à −9,79 et −10,77 eV, qui présentent de fortes localisations sur les deux paires de l'azote. La visualisation par le tracé des courbes d'isovaleurs de fonction est présentée dans la figure 1 pour l'HOMO (n_N^π).

Ainsi, les trois types de transferts analysés ($n_P \rightarrow n_N^*$, $n_N^\pi \rightarrow d_P^\pi$, $n_N^\sigma \rightarrow d_P^\sigma$) sont à l'origine de la faible longueur de liaison P—N dans l'iminophosphane, qui peut donc être considérée comme une "pseudo triple liaison".

L'ensemble des transferts en retour sur le phosphore est toutefois assez faible (population totale de 0,55 e sur les orbitales d) et, globalement, la liaison P—N apparaît comme extrêmement polaire: fort caractère positif sur le phosphore et fort caractère négatif sur l'azote (fig. 2).

Cette charge nette négative très importante sur l'atome d'azote (−1,02) est bien en accord avec les valeurs inhabituelles des déplacements chimiques δ ^{15}N observées pour ce type de systèmes (6*b*), vis-à-vis de celles caractéristiques d'un azote dicoordonné; de même la comparaison des moments dipolaires expérimental (3,1 D pour $\phi_3PN\phi$) et théorique (3,2 D pour H_3PNH) est tout à fait satisfaisante. Le caractère de ce phosphore tétracoordonné (+0,73 en charge nette totale) est nettement plus positif que celui du phosphore divalent dans HPNH (+0,49 en charge nette totale) et du phosphore trivalent dans H_2PNH_2 (+0,39 en charge nette totale). Enfin, la réactivité des iminophosphanes (6*c*) s'interprète parfaitement à partir de la polarisation $P^+—N^-$ de cette liaison.

L'analyse des facteurs géométriques et électroniques met donc en évidence le caractère particulier de la liaison P—N dans la molécule d'iminophosphane. Elle révèle une structure du type  qui doit être considérée comme une simple liaison σ, issue d'un transfert en p du phosphore vers l'azote, renforcée essentiellement par les deux transferts en retour $n_N \rightarrow d_P$.

Ce caractère est à rapprocher de celui invoqué dans le cas des ylures du phosphore pour lesquels une longueur anormalement

courte a également été obtenue pour la liaison P—C (7) et correspond à ce qui vient d'être récemment proposé à partir d'une étude théorique pour H_3PO (8).

Cette nature particulière de la liaison P=N explique la faible barrière à la rotation calculée (de l'ordre de 8 kJ/mol) et qui n'a jamais été mise en évidence expérimentalement.

La forme mise en jeu, liaison N—H en position éclipsée vis-à-vis du groupement PH_3, présente une structure électronique très voisine de celle obtenue pour une position décalée, transferts $n_N \rightarrow d_P$ du même type et du même ordre. Ainsi, des énergies électroniques très voisines sont obtenues pour les deux entités, la forme éclipsée étant défavorisée de part des répulsions internucléaires importantes (de l'ordre de 47 kJ/mol).

Ceci conditionne l'origine de la barrière à la rotation dans l'iminophosphane, le "caractère multiple" lié à des interactions $p-d$ n'étant pas modifié par la rotation, contrairement au cas de liaisons $p^\pi-p^\pi$. En effet, pour la double liaison P—N dans l'iminophosphène, une barrière beaucoup plus élevée (environ 205 kJ/mol) avait été déterminée.

En outre, la valeur plus importante (environ 26 kJ/mol) que nous avions obtenue pour la barrière à la rotation dans l'aminophosphane avait une toute autre origine (9). Dans ce cas, c'était un facteur non pas de répulsion nucléaire mais électronique, lié aux modifications d'interactions paire P – paire N, qui gouvernait la barrière.

Pour l'iminophosphane, la rotation assez aisée autour de la liaison P—N et l'ensemble des données géométriques et électroniques favorables à une migration 1–2 sont autant de facteurs qui permettent d'interpréter l'existence de l'équilibre prototropique $H_3P{=}NH \rightleftarrows H_2P{-}NH_2$.

Cet équilibre a été mis en évidence, ces dernières années, par différentes équipes: Schmidpeter et Rossknecht (10) et Binder et Fisher (11). Ces derniers ont étudiée l'influence de la température et montré la prépondérance, dans de nombreux cas, de la forme aminophosphane.

Sur les dérivés modèles examinés (H_3PNH et H_2PNH_2), nous avons obtenu une différence énergétique de l'ordre de 71 kJ/mol en faveur de l'aminophosphane. Comme le font appa-

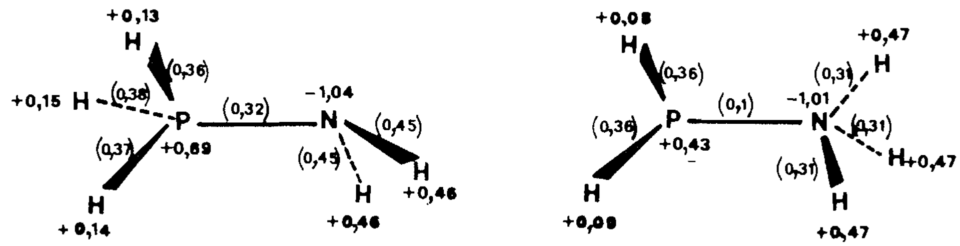

FIG. 3. $(H_3PNH_2)^+$ $(H_2PNH_3^+)$. Analyse des populations selon Mulliken. Charges nettes totales — populations de recouvrement (entre parenthèses).

raître les résultats présentés dans le tableau 1, ce sont les termes de répulsion internucléaires qui sont à l'origine de la stabilisation plus importante de l'aminophosphane.

3.1.2 *Réactivité des iminophosphanes: dimérisation*

Le phénomène de dimérisation est bien connu au niveau des liaisons phosphazènes et un grand nombre de composés diazaphosphétidines ont été synthétisés ces dernières années (12).

Lors d'une étude antérieure sur l'iminophosphène (1), l'analyse de ce phénomène a été interprétée par un mécanisme sous contrôle orbitalaire. En effet, les orbitales caractéristiques des liaisons $\pi_{P=N}$ et $\pi^*_{P=N}$ présentaient des localisations très importantes, respectivement sur l'azote et le phosphore, qui permettaient de lever les restrictions de symétrie (13) et d'envisager une addition 2+2 conduisant au dimère tête-bêche.

Pour l'iminophosphane, trois facteurs paraissent aller à l'encontre d'un mécanisme sous contrôle frontalier: (*i*) La séparation énergétique entre les deux orbitales occupée et virtuelle susceptibles d'entrer en jeu lors de la dimérisation est nettement plus importante que pour l'iminophosphène ($\simeq$ 17 eV pour l'iminophosphane, $\simeq$13 eV pour l'iminophosphène). (*ii*) L'HOMO du système présente bien un poids important sur l'atome d'azote, mais la localisation au niveau de la virtuelle est moins marquée sur le phosphore (fig. 1). (*iii*) Nous observons au niveau de cette orbitale virtuelle, une intervention des orbitales *d* du phosphore qui conduit à une diminution du recouvrement positif lors de l'approche tête-bêche.

Par contre, comme nous l'avons déjà noté, la polarité de la liaison P—N dans l'iminophosphane est très importante, avec des charges nettes de +0,73 sur P et −1,02 sur N.

Au vu de cet ensemble de résultats, nous sommes amenés à envisager une dimérisation au niveau de l'iminophosphane, mettant en jeu un mécanisme sous contrôle de charge plutôt que sous contrôle orbitalaire.

Cette conclusion se trouve confortée par les observations expérimentales selon lesquelles des substituants électrodonneurs sur l'azote ou électro-accepteurs sur le phosphore, qui tendent à accentuer la polarité de la liaison P—N, favorisent également la dimérisation (12*a*).

3.2 *Systèmes ioniques*

3.2.1 *Cations $(H_3PNH_2)^+$ et $(H_2PNH_3)^+$*

L'une des caractéristiques des iminophosphanes étant leur affinité vis-à-vis des électrophiles, nous avons entrepris l'analyse de la structure électronique du système $(H_3PNH_2)^+$ qui correspond à une protonation sur l'azote de l'iminophosphane. Cette forme peut également résulter d'une protonation sur le phosphore de l'aminophosphane.

Étant donné la prototropie $H_3PNH \rightleftarrows H_2PNH_2$, nous avons également examiné le cation $(H_2PNH_3)^+$ issu d'une protonation sur l'azote de l'aminophosphane.

L'ensemble des paramètres géométriques minimisés et la répartition des charges sur les deux cations sont présentés dans le tableau 2 et la figure 3.

TABLEAU 2. Géométries minimisées pour $(H_3PNH_2)^+$ et $(H_2PNH_3)^{+a}$

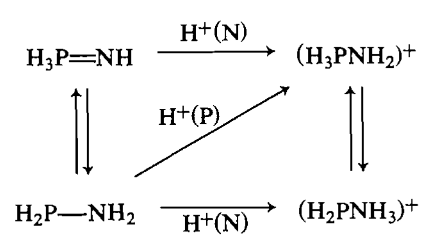
[b]E_{el}: énergie d'interaction électron−noyau, électron−électron.
[c]E_{rep}: énergie de répulsion internucléaire.



Pour le cation $(H_3PNH_2)^+$, nous observons une longueur de liaison (1,616 Å) intermédiaire entre celles de l'iminophosphane (1,532 Å) et de l'aminophosphane (1,685 Å), mais plus proche de cette dernière. De la même manière, l'indice de population obtenu pour la liaison P—N (0,32) est plus proche de celui de l'aminophosphane (0,24) que de la valeur trouvée dans le cas de l'iminophosphane (0,51).

Parallèlement, nous constatons une pyramidalisation de l'atome de phosphore plus marquée que dans l'iminophosphane. L'atome d'azote présente, quant à lui, un état d'hybridation voisin de sp^2, très proche de celui obtenu pour l'aminophosphane, la dernière orbitale occupée du système étant fortement localisée sur l'azote et correspondant à la n_N^{π}.

Au vu de sa structure géométrique, ce cation se présente plus comme le résultat d'une protonation sur le phosphore de l'aminophosphane que comme celui d'une protonation sur l'azote de l'iminophosphane.

L'analyse de population selon Mulliken fait toujours apparaître une polarité $P^+—N^-$ moins marquée que pour H_3PNH, avec un phosphore un peu moins positif et un azote légèrement plus négatif. Il faut remarquer que la charge +1 est entièrement localisée sur le groupement PH_3.

Ces résultats sont à rapprocher de ceux obtenus pour l'iminophosphène (HP=NH), à savoir que, lors d'une protonation sur l'azote, cet atome qui avait perdu des électrons en drainait toujours fortement en retour et l'espèce protonée se présentait, dans ce cas, comme un ion phosphénium $(H—P—NH_2)^+$.

De même, la structure électronique du cation $(H_3PNH_2)^+$ n'est pas celle d'un ion imminium, mais plus caractéristique d'un ion aminophosphonium du type  issu d'une protonation sur le phosphore de l'aminophosphane.

En ce qui concerne le cation $(H_2PNH_3)^+$ qui correspond à une protonation sur le site azote de l'aminophosphane, nous observons un allongement très important de la liaison P—N (tableau 2). Simultanément, nous notons un état d'hybridation plus nettement sp^3 au niveau de l'azote et une pyramidalisation très marquée au niveau du phosphore, l'HOMO du système étant localisée sur la paire de cet atome.

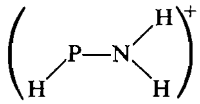
La polarité de la liaison P—N, toujours de type $P^+—N^-$, est pratiquement inchangée vis-à-vis de celle de l'aminophosphane, la charge +1 étant presque également répartie sur les deux groupements NH_3 et PH_2, avec un caractère plus positif, toutefois, chez ce dernier.

Ce cation présente donc un caractère hybride phosphane ammonium, avec une liaison P—N particulièrement longue, ce qui entraîne une importante diminution des répulsions internucléaires. Ainsi, le cation $(H_2PNH_3)^+$, en dépit du facteur électronique défavorable, apparaît comme l'espèce la plus stable énergétiquement (tableau 2).

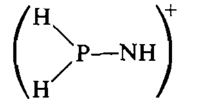
Toutefois, la différence énergétique entre les deux formes protonées $(H_3PNH_2)^+$ et $(H_2PNH_3)^+$ est faible (de l'ordre de 26 kJ/mol), soit environ quatre fois moins importante que celle obtenue précédemment entre $(H_2PNH)^+$ et $(HPNH_2)^+$. Ceci peut expliquer la détection, par Dahl (14), des deux espèces cationiques en équilibre lors de la réaction d'aminophosphanes diversement substituées avec CF_3SO_3H.

L'atome d'azote est donc le site préférentiel de protonation dans l'aminophosphane. Il faut noter qu'une étude similaire sur l'iminosphosphène nous avait conduit à la même conclusion quant à la comparaison des sites P et N. Les affinités protoniques n'ont pas été déterminées pour les composés examinés, mais les résultats obtenus sont tout à fait cohérents avec ceux de Lohr *et al.* (15) concernant les affinités protoniques en phase gazeuse de dérivés phosphorés à liaison multiple P—C pour lesquels les comparaisons avec les analogues azotés ont toujours montré des valeurs plus importantes pour ces derniers.

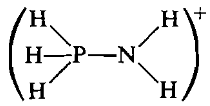
L'examen comparatif, ci-dessous, des résultats obtenus pour les quatre cations provenant de la protonation de l'iminophosphène (**1** et **2**) et de l'iminophosphane (**3** et **4**), nous conduit aux remarques suivantes.



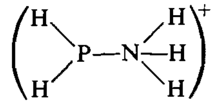
1
$d_{P—N}$ = 1,581 Å



2
$d_{P—N}$ = 1,484 Å



3
$d_{P—N}$ = 1,616 Å



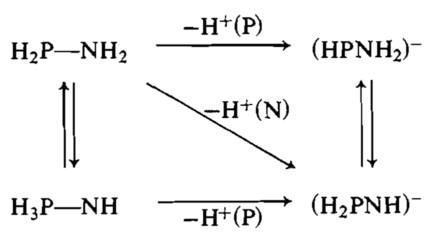
4
$d_{P—N}$ = 1,882 Å

Dans tous les cas, la polarité de la liaison P—N est du type $P^+—N^-$ et le caractère positif du phosphore va en diminuant de la structure phosphénium (**1**) au cation phospha-ammonium (**4**). Les longueurs de liaison P—N varient de 1,484 à 1,882 Å. Il est intéressant de constater que ces deux longueurs de liaison limites apparaissent dans les deux cations résultant de la protonation de l'atome d'azote d'une liaison P=N: iminophosphène pour **2** (d_{PN} = 1,481 Å), iminophosphane pour **4** (d_{PN} = 1,882 Å). Cette dernière valeur particulièrement grande est liée à la non-existence de transfert d'électrons de l'atome d'azote vers le phosphore.

3.2.2 *Anions $(H_2PNH)^-$ et $(HPNH_2)^-$*

Bien que les réactions d'abstraction d'hydrogène sur des aminophosphanes aient été fréquemment invoquées lors de synthèses de dérivés phosphorés et azotés (16), ce n'est que récemment que la structure des espèces anioniques impliquées a été discutée, par Cowley et Kemp (17), sur des bases expérimentales.

Nous avons donc entrepris l'analyse quantochimique de telles entités en examinant les deux systèmes, $(HPNH_2)^-$ et $(H_2PNH)^-$. Ils correspondent au départ d'un proton des sites P ou N de l'aminophosphane, $(H_2PNH)^-$ pouvant être aussi considéré comme issu d'une déprotonation sur le phosphore de l'iminophosphane. Il faut remarquer également que l'addition de H^- sur l'iminophosphène peut conduire formellement aux mêmes espèces.



Les valeurs minimisées des paramètres géométriques et les répartitions de charge obtenues pour $(HPNH_2)^-$ et $(H_2PNH)^-$ sont présentées dans le tableau 3 et la figure 4.

Dans le cas de $(H_2PNH)^-$, c'est-à-dire lors d'un départ de H^+ du site azote de l'aminophosphane, nous constatons que l'apport électronique ne reste pas localisé sur cet atome, mais qu'un transfert vers le phosphore intervient via une interaction $p^{\pi}-d^{\pi}$; on note ainsi une population de 0,4 sur les orbitales d du phosphore et de 0,31 sur les diffuses de ce même centre. La polarité de la liaison demeure toutefois $P^+—N^-$. Ce transfert

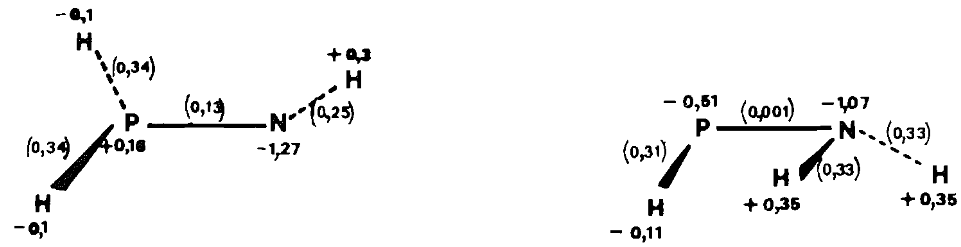


FIG. 4. $(H_2PNH)^-$ $(HPNH_2)^-$. Analyse des populations selon Mulliken. Charges nettes totales – populations de recouvrement (entre parenthèses).

TABLEAU 3. Géométries minimisées pour $(H_2PNH)^-$ et $(HPNH_2)^{-a}$

Paramètre		P—N	1,64	1,81
N—H₁	1	1,01
N—H₂

$H_4\hat{P}N$	106,48	
$H_3\hat{P}H_4$	89,54	
H_3PNH_1	132,32	60,62
H_4PNH_1	133,12	61,03
$E_{el}{}^{b}$	−452,8237	−448,9542
$E_{rep}{}^{c}$ (N—N)	56,37089	52,48178
E_t	−396,542795	−396,47239
ΔE_t	51,39	

[a]Longueurs, en angstroms; angles, en degrés; E, en hartrees; $\Delta E_t = E(H_2PNH^-) - E(HPNH_2^-)$, en kilojoules par mole.
[b]E_{el}: énergie d'interaction électron–noyau, électron–électron.
[c]E_{rep}: énergie de répulsion internucléaire.

est à l'origine de la diminution de la longueur de liaison P—N (1,64 Å) vis-à-vis de celle obtenue dans l'aminophosphane (1,685 Å).

On remarque également une pyramidalisation plus marquée de l'atome de phosphore et une rotation du système qui conduit à une augmentation de l'angle entre les paires du phosphore et de l'azote vis-à-vis de l'aminophosphane. L'HOMO de $(H_2PNH)^-$ résulte de l'interaction entre ces paires, l'avant dernière orbitale occupée correspondant à la paire de l'azote relocalisée par suite de la déprotonation.

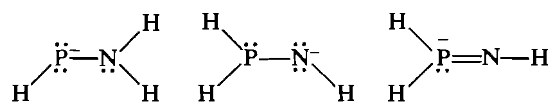
En ce qui concerne l'anion $(HPNH_2)^-$, au contraire, l'apport électronique engendré par le départ de H^+, lié à P, reste localisé sur le phosphore qui présente ainsi une charge de −0,5; on remarque également, pour ce composé, une population importante de 0,77 sur les fonctions diffuses. La répartition de charge au niveau du groupement NH_2 est inchangée par rapport à celle obtenue dans l'aminophosphane; l'atome d'azote demeure néanmoins le centre porteur de la charge négative la plus importante du système.

Étant donné qu'une interaction $p_P^\pi - d_N^\pi$ ne peut intervenir, nous observons, dans ce cas, un allongement très notable de la liaison P—N (1,685 Å dans H_2PNH_2 et 1,81 Å dans $(HPNH_2)^-$), qui s'accompagne d'une nette pyramidalisation de l'atome d'azote ($\Sigma\hat{N} = 333{,}6°$).

Il est également intéressant de noter une disposition des paires du phosphore et de l'azote identique à ce qu'elle était dans H_2PNH_2, aucune rotation n'ayant eu lieu consécutivement au départ de H^+. L'interaction entre ces paires intervient au niveau de l'avant dernière orbitale occupée du système, l'HOMO étant caractéristique de la paire du phosphore relocalisée suite au départ de H^+.

Les deux anions, $(H_2PNH)^-$ et $(HPNH_2)^-$, présentent ainsi des structures bien différenciées. Dans le cas de $(H_2PNH)^-$, elle est du type $H_2\overset{\delta^-}{P}—\overset{\delta^-}{N}H$, avec une forte charge négative sur l'atome d'azote. L'anion $(HPNH_2)^-$ correspond, quant à lui, à une structure $H\overset{\delta^-}{P} — \overset{\delta^-\delta^-}{N}H_2$, simple liaison P—N avec atome d'azote porteur de la charge négative la plus importante.

Ainsi, parmi les formes limites généralement envisagées pour ces anions, les résultats obtenus mettent parfaitement en évidence une structure **6**, et non **7**, pour l'anion $(H_2PNH)^-$ qui apparaît comme un anion de type phospha-amidure.



5 **6** **7**

Ceci va à l'encontre des conclusions énoncées par Cowley (17) qui, sur des bases expérimentales, proposait une structure de type **7** pour ce même anion.

En ce qui concerne les stabilités relatives des deux anions examinés, l'allongement notable de la liaison P—N dans $(HPNH_2)^-$ induit une diminution importante des répulsions internucléaires, ce qui conduit globalement, en dépit d'une énergie électronique plus basse pour $(H_2PNH)^-$, à une forme $(HPNH_2)^-$ favorisée énergétiquement. Il faut noter, toutefois, que la différence est assez faible entre les deux anions (de l'ordre de 51 kJ/mol).

L'aminophosphane peut être ainsi considérée comme un acide de site P. Ces résultats sont cohérents avec ceux obtenus par Lohr et Ponas (*4b*) lors d'une étude sur les acidités en phase gazeuse de systèmes à liaisons multiples C—N et C—P et, en particulier, de H_3CNH_2 et H_3CPH_2. Ces deux derniers composés sont apparus comme des acides de site hétéro-atome, H_3CPH_2 étant un acide plus fort que H_3CNH_2.

Si nous examinons maintenant l'addition de H^- sur l'iminophosphène, nous ne pouvons, au vu de la répartition de charge sur ce système ($Q_P = +0{,}49$; $Q_N = -0{,}81$), que conclure à un produit cinétique $(H_2PNH)^-$ de structure **6**, différent du produit thermodynamique $(HPNH_2)^-$ de structure **5**. Les dispositions relatives de la paire de l'azote et des protons du groupement PH_2 permettent d'envisager cette évolution via une migration 1,2, ce qui pourrait expliquer raisonnablement les résultats expérimentaux (17).

Received December 20, 1984

GEORGE A. KATSOULOS, CONSTANTINOS A. TSIPIS, and FOTIOS D. VAKOULIS. Can. J. Chem. **63**, 3249 (1985).

A new series of homobinuclear iron(III) halobisdithiocarbamate complexes antiferromagnetically coupled through a molecular halogen bridging unit has been synthesised and studied. The complexes have been characterized chemically and by spectroscopic methods and magnetic susceptibility measurements. The volatility characteristics and thermogravimetric analysis data for the new compounds are also studied. Finally, quantum-chemical calculations have been used to provide a qualitative guide to the possible pathways for the superexchange processes observed in these molecular magnetic systems, as well as to interpret their electronic spectra.

GEORGE A. KATSOULOS, CONSTANTINOS A. TSIPIS et FOTIOS D. VAKOULIS. Can. J. Chem. **63**, 3249 (1985).

On a synthétisé et étudié une nouvelle série de complexes halobisdithiocarbamate de fer(III) couplés de façon antiferromagnétique à l'aide d'un halogène moléculaire en position de pont. On a fait appel à des méthodes spectroscopiques et à des mesures de susceptibilité magnétique pour caractériser chimiquement ces complexes. On a également étudié les caractéristiques de volatilité et les données d'analyse thermogravimétrique des nouveaux composés. Finalement on a fait appel à des calculs de chimie quantique pour obtenir un guide qualitatif des voies d'accès possibles au processus de superéchange observé dans ces systèmes magnétiques moléculaires, aussi bien que pour interpréter leur spectre électronique.

[Traduit par le journal]

Introduction

The rare occurrence of iron(III) in an $S = 3/2$ ground state associated with an unusual coordination of the iron atom has made the halobis(*N*,*N*-dialkyldithiocarbamato)iron(III) complexes the object of numerous experimental and theoretical investigations (1−8). In addition, the iodobisdithiocarbamate complexes, $[Fe(R_2dtc)_2I]$, were found to react with molecular iodine in aprotic solvents (9) to yield several types of products, including those with stoichiometry $Fe(R_2dtc)_2I_2$ (where R = Me or Pr^i) and $Fe(Et_2dtc)_2I_3$. The last compound has been proved to be an iron(III) complex containing coordinated triiodide, the presence of an I_3^- unit with one of the terminal iodines bonded to the metal ion of the $\{Fe(Et_2dtc)_2\}$ group being demonstrated by ^{57}Fe and ^{129}I Mössbauer spectroscopy (10, 11). For the remaining complexes it has been suggested (9) that they may be adducts of the type $2[Fe(R_2dtc)_2I]\cdot I_2$. Furthermore, Mössbauer measurements on the molecular complex $Fe(Me_2dtc)_2I_2$ have demonstrated (11) that it contains a molecular iodine (I_2) unit mediating the formation of weakly coupled dimers with antiferromagnetic interaction. These conclusions are consistent with an X-ray crystal structure determination (12) of another derivative of this series containing the pyrrolidinyldithiocarbamato ligand. Thus, an interaction between the iodine molecule and the iodide ligands of the complex was confirmed, with the overall result that there would be a loose "dimeric" association of the type $(R_2NCS_2)_2FeI\cdots I{-}I\cdots IFe(S_2CNR_2)_2$. Although a detailed study of the effect of the particular iron(III) dithiocarbamate used on the course of the aforesaid reaction has not been undertaken, it does appear that the nitrogen substituent R has an effect on the nature of the obtained products (9, 11). Moreover, a study of the role of bridging molecular halogens (X_2') in the formation of antiferromagnetically coupled dimers would be of considerable importance. In this paper we present our results on the synthesis and the characterization of some new homobinuclear iron(III) dithiocarbamate complexes of the general formula $[Fe(R_2dtc)_2X]_2(\mu - X_2')$, as well as the theoretical prediction based on EHMO quantum-chemical calculations, of the possible pathways for the superexchange processes observed in these compounds.

Experimental

Physical measurements

Infrared spectra were recorded in the 4000−250 cm^{-1} region on a Perkin−Elmer 467 spectrophotometer using KBr pellets or Nujol mulls. Electronic spectra were obtained on a Cary 17DX spectrophotometer using freshly prepared methylene chloride solutions. Mössbauer spectra were obtained with a conventional constant accelerator spectrometer. The source was 25 mCi of ^{57}Co in a copper matrix. Mass spectra were measured on a RMU-6L Hitachi Perkin−Elmer mass spectrometer with ionisation source of T-2*p* type operating at 70 eV. The thermogravimetric curves were obtained on a TGS-2 Perkin−Elmer thermobalance using nitrogen furnace atmosphere. Magnetic susceptibility measurements in solid state were done by the Faraday technique at different magnetic field strengths using $Hg[Co(SCN)_4]$ as the calibrant. Diamagnetic corrections were made using Pascal's constants. Conductivity measurements were done in a Wheatstone bridge Model RC 216B$_2$ using 10^{-3} *M* solutions in acetone. Molecular weights were determined using a Perkin−Elmer molecular weight apparatus Model 115 in methylene chloride solutions. The elemental analysis of carbon, nitrogen, and hydrogen was performed on a Perkin−Elmer 240B Elemental Analyzer.

Starting materials

All solvents were of reagent grade and were used without further purification in synthetic work. Tris(*N*,*N*-disubstituted-dithiocarbamato)iron(III) complexes were prepared and recrystallised as previously reported (13). The halobis(*N*,*N*-dialkyldithiocarbamato)iron(III) complexes were obtained from the reaction between an iron(III) trisdithiocarbamate and aqueous hydrohalic acid (1, 2). All the other reagents were obtained commercially.

Preparation of the complexes

The new complexes were prepared according to the following general method. A solution of 2 mmol of the appropriate $[Fe(R_2dtc)_2X]$ complex in 50 cm^3 of methylene chloride was treated with 1 mmol of I_2 or Br_2 dissolved in the same solvent and the reaction mixture was left for 5 h at room temperature under continuous magnetic stirring.

*Calculated values in parentheses.

After the addition of 50 cm^3 of cyclohexane the solution was condensed to a small volume under reduced pressure, causing black crystals to separate. The resultant solid material was filtered off, washed with cyclohexane, recrystallised several times from methylene chloride–cyclohexane mixtures, and dried under vacuum.

Calculations

The quantum-chemical calculations on the $[Fe(Pr^i_2dtc)_2Br]$ complex and the linear tetratomic halogeno bridging unit were carried out by means of the LCAO-MO extended Hückel method (14). The computer program (15) used was based on the self-consistent charge method. The cartesian coordinates of the atoms were computed using a recently published (8) crystal structure of the complex which is depicted in Fig. 1. The z axis of the coordinate system has been taken along the direction of Fe—Br, and the x axis in the plane of the atoms Fe, Br, and C, and parallel to the plane of the four sulfur atoms. In order to limit the number of atomic wave functions, the isopropyl groups were replaced by hydrogen atoms, the N—H distance being 1.01 Å (16). The basis set used consisted of all the 49 valence orbitals, in which 58 electrons were placed. The radial part of the atomic wave functions were the double exponent (3*d* functions) or single exponent (all the other functions) Slater-type orbitals given in the literature (17–19).

Results and discussion

Reaction of a solution of $[Fe(R_2dtc)_2X]$ (R = Me, Et, Pr^i; X = Cl, Br, I) in methylene chloride with molecular halogens (2:1 molar ratios) rapidly gave clear solutions from which solid compounds of stoichiometry $Fe(R_2dtc)_2XX'$ (X′ = Br, I) were isolated, either by precipitation with cyclohexane or by removal of solvent under reduced pressure. The dihalide complexes crystallise as black crystals. These crystals are soluble in acetone, methylene chloride, acetonitrile, and nitromethane to give brownish solutions, and are insoluble in benzene, cyclohexane, ether, and water. The compounds are stable in the absence of moist air, while in the presence of atmospheric moisture they slowly hydrolyse. This tendency to hydrolyse increases on passing from the chloro to the iodo derivatives, perhaps because of the presence of a weak iron(III)–iodine bond. They also decompose at lower temperatures than the corresponding halobisdithiocarbamate complexes. The low values of the molar conductivity in anhydrous acetone (2–10 ohm^{-1} cm^2 mol^{-1}) indicate the non-electrolyte character of the complexes, whereas osmometric molecular-weight measurements in methylene chloride show them to be dimeric. Data from elemental analyses, decomposition temperatures, and molecular weights of the new compounds are given in Table 1.

The compounds were found to react with olefins, such as ethylene and cyclohexene, in methylene chloride solutions to afford green crystalline complexes formulated as $[Fe(R_2dtc)_2X]$ and the corresponding 1,2-addition products. The halogenation reaction were carried out at room temperature and, in the case of ethylene, under atmospheric pressure. This easy addition of halogen to an unhindered carbon–carbon double bond strongly suggests that the complexes under investigation may be adducts with molecular halogens.

The frequencies (cm^{-1}) of the most relevant absorption bands in the ir spectra of the studied compounds and their tentative assignments are presented in Table 2. The ν(C$\cdots$N)

and $\nu(\text{C}\overset{\cdot\cdot}{-}\text{S})$ stretching frequencies fall in the range 1540–1515 cm^{-1} and 1025–992 cm^{-1}, respectively. The presence of only one strong band in the region where $\nu(\text{C}\overset{\cdot\cdot}{-}\text{S})$ lies, strongly supports chelation of the dithiocarbamates, a doublet being expected in the region 1000 ± 70 cm^{-1} in the unchelated dithiocarbamates (20). However, the spectra did not show any peaks that could be ascribed to monodentate dithiocarbamato ligand or to thiuram disulfide (21). The bidentate bonding mode of the dithio-ligands was further established by the position of the $\nu(\text{C}\overset{\cdot\cdot}{-}\text{N})$ band (22). This band is shifted to somewhat higher frequencies compared to the corresponding $[Fe(R_2dtc)_2X]$ complexes (9, 23). Furthermore, single peaks have been observed in the range 370–355 cm^{-1}, which are likely to be due to metal–sulfur modes according to the observed values for the dithiocarbamates of the first-row transition metals. Finally, the bands occurring in the range 318–295 cm^{-1} were attributed to the iron–halogen stretching vibrations (24, 25) and are in good agreement with those previously reported for the five-coordinated iron(III) halobisdithiocarbamate complexes. This is an indication for the coordination of only one halogen to the metal atom, because the vibrational modes ν(Fe—X) are strongly dependent on the stereochemistry of the complex for an increasing of the coordination number results in a decrease in the M—X stretching vibrations (23, 26).

The magnetic susceptibilities corrected for diamagnetism are shown in Table 3. The room-temperature moments for all the derivatives range from 3.77 to 3.92 BM, thus approximating well the theoretical effective moment of 3.88 BM predicted for $S = 3/2$ and $g = 2.00$. The structural requirement for such behaviour can be met by a square-pyramidal symmetry around the ferric ion (27, 28).

Mössbauer spectra were recorded at liquid nitrogen temperature; the data (δ, isomer shift; Δ, quadrupole splitting) for the new complexes are listed in Table 3, and a representative spectrum is shown in Fig. 2. The spectra consisted of widely split doublets with peaks of equal area. The experimental error in the quadrupole splittings was estimated to be ± 0.03 mm s^{-1} on the bases of replicate measurements. The isomer shifts occur in the range 0.67–0.70 mm s^{-1}, relative to sodium nitroprusside. These values are comparable to the shifts expected for iron(III) dithiocarbamates (3, 29). The complexes had also quadrupole splittings in the 2.71–2.86 mm s^{-1} range similar to those of the $[Fe(R_2dtc)_2X]$ complexes (3). The similarity in magnetic susceptibility and in the Mössbauer parameters suggests a geometrical correspondence between the studied compounds and the halobisdithiocarbamates, which can be attained by the presence of a molecular halogen moiety weakly bonded to two $\{Fe(R_2dtc)_2X\}$ units as required by stoichiometry. The proposed configuration for the five-coordinated $2[Fe(R_2dtc)_2X]\cdot X'_2$ complexes is depicted in Fig. 3.

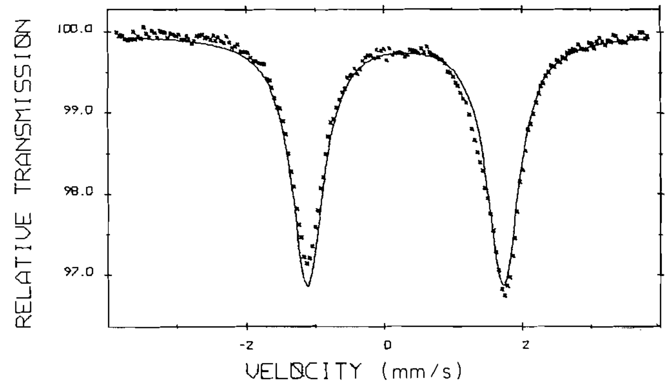

FIG. 2. Mössbauer spectrum of $[Fe(Pr^i_2dtc)_2I]_2(\mu - Br_2)$ at 77 K.

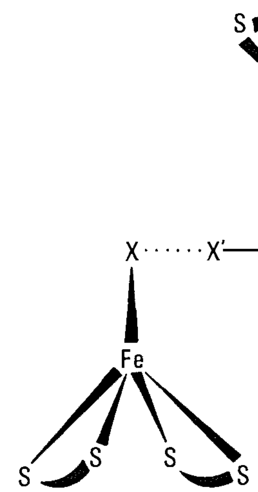

FIG. 3. Proposed structural model of the $[Fe(R_2dtc)_2X]_2(\mu - X'_2)$ complexes.

The thermogravimetric study of both the halobisdithiocarbamates and the compounds under investigation further confirms the formation of a dimeric association through a molecular halogen bridging unit. For example, the thermograms of the $[Fe(Et_2dtc)_2Cl]$ complex show three endothermic decompositions corresponding to a three-stage weight loss of 78%. A long plateau then results for which there is evidence of FeS formation. The three weight losses occur at 260, 300, and 410°C and can be attributed to the loss of $\{2Et_2NCS\}$ (found: 61.0%; calcd.: 59.9%), {Cl} (found: 9.0%; calcd.: 9.1%), and {S} (found: 8.0%; calcd.: 8.3%), respectively. On the other hand, the thermograms of $2[Fe(Et_2dtc)_2Cl]\cdot I_2$ composed of three weight losses, all of them endothermic at 110, 290, and 370°C which can be attributed to loss of $\{4Et_2NCS + 2I\}$ (found: 69.5%; calcd.: 69.8%), {2Cl} (found: 7.0%; calcd.: 6.9%), and {2S} (found: 6.5%; calcd.: 6.2%), respectively.

Finally, the mass spectra of the compounds reveal the presence of a molecular halogen moiety. The molecular ions of the dimeric species are not detected in the ms. The absence of molecular ions can be attributed either to pyrolytic decomposition, in the direct inlet, under the high temperature which was used (200–280°C), or to electron impact. However, in all spectra the ion $[Fe(R_2dtc)_2X]^+$ is present and can be regarded as direct fragment of the molecular ion upon elimination of the molecular halogen bridging unit. This is further supported by

the detection of a peak with a variable relative intensity (54−100%) due to $X_2'^{+\cdot}$ ion. In the cases of $2[Fe(R_2dtc)_2X]\cdot I_2$ complexes the base peak of the spectra corresponds to the $I_2^{+\cdot}$ ion.

The electronic spectra of the studied compounds are complicated, exhibiting a number of overlapping intense bands in the ultraviolet and visible region. The complicated nature of the spectra prevents any simple classification and rationalization in terms of the ligand-field model. This is a general problem encountered in any ligand-field interpretation of the electronic spectra of many iron(III) halobisdithiocarbamate complexes (3, 7, 9, 23, 30). Therefore, an attempt was made to interpret the electronic spectra of the dimeric complexes by means of EHMO quantum-chemical calculations on a representative mononuclear complex bearing the same FeS_4X chromophore, namely, $[Fe(Pr^i_2dtc)_2Br]$.

The calculated ground state 1e energies, charge distributions and partial wave analyses for the valence molecular orbitals associated with both the central atom and the ligand valence AO's of the complex are summarized in Table 4. The energy level spacings of the predominantly 3*d*-orbital-based MO's are given in Fig. 4. This sequence of MO's is exactly the one expected on the basis of esr measurements (2). The high energy of the $6a_2$ molecular orbital accounts for the spin pairing of the fifth *d* electron. The occupied valence molecular orbitals of the complex have energies in the range −30.49 to −9.73 eV, while the energies of the virtual MO's range from −7.85 to 80.02 eV. The two-center energy terms for the Fe—Br (−7.05 eV) and Fe—S (−4.74 eV) bonds clearly show that the former is the most covalent. This is also consistent with the

values of the overlap population which is 0.574 and 0.412, respectively. These values are characteristic for a high covalency of the two bonds which further explains the low positive charge on the central atom (Q = +0.099). Moreover, the net charges on the Br and S atoms are −0.373 and −0.039 electron units, respectively. The higher electron charge on the halogeno-ligand may also account for its weak interactions with the molecular halogen through the virtual σ^* antibonding

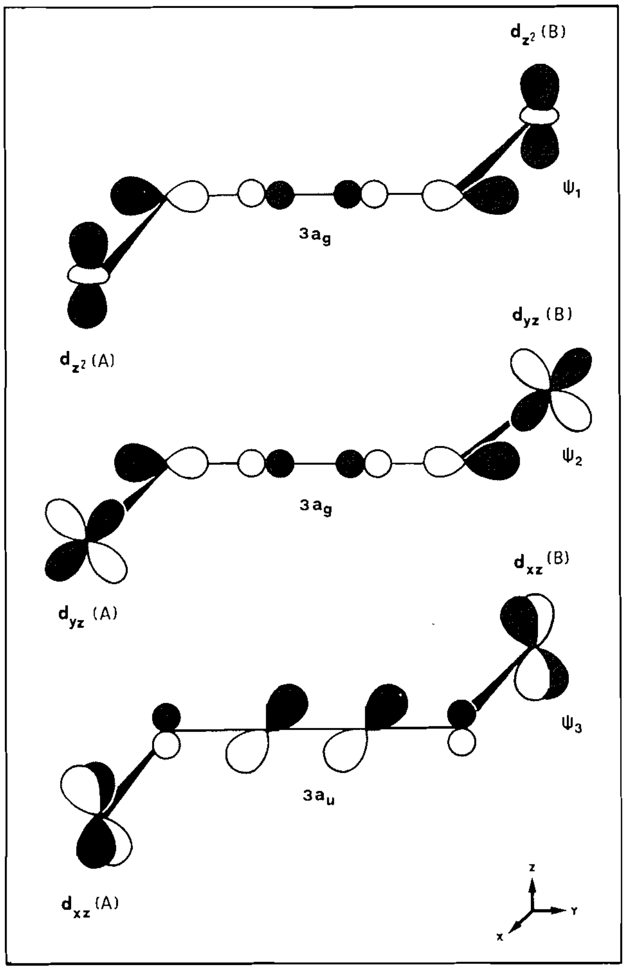

FIG. 5. The possible pairwise orbital interactions supporting the superexchange processes observed in the $[Fe(R_2dtc)_2X]_2(\mu - X_2')$ molecular magnetic systems.

MO. The accumulation of the electron density on the σ^* virtual MO of the molecular halogen due to this interaction also explains the enhancement of its reactivity towards 1,2-addition reactions to olefins.

The electronic spectral data of the complexes under investigation along with the assignments of the absorption bands are listed in Tables 5 and 6. Assignments were made by associating the observed bands with the transitions they most nearly match in energy. From these results it is evident that the electronic spectra of the $2[Fe(R_2dtc)_2X]\cdot X_2'$ complexes are similar to those of the corresponding halobisdithiocarbamates. Therefore, it is reasonable to invoke the same assignments of the bands for the dihalide complexes as well. Furthermore, the interaction between the molecular iodine and coordinated halogen in these cases persists in methylene chloride solutions since the characteristic visible peak of I_2 at 520−540 nm is missing. Unfortunately, the crystal-field bands in the electronic spectra of the compounds were impossible to observe, since the intense charge transfer bands are extended up to the ligand field part of the spectra, obscuring the weaker $d-d$ transitions. However, spectra obtained in solid state (Nujol mull) showed two distinct absorption bands at 6.9 and 8.7 kK which are in fair agreement with the spectral excitation energies derived from the quantum-chemical calculations, bearing in mind the approximate nature of the extended Hückel method.

Although facilities for low-temperature magnetic susceptibility studies were unavailable, the dependence of the room-temperature magnetic data on the magnetic field strengths strongly suggests weak magnetic exchange interactions between the two iron centers propagated probably through the linear tetratomic halogeno bridging unit (31). The low magnetic moments observed both at low and high field strengths as well as the slight decrease of the moments as the magnetic field decreases support evidence for the operation of antiferromagnetism in these compounds. The occurrence of antiferromagnetically coupled dimers and a magnetic ordering transition below 1.6 K have already been demonstrated for the $Fe(Me_2dtc)_2I_2$ complex (11) by ^{57}Fe Mössbauer spectra from 4.2 to 1.36 K and in magnetic fields up to 7.5 T. Consequently, in order to obtain additional insight on the possible pathways for the superexchange processes observed in these molecular magnetic systems, in terms of pairwise interactions of dimeric molecular orbitals (32), EHMO quantum-chemical calculations have also been used. According to these calculations the following three magnetic orbitals, depicted schematically in Fig. 5, are predicted to be the most suitable pathways for the transmission of the electronic effects over long distances:

$$\psi_1(A_g) \sim d_{z^2}(A) + 3a_g + d_{z^2}(B)$$

$$\psi_2(A_g) \sim d_{yz}(A) + 3a_g + d_{yz}(B)$$

$$\psi_3(A_u) \sim d_{xz}(A) + 3a_u - d_{xz}(B)$$

Received February 4, 1985

PIOTR MILART and TADEUSZ M. KRYGOWSKI. Can. J. Chem. **63**, 3256 (1985).

Substituent effect on the long wave band in uv/vis spectra of *p*-substituted *N*-(α-methylarylidene)-*p*-(*N*′,*N*′-dimethylamino)-anilines (X = CH_3O, CH_3, H, Cl, and NO_2) measured in eight solvents follows well the Hammett equation. Solvent effect on this band depends well on E_T only for Cl- and NO_2-substituted species. Both these findings support the conclusion that the long-wave band is in fact intramolecular charge transfer form the basicity center ($\bar{N}Me_2$ or $\bar{N}{=}C$) towards substituents.

PIOTR MILART et TADEUSZ M. KRYGOWSKI. Can. J. Chem. **63**, 3256 (1985).

Opérant dans huit solvants différents, on a mesuré l'effet des substituants sur la bande aux grandes ondes des spectres uv/vis des *N*-(α-méthylarylidènes)-*p*-(*N*′,*N*′-diméthylamino)-anilines substituées en position para par des groupements X = OCH_3, CH_3, H, Cl et NO_2; les valeurs obtenues peuvent être reliés par une équation de Hammett. L'effet du solvant sur cette bande ne dépend bien de E_T que pour les espèces substituées par les groupements Cl et NO_2. Ces deux résultats sont en accord avec la conclusion selon laquelle la bande aux grandes ondes est de fait la forme de transfert de charge intramoléculaire du centre de basicité ($\bar{N}Me_2$ ou $\bar{N}{=}C$) vers les substituants.

[Traduit par le journal]

The title compounds belong to a group of π-electron systems widely studied for their spectral properties strongly dependent on molecular geometry (1–4), which, in turn, is sometimes very complex. X-ray diffraction studies for similar systems (5, 6) corroborate this picture. In *p*- and *p*′-disubstituted benzylideneanilines with an electron donor and acceptor there occurs an intramolecular charge transfer between these substituents. Hence the title systems may bear dipoles depending on the kind of substituent at the *p*-position of the benzilidene ring. Hence it seems interesting to study solvent effect on uv/vis spectral properties of the differently *p*-substituted title compounds. For this purpose the complementary Lewis acid–base description (7) of solvent effect is applied using solvent parameters E_T (8, 9) for acidity and B_{KT} (10) for basicity. The standard Hammett rule is used to interpret the substituent effect on $\tilde{\nu}$-values.

Results and discussion

The title compounds read schematically as follows:

[1] 
with substituents X = (*a*) OCH_3, (*b*) CH_3, (*c*) H, (*d*) Cl, and (*e*) NO_2. In these systems two uv bands are observed: the E_2 band due to local excitation in one of two rings of the molecules of **1***a*–*e*, and the K-band due to intramolecular CT transition. In the long-wave part of the spectra there exists an additional band (λ ~ 350–400 nm) strongly dependent on both, the nature of substituent X, as well as the solvent in which the measurement is carried out. Table 1 presents $\tilde{\nu}$-values of the long-wave band for **1***a*–*e* measured in eight solvents. From the scheme of canonical forms for molecules under study [2],

TABLE 1. Location of the long-wave absorption band for compounds **1***a*–*e* in eight solvents

Solvent	Location of the long-wave absorption band $\tilde{\nu}$/cm^{-1}				
	1*a*	**1***b*	**1***c*	**1***d*	**1***e*
N-Hexane	28 400	27 700	27 500	26 750	23 600
Carbon tetrachloride	29 150	28 320	27 750	26 420	23 530
1,4-Dioxane	28 090	27 700	27 620	26 880	23 980
Tetrahydrofuran	27 780	27 470	27 400	26 590	23 700
Methylene chloride	28 730	28 100	27 750	26 880	24 100
Acetonitrile	28 570	28 010	27 600	27 030	24 510
Ethanol	29 300	28 700	28 250	27 400	24 570
Methanol	28 900	28 700	28 500	27 620	24 700

[2] 
it follows that both electrical poles may be involved in specific interactions with solvent molecules. Hence, two solvent parameters, one for Lewis acidity, E_T (9, 10), and the other, B_{KT} (11, 12), for Lewis basicity of the solvent, were used to describe the dependence of $\tilde{\nu}$-values on the nature of the solvent:

[3] $\tilde{\nu} = \alpha E_T^N + \tilde{\nu}_0$

and

[4] $\tilde{\nu} = \beta B_{KT} + \tilde{\nu}'_0$

Table 2 compiles the relevent data for compounds **1***a*–*e*. It is

TABLE 2. Intercepts and slopes of eqs. [3] and [4]

Compound	α	$\tilde{\nu}_0$ (cm^{-1})	Corr. coeff. of eq. [3] R	β	$\tilde{\nu}'_0$ (cm^{-1})	Corr. coeff. of eq. [4] R
1*a*	839	28 340	0.451	230	28 543	0.140
1*b*	1217	27 690	0.732	686	27 873	0.467
1*c*	1135	27 425	0.826	811	27 542	0.668
1*d*	1312	26 522	0.925	940	26 657	0.748
1*e*	1597	23 570	0.959	997	23 774	0.678

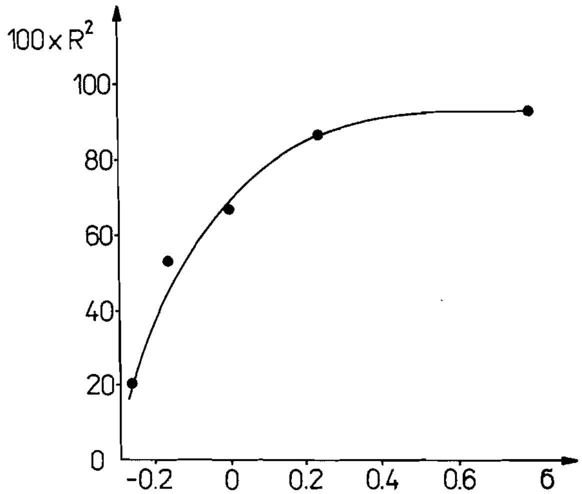

FIG. 1. Plot of the total variance explained by eq. [3], i.e. by Lewis acidity properties of solvents, against the Hammett σ_p describing an increasing dipolar character as a result of intramolecular CT of the system under study.

immediately apparent that only eq. [3] works well and only in the case when X is strongly electron accepting (Cl, NO_2). Quite unusual graph presented in Fig. 1 is obtained while plotting the squarred correlation coefficient of eq. [3] R^2 against the Hammett σ_p-constants. Its statistical meaning is that an increase of electron-accepting properties of the substituent causes an increase of percentage of the variance explained by eq. [3], i.e. by Lewis acidity of the solvents. Consequently, this means that negatively charged poles of **1***a–e* compounds are much more involved in solvent effect on electron excitation than the positively charged ones.

When we analyze the data of Table 1 by using the Hammett equation [5]

$$[5] \quad \tilde{\nu} = \rho\sigma + \tilde{\nu}''_0$$

the dependence of $\tilde{\nu}$ on the substituent effects appears to be very good (R always > 0.97). The relevant data are given in Table 3. The negative value of ρ means that an increase of electron-accepting properties of X induces a decrease of energy necessary to excite electrons involved in the transition. These electrons may come from the NMe_2— or C=$\bar{N}$-groups. This conclusion is in line with the values of the slopes in eq. [3]. For **1***d* and **1***e* the agreement of eq. [3] with experimental results ranges from good to excellent. This means that an increase of Lewis acidity of the solvents induces an increase of energy necessary to excite electrons involved in the transition. This would suggest that the transition is really an intramolecular charge transfer from most probably the $\bar{N}Me_2$-group. If the lone electron pair at the $\bar{N}$=C group had to be excited, it would need a break of near co-planarity of the whole π-electron system in **1***a–e*. However, this cannot be excluded since eq. [3]

TABLE 3. Statistical data of eq. [5]

Solvent	ρ	$\tilde{\nu}_0$ (cm^{-1})	R
n-Hexane	−4421	27 924	−0.984
Carbon tetrachloride	−5248	27 632	−0.998
1,4-Dioxane	−3886	27 297	−0.975
Tetrahydrofuran	−3901	27 032	−0.974
Methylene chloride	−4308	27 603	−0.994
Acetonitrile	−3742	27 570	−0.992
Ethanol	−4412	28 147	−0.995
Methanol	−4072	28 148	−0.979

evidently fails for $\sigma \gtrsim 0$. More detailed studies have to be undertaken in this direction.

Experimental

Compounds **1***a–e* were obtained by literature methods (13, 14) *Anal.* calcd. for **1***e*: $C_{16}H_{17}N_3O_2$ (mw 283.3); C 67.77, H 6.00, N 14.83; found: C 67.57, H 5.88, N 14.63. mp 182–183°C, ms *m/e*: 233 (M^+, 100%); 284 (M + 1, 17.7%); 268 (M − 15, 32.0%); ir (Nujol) cm^{-1}; 1590 s (C=N); 1520 s (NO_{2as}); 1345 s (NO_{2s}), ^{1}H nmr ($CDCl_3$) TMS/ppm: 8.26 (q, 4H, $J_{H,H}$ = 6 Hz); 6.90 (s, 4H); 3.08 (s, 6H); 2.40 (s, 3H).

The uv/vis spectra were recorded on a VSU-2P/Zeiss Jena, GDR/apparatus using quartz cuvettes 1.0 and 0.1 cm. The solutions were prepared directly before the measurements using solvents of spectrographic or pro analysis purity or they were purified by standard procedures (15).

Received March 26, 1985

GEORGE I. BIRNBAUM, DENNIS D. KLUG, JOHN A. RIPMEESTER, and JOHN S. TSE. Can J. Chem. **63**, 3258 (1985).

A crystal grown by slow evaporation from a solution of cyclotriveratrylene (CTV) in toluene was found to be an inclusion compound with water as the only encaged guest. Its stoichiometry is $C_{27}H_{30}O_6 \cdot xH_2O$ (x = 0.16) and it belongs to the monoclinic space group $C2/c$, with a = 24.216(21), b = 9.636(2), c = 23.117(4) Å, β = 118.08(5)°, Z = 8. X-ray intensity data were measured with a diffractometer and the structure was solved by direct methods. Least-squares refinement, which included all hydrogen atoms of the host molecule, converged at R = 0.046 for 3986 observed reflections. The geometry of the host molecule is compared to that of analogous structures and to cyclononatriene. Significant differences are ascribed to the effects of homoaromaticity and steric strain. Both the X-ray analysis and an FTIR study of the OH stretching show that the water molecules are weakly bound to the methoxy oxygen atoms of CTV. The molecular packing of CTV clathrates is discussed on the basis of crystallographic and spectroscopic evidence.

GEORGE I. BIRNBAUM, DENNIS D. KLUG, JOHN A. RIPMEESTER et JOHN S. TSE. Can J. Chem. **63**, 3258 (1985).

On a trouvé que le cristal obtenu par évaporation lente d'une solution de cyclotrivératrylène (CTV) dans le toluène est un composé d'inclusion contenant uniquement l'eau comme molécule encagée. Ce composé a pour formule $C_{27}H_{30}O_6 \cdot xH_2O$ (x = 0,16) et appartient au groupe d'espace monoclinique $C2/c$, avec a = 24,216(21), b = 9,636(2), c = 23,117(4) Å, β = 118,08(5)° et Z = 8. On a utilisé un diffractomètre pour mesurer les données d'intensité de rayons X et on a résolu la structure par des méthodes directes. On l'a affinée par la méthode des moindres carrés, qui inclut tous les atomes d'hydrogènes de la molécule hôte, jusqu'à une valeur de R = 0,046 pour 3986 réflexions observées. On a comparé la géométrie de la molécule hôte à celle de structures analogues et à celle du cyclononatriène. On attribue les différences marquantes à des effets d'hétéroaromaticité et des contraintes stériques. Tant l'analyse par des rayons X que des études IR/TF de l'élongation du groupe OH montrent que les molécules d'eau sont faiblement liées à l'atome d'oxygène du groupe méthoxy du CTV. On discute de l'entassement moléculaire des clathrates de CTV en se basant sur les données cristallographiques et spectroscopiques.

[Traduit par le journal]

Introduction

Solvates of cyclotriveratrylene (2,3,7,8,12,13-hexamethoxy-5,10-dihydro-15*H*-tribenzo[*a*,*d*,*g*]cyclononene; CTV) were first reported in the literature during the fifties (1). Subsequent infrared and X-ray diffraction studies revealed that these CTV complexes belong to a special class of channel inclusion compounds. From X-ray measurements, it was found that the unit cell dimensions of the inclusion complexes depended on the size of the guest molecules (2, 3). Two monoclinic phases have been identified (3), the unique feature of each modification being the near constancy of the unit cell dimension b. The angle β and the lengths of a and c, however, vary with the nature of the encaged molecules. So far, only one complete crystal structure is available for CTV complexes, that for CTV·0.5benzene·water (CTVBW) (4). In the crystal, the host cyclotriveratrylene cyclic trimer adopts an umbrella shape with the methyl groups approximately coplanar with the benzene rings. The benzene and water molecules were trapped inside the cavities formed by the methyl groups.

Recently, CTV clathrates have been prepared by dissolving the host compound in different organic solvents (5). The crystalline solids obtained were characterized by nmr techniques. It was found that the inclusion process for CTV is quite selective and, in some instances, depends critically on the presence or absence of water. From the analysis of the solid state ^{13}C nmr splitting patterns it was established that more than one structural type of CTV inclusion can be formed (5). For example, the solid obtained by slow cooling of a solution of CTV in hot toluene gave a ^{13}C nmr splitting pattern which could only be assigned if there were two magnetically distinct CTV molecules per asymmetric unit, with toluene as the sole occupant in the cavities. This observation is at variance with the crystal structure of CTVBW where only one CTV molecule is present in each asymmetric unit. Obviously, there are fundamental structural differences between the two compounds. More intriguingly, when the toluene solution was allowed to evaporate in air, the crystal obtained showed a completely different nmr splitting pattern which was very similar to that obtained for the benzene analogue, but no toluene was found to be present. The ^{1}H nmr spectrum of the dissolved material showed a trace of water to be present, suggesting water might be the only encaged guest.

About twenty years ago, an X-ray analysis of *cis*,*cis*,*cis*-1,4,7-cyclononatriene was carried out (6) in order to resolve contradictory predictions of homoaromaticity in that molecule (7–9). The authors concluded that the $C(sp^2)$—$C(sp^3)$—$C(sp^2)$ bond angle of 108° and the $C(sp^2)\cdots C(sp^2)$ nonbonded distance of 2.46 Å in the crown-shaped triene precluded the possibility of any meaningful homoaromaticity. However, a subsequent study established a significant extent of through-space interaction between the π-orbitals by the use of photoelectron spectroscopy (10). More recently, the structure of a CTV homologue has been studied by X-ray crystallography (11) in addition to CTVBW (4) and a complex of cyclotri-

[a]The nonhydrogen coordinates of CTV were multiplied by 10^5, the U_{eq} values by 10^4, and the parameters of O(W) and the hydrogen atoms by 10^3.

catechylene with 2-propanol (CTCP) (12). In all these molecules, the nine-membered ring also assumes a crown conformation, but the detailed geometry differs significantly from that of the unsubstituted cyclononatriene ring system. In order to investigate this fact, on which previous authors have not commented, as well as the guest−host interaction, we decided to carry out a precise crystallographic study. This seemed particularly desirable since in previous X-ray analyses (4, 6, 11, 12) the positions of the hydrogen atoms had not been refined. We obtained single crystals of a complex of CTV with water (CTVW) and subjected them to X-ray and FTIR analyses.

Experimental

Pale yellow prismatic crystals of cyclotriveratrylene hydrate were grown from slow evaporation of a saturated solution of CTV in toluene. Precession photographs showed systematic absences corresponding to space groups Cc and $C2/c$. A crystal fragment measuring 0.15 × 0.30 × 0.45 mm was mounted on an Enraf-Nonius CAD-4 diffractometer; it provided the following data:

$C_{27}H_{30}O_6.xH_2O$ (x = 0.16) fw = 453.39
Monoclinic, a = 24.216(21), b = 9.636(2), c = 23.117(4) Å, β = 118.08(5)°, V = 4759.30 Å^3, ρ_c = 1.26 g cm^{-3}, Z = 8 (20°C; CuKα_1, λ = 1.54056 Å); F(000) = 1931, μ(CuKα) = 6.8 cm^{-1}.

The cell dimensions were determined with high precision from angular settings of 22 high-order (2θ > 80°) reflections. However, their values, particularly that of a, were fluctuating during the data collection. The dimensions listed above represent averages of 15 determinations. Intensities were measured with Ni-filtered CuKα radiation, using ω/2θ scans with variable scan ranges and speeds. Three standard reflections were monitored at frequent intervals. Their intensities fluctuated by ±2% and decreased by 7% during the course of the data collection. There are 4905 unique reflections accessible to the diffractometer (2θ ≦ 150°), of which 900 with $I \leqq 3\sigma(I)$ were considered unobserved. The intensities were corrected for Lorentz and polarization factors; absorption corrections were considered unnecessary.

The structure was determined by direct methods with the aid of the computer program MULTAN78 (13). The E statistics clearly indicated a centrosymmetric space group, i.e. $C2/c$ rather than Cc. Of the 64 starting sets subjected to tangent refinement, the solution with the highest combined figure of merit yielded an E map on which all 33 nonhydrogen atoms of the CTV molecule were located. Atomic parameters were refined by block-diagonal least squares. All 30 hydrogen atoms were located on a difference Fourier map and refined with isotropic temperature parameters. The scattering factors were taken from the "International tables for X-ray crystallography" (14). Throughout the refinement the function $\Sigma w(|F_o| - |F_c|)^2$ was minimized and a factor of 0.8 applied to all shifts. The following weighting scheme was used during the final stages: $w = w_1 \cdot w_2$, where $w_1 = 1$ for $|F_o| \leqq 15$, $w_1 = 15/|F_o|$ for $|F_o| > 15$; and $w_2 = \sin^2\theta/0.5$ for $\sin^2\theta < 0.5$, $w_2 = 1$ for $\sin^2\theta \geqq 0.5$. This scheme made the average value of $w(\Delta F^2)$ independent of $|F_o|$ and $\sin^2\theta$. The refinement converged to a conventional residual index $R = (\Sigma|\Delta F|/\Sigma|F_o|)$ of 0.051 and a weighted index $R_w = (\Sigma w\Delta F^2/\Sigma wF_o^2)^{1/2}$ of 0.062. A difference Fourier map calculated at this stage revealed a residual peak

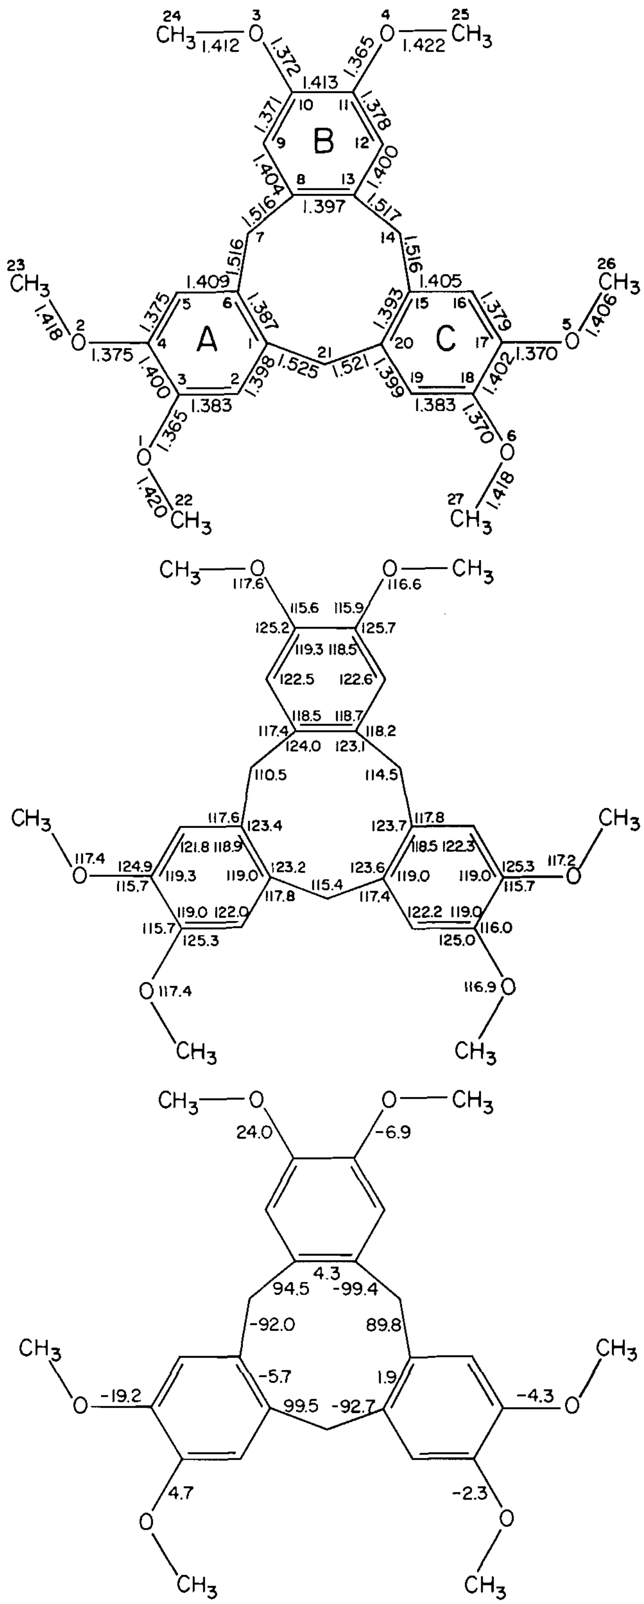

FIG. 1. Geometry of the CTV molecule. (Top) Bond distances (Å); their estimated standard deviations (esd's) are 0.002–0.003 Å. (Center) Bond angles (deg); their esd's are 0.13–0.16°. (Bottom) Torsion angles (deg); their esd's are 0.2–0.3°.

five times stronger than the background, but no other significant features. On the basis of nonbonded distances this peak was attributed to the oxygen atom of a disordered water molecule. Consequently, the refinement was resumed with the inclusion of the coordinates, an isotropic temperature parameter, and an occupancy factor for this oxygen atom. After the final cycle this occupancy factor converged to 0.16(1). The average shift for all atomic parameters equalled 0.04σ and the largest one 0.53σ. There was a significant drop of the residual indices: the final R value is 0.046 and R_w is 0.057 for 3986 observed reflections (19 low-order reflections suffered from extinction and were given zero weights). The final atomic parameters are listed in Table 1. Lists of anisotropic temperature parameters and of observed and calculated structure factors are available.[2]

The mid-infrared spectra were obtained using a Nicolet 7199 FTIR spectrometer equipped with a HgCdTe photodetector. All spectra were run with a resolution of 2 cm^{-1}. Samples (3.6 mg) were mixed with 0.40 g of KBr in a mechanical grinder and pressed into clear pellets. A KBr pellet was used as the background.

Results and discussion

The cyclononatriene ring assumes a crown conformation but certain details of its geometry (Fig. 1) are significantly different from those in unsubstituted cyclononatriene (6). We believe that this fact is due to the absence of homoaromaticity in this, as well as in related cyclic trimers. Without this stabilizing interaction, one of the aromatic rings (in the present case, ring C) is pushed away from the other two rings. Consequently, the bond angles at C(14) (114.5°) and C(21) (115.4°) and the nonbonded distances C(1)···C(20) (2.575 Å) and C(13)···C(15) (2.550 Å) are substantially increased. On the other hand, the increases of the bond angle at C(7) (110.5°) and the C(6)···C(8) distance (2.492 Å) are much smaller. Thus, instead of possessing a threefold molecular symmetry, all molecules related to CTV exhibit approximate mirror symmetry with a "mirror plane" passing through one of the methylene carbon atoms and through the midpoints of the transannular aromatic ring.

With a cyclononatriene ring in crown conformation, there are three C(sp^3)—H bonds pointed towards the center of the ring, bringing the three hydrogen atoms into close contact (Fig. 2). In the case of cyclononatriene this nonbonded distance was calculated to be 1.95 Å (6). This being the first X-ray analysis of a CTV molecule in which hydrogen parameters were refined (we normalized all C—H bond lengths to 1.09 Å), we can examine the H···H contacts in detail. It has been assumed (6, 15) that in cyclononatriene an increase of the bond angles at the trigonal carbon atoms from 120 to 124° is necessary in order to separate the intraannular hydrogen atoms. However, an increase of the C═C—C angle is normal is *cis*-substituted olefins (16). Consequently, the decrease in the tetrahedral bond angles to 108° in cyclononatriene which accompanies homoconjugation is sufficient to keep the intraannular hydrogen atoms at a distance of 1.95 Å. In CTVW, where, in the absence of homoaromaticity, two of the angles are 115.0 ± 0.5°, this separation can be achieved only by a substantial twist of the crown conformation. Thus, the endocyclic torsion angles at the aromatic bonds at rings A and B are 5.0 ± 0.7° rather than 0° (Fig. 1). Other torsion angles also differ from the values (0° and 95°) found in cyclononatriene. As a result, the intraannular H···H distances in CTVW are as follows: H(72)···H(142) 1.96 Å, H(72)···H(212) 1.96 Å, and H(142)···H(212) 2.06 Å. Similar distances are likely to occur in related molecules as well, since in all of them the crown conformation was found to be twisted (4, 11, 12).

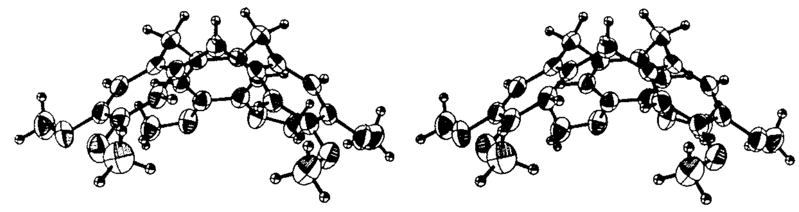

FIG. 2. Stereoscopic view of CTV. The ellipsoids correspond to 50% probability.

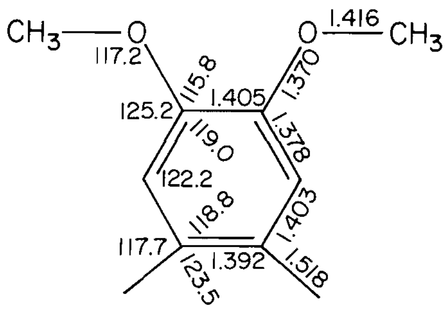

FIG. 3. Average bond lengths (Å) and bond angles (deg) in CTV.

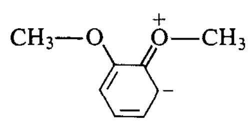
The present X-ray analysis yielded results which are significantly more precise than those of the previously reported CTV inclusion compounds; it is the first structure determination in which the parameters of all atoms of such a host molecule were refined. Consequently, it is of interest to examine other details of the geometry of cyclotriveratrylene.

The lengths of the symmetrically disposed bonds do not deviate significantly from average values, therefore these values (shown in Fig. 3) can be used in the discussion. The bond lengths in the aromatic rings are significantly unequal: they show an alternating pattern of shorter and longer bonds which indicates partial localization of the π electrons. This is a common feature of *o*-dimethoxybenzenes (17, 18), presumably indicating some contribution of the resonance form shown below.



The bond angles, apart from those in the nine-membered ring, are also quite similar and can therefore be averaged. In the aromatic rings the angles deviate significantly from 120°, reflecting the effect of substitution by electron-donating groups (19). The exocyclic angles at the methoxy-bearing carbon atoms and at the oxygen atoms are in very good agreement with values obtained from a survey of crystal structures of *o*-dimethoxybenzenes (20). The survey revealed a strong preference of near-coplanarity of the methoxy groups with the aromatic rings. On the other hand, using photoelectron spectroscopy and *ab initio* STO-3G calculations, the authors found a preference for a nonplanar conformation, with one O—CH_3 bond perpendicular to the aromatic ring, both in solution and in the gas phase. In view of the contribution of the resonance form shown above (which is only one of several possible ones), this was a surprising finding which has since been disproved, at least for the solution conformation (21, 22). In the present structure the methyl groups are somewhat displaced from the ring planes in order to diminish interactions between their hydrogen atoms and those at the ortho positions. Further relief is provided by increases of the C—C—O and C—O—CH_3 bond angles.

In agreement with the nmr study (5), the X-ray analysis shows no evidence of included toluene, water being the only guest material. It is somewhat surprising that the CTV molecules preferentially occlude the water from the air rather than the more abundant toluene molecules. This suggests that polar guest molecules are preferred over nonpolar ones. The fluctuations in the length of *a* and of the intensities of the standard reflections (see above) suggest that the occupancy factor of O(W) may have varied during the period of data collection, possibly as a function of humidity. In this inclusion compound, water molecules reside in channels between CTV molecules stacked along *y* (Fig. 4). Their oxygen atoms are at a distance of 3.086 Å from the methoxy oxygen atoms O(4), indicating a weak O(W)—H···O(4) hydrogen bond. The distance to the other methoxy oxygen, O(W)···O(3) 3.330 Å, is too long for a hydrogen bond. This weak binding of water accounts for the low occupancy factor of 0.16 which means that, on average, there is approximately one water molecule per unit cell, even though there is enough space for eight molecules. If all positions were fully occupied, the shortest O(W)···O(W) distances would be 2.783 Å.

To understand the mode of hydrogen bonding in the complex, we have measured the ir spectrum of the clathrate in the OH stretching region. It is generally recognized that there are several characteristic changes in the OH stretch mode when hydrogen bonds are formed (23–25): (*a*) a decrease in the frequency of the OH stretch band; (*b*) an increase in the half-width of this band; and (*c*) an increase in the intensity of this vibrational mode. Furthermore, there have been several studies of the relationship between the hydrogen bonded O···O distance and OH stretching frequencies (26–29). It has been found that in all cases the OH frequency shifts monotonically to lower frequencies as the O···O distance is decreased. For instance, the OH stretching frequency in the matrix isolated water dimer occurs at 3691 and 3546 cm^{-1} (30, 31), and is lowered to 3150 cm^{-1} in hexagonal ice (32). These frequency shifts can be correlated with the O···O separation of 2.976 Å in the dimer (33) and 2.72 Å in the ice (23).

Two peaks can be readily identified from the ir spectrum in the OH region (Fig. 5): a strong absorption at 3520 cm^{-1} (A, ν_1) with a band width of 38 cm^{-1} and a weak but sharp band at 3660 cm^{-1} (B, ν_3) with a half-width of 20 cm^{-1}. The two bands support the conclusion that the ν_1 symmetric and the ν_3 asymmetric stretching vibrations are shifted by about 140 and 100 cm^{-1} from the gas phase values for water (34). Their splitting is increased by 40 cm^{-1} and the band at 3520 cm^{-1} has a higher intensity than the band at 3660 cm^{-1}. This is in contrast with the gas phase spectrum for an isolated water molecule, but is in qualitative agreement with the water dimer spectrum and recent theoretical calculations on the ir stretching intensities (25). It indicates that the encaged water molecule is probably weakly hydrogen-bonded to one of the methoxy oxygen atoms of CTV. From the correlation between the

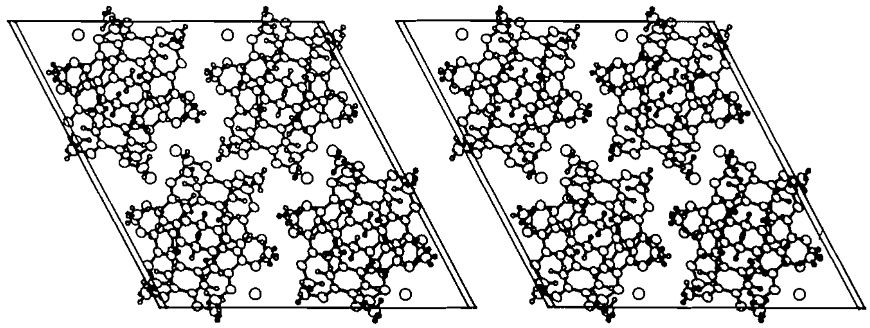


FIG. 4. Stereoscopic view along y of the molecular packing in the crystal. The isolated circles indicate possible positions of the water oxygen atoms. The directions of the axes are $x \nwarrow$ and $z \rightarrow$.

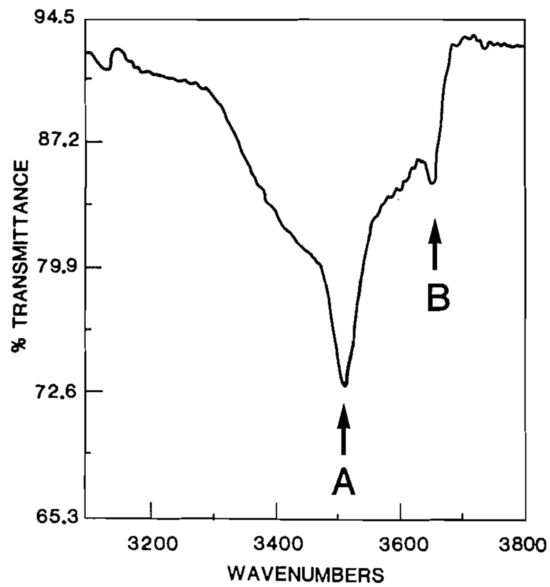

FIG. 5. Infrared spectrum of CTVW in the OH stretching region.

O···O distance and OH stretching frequencies shifts in a crystalline monohydrate (29), we estimate the O···O distance to be 2.98 Å. This value is fairly close to the O(4)···O(W) distance of 3.086 Å. Our ir data obviously do not support a water dimer structure with a short O···O distance. Therefore the water is best described as weakly bonded to the methoxy oxygen and is not tightly held. This is very similar to the situation in the CTVBW complex (4).

In several classes of organic clathrates the crystal packing of the host molecules is not affected significantly by the nature or the size of the occluded guests (35). Most notable among them are 4-*p*-hydroxyphenyl-2,2,4-trimethylchroman, widely known as Dianin's compound (36), and β-hydroquinone (37). In order to compare the packing of the CTV molecules in the present structure with that in the CTVBW crystal, we have calculated unit cell parameters for different cell choices in space group $C2/c$ (38). The parameters for CTVBW are very similar to those reported in an earlier X-ray study (3). The results, given in Table 2, show very similar cell lengths in the two crystals, but the angle β is greatly decreased in CTVBW. This gives rise to a larger unit cell (5341.0 Å^3) which can accommodate the sterically demanding benzene guest molecules.

On the basis of the ir spectra and the unit cell dimensions, it has been suggested (3) that the CTV clathrates may be classified into two monoclinic modifications. CTV clathrates of the

TABLE 2. Alternative lattice parameters for CTVBW and CTVW

Compound, space group	Lattice parameters	Transformation matrix
	$a = 22.748$ Å	0 0 1
CTVBW	$b = 9.629$ Å	0 $\bar{1}$ 0
$I2/a$	$c = 24.397$ Å	1 0 1
	$\beta = 91.91°$	
	$a = 23.117$ Å	0 0 $\bar{1}$
CTVW	$b = 9.636$ Å	0 $\bar{1}$ 0
$A2/a$	$c = 24.216$ Å	$\bar{1}$ 0 0
	$\beta = 118.08°$	

α phase have very similar a and c cell dimensions. On the other hand, the β phases have a longer c dimension (3, 4). Their ir spectra in the fingerprint region also show characteristic differences. More specifically (3), the α form shows no splitting of the ir peaks at 850, 994, and 1039 cm^{-1} and the absorption at 905 cm^{-1} is absent. We measured the ir spectrum of CTVW in this region and the positions of the peaks (in cm^{-1}) can be compared with those previously reported (3) for CTV·benzene (given in parentheses): 740 (737), 851 (850), 870 (871), 884 (882), 926 (925), 942 (942), 996 (994), 1041 (1039). Apart from a slight variation in the vibration frequencies, the two spectra are very similar. Due to better instrumental resolution, we also observed shoulders adjacent to the peaks at 851 and 1041 cm^{-1}; however, no splitting of the peaks was observed. According to the spectral features, we can identify the CTVW crystal as an α phase. The similarity in the length of the a and c cell dimensions also supports such an assignment. From limited experimental data, the α phase seems to be formed when bulky molecules are included, whereas the β phase allows the accommodation of thread-like molecules. Since water is quite small as compared with organic molecules, it is perhaps surprising that the CTVW crystal exists in the α form. Our results imply that the classification scheme may not be well founded and more structural information on this class of clathrates is needed to clarify the situation. This would be especially interesting in view of the fact that such clathrates may be used as suitable systems for photochemical reactions and as carriers of drugs.

Acknowledgments

Apart from MULTAN78 (13), all crystallographic computations were carried out with programs written by Ahmed *et al.* (39). Figures 2 and 4 were drawn with the ORTEP program of Johnson (40).

Ab initio SCF and MRD-CI description of the $A\,^2A' - X\,^2A''$ transition of the as yet unknown HNCl molecule

BRITTA L. SCHÜRMANN AND ROBERT J. BUENKER

Lehrstuhl für Theoretische Chemie, Bergische Universität – Gesamthochschule Wuppertal, Gaußstr. 20, 5600 Wuppertal 1, West Germany

Received March 15, 1985

BRITTA L. SCHÜRMANN and ROBERT J. BUENKER. Can. J. Chem. **63**, 3264 (1985).

Ab initio potential curves of the $X\,^2A''$ ground state and the first excited $A\,^2A'$ state ($^2\Pi$ in linear geometry) of HNCl are calculated employing multi-reference single- and double-excitation configuration interaction in order to aid in the search for this system experimentally. A vibrational analysis (frequencies and Franck–Condon factors) of the $A\,^2A' - X\,^2A''$ transition is undertaken by neglecting coupling between the various modes. Diagonal and off-diagonal force constants together with the fundamental frequencies have been calculated by including mode coupling for both electronic states, and oscillator strengths and radiative lifetimes are also obtained. Comparison with theoretical and experimental results for other isovalent systems is also made in order to establish trends in this group of HAB systems.

BRITTA L. SCHÜRMANN et ROBERT J. BUENKER. Can. J. Chem. **63**, 3264 (1985).

Dans le but d'aider dans la recherche expérimentale de ce système et utilisant l'interaction de configuration à excitation simple ou double et à multi-référence, on a calculé les courbes de potentiel *ab initio* de l'état fondamental $X\,^2A''$ et du premier état excité $A\,^2A'$ ($^2\Pi$ dans la géométrie linéaire) du HNCl. On a entrepris une analyse vibrationelle (fréquences et facteurs de Franck–Condon) de la transition $A\,^2A' - X\,^2A''$ en négligeant le couplage entre les divers modes. On a calculé les constantes de force, selon la diagonale et hors de la diagonale, ainsi que les fréquences fondamentales en incluant le mode de couplage des deux états électroniques et l'on a également obtenu les forces de l'oscillateur ainsi que les temps de vie radiative. Dans le but d'établir les tendances existant dans ce groupe de systèmes de type HAB, on a également établi des comparaisons avec les résultats théoriques et expérimentaux d'autres systèmes isovalents.

[Traduit par le journal]

1. Introduction

In recent years it has been possible to predict details of the spectra of a number of small polyatomic molecules with sufficiently high accuracy to help in the subsequent identification of these systems experimentally. Several examples include the H_2CS (1, 2) and HSO (3–5) systems, for which both computed electronic transition energies and vibrational frequencies could be used effectively in confirming the successful generation of previously unknown substances. At the same time a radiative lifetime of the $^2A'$ state of HSO was predicted (3) to lie in the 40–50 μs range, and recently experimental work (6) has led to an observed value of 51 ± 5 μs. In a similar theoretical study (7) vibrational frequencies and transition energies for the related system HS_2 were obtained, which have recently aided in the detection of this molecule in chemiluminescence experiments (8); again good agreement between measured and computed vibrational frequencies was observed.

With this background it seemed promising to carry out similar calculations for a number of other HAB molecules which are as yet unobserved. Because of their isovalent relationship to the HO_2–HSO–HS_2 family, the group of molecules of HAB type in which the two non-hydrogenic atoms come from the nitrogen and halogen groups of the periodic table, respectively, is especially appropriate for such a systematic theoretical investigation. The parent system HNF is known experimentally and a theoretical study of this system has recently been reported (9), again finding good agreement with observed data. The subject of the present series of calculations is HNCl, for which no experimental information is as yet available.

The aim of this study is to predict vibrational frequencies, Franck–Condon factors and radiative lifetimes for the $A\,^2A' - X\,^2A''$ transition of HNCl, as well as the equilibrium geometries of the two participating electronic states.

2. Technical details

The cartesian gaussian AO basis set employed in this work is of double-zeta + polarization quality for the nitrogen and chlorine species. The ($4s$, $2p$) nitrogen contraction is taken from Dunning (10), augmented by a set of (six-component) d-type functions ($\alpha = 0.95$), while the chlorine set ($6s$, $5p$) is adopted from the work of McLean *et al.* (11), with the addition of a d-type set with exponent $\alpha = 0.68$. For the hydrogen atom a special ($5s$) contraction of Clementi and Lie (12) plus an s-type function ($\alpha = 1.0$) and a p-type polarization function with exponent $\alpha = 0.85$ is employed. The total AO basis thus consists of 52 contracted functions and the molecule is treated in C_s symmetry.

The *ab initio* calculations are of the standard multi-reference single- and double-excitation CI type with configuration selection, energy extrapolation (13, 14) and full-CI correction (FCI, 15); the computer programs employed make use of the Table CI method (16). A core of three MO's corresponding to the $1s$ shell of nitrogen and the $1s$ and $2s$ shells of chlorine is kept doubly occupied in all configurations, while the two virtual MO's with highest orbital energy are excluded from the excitation procedure. The single- and double-excitation space is generated from two reference configurations for each state. These correspond to $\ldots 9a'^2 10a'^2 2a''^2 3a''$ and $\ldots 9a'^2 10a'^2 2a''\, 3a''^2$ for the ground state and $\ldots 9a'^2 10a'\, 2a''^2 3a''^2$ and $\ldots 9a'\, 10a'^2 2a''^2 3a''^2$ for the $^2A'$ excited state. For geometries with large r(N—H) and r(N—Cl) nuclear distances the number of reference configurations has been increased to four. In all of these calculations the c^2 value is in the 0.89–0.90 range, which is typical for a system with 19 active electrons. The total generated (MRD-CI) configuration space has an order of approximately 200 000, and the dimension of the secular equations actually solved (the selection threshold corresponds to 10 μhartree) is in the range of 6000 – 8000. For each electronic state the parent SCF orbitals are used as MO basis for constructing the many-electron basis functions. The final (FCI) results take the energy contribution of higher-than-double-excitation-configurations into account by means of the

formula (15)

$$\Delta E = \left(1 - \sum_p^{\text{ref}} c_p^2\right)(E_{\text{ref}} - E_{\text{CI}})$$

3. Potential energy curves and equilibrium geometries

The first series of calculations was undertaken to determine the equilibrium geometries of both the $^2A''$ and $^2A'$ states at the estimated full CI (FCI) level. The equilibrium structural parameters (Table 1) obtained for the ground state $^2A''$ in the given basis are: H—N = 1.026 Å, N—Cl = 1.714 Å and ∠HNCl = 102.51°; for the first excited state $^2A'$ the equilibrium geometry was calculated to be: H—N = 1.046 Å, N—Cl = 1.626 Å and ∠HNCl = 132.9°. These values have been calculated by determination of the minimum of the three-dimensional hyperface polynominal fit of the FCI energy data. The resulting T_e value corresponding to the difference of the FCI energies of these two electronic states in their equilibrium geometries is 21772 cm^{-1} (2.70 eV).

It is interesting to compare these results with the corresponding data for HNF, for which experimental results are also available. The N—H bond distances for the $X\ ^2A''$ and $A\ ^2A'$ states have been computed (9) to be 1.03 and 1.02 Å, while the observed values are somewhat larger (1.06 and 1.03 Å, respectively). The N—F bond distance decreases by 0.05 Å from ground to excited state in the computations and only 0.03 Å experimentally, so the present N—Cl decrease of 0.09 Å for HNCl is relatively large. Finally the bond angle values for HNF are 101.1° ($X\ ^2A''$) and 123.2° ($A\ ^2A'$), compared with the observed values of 105 and 125°, so a definite trend toward increased bond angle upon excitation is typical for such systems. According to qualitative MO theory (Walsh's rules) this fact is understandable in terms of the fact that the $10a'$ MO favors strongly bent geometries (doubly occupied in $^2A''$ but only singly in $^2A'$) while $3a''$ shows a much weaker trend in this direction (oppositely occupied in the two states). This state of affairs is mirrored in the spectroscopic data for such systems by the occurrence of a fairly long bending progression in both absorption and emission.

Nonetheless comparison with isovalent HSO shows that such

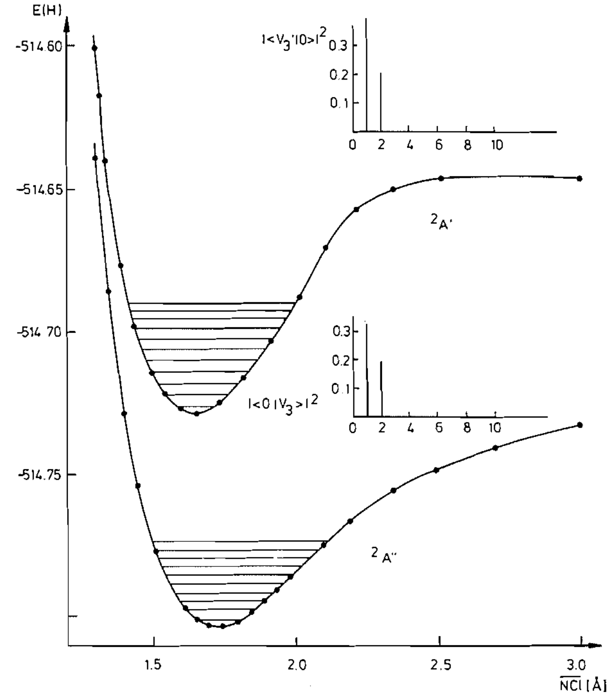

FIG. 1. Potential energy curves for the N—Cl stretching coordinate: HN = 1.026 Å, ∠HNCl = 102.51° for the ground state; HN = 1.046 Å, ∠HNCl = 132.9° for the first excited state. Franck–Condon factors for the transition from $v'' = 0$ to various v' levels and from $v_2' = 0$ to v_2'' are also given.

trends cannot be relied upon to any great degree. In this case both calculations (3) and experiment (4, 5) show that the bond angle decreases slightly upon excitation to $^2A'$, while the S—O bond length increases by 0.13 Å, in stark contrast to what is found for HNF and HNCl. At the same time the HS_2 geometrical data parallel that of HSO quite closely. Thus it is evident that there is a clear distinction between such isovalent systems, with the nitrogen–halogen HAB type showing a different pattern than their oxygen–oxygen counterparts.

The T_e value for HNF is computed at the FCI level as 2.58 eV, only 0.12 eV smaller than the present result for HNCl. These energy separations are again quite different from what is found for the HSO–HO_2–HS_2 group of isovalent species. In HO_2 the T_e value is computed (17) to be only 0.85 eV, and nearly the same result (0.86 eV) is found for HS_2 (7). The mixed system HSO has a computed T_e value of 1.56 eV (3), some 0.2 eV smaller than measured (4, 5), but its SOH isomer, not yet found experimentally, is predicted (18) to have an even smaller T_e value of only 0.65 eV.

Starting from these equilibrium geometries one-dimensional potential curves corresponding to the stretching and bending coordinates for the $^2A''$ and $^2A'$ states have been calculated without further optimization of the other structural parameters. The computations have not been extended to geometries associated with molecular fragmentation, but it is still helpful to note which asymptotes correspond to the two states under study. For N—Cl dissociation the products are in both cases Cl(^2P_u) + HN($^3\Sigma^-$). These species represent three open shells and there is therefore a change in configuration from the equilibrium structures (one open shell) in each instance; at the bond distance values treated in this work, this change in configuration has not yet occurred, so the convergence of the two N—Cl potential curves at infinite bond distance is not apparent in

TABLE 2. Franck–Condon factors $|\langle v'' | v' \rangle|^2$ for the normal modes of HNCl[a]

	H—N vibrations[a]		N—Cl vibrations		Bending vibrations

[a] In each case the fixed geometrical parameters are held equal to the respective equilibrium values of the states under consideration.

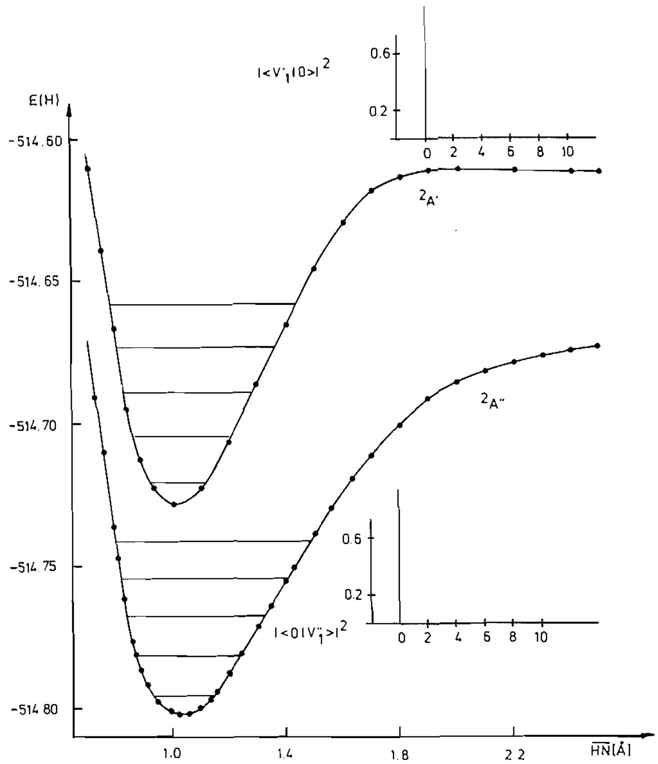

FIG. 2. Potential energy curves for the H—N stretching coordinate: NCl = 1.714 Å, ∠HNCl = 102.51° for the ground state; NCl = 1.626 Å, ∠HNCl = 132.9° for the $^2A'$ state.

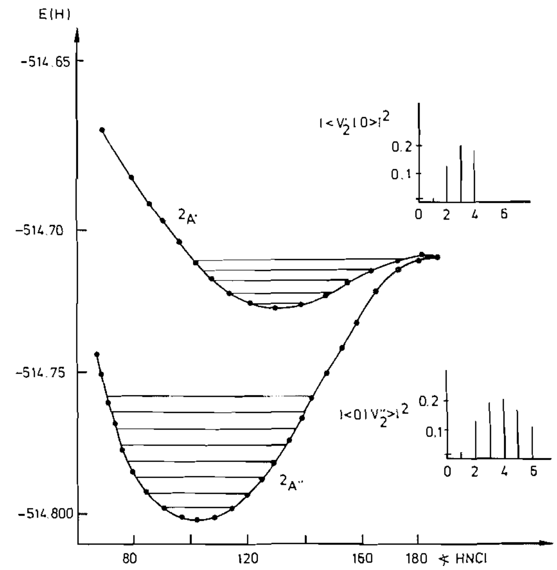

FIG. 3. Potential energy curves for the bending coordinate: NCl = 1.714 Å, HN = 1.026 Å for $^2A''$; NCl = 1.626 Å, HN = 1.046 Å for $^2A'$. Only the bound vibrational levels are calculated for the $^2A'$ state.

Fig. 1, in which the computed results are plotted. A similar situation is expected for the N—H potential curves at large distances (Fig. 2), except that in this case $X\ ^2A''$ dissociates adiabatically to H(^2S) + NCl($^3\Sigma^-$) while $A\ ^2A'$ correlates with H(^2S) + NCl ($^1\Delta$), again asymptotes with three open shells.

The corresponding bending potential curves are given in Fig. 3 and show that the two states become degenerate ($^2\pi$) in linear nuclear conformations. As a result a significant Renner–Teller interaction is expected in the region of the relatively small barrier to linearity of the upper state; an analogous situation has been found for HNF (9), for which the Renner–Teller coupling between the $X\ ^2A''$ and $A\ ^2A'$ states has been carried out explicitly.

4. Vibrational calculations and $X\ ^2A'' - A\ ^2A'$ intensity distribution

The potential curves obtained at the estimated FCI level have been fitted in terms of various polynomial expansions in order to calculate the vibrational energies within the Born–Oppenheimer approximation.

In the first approach coupling between the various modes was neglected and sixth-order polynomials were employed in each instance; standard deviations for the fits are in the order of 1×10^{-4} au. The corresponding vibrational levels and wavefunctions were then obtained in each case by diagonalizing the corresponding one-dimensional Hamiltonian matrices formed in the basis of harmonic oscillator eigenfunctions (19). These calculations were supplemented by a coupled-mode treatment employing the Wilson **F–G** matrix formalism (20), in which a strictly harmonic force field is assumed. For this purpose a three-dimensional fit to the energy hypersurface was carried out, with a root-mean-square deviation of 3×10^{-4} au being found. The resulting molecular constants and vibrational frequencies are also contained in Table 1.

The N—H stretching frequencies are 100–300 cm^{-1} higher for each electronic state than those obtained earlier for HNF (the independent-mode approximation was used exclusively for HNF (9)), but the differences are only slightly greater than the error bars expected for such calculations. In both systems it is found that the NH stretching frequency increases by 400–500 cm^{-1} upon excitation to the upper $^2A'$ electronic state. The bending frequency also shows similar behavior in HNF and HNCl upon electronic excitation, dropping in each case by roughly 300 cm^{-1}, as seems understandable on the

TABLE 3. Oscillator strengths and radiative lifetimes for the $^2A' - {}^2A''$ transition in HNCl at several nuclear geometries

Geometry NCl (au) HN = 1.939 au	∠HNCl (deg)	$f(\vec{r})$	τ (s)

3.23	102.5	0.183×10^{-2}	0.206×10^{-5}
3.23	107.0	0.168×10^{-2}	0.249×10^{-5}
3.33	102.5	0.190×10^{-2}	0.206×10^{-5}
3.23	97.0	0.197×10^{-2}	0.173×10^{-5}
HNF HN = 1.93 au NF = 2.56 au ∠HNF = 100°		0.396×10^{-2}	0.659×10^{-6}

basis of the potential curves of Fig. 3. In this case the computed frequencies should be accurate to 50−100 cm^{-1} according to previous experience with such calculations. Similar error limits are expected for the N—Cl frequencies, which indicate an increase of 140−160 cm^{-1} upon excitation. Not surprisingly, these results are uniformly smaller (by about 300 cm^{-1}) for the corresponding NF frequencies in HNF (9). Results for the deuterated isomer are also given in Table 2.

Previous experience with employing such *ab initio* calculations to aid in the identification of unknown substances has indicated that Franck−Condon factors are especially useful in this regard (3, 7). These results have been obtained in the independent-mode approximation (Table 2) and are also shown in Figs. 1−3 along with the corresponding potential curves; in each case results are given for both absorption and emission relative to the $v = 0$ level of the initial state. Vibrational progressions are expected in both the bending and N—Cl modes, particularly the former; only the O−O transition should be observed for N—H stretch, however. The most intense cold band should occur to the $^2A'$ (0,1,3) vibronic state with a computed transition energy of 26072 cm^{-1}.

As a further aid for the identification of the HNCl system, the dipole transition moment matrix element $\overrightarrow{R_{e'e''}}$ has been computed between the $X\ ^2A''$ and $A\ ^2A'$ states. These results are then employed to compute the oscillator strength f and radiative lifetime τ of the excited state according to the formulae (21):

$$[1]\quad f(r) = \frac{2}{3}\,|\,\overrightarrow{R_{e'e''}}\,|^2 \Delta E$$

and

$$[2]\quad \tau = 1.499/f(\vec{r})\,\bar{\nu}^2$$

where $\bar{\nu}$ is the transition energy in units of cm^{-1} and otherwise atomic units are assumed. For this purpose both electronic states have been obtained employing the ground state MO's as one-electron basis, in order to avoid the more cumbersome computations which are required when different (nonorthogonal) MO basis sets are used for each state. These results have been obtained at several N—Cl bond distances and bending angles and are shown in Table 3. The indication is that the transition moment is relatively insensitive to changes in nuclear conformation, so that the Franck−Condon approximation is quite acceptable for this system. A relatively long lifetime of 2.0 μs is indicated for this dipole-allowed transition, which is at least consistent with the fact that in the linear geometry the transition moment vanishes by symmetry. This lifetime is nonetheless some three times longer than that of HNF, which has also been computed in the present study (0.6 μs). An earlier prediction of the corresponding lifetime for HSO of 40 μs has recently been found to be of good accuracy, with an experimental value of 51 ± 5 μs having been reported (6).

TABLE 4. Dipole moment (D) calculated for the ground and first excited state of HNF and HNCl at the respective equilibrium geometries[a]

Molecule	$^2A''$ μ_x	$^2A''$ μ_y	$^2A''$ $\lvert\mu\rvert$	$^2A'$ μ_x	$^2A'$ μ_y	$^2A'$ $\lvert\mu\rvert$
HNF	−1.013	1.780	2.048	−1.203	1.213	1.708
HNCl	−0.090	1.700	1.702	−0.461	1.087	1.173

[a]The geometrical coordinates employed are HNF: $^2A''$, H (−0.336, 1.906), F (2.560, 0.0); $^2A'$, H (−1.068, 1.583), F (2.510, 0.0); HNCl: $^2A''$, H (−0.419, 1.893), Cl (3.239, 0.0); $^2A'$, H (−1.345, 1.448), Cl (3.037, 0.0).

Finally, the dipole moment matrix elements for both HNCl electronic states have also been computed, which information would also be needed in a treatment of the Renner−Teller coupling of this system. These results are presented along with the corresponding findings for HNF in Table 4; in all cases the equilibrium geometries are employed for a given state (see Table 1 and also Table 1 of ref. 9). The polarity of each molecule is seen to decrease upon $A\ ^2A' - X\ ^2A''$ excitation, with HNF being somewhat more polar than HNCl in each case.

Received October 9, 1984[2]

B. S. LARK and T. S. BANIPAL. Can. J. Chem. **63**, 3269 (1985).

Excess volumes of the systems acetonitrile (ACN) + acetic acid (AA), + propionic acid (PA) and + isobutyric acid (IBA) at 298.15 and 308.15 K and + trimethylacetic acid (TMA) at 313.15 K have been measured using dilatometric method. The observed values are found to be negative for the first three systems while the last system has sigmoid concentration dependence. Excess enthalpies for the first three systems at 308.15 K and for the last system at 313.15 K have also been determined and found to be positive. The results have been explained in terms of depolymerization of the acids, dipole–dipole interactions between heteromolecules and the steric hindrance caused by the increasing methylation.

B. S. LARK et T. S. BANIPAL. Can. J. Chem. **63**, 3269 (1985).

Utilisant une méthode dilatométrique, on a mesuré les volumes en excès de l'acétonitrile (ACN) avec les acides acétique (AA), propionique (AP) et isobutyrique (AIP) à 298,15 et 308,15 K ainsi qu'avec l'acide triméthylacétique (ATM) à 313,15 K. On a observé des valeurs négatives pour les trois premiers systèmes alors que dans le dernier cas les valeurs varient d'une façon sigmoïde avec la concentration. On a également déterminé les enthalpies en excès pour les trois premiers systèmes à 308,15 K et pour le dernier à 313,15 K et toutes ces enthalpies sont positives. On explique ces résultats en fonction d'une dépolymérisation des acides, d'interactions dipôles–dipôles entre des hétéromolécules et par des encombrements stériques provoqués par une augmentation de méthylation.

[Traduit par le journal]

Introduction

Excess thermodynamic functions of mixtures consisting of acetic and its methyl-substituted acids with variety of solvents have been reported previously from these (1–5) and other laboratories (6–12). These acids in the pure state exist mainly as cyclic dimers. However, trimers formed because of strong interactions between ring dimers and monomers do also exist (9). The mixing behaviour of these acids with various solvents is interesting: e.g., acetic and propionic acids when mixed with non-polar solvents show large positive excess free energies as compared to positive enthalpies and thus exhibit negative excess entropies (4–6). This behaviour has been attributed to the breaking up of acid dimer–monomer interactions on the addition of a non-polar solvent and to the formation of dimers from the monomers thus set free, which gives increasing proportions of dimers with the increasing mole fraction of non-polar component (6). Methanol (B) gives large negative excess volumes with these acids (1–3, 7, 8) because of the formation of hydrogen bonded AB and AB_2 type of complexes by the depolymerized acid (A) monomers, for which even the spectral evidence has been advanced by Izmailov (13) and Apelblat (14). Campbell and Gieskes (10) have shown that chloroform (μ = 1.15 D and ϵ = 4.806 at 298.15 K) with acetic acid gives positive excess volumes and negative excess enthalpies. The authors explain this phenomenon by the preferred association of ring dimers of acetic acid with chloroform molecules in an antiparallel dipole arrangement.

Acetonitrile is a purely polar unassociated solvent (μ = 3.37 D and ϵ = 36.01 at 298.15 K) which has very small tendency of H-bond formation (15). Excess functions of title acids in this solvent are unexplored and presently we report excess volumes and excess enthalpies for such mixtures and use the data to divulge qualitatively the role played by such a highly polar solvent.

[2] Revision received April 17, 1985.

Experimental

Acetic and propionic acids (A.R., B.D.H.) for the present work were the same as used in the earlier reports (4, 5).

Isobutyric acid (L.R., SRL) was dried by refluxing it over phosphorus pentaoxide and then fractionally distilled. Middle fraction was further refluxed over potassium permanganate and fractionally distilled. The fraction distilling at 427.5 K was collected. Trimethylacetic acid (G.R., Tokyo Kasei Kogyo Co., Ltd., Japan) was first fractionally crystallised and the liquid layer was discarded. The solid portion (mp 308.55 K) was then distilled under reduced pressure.

Acetonitrile (L.R. E. Merck) was first distilled over phosphorus pentaoxide under protection from air by a phosphorus pentaoxide tube. The same procedure was repeated until phosphorus pentaoxide no longer became coloured. This was then distilled over anhydrous potassium carbonate to remove traces of phosphorus pentaoxide and finally without a drying agent. The fraction distilling at 354.7 K was collected. The purity of the solvents was checked by determining their densities and refractive indices which have been compared with the literature (16–18) values of Table 1. The agreement is quite good. All solvents were thoroughly degassed before use.

Excess volumes have been measured by using a batch dilatometer, the design and working of which have been reported earlier (19). For measurement of excess enthalpies, adiabatic calorimeter introduced by McGlashan (20) and later modified by Nigam and Mahl (21) has been used. The two-limbed calorimeter has the advantage of the absence of the vapour phase and at the same time allows for the volume change accompanied with the mixing of the components. The presently used calorimeter had slight improvement over that of Nigam and Mahl's (21) that instead of one thermistor, two thermistors, one in its each limb were used to sense the heat changes ensuring better sensitivity. The working of this calorimeter was checked by determining H^E values for cyclohexane + benzene system at 298.15 K (Table 2). The results are fitted to the following equation by the method of least squares:

$$H^E/(\mathrm{J\ mol^{-1}}) = x(1-x)[3207.23 + 167.92(1-2x) + 86.35(1-2x)^2 + 45.07(1-2x)^3]$$

where x is the mole fraction of cyclohexane.

The differences of the presently obtained H^E values from those reported by various workers (22–28) are illustrated as a function of

composition in Fig. 1. It may be seen that scatter is quite random except in case of ref. 28, where H^E values are smaller throughout the composition range. Also the scatter is well within the uncertainty limit of this instrument.

The temperature of 150 L water-thermostat was controlled to ±0.01 K with the help of 0.01 K Beckmann thermometer calibrated by determining the transition temperature of Glauber's salt (305.534 K).

Results and discussion

Excess volumes as a function of mole fraction of the acid component for the systems ACN + AA, + PA, and + IBA at 298.15 and 308.15 K and for +TMA at 313.15 K have been summarized in Table 3, while H^E values for the first three systems at 308.15 K and for the last at 313.15 K appear in Table 4. The results have been fitted by the method of least squares to the equation,

$$[1] \quad X^E = x(1-x)[A + B(1-2x) + C(1-2x)^2 + \ldots]$$

where X^E may be V^E or H^E and x is the mole fraction of the acid. The values of the fitting parameters $A, B, C \ldots$ for the various systems along with the standard deviations (σ's) are summarized in Table 5. Systematic error analysis shows that for the uncertainties in (*i*) weights of the components taken in the dilatometer (*ii*) change in the level of the liquid of the capillary of the dilatometer on mixing of the components, (*iii*) the calibration of the capillary, and (*iv*) temperature variation of ±0.01 K, the total uncertainty in the final V^E values comes out to be ±0.002 cm^3 mol^{-1}. It is encouraging to note that the standard deviations as given in Table 5 are much within the uncertainty limits. In case of H^E measurements, the individual deviations of the measured values seldom exceed the standard deviations and are of the order of ±1% of the measured H^E values.

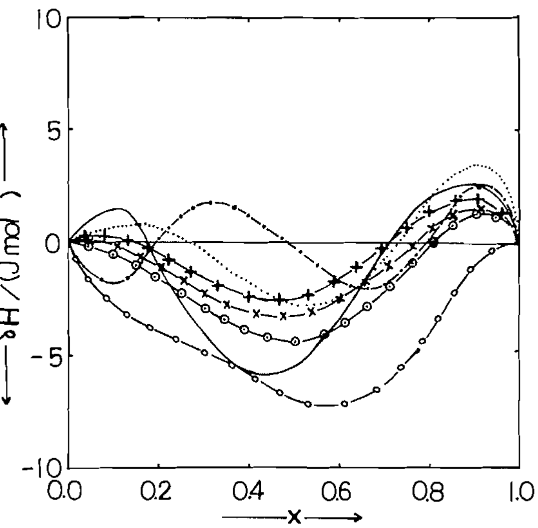

FIG. 1. Differences δH^E between the literature values and the present values as a function of x for the system $xC_6H_{12} + (1-x)C_6H_6$ at 298.15 K: -·-·- (22); -⊙- (23); -×- (24); .... (25); -+- (26) — (27); -○- (28).

V^E values as illustrated in Fig. 2 are negative for the entire concentration range at both the temperatures for all the systems except that with TMA where both positive and negative V^E values are observed. About 10% more negative V^E values at higher temperature (for first three systems only) may be explained by increased population of acid monomers to enter into hetero intermolecular interactions. It may further be seen that V^E values are most negative in case of PA and the magnitude decreases in the order:

PA > AA > IBA > TMA

The other important observation which may be made is that the minimum which in case of AA is in the acid rich region shifts slowly to the acetonitrile-rich region as the methylation of AA increases, so much so, in case of TMA sigmoid V^E dependence becomes apparent. V^E in this system is negative for x upto 0.68 and then becomes slightly positive. These observations may be explained by considering the following three

equilibria accompanying the mixing process,

[2] D—M $\rightleftharpoons$ D + M

[3] D $\rightleftharpoons$ 2M

[4] M + ACN $\rightleftharpoons$ M—ACN

where D and M denote a dimer and a monomer of the acid under question. The first process is accompanied with large volume increase in the right direction, second is isochoric, i.e., the volume of the dimer is assumed to be equal to twice the volume of the monomer (9) and the third is accompanied with large contraction. The addition of acetonitrile to any one of the acids first creates monomers by the first two steps resulting in expansion and then stronger heteromolecular dipole–dipole interactions result in the observed negative V^E values. This conclusion finds sufficient support from the contractive mixing behaviour of ACN + CH_3OH and + $(CH_3)_2CO$. V^E for equimolar mixture of ACN + MeOH as reported by Cibulka *et al.* (29) is −0.131 cm^3 mol^{-1} and the corresponding value for mixture with $(CH_3)_2CO$ which we determined separately is

$-0.132\ cm^3\ mol^{-1}$.

The dimerization constants (K_d's) of AA and PA are available in the vapour phase only and K_d for PA is higher than that of AA (Table 1). The increased K_d values should reduce the number of available (D—M) trimers and accordingly positive contribution to the overall V^E is diminished further. This is actually observed in case of PA but beyond that, i.e., for IBA V^E becomes less negative and in case of TMA sigmoid dependence is observed. This behaviour may be attributed to the increasing steric hindrance of methyl groups. The shifting of minimum to the acid poor region may be due to increase in both steric hindrance and dimerization constant. This is further supported by the findings of Cibulka *et al.* (29) who have shown that for the binary systems containing alkanol and ACN, V^E increases in the order

$$V^E(\text{ACN + normal alkanol}) < V^E(\text{ACN + branched alkanol}) < V^E(\text{ACN + secondary alkanol})$$

To arrive at the behaviour of individual acids and the solvent in each case, excess partial molar volumes ($\bar{V}^E$) were estimated and as a function of composition are illustrated in Fig. 3. It may be seen that in case of first three acids the behaviour is almost similar and the partial molar volume of both acid and solvent decreases as the concentration of the other component increases. In case of TMA, the excess partial molar volume is positive for $x \geq 0.27$ and then decreases very sharply. Contraction of ACN in this acid is much smaller than as observed in other acids and which becomes positive at its dilute end. To divulge the nature of interactions, the partial molar volume data in the dilute region have further been analyzed for values of $x_i \leq 0.15$ using the following equation

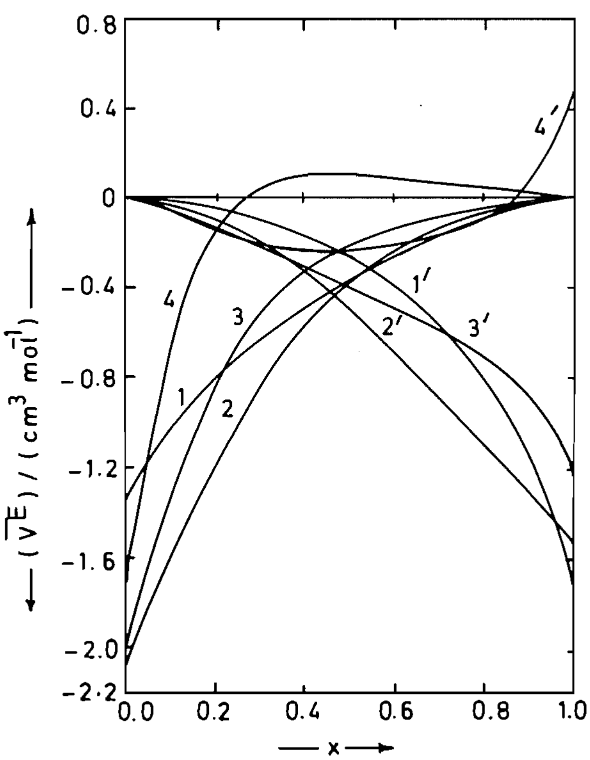

FIG. 3. Plot of $\bar{V}^E$ vs. x. *1*, *2*, *3*, *4* are the plots for AA, PA, IBA, TMA and *1′*, *2′*, *3′*, *4′* are the plots for ACN in the respective acids.

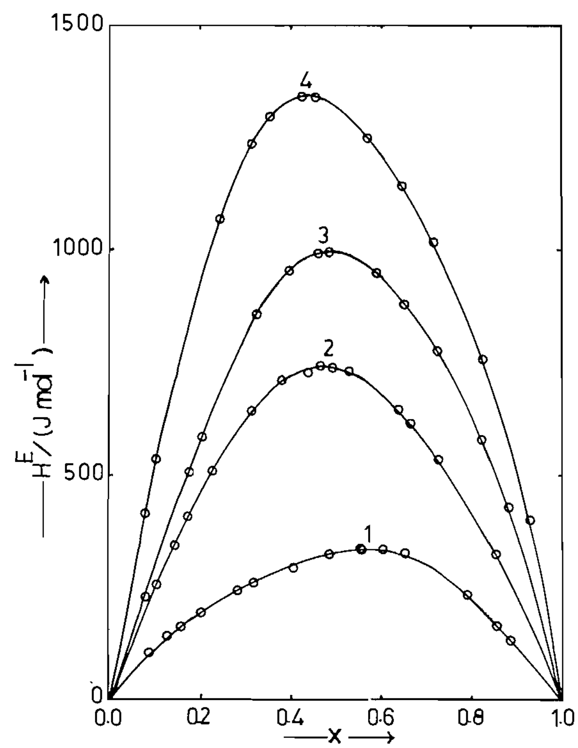

FIG. 4. Plot of H^E vs. x. *1*: AA + ACN; *2*: PA + ACN; *3*: IBA + ACN at 308.15 K; and *4*: TMA + ACN at 313.15 K.

$$[5] \quad V^E/n_i = (\bar{V}_i^0 - V_i^0) + (V_{ii}x_i + V_{iii}x_i^2 + \ldots)$$

where n_i number of moles of component i. $\bar{V}_i^0$ = molar volume of component i at infinite dilution. V_i^0 = molar volume of pure component i, V_{ii} and V_{iii} = two body and three body solute–solute interactions, i = 1,2.

The estimated values of V_i^0, $\bar{V}_i^0$, V_{ii}, and V_{iii} are summarized in Table 6. It may be seen that the values of $(\bar{V}_i^0 - V_i^0)$, i.e., volume of transfer of the solute from its pure liquid state to infinite dilution, is positive only in case of the transfer of ACN to TMA while it is negative in all other cases. The values of V_{ii} and V_{iii} show that the solute–solute interactions contribution is positive for all the acids and the values increase from AA to TMA while the acetonitrile gives negative contribution in case of TMA only. This may be due to the rebuilding of dipole–dipole interactions which at infinite dilution are torn apart by TMA molecules till when the concentration of ACN is enough to break up the acid D–M interactions.

H^E values determined for the systems under investigation are positive over the whole composition range and the magnitude decrease in the order (Fig. 4)

TMA > IBA > PA > AA

In view of the above equilibria (reactions [2]–[4]) explaining the mixing process, it may be said that endothermic contributions from the first two equilibria overweigh the possibly small exothermic contribution from the last one. The two relating evidences in support may be cited from literature. The incapability of H-bond formation between OH and CN groups result in appreciable endothermic mixing of ACN and ethanol arising mainly from depolymerization of the latter (30). H^E values in case of propionitrile + $(CH_3)_2CO$ mixtures as reported by Thacker and Rowlinson (30) do not exceed − 100 J mol^{-1} at 298.15 K. The observed trend of increasing H^E values from AA to TMA and the accompanied shift of the maximum to the acid poor region may be believed to be arising from the increasing K_d values and from steric hindrance of crowding methyl groups to dipole–dipole interactions as concluded above from the volume studies.

Phase diagram measurements and thermodynamic analysis of the $PbCl_2$–NaCl, $PbCl_2$–KCl, and $PbCl_2$–KCl–NaCl systems

ARMAND GABRIEL AND ARTHUR D. PELTON
Ecole Polytechnique, Campus de l'Université de Montréal, C.P. 6079, Succ. "A", Montréal (Qué.), Canada H3C 3A7

Received July 11, 1984[1]

ARMAND GABRIEL and ARTHUR D. PELTON. Can. J. Chem. **63**, 3276 (1985).

The phase diagrams of the $PbCl_2$–NaCl and $PbCl_2$–KCl systems have been measured by the cooling curve technique. In addition, a number of measurements at compositions in the ternary system $PbCl_2$–KCl–NaCl have been made. The binary data have been analysed along with other available thermodynamic data for the binary systems in order to obtain mathematical expressions for the binary thermodynamic properties. Various estimation procedures were then used to calculate the Gibbs energy of the ternary liquid from the binary expressions, and the ternary phase diagram calculated therefrom was compared to the experimental ternary points. In the case of the Conformal Ionic Solution equation, agreement was within 3°C at all measured points. In the case of two "geometric" estimation techniques, the Kohler and Toop equations, agreement was within 10°C but could be brought to within 3°C by the addition of only one small adjustable ternary correction term. The technique of coupled thermodynamic/phase diagram analysis permits a large reduction in the amount of experimental work necessary to measure the ternary diagram. In addition, the ternary thermodynamic expressions developed can be used to calculate all thermodynamic properties of the ternary liquid.

ARMAND GABRIEL et ARTHUR D. PELTON. Can. J. Chem. **63**, 3276 (1985).

Faisant appel à la technique de la courbe de refroidissement, on a mesuré les diagrammes de phase des systèmes $PbCl_2$–NaCl et $PbCl_2$–KCl. De plus, on a fait un certain nombre de mesures à des compositions comprises dans le système ternaire $PbCl_2$–KCl–NaCl. On a analysé les données binaires de concert avec d'autres données thermodynamiques disponibles pour les systèmes binaires dans le but d'obtenir des expressions mathématiques pour les propriétés thermodynamiques binaires. On a utilisé diverses méthodes d'évaluation pour calculer l'énergie de Gibbs du liquide ternaire à partir d'expressions binaires; on a comparé les points ternaires expérimentaux avec le diagramme de phase ternaire calculé en utilisant la méthode décrite plus haut. Dans le cas de l'équation de Solution Ionique Conformale, la correspondance se situe à moins de 3°C pour chacun des points mesurés. Dans les cas des deux techniques "géométriques" d'évaluation, les équations de Kohler ou de Toop, la correspondance est meilleure que 10°C; toutefois, elle peut être ramenée à moins de 3°C par l'addition d'un seul petit terme ajustable ternaire de correction. La technique de l'analyse des diagrammes de phase couplés à la thermodynamique permet de réduire considérablement la quantité de travail expérimental nécessaire pour mesurer un diagramme ternaire. De plus, les expressions thermodynamiques ternaires développées peuvent être utilisées pour calculer toutes les propriétés thermodynamiques du liquide ternaire.

Introduction

The complete measurement of the liquidus of a ternary system has usually involved the tedious determination of liquidus temperatures at a large number of compositions followed by a series of rather subjective interpolations to obtain isotherms and univariant lines.

The amount of experimental work can be greatly decreased while at the same time the accuracy of the diagram can be increased in many cases by the technique of computer-coupled thermodynamic/phase diagram analysis.

The first step in this method is the accurate determination of the phase diagrams of the three binary subsystems. These binary diagrams are then analysed along with other available binary thermodynamic data with a view to deriving equations for the Gibbs energies of all binary phases as functions of temperature and composition. In the next step, estimation formulae based upon solution models are used to calculate the Gibbs energies of the ternary phases from the previously obtained binary expressions. The ternary phase diagram is calculated from these thermodynamic expressions and compared to ternary liquidus temperatures measured at a few selected compositions. A few adjustable ternary correction terms may then be added to the expressions for the Gibbs energies in order to bring the calculated diagram into coincidence with the measured diagram. In this way, the shapes of all isotherms and univariant lines are consistent with thermodynamic principles and the number of experimental data points needed to obtain an accurate diagram is much reduced.

At the same time, a set of equations for all the thermodynamic properties of the binary and ternary systems is obtained. These equations are in a form well suited to computer storage and retrieval. They can be used along with suitable computer programs to generate, for example, ternary iso-activity, iso-vapour pressure, and iso-emf lines, as well as to generate polythermal projections or isothermal sections of the ternary phase diagram. Finally, the thermodynamic properties and the phase diagram are all rendered consistent.

The $PbCl_2$–KCl–NaCl system

The $PbCl_2$–KCl–NaCl system is of interest as a possible electrolyte in the electrowinning of lead.

The $PbCl_2$–NaCl phase diagram has been reported by a number of investigators (1–5). All are in agreement on the existence of one eutectic near 410°C. Most reported liquidus lines are in agreement with one another to within 10°C. The $PbCl_2$–KCl phase diagram has also been investigated several times (1, 6–10). A congruently melting compound $2PbCl_2 \cdot KCl$ with a melting point near 440°C and an incongruently melting compound, $PbCl_2 \cdot 2KCl$, associated with a peritectic near 490°C are reported along with two eutectics near 425°C and 410°C. Most reported diagrams are in agreement with one another to within 15°C. The melting point of pure

$PbCl_2$ reported by the different authors varies over a 9°C range. The $PbCl_2$–KCl–NaCl ternary phase diagram has been reported by Treis (1). Two ternary eutectics and one ternary peritectic are reported. An accuracy of about ±30°C is estimated for this ternary diagram.

In the present study, the $PbCl_2$–NaCl, $PbCl_2$–KCl, and $PbCl_2$–KCl–NaCl liquidus surfaces were studied by the method of cooling curves. The liquidus of the NaCl–KCl binary system was also measured, but is reported elsewhere (11).

Experimental

The binary and ternary liquidus curves and invariant temperatures were measured by the method of cooling curves.

Reagent grade salts were dried under vacuum and with dry HCl gas at 700°C in the case of NaCl and KCl and at 450°C in the case of $PbCl_2$. Samples of approximately 25 g were placed in sealed evacuated fused silica cells. The method of consecutive additions was not used. Samples at each composition were weighed out separately. A thermocouple was sheathed in close fitting fused silica tubes blown into the cells. The cells were placed in a grounded Inconel metal sheath and placed in a vertical electrical resistance furnace which was cooled at a rate of 1°C/min. The melt filled the cells to a depth of about 3 cm and the thermocouple sheath extended about 2 cm below the surface of the melt. Supercooling was kept to less than 2°C by attaching the cell assembly to a mechanical vibrator. A 24-gauge chromel–alumel thermocouple was used. The manufacturer's calibration was checked against the melting point of Pb, Sn, and Zn and was found to agree to within 0.5°C.

Results

Three separate measurements of the melting point of pure KCl gave 770.5, 771.2, and 771.8°C which agree well with the value of 771°C given in the most recent compilations (12). Several measurements of the melting point of pure NaCl gave values within 0.5°C of the value of 801°C given in the most recent literature (12).

Several measurements of the melting point of pure $PbCl_2$ gave 499.5 ± 1°C, in reasonable agreement with the value of 499°C given by refs. 13 and 14 and the value of 501°C given by ref. 15. Other sources, for example (12), list melting points around 495°C. Values around 495°C were also obtained in the present study unless great care was taken in drying the salt.

$PbCl_2$–NaCl

For the $PbCl_2$–NaCl system, measured liquidus points are listed in Table 1 and are plotted in Fig. 1. Accuracy is estimated to be ±2°C.

Eutectic halts were observed in the cooling curves. Measurements at five compositions near the eutectic composition (where the eutectic halt is most pronounced) gave the temperature as 409 ± 0.5°C.

$PbCl_2$–KCl

For the $PbCl_2$–KCl system, measured liquidus points are listed in Table 2 and are plotted in Fig. 2. Accuracy is estimated

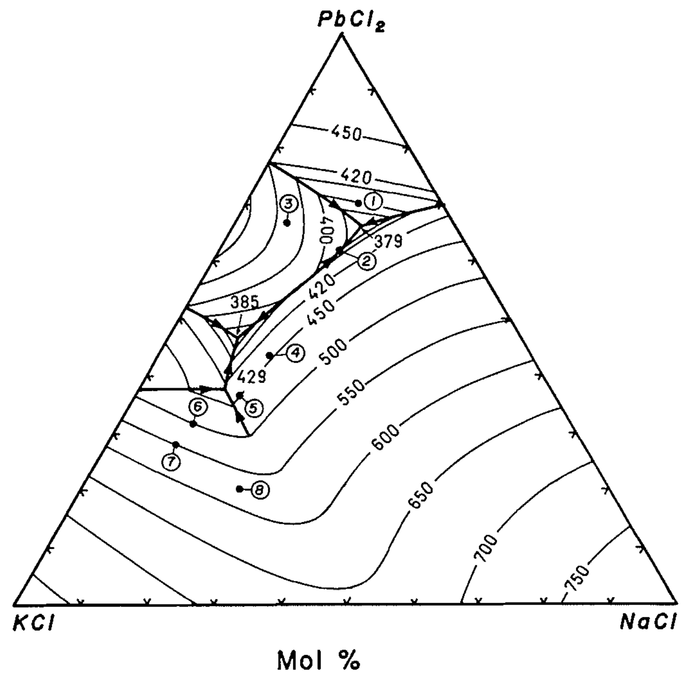

FIG. 3. The $PbCl_2$–KCl–NaCl phase diagram calculated from the thermodynamic analysis. Temperatures are in °C. Composition points indicated correspond to experimental points in Table 3.

as ±2.5°C.

Two eutectics and one peritectic were observed. Measurements of cooling curve halts at six compositions over the range $0.37 < X_{PbCl_2} < 0.55$ gave the eutectic temperature as 409 ± 0.8°C. Measurements at six compositions over the range $0.075 < X_{PbCl_2} < 0.29$ gave eutectic halts between 419 and 422°C with an average value of 420°C. Measurements at four compositions over the range $0.62 < X_{PbCl_2} < 0.66$ gave peritectic halts between 487.5 and 488°C.

$PbCl_2$–KCl–NaCl

Measurements were made at eight ternary compositions given in Table 3. These compositions are also shown on Fig. 3. Liquidus temperatures given in Table 3 are estimated to be accurate to ±3°C. Invariant halts were also observed in the cooling curves for five of the samples as indicated.

Thermodynamic analysis of binary systems

Pure components

The thermodynamic analysis of the binary systems requires a knowledge of the thermodynamic properties of the pure components. In Table 4 are listed the melting points, the enthalpies of fusion at the melting points, and the Gibbs energies of fusion of KCl, NaCl, and $PbCl_2$. The melting points are those of the present study. Enthalpies and Gibbs energies of fusion are from ref. 12. The Gibbs energies of fusion are expressed as functions of T (K) by the following expression:

$$[1] \quad \Delta G^0_{\text{fusion}} = A + BT + CT^2 + DT \ln T + ET^{-1}$$

Solid solubility – limiting slopes of liquidus curves

For a component A in a binary system A–B, the difference between the limiting slopes of the liquidus and solidus at mole fraction $X_A = 1$ is given by Raoult's law as:

$$[2] \quad (\mathrm{d}X^{\mathrm{l}}_A/\mathrm{d}T - \mathrm{d}X^{\mathrm{s}}_A/\mathrm{d}T)_{X_A=1} = \Delta H^0_{\text{fusion(A)}}/R(T^0_{\text{fusion(A)}})^2$$

where $T^0_{\text{fusion(A)}}$ and $\Delta H^0_{\text{fusion(A)}}$ are the melting point of pure A and its enthalpy of fusion at the melting point.

The liquidus curves drawn on Figs. 1 and 2 were calculated from the thermodynamic analysis discussed below under the assumption of zero solid solubility. Hence, the limiting liquidus slopes shown at compositions corresponding to pure KCl, NaCl, and $PbCl_2$ are those given by eq. [2] with $\mathrm{d}X^{\mathrm{s}}_A/\mathrm{d}T = 0$ and with values of T^0_{fusion} and $\Delta H^0_{\text{fusion}}$ from Table 4.

From the agreement with the experimental points in Figs. 1 and 2 it can be seen that solid solubility of $PbCl_2$ in NaCl and

TABLE 4. Thermodynamic properties of the pure components

	Melting point T^0_{fusion} (°C)	Enthalpy of fusion $\Delta H^0_{\text{fusion}}$ (J/mol) at T^0_{fusion}	Coefficients of eq. [1] for the Gibbs energy of fusion, $\Delta G^0_{\text{fusion}}$ (J/mol)				
			A	B	$C \times 10^3$	D	$E \times 10^{-5}$
KCl	771	26 280	4755	215.399	12.734	−33.581	1.82
NaCl	801	28 160	7735	202.091	11.925	−31.824	—
$PbCl_2$	499.5	23 850	2697	269.234	20.769	−43.426	—

KCl, or of NaCl and KCl in $PbCl_2$, is small. If error limits of ±2°C are assumed for the experimental liquidus points, then from eq [2] maximum limiting solidus slopes dX^s_A/dT of the order of 0.02 (mol% per deg) may be calculated.

In view of the low mutual solid solubility of KCl and $PbCl_2$, it is expected that the ranges of stoichiometry of the two intermediate compounds $2PbCl_2 \cdot KCl$ and $PbCl_2 \cdot 2KCl$ will be narrow. Hence, these have been indicated as stoichiometric compounds on Fig. 2.

No verification of the stoichiometry of the incongruently melting compound was made. However, the liquidus curve for this compound, when extrapolated, passes through a maximum near the composition $PbCl_2 \cdot 2KCl$.

Methodology

In the binary systems $PbCl_2$–ACl (A = Na or K), under the assumption of zero solid solubility, the following equations apply along the $PbCl_2$– and ACl–liquidus curves, respectively:

$$[3] \quad RT \ln a_{PbCl_2} = RT \ln X_{PbCl_2} + G^E_{PbCl_2} = -\Delta G^0_{\text{fusion}(PbCl_2)}$$

$$[4] \quad RT \ln a_{ACl} = RT \ln X_{ACl} + G^E_{ACl} = -\Delta G^0_{\text{fusion}(ACl)}$$

where X_i, a_i, and G^E_i are the mole fraction, activity, and excess partial molar Gibbs energy of i along the liquidus.

The excess integral molar Gibbs energy of the liquid phase may be expressed as:

$$[5] \quad G^E = \Delta H - TS^E$$

where ΔH is the molar enthalpy of mixing and S^E is the molar excess entropy. It is assumed that ΔH and S^E are independent of temperature.

For a binary system, ΔH and S^E may be conveniently expressed as polynomials in the mole fractions. In the case of molten salt solutions, it has been observed that the number of terms required in the polynomial expansions to give a satisfactory representation can sometimes be reduced if equivalent fractions rather than mole fractions are used. Furthermore, the Conformal Ionic Solution Theory discussed in the next section in relation ot the ternary calculations requires that equivalent fractions be used in the binary expansions. Since Pb^{2+} is divalent and Na^+ and K^+ are univalent, the equivalent fractions Y_i are given by:

$$[6] \quad Y_{PbCl_2} = 2X_{PbCl_2}/(2X_{PbCl_2} + X_{ACl})$$

$$[7] \quad Y_{ACl} = X_{ACl}/(2X_{PbCl_2} + X_{ACl})$$

The polynomial expansions for the molar enthalpy and excess entropy are then:

$$[8] \quad \Delta H \text{ (J/mol)} = (2X_{PbCl_2} + X_{ACl})Y_{PbCl_2}Y_{ACl}\,(h_0 + h_1Y_{ACl} + h_2Y^2_{ACl} + h_3Y^3_{ACl} + \ldots)$$

$$[9] \quad S^E \text{ (J/mol K)} = (2X_{PbCl_2} + X_{ACl})Y_{PbCl_2}Y_{ACl}\,(s_0 + s_1Y_{ACl} + s_2Y^2_{ACl} + s_3Y^3_{ACl} + \ldots)$$

where the coefficients h_i and s_i are found empirically. The number of terms in each series is chosen as the minimum required to fit the experimental data satisfactorily.

Differentiation of eqs. [8] and [9] yields the following expressions for the partial molar excess Gibbs energies of $PbCl_2$ and ACl:

$$[10] \quad G^E_{PbCl_2} = 2\sum_{j\geq 0}(h_j - Ts_j)(Y_{ACl} - jY_{PbCl_2})Y^{j+1}_{ACl}$$

$$[11] \quad G^E_{ACl} = 2\sum_{j\geq 0}(h_j - Ts_j)(j+1)Y^2_{PbCl_2}Y^j_{ACl}$$

In the case of the $PbCl_2$–NaCl and $PbCl_2$–KCl systems, ΔH has been measured by mixing calorimetry (16). These data were first fitted by a least-squares technique to obtain values of the enthalpy coefficients h_i. Next, values of the excess entropy coefficients s_i were determined in order to give the best fit to the measured $PbCl_2$– and ACl–liquidus curves in each system. To this end, a least-squares "optimisation" technique described elsewhere (17) and a computer program called FITBIN (18) were used.

Enthalpy of mixing expressions

Enthalpies of mixing in the $PbCl_2$–NaCl and $PbCl_2$–KCl systems have been measured by mixing calorimetry (16) only over the composition range $0.5 < X_{PbCl_2} < 1$. However, comparison of the experimental (16) "interaction parameter" $\lambda = \Delta H/(X_{PbCl_2}X_{ACl})$ for all the systems $PbCl_2$–ACl (A = Li, Na, K, Rb) indicates a simple dependence of λ with X_{ACl} which is not far from linearity, thereby permitting a reasonable extrapolation to be made. The following three term expressions for ΔH were thus found by least-squares regression for the $PbCl_2$–NaCl and $PbCl_2$–KCl systems, respectively:

$$[12] \quad \Delta H = (2X_{PbCl_2} + X_{NaCl})Y_{PbCl_2}Y_{NaCl}\,(-2088 + 3343Y_{NaCl} - 1937Y^2_{NaCl}) \text{ J/mol}$$

$$[13] \quad \Delta H = (2X_{PbCl_2} + X_{KCl})Y_{PbCl_2}Y_{KCl}\,(-16552 + 1167Y_{KCl} + 1046Y^2_{KCl}) \text{ J/mol}$$

The $PbCl_2$–NaCl system

With eq. [12] for ΔH, a set of coefficient s_i were found which best reproduce the measured liquidus curves. Three coefficients were found to suffice:

$$[14] \quad S^E = (2X_{PbCl_2} + X_{NaCl})Y_{PbCl_2}Y_{NaCl}\,(6.012 - 4.213Y_{NaCl} + 0.703Y^2_{NaCl}) \text{ J/mol K}$$

The phase diagram, calculated by computer with eqs. [12] and [14] for ΔH and S^E is drawn in Fig. 1. (For a description of the computer program, see ref. 18.) Agreement with the experimental points is everywhere within the experimental limits of $\pm 2°C$, and the measured and calculated eutectic agree exactly.

Furthermore, values of $G^{E}_{PbCl_2}$ calculated at 500, 600, 700, and 800°C via eqs. [10], [12], [14] agree with values measured by emf techniques (19, 20) within the experimental error limits.

The $PbCl_2$–KCl system

With eq. [13] for ΔH, the following three-term expansion for S^E was found to reproduce the measured $PbCl_2$– and KCl–liquidus curves:

$$[15] \quad S^E = (2X_{PbCl_2} + X_{KCl})Y_{PbCl_2}Y_{KCl}\,(7.950 - 14.205Y_{KCl} + 2.753Y^2_{KCl}) \text{ J/mol K}$$

Next, the following expressions for the Gibbs energies of fusion of the two intermediate compounds were determined in order to reproduce their measured liquidus curves:

$$[16] \quad \text{Compound } 2/3(PbCl_2)\cdot 1/3(KCl){:}\ \Delta G^0_{fusion} = 20700 - 29.274T \text{ J/mol}$$

$$[17] \quad \text{Compound } 1/3(PbCl_2)\cdot 2/3(KCl){:}\ \Delta G^0_{fusion} = 12107 - 15.808T \text{ J/mol}$$

The phase diagram, calculated by computer from eqs. [13], [15], [16], [17] is drawn in Fig. 2. Agreement with the experimental points is everywhere within the experimental error limits of $\pm 2.5°C$ except for two points on the $PbCl_2\cdot 2KCl$ liquidus at which the agreement is within 4°C. All measured invariant temperatures are reproduced to within 0.5°C.

Furthermore, values of $G^{E}_{PbCl_2}$ calculated at 500, 600, and 700°C via eqs. [10], [13], [15] agree with values measured by emf techniques (20) within the experimental error limits.

The NaCl–KCl system

Liquidus points in this binary system were also measured in the present study, but are reported elsewhere (11). This system exhibits complete miscibility of the solid solutions at elevated temperatures with a minimum in the solidus/liquidus at 657°C. In addition, a solid–solid miscibility gap with a consolute temperature near 500°C is observed.

A complete thermodynamic analysis of this binary system was made (11) in which measured liquidus points, miscibility gap boundaries, liquid enthalpies of mixing, and solid enthalpies of mixing at 25°C were all taken into account in order to obtain polynomial expressions for ΔH and S^E of both the liquid and solid solutions. Because of the large temperature range (25–800°C) over which data were available, a small temperature dependence was included in the expression for ΔH of the solid solution. However, the computer program TERNFIG used to calculate the ternary phase diagram as discussed below will not accept a temperature dependent ΔH. Hence, the data were re-fitted with a constant ΔH for the solid. The following expressions were obtained:

$$[18] \quad \Delta H^{liquid} = X_{NaCl}X_{KCl}\,(-2322 + 272X_{KCl}) \text{ J/mol}$$

$$[19] \quad S^{E(liquid)} = X_{NaCl}X_{KCl}\,(-1.674) \text{ J/mol K}$$

$$[20] \quad \Delta H^{solid} = X_{NaCl}X_{KCl}(27991 - 12050X_{KCl} + 7950X^2_{KCl}) \text{ J/mol}$$

$$[21] \quad S^{E(solid)} = X_{NaCl}X_{KCl}\,(12.552) \text{ J/mol K}$$

(Note that mole fractions and equivalent fractions are identical in this binary system in which both cations are univalent.)

Equations [18]–[21] differ only very slightly from those given previously (11) at temperatures above 500°C. For example, the NaCl–KCl liquidus calculated via eqs. [18]–[21] agrees everywhere within 2°C with the measured liquidus points.

Thermodynamic analysis of the ternary system

The procedure followed in the ternary analysis was as follows. First, an expression for G^E in the ternary system was calculated from the binary expressions of the preceding section by means of various estimation formulae based upon solution models. Next, the ternary phase diagram was calculated from this expression for G^E by a computer program called TERNFIG described elsewhere (18), and this calculated diagram was compared with the measured points (Table 3). If necessary, adjustable ternary correction terms were then added to the expansion of G^E in order to bring the calculated and measured diagrams into coincidence.

The Conformal Ionic Solution (CIS) Theory

The CIS theory (21–25) for an additive ternary molten salt system, which is based upon statistical mechanical perturbation theory, gives the following expression for G^E in a ternary system with components 1–2–3:

$$[22] \quad G^E \text{ (J/equivalent)} = \sum_i \sum_{j<i} a_{ij}Y_iY_j + \sum\sum_{i\neq j} b_{ij}Y_i^2Y_j + \sum\sum_{i<j} c_{ij}Y_i^2Y_j^2 + Y_1Y_2Y_3(b_{12}^{1/3} + b_{13}^{1/3})\,(b_{21}^{1/3} + b_{2/3}^{1/3}) \times (b_{23}^{1/3} + b_{13}^{1/3}) + \sum\sum_{i\neq j<k} 2(c_{ij}c_{ik})^{1/2}Y_i^2Y_jY_k$$

where, for the binary system i–j:

$$[23] \quad G^E_{ij} \text{ (J/equivalent)} = Y_iY_j(a_{ij} + b_{ij}Y_i + b_{ji}Y_j + c_{ij}Y_i^2Y_j^2)$$

Binary expressions of the type $G^E_{ij} = Y_iY_j\,(e + fY_j + gY_j^2)$ as used in eqs. [12]–[15], [18], [19] of the preceding section can easily be converted to expressions of the form of eq. [23]. (Note that as a result $b_{ij} = b_{ji}$.) Equations [22], [23] give G^E in J/equivalent. To convert to J/mol in the $PbCl_2$–KCl–NaCl system, multiply by $(2X_{PbCl_2} + X_{KCl} + X_{NaCl})$.

The ternary phase diagram calculated from eq. [22] with coefficients obtained from eqs. [12]–[15], [18], [19] is plotted in Fig. 3. As can be seen from Table 3, agreement with all experimental liquidus points is within 3°C. In addition, two ternary invariants were calculated at 379 and 385°C in agreement with the measured values. The calculations show these invariants to be ternary eutectics with compositions $X_{NaCl} = 0.20$, $X_{KCl} = 0.14$ and $X_{NaCl} = 0.11$, $X_{KCl} = 0.43$.

In addition, a ternary peritectic at 429°C is calculated at $X_{NaCl} = 0.13$, $X_{KCl} = 0.49$. Since the peritectic reaction involves the separation of the NaCl–KCl solid solution into two phases at a temperature near the consolute point where the Gibbs energy and enthalpy associated with the separation are very small, it is not surprising that this invariant was not observed in the thermal analysis experiments since the heat effect would be very small. For the same reason, the calculations are very sensitive in this area. That is, a small change in the Gibbs energy of the solid will have a large effect on the extent of solid–solid immiscibility at a given temperature. Hence, the temperature and composition of the ternary peritectic cannot be determined with accuracy.

The diagram in Fig. 3 agrees within about 25°C with that reported by Treis (1).

Because of the very good agreement of the calculations with the measurements, it was not necessary to add any adjustable ternary correction terms to eq. [22] for G^E.

Geometric estimation methods

In the "geometric" estimation formulae, G^E at a composition point in the ternary system 1–2–3 is related to G^E at one composition point in each of the three binary systems. One such formula is the Kohler equation (26):

$$[24] \quad G^E = \sum_{i \neq j < k}\sum (1 - X_i)^2 G^E_{X_j/X_k}$$

where $G^E_{X_j/X_k}$ is the value of G^E in the j–k binary at the same ratio X_j/X_k as at the ternary composition point.

Another such formula is the Toop equation (27):

$$[25] \quad G^E = \frac{X_2}{X_2 + X_3} G^E_{12} + \frac{X_3}{X_2 + X_3} G^E_{13} + (1 - X_1)^2 G^E_{23}$$

where G^E_{12} and G^E_{13} are values of G^E in the 1–2 and 1–3 binaries at the same value of X_1 as at the ternary composition point, and G^E_{23} is the value in the 2–3 binary at the same ratio X_3/X_2 as at the ternary point.

Equations [24] and [25] are exact if the solutions are regular, and may be considered as extensions of regular solution theory. The various geometrical estimation formulae have been reviewed (28).

The ternary $PbCl_2$–KCl–NaCl phase diagrams calculated from eq. [24] or from eq. [25] were very close to that shown in Fig. 3, except that the calculated ternary eutectic temperatures were 5 to 10°C too low. Consequently, one adjustable ternary correction term of the form $cX_{PbCl_2}X_{KCl}X_{NaCl}$ was added to eqs. [24] and [25], and the value of the parameter c was chosen in each case in order to best reproduce the ternary eutectic temperatures. With a value of c = 2090 J/mol in the case of the Kohler equation [24] and c = 2270 J/mol for the Toop equation [25], all three ternary invariant temperatures agreed with 1°C with those calculated by the CIS equation. Furthermore, all isotherms and univariant lines on the ternary phase diagrams calculated by the three techniques (CIS, Kohler, Toop) agreed with each other within 1 mol% everywhere.

Conclusions

Liquidus curves of the $PbCl_2$–NaCl and $PbCl_2$–KCl binary systems have been measured. A thermodynamic analysis of the measured phase diagrams, along with other available thermodynamic data for the systems, has permitted expressions for the enthalpy and entropy of the binary liquid phases to be determined which can reproduce the measured phase diagrams as well as the measured thermodynamic properties within experimental error limits.

Various estimation formulae were used to calculate the Gibbs energy of the ternary liquid from the binary data, and the ternary phase diagram calculated therefrom was compared to measured ternary liquidus and invariant temperatures. When the Conformal Ionic Solution equation was used, the calculated diagram agreed with the measured points within experimental error limits with no ternary correction terms. Similar agreement was obtained with the Kohler and Toop equations provided one small ternary correction term was added to the expression for the Gibbs energy in each case.

The ternary phase diagram resulting from this coupled thermodynamic/phase diagram analysis is estimated to be accurate to ±5° except possibily near the ternary peritectic.

The ability of a ternary Gibbs energy equation to reproduce the phase diagram is a sensitive test of its accuracy. This sensitivity has already been illustrated with regard to the aforementioned "ternary correction term". A term equal to $2720X_{PbCl_2}\cdot X_{KCl}\cdot X_{NaCl}$ J, which achieves a maximum value of only 100 J when $X_{PbCl_2} = X_{KCl} = X_{NaCl} = 1/3$, can change the ternary eutectic by 10°. Hence, eq. [22] (or eq. [24] or [25] with the one ternary correction term in each case) can be used to calculate the Gibbs energy of the ternary solution. For example, iso-activity, iso-vapour pressure, or iso-emf curves can easily be generated by computer. Separation of the Gibbs energy into enthalpy and entropy terms will be less precise. In addition, isothermal sections of the phase diagram can be computer calculated at any temperature. Hence, the storage in computer memory of a small set of coefficients along with the appropriate programs for retrieval permits the calculation of the phase diagram and all the thermodynamic properties of the ternary system.

1,*n*-Radical ions: an *ab initio* study of racemization and isomerization of the cyclopropane radical cation

DANIAL D. M. WAYNER,[1] RUSSELL J. BOYD,[2] AND DONALD R. ARNOLD[2]
Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received April 11, 1985

DANIAL D. M. WAYNER, RUSSELL J. BOYD, and DONALD R. ARNOLD. Can. J. Chem. **63**, 3283 (1985).

The surfaces for *cis–trans* isomerization and racemization of the cyclopropane radical cation ($\mathbf{1}^+$) are determined using *ab initio* calculations. It is found that polarization functions and electron correlation have large effects on the relative energies of $\mathbf{1}^+$. Orbital symmetry arguments predict that conrotatory closure of the 0,0 conformer of $\mathbf{1}^+$ should be preferred. These predictions are supported by the calculations; however, even the conrotatory closure has a significant activation barrier. Conformational changes that accompany single methylene rotation are also discussed. The implication of these results to ion cyclotron resonance and mass spectral experiments is that isomerization of $\mathbf{1}^+$ to the 0,0 conformer can occur at energies far below the barrier required to isomerize $\mathbf{1}^+$ to the propylene radical cation. However, the 0,0 conformer of $\mathbf{1}^+$ and the propylene radical cation should display similar reactivities (e.g. deprotonation). The results also indicate that, contrary to reported esr evidence, $\mathbf{1}^+$ should not exist preferentially in the 90,0 conformation.

DANIAL D. M. WAYNER, RUSSELL J. BOYD et DONALD R. ARNOLD. Can. J. Chem. **63**, 3283 (1985).

Faisant appel à des calculs *ab initio*, on a déterminé les surfaces de l'isomérisation *cis–trans* et celle de la racémisation du cation radicalaire cyclopropane ($\mathbf{1}^+$). On a trouvé que les fonctions de polarisation ainsi que la corrélation électronique influencent beaucoup les énergies relatives du cation radicalaire $\mathbf{1}^+$. Des arguments de symétrie des orbitales permettent de prédire que la fermeture conrotatoire du conformère 0,0 du radical $\mathbf{1}^+$ est privilégiée; ces prédictions sont en accord avec des calculs qui confirment toutefois que même la fermeture conrotatoire possède une énergie d'activation assez élevée. On discute également des changements de conformations qui accompagnent la rotation d'un seul méthylène. Pour la résonance des ions dans un cyclotron et pour les expériences en spectrométrie de masse, ces résultats impliquent que l'isomérisation du radical $\mathbf{1}^+$ en son conformère 0,0 peut se produire à des énergies beaucoup plus basses que celles requises pour l'isomérisation du radical $\mathbf{1}^+$ en un cation radicalaire propylène. Cependant, le conformère 0,0 du radical $\mathbf{1}^+$ et le cation radical propylène devraient avoir des réactivités semblables (comme la déprotonation). Les résultats indiquent également que, contrairement aux résultats suggérés par la rpe, le cation $\mathbf{1}^+$ ne peut exister préférentiellement sous la conformation 90,0.

[Traduit par le journal]

Introduction

The properties of the cyclopropane radical cation $\mathbf{1}^+$ have been the subject of numerous experimental (1) and theoretical (2) investigations. Mass spectra formed by collisionally activated dissociation (CAD) of $C_3H_6{}^+$ isomers (1*a*) imply that the barrier to isomerize $\mathbf{1}^+$ to the propene radical cation $\mathbf{2}^+$ is large (35 kcal mol^{-1}) while the barrier to the formation of $\mathbf{2}^+$ from "ring-opened" cyclopropane radical cation is small. The nature of this ring-opened species, however, is unclear.

Calculations by Collins and Gallup (2*a*) did not find a minimum on the energy surface of $\mathbf{1}^+$ corresponding to a ground electronic state of the ring-opened species. Other calculations (3) have estimated the strength of the one-electron, two-center bond to be about 18 kcal mol^{-1}. In this work the energy difference between $\mathbf{1}^+$ in the 90,90 conformation (4) and the 90,0 conformation was taken as an estimate of this value. The energy barrier to the formation of the ring-opened species should be *at least* the energy required to break this one-electron, two-centre bond.

It is well known that, in cyclopropane (**1**), the barrier to double methylene rotation is less than the barrier to single methylene rotation (5). Calculations (6, 7) have shown that the energy of the 0,0 conformer of **1** (the trimethylene diradical) is lower than the 90,0 conformer (in support of the experimental evidence). Furthermore, orbital symmetry considerations suggest that conrotatory closure of the 0,0 conformer should be favoured over disrotatory closure (7). There is little experimental evidence, however, in support of this prediction (8).

There has been interest recently in the applicability of orbital symmetry rules to odd electron species (9). By analogy to studies of **1**, an investigation of the synchronous (double methylene) rotation and single methylene rotation of $\mathbf{1}^+$ will give valuable insight into the electronic nature of the one-electron, two-centre bond, and may be useful to the interpretation of mass spectral and ion cyclotron resonance (icr) experiments. Furthermore, the extent of orbital symmetry control over the synchronous rotation of the methylenes in this odd-electron species can be studied.

This paper presents the results of an *ab initio* study of the *cis–trans* isomerization (single methylene rotation) and racemization (double methylene rotation) of $\mathbf{1}^+$. Comparison with similar theoretical calculations on **1** and the cyclopropyl radical reveals some similarities as well as some interesting differences. The effects of polarization functions and electron correlation are also discussed.

Details of calculations

Standard *ab initio* self-consistent field (SCF) molecular orbital (MO) calculations were carried out with the GAUSSIAN 80 programs (10) on a Perkin Elmer 3230 minicomputer. Gradient techniques (11) were used for geometry optimizations. Calculations were performed with 4-31G and 4-31G* basis sets with valence electron correlation incorporated by using Møller–Plesset perturbation theory (12) terminated at either the second (MP2) or third (MP3) order. The energies of the radical cations were computed using the open-shell, spin-unrestricted (UHF) procedure (13). Complete geometry optimizations of **1**, and of $\mathbf{1}^+$ in the 90,90 ($^2A_1$ and $^2B_2$ states), the 90,0 and 0,0 conformers (Table 1), as well as the 90,10; 90,20;

[a] All bond lengths are in Å (angstrom) and all angles are in degrees.
[b] Internuclear distance.
[c] α_i is the angle representing the wagging motion of the C(i) methylene. It is the angle between the C(i)C(3) bond and the intersection of the plane of the C(i) methylene with the plane of the carbons. α_3 is measured with respect to the C(1)C(3) bond.
[d] ω_i is the angle representing the rocking motion of the C(i) methylene. It is the angle between the line which bisects the HC(i)H methylene and the line which is the intersection of the plane of the methylene and the plane of the carbons.
[e] θ_i is the angle representing the torsional motion of the C(i) methylene. It is the angle between the plane of the C(i) methylene and the plane of the carbons.

90,30; 90,60 conformers (single methylene rotation) and the 60,60; 45,45; and 30,30 conformers (conrotatory and disrotatory synchronous double methylene rotation) were carried out at the 4-31G level. Single point calculations using the 4-31G optimized structures were carried out at the MP2/4-31G, MP3/4-31G, HF/4-31G*, and MP2/4-31G* levels.[3]

Discussion

Structural and electronic aspects of **1**$^+$ in the 90,90 ($^2A_1$ and $^2B_2$ states) and the 90,0 conformations have been discussed in detail (3). The structure of the 0,0 conformer of **1**$^+$ has not been reported. It is useful, however, to review briefly some of the features of all of these structures. The Mulliken overlap between the carbons, the charge distribution, and the spin distribution in these conformers are shown in Tables 2, 3, and 4 respectively.

An interesting feature of the $^2A_1$ structure (90,90 conformer) is that the values of α_1 and α_2 indicate that C(1) and C(2) have adopted a planar geometry (i.e. C(1) and C(2) are sp^2 hybridized). This geometry allows effective bonding between C(1) and C(2) even though ∠C(1)C(3)C(2) has increased relative to

[3] The notation MP2/4-31G*//HF/4-31G indicates that a MP2 calculation with the 4-31G* basis set has been carried out at the equilibrium geometry obtained by Hartree–Fock calculations at the 4-31G level. In Table 5 the notation is simplified to MP2/4-31G*//4-31G.

that in **1**. The magnitude of ∠C(1)C(3)C(2) (only 81.7°) and the Mulliken overlap between C(1) and C(2) (Table 2) are an indication that there is a considerable C(1)C(2) bonding interaction in this species. This geometry is consistent with the Walsh model for bonding in cyclopropane (14) in which the electron has been removed from the e_s' orbital.

The values of α_1 and α_2 in the $^2B_2$ state (90,90 conformer) are much smaller than that in the $^2A_1$ state. This structure has been described as a π-complex between ethylene and the methylene cation. It is preferable, therefore, to consider the angle β (Fig. 1), which would have a value of 180° in the case of

ethylene. For **1**$^+$ ($^2B_2$) β has a value of 167.2°. The Mulliken overlap between C(1) and C(2) has increased relative to **1**. This structure is consistent with the Walsh model in which the electron has been removed from the orbital of e'_a symmetry.

The 90,0 conformer of **1**$^+$ has approximately C_s symmetry and exists as a $^2A''$ ground state. In the 90,0 conformer of **1**$^+$ there is no evidence for bonding between C(1) and C(2). The C(1)C(3) bond has shortened while the C(2)C(3) bond (C(2) has rotated 90°) has lengthened. The interesting feature of this conformer is that while the charge density is delocalized over the three methylene groups (Table 3) the spin density is localized on C(2) (Table 4), a consequence of the orthogonality of the two methylenes. In these delocalized species, considerable spin contamination might be expected since the calculations have been carried out within the unrestricted Hartree–Fock formalism. Our results show, however, that the contamination by quartet and higher terms is substantial in the 0,0 conformer but small in the other three cases (Table 4). The application of spin annihilation methods would improve the $\langle S^2 \rangle$ values, but would not be expected to alter the basic conclusions.

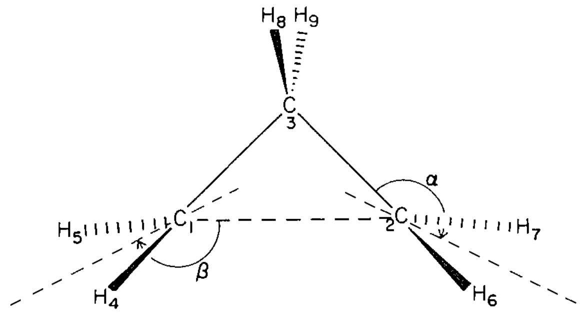

FIG. 1. Representation of bonds and angles of **1**$^+$, as defined in Table 1.

The 0,0 conformer of **1**$^+$ has C_2 symmetry and exists as a ^2A ground state. However, since the values of α_1 and α_2 in this conformer are very close to 180.0° (actually 179.95°), it could be classified in the C_{2v} point group and, as such, would have a $^2A_1$ ground state. While there is substantial overlap between C(1) and C(3) and between C(2) and C(3), there is no bond between C(1) and C(2) (Table 2). The CH bond lengths, the HCH angles, and the values of α_1 and α_2 are consistent with sp^2 hybridization at C(1) and C(2). The geometry at C(3), however, is very different. The value of ∠C(1)C(3)C(2) is anomalously large (124.8°), the C(3)H bonds are anomalously long and the HC(3)H angle is smaller than expected (Table 1). This unique geometry can be understood. The steric repulsion between the hydrogens on C(1) and C(2) must be responsible for the unusually large value of ∠C(1)C(3)C(2). The value of 124.8° is close to the value expected for a bond angle in an sp^2 hybridized carbon. If it is assumed that the hybridization at C(3) is sp^2, then each C—C bond would be formed with one of the three available sp^2 orbitals on C(3). This arrangement will leave one sp^2 and one *p*-orbital to form the two C—H bonds. Rehybridization of the sp^2 and *p*-orbitals leads to the formation of two sp^5-orbitals. The increased "*p*" character of these new orbitals leads to much longer C—H bonds (e.g. C(sp^3)—H bonds are longer than C(sp^2)—H bonds). Furthermore, the angle between two sp^5-orbitals is 101.2° (15), which is larger than the 93.0° obtained for the 0,0 conformer but, nevertheless, is in the right direction.

In the 0,0 conformer of **1**$^+$, 85% of the charge is on the C(1) and C(2) methylenes and only 15% of the charge is on the C(3) methylene. The large negative charge on C(3) is likely a result of polarization of electron density similar to that found for the 90,0 conformer (3). As expected, most of the spin density is shared between C(1) and C(2). It is found, however, that while C(3) has an excess of β-spin density, the hydrogens bonded to C(3) do *not* have, as expected, an excess of α-spin density. The reason for this unusual behaviour is not understood.

The surface for *cis–trans* isomerization and racemization of

[a] The total energy of the 90,90 ($^2A_1$) conformer at the 4-31G//4-31G, 4-31G*//4-31G, MP2/4-31G//4-31G, MP3/4-31G//4-31G, and MP2/4-31G*//4-31G levels are −116.573588, −116.632448, −116.812395, −116.840616, and −116.979836 hartrees, respectively.

1 has been studied experimentally (5) and by molecular orbital methods (6, 7). The theoretical calculations predict that the barrier to racemization is less than the barrier to isomerization. This effect has been rationalized in terms of orbital symmetry allowed opening of the cyclopropane ring. At the transition state (the 0,0 conformer) there is "pseudo-conjugation" through the central methylene, leading to the "allowed" conrotatory closure to give **1**. The energy difference between the barriers for isomerization and racemization has been estimated to be approximately 2.5 kcal mol^{-1} (7).

It is interesting to compare the results obtained for the isomerization and racemization of $\mathbf{1}^+$ to those results for **1**. At the outset, it should be noted that the work of Collins and Gallup (2*a*) predicted the energy of the $^2A_1$ conformer to be 6.6 kcal mol^{-1} higher than that of the $^2B_2$ structure. The results obtained from this study show that at all levels of theory used, the $^2A_1$ structure is lowest in energy (Table 5). Furthermore, recent experimental results have confirmed that the unpaired electron occupies the $6a_1$ orbital (16).

The calculated barrier to *cis–trans* isomerization of **1** using a minimal basis set and configuration interaction with all single and double substitutions is 52.6 kcal mol^{-1} (6*a*). This is an underestimate of the experimental value (65 kcal mol^{-1}, 8) since CI was performed only on the 90,0 conformer. Moreover, a minimal basis set is too small for accurate CI calculations. There should be a large negative correction to the energy of **1** when CI is included. Since, for $\mathbf{1}^+$ ($^2A_1$), the electron has been removed from an orbital which is predominantly bonding between C(1) and C(2), the strength of the resulting one-electron, two-centre bond should be no more than half of the bond strength in **1**. The calculated strength of the one-electron, two-centre bond depends on the basis set used (Table 5). However, even at the MP2/4-31G* level, the bond strength is still less than half of the experimental value. It is clear that as the basis set becomes more sophisticated, the calculated bond strength increases, and that inclusion of polarization functions has as great an effect as electron correlation.

The calculated energy of the 0,0 conformer of $\mathbf{1}^+$ (Table 5) is greater than the calculated energy of the 90,0 conformer when electron correlation is *not* included. However, the effect of electron correlation is to reduce the energy of the 0,0 conformer (in contrast to the effect of electron correlation on the energy of the 90,0 conformer). The result is that the relative energy of the 0,0 conformer is much less than the energy of the 90,0 conformer when electron correlation is included. This energy difference is as much as 10 kcal mol^{-1}, far greater than the analogous energy difference calculated for racemization versus isomerization in **1**.

The conrotatory closure of the 0,0 conformer of $\mathbf{1}^+$ should be an allowed process by orbital symmetry. Since this conformer has a $^2A_1$ ground state, the singly occupied MO is symmetric with respect to rotation about the C(2) axis. Examination of the

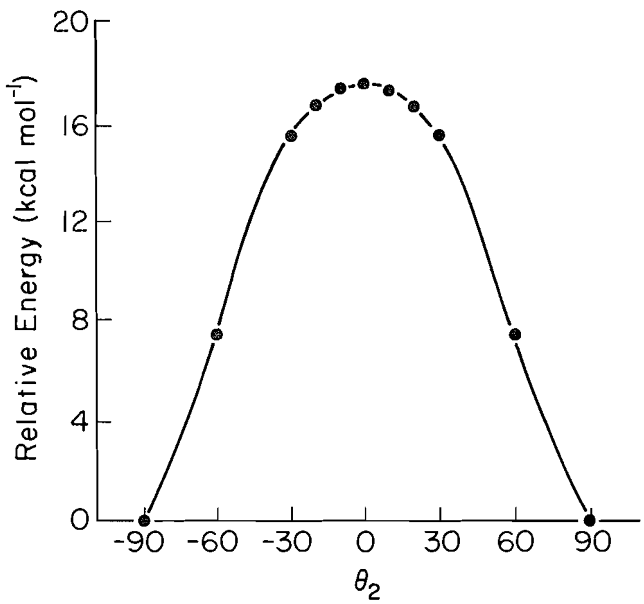

FIG. 2. Energy (relative to the 90,90 ($^2A_1$) conformer of $\mathbf{1}^+$) versus the torsional angle (θ_2) for the single methylene rotation of $\mathbf{1}^+$.

molecular orbital coefficients reveals that there is no contribution from the atomic orbitals on the C(3) methylene. This can be rationalized since the 0,0 conformer is structurally related to the allyl radical (a protonated allyl radical). The singly occupied MO of the 0,0 conformer is, in fact, electronically very similar to the singly occupied MO of the allyl radical.

The partial surface for twisting of one methylene from the $^2A_1$ state of $\mathbf{1}^+$ to the 90,0 conformer has been obtained. The fully optimized geometries of $\mathbf{1}^+$ in the 90,0; 90,10; 90,20; 90,30; 90,60; and 90,90 conformations reveal several interesting trends. The energy profile for twisting is shown in Fig. 2. It is clear that near the transition state the torsional surface is very "soft"; i.e. since there is little bonding between C(1) and C(2), rotation of C(2) has only a small effect on the relative energy. Near the $^2A_1$ structure, however, small changes in θ(2) result in larger changes in the relative energy. This is expected, since the one-electron, two-centre bond is being broken by twisting. This can be compared to twisting in the ethylene radical cation (17) where the torsional potential is much softer. At a torsional angle of 30°, the energy change is only 1.6 kcal mol^{-1} at this level of theory (compared to over 7 kcal mol^{-1} in $\mathbf{1}^+$).

The surface for synchronous conrotatory and synchronous disrotatory opening of the 90,90 conformer of $\mathbf{1}^+$ to the 0,0 conformer of $\mathbf{1}^+$ is shown in Fig. 3. The points at 90°, 60°, 45°, 30°, and 0° were obtained from the fully optimized structures in each conformation. The points at 85°, 80°, 10°, and 5° were single point calculations using the optimized structural param-

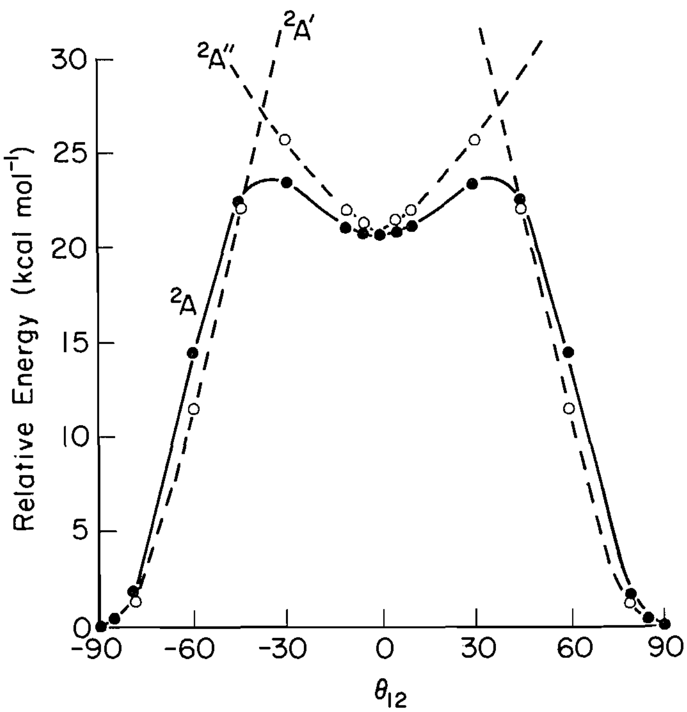

FIG. 3. Energy (relative to the 90,90 ($^2A_1$) conformer of $\mathbf{1}^+$) versus the torsional angle for (a) conrotatory double methylene rotation (●) and (b) disrotatory double methylene rotation (○) of $\mathbf{1}^+$.

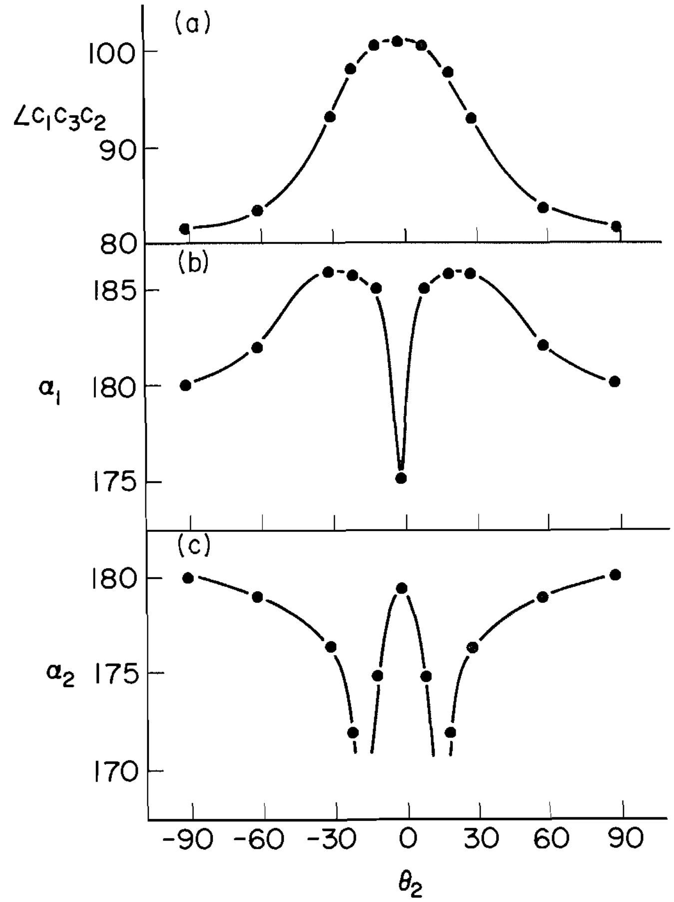

FIG. 4. (a) ∠C(1)C(3)C(2) versus torsional angle (θ_2); (b) wagging angle of the C(1) methylene (α_1, positive values are in the direction of the central methylene) versus the torsional angle (θ_2); and (c) wagging angle of the C(2) methylene (α_2, positive angles are in the direction of the central methylene) versus the torsional angle θ_2 for the single methylene rotation of $\mathbf{1}^+$.

eters from the 90,90 conformer or the 0,0 conformer.

It is found that the transformation of the 90,90 conformer ($^2A_1$) of $\mathbf{1}^+$ to the 0,0 conformer ($^2A_1$) by synchronous conrotation occurs on the ^2A surface with an activation energy of about 24 kcal mol^{-1} near a torsional angle of 40°. On the other hand, disrotation of the 90,90 conformer begins on the $^2A'$ surface while disrotation of the 0,0 conformer begins on the $^2A''$ surface. These torsional surfaces are remarkably similar to state correlation diagrams determined for disrotation and conrotation of the cyclopropyl radical (18*a*). In contrast to $\mathbf{1}^+$, however, in the case of the cyclopropyl radical the ground state orbital symmetry is not the same as the ground state orbital symmetry of the allyl radical (18*b*), so the two orbitals do not correlate with each other.

It is clear that neither disrotation nor conrotation is overwhelmingly preferred. Both modes appear to have some activation barrier. Calculations by Goddard and co-workers on the trimethylene biradical, on the other hand, suggest that disrotatory closure of the biradical is activated while conrotatary closure is activationless (7). It would appear, therefore, that the opening of $\mathbf{1}^+$ more closely parallels that of the cyclopropyl radical.

The geometric changes associated with single methylene rotation are also of interest. As the torsional angle is decreased from 90 to 0°, there is a progressive increase in the value of ∠C(1)C(3)C(2). This is expected as the extent of bonding between C(1) and C(2) decreases (Fig. 4a).

The associated wagging of the methylenes (C(1) and C(2)) is particularly intriguing. Salem and co-workers, in their study of the isomerization of **1**, found that large pyramidal distortions were associated with the trimethylene structures (6*a*). For the 90,0 conformer (of **1**) this distortion from planarity was 14° for the carbon that had twisted. At the STO-3G level, a pyramidal distortion of the C(2) methylene (in the 90,0 conformer of $\mathbf{1}^+$) of 28° is observed. However, at the 4-31G level, this distortion completely disappears.

The wagging motion of the C(1) methylene of $\mathbf{1}^+$ as the torsional angle is decreased from 90 to 0° reveals that initially there is a small pyramidal distortion away from the central methylene (Fig. 4b). This distortion reaches a minimum near $\theta_2 = 30°$ and, near the transition state, undergoes an inversion so that, at the transition state, the C(1) methylene is pyramidally distorted towards the central methylene. The inversion near the transition state is best rationalized as a result of the steric repulsion between the hydrogens of the C(1) methylene and the hydrogen of the C(2) methylene.

The C(2) methylene slowly pyramidalizes away from the C(1) methylene as the torsional angle decreases (Fig. 4c) and reaches a maximum near $\theta_2 = 15°$. At the transition state, there is no pyramidal distortion at the C(2) methylene. This motion is a response to increased steric interaction with the C(1) methylene, which moves towards one of the hydrogens bonded to C(2). The observation that the distortion of the C(2) methylene continued even after the distortion of the C(1) methylene has reached a maximum is consistent with this idea. At (or near) a torsional angle of 15°, further pyramidalization of the C(2) methylene becomes energetically less favourable than depyramidalization of the C(1) methylene. So, while the wagging motion of the C(2) methylene can be rationalized as a motion coupled to the motion of C(1), it is not immediately clear why pyramidalization of C(1) should be favourable. Goddard and co-workers (7) suggested that the pyramidal distortions in trimethylene were favourable, since this conformation avoided eclipsing of more than two bonds. This explanation is feasible in the trimethylene system where the distortions are large. For $\mathbf{1}^+$, where the distortions are much smaller, this suggestion seems less likely. However, it should be noted that this represents a non-dynamic path between the 90,90 ($^2A_1$) conformer and the 90,0 ($^2A''$) conformer, since the conformation of the C(1) methylene is fixed.

These results have some relevance to ion cyclotron resonance and mass spectral experiments reported in the literature. For example, Ausloos and co-workers reported that the proton transfer reaction between $\mathbf{1}^+$ and methanol occurred at the same rate as proton transfer from the propylene radical cation to methanol (1*c*). It was concluded that the proton transfer from $\mathbf{1}^+$ to methanol only occurred from "ring opened" $\mathbf{1}^+$ and that at an ionization voltage of 10.6 eV only 15–16% of $\mathbf{1}^+$ underwent the ring opening. It makes sense that the facile proton transfer will occur from the 0,0 conformer of $\mathbf{1}^+$, since the terminal methylenes will be in a conformation similar to the geometry of the allyl radical. The similarity of the rate coefficients to that for the propylene radical cation is expected for deprotonation from this conformation, because in both cases the proton can be lost along a line perpendicular to the developing π-system. In contrast, the "ring opened" species in the 90,90 conformation is less likely to deprotonate, since the deprotonation would either give, initially, an orthogonal π-system or synchronous rotation of two methylenes would have to occur. In neither case is the reaction expected to be even competitive with the deprotonation of the propylene radical cation.

The adiabatic ionization potential of **1** is 9.8 eV (19). It is interesting to note that, using an ionizing voltage of 10.6 eV, the initially formed ion has an excess energy of about 18 kcal mol^{-1}. That this only leads to 16% ring opening is consistent with the activation barrier of about 24 kcal mol^{-1} calculated for double methylene rotation of $\mathbf{1}^+$. An explanation of this result is important, because the barrier to isomerize $\mathbf{1}^+$ to the propylene radical cation is much larger than 20 kcal mol^{-1} (1*a*). However, it is evident from this work that isomerization of $\mathbf{1}^+$ to the propylene radical cation need not precede the deprotonation. Therefore, there is no need to invoke special conditions under which the barrier to isomerize $\mathbf{1}^+$ to the propylene radical cation would be low. The difficulty will be in distinguishing between reactions which occur from the ring opened (0,0) conformer of $\mathbf{1}^+$ and from the propylene radical cation, since their reactivities, toward deprotonation, should be similar.

Recently, Williams and co-workers have reported esr evidence for the 90,0 conformer of the cyclopropane radical cation (20) and the tetramethylcyclopropane radical cation (21). The structural assignments were based on analysis of the esr spectra that were *irreversibly* produced upon annealing a Freon matrix containing the radical cation in the 90,90 conformation. The assignments were made in part by analogy to a similar study of the oxirane radical cation (22). Clearly, these assignments cannot be correct.

In the case of oxirane, the lone pair of electrons in the 2*p* orbital will increase the bond order to the carbons. It is not surprising that the 0,0 conformer of this species is more stable than the 90,90 conformer. For $\mathbf{1}^+$, however, opening of the ring (whether by single or double methylene rotation) is endothermic. Our calculations show that the ring closure of the 90,0 conformer is activationless; therefore, if formation of this conformer were to occur, it must be reversible.

There is an alternate interpretation to the esr results of Williams and co-workers. We suggest that the irreversible reaction that occurs, upon annealing the matrix, leads to the formation of the 3-chloro-1-propyl radical, in the case of $\mathbf{1}^+$, and $C(CH_3)_2ClCH_2C(CH_3)_2\cdot$ from the tetramethylcyclopropane radical cation. The evidence in favour of this alternative is strong. Interaction of radicals and radical ions with chlorine or chloride in Freon matrices is known (23). The reported esr parameters for the 3-chloropropyl radical are very similar (within fractions of a gauss) to those parameters determined from the esr spectrum of the radical in the annealed matrix (24). In the case of the tetramethylcyclopropane radical cation (21) it was noted that the radical $CCl_3CH_2C(CH_3)_2\cdot$ has the same esr parameters as the species observed in the annealed matrix. It was suggested that the electron-withdrawing nature of $-CCl_3$ would be similar to the electron-withdrawing nature of $-C(CH_3)_2^+$ and the assignment to the perpendicular radical cations was made on this basis. However, the radical $C(CH_3)_3CH_2C(CH_3)_2\cdot$ also has a very similar spectrum (25); thus it is not unlikely that $C(CH_3)_2ClCH_2C(CH_3)_2\cdot$ also has a similar esr spectrum.

Synthesis, base strength, and prototropic behaviour of a number of alkyllumazines

ROSS STEWART[1] AND S. J. GUMBLEY

Department of Chemistry, University of British Columbia, Vancouver, B.C., Canada V6T 1Y6

Received May 17, 1985

ROSS STEWART and S. J. GUMBLEY. Can. J. Chem. **63**, 3290 (1985).

A number of lumazines and 5-deazalumazines containing a methyl group at C-7 have been prepared, their pK_{BH^+} values determined, and measurements made of the rates at which the hydrogen atoms of their 7-methyl groups undergo isotopic exchange in aqueous sulfuric acid. The presence of an alkyl group at N-8 in the protonated forms of these compounds activates the neighbouring methyl group at C-7; the effect is considerably larger than that previously observed for a methyl group at C-6, which is the other neighbouring position. The comparison of methyl and hydrogen at N-8 can be made only for the acid-catalyzed reaction because the structures of the neutral compounds, which take part in the base-catalyzed reaction, are not analogous.

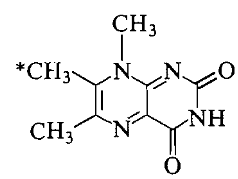
ROSS STEWART et S. J. GUMBLEY. Can. J. Chem. **63**, 3290 (1985).

On a préparé un certain nombre de lumazines et de déaza-5 lumazines contenant un groupement méthyle en position C-7; de plus, on a déterminé les valeurs de leurs pK_{BH^+} et, opérant dans de l'acide sulfurique aqueux, on a mesuré les vitesses d'échange isotopique des atomes d'hydrogènes de leurs groupements méthyles en C-7. La présence d'un groupement alkyle dans la position N-8 des formes protonées de ces composés active le groupement méthyle voisin en C-7; cet effet est beaucoup plus important que celui observé antérieurement pour un groupement méthyle en C-6, l'autre position adjacente. On ne peut faire une comparaison entre les effets des groupements méthyles et ceux des atomes d'hydrogènes en N-8 que pour les réactions acido-catalysées puisque les structures des composés neutres, qui prennent part à la réaction catalysée par les bases, ne sont pas semblables.

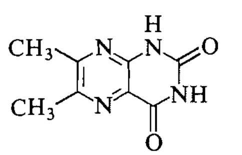
[Traduit par le journal]

Introduction

In 6,7,8-trimethyllumazine, **1**, the 7-methyl group (marked by an asterisk) is reactive and undergoes rapid general base (and general acid) catalyzed exchange in protic solvents (1–6). The presence of an *N*-alkyl group (position 8) is important here, as noted by Beach and Plaut (2), since the parent ring system has the form shown in **2**, with the consequence that a 7-methyl substituent in such compounds as **2** is relatively inert to the action of base.

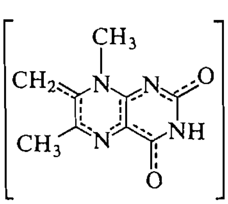


1

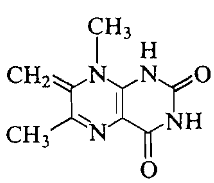


2

The kinetics and mechanism of both the general base and general acid catalyzed reactions have been thoroughly studied previously (1–6); the ease with which the two exchange processes (and other reactions) take place is a result of the stability of **3** and **4**, which are the respective intermediates in the general base and general acid catalyzed routes for **1**.



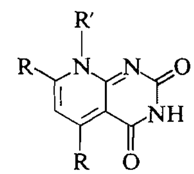
3



4

In the case of 5,7,8-trimethyl-5-deazalumazine **5** (R = R′ = CH_3), the methyl groups at the 5- and 7-positions both undergo isotopic exchange, although their reactivity is much less than is the case with the 7-methyl group in **1**.

We have previously observed that an alkyl group at position 6 activates the reactive methyl group at the neighbouring positions in **1** and **5**, whereas more distant methyl groups are



5

substantially deactivating, as shown, for example, by the mutual deactivating effects of the 5- and 7-methyl groups in **5** (R = R′ = CH_3) (6, 7).

We wished to examine the effect of a neighbouring alkyl group at nitrogen (position 8 in, for example, **1**) to see if it too activates the group at position 7. As noted earlier, the reactions of **1** and **2** with base cannot be directly compared because of structural differences. Although the general base catalyzed reaction is thus disqualified from consideration in this respect, the general acid catalyzed reaction is not. This is because protonation occurs at N-8 in **2** (7), and at N-1 in **1**,[2] which

produces identical cations except for the substitution of hydrogen for methyl at N-8 (eqs. [1] and [2]).

In the present work we compare the rate of exchange of deuterium for protium in the 7-methyl groups of **1** and **2** and at the 5- and 7-positions of **5** (R = CH_3, R′ = H or CH_3) under strongly acidic conditions. In addition, several other relevant lumazine derivatives have been prepared and examined.

Experimental

Synthesis

(a) *8-Alkyllumazines*

6-Chlorouracil was nitrated by the method of Cheng and Cheng (9) to give 6-chloro-5-nitrouracil, which was converted to the several 6-alkylamino-5-nitrouracils by treatment with the appropriate alkylamine. These compounds were then suspended in 50% ethanol–water and reduced with sodium dithionite. A 1,2-diketone (butane-2,3-dione or pentane-2,3-dione) was added to the warm solution of the diamine and the mixture heated for a further 15 min. The reaction solutions were then taken to dryness and separated on a silica gel column with methanol/water as the eluant. The resulting lumazines were recrystallized from ethanol–water to give yellow to orange crystals. The products were **1** (1), **6** (6), and **8**. The nmr spectra of **8** consisted of a triplet centered at δ 1.77 (3H), singlets at 2.97 (3H) and at 3.17 (3H), and a quartet centered at 4.96 (2H). *Anal.* calcd. for $C_{10}H_{12}N_4O_2$: C 54.54, H 5.49, N 25.44; found: C 54.34, H 5.57, N 25.58.

(b) *6,7-Dimethyllumazine (2) and 7-methyllumazine (7)*

These compounds were prepared in the same manner as the *N*-alkyllumazines, except that 5,6-diaminouracil and butane-2,3-dione and pyruvaldehyde were used. The latter compound gave a mixture of the 6- and 7-methyl isomers. (Sharefkin, using the same method, appeared to get only 7-methyllumazine (10).) The exchange reactions were carried out on the mixture and showed that the hydrogen atoms of the methyl group of only one of the components underwent exchange. Exchange was also observed for one of the methyl groups of **2**, presumably that at the 7-position since Beach and Plaut observed that 6-methyllumazine does not undergo exchange in D_2O (2). Compound **2** was recrystallized repeatedly from water and gave white crystals. *Anal.* calcd. for $C_8H_8N_4O_2$: C 50.00, H 4.20, N 29.15; found: C 49.75, H 4.30, N 29.05.

(c) *5-Deazalumazines*

Compound **9** was prepared as previously described (6). 6,7-Dimethyl-5-deazalumazine (**10**), which has been previously synthesized by Robins and Hitchings (11), was prepared by the following alternative procedure. 6-Aminouracil in 10% sulfuric acid was refluxed with the dimethyl acetal of 2-methyl-3-oxobutanal for 2 h. The solution was cooled and neutralized with aqueous ammonia and the precipitated solid crystallized repeatedly from water to give white crystals of **10**; nmr in trifluoroacetic acid, δ: 2.63 (3H), 2.93 (3H), and 8.94 (1H). 5,6-Dimethyl-5-deazalumazine (**11**) was prepared as described by Wood *et al.* (12), except that the mixture was refluxed for 3 h instead of being stirred at room temperature for 36 h; the product was recrystallized from water – dimethyl sulfoxide. The nmr spectrum of the product in trifluoroacetic acid agreed with that given by Wood *et al.*

pK_{BH^+} measurements

Basicity constants were determined spectrophotometrically in aqueous solution, essentially as previously described (6), except that aqueous sulfuric acid was used for the least basic compounds, with the H_0 value of the solution being used to calculate pK_{BH^+} (13).

Rate measurements

The exchange reaction was followed in D_2SO_4–D_2O mixtures by means of nmr spectroscopy, essentially as previously described (4, 14).

Results and discussion

In Table 1, the exchange kinetics for the lumazines and deazalumazines are given for two concentrations of sulfuric acid. The rates are generally smaller in the more concentrated acid, presumably as a result of the lower activity of water in this solution; incomplete protonation of some of the substrates in the 25% acid medium appears to be largely responsible for the variation in the ratios of the rates in the two media from compound to compound. (The weakest base among the compounds studied is 7-methyllumazine (**7**), for which pK_{BH^+} must be more negative than −2.0, judging from the effect of the additional 6-methyl group in **1** compared to **6**; because the H_0 scale was used in the pK determinations and the H_0 value of 25% sulfuric acid is only −1.4, the substrate will be less than 20% protonated in this medium.)

It is clear from a comparison of the reactivities of **1** and **2**, **6** and **7**, and **9** and **10** that replacing a hydrogen atom at position 8 with a methyl group has a large accelerating effect (between one and two orders of magnitude) on the exchange rate of the protons of the adjacent methyl group. This effect is in the same direction but is significantly greater than the effect of a methyl group at the other neighbouring position, that is, at position 6. It is also greater than the effect that *N*-methylation produces in pyrimidonium systems (15). There is always the possibility in reactions of the type considered herein that the reactive protonated intermediate is not the normal cationic form (eq. [2]) but a minor tautomer, which would make a simple comparison of rates invalid. This possibility seems remote in the present instance since the only stable neutral intermediate that can be

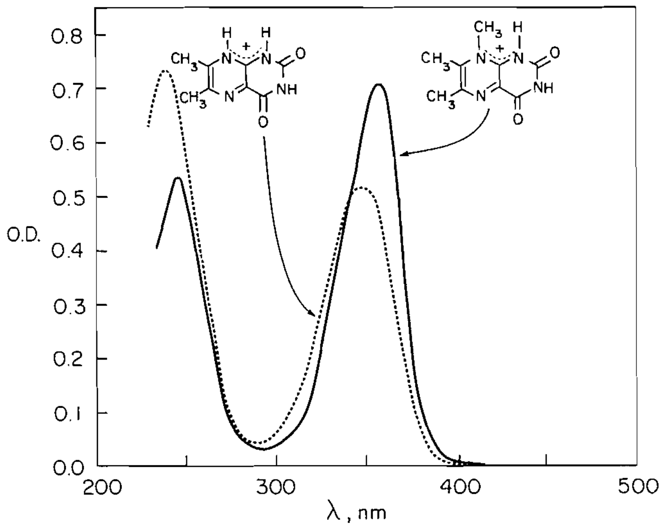

FIG. 1. Ultraviolet absorption spectra of **1** (solid line) and **2** (dotted line) in 52% aqueous sulfuric acid, $C = 5.1 \times 10^{-5}$ molar; λ_{max} and log ϵ values are, for **1**, 358 nm (4.15) and 245 nm (4.02), and for **2**, 347 nm (4.00) and 236 nm (4.15).

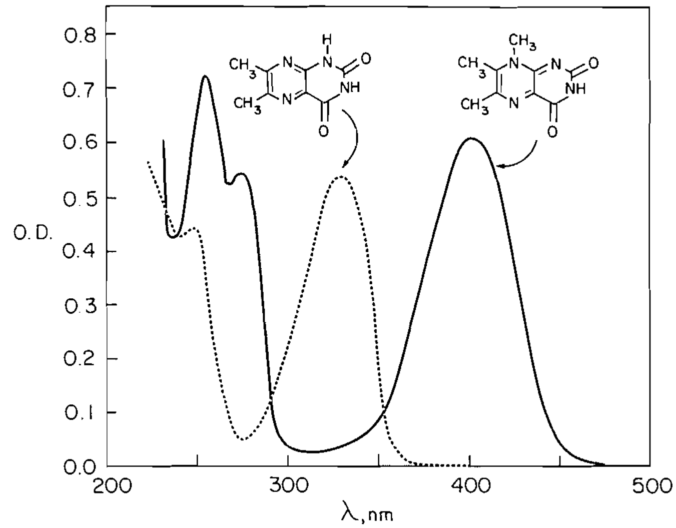

FIG. 2. Ultraviolet absorption spectra of **1** (solid line) and **2** (dotted line) in water, $C = 5.1 \times 10^{-5}$ molar; λ_{max} and log ϵ values are, for **1**, 403 nm (4.06) and 275 nm (4.02), and 255 nm (4.15), and for **2**, 328 nm (4.01) and 249 nm (3.93).

formed by deprotonating the 7-methyl group is **4**, which is derived from the predominant cation (eq. [2]). In this connection, the ultraviolet spectra of **1** and **2** are very similar in acid solution (Fig. 1), except that the 8-methyl group that is present in the conjugate acid of **1** and absent in that of **2** causes a red shift of about 10 nm in the principal absorption bands. As can be seen, the neutral forms of **1** and **2** have quite different spectra (Fig. 2). Furthermore, the nmr spectra of **1** and **2** in trifluoroacetic acid solution are very similar except for the presence of an additional methyl absorption in the conjugate acid of **1**. The 7-methyl group (that which undergoes exchange) is at δ 2.98 in **1**.H^+ and at 2.93 in **2**.H^+; the 6-methyl group is at 2.68 in **1**.H^+ and at 2.63 in **2**.H^+.

We had earlier considered the possibility that strain induced by the presence of adjacent alkyl groups might be responsible for the higher reactivity we have found to be associated with clustering of methyl groups, although it is not obvious in many cases that a partial proton loss from a C-5 or C-7 or analogous methyl group would, in fact, relieve such strain. An examination of the crystal structures of a number of alkyl substituted pyrimidonium salts that exhibit steric acceleration showed that ring strain was not the major factor in determining the reactivity of the groups in question, although it appeared to play a role in several cases (15). It is entirely possible that the lumazine system is more sensitive than the pyrimidonium system to ring strain and that this is reflected in the large effect we observe for alkylation of the nitrogen atom at position 8. At any rate, it is clear that the phenomenon of neighbouring alkyl groups increasing the prototropic reactivity of the 7-methyl group in lumazines and 5-deazalumazines applies to methyl substitution at both positions 6 and 8, with substitution at the latter position producing the larger effect. It can be seen from the results in Table 1 that the effect of ethyl at N-8 is little different from that of methyl; repeated attempts to prepare the compounds possessing an isopropyl or *tert*-butyl group at N-8 were unsuccessful.

With regard to conformational effects in the sidechains themselves, it may well be that proton loss from methyl changes the conformation from one that is gear-clashed methyl–methyl (16, 17) to one that is gear-meshed (or gear-locked) methyl– methylene. The possibility that this effect is favourable, together with a consideration of polarizability effects and hybridization changes at nitrogen, will be addressed in a subsequent publication.

Basicity constants

Lumazines that carry an 8-substituent have a ring structure of the type shown in **1** and those that lack such a group have a ring structure of the type shown in **2**. The greater stability of the latter system is reflected in the lower basicity of such compounds, the difference amounting to 1.7 p*K* units in the case of the isomeric compounds **2** and **6**. In the case of the deazalumazines the p*K* difference appears to be somewhat less, being only 1.4 units (including the inductive effect of an additional methyl group) in the cases of **9** and **10**.

Received February 14, 1985

MICHAEL JESSE BLANDAMER, JOHN MARSHALL WILLIAM SCOTT, and DANNY SUMMERS. Can. J. Chem. **63**, 3294 (1985).

The differential equations which describe the kinetics of the general reaction

$$\mathrm{A + B} \underset{k_2}{\overset{k_1}{\rightleftarrows}} \mathrm{C} \xrightarrow{k_3} \mathrm{D}$$

are cast in a nondimensional form and analysed. The problem reduces to two first-order nonlinear ordinary differential equations containing three nondimensional constants together with two initial conditions. Composition–time curves are deduced for the general case. For the case when $k_2/k_1\,[\mathrm{A}]_0 \ll 1$, where $[\mathrm{A}]_0$ is the initial concentration of A, simple analytical solutions are obtained. Numerical integrations of the full equations are reported and the analytical solutions are found to represent accurate solutions to the nonlinear problem for sufficiently small values of k_2.

MICHAEL JESSE BLANDAMER, JOHN MARSHALL WILLIAM SCOTT et DANNY SUMMERS. Can. J. Chem. **63**, 3294 (1985).

On a développé une forme sans dimensions et on a analysé les équations différentielles qui décrivent la réaction générale

$$\mathrm{A + B} \underset{k_2}{\overset{k_1}{\rightleftarrows}} \mathrm{C} \xrightarrow{k_3} \mathrm{D}$$

Le problème est alors réduit à deux équations différentielles ordinaires, non linéaires, du premier degré et contenant trois constantes sans dimensions et à deux conditions initiales. On a déduit, dans le cas général, les courbes de la composition en fonction du temps. On obtient des solutions analytiques simples pour le cas où $k_2/k_1\,[\mathrm{A}]_0 \ll 1$ ($[\mathrm{A}]_0$ est la concentration initiale de A). On rapporte des intégrations numériques des équations complètes et, dans les cas où les valeurs de k_2 sont suffisamment faibles, on a trouvé que les solutions analytiques représentent des solutions précises au problème nonlinéaire.

[Traduit par le journal]

Introduction

Recently we have been interested in the behaviour of the system,

$$[1] \quad \mathrm{A} \underset{k_2}{\overset{k_1}{\rightleftarrows}} \mathrm{B} \xrightarrow{k_3} \mathrm{C}$$

where k_1, k_2, and k_3 are first-order constants (1). The mathematical techniques for handling this and related systems are well developed. No analysis has been attempted in the case that k_1 is a second-order constant. The present contribution is an account of the formal treatment of the system

$$[2] \quad \mathrm{A + B} \underset{k_2}{\overset{k_1}{\rightleftarrows}} \mathrm{C} \xrightarrow{k_3} \mathrm{D}$$

where k_1 in eq. [2] is a second-order constant. It is intended to use the relationships and techniques discussed in this paper for a kinetic and thermodynamic discussion of the system

$$[2a] \quad \mathrm{A + B \rightleftarrows C \rightleftarrows D + E}$$

In the meantime the results reported in this paper would appear to be of general interest.

The general reaction, [2], is described by the following system of differential equations:

$$[3] \quad \frac{\mathrm{d[A]}}{\mathrm{d}t} = -k_1\mathrm{[A][B]} + k_2\mathrm{[C]}$$

$$[4] \quad \frac{\mathrm{d[B]}}{\mathrm{d}t} = \frac{\mathrm{d[A]}}{\mathrm{d}t}$$

$$[5] \quad \frac{\mathrm{d[C]}}{\mathrm{d}t} = k_1\mathrm{[A][B]} - (k_2 + k_3)\,\mathrm{[C]}$$

$$[6] \quad \frac{\mathrm{d[D]}}{\mathrm{d}t} = k_3\mathrm{[C]}$$

and subject to the boundary conditions,

$$[7] \quad \mathrm{[A]} = \mathrm{[A]}_0,\ \ \mathrm{[B]} = \mathrm{[B]}_0,\ \ \mathrm{[C]} = 0,\ \ \mathrm{[D]} = 0 \text{ at } t = 0$$

If the concentrations [A], [B], [C], and [D] are measured on the molar concentration scale, their second-order rate constant k_1 has the dimensions $\mathrm{dm^3\ mol^{-1}\ s^{-1}}$, and the first-order rate constants k_2 and k_3 have dimensions $\mathrm{s^{-1}}$. The system of eqs. [3]–[6] is symmetrical with respect to the interchange of [A] and [B].

Equation [4] may be readily integrated to give

$$[8] \quad \mathrm{[B]} = \mathrm{[A]} + \mathrm{[B]}_0 - \mathrm{[A]}_0$$

and from eqs. [3], [5], and [6] we may deduce that

[1] Author to whom correspondence may be addressed.

$$[9] \quad \frac{d[A]}{dt} + \frac{d[C]}{dt} + \frac{d[D]}{dt} = 0$$

from which we deduce the further integral

$$[10] \quad [A] + [C] + [D] = [A]_0$$

Equation [10] is more usually derived from the condition of mass balance for the system.

Elementary considerations of the isoclinals of the system lead to the following results:

(a) If $[A]_0 = [B]_0$, then

$$[11] \quad [A] \to 0, \ [B] \to 0, \ [C] \to 0, \ [D] \to [A]_0, \text{ as } t \to \infty$$

(b) if $[A]_0 > [B]_0$, then

$$[12] \quad [A] \to [A]_0 - [B]_0, \quad [B] \to 0, \quad [C] \to 0, \quad [D] \to [B]_0, \text{ as } t \to \infty$$

The symmetry of the problem with respect to A and B makes the case when $[A]_0 < [B]_0$ superfluous since it is equivalent to (b) above. The mathematical conclusions [11] and [12] follow the anticipated physical behaviour of the system for large times.

It is useful to define the following nondimensional variables:

$$[13] \quad y_1 = [A]/[A]_0; \quad y_2 = [C]/[A]_0; \quad y_3 = [D]/[A]_0; \quad y_4 = [B]/[A]_0 \text{ and } x = k_1[A]_0 t$$

With these variables the system [3]–[8] and [9] reduces to

$$[14] \quad \frac{dy_1}{dx} = (1 - \alpha)y_1 - y_1^2 + \beta y_2$$

$$[15] \quad \frac{dy_2}{dx} = -(1 - \alpha)y_1 + y_1^2 - (\beta + \gamma)y_2$$

$$[16] \quad y_1(0) = 1, \ y_2(0) = 0$$

$$[17] \quad y_3 = 1 - y_1 - y_2$$

$$[18] \quad y_4 = y_1 - (1 - \alpha)$$

where α, β, and γ are defined by the relationships

$$[19] \quad \alpha = [B]_0/[A]_0; \quad \beta = k_2/k_1[A]_0, \quad \text{and } \gamma = k_3/k_1[A]_0$$

The general problem is thus reduced to the solution of the nonlinear, autonomous system represented by eqs. [14] and [15], subject to the initial conditions [16], where α is a constant such that $0 < \alpha \leq 1$, and β and γ are both positive constants. Unfortunately, exact analytical solutions to eqs. [14] and [15] cannot be obtained, even in the special case when $\alpha = 1$. Nevertheless, the qualitative behaviour of the dimensionless quantities y_1, y_2, y_3, and y_4 is readily deduced, and the results are given schematically in Fig. 1.

Analysis

If we add eqs. [14] and [15] then

$$[20] \quad \frac{dy_1}{dx} + \frac{dy_2}{dx} = -\gamma y_2$$

Equation [20] may be integrated to yield

$$[21] \quad y_2(x) = e^{-\gamma x} - y_1(x) + \gamma e^{-\gamma x} \int_0^x e^{\gamma u} y_1(u) \, du$$

Solutions for the model are straightforward for cases when k_2 is small, i.e. when $0 < \beta \ll 1$. If $\beta = 0$, eq. [14] is reduced

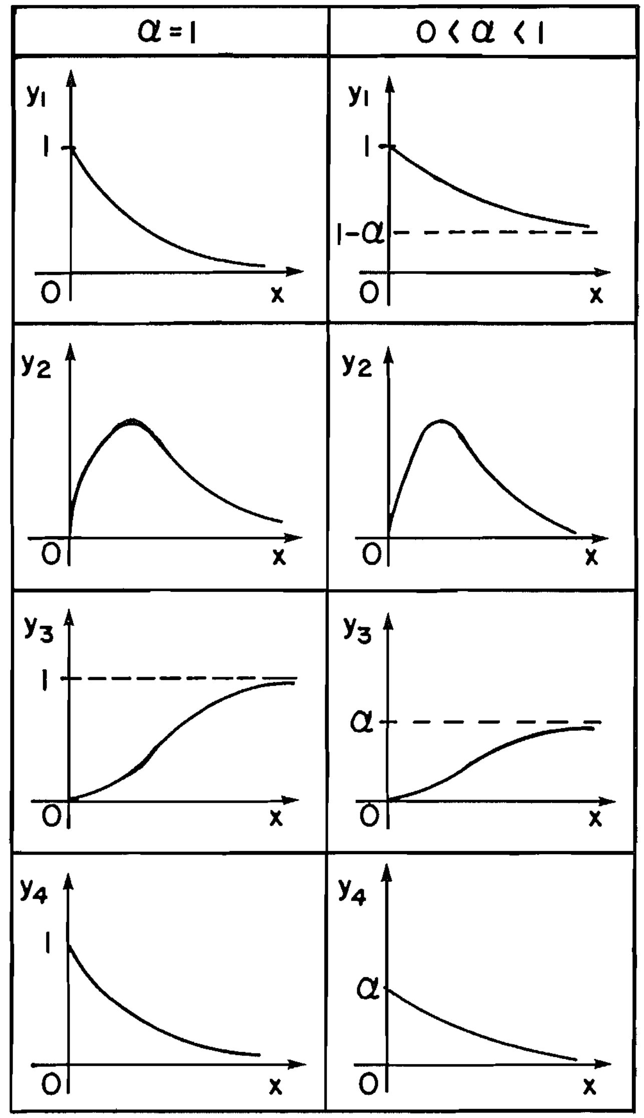

FIG. 1. Schematic solution curves of the system [14]–[18] in the cases $\alpha = 1$, and $0 < \alpha < 1$. These curves represent solutions to the reaction [2] for all possible values of the rate constants k_1, k_2, and k_3, and all initial concentrations $[A]_0$ and $[B]_0$.

to a separable equation when $\alpha = 1$, and to a Bernoulli Equation if $0 < \alpha < 1$ (e.g. see ref. 2). The appropriate solutions are given by

$$[22] \quad y_1(x) = 1/(1 + x), \quad \alpha = 1$$

$$[23] \quad y_1(x) = (1 - \alpha)/(1 - \alpha e^{-(1-\alpha)x}), \quad 0 < \alpha < 1$$

and the corresponding solutions for y_2, obtained from eq. [21], are

$$[24] \quad y_2(x) = e^{-\gamma x} - \frac{1}{x + 1} + \gamma e^{-\gamma(x+1)} I_1(x), \quad \alpha = 1$$

where

$$I_1(x) = \int_{\gamma}^{\gamma(x+1)} \frac{e^u}{u} \, du$$

$$[25] \quad y_2(x) = (1 - \alpha)\left\{1 - \frac{1}{1 - \alpha e^{-(1-\alpha)x}}\right\} + \alpha e^{-\gamma x} \times \{1 + \gamma I_2(x)\}, \quad 0 < \alpha < 1$$

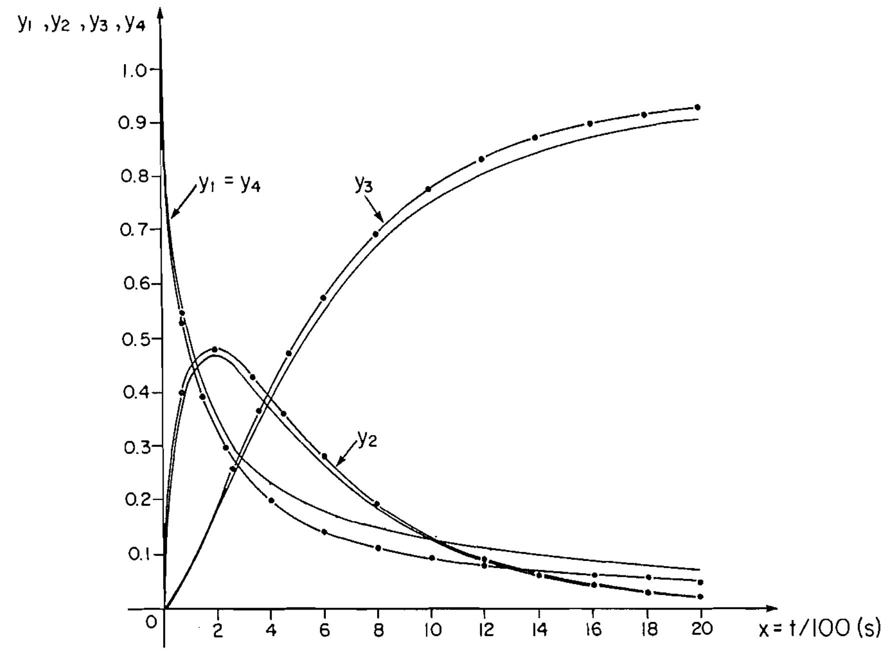

FIG. 2. Solution curves for the case k_1 = 1 $dm^3\ mol^{-1}\ s^{-1}$, $k_3 = 2.5 \times 10^{-3}\ s^{-1}$, $[A]_0 = [B]_0 = 10^{-2}$ mol dm^{-3} (i.e. $\alpha = 1$, $\gamma = 0.25$). The broken curves represent the analytical solutions [22], [24]; the full curves represent the numerical solution of the system [14]–[18] when $k_2 = 5 \times 10^{-4}\ s^{-1}$ (i.e. $\beta = 0.05$). The set of particular points shown are those of the numerical solution of [14]–[18] when $k_2 < 5 \times 10^{-5}$ s^{-1} (i.e. $\beta < 5 \times 10^{-3}$).

where

$$I_2(x) = \int_1^{e^{(1-\alpha)x}} \frac{u^{(\frac{\gamma}{1-\alpha}-1)}}{u-\alpha}\,du$$

Results [22] and [23] are well known (e.g. they appear in a slightly different form in ref. 3, pp. 335–336). The reader is also referred to the related work in refs. 6 and 7.

In general, the integrals I_1 and I_2 are not expressible in simple, closed form although they may be evaluated to any desired precision by a suitable numerical quadrature (e.g. a 5-point Newton–Cotes formula as, for instance, given in ref. 4).

The integral I_2 can be evaluated in closed form for some special cases, e.g. for $\gamma/(1-\alpha) = 1, 2, 3, \ldots,$ or for $\gamma/(1-\alpha) = 1/2$. Examples of such solutions are

$$[26] \quad I_2(x) = \ln\left\{\frac{e^{(1-\alpha)x}-\alpha}{1-\alpha}\right\}, \quad \gamma/(1-\alpha) = 1$$

$$[27] \quad I_2(x) = e^{(1-\alpha)x} - 1 + \alpha \ln\left\{\frac{e^{(1-\alpha)x}-\alpha}{1-\alpha}\right\}, \quad \gamma/(1-\alpha) = 2$$

$$[28] \quad I_2(x) = \frac{1}{\sqrt{\alpha}} \ln\left\{\left(\frac{e^{(1-\alpha)x/2}-\sqrt{\alpha}}{e^{(1-\alpha)x/2}+\sqrt{\alpha}}\right)\left(\frac{1+\sqrt{\alpha}}{1-\sqrt{\alpha}}\right)\right\}, \quad \frac{\gamma}{1-\alpha} = \frac{1}{2}$$

If desired, the solutions [21]–[24] may be extended by setting

$$[29] \quad y_1(x) = \bar{y}_1(x) + \beta Y_{11}(x) + \beta^2 Y_{12}(x) + \ldots$$

$$[30] \quad y_2(x) = \bar{y}_2(x) + \beta Y_{21}(x) + \beta^2 Y_{22}(x) + \ldots$$

where $Y_{11}(0) = Y_{12}(0) = \ldots = Y_{21}(0) = Y_{22}(0) = \ldots = 0$, and $\bar{y}_1$, $\bar{y}_2$ are the zero-order solutions given by eqs. [21]–[24]. Substitution of eqs. [29] and [30] into eqs. [13] and [10] leads to solutions for Y_{11} and Y_{21} in the form

$$[31] \quad Y_{11}(x) = \frac{1}{(x+1)^2}\int_0^x (u+1)^2 \bar{y}_2(u)\,du$$

$$[32] \quad Y_{21}(x) = -Y_{11}(x) + \gamma e^{-\gamma x}\int_0^x e^{\gamma u}\,Y_{11}(u)\,du$$

for the case $\alpha = 1$. The series solutions [29] and [30] are not considered further here. Rather, the utility of the zero-order solutions [22]–[25] is examined by comparing these with the numerical solutions of eqs. [14] and [15].

Numerical results and discussion

Figures 2 and 3 represent solutions to the model when $\alpha = 1$ and $\alpha = 0.5$, respectively. In both figures the values for k_1 and k_3 are respectively 1 $dm^3\ mol^{-1}\ s^{-1}$, $2.5 \times 10^{-3}\ s^{-1}$, and $[A]_0 = 10^{-2}$ mol dm^{-3}. In Fig. 2 we have taken $[B]_0 = 10^{-2}$ mol dm^{-3}, and in Fig. 3 we have taken $[B]_0 = 5 \times 10^{-3}$ mol dm^{-3}. Equations [14] and [15] were integrated numerically on an IBM 370 machine using an algorithm based on a modified divided-difference form of the Adams–Pece formulae and local extrapolation (see ref. 5). The algorithm adjusts the order of the interpolation scheme and the step size so as to control the local error per unit step. The analytical solutions [22]–[25] were found in general to represent accurately the numerical solutions to the full equations for sufficiently small values of the parameter β. In particular, the analytical and numerical composition–time curves are virtually coincident for values of β when $\beta < 5 \times 10^{-3}$ (or $k_2 < 5 \times 10^{-5}\ s^{-1}$) for $\alpha = 1$, and when $\beta < 0.01$ (or $k_2 < 10^{-4}\ s^{-1}$) for $\alpha = 0.5$. Numerical solutions are also given for $\beta = 0.05$ in both of the cases $\alpha = 1$ and $\alpha = 0.5$. We note that when the concentration of species B is depleted the reaction approximates a simple (first-order) reac-

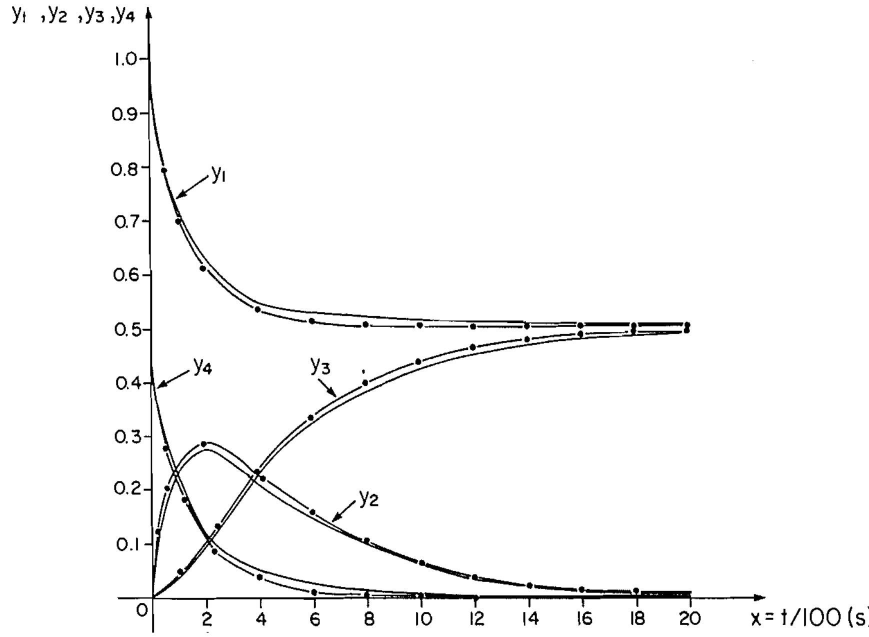

FIG. 3. Solution curves for the case k_1 = 1 dm^3 mol^{-1} s^{-1}, k_3 = 2.5 × 10^{-3} s^{-1}, [A]$_0$ = 10^{-2} mol dm^{-3}, and [B]$_0$ = 5 × 10^{-3} mol dm^{-3} (i.e. α = 0.5, γ = 0.25). The broken curves represent the analytical solutions [23], [25]; the full curves represent the numerical solution of the system [14]–[18] when k_2 = 5 × 10^{-4} s^{-1} (i.e. β = 0.05). The set of particular points shown represents those of the numerical solution of [14]–[18] when $k_2 < 10^{-4}$ s^{-1} (i.e. $\beta < 0.01$).

tion, and the model becomes virtually linear. This situation occurs in Fig. 3 for $x > 6$ (or $t > 600$ s). General solutions for [C] and [D] when [B] is negligible (or when [A] $\doteqdot$ [A]$_0$ − [B]$_0$) are given by

$$[33] \quad y_2 \doteqdot K(\alpha, \gamma)e^{-\gamma x}, \quad y_3 \doteqdot \alpha - K(\alpha, \gamma)e^{-\gamma x}$$

where K is a constant depending on the parameters α and γ. Results [33] may be deduced from the solutions [17], [18], [23], and [25] by letting $x \rightarrow \infty$.

In summary, we find that though the full nonlinear equations [13] and [14] are not amenable to analytical solutions, the simple analytical solutions [22]–[25] represent accurate, useful solutions to the nonlinear model for the case when the parameter $\beta = k_2/k_1$ [A]$_0$ is sufficiently small.

The crystal structure of a chiral *m*-cyclophane, the α-isomer of (*S*)-α-methoxy-α-(trifluoromethyl)phenylacetate ester of 13-(methoxycarbonyl)-14-hydroxy-17-methyl-[11]-*m*-cyclophane ($C_{30}H_{37}O_5F_3$, FW = 534.62) has been solved by direct methods and refined by a least-squares procedure to a final R = 0.048 for 2756 independent reflections. The crystals belong to the orthorhombic system, a = 10.8077(13), b = 13.676(3), c = 19.060(4) Å, V = 2817.2 Å^3, Z = 4, and the space group is $P2_12_12_1$. The absolute configuration of the chiral plane, using the *S*-configuration of the α-methoxy-α-(trifluoromethyl)phenylacetate ester as reference, is found to be *S*, in agreement with the X-ray result. The 14-membered ring has the slightly distorted rectangular conformation that has been described by Dale as the rectangular diamond-lattice conformation [3434]. The distortions, also observed in similar 14-membered rings, have been successfully approximated by molecular mechanics calculations.

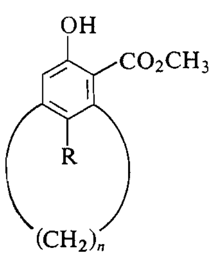
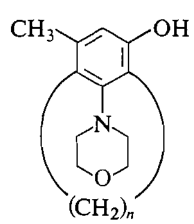
La structure cristalline d'un *m*-cyclophane chiral, l'isomère α de l'ester (*S*)-α-méthoxy-α-(trifluorométhyl)phénylacétate de 13-(méthoxycarbonyl)-14-hydroxy-17-méthyl-[11]-*m*-cyclophane ($C_{30}H_{37}O_5F_3$, PM = 534,62) a été déterminée par méthodes directes et affinée par moindres-carrés jusqu'à la valeur finale de R = 0,048 pour 2756 réflexions uniques. Les cristaux appartiennent au système orthorhombique, a = 10,8077(13), b = 13,676(3), c = 19,060(4) Å, V = 2817,2 Å^3, Z = 4 et le groupe d'espace est $P2_12_12_1$. En se basant sur la configuration *S* de l'ester α-methoxy-α-(trifluorométhyl) phénylacétate comme référence, la configuration absolue du plan chiral est aussi *S*, en accord avec la détermination par rayons X. Le cycle à 14 atomes a la conformation rectangulaire [3434] légèrement déformée telle que décrite à partir de la structure du diamant par Dale. Ces déformations, aussi observées dans d'autres cycles à 14 atomes, ont pu être raisonnablement reproduites par des calculs de mécanique moléculaire.

Introduction

We recently reported (1, 2) on the first successful optical resolution of a number of intraannularly substituted chiral *m*-cyclophanes such as **1** and **2**. The existence of enantiomerism in these compounds, which belong to the class of "planar"



1



2

dissymmetric molecules, is caused by restricted rotation of the macrocyclic hydrocarbon ring. As long as the cavity of the hydrocarbon ring is not large enough to accommodate the intraannular substituent, the hydrocarbon ring and the intraannular substituent must be located on different sides of the aromatic plane. For example, since the aromatic ring in **1** is also substituted by two different groups, the compound is chiral and, in practice, resolvable if the energy barrier of the rotation is sufficiently high. This can easily be ascertained through the use of dynamic nmr studies to probe the energy barrier of the rotational process (1).

To further investigate the stereochemical properties of these chiral *m*-cyclophanes, the absolute configurations of these compounds were needed. A number of methods are available for the correlation of absolute configurations of "planar" dissymmetric molecules, provided that a configuration standard is available (3). Since these are the first optically active *m*-cyclophanes to be resolved, direct X-ray determination was used to unequivocally deduce their absolute configurations.

Experimental

Compound **3**, the (*S*)-α-methoxy-α-(trifluoromethyl)phenylacetate ester of 13-(methoxycarbonyl)-14-hydroxy-17-methyl-[11]-*m*-cyclophane, was prepared and purified by flash chromatography into two diastereoisomers (α and β) (1). The α-diastereoisomer was recrystallized from hexane to give clear, well-developed crystals. The large crystals so obtained were cut to get a fragment of 0.18 × 0.40 × 0.40 mm, suitable for X-ray diffraction. Accurate unit-cell dimensions were derived from the angular settings of 25 well-centered reflections chosen in the range $16 < 2\theta < 38°$. The space group is $P2_12_12_1$, since the only systematic absences are of the type $h00$, $h \neq 2n$; $0k0$, $k \neq 2n$; and $00l$, $l \neq 2n$. Crystal data of interest are given in Table 1. The data collection was performed by the $\omega-2\theta$ scan method with a scan width $\Delta\omega = (1.00 + 0.14 \tan\theta)°$ on a Nonius CAD-4 automatic diffractometer. The orientation and stability of the crystal were monitored using standard reflections whose intensities were measured every hour and their orientation checked every 100 reflections. Using the CuKα graphite monochromatized radiation, the intensities of 3269 reflections were measured within the sphere of reflection limited by $2\theta_{max} = 150°$ and $0 \leq h \leq 13$, $0 \leq k \leq 17$, $0 \leq l \leq 23$. The largest fluctuation of the intensities of the standards was 1.9%. The 2756 reflections satisfying $I \geq 1.96\,\sigma(I)$ were retained for the structure determination and refinement. No absorption correction was applied since the absorption coefficient was small. The structure

was solved by direct methods using MULTAN.[2] The least-squares refinement based on F's (by the block-diagonal approximation, anisotropic for F, O, and C and isotropic for H atoms) converged to R = 0.048, R_w = 0.058, S = 1.37. The weights were derived from the counting statistics. Maximum (Δ/σ) = 0.55 and mean (Δ/σ) = 0.09. The extreme values of the residual electron density on the final difference Fourier map were −0.21 and +0.19 e Å^{-3}. Although the anomalous dispersion contributions of O and F are very small, for the other configuration, the values of R, R_w, and S are 0.048, 0.059, and 1.38, respectively, thus indicating that the most likely absolute configuration is that which was found in the first place. The scattering curves for C, O, and F were taken from Cromer and Mann (4), and from Stewart, Davidson, and Simpson (5) for H atoms. The real and imaginary parts of the anomalous scattering for O and F were those of Cromer and Liberman (6).

Results and discussion

The final atomic coordinates and the equivalent U_{iso} values are given in Table 2.[3] For the purpose of discussion of the X-ray results the atomic numbering for compound **3** is shown

[2] The programs used here are modified versions of NRC-2, data reduction; NRC-10, bond distances and angles; and NRC-22, mean planes; FORDAP, Fourier and Patterson maps (A. Zalkin); MULTAN, multisolution program; NUCLS, least-squares refinement; and ORTEP stereodrawings (7–10).

[3] Tables of atomic positions for hydrogen atoms, least-squares planes, anisotropic temperature factors, and structure factors have been deposited and may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

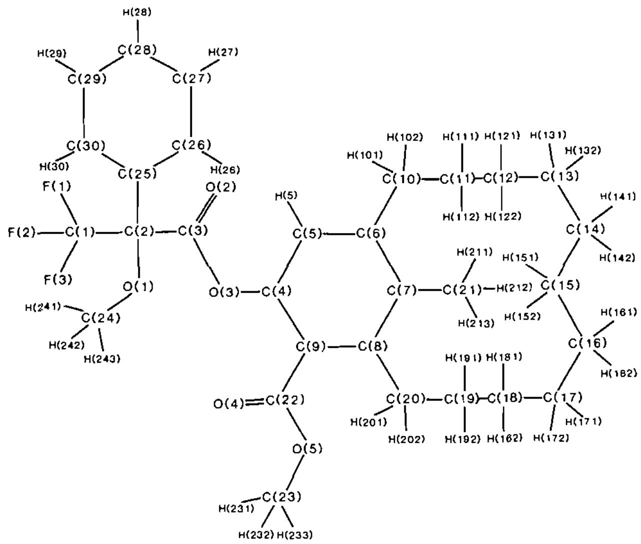

FIG. 1. Schematic view of the molecule and atomic numbering.

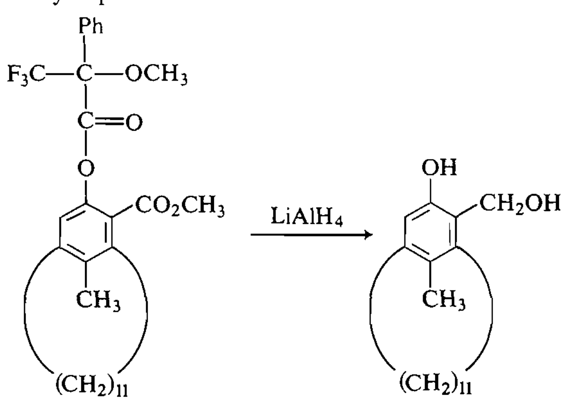
in Fig. 1 while a stereoview showing the molecular conformation is represented in Fig. 2. The bond distances and bond angles of the molecule are given in Table 3.

Since **3** was prepared from (*S*)-α-methoxy-α-(trifluoromethyl)phenylacetate acid, the chiral center at C(2) has the *S* configuration. This is in agreement with the absolute configuration indicated by the X-ray structure and represented in Fig. 2. One can deduce from Fig. 2 that the chiral plane in the *m*-cyclophane moiety of **3** has the *S*-configuration (11). Since **3** was reduced by lithium aluminium hydride to obtain (+)-13-hydroxymethyl-14-hydroxy-17-methyl-[11]-*m*-cyclophane (**4**), it follows that (+)-**4** has the *S*-configuration as well. Compound **4** can now serve as the configurational standard for other chiral *m*-cyclophanes.



α-**3** (+)-**4**

In addition to a confirmation of the absolute configuration, the X-ray structural data yielded other information of general interest, which is discussed below.

The 14-membered ring

Previous theoretical energy minimization calculations (12–15) have led to the most likely 14-membered ring conformation, which is described by Dale in terms of a diamond lattice (14, 16). At the same time, a number of crystal structures involving 14-membered rings have been reported. These are 1,8-dihydroxy-1,8-diazacyclotetradecane (17), cyclotetradecane oxime (18), cyclotetradecane (19), and cyclotetradecanone (20). In all these compounds the "rectangular" diamond-lattice conformation [3434] is favoured (see Fig. 3). In order to describe the 14-membered ring and to compare it with the theoretical and observed conformations, the following least-squares planes of atoms characterizing the "rectangular" lattice have been defined. Plane A = [C(10), C(11), C(12), C(13)]; plane B = [C(17), C(18), C(19), C(20)]; plane C = [C(6), C(7), C(8), C(10), C(20)]; and plane D = [C(13), C(14), C(15), C(16), C(17)]. These groups of atoms are not strictly coplanar, since the extreme deviations from their respective least-squares planes[3] are 20 σ, 25 σ, 8 σ, and 8 σ, respectively. Nonetheless, the general features of the rectangular conformation are apparent from the dihedral angle values. These are compared in Table 4 to the corresponding quantities in the diamond-based rectangular conformation (4). This comparison reveals, however, one important discrepancy. The C and D planes, which should be parallel to each other, form an angle of 15° between one another. It is the presence of the C(21) methyl group that is responsible for the observed distortion. The two planes are tilted with respect to one another in order to minimize the interactions between H atoms on C(21) and those on C(10) and C(11), as well as those on C(19) and C(20). The shortest intramolecular contacts are H(211)—H(191) = 2.22(5) Å, H(211)—H(111) = 2.42(5), H(212)—H(101) = 2.23(5), H(212)—H(111) = 2.57(5), H(213)—H(191) = 2.66(5), and H(213)—H(201) = 2.23(6). Other contacts are larger than 3.00 Å. To appreciate the conformation of the 14-membered ring in greater detail, the endocyclic torsion angles of this molecule and others whose structures have already been established are compared, in Table 5, to those derived from the rectangular diamond lattice.

It is apparent that none of the crystal conformations conforms strictly to the theoretical one. Even cyclotetradecane, an unsubstituted 14-membered ring, has torsion angles in its conformation deviating by as much as 10° from predicted values. There is at least one feature common to all these structures, that is, both C(10)—C(11)—C(12)—C(13) and C(17)—C(18)—C(19)—C(20) torsion angles have values always close to 170° rather than the expected 180°. This systematic difference is

significant. All the other deviations are small or may be attributed to the presence of various ring substituents. For instance, in the case of the compound under study, four torsion angles differ significantly from their counterparts in other 14-membered rings. These are the torsion angles C(8)—C(7)—C(6)—C(10), C(7)—C(6)—C(10)—C(11), C(19)—C(20)—C(8)—C(7), and C(20)—C(8)—C(7)—C(6). The effect of having the 14-membered ring fused along C(6)—C(7) and C(7)—C(8) of the benzene ring in **3** should not cause the torsion angle to deviate from 180°, and yet as much as a 10° difference is observed.

The 14-membered ring has an apparent mirror plane of symmetry. The distances from equivalent atoms to the pseudo-mirror plane, defined by O(3), C(4), C(7), C(15), and C(21) are compared in Table 6. The average deviation from a perfect plane of symmetry is less than 0.02 Å.

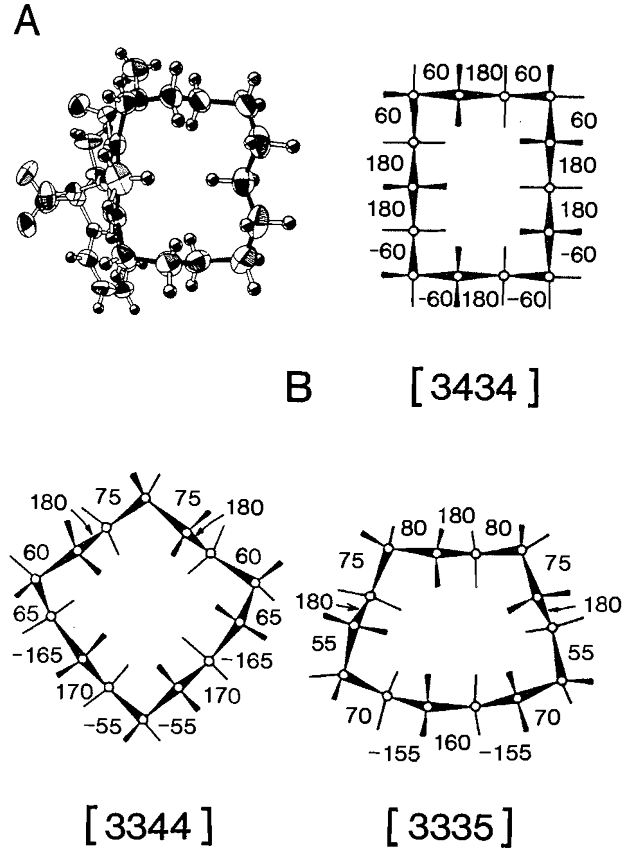

FIG. 3. (A) The conformation of the 14-membered ring of **3** shown in the same orientation. (B) The three lowest energy conformations, including the [3434] (after ref. 14) rectangular diamond conformation.

TABLE 4. Dihedral angles (degrees)

	Dihedral angles between planes					
Reference	A/B	C/D	A/C	A/D	B/C	B/D
This work	3	15	92	90	91	90
Rectangular diamond lattice (14)	0	0	90	90	90	90

The aromatic rings C(4) → C(9) and C(25) → C(30)

In the first ring, the averages of the bond distances and bond angles are 1.393 Å and 119.9°, respectively. However, the ring is very strongly distorted. When all six atoms are included in the least-squares plane calculation, C(7) is 15 σ away from the plane. Once C(7) is excluded, the five remaining atoms are closer to a plane. Then C(7) and C(21) are displaced from that plane by 0.086(3) Å and 0.318(4) Å, respectively.

This distortion is again related to the short contacts between the H atoms on C(21) and those in the 14-membered ring. The other atoms bonded to the benzene ring, C(10), C(20), and C(22), are at 0.100(3), −0.168(3), and 0.026(3) Å, respectively. There is nothing unusual in the benzene ring containing atoms C(25) → C(30); the average C(sp^2)—C(sp^2) bond distance is 1.380 Å, the six carbon atoms are coplanar, and the H atoms are all within 0.02 Å from this plane.

The trifluoro group

The three C—F distances varying between 1.325(4) and 1.343(4) Å compare well with published data. The bond angles around C(1) vary significantly, depending upon whether one or two fluorine atoms are implicated. The averages for the C—C—F and the F—C—F angles are 111.8 and 107.0°, respectively.

A view of the disposition of the various substituents at C(2) and C(3) is shown in Fig. 4 by the Newmann projection along the C(2)—C(3) bond.

There are no unduly short contacts between neighbouring molecules. The relative disposition of the molecules in their unit cell is shown in Fig. 5.

Molecular mechanics calculation

In view of some important deviations of the crystal structure of **3** and others from the "theoretical" conformation based on the diamond lattice, we have carried out a molecular mechanics calculation for **3**. Using Still's (21, 22) programs MODEL[4] (an enhanced graphics interactive version of Allinger's MM2 molecular mechanics program (23)) and RINGMAKER (a ring/chain generating program), 317 random starting conformations with torsion angle constraints of 60° resolution were generated for the 14-membered ring from an energy preminimized *m*-dimethylene substituted phenyl appendage. Multiple energy minimizations reduced these to 30 unique local energy minimized structures, 9 of which were found to be within 3.0 kcal mol^{-1} of the global energy minimum (65.2 kcal mol^{-1}) conformer. The 3.0 kcal mol^{-1} limitation was set to ignore negligibly populated conformational states.

Further minimization of the global energy minimum conformer by minor movement of the atomic coordinates of each

[4] MM2 is available from Indiana's University Quantum Chemistry Program Exchange as program number 395.

TABLE 5. Comparison of torsion angles (degrees) in 14-membered rings

atom led to a final global energy minimum of 65.0 kcal mol^{-1}. However, since MODEL only approximates delocalized π-systems as comprisng 1,3-butadiene components, the atomic coordinates of this conformer were then used as input to

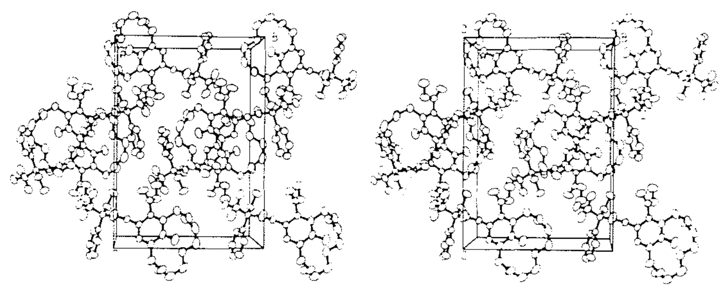

FIG. 5. Packing of the molecules in the unit cell.

MMPM,[5] a π-enhanced version of MM2 for recalculation under the π-planar non-restriction mode. This resulted in a new energy minimum of 77.8 kcal mol^{-1} and values for the torsion angles about the 14-membered ring that can be considered to be within the experimental error of the corresponding angles in the X-ray structure. For comparison, we have listed in Table 5, column 7, the torsion angles of the 14-membered ring conformer derived from the MMPM calculation. It is clear from Table 5 that, in this example, the combination of these programs has successfully approximated, within 5°, the observed deviations of the C(10)—C(11)—C(12)—C(13) and the C(17)—C(18)—C(19)—C(20) torsion angles from the ideal value of 180°. Since these deviations are also observed in all the 14-membered rings whose X-ray structures have been reported, they suggest that in the crystal structure of **3**, the deviation from the ideal diamond-lattice conformation is not due to any solid state effect in the crystal lattice, but inherent in the structure itself.

The solvolysis of metal fluorosulfates in trifluoromethyl sulfuric acid

S. P. MALLELA, J. R. SAMS, AND F. AUBKE
Department of Chemistry, The University of British Columbia, Vancouver, B.C., Canada V6T 1Y6

Received April 2, 1985

S. P. MALLELA, J. R. SAMS, and F. AUBKE. Can. J. Chem. **63**, 3305 (1985).

The quantitative conversion of fluorosulfates into trifluoromethyl sulfates is systematically investigated. The reaction proceeds initially according to the general equation

$$E(SO_3F)_n + nHSO_3CF_3 \xrightarrow[HSO_3CF_3]{T\,=\,25-80^\circ C} E(SO_3CF_3)_n + nHSO_3F$$

where E is a coordinatively saturated metal or an organometallic moiety. However, the key to a quantitative substitution is the observed degradation of the SO_3F group by excess HSO_3CF_3 and the noted observation of various volatile by-products that do not appear to interfere in the isolation of analytically pure trifluoromethyl sulfates. The fluorosulfates selected are representatives of the most common bond and coordination types—ionic or covalent with coordination through one, two, or three oxygens of the SO_3F groups. The selected substrates display a fairly wide range of solubilities in HSO_3F. All conversion attempts are successful except for one, that of polymeric $Hg(SO_3F)_2$, and a number of new SO_3CF_3 derivatives of tin, platinum, germanium, and palladium are described. The solvolysis of tin(IV) acetate in HSO_3CF_3 is reinvestigated and the syntheses of two other trifluoromethyl sulfuric acid derivatives, $CsSO_3CF_3 \cdot HSO_3CF_3$ and $CH_3CO_2H \cdot HSO_3CF_3$, are described.

S. P. MALLELA, J. R. SAMS et F. AUBKE. Can. J. Chem. **63**, 3305 (1985).

On a étudié d'une façon systématique la conversion quantitative des fluorosulfates en sulfates de trifluorométhyles. Au départ, la réaction procède d'après l'équation générale

$$E(SO_3F)_n + nHSO_3CF_3 \xrightarrow[HSO_3CF_3]{T\,=\,25-80^\circ C} E(SO_3CF_3)_n + nHSO_3F$$

dans laquelle, E est un métal saturé par coordination ou une groupement organométallique. Toutefois, la clé à une substitution quantitative est l'observation de la dégradation du groupement SO_3F par un excès de HSO_3CF_3 ainsi que celle de la formation de divers produits secondaires volatils qui ne semblent pas interférer dans l'isolement de sulfates de trifluorométhyles qui sont analytiquement purs. Les fluorosulfates choisis sont représentatifs des types de liaisons et de coordinations les plus courantes—ionique ou covalente avec des coordinations impliquant un, deux ou trois des oxygènes des groupements SO_3F. Les solubilités, dans le HSO_3F, des diverses substantes choisies correspondent à un large éventail. Tous les essais en vue d'effectuer des conversions ont réussi, à l'exception de celui réalisé sur du $Hg(SO_3F)_2$ à l'état de polymère; on décrit les propriétés d'un certain nombre de nouveaux dérivés SO_3CF_3 de l'étain, du platine, du germanium et du palladium. On a réétudié la solvolyse de l'acétate d'étain(IV) dans le HSO_3CF_3 et on décrit les synthèses de deux autres dérivés de l'acide trifluorométhylsulfurique, $CsSO_3CF_3 \cdot HSO_3CF_3$ et $CH_3CO_2H \cdot HSO_3CF_3$.

[Traduit par le journal]

Introduction

Trifluoromethyl sulfuric acid, HSO_3CF_3, and fluorosulfuric acid, HSO_3F, have many chemical and physical properties in common (1, 2). Both rank among the strongest simple protonic acids. While the exact order of acid strength is subject to some discussion (3–5), the actual difference in acidity appears to be rather small. Both are strongly ionizing solvents, and both form the basis for superacid systems with solutes such as SbF_5 and TaF_5 (5). In addition to solvent characteristics, many physical properties are intriguingly similar for both acids (1, 2).

A large number of derivatives are known for both HSO_3CF_3 and HSO_3F. These range from ionic salts with $SO_3CF_3^-$ and SO_3F^- anions (1, 2, 6), over halogen sulfonates (7) to organic esters (1, 2, 6). When covalently bonded to metals or organometallic moieties, both sulfonate groups may coordinate through one, two, or three oxygen atoms. The resulting materials often have similar molecular structures; e.g., in organotin(IV) sulfonates of the type $R_2Sn(SO_3X)_2$, with R = CH_3, C_2H_5, n-C_3H_7, n-C_4Hg and X = F or CF_3, bidentate briding sulfonate groups produce sheet-like polymers (8) with almost identical ^{119}Sn Mössbauer parameters (9) for compounds with common R groups. Sometimes, however, possibly due to steric differences between both sulfonate groups, contrasting electronic structures of the central metal are noticed. $Ag(SO_3F)_2$ is magnetically dilute down to 80 K (10), while in $Ag(SO_3CF_3)_2$ antiferromagnetism is found in the same temperature range (11).

In respect to chemical reactivity, some important differences between HSO_3F and HSO_3CF_3 are apparent.

(*i*) Self-dissociation is found primarily for HSO_3F, reflected in the equilibrium:

[1] $HSO_3F \rightarrow HF + SO_3$

for $K_d^{25^\circ C} < 3 \times 10^{-7}\ mol^2\ kg^{-2}$. This process explains both the oxidizing ability of HSO_3F as well as its use as fluorinating agent (12).

(*ii*) The S—C linkage in HSO_3CF_3, and in its derivatives, appears to be sensitive towards oxidation. As a consequence, oxidizing agents like the peroxide $S_2O_6(CF_3)_2$ (13) or the halogen derivatives $BrSO_3CF_3$ and $ClSO_3CF_3$ (14, 15) undergo spontaneous decomposition at 25°C and are of limited use in synthesis (19, 20), quite in contrast to their fluorosulfate analogues $S_2O_6F_2$, $BrSO_3F$, and $ClSO_3F$ (7, 16). These fluorosulfate analogues dissolve readily in HSO_3CF_3, but the resulting solutions are metastable and decompose exothermically (17) at room temperature.

(*iii*) The S—F linkage in HSO_3F, as well as in most fluorosulfate derivatives, is instable towards hydrolysis, in particular in acidic or strongly basic aqueous medium. On the other hand, HSO_3CF_3 is mixable with water and forms well-defined hydrates (18). It should generally be possible to isolate trifluoromethyl sulfates in high yields, where H_2O is a by-product of the reaction.

Synthetic routes to inorganic trifluoromethyl sulfates have largely involved HSO_3CF_3 as reagent in solvolysis reactions, or, to a lesser extent, salts like $AgSO_3CF_3$ in metathetical reactions. Bis(fluorosulfuryl)peroxide, $S_2O_6F_2$, in HSO_3F as solvent, on the other hand has been widely used to prepare high valent metal fluorosulfates as well ternary fluorosulfates (21–23). Due to the unavailability of similar routes in SO_3CF_3 chemistry, solvolysis reactions of the general type:

$$[2]\quad MX_n + nHSO_3CF_3 \rightarrow M(SO_3CF_3)_n + nHX$$

with X = F, Cl, Br, H, alkyl, carboxylate, etc., have been the principal preparative method. Both the reactivity and availability of suitable precursors pose obvious limitations.

It had occurred to us some time ago (24) that extension of the solvolysis reaction to fluorosulfates according to

$$[3]\quad M(SO_3F)_n + nHSO_3CF_3 \xrightarrow{HSO_3CF_3} M(SO_3CF_3)_n + nHSO_3F$$

should be feasible, which would widen the scope of synthetic routes to trifluoromethyl sulfates considerably. Indeed a number of iodine(III)trifluoromethyl sulfates (24) and iodine oxytrifluoromethyl sulfates (25) could be obtained from their fluorosulfate precursors. The observed quantitative conversion seemed initially puzzling. A subsequent study by Olah and Ohyama (26) and a reinvestigation by Noftle (27) of the reaction of the two acids HSO_3CF_3 and HSO_3F provided a possible explanation. A degradation reaction was noted, generally formulated as:

$$[4]\quad 2HSO_3CF_3 + HSO_3F \xrightarrow{25°C} \begin{cases} COF_2,\ CO_2,\ SO_2, \\ CF_3SO_3F,\ CF_3SO_3CF_3 \\ SiF_4 + \ldots, \end{cases}$$

with SiF_4 formed as a secondary product in the interaction of HF with glass. Evidence for a similar range of volatile reaction products was later noted by us during the syntheses of $Ag(SO_3CF_3)_2$ and a number of gold(III)trifluoromethyl sulfates from the corresponding fluorosulfates (11). Mechanistic proposals (26, 27) for the acid degradation reaction had agreed on the initial step, protonation of HSO_3CF_3 by HSO_3F, but had differed in respect to reactive intermediates—$CF_3SO_2^+$ (26) or CF_3^+ (27)—and in respect to some of the final products. Our interest had focussed on the apparent similarity between the acid degradation reaction and the quantitative conversion of fluorosulfates into trifluoromethyl sulfates. It became interesting to study this conversion in a more systematic manner, in order to estimate its general usefulness.

Results and discussion

The principal bond types and coordination modes of the fluorosulfate group are illustrated in Fig. 1. Covalent bonding or coordination occurs through oxygen, with similar linkages possible also for the trifluoromethyl sulfate group. All examples of bi- or tridentate fluorosulfate groups so far studied seem to involve bridging rather than chelating configurations, resulting in polymeric structures. Hence all substrates selected are solids, and some remain solids during the conversion reaction, thus allowing easy separation from excess HSO_3CF_3. For each bonding or coordination type the following fluorosulfate substrates are selected.

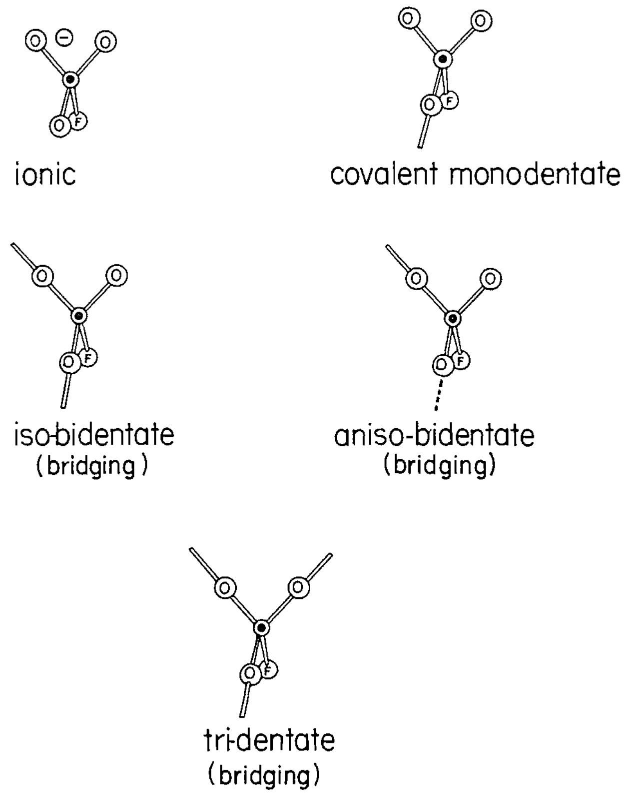

FIG. 1. The principal bonding and coordination modes of the fluorosulfate group.

(*i*) *Ionic fluorosulfates*: KSO_3F

The crystal structure of this compound is well known (28). The expected product KSO_3CF_3, like all other alkali metal trifluoromethyl sulfates, has been reported (2).

(*ii*) *Covalent monodentate*: $K_2[Sn(SO_3F)_6]$ and $Cs_2[Pt(SO_3F)_6]$

Structural studies consist of ^{119}Sn Mössbauer and vibrational spectra obtained on the solids (21, 22, 29), as well as of ^{119}Sn and ^{19}F nmr, Raman, and conductometric studies in HSO_3F solution (21, 22). Here the solvated $[M(SO_3F)_6]^{2-}$ derivatives, M = Sn or Pt, persist as integer complex ions. The corresponding $SO_3CF_3^-$ derivatives are unknown; however, the $[Sn(SO_3CF_3)_6]^{2-}$ ion appears to be present in a mixed valency tin compound formulated as $Sn(II)[Sn(SO_3CF_3)_6]$ (30).

(*iii*) *Iso-bidentate*: $(CH_3)_2Sn(SO_3F)_2$ and $GeF_2(SO_3F)_2$

Symmetrical, bridging bidentate groups are found in the polymeric, sheet-like $(CH_3)_2Sn(SO_3F)_2$ (8). The corresponding trifluoromethyl sulfate is known (31) and has, judging by the nearly identical ^{119}Sn Mössbauer spectrum, a similar molecular structure. Both sulfonates are prepared by acidolysis of either $Sn(CH_3)_4$, $(CH_3)_3SnCl$, or $(CH_3)_2SnCl_2$ in the appropriate acid, with the $(CH_3)_2Sn$ moiety resistant to further acidolysis at room temperature (31, 32). $GeF_2(SO_3F)_2$ has been obtained very recently (22) with no SO_3CF_3 analogue known. structural conclusions for $GeF_2(SO_3F)_2$ are based on vibrational spectra.

(*iv*) *Aniso-bidentate*: $Pd(II)[Pd(SO_3F)_6]$ (33) and $Mn(II)[Sn(SO_3F)_6]$ (34)

In both examples either two different metals or two different oxidation states of the same metal are encountered. The two oxidation states are +2 and +4, with the higher oxidation state implying a greater coordinating ability of the metal concerned. Structural evidence for these coordination polymers rests on

vibrational spectra, magnetic studies down to 80 K, and, in the case of the tin compound, on ^{119}Sn Mössbauer spectra. The corresponding SO_3CF_3 complexes are unknown.

(*v*) *Tridentate*: $Hg(SO_3F)_2$ and $Pd(SO_3F)_2$

The tridentate bridging fluorosulfate group is commonly encountered in metal bis(fluorosulfates) (35). Their polymeric nature and the complete lack of solubility in HSO_3F have so far prevented an X-ray diffraction study, and indirect methods, employed to confirm the proposed structures (33, 35, 36), have provided evidence for a regular octahedral environment with a $^3A_{2g}$ groundstate for Pd^{2+} (33). Only $Hg(SO_3CF_3)_2$ has been reported previously (37). Jahn Teller distortion is expected and found for $Ag(SO_3F)_2$ (10), which had previously been converted to the trifluoromethyl sulfate.

In addition to these substrates, two materials are selected, where both bidentate bridging and monodentate fluorosulfate groups are present: $Sn(SO_3F)_4$ (38) and $Cs[Sn(SO_3F)_5]$ (22). Vibrational and ^{119}Sn Mössbauer spectra have been used to deduce the structures. Only $Sn(SO_3CF_3)_4$ has been reported before (30), obtained by acidolysis of tin(IV)tetrakis(acetate) in HSO_3CF_3.

The experimental details of the conversion reactions are summarized in Table 1. Most substrates dissolve in HSO_3CF_3 either at 25°C or, like $Cs_2[Pt(SO_3F)_6]$, after heating to 60°C, indicating instantaneous reaction. However, some, like $GeF_2(SO_3F)_2$, $Hg(SO_3F)_2$, $Pd(SO_3F)_2$, and $Pd(II)[Pd(SO_3F)_6]$, remain solids throughout. Since no dramatic color changes occur, it is difficult in these cases to monitor the conversion. Due to the rather complex mixture of volatile by-products formed, the noticeable increase in vapor pressure in the reactor provides only a rough indication. Therefore the reaction times listed constitute the upper time limits observed to achieve conversion. These times do not allow any conclusions regarding the relative rates of the various conversion reactions.

The best criterion by which to judge a successful quantitative conversion is provided by chemical analysis. In particular, the sulfur to fluorine ratio and the carbon content are useful in this regard. Analytical data are not reported here, but have been made available to the referees. ^{119}Sn Mössbauer data are listed in Table 2. Vibrational spectra, ^{19}F nmr data, obtained in some cases on solids, in some instances on solutions and other physical properties, are summarized for new compounds in the experimental section. Vibrational data are mostly used for fin-

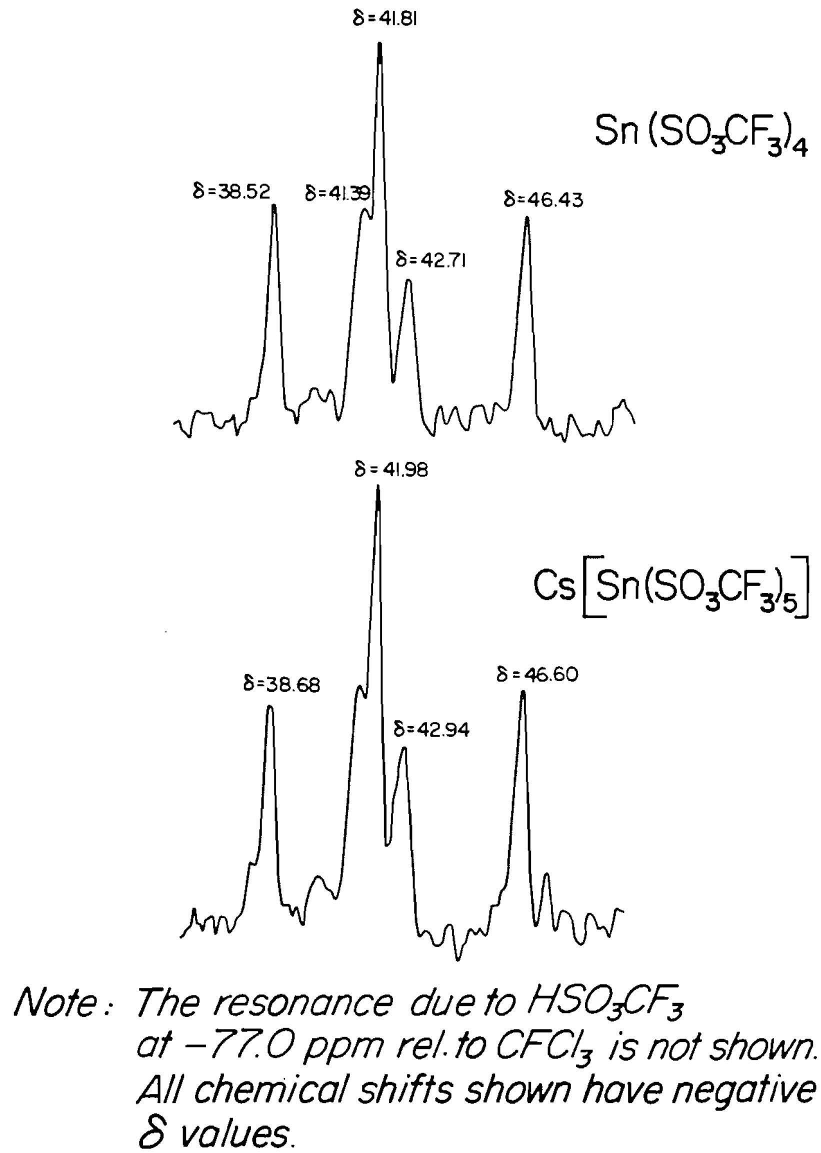

FIG. 2. The [19]F nmr spectra of $Sn(SO_3CF_3)_4$ and $Cs[Sn(SO_3CF_3)_5]$ in HSO_3CF_3 solution.

gerprinting only. Two diagnostic bands may be mentioned. Sulfur–fluorine stretching modes, usually observed between 800 and 900 cm^{-1}, should be absent in the SO_3CF_3 compounds, while a rather sharp, medium intensity ir peak with a very intense Raman counterpart is found now at ~770 cm^{-1}. In most instances strong fluorescence, found also for liquid HSO_3CF_3, prevents the acquisition of meaningful Raman data. The ^{119}Sn Mössbauer spectra for tin fluorosulfates and their SO_3CF_3 analogues differ for the most part very little. For example, the isomer shift δ and the quadrupole splitting Δ for $Cs[Sn(SO_3CF_3)_5]$, of −0.208 mm s^{-1} relative to SnO_2 and 0.499 mm s^{-1}, vary only marginally from −0.239 mm s^{-1} and 0.617 mm s^{-1}, reported previously for $Cs[Sn(SO_3F_3)_5$ (22), and a similar, possibly oligomeric, sulfonate-bridged structure is suggested for both.

A marked difference is found for the ^{19}F nmr data. Besides a rather obvious chemical shift difference (fluorosulfates have positive δ values relative to $CFCl_3$ and trifluoromethyl sulfates have negative shifts (δ between −38 and −95 ppm)), the single line resonances for $[Sn(SO_3F)_5]^-$ or $[Sn(SO_3F)_6]^{2-}$ (22, 29) are contrasted by rather broad multiplets for the triflates. A typical spectrum is shown in Fig. 2, and data for $Sn(SO_3CF_3)_4$, $Cs[Sn(SO_3CF_3)_5]$, and $K_2[Sn(SO_3CF_3)_6]$ in HSO_3CF_3 are tabulated (Table 3) and form the basis for a more detailed discussion later on.

As is apparent from Table 1 and the chemical analysis, conversions proceed quantitatively either at 25°C or, in two instances, at 60°C. There is only one exception. Highly polymeric $Hg(SO_3F)_2$ is incompletely converted even at elevated temperatures. It appears that raising the reaction temperature, first to 85°C and then to 100°C, does not increase the conversion rate but leads to rather impure materials, possibly due to side reactions with the by-products of the degradation reaction. In all other instances complete and rapid conversion is observed. A number of these conversion reactions deserve special comment.

(*i*) *Ionic salts*: The reaction of KSO_3F with an excess of HSO_3CF_3 results initially in clear solutions, from which a white, crystalline solid is obtained after removal of all volatiles *in vacuo*. Initial analysis indicates the retention of an almost equimolar amount of HSO_3CF_3. Prolonged heating to 60°C *in vacuo* produces KSO_3CF_3. A similar strong retention of excess

−38.52 ms	−38.68 ms	−39.04 ms
−41.39 s, sh	−41.50 s, sh	−41.49 s, sh
−41.81 s	−41.98 s	−42.40 s
−46.43 ms	−46.60 ms	−46.49 ms

[a] Resonance for HSO_3CF_3 is found in all cases at −77.0 ppm relative to $CFCl_3$.
[b] Relative to $CFCl_3$.

acid is noted when alkali metal fluorosulfates are prepared from their chlorides and HSO_3F. Vast and co-workers (39) have succeeded in isolating well-defined solvates of the type $MSO_3F \cdot HSO_3F$ for M = Na and Cs only, and the crystal structure of the cesium salt (40) has suggested formulation as $Cs^+[O_2FSOHOSFO_2]^-$ with a symmetrical hydrogen bridge. Similar SO_3CF_3 salts appear to be unknown; however, the cesium salt is found to form readily via:

[5] $CsCl + 2HSO_3CF_3 \rightarrow CsSO_3CF_3 \cdot HSO_3CF_3 + HCl$

No definitive structural conclusions are possible. The [1]H nmr signal is very broad, quite unlike the sharp resonance at δ = 10.9 ppm found for $CsSO_3F \cdot HSO_3F$ (41). Two [19]F nmr signals at $\delta = -93.1$ and -78.8 ppm relative to $CFCl_3$ are found and the infrared spectrum differs only marginally from that of $CsSO_3CF_3$, similar to findings (39) for $NaSO_3F \cdot HSO_3F$ and $NaSO_3F$.

(*ii*) *Isobidentate sulfonate groups*: The conversion of $GeF_2(SO_3F)_2$ to $GeF_2(SO_3CF_3)_2$ proceeds seemingly under retention of a polymeric structure with a solid–liquid mixture present throughout the reaction. A minimum reaction temperature of 60°C and a reaction time of 6 days are required. Analysis justifies formulation as $GeF_2(SO_3CF_3)_2$, but vibrational spectroscopy, which had suggested a fluorosulfate bridged polymer with a linear GeF_2 group for $GeF_2(SO_3F)_2$ (22), is less helpful in this case. Infrared spectra compare well to those of other compounds with bidentate SO_3CF_3 groups (9, 24, 25) but the GeF_2 vibrations are not clearly identifiable, due to the observation of SO_3CF_3 vibrations in the regions expected for νGeF_2 at 770 and νGeF_2 sym. at 650 cm^{-1}. The position of a medium intensity band at 726 cm^{-1} appears to be rather low for a GeF_2 stretch. Both GeF_2-sulfonates have rather similar melting points: 150°C for $GeF_2(SO_3CF_3)_2$ and 146°C for $GeF_2(SO_3F)_2$.

The other example of an isobidentate bridging fluorosulfate group, $(CH_3)_2Sn(SO_3F)_2$ (8), can be converted smoothly at 25°C to $(CH_3)_2Sn(SO_3CF_3)_2$ within 6 days. Under the reaction conditions, some solid material persists in the reaction mixture throughout, but the conversion is quantitative. Not unexpectedly, the conversion reaction can be reversed when $(CH_3)_2Sn(SO_3CF_3)_2$ is reacted with an excess of HSO_3F. This time a clear solution forms and the reaction is complete within 2 days.

With neither reaction of any synthetic interest, three comments may be made: (a) Polymers with bridging sulfonate groups are readily susceptible to solvolysis, and complete conversion is noted. (b) The GeF_2 group in $GeF_2(SO_3F)_2$ appears to be unaffected by solvolysis. (c) With acid degradation responsible for a quantitative reaction, the fluorosulfate to trifluoromethyl sulfate conversion is expected to be reversible and more examples for reversibility should exist. However, no other attempts are made by us.

(*iii*) *Mono- and bidentate*: The successful conversion of $Sn(SO_3F)_4$ to $Sn(SO_3CF_3)_4$ presents another interesting problem. It is already surprising that $Sn(SO_3F)_4$, which is extremely sparingly soluble in HSO_3F (38), dissolves in HSO_3CF_3 at 25°C in 30 min. The resulting solution remains clear, and white, solid $Sn(SO_3CF_3)_4$ is only obtained after removal of all volatiles *in vacuo*. The very same compound has been obtained previously by us (30) when tin(IV)tetrakis(acetate), $Sn(O_2CCH_3)_4$ is solvolyzed in an excess of HSO_3CF_3. Infrared spectra for both products match fairly well, and the melting point of 235°C agrees reasonably well with the reported range of 225–227°C (30). The [119]Sn Mössbauer spectrum, observed now, differs completely from the reported (30) single line spectrum with $\delta = -0.22$ mm s^{-1} relative to SnO_2. A well-resolved doublet, with $\Delta = 1.18$ mm s^{-1} and $\delta = -0.213$ mm s^{-1} is observed at 80 K. The new data agree well with those reported for $Sn(SO_3F)_4$ (38), suggesting a similar octahedral environment for tin.

A subsequent reinvestigation of the solvolysis of $Sn(O_2CCH_3)_4$ in HSO_3CF_3 provides a plausible explanation. When the reaction is performed in a dry-box as described (30) and only a small excess of HSO_3CF_3 is used, acetic acid is formed in an exothermic reaction and $Sn(SO_3CF_3)_4$ is obtained according to:

[6] $Sn(O_2CCH_3)_4 + 4HSO_3CF_3 \rightarrow Sn(SO_3CF_3)_4 + 4CH_3CO_2H$

just as reported (30). However, where a larger excess of HSO_3CF_3 is employed and acetic acid is not immediately removed, proton transfer occurs and $CH_3CO_2H_2^+SO_3CF_3^-$ forms. This material can be obtained more directly by combining equimolar amounts of the parent acids. It is a white solid that melts at +37°C and undergoes dissociation into ions in HSO_3CF_3. The solid state structure should be similar to the one reported for $CH_3CO_2H_2^+SO_3F^-$ (42), involving extensive hydrogen bridging between the individual ions resulting in polymeric chains. The infrared spectrum of $CH_3CO_2H \cdot HSO_3CF_3$ suggests a bidentate, possibly bridging trifluoromethyl sulfate group; the single [1]H resonance in the nmr spectrum of the solid at $\delta = 11.3$ ppm is consistent with hydrogen bridging. During solvolysis of $Sn(O_2CCH_3)_4$ in excess HSO_3CF_3 the initially formed $Sn(SO_3CF_3)_4$ acts as $SO_3CF_3^-$ ion acceptor, and a solid, sparingly soluble material of the composition $[CH_3CO_2H_2]_2[Sn(SO_3CF_3)_6]$ is obtained, which melts at 255°C and gives rise to a single line in the [119]Sn Mössbauer spectrum at −0.231 mm s^{-1} relative to SnO_2. Hydrogen bridging is a plausible cause of the high melting point and the limited solubility in HSO_3CF_3. The overall reaction may be formulated as:

$$[7]\quad Sn(O_2CCH_3)_4 + 8HSO_3CF_3 \xrightarrow{HSO_3CF_3} [CH_3CO_2H_2]_2[Sn(SO_3CF_3)_6] + 2CH_3CO_2H_2^+{}_{(solv)} + 2SO_3CF_3^-{}_{(solv)}$$

It appears that the course of the $Sn(O_2CCH_3)_4$ solvolysis reaction in HSO_3CF_3 depends critically on the amount of acid used and the subsequent work-up of the reaction products. The reaction may lead to $Sn(SO_3CF_3)_4$ or to the salt $[CH_3CO_2H_2]_2[Sn(SO_3CF_3)_6]$. The use of nearly stoichiometric amounts of HSO_3CF_3 to achieve complete solvolysis and the subsequent removal of all acetic acid formed are necessary in order to obtain $Sn(SO_3CF_3)_4$, while any excess of HSO_3CF_3 will favor protonation of acetic acid and precipitation of $[CH_3CO_2H_2]_2$-$[Sn(SO_3CF_3)_6]$ while $Sn(SO_3CF_3)_4$ remains in solution. These subtleties had not been recognized in our initial preparation of $Sn(SO_3CF_3)_4$ (30) and different preparations employing different reactant ratios had apparently resulted in the formation of either $Sn(SO_3CF_3)_4$, used for chemical analysis and infrared spectroscopy, or the acetate acidium salt, evidently used to obtain the single line ^{119}Sn Mössbauer spectrum reported previously (30).

Two conclusions regarding $Sn(SO_3CF_3)_4$ may be made: (*i*) Solvolysis of $Sn(SO_3F)_4$ in an excess of HSO_3CF_3 is the better synthetic route to this compound. (*ii*) Its solubility in trifluoromethyl sulfuric acid and the existence of thermally stable salts like $Cs[Sn(SO_3CF_3)_5]$ and $K_2[Sn(SO_3CF_3)_6]$, both described in this study, together with observations made during the solvolysis of tin(IV)acetate in HSO_3CF_3, suggest a promising superacid system. The ^{19}F nmr spectra, due to the three solutes $Sn(SO_3CF_3)_4$, $Cs[Sn(SO_3CF_3)_5]$, and $K_2[Sn(SO_3CF_3)_6]$, summarized in Table 3, are intriguingly similar and point to the presence of a common species in solution. In all three cases a sharp single line resonance at $\delta = -77.0$ ppm relative to $CFCl_3^-$, attributed to HSO_3CF_3, is observed and allows the conclusion that $SO_3CF_3^-$ exchange between solvent and solute does not occur.

The irregular shapes and the spacing of the resonance lines (see Fig. 2), due to the solute in the region of $\delta = -39$ to -47 ppm relative to $CFCl_3$, suggest magnetic inequivalence of individual fluorine atoms within CF_3 groups, possibly caused by steric effects in these rather bulky solute ions, since any spin–spin coupling between fluorine in different CF_3 groups or coupling with other nuclei as causes for the observed complexity is rather improbable.

A more detailed study of the HSO_3CF_3 solvent system is required to explore the promising superacidity effects more fully. Such a study is clearly beyond the scope of the investigation described here. Similarly, the results of a magnetic susceptibility study, including $Mn[Sn(SO_3CF_3)_6]$ and the two paramagnetic palladium trifluoromethyl sulfates, is currently underway, and the results will be published later.

Summary

The strictly synthetic orientation of this study permits only a few rather general comments regarding the nature of the conversion reaction utilized extensively in this study. The quantitative conversion of fluorosulfates into trifluoromethyl sulfates is observed in all but one instance, where the polymeric nature of the substrate and the tridentate configuration of the SO_3F group appear to limit reactivity. The following conclusions can be reached:

(*i*) Complete degradation of SO_3F moieties by HSO_3CF_3 is the reason for quantitative substitution of SO_3F by SO_3CF_3.

(*ii*) Substitution does not appear to involve a change in the bond type or the denticity of the sulfonate group.

(*iii*) The volatile products formed, either initially or by reaction with the glass vessel, do not affect the conversion reaction adversely or interfere in the isolation of the trifluoromethyl sulfates. It appears unlikely that H_2SO_4, which is nonvolatile under the reaction condition, is formed, with all volatiles removable at 25°C *in vacuo*.

(*iv*) The range of volatile by-products formed, as observed by gas phase infrared spectroscopy, is the same as found during the reaction of HSO_3CF_3 and HSO_3F at a 2:1 molar ratio (27). A quantitative distribution analysis is neither intended nor meaningful. Crucial steps in the proposed reaction mechanism, initial protonation of HSO_3CF_3 by the allegedly stronger acid HSO_3F (26), or the formation of $CF_3SO_2^+$ (26) or CF_3^+ (27) in HSO_3F, are in our view unlikely in these reactions. The observed formation of CO_2 and COF_2 is not easily explained by such a previous proposal (26).

In summary, while the conversion reaction appears to be general and useful, a mechanistic understanding of the degradation reaction is still lacking.

Experimental

Chemicals

Commercially available chemicals of analytical or reagent grades were used without purification. Technical grade fluorosulfuric acid (Allied Chemicals) was doubly distilled at atmospheric pressure in a counter stream of dry nitrogen. Trifluoromethane sulfuric acid (3M Company) was distilled from concentrated H_2SO_4 in a stream of dry nitrogen. Tin(IV) acetate was synthesized by the reaction of SnI_4 with $TlCO_2CH_3$ (43). The following fluorosulfates were prepared according to literature methods: KSO_3F (44), $(CH_3)_2Sn(SO_3F)_2$ (32), $(CH_3)_2Sn(SO_3CF_3)_2$ (32), $Sn(SO_3F)_4$ (22), $K_2[Sn(SO_3F)_6]$ (22), $Cs[Sn(SO_3F)_5]$ (22), $GeF_2(SO_3F)_2$ (22), $Pd(SO_3F)_2$ (33), $Hg(SO_3F)_2$ (36), $Mn[Sn(SO_3F)_6]$ (34), $Cs_2[Pt(SO_3F)_6]$ (21), and $Pd[Pd(SO_3F)_6]$ (33).

Instrumentation

Infrared spectra were recorded on a Perkin–Elmer 598 grating spectrometer. Silver chloride and bromide (Harshaw Chemicals) were used as window materials. Samples were either mulled with Nujol or hexachlorobutadiene or used without mulling agent. The Raman and Mössbauer spectrometers have been described before (22, 29). The ^{19}F nmr spectra in HSO_3CF_3 were obtained on an XL-100 spectrometer (Varian Associates). ^{1}H and ^{19}F high resolution solid-state nmr spectra were recorded on Bruker's CXP 200 MHz spectrometer. ^{1}H and ^{19}F chemical shifts are reported with respect to TMS and $CFCl_3$, respectively, with shifts to lower fields considered positive.

All moisture-sensitive solids were handled in a Vacuum Atmospheres Corp. "Dri-Lab" Model No. HE-43-2, filled with purified dry nitrogen and equipped with a Dri-Train circulating unit. All reactions were performed in Pyrex reaction vials of about 40-mL capacity, which were fitted with Kontes Teflon stem valves and equipped with Teflon-coated spin bars. All reactions were monitored by weight. Product isolation by filtration was performed in an apparatus described by Shriver (45). Chemical analysis was carried out by the Analytische Laboratorium, Gummersbach, West Germany. The carbon and hydrogen content was determined by Mr. P. Borda of this Department.

General procedure for the conversion of fluorosulfates into trifluoromethyl sulfates

A known amount of the fluorosulfate compound was filled inside the dry-box into a pre-weighed, dried reaction vial, fitted with a Teflon-coated magnetic stirring bar and a Teflon-stem stopcock. After evacuation of the reactor an approximate volume, usually 5 mL, of freshly distilled HSO_3CF_3 was transferred on a vacuum line onto the solid substrate. The reaction mixture was allowed to warm to room temperature before stirring was commenced. Occasionally, as noted in Table 1, complete or partial dissolution of the solid substrate occurred, either at 25°C or at a slightly elevated temperature. In some instances a solid remained in the reactor throughout the reaction. Product isolation involved, in all but one instance, removal of all volatiles *in vacuo*, which permitted us to follow the reaction by weighing. The solid product was subsequently dried *in vacuo* to constant weight. A slight pressure buildup in the reaction vessel was invariably noted during the reaction, but gas evolution appeared to be too slow to allow visual detection. An identical procedure was used to convert $(CH_3)_2Sn(SO_3CF_3)_2$ back to the fluorosulfate, employing about 5 mL of HSO_3F.

Additional synthetic reactions

(a) *$[CH_3CO_2H_2]_2[Sn(SO_3CF_3)_6]$*

To a 600-mg sample of $Sn(CO_2CH_3)_4$, an excess of HSO_3CF_3 was added in the dry-box and vigorously stirred. The clear solution on slow concentration *in vacuo* produced a white, crystalline product. The compound was isolated, by vacuum filtration and subsequent washing with a small amount of HSO_3CF_3, and dried *in vacuo*.

(b) *$CH_3CO_2H \cdot HSO_3CF_3$*

Nearly equimolar quantities of HSO_3CF_3 (4.91 g, 32.72 mmol) and CH_3COOH (2.02 g, 33.5 mmol) were mixed and stirred for an hour. On cooling the solution, a crystalline product was formed. The crystals were filtered and washed with a small amount of acetic acid followed by dry carbon tetrachloride, and dried *in vacuo* at room temperatue.

(c) *$CsSO_3CF_3 \cdot HSO_3CF_3$*

About 5 mL of HSO_3CF_3 were distilled onto 554.1 mg (3.29 mmol) CsCl. In a vigorous reaction at ambivant temperature, HCl was produced and removed *in vacuo*. The mixture was vigorously stirred for 30 min. On removal of all the volatile materials, a white crystalline product, $CsSO_3CF_3 \cdot HSO_3CF_3$ (1406.1 mg, 3.25 mmol), was obtained.

Characterization of new compounds

The melting points quoted are uncorrected. the nmr data are quoted relative to TMS (^1H) or $CFCl_3$ (^{19}F). Infrared data are quoted in cm^{-1}. Relative intensities are listed using the following abbreviations: s = strong, sh = shoulder, m = medium, w = weak, v = very, b = broad.

$K_2[Sn(SO_3CF_3)_6]$: white, hygroscopic solid, does not melt below 290°C, very soluble in HSO_3CF_3; ir: 1445 m, 1427 s, 1360 vs, 1230 vs, 1195 vs, 1145 s, 1100 w, sh, 1000 w, sh, 965 s, b, 930 s, sh, 895 m, 825 m, 770 m, 730 vw, 625 vs, 606 s, sh, 572 w, 560 w, 522 m-w, 511 s, 500 msh, 425 w, sh.

$Cs_2[Pt(SO_3CF_3)_6]$: deep yellow, hygroscopic solid, which does not melt below 275°C; ir: 1445 w, 1427 m, sh, 1360 vs, b, 1230 vs b, 1195 vs, 1125 s, 1100 vw, sh, 1015 w, 965 msh, 900 s, b, 815 vw, sh, 765 ms, 685 w, 642 msh, 615 s, 606 s, 578 m, 549 vw, 518 m-s, 500 m, 418 w, 395 w, 375 m, 350 w, 340 w, 321 w, 310 m. Raman: 1381 m, 1255 s, 1235 w, 1168 s, 1020 m, 771 m, 606 s, 540 m, 372 m, 328 w, 255 s, 220 s.

$GeF_2(SO_3CF_3)_2$: white, very hygroscopic glass wool-like solid, melts at 150°C, seems insoluble in HSO_3CF_3; ir: 1409 msh, 1370 vs, 1317 vs, 1245 s, 1215 s, sh, 1201 vs, 1145 vs, 1079 s, 1035 s, 1020 s, sh, 875 vw, 782 ms, 775 ms, 726 m-w, 640 s, 612 s, 585 m, 540 m, 529 s, 433 s, 419 m, 373 s, 350 s, sh, 340 s, 320 s, sh.

$Pd[Pd(SO_3CF_3)_6]$: brown-white solid, hygroscopic, thermally stable up to 250°C; ir: 1420 w, sh, 1391 s, 1365 s, 1245 s, sh, 1208 vs, 1125 m, sh, 1035 s, 940 w, 855 vw, 771 m, 639 s, 605 w, 580 w, 529 s, 504 w, 499 m, 480 vw.

$Pd(SO_3CF_3)_2$: light purple, very hygroscopic solid, which does not melt below 250°C; ir: 1425 vw, 1392 vw, 1350 m, sh, 1220 vs, b, 1180 w, sh, 1090 s, 1050 w, sh, 1030 m, 980 vs, 852 vs, 770 vw, 720 w, 635 ms, 608 s, 595 wsh, 565 ms, 527 ms, 505 vw, 415 s, 382 w, 356 s, 340 w, 332 w, 320 w.

$Cs[Sn(SO_3CF_3)_5]$: white, hygroscopic crystalline solid, which does not melt below 280°C; ir: 1440 w, sh, 1415 s, sh, 1370 vs, 1240 s, sh, 1220 s, sh, 1195 vs, b, 1135 s, b, 1095 w, sh, 985 s, b, 930 m, sh, 920 w, sh, 830 vw, 769 ms, 730 w, 625 vs, 603 s, sh, 570 vw, 512 s, 500 m. Raman: 1390 s, 1260 s, 1240 s, 1208 m, 1173 m, 1153 w, 1081 m, 1055 s, 920 m, 775 and 772 vs, 635 w, 610 w, sh, 599 s, 569 s, 536 m, 517 w, 388 m, 343 s, 328 s, 314 s, 258 s.

$[CH_3CO_2H_2]_2[Sn(SO_3CF_3)_6]$: white, very hygroscopic crystalline solid, mp 255°C; ir: 3000 vs, b, 1610 s, 1575 w, 1555 m, 1543 m, 1360 s, 1200 vs, b, 1140 s, b, 1037 w, 980 m, 895 vw, 769 m, 755 vw, 625 vs, 602 s, 570 m, 525 m, sh, 505 s, 495 s, sh, 425 w; ^{19}F nmr, solid state: broad resonance at $\delta = -79.2$ ppm.

$Sn(SO_3CF_3)_4$: white hygroscopic solid, mp 235°C; ir: 1431 w, 1400 m, sh, 1360 s, b, 1310 vw, sh, 1256 s, sh, 1210 vs, b, 1138 m, 1060 s, 1000 vs, b, 955 vw, 915 ms, 778 m, 771 m, 635 s, 613 s, sh, 575 vw, sh, 540 w sh, 515 ms, 450 vw, sh, 410 w, 381 s, 366 s, 320 wsh.

$CH_3CO_2H \cdot HSO_3CF_3$: white crystalline hygroscopic solid, melts at +37°C, very soluble in HSO_3CF_3; ir: 2920 vs, b, 2460 s, b, 1885 m, b, 1615 s, 1545 ms, 1400 m, 1365 w, 1300 s, 1195 s, b, 1145 w, 1015 s, 930 w, 895 vw, 765 m, 634 s, 615 s, 573 mw, 515 m, 500 m, 470 w, b. Raman (strong fluorescence): 2950 wb, 1305 w, 1220 w, 1020 s, 902 m, 768 ms, 635 w, 615 w, 572 w, 498 w, 480 mb, 345 m, 319 m, 209 m.

$CsSO_3CF_3 \cdot HSO_3CF_3$: white, hygroscopic solid, mp 119°C; ir: weak, very broad band at 2800–2200 cm^{-1}, 1315 m, sh, 1285 sb, 1185 vs, b, 1145 vw, sh, 1065 w, sh, 1020 vs, 940 w, 770 m, 640 s, 611 s, 565 s, sh, 555 s, 505 s, 440 s, b; ^{19}F nmr (solid state): $\delta = -93.1$ (broad), $\delta = -78.83$.

$Mn[Sn(SO_3CF_3)_6]$: white, hygroscopic solid, does not melt below 300°C; ir: 1375 vs, 1360 s, sh, 1240 s, sh, 1200 s, b, 1125 s, 1100 w, sh, 980 m, sh, 960 vs, 870 vw, sh, 775 s, 674 m, sh, 639 s, 606 s, 585 s, 535 s, sh, 525 s, 507 m, sh, 452 w, 422 w, sh, 398 s, 361 s, 351 s, sh, 335 m.

Acknowledgements

Financial support by the Natural Sciences and Engineering Research Council of Canada is gratefully acknowledged. We are grateful to Mrs. L. Sallos for technical assistance in obtaining the ^{119}Sn Mössbauer spectra and to Paul Gehrs and Grant Wong for help in some of the preparation.

A brief survey of the use of the Pummerer rearrangement for the alkylation of 1,3-oxathiolan-5-ones and 1,3-thiazolidin-4-ones

JOHN M. MCINTOSH AND RANDY K. LEAVITT
Department of Chemistry, University of Windsor, Windsor, Ont., Canada N9B 3P4

Received April 24, 1985

JOHN M. MCINTOSH and RANDY K. LEAVITT. Can. J. Chem. **63**, 3313 (1985).

Oxidation of 1,3-oxathiolan-5-ones (**1**) gives acceptable yields of sulfoxides only when C4 is unsubstituted. Sulfoxides derived from 1,3-thiazolidine-4-ones (**8**) are easily prepared. Acid-catalyzed rearrangement in the presence of 1-alkenes or benzene leads to alkylation (arylation) at C5. Alkylation of **8***c* may be generally more effective than that of **1**. An aldol condensation of **8***c* shows little stereoselectivity.

JOHN M. MCINTOSH et RANDY K. LEAVITT. Can. J. Chem. **63**, 3313 (1985).

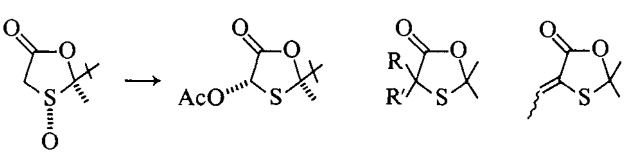
L'oxydation des oxathiolane-1,3 ones-5 (**1**) ne donne des rendements acceptables des sulfoxydes que lorsque le C4 n'est pas substitué. On peut facilement préparer les sulfoxydes qui proviennent des thiazolidine-1,3 ones-4 (**8**). La transposition acido-catalysée, en présence d'alcènes-1 ou de benzène, provoque une alkylation (ou une arylation) en position C5. L'alkylation du composé **8***c* ést généralement plus efficace que celle du composé **1**. Une condensation aldolique du composé **8***c* ne présente pas beaucoup de stéréosélectivité.

[Traduit par le journal]

Recently, we described (1) the alkylation and aldol condensation reactions of 1,3-oxathiolan-5-ones (**1**) and the use of the products in the formation of 2-mercaptoaldehydes and 2,5-dihydrothiophenes (2). In that report it was noted that the alkylation of **1***a* was unsuccessful with all alkyl halides, while alkylation of **1***b* gave acceptable yields of products only with very reactive halides. The interest in this alkylation stems from its potential to form 2-mercaptoaldehydes in a protected form from readily available starting materials. In an effort to circumvent the observed difficulties, we considered the use of the ion **3**, generated by treatment of sulfoxide **2** with acids, as the electrophilic partner in an alkylation reaction (Scheme 1). Our intent was to use olefins as the nucleophilic species, which results in an "umpolung" of the previously examined anionic alkylation. Recently disclosed examinations of closely related systems (3) prompts us to present our results at this time.

The capture of ions analogous to **3** by alkenes has been documented. In a series of papers, Tamura *et al.* (4) examined the cyclization of acyclic olefinic β-oxo-sulfoxides. The α-thiocarbocation derived formally by the elimination of OH^- from the sulfoxide was captured intramolecularly with aromatic (4*b*) and olefinic (4*a*) nucleophiles to generate 5- and 6-membered rings. Intermolecular capture (4*c*, *d*) was demonstrated with terminal alkenes. These reactions can be envisaged as proceeding either via an ene type reaction or as simple attack of the olefinic π-bond on the ion analogous to **3**. Other examples of this and related systems can also be found in the literature (5). In this report, the results of the use of **1** and the related lactams **8** in such reactions are documented.

[1]



4 **5** **6***a* R = H, R′ = OTFA **7**
b R = Me, R′ = OH
c R = Ph, R′ = H

To our knowledge, only one example of the sulfoxide derived from the 1,3-oxathiolan-5-one system has been reported. Kay and co-workers reported **4** (6) and its stereospecific Pummerer rearrangement into **5**. In our hands, oxidation of **1***a* using hydrogen peroxide in acetic acid afforded **2***a* in 87% yield. Pummerer rearrangement using TFA/TFAA in benzene gave a modest yield of **6***a* with no sign of **6***c*, the product expected from capture of **3***a* by the solvent. Clearly, the intermolecular capture of **3***a* cannot compete with the intramolecular rearrangement. In view of results to be presented later, this may be ascribed to the steric hindrance imparted by the C2 *gem* substitution and (or) the instability of the lactone function to the strongly acidic conditions of the Pummerer rearrangement. Stronger acids caused immediate decomposition of **2***a* and no identifiable products could be obtained. Oxidation of **1***b* followed by aqueous work-up gave a low yield of the hydrolyzed Pummerer product **6***b*. No sulfoxide could be detected in the spectra of the crude product. When oxidation of **1***c* was attempted, an inseparable mixture of **2***c* and a compound to which the structure **7** is assigned, on the basis of the ^1H nmr of the crude mixture (quartet at $\delta = 6.8$), was formed. In addition, large amounts of **1***c* remained in the mixture. Attempted separation of **7** or **2***c* from the reaction mixture led only to severe decomposition. The use of MCPBA or TBHP as oxidants did not improve these results. The instability of **2***c*, **6***a*, and **7** precluded their purification. It is clear from these results that the sulfoxides, like **2***b* and **2***c*, that possess C4 substituents must be unusually sensitive materials whose use in synthesis would be unattractive.

Because the lactam analogs (**8** and **9**) of **1** and **2** were expected to be more stable and because the DIBAL reduction of substituted **8** to 2-mercaptoaldehydes was expected to be routine, our attention was shifted toward this heterocycle. Three examples were examined (**8***a*, *b*, *c*). In each case these were oxidized to **9** in acceptable yields and each **9** proved to be a stable material.

Treatment of **9***a* with TsOH/Ac_2O gave **10***a*, while **10***b* (the hydrolyzed Pummerer product formed from the aqueous work-up) and **10***c* were formed from **9***b* or **9***c* respectively, on treatment with TFA/TFAA. Reaction of each **9** with benzene in concentrated H_2SO_4 gave the corresponding 5-phenyl derivatives (**11**) of **8** in 75–95% yields.[1] However, these conditions

[1] Formation of **11***b* has also been observed by I. T. Kay (personal communication).

SCHEME 2

caused immediate decomposition of the alkenes that we hoped to use in the alkylation reaction. Attempts to use H_2SO_4 or other strong Lewis (BF_3, $SnCl_4$, $AlCl_3$) or protonic (PPA, $MeSO_3H$) acids in catalytic amounts at low temperatures in the phenylation of **9***a* or **9***b* led to low yields of complex mixtures of products. The appearance of materials whose molecular weight (mass spectra) indicated the incorporation of two heterocyclic units joined by an ether linkage suggested that the presence of water formed in the Pummerer rearrangement was interfering with the desired reaction. Presumably, when concentrated H_2SO_4 is used, the water is completely protonated and cannot react further. Incorporation of anhydrous $CuSO_4$ in the sulfuric acid catalyzed reaction did not improve the results.

Sulfoxide **9***c* did react with 1-alkenes in TFA/TFAA solution to give **12** in acceptable yields (Scheme 3). 2-Alkenes (2-hexene, cyclohexene) gave mixtures of products containing **10***c* along with a mixture of "ene" products and their addition products with TFA.

The reported (3, 4) examples of successful alkylations of β-oxo-sulfoxides by alkenes under acidic conditions all utilize compounds in which a *methyl* group is attached to sulfur. It is clear from our results that increasing the size of this group has a profoundly deleterious effect on the reaction and makes this methodology of limited applicability to **1** and **8**.

In conclusion, it is worth noting that alkylation of the anion derived from lactam **8***c* gave acceptable yields of alkylated materials (**13**), even with a halide (BuI) that was unreactive with lactones **1***a* or **1***b* (Scheme 3). Methylation afforded a 6:1 mixture of mono- and dialkylated product (**13***a*) while BuI gave only monoalkylated product (**13***b*). Again, the difference may lie in the steric effect of the *gem*-dimethyl group in **1**. Aldol reactions are also possible, as is evidenced by the reaction with benzaldehyde to afford **14** as a 3:2 mixture of diastereomers **14***a* and **14***b*. Since the C2-unsubstituted lactam **8***c* is more readily prepared than the analogous lactone, the use of this

heterocycle may circumvent the difficulties encountered in the alkylation of **1** and permit an alkylative approach to a general synthesis of 2-mercaptoaldehydes.

This work represents the end of our investigations into the chemistry of these heterocycles.

Experimental

All infrared spectra were run in chloroform solution on either a Perkin–Elmer Model 180 instrument or on a Nicolet 5-DX instrument in the FT mode. The four strongest peaks are reported. The nmr spectra were run at 60 MHz (^{1}H nmr) or 22.64 MHz (^{13}C nmr) in $CDCl_3$ solution and are referenced to internal TMS. The data are presented in the format (multiplicity, number of hydrogens, coupling constant). Gas chromatographic analyses were performed using a 1.5 ft × 1/8 in. column packed with 5% OV-101 on Chromosorb W. Solvents were removed at reduced pressure and the drying agent was anhydrous $MgSO_4$. Column chromatography utilized silica gel 60 (Merck). Microanalyses were performed by Canadian Microanalytical Services, Vancouver; Guelph Chemical Laboratories, Guelph, Ontario; and Uniroyal Research Laboratories, Guelph, Ontario.

Materials

1,3-Oxathiolan-5-ones **1** (2) and thiazolidinone **8***c* (7) were prepared by literature procedures.

*3-Phenyl-2,2-pentamethylenethiazolidin-4-one (8*a*)*

A solution of the ketimine derived from aniline and cyclohexanone (24 g, 0.14 mol) and 15 g (0.16 mol) 2-mercaptoacetic acid was refluxed under a Dean–Stark water separator overnight (3 mL of water collected). The solvent was removed and the solid residue recrystallized to give **8***a*; 70%; mp 168°C (EtOH); ir: 2940, 1665, 1490, 1380 cm^{-1}; ^1H nmr: 7.4–6.9 (m, 5H), 3.9 (s, 2H), 2.3–0.45 (m, 10H); ^{13}C nmr: 171.7, 136.5, 130.4, 129.3, 128.6, 74.1, 39.2, 31.5, 24.2, 23.4. *Anal.* calcd. ($C_{14}H_{17}NOS$): C 67.97, H 6.92; found: C 68.08, H 6.96.

*3-Methyl-2,2-pentamethylenethiazolidin-4-one (8*b*)* (ref. 7)

A solution of methylamine in ethanol was prepared as follows. To a mixture of 27 mL of ethanol and 35 mL of 50% aqueous KOH, which was cooled in an ice bath, was added 21.9 g of methylamine hydrochloride. The solution was stirred for 1 h, filtered, and the layers separated. To the organic layer was added 2-mercaptoacetic acid (20.6 g, 0.22 mol) dropwise with stirring at 0°C. Stirring was continued for 1 h, the solvent was removed, the resulting solid dissolved in toluene, and 20 g of cyclohexanone was added. Refluxing under a Dean–Stark water separator followed by evaporation gave an oil which was distilled to give **8***b*; 64%; bp 120°C (0.1 Torr) (1 Torr = 133.3 Pa) ir: 3020, 2950, 1660, 1400 cm^{-1}; ^1H nmr: 3.50 (s, 2H), 2.87 (s, 3H), 2.35–2.07 (m, 10H); ^{13}C nmr: 170.1, 73.0, 36.9, 30.9, 26.9, 24.1, 22.8.

General oxidation procedure

In a typical experiment, 0.02 mol of sulfide was dissolved in 10 mL of glacial acetic acid and cooled to 0–5°C. To this was added 1.15 equiv. of 30% hydrogen peroxide dropwise with stirring. The mixture was allowed to come to ambient temperature overnight and diluted with 15 mL of water. Solid sodium bisulfite was added until a negative peroxide test was achieved. The organics were extracted into chloroform and washed with saturated aqueous bicarbonate until the washings were basic. The extracts were dried and the solvent removed to give the crude product, which was purified as noted below.

2*a*: (Continuous extraction ($CHCl_3$) was required for acceptable yields.) Chromatographic purification (EtOAc) gave **2***a*; 87%; mp 77°C; ir: 1799, 1780, 1236, 1070 cm^{-1}; ^1H nmr: 3.82 (ABq, 2H, J = 12 Hz), 1.75 (s, 3H), 1.60 (s, 3H); ^{13}C nmr: 169.5, 98.5, 52.7, 23.1, 20.0. *Anal.* calcd. ($C_5H_8O_3S$): C 40.53, H 5.44; found: C 40.06, H 5.31.

6*b*: Unstable oil (25% crude, not purified); ir: 3500–3300, 1750, 1450, 1375 cm^{-1}; ^1H nmr: 4.78 (bs, 1H, exchanges with D_2O), 1.90 (s, 3H), 1.88 (s, 3H), 1.76 (s, 3H); ^{13}C nmr: 174.3, 100.2, 86.6, 32.7, 30.9, 27.6.

9*a*: 86%; mp 166°C (benzene); ir: 2950, 1680, 1363, 1100 cm^{-1}; ^1H nmr: 7.7–7.0 (m, 5H), 3.65 (ABq, 2H, J = 15 Hz), 2.7–0.7 (m, 10H); ^{13}C nmr: 168.6, 135.8, 129.9, 129.5, 128.9, 83.5, 51.8, 32.7, 28.9, 24.0, 23.6, 22.3. *Anal.* calcd. ($C_{14}H_{17}NO_2S$): C 63.84, H 6.50; found: C 63.65, H 6.44.

9*b*: 57%; mp 123°C (CCl_4); ir: 3015, 2980, 1680, 1050 cm^{-1}; ^1H nmr: 3.53 (ABq, 2H, J = 9 Hz), 2.90 (s, 3H), 2.51–0.80 (m, 10H); ^{13}C nmr: 167.0, 82.12, 51.3, 29.7, 28.9, 23.7, 22.8, 21.7. *Anal.* calcd. ($C_9H_{15}NO_2S$): C 53.70, H 7.51; found: C 53.79, H 7.53.

9*c*: This very water-soluble compound was decomposed by continous extraction into $CHCl_3$. Therefore the work-up was modified as follows. After destruction of the excess peroxide, the solvents were removed at room temperature and 0.4 Torr pressure. The residue was taken up in $CHCl_3$, stirred with solid K_2CO_3, filtered, and evaporated. The product was crystallized by precipitation from acetone with petroleum ether to give **9***c*; 55%; mp 109°C (benzene); ir: 3010, 1695, 1225, 1055 cm^{-1}; ^1H nmr: 4.39 (ABq, 2H, J = 11 Hz), 3.53 (ABq, 2H, J = 3 Hz), 3.0 (s, 3H); ^{13}C nmr: 167.5, 70.2, 54.1, 31.1. *Anal.* calcd. ($C_4H_7NO_2S$): C 36.07, H 5.29; found: C 36.32, H 5.23.

Pummerer rearrangements

In a typical experiment, a solution of 0.2 mol of the heterocycle in 10–15 mL of TFA containing 2 equiv. of benzene was cooled to 0°C and 1.1 equiv. of TFAA was added dropwise. The mixture was stirred at 0°C for 3–4 h, diluted with water (10–15 mL), and extracted with chloroform. The extracts were washed with aqueous bicarbonate solution, dried, and evaporated. In the case of **10***a*, the reaction mixture consisted of CH_2Cl_2/benzene and a catalytic amount of TsOH, and the electrophile was acetic anhydride.

6*a*: 45%; bp 52°C (0.75 Torr); ir: 1800–1780, 1240, 1170, 1140 cm^{-1}; ^1H nmr: 6.58 (s, 1H), 2.15 (s, 3H), 2.10 (s, 3H); ^{13}C nmr: 166.9, 156.4 (q), 118.4 (q), 91.1, 80.5, 33.3, 30.0.

10*a*: 55%; mp 132°C (benzene or EtOH); ir: 2950, 1780, 1680, 1220 cm^{-1}; ^1H nmr: 7.75–6.90 (m, 5H), 6.28 (s, 1H), 2.65–0.85 (m, 13H); ^{13}C nmr: 168.9, 168.1, 135.9, 130.3, 129.5, 129.1, 74.9, 74.1, 40.6, 39.4, 24.1, 23.9, 23.4, 21.0. *Anal.* calcd. ($C_{16}H_{19}NO_3S$): C 62.92, H 6.27; found: C 63.16, H 6.31.

10*b*: 70%; mp 163°C (benzene); ir: 2950, 1670, 1395, 1200 cm^{-1}; ^1H nmr: 5.78 (bs, 1H), 5.57 (s, 1H), 2.86 (s, 3H), 2.43–0.67 (m, 10H).

10*c*: 100% crude (not purified); oil; ^1H nmr; 6.38 (d, 1H, J = 2 Hz), 4.56 (ABq, 2H, J = 8 Hz) (high field side further split, J = 2 Hz), 3.05 (s, 3H).

Phenylation reactions

To a vigorously stirred mixture of 5 mL of concentrated H_2SO_4 and 4 mL of benzene was added 0.5 g of the sulfoxide. Stirring was continued until the exotherm ceased (ca. 40 min). The yellow solution was poured over 10 g of ice and extracted into CH_2Cl_2. The phases were separated and the organic phase dried and evaporated to yield the crude product, which was purified by crystallization or chromatography.

11*a*: 93%; mp 119–121°C (benzene); ir: 2950, 1670, 1375, 1200 cm^{-1}; ^1H nmr: 7.82–7.05 (m, 10H), 5.08 (s, 1H), 2.35–0.47 (m, 10H); ^{13}C nmr: 172.3, 138.2, 136.8, 130.6, 129.3, 128.7, 127.9, 102.7, 72.3, 51.0, 40.2, 39.8, 24.2, 23.9, 23.6. *Anal.* calcd. ($C_{20}H_{19}NOS$): C 74.26, H 6.54; found: C 74.52, H 6.54.

11*b*: 95%; mp 163°C (benzene); ir: 2960, 1660, 1400, 1200 cm^{-1}; ^1H nmr: 7.77–7.2 (m, 5H), 5.00 (s, 1H), 2.95 (s, 3H), 2.36–0.85 (m, 10H); ^{13}C nmr: 170.8, 138.1, 128.3, 128.1, 127.5, 102.5, 71.3, 49.9, 38.0, 37.3, 27.7, 24.2, 22.9. *Anal.* calcd. ($C_{15}H_{19}NOS$): C 68.92, H 7.32; found: C 68.83, H 7.54.

11*c*: 76%; oil (chromatography 1:1 EtOAc/benzene); ir: 3015, 1670, 1390, 1230 cm^{-1}; ^1H nmr: 7.23 (m, 5H), 4.80 (s, 1H), 4.30 (s, 2H), 2.90 (s, 3H); ^{13}C nmr: 171.4, 138.3, 128.6, 128.2, 127.9, 50.6, 47.7, 31.7. *Anal.* calcd. ($C_{10}H_{11}NOS$): C 62.15, H 5.74; found: C 62.09, H 5.89.

Reaction with alkenes

To a cold solution of **9***c* in 20 mL TFA and 1.5 equiv. of the alkene (1-octene or 1-hexene) was added 1.1 equiv. of TFAA dropwise with stirring. After 1 h, the solution was diluted with 20 mL of water and extracted with chloroform. The extracts were washed with aqueous bicarbonate and water, dried, and evaporated to give **12***a* or **12***b*. *E*/*Z* ratios were determined by the relative peak intensities of the sp^2 carbons in the ^{13}C nmr spectra. When 2-alkenes (cyclohexene, 2-hexene) were used, ^1H nmr spectra and gas chromatography indicated the presence of complex mixtures.

12*a*: 62%; bp 193°C (13 Torr (E/Z = 3:1); ir: 2970, 2940, 1665, 1400 cm^{-1}; ^1H nmr: 5.78–5.03 (m, 2H), 4.22 (s, 2H), 3.92–3.55 (m, 1H), 2.92 (s, 3H), 2.85–0.55 (m, 13H); ^{13}C nmr: 172.4, 134.3, 133.4, 125.0, 124.4, 47.5, 36.9, 32.3, 31.3, 29.1, 28.8, 22.3, 18.9.

Anal. calcd. ($C_{12}H_{21}NOS$): C 63.39, H 9.30; found: C 62.78, H 9.27.

12*b*: 49%; bp 115°C (0.6 Torr) (E/Z = 2:1); ir: 2975, 1670, 1420, 1395 cm^{-1}; ^{1}H nmr: 5.65–5.05 (m, 2H), 4.25 (s, 2H), 3.95–3.60 (m, 1H), 2.92 (s, 3H), 2.90–0.80 (m, 12H); ^{13}C nmr: 172.4, 134.1, 133.3, 125.3, 124.7, 47.6, 37.0, 34.8, 34.5, 31.8, 31.6, 22.6, 22.4, 18.6. *Anal.* calcd. ($C_{10}H_{17}NOS$): C 60.26, H 8.59; found: C 59.92, H 8.58.

Alkylation reactions

All alkylation reactions were run as previously reported (1). Compound **13*a*** was obtained as a mixture of mono- and dimethylated products in a ratio of 6:1 as indicated by gas chromatographic analysis.

13*a*: bp 104°C (11 Torr); ir: 3010, 1670, 1500, 1400 cm^{-1}; ^{1}H nmr: 4.38 (s, 2H), 3.85 (q, 1H, J = 7 Hz), 2.97 (s, 3H), 1.55 (d, 3H, J = 7 Hz) [1.55 (s, 6H) for dimethyl derivative]; ^{13}C nmr: 178.2, 46.8, 40.7, 31.3, 19.3 [19.11].

13*b*: 44%; bp 95°C (0.5 Torr); ir: 2980, 2950, 1670, 1400 cm^{-1}; ^{1}H nmr: 4.3 (dd, 2H, J < 1 Hz), 4.0–3.5 (m, 1H), 2.95 (s, 3H), 2.5–0.7 (m, 9H); ^{13}C nmr: 172.9, 47.5, 47.2, 33.6, 31.2, 29.1, 22.1, 13.8. *Anal.* calcd. ($C_8H_{15}NOS$): C 55.45, H 8.72; found: C 55.44, H 8.89.

Aldol condensation

The aldol condensation was run as previously reported (1). Compound **14** was obtained as a mixture of diastereomers (**14*a*** and **14*b***) in an isolated ratio of 3:2. The total yield was 54%.

14*a*: 33%; mp 145°C (1:1 EtOAc/benzene); ir: 3650–3200 (no change upon dilution), 3010, 1670, 1400 cm^{-1}; ^{1}H nmr: 7.65–7.2 (m, 5H), 5.39 (ABq, 1H, J = 2.2 Hz), 3.60 (d, 1H, J = 2.5 Hz, exchangeable), 4.18 (d, 1H, J = 2.5 Hz), 4.16 (ABq, 2H, J = 7.0 Hz) (high field end split into doublet, J = 2.2 Hz), 2.95 (s, 3H); ^{13}C nmr: 171.4, 141.2, 128.4, 128.0, 126.0, 73.0, 55.4, 48.4, 31.6. *Anal.* calcd. ($C_{11}H_{13}NO_2S$): C 59.16, H 5.86; found: C 59.18, H 5.87.

14*b*: Oil (dec. on attempted distillation); ir: 3704–3224 (no change upon dilution), 3008, 1663, 1400 cm^{-1}; ^{1}H nmr: 7.5–7.1 (m, 5H), 5.2 (s, 1H, exchangeable), 4.90 (d, 1H, J = 8.5 Hz), 4.25 (d, 1H, J = 7 Hz), 4.15–3.95 (m, 2H), 2.75 (s, 3H); ^{13}C nmr: 172.9, 140.0, 128.7, 128.5, 127.2, 76.5, 52.2, 47.7, 31.6

Acknowledgements

The financial assistance of the Natural Sciences and Engineering Research Council of Canada in the form of operating grants made this work possible. The invaluable assistance of Dr. I. T. Kay in providing experimental details of his reactions is very gratefully acknowledged.

The initial oxidation stages of lactic acid by acid permanganate were investigated. The rate of the induction period was slow and then gradually increased. The kinetics of oxidation were second order, first order with respect to both lactic acid and Mn(VII). The reaction was acid catalyzed. Addition of Mn(II) ions largely increased the rate of the initial stages and decreased the rate of the following stages. The oxidation rate was decreased by the addition of F^- or $P_2O_7^{4-}$ ions. The Arrhenius equation was valid for the reaction between 16.5 and 34°C. Activation parameters were evaluated and a mechanism consistent with the results obtained was proposed.

M. M. Girgis, S. A. El-Shatoury et Z. H. Khalil. Can. J. Chem. **63**, 3317 (1985).

On a étudié les étapes initiales de l'oxydation de l'acide lactique par le permanganate de potassium en milieu acide. La vitesse de la période d'induction est lente mais elle augmente graduellement. La cinétique de l'oxydation est d'ordre deux, soit d'ordre un tant par rapport à l'acide lactique que par rapport au Mn(VII). La réaction est catalysée par les acides. L'addition d'ions Mn(II) augmente grandement la vitesse des étapes initiales et diminue celle des étapes suivantes. L'addition d'ions F^- ou $P_2O_7^{4-}$ diminue la vitesse d'oxydation. L'équation d'Arrhénius s'applique à cette réaction entre 16,5 et 34°C. On a évalué les paramètres d'activation et on propose un mécanisme qui s'accorde avec les résultats obtenus.

[Traduit par le journal]

Introduction

The extent of oxidation of organic substrate by permanganate depends mainly on the acidity of the medium. In alkaline or weakly acidic solution Mn(VII) changes to Mn(IV), while in strongly acidic medium Mn(VII) is further reduced, forming ultimately Mn(II). During this valence change of manganese almost every conceivable intermediate ion was suggested as participating oxidant. But the species having the main role as potential oxidant depends on the nature of the substrate and on the pH of the medium.

Considerable kinetic data were collected on the oxidation of organic compounds by potassium permanganate. Kinetics of oxidation of some α-hydroxy carboxylic acids, e.g. tartaric acid (1–3), citric acid (4, 5), and glycolic acid (6) by acid permanganate have been reported earlier. However, the details of permanganate oxidation of lactic acid are not yet known although kinetics of oxidation of this acid by other oxidants (7–10) has been reported. We were prompted to undertake the present investigation on the oxidation of lactic acid by permanganate in acid medium with a view to having an insight into the reaction mechanism.

Materials and method

Potassium permanganate was of GR (E. Merck) grade whereas lactic and sulphuric acids were of Analar (BDH) grade. All other reagents were chemically pure. All the solutions were prepared in doubly distilled conductivity water. The solution of $KMnO_4$ was boiled and filtered into a dark glass bottle for storage. Permanganate solutions were standardized by titration against oxalate (11), whereas lactic acid solutions were standardized by titration against sodium hydroxide.

Kinetic experiments were carried out in a temperature-controlled (±0.1°C) water bath. The reaction was initiated by adding to an equilibrated mixture of lactic acid and sulphuric acid the requisite quantity of pre-equilibrated potassium permanganate solution. The course of the reaction was followed by measuring the absorbance of the remaining permanganate ions at known intervals at 545 nm on a spectromom 402 photoelectric photometer, using a 1-cm matched silica cell. Absorption spectra were recorded on a Shimadzu UV-200 S double beam spectrophotometer, using the cell of path length 1 cm. It was verified that there is no interference due to other reagents at 545 nm. The reactions were usually followed up to not less than 70% completion.

The concentration of lactic acid was always kept in large excess, and pseudo-first-order rate constants were calculated by plotting log $[MnO_4^-]$ versus time.

Results

Reaction–time curve

The log $[MnO_4^-]$ versus time plots indicate clearly that the oxidation process has an "induction period" (2, 12) followed by "autoacceleration", Fig. 1.A. It was noticed that the extent of the "induction period" depends on the reaction conditions. The rates of the initial stages of the reaction were determined from the measurements of the slopes of the lines extended over the "induction period".

Stoichiometry and identification of reaction products

A solution of potassium permanganate (0.14 *M*) was added dropwise to a warm solution (40–50°C) of lactic acid (4 mL, 0.87 *M*) containing sulphuric acid (10 mL, 2 *M*) until a permanent permanganate colour appeared. Different titrimetric experiments verified that one mole of permanganate reacts with 1.25 ± 0.02 mol of lactic acid to produce acetic acid (13) and carbon dioxide as final oxidation products according to the stoichiometric equation

$$[1] \quad 4MnO_4^- + 5C_3H_6O_3 + 12H^+ = 5C_2H_4O_2 + 5CO_2 + 11H_2O + 4Mn^{2+}$$

Acetaldehyde and carbon dioxide were detected under experimental conditions in which [lactic acid] $\gg$ $[MnO_4^-]$. These products were identified by the 2,4-DNP[1] derivative and the turbidity of the $Ca(OH)_2$ solution, respectively. Obviously acetic acid was formed by the oxidation of acetaldehyde.

To find the yield of acetaldehyde under these experimental conditions ([lactic acid] $\gg$ $[MnO_4^-]$), lactic acid (0.24 *M*) was mixed with permanganate solution (0.004–0.012 *M*) and sulphuric acid (2 *M*). After an hour, the reaction mixture was cooled in an ice bath to which an excess of 2,4-DNP solution was added and the mixture was stored overnight in the refrigerator. The precipitated 2,4-DNP product was filtered onto a weighed crucible, dried, and weighed. A blank using acetaldehyde under the same experimental conditions was also run.

[1] DNP, 2,4-dinitrophenylhydrazine.

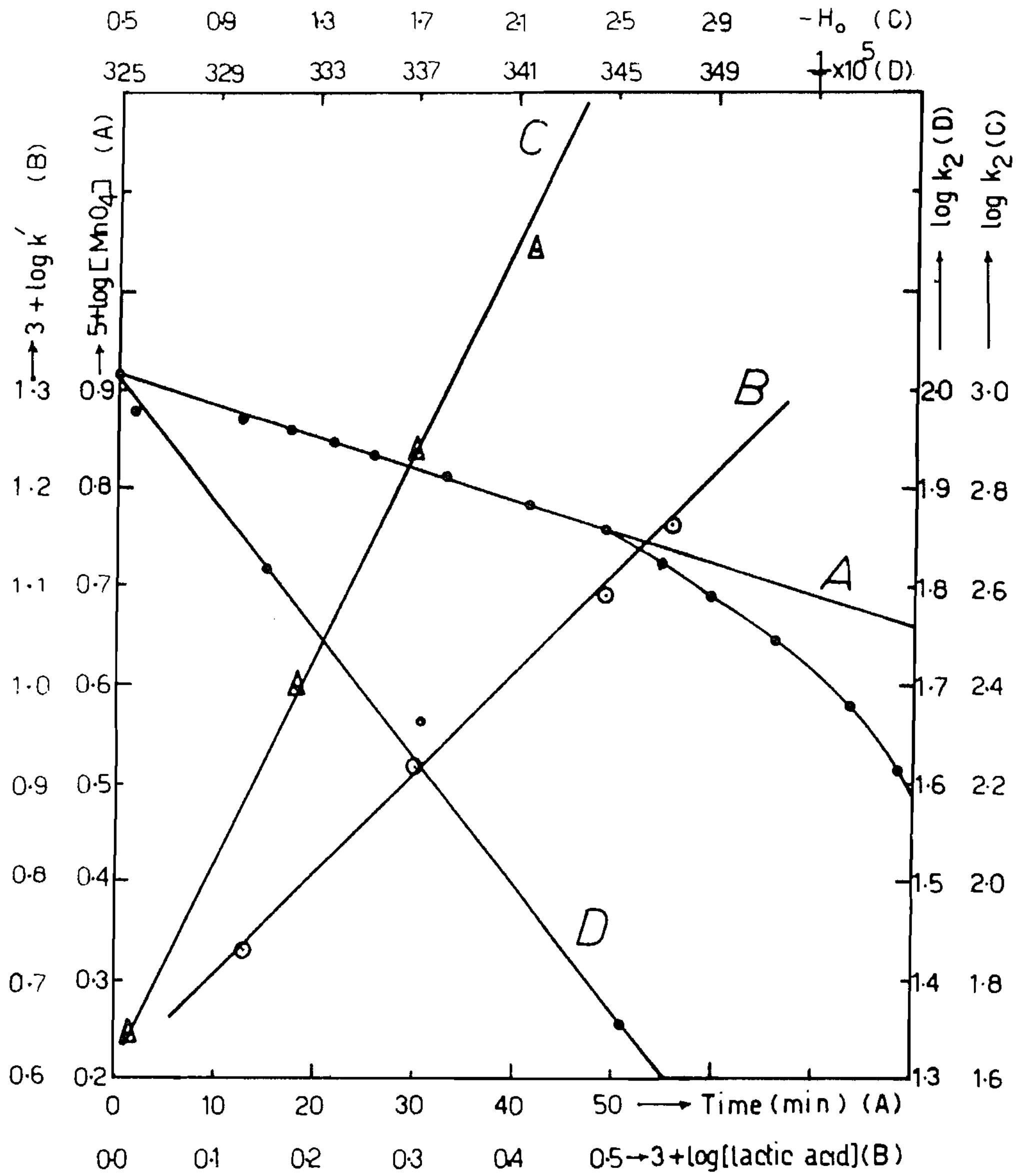

FIG. 1.A. Order with respect to [MnO_4^-]. Plot of 5 + log [MnO_4^-] versus time; [lactic acid] = 2.0 × 10^{-3} *M*; [H_2SO_4] = 2.0 *M*; temperature = 23.5°C. B. Order with respect to [lactic acid]. Plot of 3 + log *k*′ versus 3 + log [lactic acid]; [MnO_4^-] = 2.10 × 10^{-4} *M*; [H_2SO_4] = 2.0 *M*; temperature = 25°C. C. Plot of log k_2 versus $-H_0$. [MnO_4^-] = 2.11 × 10^{-4} *M*; [lactic acid] = 2.0 × 10^{-3} *M*; temperature = 23.5°C. D. The Arrhenius plot of log k_2 versus $1/T$.

It was found that the yield of 2,4-DNP derivative was 56.24% of the theoretical, according to the stoichiometric equation [2]

$$[2] \quad 2MnO_4^- + 5C_3H_6O_3 + 6H^+ = 5C_2H_4O + 5CO_2 + 8H_2O + 2Mn^{2+}$$

The precipitated 2,4-DNP derivative was recrystallized from ethanol and the product identity was established by mp and mixture mp.

Rate dependence on [permanganate]

The order with respect to permanganate was determined by studying the reaction at different initial concentrations of permanganate with fixed [lactic acid]. The [MnO_4^-] was varied in the range (0.48–10.01) × 10^{-4} *M*, [lactic acid] = 2.0 × 10^{-3} *M*, and [H_2SO_4] = 2.0 *M* at 23.5°C. Under these conditions, where [lactic acid] ≫ [MnO_4^-], the plots of log [MnO_4^-] versus time were linear, indicating the first-order dependence of rate on [$KMnO_4$] in the initial stages of the reaction, Fig. 1A. This was also confirmed by varying [$KMnO_4$], which did not show any change in pseudo-first-order rate constant (*k*′) values. The average value of *k*′ was found to be (73.6 ± 0.5) × 10^{-4} min^{-1}.

Rate dependence on [lactic acid]

The order with respect to lactic acid was deduced from the measurement of the initial rates at several lactic acid and fixed permanganate concentrations. The [lactic acid] was varied in the range (1.35–3.60) × 10^{-3} *M*, [MnO_4^-] = 2.1 × 10^{-4} *M*, and [H_2SO_4] = 2.0 *M* at 25°C. The average value of *k*′/[lactic acid] was found to be (4.03 ± 0.08) L mol^{-1} min^{-1} (Table 1). The experimental results, Fig. 1.B and Table 1, indicate that the order with respect to lactic acid is one. Thus, the reaction in the initial stages follows second-order kinetics. Our results are in good agreement with those given earlier by Sengupta *et al.* for the acid permanganate oxidation of glycolic acid (6).

TABLE 1. Effect of varying [lactic acid] on the initial rates. $[MnO_4^-]$ = 2.10 × 10^{-4} *M*; $[H_2SO_4]$ = 2.0 *M*; temperature = 25°C

[Lactic acid] × 10^3 *M*	k' × 10^3 (min^{-1})	k'/[lactic acid] (L mol^{-1} min^{-1})
1.35	5.41	4.01
2.00	8.23	4.11
3.10	12.34	3.98
3.60	14.53	4.03

TABLE 2. Effect of varying $[H_2SO_4]$ on the initial oxidation rates. $[MnO_4^-]$ = 2.11 × 10^{-4} *M*; [lactic acid] = 2.0 × 10^{-3} *M*; temperature = 25°C

$[H_2SO_4]$ *M*	k' × 10^3 (min^{-1})	$[H_2SO_4]$ *M*	k' × 10^3 (min^{-1})
2.0	8.30	4.0	83.18
3.0	31.62	5.0	173.80

Rate dependence on $[H_2SO_4]$

The reaction rates were found to increase considerably with increasing $[H_2SO_4]$, Table 2. The plot of log k_2 versus the Hammett acidity function (H_0) is linear with slope 1.04 (Fig. 1.C). Thus, an "encumbered carbonium ion" (14, 15) may be involved in the transition state involving protonation of lactic acid.

Effect of added manganous sulphate

It is reported (16) that acidified permanganate is reduced by Mn(II) to Mn(III) and Mn(IV) according to the equation:

$$[3] \quad MnO_4^- + 3Mn^{2+} + 8H^+ \rightarrow 3Mn^{3+} + Mn^{4+} + 4H_2O$$

The rate at which permanganate is reduced by Mn(II) and the effect of [Mn(II)] on the reduction rate of MnO_4^- was studied spectrophotometrically. The spectrum of acidified permanganate solution possesses absorption bands located at λ_{max} 225, 311, 490 (sh), 508, 525, 545, and 566 nm, respectively. This spectrum changes by the addition of $MnSO_4$, when the bands at 508, 525, 545, and 566 nm gradually disappear with the appearance of a single broad band of low intensity at 490 nm, and the band at 311 nm is blue-shifted to an intense shoulder located at λ_{max} 290 nm. The time needed to stabilize the new spectrum (i.e. the time required to reach a steady state of the reaction between MnO_4^- and Mn^{2+}) ranges from a few minutes to about 2 h depending on [Mn(II)]. It is worth mentioning that the new stabilized spectrum is that of Mn(III) ions (cf. Discussion).

The new oxidizing solution was prepared by adding $MnSO_4$ to an acidified permanganate solution. The mixture was kept in the dark for ~5 h before its use in lactic acid oxidation. The rate of oxidation was followed spectrophotometrically at 290 nm. The results obtained are given in Table 3 and Fig. 2. It can be noticed that the induction period disappeared completely even at low [Mn(II)] while the oxidation rates decrease gradually with increasing [Mn(II)].

Effect of added sodium pyrophosphate

It is reported that $P_2O_7^{4-}$ ions form complexes with Mn(III) and Mn(IV), while no interaction with MnO_4^- has been mentioned (17–20).[2] To substantiate the formation of Mn(III) and (or) Mn(IV) during the oxidation of lactic acid by acid permanganate and to clarify the role of these oxidizing species, different amounts of pyrophosphate were added to the reaction mixture. It was found that the oxidation rate of lactic acid is decreased by adding $P_2O_7^{4-}$ ions, while the induction period is increased with increasing $[P_2O_7^{4-}]$ (cf. Table 4). This indicates that Mn(III) and (or) Mn(IV) are the main reactive species in the autoacceleration period.

0.62	52.0
1.25	34.6
2.50	29.4
5.00	20.1

TABLE 5. Effect of added sodium fluoride on the reaction rate. $[MnO_4^-]$ = 2.01 × 10^{-4} *M*; [lactic acid] = 2.0 × 10^{-3} *M*; $[H_2SO_4]$ = 2.0 *M*; temperature = 24°C

[NaF] × 10^2 *M*	Percentage of reaction after 25 min
0.0	70.0
2.0	57.8
5.0	55.8
10.0	35.4
15.0	28.5

Effect of added sodium fluoride

The influence of NaF on the reaction rate parallels that observed with $Na_4P_2O_7$ (cf. Table 5). As [NaF] increases the rate decreases. This may be due to complex formation between Mn(III) and Mn(IV) and F^- ions (20).

Rate dependence on temperature

The reaction was studied at 16.5, 23.5, 29, and 34°C at [lactic acid] = 2.0 × 10^{-3} *M*, $[MnO_4^-]$ = 2.13 × 10^{-4} *M*, and $[H_2SO_4]$ = 2.0 *M*. The second-order rate constants (k_2) were calculated from rate expressions. The Arrhenius plot of log k_2 against $1/T$ was linear (Fig. 1.D). The value of activation energy was calculated from the slope of log k_2 versus $1/T$ and

FIG. 2.A. $\Delta S_{\ddagger}$* (e.u.)	−13.84

*At 302 K.

has been recorded along with other activation parameters (Table 6).

Discussion

The first-order dependence on both MnO_4^- and lactic acid in the initial stages of the reaction leads to a simple rate expression [*i*]; assuming that MnO_4^- ion is the main oxidizing species in the induction period:

$$[i] \qquad \frac{-\mathrm{d}[\mathrm{Mn(VII)}]}{\mathrm{d}t} = k_2[\text{lactic acid}][MnO_4^-]$$

The effect of addition of Mn^{2+}, $P_2O_7^{4-}$, and F^- ions shows conclusively that MnO_4^- ion is the main reactive oxidizing species in the "induction period" whereas Mn(III) and (or) Mn(IV) are the reactive species in the "autoacceleration period".

The decrease in the oxidation rate of lactic acid with increasing amounts of manganous sulphate added (Fig. 2) indicates that Mn(IV) is involved, as the [Mn(IV)] is expected to decrease by the addition of Mn(II) ions:

$$[4] \qquad Mn^{4+} + Mn^{2+} \rightarrow 2Mn^{3+}$$

The kinetics of oxidation of lactic acid by Mn(III) (prepared as recommended by Vogel, footnote 2) were studied spectrophotometrically at 290 nm to decide whether Mn(III) and (or) Mn(IV) is the principal reactive species in the "autoacceleration period". The spectum of manganic sulphate solution shows intense bands at λ_{max} 215 (sh) and 290 (sh) nm and an absorption band of low intensity at λ_{max} 492 nm. Under identical experimental conditions, $[H_2SO_4] = 2.0$ *M*, [lactic acid] $= 2.0 \times 10^{-3}$ *M*, [Mn(III)] = [Mn(VII)] $= 4.0 \times 10^{-4}$ *M*, and temperature = 26°C, it was found that the rate of oxidation of lactic acid by acid permanganate is 6.71×10^{-2} min^{-1} in the autoacceleration period, whereas the oxidation rate using Mn(III) is 3.89×10^{-2} min^{-1}, Fig. 2. This indicates that Mn(IV) is the principal reactive species of the autoacceleration period.

From the previous results the following mechanism can be suggested, Scheme 1.
This mechanism is in agreement with the results of Sengupta *et al.* (6), Murthy and Sundaram (21), and Bakore *et al.* (22).

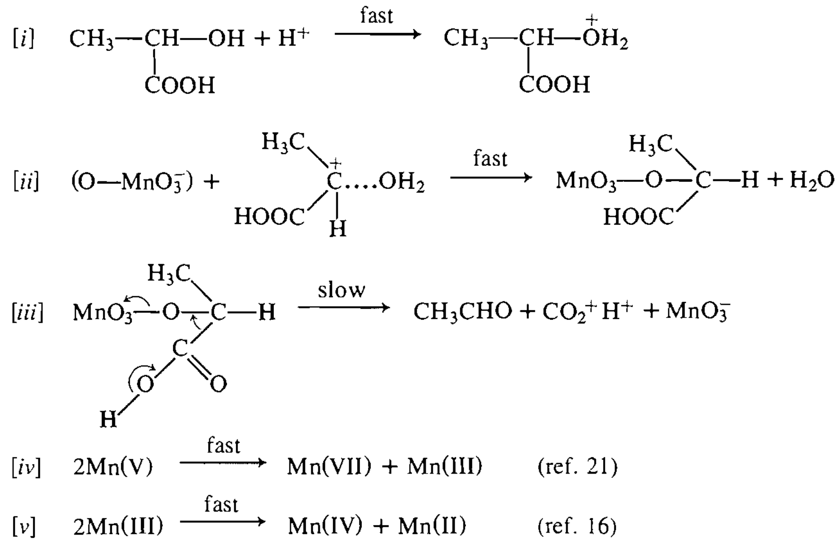
It is suggested that the induction period is followed by an autoacceleration between Mn(IV) and the substrate through complex formation:

$$[5] \qquad \mathrm{Mn(IV)} + \mathrm{HA} \underset{\text{fast}}{\overset{K_1}{\rightleftharpoons}} \mathrm{Mn(IV)A} + H^+$$

$$[6] \qquad \mathrm{Mn(IV)A} + \mathrm{HA} \underset{\text{fast}}{\overset{K_2}{\rightleftharpoons}} \mathrm{Mn(IV)A_2} + H^+$$

where A represents lactate species. By using the stability constants defined by eqs. [7] and [8],

$$[7] \qquad K_1 = \frac{[\mathrm{Mn(IV)A}][H^+]}{[\mathrm{Mn(IV)}][\mathrm{HA}]}$$



SCHEME 1

$$[8] \quad K_2 = \frac{[\mathrm{Mn(IV)A_2}][\mathrm{H^+}]}{[\mathrm{Mn(IV)A}][\mathrm{HA}]}$$

and the total concentration of Mn(IV)

$$[9] \quad [\mathrm{Mn(IV)}]_{\mathrm{total}} = [\mathrm{Mn(IV)}] + [\mathrm{Mn(IV)A}] + [\mathrm{Mn(IV)A_2}]$$

the concentrations of Mn(IV), Mn(IV)A, and Mn(IV)A_2 can be derived as

$$[10] \quad [\mathrm{Mn(IV)}] = \frac{[\mathrm{H^+}]^2[\mathrm{Mn(IV)}]_{\mathrm{total}}}{[\mathrm{H^+}]^2 + K_1[\mathrm{HA}][\mathrm{H^+}] + K_1K_2[\mathrm{HA}]^2}$$

$$[11] \quad [\mathrm{Mn(IV)A}] = \frac{K_1[\mathrm{HA}][\mathrm{H^+}][\mathrm{Mn(IV)}]_{\mathrm{total}}}{[\mathrm{H^+}]^2 + K_1[\mathrm{HA}][\mathrm{H^+}] + K_1K_2[\mathrm{HA}]^2}$$

and

$$[12] \quad [\mathrm{Mn(IV)A_2}] = \frac{K_1K_2[\mathrm{HA}]^2[\mathrm{Mn(IV)}]_{\mathrm{total}}}{[\mathrm{H^+}]^2 + K_1[\mathrm{HA}][\mathrm{H^+}] + K_1K_2[\mathrm{HA}]^2}$$

When the following competitive reactions are considered for the autoacceleration process

$$[13] \quad \mathrm{Mn(IV)A} \xrightarrow{K_a} \text{reaction products}$$

$$[14] \quad \mathrm{Mn(IV)A_2} \xrightarrow{K_b} \text{reaction products}$$

the variation of the rate of reaction with the change of substrate and hydrogen ion concentration can be expressed by the following relationship:

$$[15] \quad \text{Rate} = \frac{[K_aK_1[\mathrm{HA}][\mathrm{H^+}] + K_bK_1K_2[\mathrm{HA}]^2][\mathrm{Mn(IV)}]_{\mathrm{total}}}{[\mathrm{H^+}]^2 + K_1[\mathrm{HA}][\mathrm{H^+}] + K_1K_2[\mathrm{HA}]^2}$$

Under the experimental conditions, the factor $K_1K_2[\mathrm{HA}]^2 \ll 1$ and may be neglected. Then, eq. [15] takes the form

$$[16] \quad \text{Rate} = \frac{K'[\mathrm{HA}][\mathrm{H^+}][\mathrm{Mn(IV)}]_{\mathrm{total}}}{[\mathrm{H^+}]^2 + K_1[\mathrm{HA}][\mathrm{H^+}]}$$

where $k' = K_aK_1$. Equation [16] requires the plot of 1/rate against 1/[substrate] to be linear. The existing data satisfy this requirement. Unfortunately, the other requirement, that the plot of the reciprocal of the rate constant against the hydrogen ion concentration be linear, could not be tested because the ionic strength of the solution was not constant through the experimental conditions. Consequently, eq. [16] will no longer be expected to be valid.

The crystal structure of thomsenolite, $NaCaAlF_6 \cdot H_2O$, has been redetermined to establish the hydrogen-bonding scheme in this mineral. Both hydrogen atoms participate in branched O—H···F bonds. The hydrogen bonds link the AlF_6 octahedra to form infinite chains $\|b$, which in turn are cross-linked to form infinite double sheets $\{[AlF_6] + Ca\}$—(H_2O)—$\{[AlF_6] + Ca\}\|(001)$. The Na atoms are located exclusively in layers $\|(001)$ which separate the double sheets. A detailed comparison of thomsenolite with its dimorph, pachnolite, shows that the structure of pachnolite is obtained in essence by interchanging the positions of one half of the Na atoms and one half of the water molecules in thomsenolite. The two-dimensional, layerlike hydrogen-bonding network in thomsenolite is thereby changed to one of a three-dimensional character in pachnolite. Other features of the two structures, including the Al—F and Na···F distances, are compared and discussed in some detail.

D. ADHIKESAVALU, T. STANLEY CAMERON et OSVALD KNOP. Can. J. Chem. **63**, 3322 (1985).

On a redéterminé la structure cristalline de la thomsénolite, $NaCaAlF_6 \cdot H_2O$, dans le but d'établir la disposition des liaisons hydrogènes de ce minéral. Chacun des deux atomes d'hydrogène est impliqué dans des liaisons O—H···F ramifiées. Ces liaisons hydrogènes relient les octaèdres de AlF_6 de façon à former des chaînes infinies $\|b$ qui, à leur tour, sont réticulées pour former des doubles couches infinies $\{[AlF_6] + Ca\}$—(H_2O)—$\{[AlF_6] + Ca\}\|(001)$. Les atomes de sodium se retrouvent uniquement dans les couches $\|(001)$ qui séparent les doubles couches. Si on compare soigneusement la thomsénolite à sa forme dimorphe, la pachnolite, on s'aperçoit que, en essence, on obtient la structure de la pachnolite en interchangeant les positions de la moitié des atomes de sodium et de la moitié des molécules d'eau de la thomsénolite. Le réseau bidimensionnel des liaisons hydrogènes de la thomsénolite acquiert alors un caractère tridimensionnel dans la pachnolite. On compare d'autres caractéristiques de ces deux structures, y compris les distances Al—F et Na···F, et on les discute en détail.

[Traduit par le journal]

The hydrated fluoride mineral thomsenolite (T) has been known since 1862. Its X-ray crystal data were reported in 1946 by Ferguson (1), and its structure, with isotropic temperature factors, was determined from photographic intensities by Cocco *et al.* (2). The positions of the hydrogen atoms were not established. The absence of this detail came to our notice during our recent investigation of complex fluorides (3–5) concerned in part with hydrogen bonding, and as information on X—H···F bonds is not nearly as plentiful as that, for example, on X—H···O bonds, we set out to redetermine the structure of T with a view to completing its description.

Experimental

A small ($0.008\ mm^3$), nearly equiaxial and carefully selected crystal for this investigation was supplied by Professor H. Pauly from his comprehensive collection of fluoride minerals from Ivigtut. A CAD-4 four-circle diffractometer was used in the determination of the unit cell dimensions and in the intensity collection. The intensities were reduced by routine procedures (6). Lorentz and polarization corrections were applied, but no absorption or extinction corrections. Scattering factors were taken from ref. 7. The structure was refined using the SHELX system (8). Full-matrix least-squares ($w\Delta F^2$ = minimum) refinement was carried out with isotropic temperature factors using the positional parameters of ref. 2 as starting values. The positions, near the oxygen atom, of the maxima which were clearly visible in the difference Fourier map calculated at this stage, left no doubt that these maxima corresponded to the H atoms. The O—H bond lengths were constrained to 0.98(1) Å and the H···H distance to 1.60(2) Å, and the refinement was continued with isotropic temperature factors on the hydrogens and anisotropic on all the other atoms until $R = 4.7\%$ (Table 1). The anisotropic temperature factor is defined as $T = \exp\,[-2\pi^2(U_{11}h^2a^{*2} + U_{22}k^2b^{*2} + U_{33}l^2c^{*2} + 2U_{23}klb^*c^* + 2U_{13}hla^*c^* + 2U_{12}hka^*b^*)]$. The least-squares weights were calculated from $w^{-1} = 1.3067\sigma^2|F_o| + 0.0002F_o^2$, where σ is the weight for an individual reflection derived from the diffractometer counting statistics.

only insignificantly from those of ref. 2 (Table 3), regardless of whether scattering factors for neutral or for ionized atoms were used in the refinement. For the nonhydrogen atoms the only improvement over ref. 2 is in the anisotropic refinement. The U_{ii} are small, with only a slight anisotropy. Those of Na are the largest; this agrees with ref. 2, where Na also has the largest (isotropic) temperature factor. Corrections to the Al—F distances arising from the rigid-body motion of the AlF_6 octahedron were 0.003−0.005 Å and thus comparable to 1σ for the distance; those to the FAlF angles were completely negligible.

A projection of the structure along a (Fig. 1) shows that the structure may be regarded as consisting of {[AlF_6] + Ca} layers ‖(001) which are intercalated alternately with layers of Na atoms and layers of water molecules. The coordination polyhedra of the Na and Ca atoms are irregular. Cocco *et al.* (2) describe the F_6O_2 coordination polyhedron of Ca as a distorted square antiprism and the F_8 polyhedron of Na as an augmented trigonal prism, and this description seems adequate.

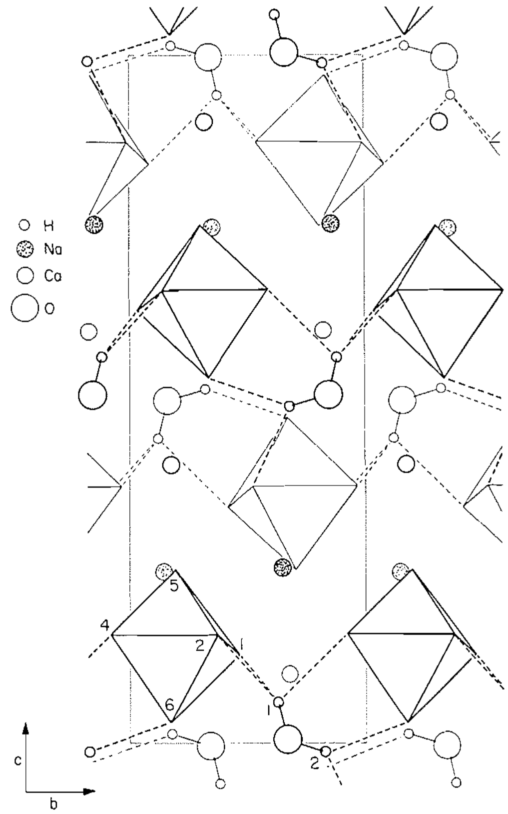

FIG. 1. Projection of the unit cell of thomsenolite along a on (100), displaying the hydrogen-bonding scheme. The hydrogen bonds are represented by broken lines; because of crowding only one of the two H···F components of the bifurcated H(2)···F bond is shown for the lower-level H(2) atoms.

The nearest cation neighbours of an oxygen atom are two almost equidistant Ca atoms (Fig. 2, top). Together with the H atoms they coordinate the oxygen atom approximately tetrahedrally. The appreciable deviations of the CaOH(1), 82(4)°, and Ca′OH(2), 120(4)°, angles from tetrahedral seem to be real, as the CaOCa′ angle is quite accurate and the dimensions to which the water molecule was constrained in the refinement represent the statistical mean for the H_2O geometry in crystalline hydrates, which is known to have only a narrow range of variation (9, 10).

Both H atoms are strongly bonded to F atoms (Table 5, Fig. 3). H(2) is involved in a fairly symmetrically bifurcated H(2)···F(6),F(3) bond, while H(1) participates in a bond to several acceptors, with O—H(1)···F(1) as the principal component. There is probably a weak participation of a more distant F neighbour in the bond to H(2). In Fig. 4 (top) OHF angles greater than 90° are plotted against their respective H···F distances. The H···F,OHF pairs are distributed fairly uniformly, with a mean of 2.31(30) Å and 123(23)°, and are strongly correlated (r = −0.93). While it is uncertain what constitutes the upper H···F limit for effective hydrogen bonding, all H···F distances corresponding to OHF ≥ 90° could in principle be viewed as involved in hydrogen-bonding interaction, especially when even the shortest H···F distances in the structure belong to bent O—H···F geometries. Without wishing to enter the "upper limit" controversy at this time,[3] we simply regard the H···F,OHF plot as a convenient description

[3] This matter will be discussed elsewhere.

of the *total* (as distinct from the local) hydrogen-bonding interaction in the crystal, the standard deviations of ⟨H···F⟩ and ⟨OHF⟩ being measures of the dispersion. This plot will be found useful when comparing T with pachnolite (see below).

The shortest H···F distance, H(1)···F(1) = 1.82(6) Å, is statistically indistinguishable from 1.85(11) Å, the mean of the sample of 33 normal (i.e. to a single acceptor) H···F bond lengths in metal fluoride hydrates (X-ray data) examined in ref. 11. It is, however, appreciably longer than the H···F distances observed for H_2O coordinated to M in octahedral $[MF_5(H_2O)]^{2-}$ complexes: 1.59(6) Å in $(NH_4)_2[AlF_5(H_2O)]$ (4) and 1.61 and 1.63 Å in $Rb[VF_4(H_2O)_2]$ (11), the shortest such distances known to date. Similarly, the shortest O···F distance in T, 2.74 Å, is typical (and close to the mean) of O_w···F distances in the sample of ref. 11 and comparable to the O_w···F distances in $A_2[MF_4F_{2/2}]\cdot H_2O$, 2.73–2.75 Å (12–15), and in $A[MF_4F_{2/2}]\cdot H_2O$, 2.80–2.82 Å (16), but longer than in the

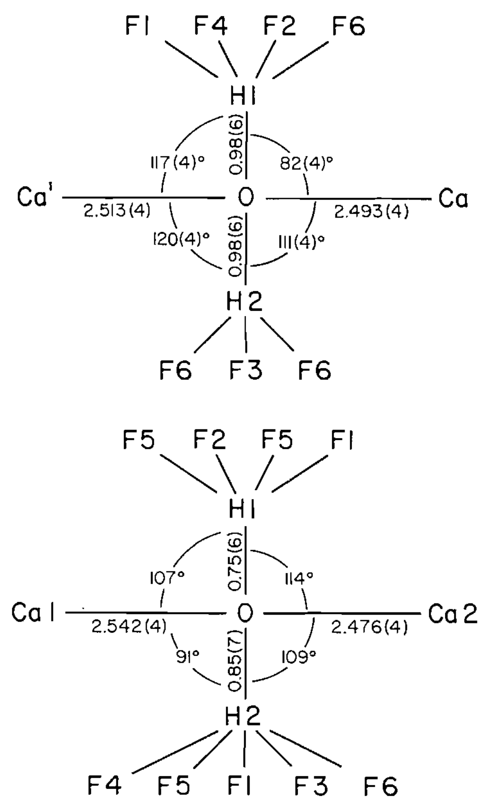

FIG. 2. Coordination of the oxygen atom in T (*top*) and P (*bottom*, after ref. 18). The CaOCa angles in T and P are 110.2(2)° and 110.5°, respectively; the HOH angles are 110(6)° and 122(6)°, respectively. Fluorine atoms at H···F distances of up to 2.9 Å are shown.

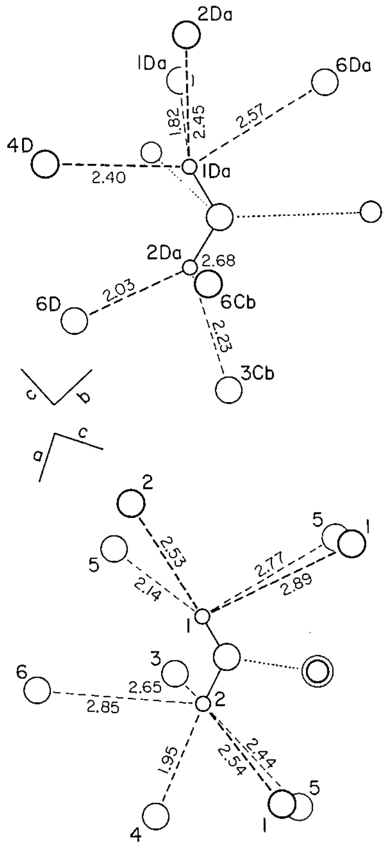

FIG. 3. Details of the hydrogen bonding in T (*top*) and P (*bottom*, after ref. 18). Projection on approximately the plane of the water molecule (on (100) in T, on (010) in P). Unlabelled circles joined to the oxygens by dotted lines are Ca atoms. For OHF angles in T see Table 5.

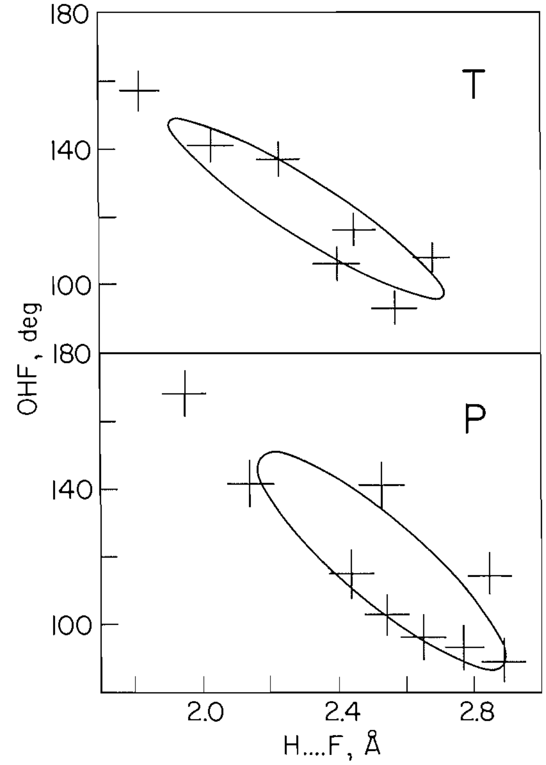

FIG. 4. Distribution of the H···F distances (≤2.9 Å) and OHF angles (≥90°) in T (*top*) and P (*bottom*, after ref. 18). The ellipses represent the normal bivariate frequency contours for half maximum frequency. Adjustment of the O—H distances in P to 0.98 Å brings the H···F, OHF distribution in P closer to that shown for T.

$A_2[MF_5(H_2O)]$ structures: 2.55 Å in $(NH_4)_2[AlF_5(H_2O)]$ (4), 2.61 Å in $Cs_2[FeF_5(H_2O)]$ (17).

The F atoms involved in the shortest H···F distances, F(1) and F(6), and the two Ca neighbours define the minimum coordination polyhedron of the water molecule. This polyhedron is, in T and $A_2[MF_4F_{2/2}]\cdot H_2O$ alike, an approximate tetrahedron. However, the AOA angle of this tetrahedron is much larger in T (and in pachnolite, see below) than in the alkali compounds, while the FOF angles are comparable:

Compound	Angle (deg) AOA	FOF
Ca_2OF_2 in T	110.2	102.3
Ca_2OF_2 in pachnolite (see below)	110.5	105.6
K_2OF_2 in $K_2MnF_5\cdot H_2O$ (12)	86.4	99.3
Rb_2OF_2 in $Rb_2MnF_5\cdot H_2O$ (14)	85.9	95.3
Cs_2OF_2 in $Cs_2MnF_5\cdot H_2O$ (13)	91.4	
Rb_2OF_2 in $Rb_2AlF_5\cdot H_2O$ (15)	86.7	83.5

Comparison with pachnolite

Pachnolite (P) is a monoclinic dimorph of T. Like the latter, it is a natural alteration product of cryolite, Na_3AlF_6. Its structure was recently reported by Hawthorne and Ferguson (18), who adopted for its description the $F2/d$ setting of $C2/c$. This setting ($\boldsymbol{a}_F = 2\boldsymbol{a}_C + \boldsymbol{c}_C$, $\boldsymbol{b}_F = \boldsymbol{b}_C$, $\boldsymbol{c}_F = \boldsymbol{c}_C$) corresponds to a very nearly orthogonal unit cell as well as to the original morphological description (1), and is retained in the following.

Hawthorne and Ferguson have pointed out that a feature common to both T and P is the presence of $[Ca_2F_{12}(H_2O)_2]^{8-}$ dimers (or, more simply, Ca_2O_2 rings), and they have shown that these dimers have, in the two structures, different orientations relative to the adopted crystallographic axes (Fig. 4 of ref. 18). Further examination brings to light an even closer similarity.

Inspection of the positional coordinates of the atoms in T (Table 3) and P (18) reveals that most of them are quite close to multiples of $\frac{1}{8}$. Furthermore, $V(P)/16 = V(T)/4$ to within 0.2%, i.e. the dimorphs are equally dense, and $a(P) \sim 2a(T)$, $b(P) \sim 2b(T)$, $c(P) \sim c(T)$, $\beta(T) - \beta(P) = 6.0°$. When the fractional coordinates are approximated by the nearest multiples of $\frac{1}{8}$ and the T cell is quadrupled by doubling a and b, the similarity of these idealized T and P structures is immediately evident (Fig. 5).

The AlF_6 octahedra in both structures are arranged in sheets ‖(010). These sheets are planar in P but undulating in T. The Ca atoms occupy analogous positions between the AlF_6 octahedra in the two structures and so do one half of the Na and one half of the O atoms, but the other half of the Na atoms in T correspond to the other half of the oxygen atoms in P, and conversely. The result of this interchange is that in T there are layers ‖(001) consisting exclusively of Na atoms; these layers alternate with similar layers consisting only of water molecules. In contrast, in P each of the corresponding layers contains both Na and O atoms in equal numbers. This has the consequence that the planes of the Ca_2O_2 rings in P are ‖(100), with the Ca atoms on C_2 axes, whereas in T the centrosymmetric rings are essentially in planes ‖(010) but tilted as a

TABLE 6. Comparison of selected interatomic distances (Å) and bond angles (deg) in T and P[a]

Distance or angle	Coordination figure	T	P
⟨Al—F⟩	AlF_6	1.806(18)	1.807(11)
⟨Na···F⟩	NaF_8 (T), NaF_9 (P)	2.47(12)	2.57(20)
⟨Ca···F⟩	CaF_6O_2	2.35(6)	2.34(4)[b]
⟨Ca···O⟩	CaF_6O_2	2.503(14)	2.509(47)
Ca···Ca	Ca_2O_2	4.108(3)	4.122(3)
O···O	Ca_2O_2	2.860(5)	2.862(6)
OCaO	Ca_2O_2	69.7(2)	69.3(18)[c]
CaOCa	Ca_2O_2	110.2(2)	110.5
⟨Al···Ca⟩	$AlCa_6$, $CaAl_6$	4.02(11)	4.02(9)
⟨Al···Na⟩	$AlNa_4$, $NaAl_4$	3.30(13)	3.30(3)[d]
⟨Ca···Na⟩	$CaNa_4$, $NaCa_4$	3.69(11)	3.68(4)

[a]For the means the value in the parentheses is the σ(mean). For other (single) values it is the esd from the structure determination.
[b]2.366 Å in CaF_2.
[c]Mean.
[d]3.39 Å in cryolithionite (22).

result of the undulation of the {$[AlF_6]$ + Ca} sheets. The rotational displacements of the AlF_6 octahedra are neglected in this idealization. However, as pointed out in ref. 18, it is these tilts that are responsible for the increase in the C.N. of Na with respect to F from eight in T to nine in P.

The geometry of the planar Ca_2O_2 rings in T and P resembles that observed with many other μ-dioxo M_2O_2 rings with M of a size comparable to Ca (19), but the dimensional similarity of these rings in the two structures (Table 6) is remarkable. The close kinship of the T and P structures is also reflected in the great similarity of the various mean interatomic distances, not only M—F and M—O, but also M—M′ (Table 6). The exception is the mean Na···F distance (2.47(12) Å in T), which is ~0.1 Å longer in P as a consequence of the increased C.N. The M—X coordination figures are AlF_6 octahedra and the less regular CaF_6O_2 and NaF_8 (or NaF_9) polyhedra.

The constancy of the mean Al—F distance in the AlF_6 octahedra is striking. The weighted mean computed from the individual Al—F means in T, P (18), α-$Li_3[AlF_6]$ (20), $Na_3[AlF_6]$ (cryolite) (21), $Na_3Li_3[AlF_6]_2$ (cryolithionite) (22), $Na_2Mg[AlF_6]F$ (weberite) (3, 23), Rb[*trans*-$AlF_2F_{4/2}$] (24), and jarlite, Na(Sr, Na, □)$_7$ (Mg, □){$[AlF_4F_{2/2}][AlF_5F_{1/2}]_2$}$_2$(OH, $H_2O)_2$ (25) — all accurately determined structures — is 1.807 Å, with a standard deviation of only 0.001 Å.[4]

The similarity of the T and P structures is also evident in the more distant coordination: in both structures the $AlCa_6$ and $CaAl_6$ coordination figures are somewhat irregular octahedra, and $NaAl_4$ and $NaCa_4$ are tetrahedra. The $AlNa_4$ and $CaNa_4$ groupings are fairly regular square pyramids (with Al or Ca at the apex) in T but highly distorted (C_2) square pyramids in P.

Hydrogen bonding in T and P

The different orientation of the Ca_2O_2 rings in the two structures results in differences in the hydrogen bonding and the

[4]In Rb_2[*trans*-$AlF_4F_{2/2}$]·H_2O (15) the unusually large elongation of the AlF_6 octahedron in the direction of the $[AlF_4F_{2/2}]_\infty^{2-}$ chain results in ⟨Al—F⟩ = 1.818(54) Å. This value has not been included in the above mean. However, the mean of the Al—F distances involving the unshared F atoms is 1.783(10) Å, i.e. identical with ⟨Al—F⟩ = 1.789(6) Å in $[AlF_5(H_2O)]^{2-}$ (4). The ⟨Al—F⟩ value in the aquo complex is smaller than in $[AlF_6]^{3-}$, which is to be expected because of the lower charge on the aquo ion.

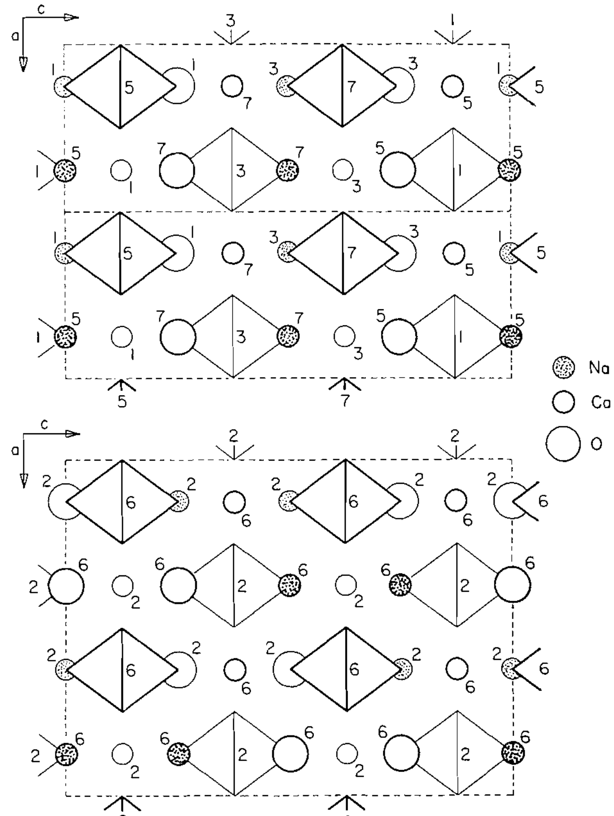

FIG. 5. Schematic representation of the relationship between the T and P structures. (*Top*) Idealized T structure. Projection of two unit cells on (010); origin shifted by (0, 0, $\frac{1}{4}$), β taken as 90°, *y* coordinates indicated in eighths of *b*(T). (*Bottom*) Idealized P structure. Projection of the lower half of the unit cell on (010); β taken as 90°, *y* coordinates indicated in sixteenths of *b*(P).

coordination of the O atom, Ca_2OH_2. A comparison can at best be approximate, given the large uncertainties in the positions of the H atoms. In the refinement of T the H_2O geometry was constrained to the mean observed in crystalline hydrates, whereas for P no constraint appears to have been applied, with the not unexpected result that O—H(1) = 0.75(6) Å, O—H(2) = 0.85(7) Å, i.e. too short, and H(1)OH(2) = 122(6)°, i.e. too large. These values, when used in the calculation of H···F distances and OHF angles, generate further uncertainties, thus affecting the comparison.

The F neighbours of a water molecule in T and P, eligible as hydrogen-bond acceptors, are shown in Fig. 3. In P the principal hydrogen bonds clearly are H(1)···F(5) and H(2)···F(4), but the bonding interaction is not necessarily restricted to these two shortest H···F distances. The OH(1)F(5) angle corresponding to H(1)···F(5) = 2.14 Å is only 142(7)° (18), and it is almost certain that the O—H(1)···F bond has a second component, with F(2) as the likely candidate. A similar, though weaker, argument can be made for H(2). Repositioning the H atoms to obtain more realistic O—H and HOH values would alter the H···F distances and OHF angles of Fig. 3: when the O—H(1) and O—H(2) distances of ref. 18 are lengthened to 0.98 Å, this adjustment alone reduces the OH(2)F(4) = 170(7)° and OH(1)F(5) = 142(7)° angles of ref. by about 20° each. The probability of the O—H···F bonds in P being nearly straight, or at least unbranched, is thus quite low, and with the H atoms properly positioned, one would expect the hydrogen-bonding situation at the water molecule in P to resemble that in T.

This expectation is supported by comparing the distributions, in T and P, of H···F distances which correspond to OHF angles favourable for O—H···F^- bonding, i.e. OHF ≥ 90° (Fig. 4). Application of a generalized *t* test (Hotelling's T^2 test) shows that the two H···F,OHF means (centres of the normal bivariate frequency contours in Fig. 4) are indistinguishable at the 0.5% significance level, i.e. there is no significant difference in the *total* hydrogen-bond engagement between T and P as measured by these distributions.[5] When the H···F and OHF values based on ref. 18 are recalculated from the lengthened O—H(1) and O—H(2) distances, the mean for P falls closer to the mean for T, so that this new mean is *a fortiori* indistinguishable from that for T. A similar result would be expected from the distribution based on more realistic (unavailable) positions of the P hydrogens.

In P the dihedral angles Ca(1)OCa(2)/F(4)OF(5) and Ca(1)-OCa(2)/H(1)OH(2) of ref. 18 are about the same, 85° and 83°, respectively, i.e. the O—H(1)···F(5) and O—H(2)···F(4) bonds are practically coplanar. In T, on the other hand, the CaOCa'/F(1)OF(6) angle, 87°, differs appreciably from the CaOCa'/H(1)OH(2) angle, 75°; this noncoincidence reflects the bifurcation of the O—H(2)···F bond.

Ultimately, a detailed comparison of the hydrogen bonds in T and P will have to await the results of a neutron-diffraction study, or at least a redetermination of both structures from low-temperature X-ray data. However, while the individual H···F and OHF values available at present suffer from large uncertainties, the overall hydrogen-bonding *schemes* can be regarded as substantially established. In T adjacent layers of AlF_6 octahedra parallel to (001) are joined by intra- and interlayer hydrogen bonds to form double layers which are separated by layers of Na atoms (Fig. 1), whereas in P the hydrogen-bond cross-linking of the AlF_6 sheets has a three-dimensional rather than a layerlike character (cf. Fig. 5).

Acknowledgments

The authors wish to thank Professor H. Pauly for selecting and supplying the thomsenolite crystal, and to the Natural Sciences and Engineering Research Council of Canada for financial support of this investigation through grants to T.S.C. and O.K.

The ir spectra of the isotopic probe ion NH_3D^+ have been used to obtain information about the symmetry, orientation, and hydrogen-bonding involvement of the ammonium ion, between 10 K and room temperature, in NH_4F, NH_4HF_2, $(NH_4)_2[Cr(H_2O)_6]F_5$, NH_4PF_6, $(NH_4)_3SiF_7$, the elpasolites $(NH_4)_2BFeF_6$ (B = Na, K) and $Cs_2NH_4MF_6$ (M = Fe, Al), and the cryolites $(NH_4)_3MF_6$ (M = Al, Cr, Fe). Several of these fluorides exhibit low-temperature transitions, some of which are evident in the probe-ion spectra. It is shown that relating the isotopically isolated ND stretching and bending frequencies to the N···F distances and to the coordination numbers of the ammonium ion reveals important trends in the dependence of the behaviour of the ion on its immediate environment in the crystal. A detailed discussion is presented of the effect of ionic size and the geometric tolerance factor *t* on the transition temperatures of cubic cryolite, perovskite, and elpasolite halides, as well as on the anisotropy of the principal thermal amplitudes of the halogen atom in such compounds. The relation between T_{tr} and the frequency of the ND stretching absorption of NH_3D^+ in the ammonium representatives of these classes of halides is also explored.

OSVALD KNOP, WOLFGANG J. WESTERHAUS, MICHAEL FALK et WERNER MASSA. Can. J. Chem. **63**, 3328 (1985).

En se basant sur les spectres IR de l'ion NH_3D^+ utilisé comme sonde isotopique, on a pu obtenir des informations concernant la symétrie, l'orientation et l'implication de l'ion ammonium dans des liaisons hydrogènes dans le NH_4F, le NH_4HF_2, le $(NH_4)_2[Cr(H_2O)_6]F_5$, le NH_4PF_6, le $(NH_4)_3SiF_7$, dans les elpasolites $(NH_4)_2BFeF_6$ (B = Na, K) et $Cs_2NH_4MF_6$ (M = Fe, Al) et dans les cryolites $(NH_4)_2MF_6$ (M = Al, Cr, Fe), à des températures allant de 10 K à la température ambiante. Plusieurs de ces fluorures présentent des transitions à basses températures et certaines d'entre elles sont très évidentes dans le spectre de l'ion sonde. On montre que si l'on relie les fréquences d'élongation et de déformation de la liaison ND isotopiquement isolée aux distances N···F et au nombre de coordination de l'ion ammonium, on peut mettre en évidence des tendances importantes entre le comportement de l'ion et sont environnement immédiat dans le cristal. On discute en détail de l'effet de la dimension de l'ion et du facteur de tolérance géométrique, *t*, sur les températures de transition des halogénures cubiques de la cryolite, de la pérovskite et de l'elpasolite ainsi que sur l'anisotropie des amplitudes thermiques principales de l'atome d'halogène de ces composés. On a également étudié la relation qui existe entre le T_{tr} et la fréquence d'absorption de l'élongation de la liaison ND de l'ion NH_3D^+ de cette classe représentative d'halogénures d'ammonium.

[Traduit par le journal]

In Part VI (2) an effort was made to explore, systematically, the dependence of the strength and type of hydrogen bonding of the ammonium ion in a variety of halides on factors such as the nature of the acceptor atom X, the coordination number of the ammonium ion and the N—H···X angle. Whilst the gross features of this dependence were successfully identified, the compounds were too few to obtain a detailed picture of the overall situation. In particular, the number of fluorides included was not sufficiently large if one considers that the fluorides determine the observed trend in a greater measure than the other halides, which exhibit a relatively narrow range of behaviour and form a fairly homogeneous group.

In the present work we have supplemented these results by obtaining the ν_1 and ν_{4bc} spectra of the NH_3D^+ probe ion in additional fluorides, including some recently described (3–5) complex ammonium fluorides in which the ammonium ion has the rare C.N. of 4 and 6. Advantage has also been taken of the improved cryogenic system to reinvestigate the spectra of some of the fluorides dealt with in ref. 2, down to 10 K. These extensions have resulted, among other things, in a better understanding of some of the problems investigated by Epple (5, 6) on undeuterated samples of the $(NH_4)_3MF_6$ (M = Al, Cr, Fe) cryolites and the $(NH_4)_2BFeF_6$ (B = Na, K) and $Cs_2NH_4MF_6$ (M = Al, Cr, Fe) elpasolites.

The compounds included in the present analysis of hydrogen bonding in ammonium fluorides are listed in Table 1. The symbols, abbreviations and numbering of the compounds follow ref. 2; $\nu_1(10)$ stands for $\nu_1(NH_3D^+)$ at 10 K etc.

Experimental

Preparation of deuterated samples

High-purity NH_4F was deuterated by recrystallization from MeOH–MeOD mixtures of the requisite composition. **54** was prepared as in ref. 4 using weakly deuterated reactants throughout.

The elpasolites **57**, **58**, **63**, and **64** were prepared by reacting par-

[i]λ-point, $\Delta S_{tr}/R$ = 3.0 (25).

tially deuterated $(NH_4)_3MF_6$ with the appropriate anhydrous fluorides in sealed Pt capsules at 300°C. The capsules were heated in an autoclave in N_2 at 100–200 atm. The compounds **57** and **58** gave very sharp diffraction patterns; the powder patterns of **63** and **64** were less well defined. Some of the **58** preparations were slightly contaminated with Cs_2SiF_6, the silicon having been introduced through accidental contact of the reactants with silica glass. Because of this and of the variation in the detail of some of the ND absorptions in the spectra of the first two **58** preparations, a special effort was made to eliminate the contamination by modifying the conditions of the high-pressure synthesis. Altogether, three undeuterated and five deuterated samples were prepared; the last 0% D and 4% D preparations were pure elpasolite phases within the limits of detection by careful X-ray powder diffractometry (both **58** and Cs_2SiF_6 are cubic). In spite of these precautions, however, the slight variability, from sample to sample, of the ND spectra remained. The reasons for the variability have not been established, but is is possible that kinetic factors are responsible, analogous to those leading occasionally and unpredictably to the suppression of low-temperature transitions in ammonium hexabromometallates(IV) (cf. footnotes 10 and 13 below).

The cryolites **59**, **60**, and **61** were precipitated from partially deuterated hot concentrated solutions of AlF_3, CrF_3, and $Fe(NO_3)_3$, respectively, in aqueous HF with excess solid NH_4F.

To prepare **62**, solutions of $(NH_4)_2SiF_6$ and excess NH_4F in 5% D_2O were mixed and evaporated on a steam bath until crystallization began. The colourless needles were washed with ether and dried in air.

Commercial reagent-grade NH_4HF_2 and NH_4PF_6 were deuterated by recrystallization from aqueous solutions containing D_2O and acidified with HF.

Infrared spectra

Unless noted otherwise the finely ground sample powders were mulled in fluorolube and the mulls were supported between CaF_2 plates. The variable-temperature spectral runs were made in the heating mode, but thermal cycling through T_{tr} was employed where applicable. Most of the spectra were recorded on a Perkin–Elmer model 180 spectrophotometer; some were also obtained with a Fourier-transform ir spectrometer (Bomem DA3.02) which became available in the later stages of this investigation. Both instruments were fitted with a closed-cycle He refrigerator.

Results

NH_4F (1)

The site symmetry S at the N atom in this crystal is C_{3v}, hence the effective symmetry E of the NH_4^+ ion is also C_{3v}. Two bands in a 3:1 intensity ratio would therefore be expected for the ν_1 and three bands, in a 2:3:3 intensity ratio, for the ν_{4bc} fundamental of the probe ion. However, as pointed out earlier (2), the displacement between the N and F hcp sublattices of this $P6_3mc$ structure is such that each ion is equidistant, at 2.708(3) Å, from its nearest counterion neighbours (7, 8) (Fig. 1). On this evidence the symmetry of the NH_4^+ ion is indistinguishable from T_d, and one band each would be expected for the two fundamentals. A *single* ν_1 and a *single* ν_{4bc} band were indeed observed, at all temperatures between 5 and 293 K, at the levels of resolution and deuteration employed in the previous study (2). We have now reinvestigated the NH_3D^+

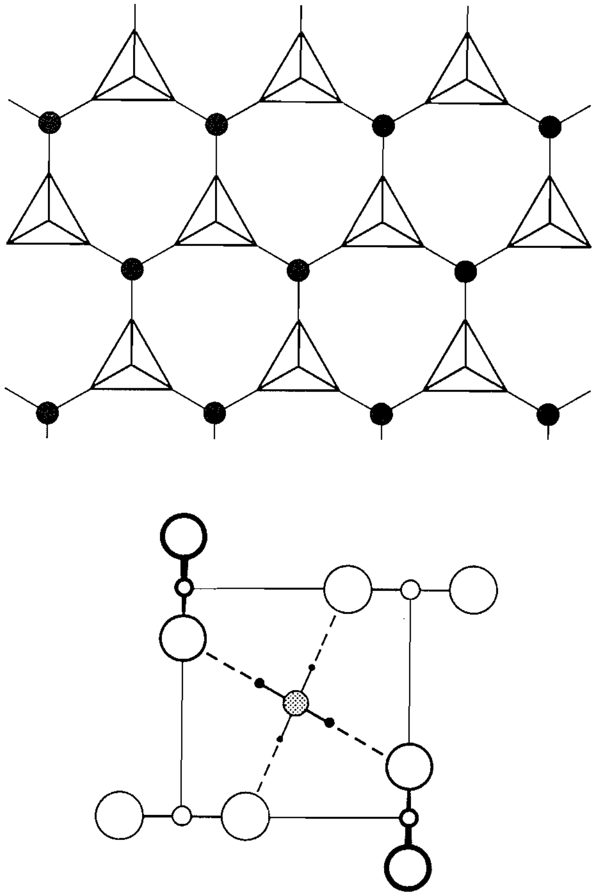

FIG. 1. Schematic representation of the hydrogen bonding in NH_4F (one layer, *top*) and NH_4HF_2 (*bottom*).

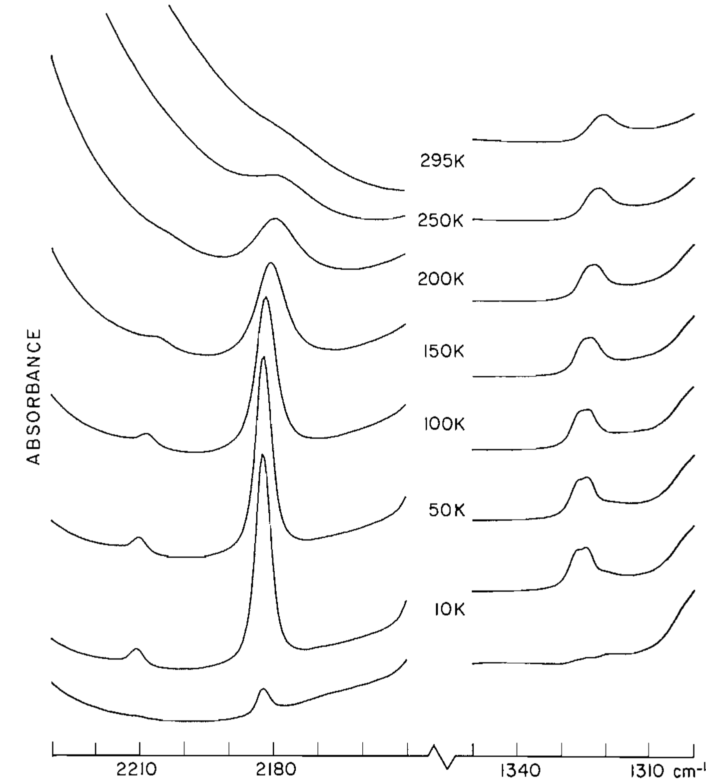

FIG. 2. Spectra of NH_4F (0.3% D) in the regions of the ND stretching fundamental ν_1 (*left*) and the ND bending fundamental ν_{4bc} (*right*) of the NH_3D^+ probe ion at different temperatures. The bottom spectrum is that of a 0.04% D sample at 10 K.

absorptions in more detail, mainly to see whether the two bands show incipient resolution under improved experimental conditions.

The ν_1 region presents a number of complications. It contains intense overtone bands of undeuterated NH_4F, so that at low deuteration the ν_1 absorption is a small band on a sloping background which changes with temperature. This and the Christiansen effect at low temperatures result in a considerable uncertainty as to the true band shape and temperature shifts. We therefore made every effort to minimize the Christiansen effect and, taking advantage of the superior sensitivity of the FT over the previously employed grating spectrometer, we were able to record very good spectra not only at ~0.3% D, but even at an estimated 0.04% D isotopic replacement, i.e. at a concentration level approaching the natural abundance of D in water.

The maximum of the ν_1 band at 10 K in these spectra (Fig. 2) was at 2182.4(2) cm^{-1}, in agreement with the previously reported value of 2182.0 cm^{-1} at 5 K (2). The small halfwidth of the band (4.0 cm^{-1} at 0.3% D and 3.3 cm^{-1} at 0.04% D), its visual symmetry, and the absence of any absorption, in the ν_1 region, responding to variable deuteration and of an intensity approximately either one-third or three times that of the 2182 cm^{-1} band, are evidence that the latter band in fact constitutes *all* of the ν_1 absorption. The two ν_1 components, if indeed distinct, cannot thus be separated by more then 2 cm^{-1}. The ν_{4bc} fundamental, on the other hand, did show structure. At 10 K it appeared as a barely resolved doublet at 1324.5 and 1326.2 cm^{-1}, with a band shape not inconsistent with the 2:3:3 triplet required by $E = C_{3v}$.

With increasing temperature both ν_1 and ν_{4bc} gradually moved to lower wavenumbers (Fig. 3). The $d\nu/dT$ coefficient was almost zero at 10 K but increased with temperature. The halfwidth of the ν_1 band changed very little with temperature up to about 100 K, after which it increased gradually. The increase was only about half that encountered with the other compounds investigated here. The integrated intensity of ν_1 decreased with increasing temperature, at first slowly and then very sharply. At room temperature the band area was only about one tenth of that at 10 K and above about 200 K the band position and halfwidth could not be measured with confidence. The halfwidth of the ν_{4bc} band remained almost stationary with temperature, while its integrated intensity decreased somewhat on warming the sample, though much less rapidly than for ν_1.

The ν_1 band was accompanied by several pairs of satellites, of which the most prominent were at 2211 and 2146 cm^{-1}, the latter enhanced by the NH_4F overtone band at 2142 cm^{-1}. The intensities of these satellites, relative to ν_1, diminished with increasing isotopic dilution and their positions shifted with temperature in the same direction though not exactly at the same rate as ν_1. The satellites appear to correspond to the in-phase and out-of-phase modes arising from pairs of adjacent NH_3D^+ ions in the crystal. Similar satellites are observed in other ammonium salts, but they are much less intense at comparable levels of deuteration. Their unusual prominence in **1** is due to the distinctive features of the NH_4F structure: the low C.N. of NH_4^+ in **1** increases the frequency of occurrence of such pairs compared with crystals of C.N. > 4, and the small

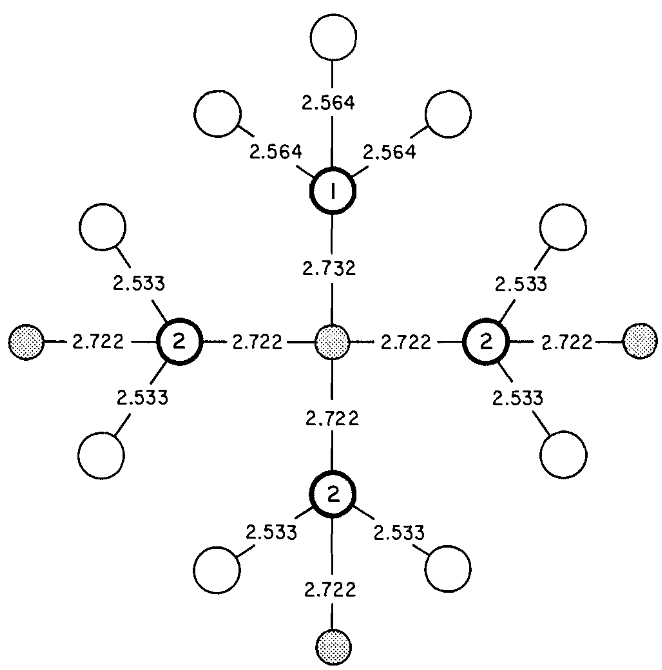

FIG. 4. Schematic representation of the hydrogen bonding of the ammonium ion in $(NH_4)_2[Cr(H_2O)_6]F_5$. Heavily outlined circles, F; open circles, O; shaded circles, N.

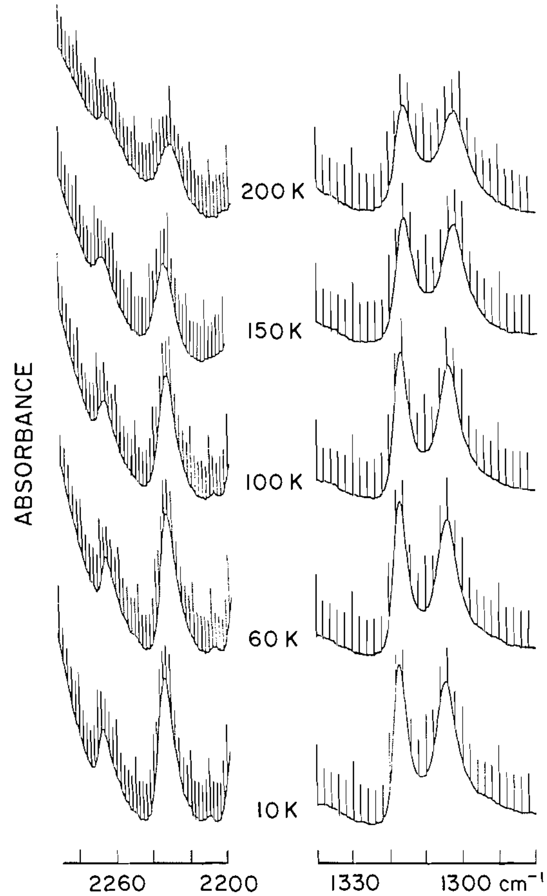

FIG. 5. Spectra of $(NH_4)_2[Cr(H_2O)_6]F_5$ (3% D) in the ν_1 (*left*) and ν_{4bc} (*right*) regions at different temperatures.

H···F separation, ~1.67 Å, which corresponds to a strong hydrogen-bonding interaction, gives rise to strong coupling of neighbouring transition dipoles.

$(NH_4)_2[Cr(H_2O)_6]F_5$ (54)

The crystal structure was originally (4) described as monoclinic ($C2/c$, no. 15; $Z = 4$) but metrically indistinguishable from orthohexagonal. It seems, however, that the true symmetry is trigonal ($P\bar{3}c1$, no. 165; $Z = 2$).[4] In the following the trigonal description has been adopted and the F and O atoms renamed accordingly (all oxygens are now equivalent; F(2) and F(3) of $C2/c$ are now F(2)).

The N atom (site symmetry C_3) is coordinated by an F(1) atom on the same threefold axis, at an N···F(1) distance of 2.732 Å, and by three nonaxial fluorines F(2) at N···F(2) = 2.722 Å. The coordination figure of N is thus an almost regular F_4 tetrahedron and resembles more closely than in any other ammonium compound the coordination of N in NH_4F. The F(1) atom in turn is coordinated by three nonaxial oxygens at 2.564 Å (Fig. 4).

For an ammonium ion of C_3 symmetry we would expect a 1:3 ν_1 doublet and a 2:3:3 ν_{4bc} triplet. Noting that in NH_4F ($E = C_{3v}$) ν_1 was a singlet and ν_{4bc} was an only partially resolved band even at 10 K, it would seem *a priori* unlikely that

[4]This has in the meantime been pointed out, independently, in a recent paper by Marsh and Herbstein (9). In $P\bar{3}c1$ the atoms would be distributed as follows: Cr in 2(b), N and F(1) in 4(d), F(2) + F(3) in 6(f), and O(1) + O(2) + O(3) in 12(g).

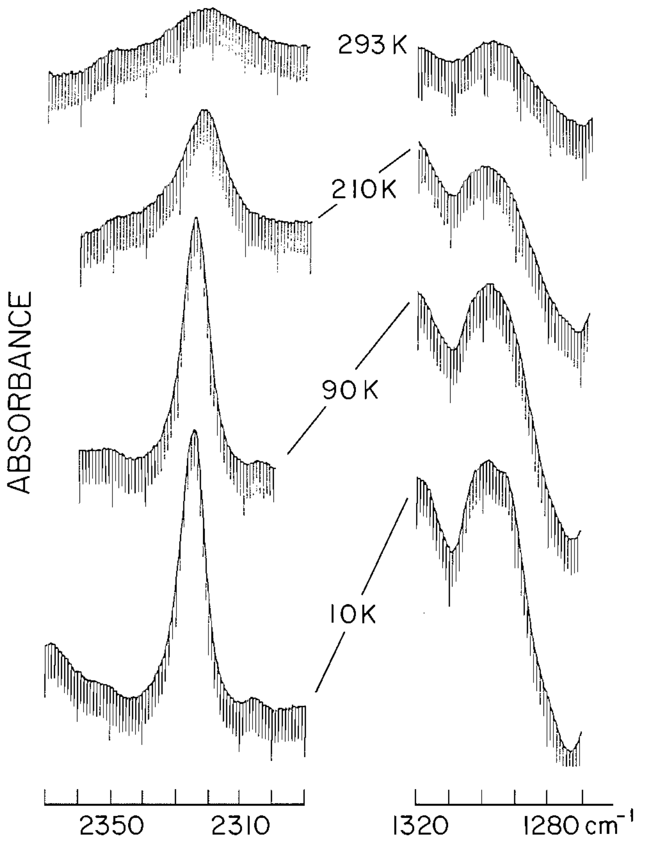

FIG. 6. Spectra of NH_4HF_2 (1.8% D) in the ν_1 (*left*) and ν_{4bc} (*right*) regions at different temperatures.

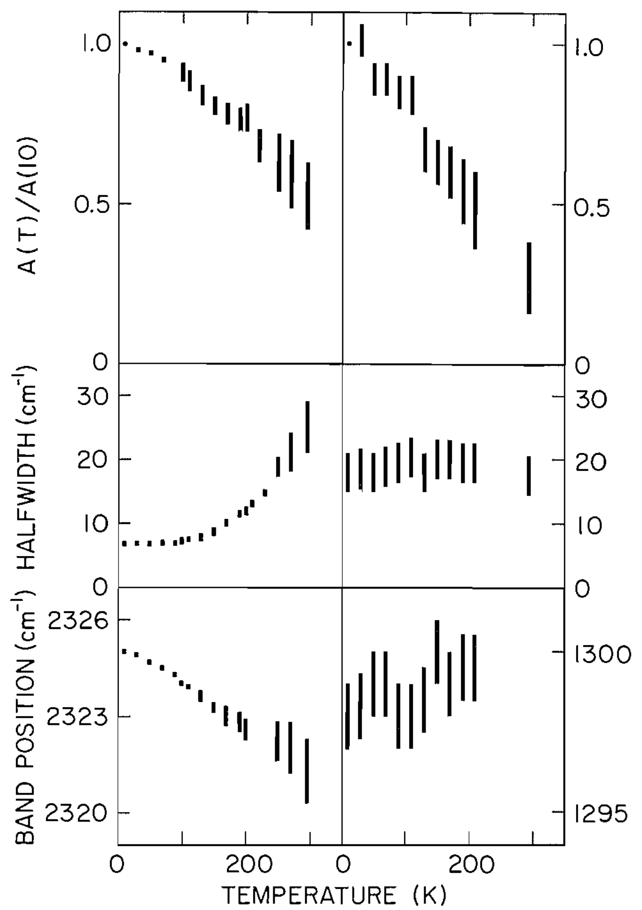

FIG. 7. Temperature variation of the ν_1 (*left*) and ν_{4bc} (*right*) peak positions, halfwidths and relative band areas $A(T)/A(10)$ in NH_4HF_2. The ν_1 band parameters have been extrapolated to 0% D; those for ν_{4bc} are for 1.8% D.

these composite absorptions would be resolved in **54**, where the N···F(1) and N···F(2) distances are practically identical and only slightly longer than the N···F distances in NH_4F.

The spectrum of the undeuterated material showed considerable complexity and was dominated by broad and very intense OH stretching bands of strongly hydrogen-bonded water of coordination. On deuteration two bands in the ND stretching region and two bands in the ND bending region appeared (Fig. 5), in positions intermediate between the corresponding respective absorptions of NH_4F and NH_4HF_2, and thus in the range expected for ν_1 and ν_{4bc}. When the lower ν_1 frequency is paired with the higher ν_{4bc} frequency, and the higher ν_1 frequency with the lower ν_{4bc} frequency, the two ν_1, ν_{4bc} points fall close to the best straight line drawn through the corresponding points for NH_4F, NH_4HF_2 and NH_4AlF_4 in the ν_1, ν_{4bc} plot of Fig. 3 of ref. 2; similarly, the two ν_1 points fall very close to the point for $\nu_1(n)$ of NH_4SnF_3 in the ν_1 vs. d(H···X) plot (Fig. 1 of ref. 2). There is thus little doubt that the observed four bands are genuine NH_3D^+ absorptions.

At 10 K the two narrow ν_1 bands, with intensities in an approximate ratio of 1:3, were at 2267(1) and 2233(1) cm^{-1}. The ν_{4bc} bands appeared at 1317 and 1304 cm^{-1}. This approximately 2:3 ν_{4bc} doublet may represent a more complex, incompletely resolved multiplet; the somewhat broader 1304 cm^{-1} feature may contain several unresolved components. The frequencies of all these bands decreased with increasing temperature by not more than 2 cm^{-1} between 10 and 200 K. The estimated halfwidths of all the ν_1 and ν_{4bc} bands at 10 K were about 9 cm^{-1}, increasing to about 14 cm^{-1} at 200 K, i.e. by an amount comparable to that observed for NH_4F.

The question arises why *two* ν_1 components, separated by 34 cm^{-1}, are observed when the N···F(1) and N···F(2) distances are practically the same. The explanation must be in the dissimilar acceptor strengths of the four nearest F neighbours of the ammonium ion. In addition to the hydrogen bond to the central nitrogen, each F(2) atom is hydrogen-bonded to another N and to two oxygens, whereas the F(1) atom is hydrogen-bonded to three oxygens (Fig. 4). This would make F(1) a weaker acceptor. The lower acceptor strength, perhaps also reflected in the marginally longer N···F(1) distance, would raise the ν_1 frequency of the axial ND bond. Explanation along these lines is consistent with the ν_1 frequency observed in NH_4F, 2183 cm^{-1} at 10 K, in which crystal the four F atoms coordinating an ammonium ion are hydrogen-bonded to three other N atoms each and thus have acceptor strength greater than any of the fluorines in **54**. From these observations it follows that for very short hydrogen-bonded N···F distances the ν_1 frequency is highly sensitive to small changes in the acceptor strength.

NH_4HF_2 (53)

This structure is a distorted version of the CsCl arrangement (*Pmna*, no. 53; Z = 4) and thus nominally it belongs to the C.N. 8 group of compounds. Although the ammonium ion in 8-coordination often is a case of 4-coordination with alternative orientations (e.g. in NH_4AlF_4), in **53** it may be considered as genuinely 4-coordinated, $E = C_2$ (Fig. 1). The N···F distances

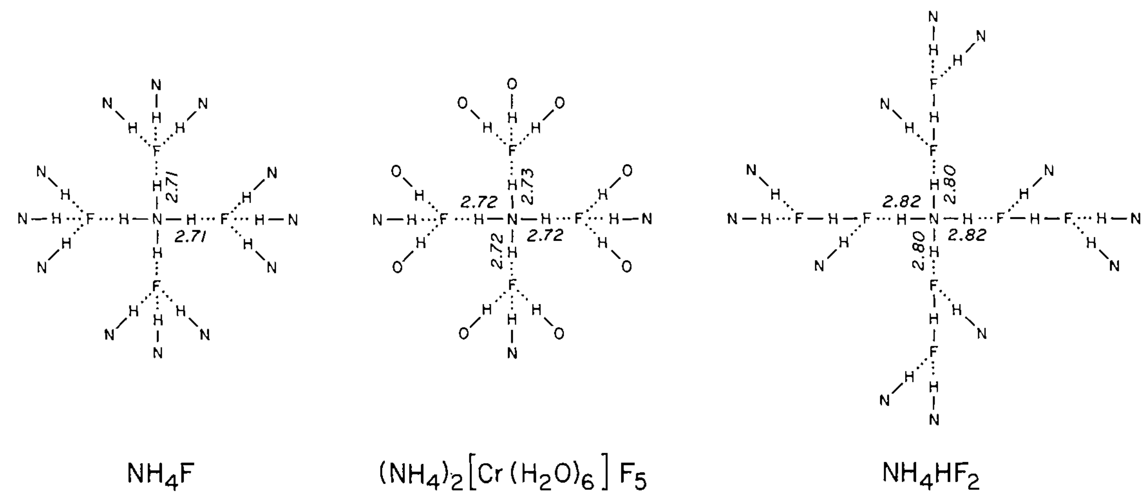

FIG. 8. Schematic representation of the environments of an ammonium ion in the 4-coordinated fluorides NH_4F, $(NH_4)_2[Cr(H_2O)_6]F_5$, and NH_4HF_2.

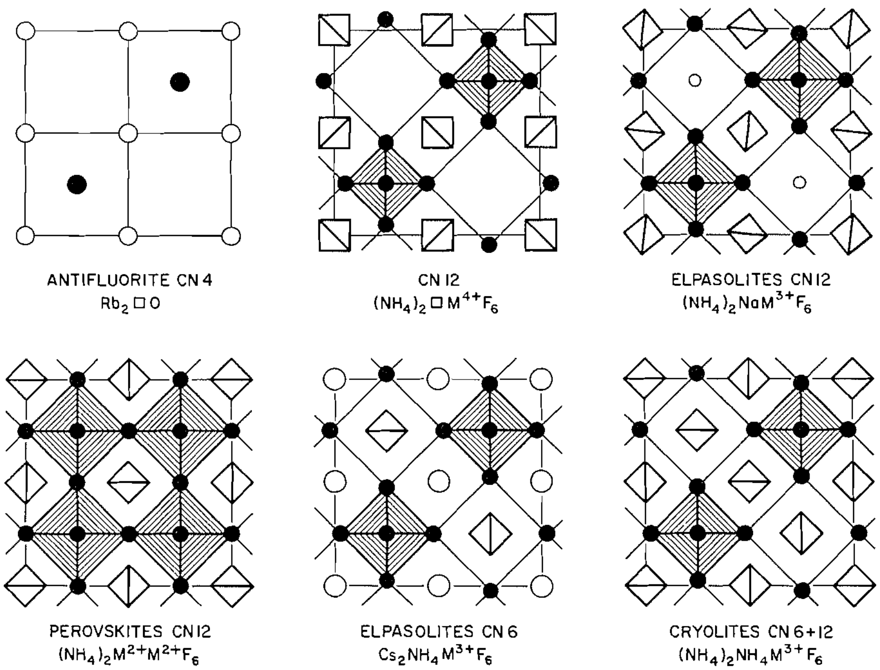

FIG. 9. Schematic representation of the relationships between the structures of complex ammonium fluorides derived from the antifluorite structure. Full circles, F; open circles, alkali ions (Na^+, Cs^+); octahedra, $[MF_6]^{2-}$ or $[MF_6]^{3-}$; tetrahedra, NH_4^+. The orientations of the ammonium ions in these room-temperature structures are well defined only in $(NH_4)_2MF_6$.

are 2.80 and 2.82 Å and the corresponding H···F distances, ~1.92 and ~1.95 Å; the N—H···F bonds are straight within the error limits of the structure determination (11). A 1 : 1 doublet would be expected for the ν_1 and a 1 : 1 : 1 : 1 quartet for the ν_{4bc} absorption.

The good quality of the spectra obtained from samples containing 0.8–3.6% D (Fig. 6) made possible extrapolation of the ν_1 band parameters to 0% D, i.e. to infinite isotopic dilution (Fig. 7). For the ν_{4bc} absorption the variation of the band parameters with the D content was insignificant.

At 10 K the ν_1 fundamental was a visually symmetric singlet at 2325 cm^{-1} which shifted gradually to 2321 cm^{-1} at room temperature (Fig. 7), i.e. in the same direction as in NH_4F and **54**. The ν_{4bc} absorption at 10 K, centred at 1298 cm^{-1}, showed evidence of at least three components; the mean position of this band remained almost stationary with temperature. The temperature variation of the ν_1 halfwidth was similar to that in NH_4F, while the width of the ν_{4bc} absorption was practically constant. The integrated intensity diminished with increasing temperature, but unlike for NH_4F the changes were more pronounced for ν_{4bc} than for ν_1.

To reconcile the probe-ion spectra with the reported crystal structure, the observed ν_1 and ν_{4bc} bands must be interpreted as an unresolved doublet and a partially resolved quartet respectively. Considering that the two nonequivalent N···F distances differ by only 0.025(4) Å (11) and that — unlike in **54** — each of the four F atoms coordinating NH_4^+ has a similar environment, it is not surprising that the presumed ν_1 doublet is unresolved.

The environments of an ammonium ion in the three fluorides

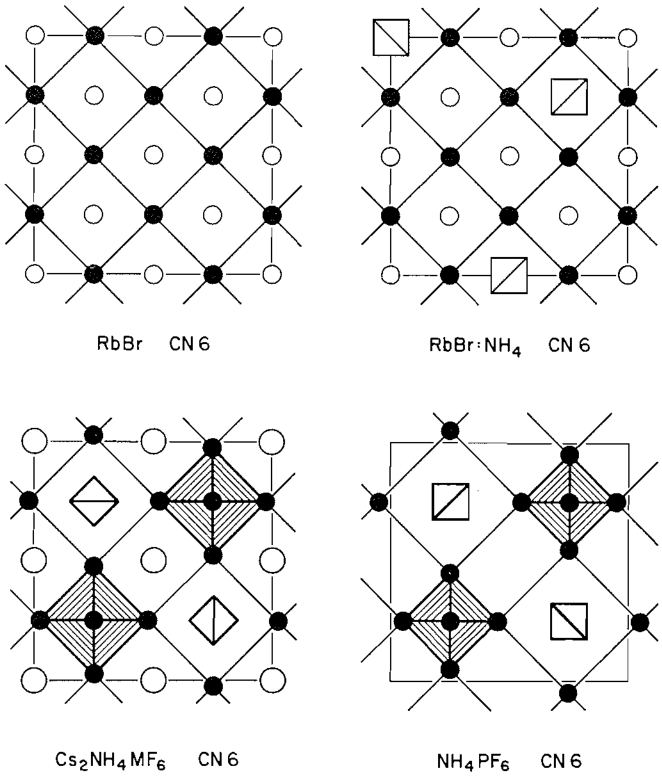

FIG. 10. Schematic representation of structures, with 6-coordinated cations, of importance for complex ammonium fluorides: NaCl type (*top left*); NaCl-type matrix containing NH_4^+ at random (*top right*). The NH_4PF_6 structure is of the NaCl type if regarded as $[NH_4^+][PF_6^-]$; for actual NH_4^+ and PF_6^- orientations see text. For symbols, see caption of Fig. 9.

with C.N. 4 (**1, 53, 54**) are compared in Fig. 8. The importance of the surrounding of the nearest-neighbour F atoms for the spectral parameters of NH_3D^+ is clearly seen.

Ammonium elpasolites and cryolites (57–61, 63, 64)

The structures of these fluorides are cubic at room temperature ($Fm3m$, no. 225; Z = 4). They are formally obtainable by filling the octahedral or the dodecahedral interstices or both in a hypothetical fcc parent structure composed of octahedral $[MF_6]$ ions:

Antifluorite type	→	Cryolites	←	NaCl type
$[(NH_4)_2]^{xii}[\square]^{vi}MF_6$		$[(NH_4)_2]^{xii}[NH_4]^{vi}MF_6$		$[\square_2]^{xii}[NH_4]^{vi}MF_6$
$(NH_4)_2SiF_6$ (**18**)		$(NH_4)_3MF_6$ (**59–61**)		NH_4PF_6 (**40**)
↓				↓
$[(NH_4)_2]^{xii}[B]^{vi}MF_6$	←	Elpasolites	→	$[A_2]^{xii}[NH_4]^{vi}MF_6$
$(NH_4)_2BFeF_6$ (**57, 63**)				$Cs_2NH_4MF_6$ (**58, 64**)

These structural relationships are represented in Figs. 9 and 10. In particular, NH_4PF_6 = $\square_2NH_4PF_6$ is to $Cs_2NH_4MF_6$ as $(NH_4)_2MF_6$ = $(NH_4)_2\square MF_6$ is to $(NH_4)_2BMF_6$, as far as interactions between adjacent cations are concerned.

The elpasolites $(NH_4)_2NaFeF_6$ (57) and $(NH_4)_2KFeF_6$ (63)

Classical description.[5] In this section it is assumed that in the $(NH_4)_2BMF_6$ structure ($Fm3m$, Z = 4) M is in 4(a) — 000 etc., B in 4(b) — $\frac{1}{2}\frac{1}{2}\frac{1}{2}$ etc., N in 8(c) — $\frac{1}{4}\frac{1}{4}\frac{1}{4}$ etc., and F in 24(e) — x00 etc. (3). The site symmetry in 8(c), T_d, is consistent with the tetrahedral symmetry of the ammonium ion. Considering that the cubic perovskites NH_4MF_3 may be represented as $(NH_4)_2BMF_6$ with B = M and x(F) = $\frac{1}{4}$, the cubic elpasolites $(NH_4)_2BMF_6$ may be regarded as ordered perovskites with B ≠ M and x(F) < $\frac{1}{4}$ (Fig. 9). The elpasolite unit cell may thus be thought of as divided into eight subcubes, each containing at its centre an ammonium ion 12-coordinated by F. This situation resembles the cubic $(NH_4)_2MF_6$ structure (Fig. 11) except that in the elpasolites *every* corner of a subcube is occupied by a metal atom, with M and B alternating. An NH_4^+ ion in its most symmetric orientation, $S \cap E = S = E = T_d$, would have the N—H vectors pointing at either the M or the B corners, unlike in $(NH_4)_2MF_6$, where these vectors point at the unoccupied corners of the subcubes. The spectroscopic expectation from this model would thus be a single ν_1 and a single ν_{4bc} absorption as long as the structure remains cubic.

[5] Objections to this classical description are briefly reviewed in Discussion.

Observed spectra. The spectra of **57** were of particularly good quality (Fig. 12). At 10 K a very regular 1:1:1:1 ν_1 quadruplet and an approximately 1:2:1:4 ν_{4bc} quadruplet were observed. On warming the sample the two absorptions persisted essentially unchanged until 157(1) K, when a sharp transition occurred (Fig. 13). The transition, which was reversible, manifested itself by the collapse of the ν_1 quartet to a broad singlet, while the ν_{4bc} multiplet collapsed to an asymmetric doublet. The ν_1 singlet, at 2372 at 160 K, shifted to higher wavenumbers with increasing temperature. The ν_{4bc} doublet was incompletely resolved (1283 and 1276 cm^{-1} at 160 K). The halfwidths of its components increased and the resolution decreased with increasing temperature until at ca. 200 K a single, practically symmetric band resulted. At the same time the

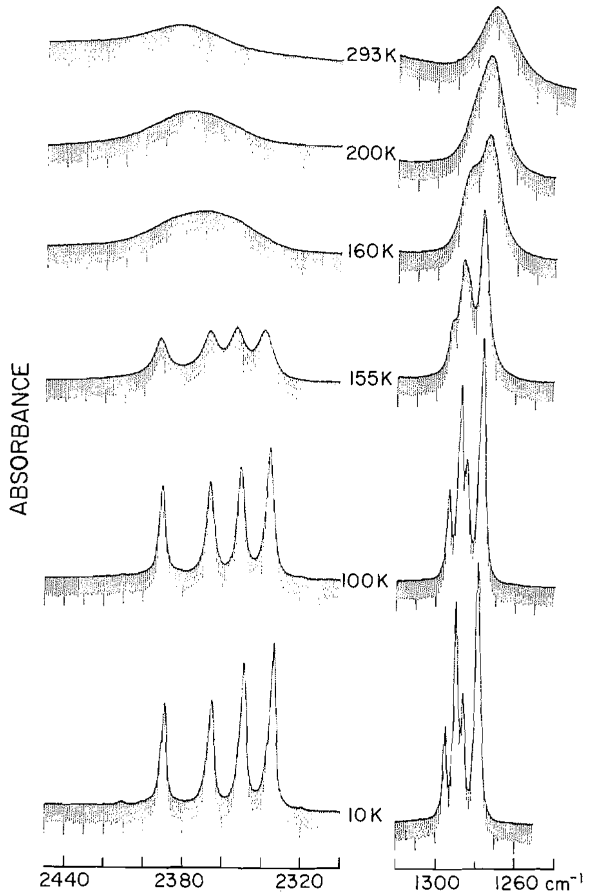

FIG. 12. Spectra of $(NH_4)_2NaFeF_6$ (4% D) in the regions of the ν_1 (*left*) and ν_{4bc} (*right*) NH_3D^+ fundamentals at different temperatures.

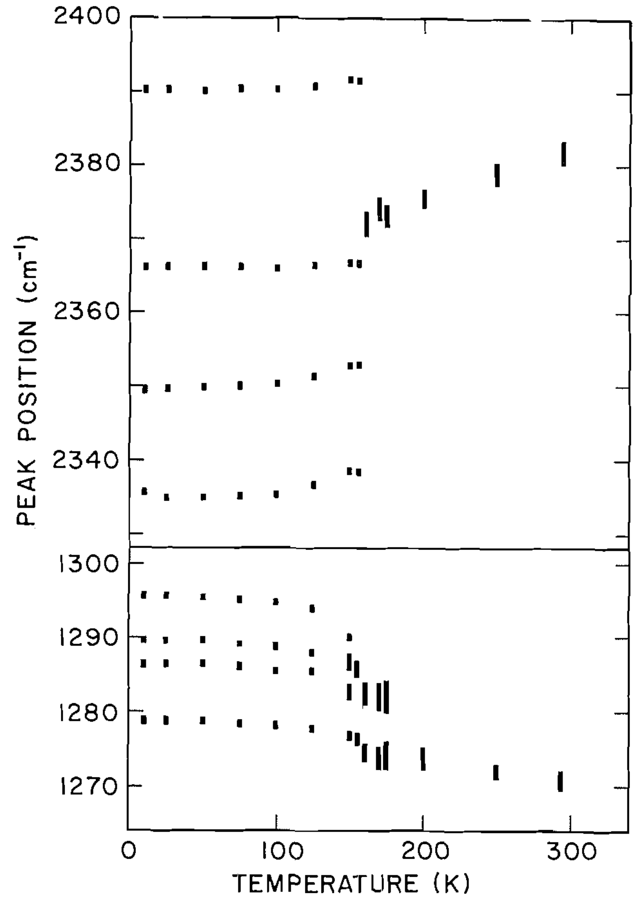

FIG. 13. Temperature variation of the peak position of the bands in Fig. 12.

bands underwent a small shift to lower wavenumbers.

The spectra of **63** resembled those of **57**, but the much higher transition temperature was difficult to estimate with any accuracy because of the considerable band breadth at sample temperatures close to room (Figs. 14 and 15). A tentative estimate of T_{tr} is 290(15) K.[6] The ν_1 component frequencies at 10 K were lower than in **57** and their spread was considerably greater, 112 cm^{-1} compared to 55 cm^{-1} in the Na compound. The ν_{4bc} absorption was again a quadruplet, but different in appearance from that in **57**. Its component intensities were estimated as 3:3:1:1. The overall frequency lowering in **63** relative to **57** is a consequence of the lattice expansion resulting from the substitution of Na (a = 8.484 Å) by K (a = 8.925 Å).

The four ν_1 components observed in the spectra of **57** (and less sharply in **63**) below T_{tr} are indicative of $E = C_1$, assuming only one type of NH_4^+ is present in the crystal. If fully resolved, the ν_{4bc} absorption for $E = C_1$ would be an octet. The observed 1:2:1:4 quadruplet is not inconsistent with this expectation. The effective symmetry $E = C_1$ corresponds to $S = C_s$ or C_1. The relative narrowness and practically no shift with temperature of the ν_1 components would indicate that the ammonium ion engages in four essentially normal hydrogen bonds, of different strength. The suddenness of the collapse of the quartet to a singlet at T_{tr} is reminiscent of the NH_4MF_3 (M = Mn, Co, Zn) perovskites (15) and points to a first-order transition.[7]

The shift of the ν_1 *singlet* to high wavenumbers with increasing temperature is characteristic of a normal rather than trifurcated hydrogen bond (15, 20). At the same time, the appearance of a ν_{4bc} *doublet* above T_{tr} instead of the singlet expected for $S = E = T_d$ of the room-temperature structure, and the gradual coalescence of this doublet to a singlet with increasing temperature are completely analogous to what is observed for the probe-ion spectra of NH_4ZnF_3 (cf. Fig. 4 of ref. 15), even to the point of similarity of the ν_1 and the ν_{4bc} frequencies at temperatures immediately above the respective T_{tr}. Referring to the argument presented for the cubic NH_4MF_3 perovskites in ref. 15, one must conclude that in **57** and **63**, too, the ammonium ions adopt, at $T > T_{tr}$, orientations of a symmetry lower than $S \cap E = T_d$, the maximum symmetry permitted by the classical structure. Similar to NH_4MF_3, the instantaneous symmetry of the ammonium ion is effectively tetragonal, with dynamic disorder over the six possible orientations relative to the directions of the crystallographic axes. The N—H···F bonds thus are not symmetrically trifurcated, with the N—H vectors pointing at Fe or Na (or K), but *normal* though bent (Fig. 11). However, unlike in NH_4MF_3, where all the corners of a subcube are occupied by the same kind of metal atom and the instantaneous symmetry is D_{2d}, in the $(NH_4)_2BMF_6$ elpasolites this symmetry can be at most S_4. This

[6] The samples prepared and studied by Massa (3) and by Epple (5) were cubic at room temperature.

[7] This agrees with the sudden disappearance of the quadrupole splitting in the Mössbauer ^{57}Fe spectrum at T_{tr} (31).

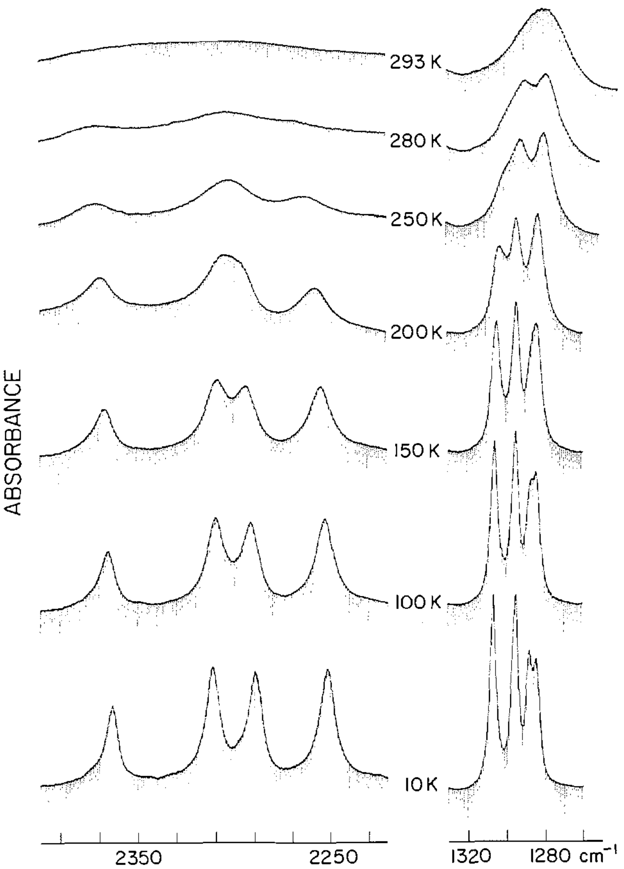

FIG. 14. Spectra of $(NH_4)_2KFeF_6$ (4% D) in the ν_1 (*left*) and ν_{4bc} (*right*) regions at different temperatures.

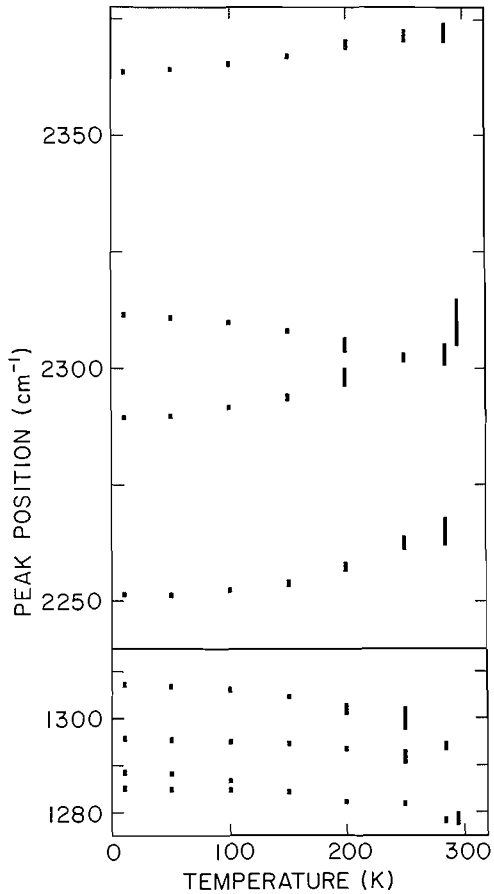

FIG. 15. Temperature variation of the peak positions of the bands in Fig. 14.

symmetry lowering would not affect the probe-ion spectrum, as a ν_1 singlet and a 1 : 1 ν_{4bc} doublet would be expected both for D_{2d} and S_4 (Table 1, ref. 15).

The difference in the corner occupancy of an elpasolite subcube and of an NH_4MF_3 unit cell is also likely the reason for the difference in the probe-ion symmetries in the respective low-temperature phases. In **57** and **63** the ν_1 absorptions are well-resolved 1 : 1 : 1 : 1 quartets, whereas in NH_4MF_3 they are 1 : 1 : 2 triplets, i.e. $E = C_1$ as against $E = C_s$. In terms of the model of ref. 15 for the perovskites, the plane of reflection of NH_4^+ in the low phase is destroyed, in the elpasolites, by the alternation of B and M at the subcube corners.

At 150 K the mean of the four ν_1 component frequencies in **57** is ~2362 cm^{-1} compared to ~2372 cm^{-1} of the singlet at 160 K, i.e. just above T_{tr} (Fig. 13). This indicates an overall strengthening of hydrogen bonding when the temperature is lowered through T_{tr}. In this respect **57** again closely resembles the NH_4MF_3 perovskites: one of the N—H···F bonds weakens on passage from the high to the low phase while the other three are strengthened, one of them appreciably (by some 35 cm^{-1}). The total high-low spread of the ν_1 component frequencies in **57** is ~55 cm^{-1} at 10 K, which compares with the corresponding spread in NH_4MnF_3, ~51 cm^{-1}; in NH_4CoF_3 and NH_4ZnF_3 the spread is only about one-half of this (15). In contrast, the spread in **63** is very large, about twice that in **57** (Fig. 15), pointing to the existence of a privileged, unusually strong N—H···F bond in the low phase. The degree of hydrogen-bond strengthening in **63** on cooling through T_{tr} could not be estimated because of the proximity of T_{tr} to room temperature (Figs. 14 and 15).

*The elpasolites $Cs_2NH_4FeF_6$ (**58**) and $Cs_2NH_4AlF_6$ (**64**)*

These elpasolites are of particular interest in that they might be expected to provide clues leading to an understanding of the vibrational behaviour of NH_4^+ in fcc alkali halide matrices, a problem which so far has eluded explanation. The ammonium ion is 6-coordinated ($S = O_h$), similar to that in KX and RbX (X = Cl, Br, I) matrices (ref. 2 and results to be published). Single ν_1 and ν_{4bc} absorptions would thus be expected, with frequencies between those in NH_4F and NH_4Cl. In **58**, for which we have low-temperature powder diffraction data, this expectation would hold down to the temperature of the reversible transition at 194(3) K.[8]

Five deuterated and three undeuterated samples of **58**, each the product of a separate high-pressure synthesis, were examined. Apart from the ND features, the intensity of which depended on the degree of deuteration, the room-temperature spectra of all eight samples were identical; those of the undeuterated samples agreed with the room-temperature spectra reported by Epple (5, 6). Some differences between samples were observed in the low-temperature spectra. The spectra shown in Fig. 16 are those of the deuterated product judged to be the purest (see Experimental).

At 10 K the ν_1 absorption consisted of a broad band centred at 2251 cm^{-1}, with a halfwidth of ~35 cm^{-1}, and a shoulder at ~2225 cm^{-1} (Fig. 16). The presence of this shoulder was

[8] At 203 K, a(cubic) = 9.196 Å; at 173 K the structure appeared to be pseudotetragonal, a = 9.118 Å, c = 9.253 Å, which would correspond to a volume reduction of about 1% on cooling through T_{tr}.

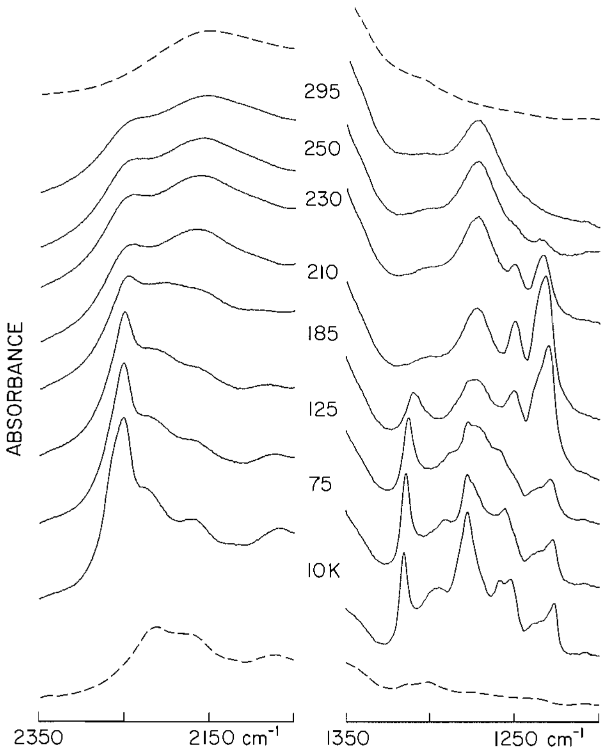

FIG. 16. FT spectra of $Cs_2NH_4FeF_6$ (4% D) in the ν_1 (*left*) and ν_{4bc} (*right*) regions at different temperatures. The spectra in broken lines are the 0% D backgrounds at 10 and 295 K, respectively.

detected only after a careful comparison with the appreciable irregular background absorption of the 0% D samples in this region. The 2251 cm^{-1} band may be considered to be an unresolved envelope of two or more features. Indeed, in the 10 K spectra of some of the samples this band was partially resolved into several components (at 2268, 2260, 2251, and 2229 cm^{-1} in the best resolved spectrum), with estimated halfwidths of ~15 cm^{-1}. This is larger than the $\nu_1(10)$ halfwidth of any of the other compounds examined in the present study and somewhat larger than for the KX and RbX matrices. Where the splitting did occur, it rapidly diminished on warming the sample and above ~70 K only a singlet was seen. With increasing temperature the 2251 cm^{-1} peak shifted to lower wavenumbers and broadened, until at room temperature only a very broad band of low peak height was visible.

The $\nu_{4bc}(10)$ absorption (Fig. 16) consisted of an unusually complex pattern of bands, with main features at 1315 and 1278 cm^{-1} and smaller bands at 1295, 1259, and 1253 cm^{-1}. An additional band at 1227 cm^{-1} was sometimes observed, as in Fig. 15. The total range of this composite absorption was at least 62 cm^{-1} (centre of gravity, ~1278 cm^{-1}). Increasing temperature caused gradual broadening and coalescence of these bands, with the outside bands moving toward the centre, as well as a sudden disappearance of the 1315 cm^{-1} peak at 195(10) K. Within the uncertainty estimate this temperature coincides with the above transition temperature established from X-ray evidence. The unusual increase of intensity of the 1227 cm^{-1} and 1253 cm^{-1} bands between 185 and 230 K (i.e. spanning the transition temperature, cf. Fig. 16) was not observed in the other samples. At room temperature only a broad singlet remained in the spectra of all the samples, consistent with the expectation from the room-temperature crystal structure.

Compared to **58**, the ND spectra of **64** were of inferior quality, owing perhaps more to poor crystallinity of the sample than to a difference between **58** and **64** *per se*. The asymmetry of the broad $\nu_1(10)$ singlet (at 2265(2) cm^{-1} and with a total halfwidth of ca. 46 cm^{-1}) decreased with increasing temperature and the peak position at 250 K was 2259(3) cm^{-1}. The $\nu_{4bc}(10)$ absorption was approximately a doublet but with clear indications of further unresolved structure. In general the ν_{4bc} absorption of **64** was reminiscent of that of **58**, with differences in the intensity distribution within the complex bands, especially at higher temperatures.

The low quality of the spectra precludes any conclusions about the possibility of existence of a structural transition in **64** between 10 and 295 K.

*The cryolites $(NH_4)_3MF_6$, M = Al (**59**), Cr (**60**), Fe (**61**)*[9]

The probe-ion spectra of the cubic phases would be expected to contain ν_1 and ν_{4bc} absorptions corresponding to those of the ammonium ion in $(NH_4)_2BMF_6$ as well as those of $Cs_2NH_4MF_6$, plus any features that might arise from the interaction of adjacent $(NH_3D^+)^{xii}$ and $(NH_3D^+)^{vi}$ ions (Fig. 8). Superposition without interaction of the $(NH_3D^+)^{xii}$ and $(NH_3D^+)^{vi}$ spectra above T_{tr} would be expected to yield two single absorptions in the ND stretching region, at ca. 2350 and 2250 cm^{-1}, respectively, and in an intensity ratio of 2:1, and a 1:1 doublet and a singlet in the ND bending region between 1280 and 1320 cm^{-1}. Unfortunately, the symmetry-lowering transitions which all three cryolites studied undergo occur above 200 K (Table 1),[10] at which temperature the appreciable broadening of the absorptions and decrease in the intensity considerably reduce the usefulness of our method for the study of the high phases, for which the structural information available is the amplest.

The X-ray powder patterns of the Cr and Fe compounds below T_{tr} could be indexed (5, 13; cf. also ref. 26) on unit cells deriving from the $Fm3m$ cell by triclinic distortions; the distortions as well as ΔV_{tr} are more appreciable for the Cr compound. A $P\bar{1}$ unit cell with $Z = 4$ would imply the existence of four nonequivalent centrosymmetric pairs of $(NH_4^+)^{xii}$ ions of $S = C_1$, and four nonequivalent types of single $(NH_4^+)^{vi}$ ions at sites of symmetry C_i. The $(NH_4^+)^{xii}$ ions would then be expected to give rise, in principle, to four ν_1 quartets and four ν_{4bc} octets. Since ammonium ions are noncentrosymmetric, the presence of the $(NH_4^+)^{vi}$ ions at sites of symmetry C_i implies twofold orientational disorder at all temperatures $T < T_{tr}$, unless a second transition is found below the lowest temperature so far investigated (i.e. below 15 K for the Fe compound, cf. ref. 22).[11] The $(NH_4^+)^{vi}$ ions, too, would then be of symmetry C_1, and four ν_1 quartets and four ν_{4bc} octets would be expected,

[9] By an oversight $(NH_4)_3FeF_6$, which was listed as **45** in ref. 2, has been renumbered here as **61**. The number **45** has been reassigned to $(NH_4)_2ReCl_6$ (cf. ref. 32).

[10] The T_{tr} obtained from C_p measurements (24, 25) and listed in Table 1 do not always agree with the estimates from X-ray powder diffraction, dta, esr, ir, and other measurements (5, 26, 27, 33, 34). A pronounced tendency to undercooling has been reported for the intermediate phase of **59** (24), and similar hysteresis phenomena known to exist in other complex fluorides (e.g. in hexafluorophosphates, cf. footnote 13) are responsible for discrepancies between different literature accounts of the same compound.

[11] Unlike **60** and **61**, the Al compound **59** has *two* low-temperature transitions (24). No information appears to be available on the crystallographic symmetry of either low-temperature phase, so we do not know whether the above arguments for **60** and **61** apply to **59**.

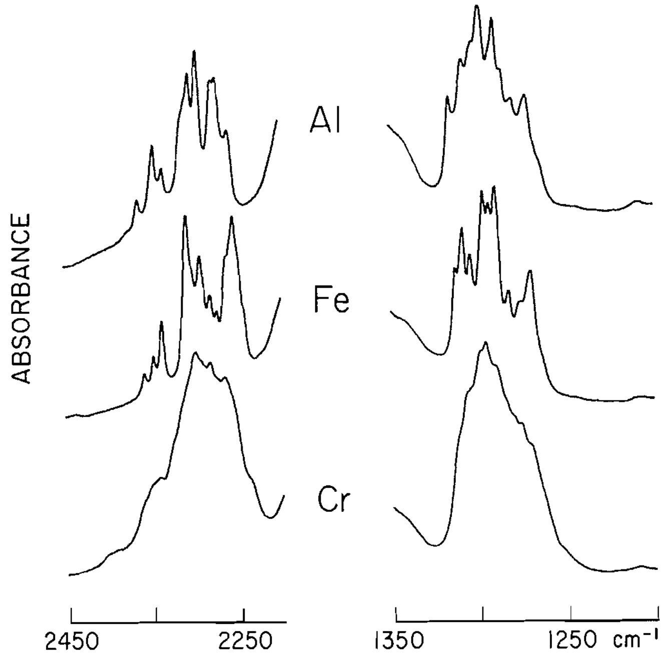

FIG. 17. Spectra of $(NH_4)_3MF_6$ (2% D) (M = Al, Cr, Fe) in the ν_1 (*left*) and ν_{4bc} (*right*) regions at 10 K. Difference FT spectra of Nujol mulls obtained by subtracting the 0% D spectra.

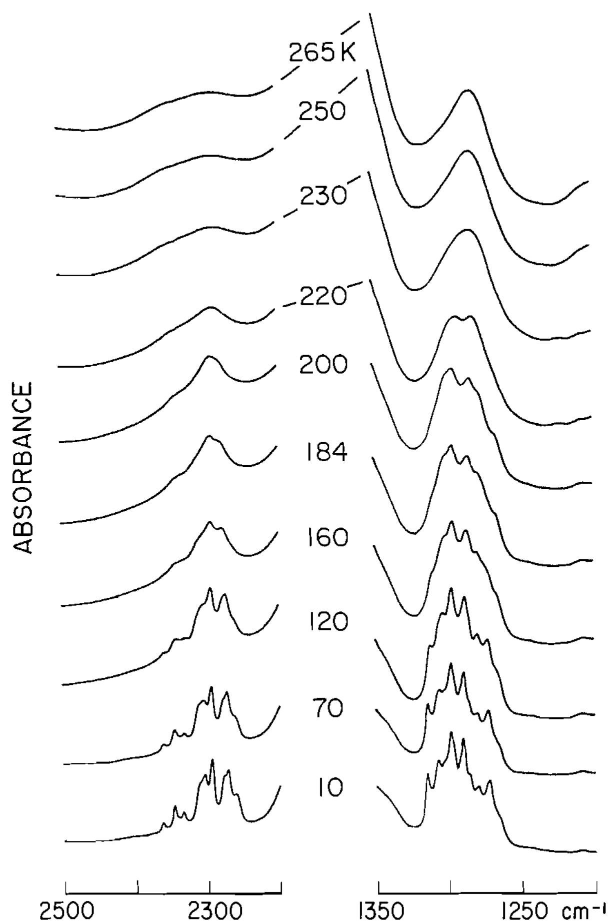

FIG. 18. Spectra of $(NH_4)_3AlF_6$ (2% D) in the ν_1 (*left*) and ν_{4bc} (*right*) regions at different temperatures.

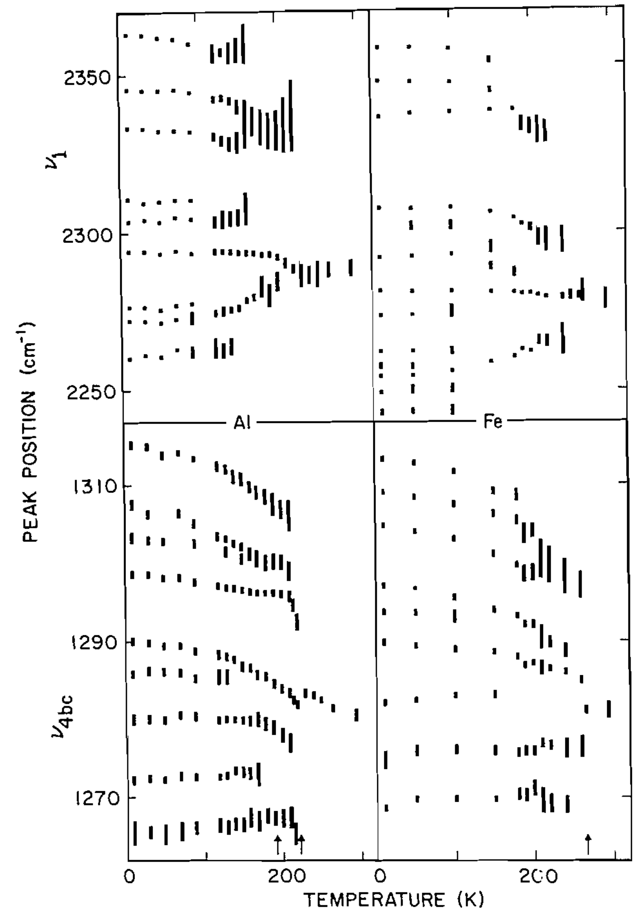

FIG. 19. Temperature variation of the peak positions of the bands in Figs. 18 and 20.

with each component in principle doubled or at least broadened in consequence of the orientational disorder.

The probe-ion spectra in the ND stretching and ND bending regions at 10 K are of the same type in all three compounds (Fig. 17). For **59** nine well-resolved ν_1 components were observed, their frequencies spanning 103 cm^{-1}, from 2260 to 2363 cm^{-1}. Shoulders and unusual breadth of the resolved features indicate the existence of an undetermined number of additional components. The highest-frequency, weak bands at 2334, 2346, and 2363 cm^{-1} (group *I*) may be assigned to the ND stretching modes of $(NH_3D^+)^{xii}$ ions, in analogy with **57** and **63**. In group *II*, of higher intensity, with bands between 2260 and 2310 cm^{-1} (centre of gravity, 2291 cm^{-1}), some of the lower-frequency bands appear to correspond to the ND stretching modes of $(NH_3D^+)^{vi}$ ions (cf. **58** and **64**), while the bands at the higher frequencies are probably a mixed set of $\nu_1(NH_3D^+)^{xii}$ and $\nu_1(NH_3D^+)^{vi}$ component bands. Detailed assignments are not possible at present.

With increasing temperature *all* the ν_1 components of **59** broadened and gradually collapsed (Figs. 18 and 19), but the collapse occurred for groups *I* and *II* separately. By 160 K region *I* showed only one broad band at 2335 cm^{-1}. By 210 K the bands of region *II* had also collapsed to a single band, at 2291 cm^{-1}. At ~225 K a large increase of width occurred, coincident with the upper transition (Fig. 18). Very little additional change was observed between 230 K and room temperature.

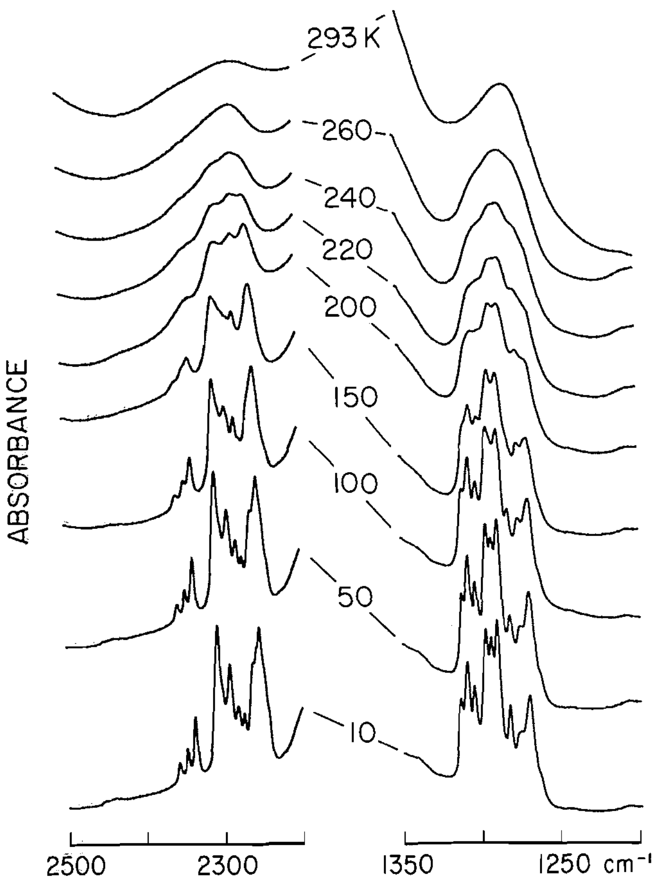

FIG. 20. Spectra of $(NH_4)_3FeF_6$ (2% D) in the ν_1 (*left*) and ν_{4bc} (*right*) regions at different temperatures.

In the ND bending region of **59** seven well-resolved components were seen, from 1266 to 1315 cm^{-1} (total range of 49 cm^{-1}), with a centre of gravity at ~1294 cm^{-1}. Comparison with the ND bending regions of **63** and **58** (Figs. 14 and 16) shows that the $(NH_3D^+)^{xii}$ and $(NH_3D^+)^{vi}$ components in the spectra of **59** almost certainly intermesh, making attempts at detailed assignment fruitless.[12] Increasing temperature caused a gradual broadening and eventual collapse of the bands until at 220 K only a broad doublet remained, at 1281 and 1292 cm^{-1}. At ~225 K a sharp change in bandwidth and band shape occurred, yielding a broad singlet at 1282 cm^{-1} (Fig. 18). Above 230 K this singlet shifted gradually to lower frequencies, ending up at 1279 cm^{-1} at room temperature.

Thus while above the upper T_{tr} the two very broad ν_1 bands are consistent in number, though not in idealized relative intensity, with the existence of $(NH_4^+)^{xii}$ and $(NH_4^+)^{vi}$ ions at sites of cubic symmetry, no structural conclusion can be made from the presence of the broad singlet in the ν_{4bc} region. Below the upper T_{tr} the ν_1 and ν_{4bc} spectra are so complex that no detailed conclusion is possible about the symmetries of the two ions, although one may reasonably assume that the respective C.N.'s are conserved, albeit in distorted environments. No evidence of the lower transition was observed in the probe-ion spectra.

The survey spectrum of **61** in the 4000–800 cm^{-1} region resembled that of **59** closely, both at room temperature and at 10 K (Fig. 20). In the $\nu_1(10)$ spectrum nine peaks were clearly resolved and the distribution of intensity approximated that for **59**. The effect of temperature also was analogous. With increasing temperature the multiplet gradually broadened and collapsed to what by 250 K was one broad asymmetric band. The large additional broadening coming into evidence between 260 and 265 K appears to be the consequence of the phase transition.

The ND bending region of **61** at 10 K, too, was very similar to that of **59** and showed a similar temperature dependence. The band resulting from the thermal collapse of the nine peaks that were clearly resolved in the 10 K spectrum (Fig. 20) still showed some structure (three residual components) at 260 K, but at 265 K only a broad singlet was observed. The same arguments are therefore applicable to the interpretation of the probe-ion spectra of **61** as advanced above for **59**.

Although the room-temperature survey spectrum of **60** resembled closely those of **59** and **61**, at 10 K the components of the probe-ion spectrum were much broader and less-well resolved. The overall pattern was clearly the same as for **59** and **61** (Fig. 17), as was also the temperature variation. However, the bands were too broad to see much change on passage through T_{tr}. It is not clear whether the less complete resolution of the probe-ion spectra is due to poor crystallinity of the material or to an intrinsic cause, e.g. fewer near-coincidences of the component frequencies, as a result of the more pronounced distortion of the structure of **60** on cooling through T_{tr}.

Considering that a typical halfwidth of $\nu_1(10)$ in ammonium halides is 5 cm^{-1}, the detail of the 10 K ND stretching absorption of **61** (Fig. 17) is reasonably well resolved, but it would be difficult to argue convincingly that the absorption contains the 12 components expected from the triclinic symmetry of the low phase. The *overall* impression, however, apart from the large variation in the intensity of the individual peaks, is that of a ν_1 spectrum arising from two nonequivalent $(NH_4^+)^{xii}$ and one $(NH_4^+)^{vi}$ ions, and this impression may well substantially correspond with the nature of the distortion of the structure below T_{tr}.

NH_4PF_6 (40)

Calorimetric and nmr (^1H, ^2H, ^{19}F) evidence indicates the existence of two transitions below room temperature (Table 1) and suggests that the upper, λ-type transition is associated with changes in the reorientational motion of the anions (30, 35, 36). The lower, "gradual" transition, at ~132 K, ought then to correspond to the onset of a cooperative process involving the ammonium ion.

The crystallography of **40** at room temperature is uncertain and nothing appears to be known about the structures of the low-temperature phases. For lack of better information we shall assume that the room-temperature phase of **40** is isostructural with the room-temperature phase *I* of KPF_6; however, even for $KPF_6(I)$ the structure cannot be regarded as completely established (cf. refs. 37 and 38). On this assumption the P and N atoms in $NH_4PF_6(I)$ are on an NaCl-type lattice ($Fm3m$, Z = 4, P in 4(a) — 000 etc., N in 4(b) — $\frac{1}{2}\frac{1}{2}\frac{1}{2}$ etc.), but for steric

[12] An unsuccessful attempt was made to identify the components by comparing the spectrum of **61** with that of $(NH_4)_{2.3}K_{0.7}FeF_6$. The latter compound was prepared especially for this purpose, in the hope that the smaller K^+ would populate exclusively the C.N. 6 sites, corresponding to $(NH_4)_2[(NH_4)_{0.3}K_{0.7}]FeF_6$ and leading to a decrease in the relative intensity of the $\nu_{4bc}(NH_4^+)^{vi}$ components. However, there was no discernible difference between the two spectra, perhaps owing to a statistical distribution of the potassium between the two types of sites.

reasons (37–39) the PF_6 octahedra cannot have the orientations shown in Fig. 10, which are the most symmetric orientations possible (F in $24(e)$ — $x00$ etc.). For the N···F distance to be reasonable, the octahedra must be rotated away from the axial directions of the unit cell. This results in a C.N. > 6 for the ammonium ion and in fractional occupancy by F of an equipoint higher than 24-fold if the diffraction symmetry is to remain $Fm3m$, i.e. that claimed for $KPF_6(I)$ (37). In the latter crystal this equipoint is taken to be $192(l)$ — xyz etc., which corresponds to 48 equivalent positions surrounding the cation in six sets of eight, one position in each set being occupied by F at any one time. The site symmetry of NH_4^+ in such a disordered structure would be *statistically* equal to O_h, with broadened ν_1 and ν_{4bc} singlets expected in the probe-ion spectrum above the upper $T_{tr} \sim 192$ K.

A preliminary account of the probe-ion spectra of **40** was given in refs. 2 and 12. Specifically, a single ν_1 and a single ν_{4bc} absorption were observed over the temperature range studied, ~90–295 K; the halfwidths at the lowest temperature were 6 and 7 cm^{-1}, respectively. The spectra did not reflect the existence of the two transitions. It is now clear from the present results for 10–293 K (Fig. 21) that in the previous experiments the lower transition had not in fact occurred.[13] Otherwise the earlier findings are confirmed.

At 10 K the ν_1 fundamental appeared to be a 1:1 doublet with components at 2441.5(3) and 2435.5(3) cm^{-1}, of about 4 cm^{-1} halfwidth. This halfwidth is quite small, comparable to that in NH_4BPh_4 (40). The ν_{4bc} fundamental at 10 K consisted of four components of about 5 cm^{-1} halfwidth, the two middle components being separated by ~1.5 cm^{-1} and hence only resolved in some of the runs (Fig. 22). With increasing temperature both the ν_1 doublet and the ν_{4bc} quartet collapsed to singlets, the collapse being complete at 120(10) K. Further increase of temperature produced a shift of ν_1 to lower and of ν_{4bc} to higher wavenumbers. There was no clear evidence of the existence of the upper transition in our spectra.

The $\nu_4 + \nu_6$ combination band of NH_4^+, which at 10 K was a narrow, clearly visible singlet at 1680 cm^{-1}, rapidly diminished with increasing temperature and by 100 K was no longer observed.

The probe-ion spectra are interpreted as follows. The collapse at 120(10) K corresponds to the lower transition. The ν_1 doublet and the ν_{4bc} quartet observed below this temperature are indicative of $E = C_2$ (consistent with the site symmetries $S = C_2$, C_{2h}, C_4) or C_{2v} ($S = C_{2v}$, D_{2h}, C_{4v}) (Table 1, ref. 15). Alternatively, though in our view less likely, there could be two crystallographically nonequivalent ammonium ions at sites of nonpolar tetragonal symmetry or D_{2h} (different orientation from that for $E = C_{2v}$) or D_2. Above ~130 K the site symmetry of the ammonium ion must be effectively cubic and $E_{eff} = T_d$ or T. The shift of ν_1 toward lower and of ν_{4bc} toward higher frequencies with increasing temperature is characteristic of weak, highly bent (bifurcated or trifurcated) N—H···F bonds (20). The ν_1 frequencies are high, between ~2432 and ~2442 cm^{-1} in the temperature range studied; values as high as these are typical of high coordination numbers and trifurcated N—H···F bonds, e.g. in $(NH_4)_2SiF_6$ or NH_4BF_4 (2), and are consistent with the observed low barrier to reorientation of the NH_4^+ ion (see Discussion).

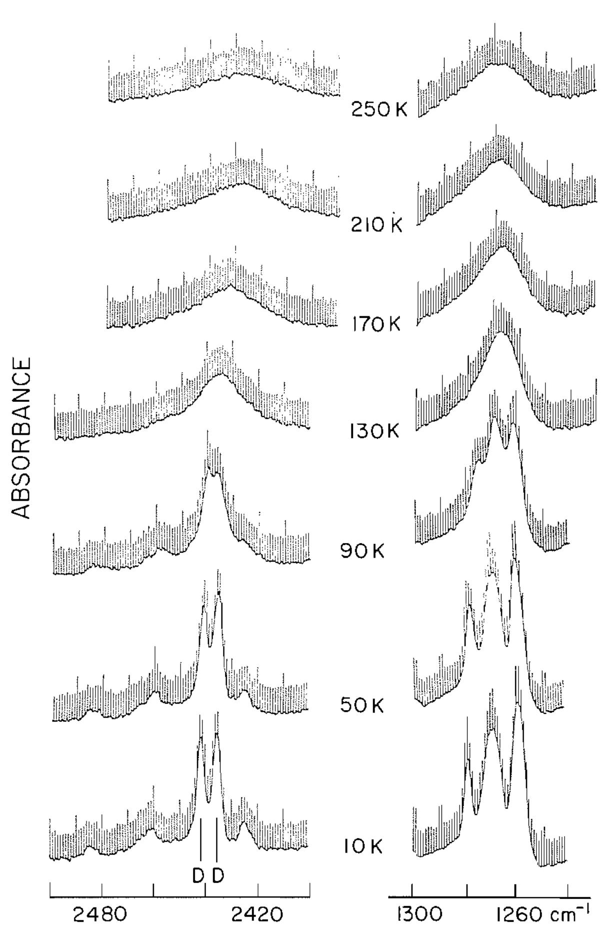

FIG. 21. Spectra of NH_4PF_6 (1% D) in the ν_1 (*left*) and ν_{4bc} (*right*) regions at different temperatures. Only the features marked D are due to the isotopically diluted NH_3D^+ ions.

$(NH_4)_3SiF_7$ (62)

The structure determination of **62** dates back to 1942 (29) and its accuracy is uncertain, but its general correctness is supported by the recent work (41) on a variety of compounds of this type ($A_2A'MF_7$: A, A' = K, Rb, Cs; M = Si, Ti, Cr, Mn, Ni). The tetragonal ($P4/mbm$, no. 127; $Z = 2$) structure is built up from SiF_6^{2-} and F^- anions and two types of NH_4^+ ions, $NH_4(1)$ in 14-coordination ($2(a)$, $S = C_{4h}$) and $NH_4(2)$ in 10-coordination ($4(h)$, $S = C_{2v}$); $NH_4(2)$ is twice as abundant as $NH_4(1)$. The approximate N···F distances for $NH_4(1)$ are 2.92 Å to F^- (2×), 3.06 Å (4×), and 3.50 Å (8×). For $NH_4(2)$ they are 2.79 Å (2×), 2.90 Å to F^- (2×), 2.98 Å (2×), and 3.09 Å (4×) (Fig. 23). A fully resolved ν_1 absorption would be expected to consist of a singlet and a doublet, and the ν_{4bc} absorption, of a doublet and a quartet, with all the component intensities ideally equal: $E = S_4$ for $NH_4(1)$ and C_{2v} for $NH_4(2)$.

At 10 K ten distinct narrow peaks were resolved in the ν_1 and no fewer than 14 in the ν_{4bc} absorption region (Fig. 24). This spectrum appears to correspond, with some unavoidable coincidences, to the 12 ν_1 and the 24 ν_{4bc} components expected for three nonequivalent, equally abundant ammonium ions of C_1 symmetry. The multiplets broadened and collapsed gradually

[13] The reason for this is difficult to establish. While the temperature control at the sample in the earlier experiments was inferior to that obtainable with the cryogenic system used at present, it is hardly likely that the actual sample temperature would have been off by more than 40 deg. Staveley *et al.* (30) experienced difficulties in obtaining reproducible C_p values with NH_4PF_6 and $RbPF_6$ as well as with $(NH_4)_2SnCl_6$ and $(NH_4)_2SnBr_6$, and suppression of low-temperature transitions in some samples of ammonium hexahalometallates(IV) was encountered in our own work (32).

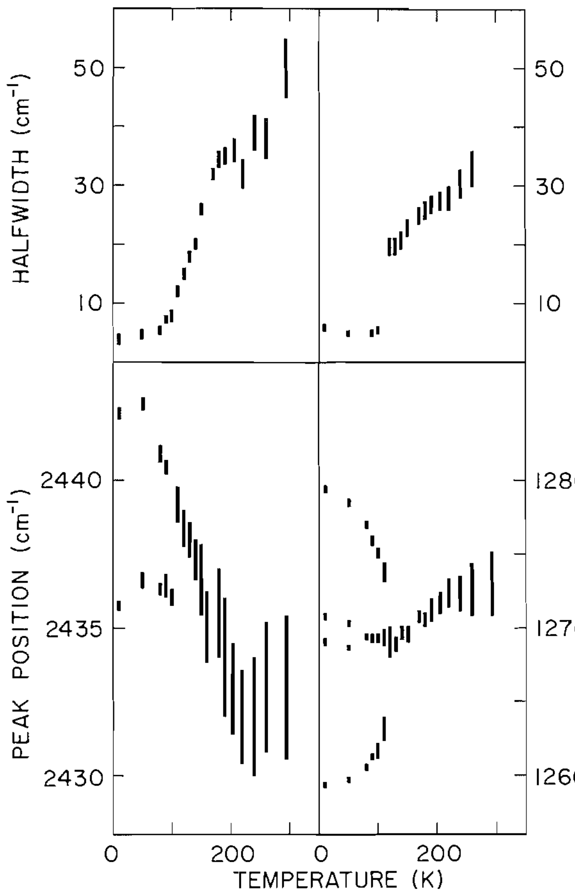

FIG. 22. Temperature variation of the peak positions of the bands in Fig. 21. The halfwidths for the lowest-temperature phase refer to the resolved single components.

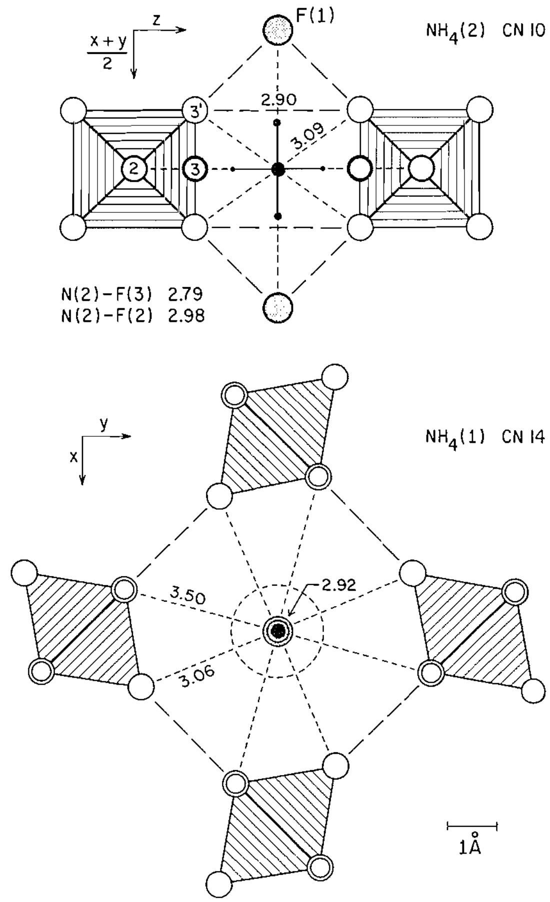

FIG. 23. Coordinations of the $NH_4(1)$ (C.N. 14, $S = C_{4h}$; *bottom*) and $NH_4(2)$ (C.N. 10, $S = C_{2v}$; *top*) ions in $(NH_4)_3SiF_7$, after ref. 29. Full circles, N; open circles, F of SiF_6^{2-}; stippled circles, F^-. In the bottom drawing the two F^- ions (on C_4) overlap in projection with N(1). The positions of the H atoms have not been determined, but if the orientation of $NH_4(2)$ matches the C_{2v} site symmetry of N(2) (as indicated in the drawing), then the hydrogen bonds are trifurcated, N—H···[F(2), 2F(3′)] for the lower and N—H···[F(1), 2F(3)] for the upper level H atoms. Assuming that the hydrogens of $NH_4(1)$ (on the dotted circle) do not point in the direction of the Si atoms, two equivalent orientations of the ammonium ion are possible; the hydrogen bonds would be asymmetrically trifurcated.

with increasing temperature. The ν_1 absorption above 100 K was on an increasingly sloping background, which made the shape and symmetry of the bands difficult to assess. At no temperature did the ν_1 and ν_{4bc} band envelopes resemble the simple bands shapes predicted for an $S = C_{4h}$ ion of single weight and an $S = C_{2v}$ ion of double weight. The possibility of existence of a transition in the 200 K region cannot be excluded.

The ν_1 frequencies are high (Fig. 25), in the range associated with NH_4PF_6 and $(NH_4)_2MF_6$. This alone would point to hydrogen bonding of the trifurcated type, in spite of the presence of F^- ions in the structure — presumably much stronger hydrogen-bond acceptors than the fluorines of the SiF_6^{2-} anions. However, the direction of the change of the ν_1 frequency with temperature could not be ascertained.

Discussion

Fluorides with C.N. 4 (1, 53, 54)

The ν_1 and ν_{4bc} frequencies in these three compounds decrease slightly with increasing temperature (Figs. 3 and 7), although in **53** the temperature variation of ν_{4bc} could not be established with certainty. Since *both* frequencies change in the same direction and the N—H···F bonds in these crystals are straight, the negative sign of the temperature coefficient $d\nu/dT$ must be attributed to the thermal variation of the lattice dimensions, i.e. expansion on heating.

The difference in the rate of decrease in the relative intensity of the ν_1 and ν_{4bc} absorption in **1** on heating (Figs. 2 and 3) is striking, as is also the constancy of the ν_{4bc} halfwidth, ~7 cm^{-1}, over the entire 10–293 K range.

NH_4PF_6 (40)

Obviously the thermal behaviour of solid **40** can be properly understood only when reliable crystallography of all three phases is available. In the interim, while attempting to secure this information, we offer the following qualitative model which permits the probe-ion spectra and other observations to be rationalized. Inasmuch as the two transitions appear to be second-order (or at least not isothermal), we assume that the basic face-centred arrangement of the P and N atoms is preserved in all the phases.

Phase I (above 192 K). The P and N atoms are in an NaCl-like cubic arrangement ($Fm3m$, $Z = 4$; cf. ref. 38). The PF_6 octahedra are rotationally displaced from their most symmetric possible orientations (i.e. those with F in $x00$ etc.) and undergo rapid reorientations as well as large-amplitude librational motions. The cation is moving in a potential field with a large number of local minima constituted by the instantaneous

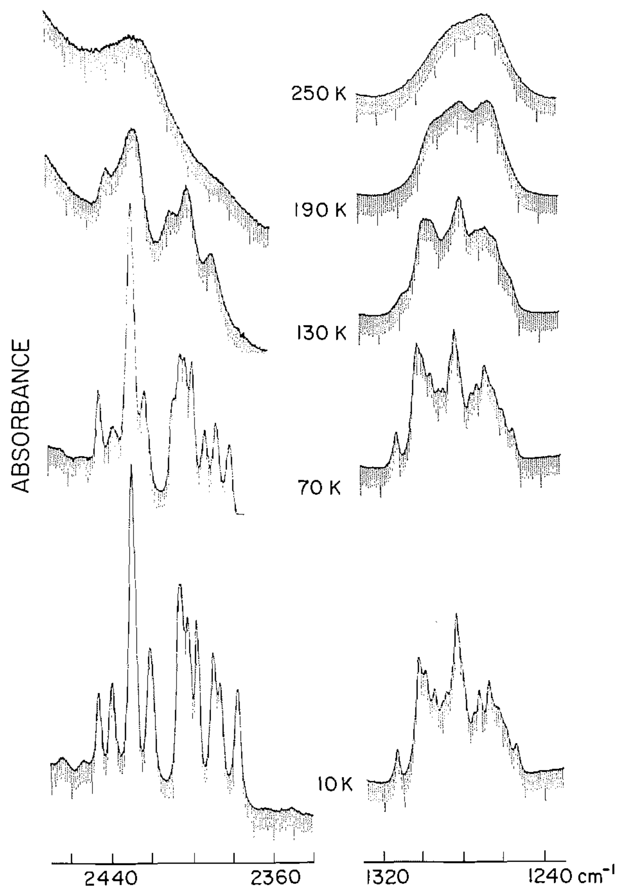

FIG. 24. Spectra of $(NH_4)_3SiF_7$ (5% D) in the ν_1 (*left*) and ν_{4bc} (*right*) regions at different temperatures.

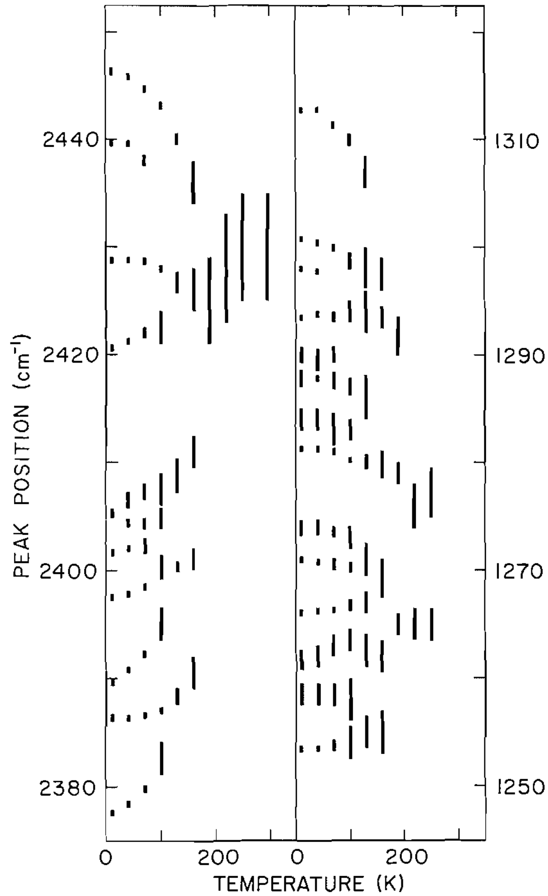

FIG. 25. Temperature variation of the peak positions of the bands in Fig. 24.

whereabouts of the F atoms (up to 48 such minima would be consistent with $Fm3m$). The *diffraction* symmetry of the crystal is thus $Fm3m$ and the effective site symmetry at N, as deduced from the probe-ion spectra, is cubic.

Phase II (132–192 K). The orientations of the rotated PF_6 octahedra are correlated, though the octahedra are still rapidly reorientating. This results in a decreased symmetry of the PF_6 sublattice, but since the ammonium ions still move in a multi-minimum, pseudospherical potential (though less "flat" than in *I*), with the F atoms at distances comparable to those in *I*, no abrupt changes are observed in the probe-ion spectra on passage through the *I* ↔ *II* transition. The effective symmetry at N is still cubic. The small but definite decrease in the ν_1 and increase in the ν_{4bc} frequency with increasing temperature (Fig. 22) indicates (20) that highly-bent hydrogen bonds are present in *II* and probably also in *I*.

Phase III (below 132 K). The PF_6 arrangement is essentially the same as in *II*, but the ammonium ions, while still reorientating rapidly, begin to respond to hydrogen-bonding interactions. Their librational motions are now increasingly restricted as the temperature decreases, with the result that the site symmetry at N is no longer cubic but C_2 or C_{2v}, and the distortion of the NH_4^+ ion (and hence the extent of the symmetry lowering of the crystal) increases smoothly with cooling. However, even at 10 K the distortion of the ammonium ion must be small, for the ν_1 absorption at this temperature is split by only about 7 cm^{-1}. The *II* → *III* transition may thus be described as a gradual change of crystallographic symmetry. The C_2 and C_{2v} site symmetries occur in a number of cubic space groups, but with $Z \neq 4$. It seems probable that the crystal symmetry of *III* is no higher than tetragonal. The increased effectivity of the hydrogen bonding in restricting the librational motion of the ammonium ion is manifested in the appearance of the $\nu_4 + \nu_6$ combination band of NH_4^+, which is absent in *II*,[14] and in the magnitude of the total splitting of ν_{4bc} at 10 K, which is about 20 cm^{-1} and thus three times that of the ν_1 splitting. It thus seems that the increased restriction of the torsional oscillation in *III* comes from a change in the coordination geometry of the ammonium ion rather than from a significant change in the H···F distance.

The ν_1 frequency in *I* and *II* differs little from the mean ν_1 frequency in *III*, and similarly for ν_{4bc}. This constancy, the negative temperature coefficient of the ν_1 and the positive temperature coefficient of the ν_{4bc} frequency all indicate that the *type* of hydrogen bonding is the same in all three phases and corresponds to highly bent, bifurcated or trifurcated N—H···F bonds. Because of the rotational displacement of the PF_6 octahedra the ammonium ion in **40** does not move inside a regular octahedron of F atoms, hence its C.N. > 6. The ν_1 and ν_{4bc} frequencies in **40** are comparable to the corresponding frequencies in cubic $(NH_4)_2MF_6$ (2, 10), but they are quite different from those for NH_4I(*I*), for NH_4^+ isolated in fcc alkali halide matrices (ref. 2 and results to be published) and, most importantly, for $Cs_2NH_4FeF_6$, the only case so far examined of

[14] The absence of this band in the room-temperature spectrum of NH_4PF_6 led Waddington (42) to conclude that the ammonium ion was free to rotate.

NH_4^+ inside a regular F_6 octahedron (cf. above and Fig. 16). The points for NH_4PF_6 (*I–III*) fall in an entirely different region of the ν_{4bc} vs. ν_1 plot (Fig. 3 of ref. 2) than the points for the C.N. 6 structures just mentioned. In fact, they fall in the extreme margin of the C.N. 12, trifurcated N—H···F bonds group. Unlike in NH_4I(*I*), the hydrogen bonding in NH_4PF_6(*I*) is not characterized by instantaneous privileged, essentially straight and strong N—H···X bonds: the ν_1 ~2250 cm^{-1} and ν_{4bc} ~1260–1320 cm^{-1} frequencies of $Cs_2NH_4FeF_6$ correspond more to the frequencies in NH_4SnF_3 (normal hydrogen bonds) and $(NH_4)_2[Cr(H_2O)_6]F_5$ than to those in **40**, even when qualitative allowance is made for the different formal charges on the F atoms in PF_6^- and FeF_6^{3-}.

Specifically, the above model is consistent with the following observations.

(*a*) The time-of-flight spectrum of slow neutrons scattered inelastically from **40** at room temperature approaches the shape expected for free rotation of NH_4^+, while the corresponding 103 K spectrum (i.e. for phase *III*) is significantly different (43).

(*b*) ^{2}H and ^{19}F nmr measurements on ND_4PF_6 (35) show that the upper transition is associated with a change in the reorientational motion of the PF_6^- ions only, while the lower transition was found to have little influence on the reorientational motions of both ions. The activation energies E_a for reorientation of the ammonium ion in *I* and *III* were found to differ only slightly: 0.71(1) kcal/mol between 170 and 300 K, and 0.83(1) kcal/mol between 20 and 71 K. The latter value is in reasonable agreement with E_a = 1.0 kcal/mol (44) and 0.90 kcal/mol (36) reported by other authors. The T_1 in *I* is long and almost temperature independent: $T_1(^1H)$ = 18 s and $T_1(^{19}F)$ = 6 s, corresponding to almost free rotation (36).

(*c*) The second moment of the ^{1}H nmr resonance, both at room temperature and at 77 K, increases by only about 50% from 1 bar to 14 kbar (45). This is consistent with the existence of a multiminimum, flat potential (i.e. C.N. > 6) and weak hydrogen bonding in all three phases.

(*d*) The upper C_p anomaly is a characteristic λ-type transition (30). In contrast, the lower transition is described as "gradual" rather than a typical λ point. This would be consistent with the postulated gradual crystallographic distortion (cf. Fig. 22) taking place simultaneously with orientational ordering of the ammonium ions (plus the attendant response from the PF_6 octahedra) on cooling below 132 K. Stated differently, the extra energy required to overcome the crystallographic distortion of the 10 K structure on heating may become significant at temperatures lower than a consideration of the C_p vs. T graph (Fig. 2 of ref. 30) alone might suggest, i.e. the ΔS_{tr} value for this transition quoted in ref. 30, 2.48 cal/deg mol, may in fact be an underestimate. Inspection of Fig. 22 and of Figs. 2 and 4 of ref. 30 would suggest 30–40 K as the temperature at which the "extra" contribution to heat capacity becomes perceptible.

(*e*) In ref. 30 the authors do not appear to exclude the possibility that the entropy change associated with the λ-transition in NH_4PF_6 and $RbPF_6$ is in fact R ln 4 = 2.75 cal/deg mol, i.e. higher than the values of 2.23 and 2.42 cal/deg mol, respectively, deduced from the experiment. The high value would be consistent with our model. If the *I* ↔ *II* transition is, for example, between $Fm3m$ (24 F in 192(*l*) — *xyz* etc.) for *I* and the subgroup $F23$ (24 F in 48(*h*) — *xyz* etc.) for *II*, the reduction in the number of possible equivalent F positions is by 192/48 = 4. Similarly, for the ammonium ion, in *III* the site symmetry S is C_2 or C_{2v}. If we assume ordering with respect to the twofold axis, $\Delta S_{tr}/R$ = 1.39 = ln 4 (1.24 measured, but see *d*), the number of equivalent NH_4^+ orientations in *II* would be 8 if $S(III) = C_2$ and 16 if $S(III) = C_{2v}$.

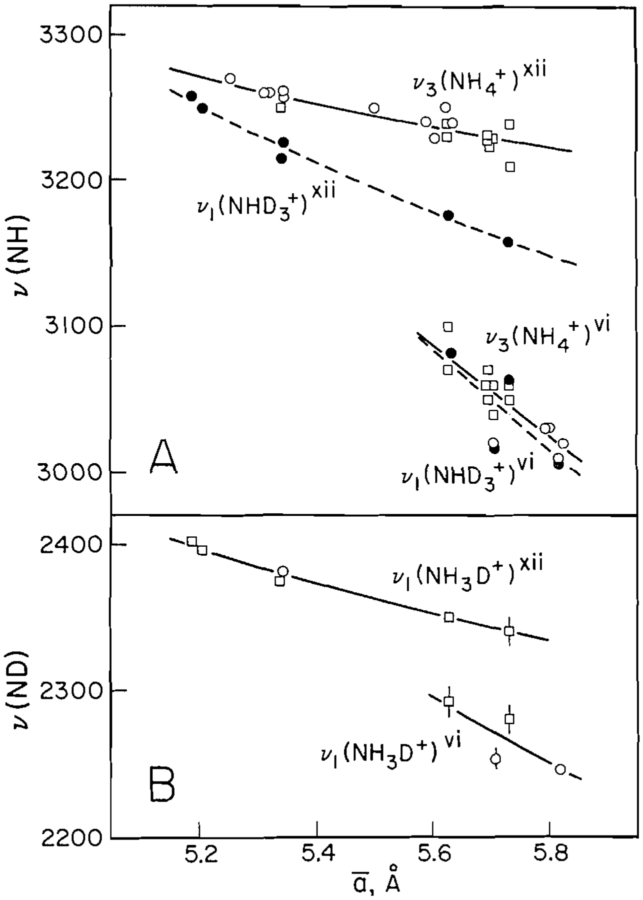

FIG. 26. Correlation of the NH stretching frequency of NH_4^+ (*A*) and the ND stretching frequency of NH_3D^+ (*B*) with $\bar{a} = (V/Z)^{1/3}$ for cubic elpasolites $(NH_4)_2BMF_6$ (B = Na, K) and $Cs_2NH_4MF_6$, cryolites $(NH_4)_3MF_6$ (squares) and perovskites NH_4MF_3. The $\nu_3(NH_4^+)$ values (room temperature) are from refs. 5, 13, and 46. The broken lines and full circles refer to the NH stretching frequencies $\nu_1(NHD_3^+)$ obtained by conversion from $\nu_1(NH_3D^+)$ (see text).

Elpasolites and cryolites: NH_4^+ vs. NH_3D^+ spectra

The effect of the C.N. (and hence of the hydrogen bonding) of the ammonium ion on the spectra of NH_4^+ in fluoride elpasolites and cryolites has been investigated by Epple and Massa (5, 6, 13) on undeuterated samples at room temperature. They were able to distinguish between the $(NH_4^+)^{vi}$ and $(NH_4^+)^{xii}$ absorptions in spite of the usual complications (broad, poorly resolved peaks, vibrational coupling and Fermi resonance) inherent in the room-temperature spectra of NH_4^+ in the NH stretching region, and they examined the implications of the coexistence of the 6- and 12-coordinated ammonium ions in the crystals as far as was possible from such spectra. It is of interest to see to what extent these NH_4^+ spectra match those of the isotopically isolated NH_3D^+ probe ion.

When Epple's $\nu_3(NH_4^+)^{xii}$ and $\nu_3(NH_4^+)^{vi}$ values for $(NH_4)_2NaMF_6$, $(NH_4)_2KMF_6$, $(NH_4)_3MF_6$, and $Cs_2NH_4MF_6$ (and also NH_4MF_3)[15] are plotted against $\bar{a}$(293) (Fig. 26*A*),

[15] Epple's $\nu_3(NH_4^+)$ values for the ammonium cryolites have been supplemented by three values estimated from the spectra shown in ref. 46.

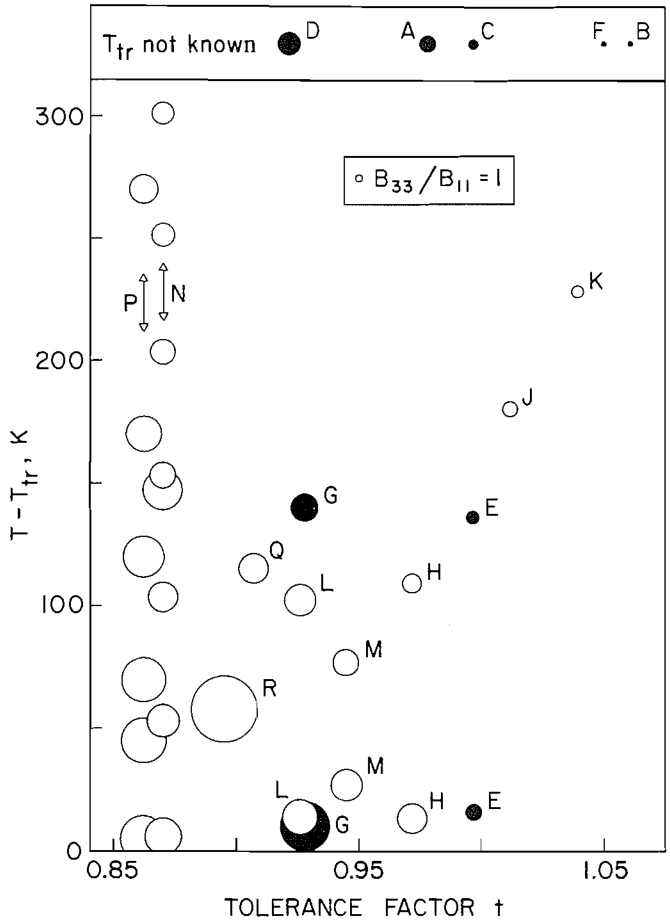

FIG. 27. Variation of the anisotropy of the principal thermal amplitudes of the X atom in cubic A_2BMX_6 elpasolites (full circles) and AMX_3 perovskites (open circles) with the tolerance factor t and the temperature difference $T - T_{tr}$. The diameters of the circles are proportional to $B_{33}/B_{11} = B_{\perp}(M - X)/B_{\parallel}(M - X)$. *A*, K_2NaCrF_6 (5); *B*, Rb_2LiFeF_6 (13); *C*, Rb_2NaFeF_6 (13, 49); *D*, Rb_2KFeF_6 (13, 49); *E*, $(NH_4)_2NaFeF_6$ (13, 31); *F*, Cs_2NaFeF_6 (13); *G*, $Cs_2NaNdCl_6$ (51); *H*, $KMnF_3$ (52–54); *J*, $KCoF_3$ (55); *K*, $KNiF_3$ (52); *L*, $RbCaF_3$ (54, 56); *M*, NH_4MnCl_3 (57); *N*, $CsPbCl_3$ (53, 58); *P*, $CsPbBr_3$ (58); *Q*, $MeNH_3PbCl_3$, and *R*, $MeNH_3PbBr_3$ (Knop, Cameron, and Adhikesavalu, to be published).

recognizable trends emerge, since the large number of compositions (M = Al, Ga, V, Cr, Fe) tends to compensate for the lack of accuracy in the indivudal estimates. The $\nu_3(NH_4^+)^{xii}$ variation with $\bar{a}$ is practically linear (r^2 = 0.82). As for $\nu_3(NH_4^+)^{vi}$, the points for $(NH_4)_3MF_6$ and $Cs_2NH_4MF_6$ have been regressed as belonging to one set, but the spread is considerable.

Regressing the available room-temperature ν_1 values linearly on $(1/\bar{a})^3$ (see below) results in a high degree of correlation for C.N. 12 ($r^2 = 0.98$) and in a poorer fit for C.N. 6 ($r^2 = 0.66$). Replotted against $\bar{a}$, the correlation lines in the observed $\bar{a}$ range are almost straight (Fig. 26*B*). When the $\nu_1(NH_3D^+)$ values for C.N. 12 are converted[16] to the corresponding $\nu_1(NHD_3^+)$ values (i.e. the isotopically isolated NH stretching frequencies), the points fall on a line which is not parallel to the $\nu_3(NH_4^+)^{xii}$ line (Fig. 26*A*). Since $\nu_1(NHD_3^+)$ is expected to vary in much the same manner as $\nu_1(NH_4^+)$, this implies that the symmetric and the antisymmetric stretching frequencies of $(NH_4^+)^{xii}$ in these fluorides converge as $\bar{a}$ decreases, i.e. increasing "chemical" lattice compression results in a significant reduction of the difference $\nu_3(NH_4^+) - \nu_1(NH_4^+)$. This convergence is analogous to that reported by Schiffer (48) for the symmetric and antisymmetric stretching modes of the H_2O molecule in crystalline hydrates.

Conversion of the $\nu_1(NH_3D^+)^{vi}$ to $\nu_1(NHD_3^+)$ frequencies for the two Cs elpasolites yields values which agree closely with Epple's $\nu_3(NH_4^+)^{vi}$ for those compounds, while the agreement is not as good for the two cryolites, **58** and **64**. It is possible that the $(NH_4^+)^{vi}$ frequencies are more sensitive to structural variation than the $(NH_4^+)^{xii}$ frequencies, and that the cryolite and the Cs elpasolite points should in fact be fitted separately. The present evidence is insufficient for resolving this problem.

The elpasolites $(NH_4)_2BFeF_6$ (57, 63)

Inadequacy of the classical model. A number of observations have been invoked in support of the suggestion (5, 13, 31, 49) that the F atoms in the cubic A_2BMF_6 elpasolites may in fact be less sharply localized than in the classical model.

(*1*) The principal thermal amplitudes B_{ii} of the F atoms show strong anisotropy. The B_{ii} in the plane perpendicular to an M—F bond (e.g. $\parallel(100)$) are several times that along the bond (refs. 13 and 49; Babel, Epple, and Massa, results to be published), and the $B_{33}/B_{11} = B\perp(M—F)/B\parallel(M—F)$ ratio increases with the decreasing tolerance factor[17] $t = (r_A^{xii} + r_F)\sqrt{2}/(r_B^{vi} + r_M^{vi} + 2r_F)$ and with decreasing temperature or, more accurately, with the decreasing difference $T - T_{tr}$. This is shown quite clearly in Fig. 27, both for cubic A_2BMX_6 elpasolites and AMX_3 (=A_2MMX_6) perovskites, in spite of the considerable dependence of the individual values of the B_{33}/B_{11} ratio on the method and accuracy of the structure refinement.

(*2*) The ^{57}Fe Mössbauer absorption of an Fe_{HS}^{3+} atom at a site of cubic symmetry (i.e. at 4(*a*) of *Fm*3*m*) should be a single, essentially unbroadened line. This is observed in $Cs_2NaFeCl_6$ both at 5 and 195 K. However, in K_2NaFeF_6, Rb_2NaFeF_6 and cubic Cs_2NaFeF_6 the linewidths of the single absorption are about twice as large at all temperatures between 5 and 600 K; even more unexpectedly, they *decrease* with increasing temperature (59). In **57**, which was investigated at our instigation by Pebler *et al.* (31), the linewidth above T_{tr} is comparable to that in the above three fluorides, but unlike in them it is practically independent of temperature.

(*3*) The absorption corresponding to the asymmetric Cr—F stretching vibration $\nu_3(F_{1u})$ in the room-temperature spectra of A_2BCrF_6 is broad and possibly asymmetric (5).

(*4*) Difference electron-density maps for K_2NaCrF_6, Rb_2NaFeF_6, and Rb_2KFeF_6 in planes perpendicualr to the M—F bond and passing through the F position of the classical model show local maxima near the F position (refs. 5 and 13; Babel, Epple, and Massa, to be published).

These observations point to displacement, static or dynamic, of the F atoms from the 24(*e*) — *x*00 etc. positions. They also raise the question of what is the proper description of the cubic elpasolite structure, and does the displacement of the F atoms from the classical position affect the conclusions from the probe-ion spectra in any significant way?

[16] The conversion is accomplished by utilizing the correlation of the isotopically isolated $\nu_1(NH_3D^+)$ and $\nu_1(NHD_3^+)$ values in $(NH_4)_2Cr_2O_7$ (47), which is linear between $\nu_1(NH_3D^+)$ = 2234 and 2392 cm^{-1} and accommodates $\nu_1(NH_3D^+)|\nu_1(NHD_3^+)$ pairs for other compounds as well (results to be published).

[17] Shannon's ionic radii (50).

The observed manifestations of the displacement would appear to be accounted for if the F atoms were placed in the equipoint 96(*j*) — *xy*0 etc. of *Fm*3*m*, with fractional occupancy (13). This would result in four symmetry-equivalent *xy*0 etc. positions, at equal distances from M, associated with each classical F position *x*00 etc., and the geometry of an individual MF_6 octahedron would depend on the (instantaneous) distribution of the six F atoms over the 24 positions, possibly subject to a minimum symmetry constraint (e.g. that MF_6 be centrosymmetric). Detailed arguments in support of this description will be reviewed elsewhere.

Effect of F displacement on probe-ion spectra. The classical description of the elpasolite structure accounts quite satisfactorily for the observed probe-ion spectra of the cubic phases. However, if the F atoms are in fact disordered over 96(*j*) — *xy*0 etc. of *Fm*3*m*, the diffraction symmetry of the crystal will remain *Fm*3*m*, but the individual MF_6 octahedra will be distorted or rotated about M. These distortions or rotations may be random or, if the disorder is dynamic, they might be correlated through a collective lattice mode. In either case the 12-coordination of NH_4^+ by F will be maintained, but the effective symmetry of an individual ion between reorientations will be $C_2 \subset S_4$ or C_1, rarely S_4. Each C_2 configuration would generate a ν_1 doublet and a ν_{4bc} quartet, and each C_1 configuration a ν_1 quartet and a ν_{4bc} octet, not necessarily resolved. The abundance-weighted superposition of all the distinct ν_1 multiplets would then result in an overall ν_1 absorption that is itself a complex multiplet or at least a broad envelope, and similarly for ν_{4bc}.

In **57** at 160 K the estimated ν_1 halfwidth was 58 cm^{-1}; in **63** an estimate is difficult because of the high T_{tr}. In NH_4MF_3 just above T_{tr} the corresponding estimated halfwidths were 60 cm^{-1} for Mn and 37 cm^{-1} for Zn (15). In the Zn compound the halfwidth was 40 cm^{-1} even at 193 K, compared with ~60 cm^{-1} for NH_4MnF_3. The ν_1 halfwidths just above T_{tr} in all three perovskites seem to mimic the magnitude of the high-low spread of the ν_1 components at 10 K in that the halfwidth is never smaller than the spread. This would seem to be the case also in **63** (Fig. 14) insofar as an estimate of the halfwidth at room temperature is possible. The symmetry of the ν_1 band shapes above T_{tr} is difficult to ascertain, given the low intensity and large width, although the bands give the general impression of being symmetric.

These halfwidths are certainly large. In the ammonium compounds we have studied to date, the $\nu_1(293)$ halfwidths rarely exceed 30–35 cm^{-1}, so the above values could be taken as evidence of the F atoms being disordered. On the other hand, it is in the cubic $(NH_4)_2BFeF_6$ and NH_4MnF_3 that the ammonium ions are librationally and reorientationally highly mobile, hence it can be argued that unusually large halfwidths are to be expected for this reason alone. As for the low-temperature phases, there is nothing in their behaviour that would suggest that ν_1 and ν_{4bc} halfwidths in these compounds should be intrinsically large. At 10 K the resolved ν_1 and ν_{4bc} bands are visually symmetric in both **57** and **63** as well as in the perovskites. The ν_1 component halfwidths were ~4 cm^{-1} in **57** and 8–10 cm^{-1} in **63**. The corresponding ν_{4bc} values were ~4 cm^{-1} in both compounds. Compared with the ν_1 and ν_{4bc} halfwidths in NH_4MF_3 at 10 K, ~11 and ~7 cm^{-1}, respectively, for NH_4MnF_3 and ~9 and ~8 cm^{-1}, respectively, for NH_4ZnF_3 (15), the elpasolite halfwidths must be regarded as narrow.

It must be concluded that the information obtainable from the probe-ion spectra neither supports nor disproves the postulated displacement of the F atoms in cubic A_2BMF_6 elpasolites and AMF_6 perovskites.

Low-temperature phases. The ν_1 and ν_{4bc} component frequencies below T_{tr} change very little with temperature (Figs. 13 and 15). This is consistent with the near constancy of the ^{57}Fe quadrupole splitting in **57** between 4.2 K and T_{tr} (31). The existence of this splitting (ca. 0.31 mm/s) indicates that the FeF_6 octahedra are not merely rotated but distorted, and this again is consistent with the low site symmetry at the NH_4^+ ion (C_1 as deduced from the probe-ion spectra) and with the nonequivalence of the N—H···F bond strengths.

Recent work (13) indicates that at 170 K the unit cell of **57** is cubic, a = 8.474 Å. Sharp Guinier patterns obtained with the sample at 150 K, i.e. just below T_{tr}, could be completely indexed on a tetragonal unit cell (a = 8.438 Å, c = 8.578 Å, c/a = 1.017, $V^{1/3}$ = 8.484 Å), but broadening of several lines suggests that the real symmetry is lower. This situation is strongly reminiscent of the NH_4MF_3 (M = Mn, Co, Zn) perovskites. Helmholdt *et al.* (16) indexed the X-ray and neutron powder patterns of the low phases of these three fluorides as tetragonal, with c/a ratios at 4.2 K between 1.014 and 1.019.[18] However, both these authors and Bartolomé *et al.* (75) adduce reasons for the actual symmetry being lower than tetragonal (cf. also ref. 15).[19]

The four ν_1 components observed in the spectra of **57** between 10 K and T_{tr} leave no doubt that the effective symmetry E of the ammonium ion is C_1 (if all the NH_4^+ ions are equivalent, i.e. the ν_1 absorption is a quartet, $S' = C_i$ or C_1) or C_{2v} or C_2 (if there are two types of NH_4^+ ions in the structure, i.e. the ν_1 absorption consists of two doublets of equal weight, $S'' = C_{4v}, C_4, D_{2h}, C_{2v}, C_{2h}, C_2$). The third possibility, $S''' = D_{2d}$, S_4, or D_2, is unlikely, as it would imply the existence of four types of ammonium ions, the four N—H···F bonds in an ion being equivalent but of different strength in each of the four types; furthermore, $E = D_{2d}$ or S_4 would imply a tetragonal unit cell. The ν_{4bc} absorption is of no help in deciding which of the three possibilities applies, as an octet would be expected in all three cases.

For the low phase to have a "zellengleiche" subgroup symmetry of *Fm*3*m* (Z = 4) and a site symmetry S' in an eightfold equipoint, or S'' in two fourfold equipoints, the cubic symmetry of the high phase would have to be reduced to no higher than monoclinic (possibly C_{2h}^3 — $F2/m$). For a "klassengleiche" subgroup symmetry the possibilities are too numerous for a conclusion to be made in the absence of further information, but even from a cursory examination of the "klassengleiche" subgroups of $F4/mmm \subset Fm3m$ it seems probable that an eligible subgroup would be no higher than orthorhombic.

It is surprising to find that pseudotetragonal distortions of the cubic cell as small as c/a ~ 1.02 should produce, in **57** and NH_4MnF_3, a high-low spread of the $\nu_1(10)$ components in excess of 50 cm^{-1}. The distortion in the low phase of **63**, where the spread is ~110 cm^{-1}, has not yet been determined. The high-low spread of ν_1 (10) (and, to a smaller extent, of ν_{4bc} (10)) appears to correlate with the tolerance factor t (Fig. 28).

The elpasolites $Cs_2NH_4MF_6$ (58, 64)

The following relates to **58**; the quality of the spectra of **64**

[18] These are the ratios from Table 3 of ref. 16. Extrapolation to 4.2 K of the a, c, and c/a curves in Figs. 2 and 3 of the same paper gives slightly different values.

[19] Tornero *et al.* (57) found single crystals of the low phase of NH_4MnCl_3 to be orthorhombic.

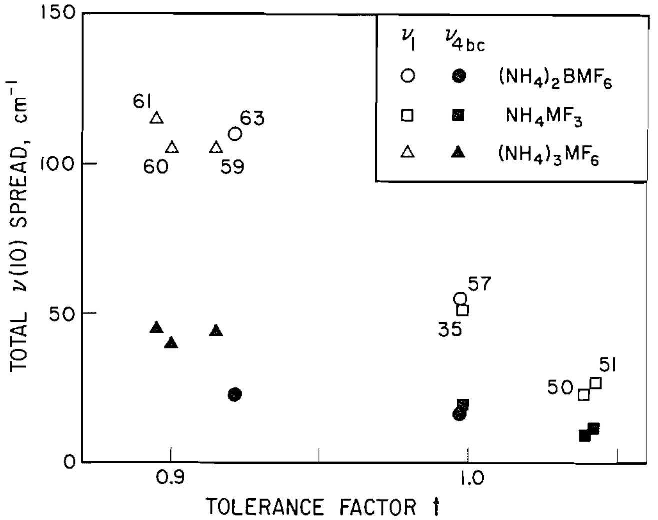

FIG. 28. Variation of the total frequency spread of the ν_1 (10) and ν_{4bc} (10) components of the $(NH_3D^+)^{xii}$ absorptions with the tolerance factor t. For the cryolites **59**–**61** the components of the $(NH_3D^+)^{xii}$ absorptions cannot be separated with confidence from those of the $(NH_3D^+)^{vi}$ absorptions; the values included in the plot represent the total range of ν_1 (10) and ν_{4bc} (10) in these fluorides.

was not good enough to provide more than a qualitative support of the results obtained with **58**.

The cubic $Cs_2NH_4MF_6$ elpasolites are at present the only known crystals that contain the ammonium ion symmetrically coordinated by six F atoms. It is therefore disappointing to find that the hoped-for opportunity for investigating the spectroscopic behaviour of the ion in **58** is frustrated by the existence of the crystallographic transition at ca. 194 K. Above T_{tr} the spectra are not well enough defined to be of much use, while below T_{tr} the NH_4^+ environment is no longer cubic and its symmetry and structure are not known.

Interpretation of the ν_1 and ν_{4bc} spectra of **58** below T_{tr} is moreover rendered uncertain by the variability of the ND absorptions from sample to sample. The ν_1 absorption observed at 10 K is a single band but not a clean singlet. The halfwidth of the main component, ca. 35 cm^{-1}, is appreciable in comparison with $\nu_1(10)$ of the probe ion in the fcc alkali halide matrices (ref. 2 and unpublished work), where the symmetric ν_1 singlet has no shoulders and a halfwidth not exceeding 12 cm^{-1}. The $\nu_1(10)$ absorption in **58** clearly is composite, but the number of components and their relative intensities cannot be established with confidence. The frequency separation of the components of this unresolved (in some spectra minimally resolved) multiplet is only about 10 cm^{-1} (ca. 20 cm^{-1} for the low-frequency shoulder). This would point to N—H···F bonds of very similar strength and thus to only a small distortion of the F_6 octahedron: in this frequency region ν_1 varies steeply with d(N···X) and thus with d(H···X) (Fig. 30), so that a large change in ν_1 corresponds to a small change in the distance. As anticipated, the peak $\nu_1(10)$ frequency is between the $\nu_1(10)$ of NH_4F and NH_4Cl, i.e. the hydrogen bonding is strong.

The surprising and entirely unexpected feature of the probe-ion spectrum of **58** is the complexity and extent of the absorption in the ND bending region (Fig. 16). The total breadth, which is at least 62 cm^{-1}, is the largest observed for ND bending in any ammonium compound to date. It is in fact larger than the total breadth of the ND bending absorption in the ammonium cryolites, which arises from both $(NH_3D^+)^{vi}$ *and* $(NH_3D^+)^{xii}$. Considering that in the fcc alkali halide matrices the halfwidth of $\nu_{4bc}(10)$ is 9–12 cm^{-1} and that, on the evidence from $\nu_1(10)$, the distortion of the F_6 coordination octahedron cannot be appreciable, this breadth is so puzzling that it invites the question, do all the components of the absorption in this region belong legitimately to ν_{4bc}? Since none of the peaks is observed in the spectra of undeuterated **58** (Fig. 16), the peaks must involve ND vibrations and thus the ammonium ion. The possibility that some of the ND absorption is due to Fermi-resonance enhanced combination or overtone bands of NH_3D^+ appears unlikely. The only bands of any intensity between 100 and 1400 cm^{-1} in Epple's spectra (6) of undeuterated $Cs_2NH_4MF_6$ are the asymmetric MF stretch $\nu_3(F_{1u})$ (at 470 cm^{-1} for Fe and 560 cm^{-1} for Al), the asymmetric MF bend $\nu_4(F_{1u})$ (at 298 cm^{-1} for Cr and 387 cm^{-1} for Al), and the $S_8(F_{1u})$ lattice mode of NH_4^+ (at 214 cm^{-1} for Cr and 215 cm^{-1} for Al). None of these fundamentals looks like a candidate for producing overtones or combinations which would give rise to absorptions of significant intensity in the 1220–1320 cm^{-1} region. It is thus concluded that the entire multiplet shown in Fig. 16 constitutes the ν_{4bc} absorption.

We can offer no explanation at present for the sample dependence of the ν_{4bc} multiplet profiles nor for the associated, seemingly erratic disappearance of the 1227 cm^{-1} component of the multiplet or for the unusual temperature variation of the intensity of the lowest-lying components (seen in Fig. 16); the same applies to the variability of the profile of the ν_1 absorption.

Variation of the ND stretching frequency

To see how the isotopically isolated ND stretching frequency varies from compound to compound, ν_1 (293) is plotted in Fig. 29 against d(N···F). This is a choice *faute de mieux*. The N···F distance may not be the most suitable parameter, but it is the best parameter available: the H···F distances are not known with sufficient accuracy (not even approximate H positions have been established in some of the structures), and the compounds included represent different structure types and C.N.'s and contain hydrogen bonds of different types. The ν_1 vs. d(N···F) plot, too, has its limitations. Some of the N···F distances are not accurately known, and for some of the compounds the room-temperature values of the ν_1 frequency are poorly defined or not available, so that estimated values had to be substituted. In **37** the F environment of the ammonium ion is quite irregular, and in **40** and in the elpasolites and cryolites the whereabouts of the F atoms are uncertain (see above).

In spite of these deficiencies Fig. 29 amply confirms, in the small, the general trends pointed out in ref. 2. The N···F distance must increase with the C.N. of the ammonium ion and hence the strength of the N—H···F bonds must decrease. This is reflected in the increase of ν_1 with d(N···F) in the sequence **1**–**54**–**53**–**39**–**50**–**18**. However, in an isostructural or quasi-isostructural series ν_1 decreases with increasing d(N···F) as a consequence of a "decompression" effect, i.e. increasing separation of the ionic charges in the structure. The perovskite and "ordered" perovskite (elpasolite and cryolite) sequence **51**–**50**–**35**–**57**–**59**–**61** is the most extended such series, but the trigonal $(NH_4)_2MF_6$ (**31**–**32**–**33**) also show this effect and the cubic $(NH_4)_2MF_6$ undoubtedly would if the d(N···F) were more accurately known.

The existence of these two trends, though clearly evident for the fluorides, is demonstrated more dramatically when other

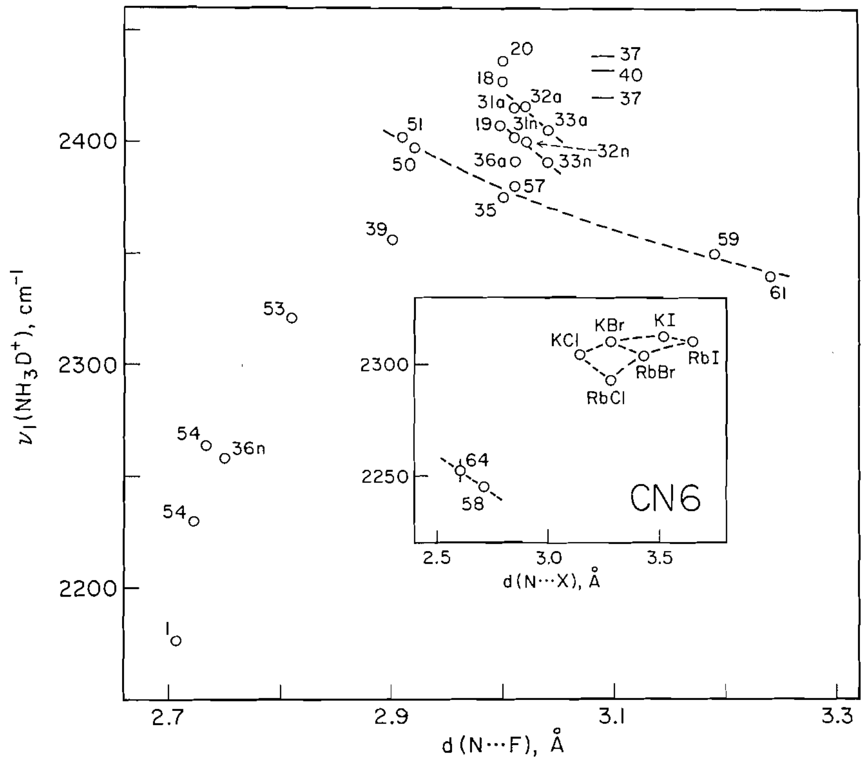

FIG. 29. Variation of the room-temperature ND stretching frequency $\nu_1 NH_3D^+$ with the N···F distance in ammonium fluorides with C.N. ≠ 6 (see text). For code numbers see Table 1; *a*, axial; *n*, nonaxial. *Inset*: the ν_1 vs. d(N···X) variation for C.N. 6, in **58** and **64** and in fcc alkali-halide matrices (ref. 2 and results to be published). Note the different *d* scales.

ammonium halides are included. In Fig. 30 and ν_1 are plotted against the inverse cube of the N···X distance. The advantage of this presentation is that it effectively linearizes the compression effect within the observed d(N···X) range.[20] The cubic $(NH_4)_2MX_6$ (X = F, Cl, Br, I) series provides a convincing illustration of the compression effect.[21] No ν_1 values are available for chloride perovskites, but if Epple's (5) $\nu_3(NH_4^+)$ = 3240 cm^{-1} for NH_4MnCl_3 is used to obtain an estimate of $\nu_1(NH_3D^+)$ (cf. Fig. 26 and footnote 16), the point for the estimate (*P* in Fig. 30) falls on an extension of the regression line for the "perovskite" fluorides.

The increase in ν_1 along the fluoride sequence **1–54–53–39–50–18** reflects the effect of decreasing acceptor strength (associated with the change in the effective ionic charge on the F atom) as well as the effect of the increasing d(N···F) and of the N—H···F bond type. In **1** and **54** the hydrogen-bond acceptors are F^- ions, whereas in the other crystals the acceptors are composite MF_n^{m-} anions of different connectivity and different formal charge on the M atom.

[20] For HF_2^- in fcc alkali halide matrices the "chemical" (i.e. not due to external pressure) compression effect appears to vary $\nu_3(HF_2^-)$ as $(1/\bar{a})^4$ (2), but this variation involves certain assumptions the validity of which is not quite clear. A plot of ν_1 against d_{NX}^{-4} is less linear than Fig. 30; we have not investigated whether the inverse cube represents the optimum power. A ν_1 vs. d_{HX}^{-3} plot is less informative than Fig. 30 owing to uncertainties in the choice and values of the H···X distances.

[21] Most of the ν_1 values in this set refer to liquid-nitrogen temperature. The consistency would improve somewhat if the actual $\nu_1(293)$ values were available: the correction would bring **20** closer to **18**, and some of the X = Cl points would be lowered by 2–5 cm^{-1}. The importance of the temperature correction decreases with increasing d(N···X).

The points for NH_4X (X ≠ F)[22] and MX:NH_4 fall in one particular region of Fig. 30. Among the conspicuous features of this group is the great similarity in the ν_1 values for NH_4Cl (**3**) and RbCl:NH_4 (**12**) (to a lesser degree also for NH_4Br (**5**) and RbBr:NH_4 (**13**)), in spite of the difference in C.N. and hence in the effective ionic radii. This observation is of fundamental importance for an understanding of the hydrogen bonding of 6-coordinated ammonium ions. We intend to discuss it elsewhere, together with two further trends in Fig. 30: (*1*) The *common-anion* tie lines for the KX:NH_4 (**9**, **12**) and RbX:NH_4 (**10**, **13**) points accommodate very well the corresponding CsX:NH_4 points **15** and **16**, respectively, again in spite of the difference in the C.N. The slopes of these straight lines are positive, i.e. they reflect a compression rather than an acceptor-strength effect. (*2*) The ν_1 values in the *common-cation* matrices (including CsX:NH_4) increase from Cl to I. In contrast, those in NH_4X (**3–5–8**) *decrease* from Cl to I, similar to $(NH_4)_2MX_6$ and probably the NH_4MF_3 perovskites.

It is not self-evident how the ν_1 frequencies in the alkali halide matrices can be related to the ν_1 frequencies in the fluorides. No instances of 4-coordinated NH_4^+ in halides are known except in fluorides, and the only fluorides in Fig. 30 that contain 6-coordinated NH_4^+ ions are **58** and **64**. However, the ν_1 frequency of an ammonium ion forming "straight" N—H···X bonds is determined principally by the N···X dis-

[22] The $\nu_1(293)$ values of NH_4Cl and NH_4Br fall in a region where ν_1 increases steeply with temperature, and $\nu_1(293)$ of NH_4I refers to the fcc phase *I*. This makes meaningful comparison at this temperature difficult. To circumvent this difficulty the $\nu_1(10)$ values are used for these halides in Fig. 30; the N···X distances are extrapolated to 10 K from literature values for different temperatures. The ν_1 values in all three halides remain practically constant up to about 150 K.

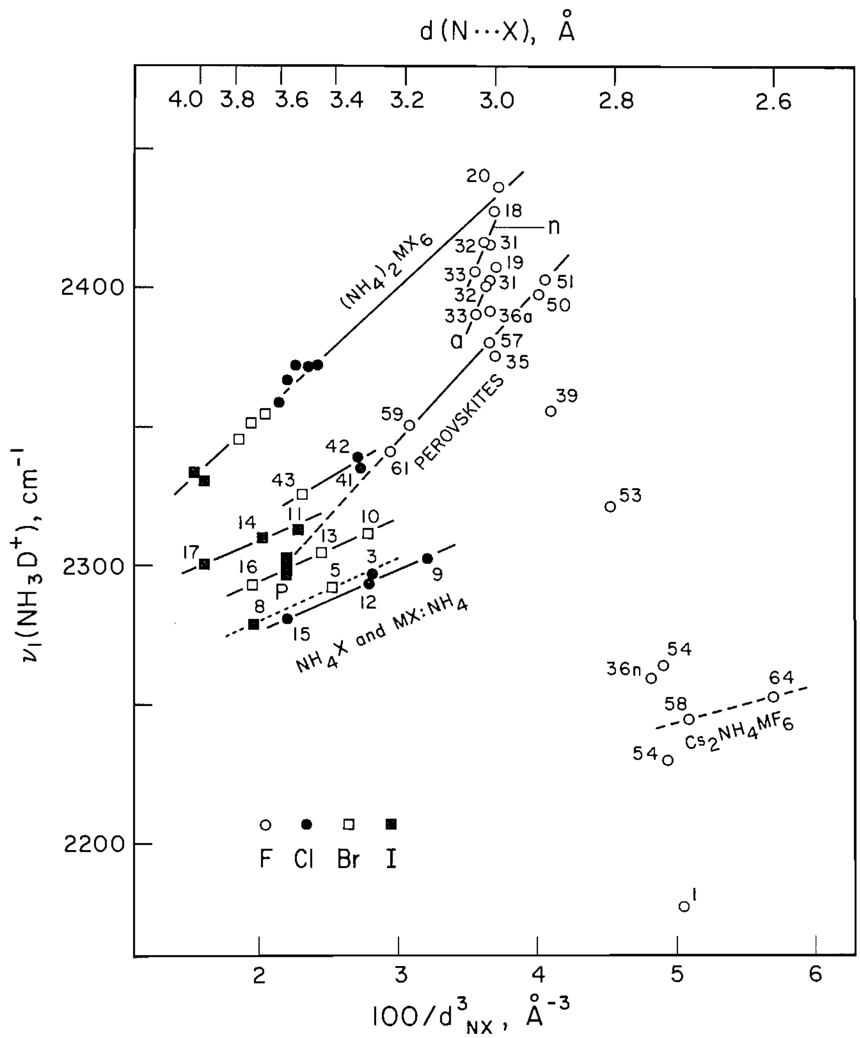

FIG. 30. Variation of the room-temperature ND stretching frequency ν_1 with the inverse cube of the N···X distance in ammonium halides. For code numbers see Table 1 and ref. 2. The two unnumbered points for $(NH_4)_2MI_6$ are for M = Pt and Te (32). For NH_4MnCl_3 (*P*) and NH_4X (**3**, **5**, **8**; 10 K values), see text. The ν_1 values are from the present work and from previous papers in this series.

tance, which in turn depends on the C.N. The orientational ambiguity which distinguishes an NH_4^+ ion in symmetric 8-coordination from that in symmetric 4-coordination is not a significant factor. A case can thus be made for comparing NH_4F with CsX:NH_4 along the sequence **1–15–16–17**, which is analogous to the fluoride sequence **1–54–53–39**. Similarly, the sequence **58–12–13–14** permits a comparison of ν_1 frequencies for 6-coordination, taking into account that the N···F distance in **58** is somewhat shorter than the nominal N···F (= Rb···F) distance would be in RbF:NH_4. An analogous sequence does not, however, obtain for NH_4F and the sc NH_4X (X = Cl, Br, I) halides (**1**, **3**, **5**, **8**) because of the decrease of ν_1 from Cl to I in the latter.

Structural transitions

Transition temperature and ionic size. Transitions from cubic to lower ("tetragonal") symmetry in A_2BMX_6 (B = A, B, M or □) halides have been shown in many cases to be the consequence of the condensation of a rotatory mode of the MX_6 octahedron on cooling. Assuming that the transition mechanism is always of this type and that comparison is thus possible, we have plotted the available T_{tr} against Shannon's r^{vi}(M) (Fig. 31) as well as against the tolerance factor *t* (Figs. 32 and 33). These plots are in many respects lacunary and the T_{tr} are often not accurately known; as well, the tolerance factor contains an accumulation of the uncertainties in the individual ionic radii as applied to the A_2BMX_6 halides. Nevertheless, examination of the plots permits the following observations.

The T_{tr} of the $(NH_4)_3MF_6$ cryolites increases with $r^{vi}(M^{3+})$ (Fig. 31). The variation can be represented, to a good approximation (r^2 = 0.96, σ = 10 deg), by a straight line. In the K_3MF_6 series the variation is, however, different: the T_{tr} *decreases* steadily at first, from Al to Ti, but then takes an upward turn with T_{tr}(In). The T_{tr} of M = Lu to Dy do not appear to be reliably known, but such as they are they provide further support for the existence of the upward turn. In fact, fitting the K_3MF_6 points of Fig. 31 to a cubic polynomial (dashed line) yields r^2 = 0.98, σ = 6.2 deg, which suggests a significant correlation. The minimum of this fit falls between Ti and Sc, but as T_{tr}(Sc) has not yet been reported, the presumed course of the variation between Ti and In cannot be verified at present.

The Rb_3MF_6 and Cs_3MF_6 series are less well defined. Apart from the T_{tr} values for Cr and Fe only upper estimates are available for some of the M = Ln compounds. When the Rb_3MF_6 points are fitted by a cubic polynomial (r^2 = 0.998, σ = 5.1 deg), the curve is quasi-parallel to the K_3MF_6 curve in

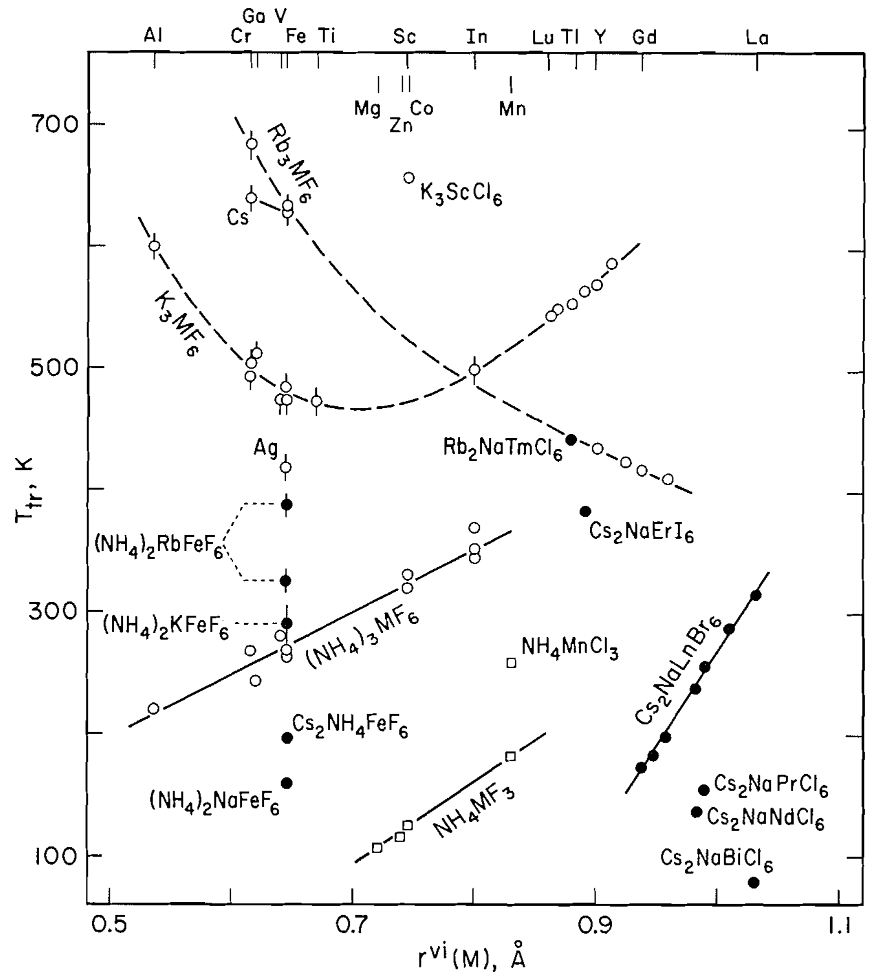

FIG. 31. Variation of T_{tr} in the cryolites A_3MF_6 (open circles), elpasolites A_2BMX_6 (full circles) and perovskites NH_4MX_3 (squares) with Shannon's effective ionic radius $r^{vi}(M)$. The T_{tr} values are from refs. 5, 13, 17, 24, 26, 34, 51, 60–74, 76–80, and from this work.

the 3*d*-element region, but it does not turn upward with increasing $r^{vi}(M)$. Instead, it keeps dropping over the entire physically possible range of $r^{vi}(M)$. The crossover of the K_3MF_6 and Rb_3MF_6 curves occurs near M = In, suggesting that the T_{tr} of the In compounds are quite similar. The set of T_{tr} values for the Cs series (not all T_{tr} shown) is of poorer quality, but the general trend appears to parallel that for Rb_3MF_6.

The T_{tr} of Rb_3MF_6 and Cs_3MF_6 (M = Cr, Fe) are higher than in the corresponding K cryolites and *some 400 deg higher* than in the corresponding $(NH_4)_3MF_6$. The essence of this observation is then that (*1*) the T_{tr} of the ammonium cryolites are much lower than the T_{tr} of any of the other cryolites studied (i.e. the presence of the NH_4^+ ion hinders the MF_6 rotatory modes from condensing), and (*2*) the increase of T_{tr} with $r^{vi}(M^{3+})$ in the $(NH_4)_3MF_6$ series is not matched by similar trends in the alkali series: for K_3MF_6 the variation is not even monotonic, and in the Rb_3MF_6 series the tend is opposite throughout, the similarity of the effective Rb^+ and NH_4^+ radii notwithstanding. Compared with Rb^+, NH_4^+ affects T_{tr} as if it were a much smaller ion.

When the cubic ($T > T_{tr}$) A_2BMX_6 (X = F, Cl, Br) elpasolites and perovskites are included in Fig. 31, it is again found that the halides containing NH_4^+ tend to have T_{tr} below ambient. The depressory effect, relative to Rb^+, of introducing a third ammonium ion into $(NH_4)_2BMF_6$ (B = Na, K, Rb), while less dramatic than for $Rb_3MF_6 \rightarrow (NH_4)_3MF_6$, still amounts to at least 60 deg (Fig. 32, inset).[23] The T_{tr} variation in the $NH_4MF_3 = (NH_4)_2MMF_6$ perovskites is roughly parallel to that for $(NH_4)_3MF_6$.

A partial rationalization of these trends in terms of a hard-sphere model is possible from the T_{tr} vs. *t* plots of Figs. 32 and 33. The ammonium compounds with the highest *t* values have the lowest T_{tr}. This is also true of most of the elpasolites and perovskites included in these plots, although for the $KMCl_3$ perovskites the trend is somewhat confused. The alkali A_3MF_6 cryolites, however, show a different behaviour.

In the elpasolites and perovskites T_{tr} is raised on replacing a smaller halogen by a larger one, i.e. on decreasing *t*: F → Cl in NH_4MX_3 and Rb_2NaTmX_6, Cl → Br → I in $CsPbX_3$ and $MeNH_3PbX_3$ (results to be published). Similarly, T_{tr} is raised by a *t*-reducing substitution of B in A_2BMF_6 and of M in AMX_3: Cs_2BHoF_6, $Cs_2NaLnBr_6$, KMF_3, $RbMX_3$, $CsMCl_3$. In contrast, *t*-reducing substitution of A in A_2BMF_6 and AMX_3 *lowers* T_{tr}:

[23] Lorient *et al.* (26) report a miscibility gap in the solid–solution system $(NH_4, Rb)_3FeF_6$ between $(NH_4)_2RbFeF_6$ (T_{tr} = 397(5) K) and $(NH_4)_{2.1}Rb_{0.9}FeF_6$. The estimated T_{tr} obtained by extrapolation from Fig. 4 of ref. 26 is 325(10) K. Since the site occupancies and the extent of order in these two limiting compositions are not known, both T_{tr} values are plotted in Figs. 31 and 32. The lower T_{tr} gives a "linear" variation of $T_{tr}[(NH_4)_2BFeF_6]$ with $r^{vi}(B)$ or *t*; the higher T_{tr} would make the depressory effect of the substitution of B by NH_4 even larger, ~130 K.

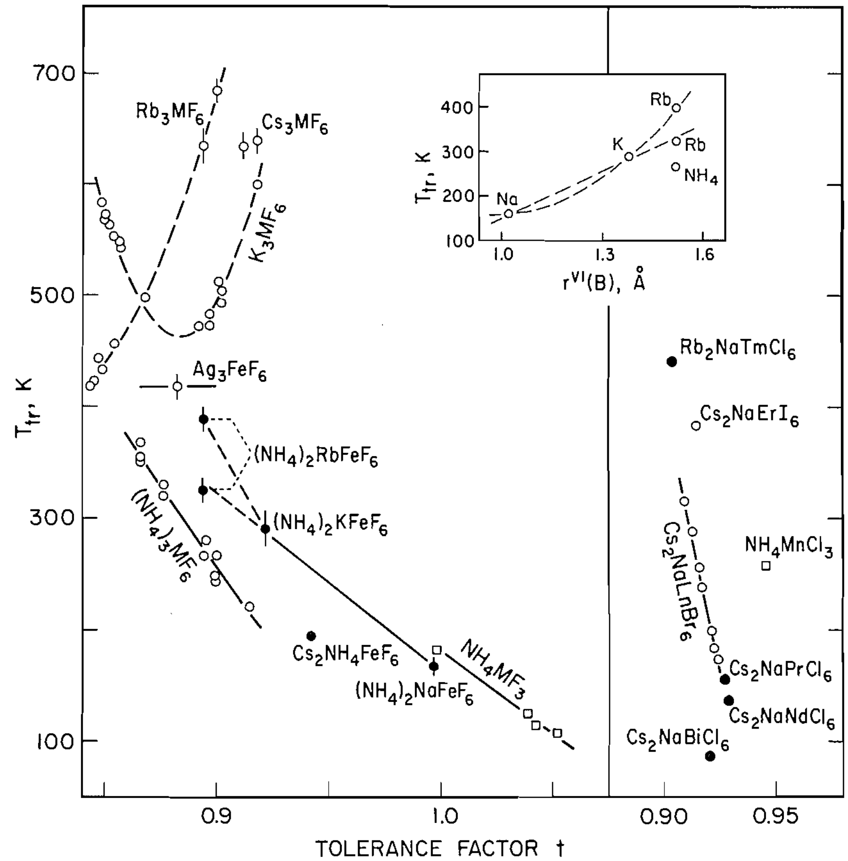

FIG. 32. (*Left*) Variation of T_{tr} in the cryolites A_3MF_6 (open circles), elpasolites A_2BMF_6 (full circles) and perovskites NH_4MF_3 (squares) with the tolerance factor *t* (see text). For sources of T_{tr} values see caption of Fig. 31; for the two T_{tr} values of $(NH_4)_2RbFeF_6$ see text. (*Right*) Variation of T_{tr} in the elpasolites A_2BLnX_6 with *t*. X = Cl (full circles), Br and I (open circles); the perovskite NH_4MnCl_3 is also included. *Inset*: Variation of T_{tr} with r^{vi} (B^+) in the series $(NH_4)_2BFeF_6$ (B = Na, K, Rb, NH_4). The lower T_{tr}(Rb) represents an estimate for $(NH_4)_{2.1}Rb_{0.9}FeF_6$; the higher T_{tr}(Rb) corresponds to $(NH_4)_2RbFeF_6$, possibly disordered (see text).

$ACaX_3$, A_2NaHoF_6.

The rate of change of T_{tr} in many of these substitution sequences is quite steep, amounting, for example, to about 100 deg per 0.01 change in *t* for the Ln substitution in $Cs_2NaLnBr_6$ and about as much for the F $\rightarrow$ Cl substitution in $RbCaX_3$. It is thus clear that T_{tr} is quite sensitive to changes in the effective ionic size and that geometry, within a given structure type, is a dominant, perhaps *the* dominant, factor affecting T_{tr}. The T_{tr}, *t* points in many of the substitution sequences can be accommodated on reasonably smooth lines. It is noteworthy that in some cases a chloride sequence is an almost smooth continuation of the corresponding fluoride sequence. Examples are $RbMF_3$ and $RbMCl_3$ (perhaps also NH_4MF_6 and NH_4MCl_3?), or the entire Cs sequence in the lower left corner of Fig. 33, and similarly for $Cs_2NaLnCl_6$ and $Cs_2NaLnBr_6$ (Fig. 32).

Figures 32 and 33 also contain material for other interesting deductions, but as these do not specifically concern ammonium compounds, they will not be discussed here. Two points may, however, be made. In some cases (e.g. $KFeF_3$) the initial lowering of the cubic symmetry is purely magnetic in origin and the T_{tr} (cubic $\rightarrow$ noncubic) cannot be compared with the transition temperatures involving condensations of rotatory modes.[24] It is conceivable, however, that a rotatory mechanism is involved in a transition occurring in such crystals at a lower temperature and that it is that T_{tr} that should appear in the T_{tr} vs. *t* plot. Secondly, if the C.N. of the B atom in cubic A_2BMX_6 elpasolites is effectively higher than six as a result of the displacement of X from the classical position, the effective ionic radius of B would be greater than the r^{vi}(B) and consequently *t* would be lower than shown in Figs. 32 and 33. The resulting change would modify, to a varying degree, the relative positions of the T_{tr}, *t* points in these figures, and there is the effect of temperature on the ionic radius as well.

The different behaviour of the alkali A_3MF_6 cryolites is at present unexplained.

Effect of T_{tr} *on the ND stretching absorption*. When considering *a* to *c* below, it must be emphasized that the volume of the available probe-ion data is limited and that the complexity (sometimes also the quality) of some of the spectra renders them intrinsically inadequate. The observations based on the present information must thus be regarded as no more than qualitative.

(*a*) The total spread of the ν_1 component frequencies in the low-temperature phases increases with the transition temperature both in the perovskite-derived and in the trigonal $(NH_4)_2MF_6$ series (Fig. 34*A*).

(*b*) The decrease $(\Delta\bar{\nu}_1)_{tr} = \bar{\nu}_1(>T_{tr}) - \bar{\nu}_1(10)$ of the mean frequency $\bar{\nu}_1$ on cooling also increases with T_{tr} (Fig. 34*B*).

(*c*) The frequency of the lowest-lying ν_1 component in the low phases decreases with increasing T_{tr}, while $(\Delta\bar{\nu}_1)_{tr}$ and the total spread increase (Fig. 35). This indicates a progressive

[24] In NH_4CoF_3 the temperatures of the crystallographic and the magnetic transition coincide (102).

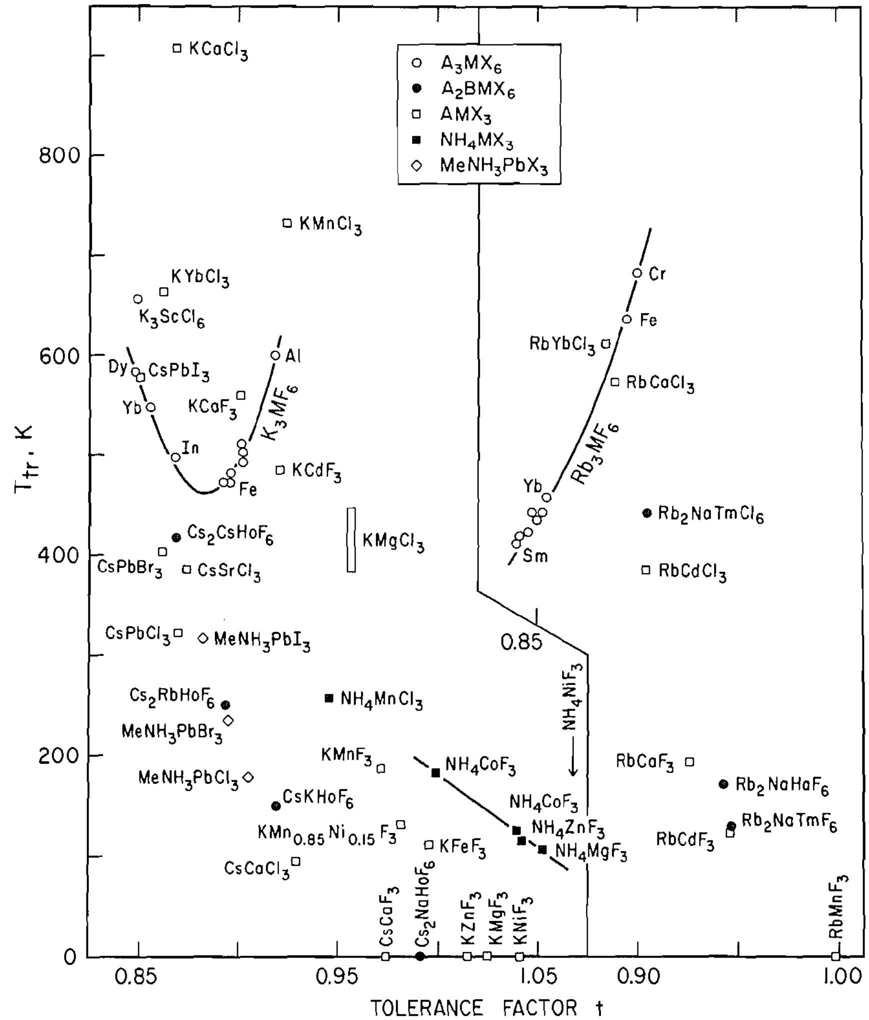

FIG. 33. Variation of T_{tr} in the cryolites A_3MX_6, elpasolites A_2BMX_6, and perovskites AMX_3 with the tolerance factor t. For sources of T_{tr} values see caption of Fig. 31 plus refs. 16, 53, 54, 58, 75, 81–102. (*Left*) K, Cs, and NH_4 compounds; (*right*) Rb compounds.

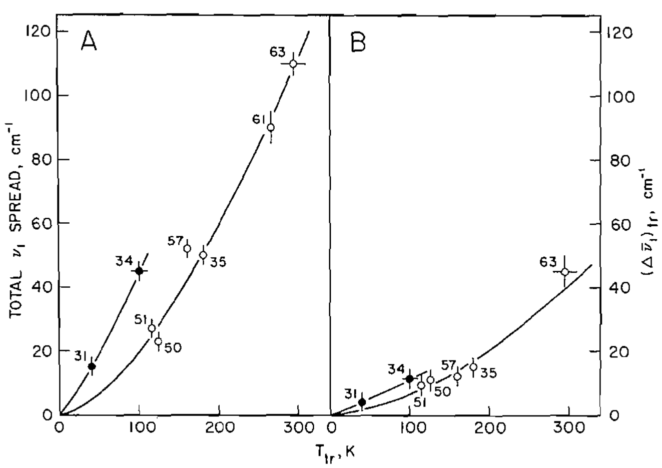

FIG. 34. (*A*) Variation of the total frequency spread, at 10 K, of the ν_1 components of the $(NH_3D^+)^{xii}$ ion with T_{tr} in perovskite-derived (open circles) and trigonal $(NH_4)_2MF_6$ (full circles) ammonium fluorides. **31**, $(NH_4)_2SiF_6$; **34**, $(NH_4)_2SnF_6$. (*B*) Variation of the ν_1 frequency decrease $(\Delta\bar{\nu}_1)_{tr}$ on cooling these fluorides through T_{tr}. In $(\Delta\bar{\nu}_1)_{tr} = \bar{\nu}_1(>T_{tr}) - \bar{\nu}_1(10)$, the first term refers to a temperature just above T_{tr} (in the cubic phases, a single frequency); the second term is the mean of the component frequencies at 10 K weighted by idealized intensity. The lines through the points are power fits cT_{tr}^{κ}.

strengthening of the strongest N—H···F bond at the expense of the others. The frequency of the highest ν_1 component approaches the limiting ν_1 value for weak N—H···F bonding modified by the compression effect.

Conclusions. While NH_4^+ and Rb^+ are dimensionally comparable, replacing Rb^+ by NH_4^+, at about the same t, has a dramatic effect on T_{tr}. In the A_3MF_6 cryolites the difference $T_{tr}(AM) - T_{tr}(NH_4M)$ amounts to as much as ~420 deg for AM = RbCr and would be expected to be even larger for RbAl.

The trends for the ammonium compounds can be rationalized, qualitatively, with recourse to the geometric meaning of the tolerance factor t. The closer t is to unity, the more complete is the contact of all the (spherical) atoms in the structure. Conversely, the more t falls below unity, the more room is there for the 12-coordinated ammonium ion, and the more opportunity for this ion to establish a strong, possibly privileged N—H···F bond at the expense of the other N—H···F bonds. This process is likely to involve a displacement of the N atom from the $\frac{1}{4}\frac{1}{4}\frac{1}{4}$ position toward the most strongly bonded F atom. The stronger this privileged bond, the lower the lowest ν_1 component frequency, the larger the spread of the ν_1 component frequencies, the larger $(\Delta\bar{\nu}_1)_{tr}$, and the greater the stability of the low phase, i.e. the higher T_{tr}. The slope of the T_{tr} vs. $r^{vi}(M)$ (Fig. 31) or the T_{tr} vs. t (Fig. 32) variation is a consequence of these trends.

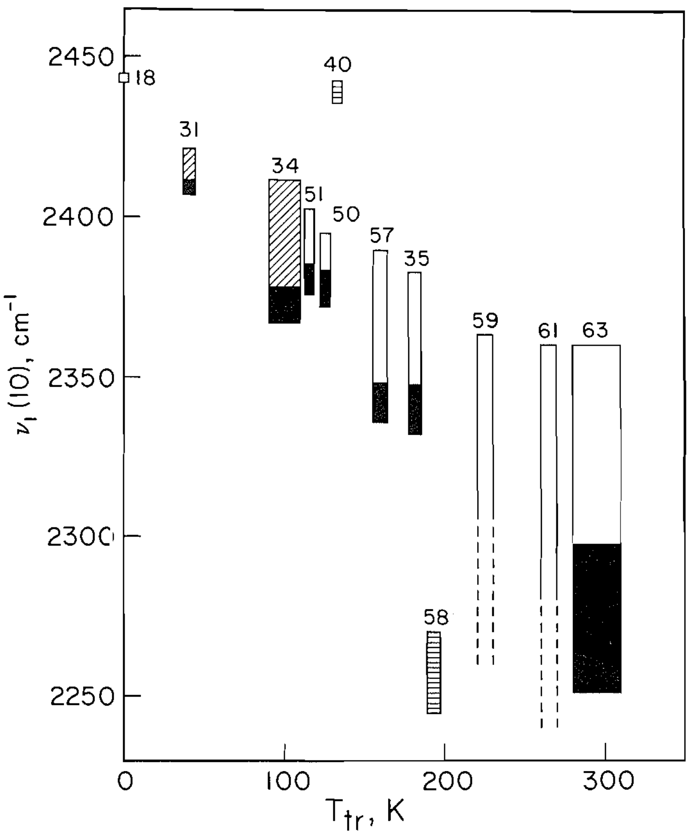

FIG. 35. Variation of the highest and the lowest ν_1 (10) component frequencies of $(NH_3D^+)^{xii}$ with T_{tr} in the perovskite-derived (open rectangles) and trigonal $(NH_4)_2MF_6$ (shaded rectangles) fluorides. The solid portion of a rectangle indicates $(\Delta\bar{\nu}_1)_{tr}$ (see caption of Fig. 34; not available for **61** and **58**; ~6 cm^{-1} for **40**).

While this rationale accounts, qualitatively, for the thermal behaviour of the above properties of the C.N.12 ammonium fluorides, it does not make clear why the large differences in T_{tr} between the ammonium and the alkali fluorides exist in the first place, i.e. what is responsible for the stability of the low phases of say K_3AlF_6 or Rb_3CrF_6 up to quite high temperatures compared with the corresponding ammonium compounds.[25] Nor does it tell us to what extent the ammonium ion is co-responsible, as a causative factor, for the occurrence of a structural transition in these compounds. It is unlikely that the marginal difference in t between Rb_3CrF_6 and K_3CrF_6, for example, would by itself produce a T_{tr} difference of 180 deg, and one has to look beyond simple packing arguments for explanations.

Acknowledgments

We thank Dr. A. Tressaud for making available unpublished results on the cryolites, and Dr. S. P. Deraniyagala for his competent assistance with the preparation of $(NH_4)_3MF_6$. This investigation was supported by a grant from the Natural Sciences and Engineering Research Council of Canada to the first-named author.

[25] The depressory effect on T_{tr} produced by replacing an alkali ion by NH_4^+ is noticeable even for the 6-coordinated sites: in the sequence $(NH_4)_2BFeF_6$ (B = Na, K, Rb, NH_4), the T_{tr} of the B = NH_4 member is unexpectedly low (Figs. 31 and 32).

Received March 21, 1985

J. ORTEGA, M. I. PAZ-ANDRADE, E. RODRIGUEZ-NUÑEZ, and E. JIMENEZ. Can. J. Chem. **63**, 3354 (1985).

The excess molar volumes, V_m^E, of 2-hexanone (MBK) with *n*-hexane, *n*-heptane, *n*-octane, *n*-nonane, *n*-decane, *n*-undecane, *n*-dodecane, and *n*-tridecane have been obtained at 298.15 K from densities measured with a vibrating tube densimeter. The V_m^E are positive over the entire composition range in all mixtures, with the exception of the MBK + *n*-hexane system, where an inversion of the sign of V_m^E is observed. In other systems, V_m^E increases with increasing size of the alkyl group in *n*-alkane.

J. ORTEGA, M. I. PAZ-ANDRADE, E. RODRIGUEZ-NUÑEZ et E. JIMENEZ. Can. J. Chem. **63**, 3354 (1985).

Opérant à 298,15 K et faisant appel aux densités mesurées à l'aide d'un densimètre à tube vibrant, on a obtenu les volumes molaires en excès, V_m^E, de l'hexanone-2 (MBC) avec le *n*-hexane, le *n*-heptane, le *n*-octane, le *n*-nonane, le *n*-décane, le *n*-undécane, le *n*-dodécane et le *n*-tridécane. Les valeurs de V_m^E sont positives dans tous les domaines de composition des mélanges, à l'exception du système MBC + *n*-hexane où l'on observe une inversion du signe de V_m^E. Dans les autres systèmes, la valeur de V_m^E augmente avec la taille du groupement alkyle des *n*-alcanes.

[Traduit par le journal]

Introduction

This paper is a study of the effect of alkane chain length on the excess volumes of binary mixtures of aliphatic ketones with *n*-alkanes (1–3). We have obtained densimetrically the value at 298.15 K of the V_m^E of eight binary mixtures of 2-hexanone (MBK) with a normal alkane C_bH_{2b+2} (b = 6 to 13). The results, together with previously published findings, suggest the possibility of specific interactions between unlike molecules.

Experimental

Component liquids

The 2-hexanone (MBK) used was supplied by Aldrich Chem. Co. with a specified purity of 99+ mol%. The eight *n*-alkanes (C_6H_{14} to $C_{13}H_{28}$) were Fluka A. G. "puriss." grade and their purity was >99.5 mol%. Both 2-hexanone and *n*-alkanes were used as received, but prior to actual measurements all liquids were dried with molecular sieve (Union Carbide Type 4A, from Fluka) and were partially degassed. The purities of the liquids were tested by measuring densities at 298.15 K. Our results agree closely with the published values (Table 1).

TABLE 1. Densities ρ of component liquids at 298.15 K

Component	ρ/(kg m^{-3}) This work	ρ/(kg m^{-3}) Literature
2-Hexanone $CH_3CO(CH_2)_3CH_3$	807.25	807.96[a]
n-Hexane C_6H_{14}	654.82	654.71[b] 654.83[c]
n-Heptane C_7H_{16}	680.13	679.46[b] 679.72[d]
n-Octane C_8H_{18}	698.42	698.62[b] 698.61[d]
n-Nonane C_9H_{20}	713.85	713.75[b] 713.94[e]
n-Decane $C_{10}H_{22}$	726.63	726.35[b] 726.11[f]
n-Undecane $C_{11}H_{24}$	736.25	736.5[b] 736.49[g]
n-Dodecane $C_{12}H_{26}$	745.32	745.18[b] 745.39[f]
n-Tridecane $C_{13}H_{28}$	752.64	752.71[b]

Determination of excess volumes

Binary mixtures were prepared by weight (6) and the probable error in the mole fraction is less than 10^{-4}. The densities, ρ, were measured with a DMA-55 digital densimeter (Anton Paar, Graz, Austria) with a reproducibility of ±0.01 kg m^{-3}. Details of the auxiliary equipment and of the operating procedure have been described previously (7, 8).

From the densities, ρ_i, and molar masses, M_i, of the pure liquids (i = 1 for MBK, 2 for *n*-alkane) and the density ρ of the mixture, the molar excess volumes are given by

$$[1]\quad V_m^E = xM_1(\rho^{-1} - \rho_1^{-1}) + (1 - x)M_2(\rho^{-1} - \rho_2^{-1})$$

where x is the mole fraction of MBK.

The results for V_m^E are estimated to be accurate to better than ±0.002 cm^3 mol^{-1} (8). The accuracy of the technique was checked by measuring the V_m^E data for the test binary mixture benzene + cyclohexane at 298.15 K and the results agree satisfactorily with the literature (6).

Results

The excess molar volumes V_m^E at 298.15 K for each of the eight binary mixtures are tabulated in Table 2 over the complete range of mole fractions x. The composition dependence of V_m^E has been calculated in accordance with the smoothing equation

$$[2] \quad V_m^E/(\mathrm{cm^3\ mol^{-1}}) = x(1-x)\sum_{i=0}^{n-1} v_i(2x-1)^i$$

where x is the mole fraction of MBK. The values of the coefficients v_i determined by the method of least squares with all points equally weighted and the standard deviations s (9) are shown in Table 3. In each case the number n of the v_i was determined by means of an F test for the validity of an additional term (10).

The experimental results for V_m^E are plotted against x in Fig. 1, together with the curves calculated in accordance with eq. [2].

Discussion

Only one of the mixtures considered here, MBK + n-heptane, appears to have been studied previously (Dusart *et al.* (2)). In general, our results for this mixture are very similar to theirs, but their V_m^E are rather higher than ours, especially $V_{m,\max}^E$ (Fig. 2); it may be pointed out that their data for the mixture MEK + n-heptane are likewise higher than those of Grolier and Benson (1).

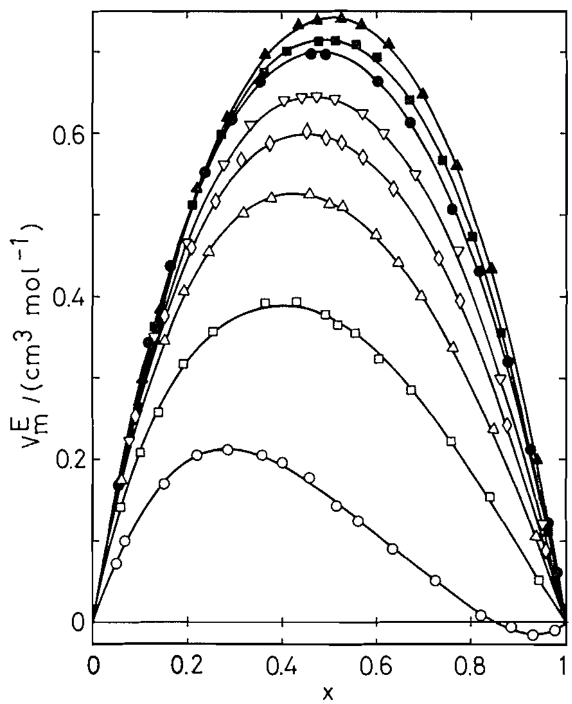

FIG. 1. Excess molar volumes, V_m^E, at 298.15 K for $\{xCH_3CO(CH_2)_3CH_3 + (1-x)C_bH_{2b+2}\}$: ○, $b = 6$; □, $b = 7$; △, $b = 8$; ◇, $b = 9$; ▽, $b = 10$; ●, $b = 11$; ■, $b = 12$; ▲, $b = 13$. The curves (—) were calculated from eq. [2] with coefficients from Table 3.

As expected, given the excess volumes (1−3) and excess enthalpies (11−14) of other 2-alkanone + n-alkane mixtures, the V_m^E are positive. This implies that the predominant effect is expansion consequent on the rupture of strong dipole−dipole interactions between ketone molecules (13). The negative values of V_m^E in the ketone-rich range of MBK + n-hexane are nevertheless indicative of important interactions between unlike molecules. The excess heat capacities, $C_{p,m}^E$ (1), and excess volumes at infinite dilution, $V_1^{E\infty}$ and $V_2^{E\infty}$ (2), show that these are probably interactions between the ketoxy group of the ketone and the alkyl group of the hydrocarbon leading to cooperative conformational arrangements such as quasi-cyclic structures (1,2).

The very steady increase in V_m^E as the size of the hydrocarbon increases suggests that with larger molecules the conformational effect is much less important. It is also interesting that the curves become more symmetrical with increasing hydrocarbon size. The V_m^E results presented in the present paper are coherent with data already published for H_m^E (11−13): for a given n-alkane mixed with different 2-alkylketones V_m^E decreases as the hydrocarbon chain of the latter lengthens (1, 2).

Formation constants for selected organo—metal (Al^{3+}, Fe^{3+})—phosphate complexes

PAUL A. ARP AND W. LENSE MEYER
Faculty of Forestry, University of New Brunswick, Fredericton, N.B., Canada E3B 6C2

Received April 11, 1985

PAUL A. ARP and W. LENSE MEYER. Can. J. Chem. **63**, 3357 (1985).

The possible formation of organo–metal–phosphate complexes (O–M–P) in aqueous solutions is examined by potentiometric titration analysis. The complex-forming solutions contain Al^{3+}-ions or Fe^{3+}-ions, organic acids (salicylic, phthalic, oxalic, and citric acids) and phosphate ions. The titrations are done within the precipitation-free pH-region from 2 to 4.5 (approximately) at 25°C under nitrogen at an ionic strength of 0.2 *M* KCl. The calibration of the electrode pair (glass-electrode, calomel-reference electrode) and the determination of the formation constants are facilitated by analyzing the pertinent curves with the ACBA-(Arena *et al.*) and MINIQUAD-(Gans *et al.*) computer programs. The results suggest (*i*) that O–M–P complexes are readily formed, and that the power of selected organic acids to form ternary mixed-ligand complexes with Al^{3+}-ions and phosphate ions decreases in the order salycilate > citrate > oxalate > phthalate. Also, Fe^{3+}-ions are found to be more strongly bound by salicylate and phosphate ions than Al^{3+}-ions. The effect of O–M–P formation on the chemical speciation of Al in buffered aqueous solutions containing mineral nutrients for the growth of biological organisms is demonstrated for a special case study.

PAUL A. ARP et W. LENSE MEYER. Can. J. Chem. **63**, 3357 (1985).

Faisant appel au titrate potentiométrique, on a étudié la formation possible de complexes organo–métal–phosphate (O–M–P) dans des solutions aqueuses. Les solutions qui forment ces complexes contiennent des ions Al^{3+} ou Fe^{3+}, des acides organiques (acides salicyclique, phtalique, oxalique ou citrique) et des ions phosphates. On a réalisé les titrates à 25°C, sous atmosphère d'azote, à une force ionique de 0,2 *M* de KCl et à des pH allant de 2 à 4,5 (approximativement) où il n'y a pas de précipitation. La calibration de la paire d'électrode (électrode de verre et électrode de référence ou calomel) et la détermination des constantes de formation sont facilitées par une analyse des courbes appropriées à l'aide des logiciels ACBA (Arena *et al.*) et MINIQUAD (Gans *et al.*). Les résultats suggèrent que les complexes O–M–P se forment facilement et que la facilité des acides organiques choisis à former des complexes ternaires comportant des ligands mixtes avec les ions Al^{3+} et phosphates diminue dans l'ordre suivant: salycilate > citrate > oxalate > phtalate. On a trouvé également que les ions salycilates et phosphates se lient plus fortement aux ions Fe^{3+} qu'aux ions Al^{3+}. Dans une étude d'un cas spécial, on a pu démontrer l'influence de la formation du complexe O–M–P sur la spéciation chimique de l'aluminium dans des solutions aqueuses tamponées contenant des sels minéraux facilitant la croissance d'organismes biologiques.

[Traduit par le journal]

Introduction

The objective of this paper is to provide information about the possible formation and the associated formation constants of various relevant and as yet poorly described chemical combinations of phosphate ions, metal ions (Fe^{3+} and Al^{3+}), and lower molecular weight organic acids (i.e. salicylic, phthalic, oxalic, and citric acid). Such combinations, in general, are likely found as mixed ligand complexes in aqueous environments with Al, Fe, phosphate, and organic substances as chemical components. The presence — or the formation — of such organo–metal–phosphate complexes (O–M–P) has many physiological and environmental implications be they related to Al^{3+}-, Fe^{3+}-, and phosphate-solubility, subsequent inter- and intra-cellular transport mechanisms for phosphate ions and metal ions, and metabolic processing of phosphate and metal ions via enzymatic substrate reactions (1). The particular organic acids examined here are also relevant in this respect because they are common metabolites, root exudates, microbial byproducts, and strong metal chelators (1).

Quantitative information about the formation constants of selected O–M–P complexes can be obtained by using an optimally adjusted potentiometric titration technique designed to eliminate chemical interferences from the complex-forming reactions, and from the electormotive force response of the electrode-pair used to trace the changing pH of the titrated solution ("titrand") following sequential "titrant" additions. The titration curves so generated can be analyzed with specialized computer programs (see below) which allow a complete and precise calibration of the electrode pair, a quantitative analysis of the organic reagents used, statistical refinement of the formation constants of the O–M–P complexes which are to be found in the titrated solutions with greatest likelihood, and the prediction of the chemical speciation of the O–M–P-containing titrand solutions as function of pH.

The following contains (*i*) a brief review of published results concerning O–M–P complexes, (*ii*) a description of the theoretical and experimental procedures to generate quantitative information about O–M–P complexation from potentiometric titration data, (*iii*) a summary of O–M–P complexes the formation of which is strongly suggested by the analysis, and (*iv*) a demonstration on how the presence of such complexes may affect the chemical speciation of, e.g., Al^{3+} in buffered aqueous solutions containing mineral nutrients for the growth of biological organisms. The subject of Al-speciation in aqueous solutions, in particular, is relevant towards understanding the toxic effects of solubilized Al on plant growth (2), aquatic organisms (see, e.g., (3)), and possible effects of Al-intake on human health (4).

The Al- and Fe-chelation effect of organic matter (e.g. humic substances) in aqueous solutions has been known for some time. The exact mechanism of organic metal-ion chelation probably involves several reactive groups such as carboxyl (—COOH), hydroxyl (—OH), carbonyl (—C=O), amine (—NH_2), and quinone (—R=O) groups (Mortensen (5)). Cheam (6), Stevenson (7), and VanDijk (8) suggest that salicylate-like groups occurring on, e.g., humic acids appear to bind Al^{3+}- and Fe^{3+}-ions by partial chemical bonding. Piccolo and Stevenson (9), in addition, demonstrate the participation of molecular OH- and COOH-groups in the humic binding of metal cations via phthalate- and salicylate-like groups.

There are few definite studies supporting the formation of ternary complexes having Al^{3+}- (or Fe^{3+}-) ions as central ions, and organic acids and phosphate ions as ligands. Levesque and Schnitzer (10), for example, conclude that actual organo–metal–phosphate (O–M–P) complexes will form in solutions containing low concentrations of reactive metal ions relative to the concentration of the metal-chelating groups normally found on, e.g., fulvic acid molecules. Metal phosphates may precipitate within the fulvic acid solution when the metal to reactive-group ratio (in equivalents) is large. Sinha (11) confirms the existence of O–M–P complexes in the soil and postulates metal-ion linkages between organic molecules and phosphate ions. In addition, it would appear from Sinha's work that phosphate bound as O–M–P complex tends (*i*) to be more mobile and water-soluble than the organic phosphate fraction of soil organic matter, and (*ii*) such a complex breaks apart in strong acid solution. Similar work by Bloom (12) has shown that phosphate ions may be either absorbed by an aluminum-peat complex or may precipitate as aluminum phosphate depending on the relative concentrations of peat and aluminum- and phosphate-ions. Quantitative analyses concerning the formation constants of O–M–P complexes via potentiometric titrations were done by Ramamoorthy and Manning (1, 13–18) with special emphasis on humic substances as organic ligands. Their results are summarized in Table 1 in terms of the notation of the following section.

Theory

The law of mass action for the general reaction

$$[1] \quad mM + n_1L1 + n_2L2 + pH \rightleftarrows M_mL1_{n_1}L2_{n_2}H_p$$

concerning ternary mixed-ligand complexation (with, say, M as metal ion, L1 as phosphate ligand, and L2 as organic ligand) is given by

$$[2] \quad \beta = \frac{[M_mL1_{n_1}L2_{n_2}H_p]}{[M]^m[L1]^{n_1}[L2]^{n_2}[H]^p}$$

with β as the formation constant for constant temperature and ionic strength of the complex-forming solution (19).

Empirical determinations of β-values via potentiometric analysis, in general, are facilitated by combining the law of mass action with the mass balance for each complex-forming component at each titration point of a complex-forming solution. For example, one may consider HA as the "complex" and A^- and H^+ as the complex-forming components for the reaction

$$[3] \quad A^- + H^+ \rightleftarrows HA$$

with

$$[4] \quad \beta = \frac{[HA]}{[H^+][A^-]}$$

The mass balance for each component leads to

$$[5] \quad H_T \equiv \text{total H-content of solution (equiv./L)} = [HA] + [H^+]$$

and

$$[6] \quad A_T \equiv \text{total A-content of solution (equiv./L)} = [HA] + [A^-]$$

The total concentrations (H_T and A_T) are generally known or can be determined from the "recipe" used to mix the complex-forming solution. Glass electrodes are particularly convenient for obtaining precise values for $[H^+]$ via the Nernst equation

$$[7] \quad E = E_0 + \frac{RT}{F} \ln \{H^+\}$$

which relates the activity of the H^+-ions in solution (i.e., $\{H^+\}$) to the electromotive force (E = emf) of the glass-electrode reference-electrode combination. The Nernst equation may then be used to obtain $[H^+]$ by noting that

$$[8] \quad E = E_0' + \frac{RT}{F} \ln [H^+]$$

with $E_0' = E_0 + (RT/F) \ln \gamma_H$ and γ_H as activity coefficient for $[H^+]$.

By summarizing, it is seen that there are five unknowns ($[H]^+$, [HA], $[A^-]$, β, and E_0') and four equations ([4] to [7]) for each titration point when $[H^+]$ is to be obtained by potentiometric analysis. This set of equations, therefore, cannot be solved by considering each titration point independently. Simultaneous examination of more than 1 titration point, in turn, leads to an overdetermined system of equations thereby enabling statistical procedures for obtaining best-fitted estimates for the parameters held in common across the various titration points (20).

At present there are several computer programs that facilitate the extraction of parametric information from potentiometric titration curves (Legett (21) and Nordstrom *et al.* (22). The ACBA-program developed by Arena *et al.* (23), for example, is particularly useful for the potentiometric examination of acids and bases (weak and strong). This program calculates the "best" acid/base formation constants and concentrations from glass-electrode emf-readings and added titrant volumes. It also refines E_0' simultaneously via nonlinear least-squares procedures.

The MINIQUAD-75 program by Gans *et al.* (24) yields best-fitted estimates from potentiometric titration data for the formation constants of complexes of the general type shown in eq. [2]. This program is also based on a nonlinear least-squares algorithm designed to minimize the deviations (residuals) between the actual and calculated concentrations of all complex-forming components present in the titrated solution in accordance with the mass balance for each such component, i.e.

$$\text{minimize} \sum_{i=1}^{n} \{[M_T](\text{calcd.})_i - [M_T](\text{actual})_i\}^2$$

$$\text{minimize} \sum_{i=1}^{n} \{[L_{j_T}](\text{calcd.})_i - [L_{j_T}](\text{actual})_i\}^2, \quad (j = 1, 2)$$

and

$$\text{minimize} \sum_{i=1}^{n} \{[H_T](\text{calcd.})_i - [H_T](\text{actual})_i\}^2$$

This is done iteratively starting from guess-estimates for each β for all the postulated complexes that may form in the solution during the course of the titration. The sum of all complexes or species considered constitutes the "refinement model". Several numerical checks throughout the iteration procedure may lead to the rejection of some or all of the postulated complexes from the refinement model. The "refined model", in turn, represents the best-fit of the actual component concentrations based on those chemical complexes or species that remain part of the refined model. The refined model, in turn, depends on the formulation of the original refinement model. Trial-and-error coupled with chemical thought, therefore, is required to yield successive model improvements until (*i*) all remaining species

are well-defined in terms of the asymptotic standard deviations associated with each β-value, and (ii) until the residuals (i.e. M_T(calcd.) − M_T(actual), L_{jT}(calcd.) − L_{jT}(actual), H_T(calcd.) − H_T(actual)] acquire a random or near random pattern about zero as function of successive titration points.

The values for the formation constants so generated may be used in conjunction with the calculation of, e.g., the chemical species distribution of aqueous solutions at given pH, temperature, ionic strength, redox potential, and imposed atmospheric conditions (e.g., total pressure and CO_2-partial pressures). This can be done with, e.g., the MINEQL computer program (Westall *et al.* (25)) which computes the concentrations (or contents) of all soluble components, soluble complexes, precipitated solids not allowed to dissolve, precipitated solids subject to dissolution, or dissolved solids subject to precipitation. In particular, the MINEQL-program contains an extensive yet readily expandable data base with an elaborate list of complexes, formation constants and solubility products. All constants (or products) are based on a temperature of $T = 25°C$ and an ionic strength of zero. All constants are recalculated with appropriate estimates for the various activity coefficients (19, 26) involved once the actual ionic strength for a given solution is specified. The input requirements of the MINEQL-program include (i) specification of the list of chemical components to be encountered (e.g., Fe, Al, H, etc.), (ii) initial estimates for the free concentrations of these components (e.g., $[Al^{3+}]$, $[Fe^{3+}]$, $[H^+]$, etc.), and (iii) the specification for all component concentrations.

Methods

Stock- and test- solutions (Table 2) were prepared with deionized water and stored (maximum 14 days) in a glove box filled with nitrogen (N_2) gas to minimize carbon dioxide contamination.

A titration cell modelled after Perrin and Sayce (27) was assembled using a flanged 200 mL Berzelius beaker and a special two-piece plexiglass seal assembly to protect the titrands from CO_2-contamination (28).

Titrant solutions were added to stirred titrand solutions with a Gilmont Precision Micrometer Buret (2.5 mL maximum capacity).

Electromotive force (emf) measurements were obtained with a glass/reference electrode pair (Orion research glass-electrode and a single-junction reference electrode Model No. 90-1) for each titration step with a precision of ±0.1 mV. The electrode pair chosen proved to be relatively free of electrode drifts with 4 N KCl as reference solution.

Titration procedures

The number of titration points and the location of these points along the pH-axis or emf-axis, in general, affects the accuracy of the titration analysis. For example, Still (29) has shown that the use of the "law of large numbers" for the determination of equivalence points and formation constants can be applied provided that each titration point carries equal weight. This diminishes the standard error of the mean by a factor of $1/\sqrt{N}$ (N = number of points). Consequently, the larger the number of observations the more confidence there is that the calculated means are good estimates of the parameters sought. About 40 to 50 equally-spaced titration points were obtained for each titration curve to comply with these observations. Furthermore, each complex-forming solution was titrated three times as a check for reproducibility.

The following solutions were tested by potentiometric titration.

(i) Solutions containing only dilute phosphoric acid (or one

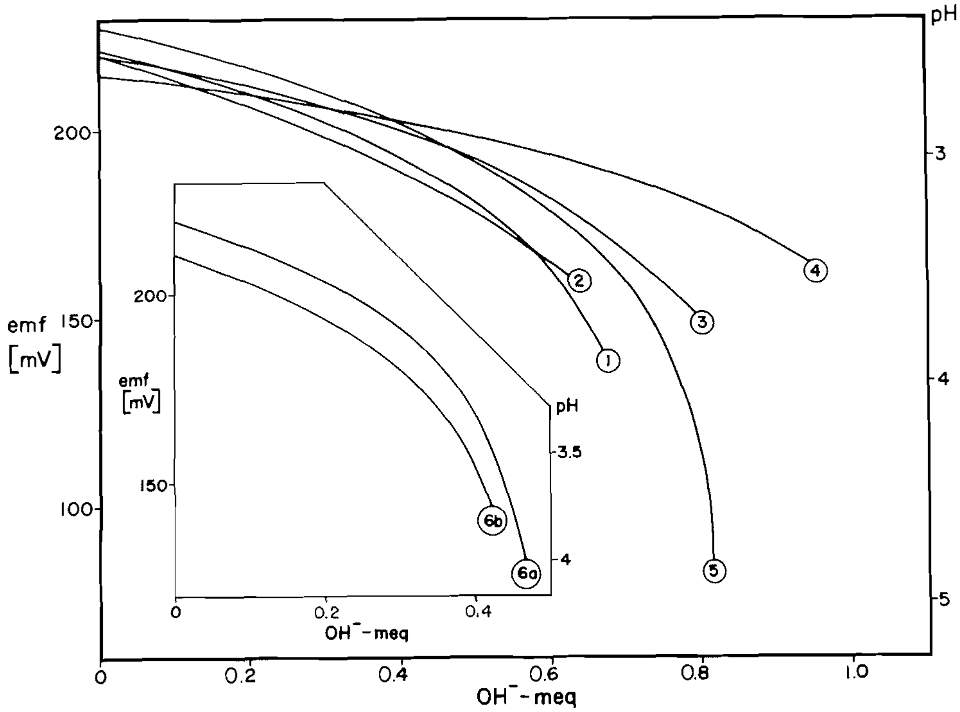

FIG. 1. Precipitation-free portions of the titration curves (emf versus mequiv. of base added) for the various complex-forming solutions in Table 2. ①: Al–Sal–PO_4, ②: Al–Pht–PO_4, ③: Al–Ox–PO_4, ④: Al–Cit–PO_4, ⑤: Fe–Sal–PO_4. The pH-scale on the right is constructed via eq. [8] with $E_0' = 370$ mV. The inset shows the titration curves for the Fe–Cit–PO_4 solutions (solution age is 3 h for (6a) and 0 for (6b).

of the organic acids listed in Table 2) were titrated and subsequently analyzed with the ACBA-program to (*a*) establish the E_0'-value in eq. [8] from time to time, and to (*b*) ascertain the precise titrand and titrant concentrations of the various stock-solutions in Table 2. The best-fitted E_0'-values so generated fluctuated drift-free between 364 and 370 mV thereby indicating that the electrode-pair employed in this study was remarkably stable for each titration and from one titration curve to another.

(*ii*) Most of the complex-forming test solution (i.e. those of Table 2) had an initial pH of $\simeq 2.5$, and were titrated with base. The resulting titration curves were subjected to analysis via the MINIQUAD program. Each titration curve was generated in the course of 2 to 3 h by adding small volume increments of titrant, one at a time. The resulting emf-response of the glass electrode as measured with a pH-meter was traced with a recorder. Digital emf-readings were taken for each volume increment once the recorder trace had stabilized. Examples of the ensuing titration curves are shown in Fig. 1 for each titration solution in Table 2.

Emf-stabilization, in general, occurred rapidly at low pH but slowed with increasing pH until complete lack of stabilization occurred on account of precipitation reactions. The first indication of such reactions terminated the titration, and only those titration points free of precipitation reactions were subjected to computer analysis. All complex-forming test solutions exhibited precipitation reactions above a certain pH-value (see Fig. 1). The Fe^{3+} solutions with oxalate and phthalate ions as ligands produced precipitation reactions soon after mixing and were, therefore, excluded from further analysis. The Fe–Cit–PO_4 solution, in contrast, remained clear initially, but yielded titration curves with increasing emf-values as function of solution age (see Fig. 1).

Results

The precipitation-free region of each titration curves for each of the stable complex-forming solutions specified in Table 2 was analyzed with the MINIQUAD program to generate information about the pH-dependent chemical species-mix for each titrated solution, and the log β-values for each ternary complex that may be present in each of these solutions in appreciable concentrations. The MINIQUAD-calculations were done in a progressive fashion starting with an initial refinement model which included all non-ternary species that may be present. The list of such species for, e.g., the Al–Ox–P mixture included Al^{3+}, $Al(OH)^{2+}$, $Al(OH)_2^+$, $AlH_2PO_4^{2+}$, HOx^-, Ox^{2-}, H_2Ox, $H_2PO_4^-$, H_3PO_4, $AlOx^+$, $Al(Ox)_2^-$, and $Al(Ox)_3^{3-}$.

All MINIQUAD-calculations based on such a list, however, led to (*i*) convergence problems, (*ii*) poor parametric estimates for the refined log β-values associated with these species, (*iii*) poor residuals for the mass-balance equations for each of the four components considered, or (*iv*) a general lack of randomness of the residual plots for each of the components as a function of successive titration points.

Adding mixed-ligand complexes of the type M–L2–L1–H with stoichiometric coefficients corresponding to 1111, 1112, or 1122 in suitable combinations strongly improved the goodness-of-fit between the MINIQUAD-calculated component concentrations and their actual counterparts as indicated in Table 3 by the "SD-values" defined as

$$SD = \left[\sum_{i=1}^{N_T} (\Delta M_i^2 + \Delta L1_i^2 + \Delta L2_i^2 + \Delta H_i^2)/DF\right]^{1/2}$$

where N_T is the number of titration points, $DF = N_T - N_\beta$ (N_β is the number of refined log β-values), and (e.g.)

$$\Delta M_i = [Al_T]_i(\text{calcd.}) - [Al_T]_i(\text{actual})$$

[a]Refinement key = 1 means that β is to be refined by MINIQUAD. Refinement key = 0 means that β is to be used to refine other formation constants in the same model.
[b]Formation constants based on ACBA-analyzed titrations or obtained from Martell and Smith (30) and adjusted for ionic strength (I = 0.2 M adjusted with KCl) using the Davies formula.
[c]Refinement key = 1 for oxalate and iron-salicylate mixtures, 0 otherwise.
[d]Average values for three separate titrations for each complex-forming solution.
[e]L1 = PO_4^{3-}; L2 = Sal, Pht, Ox, or Cit.
[f]Refers to the ± SD (residuals) across M, L1, L2, and H. Temperature = 25.0°C, titrand volume = 100.0 mL.

The general SD-range for the best-fitted models in Table 3 range from ± 5 to 10^{-7} to $\pm 4 \times 10^{-6}$ M. These values are very small when compared with the actual component concentrations ranging from 0.001 to 0.005 M for H_T, L_{jT} (j = 1, 2) and M_T (see Table 2). Other mixed-ligand species with m, n_1, n_2 = 1 or 2 and $-3 \le p \le 4$ were also added to the initial refinement list either singly or in combinations. The ensuing results, however, were in each case inferior to those already obtained with the 1111-, 1112-, and 1122-combinations. In fact, the resulting SD-values rarely fell below 10^{-5} M. Also, the "residual-plot" pattern for each component was definitely not "random" as function of successive titration points.

The admission of 1111-, 1112-, and 1122-species to the original list of nonternary species led — invariably — to the mass-balance elimination of many species considered. The final MINIQUAD models are assembled in Table 3 in terms of the remaining species for each of the precipitation-free solutions in Table 2. Also indicated in Table 3 are the log β-values which were (or were not) subject to parametric refinement (refinement key = 0 or 1, respectively). Well-established values for log β pertaining to some of the species listed, in general, were accepted as such. Their inclusion as refineable parameters, however, added chemical credibility of the final solutions when the refined log β-values were in good agreement with their well-established counterparts. For example (29),

$$\log \beta_{H_2PO_4}(\text{established}) = 18.17 \text{ vs. } \log \beta_{H_2PO_4}(\text{refined}) = 18.02 \text{ and } 18.38$$

$$\log \beta_{H_2Sal}(\text{established}) = 16.28 \text{ vs. } \log \beta_{H_2Sal}(\text{refined}) = 15.91$$

and

$$\log \beta_{H_2Pht}(\text{established}) = 7.68 \text{ vs. } \log \beta_{H_2Pht}(\text{refined}) = 7.43$$

(I = 0.2 *M* in all cases).

The species list and the corresponding values for log β in Table 3, in summary, appear to represent the best possible characterization of the chemical speciation in the complex-forming solutions as affected by potentiometric titration. The actual chemical speciation pattern in the various titrated solutions is shown in Fig. 2 as function of pH. These diagrams indicated that the O–M–P complexes Ox–Al–H_2PO_4 and Sal–Fe–HPO_4 are particularly prevalent in the pH-range from 2.5 to 4.5. Other complexes such as Ox–Al–$(H_2PO_4)_2^-$ and Cit–Al–HPO_4^- appear to be prevalent at pH > 4.5; Sal–Fe–H_2PO_4 is prevalent at pH < 2.5. O–M–P complexes such as Sal–Al–H_2PO_4 and Sal–Al–HPO_4 are also present but only in minor quantities. Other O–M–P complexes may form outside the pH range considered here, but precipitation reactions above the pH cut-off levels in Fig. 1 prevent their detection by potentiometric enquiry.

Complex-forming mixtures with Fe^{3+}, in general, appear to be sensitive to precipitation reactions in the course of time as was the case for the Fe–Ox–PO_4, Fe–Pht–PO_4, and Fe–Cit–PO_4 solutions in Table 2. The Fe–Cit–PO_4 solution, as mentioned above, was originally clear, and allowed immediate titration. In fact, the MINIQUAD analysis of the resulting curve indicated the presence of mixed-ligand complexes of the types 1111- and 1112-corresponding to log β = 26.37 and 30.32, respectively. These values, however, appeared to depend on the age of the mixture, because the other titration curve in Fig. 1 generated with a 3 h-old mixture yielded (via MINIQUAD) the same complexes but with log β = 31.87 and 35.32, respectively. It is possible that these complexes continued to exist during the ensuing precipitation reaction, and that the log β-differences were caused by slow rates of reactions or, alternatively, by time-dependent structural changes within each complex so formed.

Discussion

Comparison of formation constants

The magnitude of the formation constants decreases in the order salicylate > citrate > oxalate > phthalate for the organic acid – Al – P mixtures. This sequence is probably related to the structural changes from one type of complex to the other (i.e., five- and six-membered rings being more stable than seven-membered rings) and can be compared with the chelation sequence presented by Violante and Violante (31). These authors propose that the extent of Al^{3+}-chelation (and consequent suppression of $Al(OH)_3$-precipitation) decreases in the order citric acid > salicylic acid > oxalic acid > phthalic acid. A possible reason for the salicylate–citrate reversal between this study and that of (31) may be due to the presence (or absence) of the HPO_4^{2-}-group and subsequent steric hindrance between the phosphate ion and the large citrate-ion in the formation of OM–Al–P complexes.

Oxalic acid has the smallest physical size among the acids tested which may account for the ability of the oxalate-ions to chelate Al^{3+}-ions with two HPO_4^{2-}-ions attached. The larger size of salicylic, phthalic, and citric acids, again, may cause steric hindrance thereby reducing the number of phosphate groups per O–M–P complex to one.

Compared to Al^{3+}-ions, Fe^{3+}-ions form more stable complexes with salicylate and phosphate ions. This is probably due to differences in ionic size ($r_{Al^{3+}} = 0.53$ Å, $r_{Fe^{3+}} = 0.60$ Å) and type of electronic orbital structure available for complexation (*p*-type orbitals available for Al^{3+}, and *p*- and *d*-type orbitals available for Fe^{3+}).

The values of the individual formation constants in Tables 1 and 3 suggest that Fe^{3+}- and Al^{3+}-ions form the most stable ternary complexes with phosphate ions and organic acids among all the metal ions examined. Furthermore, Fe^{3+}-ions appear to bind citrate- and phosphate-ions slightly better than Al^{3+}-ions. The values of the formation constants of the citrate mixtures (Table 3) involving iron (or aluminum) and phosphate, however, are not as small as those presented in Table 1.

In general, there are report-based differences in assessing log β depending on which species are considered for the complex-forming components. In this paper the complex-forming components are all considered to be unprotonated (see Table 3). In contrast, some complex-forming components, as defined in other papers, carry protons, e.g. HPO_4^{2-} instead of PO_4^{3-} (see Table 1). Conversions from one log β-value to the other, however, are easily done by noting that, e.g., log β(M–Cit–PO_4–H) = log β(M–Cit–HPO_4) + log β_{HPO_4} with log β_{HPO_4} = 11.53 at *I* = 0.2 *M*.

The titration results in Table 1 for the Fe–Cit–PO_4 and Al–Cit–PO_4 mixtures when referred to mixed-ligand complexes of the type M–Cit–PO_4–H yield log β = 30.8 and log β = 31.0 for the corresponding 1111-complexes, respectively. The former log β-value compares well with the corresponding 1111-value for the 3 h-old Fe–Cit–PO_4 mixture. The difference arising for the log β-value with the Al–Cit–PO_4, in contrast, is probably due to a difference with respect to the speciation assessment of the resulting titration curves. This work generated two mixed-ligand complexes, namely a 1112-complex in addition to the 1111-complex in Table 1. In fact, the former appears to be the prevalent species within the actual titration range (see Fig. 2).

Al-speciation in a buffered nutrient solution

The possible role of O–M–P complexes in buffered solutions such as those used for growing biological organisms may be examined in terms of the chemical speciation of Al in the Ingestad-solution (32) employed for growing tree seedlings. The chemical composition of this solution is shown in Table 4 with oxalic acid as the buffering agent. Added to this solution are five levels of $Al_2(SO_4)_3.6H_2O$, and two levels of oxalic acid at 6 physiologically important pH-levels. Adjustments for each pH-level can be made by adding appropriate amounts of, e.g., 1 *M* HCl or 1 *M* NaOH. Using the specifications in Table 4 as input for the MINEQL-program yields the Al-speciation pattern illustrated in Fig. 3 for the high and low oxalic acid levels when Ox–Al–P complexes are present in accordance with the results of Table 3, and when such complexes are not considered. The following can be observed.

(*i*) Consideration of Ox–Al–P complexes significantly affects the Al-speciation as function of pH, Al-content, and oxalic acid content.

(*ii*) The postulated formation of the Ox–Al–P complexes, in general, enhances the Al- and P-solubility in the buffered solutions, particularly so at low Al-levels.

(*iii*) Ox–Al–P complexation decreases with increasing Al-concentrations on account of enhanced Al–Ox-complexation and (or) enhanced $AlPO_4$- and $Al(OH)_3$-precipitation.

(*iv*) Changes in pH from 3 to 6 favors Ox–Al–2P over Ox–Al–P formation.

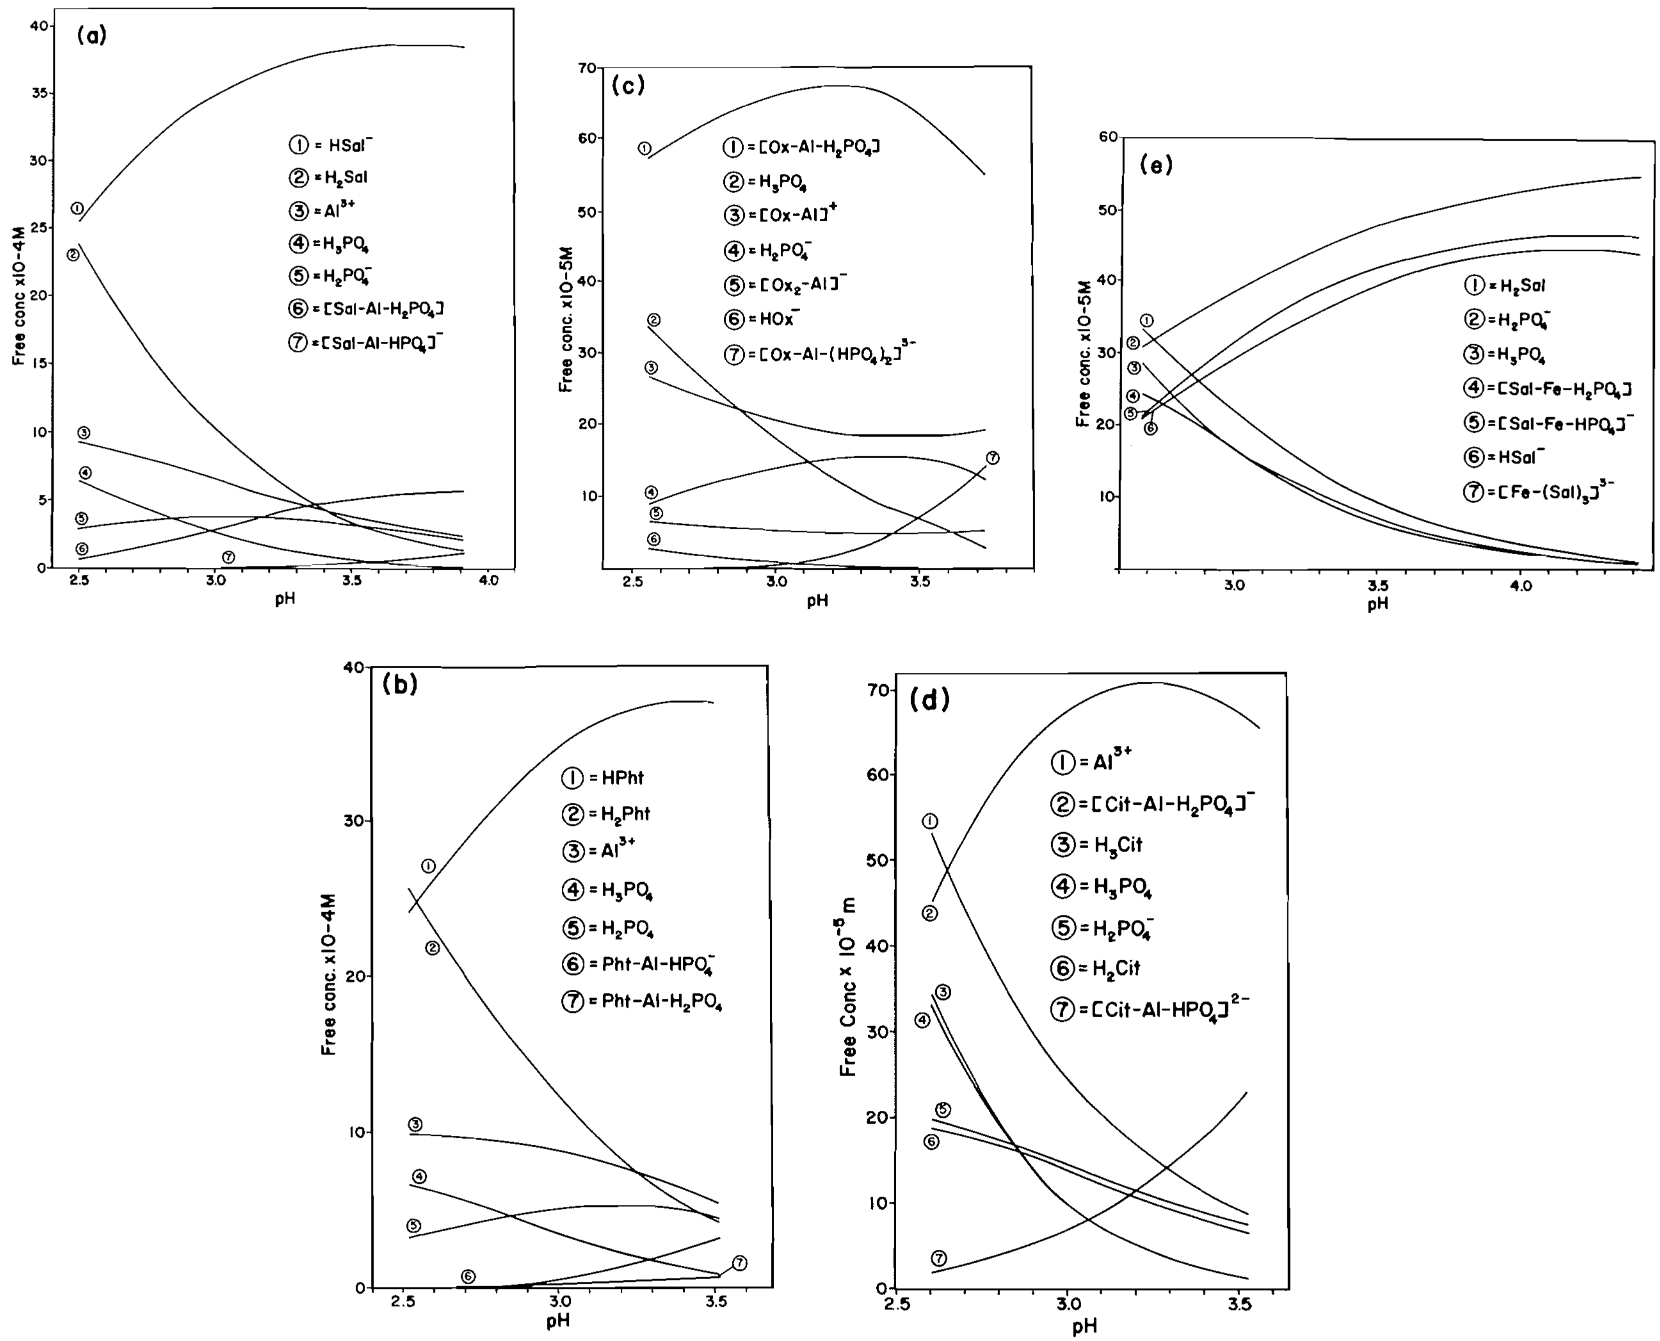

FIG. 2. Chemical speciation of the various titrand-solutions in Table 2 as function of pH. (*a*) Al–Sal–P, (*b*) Al–Pht–P, (*c*) Al–Ox–P, (*d*) Al–Cit–P, (*e*) Fe–Sal–P.

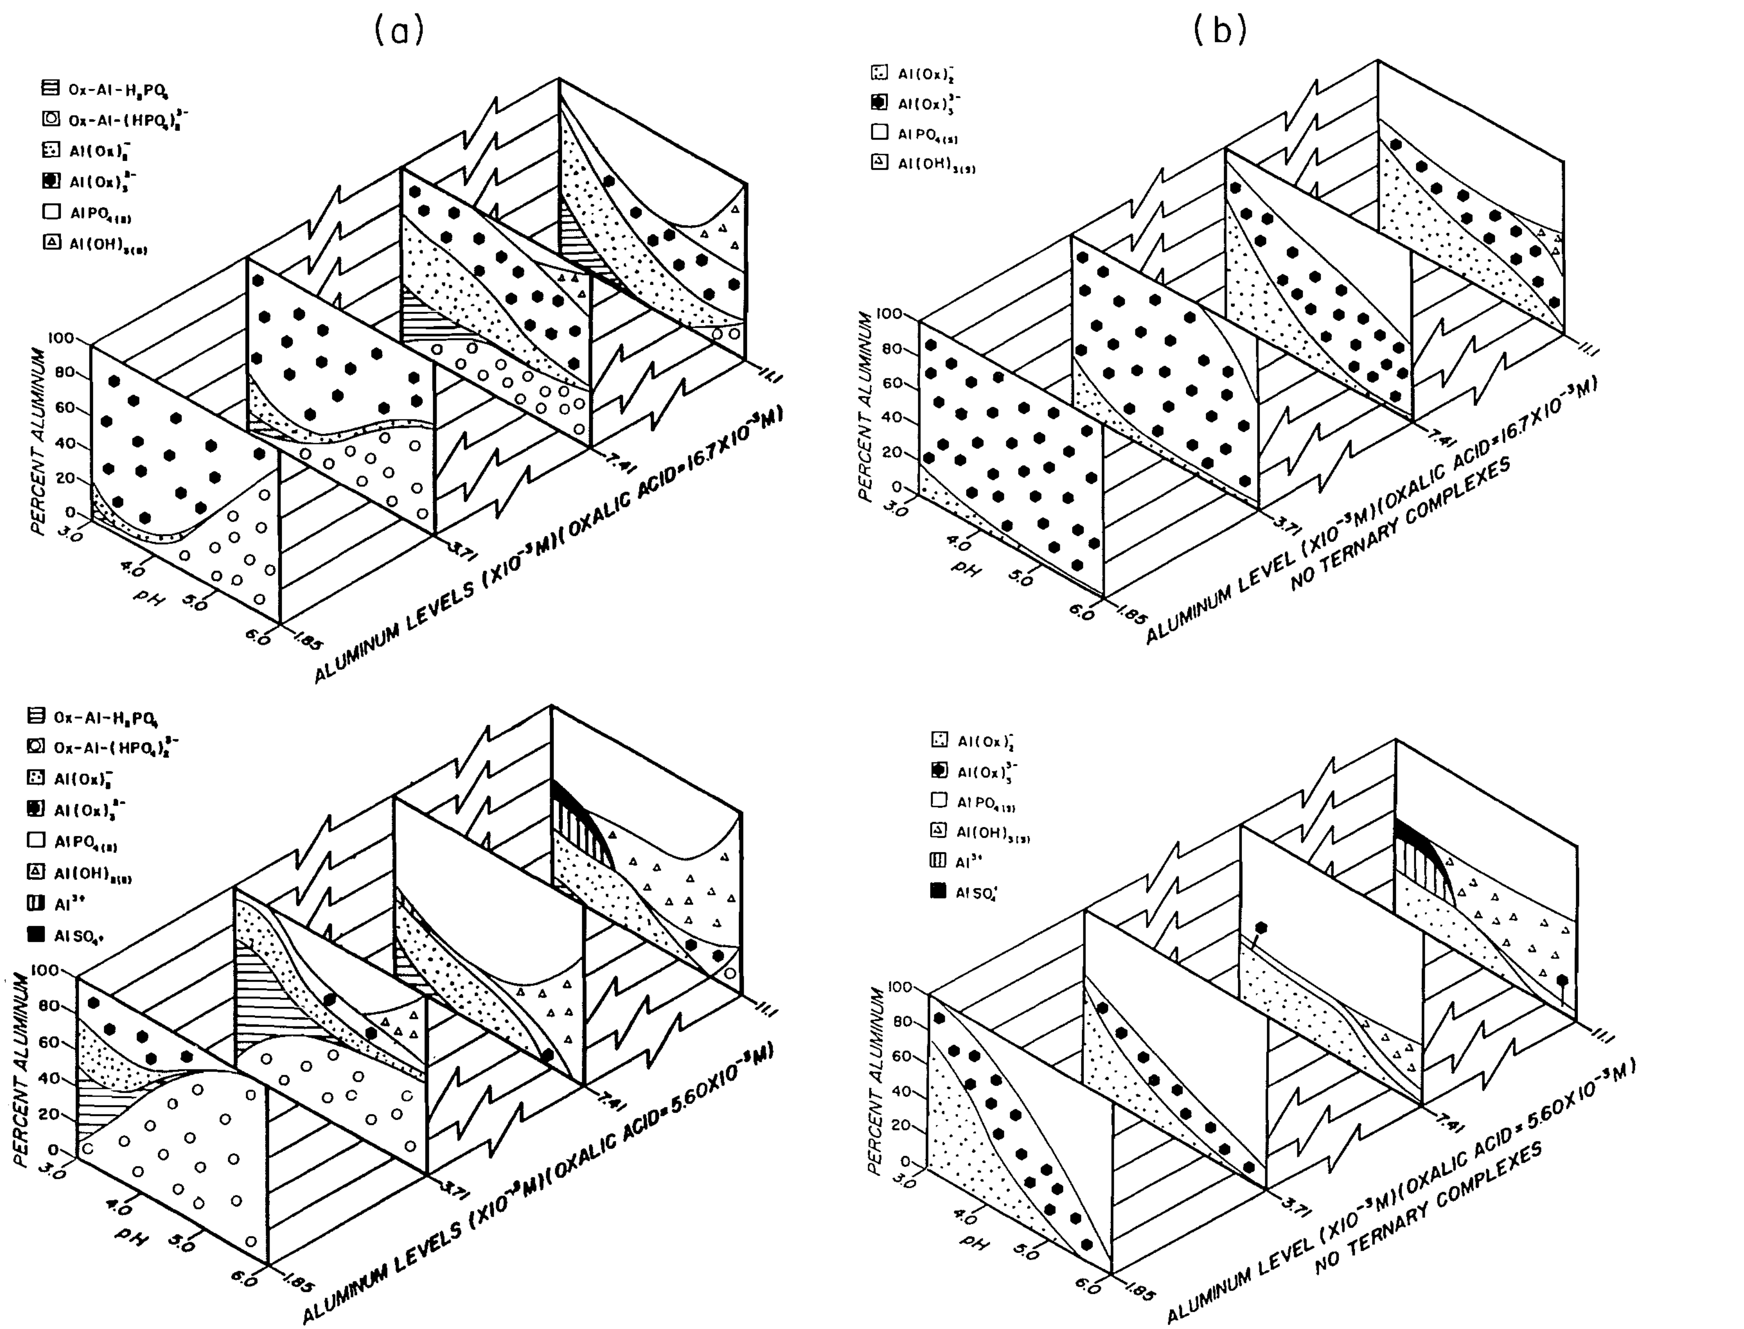

FIG. 3. Al-speciation in the buffer solutions of Table 4 as function of (*i*) pH, (*ii*) total Al- content, (*iii*) two total oxalic acid concentrations, and (*iv*) presence (*a*) or absence (*b*) of postulated Ox–Al–P complexes.

TABLE 4. Total chemical component-concentrations for the Ingestad nutrient solutions treated with 2 levels of oxalic acid, 5 levels of $Al_2(SO_4)_3$, and 6 pH-levels[a]

	Treatments		
Level	Oxalic acid (mmol/L)	Aluminum sulphate (mmol/L)	pH (adjusted with, e.g., 1 *M* HCl and 1 *M* NaOH)
1	5.6	0.00	3.0
2	16.7	1.85	3.5
3		3.71	4.0
4		7.41	4.5
5		11.10	5.0
6			6.0

[a]For all solutions: total SO_4^{2-} = 12.8 m*M*; total Ca^{2+} = 0.96 m*M*; total N = 42.84 m*M* (=$[NH_4^+]$ + $[NO_3^-]$); total Mg^{2+} = 2.10 m*M*; total PO_4^{3-} = 5.02 m*M*; total Fe^{3+} = 0.07 m*M*; total K^+ = 9.97 m*M*.

All of this suggests that O–M–P formation, in general, must be taken into account when certain growth responses of biological organisms are to be related to the chemical speciation of nutrient solutions. For example, such growth responses may be positively or negatively affected depending on the sensitivity of the growing organism with respect to, e.g., the extent of Al-solubilization, the concentration (activity) of a particular O–M-complex or O–M–P-species, or the improved availability of P and Fe due to enhanced P- and Fe-solubility.

Conclusions

The potentiometric method for extracting formation constants coupled with the ACBA and MINIQUAD data analysis proves to be a means to generate information about the chemical speciation of Al^{3+}- and Fe^{3+}-ions as affected by mixed-ligand complexation involving Al^{3+}- or Fe^{3+}-ions, phosphate ions and organic acids in aqueous solutions. This analysis indicates the presence of stable organo–metal–phosphate complexes in specifically formulated complex-forming mixtures. The magnitude of the formation constants of such complexes decreases in the order $Fe^{3+} > Al^{3+}$ and salicylate > citrate > oxalate > phthalate. Oxalic acid as a ligand yields O–M–P complexes containing two phosphate ions. The elucidation of the actual structures for the various O–M–P complexes examined in this study awaits further experimental investigations.

The potentiometric evaluations, in general, should be done repeatedly for Al^{3+}- and Fe^{3+}-complex-forming solutions of varying age to ensure that the refined log β-values are reproducible.

Hydrogen bonding of alcohols with AOT in carbon tetrachloride: an infrared study

PIERRE MÉNASSA AND CAMILLE SANDORFY
Département de Chimie, Université de Montréal, Montréal (Qué.), Canada H3C 3V1

Received April 5, 1985

PIERRE MÉNASSA and CAMILLE SANDORFY. Can. J. Chem. **63**, 3367 (1985).

The interaction of the inverted micelles of AOT (sodium di(2-ethylhexyl)sulfosuccinate) with different alcohols due to hydrogen bonding has been studied by means of infrared spectroscopy. Spectra of solutions of the alcohols with increasing concentrations of AOT showed a decrease in the intensity of the free OH stretching band. At the same time a new OH band due to a H-bonded alcohol-inverted micelle complex appears and its intensity increases as the intensity of the free band decreases. Calculated values of the equilibrium constants for the formation of the complexes *n*-alcohol–AOT, showed a decrease in alcohol–AOT association with the increase of the length of the aliphatic chains in the *n*-alcohols. Surprisingly, cholesterol behaved like a short chain while other cyclic alcohols like long chain alcohols.

PIERRE MÉNASSA et CAMILLE SANDORFY. Can. J. Chem. **63**, 3367 (1985).

L'interaction dans le tétrachlorure de carbone des micelles inverses du bis(éthyl-2-héxyl) sulfosuccinate de sodium (AOT) avec différents alcools a été étudiée par spectroscopie infrarouge. L'étude spectroscopique de différentes solutions d'alcool et d'AOT montrent une diminution de l'intensité de la bande OH libre alors que parallèllement l'intensité d'une bande associée alcool–AOT augmente. Les calculs des constantes d'association *n*-alcool–AOT indiquent une diminution du degré d'association avec la longueur de la chaîne hydrocarbure. Le cholestérol se comporte comme un alcool à chaîne courte tandis que d'autres alcools cycliques se comportent comme des alcools à chaîne longue.

Introduction

It has been known for a long time that *n*-alcohols have some anesthetic potency (1). Recently Pringle *et al.* (2) showed that this potency increases with the length of the hydrocarbon chain. However, a "cutoff" in this anesthetic effect occurs at C_{13}. The latter may still be considered as a very weak anesthetic but C_{14} has no anesthetic potency at all.

Recently Wilson *et al.* (3) in an attempt to explain this "cutoff" undertook a comparative study of H-bonding in *n*-alcohols from C_1 to C_{18}. The results they obtained could not explain this "cutoff". Instead, they showed that for the same solvent, the degree of association by hydrogen bonding of the dissolved *n*-alcohols did not depend on the length of their hydrocarbon chain. They also showed that the degree of association of esters with different alcohols was independent of their chain length. These results prompted us to start a series of experiments to ascertain whether this independence of chain length of the association of aliphatic alcohols was still true in membrane mimetic environments. Apart from the aformentioned considerations, the present study may be considered as a first step toward a more realistic approach to hydrogen bonded systems of biological importance.

Experimental

The method used was infrared spectroscopy. Since the region to be studied was the one between 4 000 and 3 000 cm^{-1}, carbon tetrachloride was chosen as a solvent. Sodium di(2-ethylhexyl)sulfosuccinate known under the commercial name of AOT was used as a detergent. This choice was dictated by the fact that its micellar parameters are fairly well established and its average aggregation number in CCl_4 (17 molecules of AOT per inverted micelle (4)) is relatively high for an inverted micelle in CCl_4. In order to compare different alcohols, association constants were calculated following a scheme described earlier (5).

The chemical AOT (Fluka, Switzerland) was purified from its residual organic and inorganic impurities according to the method described by El Seoud and da Silva (6). Traces of water were, however, found in the ir spectrum of dried AOT. Some authors questioned the feasability of inverted micelles without traces of water (7). Most of the alcohols (Aldrich Chemical Co. and Sigma Chemical Co.) were stated to be 99% pure or more. Nonanol 97% was distilled under vacuum and its purity confirmed by gc ms. *trans*-Decahydro-2-naphtol was a gift of International Flavour and Flagrance Inc. Spectroscopic grade carbon tetrachloride (American Chemicals Ltd.) was used without further purification. Its ir spectrum, recorded in a 5 mm cell, did not show any water or other impurity bands.

Spectra were recorded at room temperature on a Perkin Elmer model 521 spectrometer using 5 mm infrasil cells (Hellma Limited), and on a Nicolet 6000 F.T.I.R. instrument using 0.120 or 0.510 mm sodium chloride cells (Wilmad Glass Co Inc.). The spectra presented here have been recorded on the latter. Solvent and AOT absorption were compensated for on the Perkin-Elmer and were subtracted on the Nicolet F.T.I.R. instrument.

Results and discussion

n-*Alcohols*

All *n*-alcohols studied behaved the same way and presented the same spectral characteristics. The figures depicted in this work are those of n-hexanol. The dashed lines in Fig. 1 represent a part of the ir spectrum of a 0.2 *M* solution of hexanol in CCl_4. The band at 3639 cm^{-1} represents the non-bonded free OH stretching vibration. The shoulder at ca. 3498 cm^{-1} is that of the self-associated dimers H—O: . . . H—O and the broad band centered at about 3346 cm^{-1} is due to the self associated multimers. The solid line in Fig. 1 represents a part of the infrared spectrum of a mixture of alcohol (0.2 *M*) and AOT (0.02 *M*) in CCl_4. There is a decrease in the intensities of both the free and multimer bands. Note, however, that this last band shifted slightly toward higher frequencies indicating the presence of another band. It is clear from this figure that AOT dissociates a part of the H-bonded multimers and is associating with the free OH. Next a solution of 0.4 *M* of AOT and 0.2 *M* of alcohol in CCl_4 was prepared. A part of its ir spectrum is represented by the solid line of Fig. 2. There is a sharp decrease in the monomer band while the multimer band disappears almost completely. A new band located at ca. 3417 cm^{-1} is now present in the spectrum. Since the absorption due to AOT has been subtracted and since this new band appears only when AOT is added to the alcohol, it can only be attributed to the formation of a complex AOT . . . OH. The dimeric species are still seen around 3498 cm^{-1}. The broken line represents the spectrum of a solution of 0.20 *M* of alcohol in CCl_4.

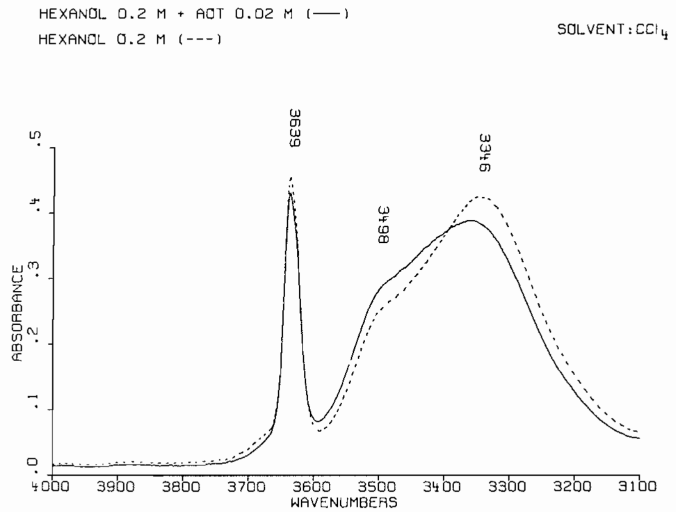

FIG. 1. Part of the infrared spectrum of (- - -) hexanol (0.2 M) and of (—) a solution of hexanol (0.2 M) and AOT (0.02 M) in CCl_4.

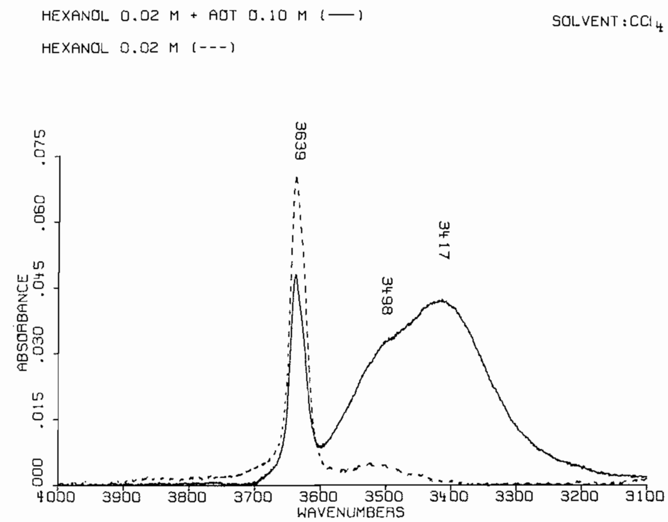

FIG. 3. Part of the infrared spectrum of 0.02 M of hexanol in CCl_4 (- - -) and a mixture of hexanol (0.02 M) and AOT (0.10 M) in CCl_4 (—).

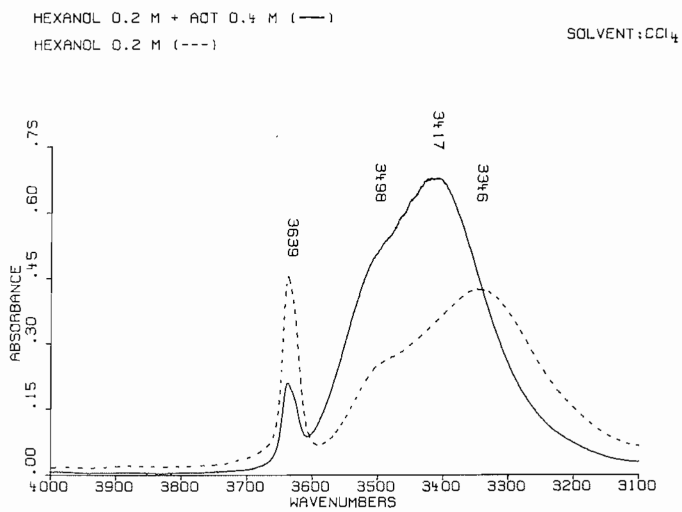

FIG. 2. Part of the infrared spectrum of (- - -) hexanol (0.2 M) and of (—) a solution containing AOT (0.4 M) and hexanol (0.2 M) in CCl_4.

TABLE 1. Formation constants, K (L mol^{-1}), of hydrogen bonded complexes between different aliphatic alcohols and AOT

n-Alcohol	Association constant K (L mol^{-1})
C_1	18.0 ± 0.7
C_3	11.0 ± 0.5
C_6	7.0 ± 0.6
C_7	9.0 ± 0.6
C_9	7.0 ± 0.3
C_{11}	6.0 ± 0.4
C_{14}	5.0 ± 0.6
C_{16}	6.0 ± 0.3

Dilute solutions of alcohols in carbon tetrachloride were then used to calculate the association constants of the complexes formed. These solutions have the advantage of containing almost exclusively monomeric species. The added AOT would have no other choice but to form a complex with the free alcohol (i.e., there is no breaking of multimers that may complicate the equilibrium). This is illustrated by Fig. 3 where the dashed line is a part of the ir spectrum of a solution of 0.02 M of hexanol in carbon tetrachloride. The intensity of the free OH band is by far stronger than that of any other band confirming that the alcohol is present almost entirely as a monomer. Adding AOT resulted in a decrease of the free band and the appearance of the 3417 cm^{-1} band. A small shoulder at ca. 3498 cm^{-1} due to the self associated dimer is also present as shown by the solid line spectrum of Fig. 3. The association constants of different alcohols were calculated by considering solutions formed from a mixture of 0.02 M of alcohol and different amounts of AOT (0.005 M to 0.150 M). The results are listed in Table 1. It is clear from this table that the association alcohol–AOT decreases with the increase of the length of the aliphatic chain of n-alcohols. This is further illustrated in Fig. 4. To understand the reason of this decrease we undertook a study of the carbonyl and sulfonate regions of the detergent. The region depicted by Fig. 5 is that of the carbonyl stretching frequency. The solid line spectrum is that of a solution of 0.010 M of AOT in CCl_4 while the broken line spectrum represents that of a mixture, in carbon tetrachloride, of 0.010 M of AOT and 0.90 M of hexanol. The intensity of the carbonyl band decreased with the addition of the alcohol. However, no shift in the band position towards lower frequencies was observed. This shift usually characterizes the C═O: . . . H—O bond. Therefore, there is no evidence that C═O groups associate with the OH of the alcohol. Figure 6 shows the asymmetric stretching vibrational region of the sulfonate group. Here again the solid line spectrum represents a solution of 0.010 M of AOT in CCl_4 while the dashed line spectrum is that of a mixture of 0.010 M of AOT and 0.90 M of hexanol in CCl_4. With the addition of hexanol, the asymmetric stretching vibration of the sulfonate located at 1250 cm^{-1} decreased in intensity and shifted to 1242 cm^{-1}. This shift and decrease in intensity of the free sulfonate band is attributable to hydrogen bonding between the sulfonate group of AOT and the hydroxyl group of the alcohol. This seems to indicate that hydrogen bonding between AOT and alcohols occurs via the sulfonate group. The latter is located deep inside the inverted micelle and is responsible for holding it together by dipole interactions (8). It seems then

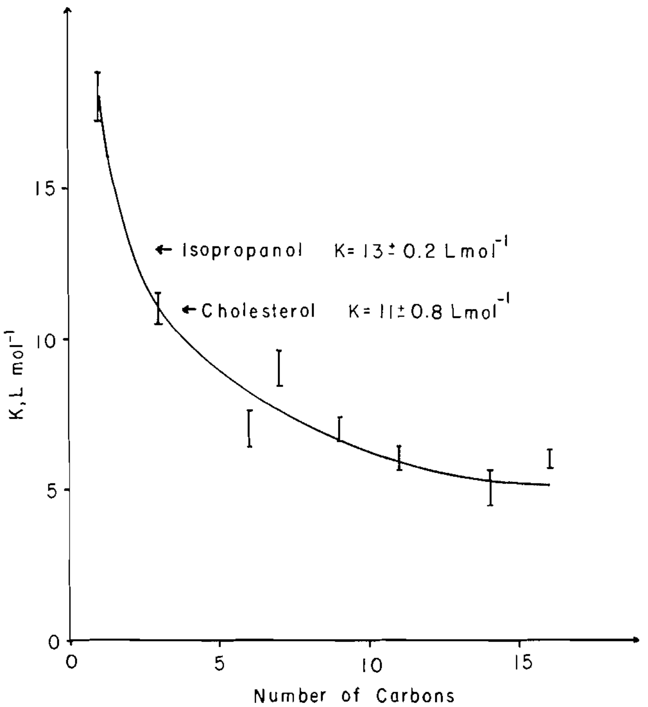

FIG. 4. Formation constants, K (L mol^{-1}), of hydrogen bonded complexes (alcohol–AOT) as a function of the number of carbons present in the aliphatic chain of the n-alcohols. The formation constants for isopropanol and cholesterol are also shown.

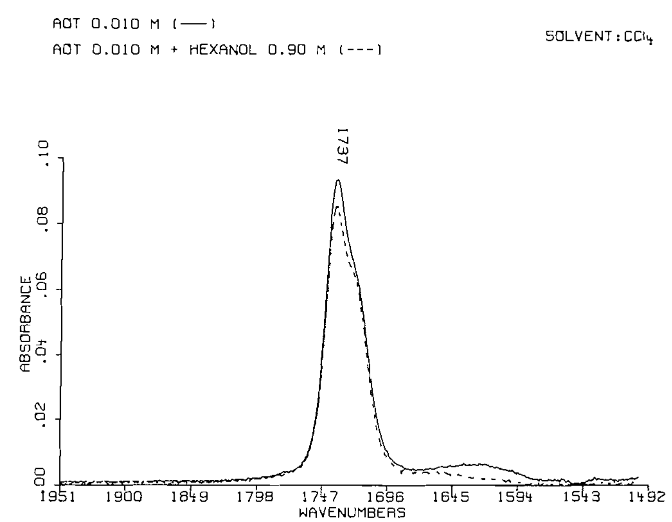

FIG. 5. Part of the infared spectrum of 0.01 M AOT (—) and a mixture of 0.01 M AOT and 0.90 M hexanol (- - -) in CCl_4.

logical that in order to reach the SO_3^- group, the OH of the alcohol must penetrate the micellar core. Thus, it appears that the longer the alcohol's paraffinic chain is, the harder it is to reach the sulfonate group and the smaller is the association constant. The association constants level off at ca. K = 6 L mol^{-1} for C ≥ 10. This shows that only a certain part of the alcohol chain is affected by the micellar core. This part can be roughly approximated by the length of a chain of 10 carbons, about 13 Å. According to the chemical structure of AOT (9), the linear length of the molecule is 12 Å. The part of the aliphatic chain laying beyond the length of an AOT molecule cannot affect the association constants since it can move freely and does not interact with the micellar tail. The association

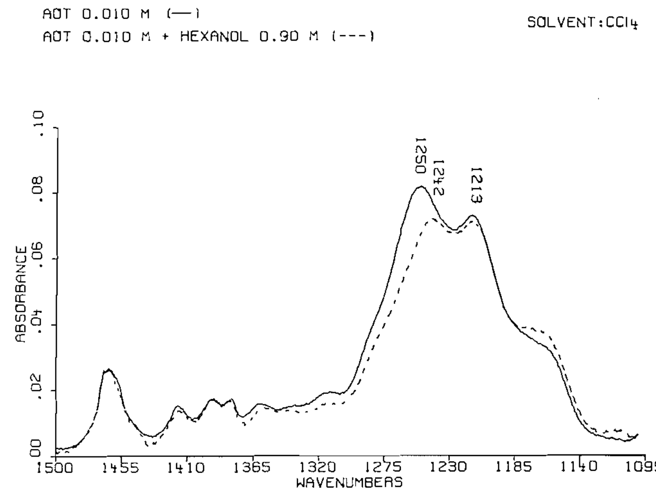

FIG. 6. Part of the infrared spectrum of (—) AOT (0.01 M) and (- - -) a solution containing AOT (0.01 M) and hexanol (0.90 M) in CCl_4.

constant of a long and branched alcohol should also be small since its OH group can hardly reach the inside of the inverted micelle. Furthermore, K of a short, branched alcohol should be large since its OH group can easily reach the inside of the inverted micelle. Moreover, the association constant of water and AOT should be extremely high since the water molecule is very small, polar and is located in the inside of the inverted micelle. The branched alcohols studied were 4-decanol and isopropanol. For isopropanol the free OH band was located at 3620 cm^{-1} and that of the OH-bonded OH . . . AOT band at ca. 3390 cm^{-1}. Although the positions of these bands are different from the respective bands of n-alcohols, upon addition of AOT the branched alcohols behaved the same way as the n-alcohols did (i.e., a decrease in the free OH band and a concomitant increase in the OH . . . AOT band). Their association constants were then calculated. As expected K of isopropanol was found to be relatively large, K = 13.0 ± 0.2 L mol^{-1} (K = 11.0 ± 0.5 L mol^{-1} for propanol), and that of 4-decanol very small, K = 2.0 ± 0.2 L mol^{-1}. The association constant of water and AOT was also calculated. Solubility considerations dictated the use of $CDCl_3$, a slightly polar solvent. The association constant of water and AOT in deuterated chloroform was found to be, as expected, extremely high, K = 57.0 ± 10.0 L mol^{-1}.

The addition of a fourth component to a three component system can alter the phase diagram of the latter (10). It is known that in the presence of small amounts of water, AOT in carbon tetrachloride forms inverted micelles. It is not known, however, to what extent these inverted micelles are affected by the presence of small amounts of cosurfactants (like alcohols). Four component systems formed of hydrocarbons, pentanol, water, and surfactants were studied by Sjöblom *et al.* (11). They showed that reversed micellar solutions were encountered only for quite high concentrations of hydrocarbons. The system we studied did not contain hydrocarbons but carbon tetrachloride which, like hydrocarbons, is an apolar solvent. In view of the results of Sjöblom *et al.* we do not have any reason to suspect major changes in the micellar form and parameters of AOT in carbon tetrachloride to which 0.02 mol of alcohol was added. Furthermore, all our experimental evidence seems to indicate the presence of inverted micelles. Therefore we feel that, in this work, the use of the words "inverted micelles" is justified.

TABLE 2. Formation constants, K (L mol^{-1}), of hydrogen bonded complexes between cyclic or branched alcohols and AOT

Alcohol	Association constant K (L mol^{-1})
Isopropanol	13.0 ± 0.2
4-Decanol	2.0 ± 0.2
Cholesterol	11.0 ± 0.8
Cyclohexylmethanol	7.0 ± 0.3
Cyclohexanol	7.0 ± 0.3
trans-Decahydro-2-naphtol	7.0 ± 0.4

Cholesterol and other cyclic alcohols

It has been recognized that excess serum cholesterol can lead to atherosclerosis (12). The latter is considered by medical authorities as a major risk factor in heart diseases. Thus the understanding of cholesterol's behaviour in membranes is important for the understanding of the way in which it interacts with the arterial wall. Parker and Bashkar (13) showed that cholesterol, like any other alcohol, self associates through hydrogen bonds. They have also shown (14) that 26-hydroxycholesterol associates with triglycerides and that this might initiate the formation of plaques causing atherosclerosis. Mercier *et al.* (15) have studied the H-bonds formed between cholesterol and ester or amide carbonyls and the way in which they are affected by various H-bond breakers. The molecule of cholesterol is known to be a planar molecule with a length of 19 Å (16). Thus according to the scheme described earlier, cholesterol should behave like a long chain alcohol with a relatively small association constant. This was not found to be the case. The association constant of cholesterol and AOT was found to be equal to $K = 11.0 \pm 0.8$ L mol^{-1}. This shows that, despite its bulky hydrocarbon radical, cholesterol behaved like a small chain alcohol (propanol). Nonetheless, a series of experiments were conducted on cyclic alcohols to see whether this "peculiar" behaviour of cholesterol is due to the interaction of the cyclic hydrocarbon radical with the inverted micelles. The cyclic alcohols studied were *trans*-decahydro-2-naphtol, cyclohexyl methanol, and cyclohexanol. The free OH band of these alochols was found between 3620 and 3640 cm^{-1} and that of the H-bonded OH . . . AOT around 3390 cm^{-1}. Their association constants with AOT were calculated. They were found equal to $K = 7.0 \pm 0.4$ L mol^{-1}, $K = 7.0 \pm 0.3$ L mol^{-1}, and $K = 7.0 \pm 0.3$ L mol^{-1} for *trans*-decahydro-2-naphtol, cyclohexyl methanol, and cyclohexanol, respectively, while as stated above, that of cholesterol is 11.0 ± 0.8 L mol^{-1}. The results are summarized in Table 2. These results are in line with the model described earlier. It clearly shows that the behaviour of cholesterol is not due to the interaction of the cycles with AOT. Fuller explanation of this behaviour will have to await further experimental work.

Conclusions

It has been shown that aliphatic alcohols and AOT form complexes in carbon tetrachloride. The degree of association of these alcohols with AOT was shown to decrease as the length of the aliphatic hydrocarbon chain increases. The association constant is probably related to the ability of the hydroxyl group of the alcohol to penetrate the inside of the inverted micelle and to bond with the sulfonate group. This was further confirmed by showing that the long branched alcohol 4-decanol has a small association constant while the association constant of the short branched alcohol isopropanol was found to be large. Cholesterol in spite of its bulky hydrocarbon radical behaved like a small chain alcohol. A study of cyclic alcohols showed that this strong association of cholesterol with AOT was not due to the interaction of the hydrocarbon cycle and AOT.

Procedures have been developed for the preparation, at levels of label which exceed 90%, of ring-deuterated diphenylamines (DPAs) with the label at specific ring positions. The compounds so prepared are DPA-d_{10}, DPA-2,4,6,2′,4′,6′-d_6, DPA-2,6,2′,6′-d_4, and DPA-4,4′-d_2.

WESLEY A. DOAK, CHARLES KNESSL, HENRYK LABAZIEWICZ, SALLY E. O'CONNOR, LIVIU PUP, GERARD PUTZ, MARIJO SCHRANZ, ROBERT I. WALTER, LING YANG et NICK H. WERSTIUK. Can. J. Chem. **63**, 3371 (1985).

On a développé des méthodes qui permettent de préparer des diphénylamines (DPA) marquées dans des positions spécifiques des cycles et à des niveaux de marquage qui dépassent les 90%. On a ainsi préparé les DPA-d_{10}, DPA-d_6-2,4,6,2′,4′,6′, DPA-d_4-2,6,2′,6′ et DPA-d_2-4,4′.

[Traduit par le journal]

Introduction

Only a limited number of deuterium-labelled diphenylamines (DPAs) have been described. Neugebauer and Bamberger (1) prepared DPA-d_{10} (here and subsequently we consider only deuterium on aromatic carbon, and ignore possible deuteration on the nitrogen atom, since that rapidly back exchanges in protic solvents) by synthesis from bromobenzene-d_5 and acetanilide-d_5. They subsequently converted this substance to DPA-3,5,3′,5′-d_4 by back exchange in refluxing acidified ethanol. We give here the preparations of DPAs specifically deuterated at other sets of structurally equivalent positions in the molecule. These labelled DPAs were subsequently converted to labelled 1-picryl-2,2-diphenylhydrazyl free radicals in which the labels served to identify the nmr or ENDOR (electron-nuclear double resonance) signals from various positions in this radical (2). With the modified methods described here, it is now possible to prepare even more fully labelled samples than were available for those studies.

A number of potential routes for the substitution of deuterium at specific sites were unsatisfactory in our hands. Lithiation of 4,4′-dibromodiphenylmethylamine, followed by quenching with deuterium oxide, was used by Shatenshtein *et al.* (3) to prepare the 4,4′-d_2 label on their tertiary amine. The reaction is unsuccessful with the secondary amine; the major product with a 3:1 mole ratio of butyllithium to amine probably is *N*-butyldiphenylamine (the mass spectrum (ms) gives the molecular ion at mass 225), formed by displacement of halogen from butyl bromide by the nucleophilic amide that is produced by the lithiation. The reduction of 4,4′-dihalodiphenylamines with lithium aluminum deuteride (4) is unsatisfactory because this expensive reagent is used so inefficiently: only the reaction of the first deuteride is fast, and later transfers are successively slower. Consequently it is necessary to use at least a fourfold excess of the reducing agent, even when the halogen is iodine. It is also necessary to quench the intermediate with excess deuterium oxide to avoid incorporation of protons when water is subsequently added to the reaction mixture. The procedure is viable: we used it for our first successful preparations of DPA-4,4′-d_2 and DPA-2,6,2′,6′-d_4.

We were slow to try hydrogenolysis (deuterolysis) of the aryl halide because representative procedures[4] specify excessively large amounts of the catalyst. When we did so, we found that reduction of halogen-substituted DPAs in alkaline ethanol over palladium on charcoal catalyst is fast and complete; this is our procedure of choice. Furthermore, brominated DPAs are superior to iodinated DPAs (which reduce substantially faster) whenever acid-catalyzed deuterium exchange is required, because the brominated compounds are distinctly more stable under the conditions of the exchange reaction.

Experimental

Ethanol-*d* was prepared by the method of Pasto and Meyer (6) from ethyl orthosilicate and deuterium oxide; the level of label was ca. 99%. This reaction is superior to that of Grieve and Sporek (7), which invariably gives an oily impurity that we have been unable to separate from the product. In all cases, ethanol-*d* was conserved by carrying out acid-catalyzed deuterium exchange in 3–5 stages with successively higher levels of label in the alcohol.

DPA and its labelled derivatives were purified by Soxhlet extraction into pentane, and (or) by sublimation at 45°C. With careful drying, these procedures give product DPAs which melt over 0.5–1° in the range 53–54.5°C. When sublimation is used, it is essential to remove residual acid from the amine by pouring an acetone solution into ice–bicarbonate solution. Sublimation with residual acid present gives poor recoveries and leaves a gummy residue that no longer melts at 53–55°C and is nearly insoluble in acetone and other solvents.

Levels of label in the products were checked by ms (Hewlett–Packard 5985A). Unfortunately, the ms of DPA (8) has no value because the very prominent $(M - 1)^+$ and $(M - 2)^+$ and weaker $(M$

[3] Revision received July 3, 1985.

[4] For example, 0.2 g halogen compound with 1 g palladium on calcium carbonate catalyst (5*a*) or 1 g catalyst with 0.5 g 7α-bromopregnenolone acetate (5*b*).

$- 3)^+$ peaks coincide with the molecular ions that arise from the most important incompletely deuterated species, and the relative intensities of these peaks vary significantly in ms runs at different times. Consequently, the quantitative determination of total label is impossible by this method, and the mass of the molecular ion M^+ is used only to confirm that the expected number of labelled positions has been reached in the major labelled product.

Positions of the labels were routinely monitored during exchange by both proton and deuterium nmr; the results obtained with the two nuclei are consistent. The proton-decoupled deuterium spectra consist of intense, somewhat broad (1–3 Hz at half-height) lines at the chemical shifts expected for the labelled sites. None of these lines display visible satellites due to introduction of label at other positions than those expected; in particular, there is no evidence for acid-catalyzed exchange in ethanol-*d* at the *meta* positions.

The 60-MHz aromatic proton spectra cannot be interpreted quantitatively; they are far from first order, and some lines are seriously broadened by unresolved structure due to coupling with other ring protons, and by the quadrupole moment of deuterium label. Better results can be obtained at 200 MHz (Bruker WP-200 SY). At this frequency, the *ortho*, *meta*, and *para* ring protons have sufficiently different chemical shifts (see discussion of DPA-d_{10}) that it is probably safe to assign all of the lines in the DPA spectrum. Duplicate spectra show scatter in the quantitative integral values from the Bruker integration routine over a range up to 7%. It is customary to assign an error of ±5% for such data (9); we believe our error may be larger. Values were confirmed by cutting out and weighing the plotted peaks; the scatter in these values was up to 10%. In these determinations, the *meta* peak was taken as an internal reference for the area due to four hydrogen atoms; this of course requires the assumption that no deuterium exchange occurs at these positions. The estimated rate ratio for electrophilic substitution at positions activated by a secondary aromatic amino group would be *ortho–para/meta* $\geq 10^6$, and this is confirmed by the absence of evidence for *meta* substitution in the deuterium nmr spectra. Our spectra were obtained with 0.10 *M* samples in DMSO-d_6 solution. The relaxation delay was set at 30 s, since our measured T_1 for the protons in DPA in DMSO solution is about 7 s. The center line of the solvent residual proton pattern was set at 2.49 ppm to establish the chemical shift scale.

Diphenylamine-d_{10}

Werstiuk's exchange procedure (10) was used to prepare this compound. DPA (17 g) and 0.5 *M* deuterium chloride in deuterium oxide (100 mL) is degassed by successive freeze–pump–thaw cycles, sealed, and heated for 30 h at 250°C. After cooling, the yellowish pellet of amine is taken up in hexane and washed with dilute potassium hydroxide solution and with water. Evaporation of the hexane gives solid, which is purified by sublimation to give 12.2 g of product; nmr indicates about 85% deuteration. A second exchange under the same conditions gives 7.4 g of sublimed product. The nmr shows weak lines due to uncoupled residual protons at 6.80 (*para*), 7.05 (*ortho*), and 7.21 ppm (*meta*) in DMSO solution. In this case, the *meta* peak is not available as an internal intensity standard; instead, the residual proton peak intensities are compared with the (possibly unreliable) N—H peak. By this standard, there are 1% residual protons at the *meta* and *para* positions, and 2% at the *ortho* positions. The mass spectrum gives the molecular ion at 179 Da (daltons). Acidification of the alkaline extracts of the crude product precipitates deuterated phenol.

Diphenylamine-2,4,6,2′,4′,6′-d_6

DPA (17 g) is refluxed for 6 h with 200 mL of ethanol-*d* which contains 0.2 *M* deuterium sulfate. (The mobile solvent deuterium is close to equilibrium with the exchangeable *ortho*, *para*, and amine H/D pool under these conditions. If 99% ethanol-*d* and D_2SO_4 are used at each stage, two exchanges to equilibrium under the conditions described would give 96% label with back exchange of the amino position assumed during work-up. However, we always used recovered ethanol-*d* at label levels in the range 75–90% for the first exchange steps, and fresh ethanol-*d* only for the last. Under these conditions, 3 or 4 exchange steps may be required to reach label levels of 95%.) After the exchange under reflux, 6 g of anhydrous Na_2CO_3 is stirred into the cold solution, the Na_2SO_4 filtered off, and solvent removed by vacuum distillation. The residue is partitioned between methylene chloride and water, the organic layer washed again, dried with anhydrous Na_2SO_4, and the solvent recovered under vacuum. The labelled product is purified by sublimation and recovered in over 90% yield. Proton nmr at 200 MHz gives line areas which show 8% residual protons at the *ortho* positions, and 4% protons at the *para* positions. These areas are measured relative to that for the *meta* proton lines; exchange is assumed to be negligible at the *meta* positions. The calculated equilibrium level is 5% residual protons after successive exchanges in 75, 90, and 99% ethanol-*d*. The mass spectrum gives the molecular ion at 175 Da.

4,4′-Dibromodiphenylamine

Three procedures for this straightforward-appearing preparation were investigated; they are listed here together with the overall yield for each. (*i*). Direct bromination of diphenylamine with bromine in acetic acid (11), 29%. (*ii*). Direct bromination with 2,4,4,6-tetrabromo-2,5-cyclohexadienone (12), 51%. (*iii*). Bromination of *N*-benzoyldiphenylamine, followed by saponification in 10% ethanolic KOH (13), 46%. The low yield in method (*i*) is due to the many (6 or 7) recrystallizations required to obtain pure product. Of the latter two methods, (*ii*) is probably better for small-scale (up to 10 g) synthesis; it would require excessive amounts of solvents on a large scale. On a mole scale, (*iii*) is best because it requires less solvent, even though there are three steps from diphenylamine. The product is pure by tlc on silica developed with cyclohexane/acetic acid (85 : 15% by volume); mp 106–107°C.

Diphenylamine-2,6,2′,6′-d_4

Much more drastic conditions are required for a reasonable exchange rate with the brominated DPA than with DPA itself. 4,4′-Dibromodiphenylamine (0.15 mol) in 225 mL of 1.7 *M* deuterium sulfate in ethanol-*d* is refluxed for 50 h, most of the solvent removed by vacuum distillation, and the liquid residue stirred into ice. The solids are then filtered, washed, and dried. After three such exchange steps the very dark and somewhat gummy residue is dissolved in methylene choride, stirred with activated silica, and the solids (which carry all of the colored impurities) filtered off. The amine can be recovered and recrystallized from heptane; the yield is 65%. Residual protons in the *ortho* positions are 6% by nmr; the calculated value after successive equilibrations with 86, 95, and 99% ethanol-*d* is 5%.

This solid is dissolved in 300 mL of 1.3 *M* ethanolic KOH, 0.5 g of 10% palladium on charcoal catalyst is added, and the mixture is reduced with hydrogen in the low pressure Parr shaker (rapid during the first hour, and complete overnight). The solution is filtered to remove spent catalyst and potassium bromide, the solvent removed under vacuum, and the amine recovered, washed thoroughly with water, dried, and purified by sublimation. The yield of purified amine exceeds 80%. Proton nmr: an A_2B pattern with the downfield (A) lines broadened by deuterium nuclear quadrupole relaxation. At 200 MHz, integration shows 8% residual *ortho* protons. Deuterium nmr shows a single line at 7.05 ppm chemical shift, and no other visible lines. The ms gives the molecular ion at 173 Da.

DPA-4,4′-d_2

4,4′-Dibromodiphenylamine (0.10 mol) is reduced in 300 mL of 1.3 *M* ethanolic KOH with deuterium gas in the presence of 0.5 g of 10% palladium on charcoal catalyst. The product is recovered and purified as described in the preceding preparation. The yields again exceed 80%. The proton nmr is an AA′BB′ pattern with the downfield lines broadened by the deuterium quadrupole relaxation. Proton nmr at 200 MHz shows 7% residual *para* protons. Deuterium nmr gives a single broadened line at 6.80 ppm, with no other visible lines. The mass spectrum gives a molecular ion at 171 Da.

Acknowledgments

We are indebted to the Research Board of the University of

Illinois at Chicago for a grant for the purchase of the deuterium probe for the WP-80 NMR, and to the U.S. Department of Energy for support during the later stages of this research. Eugene DeRose provided helpful advice on the choice of conditions for optimizing the 200-MHz nmr spectra.

The crystal and molecular structure of the title compound, $C_{15}H_{14}O_3$, is described. Crystals are monoclinic, space group $P2_1/n$, $a = 9.893(5)$, $b = 10.719(5)$, $c = 12.136(3)$ Å, $\beta = 90.56(3)°$. The molecule has a twist conformation and interactions between oxygen atoms of the methoxyl groups are thought to play some part in this.

C. FAERMAN, S. C. NYBURG, G. PUNTE, B. E. RIVERO, A. A. VITALE et N. S. NUDELMAN. Can. J. Chem. **63**, 3374 (1985).

On décrit la structure cristalline et moléculaire du composé mentionné dans le titre, $C_{15}H_{14}O_3$. Les cristaux sont monocliniques, groupe d'espace $P2_1/n$, $a = 9{,}893(5)$, $b = 10{,}719(5)$ et $c = 12{,}136(3)$ Å et $\beta = 90{,}56(3)°$. La molécule existe dans une conformation croisée et on croit que les interactions entre les atomes d'oxygène et les groupements méthoxyles jouent un rôle dans cette situation.

Introduction

An X-ray crystal structure analysis of di-*o*-anisylketone, **1**, was undertaken as part of an investigation of the molecular conformations of bridged diphenyl compounds (1). The purpose of this investigation was to determine the influence of different bridging atoms, phenyl substituents, and lattice forces on molecular conformation.

Since the crystal structure of benzophenone, **2**, has been determined (2), showing the molecule to be in a twist conformation, an *ortho* disubstituted benzophenone, **1**, was chosen to elucidate whether its conformation is governed by the arylcarbonyl group, by steric effects of the *ortho* substituents, or by crystal environment effects.

Experimental

Compound **1** was prepared from the reaction of *o*-anisyllithium with carbon dioxide. A modification of the Glaze and Ranade (3) metal–halogen interchange method was used to prepare *o*-anisyllithium; 0.7 mL (5.6 mmol) of *o*-bromoanisole was added to 6 mmol of a 0.3 *M* ligroin solution of butyllithium prepared as previously described (4), and the reaction mixture was worked up as described for the preparation of phenyllithium (5). White crystals of *o*-anisyllithium were dissolved in THF and the solution flushed with carbon dioxide.

Recrystallization from methanol yielded white crystals of **1**, mp 104–105°C (lit. (6) mp 104°C), overall yield 70%. The compound may also be obtained from the reaction of *o*-anisyllithium with carbon monoxide (7). Infrared (KBr, cm^{-1}): 2800 (st C—H), 1620 (st C═O), 1600 (st C═C), 1450 (def C—H), 1250 (st C—O), 850 (def C—H ar); nmr (CCl_4) δ: 3.5 (s, 6H,—OCH_3), 6.84 (m, 4H, ar H3, H13 and H5, H11), 7.3 (m, 4H, ar H4, H12 and H6, H10); ms *m/e* (% rel. ab.): 242 (M, 48), 211 (12), 135 (100), 77 (40).

Structure determination and refinement

The crystal used for data collection was 0.20 × 0.08 × 0.05 mm. Preliminary data were obtained photographically. All other measurements were made on an Enraf–Nonius CAD-4 diffractometer using graphite monochromatized MoK radiation ($\lambda = 0.7107$ Å). Unit cell dimensions were based on 25 centered reflections. Intensity data were collected in the $\theta-2\theta$ scan mode in quadrants $(h,k,\pm l)$ with scan width $(0.9 + 0.35 \tan\theta)$ deg to a maximum 2θ of 50°. Three standard reflections were measured every 3 h; no significant variations were observed. Reflections were measured for intensity whenever their initial scan indicated $(\sigma(I)/I) > 0.04$. A considerable number of the 5921 measured reflections were symmetry related. Of these, 2267 were unique and, in turn, of these, 1383 significant on the criterion $I > 3\sigma(I)$. Crystal data are as follows.

$C_{15}H_{14}O_3$ $M_r = 242.28$
Monoclinic, $P2_1/n$, $a = 9.893(5)$, $b = 10.719(5)$, $c = 12.136(3)$ Å, $\beta = 90.56(3)°$, $V = 1288$ Å^3, $Z = 4$ molecules/cell, $D_c = 1.26$, D_m (not det) mg m^{-3}; $\mu(\mathrm{MoK}\alpha) = 4.8$ cm^{-1}; $t = 25°C$. No absorption corrections were applied.

The structure was solved by using MULTAN (8). All atoms were located and the positions of the non-hydrogen atoms were refined anisotropically, those of the hydrogen atoms isotropically. Full-matrix least-squares refinement minimizing $\Sigma w(|F_o - F_c|)^2$ converged (maximum shift/error = 0.05) to final agreement indices $R = 0.046$, $R_w = 0.059$. In the final cycle, weights were assigned $w = 4F^2/(\sigma(I)^2 + (0.04F^2)^2)$. The final ΔF map was featureless, the largest peak being 0.2 e A^{-3}; the goodness of fit, $s = [\Sigma w\Delta F^2/(m-n)]^2$, was 1.834. Computer programs and atomic scattering factors used were those in the Enraf–Nonius SDP package (9) on a PDP 11/23 computer.

Final positional and equivalent isotropic thermal parameters, B_{eq}, for non-hydrogen atoms are given in Table 1.

Atomic labelling and bond lengths are given in Fig. 1; bond angles in Fig. 2.[4]

Results and discussion

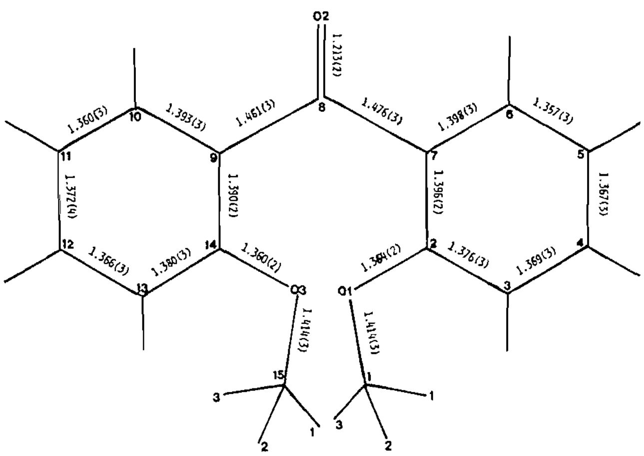

FIG. 1. Atomic labelling and intramolecular bond lengths.

in Fig. 3. The molecule has a twist conformation (11), as can be seen both from Fig. 3 and from the central torsion angles listed in Table 2. In this table are also listed the central torsion angles for three other molecules containing the benzophenone moiety, none of which, however, has any *ortho* substituents (12,13). At first sight, the conformations seem closely similar and this is suggested by an unconstrained best molecular fit (14), for example, of benzophenone (2), **2**, with **1** ($\Sigma\Delta^2$ = 0.032 Å^2). This correspondence is illustrated in Fig. 4. Nevertheless, there is some evidence that the oxygen atoms of the proximal methoxy groups have an influence on the conformation of **1**. For all the other molecules of Table 2 we have calculated what the distance between such oxygen atoms would have been had they been placed in idealized proximal *ortho* positions with the C(ar)—O bond length 1.362 Å. It can be seen that, in each case, the distance is somewhat shorter than that actually found in **1**. This suggests that the methoxy oxygen atoms in **1** are in slight steric conflict. This is also evidenced by the internal angle C7—C8—C9 of 125.4(5)° at the carbonyl group, which, as seen in Table 2, is greater than in the other three examples that lack *ortho* substituents.

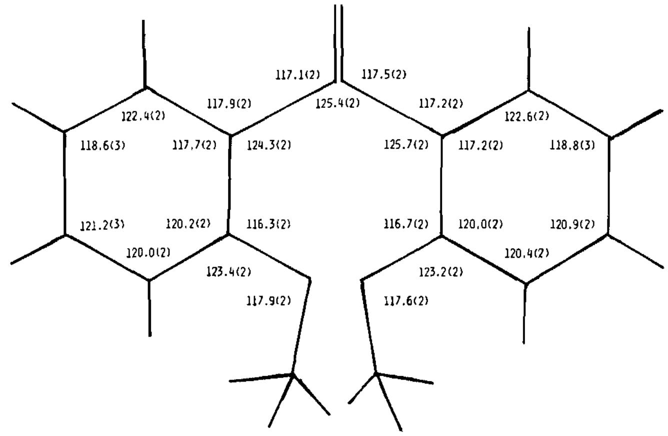

FIG. 2. Intramolecular bond angles.

It is only the oxygen atoms of the methoxyl groups that are close together; none of the hydrogen atoms of the two methyl groups are closer to each other than 3.03 Å. The bond angles at the ring carbon atoms to which the methoxyl groups are attached are of some interest. The torsion angles C1—O1—C2—C3 and C15—O3—C14—C13 are 14.0° and 8.6°, respectively. Note that angle O1—C2—C3 is larger than O1—C2—C7 (123.2° is against 116.7°) and, similarly, that O3—C14—C13 is larger than O3—C14—C9 (123.4° as against 116.3°). We have used the Cambridge Crystallographic Database (15) to retrieve all methoxy-substituted benzene rings in which the positions adjacent to methoxy are unsubstituted.[5] In every case, the exterior bond angle at the methoxy-substituted ring carbon atom was larger than 120° on the side of the smaller torsion angle and vice versa. This suggests that there is an interaction between the methyl group and the adjacent hydrogen of the benzene ring; the distances H102. . . H3 and H153 . . H13 of 2.12 and 2.31 Å, respectively, confirm this. Although there is no net force on any molecule in a crystal at equilibrium, it seems that there is a local repulsion which is forcing the methoxyl methyl groups into the plane of the benzene rings to which they are attached. Thus the methyl groups are forced up against the adjacent ring hydrogen atom and it is this interaction which opens up the exterior bond angle at the substituted ring carbon atom. There is additional supporting evidence in the present case, namely that, of the shortest ten O . . . C and C . . . C intermolecular distances, six involve the methoxy carbon atoms C1 and C15.[6] Both benzene rings are closely planar, the maximum deviation from the planes being 0.005(7) Å.[6]

An important factor governing the conformation and causing the methoxyl oxygen atoms to be in close contact is undoubtedly the need to preserve extended carbonyl resonance with the aryl rings. This will stabilize the ground state and increase the formal charge distribution on the carbonyl group. This is shown by carbonyl stretching infrared absorption frequencies. Thus, in both the crystal (16*a*) and in carbon tetrachloride solutions of dibenzophenone, **2** (16*b*), the frequency is 1670 cm^{-1} compared with a standard (unconjugated) value of 1700 cm^{-1}. One would expect the present compound to exhibit a slightly higher frequency, but it is somewhat lower, at 1620 cm^{-1}. This can

[5]The 334 REFCODES retrieved have been deposited (as in footnote 4). The results of this survey are in press (J. Mol. Struct.).

dihedral II A'—B'—C—B

Compound	(i)*	(ii)	(iii)	(iv)	Reference
Benzophenone	32.7	32.1	121.8	2.52	2
p,*p*-Dimethoxybenzophenone (molecule 1)	25.6	36.0	120.6	2.45	12
p,*p*-Dimethoxybenzophenone (molecule 2)	27.8	36.2	120.3	2.52	12
Bis(4-nitrophenyl)ketone	18.5	35.9	120.4	2.44	13
Di-*o*-anisylketone	42.2	28.3	125.4	2.89	This paper

*(i), (ii) are moduli (deg) of dihedral angles I, II respectively; (iii) angle at C; (iv) distance between hypothetically located (and, in the last case, actual) proximal *ortho* oxygen atoms with C(ar)—O = 1.362 Å.

be attributed to the presence of the electron-releasing methoxy groups.

In compounds where there is no conjugation through the carbonyl group, the conformation seems to be governed by other factors. In the case of unsubstituted diphenylmethane (17), the twist conformation may have been imposed by lattice forces. In di-*o*-anisylcarbinol (1), possibly both lattice forces and steric effects are responsible for the twist-skew conformation.

In summary, the results presented here are consistent with the view that the interaction between methoxy oxygen atoms brings about a slight conformational change in **1** relative to that found in *ortho*-unsubstituted molecules.

Iron trihydroxide has been prepared by the oxidation of $FeSO_4$ with $[Co(III)(en)(dien)]_2O_2[ClO_4]_4$, $[Co(III)(tetraen)]_2O_2[ClO_4]_4$, and H_2O_2 in acid solution. These materials have been characterized by DTA, magnetic susceptibility, Mössbauer spectroscopy, X-ray powder diffraction, and electron microscopy. Particle sizes are found to be ~80 Å in diameter, but in the case of the (tetraen) preparation we find needle-like crystallites ~1200 Å × 400 Å × 50 Å in size. The magnitudes of the hyperfine fields follow the particle size variation. These materials have quite a different behaviour from the $Fe(OH)_3$ gels prepared from basic solution.

STEVE C. F. AU-YEUNG, DONALD R. EATON, THOMAS BIRCHALL, GEORGES DÉNÈS, JOHN E. GREEDAN, CHRISTOPHER HALLETT et KRZYSZTOF RUEBENBAUER. Can. J. Chem. **63**, 3378 (1985).

On a prépare du trihydroxyde de fer en procédant à l'oxydation du $FeSO_4$ par le $[Co(III)(en)(dien)]_2O_2[ClO_4]_4$, le $[Co(III)(tétraèn)]_2O_2[ClO_4]_4$ et le H_2O_2 en solution acide. On a caractérisé ces matériaux par l'analyse thermique différentielle, par les susceptibilités magnétiques, par la spectroscopie de Mössbauer, par la diffraction des rayons-X sur des poudres et par microscopie électronique. On a trouvé que le diamètre des particules est d'evniron ~80 Å; dans le cas du produit obtenu grâce à la préparation (tétraène), on trouve toutefois des aiguilles qui sont de nature cristalline et dont les dimensions sont d'environ ~1200 Å × 400 Å × 50 Å. Les amplitudes des champs hyperfins varient en fonction de la grosseur des particules. Ces matériaux ont des comportements très différents de ceux que présentent les gels de $Fe(OH)_3$, préparés en solutions basiques.

[Traduit par le journal]

Introduction

We have recently found that the oxidation of $FeSO_4 \cdot 7H_2O$ by $\{[Co(III)(en)(dien)]_2O_2\}[ClO_4]_4$ in aqueous solution results in the precipitation of iron trihydroxide, $Fe(OH)_3$ (1). This material was shown to be quite different from any other hydrated iron(III) oxide or iron(III) hydroxides that had been reported previously (2–11). It was concluded that this sample of $Fe(OH)_3$ had an average particle size of ~80 Å in diameter and that the two types of iron environment, visible in the low temperature ^{57}Fe Mössbauer spectrum, were due to surface and bulk iron; the former having a hyperfine field of 437 kOe while the latter, presumably more magnetically ordered, has a field of 486 kOe.

We have found that, by changing the reaction conditions, it is possible to obtain other varieties of $Fe(OH)_3$, some of which only appear to differ from the earlier sample (1) in particle size, while others appear to have quite different properties. In this paper we present ^{57}Fe Mössbauer, magnetization, X-ray powder diffraction, electron microscopy and therml analytical data for a number of these hydroxides. The Mössbauer data of one of these is analysed in some detail. The results are compared to those of the gels obtained by the precipitation of Fe^{3+} from aqueous solution by strong base.

Experimental

Materials

Ferrous sulphate heptahydrate (A.C.S. spec.) and hydrogen peroxide were obtained from Baker Chemical and were used without futher purification. The Co(III) complexes were prepared according to standard literature methods (12–14).

Preparation of samples

The "powder" samples were prepared by the oxidation of Fe^{2+}, in the form of $FeSO_4 \cdot 7H_2O$, and the "gel" samples by the hydrolysis of Fe^{3+} at high pH. The majority of the samples prepared by oxidation employed peroxy cobaltate(III) complexes as the oxidant, but some samples were obtained using hydrogen peroxide as the oxidant under either acid (sample 6, Table 1), or basic (sample 8, Table 1) conditions. The peroxy complexes $\{[Co(en)(dien)]_2O_2\}^{4+}$ (en = ethylenediamine, dien = diethylenetriamine), $\{Co(tetraen)]_2O_2\}^{4+}$ (tetraen = tetraethylenepentamine), and $\{[Co(salen)]_2O_2(DMSO)_2$ (salen = bis-(salicylaldehyde)ethylinediimine, DMSO = dimethylsulfoxide) were used.

The preparation of $Fe(OH)_3$ powder samples involved dissolving stoichiometric amounts of the reactants (2:1, $FeSO_4 \cdot 7H_2O$:co-dioxygen complex) in aqueous solution under argon. In a typical preparation, 0.4654 g of the dioxygen complex was dissolved in 280 mL of argon-saturated distilled water, giving a concentration of 1.794×10^{-3} *M* in dioxygen complex. The pH of this solution was 7. $FeSO_4$, 0.2894 g, was introduced into the solution, with vigorous stirring, under a blanket of argon. Reaction started after ~10 min of stirring and was completed after 24 h, the argon atmosphere being maintained during this period. The product was collected by filtration and allowed to dry in air at room temperature until a constant weight was obtained.

The yield was 90%. The pH of the filtrate was 5.83. The crude product usually contained some Co^{2+} and free amine ligands. It was essential to wash the product by completely suspending in water, stirring for 30 min and then re-filtering. The washing procedure was usually repeated three times. The weight of the product reached a limiting value after drying by standing for two days under normal atmospheric conditions.

Electron microscopy

Samples were prepared by enclosing $Fe(OH)_3$ powder in carbon by the evaporation of carbon onto a glass microscope slide which had been sparsely coated with the powder, and mounting segments of the resultant carbon film on 3 mm copper grids. Other samples were prepared by grinding $Fe(OH)_3$ powder under butanol and allowing a drop of the suspension to dry on a carbon-coated grid. The samples were examined in a "VG Microscopes" HB5 Scanning Transmission Electron Microscope (STEM) equipped with a field emission gun, and operated at an accelerating voltage of 100 kV in the STEM mode. Electron micrographs were recorded using both bright field and dark field detectors. Energy dispersive analysis of the X-rays, emitted by the specimen, was used to qualitatively distinguish the particles of $Fe(OH)_3$ examined from small numbers of contaminant particles.

Analyses

The analyses of the materials was carried out according to the procedure already reported (1). Analytical data for the various products are summarized in Table 1, together with the measured densities. Densities, thermogravimetric analyses, Mössbauer data and magnetic measurements were carried out according to the procedures already described (1). Computer fitting of the Mössbauer data were carried out using the computer program GMFP5S (15), for time independent spectra while, for time-dependent (relaxation) spectra, a simple model described below was adopted. For the latter case a newly developed GMFPSR program was used.

Results

Chemical composition

The analytical data establish that the "$Fe(OH)_3$ powders" have a composition close to that of $Fe(OH)_3$. The "$Fe(OH)_3$ gels" deviate somewhat from this stoichiometry. That the "gels" have a different structure from those of the "powders" is evident from the behaviour under controlled thermal analysis. Figure 1 shows the differential thermal analysis (DTA) curves of these compounds measured under the same conditions. The "gels" have quite a different behaviour in that they lose all of their available H_2O molecules by ~200°C, whereas the "powders" retain one molecule of H_2O up to ~600°C. At this

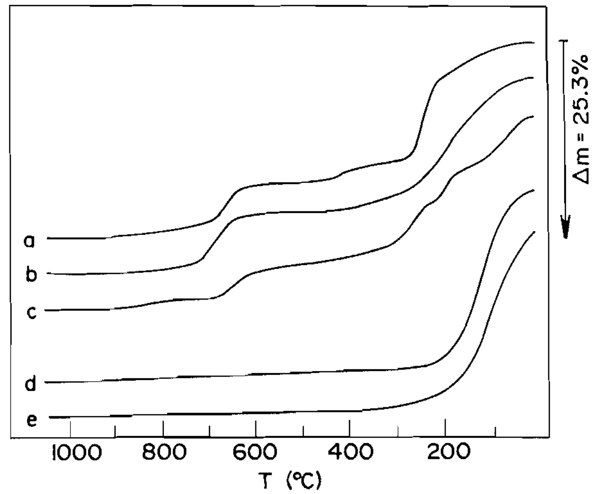

FIG. 1. Differential thermal gravimetric curves from various preparations of $Fe(OH)_3$. (*a*) Fe^{2+} + $[Co(III)(en)(dien)]_2O_2[ClO_4]_4$, 5 m*M* (powder); (*b*) $Fe^{2+} + H_2O_2$, pH = 4.5, 100 m*M* (powder); (*c*) Fe^{2+} + $[Co(III)(tetraen)]_2O_2[ClO_4]_4$, 1.8 m*M* (powder); (*d*) $Fe^{2+} + H_2O_2$, pH = 10.9, 100 m*M* (gel); (*e*) $Fe^{2+} + NH_4OH$, 100 m*M* (gel).

stage the formal composition is $Fe_2O_3 \cdot H_2O$ or FeOOH. Much stronger heating is required to remove this last water molecule and even by ~700°C a small residual amount of water (~2%) is retained. This latter stage has been characterized as "hydroxohematite", $Fe_2O_3 \cdot nH_2O$ (5).

X-ray diffraction

The X-ray powder diffraction patterns for those materials prepared from the $[Co(III)(en)(dien)]_2O_2[ClO_4]_4$ reaction both have similar powder patterns to that reported earlier (1), again with rather broad lines. The preparation using $[Co(III)(tetraen)]_2O_2[ClO_4]_4$ gives similarly broad X-ray diffraction peaks suggesting that the particle sizes are small. This broadening is illustrated in Fig. 2 which shows that part of the X-ray diffraction pattern where some of the strongest lines are observed. Those X-ray lines that could be measured were found at *d* (Å) 4.85, 4.20, 3.75, 2.70, 2.58, 2.46, 2.25, 2.19, 1.72, 1.57, 1.51, 1.46. As in our previous report on "$Fe(OH)_3$ powder" (1), the observed diffraction peaks could not be indexed to any of the known various phases of Fe_2O_3, or its hydrates, that have been published. On this figure we have indicated the positions of lines characteristic of δ'FeOOH: it is clear that none of this compound is present at room temperature.

Mössbauer spectroscopy

All of the samples examined show essentially a broadened doublet at room temperature typical of a Fe^{3+} in an oxygen ligand environment. Close examination of some of these spectra revealed that the broadened doublet was superimposed on a broad absorption indicative of the presence of a collapsed hyperfine field. This was quickly confirmed by cooling these samples to low temperature, 77 K. In addition to the paramagnetic doublet a clearly defined magnetic hyperfine spectrum was observed, but the lines were broad. Such was the case for the samples prepared using $[Co(III)(en)(dien)]_2O_2[ClO_4]_4$, 20 m*M*, or $[Co(III)(tetraen)]_2O_2[ClO_4]_4$, Fig. 3. For those preparations using lower concentrations of $[Co(III)(en)(dien)]_2O_2[ClO_4]_4$ (i.e. 5 and 8.5 m*M*), or $[Co(III)(salen)]_2O_2[DMSO]_2$ or H_2O_2 at pH 4.5, magnetic ordering only occurred below 77 K. In the case of the "$Fe(OH)_3$ gels" prepared in basic solution, magnetic ordering was only observed <77 K, that is at 4 K. At

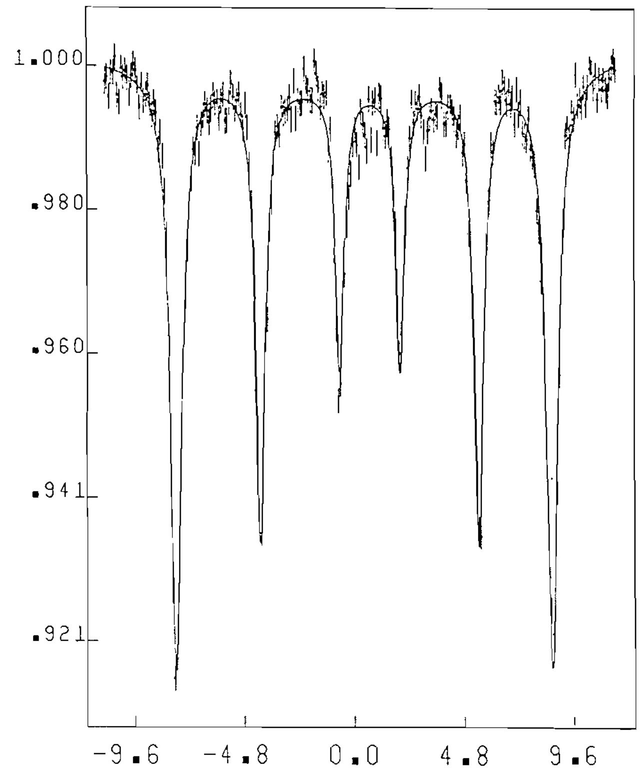

FIG. 3. ^{57}Mössbauer spectrum of $Fe(OH)_3$ gel, prepared from Fe^{2+} and H_2O_2 at pH 1.09, at 4.2 K.

room temperature and liquid nitrogen temperatures the spectra appeared as rather broad Fe^{3+} doublets suggesting that there was rather a large distribution of Fe^{3+} environments in these gels. The other paramagnetic spectra could all be fitted to overlapping doublets.

All of the data that we have obtained are summarized in Table 2. We have included data from ref. 1 pertaining to the $Fe(OH)_3$ powder preparation using a 20 m*M* solution of $[Co(III)(en)(dien)]_2O_2[ClO_4]_4$.

The behaviour of the samples which show hyperfine fields over the range of temperatures from 4.2 to 298 K is quite complex. In only one case was it possible to clearly distinguish two magnetic hyperfine sites at 4.2 K, which have been attributed as arising from bulk and surface Fe^{3+} in particles of ~80 Å diameter (1). As the temperature is raised the magnetic field collapses slowly and a paramagnetic doublet replaces the magnetic spectrum. By 298 K this conversion is virtually complete, and from this behaviour we concluded that this material was of realtively uniform particle size. None of the other samples showed more than one magnetic hyperfine component at 4.2 K (Fig. 3), but it is clear from the collapse of these spectra at higher temperature that more than one iron site is present, and at room temperature the spectra must be fitted to two quadrupole doublets. The complexity of the spectra at intermediate temperatures (see Fig. 4) for the tetraen case, and the way that the spectrum collapses, leads us to the conclusion that we are dealing here with less well ordered particles having a rather broad range of sizes. This leads to the poorly resolved spectra in the range 77–298 K (Fig. 4).

Magnetic properties

The magnetic behaviour of the powders prepared using $[Co(III)(en)(dien)]_2O_2[ClO_4]_4$ at various concentrations are very similar and the data for the sample prepared using a 20 m*M* concentration of oxidant have already been commented upon in detail (1). Similar behaviour is found for the "$Fe(OH)_3$ powder" prepared using $[Co(III)(tetraen)]_2O_2[ClO_4]_4$ (1.8 m*M*), and these data are shown in Fig. 5. At 66 K, and above, the magnetization data do not show any variation with temperature which is indicative of superparamagnetic behaviour. The data obtained in the range 66–141 K have been fitted to a Langevin function, $\sigma_g = \sigma_s \coth(mH/kT - kT/mH)$ where m is the single particle moment and σ_s the saturation moment of

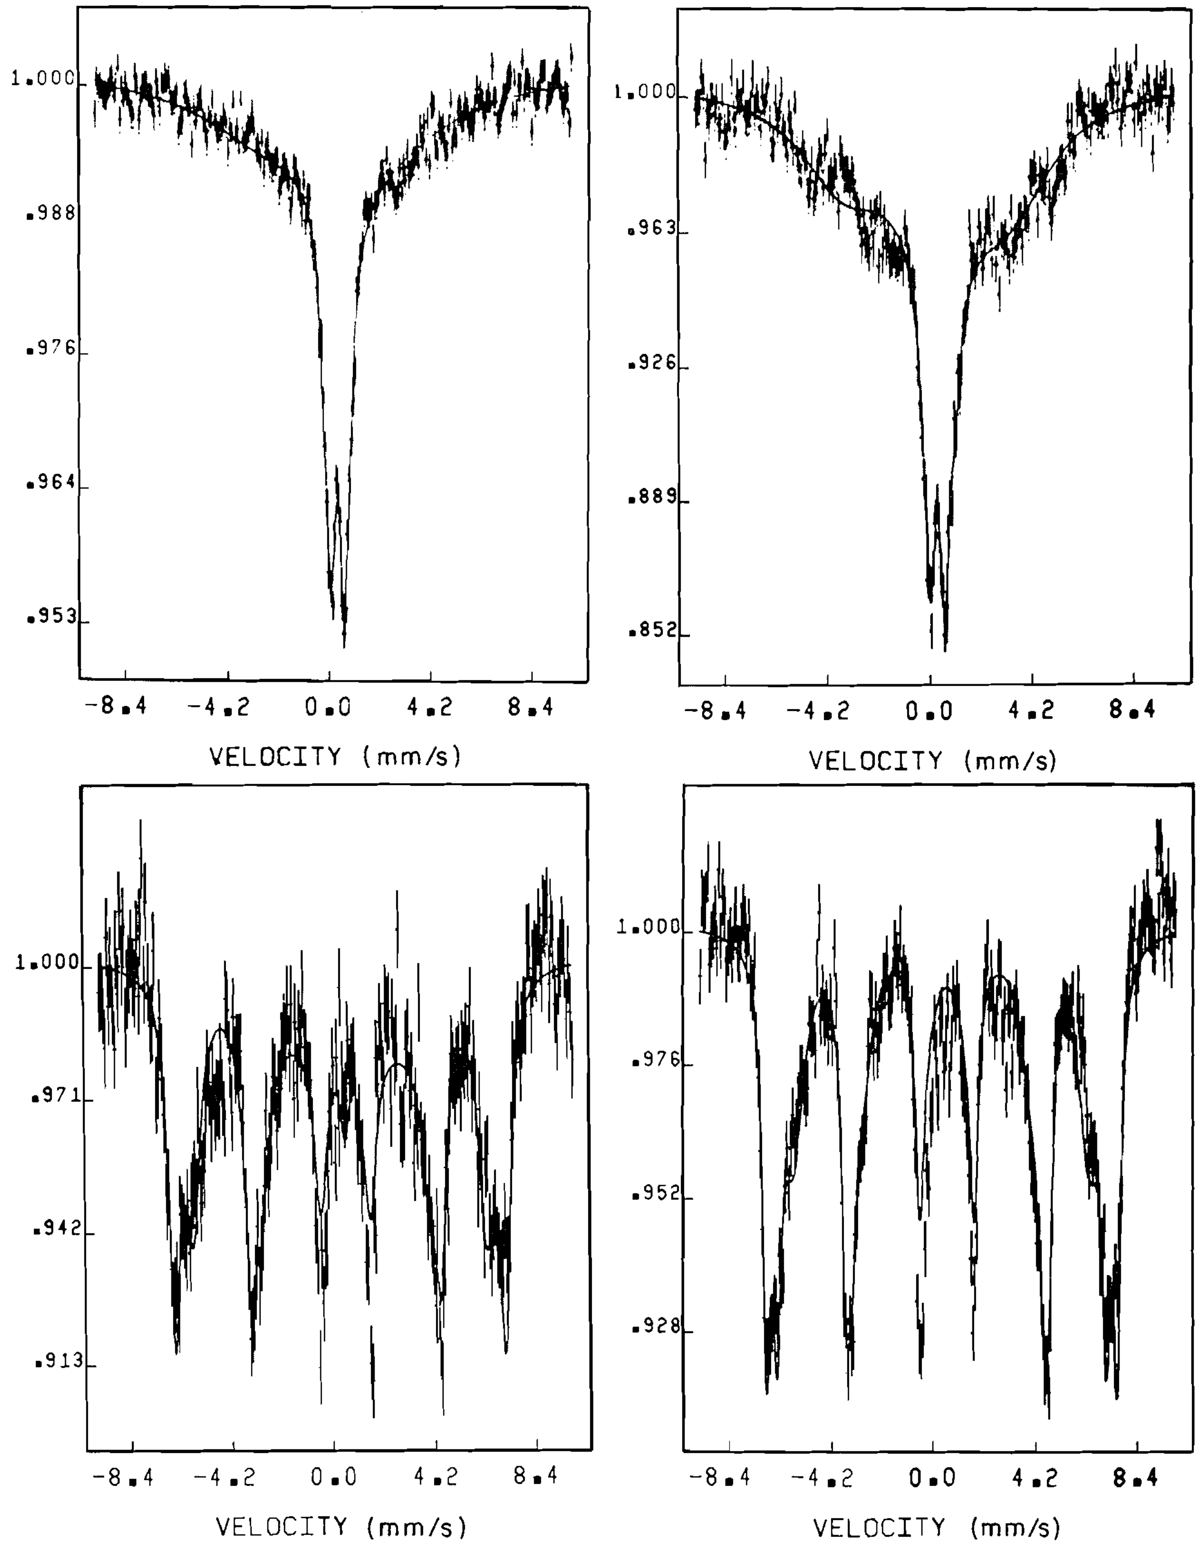

FIG. 4. ^{57}Mössbauer spectra of $Fe(OH)_3$ powder prepared from Fe^{2+} and $[Co(III)(tetraen)]_2O_2[ClO_4]_4$: sample *4*, (*a*) 298 K; (*b*) 285 K; (*c*) 150 K; (*d*) 80 K.

the bulk sample: σ_s and m were found to be 1.8 emu g^{-1} and 6.8×10^{-19} erg/Oe, respectively. These values are smaller than those obtained for the sample prepared using $[Co(III)(en)(dien)]_2O_2[ClO_4]_4$ (1). This combined with the lower density suggest that the particle size is smaller than the ~80 Å diameter found for the $[Co(III)(en)(dien)]_2O_2[ClO_4]_4$ sample.

Electron microscopy

The iron(III) hydroxide powder, prepared using the $[Co(III)(tetraen)]_2O_2[ClO_4]_4$, was investigated by electron microscopy to evaluate the morphology of the $Fe(OH)_3$ particles and the distribution of sizes of the $Fe(OH)_3$ particles.

A cursory inspection of each specimen of $Fe(OH)_3$ powder,

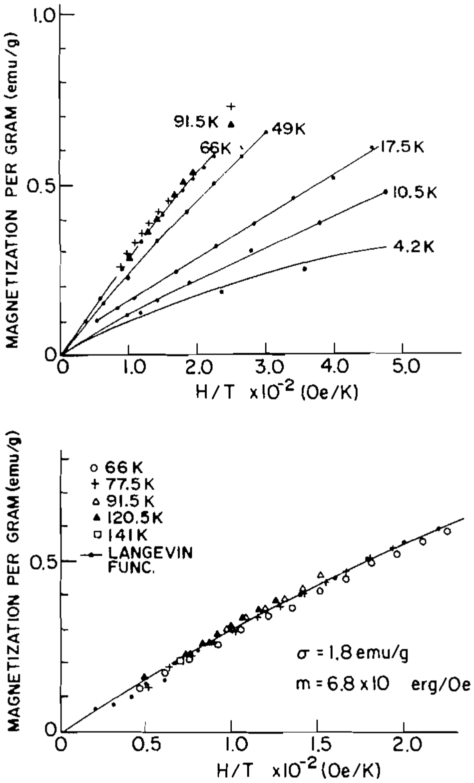

FIG. 5. Magnetization per gram versus H/T for $Fe(OH)_3$ powder prepared from Fe^{2+} and $[Co(III)(tetraen)]_2O_2[ClO_4]_4$.

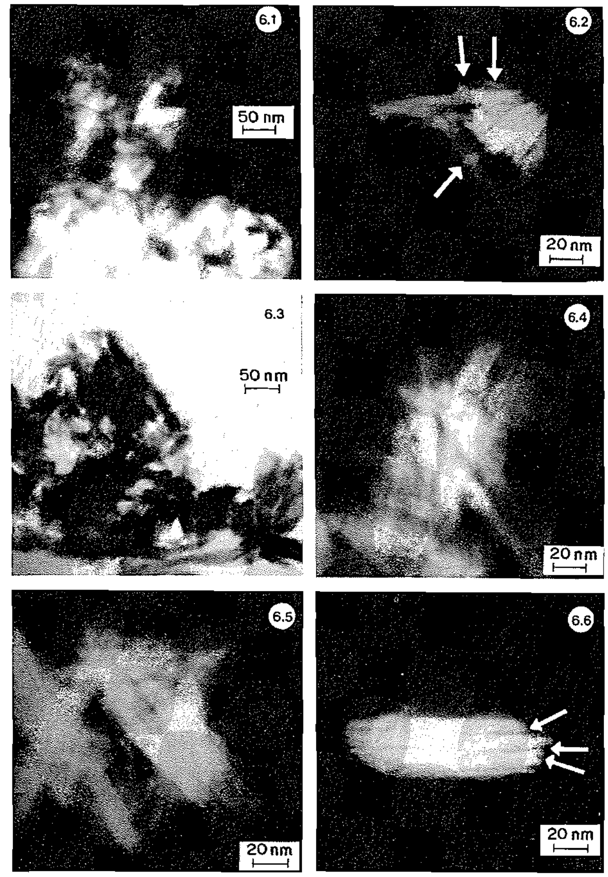

FIG. 6. Scanning transmission electron microscope photographs, *1–6*, of the $Fe(OH)_3$ powder crystallites prepared from Fe and $[Co(III)(tetraen)]_2O_2[ClO_4]_4$: *2* — arrows indicate unusually small particles, *6* — arrows indicate boundaries between different particles.

in the electron microscope, showed large areas of dark contrast which appeared to be relatively thick with regard to the penetrating power of the beam (ca. 2000 Å). Examination of these regions at higher magnification showed them to be clusters composed of large numbers of aggregated smaller particles. Some typical electron micrographs recorded from the thin areas located at, or near to, the edges of the clusters are presented in Fig. 6.

The low contrast observed in the micrographs indicates that the individual particles are thin. Indeed, the poor contrast was not significantly improved when a collector aperture was inserted into the beam to prevent scattered electrons from contributing to the bright field image. This observation reflects the limited amount of electron scattering which might be expected to be a feature of such thin particles.

It was not possible to record electron diffraction patterns which were amenable to indexing, although some weak diffraction spots were observed when the electron probe was stopped on individual particles. This observation appears to indicate that the thin particles have some degree of crystallinity and this is consistent with the regular shapes of some of the particles in Fig. 6. A future electron diffraction study might yield valuable information as to the crystallographic properties of this novel form of $Fe(OH)_3$, since powder X-ray diffraction has proved to be of limited use in the characterization of this species (1).

From Fig. 6.1 to 6.5 it appears that the $Fe(OH)_3$ powder consists of particles which take the form of needles or elongated platelets. Although the size of the microcrystals varied between 300 and 2000 Å in length and 100 and 500 Å in width, a typical microcrystal might be described as a platelet having dimensions of ca. 1200 Å by 400 Å. The precise thickness of the particles is difficult to establish in the absence of convergent beam electron diffraction patterns. However, whilst it is acknowledged that much caution must be exercised when directly interpreting contrast effects observed in electron micrographs, Fig. 6.6 shows a particle which appears to be composed of several platelets stacked "edge on" to the beam. Given this assumption the thickness of the individual microcrystals seems to be ca. 50 Å. This would be consistent with the low contrast in the images.

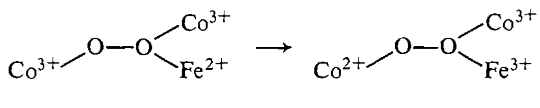
It is relevant to recall that attempts to determine the particle size of $Fe(OH)_3$ powder by applying the Scherrer formula to linewidths observed in the powder X-ray diffraction patterns of $Fe(OH)_3$ indicated particle sizes of ca. 80 Å. The direct measurement of particle size by electron microscopy could reasonably be expected to be more accurate than the inference of such data from X-ray diffraction pattern linewidths, which might rather reflect a low degree of crystallinity. However, it is notable that some very small particles were observed (Fig. 6.2) in the $Fe(OH)_3$ powder, of some 100 Å in length. These particles were only rarely encountered.

Iron(III) hydroxide powder might be expected (1) to undergo dehydration and recrystallization processes, to give $Fe_2O_3 \cdot 2H_2O$, FeOOH, and ultimately Fe_2O_3 if subjected to excessive heat and/or a vacuum. It is therefore pertinent to note that no recrystallization processes were observed in the electron microscope, and that the images of the $Fe(OH)_3$ crystals did not undergo change even on prolonged irradiation. Hence, although it is likely that some water was lost on exposing the powder to a vacuum and the beam, this did not appear to influence the crystal shapes and sizes.

Discussion

Mechanism of oxidation

The Co(III) peroxy complexes used as oxidants exist in a number of isomeric forms which have been distinguished by ^{59}Co nmr (16). It has also been shown (17) that the rate of the electron transfer reaction depends on the isomeric structure. It is usually considered that an inner sphere electron transfer mechanism is involved with the Fe^{2+} coordinated to the peroxy group:



The rate depends on the nature of the ligands attached to the Co^{3+} ions. Detailed reaction schemes have been suggested by Hyde and Sykes (18) and by McLendon and Martell (19). If $Fe(OH)_3$ is produced by hydrolysis of an Fe^{3+} compound the ligand environment of the ion will be that which is most stable for an Fe^{3+} ion at that pH. If, on the other hand, $Fe(OH)_3$ is produced by an inner sphere electron transfer reaction, the Fe^{3+} will find itself in a ligand environment appropriate to Fe^{2+} at the pH of the experiment. Given that the pK_a's of water coordinated to Fe^{2+} will differ from that of water coordinated to Fe^{3+}, this effect could lead to a difference in the environment of the Fe^{3+} in the precipitated hydroxide which could, in turn, account for the differences in physical properties described above.

Mössbauer and related phenomena

It is apparent from an examination of the data for these iron(III) hydroxides that there are three different types of product. The first, characterized by preparations using low concentrations of $[Co(III)(en)(dien)]_2O_2[ClO_4]_4$ or H_2O_2 at pH 4.5, exhibits a paramagnetic ^{57}Fe Mössbauer spectrum at room temperature. At liquid nitrogen temperature a magnetic component is visible together with a paramagnetic doublet, but on cooling further to 4.2 K the sample becomes completely ordered magnetically. The second type obtained from preparations involving relatively high (20 m*M*) concentrations of $[Co(III)(en)(dien)]_2O_2[ClO_4]_4$, or $[Co(III)(tetraen)]_2O_2[ClO_4]_4$, show Mössbauer spectra which have both paramagnetic and magnetic components present, at all temperatures from liquid nitrogen to room temperature, but are magnetically ordered at 4.2 K. The $Fe(OH)_3$ gels show the third type of behaviour in that the Mössbauer spectra remain as broad doublets until below liquid nitrogen temperature and are magnetically ordered at 4.2 K. This behaviour is typical of the $Fe(OH)_3$ gels that have been reported previously.

In an earlier report (1) we presented evidence to show that the particle size of the crystallites of $Fe(OH)_3$, from the $[Co(III)(en)(dien)]_2O_2[ClO_4]_4$ preparation, was of the order of 80 Å diameter and a broad X-ray powder diffraction pattern was obtained. Of the other samples only that from the "tetraen" preparation gave an X-ray diffraction pattern, and this showed non-uniform broad Bragg peaks (Fig. 2) suggestive of a range of particle sizes. This is consistent with the electron micrographs which showed particles ranging in length from 100 to 2000 Å. The other samples gave no X-ray patterns and presumably are composed of very small particles or amorphous material. We have chosen to discuss the behaviour of the "tetraen" sample in some detail.

The magnetization measurements versus temperature and applied field, performed upon $Fe(OH)_3$ (tetraen preparation), are indicative of a complex magnetic behaviour having at least two scales of ordering. The low temperature magnetization is dominated by a kind of microscopic antiferromagnetic ordering. However, at high temperatures, the data are fitted to a Langevin function showing the presence of superparamagnetic particles with the internal coupling being largely antiferromagnetic, but with the magnetic moment per particle not being entirely compensated. At still higher temperatures the normal paramagnetic behaviour is eventually restored indicating that a phase transition to the paramagnetic state occurs at the microscopic level. Electron microscope images indicate the presence of small plate-like particles many of which are clumped into larger aggregates (see Fig. 6) and which would be expected to behave in the manner described above.

The Mössbauer spectra are relatively simple at the extreme ends of the temperature scale, but become very complex in the superparamagnetic region. The 4.2 K spectrum consists of a unique magnetically split pattern with $H_{eff} \approx 509$ kOe and $\Delta_{eff} = -0.25$ mm/s. The lines are slightly broadened, but the magnetic field distribution is not pronounced to any significant level. This finding means that the saturation value of the hyperfine magnetic field does not depend upon the particular particle size and/or location of the Fe^{3+} within a particle. This is probably due to the fact that most of the field is produced by local Fermi terms which are only spatially fixed by the interatomic interactions.

From the Mössbauer point of view at least some proportion of the material remains magnetically ordered at room temperature where the magnetization data do not show any appreciable ordering. This phenomenon could be attributed to the fact that the techniques involved have time scales which differ by several orders of magnitude, and this is indicative of relaxation phenomena within the ensemble of Neél type particles. The quadrupole splitting $|\Delta| = 0.47$ mm s^{-1} at this high temperature limit is indicative of V_{zz} being nonco-axial with the H_{eff}. However, the quadrupole interaction is small compared with the magnetic one, and therefore most of the magnetic spectra can be treated by including the quadrupole interaction as a small perturbation, so justifying the use of the first order approximation. Unfortunately, Mössbauer measurements above room temperature provide little further information, because these $Fe(OH)_3$ samples start to lose water just above this temperature. Spectra between 80 and 298 K, recorded without an external magnetic field, are composite ones showing many widely separated hyperfine fields and in addition are smeared out by magnetic relaxation occurring at different rates.

The very fact that an unique field is observed close to saturation, while many fields are present at intermediate temperatures, indicates (Fig. 4) that the magnetic transition temperature is very poorly defined. Such a poor definition of a transition point means that a significant amount of material must be composed of very fine particles. A distribution of relaxation frequencies is most likely due to the distribution of volume and shape anisotropy between the differently shaped and sized particles (Fig. 6). The clumping of the material is likely to play some secondary role in this process.

There is an obvious correlation between relaxation frequency and hyperfine field, i.e., higher frequencies are correlated with smaller fields and this corroborates the idea that these subspectra originate in smaller particles (Table 3). The complexity

TABLE 3. Hyperfine fields and relaxation frequencies as obtained from the Mössbauer data fits to the simple "Kramer's doublet" relaxation model for the $Fe(OH)_3$ powder prepared using $[Co(III)(tetraen)]_2O_2[ClO_4]_4$: sample 4

4.2	509	—	—	0	—	—

of the magnetic behaviour prevents, in our opinion, a detailed quantitative analysis of the Mössbauer spectra unless well defined and dispersed particles, or bulk material, can be produced.

However, in order to get some idea of the system behaviour we have fitted our spectra using a very simple relaxation model as follows. Spectra were fitted, within the Lorentzian approximation, as composite ones with each component being described by the magnetic Hamiltonian, with the quadrupole interaction included as a first order approximation, and a relaxation matrix taking on the following form in the quantization coordinates,

$$\mathbf{W} = \begin{pmatrix} w & -w \\ -w & w \end{pmatrix}$$

with both states having equal probabilities at thermal equilibrium. Such a model corresponds to the exact description of the axially symmetric and isolated Kramer's doublet (20), and yields the following eigenvalues of the relaxation superoperator for the 14.4 keV of the ^{57}Fe transition

$$\lambda(m_e m_g) = iw \pm [E_M^2(m_e m_g) - w^2]^{1/2} + E_Q(m_e)$$

where

$$E_M = \pm\, g_g \mu_N H_{\text{eff}}[m_g - (g_e/g_g) m_e]$$

and

$$E_Q = \left(\frac{eQ_g V_{zz}}{4}\right)\left[m_e^2 - \frac{5}{4}\right] + S$$

All symbols have their conventional meaning with w being an average switching rate, i.e. relaxation frequency. The real (line position) and imaginary (line broadening) parts of the eigenvalue $\lambda(m_e m_g)$ are shown versus relaxation frequency w in Fig. 7. The results of the fits are summarized in Table 3, while some typical spectra are shown in Fig. 4.

No attempt was made to correct intensities (partial areas) of the "broad" and "narrow" components by using eigenvectors of the relaxation matrix **W**. However, this correction is only relevant for $w > |E_M|$ for a given pair of lines. The "broad" component is always already smeared out in this region of relaxation frequency, and therefore the correction is very small. The only parameter seriously influenced is the total area of the spectrum. This parameter can be treated, in the given context, as a phenomenological one and therefore has no special meaning. The relative contribution of different "sites" is also influenced to some extent, but they also have no special meaning for such complex spectra.

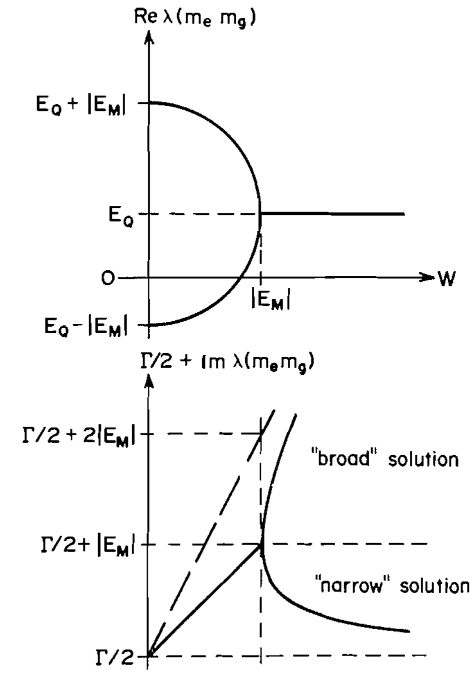

FIG. 7. The real and imaginary parts of the relaxation superoperator eigenvalues plotted versus relaxation frequency.

Conclusions

Addition of base to a solution of Fe^{3+} results in the precipitation of $Fe(OH)_3$. Oxidation of Fe^{2+} in basic solution also produces $Fe(OH)_3$. In both of these cases the precipitate is in the gelatinous form and these materials are magnetically ordered below liquid nitrogen temperature. The magnetic hyperfine fields are quite different in the two cases, being higher for the case where oxidation from Fe^{2+} to Fe^{3+} must take place. Since the DTA results show that both of these gels lose all water molecules by 250°C, we conclude that the water molecules in these two gels ($Fe_2O_3 \cdot 3H_2O$) are held in a very similar fashion in the structure. The fact that the hyperfine fields are different is perhaps due to particle size effects.

The $Fe(OH)_3$ powder, prepared by oxidation of Fe^{2+} with H_2O_2 at pH 4.5, has a similar Mössbauer behaviour to the gels. Its structure, however, must be quite different from that of the gels since the bound water molecules are lost in stages rather than all at once. The hyperfine magnetic field is smaller than for the other powders (Table 2) which we attribute to a particle size effect. No X-ray powder pattern could be observed for this material suggesting that the particle size is $\ll$80 Å in diameter. We believe that the rate of oxidation of Fe^{2+} to Fe^{3+} will govern the particle size. The "powder" preparations involving $[Co(III)(en)(dien)]_2O_2[ClO_4]_4$ and $[Co(III)(tetraen)]_2O_2[ClO_4]_4$ result in materials which have particle sizes estimated to be ~80 Å in diameter for the former case, and are ~1200 Å × 400 Å × 50 Å in the latter case (see Experimental section). As discussed above, the rate of the electron transfer reactions during these oxidations is controlled by the nature of the oxidant, and indeed the isomeric form of the Co(III) complex. Since the magnitude of the hyperfine field, in the $Fe(OH)_3$ powders, appears to follow the particle size estimates, we conclude that the oxidation of Fe^{2+} to Fe^{3+} is in the order $H_2O_2 > [Co(III)(en)(dien)]_2O_2[ClO_4]_4 > [Co(III)(tetraen)]_2O_2$-$[ClO_4]_4$.

Le produit issu de la condensation du 2,3-diaminonaphtalène avec l'acide pyruvique a été préparé, isolé sous sa forme cristalline et soumis à l'analyse par diffractions des rayons X et FT-IR. Les résultats obtenus indiquent que le dérivé existe essentiellement sous sa forme amide à l'état solide et que les molécules quasi-planaires forment, par liaisons hydrogènes, des dimères centrosymmétriques; pm 210,24, monoclinique, $C2/c$, a = 19,834(8), b = 4,636(6), c = 22,360(2) Å, β = 96,30(9)°, V = 2043,6 Å^3, Z = 8, d_0 = 1,358, d_c = 1,366 g cm^{-3}, $\lambda(\mathrm{CuK}\bar{\alpha})$ = 1,54178 Å, $\mu(\mathrm{CuK}\bar{\alpha})$ = 6,75 mm^{-1}, $F(000)$ = 880, T = 298 K, R = 0,050 pour 781 réflexions observées.

Introduction

Hinsberg was the first to report on the condensation reaction of 1,2-diaminobenzene with α-keto acids to give 3-alkyl-2-hydroxyquinoxaline (1). Later on, Morrison used this reaction as a basis for the quantitative analysis of α-keto acids from biological materials (2). The analytical advantages of this reaction reside in its rapidity and in the fact that it can be done directly in aqueous media, where under acidic conditions it yields thermally and hydrolytically stable derivatives that can readily be extracted by organic solvents.

Furthermore, the reaction is selective to α-keto acids since the formation of a six-membered ring stabilizes the derivatives, whereas other keto-containing groups form imines, which are hydrolyzed under the reaction conditions. For gas chromatographic analysis the derivatives are further converted to the trimethylsilyl ethers. This approach has been used extensively and several substituted 1,2-diaminobenzenes have been studied in order to increase the selectivity of the analysis and achieve better limits of detection (3).

In a report on the gas chromatographic analysis of quinoxalinol derivatives, Hoffman and Killinger (4) have indicated that the condensation products of the reaction of α-keto acids with 1,2-diaminobenzene existed entirely in the keto form, and not in the hydroxyquinoxaline as had been proposed previously (1, 2). They mentioned having obtained evidence from nmr and ir data that the condensation products are amides and that further silylation occurs on the nitrogen atom. Later reports by Frigerio *et al.* (5) and Langenbeck *et al.* (6) using FT-IR and mass spectrometry seem to indicate that silylation of the "quinoxalinol" derivatives takes place at the oxygen. Langenbeck suggested that an enol–keto equilibrium in solution could account for the results.

In order to eliminate the additional step of silylation necessary for the gas chromatographic analysis of the derivatives, Hayashi *et al.* (7) have used the 2,3-diaminonaphthalene derivative and hplc to analyse phenylpyruvic acid. They give the phenolic form as the reaction product but present no evidence for it. The condensation reaction of 2,3-diaminonaphthalene with pyruvic acid has also been reported by Goldstein and Streuil (8). They refer to the reaction product as 3-methyl-2-oxo-benzoquinoxaline, but do not present any structural evidence.

The use of 2,3-diaminonaphthalene to form derivatives with keto acids presents favorable conditions for their selective analysis by hplc, since the derivatives formed possess high absorbance and fluorescence properties. In seeking to use this reaction for the analysis of keto acids, we have prepared 18 derivatives (9) and have proceeded to characterize the reaction products in order to optimize the analytical method. Because some confusion remains regarding the structure of the condensation products of the reaction of 2,3-diaminonaphthalene with α-keto acids, we report here on the crystalline structure of the condensation product of 2,3-diaminonaphthalene with pyruvic acid.

Experimental

The condensation product $C_{13}H_{10}N_2O$ was prepared by reaction of pyruvic acid (Sigma Chemicals, USA) with 2,3-diaminonaphthalene hydrochloride (Aldrich Chemicals, USA) in a 2.5 *N* hydrochloric acid solution according to an existing procedure (8). The compound was isolated from the reaction media and crystals were obtained by slow vacuum sublimation. The yellow solid decomposes at 290 ± 1°C, which is in accordance with published data (8).

The mass spectrum of the compound was obtained on a Kratos MS-50 TA mass spectrometer using 70-eV electrons and a source temperature of 200°C. The molecular ion is the base peak of the spectrum and the measured monoisotopic mass at high resolution (ca. 12 000) was 210.0794, which is in accordance with the formula $C_{13}H_{10}N_2O$ (calcd. 210.0792).

FT-IR spectra were recorded on a Digilab FTS-15/C Fourier Transform Michelson interferometer, equipped with a high sensitivity

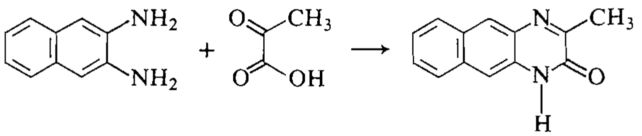

SCHEME 1

HgCdTe detector and a KBr beam splitter. The compound was introduced as KCl pellets and the resulting spectra were obtained after 1000 accumulations and subtraction of the reference material.

For the X-ray analysis, the very long flat crystalline filaments, up to 2 cm in length, were cut to an appropriate size for single crystal diffractometry. The orientation of the crystal and its unit-cell dimensions were obtained by a least-squares fit to the angular settings of 25 well-centered reflections on a Nonius CAD-4 automatic diffractometer. The crystals are monoclinic, with a unit cell of dimensions $a = 19.834(8)$, $b = 4.636(6)$, $c = 22.360(2)$ Å, $\beta = 96.30(9)°$, $V = 2043.6$ Å^3. The systematic absences of the type hkl, $h+k \neq 2n$ and $h0l$, $l \neq 2n$, are compatible with both the $C2/c$ and the Cc space groups. However, since the agreement between observed ($d_0 = 1.358$ g cm^{-3}) and calculated densities ($d_c = 1.366$ g cm^{-3}) occurs for $Z = 8$ molecules per unit cell, the most likely space group is $C2/c$. Integrated intensities were collected using Cu$K\bar{\alpha}$ ($\lambda = 1.54178$ Å) graphite-monochromatized radiation for all reflections within the hkl and $hk\bar{l}$ octants of the Ewald sphere limited by $2\theta \leq 130°$. Since the cut fragment was of dimensions 0.01 × 0.10 × 0.55 mm, the FLAT option which minimizes the absorption effects was used during the data collection. The $\omega/2\theta$ scan mode was used with a scan range defined by $\Delta\omega = (1.00 + 0.14 \tan\theta)°$. The orientation of the crystal and the intensities of three reference reflections were monitored every 100 reflections and every hour respectively. The intensity fluctuations were no higher than 2% over the duration of the measurements. The 781 reflections satisfying the criterion $I/\sigma(I) \geq 1.90$ were considered observed.

The X-ray scattering curves for C, N, and O were taken from Cromer and Mann (10) and from Stewart, Davidson and Simpson (11) for H atoms. The structure was solved by direct methods in the $C2/c$ space group using the MULTAN[2] program with all E's ≥ 1.50. The atomic coordinates and individual anisotropic temperature factors for O, N, and C atoms were refined by the block-diagonal approximation. The H atoms were found on a difference Fourier synthesis. Because of the small number of observations, the atomic coordinates and the isotropic temperature of only H(1) were refined. All the other H atoms were kept at a fixed position, 0.95 Å from their respective C atoms, and given an isotropic temperature factor B of 6.0 Å^2. At the end of the refinement, when the average (shift to σ ratio) was 0.07, $R = \Sigma\|F_o| - |F_c\|/\Sigma|F_o| = 0.050$ and $wR = [\Sigma w\Delta F^2/\Sigma wF_0^2]^{\frac{1}{2}} = 0.056$, while the goodness-of-fit, $S = [\Sigma w\Delta F^2/(m-n)]^{\frac{1}{2}} = 1.67$. The weighting scheme chosen was based on the counting statistics. The extreme fluctuations of the electron density on the final difference Fourier map were ± 0.10 e Å^{-3}.

Results and discussion

The final atomic coordinates and their standard deviations for 3-methyl-2-oxo-benzo(g)quinoxalinone are given in Table 1,[3] while the molecular structure is represented by the pair of stereoscopic drawings in Fig. 1. The molecule, which consists of a three-ring system, is best described as a naphthalene β-substituted by two amino groups taking part in a six-membered heterocycle. To that ring are attached, next to each nitrogen, a ketone and a methyl group, respectively.

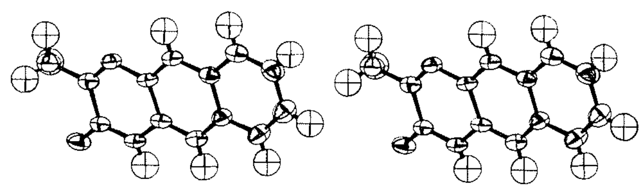

FIG. 1. Stereoscopic pair of 3-methyl-2-oxo-benzo(g)quinoxalinone.

Molecular conformation

The interatomic distances and angles are indicated on the schematic diagrams of the molecule shown in Fig. 2. In the naphthalene part of the molecule, the bond distances are alternately short and long, with values varying between 1.352(6) and 1.433(6) Å. Such an occurrence is not unusual. Indeed, it is strikingly similar to the one observed for anthracene and anthracene-like complexes with tetracyanobenzene or picric acid. The bond distances and angles from six such compounds (refs. 16−20) have been averaged and are compared in Fig. 2 to the corresponding values as found in $C_{13}H_{10}N_2O$. There are no significant differences between the two sets of bond distances and angles except for the C(13)—C(14) distance ($\Delta d = 6\sigma$) and the C(13)—C(14)—C(5) angle ($\Delta\alpha = 6\sigma$). These differences arise because of the stress imposed by N(1) being out of the molecular plane.

In the heterocycle part of the molecule, the conjugated double bonds C(2)—O(2) and C(3)—N(4), together with the

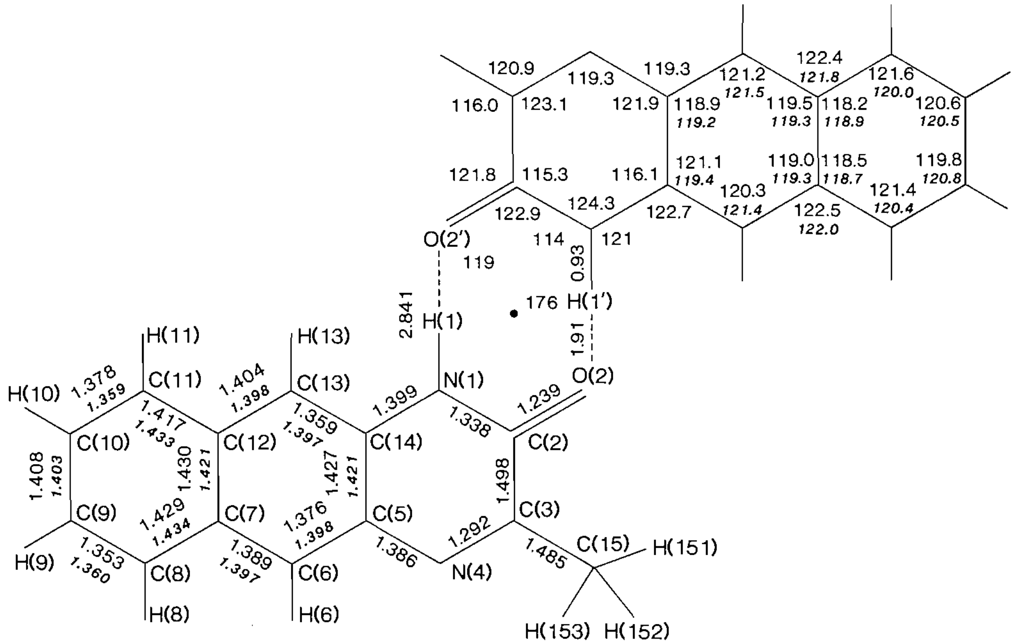

FIG. 2. Intramolecular dimensions of $C_{13}H_{10}N_2O$. The upper values are for $C_{13}H_{10}N_2O$, the values in italics refer to the corresponding distances and angles averaged from anthracene and anthracene complexes. The hydrogen bonding geometry is also included. Bond distances (Å); e.s.d. range 0.005–0.006 Å. Bond angles (°); e.s.d. range 0.3–0.4°.

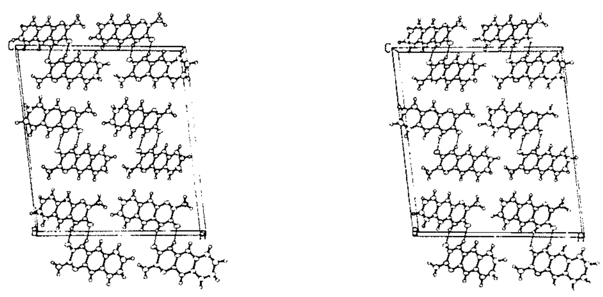

FIG. 3. Stereoscopic view of the packing of the molecules.

aromatic C(5)—C(14) bond, tend to flatten the heterocycle. Indeed, the sum of the angles in this cycle is 720.1° although there are some large deviations from 120°, especially at N(1), C(2), and C(3). The only group of atoms which is really coplanar is that constituted of C(7)−C(12), the ring farthest from the amino group. The deviations of these atoms from their mean plane ($\chi^2 = 8.9$) are of the order of 1σ. However, when the ten atoms C(5)−C(14) are included in the calculation, the deviations are more noticeable, from 5 to 10 σ. The highest deviation is noted at C(14). Of the heterocycle, C(2) and N(1) are the farthest from the above plane, at −0.101(3) and −0.133(4) Å, respectively.

Molecular packing and hydrogen bonding

H(1) is bonded to the N(1) atom at 0.94(1) Å, thus cancelling the hypothesis of enolization of the ketone at C(2). Two centrosymmetrically related molecules form a dimer through two hydrogen bonds of the type N(1)—H(1)...O(2*) where the N(1)...O(2*) distance is 2.841(5) Å. A similar situation was observed in 5-chloro-2-pyridone (21) and in 2-pyridone (22), where the N...O* distances observed in the dimers are slightly shorter, 2.796 and 2.77 Å, respectively. The characteristic geometry of the H-bonding scheme is shown schematically in Fig. 2.

The nearly planar dimers are packed in the unit cell in a herringbone manner. This arrangement is shown by the stereopair of Fig. 3.

FT-IR spectra

In order to compare these results with those that have been published in the literature on similar systems (5, 6), we have taken the FT-IR of this compound and of its deuterated analogue. The ir data are presented in Fig. 4 and are consistent with the diffraction data. The spectrum clearly indicates the presence of the carbonyl group at 1667 cm^{-1}, with additional bands at 3311, 1525, and 887 cm^{-1} that can tentatively be assigned to the NH stretching and bending modes. The 3311 band is accompanied by a series of bands in between 3233 and 3110 cm^{-1}, which can be associated with the N—H...O hydrogen bond.

The spectrum of the deuterated molecule shows that deuteration (D/H = 60:40 as measured by ms) has an effect on all the bands that are assigned to the NH group (3311, 1525, 887, and 3233−3110 cm^{-1}), thus confirming the presence of the amide form in the solid. Furthermore, in the spectrum of the partially deuterated compound, the intensity of the carbonyl band at 1667 cm^{-1} is seen to decrease by more than half and is shifted to 1652 cm^{-1}, as would be predicted by the presence of hydrogen bonding (C═O...D). A systematic study of the ir spectra of these compounds is presently being conducted on several derivatives, varying the R groups in order to confirm band assignment and the structure of the compounds in solution.

Conclusion

The results presented in this work demonstrate that the solid form of the condensation product of the reaction of 2,3-diaminonaphthalene with pyruvic acid exists predominantly in the keto form. The data obtained by both methods of analysis confirm this structure. In the X-ray analysis the compound is

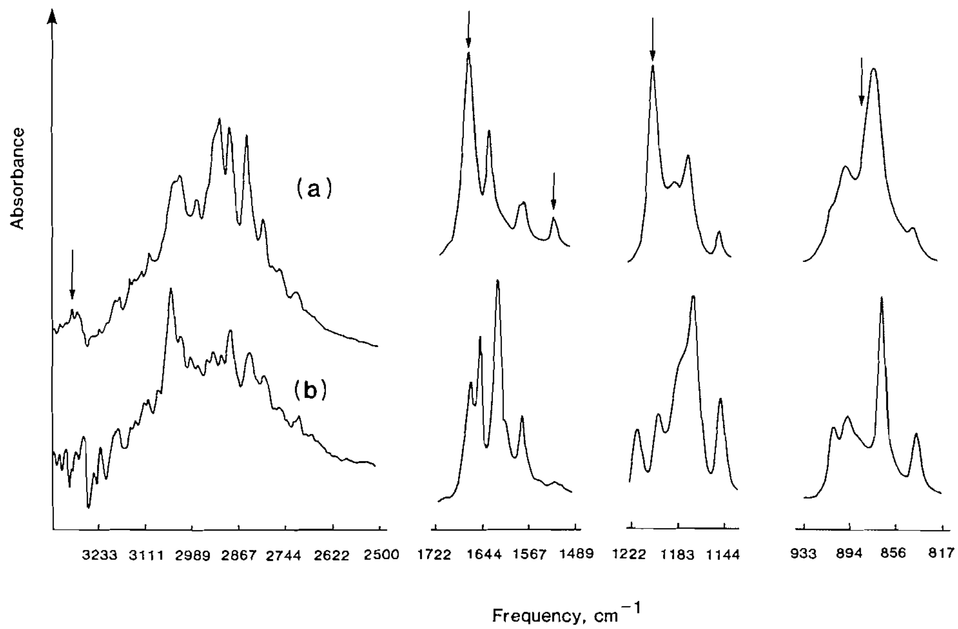

FIG. 4. FT-IR spectra of (a) 3-methyl-2-oxo-benzo(*g*)quinoxalinone; (b) D_2O exchanged as above.

found to exist solely in the amide form, the hydrogen atoms being very close to the nitrogen atoms (0.94 Å). No evidence is found for the presence of the tautomeric hydroxy form. In a similar fashion, data from the infrared analysis show the presence of the carbonyl group and also the band that can be associated to the amine at 3311, 1525, and 887 cm^{-1}. Those bands are affected by deuteration and the carbonyl band is seen as a doublet in the spectra of the partially deuterated compound, which is an indication of hydrogen bonding in the partially deuterated sample. Close examination of the ir spectra of the compound and its deuterated analogue shows a small signal at 1199 cm^{-1} that is affected by deuteration and that could possibly be related to the presence of a small amount of C—O—H. A further study on the ir spectra of several derivatives with varying R groups in the solid state and in solution is being conducted, to study the possible existence of the hydroxy compound for which there is still no evidence published.

Étude comparative dans la série des dibenzamido-alcanes, composés modèles des poly(oligométhylènes téréphtalamides)

JOSÉE BRISSON ET FRANÇOIS BRISSE[1]

Département de chimie, Université de Montréal, C.P. 6210, Succ. A, Montréal (Qué.), Canada H3C 3V1

Reçu le 2 avril 1985

JOSÉE BRISSON et FRANÇOIS BRISSE. Can. J. Chem. **63**, 3390 (1985).

La série des dibenzamido-alcanes (nDBN) a été synthétisée pour n = 2–10 et caractérisée par diffraction de rayons X et par spectroscopies infrarouge et Raman. L'étude par diffraction des rayons X révèle que l'angle dièdre ϵ entre le cycle aromatique et le groupement amide varie peu, étant en moyenne de 28,3°. Par contre, l'angle de torsion τ entre le groupement amide et la chaîne aliphatique prend des valeurs près de 180° pour n = 4, 6, 8 et 10, et près de 98°, pour n = 2, 3, 5 et 7. Dans ces derniers cas, le plan de la chaîne aliphatique est perpendiculaire au groupement amide. L'étude des spectres ir et Raman a permis de constater que la position de la bande amide V dépend de l'angle τ et peut servir à établir si celui-ci est près de 180° ou non.

JOSÉE BRISSON and FRANÇOIS BRISSE. Can. J. Chem. **63**, 3390 (1985).

The dibenzamido alcanes, nDBN, for n = 2–10, have been synthesized and characterized by X-ray diffraction and infrared and Raman spectroscopy. From X-ray diffraction it was observed than the dihedral angle ϵ between the aromatic ring and the amido group averaged 28.3° and did not vary significantly with n. The torsion angle τ between the amide group and the aliphatic chain was found to be near 180° for n = 4, 6, 8, and 10. However, for n = 2, 3, 5, and 7, τ averaged 98°. In this last case the plane of the aliphatic chain is nearly perpendicular to the plane of the amide group. The study of ir and Raman spectra in relation to conformation revealed that the position of the amide V band depends on the value of the τ angle and could be used to infer if the latter is close to 180° or not.

Introduction

Dans le cadre d'une étude portant sur la corrélation entre structure et propriété, nous nous sommes intéressés aux poly(oligométhylènes téréphtalamides) ou Nylons nT. Comme la structure de ces polyamides n'est pas facile à obtenir en diffraction de rayons X, en raison du faible nombre de taches de diffraction enregistrées, on fait appel à l'étude de composés modèles pour établir les conformations préférentielles de ce type de composé ainsi que les paramètres géométriques des molécules (distances et angles) et leurs modes d'assemblage par ponts hydrogène. Les composés modèles doivent avoir un motif chimique très semblable à celui des polymères apparentés, aussi avons nous choisi d'étudier les dibenzamido-alcanes (nDBN), pour n variant de 2 à 10 atomes de carbone. La relation entre l'un des composés modèles et le polymère parent est représentée en schéma 1.

Des études structurales par diffraction de rayons X et par spectroscopies infrarouge et Raman ont été effectuées sur ces produits ainsi que sur les deux séries d'analogues deutériés, les nDBN-d_2 pour lesquels les protons sur l'azote sont remplacés par des deutériums, et les nDBN-d_{10} pour lesquels les protons des cycles aromatiques sont remplacés par des deutériums.

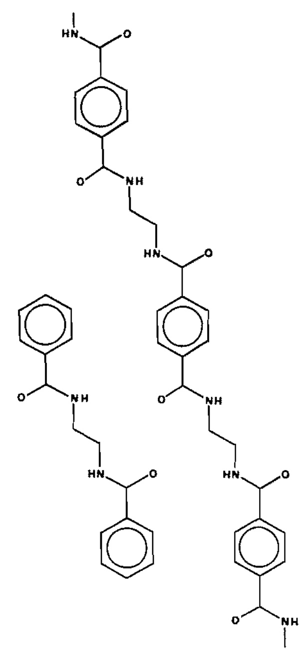

SCHÉMA 1

Partie expérimentale

Synthèse des dibenzamido-alcanes et de leurs analogues deutériés

La synthèse des dibenzamido-alcanes s'effectue par acylation de la diamine par le chlorure de benzoyle, tel que décrit par Palmer et Brisse (1). La préparation des nDBN-d_2 se fait par reflux, durant environ 6 h, des nDBN dans EtOD 95%. Les nDBN-d_{10} sont synthétisés à partir de C_6D_5COCl, de la même façon que les nDBN. Tous ont été synthétisés pour n = 2–10.

Les poly(oligométhylènes téréphtalamides) ont été synthétisés, pour n = 2–10, par polycondensation interfaciale selon la méthode de Shashoua et Eareckson (2), puis lavé avec NaOH 5%.

Les spectres infrarouges ont été enregistrés à partir de pastilles de KBr, avec un appareil IRTF Nicolet 7199 doté d'un laser HeNe de classe II. Les spectres Raman en phase solide ont été enregistrés sur un double spectromètre Spex 14018 doté d'un photomètre digital DPC-2 à partir de la raie à 514,5 nm d'un laser à argon ionisé Coherent Innova 90 série 112. Les fentes du monochromateur étaient à 100–200 μm^{-1}, ce qui correspond à une résolution de 2 cm^{-1}.

Les densités ont été mesurées par flottation dans une solution aqueuse de $ZnCl_2$. Les points de fusion ont été mesurés sur un appareil Mettler FP61 avec un taux de chauffe de 1 K min^{-1}.

Les détails des mesures de diffraction des rayons X sont rapportés dans les sections spécifiques à chacun des composés (1, 3–8).

Discussion

Les propriétés physiques des nDBN ayant un nombre pair de groupes méthyléniques sont semblables; les densités et les

[1] Auteur à qui adresser la correspondance.

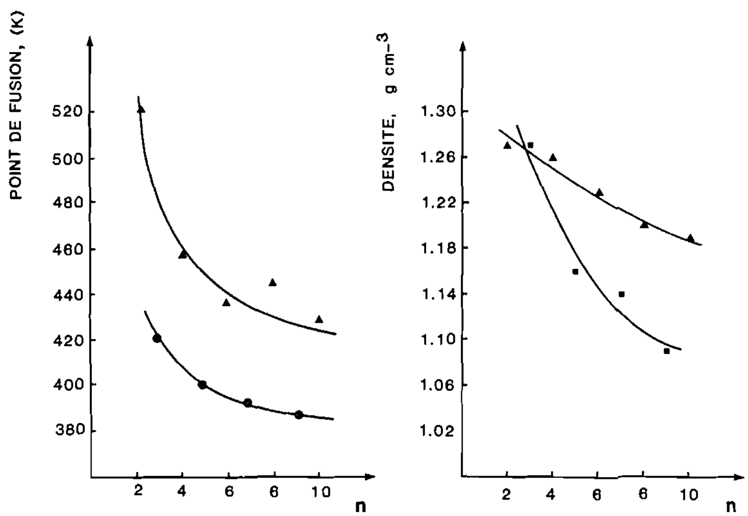

FIG. 1. Variation des points de fusion et des densités en fonction de la longueur de la chaîne.

points de fusion diminuent régulièrement lorsque le nombre d'atomes de carbone augmente en raison de la diminution relative du volume du groupement amide par rapport au restant de la molécule (fig. 1). Ces composés ont également des solubilités voisines, et l'obtention de monocristaux dans l'éthanol est rapide.

Cependant, lorsque le nombre d'unités méthyléniques de la chaîne est impair, on remarque une diminution significative des densités et des points de fusion, ce qui indique une cohésion moléculaire moins grande. Les solubilitiés sont plus élevées, et il devient plus difficile d'obtenir des monocristaux.

Les dimensions des mailles et d'autres données cristallographiques des nDBN sont présentées au tableau 1. Alors que les dimensions a et b et l'angle β varient très peu, on remarque (fig. 2) une augmentation régulière de la dimension c de la maille en fonction du nombre d'atomes de carbone de la chaîne aliphatique, pour n = 4, 6, 8 et 10. On peut exprimer cette variation linéaire des paramètres a, b et c (ângström) et du volume (ângström cube) de la maille des nDBN pairs en fonction de n par les relations:

$$a = 4{,}45 \times 10^{-3}\, n + 5{,}095$$

$$b = 8{,}70 \times 10^{-3}\, n + 5{,}291$$

$$c = 1{,}5964\, n + 21{,}976$$

$$V = 47{,}06\, n + 580{,}54$$

Il est probable qu'il en sera de même pour les autres composés pairs de cette série. Cependant, le 2DBN ne fait pas partie de cette série, et il n'existe pas de relation semblable pour les composés ayant un nombre impair de CH_2.

Les dimensions des mailles des produits deutériés ont été mesurées pour les 2DBN-d_{10}, 6DBN-d_{10}, 10DBN-d_{10}, 6DBN-d_2 et 8DBN-d_2. Les dimensions des mailles cristallines des produits deutériés sont très semblables à celles de leurs homologues non deutériés (tableau 2). Les changements sont surtout notables sur la dimension c et le volume de la maille. Toutefois, on observe que, systématiquement, les nDBN-d_{10} ont des volumes légèrement inférieurs à ceux de leurs homologues non deutériés, alors que c'est l'inverse pour les nDBN-d_2.

Les structures des dibenzamido-alcanes ont été déterminées

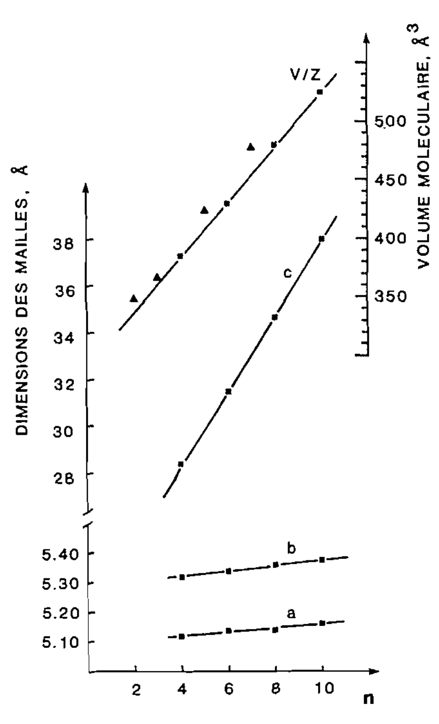

FIG. 2. Variation des paramètres de maille en fonction du nombre de méthylènes, pour n = 4, 6, 8 et 10.

pour n = 2 (1), 3 (6), 4 (4), 5 (6), 6 (5), 7 (3), 8 (7) et 10 (8). Les conformations des molécules de nDBN sont comparées à la figure 3. La structure du 5DBN présentait, à température de la pièce, un désordre évident au niveau de la chaîne aliphatique. Pour essayer d'atténuer ce désordre, nous avons effectué une seconde collection de données à T = 173 K. Effectivement, à cette température, il n'y avait plus de désordre et les distances et facteurs de température étaient alors comparables à ceux des autres dibenzamido-alcanes connus.

Distances et angles

Les distances et angles moyens des dibenzamido-alcanes sont rapportés au tableau 3, excepté pour le 10DBN, car les très faibles dimensions du cristal n'on pas permis un affinement très poussé de la structure. Les distances et angles moyens sont

comparables à 2 σ près, sauf pour les angles $C(sp^3)$—$C(sp^3)$—$C(sp^3)$ dont la moyenne est de 112,4(3)° pour les 4DBN, 6DBN et 8DBN. Pour les 3DBN, 5DBN et 7DBN, cette valeur augmente légèrement avec le nombre d'atomes de carbone en chaîne: elle passe de 112,9(3)° pour le 3DBN, à 113,5(2)° pour le 5DBN et 115,3(5)° pour le 7DBN. On ne remarque pas d'effet notable sur les moyennes des distances et des angles du 5DBN dont la structure a été mesurée à basse température.

Si l'on étudie de plus près les distances et angles du cycle aromatique des composés, on remarque que l'angle α situé sur le carbone porteur du groupement amide est systématiquement inférieur de 1 à 2° à la moyenne de 120° des angles intracycliques. Domenicano et Vaciago (9) ont attribué ceci à un effet de conjugaison entre le cycle aromatique et le substituant. Ces auteurs observaient également des valeurs supérieures à 120° pour les angles β adjacents à l'angle du carbone substitué, ce qui est aussi le cas pour tous les *n*DBN, sauf pour un des angles du 6DBN.

Conformation

On peut distinguer trois éléments importants de la conformation des dibenzamido-alcanes: (*i*) l'angle dièdre ε entre les plans du cycle aromatique et du groupement amide; (*ii*) l'angle de torsion τ qui désigne l'angle entre le groupement amide et la chaîne aliphatique; (*iii*) la conformation de la chaîne aliphatique.

On remarque, pour tous les *n*DBN, une constance au niveau de la valeur de l'angle ε (fig. 4*a*). Celui-ci est de 28,3°, en moyenne, avec des valeurs extrêmes de 19,0 (2DBN) et 34,1° (3DBN). Ces valeurs concordent bien avec celles obtenues par analyse conformationnelle des benzamides par Laupètre et Monnerie (10). Ces auteurs notaient un minimum d'énergie conformationnelle pour $\epsilon = 30°$, avec une barrière d'énergie de rotation peu élevée entre 0 et 30°. La valeur de l'angle ε ne dépend pas de la longueur de la chaîne aliphatique.

Pour ce qui est de l'angle τ (fig. 4*b*), on remarque une beaucoup plus grande dispersion des résultats avec, cependant, certaines constances. Pour les *n*DBN pairs, la valeur de cet angle se situe aux alentours de 180°, sauf dans le cas du 2DBN pour lequel cet angle est de 91,5°. Dans le cas des *n*DBN impairs, on n'observe pas d'angle τ près de 180°. La valeur de cet angle se rapproche plutôt de celle observée pour le 2DBN, la moyenne de $|\tau|$ étant de 98°. Ceci, ainsi que le mode d'empilement moléculaire, nous fait inclure le 2DBN dans le groupe des *n*DBN impairs au point de vue structural.

Trois autres composés, les *N,N'*-dibenzoyl-*para*-phénylènediamine (11), *N,N'*-diéthyladipamide (12) et *N,N'*-bis(β-chloro-éthyl)pimélamide (13), présentent des angles de torsion τ différents de 180°, soient −56,3, −124 et 162°, respectivement.

La conformation de la chaîne aliphatique des *n*DBN, pour n = 4, 6, 8 et 10, est entièrement *trans* coplanaire. C'est le cas aussi du 2DBN et du 7DBN. Par ailleurs, dans les cas du 3DBN et du 5DBN, on note des conformations $a^-tg^+a^+$ et $g^+g^+tg^+ta^+$ ($t \simeq 180°$; $g \simeq 60°$; a est non *trans*, non *gauche*), soit une alternance d'angles *gauche* et *trans* si l'on fait abstraction des premiers et derniers angles de ces séquences qui sont les angles τ.

Cohésion moléculaire et ponts hydrogène

Les molécules des dibenzamido-alcanes sont maintenues entre elles par ponts hydrogène. L'empilement moléculaire reflète les disparités entre *n*DBN pairs et impairs (fig. 5). Pour n = 4, 6, 8 et 10, chaque molécule est liée par ponts hydrogène

à deux autres, formant ainsi de longs rubans. Ces derniers sont imbriqués les uns vis-à-vis des autres par un assemblage en arête de poisson. Malgré des différences de conformation, le 3DBN adopte aussi le même arrangement. Bien que le 7DBN présente un empilement moléculaire différent, chaque molécule est liée à deux voisines par ponts hydrogène, formant aussi de longs rubans, tel que l'on peut le voir sur la figure 5.

Alors que dans les cas précédents chaque molécule était reliée à deux voisines par ponts hydrogène, dans le cas du 2DBN et du 5DBN, chaque molécule est maintenant reliée à

quatre molécules différentes. Pour le 2DBN, ceci est dû à un glissement des molécules perpendiculairement à la direction de propagation des ponts hydrogène, et a pour effet de créer un réseau bidimensionnel de ponts hydrogène, les molécules réunies entre elles formant des feuillets. On retrouve un réseau de ponts hydrogène semblable pour le *N,N'*-bis(β-chloro-éthyl)-pimélamide (13). Le 5DBN ne peut être apparenté à aucune autre structure précédemment décrite dans cette série; celui-ci forme un réseau tridimensionnel de ponts hydrogène où le premier groupement amide de chaque molécule est perpendiculaire au second. Il s'ensuit que chaque molécule est reliée à quatre voisines selon deux directions différentes, perpendiculaires entre elles, et perpendiculaires à la direction d'élongation de la chaîne aliphatique. Si l'on compare la géométrie des ponts hydrogène des dibenzamido-alcanes (tableau 4), on remarque d'abord une déviation de la linéarité des ponts hydrogène des 2, 3, 5 et 7DBN par rapport aux 4, 6, 8 et 10DBN, car pour l'angle N...O—C, on observe une variation d'au moins 10° en passant d'un groupe à l'autre. Les distances O...N et H...O sont comparables, avec des valeurs particulièrement courtes pour le 5DBN. Même la structure mesurée à la température de la pièce donnait des distances N...O plus courtes que celles des autres *n*DBN. Leur raccourcissement n'est donc pas un effet attribuable à la température à laquelle la mesure a été prise.

Spectroscopies infrarouge et Raman

Depuis plusieurs années, on remarque la publication de nombreux articles où il est question de la détermination de la conformation de polymères à partir des spectres ir et Raman. Les Nylons aliphatiques (15–18) et, plus récemment, les poly(oligométhylènes téréphtalates) (19–21) ont ainsi été étudiés. Nous avons voulu étudier la possibilité d'appliquer l'étude des spectroscopies ir et Raman aux poly(oligométhylènes téréphtalamides). Afin d'établir une base solide pour l'étude des spectres des polymères, nous avons d'abord examiné les spectres ir et Raman des *n*DBN. Les spectres de leurs analogues N-deutériés (*n*DBN-d_2) et deutériés sur le cycle

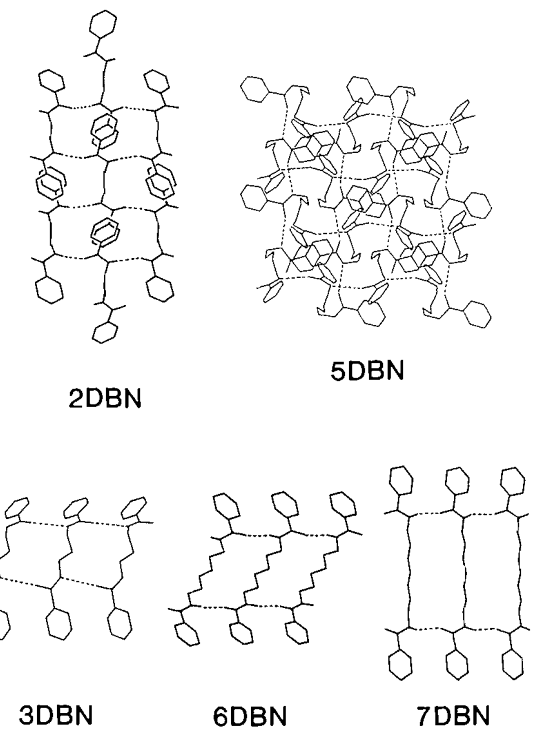

FIG. 5. Réseaux de ponts hydrogène des nDBN.

aromatique (nDBN-d_{10}) ont été utilisés pour l'attribution des bandes.[2] Les spectres ir des amides sont caractérisés par la présence de cinq bandes bien distinctes. Les bandes amide II, amide V, et la région de cisaillement des méthylènes seront surtout étudiées ici (fig. 6 et tableau 5).

(1) *Position de la bande amide II*

On observe une variation de la fréquence de la bande amide II: celle-ci passe de 1535 cm^{-1} approximativement, pour la plupart des composés, à 1562 cm^{-1} pour le 2DBN et 1553 cm^{-1} pour le 5DBN. On aurait pu attribuer cette variation aux différences de valeur de l'angle τ dans les deux formes, mais ce n'est pas le cas puisque le 3DBN et le 7DBN ne présentent pas un tel déplacement de la bande amide II. Comme ces deux composés présentent des ponts hydrogène avec quatre molécules voisines, on peut supposer que la fréquence de vibration est plus élevée, dans ce cas, en raison des contraintes accrues dans un tel réseau de ponts hydrogène.

(2) *Bande amide V*

Cette bande du spectre ir est la plus informative au point de vue conformationnel. Elle est en effet sensible à la valeur de l'angle τ. Sa valeur passe de 644–652 cm^{-1}, lorsque l'angle τ est près de 180°, à 664–673 cm^{-1}, lorsque celui-ci est différent de 180° (fig. 6 et tableau 5). Cette bande est due à la vibration de déformation hors plan δ(N—H). Lorsque l'angle τ est de 180°, la chaîne aliphatique se trouve dans le même plan que le groupement amide et la vibration hors plan peut s'effectuer sans interaction avec les méthylènes. Par ailleurs, lorsque l'angle τ est différent de 180°, les groupements méthylènes se retrouvent dans un plan perpendiculaire au groupement amide,

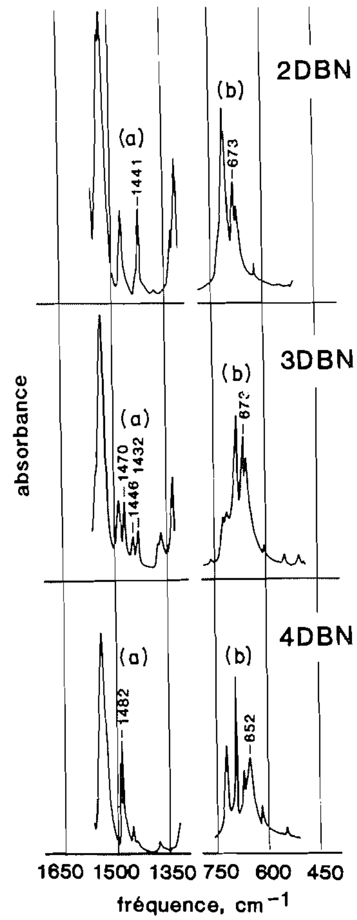

FIG. 6. Spectres infrarouges des 2DBN, 3DBN et 4DBN. (a) Région de cisaillement des méthylènes. (b) Région de la bande amide V, déformation hors plan δ(N—H).

et la vibration hors plan N—H peut être gênée par la présence des hydrogènes méthyléniques, ce qui se traduit par une augmentation de la fréquence de vibration δ(N—H).

(3) *Région de cisaillement des méthylènes*

Cette région qui s'étend de 1465 à 1431 cm^{-1} est particulièrement importante. En effet, on observe des bandes d'intensité moyenne entre 1465 et 1431 cm^{-1}, dans le cas des 2DBN, 3DBN, 5DBN et 7DBN en infrarouge, alors que celles-ci sont très faibles pour les 4DBN, 6DBN, 8DBN et 10DBN. Ces bandes sont attribuées à des vibrations de cisaillement des méthylènes. Dans les spectres Raman, par contre, les bandes entre 1465 et 1445 cm^{-1} sont d'intensité moyenne pour tous les dibenzamido-alcanes. Ceci nous mène à penser que la faible intensité de ces bandes en ir, pour les 4, 6, 8 et 10 DBN, serait due à la présence du centre de symétrie cristallographique au milieu du lien CH_2—CH_2 central de ces molécules. Les spectres du 2DBN révèlent que la bande à 1441 cm^{-1} est présente en ir, et absente en Raman. C'est l'inverse qui est observée pour les autres nDBN pairs. Ceci pourrait être dû au fait que, dans ce cas, le plan des méthylènes est perpendiculaire au plan des groupements amides. Cette vibration serait due au cisaillement des méthylènes adjacents à la fonction amide. L'intensité de ces bandes serait donc fonction de la symétrie de la chaîne et de son orientation par rapport au groupement amide.

(4) *Structure du dibenzamido-1,9 nonane (9DBN)*

Jusqu'ici, la structure du dibenzamido-1,9 nonane n'a pas pu

[2] On peut se procurer les tableaux des fréquences infrarouge et Raman des nDBN, nDBN-d_2 et nDBN-d_{10} en s'adressant au Dépôt des données non publiées, ICIST, Conseil national de recherches du Canada, Ottawa (Ont.), Canada K1A 0S2.

*TF: très forte; F: forte; m: moyenne; f: faible; tf: très faible; ep: épaulement.

être établie par diffraction de rayons X, car nous n'avons pas pu obtenir de monocristaux de taille adéquate. Cependant, nous avons pu déterminer les paramètres a, b et β de la maille par précession sur un cristal maclé. Ceci nous a permis d'indexer le diagramme de poudre du 9DBN. Les dimensions de la maille cristalline présentées au tableau 1 sont très comparables à celles du 7DBN.

L'étude des spectres ir et Raman nous permet d'affirmer que l'angle τ sera différent de 180° en raison de la position de la bande amide V qui se retrouve vers 668 cm^{-1}, comme dans le cas des 2DBN, 3DBN, 5DBN et 7DBN. On retrouve la bande amide II à 1538 cm^{-1}, comme dans le cas de la plupart des dibenzamido-alcanes, sauf du 2DBN et du 5DBN, ce qui nous fait supposer que les molécules devraient être assemblées entre elles par ponts hydrogène formant des rubans, et non par un réseau de ponts hydrogène bi- ou tri-dimensionnel. De même, les bandes à 1467 et 1431 cm^{-1} sont d'intensité moyenne en ir et en Raman, ce qui confirme la présence d'angles τ différents de 180°.

Le 9DBN aurait donc une structure comparable soit à celle du 3DBN soit à celle du 7DBN, dépendant de la conformation de la chaîne aliphatique qui n'est pas établie. On serait porté à décrire la structure du 9DBN de la même manière que celle du 7DBN, puisque leurs mailles cristallines ont de grandes analogies.

(5) *Spectroscopie des polymères*

(a) *Spectre infrarouge du Nylon 6*

Si l'on confronte les résultats obtenus par l'étude des spectres ir et Raman des dibenzamido-alcanes à ceux obtenus précédemment pour le Nylon 6 (15), on remarque une analogie évidente. Le Nylon 6 est polymorphique et l'on observe des fréquences différentes pour les bandes amide II et V des formes α et γ.

Arimoto (15) notait un déplacement de la bande amide II de 1545 pour le Nylon 6, forme α, à 1562 cm^{-1} pour le Nylon 6, forme γ. Le Nylon 6, forme α, est entièrement *trans* coplanaire, alors que dans le modèle proposé par Vogelsong (14) pour la forme γ du Nylon 6, on note un réseau de ponts hydrogène tridimensionnel, semblable à celui du 5DBN. Ceci viendrait appuyer la relation entre ce déplacement de fréquence et le type de réseau de ponts hydrogène.

D'autre part, on constate une augmentation de la fréquence de la bande amide V lorsque l'on passe de la forme α à la forme γ du Nylon 6; celle-ci varie de 692 à 708 cm^{-1} (15). Comme on observe une valeur de l'angle τ de $-93°$ (14) pour la forme γ du Nylon 6, on peut ici aussi attribuer ce déplacement à la valeur de l'angle τ, comme pour les dibenzamido-alcanes.

(b) *Structure du Nylon 6T*

La période de répétition du Nylon 6T est connue; elle est de 15,60 Å (22, 23). Si ce composé était entièrement *trans* coplanaire avec des angles ϵ de $\pm 30°$, on observerait une période de répétition de 16,10 Å. L'écart entre ces deux valeurs peut s'expliquer soit par la présence d'un angle de torsion *gauche* au sein de la chaîne aliphatique, soit par une valeur de l'angle τ de 99°. L'étude du spectre ir du Nylon 6T est en accord avec une valeur de l'angle τ différente de 180°, puisque l'on observe des bandes d'intensité moyenne entre 1450 et 1420 cm^{-1} et que la bande amide V se retrouve à une fréquence de 670 cm^{-1} comme pour les 2DBN, 3DBN, 5DBN et 7DBN.

Conclusion

L'analyse des dibenzamido-alcanes nous a permis d'établir: (*i*) que la valeur de l'angle ϵ entre le groupement aromatique et le groupement amide varie très peu et est en moyenne de 28,3°; (*ii*) que l'angle τ entre le groupement amide et la chaîne aliphatique peut varier et prend des valeurs proches de 180 ou 90°; (*iii*) que la conformation *trans* coplanaire et les conformations composées d'une alternance d'angles *gauche* et *trans* sont favorisées; (*iv*) qu'on peut, à l'aide de la spectroscopie ir, déterminer si l'angle τ est près de 180° ou non.

Adducts of diphenyllead diselenocyanate with some O- and N-donor ligands[1]

IVOR WHARF, RYSZARD WOJTOWSKI, AND MARIO ONYSZCHUK[2]
Department of Chemistry, McGill University, Montreal, P.Q., Canada H3A 2K6

Received March 22, 1985

IVOR WHARF, RYSZARD WOJTOWSKI, and MARIO ONYSZCHUK. Can. J. Chem. **63**, 3398 (1985).

The preparation and properties of $Ph_2Pb(SeCN)_2$ have been reinvestigated. Infrared spectra show that the solid is polymeric with stronger Pb—Se and weaker Pb—N bonds. In *N,N*-dimethylformamide (DMF) solution ν(CN) values are consistent with complete ionization to $NCSe^-$, but coordinated N- and Se-bound selenocyanate species are observed when DMF/CH_2Cl_2 mixtures are used as solvents. The first 1:2 adducts of $Ph_2Pb(SeCN)_2$ with hexamethylphosphoramide (HMPA), triphenylphosphine oxide (Ph_3PO), pyridine-*N*-oxide (pyO), 2,4,6-collidine-*N*-oxide (collO), and dimethyl sulphoxide (DMSO) have been prepared, while with 4-picoline-*N*-oxide (4-picO) a 1:4 adduct is obtained. Infrared data show $Ph_2Pb(SeCN)_2\cdot 2L$ (L = HMPA, Ph_3PO, collO) are in fact isoselenocyanates, but the pyO and DMSO adducts are selenocyanates. Amine adducts $Ph_2Pb(SeCN)_2\cdot 2L$ (L = morpholine (morph), quinoline (quin), piperidine (pipy)) and $Ph_2Pb(SeCN)_2\cdot 3LL$ (LL = α,α'-dipyridyl (dipy), 1,10-phenanthroline (phen)) have been prepared. Infrared data suggest that amine adducts most probably have *N*-bonded selenocyanate groups, in some cases with ionic selenocyanate also present. The adduct with 4-picO also contains ionic selenocyanate.

IVOR WHARF, RYSZARD WOJTOWSKI et MARIO ONYSZCHUK. Can. J. Chem. **63**, 3398 (1985).

On étudie de nouveau la préparation et les propriétés du $Ph_2Pb(SeCN)_2$. Les spectres infrarouges révèlent que le solide est un polymère ayant des liaisons Pb—Se plus fortes et des liaisons Pb—N plus faibles. En solution dans le *N,N*-diméthylformamide (DMF), les valeurs de ν(CN) sont en accord avec une ionisation complète donnant des ions $NCSe^-$; cependant, si on utilise des mélanges de DMF/CH_2Cl_2 comme solvants, on observe la présence d'espèces sélénocyanates N- et Se-coordonnées. On a préparé les premiers adduits-1:2 du $Ph_2Pb(SeCN)_2$ avec l'hexaméthylphosphoramide (HMPA), l'oxyde de triphénylphosphine (Ph_3PO), le *N*-oxyde de pyridine (pyO), le *N*-oxyde de collidine-2,4,6 (collO) et le diméthylsulfoxyde (DMSO) tandis qu'avec le *N*-oxyde de picoline-4 (picO-4) on obtient un adduit 1:4. Les spectres infrarouges révèlent que les complexes $Ph_2Pb(SeCN)_2\cdot 2L$ (L = HMPA, Ph_3PO, collO) sont en fait des isosélénocyanates alors que les adduits avec la pyO ou le DMSO sont des sélénocyanates. On a préparé les adduits aminés $Ph_2Pb(SeCN)_2\cdot 2L$ (L = morpholine (morph), quinoline (quin), pipéridine (pipy)) et $Ph_2Pb(SeCN)_2\cdot 3LL$ (LL = α,α'dipyridyle (dipy), phénantroline-1,10 (phen)). Les données infrarouges suggèrent que les adduits aminés sont probablement des groupes sélénocyanates liés par l'azote et que, dans certains cas, il y a aussi du sélénocyanate sous forme ionique. L'adduit avec le picO-4 contient également du sélénocyanate sous la forme ionique.

[Traduit par le journal]

Introduction

In a study of adducts formed by triphenyllead isothiocyanate and selenocyanate (1) significant changes in bonding were noticed on going from $Ph_3PbNCS\cdot L$ (all Pb—N bonded) to $Ph_3PbNCSe\cdot L$ (Pb—N or Pb—Se bonded) depending on L, with the latter systems showing linkage isomerism in solution. Therefore, we decided to study the adducts formed by diphenyllead diselenocyanate with a variety of O- and N-donor ligands for comparison with their thiocyanate analogues, $Ph_2Pb(NCS)_2\cdot 2L$, which were reported earlier (2). As before, NCSe group frequencies, particularly ν(CN) and ν(CSe), have been used to determine the selenocyanate bonding mode in these compounds.

Diphenyllead diselenocyanate was prepared earlier (3) using selenium selenocyanate and triphenyllead selenocyanate. We now report a more convenient preparation with higher yield from diphenyllead dichloride, together with a more detailed study of the selenocyanate.

Experimental

All experimental procedures were as described earlier (1, 2). Diphenyllead dichloride (Alfa) was used as received. All operations were carried out in the *absence of light*.

[1] Presented in part by I.W. at the Fourth International Conference on the Organometallic and Coordination Chemistry of Germanium, Tin and Lead, Montreal, Canada, Aug. 8–11, 1983, paper P-19.

Preparations

Diphenyllead diselenocyanate

Diphenyllead dichloride (13.0 g) was stirred in methanol (1.0 L) at room temperature for 45 min. Potassium selenocyanate (13.0 g) was added to the well-stirred suspension and the mixture vigorously stirred for 2.5 h at room temperature. It was then poured into stirred ice-cold water (1.0 L). The resulting white solid was filtered, washed with water, and dried in a vacuum desiccator; yield, 97%, mp 179°C (dec.). *Anal.* calcd. for $(C_6H_5)_2Pb(SeCN)_2$: C 29.4, H 1.75, N 4.9; found: C 29.7, H 1.8, N 4.9.

Adducts of diphenyllead diselenocyanate

O-Donor adducts. Diphenyllead diselenocyanate (1.0 g) (**I**) was stirred at room temperature with a toluene solution containing a large excess of the ligand for 24–48 h. The white *adduct* obtained was filtered, washed with toluene, and dried in vacuum at room temperature.

Prepared in this manner from **I** were *$Ph_2Pb(SeCN)_2\cdot 2Ph_3PO$* using Ph_3PO (2.0 g) in toluene (20 mL); yield, 81%, mp 137°C. *Anal.* calcd. for $C_{50}H_{40}N_2O_2P_2PbSe_2$: C 53.2, H 3.6, N 2.5; found: C 53.1, H 3.6, N 2.35. Ir (Nujol mull): 1142 cm^{-1} (coordinated P═O); *$Ph_2Pb(SeCN)_2\cdot 2DMSO$* using DMSO (2.0 g) in toluene (10 mL); yield, 95%, mp 70°C (dec.). *Anal.* calcd. for $C_{18}H_{22}N_2O_2PbS_2Se_2$: C 29.7, H 3.0, N 3.85; found: C 29.8, H 2.9, N 3.8. Ir (Nujol mull): 950, 946 cm^{-1} (coordinated S═O); *$Ph_2Pb(SeCN)_2\cdot 2pyO$* using pyO (1.0 g) in toluene (50 mL); yield, 45%, mp 97°C. *Anal.* calcd. for $C_{24}H_{20}N_4O_2PbSe_2$: C 37.85, H 2.6, N 7.35; found: C 38.1, H 2.6, N 7.2. Ir (Nujol mull): 1206 cm^{-1} (coordinated N → O); *$Ph_2Pb(SeCN)_2\cdot 4(4\text{-}picO)$* using 4-picO (1.0 g) in toluene (100 mL); yield, 80%, mp 103°C. *Anal.* calcd. for $C_{38}H_{38}N_6O_4PbSe_2$: C 45.3, H 3.8, N 8.3%; found: C 45.1, H 3.8, N 8.1. Ir (Nujol mull): 1202 cm^{-1}

(coordinated N → O); *$Ph_2Pb(SeCN)_2 \cdot 2collO$* using collO (3.0 g) in toluene (10 mL); yield, 78%, mp 111°C. *Anal.* calcd. for $C_{30}H_{32}N_4O_2PbSe_2$: C 42.6, H 3.8, N 6.6; found: C 43.0, H 3.9, N 6.55. Ir (Nujol mull): 1199 cm^{-1} (coordinated N → O).

Diphenyllead diselenocyanate-hexamethylphosphoramide (1:2)

Pentane (50 mL) was added to a mixture of **I** (1.0 g) in HMPA (4.0 g) which had been stirred at room temperature for 24 h. Further stirring (2 h) gave the crystalline *adduct* which was filtered, washed with pentane, and dried as above; yield, 68%, mp 124°C. *Anal.* calcd. for $C_{26}H_{46}N_8O_2P_2PbSe_2$: C 33.6, H 5.0, N 12.05; found: C 33.8, H 5.1, N 12.0. Ir (Nujol mull): 1192 cm^{-1} (coordinated P=O).

N-Donor adducts. Diphenyllead diselenocyante (1.0 g) (**I**) was stirred at room temperature with a pentane, benzene, or anhydrous ether solution of a large excess of the ligand for 24–48 h. The white *adduct* (sometimes first formed as an oil) was filtered, washed with the reaction solvent, and dried in air or in vacuum at room temperature.

Prepared in this manner from **I** were *$Ph_2Pb(SeCN)_2 \cdot 2morph$* using morpholine (3.0 g) in anhydrous ether (40 mL); yield, 75%, dec. 77–83°C. *Anal.* calcd. for $C_{22}H_{28}N_4O_2PbSe_2$: C 35.4, H 3.8, N 7.5; found: C 34.9, H 3.8, N 7.2; *$Ph_2Pb(SeCN)_2 \cdot 2quin$* using quinuclidine (3.0 g) in pentane (20 mL); yield, 92%, mp 107°C. *Anal.* calcd. for $C_{28}H_{36}N_4PbSe_2$: C 42.4, H 4.6, N 7.05; found: C 42.1, H 4.5, N 7.0; *$Ph_2Pb(SeCN)_2 \cdot 3dipy$* using α,α′-dipyridyl (1.5 g) in pentane (15 mL); yield, 90%, dec. 113–123°C. *Anal.* calcd. for $C_{44}H_{34}N_8PbSe_2$: C 50.8, H 3.3, N 10.8; found: C 51.4, H 3.25, N 10.95; *$Ph_2Pb(SeCN)_2 \cdot 3phen$* using 1,10-phenanthroline (2.0 g) in benzene (20 mL); yield, 98%, mp 138°C (dec.). *Anal.* calcd. for $C_{50}H_{34}N_8PbSe_2$: C 53.95, H 3.1, N 10.1; found: C 53.2, H 3.45, N 10.1.

Diphenyllead diselenocyanate-piperidine (1:2)

A mixture of **I** (1.0 g) and piperidine (3.0 g) was stirred for 4 h at room temperature to form an oily solution. Adding pentane (15 mL) produced an oily mixture which with further stirring (24 h) gave the pale yellow *adduct*, which was isolated as above; yield, 98%, mp 36–39°C (dec.). *Anal.* calcd. for $C_{24}H_{32}N_4PbSe_2$: C 38.9, H 4.3, N 7.55; found: C 39.0, H 4.4, N 7.7.

Results and discussion

Properties

As reported earlier (3), $Ph_2Pb(SeCN)_2$ is a white powder insoluble in water and non-coordinating solvents, but soluble in strong donor organic solvents like dimethylformamide, dimethylsulphoxide, etc. However, we have found that it is light-sensitive, unlike $Ph_3PbSeCN$, turning pink on slight exposure and dark red on strong exposure to light. Presumably this reflects a stronger tendency to decompose with loss of selenium than found for $Ph_3PbSeCN$. Although apparently insoluble in weak donor solvents like acetone and tetrahydrofuran, $Ph_2Pb(SeCN)_2$ rapidly became pink when shaken with these solvents indicating sufficient solubility to promote decomposition, while $Ph_3PbSeCN$ also tends to decompose more easily in solution.

All adducts are white solids (except $Ph_2Pb(SeCN)_2 \cdot 2pipy$ which is pale yellow) with melting points (~100°C) often with decomposition, which are lower than those of their thiocyanate analogues (2). The same trend was noted earlier (1) when comparing corresponding data for $Ph_3PbX \cdot L$ (X = NCS or SeCN) pairs. All adducts decomposed when washed with organic solvents, e.g., benzene, acetone, etc., leaving behind insoluble $Ph_2Pb(SeCN)_2$, unlike those of $Ph_2Pb(NCS)_2$, including $Ph_2Pb(NCS)_2 \cdot 2HMPA$ which could be recrystallized from benzene. In this work $Ph_2Pb(NCSe)_2 \cdot 2HMPA$ could only be recrystallized by using a large excess of HMPA.

Attempts to isolate adducts of $Ph_2Pb(SeCN)_2$ with *N,N*-dimethylformamide (DMF), trimethylphosphate, triphenylphosphine sulphide, pyridine and picolines, pyrrolidine, and *N,N,N′,N′*-tetramethylethylene diamine were unsuccessful by the methods used here. Since DMF formed an adduct with $Ph_2Pb(NCS)_2$, this result could imply that the selenocyanate analogue is the weaker Lewis acid. However, when adduct formation requires the fission of chalcocyanate bridges before metal-ligand bonds can be formed, the range of adducts prepared may not reflect the relative strengths of similar Lewis acids, as was found earlier for the $Ph_3PbSeCN/Ph_3PbNCS$ pair.

Infrared spectra and selenocyanate bonding

When as in the present case substances cannot be obtained as single crystals because of the preparative methods used, or cannot be examined in solution due to their insolubility and/or decomposition, solid state infrared measurements remain as the only readily available method for studying the structures of these compounds.[3] All compounds showed the absorptions (1700–400 cm^{-1}) expected for the "Ph_2Pb" moiety as well as, for the adducts, ligand peaks, including those shifted by ligand coordination to the lead atom. In particular, ν(SO) values show the DMSO ligands are O-bonded in the adduct with this ligand, and there are no absorptions in the region for S-bonded DMSO (4). Of more significance are selenocyanate group frequencies ν(CN), ν(CSe), and ν(NCSe) as these indicate the mode of coordination. The vibrational criteria for determining NCSe bonding type used here were those proposed by Norbury (5) and have been listed elsewhere (1). Although δ(NCSe) values (or overtones) provide some useful information, in this work, we found definite identification of these weak to very weak absorptions, often overlapping with phenyl or ligand bands virtually impossible, and so only ν(CN) and ν(CSe) values have been reported in Table 1. Nearly all ν(CN) absorptions have weak shoulders 40–50 cm^{-1} to lower frequency, corresponding to the expected $\nu(^{13}CN)$ peaks.

(i) $Ph_2Pb(SeCN)_2$

Values of ν(CN) and especially ν(CSe) show $Ph_2Pb(SeCN)_2$ has bridging selenocyanate groups giving a polymeric structure similar to that proposed earlier for $Ph_2Pb(NCS)_2$ (2). The previous (3) assumption of lead–selenium bonding based on the ν(CN) value alone is inconsistent with the properties of $Ph_2Pb(SeCN)_2$, although Pb—Se bonds are probably stronger than Pb—N bonds in the suggested structure. In $Ph_2Pb(NCS)_2$ it is the Pb—N bonds which are stronger.

The infrared spectrum of a solution of $Ph_2Pb(SeCN)_2$ in dimethylformamide (0.01–0.025 *M*) has a single sharp absorption (2066 cm^{-1}; $\nu_{1/2}$ = 13–16 cm^{-1}; $A_{CN} = 2.7 \times 10^4$)[4] in the ν(CN) region characteristic of ionic selenocyanate. Thus $Ph_2Pb(SeCN)_2$ dissolves only when ionization can occur in a strong donor solvent, L.

$$Ph_2Pb(SeCN)_2(s) \overset{\text{excess L}}{\rightleftarrows} Ph_2PbL_4^{2+} + 2NCSe^-$$

To determine whether other species may exist, following our earlier work (6), the DMF was diluted with a non-coordinating solvent, CH_2Cl_2. In 50% (v/v) DMF/CH_2Cl_2 solutions of $Ph_2Pb(SeCN)_2$ (0.010–0.012 *M*) only one ν(CN) peak was observed (2067 cm^{-1}; $\nu_{1/2}$ = 17 cm^{-1}; $A = 3.0 \times 10^4$) but further dilution (20% DMF/CH_2Cl_2) caused a weak absorption

[3] Raman spectra of $Ph_2Pb(SeCN)_2$ and its adducts could not be obtained because of their ready tendency to undergo thermal- and photo-decomposition.

[4] $\nu_{1/2}$ is the width at half-peak height; A_{CN} is the integrated molar absorptivity in M^{-1} cm^{-2} $(NCSe)^{-1}$.

[a] ν(CN) for $Ph_2Pb(SeCN)_2$.
[b] Obscured by ligand bands.
[c] ν(CSe) for $Ph_2Pb(SeCN)_2$.

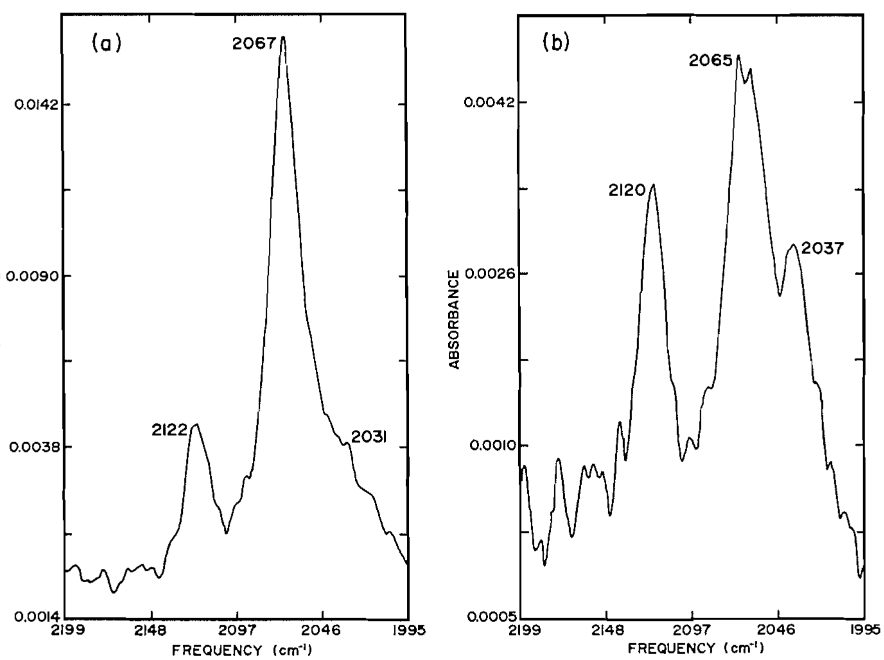

FIG. 1. Infrared spectra in the ν(CN) region of $Ph_2Pb(SeCN)_2$ in (*a*) 10% DMF/CH_2Cl_2 (0.0030 *M*), and (*b*) 5% DMF/CH_2Cl_2 (0.0021 *M*).

at 2120 cm^{-1} ($\nu_{1/2} \sim 16\ cm^{-1}$) to appear, indicative of a species containing the Pb—SeCN unit. This peak grows as more CH_2Cl_2 is added and in 10% DMF/CH_2Cl_2 the infrared spectrum (Fig. 1(*a*)) has a broad shoulder at 2031 cm^{-1} showing an N-bonded species is also present. Finally in 5% DMF/CH_2Cl_2 (Fig. 1(*b*)) two quite distinct peaks which may be assigned to Se-bonded and N-bonded selenocyanate groups were observed at 2120 and 2037 cm^{-1}, respectively. Unfortunately, as DMF is diluted with CH_2Cl_2 the solubility of $Ph_2Pb(SeCN)_2$ decreased so that in the last case (5% DMF/CH_2Cl_2), the saturated solution concentration was ≤ 0.002 *M*. With this in mind it would be unwise to attribute the splitting of the absorption at

~2065 cm^{-1} definitely to the presence of a new solute species rather than to the background "noise" expected in the spectrum of such a dilute solution. Further dilution of DMF by CH_2Cl_2 caused $Ph_2Pb(SeCN)_2$ to precipitate from even more dilute solutions, rendering solution infared studies impossible. Bearing in mind that adducts $Ph_2Pb(SeCN)_2 \cdot 2L$ do not appear to dissolve in CH_2Cl_2, it is likely that the new species which form as the DMF mixture is diluted further are still ionic, e.g., $Ph_2Pb(SeCN)L_3^+$ (L = DMF) with both Se-bonded and N-bonded isomers present. Since A_{CN}(N-bonded) $\geq 10A_{CN}$(Se-bonded) the higher intensity of the 2120 cm^{-1} absorption compared with that at 2035 cm^{-1} shows that the Se-bonded species predominates in this case, as was found also for $Ph_3PbSeCN \cdot L$ in 5% DMF/CH_2Cl_2 (6).

(ii) Adducts with O-donor ligands

Values of ν(CN) and ν(CSe) show $Ph_2Pb(SeCN)_2 \cdot 2pyO$ to be a true selenocyanate as is the DMSO adduct even though this dissociated to some extent when mulled. In contrast, adducts with HMPA and collO are N-bonded, although a weak absorption at ~2110 cm^{-1} might indicate some Pb—SeCN units are present. While there seems to be a general trend for stronger "hard" O-donor ligands to favour N-bonded species (1) this is perhaps not always the case. Thus, the triphenylphosphine oxide adduct of $Ph_2Pb(SeCN)_2$ is clearly N-bonded unlike the adduct with $Ph_3PbSeCN$ which is Se-bonded (1). While all adducts, $Ph_2Pb(SeCN)_2 \cdot 2L$, probably have linear "Ph_2Pb" units (cf. Ph_2PbCl_2 (7)), it is not possible to decide unambiguously from infrared data alone whether the ligands (and NCSe groups) are *trans* or *cis* in these compounds, although a single infrared absorption would favour the trans arrangement.

The adduct with 4-picoline-*N*-oxide is unusual not only in regard to its stoichiometry but also in its complex infrared spectrum in the ν(CN) region even though Se-bonded selenocyanate is clearly absent. Since no $\nu(N \rightarrow O)$ absorption due to free ligand is observed, the most plausible structure is ionic, probably $[Ph_2Pb(4\text{-picO})_4^{2+}]$ $[NCSe^-]_2$. However, the sharp peaks at ~2050 cm^{-1} require extensive crystal lattice effects to account for the splitting and lowering of the ν(CN) value from that found for KNCSe (2070 cm^{-1}) (8) while the broader and strong absorption at 2063 cm^{-1} could be assigned to either ionic or N-bonded selenocyanate groups.

(iii) Adducts with N-donor ligands

Adducts with monodentate N-donor ligands have the simple formula $Ph_2Pb(SeCN)_2 \cdot 2L$ but their spectra in the ν(CN) region are more complex than those for O-donor adducts with the same formula. For example, the morpholine adduct shows a doublet at ~2090 cm^{-1} which could indicate Se-bonded or N-bonded selenocyanate groups. However, the peak shape favours the latter assignment as do the ν(CSe) values observed. It is not possible to decide unequivocally whether the observed splittings in ν(CN) are due to a *cis*-$Pb(morph)_2$ arrangement in the adduct or strong crystal lattice effects. In contrast, the spectrum in the ν(CN) region of the quinoline adduct is even more complex. Sharp peaks at ~2070 cm^{-1} show the presence of ionic selenocyanate with lattice effects accounting for the splitting, while the broader ν(CN) absorption at 2030 cm^{-1} and ν(CSe) at 618 cm^{-1} are clearly due to N-bonded selenocyanate. Thus, we suggest that the bulkier quinoline ligand stabilizes the formation of 4-coordinate ions $Ph_2Pb(quin)_2^{2+}$ and adduct molecules which may have a *trans*-$Pb(quin)_2$ geometry. The similarity of ν(CN) values for this adduct and those with O-donor ligands which are also possibly trans is noteworthy.

Coordination-sensitive ring modes of the ligand show both complexed (815, 567 cm^{-1}) and "free" (800, 555 cm^{-1}) ligand molecules are present in the piperidine adduct (4). This is supported by the low melting point of this adduct and its tendency to lose piperidine readily on standing in the open. Similar intensities for equivalent "free" and complexed ligand bands suggest that only one piperidine molecule is attached to each lead with hexa-coordination maintained by equal numbers of bridging and terminal NCSe groups being present. The selenocyanate group infrared data are consistent with this picture while ν(CSe) at 613 cm^{-1} confirms that the terminal selenocyanates are N-bonded.

The $Ph_2Pb(SeCN)_2$ adducts with bidentate N-donor ligands show a quite different stoichiometry from that of their thiocyanate analogues. In the dipyridyl adduct spectrum the 2 to 1 intensity ratio of δ(CH) (out-of-plane) ligand mode absorptions at 756 cm^{-1} ("free") and 769 cm^{-1} (complexed) (4) suggests that the adduct formula is $Ph_2Pb(SeCN)_2dipy \cdot 2dipy$, i.e., only one of the three dipyridyl molecules is acting as a ligand. As with $Ph_2Pb(NCS)_2dipy$, the infrared spectrum of the selenocyanate compound can be assigned to a structure with both bridging and N-bonded selenocyanate groups. However, alternate monomeric structures containing *cis*-(SeCN—Pb—SeCN) or *cis*-$Pb(NCSe)_2$ moieties cannot be ruled out, although in the latter case strong vibrational coupling between geminal C—N bonds is required to account for the widely separated ν(CN) frequencies. The more complex pattern observed for the 1,10-phenanthroline adduct suggests at least two selenocyanate species are present, i.e., the pair of sharp peaks centered on 2068 cm^{-1} may be assigned to $NCSe^-$ with lattice effects accounting for the splitting, while the two broad absorptions at lower frequency can be assigned to N-bonded selenocyanates in a cis arrangement. Thus it is possible this adduct contains both $[Ph_2Pb(phen)_2]^{2+}[NCSe^-]_2$ and *cis*-$Ph_2Pb(NCSe)_2 \cdot phen$ species with the remaining ligands uncomplexed in the lattice as shown by absorptions at 1506, 734, 705, and 621 cm^{-1}, while bound ligands absorb at 1514, 719, and 635 cm^{-1} (4).

Conclusion

Infrared spectral data usually enable only general conclusions to be drawn regarding the chemical bonding and geometry found in complex ions and molecules, especially when complementary Raman data are not available. For the compounds studied here it was possible to suggest the type of lead–selenocyanate bonding for most adducts with O-donor ligands, but those with N-donor ligands clearly had more complex behaviour and the types of bonding proposed are very tentative. As with $Ph_2Pb(NCS)_2 \cdot 2L$ (except when L = HMPA) systems (2), the diphenyllead diselenocyanate adducts reported here were obtained as powders which could not be recrystallized without decomposition, thus rendering the necessary X-ray diffraction studies impossible at this time. Other techniques, e.g., ^{14}N nqr spectra (9) or solid state NMR measurements (10) which have been used to study thiocyanate complexes, may be required to determine better the structures of the compounds reported in this paper.

Solubility of carbon dioxide in water–t-butanol solutions

PEETER KRUUS AND CATHERINE A. HAYES
Department of Chemistry, Carleton University, Ottawa, Ont., Canada K1S 5B6

Received March 19, 1985

PEETER KRUUS and CATHERINE A. HAYES. Can. J. Chem. **63**, 3403 (1985).

The solubility of carbon dioxide has been determined in tertiary butanol – water mixtures over the temperature range 1–25°C. The solubility exhibits a sharp, temperature-dependent minimum in water-rich solutions corresponding to a maximum in the activity coefficient of t-butanol, which has also been determined. The activity coefficient of t-butanol has a prominent temperature-dependent maximum ($\gamma > 7.0$) at a solution composition of about 0.06 mole fraction alcohol. Application of the scaled particle theory indicates that volume effects are a governing factor in the gas solubility, but are insufficient to explain the total effect. The pH of t-butanol–water and t-butanol–water–CO_2 mixtures reveals no major anomalous solvation effect.

PEETER KRUUS et CATHERINE A. HAYES. Can. J. Chem. **63**, 3403 (1985).

Opérant dans un intervalle de temperature aliant de 1 à 25°C, on a déterminé la solubilité du dioxyde de carbone dans des mélanges de *tert*-butanol/eau. La solubilité présente un minimum prononcé qui dépend de la température dans des solutions riches en eau qui correspondent à des maxima dans les coefficients d'activité du *tert*-butanol que l'on a aussi déterminés. A une composition de la solution correspondant à une fraction molaire en alcool d'environ 0,06, les coefficients d'activité du *tert*-butanol présentent un important maximum ($\gamma > 7,0$) qui varie avec la température. L'utilisation de la théorie des particules divisées indique que les effets de volume sont les facteurs qui influencent la solubilité du gaz; toutefois, ils ne suffisent pas pour expliquer l'effet global. Le pH de mélanges de *tert*-butanol/eau et de *tert*-butanol/eau/CO_2 ne révèle pas d'anomalies importantes dans l'effet de solvatation.

[Traduit par le journal]

1. Introduction

Carbon dioxide in its various states plays an important role in both natural and industrial processes. Recently, liquid and supercritical carbon dioxide have found wide-scale use for extractions in the food and mining industries, and are of potential use in tertiary oil recovery. Although many bulk properties of carbon dioxide solutions have been characterized, little is known of the fundamental interactions of carbon dioxide with nonelectrolyte solutes in aqueous solution. The study of simple carbon dioxide – nonelectrolyte – water systems may provide models which can be applied to more complex systems.

Tertiary butanol was chosen as a co-solute in this study for several reasons: (*i*) it is miscible with water in all proportions, (*ii*) many properties of t-butanol–water solutions have been investigated (1, 2), and (*iii*) the peculiar features of alcohol–water solutions are particularly well-developed in aqueous t-butanol due to its bulky alkyl group. Although there have been several studies of the solubility of gases in water–alcohol systems (3, 4), the combination of water (subscript 1) – t-butanol (subscript 2) – carbon dioxide (subscript 3) has not been investigated to date.

The solubility of a substance in a two-component solvent system is fundamentally related to the chemical potentials of the two solvent components. Other "continuum" properties of the solvent system are also related to the chemical potentials (or their derivatives) of the components. Kenttamaa *et al.* (2) have obtained the activities of the components of water–t-butanol at temperatures above 25°C. However, in spite of the great number of experimental studies of continuum-type properties of this system (1, 5, 6) the component activities at temperatures below 25°C have not been reported in the literature. Such activities are reported here for 1°C and 10°C.

Experimental

(a) Materials

The following chemicals were used in this study: filtered Millipore deionized water, freshly distilled Fisher Certified t-butanol, Matheson Research Grade carbon dioxide (99.95%), and helium (99.9999%). The composition of the water–t-butanol solvent mixture was determined through refractive index measurements.

(b) Apparatus

The apparatus for the measurement of gas solubility can best be described as a modified BET-type apparatus used normally to measure the adsorption of gas on a solid. It consists of a constant-volume manometer, a seven-bulb gas burette, and a solubility cell which contains the liquid sample. The volume of each bulb in the gas burette is known to ± 0.0002 cm^3 through determination of the mass of mercury it contains. The mercury level in the manometer is read with a cathetometer to ± 0.0001 cm. The solubility cell is constructed with a Teflon stopcock so that there is no contamination of the sample by vacuum grease. The sample is stirred magnetically and thermostatted to ± 0.05°C. The vacuum in the system is monitored with a thermocouple gauge (Veeco type RG-31X).

The line volume (which is all capillary tubing) and the dead volume (the volume between the first stopcock leading to the line and the liquid level in the solubility cell) were determined with research grade helium assuming He to be an ideal gas. The line volume was 15.53 ± 0.08 cm^3; the dead volume (cell empty) was 34.12 ± 0.25 cm^3. Temperatures were monitored with a five junction chromel–alumel thermocouple referenced to an ice bath.

In order to check for any adsorption of CO_2 on the glass walls of the tubing, the line volume and dead volume were also calibrated with CO_2, assuming ideal gas behaviour. The results were within 1.0% of those obtained with helium.

(c) Vapour pressure and gas solubility measurements

The procedures followed for these measurements are quite similar, and are briefly outlined here.

The sample of water–t-butanol was first degassed under vacuum by at least five freeze–pump–thaw cycles, weighed, then stirred and thermostatted to the desired temperature. The equilibrium time required before a vapour pressure measurement was typically 1 h.

For solubility measurements, the line volume was evacuated, typically to 0.0001 Torr, and then filled with CO_2 to a pressure of about 700 Torr. The number of moles of CO_2 in the line volume was determined from three volume/pressure measurements, the level of mercury in the manometer and the burette was then adjusted to give the desired pressure of CO_2, and the gas was admitted to the sample cell. When equilibrium was reached after about 1 h, the first stopcock was closed and the number of moles of CO_2 remaining in the line

volume was measured. The number of moles of CO_2 remaining in the dead volume could be calculated from the equilibrium pressure and the known dead volume; the number of moles of CO_2 absorbed by the sample could thus be calculated.

This procedure was repeated until at least five points were obtained for a Henry's law plot of P_3 vs. X_3. At the end of the experiment the composition was determined through a measurement of the refractive index as the degassing procedure preferentially removed the alcohol and altered the initial composition. The typical time required for the complete experiment was 10 h.

In calculating the number of moles of CO_2, the pressure was corrected for the non-ideality of the gas according to the virial equation of state with values of coefficients from ref. 7. For these calculations the gas temperature was assumed to be the room temperature in the line volume and the sample temperature in the dead volume. The dead volume was corrected for the volume of the sample using densities of water–*t*-butanol solutions found in ref. 8 for 10°C and 25°C; densities at 0°C (9) were used to correct the dead volume for measurements at 1°C.

Clearly the gas contained in the dead volume consists of both carbon dioxide and sample vapour, but it can be assumed that the line volume contains only carbon dioxide since it is composed of capillary tubing, and as pressure changes from the line volume to the dead volume were always positive. The gas pressure was corrected for the presence of sample vapour in the dead volume through an iteration procedure assuming Raoult's law.

(d) Refractive index measurements

Refractive index measurements were made with an Abbe refractometer (Officione Galileo) thermostatted at 25.00 ± 0.05°C. Using solutions prepared from *t*-butanol dried over 4A molecular sieves, a calibration curve was constructed and fitted to a sixth-order polynomial. The composition of all water–*t*-butanol solutions prepared were then calculated from refractive index measurements. In the composition region of most interest ($X_2 \sim 0.1$), X_2 could be obtained to an accuracy of ±0.0001 by this method. At higher (>0.4) ranges of X_2, n is not as sensitive to X_2 and the accuracy was lower (±0.0005 to ±0.001 mole fraction alcohol).

(e) pH measurements

Measurements of pH were made with a combination glass Ag/AgCl electrode (Fisher 13-639-92) and a digital pH meter (Fisher Model 620). The pH meter calibration was checked by using buffer solutions at pH 4, 7, and 10. For the measurement of the pH of water–*t*-butanol solutions, the water was first degassed by refluxing and then sparged continuously with argon during the experiment. Solid *t*-butanol was gradually added to the solution, which was magnetically stirred and thermostatted to 25.00 ± 0.05°C.

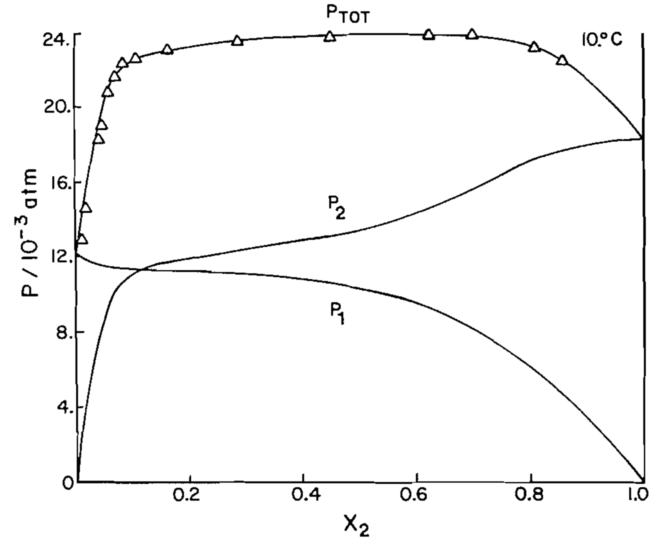

FIG. 1. Vapour pressures of *t*-butanol–water mixtures at 10.00°C: △, experimental points; —, computer-fitted curves.

For the measurement of the pH of water – *t*-butanol – carbon dioxide solutions, a water – *t*-butanol solution was first degassed under vacuum by several freeze–pump–thaw cycles. The solution was then quickly transferred to the measuring flask and carbon dioxide was bubbled continuously through the sample. The pH reading usually equilibrated within minutes. The refractive index of the solution was tested immediately after a pH reading was taken to check the solution composition.

Results

*(a) The solvent system water–*t*-butanol*

The vapour pressures of water–*t*-butanol mixtures were measured over the concentration ranges where the samples were liquid at 10.00°C and 1.00°C. The vapour pressure of pure *t*-butanol and water were taken from ref. 10 as it was difficult to reach equilibrium when the system contained only water. The vapour pressures at 25°C have been measured previously by Brown and Ives (11). The experimental vapour pressures are given in Table 1. The shapes of the total vapour pressure curves for 10°C (Fig. 1) and 1°C are similar to that reported by Brown and Ives for 25°C and by Kenttamaa *et al.* at 25, 50, and 75°C (2).

Brown and Ives used an equilibrium still to make their vapour pressure measurements and were able to determine the composition of the vapour phase with this apparatus. The partial pressure of each component was then calculated by an application of the Duhem–Margules relation. Using their data for the partial pressure of each component at 25°C, the partial pressures at other temperatures could be calculated under the assumption that the activity coefficient of the water is relatively insensitive to temperature.

The calculations were done as follows. The activity coefficient of water, γ_1, was calculated from the partial pressure of water at 25°C according to Raoult's law. It was then assumed that the activity coefficient of water changes negligibly (within experimental error) in the temperature range 1–25°C. This

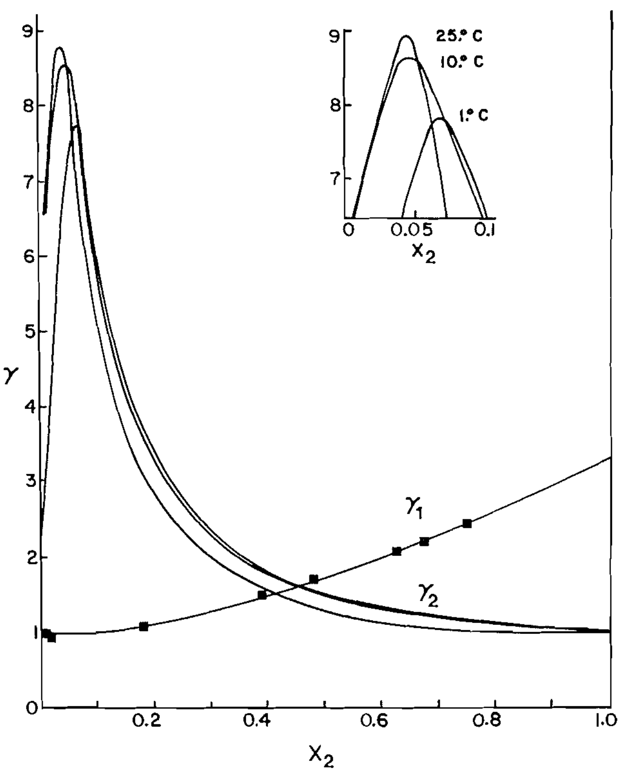

FIG. 2. Activity coefficients of t-butanol and water determined from vapour pressures. — data for γ_1 as taken from refs. 2 and 11 for 25.0°C. The γ_1 curve is assumed temperature independent. ■, data at 50.0°C from ref. 2.

assumption seems justified, as the γ_1 values at 50°C from ref. 2 are essentially the same as those at 25°C from refs. 2 and 11 (Fig. 2). The partial pressure of water at a given temperature was then calculated and the partial pressure of t-butanol determined by subtraction from the known total pressure. The activity coefficient of t-butanol is thus

$$[1] \quad \gamma_2(T) = \frac{P_{TOT}(T) - \gamma_1(25°C)X_1P_1^{\bullet}(T)}{X_2P_2^{\bullet}(T)}$$

The activity coefficients calculated in this manner were found to be consistent with the Gibbs–Duhem relation to within about 0.8%. The smoothed data for the system at 25, 10, and 1°C are tabulated in Table 2. The rms deviation for the computer fit of the total pressure curves obtained in this study ranged from (0.04 to 0.12) × 10^{-3} atm; the data of Brown and Ives were fitted with an rms deviation of about 0.24 × 10^{-3} atm. This is another indication that no great errors are introduced by assuming γ_1 to be independent of temperature from 0 to 25°C.

The large positive deviation from Raoult's law of the alcohol partial pressure is seen in Fig. 1, and more clearly in Fig. 2 where the activity coefficients of t-butanol and water as a function of solution composition are given. The activity coefficient of t-butanol exhibits a temperature-dependent maximum at a low mole fraction of alcohol (X_2 = 0.04 at 25°C, 0.05 at 10°C, and 0.07 at 1°C). The data of Kenttamaa *et al.* (2) are not detailed enough to note the value of X_2 at which γ_2 is a maximum. The magnitude of their maximum value of γ_2 does, however, also show an increase with temperature, as in Fig. 2. For 25°C they report $\gamma_{2,max}$ = 10.7 at X_2 = 0.033, for 50°C, $\gamma_{2,max}$ = 15.7 at X_2 = 0.011, and for 75°C, $\gamma_{2,max}$ = 25.5 at X_2 = 0.010.

The excess Gibb's free energy of mixing ΔG_M^E, is defined by the relation:

$$[2] \quad \Delta G_M^E = RT(X_1 \ln \gamma_1 + X_2 \ln \gamma_2)$$

The ΔG_M^E values calculated for water–t-butanol mixtures at different temperatures are illustrated in Fig. 3. The maximum ΔG_M^E values occur at $X_2 \sim 0.4$, as in the case for higher temperatures (2). It is in principle possible to calculate ΔH_M and ΔS_M^E from a knowledge of the temperature dependence of ΔG_M^E, but the data obtained here are not detailed enough for a meaningful calculation.

(b) Solubility of carbon dioxide in t*-butanol–water mixtures*

The accuracy of the experimental method used to calculate the solubility of CO_2 can be estimated by comparing the results for the solubility of CO_2 in pure water at 25.00°C with those available in the literature (12–14). The value obtained in this study agrees with the literature values to within 3%. Some of this deviation arises from the ideal gas assumption used to convert the Henry's law constant to the Bunsen coefficient and the Ostwald solubility coefficient for comparison with the literature values. However, the main source of error in this experiment was the assumption that the gas in the dead volume is at the same temperature as the sample. It is, however, difficult to apply a correction to the thermal gradient from the sample to the room temperature. Such errors would have negligible effects in considerations of relative solubilities.

Plots (P_3 vs. X_3) for the solubility of CO_2 were linear to within an average standard deviation of 1.5% (Table 3) with no regular deviation from linearity. The pressures used were sufficiently low so that the error introduced in replacing fugacity by partial pressure is negligible (1%) and the second term in the expansion $P_3 = k_H X_3 + k' X_3^2 + \ldots$ gives a negligible contribution. The intercepts of the lines did not always pass through zero pressure as expected. The small positive intercept values noted are probably due to incomplete degassing and the assumption of uniform dead volume temperature. Figure 4 shows that there is at all three temperatures a minimum in solubility (maximum in k_H) at low X_2. It was not possible to determine the point of minimum solubility more precisely, as the solvent composition changed in the degassing procedure and could not be exactly predetermined.

The free energy change of solution, ΔG^0_{sol}, was calculated from the Henry's Law constant and is included in Table 3. The enthalpy change, ΔH^0_{sol}, and entropy change, ΔS^0_{sol} of solution at 10°C as a function of alcohol concentration are shown in Fig. 5. The shapes of these curves are similar to those for the solution of CO_2 in water–ethanol (4).

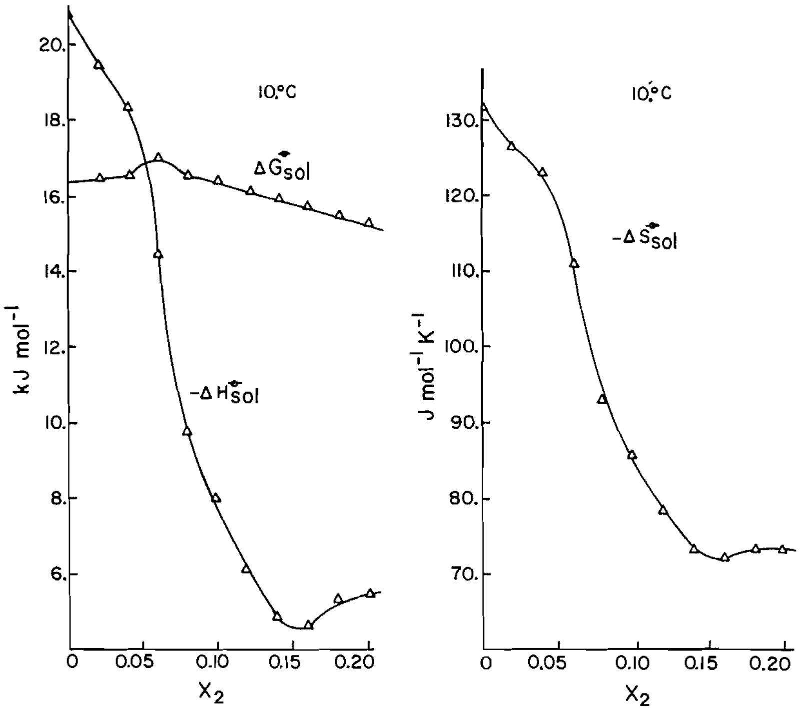

FIG. 5. Free energy, enthalpy, and entropy of solution of carbon dioxide in *t*-butanol–water mixtures at 10°C.

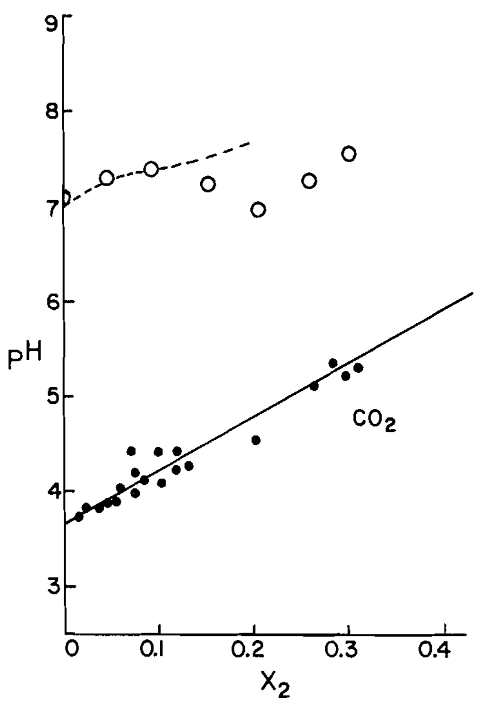

FIG. 6. pH of *t*-butanol–water and *t*-butanol–water–CO_2 mixtures at 25°C. ○, *t*-butanol–water mixtures sparged with Ar; ---, predicted pH of *t*-butanol–water mixtures from K_W values; ●, *t*-butanol–water mixtures sparged with CO_2.

(c) pH measurement

The measurements of *t*-butanol–water mixtures with an argon and a CO_2 sparge are illustrated in Fig. 6. Addition of *t*-butanol to pH 4, 7, and 10 buffers indicated a small linear increase in pH readings with addition of alcohol in all three cases. Such a change can be related to the change in the pK of the buffer due to the addition of *t*-butanol and a change in the junction potential. The latter effect is negligible as compared to experimental error.

The effect of the changing dielectric constant on the ionization constant of water must also be considered. Woolley *et al.* (15) have obtained measurements of K_W in *t*-butanol–water mixtures, from which the change in pH due to the change in K_W can be predicted. In Fig. 6, the "predicted" pH curve and the experimental pH curve obtained in this study are seen to be similar in value and in slope for dilute solutions.

In aqueous media at pH less than 7, carbon dioxide species exist as $CO_2(aq)$, $H_2CO_3(aq)$, and $HCO_3^-(aq)$. Assuming that $[CO_2(aq)] \gg [H_2CO_3(aq)]$ (16); $[HCO_3^-(aq)] \simeq [H^+(aq)] \simeq a_H$, the first dissociation constant of carbonic acid can be written as

$$[3] \quad K_1' = (a_H)^2/([CO_2(aq)] - a_H)$$

The concentration of $CO_2(aq)$ can be determined from the known solubility of CO_2 in *t*-butanol–water mixtures so that it is possible to calculate the values of pK_1' shown in Table 4. The standard state used here is that for the molarity composition scale in order to be consistent with other data (16).

The value of pK_1' in pure water calculated from the experimental pH is 5.92, as compared to Harned and Davies' (16) value of 6.352. The increase in pK_1' indicated in Table 4 is to be expected since the dielectric constant of the solvent is decreasing. The distance of closest approach, d, of the two ions formed by the dissociation of carbonic acid (H^+ and HCO_3^-) can be estimated from a plot of ln K_1' vs. $1/\epsilon$ using the Fuoss equation. The value obtained using the relative permittivity values from ref. 11 is 0.11 nm, which is of the correct order of magnitude.

Discussion

*(a) The solvent system water–*t*-butanol*

Figure 7 summarizes the behaviour of some "continuum" properties of water–*t*-butanol in the low X_2 range. Ultrasonic absorption and Rayleigh scattering are included in Fig. 7 as

they involve interactions with sufficiently large wavelengths of sound and light, respectively, to be considered in terms of continuum models (5, 6).

Analyses of such data have also been carried out on the basis of molecular level models (17, 18). However, extrema in such properties are fundamentally related to extrema in the chemical potentials (or their derivatives) of the components. A desirable test of molecular-level models would be to use them to predict data for fundamental properties such as activities in addition to the more specific derived properties.

Deviations from Raoult's law for mixtures indicate non-ideal interactions between the solute and solvent molecules. The strong positive deviation of γ_2 in water-rich solution indicates that the alcohol molecules are on the average in a less favourable environment despite the possibility of formation of favourable hydrogen bonds with the water. This positive deviation arises from the strong interaction between the bulky, hydrophobic alkyl group of the alcohol and surrounding water molecules. It is interesting to note that the magnitude of this positive deviation in γ_2 becomes greater as temperature increases (Fig. 2 and ref. 2).

This phenomenon of "hydrophobic hydration" is thought to increase the water structure in the immediate vicinity of the hydrophobic residue. The sharp maximum which occurs in γ_2 at about $X_2 = 0.05$ at 25°C can be interpreted as corresponding to a maximum in the structuring effect on the surrounding water. At concentrations of alcohol greater than this maximum, the addition of further alcohol causes a rapid destruction of the water structure. The shift of the maximum to slightly lower alcohol concentrations (Fig. 2) and the increase in $\gamma_{2,\max}$ (Fig. 2, ref. 2) as the temperature is raised may be due to the smaller degree of structuring present in pure water. At higher temperatures, the structuring caused by the alcohol can be greater, but will be destroyed at lower alcohol concentrations due to greater thermal motion.

Desnoyers and colleagues (19, 20) have suggested that the sharp extrema in various thermodynamic properties of *t*-butanol–water solutions are due to transitions which resemble micellization. These "microphases" cannot be called micelles however, because alcohols do not form well-defined aggregates in water.

Mikhailov (21) has predicted the activity coefficients of ethanol and water in mixtures covering the entire concentration range based on the model he has proposed for aqueous solutions of nonelectrolytes. The predicted activity coefficient curves exhibit a sharp maximum in γ_{EtOH} in dilute solution and

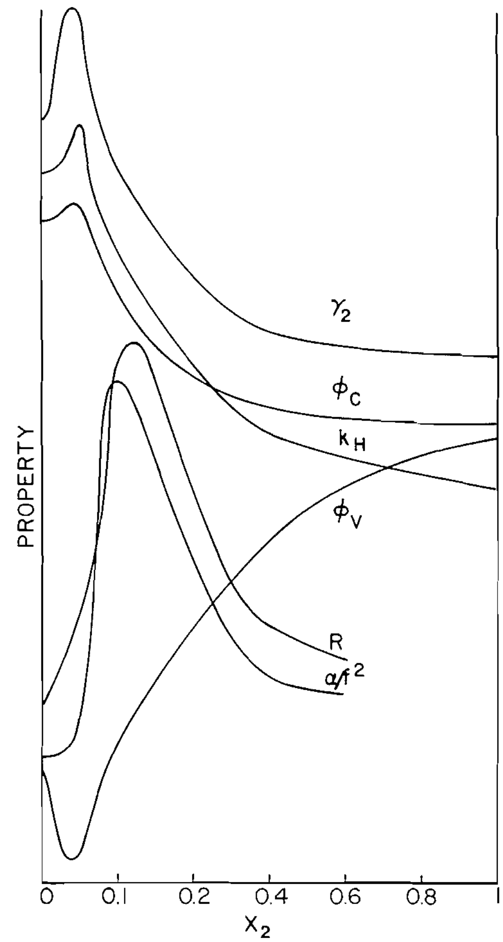

FIG. 7. Properties of *t*-butanol–water mixtures at 25°C: γ_2 activity coefficient of TBA (this work), k_H solubility of carbon dioxide (this work). ϕ_C apparent molal heat capacity of TBA (8), ϕ_V apparent molal volume of TBA (8), R, Rayleigh scattering intensity (18), α/f^2 ultrasonic absorption (26).

a positive deviation in γ_1 in more concentrated solutions. These features agree well with the curves experimentally obtained for *t*-butanol–water in this study.

The component activities in the system water–*t*-butanol obtained at three temperatures in this study are fundamental in understanding all equilibrium continuum properties. It seems desirable to check proposed models of systems against these data as well as against data derived from them.

(b) Solubility of carbon dioxide

The Henry's Law constant is related to the Gibbs free energy of solution as $\Delta G^0_{sol} = -RT \ln k_H$. The ΔG^0_{sol} for carbon dioxide in *t*-butanol–water mixtures over the entire mole fraction range at 25°C is shown in Fig. 8 as a function of both mole and volume fraction. The experimental data can be compared to an "ideal" curve where

$$[4] \quad \Delta G^{id}_{sol} = f_1 \Delta G^0_{sol,1} + f_2 \Delta G^0_{sol,2}$$

where f refers to either mole or volume fraction and $\Delta G^0_{sol,2}$ ($= -RT \ln k_{H,2}$) refers to the Gibbs free energy of solution of CO_2 in pure *t*-butanol.

When ΔG^0_{sol} is plotted as a function of the volume fraction of *t*-butanol, the curve retains the same features as the mole fraction dependent curve. The curves can be compared to the "ideal" curve by considering the excess free energy of solution, $\Delta G^E_{sol} = \Delta G^0_{sol} - \Delta G^{id}_{sol}$. For the volume fraction curve, ΔG^E_{sol}

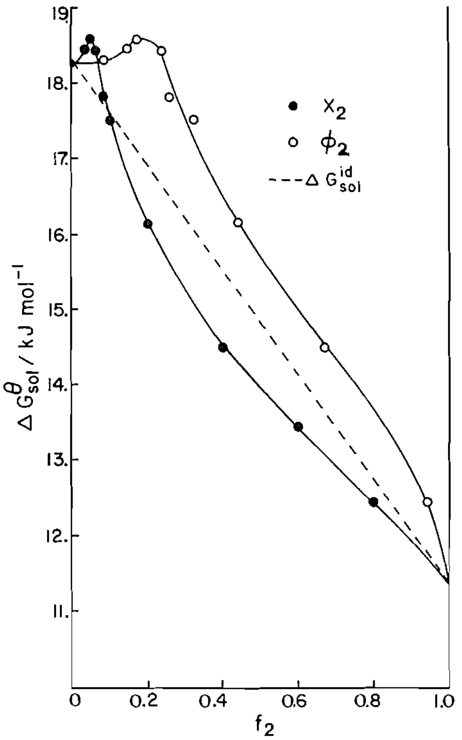

FIG. 8. — ΔG^0_{sol} for carbon dioxide solubility in *t*-butanol–water mixtures at 25.0°C as a function of mole fraction (●) and volume fraction (○) of *t*-butanol. --- ΔG^{id}_{sol} (see text for definition).

will be positive over the whole concentration range; whereas for the mole fraction curve ΔG^E_{sol} becomes negative at about $X_2 = 0.1$.

The data are analyzed in both ways, as in a study of the solubility of electrolytes in aqueous non-electrolyte solutions, the solubilities were best fitted by an expression incorporating the volume fraction rather than the mole fraction of the organic cosolute (22). When the solute molecules interact primarily with individual solvent molecules, then it is more reasonable to do the analysis using a mole fraction scale. When the interaction is primarily of a "continuium" kind, e.g. involving the dielectric constant, then a volume fraction scale is more reasonable.

The shape and temperature dependance of the ΔG^E_{sol} functions when considered on a mole fraction scale are for this system quite similar to those observed for the solubility of Ar, H_2, and He as calculated by Lucas and Cargill (23). The difference noted are that the data of Cargill shows that ΔG^E_{sol} exhibits a small negative minimum at very low mole fraction of alcohol; and the absolute magnitudes of ΔG^E_{sol} are less than in the carbon dioxide – water – *t*-butanol system.

From the ΔG^E_{sol} curves for the solubility of CO_2 in *t*-butanol–water mixtures it is possible to calculate the activity coefficient of carbon dioxide from $\mu_3^E = RT \ln \gamma_3$. Several reference states can be used to express activity coefficients, but the meaningful one here is Raoult's Law, where the reference state for the solute is unit mole fraction. When the pressure is sufficiently low to equate fugacity and partial pressure, then the solute activity is defined as

$$[5] \quad a_3 = P_3/P_3^{\bullet} = \gamma_3 X_3; \qquad \gamma_3 = k_H/P_3^{\bullet}$$

where $P_3^{\bullet}$ is the vapour pressure of the pure liquid solute. Thus the activity coefficient approaches unity as X_3 approaches the pure solute.

TABLE 5. Activity coefficient of CO_2 in CO_2–H_2O–TBA mixtures at 25.00°C

X_2	X_3 ($\times 10^{+4}$)	γ_3	μ_3^E	ΔG_t^E (kJ mol^{-1})
0	6.28	25.1	7.99	0
0.02	6.25	25.2	8.00	0.01
0.04	5.72	27.5	8.22	0.23
0.05	5.55	28.4	8.30	0.31
0.06	5.89	26.8	8.15	0.16
0.08	7.52	20.9	7.54	−0.45
0.10	8.59	18.3	7.21	−0.78
0.20	14.71	10.7	5.88	−2.11
0.40	28.82	5.5	4.23	−3.76
0.60	43.86	3.6	3.18	−4.81
0.80	65.79	2.4	2.17	−5.82
1.00	101.52	1.6	1.17	−6.82

Using the value $P_3^{\bullet} = 63.49$ atm at 25°C (10) the activity coefficients of carbon dioxide in the alcohol–water mixtures were calculated from the experimental Henry's Law constant at 25.00°C. The results (Table 5) indicate that the activity coefficient (and the excess chemical potential) of carbon dioxide in the mixture reaches a maximum at $X_2 = 0.05$. The activity coefficient of *t*-butanol in water also shows a maximum at this mole fraction (Fig. 7). The value of γ_3 in water is about 15 times that in the alcohol, where it is close to unity. This indicates that the affinity of the carbon dioxide gas for the alcohol is similar to its affinity for liquid carbon dioxide. The free energy of transfer from water to *t*-butanol (Table 3) also reflects this difference.

(c) Models for the solubility of CO_2 in water–TBA

The variation of CO_2 solubility with composition of the water–*t*-butanol mixture can involve energy, entropy, and volume effects. Scaled particle theory provides a method for estimating the importance of volume effects. Lucas and Cargill (23) have compared the experimental free energies of solubility of He, H_2, and Ar in water–ethanol and water–*t*-butanol mixtures with values predicted by the scaled particle theory (SPT). Their calculated excess free energies of solution show a similar dependence on alcohol concentration as that observed experimentally.

The expression for the free energy of solution, ΔG^0_{sol}, derived from SPT is:

$$[6] \quad \Delta G^0_{sol} = G_c + RT \ln (RT/V) + G_i$$

In [6], V is the apparent molar volume of the mixture, and G_c is the free energy of cavity formation, given by:

$$[7] \quad G_c/RT = \Big\{-\ln (1 - y) + [3X/(1 - y)] D_3 + [3Y/(1 - y)^2 + 4.5X^2/(1 - y)^3] D_3^2 + \frac{N\pi P}{6RT} D_3^3\Big\}$$

$$y, X, Y = \frac{N\pi}{6} \frac{X_1 D_1^p + X_2 D_2^p}{X_1 V_1^{\bullet} + X_2 \phi_{V,2}}$$

where p equals 3 for y, 2 for X, and 1 for Y; D_1, D_2, D_3 are the hard sphere diameters of water, alcohol, and gas, respectively; $V_1^{\bullet}$ is the molar volume of pure water and $\phi_{V,2}$ is the apparent molal volume of the alcohol in the mixture.

The contribution of the free energy of interaction, G_i, was

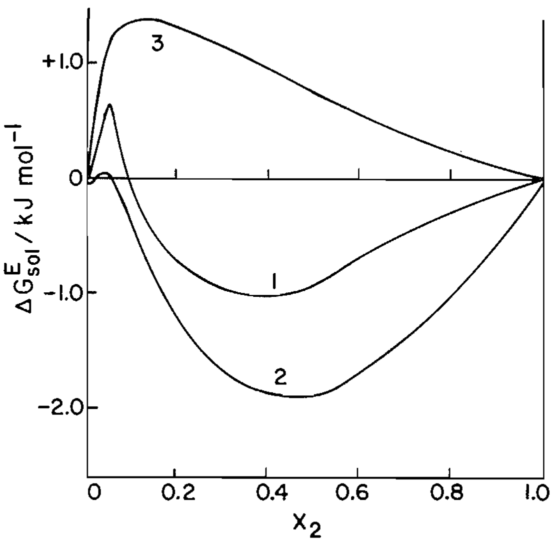

FIG. 9. Excess free energy of solution ΔG^{E}_{sol} of CO_2 in *t*-butanol–water mixtures at 25°C. Curve *1*. Experimental ΔG^{E}_{sol} (see Fig. 8). Curve *2*. Scaled particle theory. Curve *3*. Scaled particle theory, ideal volume of mixing.

neglected by Lucas and Cargill on the assumption that when a gas is transferred from water to another polar solvent, G_i is very small. The calculated and experimental free energies of transfer from alcohol to water were found to be similar, which lends some validity to this assumption.

The SPT and experimental values for the free energy of solution were compared by computing ΔG^{0}_{sol} for carbon dioxide in water–*t*-butanol mixtures at 25°C using experimental apparent molar volumes (8). The computer program was tested by calculating the free energy of transfer of argon from water to *t*-butanol at 25°C. The value of 9.21 kJ mol^{-1} computed at 25°C compares well with the value of 9.1 kJ mol^{-1} computed by Lucas and Cargill at 12°C.

The excess free energy of solution, ΔG^{E}_{sol}, for carbon dioxide is illustrated in Fig. 9. The ΔG^{E}_{sol} used in Fig. 9 are calculated using the computed values of $\Delta G^{0}_{sol,1}$ and $\Delta G^{0}_{sol,2}$; these computed values are about three times the experimental values for the case $D_3 = 0.394$ nm (24), $D_1 = 0.2733$ nm (24), and $D_2 = 0.529$ nm (25) (curve 2). The computed curve exhibits a small minimum at $X_2 = 0.015$ and a maximum at $X_2 = 0.05$. The minimum, which corresponds to a slight increase in carbon dioxide solubility, was not observed experimentally. This is possibly because the initial increase in solubility falls within the experimental error of the present study. The height of the computed maximum is much smaller than that observed experimentally.

An increase in the alcohol diameter changes the magnitude and concentrations dependence of ΔG^{0}_{sol} dramatically, but a corresponding increase in D_3 or D_1 has only a slight effect, with no change in the shape of the curve. It is of some interest to compute the solubility of carbon dioxide in "ideal" water–*t*-butanol mixtures; that is, assuming that the volume of mixing is zero rather than using experimental values of the molar volume. Curve 3 in Fig. 9 shows the value of this "excess ideal free energy" to be positive and to reach a maximum at $X_2 = 0.1$. The difference between curves 2 and 3 is an indication of the effect of the non-idealities of the system volume on the solubility of carbon dioxide. It is quite obviously a very important effect.

The variation in the chemical potential of carbon dioxide in *t*-butanol–water mixtures as a function of alcohol concentration is qualitatively the same as the variation of the chemical potentiel of the alcohol itself. The minimum in the gas solubility in very dilute alcohol solutions corresponds to the maximum in the activity coefficient curve of *t*-butanol and shows the same trends with temperature. A qualitative explanation of the variation of the solubility of carbon dioxide with concentration would be similar to the explanation of the variation of the activity coefficient of *t*-butanol with concentration given earlier.

The dependence of the photochemically induced reduction of lumiflavin on pH, light intensity, and concentration of sulphydryl compounds

PARMINDER S. SURDHAR AND DAVID A. ARMSTRONG
Department of Chemistry, University of Calgary, Calgary, Alta., Canada T2N 1N4

Received March 19, 1985

PARMINDER S. SURDHAR and DAVID A. ARMSTRONG. Can. J. Chem. **63**, 3411 (1985).

The spectral changes which occur on photolysis of flavin solutions containing β-mercaptoethanol (RSH) and lipoamide ($L(SH)_2$) are in accord with the formation of dihydroflavin, except at pH values below 3 for RSH. Here an oxygen-stable product is formed, which has λ_{max} 360 nm and is probably a C-4a substituted dihydroflavin. The fraction of flavin present when FlH_2 reaches a photostationary state $f(FlH_2)_{ps}$ is dependent on pH and on the absorbed light intensity I_a. At certain pH values the actual photostationary concentration of FlH_2 is linear in the concentration of RSH, but for the lipoamide system shows a more complex dependence on concentration. The initial quantum yields are independent of absorbed light intensity in the pH range 7 to 10 for RSH, and increase strongly with pH in the region 7 to 9 for both sulphydryl compounds. In the pH range 5–6 they are linear in sulphydryl concentration. For RSH the results can be explained by a mechanism in which flavin triplet abstracts a hydrogen atom from RSH to form RS· and ·FlH radicals. These radicals undergo back reaction to RSH and Fl or form RSSR and FlH_2 by one of two mechanisms: (*a*) formation of $RS\dot{S}R^-$, which electron transfers to Fl or ·FlH or (*b*) reaction of RS· with ·FlH--RSH complexes. The results with $L(SH)_2$ can be explained similarly.

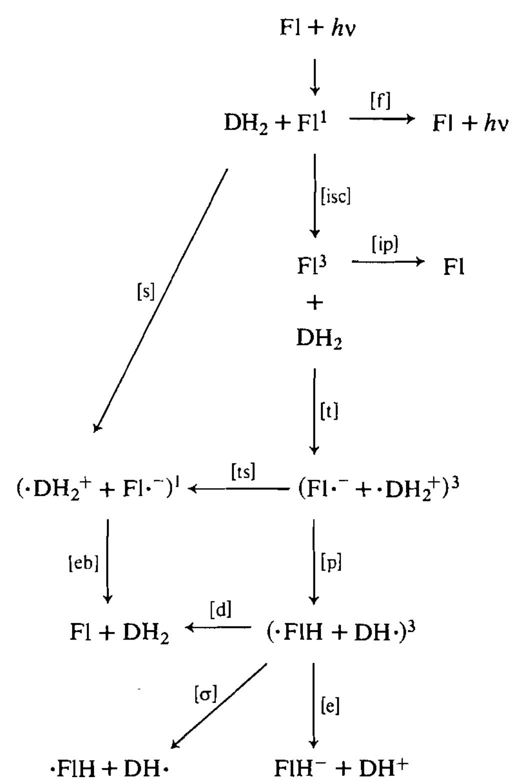
PARMINDER S. SURDHAR et DAVID A. ARMSTRONG. Can. J. Chem. **63**, 3411 (1985).

Les changements spectraux qui se produisent lors de la photolyse de solutions de flavines contenant du β-mercaptoéthanol (RSH) et de la lipoamide ($L(SH)_2$) pourraient être expliqués par la formation de la dihydroflavine, à l'exception des pH inférieurs à 3 dans le cas du RSH. Dans ces cas, il y a formation d'un produit qui est stable vis-à-vis de l'oxygène, qui présente un λ_{max} à 360 nm et qui est probablement une dihydroflavine substituée en position C-4a. La fraction de flavine qui est présente quand la FlH_2 atteint un état photostationnaire, $f(FlH_2)_{ps}$, qui dépend du pH et de l'intensité de la lumière absorbée, I_a. A certains pH, la concentration photostationnaire réelle de la FlH_2 varie d'une façon linéaire avec la concentration en RSH; dans le cas du système de la lipoamide, on note toutefois une relation plus complexe avec la concentration. Dans le cas du système du RSH et à des pH allant de 7 à 10, les rendements quantiques initiaux ne dépendent pas de l'intensité de la lumière absorbée; toutefois, pour chacun des composés sulfurés et à des pH allant de 7 à 9, ces rendements augmentent rapidement. Aux pH allant de 5 à 6, ils sont linéaires avec les concentrations en sulfhydryles. Pour le système RSH, les résultats peuvent être expliqués par un mécanisme dans lequel l'état triplet d'une flavine enlève une hydrogène du RSH pour former des radicaux RS· et ·FlH. Ces radicaux subissent des réactions de retour vers le RSH et la Fl ou ils forment du RSSR et de la FlH_2 par l'un des deux mécanismes suivants: (*a*) formation de $RS\dot{S}R^-$ qui donne des réactions de transferts d'électron conduisant à la Fl ou au ·FlH ou (*b*) réaction du RS· avec des complexes ·FlH--RSH. On peut expliquer de la même manière les résultats obtenus avec le $L(SH)_2$.

[Traduit par le journal]

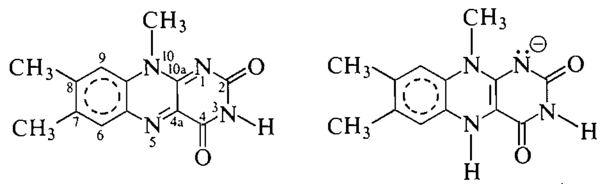
Introduction

Flavin molecules are prosthetic groups in a large number of essential oxidation-reduction enzymes (1) and there is a strong interest in the redox chemistry of their ground and excited states (2–5). Scheme 1 depicts the sequences of reactions which have been postulated to explain products formed on photolysis with light in the wavelength range 400–500 nm. Here DH_2 represents a reductant or hydrogen donor and Fl the oxidised form of the flavin, while $Fl\cdot^-$ and $FlH\cdot$ are the anionic and neutral forms of the semiquinone free radical. Fl^1 and Fl^3 are the flavin singlet and triplet excited states. For common flavins, such as flavin mononucleotide (FMN), flavin adenine dinucleotide (FAD), and lumiflavin (LFl), the 1,5-dihydroflavin or FlH_2 form has a pK in the region of 6 to 7 (6). The



SCHEME 1. Reactions:
[f] = fluorescence,
[isc] = intersystem crossing,
[ip] = triplet decay via isc and phosphorence,
[s] = singlet quenching,
[t] = triplet quenching,
[ts] = triplet → singlet,
[p] = proton transfer,
[d] = back donation,
[eb], [e] = electron transfer,
[σ] = outward diffusion of geminate pair.

pK for the semiquinone is near 8.3 (7). The structural formulae of lumiflavin, Fl, and dihydrolumiflavin anion, FlH^-, are



Detailed photochemical and flash photolysis experiments (2–5, 8–10) have been performed with a large variety of DH_2 species, so that values of k_t have been determined for phenols, amines, amino acids, and certain sulphur-containing compounds, as well as the photophysical constants k_f and k_{isc}.

The case of the sulphydryl-containing amino acid L-cysteine is particularly interesting. Here the value of k_t at pH 7 ($4.5 \pm 0.5 \times 10^7\ M^{-1}\ s^{-1}$) is some hundred fold or more larger than for glycine (8), implying that the sulphydryl group is involved in reaction [t]. Furthermore there are strong indications that the quenching process occurs by $\cdot H$ transfer rather than the sequence [t] and [p] as in Scheme 1. This observation is actually in line with the well-known hydrogen-donating ability of sulphydryl molecules (RSH) (11) and the reaction may be written:

[1] $\quad Fl^3 + RSH \rightarrow (\cdot FlH + RS\cdot)^3$

Ahmad and Armstrong (12) have studied the reactions of $RS\cdot$ radicals with flavin species. They pointed out that the redox potential of reaction [2] is relatively high

[2] $\quad RS\cdot + e^- \rightleftharpoons RS^-$

($E_2^0 \cong 1.0$ V), and that $RS\cdot$ would oxidise $\cdot FlH$ and FlH_2. However, at pH $\geqq$ pK_i ($\cong$8.5 for cysteine (13)), $RS\cdot$

[*i*] $\quad RSH \rightleftharpoons RS^- + H^+$

forms $RS\dot{S}R^-$

[*b*] $\quad RS^- + RS\cdot \rightleftharpoons RS\dot{S}R^-$

This species was shown to reduce Fl (12).

[3*b*] $\quad RS\dot{S}R^- + Fl \rightarrow RSSR + Fl\cdot^-$

It would also be capable of reducing $\cdot FlH$:

[3*b*′] $\quad RS\dot{S}R^- + \cdot FlH \rightarrow RSSR + FlH^-$

It follows that at pH values below pK_i the back reaction

[3] $\quad (\cdot FlH + RS\cdot)^3 \rightarrow Fl + RSH$

should be the dominant route for removal of the radical pair formed in [1]. This also should be true for radical pairs, which initially separate from each other (reaction [σ] in scheme 1) and subsequently react by random diffusion.

[3*a*] $\quad \cdot FlH + RS\cdot \rightarrow Fl + RSH$

In either event the fraction of radical pairs producing FlH^- (or FlH_2) should be small. On the other hand at pH $\geqq$ pK_i reactions [3*b*] and [3*b*′] may compete with [3*a*]. Thus the yield of dihydroflavin should rise with increasing pH in the region of pK_i, until it reaches a maximum. The surprising feature of the experiments with cysteine was the fact that a relatively large proportion of $\cdot FlH + RS\cdot$ radical pairs actually formed FlH_2 at pH 7 (3), which is well below pK_i (13). This observation suggests that there are additional reactions to those considered above.

The present study was undertaken with the objective of determining the initial quantum yields and maximum concentrations of FlH_2 formed by photolysis in the presence of sulphydryl molecules, and studying their dependence on pH, light intensity, and RSH concentration. The flavin used was lumiflavin and β-mercaptoethanol was chosen as the RSH molecule. It is simpler than cysteine in that ionisation of the —SH group is the only process which leads to changes in net charge of the molecule with pH. The pK_i and the magnitude of K_b are known to be 10.0 and $1.8 \times 10^3\ M^{-1}$, respectively (14, 15). The disulphydryl lipoamide $L(SH)_2$ was also used. It differs from monosulphydryls in that the disulphide anion ($L\dot{S}_2^-$) and its protonated form ($L\dot{S}_2H$), which has a pK of 5.5 (16–18), are both considered to exist as stable ring structures:

[*b*1] 
($L\dot{S}_2H$) $\qquad$ ($LS_2^-\cdot$)

Thus in this system $L\dot{S}_2H$ replaces the $RS\cdot$ species. Also the proportions of $L\dot{S}_2H$ and $LS_2^-\cdot$ are independent of $[L(SH)_2]$ and are determined only by pH, while with RSH the proportion of $RS\dot{S}R^-$ increases with [RSH].

Experimental

Materials

Lumiflavin and β-mercaptoethanol (RSH) were supplied by Sigma Chemical Co. Dihydrolipoamide ($L(SH)_2$) was prepared from lipoamide by the method of Reed *et al.* (19). All other chemicals were the purest grade available and used as supplied.

Methods

All solutions were prepared from triply distilled water and saturated with high purity N_2O (Matheson), which was first passed through a column of "ridox" (Fisher Scientific Company) to remove traces of oxygen. All solutions were buffered with phosphate buffer and protected from light as much as possible. For all solutions of $L(SH)_2$ and RSH above pH 9, the buffer and other solutes were added and the solution deareated before the addition of $L(SH)_2$ or RSH. Finally the pH was adjusted by the addition of NaOH or perchloric acid. This was done in order to minimise air oxidation of the sulphydryl. All experiments were carried out at 23 ± 2°C. Concentrations of Fl and FlH_2 were calculated with the following extinction coefficients at 44o nm — Fl: 12320 pH 4–8; 12045 pH 9–11; FlH_2/FlH^-: 1454 pH 4–6, 1488 pH 7–8, 1230 pH 9–11.

Apparatus

The photolysis lamp consisted of a 250 W Halogen Bellophot fitted with a water filter. The light was collimated through filters with maximum λ and minimum λ transmissions of 465 and 420 nm, respectively. Light intensities at various distances were determined chemically using ferrioxalate actinometry (20). The actinometer solution was 0.15 *M* potassium ferrioxalate in 0.1 *N* sulphuric acid. A molar extinction coefficient of $1.05 \times 10^4\ M^{-1}\ cm^{-1}$ at 510 nm for 1,10-phenanthroline complex was determined experimentally by the procedures of Hatchard and Parker (20).

The spectrum incident on the 1 cm square quartz photolysis cell was calculated form the emission spectrum of the lamp and the percentage transmission of the filters. The fraction of light absorbed over the band of wavelengths was calculated from the absorption spectrum of each irradiated solution.

Steady state radiolyses were performed in an AECL ^{60}Co γ cell with a steady dose rate of ~10.0 Gy min^{-1}. The dose rate was determined by ferrous sulphate dosimetry, assuming $G(Fe^{3+}) = 15.6$ molecules per 100 eV (21), and checked periodically to correct for the natural decay of the isotope. The net number of moles of radicals produced per litre of solution for a given radiation dose, e_{red}, was calculated by means of eq. [12] of ref. 22.

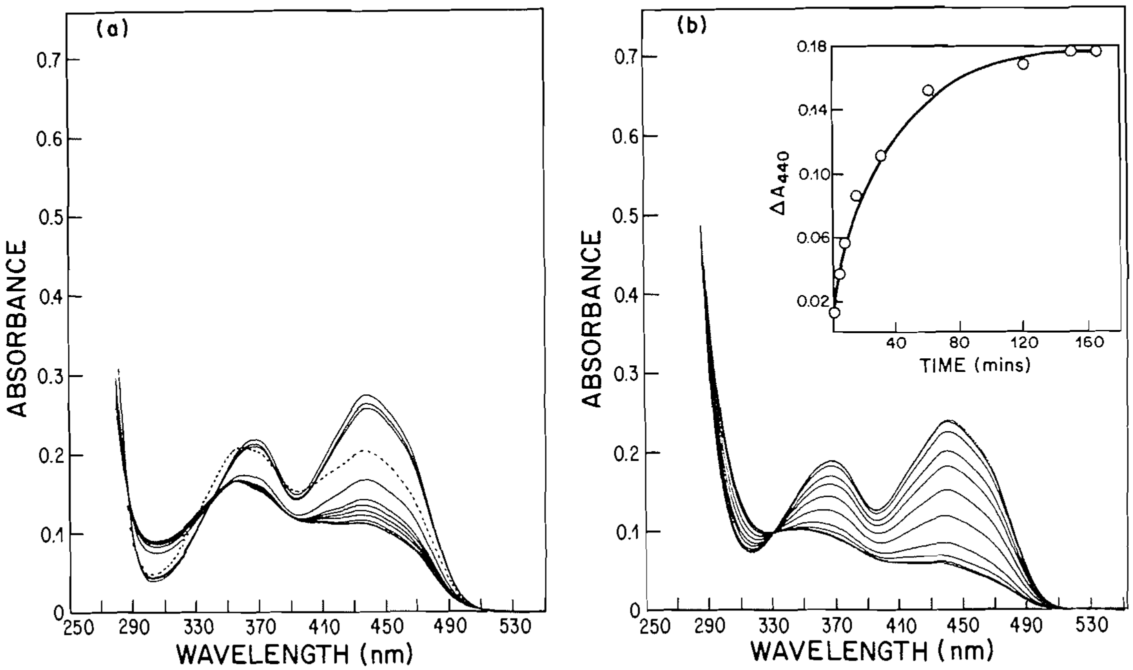


FIG. 1. Spectra obtained from N_2O-saturated solution of 20–23 μ*M* lumiflavin in 10 m*M* RSH and 10 m*M* phosphate buffer at (*a*) pH 3 and (*b*) pH 9 before and after photolysis with light intensities (I_0) of 6.82×10^{-6} and 2.09×10^{-7} einsteins cm^{-2} s^{-1}, respectively. Dashed lines (----) show spectra after aeration, the one in (*b*) coinciding with initial spectrum. Inset: Changes in ΔA_{440} versus time after photolysis.

Results

Spectral changes

The changes in absorbance which occur on photolysis of flavin solutions containing β-mercaptoethanol are illustrated in Fig. 1*a* and *b*. As shown in Fig. 1*b*, at pH 9 the flavin absorption is reduced by each successive exposure to light, until finally a photostationary state is reached. The change in absorbance at 440 nm (ΔA_{440}) has been plotted as a function of photolysis time in the inset. On addition of air the initial flavin absorbance is restored, dashed line in Fig. 1*b*. This feature, the isobestic point at 333 nm and the nature of the spectral changes are in accord with the formation of dihydroflavin, a conclusion which also conforms with the earlier study of Heelis *et al.* (3).

At pH values below 3 the changes in absorbance are different. As illustrated in Fig. 1*a* the absorbance above 330 nm is suppressed less before the stationary state is reached and there is no longer a clear cut isobestic point. In addition, on aeration the flavin absorbance is not entirely restored. The spectral changes indicate that in addition to FlH_2 an oxygen-stable product has been formed and that this has isobestic points with Fl at ~358, ~382, and ~402 nm. By estimating the concentration of FlH_2 in the mixture at the photostationary state from the change in ΔA at 440 nm on addition of air and that of residual Fl from the absorbance at 470 nm where the absorbance of reduced flavins is mall, we were able to calculate the absorbance due to Fl and FlH_2 from their known spectra. The absorbance of the other product was then obtained by subtraction from the absorbance of the mixture. This was found to have a maximum at 360 nm, which is typical of a 4*a*-substituted dihydroflavin (23, 24), such products being formed by additions of free radicals to ·FlH radicals. In the present instance the oxygen-stable product was shown to be stable under our conditions both at low and high pH. Thus there is no evidence for its reacting with RSH or RS^-. Its identification and properties were not pursued further here.

The photochemical effects observed with lipoamide as the sulphydryl were similar to those described above, except that there was no evidence for an oxygen-stable product and reversible reduction to FlH_2 was seen at all pH values.

Photostationary concentrations

The fraction of flavin present as FlH_2 in the photostationary state[1] $f(FlH_2)_{ps}$ has been plotted as a function of pH in Fig. 2*a* and *b* for solutions containing 10 m*M* β-mercaptoethanol and 1.0 m*M* lipoamide, respectively. Data are shown for different incident light intensities, I_0.

The results obtained for γ-radiolysis in the absence of light are included for comparison.[2] It is apparent that with both sulphydryl molecules $f(FlH_2)_{ps}$ is (*a*) dependent on pH, (*b*) increases with incident light intensity, (*c*) is larger for the photochemically than the radiation chemically stimulated system.

As a means of demonstrating that a true photostationary state was involved, it was shown that if after reaching a stationary state at a high intensity, the solution was subjected to a lower intensity then $f(FlH_2)_{ps}$ decreased to the value characteristic of that intensity.

The photostationary concentration of FlH_2 was measured in the presence of varying [RSH] at pH 6, where it is about half way to its maximum value at the higher intensity in Fig. 2*a*. It can be seen from Fig. 3 that $[FlH_2]_{ps}$ is linear in [RSH] and proportional to $I_a^{1/2}$. Here it should be noted that I_a, the absorbed light intensity averaged over the cell length, was calculated from the observed concentration of Fl at the stationary

[1] The formula $f(FlH_2)_{ps}$ has been used to denote reduced flavin present at the photostationary state regardless of pH.

[2] Note that in the first approximation $[FlH_2]_{ps}$ should be independent of the γ ray dose rate. Unfortunately it was not practical to check this point by altering the dose rate to give a range of radical production rates in the same range as those obtained in photolysis.

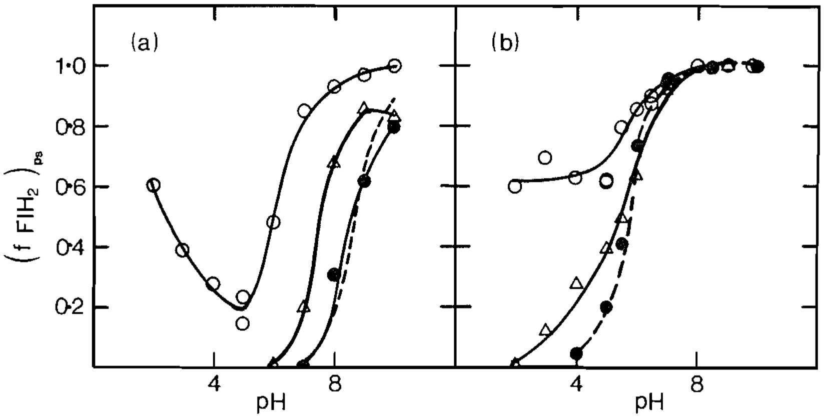

FIG. 2. Values of $f(\mathrm{FlH_2})_{ps}$ versus pH for the photoreduction of lumiflavin with 10 mM RSH (a) and 1 mM $\mathrm{L(SH)_2}$ (b) at light intensities (I_o) of (○) 6.82×10^{-6}, (△) 2.09×10^{-7} einsteins $\mathrm{cm^{-2}\ s^{-1}}$, respectively. The solid (●) points are for γ-radiolysis at a radical formation rate of 1.1×10^{-7} M $\mathrm{s^{-1}}$, and the dashed lines (----) are the calculated fraction of B· radicals.

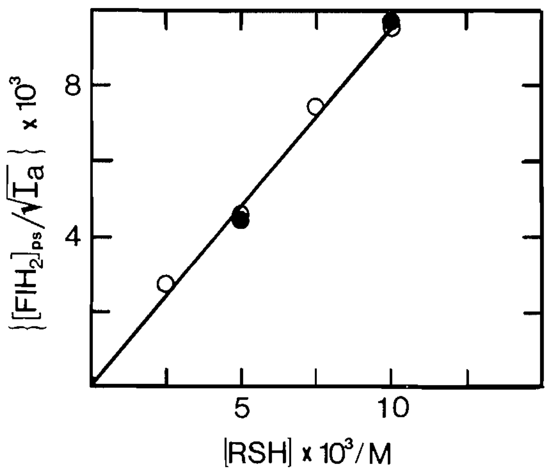

FIG. 3. Plot of $\{[\mathrm{FlH_2}]_{ps}/\sqrt{I_a}\} \times 10^3$ versus the concentration of RSH at pH 6 using light intensities (I_o) of (○) 6.82×10^{-6}, (●) 3.68×10^{-5} einsteins $\mathrm{cm^{-2}\ s^{-1}}$, respectively.

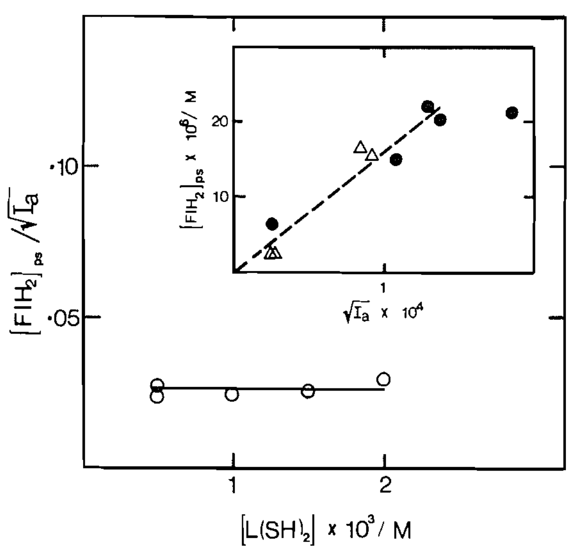

FIG. 4. Plot of $[\mathrm{FlH_2}]_{ps}/\sqrt{I_a}\}$ versus the concentration of $\mathrm{L(SH)_2}$ at pH 5 using light intensity (I_o) of 6.82×10^{-6} einsteins $\mathrm{cm^{-2}\ s^{-1}}$. Inset: plot of $[\mathrm{FlH_2}]_{ps} \times 10^6/M$ versus $\sqrt{I_a} \times 10^4$ using light intensities in the range $1-226 \times 10^{-7}$ einsteins $\mathrm{cm^{-2}\ s^{-1}}$ at pH 3 (△) and at pH 4 (●), respectively.

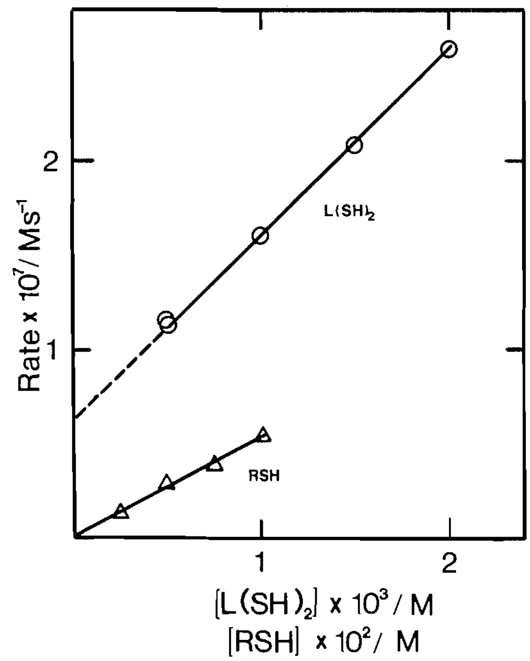

FIG. 5. Plot of initial rate versus concentration of $\mathrm{L(SH)_2}$ and RSH at pH 5 and 6, respectively, using light intensities (I_o) of 6.82×10^{-6} einsteins $\mathrm{cm^{-2}\ s^{-1}}$.

state and the incident light intensity.

For the lipoamide system in the pH range 3 to 5, where $f(\mathrm{FlH_2})_{ps}$ was rising with pH, $[\mathrm{FlH_2}]_{ps}$ is again apparently linear in $I_a^{1/2}$. However, in this instance it was independent of $[\mathrm{L(SH)_2}]$, see Fig. 4. Also the results were less reproducible.

Initial rates and quantum yields

The initial slopes of plots like the inset in Figure 1b were divided by ($\epsilon_{\mathrm{Fl}} - \epsilon_{\mathrm{FlH_2}}$) and used to calculate initial rates. The dependences of these on sulphydryl concentration were determined at pH values in the region 5 to 7, Fig. 5. For both systems they are linear in concentration. However, there is an intercept or concentration-independent component for lipoamide, which is not present for RSH.

Quantum yields, calculated by dividing the initial rates of flavin reduction by the absorbed intensity, are depicted in Fig. 6a and b for 10 mM RSH and 1 mM $\mathrm{L(SH)_2}$ respectively. A

[7] $Fl + RS\cdot + RSH \leftarrow A\cdot + RSFlH$	
	[8] $RSFlH + RS^- + H^+ \rightarrow RSSR + FlH_2$

* A few obvious alterations are needed to balance these equations for $L(SH)_2$.

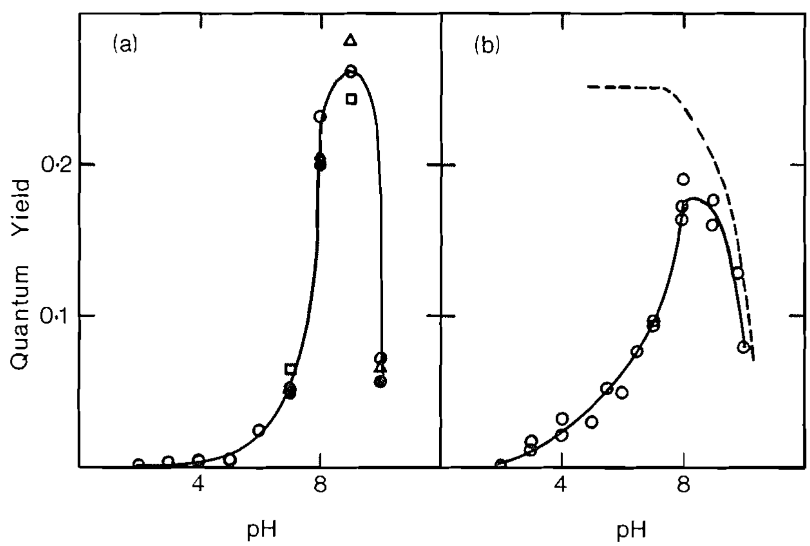

FIG. 6. Plots of quantum yield versus pH for (*a*) RSH and (*b*) $L(SH)_2$ using light intensities (I_0) of (△) 2.09×10^{-7}, (●) 3.22×10^{-7}, (○) 6.82×10^{-6}, and (□) 3.68×10^{-5} einsteins $cm^{-2}\,s^{-1}$, respectively. Dashed line (----) shows the relative quantum yields for the photoreduction of riboflavin by EDTA from Fife and Moore (4). The ordinate scale for this has been multiplied by 0.255.

strong dependence on pH is clearly evident. Also demonstrated for the RSH system is the fact that these initial yields are independent of absorbed intensity (see different sets of points) for pH in the range 7 to 10.

Discussion

The mechanism

The flavin molecule reactions considered here are summarised in Table 1. In the γ-radiolysis experiments there are the additional reactions producing the $RS\cdot$ or $L\dot{S}_2H$ radical (18):

[9] $H_2O \rightsquigarrow e^-_{aq} + \cdot H + \cdot OH + H_2O_2 + H_2$

[10] $e^-_{aq} + N_2O + H_2O \rightarrow N_2 + OH^- + \cdot OH$

[11] $\cdot OH\ (\text{or}\ \cdot H) + RSH \rightarrow H_2O\ (\text{or}\ H_2) + RS\cdot$

[11*l*] $\cdot OH\ (\text{or}\ \cdot H) + L(SH)_2 \rightarrow H_2O\ (\text{or}\ H_2) + L\dot{S}_2H$

For convenience these radicals are symbolised by $A\cdot$ in Table 1, while the $RS\dot{S}R^-$ and $LS_2^-\cdot$ radicals formed in reaction [*b*] and [*b*1], respectively (see Introduction) are referred to as $B\cdot$ radicals. Since these two reactions and the reverse processes are known to be rapid (14, 25) it is reasonable to assume as a first approximation that equilibrium is maintained between the $A\cdot$ and $B\cdot$ radicals. One then has

$$[B\cdot] = [A\cdot]\theta_B$$

where θ_B is given by

$$\theta_B = [RSH]_{total}\,K_b\{1 + [H^+]/K_i\}^{-1}$$

for RSH, and

$$\theta_B = K_{b1}[H^+]^{-1}$$

for $L(SH)_2$ respectively. It may be recalled that the $B\cdot$ radicals are reductive and the $A\cdot$ radicals oxidative towards FlH_2 and $\cdot FlH$ (ref. 12 and above).

All of the reactions down to [3*a*] and [4] in Table 1 were contained in the mechanism of Ahmad and Armstrong (12). However, those below [4] are new, and the equilibrium

[*c*] $RSH\ \text{or}\ L(SH)_2 + \cdot FlH \rightleftharpoons \cdot C$

has been assumed for $\cdot$FlH and its complex with RSH or $L(SH)_2$, $\cdot$C. The evidence for this stems from recent studies of flavin semiquinone spectra in the presence of RSH or RS^- molecules (26, 27). In the equations which follow we write $[\cdot C] = \theta_C[\cdot FlH]$, where θ_C is equal to K_c[RSH].

Given the existence of the complex $\cdot$C, it is feasible to consider the formation of FlH_2 via [3*c*]. Also the production of a C-4a adduct RSFlH could be explained through reactions [3″] and [3*c*″]. Reaction [3*c*′] is incorporated for completeness. There are then three pathways for the formation of FlH_2 from $\cdot$FlH: [3*b*′], [3*c*], and [3″] or [3*c*″] + [8]. However, as we have seen earlier, the present experiments indicate that the oxygen-stable product is stable to both RSH and RS^-. Thus there is no evidence for reaction [8] in this system. Also the C-4a adduct is not seen at pH > 3. Therefore the last pathway is not considered further here.

The photostationary state

Application of the steady state approximation now leads to the following equation for $[FlH_2]_{ps}$, in which ρ is proportional to I_a (see further below):

$$[12]\quad [FlH_2]_{ps} = \frac{\rho}{k_4[A\cdot]_{ps}} + k_{3b}\theta_B[Fl]_{ps}/k_4 + [k_{3b'}\theta_B - k_{3a} + (k_{3c} - k_{3c'})\theta_C]\,[\cdot FlH]_{ps}/k_4$$

For radiolysis the first term in ρ is zero. Furthermore, if θ_B is zero, the second term is zero and there is no process for converting Fl to $\cdot$FlH. It follows that $[FlH_2]_{ps}$ for the γ radiolysis will be near zero unless θ_B is significant (≧ 0.1). Also it will be less than $[FlH_2]_{ps}$ for photolysis under comparable conditions and should more closely depend on θ_B or more specifically the fraction of radicals present as B$\cdot$, $(\theta_B(1 + \theta_B)^{-1})$. These features are confirmed by the data in Fig. 2*a* and *b*. Note that $\theta_B(1 + \theta_B)^{-1}$, which has been plotted as a function of pH, closely parallels the points for γ-radiolysis.

Unfortunately the mechanism is too complex for exact expressions for the values of $[A\cdot]_{ps}$ and $[\cdot FlH]_{ps}$ to be derived. However, an approximate relation, which is a useful semi-quantitative quide, may be obtained, if one assumes that $k_5[\cdot FlH]^2_{ps} \cong k_{-5}[Fl]_{ps}\,[FlH_2]_{ps}$ and $[\cdot FlH]_{ps} \cong [A\cdot]_{ps}$, viz:

$$[13]\quad [FlH_2]_{ps} = \{2k_{3b'}\theta_B + 2k_{3c}\theta_C\}\rho^{1/2}k_4^{-1} \times \{k_{3b'}\theta_B + k_{3a} + \theta_C(k_{3c} + k_{3c'})\}^{-1/2}$$

The latter assumption is reasonable in the regions of low efficiency of reduction where the k_{3c} and $k_{3c'}$ terms are small and reaction [3*a*] dominates over [3*b*′]. Thus expression [13] reduces to:

$$[14]\quad [FlH_2]_{ps} = \{2k_{3b'}\theta_B + \theta_C 2k_{3c}\}\rho^{1/2}/k_4k_{3a}^{1/2}$$

This equation predicts the dependence of $[FlH_2]_{ps}$ on $\rho^{1/2}$ which is seen in Fig. 3 and the inset in Fig. 4. Basically the reason for this dependence is the competition for A$\cdot$ radicals between FlH_2 (reaction [4]) and $\cdot$C (reaction [3*c*]). At low reduction efficiencies (i.e. low pH) the concentration of $\cdot$C is controlled largely by reaction [3*a*], and is therefore approximately dependent on $\rho^{1/2}$.

One may note that we were unable to explain the dependence on $\rho^{1/2}$ on the basis of B$\cdot$ radical reactions alone. However, at high pH, where θ_B becomes > 1, reactions [3*b*] and [3*b*′] should become more important than [3*a*] and the "B$\cdot$ mechanism" takes over. The $f(FlH_2)_{ps}$ loses its intensity dependence, Fig. 2*a* and *b*.

The sulphydryl molecule concentration dependence is obtained on substituting the appropriate formulae for θ_B and θ_C. For RSH it is linear with zero intercept:

$$[15]\quad [FlH_2]_{ps} = 2\{k_{3b'}K_b/(1 + [H^+]/K_i) + k_{3c}K_C\}\,[RSH]_{total} \times (\rho^{1/2}/k_4)/k_{3a}^{1/2}$$

which is in accord with the data in Fig. 3. In the case of $L(SH)_2$ there is an $[L(SH)_2]$ independent term, arising from θ_B, viz:

$$[16]\quad [FlH_2]_{ps} = 2\{k_{3b'}K_{b1}/[H^+] + k_{3c}K_C[L(SH)_2]_{total}\} \times (\rho^{1/2}/k_4)/k_3^{1/2}$$

From the data in Fig. 5 this term seems to dominate, since there is no evidence for a strong positive slope.

Initial rates

Application of the steady state assumption to the concentrations of intermediates leads to the following expression for the initial rate of formation of FlH_2:

$$[17]\quad \frac{d[FlH_2]}{dt} = \{k_{3b'}\theta_B + k_{3c}\theta_C\}\frac{2\rho + r - 2k_5[\cdot FlH]^2}{2[k_{3b'}\theta_B + k_{3a} + \theta_C(k_{3c} + k_{3c'})]} + k_5[\cdot FlH]^2$$

Here ρ and *r* are, respectively, the rates of formation of A$\cdot$ radicals in reactions [1] and [11] or [11*l*], respectively. The former applies in photolysis and the latter in radiolysis. If the same assumptions are made for the region of low efficiency of reduction as before, then for photolysis with RSH one has:

$$[18]\quad \frac{d[FlH_2]}{dt} = \{k_{3b'}K_B/\{1 + [H^+]/K_i\} + k_{3c}K_C\}\,[RSH]_{total} \times \rho/k_{3a}$$

and with $L(SH)_2$:

$$[19]\quad \frac{d[FlH_2]}{dt} = \{k_{3b'}K_{b1}/[H^+] + k_{3c}K_C[L(SH)_2]_{total}\} \times \rho/k_{3a}$$

Again in each case there is a linear dependence on sulphydryl molecule concentration. However, for $L(SH)_2$ there is a concentration independent term containing $k_{3b'}K_{b1}$. This can explain the presence of the intercept for $L(SH)_2$ plot in Fig. 5. The linear portion of that plot is consistent with the occurrence of reaction [3*c*]. In further agreement with the mechanism there is no intercept for RSH.

Quantum yields

The maximum value of $d[FlH_2/dt$ is seen from expression [17] to occur for the condition $\{k_{3a} + \theta_C k_{3c'}\} \ll (k_{3b'}\theta_B + k_{3c}\theta_C)$. Expression [17] then reduces to:

$$\frac{d[FlH_2]}{dt} = \rho$$

for photolysis and *r*/2 for radiolysis. The efficiencies of conversion, ε, may be defined as $(d[FlH_2]/dt)/\rho$ and $2(d[FlH_2]/dt)/r$ for photolysis and radiolysis, respectively. Values of ε may be calculated from the data of Ahmad and Armstrong (12) for γ-radiolysis of the FAD–$L(SH)_2$ system at pH 7. The magnitude of ε was 1.0 ± 0.1 independent of $[L(SH)_2]$ in the range 0.5 to 1.5 m*M*. Similar results were obtained here for LFl–$L(SH)_2$. At lower pH values ε falls as expected, becoming zero at about pH 4. Values of ε for RSH are summarised in Table 2. At pH 7 and below it was immeasurably small in 10 m*M* solutions. It rises steeply at pH 8 to

TABLE 2. Values of ϵ for RSH

[LFl] μM	[RSH] mM	pH	eff., ϵ	θ_B	f_B*
22.09	10.0	8	0.83	0.18	0.15
17.90	10.0	9	0.84	1.64	0.62
22.85	10.0	10	0.75	9.00	0.90
21.50	10.0	11	1.09	16.4	0.94
24.03	5.0	10	0.56	4.50	0.82
23.66	7.5	10	0.63	6.75	0.87
22.85	10.0	10	0.75	9.00	0.90
23.13	12.5	10	0.81	11.25	0.92
22.93	15.0	10	0.88	13.50	0.93

*$f_B = \theta_B(1 + \theta_B)^{-1}$.

about 0.8 remaining at 0.75 to 1.1 up to pH 11. At pH 10 it increases with concentration of RSH.

An interesting feature is that the fraction of B· radicals $\theta_B(1 + \theta_B)^{-1}$ (see columns 4 and 6) does not correlate well with ϵ. This is probably an indication that the complex ·C is involved in the ·FlH to FlH_2 step of the γ-radiolysis mechanism, although as pointed out above the Fl to ·FlH stage is supported here only by B· radicals.

The overall quantum yields in Fig. 6*a* and *b* could be used to calculate ϵ, if the quantum yield Φ(·FlH) for eaction [1] were known. Actually this has been measured only for the cysteine–FMN system at pH 7 and 4.1, where it is 0.14 and 0.45, respectively (8). Assuming similar yields apply to the β-mercaptoethanol–LFl system, on dividing the quantum yields in Fig. 6*a* by these numbers one obtains $\epsilon = 0.41$ and 0.009 at pH 7.0 and 4.1, respectively. These results, though approximate, demonstrate clearly the pH dependence of ϵ.

The above results of Heelis *et al.* (8) demonstrate that Φ(·FlH) falls off with pH for cysteine. The reason for this is not clear. However, a dependence of Φ_{isc} on pH has been demonstrated with other hydrogen donating solutes (4). This is shown by the dashed line in Fig. 6*b*. It would be reasonable to suppose that this drop off at pH > 8 is responsible for the fall off in the overall quantum yields for FlH_2/FlH^-. More detailed conclusions cannot be drawn until further values of Φ(·FlH) have been reported.

Finally there is one published quantum yield of FlH_2 for FMN in 0.04 *M* cysteine at pH 7, with which the present results may be compared. This is the value of 0.076 ± 0.008 reported by Heelis *et al.* (3). It is in good agreement with our value of 0.050 to 0.065 for RSH in Fig. 6*a*.

To summarise, the present study has confirmed that photoreduction of Fl to FlH_2 occurs in the presence of sulphydryl molecules, and demonstrated the formation of photostationary FlH_2 concentrations and a strong dependence of the initial quantum yields on pH. The mechanism proposed rationalises these observations and the dependences of the initial rates on sulphydryl concentration. While the reactions of B· radicals undoubtedly play a dominant role at high pH, there is also evidence for reduction of ·FlH, which is precomplexed with sulphydryl, by RS· radicals in reaction [3*c*]. That process may be rewritten as

[3*ci*] $RS\cdot + RSH\text{--}\cdot FlH \rightarrow RSSR + FlH_2$

or, if the RSH in the complex is deprotonated, as

[3*cj*] $RS\cdot + RS^-\text{--}\cdot FlH \rightarrow RSSR + FlH^-$

Further studies of these reactions will be undertaken and their relevance to biological flavin systems will be examined.

Total synthesis of the stemodane-type diterpenoids (±)-stemodin and (±)-maritimol. Formal total synthesis of (±)-stemodinone and (±)-2-desoxystemodinone

EDWARD PIERS, BRIAN F. ABEYSEKERA, DAVID J. HERBERT, AND IAN D. SUCKLING

Department of Chemistry, University of British Columbia, 2036 Main Mall, University Campus, Vancouver, B.C., Canada V6T 1Y6

Received June 4, 1985

EDWARD PIERS, BRIAN F. ABEYSEKERA, DAVID J. HERBERT, and IAN D. SUCKLING. Can. J. Chem. **63**, 3418 (1985).

Total syntheses of the stemodane-type diterpenoids (±)-stemodin (**2**) and (±)-maritimol (**4**), as well as formal total syntheses of (±)-stemodinone (**3**) and (±)-2-desoxystemodinone (**5**), are described. The known ketol **12** was converted into the tricyclic enone **7**. Photoaddition of allene to **7** gave (96%) a mixture of the photoadducts **20**–**23** (40:51:6:3, respectively). Ozonolysis of **20**, followed by treatment of the resultant dione **24** with MeONa–MeOH (room temperature, 2.5 h), provided the keto ester **26** (94%). Subjection of **21** to an identical sequence of reactions gave (86%) the *same* product **26**. On the other hand, when the dione **25** was treated with MeONa–MeOH under much milder conditions (0°C, 5 min), the isomeric keto esters **27** (39%) and **28** (33%) were produced. Both **27** and **28**, upon reaction with MeONa–MeOH at room temperature, were converted efficiently into **26**. Reduction ($NaBH_4$ or Li*sec*-Bu_3BH) of **26** provided separable mixtures of the ester alcohol **32** and the lactone **33**, which could be transformed readily into the dimesylates **35** and **39**, respectively. Reaction of **35** and **39** with NaCN in warm hexamethylphosphoramide afforded the dinitriles **37** and **40**, both of which, upon treatment with *t*-BuOK in refluxing *t*-BuOH, produced the same enaminonitrile **41**. Acid hydrolysis of **41** provided the dione **42**. Preparatively, compound **26** could be transformed conveniently into the dione **42** (52% overall yield) without separation of mixtures of isomeric synthetic intermediates. Treatment (CH_2Cl_2, −95°C) of **42** with Me_3SiI–Et_3N, followed by oxidation of the resultant products **46** and **47** with $Pd(OAc)_2$ in acetonitrile, gave the bis enones **48** (67%) and **49** (19%). Compound **48** was converted into the dione **52** which, upon reaction with $(i\text{-PrO})_3TiMe$ in ether, provided an 86:14 mixture of the keto alcohols **53** and **54** (63% from **48**). Reduction ($NaBH_4$) of **53** afforded (±)-maritimol (**4**). On the other hand, conversion of the 86:14 mixture of **53** and **54** into the *p*-toluenesulfonylhydrazones **55** and subsequent reaction of **55** with NaH in refluxing toluene gave the alkene alcohols **56** (58%) and **57** (12%). Hydroboration–oxidation (9-BBN, refluxing tetrahydrofuran; NaOH, H_2O_2) of **56** afforded (88%) (±)-stemodin (**2**).

EDWARD PIERS, BRIAN F. ABEYSEKERA, DAVID J. HERBERT et IAN D. SUCKLING. Can. J. Chem. **63**, 3418 (1985).

On décrit des synthèses totales des diterpénoïdes, du type stémodane, (±)-stémodine (**2**) et (±)-maritimol (**4**) ainsi que des synthèses totales formelles de la (±)-stémodinone (**3**) et de la (±)-déoxy-2 stémodinone (**5**). On a transformé le cétol connu **12** en énone tricyclique **7**. La photoaddition de l'allène sur **7** conduit à un mélange (96% de rendement) des photoadduits **20**–**23** (présents respectivement dans les rapports 40:51:6:3). L'ozonolyse du composé **20**, suivie par un traitement de la dione **24** qui en résulte par du MeONa–MeOH (température ambiante, 2,5 h), conduit au céto-ester **26** (94%). Lorsqu'on soumet le composé **21** à une série identique de réactions, il y a formation du *même* composé **26** (86%). Par ailleurs, si l'on traite la dione **25** par du MeONa–MeOH, dans des conditions beaucoup plus douces (0°C, 5 min), il y a formation des céto-esters **27** (39%) et **28** (33%). Les composés **27** et **28**, par réaction avec du MeONa–MeOH à la température ambiante, sont transformés d'une façon efficace en **26**. La réduction de **26** par du $NaBH_4$ ou par du Li*sec*-Bu_3BH conduit à des mélanges de l'ester alcool **32** et de la lactone **33** qui peuvent être séparés et qui peuvent respectivement être transformés en dimésylates **35** et **39**. La réaction des composés **35** et **39** avec du NaCN dans de l'hexaméthylphosphoramide à chaud conduit aux dinitriles **37** et **40** qui, par traitement avec du *tert*-BuOK dans du *tert*-BuOH au reflux, conduisent tous les deux à la même ènaminonitrile **41**. L'hydrolyse acide de **41** conduit à la dione **42**. Sur une base préparative, on peut facilement transformer le composé **26** en dione **42** (rendement global de 52%) sans séparer les mélanges d'intermédiaires de synthèse. La réaction (CH_2Cl_2, −95°C) du composé **42** avec du Me_3SiI–Et_3N, suivie d'une oxydation des produits **46** et **47** qui en résultent par du $Pd(OAc)_2$ dans l'acétonitrile, conduit aux bis-énones **48** (67%) et **49** (19%). On peut transformer le composé **48** en dione **52** qui, par réaction avec du $(i\text{-PrO})_3TiMe$ dans de l'éther, conduit à un mélange 86:14 des céto-alcools **53** et **54** (63% à partir de **48**). La réduction ($NaBH_4$) de **53** conduit au (±)-maritimol (**4**). Par ailleurs, la transformation d'un mélange 86:14 de **53** et de **54** en *p*-toluènesulfonylhydrazones **55** et la réaction subséquente de ce dérivé avec du NaH dans du toluène au reflux conduit aux alcools oléfiniques **56** (58%) et **57** (12%). L'hydroboration suivie d'une oxydation (BBN-9, tétrahydrofuranne au reflux; NaOH, H_2O_2) du composé **56**, permet d'obtenir (88%) la (±)-stémodine (**2**).

[Traduit par le journal]

Introduction

More than a decade ago, Hesp and co-workers reported (1) the isolation and structural elucidation of (+)-aphidicolin, a diterpenoid metabolite from the fungus *Cephalosporium aphidicola* Petch.[1] This natural product was shown (1) to have the constitution and absolute stereochemistry shown in **1** and to exhibit antiviral (3) and antitumor (4) activity. These interesting physiological properties, along with the fact that aphidicolin (**1**) possesses a novel diterpenoid carbon skeleton, have prompted a considerable number of synthetic investigations. Indeed, during the past six years, several elegant, well-designed total syntheses of (±)-**1** have been completed (5) and other reports (6) have described approaches to the synthesis of this interesting substance.

Various examinations of the above-ground portion of *Stemodia maritima* L. (Scrophulariaceae), a plant used on the Caribbean island of Curacao for the treatment of venereal disease, have resulted in the isolation of a number of diterpenoids, including (−)-stemodin (**2**) (7), (+)-stemodinone (**3**) (7), (+)-maritimol (**4**) (8), and (+)-2-desoxystemodinone

[1] (+)-Aphidicolin was subsequently isolated from *Nigrosporum sphaerica* (2).

(5) (9).[2] Although these naturally occurring substances have structures that are quite similar to that of aphidicolin (**1**), it is evident that the aphidicolane- and stemodane-type diterpenoids differ in the stereochemical arrangement of rings C and D.

Some time ago, we initiated a program with the aim of completing the total synthesis of (±)-aphidicolin and (some of) the stemodane-type diterpenoids. We describe herein the portion of this investigation which culminated in the preparation of (±)-stemodin (**2**) and (±)-maritimol (**4**) and in the formal total synthesis of (±)-stemodinone (**3**) and (±)-2-desoxystemodinone (**5**).[3] Several other reports of the synthesis of stemodane-type diterpenoids have been published (6*g*, 9, 10, 13–16).

Results and discussion

(a) *Synthetic plan (see Scheme 1)*

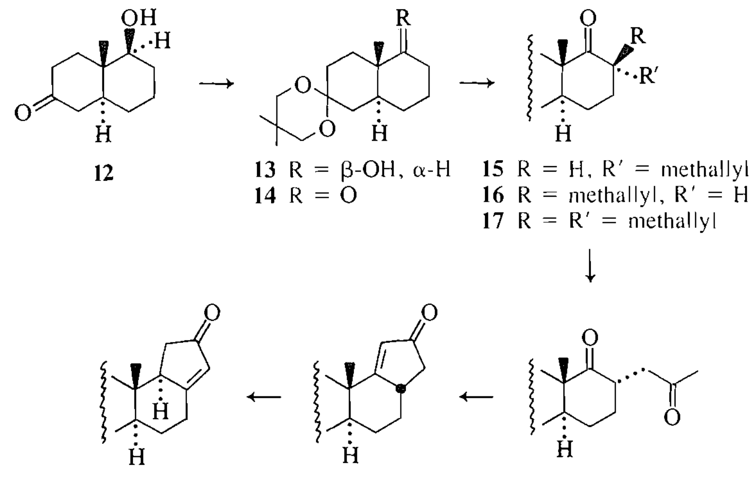
An examination of the structures of **1**–**5** indicates that, although the nature, position, and arrangement of functional groups on ring A of these substances varies significantly, it should be possible to synthesize all of these diterpenoids from a common precursor. More explicitly, since the basic carbon skeleton of rings A, B, and C is common to compounds **1**–**5**, it appeared that an intermediate such as the enone ketal **7** could serve as a suitable synthetic precursor for these natural products. In our originally formulated plan, we proposed to introduce, in each of the two possible stereochemical orientations, a suitable two-carbon unit at the β-carbon of the α,β-unsaturated ketone function in **7**. Stereo- and (or) regiochemically controlled synthetic manipulations on the resultant products would, hopefully, lead to the intermediates **8** and **10** (X = leaving group). Successful reaction of each of the latter substances with a reagent synthetically equivalent to the d^1,d^1 carbonyl synthon (see ref. 17) would provide the keto ketals **9** and **11**, respectively. In order to convert compound **9** into (±)-aphidicolin (**1**), the keto group in ring D and the "hidden" carbonyl function in ring A would have to serve as handles for the introduction of the necessary appendages and functionalities. Similarly, suitable synthetic operations involving the keto and ketal groups of **11** would, presumably, provide the stemodane-type diterpenoids **2**–**5**.

(b) *Preparation of the keto ketal 7 (see Scheme 2)*

Ketalization of the known ketol **12** (18) with 2,2-dimethyl-1,3-propanediol provided the crystalline ketal alcohol **13**, which, upon oxidation with pyridinium chlorochromate in the presence of sodium acetate (19), gave the keto ketal **14** (mp 68–70°C). Conversion of the latter material into the desired enone **7** was accomplished satisfactorily via two different routes. One of these, involving a new cyclopentenone annulation method that had been developed in our laboratory, has been described (20). The other, which was somewhat more amenable to large scale reactions, was patterned on work done by Brown and Ragault (21) and was similar to the annulation method employed by McMurry *et al.* (5*b*) in their synthesis of (±)-aphidicolin (**1**). Thus, alkylation (lithium diisopropylamide, tetrahydrofuran, 0°C; excess methallyl iodide, −78°C to room temperature) of the ketone **14** gave a mixture of compounds that included the desired monoalkylation product **15**,

[2] Another diterpenoid, named stemodinol, was isolated from *S. maritima* L. and was assigned the structure represented by formula **6** (8). However, subsequent work (9, 10) showed that this substance was, in fact, identical with (+)-stemarin (11), a diterpenoid possessing a carbon skeleton different from that of compounds **2**–**5**. Apparently, **6** has not yet been obtained from natural sources.

[3] A portion of this work has been reported in preliminary form (12).



SCHEME 2

the corresponding epimer **16**,[4] and a small amount of the dialkylation product **17**. Since **16** (axial methallyl group) would be expected to be considerably less stable than **15**, the mixture was treated briefly with sodium methoxide in methanol. The resultant material consisted of a mixture of **15** and **17** in a ratio of ~95:5, respectively. Although these two substances could be separated by column chromatography and were individually characterized, the next step of the reaction sequence was typically carried out on the crude mixture. Thus, treatment of the 95:5 mixture of **15** and **17** with six equivalents of sodium metaperiodate, a catalytic amount of osmium tetroxide, and one equivalent of sodium acetate[5] in *tert*-butyl alcohol – water provided, after purification of the crude product by means of fractional crystallization and column chromatography, the crystalline (mp 90–91°C) ketal dione **18** (88% from **14**).

The synthetically crucial conversion of the dione **18** into the enone **7**, involving base-promoted intramolecular aldol condensation – dehydration, proved to be problematic. Not unexpectedly, the difficulties were associated entirely with the fact that the desired, initially formed enone **7** can, in the presence of base, isomerize to the positional isomer **19**. In fact, appropriate experiments showed that **19** is thermodynamically more stable than **7** and, thus, since **19** was of no use in our synthetic efforts, it was important to find reaction conditions under which the conversion of **18** into **7** was (considerably) faster than the transformation of **7** into **19**. Several procedures (different bases, solvents, and reaction conditions) were investigated and, eventually, it was found that the most satisfactory results were obtained employing a method (sodium hydride, catalytic amount of *tert*-amyl alcohol, benzene, reflux) similar to that used by McMurry *et al.* (5*b*) in their synthesis of (±)-aphidicolin. However, when the reaction was allowed to proceed until (nearly) all of the starting material **18** had been consumed, even this procedure produced significant amounts of the unwanted enone **19**. Therefore, the reaction mixture was monitored and work-up was carried out when traces of **19** began to appear. Chromatographic separation of the mixture thus obtained gave ~11% of the starting material **18**, 73% (83% based on consumed starting material) of the desired enone **7**, and <5% of the enone **19**.

It is pertinent to comment briefly on the stereochemistry assigned to compound **19**. This assignment was based initially on the prediction that, of the two possible epimers that could be formed from isomerization of **7**, enone **19** would be the more stable isomer. In the alternative diastereomer (β allylic bridgehead proton), ring B is required to adopt an unstable, boat-like conformation. Evidence supporting the stereochemical conclusion was obtained by examining the ^{1}H nmr spectrum of **19**. A molecular model of this compound shows that the protons of the angular methyl group are situated within the "shielding cone" (22) of the carbon–carbon double bond of the enone system, and, therefore, these protons should resonate at unusually high field. This is indeed the case, since the ^{1}H nmr spectrum of **19** exhibits a 3-proton singlet at δ 0.64. In contrast, the angular methyl group of **7** produces a singlet at δ 1.13.

(c) *Conversion of the keto ketal **7** into the keto ester **26** (see Scheme 3)*

Bearing in mind our original synthetic plan (Scheme 1), it was necessary at this stage of the synthesis to introduce a two-carbon unit to the β carbon of the α,β-unsaturated ketone function of **7**. Initial attempts in this direction, involving treatment of **7** with lithium divinylcuprate (23) under a variety of reaction conditions, failed to produce any of the desired conjugate addition product(s).[6] Therefore, an alternative method had to be adopted.

A reaction sequence involving photoaddition of allene to an enone, oxidative cleavage of the carbon–carbon double bond of the photoadduct, and subsequent ring opening of the resultant dione has been employed quite frequently as a method for the overall conjugate addition of a functionalized two-carbon side chain to an α,β-unsaturated ketone (6*d*, 9, 10, 11*b*, 15, 24). Therefore, it seemed appropriate to investigate the photochemically induced cycloaddition of allene to the enone **7**.

Irradiation of a tetrahydrofuran solution (−78°C) of allene and compound **7** provided, in 96% yield, a mixture of four isomeric products, **20–23**, in a ratio of 40:51:6:3, re-

---

[4] The relative amounts of **15** and **16** varied somewhat from experiment to experiment.

[5] In the absence of sodium acetate, a small amount of ketal hydrolysis occurred.

[6] Similar observations were recorded independently by McMurry *et al.* (5*b*), who were unsuccessful in effecting conjugate addition of various reagents (including divinylcuprate) to an enone structurally similar to **7**.

spectively (glc analysis). Subjection of the mixture to column chromatography on silica gel provided the two major products **20** (mp 134–135°C, 39% yield) and **21** (mp 132–134°C, 42% yield). On the basis of spectral data, it was clear that these two substances were isomeric and, taking into account literature precedents (6*d*, 9, 10, 11*b*, 15, 24, 25) regarding the regiochemistry of allene photoaddition to enones, the constitutions of **20** and **21** could be assigned with confidence. However, at this stage, the stereochemical designations could not be made unambiguously. Consequently, a suitable crystal of the isomer with mp 134–135°C was subjected to X-ray analysis, which showed conclusively that this substance possessed the constitution and relative stereochemistry shown in **20** (26). The isomeric photoaddition product with mp 132–134°C was, therefore, assigned the structure represented by formula **21**.[7]

In the execution of a total synthesis of a complex natural product, it is usually desirable that each (crucial) step, involving the introduction of one or more new chiral centers, be accomplished in a highly stereoselective manner. Therefore, the lack of stereoselectivity observed in the photochemically induced addition of allene to the cyclopentenone **7**[8] was initially disconcerting. On the other hand, since our original objectives included the synthesis of both aphidicolane- and stemodane-type diterpenoids and since the photoadducts **20** and **21** could be separated quite readily, it appeared that we could, in fact, take advantage of the non-stereoselective nature of the cycloaddition reaction. Thus, it seemed likely that **20** could be employed as a precursor for the stemodane natural products, while **21** could serve as an intermediate for the synthesis of (±)-aphidicolin.

Treatment (−78°C, dichloromethane containing a small amount of methanol) of the photoadduct **20** with ozone, followed by reduction of the ozonide with dimethylsulfide, gave the rather unstable dione **24**. When the latter material was allowed to react with sodium methoxide in dry methanol (room temperature, 2.5 h),[9] the keto ester **26**, mp 139–140°C, was produced in high yield.

When the photoadduct **21** was subjected to a sequence of reactions identical with that outlined above, an unexpected and initially puzzling result was obtained. Thus, the product, formed cleanly and efficiently, was not the anticipated keto ester **27** but, in fact, proved to be the same product **26** as had been obtained from the photoadduct **20**. This surprising result led to some uncertainty with respect to the stereochemistry which had been assigned to **21**. Therefore, conclusive evidence regarding this point was sought.

In contrast to **20**, the photoadduct **21** did not crystallize easily. Nevertheless, after many attempts at recrystallization, it was possible to obtain a single crystal suitable for X-ray analysis. This study (28) showed that the photoadduct in question definitely possessed the constitution and relative stereochemistry shown in formula **21**. Furthermore, reduction of **21** with sodium borohydride, followed by treatment of the resultant alcohol **29** with *p*-bromobenzoyl chloride in pyridine, provided the *p*-bromobenzoate **30**, mp 184–185°C. Recrystallization of this material from ethanol produced crystals of high quality. An X-ray crystallographic study (28) showed conclusively that this substance possessed structure **30**.

With the structures of **20** and **21** firmly established, it was of some interest to determine how the reaction sequence outlined above (O_3; Me_2S; MeONa, MeOH) converts **21** into the keto ester **26**. To obtain evidence concerning this point, the unstable diketone **25** (obtained by ozonolysis–reduction of **21**) was treated with sodium methoxide in methanol at 0°C for 5 min. The mixture of substances thus produced contained only a trace of the keto ester **26** and consisted nearly entirely of two new products. Subjection of this mixture to column chromatography provided the keto ester **27** (mp 156–157°C, 39%) and, remarkably, the cyclobutanone **28** (mp 157–158°C, 33%). Also obtained was a mixed fraction (13%) containing **26**–**28** (ratio ~1:6:4, respectively).

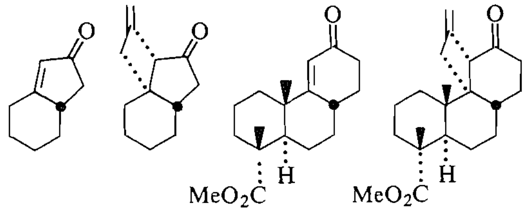
The spectral properties of **27**, which were similar to but clearly different from those of the previously obtained keto ester **26**, left little doubt concerning the structure of this new diastereomer. Although **27** should serve as a suitable synthetic precursor for (±)-aphidicolin (**1**), the low yield of this material from **21** (due to competitive formation of the cyclobutanone **28**) precludes the use of the route **21** → **25** → **27** as a viable pathway for the preparation of (±)-**1**. Of course, the photoadduct **21** could be used as the starting point for an alternative route to (±)-**1**, but we have not yet done any work in this direction.

Evidence for the structure of the cyclobutanone **28**, which was shown (mass spectrometry) to be isomeric with **26** and **27**, was obtained readily from spectral data. The ir spectrum of **28** shows carbonyl stretching absorptions at 1760 and 1720 cm^{-1}, while the ^1H nmr spectrum exhibits a three-proton singlet (δ 3.70, CO_2Me) and a four-proton ABMN system in the regions δ 2.57–2.78 and δ 2.91–3.08 (CH_2COCH_2). It is known (29) that protons on a cyclobutanone ring such as that present in **28** exhibit, in addition to the expected geminal couplings, long range couplings (both *cis* and *trans*) across the four-membered ring. While complete analysis of the coupling constants and chemical shifts of these four protons in **28** was not carried out, it was observed that irradiation of the higher field (δ 2.57–2.78) two-proton multiplet essentially removed the large (J = 18 Hz) geminal couplings from the δ 2.91–3.08 multiplet. This decoupling experiment indicated that the AB and MN parts of this ABMN system are, in each case, due to protons on different carbon atoms of the four-membered ring.

Treatment of the keto esters **27** and **28** with sodium methoxide in methanol (room temperature, 2.5 h) led, in each case, to the clean, efficient (91%, 81%, respectively) formation of the isomeric substance **26**. On the basis of these reactions,

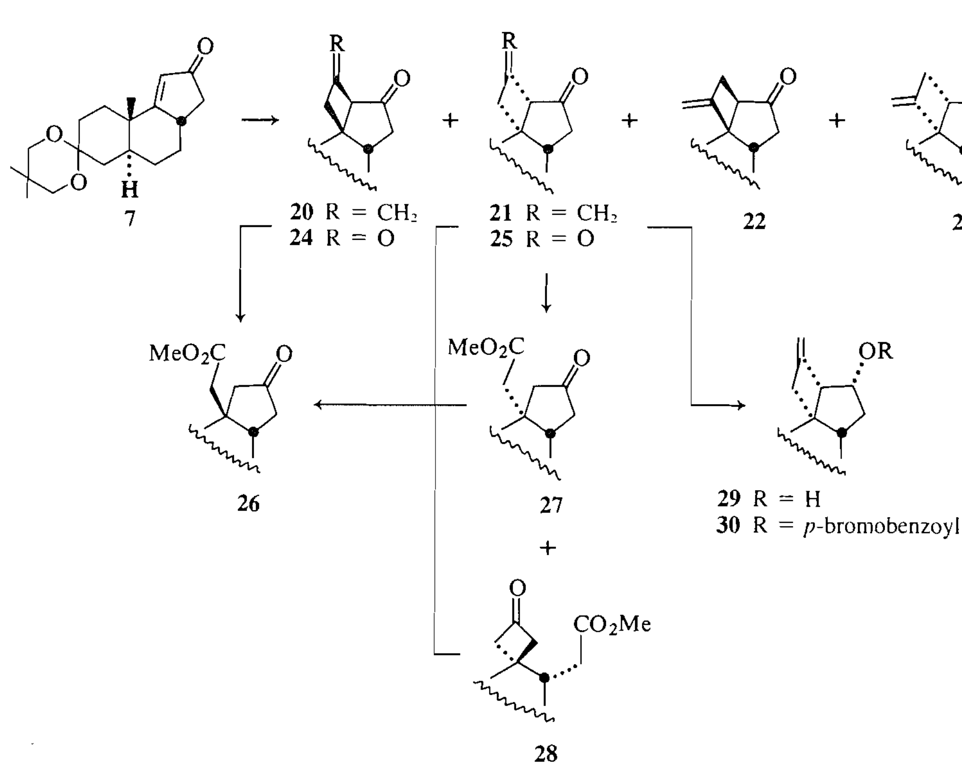
[7] The structures of the two minor products, **22** and **23**, obtained from photoaddition of allene to **7** are discussed at the end of this section of the paper.

[8] Interestingly, photoaddition of allene to the enone **i** provides exclusively the ketone **ii** (27). Furthermore, a similar transformation involving a cyclohexenone **iii** structurally similar to **7** provides, highly stereoselectively, the photoadduct **iv** (11*b*). A comparison of the reactions involving substrates **7** and **iii** makes it clear that the size of the enone ring has a profound effect on the stereochemistry of the photoaddition process.

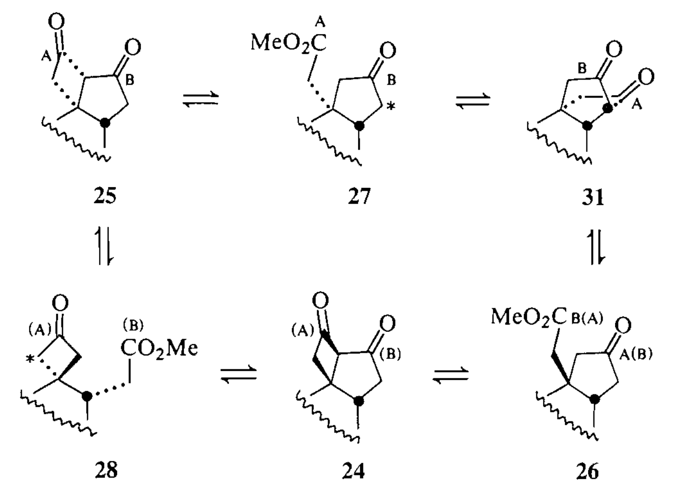


i **ii** **iii** **iv**

[9] It was shown subsequently that the conversion of **24** into **26** (with NaOMe–MeOH) was complete after the reaction mixture had been stirred for a few minutes at 0°C.



SCHEME 3

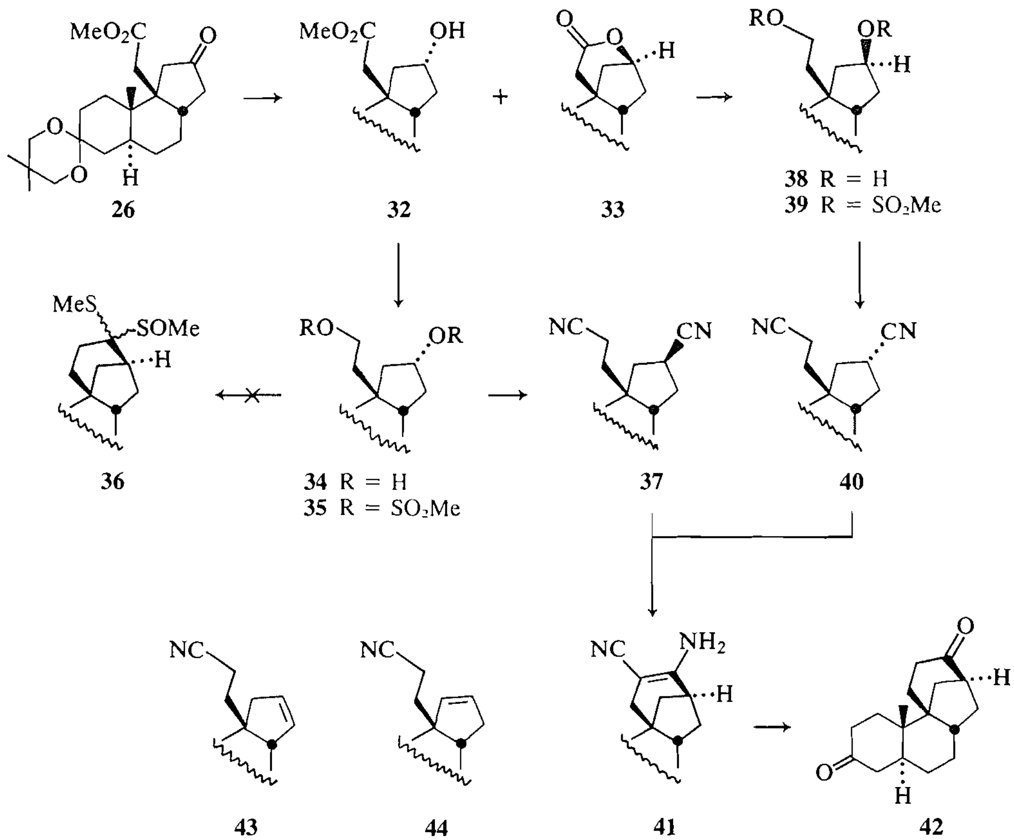


SCHEME 4

along with those summarized above, it seems reasonable to propose that the dione **25** is converted into **26** via two distinct pathways (see Scheme 4). Attack of methoxide ion on carbonyl A of **25**, followed by ring opening and protonation of the resultant enolate anion, provides the keto ester **27**, which, as noted above, can be isolated. Intramolecular condensation of **27**, involving C* and the ester carbonyl A, would lead to the dione **31** that, upon retro-condensation (attack of methoxide ion on carbonyl B), would give the final product **26**. On the other hand, the cyclobutanone **28** (also isolable) is evidently formed by initial attack of methoxide ion on carbonyl B of **25**. Subsequent condensation involving C* and the ester carbonyl (B) of **28** would produce the dione **24**. As already recorded earlier, the latter substance is rapidly transformed, presumably by methoxide ion attack on carbonyl (A), into **26**. It is interesting to note that in the first pathway, involving intermediates **27** and **31**, the ester carbonyl of **26** is ultimately derived from the cyclopentanone carbonyl of **25**, while in the second route the CO_2Me group of **26** finds its origin in the cylobutanone carbonyl of **25**.

The conversion **25** → **28** represents an unusual (probably unique) base-promoted cleavage of a bicyclo[3.2.0]heptane-2,7-dione system. Clearly, the only expected product, resulting from initial attack of methoxide ion on the strained cyclobutanone carbonyl of **25**, was the keto ester **27**. The formation of a significant quantity of **28** was, therefore, surprising and initially puzzling. However, molecular models show that the five-membered ring in **25** suffers from considerable angle strain and, consequently, one would expect the carbonyl group B of this material to be unusually susceptible to attack by nucleophilic reagents. On this basis, it is possible to rationalize, in a qualitative sense, why methoxide ion attack on carbonyl B of **25** is competitive with attack at the (probably) more strained, but quite hindered, cyclobutanone carbonyl group. In contrast, the cyclopentanone ring of **24** appears to be relatively free of angle strain and, apparently, treatment of this substance with methoxide ion leads directly and exclusively to the keto ester **26**.

If one considers the structures of compounds **24**–**28** and **31** (see Scheme 4), it is not difficult to understand why, thermodynamically speaking, the keto ester **26** is considerably more stable than each of the substances **24**, **25**, **28**, and **31**. Therefore, since all of the conversions shown in Scheme 4 are, in principle, reversible, each of the latter intermediates should eventually be transformed into **26**. However, why does the equilibrium **27** $\rightleftharpoons$ **26** favor the latter isomer? Or, in other words, why is **26** more stable than **27**? Conformational analysis indicates that the non-bonded interactions present in the two compounds are quite similar. However, molecular models indicate that angle strain in the five-membered ring of **27** (compare with **25**, see above) is considerably greater than that in the

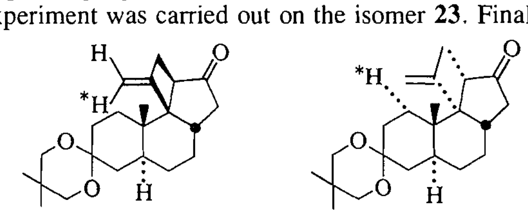


SCHEME 5

corresponding ring of **26** (compare with **24**, see above). On this basis, it is possible to rationalize, qualitatively, the fact that **27** is converted efficiently into the isomer **26**.

The results summarized above showed that, insofar as the synthesis of stemodane-type diterpenoids was concerned, the non-stereoselective nature of the photoaddition of allene to the enone **7** was of little consequence, since both of the major photoadducts **20** and **21** could be converted efficiently into the keto ester **26**, a promising stemodane precursor. Furthermore, it was obvious that chromatographic separation of **20** and **21**, although readily accomplished, was unnecessary. Thus, subjection of the mixture of photoadducts **20–23** (ratio 40:51:6:3, respectively, *vide supra*) to the sequence of reactions (O_3; Me_2S; MeONa, MeOH) developed earlier provided a mixture of compounds from which the keto ester **26** could be isolated (73% overall yield from the enone **7**) by flash column chromatography (30).

The first-eluted fractions of the above-mentioned chromatography contained a small amount of a mixture of the minor photoadducts **22** and **23**.[10] Since it seemed desirable to characterize these compounds, the mixture was resubjected to chromatography. The pure compounds **22** (mp 132–133.5°C) and **23** (mp 146–148°C) thus obtained were, on the basis of mass spectrometric measurements, isomeric with the previously isolated photoadducts **20** and **21**. The stereochemical assignments were made on the basis of the ^{1}H nmr spectra of **22** and **23**. First of all, the spectrum of **23** shows an unusually high-field (δ 0.89) one-proton multiplet. Examination of a molecular model of this material shows that the proton H* is situated directly in the "shielding cone" (22) produced by the olefinic double bond. No similarly shielded proton is found in the isomer **22**. Secondly, examination of a molecular model of **22** shows that one of the olefinic protons (H* in **22**) is very near to the angular methyl group. This close proximity was corroborated by a nuclear Overhauser effect (nOe) difference experiment (31). Thus, irradiation at δ 0.94 (the tertiary methyl groups of **22** resonate at δ 0.89, 0.94, and 0.99) caused a small enhancement of the signal (δ 5.26) due to one of the olefinic protons. No corresponding signal enhancement was observed when a similar experiment was carried out on the isomer **23**. Finally, one



22 **23**

of the olefinic protons of the photoadduct **22** resonates (δ 5.26) significantly downfield from the olefinic protons in compounds **20**, **21**, and **23** (δ 4.80–5.02). Since steric compression is known to deshield protons (22), this evidence is also consistent with one of the olefinic protons of **22** being in close proximity to the angular methyl group. Indeed, it was the δ 5.26 signal that showed enhancement when the resonance due to the angular methyl group was irradiated.

(d) *Conversion of the keto ester **26** into the dione **42** (see Scheme 5)*

Since a suitable procedure for the efficient conversion of

[10] Probably due to the very hindered nature of the carbon–carbon double bonds in **22** and **23**, these substances, apparently, underwent ozonolysis much more slowly than the isomeric photoadducts **20** and **21**.

enone **7** into the keto ester **26** had been developed, the next stage of the original synthetic plan for the synthesis of the stemodane-type diterpenoids (see Scheme 1) could be pursued. To that end, compound **26** had to be converted into an intermediate of general structure **10** (X = leaving group), thus allowing for an investigation of the reaction of the latter substance with a d^1,d^1 carbonyl reagent (to produce **11**).

Reduction of **26** with sodium borohydride in methanol gave a 1 : 1 mixture of the alcohol **32** and the lactone **33** (mp 194°C), which could be separated readily by chromatography. In attempts to increase the relative amounts of the desired product **32**, compound **26** was reduced with lithium tri-*sec*-butylborohydride in tetrahydrofuran at −78°C. Separation of the resultant product mixture gave the alcohol **32** (74%) and the lactone **33** (23%). Treatment of **32** with lithium aluminum hydride in ether, followed by reaction of the resultant diol **34** with methanesulfonyl chloride in pyridine, gave the dimesylate **35**. The latter substance is identical with **10** (X = OMs) and, consequently, the preparation of a key, originally postulated intermediate had been achieved.

Although a number of reagents which are synthetically equivalent to the d^1,d^1 carbonyl synthon are known (32), it appears that methyl methylthiomethyl sulfoxide (**45**) (33) is particularly effective for the conversion of 1,ω-dihaloalkanes or 1,ω-di(*p*-tosyloxy)alkanes into cyclic ketones. However, when the dimesylate **35** was treated (tetrahydrofuran, −78°C to 0°C, 30 min; room temperature, 12 h) with an excess (2.5 equivalents) of the anion of **45** (prepared by reaction of **45** with *n*-butyllithium) the major substance isolated was the starting material **35**. Although the crude product contained a number of minor components, none of these had the spectral characteristics expected for the desired product **36**.

Attempts to convert **35** into **36** using modified reaction conditions (e.g. use of $[MeSCHSOMe]^-K^+$, addition of hexamethylphosphoramide to the reaction mixture, higher temperatures) also proved to be unsuccessful. Although varying amounts of starting material were consumed, careful spectroscopic examination of the product mixtures provided no evidence for the presence of compound **36**.

It seems reasonable to propose that failure to effect conversion of **35** into **36** was due primarily to steric factors. The anion of **45** is relatively bulky and molecular models indicate that both of the carbon centers bearing the mesyloxy group are quite hindered toward S_N2-type attack of a nucleophile. In any case, it was evident that our original synthetic plan had to be modified. Explicitly, it appeared that ring D of the diterpenoid skeleton would have to be formed via a route involving reaction of the dimesylate **35** with a nucleophile that is much smaller than the anion of **45**.

When compound **35** was allowed to react with excess sodium cyanide in hexamethylphosphoramide (room temperature, 3 h; 60°C, 48 h), the crystalline dinitrile **37** was produced in 60% yield. It was gratifying to find that treatment of **37** with potassium *tert*-butoxide in refluxing *tert*-butyl alcohol (34) effected smoothly a Thorpe–Ziegler condensation (35) to afford, in 90% yield,[11] the enaminonitrile **41**, mp 213–215°C.

It seemed likely that, since the secondary cyano group of the dinitrile **40** should be susceptible to base-catalyzed epimerization, this substance should also undergo a Thorpe–Ziegler cyclization. Indeed, conversion of the lactone **33**, via the intermediates **38** and **39**, into the dinitrile **40** (mp 194°C), followed by treatment of the latter material with potassium *tert*-butoxide in hot *tert*-butyl alcohol (34), provided the enaminonitrile **41** in 47% overall yield.

Although conversion of the keto ester **26** into the dinitriles **37** and **40**, along with the Thorpe–Ziegler cyclization of the latter materials, provided an efficient pathway for the construction of ring D of the stemodane carbon skeleton, it was in the next step of the synthesis that this route lost some of its attractiveness. It is known that base hydrolysis of enaminonitriles is, at best, problematic and, in fact, usually fails to provide useful quantities of ketonic products. On the other hand, while acid hydrolysis – decarboxylation is usually efficiently successful, such a procedure would, in the case of **41**, also hydrolyze the ketal group on ring A. Clearly, to make use of the resultant product **42** in subsequent steps of the synthesis, one would have to distinguish chemically between two environmentally similar carbonyl groups.

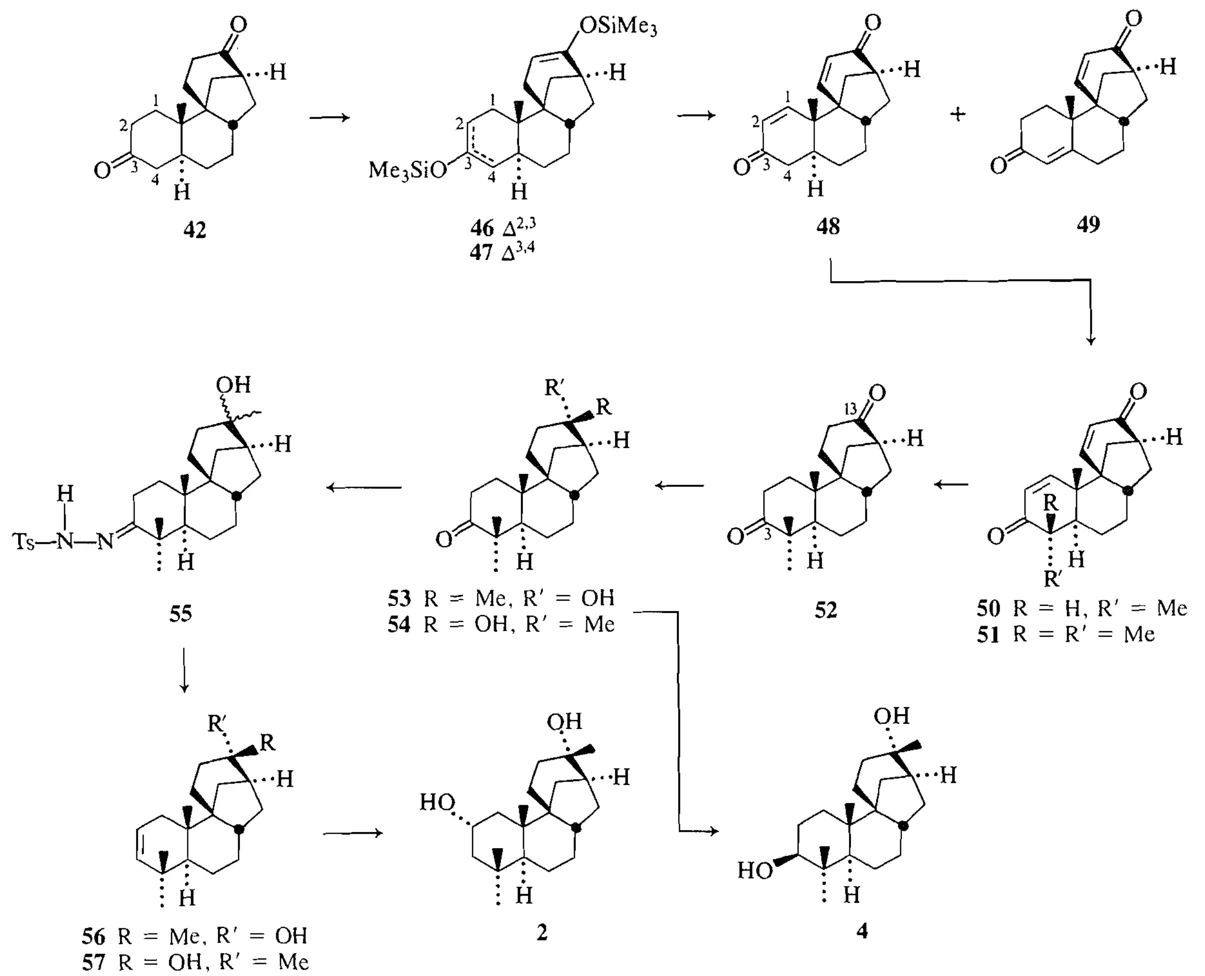
One possible way to avoid this problem would be to convert the dinitriles **37** and **40** into the corresponding di-esters and subject the latter compounds to Dieckmann condensation (35). Base hydrolysis and decarboxylation of the resultant β-keto ester could, presumably, be carried out under conditions that would not be deleterious to the ketal function on ring A. However, although both **37** and **40** could be converted by standard reactions into the corresponding di-esters, all attempts to effect Dieckmann cyclization of the latter substances, using a variety of bases, solvents, and reaction conditions, failed. These failures, although puzzling, led us back to an investigation of a synthetic route involving the enaminonitrile **41** as an intermediate.

Acid hydrolysis of **41** with phosphoric acid in refluxing aqueous acetic acid (34)[11] afforded, in 80% yield, the crystalline dione **42**, mp 132°C. At this stage, there appeared to be little doubt that this material possessed the structure implied by formula **42**. However, since the dione was formed under strongly acidic conditions and since the possibility of acid catalyzed rearrangements could not be rigorously excluded, independent structural evidence was sought. Gratifyingly, an X-ray crystallographic study (36) showed conclusively that the hydrolysis product had the constitution and relative stereochemistry shown in **42**.

The results summarized above showed clearly that, in the route eventually adopted for the transformation of the keto ester **26** into the dione **42**, the presence or absence of stereoselectivity in the reduction of the ketonic carbonyl group of **26** is irrelevant. Indeed, in preparative scale reactions, the conversion of **26** into **42** could be done without separation of isomeric compounds. Thus, reduction of **26** with excess lithium aluminum hydride, conversion of the resultant mixture of diols **34** and **38** into the corresponding dimesylates **35** and **39**, and subsequent reaction of the latter mixture with cyanide ion in warm hexamethylphosphoramide afforded, in 63% overall yield,[12] a mixture of the dinitriles **37** and **40**. Subjection of this mixture to Thorpe–Ziegler cyclization, followed by acid hy-

[11] It was found that the Thorpe–Ziegler condensation, as well as the subsequent hydrolysis–decarboxylation of the resulting enaminonitrile **41** (*vide infra*), had to be carried out with the careful exclusion of oxygen. If this was not done, significant amounts of a side product, apparently arising from oxidation of the enaminonitrile moiety, were formed.

[12] Also isolated, in 6% yield, was a 1 : 1 mixture of the two elimination products, the olefinic nitriles **43** and **44** (see Scheme 5).



SCHEME 6

drolysis of the resultant crude enaminonitrile **41**, provided the dione **42**. In this manner, the latter substance was obtained from the keto ester **26** in 52% overall yield.

(e) *Conversion of the dione* **42** *into (±)-maritimol (4) and (±)-stemodin (2) (see Scheme 6)*

As pointed out earlier, in order to prepare stemodane-type diterpenoids from the dione **42**, it was necessary at this stage to distinguish chemically between the two carbonyl groups of the latter intermediate. In this connection, if one bears in mind that introduction of two methyl groups at C-4 of **42** is also required, it appears that conversion of **42** into the corresponding bis enone **48** would be synthetically profitable. Explicitly, it is obvious that **48** could be converted into only one enolate anion and the latter species would involve the carbon center (C-4) at which the two methyl groups have to be introduced.

Although there are many different methods via which a ketone can be converted into the corresponding enone, efficient transformation of **42** into **48** proved to be nontrivial. For example, treatment of **42** with excess lithium diisopropylamide under conditions presumed to lead to kinetically controlled deprotonation (37), followed by trapping of the bis enolate anions with *tert*-butyldimethylsilyl chloride, gave a 1:1 mixture of positionally isomeric bis enol ethers (**46**, **47**, t-BuMe$_2$Si in place of Me$_3$Si). Therefore, it was apparent that conversion of **42** into **48** had to be accomplished via a route other than that initially involving kinetically controlled deprotonation of **42**.

Eventually, after a substantial number of unsuccessful or only moderately successful experiments, it was found that treatment of **42** with an excess of freshly prepared trimethylsilyl iodide (38) in the presence of triethylamine in cold (−95°C) dichloromethane for 1 h led to a mixture of the bis enol ethers **46** and **47** in a ratio of about 4-5:1, respectively.[13] Oxidation of this mixture with palladium(II) acetate in acetonitrile (39), followed by chromatographic separation of the resultant products, gave the crystalline bis enones **48** (67%) and **49** (19%).

Dimethylation of the bis enone **48** also proved to be somewhat more difficult than anticipated. Eventually, it was found that a 2-step process gave the most satisfactory result. Rapid treatment of the enolate anion (lithium bis(trimethylsilyl)amide, dimethoxyethane, 0°C) of **48** with a large excess of methyl iodide gave nearly exclusively (95%) the monomethylated product **50**, mp 149–150°C. The stereochemistry at C-4 of this substance was shown by a ^{1}H nmr decoupling experiment. Irradiation at δ 1.17 (3-proton doublet due to C-4 methyl group) caused collapse of the doublet of quartets at δ 2.38 (C-4 proton) to a clean doublet with J = 13 Hz (geminal *trans* diaxial coupling). Subjection of **50** to a second methylation via

[13] Use of higher reaction temperatures and (or) other bases (e.g. i-Pr$_2$NEt, (Me$_3$Si)$_2$NH), as well as use of other silylating agents (e.g. Me$_3$SiCl, Me$_3$SiOSO$_2$CF$_3$) gave mixtures of **46** and **47** containing lower proportions of the desired product **46**.

a very similar procedure provided the required bis enone **51**, mp 154–156°C, in 77% yield from **48**.[14]

Catalytic hydrogenation of compound **51** proceeded smoothly to generate the crystalline dione **52** in nearly quantitative yield. Thus, the overall conversion of **42** into **52** had been accomplished quite efficiently and, importantly, had provided a synthetic intermediate in which the two carbonyl groups were now, in terms of steric hindrance, quite different.

In other reported syntheses of stemodane-type diterpenoids (9, 10, 13–15), the chiral center at C-13 was introduced in a variety of ways. However, since C-13 of **52** is, compared to C-3, relatively unhindered and since the methyl group of the desired tertiary alcohol **53** is equatorially oriented, it appeared that the desired transformation **52** → **53** might be accomplished directly by treating **52** with a bulky methyl-transfer reagent that is known to add a methyl group to the equatorial side of cyclohexanone carbonyl functions. Indeed, such a reagent, methyltriisopropoxytitanium (40, 41), is known and it was pleasing to find that when the dione **52** was allowed to react (ether, room temperature) with an excess of this reagent, the epimeric keto alcohols **53** and **54** (ratio ~86 : 14, respectively) were produced in 82% yield. Although these isomers were difficult to separate by chromatography, a pure sample of the major isomer **53**, mp 93°C, could be obtained by a combination of chromatography and fractional crystallization.

Reduction of (±)-stemodan-13α-ol-3-one (**53**) with sodium borohydride in methanol, followed by purification (chromatography, fractional crystallization) of the crude product, gave, in 73% yield, (±)-maritimol (**4**), mp 221–222°C, which showed glc and tlc behavior, as well as ^{1}H nmr and mass spectra, identical with those of an authentic sample of (+)-maritimol.[15]

Treatment of an 86 : 14 mixture of the epimeric keto alcohols **53** and **54** with 1.3 equiv. of *p*-toluenesulfonylhydrazide in hot ethanol gave a mixture of the crude *p*-toluenesulfonylhydrazones **55**. Reaction of this crude material with sodium hydride in refluxing toluene, followed by chromatographic separation of products thus obtained, gave (±)-stemod-2-en-13α-ol (**56**) (58%) and (±)-stemod-2-en-13β-ol (**57**) (12%).

Although the alkene **56** had been converted previously into (±)-stemodin (**2**) via a 4-step sequence (13), it appeared that this transformation might be accomplished more directly. To that end, a tetrahydrofuran solution of compound **56** and an excess of 9-borabicyclo[3.3.1]nonane was refluxed for 48 h. Oxidation of the resultant organoborane mixture with alkaline hydrogen peroxide provided, after purification of the crude product, (±)-stemodin (**2**), mp 220.5–222°C, in 88% yield. This material exhibited chromatographic (glc, tlc) behavior and spectra (^{1}H nmr, mass) identical with those of an authentic sample of (−)-stemodin.[16]

It should be pointed out that the racemic keto alcohol **53** has been converted into (±)-2-desoxystemodinone (**5**) (15), while the alkene **56** has been transformed into (±)-stemodinone (**3**) (13). Consequently, the work described in this paper completes another formal total synthesis of each of the stemodane diterpenoids (±)-**3** and (±)-**5**.

Experimental

General information

Melting points and distillation temperatures are uncorrected. Ultraviolet (uv) spectra were recorded on methanol solutions using a Cary model 15 spectrophotometer. Infrared (ir) spectra (liquid films, chloroform solutions, or KBr pellets) were measured using Perkin–Elmer model 710 or 710B spectrophotometers. Proton nuclear magnetic resonance (^{1}H nmr) spectra were, unless otherwise noted, recorded on deuterochloroform solutions. Signal positions are given in δ units, with tetramethylsilane as the internal standard. In the case of compounds containing one or more trimethylsilyl groups, the chemical shifts were measured relative to the chloroform signal (δ 7.25). High resolution mass spectrometric measurements were recorded with a Kratos MS-50 mass spectrometer. Gas–liquid chromatography (glc) was accomplished with Hewlett–Packard models 5832A or 5880A gas chromatographs. Microanalyses were performed in the Microanalytical Laboratory at the University of British Columbia.

Preparation of the ketal alcohol 13

A solution of the ketol **12** (18) (6.10 g, 33.5 mmol), 2,2-dimethyl-1,3-propanediol (10.4 g, 100 mmol), and *p*-toluenesulfonic acid (100 mg) in 200 mL of benzene was refluxed (nitrogen atmosphere) under a Dean–Stark water trap. After 2 h, the solution was cooled, diluted with 100 mL of ether, and then was successively washed with saturated aqueous sodium bicarbonate, water, and brine. The organic phase was dried ($MgSO_4$) and concentrated. Distillation (air-bath temperature 133–137°C/0.15 Torr (1 Torr = 133.3 Pa)) of the residual material gave 8.0 g (89%) of the ketal alcohol **13**. An analytical sample, obtained by recrystallization of a small amount of this material from pentanes, exhibited mp 80–81°C; ir ($CHCl_3$): 3480 cm^{-1}; ^{1}H nmr δ: 0.85, 0.93, 0.99 (s, s, s, 3H each), 3.30 (unresolved m, 1H), 3.40–3.60 (m, 4H). *Anal.* calcd. for $C_{16}H_{28}O_3$: C 71.60, H 10.52; found: C 71.76, H 10.44.

Preparation of the keto ketal 14

A mixture of pyridinium chlorochromate (19) (11.8 g, 55.0 mmol), sodium acetate (800 mg, 10.7 mmol), and the ketal alcohol **13** (7.2 g, 26.8 mmol) in 100 mL of dry dichloromethane was stirred for 3 h at room temperature. Ether (100 mL) was added and the resultant mixture was passed through a short column of neutral alumina. The column was washed thoroughly with ether, the combined eluate was concentrated, and the residual material was recrystallized from a mixture of ether and pentanes to give 6.30 g (88%) of the keto ketal **14**, which exhibited mp 68–70°C; ir ($CHCl_3$): 1705 cm^{-1}; ^{1}H nmr δ: 0.89, 1.02, 1.12 (s, s, s, 3H each), 3.30–3.70 (m, 4H). *Anal.* calcd. for $C_{16}H_{26}O_3$: C 72.14, H 9.84; found: C 71.95, H 9.94.

Alkylation of the keto ketal 14 with methallyl iodide

To a cold (−78°C), stirred solution of lithium diisopropylamide (22.5 mmol) in 50 mL of dry tetrahydrofuran, under an atmosphere of argon, was added dropwise (syringe) a solution of 5.0 g (18.8 mmol) of the keto ketal **14** in 10 mL of dry tetrahydrofuran. After the solution had been stirred at 0°C for 30 min, it was recooled to −78°C and 8 mL (~70 mmol) of neat methallyl iodide was added rapidly. The mixture was stirred at 0°C for 2 h and at room temperature for 1 h. The volatile materials were removed under reduced pressure, the residual viscous oil was dissolved in 50 mL of methanol containing a small amount of sodium methoxide, and the resultant solution was stirred (argon atmosphere) at room temperature for 15 min. Removal of the methanol solvent left a solid which was dissolved in ether. The solution was washed successively with aqueous ammonium chloride and brine (3 times), and dried ($MgSO_4$). Removal of the solvent afforded 6.34 g of a white solid which, on the basis of glc analysis, contained the starting material **14** (0.5%), the desired ketone **15** (94%), and the di-alkylated ketone **17** (5%). Subjection of a small amount of this mixture to flash

[14] Other procedures for the conversion of **48** into **51**, including excess potassium *tert*-butoxide and methyl iodide in refluxing *tert*-butyl alcohol, excess lithium diisopropylamide and methyl iodide in tetrahydrofuran (−78°C to room temperature), and excess potassium hydride and methyl iodide in tetrahydrofuran (room temperature), gave varying amounts of starting material and the mono- and dimethylated products **50** and **51**.

[15] We are very grateful to Professor C. D. Hufford for providing a generous sample of (+)-maritimol.

[16] We are very grateful to Dr. P. S. Manchand for providing a generous sample of (−)-stemodin.

column chromatography (30) (elution with 10% ethyl acetate in hexanes) provided samples of the products **17** (eluted first) and **15**.

Ketone **17**, a colorless, viscous oil, exhibited ^{1}H nmr (80 MHz) δ: 0.91, 1.03, 1.08 (s, s, s, 3H each), 1.61, 1.71 (br s, br s, 3H each), 3.27–3.73 (m, 4H), 4.64, 4.86 (m, m, 2H each). *Exact Mass* calcd. for $C_{24}H_{38}O_3$: 374.2821; found: 374.2821.

Ketone **15**, a white solid, was recrystallized from a mixture of ether and hexanes and exhibited mp 87°C; ir ($CHCl_3$): 1700, 1630, 1105, 1095 cm^{-1}; ^{1}H nmr (400 MHz) δ: 0.90, 1.03, 1.15 (s, s, s, 3H each), 1.69 (br s, 3H), 1.93 (d of t, 1H, J = 13, 2.5 Hz), 2.08 (m, 1H), 2.36 (d of d of d, 1H, J = 14, 6, 3 Hz), 2.54 (d of d, 1H, J = 15, 5 Hz), 2.80 (m, 1H), 3.39, 3.44 (d of d, d of d, 1H each, J = 11, 1 Hz in each case, equatorial ketal methylene protons), 3.51, 3.59 (d, d, 1H each, J = 11 Hz in each case, axial ketal methylene protons), 4.63, 4.75 (br s, br s, 1H each). *Exact Mass* calcd. for $C_{20}H_{32}O_3$: 320.2351; found: 320.2353.

Preparation of the diketone 18

To a stirred mixture (room temperature) of sodium metaperiodate (24.13 g, 112.8 mmol, freshly recrystallized from water), sodium acetate (1.54 g, 18.8 mmol), a catalytic amount of osmium tetroxide, and 200 mL of distilled water was added in one portion a solution of the mixture of ketones **15** and **17** (6.34 g, prepared as described above) in 150 mL of distilled *tert*-butyl alcohol. The mixture was stoppered and stirred for 2 h, after which time the initially formed brown color had been discharged. Distilled water (150 mL) was added, the mixture was stirred for a further 4 h, and then was extracted thoroughly with ether. The combined ethereal extract was washed with brine, dried ($MgSO_4$), and concentrated under reduced pressure. The remaining brown oil was dissolved in ether and the solution was filtered through a plug of silica gel to remove much of the colored material. Removal of the solvent, followed by crystallization of the residual oil from hexanes afforded 4.51 g (74%) of the dione **18** as off-white crystals exhibiting mp 89–91°C. Flash column chromatography (30) (elution with 20% ethyl acetate in hexanes) of the material from the mother liquor afforded a further 0.80 g of **18** (total yield = 5.31 g, 88%). Recrystallization of a small amount of this material from hexanes afforded an analytical sample of **18** as colorless needles, mp 90–91°C; ir ($CHCl_3$): 1700 cm^{-1}; ^{1}H nmr (400 MHz) δ: 0.88, 1.02, 1.17 (s, s, s, 3H each), 1.91 (d of t, 1H, J = 13, 3 Hz), 2.09 (d of d, 1H, J = 17, 5 Hz), 2.20 (s, 3H), 2.35 (d of q, 1H, J = 14, 3.5 Hz), 2.92 (d of d, 1H, J = 17, 8 Hz), 3.32 (m, 1H), 3.36–3.60 (m, 4H). *Anal.* calcd. for $C_{19}H_{30}O_4$: C 70.77, H 9.38; found: C 70.73, H 9.45.

Preparation of the enones 7 and 19

To sodium hydride (11.6 mmol, washed free of oil with ether), under an atmosphere of argon, was added dry benzene (200 mL) and dry *tert*-amyl alcohol (500 μL, 4.7 mmol). After the mixture had been stirred at room temperature for 20 min, 3.0 g (9.3 mmol) of the crystalline dione **18** was added and the resultant mixture was refluxed for 1 h. The cooled reaction mixture was treated with aqueous ammonium chloride and ether. The organic extract was washed with brine, dried ($MgSO_4$), and concentrated. Gas–liquid chromatographic analysis of the remaining yellow oil showed that it was a mixture of the starting material **18** (13%), the tricyclic enone **7** (82%), and the isomeric enone **19** (5%). Separation of this mixture by preparative hplc (silica gel, elution with 30% ethyl acetate in petroleum ether) and rechromatography of the mixed fractions by flash column chromatography (30) (solvent as above) afforded 333 mg (11%) of recovered starting material **18** as the first-eluted component, 2.08 g (73%, 83% based on consumed starting material) of the desired enone **7**, mp 115–117°C, and 139 mg (5%) of a mixture of the enones **7** and **19**.

Recrystallization (ether–hexanes) of a small sample of the major product afforded an analytical sample of the enone **7**, which exhibited mp 115–116°C; uv λ_{max}: 230 nm (ε 17 100); ir ($CHCl_3$): 1690, 1670, 1600 cm^{-1}; ^{1}H nmr (400 MHz) δ: 0.94, 1.00, 1.13 (s, s, s, 3H each), 1.18 (m, 1H), 1.39–1.67 (diffuse, 6H), 1.73 (q of d, 1H, J = 14, 4 Hz), 1.96 (d of d, 1H, J = 18, 2 Hz), 1.99 (d of t, 1H, J = 13, 3 Hz), 2.18 (m, 1H), 2.34 (d of d of d, 1H, J = 13.5, 6.5, 3 Hz), 2.57 (d of d, 1H, J = 18, 7 Hz), 2.98 (m, 1H), 3.42–3.61 (m, 4H), 5.80 (d, 1H, J = 1.5 Hz). Decoupling experiments: irradiation at δ 5.80 sharpened the multiplet at δ 2.98; irradiation at δ 2.98 caused the doublet at δ 5.80 to collapse to a singlet and the signals at δ 2.57 and δ 1.96 to collapse to doublets, J = 18 Hz; irradiation at δ 2.57 sharpened the multiplet at δ 2.98 and changed the signal at δ 1.96 to a doublet, J = 2 Hz. *Anal.* calcd. for $C_{19}H_{28}O_3$: C 74.96, H 9.27; found: C 74.76, H 9.47.

Flash column chromatography (30) (4:2:3 cyclohexane–hexanes–ethyl acetate, 3-cm column) of the mixture of **7** and **19** (see above), followed by crystallization (ether–hexanes) of the material obtained from the appropriate fractions, afforded a pure sample of the enone **19**, which exhibited mp 139–140°C; uv λ_{max}: 232 nm (ε 17 000); ir ($CHCl_3$): 1690, 1665, 1610, 1105 cm^{-1}; ^{1}H nmr (400 MHz) δ: 0.64, 0.93, 1.04 (s, s, s, 3H each), 1.31–1.49 (diffuse, 5H), 1.62 (m, 1H), 1.77 (t of t, 1H, J = 13, 3.5 Hz), 1.96 (d of t, 1H, J = 13, 3.5 Hz), 2.17 (d of d, 1H, J = 19, 2 Hz), 2.24–2.41 (m, 2H), 2.30 (d of d, 1H, J = 19, 7 Hz), 2.54 (br d, 1H, J = 7 Hz), 2.80 (br d of d, 1H, J = 15, 5 Hz), 3.45–3.65 (m, 4H), 5.90 (d of d, 1H, J = 2, 2 Hz). Decoupling experiments: irradiation at δ 5.90 sharpened the signal at δ 2.54; irradiation at δ 2.54 collapsed the signals at δ 5.90, 2.17, and 2.30 to doublets, J = 2, 19, and 19 Hz, respectively; irradiation at δ 2.17 sharpened the signal at δ 2.54. *Exact Mass* calcd. for $C_{19}H_{28}O_3$: 304.2039; found: 304.2039.

Photoaddition of allene to the enone 7. Isolation and characterization of the photoadducts 20 and 21

A cold (−78°C), stirred solution of the enone **7** (3.0 g, 9.87 mmol) and allene (5 mL) in 55 mL of dry tetrahydrofuran, contained in a Pyrex tube, was irradiated (450-W Hanovia lamp) for 7 h. During this time, a slow stream of argon was bubbled through the solution. The vigorously stirred solution was allowed to warm to room temperature and the solvent was then removed under reduced pressure. Flash column chromatography (30) (elution with 20% ethyl acetate in hexanes, 5-cm column) of the residue gave 3.25 g (96%) of a mixture (viscous oil) of the four photoadducts **20–23**, in a ratio (glc) of 40:51:6:3, respectively. Subjection of this mixture to flash column chromatography (elution with a 10:5:2 mixture of cyclohexane, hexane, and ethyl acetate) provided a white solid that, upon recrystallization from ether–hexanes, gave 1.32 g (39%) of the photoadduct **20**, which exhibited mp 134–135°C; ir ($CHCl_3$): 1725, 1670 cm^{-1}; ^{1}H nmr (400 MHz) δ: 0.87, 0.95, 0.97 (s, s, s, 3H each), 1.73 (br m, 1H), 1.89 (d of d, 1H, J = 17, 1 Hz), 1.95 (d of t, 1H, J = 14, 3 Hz), 2.12–2.27 (m, 2H), 2.66 (br d of d, 1H, J = 17, 3 Hz), 2.83 (br d of d, 2H, J = 17, 2.5 Hz), 2.93 (d of d, 1H, J = 17, 6 Hz), 3.26 (br s, 1H), 3.41–3.55 (m, 4H), 4.80 (br d, 1H, J = 2.5 Hz), 4.95 (br d, 1H, J = 2 Hz). *Anal.* calcd. for $C_{22}H_{32}O_3$: C 76.70, H 9.36; found: C 76.90, H 9.47. *Exact Mass* calcd.: 344.2351; found: 344.2349.

Further elution of the column with the same solvent mixture afforded 1.42 g (42%) of the photoadduct **21**, mp 132–134°C (recrystallization from ether–hexanes); ir ($CHCl_3$): 1725, 1670 cm^{-1}; ^{1}H nmr (400 MHz) δ: 0.90, 0.95, 1.00, (s, s, s, 3H each), 1.90 (d of t, 1H, J = 13, 3 Hz), 2.19 (d of d of d, 1H, J = 15, 6, 1 Hz), 2.23 (m, 1H), 2.38 (m, 1H), 2.45 (m, 1H), 2.68–2.83 (br AB pair of d, 2H, J = 17 Hz), 3.09 (br s, 1H), 3.43–3.58 (m, 4H), 4.78 (br d, 1H, J = 2.5 Hz), 4.92 (br d, 1H, J = 2 Hz). Decoupling experiments: irradiation at δ 3.09 simplifies the signal at δ 2.19 to a d of d, J = 15, 6 Hz; irradiation at δ 2.22 (δ 2.19 and 2.23 signals) simplifies the multiplet at δ 2.45. *Anal.* calcd. for $C_{22}H_{32}O_3$: C 76.70, H 9.36; found: C 76.99, H 9.63. *Exact Mass* calcd.: 344.2351; found: 344.2343.

Preparation of the alcohol 29 and the p*-bromobenzoate 30*

To a cold (0°C), stirred solution of the photoadduct **21** (67 mg, 0.195 mmol) in 20 mL of methanol was added an excess of sodium borohydride. The reaction mixture was allowed to warm to room temperature and was stirred for 40 min. The solvent was removed under reduced pressure and the residue was partitioned between ether and water. The organic phase was washed with brine and dried ($MgSO_4$). Removal of the solvent provided 63 mg (93%) of the alcohol **29** as a viscous colorless oil which could not be induced to crystallize. The oil exhibited ir ($CHCl_3$): 3540, 3450, 1660 cm^{-1}; ^{1}H nmr (80 MHz) δ: 0.85, 0.93, 0.98 (s, s, s, 3H each), 3.31–3.67 (m, 4H), 4.10 (br m, 1H), 4.86 (m, 2H). *Exact Mass* calcd. for $C_{22}H_{34}O_3$: 346.2508; found: 346.2509.

Treatment of the alcohol with *p*-bromobenzoyl chloride (pyridine, room temperature, 16 h) provided the *p*-bromobenzoate **30**, which was purified by preparative tlc and recrystallized from ethanol. Compound **30** exhibited mp 184–185°C; ir ($CHCl_3$): 1700, 1665, 1590 cm^{-1}; ^{1}H nmr (270 MHz) δ: 0.89, 0.92, 0.99 (s, s, s, 3H each), 2.44, 2.65 (br d, br d, 1H each, J = 19 Hz in each case), 3.29 (br d, 1H, J = 9 Hz), 3.39–3.60 (m, 4H), 4.58, 4.74 (br d, br d, 1H each, J = 2 Hz in each case), 5.15 (m, 1H), 7.54 (br d, 2H, J = 8 Hz), 7.86 (br d, 2H, J = 8 Hz). *Exact Mass* calcd. for $C_{29}H_{37}{}^{79}BrO_4$: 528.1875; found: 528.1871.

*Conversion of the photoadduct **21** into the keto esters **27** and **28***

A cold (−78°C) solution of the photoadduct **21** (88 mg, 0.255 mmol) in 15 mL of dry dichloromethane containing 16 μL (0.383 mmol) of dry methanol was treated with a stream of dry ozone in oxygen until the solution remained blue. After the solution had been flushed with a stream of dry oxygen until colorless, it was treated with 200 μL of dry dimethyl sulfide. The solution was stirred under an atmosphere of argon for 15 min at −78°C and for 2 h at room temperature. Removal of the volatile materials gave a partially crystalline viscous oil which was dissolved in 20 mL of dry methanol. The solution was cooled to 0°C and a small amount of methanolic sodium methoxide was added. After the solution had been stirred at 0°C for 5 min, 2 drops of glacial acetic acid were added and the resulting mixture was concentrated under reduced pressure. The residual material was dissolved in ether and the solution was washed successively with 10% aqueous sodium carbonate and brine, dried ($MgSO_4$), and concentrated. The remaining oil (85 mg) was subjected to flash column chromatography (30) (elution with a 4:2:3 mixture of cyclohexane, hexanes, and ethyl acetate, respectively). The first-eluted material, upon recrystallization from ether–hexanes, gave 32 mg (33%) of the cyclobutanone **28**, mp 157–158°C; ir ($CHCl_3$): 1760, 1720 cm^{-1}; ^{1}H nmr (400 MHz) δ: 0.91, 0.98, 1.00 (s, s, s, 3H each), 1.77 (d of d of d, 1H, J = 14, 7, 4 Hz), 1.89 (d of t, 1H, J = 14, 3 Hz), 2.01 (d of d, 1H, J = 15, 10 Hz), 2.26 (d of d of d, 1H, J = 13, 7, 4 Hz), 2.45 (d of d, 1H, J = 15, 3 Hz), 2.55 (m, 1H), 2.57–2.78 (AB part of ABMN system, 2H), 2.91–3.08 (MN part of ABMN system, 2H), 3.41–3.62 (m, 4H), 3.69 (s, 3H). Decoupling experiments: irradiation at δ 2.01 removes the 15-Hz coupling from the signal at δ 2.45 and simplifies the multiplet at δ 2.55; irradiation at δ 2.71 essentially removes the large (J = 18 Hz) couplings from the δ 2.91–3.08 multiplet. *Exact Mass* calcd. for $C_{22}H_{34}O_5$: 378.2406; found: 378.2410.

Further elution of the column gave 13 mg (13%) of a mixture of the keto esters **26–28** in the approximate ratio (^{1}H nmr) of 1:6:4, respectively.

Further elution of the column afforded 38 mg (39%) of the keto ester **27**, which, after recrystallization from hexanes, exhibited mp 156–157°C; ir ($CHCl_3$): 1725 (br) cm^{-1}; ^{1}H nmr (400 MHz) δ: 0.89, 1.03, 1.04 (s, s, s, 3H each), 1.65–1.75 (m, 2H), 1.84–1.96 (m, 2H), 2.03–2.21 (AB part of ABX system, 2H, J_{AB} = 18 Hz), 2.15 (d, 1H, J = 18 Hz), 2.30 (m, 1H), 2.34 (d, 1H, J = 15 Hz), 2.43 (m, 1H), 2.49 (d, 1H, J = 18 Hz), 2.73 (d of d, 1H, J = 15, 1 Hz), 3.42–3.62 (m, 4H), 3.59 (s, 3H). *Anal.* calcd. for $C_{22}H_{34}O_5$: C 69.81, H 9.05; found: C 69.84, H 8.96. *Exact Mass* calcd.: 378.2406; found: 378.2407.

*Preparation of the keto ester **26***

(a) *From the photoadduct **20***

Ozonolysis of the photoadduct **20**, followed by treatment of the resultant dione **24** with sodium methoxide in methanol, was carried out via a procedure identical with that described above (**21** → **27** + **28**). From 58 mg of compound **20** there was obtained 60 mg (94%) of the keto ester **26**, which, after recrystallization from ether–hexanes, exhibited mp 139–140°C; ir ($CHCl_3$): 1720 (br) cm^{-1}; ^{1}H nmr (400 MHz) δ: 0.92, 1.00, 1.02 (s, s, s, 3H each), 1.70–1.80 (m, 2H), 1.88 (d, 1H, J = 19 Hz), 1.93 (d of t, 1H, J = 14, 3 Hz), 2.17 (d of d of d, 1H, J = 13, 6, 3 Hz), 2.33–2.44 (m, 3H), 2.46–2.61 (m, 3H), 3.40–3.57 (m, 4H), 3.63 (s, 3H). *Anal.* calcd. for $C_{22}H_{34}O_5$: C 69.81, H 9.05; found: C 69.65, H 8.94. *Exact Mass* calcd.: 378.2406; found: 378.2410.

(b) *From the photoadduct **21***

Ozonolysis of compound **21** (295 mg, 0.86 mmol) was carried out via a procedure very similar to that described above. A solution of the resultant crude dione **25** in methanol containing a small amount of sodium methoxide was stirred at room temperature for 2.5 h. Work-up as described above, followed by recrystallization of the crude product from ether–hexanes, gave 275 mg (85%) of the keto ester **26**.

(c) *From the keto ester **27***

A solution of compound **27** (54 mg, 0.143 mmol) in 20 mL of dry methanol containing a small amount of sodium methoxide was stirred at room temperature (argon atmosphere) for 2.5 h. Most of the solvent was removed (reduced pressure) and the residue was partitioned between ether and water. The organic phase was washed with brine, dried ($MgSO_4$), and concentrated to yield 49 mg (91%) of the keto ester **26**.

(d) *From the keto ester **28***

Conversion of the cyclobutanone **28** into compound **26** was accomplished via a procedure identical with that described above (**27** → **26**). From 36 mg (0.095 mmol) of **28** there was obtained 29 mg (81%) of **26**.

(e) *From a mixture of the photoadducts **20–23***

A mixture of the photoadducts **20–23** (ratio 40:51:6:3, respectively, *vide supra*) was subjected to ozonolysis via a procedure very similar to that described previously (**21** → **27** + **28**, see above). The quantities of reagents and solvents were as follows: photoadduct mixture, 3.11 g (9.02 mmol); methanol, 550 μL (13.53 mmol); dichloromethane, 100 mL, dimethyl sulfide, 3 mL.

The semi-solid material obtained after work-up of the ozonolysis reaction was dissolved in dry methanol (80 mL) containing freshly prepared sodium methoxide and the resulting solution was stirred at room temperature for 4 h. The methanol was removed (reduced pressure) and the residual material was dissolved in ether. The solution was washed with brine, dried ($MgSO_4$), and concentrated to give a colorless solid. Flash column chromatography (30) (elution with a 2:1:1 mixture of cyclohexane, hexanes, and ethyl acetate) of this material gave initially 88 mg of a mixture of compounds that contained mainly the minor photoadducts **22** and **23** (see below).

Further elution of the column gave a white solid, which upon recrystallization from hexanes provided 2.60 (76%) of the desired keto ester **26**.

*Purification and characterization of the photoadducts **22** and **23***

Flash column chromatography (30) (elution with a 10:5:2 mixture of cyclohexane, hexanes, and ethyl acetate) of 119 mg of mixture containing mainly the minor photoadducts **22** and **23** (see previous experiment for the origin of this material) afforded, as the first-eluted compound, 62 mg of **23**. Recrystallization of this material from ether–hexanes provided pure **23**, which exhibited mp 146–148°C; ir ($CHCl_3$): 1720, 1660, 1100 cm^{-1}; ^{1}H nmr (400 MHz) δ: 0.89 (m, 1H), 0.97 (s, 6H), 1.00 (s, 3H), 1.71 (m, 1H), 1.88 (d of d, 1H, J = 17, 2 Hz), 1.98 (d of t, 1H, J = 13, 3 Hz), 2.16 (d of q, 1H, J = 13, 3 Hz), 2.26–2.35 (m, 2H), 2.67 (br d, 1H, J = 10 Hz), 2.88 (d of d, 1H, J = 17, 6 Hz), 2.90 (m, 1H), 3.47, 3.52 (s, s, 2H each), 5.00 (t, 1H, J = 2.5 Hz), 5.01 (t, 1H, J = 2 Hz). In a difference nOe experiment, irradiation at δ 0.97 gave rise to no enhancement of the signals at δ 5.00 or 5.01. *Exact Mass* calcd. for $C_{22}H_{32}O_3$: 344.2351; found: 344.2347.

Further elution of the column afforded 31 mg of the photoadduct **22**, which, after recrystallization from hexanes, exhibited mp 132–133.5°C; ir ($CHCl_3$): 1720, 1650, 1100 cm^{-1}; ^{1}H nmr (400 MHz) δ: 0.89, 0.94, 0.99 (s, s, s, 3H each), 1.85 (t of d, 1H, J = 14, 4 Hz), 1.90–2.00 (m, 2H), 1.90–2.00 (m, 2H), 2.13–2.29 (m, 4H), 2.46 (d, 1H, J = 15 Hz), 2.52 (br d, 1H, J = 10 Hz), 2.78 (d of d of t, 1H, J = 16, 11, 3 Hz), 3.43–3.58 (m, 4H), 5.11 (br s, 1H), 5.26 (t, 1H, J = 3 Hz). In a difference nOe experiment, irradiation at δ 0.94 led to enhancement of the signal at δ 5.26. *Exact Mass* calcd. for $C_{22}H_{32}O_3$: 344.2351; found: 344.2359.

Reduction of the keto ester 26. Preparation of the alcohol 32 and the lactone 33

(a) *Reduction with sodium borohydride*

A solution of the keto ester **26** (240 mg, 0.63 mmol) and sodium borohydride (190 mg, 5 mmol) in 25 mL of methanol was stirred at room temperature for 30 min, and the methanol was then removed under reduced pressure. The residual material was partitioned between ether and water. The organic phase was washed twice with water, dried (Na_2SO_4), and concentrated. The remaining oil was subjected to column chromatography on silica gel. Elution of the column with 4:1 methylene chloride – ether gave 108 mg (49%) of the lactone **33**, which, after recrystallization from methanol, exhibited mp 194°C; ir ($CHCl_3$): 1730, 1115, 1100 cm^{-1}; ^{1}H nmr δ: 0.88, 0.92, 1.00 (s, s, s, 3H each), 3.50 (m, 4H), 4.78 (m, 1H). *Anal.* calcd. for $C_{21}H_{32}O_4$: C 72.38, H 9.26; found: C 71.97, H 8.95. *Exact Mass* calcd.: 348.2301; found: 348.2304.

Further elution of the column with the same solvent mixture provided 121 mg (50%) of the alcohol **32** as a viscous, colorless oil that exhibited one spot on tlc analysis; ir ($CHCl_3$): 3400, 1725, 1115, 1095 cm^{-1}; ^{1}H nmr δ: 0.95 (s, 3H), 0.99 (s, 6H), 3.58 (m, 4H), 3.65 (s, 3H), 4.54 (m, 1H). *Exact Mass* calcd. for $C_{22}H_{36}O_5$: 380.2562; found: 380.2561.

(b) *Reduction with lithium tri-*sec*-butylborohydride*

A cold (−78°C) solution of compound **26** (25 mg, 0.066 mmol) and lithium tri-*sec*-butylborohydride (0.10 mmol) in 5 mL of dry tetrahydrofuran was stirred at −78°C for 3 h. Water (1 mL), 1 *M* aqueous sodium hydroxide (100 μL), and 30% hydrogen peroxide (25 μL) were added consecutively and the mixture was stirred at room temperature for 15 min. The mixture was extracted thoroughly with ether and the combined extract was dried (Na_2SO_4) and concentrated. Separation of the mixture of products by column chromatography as described above gave 5.3 mg (23%) of the lactone **33** and 18.6 mg (74%) of the alcohol **32**.

Preparation of the diol 34

A solution of ester alcohol **32** (57 mg, 0.15 mmol) and lithium aluminum hydride (14.4 mg, 0.38 mmol) in 6 mL of dry ether was stirred at 0°C for 15 min and at room temperature for 30 min. Excess reducing agent was destroyed by careful addition of solid sodium sulfate decahydrate. The mixture was filtered and the collected solid material was washed thoroughly with ether. Removal of the solvent from the combined filtrate gave 50 mg (94%) of the diol **34** as a colorless oil that exhibited one spot on tlc analysis; ir ($CHCl_3$): 3400 (br), 1120, 1100 cm^{-1}; ^{1}H nmr δ: 0.94 (s, 3H), 0.96 (s, 6H), 3.52 (m, 4H), 3.70 (t, 2H, J = 8 Hz), 4.54 (m, 1H). *Exact Mass* calcd. for $C_{21}H_{36}O_4$: 352.2613; found: 352.2613.

Preparation of the diol 38

A vigorously stirred solution of the lactone **33** (50 mg, 0.14 mmol) and lithium aluminum hydride (13.3 mg, 0.35 mmol) in 10 mL of dry ether was refluxed for 2.5 h. The cooled solution was subjected to a work-up procedure identical with that described above. Recrystallization of the crude product gave 48 mg (95%) of the diol **38**, mp 180–182°C; ir ($CHCl_3$): 3350 (br), 1120, 1100 cm^{-1}; ^{1}H nmr δ: 0.93 (s, 6H), 1.00 (s, 3H), 3.51 (br s, 4H), 3.80 (t, 2H, J = 7 Hz), 4.55 (m, 1H). *Exact Mass* calcd. for $C_{21}H_{36}O_4$: 352.2613; found: 352.2623.

Preparation of the dimesylate 35

A solution of the diol **34** (50 mg, 0.14 mmol) and methanesulfonyl chloride (54 μL, 0.70 mmol) in 10 mL of dry pyridine was stirred at room temperature overnight and was then poured into 10 g of crushed ice. The mixture was extracted with ether, and the combined ether extract was washed with water and dried (Na_2SO_4). Removal of the solvent, followed by column chromatography of the remaining oil on silica gel (elution with 9:1 methylene chloride – ether), provided 57.7 mg (80%) of the dimesylate **35** as a pale yellow oil which exhibited ir ($CHCl_3$): 1360, 1340, 1170 cm^{-1}; ^{1}H nmr δ: 0.93, 0.94, 1.00 (s, s, s, 3H each), 3.01, 3.04 (s, s, 3H each), 3.5 (m, 4H), 4.3 (t, 2H, J = 8 Hz), 5.28 (m, 1H). *Exact Mass* calcd. for $C_{23}H_{40}O_8S_2$: 508.2165; found: 508.2160.

Preparation of the dimesylate 39

Compound **39** was prepared from the diol **38** via a procedure identical with that used for the conversion of **34** into **35**. From 50 mg of the diol **38** there was obtained 68.5 mg (95%) of the dimesylate **39** as a pale yellow oil which showed ir ($CHCl_3$): 1350, 1330, 1175 cm^{-1}; ^{1}H nmr δ: 0.93, 0.97, 1.01 (s, s, s, 3H each), 3.02, 3.03 (s, s, 3H each), 3.5 (m, 4H), 4.4 (t, 2H, J = 8 Hz), 5.3 (m, 1H). *Exact Mass* calcd. for $C_{23}H_{40}O_8S_2$: 508.2165; found: 508.2167.

Preparation of the dinitrile 37

A stirred solution of the dimesylate **35** (30 mg, 0.059 mmol) in 3 mL of dry hexamethylphosphoramide at room temperature was treated with sodium cyanide until the solution was saturated. The mixture, under an atmosphere of argon, was stirred at room temperature for 3 h and then at 60°C for 48 h. The cooled reaction mixture was diluted with ether, washed once with water, twice with saturated aqueous copper sulfate, once with brine, and dried (Na_2SO_4). Removal of the solvent, followed by column chromatography of the residue on silica gel (elution with 3:1 hexanes – ethyl acetate) gave a white solid that, upon recrystallization from methanol, provided 13.1 mg (60%) of the dinitrile **37**, mp 159–161°C; ir ($CHCl_3$): 2240, 2230 cm^{-1}; ^{1}H nmr δ: 0.91, 0.98, 1.01 (s, s, s, 3H each), 3.03 (m, 1H), 3.5 (m, 4H). *Exact Mass* calcd. for $C_{23}H_{34}N_2O_2$: 370.2620; found: 370.2619.

Preparation of the dinitrile 40

Transformation of the dimesylate **39** into the dinitrile **40** was carried out via a procedure identical with that described above (**35** → **37**). From 30 mg of **39** there was obtained 14.2 mg (65%) of **40**, mp 194°C; ir ($CHCl_3$): 2240, 2230 cm^{-1}; ^{1}H nmr δ: 0.95 (s, 6H), 0.97 (s, 3H), 2.95 (m, 1H), 3.5 (br s, 4H). *Exact Mass* calcd. for $C_{23}H_{34}N_2O_2$: 370.2620; found: 370.2618.

Preparation of a mixture of dinitriles 37 and 40 from the keto ester 26 (preparative scale)

To a cold (0°C), stirred suspension–solution of lithium aluminum hydride (360 mg, 9.5 mmol) in 50 mL of dry ether was added, dropwise, a solution of the keto ester **26** (2.40 g, 6.33 mmol) in 100 mL of dry ether. The mixture was allowed to warm to room temperature and stirred for 4 h. The mixture was recooled to 0°C and excess reducing agent was destroyed by careful addition of solid $Na_2SO_4 \cdot 10H_2O$. The resulting mixture was filtered through a plug of Florisil and the collected solid was washed thoroughly with ethyl acetate. Concentration of the combined filtrate gave 2.17 g of a mixture (white solid) of the epimeric diols **34** and **38**.

To a cold (0°C), stirred solution of the epimeric diols and dry triethylamine (2.55 mL, 18.3 mmol) in 30 mL of dry dichloromethane was added, dropwise, 1.03 mL (13.3 mmol) of methanesulfonyl chloride. The solution was stirred at 0°C for 1 h, was diluted with dichloromethane, washed consecutively with cold water and brine, and dried ($MgSO_4$). Removal of the solvent gave a yellow residue, which was dissolved in dichloromethane. The solution was filtered through a short column of silica gel and the column was washed with ethyl acetate. Removal of the solvent from the combined eluate afforded 3.15 g of the epimeric dimesylates **35** and **39**.

The mixture of **35** and **39** was dissolved in dry hexamethylphosphoramide (25 mL) and enough sodium cyanide was added to saturate the solution. The resulting mixture was stirred, under an atmosphere of argon, at 62°C for 16 h. The cooled reaction mixture was partitioned between ether and water and the aqueous phase was extracted twice with ether. The combined organic extract was washed twice with aqueous copper sulfate, once with brine, and dried ($MgSO_4$). Removal of the solvent gave 2.48 g of a yellowish semisolid, which was subjected to flash column chromatography (30) on silica gel. Elution with a mixture of 25% ethyl acetate in hexanes provided 142 mg (6%) of a mixture (~1:1, glc analysis) of the isomeric olefinic nitriles **43** and **44** as a colorless, viscous oil which exhibited ir ($CHCl_3$): 2230, 1100 cm^{-1}; ^1H nmr (80 MHz) δ: 0.92, 0.95, 1.00 (s, s, s, 9H total), 3.34–3.70 (m, 4H), 5.43–5.93 (m, 2H). *Exact Mass* calcd. for $C_{22}H_{33}NO_2$: 343.2511; found: 343.2513.

Further elution (35% ethyl acetate in hexanes) of the column gave 1.48 g (63%) of a mixture of the epimeric dinitriles **37** and **40** (ratio ~1:2, respectively, glc analysis) as a white solid that exhibited ir (KBr): 2220, 2210 cm^{-1}; ^1H nmr (80 MHz) δ: 0.91, 0.96, 0.98, 1.00 (s, s, s, s, 9H total), 2.98 (br m, 1H), 3.35–3.68 (m, 4H). *Exact Mass* calcd. for $C_{23}H_{34}N_2O_2$: 370.2620; found: 370.2620.

*Preparation of the enaminonitrile **41***

(a) *From the dinitrile 37*

A stirred solution of the dinitrile **37** (20 mg, 0.054 mmol) in 1 mL of dry *tert*-butyl alcohol containing a small amount of freshly prepared potassium *tert*-butoxide was refluxed, under an atmosphere of argon, for 24 h. The solvent was removed (vacuum pump) and the residue was partitioned between water and ether. The organic phase was dried (Na_2SO_4) and concentrated to give a colorless oil that crystallized upon addition of a few drops of methanol. Recrystallization from methanol gave 18 mg (90%) of the enaminonitrile **41** as white needles that exhibited mp 213–215°C; ir ($CHCl_3$): 3490, 3390, 2165, 1642, 1605 cm^{-1}; ^1H nmr δ: 0.90, 0.92, 1.01 (s, s, s, 3H each), 3.52 (m, 4H), 4.23 (br s, 2H). *Exact Mass* calcd. for $C_{23}H_{34}N_2O_2$: 370.2620; found: 370.2618.

(b) *From the dinitrile 40*

The enaminonitrile **41** was obtained from the dinitrile **40** via a procedure identical with that described above. From 20 mg of **40** there was obtained 16 mg (80%) of compound **41**.

*Preparation of the dione **42***

(a) *From the enaminonitrile 41*

To a deoxygenated mixture of glacial acetic acid (1 mL), water (100 μL), and 85% phosphoric acid (400 μL) was added 18 mg (0.049 mmol) of the enaminonitrile **41** and the resulting solution was refluxed, under an atmosphere of argon, for 24 h. The cooled reaction mixture was poured onto 2 g of crushed ice and sodium bicarbonate was added until the mixture was basic. The mixture was extracted with ether and the combined extract was washed with brine and dried (Na_2SO_4). Removal of the solvent gave an oil, which was purified by column chromatography (silica gel, elution with 1:1 hexanes – ethyl acetate). The material thus obtained was recrystallized from ether–hexanes, affording 10.1 mg (80%) of the tetracyclic dione **42** as colorless cubes, mp 132°C; ir ($CHCl_3$): 1705 cm^{-1}; ^1H nmr (400 MHz) δ: 1.15 (s, 3H), 1.73 (br m, 1H), 1.85 (br m, 1H), 1.90–2.05 (m, 4H), 2.09 (br m, 1H), 2.14–2.44 (m, 7H), 2.52 (d of d of t, 1H, J = 18, 9, 1 Hz), 2.70 (br t, 1H, J = 7 Hz). *Anal.* calcd. for $C_{17}H_{24}O_2$: C 78.42, H 9.29; found: C 78.29, H 9.28. *Exact Mass* calcd.: 260.1776; found: 260.1774.

(b) *From a mixture of epimeric dinitriles 37 and 40 (preparative scale)*

A stirred solution of a mixture of the dinitriles **37** and **40** (602 mg, 1.62 mmol, *vide supra*) in 10 mL of dry *tert*-butyl alcohol containing a small amount of freshly prepared potassium *tert*-butoxide was refluxed (argon atmosphere) for 5 h, after which time the solvent was removed under reduced pressure (vacuum pump). To the residual solid was added a deoxygenated mixture of acetic acid (10 mL), water (1 mL), and 85% phosphoric acid (4 mL) and the resulting solution was refluxed with stirring (argon atmosphere) for 40 h. The cooled reaction mixture was partitioned between water and dichloromethane and the aqueous phase was extracted twice with dichloromethane. The combined organic extract was washed with brine, twice with aqueous sodium bicarbonate, and then again with brine. The solution was dried ($MgSO_4$) and the volatile materials were removed under reduced pressure to afford 444 mg of a pale brown oil. Flash column chromatography (30) of this material (elution with ether), followed by recrystallization of the solid thus obtained, gave 351 mg (83%) of the dione **42**, mp 132°C.

*Preparation of the bis enones **48** and **49***

To a cold (−95°C), stirred solution of the dione **42** (251 mg, 0.964 mmol) and triethylamine (806 μL, 5.78 mmol) in 20 mL of dry dichloromethane, under an atmosphere of argon, was added, dropwise, 686 μL (4.82 mmol) of freshly prepared trimethylsilyl iodide (38). The orange solution was stirred for 1 h at −95°C, was diluted with petroleum ether, and was then allowed to warm to room temperature. The reaction mixture was washed with cold aqueous sodium bicarbonate, dried (Na_2SO_4), and concentrated under reduced pressure. Gas–liquid chromatographic analysis of the remaining yellow oil indicated the presence of the two isomeric bis trimethylsilyl enol ethers **46** and **47**, in a ratio of 4:1. This material was dissolved in 20 mL of dry acetonitrile, 472 mg (2.12 mmol) of palladium(II) acetate was added, and the solution was stirred under an atmosphere of argon at room temperature for 14 h. The reaction mixture was filtered through a short column of silica gel and the column was washed thoroughly with ether. Removal of the solvent from the combined eluate gave a viscous brown oil, which was subjected to flash column chromatography (30) (elution with ether). Recrystallization (ether) of the first-eluted component gave 165 mg (67%) of the bis enone **48**, which exhibited mp 155–157°C; ir (KBr): 1680, 1660 cm^{-1}; ^1H nmr (400 MHz) δ: 1.34 (s, 3H), 1.70 (d, 1H, J = 12 Hz), 1.75 (d of d of d, 1H, J = 14, 8, 2 Hz), 1.84 (d of d, 1H, J = 14, 8 Hz), 1.99 (m, 1H), 2.15 (m, 1H), 2.29 (d of d of d, 1H, J = 12, 6, 2.5 Hz), 2.30–2.49 (m, 3H), 2.94 (broad t, 1H, J ~ 7 Hz), 5.89 (d, 1H, J = 10.5 Hz), 6.00 (d of d, 1H, J = 10, 2 Hz), 6.72 (d, 1H, J = 10.5 Hz), 7.33 (d of d, 1H, J = 10, 2.5 Hz). Decoupling experiment: irradiation at δ 2.94 causes (a) collapse of the signal at δ 6.00 to a doublet (J = 10 Hz), (b) collapse of the δ 2.29 signal to a d of d (J = 12, 2.5 Hz), and (c) collapse of the δ 1.75 signal to a d of d (J = 14, 2 Hz). *Anal.* calcd. for $C_{17}H_{20}O_2$: C 79.65, H 7.86; found: C 79.49, H 7.88. *Exact Mass* calcd.: 256.1464; found: 256.1463.

Further elution of the column afforded 47 mg (19%) of the bis enone **49**, which after recrystallization from ether exhibited mp 147–149°C; ir (KBr): 1680, 1665, 1650, 1605 cm^{-1}; ^1H nmr (400 MHz) δ: 1.50 (m, 1H), 1.55 (s, 3H), 1.71–1.97 (diffuse m, 4H), 2.01 (d, 1H, J = 12 Hz), 2.04–2.15 (m, 2H), 2.27–2.61 (diffuse m, 4H), 2.91 (br t, 1H, J ~ 7 Hz), 5.86 (d, 1H, J = 1.5 Hz), 5.93 (d of d, 1H, J = 10, 2 Hz), 7.26 (d of d, 1H, J = 10, 3 Hz). *Exact Mass* calcd. for $C_{17}H_{20}O_2$: 256.1463; found: 259.1459.

*Alkylation of compound **48**. Preparation of the bis enones **50** and **51***

To a cold (0°C), stirred solution of lithium bis(trimethylsilyl)amide (3.77 mmol) in 30 mL of dry dimethoxyethane, under an atmosphere of argon, was added, dropwise, a solution of the bis enone **48** (186 mg, 0.73 mmol) in 5 mL of dry dimethoxyethane. After the solution had been stirred at 0°C for 1 h, methyl iodide (15 mL) was added rapidly. The mixture was stirred at 0°C for 30 min and at room temperature for 1 h. A few drops of saturated aqueous ammonium chloride were added, the volatile materials were removed under reduced pressure, and the residual oil was partitioned between ether and aqueous ammonium chloride. The organic phase was washed with aqueous sodium thiosulfate and brine, dried (Na_2SO_4), and concentrated to afford 206 mg of a white solid. Flash column chromatography (30) (elution with 35% hexanes in ether) of a small amount of this material gave a pure sample of the bis enone **50**, which, after recrystallization from ethyl acetate – hexanes, exhibited mp 149–150.5°C; ir ($CHCl_3$): 1675, 1660 cm^{-1}; ^1H nmr (400 MHz) δ: 1.17 (d, 3H, J = 7 Hz), 1.25–1.48 (m, 2H), 1.37 (s, 3H), 1.68 (d, 1H, J = 12 Hz), 1.71 (m, 1H), 1.73 (d of d of d, 1H, J = 14, 8, 2 Hz), 1.84 (d of d, 1H, J = 14, 7 Hz), 1.91–2.07 (m, 2H), 2.15 (m, 1H), 2.27 (d of d of d, 1H, J =12, 6, 3 Hz), 2.38 (d of q, 1H, J = 13, 7 Hz), 2.91 (br t, 1H, J = 7 Hz), 5.87 (d, 1H, J = 10.5 Hz), 5.98 (d of d, 1H, J = 10.5, 2.5 Hz), 6.65 (d, 1H, J = 10.5 Hz), 7.32 (d of d, 1H, J = 10.5, 3 Hz). Decoupling experiment: irradiation at δ 1.17 caused collapse of the signal at δ 2.38 to a doublet (J = 13 Hz). *Exact Mass* calcd. for $C_{18}H_{22}O_2$: 270.1620; found: 270.1621.

The crude monomethylation product **50** (206 mg, see above) was alkylated again under identical reaction conditions, except that, after addition of the methyl iodide, the reaction mixture was stirred at room temperature for 6 h. Recrystallization (ether–hexanes) of the white solid obtained from work-up gave 126 mg of the bis enone **51**. Flash column chromatography (30) (elution with 35% hexanes in ether) of the material from the mother liquor afforded a futher 34 mg of **51**, for a total yield of 160 mg (77%). The crystalline bis enone **51** exhibited mp 154–156°C; ir ($CHCl_3$): 1660 (br) cm^{-1}; ^{1}H nmr (400 MHz) δ: 1.16, 1.20, 1.44 (s, s, s, 3H each), 1.37 (m, 1H), 1.68 (d, 1H, J = 12 Hz), 1.74 (d of d of d, 1H, J = 14, 8, 2 Hz), 1.83 (d of d, 1H, J = 14, 7.5 Hz), 2.04–2.21 (m, 3H), 2.30 (d of d of d, 1H, J = 12, 6, 3 Hz), 2.92 (br t, 1H, J ~ 7 Hz), 5.89 (d, 1H, J = 10.5 Hz), 5.99 (d of d, 1H, J = 10.5, 2.5 Hz), 6.66 (d, 1H, J = 10.5 Hz), 7.35 (d of d, 1H, J = 10.5, 3 Hz). Decoupling experiment: irradiation at δ 7.35 collapses the signal at δ 5.99 to a doublet (J = 2.5 Hz) and simplifies the signal at δ 2.30 to a d of d (J = 12, 6 Hz). *Anal.* calcd. for $C_{19}H_{24}O_2$: C 80.24, H 8.51; found: C 80.08, H 8.40. *Exact Mass* calcd.: 284.1776; found: 284.1778.

Preparation of (±)-17-nor-stemodane-3,13-dione (52)

A mixture of the bis enone **51** (77.5 mg, 0.273 mmol), dry dioxane (3 mL), and a small amount of 5% palladium-on-carbon was stirred vigorously under an atmosphere of hydrogen at room temperature and atmospheric pressure. After 2 h, tlc analysis indicated that no starting material remained. The mixture was diluted with ethyl acetate and filtered through a plug of Celite. Concentration of the filtrate afforded 77.6 mg (99%) of the dione **52** as a colorless solid. Recrystallization of a small amount of this material from ethyl acetate – hexanes provided a pure sample of **52**, which exhibited mp 151–152°C; ir ($CHCl_3$): 1700 cm^{-1}; ^{1}H nmr (400 MHz) δ: 1.10, 1.12, 1.18 (s, s, s, 3H each), 1.26 (m, 1H), 1.46–1.79 (diffuse m, 7H), 1.89–1.99 (m, 4H), 2.04 (m, 1H), 2.18–2.30 (m, 2H), 2.34 (d of d of d, 1H, J = 16, 5, 3 Hz), 2.50 (br d of d of d, 1H, J = 17, 9, 9 Hz), 2.58 (d of d of d, J = 16, 13, 6 Hz), 2.69 (br t, 1H, J ~ 7 Hz). *Anal.* calcd. for $C_{19}H_{28}O_2$: C 79.12, H 9.78; found: C 79.03, H 9.80. *Exact Mass* calcd.: 288.2089; found: 288.2086.

Preparation of a mixture of (±)-stemodan-13α-ol-3-one (53) and (±)-stemodan-13β-ol-3-one (54). Characterization of 53

To a stirred solution of the dione **52** (20.8 mg, 0.072 mmol) in 2 mL of dry ether, under an atmosphere of argon, was added 1 mL (~4 mmol) of neat methyltriisopropoxytitanium (40, 41) and the resulting solution was stirred at room temperature for 10 h. The solution was poured carefully into a well-stirred mixture of ether and 1 *N* hydrochloric acid and the aqueous phase was extracted twice more with ether. The combined organic extract was washed with aqueous sodium bicarbonate and brine, dried ($MgSO_4$), and concentrated. Flash column chromatography (30) (elution with 30% tetrahydrofuran in hexanes) of the residual material gave 18.0 mg (82%) of an 86:14 mixture (glc analysis) of the epimeric keto alcohols **53** and **54**. This oil exhibited ir ($CHCl_3$): 3580, 3400, 1690 cm^{-1}; ^{1}H nmr (80 MHz) δ: 1.09, 1.12, 1.13, 1.24 (s, s, s, s). *Exact Mass* calcd. for $C_{20}H_{32}O_2$: 304.2403; found 304.2405.

In another experiment, carried out as described above, concentration of the later fractions obtained from chromatography of the crude reaction product afforded a viscous oil containing mainly (94%) the alcohol **53**. Crystallization of this oil from hexanes provided a pure sample of (±)-stemodan-13α-ol-3-one (**53**), mp 93°C (lit. (15) mp 90–91°C); ir ($CHCl_3$): 3570, 3320, 1690, 905 cm^{-1}; ^{1}H nmr (400 MHz) δ: 1.09, 1.10, 1.12, 1.14 (s, s, s, s, 3H each), 1.91–2.03 (m, 3H), 2.29 (d of d of d, 1H, J = 16, 4.5, 3.5 Hz), 2.57 (d of d of d, 1H, J = 16, 14, 6 Hz). *Exact Mass* calcd. for $C_{20}H_{32}O_2$: 304.2402; found: 304.2404.

Preparation of (±)-maritimol (4)

A solution of the keto alcohol **53** (11.7 mg, 0.038 mmol) in 2 mL of methanol containing excess sodium borohydride was stirred at 0°C for 2 h, and the solvent was removed under reduced pressure. The residue was partitioned between ethyl acetate and brine. The organic phase was dried ($MgSO_4$) and concentrated. Crystallization of the residual oil from ethyl acetate gave 5.6 mg of (±)-maritimol (**4**). Chromatography of the material from the mother liquor on silica gel (elution with 1:1 ethyl acetate – hexanes) afforded an additional 3 mg of crystalline (±)-maritimol (**4**), for a total yield of 8.6 mg (73%). Recrystallization from ether–hexanes gave a pure sample of (±)-**4**, which exhibited mp 221–222°C (lit. (14) mp 212.5–214°C and (15) mp 211.5–212.5°C); ir (KBr): 3340 (br) cm^{-1}; ^{1}H nmr (400 MHz, $CDCl_3$–$(CD_3)_2SO$) δ: 0.84, 0.95, 1.02, 1.11 (s, s, s, s, 3H each), 1.75 (s, 1H, exchanges with D_2O), 1.83 (d, 1H, J = 12 Hz), 1.88–1.98 (m, 2H), 2.04 (d, 1H, J = 6 Hz, exchanges with D_2O), 3.18 (d of d of d, 1H, J = 13, 6, 5 Hz; on addition of D_2O, d of d, J = 13, 5 Hz). This material was identical with a sample of (+)-maritimol (8) by glc (coinjection), tlc (four solvent systems), ^{1}H nmr (400 MHz), and mass spectrometry. *Anal.* calcd. for $C_{20}H_{34}O_2$: C 78.38, H 11.18; found: C 78.26, H 11.28. *Exact Mass* calcd.: 306.2559; found: 306.2560.

Preparation of (±)-stemod-2-en-13α-ol (56) and (±)-stemod-2-en-13β-ol (57)

A stirred solution of an 86:14 mixture of the keto alcohols **53** and **54** (*vide supra*) (61.1 mg, 0.201 mmol), and *p*-toluenesulfonylhydrazide (48.6 mg, 0.261 mmol) in 1 mL of absolute ethanol was refluxed under an argon atmosphere for 3 h. A white precipitate formed. The mixture was concentrated and the residue was dried under vacuum (oil pump) for 3 h to provide the crude *p*-toluenesulfonylhydrazones **55**. A stirred suspension of this material in 15 mL of dry toluene was treated with sodium hydride (5.34 mmol, 225 mg of a 57% dispersion in mineral oil, freed of oil by washing three times with ether) and the resulting mixture was refluxed under an atmosphere of argon for 3 h. The reaction mixture was cooled to room temperature, excess base was destroyed by **cautious** addition of water, and the resulting mixture was partitioned between ether and aqueous ammonium chloride. The aqueous phase was extracted once more with ether and the combined extract was washed with brine, dried ($MgSO_4$), and concentrated. The remaining oil was subjected to column chromatography (15 g silica gel, elution with 15% ethyl acetate in hexanes) to afford 33.5 mg (58%) of (±)-stemod-2-en-13α-ol (**56**) as a white solid. Recrystallization of a small amount of this material from hexanes gave an analytical sample of **56**, which exhibited mp 129.5–131°C (lit (13) mp 119–122°C; (15) mp 128–129°C); ir ($CHCl_3$): 3600 cm^{-1}; ^{1}H nmr (400 MHz) δ: 0.92, 0.96, 0.97, 1.12 (s, s, s, s, 3H each), 2.08 (br d, 1H, J = 17 Hz), 5.32 (d of d, 1H, J = 10, 2.5 Hz), 5.50 (d of d of d, 1H, J = 10, 6.5, 2.5 Hz). *Anal.* calcd. for $C_{20}H_{32}O$: C 83.27, H 11.18; found: C 83.27, H 11.10. *Exact Mass* calcd. : 288.2453; found: 288.2455.

Further elution of the column afforded 7.0 mg (12%) of (±)-stemod-2-en-13β-ol (**57**) as a white solid that, after recrystallization from heptane, exhibited mp 153–154°C (lit. (13) mp 147–149°C); ir (KBr): 3300 cm^{-1}; ^{1}H nmr (80 MHz) δ: 0.90 (s, 3H), 0.95 (s, 6H), 1.23 (s, 3H), 5.18–5.62 (m, 2H). *Exact Mass* calcd. for $C_{20}H_{32}O$: 288.2453; found: 288.2456.

Preparation of (±)-stemodin (2)

A solution of the alkene **56** (33.3 mg, 0.116 mmol) and 9-borabicyclo[3.3.1]nonane (200 mg) in 3 mL of dry tetrahydrofuran, under an atmosphere of argon, was refluxed for 48 h. The cooled reaction mixture was treated consecutively with 3 mL of ethanol, 3 mL of 7 *M* aqueous sodium hydroxide, and 3 mL of 30% aqueous hydrogen peroxide, and was then heated at 50°C for 1 h. The cooled mixture was partitioned between ethyl acetate and aqueous sodium bicarbonate. The aqueous phase was extracted with ethyl acetate and the combined extract was washed with brine, dried ($MgSO_4$), and concentrated. Column chromatography (25 g silica gel, elution with 3:1 ethyl acetate – hexanes) of the residual oil afforded 31.3 mg (88%) of (±)-stemodin (**2**) as a white solid. Recrystallization (acetone–hexanes or ethyl acetate) of this material provided (±)-**2** as colorless plates, which exhibited mp 220.5–222°C (lit. (13) mp 218–220°C); ir (KBr): 3300 cm^{-1}; ^{1}H nmr (400 MHz, $CDCl_3$–$(CD_3)_2SO$) δ: 0.90, 0.94, 0.97, 1.08 (s, s, s, s, 3H each), 1.59–1.76 (m, 5H), 1.85–2.00 (m, 4H), 2.87, 3.41 (br s, br s, 1H each), 3.67 (m, 1H). On addition of

D_2O, the signals at δ 2.87 and 3.41 disappeared and the signal at δ 3.67 simplified. This material was identical with an authentic sample of (−)-stemodin (7) by glc (coinjection), tlc (four solvent systems), ^1H nmr (400 MHz), and mass spectrometry. *Exact Mass* calcd. for $C_{20}H_{34}O_2$: 306.2558; found: 306.2558.

The ion-pair mechanism and bimolecular displacement at saturated carbon. V.[1] Racemization and bromide – radio-bromide exchange for substituted 1-phenylbromoethanes in acetone

ALLAN R. STEIN[2] AND ELIZABETH A. MOFFATT

Department of Chemistry, Memorial University of Newfoundland, St. John's, Nfld., Canada A1B 3X7

Received March 29, 1985

ALLAN R. STEIN and ELIZABETH A. MOFFATT. Can. J. Chem. **63**, 3433 (1985).

Results of kinetic studies of the racemizations and *radio*-bromide exchanges with 1-arylbromoethanes in acetone with added LiBr are reported. The results are direct empirical evidence supporting the ion-pair mechanism for bimolecular nucleophilic displacement at saturated carbon. For the unsubstituted and less electron rich substrates, behaviour expected for a classical S_N2 mechanism is found, but for 1-(4-methylphenyl)bromoethane, the racemization rate is greater than twice the exchange rate, indicating internal return with racemization from a solvated ion pair. For 1-(3,4-dimethylphenyl)bromoethane, the carbocation is sufficiently stabilized that the reaction shows intermediate behaviour; the racemization rate is significantly less than twice the exchange rate, for example. Through the series from the electron withdrawer to electron donor substituted substrate, the activation parameter ΔH^{+} progressively decreases and ΔS^{+} becomes rapidly more negative.

ALLAN R. STEIN et ELIZABETH A. MOFFATT. Can. J. Chem. **63**, 3433 (1985).

On rapporte les résultats obtenus lors d'études cinétiques relatives aux racémisations et aux échanges de *radio*-bromures d'aryl-1 bromoéthanes dans de l'acétone à laquelle on a ajouté du LiBr. Les résultats obtenus correspondent à des données empiriques directes qui apportent un support au mécanisme par paire d'ions lors des réactions de substitutions nucléophiles bimoléculaires au niveau de carbones saturés. Dans les cas des substrats qui ne sont pas substitués ou qui sont moins riches en électrons, on observe le comportement attendu pour un mécanisme S_N2 classique; toutefois, avec le (méthyl-4 phényl)-1 bromoéthane, la vitesse de racémisation est au moins deux fois plus grande que la vitesse d'échange et ceci suggère la présence d'un retour interne avec racémisation dans une paire d'ions solvatés. Dans le cas du (diméthyl-3,4 phényl)-1 bromoéthane, le carbocation est suffisamment stabilisé pour que la réaction présente un comportement intermédiaire; par exemple, la vitesse de racémisation est au moins deux fois plus faible que la vitesse d'échange. Lorsque l'on passe des substrats portant des groupements électroaffinitaires à ceux portant des groupements électro-donneurs, il y a une diminution graduelle du ΔH^{+} alors que le ΔS^{+} devient rapidement plus négatif.

[Traduit par le journal]

Since Sneen and Larsen (1), in 1969, proposed an elaboration of the Winstein ion-pair scheme (2) as a "unified mechanism" for nucleophilic substitutions at saturated carbon, it has slowly been gaining respectability, so much so that the ion-pair mechanism now receives extensive discussion in undergraduate textbooks (3).

The ion-pair mechanism can perhaps best be approached by considering the process of ionization and dissociation of a substrate RX. This can be considered a stepwise process of ionization to a contact or intimate ion pair within a solvation sheath or cage followed by separation of the two ions, R^+ and X^-. The separation of the ions would occur with layer by layer of solvent inserting itself between the ions to give, progressively, the solvent-separated ion pair with one, the solvated ion pairs with two, with three, with four, and so on, layers of solvation between the ions until finally the free, independently solvated, dissociated ions are reached. In principle at least, every stage of this ionization – solvent separation – dissociation process is reversible. Introducing a nucleophile, Z^-, could, again in principle, lead to nucleophilic attack at any stage of the dissociative process as indicated in Scheme 1.

Nucleophilic attack concurrent with ionization would, of course, represent the classical Hughes–Ingold bimolecular nucleophilic substitution, the S_N2 mechanism (4), whereas attack after complete dissociation of the initially formed ion pair would represent their unimolecular reaction, the S_N1 mechanism (5).

There is much direct or empirical evidence for the involvement of ion pairs in reactions at or near the unimolecular extreme, that is for S_N1 reactions (2, 6), but while evidence is accumulating for ion-pair involvement in bimolecular displacements, it is generally indirect. Thus computer simulations of bimolecular processes may require an intermediate species, or an intermediate may be implied by various correlations (7, 8). Such intermediates *could* be ion pairs. Direct empirical evidence is, to say the least, rare. It was in hopes of finding such direct evidence that the study reported here was undertaken.

Scheme 2 contains minimal representations for the S_N2 or ion-pair bimolecular, A, and S_N1 unimolecular substitution, B. In the following discussion we will assume the substrate was optically active. If *X is identical to X, any chirality is lost by the central-intermediate or transition-state stage. If, however, *X ≠ X, be they different neutral species (e.g. H_2O vs. CH_3OH), anions (e.g. CN^- vs. Cl^-), or even isotopic (e.g. *radio*-bromide vs. bromide) as in our case, chiral differentiation remains throughout in A but not in B. Thus if return to starting material occurs with the *same* anion in an S_N2 process, i.e. Scheme 2A, chirality of the substrate is retained. There has been neither racemization nor exchange. Should substitution occur, both exchange of covalently bound X and ionic *X *and* inversion of the stereochemistry of the substrate take place. Ignoring any isotope effect on optical activity, that single substitution results in the loss of two units of optical rotation, one for the molecule of substrate inverted and, because its rotational contribution is now opposite, another to cancel that contribution. A single exchange with inversion gives two molecules as a inactive racemic mixture. In the classical S_N2 mechanism, the only route for racemization is

[1] While not sequentially numbered, refs. 22–24 and ref. 15 are considered parts I–IV of this series.

through nucleophilic substitution so that the racemization rate constant, k_{rac} should be precisely twice the exchange (or inversion) rate constant, k_{exch} (10).

If a bimolecular ion-pair mechanism is operating, i.e. a substitution towards the left-hand side of Scheme 1, there is another possibility. Should the ion pair become sufficiently separated for the carbocation to turn over with respect to the leaving group, internal return with inversion could occur. Such racemization without exchange would result in a racemization rate greater than twice the exchange or substitution rate. The probability that such internal return with racemization would occur should increase as the ion-pair species becomes longer lived, increasing the time available for solvent separation. Presumedly several layers of solvation would be required to "lubricate" the roll over of the carbocation.

Of course, should ion-pair separation–dissociation be favoured too much, return becomes unlikely and, in the extreme, the reaction follows the classical S_N1 mechanism indicated in Scheme 2B. Complete separation of the carbocation and the leaving group occurs before nucleophilic attack; all chiral information is lost and the leaving group enters the anion "pool". Attack by anion can occur from either side of the dissociated carbocation to give racemization with exchange; the rate constants for racemization and exchange would be equal.

The chiral 1-phenylbromoethanes, with bromide ion as the nucleophile, were selected for study. Since the leaving group and the nucleophile are the same, separation of substrate and product was unnecessary, all reactions are *pseudo*-first order, and the implied symmetry of the reaction coordinate minimizes problems associated with specific solvation effects, etc. Substitution was followed through bromide – *radio*-bromide (^{82}Br) exchange using the electrodeposition method of Beronius (9). Stereochemical inversion results in racemization of the substrate and was followed polarimetrically. There will be contributions to the observed rate of racemization from substitution and from internal return with inversion. Phenyl substituent effects on the racemization and exchange kinetics in acetone were studied initially and are reported here.

Results and discussion

The preparation of the optically active substrates is discussed in the following paper (11) and the methods employed in following the racemization and radio-bromide exchange rates have previously been presented (9, 10).

In Table 1, racemization and exchange rate constants for the various phenyl-substituted 1-phenylbromoethanes at a number of temperatures and lithium bromide concentrations in acetone are reported. The rate constants reported are usually the averages of two or three runs under the same conditions but occasionally only one (especially for the 4-nitro compound), or as many as ten, was done. In comparing the rate constants it must be kept in mind that while all but the racemization studies on 1-(4-bromophenyl)bromoethane was done by the principal investigator over a decade, racemizations were done in three different laboratories, the exchanges in two, using solvent of different origin, different equipment, different thermostat baths, and thermometers (calibrated only at 0°C). Additionally, traces of moisture greatly retard the reactions; those at the lower lithium bromide concentrations were especially sensitive. Thus exchange studies on the nitro compound with [LiBr] = 0.0005 M at 25°C gave rate constants of $10.24 \pm 0.20 \times 10^{-3}$ L mol^{-1} s^{-1} with solutions that had been stored in Parafilm-wrapped glass-stoppered volumetric flasks for 6 days and $14.67 \pm 0.16 \times 10^{-3}$ L mol^{-1} s^{-1} with freshly prepared solutions. Addition of a few microliters of water per 100 mL, a concentration of about 1×10^{-3} M water, produced similar or larger retardations. The obvious solution of using aqueous acetone was ruled out because even 0.5% water resulted in some hydrolysis of 1-phenylbromoethane, as evidenced by an accelerating rate of racemization—the bromide ion produced by hydrolysis increases the halide ion concentration and hence the reaction rate. While considerable care was taken to obtain internally consistent results, variations are greater than desirable.

Similar marked rate retardations by added water have been reported by other workers for bimolecular processes. Thus Bohme and Raksit (12*a*), in a recent study of the influence of

* A single run was done.

hydration in gas phase substitutions by, for example, the hydroxide ion in methyl halides, found a marked rate retardation as the nucleophile is mono-, di-, or trihydrated. Similar rate retardations are observed for traces of water in aprotic, relatively nonpolar solvents. Holmgren and Beronius (12*b*), for example, report the rates of bromide exchanges in acetone as the water concentration is increased. The rate halves with the addition of about 0.4% water.

By contrast, for unimolecular processes in aprotic solvents, the addition of water commonly accelerates substitutions. Farinacci and Hammett (13*a*) reported nearly 50 years ago that addition of small amounts of water to the ethanol used in ethanolysis of diphenylmethyl chloride increased the solvolysis rate but left the product almost exclusively the ethyl ether.

TABLE 2. Typical alkyl bromide concentrations (all RBr concentrations have units × 10^{-2} *M*)

Compound used	Racemization studies	Exchanges at given [LiBr] 0.01 *M*	0.002 *M*	0.0005 *M*
4-Nitro	7.0	6.7	1.4	1.4
4-Bromo	9.0	6.5	1.4	1.4
Unsubstituted	7.5	7.4	1.6	1.6
4-Methyl	18.0	6.6	1.5	1.4
3,4-Dimethyl	23.0	6.0	1.4	1.4

Other workers (refs. 13*b*, *c*, and, for related discussion, ref. 13*d*) have reported similar accelerations and observed (13*a*) that, for S_N1 reactions in binary (aqueous) solvents, rate constants vary with the log of the water concentration for low water concentrations; the slope gives the number of water molecules involved.

This difference in behaviour for uni- and bimolecular processes presumedly arises principally because, in the former, the effective H-bonding solvation of the leaving group facilitates its departure as an anion whereas, in the latter, similar solvation of the nucleophile markedly reduces its nucleophilicity.

k_{rac}/k_{exch} *ratios*

In the introduction we indicated that the racemization rate could exceed twice the exchange rate if there was significant return with inversion. The average calculated ratio of k_{rac}/k_{exch} for unsubstituted 1-phenylbromoethane, for all LiBr concentrations at each temperature, ranges from 1.93 to 1.95 and averages 1.940 ± 0.069 overall. Clearly there is no evidence for ion-pair return with racemization here, nor is there for the compounds with bromo- or nitro-substituents, as perusal of the data reported in Table 1 will confirm.

As predicted, increasing the stability of the carbocation and hence of the ion pair by introducing a *para*-methyl substituent results in k_{rac}/k_{exch} ratios greater than 2. Averaged over the concentration range of LiBr, the ratio is 2.58 ± 0.07, 2.33 ± 0.23, 2.38 ± 0.14, and 2.23 ± 0.39 at 25, 30, 35, and 40°C respectively. The overall average for all values is 2.36 ± 0.24, a ratio that would be more convincing if the variation was less. However, that ratio means that racemization via an internal return pathway is over one-third as fast as substitution.

If one methyl is good, two should be better, so that (3,4-dimethylphenyl)bromoethane substrate was studied. With this compound great difficulty was experienced in, first, making half esters of the corresponding ethanol without dehydration and hence accomplishing the resolution of the alcohol until the current procedure (11) was developed, and, finally, in converting the alcohols to bromide without extensive racemization (11). In both the racemization and the exchange studies, reproducibility was a real problem. Elimination of HBr seems to be largely responsible for this lack of reproducibility. Even on storage in an evacuated sealed ampoule for a few days at −5 to −10°C, neat, optically active substrate begins to racemize at increasing rates. The liquid eventually becomes cloudy and, after months at room temperature, partially polymerized styrene separates out. The racemic material used for the exchange studies behaves similarly; it also had to be freshly made and (or) redistilled every few days.

In both sets of measurements, the concentration of the alkyl bromide was much higher than that of the lithium bromide. Exchange rates were determined by starting with ionic bromide containing ^{82}Br ions; the decreasing radioactivity of samples of

*Calculated from data given by Beronius *et al.* in ref. 14.

the ionic bromide electrodeposited on silver discs at appropriate times was then used to follow ionic–covalent bromide exchange. In effect, isotopic dilution of ^{82}Br was occurring; the infinity value V_∞ corresponds to statistical distribution of ^{82}Br between RBr and ionic material, that is, $V_\infty = V_0$ ([LiBr]/[RBr] + [LiBr]). To get a reasonable variation in values through the reaction and minimize the effect of random errors, the concentration of the alkyl bromide had to be much larger than that of the lithium bromide. Concentration ratios of about 8:1 at the highest and 25:1 at the lowest LiBr concentration were used. For the racemizations, it was the measured initial rotation that dictated concentrations. For minimally acceptable signal-to-noise ratio, the initial rotation had to be 0.25° or more. Typical concentrations are given in Table 2. Because of the relatively low optical activities of the 3,4-dimethyl substrate, the concentrations had to be especially high in the racemization studies; here, the molar ratio of RBr to LiBr ranged from 23 to 460.

*Only two data points, hence no error limits can be calculated.
†Rate constant becomes 21.340 ± 0.089 × 10^{-3} L mol^{-1} s^{-1} if the two data points (at 0.102 and 0.200 M LiBr) of Hughes *et al.* (25) are included in the calculations.
‡Relatively few concentrations of LiBr were used so that error limits are usually large.

Since elimination would liberate HBr, the bromide ion so produced would increase the bromide concentration and activity in the reaction mixture. At 0.002 M LiBr, 0.1% elimination could increase the bromide ion concentration by over 10% for the racemizations versus 0.7% for the exchanges. This additional bromide ion would accelerate the racemization and exchanges. The errors introduced from this source would be greatest at the lower concentrations of lithium bromide, so those rates and hence rate ratios are least secure.

For the 3,4-dimethyl compound, all values of the k_{rac}/k_{exch} ratios are less than the theoretical value of 2.00 for the S_N2 mechanism; at 30°C, they are 1.84, 1.98, 1.72, and 1.10 at 0.01, 0.005, 0.002, and 0.0005 M lithium bromide respectively and, for all the data points available, average 1.52 ± 0.39. Yet, because of the concentrations employed, any HBr in the added RBr should increase, not decrease that ratio. Consequently there has been a significant mechanistic change in going from the 4-methyl- to the 3,4-dimethyl compounds.

Effect of LiBr concentration

In Fig. 1, rate ratios, the reaction rate at the appropriate concentration, that is $k \times$ [LiBr], divided by the rate at [LiBr] = 0.0005 M, are plotted as a function of LiBr concentration at 30°C. All the compounds but (1-(3,4-dimethylphenyl)bromoethane fall on, or very near, the curve for the unsubstituted compound. For the 3,4-dimethyl compound, the racemization rate increases much more rapidly, the exchange less rapidly than for the other substrates, as the concentration of LiBr is increased.

In our discussion above, we indicated that any elimination of HBr and the concomitant increase in rate should have been most significant for the lowest lithium bromide concentrations. For the racemization studies with the 3,4-dimethyl compound, however, the deviations are just the opposite—either the rates for high LiBr concentrations are "excessive" or that at the lowest is far too low. Exchanges deviate in the opposite sense. For both reactions, like the reactions of the other compounds, the rates are clearly dependent upon the concentration of the inorganic bromide. They are not unimolecular processes.

Beronius *et al.* have determined the dissociation constants for lithium bromide in acetone (14). Using their equilibrium data and applying similar data analysis, our observed racemization rates can be corrected for the activity of the bromide ion. The results obtained are summarized in Tables 3 and 4. Several features stand out. Firstly, the reaction order in nucleophile reported in Table 4, i.e. the slope of a plot of the log of the observed rate $k_{rac} \times$ [LiBr] vs. the log of the calculated bromide ion activity from Table 3, should be unity. It is per-

§ Reaction was followed for only 190 h or to 5% completion.

haps significantly above one for the *p*-methyl substrate and averages 1.2 for the 3,4-dimethyl substrate. Thus, as we noted earlier, for the latter compound, the rate of racemization increases more rapidly with lithium bromide concentration than it should for a S_N2 process.

Another feature of the results in Table 4 is worth comment. Despite the fact that reaction rates for the 3,4-dimethyl compound are somewhat unexpectedly lower than the 4-methyl rates, the progressive decrease in $\Delta H^{\ddagger}$ continues as the carbocation stability increases. The markedly more negative $\Delta S^{\ddagger}$ accounts for the rate falloff. This variation in the activation parameters, using values not corrected for association of LiBr and preliminary results for the 3,4-dimethyl substrate, has already been discussed (15).

Elimination rates

We have already considered the effect of elimination of HBr from a small portion of the substrate prior to its addition to the acetone – lithium bromide mixture. The possibility of elimination being a competing reaction has not yet been considered. What would be the expected effect of a parallel elimination process?

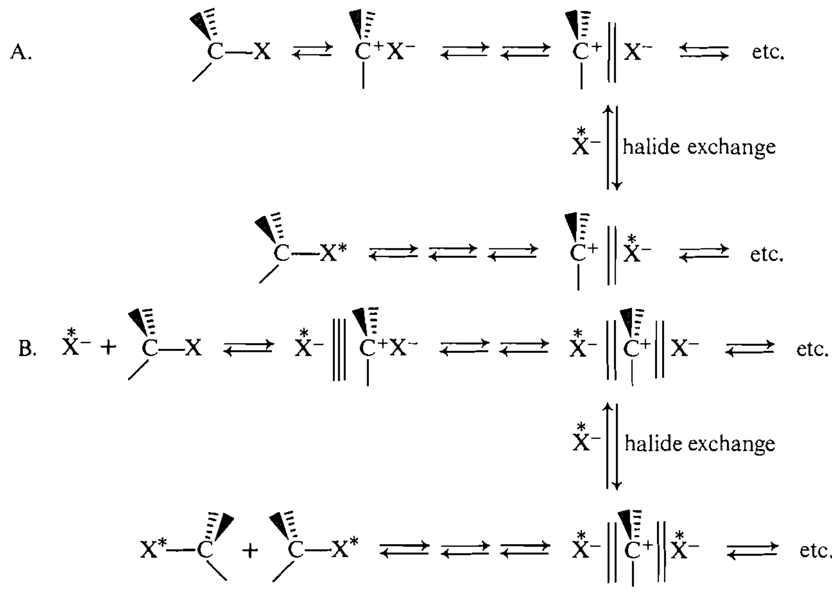
For a bimolecular nucleophilic substitution process, the racemization rate should be twice that of exchange. Elimination of HBr would, of course, give achiral alkene with loss of one, not two, units of optical activity. The liberated bromide ion would result in isotopic dilution of the *radio*-labelled lithium bromide solution and, hence, be indistinguishable from an exchange. For elimination, apparent "racemization" and "exchange" rates would be equal.

A reaction mixture in which both substitution and elimination were occurring would, at first glace, seem to explain a lot of our observations for the 3,4-dimethyl compound. The k_{rac}/k_{exch} ratio would be expected to fall between the value of 2 for the S_N2 and 1 for the elimination pathway. Solvation effects, principally about the proton and bromide eliminated, could account for the large negative entropy of activation. Explaining the higher than unity reaction order in bromide is a problem unless the elimination process is very sensitive to ionic strength.

There are other problems, however, with this facile explanation. We have not considered the effect of the liberated halide ion on the rates of racemization and exchange—it should increase the rates of both. There should be an autocatalytic effect as the reaction proceeds and the halide ion concentration increases. None was observed. Nonetheless, the rate of elimination was examined.

Over three or four half-lives for the racemization reactions, it was not possible to detect any consistent decrease in the area of the alkyl bromide peak by glc for the unsubstituted, or for the methyl-, bromo-, or nitro-substituted species (10). When lutidine was added to the acetone solutions, determination of elimination rates became possible. Some are presented in Table 5. The rate of elimination is apparently independent of bromide ion concentration and, at 0.002 M LiBr for the 3,4-dimethyl compound, corresponds to about 5% of the racemization rate. It must be kept in mind that this is in the presence of added base. In butyl tosylate solvolysis, Dannenberg *et al.* (16), found that the amount of 2-butene increased with the concentration of trifluoroacetate ion in the CF_3CO_2Na/CF_3CO_2H buffer. Similarly, in the solvolysis of 1-(4-methylphenyl)-1-chloroethane in 50:50 TFE/H_2O, Richard and Jencks (17) report that the fraction of the product represented by 4-methylstyrene increases linearly with added sodium acetate, even for such weakly basic acetates as chloro- and trifluoroacetates. Thus even extremely weak base is enough to divert the reactions towards elimination. With lutidine added in excess, as it was for the results reported in Table 5, elimination could also have been accelerated. Consequently the elimination rates reported should be considered upper limits. Without lutidine, the eliminations were much slower and the bromide ion concentration tended to reach a plateau value a bit above the initial concentration, a value which varied considerably even in duplicate runs. Thus under the racemization and exchange conditions, elimination is apparently considerably slower and is apparently a reversible process. Addition of a large excess of an alkene, cyclohexene, had only a small retarding effect, so HBr was not intercepted to any extent under racemization conditions.

These results do not rule out the possibility of racemization via elimination followed by re-addition, all within a solvent cage or solvation sheath. Here though, unlike, say, the racemization of norbornyl brosylate (2) where only a small translation, the oxygen equilibration of esters (18) where only a small rotation, or the *cis–trans* isomerism through linear vinylic carbocations (19) where a facile rotation or migration is required, the HBr must migrate to the other side of the planar styrene. Here, unlike the situation for ion pairs, there would be no electrostatic attraction between the species involved and, especially in the presence of the added lutidine, it is unlikely the solvent cage lifetime would be sufficiently long for such a migration to occur to a significant extent. Consequently it can



SCHEME 3

be concluded that elimination is a competing but much slower process that can not explain the observed racemization and exchange rate behavior.

A mechanistic explanation

As substituents on 1-phenylbromoethane are changed through the series p-NO_2, p-Br, none, p-CH_3 and 3,4-$(CH_3)_2$, the average value of the k_{rac}/k_{exch} ratio changes from essentially 2.00 for the first three to 2.36 and 1.52 for the last two compounds, respectively. The p-CH_3 rate ratio of greater than 2.00, the value predicted for the classical S_N2 mechanism, is easily accommodated by, and in fact is confirmatory of, the simple ion-pair mechanism depicted in Scheme 1. The ion-pair lifetime has become sufficient for carbocation inversion to occur before collapse, that is, for internal return with racemization to occur. Interestingly, Richard and Jencks, in their extensive study of the solvolyses of various 1-phenylethyl substrates, found that it was also the p-CH_3 substituted one which clearly showed internal return from an ion pair (17).

When the carbocation and hence the ion pair is further stabilized as with the 3,4-$(CH_3)_2$ substrate, the simple ion-pair scheme is not adequate in explaining the observations. The progressive change in activation parameters does not suggest a major mechanistic discontinuity (15); the enthalpy and entropy of activation decrease progressively, with the latter becoming markedly more negative, through the series of substrates as the expected carbocation/ion pair becomes more stable. Yet for the dimethyl compound, the k_{rac}/k_{exch} ratio is appropriate for a reaction of mixed mechanism, one about 50:50 classical S_N1/S_N2. The racemization, however, does not shift from first towards zeroth order in bromide ion; rather, the order increases to slightly over one. Clearly the S_N1-S_N2 mechanistic pair also are inadequate in explaining the results.

A logical modification to the ion-pair mechanism readily accommodates the observations. In a simplistic form, it is shown in Scheme 3A. Including exchange of leaving group with the anion pool allows for some retention of configuration with bromide exchange. Perhaps a more realistic version, with leaving group – anion pool exchange occurring through a solvated triple ion, is shown as Scheme 3B. Without getting involved in any controversy about the timing of nucleophilic involvement, that is, does it commence prior to (17, 20), concurrent with (21), or subsequent to (1*b*, 7, 8*a*) breaking of the substrate – leaving group bond to form the ion pair, the triple ion is quite analogous to the proposals of Jencks (17, 20) and of Bentley and Schleyer (21) and their respective co-workers. The nucleophilic involvement of solvent in the latter and of a good nucleophile in the former is replaced by that of a nucleophile identical to the leaving group to give a symmetrical species.

As pointed out by Bentley *et al.* (21), there is a marked tendency to treat the extended ion-pair scheme of Winstein (2), or as applied by Sneen (1), literally, that is, to ignore the fact that the reaction is occurring in a solvent, often with other added species present. Thus there are substrate–solvent (dipole–dipole) and ion pair – solvent (ion–dipole) interactions as well as substrate and ion-pair interactions with other species in solution, all of which are rarely shown or explicitly considered in mechanistic presentations. The "special salt effects" first noted by Winstein (2) confirm direct ion (or salt) involvement in ion-pair mechanisms. Added "inert" electrolyte at low concentration in relatively non-ionizing media can greatly promote dissociation of ion pairs. That this is through some sort of one-on-one interaction between the electrolyte and substrate is confirmed by the fact that, at higher salt concentrations where there is a generous supply of added ions, the rate acceleration becomes simply that of a normal salt effect. In more polar solvents, solvent dipole orientation can swamp the ion electric field in promoting dissociation. In our case, backside "nucleophilic assistance" (21) in ionization and (or) dissociation of the substrate would be by the $\delta(-)$ carbonyl oxygen of acetone and by Br^-. Li^+ might also play a role, for example, in facilitating the front-side leaving group – anion pool bromide exchange.

In any event, incorporation a leaving group exchange branch in the ion-pair mechanism allows for substitution—bromide exchange—with retention of configuration or, perhaps more accurately, collapse from triple ion to racemic substrate. Either would result in the k_{rac}/k_{exch} ratio falling below the S_N2 value of 2.00. The contribution to the racemization rate made by leaving group exchange at the triple ion—it should be second order in bromide ion—would also account for the changes in reaction order.

Conclusions

The results reported here strongly support the ion-pair mechanistic scheme for bimolecular displacement at saturated carbon. The effect of increasing the stability of the carbocation and hence the ease of ionization/separation is best explained through the ion-pair mechanism of Scheme 1, modified to include the ionization/separation assistance of other ions in solution as in Scheme 3B.

For the substrates lacking electron donating substituents, the ion pairs are not sufficiently stable and long lived to undergo the significant solvent separation required for inversion without exchange before collapse to starting material or rear-side attack by nucleophile. With moderate stabilization, as by the p-CH_3 group, the average point of nucleophilic attack is shifted sufficiently to the right, towards ion-pair separation, to permit internal return with racemization, and k_{rac}/k_{exch} becomes greater than the theoretical S_N2 value of 2.00. As the stability is further increased, as with our 3,4-dimethyl substrate, ion-pair lifetimes become still greater and exchange of anion involved in the ion pair with the anion pool can occur; exchange becomes more rapid. Relative exchange and racemization rates are intermediate between those predicted for the classical S_N2 and S_N1 mechanisms. This logical progression thus explains the observations reported in this paper.

The effects of solvent and isotopic substitution are currently under investigation.

Experimental

All solvents were reagent or Analar grade; the acetone was freshly distilled from Type 4A molecular sieves under dry tank nitrogen that was further dried by bubbling it through concentrated-H_2SO_4 followed by a column of Type 3A molecular sieves. The analytical grade (Merck or BDH) lithium bromide was oven dried at 225–250°C, the reagent grade (BDH) 2,6-dimethylpyridine (lutidine) was doubly vacuum distilled through a short column, and the silver nitrate was reagent grade.

Chiral substrates were prepared by the procedures described in the following paper (11), racemic ones by treating the corresponding racemic 1-phenylethanol instead of the resolved one with HBr in benzene or toluene. The racemic 1-phenylethanols, except the commercially available unsubstituted compound (Eastman), were made from the corresponding commercially available acetophenone by reduction with $NaBH_4$ in ice/aqueous methanol by procedures analogous to that reported for 1-(4-nitrophenyl)ethanol (11). The 1-phenylethanols were free of carbonyl absorptions in the ir, the bromides free of OH absorptions, and all gave clean nmr spectra in $DCCl_3$. Physical properties of the chiral materials have been reported (11); those of the racemic materials were almost identical.

For the kinetics reported in this paper, temperature control was better than 0.02°C for the longest runs, ±0.01°C in general. Standard linear regression analysis was done on the data; for the eliminations, the infinity value was determined iteratively. When a single run was done, the error range reported in Tables 1 and 5 is the standard deviation or σ of the linear regression. When duplicate or multi-runs were done, the standard deviation on the average value is reported. Generally the regression correlation coefficient was 0.99–0.99999, with polarimetry being near the upper end and exchanges and eliminations, which were aliquot methods with relatively few points, being nearer the lower end of the range. For all but the slowest reactions, two to three or more half-lives were used.

Kinetics of racemization were followed using a Perkin–Elmer model 141MC polarimeter as previously described (10). All solutions were prepared, stored, and transferred in a dry nitrogen-filled glove bag or box. the solution was prepared, and the jacketted cell was filled and quickly removed from the bag, connected to the constant temperature bath, and placed in the polarimeter. Rotations and times were measured from the graph of the potentiometric recorder with the first value taken some 5–8 min after the solution was initially prepared. Results are reported in Tables 1, 4, and 5.

Kinetics of exchange were followed as previously outlined (10). For 1-(3,4-dimethylphenyl)bromoethane the $Li^{82}Br$ was prepared by neutron bombardment of inactive salt in the reactors of Atomic Energy of Canada, Chalk River, Ontario; for the rest, the source was Aktiebolaget Atomenergi, Isotopservice, Nykoping, Sweden.

Kinetics of elimination were followed in anhydrous acetone with added lutidine as follows. Stock solutions of acetone 0.02000 ± 0.0005 M in LiBr were prepared and sealed in hypo-vials in a dry nitrogen-filled glove bag. This solution was diluted with freshly distilled acetone as required; 25 mL with 1 mL lutidine diluted to 250 mL gave a solution 2.00×10^{-3} M in LiBr and 34.3×10^{-3} M in lutidine. After 50 mL of this solution in a glass-stoppered volumetric flask had equilibrated to the desired temperature in the thermostatted bath, a weighed amount of the alkyl bromide, e.g. 0.1284 g of the p-methyl substrate, to give a 12.90×10^{-3} M solution, was added with a syringe, the reaction timer started, and the flask quickly removed, shaken, and returned to the bath. An aliquot, usually 3 mL, was removed with a pipet, the elapsed time noted, and the solution run into the upper of two chilled 50-mL separatory funnels which contained 15 mL of ice-cold, distilled water and 10 mL of cold ether. The funnel was immediately shaken for 10 s, allowed to settle for 30 s, and the aqueous layer drained into the second funnel, which contained 10 mL of ether. Shaking and settling were repeated, the aqueous layer drained into a small flask and 5, 10, or 15 mL pipetted into the cell of a Radiometer TTTld/SBR2C automatic titrator. The potentiometric titration of aqueous bromide ion was done with 5.00×10^{-3} M $AgNO_3$ using silver and calomel electrodes. The first aliquot could be removed at 60-s, subsequent ones at as little as 5-min intervals but, as most reactions were very slow, the 10–15 points were normally taken at much longer intervals and 2–5 runs were done simultaneously. Blanks were run without added RBr and, for slower runs, the first kinetic point agreed to within a few percent of the blank value and the least-squares calculated $t = 0$ value. For example, with the unsubstituted compound in 2.00×10^{-3} M LiBr at 45°C, reaction was only approximately 5% complete with the tenth and last point at 687 600 s—8 days—but gave $k = 6.54 \pm 0.01 \times 10^{-8}$ s^{-1} with R = 0.9997, blank zero 5.35; least-squares calculated $t = 0$, 5.313; value at 900 s, 5.40. Faster runs tended to behave better as a much larger fraction of reaction was available. Results are reported in Table 5.

Preparation of chiral 1-phenylethanols and bromides

ALLAN R. STEIN,[1] ROBERT D. DAWE, AND JAMES R. SWEET

Department of Chemistry, Memorial University of Newfoundland, St. John's Nfld., Canada A1B 3X7

Received March 29, 1985

ALLAN R. STEIN, ROBERT D. DAWE, and JAMES R. SWEET. Can. J. Chem. **63**, 3442 (1985).

A fast, convenient procedure for preparing and resolving moderate to large quantities of chiral secondary alcohols is described. The general procedure involves a one-pot conversion of the ketone (various acetophenones) to the half-ester of a diacid (succinic, phthalic...) and resolution with (+)- and (−)-1-phenylethylamines. Overall yields of the enantiomeric alcohols, the variously substituted 1-phenylethanols, are generally 65–85% with optical purities of approximately 90%. Properties and optical rotations of a number of chiral 1-phenylethanols and of the bromides made from them are tabulated. A discussion of optical purity determinations using nmr methods is included and absolute configurations are reported.

ALLAN R. STEIN, ROBERT D. DAWE et JAMES R. SWEET. Can. J. Chem. **63**, 3442 (1985).

On décrit une méthode simple et rapide de préparer et de résoudre en antipodes optiques des quantités importantes d'alcools secondaires chiraux. La méthode générale implique une conversion, dans un seul récipient, de la cétone (diverses acétophénones) en esters acides de diacides (acides succinique, phtalique...) puis une résolution par les phényl-1 éthylamines (+) et (−). Les rendements globaux en alcools énantiomériques, divers phényl-1 éthanols substitués, sont de l'ordre de 65 à 85% et les puretés optiques sont d'environ 90%. On rapporte les propriétés et les rotations optiques d'un certain nombre de phényl-1 éthanols chiraux ainsi que celles des bromures qui en résultent. On rapporte aussi une discussion relative à l'utilisation de la rmn pour la détermination des puretés optiques ainsi que les configurations absolues.

[Traduit par le journal]

For a continuing study of the ion-pair mechanism for nucleophilic displacement at saturated carbon (1), relatively large quantities of variously phenyl-substituted chiral 1-phenylbromoethanes were required. These were best made from the corresponding chiral 1-phenylethanols with hydrogen bromide in toluene or benzene. Since the optical resolutions evolved in this study are quite convenient and efficient, give a high optical purity, and can be extended to other substituents, halides, and carbon skeletons, they are reported in some detail.

Several of the chiral phenyl-substituted 1-phenylethanols have previously been resolved; the resolution of the parent compound, 1-phenylethanol itself, is a well-established process which nonetheless presents some difficulties. The classical Downer and Kenyon procedure (2) calls for the resolution of the mono- or half-ester of phthalic acid, i.e. (±)-1-phenylethyl hydrogen phthalate, in acetone with brucine, not the safest or most pleasant material to use in large quantities. Unless there are seed crystals available, obtaining the (−)-enantiomer of the half-ester instead of the racemic hydrogen phthalate salt of brucine can be quite a challenge! Even then, obtaining high optical purity requires removal of the racemic half-ester from the recovered chirally enriched hydrogen phthalate obtained by removal of the brucine from the precipitated salt through repeated large-volume acid extractions. This removal of the less soluble racemic half-ester is best accomplished by careful and repeated fractional crystallizations from carbon disulfide. The other enantiomer must be recovered from the somewhat enriched original mother liquor, again after removal of the unprecipitated brucine and by repeated crystallization and removal of the racemic ester from carbon disulfide. Obtaining moderate yields of resolved material requires repeated recycling of the recovered racemate.

At least the 1-(4′-nitrophenyl)ethanol analog has been made by electrophilic substitution on chiral unsubstituted 1-phenylethanol but yields of the 4-isomer were less than 25% (3). In addition, the optical purity was low and the desired product was accompanied by a higher yield of the 2-isomer. Selected chiral phenylethanols, generally the unsubstituted and occasionally the 4′-methyl analogue, have been made by asymmetric reduction of the corresponding acetophenones (4, 5) using metal hydrides complexed with naturally occurring chiral alcohols, for example, $LiAlH_3(OR^*)$, $LiAlH_2(OR^*)_2$, or $LiAlH(OR^*)_3$ where HOR* is *N*-methylephedrine, $C_6H_5CHOHCH(N(CH_3)_2)$-CH_3, or other chiral alcohol (4*b*). Needless to say, the required reagents are expensive to use for a large-scale preparation and usually only one of the enantiomeric alcohols is obtainable. Optical purities were generally 35–85%.

An enzymatic method that allows isolation of both enantiomeric alcohols in good yields and high activity has recently been published (5). It involves use of a carbonyl esterase as a stereoselective transesterification catalyst on the racemic alcohol and an excess of an ester. One enantiomer of the alcohol is recovered unreacted, the other after hydrolysis of the newly formed chiral ester. Should the method prove general, it alone may prove competitive with that published below for making relatively large quantities of both enantiomers of chiral alcohols with high optical purities.

Classically, optical purities were relative, that is, the optical rotation of a newly prepared sample was compared to the literature value, supposedly the highest optical activity yet achieved for the compound. More recently, the different chemical shifts exhibited by "diastereomeric species" in nuclear magnetic resonance spectroscopy have been utilized (6, 7). Most commonly the chiral substrate is an alcohol or an amine and the "diastereomeric species" is generated by use of a chiral H-bonding solvent (6*a*) or a chiral lanthanide paramagnetic nmr shift reagent, usually a europium(II) or phaseodymium(III) complex (6*b*), or by derivatizing with a chiral acid (6*c*).

Results and discussion

Since (+)- and (−)-phenylethylamines are commercially available, it seemed worthwhile to evolve procedures using these amines and the appropriate half-esters of the corresponding alcohols. The procedures finally arrived at for the various species are summarized below. Selected ones are presented in more detail in the experimental section.

[a] Unless otherwise noted, phthalic acid half-esters were resolved in ether and base catalysis was used for their hydrolyses.
[b] 1-Phenylethanol prepared and resolved.
[c] Yields are based upon starting acetophenone except where otherwise noted. The total yield is the sum of the yields for the two diastereomeric salts.
[d] Salt of half-ester and (+)- or (−)-1-phenylethylamine.
[e] Boiling point in °C(uncorrected)/pressure in Torr, sign of rotation and yield respectively of the alcohol obtained from the diastereomeric salt of the indicated 1-phenylethylamine.
[f] The corresponding racemic 1-phenylethanol was used to make the half-ester. Yields are based upon this alcohol.
[g] 80–100°C petroleum ether.
[h] Yields based upon $LiAlD_4$.
[i] The viscous biphthalate half-ester crystallized after prolonged pumping and chilling. These crystals were repeatedly washed with pe[g].
[j] The resolving solvent was acetone.
[k] The resolving solvent was ethyl acetate.
[l] Succinic half-ester was used and the hydrolysis was acid catalyzed.

In general, the commercially available substituted acetophenones were reduced in anhydrous tetrahydrofuran (THF) with $LiAlH_4$ and $LiAlD_4$. A slight excess of purified anhydride, usually phthalic or succinic anhydride, was then added to the solution. (Commerical anhydrides contain small to moderate amounts of the diacids, which destroy the desired alcohol salt and markedly reduce yields of the half-ester.) Standard work-up and one or two recrystallizations generally gave yields of 85–98% (based upon starting acetophenone) in this one-pot reduction–esterification to half-ester.

Since the nitro group is also reduced by $LiAlH_4$, 4-nitroacetophenone was reduced to the corresponding ethanol with $NaBH_4$ in ice – aqueous methanol solution. The 4-nitrophenylethanol and phenylethanol itself, which is commercially available, were then converted to the half-ester by treating them with the appropriate acid anhydride and an excess of pyridine.

In the procedure for resolving the half-esters, a near-saturated solution of the half-ester in the solvent indicated in Table 1 was treated with about one-third of a molar equivalent of, for example, *d*-(+)-1-phenylethylamine. A precipitate formed, sometimes immediately, sometimes after some hours in a refrigerator—stubborn cases responded well to seed crystals once these were available. Filtering and washing gave varying amounts of diastereomeric salt. The mother liquor was extracted with acid to recover unprecipitated amine. Addition of slightly more than one-half of a molar-equivalent of the (−)-amine precipitated the other diastereomeric salt. Recycling gives near quantitative yields of the two salts.

Partition of the diastereomeric salt between ether and aqueous hydrochloric acid allowed isolation of the chiral half-ester from the ether layer. Subsequent hydrolysis, with acid or base catalysis, gave the chiral 1-phenylethanols. The combined yields of the enantiomeric phenylethanols were 60–85% based upon starting ketone. Well over 70% of the phenylethylamines could be recovered from the combined acidic aqueous solutions by basification with sodium hydroxide or carbonate followed by extractive work-up and distillation. If the intermediate acid extractions of unprecipitated amines were thoroughly done, the recovered 1-phenylethylamines had rotations unchanged from those of the original materials.

Conversion of the alcohols to the bromides was accomplished by bubbling hydrogen bromide into a benzene or toluene solution—the latter solvent tended to give severe foaming problems in the subsequent vacuum distillations—of the resolved alcohol, generally at −10 to 0°C. The 4-nitro alcohol reacted very slowly and required warming and prolonged contact. For the others, especially the 4-methyl- and the 3,4-dimethyl-substituted alcohols, contact times and temperatures had to be minimized and the vacuum distillation performed quickly and smoothly to prevent excessive racemization of the bromides. Hydrogen bromide in benzene or toluene proved more satisfactory than other recipes tried; both yields and optical activities were higher than for other procedures, including PBr_3 or PBr_5 in ether, triphenylphosphine and bromine, or *N*-bromosuccinimide in pyridine. Also the aromatic hydrocarbon solvents were much more satisfactory than solvents like hexane, chloroform, or carbon tetrachloride, presumedly because the solubility of the hydrogen bromide is higher in the aromatic hydrocarbon solvents.

Details of the synthesis and resolution of several of the alcohols are given in the experimental section. The acid anhydride, the solvents, and the hydrolysis procedures used for the specific alcohols are given in Table 1. The optical rotations of samples of the various 1-phenylethanols and of the bromides derived from them are reported in Table 2, the optical or enantiomeric purities of the alcohols in Table 3.

In all cases, the half-esters had rotations opposite to those of the 1-phenylethylamine used in their resolution; the resultant phenylethanols had the same sign of rotation as the amine used. Only for the 1-(4′-methyl- and 3′,4′-dimethylphenyl)ethanols are the signs of rotation of the ethanols and bromides made from them the same.

Optical purities

The results of determinations of optical purities of the resolved alcohols with the chiral shift reagent Eu-Opt[2] are summarized in Table 3. Cervinka *et al.* (8) and Okamoto *et al.* (9) previously used chiral nmr shift reagents to determine the optical purities of several of the same 1-phenylethanols. Based upon their measurements, the optical purity of our 1-phenylethanol was 93.6 or 92.5% respectively vs. our 99.7%. According to the former authors (8), our 4′-methyl derivative had an optical purity of 88.6%, almost identical to our determination. While the latter authors (9) also reported optical purities for 1-(4′-nitrophenyl)ethanol, it is not clear how they measured their optical activity so that we were unable to relate our activity to theirs.

With Eu-Opt[2] large shifts occurred; for example, with a molar ratio of 4:3 of 1-(3,4-dimethylphenyl)ethanol to shift reagent in $DCCl_3$ at 0°C on the 360-MHz machine, the aromatic proton multiplet was shifted from δ 7.16–7.08 to 7.65–7.27, the methine proton quartet from δ 4.82 to a pair of quartets centred at 5.965 and 5.935, the hydroxylic proton from δ 1.96 to 6.42, the aromatic methyl protons from δ 2.29 and 2.25 to 2.37 and 2.34, and the other methyl proton doublet at δ 1.48 to an ill-resolved "doublet" at 2.10. All signals are extensively broadened, the signal-to-noise ratio is degraded, and new signals due to the camphato residues of the shift reagent interfere with the region upfield of about δ 3. With decoupling from the α-methyl protons, the methine pair of quartets became two singlets at δ 5.965 for the (+)- and at δ 5.935 for the (−)-enantiomer. The overlap of the broadened peaks was such that, for the racemic mixture, the valley height was more than half the peak height, and for the (−)-alcohol, the (+)-enantiomer showed up as a very small blip on the upfield shoulder of the signal due to the major enantiomer. "Deconvolution" techniques had to be resorted to. Areas and hence enantiomeric purities have considerable uncertainty associated with them. Thus the determined ratio of (+)- to (−)-enantiomer for racemic mixtures ranged from as good as 48.4:51.6 to as bad as 43.1:56.7. Such uncertainties, with a standard deviation of 5.1 parts in 50 for the five racemic mixtures, reduce one's confidence in all of the results.

Despite a report in the literature that the purity of partially resolved 1-(4-nitrophenyl)ethanol was determinable (9), we were unable to separate any of the proton signals into contributions for the enantiomers even with substrate to shift reagent ratios as high as 1:2 at temperatures as low as −50°C on the high-field machine. The oxygens of the nitro group apparently compete very successfully with that of the hydroxyl for the Lewis acid shift reagent.

Commercial availability of resolved 2-methoxy-2-trifluoromethyl-2-phenylacetic acid, MTPA, facilitates determination of optical purities through use of the diastereomeric esters, the method of Dale and Mosher (6*c*). Their derivatization method has the advantage that several nuclei can be used; there are internal checks. Thus, with the 1-(4-methylphenyl)ethyl esters of (+)-MTPA, the methine proton (with decoupling from the methyl protons), the methoxy proton, the *para*-methyl and the aliphatic methyl protons (with decoupling from the methine proton), all could be used in proton, and the trifluoromethyl fluorines in fluorine, nmr.

[2]Eu-Opt is $Eu(C_{12}H_{14}F_3O_2)_3$, tris-[3-trifluoroacetyl-(+)-camphato]europium(III) available from the Alfa Division of Ventron Corporation.

[d] Coupled to methine proton, J = 6.6 Hz.
[e] Coupled to methoxy protons, J = 1.3 Hz.
[f] Calculated ratio from average of (+)-enantiomeric analysis values, 74.1% (+) and 25.9% (−).

The derivatization method with MTPA does have its disadvantages. It requires considerably more laboratory time but generally less effort on the spectrometer than the chiral shift reagent method. It depends upon quantitative conversion of, in our case, the alcohol to the ester. To minimize enantiomeric discrimination, minimal work-up and no separation of the diastereomeric esters is possible. Thus any impurities (grease, solvent and reagent residues, and the like) remain in the sample after preparation and extractive work-up. The aliphatic methyl proton signals, typically at δ 1.54–1.56 and 1.58–160, were especially prone to interference from trace impurities. Additionally, the MTPA used must be optically pure. It is prepared by resolving the acid with α-phenylethylamine (10) so that 100% optical purity is highly unlikely. Since enantiomers would have coincidental signals, the optical purities determined using MPTA are minimum values.

Since the chiral shift reagent method was found unsuitable for 4-nitrophenylethanol, the results using the diastereomeric esters prepared by derivatizing with (+)-MTPA are presented in Table 4. Overall, the results with MPTA show somewhat better internal agreement than do those with the shift reagent.

In Table 3, the determined optical purities or enantiomeric excesses of the particular samples of the alcohols of Table 2 are presented. Also included in Table 2 are the configurations of the alcohols. The configuration of (−)-phenylethanol has been related to (−)-lactic acid and consequently was assigned the (*S*) configuration (11). Dale and Mosher (6*c*) have established that MPTA esters can be used to assign configurations to alcohols. Using esters of (*R*)-(+)-MPTA, for (*S*)-phenylethanol the methyl group, as the medium sized group, is shielded by the phenyl of the acid residue. Thus these CH_3 protons appear at higher fields than those of the (*R*) configuration. Since substituents on the phenyl of the alcohol should enhance, not invert, the relative bulk of the aromatic vs. the methyl group, the same relative shifts would be predicted for our substituted phenylethanols. In all cases examined, the CH_3 protons for the ester of the (−)-alcohol wih *R*-(+)-MPTA were at higher fields and hence all are (*S*)-(−)-phenylethanols.

For the studies contemplated (1), the actual optical purity of the required bromides did not matter. Consequently no attempt was made to maximize the activities of the intermediate alcohols. Nor were the particular samples of the alcohols and their corresponding half-esters and bromides, for which physical properties, optical rotations, and optical purities are recorded, necessarily the ones with the highest purities; they simply reflect the particular samples of the alcohols used in the optical purity determinations. The use of more dilute solutions, a smaller mole fraction of chiral amine, and additional slurrying of the salt in the appropriate solvent increases the laboratory time but gives higher activities.

Finally, conversion of the alcohols to the bromides, especially for the methyl-substituted ones, leads to completely or nearly completely racemic products if care is not exercised. Consequently, considerable racemization almost certainly occurs in all cases. The optical purity of the bromide must not be equated to that of the alcohol used to prepare it; the alcohol purity merely establishes the maximum limit for bromide purity.

Experimental

Solvents

All solvents used were ACS or Reagent Grade. The THF was dried and purified by standing, with periodic shaking, over KOH pellets for several days before being refluxed for several hours over, and then distilled from $LiAlH_4$ under nitrogen, which itself had been further dried by bubbling through concentrated sulfuric acid followed by a column of Type 4A molecular sieves. The THF was distilled as required using oven-dried glassware.

Acetophenones

Commercial products were freshly vacuum distilled.

Acid anhydrides

Commercially available phthalic and succinic anhydrides from a variety of suppliers were found to contain 8–20% of the corresponding diacid. Purification is possible by repeated sublimations, but was more easily accomplished by recrystallization from chloroform. The diacid is almost totally insoluble whereas the anhydride is quite soluble. After drying briefly in a hood, the recrystallized anhydride was pumped for some hours at room temperature or with gentle heating. The anhydride was stored in an evacuated flask until required.

Melting and boiling points are uncorrected. Optical rotations were measured on a Perkin Elmer Model 141MC recording polarimeter using sodium (489 nm) and mercury vapour lamps as light sources.

Preparation of the half-esters

To illustrate the generalized procedures, the preparation of two particular half-esters, one from the acetophenone in one pot, the other via the phenylethanol, are presented here.

1-(4'-Methylphenyl)ethyl hydrogen phthalate

Under dried N_2, THF (approximately 250 mL) was distilled into an oven-dried flask containing a magnetic stirrer bar and 6.3 g (0.166 mol) of $LiAlH_4$. With stirring, chilling in ice, and still under N_2, 80.2 g (0.598 mol) of 4-methylacetophenone was added over a 40-min period. The mixture was then refluxed gently for 4 h. After cooling to ice temperature, 89.2 g (0.602 mol) of phthalic anhydride was added in four batches over 20–30 min with stirring, which was continued as the reaction was slowly heated and refluxed overnight.

Work-up consisted of removing the bulk of the THF on a rotatory evaporator (rot. evap.) and taking up the residue in about 400 mL of diethyl ether and 250 mL of 3.5 *M* HCl. The ethereal layer was washed several times with more dilute acid, water, and then saturated aqueous NaCl before being dried briefly over Na_2SO_4. The aqueous fractions were reextracted with ether, which was similarly treated and added to the first ethereal layer. The ether was removed, leaving a viscous cloudy oil, which was transferred to a 2-L Erlenmeyer flask. About 750 mL of 80–100°C petroleum ether was added and heated to boiling. The solution was decanted carefully from the undissolved half-ester into a 1-L Erlenmeyer flask. After cooling and chilling, the solvent was decanted from the crystalline product back into the first flask and the procedure repeated until only white crystals of phthalic acid (5.5 g, corresponding to 5.5% of the starting anhydride) remained in the original flask. The yield of half-ester was 149.2 g, 88%, mp 118.5–120.5°C. The deuterium-labelled analog was made on a 0.1-molar scale using $LiAlD_4$ as the limiting reagent.

1-(4'-Nitrophenyl)ethyl hydrogen succinate

To 130.0 g (0.788 mol) of 4-nitroacetophenone in a 1-L flask, about 250 g of ice and 400 mL of methanol were added. With magnetic stirring, 9.25 g (0.244 mol) of $NaBH_4$ was added in four batches over a half-hour period. After another half hour, the mixture, with continued stirring, was slowly heated to reflux and refluxed overnight. Once the bulk of the methanol had been removed on the rot. evap., ether and about a 50% excess of hydrochloric acid were added to the two-phase mixture. After washing with several portions of each of 1 *M* HCl, water, and saturated aqueous NaCl and drying over Na_2SO_4, the ethereal layer, combined with the ethereal layers from reextracting the aqueous fractions, was concentrated. Two vacuum distillations at 127.5°C and 0.65 Torr (1 Torr = 133.3 Pa) gave (4'-nitrophenyl)ethanol (113.3 g, 86%). It was not, however, necessary to isolate the alcohol; addition of benzene to the concentrate from the ethereal layers and azeotroping the water from the mixture allowed the crude product to be used directly, as was done in the following steps.

To the benzene–alcohol solution (or to the isolated alcohol) were added 100 mL of pyridine and 85.7 g (0.855 mol) of recrystallized succinic anhydride. The mixture was heated to 75–80°C with magnetic stirring overnight, the bulk of the excess pyridine removed on the rot. evap., 250 mL of ether added, and the mixture repeatedly extracted with ice-cold 2–3 *M* HCl to remove the remaining pyridine. The ethereal layer was combined with that from reextracting the various aqueous fractions, washed with water and saturated aqueous NaCl several times, dried, and concentrated on the rot. evap. The residue was taken up in 600 mL of hot toluene, decolorized with a generous amount of charcoal, and allowed to cool with periodic scratching to induce crystallization. A second and third crop of half-ester was obtained by concentrating the toluene phase. Based upon *p*-nitroacetophenone, the total yield of half-ester was 183 g (87%) without, 160 g (76%) with isolation of the alcohol.

Preparation of diastereomeric salts of half-esters and (+)- and (−)-1-Phenylethylamine

To illustrate the procedures employed, resolutions in a water insoluble solvent (ether) and in a water soluble one (acetone) are outlined.

Resolution of the 4'-methyl half-ester

In a 1-L Erlenmeyer flask, 147.5 g (0.519 mol) of the phthalate half-ester was dissolved in 400 mL of the ether by stirring and gentle warming. After chilling to ice temperatures, with sitrring, 27.0 g (0.223 mol) of (+)-phenylethylamine was added in 1- to 2-mL portions to minimize overheating and boiling. After several minutes, snow-like crystals formed ever faster until the solution gelled, and, despite continued cooling, considerable ether boiled off due to the heat of crystallization. The flask was placed in a freezer for 5 h, the solid was broken up with a stirring rod, and the thick slurry suction filtered. The solid was twice returned to the flask and slurried with fresh ether, chilled, and refiltered to give 82.1 g or 78% of the theoretical amount of salt based upon the chiral amine.

The combined filtrates were extracted with several 250-mL portions and several smaller portions of ice-cold 1.5 *M* HCl, water, and saturated NaCl. The volume of the ethereal layer, combined with that from reextracting the various aqueous phases, was reduced to about 600 mL and 28.4 g (0.234 mol) of (−)-amine added as before. Similar boiling occurred. Filtering and washing as before gave 86.9 g or 82.5% of the ammonium salt based on the starting chiral amine.

The combined ethereal washes and filtrates were treated as before except that they were reduced to approximately 300 mL before 10.5 g (0.086 mol) of the (+)-amine was added. The usual work-up gave 23.1 g for a total of 105.2 g or 100% of the (+)-amine diastereomeric salt based upon the starting racemic half-ester. (An estimated 5–6 g of the product was amine salt of phthalic acid from impurities in, and from hydrolysis of, the half-ester.) A second crop of the (−)-amine salt was obtained by adding 7.0 g of the amine to a concentrated ethereal phase after the usual work-up. The yield of the salt was 10.0 g, giving a total yield of the other diastereomeric salt of 96.9 g or 92.1%.

The combined yield of the diastereomeric salts was 84.5% based upon starting 4-methylacetophenone. (Approximately 80% of the unprecipitated chiral amines was recovered by neutralizing the first acid wash fractions with NaOH pellets, ether extraction, washing, drying, and vacuum distillation.) The salts were stored until required.

Resolution of the 4'-bromo half-ester

With cooling and stirring, 27.8 g (0.229 mol) of (−)-1-phenylethylamine was added to the solution of 175 g (0.501 mol) of 1-(4'-bromophenyl)ethyl hydrogen phthalate in 400 mL of acetone. After a half hour the solution was seeded with a crystal of the salt (or scratched repeatedly the first time) and placed in a freezer. The next morning, the slurry was filtered and the salt, returned to the flask, slurried with, then refiltered from, fresh fractions of chilled acetone three times. After drying, 53.0 g of the (−)-amine salt was obtained.

The combined acetone fractions were stripped of acetone on the rot. evap. and the residue taken up in ether, which was in turn extracted with aqueous acid etc. as in the previous example. After drying, the ether was removed on the rot. evap., the residue taken up in about 400 mL of acetone, and 30.0 g (0.248 mol) of (+)-amine added. After standing in a freezer overnight, work-up as before gave 90.5 g of the (+)-amine salt. The filtrate was treated as before except that the residue from the ether was taken up in only 250 mL of acetone and 15.2 g (0.125 mol) of the (−)-amine was added to give 49.9 g of the salt. Recycling with 8.9 g (0.073 mol) of the (+)-amine gave 24.5 g of salt. Finally 6.25 g (0.052 mol) of the (−)-amine was used to obtain 14.1 g of salt.

The combined yields of the two diastereomeric ammonium biphthalate salts were 117.0 g or 99.4% and 115.0 g or 97.6% of the (−)- and (+)-amine salts, respectively, or a total of 98.5% based upon the half-ester. Based upon 4-bromoacetophenone the combined yield of the resolved ammonium salts was 83.0%.

Isolation of the chiral alcohols

Only a generalized procedure is outlined since, with the exception of the nitro substrates, all were treated similarly.

The diastereomeric amine salt was partitioned between ether and ice-cold 2 *M* HCl by stirring magnetically for 15–60 min. The ethereal layer was reextracted with several more portions of chilled acid, washed several times with water, and concentrated on the rot. evap. About two molar equivalents of 3 *M* NaOH were added and the solution heated at gentle reflux with stirring for several hours, usually overnight. After chilling, the organic layer was extracted with several fractions of ether, which in turn was washed several times with 1 *M* base, water, and saturated aqueous NaCl before being dried over K_2CO_3. Concentration, followed by vacuum distillation, gave the chiral 1-phenylethanol, typically in 95–98.5% yield based upon the salt. Boiling points and yields are given in Table 1. The chiral amine was recovered from the original aqueous acid phases by basification, extraction with ether, and vacuum distillation, with about 75% recovery of material with an optical activity the same as, and on occasion even slightly higher than, the starting amine.

NOTE: The base-catalyzed hydrolysis of the nitro substrate gave intractable tars. Acid-catalyzed hydrolysis with the obvious modifications in procedure was done for this case. Acid catalysis is, of course, possible for the other compounds but the fact that the diacid produced is soluble in the aqueous phase in the case of base hydrolysis simplified the work-up and makes that the preferred method.

Optical purities of the ethanols

Chiral shift reagent, Eu-Opt

Analogous procedures were used for all of the cases examined so that only the 1-(3',4'-dimethylphenyl)ethanol compound is discussed.

To a nmr tube containing 20 μL (approx. 1.3×10^{-4} mol) of 1-(3',4'-dimethylphenyl)ethanol in 400 μL of $DCCl_3$, the amount of a solution of Eu-Opt (0.1797 g, 0.201 mmol/mL in $DCCl_3$) added was incrementally increased. A multi-scan nmr spectrum was obtained after each Eu-Opt addition. The α-H quartet centred at 4.81 δ in the absence of shift reagent was progressively shifted and separated into overlapping quartets. With 50 μL of added shift solution the separation was moderately good and the temperature was lowered to 0°C—the pair of quartets was then centred at δ 5.965 and 5.935. Decoupling from the methyl protons resolved that signal into an incompletely resolved pair of singlets with an area ratio of 47.8:52.2. Running the spectrum of the (−)-alcohol at the same shift reagent concentration and temperature gave a "clean" quartet at δ 5.93, which, on decoupling from the methyl protons, gave a broad singlet (δ 5.925) with a small up-field shoulder (δ 5.96) due to traces of the other enantiomer. Deconvolution gave the area ratio 5.6:94.4 for the (+)- and (−)-enantiomers respectively. The optical purity of the (−)-3,4-dimethylphenylethanol is thus approximately 89%. Mixed samples of the racemic and (−)-alcohols were also run to check the consistency of the determinations. For example, a mixture of 10 μL of each of (±)- and (−)-alcohols gave the area ratio 25.4:74.6 versus the calculated ratio 27.8:72.2 based upon the just determined purity of the (−)-alcohol.

Diastereomeric esters of (+)-MTPA (6*c*, 10)

(+)-MTPA (Sigma Chemical Company) was converted to the acid chloride with freshly distilled thionyl chloride (10). In oven-dried vials equipped with a screw cap and a Teflon-lined septum, about 0.10 mmol of the alcohol (12–15 μL depending upon its molar mass and density), 300 μL of each of molecular sieve dried pyridine and carbon tetrachloride, and 25 μL (34 mg, 0.14 mmol) of the (+)-MTPA-Cl were injected, shaken, and allowed to stand overnight (12–14 h). An excess, 25 μL (21 mg, 0.20 mmol) of 3-dimethylaminopropylamine was added to convert any excess (+)-MTPA-Cl into the aqueous acid soluble aminoamide. After shaking and standing for 30–90 min, the contents of the vial were quantitatively transferred to a 25-mL separatory funnel, taken up in 10 mL of ether, and the ethereal layer extracted successively with two chilled 10- to 15-mL portions of each of 3 *M* HCl, concentrated K_2CO_3, and saturated salt solution. The ethereal layer was poured onto a layer of molecular sieves in a small flask, stoppered, and allowed to stand with occasional swirling for several hours.

The solution was pipetted into a pear-shaped flask and the ether removed on a rot. evap. Three small portions of $DCCl_3$ were added and stripped off to ensure that the last traces of ether were removed and the residue was taken up in 400 μL of $DCCl_3$ for nmr analysis.

In the proton spectrum, the aliphatic methyl (δ ~1.6), the aromatic methyl if present (δ ~2.3), the methoxy (δ ~3.5), and the methine (δ ~6.1) protons were expanded, decoupled if necessary, and, if separation was adequate, the relative areas for the signals of the two diastereomeric components determined. Fluorine nmr was also used. Results for 4-nitrophenylethanol are reported in Table 4 and selected results are summarized in Table 3.

Preparation of chiral substituted 1-phenylbromoethanes

The chiral 1-phenylethanol was added to about eight volumes of benzene or toluene and chilled in an ice–acetone bath to well below 0°C for all except the 4'-bromo and 4'-nitro compounds, which were run near 0 and 40°C respectively. Hydrogen bromide gas was bubbled in at a relatively slow rate to reduce heating effects; the rate was such that the solution was saturated in HBr in about 5 min. With continuous slow bubbling or periodic resaturation with HBr, the methyl-substituted materials were allowed to stand less than 5, the unsubstituted, about 10, the bromo-substituted, about 20 min, and the nitro-substituted, several hours, before the lower aqueous layer was removed with a dropping pipet and the excess HBr removed at aspirator pressures and the same temperature as that at which the reaction was run. A nitrogen bleed was used to prevent bumping. After a few minutes, the solution was decanted from the remaining water into a clean pear-shaped flask and the remaining HBr and aromatic solvent removed on a vacuum pump. The product was then vacuum distilled as quickly and smoothly as possible to minimize racemization. Heating was best done with a micro-burner for speed. The boiling points and pressures are tabulated in Table 2. Using 5–8 g of the alcohols, yields of 85–95% of the corresponding bromide, which showed no OH-absorption in the infrared, were obtained. The nmr spectra were clean. The optical activities of the alcohol and of the bromide made from that particular batch of the alcohol are presented in Table 2.

The use of homogeneous and heterogeneous Lewis acids to catalyse the photoisomerizations of phenols

SATISH K. CHADDA AND RONALD F. CHILDS[1]
Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received April 22, 1985

SATISH K. CHADDA and RONALD F. CHILDS. Can. J. Chem. **63**, 3449 (1985).

The reaction of methyl substituted phenols with CH_2Cl_2 solutions of Al_2Br_6 leads to the formation of two types of complexes. In both of these the aluminum is bound to the oxygen atom of the phenol but they differ in that the OH proton can either remain on oxygen, oxonium complex, or migrate to one, usually the *para*, ring carbon, keto complex. The equilibrium position between the two types of complex depends on the position of the methyl groups. Irradiation of a complex of the keto type leads initially to the formation of a complexed bicyclo[3.1.0]hexenone and subsequently to the formation of an isomeric complexed phenol. Only in the case of the tetramethylphenols is the yield of the bicyclic ketone high enough to warrant the use of this photoisomerization as a preparative procedure, although the technique can be used to isomerize a range of phenols to their 4-substituted isomers. The photoisomerizations are not restricted to the use of a homogeneous Lewis acid such as Al_2Br_6 but heterogeneous aluminosilicates can also be used. The adsorption of 2,3,5,6-tetramethylphenol, **1***h*, on an aluminosilicate was monitored quantitatively and it was shown that a monolayer was formed in which the phenol was at least partially present in the keto form. Irradiation of **1***h* in the presence of stirred slurries of the aluminosilicate led to the formation of 2,3,4,6-tetramethylphenol. No bicyclic ketones were present in the contacting solution but traces were detected on the catalyst when the irradiations were carried out on adsorbed material in the absence of a solvent. In the case of heterogeneous acids, the selectivity in the adsorption of the starting phenol and the photoproducts is important in determining the composition of the final mixture.

La réaction de phénols substitués par des groupements méthyles avec des solutions de Al_2Br_6 du CH_2Cl_2 conduit à la formation de deux types de complexes. Dans chacun de ces complexes, l'aluminium est lié à l'atome d'oxygène du phénol; toutefois, ils diffèrent par le fait que le proton du OH peut soit demeurer sur l'oxygène, complexe onium, soit migrer sur l'un, généralement celui en *para*, des carbones du cycle, complexe céto. La position de l'équilibre entre ces deux types de complexes dépend de la position des groupements méthyles. L'irradiation d'un complexe de type céto conduit initialement à la formation d'une bicyclo[3.1.0]hexènone complexée et subséquement en un phénol complexé isomère. Il n'y a que dans les cas des tétraméthylphénols que les rendements en cétones bicycliques sont suffisamment élevés pour justifier l'utilisation de cette photoisomérisation comme méthode préparative, même si cette technique peut être utilisée pour transformer un grand nombre de phénols en leurs isomères substitués en position 4. Les photoisomérisations ne sont pas restreintes à l'usage d'un acide de Lewis homogène, comme le Al_2Br_6; on peut aussi utiliser des aluminosilicates hétérogènes. On a déterminé les taux d'adsorption du tétraméthyl-2,3,5,6 phénol, **1***h*, sur un aluminosilicate et on a montré qu'il se forme une monocouche dans laquelle le phénol est présent, au moins en partie, sous la forme céto. L'irradiation de **1***h* en présence de suspensions agitées d'aluminosilicates conduit à la formation de tétraméthyl-2,3,4,6 phénol. On n'a pas trouvé de cétones bicycliques dans la solution en contact; toutefois, on en a détectée sur le catalyseur lorsqu'on a effectué des irradiations sur des matériaux adsorbés, en l'absence de solvant. Dans les cas des acides hétérogènes, la sélectivité dans l'adsorption du phénol de départ et des photoproduits est importante dans la détermination de la composition du mélange final.

[Traduit par le journal]

Phenols are relatively basic molecules that can be protonated readily in a variety of strong and super-acid media (1). Two types of cations can be formed, with protonation occurring either on oxygen to form an oxonium ion or on one of the ring carbons to give a protonated ketone structure. The preferred site of protonation depends both on the nature of the acid medium used and on the substituents on the phenol.

Ring protonated phenols have been shown to isomerize on irradiation to yield protonated bicyclo[3.1.0]hex-3-en-2-ones (2). This facile photoisomerization of the C-protonated phenols stands in marked contrast to the general lack of photochemical reactivity of the parent phenols or their oxygen protonated counterparts. Protonated bicyclo[3.1.0]hexenones are photochemically labile and undergo further reaction on irradiation, Scheme 1. With appropriate wavelength control of the illumination system it is possible to stop these reactions at either the bicyclic ketone or isomeric phenol stage.

This photochemical isomerization of *para*-protonated phenols is analogous to the photoisomerizations of 2,5-cyclohexadienones (3) and as such it is potentially a very useful method of preparing a wide variety of bicyclo[3.1.0]hexenones with one or two hydrogens at C6 (4). In addition to their potential synthetic utility, these photoreactions of protonated phenols hold promise as candidates for a photochemical latent heat storage system (5).

The principal disadvantage of these photoisomerization reactions, which prevents their widespread use for either synthetic purposes or solar energy storage, lies in the need to use strong acids as solvents. These acids must be neutralized to recover the products, and the scale-up of these vigorously exothermic reactions is always difficult.

We have sought ways around this problem of the use of strong protic acids and report here the results of a study of two related approaches. These involve the use of a Lewis acid to catalyse the photoisomerizations and, secondly, the use of heterogeneous acids as photocatalysts. The latter possibility would be particularly attractive in terms of energy storage.

Results and discussion

Homogeneous Lewis acids

Koptyug *et al.* have investigated the reactions of aluminum trichloride and tribromide with various methyl substituted phe-

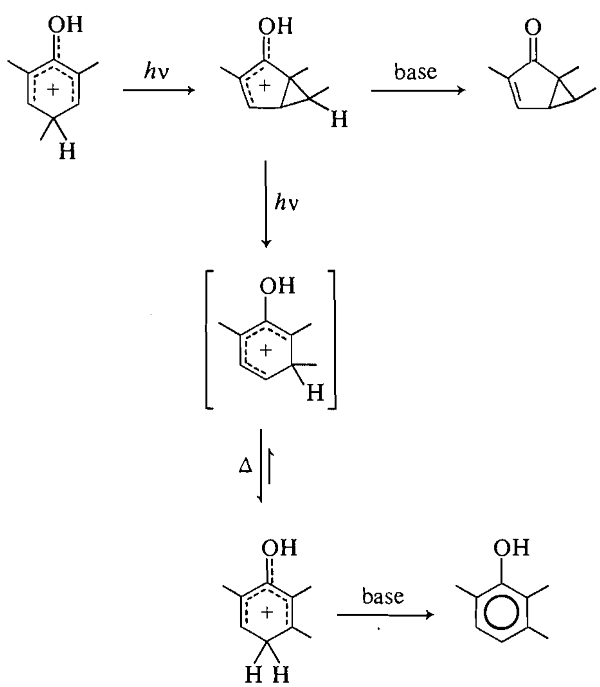

SCHEME 1

nols and found that two types of complexes can be formed, eq. [1] (6). In each of these complexes the Lewis acid is bound to the oxygen of the phenol but the OH proton can either remain on oxygen, **2**, or migrate to the *para* ring carbon, **3**. The position of the equilibrium established between **2** and **3** was shown to depend both on the substituents on the phenol and also on the ratio of Lewis acid to phenol used. It was found necessary to have at least one methyl group in a *meta* position in order for the keto type complex **3** to be the major species present.

We have reexamined the reactions of phenols **1***a*–*c* with Al_2Br_6 and have confirmed the results of Koptyug *et al.* (6). In each case the phenol was reacted with a slight molar excess of the Lewis acid in CH_2Cl_2 (or CD_2Cl_2) solution and the ¹H nmr (nuclear magnetic resonance) and uv (ultraviolet) spectra obtained (Table 1). Complexes of the hydroxy form, **2**, were the major species present in phenols **1***a*, *d*, *e*, *f*, and *i*, while the keto complexes, **3**, predominated with **1***b*, *e*, *g*, and *h*. In general, under the conditions used here, it was found that not only was it important to have a methyl group in the *meta* position for the formation of the keto form **3** of these complexes but also that the *para* position should be unsubstituted. This pattern of substituent effects is understandable in terms of the stabilizing effect of a methyl group on benzenium cations (7). In the case of **1***i* it would seem that the effect of two methyl

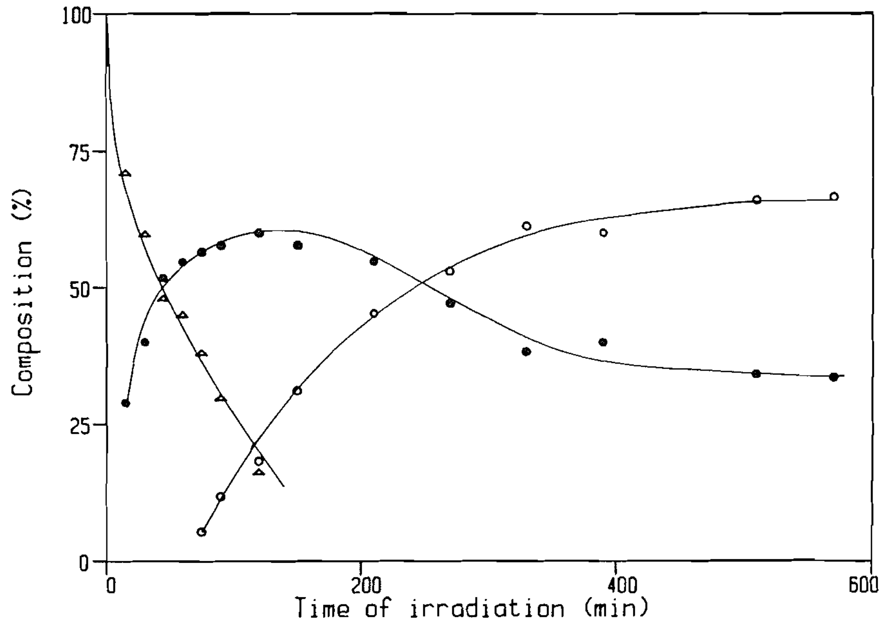

FIG. 1. Change in composition on irradiation of **1***h*; △, **1***h*; ●, **1***i*; ○, **4**.

groups in the *meta* positions outweighs the expected destabilizing effect that the *para* methyl group exerts on the keto complexes. The uv spectra of the various complexes are given in Table 1. It can be seen from these data that the keto complexes exhibit quite different uv spectra from those of the hydroxy complexes. Typically the keto complexes have strong adsorption maxima at wavelengths above 300 nm. Similar uv spectra have been reported for protonated 2,5-cyclohexadienones (8) and *para* protonated phenols (2).

Photoisomerizations

Unless otherwise specified, all irradiations were carried out using a Rayonet photoreactor and 300-nm lamps, conditions which have been shown to generally maximize the formation of bicyclic products. The reactions were followed by obtaining ^{1}H nmr spectra of the irradiated solutions and subsequently more detailed product analyses were carried out by gc (gas chromatography) after neutralization of the Lewis acids. Control reactions were carried out in each case to ensure that the observed reactions were photochemical rather than thermally induced.

The simplest cases present are the result of the irradiation of solutions of **1***f*, **1***a*, **1***d*, and **1***c*, as no photoisomerizations were observed. The $AlBr_3$ complexes of each of these phenols are primarily in the oxonium form (**2***f*, **2***a*, **2***d*, and **2***e*, respectively) and the failure to undergo photoisomerization is entirely consistent with the corresponding lack of reactivity of these oxonium ions in strong acid solutions (2, 4).

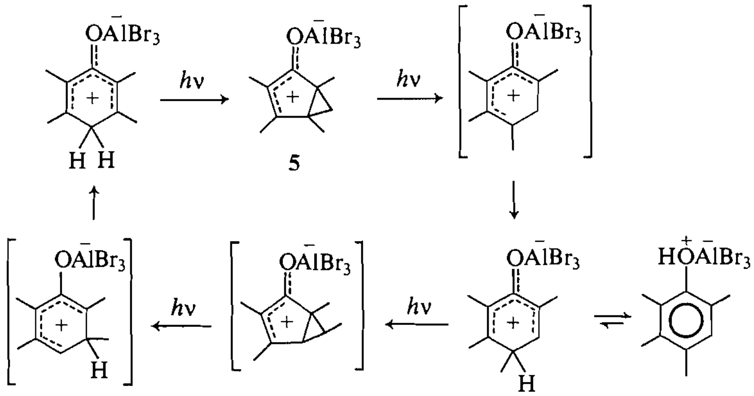
Irradiation of a solution of **1***h* in the presence of an equivalent amount of $AlBr_3$ led to the formation of **4** and subsequently **1***i*, eq. [2]. The identity of **4** was established by

[2] 
1*h* **4** **1***i*

comparison with authentic material using ^{1}H nmr and gc (4). The maximum conversion of **1***h* to **4** was ca. 60% and this was reached relatively early in the reaction, Fig. 1. Eventually a photostationary state appeared to be set up between **4** and **1***i*. To confirm this, a solution of **1***i* in the presence of $AlBr_3$ was irradiated. A mixture of **4** and **1***i* was obtained with a similar ratio to that reached starting with **1***h*. During the early stages of this reaction small amounts of **1***h* were detected in the reaction mixture. The $AlBr_3$ complex of the bicyclic ketone **4** was shown to be thermally stable under the reaction conditions. Irradiation of a CH_2Cl_2 solution of this complex led to the formation of the $AlBr_3$ complex of **1***i*. The effect of the variation in the molar ratio of Lewis acid to phenol **1***h* used in these reactions was examined. No difference in the composition of the resulting products was observed as the ratio was changed from 1 : 1 to 1 : 2 to 1 : 4 (phenol/$AlBr_3$). No photoisomerization of **1***h* or **1***i* could be detected in the absence of $AlBr_3$.

These results clearly indicate that it is possible to catalyze the photoreactions of these tetramethylphenols using a strong Lewis acid. The reactions observed are directly comparable to the reactions observed in FSO_3H or CF_3SO_3H solutions and can be understood in terms of the interrelationships shown in Scheme 2. The distribution of products observed in these reactions of the $AlBr_3$ complexes of **1***h* is different from that obtained in protic acid solution in that a much higher limiting concentration of **1***i* is obtained. This can be readily understood in terms of the thermodynamic preference for the complex of **1***i* to be in the photochemically inert oxonium form, with only small amounts being in the photochemically active dienone form. The importance of this equilibrium is more pronounced in the photoreactions of some of the other phenols described below.

Irradiation of **1***g* in the presence of $AlBr_3$ led to the formation of **1***f* and only traces (<4% maximum concentration) of materials which were possibly isomeric bicyclo[3.1.0]hexenones, although these materials were not isolated and characterized in view of the small amounts present. As has already been shown, **1***f* is inert when irradiated in the presence of $AlBr_3$ because it preferentially exists as the oxonium complex. The photoisomerization of **1***g* can be understood in terms of the sequence of reactions shown in the top part of Scheme 2. The difference



SCHEME 2

in this case is that the Lewis acid complex of 1*f* is in the photochemically inert oxonium form and this serves as the sink for the reaction.

The photochemical behaviour of 1*b* in the presence of $AlBr_3$ was similar to that of 1*g* described above in that the major products were again isomeric phenols, eq. [3]. In this case these photoproducts were identified as 1*a* and 1*e*. Traces of other unidentified products were present.

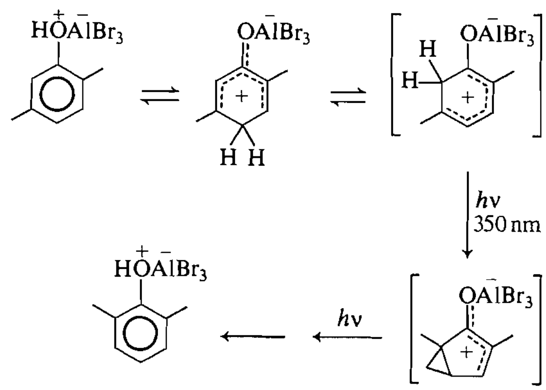
[3] 
1*b* 1*a* 21% 1*d* 76% 3%

In the case of 1*c*, irradiation in the presence of $AlBr_3$ led to the formation of two major products, which were identified as 1*e* and 1*b*. Traces of materials (<2.5%) that could be bicyclic ketones were detected by gc, and also small amounts of 1*a*, eq. [4]. As 1*b* is photochemically active when complexed, the amount of 1*b* present decreased with longer irradiation times.

The $AlBr_3$ catalysed photoisomerizations of 1*b* and 1*c* differ from the reactions described above in that a net migration of a methyl group from the *meta* to the *ortho* position has occurred. These reactions were shown to be photochemically rather than thermally initiated. One possible route whereby this could occur would be if, in addition to the C4 protonated complexes present as the predominant species in solution of 1*b* and 1*c* and $AlBr_3$, smaller amounts of the two *ortho* C-protonated forms were present. These species, by analogy with the protonated 2,4-cyclohexadienones, photoisomerize as shown in Scheme 3 (3, 9).

[4] 
1*c* 1*b* 14% 1*e* 82% 4%

Careful examination of the ^1H nmr spectra of solutions of 1*b* and 1*c* in the presence of $AlBr_3$ did not show any evidence for the presence of *ortho* protonated complexes. If these species were present they were either in rapid exchange with the major *para* protonated complexes, 3*b* and 3*c* respectively, or in such small amounts that they were below nmr detection limits.



SCHEME 3

The uv spectra of protonated 2,4-cyclohexadienones exhibit bands at substantially longer wavelengths than protonated 2,5-cyclohexadienones (8, 9) and, if comparable *ortho* protonated complexes were present, it should be possible to detect them in the uv spectra of 1*b* and 1*c*/$AlBr_3$ solutions. No distinct band could be observed in their spectra that could be attributed to the *ortho* protonated complexes but it should be noted that there is a very large band associated with the *para* protonated complexes, which trails into the region expected for the *ortho* protonated complexes, and small amounts of these materials would not be detected. However, if these *ortho* complexes were involved, then the yields of the products from any *ortho* protonated species should be increased as longer wavelength light is used. This is indeed the case, as is evident from the data in Table 2. For example, irradiation of 1*b* in the presence of $AlBr_3$ using 350-nm lamps led to the exclusive formation of 1*a*. These results give strong support to the sequence of events depicted in Scheme 3.

Solid Acid Catalysts

Aluminosilicates contain both Bronsted and Lewis acid sites. These materials can be very acidic when dry and they should be capable of either protonating or complexing with a phenol (9).

The adsorption of 1*h* on an aluminosilicate containing 12% Al_2O_3 was followed quantitatively by gc and the results shown in Fig. 2. It would seem that a monolayer coverage of the catalyst occurs with about 0.4 mmol of 1*h*/g of catalyst being adsorbed. As the concentration of 1*h* in the contacting cyclohexane solution was increased beyond 2×10^{-2} *M*, a gradual increase in amount absorbed was noted. The phenol 1*h* was recovered unchanged on treatment of the catalyst or reaction mixture with water.

[a] Irradiations carried out at 300 nm in glass apparatus with ca. 1 g of catalyst and 25 mL of cyclohexane as solvent.

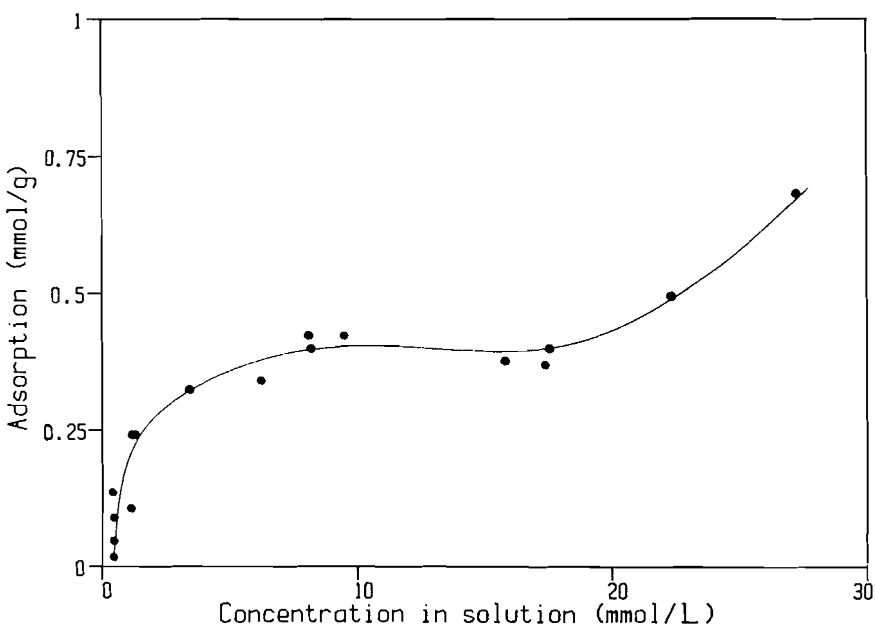

FIG. 2. Adsorption of **1***h* on aluminosilicate.

In order to characterize the nature of the adsorbed species, the uv spectra of slurries of the catalyst were examined in the presence of CH_2Cl_2 solutions of the phenol **1***h*. A new strong absorption band was found at 322 nm, which was absent in either the spectrum of the phenol itself in CH_2Cl_2 or the catalyst slurry in CH_2Cl_2 in the absence of the phenol. It was not possible to make reliable quantitative measurements of the new band but clearly the position of its absorption maximum is entirely consistent with the formation of ring protonated (keto type) complexes of **1***h*.

Irradiation of **1***h* in the presence of the aluminosilicate was carried out at 300 nm while stirring the cyclohexane/catalyst mixtures. The composition of the solution in contact with the catalyst and the composition of the materials adsorbed on the catalyst were determined by gc. The only photoproduct detected, in both the solution in contact with the catalyst and also

[a] All irradiations carried out in cyclohexane (50 mL) using 300-nm lamps for 24 h and Pyrex apparatus.
[b] Total yield of **1***i* in the resulting solution and adsorbed on the catalyst.

adsorbed on the catalyst, was **1***i*. As can be seen from Table 3, the proportion of **1***i* in solution and adsorbed on the catalyst was approximately the same throughout the course of the irradiation, suggesting that the two phenols are adsorbed to about the same extent on the aluminosilicate.

The effect of concentration of the phenol **1***h* on the photoreaction was examined (Table 4). It is clear from these data that quite high substrate/catalyst loadings can be used and the photoreaction still proceeds to give **1***i*. There appears to be an optimum loading in terms of efficiency of the photoreaction in the region of 0.035 g of **1***h*/g of catalyst; however, it should be noted that the conversions to **1***i* in the cases with low catalyst loadings are very high and the recorded conversions are limited by the amount of **1***h* present.

It should be stressed that no photoreactions of **1***h* were observed in the absence of the aluminosilicate and no isomerization of **1***h* to **1***i* could be detected in the presence of the catalyst but the absence of light. The isomerizations observed are clearly photochemical reactions that are occurring on the catalyst surface. The photoreaction is not limited to **1***h*. The conversion of **1***g* to **1***f* was also observed on irradiation of a cyclohexane solution in the presence of the aluminosilicate.

While it would seem most likely that the aluminosilicate functions in a comparable manner to the homogeneous Lewis or Bronsted acid catalyst with photoisomerizations of phenols, the question arises as to why, in the case of this heterogeneous acid, no bicyclic ketone, **4**, is produced in these reactions. One possibility is that the ketone is more strongly adsorbed to the catalyst surface than either of the phenols and that it undergoes further photoisomerization to give **1***i*. In order to check for this, competitive adsorptions of **1***h* and **4** were carried out (Table 5). From the data given in this table it can be seen that **4** is indeed much more strongly adsorbed than **1** on aluminosilicate. In view of the facility with which protonated or complexed **4** can undergo photoisomerization to **1***i*, it is likely that the adsorbed ketone undergoes a comparable photoreaction.

It is interesting to note that when **1***h* is vacuum deposited in low surface concentration on aluminosilicate and then irradiated, low concentrations (6%) of **4** can be detected in the presence of **1***i* (94%) at relatively low total conversions of **1***h*. It would seem clear that the overall chemistry occurring on the catalyst surface is very similar to that occurring in solutions of these phenols containing strong Bronsted or Lewis acids.

Conclusion

The results presented here confirm our original suggestion that Lewis acids and heterogeneous acid surfaces could function as catalysts for the photoiosmerization of phenols. However, apart from one case (**1***h* with $AlBr_3$), these reactions do not provide a convenient synthetic route to bicyclo[3.1.0]-hexenones. The major cause of this failure would seem to lie in the relative basicities of the bicyclic ketones as compared to the phenols, coupled with the photochemical inertness of the secondary photoproducts of these bicyclic materials. The exception to this generalization is the case of **4**, where **1***i*, its photoproduct, is still photochemically active and converted back to **4**. The importance of the relative basicities of starting material and product in Lewis acid catalysed photoreactions has been previously noted (10).

Experimental

Materials

All solvents were dried and distilled in oven-dried glassware under nitrogen immediately before use. The phenols were obtained commercially and purified by distillation. Aluminum bromide was sublimed before use. Aluminosilicate pellets (Stern chemicals) containing 12% Al_2O_3 were powdered and dried under vacuum at 350°C for 24 h before use.

General

The ^{1}H nmr spectra were obtained on a Varian EM390 instrument. The uv spectra were recorded on a Pye Unicam SP8-100 spectrometer. Gas chromatography was carried out using a Varian 3700 or a Hewlett Packard 5790A instrument, coupled with Varion CDS111 and HP3390A integrators, respectively. Columns used were 8 ft × 1/8 in. copper column packed with 10% PEGA on Chromosorb W and 10 ft × 1/8 in. stainless steel column packed with 10% Fluorad FC431 on Chromosorb W.

Photochemical procedures

Irradiations were carried out using a Rayonet photoreactor (Southern New England Ultraviolet Company) with ten lamps.The lamps used were RPR 3000 Å or RPR 3500 Å, depending on the wavelength desired.

For nmr work, the samples were prepared in 5-mm nmr tubes sealed with plastic caps and Teflon tape. Pyrex tubes of 1.5-cm diameter were used for preparative work. The reaction mixtures were stirred with magnetic stirrer during irradiation.

Preparation of solutions of complexes

All the manipulations were carried out in a nitrogen-filled glove bag. Solutions of the complexes were prepared by adding the purified phenols to a suspension of $AlBr_3$ in methylene chloride at −78°C. The reaction mixture was slowly brought to room temperature. The ratio of phenol to $AlBr_3$ was controlled by weighing both components. Unless otherwise stated, a 1.1 to 1.2 molar excess of the Lewis acid was used.

Adsorption studies were carried out using weighed samples of dried Al_2O_3/SiO_2 catalyst and varying amounts of **1***h* in dry cyclohexane. The uptake of **1***h* was followed by analyzing the solution by gc, using naphthalene as an internal standard. The adsorption was followed until no further change in concentration was observed. Competitive adsorption of **1***h* and its photoisomers was carried out by adding a known amount of phenol and its photoisomer to dried Al_2O_3/SiO_2 catalyst in 25 mL of cyclohexane. After 24 h stirring, the composition of isomers in the solution and on the catalyst was determined by analytical gc.

Desorption

The composition of products on Al_2O_3/SiO_2 after irradiation was determined by stirring the catalyst for 2 h in the presence of water and extracting the organic materials with CH_2Cl_2.

Analysis of products

Phenols **1**a–e were converted to their benzoates using benzoyl chloride while phenols **1**h and **1**i were converted to trimethylsilylaryl ethers using bis(trimethylsilyl)trifluoroacetamide, BSTFA. Products were identified by comparison with derivatives of authentic samples, and quantitively determined by gc using naphthalene as an internal standard.

The products were recovered from the $AlBr_3$ reaction mixtures by adding the mixtures slowly to water – methylene chloride mixture at 0°C. The methylene chloride layer was separated and washed well with water. The dried solutions (Na_2SO_4) were filtered and the CH_2Cl_2 was removed by evaporation through a Vigreux column.

Benzoates were prepared by adding 0.1 g of product to 5 mL of 5% NaOH solution. To this 0.5 mL benzoyl chloride was slowly added and the mixture stirred for 1 h. After leaving the reaction mixture for 12 h at room temperature, it was extracted with ether. The ether extract, after washing with water, gave the appropriate benzoates.

Trimethylsilyl aryl ethers were prepared by adding 100 μL BSTFA to a solution of 100 μL reaction mixture in dry cyclohexane and 10 μL pyridine in a screw cap septum reacti-vial. The reaction mixture was allowed to stand at room temperature for 1 h to obtain the silyl ethers.

Control experiments were run with both procedures using mixtures of phenols with known compositions in order to ensure that the assay methods were reliable.

Preparation, infrared spectra, and crystal structure of two modifications of the (thymidinato-N^3)methylmercury(II) complex

FRANCE GUAY AND ANDRÉ L. BEAUCHAMP[1]

Département de Chimie, Université de Montréal, C.P. 6210, Succ. A, Montréal (P.Q.), Canada H3C 3V1

Received June 20, 1984[2]

FRANCE GUAY and ANDRÉ L. BEAUCHAMP. Can. J. Chem. **63**, 3456 (1985).

Reaction of CH_3HgOH with thymidine (HT) yielded the neutral CH_3HgT complex crystallizing as a hydrated or an anhydrous material, depending on preparation conditions. Both forms were examined by X-ray diffraction. The anhydrous variety is monoclinic, space group $P2_1$, a = 4.798(6), b = 14.270(8), c = 10.390(4) Å, β = 102.74(9)°, and Z = 2 molecules per cell. The structure was refined on 1552 nonzero MoKα reflections to a conventional R factor of 0.034. The hydrated form belongs to the orthorhombic space group $P2_12_12_1$, a = 10.484(3), b = 14.633(3), c = 18.538(5), Z = 8. The structure was refined on 1816 nonzero MoKα reflections to R = 0.036. In both forms, the CH_3Hg^+ ion is linearly bonded to the deprotonated N(3) site of thymidine. The water molecules and hydroxyl groups in the ribose unit participate in a hydrogen bonding network, in which the carbonyl groups are involved as acceptors. The infrared spectra of the two forms differ significantly only by the absorptions due to the water molecules. By comparing with the spectrum of thymidine, diagnostic regions for complexation with deprotonated thymidine have been proposed.

FRANCE GUAY et ANDRÉ L. BEAUCHAMP. Can. J. Chem. **63**, 3456 (1985).

La réaction de CH_3HgOH avec la thymidine (HT) conduit au complexe neutre CH_3HgT, qui cristallise sous forme hydratée ou anhydre, selon les conditions de préparation. Les deux formes ont été étudiées par diffraction des rayons X. La forme anhydre est monoclinique, groupe spatial $P2_1$, a = 4,798(6), b = 14,270(8), c = 10,390(4) Å, β = 102,74(9)°, Z = 2 molécules par maille. La structure a été affinée au moyen de 1552 réflexions MoKα significativement observées jusqu'à un facteur R conventionnel de 0,034. La forme hydratée appartient au groupe orthorhombique $P2_12_12_1$, a = 10,484(3), b = 14,633(3), c = 18,538(5) Å, Z = 8. La structure a été affinée au moyen de 1816 réflexions MoKα significativement observées jusqu'à R = 0,036. Dans les deux sortes de cristaux, l'ion CH_3Hg^+ est linéairement lié au site N(3) déprotoné de la thymidine. Les molécules d'eau et les groupes hydroxyles du ribose participent à des liaisons hydrogène, pour lesquelles les groupes carbonyles jouent le rôle d'accepteurs. Les spectres infrarouges des deux formes ne diffèrent appréciablement que dans les régions associées à la molécule d'eau. Par comparaison avec le spectre de la thymidine, on identifie des régions diagnostiques pour la complexation avec la thymidine déprotonée.

Introduction

It has been shown by various methods that mercury reacts with N(1)-blocked uracil and thymine ligands by displacing the acidic N(3)-H proton (1–7). Substitution by the less electron-attracting metal atom is expected to increase the basic character of the nearby carbonyl groups. In agreement with this assumption, when CH_3HgMT (where MT^- = deprotonated 1-methylthymine) is allowed to precipitate in the presence of simple salts, mixed compounds such as $CH_3HgMT\cdot NaClO_4$ (8) and $CH_3HgMT\cdot \frac{1}{2}NaNO_3$ (7) are obtained. The carbonyl groups of the thymine unit have been shown to interact with the Na^+ ions in these mixed compounds. In order to determine whether such Na^+–carbonyl interaction are retained when good hydrogen-bond donors are simultaneously present, attempts were made to obtain mixed compounds containing the similar CH_3HgT complex, in which the ligand would be the deoxynucleoside thymidine HT. No mixed complexes could be prepared, but two forms of the neutral CH_3HgT complex have been isolated. They are discussed in the present paper.

Experimental section

Preparation

CH_3HgT

Thymidine (Het-Chem, 0.243 g, 1 mmol) was mixed with 1.0 mL of 1 *M* aqueous CH_3HgOH (Alfa) in 30 mL of hot 95% ethanol. After evaporation at room temperature to dryness, the solid was washed with absolute ethanol and dried *in vacuo*. Yield: 0.34 g. *Anal.* calcd. for $C_{11}H_{16}N_2O_5Hg$: C 28.92, H 3.53, N 6.13, Hg 43.91; found: C 29.37, H 3.67, N 6.08, Hg 43.68.

$CH_3HgT\cdot 0.69H_2O$[3]

Thymidine and CH_3HgOH were mixed (same proportions as above) in 30 mL of hot water. The mixture was allowed to evaporate at room temperature to a volume of 10 mL. The solid was filtered and dried *in vacuo*. Yield: 0.33 g, 70%. *Anal.* calcd. for $C_{11}H_{16}N_2O_5Hg$, $0.69H_2O$: C 28.15, H 3.73, N 5.97, Hg 42.74; found: C 28.41, H 3.90, N 5.95, Hg 42.37.

Infrared spectroscopy

The spectra were recorded on KBr pellets with a Digilab FTS-15 C/D Fourier-transform infrared spectrometer equipped with a Globar source and a wide-band mercury cadmium telluride detector (Infrared Associates, New Brunswick, NJ). Typically, 100 interferograms of 4096 points recorded with an optical velocity of 1.2 cm s^{-1} and maximum optical retardation of 0.5 cm were co-added, apodized with a boxcar function, and Fourier transformed with 4 levels of zero filling resulting in a spectral resolution of 2 cm^{-1}. The apparatus was purged with nitrogen during the experiment.

Crystallographic measurements and structure resolution

CH_3HgT

$C_{11}H_{16}HgN_2O_5$ fw = 456.8

Monoclinic, $P2_1$, a = 4.798(6) Å, b = 14.270(8) Å, c = 10.390(4) Å, β = 102.74(9)°, V = 693.9 Å^3, D_o = 2.16(2) g cm^{-3}, Z = 2, D_c = 2.186 g cm^{-3}, λ(MoK$\bar{\alpha}$) = 0.71069 (graphite monochromator), t = 20°C, μ(MoKα) = 110.9 cm^{-1}, crystal thickness (mm) between pairs of faces: 0.64 ($0\bar{1}0$–010) × 0.06 ($00\bar{1}$–001) × 0.06 ($01\bar{1}$–$0\bar{1}1$) × 0.10 ($0\bar{1}\bar{1}$–011), transmission range: 0.33–0.60, average fluctuation of standard reflections: ±1.6%.

Space group was determined from precession and cone axis photographs. The systematic absences ($0k0$, $k \neq 2n$) were consistent with space groups $P2_1$ and $P2_1/m$, but the latter was rejected as inconsis-

[3] Formula based on an occupancy factor of 0.38 for water molecule W(2).

tent with the presence of asymmetric centers in the D-deoxyribose unit. The intensity data were collected with an Enraf-Nonius CAD4 diffractometer, following a procedure described elsewhere (9). A set of 2099 *hkl* and $hk\bar{l}$ reflections in a reflection sphere limited by 2θ = 60° was collected. The 1552 reflections significantly above backgrounds ($I > 3\sigma(I)$) were retained for structure resolution.

The structure was solved by the heavy-atom method and refined on $|F_o|$ by full-matrix least-squares in the early stages. The *x* and *z* coordinates of Hg were determined from a Patterson synthesis, whereas the *y* coordinated was arbitrarily set to 0.25 to fix the origin along *b*. The difference Fourier map (ΔF) phased on Hg showed $P2/m$ symmetry as expected, but the pyrimidine ring and both carbonyl oxygens from one of the two overlapping images could be unambiguously assembled. A subsequent ΔF map phased on the known portion of the structure revealed the positions of all the remaining non-hydrogen atoms. Isotropic refinement converged to $R = \Sigma||F_o| - |F_c||/\Sigma|F_o| = 0.120$ and $R_w = [\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2]^{1/2} = 0.143$. At this stage, it was checked that the D-deoxyribose unit had the correct absolute configuration. Refinement was continued by block-diagonal least squares. The hydrogen atoms (except that of O(5′A)) were located from the ΔF map. They were introduced into the structure at idealized positions (B = 6.0 Å^2, C—H = 0.95 Å). The hydrogen parameters were not refined, but the coordinates were recalculated after each least-squares cycle. Anisotropic refinement of all non-hydrogen atoms reached convergence for R = 0.034 and R_w = 0.038. The goodness-of-fit ratio was 1.27. The final ΔF map showed a general background below ±0.7 e/Å^3, with a few extra peaks in the range 0.9–2.6 e/Å^3 near mercury.

CH_3HgT hydrate

$C_{11}H_{16}HgN_2O_5$, 0.69 H_2O fw = 469.28

Orthorhombic, $P2_12_12_1$, a = 10.484(3) Å, b = 14.633(3) Å, c = 18.538(5) Å, V = 2844.0 Å^3, D_o = 2.18(2) g cm^{-3}, Z = 8, D_c = 2.193 g cm^{-3}. λ(MoK$\bar{\alpha}$) = 0.71069 Å, t = 20°C, μ(MoKα) = 108.1 cm^{-1}, thickness (mm) between pairs of faces: 0.30 ($001-00\bar{1}$) × 0.24 ($20\bar{1}-\bar{2}01$) × 0.20 ($010-0\bar{1}0$), transmission range: 0.06–0.23; average fluctuation of standards: ±1.4%.

Space group was unambiguously defined from the systematic absences ($h00$, $h \neq 2n$; $0k0$, $k \neq 2n$; $00l$, $l \neq 2n$) noted on precession films. A set of 2684 independent *hkl* reflections in a sphere limited 2θ = 49° was collected, of which 1816 were retained as significantly above background ($I > 3\sigma(I)$).

The structure was solved by the heavy-atom method and refined on $|F_o|$ by full-matrix least-squares in the early stages. Both non-equivalent Hg atoms were located from a Patterson map, and the non-hydrogen atoms were progressively identified from structure factor calculations and ΔF maps. Electron density was found at suitable positions for all non-hydrogen atoms of both independent CH_3HgT units and two water molecules. Isotropic refinement converged to R = 0.064 and R_w = 0.069. Absolute configuration was checked at this point. Mercury was then refined anisotropically. It was then noticed that O(5′B) and water molecule W(2) had very high thermal motion. In addition, the ΔF map showed a residual peak properly located to correspond to an alternate position for O(5′B). Thus, two positions O(5′B) and O(5″B) were assigned to this terminal hydroxyl group with half occupancies.

Refinement was continued by full-matrix least-squares as above, except that besides the coordinates and isotropic temperature factors, occupancy factors were also refined for O(5′B), O(5″B), and W(2). For these atoms, only 20% of the calculated shifts were applied at each cycle to stabilize the convergence process. The occupancy factors converged to 0.40(5), 0.61(4), and 0.33(5) for W(2), O(5′B), and O(5″B), respectively. As total occupancy for O(5′B) and O(5″B) must be unity, the corresponding factors were normalized to 0.65 and 0.35, respectively, and kept constant in the subsequent steps of the refinement, whereas the occupancy factor of W(2) remained an adjustable parameter. The last steps were carried out by block-diagonal least squares. The hydrogens attached to C(8) and the ribose carbons were visible in the ΔF map and they were fixed at idealized positions (B = 6.0 Å^2, C—H = 0.95 Å). Their parameters were not refined, but their

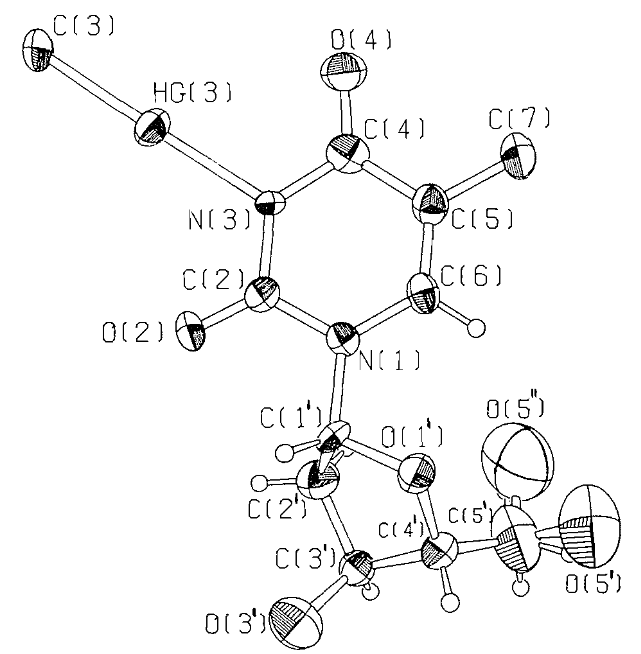

FIG. 1. ORTEP drawing of the CH_3HgT molecule B in the hydrated ($P2_12_12_1$) compound. Ellipsoids correspond to 50% probability. The two disordered positions for the terminal 5′ hydroxyl of molecule B are shown, O(5″) corresponding to the minor component (occupancy factor = 0.33(5)). No disorder is found for molecule A (anhydrous compound) and molecule C (hydrated compound).

coordinates were recalculated after each least-squares cycle. The methyl and hydroxyl hydrogens were not detected in the ΔF map. All non-hydrogen atoms were anisotropically refined and convergence was reached for R = 0.036, R_w = 0.038 and a goodness-of-fit ratio of 1.21. As a check on the validity of the occupancy factors for O(5′B) and O(5″B), extra cycle were calculated including the occupancy factors of these atoms in the refinement. The parameters of the remaining non-hydrogen atoms shifted by <0.05σ. The occupancy factor of O(5′B) and O(5″B) returned to the values found earlier (σ = 0.04), while their temperature factors changed slightly as expected. Therefore, the parameters obtained with the normalized values for these occupancy factors were retained. The general background in the final ΔF map was below ±0.9 e/Å^3. Some peaks near Hg were in the range ±0.9–1.2 e/Å^3.

The refined coordinates for both structures are listed in Table 1. Tables of temperature factors and structure factor amplitudes are provided in the supplementary material.[4] The form factors used were those of Cromer and Waber (10), except for hydrogen (11). The anomalous dispersion terms of Hg (12) were included in structure factor calculations. The programs used are listed elsewhere (13).

Results and discussion

Description of the structures

These two structures contain three non-equivalent CH_3HgT units: the hydrated compound consists of two independent molecules (B and C), whereas the molecules in the anhydrous form are all equivalent (type A). In all cases, the CH_3Hg^+ ion is

[4] Distances and angles in the thymidine ligands, tables of structure factor amplitudes, temperature factors, calculated hydrogen coordinates, least-squares plane calculations, distances and angles around oxygen atoms, as well as copies of the infrared spectra for both compounds may be purchased from the Depository of Unpublished data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

[a] Molecule A in the anhydrous compound ($P2_1$), B and C in the hydrated compound ($P2_12_12_1$).

bonded to the deprotonated N(3) site of the pyrimidine ring (Fig. 1), in the same manner as in the corresponding 1-methylthymine complex (7). The usual linear coordination of mercury is observed (Table 2). The departure from linearity in molecule C is significant (C(3C)—Hg(3C)—N(3C) = 176.8(7)°), although relatively small and not unprecedented. The Hg—N and Hg—C bond lengths (averaging 2.09(1) and 2.04(2) Å, respectively) correspond within experimental errors with those found in similar compounds (6, 7).

Linearly coordinated mercury usually forms a variable number of weaker bonds or contacts with donor atoms in the region of the equatorial plane (assuming the H_3C—Hg—N direction to be axial). In the present case, the carbonyl groups O(2) and O(4) fill some of the space in the equatorial region, and it is not clear whether these intramolecular Hg…O contacts (Table 3) have significant bonding character, even if some of them are below the 3.0 Å limit corresponding to the sum of the van der Waals radii (14). Indeed, the C=O…Hg angles are ~70°, and electron density along this direction is not expected to be high (15). The intramolecular Hg—O distances are shorter with O(4) than with O(2), and this would be consistent with the greater basicity of the former. However, these differences may simply reflect distortions imposed by packing on the tube-like CH_3Hg^+ group extending far into the structure. The best Hg…O contacts are intermolecular and they involve the O(1′) atom of the ribose rings: Hg(3B)—O(1′C) = 2.90(1) Å and Hg(3C)—O(1′B) = 2.89(1) Å. They play an important part in packing for the hydrated complex (*vide infra*).

The distances and angles in the pyrimidine rings are provided in the supplementary material. Within the experimental errors (σ ~ 0.02 Å on distances and ~1° on angles), they compare well with those of free thymidine (16). The six-membered ring is planar within 0.04 Å (4σ) for molecule A and within 0.01 Å

(1σ) for molecules B and C. In molecules A and C, the CH_3Hg^+ group significantly deviates from the plane. The atom-to-plane distances are Hg(3A), 0.1915(4); C(3A), 0.38(2); Hg(3C), 0.255(1); C(3C), 0.58(2) Å. This supports the existence of packing effects on this linear group, which would normally lie in the plane and form equal Hg—N—C angles. Other exocyclic atoms also depart from the plane of the ring, namely O(4A) (0.12(1) Å), C(1′B) (0.15(2) Å), and O(4C) (0.03(1) Å).

The conformation of the ribose portion in nucleosides has been discussed by Sundaralingam (17). The rings for the three complexes have a C(3′)-*exo* conformation, the C(3′) atom being 0.46(1), 0.53(2), and 0.30(2) Å above the C(1′)—O(1′)—C(2′)—C(4′) plane for molecules A, B, and C, respectively. The torsion angles given in Table 4 show that the conformation of thymidine is not drastically changed in the complexes. The relative orientation of the pyrimidine moiety with respect to the deoxyribose ring corresponds to the *anti*

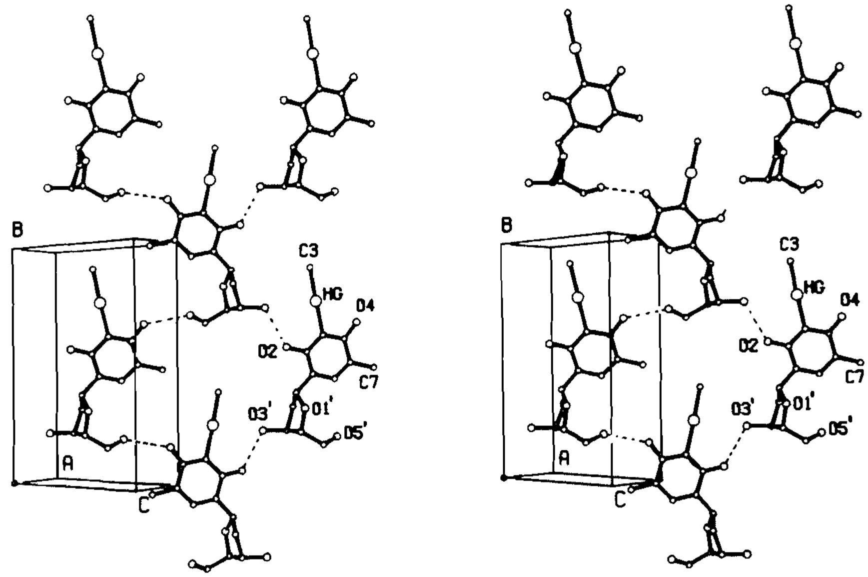

FIG. 2. Stereo view of the unit cell of the anhydrous compound ($P2_1$). The cell origin is shown as a black dot. Some atoms are labelled in one of the molecules. The others can be identified by comparison with Fig. 1. Dashed lines correspond to hydrogen bonds.

configuration as in thymidine, but the C(6)—N(1)—C(1′)—O(1′) angle spans a range of ±23° about the value of 39° found in thymidine. This angle is very sensitive to ring stacking and H-bonding. The orientation of the terminal O(5′) hydroxyl group is not a highly restricted variable in this structure, and the torsion angle about C(4′)—C(5′) seems to adjust to H-bonding opportunities.

A packing pattern for the anhydrous compound is shown in Fig. 2. The structure consists of layers in which each CH_3HgT molecule is anchored to four neighbors by strong hydrogen bonds (O...O = 2.74–2.77 Å) (Table 3). Each molecule provides two H-bond donors (O(3′A) and O(5′A) hydroxyl groups) and two acceptor sites (O(2A) and O(4A) carbonyl groups). These superimposed layers interact mainly by normal van der Waals contacts. The only particular contact involving Hg(3A) is established with an adjacent O(3′A) group at 3.09(1) Å, which is already strongly hydrogen-bonded with the O(2A) carbonyl oxygen.

In the anhydrous form, the O(1′) atom plays no particular role in hydrogen bonds or contacts with mercury. Its role is more important in the hydrated form. The structure can be described as irregular columns of molecules stacked along the *b* direction (Fig. 3). Molecules of type B alternate with molecules of type C along the column. They are grouped in pairs by means of two complementary Hg...O(1′) contacts of 2.89 Å. In both cases, the geometry is favorable: O(1′) lies near the equatorial plane of mercury, whereas the Hg—O(1′) direction defines roughly equal Hg—O(1′)—C(1′) and Hg—O(1′)—C(4′) angles. Between these pairs is found another pair of complementary Hg...O contacts, this time with O(4). They are longer (2.99 Å) than those with O(1′) and they compare well with those found for the columns of CH_3HgMT molecules in the crystal of the hemihydrate (7). B...C pairs belonging to adjacent columns are joined in the *a* direction (Fig. 3) by a pattern of four hydrogen bonds centered on the non-disordered water molecule W(1), acting as a donor to O(2C) and O(3′B), and as an acceptor from O(5′C). The pattern is completed with an extra O(3′B)—H...O(4B) interaction. Therefore, in the *ab* plane, cohesion is achieved through Hg...O contacts along *b*

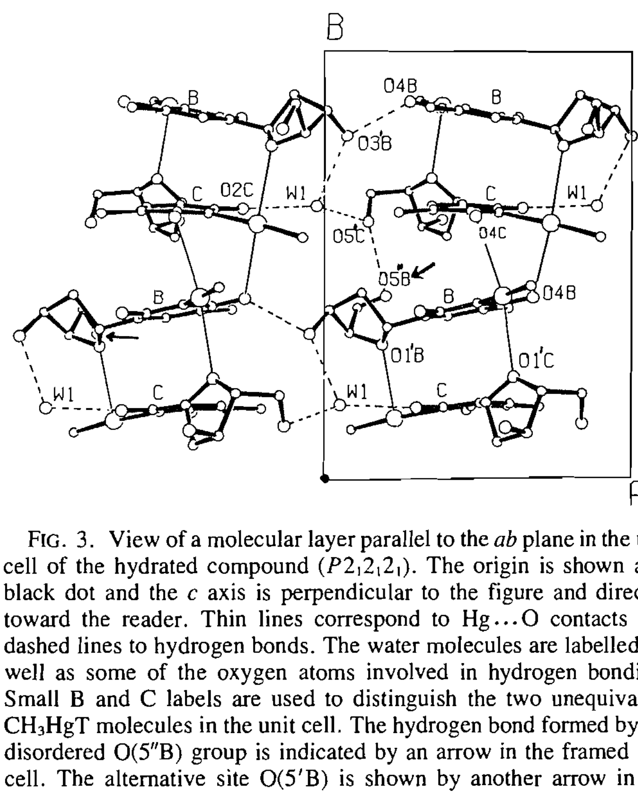

FIG. 3. View of a molecular layer parallel to the *ab* plane in the unit cell of the hydrated compound ($P2_12_12_1$). The origin is shown as a black dot and the *c* axis is perpendicular to the figure and directed toward the reader. Thin lines correspond to Hg...O contacts and dashed lines to hydrogen bonds. The water molecules are labelled, as well as some of the oxygen atoms involved in hydrogen bonding. Small B and C labels are used to distinguish the two unequivalent CH_3HgT molecules in the unit cell. The hydrogen bond formed by the disordered O(5″B) group is indicated by an arrow in the framed unit cell. The alternative site O(5′B) is shown by another arrow in the unframed unit cell.

and by hydrogen bonding along *a*. Part of the time, the O(5′) group of molecule B in its minor orientation O(5″B) contributes to cohesion within the columns by forming an O(5″B)—H...O(5′C) bond of 2.94(7) Å (indicated by an arrow in the framed unit cell, Fig. 3, right). It should be noted that in its major orientation O(5′B), this group assumes no particular role in the *ab* plane (see unframed cell, left of Fig. 3).

The columns along *b* and the intervening hydrogen-bond network define layers parallel to the *ab* plane, which are viewed down the *b* axis in Fig. 4. These layers are centered at

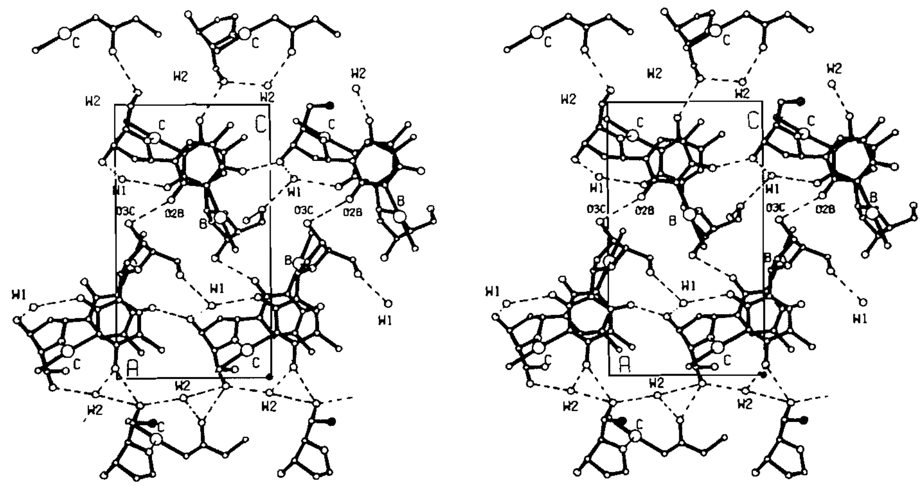

FIG. 4. Stereo view of the unit cell of the hydrated ($P2_12_12_1$) CH_3HgT compound down the b axis. The origin is indicated by a black dot. The b axis in perpendicular to the drawing and directed toward the reader. Hg...O contacts are shown as thin lines and hydrogen bonds as dashed lines. No disorder is present in the inter-layer region at $z \sim 1/2$. In the $z \sim 0$ (or ~ 1) region, occupancy for W(2) is only 0.37 and the O(5′) group of molecule B is disordered over the sites O(5′B) (occupancy 0.63, white spheres) and O(5″B) (occupancy 0.37, black spheres). All O...O contacts shorter than 3.1 Å are shown in the $z \sim 0$ region. The local hydrogen-bonding patterns proposed to explain the disorder are shown in the $z \sim 1$ region. An enlarged view of this region with atoms labelled is given in Fig. 5.

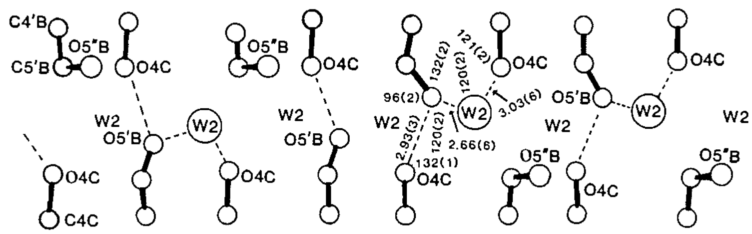

FIG. 5. Model proposed for the hydrogen-bonding pattern in the $z \sim 0$ (or ~ 1) inter-layer region of the unit cell of the hydrated compound. The circled W2 sites are those actually occupied.

$z \sim \frac{1}{4}$ and $\sim \frac{3}{4}$. They are symmetry equivalent, but the two inter-layer regions, at $z \sim 0$ (or ~ 1) and $\sim \frac{1}{2}$, respectively, are not. In the $z \sim \frac{1}{2}$ region, there is no disorder and besides normal van der Waals contacts, an O(3′C)—H...O(2B) hydrogen bond of 2.85(2) Å provides packing interactions.

The other inter-layer region is more complex. All the atomic positions for W(2), O(5′B), and O(5″B) are shown in the $z \sim 0$ layer in Fig. 4, together with the O...O contacts shorter than 3.1 Å. The occupancy values are 0.40, 0.65, and 0.35 (σ = 0.05), respectively, for these three atom types. Interpretation in terms of local hydrogen-bonding patterns is not unambiguous. We are retaining the following model, which is based on the fact that the occupancy factors for W(2) and O(5″B) are not significantly different. The average value (0.37) will be used for both in the following discussion. We are also assuming that the occupancy of these two sites is correlated, that is, the occupancy of a W(2) site (37% of the time) forces the O(5″B) orientation for an equal number of terminal O(5′) groups in B molecules. The assumed pattern is shown in the right portion of the $z \sim 1$ layer (Fig. 4), which is schematically represented in Fig. 5, with atom labels, distances and angles. A link in created between two O(4C) carbonyl groups by means of a W(2) water molecule and an O(5′B) hydroxyl group. The angles are all favorable and the W(2)—H...O(5′B) interaction of 2.66(6) Å is particularly strong. Another nearby O(5′B) position at 3.03(6) Å from the same W(2) molecule is not in a favorable orientation to hydrogen bond. This hydroxyl group is assumed to possess the O(5″B) orientation, thus forming a hydrogen bond with O(5′C) in the b direction as discussed earlier (Fig. 3), with an O...O separation of 2.94(7) Å and more favorable angles. When the O(5″B) site is occupied, the next W(2) molecule is deprived from its best hydrogen-bonding partner and, for this reason, this W(2) site would be vacant. This is the basic unit of the hydrogen-bond pattern.

In this unit, half of the W(2) sites are occupied. As the occupancy factor of W(2) is less than 0.50, there must be gaps between the units as they are repeated along c. If every fifth W(2) site is also vacant, as shown in Fig. 5, the vacant (V) and occupied (O) W(2) sites would be distributed along c as follows:

—(O—V—O—V)—V—(O—V—O—V)—V—

This would correspond to 0.40 occupancy for W(2), and also for O(5″B) since the presence of a W(2) molecule is assumed to force the O(5″B) orientation for the adjacent hydroxyl group. In fact, these occupancies are slightly lower (0.37), indicating that the gaps occur, on the average, slightly more often than 20% of the time. It should be noted that the present model does not imply a periodic pattern: strings of successive units without gaps may be longer than 2, and the gaps may consist of more than one missing W(2) molecule.

The above discussion takes care of only some of the O(5′B) sites, those which are part of the basic unit defined above (i.e. 0.37). The remaining O(5′B) sites are those facing the gaps, where consecutive W(2) sites are vacant. this is represented in Fig. 4 (layer $z \sim 1$, left) and in Fig. 5 (middle). In this case,

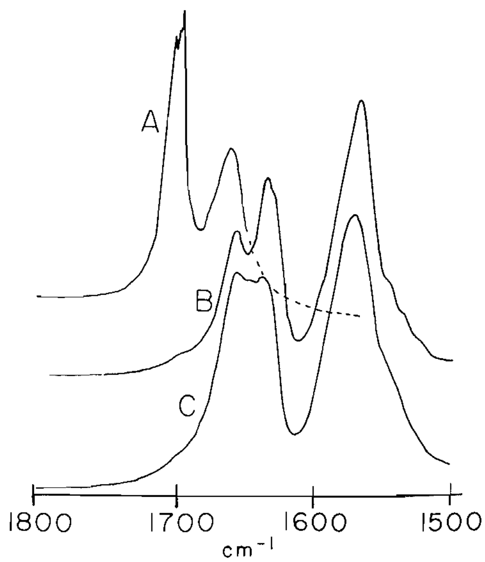

FIG. 6. Infrared spectra (1800–1500 cm^{-1}) of thymidine (A) and the methylmercury complexes (B = anhydrous $P2_1$ form; C = hydrated $P2_12_12_1$ form).

the hydroxyl group occupying an O(5′B) site is hydrogen-bonded to O(4C) as it is within the basic unit, but does not participate in other H-bonding interactions.

Infrared spectroscopy

The infrared spectra of thymidine and its CH_3Hg^+ complex are compared in Fig. 6 and Table 5. Copies of the spectra are provided in the supplementary material.[4]

The vibrations of the pyrimidine and sugar units have been discussed by several authors (18–21). However, owing to the absence of a detailed analysis for thymidine itself, the present discussion will be restricted to a few spectral features found to be useful as diagnostic for N(3) complexation in the methyl–thymine system (22).

The presence of the CH_3Hg^+ group is evident from the characteristic methyl C—H stretching band at 2925 cm^{-1}, which has become the dominant feature in the ν(C—H) region for the complexes. The medium band at 1202 cm^{-1} probably originates from the $\delta(CH_3)$ mode of the same group. The $\rho(CH_3)$ (~800 cm^{-1}) and Hg—C modes (~560 cm^{-1}) usually observed in infrared (22) are masked here by ligand bands.

The spectra show that the N(3)—H proton has been substituted. The broad absorption underlying the ν(C—H) region for thymidine (2600–3400 cm^{-1}) and containing a contribution (~3100 cm^{-1}) (22) from ν(N—H) motion, is removed from the spectra of the complexes. The remaining strong band in this region arises from the deoxyribose OH groups (and water molecules). The disappearanc of the γ(N—H) mode simplifies the spectrum at ~900 cm^{-1}, but the presence of deoxyribose bands in this region complicates the analysis. As to the δ(N—H) mode, it has been calculated to occur ca. 1453 cm^{-1} and thymidine indeed contains a band at this position, which disappears in the complexes. Another nearby band is shifted from 1477 to 1464 cm^{-1} by complexation. Similar displacements have been noted in Raman upon CH_3Hg^+ complexation of uridine (4) and TMP (2), and in infrared and Raman, for 1-methylthymine (22). This shift could be due to loss of coupling with N—H motion for a ring mode.

The 1500–1800 cm^{-1} spectral region (Fig. 6) is devoid of strong absorptions from the sugar moiety. Free thymidine shows a triplet at 1704 cm^{-1} mainly due to C(2)=O(2) stretching (18, 23). A broad band at 1650, together with a weak component at ~1630 cm^{-1} (masked here, but observed in D_2O solutions of TMP (2)) originate mainly from coupled motion of the C(5)=C(6) and C(4)=O(4) bonds. The changes introduced by complexation have been discussed in the case of 1-methylthymine (22). Three well-separated bands are observed at 1639, 1618, and 1579 cm^{-1}. The latter band is believed to arise mainly from the C(4)=O(4) bond, having lost some double bond character. A similar effect on C(2)=O(2) produces a negative shift of the absorption originally found at 1704 cm^{-1} in thymidine, so that the pair of bands at 1639/1618 cm^{-1} results from coupled C(5)=C(6) and C(2)=O(2) motions.

A few spectral changes are in good agreement with those observed in the Raman spectra of similar systems. For instance, a weak, but clearly observed, band of thymidine at 1254 cm^{-1} seems to shift to higher wavenumber and coalesce with the strong 1288 cm^{-1} band for the complexes. Similar shifts were observed in Raman for TMP (1239 to 1247 cm^{-1}) (2) and 1-methylthymine (1241 to 1262 cm^{-1}) (22). Another example is the disappearance of the band at 1172 cm^{-1}, possibly centered in the N(1)—C(1′) glycosidic bond (21), which is apparently displaced to 1145 cm^{-1}. Similarly, a band at 1172 cm^{-1} disappears from the Raman spectrum of TMP after complex formation, whereas significant intensity increase is noted at 1140 cm^{-1} (2).

The presence of water in the hydrated compound produces a $\delta(H_2O)$ peak at 1649 cm^{-1} (spectrum C, Fig. 6), superimposed on the double bond stretching bands. Besides, a doublet at 947/934 cm^{-1} for the anhydrous compound occurs as 933/928 cm^{-1} in the hydrated complex. This spectral region contains several bands originating from the deoxyribose unit (20, 21) and the observed shift reflects the difference in hydrogen bonding in the two compounds.

Conclusion

Both forms of the present CH_3Hg—thymidine compound show the characteristics already noted for the analogous 1-methylthymine compound (7), namely, binding to the deprotonated N(3) site and minimal interactions with the adjacent carbonyl groups. The oxygen donors in the deoxyribose moiety do not affect this general behavior, thus confirming the low affinity of CH_3Hg^+ for this component of DNA. The same solid phases were obtained in all our attempts to prepare "adducts" with $NaNO_3$, $NaClO_4$ and other salts, which had been found to form such "adducts" with the CH_3Hg–methylthymine complex (7, 8). This suggests that carbonyl groups forming H-bonds with deoxyribose hydroxyl groups provide good stabilization to the crystal and that their affinity for hard cations like Na^+ is not very strong.

Composite ZSM-5 zeolite/asbestos catalysts

RAYMOND LE VAN MAO,[1] PIERRE LÉVESQUE, BERNARD SJIARIEL, AND PETER HANS BIRD
Concordia University, Department of Chemistry, 1455 de Maisonneuve Blvd. West, Montreal, P.Q., Canada H3G 1M8

Received April 30, 1985

RAYMOND LE VAN MAO, PIERRE LÉVESQUE, BERNARD SJIARIEL, and PETER HANS BIRD. Can. J. Chem. **63**, 3464 (1985).

A procedure has been developed which allows growth of the zeolite ZSM-5 in chrysotile (asbestos) fibers which have previously had magnesium partially leached out. The resulting materials, when used as catalysts in the conversion of methanol into hydrocarbons showed very interesting product selectivities: i.e., (*a*) at high magnesium leaching degree (MLD), relatively larger amounts of aromatics and isoparaffins were produced; and (*b*) at low MLD, light olefins were the main products in the gaseous phase.

From NH_3 absorption/temperature programmed desorption studies, it was suggested that at lower MLD (higher magnesium content) the dual acidic and basic adsorption sites were responsible for the enhanced production of light olefins from methanol conversion.

RAYMOND LE VAN MAO, PIERRE LÉVESQUE, BERNARD SJIARIEL et PETER HANS BIRD. Can. J. Chem. **63**, 3464 (1985).

On a développé un procédé de cristallisation de la zéolite ZSM-5 dans les fibres d'amiante chrysotile dont une partie du magnésium a été lixiviée. Le matériel résultant, utilisé comme catalyseurs de conversion du méthanol en hydrocarbures, présente d'intéressantes sélectivités en produits; c'est-à-dire: (*a*) à un haut degré de lixiviation (MLD), les aromatiques et les isoparaffines se forment en quantités relativement larges; et (*b*) à un MLD inférieur, les oléfines légères sont les produits principaux dans la phase gazeuse.

Des études d'adsorption et de désorption à température programmée de l'ammoniac, il a été suggéré qu'à un MLD inférieur (ou à un contenu supérieur en magnésium), les sites acides et basiques en "duo" étaient responsables de cette augmentation de production des oléfines légères à partir du méthanol.

Introduction

The zeolite ZSM-5 has received great attention in recent years because of its high shape selectivity in many industrially important reactions. These include xylene isomerization, toluene disproportionation, aromatic alkylation, and methanol conversion to gasoline (1). The shape selectivity is attributed to its tridimensional channel network, and a pore size intermediate between the small pore (A type) and large pore (X and Y type) zeolites.

Doping or coating the pure ZSM-5 zeolite with inorganic materials can lead to an enhanced product selectivity (2, 3). The same phenomenon was observed by aggregation of the ZSM-5 microcrystals (4). Effects at the pore openings were suggested (4).

In the present paper, the preparation of a composite ZSM-5 zeolite/asbestos catalyst is described. It consists of partially leaching the magnesium out of the chyrsotile asbestos fibers and then growing the ZSM-5 zeolite into the leach asbestos macrostructure (5).

The composite catalysts were characterized by usual physico-chemical techniques and were tested in the catalytic conversion of methanol. The data for some "ZSM-5/asbestos" catalysts were compared to data obtained by using pure ZSM-5 catalysts with similar characteristics.

Experimental

Preparation of the catalysts (5)

Chrysotile fibers were first subjected to the Mg leaching operation. Mineral and organic acids were used as leaching agents. In general, the asbestos fibers (7 TF-12 short fiber grade[2]) were digested with a mineral acid solution (usually HCl) at 80°C for several hours. After dilution with cool water, the suspension was allowed to settle for a while, then filtered, washed with water and finally dried at 120°C. The experimental parameters for the preparation of the leached asbestos (Alix) are reported in Table 1.

The resulting solid materials (Alix) were mixed with aqueous solutions containing tetrapropylammonium bromide (TPA, Br), NaOH, and sodium aluminate in proportions shown in Table 2. The suspensions were loaded in an autoclave and heated at 170°C (±5°C) for 10 days. After unloading, the suspensions were filtered and the solids were washed thoroughly with distilled water, dried, and finally calcined at 550°C for 10 h. Thereafter, the solids were submitted to NH_4^+ ion-exchange using NH_4Cl aqueous solution (1 *M*). The NH_4^+ forms when activated at 550°C for at least 10 h, yielded the acid forms (or H-forms) of the catalysts.

The acid forms of the catalysts were intimately mixed with bentonite (20% by weight) and made into pastes with water. The pastes were pressed into 1 mm od extrudates.

Physico-chemical characterization

Elemental analysis, X-ray diffraction powder pattern determination, scanning electron microscopy (SEM), the adsorption of water and *n*-hexane, and the adsorption/temperature programmed desorption of ammonia, were techniques used to characterize our samples.

(a) Elemental analysis

Common techniques via atomic absorption were used for Si, Al, Na, Mg, and Fe concentration measurements.

Two derived quantities were particularly significant.

The first, the magnesium leaching degree (MLD), is defined as:

$$(\mathrm{MLD}) = \frac{(\mathrm{MgO})_i - (\mathrm{MgO})_f}{(\mathrm{MgO})_i} \times 100\ (\%)$$

where $(MgO)_i$ and $(MgO)_f$ are, respectively, the initial and final magnesium contents (on the dried oxide basis).

The second is the (Mat/Al) atom ratio:

$$(\mathrm{Mat/Al}) = \frac{(\mathrm{Si}) + (\mathrm{Al}) + (\mathrm{Na}) + (\mathrm{Mg}) + (\mathrm{Fe})}{(\mathrm{Al})}$$

where (Si), (Al), (Na), (Mg), (Fe) are the numbers of atoms of each element in a dehydrated sample.

In the case of our composite catalysts, this ratio can be seen as proportional to the reciprocal of the aluminum atom concentration, and thus acid site concentration.

*Silica gel Baker: (1) = 60% in SiO_2; (2) = 90% in SiO_2; (3) the product was dried 12 h at 120°C and then further 12 h at 550°C.

TABLE 3. *n*-Hexane and water adsorption = operating conditions

Adsorbate	Critical diameter (Å)	Vaporization temperature (°C)	Vapor pressure (Torr)	Adsorption temperature (°C)	Time required
n-Hexane	4.9	0	45	25	3 h
Water	2.8	22	22	25	Overnight

$$(\mathrm{Mat/Al}) = \frac{\text{constant}}{(\mathrm{Al})} \simeq \frac{\text{constant}}{(\mathrm{H^+})}$$

The (Mat/Al) atom ratio is equivalent to the (Si/Al) ratio commonly used for pure zeolites.

(b) X-ray powder diffraction

The ZSM-5 zeolite was identified by means of its characteristic of diffraction pattern (6). The degree of crystallinity (DC) in ZSM-5 zeolite structure of the samples was determined by a procedure similar to that of Kulkarni *et al.* (7). However, to ensure that the measurement did not depend on sample preparation, we used $BaCl_2$ as internal standard: this compound exhibits a strong diffraction peak at 2θ = 31.0–32.5°. The pure ZSM-5 zeolite sample (HP-38) was assigned a 100% value of crystallinity.

(c) Scanning Electron Microscopy (SEM)

Using the Hitachi Model S-20 SEM, it was possible to follow the morphological change of our samples: original asbestos fibers → leached fibers (Alix) → ZSM-5/asbestos catalyst. The SEM observations were necessary for ascertaining that our samples were not simply mechanical mixtures of "ZSM-5" and "unconverted asbestos".

(d) Adsorption of water and n*-hexane*

The adsorbates used were water and *n*-hexane. The technique adopted has been described elsewhere (8, 9). The operating conditions are reported in Table 3. Adsorption measurements were done on both the catalyst H-forms, and the magnesium leached asbestos (Alix) which had been used for the catalyst preparation. The relative adsorption affinity index (RAI) was defined as the volume ratio of adsorbed *n*-hexane to adsorbed water in zeolites. This index was used to evaluate the hydrophobic character of the ZSM-5 based materials (8–10).

(e) Adsorption/temperature programmed desorption of ammonia (A/TPD)

In order to study the acid strength and density of our samples, ammonia was adsorbed on the catalyst (final form) at 373 K and at room temperature, and then desorbed in a temperature programmed way (up to 723 K, heating rate = 5 K/min). The procedure used was similar to that described in reference (11). To minimize the phenomenon of physi-sorption, most likely with the adsorption performed at room temperature, vigorous flushing with nitrogen was carried out prior to the desorption phase. During the NH_3 desorption operation, the nitrogen stream which carried the desorbed ammonia was bubbled into a solution of diluted HCl. After the desorption step, this HCl solution was titrated with NaOH and the amount of NH_3 desorbed was calculated knowing the NaOH titer, and original HCl concentration. The amount of ammonia adsorbed at 100°C and then desorbed was believed to be related to acid sites of medium and strong character (11), while that adsorbed at room temperature should be related to the overall acidity which should include indeed weak sites.

Catalytic experiments

Catalytic tests were performed by injecting methanol using an injection syringe on an infusion pump into a methanol vaporizer gas mixer. Nitrogen gas was supplied to the methanol vaporizer and gas mixer from a cylinder connected in-line with a flowmeter. The vaporized methanol was then carried by the nitrogen gas through a catalyst bed set in a catalytic reactor contained inside an oven which was thermoregulated. A chromel–alumel thermocouple was placed in the catalyst bed and was used, in conjunction with a digital thermometer unit, to monitor the temperature of the catalyst bed. The gaseous mixture flowing out of the catalytic reactor was run through a series of condensors maintained at 5–10°C, to a liquid collector immersed in an ice bath followed by a cylinder from which gas sampling was carried out.

Following a pre-run of 10 min, the liquid products were collected and the gaseous ones were analyzed periodically by gas chromatography using a 3.5 m long column packed with Chromosorb P coated with 20% by weight of Squalane. The GC used was a dual FID Hewlett-Packard Model 5790. It was equipped also with a capillary column (length: 50 m; PONA type fused silica coated with a cross-linked polymer) which was used for accurate analyses of the liquid fractions after a run was completed. The composition of the aqueous layer was also determined by gc using a methanol in water calibration standard.

Table 4 reports the reaction conditions used in the experiments.

TABLE 4. Reaction conditions

$$\text{W.H.S.V.} = \frac{\text{g of injected methanol per hour}}{\text{g of catalyst}}\ (h^{-1})$$

Results and discussion

Table 5 reports the main physico-chemical characteristics of the sample studied. In this table, the label HA represents catalysts prepared from the 7T12 asbestos fibers and HP stands for catalysts made from pure ZSM-5 zeolite. The characteristics shown are: the magnesium leaching degree (MLD) in % wt/wt, the (Mat/Al) atom ratio, the iron content FC (% by weight), the degree of crystallinity, DC, in %. Table 6 reports the sorptive capacities, in % wt/wt, and in particular the RAI values, of our samples and of their Alix precursors. Table 7 reports the acidity measurements (as obtained through ammonia adsorption and desorption) of our samples and their alix precursors. Figures 1, 2, and 3 are the electron micrographs of samples (acid form) HA-39, HA-49, and HA-48, respectively (with magnifications as indicated).

Tables 8 and 9 report the catalytic conversion and product selectivities of all our catalysts at 400°C, and of the HP-38 and HA-60 samples at various temperatures, respectively. The methanol conversion is the C atom based yield in hydrocarbons. The balance (in C atoms) includes volatile gases (CO_2, H_2, etc.), dimethyl ether and methanol found in the liquid phase and C deposited onto the catalyst.

It can be expressed as follows:

$$\text{Conversion} = \frac{(NC)_{Prod}}{(NC)_{feed}} \times 100$$

where $(NC)_{feed}$ is the number of C atoms in the (methanol) feed and $(NC)_{Prod}$ is the number of C atoms in the (hydrocarbon) products.

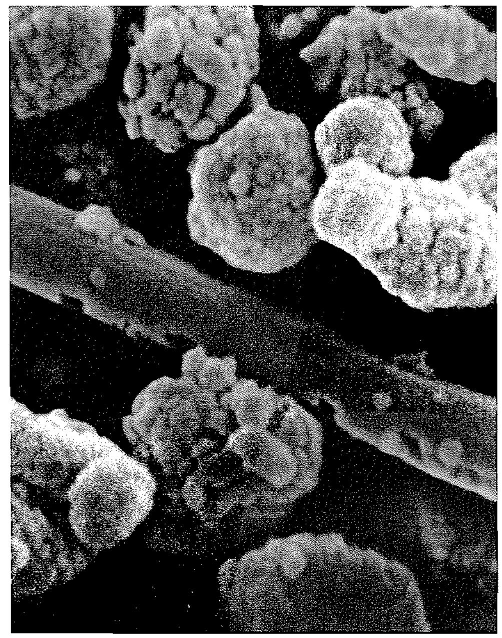

FIG. 1. SEM of the HA-39 sample (MLD = 97%). Magnification ×20 000.

The product selectivity is expressed as follows:

$$\text{PS (\%)} = \frac{\Sigma_i C_i}{\Sigma C} \times 100$$

where ΣC and $\Sigma_i C_i$ are the sums of all hydrocarbons produced and of the selected products, respectively.

If we compare the degree of crystallinity in the ZSM-5 zeolite structure, and the (Mat/Al) ratio of our samples, they are very close to each other. Scanning electron microscopy studies showed that while the leached asbestos (Alix) kept the fibrous form of the original chrysotile asbestos even at a high magnesium leaching degree (Alix 001/2, MLD = 98%), the composite ZSM-5/asbestos samples had a clearly degraded structure. Submicron ZSM-5 zeolite particles were embedded in the asbestos remnants, which resembled blocks, a few microns in size (see Figs. 1, 2, and 3). Moreover, these submicron zeolite particles decreased in size as the magnesium leaching degree decreased (approximate size of ZSM-5 particles in the HA-60 sample (80% MLD) = 0.02 micron). The RAI values decreased at lower MLD (see Table 6). This suggested that the

* Expressed in 10^{-4} mol of NH_3/g of catalyst.
† Z_a/Z_{Al} is the ratio of the molar amount of NH_3 adsorbed to the molar amount of Al present in 1 g of catalyst.
‡ With HP and HA samples = circa 95% NH_3 desorbed at 423–473 K and circa 5%, at 673–723 K.

hydrophobicity of the composite catalyst was closely dependent upon the magnesium content, e.g. a higher magnesium content, a lower hydrophobicity. A similar behavior observed with the Alix samples strongly supports this statement (Table 6). With the composite samples, the NH_3 adsorption was higher at lower magnesium leaching degree both for room temperature and 100°C operations while the Alix samples exhibited low adsorption of NH_3 (see Table 7). This behavior of the composite catalysts could not be accounted for on the basis of an enhanced acidity due to the formation of a larger amount of mixed oxides (SiO_2–MgO) at low MLD, although acidity was said to exist in mixed oxides (e.g. SiO_2–MgO) (12). Increased NH_3 adsorption at low MLD was better related to the presence of basic sites (from MgO) along with the acid sites. (The Bronsted sites were probably located on the external surface of the zeolite particles. The amount of such acid sites increased with the external surface area and corresponding particle size decrease, e.g. at low MLD as observed through the SEM.) In fact, NH_3 was expected to be dissociated into $\bar{N}H_2$ and H^+ when adsorbed onto both basic and acidic sites (12) (see also Fig. 4). Upon heating, these species would recombine and be desorbed as gaseous NH_3. Such an increased NH_3 adsorption was not observed with the Alix samples because they had only basic sites. No acid sites existed which could adsorb the $\bar{N}H_2$ species from the dissociated ammonia.

Table 8 shows that when the MLD was higher than 90%, the composite catalysts exhibited catalytic properties quite similar to those of a pure ZSM-5 based catalyst. However, when the MLD was less than 90%, more light olefins were produced at the expense of the paraffins (primarily) and the aromatics. A possible explanation could be the effect of the smaller zeolite particles at higher MLD, in provoking the lack of selectivity (to hydrocarbons higher than light olefins) in the reaction. However, it seems unlikely that a small change in crystallite size could

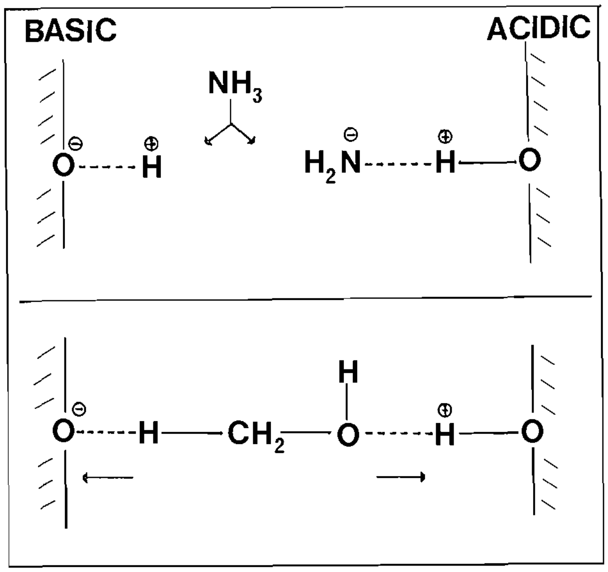

FIG. 4. Effects of simultaneous presence of acidic (zeolite) and basic sites (MgO) on NH_3 adsorption and on methanol conversion into olefins.

bring about such a large variation in the product spectrum (see Table 8).

Thus a possible explanation should be found in the two most probable effects of MgO on the Bronsted acid sites which were mainly located on the external surface of the tiny zeolite particles embedded in the asbestos remnants.

The first effect of the MgO could be a "partial neutralization" of the acid sites with a subsequent decrease in the medium and strong acidity (see Table 7, column "temperature 100°C", cases of samples HA-39 and HA-45 with 97% and 94% as MLD, respectively; e.g. low Mg contents). Such a MgO effect was fairly well supported by the fact that, though the acid sites were located at the external surface of the zeolite particles (e.g. there was no beneficial effect in terms of coking prevention, from the shape-selective framework of the ZSM-5 zeolite), the carbon deposit onto the composite catalysts was very low (less than 1% wt/wt for 4-hour runs at 400°C) while the pure ZSM-5 based catalyst like the HP-68 received about 2% wt/wt of coking under the same reaction conditions. This seemed to be in fair agreement with the work of Chang *et al.* (13) which showed an increased production of light olefins with a decreasing Bronsted acidity (high SiO_2/Al_2O_3).

However, according to our ammonia adsorption data (Table 7), composite catalysts which were very selective in olefin formation (MLD lower than 90%) exhibited also a high NH_3 adsorption both at room temperature and at 100°C. Such a phenomenon could be explained by a dissociative adsorption of NH_3 on dual acid-basic sites (see Fig. 4). The regular distribution of the MgO sites facing the SiO_2 sites in the original asbestos fibers could be assumed to remain non significantly changed when Bronsted acid sites (H^+--^-Al) were introduced into the zeolite particles following the crystallization of the SiO_2 component of the asbestos. Therefore, a plausible explanation, different from the "acid–base neutralization" and which could be applied to our data has been given by Swabb and Gates (14) who studied the dehydration of methanol over H-mordenite at 155–240°C, and detected traces of olefin at 240°C. Olefin formation was explained by an α-elimination mechanism (see also the mechanistic review by Chang (15)) and the methanol bond scission was said to be facilitated by cooperative action of acidic and basic sites in the zeolite lattice (14) (see Fig. 4). This mechanistic view could bring our catalytic data over methanol, very close to ammonia sorption results: basically, methanol does not greatly differ in terms of adsorption from ammonia.

Conclusion

With pure ZSM-5 based catalysts, for the conversion of methanol, olefins were regarded as the initial products followed by their conversion into paraffins and aromatics (16) and their production was mainly related to the existence of acid sites having a certain acid strength (17). However, the high olefins yield observed with our composite ZSM-5 (asbestos catalysts having a magnesium leaching degree less than 90% (see Tables 8 and 9)) could be better explained by the simultaneous presence (in addition to the acid sites inside the zeolite pores) of acid sites on the external surface of the small zeolite particles and of basic sites due to the MgO of the asbestos remnants. This interaction led to the formation in larger yields of olefins which did not undergo further transformation. This hypothesis of the dual presence of acidic and basic sites was strongly supported by greater adsorption of ammonia on these composite catalysts which had higher MgO contents. Such an enhanced NH_3 sorptive behavior was not observed either on leached asbestos precursors (Alix) (only basic sites due to the MgO) nor on pure ZSM-5 (large sized crystals with no basic sites). The regular increase in olefins formation and in ammonia adsorption which was parallel to the regular decrease in zeolite particle size (i.e., a parallel increase in zeolite external surface in contact with the asbestos remnants) suggested a strong interaction of the "microstructural" support (asbestos remnants) and the sub-micron size zeolite particles. Therefore, these phenomena were quite different from the effects observed with the ZSM-5 zeolites on which Mg (18) or P (18, 19) was deposited. These Mg or P bearing zeolites were very selective to the *para*-isomer in the alkylation reaction of alkylaromatics probably due to a change in diffusion resistance (18, 19).

Moreover, the microstructural support (asbestos remnants) could "bear" transition metal ions leading to a composite catalyst which was found to be very selective to the simultaneous production of olefins and aromatics (20).

Pd/SiO_2–$AlPO_4$ systems. Influence of the preparation variables on their catalytic activity[1]

A. ALBA, M. A. ARAMENDIA, V. BORAU, C. JIMENEZ, AND J. M. MARINAS
Department of Organic Chemistry, Faculty of Sciences, Córdoba University, 14005-Córdoba, Spain

Received June 25, 1984[2]

A. ALBA, M. A. ARAMENDIA, V. BORAU, C. JIMENEZ, and J. M. MARINAS. Can. J. Chem. **63**, 3471 (1985).

A study on the liquid phase hydrogenation of cyclohexene over a series of Pd catalysts supported on various SiO_2–$AlPO_4$ systems (using a concentration of 2.47 *M*, with methanol as solvent, the initial hydrogen pressure is 5 bar and reaction temperature 300 K) is reported in this paper. The reaction has been studied as a standard in order to determine the most suitable preparation conditions for these catalysts.

We have also studied the influence of other factors such as the kind of support, the nature of the metal precursor, the previous calcination of the precursor, the addition of alkaline hydroxides, and the catalyst reduction with various agents, on the catalytic activity of different Pd-supported systems.

A. ALBA, M. A. ARAMENDIA, V. BORAU, C. JIMENEZ et J. M. MARINAS. Can. J. Chem. **63**, 3471 (1985).

On a étudié l'hydrogénation en phase liquide du cyclohexène sur un série de catalyseurs de Pd supportés par divers systèmes de SiO_2–$AlPO_4$ (utilisant une concentration de 2,47 *M*, le méthanol comme solvant, une pression initiale d'hydrogène de 5 bar et une température de réaction de 300 K). Cette étude a été réalisée comme modèle pour déterminer les conditions les plus appropriées pour la préparation de ces catalyseurs.

Nous avons aussi étudié l'influence de faceurs tels que la nature du support, la nature du précurseur du métal, les calcinations antérieures du précurseur, l'addition d'hydroxydes alcalins et la nature des agents de réduction du catalyseur sur l'activité catalytique de divers systèmes catalytiques portant du Pd.

[Traduit par le journal]

Introduction

The catalytic activity of a supported metal depends on a series of variables such as the texture, acid–base and redox properties of the supports used, as well as on the metal dispersion, metal–support interaction, etc. On the other hand, most of these characteristics depend, in turn, on the conditions used in the preparation of the metal-supported catalyst.

In this context, several authors have studied the effect of the preparation procedure on the surface properties of various metal-supported catalysts. Thus, Hyde and Rudhan (1) have recently reported on rhodium supported on γ-alumina, and Hanika *et al.* (2) have studied the relationship between the preparation conditions and the activity of supported platinum catalysts.

In earlier papers we have shown the usefulness of aluminium orthophosphate ($AlPO_4$), $AlPO_4$–Al_2O_3, and SiO_2–$AlPO_4$ systems as supports for dispersed metals such as Ni (3, 4), Pd (5, 6), Pt (7, 8), and Rh (9, 10). Since these supports have acidic and basic sites likely to take part in the catalytic process, the metal systems are bifunctional catalysts which can act simultaneously as acid–base or metal catalysts able to catalyze both C—C bond cleavage (11) and hydrogenation (or dehydrogenation) of hydrocarbons.

On the other hand, it has been pointed out that the catalyst activity might be determined by the interaction between metal particle and support, which is known as the "support effect" (12).

As for nickel supported on phosphate-containing materials such as aluminium phosphate (13), mixed alumina–aluminium phosphate (14), and mixed magnesia – alumina – aluminium phosphate (15), it has been proved that these systems suppress the hydrogen chemisorption characteristic of a strong metal–support interaction (SMSI) state.

We have shown (4, 16) that for nickel, the metal–support interaction follows the trend

$$Ni/SiO_2 < Ni/SiO_2\text{–}AlPO_4 < Ni/AlPO_4$$

We have recently studied in our laboratory (17) the hydrogenation of 1-hexene following several procedures for preparing the Ni/$AlPO_4$ supported catalysts and comparing the tendency of various precursors to yield different crystallite diameters for the catalyst. On the other hand, the prior impregnation of the support with alkali cations greatly influences the catalyst activity, with no change in the real rate of the catalyzed reaction.

This paper deals with the liquid-phase catalytic hydrogenation of cyclohexene as a standard reaction which Boudart and co-workers (18) have convincingly shown to be structure-insensitive, and which we have studied by hydrogenation over new Pd catalysts supported on SiO_2–$AlPO_4$.

The purpose of the present study is to systematically investigate the effect of various pretreatment steps and controllable preparation variables on the catalytic activity of the resulting systems. Among these variables, we have taken into account the kind of support, the nature of the metal precursor (either inorganic salts or organometals), the addition of alkaline hydroxides, the calcination or the lack thereof prior to the metal reduction and its nature (either with hydrogen or by various chemicals).

Experimental

Supports

Supports denominated APS_1, APS_2. APS_3, and APS_4 have been synthesized by procedures reported elsewhere (19, 20). They consist of SiO_2–$AlPO_4$, 80:20 in weight, and their texture properties, summarized in Table 1, have been described previously.

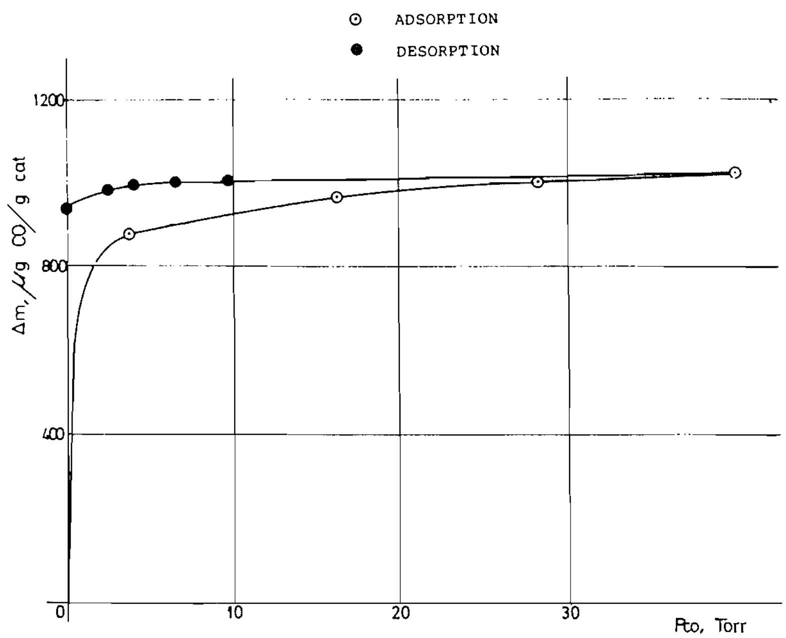

FIG. 1. CO adsorption–desorption isotherm for catalyst $Pd_{0.68}S^+$ C.

Support AP is made of pure aluminium phosphate synthesized as reported in ref. 21. A summary of its texture properties has been included in Table 1.

The silica used was supplied by Merck, ref. 7734. All supports were sieved through 70-230 mesh.

Metal systems

Catalysts have been obtained either by impregnation or by ion exchange.

Catalysts $Pd_{0.68}S^+$, Pd_xAPS^+, and $Pd_{0.97}AP^+$ have been synthesized by cation exchange between $Pd(NH_3)_4^{2+}$ and the corresponding support: S, APS_x, AP (see above); catalysts Pd_3 support K, N, M, O, P, and Q have been obtained by impregnation of the corresponding support with a solution of $PdCl_2$, $Pd(NH_3)_4^{2+}$, Na_2PdCl_4, $Pd(NO_3)_2$, palladium(II) acetylacetonate and palladium(II) acetate, respectively, with H_2O as solvent for the first three reagents and *N*,*N*-dimethylformamide for the rest. In all cases, the subscripts in the labels of the catalysts stand for the metal loading (% weight).

The precursor systems were dried at 393 K for 24 h, then heated from 293 K in air at a constant heating rate of 1 deg min^{-1}, the final temperature being kept constant for 15 min. A similar treatment up to and at 573 K in a hydrogen stream (60 mL min^{-1}) was then given. When naming the catalysts, C and NC stand for samples calcined or uncalcined before reduction, respectively. The type and amount of alkaline hydroxide added (NaOH, KOH, etc.) is also indicated.

When the metal precursor has been chemically reduced, the reducing agent used in each case is indicated.

Chemicals

All chemicals were either Fluka or Merck puris.

Procedure

Specific area and pore volume

The specific surface area (S_{BETN_2}, A_{N_2} = 16.2 Å^2) of the supports was determined on a volumetric adsorption apparatus. The pore volume was obtained from the desorption branch of the nitrogen adsorption–desorption isotherm, following the Innes method as modified by Lippens *et al.* (22). An average pore radius ($\bar{r}_p$, Table 1) was obtained directly from the experimental plots.

Metal loading

The chemical analysis of the metal loading was performed by atomic absorption spectrometry at λ = 247.8 nm, using a Perkin–Elmer 370 instrument with a hollow cathode lamp. An aqueous solution (5%) of lanthanum oxide was added in order to eliminate the interference from aluminium.

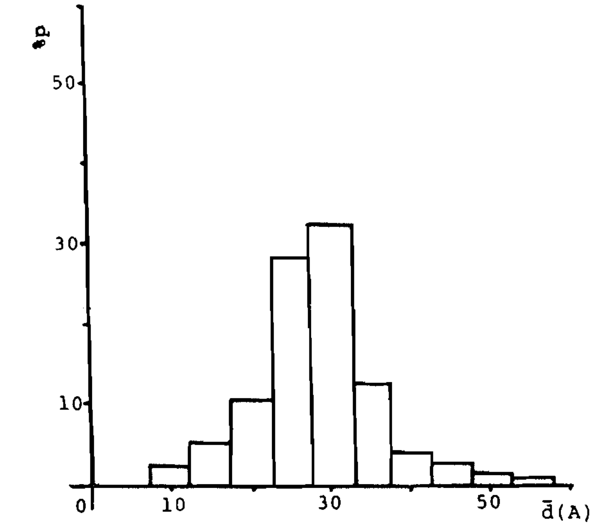

FIG. 2. Metal particle size distribution for catalyst $Pd_{0.68}S^+$ C.

Metal surface area

The metal surface area has been determined by CO chemisorption, transmission electron microscopy (TEM), and X-ray diffraction for catalysts with a metal loading equal to or less than 1%. Prior to carrying out X-ray measurements, these catalysts were subject to a procedure for enriching the sample with metal loading, involving the dissolution of the support into hydrofluoric acid in much the same way as in the extractive replica method used to prepare the samples for TEM measurements. In an earlier work it was shown that this treatment does not modify the results obtained by the X-ray technique (9). The remainder of metal catalysts were assayed by X-ray diffraction.

Carbon monoxide chemisorption

CO chemisorption measurements have been carried out by means of a thermogravimetric procedure, using a Cahn RG thermobalance. Prior to starting the measurements, the systems was subject to an operation involving the cleaning of the metal surface by applying a high vacuum (10^{-4}–10^{-5} Torr) at 448 K for 10 h.

The adsorption isotherm was run with high-purity (over 99.97%) CO supplied by the "Societé de l'Air Liquide". Before being introduced into the storage flask of the gravimetric system, the gas was passed through a purifying train and condensed at the temperature of liquid nitrogen. An adsorption temperature of 301 K and pressures ranging from 10^{-4}–40 Torr were used. The isotherm was recorded under these conditions by plotting Δm (μg adsorbed CO/g catalyst) vs. CO pressure. Figure 1 shows the shape of the isotherm obtained for catalyst $Pd_{0.68}S^+$ C.

The amount of chemisorbed gas was assessed by extrapolating the desorption branch of the isotherm to zero.

Blank isotherms were recorded for all the supports in order to make the corrections corresponding to the adsorption of CO on the support. In our case, the extent of adsorption was nil, and therefore, weighing fluctuations fell in the experimental error range. A value of 1.15 was chosen for the stoichiometric coefficient of CO following recommendations from other authors (23–25). A spherical particle model was assumed to calculate the average metal particle size ($\bar{d}_{CO}$).

TEM measurements

Transmission electron microscopy measurements were carried out on a Philips AM-300 instrument working at 100 kV. Samples were prepared by an extractive replica method, and metallic size distribution was determined by counting 1400–3000 particles. Figure 2 shows the distribution particle as a function of their size for catalyst $Pd_{0.68}S^+$ C. The average diameter ($\bar{d}_{TEM}$) was obtained from the volume/surface ratio.

X-ray diffraction measurements

X-ray diffractograms were recorded on a Philips 1130/00/60 apparatus by using the CuKα radiation, with λ = 1.5418 Å. The half-peak width was graphically measured, at an angle 2θ = 40.10° corresponding to plane (111) of Pd, and a value of 0.89 was taken for constant C of the Debye–Scherrer equation (26).

TABLE 2. Influence of the support on the catalyst activity[a]

Catalysts	$\bar{d}_{CO}$ (Å)	$\bar{d}_{TEM}$ (Å)	$\bar{d}_{X-R}$ (Å)	$10^5\ r'_0$(mol s^{-1} m_{Pd}^{-2})

Catalytic activity

Hydrogenation runs were carried out in a conventional low-pressure Gerhardt hydrogenator equipped with a manometer which showed hydrogen pressure in the reaction vessel. Reactions were accomplished in a 2.47 M solution (20 mL) at 300 K, under an initial hydrogen pressure of 5 bar. A fresh 5 × 10^{-4} g Pd sample of catalyst was used for each experiment. The reaction temperature was controlled by pumping water from a thermostatic bath through the vessel jacket.

The reaction rate was calculated by taking the initial slope of the plot of the decrease in the hydrogen pressure at the manometer versus time. Blank tests were performed prior to obtaining kinetic data in order to check the absence of phenomena other than those inherent in the catalytic process. Neither the support nor any other parts of the reactor used proved to be active in the reduction of cyclohexene. No diffusion phenomena, which might distort the results obtained, were observed under the present reaction conditions.

The rate of the hydrogen transfer from the gas-phase to the reaction medium was shown not to be the rate-determining step of the process. Under our working conditions we have shown that the initial rate of reaction increases linearly with the amount of catalyst used.

Product analysis

The reaction products were analyzed by using a Hewlett-Packard 5830 A gas chromatograph fitted with a H-P18850 GC terminal; the column was packed with 5% Carbowax 20 M on 80/100 chromosorb G-AWDMCS. Under our experimental conditions the only product detected in the hydrogenation of cyclohexene was cyclohexane. The nature of the products was confirmed by coupling the gc apparatus to a Hewlett-Packard 5992B mass spectrometer.

Results and discussion

Table 1 lists the texture properties and the isoelectric points of the different supports used. All these supports have a high specific surface (as determined by the BET method) and an average pore radius to allow the occurrence of ion exchange inside the pores.

From the study of the Z potential curves (6, 27) it can be concluded that at pH's above the isoelectric point all the supports can act as cation exchangers. The complex $Pd(NH_3)_4Cl_2$, in which the metal nucleus is in a cation form, was used with this purpose.

Table 2 gathers the average metal particle diameters found by CO chemisorption, transmission electron microscopy, and X-ray diffraction. The particle size values obtained by the three procedures are very much alike. In fact, only catalyst $Pd_{0.68}S^+$

[b] As used for the impregnation of the support.

C, which has a very small particle size (as determined by CO chemisorption), represents a higher extent of dispersion from the results obtained. As a rule, particle sizes obtained by CO chemisorption and TEM are practically the same, whereas those found by X-ray diffraction are slightly larger as compared to catalysts with a small particle size. This is a not surprising finding, considering the fact that no small crystallites can be observed by the X-ray diffraction technique.

The specific activity of the catalysts obtained by ion exchange was determined in the hydrogenation reaction of cyclohexene (Table 2), using the values of metal surface found by CO chemisorption. As can be seen, it is the silica support which yields the most disperse and active systems. Those supported on SiO_2-AlPO_4 show medium activities. The system obtained over $AlPO_4$, although with a similar particle size to that of SiO_2-AlPO_4 supports, show a low specific activity. This fact can be attributed to a strong metal–support interaction (16).

Table 3 shows the results of average metal particle diameter and catalytic activity found for the catalysts synthesized from various precursor salts over support APS_2, using either water or dimethylformamide (DMF) as impregnating solvent, depending on the solubility of the different salts employed.

The best dispersed system is obtained from Pd(II) acetylacetonate, which is logical in view of the type of interaction between this precursor and the OH groups of the supports, yielding a great extent of dispersion according to several authors (28).

$$—OH + Pd(AcAc)_2 \rightleftharpoons —O—Pd(AcAc) + AcAcH\ (ads)$$

The influence of the metal precursor is drastic. Thus, whilst Na_2PdCl_4 (which yields PdO after calcination) can be reduced at room temperature, resulting in good dispersion, it sinters easily above 573 K. Conversely, $Pd(NH_3)_4Cl_2$ cannot be reduced below 373 K, but yields good dispersion even at high temperatures. This type of precursor may be interesting if the catalyst should remain at high temperatures for a long time, as in our hydrogen-transfer reduction reactions. The high stability of the $Pd—NH_3$ bond makes it obviously difficult to reduce this precursor. Analogous results have been found by Gubitosa *et al.* (29).

TABLE 4. Promoting effect of NaOH and comparison between various alkaline hydroxides[a]

10^4 additive (mol g_{Cat}^{-1})	$\bar{d}_{X-R}$ (Å)	$10^3\ r_0$ (mol s^{-1} g_{Pd}^{-1})
—	89	2.37

11.12 LiOH	88	7.38
11.12 KOH	57	8.47

[a] Catalyst: Pd_3APS_2K C; T = 300 K; V_T = 20 mL; C = 2.47 M; 5 × 10^{-4} g Pd; $\bar{d}$, average particles diameter as determined by X-ray diffraction; r_0, initial reduction rate.

On the other hand, we have found that the reduction with Na_2PdCl_4 (PdO) at 373 K is not complete, but takes place in two steps: a first one at room temperature and a subsequent one around 503 K for all supports except AP, for which it occurs at approximately 593 K. Vasudevan *et al.* (30) have found similar results on the study of $Pd/\gamma-Al_2O_3$ catalysts, the two reduction steps occurring at room temperature and at 513 K, respectively. This fact may be due to the formation of various types of oxides with different ease of reduction.

As to the use of organometals (palladium acetate and acetylacetonate) as metal precursors, literature (30) indicates they do not yield bulky oxides when the systems are calcined at temperatures below 573 K, giving rise to high mononodal dispersion. In our case, the palladium acetate and acetylacetonate employed can be partially reduced with H_2 at room temperature, finding optimum reaction conditions similar to those of Na_2PdCl_4, as long as a temperature of 573 K is not exceeded.

The higher metal dispersion provided by the acetylacetonate as opposed to that of the acetate, may be due to the larger volume of the ligand of the former. As can be observed, the calcination prior to the reduction has a varying influence on the metal particle size according to the precursor salt.

TABLE 5. Influence of the reducer on the catalyst activity[a]

Reducer		$10^3\ r_0$ (mol s^{-1} g_{Pd}^{-1})	X (% 2h)
H_2		0.78	5.1
 Hydroquinone	→  + H_2	0.03	0.3
 Formaldehyde	→ $CO + H_2$	0.28	2.1
 Formic acid	→ $CO_2 + H_2$	0.13	1.1
$NH_2-NH_2\cdot H_2O$ Hydrazine hydrate	→ $N_2 + H_2O + 2H_2$	0.50	2.9
$2NH_2OH\cdot HCl$ Hydroxylamine	→ $N_2 + 2HCl + 2H_2O + H_2$	1.37	7.8
$NaBH_4$	→ $BNa + 2H_2$	1.40	10.2
$(N_2H_5)_2SO_4$ Hydrazine sulphate	→ $H_2SO_4 + 2N_2 + 4H_2$	0.10	0.8
 Cyclohexene	→  + $2H_2$	13.83	82.2

[a]Catalyst: Pd_1APS_3N C; T = 300 K; V_T = 20 mL; C = 2.47 M; 5 × 10^{-4} g Pd; r_0, initial reduction rate; X (% 2h), conversion of cyclohexene to cyclohexane, in wt.%, after 2 h reaction.

On comparing the catalytic activity values found, the results are different if expressed by square meter or by gram of Pd. Although no generalization can be made, calcination usually results in more active catalysts, even though the best specific activity results are obtained using Pd(II) nitrate reduced uncalcined.

A more marked influence of the particle size and catalytic activity is observed when adding alkaline hydroxides in the preparation of the catalyst. This is of special interest since their effect has been described to show in: (a) increasing the selectivity or specificity of a reaction; (b) increasing the catalyst activity; and (c) lengthening the catalyst lifetime.

The order in which the metal precursor and the alkaline metal are added onto the support has been shown to be important on the final activity of the systems; thus, with Co/γ-Al_2O_3 systems, Lycourghiotis *et al.* (31) have observed that the worst results are obtained if cobalt is first added and the alkaline metal is added in a second step, after calcination. We have used three different methods: Method 1, the support is first impregnated with an aqueous solution of $PdCl_2$, then filtered, dried, and calcined, and a second impregnation with aqueous NaOH is then performed. Method 2, the support is first impregnated with aqueous NaOH, and then with $PdCl_2$. Method 3, only one

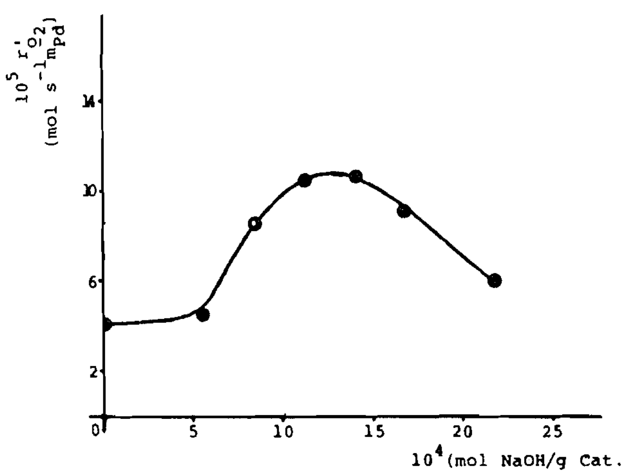

FIG. 3. Specific activity of catalyst Pd_3APS_2K C as a function of the amount of NaOH added.

impregnation with an aqueous solution containing NaOH and $PdCl_2$ is carried out.

Similar to the results reported by Lycourghiotis *et al.* (31), method 1 yields very low metal dispersion. As methods 2 and

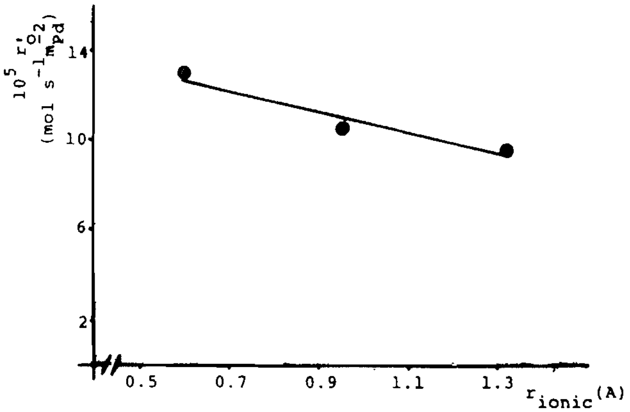

FIG. 4. Specific activity of catalyst Pd_3APS_2K C as a function of the radius of the alkaline cation added.

3 lead to similar results, method 3 is chosen.

Table 4 gathers the values of particle size and catalytic activity per g of metal found for catalysts to which various amounts of alkaline hydroxides are added. As can be seen, the catalyst with the greatest activity and most suitable particle size is that containing 8.34×10^{-4} mol of NaOH per g of catalyst.

Figure 3 reflects a similar behaviour in the plot of the specific catalytic activity as a function of the amount of sodium hydroxide added. For a given amount of alkali added, the specific catalytic activity decreases with increasing ionic radius of the alkaline metal (Fig. 4). Insofar as the specific catalytic activity is not directly related to the particle size, it must be a function of parameters involved in (1) change in the number of active centres of the catalyst or in the surface morphology; and (2) modification of the metal–support interactions.

Mross (32), in a comprehensive review on the effect of the addition of alkaline hydroxides to heterogeneous catalysts in different reactions, suggests several reasons to account for such an effect: (*a*) the alkali may act as an active component; (*b*) acid centres may be neutralized; (*c*) the population of basic centres may increase; (*d*) an electronic interaction between the metal and the alkali may occur; (*e*) the active component of its precursors may be rendered less volatile. In this context, we have shown (33) the gradual addition of alkaline hydroxides up to a given ratio result both in a significant increase in the population of basic centres and in a decrease in the number of oxidizing centres, whereas acidic and reducing centres remain practically unaltered.

The reducing agent used is another variable affecting the synthesis of Pd catalysts. In every case, the reductant was used dissolved in methanol (V_t = 20 mL), employing 20 mol of the agent per mol of $Pd(NH_3)_4Cl_2$ and reducing in reflux (358 K) for 8 h. The results thus obtained are listed in Table 5 and compared with those found for the catalyst reduced in a hydrogen stream under conditions identical with those in Table 3. The best results are obtained for the catalyst reduced with cyclohexene. Hydroxylamine and $NaBH_4$ also yield acceptable results from a catalytic point of view, better than those obtained by reducing the precursor with gaseous hydrogen. The remaining reductants used yield poor results, especially for hydrazine sulphate. We cannot rule out an inhibitory effect exerted by some of the chemical agents used to reduce the catalyst. On the other hand, this potential effect cannot be eliminated by successive washing of the catalysts. Therefore, we have opted for providing the activity per g of Pd and conversion after 2 h for such catalysts instead of their specific activity.

In summary, we can state that the nature of the support, the type of metal precursor used, the addition of alkaline hydroxides, and the reductant of the precursor are potential factors exerting a significant influence on the activity of the resulting catalyst. Therefore, no accurate prediction of a catalyst activity can be made unless every synthetic variable is individually optimized.

Sélectivité du transport de Ca^{2+}/Mg^{2+} à travers une membrane liquide par A.23187 (calcimycine) et son dérivé N-méthyle

JEAN BOLTE, COLETTE DEMUYNCK ET GEORGES JEMINET
Laboratoire de Chimie Organique Biologique, ERA 392 du CNRS, Université de Clermont II, B.P. 45, 63170 Aubière, France

Reçu le 14 janvier 1985

JEAN BOLTE, COLETTE DEMUYNCK et GEORGES JEMINET. Can. J. Chem. **63**, 3478 (1985).

Le transport préférentiel de Ca^{2+}/Mg^{2+} par A.23187 est mis en évidence dans une cellule eau/$CHCl_3$/eau. Par des mesures de flux d'extraction et de flux de libération dans une demi-cellule eau/$CHCl_3$, on montre que la sélectivité du transport est liée à une cinétique de libération nettement différente pour les deux ions, qui pourrait s'expliquer par la structure des complexes dimériques formés, si on se réfère aux études cristallographiques correspondantes. La méthylation du groupement —$NHCH_3$ entraîne une inversion de la sélectivité de transport.

JEAN BOLTE, COLETTE DEMUYNCK, and GEORGES JEMINET. Can. J. Chem. **63**, 3478 (1985).

Operating in a cell of water/$CHCl_3$/water, it is shown that there is a preferential transport of Ca^{2+}/Mg^{2+} by A.23187. On the basis of measurements of flux of extraction and of flux of liberation in a half-cell of water/$CHCl_3$, it is shown that the selectivity of the transport is related to the kinetics of liberation, which is markedly different for the two ions and which could be explained by the structure of the complex dimers that are formed, according to the corresponding crystallographic studies. The methylation of the —$NHCH_3$ entails an inversion of the selectivity in the transport.

[Traduit par le journal]

Introduction

L'étude du transport cationique induit par les antibiotiques polyéthers carboxyliques, à travers une membrane liquide épaisse, a été abordée au laboratoire dans le cadre plus général d'une recherche menée sur le mode d'action de ces composés.

Un premier travail consacré aux ionophores X.537A, A.23187 et X.14547A (1), classés comme des transporteurs des ions divalents (2), avait permis de mettre en évidence dans le système triphasique eau/$CHCl_3$/eau: (*i*) l'existence d'une courbe sigmoïdale de transport reliant le flux ionique $J_{Ca^{2+}}$ au pH du compartiment d'extraction, et (*ii*) le décalage des courbes d'un ionophore à l'autre, attribué aux différences de stabilité des associations formées aux interfaces avec H^+ et Ca^{2+}.

Récemment, une étude semblable a été abordée d'une manière approfondie pour des polyéthers couronnes de synthèse portant une ou deux fonctions —COOH (3).

Des trois ionophores cités, A.23187 (composé **1**, fig. 1) est le seul qui transporte préférentiellement les cations divalents et particulièrement Ca^{2+} et Mg^{2+} présents "in vivo" dans les compartiments cellulaires (4). Il paraissait donc intéressant d'étudier dans le système modèle évoqué la sélectivité de transport de ces deux ions et d'en préciser l'origine. Dans les conditions expérimentales utilisées mettant ou non en compétition les deux ions, on observe que $J_{Ca^{2+}} > J_{Mg^{2+}}$ quel que soit le pH. J représente le nombre de moles transportées par s et par cm^2. Le même transport préférentiel a été mentionné dans des vésicules de D.M.P.C. (5), des B.L.M. (6), ou dans la membrane mitochondriale (7). Une étude récente fait apparaître une augmentation de cette sélectivité pour un analogue bromé sur le cycle benzénique de A.23187 (8). Par opposition, le présent travail montre qu'une méthylation du groupement —$NHCH_3$ (composé **2**, fig. 1) entraîne une inversion de cette sélectivité.

Les valeurs des constantes thermodynamiques de complexation mesurées dans le méthanol ne permettent pas de prévoir les sélectivités observées; la détermination des cinétiques d'échange dans une demi-cellule eau/chloroforme autorise une interprétation des résultats en relation avec la structure des complexes dimériques connus à l'état cristallin.

A. *Étude de la sélectivité Ca^{2+}/Mg^{2+} pour A.23187* **1**. *Transport dans une cellule eau/$CHCl_3$/eau*

Les variations du flux ionique J en fonction du pH du compartiment d'extraction sont représentées sur la fig. 1.

Pour Ca^{2+}, J est inférieur à 10^{-12} mol s^{-1} cm^{-2} (limite de sensibilité de la méthode) lorsque pH < 6,6, puis il augmente jusqu'à pH 9 sans atteindre un palier distinct. Pour Mg^{2+}, on ne décèle aucun transport à pH < 7,4, au-delà duquel le flux reste faible. Il existe donc un transport préférentiel en faveur de Ca^{2+} qui se trouve confirmé si les deux cations sont présents en compétition dans la phase aqueuse d'extraction, la mesure du flux à pH 8,5 montre alors un transport exclusif de Ca^{2+} avec une valeur $J = 1 \times 10^{-11}$ mol s^{-1} cm^{-2}.

Une telle sélectivité n'est pas apparente pour les constantes de formation des complexes 1:1 et 2:1 mesurées dans le méthanol (1) exprimées sous la forme:

$$[1]\quad A^- + M^{2+} \overset{\beta_{AM^+}}{\rightleftharpoons} AM^+$$

$$\log \beta_{ACa^+} = 8{,}2 \qquad \log \beta_{AMg^+} = 7{,}6$$

$$[2]\quad 2A^- + M^{2+} \overset{\beta_{A_2M}}{\rightleftharpoons} A_2M$$

$$\log \beta_{A_2Ca} = 16{,}2 \qquad \log \beta_{A_2Mg} = 15{,}9$$

ou pour l'équation globale de l'échange:

$$[3]\quad 2AH + M^{2+} \overset{\beta'_{A_2M}}{\rightleftharpoons} A_2M + 2H^+$$

$$\beta'_{A_2Ca} = 2{,}09 \times 10^{-6} \qquad \beta'_{A_2Mg} = 1{,}04 \times 10^{-6}$$

La différence de flux ionique doit donc se créer au cours des échanges aux interfaces dans le processus global représenté sur la fig. 2 pour un transport par l'intermédiaire d'un complexe 2:1.

Pour préciser ce point nous avons utilisé une approche expérimentale en étudiant les cinétiques d'échange dans une demi-cellule eau/$CHCl_3$, à partir de l'acide libre, pour obtenir une information sur l'entrée de M^{2+} dans la phase organique ou, à partir du complexe 2:1, pour la libération du cation dans la phase aqueuse. Ces conditions expérimentales diffèrent donc

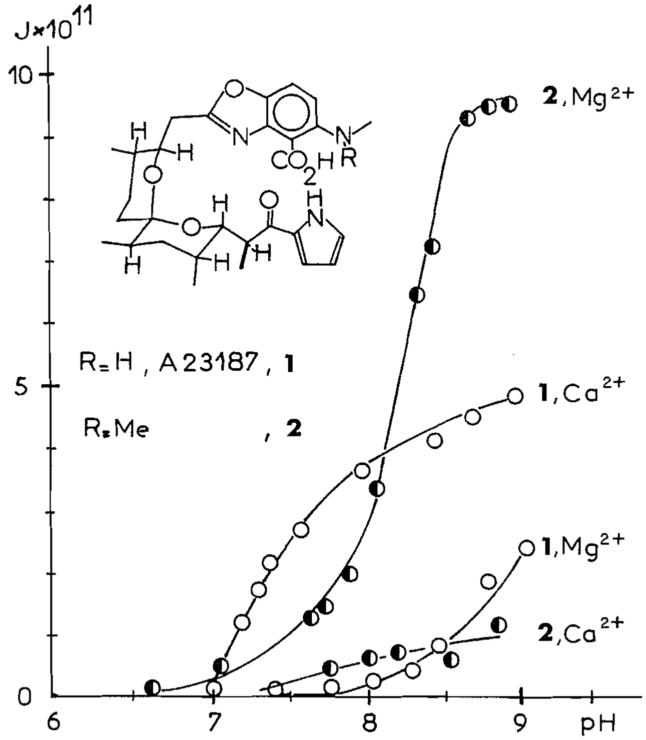

FIG. 1. Transport non compétitif de Ca^{2+} et Mg^{2+} par **1** (○) et **2** (◐), dans une cellule eau/$CHCl_3$/eau. Variations du flux J en mol s^{-1} cm^{-2} en fonction du pH de la phase aqueuse d'extraction. Conditions initiales: [ionophore]$_{org.}$ = 4×10^{-4} M, $[M^{2+}]_{aq.}$ = 10^{-2} M.

nécessairement du processus dynamique qui s'établit au cours du transfert triphasique. L'information recueillie sous cette forme permet cependant de proposer une explication à la discrimination Ca^{2+}/Mg^{2+} qui s'opère.

Cinétique d'extraction dans une demi-cellule eau/$CHCl_3$

On mesure la cinétique d'entrée de Ca^{2+} ou Mg^{2+} dans la phase organique contenant l'antibiotique (4×10^{-4} M) à partir d'une solution aqueuse 10^{-2} M de ces cations tamponnée à pH 8,5 qui correspond à un maximum d'extraction. La pente des droites représentant la quantité de cation extrait en fonction du temps permet d'accéder aux flux initiaux d'entrée qui sont respectivement:

$$J_{Ca^{2+}} = 1,1 \times 10^{-10} \text{ mol s}^{-1} \text{ cm}^{-2}$$

$$J_{Mg^{2+}} = 1,2 \times 10^{-10} \text{ mol s}^{-1} \text{ cm}^{-2}$$

Ces valeurs ne reflètent aucune différence notable entre les deux cations.

Cinétique de libération dans une demi-cellule eau/$CHCl_3$

La cinétique d'apparition de Ca^{2+} ou Mg^{2+} dans la phase aqueuse tamponnée à pH 7,0 est mesurée à partir des sels cristallisés de A.23187 dissous dans la phase organique à la concentration 2×10^{-4} M. Les courbes ainsi obtenues sont représentées sur la fig. 3. La différence entre les vitesses de libération des deux ions est apparente, les flux initiaux sont respectivement:

$$J_{Ca^{2+}} = 4,5 \times 10^{-10} \text{ mol s}^{-1} \text{ cm}^{-2}$$

$$J_{Mg^{2+}} = 3,5 \times 10^{-11} \text{ mol s}^{-1} \text{ cm}^{-2}$$

soit un rapport $J_{Ca^{2+}}/J_{Mg^{2+}} \sim 13$. Le même type de courbe est obtenu dans l'intervalle de pH 7,0–1,0. Les flux initiaux mesu-

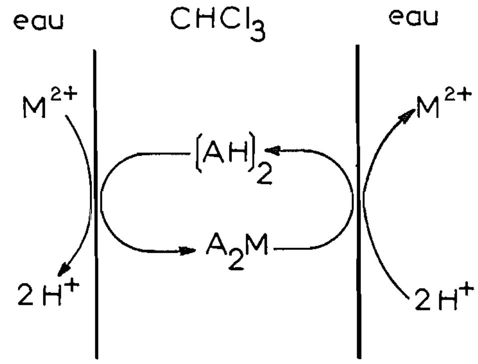

FIG. 2. Représentation du mécanisme d'échange $M^{2+} \leftrightarrow 2H^+$ aux interfaces, dans le transport à travers une membrane liquide épaisse.

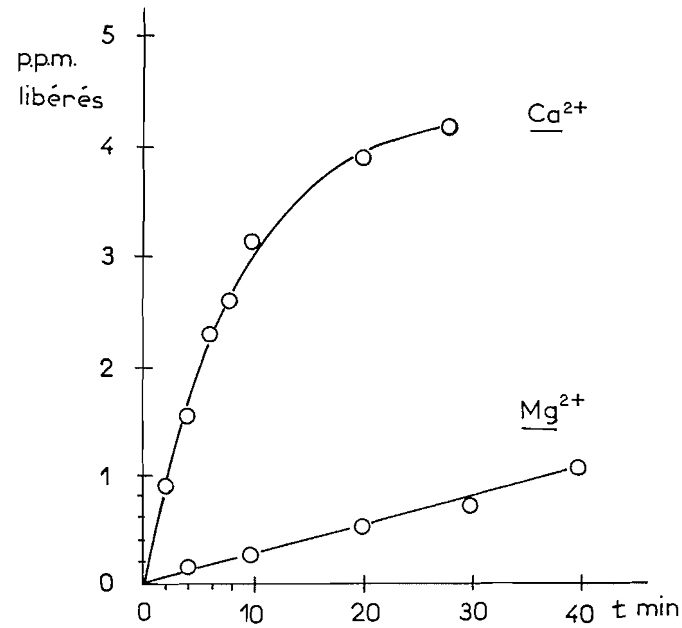

FIG. 3. Libération non compétitive de Ca^{2+} et Mg^{2+} dans la phase aqueuse, à partir des complexes cationiques dimères de la Calcimycine dissous dans la phase chloroformique, pour un système eau/$CHCl_3$. Conditions initiales: [complexe] = 2×10^{-4} M, pH de la phase aqueuse = 7,0.

rés sont indépendants de $[H^+]$ dans la phase aqueuse.

Les premières études cinétiques entreprises en phase homogène dans le méthanol ou le mélange méthanol 70/eau 30 (w/w) par des techniques de flux stoppé ou saut de température (9) donnent pour la constante cinétique globale de dissociation du complexe 1:1 qui constitue l'étape limitante (en s^{-1}):

Ca^{2+}	MeOH	2,2 ± 1,4	Mg^{2+}	MeOH	0,3 ± 0,2
MeOH 70/eau 30		>600		MeOH 70/eau 30	89 ± 20

Ceci conduit les auteurs à admettre que si l'étape limitante dans le transport est la libération du cation, on doit attendre une sélectivité de l'ordre de 8 en faveur de Ca^{2+}. Les résultats mentionnés dans ce travail qui décrivent une cinétique globale de libération à l'interface eau/$CHCl_3$ sont en accord avec cette proposition.

Les différences de propriétés des ions Ca^{2+} et Mg^{2+} en biologie ont été fréquemment discutées notamment par Williams (10). Il note que Ca^{2+} (1,06 Å) s'associe aux ligandes avec un indice de coordination minimum de 6 mais plus fréquemment 7 ou 8 dans une géométrie irrégulière (angles et longueurs de liaison), alors que Mg^{2+} (0,78 Å) est généralement hexacoordiné dans une géométrie proche de l'octaèdre. Pour l'assemblage moléculaire très particulier que représente le dimère de A.23187 la proposition de Williams est respectée si l'on compare l'heptacoordination irrègulière de Ca^{2+} (11) et l'hexacoordination octaédrique de Mg^{2+} (12). Cet aspect a été examiné récemment par Gresh et Pullman (13) au moyen de simulations théoriques à partir des données cristallographiques. Ils montrent que la présence d'une molécule d'eau observée dans le cristal du complexe avec Ca^{2+} comme 7ème site coordinant (11) est nécessaire pour assurer au complexe une stabilité comparable à celle du complexe avec Mg^{2+}; la possibilité d'un co-transport de molécules d'eau dans la migration intramembranaire est envisagée par les auteurs.

Ces différences structurales observées à l'état cristallin constituent un argument en faveur d'une différenciation entre les vitesses de libération des ions Ca^{2+} et Mg^{2+} à partir de leurs complexes, si l'on admet des structures comparables en solution. Il serait intéressant de préciser le mécanisme de cette discrimination cinétique. Dans un premier temps nous nous proposons d'étudier la présence éventuelle de molécules d'eau dans l'espèce qui assure le transport; cela nécessite la mise au point d'un processus expérimental approprié.

B. *Sélectivité Ca^{2+}/Mg^{2+} pour N-Me A.23187* **2**

Les deux substituants —$NHCH_3$ et —COOH (ou —COO^-) dans A.23187 (fig. 1, R = H) présentent une chélation intramoléculaire —NH (CH_3)···O=C(···) qui les maintient dans le plan du benzoxazole, si l'on se rapporte aux résultats radiocristallographiques donnés sur l'acide libre (14) et les sels complexes (11, 12). L'introduction d'un deuxième groupement méthyle sur —$NHCH_3$ (15) (fig. 1, R = CH_3) supprime cette possibilité de chélation et entraîne une modification des propriétés d'association avec les cations qui apparaît à l'examen des constantes de formation des complexes 1:1 et 2:1 dans le méthanol (16) (équilibres [1]–[3]).

$$\log \beta_{A'Ca^+} = 4{,}7 \qquad \log \beta_{A'_2Ca} = 8{,}5$$
$$\log \beta_{A'Mg^+} = 5{,}2 \qquad \log \beta_{A'_2Mg} = 9{,}5$$
$$\beta'_{A'_2Ca} = 1{,}26 \times 10^{-13}$$
$$\beta'_{A'_2Mg} = 1{,}25 \times 10^{-12}$$

où l'on observe une nette déstabilisation des associations formées.

Les résultats du transport cationique dans un système eau/$CHCl_3$/eau par cet ionophore modifié sont représentés sur la fig. 1. L'ion Mg^{2+} est transporté préférentiellement à Ca^{2+}, le flux maximun atteint étant supérieur à celui de Ca^{2+} pour A.23187 bien que la stabilité des complexes soit très inférieure. On avait déjà observé un phénomène semblable pour X.537A (1).

Lorsque les deux cations sont présents en compétition dans la phase d'extraction, les flux initiaux mesurés à pH 8,5 sont respectivement

$$J_{Ca^{2+}} = 0{,}2 \times 10^{-11} \text{ mol s}^{-1} \text{ cm}^{-2}$$
$$J_{Mg^{2+}} = 2{,}3 \times 10^{-11} \text{ mol s}^{-1} \text{ cm}^{-2}$$

La faible modification introduite sur la structure naturelle a donc pour effet d'inverser la sélectivité du transport Ca^{2+}/Mg^{2+} dans ce système membranaire.

Comme précédemment, les flux initiaux correspondant aux phénomènes d'extraction et de libération des cations dans une demi-cellule eau/$CHCl_3$ ont été mesurés; on obtient les valeurs suivantes:

Flux d'extraction	Flux de libération
$J_{Ca^{2+}} = 1{,}7 \times 10^{-11}$	$J_{Ca^{2+}} = 8 \times 10^{-11}$
$J_{Mg^{2+}} = 5{,}3 \times 10^{-11}$	$J_{Mg^{2+}} = 15 \times 10^{-11}$

Les flux d'entrée sont plus faibles si l'on se réfère à A.23187. Par ailleurs, tant à l'entrée qu'à la sortie de la phase organique les valeurs des flux sont en faveur de Mg^{2+} ce qui peut entraîner un transport global préférentiel de ce cation. Ainsi la transformation de —$NHCH_3$ en —$N(CH_3)_2$ suffit pour créer des effets stériques et électroniques autour du —CO_2H qui modifient la structure des complexes dimériques formés et par voie de conséquence les cinétiques d'échange aux interfaces, confirmant ainsi les observations faites pour A.23187.

En conclusion, il est nécessaire d'insister sur le fait que ces résultats ne sont pas nécessairement transposables systématiquement à d'autres phases membranaires, en particulier à la membrane mitochondriale (4) où un bon ionophore des cations divalents doit posséder des constantes d'associations élevées avec ces cations, compte tenu de la compétition avec les sites propres de la mitochondrie; c'est le cas de A.23187, mais c'est un transporteur lent (9).

Les premiers résultats obtenus avec N-Me A.23187 qui forme des complexes moins stables montrent effectivement que c'est un ionophore peu efficace dans cet organite.[1]

Le transport préférentiel de Ca^{2+}/Mg^{2+} mis en évidence pour A.23187 dans différentes conditions expérimentales (5–7) est très vraisemblablement attribuable à une cinétique de libération différente pour ces deux ions comme dans la membrane liquide chloroformique qui constitue sur ce point un modèle intéressant.

Partie expérimentale

Produits

L'antibiotique A.23187 **1** est isolé à partir d'une culture en fermenteur de 20 L de la souche NRRL 3882 (*Streptomyces chartreusis*) (1). La préparation du dérivé **2** est décrite dans la réf. 15.

Les sels de Ca^{2+} et Mg^{2+} sont préparés et isolés selon la technique de Deber et Pfeiffer (17). Le complexe cristallisé obtenu avec Mg^{2+} a servi conjointement pour les déterminations radiocristallographiques (12). Pour la N-méthylcalcimycine **2**, les sels de Ca^{2+} et Mg^{2+} sont préparés *in situ* en agitant au vortex une solution chloroformique 2×10^{-4} *M* du dérivé et une solution aqueuse tamponnée à pH 10,3 des sels $Mg(ClO_4)_2$ ou $Ca(ClO_4)_2$ Merck, 10^{-2} *M*. La formation du complexe 2:1 dans la phase chloroformique est totale, elle est vérifiée sur une quantité aliquote par libération des cations à l'aide d'HCl 0,1 *N* et mesure de leur concentration par absorption atomique (appareil Perkin–Elmer 420).

Les solutions aqueuses sont tamponnées par un mélange tricine–triéthanolamine Merck 10^{-2} *M*, le pH est ajusté avec une précision de 0,02 unités.

Transport triphasique eau/$CHCl_3$/eau (fig. 1)

La cellule utilisée et les conditions du transport ont été décrites précédemment (1). La phase chloroformique est préalablement saturée d'eau, elle contient l'ionophore **1** ou **2** à la concentration 4×10^{-4} *M*. La phase aqueuse d'extraction ou d'entrée est une solution 10^{-2} *M* de $Ca(ClO_4)_2$ ou $Mg(ClO_4)_2$ Merck.

On mesure les flux ioniques exprimés en mol s^{-1} cm^{-2} à l'établissement du régime quasi-stationnaire dans la phase aqueuse de libération ou de sortie, maintenue à pH 7,0, pour chaque valeur du pH

[1] J. Guyot, travaux non publiés.

de la phase d'entrée. Pour cela, un échantillon de 1 mL est prélevé dans la phase de sortie à intervalles de temps réguliers et dosé par absorption atomique, la même quantité de phase aqueuse tamponnée est introduite dans la cellule en compensation.

Le pH de la phase d'entrée est contrôlée en permanence.

Cinétiques de libération eau/$CHCl_3$ (fig. 3)

Une solution chloroformique (6 mL) préalablement saturée d'eau contenant le complexe de Ca^{2+} ou Mg^{2+} des composés **1** ou **2** à la concentration 2×10^{-4} *M* et 6 mL d'une solution aqueuse à pH 7,0 (tampon tricine 10^{-2} *M*) sont mis en contact dans une cellule cyclindrique thermorégulée à 25°C (diamètre intérieur 2 cm, hauteur 6 cm).

La phase organique est agitée par un agitateur magnétique tournant à 600 tours/min et la phase aqueuse par une baguette de verre (diamètre 3 mm) terminée par une pale rectangulaire de 6 × 3 mm mue par un moteur électrique synchrone tournant à 600 tours/min. La concentration des cations dans la phase aqueuse est mesurée par absorption atomique.

Cinétiques d'extraction eau/$CHCl_3$

La même cellule que précédemment est utilisée. Une solution chloroformique (6 mL) de **1** ou **2** à la concentration 2×10^{-4} *M* et 6 mL d'une solution tamponnée à pH 8,5 (triéthanolamine–tricine) de $Ca(ClO_4)_2$ ou $Mg(ClO_4)_2$ 10^{-2} *M* sont mis en contact et agitées comme ci-dessus.

La vitesse d'apparition du cation dans la phase organique est mesurée en prélevant 1 mL de celle-ci que l'on traite par 1 mL de HCl 0,1 *N* pour libérer le cation et le doser. Pour faire des mesures en fonction du temps on opère avec une série de cellules synchronisées. Les valeurs de flux initiaux mentionnés portent sur trois mesures.

Structure cristalline du complexe de magnésium de la calcimycine (A. 23187)

MARC ALLÉAUME[1] ET YVETTE BARRANS

Laboratoire de cristallographie, U.A. 144, C.N.R.S., Université de Bordeaux I, 33405 Talence Cédex, France

Reçu le 14 janvier 1985

MARC ALLÉAUME et YVETTE BARRANS. Can. J. Chem. **63**, 3482 (1985).

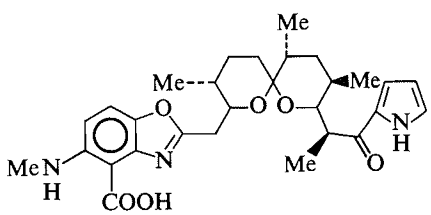
Le complexe de magnésium 1:2 de l'antibiotique calcimycine (A. 23187) cristallise dans le groupe spatial $P2_1$, avec des paramètres de maille a = 11,152(2), b = 27,684(2), c = 10,168(2) Å, β = 107,02(2)° et Z = 2. La structure a été affinée jusqu'à un facteur de reliabilité R = 0,063 pour 3473 réflexions observées. La coordination octaédrique de l'ion Mg^{2+} est hautement symétrique. Chaque ion calcimycine est lié à Mg^{2+} par un oxygène carbonyle, un oxygène carboxyle et l'azote du cycle benzoxazole. Les distances Mg—O sont respectivement de 2,00 Å et 2,06 Å, les distances Mg—N sont de 2,23 Å ($\sigma \simeq$ 0.01 Å).

MARC ALLÉAUME and YVETTE BARRANS. Can. J. Chem. **63**, 3482 (1985).

The 1:2 magnesium ion complex of the antibiotic calcimycine (A. 23187) crystallizes in the space group $P2_1$ with cell dimensions a = 11.152(2), b = 27.684(2), c = 10.168(2) Å, β = 107.02(2)°, and Z = 2. The structure was refined to an R = 0.063 based on 3473 observed reflections. The octahedral coordination of the Mg^{2+} ion is highly symmetrical. Each calcimycine ion is bound to Mg^{2+} through a carboxyl oxygen, a carbonyl oxygen, and the nitrogen of the benzoxazole ring system. The Mg—O distances are respectively 2.00 Å and 2.06 Å, the Mg—N distances 2.23 Å ($\sigma \simeq$ 0.01 Å).

La calcimycine ou A. 23187 est un polyéther monocarboxylique doué de propriétés ionophores: il complexe et transporte essentiellement les cations divalents Ca^{2+}, Mg^{2+}.

Plusieurs structures cristallines de la calcimycine[2] ont été déterminées: calcimycine, acide libre (1); 2[calci]$^-$ Ca^{2+}, 2 éthanol (2); 2[calci]$^-$ Ca^{2+}, H_2O (3); et, plus récemment, 2[calci]$^-$ Fe^{2+}, 2 éthanol (4). Nous publierons prochainement la structure du complexe 2[calci]$^-$ Mn^{2+}.



Calcimycine = A.23187

Les conditions d'extraction et de purification de la calcimycine à partir de la souche de *Streptomyces chartreusensis* sont précisées dans l'article suivant (5).

Partie expérimentale

Les cristaux du complexe 2[calci]$^-$ Mg^{2+} ont été obtenus par cristallisation d'une solution dans un mélange méthanol + acétone. Le cristal utilisé pour la collection des données était une aiguille prismatique de dimensions 0,20 × 0,30 × 0,25 mm³. Toutes les données cristallographiques—paramètres cristallins et intensités diffractées—ont été mesurées sur un diffractomètre Enraf–Nonius CAD-4 équipé d'un monochromateur au graphite ($\lambda K_{\alpha 1}$ = 1,5405 Å). Le tableau 1 résume les données cristallographiques et les conditions de mesure.

Affinement de la structure

Sur les 5207 réflexions indépendantes mesurées, 3473 réflexions "observées" ($I > 3\sigma(I)$) ont été utilisées dans la suite des calculs, après correction de Lorentz et de polarisation. Aucune correction d'absorption n'a été appliquée ($\mu R < 0{,}002$). La structure a été déterminée par méthodes directes en utilisant le programme MULTAN. Les 2/3 des atomes "lourds" sont apparus sur la première carte de densité électronique. Après 7 cycles d'affinement isotrope portant sur les 77 atomes "lourds", 3 cycles d'affinement anisotrope furent conduits avant l'introduction des atomes d'hydrogène. Tous les atomes d'hydrogène ont été affectés d'un coefficient d'agitation thermique isotrope. Les hydrogènes portés par les groupements méthyle n'ont pas été introduits dans l'affinement. Trois nouveaux cycles d'affinement sur ces 119 atomes ont conduit à un facteur de reliabilité R = 0,063 pour les 3473 réflexions observées ($R = \Sigma\|F_o| - |F_c\|/\Sigma|F_o|$), et un paramètre d'accord $s = \left(\frac{\Sigma w\Delta^2}{m-n}\right)^{1/2} = 1{,}52$. La densité électronique résiduelle sur la carte de Fourier-différence finale est inférieure à 0,30 e Å^{-3}. Les coordonnées atomiques (tableau 2), les paramètres d'agitation thermique anisotrope[3] ou isotrope (atomes d'hydrogène) ont été affinés par moindres carrés, en bloc diagonal; valeur minimisée $\Sigma\, w(|F_o| - |F_c|)^2$; schéma de pondération: $\sqrt{w} = 1$ si $|F_o| < p$ et $\sqrt{w} = p/F_o$ si $|F_o| > p$ avec $p = [F^2_{o(max)}/10]^{1/2}$; facteurs de diffusion de International Tables for X-Ray Crystallography (1974) pour les atomes lourds et de Stewart *et al.* (6) pour les atomes d'hydrogène.

Discussion

Comme dans le complexe de Ca^{2+}, 2 ions [calci]$^-$ s'associent tête-bêche pour créer une cavité complexante fermée. Chaque ion [calci]$^-$ forme une demi-coquille (fig. 1). Les 2 demi-coquilles identiques qui encagent le cation Mg^{2+} se déduisent l'une de l'autre par un pseudo-axe binaire $\psi(A_2)$ passant par le cation (fig. 1). Deux liaisons hydrogène identiques N(32)—H(321)... O(73) et N(72)—H(721)... O(33), avec N—O quasi identiques (2,84 Å et 2,85 Å), complètent la stabilisation de ce système complexant. Il faut cependant remarquer que les angles OH... N sont voisins de 150° ($\sigma \simeq$ 10°), ce qui implique une liaison hydrogène moins forte que ne l'indiquent les seules distances N... O.

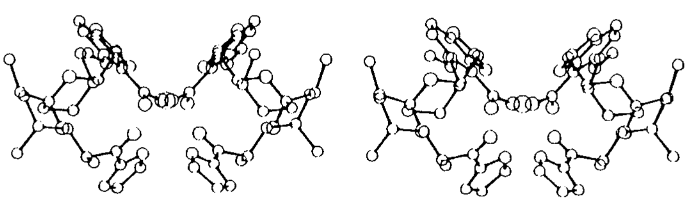

FIG. 1. Projection stéréographique du complexe sur un plan passant par $\psi(A_2)$.

C(5) et C(45), aucune variation significative n'apparaît entre les ions $[\text{calci}]_I^-$ et $[\text{calci}]_{II}^-$. La figure 2 donne les valeurs moyennes des distances et des angles.[4]

Cette identité conformationnelle des ions I et II est confirmée par l'accord entre les deux séries d'angles de torsion χ (tableau 3) ($(\delta\chi)_{max} = 4°$, $(\delta\chi)_{moy} = 2{,}3°$, $\sigma(\delta_{moy}) = 1{,}5°$)). Il faut noter que dans le complexe de Ca^{2+} (3) les variations d'angles de torsion entre les ions I et II sont beaucoup plus importantes ($(\delta\chi)_{max} = 20°$; $(\delta\chi)_{moy} = 6{,}4°$; $\sigma(\delta_{moy}) = 4{,}2°$).

Le tableau 4 donne les écarts significatifs aux groupements plans benzoxazole et cétopyrrole. L'écart de l'atome C(9) est dû aux contraintes stériques imposées par le spiroacétal. La variation de position des méthyles C(25)I et C(65)II pourrait

[4]Les figures 2′ et 2″ donnant respectivement les longueurs de liaisons et les angles de valence de chacun des 2 ions $[\text{calci}]^-$ ont été déposées; on peut les acheter en s'adressant au Dépôt des données non publiées, ICIST, Conseil national de recherches du Canada, Ottawa (Ont.), Canada K1A 0S2.

être liée aux variations de distances autour du carbone C(5) signalées plus haut.

Il faut noter que l'ion Mg^{2+} est toujours voisin du plan du cycle, ce qui correspond à la géométrie la plus favorable de l'interaction ion–ligande pour les 3 ligandes O(carboxyle), O(carbonyle), N(pyrrole).

2. *Environnement du cation*

La complexation hexacoordonnée de l'ion Mg^{2+} est assurée par 4 atomes d'oxygène et 2 atomes d'azote, chacun des 2 ions $[calci]^-$ apportant la même contribution à cette complexation (tableau 5). Ces 6 ligandes forment un octaèdre quasi parfait autour de Mg^{2+}. La figure 3 donne une représentation schématique de cet octaèdre, le pseudo-axe binaire $\psi(A_2)$ étant dans le plan de la figure.

Si l'on admet que les distances cation–ligande sont pratiquement égales à la somme (rayon ionique + rayon de van der Waals), et que pour les atomes impliqués dans ces coordinations octaédriques, les contacts $[calci]_I^-$ – $[calci]_{II}^-$ (comme N(31) .... N(71) ou O(38) ... O(73)) sont de type contacts de van der Waals, on est conduit à prendre les valeurs suivantes: $R_{Mg^{2+}}$ = 0,60 Å; $R_{O\ carboxyle}$ = 1,40 Å; $R_{O\ carbonyle}$ = 1,46 Å; R_N = 1,65 Å.

Les valeurs que nous proposons sont légèrement différentes de celles habituellement admises (7, 8). Le tableau 5, colonnes (a) et (b), montre qu'elles donnent, pour le complexe étudié, un excellent accord entre les distances "observées" et les distances calculées à partir de nos propres valeurs. Il en est de même pour d'autres complexes hexacoordonnés de Mg^{2+}. La structure de Mg-malate pentahydrate (9) donne des résultats comparables: Mg^{2+} ... O de 2,02 à 2,11 Å. Ces valeurs sont aussi en accord avec les distances cation–ligande observées dans le complexe de Ca^{2+} monohydraté (3), à condition de prendre un rayon ionique $R_{Ca^{2+}} \simeq$ 0,90 Å. Les distances cation–ligande calculées vont de 2,30 Å à 2,55 Å, les distances moyennes observées étant de 2,27 Å à 2,63 Å.

De plus, ces deux séries de valeurs calculées pour les complexes de Mg^{2+} et de Ca^{2+} sont identiques aux valeurs obtenues par minimisation d'énergie (10). La comparaison des distances cation–ligande dans ces deux structures permet d'affirmer que la première structure de complexe publiée (2) a été interprétée incorrectement: il ne s'agit pas d'un complexe de Ca^{2+}, mais bien d'un complexe de Mg^{2+}. Les distances cation–ligande vont de 1,92 Å à 2,22 Å. Ces valeurs, voisines de celles produites par le présent travail, ne peuvent être attribuées à des distances Ca^{2+}–ligande, qui sont de 0,30 Å plus grandes.

Conclusions

Les deux traits majeurs du complexe $2[calci]^- Mg^{2+}$ à l'état cristallin sont (*i*) l'identité conformationnelle des 2 ions

[calci]$^-$; et (*ii*) la symétrie octaèdrique quasi parfaite des 6 ligandes qui assurent la complexation de l'ion Mg^{2+}.

La grande symétrie du complexe de Mg^{2+} ne se retrouve pas dans le complexe de Ca^{2+}; nous pensons que ces caractéristiques structurales, si elles se conservent en solution, pourraient être liées au transport préférentiel du Ca^{2+} par rapport au Mg^{2+} (5). La décomplexation du cation est, avec ce type de complexe, une opération de "rupture de symétrie", que favoriserait une dissymétrie préexistante, comme celle que présente le complexe de Ca^{2+}.

[2] $CH_3 + CH_3COCH_3 \rightarrow CH_4 + CH_3COCH_2$

[7] $CD_3 + CD_3COCD_3 \rightarrow CD_4 + CD_3COCD_2$

[11] $CH_3 + CH_3NNCH_3 \rightarrow CH_4 + CH_3NNCH_2$

has been undertaken, and the following rate constants, based on the value $10^{13.34}$ cm^3 mol^{-1} s^{-1} for the recombination of CH_3 and CD_3 radicals, are recommended:

$$\log k_2 = (11.54 \pm 0.03) - (40490 \pm 280)/19.145T$$

$$\log k_7 = (11.78 \pm 0.08) - (48500 \pm 690)/19.145T$$

$$\log k_{11} = (11.05 \pm 0.07) - (33390 \pm 560)/19.145T$$

$$\log k_{11}(\text{corr}) = (11.21 \pm 0.08) - (34570 \pm 590)/19.145T$$

where k is in cm^3 mol^{-1} s^{-1}, E is in J mol^{-1}, the error limits are standard deviations, and k_{11}(corr) refers to the rate constant corrected for the intramolecular elimination of C_2H_6 in the photolysis of CH_3NNCH_3.

NEVILLE L. ARTHUR et PAULA J. NEWITT. Can. J. Chem. **63**, 3486 (1985).

On a procédé à une évaluation des données cinétiques relatives aux réactions

[2] $CH_3 + CH_3COCH_3 \rightarrow CH_4 + CH_3COCH_2$

[7] $CD_3 + CD_3COCD_3 \rightarrow CD_4 + CD_3COCD_2$

[11] $CH_3 + CH_3NNCH_3 \rightarrow CH_4 + CH_3NNCH_2$

et, en se basant sur la valeur de $10^{13.34}$ cm^3 mol^{-1} s^{-1} pour la recombination des radicaux CH_3 et CD_3, on recommande les constantes de vitesses suivantes:

$$\log k_2 = (11{,}54 \pm 0{,}03) - (40490 \pm 280)/19{,}145T$$

$$\log k_7 = (11{,}78 \pm 0{,}08) - (48500 \pm 690)/19{,}145T$$

$$\log k_{11} = (11{,}05 \pm 0{,}07) - (33390 \pm 560)/19{,}145T$$

$$\log k_{11}(\text{corr}) = (11{,}21 \pm 0{,}08) - (34570 \pm 590)/19{,}145T$$

dans lesquelles k est en cm^3 mol^{-1} s^{-1}, E est en J mol^{-1}, les limites d'erreur sont les déviations standards et k_{11}(corr) se réfère à la constante de vitesse corrigée pour l'élimination intramoléculaire de C_2H_6 lors de la photolyse du CH_3NNCH_3.

[Traduit par le journal]

Introduction

A vast quantity of kinetic data on the hydrogen transfer reactions of CH_3 and CD_3 radicals has been gathered over the past thirty years (1, 2). This has been made possible by the availability of convenient, clean, sources of radicals: the photolyses of acetone, acetone-d_6, and azomethane.

For kinetic studies of this kind, the key reactions in the photolysis of acetone (3) are:

[1] $CH_3COCH_3 + h\nu \rightarrow 2CH_3 + CO$

[2] $CH_3 + CH_3COCH_3 \rightarrow CH_4 + CH_3COCH_2$

[3] $2CH_3 \rightarrow C_2H_6$

and the rate constant for reaction [2] is evaluated relative to that for [3] from the expression

[4] $k_2/k_3^{\frac{1}{2}} = R_{CH_4}[2]/(R_{C_2H_6}^{\frac{1}{2}}[CH_3COCH_3])$

where R represents the rate of formation. When acetone is photolyzed in the presence of a substrate, CH_4 is also formed:

[5] $CH_3 + RH \rightarrow CH_4 + R$

Provided that k_2 is known, that part of the total CH_4 resulting from reaction [2] can be calculated from $R_{C_2H_6}$, and subtraction gives $R_{CH_4}[5]$. $k_5/k_3^{\frac{1}{2}}$ is then obtained from

[6] $k_5/k_3^{\frac{1}{2}} = R_{CH_4}[5]/(R_{C_2H_6}^{\frac{1}{2}}[RH])$

k_2 and k_5 can be evaluated by inserting a value of k_3 from the literature.

In the case of acetone-d_6, two isotopically distinguishable methanes are formed:

[7] $CD_3 + CD_3COCD_3 \rightarrow CD_4 + CD_3COCD_3$

[8] $CD_3 + RH \rightarrow CD_3H + R$

k_8 can be evaluated by means of an expression analogous to eq. [6], or the ratio k_8/k_7 can be obtained from

$$[9] \quad k_8/k_7 = R_{CD_3H}[CD_3COCD_3]/(R_{CD_4}[RH])$$

and substitution for k_7 gives a value for k_8.

The relevant reactions in the photolysis of azomethane are

$$[10] \quad CH_3NNCH_3 + h\nu \rightarrow 2CH_3 + N_2$$

$$[11] \quad CH_3 + CH_3NNCH_3 \rightarrow CH_4 + CH_3NNCH_2$$

$$[3] \quad 2CH_3 \rightarrow C_2H_6$$

and a relation similar to eq. [4] allows k_{11} to be evaluated from R_{CH_4} and $R_{C_2H_6}$. However, there is a considerable amount of evidence (5, 6) that suggests that about 0.9% of the N_2 formed in the photolysis is produced by the intramolecular elimination reaction

$$[12] \quad CH_3NNCH_3 + h\nu \rightarrow C_2H_6 + N_2$$

and the expression for k_{11}, corrected for the occurrence of reaction [12], therefore becomes

$$[13] \quad k_{11}(\text{corr})/k_3^{\frac{1}{2}} = R_{CH_4}[11]/\{(R_{C_2H_6} - 0.009R_{N_2})^{\frac{1}{2}} \times [CH_3NNCH_3]\}$$

When azomethane-substrate mixtures are photolyzed, reaction [5] must be added to those above. k_5 may be evaluated, either by the analogue of eq. [6], ignoring the small correction for reaction [12], or, taking it into account, by means of the relation

$$[14] \quad k_5/k_3^{\frac{1}{2}} = R_{CH_4}[5]/\{(R_{C_2H_6} - 0.009R_{N_2})^{\frac{1}{2}}[RH]\}$$

where $R_{CH_4}[5]$ is calculated from $k_{11}(\text{corr})$ via eq. [13].

It can be seen from the above that rate constants for a particular hydrogen transfer reaction can only be evaluated if rate constants for attack on the radical source have previously been measured. In order to determine whether a particular set of data for abstraction from the radical source falls within acceptable limits, and therefore whether subsequent data collected in the same system can be regarded as reliable, best values for the Arrhenius parameters for attack on the radical source must be established.

Because of the limited amount of published rate constant data available for attack on CH_3COCH_3, CD_3COCD_3, and CH_3NNCH_3, previous evaluations (1, 4) have been confined to the averaging of Arrhenius parameters. We have obtained a large quantity of additional data by communicating with the authors, or by reference to theses, and the evaluation presented here is therefore based on a sounder statistical approach than has previously been used.

Evaluation procedure

The handling of the large amount of data involved in this work was greatly facilitated by the availability of an interactive computer-based storage, retrieval, and analysis system developed in this laboratory (7). For each investigation of a particular reaction, an input file in a standard format is created, containing the following information: authors, bibliographical reference, radical source, reference reaction, temperature and pressure ranges, comments, the rate constant versus temperature data, and the Arrhenius parameters resulting from a least-squares treatment of the data.[1]

The information contained in the files can be retrieved according to reaction type (attacking radical), reaction, author or reference, and the data from selected files can be combined into a single large set. A least-squares analysis of the data is then carried out to yield the Arrhenius parameters and their standard deviations; the output includes a value for the deviation of each data point from the line of best fit, and the data point furthest from the line is identified. This, or any other, point can be temporarily deleted and the remainder of the set reanalysed, a process which can be repeated at the discretion of the evaluator. To assist in the visual interpretation of the data analysis, the option of a hard copy Arrhenius plot is available at any stage of the analysis procedure.

Results and discussion

CH_3 attack on acetone

Of the 40 studies of abstraction from acetone by CH_3 radicals in the open literature, only 21 contain rate constant data. We obtained a further 12 sets of data from the authors or from theses, leaving only 7 studies for which data are not now available. All of the results are summarized in Table 1, together with the corresponding temperature ranges, and also rate constants evaluated at 400 K. The Arrhenius parameters quoted have been recalculated by us from the original data by the method described in the previous section, but without eliminating any of the data points. A number of discrepancies between these values and those originally reported were noticed, especially in the work done before electronic calculators and computers came into common use.

Most of the data fall within the temperature range 393–523 K (120–250°C), and data outside of this range were excluded. Three reasons contributed to this decision: the Arrhenius plot is known to be nonlinear at temperatures below about 393 K (3); product analyses outside these limits are less reliable than within (at high temperatures much more CH_4 is formed than C_2H_6, whereas at low temperatures C_2H_6 predominates); and, because the points are at the ends of the line, inclusion of the small number of rate constants involved would have had a disproportionate effect on the calculated Arrhenius parameters. In addition to these data, those contained in ref. 14 were also omitted because in that case CH_3 radicals were generated by means of the thermal decomposition of di-*tert*-butyl peroxide, rather than by the photolysis of acetone.

The combined data set edited in this way consisted of 395 points in 31 individual sets. Analysis by the method described in the previous section showed that 4 points were greater than 4 standard deviations from the line of best fit. After these points had been deleted, and taking the value of k_3 to be $10^{13.34}$ cm^3 mol^{-1} s^{-1} (48, 49), analysis of the remaining 391 points (in 31 sets) gave

$$[15] \quad \log k_2 = (11.54 \pm 0.03) - (40490 \pm 280)/19.145T$$

where k_2 and A_2 are in cm^3 mol^{-1} s^{-1} and E is in J mol^{-1}. The data points and the line represented by eq. [15] are shown in Fig. 1.

The averages of the Arrhenius parameters listed in Table 1 (omitting the very low results of ref. 9 and those from experiments in which di-*tert*-butyl peroxide was the radical source (14, 18)) are: $\log A = (11.48 \pm 0.23)$ and $E = (39.84 \pm 1.57)$ kJ mol^{-1}, where the error limits are standard deviations from the mean. These values are slightly lower than those suggested by Kerr and Parsonage (1), $\log A = (11.54 \pm 0.2)$, $E = (40.6 \pm 2.1)$ kJ mol^{-1} and Arthur *et al.* (4), $\log A = 11.54$, $E = 40.29$ kJ mol^{-1}. In view of the much larger quan-

[1]A complete set of these data files is available and may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6.

tity of data involved in the present evaluation, the more rigorous approach employed, and the errors found in some of the reported Arrhenius parameters, the agreement between the Arrhenius parameters proposed in the earlier evaluations and those recommended here must be regarded as fortunate.

It is our opinion that the performance of a particular experimental system can be considered satisfactory only if the data obtained with it for CH_3 attack on acetone yield Arrhenius parameters that lie within four standard deviations of the values given in eq. [15]. Our recommended values for the Arrhenius parameters for this reaction are therefore log A = (11.54 ± 0.12) and E = (40.49 ± 1.12) kJ mol^{-1}. On this basis the error limits suggested by Kerr and Parsonage are rather too generous.

CD_3 attack on acetone-d$_6$

Of the 19 studies of deuterium abstraction from CD_3COCD_3 by CD_3 radicals in the literature, only 9 include rate constant – temperature data. We have secured a further 6 sets of data through correspondence with the authors.

A summary of the Arrhenius parameters is presented in Table 2. Before the combined data were analysed, rate constants outside the range 393–523 K were excluded, leaving 183 of the original 242 points in 14 individual sets. Least-squares analysis of these data, together with the same value for k_3 as for CH_3 recombination (49), yielded

$$[16] \quad \log k_7 = (11.78 \pm 0.08) - (48500 \pm 690)/19.145T$$

where the units are the same as before. An Arrhenius plot of the data is shown in Fig. 2. All of the data points were found to be within four standard deviations of the line of best fit. It is interesting to note that with one exception, the only values of the Arrhenius parameters for the individual studies more than four standard deviations from the values in eq. [16] come from

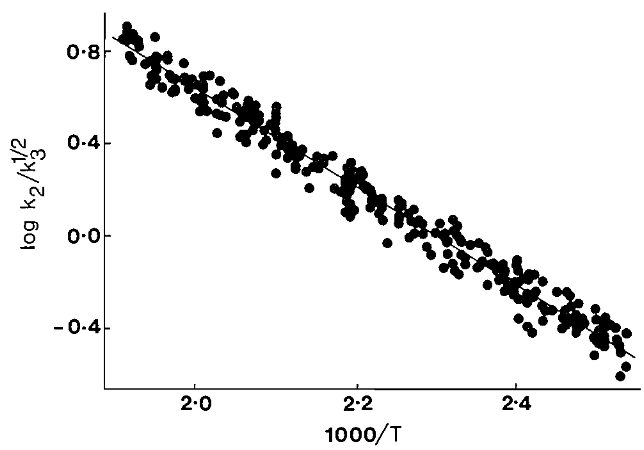

FIG. 1. Hydrogen abstraction from acetone by CH_3 radicals.

work undertaken prior to 1955, before samples of acetone-d_6 of high isotopic purity became available commercially.

The arithmetic means of the Arrhenius parameters from Table 2 are log A = (11.61 ± 0.22) and E = (46.71 ± 2.20) kJ mol^{-1}. These values are somewhat lower than those in eq. [16] as a result of the influence on them of several low values derived from a small number of points. The values recommended by Kerr and Parsonage, log A = (11.68 ± 0.2) and E = (47.7 ± 2.1) kJ mol^{-1}, and by Arthur *et al.*, log A = 11.69 and E = 47.99 kJ mol^{-1}, would also have been similarly affected.

We consider that Arrhenius parameters which fall more than four standard deviations outside the values given in eq. [16] are almost certainly unreliable, and therefore our recommended values are log A = (11.78 ± 0.32) and E = (48.50 ± 2.76) kJ mol^{-1}.

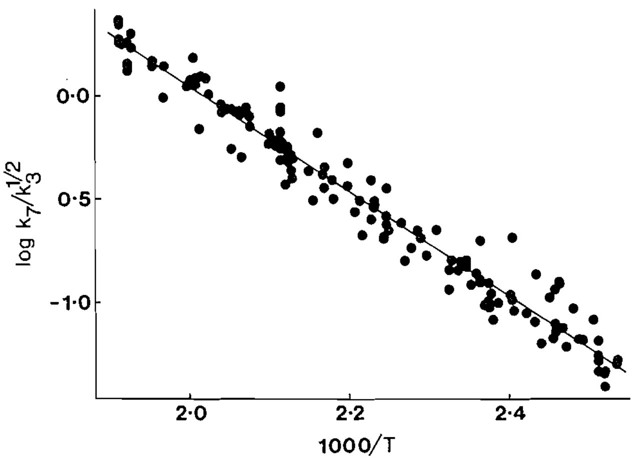

FIG. 2. Deuterium abstraction from acetone-d_6 by CD_3 radicals.

Kinetic isotope effect for CH_3 attack on CH_3COCH_3/CD_3COCH_3

If it is assumed that the reactivities of CH_3 and CD_3 radicals are equal (47, 51), the kinetic isotope effect for attack on CH_3COCH_3 and CD_3COCD_3 can be evaluated from

$$[17] \quad \log(k_H/k_D) = (\log A_H - \log A_D) + (E_D - E_H)/19.145T$$

Substituting our recommended values into this equation leads to $A_H/A_D = 0.58$, $E_D - E_H = 8.01$ kJ mol^{-1}, and $k_H/k_D = 6.4$ at 400 K.

Experimental kinetic isotope effects are usually compared with those predicted by the simple model that assumes the bond being attacked is broken in forming the transition state (4). According to this model, the ratio of A factors, A_H/A_D, is 1, and the difference in activation energies, $E_D - E_H$, is identified with the difference in zero-point energies of the C—H and C—D bonds, Δzpe. k_H/k_D is therefore given by

$$[18] \quad \log(k_H/k_D) = \Delta\text{zpe}/19.145T$$

The vibrational frequencies of these bonds in CH_3COCH_3 and CD_3COCD_3 are 2937 cm^{-1} and 2123 cm^{-1}, respectively (59), from which Δzpe = 4.87 kJ mol^{-1}, and hence $k_H/k_D = 4.3$ at 400 K. Comparison of the predicted and experimental values shows that $E_D - E_H > \Delta$zpe, $A_H/A_D < 1$, and $k_H/k_D > 4.3$ at 400 K. This may be due to the occurrence of quantum mechanical tunnelling (60), or to the loss of bending vibrations in the transition state (61).

CH_3 attack on azomethane

We have traced 31 studies of the reaction of CH_3 radicals with azomethane, but in only 10 of these were rate constant – temperature data reported. Although we have obtained a further 8 sets of data from the authors, the proportion of the total for which data are now available is still more than 20% less than for CH_3 attack on acetone and acetone-d_6.

The Arrhenius parameters for each study, together with the corresponding temperature ranges, are summarized in Table 3. As before, the Arrhenius parameters have been recalculated from the orginal data wherever possible.

We conducted two evaluations of the combined data: one of rate constants uncorrected for the intramolecular elimination of C_2H_6, reaction [12]; and the other of corrected data. In each case only rate constants within the temperature range 333–463 K (60–190°C) were considered, and the data of ref. 62 and 69 were omitted because of their unusually high degree of scatter.

After pruning the data in this way, 12 sets of rate constants uncorrected for reaction [12] remained, containing 166 points. Least-squares analysis of these data, with the same value of k_3 as before, gave

$$[19] \quad \log k_{11} = (11.05 \pm 0.07) - (33390 \pm 560)/19.145T$$

An Arrhenius plot of the data is shown in Fig. 3. The simple averages of the Arrhenius parameters for these 12 sets of data, taken from Table 3, are log A = (10.89 ± 0.30) and E = (32.56 ± 1.96) kJ mol^{-1}. These values are somewhat lower than those obtained in a similar way by Kerr and Parsonage: log A = (11.05 ± 0.03) and E = (33.1 ± 2.1) kJ mol^{-1}. Again, the agreement between these values and those given in eq. [19] is rather fortuitous, especially since Kerr and Parsonage did not distinguish between Arrhenius parameters corresponding to corrected and uncorrected rate constants. On the basis that Arrhenius parameters that fall outside four standard deviations from the values given in eq. [19] are suspect, we recommend the values log A = (11.05 ± 0.28) and E = (33.39 ± 2.24) kJ mol^{-1}.

Fifteen studies have reported Arrhenius parameters derived from rate constants corrected for the intramolecular elimination of C_2H_6. Of these only 8 contained tables showing the rate of

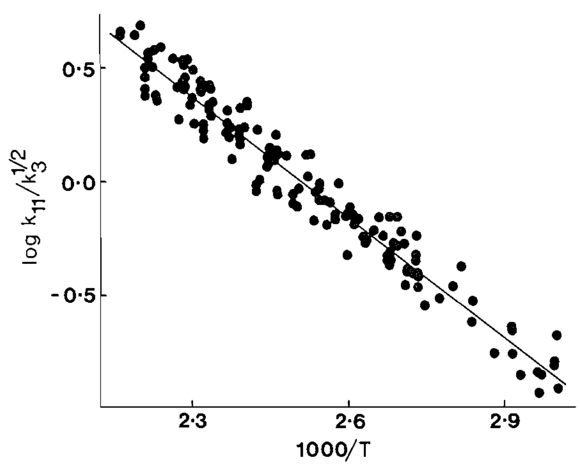

FIG. 3. Hydrogen abstraction from azomethane by CH_3 radicals.

nitrogen formation, R_{N_2}, and hence only for these could rate constants and Arrhenius parameters be recalculated. Analysis of the 128 points involved gave

$$[20] \quad \log k_{11}(\text{corr}) = (11.21 \pm 0.08) - (34570 \pm 590)/19.145T$$

These values are slightly higher than those corresponding to the uncorrected data. The simple averages of the 8 pairs of Arrhenius parameters are log A = (11.00 ± 0.46) and E = (33.09 ± 3.33) kJ mol^{-1}. We recommend that only Arrhenius parameters which fall within the range log A = (11.21 ± 0.32) and E = (34.57 ± 2.36) kJ mol^{-1} should be considered satisfactory.

M. CHASTRETTE et J. CARRETTO. Can. J. Chem. **63**, 3492 (1985).

Le calcul et l'interprétation des paramètres empiriques de polarité des solvants sont abordés dans cet article à l'aide de méthodes statistiques multivariées. L'importance de l'échantillon traité (57 solvants aprotiques et 24 solvants protiques) garantit une bonne représentativité de l'ensemble des solvants. Les données recueillies sur les solvants sont des constantes physiques (constante diélectrique, moment dipolaire, indice de réfraction, réfraction molaire, température d'ébullition, paramètre δ de Hildebrand) ou des grandeurs théoriques (niveaux d'énergie des orbitales frontières). Les méthodes utilisées sont l'analyse factorielle et la régression multiple. Les résultats obtenus montrent que le paramètre E_T mesure la polarité, la polarisabilité et la cohésion du solvant dans les proportions respectives de 43, 39 et 18% pour les solvants aprotiques. Pour π^* ces proportions sont de 53, 18 et 29%. Dans le cas des solvants protiques E_T est expliqué par les mêmes variables, sauf pour 5 solvants plus acides que l'eau, par suite de la basicité de l'oxygène de la bétaïne qui sert à définir E_T.

M. CHASTRETTE and J. CARRETTO. Can. J. Chem. **63**, 3492 (1985).

Using multivariational statistical methods, the calculation and interpretation of empirical parameters of the polarity of solvents has been reexamined. The size of the sample used (57 aprotic solvents and 24 protic solvents) assures that it is representative. For each solvent, the data tabulated include some physical constants (dielectric constants, dipole moments, refractive indices, molar refractions, boiling points, Hildebrand's δ parameters) or theoretical values (energy levels of frontier orbitals). The methods used are factorial analysis and multiple regression. The results obtained show that, for the aprotic solvents, the parameter E_T is a measure of the polarity, of the polarizability, and of the cohesion of the solvent to the extent of 43, 39, and 18% respectively. For the parameter π^*, these proportions are respectively 53, 18, and 29%. For the protic solvents, the parameter E_T is explained by the same variables except for 5 solvents more acidic than water; this anomaly is explained by the basicity of the oxygen of the betaine used to define E_T.

[Journal translation]

Introduction

Dans les approches quantitatives de l'effet des solvants sur les processus chimiques, une propriété mesurant cet effet est considérée comme une fonction linéaire, soit d'un ou plusieurs paramètres empiriques, soit d'une ou plusieurs grandeurs physicochimiques du solvant, soit de combinaisons des deux types de variable.

De nombreuses échelles empiriques ont été proposées pour rendre compte: (*i*) de la polarisabilité et de la polarité des solvants, comme E_T (1) et E_T^N (2), Z (3) et π^* (4); (*ii*) de leur acidité et de leur basicité de Lewis, comme par exemple AN et DN (5) ou ΔH BF_3 (6); (*iii*) de leur basicité (en tant qu'accepteurs de liaisons H), comme B (7) ou β (8*a*). Taft et coll. (8*b*) ont aussi défini une échelle d'acidité des solvants en tant que donneurs de liaisons H avec α.

Ces échelles ont en commun d'être définies par la variation de propriétés spectroscopiques d'une ou plusieurs molécules-sondes (ou de propriétés thermodynamiques de réactions modèles) quand on passe d'un solvant à un autre. C'est d'ailleurs ce qui limite leur efficacité quand on veut les utiliser seules dans des conditions trop différentes de celles dans lesquelles elles ont été définies (9, 10*a*).

Pour améliorer les résultats en essayant de prendre en compte toutes les interactions soluté–solvant, plusieurs auteurs ont préconisé une approche multiparamétrique (4, 5, 13, 14). Certains autres (9, 11, 15) ont fait intervenir dans leurs relations à la fois des paramètres empiriques et des grandeurs physiques caractéristiques des solvants.

Les difficultés rencontrées pour attribuer un sens physique précis aux paramètres empiriques et pour les utiliser valablement dans des conditions variées ont conduit à n'utiliser (16) que des grandeurs physicochimiques. De même le paramètre π^* de Taft et Kamlet a été calculé (17, 18) à partir de fonctions de la constante diélectrique et de l'indice de réfraction des solvants.

À partir de nombreuses données cinétiques, thermodynamiques et spectroscopiques, C. G. Swain *et al.* (19*a*) ont calculé les deux paramètres A et B nommés "acité" et "basité". D'après ces auteurs, A mesure la capacité d'un solvant à solvater les anions et B sa capacité à solvater les cations, ce que contestent Taft *et al.* (19*b*).

La notion de polarité d'un solvant étant la plus largement utilisée dans la pratique quotidienne des chimistes, il est important de savoir ce que mesurent les paramètres empiriques de polarité. Or (20, 21), il y a encore un grand fossé à combler pour établir les fondements théoriques de l'interprétation des interactions entre molécules-sondes et solvants. Dans un précédent article (12) nous avons montré que les paramètres E_T, Z et AN peuvent être calculés correctement à partir de quatre propriétés physicochimiques des solvants purs (moment dipolaire μ, constante diélectrique ϵ, réfraction molaire RM et paramètre δ de Hildebrand). Dans le présent article nous étendons cette étude à un nombre beaucoup plus élevé de solvants (81 au total)

liaisons hydrogène, pour lesquels nous avons pu rassembler à la fois les valeurs des propriétés physiques retenues et celles des paramètres E_T, Z et π^*. Pour E_T l'échantillon comporte 81 solvants, répartis en 57 solvants ne pouvant donner de liaison hydrogène (appelés ici SLH) et 24 solvants donneurs de liaisons hydrogène (appelés ici ALH). Les 57 solvants SLH comportent 20 aromatiques et 6 aliphatiques chlorés (tableau 1). Les solvants ALH comportent l'eau, 18 alcools, 2 acides carboxyliques et 3 amides (tableau 2).

Choix des variables physicochimiques et de la forme des fonctions utilisées

En plus de ϵ et de n_D, liés respectivement à la polarité et à la polarisabilité, nous avons retenu le moment dipolaire μ, la réfraction molaire RM (produit du volume moléculaire par la fonction $(n^2 - 1)/(n^2 + 2)$), la température d'ébullition T_e, et le paramètre de solubilité δ de Hildebrand (22). Il serait sans doute préférable d'utiliser la pression interne P_i plutot que δ. En effet δ est définit à partir de la densité d'énergie de cohésion et donc à partir de l'énergie mise en jeu pour vaporiser le solvant en supprimant toutes les interactions. Au contraire P_i est définie comme la variation d'énergie interne lors d'un expansion élémentaire du liquide, au cours de laquelle toutes les interactions entre molécules (et en particulier les liaisons hydrogène) ne sont pas rompues (23). P_i traduit donc mieux la situation créée par l'introduction d'une molécule de soluté, mais comme on n'en connaît la valeur que pour un nombre insuffisant des solvants que nous étudions ici, nous avons utilisé δ.

Le moment dipolaire μ, le paramètre de solubilité δ et la température d'ébullition T_e ont été utilisés directement. La constante diélectrique ϵ peut intervenir sous forme de différentes fonctions analysées par Taft et coll. (réf. 24, pp. 488–500). L'un de nous (25) a étudié le degré de similitude de ces fonctions pour des valeurs de ϵ comprises entre 2 et 80. Pour $\epsilon > 6$ toutes les fonctions sont proportionnelles, sauf celle de Block–Walker, $\theta(\epsilon)$, qui surestime sans doute l'importance de l'effet de saturation. Une variable tenant compte de la séparation des effets d'orientation et de polarisation électronique a été utilisée dans des corrélations (18, 26) sans avantage très déterminant sur les expressions classiques. Nous avons donc retenu la fonction de Kirkwood–Onsager, $(\epsilon - 1)/(2\epsilon + 1)$, que nous appelons KIR dans la suite.

En ce qui concerne l'indice de réfraction n_D, nous avons vérifié que les différentes fonctions dans lesquelles il intervient généralement sont très bien corrélées avec lui: ainsi $r = 0,998$ pour $(n^2_D - 1)/(n^2_D + 1)$ et $(n^2_D - 1)/(2n^2_D + 1)$; $r = 0,999$ pour $(n^2_D - 1)/(n^2_D + 2)$. Nous avons donc utilisé simplement n_D.

Les deux échantillons SLH et ALH ont été traités séparément. Les six variables physicochimiques appelées X_i dans la suite sont présentées dans les tableaux 1 et 2.

Méthodes statistiques

Aucune hypothèse n'est faite a priori sur la dépendance entre un paramètre particulier et les variables que sont les propriétés des solvants purs. Dans un premier temps on tente, par une analyse en composantes principales (12, 35), de définir les relations entre les variables, puis de les remplacer par des facteurs qui en sont des combinaisons linéaires. Ensuite, on cherche si l'information associée aux facteurs permet de rendre compte de la variation des paramètres empiriques, en effectuant une régression de ces derniers sur les facteurs. Enfin, une régression multiple d'un paramètre empirique sur les propriétés du solvant pur permet de préciser la signification de ce paramètre.

2. Résultats

2.1. *Solvants SLH*

Cas de E_T

Le paramètre E_T a été utilisé dans de très nombreuses corrélations avec des vitesses de réaction (10). Il est curieux de

TABLEAU 3. Coefficients de corrélation entre facteurs et variables pour 57 solvants SLH

Variable	F_1	F_2	F_3	F_4	F_5	F_6
KIR	0,920	0,162	0,139	0,304	0,120	0,027

T_e	0,520	0,803	0,156	0,227	0,001	0,094

constater la variété des interprétations qui en sont données. E_T a été considéré uniquement comme une mesure des propriétés électrophiles du solvant par plusieurs auteurs parmi lesquels Krygowski (15, 27–29), Mayer (30) et Koppel et Pal'm (7, 13); ces derniers ont en effet défini leur échelle d'acidité de Lewis à partir de E_T en lui enlevant la contribution de la polarité et de la polarisabilité. Ce point de vue a été contesté (31, 12). Taft et coll. (32) considèrent E_T comme un paramètre de polarité/polarisabilité contenant une contribution importante des propriétés électrophiles des solvants. D'autres ont noté de fortes corrélations de E_T avec le paramètre de solubilité de Hildebrand, δ (12), ou avec δ^2 ou avec ln δ (33). Enfin, récemment, le role des forces de dispersion déjà signalé (9) a été mis en évidence par Haak et Engberts (34). Il nous a semblé intéressant de comparer les importances relatives de ces différentes variables dans le calcul et l'interprétation de E_T.

Il est possible, en utilisant les six variables physicochimiques X_i précisées plus haut, d'étudier 57 solvants SLH (tableau 1). Dans un premier temps il fallait vérifier que les variables X_i retenues fournissaient bien une information suffisante pour déterminer E_T. Pour ce faire, tenant compte de ce que ces variables X_i ne sont pas indépendantes les unes des autres, nous avons effectué une analyse en composantes principales normée (11, 35*a*) permettant de définir à partir des variables X_i six facteurs F_i totalement indépendants. Le tableau 3 présente les valeurs des coefficients de corrélation entre les facteurs F_i et les grandeurs physiques X_i. Cette analyse permet de sélectionner les facteurs qui portent le plus d'information. Dans le cas des 57 solvants SLH, les trois premiers facteurs contiennent 94,2% de l'information totale.

E_T peut être calculé par une regression orthogonalisée (35*b*) sur ces trois facteurs. Le coefficient de F_3 n'est pas significatif;[2] on obtient l'équation [1]:

$$[1] \quad E_T = 38,79\ (\pm 0,12) + 2,11\ (\pm 0,07)\ F_1 - 0,658\ (\pm 0,08)\ F_2$$

$n = 57$; $r = 0,971$; $s = 0,87$; $F = 297$. Cette équation rend compte de 94,3% de la variance de E_T[3] (87,8% pour F_1 seul). D'après le tableau 3 on constate qu'il est difficile d'attribuer une signification physique aux différents facteurs retenus. F_1 est très lié aux variables de polarité (KIR, μ et δ) alors que F_2 est lié aux variables de polarisabilité (RM et n_D). La signification de F_3 reste obscure mais il n'intervient pas dans E_T. L'équation [1] montre que l'analyse de E_T en termes de variables physicochimiques du solvant pur est possible (l'information totale est suffisante).

Il nous paraît préférable d'utiliser directement les variables physicochimiques, pour obtenir une interprétation claire.

Pour les 57 solvants SLH considérés, la régression entre E_T et les valeurs de X_i est la suivante:[4]

$$[2] \quad E_T = 35,58\ (\pm 2,75) + 22,11\ (\pm 1,86)\ \text{KIR} + 1,358\ (\pm 0,127)\ \delta - 12,63\ (\pm 1,91)\ n_D$$

$n = 57$; $r = 0,971$; $s = 0,86$; $F = 301$. Les coefficients de RM, μ et T_e ne sont pas significatifs. L'équation [2] rend compte de 94,4% de la variance de E_T (89,8% à partir de KIR et δ; et 81,5% à partir de KIR seul).[3]

Pour préciser l'importance relative des trois variables physicochimiques dans la détermination de E_T on dispose d'une méthode employée par Gore (36), Krygowski (27) et plus récemment par Maccarone et Perrini (37) qui consiste à pondérer les coefficients de la régression par les écarts-types des variables. On trouve ainsi que KIR est le plus important (43,2%), suivi de δ (38,5%) et de n_D (18,3%). L'équation [2] montre que E_T est lié (*i*) à la polarité du solvant par l'intermédiaire de KIR. KIR et μ étant bien corrélés ($r = 0,913$), il est normal qu'une seule des variables apparaisse dans [2]; (*ii*) à la polarisabilité, à travers l'indice de réfraction n_D avec un coefficient de régression négatif indiquant que E_T croit lorsque la polarisabilité du solvant diminue; (*iii*) à la cohésion, par l'intermédiaire du paramètre δ de Hildebrand. On ne doit pas s'étonner que E_T, qui apparaît comme un bon paramètre de polarité/polarisabilité, dépende aussi nettement de δ car les échelles empiriques de polarité peuvent toutes faire intervenir plus ou moins l'énergie de cohésion du solvant. Cette dépendance multiple explique que l'échelle de Dimroth et Reichardt soit employée avec succès pour rendre compte des effets de la polarité des solvants (10*b*).

Pour déterminer l'influence du choix des solvants sur les résultats obtenus, nous avons traité séparément une sous-population de 19 solvants aliphatiques non halogénés (que Taft *et al.* nomment "select solvents"). Ces solvants ont été choisis parce que communs à notre échantillon et à la liste de "select solvents" donnée par Taft et coll. dans une publication récente (38) (ils sont marqués d'un signe + dans le tableau 1). La régression de E_T sur les variables physicochimiques conduit à retenir l'équation:

$$[3] \quad E_T = 60,68\ (\pm 11,7) + 11,53\ (\pm 4,77)\ \text{KIR} + 2,22\ (\pm 0,36)\ \delta - 33,86\ (\pm 9,5)\ n_D$$

$r = 0,980$; $n = 19$; $s = 0,835$; $F = 124$.

On constate que les variables significatives restent les mêmes que pour l'échantillon entier mais surtout qu'il est nécessaire de faire intervenir la cohésion du solvant pour obtenir une corrélation acceptable (avec seulement KIR, $r = 0,922$; avec δ seul, $r = 0,922$; avec KIR et δ, $r = 0,963$). L'introduction du paramètre δ rend inutile l'emploi dans la corrélation de termes croisés (comme par exemple le produit KIR $\times$ n_D).

Par ailleurs, il est connu que E_T est bien corrélé avec AN (2) mais nous avons montré que AN était non seulement une mesure de l'acidité mais aussi une bonne mesure de la polarité des solvants (12). Ceci est confirmé par la bonne corrélation observée entre AN et π^* (38, 39). Pour vérifier si E_T dépend réellement de l'acidité de Lewis des solvants, nous avons étudié la

[2] Les coefficients de régression sont considérés comme significatif quand leur probabilité critique est inférieure à 5%. Le plus souvent elle est inférieure à 0,1%.

[3] Les valeurs de E_T ne sont pas normalisées.

[4] Dans le cas des solvants SLH, pour le calcul de E_T, le résultat obtenu en remplaçant δ par δ^2 dans le groupe de variables δ, KIR et n_D est pratiquement le même qu'avec δ.

corrélation entre E_T et l'énergie de la plus basse orbitale non occupée, LUMO. En effet, Sabatino *et al.* (40) ont montré que l'énergie de l'orbitale LUMO et AN se comportaient de manière tout à fait semblable dans des corrélations avec des vitesses de réaction et des énergies de solvatation. Pour 53 solvants SLH de notre échantillon dont les valeurs de LUMO sont connues (25), le coefficient de corrélation entre E_T et LUMO est $r = 0,423$. E_T n'est donc pratiquement pas lié à l'acidité de Lewis des solvants SLH.

Cas de Z

L'étude de Z a été menée pour 29 solvants SLH (ceux de l'échantillon de 57 solvants pour lesquels Z est connu). Le calcul de Z n'a été effectué qu'à partir des variables physicochimiques (tableau 1). Les corrélations entre ces différentes variables sont du même ordre que pour l'ensemble des 57 solvants SLH. L'équation [4] permet de rendre compte de 87% de la variance de Z:

$$[4] \quad Z = 104,1\ (\pm 10,70) - 0,499\ (\pm 0,059)\ \mathrm{RM} - 26,30\ (\pm 7,97)\ n_D + 0,082\ (\pm 0,007)\ T_e$$

$n = 29$; $r = 0,933$; $s = 3,925$; $F = 56$.

Il faut noter que δ, dont le coefficient dans la régression multiple n'est pas significatif, est le paramètre qui, considéré seul, présente la plus forte corrélation avec Z ($r = 0,828$). Parmi les trois variables dont dépend Z, l'importance de l'indice de réfraction est nettement la plus grande: 62,7%, contre 20,7% pour la température d'ébullition et 16,6% pour la réfraction molaire. Z semble donc dépendre principalement de la polarisabilité du solvant: quand celle-ci augmente, Z diminue. Comme pour E_T, aucune corrélation significative n'existe entre Z et LUMO.

Cas de π^*

Les valeurs de π^* sont connues pour 52 des 57 solvants de notre échantillon de solvants SLH (tableau 1). Les trois premiers facteurs obtenus par analyse en composantes principales normée à partir des X_i portent 94,5% de l'information totale. Mais l'équation obtenue par régression de π^* sur ces trois facteurs ne rend compte que de 81,3% de la variance de π^*. En considérant les quatre premiers facteurs on obtient l'équation [5] qui ne permet d'expliquer que 88,6% de la variance de π^*:

$$[5] \quad \pi^* = 0,647\ (\pm 0,011) + 0,889\ (\pm 0,05)\ F_1 + 0,212\ (\pm 0,059)\ F_2 + 0,477\ (\pm 0,107)\ F_3 + 0,936\ (\pm 0,17)\ F_4$$

$n = 52$; $r = 0,941$; $s = 0,007$; $F = 92$.

La prise en compte du cinquième facteur n'apporte pas d'amélioration sensible ($r = 0,947$; $s = 0,006$; $F = 80$). Attribuer une signification physique aux facteurs F_i est tout aussi complexe que dans le cas de E_T et nous avons préféré établir la régression multiple qui permet de calculer π^* en fonction des propriétés physiques elles-mêmes:

$$[6] \quad \pi^* = -2,419\ (\pm 0,249) + 1,85\ (\pm 0,173)\ \mathrm{KIR} + 0,043\ (\pm 0,011)\ \delta + 1,33\ (\pm 0,249)\ n_D$$

$n = 52$; $r = 0,946$; $s = 0,006$; $F = 138$.

L'équation [6] rend compte de 89,6% de la variance de π^* (64,8% avec KIR seul; 61% avec δ seul). D'après [6], π^* est lié, comme E_T, à la polarité, à la polarisabilité et à la cohésion du solvant. C'est le paramètre de Kirkwood qui est ici le plus important dans la détermination de π^* (53,2%), suivi de n_D (28,5%) et de δ (18,3%). À partir des variables physicochimiques choisies, même en gardant près de 99% de l'information, on ne peut pas calculer π^* de façon satisfaisante. Pour 48 des 52 solvants pour lesquels on connaît les valeurs de LUMO, le coefficient de corrélation simple entre π^* et LUMO est $r = 0,715$. π^* apparaît donc très faiblement lié à l'acidité de Lewis du solvant. En faisant intervenir ce paramètre dans l'équation de régression on obtient:

$$[7] \quad \pi^* = -1,929\ (\pm 0,291) + 1,697\ (\pm 0,182)\ \mathrm{KIR} + 0,035\ (\pm 0,011)\ \delta + 1,006\ (\pm 0,197)\ n_D - 0,015\ (\pm 0,005)\ \mathrm{LUMO}$$

$n = 48$; $r = 0,955$; $s = 0,006$; $F = 113$.

Cette équation rend compte de 91,2% de la variance de π^*. En effectuant le même calcul pour E_T, on constate que le coefficient de LUMO dans l'équation de régression n'est pas significatif.

Suivant Bekarek (17) nous avons repris le calcul de π^* en fonction des variables physicochimiques pour, respectivement, 25 solvants aliphatiques non-halogénés et 18 solvants aromatiques, appartenant tous à notre échantillon de 52 solvants SLH. Dans les deux cas, le calcul de π^* se trouve nettement amélioré. Pour les 18 solvants aromatiques, la régression fait intervenir KIR, RM et n_D ($r = 0,964$, $s = 0,002$). Dans le cas des 25 solvants aliphatiques non halogénés (repérés par le signe × dans le tableau 1), π^* peut être calculé à partir de KIR, δ et n_D:

$$[8] \quad \pi^* = -2,616\ (\pm 0,649) + 2,082\ (\pm 0,258)\ \mathrm{KIR} + 0,040\ (\pm 0,014)\ \delta + 1,409\ (\pm 0,488)\ n_D$$

$n = 25$; $r = 0,963$; $s = 0,007$; $F = 90$.

Pour 36 solvants "select", dont 23 figurent aussi dans notre échantillon, Abboud *et al.* (26) ont obtenu l'équation:

$$[9] \quad \pi^* = -0,95\ (\pm 0,28) + 1,19\ (\pm 0,09)\ A_1 + 5,05\ (\pm 1,43)\ A_2$$

$n = 36$; $r = 0,983$; $s = 0,05$; $F = 472$, avec

$$A_1 = (\epsilon - 1)/(\epsilon + 2) - (n^2_D - 1)/(n^2_D + 2)$$
$$\text{et } A_2 = (n^2_D - 1)/(2n^2_D + 1)$$

Les fonctions A_1 et A_2 (de ε et de n_D) conviennent donc mieux au calcul de π^* que KIR et n_D lui-même.

2.2. *Solvants ALH*

En raison de la faible taille des échantillons de solvants ALH pour lesquels on connaît π^* ou Z, nous avons mené cette étude uniquement pour E_T. L'échantillon de 24 solvants considéré comprend l'eau, 18 alcools primaires ou secondaires, 3 amides non tertiaires et 2 acides carboxyliques (tableau 2). Une étude similaire à celle qui a été effectuée pour les solvants SLH a été réalisée pour ces solvants qui peuvent participer à des liaisons hydrogène. Une analyse factorielle normée effectuée sur les six variables physicochimiques X_i fournit six facteurs F_i indépendants. Il faut considérer les 4 premiers facteurs pour rendre compte de 96,2% de l'information totale. La régression orthogonalisée sur ces quatre facteurs conduit à:

$$[10] \quad E_T = 51,708\ (\pm 0,474) + 2,27\ (\pm 0,299)\ F_1$$

$n = 24$; $r = 0,85$; $s = 5,40$; $F = 57,5$, les coefficients des autres facteurs n'étant pas significatifs. Cette relation n'explique que 72% de la variance de E_T. De plus, les tests de qualité de la régression [10] (41) (variance des écarts (42*a*); test

TABLEAU 4. Coefficients de corrélation entre facteurs et variables pour 19 solvants ALH

Variable	F_1	F_2	F_3	F_4	F_5	F_6
KIR	0,820	0,218	0,266	0,456	0,029	0,022
RM	0,817	0,483	0,099	0,145	0,234	0,114
μ	0,574	0,624	0,399	0,343	0,013	0,065
δ	0,874	0,050	0,460	0,021	0,102	0,111
n_D	0,272	0,891	0,170	0,133	0,288	0,051
T_e	0,059	0,955	0,189	0,076	0,147	0,149

ψ d'Exner (42*b*)) ne sont pas satisfaisants. Reichardt (10*c*) reconnaît que la principale limite de l'échelle de polarité définie par E_T réside dans le fait que les valeurs de E_T ne sont pas mesurables dans les solvants acides. En effet, toute addition d'acide à une solution contenant la bétaïne de Dimroth provoque la protonation de l'oxygène phénolique. Nous avons donc repris ce calcul après avoir éliminé de notre échantillon les solvants plus acides que l'eau, c'est-à-dire les acides formique et acétique (pK_a = 3,75 et 4,75), le trifluoroéthanol (pK_a = 12,4 (43), l'éthylèneglycol (pK_a = 14,2) et le méthoxy-2 éthanol (pK_a = 14,8 (44)). L'étude effectuée sur les 19 solvants ALH restant (tableau 2, solvants sans*) à partir des trois premiers facteurs qui portent 96,6% de l'information totale, conduit à:

$$[11] \quad E_T = 50{,}89\ (\pm 0{,}27) + 2{,}117\ (\pm 0{,}157)\ F_1 + 2{,}672\ (\pm 0{,}436)\ F_3$$

r = 19; n = 0,967; s = 1,40; F = 73.

La qualité de la régression se trouve sensiblement améliorée puisque l'équation [11] explique 93% de la variance de E_T (F_1 seul en explique 77%). Dans ce cas, comme dans celui des solvants SLH, il n'est pas possible de faire le lien de façon univoque entre un facteur F_i et une propriété caractéristique des solvants (tableau 4). Le calcul à partir des propriétés des solvants purs limité aux 19 solvants finalement retenus conduit à l'équation:

$$[12] \quad E_T = 126{,}60\ (\pm 18{,}15) + 0{,}93\ (\pm 0{,}079)\ \delta - 66{,}28\ (\pm 13{,}24)\ n_D + 0{,}038\ (\pm 0{,}009)\ T_e$$

n = 19; r = 0,982; s = 0,765; F = 138.

La relation [12] rend compte de 96,4% de la variance de E_T (δ seul en explique 90,5%). C'est δ qui a l'importance relative la plus grande (41,9%), suivi par l'indice de réfraction n_D (31,5%) puis par la température d'ébullition T_e (26,6%). Ceci montre que, pour les 19 solvants ALH pas trop acides, E_T est lié à la cohésion et à la polarisabilité du solvant. L'existence d'une faible corrélation (r = 0,791) entre δ et KIR suggère un lien plus faible avec la polarité. Il n'existe pas de corrélation significative entre E_T et LUMO pour les 17 solvants ALH de notre échantillon pour lesquels les valeurs de LUMO sont connues. Par contre, nous avons constaté que l'introduction du paramètre α de Taft dans l'équation de régression de E_T améliore nettement le résultat obtenu pour des solvants d'acidité variée (acide acétique, formamide, alcools, eau) (pour $E_T = f(\text{KIR}, \delta, \alpha)$, n = 10, r = 0,989, s = 0,64). Mais, α étant connu (32) pour 10 seulement des 24 solvants ALH, ce résultat n'a pas une grande portée.

3. Discussion

Pour les solvants SLH, ce sont les mêmes variables physicochimiques KIR, δ et n_D qui interviennent dans les équations de régression de E_T et π^*. Les deux paramètres empiriques apparaissent donc liés à la polarité et à la polarisabilité comme l'ont déjà observé de nombreux chercheurs. Nous montrons de plus que E_T et π^* contiennent une contribution importante de la cohésion de solvant, par l'intermédiaire du paramètre δ de Hildebrand. Ce paramètre permet de tenir compte de l'énergie nécessaire pour former dans le solvant une cavité où loger le soluté. Il convient donc de comparer les différents paramètres de polarité en tenant compte de ces trois aspects et non plus seulement des deux premiers. L'importance relative des trois variables n'est pas la même pour E_T et pour π^* (tableau 5) et, de plus, le signe du coefficient de n_D dans la régression est différent.

TABLEAU 5. Importances relatives de KIR, δ et n_D dans le calcul de E_T et π^* (solvants SLH)

	Nb. solv.	KIR	δ	n_D
E_T	57	43,2%	38,5%	18,3%
E_T	52	44,7%	38,3%	17,0%
π^*	52	53,2%	18,3%	28,5%

Il est possible d'intepréter la contribution plus élevée de δ pour E_T que pour π^* en considérant que la bétaïne utilisée pour définir E_T est bien plus volumineuse que les composés utilisés dans la définition de π^*.

Si l'on admet (18 et références citées) que l'énergie de solvatation due à la polarisation électronique est donnée par l'équation:

$$\Delta E = \frac{\mu^2_E - \mu^2_G}{r^3} \times \frac{n^2_D - 1}{2n^2_D + 1}$$

(où μ_E et μ_G sont respectivement les moments dipolaires des états excité et fondamental) on peut rendre compte du signe du coefficient de régression de n_D qui est celui de la différence $\mu^2_E - \mu^2_G$. En effet, d'après Reichardt (10*d*) les moments dipolaires à l'état excité et à l'état fondamental de la *p*-nitro-*N*,*N*-diéthyl aniline, qui a servi parmi d'autres composés semblables à la définition de π^*, sont respectivement de 12,9 et 5,1 D, ce qui correspond à $\mu^2_E - \mu^2_G = 140{,}4$. Pour le bétaïne de Dimroth, les moments dipolaires à l'état excité et fondamental sont respectivement de 6 et 14,7 D, ce qui correspond à $\mu^2_E - \mu^2_G = -180{,}1$. Il est donc normal de trouver que le coefficient de régression pour la variable n_D est positif pour π^* et négatif pour E_T.

Pour les 52 solvants SLH communs aux deux études, E_T et π^* ne présentent qu'une corrélation très moyenne (r = 0,788). Kamlet, Abboud et Taft (réf. 24, p. 573) ont aussi constaté ce fait et l'attribuent à un dosage de polarisabilité et de polarité différent pour les deux paramètres empiriques, ce qui est vérifié si l'on considère le tableau 5. D'ailleurs, nous constatons que la corrélation entre E_T et π^* est nettement meilleure quand l'équation de régression fait intervenir n_D (r = 0,933, s = 0,008, n = 50), lié à la polarisabilité. Taft et coll. (4) obtiennent aussi une nette amélioration de la corrélation entre E_T et π^* en étudiant séparément des familles de solvants de même type (aliphatiques non chlorés, aliphatiques polychlorés, aromatiques) ayant des caractéristiques de polarisabilité communes.

Pour les solvants ALH, E_T peut être calculé à partir des grandeurs physicochimiques, à condition de ne pas prendre en considération les solvants les plus acides (pK_a < 15). Ceci correspond au caractère basique de la bétaïne de Dimroth dont

TABLEAU 6. Importances relatives de quatre variables physicochimiques dans le calcul de E_T

	δ	n_D	KIR	T_c
57 solvants SLH	38,5%	18,3%	43,2%	—
19 solvants ALH	41,9%	31,5%	—	26,6%

les solvants les plus acides provoquent la protonation de l'oxygène phénolique (10*c*). Pour les deux types de solvants, E_T dépend significativement de la polarisabilité, à travers l'indice de réfraction, et de la cohésion, par l'intermédiaire de δ. KIR, bien corrélé avec le moment dipolaire, intervient dans l'expression de E_T pour les solvants SLH. Par contre, ni KIR ni μ ne figurent dans l'expression de E_T pour les solvants ALH. Il faut toutefois noter que, dans ce dernier cas, il existe une corrélation faible ($r = 0,791$) entre δ et KIR. Pour E_T, δ a une importance relative notable et remarquablement proche pour les deux types de solvants (cf. tableau 6). Ceci montre l'influence très importante du processus de création d'une cavité dans le solvant et donc la nécessité de prendre en compte une grandeur liée à la cohésion du solvant dans tout traitement des effets de solvant.

Conclusion

Dans cette étude qui généralise la précédente (12) nous avons calculé E_T uniquement à partir de variables physicochimiques caractéristiques des solvants purs. Cette démarche nous a permis, pour un nombre raisonnable de solvants (57 SLH et 19 ALH), de rendre compte de plus de 94% de la variance de E_T et de conclure que l'échelle empirique de Dimroth et Reichardt est bien une échelle de polarité–polarisabilité avec une forte influence de la cohésion et une très faible influence de l'acidité du solvant.

En ce qui concerne π^* et Z, et pour les échantillons de solvants SLH correspondants (52 pour π^*, 29 pour Z), une conclusion plus nuancée s'impose bien que les mêmes effets soient mis en évidence.

Les réactions du trioxyde de chlore (Cl_2O_6) sur les $InCl_3$ et $TlCl_3$ anhydres ou $InCl_3,4H_2O$ ont conduit à deux nouveaux perchlorato métallates de chloryle $ClO_2In(ClO_4)_4$ et $ClO_2Tl(ClO_4)_4$. Par dégradation thermique sous vide dynamique, ces deux sels de chloryle donnent respectivement, vers 80°C, $In(ClO_4)_3$ et $Tl(ClO_4)_3$. $Tl(ClO_4)_3$ se transforme dès 95°C en $TlO_{0.5}(ClO_4)_2$ alors que $In(ClO_4)_3$ est stable jusqu'à 272°C. $In(ClO_4)_3$ et $Tl(ClO_4)_3$ cristallisent dans le même groupe d'espace $P\bar{3}$. La meilleure interprétation des spectres de vibration ir et Raman peut être effectuée en considérant une molécule polymère de type AsI_3. Les groupes (ClO_4) sont bidentés en pont et fortement liés au métal. Les composés $ClO_2M(ClO_4)_4$ (M = In, Tl) sont des complexes définis comportant le cation ClO_2^+ en interaction avec l'anion $M(ClO_4)_4^-$. Il existe dans cet anion des groupes (ClO_4) monodentés et bidentés.

MOHIEDDINE FOURATI, MONCEF CHAABOUNI, HASSINE FERID AYEDI, JEAN-LOUIS PASCAL, and JACQUELINE POTIER. Can. J. Chem. **63**, 3499 (1985).

Reactions of chlorine trioxide (Cl_2O_6) with anhydrous $InCl_3$, $TlCl_3$, and $InCl_3\cdot4H_2O$ have been investigated. They give two chloryl perchlorato metallates: $ClO_2In(ClO_4)_4$ and $ClO_2Tl(ClO_4)_4$, which can be decomposed on heating (80°C) under dynamic vacuum. They yield respectively $In(ClO_4)_3$ and $Tl(ClO_4)_3$. $Tl(ClO_4)_3$ appears to have weaker thermal stability than $In(ClO_4)_3$, which is stable up to 272°C; the former decomposes starting at 95°C to give $TlO_{0.5}(ClO_4)_2$. $In(ClO_4)_3$ and $Tl(ClO_4)_3$ have the same space group $P\bar{3}$. The best assignment of their ir and Raman vibrational spectra can be made on the basis of a polymeric structure (AsI_3 type) with bridging bidentate perchlorato groups strongly bonded to the metal. The $ClO_2M(ClO_4)_4$ (M = In, Tl) salts are well defined. The cation ClO_2^+ is unambiguously characterized; it interacts with the anion $M(ClO_4)_4^-$, which has monodentate and bidentate perchlorate groups.

Introduction

L'utilisation d'agents perchloratants efficaces tels que Cl_2O_6, $HClO_4$, $ClClO_4$,... a permis à Schmeisser et Brandle (1), Rosolovskii et coll. (2), Christe et coll. (3) et nous-mêmes (4) de préparer plusieurs complexes perchlorato anhydres des métaux de transition et d'éléments du bloc p.

Dans la colonne III, il a été mis en évidence des complexes de type $MCl(ClO_4)_2$ (M = B (5)); $MCl_2(ClO_4)$ (M = B (5) et Ga (6)); $M(ClO_4)_3$ (M = B (5), Al (2*a*) et Ga (6)); $A_nM(ClO_4)_{3+n}$ (M = B, n = 1, A = alcalin, NH_4^+, NO_2^+; M = Al, n = 1, A = ClO_2^+; $1 < n < 3$, A = alcalin, NH_4^+, NO_2^+; M = Ga, n = 1, A = ClO_2^+ (5–11). Aucun perchlorate anhydre d'In(III) ou de Tl(III) analogue aux précédents n'est connu. Seuls sont signalés dans la littérature des perchlorates In(I) et de Tl(I) (12*a*, 13) ainsi que des complexes de type $ML_x(ClO_4)_z$; M = In, Tl, L = base organique (12*b*, 13).

L'étude des structures de $Sn_3O_2Cl_4(ClO_4)_4$, $Sb_2Cl_6(O)(OH)(ClO_4)$ par RX (rayons X) (14, 15) et des complexes de type $M(ClO_4)_2$ (M = Cu (16*a*), Co, Ni (16*b*)) par EXAFS (Extended X-Ray Absorption Fine Structure) a permis d'affiner les données de la spectroscopie de vibration.

On a pu établir d'une façon rigoureuse les corrélations: fréquences des vibrations ↔ longueurs des liaisons et nombre de vibrations ↔ géométrie du ligand (*monodenté, bidenté en pont, tridenté en pont.*)

Nous présentons ici le mode de préparation des perchlorates anhydres d'indium(III) et de thallium(III) et proposons une analyse structurale des composés obtenus. Cette analyse repose sur les données de la spectroscopie de vibration ir et Raman, des diagrammes de poudre X et de récents résultats en EXAFS sur $Ga(ClO_4)_3$ (17).

Partie expérimentale

Attention: Le trioxyde de chlore et les perchlorates anhydres sont des composés très réactifs, particulièrement au contact des matières organiques ou sous les chocs. Les réactions doivent être surveillées attentivement. Les complexes sont extrêment hygroscopiques; ils sont manipulés sur une ligne de vide (18) ou dans une boîte à gant contenant de l'azote très sec.

Produits de base

La préparation et la purification du trioxyde de chlore ont déjà été décrites (19). $InCl_3$ (Alfa Ventron ou Merck pour analyse) et $TlCl_3$ (Cerac (99,9)) sont utilisés sans purification préalable.

$InCl_3,4H_2O$ est obtenu par recristallisation dans l'eau de $InCl_3$ anhydre et chauffage sous vide à 50–60°C jusqu'à poids constant.

Méthodes d'analyse

Les appareils d'analyse ir, Raman et RX sur poudre ainsi que les méthodes d'échantillonnage sont présentées par ailleurs (4, 5).

Pour l'analyse chimique, la mise en solution des perchlorates anhydres est effectuée avec beaucoup de précautions (4). Les dosages de In (20), Tl (20), de ClO_2^+ (4, 21) et de ClO_4^- (22) sont effectués généralement de façon classique comme indiqué dans la légende du tableau 1. Seule l'analyse de ClO_4^- dans les complexes du thallium fait l'objet d'une méthode originale mise au point au cours de ce travail.

Par suite d'une réaction de complexation secondaire (23), les complexes du thallium ne peuvent pas être titrés par potentiométrie grâce

au chlorure de tétraphényl-arsonium (22).

La concentration en ClO_4^- est déterminée en utilisant une courbe d'étalonnage préalablement établie à partir des potentiels d'électrode de plusieurs solutions étalons de perchlorates de potassium ($5 \times 10^{-4} < M < 5 \times 10^{-2}$). Pour tous les échantillons la force ionique est maintenue constante par addition de $(NH_4)_2SO_4$.

Synthèse des complexes perchlorato d'indium et de thallium

Les mécanismes de synthèses et de décomposition obeissent à des règles déjà rencontrées (4):

(*i*) À partir d'un chlorure anhydre:

[1] $MCl_3 + 4Cl_2O_6 \rightarrow ClO_2M(ClO_4)_4 + 3ClO_2 + 3/2Cl_2$

[2] $ClO_2M(ClO_4)_4 \rightarrow M(ClO_4)_3 + Cl_2O_6$

(*ii*) À partir d'un chlorure hydraté:

[3] $MCl_3 \cdot nH_2O + 3Cl_2O_6 \rightarrow M(ClO_4)_3\, nH_2O + 3ClO_2 + 3/2Cl_2$

[4] $M(ClO_4)_3 \cdot nH_2O + (n + 1)Cl_2O_6 \rightarrow ClO_2M(ClO_4)_n + nHClO_3 + nHClO_4$

Contrairement au bore (5) et au gallium (6), on n'obtient jamais avec l'indium et le thallium, dans un premier stade, des complexes de type $MCl_{n-1}(ClO_4)_n$.

Dans une expérience classique on distille à −180°C sur 0,5 à 6 × 10^{-3} mole de chlorure, un excès de Cl_2O_6 (2 à 5 fois plus). On laisse ensuite rechauffer doucement ce mélange jusquà 10°C, puis on agite plusieurs heures (de 3 à 8 h) jusqu'à ce que le maximum de trioxyde de chlore soit consommé. Durant l'agitation on note un fort dégagement de ClO_2, O_2, Cl_2. Ces gaz doivent être éliminés périodiquement sous vide dynamique du milieu réactionnel. Après avoir enlevé par pompage l'excès de Cl_2O_6, on aboutit un composé orange qui enrobe souvent des particules de chlorure qui n'ont pas réagi. On broit ce mélange en boîte à gant puis on le retraite par Cl_2O_6. Le

[a] Les échantillons de $ClO_2Tl(ClO_4)_4$ sont protégés par une feuille en Kapton; elle ne permet pas de faire de bonnes mesures d'intensités relatives. La signification de s, m, w est donnée dans le tableau 3.

produit final est un sel de chloryle pur, $ClO_2M(ClO_4)_4$. Par chauffage sous vide dynamique du sel de chloryle on obtient $M(ClO_4)_3$. Cette dernière opération doit être menée **avec précaution**, avec le sel de thallium pour éviter la formation d'un oxo perchlorato complexe.

Les caractéristiques des réactions, l'analyse des composés isolés sont reportées dans le tableau 1. On doit remarquer que $In(ClO_4)_3$ est stable jusqu'à 272°C.

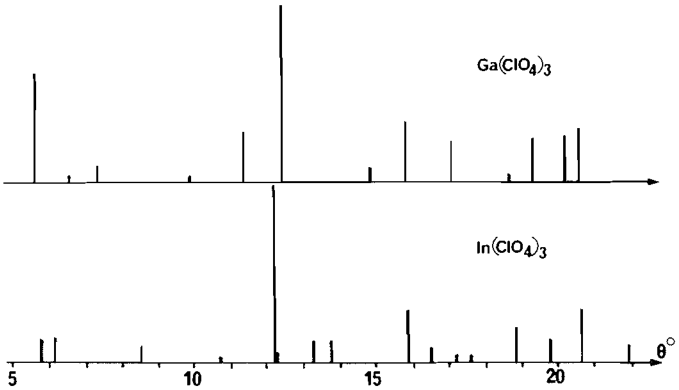
Résultats

Analyse structurale

Les composés synthétisés sont anhydres car les spectres ir et Raman (figures 1–4) ne présentent aucune bande ou raie dans les domaines de vibrations du vibrateur O—H (3600–3000 cm^{-1} et 1800–1500 cm^{-1}).

In(ClO₄)₃

La similitude des spectres ir et Raman de $In(ClO_4)_3$ et $Ga(ClO_4)_3$ (fig. 1 et réf. 6) indique que l'environnement du métal et la symétrie locale sont identiques dans les deux complexes.

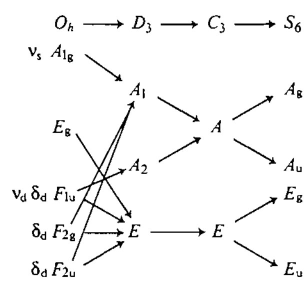


Leurs diagrammes de poudre sont cependant différents. Il est possible d'indexer les raies de celui de $Ga(ClO_4)_3$ à partir du groupe $R\bar{3}$ (17). Pour $In(ClO_4)_3$ on est conduit à adopter le groupe $P\bar{3}$ pour lequel les arrangements dans la maille sont voisins (tableau 2). On reste ainsi cohérent avec les données de la spectroscopie de vibration.

Une étude structurale par EXAFS de $Ga(ClO_4)_3$ (17) a montré que sa structure dérive de celle de AsI_3 (24). C'est un polymère à structure lamellaire, la distance Ga—Ga est de 4,71 Å. Les groupes ClO_4 sont bidentés en pont (fig. 5 et réf. 17).

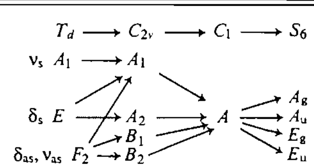
Autour de chaque atome de métal la symétrie locale est D_3. Dans le cristal le groupe facteur est S_6. Ceci conduit au tableau de corrélation 3*a* pour le squelette MO_6.

TABLEAU 3*a*



Pour les groupes ClO_4 on peut dresser le tableau de corrélation 3*b*.

TABLEAU 3*b*



Il est bien évident que l'on ne pourra observer, pour les 6 molécules contenues dans la maille, les $((3 \times 16 \times 6) - 3 = 285)$ vibrations attendues. Par contre, on peut rendre compte des perturbations et effets de multiplicité pour les groupes ClO_4 et des vibrations du squelette métal–oxygène.

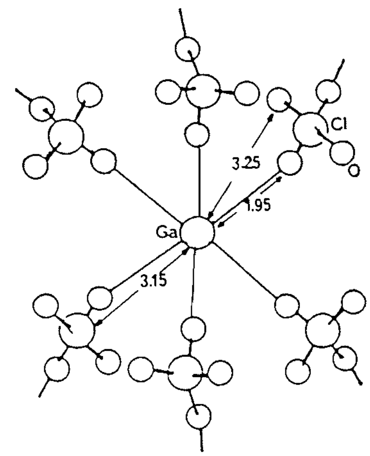


FIG. 5. Environnement de Ga dans $Ga(ClO_4)_3$ d'après réf. 17.

On note, pour les 18 modes de vibration attendus du groupe ClO_4 entre 1400 et 400 cm^{-1}, 14 composantes principales en Raman et 12 en ir. L'activité sélective ir–Raman prévue est vérifiée en particulier dans le domaine des vibrations de valence ClO_t (O_t = oxygène terminal) (fig. 1).

La présence de ligands ClO_4 bidentés est confirmée par 4 groupes de bandes ou raies dans le domaine des vibrations de valence (18, 25) (cf. tableau 4). Sous l'effet du groupe facteur (tableau 3*b*) chacun de ces modes de vibrations se dédouble en deux composantes A_g et E_g en Raman et A_u et E_u en ir (tableau 4). Par exemple ν_{as} ClO_t est observé à 1326 et 1306 cm^{-1} en Raman et 1290 et 1275 cm^{-1} en ir et ν_s ClO_t apparait à 1202 et 1156 cm^{-1} en Raman et 1165 et 1143 cm^{-1} en ir. L'effet de multiplicité dû à la présence de 6 motifs dans la maille permet d'expliquer, notamment les composantes à 1305 cm^{-1} en ir et à 1293 cm^{-1} en Raman. La plus faible résolution dans le domaine des modes de déformation de ClO_4 (700–400 cm^{-1}) ne permet pas de voir l'ensemble des composantes attendues (fig. 1). Les attributions les plus logiques sont données dans le tableau 4.

Quatre raies en Raman (autour de 241 cm^{-1}) et deux bandes en ir (vers 222 cm^{-1}) caractérisent les vibrations de valence du squelette.

Bien que le groupe ClO_4 soit fortement lié au métal, d(In—O) = 2,19 Å (17), les fréquences moyennes ν In—O ($\simeq$230 cm^{-1}) sont inférieures à celles notées pour l'acétylacétonate, ν_s: 444 cm^{-1} (27), les acétates, ν_s: 300 cm^{-1} (28) ou d'autres complexes organo métalliques signalés dans la littérature (29). Ceci est bien sur lié à la faible basicité du groupe ClO_4.

En dessous de 150 cm^{-1} on attend les vibrations de déformation de l'octaèdre et les modes de réseau. Une attribution spécifique semble délicate, cependant, sans ambiguïté, les raies à 143, 137 et 107 cm^{-1} doivent plutôt décrire des modes de déformation de symétrie A_g et E_g.

Tl(ClO₄)₃

La comparaison des diagrammes de poudre de $In(ClO_4)_3$ et $Tl(ClO_4)_3$ (tableau 2) montre que ces deux complexes cristallisent dans le même groupe d'espace. Leurs spectres ir sont identiques, ainsi qu'une grande partie de leurs spectres Raman. Par contre, le domaine des vibrations de valence ClO_p présente en Raman une grande différence. Pour l'indium on relève trois raies à 872, 945 et 896 cm^{-1} et deux pour le thallium à 799 et 917 cm^{-1}. Les vibrations du pont étant les plus affectées par le mode de coordination, on pourrait expliquer ces différences par

TABLEAU 4. Attributions des bandes ir et des raies Raman de $In(ClO_4)_3$ (s: fort, m: moyen, w: faible, sh: épaulement)

l'existence de groupements $Tl(ClO_4)_3$ discrets comportant des groupes ClO_4 bidentés chelatants. Cependant, ce type d'engagement est rare (26). En l'absence de toute autre information, on conservera pour $Tl(ClO_4)_3$ le même type d'analyse que précédemment. On admet que l'évolution des vibrations ν ClO_p est liée aux différences de masse et de rayon ionique de l'élément central. La moyenne des fréquences ν ClO_p (889 cm^{-1}) dans $Tl(ClO_4)_3$ subit un déplacement normal par rapport aux complexes de la même série $Al(ClO_4)_3$: 935 cm^{-1}, $Ga(ClO_4)_3$: 901 cm^{-1}, $In(ClO_4)_3$: 906 cm^{-1}.

Comme attendu, les vibrations de valence ν MO du squelette TlO_6 apparaissent à des fréquences plus basses que celui de InO_6: $\Delta\nu_s = -18$ cm^{-1}. Les principales attributions sont notées sur le spectre (fig. 2).

$ClO_2M(ClO_4)_4$ (M = In, Tl)

Les diagrammes de poudre (tableau 2) montrent que ces sels sont des complexes définis puisque on n'y retrouve pas les raies de $M(ClO_4)_3$. Les spectres ir et Raman sont donnés sur les figures 3 et 4. On note une certaine similitude.

Le cation ClO_2^+ est défini par les bandes ou raies caractéristiques vers 1300 (ν_{as}), 1055 (ν_s) et 515 (δ) cm^{-1}.

Sur les spectres on relève des composantes à des fréquences voisines de celle observées pour le perchlorato métal correspondant. Elles sont attribuées à des groupes ClO_4 bidentés en pont. Il apparaît en outre des bandes et raies supplémentaires, par exemple pour l'indium, dans le domaine des vibrations de valence à 1225 (ir), 1240 (R), 1000 (ir), 1023 (R), 855 (ir) et 759 (R). Elles sont caractéristiques de groupes ClO_4 monodentés, ainsi que la raie à 375 cm^{-1} (balancement de ClO_3) (18).

L'existence des deux types de ligand est confirmé par la présence de trois bandes dans le domaine des vibrations ν MO alors qu'on en observe au plus deux pour le perchlorato métal (par exemple, pour les complexes d'indium, on a respectivement en ir: 290, 270, 220 et 250, 195 cm^{-1}).

On doit noter que à la différence du ligand NO_3 (30) le ligand ClO_4 ne parait pas apte à donner une environnement 8 pour Tl.

La raie Raman vers 760 cm^{-1} attribuée à ν_s Cl—O_p du groupe ClO_4 monodenté est caractéristique d'une coordination forte entre le métal et le ligand. Ceci devrait se traduire par l'apparition, vers 1300 cm^{-1}, de bandes correspondant à ν_{as} Cl—O_t (5). Ici cette vibration est relevée autour de 1220 (ir), 1240 cm^{-1} (R), alors que pour $ClO_2Ga(ClO_4)_4$ elle est observée vers 1235 cm^{-1}. Pour le complexe du gallium, ce déplacement vers les basse fréquences a été expliqué par une interaction métal–perchlorate supplémentaire conduisant à une semi-coordination (18). Il semblerait plus logique d'admettre une interaction entre ClO_2^+ et les groupes ClO_4 monodentés dans $M(ClO_4)_4^-$. Ceci tendrait à recréer des enchaînements comparables à ceux rencontrés dans Cl_2O_6 liquide (31). Cette hypothèse n'est pas aberrante puisque des interactions ClO_2^+–anion ont été observées lors de l'étude structurale de $ClO_2Sb_2F_{11}$, ClO_2GeF_5 et ClO_2BF_4 (32). Elle permet de plus, de rendre compte du mécanisme réactionnel de la transformation relativement facile de $ClO_2M(ClO_4)_4$ en $M(ClO_4)_3$ avec élimination de ClO_2ClO_4.

Conclusion

Grâce à ce travail, on a pu compléter l'étude des complexes perchlorato des éléments du groupe IIIB. L'action de Cl_2O_6 sur $InCl_3$ (ou $InCl_3,4H_2O$) et $TlCl_3$ conduit à la formation de quatre nouveaux perchlorates anhydres, deux perchlorato-métal $M(ClO_4)_3$ et deux sels de chloryle $ClO_2M(ClO_4)_4$ (M = In, Tl).

L'analyse structurale par spectroscopie de vibration infrarouge et Raman et diagrammes de poudre RX a permis de montrer que les perchlorato métal, $M(ClO_4)_3$ (M = In, Tl) ont des structures proches de celle de $Ga(ClO_4)_3$. Ce sont des polymères avec des groupes ClO_4 bidentés en pont où tous les groupes ClO_4 sont en interactions forte avec le métal, alors que dans $ClO_2In(ClO_4)_4$ et $ClO_2Tl(ClO_4)_4$ il faut distinguer des groupes ClO_4 de même nature que les précédents et des groupes ClO_4 monodentés présentant une interaction importante avec l'ion chloryle. Par ailleurs, on a pu mettre en évidence les évolutions des fréquences de vibration ν ClO_p et ν MO dans la colonne IIIB pour la série $M(ClO_4)_3$ (M = Al, Ga, In et Tl). Elles sont directement liées aux rayons ioniques et à la masse de l'élément central.

Remerciements

Ce travail a été réalisé dans le cadre d'accords de coopération CNRS (France) – DRST (Tunisie). Les auteurs du mémoire remercient ces organismes pour les liens qu'ils ont su renforcer entre les deux laboratoires et l'aide financière qu'ils leur ont apporté.

The pK_a's of 13 heterocyclic aromatic compounds have been measured in tetrahydrofuran (THF) using ^{13}C nmr spectroscopy. The acidifying effect of a nitrogen heteroatom is seen to be quite large (4–6 pK units versus C—H) on an adjacent C—H bond but small on a more remote hydrogen. Most of these aromatic heterocycles are sufficiently acidic, pK_a < 34, to be completely deprotonated by lithium tetramethylpiperidide in THF. Benzoxazole appears to be an extremely strong carbon acid, its ring-opened isomer having a pK_a of less than 15.7.

ROBERT R. FRASER, TAREK S. MANSOUR et SYLVAIN SAVARD. Can. J. Chem. **63**, 3505 (1985).

Faisant appel à la rmn du ^{13}C et opérant dans le tétrahydrofuranne (THF), on a mesuré les pK_a de 13 composés hétérocycliques aromatiques. L'effet produit par l'acidification d'un azote hétéroatomique est assez important (4–6 unités de pK par rapport à un C—H) pour une liaison C—H adjacente; toutefois, cet effet n'est pas important pour les hydrogènes plus éloignés. La plupart de ces hétérocycles aromatiques sont suffisamment acides, pK_a < 34, pour être déprontonés par le tétraméthylpipéridure dans le THF. Le benzoxazole semble être une acide carboné extrèmement fort; le pK_a de son isomère à cycle ouvert est plus bas que 15,7.

[Traduit par le journal]

In recent times, the metalation of organic compounds has become an exceedingly useful component of synthetic methodology, the current reagent of choice being lithium diisopropylamide, (LDA) (1), or lithium tetramethylpiperidide, (LTMP) (2). Use of these and other lithiated dialkylamines (3) is preferable to direct treatment of a weak organic acid with butyl or methyllithium, as their selectivity in deprotonation avoids harmful side reactions. Nevertheless, alkyllithiums are still often employed in instances in which LDA or its counterparts might be more effective. To determine how strong a base is required for a given deprotonation, one simply requires knowledge of the pK_a of the proton to be removed. Then, lithiation of an amine less acidic by at least 4 pK units will provide the requisite base. For this reason, the measurement of acidities of weak carbon acids in THF is of considerable practical importance to organic chemists. Until recently, most of the accumulated data on weak carbon acid acidities have been obtained in DMSO (4) or cyclohexylamine (5) as solvent. However, it has been established that there are often significant solvent effects on acidity that are not completely predictable (5, 6). We have therefore recently undertaken a series of determinations of pK values in THF. Those compounds studied included arylmethanes (7), benzene derivatives (8), hindered amines (9), and alkylpyridines (10). In this paper we wish to describe pK measurements on a series of 5-membered aromatic heterocycles and some of their benz-fused derivatives.

Method of pK_a *measurement*

As in previous studies, we have used ^{13}C nmr to measure the relative concentrations of all four species in equilibrium, eq. [1],

$$[1] \quad HA_1 + A_2^- \rightleftharpoons A_1^- + HA_2$$

from which $K = K_1/K_2$ and thus yields a $\Delta pK = -\log K = pK_1 - pK_2$ (5). In most cases the measurements were done on a mixture of the heterocyclic compound and an equivalent of lithiated amine after equilibration at room temperature. In addition to LTMP and LDA we have used five other lithiated amines whose acidities vary from 25.8 to 39.5 (9) and thereby provide a wide accessibility of measurable pK. Certain of the lithiated heterocycles proved to be unstable at room temperature, in which cases we have carried out the pK_a determination at −60°C.[2] When decomposition persisted at the lower temperature, we carried out the measurement of the heterocycle in equilibrium with a second carbon acid of appropriate acid strenth.[3] For comparison, both types of equilibrium measurements were done with benzothiophene. There was a 1-unit difference in pK between the two methods. For two other compounds, *N*-methylpyrrole and dimethylaminopyrrole, the difference was negligible. As a verification of the nmr method, we routinely examined a sample of each heterocyclic compound after quenching the equilibrium mixture with methanol-*O-d*. The % deuterium content, as measured by mass spectrometry, was slightly lower (5–10%) than the % metalation measured by nmr. Such differences were not enough to alter the value for the pK_a beyond the experimental error of 0.2 pK units, and the lower ms value probably reflects traces of proton impurity in the medium, i.e. slight excess of amine or uptake of moisture in methanol-*O-d*. The results appear in Table 1.[4]

[1] This is the fifth in a series of papers describing acidity measurements in tetrahydrofuran (THF). Parts III and IV are assigned to refs. 11 and 9 respectively.

[2] In all cases that we have examined, there has been no observable change in ΔpK over this 90° temperature range (11). We earlier observed no pK change for a 5-fold change in concentration (7).

[3] Decomposition prevented us from studying benzothiazole in equilibrium with its lithio derivative. Nevertheless, we were able to assess its pK from low temperature experiments in which it was either completely deprotonated or untouched in the presence of lithiated amines (see Table 1). Extensive use of 2-lithiobenzothiazole in synthesis has been reported by Corey and Boger (12). Unfortunately, lack of solubility prevented us from obtaining any acidity data for n-propylbenzimidazole.

[4] As mentioned in our first paper (7), these pK values likely represent ion-pair or ion-aggregate acidities. The extent of aggregation has recently been found to vary considerably with structure (33). Since it can also vary with solvent and thereby influence pK, we feel the data in THF, though representing uncertain species, are the most useful to organic chemists.

TABLE 1. Heteroaromatic proton acidities (pK_1)

Acid$_1$		Reference acid (pK_2)	K_{eq}	$-\log K$	pK_1
1		DIPA (35.7)	1.3	−0.1	35.6
2		$(CH_3)_3C—N(H)—Si(CH_3)_3$ (33.6)	4	−0.6	33.0
3		 (39.5)	1.0	0	39.5[a]
		$C_6H_5SCH_3$ (38.1)	.027	+1.6	39.7
4		$C_6H_5SCH_3$ (38.1)	14.4	−1.2	36.9
		TMP (37.3)	1.7	−0.2	37.1
5		Furan (35.6)	0.45	+0.3	35.9
6		$(CH_3)_3C—N(H)—Si(CH_3)_3$ (33.6)	0.84	+0.1	33.7
7		$(CH_3)_3Si—N(H)—Si(CH_3)_3$ (25.8)	0.4	+0.4	26.2[b]
8		$(CH_3)_3Si—N(H)—Si(CH_3)_3$ (25.8)	<0.003	+2.5	>28.3[c]
9		Thiophene (33.0)	0.6	+0.2	33.2
10		Thiophene (33.0)	4.6	−0.6	32.4
		$(CH_3)_3CCH_2N(H)—Si(CH_3)_3$ (33.2)	0.5	+0.3	33.5
11		$C_6H_5—SCH_3$ (38.1)	0.95	0	38.1
12		$C_6H_5—CH_2CN$ (18.7)	>10^3	<−3	<15.7[d]
13		$(CH_3)_3Si—N(H)—Si(CH_3)_3$ (25.8)	<0.01	>+2	>27.8[c]
		$CH_3CH_2CH_2—N(H)—Si(CH_3)_3$ (30.9)	>100	<−2	<28.9[c]

[a]Due to slow equilibration K_{eq} was estimated by extrapolation, and verified by the second determination below.
[b]The value for K measuring the deuterium content of a sample quenched with CH_3OD at 5°C.
[c]Determined at −60°C. All other metalated amines caused decomposition at this temperature.
[d]As explained in the text, the pK being measured is that of *o*-isocyanophenol.

Discussion of results

The data in Table 1 reveal several qualitative correlations between structure and acidity. For the monocyclic 5-membered heterocycles, there is a significant acid strengthening effect of the heteroatom on the adjacent C—H bond (α) with S > O > N in acidifying influence (i.e. **2** > **1** > **3** in acidity). The effect of a second nitrogen heteroatom is appreciable (**6** vs. **3**) when α, causing a 4–6 pK unit decrease, but becomes smaller (**5** vs. **3**) when β. An attached benzene ring has a small, somewhat variable, acidifying effect of up to 3 pK units, and tends to decrease the effect of the heteroatom, for example in benzothiophene, **10**, vs. benzofuran, **9**. Table 3 summarizes all the pK data.

TABLE 2. ^{13}C chemical shifts (ppm from THF = 69.00)

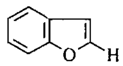
[a] Signals for the lithio derivative were slightly broadened, so that quaternary carbons were not observed (n.o.) in some cases.
[b] R represents the shifts calculated for the ring-opened isomer. In these two cases the numbering system does not apply.

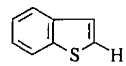
From the data in Tables 1 and 3 it can be seen that benzothiazole (pK_a = 28–29)[3] is about 4 pK units more acidic than benzothiophene. For comparison, the pK values for the same two compounds in cyclohexylamine were 28.1 and 37.0, the latter being clearly sensitive to the change in solvent, as are the acidities of thiophene and benzofuran (38.2 and 36.8 respectively, in cyclohexylamine (13)). These are the only examples for which data on another solvent are available. However, there are some data on the kinetic acidities of several of the heterocycles and related derivatives. Wherever comparisons can be made, our acidity data are in agreement with the data on rates of isotopic exchange. Grieco and co-workers recently reported that the presence of an *N*-dimethylamino group in pyrrole improved the ease of ring lithiation and subsequent substitution reactions (14). Though the exchange rates of imidazole and pyrazole are not known, their azolium salts differed by a factor of 3×10^4, the imidazolium salt reacting faster (15). Olofson *et al.* (16) showed that the replacement of a carbon in thiazole by one or more nitrogen atoms increased the exchange rate by a factor of 10^4. And while the order of exchange rates was thiazole > oxazole > imidazole in the base-catalyzed process (17), the condensed ring derivatives showed a reversal, benzoxazole being deuterated 30 times faster than benzothiazole (18).

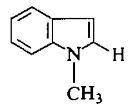
In view of the exchange data we would expect benzoxazole to be more acidic than benzthiazole. Nevertheless, it was surprising to find that benzoxazole was completely deprotonated even by lithiated phenylacetonitrile, whose pK we have determined to be 18.7.[5] Benzoxazole then appears to have a pK_a of less than 16! That this value is not a true pK was indicated by the ^{13}C nmr shifts for its lithio derivative. These values appear in Table 2 along with the chemical shifts calculated for 2-isocyanophenoxide ion on the basis of the reported shifts for isocyanobenzene (19) and phenoxide ion (20). The excellent agreement shows that deprotonation of benzoxazole leads to formation of the ring-opened phenoxide ion. Several examples of similar equilibria for oxazoles (21, 22) and oxazolines (23) have been reported. We have further corroborated this point by isolating, after addition of trimethylsilyl chloride, the silyl ether of 2-isocyanophenol. Interestingly, the addition of dimethyl sulfate produces not only 2-isocyanoanisole (86%) but also 14% of 2-methylbenzoxazole, presumably by competitive C-alkylation of trace amounts of the ring-closed tautomer. Protonation also reforms benzoxazole. We have a clear indication that lithiated benzothiazole does not ring open in the same way. First of all, the ^{13}C shifts for the lithiated compound do not correspond closely to those calculated for 2-isocyanobenzenethiolate ion (see Experimental for thiophenoxide shifts). Secondly, reaction of the anion with trimethylsilyl

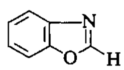
[5] By stepwise comparisons beginning with bistrimethylsilylamine and 3-methylpentyne, the following pK's were determined: 3-methylpentyne, 23.6; phenylacetylene, 21.6; indene, 20.9; and phenylacetonitrile, 18.7.

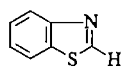
TABLE 3. Summary of pK data

			35.6	33.0	39.5	37.1
			33.7	35.9	26.2	>28.3
			






33.2	32.4(33.5)	38.1	
			




<15.7[a]	~28		

[a] Actually represents o-isocyanophenol.

chloride gave only 2-trimethylsilylbenzothiazole.

From the synthetic point of view, the data in Table 1 allow the following conclusions to be drawn. Thiophene, N-methylimidazole, and 1-propyl-1,2,4-triazole will give >97% lithiation on treatment with LDA in THF, as will all benz derivatives except N-methylindole. Furan can be completely metalated by the strong base utilized in evaluating the acidity of N-methylpyrrole. N-methylpyrrole and its dimethylamino derivative are insufficiently acidic for complete metalation by any lithiated amine.

In every example studied, the sole site of lithiation has been at the carbon adjacent to the heteroatom or in between two heteroatoms, whenever such a position is present. It is clear that the metalation of heterocycles under our conditions (of equilibration) gives different results from metalation using an alkyllithium (24). There are several examples in which more than one site is attacked under the latter condition, e.g. thiazole, methylimidazole. In those cases, as in the ortholithiation of monosubstituted benzenes (8), there is a directing effect of the basic substituent that enhances the rate of metalation of the secondary less acidic site.

Experimental

The preparation of samples for nmr was the same as given below except those few cases in which a second carbon acid was used instead of an amine as the reference acid.

Each sample was prepared in a 10-mm septum-capped nmr tube (Wilmad Glass, Buena, NJ) fitted with an argon inlet and outlet. To a solution of 1.5 mequiv. of amine in 2 mL of freshly distilled THF at 0°C was added 1.5 mequiv. of methyllithium in ether. After 15 min a solution of 1.5 mequiv. of hydrocarbon in 1 mL of THF was added at 0°C. The cap was wrapped in Parafilm and the tube then warmed and transferred to the probe of a Varian FT-80 nmr spectrometer operating at 27°C. In a few instances metalation and spectral acquisition were done at low temperature to avoid decomposition. Spectra were accumulated using a small pulse angle (30°) and a 2-s repetition rate. That differential relaxation times were unimportant was shown by extending repetition rate to 3 s without affecting integral ratios. Other factors of quantitative influence, such as differential nOe's (nuclear Overhauser enhancements), were eliminated by using an empirically derived correction factor. For example, this factor applied to the methylene signals of TMP and LTMP was arrived at by measuring the integral for TMP prior to, then after, the addition of 0.5 equiv. of methyllithium as well as that of the LTMP produced, both relative to naphthalene present as an internal standard. We estimate the accuracy of K to be ±30%, leading to an uncertainty in ΔpK of ±0.2 pK units or less. Mass spectral measurements were carried out using a VG 707-E mass spectrometer.

Most of the heterocyclic compounds used herein were purchased from Aldrich Chemical Company and were purified and dried prior to use when necessary. N-propyl pyrazole and n-propyl-1,2,4-triazole, however, were made by alkylation of the parent heterocycle.

The site of metalation, as indicated in Table 1, was in each instance determined by comparison of the ^{13}C spectrum of a sample quenched with methanol-O-d with that of the starting material. The assignments to individual signals in the ^{13}C spectra were available from previous literature, except for the triazole **1**. In the fully coupled spectrum of this compound, C5 was clearly differentiated from C2 by its long range coupling to a CH_2 group. The ^{13}C shifts for all compounds and their lithio derivatives are summarized in Table 2. The shifts in tetrahydrofuran did not differ greatly from those reported in $CDCl_3$ for furan (25), thiophene (25), N-methylpyrrole, (26) N-methylimidazole (26), N-propylpyrazole (26, 27), indoles (28), benzofuran (29), benzothiophene (29, 30), benzoxazole (31), and benzothiazole (32). The ^{13}C shifts for lithium thiophenoxide, as determined in THF (0.5 M), were 148.9(C1), 134.0(C2), 128.5(C3), and 121.8(C4).

Reactions of lithiated benzoxazole

Metalation of 2 mequiv. benzoxazole was carried out using 2 mequiv. of lithiated bis-trimethylsilylamine in 2 mL of THF at 0°C. Addition of 2 mequiv. of trimethylsilyl chloride gave, after 15 min at room temperature, the trimethylsilyl ether of O-isocyanophenol as the only detectable product (by ^1H and ^{13}C nmr). The crude product showed a strong bond in the ir at 2130 cm^{-1}; ms, P^+ 191; ^{13}C nmr ($CDCl_3$): 153.0 (q), 131.7, 129.2, 123.4, 122.4. The products of the reaction carried out similarly with dimethylsulfate (2 days at room temperature) were identified as 2-isocyanoanisole, ir, 2130 cm^{-1} (strong); ms, P^+ 133; ^{13}C nmr ($CDCl_3$): 156.7 q, 132.0, 129.1, 122.0, 113.7, 57.1; ^1H nmr ($CDCl_3$): CH_3 singlet at 3.95; and 2-methylbenzthiazole, ms, P^+ 133; ^1H nmr ($CDCl_3$): CH_3 singlet at 2.62. The ratio of low field to high field methyl singlets was 86.14.

Reaction of lithiated benzothiazole

Treatment of 1 mequiv. of benzothiazole with 1 mequiv. of LDA in 5 mL of THF at −74°C and subsequent addition of 1.1 mequiv. of trimethylsilyl chloride yielded a crude liquid product (>90% pure by ^1H nmr) whose mass spectrum showed a parent peak at 207, in accord with a silyl derivative. The ^{13}C spectrum (THF): 158.2(C2), 125.0(C4), 127.2(C5), 126.7(C6), 123.2(C7), 155.6(C8), 137.9(C9) −0.3(Si-CH_3) is consistent with the ring-closed derivative (see Table 2, benzthiazole, for comparison).

The 5-*endo-trig* cyclization reactions of α'-hydroxy α,β-unsaturated carbonyl compounds to form the 3-furanone ring system has been investigated by means of MNDO calculations. In acid medium, the activation energy for ring formation is reduced by protonation of the carbonyl oxygen and by electron-releasing β-substituents, both of which facilitate torsion about the α,β-CC bond. Rotation about the α,β-CC bond is essentially complete when the transition structure is achieved. In reverse ring opening, heterolytic rupture of the C—O bond is aided by prior enolization since induced polarization of the enol π system acts to stabilize the developing cationic centre at the β-carbon. In basic medium, ring closure is hindered by the combined effects of the intrinsic barrier to cyclization and solvation of the intermediate alkoxide. Ring opening in basic medium is prevented by prohibitively high intrinsic barriers except when a strongly electron-releasing group such as *p*-O(−)-phenyl is at the β-carbon.

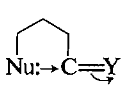
GRAHAM W. L. ELLIS, DONALD F. TAVARES et ARVI RAUK. Can. J. Chem. **63**, 3510 (1985).

Faisant appel à des calculs MNDO, on a étudié les réactions de cyclisation du type *endo*-5 *trig* des composés carboxylés α,β-insaturés, portant un groupement d'hydroxy en position α', qui conduisent au système cyclique de la furanone-3. En milieu acide, la protonation de l'oxygène du carboxyle ainsi que la présence de substituants électrodonneurs en position β, qui toutes deux facilitent la rotation autour de la liaison carbone–carbone, réduisent l'énergie d'activation de la réaction. La rotation autour de la liaison carbone–carbone en α,β est totale au moment de la transition de structure. Contrairement à l'ouverture de cycle, l'énolisation préalable facilite la scission hétérolytique de la liaison C—O puisque la polarisation induite des systèmes énoliques π agit de façon à stabiliser le centre cationique en voie de formation au niveau du carbone en position β. En milieu basique, les effets combinés de la barrière intrinsèque à la cyclisation et la solvatation de l'alcoolate intermédiaire empêchent la cyclisation. La haute barrière intrinsèque inhibe l'ouverture de cycle en milieu basique mais la présence de groupements fortement électrodonneurs tels le *p*-O(−)-phényl au niveau du carbone en position β annule cet effet.

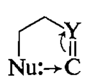
[Traduit par le journal]

Introduction

The role of stereoelectronic factors in controlling organic ring-forming and ring-breaking reaction pathways is a subject of current experimental (1–8) and theoretical (9–11) interest. In the case of smaller rings (less than eight atoms) where entropy considerations are not dominant, the formation of rings is governed largely by two interrelated factors. First, the atoms to be bonded must be able to approach each other sufficiently closely to initiate bond formation. Secondly, the approach path must be more or less compatible with the electronic requirements of the nucleophilic and electrophilic functionalities. The first factor includes angular and torsional strain that must be overcome. For 3- and 4-membered rings, even in the absence of substituents, strain energy may add substantially to the activation energy of the ring-forming step and correspondingly facilitate the reverse process. That the electronic (orientational) factor is important in chemical reactions has been demonstrated in the classic studies of Hughes, Ingold, and Rose (12), who established the antiperiplanar requirement in E2 eliminations. The collinear backside approach, which results in Walden inversion in the S_N2 reaction, is similarly well established. The latter reaction is a ready route to cyclic systems. Baldwin has introduced a general set of rules governing ring-closure reactions (1, 2). Of particular interest in the present context are those pertaining to the formation of 5-membered rings by nucleophilic addition to trigonal carbon, namely, the processes 5-*exo-trig* and 5-*endo-trig*, in Baldwin's terminology (1, 2).



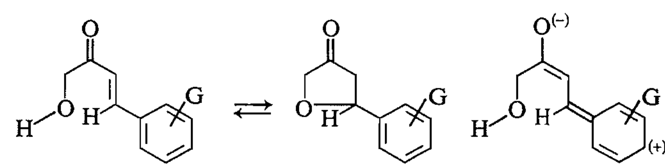
5-*exo-trig*



5-*endo-trig*

The former is a "favoured" process whereas the latter is "disfavoured", ostensibly because the trajectory (or approach vector) required by electronic factors can be achieved for the former but is sterically inaccessible for the latter (10). The approach vector (10) required for addition to a double bond has been deduced from crystallographic data (13) and from experimental (4, 8, 14, 15) and theoretical (9, 14, 16–18) studies of nucleophilic additions to the carbonyl group.

Cyclizations of the type **1** to **2** are of special interest. The ring closure of **1** to **2** is nominally a "disfavoured" 5-*endo-trig* cyclization, but has characteristics of the "favoured" 5-*exo-trig* process to the extent that the structure **3** is important for the



1 **2** **3**

description of **1**. Under conditions of basic catalysis for intermolecular Michael additions, neither the forward nor reverse transformation, **4** ⇌ **5**, is observed (3).

However, in acidic medium, the reaction proceeds quite readily. Presumably, under acid catalysis, the barrier to rotation of the α,β-CC bond may be reduced due to protonation of the carbonyl oxygen and by involving canonical structures **6** and **7** (5, 7). That this is the case is supported by the fact that electron-donating groups on the phenyl ring accelerate the reaction, giving a negative ρ value for the cyclization (5, 7). However, contributions of structures **6** and **7** restrict the approach of the nucleophilic hydroxy group by imposing double bond character internal to the incipient ring. Evidently, it is the rotation about the α,β-CC bond that is important. This question was

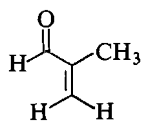
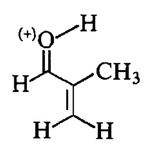
7

addressed in an earlier MNDO study by Perkins *et al.* on the model systems, **8** and **9**. Protonation of the carbonyl oxygen was calculated to lower the barrier to rotation about the α,β-CC bond by 100 kJ/mol (11).

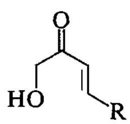
In order to examine more closely the cyclization process, we report here the results of a MNDO investigation of the mechanism of interconversion of **10** and **11**, where R may be hydrogen atom or phenyl group.



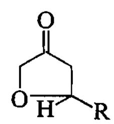
8



9



10



11

Method

Calculations were carried out using the MNDO program (19). The reaction coordinate was taken to be R_{CO}, the distance between the oxygen nucleophile and the β carbon atom. At selected fixed values of R_{CO} all remaining geometric parameters were optimized. The calculated heat of formation (ΔH_f) at each value of R_{CO} serves to define the potential energy profile of the reaction. For most species, two minima were located in the potential energy profile, corresponding to equilibrium structures of the cyclized species and a conformation of the acyclic species that is closest to the cyclic species. The transition structures were determined reasonably closely. While absolute energy changes cannot be compared directly with free energy changes since solvation effects are not included in the calculation, it will be seen that examination of structural changes that take place along the reaction coordinate lends important insight into the extent and timing of bond making and breaking during the cyclization process.

Results and discussion

*Acid catalyzed cyclization **10** ⇌ **11***

In acid medium, two alternate or competing pathways may be envisioned for the 5-*endo-trig* process for molecules such as **1**, **4**, or **10**. These are shown in Scheme 1.

We consider the reaction first in the forward direction, **10** (R = H) → **11** (R = H), via **12**, **13**, and **14**. The potential energy profile and selected structures for the rate-determining step, **12** (R = H) → **13** (R = H), are shown in Fig. 1. Numerical data are presented in Table 1. In the acyclic structure, **12** (R = H), the protonated enone portion of the molecule is planar and the hydroxyl group is rotated out of the plane by about 60°. The oxygen to β-carbon distance, R_{CO}, shown by a dashed line, is 3.25 Å. Rotation about the α,β-CC bond is pronounced at R_{CO} 2.5 Å (**12***a*), ΔH_f = 35 kJ/mol, and becomes rapid as the transition structure is approached (**12***b* → **T.S.**). The transition structure is 117 kJ/mol higher in energy and has R_{CO} = 1.95 Å. While the β-methylene group is still almost planar, rotation is essentially complete. Descent from the transition structure to the equilibrium cyclic protonated enol (**T.S.** → **13***a* → **13** (R = H) is accompanied by rapid rehybridization of the β carbon. The ring is almost planar in the transition structure and becomes planar by the time the R_{CO} value reaches 1.85 Å (**13***a*). The calculated equilibrium value of R_{CO} for **13** (R = H) is 1.49 Å. The transformation **11** (R = H) is completed by deprotonation of the ether oxygen, **13** (R = H) → **14** (R = H), followed by ketonization, **14** (R = H) → **11** (R = H), which may involve several protonation and deprotonation steps.

Ring opening must follow the same sequence of events in reverse by the principle of microscopic reversibility. It is noteworthy that ring opening of **13** (R = H) proceeds by in-plane stretching of the C—O bond. No resonance stabilization of the developing cationic centre by the adjacent enol π orbitals is possible until the transition structure is achieved. Instead, the developing cationic centre is stabilized by induced polarization of the enol π system. Mulliken population analysis reveals that this is the case. As one proceeds from **13** (R = H) to the point, **13***a*, where rotation about the α,β-CC bond begins, the buildup

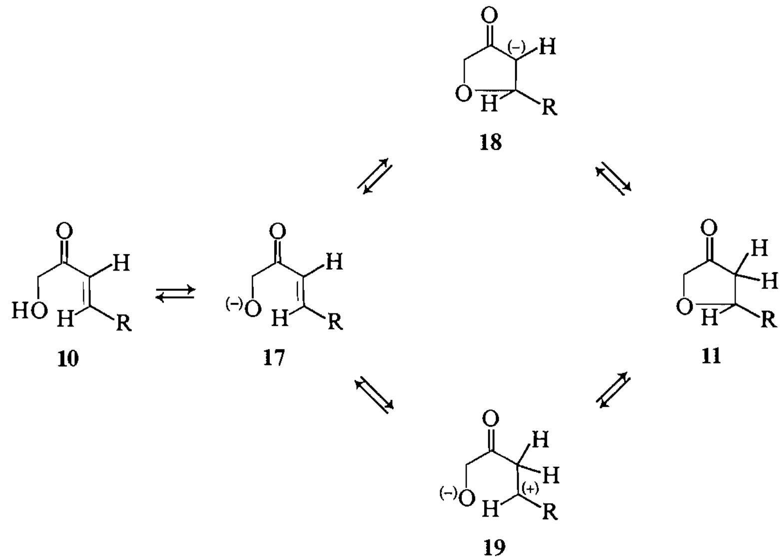
[a] Distances in angstroms, energies in kilojoules per mole.

of charge on the cationic centre, by +0.236 to +0.474, is partially compensated by an increase in charge at the α-carbon, by −0.106 to −0.355. Thus prior enolization of the ketone would seem to be necessary for facile rupture of the C—O bond even though the π orbitals cannot participate in resonance delocalization of the developing charge at the cationic centre.

The alternative mechanism, **10** → **15** → **16** → **11**, avoids the enolization step but requires prior protonation of the α-carbon atom of the enone system whose basicity is expected to be very low compared to that of the carbonyl oxygen. Structure **15** (R = H), shown in Fig. 2, is on the edge of the flat portion of the potential curve and has distance R_{CO} = 2.735 Å. The cationic centre is rotated to position the OH group over it in such a way as to maximize the attractive interaction between the empty $2p$ orbital of the cationic site with a nonbonded orbital of the oxygen atom. While **15** (R = H) has a twisted structure, the skeleton can become essentially planar and the —OH can approach the cationic centre at the β-carbon to within 2.0 Å with little gain in energy, arriving at structure **15***a*. Subsequently, shortening of R_{CO} from 2.0 Å to the equi-



SCHEME 2

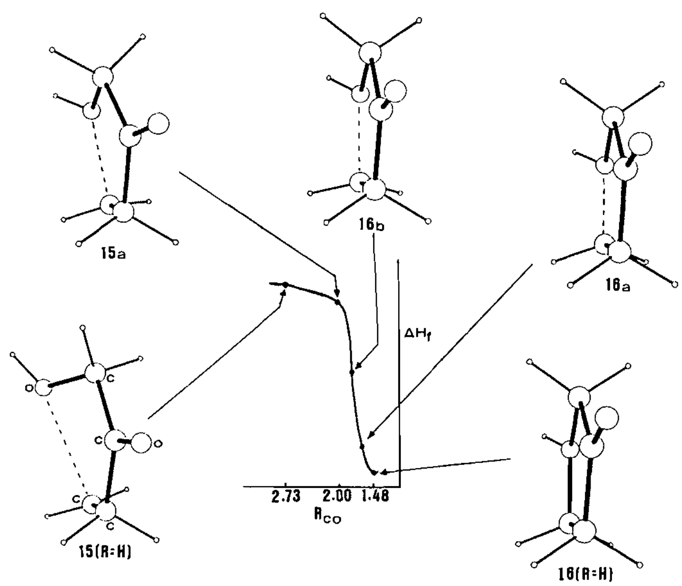


FIG. 2. The reaction coordinate and selected structures for **15** (R = H) $\rightleftharpoons$ **16** (R = H). The dashed line is the reaction coordinate R_{CO}.

librium distance, 1.48 Å, **16** (R = H), is accompanied by rapid rehybridization of the β-carbon (see **16***b* and **16***a*). Most of the increase in internal stability occurs at this stage. The heavy atom skeleton of the protonated furanone, **16** (R = H), is planar.

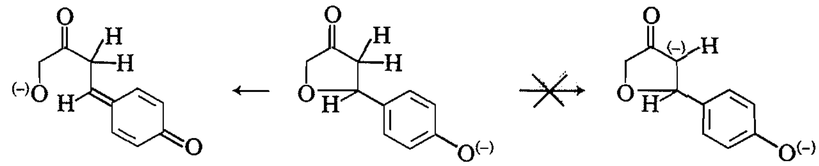
The rate-limiting factor for the forward reaction, **10** → **15** → **16** → **11**, may very well be the production of **15**. It is expected that, in solution, **15** will transfer a proton or will cyclize essentially without activation to **16**. Selected points along the reaction profile, **15** (R = H), shown in Fig. 2, confirm this view. The heat of formation of the protonated furanone, **16** (R = H), 460 kJ/mol, is calculated to be the same as the enolic form, **13** (R = H). By contrast, the α-C protonated form, **15** (R = H), is higher in energy than the O protonated form, **12** (R = H), by 166 kJ/mol. Indeed, **15** (R = H) is higher in energy than **T.S.** (Fig. 1) for the process **12** (R = H) → **13** (R = H) by 49 kJ/mol.

*Acid catalyzed cyclization **12** (R = Ph) $\rightleftharpoons$ **13** (R = Ph)*

The geometrical details for the acid catalyzed cyclization, **12** (R = Ph) $\rightleftharpoons$ **13** (R = Ph), are given in Table 1. The presence of the phenyl group has a negligible effect on the barrier to ring closure, 109 kJ/mol, but greatly facilities the reverse, 28 kJ/mol. The difference is due to preferential stabilization of the dienol form, **12** (R = Ph). In **12** (R = Ph), all of the atoms of the protonated enone moiety and the phenyl group are coplanar. The hydroxy group is almost perpendicular to the plane at R_{CO} = 3.40 Å. Rotation about the α,β-CC bond as R_{CO} decreases is significantly more advanced in the early stages of the cyclization than at a comparable point along the reaction coordinate for **10** (R = H) → **11** (R = H). As in that case, the geometry at the β-carbon atom remains planar and the phenyl group also lies in the plane. The transition structure has nearly a planar ring with R_{CO} = 1.9 Å. The cyclic structure, **13** (R = Ph), has a planar ring with R_{CO} = 1.52 Å. The equilibrium orientation of the phenyl group is perpendicular to the C—O bond. In this orientation, interaction between the phenyl π system and the low-lying σ^* orbital of the C—O bond is maximized. Electron release from the phenyl results in partial occupancy of the σ^*_{CO} and accounts for the slightly longer C—O bond length and the greater ease of bond dissociation.

The alternate route via **15** (R = Ph) and **16** (R = Ph) is calculated to be energetically more favourable than in the case where R = H. The presence of the electron-releasing phenyl group reduces the requirement of enol π polarization for the stabilization of the developing cationic β centre (by rotation about the α,β-CC bond in **12**, or by heterolytic dissociation of the labile bond in **13** → **12**). We have not explored the reaction profile for **15** (R = Ph) → **16** (R = Ph) but have determined the equilibrium geometries and energies of these species. The calculated heat of formation of **16** (R = Ph) is only 6 kJ/mol higher than that of **15** (R = Ph).

As in the case of the R = H species, the energies of the ether-oxygen protonated keto (**16** (R = Ph)) and enol (**13** (R = Ph)) forms are very similar, the latter being calculated to be 4 kJ/mol more stable. The acyclic α-C protonated structure, **12** (R = Ph), is computed to be 80 kJ/mol less stable than the O protonated species, **15** (R = Ph).



19 (R = p-O$^{(-)}$-Ph) **11** (R = p-O$^{(-)}$-Ph) **18** (R = p-O$^{(-)}$-Ph)

*The reaction in basic medium: **10** ⇌ **11***

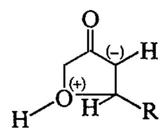
In basic medium, the cyclization reaction may proceed by the two pathways shown in Scheme 2. The route **10** → **17** → **18** → **11** is analogous to the path **10** → **12** → **13** → **11** in acidic medium (Scheme 1). Similarly, the route **10** → **17** → **19** → **11** corresponds to the path **10** → **15** → **16** → **11** of Scheme 1.

As stated in the Introduction, neither the forward nor the reverse transformation takes place in basic medium in the case of **4** (G = H) or **4** (G = OCH_3) or similar compounds (3). The failure to react has been shown to be due to a high barrier to interconversion rather than to an unfavourable equilibrium (3). The large barrier to ring opening was attributed to the orthogonality of the C—O bond and the enolate π system. Ring closure was said to be prevented by the inability of the O(−) nucleophile to achieve the required approach vector. The calculated results for **17** (R = H) ⇌ **18** (R = H) and **17** (R = Ph) ⇌ **18** (R = Ph) are given in Table 1 and do not entirely support this view. The ring opening of both **18** (R = H) and **18** (R = Ph) is hindered by very large barriers, 227 kJ/mol and 202 kJ/mol, respectively, in agreement with experiment. However, the reverse cyclization, **17** → **18**, in each case, is hindered by barriers of the same magnitude as found for the acid catalyzed cyclization, namely 89 kJ/mol (R = H) and 87 kJ/mol (R = Ph). The reason for the large difference in the barriers to the forward and reverse reactions is the greater stability of the enolate anion over the alkoxide anion. Bearing in mind that the calculation is performed for an isolated anion in vacuum, the calculated differences, 138 kJ/mol (R = H) and 115 kJ/mol (R = Ph), between alkoxide and enolate forms, are probably not unreasonable. Preferential solvation of the alkoxide in protic solvents would reduce the free energy difference between the two anions and simultaneously increase the barrier hindering cyclization.

The alternative route, via **19**, is unlikely unless the formal cationic β-C centre of **19** can be stabilized by R. Since **4** (G = OCH_3) and **5** (G = OCH_3) do not interconvert in basic medium, a p-methoxyphenyl group is not sufficiently electron releasing to allow the reaction to proceed by either mechanism. However, with G = OH, **5** is smoothly converted to **4** in NaOMe/MeOH. In this medium, the prevalent form is not **5** (G = OH) but **5** (G = O(−)). In the present context, prior ionization of **11** (R = p-OH—Ph) to **11** (R = p-O(−)—Ph) increases the ease of transformation to **19** (R = p-O(−)—Ph) and decreases the probability of a second proton abstraction to form **18** (R = p-O(−)—Ph), which is a dianion.

*The reaction in neutral medium: **10** → **20***

The forward transformation is not observed under neutral conditions. The calculations indicate that the zwitterionic forms, **20** (R = H) and **20** (R = Ph), lie 227 kJ/mol and 253 kJ/mol, respectively, above the starting materials, **10** (R = H) and **10** (R = Ph). While the energy differences will be decreased in polar medium, it would remain highly unlikely that a structure such as **20** could be achieved in the absence of acids or bases. The calculations suggest little or no activation energy for the ring opening of **20**.



20

Conclusions

The 5-*endo-trig* cyclization of structures such as **1**, **4**, or **10** proceeds readily in acid medium via structures, e.g., **12**, in which the carbonyl oxygen is protonated. The reaction is facilitated by the lowered barrier to rotation about the α,β-CC bond that ensues from protonation of the carbonyl oxygen and by participation of electron-releasing substituents at the β position. Rotation about the bond is essentially complete in the transition structure. In the reverse step, **13** → **12**, the barrier to heterolytic bond rupture is lowered as a result of stabilization of the developing carbocation by polarization of the π system of the enol. The results of the calculations do not rule out the possibility that cyclization may proceed via the alternate pathway (i.e., via **15** and **16**) if sufficiently electron-releasing substituents are present at the β carbon.

In basic medium, the reaction does not proceed in either direction except when R = p-O(−)—Ph. The calculations indicate that an intrinsically high barrier is the operative factor preventing ring opening from the enolate (**18** → **17**). The reverse cyclization is not hindered by a prohibitively high barrier in the absence of selective stabilization of the alkoxide, **17**, in polar solvents. It is likely that the ring opening observed (3) when R = p-O(−)—Ph takes place via the alternate route involving **19** (R = p-O(−)—Ph).

Received April 12, 1985

W. KLIEGEL, H.-W. MOTZKUS, STEVEN J. RETTIG, and JAMES TROTTER. Can. J. Chem. **63**, 3516 (1985).

Details of the preparation and physical properties of $(Me_4N)^+ (Ph_4B_3O_3)^-$ are given. Crystals of tetramethylammonium 2,4,6,6-tetraphenyl-1,3,5-trioxa-2,4-dibora-6-boratacyclohexane are orthorhombic, a = 18.130(2), b = 11.9745(7), c = 12.5187(5) Å, Z = 4, space group $Pna2_1$. The structure was solved by direct methods and was refined by full-matrix least-squares procedures to R = 0.056 and R_w = 0.064 for 1460 reflections with $I \geq 2\sigma(I)$. The crystal structure consists of discrete tetramethylammonium cations and tetraphenylboroxinate anions, the first such anion to be structurally characterized. The six-membered B_3O_3 ring is significantly non-planar, having a flattened O(1)-envelope conformation (maximum deviation from the mean plane = 0.074(4) Å for O(1)). The boroxine ring in the anion shows significant deviations from the D_{3h} symmetry observed for neutral boroxines. Important mean structural parameters: $B(sp^3)$—O = 1.494(2), $B(sp^2)$—O[$B(sp^3)$] = 1.320(9), $B(sp^2)$—O[$B(sp^2)$] = 1.389(3) Å, O—$B(sp^3)$—O = 110.5(5), O—$B(sp^2)$—O = 121.7(6), $B(sp^2)$—O—$B(sp^2)$ = 118.9(5), and $B(sp^3)$—O—$B(sp^2)$ = 122.9(1)°.

W. KLIEGEL, H.-W. MOTZKUS, STEVEN J. RETTIG et JAMES TROTTER. Can. J. Chem. **63**, 3516 (1985).

On rapporte les détails relatifs à la préparation et aux propriétés physiques du composé $(Me_4N)^+ (Ph_4B_3O_3)^-$. Les cristaux du tétraphényl-2,4,6,6 trioxa-1,3,5 dibora-2,4 borata-6 cyclohexane de tétraméthylammonium sont orthorhombiques, avec a = 18,130(2), b = 11,9745(7), c = 12,5187(5) Å, Z = 4 et groupe d'espace $Pna2_1$. On a résolu la structure par des méthodes directes et on l'a affinée par la méthode des moindres carrés (matrice entière) jusqu'à des valeurs de R = 0,056 et R_w = 0,064 pour 1460 réflexions indépendantes avec $I \geq 2\sigma(I)$. La structure comporte des cations tétraméthylammonium et des anions tétraphenylboroxinates individuels; dans ce dernier cas, il s'agit du premier tel anion à être caractérisé. Le cycle B_3O_3 à six chaînons dévie considérablement de la planéité; il existe sous une conformation O(1)-enveloppe aplatie (la déviation maximale du plan moyen = 0,074(4) Å pour le O(1)). Le cycle boroxine de l'anion dévie considérablement de la symétrie D_{3h} qui a été observée dans le cas des boroxines neutres. Les paramètres structuraux moyens importants sont: $B(sp^3)$—O = 1,494(2), $B(sp^2)$—O[$B(sp^3)$] = 1,320(9), $B(sp^2)$—O[$B(sp^2)$] = 1,389(3) Å, O—$B(sp^3)$—O = 110,5(5), O—$B(sp^2)$—O = 121,7(6), $B(sp^2)$—O— $B(sp^2)$ = 118,9(5) et $B(sp^3)$—O—$B(sp^2)$ = 122,9(1)°.

Introduction

X-ray crystallographic analyses of heterocyclic boron compounds containing BOBON ring systems such as **1** (1) and **2** (2) or of polycyclic compounds such as **3**, which contain the same BOBON ring system (3–5), reveal a remarkably short B—O distance between the tricoordinated boron atom and the oxygen atom within the $B(sp^2)$—O—$B(sp^3)$ moiety in each case. This indicates a strong $pp(\pi)$-interaction between the tricoordinate boron atom and the oxygen atom (6, 7) at this site of the BOBON ring which represents an anhydridic bond between a boronic acid and a tetracoordinated borinic (**1** and **2**) or boronic acid (**3**). Replacement of the N—O unit (hydroxylamine component) in **1** or **2** by an O—B—O unit (a second boronic acid component) should lead to a boroxine ring system with one negatively charged tetrahedral boron atom and two very short B—O bonds of the type described above (cf. formula **4**).

It was thus of special interest to determine whether it would be possible to prepare and isolate a mixed anhydride of phenylboronic and diphenylborinic acids having an anionic boroxine structure. For "external" compensation of the negative charge, a tetraalkylammonium cation was chosen in order to produce a salt soluble in organic solvents. To the best of our knowledge, no tetraaryl- or tetraalkylboroxine salts have been reported in the literature to date. If donor–acceptor complexes of boroxines and Lewis bases (O, N, or P donors "D") of the general formula **5** are excluded, compound **4** would be the first example of a tetrakis(organyl)boroxine salt. Structure analyses of compounds of the type **5** have recently been reported by Yalpani and Boese (8). In solutions of **5** an equal participation of the three boron atoms in the donor–acceptor bond suggests intramolecular fluctuation (8, 9).

For the synthesis of **4**, two equivalents of phenylboronic acid were reacted with one equivalent of diphenylborinic acid in the presence of tetramethylammonium hydroxide. A high-melting crystalline product was obtained, the elemental composition and spectral data being consistent with the proposed structure **4**. An X-ray crystallographic analysis was undertaken to provide unambiguous proof.

Experimental

Tetramethylammonium 2,4,6,6-tetraphenyl-1,3,5-trioxa-2,4-dibora-6-boratacyclohexane, 4

Oxybis(diphenylborane) (0.87 g, 2.5 mmol) and phenylboronic acid (1.22 g, 10 mmol) were dissolved in 5 mL ethanol. After the addition of tetramethylammonium hydroxide (5 mmol, 20% solution in methanol), the mixture was evaporated *in vacuo*. The remaining oil was crystallized by cooling and the addition of ether. Yield: 2.33 g (100%). After recrystallization from acetone at −10°C there remained

1.0 g (43%) of colorless crystals. Mp. 290–296°C (decomp.). *Anal.* calcd. for $C_{28}H_{32}B_3NO_3$: C 72.63, H 6.97, N 3.03; found: C 72.61, H 6.92, N 3.04. ^{1}H nmr (90 MHz, DMSO-d_6): δ(ppm) = 2.97 (s, NMe_4), 7.10 (m, 6 H, *m*- and *p*-H of Ph_2B), 7.47 (m, 6 H, *m*- and *p*-H of 2 PhB), 7.70 (m, 4 H, *o*-H of Ph_2B), 8.17 (m, 4 H, *o*-H of 2 PhB).

The substance gives a blue-colored solution upon reaction (10) with diphenylcarbazone in methanolic solution, indicating the presence of a Ph_2B grouping. Crystals suitable for X-ray analysis were obtained by recrystallization from acetone at low temperature.

X-ray crystallographic analysis

A crystal bounded by the 12 faces (followed by the distances in mm between parallel faces): ±(−1 0 2), 0.30, ±(1 0 2), 0.32, ±(−1 0 1), 0.36, ±(1 0 1), 0.30, ±(0 1 −1), 0.51, ±(0 1 1), 0.52 was mounted in a general orientation. Unit-cell parameters were refined by least-squares on 2 sin θ/λ values for 25 reflections (2θ = 40–50°) measured on a diffractometer with Cu-*K*α radiation ($\lambda(K\alpha_1)$ = 1.540562, $\lambda(K\alpha_2)$ = 1.544390 Å). Crystal data at 22°C are:

$C_{28}H_{32}B_3NO_3$ f.w. = 463.0
Orthorhombic, a = 18.130(2), b = 11.9745(7), c = 12.5187(5) Å, V = 2717.7(4) Å^3, Z = 4, ρc = 1.132 Mg m^{-3}, $F(000)$ = 984, μ(Cu-*K*α) = 5.21 cm^{-1}. Absent reflections: $0kl$, $k + l$ odd, and $h0l$, h odd, space group $Pna2_1$ (C^9_{2v}, No. 33) from structure analysis.

Intensities were measured with graphite-monochromated Cu-*K*α radiation on an Enraf-Nonius CAD4-F diffractometer. An ω−2θ scan at 0.72–10.06° min^{-1} over a range of (0.80 + 0.15 tan θ) degrees in ω (extended by 25% on both sides for background measurement) was employed. Data were measured to 2θ = 150°. The intensities of 3 check reflections, measured every 3600 s throughout the data collection, showed only small random fluctuations. Of the 2925 independent reflections measured and processed,[2] 1460 (49.9%) had intensities greater than or equal to $2\sigma(I)$ above background where $\sigma^2(I) = S + 2B + (0.03(S - B))^2$ with S = scan count and B = normalized background count. The paucity of data, partially a result of the washout of high-angle reflections, seems to be characteristic of light-atom structures consisting primarily of planar rings.

The noncentrosymmetric space group $Pna2_1$ was indicated by the *E*-statistics and by the number of molecules in the unit-cell. The structure was solved by direct methods, the coordinates of all non-hydrogen atoms being determined from an *E*-map. Refinement of the non-hydrogen atoms with anisotropic thermal parameters gave R = 0.083. The hydrogen atoms were introduced as fixed contributors in idealized positions (staggered methyl groups, C(sp^2)—H = 0.97, C(sp^3)—H = 0.98 Å), recalculated after each cycle of refinement. The large thermal parameters obtained for the carbon atoms of the tetramethylammonium cation [C(1)—C(4)] may actually represent thermal motion or may result from minor disordering, such being often noted for structurally isolated tetrahedral moieties. The scattering factors of ref. 11 were used for non-hydrogen atoms and those of ref. 12 for hydrogen atoms. The weighting scheme $w = 1/\sigma^2(F)$, where $\sigma^2(F)$ is derived from the previously defined $\sigma^2(I)$, gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of both $|F_o|$ and sin θ/λ and was employed in the final stages of full-matrix refinement of variables. Reflections with $I < 2\sigma(I)$ were not included in the refinement. Convergence was reached at R = 0.056 and R_w = 0.064 for 1460 reflections with $I \geq 2\sigma(I)$. For all 2925 reflec-

[2]The computer programs used include locally written programs for data processing and locally modified versions of the following: MULTAN 80, multisolution program by P. Main, S. J. Fiske, S. E. Hull, L. Lessinger, G. Germain, J. P. Declercq, and M. M. Woolfson; ORFLS, full-matrix least-squares, and ORFFE, function and errors, by W. R. Busing, K. O. Martin and H. A. Levy; FORDAP, Patterson and Fourier syntheses, by A. Zalkin; ORTEP II, illustrations, by C. K. Johnson.

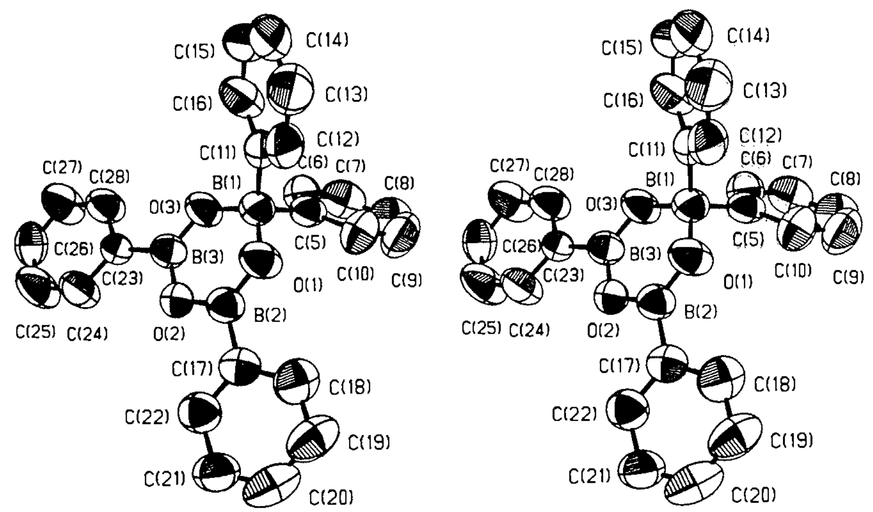

FIG. 1. Stereoscopic view of the $[(C_6H_5)_4B_3O_3]^-$ anion; 50% probability thermal ellipsoids are shown.

tions $R = 0.145$. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$ and $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$.

On the final cycle of refinement the mean and maximum parameter shifts corresponded to 0.01 and 0.14σ, respectively. The mean error in an observation of unit weight was 2.977. A final difference map showed maximum fluctuations of ± 0.18 e $Å^{-3}$. The final positional and thermal parameters appear in Tables 1 and 6[3], respectively. Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[3] Bond distances, bond angles, and intraannular torsion angles appear in Table 2–4, respectively. Calculated hydrogen parameters (Table 5) and a complete listing of torsion angles (Table 7) are included as deposited material.

Results and discussion

The structure consists of discrete Me_4N^+ cations and $[(C_6H_5)_4B_3O_3]^-$ anions, separated by normal van der Waals distances. There are no interionic H···H contacts less than 2.4 Å and the minimum cation–cation, cation–anion, and anion–anion contacts are >4.0, 3.56(2) [C(3)···C(10) $(1/2 - x, y - 1/2, z - 1/2)$], and 3.61(2) Å [O(2)···C(14) $(1 - x, 1 - y, z - 1/2)$], respectively. The isolated tetraphenylboroxinate anion reported here is the first such to be structurally characterized. The only related structures in the literature to date are a pair of triphenylboroxine–amine adducts (8) and a N→B coordinated polycyclic ring system ("tribenzotaralene") containing a nearly planar boroxine ring (13). In the latter case, only the N—B distance was reported in a brief communication.

Electron diffraction studies indicate that trimethylboroxine, $(MeB{=}O)_3$ (14), and boroxine, $(HB{=}O)_3$ (15), both contain planar ring systems with equal B—O distances of 1.39(2) and 1.376(2) Å, respectively. Among the borates and boric acid derivatives which have been studied by X-ray diffraction methods, several contain partial boroxine structures or have the boroxine skeleton. In general the boroxine ring is found to be planar, or nearly so, and to possess approximate D_{3h} symmetry.

The presence of the tetracoordinated boron atom induces a marked geometrical distortion of the boroxine ring, similar to,

N —C(3)	1.413(14)	C(17)—C(22)	1.386(9)
N —C(4)	1.419(14)	C(18)—C(19)	1.343(11)
B(1)—C(5)	1.627(11)	C(19)—C(20)	1.368(13)
B(1)—C(11)	1.624(9)	C(20)—C(21)	1.344(10)
B(2)—C(17)	1.565(10)	C(21)—C(22)	1.420(10)
B(3)—C(23)	1.566(8)	C(23)—C(24)	1.366(9)
C(5)—C(6)	1.378(9)	C(23)—C(28)	1.375(9)
C(5)—C(10)	1.380(9)	C(24)—C(25)	1.364(10)
C(6)—C(7)	1.422(11)	C(25)—C(26)	1.330(11)
C(7)—C(8)	1.319(11)	C(26)—C(27)	1.332(11)
C(8)—C(9)	1.359(12)	C(27)—C(28)	1.369(9)

but of greater magnitude than those noted for the triphenyl boroxine – amine adducts (8). These distortions involve distances and angles in the B_3O_3 ring as well as the planarity of the boroxine ring, reducing the symmetry of the anion to approximately C_{2v}.

The mean[4] $B(sp^3)$—O, $B(sp^2)$—O[$B(sp^3)$], and $B(sp^2)$—O[$B(sp^2)$] distances in **4** of 1.494(2), 1.320(9), and 1.389(3) Å may be compared to the corresponding values of 1.458(14) and 1.457(8), 1.353(3) and 1.357(2), 1.389(1) and 1.392(7) Å for the two triphenylboroxine–amine adducts (8). The differences result from the relatively greater strength of the B—C bond in **4** relative to the N→B interactions in the adducts (B—N = 1.663(8) and 1.714(10) Å). The very short B(2)—O(1) and B(3)—O(3) bonds in **4** are not unexpected and are comparable to bonds in analogous $B(sp^2)$—O—$B(sp^3)$ systems: **1** (1); 1.333(4); **2** (2); 1.340(3); **3** (3–5); 1.337(2), 1.341(3), 1.334(2) Å. Similar B—O bonding

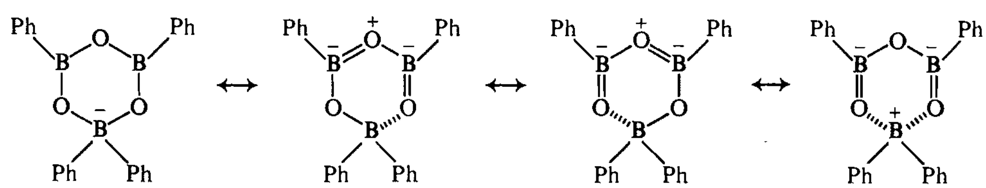
arrangements are found in the roughly comparable cyclic structures of pentaborates having spiro-fused boroxine rings as a basic structural unit as in **6**. This basic framework, built up from a BO_4 tetrahedron and four BO_3 triangles, has been established by structure determinations of various monoanionic pentaborates and combined polyborates (16). In these compounds the B(sp^2)—O bonds of B(sp^2)—O—B(sp^3) moieties are generally slightly shorter than the other B(sp^2)—O bonds. Thus in ammonium pentaborate (lardellite) the mean endocyclic B—O distance is 1.34 Å for B(sp^2)—O[B(sp^3)] bonds while the remaining B(sp^2)—O bonds average 1.39 Å and the B(sp^3)—O bonds 1.47 Å (17). Comparable short B(sp^2)—O distances also occur for exocyclic B—O bonds of anionic nature such as those in potassium metaborate (18), which has the boroxine structure **7**. The $B_3O_6^-$ anion shows exocyclic B—O distances of 1.331(10) Å and endocyclic distances of 1.398(5) Å (18). The calculated π-bond order for a B—O bond of 1.33 Å is about 0.6 (6), the bond energy being 130 kcal/mol (19).

The considerable π-bond character of the B(2)—O(1) and B(3)—O(3) bonds in **4** suggests a more important contribution of resonance form **4**d to the resonance hybrid **4**$a \leftrightarrow$ **4**$b \leftrightarrow$ **4**$c \leftrightarrow$ **4**d than that of **4**b or **4**c. This is supported by the length of the B(sp^3)—O bonds which are comparable in length to those in **1** (1.495(4) Å), **2** (1.487(3) Å), and those in other diphenylboron chelates with one or two oxygen ligands (1.476(2) − 1.580(3) Å) (20−27). In further support of the π-bonding argument, the longer of the two bonds (B(2)—O(1)) is observed where there is a larger local deviation from planarity (see Table 4). The B—O distances in the tetrahedral BO_4 groupings of various borates have been compiled (28, 29) and range from 1.470 to 1.510 Å. The B(sp^3)—O distances in the triphenylboroxine−amine adducts are in the range 1.444(6) to 1.472(8) Å (8).

The O—B—O and B—O—B angles in the unsubstituted boroxine molecule (15) are all 120.0(6)°. The presence of the tetrahedral B atom in **4** induces changes in all intracyclic bond angles. The O—B(1)—O angle is reduced to 110.5(5)° and



4a **4**b **4**c **4**d

the opposite angle at O(2) to 118.9(5)°, the remaining four angles increase to mean values of 122.9(1)° at O and 121.7(6)° at B. Angular distortions in the triphenylboroxine–amine adducts are similar but of lesser magnitude (e.g. 113.0(5) and 113.5(5)° at the tetrahedral B atom). Even smaller angles at B (106.9–107.5°) have been observed in other six-membered diphenylboron O—B—O chelate rings (23, 24).

The boroxine ring in **4** is significantly non-planar ($\chi^2 = 497$, maximum deviation from the mean plane = 0.074(4) Å for O(1)), having a flattened O(1)-envelope conformation. The two amine adducts (8) once again show intermediate parameters, the boroxine rings being planar to within 0.034 Å. All four phenyl rings are planar to within experimental error. The phenyl rings bonded to the two trigonal planar boron atoms are rotated out of the B(2) and B(3) coordination planes by 0.7(4) and 11.2(4)°, these values being normal for trigonal planar $PhBO_2$ moieties.

As noted for **1** (1), **2** (2), **3** (3–5), and the triphenylboroxine–amine adducts (8), the B(sp^3)—C bonds are significantly longer than the B(sp^2)—C bonds. This once again demonstrates the delocalization of aromatic π-electron density into the trigonal planar boron system and the impediment of such an interaction with tetrahedral boron. The mean B(sp^3)—C(Ph) distance of 1.626(2) Å is near the high end of the range of 1.598 to 1.639 Å observed for diphenylboron chelates.

The bond lengths and angles in the phenyl rings show the patterns characteristically induced by B-substitution (ref. 30 and references therein) although some of the distances are shortened as a result of thermal motion. The inequality of the N—C distances of the Me_4N^+ cation (Table 2) is also an artifact of thermal motion, the longer bond being associated with the one carbon atom (C(1)) which has relatively low thermal motion.

Vibrational spectral studies of solutions at elevated temperatures and pressures. VII. Raman spectra and dissociation of nitric acid

C. I. RATCLIFFE AND D. E. IRISH

Guelph-Waterloo Centre for Graduate Work in Chemistry, Waterloo Campus, Department of Chemistry, University of Waterloo, Waterloo, Ont., Canada N2L 3G1

Received March 19, 1985

C. I. RATCLIFFE and D. E. IRISH. Can. J. Chem. **63**, 3521 (1985).

An exploratory study of the Raman spectra of nitric acid solutions up to 250°C has been undertaken. The decrease in the frequencies of the νN—(OH) and δNO_2 bands of HNO_3 as temperature and concentration increase have been interpreted in terms of the reduced strength of hydrogen bonding. Approximate values of the degree of dissociation α have been determined and show that nitric acid is a very much weaker acid at high temperatures.

C. I. RATCLIFFE et D. E. IRISH. Can. J. Chem. **63**, 3521 (1985).

On a entrepris une étude préliminaire des spectres Raman de solutions d'acide nitrique, à des températures allant jusqu'à 250°C. On a observé une diminution dans les fréquences des bandes νN—(OH) et δNO_2 du HNO_3; on interprète ces résultats en fonction d'une diminution dans la force de la liaison hydrogène. On a déterminé les valeurs approximatives du degré de dissociation α et elles démontrent que l'acide nitrique est un acide beaucoup plus faible à des températures plus élevées.

Introduction

The study of processes in aqueous solutions at temperatures well above 100°C and at elevated pressures is currently of great interest because of its considerable importance in such areas as corrosion in power plants, aqueous subsurface extraction of oil and minerals, geothermal energy sources, and geological mineral formation (1). The dielectric constant of water decreases substantially as temperature increases and this property, in the absence of other factors, increasingly promotes ion association. As part of a larger program of research in this area we have studied the effects of increasing temperature on the Raman spectra of several acids in water, at pressures sufficient to maintain the liquid state. Perchloric acid remains a "strong" acid at high temperatures (2). However, for solutions of nitric and sulphuric acid, large increases occur in the populations of the ionogens (i.e.; the molecular forms (3)) as the temperature rises (this work and other works to be published). The following account presents some preliminary results concerning nitric acid to illustrate this effect and to further demonstrate the potential usefulness of the technique.

Experimental

Raman spectra between 3 and 250°C were obtained using the same furnace and spectrometer described in earlier papers in this series (2, 4, 5). Since the pressures used in this apparatus to maintain the liquid state at high temperatures are insufficient to keep the density constant it is most convenient to describe the solutions in terms of molality m (mol kg^{-1} H_2O) or stoichiometric mole ratio N ($=H_2O:HNO_3$) which are density independent. The two solutions studied were $N = 1.493$ (37.21 m) and $N = 5.063$ (10.97 m) which, at 25°C, are roughly 15.6 and 8.1 molar. We will refer to the two as $N = 1.5$ and 5. When attempts were made to go much above 100°C for $N = 1.5$ and 250°C for $N = 5$, the additional heat absorbed from the laser beam caused local instabilities in the liquid (presumably due to formation and collapse of small bubbles) which made it impossible to obtain reliable spectra.

Results and discussion

It is well known that at room temperature aqueous solutions of nitric acid contain a significant population of undissociated HNO_3 molecules especially for $N < 12$ (6–9); therefore bands of both NO_3^- and molecular HNO_3 appear in the spectra of the two concentrated solutions studied here, even at 3°C. Although the HNO_3 molecule strictly has C_s symmetry the bands of the O′—NO_2 unit in solution behave as though the molecule were a C_{2v} species, i.e., (HO)—NO_2 where (HO) is treated as a single unit. This is reflected in the polarisation behaviour of the modes, exemplified for the $N = 1.5$ solution in Fig. 1. Only those modes which would be polarised under C_{2v} symmetry show any appreciable polarisation. The bands have all been assigned previously (though not without debate (10–16)) and mode descriptions and frequencies at the extremes of temperature studied here are given in Table 1. The modes of NO_3^- are assigned according to D_{3h} symmetry; in aqueous nitrate solutions the degeneracy of the $\nu_3(E')$ mode is lifted because of distortions caused by aquation (17, 18), but the weakness of the two component bands and the overlap with the intense 1302 cm^{-1} band of HNO_3 prevents the detection of the ca. 1340 cm^{-1} component.

The effects of increasing temperature are shown in Figs. 2 and 3. In Fig. 3 the same series of spectra have been normalised in two ways to emphasize those bands which (a) increase in intensity with increasing temperature (i.e. HNO_3) and (b) those which decrease in intensity with increasing temperature (i.e. NO_3^-). The changes are very prominent; nitric acid is seen to be a very much weaker acid at high temperature.

The overtone of the out-of-plane bending mode of NO_3^- and the NO_2 antisymmetric stretch of HNO_3 overlap considerably in the 1600–1700 cm^{-1} region, but it is quite clear from the effects of temperature (Fig. 3) and the polarisation behaviour that both are present. It may also be inferred, at least from the spectra at $N = 1.5$ or at high temperature, that the NO_3^- mode has the lower frequency. Although the bending mode of H_2O should also occur in this region it is expected to be much weaker.

A striking feature of the effect of increasing temperature (Fig. 3) is the large decrease in frequency of the N—O′ stretching mode (from 966 cm^{-1} to 940 cm^{-1} for $N = 5$) and the NO_2 scissors bending mode (from 697 cm^{-1} to 679 cm^{-1} for $N = 5$) of HNO_3. Similar behaviour has been observed for the S—O′

stretching mode of HSO_4^- (19). Appreciable reductions in frequency also occur for the same two modes as N decreases. This shift is attributed to changing hydrogen bond strengths between the N—O—H bond and the surrounding medium. From a comparison of the structures of HNO_3 and NO_3^- (20), it is clear that the N—O′ bond is longer and hence should be weaker than the bonds of NO_3^-; thus the N—O′ bond is expected to have a lower stretching frequency. If the proton of HNO_3 is pulled further away from the oxygen as in a hydrogen bonding interaction the —O′—NO_2 grouping should tend towards becoming more like an NO_3^- ion. This would lead to a strengthening of the N—O′ bond and a reduction in the NO_2 angle, and thus to higher frequencies for the N—O′ stretching mode and the —NO_2 scissors bending mode. Evidence in favour of this may be found in the frequencies reported for HNO_3 in the vapour (13) and in matrix isolation studies (16, 21), Table 2. In the non-hydrogen bonded states, i.e. vapour or isolated monomer, the frequencies have their lowest values; they increase as soon as hydrogen bonding occurs either as HNO_3---HNO_3 or H_2O---HNO_3. Comparison of the frequencies of the nitric acid dimer versus the monohydrate complex, and for the liquid (10, 11, 13) versus solutions also indicates that the hydrogen bonding between HNO_3 and H_2O and/or $(H_{aq})^+$ is stronger than to other HNO_3 molecules; see Table 2. We can thus account for the behaviour as N increases; i.e., as $[HNO_3]$ decreases and $[H_2O]$ increases, the medium becomes more strongly hydrogen bonding. Increasing the temperature promotes ion association and thus $[HNO_3]$ increases and the medium becomes less strongly hydrogen bonding. In addition, increased temperature is expected to cause a general reduction in the strength of hydrogen bonding, an effect which is well

Top frame: spectra normalised on the symmetric stretching band of NO_3^-, temperature increases from bottom to top. Lower frame: spectra normalised on the —NO_2 symmetric stretching band of HNO_3, temperature increases from top to bottom.

known for water (5). On average the increased thermal motion causes fewer intermolecular configurations to be optimum for hydrogen bonding.

Dissociation of HNO_3 in solution

The dissociation of nitric acid has been the subject of a number of earlier studies, including one from this laboratory (7), using spectroscopic and other techniques (8, 9, 22–29). Of these only the salt solubilities measured by Marshall and Slusher (28, 29) have been studied at temperatures above 90°C,

and we shall compare their results with those of the present study. We shall consider the overall dissociation

$$\underset{(1-\alpha)m}{HNO_3} + nH_2O \rightleftharpoons (H_{aq})^+ + \underset{\alpha m}{NO_3^-}$$

though an intermediate step involving ion-pair formation and dissociation is thought to occur (7); evidence of bands due to the associated species H_2O---HNO_3 and H_3O^+---NO_3^- have been reported in a Raman study of the $N = 1$ liquid and glass (30), and at very high concentrations, ($4HNO_3 \cdot H_2O$), evidence for $[NO_3 \cdot 3HNO_3]^-$ has been presented (31).

These preliminary studies allow us to obtain reasonable estimates of α, the degree of dissociation, at different temperatures, but only by relating parameters derived from the spectra to α values determined in other studies for one or two specific concentrations and temperatures. Values of α at room temperature and the two concentrations studied here can be obtained from the tables or plots given in previous ir (6) and Raman (8, 9) work. We will use both sets independently since they are not completely in agreement (the ir results give slightly larger α values than the Raman results); specifically for $N = 5$, $\alpha = 0.75$ and for $N = 1.5$, $\alpha = 0.2$ from ir (6) and $\alpha = 0.63$ and 0.17, respectively, from Raman (8, 9) both at room temperature. (Accuracy is limited by ability to read the published graphs.) We initially attempted to use the *ratio* of the peak heights of $\nu_{sym}(NO_3^-)$ and ν_{sym}(—NO_2 of HNO_3) since this should have the simple dependence on α:

$$R = C\alpha/(1-\alpha)$$

where C is a constant, assuming the two peak heights are proportional to the amounts of the two species they represent. However, the value of C obtained by substituting previously known α's was substantially different for the two concentrations. We finally chose the following method of obtaining approximate α values. After subtracting an appropriate linear baseline over the 200–1400 cm^{-1} range, we obtained the total integral for each spectrum. These integrals were then scaled so as to effect a normalisation on the peak of the $\nu_{sym}(NO_3^-)$ band. We then made a number of assumptions: that there are only two species present in significant amounts which contribute to the spectra (NO_3^-/HNO_3), that the two species contribute intensity proportional to the amount present, and that the *peak* intensity of the NO_3^- band is proportional to the quantity of NO_3^- present. The normalised integrals (I) will then be the sum of a constant contribution (X) from NO_3^- and a variable contribution from HNO_3 (dependent on α):

$$I = X + \frac{Y(1-\alpha)}{\alpha}$$

X and Y can be determined by substituting the previously known values of α at room temperature for the two concentrations, and then α at other temperatures can be obtained. Alternatively we can normalise on the $\nu_{sym}NO_2$ (HNO_3) peak (instead of NO_3^-) and with appropriate changes to the equation again arrive at α values. The results are given in Table 3, from which it may be seen that the values of α based on integrations normalised in either way are in quite reasonable agreement, but as expected the two sets of values referenced to the previous ir or Raman results retain a significant difference.

Marshall and Slusher (28) express their results concerning the ionisation of nitric acid in the range up to 350°C in terms of the extended Debye–Hückel equation

$$\log Q_n = \log K_n + 2S\sqrt{I}/(1 + 1.6\sqrt{I}) \qquad \text{(their equation [25])}$$

where $2S$ is the Debye–Hückel limiting slope for a particular temperature (given in ref. 32), and I is the ionic strength given by

$$I = 0.5 \sum_i m_i z_i^2$$

where m_i = molality of ion, z_i = charge of ion. They found that the temperature variation of the ionisation constant can be fitted to the equation (in molal terms):

$$\log K_n = 5.424 - 134.37/T - 0.01199T \qquad \text{(their equation [32])}$$

The equations apply for the reaction $HNO_3 \rightleftharpoons H^+ + NO_3^-$ for which

$$Q_n = \frac{m\alpha \cdot m\alpha}{m(1-\alpha)} \text{ and } I = m\alpha$$

Hence

$$\log (m\alpha^2/(1-\alpha)) = \log K_n + 2s\sqrt{m\alpha}/(1 + 1.6\sqrt{m\alpha})$$

from which α can be calculated for various molalities and temperatures. The results for the $N = 5$ sample are included in Table 3; they are significantly different from the spectroscopic values. A lack of agreement is not unexpected. Marshall and Slusher's (28) values of K_n were determined from measurement of the solubility of $CaSO_4$ in HNO_3/H_2O mixtures with concentrations of acid less than 3.4 m, with the exception of two samples. Their extended Debye–Hückel formulations cannot be expected to apply to the two high concentrations studied spectroscopically, and thus only the estimates for the $N = 5$ sample are given in Table 3 to show the trend. Their analysis also neglects contributions from the ion pairs $CaNO_3^+$ and $CaSO_4$ which must form in their solutions; the inclusion of these equilibria in the data refinement will alter the values of K_n somewhat.

A careful study of the molal intensities of NO_3^- and HNO_3 at different temperatures is required to better quantify the Raman data. It is well known that proton exchange affects the bandwidths (33, 34), and that there is a finite concentration of the intermediate ion pair $H_3O^+ \cdot NO_3^-$ (7). All of these factors must be taken into account to obtain more reliable values of α.

We conclude with a few remarks about the "weakness" of nitric acid. Leuchs and Zundel (6) visualise the ionisation process in terms of a double well hydrogen bonding potential between the H_2O and HNO_3 molecules. For $N < 1$ solutions the well at the HNO_3 end is deeper (Zundel's proton boundary structure **I**) but as N increases the deeper well moves to the H_2O side, thus stabilising H_3O^+ (proton boundary structure **II**). In isolation the molecular complex $H_2O \cdot HNO_3$ is observed to be the stable form (21), rather than $H_3O^+NO_3^-$, since more water molecules are necessary to hydrogen bond and thus to stabilise H_3O^+. Recent *ab initio* calculations (35) substantiate this but furthermore indicate that in the isolated complex there is only one well in the H_2O---HNO_3 hydrogen bond potential, situated at the HNO_3 end. This implies that the double minimum potential forms only for the condensed medium, where even for $N < 1$ there are always other HNO_3 or H_2O molecules to accept hydrogen bonds. We might visualise the effect of increasing temperature as a shift from proton boundary structure **II** back to **I**, caused by a destabilisation of H_3O^+ as the general hydrogen bonding to other molecules decreases.

Previous work from our laboratory has been concerned with investigating the photochemical reactivity of the tetrahydro-1,4-napthalenedione system, both in solution and the solid state. The results obtained prompted us to extend our studies to the analogous tetrahydro-1,4-anthracenedione system. The most direct method of synthesis of the desired compounds is through Diels–Alder addition of *o*-quinodimethane to *p*-quinones. Because of the ease with which the adducts would be expected to undergo bis-enolization to the corresponding hydroquinones, their preparation requires mild, neutral conditions. After much experimentation, success was achieved using the Durst–Charlton sulfur dioxide extrusion method for generating *o*-quinodimethane from 3,6-dihydro-1,2-oxathiin-2-oxide. *In situ* trapping using *p*-benzoquinone and other substituted *p*-quinones afforded the desired adducts in reasonable yields. In the case of duroquinone and 2,3-dimethyl-1,4-naphthalenedione, fluoride ion-catalyzed generation of *o*-quinodimethane from [*o*-[α-(trimethylsilyl)methyl]benzyl]trimethylammonium bromide by the method of Ito also gave acceptable results; however, the bis-enolizable adducts were not stable under these eaction conditions.

SYED ASKARI, SUSAN LEE, ROBERT R. PERKINS et JOHN R. SCHEFFER. Can. J. Chem. **63**, 3526 (1985).

Dans un travail antérieur réalisé dans notre laboratoire, on a examiné la réactivité photochimique du système tétrahydronaphtalènedione-1,4 tant en solution qu'à l'état solide. Les résultats obtenus nous ont incité à étendre nos études au système analogue de la tétrahydroanthracènedione-1,4. La méthode la plus directe de synthèse des composés désirés implique une addition de Diels–Alder du *o*-quinodiméthane sur des *p*-quinones. Compte tenu du fait qu'il est à prévoir que les adduits subiront facilement une bis-énolisation conduisant aux hydroquinones correspondantes, il est important d'utiliser des conditions neutres et douces pour leur préparation. Après beaucoup d'expérimentation, on a fait appel à la méthode de Durst–Charlton d'extrusion du bioxyde de soufre pour générer avec succès le *o*-quinodiméthane à partir de l'oxyde-2 de la dihydro-3,6 oxathiine-1,2. La réaction *in situ* de ce dérivé avec de la *p*-benzoquinone et d'autres *p*-benzoquinones substituées a permis d'obtenir les produits désirés, avec des rendements raisonnables. Dans les cas de la duroquinone et de diméthyl-2,3 naphtalènedione-1,4, il a aussi été possible d'obtenir des résultats acceptables en utilisant la méthode de I to qui implique une génération, catalysée par les ions fluorures, du *o*-quinodiméthane à partir du bromure de [*o*-[α-(triméthylsilyl)méthyl] benzyl]triméthylammonium; toutefois, dans ces conditions, les produits bis-énolisables n'étaient pas stables.

[Traduit par le journal]

Introduction

The Diels–Alder adducts formed between *p*-quinones and cyclic as well as acyclic 1,3-dienes have served, as a result of their photochemical rearrangements, as a rich source of novel polycyclic ring systems (1–13). Three representative examples are shown in Scheme 1. Because, among other things, the presence of an aromatic double bond at the 6,7–position would be expected to affect the formation of photoproducts analogous to **3**, **6**, and **8**, we decided to prepare and photolyze the 6,7-benzo analogue of ene-dione **1**, namely *cis*-4a,9a,9,10-tetrahydro-1,4-anthracenedione, **12** (Table 1). This paper reports the synthesis of compound **12** and five of its methylated and benzannelated derivatives; the photochemistry of these systems will be reported in a separate publication.

The most direct synthesis of the desired tetrahydro-1,4-anthracenediones is through Diels–Alder addition of *p*-quinones to the diene *o*-quinodimethane. Despite the enormous body of literature dealing with the generation and both the intermolecular (14–19) and intramolecular (20–22) Diels–Alder reactions of *o*-quinodimethane and its derivatives, there are very few reports which use simple *p*-benzoquinones as the trapping agents (23). This is largely due to the fact that, until recently, the reaction conditions required to generate *o*-quinodimethanes were such that the initial adducts (e.g., **12**) were not stable. Ene-diones analogous to **12** enolize readily at elevated temperatures or in the presence of acid or base to afford the corresponding hydroquinones. These hydroquinones, in turn, are oxidized readily to the fully aromatic 1,4-anthracenediols.

Results and discussion

We have investigated three methods for the synthesis of *cis*-4a,9a,9,10-tetrahydro-1,4-anthracenedione (**12**) and its derivatives. All three involve relatively mild and, at least in the initial stages of reaction, neutral conditions. Each is discussed separately below.

The first procedure was based on the work of Han and Boudjouk (24*a*; see also ref. 24*b*). These authors showed that *o*-quinodimethane can be generated by treatment of α,α-dibromo-*o*-xylene (**9**) with powdered zinc under conditions of ultrasound sonication at room temperature; trapping with maleic anhydride, dimethyl maleate, methyl acrylate, and methyl vinyl ketone provided the corresponding adducts in good yield. We found, however, that when mixtures of α,α-dibromo-*o*-xylene, zinc powder, and either *p*-benzoquinone or duroquinone were subjected to ultrasound treatment, no adducts were formed, and the dibromoxylene could be recovered unchanged. This difference in reactivity can be attributed to involvement of the zinc in reducing the quinones rather than participating in *o*-quinodimethane formation.

The second procedure that we tested for its suitability in preparing *o*-quinodimethane under sufficiently mild conditions was the fluoride ion-catalyzed decomposition of [*o*[α-(trimethylsilyl)methyl]benzyl]trimethylammonium bromide (**10***a*) reported by Ito, Nakatsuka, and Saegusa (16, 17). These workers showed that treatment of ammonium salt **10***a* with tetrabutyl-

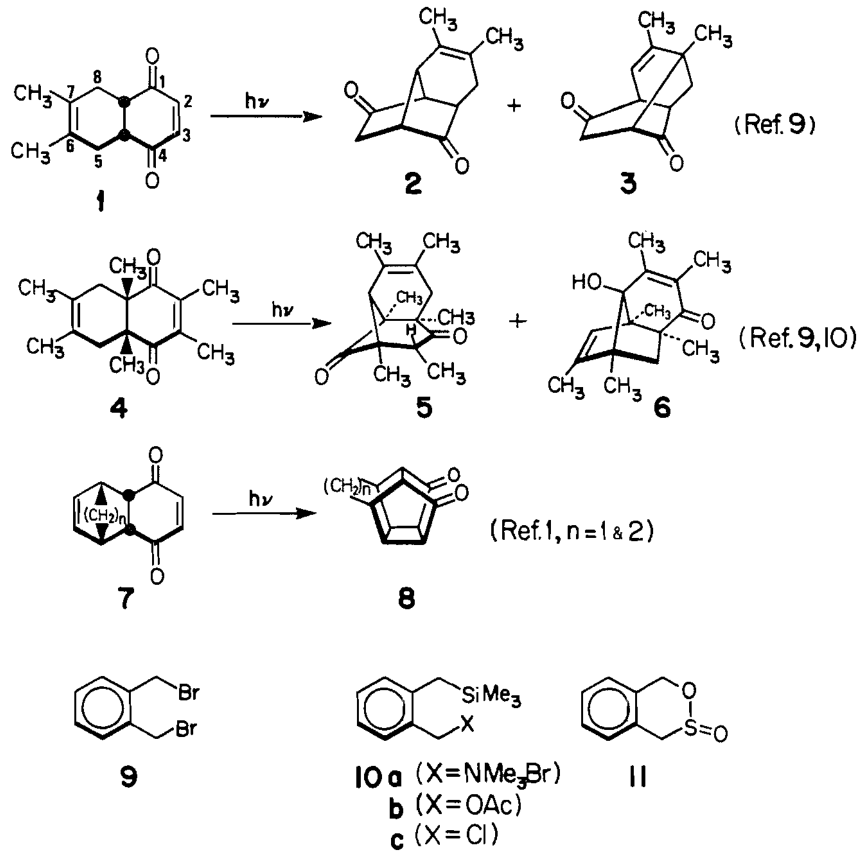

SCHEME 1

ammonium fluoride (TBAF) at room temperature is an efficient source of *o*-quinodimethane. Indeed, when an acetonitrile solution containing the ammonium salt **10***a*, TBAF, and either duroquinone or 2,3-dimethyl-1,4-naphthalenedione was allowed to react, the Diels–Alder adducts **16** and **17** were formed in modest yields (Table 1). Our initial apprehension, subsequently justified, was that the trimethylamine generated in this procedure would be capable of catalyzing the bis-enolization of the adducts bearing only hydrogen atoms at positions 4a and 9a (e.g., **12**). Thus, when *p*-benzoquinone or 2-methyl-*p*-benzoquinone were used as the dienophiles, no ene-dione-containing products could be isolated. A control experiment using 6,7-dimethyl-1,4-naphthalenedione (**1**) verified that small amounts of tertiary amines are, in fact, capable of inducing aromatization to the corresponding 5,8-dihydro-1,4-naphthalenediols. We next reasoned that this problem could be overcome by changing the nature of the leaving group in the *o*-quinodimethane precursor from trimethylamine to the less basic acetate ion. The required precursor **10***b* was readily available by conventional procedures, but despite the fact that **10***b* gave an even better yield of adduct **16** than **10***a* (61% vs. 44%), when treated with TBAF in the presence of duroquinone, it nevertheless proved totally ineffective in the preparation of the desired adduct **12**. Similar negative results were obtained with *p*-benzoquinone when the leaving group was chloride ion (precursor **10***c*). With these results, we finally decided to check the stability of similar 4a,9a hydrogen-containing adducts such as **1** to TBAF in acetonitrile. To our surprise, this caused adduct **1** to undergo rapid bis-enolization, even under the most anhydrous conditions we were able to achieve. Furthermore, the use of the Ito method with 2,5-dimethyl-*p*-benzoquinone as the dienophile afforded a 20% yield of the *trans*-adduct **14***t* rather than the *cis* isomer **14***c* (Table 1). With the successful preparation of the *cis*-adduct **14***c* (*vide infra*), we were able to verify that *cis* to *trans* isomerization of **14***c* does take place under the Ito reaction conditions.

We were finally successful in preparing the bis-enolizable adducts **12**, **13**, and **15** (Table 1) using 3,6-dihydro-1,2-oxathiin-2-oxide (**11**) as the *o*-quinodimethane precursor. Jung, Molin, Van den Elzen and Durst (25) were the first to synthesize sultine **11**. They showed, using maleic anhydride as the trapping agent, that **11** decomposes smoothly in refluxing benzene to *o*-quinodimethane and sulfur dioxide. An improved procedure for the synthesis of sultine **11** has been developed recently by Charlton and Durst (26). This sequence, involving as the key step the trapping of the photoenol of *o*-tolualdehyde by sulfur dioxide (27), provided us with gram quantities of sultine **11** on a routine basis. In addition to ene-diones **12**, **13**, and **15**, sultine **11** could be used to prepare adducts **14***c* and **16** (and presumably adduct **17**, although this was not tried). In general, the sultine method afforded higher yields (50–60%) than the trimethylsilyl ammonium salt method (20%). The one exception to this rule was duroquinone, which showed greater reactivity under the latter conditions (44% vs. 26%). That duroquinone reacts at all under these mild conditions is remarkable in view of the high temperature, sealed tube conditions required to bring about the Diels–Alder reaction between duroquinone and 2,3-dimethylbutadiene (28); this is presumably a testimony to the high reactivity of *o*-quinodimethane. Interestingly, tetraethyl-*p*-benzoquinone failed to react with *o*-quinodimethane generated by the trimethylsilyl ammonium salt procedure.

The solution phase and solid state photochemistry of adducts **12**–**17** is under active investigation.

TABLE 1. Structures, yields, and melting points of adducts synthesized

Adduct structure	Adduct mp	Quinone	*o*-Quinodimethane precursor	Yield
 **12**	122–123°C		**11**	48%
 **13**	110–111°C		**11**	60%
 **14c**[a]	80–81°C		**11**	62%
14t[b]	119–120°C		**10a**	19%
 **15**	156–157°C		**11**	52%
 **16**	84–85°C		**11**	26%
			10a	44%
			10b	61%
 **17**	101–102°C		**10a**	20%

Experimental

General

Melting points were determined on a Fisher–Johns hot stage apparatus and are uncorrected. Infrared (ir) spectra were obtained on a Perkin–Elmer 710B instrument using KBr discs and are reported as ν_{max} in cm^{-1}. ^{1}H nuclear magnetic resonance (nmr) spectra were recorded at 400 MHz on a Bruker WH-400 instrument using $CDCl_3$ as the solvent and TMS as the internal standard; signal positions are given in δ, and their multiplicities, integrated areas, coupling constants, and assignments are indicated in parenthesis. Mass spectra (ms) were obtained with a Kratos MS-50 instrument operating at 70 eV; the relative intensity of each ion is given in parentheses. The elemental analyses were carried out in the departmental microanalytical laboratory by Mr. P. Borda. Flash chromatography was done using Merck 9385 silica gel with the columns being slurry-packed in the eluting solvent.

Acetonitrile was distilled from calcium hydride and stored over 4 Å molecular sieve. Tetrabutylammonium fluoride was prepared by the method of Kuwajima, Murofushi, and Nakamura (29), freeze dried, and stored in vacuum-sealed tubes under argon over P_2O_5 in a vacuum desiccator. Quinones were purified by sublimation, recrystallization, or both. [*o*-[α-(Trimethylsilyl)methyl]benzyl]trimethylammonium bromide (**10***a*) was prepared by the method of Ito, Nakatsuka, and Saegusa (16), and sultine **11** was prepared according to the procedure of Charlton and Durst (26).

cis-4a,9a,9,10-Tetrahydro-1,4-anthracenedione (12)

A solution of 1.00 g (5.95 mmol) of sultine **11** (26, 27) and 0.96 g (8.92 mmol) of freshly sublimed *p*-benzoquinone in 10 mL of anhydrous benzene was refluxed for 1.75 h. Benzene was removed *in vacuo* to give an orange solid which, after two recrystallizations from methanol, afforded 0.60 g (48%) of adduct **12** as off-white needles, mp 122–123°C; ν_{max} (KBr): 1680 cm^{-1} (C=O); δ ($CDCl_3$, 400 MHz): 7.18–7.06 (m, 4H, aromatics), 6.72 (s, 2H, vinyls), 3.40 (m, 2H, 4a,9a methines), 3.22 (dd, J = 18 and 6 Hz, 2H, benzylic hydrogens), 2.92 (dd, J = 18 and 4 Hz, 2H, benzylic hydrogens); m/e (relative intensity): 212 (M^+, 100), 195 (69), 184 (32), 165 (75), 152 (65), 141 (30), 128 (75), 115 (45). *Anal.* calcd. for $C_{14}H_{12}O_2$: C 79.23; H 5.70; found: C 79.00, H 5.50.

2-Methyl-cis-4a,9a,9,10-tetrahydro-1,4-anthracenedione (13)

The reaction between 1.00 g (5.95 mmol) of sultine **11** and 1.02 g (8.37 mmol) of toluquinone was carried out as described above to afford, after recrystallization from methanol, 0.80 g (60%) of adduct **13** as light yellow needles, mp 110–111°C; ν_{max} (KBr): 1690, 1675 cm^{-1} (C=O); δ($CDCl_3$, 400 MHz): 7.15–7.06 (m, 4H, aromatics), 6.58 (br s, 1H, vinyl), 3.42–3.30) (m, 2H, 4a,9a methines), 3.45–3.26 (m, 2H, benzylic hydrogens), 2.97–2.86 (m, 2H, benzylic hydrogens), 2.02 (d, J = 2 Hz, 3H, methyl); m/e (relative intensity): 226 (M^+, 44), 211 (33), 198 (100), 183 (46), 165 (72), 152 (33), 141 (30), 128 (90), 115 (55). *Anal.* calcd. for $C_{15}H_{14}O_2$: C 79.62, H 6.24; found: C 79.83, H 6.29.

2,4a-Dimethyl-cis-4a,9a,9,10-tetrahydro-1,4-anthracenedione (14c)

Reaction, as before, between 1.00 g (5.95 mmol) of sultine **11** and 1.21 g (8.92 mmol) of 2,5-dimethyl-*p*-benzoquinone gave, after recrystallization of the crude reaction mixture from methanol, 0.88 g (62%) of adduct **14***c*, mp 80–81°C; ν_{max} (KBr): 1680 cm^{-1} (C=O); δ($CDCl_3$, 400 MHz): 7.17–7.00 (m, 4H, aromatics), 6.52 (q, J = 1.5 Hz, 1H, vinyl), 3.38 (dd, J = 17 and 5 Hz, 1H, benzylic hydrogen at 9), 3.17 (d, J = 16 Hz, 1H, benzylic hydrogen at 10), 3.06 (m, 1H, 9a methine), 2.93 (dd, J = 17 and 6 Hz, 1H, benzylic hydrogen at 9), 2.53 (d, J = 16 Hz, 1H, benzylic hydrogen at 10), 2.00 (d, J = 1.5 Hz, 3H, vinyl methyl), 1.35 (s, 3H, 4a methyl); m/e (relative intensity): 240 (M^+, 18), 225 (16), 212 (85), 197 (100), 179 (28), 128 (47). *Anal.* calcd. for $C_{16}H_{16}O_2$: C 79.97; H 6.71; found: C 80.01, H 6.60.

cis-5a,11a,6,11-Tetrahydro-5,12-naphthacenedione (15)

Reaction, as before, using 1.00 g (5.95 mmol) of sultine **11** and 1.30 g (8.22 mmol) of 1,4-naphthalenedione afforded, after recrystallization from methanol, 0.80 g (52%) of adduct **15**, mp 156–157°C; ν_{max} (KBr): 1680 cm^{-1} (C=O); δ($CDCl_3$, 400 MHz): 8.08 (dd, J = 6 and 3 Hz, 2H, aromatics 1 and 4), 7.75 (dd, J = 6 and 3 Hz, 2H, aromatics 2 and 3), 7.17–7.07 (m, 4H, aromatics 7–10), 3.62–3.54 (m, 2H, 5a,11a, methines), 3.35–3.25 (m, 2H, benzylic hydrogens), 3.04–2.94 (m, 2H, benzylic hydrogens); m/e (relative intensity): 262 (M^+, 100), 245 (59), 244 (89), 215 (46), 202 (13), 128 (15). *Anal.* calcd. for $C_{18}H_{14}O_2$: C 82.42, H 5.38; found: C 82.15, H 5.29.

2,3,4a,9a-Tetramethyl-cis-4a,9a,9,10-tetrahydro-1,4-anthracenedione (16)

To a stirred solution of 2.44 g (7.72 mmol) of [*o*-[α-(trimethylsilyl)methyl]benzyl]trimethylammonium bromide (**10***a*) (16) and 3.80 g (23.2 mmol) of duroquinone in 50 mL of anhydrous acetonitrile was added, over a period of 30 min, 4.04 g (15.4 mmol) of tetrabutylammonium fluoride (29) in 15 mL of anhydrous tetrahydrofuran. After stirring under nitrogen overnight at room temperature, 10 mL of water was added, and the organic layer was extracted with ether, dried over sodium sulfate, and concentrated in *vacuo* to afford 3.68 g of dark oil. Purification by flash chromatography using 1:4 ethyl acetate – petroleum ether (30–60°C) gave 1.16 g of light yellow solid. Recrystallization from 1:1 ethyl acetate – hexane afforded adduct **16** (0.94 g, 44%) as nearly colorless crystals, mp 84-85°C; ν_{max} (KBr): 1664 cm^{-1} (C=O); δ ($CDCl_3$, 400 MHz): 7.12–7.02 (m, 4H, aromatics), 3.35 (d, J = 17 Hz, 2H, benzylic hydrogens), 2.55 (d, J = 17 Hz, 2H, benzylic hydrogens), 1.98 (s, 6H, vinyl methyls), 1.22 (s, 6H, 4a,9a methyls); m/e (relative intensity): 268 (M^+, 34), 253 (14), 240 (68), 225 (100), 210 (20), 207 (30). *Anal.* calcd. for $C_{18}H_{20}O_2$: C 80.56, H 7.51; found: C 80.45, H 7.51.

5a,11a-Dimethyl-cis-*5a,11a,6,11-tetrahydro-5,12-naphthacenedione (17)*

Reaction, as above, between 4.00 g (21.5 mmol) of 2,3-dimethyl-1,4-naphthalenedione, 6.80 g (21.5 mmol) of ammonium salt **10***a*, and 8.41 g (32.2 mmol) of TBAF in 60 mL of anhydrous acetonitrile afforded, after chromatography and recrystallization from 30–60°C petroleum ether, 1.20 g (20%) of crystalline adduct **17**, mp 101–102°C; ν_{max} (KBr): 1680 cm^{-1} (C═O); δ ($CDCl_3$, 400 MHz): 8.05 (dd, J = 6 and 3 Hz, 2H, aromatics 1 and 4), 7.73 (dd, J = 6 and 3 Hz, 2H, aromatics 2 and 3), 7.17–7.04 (m, 4H, aromatics 7–10), 3.42 (d, J = 16 Hz, 2H, benzylic hydrogens), 2.65 (d, J = 16 Hz, 2H, benzylic hydrogens), 1.33 (s, 6H, methyls); m/e (relative intensity): 290 (M^+, 16), 275 (9), 262 (100), 247 (44), 229 (11). *Anal.* calcd. for $C_{20}H_{18}O_2$: C 82.73, H 6.25; found: C 82.47, H 6.31.

2,4a-Dimethyl-trans-*4a,9a,9,10-tetrahydro-1,4-anthracenedione (14*t*)*

Reaction, as above, between 0.86 g (6.32 mmol) of 2,5-dimethyl-*p*-benzoquinone, 1.00 g (3.82 mmol) of rigorously dried ammonium salt **10***a*, and 1.65 g (6.32 mmol) of anhydrous TBAF in 50 mL of anhydrous acetonitrile afforded, after flash chromatography and recrystallization of the crude product from 30–60°C petroleum ether, 0.15 g (19%) of adduct **14***t*, mp 119–120°C; ν_{max} (KBr): 1680 and 1660 cm^{-1} (C═O); δ ($CDCl_3$, 400 MHz): 7.20–7.13 (m, 4H, aromatics), 6.57 (br d, J = 2Hz, 1H, vinyl), 3.21–2.95 (m, 5H, benzylic hydrogens and methine at 9a), 2.06 (d, J = 2 Hz, 3H, vinyl methyl), 1.15 (s, 3H, 4a methyl); m/e (relative intensity): 240 (M^+, 100), 225 (99), 212 (25), 197 (44), 179 (19), 141 (17), 128 (43), 115 (23), 96 (11), 69 (31). *Anal.* calcd. for $C_{16}H_{16}O_2$: C 79.97, H 6.71; found: C 80.00, H 6.62.

*[*o*-[α-(Trimethylsilyl)methyl]benzyl]acetate (10*b*)*

To a stirred solution of sodium acetate (0.2 g, 2.4 mmol) in 50 mL of freshly distilled acetic anhydride was added 5.00 g (22.5 mmol) of [*o*-[α-(trimethylsilyl)methyl]benzyl]dimethylamine (16). After refluxing for 24 h, acetic anhydride was removed *in vacuo* and the resulting crude product dissolved in ether. The ether solution was washed with 10% aqueous sodium bicarbonate solution dried over sodium sulfate, and concentrated in *vacuo* to give a brown oil which was distilled at 55°C and 0.3 Torr (1 Torr = 133.3 Pa) to afford 3.99 g (77%) of acetate **10***b* as a colorless liquid: ν_{max} ($CHCl_3$): 1720 cm^{-1} (C═O); δ ($CDCl_3$, 400 MHz): 7.34–7.02 (m, 4H, aromatics, 5.08 (s, 2H, —OCH_2), 2.18 (s, 2H, —$SiCH_2$), 2.10 (s, 3H, methyl), 0.03 (s, 9H, —$SiMe_3$); m/e (relative intensity): 236 (M^+, 58), 221 (44), 117 (22), 104 (100), 73 (55). *Anal.* calcd. for $C_{13}H_{20}O_2Si$: C 66.05, H 8.52; found: C 66.30, H 8.60. The reaction between compound **10***b* (100 mg, 0.43 mmol), duroquinone (208 mg, 1.26 mmol), and TBAF (0.22 g, 0.84 mmol) followed by the usual work-up afforded 69 mg (61%) of adduct **16** whose properties were identical to those reported above. Neither **10***b* nor **10***c* (compound **10***c* is reported by Ito *et al.* (16) without experimental detail) gave any trace of adduct **12** when decomposed by anhydrous TBAF in the presence of *p*-benzoquinone.

Complexes of hybrid ligands. Pd^{2+} and Pt^{2+} complexes of new fluoro-alcohol thioether ligands; the use of thioether inversions to make structural assignments[1]

RENÉ T. BOERÉ AND CHRISTOPHER J. WILLIS

Department of Chemistry, The University of Western Ontario, London, Ont., Canada N6A 5B7

Received April 17, 1985

RENÉ T. BOERÉ and CHRISTOPHER J. WILLIS. Can. J. Chem. **63**, 3530 (1985).

The fluorinated alcohol–thioethers $RSCH_2C(CF_3)_2OH$ (R = Me, Ph) have been synthesized by the reaction of $RSCH_2Li$ with $(CF_3)_2CO$. By ionization of the fluoroalcohol group, these may act as bidentate, uninegative, ligands L^-. The presence of the soft thioether function in the hybrid ligand stabilizes the bond to the harder fluoro-alkoxy group, and complexes with soft transition metals are formed. Neutral complexes PdL_2 and PtL_2 have been synthesized, and, by the use of nmr, the geometry of the complexes is assigned as *cis* for Pt complexes, while both *cis* and *trans* are observed for Pd.

The barrier to inversion at coordinated thioether is studied by dynamic nmr, and observation of coalescence temperatures leads to values of $\Delta G‡$ of 73–74 kJ/mol for *cis*-PdL_2, 67–69 kJ/mol for *trans*-PdL_2, and 89 ± 1 kJ/mol for *cis*-PtL_2.

RENÉ T. BOERÉ et CHRISTOPHER J. WILLIS. Can. J. Chem. **63**, 3530 (1985).

On a synthétisé des thioéthers alcools fluorés, $RSCH_2C(CF_3)_2OH$ (R=Me, Ph), en faisant réagir du $RSCH_2Li$ sur la $(CF_3)_2CO$. Par ionisation du groupement fluoroalcool, ces composés peuvent agir comme des ligands, L^-, bidentates et mononégatifs. La présence, dans le ligand hybride, de la fonction thioéther molle permet de stabiliser la liaison avec le groupement fluoroalkoxy qui est plus dur et il y a formation de complexes avec les métaux de transition mous. On a synthétisé les complexes neutres PdL_3 et PtL_2 et, faisant appel à la rmn, on a établi que la géométrie des complexes du Pt est *cis* alors que, dans le cas des complexes du Pd, on retrouve des complexes *cis* ainsi que des complexes *trans*.

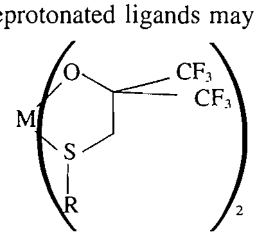
Faisant appel à la rmn dynamique, on a étudié la barrière à l'inversion au niveau des thioéthers coordonnées; l'observation des températures de coalescences permet d'établir les valeurs des $\Delta G‡$, qui sont 73–74 kJ/mol pour le PdL_2-*cis*, 67–69kJ/mole pour le PdL_2-*trans* et 89±1 kJ/mol pour le PtL_2-*cis*.

[Traduit par le journal]

Introduction

In previous studies on highly fluorinated alkoxides of transition elements, we have concentrated on bidentate or multidentate ligands in which the potential donor sites comprise one or more fluorinated alkoxy groups, $C(CF_3)_2O^-$, in conjunction with other hard donors coordinating through oxygen or nitrogen (2). Such ligands preferentially form stable complexes with the first-row transition metal ions of hard or intermediate character, but we have recently extended their range of application by the synthesis of a number of Pt^{2+} complexes in which the chelating perfluoropinacolato dianion, $^-OC(CF_3)_2C(CF_3)_2O^-$ (PFP^{2-}), is present in conjunction with soft coligands containing phosphine or thioether donors (3). Thus, alkoxides of metal ions which are soft acids in the Pearson HSAB classification (4) may be prepared, with the PFP^{2-} ligand imposing *cis*-geometry on $L_2M—O—C(CF_3)_2C(CF_3)_2—O$ (**1**, L = SR_2 or PR_3; M = Pd or Pt).

In this paper, we describe the synthesis and application of new "hybrid" ligands $RS—CH_2—C(CF_3)_2—OH$, (**2**, R = Me; **3**, R = Ph), in which the thioether function is combined with a highly fluorinated tertiary alkoxide in a molecule suitable for chelation to metals in a five-membered ring. Neutral bis-complexes of the deprotonated ligands may then be prepared:



R = Me, M = Pd (**4**) or Pt (**5**); R = Ph, M = Pd (**6**) or Pt (**7**)

These complexes are capable of existing in either *cis* or *trans* geometrical isomers (using the terms with reference to the orientation of two soft donor sites). However, the presence of two pyramidal coordinated thioethers means that these geometric forms may each exist as diasteroeomeric pairs, the substituents on sulfur being either on the same side of the coordination plane ("*syn*") or on opposite sides ("*anti*"). From nmr studied reported here, we demonstrate that all four of these isomers coexist in the palladium complexes **4** and **6**, but that the platinum complexes **5** and **7** are found in the *cis*-form only under the conditions of the experiment. We have furthermore used dynamic nuclear magnetic resonance (DNMR) measurements to establish the relative barriers to inversion at coordinated sulfur in assigning the isomers. Although such inversion is a well-established phenomenon in thioether coordination chemistry (5 – 7), there has only been one previous example of its use as the primary means of assigning geometrical structures (8).

Experimental section

General information

Microanalysis was performed by Guelph Analytical Laboratories, Guelph, Ontario; all analytical data are in Table 1.[2] Solution molecular weights were determined by Malissa-Reuter Laboratories, West Germany. Infrared spectra were recorded on a Beckmann 4250 spectrometer, mass spectra on a Varian MAT 311A instrument, and nmr spectra on a Varian XL-100 spectrometer at 100.1 MHz for ^1H and 94.1 MHz for ^{19}F. Chemical shifts are reported from TMS or $CFCl_3$; positive shifts are downfield. Variable-temperature nmr spectra were recorded over the range −20 to +160°C; temperature settings of the spectrometer were checked with a Doric Trendicator 400 type T digital thermometer calibrated to ±0.5°C at the ice-point.

[1]Taken in part from ref 1(*a*). A preliminary account was presented in ref. 1(*b*).

[2]Table 1 may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

Volatile compounds were manipulated on a conventional vacuum line. Glass apparatus and solvents were rigorously dried before use for ligand preparation. Air-sensitive materials were transferred using serum caps and syringes. *n*-Butyl lithium, thioethers, *N,N,N',N'*-tetramethylethylenediamine (TMED), and 1,4-diazabicyclo[2.2.2]-octane (DABCO) were commercial samples (Aldrich).

Ligand synthesis

(*i*) 2-Methylthio-1,1-bis(trifluoromethyl)ethanol, **2**. The procedure was based on that of Petersen (9), modified for handling the gaseous ketone. A 100 mL two-necked flask was attached to a stopcock arranged to permit alternate evacuation and pressurization (~10 cm Hg above atmospheric) with argon. It was equipped with a magnetic stirrer and serum cap, evacuated, and filled with dry argon. *n*-Butyl lithium (50 mL) in hexane solution (1.55 *M*, 78 mmol) was added by syringe, followed by 11.8 mL (78 mmol) of TMED. With stirring, dimethyl thioether (6.0 mL, 82 mmol) was added and the resulting white suspension stirred at 25°C for 4 h. Meanwhile anhydrous ether (75 mL) was introduced into a 250 mL two-necked RB flask equipped with magnetic stirrer and serum cap, the solvent outgassed and cooled to −196°C, then hexafluoroacetone (13.0 g, 78 mmol; Matheson) condensed in. The flask was warmed to −78°C in a CO_2/acetone cooling bath with stirring to dissolve hexafluoroacetone, then brought to atmospheric pressure with argon.

Using a 36" 16 gauge stainless-steel double-ended argon-filled needle extending through the serum caps, the lithium methyl − thioether suspension was transferred into the hexafluoroacetone solution at −78°C with continuous stirring. Reaction was vigorous at this temperature and a deep orange color appeared. Stirring was continued during 30 min at −78°C, then the suspension allowed to warm slowly to about 0°C, then poured into a mixture of concentrated HCl (100 mL) and ice (100 g). The product was extracted with ether, dried ($MgSO_4$) and distilled to give ligand **2**, bp 113°C/760 mm, 11.0 g (62% yield), characterized by analysis, mass spectrum (parent ion m/e = 228), and nmr ($CDCl_3$ solution; ^1H, s, δ = 4.46 (1 H); s, δ = 3.14 (2 H); s, δ = 2.20 (3 H) ppm; ^{19}F, s, δ = −78.14 ppm).

(*ii*) 2-Phenylthio-1,1-bis(trifluoromethyl)ethanol, **3**. The lithiation of thioanisole was carried out, using DABCO instead of TMED, according to the procedure of Corey and Seebach (10). THF was used as solvent throughout; other conditions, and workup, were the same as used in the preparation of **2**. The product **3** was distilled under vacuum (bp 60°C/1−2 Torr,); repeated distillation was necessary to remove traces of unreacted thioanisole, reducing the yield of pure product to 33%. Characterized by analysis, mass spectrum (parent ion m/e = 290), and nmr ($CDCl_3$ solution, ^1H m, δ = 7.24 − 7.46 (5 H); s, δ = 4.29 (1 H); s, δ = 3.54 (2 H) ppm; ^{19}F, s, δ = −77.5 ppm).

For convenient reference, the anionic forms of the ligands will be abbreviated in this paper to Me—S—O^- and Ph—S—O^-.

Preparation of complexes. (*i*) Reactions using 2-thiomethyl-2,2-bis(trifluoromethyl)ethanol, **2**.

The palladium complex was prepared by dissolving $PdCl_2$ (0.200 g, 1.13 mmol) in dimethylformamide (DMF, 40 mL) and adding ligand **2** (0.52 g, 2.26 mmol) followed by the stoichiometric amount of KOH (2.26 mmol) in ethanol. (In this and the following reactions, it was found convenient to measure out KOH volumetrically using a standardized solution, about 0.09 *M*, in ethanol.) Precipitated KCl was removed by centrifugation and the orange-red solution stirred 15 h, then solvents removed by vacuum evaporation at 25°C, and the residue extracted with acetone. Crystallization from ether gave the palladium bis-complex, Pd(Me—S—O)$_2$, **4**, as orange platelets, mp 199−201°C.

The platinum analogue was prepared by dissolving K_2PtCl_4 (1.01 g, 2.43 mmol) in DMF (50 mL) and adding ligand **2** (1.11 g, 4.90 mmol) followed by KOH (4.90 mmol) in ethanol, After stirring 6 days/25°C, precipitated KCl was removed, then solvents removed by vacuum evaporation at 25°C. The residue was extracted with warm acetone, the solution reduced in volume and chloroform added to precipitate the platinum bis-complex, Pt(Me—S—O)$_2$, **5**. Recrystallization from acetone/chloroform gave a pale yellow solid whose infrared spectrum showed the presence of water. An anhydrous analytical sample was obtained by vacuum sublimation at ~200°C.

(*ii*) Reactions using 2-phenylthio-2,2-bis(trifluoromethyl)ethanol, **3**. The palladium bis-complex, Pd(Ph—S—O)$_2$, **6**, was prepared by the same route as its methylthio analogue; pale orange platelets from ether, mp 198−199°C.

The platinum bis-complex, Pt(Ph—S—O)$_2$, **7**, was prepared by the same route as its methythio analogue, except that CH_2Cl_2 was used for the extraction of the solid residue and the product recrystallized from chloroform/acetone to give the complex as yellow needles, mp 190−191°C.

Characterization

Analytical data are given in Table 1.[2] All of the new complexes had infrared spectra consistent with their proposed structures. Mass spectra showed a parent ion for each neutral complex and similar fragmentation patterns. In order to eliminate the possibility of spurious nmr data resulting from association of the complexes ML_2, molecular weights for **4** and **5** were determined osmometrically in acetone. Three different concentrations in the range 0.006 to 0.03 *M* were used in each case, and results showed no significant association or concentration dependence of mw. (Found for **4**: 547 ± 8, calcd. 528. Found for **5**: 653 ± 7, calcd. 617.) Nuclear magnetic resonance spectra, which formed the principal means of characterization and structure determination, are discussed in detail below.

Results and discussion

Ligand synthesis

The lithium derivatives of thioethers have been extensively studied by Petersen and co-workers (9). We have restricted our study to derivatives of methyl-thioethers R—S—CH_3, where the CH_3 group is lithiated, but the reaction is capable of wide variation both in the nature of the R group and through the lithiation of alkyl groups other than methyl. However, little use has been made of these reagents for introducing a thioether function into a potential ligand system. In view of the highly electrophilic nature of hexafluoroacetone, we had little doubt that it would react with the intensely nucleophilic lithium derivatives of the thioethers. These are prepared by the deprotonation of methyl thioethers using *n*-butyl lithium in the presence of multidentate nitrogen bases:

$$\mathrm{CH_3\text{-}S\text{-}R} + {}^{n}\mathrm{Bu\text{-}Li} \xrightarrow[\text{hexane, 25°C}]{\text{(B)}} \mathrm{LiCH_2\text{-}S\text{-}R(B)} + \mathrm{C_4H_{10}}$$

$$\Big\downarrow \;\; (1)\ \mathrm{(CF_3)_2CO} \quad (2)\ \mathrm{H^+/H_2O}$$

$$\mathrm{HO\text{-}C(CF_3)_2\text{-}CH_2\text{-}S\text{-}R}$$

[(B) = TMED or DABCO]

We find that reaction of these lithium reagents with hexafluoroacetone is extremely vigorous, and cooling to dry-ice temperature is essential to obtain good yields of the fluorinated alcohol−thioethers. Choice of solvent is important in these syntheses because of the tendency of fluorinated alcohols to form stable complexes with some ethers. Ligand **2** was prepared in diethyl ether; ligand **3** in THF.

Our principal aim in the study reported in this paper was to prepare neutral complexes in which two molecules of the bifunctional ligand (in the ionized form) are coordinated to a dipositive metal atom. The divalent ions of the nickel triad were used in an attempt to make square-planar complexes. The synthetic approach initially used was that which had been successful in previous preparations of fluorinated alkoxides of transition metals; the addition of base to a 2:1 mixture of ligand and metal chloride in ethanol solution. With Ni^{2+}, an inter-

action appeared to be occurring, but well-defined products could not be isolated. By employing dimethylformamide as solvent for the metal halides, stable, well-characterized, Pd^{2+} and Pt^{2+} complexes were obtained. The preferential formation of stable complexes with the heavier metals of the triad indicates the dominant effect of the soft thioether function in the O_2S_2 donor set.

Nuclear magnetic resonance studies and the identification of isomers

The nmr spectra of all four complexes have been obtained in d_6-acetone and d_6-DMSO (the latter for high-temperature work); sufficient concentrations could not be obtained with less polar solvents. The data are summarized in Table 2; the spectra are strongly temperature-dependent, and data are generally given for the limits of slow and fast exchange, unless further detail is warranted (as with compound **4**).

For the complex $Pt(Me—S—O)_2$, **5**, it is immediately apparent from both ¹H and ¹⁹F spectra at ambient temperature that two isomers are present. The $CH_3—S$ signals are at 2.93 and 2.89 ppm, with ^3J(Pt,H) values of 54.7 and 52.9 Hz, respectively. The similarity in the values of the coupling constants shows that these species are not due to *cis–trans* isomerism of the O_2S_2 donor set, which should give a large difference in ^3J. For example, in the complex $PtCl_2(SMe_2)_2$ the values of ^3J(Pt,H) are 49.0 and 40.0 Hz for the *cis* and *trans* isomers respectively (11). The two isomers of **5** therefore differ only in the orientation of the Me—S groups.

The ^{19}F spectrum consists of two sets of doublets of quartets, indicating non-equivalent CF_3 groups in each isomer; this would be expected from the presence of the pyramidal coordinated thioether in the chelate ring. Coupling constants between fluorine atoms in each set are in the range 9–10 Hz, typical for geminal CF_3 groups.

The suggestion that these two forms of the complex are diastereomers related by inversion at the thioether ligand is supported by variable-temperature nmr studies. When a solution in d_6-DMSO is heated, the separate CH_3—S signals collapse and coalesce together around 128°C, and further heating to 146°C produces a sharp singlet. The ^{195}Pt satellites remain throughout, showing that the thioether remains coordinated to the metal. Behaviour of this type is typical of a complex in which inversion at the thioether ligands is becoming rapid on the nmr time-scale, leading to effective equivalence of the CH_3—S groups. The same trend is apparent in the ^{19}F spectra, but the coalescence temperature is higher (because of the greater value of the chemical shift difference for the CF_3 groups) and cannot be reached before significant sample decomposition has occurred.

In the phenyl-containing complex, $Pt(Ph—S—O)_2$, **7**, the nmr data are less informative because of the absence of the CH_3 probe with its associated coupling to ^{195}Pt. However, the ^{19}F signals for **7** are entirely analogous to those of **5**, consisting of one well-separated doublet of quartets, and another which has strong second-order character. We interpret this to mean that **7** also exists as two diasteromers of a single geometric isomer. Because of the greater solubility of this complex, well-resolved ligand resonances were observed in both d_6-acetone and d_6-DMSO solutions, and these are clearly attributable to two overlapping AB type resonances. On heating the solutions, decomposition occurred before coalescence had been reached in either the fluorine or proton (CH_2 region) spectra. At no point in the variable-temperature nmr studies, below or above ambient temperature, was any evidence seen for a third species.

The situation for the palladium complex **4** is quite different. Variable-temperature ^1H spectra at equilibrium are presented in Fig. 1.

Both ^1H and ^{19}F spectra are strongly temperature-dependent, but is is clear that there are four separate $—SCH_3$ resonances at 0°C, labelled 1–4; on warming to ambient temperature, the signals labelled 3 and 4 collapse to a broad singlet. Our interpretation of this spectrum has been assisted by its time-dependence at 32°C. In a freshly-prepared solution in d_6-acetone, the peaks labelled 1 and 2 are present in a 60:40 ratio, and the CH_2 region can be clearly identified as two overlapping AB signals (Table 2), giving a situation parallel to that of the platinum complex **5**. The peak labelled 3,4 is extremely small if the spectrum is recorded immediately after sample dissolution. After about 1 h, the equilibrium spectrum of Fig. 1 is attained, and the CH_2 region becomes obscured by the presence of a broad resonance associated with 3,4. Cooling produces the lower trace in the figure, while warming to 65°C causes 1 and 2 to coalesce, and alters the proportions of the isomers. The ^{19}F spectra show similar behaviour, with freshly-prepared samples showing two sets of doublets of quartets, one with a large value of Δ_{AB} and the other a very small value. On equilibrating and cooling to 0°C, signals corresponding to four species are observed.

These observations may be rationalized on the assumption

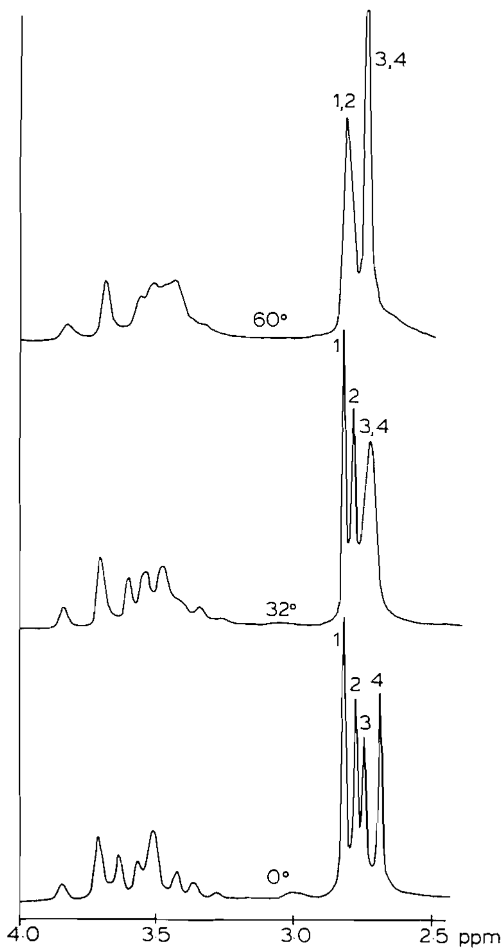

FIG. 1. Variable-temperature ^1H spectra of $Pd(Me—S—O)_2$, **4**.

that $Pd(Me—S—O)_2$ exists in solution as an equilibrium mixture of the four possible isomers: *cis–syn*, *cis–anti*, *trans–syn*, and *trans–anti*. We have previously demonstrated, in PFP^{2-} complexes of type **1**, that the *trans* effect of the $—C(CF_3)_2O^-$ group on the barrier to thioether inversion is considerably less than that of chloride (3). For example, in the SEt_2 complex $Pt(PFP)(SEt)_2$, $\Delta G‡$ is 75.5 kJ mol^{-1}, whereas in *cis*- and *trans*-$PtCl_2(SEt_2)_2$ $\Delta G‡$ values of 70.3 and 58.2 kJ mol^{-1}, respectively, have been reported (12). Assuming the validity of this *trans*-effect series for palladium, we would expect the *trans*-form of **4** to have the lower coalescence temperature for thioether inversion. This conclusion also depends on the relative separation of the signals in the two isomers, and we have calculated the actual values of $\Delta G‡$ (see below), which are in the expected order. We therefore assign peaks 1 and 2 in the figure to the *cis*-geometrical isomer, while 3 and 4 are diastereomers of the *trans*-isomer.

Complex **4** is thus probably *cis* in the solid state, undergoing rapid equilibration on dissolution in acetone to give the equilibrium *cis–trans* mixture. The proportion of *trans* increases from 40% at 0°C to 62% at 65°C, giving a ΔH value of 10.6 kJ mol^{-1} for the *cis*→*trans* interconversion.

Because of the greater chemical shift of the CH_2 and CF_3 spectra, their signals broadened but did not coalesce at 65°C, the highest temperature obtainable in acetone solution. When spectra were run in DMSO in order to reach higher temperatures, an immediate difference was observed in the behaviour of the complex: no signal for the *trans*-isomer appeared at ambient temperature. However, additional signals assignable to the *trans*-isomer (undergoing rapid *syn*−*anti* isomerization) began to appear at 50°C in the CH_3—S, CH_2, and CF_3 regions of the spectra. At 90°C, the ^{19}F spectrum consisted of a very broad coalesced peak for the *cis*-isomer and a sharp singlet for *trans*. By 110°C, the CH_2 region still showed separate peaks for *cis* and *trans*, but the CH_3—S signal had collapsed to a singlet, indicating rapid interconversion of all four isomers. The CH_2 signal also coalesced at higher temperature, but sample decomposition interfered with further measurements.

In view of the small differences in energy between the various isomers of complex **4**, it is not surprising that their proportions in the mixture are solvent-dependent. The preferential formation of the *cis*-isomer in going from acetone to DMSO would be expected from the greater polarity of the latter (13).

Assignment of the diastereomers

We have demonstrated that Pd(Me—O—S)$_2$, **4**, exists as a mixture of *cis*- and *trans*-isomers, and that the *cis*-isomer is thermodynamically the more stable form. On the basis of the barrier heights to inversion, $\Delta G\ddagger$, and the magnitude of the coupling ^3J(Pt,H) for **5**, in conjunction with our previous studies of PFP^{2-} complexes of Pt^{2+} with thioethers (3), we suggest that the sole isomeric species for **5** and **7** is in each case the *cis*-isomer. Complex **5** therefore consists of *cis*−*syn* and *cis*−*anti* isomers, and their approximately equal populations at ambient temperature show that there is little difference in energy between them. Assignment of the *syn* and *anti* forms cannot be made with certainty, but the spectra provide some evidence.

Consideration of molecular models shows a significant degree of steric interaction between the CH_3—S groups in the *syn*-isomer, which is minimized by the adoption of an "overall-envelope" configuration; that is, both of the chelate rings are in an envelope configuration on the same side of the coordination plane of the metal and opposed to the two R—S substituents. This locks the rings into a specific orientation which increases the difference in the environment of the pseudo-axial and -equatorial CF_3 groups, resulting in a larger difference in chemical shift, Δ_{AB}, between them. No such restraint applies in the *anti*-isomer, and the difference in environment between the CF_3 groups is therefore smaller. Since one species shows a value of 126 Hz for Δ_{AB} and the other of only 58 Hz, we assign the former as *cis-syn* and the latter as *cis*−*anti*. Similar steric arguments have been used by Abel to assign isomers of chelating dithioether complexes (14).

We have assigned the *syn*- and *anti*-forms of Pt(Ph—S—O)$_2$ on the same basis. The species with the larger value of Δ_{AB} for the CF_3 groups is assigned as the *cis-syn* form, the other as the *cis*−*anti*. For both **5** and **7**, the ^1H spectra have been tentatively assigned *from* the ^{19}F spectra using relative integration.

For the palladium complexes **4** and **6**, we have used the same configurational reasoning to assign the *syn* and *anti* forms of the *cis*-isomer as shown in Table 2. Such an assignment suggests a slight preference for the anti configuration in the temperature range studied, consistent with our postulate of greater steric repulsion for the *syn* form. However, the differences are not large, and no great weight can be attached to these results.

For the *trans*-isomer of **4** at 0°C, the ^{19}F spectrum indicates one species with equivalent CF_3 groups ($\Delta_{AB} = 0$), while the other is separated into quartets ($\Delta_{AB} = 81$ Hz). In this geometric form, the *anti*-isomer has the higher symmetry, and is more likely to correspond to the singlet CF_3 resonance. The ^1H spectra are tentatively assigned by integration, and in each case the *anti* configuration has CH_3—S resonances slightly to low field of the *syn*.

For the complex Pd(Ph—S—O)$_2$, **6**, the nmr spectra give less information because of the absence of the CH_3—S probe. At ambient temperature, the ^{19}F spectra in both acetone and DMSO shows three sets of signals, which may be analyzed in a similar manner to those of previous complexes studied. A doublet of quartets with a large value of Δ_{AB} (133 Hz) may be assigned to the *cis*−*syn* isomer, while a second-order multiplet with Δ_{AB}(effective) = ~5−7 Hz is assigned to the *cis*−*anti* isomer. The *trans*-isomer consists of a rapidly-inverting *syn*−*anti* mixture giving a sharp singlet; the proportion of the *trans*-isomer is ~30% in acetone and ~15% in DMSO.

The CH_2 region of the spectrum of **6** may be analyzed in terms of AB doublets as before. At ambient temperature in acetone, the signal for the *trans*-isomer is not observed because of exchange broadening, but it appears as a singlet at 3.69 ppm at 60°C. In DMSO, the spectra in this region are similar. The signals from the *cis*-isomers coalesce on heating, and an average singlet due to *syn*−*anti* interconversion is seen at 80°C; the *cis*/*trans* ratio is approximately 70/30.

Thioether inversion studies

Inversion at a single sulfur atom in complexes **4** and **5** will result in the interconversion of the diastereomeric isomers. Since these are species with different energies and populations, the process is classified as *non-mutual inversion*, and it may be followed by dynamic nmr. We have discussed the treatment of data previously in connection with perfluoropinacol−thioether complexes (3), and a comprehensive account is given by Sandström (15).

The rate constants for the major—minor (k_A) and minor—major (k_B) interconversion reactions may be estimated from the half-height linewidths at coalescence, w^*, using the equations:

$$k_A = P_A \frac{2\pi w^*}{X} \qquad k_B = P_B \frac{2\pi w^*}{X}$$

where the factor X depends on the ratio of the populations of the two forms, P_A and P_B. From the rate constants, the free energy of activation, $\Delta G\ddagger$, may then be found using the Eyring equation. Since $\Delta S\ddagger$ has consistently been found to be equal to zero or near zero for thioether inversion (16), little error is incurred by comparing $\Delta G\ddagger$ at different temperatures for different molecules. The calculations and results are summarized in Table 3.

The populations P_A and P_B are, as much as possible, extrapolations from the observable low-temperature region to the coalescence point. In the Pt complex **5**, the populations at T_c become fortuitously equal, so the classical equation of Gutowsky and Holm (17) has been used to obtain k ($=k_A = k_B$).

We are now able to justify the assignment of the stereochemistry of the complexes. Considering first the thioether inversion energies in Table 3, it is clear that, for the *cis*-isomer of the Pd complex **4**, the barrier to inversion is lower than in the *cis* Pt complex **5**. This is a general effect; for example, differences of 9 kJ mol^{-1} have been observed between Pd and Pt for the complexes MX_2L_2, where L is a monodentate cyclic thioether (18), 10−15 kJ mol^{-1} for various chelating dithioether complexes of PdX_2 and PtX_2 (14), and 5 kJ mol^{-1} for *trans*-$MX_2[S(CH_2SiMe_3)_2]_2$ (19). In each case, the barrier is lower for Pd than for Pt. In the following discussion, we adopt the classical mechanism of pyramidal inversion, with a planar

transition state, which has long been proposed for the inversion of tri-coordinate compounds of nitrogen, sulfur, and other main-group elements (20, 21). This model has recently come to be adopted for compounds of transition elements (5, 6). Two factors may be invoked to explain the lower barriers to inversion in Pd^{2+}. The first is the difference in electronegativity between the two metals: values are 1.44 for Pt and 1.35 for Pd (22). An increase in the electronegativity of the atom bonded to sulfur in a thioether complex increases the *s*-character of the remaining lone pair on the sulfur atom in the ground state, thus raising the barrier to inversion (20). A second factor, operating in the same direction, is that the stability of the intermediate with planar sulfur is increased by the more efficient π-overlap between S and Pd ($3p-4d$) than between S and Pt ($3d-5d$). A much smaller difference has been reported between isostructural chromium(0) and tungsten(0) complexes, for which these two factors work in opposite directions (6).

When a thioether function is incorporated into a chelate ring, there is generally an increase in the barrier to inversion. This probably occurs because there is a greater departure from the ideal 120° angle in the transition state when the sulfur atom is in a ring. A comparison of data on the Pt complex **5** with other complexes containing similar donor sets supports this trend. Our results on perfluoropinacolato (PFP^{2-}) complexes of Pt give $\Delta G‡$ values of 75.5 ± 1 kJ mol^{-1} for $Pt(PFP)(SEt_2)_2$, where the thioether is not chelated, and 86.5 ± 1 kJ mol^{-1} for Pt(PFP)(DTH) (3). Precise structural data are not available for the latter, but a reasonable estimate for the bond angle at sulfur in chelated dithiahexane, based on known values for chelated thioethers (7), would be 104°. In related Pt complexes of $Me—S—O^-$, we have found bond angles at sulfur averaging 97° (23). The value of $\Delta G‡$ is thus found to increase as the size of the chelate ring is reduced, due to an angle-strain effect on the transition state. Thus $\Delta G‡$ is about 13 kJ higher for the Me—S—O ring than for the unstrained SEt_2 complex of PFP^{2-}. From the series quoted earlier, a difference of 18 kJ is found between similar complexes where R_fO^- and R_2S are *trans* to a thioether. The hypothetical $\Delta G‡$ for *trans*-Me—S—O would thus be about 70 kJ. Thus predicted thioether inversion barriers allow us to assign the *cis* geometry to these complexes.

Precedent would suggest that *cis* geometry is more likely for an O_2S_2 donor set on platinum. The bis(monothio-β-diketonates) of both Pd^{2+} and Pt^{2+} are known to be *cis* (24), as is $(CH_3COO)_2Pt(SEt_2)_2$ (8). Values of ^3J(Pt,H) for the CH_3—S groups in **5** are fully consistent with *cis* geometry, which would of course place them *trans* to the fluorinated alkoxy groups. In the perfluoropinacol complex $Pt(PFP)(SMe_2)_2$, which has the same donor set on the metal in unambiguously *cis* geometry, ^3J is 44.0 Hz (3). However, other results show that the coupling to ^{195}Pt is often increased when the thioether is incorporated into a chelate ring. For example, in the 2,5-dithiahexane complex Pt(PFP)(DTH), ^3J is increased to 47–48 Hz (3). In related studies on other chelated Pt(Me—S—O) complexes (25), ^3J is 60.5 Hz for CH_3—S *trans* to Cl^-, 50.0 Hz *trans* to SEt_2, and ~41 Hz *trans* to phosphines. We have demonstrated that the $—C(CF_3)_2O^-$ group has a *trans* influence intermediate between Cl^- and R_2S (3), so the ^3J values of 53–55 Hz observed in $Pt(Me—S—O)_2$ are in the expected region for *cis* geometry. The value of ^3J has been shown to vary in a Karplus-type manner in $PtCl_2\{S(CH_2Ph)_2\}_2$, with $J(trans) \approx 55.7$ Hz and $J(gauche) \approx 29.3$ Hz (12). In complexes of S-methyl-cysteine, containing an S,N-coordinated five-membered ring, ^3J was found to be ~55 Hz with Cl^- *trans* to the S—CH_3 function and 44–51 Hz with NH_3 or en *trans* (26).

In the palladium complexes, the differences between the activation energies for thioether inversion of the *cis*- and *trans*-forms are only 5 to 6 kJ mol^{-1}. This is much less than for the platinum complexes discussed above, implying that ring effects may make a larger contribution to the size of $\Delta G‡$ than *trans*-effects. However, the absolute range of $\Delta G‡$ values for Pd are found to be much smaller, and these smaller differences are fully consistent with those of other palladium complexes which we have studied (25).

Conclusions

The use of the new hybrid ligands has enabled us to prepare some interesting analogues to the earlier type **1** complexes. We have demonstrated that the Pt^{2+} complexes **5** and **7** exist as syn and anti forms of the *cis*-isomer on the basis of the calculated ΔG values and the size of the coupling constants in **5**. Similarities in the ^{19}F spectra then allow us to transfer to the latter conclusions reached for the former. The observation of *cis*–*trans* isomerism for the Pd^{2+} complexes, with the *cis*-isomer being more stable, supports our contention that the platinum complexes must be *cis*, in agreement with the greater influence of antisymbiosis in the softer metal ion (4).

The presence of two independent nmr probes, ^1H and ^{19}F, has also enabled us to attempt assignments of the diastereomers in solution; although not definitive in every case, this has shown the potential of using multinuclear nmr in making structural assignments of coordination compounds.

3′,5′-cyclic nucleotides and by one of the present authors (5) using naturally occurring nucleosides.

Accumulation of ^{13}C nmr data has shown that C2′ of a nucleoside always exhibits a lower chemical shift than C3′, contrary to the recent announcement by Chang *et al.* (6) who assigned ^{13}C chemical shifts of methylated nucleosides based on wrong assignments of C2′ and C3′ of adenosine.

We encountered difficulty in assigning C2′ and C3′ of cyclonucleoside derivatives (7), whose H-2′ and H-3′ signals in ^{1}H nmr spectra were found to be a pair of doublets, exhibiting no coupling with H-1′ and H-4′. Thus, our early assignments of C2′ and C3′ of 8,5′-*O*-cycloadenosine derivatives by selective ^{1}H-decoupling were based on the fact that, in many nucleoside derivatives, H-2′ exhibited a lower chemical shift than H-3′.

Now unambigous assignments of H-2′ have been achieved using nOe (nuclear Overhauser enhancement) difference spectra irradiating H-1′, giving 4−8% nOe to H-2′. Subsequent selective ^{1}H-decoupling led to identification of C2′ and C3′ peaks, and our earlier assignments thus required revision.

In the case of isopropylidene derivatives of nucleosides, the signal of C2′ given as a doublet was always found to have a narrower line width than those of C3′ and C4′, reflecting the number of hydrogens which caused the long-range (two and three bond) C—H couplings.

The ^{13}C chemical shifts of several adenosine derivatives, including 8,5′-*O*- and 3,5′-*N*-cycloadenosine derivatives, are listed in Table 1. Throughout these compounds the C2′ signals were always located at lower magnetic fields than the C3′ signals, showing that ^{13}C chemical shifts of C2′ and C3′ were insensitive to the structural alterations of the base moiety.

However, chemical shifts of C5′ were found to reflect the nucleoside and cyclonucleoside structures: ^{13}C—O—H δ 62; ^{13}C—O—R (R = acyl) δ 64; ^{13}C—O—R (R = alkyl) δ 69; ^{13}C—O—N δ 49−51; ^{13}C—O—N^+ δ 57−58.

When the ^{13}C chemical shifts of C5 and C6 of compounds **2** and **3** were compared, it was evident that introduction of an acyl group at N6 of the adenine ring caused considerable increase in the C5−C6 bond polarity, i.e., shielding at C6 accompanied by deshielding at C5. However, in the case of the ring-cleaved compounds **12** and **13**, this trend was no longer observed, suggesting a contribution of the 6π-electrons of the pyrimidine ring to increase the C5—C6 bond polarity.

Similarly, affording positive charge at N3 of adenosine derivatives resulted in shielding at C4, to a considerable extent, as was shown by comparison of **1** with **11** as well as **16** with **17**.

Numbering of the compounds

The original numbering of adenosine is maintained in all the compounds listed here for the reader's convenience.

Experimental

Preparation of the compounds

Consult the following papers (reference numbers in parentheses): **2−4** (9), **5** (8), **6** (8 and 15), **7** (8 and 15), **8** (10), **9** and **10** (11), **11** (13), **12** and **13** (11 and 12), **14** and **15** (12), **17** (14), **18** (12).

Method

The nmr spectra were recorded by JEOL GX-400 and FX-100 spectrometers. ^{13}C chemical shift assignments were made based upon homo-spin decoupling on ^{1}H nmr, followed by selective decoupling and long-range selective decoupling (LSPD) on ^{13}C nmr in the case of **1**, **12**, **14**, and **16**. Assignments of H-2′, in the case of isopropylidene derivatives of nucleosides, were made based on nOe difference spectra, 4−8% nOe being observed for H-2′ {H-1′}.

Solvent

$CDCl_3$ for **5**, **6**, **7**, **15**, and **18**; DMSO-d_6 for other compounds. Difference of ^{13}C chemical shifts in these two solvents is less than 1 ppm in most cases.

The cleavage of aspirin by α- and β-cyclodextrins in basic aqueous solution

OSWALD S. TEE[1] AND BRYAN K. TAKASAKI[2]

Department of Chemistry, Sir George Williams Campus, Concordia University, Montreal, P.Q., Canada H3G 1M8

Received May 1, 1985

OSWALD S. TEE and BRYAN K. TAKASAKI. Can. J. Chem. **63**, 3540 (1985).

The deacetylation of aspirin is promoted by α- and β-cyclodextrins (αCD and βCD) in basic aqueous solution. From saturation kinetics the dissociation constants (K_d) for the aspirin anion − CD complexes are 12 m*M* (αCD) and 20 m*M* (βCD). At pH 12.25 the limiting rate constant for ester cleavage is 14 times (αCD) and 7 times (βCD) that in the medium alone. For the 4-chloroaspirin anion (K_d = 3.8 m*M*) the cleavage induced by αCD is 240 times that in the medium, but 5-chloroaspirin shows a very small effect. The results are discussed in terms of a model derived from that of Bender and co-workers (1967) and are compared to earlier work. For the αCD anion, the 4-chloroaspirin anion is almost as good as "substrate" as *m*-chloro- and *m*-*tert*-butylphenyl acetates. Compared to hydroxide ion, the αCD anion is better at cleaving 4-chloroaspirin (2000×) and aspirin (36×).

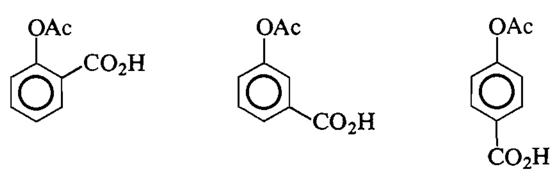
OSWALD S. TEE et BRYAN K. TAKASAKI. Can. J. Chem. **63**, 3540 (1985).

Dans des solutions aqueuses de base, la déacétylation de l'aspirine est facilitée par les cyclodextrines α et β. En se basant sur des cinétiques à saturation, on a pu établir que les constantes de dissociation (K_d) des complexes anion de l'aspirine/CD sont 12 m*M* (αCD) et 20 m*M* (βCD). À un pH de 12,25, les constantes limites de vitesse pour la coupure de l'ester sont respectivement 14 fois (αCD) et 7 fois (βCD) celle observé dans le milieu réactionnel seul. Dans le cas de l'anion chloro-4 aspirine (K_d = 3,8 m*M*), la coupure induit par la αCD est 240 fois plus rapide que celui observé dans le milieu réactionnel seul; toutefois, avec la chloro-5 aspirine, l'effet observé est petit. On discute des résultats en fonction d'un modèle dérivé de celui proposé par Bender et coll. (1967) et on les compare à ceux obtenus dans un travail antérieur. Pour l'anion de la αCD, l'anion de la chloro-4 aspirine est un substrat qui est pratiquement aussi bon que les acétates des *m*-chloro et *m*-*tert*-butylphényles. Par comparaison avec l'ion hydroxyle, l'anion de la αCD provoque des coupures beaucoup plus rapides de la chloro-4 aspirine (2000×) et de l'aspirine (36×).

[Traduit par le journal]

The solubility of aspirin (*O*-acetylsalicylic acid, ASA) in water is quite low (1 g/300 mL) (1). However, it can be increased substantially by the addition of the complexing agents α- and β-cyclodextrin, the effect of the latter being greater (2). β-Cyclodextrin also stabilizes solid aspirin (3). Any attempts to use these effects for pharmaceutical purposes (2, 3) should take into account the ability of cyclodextrins to promote the deacylation of phenyl acetates in aqueous solution (4). In the strictest sense of the word, cyclodextrins do not *catalyze* the hydrolysis of these esters since their deacylation results in the formation of an acetylcyclodextrin, which undergoes hydrolysis relatively slowly (4).

The seminal studies carried out by Bender and co-workers (4, 5) included *m*- and *p*-carboxyphenyl acetates (**2**, **3**) but not,



1   **2**   **3**

1^- = anion 2^- = anion 3^- = anion

surprisingly, ASA (**1**) (4). In view of the lack of a prior study and the potential interest of its results, it seemed worthwhile to examine the behavior of ASA under hydrolytic conditions in the presence of cyclodextrins. For comparative purposes, 4-chloro- and 5-chloroaspirin were also studied briefly.

TABLE 1. Rate constants for the cleavage of aspirin in presence and absence of α- and β-cyclodextrin at various pHs[a]

	k_{obs} (s^{-1})		
pH	No CD	αCD	βCD
13.55	0.116	0.137	0.123
13.25		0.0981	0.0580

11.85	0.00188	0.0198	0.00990
11.51		0.0102	

[a]At 25°C, *I* = 1.0 *M* (NaCl), $[ASA]_o$ = 0.5 m*M*, [CD] = 10 m*M*.

Results and discussion

The rate of hydrolysis of aspirin is very slow at intermediate pHs but it rises monotonically with hydroxide ion in aqueous base (6). For the sake of convenience we chose the pH range 11−14 which is close to that used by Bender and co-workers (4, 5). Moreover, within this range lie the apparent pK_as of the secondary hydroxyls of cyclodextrins that are involved in ester cleavage (4, 5, 7).

Table 1 and Fig. 1 show pH−rate data for the deacylation of ASA in the absence of and in the presence of α- and β-cyclodextrin (αCD and βCD). As expected from earlier work (6), the rate constant for hydrolysis in the absence of cyclodextrin simply increases linearly with [OH^-]. However, with αCD or βCD present the cleavage is faster at lower pH, the effect levelling off above pH 12 until by pH 13.5 normal

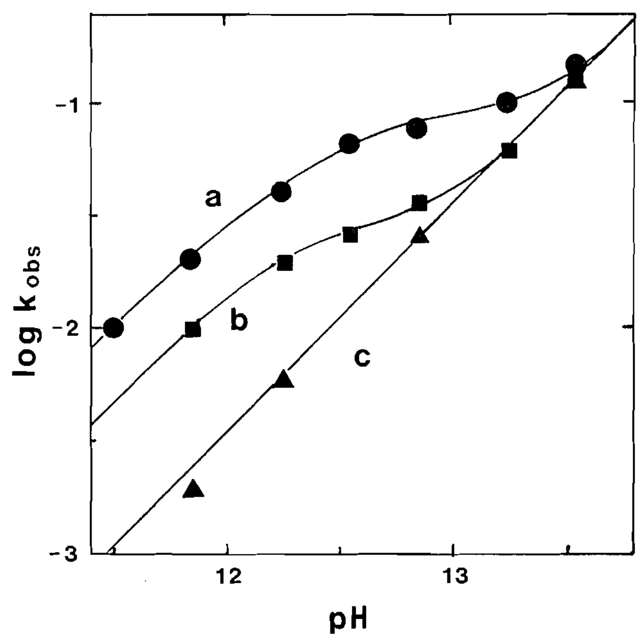

FIG. 1. pH–rate profiles for the cleavage of aspirin anion: (a) with 10 mM αCD; (b) with 10 mM βCD; (c) with no CD.

TABLE 2. Rate constants for the cleavage of aspirin as a function of cyclodextrin concentration[a]

[CD] (mM)	$10^3\ k_{obs}$ (s^{-1}) αCD	$10^3\ k_{obs}$ (s^{-1}) βCD
0	5.70	5.70
1.0	11.8	7.23
2.0	16.9	8.67
4.0	25.8	11.2
6.0	31.9	13.1
8.0	37.7	15.2
10.0	40.1	16.5

[a]At 25°C, I = 1.0 M (NaCl), pH = 12.25, $[ASA]_o$ = 0.25 mM.

hydrolysis by OH^- is dominant. This behaviour parallels that seen earlier for other phenyl esters (4, 5), the levelling-off being due to the cyclodextrin pK_as around 12.1 (4, 5, 7).

At fixed pH and varying CD concentration the observed first-order rate constants (k_{obs}) (Table 2) vary in a curvilinear manner (Fig. 2) appropriate to Michaelis–Menten type kinetics (8*a*). The simplest model that fits this behaviour involves reaction via a substrate–CD complex (7), as depicted below in eq. [1].

$$[1] \quad \mathrm{S} + \mathrm{CD} \underset{K_d}{\rightleftharpoons} \mathrm{S\cdot CD} \xrightarrow{k_c}$$
$$\downarrow k_u$$

For this reaction scheme the expected form of k_{obs} is:

$$[2] \quad k_{obs} = \frac{k_u K_d + k_c[\mathrm{CD}]}{(K_d + [\mathrm{CD}])}$$

where k_u is the "uncatalyzed" rate constant (in the absence of CD), k_c is that for the ASA–CD complex, and K_d is the dissociation constant of the complex. Analysis of the data in terms of eq. [2] was carried out in four ways: (a) linear regression $1/(k_{obs} - k_u)$ vs. $1/[\mathrm{CD}]$, a Lineweaver–Burk approach (7);

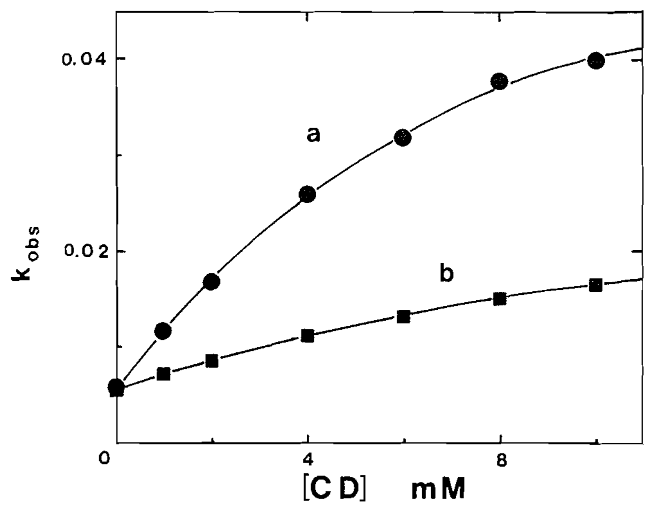

FIG. 2. Rate of cleavage of aspirin anion as a function of cyclodextrin concentration: (a) αCD; (b) βCD.

TABLE 3. Constants for the cleavage of phenyl acetates by cyclodextrins in aqueous solution

Substrate	CD	K_d (M)	$10^3 \cdot k_u$ (s^{-1})	$10^3 \cdot k_c$ (s^{-1})	k_c/k_u	Note
$\mathbf{1}^-$(ASA anion)	α	0.012	5.70	82.3	14	a
	β	0.020	5.70	38.0	6.7	a

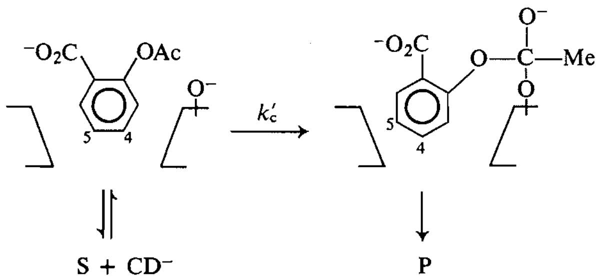
[a]This work. At 25°C, I = 1.0 M (NaCl), pH 12.25.
[b]Bender and co-workers (4). At 25°C, I = 0.2 M, pH 10.60, 0.5% acetonitrile.
[c]As previous, but pH 10.01.

(b) linear regression of $(k_{obs} - k_u)$ vs. $(k_{obs} - k_u)/[\mathrm{CD}]$, an Eadie–Hofstee approach (7); (c) non-linear fitting of eq. [2] keeping k_u fixed at the experimental value; and (d) likewise, but treating k_u as a fitting parameter. All four approaches gave excellent fits and very similar values for k_c and K_d. In the following we simply present the values obtained by (b) since the Eadie–Hofstee type of analysis is statistically superior to (a), even though the latter usually gives better looking linear plots (9).

Table 3 contains values of k_u, k_c, and K_d obtained at pH 12.25 in this study, together with some relevant values from Bender and co-workers (4), obtained at slightly lower pHs. Note that in these basic media the carboxyl-bearing substrates **1**, **2**, **3**, and **4** (see below) will be present as their respective anions $\mathbf{1}^-$, $\mathbf{2}^-$, etc.

The anion of aspirin ($\mathbf{1}^-$) binds fairly well to αCD and βCD (K_d = 12 and 20 mM), about 10 times more strongly than its *m*- and *p*-isomers. Presumably this is because the four unsubstituted positions of $\mathbf{1}^-$, which should be relatively hydrophobic, can reside in the cavities of the cyclodextrins, while the polar carboxylate and ester groups are in a largely aqueous environment (see Scheme 1). In contrast, both of the anions $\mathbf{2}^-$ and $\mathbf{3}^-$ must have one or other of their polar groups in the hydrophobic cavity. With phenyl acetate, where this problem does not arise, the binding is stronger and comparable to that of the ASA anion (Table 3).



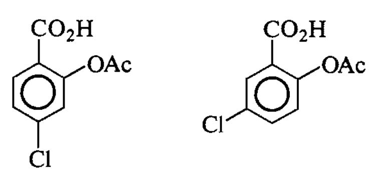
SCHEME 1

The rate enhancements (see k_c/k_u, Table 3) for the cleavage of aspirin by αCD and βCD are modest[3] and they parallel the binding of the substrate: for αCD the value of k_c/k_u and the binding are twice as large as for βCD. These differences are small but they may reflect the larger cavity size of βCD (7) in which **1**⁻ may sit deeper, but less snugly, so that the acetoxyl group is less accessible to the secondary hydroxyls that induce cleavage (4, 5, 7).

Despite showing much weaker binding to αCD, both **2**⁻ and **3**⁻ show comparable k_c/k_u values to the ASA anion. Thus, as is now generally recognized, good substrate binding is not of overriding importance in facilitating catalysis. Of more importance is the binding of transient intermediates and the transition states that flank them (10). The "catalytic" effect for the *meta*-substituted substrate **2**⁻ is about 5 times that for **1**⁻, which in turn is twice as large as that for the *p*-isomer **3**⁻. It was found by Bender and co-workers (4, 5, 7) that in general *m*-isomers show larger effects than *p*-isomers, a point which will arise again later. Phenyl acetate, which binds about as strongly as the ASA anion to αCD, shows a similar rate enhancement (Table 3).

Scheme 1 shows a depiction of the principal steps envisaged for the cleavage of the aspirin anion **1**⁻ by a cyclodextrin. In a guest–host complex (3, 7) formed from **1**⁻ and CD, the aspirin anion sits with its carboxylate and acetoxyl groups outside the cavity. The rate-limiting step is nucleophilic attack by an ionized secondary hydroxyl to give a tetrahedral intermediate, which undergoes fast phenolate loss to give acetylated cyclodextrin (4).

To provide support from Scheme 1 we have studied the behaviour of 4-chloro- and 5-chloroaspirin (**4** and **5**) with αCD.



4 **5**

With the 4-chloro derivative one expects better substrate binding *and* better "catalysis," as the acetoxyl group should be held close to the secondary hydroxyl groups. On the other hand, with the 5-chloroaspirin the acetoxyl group should be held further from these OHs and so weaker "catalysis" is expected. These expectations, which are based on the earlier findings for *m*- and *p*-substituted phenyl acetates (4), were fully realized.

[3]The values for ASA given in Table 3 are for pH 12.25, close to the apparent pK_as of the CDs. At lower pHs the rate enhancements should be about twice as large.

TABLE 6. Constants for the attack of hydroxide ion and cyclodextrin anions on aspirin and other phenyl acetates[a]

Substrate	CD	k_{OH} (M^{-1} s^{-1})	k_c' (s^{-1})	k_c'/k_{OH} (M)	k_2' (M^{-1} s^{-1})	k_2'/k_{OH}
1^-(ASA anion)	α	0.326	0.141	0.433	12	36
	β	0.326	0.0649	0.199	3.3	10
4^-	α	0.787	6.00	7.62	1600	2000
PhOAc	α	2.02	0.714	0.354	32	16
m-ClPhOAc	α	4.94	9.78	1.98	1750	350

[a]Rate constants are: k_{OH}, attack of OH^-; k_c' reaction within ester·CD anion complex; k_2', apparent value for attack of CD anion on ester (= k_c'/K_d).

Table 4 and Fig. 3 show pH−rate data for 4-chloroaspirin with and without added αCD. Clearly, there is substantially faster cleavage in the presence of αCD (~200×) at the lower pHs. In contrast, for 5-chloroaspirin a very small effect was observed: at pH 12.25, k_{obs} = 0.0134 s^{-1} with no CD added and 0.0174 s^{-1} with 10 mM αCD. In view of this small rate increase (30%), we did not attempt to measure saturation kinetics for **5**. However, for **4** we obtained the rate data given in Table 5, from which were obtained the values of k_c and K_d given in Table 3.

Just as a *m*-chloro substitutent increases the binding of phenyl acetate (3.9×), the 4-chloro substituent increases the binding of the ASA anion (3.2×). The effect on the rate of cleavage is, however, larger. For *m*-ClPhOAc the ratio k_c/k_u is 5.9 times that for PhOAc whereas for 4^- the ratio is 17 times that for the unsubstituted aspirin anion. Moreover, the k_c/k_u ratio for 4^- is larger (240×) than found for *m*-ClPhOAc (160×). At lower pH, away from the pK_a of the CD hydroxyls, the effect for 4^- would be larger still.[3]

To take explicit account of pH and the ionization of the CD hydroxyls (4, 5) a more complete rate equation is required. The reaction outlined in Scheme 1 may be represented by eq. [3],

$$[3] \quad S + CD \underset{K_d}{\rightleftharpoons} S.CD \overset{K_a}{\rightleftharpoons} S.CD^- \overset{k_c'}{\rightarrow}$$

which also suffices to define appropriate constants. For this pathway the expected form of k_{obs} as a function of acidity and CD concentration is:[4]

$$[4] \quad k_{obs} = \frac{k_c'K_a[CD]}{(K_d[H^+] + [CD](K_a + [H^+]))}$$

If we impose limiting (saturation) conditions, $[CD] \gg K_d$, so that k_{obs} becomes equal to k_c (see eq. [2]), then eq. [4] simplies to eq. [5]. This equation, through appropriate rearrangement,

$$[5] \quad k_c = k_c'K_a/(K_a + [H^+])$$

allows us to correct results obtained at different pHs to a common basis, namely, the rate constant (k_c') for reaction within the substrate·CD anion complex (see eq. [3] and Scheme 1). Values of k_c', thus obtained, are presented in Table 6.

For the aspirin anion 1^- reacting with αCD (or βCD) the value of k_c' is appreciably lower than that for phenyl acetate with αCD. Also for the 4-chloro anion 4^- k_c' is slightly lower than that for *m*-ClPhOAc. However, these comparisons ignore the intrinsic reactivities of the different substrates for which k_{OH}, the rate constant for attack of hydroxide ion, provides a measure. If we "normalize" k_c' by division by k_{OH} (Table 6), a different picture emerges: cleavage of 4^- by αCD anion is clearly superior to that of *m*-ClPhOAc and cleavage of 1^- is comparable to that of PhOAc.

The data in Table 6 also provide for one further comparison, which emphasizes the effect of complexation on the rate of ester cleavage. We define $k_2' = k_c'/K_d$, which is the apparent second-order rate constant for the attack of the CD anion on the ester substrate[5] (see eq. [6]). The values of k_2' in

$$[6] \quad S + CD^- \overset{k_2'}{\rightarrow}$$

Table 6 provide a measure of the reactivity of the cyclodextrin anion towards the various substrates, i.e. its "substrate specificity".[6] From this viewpoint, the 4-chloroaspirin anion and *m*-ClPhOAc are very similar and are 50−100 times better substrates for αCD than PhOAc and the ASA anion. The values of k_2' (3.3−1750 M^{-1} s^{-1}) fall within the range of k_{cat}/K_m values (0.13−3 × 10^5 M^{-1} s^{-1}) found for chymotrypsin with various amide and ester substrates (8*d*). The "best" substrate found by Bender's group (4, 5) was *m-tert*-butylphenyl acetate, for which k_2' = 2100 (αCD) and 3.1 × 10^4 M^{-1} s^{-1} (βCD). Much larger specificities have been found subsequently by Breslow's group, using carefully designed substrates (11).

Table 6 also lists values of k_2'/k_{OH}, which account for the different substrate reactivities and measure the superiority of the CD anion over hydroxide ion in promoting ester cleavage. This ratio is largest for the 4-chloroaspirin anion (2000), similar to that found for *m-t*-BuPhOAc (1700) with αCD (5). Again, larger ratios can be found in Breslow's work (11).[7]

Experimental

Commercial aspirin was recrystallized from water before use. 4-Chloro and 5-chloroaspirins (12) were made by acetylation (13) of the corresponding chlorosalicylic acids obtained from Aldrich. Cyclodextrins (Aldrich) were used as received.

[4]The derivation of eq. [4] assumes $[CD] \gg [S]$, which is true for most of the experiments and certainly for the limiting condition $[CD] \gg K_d$. It is also implicit that ionization of one of the secondary hydroxyls of the CD does not significantly alter K_d. For convenience also, we ignore the contribution from normal hydrolysis since it is negligible when the limiting conditions are imposed.

[5]For reaction of the ester·CD anion complex: rate = $k_c'[S.CD^-]$, whereas for reaction of the ester with the CD anion: rate = $k_2'[S][CD^-]$ (see eq. [6]). Equating these two expressions leads to $k_2' = k_c'/K_d$. This approach was used earlier by Bender and coworkers (5) and is equivalent to the use of k_{cat}/K_m for enzymes (8*b*,*c*).

[6]One frequent use of k_{cat}/K_m is as a measure of substrate specificity (8*c*).

[7]After acceptance of this paper we became aware of previous work on the cleavage of ASA by CDs: see ref. 16. This paper, which is mainly concerned with aryl phosphate cleavage, contains results which are compatible with the present study.

Substrate solutions were prepared by dilution of an aliquot of a stock 0.01 *M* aspirin solution into a cyclodextrin solution, all in 1.0 *M* aqueous NaCl solution. For kinetic experiments these were mixed (1:1) in a stopped-flow apparatus (14) with aqueous NaOH + NaCl solutions (total $I = 1.0$ *M*). Initial concentrations (after mixing) of substrate were 0.25 or 0.50 m*M*, of CD were 0–10 m*M*, and final pHs were calculated from the final $[OH^-]$ and an activity correction for $I = 1.0$ *M*.

Kinetics were measured at 25.0 ± 0.1°C using an Aminco DW-2 spectrophotometer + stopped flow accessory (14) by monitoring salicylate ion appearance at 310 nm. Fast runs used the data acquisition described previously (15). For slower runs the output voltage (2 V/abs. unit) of the DW-2 was captured by a Cyborg Isaac 91a interfaced to an Apple II microcomputer.

Rate constants were calculated from least-squares analysis of ln $(A_\infty - A)$ vs. time for data covering >90% reaction, A_∞ being obtained after 10 half-lives. Excellent straight lines ($r > 0.9995$) were obtained and the quoted rate constants are the average of 4–5 determinations.

Oxidation of hydrocarbons. 15. A study of the oxidation of alkenes by methyltributylammonium permanganate

JOAQUIN F. PEREZ-BENITO AND DONALD G. LEE[1]
Department of Chemistry, University of Regina, Regina, Sask., Canada S4S 0A2

Received February 27, 1985

JOAQUIN F. PEREZ-BENITO and DONALD G. LEE. Can. J. Chem. **63**, 3545 (1985).

A study of the reduction of methyltributylammonium permanganate by a large number of alkenes in methylene chloride has dispelled a current uncertainty concerning the nature of the inorganic product obtained. It is colloidal manganese dioxide and not a manganate(V) cyclic diester as previously supposed. This product is stabilized in methylene chloride solutions by adsorption of the alkene, which decreases its polarity at the solvent interphase. The solubility of the colloid is therefore a function of both the concentration and the identity of the alkene. In certain (atypical) cases, where acidic compounds are present, the product is further reduced to manganese(III).

JOAQUIN F. PEREZ-BENITO et DONALD G. LEE. Can. J. Chem. **63**, 3545 (1985).

En se basant sur une étude de la réduction du permanganate de méthyltributylammonium par un grand nombre d'alcènes dans le chlorure de méthylène, on a pu éliminé un doute concernant la nature de produit inorganique obtenu. Il s'agit du dioxyde de manganèse à l'état colloïdal et non pas un diester cyclique du manganèse(V) tel qu'il avait été suggéré antérieurement. Dans des solutions de chlorure de méthylène, ce produit est stabilisé par une adsorbtion de l'alcène qui en diminue la polarité à l'interface du solvant. La solubilité du colloïde est donc fonction à la fois de la concentration et de la nature de l'alcène. Dans certains cas qui ne sont pas typiques et dans lesquels il existe des composés acides, le produit est alors réduit en manganèse(III).

[Traduit par le journal]

Introduction

When alkenes are oxidized by permanganate ion, an intermediate can be detected under certain conditions. For example, Wiberg, Deutsch, and Roček (1) observed that a reactive species could be detected spectrophotometrically when crotonic acid and permanganate were allowed to react in a neutral aqueous medium. Lee and Brownridge (2) also detected an intermediate during the oxidation of cinnamic acid in acidic aqueous solutions and it was assumed that this species was likely a cyclic manganese(V) diester, **1**, that had been previously proposed as an intermediate for this reaction (3).

[1] 
1

However, attempts by Simándi and Jáky (4) to determine the oxidation state of the intermediate led them to conclude that the detected species was a soluble manganese(IV) compound, H_2MnO_3. Unfortunately these results were not unequivocal and it was later pointed out (5) that they were also consistent with the intermediate being a manganese(V) species such as **1**.

Under certain conditions, a semi-stable product having approximately the same spectral properties as the intermediate is formed. For example, Freeman and his co-workers (6) found that the oxidation of uracils at pH 6.7 gave a long-lived intermediate, which was determined to have an oxidation state between +3.3 and +3.8. More recently, it has been observed that the product produced when alkenes are oxidized by quaternary ammonium permanganates in nonaqueous solvents is remarkably similar to the intermediate detected by Freeman (5, 7). Because of the stability of this product, we have made an attempt to characterize it and thus dispel the uncertainty regarding its nature that now exists.

[1] Author to whom correspondence may be addressed.

As described in the following paper, our results provide compelling evidence that the product obtained from the oxidation of most alkenes is a colloid of manganese(IV) oxide.

Experimental

Absorbances were measured and the spectra recorded by use of a Hewlett–Packard 8450A uv–vis spectrophotometer.

Anhydrous methylene chloride, purified by double distillation over 4A molecular sieves, was used in all experiments except those in which the effect of water on the reaction was studied.

The oxidant, methyltributylammonium permanganate, was obtained by reaction of an aqueous solution of methyltributylammonium bromide with potassium permanganate (8). All of the reducing agents are commercially available compounds.

The concentration of permanganate was approximately 3×10^{-4} *M* in all experiments. The ratio [reductant]/[oxidant] was about 5 in the experiments in which the final oxidation state of manganese was determined, and about 25 for experiments in which the isosbestic points and final spectra were recorded. The oxidation state of manganese in the brown-yellow species formed from the reduction of methyltributylammonium permanganate by the different reducing agents was determined iodometrically. In a typical experiment a 50-mL flask containing 1-decene (1.5×10^{-3} *M*) in dry methylene chloride was placed in a water bath at 25.0 ± 0.1°C until thermal equilibrium had been attained. Solid methyltributylammonium permanganate (5×10^{-3} g) was then added and the solution stirred until homogeneous. An approximately 2-mL aliquot was immediately transferred to a cuvette in the thermostated cell compartment of the spectrophotometer, and the progress of the reaction was followed by sequentially scanning the solution at constant intervals. When the spectrum showed that all of the permanganate had been reduced, 2 mL of a freshly prepared solution of tetrabutylammonium iodide in methylene chloride (3×10^{-2} *M*) and 5 mL of glacial acetic acid were added to 2.0 mL of the reaction product. An immediate reaction (producing a dark yellow solution) occurred. The color was so intense that dilution (to 50 mL) was required before the concentration of the iodine liberated could be assayed spectrophotometrically.

The spectrum of the quaternary ammonium triiodide (QI_3) exhibited maxima at 365 and 294 nm in methylene chloride solutions. The absorbance at 365 nm, the peak used for these analyses, obeyed Beer's Law and exhibited a molar absorptivity of 2.62×10^4.

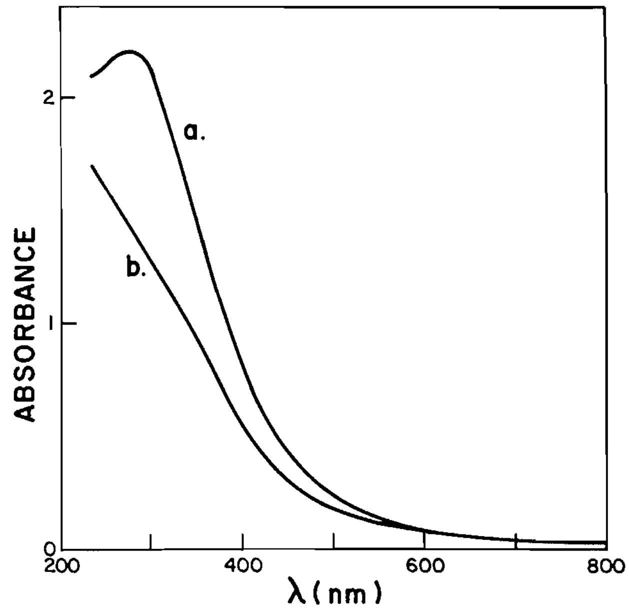

FIG. 1. Absorption spectrum of the product obtained from the reduction of methyltributylammonium permanganate (3.00×10^{-4} *M*) by 2,3-dihydrofuran (7.94×10^{-3} *M*). Spectrum "a" was obtained immediately after all of the permanganate had been reduced. Spectrum "b" was obtained after aging the product solution for 2 days.

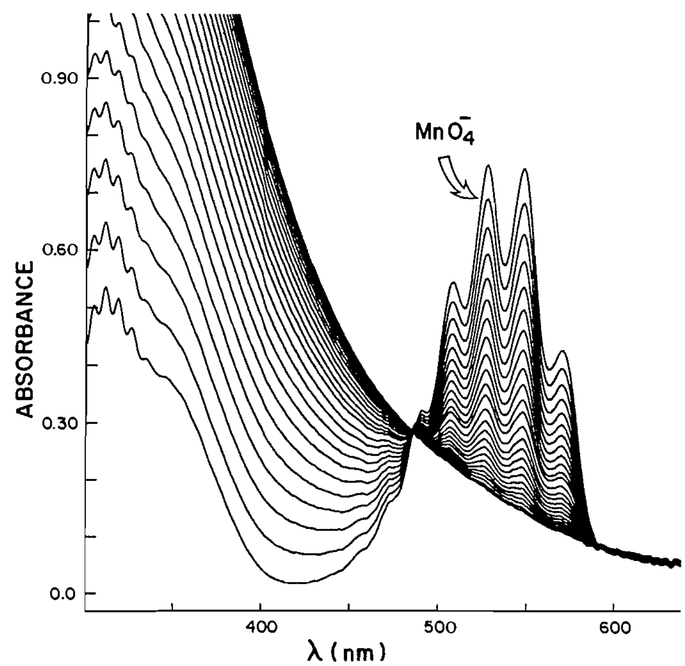

FIG. 2. Successive scans at 5-min intervals for the reduction of methyltributylammonium permanganate (2.84×10^{-4} *M*) by 2-methyl-1-butene (7.41×10^{-3} *M*) in methylene chloride at 25°C.

Application of this iodometric method to the titration of methyltributylammonium permanganate solutions of various concentrations indicated its reliability. The results from 19 different experiments confirmed that manganese is reduced by iodide ion to the +2 oxidation state under these conditions, and the results presented in Tables 1–3 are all based on this conclusion.

Results

The oxidation states of the products obtained from the reduction of methyltributylammonium permanganate by 26 different alkenes are summarized in Table 1. Also included in Table 1 is a list of the isosbestic points observed when the solutions were scanned sequentially as the reactions progressed.

The spectrum of the product obtained immediately following the completion of the reaction exhibited an absorption band with a maximum at about 280 nm (Fig. 1a). However, on standing, this band slowly disappeared and the final spectrum resembled that of a colloid, where energy loss from the incident uv–vis radiation is due to scattering rather than absorption (9) (Fig. 1b).

Sharp isosbestic points were observed when the rate of permanganate reduction was fast relative to the rate of flocculation of the colloidal product (Fig. 2). However, when the rate of flocculation was comparable to the rate of reduction, the isosbestic point was less sharply defined (Fig. 3). In any event, the occurrence of isosbestic points indicates that no long-lived intermediates are formed as the reaction proceeds.

The oxidation states of the products obtained from the reduction of methyltributylammonium permanganate by a representative alkyne, amine, and alcohol (given in Table 2) confirm that a similar product is formed regardless of the nature of the reductant.

Discussion

The results presented in Table 1 clearly indicate that the oxidation state of the initial product obtained from the reduction of permanganate by alkenes is +4. This product exhibits an absorption maximum (at about 280 nm) superimposed on

TABLE 2. Data for the reduction of methyltributylammonium permanganate by non-olefinic compounds in methylene chloride

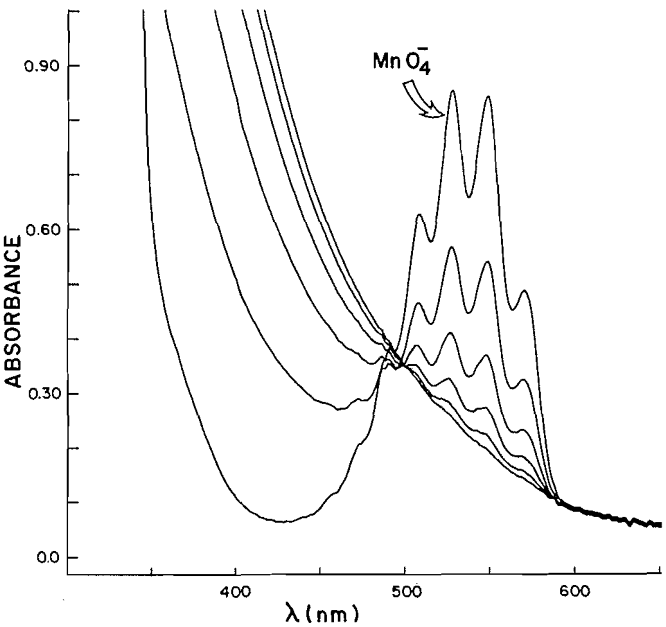

FIG. 3. Successive scans at 10-min intervals for the reduction of methyltributylammonium permanganate (3.24×10^{-4} *M*) by *cis*-stilbene (7.54×10^{-3} *M*) in methylene chloride at 25°C.

what appears to be a spectrum resulting from the scattering of light by a colloid. On standing, this absorption band slowly disappears and, for several alkenes, the spectrum of the resulting solution conforms quite closely to Rayleigh's Law for light scattering (9) (Fig. 1). This change in the spectrum is accompanied by a reduction in the measured oxidation state of the product from +4 to about +3.6.

An attractive explanation for these observations is that the absorption band at 280 nm is due to a π-bond between the alkene and MnO_2, the capacity of manganese dioxide to strongly adsorb organic molecules being well known (10). Such complexation would help to solubilize a colloid of MnO_2 in methylene chloride by providing an external lipophilic surface to the solvent. With time, however, oxidation of the alkene would lower the average oxidation state of the manganese.

The latter was demonstrated by adding an excess of 1-tetradecene to the colloidal product obtained from the reduction of methyltributylammonium permanganate. Iodometric titrations showed that this otherwise stable product was gradually reduced from an oxidation state of +3.96 to +3.60 (Fig. 4). The failure to obtain complete reduction (to +3.0) is probably a consequence of the inaccessibility of much of the MnO_2 to complexation with the alkenes.

A linear relationship between log (absorbance) and log λ

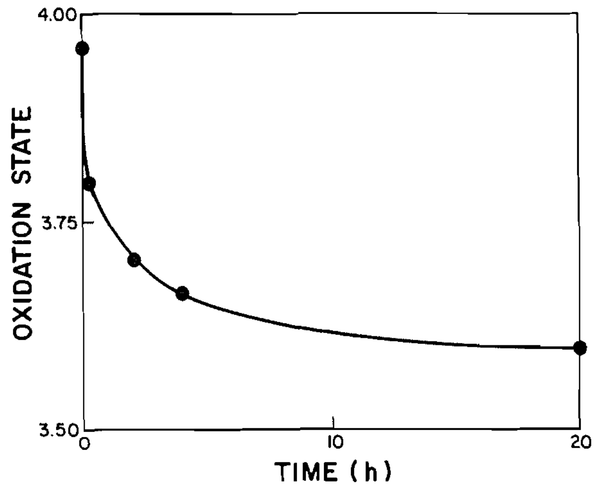

FIG. 4. Oxidation state vs. time when an excess of 1-tetradecene was added to the product freshly obtained from the reduction of methyltributylammonium permanganate (3.09×10^{-4} *M*) by 1-tetradecene (1.58×10^{-3} *M*).

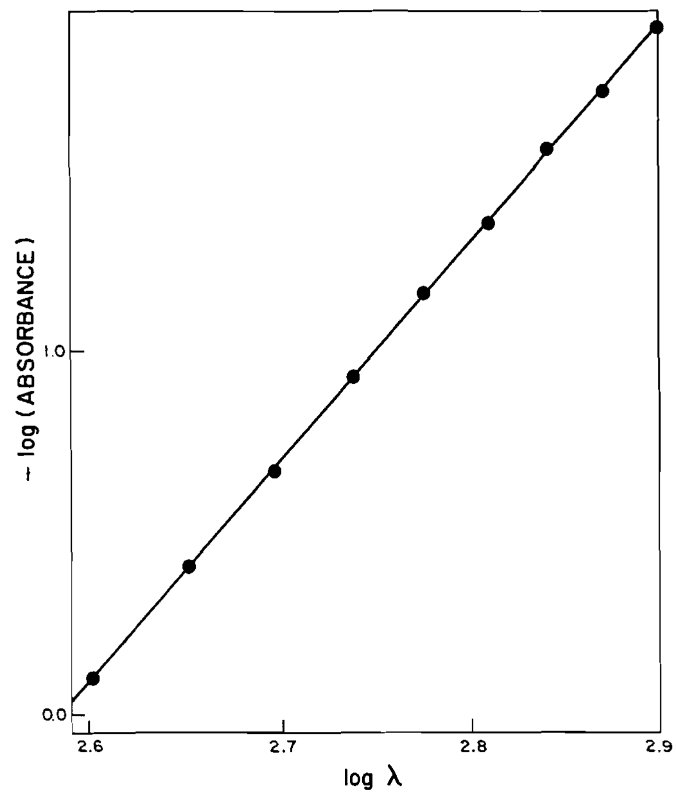

FIG. 5. Log *A* vs. log λ for the product obtained from the reduction of methyltributylammonium permanganate (2.74×10^{-4} *M*) by α-methylstyrene (7.69×10^{-3} *M*) in methylene chloride at 25°C.

would be expected if the product is present in the form of colloidal particles, i.e., if all of the energy lost is due to light scattering. This is a consequence of Rayleigh's Law, which can be written as in eq. [2],

$$[2] \quad A = C/\lambda^4$$

where *A* is the absorbance, λ the wavelength, and *C* a constant depending on the polarizability, mass, and concentration of the colloidal particles.

A typical plot of $-\log A$ vs. $\log \lambda$ has been reproduced in Fig. 5. Although these plots were all linear, with correlation coefficients of 0.99 or better, the slopes in every case were somewhat greater than the theoretical value of 4. Table 1 contains a summary of the slopes observed in those cases where precipitation did not occur. Consequently, it can be seen that all of the evidence available is in reasonably good agreement with the suggestion that the product is actually colloidal.

Although precipitation of manganese dioxide eventually occurs with some reducing agents, no turbidity could be detected at the end of the reactions. It seems likely that the solubility of the colloid is increased by adsorption of alkenes on its surface (thus decreasing the polarity of the colloid/solvent interphase). This suggestion is supported by the observation that the stability of the colloid in solution depends on the nature and the concentration of the alkene used in its preparation. For example, when 1-tetradecene is used as the reducing agent a 3-fold excess of alkene is sufficient to keep the colloid in solution; only when the ratio [alkene]/[$QMnO_4$] is less than 3 can precipitation be observed. However, in the case of 1-octene a 7-fold excess of alkene is necessary to keep the colloid in solution, and in the case of *cis*-stilbene even a 250-fold excess cannot prevent manganese dioxide from precipitating shortly after the end of the reaction.

The dependence of the solubility of the colloid on the nature of the reducing agent used in its preparation can be most easily explained by adsorption, which is well known to be a very specific process (11). Its dependence on the concentration of alkene must be a consequence of the adsorption isotherm, which determines the amount of adsorbate present on the colloid surface as a function of its concentration in solution.

Since there is an overwhelming abundance of evidence (3) that these reactions are initiated by the formation of a cyclic manganese(V) diester, **1**, it has previously been suggested that the detected product of the reaction could actually be a dimer or a polymer of **1** (5). This possibility appears, however, to be inconsistent with an oxidation state of +4, and with the observation that products of similar properties are also obtained from the reduction of permanganate by alkynes, alcohols, and amines under these conditions (Table 2).

No spectral evidence for the existence of an intermediate such as **1** can be found in the scans reproduced in Figs. 2 and 3. This means that the intermediate, assuming it exists, must either be present in very low concentration or else transparent in the spectral region scanned. In order to investigate the latter possibility an attempt was made to detect it iodometrically as the reaction progressed. Since the concentration of permanganate can be determined spectrophotometrically, the total concentration of product plus any intermediate can be obtained from the difference between the initial amount of permanganate and the amount present at any given time. The average oxidation state of the product plus any intermediate can then be determined from the magnitude of the iodine titer. As the results summarized in Table 3 indicate, the residual oxidation state remains close to 4 throughout the reaction. Consequently, it must be assumed that **1** is rapidly reduced to the observed product, colloidal manganese dioxide, most likely by abstraction of a hydrogen atom from the solvent.

Additional evidence for the colloidal nature of the product can be demonstrated by monitoring the absorbances of the solution at 418 and 526 nm simultaneously. Given that both reactant and product absorb light at 526 nm, the absorbance at this wavelength will be:

TABLE 3. Oxidation state of the product obtained from the reduction of methyltributylammonium permanganate (3.39×10^{-4} *M*) by cyclododecene (1.56×10^{-3} *M*) in methylene chloride at 25.0°C

% Reaction[a]	Oxidation state
16	3.73
29	3.91
41	4.07
53	4.03
64	4.14
75	4.12
85	4.09
98	3.97

[a] Defined as: $100[QMnO_4]_{consumed}/[QMnO_4]_{initial}$.

$$[3] \quad A(526) = \epsilon_R^{526}\, c + \epsilon_P^{526}\, (c_0 - c)$$

where ϵ_R^{526} and ϵ_P^{526} are, respectively, the extinction coefficients at 526 nm for the reactant, $QMnO_4$, and the product, and c and c_0 are permanganate concentrations at a particular time and initially. Since it has been demonstrated that no intermediates are present in the system in any appreciable amount, the concentration of the product can be assumed to be $c_0 - c$.

Due to the transparency of permanganate at 418 nm, the absorbance at this wavelength will be:

$$[4] \quad A(418) = \epsilon_P^{418}\, (c_0 - c)$$

where ϵ_P^{418} is the extinction coefficient of the product at 418 nm.

From eqs. [3] and [4] it is easy to derive eq. [5].

$$[5] \quad A(526) = \epsilon_R^{526}\, c_0 - [(\epsilon_R^{526} - \epsilon_P^{526})/\epsilon_P^{418}]\, A(418)$$

Equation [5] implies that a linear relationship should exist between $A(526)$ and $A(418)$. However, Fig. 6a shows that a slightly concave curve is actually obtained for the oxidation of *cis*-stilbene by permanganate in anhydrous methylene chloride solutions. A linear relationship was found only when the same reaction was followed in the presence of excess methyltributylammonium chloride (Fig. 6b). On the other hand, addition of a small amount of water to the solution caused the concavity of the curve to increase dramatically (Fig. 6c). This was accompanied by turbidity due to precipitation of manganese dioxide.

The three different situations reflected in Fig. 6 are a consequence of the colloidal nature of the product. Flocculation of the colloidal particles explains the slight concavity of the curve when the reaction was followed in the absence of both water and methyltributylammonium chloride (Fig. 6a). Flocculation would provoke an increase in the size of the colloidal particles and, consequently, an increase in the radiation scattered. According to eq. [5], if the extinction coefficients of the product, ϵ_P^{526} and ϵ_P^{418}, increase as the reaction is progressing, the absolute value of the slope of the $A(526)$ vs. $A(418)$ plot will decrease, and a concave curve will be obtained.

If this interpretation is correct, the effect of an addition of methyltributylammonium chloride or water is simply to decrease or increase the rate of flocculation. When the reaction is followed in the presence of water, the rapidity of the flocculation process can explain not only the concave curve shown in Fig. 6c, but also the precipitation of manganese dioxide that is observed experimentally.

The organic products produced under these conditions may be isolated by treatment of the brown-yellow methylene chlo-

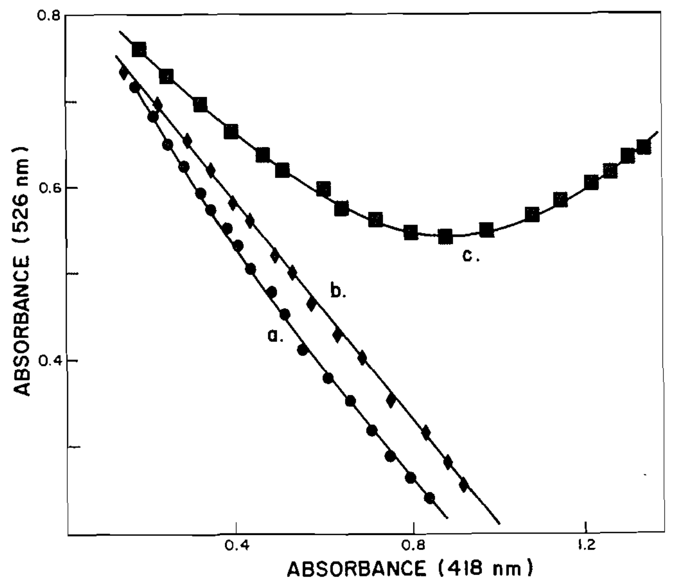

FIG. 6. Absorbance at 526 nm vs. absorbance at 418 nm for the reduction of methyltributylammonium permanganate (3.06×10^{-4} *M*) by *cis*-stilbene (1.50×10^{-3} *M*). "a", no additives; "b", methyltributylammonium chloride (2.53×10^{-2} *M*) added; "c", water (2.56×10^{-2} *M*) added.

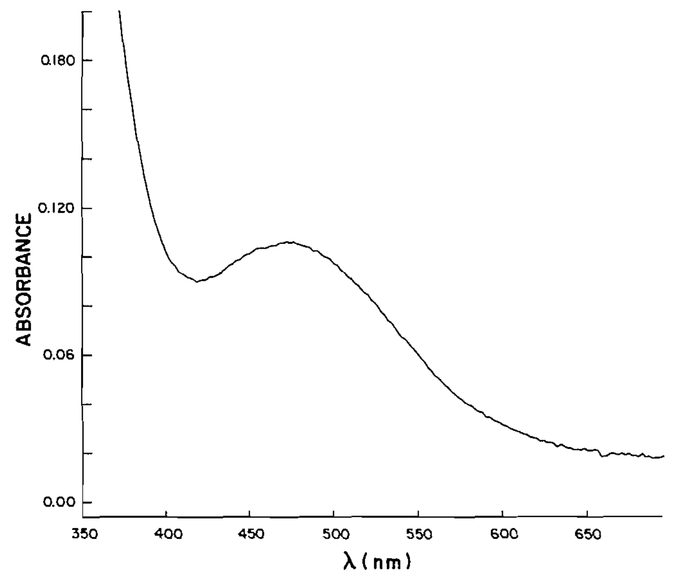

FIG. 7. Spectrum of the product obtained from the reduction of methyltributylammonium permanganate (2.70×10^{-4} *M*) by oleic acid (7.59×10^{-3} *M*) in methylene chloride at 25°C.

ride solutions with either dilute aqueous base or acid. If this aqueous solution is basic, diols are obtained; if it is acidic, cleavage products (aldehydes or ketones) are produced (7). Thus, it appears as if manganese dioxide cleaves diols under acidic conditions, a conclusion that is entirely consistent with the fact that MnO_2 is known to have a much higher reduction potential under acidic conditions than it has under basic conditions (12).

During the course of this study it was observed that the reduction of methyltributylammonium permanganate by two unsaturated compounds produced unusual products. When oleic acid was used as the reductant, the product had an apparent oxidation state of +3.25 and exhibited a spectrum quite differ-

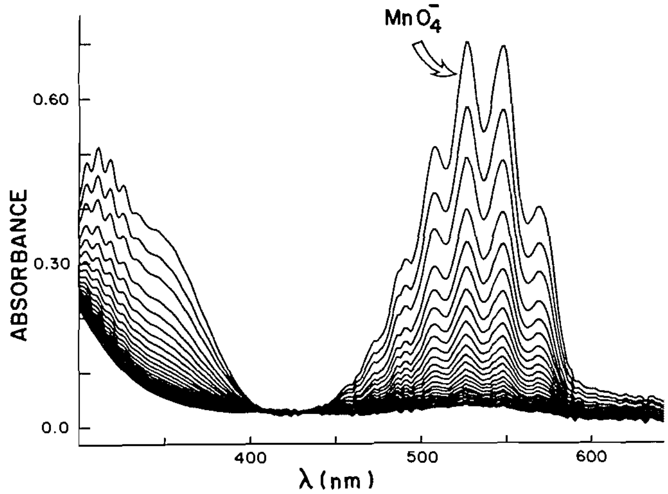

FIG. 8. Successive scans at 2-min intervals for the reduction of methyltributylammonium permanganate (2.67×10^{-4} *M*) by perfluorocyclohexene (1.65×10^{-3} *M*) in methylene chloride at 25°C.

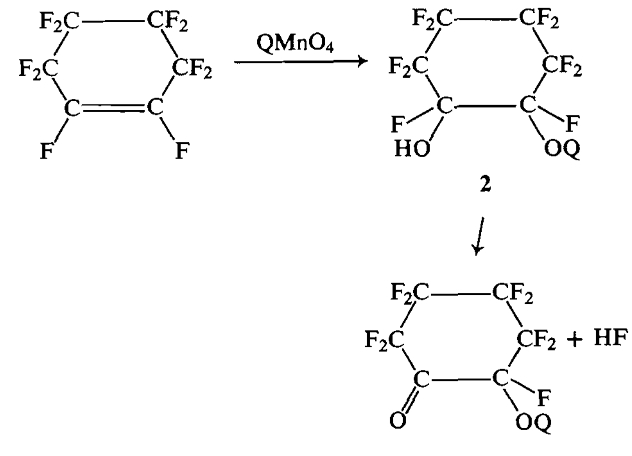
ent from those previously described (Fig. 7). Since manganese(III) is known to have an absorption maximum at 470 nm (coincident with that in Fig. 7), it appears as if the product is a mixture of Mn^{3+} and MnO_2 with the former predominating. The more complete reduction observed in this case could be related to the presence of acidic compounds in the solution.

The other reductant that produced an atypical product was perfluorocyclohexene (Fig. 8). The lower oxidation state of the product of this reaction (+3.25), which is similar to that previously reported for the oxidation of 5-fluorouracil (6), may also have been caused by the presence of acidic molecules in the solution. The initially formed product, **2**, would readily release HF to the solution as in eq. [6].

[6]



Summary

In conclusion, the results described herein establish that the brown-yellow product of these reactions is actually a soluble form of manganese dioxide. It is not a manganese(V) compound, as has been presumed in previous publications (5). The properties of this product indicate that it is a colloid, and flocculation appears to be responsible for the lack of good isosbestic points under certain conditions. For example, it can be seen from Fig. 3 that the crossover points near 490 nm move progressively to higher wavelengths—exactly the effect expected if flocculation of the MnO_2 particles was occurring as the redox reaction progressed. When a large excess of alkene

is present flocculation is suppressed, presumably because the colloidal manganese dioxide particles are stabilized by complexation with unsaturated compounds.

The presence of small amounts of water dramatically increases the rate of flocculation, whereas an excess of quaternary ammonium ion has the converse effect (Fig. 6).

Finally, when acidic compounds are present, manganese is reduced to a lower oxidation state and the spectral changes observed as the reaction progresses are greatly changed (Fig. 8).

A simple expression already used with success for computing atomization energies of alkanes and other molecules has been applied to alkenes. This has required evaluation of a term F which had been taken equal to zero in previous applications of the same equation. In order to explain the physical meaning of this novelty, we have been led to introduce a "principle" stating that the electrostatic potential created by σ electrons associated to any given atom of a molecule is well reproduced by a single charge centered at the nucleus and that the special behavior of alkenes is associated with residual π AO-centroid displacements with respect to the carbon nuclei. Direct computation of *in situ* valence AO's from optimized 4-31G* molecular orbitals yields a *pd* hybridization of the π AO's of the carbon atoms which does account for most of the expected F value. This indicated that use of simple equations derived from general theory and the application of simple principles or rules to the analysis of sophisticated molecular computations can yield a simple and quantitatively satisfactory picture of molecular reality.

SÁNDOR FLISZÁR, GIUSEPPE DEL RE et MICHEL COMEAU. Can. J. Chem. **63**, 3551 (1985).

On applique aux alcènes l'expression simple qui a permis de calculer les énergies d'atomisation des alcanes et d'autres molécules. Cette nouvelle utilisation implique l'évaluation d'un terme F qui avait été considéré nul dans les applications antérieures de cette équation. Dans le but d'expliquer la signification physique de cette nouvelle approche, nous sommes conduits à introduire un "principe" qui veut que le potentiel électrostatique créé par les électrons σ associés à n'importe quel atome d'une molécule est bien reproduit par une charge unique centrée sur le noyau. De plus, le comportement particulier des alcènes est associé à des déplacements par rapport aux noyaux des carbones, de centroides d'OA π. Les calculs des OA de valence in situ à partir des orbitales moléculaires optimisées 4-31G* conduisent à une hybridation *pd* des OA π des atomes de carbone qui rend compte des valeurs de F attendues. Ceci indique que l'utilisation d'équations simples dérivées de la théorie générale et l'application de principes ou de règles simples à l'analyse des calculs moléculaires compliqués peuvent conduire de façon satisfaisante à une image simple et quantitative de la réalité moléculaire.

[Traduit par le journal]

Introduction

Chemical bonds play an important role in the description of molecular systems. They are best investigated at 0 K, with reference to equilibrium molecules in their hypothetical vibrationless state (1). The corresponding atomization energy

$$[1] \quad \Delta E_a^* = \Sigma\epsilon_{ij} + \Delta E_{nb}$$

is conveniently partitioned into a non-bonded part, ΔE_{nb}, and a sum in which each ϵ_{ij} describes the energy contribution of an individual bonded atom pair ij. Estimates of ΔE_{nb} in σ systems (1–4) indicate that ΔE_{nb} is ~0.02–0.05% of ΔE_a^*. Hence, the theory of ΔE_a^* is essentially a theory of bond energies, at least in most organic molecules. Typical ethylenic carbon–carbon double bonds and related topics of fundamental importance in the theory of chemical bonding are the subject of the work reported here.

The scope of this study is best outlined by briefly reviewing relevant earlier results. Reference bond energies, ϵ_{ij}^0, can be deduced (2, 5) from appropriately selected reference molecules, e.g. $\epsilon_{C=C}^0 = 139.27$ kcal mol^{-1} for ethylene (6) and $\epsilon_{C-C}^0 = 69.633$, $\epsilon_{CH}^0 = 106.806$ kcal mol^{-1} for ethane (2). Straightforward addition of reference bond energies does not provide correct descriptions of alkanes or alkylsubstituted ethylenes, since molecular electroneutrality is not automatically ensured in this manner (1, 2). Charge normalization adds a term to $\Sigma\epsilon_{ij}^0$, thus leading to correct values of ΔE_a^*, the correction being of great numerical as well as theoretical importance. The present investigation is devoted to the approach that has permitted to bridge the gap between $\Sigma\epsilon_{ij}^0$ and ΔE_a^* in terms of changes in nuclear–electronic interactions accompanying charge normalization.

The key to the charge renormalization effects is provided by the quantity ΔV_{nc}, viz. the total change in the nuclear–electronic potential energy occurring when the valence-electron population of each atom i changes from N_i^0 (the value in the reference molecule) to $N_i = N_i^0 + \Delta N_i$, with the constraint that $\Sigma_i N_i$ should satisfy molecular electroneutrality. In the spirit of the Politzer–Parr core-valence separation (7), we write (1, 2)

$$[2] \quad \Delta V_{nc} = -\sum_i Z_i^{eff}\Big[N_i\langle r_i^{-1}\rangle - N_i^0\langle r_i^{-1}\rangle^0 + \sum_{j\neq i}(N_j\langle r_{ij}^{-1}\rangle - N_j^0\langle r_{ij}^{-1}\rangle^0)\Big]$$

where the Z_i^{eff}'s are "effective" nuclear charges (e.g., 4 for carbon). The quantities appearing in the square brackets are defined in terms of a suitable partitioning of the molecular electron density into atomic contributions ρ_i and of the equilibrium coordinates, $\boldsymbol{r}_i$, of the nuclei, i.e.,

$$[2a] \quad \begin{aligned} &\int \frac{\rho_i(\boldsymbol{r})}{|\boldsymbol{r}-\boldsymbol{r}_i|}\,d\boldsymbol{r} = N_i\langle r_i^{-1}\rangle \text{ with } \int\rho_i(\boldsymbol{r})\,d\boldsymbol{r} = N_i \\ &\int \frac{\rho_j(\boldsymbol{r})}{|\boldsymbol{r}-\boldsymbol{r}_i|}\,d\boldsymbol{r} = N_j\langle r_{ij}^{-1}\rangle \text{ with } \int\rho_j(\boldsymbol{r})\,d\boldsymbol{r} = N_j \end{aligned}$$

Thus, $\langle r_i^{-1}\rangle$ and $\langle r_{ij}^{-1}\rangle$ can be interpreted as the average inverse distances from Z_i^{eff} to the centers of the electron populations N_i and N_j, respectively; the superscript zero indicates the corresponding expressions for the reference molecule. Considering, where appropriate, also modifications in bond lengths, the ac-

[1] Visiting scientist. Permanent address: Cattedra di Chimica Teorica della Facoltà di Scienze, Via Mezzocannone 4, I-80134, Napoli, Italia.

companying change in nuclear repulsion can be added to the above expression in the form

$$[3] \quad 2(V_{nn} - V_{nn}^0) = \sum_i \sum_j Z_i^{eff} Z_j^{eff} [\langle R_{ij}^{-1}\rangle - \langle R_{ij}^{-1}\rangle^0]$$

where the summation extends over all bonded atom pairs. Combining eqs. [2] and [3], we obtain $\Delta(V_{nc} + 2V_{nn})$, i.e., the change in $(V_{nc} + 2V_{nn})$ resulting from changes in electron populations and bond lengths. Following Politzer's well documented approximation, $E \simeq (3/7)(V_{nc} + 2V_{nn})$, for the total molecular energy (5, 8), we can thus easily deduce energy changes resulting from modifications in orbital shapes and equilibrium distances. The general expression obtained from eqs. [1]–[3] is

$$[4] \quad \Delta E_a^* = \Sigma\epsilon_{ij}^0 + F + \sum_{i \neq j} \sum_j a_{ij}\Delta q_i + \Delta E_{nb}$$

where $\Sigma_i\Sigma_j a_{ij}\Delta q_i$ is the energy associated with the changes, Δq_i, of the net atomic charges with respect to the reference molecule. The calculation of all the terms of eq. [4] but F has been described elsewhere (1, 2, 6) and will not be discussed here. Attention is focussed on

$$[5] \quad F = -\frac{3}{7}\sum_i \sum_j Z_i^{eff} q_j(\langle r_{ij}^{-1}\rangle - \langle r_{ij}^{-1}\rangle^0) - \frac{3}{7}\sum_i \sum_j Z_i^{eff} Z_j^{eff}[\langle R_{ij}^{-1}\rangle - \langle R_{ij}^{-1}\rangle^0 - (\langle r_{ij}^{-1}\rangle - \langle r_{ij}^{-1}\rangle^0)]$$

which contains information regarding orbital shapes and internuclear distances. In [5], $q_j = Z_j^{eff} - N_j$ is the net atomic charge of atom j bonded to i.

Physical interpretation of F

First of all, let us point out that calculations of ΔE_a^* assuming F to be negligible have given agreement with experiment to within ~0.2 kcal mol^{-1} (average deviation) for over 70 saturated hydrocarbons with energies ranging between 400 and 4000 kcal mol^{-1} (1, 2). This is a strong indication that F is in fact negligibly small in saturated hydrocarbons. With this point in mind, let us define the external electrostatic potential at atom i as

$$[6a] \quad V_i = -\sum_j (N_j\langle r_{ij}^{-1}\rangle - Z_j^{eff}R_{ij}^{-1})$$

Let us also introduce the corresponding expression obtained when the electron populations are kept at their proper values in the molecule under study, but the inverse-distance terms referring to the bonded partners j are replaced by their values in the reference molecule, i.e.,

$$[6b] \quad V_i^{nr} = -\sum_j [N_j\langle r_{ij}^{-1}\rangle^0 - Z_j^{eff}(R_{ij}^{-1})^0]$$

Then, clearly,

$$[7] \quad F = -\frac{3}{7}\sum_i Z_i^{eff}(V_i - V_i^{nr})$$

The condition that F should vanish can be satisfied either because the various atomic contributions to F cancel, or because the individual terms in the summation over i vanish. Since it seems unlikely that cancellation of terms associated to different atoms would take place systematically in a large number of molecules, we shall assume that the results obtained for alkanes mean that, to a good approximation,

$$[8] \quad V_i \simeq V_i^{nr}$$

for any atom of any saturated hydrocarbon.

The most direct interpretation of eq. [8] follows from the observation, suggested by eqs. [6a], [b], that F is essentially a "relaxation" term. In fact, $V_i - V_i^{nr}$ represents the difference between the electrostatic potential at the ith nucleus in the given molecule and the potential which the same nucleus would feel if the atomic orbitals and the equilibrium distances remained the same as in the reference molecule in spite of the change in electron populations. With this picture in mind, eq. [8] reads: "Whenever the atoms under consideration in a given molecule are in the same valence states as in the reference molecule, the relaxation process is such that the potential created by the other atoms at the ith nucleus is the same as would be predicted by leaving the pertinent internuclear distances and the shapes of atomic electron densities as they are in the reference molecule, the electron populations being changed as required by the new situation". This may mean that changes in the nuclear positions and in the centroids of the atomic orbitals always take place so as to leave the ratio between the expectation value $\langle r_{ij}^{-1}\rangle$ and R_{ij}^{-1} the same as in the reference molecule or, at least, that changes are insignificant. It is impossible to decide which alternative applies from a study of the paraffins, since their bond distances and atomic orbitals are expected to be practically constant.

In contrast, consideration of ethylene could provide an instructive test. Computation of its atomization energy with $F = 0$ yields a result larger than the experimental one by ~9.6 kcal mol^{-1}. Similarly, an error of ~19.2 kcal mol^{-1} would be made in the computation of tetramethylethylene. Although estimates of this type are not free from difficulties, which are discussed in detail further below, the uncertainty they carry does not exceed a few tenths of a kcal mol^{-1} for one CH or CC bond, meaning that the discrepancies between theory and experiment are certainly real. Therefore, we have investigated the possibility that they may be associated with changes in valence states resulting in $F \neq 0$.

The ethylenic C=C bond

A simple way of satisfying eq. [8] consists in assuming that

$$[9] \quad \langle r_{ij}^{-1}\rangle \simeq R_{ij}^{-1}$$

when all bonds are σ bonds at their equilibrium geometries,[2] as in our calculations on the alkanes. Defining a density $\rho_{\mu j}$ and an electron population $N_{\mu j}$ associated with each valence atomic orbital μ of atom j, such that[3]

$$[10] \quad \int \frac{\rho_{\mu j}(\boldsymbol{r})}{|\boldsymbol{r} - \boldsymbol{r}_i|} d\boldsymbol{r} = N_{\mu j}\langle r_{\mu ij}^{-1}\rangle$$

we can write

[2] This simplifying hypothesis is supported by examination of SCF potentials at the nuclei, showing that eq. [9] holds at least to within ~5%, both for CH and CC bonds (to be published). It is especially useful here because it permits one to isolate the relevant conceptual points in a straightforward manner within the simple framework of the point-charge approximation.

[3] Definition [10] implies that orbital products can be well approximated in the average by some Mulliken-type expansion (9, 10). This does not imply that the populations introduced are gross Mulliken populations (11).

$$[11]\quad \sum_{\mu} \frac{N_{\mu j}}{N_j} \langle r_{\mu ij}^{-1} \rangle = 1/R_{ij}$$

Equation [11] reads: the average of the expectation values of $|r - r_i|^{-1}$ for the various valence AO's of atom j, weighted by the ratios of the orbital populations to the total atomic population of atom j equals the inverse of the i–j distance. For all their simplicity, eqs. [10] and [11] cannot be tested numerically by direct calculation. The reason is that the partitioning of the total electron density into atomic contributions is still an open question, in spite of an important conceptual step forward due to Parr (12). A practical step in the same direction is the construction of suitable *in situ* valence atomic orbitals (VAO) from accurate *ab initio* computations (13), as advocated a long time ago by Mulliken (14) and discussed by one of us (15). As will be seen, such *in situ* VAO's do provide useful information, but they are of no help in solving the additional problem of assigning suitable populations to the orbitals and of dividing overlap populations into atomic contributions. In view of this situation, we take eq. [8] and the sufficient (not necessary) condition [11] as statements whose validity rests on empirical evidence, at least for saturated hydrocarbons. Their extension to unsaturated hydrocarbons remains a problem, even though the success of approximations of molecular properties in terms of point charges located at the nuclei could be traced back to a general principle of that kind, as suggested long ago (16). A solution can be found by the following argument.

In paraffins, the bonds formed by carbon are either CH or CC single bonds; of course, the electron density around C is not exactly spherical, but special multipole contributions appear to vanish to the extent that one can regard that the CH electron density adjusts to that of CC, and conversely, so that electrostatic effects are adequately described by a point charge located at C. Now suppose that one bond to hydrogen is removed and replaced by a π bond of the same atom to another carbon atom. Changes in geometry and hybridization will, of course, occur but, at least to first order, the resulting π atomic orbital will not be able to participate in a possible mutual readjustment of the AO centroids, due to its different symmetry. Thus, we have to expect that condition [11] also applies to the simple mono-olefins considered here, with the restriction that it only concerns σ orbitals. In other words, ethylenic carbon atoms will obey a "principle" of σ-bond electrostatic balancing, i.e.,

$$[12]\quad N_j\langle r_{ij}^{-1}\rangle = \int \frac{\rho_j(\boldsymbol{r})}{|\boldsymbol{r}-\boldsymbol{r}_i|}\,\mathrm{d}\boldsymbol{r} = \sum_{\mu}\int \frac{\rho_{\mu j}(\boldsymbol{r})}{|\boldsymbol{r}-\boldsymbol{r}_i|}\,\mathrm{d}\boldsymbol{r}$$
$$= \frac{N_j - N_{j\pi}}{R_{ij}} + N_{j\pi}\langle r_{\pi ij}^{-1}\rangle$$

Let us now consider $\langle r_{\pi ij}^{-1}\rangle$. A π atomic orbital is essentially a pure p orbital; if there is any polarization (as will be discussed below), this will involve a very small displacement, $\Delta \boldsymbol{r}_{\pi j}$, of the centroid of the orbital. Then a monopole approximation of the π term of eq. [12] suffices, giving

$$[13]\quad \langle r_{ij}^{-1}\rangle = \frac{1 - N_{j\pi}/N_j}{R_{ij}} + \frac{N_{j\pi}/N_j}{|\boldsymbol{r}_j + \Delta\boldsymbol{r}_{\pi j} - \boldsymbol{r}_i|}$$

If this simple expression is sufficient to account for the discrepancies observed in calculations of olefins based on alkane reference bonds, we can claim that the "principle" [11] is, indeed, satisfied by ethylenic hydrocarbons.

Turning now to direct theoretical evaluations, we consider $|\Delta \boldsymbol{r}_{\pi j}|$ as the displacement (on the C═C axis) of the centroid of the π orbital with respect to the center j. Of course, such a displacement can differ from zero only if some hybridization is allowed which, in the case of a π orbital, must consist in admixture of the suitable $d\pi$ orbital. We have determined the hybrid in question from 4-31G calculations with d polarization functions for carbon and optimization of all scale factors, followed by a calculation of *in situ* valence orbitals, and of their characteristics, according to refs. 13, 17[4] (Appendix I).

TABLE 1. A calculation of atomization energies, eq. [4], using ethane C—H and C—C reference bonds with and without SCF π-AO centroids

	ΔE_a^*, kcal mol^{-1}		
Molecule	$F = 0$	Eqs. [4], [5], [13]	Exptl.[a]
Ethylene	571.80	564.12	562.10
Propene	870.62	861.02	858.56
Tetramethylethylene	1765.94	1749.58	1746.64

[a] Extracted from ref. 6.

In ethylene, the centroid of the π orbital is found to lie 0.0292 Å from the carbon atom, on the C═C axis. In propene, the centroid inward shifts, $\Delta r_{\pi j}$, are 0.0281 Å from C-1 and 0.0299 Å from C-2. The shift is 0.0280 Å in tetramethylethylene. Using the ethylene reference populations $N_{j\pi} = 1$ and $N_j = 3.9923$ e (6), we calculate the appropriate $\langle r_{ij}^{-1}\rangle$'s from eq. [13] and the experimental geometries indicated in ref. 18, as explained in Appendix II. Finally, F is deduced from eq. [5] and used in the calculation of ΔE_a^* by means of eq. [4]. The results are given in Table 1.

The following should be considered in an assessment of the approach having led to these results. In the first place, π orbital centroids deduced from SCF calculations clearly support the validity of the first-order approximation, eq. [13]: $\langle r_{ij}^{-1}\rangle$ values estimated in this manner lead to acceptable energies. In the present approach, improvements in the SCF wave functions consistently improve the agreement with experimental energies,[5] thus suggesting that, in fact, the quality of eq. [13] may even be better than what could be inferred at first sight from Table 1. It is also important to point out that the approximation involved in the definition [5] of F itself is excellent.[6] Therefore, the quality of the energies calculated from eq. [4] rests now primarily with the proper evaluation of $\langle r_{ij}^{-1}\rangle$. Tentatively, assuming that $\langle r_{ij}^{-1}\rangle$ is, indeed, adequately described by eq. [13], a 0.036 Å inward shift of the π orbital centroid can be shown to yield energies which are at the level of experimental accuracy. The true merits of this fine-tuning, which appears to be a realistic one when compared to its SCF counterpart, ~0.03

[4] An analysis of the σ orbitals will be presented separately. Here, we only point out that the σ hybrid AO's of carbon in ethylene, as obtained with the input data of Table 2 and Boys' localization criterion, appear to satisfy eq. [11] with entirely reasonable populations: the position vectors of their centroids give a zero population-weighted average if the CH hybrids are assigned ~0.96 e, and the CC hybrid 1.07 e.

[5] The use of standard exponents in the calculation of ethylene, for example, leads to $\Delta r_{\pi j} = 0.026$ Å, $\langle r_{ij}^{-1}\rangle = 0.49007$ au, $F = -6.82$, and $\Delta E_a^* = 564.98$ kcal mol^{-1}, which represents a worsening of the final result by 0.86 kcal mol^{-1} with respect to a fully optimized calculation.

[6] This approximation rests with the factor (3/7) which is used instead of its exact counterpart (5, 8). The latter, deduced from Hartree–Fock calculations, differs from 3/7 by no more than 0.5% for the molecules under scrutiny (1).

Å, are best illustrated by the following numerical examples, both as regards its practical aspects in applications of this theory to actual chemical problems and its conceptual simplicity disclosing a new insight into the nature of the chemical bond.

Energy calculations at the level of experimental accuracy

No test of a theory could be more severe than a direct comparison with experimental results. All the parameters required in energy calculations of saturated hydrocarbons were deduced from theory (1, 2). The only minor adjustment has concerned the ethane carbon net charge, selected as reference, in that the value 35.1 me was preferred over that derived from optimized 4-31G calculations with configuration interaction, 37.8 me — an adjustment which is easily justifiable on theoretical grounds (19). In view of the quality of the results thus obtained, we have no hesitation in treating the alkyl parts of ethylenic hydrocarbons in precisely the same manner, using the parameters and the charges described earlier (1, 2, 6). Namely, we use

$$[14] \qquad \epsilon_{ij} = \epsilon_{ij}^{0} + a_{ij}\Delta q_i + a_{ji}\Delta q_j$$

with ϵ_{CH}^{0} = 106.806 kcal mol^{-1}, $a_{HC} = -1.007$, and $a_{CH} = -0.394$ au for ethane-like CH bonds, and ϵ_{CC}^{0} = 69.633 kcal mol^{-1}, $a_{CC} = -0.777$ au for sp^3–sp^3 CC bonds.

The problem encountered here lies in the evaluation of CH and CC bonds formed by an ethylenic sp^2 carbon, because the corresponding a_{ij} values, $a_{CH} = -0.335$ and $a_{CC} = -0.718$ au, respectively, differ from those involving a sp^3 carbon atom. Tentatively taking the averages of the appropriate a_{ij}'s, we obtain for the CH and C(sp^2)—C(sp^3) bonds formed by an ethylenic carbon with net charge 7.7 me (1 au = 627.51 kcal mol^{-1}),

$$[15a] \qquad \epsilon_{CH} = 106.806 + \frac{1}{2}(-0.394 - 0.335) \times (-27.4 \times 10^{-3}) \times 627.51 = 113.07 \text{ kcal mol}^{-1}$$

$$[15b] \qquad \epsilon_{CC} = 69.633 + \frac{1}{2}(-0.777 - 0.718) \times (-27.4 \times 10^{-3}) \times 627.51 = 82.49 \text{ kcal mol}^{-1}$$

The increase in electron population, 27.4 me, accompanying the replacement of the ethane carbon by that of ethylene has thus been taken care of. In spite of minor uncertainties, eqs. [15*a*], [*b*] appear to be reasonably accurate. (Indeed, their use yields excellent results in the calculation of benzenoid CH bonds and of CC single bonds like that found in toluene, for a collection of 36 benzenoid hydrocarbons (20).) While the energy change associated with π-bond formation is included in $\epsilon_{C=C}^{0}$ = 139.27 kcal mol^{-1}, the effects related to the centroid shift of the atomic π orbitals still need to be evaluated.

In principle, one can resort to calculations of F — a task which is not free from difficulties, particularly at a level approaching that of experimental accuracy. It is simpler to proceed as follows, by taking advantage of the results indicated in Table 1. The theoretical contributions to F (Appendix II) are −1.92 for each ethylene CH and −4.09 kcal mol^{-1} for each tetramethylethylene CC single bond; the corresponding contributions of the bonds formed by the propene C-2 atom are −1.76 and −4.31 kcal mol^{-1}. The combined contributions are virtually the same in both cases. Similarly, three ethylene CH plus one tetramethylethylene CC single bond total −9.85 kcal mol^{-1} — an approximation which is reasonably close to the theoretical value, F = −9.60 kcal mol^{-1}, deduced for propene. The regularities are striking, despite the marked differences both in geometrical parameters and in the SCF Δr values between the molecules involved in this comparison. Capitalizing now on these regularities, we propose the following simple approximation which is consistent with the essential theoretical features disclosed in this study. Assuming an inward shift of 0.036 Å for a π orbital and R_{ij}'s of 1.08 and 1.53 Å for the CH and CC single bonds, respectively, at an angle of ~123° with the double bond, eq. [13] yields $\langle r_{HC}^{-1}\rangle = 0.48758$ and $\langle r_{CC}^{-1}\rangle = 0.34463$ au. The F values deduced from eq. [5] are thus −2.39 for *one* CH bond and −4.80 kcal mol^{-1} for *one* C(sp^2)—C(sp^3) bond. Finally, including these results into the ϵ_{ij}'s calculated above, eqs. [15*a*], [*b*], one obtains

$$[16a] \qquad \epsilon_{CH}^{0} = 110.68 \text{ kcal mol}^{-1}$$

$$[16b] \qquad \epsilon_{CC}^{0} = 77.69 \text{ kcal mol}^{-1}$$

for the new reference bonds involving an ethylenic C(sp^2) atom, with net charge 7.7 me. The hydrogen and C(sp^3) net charges are still those of ethane, −11.7 and 35.1 me, respectively. As regards the values (16*a*], [*b*], it is clear that their derivation is well within the limits of uncertainty set by our SCF analysis of charge centroids and by eq. [13].

The new ϵ_{ij}^{0}'s described in eqs. [16*a*], [*b*] were tailored to include the characteristic features of the sp^2 carbon of ethylene, as regards both the magnitude and the location of its charge. The use of these reference bond energies in the construction of the $\Sigma\epsilon_{ij}^{0}$ part of eq. [4] considerably simplifies the calculation of atomization energies because, under these circumstances, F should again be expected to vanish.[7] Indeed, for a collection of ~50 olefins calculated in this approach (6, 21), the average deviation between theoretical and experimental atomization energies is ~0.25 kcal mol^{-1}. Briefly, we are back at the point which has initiated our argument, eq. [8]: the use of the appropriate set of reference bond energies, incorporating the particular characteristics regarding charge centroids, suffices in the calculation of ΔE_a^* energies, at least within the present limits of experimental accuracy. This holds true also for benzenoid hydrocarbons (20), ethers, aldehydes, and ketones (3). The validity of eq. [8] is gratifying because it measures, in a way, the degree of transferability of basic bond properties — a transferability which appears to be pronounced, indeed.

Conclusion

The discussion and results reported above are to some extent a further step toward solving a persistent problem of theoretical chemistry: bridging the gap between the apparent simplicity of observed molecular behavior and the intricacies and ambiguities which plague the translation of accurate quantum mechanical results into simple chemical concepts and rules. The extraordinary accuracy with which eq. [4] allows prediction of atomization energies is a strong indication that hidden regularities can be discovered as a result of patient processing of general theory, but the price to be paid is that the use of final equations such as [4] often rests on simplifying assumptions

[7] The following may serve as an example. Using the ethylene-H net charge, −3.85 me (corresponding to its C charge of 7.7 me), i.e., Δq_H = 7.85 me, it results that $a_{HC}\Delta q_H = -4.96$ and, from [16*a*], ϵ_{CH} = 105.72 kcal mol^{-1}. Four of these CH bonds, plus the theoretical $\epsilon_{C=C}^{0}$ = 139.27 double bond contribution, lead to $\Delta E_a^*(C_2H_4)$ = 562.15 kcal mol^{-1}, in good agreement with its experimental counterpart, 562.22 kcal mol^{-1}.

which cannot be proven *a priori* to be of minor import. In the case at hand, those approximations are (*i*) the proportionality between the nuclear–electronic potential energy and the total (BO) energy and (*ii*) the point-charge model of a saturated hydrocarbon molecule. The agreement within experimental accuracy of over 170 predicted and experimental atomization energy values provides an *a posteriori* argument for claiming that those approximations are in fact very good ones. But then, as has been shown above, they must be interpreted as general rules which the partitionings of electron densities obtained from accurate electronic wavefunctions must obey. This is especially important in problems like the extension of eq. [4] to cover olefins as well as paraffins; for that extension, as has been seen, requires explicit introduction of the $\sigma-\pi$ separation. As a consequence, the point-charge approximation must be reformulated as a "principle" valid for the averages of electrostatic potentials of the σ orbitals of any given atom in a hydrocarbon molecule. This has two distinct practical advantages: it suggests a very simple numerical correction which allows application to ethylenic hydrocarbons of the same scheme as used for paraffins and assigns that correction an extremely simple physical interpretation (that of π centroid displacement) susceptible of numerical evaluation from accurate *ab initio* computations. On the other hand, it involves three important conceptual features: (*i*) the notion of *in situ* atomic orbitals, which must now be introduced explicitly, (*ii*) the postulate that there is a Mulliken-type partitioning of the molecular electron density into atomic orbital contributions which obeys the "principle of orbital balancing", and (*iii*) the implication that a CH bond or a CC bond in an olefin have the same basic properties as in a paraffin, except for the effective net charges of the atoms involved.

The internally coherent picture thus obtained, together with the excellent agreement with experiment also holding for olefins, provide a strong indication that the analysis of accurate *ab initio* computations into models, rules, and properties meaningful to chemists should be carried out precisely along the lines emerging from the above remarks. This conclusion, in addition to the concrete formulation of a principle valid within an atomic orbital picture, and to the explanation of the apparent deviation of the atomization energies of ethylenic hydrocarbons from the scheme valid for paraffins, seems to us a very important outcome of the application of eq. [4]: it points the way to a revised version of the elementary LCAO picture (whose merits are undeniable) where highly sophisticated computations provide the numerical support of an otherwise simple interpretational scheme.

Appendix I

Table 2 indicates relevant details concerning the basis and SCF results.

As concerns the calculation of *in situ* VAO's, we illustrate the procedure for the π bond, the one we are mainly interested here, and which is especially simple. Using the standard GO-SCF notation (cf. Table 2), the contribution of one carbon atom to the occupied π MO of ethylene has the form

$$[\mathrm{A1}] \quad c_\pi|\overline{p\pi}\rangle = 0.35975\,|2p_y\rangle + 0.32403\,|3p_y\rangle - 0.02715\,|4d_{yz}\rangle$$

where $|\overline{p\pi}\rangle$ and c_π denote that single normalized π atomic orbital and that coefficient which satisfy the equality [A1]. As is well kown, the p components of the right-hand term of eq. [A1] are not mutually orthogonal: their overlap is $S_{pp'}$ = 0.54632. Using this value, it is easy to see that

$$c_\pi = (0.35972^2 + 0.32403^2 + 0.02715^2 + 2 \times 0.35972 \times 0.32403 \times 0.54632)^{1/2} = 0.60209$$

and, consequently, that

$$[\mathrm{A2}] \quad |\overline{p\pi}\rangle = 0.59750\,|2p_y\rangle + 0.53817\,|3p_y\rangle - 0.04510\,|4d_{yz}\rangle$$

is the π hybrid orbital whose centroid we want to find. For the position vector of the centroid with respect to the center of the Gaussian functions entering [A2] we have

$$[\mathrm{A3}] \quad \Delta\boldsymbol{r} = \langle\overline{p\pi}|x|\overline{p\pi}\rangle\,\boldsymbol{i} + \langle\overline{p\pi}|y|\overline{p\pi}\rangle\,\boldsymbol{j} + \langle\overline{p\pi}|z|\overline{p\pi}\rangle\,\boldsymbol{k}$$

with $\boldsymbol{i}, \boldsymbol{j}, \boldsymbol{k}$ the standard unit vectors of the coordinate system. By symmetry, only the last term of the right-hand side of eq. [A3] is nonzero, and straightforward calculation of the appropriate linear combination of integrals over the gaussian functions entering [A2] gives the required result.

[a] The conversion factors 1 bohr = 0.529 Å and 1 hartree = 627.51 kcal mol^{-1} were used.

Appendix II

The calculation of F is presented here in a bond-by-bond approach, giving the individual contributions, F^{bond}; F is simply their sum over the 4 bonds formed by the two ethylenic carbons. Equation [5] is used with $(R_{ij}^{-1})^0 = \langle r_{ij}^{-1} \rangle^0$, taking ethane as reference, i.e., $(R_{\mathrm{CH}}^{-1})^0 = 0.48266$ au (corresponding to $R_{\mathrm{CH}} = 1.096$ Å) and $(R_{\mathrm{CC}}^{-1})^0 = 0.34553$ au (corresponding to $R_{\mathrm{CC}} = 1.531$ Å). The quantity $|\boldsymbol{r}_j + \Delta \boldsymbol{r}_{\pi j} - \boldsymbol{r}_i|$ of eq. [13] is

$$|\boldsymbol{r}_j + \Delta \boldsymbol{r}_{\pi j} - \boldsymbol{r}_i| = [R^2 + (\Delta r)^2 - 2R\,\Delta r \cos \alpha])^{1/2}$$

where R is the length of the C(sp^2)—i bond and α the angle it forms with C=C. The theoretical shift of the π-AO centroid (lying on C=C) is $\Delta \boldsymbol{r}$. Experimental geometries are from ref. 18, including that of ethane. The input parameters for use in, and the results deduced from, eq. [13] are indicated in Table 3, as well as the F^{bond} results derived from eq. [5].

The crystal field strength of the nitro ligand and the chemistry of the hexanitrocobaltate(III) anion

RICHARD J. BUIST, STEVE C. F. AU-YEUNG, AND DONALD R. EATON[1]
Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received April 29, 1985

RICHARD J. BUIST, STEVE C. F. AU-YEUNG, and DONALD R. EATON. Can. J. Chem. **63**, 3558 (1985).

The chemical and spectroscopic properties of the hexanitrocobaltate(III) anion are not in accord with the classification of the N-bonded nitrite ion as a strong field ligand. The nitro groups are rapidly displaced by other ligands, including water, and in dilute aqueous solution spontaneous reduction to Co(II) occurs. Comparison of solid state and solution vibrational and ^{59}Co nmr spectra demonstrates that the principal species in solution is the same as in the solid. All ligands are N-bonded. However, within 2 or 3 min of dissolution new species appear. An electron transfer mechanism for ligand exchange is suggested. It is shown that the band at 480 nm arises from the first $d-d$ transition of the pentanitroaquacobaltate(III) ion and not from a hexanitrocobaltate(III) transition. The composition of the aged solutions has been studied by ^{59}Co, ^{14}N, and ^{17}O nmr. At least 10 different species are apparent in the ^{59}Co spectra. They have been assigned to mixed nitro/nitrito/aqua ions. Electron transfer can also lead to the formation of Co^{2+} and NO_3^- ions, both ions being detected by ^{14}N and ^{17}O nmr spectroscopy. The Co complexed nitro ligand has been detected for the first time in the ^{14}N nmr spectrum. Analysis of ^{59}Co chemical shifts shows that the crystal field strength of the nitro ligand falls steadily with the number of nitro groups in the molecule. The *cis* groups are four times more effective than the *trans* groups in causing this change. The cyano ligand shows the opposite behaviour — the crystal field strength increases with substitution and *trans* groups have a larger effect than *cis* groups. The reactions of the hexanitrocobaltate(III) ion with ethylenediamine and with cyanide ions have been studied by ^{59}Co nmr. Mixed nitro complexes are formed with ethylenediamine but mixed nitrito complexes predominate with cyanide.

RICHARD J. BUIST, STEVE C. F. AU-YEUNG et DONALD R. EATON. Can. J. Chem. **63**, 3558 (1985).

Les propriétés chimiques et spectroscopiques de l'anion hexanitrocobaltate(III) ne correspondent pas à la classification de l'ion nitrite lié par l'azote comme une ligand de champ fort. Les groupements nitro sont rapidement remplacés par d'autres ligands, y compris l'eau, et, en solutions aqueuses diluées, il se produit une réduction spontanée en Co(II). Une comparaison des spectres vibrationnels ainsi que rnm du ^{59}Co, tant à l'état solide qu'en solution, démontre que les principales espèces en solution sont les mêmes qu'à l'état solide. Tous les ligands sont liés par l'azote. Toutefois, il apparaît de nouvelles espèces en moins de trois minutes après leur dissolution. On suggère que l'échange de ligand se produit par un mécanisme impliquant un transfert d'électron. On démontre que la bande à 480 nm provient de la première transition $d-d$ de l'ion pentanitroaquacobaltate(III) et non pas d'une transition de l'hexanitrocobaltate(III). Faisant appel à la rmn du ^{59}Co, du ^{14}N et du ^{17}O, on a étudié la composition de solutions qui avaient vieilli. On peut déceler la présence d'au moins dix espèces différentes à l'aide de la rmn du ^{59}Co. On les a attribuées à des ions mixtes nitro/nitrito/aqua. Les transferts d'électrons peuvent aussi conduire à la formation des ions Co^{2+} et NO_3^- et ces deux ions ont pu être détectés par rmn du ^{14}N et du ^{17}O. Grâce à la rmn du ^{14}N, on a pu détecter pour la première fois la présence d'un ligand nitro complexé à un Co. L'analyse des déplacements chimiques du ^{59}Co démontre que la force du champ cristallin du ligand nitro diminue régulièrement avec le nombre de groupements nitro dans la molécule. Les groupements *cis* sont quatre fois plus efficace que les groupements *trans* pour provoquer ce changement. Avec les groupements cyano, on observe un comportement inverse — la force du champ cristallin augmente avec la substitution et les groupements *trans* ont un effet qui est plus grand que les groupements *cis*. Faisant appel à la rmn du ^{59}Co, on a étudié les réactions de l'ion hexanitrocobaltate(III) avec l'éthylènediamine et les ions cyanures. Il se forme des complexes nitro avec l'éthylènediamine; toutefois, avec les ions cyanures, il se forme des complexes nitrito.

[Traduit par le journal]

Introduction

Ligand field theory provides a convenient framework for the discussion of the chemistry of most transition metal complexes in which the metal is in one of its "normal" oxidation states. The spectrochemical series serves to systematize much of this chemistry. In writing down such a series the underlying assumption is that the bonding characteristics, and hence the relative crystal field splitting ability, of a given ligand will remain constant with changes of the metal ion and of the other ligands. The present paper will discuss a series of complexes for which the crystal field splitting of one ligand depends on the other ligands present.

A large number of transition metal complexes containing the nitro group have been reported. The area has been reviewed recently by Hitchman and Rowbottom (1). There are several possible modes of coordination for this ligand of which the most common are unidentate bonding by an oxygen to give a nitrito complex and unidentate binding through the nitrogen to give a nitro complex. The N-bonded nitro group is usually described as a strong field ligand. Thus Lever (2) places it between ethylenediamine and cyanide in the spectrochemical series with a ligand field strength approximately equal to that of bipyridyl or *o*-phenanthroline. Basolo and Pearson (3) attribute the high ligand field strength of the N-bonded nitro group to π donation from the metal ion. Most of the data used to reach these conclusions have been obtained from spectroscopic studies of Co(III) complexes since the Cr(III) compounds, for example, are usually O-bonded. Thus Wentworth and Piper (4) obtained D_q values in the range 3100−3200 cm^{-1} from the spectra of mono- and di-nitroCo(III) amines. This value may be compared with those of 3600 cm^{-1} for cyanide and 2530 cm^{-1} for ethylenediamine in Co(III) complexes.

The spectroscopy of Co(III) complexes containing more than two nitro groups is less well understood and the cobaltinitrite

[1]Author to whom correspondence should be addressed.

ion, $Co(NO_2)_6^{3-}$, in particular has been the subject of some disagreement. Most early papers assign a weak band around 480 nm to the $^1A_{1g} \rightarrow {}^1T_{1g}$ ligand field transition and this value has been used in all the reported correlations with ^{59}Co chemical shifts. Caulton and Fenske (5) pointed out that this value is inconsistent with the high D_q values quoted above and suggested that the band was a spin-forbidden ligand-to-metal charge transfer transition. Garnier (6) disagreed with this assignment, was able to move the band maximum to higher energy by some 4500 cm^{-1} by Gaussian analysis of the overlapping bands, and concluded that the $d-d$ transitions of all Co(III) nitro/ammine complexes were consistent with the rule of average environment. Barnes, Duncan, and Peacock (7) in a solid state study do not specifically refer to this band and suggest a rather different energy level scheme to that of Caulton and Fenske.

There have been numerous reports of the ^{59}Co nmr spectrum of the $Co(NO_2)_6^{3-}$ ion (8−14). Proctor and Yu (8) reported two lines and suggested that the less intense line probably arose from an isomeric molecule. Interestingly this is the first literature report of two separate nmr resonances from a single sample. Gasser and Richards (9) studied the temperature and nitrite ion concentration dependence of the relative intensities of the two lines and concluded that the high frequency line represented a mixture of an aquated hydrolysis product and a nitrito isomer. Several of these papers correlated the chemical shift of the more intense line with the 480 nm absorption band and reported satisfactory agreement with theory. More recently Rose and Bryant (14) found only a single ^{59}Co line which decreased in intensity with time. They also examined the ^{14}N spectrum showing that nitrate ion was present and inferred the existence of Co^{2+} from line broadening. The ^{59}Co nmr spectra of the series of complexes $Co(NH_3)_n(NO_2)_{6-n}$ have been reported by Juranic *et al.* (15) and by Pujar (16, 17). There is reasonable agreement between the two sets of experimental data. On increasing NO_2^- substitution the chemical shifts move to higher field, reach a maximum and then return to lower field. Juranic points out that this behaviour indicates a deviation from the rule of "average environment" for transition metal complexes. These authors also showed that the first absorption bands for the nitro/ammine complexes showed a parallel trend. Ethylenediamine/nitro complexes show similar behaviour. An earlier paper from this laboratory (18) proposed a simple point charge model for estimating ^{59}Co chemical shifts which gave satisfactory results for some 70 complexes involving a wide variety of ligands. If the nitro parameter obtained from the penta-ammine nitro complex is used to calculate the shift of the hexanitro complex a value of 5139 ppm is obtained compared with the experimental value of 7470 ppm. Clearly this simple model is unsatisfactory.

There are also anomalies in the aqueous chemistry of the cobaltinitrite ion. Crystal field theory predicts that strong field ligand will stabilize the d^6 Co(III) configuration relative to d^7 Co(II). Thus cobaltocyanide is a strong reducing agent and cobalticyanide shows no oxidizing properties. Cobalt amine complexes show similar, though less pronounced, oxidation/reduction properties. The spontaneous decomposition of cobaltinitrite solution to give Co^{2+} observed by Rose and Bryant (14) and by other authors is therefore unexpected. Slow ligand exchange is also the rule for strong field octahedral Co(III) complexes. Thus $Co(NH_3)_6^{3+}$ shows no ligand exchange in aqueous ammonia in 162 days (19) and $Co(CN)_6^{3+}$ is similarly inert. In contrast Matsko *et al.* (20) found half-lives of less than 10 min for the isotopic exchange between nitrite ions and cobaltinitrite. The replacement of nitro groups by amino acids has a very similar half-life (21).

The present paper is concerned with the origin of these spectroscopic and chemical anomalies. We have considered two main possibilities: (*a*) The major species in aqueous solution may not be the octahedral nitro complex. Interaction with the solvent may have led to isomerization, aquation, or some other chemical reaction which results in a product having properties different from those expected for the hexanitrocobaltate(III) anion. (*b*) The bonding properties and crystal field splitting of the nitro group may differ significantly in the Co hexanitro complex from the corresponding properties in complexes with only one or two nitro groups.

Possibility (*a*) will be discussed first.

Solid and solution spectra

The structure of the cobaltinitrite ion in the solid has been determined by X-ray crystallography (22). It is a regular octahedron with T_h symmetry with all of the nitro groups N bonded. If the structure in solution was different, the difference should be made apparent by a comparison of solid and solution spectra. Vibrational and ^{59}Co nmr spectra have been used for this purpose.

The infrared and Raman spectra of solid sodium cobaltinitrite have been measured. Both agree well with the spectra reported in the literature (23, 24). The Raman spectrum of aqueous sodium cobaltinitrite has also been measured and is in agreement with literature reports (23, 25). All the major peaks are shifted by no more than a few wavenumbers from the solid state frequencies.

The ^{59}Co nmr has been measured in the solid state. A single resonance is observed which shows some field dependent structure due to second order quadrupolar effects. The chemical shift is 7601 ± 3 ppm compared with 7470 ppm for the most intense resonance in aqueous solution. An analysis of the field dependent structure, which will be reported elsewhere, gives only a small quadrupole coupling constant as anticipated for a basically octahedral species. It would be desirable to obtain the spectrum in non-aqueous solution but low solubility limits the choice of solvents. In a 2.5:1 (w/w) mixture of acetonitrile and water the observed chemical shift is 7589 ppm and in a 1:1.5 (w/w) mixture of DMSO and water the shift is 7584 ppm. In each case and in a 1:1 (w/w) mixture of methanol and water the shift is 7546 ppm. In each case the shift in the non-aqueous solvent mixture is closer to the solid state value. These differences are compatible with hydrogen bonding effects. Shifts of 100−300 ppm to high field have been reported in hydrogen bonding solvents for cobalticyanide anions (26). Interaction with the hydrogen removes negative charge, encourages π back bonding and leads to a "stronger" field ligand. Thus the chemical shifts indicate the most hydrogen bonding in aqueous solution and the least in the solid state. The chemical shift in the solid is even less consistent with a strong field ligand than that in solution.

Solutions of cobaltinitrite are unstable below pH 4 decomposing with the evolution of N_2O_4. They are also unstable in basic solutions since cobalt hydroxides are precipitated. There is no significant variation of the ^{59}Co chemical shift over the accessible pH range.

We conclude that the major species in aqueous solutions of sodium cobalticyanide is the $Co(NO_2)_6^{3-}$ ion, that the resonance at 7470 ppm is correctly assigned to this species and that the

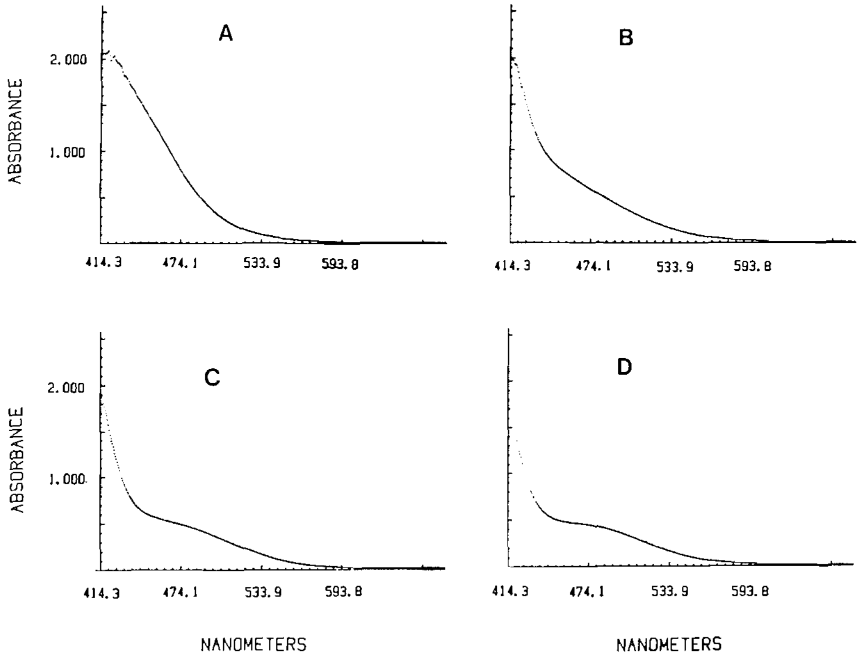

FIG. 1. Electronic spectra of 2.7 mM aqueous cobaltinitrite (l = 1 cm) for varying lengths of time after dissolution (A) t = 2 min, (B) t = 4 min, (C) t = 6 min, (D) t = 9 min.

perturbations due to hydrogen bonding or protonation produce only a modest high field shift.

The electronic spectrum of cobaltinitrite solutions

The above assignment of the ^{59}Co chemical shift raises the question of the correct assignment of the 480 nm band in the electronic spectrum. This band does not appear clearly in the solid state spectrum (7). The usual correlation between chemical shifts and the energy of the $d-d$ transition leads to a prediction of 460 nm for the $d-d$ transition which is slightly high but not decisively so. Figure 1 shows spectra of a 2.7 mM solution of sodium cobaltinitirite taken 2, 4, 6, and 9 min after dissolution. The intensity of the 480 nm band is clearly increasing with time and is zero at time zero. There is a parallel decrease in the intensity of the strong band at 355 nm. The half life for this process is of the order of 2 or 3 min. The 480 nm band does not therefore arise from $Co(NO_2)_6^{3-}$ but from a decomposition product. The nature of this decomposition product will be considered below.

$Co(NO_2)_6^{3-}$ has a centre of symmetry and the intensity of the $d-d$ transition would be expected to be about an order of magnitude less than that for a molecule without a centre of symmetry. Examination of Fig. 1A shows that the absorbance at 460 nm from the wing of the charge transfer band is greater than 1.0 for a 2.7 mM solution. The $d-d$ transition will therefore not be directly observable.

^{59}Co nmr spectra

In agreement with previous reports we find that the most intense line in the spectrum of a freshly prepared solution of sodium cobaltinitrite has a chemical shift of 7470 ppm. This line has a half width of 55 Hz, corresponding to a T_2 of 5.6 ms. The T_1, measured by inversion recovery, is 37.5 ms. The difference between T_1 and T_2 arises from scalar relaxation of the second kind as suggested by Rose and Bryant (14). If scalar coupling to six equivalent nitrogens contributes to the relaxation rate theory (27) predicts:

$$\frac{1}{T_2} - \frac{1}{T_1} = 16\pi^2 J^2 T_{1N}$$

The T_1 of the ^{14}N has been measured directly using a high power instrument. A value of 150 μs was obtained. The above formula gives a value of 80 Hz for the Co—N spin−spin coupling constant. This is compatible with literature values (28) for coupling between ^{15}N and ^{59}Co. The linewidth of the cobaltinitrite resonance therefore arises largely from scalar relaxation and can have only a small quadrupolar contribution. This provides further evidence for a symmetric N-bonded structure in solution.

On standing a variety of other lines appear in the ^{59}Co spectrum as illustrated in Fig. 2 and listed in Table 1. The most intense of thes new lines is at 8052 ppm. Figure 3 shows plots of the decrease in intensity of the 7470 line and the increase in the intensity of the 8052 line. Both curves are exponential in character with the half-life for the decay of the 7470 line measured as 150 s and that for the increase of the 8052 line as 180 s. These half-lives are very similar to the rate of appearance of the 480 nm band shown in Fig. 1. The relative intensity of the 8052 line compared to the 7470 line increases with dilution and decreases with the addition of sodium nitrite. Table 1 contains data illustrating these observations which are consistent with an equilibrium involving dissociation of the cobaltinitrite ion. These data indicate a dissociation constant of around 0.1 M. On further standing the intensity of the 8052 line decreases and the other lines in Fig. 2 gain intensity. A ^{59}Co chemical shift of 8052 ppm correlates very well with a $d-d$ transition at 480 nm. Thus, for example, $Co(NH_3)_6^{3+}$ has a chemical shift of 8175 ppm and a $d-d$ band at 476 nm. We assign the 8052 line to $Co(NO_2)_5H_2O^{2-}$ formed by dissociation of the cobaltinitrite ion. The assignment of the other lines in Table 1 will be discussed below.

^{14}N nmr of cobaltinitrite solutions

A set of ^{14}N spectra of cobaltinitrite solutions of various concentrations and after varying aging periods is shown in

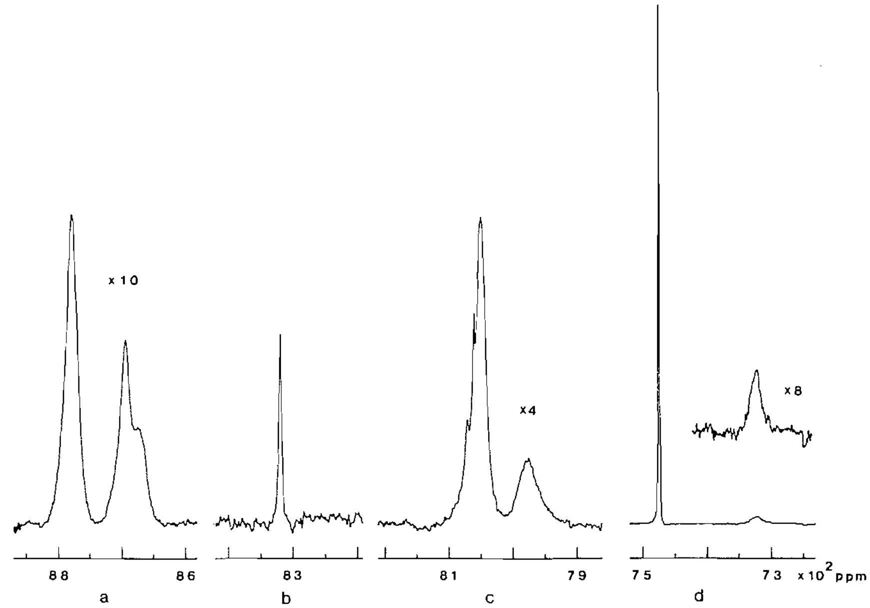

FIG. 2. ^{59}Co nmr spectra of $Na_3Co(NO_2)_6$ aqueous solutions. The assignments of the lines are given in Table 1. The initial spectrum shows the line at 7470 ppm. The other lines appear on aging. The line at 8815 ppm is only observed in concentrated solution (0.9 *M*).

Fig. 4. Three lines are apparent. The sharp line at zero ppm is the nitrate resonance. The line at 235 ppm, half-width 170 Hz, is assigned to free nitrite by comparison with the spectrum of sodium nitrite. The broad line, chemical shift 95 ppm line width 2200 Hz, is complexed nitrite. Rose and Bryant (14) in their report of the ^{14}N spectrum did not detect the very broad complexed resonance and assigned the complex to the free nitrite peak. Earlier authors (29) had assigned the sharp nitrate resonance to complexed nitrite. The chemical shift for complexed nitrite may be compared with the value of 44–46 ppm reported for a nitro rhodium complex (30) and with 4 ppm for nitromethane.

These spectra show several features of interest. The ratio of free nitrite to complexed nitrite increases with dilution as expected for a dissociative equilibrium. At high concentration this ratio does not change considerably with aging up to 28 days. The nitrate peak appears only with aging and most noticeably with dilute solutions. Its appearance is accompanied by a downfield shift and broadening of the free nitrite resonance. There is no similar shift or broadening of the complexed nitrite peak. Oxidation of nitrite to nitrate is plausibly accompanied by the reduction of Co(III) to Co(II) (14) and the inter-

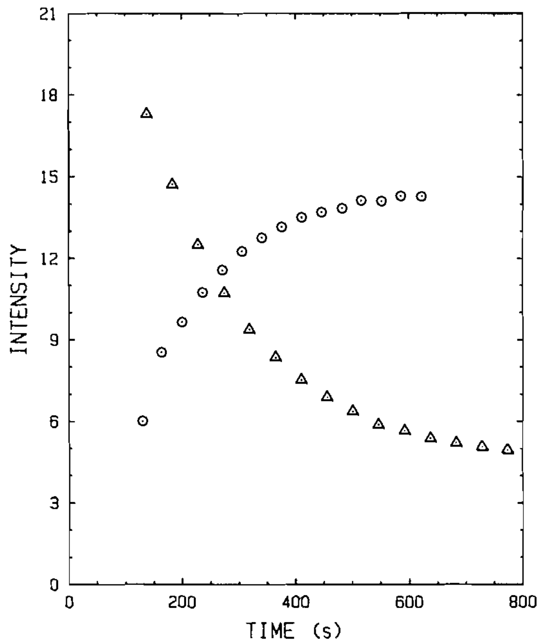

FIG. 3. ^{59}Co nmr spectra as a function of time after dissolution. $[Na_3Co(NO_2)_6]$ = 0.10 *M*. Circles represent intensity of δ 7470 peak (measured at 5.9 T); triangles that of δ 8052 peak (measured at 9.4 T).

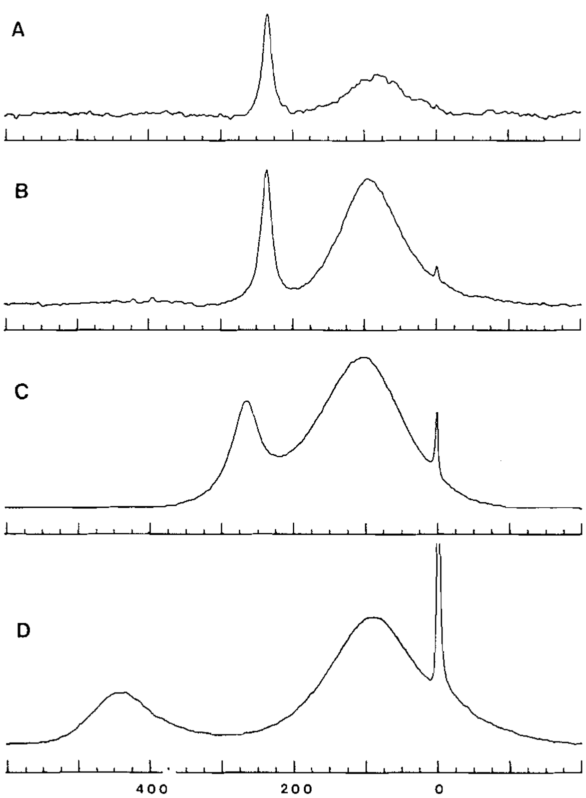

FIG. 4. ^{14}C nmr spectra obtained at 4.7 T (*A*) 0.1 *M* cobaltinitrite, aged 5 min, (*B*) 0.5 *M* cobaltinitrite, aged 5 min, (*C*) 1.1 *M* cobaltinitrite, aged 4 h, (*D*) same solution as (*C*), aged 28 days.

action of the nitrite ions with the paramagnetic Co ions causes the observed effect. This was confirmed by an experiment in which Co^{2+} ions were added to a solution of sodium nitrite. Addition of sodium nitrite to the cobaltinitrite solution enhances the intensity of the free nitrite peak as expected but also suppresses the formation of nitrate indicating that the aqua species is a necessary intermediate in the oxidation/reduction reaction.

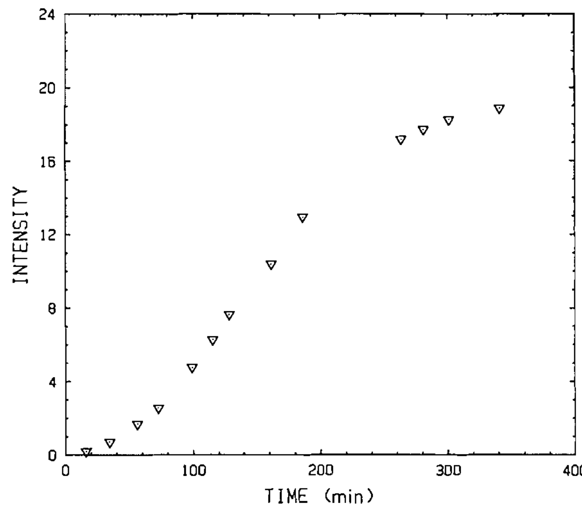

FIG. 5. ^{17}O nmr (9.7 T) intensity as a function of time after dissolution $[Na_3Co(NO_2)_6]$ = 0.9 *M*.

The ^{17}O spectrum of cobaltinitrite solutions

Spectra have been obtained from solutions containing ^{17}O in natural abundance and from solutions in water enriched to 18% in ^{17}O. In the natural abundance experiments the most intense line arises from water. This line shifts downfield and broadens with aging of the solution. The rate at which this occurs is comparable to the rate of the shift and broadening of the ^{14}N resonance of free nitrite and can be ascribed to a similar cause, complexing of the water to Co^{2+} from the reduction of the cobaltinitrite. In 0.9 *M* cobaltinitrite solutions additional lines, each with about 10% of the water line intensity, are observed at 168 ppm (linewidth 175 ± 10 Hz) and at 691 ppm (linewidth 1100 Hz). Sodium nitrite gives a line at 660 ppm (linewidth 135 ± 10 Hz). The 168 ppm signal shifts and broadens with time in a manner similar to the water signal and must therefore be a ligand capable of complexing to Co^{2+}. Its assignment is uncertain. The broad 691 ppm signal is reasonably assigned to complexed nitrite.

The sample dissolved in enriched ^{17}O water initially shows only the water resonance and a signal at −70 ppm which is assigned to complexed water in the pentanitroaqua compound. On standing a signal at 690 ppm (linewidth 1550 Hz) with a shoulder at 660 ppm increases in intensity with time. The time dependence is shown in Fig. 5. This result demonstrates a process by which ^{17}O from the water is incorporated in the nitrite ion. The shape of the curve of Fig. 5 shows that there is an induction period of approximately an hour before the rate of exchange reaches its highest value. The pH of the solution dropped from 5.2 to 4.3 on standing for 8 h due to the formation of nitrous and nitric acids. Isotopic oxygen exchange between nitrite ions and water has been studied by several groups (31, 32). The most recent study (32) indicates a half-life of approximately 24 h for the acid catalyzed exchange at pH 6.26. A rough calculation indicates that the data of Fig. 5 can be accomodated by ^{17}O exchange with free nitrite if allowance is made for the pH change but exchange with complexed nitrite cannot be completely ruled out.

[a] *1*, shift parameter in units of 10^5; *2*, using eq. [1].

The ^{59}Co nmr of complexes with ammonia, nitro, and cyano ligands

In an earlier publication (18) we suggested an empirical formula for calculating ^{59}Co chemical shifts in hexacoordinated Co(III) complexes, namely

$$\delta = \frac{1}{3}\left(\frac{1}{S_1 + S_2} + \frac{1}{S_3 + S_4} + \frac{1}{S_5 + S_6}\right) - 11000$$

In this formula S_1 and S_2 are parameters characteristic of the ligands on the x axis, S_3 and S_4 similar parameters for the ligands on the y axis, and S_5 and S_6 refer to the ligands on the z axis. The shifts are given in ppm and a single set of S parameters, one for each type of ligand, sufficed to calculate the chemical shifts of some 80 complexes with a standard deviation of less than 1% of the total shift range. The validity of the rule of average environment is implicit in the use of this formula. The chemical shifts of nitro complexes cannot be fitted to this formula if a constant shift parameter is assumed. The fit for cyano complexes is less satisfactory than for other ligands — three out of the four complexes for which the discrepancies between observed and calculated shifts were greater than 200 ppm involved this ligand.

These problems are illustrated by the data of Table 2 for mixed ammine complexes. For the nitro series increasing nitro substitution first results in a high field shift but with more than three nitro ligands the shifts return to low field. Juranic (15) pointed out that this behaviour is inconsistent with the rule of average environment. There are also other problems. For all other reported complexes the *trans* isomer has a larger shift than the *cis* isomer and the *mer* isomer a larger shift than the *fac* isomer. The converse is true in the nitro/ammine series. It is usually possible to distinguish the different isomers from the line width considerations (18) — *cis* complexes give narrower lines than *trans* and *fac* isomers narrower lines than *mer*. For this series the linewidths are very similar and do not provide a convenient criterion for assignments. It seems probable though that the literature assignments are correct since the method of preparation is specific for the *cis* compound (33) and crystal structures have been reported for both the *mer* and *fac* complexes (34, 35). The reversal of the chemical shifts must therefore be accepted. For the cyano compounds the discrepancies are less obvious but a good fit cannot be obtained with a single CN parameter. In Table 2 the results of calculating the values of S_{NO_2} and S_{CN} for each complex assuming the value of S_{NH_3} given previously are tabulated. With increasing nitro or cyano substitution a steady decrease in the nitro parameter and a steady increase in the cyano parameter is apparent. In both cases the effect of introducing a *cis* ligand is different from the effect of introducing a *trans* ligand. The parameters can be reasonably fitted by the equations:

$$[1] \quad \begin{aligned} S_{NO_2} &= (3.096 - 0.093n_{cis} - 0.023n_{trans}) \times 10^{-5} \\ S_{CN} &= (4.203 + 0.020n_{cis} + 0.301n_{trans}) \times 10^{-5} \end{aligned}$$

where n_{cis} is the number of NO_2 or CN ligands *cis* to the NO_2 or CN ligand for which the shift parameter is required and n_{trans} is the corresponding number of *trans* ligands. The shifts resulting from the use of these formulae are given as the calculated values in Table 2. We note that these calculations correctly predict the order of the *cis* and *trans* and *mer* and *fac* chemical shifts.

The implications of the above formulae are that increasing the number of nitro ligands makes each successive nitro group a weaker field ligand and that substituting a nitro ligand *cis* has a four times larger effect than substituting one *trans*. A recent paper (42) has considered the effect of nephelauxetism on ^{59}Co chemical shifts and has shown that in theory the energy of the first $d-d$ transition should be multiplied by the nephelauxetic ratio to obtain a correlation with ^{59}Co chemical shifts. Deviations in the chemical shift could therefore be ascribed either to a change in $10D_q$ or to a change in β or to changes in both. The linear correlation with the unweighted optical data reported by Juranic (15) argues that changes in $10D_q$ are most important. Since both $10D_q$ and β reflect the bonding properties of the ligand it is clear that these properties are changing with increasing substitution. We have also considered the possible contributions of charge transfer transitions to ^{59}Co chemical shifts but there does not seem to be any strong reason to invoke such an effect in the present case. Steric considerations provide a possible explanation of this observation. The negative charge on the nitro group has been shown (22) to be predominantly on the oxygen atoms and repulsive interactions between NO_2 ligands, particularly when they are *cis* to each other, must be anticipated. This will weaken the crystal field splitting of successive nitro substituents. For the cyano ligands increasing substitution results in larger crystal field splitting with *trans* ligands having a greater effect than *cis* ligands. It seems unlikely that this effect has a steric origin.

The assignment of the nmr spectra of cobaltinitrite solutions

The ^{59}Co chemical shift parameters for the nitro group obtained above can now be used to assign the lines in the cobaltinitrite spectrum of Fig. 2. The calculated chemical shifts of 8108 ppm for the pentanitroaqua complex or 8092 ppm for the pentanitrohydroxo complex are consistent with the assignment of the 8052 line already made. The neighboring lines at 8065 and 8074 ppm possibly arise from isomers of the monoaqua complex differing in the relative orientations of the nitro substituents. This suggestion is consistent with the observation that the chemical shifts are very similar, since the ligands are the same, but the line widths, depending on quadrupole relaxation and hence on the electric field gradients, are quite different. The possibility that hydrogen bonding could affect the orientation of the nitro groups is supported by the crystallographic structures of *mer* and *fac* $Co(NO_2)_3(NH_3)_3$ (34, 35) in which the NO_2 groups are twisted by 20−30° from their orientations in the hexanitro complex by interactions with the other ligands. The data of Table 1 were obtained on the WM400 instrument and it is notable that these lines are much less well resolved at lower fields, suggesting that chemical exchange due to rotation of the nitro groups may be occurring. From the frequency separation of the lines a lifetime of greater than 2×10^{-4} s would be required. There seems to be little precedent for estimating the barrier for rotation about a Co—N bond. We are unable to suggest alternative assignments for these lines. The line at 7970 probably does not belong to this group since its intensity varies with time in a manner different from its neighbours. It increases in intensity more slowly and remains longer suggesting that it is a later product in the reaction scheme. Assignment to *trans*-$[Co(NO_2)_4(ONO)_2]^{3-}$ is suggested on the basis of the calculated shift of 7811 ppm. The *cis*-tetranitrodiaqua complex has a calcualted shift of 8846 ppm and the lines at 8670, 8693, and 8790 can be plausibly assigned to isomers of this species differing in the nitro group orientations. It is notable that higher aquated species are all predicted to occur at shifts greater than 9000 ppm and are definitely not observed. Since the hexaqua Co(III) ion is reduced even by water it is reasonable that trisaqua and more highly aquated species would be reduced by the nitrite ion to give Co^{2+} and NO_3^- as indicated by the ^{14}N spectra. The remaining lines of Fig. 1 can best be ascribed to complexes containing the nitrito ligand. Thus the line at 8315 ppm can be assigned to the *cis*-tetranitroaquanitrito compound (calculated 8331 ppm) or less likely the *trans* isomer (calculated 8456 ppm). The only remaining line is at 7318 ppm. This is best assigned as the pentanitronitrito complex although the agreement with calculation (7573 ppm) is not particularly good. Thus all of the lines in this spectrum can be satisfactorily assigned to the combined effects of hydrolysis and isomerization involving nor more than two nitro ligands.

The mechanism of ligand exchange

The observed half lives for the aquation of the cobaltinitrite ion from the visible spectra (2.7 m*M* concentration) and the nmr (0.5 *M* concentration) correspond to a first order rate constant of approximately 4×10^{-3} s^{-1}. This anomalously high rate suggests that a mechanism other than simple dissociation may be involved. An attractive possibility is a rate determining step of electron transfer from NO_2^- to Co^{3+}, followed by rapid ligand exchange of the resulting labile Co^{2+} complex, with the reaction being completed by rapid reverse electron transfer from Co^{2+} to NO_2, i.e.

[1]	$LCo^{3+}NO_2^-$	$= LCo^{2+} + NO_2$	Slow
[2]	$LCo^{2+} + L'$	$= L'Co^{2+} + L$	Fast
[3]	$L'Co^{2+} + NO_2$	$= L'Co^{3+}NO_2^-$	Fast
[4]	$NO_2 + NO_2 + H_2O$	$= NO_3^- + NO_2^- + 2H^+$	Slow

An electron transfer mechanism for Co^{3+} ligand exchange was first suggested to account for rapid base catalysed hydrolyses (36) but did not achieve great popularity. More recently (37) a very similar mechanism has been convincingly demonstrated for the ligand substitution reactions of peroxo/ammine complexes of Co(III). Interestingly the rate reported in this latter paper (4.9×10^{-3} s^{-1}) is very similar to that given above. Since NO_2^- is an oxidizable ligand this mechanism provides a ready rationalization of the difference from ligand exchange mechanisms involving non-oxidizable ligands such as CN^- and NH_3. Reaction [4] is well established and competes with reaction [3] leading to irreversible oxidation/reduction. Thus all of the observed products can be accounted for by a single mechanism and the very similar rates reported for aquation, nitrite exchange (20), and substitution by other ligands (21) are explained as arising from a common rate determining step. Subsequent hydrolysis steps to give diaqua and more highly substituted species are slower as would be anticipated from the smaller number of nitro groups available to donate electrons.

Reactions with ethylenediamine and cyanide

The observation that nitro ligands are readily replaced by water in the hexanitro complex suggest that replacement by other ligands may be equally facile. The reactions with ethylenediamine and with cyanide ion have therefore been investigated by ^{59}Co nmr.

Figure 6 shows a spectrum obtained from a mixture of 0.1 *M* $Co(NO_2)_6^{3-}$ and 0.41 *M* ethylenediamine which has been allowed to equilibrate for 7 days. There is actually relatively little change in the spectrum after 30 min of reaction. The principal difference is that a line at 7530 ppm, which appears quite strongly in the initial spectrum, disappears on standing. It may be noted that even though the ethylenediamine is present in stoichiometric excess the very stable trisethylenediamine complex is not the major product. The observed chemical shifts and linewidths are given in Table 3 together with calculated and literature values. The five high field lines of Fig. 6 are assigned to the expected species $Co(NO_2)_6^{3-}$, $Co(en)_3^{3+}$, $Co(en)(NO_2)_4^-$, *cis*-$Co(en)_2(NO_2)_2^+$, and *trans*-$Co(en)_2(NO_2)_2^+$. It is notable that the lines of the nitro complexes are all found to rather higher field than expected from the calculations and the linewidths are considerably greater than would have been anticipated. It is suggested that the excess ethylenediamine is present as a second sphere ligand hydrogen bonded to the nitro ligands. High field shifts (26) and line broadening (38) are the expected results of such hydrogen bonding. The low intensity lines at 9356, 9342 ppm are assigned to conformational or to *cis−trans* isomers of $Co(en)_2(OH)_2^+$ (calculated 9309 ppm) or the corresponding aqua complex. Yajima *et al* (39) assigned the *cis* and *trans* isomers with only a very small chemical shift difference (9300 and 9280) but this is unexpected and we have some preference for assigning the two lines to conformational isomers of the *cis* compound. The line at 8510 ppm is best ascribed to $Co(en)_2(H_2O)(ONO)^{2+}$ (calculated 8787 but possibly H bonded) although it is perhaps a little surprising that this complex does not rapidly convert to the nitro isomer. These are presumably products of the reaction of en with the hydrolysis products of $Co(NO_2)_6^{3-}$ which accounts for their low intensity. The remaining features are the intense line at 7785 ppm and the weaker line at 7530 ppm. These are best assigned to the *mer* and *fac* isomers of $Co(NO_2)_3(en)(H_2O)$ or the hydroxy equivalents. The relative line widths suggest that the 7785 ppm

TABLE 3. ^{59}Co nmr spectrum from the reaction of ethylenediamine and sodium cobaltinitrite

Observed chemical shift (ppm)	Linewidth (Hz)	Relative intensity	Assignment	Chemical shift: Refs. 15, 39, 40	Chemical shift: Calculated
9356	260	12	*cis*-$Co(en)_2(H_2O)_2$	9150	9310
			cis-$Co(en)_2(OH)_2$	9300	
9342	150		*trans*-$Co(en)_2(H_2O)_2$	9100	9780
			trans-$Co(en)_2(OH)_2$	9280	
8510	1350	2.3	$Co(en)_2(H_2O)(ONO)$		8781
7785	840	100	*mer*-$Co(NO_2)_3enH_2O$		7607
7530	150		*fac*-$Co(NO_2)enH_2O$		7669
7483	395	40	$Co(NO_2)_6$	7470	7510
7123	115	24	$Co(en)_3$	7146	7149
7035	1000	11	$Co(en)(NO_2)_4$	6795	6737
6539	1477	36	*cis*-$Co(en)_2(NO_2)_2$	6551	6627
6337	1453	103	*trans*-$Co(en)_2(NO_2)_2$	6323	6552

resonance is the *mer* isomer since it is much broader. The loss of the 7530 line on standing is presumably due to isomeric conversion to the more stable *mer* compound. The calculated shifts (*mer* 7603, *fac* 7669) are very similar but suggest the opposite assignment. Assignment of the more intense line to the *mer* isomer is consistent with the widely reported preferential formation of *mer*-$Co(NO_2)_3(NH_3)_3$.

The reaction of cobaltinitrite with cyanide produces the ^{59}Co spectra of Fig. 7*a* (0.2 *M* cobaltinitrite + 1.0 *M* cyanide) and 7*b* (0.05 *M* cobaltinitrite + 0.1 *M* cyanide). Data obtained from three different mixtures are presented in Table 4. Even with 5 mol of cyanide to 1 mol of cobaltinitrite, cobalticyanide is not the major product. The most intense line is at 1630 ppm and is best assigned as $Co(CN)_5(ONO)^{3-}$ (calculated 1372 ppm). The pentacyanonitro complex has been observed in other experiments at 609 ppm (40) but is definitely not seen in these mixtures. The other line at 2550 ppm can be assigned to the *cis*-tetracyanodinitrito complex (calculated 2835 ppm). A mixture of 1.0 *M* in cobaltinitrite and 1.0 *M* in cyanide ion also showed a line at 3621 ppm assigned to *trans*-$Co(CN)_4(ONO)_2^{3-}$ (calculated 3601 ppm). We find no evidence for mono or dinitro/cyano complexes. This observation is analogous to the report (41) that the pentacyano isothiocyanato Co(III) complex is formed in preference to the thiocyanato isomer in some reactions. In the solution most dilute in cyanide, lines at 6614 ppm and 6477 ppm can be assigned to *mer*-$Co(NO_2)_3(CN)(ONO)(H_2O)$ and *cis*-$Co(NO_2)_4(CN)(H_2O)$. The remaining lines in Table 4 are assigned to species not containing cyanide ligands. The multiplicity of lines with similar chemical shifts suggests conformational isomerism. The ^{14}N nmr spectra of these mixtures have also been examined. Separate resonances for free nitrite, coordinated nitrite, free cyanide, and complexed cyanide are observed but the different complexes are not distinguished.

Conclusion

The crystal field strength of the nitro ligand varies according to the number of nitro groups in the complex. If only one or two nitro ligands are present it is a strong field ligand. By the time the cobaltinitrite ion is reached it is a significantly weaker

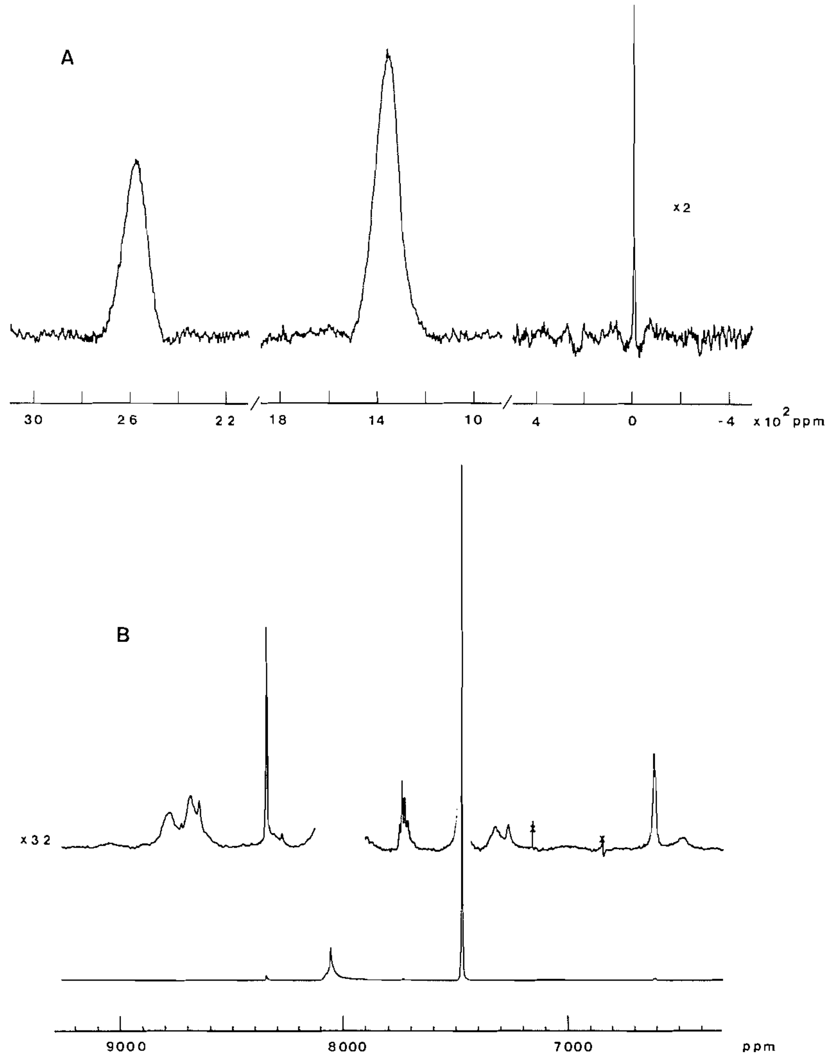

FIG. 7. ^{59}Co nmr spectra of fresh (aged 1 h) mixtures of sodium cobaltinitrite and sodium cyanide in water. (*A*) $[Na_3Co(NO_2)_6]$ = 0.2 *M*, [NaCN] = 1.0 *M*, B_0 = 5.9 T. (*B*) $[Na_3Co(NO_2)_6]$ = 0.5 *M*, [NaCN] = 0.1 *M*, B_0 = 4.7 T. Spikes are marked with crosses.

[a]*A*, 0.2 *M* $Co(NO_2)_6^{3-}$ + 0.1 *M* CN^-; *B*, 1.0 *M* $Co(NO_2)_6^{3-}$ + 1.0 *M* CN^-; *C*, 0.5 *M* $Co(NO_2)_6^{3-}$ + 0.1 *M* CN^-.

ligand and the spectroscopic and chemical properties reflect this change. Ligand exchange is facile and irreversible reduction takes place slowly. ^{59}Co nmr can readily detect these changes in crystal field strength. In aqueous solutions of cobaltinitrite a variety of Co(III) species are present. All contain at least four nitro ligands with the remaining two positions being filled by aqua or nitrito groups. Electron transfer leads to the reduction of Co^{3+} to Co^{2+} and the oxidation of NO_2^- to NO_2 which is then hydrolysed to give NO_2^- and NO_3^-. These species have been detected by ^{14}N and ^{17}O nmr.

^{59}Co nmr is also a very convenient technique for following ligand exchange reactions. Such reactions may give surprisingly complex mixtures of products as is demonstrated by the reactions of cobaltinitrite with ethylenediamine and with cyanide ion. The products may not be those initially anticipated, e.g., nitrito rather than nitro isomers. With the added sensitivity and dispersion of high field FT NMR spectrometers, large numbers of resonances can be observed. Thus in the case of cobaltinitrite solutions we report 10 lines where only two had been seen previously. ^{59}Co nmr is therefore a powerful technique for investigating the solution chemistry of Co(III). The problem lies in assigning the multiplicity of lines. The point charge model developed previously is helpful in this respect but a fair amount of empirical data collecting will likely be required to establish the pattern of the chemical shifts.

Experimental

Sodium cobaltinitrite was purchased from Fisher (reagent grade liquid and solid) and was used without further purification. ^{59}Co nmr spectra were obtained at various fields — 2.14 T (Bruker WH90), 4.7 T (Bruker CXP 200), 5.9 T (Bruker WM 250), and 9.5 T (Bruker WM 400). The temperature is each case was 21 ± 1°C. Potassium cobalticyanide, saturated ammonium nitrate (NO_3^- resonance), and distilled water were used as external calibration standards for the ^{59}Co, ^{14}N, and ^{17}O spectra, respectively. A Tracor-Northern 6050 instrument, which is equipped with a diode detector array, was used to obtain the spectra of Fig. 1. Infrared spectra were run in KBr discs using a Perkin-Elmer 283 instrument and Raman spectra on a Spex model 14018 spectrometer equipped with a helium–neon laser. ^{17}O nmr spectra were obtained on the WM 400 instrument. The enriched sample gave a S/N ratio of 729 on the water peak with only eight scans. The best ^{14}N spectra were obtained on the CXP 200 instrument using a high power probe. On this probe, the 90° pulse width is 5–10 μs. These short pulse widths are necessary to obtain good spectra for resonances such as coordinated nitrite which have very short relaxation times.

Infrared spectra of hydrogen bonded complexes of 2,6-dichlorophenol derivatives and oxygen bases have been studied over a broad ΔpK_a range (from −10.55 to +1.69). For the complexes of 1:1 stoichiometry typical evolution of spectra, similar to those for other hydrogen bonded systems, have been found. With an increase of ΔpK_a, the hydroxyl group stretching vibration band shifts to lower frequencies until the inversion region is reached, where hydrogen bonded (HB) and proton transfer (PT) forms occur in equilibrium, then a broad background absorption is observed. The centre of gravity of the broad protonic bands, ν_{cg}, calculated from the integrated intensity over the whole infrared region have been correlated with ΔpK_a and the contribution of the PT form. It has been shown that the minimum on the plot ν_{cg} vs. ΔpK_a is reached close to the inversion point, where $K_{PT} = 1$. The observed correlations and the change in the shape of the broad protonic absorption are consistent with expectations of theories based on the concept of the double minimum potential function and the stochastic mechanisms of band broadening.

R. WOLNY, A. KOLL et L. SOBCZYK. Can. J. Chem. **63**, 3568 (1985).

Utilisant un large intervalle de ΔpK_a (allant de −10,55 à +1,69), on a étudié les spectres infrarouges des complexes des dérivés du dichloro-2,6 phénol et des bases oxygénées liés par des liaisons hydrogènes. Dans le cas des complexes du type 1:1, on a trouvé une évolution typique des spectres semblable à celle des autres systèmes liés par des liaisons hydrogènes. Lorsque le ΔpK_a augmente, la bande de vibration d'élongation du groupe hydroxyle glisse vers les basses fréquences jusqu'à atteindre la région d'inversion où les formes hydrogène lié (HL) et transfert de proton (TP) existent à l'équilibre; on observe alors une large absorption de fond. On a établi une corrélation entre le centre de gravité des bandes protoniques larges, ν_{cg}, calculé à partir de l'intensité intégrée sur toute la région infrarouge, avec le ΔpK_a et la contribution de la forme TP. On montre que l'on atteint le minimum de la courbe ν_{cg} en fonction du ΔpK_a près du point d'inversion où $K_{PT} = 1$. Les corrélations observées et le changement de forme de l'absorption protonique large sont en accord avec les attentes des théories fondées sur le concept de la fonction de potentiel du minimum double et sur le mécanisme stochastique de l'élargissement de la bande.

[Traduit par le journal]

Introduction

There is a number of papers dealing with infrared behaviour of hydrogen bonded adducts containing oxygen bases with various proton donors. Among them, are the results obtained by Hadži *et al.* (1−3), Szafran *et al.* (4−7), and Gramstad *et al.* (8−10). The complexes of oxygen bases appeared to be a convenient object for the studies of hydrogen bonding and its spectroscopic features due to a broad range of the proton acceptor properties and relatively high stability. However, the interpretation of the ir spectroscopic behaviour can be difficult because of the formation of adducts of varying composition, including ionic states with homoconjugated cations and anions. In some papers, the influence of the ΔpK_a of interacting components on the ir behaviour has been reported (7, 11, 12). However, the data available so far are not sufficient for formulating more general conclusions concerning the relationship between the donor−acceptor properties of interacting components and spectroscopic features of hydrogen bonded adducts. The aim of the present work was the study of ir spectra of hydrogen bonded adducts composed of oxygen bases and 2,6-dichlorophenol derivatives. For such systems there are informations available on the complexation equilibria (13) and the charge distribution within the hydrogen bridge expressed by the dipole moment increment (14). The magnitude of this increment correlates with the equilibrium constant of the intracomplex proton transfer and the ΔpK_a value of interacting components. In addition, the dipole moment increment describes semiquantitatively the potential for the proton motion and, in particular, informs about the so-called inversion point corresponding to the situation with either an equal population of two protonic states (pseudosymmetric hydrogen bond in the dynamical sense) or with one broad potential minimum for the proton motion. Such a situation, as can be suspected, should be reflected markedly in ir spectra.

Experimental

The ir spectra were recorded on a Perkin Elmer 180 spectrophotometer at room temperature in CCl_4 solutions contained in KBr cells of 2 mm thickness. To get the spectra of complexes of 1:1 compositon, equal concentrations of base and phenol 0.01 *M* were used. In such conditions, the contribution of complexes other than those of 1:1 composition can be neglected. The excess of oxygen bases shifts the equilibrium towards homoconjugated cations $[OHO]^+$, while an excess of phenol causes the formation of complexes of various composition $(AH)_nB$, the most stable being that with $n = 2$. The concentrations used in the ir studies were similar to those for the study of complexation equilibria (13) and dipole moments (14). The studies at relatively low concentrations allowed to avoid, to a large extent, the self-association of strongly polar complexes. The osmometric studies performed on most polar TBNO · DCNP adducts in CCl_4 showed that the association degree under experimental conditions used in this work reaches about 10%. For the complexes of lower polarity the association degree is much smaller.

The origin of the compounds investigated was the same as in previous studies. Their list, with the abbreviations used, is presented in Table 1. All operations connected with the preparation of the solutions and the cell filling were performed in a dry box.

Results and discussion

The informations about the systems investigated are collected in Table 1. They contain the ΔpK_a values, defined as $pK_a(BH^+) - pK_a(AH)$, the position of the high frequency protonic band ν_3OH (stretch) and the position of the centre of gravity, ν_{cg}, of the whole protonic broad bands (intergrated over the whole ir region). ν_{cg} defined as

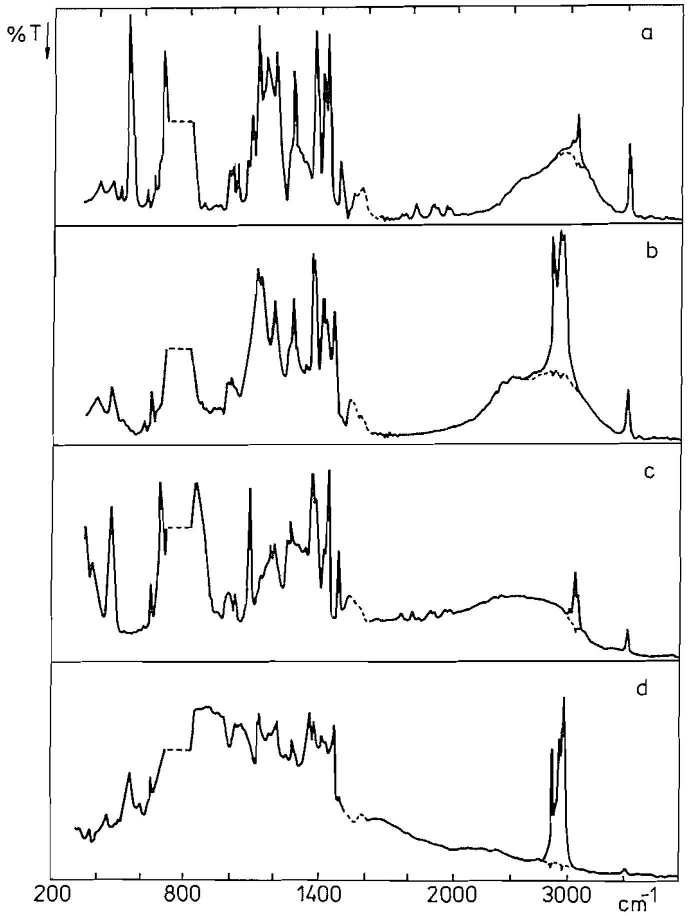

FIG. 1. Evolution of the ir spectra for the complexes of oxygen bases with PCP: (*a*) TPPO · PCP (ΔpK_a = −5.88), (*b*) TOPO · PCP (ΔpK_a = −4.22, (*c*) TPASP · PCP (ΔpK_a = −2.11), (*d*) TBNO · PCP (ΔpK_a = 0.49).

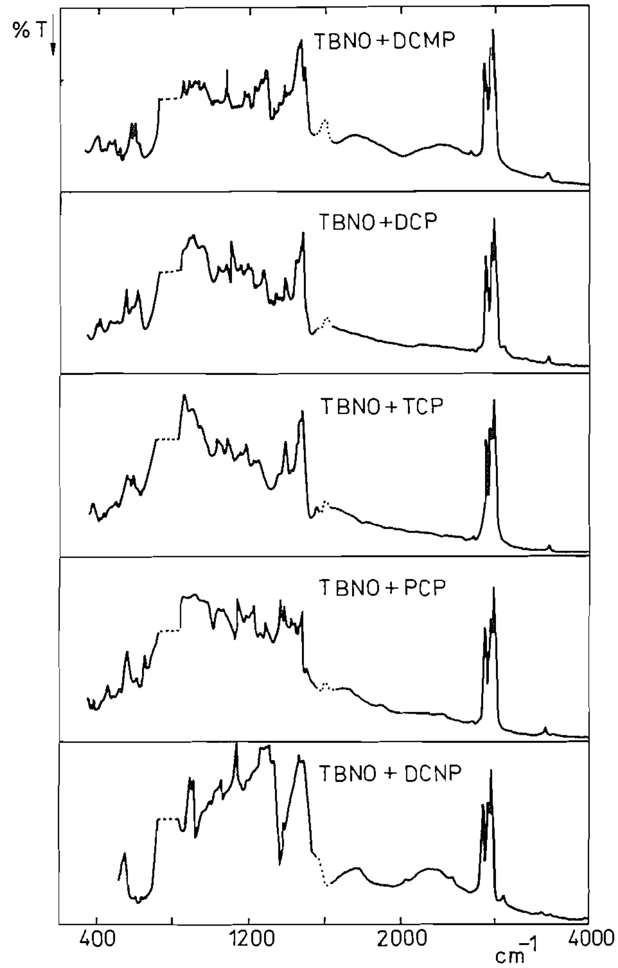

FIG. 2. Behaviour of the broad protonic absorption for TBNO complexes.

$$[1] \quad \nu_{cg} = \int \log\left(\frac{I_0}{I}\right) \nu d\nu \Big/ \int \log\left(\frac{I_0}{I}\right) d\nu$$

was calculated by using a computer.

The evolution of the absorption related to the protonic vibrations is illustrated taking selected PCP complexes as examples (Fig. 1). Most characteristic is the fact that close to the inversion point, which for the investigated systems corresponds to $\Delta pK_a \simeq -0.3$, the ν_s(OH) band becomes very broad and overlaps with a new low frequency broad absorption creating a "continuum". For the complexes directly in the inversion range, the band assignable to the OH stretching vibrations is shifted to lower frequencies, has a doublet character (the minimum is always located at about 2000 cm^{-1}) and a low intensity. The lowest intensity occurs at ΔpK_a = −1.15. The situation is illustrated by the behaviour of TBNO complexes, for which the proton transfer equilibrium was previously detected (Fig. 2) (13). The boundary systems, i.e., TBNO · DCMP and TBNO · DCNP, correspond to an almost complete shift of the proton transfer equilibrium to OH...O and O^-...HO^+ states, respectively. Their spectra are very similar in both the high frequency (the doublet) and the low frequency (background absorption) range. The high frequency doublet practically vanishes for complexes of TCP and DCP, while in the case of PCP complex, for which the PT state exceeds 60%, it appears clearly again. The proton transfer situation in the systems studied, derived from dipole moments and uv spectra, is illustrated in Fig. 3. There is only a little discrepancy for the two independent methods. The inversion point corresponding to 50% of PT state is located at $\Delta pK_a \simeq -0.3$.

Plotting the ν_{cg} value against ΔpK_a we obtain the curve with characteristic minimum close to the inversion point (Fig. 4). The anomaly on the $\nu_{cg} = f(\Delta pK_a)$ plot appears a little bit before reaching the inversion point, which seems to be understandable in the light of the following reason. The dipole moment increment of the contribution of the proton transfer state is related to the equilibrium process governed by the free energy change ΔF_{PT}. It means that the two minima for the proton motion in the free energy scale with a contribution of the entropy effect evoked by the reorganisation of the solvent molecules may be different to those in the potential energy scale for the adiabatic motion of protonic vibrations. The confirmation of such an argumentation is found in studies of the entropy effect based on the measurements of K_{PT} as a function of T. The ΔS_{PT} in all the cases investigated so far is characterised by negative values (15, 16).

In the interpretation of the results one should consider a possible contribution in the recorded spectra of homoconjugated $[OHO]^+$ and $[OHO]^-$ ions. The detailed analysis of equilibria based on uv and ir (in the overtone region) indicates that under experimental conditions the contribution of these ions can be neglected. This conclusion is supported by the results of dielectric (14), electric conductivity (17), and osmometric

studies. The last two methods, in particular, eliminate the involvement of 2:2 complexes which have been detected for some other systems with oxygen bases (18). This is most probably due to the essential steric hindrance in 2,6-dichlorophenols, which does not allow the formation of homoconjugated anions in this case. The formation of such anions is also excluded for $(AH)_2B$ complexes, even for the strongest proton donors and acceptors. The second phenol molecule is attached to 1:1 species via relatively weak hydrogen bond (13, 14). Based on the infrared spectra themselves it is very difficult to exclude the presence of $[OHO]^-$ homoconjugated anions because of the great similarity of background absorption for the 1:1 and 2:1 species.

In Fig. 5 ($a-d$) we compare the spectra of solid complexes (which can be easily isolated in crystalline state) $TBNO_1 \cdot DCNP_1$ and $(TBNO)_2 \cdot DCNP$, in CCl_4 solutions. For 2:1 adducts in the solid state the high frequency absorption above 1600 cm^{-1} almost completely disappears. In the solution there remains very weak high frequency doublet which could indicate that some of 1:1 complex is present in equilibrium. Some difference is visible in the backgorund absorption consisting in

larger extension of this absorption towards low frequency. On the other hand, we find a distinct difference in the spectra of the 1:1 complexes in the solid state and in solution. This difference arises from the fact that the crystalline state favours the proton transfer ionic state. Already in the solution the PT equilibrium is shifted towards the ion pairs, but in the solid state purely ionic form $O^- \ldots H—O^+$ is reached with the hydrogen bridge which is a mirror image of the usual non-proton-transfer hydrogen bond. They correspond to the boundary potential curves *a* and *d* shown in Fig. 6.

It seems that just using the anticipated evolution of the potential energy curves shown schematically in Fig. 6, one can also understand the evolution of ir spectra of the complexes under investigation. The particular spectroscopic properties of complexes belonging to the inversion range result most probably from the appearance of the second minimum for the proton motion a strong anharmonicity of the potential. The appearance of a second minimum on the level similar to the first one causes additional protonic transitions of similar intensities and widths. The analysis of the shape of the protonic bands, assuming a double minimum potential, performed in two somewhat different ways leads to quite similar results. In the semiempirical approach proposed by Romanowski and Sobczyk (19, 20), the evolution of ir spectra for OHO bridges of varying length has been calculated by assuming the coupling of protonic vibrations with low frequency, strongly damped, bridge vibrations. These authors showed that a flow frequency background absorption appears for sufficiently short bridges with double minimum for the proton motion. In the case of strong symmetrical bonds the high frequency absorption almost completely disappears. Similar results have been obtained by Zundel, Weidemann, and co-workers (21, 22). They calculated the shape of protonic bands by assuming the fluctuations of electric field and bridge length and showed that this shape can be substantially changed for various hydrogen bonds. In particular, the intensities of low and high frequency parts of the broad absorption are very sensitive to the hydrogen bond strength. The interpretation based on the assumption of a double minimum potential for the complexes of inversion range is supported by the isotopic effect. The calculations performed by Zundel *et al.* (23) showed, that in the case of broad "continuous" protonic absorption the total effect consists of the narrowing on both sides of the band and a drop of intensity. Such effect is observed in the case of complexes belonging to the inversion region. This is well demonstrated in Fig. 5 where the spectrum of the non-deuterated $TBNO_1 \cdot DCNP_1$ complex (*b*) is compared with that of the deuterated (75%) one (*e*). Quite similar features are reported for other complexes where nearly symmetrical double minimum potential for the proton motion is expected (11, 12, 24).

The preparation and spectral properties of the complexes of 6-amino-3-methyl-5-nitroso-uracil (HAMNU) with Zn(II), Cd(II), and Hg(II) ions are reported. The results suggest that the exocyclic oxygen and nitrogen atoms have a much greater tendency to bind to these ions than the ring nitrogen atoms. In Zn(II) and Cd(II) complexes, the ligand is N,O-coordinated through the 5-nitroso and 6-oxide groups of (AMNU) in nitrosophenolic anionic form. In the Hg(II) complexes, the ligand seems to be bound in neutral form. Tetrahedral structures are proposed in all cases.

J. M. SALAS-PEREGRIN, M. N. MORENO-CARRETERO et E. COLACIO-RODRIGUEZ. Can. J. Chem. **63**, 3573 (1985).

On rapporte la préparation et les propriétés spectrales des complexes de l'amino-6 méthyl-3 nitroso-5 uracile (AMNU) avec les ions Zn(II), Cd(II) et Hg(II). Les résultats suggèrent que les atomes d'oxygène et d'azote exocycliques tendent à se lier plus facilement à ces ions que les atomes d'azote du cycle. Dans les complexes de Zn(II) et de Cd(II), la coordination-N,O du ligand est assumée par les groupements nitroso-5 et oxyde-6 du AMNU existant sous la forme anionique nitroso-phénolique. Dans les complexes du Hg(II), le ligand semble être lié à la forme neutre. Dans tous les cas, on suggère l'existence de structures tétraédriques.

Introduction

The work of Rosenberg and the discovery of the antitumor action of some platinum(II) complexes (1, 2) have aroused extraordinary investigations into the interaction between metal ions and the nucleic acids, and their constituents, the nucleosides and nucleotides.

The pyrimidine bases that are found in living systems have a large number of positions to bind a metal ion, using, generally, their heterocyclic and amidic nitrogen atoms to make covalent bonds with several metal ions.

The exocyclic oxygen and nitrogen atoms of some pyrimidine derivatives share in selective reactions with metal ions as is shown in the "platinum pyrimidine blues" (3, 4). On the other hand, the exocyclic groups of pyrimidine bases, besides playing an important role in the formation of metal–pyrimidine bonds, can operate as acceptors or donors in hydrogen bonds, which help to stabilize the crystal structure of the complexes.

Investigations determing the binding sites of pyrimidine derivatives to metal ions are the first steps for the understanding of the biological role of some of these complexes (5–8) and have been the subject of several review articles (9, 10). As an extension of these studies, we report the preparation and spectral study of complexes of 6-amino-3-methyl-5-nitroso-uracil (HAMNU) with Zn(II), Cd(II), and Hg(II) ions.

Experimental

6-Amino-3-methyl-5-nitrosouracil was prepared by hydrolysis of 4-amino-1,6-dihydro-1-methyl-2-methoxy-5-nitroso-6-oxopyrimidine according to the method previously reported (11). All the chemicals used in this work were analytical reagent grade.

The complexes were prepared as follows: $Zn(AMNU)_2 \cdot 4H_2O$: a solution of zinc acetate (4 mmol) in water (10 mL) was added slowly and with stirring to a hot aqueous solution (100 ml) of the ligand (2 mmol). The resulting red solution was allowed to cool slowly to room temperature. Red crystals appeared after a few days.

$Cd(AMNU)_2 \cdot 2H_2O$ and $Cd(AMNU)_2$: These compounds were obtained by mixing hot solutions containing 2 mmol of HAMNU and 8 mmol of cadmium chloride, respectively. By evaporating at room temperature for 24 h, an orange powder was obtained. From the filtrate solution, red crystals can be isolated after a few days.

$HgCl_2(HAMNU)_2 \cdot 2H_2O$ and $HgCl_2(HAMNU)_2 \cdot H_2O$: An aqueous solution containing 8 mmol of $HgCl_2$ was added slowly and with stirring, to a hot concentrated aqueous solution of the ligand (2 mmol). After standing for about 2 days, red crystals were isolated. From the resulting filtrate solution, a pale rose powder was obtained after a few days.

All the compounds were filtered, washed with water and ethanol, and dried with diethyl ether.

Chemical analysis of C, H, and N was performed with a Carlo Erba 1106 Microanalyzer. Determination of Zn and Cd was carried out by atomic absorption spectrometry using a Perkin Elmer model 290 spectrophotometer and Hg analyzed using a Perkin Elmer 5000 apparatus. The percentage of water in the isolated complexes was determined by thermographic techniques, using a Mettler TG-50 thermobalance. The heating rate was 10°C min^{-1}. For zinc and cadmium complexes a static atmosphere of air was used. For mercury complexes, a dynamic atmosphere of nitrogen (100 ml min^{-1}) was utilized. The results obtained are listed in Table 1.

The absorption spectra in the uv–visible region (200–700 nm) were recorded on a Beckman Acta C-III spectrophotometer.

Infrared spectra were recorded in KBr pellets (4000–200 cm^{-1}) and polyethylene pellets (650–200 cm^{-1}) on a Beckman-4250 spectrophotometer.

^1H nmr spectra were recorded on a Hitachi Perkin Elmer model R-600 FT-NMR spectrometer, using dimethylsulfoxide-d_6 as solvent and TMS as internal reference.

Results and discussion

The 4-keto-5-nitroso portion of 6-amino-3-methyl-5-nitrosouracil (HAMNU) may exist in several tautomeric forms: dike-

tonic (**I**), nitroso–phenolic (**II**), and keto–oximic (**III**) forms. Infrared data of HAMNU indicate that, in solid phase, the diketonic form is the most stable (11). Nevertheless, when this ligand is coordinated to metal ions in anionic form, nitroso–phenolic and keto–oximic forms are favoured because both have easily dissociable hydrogen atoms and the formation of a chelate can occur most readily.

The absorption maxima of these complexes in the ultraviolet–visible region are given in Table 2 and the assignment of the bands has been established according to bibliographic data (12–16).

A marked difference between the visible spectra of these complexes and the visible spectrum of free HAMNU is the hypsochromic shift (38 nm) of the band corresponding to the absorption of the chromophore group that takes place in the case of Zn(II) and Cd(II) complexes. It may indicate that the nitroso group is bound to the metal, whilst in the visible spectra of Hg(II) complexes, this displacement barely exists. These observations are in agreement with those found for some metal complexes with 6-amino-5-nitrosouracil (17, 18).

In Table 3 are given the ^1H nmr data of HAMNU and its isolated complexes. The signals between 9.7 and 11.7 ppm have been assigned to the resonance of N_1—H protons (17–19) and their presence indicates that the ligand is not bound to metal ions through the N_1 atom. On the other hand, this signal appears shifted with respect to its position in the ^1H nmr spectra of the free ligand, following two behavior types clearly defined. When the ligand is coordinated in anionic form (Zn(II) and Cd(II) complexes), this signal is shifted upfield, probably because of the increase of electronic density in the pyrimidine ring as a result of deprotonation (20). If HAMNU acts as a neutral ligand ((Hg(II) complexes), this signal appears shifted downfield, since coordination produces a decrease of negative charge density in the pyrimidine ring (21). Moreover, the ^1H nmr spectra show a signal at about 8 ppm, which has been assigned to the iminic proton, in the Zn(II) and Cd(II) complexes, and to the aminic hydrogens in the Hg(II) complexes (17).

The $Zn(AMNU)_2 \cdot 4H_2O$, $Cd(AMNU)_2 \cdot 2H_2O$, and $Cd(AMNU)_2$ complexes show practically the same infrared spectra. These show two bands in the 3400–3100 cm^{-1} range. The band at higher wavenumber corresponds to the ν(N—H) stretching vibration of the imino group and the other may be assigned to the $\nu(N_1$—H) stretching vibration. The position of these bands is similar to those found for other analogous complexes with 6-amino-5-nitrosouracil derivatives (17, 18, 22). The ν(C=O) band is shifted approximately 60 cm^{-1} to lower wavenumber from its position in the ir spectrum of free HAMNU (11), which can be a result of the change of the electronic density in the ring after coordination. This has also been observed in analogous pyrimidine derivative complexes (23). Likewise, we observe a band at about 1500 cm^{-1}, which corresponds to the ν(N=O) stretching vibration of the nitroso group. The presence of this band and the band corresponding to the ν(N—H) vibration of the imino group indicate that the coordination of HAMNU to Zn(II) and Cd(II) ions takes place through the tautomer anionic form **II**.

Two new bands in the 600–200 cm^{-1} region, corresponding to ν(ML) vibrations, are certainly assignable to ν(M—N) modes (18, 24–26). Likewise, there are no bands due to the existence of coordinated water molecules.

On the basis of the obtained data, we suggest that, in the Zn(II) and Cd(II) complexes, the ligand is bound to metal ion in iminic anionic form **II**, through the nitrogen and oxygen atoms of 5-nitroso and 6-oxide groups, respectively. This coordination mode coincides with the one found, from X-ray structural studies on analogous 5-nitrosopyrimidine derivative complexes (27–29).

This binding mode could be supported in the ir spectra by the appearance of the band corresponding to ν(C—O) stretching vibration. However, this band has not been observed since, due to the delocalization of negative charge by conjugation, this C—O bond may show an appreciable double bond contribution. Consequently, this band must appear at around 1300 cm^{-1} (30) and could be masked by the ν(C—N) bands of the ligand (18, 21). The lack of a shift of the ν(N=O) band to lower wavenumber in the ir spectra of $Zn(AMNU)_2 \cdot 4H_2O$ and $Cd(AMNU)_2$ can be also explained by the above-mentioned conjugation, since the loss of electronic density of the nitrogen atom as consequence of the coordination may be counteracted by the delocalization of free negative charge of the oxygen atom of 6-oxide group and thus loses the single character of the C—O whereas the electronic density of the N=O bond remains practically unaffected.

Finally, in view of the fact that the water molecules are out of the coordination sphere, it is reasonable to conclude that for these three complexes the most probably structure is a distorted tetrahedron.

The ir spectra of the Hg(II) complexes show that at about 3300 cm^{-1}, a broad band can be assigned to the ν(N—H) stretching vibration of an amino group. This band is confirmed by the band around 1660 cm^{-1} that corresponds to δ(N—H) in-plane deformation of this group. Bands at 3170 cm^{-1} ($HgCl_2(HAMNU)_2 \cdot 2H_2O$) and 3200 cm^{-1} ($HgCl_2(HAMNU)_2 \cdot H_2O$) can be assigned to $\nu(N_1$—H) vibration. The displacement to lower wavenumber of the bands corresponding to ν(C=O) and ν(N=O) stretching vibrations is smaller than that observed in the Zn(II) and Cd(II) complexes, which agrees with the interaction in the neutral form of HAMNU. This assumption is also corroborated by the ^1H nmr data of these complexes.

* Broad band.
† Not observed due to overlapping with δ(O—H).
‡ Not observed.
§ In polyethylene pellets.

The far ir spectrum of $HgCl_2(HAMNU)_2 \cdot 2H_2O$ shows two bands at 225 and 210 cm^{-1}, which may be assigned to the ν(Hg—Cl) stretching vibrations (31). Moreover, there are no bands assignable to $\nu(Hg—OH_2)$ mode. The presence of two bands for ν(Hg—Cl) mode suggests three structural possibilities for this complex: *cis*-planar, octahedral polymeric with chlorine bridging and tetrahedral.

The first is improbable because of the electronic configuration of metal ion (d^{10}). The octahedral polymeric structure is not normal in Hg(II) complexes and is present only in some adducts of mercury chloride with solvents such as methanol (32, 33), pyridine (34), and 1,4-dioxane (35).

For these reasons, and taking into account the similarity of spectral data for both Hg(II) complexes, it seems logical to propose for them a distorted tetrahedral structure, in which the HAMNU acts as a monodentate ligand (tautomer form **I**). In view of the several occasions in which crystal structure determinations proved that binding site assignments made on the basis of spectral evidence for pyrimidine metal complexes were incorrect (29, 36–38), it would be rather naive to reach even a tentative conclusion favoring some atom of the exocyclic substituents over another one as the binding site of HAMNU in these Hg(II) complexes with this ligand.

The use of orthogonal collocation in the treatment of the problem of an array of ultramicroelectrodes is presented and compared to existing digital simulation techniques.

JOHN CASSIDY, JAMAL GHOROGHCHIAN, FERESHTEH SARFARAZI et STANLEY PONS. Can. J. Chem. **63**, 3577 (1985).

On rapporte les résultats obtenus lors de l'usage de collocations orthogonales dans l'examen du problème d'un arrangement d'ultramicroélectrodes et on les compare aux résultats obtenus par les techniques existantes de simulation digitale.

[Traduit par le journal]

Introduction

The geometries and methods of construction of ultramicroelectrodes have been approached in many ways since the pioneering work in the area by Bindra *et al.* (1) at Southampton in the early 1970's. The analytical theoretical characterizations of some of the geometries have been developed and are just now beginning to appear in the literature. Although several electrode geometries hold great promise in terms of ease of construction, performance and ease of mass transport description, the round disk electrode has maintained popularity in use, primarily because of the convenience in preparing them in the 10 to 50 μm diameter range (2, 3). These comparatively large microelectrodes have significant analytical applications and characterization of their behavior is important. We provide characterization of some arrays of this type of ultramicroelectrode in this report by orthogonal collocation simulation.

The effect of the magnitude of the circumference to surface area ratio of disk electrodes embedded in insulators on the response of conventional electrochemical techniques has been studied by a number of groups, including ourselves, in the earlier parts of the series (4–7). In the limit, when the surface area approaches atomic dimensions, the ratio becomes large and hemispherical diffusion becomes predominant. Under such conditions, the mass transport coefficient varies as $1/r$ where r is the radius of the ultramicroelectrode at small dimensions. Heterogeneous rate measurements and stochastic process studies may be greatly facilitated (1) under these conditions. Reaction mechanistic studies are also facilitated but without the benefit of spectroelectrochemistry and direct product analysis due to the extremely small amounts of electrogenerated species formed. This problem may be mitigated by the construction of clusters or arrays of ultramicroelectrodes arranged so that their individual diffusion fields are isolated on the timescale of the experiment. Thus processes which normally occur at individual electrodes at high mass transport rates are essentially amplified to a level where analyses by product isolation or conventional spectroelectrochemical techniques are easily implemented. The possibilities of using microelectrodes in the form of colloidal particles as heterogeneous catalysts and fluidized bed reactors have also been examined (8–10). Work has proceeded on a variety of ultramicroelectrode array geometries, including cross sections of epoxy embedded reticulated carbon arrays (11, 12) and arrays for liquid chromatography detectors (13). Geometries include those created by photoresist images (14, 15), carefully placed contiguous carbon fibers (13), sites of inactive oxides on metal substrates (16, 17), metal mesh (18), and platinum particles dispersed in polymer films (19, 20). A variety of new geometries which may be able to be prepared at the 100 Å level has been reported (21).

Disk electrodes, embedded in an insulator, exhibit uneven nonlinear diffusion unless the edge of the electrode is confined by the perpendicular walls of the cell. Since the flux at the edge is greater than that towards the center, the overpotential near the edge will be greater than at the center. There will also be a reduction in overpotential caused by the resistance to charge transfer across the face of the electrode (22). The resulting secondary or tertiary current distribution must be considered in any full analytical treatment of the disk electrode. Whereas the iR drop through the solution is small at a microelectrode due to the small current, the effect on potential distribution across the face of the electrode may still be considerable because of the very uneven current distribution. When this is taken into account along with the activation and transport overpotentials then the resulting "quaternary distribution" may be defined. These complications are currently under investigation using an iterative procedure.

Theory

The original analytical approach for the array, reviewed by Gueshi *et al.* (14), assumed that a steady state current was reached, and the resulting Laplace equation could be solved. For the rather large diameter electrodes used in most work today (>5 μm) this is not a valid assumption since the rate of reaction will vary across the surface of a disk. The electrode is non-uniformly accessible. Reller *et al.* (23) used a digital simulation approach similar to that of Feldberg (24) to examine chronoamperometry at an array of microelectrodes and showed that while the original analytical solutions were correct at long and short times, at intermediate times they were not because of the "steady state" assumption. More recently Shoup and Szabo used a hopscotch algorithm and presented an equation for a general solution (25). Comparison between the regular hexagon model (Fig. 1*a*) and various reticulated arrays has been made (26). Although the hexagonal model is most popular because of its symmetrical advantages (14, 25, 27), disks have also been positioned in square arrays (28) and strips (29). Numerous electrochemical techniques have been considered, including chronopotentiometry (30), cyclic voltammetry (23, 31), Faradaic impedance (32), and chronoamperometry (14, 27) which is considered here.

[1]To whom all correspondence should be addressed.

Orthogonal collocation techniques approximates the concentration profiles by utilization of orthogonal polynomials. The differential equation is accurately satisifed at certain points — the zeros or roots of the approximation polynomials. The problem is ultimately reduced to a system of coupled ordinary differential equations which are simultaneously solved by conventional means. In the case of cylindrical co-ordinates, the following trial function in two dimensions x and r is chosen:

$$[1]\quad C(x,r,t) = \sum_{l=1}^{N_r+2} \sum_{j=1}^{N_x+2} \lambda_{j,l} x^{j-1} r^{l-1}$$

where $C(x,r,t)$ is the concentration at a distance x above the electrode and radial distance r away from the center of the electrode as shown in Fig. 1*b*. N_r and N_x are the number of internal collocation points and $\lambda_{j,l}$ is determined by the number of points and the type of polynomial chosen (*vide infra*). After differentiation and substitution the following relations are found, where $A_{i,j}$, $B_{i,j}$, $C_{l,k}$, $D_{l,k}$ are constants, the values of which are detailed in earlier papers (4–7), and need only to be calculated once for a given geometry and polynomial.

$$[2]\quad \begin{aligned} \left(\frac{\partial C}{\partial x}\right)_{x_i,r_k} &= \sum_{j=1}^{N_x+2} A_{ij} C(x_j,r_k,t) \\ \left(\frac{\partial^2 C}{\partial x^2}\right)_{x_i,r_k} &= \sum_{j=1}^{N_x+2} B_{ij} C(x_j,r_k,t) \\ \left(\frac{\partial C}{\partial r}\right)_{x_j,r_k} &= \sum_{l=1}^{N_r+2} C_{l,k} C(x_j,r_l,t) \\ \left(\frac{\partial^2 C}{\partial r^2}\right)_{x_j,r_k} &= \sum_{l=1}^{N_r+2} D_{l,k} C(x_j,r_l,t) \end{aligned}$$

In this paper, the model due to Gueshi (14) is used (see Fig. 1*a*). The geometry is characterized by many contiguous unit cells, each an image of the other, so that there is perfect symmetry maintained in the macroscopic sense. The following simple electron transfer reaction is examined:

$$[3]\quad \mathrm{A} \underset{+ne^-}{\overset{-ne^-}{\rightleftarrows}} \mathrm{B} \qquad E^0$$

The diffusion equation in cylindrical coordinates is

$$[4]\quad \frac{\partial C_A}{\partial t} = D_A\left[\frac{\partial^2 C_A}{\partial x^2} + \frac{1}{r}\frac{\partial C_A}{\partial r} + \frac{\partial^2 C_A}{\partial r^2}\right]$$

Given that the diffusion coefficients of the two species are similar, and the fraction of the surface covered with electrodes is θ, the boundary conditions are the following:

$$[5]\quad t = 0,\ x \geq 0,\ r \geq 0 \qquad \begin{aligned} C_A(x,r,0) &= C_A{}^0 \\ C_B(x,r,0) &= 0 \end{aligned}$$

$$[6]\quad t > 0,\ x \to \infty,\ r \geq 0 \qquad \begin{aligned} C_A(\infty,r,t) &= C_A{}^0 \\ C_B(\infty,r,t) &= 0 \end{aligned}$$

$$[7]\quad t > 0,\ x = 0,\ 0 < r < r_0 \qquad \frac{C_B(0,r,t)}{C_A(0,r,t)} = \exp\left[\frac{nF}{RT}(E^0 - E)\right]$$

$$[8]\quad t > 0,\ x = 0,\ 0 < r < r_0 \qquad C_A(0,r,t) = 0$$

$$[9]\quad t > 0,\ x = 0,\ 0 < r < r_0 \qquad \left(\frac{\partial C_A}{\partial x}\right)_{x=0} = -\left(\frac{\partial C_B}{\partial x}\right)_{x=0}$$

$$[10]\quad t > 0,\ x = 0,\ r_0 < r < r_0' \qquad \left(\frac{\partial C_A}{\partial x}\right)_{x=0} = \left(\frac{\partial C_B}{\partial x}\right)_{x=0} = 0$$

$$[11]\quad t > 0,\ \text{at all } x,\ r = r_0' \qquad \left(\frac{\partial C_A}{\partial r}\right)_{r=r_0'} = \left(\frac{\partial C_B}{\partial r}\right)_{r=r_0'} = 0$$

$$[12]\quad t > 0,\ \text{at all } x,\ r = 0 \qquad \left(\frac{\partial C_A}{\partial r}\right)_{r=0} = \left(\frac{\partial C_B}{\partial r}\right)_{r=0} = 0$$

As before the cylindrical geometry is divided into the space above the electrode surface and above the insulator where the concentrations are C_1 and C_2, respectively. At the interface the following equations hold for all species

$$[13]\quad t > 0,\ x \geq 0,\ r = r_0 \qquad \begin{aligned} C_1(x,r_0,t) &= C_2(x,r_0,t) \\ \left(\frac{\partial C_1}{\partial r}\right)_{r=r_0} &= \left(\frac{\partial C_2}{\partial r}\right)_{r=r_0} \end{aligned}$$

r_0 is the radius of the active disk and the total area of a hexagon unit is approximated by a disk of area $\pi r_0'^2$. The radii are therefore related by

$$[14]\quad \theta = 1 - (r_0/r_0')^2$$

The transformations to converted the problem to dimensionless units and to a space between 0 and 1 are as follows:

$$[15]\quad \begin{aligned} X &= \frac{x}{L} \\ C_A^* &= \frac{C_A}{C_A{}^0} \\ R &= \frac{r}{r_0} \\ R' &= \frac{r' - r_0}{r_0' - r_0} \\ T &= \frac{Dt}{r_0^2} \end{aligned}$$

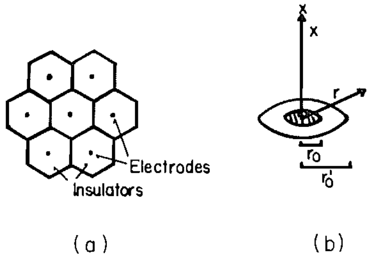

FIG. 1. (*a*) Hexagonal array model; the shaded area is active. (*b*) Cylindrical co-ordinates.

L is some distance into solution where no diffusion occurs during the time of the experiment. The dimensionless diffusion equations are:

(a) Above the active surface

$$[16] \quad \frac{\partial C^*_{A_1}}{\partial T} = \beta \frac{\partial^2 C^*_{A_1}}{\partial X^2} + \frac{1}{R}\frac{\partial C^*_{A_1}}{\partial R} + \frac{\partial^2 C^*_{A_1}}{\partial R^2}$$

where A_1 denotes the species A above the active area. An identical equation results for C_{B_1}.

(b) Above the insulator

$$[17] \quad \frac{\partial C^*_{A_2}}{\partial T} = \beta \frac{\partial^2 C^*_{A_2}}{\partial X^2} + \frac{1}{\gamma(R'\gamma + 1)}\left(\frac{\partial C^*_{A_2}}{\partial R'}\right) + \frac{1}{\gamma^2}\left(\frac{\partial^2 C^*_{A_2}}{\partial R'^2}\right)$$

and

$$\beta = (r_0/L)^2 \text{ and } \gamma = \left(\frac{1}{\sqrt{1-\theta}} - 1\right)$$

where A_2 denotes the species A above the insulator. An identical equation results for B_2. Legendre polynomials have been used for discretization in both the x and r directions. The summations [2] may be substituted into the original diffusion equations.

After substitution, expressions for the time derivative of the concentration of the species as a function of the concentration at the collocation points are obtained. For example, for species A above the active area,

$$[18] \quad \frac{dC^*_{A_1}}{dT} = \beta B_{i,N_X+2} + \sum_{j=2}^{N_X+1} B_{i,j} C^*_{A_1}(X_j,R_k,T) + \sum_{l=2}^{N_R+1} \frac{1}{C_{1,1}V} \times (-\gamma G_l I_{N_R+2,k} + V I_{l,k}) C^*_{A_1}(X_i,R_l,T) + \sum_{l=2}^{N_R+1} - \frac{H_l I_{N_R+2,k}}{VC_{1,1}} C^*_{A_2}(X_i,R_l,T)$$

where $I_{l,k} = E_{l,k}C_{1,1} - E_{1,k}C_{l,1}$

$$V = (H_1 + \gamma G_{N_R+2})$$

$$[19] \quad G_l = \frac{C_{1,N_R+2}C_{l,1}}{C_{1,1}} - C_{l,N_R+2}$$

$$H_l = C_{l,1} - \frac{C_{N_R+2,1}C_{l,N_R+2}}{C_{N_R+2,N_R+2}}$$

This system of ordinary differential equations is solved simultaneously, and the concentrations at the collocation points found. The current is evaluated as

$$[20] \quad i = nFD_0 \int_0^{r_0} \left(\frac{\partial C_A}{\partial x}\right)_{x=0} 2\pi r dr$$

and the dimensioned flux is

$$[21] \quad \frac{i}{\pi r_0'^2} = \frac{2nFC_A{}^0 D_0 \sqrt{\beta}(1-\theta)}{r_0} \int_0^{r_0} \left(\frac{\partial C_A}{\partial x}\right)_{x=0} r dr$$

where the integral is evaluated by a Gaussian quadrature technique in a manner similar to that described earlier in the series (4−7, 33).

Results and discussion

At short times, diffusion to the array will be controlled by the diffusion to the individual microelectrodes, i.e., the diffusion is highly nonlinear. At long times, the "near" hemispherical diffusion fields of adjacent microelectrodes will overlap and the mass transport resembles diffusion to a planar electrode. Practically at long times ($Dt/r_0^2 > 3 \times 10^{-2}$) convection occurs (6).

The value of β, which is a function of L, is given by

$$[22] \quad \beta = \left(\frac{r_0}{L}\right)^2$$

The simulated current is a function of β which is chosen from the following inequality

$$[23] \quad \beta \leq \frac{0.1}{T_{max}}$$

where T_{max} is the total dimensionless time of the experiment (Dt/r_0^2). This condition allows stable integration by the DHPCGL (SSP Library) subroutine, and an iterative change in β for each time step such as [24] was found to be no more effective.

$$[24] \quad \beta_{n+1} = \frac{T_n \beta_n}{T_{n+1}}$$

With the number of internal points equal to six, the C.P.U. time for a complete run from $1/t = 100$ s^{-1} to $1/t = 2$ s^{-1} is about 120 s.

A rule of thumb for natural convection to occur in this case is given by:

$$[25] \quad \begin{cases} \text{At short times:} \\ \quad R_a > 67.94 \text{ for convection to occur (34).} \\ \text{At long times:} \\ \quad R_a > 1100.65 \text{ for convection to occur (35).} \end{cases}$$

Where R_a is the Rayleigh number

$$[26] \quad R_a = \frac{l^4 g}{\mu D}\left(\frac{d\rho}{dx}\right)$$

where D is the diffusion coefficient, ρ the density, g, gravity, and μ is the viscosity. At short times l is the radius of the unit cell and at long times l represents a characteristic dimension of the macroscopic array such as the array radius, if the array takes the form of a disk. R_a is a function of the dimension to the fourth power and for a unit cell convection is very unlikely to occur. However, this is not the case when the macroscopic electrode is considered.

Depending on the value chosen for θ, and r_0 the microelectrodes may be far enough apart to be isolated from each other, or close enough that their diffusion layers overlap. In the former case convection is unlikely to occur and this property has been used in flow rate independent detectors. Results for both these situations are presented.

In Fig. 2 the results of the present technique are compared to those calculated by Lindemann and Landsberg and Reller *et al.*

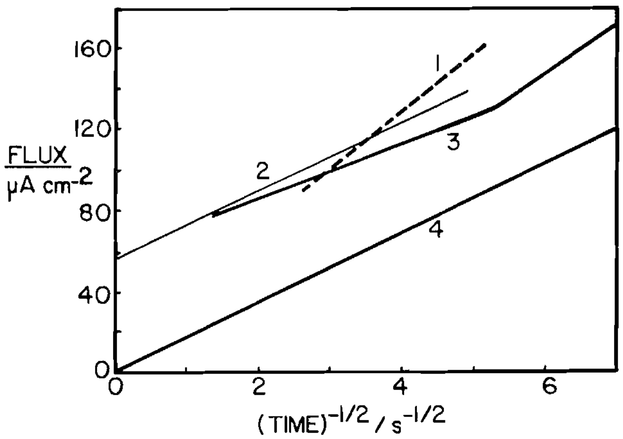

FIG. 2. Flux per total area vs. $t^{-1/2}$. Curve *1*: Lindemann and Landsberg result from ref. 27; curve *2*: result from Reller *et al.* from ref. 27; curve *3*: collocation result with $\theta = 0.99$, $r = 19.9$ μm, $C^0 = 0.01$ *M*, $D = 1 \times 10^{-5}$ cm²/s, $\beta = 1.9$; curve *4*: flux per total area by Cottrell equation.

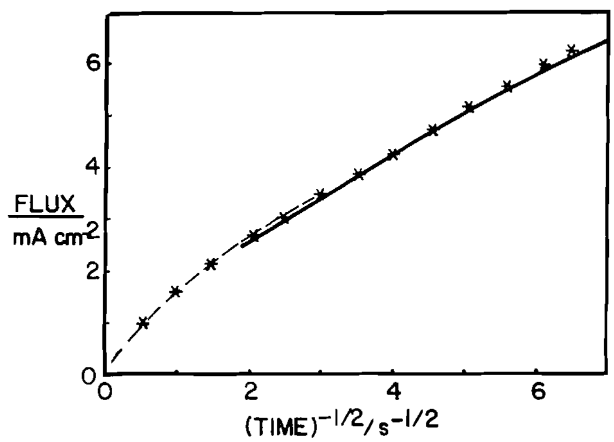

FIG. 3. Flux per total area vs. $t^{-1/2}$. *: estimated from Reller *et al.* in ref. 27; ---: calculated from equation from Shoup and Szabo, Table 2 in ref. 25 with $\theta = 0.528$, —— orthogonal collocation result with $C^0 = 0.01$ *M*, $D = 1 \times 10^{-5}$ cm²/s, $\theta = 0.53$, $\beta = 0.1$, $r = 43.9$ μm.

in ref. 27 for a highly blocked surface, i.e., 99% inactive, ($\theta = 0.99$, $r_0' = 199.9$ μm, $r_0 = 19.9$ μm). Our results agree with those of Reller *et al.* and extrapolation to infinite time, in the absence of convection, yields a finite current, characteristic of individual hemispherical diffusion at each microelectrode. The current per unit area is seen to be greater for active sites distributed in an insulator than for the pure semi-infinite linear diffusion. In Fig. 3 our results are compared with those of Reller *et al.* from Ref. 27 and Shoup and Szabo from ref. 25. In this case the blocked area is of the same order as the active area and at $1/\sqrt{t} = 2$ s$^{-1/2}$ the diffusion layers of the microelectrodes have overlapped forming a blanket diffusion layer. Thus convection is likely to be able to complicate the mass transport. As can be seen, however for intermediate times there is excellent agreement among the three simulations. In all the results presented, six internal collocation points were used and β was found using the inequality (23).

In Fig. 4 a comparison is made between the experimental results from curve 1 in ref. 36, the calculated results from ref. 25 with $\theta = 0.841$ and our calculations. Our results compare well with the experimental results and those of Reller *et al.* in ref. 27. However, at long time periods the outer boundary conditions are violated. This problem is alleviated using a greater number of collocation points which is only necessary for larger values of θ.

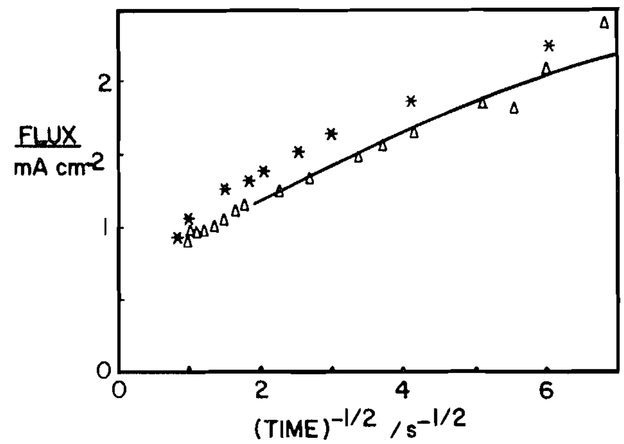

FIG. 4. Flux per total area vs. $t^{-1/2}$. *: calculated from Table 7 in ref. 25, with $\theta = 0.841$; △: experimental data estimated from curve *1* in ref. 36; ——: result from orthogonal collocation, $D = 6.8 \times 10^{-6}$ cm²/s, $C = 0.01$ *M*, $\theta = 0.84$, $r = 12.5$ μm, $\beta = 0.01$.

Since heterogeneous kinetics can be observed more readily at arrays of microelectrodes due to the accelerated rate of mass transport, other electrochemical experiments are useful in the kinetic analysis. Cyclic voltammetry is one useful technique for these studies, and is currently under investigation.

Comparison of calculation times between the orthogonal collocation technique and explicit or implicit fixed and variable grid finite difference methods still supports the conclusion reached in earlier reports; the calculation time required for the collocation method is still at least an order of magnitude faster than the finite difference schemes for the same local error. The initial mathematical rigor, however, is somewhat more demanding.

Conclusion

Orthogonal collocation was used to simulate the diffusion process at an array of ultramicroelectrodes. Despite the fact that no account was taken of the current and potential distributions across the face of each electrode, the simulated curves compare well with the experimental results. A more complete solution, taking into account current and potential distributions across the face of the electrode is necessary for cyclic voltammetry. As can be seen in Fig. 2, the enhancement of current compared to that of semiinfinite linear diffusion can be used for more efficient recovery of metals or catalysts. The next logical progression in the series is three dimensional arrays of ultramicroelectrodes in the form of bipolar fluidized bed reactors which are currently under consideration.

A. C. HOPKINSON and M. H. LIEN. Can. J. Chem. **63**, 3582 (1985).

Ab initio molecular orbital calculations with a 6-31G* basis set have been used to optimise structures for CX^+, $CHX^{+\bullet}$, CHX (both singlets and triplets), H_2CX^+ and H_3CX (X = H, CH_3, NH_2, OH, F, CN, and NC). Single point calculations were then performed on the 6-31G* optimised structures using a configuration interaction method involving all single and double excitations from the valence shell. Stabilisation energies for the carbocations are compared with those already reported for H_2CX^+. For the carbenes the single-triplet energy gap is examined as a function of substituent and the stabilisation energies of the singlet carbenes are compared with those of the isoelectronic carbocations H_2CX^+. Proton affinities are reported for the singlet carbenes and are compared with the proton affinities of similarly substituted ethylenes, $H_2C{=}CHX$.

A. C. HOPKINSON et M. H. LIEN. Can. J. Chem. **63**, 3582 (1985).

On a utilisé des calculs d'orbitales moléculaires *ab initio* avec une base 6-31G* pour optimiser des structures pour CX^+, $CHX^{+\bullet}$, CHX (tant sous forme de singulets que de triplets), H_2CX^+ et H_3CX (X = H, CH_3, NH_2, OH, F, CN et NC). Faisant appel à une méthode d'interaction de configuration impliquant toutes les excitations simples et doubles des couches de valence, on a alors effectué des calculs à point unique sur des structures optimisées en 6-31G*. On a comparé les énergies de stabilisation des carbocations avec celles rapportées antérieurement pour le H_2CX^+. Dans le cas des carbènes, on a examiné la différence d'énergie singulet/triplet en fonction du substituant; de plus, on compare les énergies de stabilisation des carbènes singulets avec celles des carbocations isoélectroniques H_2CX^+. On rapporte les affinités protoniques des carbènes triplets et on les compare avec les affinités protoniques des éthylènes $H_2C{=}CHX$ substitués d'une façon similaire.

[Traduit par le journal]

It has long been established that increasing the substitution at a carbocation centre increases the stability of the ion. Tertiary cations, RR′R″C$^+$, then, are the most stable and the primary carbenium ions, RCH_2^+, are the least stable. In tertiary cations all three groups are potential π-donors and the tertiary ions $(CH_3)_2CX^+$ show considerably less substituent dependence than the primary ions H_2CX^+ (1−6). Indeed, the highest substituent sensitivity ever observed is for the formation of H_2CX^+ from electron impact on H_3CX in the gas phase (7).

Substituents containing a heteroatom with a lone pair of electrons in the α-position (X = NH_2, OH, and F) function both as strong π-donors to the "vacant" p-orbital on C^+ and also as σ-acceptors. This class of substituents is the most effective at stabilising carbenium ions. Recently there has been considerable interest, both experimental (8−12) and theoretical (1,2,4−6) in carbenium ions containing an α-substituent which is usually both σ- and π-electron-withdrawing (X = NO_2, CHO, COOR, CN).[1] Here the substituents are destabilising, but in primary carbenium ions the destabilisation is less than expected on the basis of inductive electron-withdrawal. Calculations (5, 6) have shown that in these ions the substituents function as π-donors to the "vacant" *p*-orbital on the electron-deficient carbocation carbon.

All the theoretical studies to date have focussed on substituent effects in ions in which the cationic carbon has three σ bonds. Having observed that primary carbocations are more substituent dependent than tertiary carbocations it seemed possible that ions $CHX^{+\bullet}$ and CX^+ would have even greater substituent dependence. We now report our *ab initio* molecular orbital study of ions CX^+, $CHX^{+\bullet}$, and H_2CX^+ where X is H, CH_3, NH_2, OH, F, CN, and NC.

Carbenes, CHX, also contain an electron-deficient carbon atom and α-substituents having a lone pair of electrons are known to stabilise the singlet state (13−20). Here there is no positive charge to assist in attracting the lone pair to the carbene centre and substituent effects are therefore smaller than in the carbocations. Carbenes have previously been examined at various levels of theory (15−20) and we have included them here to permit comparison with the carbocations.

All molecules and ions were subjected to geometry optimisation at the 6-31G* level of theory (21) using the gradient techniques (22, 23) in the MONSTERGAUSS program (24). Single point calculations were then performed with a CI program using the direct CI method (25) and including all single and double excitations from the valence shell to all the virtual orbitals.

Results

(a) Carbocations

The effect of X in the carbocations relative to its effect in methane can be assessed from reactions [1], [2], and [3] using the total energies reported in Table 1. A positive energy for these reactions (i.e. an endothermic reaction) indicates that the substituent is more stabilising in the cation than in methane and we define the substituent stabilisation energy as ΔE for reactions [1]−[4]. With the exception of the cyano group, all the substituents are stabilising (Table 2), with the largest effect being in CX^+ and the smallest in H_2CX^+.

[1] $CX^+ + CH_4 \rightarrow H_3CX + CH^+$

[2] $HCX^{+\bullet} + CH_4 \rightarrow H_3CX + CH_2^{+\bullet}$

[1] Indirectively-destabilised carbocations have been reviewed in ref. 12.

[a]At the 6-31G*//6-31G* level the open cation is the more stable while at the CI//6-31G* level the symmetrically bridged ion has the lower energy (29). At both levels of theory the two structures are very close in energy and we report energies for the open cation here.

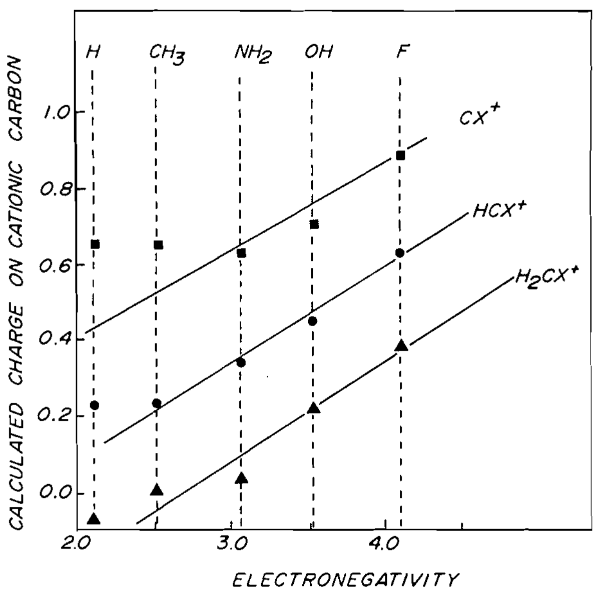

FIG. 1. Plot of calculated charge on the cationic carbon (6−31G*//6-31G*) against the electronegativity (Allred-Rochow electronegativities from ref. 27) of the heteroatom atom attached to the cationic carbon.

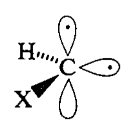
[3] $H_2CX^+ + CH_4 \rightarrow H_3CX + CH_3^+$

Inclusion of correlation energy increases all the stabilisation energies by 10−12 kcal/mol. As in other carbocations, π-donors produce the most dramatic stabilisation with the amino group being the most effective. The cyano group is destabilising in *all* the carbocations, with the destabilisation being smallest in CCN^+ and largest in H_2CCN^+. From these results then we find the increase in substituent stabilisation with the decrease in ion size, as first noted for ions $(CH_3)_2CX^+$, CH_3CHX^+, and CH_2X^+, is continued as the size of the ion is further decreased to $CHX^{+\bullet}$ and CX^+.

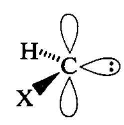
In all the cations hydrogen is the least electronegative element attached to the cationic carbon and most of the positive charge of the ion is carried by the hydrogens. Consequently for a given substituent X the positive charge on the cationic carbon is largest in CX^+ and smallest in CH_2X^+ (e.g. when X is NH_2 the charge on C^+ is +0.624 in CNH_2^+, +0.324 in $HCNH_2^{+\bullet}$, and +0.038 in $H_2CNH_2^+$). For each series of carbocations the total charge on C^+ increases roughly linearly with the electronegativity of the heteroatom (27) (Fig. 1). The amino group is the strongest π-donor (Table 2) but for *each* substituent the amount of π-donation increases slightly on going from CX^+ to $CHX^{+\bullet}$ to H_2CX^+, notwithstanding the increasing separation between C^+ and X along this series of ions. The total positive charge on X decreases from CX^+ to H_2CX^+, and since π-donation is smallest in CX^+, then in the three types of carbocations —C^+ must be the strongest σ-acceptor and —CH_2^+ the weakest.

(b) Carbenes

Methylene is a ground state triplet (**1***a*), lying ~10 kcal/mol below the singlet state (**1***b*) (28). If the substituent X is a



1*a*



1*b*

π-donor then, as in carbocations, the singlet structure is stabilised by donation into the "vacant" *p*-orbital on the carbene carbon. This interaction has been studied previously at various levels of theory (17−20) and while our calculations used a larger basis set than in most studies, the overall trends and conclusions which we find are in agreement with the literature. At the 6-31G*//6-31G* level the singlet−triplet splitting (S−T gap) is negative for the two strongest π-donors, NH_2 and OH, indicating that the singlet states are lower in energy (Table 3). At the CI//6-31G* level, as expected due to the larger correlation energy of the singlets, all the singlets are lowered in energy relative to the triplets and at this level the singlet state is now lower than the triplet for CHF.

In the carbenes studied here π-donation, where possible, is the dominant interaction and clearly stabilises the singlet relative to the triplet. However, the cyano substituent, which usually functions as both a σ- and π-acceptor, is also weakly stabilising (by 4 kcal/mol at 6-31G*//6-31G*) and here again the stabilisation can be attributed to π-effects. In singlet cyanomethylene, as in carbocations, the cyano group functions as a π-donor, although the magnitude of the donation is smaller

than in carbocations (in HC(CN) the π-population of the carbene p-orbital is 0.109e, compared with the π-population of 0.261e on the cationic carbon of $HC(CN)^{+\bullet}$). In triplet cyanomethylene the cyano group reverts to its normal role as a π-acceptor, although the π-donation from the carbene carbon is very small (0.036e).

The S−T gap for a large number of carbenes has been found to correlate with Δq_π, the change in π-electron density of benzene on introducing the substituent X (20). We find that the S−T gap from our calculations correlates with Δq_π (correlation coefficient 0.965 at 6-31G*//6-31G*, 0.995 at CI//6-31G*), and also shows a similar linear correlation with the π-density of the "vacant" p-orbital on the carbene carbon of the singlet (correlation coefficients 0.954 at 6-31G*//6-31G* and 0.995 at CI//6-31G*). For both plots the cyano and isocyano substituents deviate the most and as these two substituents were not considered at the CI level, then the correlations with the CI data are better.

Reaction [4] has been used to estimate substituent stabilisation of carbenes over and above any stabilisation in methane (17). All substituents are stabilising in

[4] $HCX + CH_4 \rightarrow CH_2 + H_3CX$

both the singlets and the triplets, but the only large effects are for π-donors in the singlets (see Table 3). As with the carbocations inclusion of correlation energy increases the stabili-

TABLE 4. Proton affinities (kcal/mol) of singlet carbenes CHX and alkenes $H_2C{=}CHX$

[a]Using the bridged $C_2H_5^+$ ion, the proton affinities are 243.2 kcal/mol (6-31G*//6-31G*) and 247.9 kcal/mol (CI//6-31G*).

sation energies by between 2 and 10 kcal/mol. For singlet carbenes containing π-donors the stabilisation is smaller than in the cations H_2CX^+ when X is NH_2 (61.6 kcal/mol compared with 98.8 kcal/mol) and X is OH (51.2 kcal/mol compared with 64.7 kcal/mol), but the stabilisation of CHF is greater than that of H_2CF^+(32.9 kcal/mol compared with 23.9 kcal/mol). Also the cyano group which is destabilising in all carbocations is weakly stabilising in both singlet and triplet carbenes.

(c) Proton affinities of singlet carbenes

The proton affinity of a carbene is the negative of the enthalpy of the reaction described by reaction [5]. The parent carbene (X = H) has a proton affinity of 224.6 kcal/mol at the 6-31G*//6-31G* level and 220.7 kcal/mol at CI//6-31G*

[5] $CHX + H^+ \rightarrow H_2CX^+$

(Table 3). These are considerably higher than the proton affinity of ethylene (reaction [6], X = H) which is calculated to be 175 kcal/mol at the 6-31G*//6-31G* level (6).

[6] $H_2C{=}CHX + H^+ \rightarrow H_3C{-}CHX^+$

The product of protonation of ethylene, the ethyl cation $CH_3CH_2^+$, is stabilised by hyperconjugation between the methyl group and the cationic carbon (at the 6-31G*//3-21G level the stabilisation is 30 kcal/mol (6). This stabilisation is measured relative to that afforded by the hydrogen atom in CH_3^+, so the high proton affinity of singlet CH_2 relative to that of C_2H_4 results from the high energy of singlet CH_2.

The inclusion of correlation energy in the protonation reaction has little effect on the calculated proton affinities of any of the five carbenes examined. π-Donating substituents are weakly stabilising in ethylene (28) but are strongly stabilising in α-X-ethyl cations (6), with the result that the proton affinities of alkenes $H_2C{=}CHX$ are larger for π-donors and are very substituent dependent (Table 4). The cyano group is weakly stabilising in acrylonitrile, $H_2C{=}CH(CN)$ (28), and is destabilising in $CH_3CH(CN)^+$ (6) and consequently the proton affinity of acrylonitrile is 18.2 kcal/mol less than that of ethylene. By comparison, in the protonation of singlet carbenes, both CHX and CH_2X^+ are strongly stabilised by π-donors and the proton affinities of the carbenes are therefore less substituent dependent than those of the ethylenes. For example, the strongest π-donor, the NH_2 group, increases the proton affinity of methylene by 31.9 kcal/mol compared with an increase of 66.1 kcal/mol in ethylene.

Conclusions

The increase in dependence on substituents previously observed on going from a tertiary carbenium ion to a primary carbenium ion is continued when the coordination at the cationic carbon is reduced from three. The stabilisation energies of ions $CHX^{+\bullet}$ are all larger than those of CH_2X^+ but the differences are less than 7 kcal/mol, reflecting the fact that the electronic structures at the cationic carbons are similar in the two classes of ions ("sp^2 hybridised" with a vacant p-orbital which interacts with π-donors). In CX^+ the carbon atom is "sp hybridised" and there are two vacant p-orbitals available to interact with the substituent; the substituent effects in ions CX^+ are therefore much larger than in $CHX^{+\bullet}$ and CH_2X^+. Using the amino-substituted carbocations as an example then the stabilisation energies (kcal/mol) on going from the tertiary carbenium ion to CX^+ are 63.4 for $(CH_3)_2C^+NH_2$, 72.3 for $(CH_3)HC^+NH_2$, 86.5 for $H_2C^+NH_2$, 89.6 for $HCNH_2^{+\bullet}$, and 114.6 for CNH_2^+ (all calculations at 3-31G* level). In carbocations the α-cyano group is a weak π-donor but the overall effect is destabilising even in CCN^+. Nevertheless the destabilisation by cyano is smallest in CCN^+ (stabilisation energy is -5.4 kcal/mol) and becomes progressively larger up to $(CH_3)_2C^+CN$ (stabilisation energy -19.5 kcal/mol).

Substituents are only weakly stabilising in triplet carbenes, CHX, but in the corresponding singlets there is strong $\pi \rightarrow p$ stabilisation as in carbocations. For the strongest π-donors, NH_2 and OH, and also for CH_3 which interacts with adjacent vacant p-orbitals through hyperconjugation, the substituent stabilisation is larger in $CHX^{+\bullet}$ than in CHX. However, for the other substituents the stabilisation is larger in the singlet carbenes CHX and the cyano group, which destabilises all carbocations, is weakly stabilising.

L'activité et le coefficient d'activité de l'eau dans les mélanges eau – nitrate d'éthylammonium (NEA) entre l'eau pure et le sel pur fondu ont été déterminés par des mesures de pressions de vapeur à 298,15 K. Le comportement de l'eau dans la gamme de fraction molaire du sel, comprise entre 0,3 et 1 peut être décrit au moyen d'une relation linéaire entre le logarithme du coefficient d'activité de l'eau γ_E, la fraction molaire, X du sel et l'enthalpie libre de dilution de l'eau à dilution infinie dans le NEA pur, $\Delta G_E^{\ominus}$:

$$\ln \gamma_E = \frac{\Delta G_E^{\ominus}}{RT} X$$

L'interprétation des résultats expérimentaux a également été tentée à l'aide de l'équation B.E.T. Il apparaît que dans les mélanges eau–NEA, le terme énergétique relatif à l'adsorption de l'eau est voisin de zéro. On montre que dans ce cas précis, la relation empirique proposée et l'équation B.E.T. conduisent à une même description du comportement de l'eau et du sel, tant au plan de l'enthalpie libre qu'à celui des volumes.

M. BIQUARD, P. LETELLIER, and M. FROMON. Can. J. Chem. **63**, 3587 (1985).

The activity and activity coefficient of water in water and ethylammonium nitrate (EAN) mixtures were determined by vapor pressure measurements between pure water and pure fused salt at 298.15 K. For a wide range of mole fractions of salt, ($0.3 < X \leq 1$) the behaviour of water can be described very accurately by a "one parameter" empirical equation which involves activity coefficient, γ_E, mole fraction of EAN, and limiting Gibbs energy of the dilution of water in pure fused salt, $\Delta G_E^{\ominus}$:

$$\ln \gamma_E = \frac{\Delta G_E^{\ominus}}{RT} X$$

Interpretation of experimental results was also attempted by use of the B.E.T. equation. It appears that the energy, $\Delta E_d = E - E_L$, in those solutions is very low. Partial molar volumes of water and salt are also discussed in relation to empirical and B.E.T. equations. It can be shown that the two equations lead to similar results.

Introduction

L'utilisation d'un sel fondu à la température ambiante, le nitrate d'éthylammonium, NEA, (T_f = 14°C), miscible à l'eau en toute proportion, permet l'étude thermodynamique à 298,15 K des interactions qui s'établissent entre un électrolyte et l'eau, pour une gamme de composition étendue, comprise entre l'eau pure et le sel pur fondu.

Il a déjà été exposé, dans une publication antérieure (1), une étude volumétrique des mélanges eau–NEA au cours de laquelle il a été montré que le volume molaire partiel de l'eau varie linéairement avec sa fraction molaire dans le milieu.

Afin de juger de la généralité de cette dernière propriété et de ses implications sur les autres grandeurs thermodynamiques, la détermination des activités de l'eau et du sel a été entreprise dans ces mêmes milieux en utilisant une méthode précise de mesure de pressions de vapeur.

I. Technique expérimentale et résultats expérimentaux

Technique expérimentale

(a) Le nitrate d'éthylammonium (NEA) a été préparé par une technique proche de celle proposée par Evans *et al.* (2): Une solution d'éthylamine à 33% (Prolabo) est neutralisée par de l'acide nitrique de densité égale à 1,33 (Prolabo) dans un becher refroidi dans un bain de glace. La solution saline est concentrée à l'évaporateur rotatif à 60°C pendant 3 h et l'eau de la solution concentrée est éliminée par séchage sous vide pendant 3 jours en présence de P_2O_5. Le point de fusion du sel a été trouvé égal à 14°C.

(b) Les tensions de vapeur ont été mesurées à l'aide d'une jauge de précision Texas Instrument (3). Après dégazage par congélation et fusion successives, les solutions sont plongées dans un bain thermostaté à 298,15 K. La précision obtenue sur les tensions de vapeur est de $\pm 1 \times 10^{-2}$ Torr (1 Torr = 133.3 Pa).

(c) Les solutions ont été préparées par gravimétrie à partir d'eau bidistillée et de sel fondu pur.

Résultats expérimentaux

Les pressions de vapeur mesurées au-dessus des différentes solutions de fraction molaire X en NEA sont reportées dans le tableau 1.

La tension de vapeur de l'eau pure, P_E^0, a été déterminée à 298,15 K et trouvée égale à 23,75 Torr, ce qui correspond à la valeur généralement admise (4).

Les mesures réalisées avec le sel pur conduisent à une pression de vapeur inférieure à 4×10^{-2} Torr. Il est donc légitime de considérer que la pression de vapeur mesurée au-dessus des solutions correspond uniquement à celle de l'eau.

L'activité et le coefficient d'activité de l'eau, référés à l'eau pure, ont été calculés au moyen des relations:

$$a_E = \frac{P}{P_E^0} \quad \text{et} \quad \gamma_E = \frac{P}{P_E^0(1-X)}$$

où X est la fraction molaire du sel dans la solution. Il n'a été apporté aucune correction de fugacité des gaz dans le calcul des activités de

l'eau, le coefficient de fugacité étant très proche de l'unité dans les conditions expérimentales.[3] Les valeurs de a_E et γ_E sont également regroupées dans le tableau 1.

II. Interprétation

L'analyse des résultats expérimentaux sera envisagée dans le cadre de différents modèles de solution exposés dans la littérature.

Toutefois ce travail faisant suite à une étude se rapportant aux volumes molaires partiels de l'eau et du NEA dans leurs différents mélanges, il est indispensable de prendre en compte les résultats obtenus à cette occasion. À ce titre, le paragraphe ci-dessous sera consacré aux conséquences, sur les potentiels chimiques, des principales relations expérimentales établies pour les volumes molaires partiels.

Comportement de l'eau dans les mélanges eau–NEA

Il a été montré (1) que les variations du volume molaire partiel de l'eau, dans les solutions salines de fraction molaire X supérieure à 5×10^{-2} pouvaient être décrites au moyen de la relation empirique:

$$[1] \quad \bar{V}_E = V_E^0 + (V_E^\ominus - V_E^0)\, X$$

dans laquelle V_E^0 et $V_E^\ominus$ sont respectivement les volume molaire et volume molaire partiel de l'eau infiniment diluée dans le NEA. L'expression du potentiel chimique, de l'eau, référé à

$$[2] \quad \mu_E = \mu_E^0 + RT \ln(1 - X) + RT \ln \gamma_E$$

l'eau pure permet d'établir, par dérivation par rapport à la pression, à *température et composition constantes*, une relation entre le coefficient d'activité γ_E et le volume molaire partiel de l'eau.

$$[3] \quad \bar{V}_E = V_E^0 + RT \left[\frac{\partial \ln \gamma_E}{\partial P}\right]_{T,X}$$

L'identification des relations [1] et [3] conduit à:

$$[4] \quad \left[\frac{\partial \ln \gamma_E}{\partial P}\right]_{T,X} = \left[\frac{V_E^\ominus - V_E^0}{RT}\right] X$$

Les potentiels chimiques normaux de l'eau pure, μ_E^0, et de l'eau infiniment diluée dans le NEA, $\mu_E^\ominus$, peuvent être introduits dans l'équation [4]

$$\left[\frac{\partial \ln \gamma_E}{\partial P}\right]_{T,X} = \frac{X}{RT}\left[\frac{\partial(\mu_E^\ominus - \mu_E^0)}{\partial P}\right]_{T,X}$$

soit encore si l'on convient de noter $\Delta G_E^\ominus$, l'enthalpie libre de dilution de l'eau à dilution infinie dans le sel pur:

$$\Delta G_E^\ominus = \mu_E^\ominus - \mu_E^0$$

$$[5] \quad \left[\frac{\partial \ln \gamma_E}{\partial P}\right]_{T,X} = \frac{X}{RT}\left[\frac{\partial \Delta G_E^\ominus}{\partial P}\right]_{T,X}$$

Si l'on suppose la validité de l'équation [5] vérifiée pour toute pression, son intégration en fonction de cette variable peut être envisagée à fraction molaire et température constantes, entre la pression atmosphérique et une pression non définie de référence:

$$[6] \quad \ln \gamma_E = \frac{\Delta G_E^\ominus}{RT} X + f(X)$$

$f(X)$ est une constante d'intégration, dont la valeur dépend de la pression choisie en référence; $f(X)$ est susceptible de varier avec la composition du mélange et la température. Sa valeur est fixée pour le sel pur ($X = 1$). Dans ce milieu, l'eau apparaît comme un soluté possédant les propriétés de l'état infiniment dilué. Par définition, son coefficient d'activité, par rapport à cette dernière référence est égal à l'unité, et son coefficient d'activité référé à l'eau pure tend vers une limite finie.

$$[7] \quad \lim_{X \to 1} (\ln \gamma_E) = \frac{\Delta G_E^\ominus}{RT}$$

La relation [6] permet de retrouver cette condition avec:

$$[8] \quad \lim_{X \to 1} f(X) = 0$$

La relation [6] montre qu'une variation linéaire, observée pour les volumes molaires partiels, n'implique pas nécessairement une propriété identique pour les potentiels chimiques. Afin de juger de l'importance relative des quantités intervenant dans l'équation [6], les valeurs de ln γ_E ont été reportées sur la figure 1 en fonction de la fraction molaire du NEA.

Compte tenu de l'incertitude inhérente aux valeurs des coefficients d'activité de l'eau, particulièrement pour les mélanges les plus riches en sel, il apparaît que les points expérimentaux pour $0,3 < X \leq 1$ se placent convenablement sur une droite de pente égale à $-0,370$ passant par l'origine.

Cette propriété permet d'être assuré que la constante d'in-

[3] La relation entre le coefficient de fugacité et le premier terme de l'équation du viriel B_{11} pour une phase vapeur pure est:

$$\Gamma_i = \frac{f_i}{p_i} = \exp\left(-\frac{B_{11} P_i}{RT}\right)$$

Dans le cas de l'eau:

$$B_{11} = -1056 \text{ mL mol}^{-1}$$

soit pour l'eau *pure* à 298,15 K:

$$\Gamma_i = 1,0013$$

Les pressions de vapeur d'eau des mélanges eau–sel étant inférieures à celle de l'eau pure, les coefficients de fugacité en seront d'autant plus proches de l'unité.

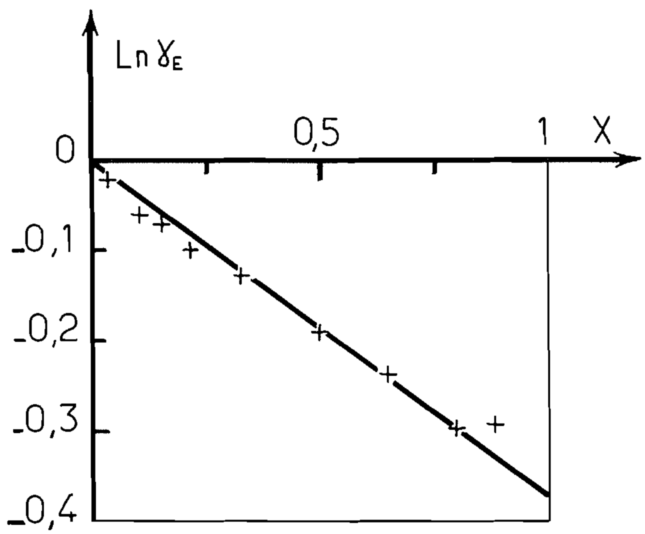

FIG. 1. Variation de ln γ_E avec la fraction molaire du sel dans le mélange eau–NEA.

tégration $f(X)$, nulle dans le sel pur, garde une valeur suffisamment faible pour être négligée dans la gamme $0{,}3 < X \leq 1$. Dans ce domaine de concentration les valeurs du coefficient d'activité de l'eau, référé à l'eau pure, sont décrites par:

$$[9] \quad \ln \gamma_E = \frac{\Delta G_E^\ominus}{RT} X$$

dans laquelle $\Delta G_E^\ominus = -919$ Joules. La relation [9] constitue un cas particulier de l'équation [6] pour une pression, une température et un domaine de composition donnés. L'activité de l'eau, a_E, peut ainsi être calculée à partir de la relation:

$$[10] \quad a_E = (1 - X)\, e^{\frac{\Delta G_E^\ominus}{RT} X}$$

et sa pression de vapeur par:

$$[11] \quad P_E = P_E^0 (1 - X)\, e^{\frac{\Delta G_E^\ominus}{RT} X}$$

Les valeurs de P_E calculées au moyen de l'équation [11] sont reportées dans le tableau 2 en regard de celles déterminées expérimentalement et l'on conviendra de leur excellent accord dans la gamme de composition considérée.

Les courbes de pression de vapeur de l'eau correspondantes à l'équation [11] (courbe a), aux lois des solutions idéales pour le sel non dissocié (courbe b) et totalement dissocié (courbe c) sont reportées sur la figure 2. Les points expérimentaux se placent sur la courbe a dans la gamme des fractions molaires $0{,}3 < X \leq 1$.

L'équation [11] permet de déterminer la valeur de la constante de Henry de l'eau dans le sel pur fondu. Elle correspond à la valeur de la tangente à la courbe $P_E = f(1 - X)$ pour $X = 1$:

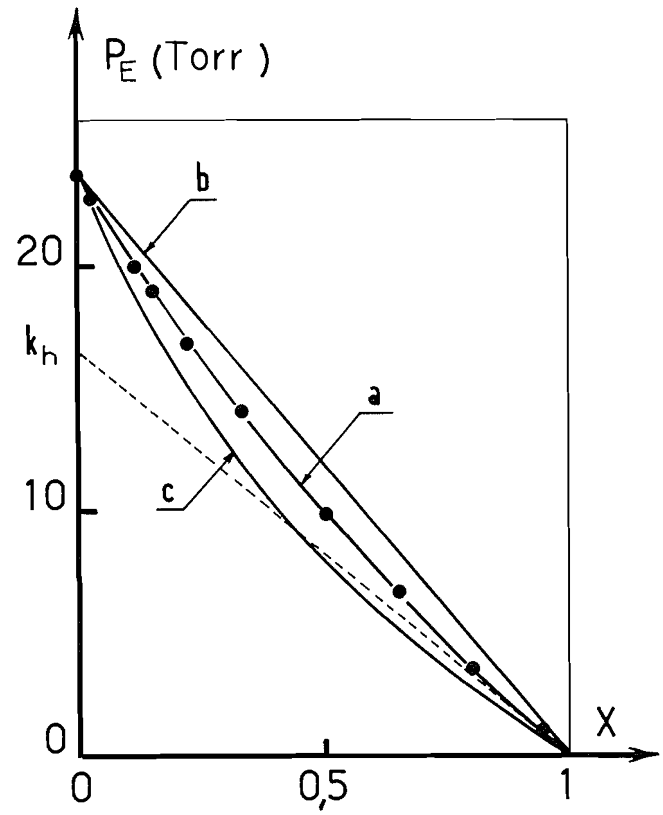

FIG. 2. Variation de la pression de vapeur de l'eau en fonction de X. Courbe a, calculée à partir de l'équation [11]. Courbe b, comportement idéal pour le sel non dissocié. Courbe c, comportement idéal pour le sel totalement dissocié. Les points expérimentaux sont figurés par des cercles.

$$[12] \quad k_h = \lim_{X \to 1} \left[\frac{\partial P_E}{\partial(1 - X)}\right] = P_E^0\, e^{\frac{\Delta G_E^\ominus}{RT}}$$

soit dans le cas présent k_h (Torr, X) = 16,4. La droite de Henry est tracée en pointillés sur la figure 2.

Comportement du sel dans les mélanges eau–NEA dans la gamme de composition $0{,}3 < X \leq 1$

Le potentiel chimique du sel μ_S peut être calculé en fonction de X, en utilisant la relation de Gibbs–Duhem.

Le potentiel chimique de l'eau s'écrit (relations [2] et [9]):

$$[13] \quad \mu_E = \mu_E^0 + RT \ln(1 - X) + \Delta G_E^\ominus X$$

La relation de Gibbs–Duhem implique que:

$$(1 - X)\, d\mu_E + X\, d\mu_S = 0$$

soit:

$$[14] \quad d\mu_S = (RT - \Delta G_E^\ominus) \frac{dX}{X} + \Delta G_E^\ominus\, dX$$

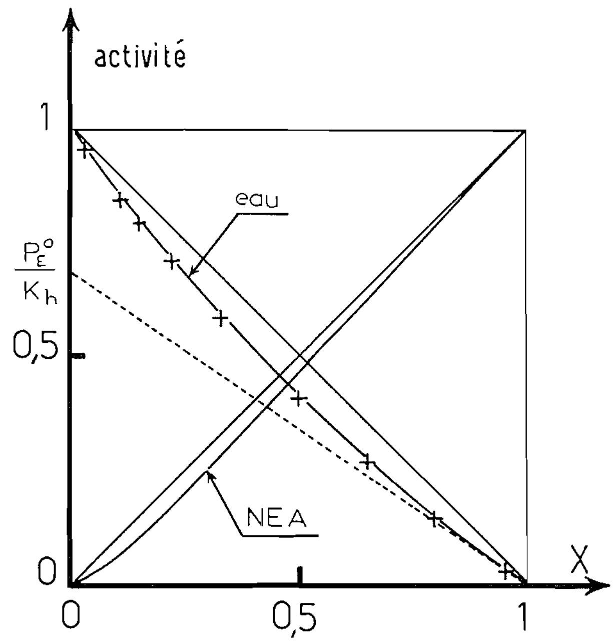

FIG. 3. Variation des activités de l'eau et du NEA avec X (calculées au moyen des équations [9] et [16]). Les points expérimentaux sont figurés par des croix.

L'intégration par rapport à X de l'équation [14], en se fixant comme borne l'état correspondant au sel lorsqu'il est pur ($X = 1$; $\mu_S = \mu_S^0$), conduit à:

$$[15] \quad \mu_S = \mu_S^0 + RT\left[1 - \frac{\Delta G_E^\ominus}{RT}\right]\ln X - \Delta G_E^\ominus (1 - X)$$

Le coefficient d'activité du sel référé au sel pur γ_S s'écrit alors:

$$[16] \quad \ln \gamma_S = -\frac{\Delta G_E^\ominus}{RT}(\ln X + (1 - X))$$

Les variations de l'activité de l'eau et du sel sont représentées sur la figure 3. Les points reportés correspondent aux résultats expérimentaux obtenus pour l'eau. On remarque que le sel présente un comportement quasi idéal pour X supérieur à 0,80.

Conclusion

Comme on a pu le constater, les propriétés de l'eau et du NEA dans leurs mélanges $0{,}3 < X \leq 1$ sont remarquablement décrites tant au plan de l'enthalpie libre qu'à celui des volumes molaires partiels, par *l'équation [9] et ses conséquences.* Toutefois l'examen de modèles de solution déjà établis montre que les résultats expérimentaux peuvent être décrits dans la même zone de composition avec une précision comparable par d'autres systèmes d'équations.

Comportements modèles

L'équation B.E.T.

D'une manière générale, l'interprétation du comportement de l'eau et du sel dans les solutions salines concentrées s'effectue au moyen de différents modèles dérivant de celui proposé initialement par Brunauer, Emmett et Teller (équation B.E.T.) (5). L'équation B.E.T. a été adaptée par Stokes et Robinson (6) pour décrire les propriétés de l'eau dans les solutions d'électrolyte concentré:

$$[17] \quad \frac{a_E \cdot X}{(1 - X)(1 - a_E)} = \frac{1}{Cr} + \frac{C - 1}{Cr} a_E = Y$$

On conviendra de noter Y cette fonction. Dans cette relation, C est donné approximativement par:

$$[18] \quad C = e^{-\frac{E - E_L}{RT}} = e^{-\frac{\Delta E_d}{RT}}$$

E est l'énergie molaire d'adsorption de l'eau sur un site disponible dans le sel fondu; E_L est l'énergie molaire de condensation de l'eau; r est le rapport du nombre de sites disponibles, au nombre de moles de sel dans le sel pur. La validité de cette relation a été discutée pour de très nombreux systèmes (à titre d'exemples 7–12).

Lorsqu'elle est vérifiée, l'équation B.E.T. fait intervenir des paramètres liés aux grandeurs thermodynamiques caractéristiques de la dilution de l'eau pure à dilution infinie dans le sel fondu. En effet, lorsque le sel devient pur ($X = 1$), le coefficient d'activité γ_E de l'eau tend vers une limite finie (éq. [7]).

$$[19] \quad \lim_{X \to 1} (\gamma_E) = \frac{1}{Cr} = e^{\frac{\Delta G_E^\ominus}{RT}}$$

soit encore en tenant compte de l'équation [18]:

$$[20] \quad \ln r = -\frac{1}{RT}(\Delta G_E^\ominus - \Delta E_d)$$

Si l'on considère de plus que l'énergie $\Delta E_d = E - E_L$ peut ne constituer dans le cas général qu'une partie de l'enthalpie de dilution de l'eau dans le sel fondu (on supposera que le terme relatif au travail est suffisamment faible pour être négligé), le bilan thermique relatif à cette opération prend la forme:

$$\Delta H_E^\ominus = H_E^\ominus - H^0 = \Delta E_d + \Delta H_E^i$$

ΔH_E^i représente l'éventuelle contribution thermique des interactions autres que celles impliquées par l'adsorption. L'équation [20] devient alors:

$$\ln r = -\frac{1}{RT}(\Delta G_E^\ominus - \Delta H_E^\ominus + \Delta H_E^i)$$

et si l'on convient de noter $\Delta S_E^\ominus$ l'entropie de l'eau à dilution infinie:

$$[21] \quad \ln r = +\frac{\Delta S_E^\ominus}{R} - \frac{\Delta H_E^i}{RT}$$

ou encore:

$$[22] \quad r = \frac{e^{\Delta S_E^\ominus / R}}{e^{\Delta H_E^i / RT}}$$

La vérification de la validité de l'équation B.E.T. a été tentée à partir des valeurs de l'activité de l'eau déterminées pour les mélanges eau–NEA.

La quantité Y est reportée sur la figure 4 en fonction de l'activité de l'eau. Le tracé obtenu correspond à une droite horizontale dans la gamme de composition $0{,}3 \leq X \leq 1$ dont l'ordonnée à l'origine est égale à:

$$Y_0 = 0{,}705$$

Si l'on s'en tient aux hypothèses à l'origine de l'équation B.E.T., cette propriété indique que le terme d'adsorption possède une valeur très faible ($C \approx 1$; $\Delta E_d \approx 0$).

L'équation B.E.T. se réduit alors à:

$$\gamma_E \times \frac{X}{1 - a_E} = \frac{1}{r}$$

Dans ce cas particulier les variations du coefficient d'activité de

TABLEAU 3. Volumes molaires partiels de l'eau ($\bar{V}_E$) et du sel ($\bar{V}_S$) expérimentaux, calculés au moyen des relations [1] puis [24] dans les mélanges eau–NEA

Volume molaire partiel (cm^3 mol^{-1})	X								
	0	4,22 × 10^{-2}	0,100	0,186	0,336	0,441	0,625	0,819	1
$\bar{V}_E$ exp	18,07	18,0	17,9	17,8	17,5$_5$	17,4	17,2	16,9	16,7
$\bar{V}_E$ calc. [1]	—	18,0	17,9	17,8	17,6	17,5	17,2	16,9	—
$\bar{V}_E$ calc. [24]	—	18,0	17,9	17,7	17,5	17,3	17,1	16,9	—
$\bar{V}_S$ exp	82,8	85,6	87,2	88,1	88,7	89,0	89,2	89,3	89,3

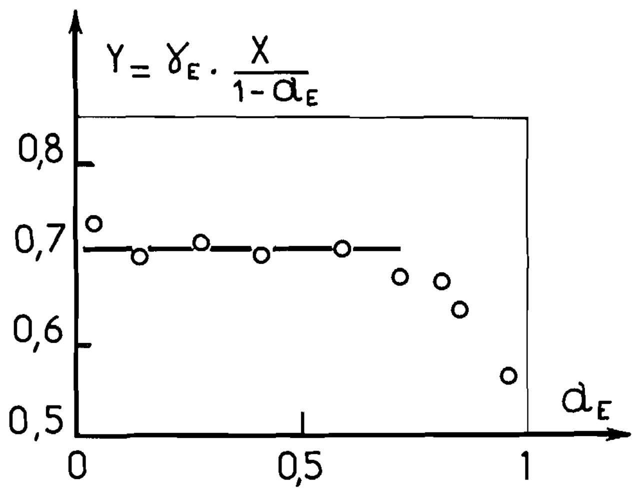

FIG. 4. Vérification de la validité de l'équation B.E.T. (éq. [17]).

l'eau sont décrites par:

$$[23] \quad \gamma_E = \frac{1}{1 + X(r-1)}$$

avec:

$$[23'] \quad r = e^{-\frac{\Delta G_E^{\ominus}}{RT}} = 1{,}42$$

soit $\Delta G_E^{\ominus}$: -865 J. La chaleur de dilution de l'eau à dilution infinie dans le sel pur a été mesurée par Mirejovsky et Arnett (13); elle s'identifie pour les mélanges eau–NEA à l'enthalpie d'interaction:

$$\Delta H_E^i = \Delta H_E^{\ominus} = 1339 \text{ J}$$

Le terme entropique est donc égal à $\Delta S_E^{\ominus} = 7{,}4$ J K^{-1}. Bien que d'origine totalement différente, on remarquera que la valeur $\Delta G_E^{\ominus}$ obtenue par l'équation B.E.T. est tout à fait comparable à celle déterminée dans le précédent paragraphe.

De la même manière que précédemment les valeurs de γ_E et des pressions de vapeur ont été recalculées à partir de la relation [23] (tableau 2). Malgré leurs formes très éloignées, les équations [11] et [23] conduisent à des valeurs comparables, si ce n'est le plus souvent identiques, et décrivent tout aussi bien l'une que l'autre la réalité expérimentale. Cette caractéristique se conserve lors de la dérivation avec la pression.

Le potentiel chimique de l'eau peut être écrit sous la forme:

$$\mu_E = \mu_E^0 + RT \ln(1 - X) - RT \ln(1 + X(r-1))$$

Si l'on suppose que r est un paramètre qui dépend de la pression,

$$\bar{V}_E = V_E^0 - RT \frac{X}{1 + X(r-1)} \left(\frac{\partial r}{\partial P}\right)_{T,X}$$

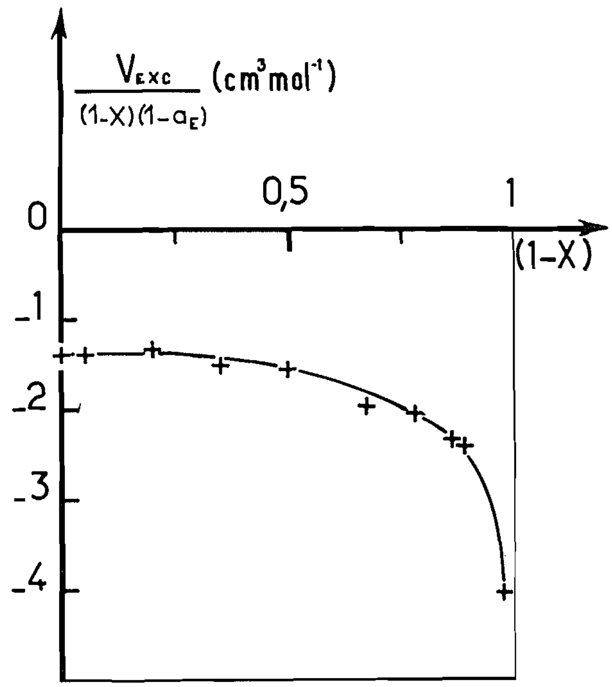

FIG. 5. Vérification de la relation proposée par Abraham (relation [25]).

Lorsque X tend vers l'unité, $\bar{V}_E$ s'identifie à $V_E^{\ominus}$

$$V_E^{\ominus} = V_E^0 - \frac{RT}{r}\left(\frac{\partial r}{\partial P}\right)_{T,X}$$

soit:

$$[24] \quad \bar{V}_E = V_E^0 + (V_E^{\ominus} - V_E^0)\frac{rX}{1 + (r-1)X}$$

Les valeurs expérimentales de $\bar{V}_E$ ainsi que celles calculées par les relations [1] et [24], avec la valeur de $r = 1{,}42$, sont reportées dans le tableau 3.

Comme pour l'enthalpie libre les deux systèmes d'équations décrivent avec une égale précision les propriétés de l'eau dans la solution. Il faut toutefois remarquer que l'on ne peut les identifier, et cela apparaît clairement dans l'expression [24] où le terme $r/[1 + (r-1)X]$ ne peut être constant et égal à l'unité lorsque la composition du milieu se modifie. Il s'en éloigne cependant suffisamment peu pour que l'on ne puisse pas mettre en évidence un écart significatif sur la valeur de $\bar{V}_E$ calculée.

Relation proposée par Abraham (14)

À partir d'un calcul impliquant l'équation B.E.T. et une hypothèse (différente de celle développée par Kodejš et Sacchetto (15)) concernant les contributions volumiques au volume total de la solution, de l'eau adsorbée et de l'eau libre, Abraham établit une relation entre le volume d'excès, V_{exc}, d'un mélange eau–sel et l'activité de l'eau dans ce même milieu.

$$[25] \quad V_{exc} = (1 - X)(1 - a_E)[V_E^{\ominus} - V_E^0 + A(1 - X)]$$

dont le domaine d'application a été fixé par l'auteur à $0 < (1 - X) < 0{,}5$. La vérification de la validité de cette relation pour les mélanges eau–NEA a pu être tentée à partir des valeurs de $\bar{V}_E$ précédemment déterminées (1) et la figure 5 représente les variations de la quantité $V_{exc}/(1 - X)(1 - a_E)$ en fonction de la fraction molaire de l'eau.

Comme on peut le constater, les valeurs reportées, relatives il est vrai à un domaine de composition plus étendu que celui proposé par l'auteur, ne conduisent pas au tracé d'une droite mais à celui d'une courbe qui s'identifie pour les fractions molaires de l'eau les plus faibles, à une horizontale ($A = 0$) d'ordonnée à l'origine ($V_E^{\ominus} - V_E^0$). On peut à ce titre remarquer que le terme $A(1 - X)$ n'a été introduit dans l'équation [25] par l'auteur que pour rendre compte des résultats expérimentaux analysés, mais que les démonstrations exposées ne l'impliquent nullement.

Il semble ainsi que les hypothèses à la base du modèle d'interaction développé par Abraham soient justifiées pour les solutions les plus concentrées en sel.

Nos résultats expérimentaux montrent également que la procédure de détermination de $V_E^{\ominus}$ au moyen de la méthode d'extrapolation linéaire proposée par l'auteur, peut entraîner une incertitude d'autant plus importante que le domaine d'étude concerne des solutions dont la composition s'éloigne de celle du sel pur.

M. PALLER and R. D. DOEPKER. Can. J. Chem. **63**, 3593 (1985).

The gas-phase photolysis of spiropentane has been investigated using xenon (147.0 nm) resonance radiation. Major products observed in order of decreasing importance are ethylene, allene, methylacetylene, 1,2-butadiene, acetylene, propylene, and vinylacetylene. Nitric oxide was used as a radical scavenger while hydrogen sulfide and hydrogen iodide were employed as radical interceptors in the determination of the relative importance of radical and molecular processes. CH_3/CH_2 and $CH_3C{\equiv}C\cdot$ radicals were identified and quantified. Seven primary reaction channels were postulated of which those involving the "elimination" of ethylene were the most predominant accounting for 71% of the photodecomposition.

M. PALLER et R. D. DOEPKER. Can. J. Chem. **63**, 3593 (1985).

Utilisant la résonance de radiation du Xénon (147,0 nm), on a examiné la photolyse en phase gazeuse du spiropentane. Les produits principaux observés, par ordre décroissant d'importance, sont: l'éthylène, l'allène, le méthylacétylène, le butadiène-1,2, l'acétylène, le propylène et le vinylacétylène. On a utilisé de l'oxyde nitrique comme piège de radicaux alors que l'on a utilisé du sulfure d'hydrogène et l'iodure d'hydrogène pour intercepter les radicaux dans la détermination des quantités relatives des processus radicalaires et moléculaires. On a identifié et mesuré les radicaux CH_3/CH_2 et $CH_3C{\equiv}C\cdot$. Le mécanisme réactionnel fait appel à sept voies primaires; celles impliquant l'"élimination" de l'éthylène prédominent puisqu'elles tiennent compte de 71% de la photodécomposition.

[Traduit par le journal]

Introduction

Throughout the years, a series of investigations have been carried out in order to identify the primary and secondary reaction channels for the neutral excited (8.4 eV and 10.0 eV) alkyl-substituted cyclopropane molecule. The most recent previous study in this series examined the photolysis of 1,1-dimethylcyclopropane (1) and disclosed that a methylene elimination process, reaction [1], was of major importance, with a quantum efficiency of 0.34 at 147.0 nm. Tang and Yeh (2) examined the 147.0 nm photolysis of spiropentane but

[1]  $+ h\nu \rightarrow CH_2 + \text{iso-}C_4H_8$

were unable to identify any C_4 products or the presence of methane and/or ethane in their photolysis mixture. These authors concluded that methylene elimination reaction channel was unfavorable and thereby negligable in the 147.0 nm photolysis of spiropentane.

From examination of the methylene elimination process for other alkyl-substituted cyclopropanes determined in the laboratories at the University of Miami (1, 3) and other laboratories (4, 5), it was learned that a quantum yield of around 0.30 might well be expected for the methylene elimination process from spiropentane. In order to evaluate better the role of the methylene elimination process in the alkyl-substituted cyclopropane systems, the 147.0 nm photolysis of spiropentane was reinvestigated.

Experimental

Materials

A commercial sample of spiropentane was purified by vapor chromatography using a 12 ft column of 30% squalane on Chromosorb P held at 50°C. A second purification was necessary due to an unidentified impurity near the retention time of the spiropentane. This purification (also by vapor chromatography) involved a 6 ft aluminum column at 95°C. The resulting spiropentane showed no impurities at levels greater than 0.005%. Low temperature trap-to-trap distillation techniques were employed to purify HI, NO, and H_2S while other additives obtained commercially were used without futher purification.

Irradiation and analysis

The vacuum–ultraviolet photolyses were carried out at 25°C (room temperature) in a static system using a 600 cm^3 reaction vessel and a titanium "gettered" Xenon (147.0 nm) resonance lamp equipped with a LiF window. Irradiation procedures have been reported previously (3). Analysis was performed by vapor chromatography (25 ft, 30% squalane at 60°C).

Actinometry

The chemical actiometers used at 147.0 nm were 1,1-dimethylcyclopropane $\Phi_{C_2H_4} = 0.26$) (1), and cyclopentene ($\Phi_{C_2H_4} = 0.24$) (6).

Results

The quantum yields of the observed major products of the photolyses of spiropentane at 147.0 nm are reported in Tables 1–3. This datum is representative of that collected under a variety of experimental conditions. In addition, the following observations and controls should be reported. (*1*) Irradiation times were selected in order to hold the total conversion of spiropentane below 0.05% for all experiments where quantum yields were obtained. (*2*) Small amounts of ethane ($\Phi_{C_2H_6} = 0.02$) were obtained when the photolyses were carried out without scavenger. (*3*) Extensive use of the radical interceptors H_2S (7) and HI (8) was employed in this investigation with those involving HI given in Table 3, and those involving H_2S summarized below: A maximum quantum yield for methane was obtained when the photolysis mixture contained from 10–15% H_2S. *No* increase in quantum yields was observed for any other products (including methyl acetylene and allene) for

a 1 Torr spiropentane – 0.15 Torr H_2S photolysis mixture. The same results were observed for the above mixture even with the addition of 50 Torr of Ne. The maximum quantum yield of CH_4 observed was $\Phi_{CH_4} = 0.15$. (*4*) No products were found that could be identified as C_5. No real attempt was made to establish the presence or absence of C_6 hydrocarbons nor were hydrogen yields obtained.

Discussion

The most abundant stable product of the 147.0 nm photolysis of spiropentane is ethylene $\Phi_{C_2H_4} = 0.71$. Since ethylene quantum yields are independent of pressure and additive it can be assumed that it is produced through one or more primary reaction channels. The formation of ethylene along with allene (reaction [2])

[2]  $+ h\nu \rightarrow C_2H_4 + CH_2{=}C{=}CH_2$

has been observed in thermal (9), photochemical (10), and chemical excitation (11) studies. Tang and Yeh (2) also postulated that reaction [2] is of major importance in the 147.0 nm photolysis of spiropentane but did not attempt to quantify its quantum yield. These authors did report quantum yields of $\Phi_{C_2H_4} = 1.11 \pm 0.16$, $\Phi_{allene} = 0.525$, and $\Phi_{methylacetylene} = 0.152$.

In the studies of Flowers and Frey (9*a*) and Burkhardt (11*c*), methylenecyclobutane was reported as a competitive product at high pressure while methylenecyclobutane was not observed by Tang and Yeh (2) nor was it observed in the present study for the 147.0 nm photolysis. Since methylenecyclobutane was not observed with pressure up to 200 Torr (argon), coupled with the absence of a pressure effect observed on the quantum yields of ethylene, allene, and methylacetylene, it may be concluded that excited molecule(s) leading to the formation of C_2H_4 and C_3H_4 must have a life-time of but a few molecular vibrations, but also long enough to permit rearrangements to occur leading to the production of methylacetylene (reaction [3]).

[3]  $+ h\nu \rightarrow C_2H_4 + CH_3C{\equiv}CH$

If it can be assumed that all the allene and the methylacetylene formed in the absence of HI originates from reactions [2] and [3] respectively then $\phi_2 = \Phi_{C_3H_4}$ (allene) = 0.29 and $\phi_3 = \Phi_{C_3H_4}$ (methylacetylene) = 0.14. The total C_3H_4 production of 0.43 when compared to $\Phi_{C_2H_4} = 0.71$ indicates yet another primary reaction channel for the formation of C_2H_4. Table 3 reveals that the quantum yield of methylacetylene increased by approximately 0.21 when HI was present while allene was unaffected. An increase in the total yield of C_3H_4 products, with the addition of HI, points to the presence of C_3H_3 radicals. It is apparent though, that the C_3H_3 radical is not propargyl ($\cdot CH_2{-}C{\equiv}CH \rightleftarrows CH_2{=}C{=}CH\cdot$) since this species should lead to both allene and methylacetylene (12). As only methylacetylene is formed by the addition of HI, the methylethynyl ($CH_3{-}C{\equiv}C\cdot$) radical must be the precursor to the increased methylacetylene, reactions [4] and [5]).

[4]  $+ h\nu \rightarrow C_2H_4 + H + CH_3C{\equiv}C\cdot$

[5] $CH_3C{\equiv}C\cdot + HI \rightarrow CH_3C{\equiv}CH + I$

If it can be assumed that all C_3H_3 radicals are intercepted at 1 Torr pressure, the quantum yield of reaction [4] may be set equal to the increase in quantum yield for methylacetylene when HI is present. That is, $\phi_4 = \Phi_{C_3H_3} = \Phi(CH_3C{\equiv}CH)_{total} - \Phi(CH_3C{\equiv}CH)_{with\ NO} = 0.21$. Table 3 appears to show a decrease in C_3H_3 formation with an increase in total pressure.

TABLE 3. Photolysis of spiropentane at 147.0 nm

[a] Methylacetylene.
[b] Allene.
[c] Vinylacetylene.
[d] Cyclobutene.
[e] 1,2-Butadiene.

This effect is not accompanied by an increase in allene nor a general pressure effect on methylacetylene in the presence of NO. It must be concluded, therefore, if this pressure effect is not an experimental artifact, that the intermediate responsible must not be simply a "hot" C_3H_4 species. Secondly since no C_5-products were observed, speculation of the nature of this intermediate is not warranted.

The total of the quantum yields of ethylene formation from reactions [2], [3], and [4] of 0.64 still points to an additional reaction channel leading to the formation of ethylene. The key to this reaction channel may well involve an expected methylene elimination process. It may be noted that the methylene elimination processes from methylcyclopropane (3*a*), 1,1-dimethylcyclopropane (1), ethylcyclopropane (3*c*), and vinylcyclopropane (3*d*) all indicate that nearly 30% of the primary processes involve the elimination of methylene.

It can be noted in Tables 1–3 that vinylacetylene is independent of pressure and unaffected by addition of additives. The formation of vinylacetylene may occur with the elimination of methylene, ring opening and $2H/H_2$ elimination (reaction [6]).

[6]  $+ h\nu \rightarrow CH_2 + 2H/H_2 + C_4H_4$

The quantum yield of reaction channel [6] can be assigned a value equal to the quantum yield of vinylacetylene $\phi_5 = \Phi_{C_4H_4} = 0.06$. A second process that certainly involves a CH_2 elimination is the formation of 1,2-butadiene. Reaction [7], may be postulated for this reaction channel. If it can be assumed that reaction [7]

[7]  $+ h\nu \rightarrow CH_2 + CH_3C{=}C{=}CH_2$

is the sole source of 1,2-butadiene, then the quantum yield of reaction [7] may be equated to the quantum yield of 1,2-butadiene, $\phi_6 = \Phi_{C_4H_6\text{-}1,2} = 0.14$. Cyclobutene formation shows a decided pressure sensitivity as well as a sensitivity to the presence of HI/H_2S. The formation of cyclobutene therefore must be associated with a secondary reaction channel which at present remains unknown.

On the other hand, propylene $\Phi_{C_3H_6} = 0.08$ is seen to be independent of pressure and unaffected by HI/H_2S additives. Two possible pathways may be postulated, both involving a rearrangement of the excited intermediate. The total quantum yield of propylene production may be distributed between

[8*a*]  $+ h\nu \rightarrow H + C_2H + C_3H_6$

TABLE 4. Quantum yields for the primary reaction channels of the 147.0 nm photolysis of spiropentane

Reaction	Quantum yield
 $+ h\nu \xrightarrow{[2]} C_2H_4 + H_2C{=}C{=}CH_2$	0.29
$\xrightarrow{[3]} C_2H_4 + H_3C{-}C{\equiv}CH$	0.14
$\xrightarrow{[4]} C_2H_4 + H_3C{-}C{\equiv}C\cdot + H$	0.21
$\xrightarrow{[6]} CH_2 + 2H/H_2 + H_2C{=}CH{-}C{\equiv}CH$	0.06
$\xrightarrow{[7]} CH_2 + CH_3CH{=}C{=}CH_2$	0.14
$\xrightarrow{[8]} \left\{\begin{matrix} H + C_2H + C_3H_6 \\ C_2H_2 + C_3H_6 \end{matrix}\right\}$	0.08
$\xrightarrow{[9]} \left\{\begin{matrix} CH_2 + C_2H_2 + C_2H_4 \\ CH_3 + C_2H + C_2H_4 \end{matrix}\right\}$	0.07
Total	0.99

[8*b*] $\rightarrow C_2H_2 + C_3H_6$

reactions [8*a*] and [8*b*] which are indistinguishable without hydrogen yields. The ethynyl radical is not expected to be scavenged by NO (13) but may abstract a hydrogen from a hydrocarbon (14) to produce acetylene. The total quantum yield of acetylene shows a constant low pressure value of 0.10 and a pressure dependent component increasing to a value of 0.17 at 200 Torr Ar. The yield of acetylene associated from reaction [8] is insufficient to account for the total acetylene found in the photolysis of spiropentane. Coupling this "excess" acetylene with the unaccounted ethylene, the following primary reaction channels may be postulated. Based on ethylene yields, the quantum yield for eaction [9]

[9*a*]  $+ h\nu \rightarrow C_2H_4 + C_2H_2 + CH_2$

[9*b*] $\rightarrow C_2H_4 + C_2H + CH_3$

should be $\phi_9 = \Phi_{C_2H_4} - \phi_2 - \phi_3 - \phi_4 = 0.71 - 0.29 - 0.14 - 0.21 = 0.07$.

An examination of all the above postulated mechanisms reveals a predicted CH_2/CH_3 quantum yield equal to $\phi_6 + \phi_7 + \phi_9 = 0.06 + 0.14 + 0.07 = 0.27$. This value of 0.27 is within reasonable agreement to the experimental value of $\Phi_{CH_2/CH} = 0.25$ obtained through the use of HI in the photolysis mixture. Since it is not possible to distinguish between methyl radicals formed through a rearrangement (reaction [9*b*]) and a triplet methylene abstraction process, with the data available, this yield can not be used to distinguish between the two pathways in reaction [9]. A total methylene elimination of approximately 0.27 ($\phi_6 + \phi_7 + \phi_9$) appears to be constant with these values obtained for the other substituted cyclopropanes (1, 3, 4 and 5).

Summary and conclusion

The vacuum–ultraviolet (147.0 nm) photolysis of spiropentane may be described by seven primary reaction channels. Quantum efficiencies of these pathways are summarized in Table 4. Although it is apparent that certain possibly informative data is missing from this study, the quantitative conclusions appear to be compatible with previous studies in the vacuum–ultraviolet photolysis of alkyl substituted cyclopropanes.

The polarized infrared and Raman spectra of ammonium hydrogen bis(trichloroacctate) single crystal have been investigated in the 4000–350 cm^{-1} and 4000–10 cm^{-1} range, respectively. The infrared spectra have been measured at room and low temperatures. An assignment of the bands in terms of approximate type of motion is given. The asymmetric stretching vibration, ν_aOHO, of the strong hydrogen bond gives rise to a very broad infrared absorption, with a maximum around 800 ± 50 cm^{-1}, which is polarized strictly along a tetragonal $Z(c)$ direction of this crystal. For this vibration a correlation field (Davydov or factor group) splitting is not observed. The out-of-plane deformation vibration, γOHO, obeys selection rules for the C_2 site symmetry group. This result and also an interpretation of the νC=O vibration strongly suggest that a potential energy function of the strong hydrogen bond has a single symmetric minimum.

VENETA VIDENOVA-ADRABINSKA, JAN BARAN, HENRYK RATAJCZAK et WILLIAM J. ORVILLE-THOMAS. Can. J. Chem. **63**, 3597 (1985).

Opérant respectivement dans les intervalles de fréquence allant de 4000 à 350 cm^{-1} et de 4000 à 10 cm^{-1}, on a étudié les spectres infrarouges et Raman polarisés d'un monocristal de bis(trichloroacétate) acide d'ammonium. On a mesuré les spectres infrarouges à la température ambiante et à des températures plus basses. On propose une attribution des bandes en fonction du type approximatif de mouvement. La vibration d'élongation asymétrique ν_aOHO de la liaison hydrogène forte donne lieu à absorption infrarouge qui est très large, qui présente un maximum à environ 800 ± 50 cm^{-1} et qui est polarisée selon une direction tétragonale $Z(c)$ du cristal. Dans le cas de cette vibration, on n'a pas observé de dédoublement du champ de corrélation/facteur de Davidov ou de groupe. La vibration de déformation hors-plan, γOHO, suit les règles de sélection du groupe de symétrie C_2. Ce résultat ainsi qu'une interprétation de la vibration νC=O suggèrent fortement qu'une fonction d'énergie potentielle de la liaison hydrogène forte ne possède qu'un seul minimum symétrique.

Introduction

The structural and dynamic aspects of hydrogen bonds have always attracted considerable attention. Most studies are on the solid state. Knowledge of the structure of hydrogen bonds and their environment obtained from diffraction methods are very useful not only for classification purposes but also for the interpretation of vibrational spectra, particularly when polarized light is used. In the case of very strong hydrogen bonds the main problem is the symmetry of the hydrogen bond potential. The diffraction methods give only the average position of atoms but the distinction between either dynamic or statistical disorder (double minima potential) and a true symmetry (centred single minimum) might possibly be obtained from infrared and Raman spectroscopy. Most spectroscopic work has been done on acid salts of carboxylic acids of the general formula Me^+[RCOOHOOCR]$^-$ by Hadži *et al.* (1–11, 16). The main results of the investigations may be summarized as follows (8): systems having an O—O distance of about 2.45 Å show a broad and strong infrared absorption between 500 and 1200 cm^{-1}. This was attributed to the asymmetric stretching ν_aOHO vibration. The number and symmetry character of the transitions connected with the OHO vibrations would be most relevant to the problem of the symmetry of the hydrogen bond potential function but much uncertainty is brought in by their bandwidth in infrared spectra and their weakness in Raman spectra even when transitions are allowed. Very large correlation splittings of the ν_aOHO vibration have been found only in the cases of KH–biphenylacetate and KH–dibenzoate (6) and KH–bis(dibromoacetate) (12). Information on the symmetry of the potential function may be obtained from an analysis of the νC=O modes. Although the selection rules appear to be operative in the cases where the centre of the hydrogen bond is on the C_i site, some extra bands in the νC=O region have also been detected in both polarized infrared and Raman spectra (5, 10). Therefore we decided to measure polarized infrared and Raman spectra of ammonium hydrogen bis(trichloroacetate) (AHTCA) and its potassium analogue (KHTCA). Both belong to the same space group ($I\bar{4}2d$, tetragonal system) and contain very strong crystallographically symmetric, C_2, hydrogen bonds with O—O distances of 2.46(2) Å and 2.456(4) Å in KHTCA and AHTCA (13, 14), respectively. The ^{35}Cl nqr studies (15) have shown that in these crystals the

hydrogen bond potential might be either a single symmetrical or a double symmetrical with a dynamical disorder.

Experimental

The $NH_4H(Cl_3CCOO)_2$ was prepared by dissolving stoichiometric amounts of trichloroacetic acid and ammonium carbonate in water. The single crystals suitable for infrared and Raman spectra measurements were obtained by the slow evaporation method at a constant temperature of 20°C. The crystal was oriented with the aid of the X-Ray method and a polarizing microscope. A plate about 4 mm thick parallel to the optic axis Z was cut. The optic axis Z is parallel to the tetragonal c direction. The plate was stuck to the KBr window and polished until the measurement of polarized spectra was possible. The infrared spectra were measured with the electric vector of radiation parallel and perpendicular to the optic axis Z, respectively. The infrared spectra were measured with a Perkin-Elmer M180 spectrophotometer equipped with a wire grid polarizer. A CTI-Cryogenics low temperature cryostat was used to obtain infrared spectra at 20 K temperature. For the Raman spectra measurement a single crystal cubic sample was prepared. The edges of this cube were parallel to the $X(a)$, $Y(b)$, and $Z(c)$ directions. The spectra were measured with a Cary 82 Raman spectrometer using the 514 nm line of an argon-ion laser.

Discussion

Crystal structure and selection rules

The crystal of AHTCA belongs to the space group $I\bar{4}2d$ ($=D_{2d}^{12}$) of the tetragonal system (14). A primitive unit cell contains four molecular units. Two trichloroacetic acid groups are connected by a very strong crystallographically symmetric (twofold symmetry, with the C_2 axis perpendicular to the tetragonal $Z(c)$ axis) hydrogen bond with an O—O distance of 2.456(6) Å. Ammonium cations are situated on the C_2 symmetry axes which are parallel to the tetragonal $Z(c)$ axis. Other heavy atoms occupy the C_1 positions. The results of a factor group analysis are given in Table 1. The correlation diagram between a site symmetry group C_1 of trichloroacetic group and a C_2 ($\perp Z$) site symmetry group of the $H(Cl_3CCOO)_2$ anion and a factor group D_{2d} is given in Table 2. Every internal vibration of the trichloroacetic group should split into two components of A and B type symmetry as a result of an interaction inside the $H(Cl_3CCOO)_2$ anion. Interaction between the internal vibrations of the four $H(Cl_3CCOO)_2$ anions in the primitive unit cell leads to a correlation (Davydov or factor group) splitting.

Let us suppose that protons lie on the C_2 symmetry axes which are perpendicular to the tetragonal Z axis. In this case the asymmetric stretching ν_aOHO and the in-plane deformation

[b] Abbreviations similar as those in Table 1.
[c] Unit cell group is equivalent to the factor group.

δOHO vibrations transform according to the B type representation of the C_2 site symmetry group (see Table 2). Similarly, the out-of-plane γOHO vibration transforms according to the A type representation. The correlation coupling between the vibrations of the four protons in the primitive unit cell gives two infrared modes ($B_2(Z)$, $E(X,Y)$) for the ν_aOHO and two infrared modes ($B_2(Z)$, $E(X,Y)$) for the δOHO vibrations. Only one infrared mode of E type symmetry is expected for the γOHO vibrations. The B_2 type modes are supposed to interact with radiation polarized parallel to the tetragonal $Z(c)$ axis. The E type modes should interact with radiation polarized perpendicular to the tetragonal $Z(c)$ axis.

Band assignment

The polarized infrared spectra of the AHTCA single crystal are shown in Fig. 1. The polarized Raman spectra are presented in Fig. 2. The wavenumbers of the bands, their relative intensities, and a tentative assignment are listed in Table 3.

The bands observed in the interval 4000–300 cm^{-1} arise from: (*i*) the vibrations of the protons in the strong hydrogen bonds, (*ii*) the internal vibrations of the trichlororacetic acid residues, and (*iii*) the internal vibrations of the ammonium groups. In the assignment of the bands the characteristic group frequencies (17), the polarization properties of the bands (compared with those predicted on the base of the bond moment polar model (19)) and the correlation chart diagram (Table 2) were used. The infrared spectra of the AHTCA are very similar to the spectra of the potassium analogue (20). They are differ-

ent only in the region of the NH_4^+ group vibrations whose detailed interpretation will be given elsewhere.

Hydrogen bond vibrations

The asymmetric stretching vibration

The most characteristic feature of the powder infrared spectrum is a broad and strong absorption observed in the region between 1500−400 cm^{-1} with a maximum at 850 ± 30 cm^{-1}. This strong and broad absorption appears only in the spectrum polarized parallel to the tetragonal $Z(c)$ axis. Only four "transmission windows" at 1722, 1348, 728, and 445 cm^{-1} are observed in this absorption. The top of this absorption is very flat in the spectrum measured at room temperature. At low temperature (20 K) its maximum is at about 800 ± 50 cm^{-1}. This absorption would correspond to the B_2 type mode of the ν_aOHO. The E type mode is expected in the spectrum polarized perpendicular to the Z axis. In perpendicular spectrum a resonance transmission feature at 1500 cm^{-1} is observed at low temperature. This may indicate the presence of a broad absorption in this region. A careful investigation shows a slightly higher background in the region between ~1100−1900 cm^{-1} in the spectrum polarized perpendicular to the Z axis measured at room temperature. However, it is difficult to accept that this feature is arising from the E type mode of the ν_aOHO vibration. A background is not observed in the infrared spectrum of KHTCA crystal (20), polarized perpendicular to the Z axis (both crystals are isomorphous). We think that the background observed in the spectrum of ammonium salt arises from an overlapping of broad bands observed in the region between 1900−1100 cm^{-1}. Observed low-temperature decreasing of the background may be a result of a narrowing of the bands which appear in this region. Hence the resonance type transmission feature observed at 1500 cm^{-1} may be accidental. If this is true, then we may suggest that the correlation (Davydov) splitting of the ν_aOHO vibration is not observed in this crystal. From this experimental fact it follows that the ν_aOHO transition dipole moment is parallel to the tetragonal Z axis of the crystal. Now we may determine an orientation of this dipole transition moment with respect to the molecular structure of the dimer with hydrogen bond using Fig. 3. A line between carbon atoms of the two carboxylic groups bonded by the O···H···O hydro-

[a]Abbreviations: v very, s strong, m medium, w weak, sh shoulder, t transmission window.
[b]The Damen–Porto–Tell notation is used in single crystal Raman work. Intensities relative to the band at 437 cm^{-1} (100) are given in parentheses.

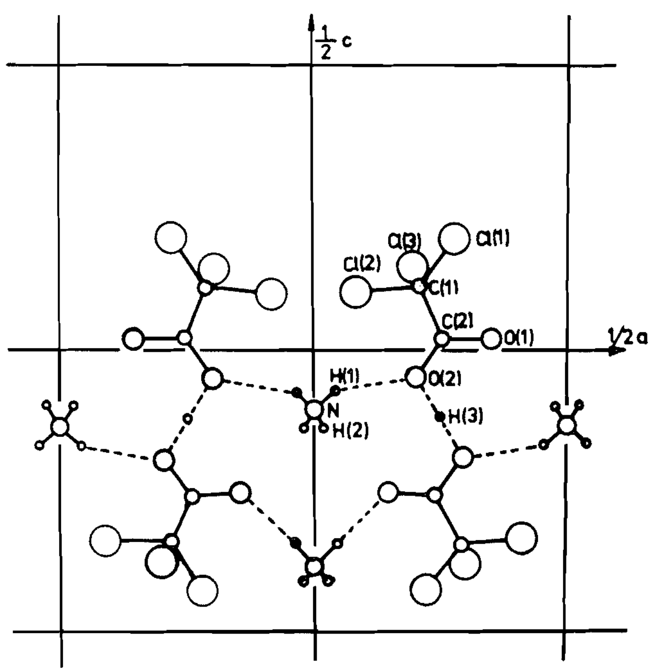

FIG. 3. Projection of the crystal structure of ammonium hydrogen bis(trichloroacetate) on the *ac* plane. The *c* tetragonal direction is parallel to the optic axis *Z*.

gen bond is parallel to the tetragonal $Z(c)$ direction. Hence the transition dipole moment of the ν_aOHO vibration is parallel to this line and makes an angle of about 30° with the O···O hydrogen bond direction. Similar behaviour of this broad absorption band has been observed in the other cases (10).

The out-of-plane deformation vibration

The well-shaped band at 1185 cm^{-1} in the spectrum polarized perpendicular to the *Z* axis has been assigned to the out-of-plane deformation vibration. Its polarization corresponds very well to that expected for the assumption that protons occupy the C_2 site symmetry. At low temperatures this band is very narrow and its maximum is at 1215 cm^{-1} with two shoulders at 1175 and 1185 cm^{-1}.

The in-plane deformation vibration

It is very difficult to assign a band to this vibration because of the presence of bending bands of the NH_4^+ group in the expected region. However, as with the potassium salt (20) a band at 1540 cm^{-1} polarized parallel to the *Z* axis has been assigned to this vibration. At low temperatures the shape of this band is highly varying.

The symmetric stretching ν_sO···O vibration

The selection rules allow this vibration in the infrared and Raman spectra. In the expected region, below 250 cm^{-1}, one observes many bands which are related to the lattice vibrations. Hadži *et al.* (16) have assigned, in the Raman spectra of RbHTCA, a band at 133 cm^{-1} to the symmetric stretching ν_sO···O vibration. However, there is no band at this frequency in our spectra. It is interesting to note that in Raman spectra of AHTCA there is a band at 536 cm^{-1} with the strongest *zz* component. The origin of this band is not clear. No band was found in this region in the infrared spectra at room temperatures. The bands at 550 and 512 cm^{-1} observed in the low temperature spectrum polarized parallel to the *Z* axis are uncertain since a change of gratings in this region takes place in the spectrophotometer. However, a Raman band of similar shape appears in the spectra of the other acid salts (20). It is worth noting that a "transmission window" at 573 cm^{-1} is observed at low temperatures in the infrared spectrum polarized parallel to the Z axis measured. It may be the result of an interaction of this vibration with the ν_aOHO vibration.

Internal vibrations of the trichloroacetic acid group

The νC=O stretching vibration

The bands associated with this vibration may give very useful information on the symmetry of the hydrogen bond potential function. A general discussion on the νC=O and νC—O stretching vibrations has been given by Svanfeldt *et al.* (21). Taking into account a correlation (Davydov) splitting, one can expect two infrared bands polarized perpendicular to the tetragonal Z axis and one band polarized parallel to the Z axis. Five bands are expected in the Raman spectra. Three Raman bands should have similar frequencies to the frequencies of the infrared bands (see Table 2). In the infrared spectrum polarized parallel to the Z axis a very strong band at 1780 cm^{-1}, asymmetric from the high frequency side and a deep transmission "hole" from its low frequency side (at 1722 cm^{-1}), is observed. In the spectrum polarized perpendicular a very strong band at 1760 cm^{-1} with shoulders at 1695 and 1660 cm^{-1} appears. In the Raman spectra there are two bands at 1716 cm^{-1} and at 1676 cm^{-1} in this region. They are observed in all Raman spectra but their intensity is strongest for the *xx* and *zz* components, respectively. The latter Raman band and infrared shoulder at 1660 cm^{-1} have been assigned to the ν_2 vibration of the ammonium ion. The former Raman band corresponds to the νC=O stretching vibration. Its frequency is close to that found for a band observed in the powder Raman spectra of potassium and rubidium analogues (16). Hence the correlation splitting expectation is not met by the experimental Raman data. The other possibility is to consider only coupling between the two C=O groups belonging to the acid groups bonded by the hydrogen bond. In this case the theory predicts two bands in the Raman and infrared spectra at similar frequencies. However, one may expect that the Raman band corresponding to the B type mode of the C_2 site group could be very weak. The infrared band corresponding to the A type component may have very weak intensity and should be polarized perpendicular to the tetragonal Z axis. The infrared polarization behaviour of the B component may depend on an orientation of the transition dipole moment of the νC=O vibration with respect to the C=O bond. In AHTCA crystal the C=O bonds are almost perpendicular to the tetragonal Z axis (Fig. 3). It is known that the transition dipole moment of the νC=O vibration may be as far as 40° out of the C=O bond direction (6). Hence the B type νC=O vibration may be observed in both polarized infrared spectra. We think that the shoulder at 1695 cm^{-1} in the infrared spectrum polarized perpendicular to the Z axis and the Raman band at 1716 cm^{-1} correspond to the A type component of the νC=O vibration. The infrared band at 1780 cm^{-1} polarized parallel and the band at 1760 cm^{-1} polarized perpendicular to the Z axis arise from the B type component of the νC=O vibration. One has to explain the different frequencies of these two bands. We suggest that this may be a result of an interaction of the B component of the νC=O vibration with the ν_aOHO broad absorption. Since the ν_aOHO transition dipole moment is polarized parallel to the Z direction but the B type transition moment of the νC=O is not perpendicular nor parallel to the Z direction, this interaction may have the character proposed by Marzocchi *et al.* (18). As a result of this interaction a dispersive type of "transmission window" with a minimum at 1722 cm^{-1} and a maximum at 1780 cm^{-1} appears. At low temperature the asymmetric band polarized parallel to the Z axis changes into an almost symmetric band with a maximum at 1775 cm^{-1}, a side band at 1810 cm^{-1}, and a shoulder at 1760 cm^{-1}. The band polarized in the perpendicular direction changes much less. The shoulder at 1695 cm^{-1} is better resolved and the shoulder at 1660 cm^{-1} is a well-resolved band.

The C—O stretching vibration

In the Raman spectra a depolarized band at 1344 cm^{-1} has been assigned to this vibration. It has the strongest intensity in the *xx* spectrum. In the infrared spectrum polarized parallel to the Z axis close to this frequency, a "transmission window" at 1348 cm^{-1} occurs. At low temperature a band at 1335 cm^{-1} is observed. A weak band at 1335 cm^{-1} is observed in the spectrum polarized perpendicular to the Z axis.

The other internal vibrations of the acid group

Bands at 835, 850, 675, and a shoulder at 875 cm^{-1} have been assigned to the $\nu_a CCl_3$ and $\nu_s CCl_3$ vibrations. These bands are very strong in the spectrum polarized perpendicular to the Z axis. In the Raman spectra there are bands at very similar frequencies. It is possible that the Raman band at 771 cm^{-1} and a shoulder in infrared spectrum polarized parallel to the Z axis at 770 cm^{-1} also arises from the stretching νCCl vibration (17). The bands observed at 710 and 720 cm^{-1} have been assigned to the deformation vibration of the COO groups. It is worth emphasizing that the Raman bands at 686 and 676 cm^{-1} are the strongest in the *xx* spectrum and are not observed in the *zz* Raman spectrum. The strongest depolarized Raman band at 437 cm^{-1} may be assigned to the $\nu_s CCl_3$ symmetric bending vibration (17). In the infrared spectra two bands at 438 and 420 cm^{-1}, polarized parallel to the Z axis, are observed. Following Hadži *et al.* (16), the former may be assigned to the ρOCO rocking vibration.

The νC—C stretching vibration gives rise to a very weak infrared band at 952 cm^{-1}, which is polarized perpendicular to the Z axis. There is no band nor "transmission window" in the absorption polarized parallel to the Z axis. Although the C—C bond is at an angle of 28° to the Z axis, one could expect the appearance of a band or "transmission window" in this spectrum. In the Raman spectra this vibration gives rise to the band at 956 cm^{-1}, which is the strongest in the *zz* spectrum.

Conclusion

It has been shown that the ν_aOHO vibration gives rise to a very broad absorption which is polarized parallel to the tetragonal $Z(c)$ axis. We do not observe any similar feature in the spectrum polarized perpendicular to the $Z(c)$ axis. Hence, we may suggest that for the ν_aOHO vibration a correlation field (Davydov or factor group) splitting is not observed.

For the out-of-plane deformation γOHO vibration, the correlation field coupling and the site group ($C_2 \perp Z$) symmetry predictions are similar for the infrared spectra. In either case only one band polarized perpendicular to the $Z(c)$ axis is expected. The appearance of only one infrared band polarized perpendicular to the $Z(c)$ axis allows us to confirm that protons occupy a site of C_2 symmetry, hence, the hydrogen bond potential is symmetrical with a single minimum.

This suggestion finds also confirmation in the analysis of the νC=O stretching vibration. If one takes into account only the infrared data, the agreement with a theoretical prediction on the basis of a correlation field coupling is surprisingly good. Two bands polarized perpendicular (E type) and one band polarized parallel (B_2 type) to the $Z(c)$ axis are observed in the polarized infrared spectra. The $\nu C{=}O$ band polarized parallel to the $Z(c)$ axis has a characteristic shape. A similar shape of the $\nu C{=}O$ band is observed in polarized infrared spectra of other acid salts (10, 22) in which a strong and broad absorption appears. This shape is characterized by a "transmission window" around 1700 cm^{-1} and an asymmetry observed on the high frequency side. We suggest that this feature may be connected with an interaction between the broad ν_aOHO absorption and the $\nu C{=}O$ mode of B_2 symmetry, when the correlation field coupling appears, or B symmetry, when only the coupling between the $\nu C{=}O$ vibrations inside the hydrogen-bonded dimer occurs. We suppose that the latter case is more reasonable because the correlation splitting of the $\nu C{=}O$ vibration is not observed in the polarized Raman spectra. Hence, the B type $\nu C{=}O$ mode, being a result of the out-of-phase coupling between the $\nu C{=}O$ vibrations inside the dimer (whose site group symmetry is C_2) interacts with the ν_aOHO vibrations. Since the transition dipole moment of this B type $\nu C{=}O$ mode is neither parallel nor perpendicular to the ν_aOHO transition dipole moment, a result of its interaction would be a "transmission window" at 1722 cm^{-1} and a dispersive shape of the $\nu C{=}O$ band observed in the infrared spectrum, in which a broad absorption occurs. This interaction may have a character similar to that proposed by Marzocchi *et al.* (18) and it may be responsible for the different frequencies of the $\nu C{=}O$ bands, arising from the B type mode, which are observed in the infrared spectra polarized parallel and perpendicular to the $Z(c)$ axis.

Étude cinétique de l'ouverture thermique de la liaison C—C d'aziridines et d'époxydes dipôles-1,3 potentiels. II. Influence des substituants

AÏCHA DERDOUR ET FERNAND TEXIER

Laboratoire de synthèse organique, ONRS 75B/033, Institut de Chimie, Université d'Oran, Es-Sénia, Algérie

Reçu le 25 septembre 1984[1]

AÏCHA DERDOUR et FERNAND TEXIER. Can. J. Chem. **63**, 3605 (1985).

L'étude cinétique de l'ouverture thermique de la liaison C—C des cyano-2 aziridines **1**, des alcoxycarbonyl-2 aziridines **2**, des aroyl-2 aziridines **3** et des dicyano-2,2 époxydes **4** diversement substitués en 1 et 3 montre que (*i*) la stéréochimie des carbones cycliques a peu d'influence sur la vitesse d'ouverture électrocyclique; (*ii*) un substituant aryle en 1 favorise la réaction par rapport à un alkyle et d'une manière générale, la réaction est facilitée par des substituants qui rapprochent les niveaux d'énergie du doublet P de l'hétéroatome et l'OM $\sigma^*_{C\text{-}2-C\text{-}3}$. Elle est également favorisée par la dissymétrie de substitution des carbones 2 et 3. Les résultats sont discutés dans le cadre de la théorie des relaxations.

AÏCHA DERDOUR and FERNAND TEXIER. Can. J. Chem. **63**, 3605 (1985).

A kinetic study concerning the thermal opening of the C—C bond of 2-cyanoaziridines (**1**), 2-alkoxycarbonylaziridines (**2**), 2-aroylaziridines (**3**), and 1,3-substituted 2,2-dicyanoepoxides (**4**) has shown that (*i*) the stereochemistry of the cyclic carbon atoms has little influence on the rate of the electrocyclic opening; (*ii*) the presence of an aryl substituent in position 1, as opposed to an alkyl substituent, favors this reaction and, in general, the reaction is favored by the presence of substituents which produce energy levels closer to those of the P doublet of the heteroatom and of the $\sigma^*_{C\text{-}2-C\text{-}3}$ MO. This reaction is also favored by a dissymmetry of the substitution on the 2 and 3 carbons. The results are discussed in terms of the theory of relaxations.

[Journal translation]

Les facteurs qui favorisent l'ouverture thermique des hétérocycles isoélectroniques de l'anion cyclopropyle (aziridines, époxydes...) en dipôles-1,3 correspondants ne semblent pas être complètement dégagés, malgré quelques travaux expérimentaux (1–3) et les explications basées sur la méthode des relaxations (4).

Afin de préciser l'influence des substituants sur la réaction péricyclique, nous avons étudié, à l'aide des méthodes décrites dans l'article précédent (5), la cinétique d'ouverture de la liaison C—C des aziridines **1**, **2** et **3** et des époxydes **4**.

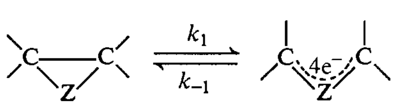
4

L'objet de ce mémoire est d'examiner l'influence de la configuration relative des carbones cycliques de l'aziridine et celle de divers substituants sur la réaction d'ouverture électrocyclique schématisée comme suit:



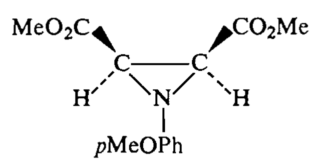
Aziridine ------ Ylure d'azométhine (Z = N—R)
Epoxyde ------ Ylure de carbonyle (Z = O)

[1] Revision reçue le 30 juillet 1985.

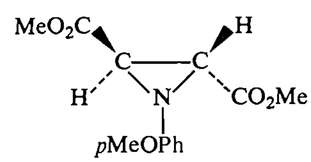
Résultats expérimentaux

1. *Influence de la configuration relative des carbones cycliques de l'aziridine*

Huisgen *et al.* ont montré que la stéréochimie *cis* ou *trans* des deux aziridines isomères **2***d* (*cis*) et **2***e* (*trans*) influe peu sur leur vitesse d'ouverture électrocyclique (3*a*):

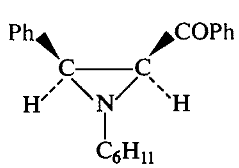


2*d* (*cis*)

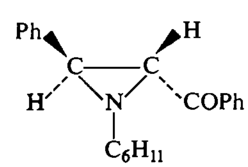


2*e* (*trans*)

Nous avons montré qu'il en était de même pour les deux aziridines isomères **3***a* (*cis*) et **3***b* (*trans*), quelle que soit la température de la réaction. Les résultats rassemblés dans le tableau 1 indiquent que la configuration relative des carbones cycliques ne joue qu'un rôle mineur sur la vitesse d'ouverture du cycle, contrairement à ce qui est observé lors de la transformation de dérivés cyclopropaniques en cations allyles, puisque dans ces cas, la stéréochimie joue un rôle prépondérant sur la vitesse de la réaction (6).



3*a cis*



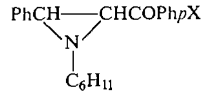
3*b trans*

2. *Influence du substituant de l'azote* (cas des aziridines)

Oehlschlager *et al.* ont montré que l'ouverture des *N*-arylaziridines **5** en ylures d'azométhine **6** à 110°C est favorisée par des substituants X et X′ électrodonneurs (2).

Pour notre part, nous avons montré que l'ouverture de l'aziridine est favorisée par substituant phényle comparé à un alkyle.

TABLEAU 1. Constantes cinétiques d'ordre 1 (k_1, 10^4 s^{-1}) et paramètres d'activation correspondant à l'ouverture thermique des aziridines **3** (solvant: toluène)



3

3: à l'exception de **3***a*, les substituants des carbones sont *trans*

		k_1 (10^4 s^{-1})

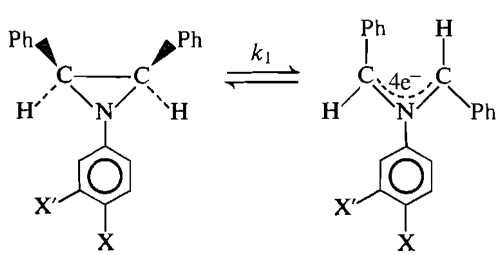
2*d*	*p*MeO Ph	H	CO_2Me				28,5[d]		−1,5	29
2*e*	*p*MeO Ph	H	CO_2Me	[d]	[d]	[d]	29,5[d]		+0,5	29

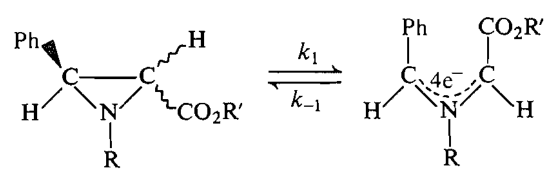
[a]T, ±0,2°C.
[b]Les $\Delta H^{\ddagger}$ sont mesurées à partir de constantes de vitesse déterminées en vitesse initiale (réf. 5); la précision est ±2 kcal mol^{-1}. Les $\Delta S^{\ddagger}$ sont obtenues avec précision de ±5 ue.
[c]Compte tenu de la difficulté à obtenir la constante de vitesse (réf. 5) nous avons renoncé à déterminer les paramètres d'activation.
[d]Ces aziridines ont été étudiées par Huisgen et Mader (3*a*), dans l'acétate d'éthyle. Les aziridines étudiées au cours de ce travail ont des $\Delta S^{\ddagger}$ largement négatives; ceci est dû en partie à une solvatation spécifique des aziridines dans les solvants aromatiques (1).



5 (*cis*) **6** (*trans*)

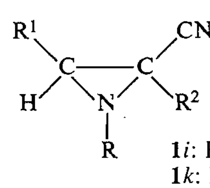
Ainsi à la température de 121,5°C, l'aziridine **2***b* dont l'azote est substitué par un phényle s'ouvre 16 fois plus vite (k_1 (**2***a*) = 6,35 × 10^{-4} s^{-1}; k_1 (**2***b*) = 100 × 10^{-4} s^{-1}) que l'aziridine **2***a* dont l'azote est substitué par un cyclohexyle.

Il en est de même pour l'ouverture des cyano-2 aziridines **1***i*, et **1***k*; la réaction électrocyclique est favorisée par un phényle



2*a*: R = C_6H_{11}; R′ = Me (*cis* par rapport au phényle)
2*b*: R = Ph; R′ = Et (*trans* par rapport au phényle)

comparé au cyclohexyle; ainsi à T = 121,5°C: k_1 (**1***i*) = 0,86 × 10^{-5} s^{-1} et k_1 (**1***k*) = 1,5 × 10^{-5} s^{-1}.



1*i*: R¹ = Me; R² = H; R = C_6H_{11}
1*k*: R¹ = H; R² = Me; R = Ph

3. *Influence des substituants des carbones cycliques*

3.1. *Influence des groupements fonctionnels substituant le* C_2

Selon la littérature, la formation d'un ylure d'azométhine à partir d'une aziridine est favorisée par un groupement électro-attracteur activant, ester, cétone ou nitrile, substituant le(s) carbone(s) cyclique(s) (7). La comparaison de la vitesse d'ouverture des aziridines **1**, **2** et **3** substituées en 1 par un cyclohexyle et en 3 par un phényle montre que la constante k_1 suit l'aptitude du groupement fonctionnel à stabiliser une charge négative: À T = 121,5°C, dans le toluène, k_1 (**3***a*): $43{,}4 \times 10^{-4}$ s^{-1} > k_1 (**2***a*): $6{,}35 \times 10^{-4}$ s^{-1} > k_1 (**1***a*): $2{,}92 \times 10^4$ s^{-1}.

Si l'on considère les aziridines **3** dont le phényle lié au carbonyle est substitué en *para* par un groupement X, nous remarquons que l'effet du substituant X est modéré, mais lorsqu'il est électrodonneur, il ralentit l'ouverture, alors qu'il l'accélère quand il est électroattracteur, comme le montrent les résultats rassemblés dans le tableau 1.

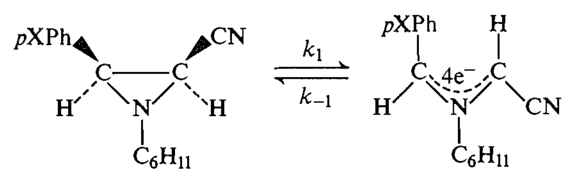
Les paramètres d'activation correspondant à l'ouverture des aziridines **2** sont rassemblés dans le tableau 2. Ils montrent que le composé **2***c* s'ouvre plus facilement que les aziridines **2***d* et *e* étudiées par Huisgen *et al.* (3*c*), malgré la présence du méthoxy sur le phényle lié à l'azote. Il faut noter toutefois que l'aziridine **2***b* s'ouvre plus aisément que les composés **2***c* et **2***d*. À titre d'exemple, nous avons reporté ci-dessous les k_1 observées à T = 120°C.

3.2. *Substitution en position 3 par des groupements alkyles et aryles*

3.2.1. Dans une publication préliminaire, nous avons montré que l'ouverture thermique des cyano-2 aziridines en ylures d'azométhine est favorisée en remplaçant l'hydrogène en 3 par un phényle (1). Les résultats rassemblés dans le tableau 3 concernant les paramètres d'activation des aziridines **1***a*, *i*, *j* et *h*, montrent que la facilité de formation de l'ylure d'azométhine suit la séquence: R^1 = Ph > H > Me > Me_2CH. Ainsi, à la température de 120°C, la constante k_1 est divisée par environ un facteur 10 lorsque l'on remplace le phényle par un hydrogène et par un facteur 40 lorsque R^1 = Me. Toutefois, la variation de log k_1 en fonction des σ^* de Taft (8) n'est pas une relation linéaire.

3.2.2. *Cas des* N-*cyclohexyl-cyano-2* p*X phényl-3 aziridines*

Les résultats concernant l'ouverture d'une série de phényl-3 aziridines **1** dont le phényle est substitué en *para* par un groupement X (Me_2N—, MeO—, H, Cl, Br, CN, NO_2) sont rassemblés dans le tableau 4.



Contrairement à ce qui était attendu, la réaction électrocyclique est favorisée par un substituant X électrodonneur et défavorisée par un groupement X électroattracteur. Si l'on prend la constante de vitesse d'ouverture de l'aziridine **1***a* (X = H) égale à l'unité, nous obtenons les valeurs relatives suivantes (T = 121,5°C, solvant: toluène): k_1^{rel} (X = H) = 1,00; Me_2N— = 4,41; MeO— = 1,97; Cl = 0,95; Br = 0,94; C≡N = 0,89; NO_2 = 0,86.

L'influence du substituant X est donc modérée, mais elle est l'inverse de celle observée avec les aroyl aziridines dont le phényle lié au carbonyle est substitué en *para*. La figure 1 représentant log k_1 en fonction des σ de Hammett (8) montre que les substituants ayant un σ positif sont correctement alignés (ρ = −0,08); le diméthylamino et le méthoxy sont également alignés avec H, mais la droite n'a pas la même pente (ρ = −0,38).

3.2.3. *Cas des dicyano-2,2 phényl-3 époxydes* **4**

Les résultats relatifs à l'ouverture thermique des époxydes **4** en ylures de carbonyle correspondants sont rassemblés dans le tableau 5.

Ils sont analogues à ceux obtenus avec les aziridines **1**;

TABLEAU 4. Constantes cinétiques d'ordre 1 (k_1, 10^5 s^{-1}) et paramètres d'activation correspondant à l'ouverture des *N*-cyclohexy, cyano-2, *p*X phenyl-3, aziridines (solvant: toluène)

l'ouverture est favorisée par un substituant X électrodonneur tel que MeO et défavorisée par un substituant électroattracteur: k_1^{rel} (T = 121,5°C, solvant: CCl_4) H = 1,00; MeO = 4,00; Cl = 0,91; NO_2 = 0,70.

3.2.4. *Paramètres d'activation*

Si nous considérons l'ensemble des paramètres d'activation obtenus pour l'ouverture d'aziridines diversement substituées (tableaux 1−5), nous remarquons que l'enthalpie d'activation $\Delta H^{\ddagger}$ varie en sens inverse du facteur de fréquence log A_{ex} qui est relié simplement au $\Delta S^{\ddagger}$. Plus l'ouverture de l'aziridine est facile (cas de l'aziridine **2***b* par rapport à **1***a* ou **3***a*) et moins la constante de vitesse est dépendante de la température, ce qui se traduit par un facteur de fréquence log A_{ex} faible et par voie de conséquence un $\Delta S^{\ddagger}$ largement négatif.

Les valeurs largement négatives des $\Delta S^{\ddagger}$ peuvent paraître surprenantes. Toutefois, il faut remarquer que la faible évolution des constantes de vitesse (pour une série donnée, le $\Delta G^{\ddagger}$ varie peu) est dûe à la compensation de l'entropie d'activation.

Ce phénomène semble être une caractéristique des réactions unimoléculaires puisque une évolution analogue des $\Delta H^{\ddagger}$ et log A_{ex} a été observée lors d'isomérisations unimoléculaires effectuées en phase gazeuse (9).

De plus, il a été montré à l'aide de la rmn (résonance ma-

gnétique nucléaire) que si une aziridine est dissoute dans un solvant benzénique, le noyau aromatique a tendance à se placer le plus loin possible du doublet de l'azote (10). C'est pourquoi il a été envisagé une interaction spécifique entre les OF du solvant aromatique et l'OM σ^*_{C-C} destinée à se rompre (1). La solvatation spécifique des aziridines dans le toluène est donc en partie à l'origine des $\Delta S^{\ddagger}$ largement négatifs (11).[2] En effet, les paramètres d'activation de l'aziridine **1***c* mesurés dans le CCl_4 sont plus classiques (tableau 4, note de base de tableau), le $\Delta S^{\ddagger}$ est moins négatif; dans un tel solvant, il n'y a pas de solvatation spécifique.

Discussion

1. *Influence de la stéréochimie des aziridines*

L'ouverture conrotatoire d'une aziridine peut se faire, "a priori", de deux manières (droite ou gauche) conduisant ainsi à deux configurations *U* et *W* de l'ylure d'azométhine correspondant, selon les schémas 1 et 2.

La constante de vitesse d'ouverture d'une aziridine de stéréochimie donnée est la somme des constantes de vitesse de formation des deux configurations de l'ylure d'azométhine correspondant:

$$k_1\ (\text{Az. }trans) = k_1\ (\text{D }tr) + k_1\ (\text{G }tr)$$
$$k_1\ (\text{Az. }cis) = k_1\ (\text{D }cis) + k_1\ (\text{G }cis)$$

Ces différentes configurations *U* et *W* n'étant pas détectables par l'expérience, les mesures expérimentales ne peuvent distinguer k_1 (D) et k_1 (G).

D'après nos résultats et ceux de Huisgen *et al.* (3*c*), k_1 (Az. *trans*) ≃ k_1 (Az. *cis*). Un raisonnement basé sur la minimisation des contraintes stériques dans l'ylure formé (12) permet de montrer que le mode d'ouverture le plus facile est celui qui conduit à l'ylure *W cis*

$$k_1\ (\text{D }trans) > k_1\ (\text{D }cis) \text{ ou } k_1\ (\text{G }cis)$$

Cependant, la stéréochimie de l'ouverture des cations et anions cyclopropyles n'est pas gouvernée par des interactions stériques, mais par les propriétés des orbitales (13). Lors de la solvolyse des dérivés cyclopropaniques, des deux modes d'ouverture disrotatoires possibles "a priori", un seul a lieu effectivement: il correspond à celui pour lequel l'énergie de relaxation est la plus grande en valeur absolue (4).

L'explication de la formation préférentielle d'un ylure d'azométhine à l'aide des interactions stériques ne tient que dans la mesure où les interactions orbitalaires pour les deux modes d'ouvertures, D ou G, sont équivalentes. Ceci serait toujours vérifié quels que soient les substituants portés par les carbones de l'aziridine, si l'azote était plan dans l'état de transition. Quel que soit le mode d'ouverture conrotatoire D ou G, l'énergie de relaxation dûe au transfert de charge P→ σ^*_{C-C} serait la même (voir schéma 3). Si on se limite aux interactions entre les

[2] Le changement de solvant aromatique entraîne une modification des paramètres d'activation de l'aziridine **1***a*: ainsi, le remplacement du toluène par le nitrobenzène entraîne une diminution du $\Delta H^{\ddagger}$ (de 27 à 24,5 kcal mol^{-1}) et une diminution du $\Delta S^{\ddagger}$ (de −7 à −14 ue). Ces résultats sont en accord avec la règle générale; lorsque $\Delta H^{\ddagger}$ décroît, $\Delta S^{\ddagger}$ décroît algébriquement.

TABLEAU 6. Charges totales sur les atomes de l'ylure d'azométhine non substitué

1,24	−0,246	+0,288
1,26	−0,243	+0,266
1,28	−0,239	+0,251
1,30	−0,236	+0,222
1,32	−0,231	+0,222

orbitales frontières, cette énergie est représentée par l'équation [1] (4):

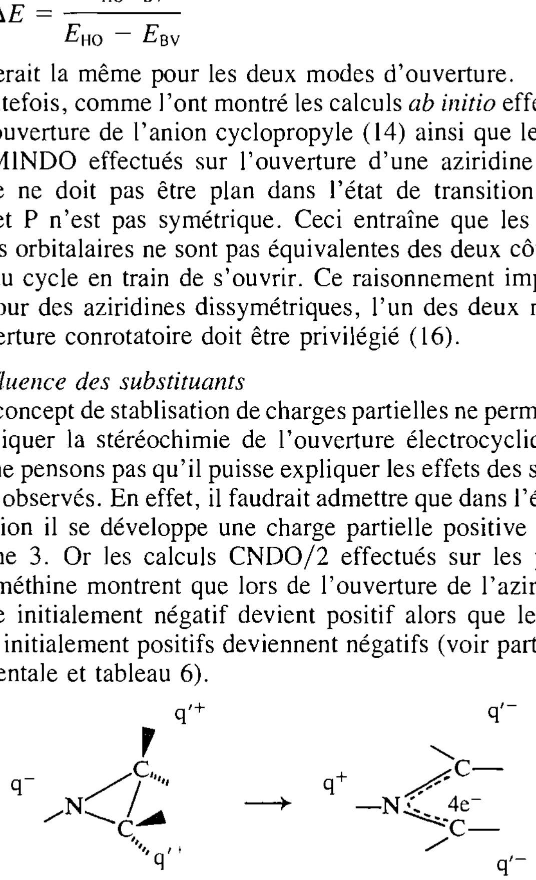
$$[1] \quad \Delta E = \frac{H^2_{\mathrm{HO-BV}}}{E_{\mathrm{HO}} - E_{\mathrm{BV}}}$$

Elle serait la même pour les deux modes d'ouverture.

Toutefois, comme l'ont montré les calculs *ab initio* effectués sur l'ouverture de l'anion cyclopropyle (14) ainsi que les calculs MINDO effectués sur l'ouverture d'une aziridine (15), l'azote ne doit pas être plan dans l'état de transition et le doublet P n'est pas symétrique. Ceci entraîne que les interactions orbitalaires ne sont pas équivalentes des deux côtés du plan du cycle en train de s'ouvrir. Ce raisonnement implique que pour des aziridines dissymétriques, l'un des deux modes d'ouverture conrotatoire doit être privilégié (16).

2. *Influence des substituants*

Le concept de stablisation de charges partielles ne permet pas d'expliquer la stéréochimie de l'ouverture électrocyclique et nous ne pensons pas qu'il puisse expliquer les effets des substituants observés. En effet, il faudrait admettre que dans l'état de transition il se développe une charge partielle positive sur le carbone 3. Or les calculs CNDO/2 effectués sur les ylures d'azométhine montrent que lors de l'ouverture de l'aziridine, l'azote initialement négatif devient positif alors que les carbones initialement positifs deviennent négatifs (voir partie expérimentale et tableau 6).



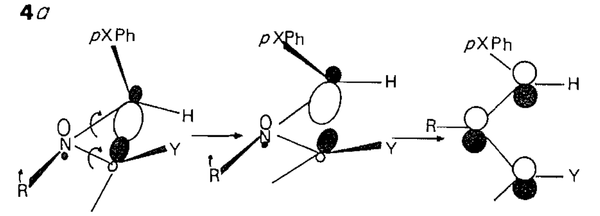
Compte tenu du fait que l'équilibre aziridine ⇌ ylure d'azométhine ou époxyde ⇌ ylure de carbonyle est considérablement déplacé vers l'hétérocycle fermé, selon le principe de Hammond, l'état de transition doit avoir une structure proche du dipôle-1,3 final. Des calculs *ab initio* effectués sur l'ouverture de l'anion cyclopropyle ont montré qu'il en devait être ainsi, tout au moins pour les longueurs de liaison (14).

Si l'on admet que la force motrice de la réaction est le transfert de charge du doublet de l'hétéroatome sur l'OM σ^*_{C-C} et que la réactivité est correctement interprétée par la théorie des relaxations, l'ouverture est d'autant plus aisée que l'énergie de relaxation (4) est grande en valeur absolue (éq. [1]).

2.1. *Substituants en position 1*

Dans des séries distinctes d'hétérocycles (aziridines et époxydes) ou dans des séries d'hétérocycles portant les mêmes

4*a*



4*b*

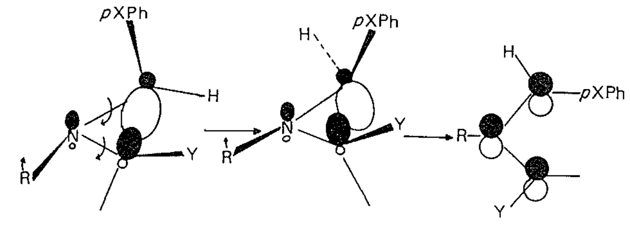


SCHÉMA 4. Interactions orbitalaires lors de l'ouverture conrotatoire d'une aziridine. État de transition.

substituants sur les carbones, la différence d'énergie entre le doublet de l'hétéroatome et l'OM σ^*_{C-C} destinée à se rompre, gouverne l'aptitude à l'ouverture.

La réactivité comparée des aziridines et époxydes a été discutée précédemment (1, 4) et nos résultats sont en accord avec le fait qu'à substituants identiques sur les carbones, les aziridines s'ouvrent plus aisément que les époxydes (17, 18). L'énergie du doublet de l'oxygène est plus basse que celle du doublet de l'azote (19), ce qui entraîne un transfert de charge du doublet P sur l'OM σ^*_{C-C} plus important dans le cas des aziridines.

L'influence des substituants donneurs sur le phényle lié à l'azote des aziridines **5** a été expliquée de la même manière (4).

La plus grande réactivité des aziridines *N*-phényles par rapport aux aziridines *N*-alkyles observée expérimentalement s'explique par la méthode des relaxations, puisque l'énergie d'interaction du doublet P avec l'OM σ^* est la plus grande lorsque le substituant de l'azote est un phényle.[3]

La facilité d'ouverture du cycle suit la facilité d'inversion de l'azote; en effet, la barrière d'inversion est plus faible dans le cas d'une aziridine *N*-phényle que dans le cas des aziridines *N*-alkyles; la différence est de l'ordre de 5 kcal mol^{-1} (20).

2.2. *Substituants en 2 et 3*

L'examen des tableaux montre que l'ouverture de la liaison C—C est facilitée par une substitution dissymétrique des carbones 2 et 3. Parmi les aziridines étudiées, **2***b* est la plus réactive. Puisque l'influence des substituants sur l'énergie des OM est additive en première approximation, ceci indique que dans une série d'hétérocycles de structures peu différentes, lorsque l'on passe d'un composé à l'autre, la variation du numérateur de l'équation [1] l'emporte sur celle du dénominateur. En effet, si la réactivité péricyclique était gouvernée uniquement par la différence d'énergie entre le doublet P et l'OM σ^*_{C-C}, la réactivité de **2***b* devrait se situer entre celle de **2***e* et **5**.

Cela n'a de sens que si l'on admet que l'azote qui passe de la forme pyramidale à la forme plane n'est pas encore plan dans l'état de transition (schéma 4).[4]

[3] O. Henri-Rousseau et N. Nafi. Communication personnelle.

[4] Dans le cas des époxydes, l'un des doublets joue le rôle du doublet de l'azote alors que l'autre joue le rôle de la liaison N—R.

Lorsque les substituants des carbones sont différents, l'OM σ^* est alors polarisée et les coefficients C_2 et C_3 sont d'autant plus différents que l'on a d'une part un substituant électro-attracteur et d'autre part un substituant électrodonneur (effet "push–pull"). Dans ces conditions, quel que soit le mode d'ouverture conrotatoire privilégié *a* ou *b*, plus l'OM est dissymétrique et plus H^2_{HO-BV} est important et plus l'ouverture est aisée.

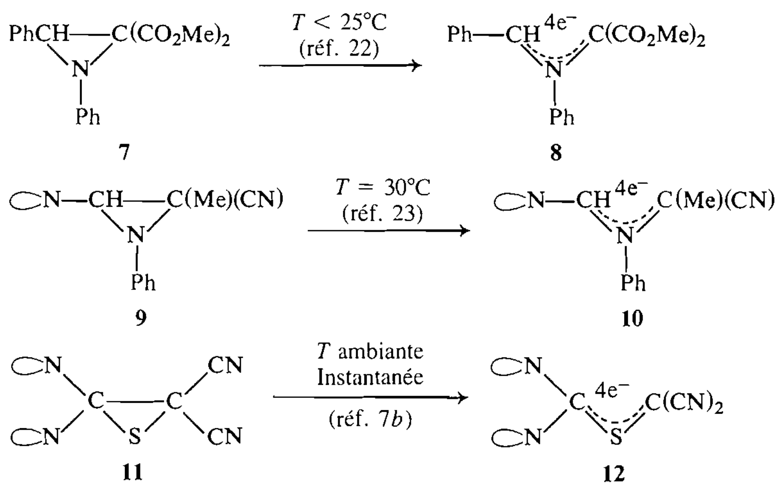
La séquence de réactivité des aziridines **1***a*, **2***a* et **3***a* suit l'augmentation de la polarisation de l'OM σ^* due au substituant Y. L'influence des substituants X sur la polarisation de cette OM permet de comprendre la réactivité des aziridines et des époxydes dont le phényle en 3 est substitué: plus X est donneur et plus la dissymétrie de l'OM σ^* augmente entrainant un accroissement de l'hamiltonien d'interaction H^2_{HO-BV}. Dans les composés **1** et **4**, les substitants X ont deux effets antagonistes: (*i*) un substituant électrodonneur, en relevant l'énergie de l'OM σ^*, défavorise le transfert de charge $P_N \rightarrow \sigma^*_{C-C}$; (*ii*) ce même substituant en augmentant la dissymétrie de l'OM σ^* favorise la réaction. L'antagonisme des deux effets pourrait expliquer que l'influence des substituants X est globalement faible, mais nos résultats expérimentaux indiquent que l'influence d'un tel substituant sur la dissymétrie (numérateur de l'équation [1]) l'emporte sur la variation du niveau d'énergie (dénominateur de l'équation [1]).

Dans les composés **3**, X substitue le phényle lié au carbonyle et, dans ces conditions, les deux effets vont dans le même sens; ainsi, le groupement NO_2 abaisse l'énergie de l'OM σ^* et accroit la polarisation de cette OM, favorisant la réaction électrocyclique.

L'influence d'un méthyle en 3 comparé à un hydrogène (cas des aziridines **1***i*, R = Me, et **1***j*, R = H) s'explique de la même manière. Un carbone sp^3 étant plus électronégatif que l'hydrogène, le méthyle compense partiellement l'influence du nitrile sur la dissymétrie de l'OM σ^*_{C-C} et de ce fait diminue la vitesse d'ouverture, par rapport à l'hydrogène.

Nos résultats semblent en accord avec les prévisions d'Épiotis qui, dans une approche théorique différente, prévoyait une augmentation de la réactivité péricyclique avec l'augmentation de la polarité de l'état de transition (21).

Le raisonnement qui précède permet de comprendre l'ouverture aisée des hétérocycles **7**, **9** et **11**. L'effet $-I$ des substituants en 2 et 3, en abaissant l'énergie de l'OM σ^* et la forte dissymétrie de cette OM due à l'effet "push–pull" des substituants +M en 3 et −M en 2, favorise le transfert de charge $P_N \rightarrow \sigma^*_{C-C}$ et, partant, l'ouverture du cycle.



D'après ce travail, on peut prévoir que quand deux aziridines portent des substituants identiques, celle qui présente la plus grande dissymetrie doit donner plus aisément l'ylure d'azométhine correspondant.

En conclusion, cette étude permet de dégager les points essentiels suivants: (*i*) la configuration relative des carbones cycliques a peu d'influence sur la vitesse d'ouverture électrocyclique des aziridines; (*ii*) l'ouverture est globalement favorisée par des substituants qui rapprochent les niveaux d'énergie du doublet P d'une part et de l'OM σ^*_{C-C} d'autre part. Toutefois, la dissymétrie de substitution des carbones 2 et 3 joue un rôle important; au fur et à mesure qu'elle croit, la vitesse d'ouverture augmente.

Partie expérimentale

1. *Détermination des constantes de vitesse* k_i

Les constantes cinétiques concernant l'ouverture électrocyclique des composés **1**, **2**, **3** et **4** étudiées au cours de ce travail sont déterminées en suivant la disparition de l'hétérocycle au cours de la réaction d'addition à l'ACDM. Le dosage des cyano-2 aziridines **1** est effectué à l'aide de l'ir (disparition de la bande $\nu_{C\equiv N}$ vers 2240 cm^{-1}) et celui des autres composés, à l'aide de la chromatographie en phase liquide selon le mode opératoire décrit dans un mémoire précédent (5).

2. *Détermination des paramètres d'activation*

Les paramètres d'activation, $\Delta E^{\ddagger}$, $\Delta H^{\ddagger}$, $\Delta S^{\ddagger}$ et $\Delta G^{\ddagger}$ sont déterminés à l'aide de méthodes standard (9), après avoir mesuré la constante de vitesse d'ouverture k_1 à, *au moins*, 5 températures différentes.

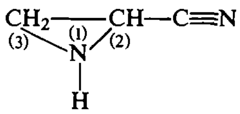
La pente de la droite (coefficient de corrélation r = 0,996), représentant le log k_1 en fonction de $1/T$, permet de calculer l'énergie d'activation $\Delta E^{\ddagger}$. L'ordonnée à l'origine correspond à log A_{ex}.

Compte tenu des diverses gammes de température étudiées en fonction des substituants du cycle, le $\Delta H^{\ddagger}$ est calculé, dans chaque cas, à la température moyenne, alors que le $\Delta S^{\ddagger}$ est toujours calculé pour T = 100°C. Dans les tableaux, nous n'avons reporté que les constantes de vitesse obtenues aux mêmes températures, dans une série donnée. Les résultats rassemblés dans les tableaux sont donnés avec un pourcentage de confiance de 90%.

3. *Calculs CNDO/2*

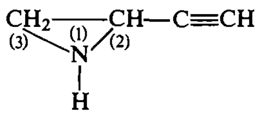
Les calculs CNDO/2 ont été effectués sur les aziridines **7** et **8** en considérant les angles du cycle égaux à 60°, l'azote étant pyramidal et les longueurs de liaison C—N = 1,487 Å, C—C = 1,509 Å. Les valeurs des charges ainsi obtenues sont reportées ci-dessous.

La géométrie des ylures d'azométhine n'étant pas connue, les angles de liaison sont pris égaux à 120° pour les carbones terminaux du dipôle et de l'azote central.



7

$q_1 = -0{,}157$
$q_2 = +0{,}04$
$q_3 = +0{,}016$

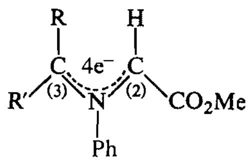


8

$q_1 = -0{,}163$
$q_2 = +0{,}065$
$q_3 = +0{,}007$

Les calculs rassemblés dans le tableau 6 ont été effectués sur l'ylure d'azométhine non substitué pour diverses longueurs de la liaison C—N; ils montrent que les charges évoluent peu.

Les calculs CNDO/2 concernant les ylures d'azométhine résultant de l'ouverture des aziridines **2*b*** nous ont été aimablement communiqués par Monsieur le Professeur R. Carrié (Université de Rennes) que nous remercions vivement.



R = Ph R′ = H, $q_2 = -0{,}264$ $q_3 = -0{,}061$
R = H R′ = Ph, $q_2 = 0{,}245$ $q_3 = -0{,}073$

Design and reactivity of organic functional groups—utility of imidazolylsulfonates in the synthesis of monobactams and 3-amino nocardicinic acid[1]

STEPHEN HANESSIAN,[2] CLAUDE COUTURE, AND HEINZ WYSS
Department of Chemistry, Université de Montréal, Montréal (Qué.), Canada H3C 3V1

Received May 30, 1985

STEPHEN HANESSIAN, CLAUDE COUTURE, and HEINZ WYSS. Can. J. Chem. **63**, 3613 (1985).

The imidazolylsulfonate group has been found to be a versatile leaving group in the intramolecular cyclization of *p*-methoxyphenyl amides and related derivatives of *N*-substituted L-serine to give the corresponding β-lactams.

STEPHEN HANESSIAN, CLAUDE COUTURE et HEINZ WYSS. Can. J. Chem. **63**, 3613 (1985).

Le groupement imidazolylsulfonate est un excellent groupe partant dans des réactions de cyclisation intramoléculaire des *p*-méthoxyphényle amides et d'autres dérivés de la L-sérine. Les produits de cyclisation sont les β-lactames correspondants.

Since the emergence of the monobactam family of monocyclic β-lactam antibiotics (1, 2) much effort has been devoted to their total synthesis (3–5), particularly since they have demonstrated potent antibacterial activity and high stability toward β-lactamases (6). Several reports have also been concerned with the synthesis of 2-oxo-azetidines (7), 4-substituted-2-azetidinones (8), 2-amino-4-substituted-2-azetidinones (9), and related compounds (10). The same monocyclic β-lactam system occurs also in the structure of the nocardicin group of antibiotics (11). Several elegant syntheses of this class of natural products and their components in optically active (12, 13) and racemic forms (14) have been reported. Some relevant structures are shown in Scheme 1. New types of 3-amino-2-azetidinones are continually being discovered from fermentation sources (15). We recently reported the total and stereocontrolled synthesis of 4-substituted 3-amino-2-azetidinones (16), which are known to be immediate precursors to potent antibotics in this series (9).

As already discussed (1, 2), a practical access to the monobactams in general could take advantage of the chiron approach (17) utilizing *N*-substituted L-serine or related amino acid derivatives as templates. A high degree of convergence in functionality and sense of chirality can thus be achieved with the intended target while utilizing the same number of required carbon atoms (Scheme 2). Ring closure by intramolecular attack of the amine nitrogen with a suitable leaving group on the hydroxyl terminus, as previously demonstrated for β-halopropionamides (7) or related derivatives (3–5), would complete the task of assembling the diminutive yet important synthetic intermediate. In spite of the seemingly trivial nature of this exercise, it should be noted that racemization, elimination, and intramolecular reactions could effectively compete with ring closure (5) and loom as major threats to such a strategy.

Most of the current syntheses of monobactams rely on using an *N*-alkoxy hydroxamate or *N*-sulfonic acid derivative, in which the NH is significantly acidic, hence more reactive in the internal displacement reaction (4).

We wish to report an exceptionally mild and efficient ring closure reaction of *N*-substituted serine amides, based on a novel activation of the hydroxyl group as the imidazolylsulfonate (imidazylate) (18; for a preliminary announcement of a portion of this work, see also ref. 19). This method leads to the efficient syntheses of (*S*)-3-amino-2-azetidinone and 3-amino nocardicinic acid. Thus, treatment of *N*-[(benzyloxy)-carbonyl]-L-serine *p*-(methoxyphenyl) amide **2***a* or the corresponding N-Boc derivative **2***b* with *N*,*N*-sulfuryl diimidazole (20) in DMF, and adding sodium hydride at −40°C, resulted in sequential *O*-imidazolysulfonylation and ring closure to give the crystalline azetidinones **3***a* and **3***b* in 70 and 85% yields, respectively, isolated by direct crystallization (Scheme 3). Bose and co-workers (5) have reported the successful application of the Mitsunobu reaction (21) to the toluidide derived from *N*-benzyloxycarbonyl L-serine, and the isolation of a β-lactam in 53% yield. Cleavage of the *p*-anisyl group with ceric ammonium nitrate (22) led to the known crystalline azetidinone derivatives **4***a* and **4***b*, respectively, in 70% yield. The isolation of these compounds in good yields indicates that the internal cyclization via the imidazolylsulfonates (Scheme 3) proceeded without racemization, elimination, or aziridine formation (5). The transformation of **4***a* and **4***b* into biologically active monobactams has been described elsewhere (3). Application of the same reaction conditions to the L-threonine series (Scheme 4) gave a poor yield of the expected cyclization product, with aziridine formation being prevalent. Since the imidazolylsulfonate is known to be an excellent leaving group in displacement reactions of secondary alcohols (18), it is likely that aziridine formation in the L-threonine derivatives is the result of the prevalence of a particular conformation in solution that favors attack by the carbamate nitrogen. Related examples can also be encountered in other work (5).

We then turned our attention to the prospects of utilizing the *O*-imidazolylsulfonyl group in the intramolecular cyclization of a precursor to 3-amino nocardicinic acid (Scheme 5). Thus, *N*-phthalimido L-serine **5** (23) was converted into the corresponding dipeptide derivative **6** (24) and the latter was subjected to ring closure via the imidazylate procedure. Under conditions that led to smooth cyclization, in the case of **2***a* or **2***b*, little if any reaction took place. However, gradual warming of the reaction mixture to 0°C led to the expected cyclization to give the diastereomeric β-lactams **8** and **9** (1 : 1) in 46% yield. It was found that simple treatment of **6** with fluoride ion in the presence of *N*,*N*-sulfuryl diimidazole resulted in the desired ring closure to give **8** and **9** in 63% yield as a 1 : 1 mixture of diastereomers. Thus, even though the conditions for cyclization were extremely mild and essentially neutral, considerable epimerization had occurred at the highly susceptible benzylic carbon, which is not unexpected in this series (13*b*). Again, little if any β-elimination was observed, in contrast to the results of the Mitsunobu reaction under some conditions

(13*b*). It should be noted, however, that Townsend and Nguyen had succeeded in considerably improving the ratio of **8** and **9** by utilizing tri-n-butylphosphine in the Mitsunobu reaction (13*b*). Catalytic debenzylation of the mixture of **8** and **9** led to **10** and **11**, from which the desired natural isomer **10** could be separated by direct fractional crystallization. The mother liquors were subjected to repeated equilibration in the presence of triethylamine to give **10** in 67% yield. The final mother liquors consisted of a 1:2 mixture of **10** and **11**, respectively. The overall yield of **10** from *N*-phthalimido L-serine **5** was ~33%. The conversion of **10** into (−)-3-amino nocardicinic acid by sequential deprotection has been previously described (13*a*).

Experimental

Melting points are uncorrected. Optical rotations were measured on a Perkin–Elmer automatic spectropolarimeter model 141. The ^{1}H nmr spectra were recorded on Bruker WH 900 and 400 MHz instruments with tetramethylsilane as internal standard in deuteriochloroform as solvent. Mass spectra were recorded on a VG 1212 low resolution mass spectrometer by the direct chemical ionization technique (DCI). Column chromatography was done by the flash technique. EDAC.HCl is the abbreviation for 1-ethyl-3-(3-dimethylaminopropyl) carbodiimide hydrochloride.

N-*Benzyloxycarbonyl* L-*serine* (N-p-*methoxyphenyl)amide* (**2**a)

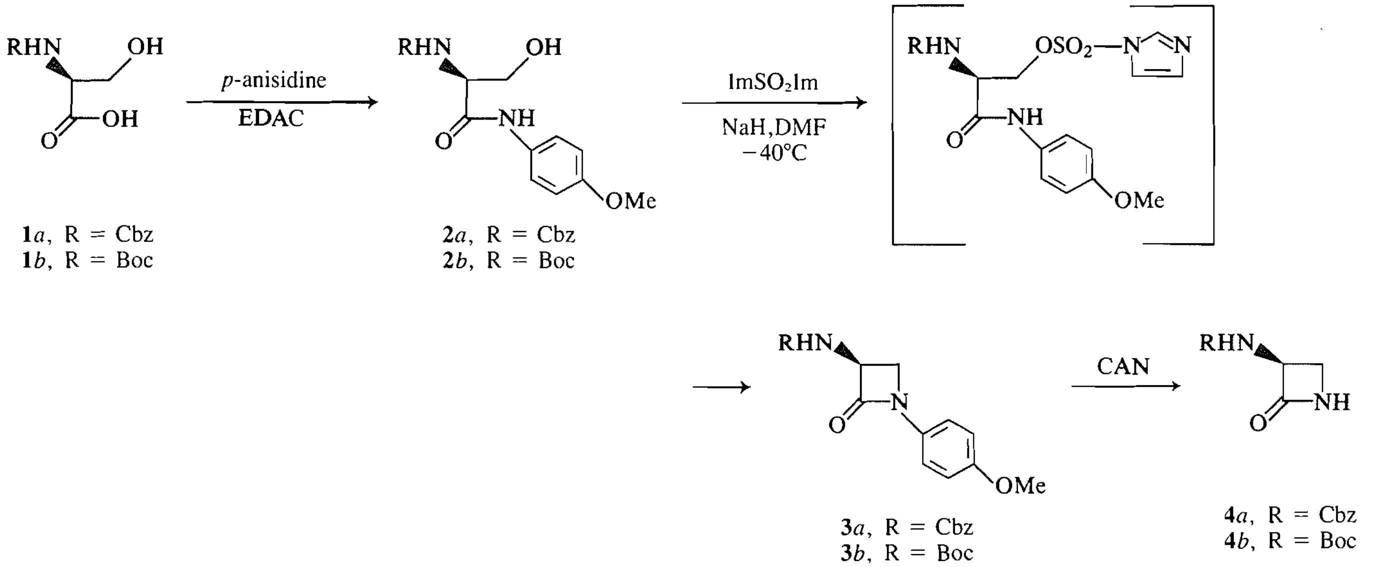
To a solution of **1***a* (1.5 g, 6.28 mmol) in 8 mL of THF were added, in succession, 960 mg (1.1 equiv.) of 1-ethyl-3-(3-dimethylaminopropyl) carbodiimide hydrochloride (EDAC.HCl) (25) in 8 mL of dichloromethane. The solution was stirred for 1 h, the solvents were evaporated, and the residue was suspended in ethyl acetate. Washing with dilute aqueous hydrochloric acid, aqueous sodium bicarbonate, then water, and processing the organic phase in the usual manner gave a colorless solid. Trituration with a mixture of ethyl acetate and hexanes (1:1) gave 1.79 g (83%) of the title compound, which was used as such in the next step. Recrystallization of a portion from ethyl acetate gave an analytical sample, mp 146–147°C; $[\alpha]_D$ −16° (*c* 1, THF); λ_{max}: 1660 (amide) cm^{-1}; ms: 345 (M + 1), etc. *Anal.* calcd. for $C_{18}H_{19}N_2O_5$: C 62.79, H 5.81, N 8.14; found: C 62.86, H 5.79, N 8.17.

N-tert-*Butoxycarbonyl* L-*serine* (N-p-*methoxyphenyl)amide* (**2**b)

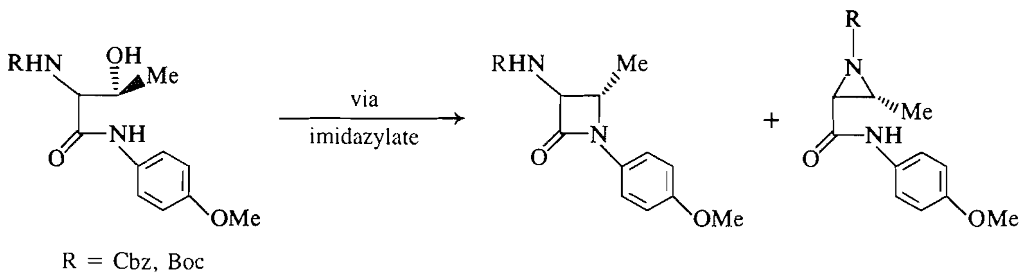
A solution containing **1***b* (8.85 g, 43 mmol), 5.83 g (1.1 equiv.) of *p*-anisidine, and 9.07 g (1.1 equiv.) of EDAC.HCl in a total of 75 mL of THF and 25 mL of dichloromethane was stirred and processed as described for **2***a*. The title compound was obtained as a colorless solid in 68.6% yield (9.18 g). Recrystallization from ethyl acetate gave pure product, mp 105–106°C; $[\alpha]_D$ −76° (*c* 1, $CHCl_3$); λ_{max}: 1660 (amide) cm^{-1}; ms: 311 (M + 1), etc. *Anal.* calcd. for $C_{15}H_{21}N_2O_5$: C 58.06, H 7.10, N 9.03; found: C 58.14, H 7.12, N 8.92.

(S)-3-N-[(*Benzyloxycarbonyl)amino]-1*-p-*methoxyphenyl-2-azetidinone* (**3**a)

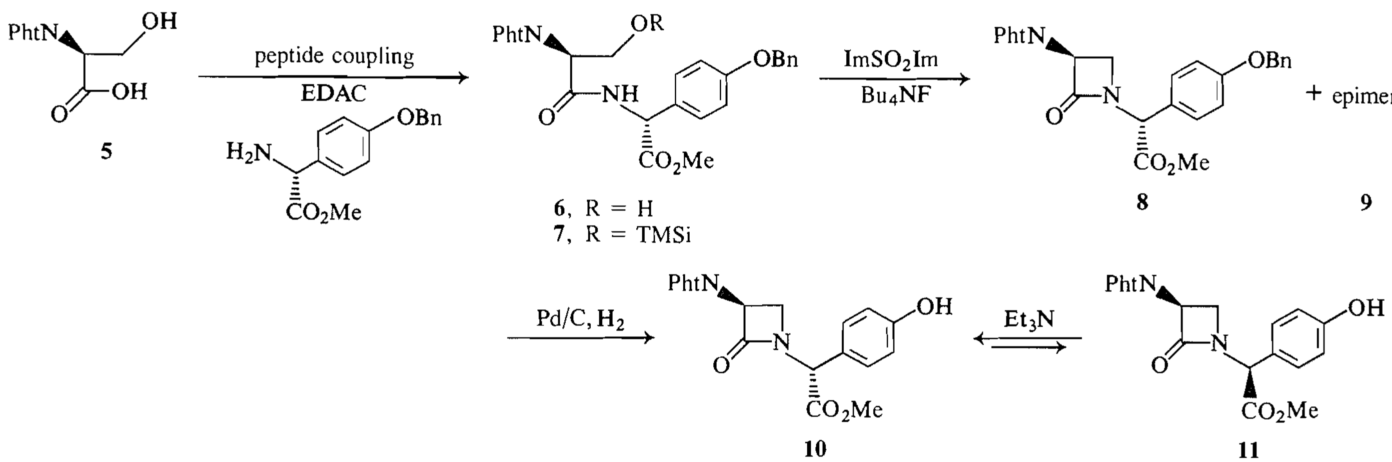
A solution containing **2***a* (2 g, 5.81 mmol) in 30 mL of DMF was added dropwise at 0°C to 5 mL of DMF containing 348 mg (1.5 equiv.) of sodium hydride (60% suspension in mineral oil) that was previously washed with hexanes. The mixture was cooled to −40°C and 1.72 g (1.5 equiv.) of *N*,*N*-sulfuryl diimidazole in 7 mL



SCHEME 3



SCHEME 4



SCHEME 5

of DMF was added with efficient stirring under argon over a period of 25 min. After stirring for a further 30 min, the solution was allowed to warm up to room temperature, methanol (0.5 mL) and chloroform (100 mL) were added, and the solution was washed with saturated brine, then with water. Processing the organic phase gave a colorless solid, which when triturated with ethyl acetate gave 1.42 g (75%) of the desired product **3*a***. Recrystallization from a mixture of ethyl acetate and dichloromethane gave an analytical sample, mp 178°C; $[\alpha]_D$ +35.8° (*c* 1, $CHCl_3$); λ_{max}: 1740 (β-lactam C═O), 1700 (urethane C═O) cm^{-1}; ^1H nmr (90 MHz) ppm: 3.50 (dd, H4β, J = 2.3, 5.3 Hz), 3.73 (s, 3H, OCH_3), 3.88 (t, H4α, J = 5.3 Hz), 4.90 (dd, H3), 5.09 (s, 2H, OCH_2Ph), 5.8 (bd, N*H*, J ~ 8 Hz), 7, 7.3 (arom); ms: 327 (M + 1), etc. *Anal.* calcd. for $C_{18}H_{17}N_2O_4$: C 66.26, H 5.52, N 8.59; found: C 66.16, H 5.53, N 8.42.

*(S)-3-[(*tert*-Butoxycarbonyl)amino]-1-*p*-methoxyphenyl-2-azetidinone (3b)*

A solution containing 0.5 g (1.61 mmol) of **2*b***, 96.8 mg (1.5 equiv.) of sodium hydride, and 480 mg (1.5 equiv.) of *N*,*N*-sulfuryl diimidazole in a total of 13 mL of DMF was stirred at −20°C (addition done at −20°C) under argon for 1 h. Work-up as described above gave a solid, which was recrystallized from ethyl acetate to give 406 mg (85%) of the title compound, mp 180–180.5°C; $[\alpha]_D$ +48.5° (*c* 1.30, $CHCl_3$); λ_{max}: 1750 (β-lactam C═O), 1680 (urethane C═O) cm^{-1}; ^1H nmr (90 MHz) ppm: 1.46 (s, 9H, *tert*-butyoxycarbonyl), 3.51 (dd, H4β, J = 2.3, 5.3 Hz), 3.79 (s, 3H, OCH_3), 3.86 (t, H4α, J = 5.3 Hz), 4.90 (m, H3), 5.54 (dd, NH, J ~ 7 Hz), 7.6 (arom); ms: 293 (M + 1), etc. *Anal.* calcd. for $C_{15}H_{19}N_2O_4$: C 61.64, H 6.85, N 9.59; found: C 61.72, H 6.81, N 9.60.

(S)-3-[Benzyloxycarbonyl)amino]-2-azetidinone (4a)

To a cooled solution of **3***a* (760 mg, 2.33 mmol) in 60 mL of acetonitrile was added a solution of ceric ammonium nitrate (3.8 g, 3 equiv.) in 15 mL of water, dropwise and with stirring. After 30 min at 0°C, the solution was allowed to warm up to room temperature, diluted with water, and extracted with ethyl acetate (100 mL × 3). Processing the organic phase in the usual manner and decolorization with 10% aqueous sodium sulfite gave the title compound as a colorless solid. Trituration with ethyl acetate and hexanes (1:1) gave 360 mg (70%) of **4***a*, mp 164–165°C; $[\alpha]_D$ −17.6° (*c* 1.4, MeOH) (lit. (3) mp 163–164°C; $[\alpha]_D$ −17.8°). The overall yield from L-serine was ~40%; ^{1}H nmr (90 MHz) ppm: 3.33 (dd, H4β, *J* = 2.3, 5.3 Hz), 3.60 (t, H4α, *J* = 5.3 Hz), 4.83 (m, H3), 5.1 (s, 3H, OCH_3), 5.43 (m, NH β-lactam C=O); ms: 221 (M + 1), etc. *Anal.* calcd. for $C_{11}H_{11}N_2O_3$: C 60.00, H 5.45, N 12.73; found: C 59.95, H 5.39, N 12.52.

(S)-3-[(tert-Butoxycarbonyl)amino]-2-azetidinone, (4b)

A solution of **3***b* (800 mg, 2.74 mmol) in 70 mL of acetonitrile was treated with ceric ammonium nitrate (1.65 g, 3 equiv.) in 5 mL of water as described for **4***a*. Processing of the reaction mixture gave the title compound **4***b* (350 mg) in 70% yield after recrystallization from ethyl acetate and hexanes (5:1), mp 172–173°C; $[\alpha]_D$ −18.9° (*c* 1, MeOH) (lit. (3) mp 173–175°C; $[\alpha]_D$ −23.5°; lit. (13*c*) mp 171.5–172.5°C; $[\alpha]_D$ −19.8°); λ_{max}: 1760 (β-lactam C=O) cm^{-1}; ^{1}H nmr (90 MHz) ppm: 1.43 (s, 9H, *tert*-butoxycarbonyl), 3.26 (dd, H4β, *J* = 2.3, 5.3 Hz), 3.54 (t, H4α, *J* = 5.3 Hz), 4.76 (m, H3), 5.43 (dd, *J* ~ 8 Hz, NH β-lactam), 6.9 (m, urethane NH); ms: 189 (M+), etc.

Preparation of dipeptide 6

To a solution of *N*-phthalimido L-serine (86 mg, 0.37 mmol) in 0.5 mL of THF were added successively 109 mg (1.1 equiv.) of 4-*O*-benzyl-*p*-hydroxyphenyl L-glycine methyl ester (13*d*) in 0.5 mL of THF and 77 mg (1.1 equiv.) of EDAC.HCl suspended in 5 mL of dichloromethane. After stirring for 2.5 h at room temperature the solution was evaporated to dryness, the residue was dissolved in dichloromethane, and the solution was washed with aqueous acid, then aqueous bicarbonate, and finally with water. Processing of the organic phase gave 140 mg (78.5%) of the desired dipeptide **6** as a colorless solid. Recrystallization from a mixture of ethyl acetate and hexanes gave pure material (103 mg, 58%); compare 48% with a DCC coupling (24); mp 185–186°C; $[\alpha]_D$ −115.5° (*c* 1, $CHCl_3$) (lit. (24) mp 189–191°C; $[\alpha]_D$ −188°); ^{1}H nmr (90 MHz) ppm: 3.39 (bs, OH), 3.65 (s, 3H, CO_2CH_3), 3.7–4.9 (m, 3H, H3, H 4.4′), 5.00 (s, 2H, OCH_2Ph), 5.47 (d, 1H, *J* = 6 Hz, *CH*—CO_2CH_3), 7.34 (NH), 7.38–7.78 (arom). A single isomer was detected when the spectrum was recorded in the presence of a shift reagent [Eu(hfc)$_3$]; ms: 489 (M + 1).

Intramolecular cyclization of 6 to a mixture of 8 and 9

A solution of **6** (370 mg, 0.76 mmol) in 15 mL of THF was treated with 1.14 mL (1.5 equiv.) of a 1 *M* solution of tetra-n-butylammonium fluoride in THF, then with 225 mg (1.5 equiv.) of *N,N*-sulfuryl diimidazole. After stirring overnight, a few drops of aqueous acetic acid were added, the solvent was evaporated, and the residue was dissolved in dichloromethane. Washing with aqueous hydrochloric acid, then water, and usual processing gave a syrup that was chromatographed (ethyl acetate – hexanes 1:1) to give a mixture of **8** and **9** (224 mg, 63%) as a colorless solid, mp 55–65°C; $[\alpha]_D$ −110.5° (*c* 1, $CHCl_3$); λ_{max}: 1745 (β-lactam C=O), 1760 (phthalimido), 1720 (CO_2CH_3) cm^{-1}; ^{1}H nmr (90 MHz) ppm: 2.10–3.60 (dd, H4β), 3.8, 3.82 (s, H, CO_2CH_3), 3.70–4.08 (t, H4α), 5.07 (s, 2H, OCH_2Ph), 5.32–5.55 (dd, H3), 5.69, 5.76 (s, *C*HCO_2CH_3), etc; ms: 471 (M + 1), etc.

(S)-3-(Phthalimido)-1-(p-hydroxyphenyl-L-glycinyl methyl ester)-2-azetidinone 10 and its epimer 11

A solution containing 231 mg (0.6 mmol) of a mixture of **8** and **9** in a mixture of methanol and acetic acid (1:1, 15 mL) was hydrogenated in the presence of 150 mg of 10% palladium-on-charcoal. After an overnight treatment, the catalyst was filtered, washed with methanol, and the filtrate was coevaporated with benzene several times to remove all the residual acetic acid. The residue thus obtained (quant.) showed a 2:1 mixture (nmr) of **10** and **11**, respectively. Fractional recrystallization from ethyl acetate – hexanes (4:1) gave 68 mg of **10** as colorless crystals, mp 169–171°C; $[\alpha]_D$ −238.5° (*c* 0.58, MeOH) (lit. (24) mp 169–170°C; $[\alpha]_D$ −239°; lit. (13*d*) mp 203–204°C; $[\alpha]_D$ −236°; λ_{max}: 1770 (β-lactam C=O), 1750 (phthalimido), 1730 (CO_2CH_3) cm^{-1}; ^{1}H nmr (90 MHz), ppm: 3.46 (dd, H4β, *J* = 2.9, 5.5 Hz), 3.79 (s, 3H, CO_2CH_3), 3.95 (t, H4α, *J* = 5.5 Hz), 5.51 (dd, *J* = 2.9, 5.5 Hz), 7.1–7.76 (arom.); ms: 381 (M + 1), etc.

Treatment of the mother liquors of recrystallization overnight with dichloromethane containing ~10% triethylamine, evaporation to dryness, and chromatography (ethyl acetate – hexanes 2:1) gave a mixture of **10** and **11** in a ratio of 2:1. After recrystallization, a further 75 mg of **10** was obtained, for a total of 142 mg (67%). The final mother liquors gave 28 mg of a 1:2 mixture of **10** and **11**, respectively.

A series of *E* and *Z* isomers of substituted 4-(1-ethoxyethylidene)-5-oxazolones and thiazolones have been prepared and their ^{1}H and ^{13}C spectra recorded. The vinylic methyl ^{1}H chemical shifts showed minimal differences between *E* and *Z* isomers whereas the vinylic OCH_2 ^{1}H signals differed by 0.15−0.43 ppm, with the *Z* isomer being consistently the more deshielded. Both vinylic methyl and OCH_2 groups showed different ^{13}C resonances for each isomer, with the *Z* isomers being the more deshielded. The *Z* geometry was conclusively defined for one isomer of 4-(1-ethoxyethylidene)-2-phenyl-5-oxazolone, **5**, by X-ray crystallography and this was sufficient to assign the geometry of the remaining pairs of *E* and *Z* isomers. Oxazolone **5** has the space group $P2_1/n$ and cell dimensions a = 9.219(3), b = 19.899(5), c = 7.459(1) Å, β = 118.01(2)°, and has four formula units in the unit cell. Intensities were measured with use of MoKα radiation and a Nicolet P3 diffractometer. The crystal structure was determined by standard methods and refined to R_1 = 0.0709, R_2 = 0.0696 based on 1419 independent reflections. The molecule is essentially planar and most bond lengths and angles are normal. Exceptions are the very short C(olefin)—O(ether) bond (1.339(4) Å) and the large ether C—O—C angle (122.1(3)°) caused by extreme delocalization in the O(ether)CCCO(carbonyl) system. The planarity causes a number of strong intramolecular repulsive interactions, causing an exceptionally small external olefin angle, O(ether)CC(methyl), of 108.1(4)°. The ethoxyl side chain of **5** adopts a conformation in the solid state which places the methylene of the OCH_2 group adjacent to the oxazole ring nitrogen. This conformation is proposed to persist in solution phases and is consistent with the observed ^{13}C chemical shifts and known γ and δ substituent effects.

R. A. BELL, R. FAGGIANI, C. J. L. LOCK et R. A. MCLEOD. Can. J. Chem. **63**, 3618 (1985).

On a préparé une série d'isomères *E* et *Z* des (éthoxy-1 éthylidène)-4 oxazolones-5 et thiazolones-5 et on a enregistré leurs spectres rmn du ^{1}H et du ^{13}C. En rmn du ^{1}H, les déplacements chimiques des méthyles vinyliques ne présentent que des différences minimales entres les isomères *E* et *Z* alors que les déplacements chimiques des OCH_2 vinyliques diffèrent par 0,15−0,43 ppm; dans tous les cas, l'isomère *Z* est le plus déblindé. En rmn du ^{13}C, les groupements méthyles ainsi que les OCH_2 vinyliques de chacun des isomères présentent tous des résonances différentes; les isomères *Z* sont toujours les plus déblindés. Utilisant la diffraction des rayons-X, on a défini d'une façon non ambigue la géometrie *Z* de l'isomère **5** de la (éthoxy-1 éthylidène)-4 phényl-2 oxazolone-5 et cette démonstration est suffisante pour attribuer la géométrie des autres paires d'isomères *E* et *Z*. L'oxazolone **5** cristallise dans le group d'espace $P2_1/n$ avec a = 9,219(3), b = 19,899(5), c = 7,459(1) Å, β = 118,01(2)° et quatre molécules par maille. On a mesuré les intensités à l'aide de la radiation MoKα et un diffractomètre Nicolet P3. On a déterminé la structure cristalline par les méthodes usuelles et on l'a affinée jusqu'à des valeurs de R_1 = 0,0709 et R_2 = 0,0696 pour 1419 réflexions indépendantes. La molécule est essentiellement planaire et la plupart des longueurs et des angles sont normaux. La liaison C(oléfine)—O(éther) qui est très courte (1,339(4) Å) et l'angle de l'éther C—O—C qui est très grand (122,1(3)°) sont des exceptions qui sont causées par une délocalisation extrême dans le système O(éther)-CCCO(carbonyle). La planéité provoque un grand nombre d'interactions répulsives intramoléculaires qui font que l'angle oléfinique externe, O(éther)CC(méthyle), est extrèmement petit (108,1(4)°). À l'état solide, la chaîne latérale éthoxyle du composé **5** adopte une conformation telle que le groupement OCH_2 se trouve dans une position adjacente de l'azote du cycle oxazole. On croit que cette conformation persiste en solution et qu'elle est en accord avec les déplacements chimiques ainsi que les effets γ et δ de substituants observés en rmn du ^{13}C.

[Traduit par le journal]

Introduction

4-(1-Alkoxyethylidene)-5-oxalozones and the corresponding 5-thiazolones can exist as geometric isomers. Potentially one should be able to differentiate between *E* and *Z* isomers by examining the ^{1}H nmr chemical shifts of protons at positions a, a′, b, b′, c, c′, d, and d′ (see Fig. 1). In practice, however, positions b, b′, c, and c′ are the more important. This arises because in many compounds of interest the protons at both the a and a′ positions are substituted by other atoms and the difference in shifts of protons at d and d′ is too small to be of practical use.

Nevertheless, examination of shifts of protons at a and a′ is of interest since they can be correlated with the shifts of protons at b, b′, c, and c′, and much work has been done on the ^{1}H nmr of the isomers of compounds of type **1** (Fig. 2) where at least one H substituent is present and the other substituent is alkyl or aryl. The majority of the assignments have been made by correlation of the spectra of the oxazolones **1** (R^1 or R^2 = H) with the spectra of the base catalysed hydrolysis products of **2** (1−5). The problem of the unambiguous assignment of the *E* and *Z* geometry to a particular series of compounds has been solved by combined ^{1}H nmr and crystallographic studies. The structures of the oxazolone **3** and the ring opened product **4** have been determined by X-ray diffraction (6,7). It has been established (8) that the thermodynamic product, obtained by the Plochl−Erlenmeyer synthetic route (9,10) is of *Z* geometry, whereas the *E* geometry is obtained by photo-irradiation, or acid promoted isomerization of the *Z* isomer (8,11). From this, ^{1}H nmr assignments have been made for the olefinic protons in the *E* and *Z* isomers of the oxazolones **1** and their hydrolysis products **2**. These resonances of the olefinic protons in **1** and **2** (R^1 or R^2 = H) are at higher field for the *Z* isomer (8). This assignment has, in turn, allowed the assignment of

the resonances of the allylic protons in **1** and **2** (b and b' in Fig. 1) (4).

Attempts to extrapolate the data to systems where neither R^1 nor R^2 = H have met difficulties. Recently two different research groups have assigned *E* and *Z* geometries to isomers of compounds of type **1** and **2** that are contrary to extrapolation from the work described above. The first group (12) (for **1** and **2**, $R^1 = CH_3$, $R^2 = CH_2CH_3$ and $R^1 = CH_2CH_3$, $R^2 = C_6H_5$ or CH_3) based their assignments on ^{1}H nmr solvent shifts, and the second group (13, 14) (for **1** and **2**, $R^1 = CH_3$, $R^2 = C_6H_5$ and $R^1 = C_6H_5$, $R^2 = CH_3$) based their assignments on the relative chemical shift positions, assuming that the methyl group closest to the carbonyl group was the more deshielded. Our own interest is in isomerism in 4-(1-alkoxyethylene)-5-oxazolones and the corresponding 5-thiazolones. Two isomers have been reported previously for 2-benzyl-4-methoxymethylene-5-oxazolone; the first was prepared by the penaldate method and the second by the addition of diazomethane to the hydroxymethylene derivate (15). Two isomers have also been reported for 4-(1-ethoxyethylidene)-2-phenyl-5-oxazolone, **5** (16, 17). No attempts were made to assign a particular structure to any of the above isomers.

In the work described here, two series of isomers of a number of 4-(1-alkoxyethylidene)-5-oxazolone and thiazolone compounds have been prepared (see Fig. 3), and it has proved possible to differentiate between the two series of isomers by ^{1}H and ^{13}C nmr spectroscopies. Nevertheless, in light of the

ambiguity caused by the extrapolation mentioned above, it seemed unwise to assign the structures on the basis of the work on compounds **1** (R^1 or R^2 = H), particularly because of the greater electronegativity of the oxygen atom. Thus we have examined the structure of one of our compounds by X-ray diffraction, and this has allowed the assignment of specific structures to each series.

Results

Syntheses

The 4-(1-alkoxyethylidene)-5-oxazolones and 5-thiazolones used in this work are listed in Fig. 3. The majority were prepared by the reaction of triethyl orthoacetate and acetic anhydride with the appropriate *N*-acyl or *N*-aroyl glycinate, for the oxazolones, or *N*-dithiocarbalkyl or *N*-thiocarbalkoxy glycinate, for the corresponding thiazolones. The synthetic processes are summarized in Schemes 1–3. In general, the orthoacetate – acetic anhydride procedure gave an equilibrium mixture of the *E* and *Z* isomers in a ratio which varied from 1:5 to 1:3 (*E*/*Z*). The only exceptions to this were the 2-alkyl-4-(1-ethoxyethylidene)-5-oxazolones **6** and **7**, which gave only the *Z* isomer from this reaction. The *E* isomers of **6** and **7**, as for other compounds with the exception of 4-(1-ethoxyethylidene)-2-thioxo-5-thiazolidinone, **19**, and the hydroxyethylidene compounds **11**, **12**, and **16**, were available either by photo-irradiation of the *Z* isomers, or by acid catalysed exchange. The *E* and *Z* isomers were separable, and able to be purified, by flash column chromatography on silica gel supports.

The 1-hydroxyethylidene oxazolone, **11**, was prepared by the action of acetic anhydride and 3-methylpyridine on sodium *N*-benzoylglycinate, and the 1-hydroxyethylidene oxazolone, **12**, by hydrolysis of the corresponding 1-ethoxyethylidene derivative, **5**, with concentrated hydrobromic acid (see Scheme 1). The 1-hydroxyethylidene thiazolone, **16**, was prepared by the hydroxide ion hydrolysis of the 1-ethoxyethylidene compound, **14** (see Scheme 2). The 1-methoxyethylidene oxazo-

lone, **10**, and the corresponding thiazolone, **17**, were both obtained by the reaction of diazomethane on the hydroxy compounds **12** and **16**, respectively. These reactions led to the formation of only one isomer in each case: **10** being assigned the *Z* geometry and **17** the *E* (see Discussion).

The 2-thioxo-thiazolidinone derivative **19** was synthesized from glycinamide hydrochloride and carbon disulphide as outlined in Scheme 4. The orthoacetate – acetic anhydride procedure gave only one isomer, (*Z*)-**19**.

Spectroscopic data

Selected ^1H and ^{13}C nmr data are summarized in Table 1. The remaining chemical shift data are given in the experimental section under each compound. The protons of an OCH_2 group (C(8)) (hydrogens on a carbon atom at sites b or b′ in Fig. 1) showed the greatest differences in chemical shift between the *E* and *Z* geometric isomers, the trend being consistent for all compounds examined. The vinylic CH_3 protons (hydrogens on a carbon atom at sites a or a′, C(7)) showed very small chemical shift changes and are included in Table 1 for comparison. The vinylic CH_3 carbon, on the other hand, showed a consistent trend in the ^{13}C chemical shift differences between the two isomers, as did the carbon of the OCH_2 group. These consistent trends, together with the absolute geometry of the 4,6-double bond in 4-[(Z)-1-ethoxyethylidene]-2-phenyl-5-oxazolone, **5**, as determined by X-ray crystallography, were used to assign the geometric isomers in both the oxazolone and the thiazolone series. The assignments are included in Table 1.

X-ray structural data

The crystal data for 4-[(Z)-1-ethoxyethylidene]-2-phenyl-5-oxazolone, (Z)-**5**, are given in Table 2. The atomic positional parameters and temperature factors for non-hydrogen atoms are given in Table 3 and selected interatomic distances and angles are given in Table 4. Tables of hydrogen atom positional and thermal parameters, bond lengths and angles involving hydrogen atoms, best planes and dihedral angles have been deposited.[3]

Discussion

E *and* Z *geometry assignment*

The geometry assignments of the 4-(1-alkoxyethylidene)-5-oxazolones and the 4-(1-alkoxyethylidene)-5-thiazolones prepared in this work were made on the basis of the consistent ^1H and ^{13}C chemical shift differences observed for the protons and carbon atom of the vinylic OCH_2 group (C(8)), and the carbon atom of the vinylic CH_3 group (C(7)), together with the structure of one compound, 4-[(Z)-1-ethoxyethylidene]-2-phenyl-5-oxazolone, (Z)-**5**, as determined by X-ray diffraction. For all compounds studied, one isomer, the thermodynamically more stable isomer, was always less polar in its chromatographic behaviour than the other isomer. The less polar isomers consistently showed the C(8) protons to be deshielded by 0.2–0.4 ppm relative to the more polar isomers (see Table 1). There was further consistency in the ^{13}C nmr spectra, where the less polar isomers showed C(8) to be deshielded by 0.6–1.8 ppm relative to the more polar isomer. The only exception to the trend in the C(8) ^{13}C chemical shifts was noted for compound **13** where the spectrum, recorded in acetone-d_6, showed both isomers with identical chemical shifts. Since both oxazolones and thiazolones exhibited the same trends, defining the geometry of one isomer was sufficient to assign the geometry of both series or compounds. The less polar isomer of compound **5** was subjected to X-ray diffraction analysis and this was found to be the *Z*-geometric isomer.

[3]Tables of hydrogen atom positional and thermal parameters, bond lengths and angles involving hydrogen atoms, best planes, dihedral and torsion angles, and the moduli of F_o and F_c have been deposited and may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

The ^{1}H chemical shift of the C(7) methyl group (positions a or a′ in Fig. 1) showed very small differences between the *E* and *Z* isomers. In general, the *E* isomer was the more deshielded, by 0.01−0.11 ppm, than the *Z* isomer, but compound **15** showed equality of the two methyl shifts and compound **6** (Table 1) showed the methyl of the *Z* isomer to be the more deshielded by 0.03 ppm. The vinylic methyl ^{1}H nmr shifts in the 4-alkoxyethylidene series cannot therefore be used to define unambiguously the stereochemistry of the geometric isomers. In view of this, and of the very small shifts observed for the corresponding 4-alkylidene-5-oxazolones, it is not surprising that previous authors have arrived at divergent isomer assignments when basing their arguments on the relative shifts of vinylic methyl or alkyl groups (4, 8, 12−14). The shielding/deshielding regions about the 5-carbonyl group and the ring N atom are fortuitously similar for the vinylic alkyl site and must not be used for isomer assignment. However, for protons on atoms one further out from the double bond, at the b or b′ site in Fig. 1, the spatial anisotropies about the 4,6-double bond are different for compounds of the 1-alkoxyethylidene type and distinct chemical shift changes are observed. This should be contrasted with the 1-methylpropylidene structures where atom a (or a′) is a carbon atom and where protons on b (or b′) atoms show small chemical shift differences (ca. 0.02 ppm) (12). We attribute this alteration in spectroscopic behaviour to the preferred conformations adopted by the 1-alkoxyethylidene compounds (see X-ray section below).

The two hydroxy compounds **12** and **16** were interesting in that they were obtained as single isomers, but the oxazolone **12** existed as the *Z* isomer whereas the thiazolone **16** existed as the *E* isomer. These geometries were demonstrated by trapping the isomers with diazomethane, when **12** gave (*Z*)-**10** and **16** gave (*E*)-**17**, as determined by a comparison of the ^{1}H and ^{13}C nmr chemical shifts of these methyl ethers with other compounds listed in Table 1. Evidently the presence of an O atom or an S atom in the ring causes subtle changes in the relative basicities of the ring N atom and the carbonyl O, with an oxygen causing the N atom to be more basic and hydrogen bond to the hydroxyl group of **12** more effectively than the carbonyl O. The reverse was true in the thiazolone **16**.

Compound **19** was assigned the thioamide structure and not the thiazolone tautomer on the basis of its ^{1}H nmr spectrum, which showed a hydrogen bonded N-H proton at 9.31 ppm, its ^{13}C spectrum, which gave a C(1) signal at 184 ppm (or 186 ppm), and its infrared spectrum, which showed a characteristic N—H stretch at 3110 cm^{-1}.

Synthesis

The general synthetic approaches and interrelationship of the 4-(1-ethoxyethylidene)-5-oxazolones and the 5-thiazolones are shown in Schemes 1−3. The orthoester − acetic anhydride procedure led to mixtures of *E* and *Z* isomers with the *Z* isomer predominating. These pairs of isomers were separable by flash column chromatography on silica gel. The acetic anhydride − 3-methylpyridine reagent used for the preparation of the 1-hydroxyethylidene compound, **11**, gave a single isomer.

Two methods have been used to isomerize (*Z*)-4-phenylmethylene-5-oxazolones to the less stable *E* geometry (8, 11). Strong acids, such as polyphosphoric acid or concentrated aqueous hydrobromic acid, can be used, or photo-irradiation employed. In our hands the acid procedures were found to be unsuccessful in carrying out the isomerization of the oxazolones (*Z*)-**5** and (*Z*)-**9**. When a mixture of (*E* and *Z*)-**9** was treated with hydrobromic acid, dissolution occurred and the *E*

isomer was converted to the Z material for short reaction periods. Longer reaction times resulted in hydrolysis to compound **11**. Since **9** had very poor water solubility, its solution in concentrated HBr suggested that it became highly protonated and that this state further increased the thermodynamic stability of the Z isomer. The experiment unfortunately does not define the site of protonation.

Photo-irradiation proved to be generally applicable in isomerizing both the oxazolone and thiazolone series of compounds. Photostationary states were formed from which both E and Z isomers could be isolated. The only alkoxyethylidene compound which did not undergo isomerization to an isolable E isomer in chloroform solution with 300-nm wavelength radiation was 4-(1-ethoxyethylidene)-2-thioxo-5-thiazolidinone, **19**. The only isolated, or detected, isomer of **19** was assigned the Z geometry because short term, base catalysed methylation with methyl iodide led to the kinetic formation of (Z)-**14** (see Table 1), while longer reaction times in the presence of base gave a mixture of (E and Z)-**14**.

X-ray and conformational analysis

The molecule, (Z)-**5**, is shown in Fig. 4 and selected interatomic distances given in Table 4. The molecule (except for hydrogen atoms) is essentially planar, although there are minor deviations, the largest distances out of the oxazolone ring plane being C(6) 0.055(4), C(7) 0.136(6), O(3) 0.065(3), and C(9) −0.087(9) Å. The geometry is Z and there is evidence of some very strong repulsive interactions. One can compare bond distances and angles observed here with those observed in the structure of the related 4-(2,4-dinitro)benzylidene-2-phenyloxazolin-5-one, **3** (7). Bond angles within the oxazolone and phenyl rings of both compounds are not significantly different, nor are the bond lengths within the phenyl ring. There are significant differences in the two compounds for bond lengths within the oxazolone rings and in the olefinic bonds that are consistent with less delocalization in the C(4)—N(3)—C(2)—O(1) system of **5** and more delocalization in the C(6)—C(4)—C(5)—O(2) system of **5** than in the corresponding systems of **3**. This is caused by the interaction of the C(6)—C(4)—C(5)—O(2) system of **5** with O(3). The multiple bond character in the C(6)—O(3) bond is considerable. This bond is short (1.339(4) Å) and at the low end of the range of values of 1.35−1.73 Å observed in CH_3—O—aryl (ref. 18, and references therein) or aryl—O—aryl ethers (ref. 19, and

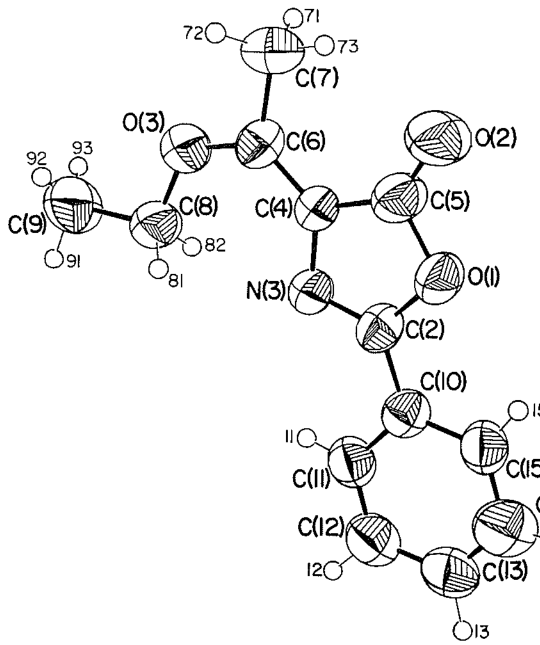

FIG. 4. The molecule 4-[(2)-1-ethoxyethylidene]-2-phenyl-5-oxazolone showing the atom numbering. Hydrogen atoms are indicated by affixes only and smaller numbers.

references therein). Further, the C(6)—O(3)—C(8) angle (122.1(3)°) is much larger than the angles usually found in CH_3—O—aryl ethers (range 116−119°) and is comparable to the value found in the ditropylium ether cation (123.6(5)°) and diaryl ethers (20). That the angle is so large must be caused by very extreme delocalization and strong π bonding to O(3), since there is obvious crowding at C(6). The crowding can be seen best by comparison with **3** and is caused by the repulsive interaction between the C(8) methylene group and N(3) together with the repulsive interaction between the C(7) methyl group and O(2). These effects cause the angles C(5)—C(4)—C(6) and C(4)—C(6)—C(7) to be larger than corresponding angles in **3** (123.4(3)°, 124.6(4)° versus 120.8°, 119°). N(3)— C(4)—C(6) and C(4)—C(6)—O(3) (127.9(3)°, 127.3(3)°) are much larger than the expected olefinic angle of 120°, because of the repulsive interaction of C(8) and the oxazolone ring. Nevertheless, they are significantly less than those observed in **3** (131.2°, 128.9°) because the two hydrogen atoms H(8, 1), H(8, 2) fit around the N(3) atom rather than pointing straight at it as does the phenyl hydrogen in **3**, and this allows a closer approach of C(8). Further evidence of crowding is shown by the very small C(7)—C(6)—O(3) angle of 108.1(4)°. While such angles at the ends of olefins have been observed when the attached atoms are part of a ring, such as N(3)—C(4)—C(5) (108.6°) and the corresponding angle in **3** (108.0°), to our knowledge angles this small have not been observed in normal olefins.

Once these restraints are put in place, the complete arrangement of the molecule is determined. The methyl group at C(7) is oriented such that H(7,1) and H(7,2) fit on either side of O(3) giving a short H(7,3)—O(2) distance (2.26 Å). Nevertheless, this is comparable to the O(1)—H(15) distance of 2.39 Å; apparently the greater electronegativity of oxygen allows much shorter C—H . . . O distances than in C—H . . . N, possibly because of weak hydrogen bonding. Similarly the CH_2 group at C(8) is oriented to put H(8, 1) and H(8, 2) on either side of N(3), giving H . . . N distances (H(8, 1) 2.45 Å; H(8, 2), 2.63 Å) comparable to N(3)—H(11) 2.60 Å and those in **3**, and ensuring C(9) is essentially coplanar with the remainder of the molecule.

Because a molecule is planar in the solid state does not mean it remains so in solution. Nevertheless, physical and spectroscopic data (see below) suggest that (*Z*)-**5** and related oxazolone isomers do indeed retain a preferred planar conformation in solution. We assume that this is caused by the very strong delocalization on to O(3). In addition there would be a substantial barrier to the C(8) methylene group moving past the C(7) methyl group, largely because of the extraordinarily small C(7)—C(6)—O(3) angle. In the most favourable orientation, and using the parameters herein, the C(7) . . . C(8) distance would be 2.58 Å, much less than the sum of the van der Waals radii. Similarly, the calculated H . . . H distance of 1.68 Å is much less than the van der Waals distance of 2.58 Å. Similar calculations show why this *Z* isomer is more stable than the *E* isomer. The calculated O(3) . . . O(2) distance of 3.17 Å in the *E* isomer is acceptable, but the C(7)—H . . . N(3) distances, ranging from 1.77 to 1.79 Å depending on the orientation, are very much shorter than typical values of 2.45−2.6 Å. Even a change in the angles at the olefin to shorten the O(2) . . . O(3) distance and increase the N . . . H distances does not give as favourable an arrangement as that observed for the *Z* isomer.

The packing of the molecules in the unit cell is shown in Fig. 5. Molecules are arranged in stacks along the **c** direction at $x = 1/2$, $y = 1/4, 3/4$. Adjacent molecules in a particular stack are related by the **c** glide plane so they are arranged head-to-tail and are roughly parallel, which maximizes the $\pi-\pi$ interactions. The molecules in a particular stack are tilted with respect to the stack direction, the tilt being in opposite directions in the stacks at $z = 1/4$ and $z = 3/4$. There is some overlap between these stacks in the **b** direction. In the **a** direction contact between stacks occurs near the **bc** plane and is between pairs of ethoxy groups and also between the phenyl ring on one molecule and the oxazolone ring on the adjacent molecule. All interactions are of the van de Waals type.

That the conformation adopted by the ethoxy side chain in (*Z*)-**5** (Fig. 3) in the solid state and, by analogy, the other (*Z*) isomers, is most likely preserved in solution phases was suggested by two pieces of experimental evidence: firstly, (*Z*)-**5** showed low polarity on chromatographic supports in contrast to the *E* isomer, and secondly, the relatively large deshielding (0.2−0.4 ppm) of the OCH_2 protons in the ^{1}H nmr spectrum of (*Z*)-**5** in comparison (*E*)-**5**, together with the downfield shift of the OCH_2 carbon (C(8)) in the ^{13}C nmr spectrum of (Z)-**5**. The low polarity of (*Z*)-**5** is consistent with the N(3) eclipsed conformation being the preferred conformation in solution, since this conformation has the N(3) atom effectively buried by the two hydrogen atoms attached to C(8) and therefore no longer a polar site in the molecule. Adsorption on a silica gel surface is thus restricted to the carbonyl and lactone oxygens, O(1) and O(2). The *E* isomer, on the other hand, has N(3) buttressed by a methyl group but with the lone pair still available for interaction with a silica surface and this, together with O(1) and O(2), gives the *E* isomer three polar interacting sites and thus higher chromatographic polarity. If the *Z* isomer were to possess significant conformer populations, with the ethyl fragment of the ethoxy group either out of the oxazolone ring plane or with C(8) adjacent to the C(7) methyl (see Fig. 6(a)), N(3) would lose its steric shielding and be free to interact with a silica surface. The chromatographic polarity of both *E* and *Z* isomers would then be expected to be similar.

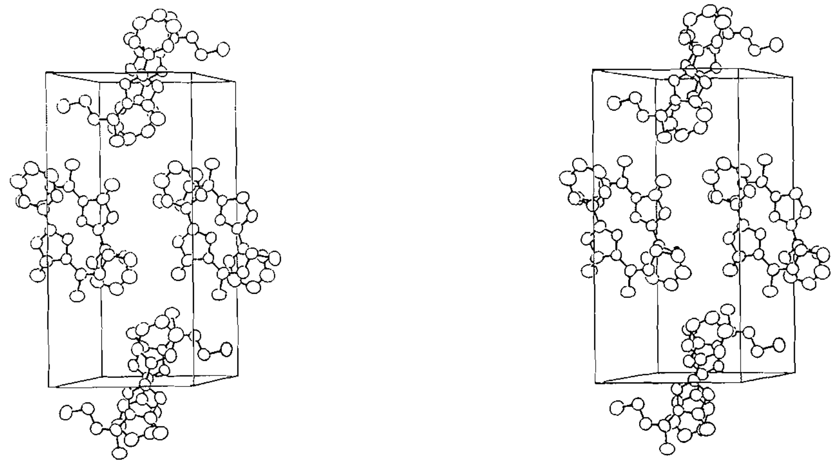

FIG. 5. The packing of the molecule within the unit cell. **a** and **b*** are parallel to the bottom and side of the page respectively and the view is down **c***. Hydrogen atoms have been omitted for clarity.

The [1]H nmr spectrum of (Z)-**5** showed the OCH_2 protons to be deshielded by 0.43 ppm relative to those in (*E*)-**5**. This large deshielding is again consistent with (Z)-**5** retaining the solid state, N(3) eclipsed, conformation in solution. Significant population of conformations either with C(8) out of the oxazolone plane or with C(8) close to the C(7) methyl would reduce the intense deshielding effects arising from the C(2)−N(3) double bond and the N(3)... CH_2 hydrogen steric compressions. Comparison with the *E* isomer shows that the OCH_2 group can take up conformations where C(8) is either adjacent to O(2) or to C(7) or slightly out of the oxazolone ring plane (see Fig. 6(b) and (C)). The first two conformations show strong steric compressions and the C(8)... O(2) arrangement expected to show intense deshielding arising from the carbonyl group anisotropy. The C(8) protons in the *E* isomer, occurring at 4.30 ppm, are thus anticipated to be deshielded relative to an unhindered ethoxy − vinyl ether system (for example, in (Z)-4-ethoxypent-3-en-2-one the ethoxy CH_2 signal occurs at 4.11 ppm (21)). The greater deshielding experienced by the *Z* isomer CH_2 (ca. 4.5 ppm) is therefore strong evidence for the N(3) eclipsed conformation being preferred in solution.

The [13]C nmr spectra of (Z)-**5** and (*E*)-**5** provide further compelling evidence for the conformational preference of the ethoxy group in solution. Comparison of the chemical shift of C(8) in both isomers shows the *Z* isomer C(8) resonance to be 2.6 ppm downfield from that of the *E* isomer. This is consistent with (Z)-**5** retaining the N(3) eclipsed conformation since N(3) is an atom which is in a δ-position with respect to C(8) and such arrangements are known to produce deshielding effects (22). If the conformation with the C(8) CH_2 group adjacent to the C(7) methyl (see Fig. 6(a)) were significantly populated, then an upfield shift would be anticipated because these two carbons are in a γ-relationship to each other (22). Any other conformation with C(8) out of the oxazolone ring plane would likewise reduce the deshielding effect of N(3). The chemical shift of C(8) in the *E* isomer is probably dominated by the shielding γ-effect arising from the conformation with C(8) and the C(7) methyl juxtaposed (Fig. 6(c)). The conformation with C(7) adjacent to O(2) is equivalent to a δ-interaction and little is known of such interactions. They are most likely deshielding in nature by analogy with O and N atom δ-effects (23).

It is interesting to note that the chemical shift of the C(7) methyl group in the series of *E* and *Z* isomers is consistent with the expected γ and δ effects of N and O atoms (see Table 1). Thus the *Z* isomers, with O(2) in a δ-position with respect to C(7), show the C(7) signals to be deshielded, while the *E* isomers, with N(3) in a γ-position with respect to C(7), show the C(7) signals to be shielded.

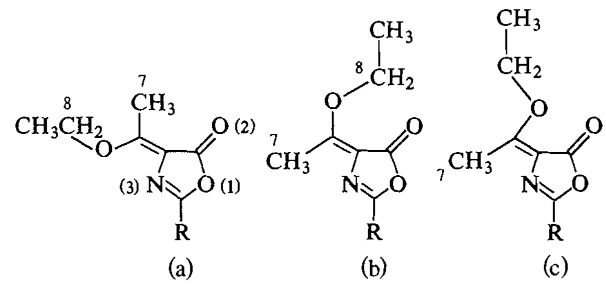

FIG. 6. Possible conformations of the ethoxy side chain in (a), (*Z*)-4-(1-ethoxyethylidene)-5-oxazolones, and (b), (c), (*E*)-4-(1-ethoxyethylidene)-5-oxazolones.

Experimental

Melting points were recorded on a Kofler micro hot stage apparatus and are uncorrected. Proton magnetic resonance ([1]Hmr) spectra were recorded on a Varian EM-390 spectrometer in deuteriochloroform using tetramethylsilane (TMS) as internal standard except where noted otherwise. The abbreviations s = singlet, d = double, t = triplet, q = quartet, and m = multiplet are used in the description of the spin−spin splitting patterns present in the spectra. The natural abundance carbon-13 magnetic resonances ([13]Cmr) were recorded on a Bruker WP80 instrument (at 20.115 MHz) in deuteriochloroform with TMS as the internal standard except where noted. Low resolution mass spectra (ms) and high resolution mass spectra (hrms) were recorded at 70 eV on a Micromass 7070F double focusing mass spectrometer, the samples being introduced through a direct inlet system. Infrared spectra (ir) were recorded on a Perkin Elmer 283 spectrometer. Liquid ir samples were run neat, while solids were prepared in potassium bromide discs (unless indicated otherwise). The symbols (s) = strong, (m) = medium, and (w) = weak are used in recording of ir data to indicate the intensity of the recorded bands.

Diazomethane was prepared by the method of de Boer and Backer (24) using ethereal *N*-methyl-*N*-nitroso-*p*-toluenesulfonamide (Diazald) in alcoholic sodium hydroxide.

Column chromatography was carried out using silica gel 60 (E. Merck Co. suppliers) of 0.063−0.200 mm particle size (70−230 mesh ASTM). Samples of low solubility were introduced onto the chromatographic column in a minimum volume of chloroform.

Silica gel 60 F_{254} (F. Merck Co.) plates of 0.2-mm thickness were used for analytical thin layer chromatography (tlc).

Collection of diffraction data

A homogeneous prismatic crystal was used for the X-ray studies and precession photographs showed the crystal was monoclinic. The cell parameters were obtained by least-squares refinement from the setting angles of 15 automatically centred reflections ($17° < 2\theta < 27°$) on a Nicolet P3 diffractometer with use of graphite monochromatized MoKα radiation (λ 0.71069 Å). Crystal data and other numbers related to the data collection are given in Table 2. The density was measured by flotation in aqueous zinc bromide solution. Intensity data were measured with used of the P3 diffractometer and a coupled θ(crystal) − 2θ(counter) scan. The methods of selection of scan rates and initial data treatment have been described (25, 26) (limits, from 4.88 to 29.3 deg min^{-1}). Corrections were made for Lorentz polarization effects, but not for absorption. This will introduce a maximum error in F_o of <0.1%.

Solution of the structure

The phases were determined by direct methods with use of 50 reflections with $|E| > 1.5$ and 12 sets of starting phases. A series of full-matrix least-squares refinements followed by electron density difference syntheses revealed all the atoms. In all further refinements the positional parameters of all atoms, isotropic temperature factors of hydrogen atoms, and anisotropic temperature factors of all other atoms were varied. Full-matrix least-squares refinement, which minimized the function $\Sigma w(|F_o| - |F_c|)^2$, was terminated when the maximum shift/error was <0.2. Corrections were made for secondary extinction by the method used in SHELX.[4] Scattering curves were taken from Cromer and Waber (27) and did not include corrections for anomalous dispersion effects.

2-Benzylthio-4-[E and Z-1-ethoxyethylidene]-5-thiazolone, ***13***

The method of Knott (28) for the preparation of **13** was used with some modifications.

To 0.75 mL of acetic anhydride were added 50.5 mg (0.27 mmol) of *N*-dithiocarbobenzyloxyglycine, **20** (29). This mixture was swirled and warmed on a steam bath until dissolution of the solid. The mixture was removed from the heat source and one crystal of toluenesulfonic acid (approximately 1 mg) was added. Immediately following this, 42 μL (37 mg. 0.27 mmol) triethyl orthoacetate was added, the mixture swirled to ensure homogeneity and replaced on the steam bath for 10 min. Upon removal from the heat, the mixture was diluted with 1 mL saturated sodium bicarbonate solution and 5 mL water and extracted twice with chloroform. The chloroform layer was dried with anhydrous sodium sulfate, filtered, and the volatiles removed, initially by rotoevaporator distillation and, finally, by evacuation at 0.5 Torr (1 Torr = 133.3 Pa) overnight. This left 61 mg of **13** as a yellow oil (quantitative yield) with a 5:1 ratio of *Z*/*E* isomers as indicated by ^{1}Hmr spectroscopy. This mixture was sufficiently pure for further experiments. Small quantities of **13** were purified by Kugelrohr distillation at 190−200°C and 0.3 Torr (lit. (28) bp 208°C at 1 Torr) without substantial losses because of polymerization. Otherwise, purification and isomer separation were effected by flash column chromatography on silica gel (7% ethyl acetate in 30−60 petroleum ether). An experiment using 233 mg of **20**, after chromatography through a 2 mm × 0.15 m column of silica gel, gave 192 mg of pure *Z* isomer (67% yield). Compound **13** showed: tlc (25% ethyl acetate in petroleum ether): R_f 0.65 (*Z*) 0.33 (*E*); ir, ν_{max}: 2986 (m), 1694 (s) (C=O), 1640 (m) (C=N), 1602 (m, shoulder), and 1574 (s) (exocyclic C=C) cm^{-1}; ^{1}Hmr, Z, δ: 1.39 (t, *J* = 7 Hz, 3H, ether CH_3), 2.44 (s, 3H, vinyl CH_3), 4.40 (s, 2H, benzyl CH_2), 4.55 (q, *J* = 7 Hz, 2H, ester CH_2), 7.22−7.44 (m, 5H, aromatic); *E*, δ: 1.43 (t, *J* = 7 Hz, 3H, ether CH_3), 2.54 (s, 3H, vinyl CH_3), 4.27 (q, *J* = 7 Hz, 2H, ether CH_2), and 7.22−7.44 (m, 5H, aromatic); ^{13}Cmr, (*Z*), δ: 154.0(152.6) (C-2), 129(128.2) (C-4), 193.3(192.3) (C-5), 165.2(165.9) (C-6), 17.4(16.5) (C-7), 68.3(68.2) C-8), 15.4(14.9) (C-9), 35.2(34.8) (benzyl CH_2), 136.5(137.0) (*ortho* C), 129.0(129.1) (*meta* C), 128.7(128.5) (*para* C), 127.6(127.4) (subst. C) (shifts in parentheses were recorded in acetone-d_6 solvent); (*E*), δ: 169.7 (C-6), 16.5 (C-7), 65.8 (C-8), 14.9 (C-9), 34.8 (benzyl CH_2), 137.0 (*ortho* C), 129.1 (*meta* C), 128.5 (*para* C), 127.4 (subst. C) (signals for C-2, 4, and 5 were too weak to be observed above noise); hrms calcd. for $C_{14}H_{15}NO_2S_2$: 293.0477; found: 293.0521; ms, *m*/*z* (RI%): 293 (25) and 91 (100).

*2-Ethoxy-4-[(Z)-1-ethoxyethylidene]-5-thiazolone, (Z)-**15***

The method of Knott (28) for the preparation of **13** was used with some modification.

To 14 mL of acetic anhydride was added 0.870 g (5.34 mmol) of *N*-thiocarbethoxyglycine (30). This mixture was swirled and warmed on a steam bath until dissolution of the solid. The mixture was removed from the heat source, after which 8 mg (0.05 mmol) of toluenesulfonic acid and 1.5 mL (1.3 g, 8.0 mmol) of triethyl orthoacetate were added in rapid succession. The solution was swirled to ensure homogeneity and replaced on a steam bath for 5 min. After removal from the steam bath, the volatiles were removed by rotoevaporator distillation with strong heating (forced air heater) and then by evacuation for 30 min. Flash column chromatography of the residue on silica gel (7.5% ethyl acetate in petroleum ether) gave 0.288 g (25%) of pure (*Z*)-**15** as a pale yellow oil. Some *E* isomer was also present in the crude reaction mixture, as evidenced by tlc. Separation of this isomer was not possible from other side-products by the chromatography method employed. The *E*/*Z* ratio in the crude mixture was not determined. Compound (*Z*)-**15** showed: ir, ν_{max}: 1699 (s) (CO), 1606 (s) (C=N), and 1570 (s) (C=C) cm^{-1}, ^{1}Hmr, δ: 1.38 (t, *J* = 7 Hz, 6H, both ethyl CH_3's), 2.40 (5, 3H, vinyl CH_3), 4.43 (q, *J* = 7 Hz, 2H, 2-ethoxy CH_2), and 4.50 (q, *J* = 7 Hz, 2H, vinyl ethoxy CH_2); ^{13}Cmr (acetone-d_6), (*Z*), δ: 157.7 (C-2), 126.7 (C-4), 191.4 (C-5), 162.7 (C-5), 162.7 (C-6), 17.5 (C-7), 67.9 (C-8), 15.2 (C-9), 65.5 (ethoxy CH_2), 14.0 (ethoxy CH_3); (*E*), δ: 158.0 (C-2), 129.1 (C-4), 194.2 (C-5), 164.5 (C-6), 16.0 (C-7), 65.0[a] (C-8), 14.8 (C-9), 65.4[a] (ethoxy CH_2), 14.0 (ethoxy CH_3); ((a), assignments may be reversed); hrms calcd. for $C_9H_{13}NO_3S$: 215.0616; found: 215.0613; ms, *m*/*z* (RI%): 215 (95) [M^+]. 187(40), 172(15), 159(100) [$M^+ - C_3H_4O$], 141(60), 71(75), 70(35), and 56(30).

4-[(Z)-1-Ethoxyethylidene]-2-thiono-5-thiazolinone, ***19***

The method of Cook *et al.* (31), with modification, was used for the preparation of the 4-ethoxymethylene analogue.

After dissolution of 92.2 mg (0.69 mmol) of 2-mercapto-4*H*-5-thiazolone (see the following preparation) in 2 mL warm acetic anhydride, 79 μL (83 mg, 1.38 mmol) were added in rapid succession. Immediately, the reaction flask was swirled to ensure homogeneity and placed on a steam bath for 10 min. On removal from the steam bath, the volatiles were removed by rotoevaporator distillation (25 Torr) with strong heating (forced-air heater). The solid residue was recrystallized from absolute ethanol (decolourizing charcoal) to give 80.2 mg (57%) of **19**, the pure *Z* isomer, as tan crystals, mp 185−186°C. Compound **19** showed: ir, ν_{max}: 1703 (s) (C=O), 1682 (m) (C=N), and 1607 (s) (C=C) cm^{-1}; ^{1}Hmr ($CDCl_3$, δ: 1.42 (t, *J* = 7 Hz, 3H, ester CH_3), 2.46 (s, 3H, vinyl CH_3), 4.24 (q, *J* = 7 Hz, 2H, ester CH_2); (acetone-d_6), δ: 1.38 (t, *J* = 7 Hz, 3H, ester CH_3), 2.20 (s, 1H, SH), 2.51 (s, 3H, vinyl CH_3), and 4.36 (q, *J* = 7 Hz, 2H, ether CH_2); ^{13}Cmr (acetone-d_6), (*Z*), δ: 184.1 (C-2),[a] 120.7 (C-4), 186.1 (C-5),[a] 155.2 (C-6), 12.2 (C-7), 65.5 (C-8), 14.4 (C-9); ((a), assignments may be reversed). Observation of long-range coupling between the 15.0 and 66.1 ppm resonances during a gated decoupling experiment definitively assigned the two methyl signals. hrms calcd. for $C_7H_9NO_2S_2$: 203.0075; found: 203.0082; ms, *m*/*z* (RI%): 203(100), 175(45), 141(50), 113(20), and 71(35).

2-Mercapto-4H-5-thiazolone

2-Mercapto-4*H*-5-thiazolone was prepared by the method of Cook *et al.* (31) from glycinamide and also directly from the commercially

---

[4]All calculations were carried out on CYBER 170/730 and 815 computers. Initial data treatment used the XRAY 76 package (39). Structure solution and refinement was done by use of the SHELX package (40), and diagrams were prepared with use of ORTEP II (41).

available glycinamide hydrochloride as described below.

Glycinamide hydrochloride (1.00 g, 9.05 mmol), potassium carbonate (1.25 g, 9.06 mmol), and potassium hydroxide (0.51 g, 9.1 mmol) were dissolved in 5 mL water. Into this solution was added 0.60 mL (0.76 g, 10 mmol) carbon disulfide. The mixture was stirred vigorously for 5.5 h at room temperature after which 2.0 mL 50% sulfuric acid was added rapidly (**caution: effervescence!**) with continued stirring. After about 30 s, as a yellow precipitate was formed, the solution was diluted with 5 mL water. Stirring continued a further 30 min after which the precipitate was filtered, washed with water, and dried *in vacuo*, giving 0.509 g of product (42%). This sample was sufficiently pure for subsequent preparations; mp (dec.) >300°C (lit. (31) mp (dec.) >300°C); ^{1}Hmr (acetone-d_6), δ: 2.75 (br s, 1H, —SH) and 4.70 (s, 2H, methylene).

2-Benzyl-4-[(Z)-1-ethoxyethylidene]-5-oxazolone, (Z)-6

The preparation of 4-(1-ethoxyethylidene)-5-oxazolones (or, in general, 4-(1-akloxyalkylidene)-5-oxazolones) by the action of triethyl orthoacetate (or other orthoesters) and acetic anhydride on *N*-acylglycines is well documented in the literature (15, 16, 32).

To a hot solution of *N*-(phenylacetyl)glycine (33) (1.04 g, 5.39 mmol) in 12 mL acetic anhydride was added 3.0 mL triethyl orthoacetate (2.6 g, 16 mmol) and the solution heated on a steam bath for 20 min. After this, the solvent was removed with strong heating (forced-air heater) at reduced pressure (25 Torr). The crude product, after eluting through a 20 mm × 0.18 m silica gel column with 10% ethyl acetate in petroleum ether, provided 0.580 g of pure **6** (44%) as a pale yellow oil that solidified on standing overnight (mp 37–41°C).

Compound (Z)-**6** showed: ir, ν_{max}: 2990 (m), 2932 (m), 1795 (m), 1762 (s) (C=O), 1693 (s) (C=N), 1604 (s), and 1595 (s) (exocyclic C=C) cm^{-1}; ^{1}Hmr, δ: 1.39 (t, J = Hz, 3H, ether CH_3), 2.44 (s, 3H, vinyl CH_3), 3.83 (s, 2H, benzyl CH_2), 4.57 (q, J = 7 Hz, 2H, ether CH_2), and 7.33 (br s, 5H, aromatic); ^{13}Cmr, δ: 158.2 (C-2), 114.3 (C-4), 168.7 (C-5), 166.5 (C-6), 16.5 (C-7), 68.1 (C-8), 15.2 (C-9), 35.6 (C-10), 134.2 (C-11), 128.8 (C-12), 129.1 (C-13), 127.3 (C-14); hrms calcd. for $C_{14}H_{15}NO_3$: 245.1052; found: 245.1023; ms, m/z (RI%): 245 (10), 118 (35), 91 (100), and 65 (25).

2-(1,1-Dimethylethyl)-4-[(Z)-1-ethoxyethylidene]-5-oxazolone, (Z)-7, 4-[(Z)-1-ethoxyethylidene]-2-phenyl-5-oxazolone, (Z)-5, 2-(4-bromophenyl)-4-[(E and Z)-1-ethoxyethylidene]-5-oxazolone, 8, and 2-(4-chlorophenyl)-4-[(E and Z)-1-ethoxyethylidene]-5-oxazolone, 9

The products (Z)-**7**, (Z)-**5**, **8**, and **9** were obtained from *N*-pivaloylglycine, (prepared as in ref. 34; recrystallized from acetone – petroleum ether), *N*-benzoyglycine (Eastman suppliers), *N*-(4-bromobenzoyl)glycine (35, 36), and *N*-(4-chlorobenzoyl)glycine (35, 36), respectively, using the procedure described above (for the *Z*-benzyl analogue) with the following changes:

In the preparation of (Z)-**7**, the *N*-pivaloylglycine in acetic anhydride was heated on a steam bath for 5 min before triethyl orthoacetate addition. Column chromatographic purification utilized 5% ethyl acetate in petroleum ether. Yield of (Z)-**7** from 222 mg of pivaloylglycine was 188 mg (64%) of a light yellow oil, which solidified in the refrigerator on storage (mp 35–38°C).

In the preparation of **5** both *E* and *Z* isomers were present in the crude mixture in a ratio of 1:5 (*E*/*Z* as indicated by ^{1}Hmr spectroscopy). The pure *Z* isomer was obtained by recrystallization from absolute ethanol or ethanol–water (mp 111–112°C; lit. (16, 17) mp 112–113°C, (32) mp 113°C). A yield of 1.34 g (52%) was obtained from 2.0 g (11 mmol) *N*-benzoylglycine.

In the preparation of **8**, both *E* and *Z* isomeric products cocrystallized on recrystallization of the crude mixture from absolute ethanol, giving a 1:4 ratio of *E* to *Z* (as determined by ^{1}Hmr spectroscopy; yellow-orange plates, mp 116–124°C). A yield of 0.341 g (65%) was obtained from 0.441 g (1.7 mmol) of *N*-(4-bromobenzoyl)-glycine. Flash chromatography of 0.278 g of this mixture of isomers (10% ethyl acetate in petroleum ether as the eluant) gave 0.215 g (45%) of pure *Z* isomer (yellow-orange plates from absolute ethanol, mp 128.5–129.5°C) and 55 mg (12%) of the pure *E* isomer (cream-coloured needles from absolute ethanol, mp 142.0–143.0°C); tlc of (*E* and *Z*)-**8** (developed with 10% ethyl acetate in petroleum ether) gave R_f 0.08 (*E*) and 0.36 (*Z*).

Similarly, 1.39 g (6.53 mmol) of *N*-(4-chlorobenzoyl)glycine gave 1.32 g (76%) of a co-crystalline mixture of *E* and *Z* isomers of **9** (1:4 ratio as determined by ^{1}Hmr spectroscopy). Flash chromatography of 0.503 g of this mixture (20% ethyl acetate in petroleum ether as eluant) gave 0.398 g *Z* isomer (orange plates from absolute ethanol, mp 122.5–123.0°C, 60% yield) and 90.8 mg *E* isomer (colourless needles from absolute ethanol, mp 130–132°C, 14%); tlc of (*E* and *Z*)-**9** (developed with 30% ethyl acetate in petroleum ether) gave R_f 0.18 (*E*) and 0.52 (*Z*).

Compound (Z)-**7** showed: ir, ν_{max}: 1788 (s) (C=O), 1764 (s) (C=O), 1643 (s) (C=N), and 1598 (s) cm^{-1}; ^{1}Hmr, δ: 1.28 (s, 9H, *tert*-butyl), 1.38 (t, J = 7 Hz, 3H, ether CH_3), 2.42 (s, 3H, vinyl CH_3), and 4.64 (g, J = 7 Hz, 2H, ether CH_2); ^{13}Cmr (acetone-d_6), δ: 165.2 (C-2),[a] 113.8 (C-4), 168.6 (C-5), 165.5 (C-6),[a] 16.8 (C-7), 68.8 (C-8), 14.9 (C-9), 33.6 (C-9), 33.6 (C-10), 26.9 (C-11); ((a), assignments may be reversed); hrms calcd. for $C_{11}H_{17}NO_3$: 211.1208; found: 211.1217; ms, m/z (RI%): 211 (15), 183 (10), 168 (15), 167 (15), and 57 (100).

Compound (Z)-**5** showed: ir, ν_{max}: 1786 (m), 1758 (s) (C=O), 1640 (s) (C=N), 1602 (m), and 1587 (s) (exocyclic C=C) cm^{-1}; ^{1}Hmr δ: 1.43 (t, J = 7 Hz, 3H, ether CH_3), 2.49 (s, 3H, vinyl CH_3), 4.73 (q, J = 7 Hz, 2H, ether CH_2), 7.36–7.53 (m, 3H, aromatic), and 7.92–8.07 (m, 2H, aromatic); ^{13}Cmr, δ: 155.4 (C-2), 116.4 (C-4), 168.6 (C-5), 166.9 (C-6), 17.6 (C-7), 69.0 (C-8), 15.3 (C-9), 127.0 (C-10), 127.0 (C-11), 128.7 (C-12), 131.3 (C-13).

Compound (*E*)-**8** showed: ir, ν_{max}: 1793 (s), 1770 (m), 1645 (s), 1597 (s), and 1584 (s) cm^{-1}; ^{1}Hmr δ: 1.45 (t, J = 7 Hz, 3H, ether CH_3), 2.53 (s, 3H, vinyl CH_3), 4.35 (q, J = 7 Hz, 2H, ether CH_2), 7.58 and 7.84 (AA′ BB′, J_{ortho} = 9 Hz, 2H and 2H, aromatic); ^{13}Cmr, δ: 154.9 (C-2), 118.4 (C-4), 169.4 (C-5), 163.5 (C-6), 15.9 (C-7), 66.5 (C-8), 15.2 (C-9), 125.9 (C-10),[a] 128.4 (C-11), 132.0 (C-12), 126.1 (C-13);[a] ((a) assignments may be reversed); hrms calcd. for $C_{13}H_{12}NO_3Br$: 309.0000; found: 309.0046; ms, m/z (RI%): 283 (20), 281 (20), 265 (20), 263 (20), 185 (100), 183 (100), 157 (30), 155 (30), 104 (10), 76 (30), and 75 (20).

Compound (Z)-**8** showed: ir, ν_{max}: 1792 (s), 1762 (m), 1637 (s), 1592 (s), and 1581 (s) cm^{-1}; ^{1}Hmr, δ: 1.45 (t, J = 7 Hz, 3H, ether CH_3), 2.51 (s, 3H, vinyl CH_3), 4.72 (q, J = 7 Hz, 2H, ether CH_2), 7.58 and 7.85 (AA′ BB′, J_{ortho} = 9 Hz, 2H and 2H, aromatic); ^{13}Cmr, δ: 154.5 (C-2), 114.9 (C-4), 168.2 (C-5), 167.4 (C-6), 17.6 (C-7), 69.1 (C-8), 15.2 (C-9), 125.5 (C-10), 128.5 (C-11), 132.0 (C-12), 126.3 (C-13); hrms calcd. for $C_{13}H_{15}NO_3Br$: 309.0000; found: 309.0059; ms: indistinguishable from the *E* isomer.

Compound (*E*)-**9** showed: ir, ν_{max}: 1792 (s) (C=O), 1769 (m) (C=O), 1644 (s) (C=N), 1599 (m), and 1583 (s) cm^{-1}; ^{1}Hmr, δ: 1.47 (t, J = 7 Hz, 3H, ether CH_3), 2.55 (s, 3H, vinyl CH_3), 4.37 (q, J = 7 Hz, 2H, ethyl CH_2), 7.43 and 8.94 (AA′ BB′, J_{ortho} = 9 Hz, 2H and 2H, aromatic); ^{13}Cmr, δ: 154.9 (C-2), 118.4 (C-4), 169.2 (C-5), 163.6 (C-6), 15.9 (C-7), 66.5 (C-8), 15.2 (C-9), 125.5 (C-10), 128.2 (C-11), 129.1 (C-12), 137.6 (C-13); hrms calcd. for $C_{13}H_{12}NO_3Cl$: 265.0506; found: 265.0502; ms, m/z (RI%): 267 (5) and 265 (15) [M^+], 239 (3), 237 (10), 221 (3), 219 (10), 141 (30), 139 (100), 113 (10), 111 (30), and 75 (15).

Compound (Z)-**9** showed: ir, ν_{max}: 1791 (s) (C=O), 1762 (m) (C=O), 1637 (s) (C=N), 1596 (m), 1580 (s) cm^{-1}; ^{1}Hmr, δ: 1.44 (t, J = 7 Hz, 3H, ether CH_3), 2.52 (s, 3H, vinyl CH_3), 4.74 (q, J = 7 Hz, 2H, ether CH_2), 7.43 and 8.95 (AA′ BB′, J_{ortho} = 9 Hz, 2H and 2H, aromatic); ^{13}Cmr, δ: 154.5 (C-2), 115.0 (C-4), 168.3 (C-5), 167.4 (C-6), 17.5 (C-7), 69.1 (C-8), 15.3 (C-9), 125.2 (C-10), 128.4 (C-11), 129.1 (C-12), 137.8 (C-13); hrms calcd. for $C_{13}H_{12}NO_3Cl$: 265.0506; found: 265.0554; ms: indistinguishable from the *E* isomer.

4-[(Z)-1-Methoxyethylidene]-2-phenyl-5-oxazolone, (Z)-10

The oxazolone (Z)-**10** (mp 101–102°C from 95% ethanol, lit. (ref. 15, p. 830) 101–102°C from petroleum ether) was prepared by the action of diazomethane on the hydroxymethylene analogue (ref. 15, p. 830), which, in turn, was prepared by the method of

Attenburrow *et al.* (37) from acetic anhydride and sodium hippurate. Compound (Z)-**10** showed: ^{1}Hmr, δ: 2.55 (s, 3H, vinyl CH_3), 4.30 (s, 3H, OCH_3) 7.45–7.55 (m, 3H, aromatic), and 7.98–8.15 (m, 3H, aromatic); ^{13}Cmr, δ: 167.2 (C-2), 115.8 (C-4), 168.4 (C-5), 155.4 (C-6), 16.3 (C-7), 59.6 (C-8), 126.6 (C-10), 127.3 (C-11), 128.8 (C-12), 131.8 (C-13).

*2-Benzylthio-4-[(E)-1-hydroxyethylidene]-5-thiazolone, **16***

Hydrolysis of the 4-(1-alkoxyalkylidene) side chain of 5-thiazolones is analogous to those in the literature for the oxazolone series (15, 38). To thiazolone, (Z)-**13** (35 mg, 0.12 mmol), was added, with stirring, 2 mL of 2 *M* potassium hydroxide in 95% ethanol. The mixture was heated on a hot plate until most of the solid dissolved. The solution was cooled and decanted from the remaining residue and acidified (to litmus) with 1 *M* hydrochloric acid. The solution was diluted with 5 mL of water, extracted twice with chloroform, and the chloroform layer dried over anhydrous sodium sulfate. After removal of solvent (rotoevaporator and then vacuum; 0.5 Torr, 30 min), a light pinkish solid of the hydroxymethylene oxazolone **16** remained. After recrystallization from acetone–water a yield of **19** mg (60%) was obtained (mp 102–104°C). Compound **16** showed: ir, ν_{max}: 1680 (s) (C=O), 1655 (m) (C=N), 1578 (s), and 1570 (s) cm^{-1}; ^{1}Hmr, δ: 2.44 (s, 3H, CH_3), 4.35 (s, 2H, benzyl CH_2), 7.27–7.41 (m, 5H, aromatic), and 9.85 (br s, 1H, OH); hrms calcd. for $C_{12}H_{11}NO_2S_2$: 265.0231; found: 265.0217; ms, *m/z* (RI%): 265 (25) and 91 (100).

*2-Benzylthio-4-[(E)-1-methoxyethylidene]-5-thiazolone, (E)-**17***

Thiazolone **16** (10.2 mg, 38.5 mol) was dissolved in excess diazomethane in ether. After 10 min, the excess diazomethane was removed by passing a stream of nitrogen through the solution. Removal of solvent (by rotoevaporator) and purification by silica gel column chromatography (10% ethyl acetate in petroleum ether eluant) gave 4.4 mg (41%) of (*E*)-**17** as an oil. This was assigned the *E* stereochemistry from its ^{1}Hmr spectrum. Compound (*E*)-**17** showed: ^{1}Hmr, δ: 2.54 (s, 3H, vinyl CH_3), 4.01 (s, 3H, OCH_3), 4.36 (s, H, benzyl CH_2), and 7.26–7.40 (m, 5H, aromatic); ms, *m/z* (RI%): 279 (25) and 91 (100).

*4-[(E and Z)-1-ethoxyethylidene]-2-methylthio-5-thiazolone, **14***

Potassium carbonate (304 mg, 2.2 mmol), **19** (149 mg, 0.734 mmol), and methyl iodide (0.14 mL, 312 mg, 2.2 mmol) were stirred in 2 mL of acetone for 30 min. Following this, the mixture was diluted with 10 mL of water, extracted twice with chloroform, the chloroform layer dried over anhydrous sodium sulfate, and the solvent removed by rotoevaporator and then vacuum (0.5 Torr, 60 min) to give 145 mg (91%) of (Z)-**14** as an oil that solidified to tan coloured needles (mp 35.0–37.5°C) on standing. This product was one isomer only and was assigned the *Z* geometry from its ^{1}Hmr spectrum. When the reaction time was longer (approximately 14 h), an equilibrium mixture of the *E* and *Z* isomers was obtained (7:2 = *Z*/*E* as determined by ^{1}Hmr spectroscopy) as an oil. Compound **14** showed: ir, *Z*, ν_{max}: 3024 (s), 3000 (m), 2936 (m), 1695 (s) (C=O), 1672 (s) (C=N), and 1570 (exocyclic C=C) cm^{-1}; ^{1}Hmr, *Z*, δ: 1.40 (t, *J* = 7 Hz, 3H, ether CH_3), 2.45 (s, 3H, vinyl CH_3), 2.59 (s, 3H, SCH_3), and 4.53 (q, *J* = 7 Hz, 2H, ethyl CH_2); *E*, δ: 1.40 (t, *J* = 7 Hz, 3H, ethyl CH_3), 2.56 (s, 3H, vinyl CH_3), 2.59 (s, 3H, SCH_3), and 4.26 (q, *J* = 7 Hz, 2H, ether CH_2); ^{13}Cmr, (Z)-**14**, δ: 165.0 (C-2), 128.9 (C-4), 193.6 (C-5), 155.2 (C-6), 17.6 (C-7), 68.5 (C-8), 15.5 (C-9), 13.7 (C-10); (*E*)-**14** (acetone-d_6), δ: 165.9 (C-2), 128.5 (C-4), 153.9 (C-6), 17.1 (C-7), 68.8 (C-8), 15.1 (C-9), 13.0 (C-10); C-5 signal too weak to assign; hrms calcd. for $C_8H_{11}NO_2S_2$: 217.0231; found: 217.0251; ms, *m/z* (RI%): 217 (50), 189 (45), 142 (35), and 91 (100).

The three methyl resonances were definitively assigned by observation of long-range coupling between the 15.5 and 68.5-ppm resonances during a gated coupling experiment.

*2-Benzylthio-4-[(Z)]-1-ethoxyethylidene)-5-thiazolone, (Z)-**13** from **19***

With the same procedure as that given above, (Z)-**13** was prepared from potassium carbonate (44 mg, 0.37 mmol), **19** (25 mg, 0.123 mmol), and benzyl bromide (37 μL, 55 mg, 0.32 mmol) in 92% yield (23 mg). The product so prepared was identical by tlc and ^{1}Hmr spectroscopy to the Z isomer obtained by the action of triethyl orthoacetate on **20**.

*2-Benzylthio-4-[(EandZ)-(1-methoxyethylidene]-5-thiazolone, **17** and 4-[(E and Z)-1-methoxyethylidene]-2-methylthio-5-thiazolone, **18**, by alcoholic exchange*

Precedence for acidic exchange reactions of the alkoxy substituent of 4-(1-alkoxyethylidene)-5-thiazolones is given in the work of Knott (28).

The oxazolone (Z)-**14** (11.2 mg, 52 mmol) was dissolved in 1 mL of methanol and a stream of hydrogen chloride gas was passed through the solution for approximately 30 s (the resulting acid concentration was not determined). After 1 h at room temperature, the reaction was quenched with 5 mL saturated sodium bicarbonate and the resulting mixture extracted twice with chloroform, the chloroform layer dried over anhydrous sodium sulfate, and the solvent removed by rotoevaporation and evacuation at 0.5 Torr. The residue (10.1 mg, 96%) was a 1:3 ratio (as determined by ^{1}Hmr spectroscopy) of *E* to *Z* isomers of **18** (mp 83–90°C). These were the only products observed by tlc and ^{1}Hmr spectroscopy. Compound **18** showed: tlc (20% ethyl acetate in pet. ether): R_f 0.15 (*E*), 0.34 (Z); ir, ν_{max}; 1678 (s) (CO), 1655 (m) (CN), 1595 (s), 1572 (s) cm^{-1}); ^{1}Hmr (DMSO-d_6), *E*, δ: 2.58 (s, 3H, vinyl CH_3), 2.58 (s, 3H, SCH_3), and 3.98 (s, 3H, OCH_3); *Z*, δ: 2.50 (s, 3H, vinyl CH_3), 2.58 (s, 3H, SCH_3), and 4.09 (s, 3H, OCH_3); ms, *m/z* (RI%): 203 (50) [M^+], 174 (10), 156 (15) [$M^+ - SCH_3$], 91 (100) [CH_3SCS^+].

Similarly, a 1:3 ratio f *E* to *Z* isomers of **17** were prepared using the procedure above. Compound **17** showed: tlc (25% ethyl acetate – pet. ether): R_f 0.16 (*E*), 0.49 (*Z*); ir, ν_{max}: 1682 (s) (C=O), 1678 (s) (C=N), 1600 (m, shoulder), 1582 (s) cm^{-1}; ^{1}Hmr, δ: 2.54 (s, 3H, vinyl CH_3), 4.01 (s, 3H, OCH_3), 4.36 (s, H, benzyl CH_2), and 7.26–7.40 (m, 5H, aromatic); *Z*, δ: 2.48 (s, 3H, vinyl CH_3), 4.15 (s, 3H, OCH_3), 4.42 (s, 2H, benzyl CH_2), and 7.26–7.40 (m, 5H, aromatic); ^{13}Cmr, (Z)-**17**, δ: 16.1 (C-7), 59.0 (C-8), 34.8 (C-10), 129.3 (C-12), 128.8 (C-13), 127.7 (C-14); signals for C-2, C-4, C-5, C-6, and C-11 too weak for definitive assignment; (*E*)-17, δ: 15.4 (C-7), 56.9 (C-8), 34.8 (C-10), 129.3 (C-12), 128.8 (C-13), 127.7 (C-14); signals for C-2, C-4, C-5, C-6, and C-11 too weak for definitive assignment; hrms calcd. for $C_{13}H_{13}NS_2O_2$: 279.0342; found: 279.0341; ms, *m/z* (RI%): 279 (25) [M^+] and 91 (100).

*Photoisomerization of **5**, **6**, **7**, **10**, **14**, and **15** and isolation of (E)-**6**, (E)-**5**, and (E)-**15***

Photoisomerization of phenylmethylene oxazolones have been reported (11).

Irradiations were carried out in a Rayonet Photochemical reactor with 300-nm lighting.

On approximately 30-μmol scale, compounds **5**, **6**, **7**, **10**, **14**, and **15** were irradiated in 5-mm nmr tubes (4-mm id) in 0.5 mL $CDCl_3$. The isomerizations were monitored by ^{1}Hmr. Photostationary states were obtained after 2 days of irradiation, giving a 2:3 ratio of *E* to *Z* isomers for **5**, **6**, and **10** and a 1:2 ratio for **7** and **15**. Compound **14** required the presence of solid potassium carbonate for a photostationary state (with an *E* to *Z* ratio of 1:3). The same photostationary ratio of **14** was obtained on irradiation in petroleum ether. In all the irradiations, the two isomeric products were the only products observed as indicated by tlc and ^{1}Hmr spectroscopy.

On a preparative scale, pure (Z)-**6** (0.220 g, 0.898 mmol) was dissolved in 8 mL of chloroform and place din a 10-mm od tube (9-mm id) and irradiated for 26 h. Solvent was removed and flash chromatography (initially with 20% ethyl acetate in petroleum ether until elution of the *Z* isomer, then 30% ethyl acetate to elute the *E* isomer) gave 142 mg of recovered (Z)-**6** (65%) and 68 mg (*E*)-**6** (31%), both as pale yellow oils.

Similarly, when (Z)-**5** (0.148 g, 0.642 mmol) was irradiated for 18 h, 58.0 mg (39%) of pure (*E*)-**5** was obtained (mp 132.0–134.5°C from absolute ethanol, lit. (16) mp 136–138°C) with 84.8 mg (57%) (Z)-**5** recovered after flash chromatography (elution with 15% ethyl acetate – petroleum ether).

Similarly when (Z)-**15** (150.1 mg, 0.698 mmol) was irradiated for

6 h, 44.9 mg (30%) of pure (*E*)-**15** was obtained (as a pale yellow oil) with 98.0 mg (65%) (*Z*)-**15** recovered after flash chromatography (elution with 7.5% ethyl acetate − petroleum ether).

For these compounds, the following tlc data were obtained with ethyl acetate (shown as per cent) in petroleum ether: **6** (30%): R_f 0.15 (*E*), 0.47 (Z); **10** (30%): R_f 0.15 (*E*), 0.35 (Z); **14** (15%): R_f 0.19 (*E*), 0.53 (Z); **7** (20%): R_f 0.26 (*E*), 0.62 (Z); **15** (15%): R_f 0.28 (*E*), 0.51 (Z).

Compound (*E*)-**5** showed: ^{1}Hmr, δ: 1.43 (t, J = 7 Hz, 3H, ether CH_3), 2.51 (s, 3H, vinyl CH_3), 4.30 (q, J = 7 Hz, 2H, ethyl, CH_2), 7.36−7.53 (m, 3H, aromatic), and 7.92−8.07 (m, 2H, aromatic); ^{13}Cmr, δ: 155.8 (C-2), 118.5 (C-4), 168.7 (C-5), 163.9 (C-6), 15.8 (C-7), 66.4 (C-8), 15.2 (C-9), 126.7 (C-10), 127.2 (C-11), 128.7 (C-12), 131.6 (C-13).

Compound (*E*)-**6** showed: ir, ν_{max}: 1805 (s) (C=O), 1770 (s) (C=O), 1665 (s) (C=N), 1606 (m), 1588 (m) cm^{-1}; ^{1}Hmr, δ: 1.37 (t, J = 7 Hz, 3H, ethyl CH_3), 2.41 (s, 3H, vinyl CH_3), 3.80 (s, 2H, benzyl CH_2), 4.29 (q, J = 7 Hz, 2H, ethyl CH_2), 7.33 (br s, 5H, aromatic); ^{13}Cmr, δ: 158.4 (C-2), 117.4 (C-4), 168.2 (C-5), 164.1 (C-6), 15.9 (C-7), 66.3 (C-8), 15.2 (C-9), 35.8 (C-10), 134.2 (C-11), 128.8 (C-12), 129.1 (C-13), 127.3 (C-14); hrms calcd. for $C_{14}H_{15}NO_3$: 245.1052; found: 245.1057; ms: indistinguishable from that of (Z)-**6**.

Compound (*E*)-**7** showed: ^{1}Hmr, δ: 1.27 (s, 9H, *tert*-butyl), 1.40 (t, J = 7 Hz, 3H, ethyl CH_3), 2.43 (s, 3H, vinyl CH_3), 4.30 (q, J = 7 Hz, 2H, ethyl CH_2).

Compound (*E*)-**10** showed: ^{1}Hmr, δ: 2.53 (s, 3H, vinyl CH_3), 4.04 (s, 3H, OCH_3), 7.45−7.55 (m, 3H, aromatic), and7.98−8.15 (m, 3H, aromatic); ^{13}Cmr (acetone-d_6), δ: 165.2 (C-2),[a] 113.8 (C-4), 168.6 (C-5), 165.5 (C-6),[a] 16.8 (C-7), 68.8 (C-8), 14.9 (C-9), 33.6 (C-10), 26.9 (C-11); ((a), assignments may be reversed).

Compound (*E*)-**15** showed: ir, ν_{max}: 1704 (s) (C=O), 1608 (s) (C=N), and 1573 (s) (C=C) cm^{-1}; ^{1}Hmr, δ: 1.38 (t, J = 7 Hz, 6H, both ethyl CH_3's), 2.40 (s, 3H, vinyl CH_3), 4.20 (q, J = 7 Hz, 2H, vinyl CH_2); ^{13}Cmr (acetone-d_6), δ: 158.0 (C-2), 129.1 (C-4), 194.2 (C-5), 164.5 (C-6), 16.0 (C-7), 65.0 (C-8),[a] 14.8 (C-9), 65.4 (C-10),[a] 14.0 (C-11); ((a), assignments may be reversed); ms: indistinguishable from that of (Z)-**15**.

Attempted oxazolone isomerization with concentrated HBr; preparation of 2-(4-chlorophenyl)-4-(1-hydroxyethylidene)-5-oxazolone, 11

4-Phenylmethylene-5-oxazolone isomerization of Z to E geometry has been accomplished by the action of concentrated aqueous hydrobromic acid solution (8).

A mixture of the two isomers of **9** (33 mg, 0.12 mmol) as prepared directly from *N*-(4-chlorobenzoyl)glycine was suspended in 48% hydrobromic acid solution at 0°C. Anhydrous hydrogen bromide was bubbled into the solution. After 10 min, the compound completely dissolved and after hydrogen bromide saturation (another 10 min), the flask was stoppered and left in the refrigerator (−2°C) for 7 h. The resulting precipitate was filtered and washed with water and dried *in vacuo*, yielding 16.2 mg (55%) of a light yellow powdery solid (mp 204−205°C, melts and immediately evaporates) assigned structure **11**.

In a similar experiment, 5 min following dissolution of the azalactone, the solution was quenched by the addition of ice-water and 10% aqueous potassium carbonate. A precipitate was formed, which was extracted with dichloromethane, the dichloromethane layer dried over anhydrous sodium sulfate and then removed by rotoevaporation. The product on analysis by both tlc and ^{1}Hmr spectroscopy showed no (*E*)-**9**; ^{1}Hmr showed (Z)-**9** (approximately 90%) and **11** (approximately 10%).

Compound **11** showed: ir, ν_{max}: 1784 (s), 1607 (m), and 1560 (s) cm^{-1}; ^{1}Hmr (DMSO-d_6), δ: 2.39 (s, 3H, CH_3), 7.58 and 7.93 (AA′BB′, J_{ortho} = 9 Hz, 2H and 2H, aromatic); hrms calcd. for $C_{11}H_8NO_3Cl$: 237.0192; found: 237.0161; ms, m/z (RI%): 239 (10) and 237 (30) (M^+), 221 (2) and 219 (5) [$M^+ - H_2O$], 141 (30), 139 (100), 113 (10), 111 (30), and 75 (15).

COMMUNICATION

An analysis of bond length information for oxygen atoms adsorbed on well-defined metal surfaces

K. A. R. MITCHELL AND SUSAN A. SCHLATTER
Department of Chemistry, University of British Columbia, 2036 Main Mall, Vancouver, B.C., Canada V6T 1Y6

Received August 15, 1985

K. A. R. MITCHELL and SUSAN A. SCHLATTER. Can. J. Chem. **63**, 3631 (1985).

New bond valence – bond length relations deduced by Brown and Altermatt for solid state structures have been used for rationalizing O—M interatomic distances, measured by various surface crystallographic techniques, for O atoms chemisorbed on well-defined metal (M) surfaces. The advantages of this approach, over the Pauling–Schomaker–Stevenson approach used previously, are especially apparent for initial rationalizations of new information on the nearest-neighbor and next-nearest-neighbor bond lengths for O adsorbed on long-bridge sites of (110) surfaces of face-centered cubic metals.

K. A. R. MITCHELL et SUSAN A. SCHLATTER. Can. J. Chem. **63**, 3631 (1985).

On a utilisé les nouvelles relations entre les valences de liaison et les longueurs des liaisons qui ont été déduites par Brown et Atermatt pour des structures à l'état solide pour rationaliser les distances interatomiques O—M, mesurées par diverses techniques cristallographiques de surface, pour des atomes de O liés par chemisorption sur des surfaces métalliques (M) bien définies. Les avantages de cette approche, par rapport à celle de Pauling–Schomaker–Stevenson qui a été utilisée antérieurement, sont spécialement apparents lors des rationalisations initiales de nouvelles informations relatives à des longueurs de liaison avec le plus proche voisin ainsi que le suivant pour des O adsorbés sur des sites de surfaces (110) impliquant de longs ponts sur des métaux cubiques à face centrée.

Introduction

An understanding of bond lengths in chemisorption is required as one step in the development of atomistic models of chemical processes at surfaces. A recent review of bond length data available from the methods of surface crystallography (e.g., LEED, SEXAFS, photoelectron diffraction and ion scattering) suggested that good levels of correspondence can now be reached when different techniques are applied to surfaces involving the chemisorption of atoms (X) on well-defined surfaces of metals (M) (1). Hitherto most discussions in the literature have related measured surface X—M interatomic distances to values obtained either by packing "hard spheres" of listed radii (2), or to values measured from other areas of structural chemistry (3), but without regard in either case to the actual structural arrangements or chemical bonding involved. Nevertheless the recent survey (1) by one of the present authors showed that many measured X—M interatomic distances can apparently be interpreted to a fair degree with bond order – bond length relations of the type used by Pauling in combination with the Schomaker–Stevenson approach for determining single bond lengths (4). The latter provides empirical evidence that the chemisorption bonding can, at least to a first approximation, be treated analogously to the chemical bonding schemes which are well-established in the other main categories of structural chemistry, namely discrete molecules and the triperiodic solid state. Even so, the match up between measured and predicted X—M surface bond lengths is not always satisfactory (1); in some instances this may be because of errors in the earlier experimental analyses, but in other cases (e.g., for O on the (111) surface of aluminum) the Pauling–Schomaker–Stevenson (PSS approach appears deficient.

This present paper explores a refinement to the earlier interpretation of surface bond lengths (1). The approach initiated here uses the bond length correlations proposed very recently by Brown and Altermatt (5) for particular combinations of oxygen and M atoms. Such systems were chosen for this exploratory purpose because some new surface structural data, which have just become available for oxygen chemisorption on (110) surfaces of face-centered cubic (fcc) metals, suggest that the PSS approach may be less reliable for discussing bond distances between O atoms and second-layer metal atoms (insufficient information was available previously for discussing this topic in ref. 1). Also the bond length relations just produced by Brown and Altermatt (5) cover most O—M combinations for which surface structural data are currently available.

Calculations

Brown and Altermatt (5) proposed the use of expressions with the form

$$[1] \quad r = r_0 - 0.85 \log s$$

for a particular interatomic distance of bond valence s, where r_0 is the corresponding distance for a bond of unit valence (6). These authors listed values of r_0 for various combinations of atoms as deduced from analyses of large amounts of structural information, especially from X-ray crystallography. When values of r_0 are given for more than one oxidation state of M that for the lowest state is taken for estimating surface bond distances. The specific values used are detailed in Table 1, where O—M interatomic distances measured by surface crystallographic techniques are compared with those predicted both with the PSS approach used in ref. 1 and with the approach of Brown and Altermatt. For the latter, in situations where inequivalent O—M bonds can occur, a range of O—M interlayer spacings is considered, and the favoured interlayer spacing is fixed (and correspondingly the predicted bond lengths) by the condition that the sum of bond valences at each O atom is two according to eq. [1]. The calculations reported in Table 1 assume the same adsorption site as reported in the structural determination; they also assume that the structure of the metal

TABLE 1. O—M interatomic distances predicted by both the PSS approach used in ref. 1 and by eq. [1], and compared with values measured by surface crystallography

			O—M distance (Å)

is neither reconstructed nor relaxed (except a relaxation is included for Zr(0001) where O is indicated (21) to incorporate into the metal structure, at least to the depth probed by LEED).

In Table 1, n indicates the number of O—M bonds of each type; for example, for adsorption on a hollow site of three-fold coordination on a fcc(111) surface there are three equal bond lengths, whereas for adsorption on the long-bridge sites of a fcc(110) surface two pairs of O—M bond lengths occur, corresponding to bonds from O to M atoms in the top metal layer and to those in the second metal layer. Various important adsorption geometries are illustrated in ref. 22.

Discussion

In most cases the use of eq. [1] with the tabulated values (5) for r_0 gives an encouraging correspondence to the O—M bond lengths measured by surface crystallography, although the predicted O—Ni values appear slightly short for both (100) and (111) surfaces. The advantages of the new relations over the PSS approach (1) are particularly noticeable for O adsorbed on the long-bridge sites of fcc(110) surfaces. The recent analyses with SEXAFS for O chemisorbed on Ag(110) (7) and Cu(110) (14) indicate that the surfaces remain unreconstructed on adsorption, however the structure with Ni(110) has been controversial (18). Initially O was believed to adsorb on the short-bridge site of the unreconstructed metal surface (19), but the then reported O—Ni distance of 1.91 Å is clearly inconsistent with the value (1.65 Å) from eq. [1] as well as that (1.75 Å) from the PSS approach. The recent experimental information for Ni(110) suggests that O adsorbs on the long-bridge sites, but with missing nickel atoms in alternate [001] rows of the top metal layer (18). The bond lengths reported for this surface in Table 1 are from a low-energy ion scattering experiment which indicates the O atoms are held 0.25 Å above the Ni surface. The driving force for the missing-row model presumably depends on strong O—Ni bonds being formed at the expense of neighboring Ni—Ni bonding in the topmost metal layer.

TABLE 2. O—M bond valences for O adsorbed on long-bridge sites and center sites of some fcc(110) surfaces[a]

M	Long-bridge		Center	
Ag	0.57(2)	0.43(2)	0.16(4)	1.37(1)
Cu	0.65(2)	0.35(2)	0.22(4)	1.12(1)
Ni	0.67(2)	0.34(2)	0.23(4)	1.08(1)

[a]The number of bonds of each type are given in parentheses. In each case the height of the adsorbed atom above the surface is chosen so that the sum of bond valences to O is 2 according to eq. [1].

For many examples in Table 1, the O atoms adsorb on those sites which provide maximum coordination and equal bond valences in the various bonds. However, a compromise appears necessary at the fcc(110) surfaces. At these surfaces, adsorption on a center site would enable bonding to four atoms in the topmost metal layer and to one in the second layer (total five), whereas on a long-bridge site, which is the favored site for the examples in Table 1, each O atom bonds to a total of just four M atoms. The data in Table 2 for O—M bond valences predicted with eq. [1] for these sites therefore suggest that more-balanced O—M bond valences in combination with a less-than-maximum coordination number for O (as for long-bridge site) is favored over the situation which combines less-balanced bond valences with the maximum coordination number (as for center site). As more structural data become available, such analyses should aid the development of insight into why particular adsorption sites are favored in individual cases (incidentally, in examples available so far, both S and Se appear to adsorb on the center sites of fcc(110) surfaces (1)).

In summary, this work indicates that the bond length – bond valence relations given by Brown and Altermatt have helpful applications to interpreting structural information for the chemisorption of oxygen on well-defined metal surfaces. Extensions to wider-ranging combinations of X and M, as suitable data become available for systematic study, may be useful for two purposes: (*i*) to discuss aspects of chemisorption bonding, especially in relation to the bonding occurring in similar bonds in the other more-established branches of structural chemistry; and (*ii*) to provide a framework for assessing the general reasonableness, or otherwise, of structural information as produced by the methods of surface crystallography.
